few Ångstroms. Within a continuum framework, this can be approached by including additional physics, such as long range van der Waals forces [12, 34, 41] in a dynamic model of the precursor layer itself (as in [16]).

The second approach that has received extensive study is to keep the distinct contact line but remove the stress singularity by modifying the boundary condition between the liquid and the solid surface at or near the contact line. The most promising way to do this is to introduce the *Navier slip condition*, proposed by Navier [32] in 1832 during the long debate over whether a fluid can slide over a solid surface [15]. The Navier condition was apparently first invoked in the context of lubrication theory by Greenspan [17] and has since been included in numerous studies of contact lines [2, 22, 31, 38, 39]. Again, this is an attempt to resolve the issue using only hydrodynamics, rather than dealing with the atomic scale forces that are undoubtedly significant near the contact line. Nonetheless, it is plausible to believe that the effect of these forces at the macroscopic scale could be captured in an empirical law like the Navier slip condition. Once a choice of slip model is made, there is still the question of the need for a boundary condition at the contact line. Greenspan [17] proposed that the speed of the contact line is related to the contact angle. This was further considered for spreading drops by Haley and Miksis [18] and Ehrhard and Davis [14]. Hocking [23] considers using the static contact angle for the dynamic problem. In the case of complete wetting, a zero contact angle solution is preferred. For the general lubrication PDE, existence of such "zero contact angle" solutions with slip was proved rigorously in one space dimension [3, 8]. In this case, the zero contact angle condition replaces the boundary condition or fixed contact angle condition at the contact line. A natural question, which we address, is whether the PDE admits traveling wave solutions with a prescribed nonzero contact angle condition.

In this paper, we consider a thin film being driven up an inclined solid surface by a surface or Marangoni stress. These driven films have been studied extensively theoretically, experimentally, and numerically [5, 6, 10, 11, 27, 28, 29, 37, 36]. In particular, in a series of papers on the precursor model, we found interesting novel structures for traveling waves and their stability [4, 6, 7]. Our purpose in this paper is to explore the Navier slip model as an alternative to the precursor model for Marangoni driven films. Among other conclusions, we find that for a given slip length and film thickness, there is a finite range of contact angles that admit traveling wave solutions.

In section 2, we give a brief derivation of the fourth order nonlinear PDE governing the evolution of film height, using the lubrication approximation to the Navier–Stokes equations for two-dimensional incompressible flow. This derivation shows how the Navier slip condition enters the thin film PDE. Also in section 2 we show how traveling wave solutions with a contact line satisfy a third order ODE, in which the traveling wave speed is determined by the upstream height. The PDE and associated traveling wave ODE can be used to study contact lines under three scenarios, each of which we consider in this paper:

I. Flow in which gravity is the only driving force. For example, a layer of fluid wetting a dry surface as it slides down the surface under the action of gravity.

II. Flow in which the Marangoni force dominates gravity.

III. Flow in which Marangoni force and the force due to gravity are balanced.

The main results of this paper, both analytical (in section 3) and numerical (in section 4) concern flow in which forces are balanced, but our numerical results add something to the understanding of the first two scenarios as well.

In section 3 we analyze the traveling wave ODE near the contact line when Marangoni forces are present, under the Navier slip condition. Curiously, the leading order terms of the ODE are independent of the precise form of the Navier slip condition; we are led to the problem of finding a function $y = y(x)$ (representing the film height) that is positive for $x > 0$ and satisfies

$$yy''' = 1, \quad x > 0, \quad y(0) = 0. \tag{1.1}$$

This equation would appear to fall under the extensive classification of solutions of the more general third order ODE $y^n y''' = 1$ contained in the paper of Boatto, Kadanoff, and Olla [9]. However, we observe that the case $n = 1$ is special, and we find a different structure for the solutions. In section 3.1, we find a two-parameter family of asymptotic solutions

$$y(x) = ax + \frac{1}{2a}x^2 \log x + bx^2 + \text{h.o.t.}, \tag{1.2}$$

where h.o.t. denotes higher order terms and $a > 0$ and b are free parameters. We show how the series can be continued indefinitely, and in section 3.1 we perform a reduction to a polynomial planar vector field that establishes the dimension of the solution set.

In section 4 we present various results of numerical integration of the third order traveling wave ODE. The technique we use is similar to that in earlier studies of the precursor layer model [6], but here we show how the entire phase space can be understood by focusing on the structure of stable and unstable invariant manifolds associated with equilibria. Phase portraits are three-dimensional, since the ODE is third order, so we visualize invariant manifolds through their intersection with carefully chosen Poincaré sections.

The numerical solutions are compared with the asymptotic form (1.2) near the contact line. The numerical results highlight various interesting issues. We find a finite range of contact angles for each wave speed. This has relevance for the use of a boundary condition relating contact angle and wave speed, as considered in [14, 18], or for the case of a fixed contact angle condition, as considered in [31, 38] for singular slip and in [20, 21, 23] for nonsingular slip. Moreover, at a given speed and at a given contact angle in this range, there may be several different traveling waves. The latter property is specific to the case in which gravity and Marangoni effects balance and is related to the nonconvexity of the flux function in the lubrication model. This particular effect is well understood for the same problem in which a simpler precursor film model is used to remove the contact line singularity [6].

2. The lubrication approximation and traveling waves. In section 2.1, we outline the lubrication approximation and formulate the PDE that governs the motion of the thin liquid layer, including the Navier slip condition. In section 2.2, we derive a third order ODE whose solutions are traveling wave solutions of the PDE.

2.1. The thin film PDE. Consider a thin liquid film moving slowly up a flat solid surface, inclined at an angle α to the horizontal. The film is driven by a constant surface stress τ, and gravity also acts on the film, as indicated in Figure 2.1. We shall consider the film to be uniform in the transverse direction. This means that the transverse velocity is zero, the in-plane velocity (u, v) and pressure p are functions of x, z, and time t, and the free surface is given by $z = h(x, t)$, where h is a function to be determined. The lubrication approximation reduces the description of the flow to a PDE for $h(x, t)$.

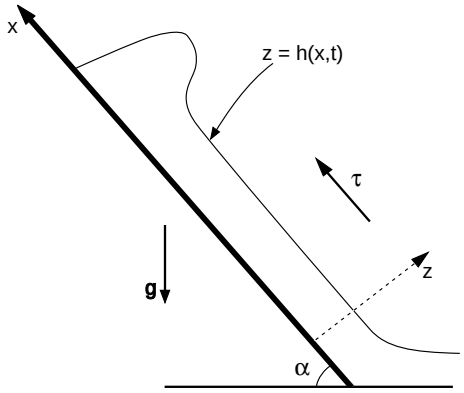

FIG. 2.1. *Thin film propagating up an inclined solid surface.*

The Navier–Stokes equations for the two-dimensional flow of the figure are as follows:

$$\begin{aligned} &\text{(a)} && \rho(u_t + uu_x + vu_z) = -p_x + \mu(u_{xx} + u_{zz}) - \rho g \sin\alpha, \\ &\text{(b)} && \rho(v_t + uv_x + vv_z) = -p_z + \mu(v_{xx} + v_{zz}) - \rho g \cos\alpha, \\ &\text{(c)} && u_x + v_z = 0. \end{aligned} \tag{2.1}$$

Here, ρ is the density, taken to be constant, consistent with the incompressibility condition (2.1c), and μ is the viscosity.

In the lubrication approximation, we exploit two small quantities to reduce the complexity of the equations, keeping only leading order terms but maintaining a balance between terms that are significant, namely surface stresses and viscous forces. Let H be a typical thickness of the film, say a maximum thickness. This is assumed small compared to a typical length scale L along the solid surface. The other small parameter is the Reynolds number $Re = \rho UH/\mu$, calculated with respect to the thickness length scale, but where U is a typical velocity in the x-direction parallel to the solid surface.

The lubrication approximation that emerges as the leading order terms consists of two equations, with unknowns velocity u parallel to the solid surface and pressure p (the normal velocity v is given separately by the incompressibility condition (2.1c)):

$$\begin{aligned} &\text{(a)} && p_x = \mu u_{zz} - \rho g \sin\alpha, \\ &\text{(b)} && p_z = -\rho g \cos\alpha. \end{aligned} \tag{2.2}$$

To this system we add boundary conditions at $z = 0$ and $z = h$:

$$\begin{aligned} &\text{(a)} && p = p_A - \gamma h_{xx} && \text{on} \quad z = h, \\ &\text{(b)} && \mu u_z = \tau && \text{on} \quad z = h, \\ &\text{(c)} && k(h)u_z = u && \text{on} \quad z = 0. \end{aligned} \tag{2.3}$$

Here, p_A denotes atmospheric pressure, γ is the coefficient of surface tension, taken

to be constant, τ is a constant surface stress[1] coupled to the flow by the rate of shear strain appearing on the left-hand side of (2.3b). (Other mechanisms produce a surface stress, such as gradients in the concentration of a surfactant or airflow over the surface.) The boundary condition (2.3c) expresses the Navier slip condition, in which $k(h)$ is a coefficient with dimension of length that becomes essentially zero away from the contact line (i.e., for $h > h_0$ where h_0 is small). As in earlier work on the Navier slip condition, we take $k(h)$ to be a smooth and positive function; it would be possible to cut $k(h)$ off at a specified distance from an advancing contact line. For simplicity we choose only smooth functions $k(h)$ as in [17, 18, 39, 31]. Specific forms for $k(h)$ will be given later.

To derive an equation for $h(x,t)$, we first integrate system (2.2) using the boundary conditions (2.3) to obtain an expression for u in terms of z and h. Then u is averaged across the film to get an average velocity Q, expressed entirely in terms of h and derivatives of h. Finally, this formula for Q is substituted into the equation

$$h_t + (hQ)_x = 0$$

expressing conservation of mass. This procedure, explained in detail and in greater generality elsewhere [17, 31], leads to the single equation

$$h_t + \left\{ \frac{\tau}{2\mu} q(h) - \frac{\rho g \sin\alpha}{3\mu} c(h) - \frac{\rho g \cos\alpha}{3\mu} c(h) h_x + \frac{\gamma}{3\mu} c(h) h_{xxx} \right\}_x = 0, \tag{2.4}$$

in which

$$q(h) = h^2 + 2hk(h), \quad c(h) = h^3 + 2h^2 k(h) \tag{2.5}$$

would be quadratic and cubic functions (respectively) were it not for the modifications from the Navier slip condition.

From (2.4) we can realize the three cases of the introduction:

1. Gravity dominates: $\tau = 0$.
2. Marangoni forces dominate: $\tau >> \rho g \sin\alpha$.
3. Gravity and Marangoni effects are in balance: $\tau \sim \rho g \sin\alpha$.

In each case, a slightly different scaling of the variables leads to nondimensional equations. We give the details in the third case, rescaling the variables as in [6]. We introduce length scales H, L and a corresponding time scale T:

$$h = H\hat{h}, \quad x = \hat{x}L, \quad \text{and} \quad t = T\hat{t}. \tag{2.6}$$

Balancing the competing convective effects of gravity and Marangoni forces in (2.4) gives $H = \frac{3\tau}{2\sin\alpha\rho g}$. Setting L to be the capillary length on which surface tension balances the driving forces gives $L = (\frac{2\gamma H^2}{3\tau})^{1/3} = (\frac{3\gamma\tau}{2\rho^2 g^2 \sin^2\ a})^{1/3}$. The time scale is then chosen to be the one on which all three of these effects balance, $T = 2\frac{\mu}{\tau^2}(\frac{4}{9}\tau\gamma\rho g\sin\alpha)^{1/3}$.

This leads to the equation

$$\begin{aligned} h_t + \left(\left(h^2 + \frac{2}{3} h K(h) \right) - (h^3 + h^2 K(h)) \right)_x \\ = D\left((h^3 + h^2 K(h)) h_x \right)_x - \left((h^3 + h^2 K(h)) h_{xxx} \right)_x, \end{aligned} \tag{2.7}$$

[1]Here, we assume a constant surface tension gradient, proportional to the constant temperature gradient in experiments [37, 36], in the regime in which surface tension depends linearly upon temperature.

where $D = \frac{\rho g \cos\alpha\, T H^3}{3\mu L}$ and

$$K(h) = \frac{3k(Hh)}{H}. \tag{2.8}$$

We remark that D is typically small and is zero for a vertical plane ($\alpha = \pi/2$). It will be convenient to label the flux $f(h)$ on the left-hand side of (2.7),

$$f(h) = \left(h^2 + \frac{2}{3}hK(h)\right) - (h^3 + h^2K(h)), \tag{2.9}$$

and to use the notation

$$C(h) = h^3 + h^2K(h). \tag{2.10}$$

Then the depth-averaged velocity Q is given by

$$Q = (f(h) - DC(h)h_x + C(h)h_{xxx})/h, \tag{2.11}$$

and the PDE (2.7) is

$$h_t + f(h)_x = D(C(h)h_x)_x - (C(h)h_{xxx})_x. \tag{2.12}$$

In cases 1 and 2, a similar rescaling leads to equations similar to (2.12) but with different flux functions $f(h)$ (see [31]). Specifically:

1. When gravity dominates, the thin film will be coating by flowing down the solid surface. Reversing x so that increasing x is in the direction of flow, we obtain (2.12) with

$$f(h) = h^3 + h^2K(h). \tag{2.13}$$

2. When Marangoni forces dominate, the gravity term in the flux drops out, and we are left with

$$f(h) = h^2 + hK(h). \tag{2.14}$$

2.2. Traveling waves. We seek traveling wave solutions of (2.12). These take the form $h(x,t) = \overline{h}(x - st)$, where $\overline{h}$ is a function of the single traveling wave variable $\xi = x - st$, and s is the wave speed. Substituting into the PDE, and integrating once, we obtain (dropping the bars)

$$E - sh + f(h) = DC(h)h' - C(h)h''', \tag{2.15}$$

in which $'$ denotes differentiation with respect to ξ, and E is the constant of integration.

Now we are interested particularly in solutions that have a contact line, at which $h = 0$. Since the ODE is autonomous, we can assume the contact line is at $\xi = 0$. Upstream (i.e., $\xi \longrightarrow -\infty$), we assume the traveling wave approaches a constant height, with at least the first three derivatives approaching zero. Thus, we have boundary conditions

$$h(-\infty) = h_-, \qquad h'(-\infty) = h''(-\infty) = h'''(-\infty) = 0, \qquad h(0) = 0. \tag{2.16}$$

Letting $\xi \longrightarrow -\infty$, we find $E = sh_- - f(h_-)$.

At the other end, letting $\xi \longrightarrow 0-$, we have $Q \longrightarrow s$. (I.e., the average speed approaches the speed of the traveling wave at the contact line.) Using (2.11), we can rewrite (2.15) as

$$-s + Q(h) = E/h.$$

Letting $h \longrightarrow 0$ leads to the conclusion $E = sh_- - f(h_-) = 0$. Thus, the wave speed *s is determined by the upstream height h_-*:

$$s = \frac{f(h_-)}{h_-}. \tag{2.17}$$

In conclusion, the traveling wave satisfies the ODE

$$C(h)h''' = sh - f(h) + DC(h)h', \tag{2.18}$$

with boundary conditions

$$h(-\infty) = h_-, \quad h(0) = 0. \tag{2.19}$$

Finally, we discuss the leading order terms at the contact line in (2.18). To do so, we need to specify the constitutive function $k(h)$ in the Navier slip condition (2.3c). The form of this function is not decided upon [17, 18], but the idea is that slip should be confined to a small neighborhood of the contact line, where h is very small. Thus, $k(h)$ should be chosen so that it is nearly zero unless h is very small. Typically, $k(h)$ is chosen to be a power of h; in order to satisfy the above requirement, this power should be negative. Thus we take

$$k(h) = \eta h^{n-2}, \tag{2.20}$$

with $n < 2$ and $\eta > 0$. In [17], the choice is $n = 1$. This slip model was derived by Neogi and Miller for flow over a porous surface [33]. Other choices are possible, including $n = 2$ which can model polymer flow [12]. Note that for $n > 2$, $k(h)$ grows away from the contact line. With the choice (2.20), the function $K(h)$ defined in (2.8) becomes

$$K(h) = \beta h^{n-2}, \tag{2.21}$$

with $\beta = 3\eta H^{n-3}$. In particular, there are two parameters in this relation, namely β and n.

Now consider the leading order terms as $h \longrightarrow 0$, i.e., near the contact line. We have $C(h) = h^3 + h^2K(h) \sim \beta h^n$. Asymptotics for $f(h)$ depend on which case we are considering. In case 1, in which gravity dominates, $f(h) = h^3 + h^2K(h) \sim \beta h^n$. In case 2 and case 3, the terms from the Marangoni force are higher order. Specifically in case 3, $f(h) = (h^2 + \frac{2}{3}hK(h)) - (h^3 + h^2K(h)) \sim \frac{2}{3}\beta h^{n-1}$.

Retaining leading order terms in the ODE, we get, in case 1, the equation

$$\beta h^{n-1}h''' = s + \beta h^{n-1} + D\beta h^{n-1}h'. \tag{2.22}$$

Thus, for case 1, the choice $n = 1$ leads to a constant coefficient equation. Notably, there is then no singularity at $h = 0$.

In cases 2 and 3, we obtain the singular equation

$$hh''' = -\frac{2}{3} + Dhh'. \tag{2.23}$$

At the contact line, we expect h' to be finite (although it would be reasonable to consider solutions with a vertical tangent at the contact line). Moreover, the parameter D will be considered small or zero. Thus, we take $Dhh' \sim 0$ to leading order. Note that in arriving at (2.23), we have depended on two important assumptions: (1) There is a surface driving force $\tau > 0$, and (2) $n < 2$ in (2.20).

Rescaling ξ in (2.23), and dropping the last term, we are led to consider the initial value problem

$$yy''' = 1, \quad y(x) > 0 \quad \text{for} \quad x > 0, \quad y(0) = 0, \tag{2.24}$$

in which $x = -(\frac{2}{3})^{1/3}\xi$ and $y(x) = h(\xi)$.

3. Solutions near the contact line. In this section we explore properties of the initial value problem (2.24). In subsection 3.1 we establish an asymptotic series solution that has two free parameters, and in subsection 3.2 we reduce the third order equation to a planar vector field, whose phase portrait proves the existence of a two-parameter family of solutions.

3.1. Asymptotics. In this subsection, we elaborate on the proposed family (1.2) of solutions of (2.24) and show how the terms of an asymptotic series can be calculated systematically. To this end, consider the series[2]

$$y(x) = ax + \frac{1}{2a}x^2 \log x + bx^2 + \Sigma(x), \tag{3.1}$$

where $\Sigma(x)$ is expressed as a series with coefficients to be determined:

$$\Sigma(x) = \sum_{k=3}^{\infty} \sum_{j=2}^{k} d_{k\,j} x^k (\log\, x)^{k-j}. \tag{3.2}$$

Note that the series is organized as a sum of terms of increasing order (as $x \to 0+$). We will show that the coefficients $d_{k\,j}$ may be calculated in the same order: $d_{32}, d_{33}, d_{42}, d_{43}, d_{44}, d_{52}, \ldots$. In what follows, it will be helpful to adopt the convention that $d_{km} = 0$ whenever $m \le 1$.

Consider a single term $z_{kj}(x) = x^k (\log\, x)^{k-j}$ with $k \ge 3, 2 \le j \le k$. Then

$$z_{kj}''' = x^{k-3} \left\{ A_k (\log\, x)^{k-j} + B_{kj} (\log\, x)^{k-j-1} + C_{kj} (\log\, x)^{k-j-2} + A_{k-j} (\log\, x)^{k-j-3} \right\},$$

where the coefficients A, B, C are nonnegative; most importantly $A_k > 0$ for $k \ge 3$. They are given by the formulae

$$A_k = \begin{cases} k(k-1)(k-2) & \text{if} \quad k \ge 3, \\ 0 & \text{if} \quad k \le 2, \end{cases} \qquad B_{kj} = \begin{cases} (3k^2 - 6k + 2)(k-j) & \text{if} \quad k > j, \\ 0 & \text{if} \quad k \le j, \end{cases}$$

$$C_{kj} = \begin{cases} 3(k-1)(k-j)(k-j-1) & \text{if} \quad k \ge j+2, \\ 0 & \text{if} \quad k \le j+1. \end{cases}$$

[2]Hocking [19] considered a leading order expansion of this form for a correction to the trailing edge of Huppert's solution [24] for flow down an inclined plane.

Thus

$$\begin{aligned} y''' &= \frac{1}{ax} + \sum_{k=3}^{\infty}\sum_{j=2}^{k} d_{kj} z'''_{kj} \\ &= \frac{1}{ax} + x^{-3}\sum_{k=3}^{\infty}\sum_{j=2}^{k} \alpha_{kj} x^k (\log\, x)^{k-j}, \end{aligned} \tag{3.3}$$

where the coefficients α_{kj} are linear combinations of the d_{kj}'s:

$$\alpha_{kj} = A_k d_{kj} + B_{kj-1} d_{kj-1} + C_{kj-2} d_{kj-2} + A_{k-(j-3)} d_{kj-3}. \tag{3.4}$$

(Recall $d_{km} = 0$ if $m \le 1$.)

Now substitute (3.1), (3.3) into (1.1):

$$\begin{aligned} &\left[ax + \frac{1}{2a}x^2 \log x + bx^2 + \sum_{k=3}^{\infty}\sum_{j=2}^{k} d_{kj} x^k (\log\, x)^{k-j}\right] \\ &\qquad \times \left[\frac{1}{ax} + \sum_{k=3}^{\infty}\sum_{j=2}^{k} \alpha_{kj} x^{k-3} (\log\, x)^{k-j}\right] = 1. \end{aligned} \tag{3.5}$$

Equating terms, we get a family of equations for the coefficients d_{kj} (recall the coefficients α_{kj} depend linearly on the d's):

$$\begin{aligned} x\log x: &\qquad \frac{1}{2a^2} + a\alpha_{32} = 0, \\ x: &\qquad \frac{b}{a} + a\alpha_{33} = 0, \end{aligned} \tag{3.6}$$

$x^{k-2}(\log x)^{k-j}$:

$$a\alpha_{kj} + \tfrac{1}{2a}\alpha_{k-1j} + b\alpha_{k-1j-1} + \tfrac{1}{a} d_{k-1j-1} + \sum_{m+p=k+1}\ \sum_{n+q=j+1} d_{mn}\alpha_{pq} = 0. \tag{3.7}$$

In the final sum, the additional constraints on the indices are implied from (3.5):

$$m \ge 3, \quad p \ge 3, \quad 2 \le n \le m, \quad 2 \le q \le p.$$

In particular, these imply

$$m \le k-2 \quad \text{and} \quad p \le k-2. \tag{3.8}$$

Also note that there is no contribution from the double sum if $k = 4$, or when $j = 2$.

Now from (3.4), we observe that the equation for the coefficient of $x^{k-2}(\log x)^{k-j}$ has a term $aA_k d_{kj}$, and the other terms involve d_{km} with $m \le j-1$ (these terms come from α_{kj}) and d_{mq} with $m \le k-1, 2 \le q \le m$. Consequently, the equations can be solved successively for the coefficients d_{kj} in their natural order associated with terms of increasing order in the asymptotic expansion. Thus, the asymptotic series can be continued to all orders and defines a two-parameter family of formal solutions of the ODE (1.1).

3.2. Reduction to a planar vector field. In this subsection, we reduce the ODE to a planar vector field that we analyze directly. While this is not a new technique (see, for example, [9, 40], where similar reductions are performed on other third order ODEs related to similarity solutions of thin film equations), the real interest lies in using the planar vector field to identify a family of solutions of the ODE with the two-parameter family of asymptotic solutions in the previous subsection.

Consider the ODE (1.1):

$$yy''' = 1. \tag{3.9}$$

Since this equation is autonomous and has a natural scaling invariance (scaling x by a^2 and y by a^3 leaves the equation unchanged), we can reduce the equation to a second order equation that is also autonomous. This is achieved by writing $w = y'$ and letting the independent variable be y. Thus, (3.9) becomes the second order equation

$$yw\frac{d}{dy}w\frac{dw}{dy} = 1. \tag{3.10}$$

Now $y\frac{d}{dy}$ is the logarithmic derivative, so we redefine the independent variable as $\eta = \log y$, leading to

$$w\frac{d}{d\eta}w\frac{dw}{d\eta} = w^2\frac{dw}{d\eta} + e^\eta. \tag{3.11}$$

Now we write this equation as a first order system and rescale to make it autonomous. First let $v = w\frac{dw}{d\eta}$. Then

$$w\frac{dv}{d\eta} = e^\eta + vw, \quad w\frac{dw}{d\eta} = v. \tag{3.12}$$

Now we remove the singularity at $w = 0$ (or rather send it to infinity) by letting $u = 1/w$. Then

$$\frac{du}{d\eta} = -u^3v, \quad \frac{dv}{d\eta} = e^\eta u + v. \tag{3.13}$$

Finally we scale the variables to make the system autonomous:

$$U = e^{\eta/3}u, \qquad V = e^{-2\eta/3}v,$$

leading to the system

$$U' = \frac{1}{3}U - U^3V, \quad V' = U + \frac{1}{3}V. \tag{3.14}$$

In terms of the original variables, x, y, we have $U = y^{1/3}/y'$, $V = y^{1/3}y''$. The asymptotic form (1.2) of the solutions approaching $y = 0$ yields

$$U \sim a^{-2/3}x^{1/3} \longrightarrow 0+, \qquad V \sim a^{-2/3}x^{1/3}\log x \longrightarrow 0- \tag{3.15}$$

as $x \longrightarrow 0+$. Note that $V/U \sim \log x \longrightarrow -\infty$ as $x \longrightarrow 0+$. Thus we are interested in solutions of (3.14) approaching the origin as the independent variable $\eta = \log y$ approaches $-\infty$, with $U(\eta) > 0, V(\eta) < 0$.

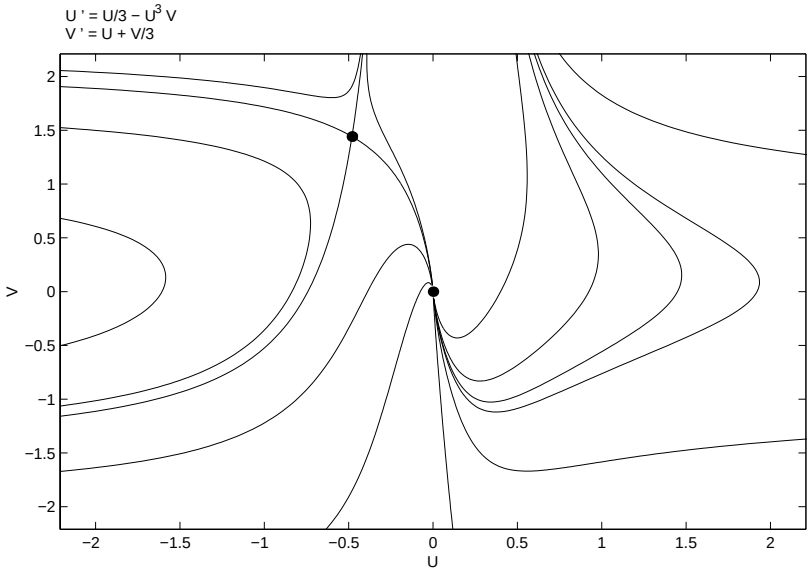

FIG. 3.1. *Phase portrait for system* (3.14).

The origin is an equilibrium with a double eigenvalue $1/3$, but a single eigenvector $(U, V) = (0, 1)$. The phase portrait is shown in Figure 3.1. Note that the saddle point at $V = -3U, U = -3^{-2/3}$ in the second quadrant is not relevant to us. The stable and unstable manifolds correspond to solutions with $y \longrightarrow \infty$ or $y \longrightarrow 0-$. It is straightforward to prove that the trajectories in the fourth quadrant have a unique minimum as they cross $V = -3U$ and cross the U axis as shown in the figure. Indeed, $dV/dU = 3$ on the U axis and is zero on the line $V = -3U$. Moreover,

$$\frac{dV}{dU} = \frac{U + \frac{1}{3}V}{\frac{1}{3}U - U^3V} < 3$$

and is positive for $U > 0,\ V < 0$. Thus, trajectories terminating at any point $U_1 > 0$ on the U axis are monotonically increasing from a point $(U_0, -3U_0)$ with $0 < U_0 < U_1$ and decrease monotonically to the left of the line $V = -3U$. However, the V axis is invariant for the vector field (3.14), so the trajectories are forced into the origin as η decreases. On every ray $V = -AU$ with $A > 3$, we have

$$\frac{dV}{dU} = \frac{U + \frac{1}{3}V}{\frac{1}{3}U - U^3V} > -A.$$

Consequently, trajectories cross every such ray as they approach the origin, proving that $dV/dU \longrightarrow -\infty$ as $\eta \longrightarrow -\infty$. In fact, neglecting the U^3V term as trajectories approach the origin, we find $V \sim 3U \log(U/U_0)$ as $U \longrightarrow 0+$.

This analysis of the fourth quadrant of the vector field proves that there is a one-parameter family of trajectories parameterized by $U_0 > 0$. The trajectories are also invariant under translation of η by a constant, since system (3.14) is autonomous. But $\eta = \log y$, so this corresponds to multiplying y by a constant, accompanied by the corresponding scaling of x, according to the natural scale invariance of (1.1). This is the second parameter that is apparent in the asymptotic series. We have thus proved the following proposition.

PROPOSITION 3.1. *There is a two-parameter family of solutions of the initial value problem* (1.1).

4. Numerical results. In this section, we show results of numerical simulations of the full traveling wave ODE in the spirit of [6]. In particular, we illustrate how solutions corresponding to contact lines relate to the parameters a, b in the asymptotic expansion derived in section 3.1, but we also explore the two simpler cases 1 and 2, in which gravity or the Marangoni forces dominate, respectively.

It is convenient to write the third order equation as a first order system, in which we replace h by u:

$$\begin{aligned} u' &= v, \\ v' &= w, \\ w' &= g(u, v, s), \end{aligned} \tag{4.1}$$

where $g(u, v, s) = \frac{su - f(u)}{C(u)} + Dv$.

The main parameter s is the traveling wave speed. We take $D = 0$, corresponding to fluid flowing down a vertical wall. The functions f, C were given in section 2:
Case I (gravity dominates): $f(u) = u^3 + u^2 K(u)$.
Case II (Marangoni force dominates): $f(u) = u^2 + uK(u)$.
Case III (gravity and Marangoni force are comparable): $f(u) = u^2 - u^3 + K(u)(\frac{2}{3}u - u^2)$.
Recall also the formulae for C and K:

$$C(u) = u^3 + K(u)u^2, \quad K(u) = \beta u^{n-2}. \tag{4.2}$$

In the function K, there are additional parameters $\beta > 0$ and $n < 2$; generally, we take $n = 1$ and $\beta = 0.01$, but we shall also consider the effect of varying β.

Equilibria of system (4.1) are $(u, v, w) = (\overline{u}, 0, 0)$, with $g(\overline{u}, 0, s) = 0$. I.e.,

$$f(\overline{u}) = s\overline{u}. \tag{4.3}$$

We study all the stable and unstable manifolds of equilibria, their boundaries, intersections, and behavior at $u = 0$ in order to gain some understanding of the overall phase portrait.

Computational algorithm. Trajectories for (4.1) are computed using the implicit Adams method in the LSODE package. To compute trajectories along a stable manifold starting near an equilibrium, we integrate backward in time. As for computing trajectories forward in time along an unstable manifold, this process is stable until the manifold comes near another equilibrium.

It is convenient and instructive (see [6]) to use a two-dimensional Poincaré section $\Sigma_{u=const}$ to represent these invariant manifolds. The Poincaré section with u constant has the property that trajectories cross it transversally, unless $v = 0$. In particular, the invariant manifolds intersect Σ_u in points or curves, depending on whether the manifold is one- or two-dimensional. In the Poincaré section, we shall easily visualize when a two-dimensional invariant manifold for one equilibrium is bounded by a one-dimensional invariant manifold for a different equilibrium.

Transverse intersections of two-dimensional manifolds correspond to structurally stable heteroclinic orbits between equilibria. In the Poincaré section, these appear as transverse intersections of curves.

We are interested in solutions $(u, v, w)(\xi)$ that reach $u = 0$ at a finite value of ξ. Specifically, we will say a trajectory $(u(\xi), v(\xi), w(\xi)), \xi < \xi_0$ *touches down* at $\xi = \xi_0$ if $u(\xi) \longrightarrow 0+$ as $\xi \longrightarrow \xi_0-$ and $u(\xi) > 0$ for $\xi < \xi_0$. Similarly, we will say $(u(\xi), v(\xi), w(\xi))$ is *unbounded* if $u(\xi) \longrightarrow \infty$ as $\xi \longrightarrow \pm\infty$.

The numerical results were obtained for specific choices of parameters: $s = 2/9$, $D = 0$, $n = 1$. (The choice $n = 1$ was suggested in [17].) The choice of s is intended to be representative of the physical solutions of interest. In case I, different choices of β are considered, while in cases II and III, $\beta = 0.01$ is taken to be representative.

4.1. Case I: Gravity dominates. When gravity dominates, (4.1) has the cubic polynomial flux function

$$f(u) = u^3 + \beta u. \tag{4.4}$$

Note that (4.1) has the symmetry property that it is unchanged by changing the sign of u and ξ. (Then w changes sign, but v does not.)

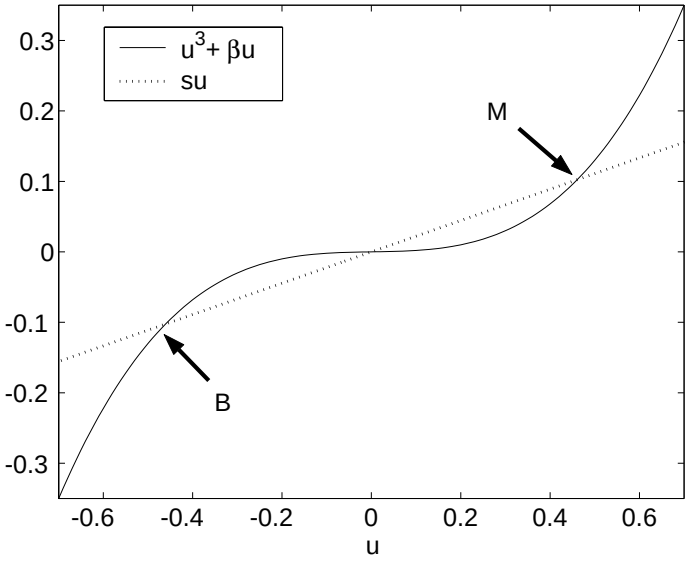

FIG. 4.1. $f(u)$ *and* su.

In Figure 4.1, we show (4.3) for $\beta = 0.01$. The equation has two solutions corresponding to equilibria of (4.1), namely $\overline{u} = \pm\frac{\sqrt{190}}{30}$. (Note that the solution $\overline{u} = 0$ is *not* an equilibrium.) The associated equilibria are

$$B = \left(-\frac{\sqrt{190}}{30}, 0, 0\right), \quad M = \left(\frac{\sqrt{190}}{30}, 0, 0\right).$$

Although B is not physical since it corresponds to negative u, it is nonetheless helpful to consider the associated invariant manifolds.

Linearizing around M, we find the system has two complex conjugate eigenvalues with positive real part (corresponding to a two-dimensional unstable manifold denoted $W^U(M)$), and one real, negative eigenvalue (corresponding to a one-dimensional stable manifold denoted $W^S(M)$). Correspondingly, the equilibrium B

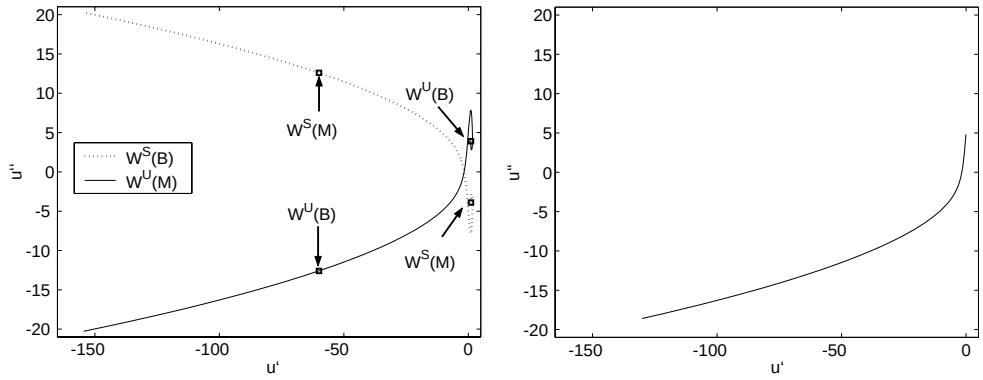

FIG. 4.2. *Case* I *with* $\beta = 0.01$. (a) Σ_0. (b) *Trajectories with a contact line. Shown are only the values at the first intersection with* Σ_0.

has a two-dimensional stable manifold $W^S(B)$ and a one-dimensional unstable manifold $W^U(B)$.

As described in [6, 30], the nature of the two-dimensional manifolds changes from node to focus as the parameter D varies away from zero. In discussing the phase portraits here (with $D = 0$), we consider the focus case only, for which the two associated eigenvalues are complex conjugates. This implies that, near M, solutions along the unstable manifold spiral out. Thus to compute the unstable manifold, we compute trajectories starting from a locus of points along a straight line through M in the tangent plane.

Global picture of phase space. We are interested in how trajectories touch down, so we study the Poincaré section Σ_0 at $u = 0$. By symmetry, the invariant manifolds of B and M are reflections of each other across the plane $u = 0$. The manifolds $W^U(B)$ and $W^S(M)$ are one-dimensional, so they intersect Σ_0 in isolated points, if at all. Each one-dimensional invariant manifold has two connected components, or branches, separated by the equilibrium. Referring to Figure 4.2(a), representing the Poincaré plane $u = 0$, for $\beta = 0.01$, we observe that one branch of $W^U(B)$ intersects Σ_0 twice: first at $(u, u', u'') = (0, 1.06, 3.9)$, then at $(0, -60.0, -12.6)$.[3] The other branch is unbounded at $u = -\infty$ and does not intersect Σ_0. Similarly, one branch of $W^S(M)$ intersects Σ_0 at $(u, u', u'') = (0, 1.06, -3.9)$, while the other branch is unbounded at $u = \infty$ and does not intersect Σ_0.

The two-dimensional manifolds $W^U(M)$ and $W^S(B)$ intersect Σ_0 in curves (see Figure 4.2(a)). $W^U(M)$ is bounded on both ends by the same branch of $W^U(B)$. Near this boundary $W^U(M)$ wraps around $W^U(B)$ an infinite number of times. The spiral of $W^U(M)$ around the first intersection of $W^U(B)$ near $(0, 1.06, 3.9)$ can be seen in Figure 4.2(a). By the time $W^U(B)$ intersects the second time near $(0, -60.0, -12.6)$, the spiral of $W^U(M)$ has become so elongated that it cannot be resolved at this scale.

The points P on Σ_0 of physical interest are those which represent trajectories from M that hit $u = 0$ for the first time at P. These correspond to traveling wave solutions which asymptote to $u = \frac{\sqrt{190}}{30}$ at $\xi = -\infty$ and have a contact line. Although trajectories continue into negative u values, solutions with $u < 0$ are no longer phys-

[3]Here and throughout this section, we give the numerical values of intersection points to one or two decimal places.

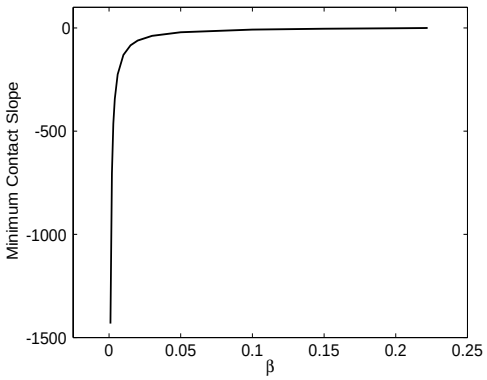

FIG. 4.3. *Minimum slope at $u = 0$ as a function of β, case* I.

ical. All trajectories in $W^U(M)$ hit $u = 0$. The curve of points corresponding to first intersections are shown in Figure 4.2(b). Note that one end of the curve terminates at $u' = 0$. This corresponds to a trajectory that turns around at $u = 0$. This same trajectory eventually winds around to intersect Σ_0 again, this time with a touchdown of slope $u' = -130.1$, corresponding to the other end of the curve shown in Figure 4.2(b). For trajectories inside this orbit, we obtain the finite range of touchdown slopes, spanning $-130.1 \le u' \le 0$. Such large slopes may of course take the model outside its range of validity. However, the slopes here are dimensionless, and may correspond in dimensional variables within the range of the model. This issue is examined in the context of thin film rupture in the paper of Zhang and Lister [42].

Dependence of the range of contact slopes on β. In Figure 4.3, we show how the minimum contact angle varies with the parameter β (from the Navier slip condition (4.2)) in the range $0 < \beta < 2/9$. Keeping $s = 2/9$, $D = 0$, and $n = 1$ fixed, the phase space of solutions is topologically equivalent for $0 < \beta < \frac{2}{9}$. As $\beta \to 0$, M and B approach $(\pm\frac{\sqrt{2}}{3}, 0, 0)$. As β increases from 0, M and B move closer together until all solutions of (4.3) vanish at $\beta = \frac{2}{9}$, where $f'(0) = s$. For all β in this range, the maximum contact slope is zero. The minimum contact slope decreases with decreasing β, as seen above. The plot shows computed values for the minimum value of u' at $u = 0$ for β ranging from 0.001 to 0.22.

4.2. Case II: Marangoni convection dominates. Now consider (4.1) when the Marangoni convection term dominates. In this subsection we consider only $\beta = 0.01$; in this case and in case III we compute solutions only in the physical range $u \ge 0$. The new flux function is quadratic:

$$f(u) = u^2 + \beta. \tag{4.5}$$

For different values of s, the ODE will have zero, one, or two equilibria. The case with $s = 2/9$ is shown in Figure 4.4. The two equilibria are

$$B = \left(\frac{10 - \sqrt{19}}{90}, 0, 0\right), \quad M = \left(\frac{10 + \sqrt{19}}{90}, 0, 0\right).$$

M has a two-dimensional unstable manifold $W^U(M)$ and a one-dimensional stable manifold $W^S(M)$. B has a two-dimensional stable manifold $W^S(B)$ and a one-dimensional unstable manifold $W^U(B)$.

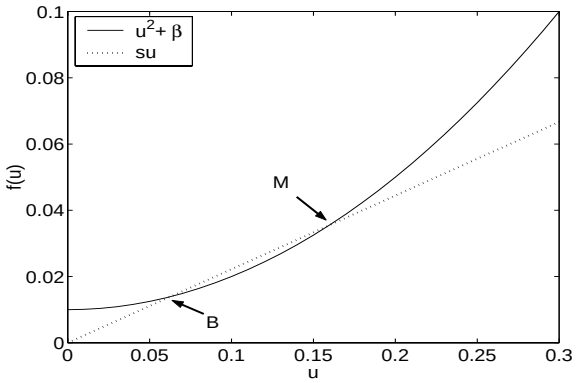

FIG. 4.4. *$f(u)$ and su, case* II*, with $\beta = 0.01$.*

The dynamics at the contact line are now fundamentally different than in the gravity dominated case. The flux function makes the differential equation (4.1) singular at $u = 0$. Note that if (u, v, w) touches down, then $w = u''$ will become unbounded in finite time, so an adaptive time step procedure such as the one we use is essential to capture detailed behavior near $u = 0$. The most important difference from the gravity dominated case is that now trajectories cannot be computed beyond $u = 0$. Thus, trajectories generically fall into two cases: those which touch down in finite time and those which escape to $u = \infty$. Between these two cases are heteroclinic orbits that approach equilibria as $\xi \longrightarrow \pm\infty$.

Global picture of phase space. Since u'' is unbounded at $u = 0$, it is not possible to study Σ_0. Instead, we choose the section $\Sigma_{0.1}$ between B and M. The information about boundaries and dimensions can be read off as before. It is necessary, however, to do further computations to find the range of contact slopes. Intersections of the two-dimensional manifolds again correspond to heteroclinic orbits between equilibria, representing traveling wave solutions with a precursor layer, as in [6].

Both branches of $W^S(M)$ are unbounded. One does not pass $\Sigma_{0.1}$. The other branch intersects $\Sigma_{0.1}$ at $(u, u', u'') = (0.1, 0.16, -0.43)$, narrowly avoids $u = 0$, and intersects again at $(u, u', u'') = (0.1, -2.00, 20.71)$ before heading to $u = \infty$. In contrast, both branches of $W^U(B)$ touch down. One branch does not intersect $\Sigma_{0.1}$. The other intersects first at $(0.1, 0.15, 0.52)$, then at $(0.1, -1.72, -2.02)$ before touching down. These intersection points are labeled in Figure 4.5.

The two-dimensional manifolds $W^U(M)$ and $W^S(B)$ intersect transversally in a single heteroclinic orbit from M to B. Hence the two branches of $W^U(B)$ are boundaries of $W^U(M)$. The curve $W^U(M)$ shown in the Poincaré section of Figure 4.5 represents trajectories that can intersect $\Sigma_0.1$ several times. All trajectories in $W^U(M)$ touch down, with a finite range of contact angles. For the specific parameters $\beta = 0.01$, $s = 2/9$, we find this range to be $-2.436 < u' < -0.464$. Note that, unlike in the gravity driven case, there are no trajectories with contact slope arbitrarily close to 0.

4.3. Case III: The full equation. We now consider the full equation with $\beta = 0.01$ and

$$f(u) = u^2 - u^3 + \beta\left(\frac{2}{3} - u\right). \tag{4.6}$$

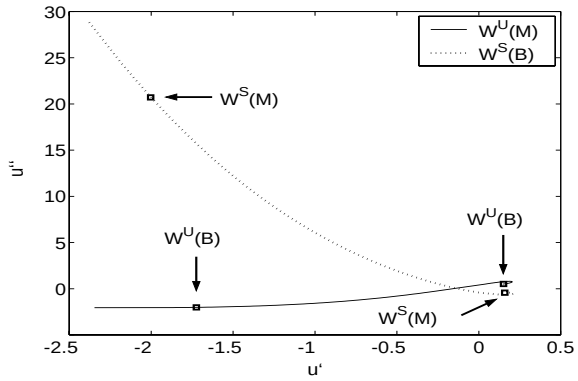

FIG. 4.5. $\Sigma_{0.1}$, *case* II.

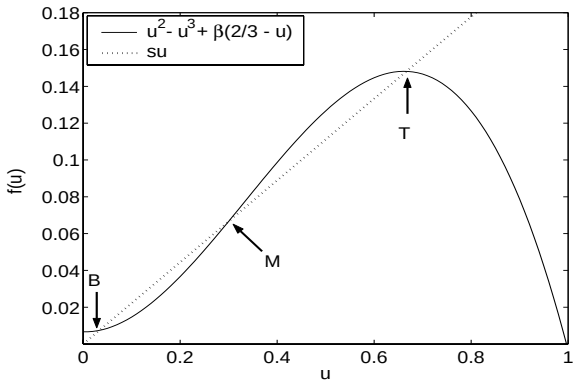

FIG. 4.6. $f(u)$ *and* su, *case* III, $\beta = 0.01$.

See [6] for a parallel discussion of the precursor model case without Navier slip. The flux is now nonconvex, which means the ODE may have one, two, or three equilibria, depending on the value of s. For $s = 2/9$, (4.3) has three solutions. We will find that phase space becomes correspondingly more complicated. The three equilibria (see Figure 4.6) are labeled

$$B = (1/30, 0, 0), \quad M = (3/10, 0, 0), \quad T = (2/3, 0, 0),$$

for bottom, middle, and top. M has a two-dimensional unstable manifold $W^U(M)$ and a one-dimensional stable manifold $W^S(M)$. The other equilibria B and T have two-dimensional stable manifolds $W^S(B), W^S(T)$ and one-dimensional unstable manifolds $W^U(B), W^U(T)$.

As in the case where Marangoni convection dominates gravity, trajectories in the invariant manifolds either will be heteroclinic orbits, unbounded, or will touch down. There is a Lyapunov function that prevents periodic or homoclinic orbits (cf. [6]). Solutions cannot be computed past $u = 0$ since the ODE becomes singular. In what follows, we describe results with respect to the Poincaré section $\Sigma_{0.2}$ between B and M at $u = 0.2$.

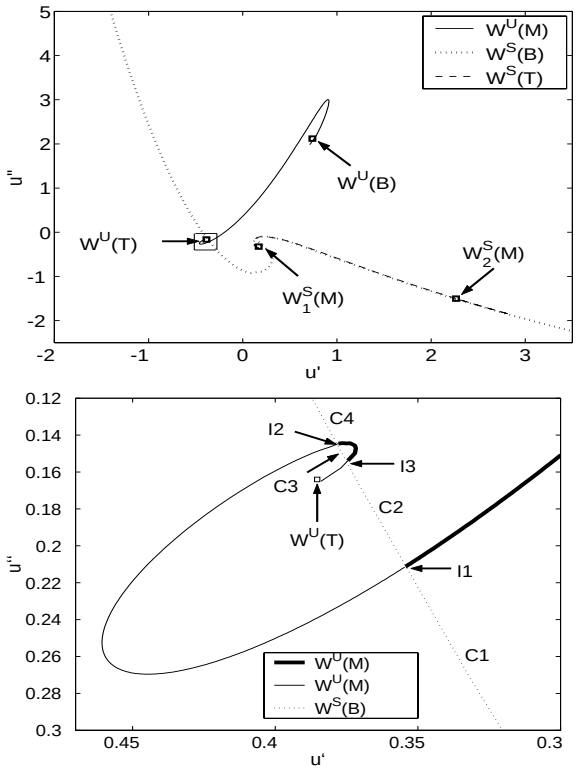

FIG. 4.7. *Case* III. (a) $\Sigma_{0.2}$. (b) *Blow-up of small box in* (a).

The one-dimensional manifolds. $W^U(B)$, $W^U(T)$, and $W^S(M)$ are the one-dimensional invariant manifolds. One branch of $W^U(B)$ touches down and does not pass through $u = 0.2$. The other branch becomes unbounded in u and passes $\Sigma_{0.2}$ at $(0.2, 0.739, 2.120)$. $W^U(T)$ exhibits similar behavior, with an unbounded branch that does not pass through $\Sigma_{0.2}$ and a branch that touches down and hits $\Sigma_{0.2}$ at $(0.2, -0.385, -0.164)$. Both branches of $W^S(M)$ touch down. One branch, $W_1^S(M)$, passes through $\Sigma_{0.2}$ at $(0.2, 0.169, -0.324)$. The other, $W_2^S(M)$, passes through at $(0.2, 2.264, -1.503)$.

The unstable manifold of M. The manifold $W^U(M)$ crosses $W^S(B)$ in three orbits, shown as intersection points in Figure 4.7(b). Note also that $W^U(M)$ wraps infinitely many times around both $W^U(B)$ and $W^U(T)$. These spirals indicate connections from M to both T and B. Connections to B are already evident. Connections to T would appear as an intersection of $W^U(M)$ and $W^S(T)$ in any Poincaré section placed between M and T.

The structure of the intersection of $W^U(M)$ with $W^S(B)$ is shown in more detail in Figure 4.7(b). $W^U(M)$ intersects $W^S(B)$ three times. Each of these intersections I1, I2, and I3 corresponds to a heteroclinic orbit from M to B. Furthermore, $W^S(B)$ divides the qualitative behavior of trajectories on $W^U(M)$. All trajectories on the same side as $W^U(T)$, i.e., between I1 and I2 and between I3 and $W^U(T)$, touch down. All trajectories on the other side, i.e., between $W^U(B)$ and I1 and between I2 and I3, are unbounded.

The stable manifold of T. $W^S(T)$ also has two boundaries, which are the two branches of $W^S(M)$. The spiral at $W_1^S(M)$ can be seen clearly, while the spiral at $W_2^S(M)$ is four orders of magnitude longer than it is wide, and requires corresponding resolution to be seen.

The stable manifold of B. Each trajectory on the stable manifold of B (which hits $\Sigma_{0.2}$) comes out from $B = (1/30, 0, 0)$, passes through $u = 0.2$, turns around, and hits $u = 0.2$ again before touching down. Thus each trajectory appears as two points on $\Sigma_{0.2}$. $W^S(B)$ is split by $W^U(M)$ into four distinctly behaving sheets which we label C1, C2, C3, and C4.

The sheet C1 approaches the heteroclinic orbit I1 at one end and wraps around $W_1^S(M)$ at the other. The sheet wraps back on itself around $(0.2, 0, -1)$. Each trajectory has one point between I1 and $(0.2, 0, -1)$ (where u is increasing) and one point between $(0.2, 0, -1)$ and $W_1^S(M)$ (where u is decreasing). Trajectories which pass very close to I1 going out also pass very close to $W^S(M)$ coming back. In fact, C1 spirals around $W_1^S(M)$ infinitely many times.

Outgoing trajectories in C2 are bounded by I1 and I3. The trajectories which pass very close to I1 spiral around $W_2^S(M)$ on their second pass, and the trajectories which pass very close to I3 spiral around $W_1^S(M)$ when they return. Trajectories between these two boundaries are very close to $W^S(T)$ on their return.

Outgoing trajectories on C3 are bounded by I3 and I2. Trajectories that pass near both of these orbits on the way out spiral tightly around $W_2^S(M)$ on their way back. Trajectories between the two boundaries form a thin loop that follows $W^S(T)$ very closely, and stretches down to $(0.2, 2.84, -1.86)$.

Finally, outgoing trajectories on C4 are bounded on one side by I2. The trajectories which pass near to I2 spiral tightly around $W_1^S(M)$ on their return journey. Trajectories which pass further away from C1 return in a line that follows $W^S(T)$ and eventually stretches beyond it.

Note that both $W_1^S(M)$ and $W_2^S(M)$ have quadruple spirals, that is, four sheets wrapping around them infinitely many times. $W_1^S(M)$ has one boundary each of $W^S(T)$, C1, C2, and C4, whereas $W_2^S(M)$ has one boundary each from $W^S(T)$ and C2, and two from C3.

4.4. Connection to the asymptotics. In the computations for case III, for a given wave speed s, we find a one-parameter family of trajectories that touch down. Here we relate this one-parameter family to the two-parameter family of local touch down solutions given by the asymptotics of section 2. Specifically for $s = 2/9$, we find a finite range of values for the parameter a in the asymptotic solution.

With the scaling $\xi - \xi_0 = -(\frac{2}{3})^{1/3}x$ of section 2, the asymptotic expansion about a point $\xi = \xi_0$ of touchdown becomes

$$h(\xi) = -a\left(\frac{2}{3}\right)^{\frac{1}{3}}\eta + \frac{1}{2a}\left(\frac{2}{3}\right)^{\frac{2}{3}}\eta^2 \log\left(-\left(\frac{2}{3}\right)^{\frac{1}{3}}\eta\right) + b\left(\frac{2}{3}\right)^{\frac{2}{3}}\eta^2 + \text{h.o.t.}, \tag{4.7}$$

in which $\eta = \xi - \xi_0 < 0$. In particular, the contact slope is given by $v(\xi_0) = -a\left(\frac{2}{3}\right)^{1/3}$. We can read off the limiting value of $v(\xi)$ as u approaches zero and thus obtain the value of a. Corresponding values for b also come from the form (1.2). Specifically, we find

$$w = u'' = \frac{1}{a}\left(\frac{2}{3}\right)^{\frac{2}{3}} \log\left(-\left(\frac{2}{3}\right)^{\frac{1}{3}}\eta\right) + \frac{3}{2a}\left(\frac{2}{3}\right)^{\frac{2}{3}} + 2\left(\frac{2}{3}\right)^{\frac{2}{3}} b + \text{h.o.t.} \tag{4.8}$$

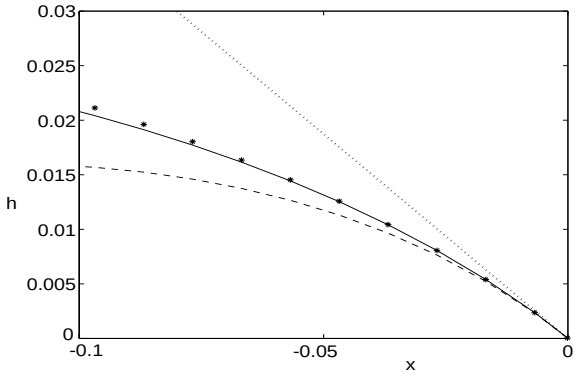

FIG. 4.8. *.....first order, - - -second order, *****third order, a=0.429, b=0.762.*

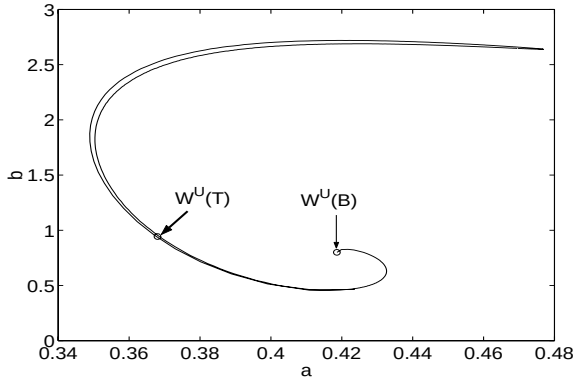

FIG. 4.9. *Asymptotic parameters a and b.*

Thus,

$$e^{\left(a\left(\frac{3}{2}\right)^{2/3}w(\xi)\right)} \approx -\left(\frac{2}{3}\right)^{1/3} e^{\left(\frac{3}{2}+2ab\right)}(\xi-\xi_0). \tag{4.9}$$

Consequently, $e^{\left(a\left(\frac{3}{2}\right)^{2/3}w(\xi)\right)}$ approaches a constant slope m as u approaches zero. Computing this value of m from the calculated trajectory, and the parameter a as above, the expression

$$m = -\left(\frac{2}{3}\right)^{1/3} e^{\left(\frac{3}{2}+2ab\right)} \tag{4.10}$$

determines b. In Figure 4.8, we show a sample comparison between the first three terms of the asymptotic expansion with the corresponding numerical solution of the full equation, with parameters a, b calculated as described above.

Range of *a* and *b*. Plotting the two asymptotic parameters a and b against each other, for all trajectories on $W^U(M)$ which touch down, gives a curve in the (a, b) plane. Consider the close up Poincaré section of the intersection between $W^U(M)$ and $W^S(B)$. In Figure 4.9, we show this curve for points on $W^U(M)$ between I1 and

I2 corresponding to trajectories that touch down in finite time. Points adjacent to I_1 and I_2 correspond to identical values of a and b, in fact, the same values as for the branch of $W^U(B)$ that touches down. The curve in Figure 4.9 varies smoothly but very nearly doubles back on itself. Trajectories near the heteroclinic orbits approach B and then shoot off along $W^U(B)$.

The points along $W^U(M)$ from I3 to $W^U(T)$ give another one-parameter family of solutions. Their a, b values range continuously from the a, b value of the branch of $W^U(B)$ that touches down (since I2 is another heteroclinic orbit) to the a, b value of the branch of $W^U(T)$. This second curve closely follows the first one.

5. Discussion. In this section, we discuss the significance of the results for the traveling wave problem and the moving contact line. The most striking conclusion from our numerical results is that for each of the three problems considered, there is a limited range of contact angles. This particular observation has not been noted in previous studies of the traveling wave problem with slip [31, 38] for the case of gravity driven films. For the Marangoni cases II and III the effect is even more pronounced; the range does not include a zero contact angle, in contrast to well-known results for (2.12) without convection (i.e., $f = 0$) for both traveling waves [9] and weak solutions of the full PDE [8, 3]. For example, in case I, Figure 4.2(b), for each contact slope u' in the range $(-130.1, 0]$, there is a unique traveling wave solution that touches down with that slope. In contrast, in case III, not only are there no traveling waves that touch down with zero slope, but for each slope in the range there can be more than one traveling wave with that touchdown slope, as demonstrated in Figure 4.9.

In experiments, the contact line speed is often observed to be related to the dynamic contact angle or the slope of the film as the thickness approaches zero. For the model, this would result in a boundary condition relating the contact angle to the speed of the wave. Since the upstream thickness is related to the speed s via (2.17), for traveling waves, such a boundary condition becomes a relationship between upstream thickness and contact angle. In case I, the boundary condition would select a unique traveling wave, provided the contact slope is in the admissible range. However, in case III, such a law does not in general select a unique traveling wave. A similar nonuniqueness was found for the precursor model [6] in the case of gravity and opposing Marangoni stress.

There is also the issue of whether the contact angle should be related to the slope of the free surface at zero height, or to an observed slope, that might be taken to be the maximum slope, generally slightly away from the contact line itself. There is much discussion of this issue in the literature (see [25, 26] and the references therein). The Navier slip condition is an attempt to incorporate in a continuum model the physical effects at the molecular scale. For this reason, the asymptotic results apply strictly at the contact line. As in [25], it would be possible to carry out matched asymptotics to relate the asymptotic solution at zero height to solutions of the full problem away from a small neighborhood of the contact line. In this paper, we have instead compared numerical solutions with the asymptotic solution; the discussion above is based on this comparison.

Case III is particularly interesting because of the nonconvex flux and the connection to compressive and undercompressive waves discussed in [6]. The notion of compressive and undercompressive carries over to this paper in the following way: we call trajectories from M that touch down compressive traveling waves. If the trajectory from T touches down, we refer to it as an undercompressive wave. Unlike the precursor model in [6], we do not have characteristics ahead of the wave, hence these

names are used to distinguish between cases where characteristics from the bulk film go into the contact line (compressive) or come out of the contact line (undercompressive). In the former case, information from the bulk can influence the contact line. In the latter case, information from the contact line is carried into the bulk.

Note that there is a range of speeds for which we have three equilibria B, M, and T. We conjecture that for speeds in an interval within this range, one branch of the unstable manifold from T touches down to $u = 0$. Each such trajectory will have a touchdown angle. It would be interesting to know if a given boundary condition at the contact line selects a unique undercompressive wave.

It would be interesting to consider the traveling waves that touch down in the context of the dynamic free boundary problem for the PDE (2.12). We expect that the structure of case III is as rich as that for the precursor model [6, 4]. The contact line raises a new issue: that of how to treat the free boundary for the full PDE. The full nonlinear dynamics have not been explored, with the exception of [35], in which a special case of the PDE without convection was studied.

Acknowledgment. We gratefully acknowledge helpful discussions with David Schaeffer.

AVERAGING OF DISPERSION-MANAGED SOLITONS: EXISTENCE AND STABILITY*

DMITRY E. PELINOVSKY† AND VADIM ZHARNITSKY‡

Abstract. We consider existence and stability of dispersion-managed solitons in the two approximations of the periodic nonlinear Schrödinger (NLS) equation: (i) a dynamical system for a Gaussian pulse and (ii) an average integral NLS equation. We apply normal form transformations for finite-dimensional and infinite-dimensional Hamiltonian systems with periodic coefficients. First-order corrections to the leading-order averaged Hamiltonian are derived explicitly for both approximations. Bifurcations of soliton solutions and their stability are studied by analysis of critical points of the first-order averaged Hamiltonians. The validity of the averaging procedure is verified and the presence of ground states corresponding to dispersion-managed solitons in the averaged Hamiltonian is established.

Key words. existence and stability of pulses, optical solitons, dispersion management, averaging theory, normal form transformations, errors and convergence of asymptotic series, periodic NLS equation, integral NLS equation, Gaussian approximation

1. Introduction.

1.1. Motivations. Ultrafast high–bit-rate optical communication networks are enhanced by the dispersion management technology when two optical fibers of opposite dispersion are periodically concatenated into a line [1]. If the communication network has low path-averaged dispersion and high local dispersion, the data signals are optimally transmitted from the input to output ends through a periodic sequence of compression and expansion cycles. The long-haul dispersion management is technologically combined with standard loss management when a periodic chain of amplifiers compensates distributive fiber losses.

Many recent experimental groups reported revolutionary performance of dispersion-managed (DM) pulses in optical communication networks [2, 3]. Two regimes were studied in detail: DM solitons and chirped return-to-zero pulses. DM solitons are time bits transmitted stationary on the average through the long-haul communication network [2]. The chirped return-to-zero pulses are weakly broadened on the average due to transmission, and some post-transmission compression may be required at the output of the network [3].

This paper addresses the stationary DM solitons and resolves yet open problems of existence and stability of stationary DM solitons described by a periodic nonlinear Schrödinger (NLS) equation. Theoretical studies of DM solitons are based on one of the three averaging methods: (i) variational Gaussian approximation, (ii) asymptotic reduction to an integral NLS equation, and (iii) numerical split-step averaging algorithm (see the latest reviews [4, 5, 6]).

The variational Gaussian approximation truncates the periodic NLS equation at a finite-dimensional Hamiltonian system with periodic coefficients. The truncation is performed by integrating the Lagrangian density of the NLS equation over the Gaussian pulse and varying the resulting function with respect to parameters of the Gaussian pulse [7, 8]. Periodic orbits of the nonautonomous Hamiltonian system correspond to stationary DM solitons [9, 10]. In an optimal design of the dispersion map, the evolution length for dispersion variations is much shorter than the lengths of average dispersion and fiber nonlinearity. Within this limit, the nonautonomous Hamiltonian system can be averaged over the map period. The averaging procedure results, at the leading-order approximation, in a planar dynamical system [11, 12]. Existence and stability of DM solitons can be studied by analyzing trajectories on a phase plane near the critical points of the Hamiltonian system [13]. One of the drawbacks of the Gaussian approximation is the lack of information about the error of the averaging procedure.

The asymptotic reduction to an integral NLS equation is also based on averaging of the periodic NLS equation over a short period of the dispersion map [14, 15]. The method is, however, much more general, since the kernel for the averaging transformation is the most general Fourier solution of the linear periodic Schrödinger equation, which includes the Gaussian pulse as a particular case. Stationary DM solitons are approximated by the time pulse solutions of the nonlinear eigenvalue problem associated with the integral NLS equation. The DM soliton solutions have constantly rotating complex phase along the fiber [15, 16]. Only when the integral NLS equation is approximated at the Gaussian pulse [17], the resulting dynamical system reproduces the same planar Hamiltonian system as in [13]. In the asymptotic reduction method, the integral NLS equation can be viewed as the leading-order term in a set of canonical transformations applied to the periodic NLS equation [18].

At last, the numerical split-step averaging algorithm is applied to separate the pulse resolution in time and the almost periodic evolution of the pulse along the fiber by averaging the output of the split-step method over many time periods [5, 6]. A single pulse with a preserved value of energy was found to converge to a stationary DM soliton unless various resonances and temporal instabilities resulted in an unpredictable loss of convergence of the numerical algorithm [6, 19].

We are motivated by a number of averaging methods applied to the periodic NLS equation and by contradictory results on existence and stability of DM solitons found within these methods. In order to justify and clarify these methods, we develop a systematic asymptotic procedure for averaging of the periodic NLS equation, based on normal form transformations. We extend the perturbation expansions to the next order, where the first-order corrections to the leading-order equations are derived. The validity of averaging methods and the errors (accuracy) of the leading-order and first-order approximations are proved rigorously for a two-step dispersion map. Branches of stationary DM solitons and their stability are analyzed within the averaged equations.

This paper is structured as follows. In section 1.2 we describe the physical model, parameters, and normalizations. In section 1.3 we discuss two approximations of DM solitons and summarize the previously known results, together with our main propositions. In sections 2.1–2.4 we study the Gaussian approximation, in combination with the leading and first orders of the averaging method. We find explicitly analytical curves for existence and stability of the DM solitons in this lower-dimensional approximation. In sections 3.1–3.3 we analyze the full PDE problem and prove convergence of the leading and first orders of the averaging method. The existence of

ground states is proved in the averaged equation but the analytical curves are implicit in this higher-dimensional approximation. Section 4 describes open problems of analysis beyond the first-order averaging theory.

1.2. Model and parameterizations. The NLS equation for optical pulses in dispersion-compensated fibers is

$$i\frac{\partial U}{\partial Z} - \frac{1}{2}\beta_2(Z)\frac{\partial^2 U}{\partial T^2} + \gamma_2(Z)|U|^2 U = 0, \tag{1.1}$$

where $U(Z,T)$ is the electric field envelope of the carrier wave at the operating wavelength λ_0, while $\beta_2(Z)$ and $\gamma_2(Z)$ are the fiber dispersion and nonlinearity [1]:

$$\beta_2 = -\frac{\lambda_0^2}{2\pi c}D(Z), \quad \gamma_2 = \gamma \exp\left[\int_0^Z g(Z')dZ' - \alpha Z\right], \quad \gamma = \frac{2\pi n_2}{\lambda_0 A_{\rm eff}}\ (>0). \tag{1.2}$$

All units in (1.1)–(1.2) have dimensional form, such that $D(Z)$ is the dispersion coefficient measured in ps/(nm $\times$ km), c is the speed of light in km/sec, $|u|^2$ is the light intensity in mW, n_2 is the nonlinear refractive index in $(\mu\text{m})^2$/mW, $A_{\rm eff}$ is the effective fiber area in $(\mu\text{m})^2$, α is the distributive loss coefficient in km^{-1}, and $g(Z)$ is the periodic amplification. For example, if $A_{\rm eff} = 50(\mu\text{m})^2$, $c = 3\ 10^5$km/sec, $\lambda_0 = 1.5\mu$m, $n_2 = 2.5\ 10^{-11}(\mu\text{m})^2$/mW, and $D = 0.12$ps/(nm $\times$ km), then $\beta_2 \approx -0.1\text{ps}^2$/km and $\gamma \approx 2\ 10^{-3}(\text{mW} \times \text{km})^{-1}$, which are reasonable values for these coefficients.

The dispersion map $D(Z)$ consists of two piecewise-constant fibers of lengths L_1 and L_2 in km, such that $L_1 + L_2 = L_{\rm DM}$, which have dispersion values D_1 and D_2. The total number of fiber segments is $N_{\rm DM}$. The amplification map $g(Z)$ is periodic with period $L_{\rm AM}$, where the ratio $L_{\rm DM}/L_{\rm AM}$ is integer. A typical loss compensation due to erbium-doped fiber amplifiers is

$$g = \alpha L_{\rm AM} \sum_{n=1}^{N_{\rm AM}} \delta(Z - nL_{AM}), \tag{1.3}$$

where $N_{\rm AM}$ is the number of amplifiers over the transmission line: $Z \in [0, N_{\rm DM}L_{\rm DM}]$ and the amplifiers compensate the losses exactly. As a result, the fiber nonlinearity $\gamma_2(Z)$ is a periodic function with period $L_{\rm AM}$. We will use throughout the paper the lossless approximation when $\gamma_2(Z) = \gamma$ is constant. The lossless approximation occurs in the limit $L_{\rm AM} \ll L_{\rm DM}$, when $\lim_{L_{\rm AM}\to 0}\int_0^Z g(Z')dZ' = \alpha Z$. This approximation is sufficiently accurate for modeling fibers with distributed (e.g., Raman) amplification or fibers with several amplifiers at the dispersion compensation period L_{DM} [1]. In other cases, our results are still expected to hold qualitatively.

We can rescale variables (Z,T,U) by introducing characteristic pulse power P_0 in mW, characteristic pulse width T_0 in ps, and characteristic (nonlinear) length $L_{\rm NL} = (\gamma P_0)^{-1}$ in km:

$$Z = L_{\rm NL}z, \quad T = T_0 t, \quad U = \sqrt{P_0}u. \tag{1.4}$$

The periodic NLS equation (1.1) in new variables reduces to the dimensionless form [1],

$$i\frac{\partial u}{\partial z} + \frac{m}{2\epsilon}d\left(\frac{z}{\epsilon}\right)\frac{\partial^2 u}{\partial t^2} + \frac{1}{2}d_0\frac{\partial^2 u}{\partial t^2} + |u|^2 u = 0, \tag{1.5}$$

with the dimensionless parameters

$$m = \frac{\lambda_0^2 L_1 L_2 (D_1 - D_2)}{4\pi c L_{\rm DM} T_0^2}, \quad d_0 = \frac{\lambda_0^2 (D_1 L_1 + D_2 L_2)}{2\pi c \epsilon T_0^2}, \quad \epsilon = \gamma L_{\rm DM} P_0. \tag{1.6}$$

The normalized periodic function $d(\zeta)$ has the unit period for $\zeta = z/\epsilon$ and zero average: $d(\zeta+1) = d(\zeta)$ and $\int_0^1 d(\zeta) d\zeta = 0$. It is defined explicitly as

$$\begin{aligned} d &= \frac{2}{l} \quad \text{for} \quad \zeta \in [0, l), \\ d &= \frac{2}{l-1} \quad \text{for} \quad \zeta \in [l, 1), \end{aligned} \tag{1.7}$$

where $0 < l < 1$ is the ratio of the first fiber leg to the total map period, i.e., $l = L_1/L_{\rm DM}$. We assume that the first leg is for the focusing fiber, i.e., $D_1 > 0$, and the second leg is for the defocusing fiber, i.e., $D_2 < 0$. As a result, the parameter m is positive, $m > 0$. The general problem (1.5) has four parameters:

- m (> 0)—the strength of the local (varying) dispersion,
- d_0—the strength of the average dispersion,
- ϵ (> 0)—the period of the dispersion map,
- l $(0 < l < 1)$—the relative length of the focusing fiber leg to the total map period.

Parameters m and ϵ can be normalized to unity by applying the transformation to the periodic NLS equation (1.5):

$$\zeta = \frac{z}{\epsilon}, \qquad \tau = \frac{t}{\sqrt{m}}, \qquad w(\zeta, \tau) = \sqrt{\epsilon} u(z, t), \tag{1.8}$$

where $w(\zeta, \tau)$ solves the standardized periodic NLS equation:

$$i \frac{\partial w}{\partial \zeta} + \frac{1}{2} d(\zeta) \frac{\partial^2 w}{\partial \tau^2} + \frac{1}{2} D_0 \frac{\partial^2 w}{\partial \tau^2} + |w|^2 w = 0, \qquad D_0 = \frac{\epsilon d_0}{m}. \tag{1.9}$$

Thus, the periodic NLS equation (1.9) depends only on two parameters: l (through $d(\zeta)$) and D_0.

In this paper, we study a formal asymptotic limit $\epsilon \to 0$ of solutions $u(z,t)$ of the periodic NLS equation in the form (1.5). This asymptotic limit corresponds to the limit of small solutions $w(\zeta, \tau)$ (in a $L^2(\mathbb{R})$ norm) of the periodic NLS equation in the form (1.9).

1.3. DM solitons and main results on existence and stability. DM solitons can be defined as special solutions of the periodic NLS equation (1.5) in two conventional approximations: (i) Gaussian pulse [7, 8] and (ii) an averaged integral NLS equation [14, 15].

DEFINITION 1.1. *A DM soliton is an approximate quasi-periodic solution of the NLS equation* (1.5) *in the form of the Gaussian pulse with variable coefficients:*

$$u(z,t) = \sqrt{c}\, \exp\left(-\frac{t^2}{2(a+ib)} + i\phi \right), \tag{1.10}$$

where $a(z+\epsilon) = a(z)$, $b(z+\epsilon) = b(z)$, $\phi(z+\epsilon) = \phi(z) + \epsilon\mu$, *and*

$$c = \frac{e a^{1/2}}{\sqrt{2}(a+ib)}, \qquad e = \sqrt{\frac{2}{\pi}} \int_{-\infty}^{\infty} |u|^2(z,t) dt. \tag{1.11}$$

The three varying parameters $a(z)$, $b(z)$, and $\phi(z)$ are the pulse width, chirp, and the gauge rotation phase, respectively. The constant parameters μ and e are the phase propagation constant and the pulse energy, respectively.

The variational equations are derived by minimizing the Lagrangian density of the periodic NLS equation (1.5) at the Gaussian pulse (1.10) (see, e.g., [22]). It is then found that the varying parameters $a(z)$ and $b(z)$ satisfy the nonautonomous dynamical system:

$$\frac{da}{dz} = \frac{ea^{5/2}b}{(a^2+b^2)^{3/2}}, \tag{1.12}$$

$$\frac{db}{dz} = \frac{m}{\epsilon} d\left(\frac{z}{\epsilon}\right) + d_0 - \frac{ea^{3/2}(a^2-b^2)}{2(a^2+b^2)^{3/2}}. \tag{1.13}$$

The phase parameter $\phi(z)$ is coupled with $a(z)$ and $b(z)$ by the nonhomogeneous equation:

$$\frac{d\phi}{dz} = \frac{ea^{1/2}(3a^2+5b^2)}{8(a^2+b^2)^{3/2}}. \tag{1.14}$$

The dynamical system (1.12)–(1.13) has been studied numerically under different parameterizations (see reviews [4, 5, 6]). The system was found to be Hamiltonian [9], where the phase plane was used for matching trajectories of two autonomous systems derived for the piecewise-constant function $d(z)$. Existence of periodic solutions of (1.12)–(1.13) was recently proved by Kunze [10]. The leading-order averaging system was derived from (1.12)–(1.13) by Turitsyn et al. [11, 12]. A single branch of periodic solutions of the system was found for $d_0 \geq 0$, while two branches coexist for $d_{\min} < d_0 < 0$ at any given e [13].

DEFINITION 1.2. *DM soliton is a stationary pulse solution of the averaged integral NLS equation:*

$$\mu\hat{W}(\omega) = -\frac{1}{2}d_0\omega^2\hat{W}(\omega) + \iint_{-\infty}^{\infty} \frac{\sin\left[m(\omega-\omega_1)(\omega-\omega_2)\right]}{m(\omega-\omega_1)(\omega-\omega_2)}\hat{W}(\omega_1)\hat{W}(\omega_2)\hat{W}(\omega_1+\omega_2-\omega)d\omega_1 d\omega_2, \tag{1.15}$$

where $\hat{W}(\omega) \in H^s(\mathbb{R})$ with $s \geq 1$ and $d_0 > 0$.

The integral NLS equation (1.15) is derived from the periodic NLS equation (1.5) in the limit $\epsilon \to 0$ by using the asymptotic averaging method explained in section 3. The integral NLS equation (1.15) follows from (3.15) for stationary pulse solutions: $\hat{V}(z,\omega) = \hat{W}(\omega)e^{i\mu z}$, where $\hat{W}(\omega)$ is real function.

Existence of stationary pulse solutions of (1.15) for $d_0 > 0$ and $\mu > 0$ was proved by Zharnitsky et al. [18]. Recently Kunze proved existence of ground state solutions $\hat{W}(\omega) \in L^2(\mathbb{R})$ for $d_0 = 0$ and $\mu > 0$ [20], which was a considerably more difficult problem due to the absence of the gradient term in the Hamiltonian. Numerical results suggest nonexistence of ground state solutions for $d_0 < 0$ due to resonance of stationary pulses with linear spectrum of the averaged integral NLS equation [13, 21]. Iterations of a numerical method for finding stationary pulse solutions of (1.15) diverge for both branches of the Gaussian pulse solutions, which exist for (1.12)–(1.13) with $d_{\min} < d_0 < 0$ (see details in [21]). No rigorous results on nonexistence of ground states of (1.15) for $d_0 < 0$ are yet available.

Definitions 1.1 and 1.2 above are commuting in the sense that (i) the system (1.12)–(1.13) can be averaged in the limit $\epsilon \to 0$ [13] and (ii) the variational Gaussian approximation can be applied to the integral NLS equation (1.15) [17]. Both the reductions result in the same set of equations for an averaged Gaussian pulse. In order to analyze the parameter dependence of DM solitons, we consider the following two equivalent parameterizations.

Suppose there exist periodic solutions of (1.12)–(1.13) or stationary pulse solutions of (1.15). The DM solitons are parameterized as $e = f_\mu(\mu; d_0, l, m, \epsilon)$, where $e = f_\mu(\mu)$ is a continuous (possibly multibranched) function of μ. Indeed, solutions $\hat{W}(\omega)$ of (1.15) smoothly depend on parameter μ in the domain of their existence, where $\hat{W}(\omega) \in H^s(\mathbb{R})$ with $s \geq 1$. Then, the function $e = f_\mu(\mu)$ is defined by (1.11) as a continuous function of μ. If there are several solutions of (1.15) for the same value of μ, the function $e = f_\mu(\mu)$ has several branches for a fixed value of μ. Alternatively, solutions $(a(z), b(z))$ of (1.12)–(1.13) smoothly depend on e in the domain of their existence. Then, μ is defined by $\mu = (\phi(z+\epsilon) - \phi(z))/\epsilon = f_\mu^{-1}(e)$. The function $e = f_\mu(\mu)$ is invertible for each branch of solution, where $f'_\mu(\mu) \neq 0$.

For an alternative parameterization, we define the effective pulse width as

$$\tau^2(z) = \frac{2}{e}\sqrt{\frac{2}{\pi}} \int_{-\infty}^{\infty} t^2 |u|^2(z,t) dt \tag{1.16}$$

and the minimal pulse width as

$$\tau^2_{\min} = \min_{z \in [0,\epsilon]} \tau^2(z). \tag{1.17}$$

The DM solitons are parameterized as $e = f_s(s; d_0, l, m, \epsilon)$, where $s = 1/\tau^2_{\min}$ is the square inverse of the minimal pulse width. The function $e = f_s(s)$ is a continuous (possibly multibranched) function of s. For each branch of stationary pulse solutions of (1.15), there exists a continuous map $s = h_\mu(\mu)$ defined by (1.16). Then, the function $e = f_s(s)$ is parameterized by μ. Also, for each branch of periodic solutions of (1.12)–(1.13), there exists a continuous function $s = f_s^{-1}(e)$ defined by

$$\tau^2_{\min} = \min_{z \in [0,\epsilon]} \frac{(a^2 + b^2)}{a} = \min_{z \in [0,\epsilon]} a(z). \tag{1.18}$$

Here we have used (1.10), (1.11), and (1.17) for the first equality and (1.12) for the second equality. The function $e = f_s(s)$ is inverted for each branch of solution, where $f'_s(s) \neq 0$.

LEMMA 1.3. *DM solitons are parameterized by three parameters: $E = \epsilon e/\sqrt{m}$ (energy), $M = \epsilon\mu$ (propagation constant), and $S = ms$ (map strength).*

Proof. The statement is proved by applying transformation (1.8) to the integral quantities (1.11) and (1.16) and to the phase $\phi(z)$ of the Gaussian pulse (1.10). ∎

The DM solitons can be analyzed in the Gaussian approximation for several alternative representations in variables E, M, and S: (i) on the plane (D_0, E) for different values of S; (ii) on the plane (S, E) for different values of S_0; (iii) on the plane (S, M) for different values of D_0; and (iv) on the plane (M, E) for different values of D_0. The four equivalent representations are shown on Figure 1.1(a)–(d), where we reproduce our main results on computations of the first-order averaging theory for the Gaussian approximation. The parameter l is fixed at $l = 0.1$. The solid curves show the result of the first-order averaging theory for $\epsilon > 0$. The dotted curves show the result of the leading-order averaging theory in the limit $\epsilon = 0$.

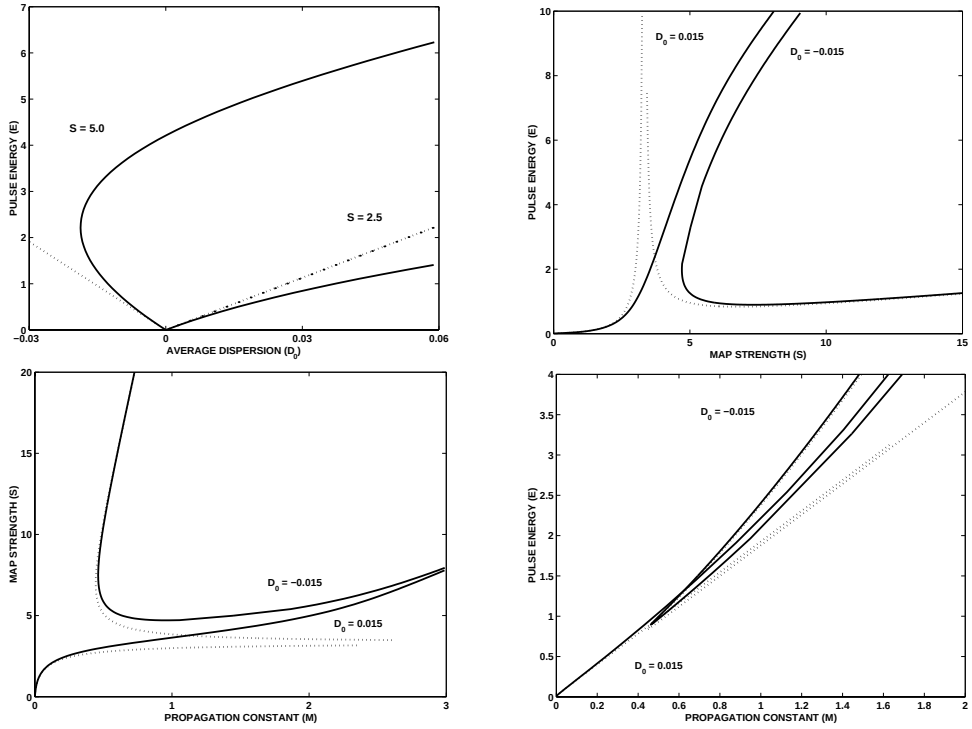

FIG. 1.1. *Parameterizations of DM solitons in the first-order averaging theory for Gaussian approximation:* (a) *plane* (D_0, E) *for* $S = 2.5$ *and* $S = 5$*;* (b) *plane* (S, E) *for* $D_0 = 0.015$ *and* $D_0 = -0.015$*;* (c) *plane* (S, M) *for* $D_0 = 0.015$ *and* $D_0 = -0.015$*; and* (d) *plane* (M, E) *for* $D_0 = 0.015$ *and* $D_0 = -0.015$*. The dotted curves display the leading-order averaging theory.*

There exists only one branch of periodic solutions of (1.12)–(1.13) for $0 < S \leq S_{\rm thr}$, where $S_{\rm thr} \approx 3.32$. This branch extends for $D_0 \geq 0$ (see Figure 1.1(a)). When $S > S_{\rm thr}$, the dependence of E versus D_0 becomes two-folded: two branches of periodic solutions exist for $D_{\rm min} < D_0 < 0$ and one branch exists for $D_0 \geq 0$. When $S \to \infty$, all branches of periodic solutions diverge to infinitely large values of E (see Figure 1.1(b)).

The role of planes (D_0, E), (S, E), and (S, M) is different from that of the plane (M, E) in the leading-order averaging theory. Indeed, the leading-order averaged system (dotted curves on Figures 1.1(a)–(d)) describes only the lower branch of periodic solutions for $D_0 < 0$ (see Figure 1.1(a)). The functions $E = f_S(S)$ and $M = h_S(S)$ are single-branched for any S (see Figures 1.1(b), (c)). However, the function $E = f_M(M)$ has two branches at the leading-order approximation (see Figure 1.1(d)), i.e., two solutions for E correspond to the same value of M, and vice verse.

For $D_0 \geq 0$, there is only one branch of periodic solutions. This branch is bounded by the threshold value $S < S_{\rm thr}$ in the leading-order approximation (see Figures 1.1(a)–(c)), while the function $E = f_M(M)$ is unbounded on the plane (M, E) (see Figure 1.1(d)). Thus, again the planes (D_0, E), (S, E), and (S, M) give bad leading-order approximations of periodic solutions compared to the plane (M, E).

The discrepancy between the four alternative parameterizations of periodic solutions of (1.12)–(1.13) disappears in the first-order averaging approximation, shown on Figures 1.1(a)–(d) by solid curves. Indeed, all curves are unbounded for $D_0 \geq 0$ and

all curves become two-valued functions of S, M, and E for any $D_0 < 0$. The upper branch of periodic solutions on the planes (D_0, E), (S, E), and (S, M) is captured in the first-order averaging theory (see Figure 1.1(a)–(c)). On the other hand, the single branch for $D_0 \geq 0$ and the two branches for $D_0 < 0$ are weakly affected on the plane (M, E) in the first-order approximation, compared to the leading-order theory (see Figure 1.1(d)). Thus, the plane (M, E) is the most appropriate tool for analysis of periodic solutions both in the leading-order and first-order averaging theory.

We can now formulate algebraically the main results of the paper for existence and stability of DM solitons. The results are written in terms of parameters ϵ, m, d_0, e, μ, and s, while the transformation to parameters D_0, E, M, and S is prescribed by Lemma 1.3. The results are proved for the Gaussian pulse approximation by explicit computations (section 2) and for the averaged integral NLS equation by standard PDE analysis (section 3).

PROPOSITION 1.4. *Parameters of DM solitons have the following expansions in powers of ϵ:*

$$d_0 = em^{1/2} g_d^{(0)}(my) + \epsilon e^2 (1-2l) g_d^{(1)}(my) + \mathrm{O}(\epsilon^2), \tag{1.19}$$

$$\mu = \frac{e}{m^{1/2}} g_\mu^{(0)}(my) + \epsilon \frac{e^2}{m} (1-2l) g_\mu^{(1)}(my) + \mathrm{O}(\epsilon^2), \tag{1.20}$$

$$s = y + \epsilon \frac{e}{m^{3/2}} g_s^{(1)}(my, l) + \mathrm{O}(\epsilon^2), \tag{1.21}$$

where y is a parameter and the functions $g_d^{(0,1)}$, $g_\mu^{(0,1)}$, and $g_s^{(1)}$ are continuous for $y > 0$.

Proof. Here we prove the result only in the limit $\epsilon \to 0$, when the leading-order averaging theory results in the integral NLS equation (1.15). The kernel of (1.15) is independent of l. Consider the scaling transformation $\hat{W}(\omega) = \lambda \hat{W}'(\omega)$. This transformation leaves (1.15) invariant if parameters μ, d_0, e, s, and m in (1.11), (1.15), and (1.16) transform as follows:

$$\mu = \lambda^2 \mu', \quad d_0 = \lambda^2 d_0', \quad e = \lambda^2 s', \quad s = s', \quad m = m'. \tag{1.22}$$

It is clear from (1.22) that the ratios d_0/e and μ/e are invariant under this transformation and are, therefore, functions of s and m. The particular form used in (1.19)–(1.20) has been chosen to match with explicit computations of functions $g_d^{(0)}(my)$ and $g_\mu^{(0)}(my)$. ∎

COROLLARY 1.5. *In the limit $\epsilon \to 0$, the functions $e = f_s(s)$, $\mu = h_s(s)$, and $e = f_\mu(\mu)$ have the form*

$$e = \frac{d_0}{\sqrt{m} g_d^{(0)}(ms)}, \quad \mu = \frac{d_0}{m} \frac{g_\mu^{(0)}(ms)}{g_d^{(0)}(ms)}, \quad \frac{\mu\sqrt{m}}{e} = g_\mu^{(0)} (g_d^{(0)})^{-1} \left(\frac{d_0}{e\sqrt{m}} \right). \tag{1.23}$$

COROLLARY 1.6. *In the limit $\epsilon \to 0$ and $d_0 = 0$, the function $e = f_\mu(\mu)$ has the form*

$$e = \alpha \mu, \qquad \alpha = \frac{\sqrt{m}}{g_\mu^{(0)}(ms_*)},$$

where $s = s_*$ is the root of the equation $g_d^{(0)}(ms_*) = 0$.

PROPOSITION 1.7. *In the limit $\epsilon \to 0$ and $m \to 0$, the functions $e = f_\mu(\mu)$ and $s = f_\mu(\mu)$ have the form*

$$e^2 = d_0 \hat{f}_\mu(\mu), \qquad s = \frac{1}{d_0}\hat{h}_\mu(\mu). \tag{1.24}$$

Proof. In the limit $m \to 0$, the integral NLS equation (1.15) becomes the Fourier form of the NLS equation. Consider the scaling transformation for the NLS equation: $\hat{W}(\omega) = \lambda \hat{W}'(\omega')$ and $\omega = \lambda^{-1}\omega'$. This transformation leaves the NLS equation invariant if parameters μ, d_0, e, and s in (1.11), (1.15), and (1.16) transform as follows:

$$\mu = \mu', \qquad d_0 = \lambda^2 d_0', \qquad e = \lambda e', \qquad s = \lambda^{-2} s'. \tag{1.25}$$

It is clear from (1.25) that the quantities e^2/d_0 and sd_0 are invariant under this transformation and are, therefore, functions of μ. ∎

PROPOSITION 1.8. *A single branch of DM solitons exists and is linearly stable for $d_0 \geq 0$ in both Gaussian and integral NLS approximations. Two branches of DM solitons exist for $d_0 < 0$ in the Gaussian approximation. For a fixed μ, the branch with larger e is linearly unstable and the branch with smaller e is linearly stable.*

Linearized stability of DM solitons in the Gaussian approximation (1.12)–(1.13) was studied by Pelinovsky in the limit $\epsilon \to 0$ [13]. We extend this analysis in the first-order averaging theory in section 2 of this paper. Zharnitsky et al. [18] proved that the DM solitons are ground states of the averaged integral NLS equation (1.15) for $d_0 > 0$. The ground states realize a stable minimum of the Hamiltonian functional. We extend this result for the first-order averaged Hamiltonian in section 3. Open problems for nonexistence of ground states for $d_0 < 0$ and nonexistence of quasi-periodic solutions of the periodic NLS equation (1.5) are discussed in section 4.

2. Variational Gaussian approximation. Here we analyze the dynamical system (1.12)–(1.13) derived in the variational Gaussian approximation. We construct the Hamiltonian structure for the system and develop a systematic averaging procedure based on the theory of canonical transformations in section 2.1. The first-order corrections to the leading-order averaged theory are computed in section 2.2. Existence and stability of critical points of the first-order averaged Hamiltonian are studied in sections 2.3 and 2.4.

The dynamical system (1.12)–(1.13) can be written as a Hamiltonian system in canonical variables (ξ, η):

$$\xi = b - m d_{-1}\left(\frac{z}{\epsilon}\right), \qquad \eta = \frac{1}{a}, \tag{2.1}$$

where $d_{-1}(\zeta)$ is the antiderivative of $d(\zeta)$ for $\zeta = z/\epsilon$ with unit period and mean zero:

$$d_{-1}(\zeta) = \int_0^\zeta d(\zeta')d\zeta' - \int_0^1 d\zeta \int_0^\zeta d(\zeta')d\zeta'. \tag{2.2}$$

For the piecewise-constant approximation $d(\zeta)$ in (1.7), the mean-zero antiderivative $d_{-1}(\zeta)$ is

$$\begin{aligned} d_{-1} &= \frac{2\zeta}{l} - 1 \quad \text{for} \quad \zeta \in [0, l), \\ d_{-1} &= \frac{2(\zeta - 1)}{(l-1)} - 1 \quad \text{for} \quad \zeta \in [l, 1). \end{aligned} \tag{2.3}$$

The system (1.12)–(1.13) in canonical variables (ξ, η) has a classical Hamiltonian structure:

$$\frac{d\xi}{dz} = \frac{\partial H}{\partial \eta}, \qquad \frac{d\eta}{dz} = -\frac{\partial H}{\partial \xi}, \tag{2.4}$$

where the Hamiltonian $H = H(\xi, \eta, z/\epsilon)$ is

$$H = d_0 \eta - e \left(\frac{\eta}{1 + \eta^2 (\xi + m d_{-1}(z/\epsilon))^2} \right)^{1/2}. \tag{2.5}$$

The decoupled equation (1.14) for the phase parameter $\phi(z)$ can be expressed through $H(\xi, \eta, z/\epsilon)$ as

$$\frac{d\phi}{dz} = \frac{1}{4} \left(d_0 \eta + \eta \frac{\partial H}{\partial \eta} - 2H \right). \tag{2.6}$$

There exists a canonical transformation from the Hamiltonian structure (2.4)–(2.5) to the one studied in [9]. The canonical transformation (2.1) and the Hamiltonian (2.5) were first reported by Turitsyn et al. [12]. The Hamiltonian structure (2.4)–(2.5) is more convenient for developing a systematic averaging procedure based on series of canonical transformations in powers of ϵ. We will study solutions of the system (2.4)–(2.5) in the domain $\mathcal{D}_+$:

$$\mathcal{D}_+ = \{ (\xi, \eta) : \ \xi \in \mathbb{R}, \ \eta > 0 \}. \tag{2.7}$$

LEMMA 2.1. *Suppose the initial point (ξ_0, η_0) belongs to $\mathcal{D}_+$. Then, a solution $(\xi(z), \eta(z))$ stays in $\mathcal{D}_+$ for any finite z: $0 \le z \le z_0 < \infty$.*

Proof. Integrating (1.12) in the canonical variables (2.1), one can find

$$\frac{1}{\eta^{1/2}} = \frac{1}{\eta_0^{1/2}} + \frac{e}{2} \int_0^z \frac{\eta (\xi + m d_{-1}) dz}{(1 + \eta^2 (\xi + m d_{-1})^2)^{3/2}}.$$

Since the integrand is never singular, the triangular inequality implies for $0 \le z \le z_0$ that

$$\left| \frac{1}{\eta^{1/2}} \right| \le \frac{1}{\eta_0^{1/2}} + \frac{eM}{2} z_0,$$

where

$$M = \max_{0 \le z \le z_0} \frac{\eta |\xi + m d_{-1}|}{(1 + \eta^2 (\xi + m d_{-1})^2)^{3/2}}.$$

Therefore, the point (η, ξ) never crosses the left boundary of $\mathcal{D}_+$ at $\eta = 0$. Direct integration of (1.12)–(1.13) with the variables (2.1) and similar estimates of the resulting integrals show that $|\xi|$ and η remain bounded in the domain $\mathcal{D}_+$ for any finite z: $0 \le z \le z_0$. ∎

2.1. Averaging of the periodic Hamiltonian system (2.4)–(2.5). The periodic Hamiltonian system (2.4)–(2.5) is averaged according to the formalism of normal form transformations [23]. We denote $\zeta = z/\epsilon$ such that $H = H(\xi, \eta, \zeta)$. In the domain $\mathcal{D}_+$ defined by (2.7), there exists a near-identity generating function:

$$F(\xi, y, \zeta) = \xi y + \sum_{n=1}^{N+1} \epsilon^n F_n(\xi, y, \zeta) + \mathrm{O}(\epsilon^{N+2}), \tag{2.8}$$

where the correction terms $F_n(x,y,\zeta)$ for $1 \le n \le (N+1)$ are periodic mean-zero functions of ζ:

$$F_n(x,y,\zeta+1) = F_n(x,y,\zeta), \qquad \int_0^1 F_n(x,y,\zeta)d\zeta = 0. \tag{2.9}$$

The generating function $F(\xi,y,\zeta)$ defines the near-identical canonical transformation

$$x = \frac{\partial F}{\partial y}(\xi,y,\zeta), \qquad \eta = \frac{\partial F}{\partial \xi}(\xi,y,\zeta) \tag{2.10}$$

and takes the Hamiltonian $H(\xi,\eta,\zeta)$ to the form

$$\begin{aligned} H_{\rm new}(x,y,\zeta) &= H(\xi(x,y,\zeta),\eta(x,y,\zeta),\zeta) + \frac{1}{\epsilon}\frac{\partial F}{\partial \zeta}(\xi(x,y,\zeta),y,\zeta) \\ &= H_N(x,y) + {\rm O}(\epsilon^{N+1}), \end{aligned} \tag{2.11}$$

where $H_N(x,y)$ is the Nth-order averaged Hamiltonian:

$$H_N(x,y) = \sum_{n=0}^{N} \epsilon^n h_n(x,y). \tag{2.12}$$

When the remainder term of order of ${\rm O}(\epsilon^{N+1})$ is neglected, the new canonical variables (x,y) solve the averaged Hamiltonian dynamical system:

$$\frac{dx}{dz} = \frac{\partial H_N}{\partial y}, \qquad \frac{dy}{dz} = -\frac{\partial H_N}{\partial x}. \tag{2.13}$$

The difference between solutions of the full system (2.4) and the averaged system (2.13) is controlled with the accuracy of ${\rm O}(\epsilon^{N+1})$ on the interval $0 \le z \le z_0$. Convergence and bounds of the normal-form transformations in Hamiltonian systems with fast dependence on time was proved by Neishtadt [24].

The canonical transformation (2.10)–(2.11) follows from the invariance of the Lagrangian of the system (2.4) [23]:

$$\mathcal{L} = \eta\frac{d\xi}{dz} - H(\xi,\eta,\zeta) = -x\frac{dy}{dz} - H_{\rm new}(x,y,\zeta) + \frac{dF}{dz}(\xi,y,\zeta).$$

In the domain $\mathcal{D}_+$, the Hamiltonian $H(\xi,\eta,\zeta)$ is a C^∞ function of ξ and η. Then, the generating functions $F_n(\xi,y,\zeta)$ are C^∞ functions of ξ and y. Provided the asymptotic series (2.8) converges uniformly, there exists ϵ_0 such that for $0 \le \epsilon \le \epsilon_0$

$$\frac{\partial^2 F}{\partial y \partial \xi} = 1 + \sum_{n=1}^{N+1} \epsilon^n \frac{\partial^2 F}{\partial y \partial \xi} + {\rm O}(\epsilon^{N+2}) > 0.$$

According to the inverse function theorem, the near-identity transformations (2.10) define classical perturbation series for $\xi(x,y,\zeta)$ and $\eta(x,y,\zeta)$ in powers of ϵ (see Chapter 2.2(a) in [23]). Here, ζ is the fast "time" for periodic oscillations of $H(\xi,\eta,z/\epsilon)$ and z is the slow "time" for averaged dynamics of the new canonical variables (x,y).

For $N = 0$, the leading-order averaged dynamical system is

$$\frac{dx}{dz} = \frac{\partial h_0}{\partial y}, \qquad \frac{dy}{dz} = -\frac{\partial h_0}{\partial x}, \tag{2.14}$$

where $h_0(x,y)$ is the leading-order averaged Hamiltonian $H_0(x,y)$:

$$H_0(x,y) = h_0(x,y) = \int_0^1 H(x,y,\zeta)d\zeta. \tag{2.15}$$

The leading-order averaged Hamiltonian can be computed explicitly from (2.3), (2.5), and (2.15) as

$$h_0(x,y) = d_0 y - \frac{e}{2my^{1/2}} \log\left[f_0(x,y)\right], \tag{2.16}$$

where

$$f_0(x,y) = \frac{y(x+m) + (1+y^2(x+m)^2)^{1/2}}{y(x-m) + (1+y^2(x-m)^2)^{1/2}}. \tag{2.17}$$

The leading-order Hamiltonian $h_0(x,y)$ does not depend on parameter l. However, the first-order correction term $h_1(x,y)$ does depend on l in the first-order averaged Hamiltonian $H_1(x,y)$.

2.2. First-order averaged Hamiltonian $H_1(x,y)$. The first-order averaged Hamiltonian can be easily derived from the formalism of the normal form transformations. It follows from (2.8), (2.10), and (2.11) that the first-order correction term $F_1(x,y,\zeta)$ is the periodic mean-zero function of ζ:

$$F_1(x,y,\zeta) = \left\{h_0(x,y) - H(x,y,\zeta)\right\}_{-1}, \tag{2.18}$$

where $\{H(x,y,\zeta)\}_{-1}$ is the mean-zero antiderivative of $H(x,y,\zeta)$ in ζ; see (2.2). Expanding the near-identity canonical transformations (2.8) and (2.10) in powers of ϵ, we define the perturbation series for $\xi(x,y,\zeta)$ and $\eta(x,y,\zeta)$:

$$\xi = x + \epsilon\xi_1(x,y,\zeta) + \mathrm{O}(\epsilon^2), \qquad \xi_1 = -\frac{\partial F_1}{\partial y}(x,y,\zeta), \tag{2.19}$$

$$\eta = y + \epsilon\eta_1(x,y,\zeta) + \mathrm{O}(\epsilon^2), \qquad \eta_1 = \frac{\partial F_1}{\partial x}(x,y,\zeta). \tag{2.20}$$

Similarly, the first-order correction term $h_1(x,y)$ is found in the form

$$h_1(x,y) = \int_0^1 \left(-\frac{\partial H}{\partial x}\frac{\partial F_1}{\partial y} + \frac{\partial H}{\partial y}\frac{\partial F_1}{\partial x} - \frac{\partial^2 F_1}{\partial\zeta\partial x}\frac{\partial F_1}{\partial y} \right)(x,y,\zeta)d\zeta \tag{2.21}$$

$$= \int_0^1 \left(\frac{\partial H}{\partial y}\frac{\partial F_1}{\partial x} \right)(x,y,\zeta)d\zeta, \tag{2.22}$$

where we have used (2.9) and (2.18) for the second equality in (2.22). The first-order averaged dynamical system (2.13) then takes the form

$$\frac{dx}{dz} = \frac{\partial h_0}{\partial y} + \epsilon\frac{\partial h_1}{\partial y}, \qquad \frac{dy}{dz} = -\frac{\partial h_0}{\partial x} - \epsilon\frac{\partial h_1}{\partial x}. \tag{2.23}$$

A remarkable result is that the first-order correction term $h_1(x,y)$ vanishes in the case of symmetric maps, when $l = 1/2$.

LEMMA 2.2. *When the dispersion map is symmetric, i.e., $l = 1/2$, then $h_1(x,y) = 0$ and $F_1(x,y,0) = F_1(x,y,l) = 0$.*

Proof. When $d(\zeta) = 4$ for $z \in [0, 1/2)$ and $d(\zeta) = -4$ for $z \in [-1/2, 0)$ (see (1.7)), the mean-zero antiderivative function $d_{-1}(\zeta)$ is even in ζ, i.e., $d_{-1}(-\zeta) = d_{-1}(\zeta)$ (see (2.3)). As a result, the Hamiltonian $H(x, y, \zeta)$ in (2.5) can be represented by the Fourier cosine-series:

$$H(x, y, \zeta) = h_0(x, y) + \sum_{n=1}^{\infty} c_n(x, y) \cos(2\pi n\zeta), \tag{2.24}$$

where $c_n(x, y)$ are some Fourier coefficients. As a result, the first-order correction term $F_1(x, y, \zeta)$ given by (2.18) is computed as the Fourier sine-series:

$$F_1(x, y, \zeta) = -\sum_{n=1}^{\infty} \frac{1}{2\pi n} c_n(x, y) \sin(2\pi n\zeta). \tag{2.25}$$

It is clear that $F_1(x, y, 0) = F_1(x, y, 1/2) = 0$. The first-order correction $h_1(x, y)$ given by (2.22) is the average of the product of the Fourier cosine- and sine-series, which is zero. □

In general case, when $l \neq 1/2$, the first-order averaging theory is equivalent to the following result. If (x, y) solve the averaged equations (2.23) and (ξ, η) solve the full equations (2.4)–(2.5) with close initial values—$|\xi_0 - x_0 - \epsilon\xi_1(x_0, y_0, 0)| \leq c_x\epsilon^2$ and $|\eta_0 - y_0 - \epsilon\eta_1(x_0, y_0, 0)| \leq c_y\epsilon^2$, where c_x and c_y are some constants, then the solutions (x, y) and (ξ, η) remain within the linear accuracy in ϵ at the distances $0 \leq z \leq z_0$:

$$\sup_{z\in[0,z_0]} |\xi(z) - x(z) - \epsilon\xi_1(x, y, \zeta)| \leq C_x\epsilon^2, \qquad \sup_{z\in[0,z_0]} |\eta(z) - y(z) - \epsilon\eta_1(x, y, \zeta)| \leq C_y\epsilon^2, \tag{2.26}$$

where C_x and C_y are some constants. The standard proof of this statement is based on convergence of the perturbation series (2.19)–(2.20) [23].

When the dispersion map is symmetric with equal legs, i.e., $l = 1/2$, the corrections $\xi_1(x, y, \zeta)$ and $\eta_1(x, y, \zeta)$ vanish at the points $\zeta = 0$ and $\zeta = \frac{1}{2}$. As a result, the distance between solutions (x, y) and (ξ, η) remains within the quadratic accuracy in ϵ at the ends of the dispersion map, i.e., at $z = k\epsilon$ and $z = (k - \frac{1}{2})\epsilon$, where $k \in \mathbb{Z}_+$:

$$\sup_{z\in[0,z_0]} |\xi(z = k\epsilon) - x(z = k\epsilon)| \leq C_x\epsilon^2, \qquad \sup_{z\in[0,z_0]} |\eta(z = k\epsilon) - y(z = k\epsilon)| \leq C_y\epsilon^2. \tag{2.27}$$

This result is related to the Strang's work [25] on symmetrization of the split-step methods for solving PDEs. The quadratic convergence occurs only at the ends of the dispersion map, while it is linear in the interior of the dispersion map.

Remark 2.1. The symmetric dispersion map with $l = 1/2$ can be translated for any ζ_0 such that $d(\zeta + \zeta_0) = -d(\zeta_0 - \zeta)$. The first-order correction $h_1(x, y)$ vanishes for all such symmetric maps. In particular, the symmetric dispersion map used in numerical modeling of the NLS equation by the split-step method is $d(\zeta) = 4$ for $\zeta \in [0, 1/4) \cup [3/4, 1)$ and $d(\zeta) = -4$ for $\zeta \in [1/4, 3/4)$. This map is equivalent to our symmetric map with $l = 1/2$ by the translation with $\zeta_0 = 1/4$.

The first-order correction term $h_1(x, y)$ can be found explicitly by direct compu-

tations from (2.3), (2.5), (2.16), (2.18), and (2.22). The explicit formula is

$$\begin{aligned} h_1(x,y) &= \frac{e^2(1-2l)}{8m^2}\left[\frac{(x+m)}{1+y^2(x+m)^2}-\frac{(x-m)}{1+y^2(x-m)^2}\right] \\ &+ \frac{e^2(1-2l)}{16m^3y^2}\left[\log\left[f_0(x,y)\right]+\frac{2y(x-m)}{(1+y^2(x-m)^2)^{1/2}}-\frac{2y(x+m)}{(1+y^2(x+m)^2)^{1/2}}\right] \\ &\times\left[\log\left[f_0(x,y)\right]+\frac{xy}{(1+y^2(x-m)^2)^{1/2}}-\frac{xy}{(1+y^2(x+m)^2)^{1/2}}\right] \\ &+ \frac{e^2(1-2l)}{16m^3y^2}\left[\frac{3+y^2(x+m)^2}{(1+y^2(x+m)^2)^{1/2}}-\frac{3+y^2(x-m)^2}{(1+y^2(x-m)^2)^{1/2}}\right] \\ &\times\left[\frac{1}{(1+y^2(x+m)^2)^{1/2}}-\frac{1}{(1+y^2(x-m)^2)^{1/2}}\right], \end{aligned} \tag{2.28}$$

where $f_0(x,y)$ is defined by (2.17). We confirm from (2.28) that $h_1(x,y)=0$ for $l=1/2$. The first-order averaged Hamiltonian $H_1(x,y)$ is analyzed next for existence and stability of critical points. The critical points of the averaged Hamiltonian correspond to the Gaussian approximation of the DM solitons.

2.3. Existence of critical points of the first-order averaged Hamiltonian. The first-order averaged Hamiltonian is $H_1(x,y)=h_0(x,y)+\epsilon h_1(x,y)$, where $h_0(x,y)$ and $h_1(x,y)$ are given explicitly in (2.16) and (2.28).

LEMMA 2.3. *The points $(0,y_*)$ are critical points of the first-order averaged Hamiltonian $H_1(x,y)$ if y_* is an extremum of the function $H_1(0,y)$:*

$$\begin{aligned} H_1(0,y) &= d_0 y - \frac{e}{2my^{1/2}}\log\left[\hat{f}_0(my)\right] \\ &+ \epsilon\frac{e^2(1-2l)}{16m^3y^2}\left[\log^2\left[\hat{f}_0(my)\right]-\frac{4my}{(1+m^2y^2)^{1/2}}\log\left[\hat{f}_0(my)\right]+\frac{4m^2y^2}{1+m^2y^2}\right], \end{aligned} \tag{2.29}$$

where $\hat{f}_0(my)=f_0(0,y)$, i.e.,

$$\hat{f}_0(my)=\left[\frac{(1+m^2y^2)^{1/2}+my}{(1+m^2y^2)^{1/2}-my}\right].$$

Proof. The variation of $h_0(x,y)$ in x leads to the only solution $x=0$. The same solution gives also an extremum of $h_1(x,y)$ in x. The variation of $H_1(0,y)$ in y defines the critical point $y=y_*$. □

Proof of Proposition 1.4. The first equation (1.19) follows from the condition $H_1'(0,y)=0$. The continuous functions $g_d^{(0,1)}$ are computed explicitly:

$$g_d^{(0)} = -\frac{1}{4m^{3/2}y^{3/2}}\left[\log\left[\hat{f}_0(my)\right]-\frac{4my}{(1+m^2y^2)^{1/2}}\right], \tag{2.30}$$

$$\begin{aligned} g_d^{(1)} &= \frac{1}{8m^3y^3}\left[\log^2\left[\hat{f}_0(my)\right]\right. \\ &\left.- \frac{2my(2+3m^2y^2)}{(1+m^2y^2)^{3/2}}\log\left[\hat{f}_0(my)\right]+\frac{4m^2y^2(1+2m^2y^2)}{(1+m^2y^2)^2}\right]. \end{aligned} \tag{2.31}$$

The second equation (1.20) follows from the nonhomogeneous equation (2.6) reduced for the perturbation expansion (2.19)–(2.20):

$$\frac{d\phi}{dz} = \frac{1}{4}\left[d_0 y + y\frac{dx}{dz} + y\frac{\partial \xi_1}{\partial \zeta} - 2H(x,y,\zeta) + \epsilon\left(d_0\eta_1 + \eta_1\frac{\partial H}{\partial y}(x,y,\zeta)\right.\right. \\ \left.\left. + \; y\left(\frac{\partial \xi_1}{\partial x}\frac{dx}{dz} + \frac{\partial \xi_1}{\partial y}\frac{dy}{dz}\right) + y\frac{\partial \xi_2}{\partial \zeta} - 2\left(\frac{\partial H}{\partial x}\xi_1 + \frac{\partial H}{\partial y}\eta_1\right)(x,y,\zeta)\right) + \mathrm{O}(\epsilon^2)\right]. \tag{2.32}$$

Integrating (2.33) over $\zeta \in [0,1]$ at the critical point $(0, y_*)$, we define μ as

$$\mu = \frac{1}{\epsilon}\left(\phi(z+\epsilon) - \phi(z)\right) = \frac{1}{4}\left[d_0 y_* - 2h_0(0,y_*) - 3\epsilon h_1(0,y_*) + \mathrm{O}(\epsilon^2)\right], \tag{2.33}$$

where we have utilized (2.15) and (2.22). The continuous functions $g_d^{(0,1)}$ in (1.20) are computed explicitly:

$$g_\mu^{(0)} = \frac{1}{16 m^{1/2} y^{1/2}}\left[5\log\left[\hat{f}_0(my)\right] - \frac{4my}{(1+m^2y^2)^{1/2}}\right], \tag{2.34}$$

$$g_\mu^{(1)} = -\frac{1}{64 m^2 y^2}\left[5\log^2\left[\hat{f}_0(my)\right]\right. \\ \left. - \; \frac{2my(8+9m^2y^2)}{(1+m^2y^2)^{3/2}}\log\left[\hat{f}_0(my)\right] + \frac{4m^2y^2(4+5m^2y^2)}{(1+m^2y^2)^2}\right]. \tag{2.35}$$

The third equation (1.21) follows from (1.18):

$$s = \frac{1}{\tau_{\min}^2} = \max_{0\le z\le \epsilon}\eta(z) = y + \epsilon \max_{0\le\zeta\le 1}\eta_1(0,y_*,\zeta) + \mathrm{O}(\epsilon^2). \tag{2.36}$$

If (a,b) is a nonconstant periodic solution of z, then $a(z)$ has at least two extremal points on the interval $z \in [0,\epsilon)$. The extremal values for $a(z)$ occur for $z = z_*$, where $b(z_*) = 0$; see (1.12). It follows from (2.3) and (2.18) that $d_{-1}(\zeta_*) = 0$ and $F_1(0,y_*,\zeta_*) = 0$ for $\zeta_* = l/2$ and $\zeta_* = (1+l)/2$. As a result, $b(z_*) = \mathrm{O}(\epsilon^2)$ and $\xi(\zeta_*) = \mathrm{O}(\epsilon^2)$, see (2.1) and (2.19), i.e., $a(z)$ and $\eta(z)$ have extrema for $z_* = \epsilon\zeta_*$. Computing the derivative of $F_1(x,y,\zeta)$ in x for $(0,y_*,\zeta)$, we find that the maximal value of $\eta_1(0,y_*,\zeta_*)$ occurs at $\zeta_* = l/2$ and the continuous functions $g_s^{(1)}$ in (1.21) are computed explicitly:

$$g_s^{(1)} = \frac{m^{1/2}y^{1/2}}{2}\left(l + \frac{l-1}{(1+m^2y^2)^{1/2}}\right) + \frac{(1-2l)}{4m^{1/2}y^{1/2}}\log\left[\hat{f}_0(my)\right]. \tag{2.37}$$

□

Figures 1.1(a)–(d) are constructed with the help of explicit formulas (1.19)–(1.21), (2.30)–(2.31), (2.34)–(2.35), and (2.37). The dotted curves show the limit $\epsilon = 0$, the solid curves show the results of the first-order averaging theory for $\epsilon > 0$, with $l = 0.1$ fixed. The first-order averaging theory corresponds well to numerical analysis of the full equations (1.12)–(1.13); see [4, 7, 8].

2.4. Stability of critical points of the first-order averaged Hamiltonian. Linear stability of the critical points $(0, y_*)$ in the first-order averaged system (2.23) is defined by concavity of the quadratic form:

$$H_1(x,y) - H_1(0,y_*) = \frac{1}{2}\frac{\partial^2 H_1}{\partial x^2}\bigg|_{(0,y_*)}x^2 + \frac{1}{2}\frac{\partial^2 H_1}{\partial y^2}\bigg|_{(0,y_*)}(y-y_*)^2, \tag{2.38}$$

since the derivative of $H_1(x,y)$ in x is zero for any $(0,y)$. The critical point $(0,y_*)$ is linearly stable if it corresponds to an extremum of the quadratic form (2.38); the stable critical points are centers on the phase plane (x,y). The critical point is linearly unstable if it corresponds to a saddle point of the quadratic form (2.38). The unstable critical points appear as saddle points on the phase plane (x,y). It is easy to analyze the linear stability of the critical point $(0,y_*)$ with the help of the function $e = f_s(s)$ shown on Figure 1.1(b).

LEMMA 2.4. *The critical point $(0,y_*)$ of the first-order averaged Hamiltonian $H_1(x,y)$ is stable for $d_0 \geq 0$. For $d_0 < 0$, define $s_{\rm thr}$ and $s_{\rm stab}$ as the turning and minimal points of the curve $e = f_s(s)$, i.e., $f_s'(s_{\rm thr}) = \infty$ and $f_s'(s_{\rm stab}) = 0$. The critical point $(0,y_*)$ is stable for $d_0 < 0$ in the following cases:* (i) *for the upper branch of the curve $e = f_s(s)$, when $s \geq s_{\rm thr}$ and* (ii) *for the lower branch of the curve $e = f_s(s)$, when $s_{\rm thr} < s < s_{\rm stab}$.*

Proof. It follows from (2.16) that

$$\left.\frac{\partial^2 h_0}{\partial x^2}\right|_{x=0} = \frac{e y^{5/2}}{(1+m^2y^2)^{3/2}} > 0$$

for any $y > 0$. Therefore, there exists ϵ_0 such that the curvature of $H_1(x,y)$ is positive in x for $0 \leq \epsilon \leq \epsilon_0$. Then, the stability criterion is $H_1''(0,y_*) > 0$, where

$$H_1''(0,y) = -em^{3/2} g_d^{(0)\prime}(my) - \epsilon e^2 m(1-2l) g_d^{(1)\prime}(my) = f_s'(s) W(s),$$

where

$$W(s) = \left[g_d^{(0)}(my) + 2\epsilon e(1-2l) g_d^{(1)}(my) + \mathrm{O}(\epsilon^2) \right] \left[1 + \epsilon \frac{e}{m^{1/2}} g_s^{(1)\prime}(my,l) + \mathrm{O}(\epsilon^2) \right].$$

For $d_0 > 0$, it follows from Figure 1.1(b) and (1.19) that $f_s'(s) > 0$ and $g_d^{(0)}(my) > 0$ for any $y > 0$. As a result, there exists ϵ_0 such that the curvature of $H_1(0,y)$ is positive in y for $0 \leq \epsilon \leq \epsilon_0$. Therefore, the critical point $(0,y_*)$ is stable for $d_0 \geq 0$ and $0 \leq \epsilon \leq \epsilon_0$.

For $d_0 < 0$, the upper and lower branches of the function $e = f_s(s)$ are separated by the point $s = s_{\rm thr}$, where $f_s'(s_{\rm thr}) = \infty$ (see Figure 1.1(b)). Since $H_1''(0,y)$ may not be singular in the domain $y > 0$, the function $W(s)$ changes sign at $s = s_{\rm thr}$. It follows from (1.19) that $g_d^{(0)}(my) < 0$ for $d_0 < 0$. Therefore, it is clear that $W(s) > 0$ for the upper branch of $e = f_s(s)$ and $W(s) < 0$ for the lower branch of $e = f_s(s)$ on Figure 1.1(b). On the other hand, $f_s'(s) > 0$ for the upper branch of $e = f_s(s)$ and $f_s'(s) < 0$ for the lower branch of $e = f_s(s)$ between $s_{\rm thr} < s < s_{\rm stab}$, where $f_s'(s_{\rm stab}) = 0$; see Figure 1.1(b). As a result, the curvature of $H_1(0,y)$ in y is positive for the two cases (i) and (ii). For the lower branch of $e = f_s(s)$ at $s > s_{\rm stab}$, the curvature of $H_1(0,y)$ in y is negative, since $f_s'(s) > 0$ and $W(s) < 0$. As a result, the critical point $(0,y_*)$ is linearly unstable for the lower branch of $e = f_s(s)$ at $s > s_{\rm stab}$. □

Lemma 2.4 corresponds to Proposition 1.8 for Gaussian pulses in the first-order averaging theory. At the plane (μ,e), the point $s = s_{\rm stab}$ is the point of minimal e, i.e., it is a branching point of the function $e = f_\mu(\mu)$. As a result, for $d_0 < 0$, the upper branch of the function $e = f_\mu(\mu)$ is linearly unstable, while the lower branch of the function $e = f_\mu(\mu)$ is linearly stable [13].

We compute the phase plane $H_1(x,y) = \text{const}$ of the first-order averaged Hamiltonian from (2.16) and (2.28). The phase plane is shown on Figure 2.1(a)–(b) in standardized variables $X = x/m$ and $Y = my$ for $D_0 = 0.015$ and $D_0 = -0.015$,

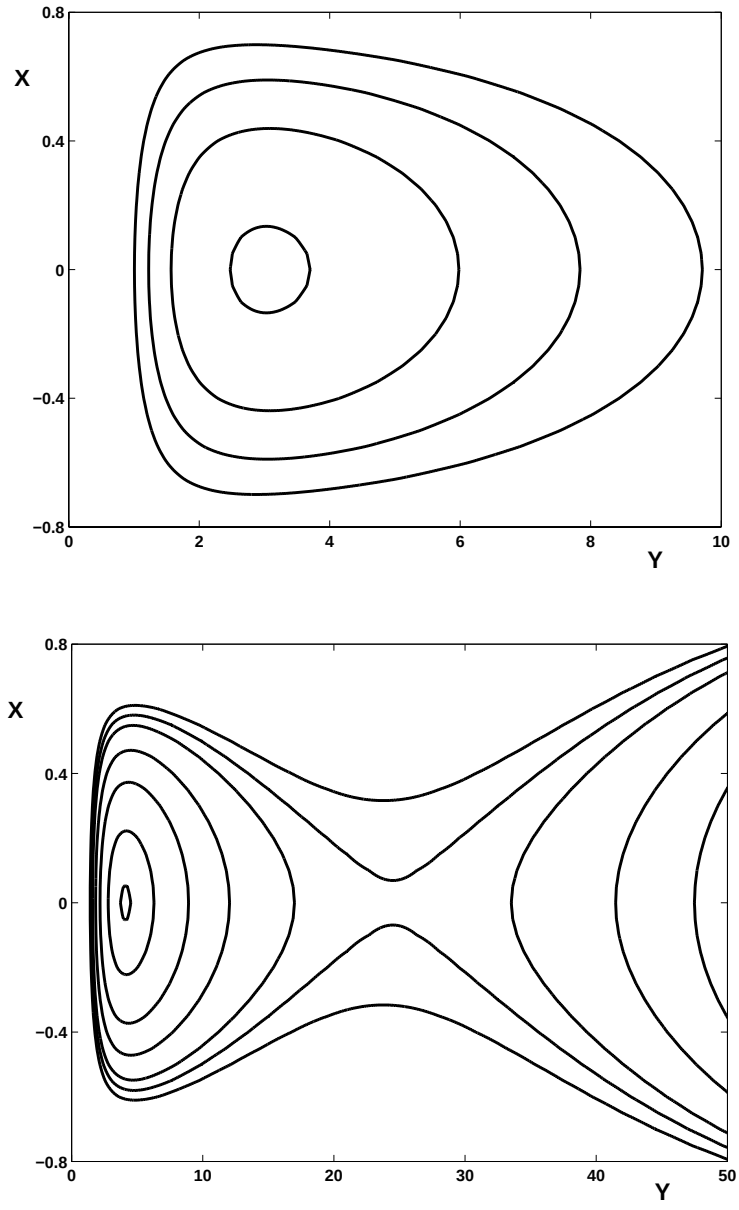

FIG. 2.1. *The contour levels of the first-order averaged Hamiltonian* $H_1(X, Y)$ *for* $D_0 = 0.015$ (a) *and* $D_0 = -0.015$ (b). *The other parameters are* $E = 2$ *and* $l = 0.1$.

with $l = 0.1$. In the initial-value problem, the energy parameter is constant, taken as $E = 2$.

For $D_0 \geq 0$ there is only one critical point, which is a center (see Figure 2.1(a)). The trajectories of the dynamical system (2.23) are all closed around the stable center point. This dynamics corresponds to small oscillations of the DM soliton, perturbed by an initial condition.

For $D_0 < 0$, two critical points coexist for the same value of E. The critical point with a larger value of Y_* is unstable (saddle point), while that with smaller value of Y_* is stable (center) (see Figure 2.1(b)). The critical point with a larger value of Y_* corresponds to a shorter DM soliton. If the shorter soliton is shortened by an initial perturbation, i.e., $Y(0) > Y_*$, it is destroyed, since the trajectory (X, Y) is unbounded on the phase plane of the first-order averaged system. We speculate that the shorter soliton transforms into chirped quasi-linear waves but this process is beyond the variational Gaussian approximation. Since solutions of (1.12)–(1.13) are bounded in the domain $\mathcal{D}_+$ for any finite z, the transformation happens over infinite propagation distances z.

In the other case, when the shorter DM soliton is broadened by the initial perturbation, i.e., $Y(0) < Y_*$, the trajectory (X, Y) is trapped inside the separatrix loop of the center point. In this case, the pulse undertakes large-amplitude oscillations around the stable longer DM soliton, similarly to the case $D_0 \geq 0$. Instability of short DM solitons along the lower branch of the (E, S) curve is confirmed in numerical computations [7].

3. Reduction to an averaged integral NLS equation. Here we analyze and extend the integral NLS equation (1.15), derived by means of averaging of the periodic NLS equation (1.5). We develop a formal method of canonical transformations for PDEs in section 3.1. In the leading and first orders in powers of ϵ, we prove convergence of the periodic NLS equation (1.5) to an averaged integral NLS equation in section 3.2. Existence of ground states of the first-order averaged Hamiltonian is proved for the case $d_0 > 0$ in section 3.3.

The periodic NLS equation (1.5) has the standard Hamiltonian structure:

$$i\frac{\partial u}{\partial z} = \frac{\delta H}{\delta \bar{u}}, \qquad -i\frac{\partial \bar{u}}{\partial z} = \frac{\delta H}{\delta u}, \tag{3.1}$$

where the Hamiltonian $H = H(u, \bar{u}, z/\epsilon)$ is

$$H = \frac{1}{2}\int_{-\infty}^{\infty} \left[\frac{m}{\epsilon} d\left(\frac{z}{\epsilon}\right) \left|\frac{\partial u}{\partial t}\right|^2 + d_0 \left|\frac{\partial u}{\partial t}\right|^2 - |u|^4 \right] dt. \tag{3.2}$$

LEMMA 3.1. *Define a fundamental solution of the linear periodic equation*

$$i\frac{\partial u}{\partial z} + \frac{m}{2\epsilon} d\left(\frac{z}{\epsilon}\right) \frac{\partial^2 u}{\partial t^2} = 0 \tag{3.3}$$

in the operator form:

$$u(z,t) = T\left(\frac{z}{\epsilon}\right) u(0,t). \tag{3.4}$$

The operator $T(\zeta)$ for $\zeta = z/\epsilon$ is a unitary operator with unit period:

$$T^{-1}(\zeta) = \overline{T}(\zeta), \qquad T(\zeta + 1) = T(\zeta), \tag{3.5}$$

where $\bar{T}$ is complex conjugate.

Proof. In the Fourier space of t, the operator $T(\zeta)$ is a multiplication operator:

$$\hat{u}(z,\omega) = T_\omega(\zeta)\hat{u}(0,\omega), \qquad T_\omega(\zeta) = e^{-\frac{im}{2} d_{-1}(\zeta)\omega^2}, \tag{3.6}$$

where $d_{-1}(\zeta)$ is given by (2.2)–(2.3) and $\hat{u}(\zeta,\omega)$ is the Fourier transform of $u(\zeta,t)$ in t. The two properties (3.5) follow from the Fourier form (3.6). □

Using a linear canonical transformation

$$u(z,t) = T(\zeta)v(z,t), \qquad \bar{u}(z,t) = T^{-1}(\zeta)\bar{v}(z,t), \qquad \zeta = \frac{z}{\epsilon}, \tag{3.7}$$

we eliminate the fast periodic term from (1.5) and rewrite the Hamiltonian system (3.1) in new canonical variables $(v,\bar{v})$,

$$i\frac{\partial v}{\partial z} = \frac{\delta H}{\delta \bar{v}}, \qquad -i\frac{\partial \bar{v}}{\partial z} = \frac{\delta H}{\delta v}, \tag{3.8}$$

with the new Hamiltonian $H = H(v,\bar{v},\zeta)$:

$$H = \frac{1}{2}\int_{-\infty}^{\infty}\left[d_0\left|\frac{\partial v}{\partial t}\right|^2 - |T(\zeta)v|^4\right]dt. \tag{3.9}$$

The periodic NLS equation in new variables $(v,\bar{v})$ can be written in the operator form:

$$i\frac{\partial v}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 v}{\partial t^2} + T^{-1}(\zeta)\left(|T(\zeta)v|^2\,T(\zeta)v\right) = 0. \tag{3.10}$$

In the Fourier space of t, the operator equation (3.10) takes the form of a periodic integral NLS equation:

$$i\frac{\partial \hat{v}}{\partial z}(\omega) - \frac{1}{2}d_0\omega^2\hat{v}(\omega) + \int\!\!\int_{-\infty}^{\infty} K_\omega(\zeta)\hat{v}(\omega_1)\hat{v}(\omega_2)\bar{\hat{v}}(\omega_1+\omega_2-\omega)d\omega_1 d\omega_2 = 0, \tag{3.11}$$

where $K_\omega(\zeta)$ is defined by

$$K_\omega(\zeta) = e^{-\frac{im}{2}d_{-1}(\zeta)(\omega_1^2+\omega_2^2-(\omega_1+\omega_2-\omega)^2-\omega^2)} = e^{imd_{-1}(\zeta)(\omega-\omega_1)(\omega-\omega_2)}. \tag{3.12}$$

The asymptotic reduction of (3.11) to an integral NLS equation is based on averaging of the Hamiltonian (3.9) in ζ [18]. A direct averaging method produces the following leading-order averaged Hamiltonian $H_0(V,\bar{V})$:

$$H_0(V,\bar{V}) = h_0(V,\bar{V}) = \int_0^1 H(V,\bar{V},\zeta)d\zeta = \frac{1}{2}\int_{-\infty}^{\infty}\left[d_0\left|\frac{\partial V}{\partial t}\right|^2 - \int_0^1 |T(\zeta)V|^4 d\zeta\right]dt. \tag{3.13}$$

The leading-order averaged Hamiltonian $H_0(V,\bar{V})$ generates the averaged integral NLS equation in the operator form:

$$i\frac{\partial V}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 V}{\partial t^2} + \int_0^1 T^{-1}(\zeta)\left(|T(\zeta)v|^2\,T(\zeta)v\right)d\zeta = 0. \tag{3.14}$$

In the Fourier space of t, the integral NLS equation (3.14) takes an explicit form:

$$i\frac{\partial \hat{V}}{\partial z}(\omega) - \frac{1}{2}d_0\omega^2\hat{V}(\omega) + \int\!\!\int_{-\infty}^{\infty}\langle K_\omega\rangle\hat{V}(\omega_1)\hat{V}(\omega_2)\bar{\hat{V}}(\omega_1+\omega_2-\omega)d\omega_1 d\omega_2 = 0, \tag{3.15}$$

where $\langle K_\omega \rangle$ is the average of $K_\omega(\zeta)$ over $\zeta \in [0,1]$. When the antiderivative function $d_{-1}(\zeta)$ is given by (2.3), the kernel $\langle K_\omega \rangle$ is computed explicitly as

$$\langle K_\omega \rangle = \frac{\sin m(\omega-\omega_1)(\omega-\omega_2)}{m(\omega-\omega_1)(\omega-\omega_2)}. \tag{3.16}$$

The integral equation (3.15) with the kernel (3.16) becomes (1.15) for stationary pulse solutions: $\hat{V}(z,\omega) = \hat{W}(\omega)e^{i\mu z}$.

The asymptotic reduction of the periodic NLS equation (1.5) to the averaged integral NLS equation (3.15) was first derived in [14, 15]. Higher-order corrections to the averaged integral NLS equation were considered in [26, 27] with the help of formal Lie transformations. We develop a method of formal canonical transformations for the Hamiltonian $H(v,\bar{v},\zeta)$ and, in addition, we prove convergence of the averaging procedure at the leading and first orders in powers of ϵ.

3.1. Averaging of the periodic integral NLS equation (3.11)–(3.12). The periodic integral NLS equation (3.11)–(3.12) can be averaged with the help of the normal form transformations, formally generalized for infinite-dimensional Hamiltonian systems. In this generalization, the generating functional $F(v,\bar{V},\zeta)$ replaces the generating function $F(\xi,y,\zeta)$ (see (2.8)):

$$F(v,\bar{V},\zeta) = \int_{-\infty}^{\infty} dt \left[v\bar{V} + \sum_{n=1}^{N+1} \epsilon^n F_n(v,\bar{V},\zeta) + \mathrm{O}(\epsilon^{N+2}) \right], \tag{3.17}$$

where the correction terms $F_n(V,\bar{V},\zeta)$ for $1 \le n \le (N+1)$ are periodic mean-zero functions of ζ:

$$F_n(V,\bar{V},\zeta+1) = F_n(V,\bar{V},\zeta), \qquad \int_0^1 F_n(V,\bar{V},\zeta)d\zeta = 0. \tag{3.18}$$

The generating functional $F(v,\bar{V},\zeta)$ defines the near-identical canonical transformation

$$\bar{v} = \frac{\delta F}{\delta v}, \qquad V = \frac{\delta F}{\delta \bar{V}}, \tag{3.19}$$

and takes the Hamiltonian $H(v,\bar{v},\zeta)$ to the form

$$\begin{aligned} H_{\rm new}(V,\bar{V},\zeta) &= H(v(V,\bar{V},\zeta),\bar{v}(V,\bar{V},\zeta),\zeta) + \frac{i}{\epsilon}\frac{\partial F}{\partial \zeta}(v(V,\bar{V},\zeta),\bar{V},\zeta) \\ &= H_N(V,\bar{V}) + \mathrm{O}(\epsilon^{N+1}), \end{aligned} \tag{3.20}$$

where $H_N(V,\bar{V})$ is the Nth-order averaged Hamiltonian

$$H_N(V,\bar{V}) = \sum_{n=0}^{N} \epsilon^n h_n(V,\bar{V}). \tag{3.21}$$

When the remainder term of order of $\mathrm{O}(\epsilon^{N+1})$ is neglected, the new canonical variables $(V,\bar{V})$ solve the averaged Hamiltonian dynamical system:

$$i\frac{\partial V}{\partial z} = \frac{\delta H_N}{\delta \bar{V}}, \qquad -i\frac{\partial \bar{V}}{\partial z} = \frac{\delta H_N}{\delta V}, \tag{3.22}$$

The difference between solutions of the full system (3.8) and the averaged system (3.22) is controlled with the accuracy of $\mathrm{O}(\epsilon^{N+1})$ on the interval $0 \le z \le z_0$.

The Lagrangian functional for the system (3.8) is transformed as follows:

(3.23)
$$L = i\int_{-\infty}^{\infty} \bar{v}\frac{\partial v}{\partial z}dt - H(v,\bar{v},\zeta) = -i\int_{-\infty}^{\infty} V\frac{\partial \bar{V}}{\partial z}dt - H_{\text{new}}(V,\bar{V},\zeta) + i\frac{dF}{dz}(v,\bar{V},\zeta),$$

where

$$\frac{dF}{dz} = \frac{1}{\epsilon}\frac{\partial F}{\partial \zeta} + \int_{-\infty}^{\infty} dt\left(\frac{\partial v}{\partial z}\frac{\delta F}{\delta v} + \frac{\partial \bar{V}}{\partial z}\frac{\delta F}{\delta \bar{V}}\right).$$

If $F(V,\bar{V},\zeta)$ generates $\bar{v}$ and V according to (3.19), then the Hamiltonian $H(v,\bar{v},\zeta)$ transforms according to (3.20). The method of normal form transformations in (3.17)–(3.23) is a formal algorithmic procedure. Still we are able to prove convergence of the first-order averaged theory in a suitable function space; see section 3.2.

The difference between solutions of the averaged integral NLS equation (3.15) and the periodic integral NLS equation (3.11) is defined with the help of the first-order correction $F_1(V,\bar{V},\zeta)$ in (3.17). The first-order correction can be found from (3.9), (3.13), and (3.20):

$$F_1(V,\bar{V},\zeta) = \frac{-i}{2}\left\{|T(\zeta)V|^4 - \int_0^1 |T(\zeta)V|^4\, d\zeta\right\}_{-1}, \tag{3.24}$$

where $\{*\}_{-1}$ stands for the mean-zero antiderivative in ζ defined by (2.2). Expanding the near-canonical transformations (3.17) and (3.19) in powers of ϵ, we define the perturbation series for $v(V,\bar{V},\zeta)$:

$$v = V + \epsilon i\Phi(V,\bar{V},\zeta) + O(\epsilon^2), \qquad \bar{v} = \bar{V} - \epsilon i\overline{\Phi(V,\bar{V},\zeta)} + O(\epsilon^2), \tag{3.25}$$

where $\Phi(V,\bar{V},\zeta)$ is formally computed as

$$\Phi = \left\{T^{-1}(\zeta)\left(|T(\zeta)V|^2\, T(\zeta)V\right) - \int_0^1 T^{-1}(\zeta)\left(|T(\zeta)V|^2\, T(\zeta)V\right)d\zeta\right\}_{-1}. \tag{3.26}$$

In the Fourier form, $\Phi(V,\bar{V},\zeta)$ is expressed explicitly as $\hat{\Phi}_\omega(V,\bar{V},\zeta)$:

$$\hat{\Phi}_\omega = \iint_{-\infty}^{\infty} \{K_\omega(\zeta) - \langle K_\omega\rangle\}_{-1}\, \hat{V}(\omega_1)\hat{V}(\omega_2)\hat{\bar{V}}(\omega_1+\omega_2-\omega)d\omega_1 d\omega_2. \tag{3.27}$$

With the use of correction $\Phi(V,\bar{V},\zeta)$, the first-order correction term $h_1(V,\bar{V})$ of the new averaged Hamiltonian is found in the form

$$h_1(V,\bar{V}) = -i\int_{-\infty}^{\infty} dt\int_0^1 \left(|T(\zeta)V|^2\left(T^{-1}(\zeta)\bar{V}\right)T(\zeta)\Phi(V,\bar{V},\zeta) \ - \text{c.c.}\right)d\zeta, \tag{3.28}$$

where c.c. stands for complex conjugation and we have used the periodicity of $\Phi(V,\bar{V},\zeta)$ in ζ. The first-order correction $h_1(V,\bar{V})$ vanishes in the case of symmetric maps, when $l = 1/2$.

LEMMA 3.2. *When the dispersion map is symmetric, i.e., $l = 1/2$, then $h_1(V,\bar{V}) = 0$ and $\Phi(V,\bar{V},0) = \Phi(V,\bar{V},l) = 0$.*

Proof. If $l = 1/2$, then the mean-zero antiderivative function $d_{-1}(\zeta)$ is even: $d_{-1}(-\zeta) = d_{-1}(\zeta)$. The operator $\hat{T}_\omega(\zeta)$ and the kernel $K_\omega(\zeta)$ in (3.6) and (3.12) are even functions of ζ and can be expanded into the Fourier cosine-series, e.g.,

$$K_\omega(\zeta) = \langle K_\omega \rangle + \sum_{n=1}^{\infty} k_{\omega n} \cos(2\pi n \zeta). \tag{3.29}$$

It follows from (3.27) that the first-order correction $\hat{\Phi}_\omega(V, \bar{V}, \zeta)$ is expanded into the Fourier sine-series:

$$\hat{\Phi}_\omega(V, \bar{V}, \zeta) = \sum_{n=1}^{\infty} \phi_{\omega n}(V, \bar{V}) \sin(2\pi n \zeta). \tag{3.30}$$

The integrand of (3.28) contains only the product of the Fourier cosine- and sine-series, which has zero mean. □

The first-order averaged Hamiltonian is finally defined as $H_1(V, \bar{V}) = h_0(V, \bar{V}) + \epsilon h_1(V, \bar{V})$, where $h_0(V, \bar{V})$ and $h_1(V, \bar{V})$ are given by (3.13) and (3.28).

3.2. Averaging theorems for the first-order averaged integral NLS equation. Here we justify the first-order averaging theory for the periodic integral NLS equation (3.10). In order to shorten notation, we introduce the operator $Q(v, \zeta)$ for the cubic nonlinear term in (3.10):

$$Q(v, \zeta) = Q(v, v, v, \zeta), \qquad Q(u, v, w, \zeta) = T^{-1}(\zeta) \left(T(\zeta) u \, T(\zeta) v \, \overline{T(\zeta) w} \right). \tag{3.31}$$

In the operator form,

$$\Phi(V, \bar{V}, \zeta) = \left\{ Q(V, \zeta) - \langle Q \rangle(V) \right\}_{-1},$$

and the first-order averaged integral NLS equation can be written in the form

$$i \frac{\partial V}{\partial z} + \frac{1}{2} d_0 \frac{\partial^2 V}{\partial t^2} + \langle Q \rangle(V) + \epsilon \langle Q_1 \rangle(V) = 0, \tag{3.32}$$

where

$$\langle Q \rangle(V) = \int_0^1 Q(V, \zeta) d\zeta, \tag{3.33}$$

and

$$\langle Q_1 \rangle(V) = \frac{\delta h_1}{\delta \bar{V}} = i \int_0^1 \left[Q(V, V, \Phi, \zeta) - 2 Q(V, \Phi, V, \zeta) \right] d\zeta. \tag{3.34}$$

First, we list some properties of Q and Φ and formulate a local existence result for the first-order averaged integral NLS equation (3.32).

PROPOSITION 3.3. *Let u, v, w be in $H^s(\mathbb{R})$ $(s \geq 0)$; then the following inequalities hold:*

$$||Q(u, v, w, \zeta)||_{H^s} \leq C_s ||u||_{H^s} ||v||_{H^s} ||w||_{H^s}, \tag{3.35}$$

$$||Q(u, \zeta)||_{H^s} \leq C_s ||u||^3_{H^s}, \tag{3.36}$$

$$||\langle Q(u) \rangle||_{H^s} \leq C_s ||u||^3_{H^s}, \tag{3.37}$$

$$||\Phi(u, \bar{u}, \zeta)|| \leq C_s ||u||^3_{H^s}, \tag{3.38}$$

$$||Q(u, u, \Phi(u, \bar{u}, \zeta), \zeta)|| \leq C_s ||u||^5_{H^s}, \tag{3.39}$$

$$||\langle Q(u, u, \Phi(u, \bar{u}, *), *) \rangle|| \leq C_s ||u||^5_{H^s}. \tag{3.40}$$

Proof. The first inequality is proven using the well-known property of $H^s(\mathbb{R})$ with, e.g., $s \geq 1$,

$$||uv||_{H^s} \leq C_s||u||_{H^s}||v||_{H^s},$$

the isometric properties of $T(\zeta)$,

$$||T(\zeta)u||_{H^s} = ||u||_{H^s},$$

and

$$T(\zeta)Q(u,v,w,\zeta) = T(\zeta)uT(\zeta)v\overline{T(\zeta)w} \Rightarrow ||T(\zeta)Q(u,v,w,\zeta)||_{H^s}$$
$$\leq C||T(\zeta)u||_{H^s}||T(\zeta)v||_{H^s}||T(\zeta)w||_{H^s} \Rightarrow ||Q(u,v,w,\zeta)||_{H^s} \leq C||u||_{H^s}||v||_{H^s}||w||_{H^s}.$$

The remaining inequalities (3.36)–(3.40) are obtained by direct application of the first inequality (3.35). ∎

PROPOSITION 3.4. *Let $V(0) \in H^s(\mathbb{R})$ with $s \geq 1$. Then there exists $z_0 > 0$ such that the first-order averaged equation* (3.32) *has a unique solution $V(z) \in L^\infty([0,z_0], H^s(\mathbb{R}))$.*

Proof. The local existence for (3.32) with $\epsilon = 0$ has been proven in [28] by using the standard application of contraction mapping. In the general case, when $\epsilon \neq 0$, the proof of local existence is similar. First, we rewrite (3.32) in the integral form:

$$V(z) = T_0(z)V(0) + \int_0^Z T_0(z-z')\left(\langle Q\rangle(V(z')) + \epsilon\langle Q_1\rangle(V(z'))\right)dz',$$

where $T_0(z)$ is the operator associated with the fundamental solution of the linear Schrödinger equation:

$$i\frac{\partial V}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 V}{\partial t^2} = 0.$$

Estimating the difference between two solutions, we obtain

$$||V_1(z) - V_2(z)||_{H^s} \leq z_0 C_s(||V_1(0)||_{H^s}, ||V_2(0)||_{H^s}, \epsilon)||V_1(0) - V_2(0)||_{H^s},$$

which is a contraction if z_0 is sufficiently small (uniformly in ϵ). Using the standard energy estimates, we also obtain

$$\frac{\partial}{\partial z}||V(z)||^2_{H^s} \leq C_s(||V(z)||^2_{H^s}, \epsilon)||V(z)||^2_{H^s},$$

where C_s is a smooth function in both variables, thus implying uniqueness. ∎

PROPOSITION 3.5. *Let $V(0) \in H^1(\mathbb{R})$ and $d_0 \neq 0$. Then there exists a global solution $V \in L^\infty([0,\infty), H^1(\mathbb{R}))$ with initial data $V(0)$.*

Proof. For the proof we use first-order averaged Hamiltonian $H_1(V,\bar{V})$, conserved in z. It is shown in section 3.3 that the Hamiltonian $H_1(V,\bar{V})$ is bounded uniformly in $\epsilon \in [0,\epsilon_0]$, provided $||V||_{L^2}$ is fixed. Therefore, since the Hamiltonian is conserved in z, the gradient term must be bounded:

$$\int_{-\infty}^{\infty} |\partial_t V(z)|^2 dt \leq C(||V(0)||_{L^2}, ||\partial_t V(0)||_{L^2}, d_0),$$

which implies that $||V(z)||_{H^1}$ is uniformly bounded, thus proving global existence of solutions. ∎

Remark 3.1. If $d_0 = 0$, then a global solution $V(z)$ still exists in $H^1(\mathbb{R})$, although it is not uniformly bounded.

Before proving convergence of the first-order averaging theory, we reproduce the leading-order averaging theory from [28].

THEOREM 3.6 (see [28]). *Let $V(z) \in L^\infty([0,z_0], H^s(\mathbb{R}))$, where $s \geq 2$, be a solution of the averaged NLS equation* (3.32) *with $\epsilon = 0$ and $v(z)$ be a solution of the full equation* (3.10) *such that $||v(0) - V(0)||_{H^{s-2}} \leq C\epsilon$. Then, for sufficiently small positive $\epsilon < \epsilon_0$ we have $v(z) \in L^\infty([0,z_0], H^{s-2}(\mathbb{R}))$ and the solutions stay close at the distances $0 \leq z \leq z_0$:*

$$\sup_{z\in[0,z_0]} ||v(z) - V(z)||_{H^{s-2}} \leq C\epsilon. \tag{3.41}$$

We prove the analogous theorem for the first-order averaged integral NLS equation (3.32).

THEOREM 3.7. *Let $V(z) \in L^\infty([0,z_0], H^s(\mathbb{R}))$, where $s \geq 4$, be a solution of the first-order averaged integral NLS equation* (3.32) *and $v(z)$ be a solution of the full equation* (3.10) *such that $||v(0) - V(0) - i\epsilon\Phi(V(0), \bar{V}(0), 0)||_{H^{s-4}} \leq C\epsilon$. Then, for sufficiently small positive $\epsilon < \epsilon_0$ we have $v(z) \in L^\infty([0,z_0], H^{s-4}(\mathbb{R}))$ and the solutions are ϵ-close on $0 \leq z \leq z_0$:*

$$\sup_{z\in[0,z_0]} ||v(z) - V(z) - i\epsilon\Phi(V, \bar{V}, \zeta)||_{H^{s-4}} \leq C\epsilon^2. \tag{3.42}$$

Proof. We start with the averaged integral NLS equation (3.32) and use near-identical transformations to transform it to the periodic integral NLS equation (3.10). In the last step we compare the solutions of the transformed and the reduced equations by using Gronwall's inequality. This approach has a technical advantage over the "direct" approach, which starts from the original equation (3.10) and transforms it to the averaged equation (3.32). Indeed, for the periodic equation (3.10), there is no a priori ϵ-independent estimate on the existence interval.

Let us make a transformation $V = v_1 - w_1$ in (3.32), where v_1 is a new variable and w_1 is a small correction. We formally obtain

$$\begin{aligned} &i\frac{\partial v_1}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 v_1}{\partial t^2} + Q(v_1,\zeta) \\ &\qquad = i\frac{\partial w_1}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 w_1}{\partial t^2} + Q(v_1,\zeta) - \langle Q\rangle(V) + \epsilon\langle Q_1\rangle(V). \end{aligned} \tag{3.43}$$

Choosing $w_1 = i\epsilon\Phi(V, \bar{V}, \zeta)$, we obtain

$$i\frac{\partial v_1}{\partial z} + \frac{1}{2}d_0\frac{\partial^2 v_1}{\partial t^2} + Q(v_1,\zeta) = R_1(V,\zeta), \tag{3.44}$$

where

$$\begin{aligned} R_1(V,\zeta) = &-\epsilon\frac{\partial}{\partial z}\Phi(V,\bar{V},\zeta) + \epsilon i\frac{1}{2}d_0\frac{\partial^2}{\partial t^2}\Phi(V,\bar{V},\zeta) \\ &+ Q(v_1,\zeta) - Q(V,\zeta) + \epsilon\langle Q_1\rangle(V). \end{aligned} \tag{3.45}$$

We expand the right-hand side of (3.46) as

$$\begin{aligned} Q(v_1,\zeta) - Q(V,\zeta) &= Q(V + i\epsilon\Phi,\zeta) - Q(V,\zeta) \\ &= -i\epsilon Q(V,V,\Phi,\zeta) + 2i\epsilon Q(V,\Phi,V,\zeta) - \epsilon^2 Q(\Phi,\Phi,V,\zeta) \\ &\quad + 2\epsilon^2 Q(\Phi,v_1,\Phi,\zeta) + i\epsilon^3 Q(\Phi,\zeta). \end{aligned}$$

If $\langle Q_1 \rangle(V)$ is defined by (3.34), then (3.46) transforms to the periodic NLS equation with a mean-zero error mismatch of order $\mathrm{O}(\epsilon)$:

$$\begin{aligned} R_1 = &-\epsilon \frac{\partial}{\partial z}\Phi(V,\bar{V},\zeta) + \epsilon i \frac{1}{2} d_0 \frac{\partial^2}{\partial t^2}\Phi(V,\bar{V},\zeta) \\ &- i\epsilon\{Q(V,V,\Phi,\zeta)\} + 2i\epsilon\{Q(V,\Phi,V,\zeta)\} \\ &- \epsilon^2 Q(\Phi,\Phi,V,\zeta) + 2\epsilon^2 Q(\Phi,v_1,\Phi,\zeta) + i\epsilon^3 Q(\Phi,\zeta), \end{aligned}$$

where $\{Q\}$ stands for the mean-zero periodic part of Q in ζ. By using properties of Q and Φ from Proposition 3.3 and taking into account the loss of two derivatives, we find the estimate $||R_1(V,\zeta)||_{H^{s-2}} \leq C\epsilon$.

Now, we carry out another transformation $v_1 = v_2 - w_2$, where $w_2 = -i\epsilon \{R_1(V,\zeta)\}_{-1}$. The mean-zero antiderivative of $R_1(V,\zeta)$ in ζ satisfies the estimate $||w_2||_{H^{s-2}} \leq C\epsilon^2$. After rearranging the terms we recover the equation

$$i\frac{\partial v_2}{\partial z} + \frac{1}{2} d_0 \frac{\partial^2 v_2}{\partial t^2} + Q(v_2,\zeta) = R_2(V,\zeta), \tag{3.46}$$

where $R_2(V,\zeta)$ has a long expression in powers of ϵ^2 and higher. With the help of Proposition 3.3, we can estimate all terms of R_2 as $||R_2(V,\zeta)||_{H^{s-4}} \leq C\epsilon^2$. Comparing solutions of (3.46) and (3.10), we obtain an equation for the difference $f := v_2 - v$:

$$i\frac{\partial f}{\partial z} + \frac{1}{2} d_0 \frac{\partial^2 f}{\partial t^2} + Q(v_2,\zeta) - Q(v,\zeta) = R_2(V,\zeta). \tag{3.47}$$

The difference in the left-hand side of (3.47) can be estimated as

$$\begin{aligned} ||Q(v_2,\zeta) - Q(v,\zeta)||_{H^{s-2}} &= ||Q(v_2,\zeta) - Q(f - v_2,\zeta)||_{H^{s-2}} \\ &\leq C_s(||f||_{H^{s-2}}, ||v_2||_{H^{s-2}})||f||_{H^{s-2}}. \end{aligned}$$

The growth of f can be estimated by using the standard energy estimates. We differentiate the equation for f $1, 2, \ldots, n$ times, multiply each of them with $\partial_k \overline{f}$ $(k = 1, 2, \ldots, n)$, subtract complex conjugates, and finally take the sum to obtain

$$\frac{\partial}{\partial z}||f||^2_{H^n} \leq C_s(||f||_{H^n}, ||v_2||_{H^n})||f||^2_{H^n} + C||R_2||_{H^n}||f||_{H^n}.$$

In the last inequality, we can take n: $0 \leq n \leq s-4$ (thus, we have to assume $s \geq 4$) and using Gronwall's inequality, we obtain

$$||f(z)||_{H^{s-4}} \leq C_1(e^{C_2 z}\epsilon^2 + ||f(0)||_{H^{s-4}}),$$

which proves (3.42). □

COROLLARY 3.8. *Suppose the dispersion map $d(\zeta)$ is symmetric with equal legs, i.e., $l = 1/2$. If the solutions $V(z)$ and $v(z)$ are close in the sense of $||v(0) - V(0)||_{H^{s-4}} \leq C\epsilon^2$, then for sufficiently small positive $\epsilon < \epsilon_0$ the solutions remain within the quadratic accuracy at the distances $0 \leq z \leq z_0$ at the points $z = k\epsilon$ and $z = (k - \frac{1}{2})\epsilon$, where $k \in \mathbb{Z}_+$:*

$$\sup_{z \in [0,z_0]} ||v(z = k\epsilon) - V(z = k\epsilon)||_{H^{s-4}} \leq C\epsilon^2. \tag{3.48}$$

The quadratic convergence is based on the fact that $h_1(V,\bar{V}) = 0$ for $l = 1/2$ and $\Phi(V,\bar{V},0) = \Phi(V,\bar{V},l) = 0$; see Lemma 3.2. As a result, we have an improved (quadratic) convergence between solutions of the periodic integral NLS equation (3.11) and the integral NLS equation (3.15). It is only the linear convergence between solutions of the full and averaged equations valid at any point z of the dispersion map in the general case $l \neq 1/2$.

3.3. Existence and stability of ground states of the first-order averaged Hamiltonian. The first-order averaged Hamiltonian functional $H_1(V,\bar{V})$ is a constant of motion in the averaged system; therefore its extrema are expected to be stable solutions. Unfortunately, Hamiltonians in such problems are not bounded from either above or below. The way out is to consider a constrained variational problem, since there exists another conserved quantity e defined by (1.11). We show that the obtained Hamiltonian possesses a constrained minimum for the case $d_0 > 0$. The constrained minimum implies stability of a stationary pulse in this case.

Let us consider the following minimization problem:

$$P_E = \inf\left\{ H_1(V,\bar{V}), V \in H^1(\mathbb{R}), \int_{-\infty}^{+\infty} |V|^2 dt = E \right\}. \tag{3.49}$$

First, we show that the Hamiltonian is bounded from below, $P_E > -\infty$, which is a necessary condition for the presence of a smooth minimizer. Note that the Hamiltonian is unbounded from above for $d_0 > 0$ because of the gradient term in (3.13).

PROPOSITION 3.9. *The Hamiltonian functional $H_1(V,\bar{V})$ is uniformly bounded from below if $d_0 \geq 0$ and E is fixed.*

Proof. Since the gradient term is positive, we need only to establish the boundedness of the other two terms. The leading-order term $h_0(V,\bar{V})$ can be bounded by applying Hölder and Strichartz estimates [28]:

$$\int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)V|^4 dt d\zeta = \int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)V||T(\zeta)V|^3 dt d\zeta$$

$$\leq \left(\int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)V|^2 dt d\zeta \right)^{\frac{1}{2}} \left(\int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)V|^6 dt d\zeta \right)^{\frac{1}{2}} \leq E^{\frac{1}{2}} C_S E^{\frac{3}{2}} = C_S E^2,$$

where we have used the isometry of $T(\zeta)$ in $L^2(\mathbb{R})$ as well as the Strichartz inequality:

$$\int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |T(\zeta)V|^6 dt dz \leq C_s^2 E^3.$$

Now we estimate the first-order term $h_1(V,\bar{V})$ as

$$\begin{aligned}
&\left| \int_0^1 \int_{-\infty}^{+\infty} \overline{T(\zeta)V}^2 \, T(\zeta)V \, T(\zeta)\Phi(V,\bar{V},\zeta) \, dt d\zeta \right| \\
&\leq \left(\int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)V|^6 dt d\zeta \right)^{\frac{1}{2}} \left(\int_0^1 \int_{-\infty}^{+\infty} |T(\zeta)\Phi(V,\bar{V},\zeta)|^2 dt d\zeta \right)^{\frac{1}{2}} \\
&\leq C_S E^{\frac{3}{2}} \left(\int_0^1 \int_{-\infty}^{+\infty} |\Phi(V,\bar{V},\zeta)|^2 dt d\zeta \right)^{\frac{1}{2}}.
\end{aligned}$$

The integral of $|\Phi(V,\bar{V},\zeta)|^2$ in ζ can be estimated from the definition (3.26), rewritten as

$$\Phi(V,\bar{V},\zeta) = \int_0^{\zeta} \Psi(\zeta_1,t) d\zeta_1 - \int_0^1 \int_0^{\zeta_2} \Psi(\zeta_1,t) d\zeta_1 d\zeta_2 - \left(\zeta - \frac{1}{2} \right) \int_0^1 \Psi(\zeta_1,t) d\zeta_1,$$

where we used the notation

$$\Psi(\zeta,t) = T^{-1}(\zeta) \left(|T(\zeta)V|^2 T(\zeta)V \right).$$

The product $|\Phi|^2$ contains 10 terms, which can be estimated in a straightforward way using Strichartz estimate. We give an example of how to carry out one of these estimates:

$$\begin{aligned}
&\left|\int_0^1 d\zeta \int_{-\infty}^{\infty} dt \left[\int_0^{\zeta} \Psi(\zeta_1,t)d\zeta_1 \int_0^1 \int_0^{\zeta_3} \overline{\Psi(\zeta_2,t)}d\zeta_2 d\zeta_3\right]\right| \\
&\le \left|\int_0^1 d\zeta \int_{-\infty}^{\infty} dt \left[\int_0^1 |\Psi(\zeta_1,t)|d\zeta_1 \int_0^1 \int_0^1 |\Psi(\zeta_2,t)|d\zeta_2 d\zeta_3\right]\right| \\
&= \left|\int_{-\infty}^{\infty} dt \left[\int_0^1 |\Psi(\zeta_1,t)|d\zeta_1 \int_0^1 |\Psi(\zeta_2,t)|d\zeta_2\right]\right| \\
&= \int_0^1 d\zeta_2 \int_0^1 d\zeta_1 \int_{-\infty}^{\infty} dt|\Psi(\zeta_1,t)||\Psi(\zeta_2,t)| \\
&\le \left(\int_0^1 d\zeta_1 \int_0^1 d\zeta_2 \int_{-\infty}^{\infty} dt|\Psi(\zeta_1,t)|^2\right)^{\frac{1}{2}} \left(\int_0^1 d\zeta_1 \int_0^1 d\zeta_2 \int_{-\infty}^{\infty} dt|\Psi(\zeta_2,t)|^2\right)^{\frac{1}{2}} \\
&\le \int_0^1 \int_{\infty}^{\infty} |\Psi(\zeta,t)|^2 dtd\zeta.
\end{aligned}$$

The last integral is estimated using the definition of $\Psi(\zeta,t)$ and the Strichartz estimate:

$$\begin{aligned}
\int_0^1 \int_{-\infty}^{\infty} |\Psi(\zeta,t)|^2 dtd\zeta &= \int_0^1 \int_{-\infty}^{\infty} \left|T^{-1}(\zeta)\left(T(\zeta)V^2\overline{T(\zeta)V}\right)\right|^2 dtd\zeta \\
&= \int_0^1 \int_{-\infty}^{\infty} |T(\zeta)V|^6 dtd\zeta \le C_S^2 E^3. \qquad (3.50)
\end{aligned}$$

Therefore the term $h_1(V,\bar{V})$ in the Hamiltonian $H_1(V,\bar{V})$ is bounded by $C_S E^{3/2} C_S E^{3/2} = C_S^2 E^3$. □

The next step is to verify the subadditivity condition which is necessary for the construction of a converging minimizing sequence [31]. The subadditivity property holds in the case $\epsilon = 0$ (see [28]). Here we show that it also holds for sufficiently small ϵ.

LEMMA 3.10. *For any $E > 0$ there exist $\epsilon_0 > 0$ (which may depend on E) such that for any $0 < \epsilon < \epsilon_0$ any minimizing sequence V_n possesses a subsequence V_{n_k} satisfying the subadditivity property*

$$P_{E_1+E2} < P_{E_1} + P_{E_2} \text{ provided } E = E_1 + E_2. \qquad (3.51)$$

Proof. The proof is a simple application of a scaling argument, followed by some estimates using smallness of ϵ. Consider a one-parameter family $V^\lambda = \sqrt{\lambda}V$ with $\lambda \in (0,1)$; then

$$E^\lambda = \int_{-\infty}^{\infty} |V^\lambda|^2 dt = \lambda E.$$

Introducing the notation for the Hamiltonian,

$$H_1(V,\bar{V}) = H^{(2)}(V,\bar{V}) - H^{(4)}(V,\bar{V}) + \epsilon H^{(6)}(V,\bar{V}),$$

where $H^{(2,4,6)}(V,\bar{V})$ represent quadratic gradient term, positive quartic term, and the sixth order perturbation term, respectively. The Hamiltonian then scales as follows:

$$H_1^\lambda = \lambda H^{(2)} - \lambda^2 H^{(4)} + \lambda^3 \epsilon H^{(6)}$$

and then

$$H_1^\lambda - \lambda H_1 = (\lambda - \lambda^2) H^{(4)} + (\lambda - \lambda^3)\epsilon H^{(6)} = \lambda(1-\lambda)(H^{(4)} + (1+\lambda)\epsilon H^{(6)}).$$

Note that for $\epsilon = 0$, $H_1^\lambda > \lambda H_1$, which implies the subadditivity $P_{\lambda E} > \lambda P_E$. The latter results in (3.51) for the same E. For sufficiently small ϵ, the condition (3.51) is expected to hold since $H^{(6)}$ is uniformly bounded. Indeed, if we fix $E > 0$, then for $\epsilon = 0$ the infimum is negative, $P_E^0 < 0$, as shown in [28]. For positive ϵ, the infimum cannot change by more than $\epsilon C_S^2 E^3$; therefore $P_E^\epsilon \le P_E^0 + \epsilon C_S^2 E^3$ remains negative.

By definition, for any minimizing sequence we have $H(V_n) \to P_E^\epsilon$ and therefore for sufficiently large $n \ge N$ the quartic term $H^{(4)}$ has to be bounded from below:

$$H^{(4)} \ge |P_E^\epsilon| - \epsilon C_S^2 E^3 - \delta(N) \Rightarrow H^{(4)} \ge |P_E^0| - 2\epsilon C_S^2 E^3 - \delta(N).$$

Then we prove the estimate:

$$\begin{aligned} H^{(4)} + (1+\lambda)\epsilon H^{(6)} &\ge |P_E^0| - 2\epsilon C_S^2 E^3 - \delta(N) - 2\epsilon C_S^2 E^3 \\ &= |P_E^0| - 4\epsilon C_S^2 E^3 - \delta(N) \ge |P_E^0| - 5\epsilon C_S^2 E^3, \end{aligned}$$

where the last step in the inequalities was done by taking N sufficiently large. Therefore, by requiring that

$$5\epsilon C_S^2 E^3 < \frac{1}{2}|P_E^0|$$

we achieve the subadditivity condition for the minimizing sequence. □

We will also use lemma on localization from [28]. The lemma says that finite energy cannot propagate too far in the linear Schrödinger equation if the initial data are sufficiently smooth.

LEMMA 3.11 (see [28]). *Let $V \in H^1(\mathbb{R})$, $T(\zeta)$ be a free Schrödinger propagator and let*

$$\epsilon(\zeta) = \sup_{\xi \in \mathbb{R}} \int_{\xi-1}^{\xi+1} |T(\zeta)V|^2 dt. \tag{3.52}$$

Then the following estimate holds:

$$\epsilon(\zeta) \le 2\epsilon(0) + \sqrt{\epsilon^2(0) + 2C\epsilon(0)\zeta}. \tag{3.53}$$

Now, we are ready to establish the convergence of a minimizing sequence. The two results above make the convergence proof straightforward and very similar to the one with $\epsilon = 0$; see [28]. Therefore, we sketch only the proof of the main result, providing details only when they are different from the case $\epsilon = 0$.

PROPOSITION 3.12. *If $d_0 > 0$ and $0 < \epsilon < \frac{|P_E^0|}{10\, C_S^2 E^3}$, then there exists a minimizer $W \in H^1(\mathbb{R}) \cap C^\infty(\mathbb{R})$ of the constrained minimization problem* (3.49).

Proof. First we observe that any minimizing sequence $V_n \in H^1(\mathbb{R})$ must possess a bounded derivative

$$\int_{-\infty}^{\infty} \left| \frac{\partial V_n}{\partial t} \right|^2 dt < C, \tag{3.54}$$

for otherwise $\{H_1(V_n, \bar{V}_n)\}_{n=0}^{\infty}$ would have an unbounded subsequence (since $H^{(2)}(V_n, \bar{V}_n)$ would dominate over $H^{(4)}(V_n, \bar{V}_n)$ and $H^{(6)}(V_n, \bar{V}_n)$, which are uniformly bounded). Then there exists a weakly converging subsequence in $L^2(\mathbb{R})$. In order to assure the strong convergence $V_n \to W$ with W satisfying the constraint (3.49), we have to show that the sequence is tight (the energy does not escape to infinity[1]). We assume that $n > N$ with N sufficiently large so that the subadditivity condition would hold. Now, we use the concentration-compactness principle [29], which says that there exists a subsequence V_{n_k}, denoted by V_k, for which one of the following statements is true:

1. (convergence) For some sequence $\{t_k\}_{k=0}^{\infty}$ the translated sequence converges to some limit $V_k(t - t_k) \to W$ (as $k \to \infty$) satisfying the constraint (3.49).
2. (vanishing) The following identity is true:
$$\sup_{y \in \mathbb{R}} \int_{y-1}^{y+1} |V_k|^2 dt \to 0 \quad \text{as} \quad k \to \infty.$$
3. (splitting) There exist $E_1, E_2 > 0$ ($E = E_1 + E_2$) such that for any $\epsilon > 0$ one can find two sequences v_k, w_k and $K > 0$ so that for any $k > K$ we have
$$\int_{-\infty}^{\infty} |V_k - (W_k + U_k)|^2 dt < \epsilon,$$
where
$$\int_{-\infty}^{\infty} |W_k|^2 dt = E_1, \qquad \int_{-\infty}^{\infty} |U_k|^2 dt = E_2$$
such that
$$\operatorname{dist}(\operatorname{supp}(W_k), \operatorname{supp}(U_k)) \to \infty.$$

Our goal is to rule out the second and the third possibilities in order to prove convergence of a minimizing sequence. It has been shown in [28] for $\epsilon = 0$ that vanishing implies that $H^{(4)}(V_k, \bar{V}_k) \to 0$. This is in contradiction with the sequence being minimizing as the infimum is negative and $H_1(V_k, \bar{V}_k) \to 0$. The proof that $H^{(4)}(V_k, \bar{V}_k) \to 0$ is based on Cazenave's estimate [30],

$$\int_{-\infty}^{\infty} |V|^4 dt \le C \, ||V||_{H^1}^2 \, \sup_{y \in \mathbb{R}} \int_{y-1}^{y+1} |V|^2 dt, \tag{3.55}$$

and on the lemma on localization (3.52)–(3.53). Combing these estimates in a similar way, we prove that $H^{(6)}(V_k) \to 0$.

We also show that the splitting may not occur. By contradiction, we assume that splitting occurs and show that the sequence is not minimizing by using the subadditivity condition (3.51). The proof is identical to the one in [28] and therefore is omitted here.

Since both the vanishing and splitting scenarios do not occur, the concentration-compactness principle implies that the sequence $V_k \to W$ strongly in $L^2(\mathbb{R})$ [29]. Using the standard argument (see section 3.1 in [28]), we show that $V_k \to W$ strongly in $H^1(\mathbb{R})$. The minimizer weakly satisfies the Euler–Lagrange equation

$$-\mu W + \frac{1}{2} d_0 W''(t) + \langle Q \rangle(W) + \epsilon \langle Q_1 \rangle(W) = 0. \tag{3.56}$$

[1]There is no problem with the local loss of compactness since on any finite interval $I \subset \mathbb{R}$ the space $H^1(I)$ is compactly embedded in $L^2(I)$.

Using the bootstrapping procedure, we show that the solution is smooth. If $W \in H^1(\mathbb{R})$, then $\langle Q \rangle(W) + \epsilon \langle Q_1 \rangle(W) \in H^1(\mathbb{R})$. Due to the presence of the term $d_0 W''(t)$ in (3.56), the solution is extended to function space $W \in H^3(\mathbb{R})$. Continuing this, we obtain that $W \in H^s(\mathbb{R})$ for any $s \geq 1$ and $W \in C^\infty(\mathbb{R})$. □

The minimizer $W(t)$ obtained in Proposition 3.12 defines a stationary pulse solution $V(z,t) = W(t)e^{i\mu z}$ of the first-order averaged integral NLS equation, where $\mu = f_\mu^{-1}(e)$ and $e = f_\mu(\mu)$ is a continuous function. Thus, the existence and stability of a single branch of DM solitons is proved for $d_0 > 0$ in the first-order averaged integral NLS equation (3.32). This completes the proof of Proposition 1.8 for the integral NLS approximation. If the stationary pulse solutions $W(t)$ are computed numerically, all other parameters of DM solitons can be computed for the case $d_0 > 0$, in direct correspondence with Proposition 1.4. Otherwise, the analytical dependencies in (1.19)–(1.21) remain implicitly defined by the averaged integral equation (3.56).

4. Conclusion. We have studied existence and stability of dispersion-managed (DM) solitons for the periodic NLS equation. We defined the DM solitons either as periodic solutions of a low-dimensional system for parameters of a Gaussian pulse or as stationary pulse solutions of the averaged integral NLS equation. In both cases, we have found and analyzed the first-order averaged Hamiltonian. Some open problems appear beyond this analysis and are worth mentioning here.

First, it is a conjecture that DM solitons do not exist as quasi-periodic solutions of the periodic NLS equation (1.5), contrary to the approximating Gaussian pulses. Recent work of Yang and Kath [19] discusses parametric resonances between localized pulses and linear Bloch waves associated with the varying dispersion $d(z)$. Asymptotic and numerical analysis confirmed that the quasi-periodic pulses produce nonlocalized radiation tails, which escape the localized region to infinity [19]. The radiation tail is exponentially small in the limit $\epsilon \to 0$, i.e., it appears beyond any asymptotic expansion in powers of ϵ. In our analysis, all the resonant terms are removed from the leading and first order of the asymptotic series. As a result, the quasi-periodic pulses exist in the averaged integral NLS equation (3.32), at least for $d_0 > 0$.

Second, the first-order constrained Hamiltonian $H_1(V, \bar{V})$ was shown to possess a constrained minimum only for $d_0 > 0$. With the use of the new work by Kunze [20], the constrained minimum can be shown to exist for $d_0 = 0$. However, it is impossible to prove whether or not a local extremum of the averaged Hamiltonian exists for $d_0 < 0$ even in the limit $\epsilon \to 0$. Indeed, the operator $\mu - \frac{1}{2} d_0 \partial_{tt}$ is not positive-definite for $\mu > 0$ and $d_0 < 0$, and a strong resonance occurs between spectra of a localized pulse and linear waves. As a result, the Hamiltonian functional $H_1(V, \bar{V})$ is unbounded from below even for the constrained problem (3.49).

Two branches of Gaussian pulse solutions exist for $d_0 < 0$: one is stable and the other one is unstable in the propagation in z. However, iterations of a numerical method quickly diverge for the branch of unstable Gaussian pulses [13] and slowly diverge for the branch of stable Gaussian pulses [21]. Rigorous analysis of existence or nonexistence of stationary solutions of the problem (3.56) with $d_0 < 0$ is not completed yet.

Finally, the higher-order averaged Hamiltonian can be found and analyzed for the case $d_0 > 0$ in a similar manner. However, the constrained minimization procedure fails already for the second-order Hamiltonian, which has a correction $H^{(8)}(V, \bar{V})$ that contains eight powers of V and $\bar{V}$. Because of such higher-order nonlinearity, the correction $H^{(8)}(V, \bar{V})$ is not be bounded from below by the Strichartz estimate (3.50). Therefore, higher-order averaged equations become less useful for analysis.

UNIFORM ASYMPTOTIC EXPANSION OF THE SQUARE-ROOT HELMHOLTZ OPERATOR AND THE ONE-WAY WAVE PROPAGATOR*

MAARTEN V. DE HOOP† AND A. K. GAUTESEN‡

Abstract. The Bremmer coupling series solution of the wave equation, in generally inhomogeneous media, requires the introduction of pseudodifferential operators. Such operators appear in the diagonalization process of the acoustic system's matrix of partial differential operators upon extracting a principal direction of (one-way) propagation. In this paper, in three dimensions, uniform asymptotic expansions of the Schwartz kernels of these operators are derived. Also, we derive a uniform asymptotic expansion of the one-way propagator appearing in the series. We focus on designing closed-form representations, valid in the high-frequency limit, taking into account *critical scattering-angle* phenomena. The latter phenomena are not dealt with in the standard calculus of pseudodifferential operators. Our expansion is not limited by propagation angle. In principle, the uniform asymptotic expansion of a kernel follows by matching its asymptotic behaviors away and near its diagonal.

Key words. wave field decomposition, Bremmer series, uniform asymptotics

1. Introduction.

Directional wave field decomposition is a tool for analyzing and computing wave propagation in configurations with a special directionality, such as a waveguiding structure. Such a method consists of three main steps: (i) decomposing the field into two constituents, propagating "one-way" upward or downward along a preferred or principal direction, (ii) computing the interaction of the counterpropagating constituents, and (iii) recomposing the constituents into observables at the positions of interest. The Bremmer series [1] then synthesizes the constituents into a full-wave solution. Each term in the series represents a wave constituent that has traveled up and down along the principal direction a number of times equal to its order. Thus we are able to trace waves: evolution is no longer in time but now in the vertical coordinate, vertical being identified with the principal direction. The microlocal analysis of the one-way wave propagator can be found in Treves [2].

Applications of the generalized Bremmer series solution to the wave equation include (i) the identification and elimination of multiple scattered wave constituents and (ii) the formulation of various imaging and inverse scattering procedures in remote sensing. In general, the inverse scattering problem can be decomposed into a coupled inverse "contrast-source" or "reflectivity"–inverse "constituency" problem. With the aid of time-reversal mirrors, each pair of successive terms in the Bremmer series can be exploited to construct the reflectivity (see de Hoop [3]).

The generalized Bremmer series can be viewed as a full-wave extension of the (high-frequency) geometrical ray series representation of the wave field embedded

in the Kirchhoff approximation (see Frazer [4]). The Maslov canonical operator is replaced by a Trotter product (see de Hoop, Le Rousseau, and Biondi [5]). The Bremmer series–Trotter product approach encompasses the microlocal, Kirchhoff–Maslov, representation of the wave field. Extensive lists of references to applications of the generalized Bremmer series in exploration and crustal seismology, ocean acoustics, and integrated optics can be found in Van Stralen, de Hoop, and Blok [6].

De Hoop [1] originally formulated the generalized Bremmer series modeling method in the time-*Laplace* domain. Owing to the fact that the medium can vary in the directions transverse to the preferred direction, pseudodifferential calculus became a natural tool to introduce the up and downgoing Green's functions: pseudodifferential operators appear in the directional (de)composition, in the downward and upward propagation or continuation, and in the interaction (reflection and transmission) between the counterpropagating constituents due to variations in medium properties in the preferred direction. The time-Laplace domain is not amenable to computations, however.

Various approaches have been developed over the years in the time-*Fourier* domain to approximate the operators appearing in the Bremmer series to make numerical computations feasible. An overview of the approaches based on rational (paraxial) expansions of the operator symbols can be found in Van Stralen, de Hoop, and Blok [6]. An overview of approaches based on phase-screen-like approximations of the operator symbols can be found in de Hoop, Le Rousseau, and Wu [7]. With these numerical approaches, however, critical "scattering-angle" phenomena such as the ones associated with rays the tangents to which become horizontal (for example, turning rays) cannot be modeled. With the approach proposed in this paper, this limitation is removed. In particular media, spectral analysis can be employed to find exact time-Fourier representations of mentioned operators (see Fishman, de Hoop, and van Stralen [8]).

In this paper, our goal is to gain analytic insight into the propagation and scattering of waves as described by the generalized Bremmer series—while developing a time-*Fourier* analysis of the constituent operators. We extend earlier results (Fishman, Gautesen, and Sun [9] and de Hoop and Gautesen [10]) in this direction that were derived in two dimensions to three (and higher) dimensions. Instead of using pseudodifferential operators in the time-Laplace domain, we will here employ microlocal and uniform asymptotics techniques combined in the time-Fourier domain. We focus our analysis on the development of a uniform asymptotic expansion of the transversal part of the one-way wave operator kernel (of the square-root Helmholtz type) and the associated one-way wave propagator. For the completion of the Bremmer coupling series we refer the reader to our earlier paper.

The uniform asymptotic expansions also provide the basis for a numerical scheme. Such a scheme would involve the computations of (i) a spatially varying effective index of refraction and (ii) a spatially varying effective "distance" in the transverse directions, and then applying the kernel. The effective index of refraction and the effective metric are computed along the bicharacteristics constrained to the plane spanned by transverse directions.

The outline of this paper is as follows. In the next section a summary of the method of directional decomposition, leading to a coupled system of one-way wave equations is given. In section 3, the medium is decomposed into thin slabs. In each thin slab we introduce a "characteristic" Green's function. In section 4 we introduce representations of the square-root operator and the one-way wave propagator in terms of the characteristic Green's function. The key effort is developing a uniform

asymptotic expansion of the characteristic Green's function. Such an expansion in the absence of transverse caustics is developed in section 5 and in the presence of transverse caustics in section 6. In both cases an "inner" (near-field) and "outer" (far-field) representation is derived upon which a matching procedure in a boundary layer is invoked. The latter synthesizes the uniformly valid expression. Section 7 summarizes the main result of the paper: the uniform asymptotic expansion for the square-root operator and the likewise expansion for the one-way wave propagator in higher dimensions. We conclude with a discussion (section 8).

2. Directional wave field decomposition. For the details on the derivation of the Bremmer coupling series solution of the acoustic wave equation, we refer the reader to de Hoop [1]. Here, we restrict ourselves to a summary of this wave field decomposition method.

Notation, transformations. We consider acoustic waves in a three-dimensional configuration. In this configuration, let p denote the pressure and $(v_{1,2}, v_3) = (v_1, v_2, v_3)$ the particle velocity. We introduce the Fourier transformation with respect to time t as

$$(\mathcal{F}\{p, v_{1,2}, v_3\})(x_{1,2}, x_3, \omega) = \int_{t\in\mathbb{R}_{\geq 0}} \{p, v_{1,2}, v_3\}(x_{1,2}, x_3, t)\ \exp(\mathrm{i}\omega t)\,\mathrm{d}t \tag{2.1}$$

for $\mathrm{Im}\{\omega\} > 0$. Under this transformation, assuming zero initial conditions, we have $\partial_t \to -\mathrm{i}\omega$.

In each subdomain of the configuration where the acoustic properties vary continuously with position, the acoustic wave field $\{p, v_{1,2}, v_3\}$ satisfies the system of partial differential equations

$$\partial_k p - \mathrm{i}\omega\rho\, v_k = f_k, \tag{2.2}$$

$$-\mathrm{i}\omega\kappa\, p + \partial_1 v_1 + \partial_2 v_2 + \partial_3 v_3 = q. \tag{2.3}$$

Here, ρ denotes the volume density of mass, κ the compressibility, q the volume source density of injection rate, and f_k the volume source density of force.

The spatial variation of the wave field along a direction of preference can now be expressed in terms of the variation of the wave field in the direction perpendicular to it. The direction of preference or principal direction is taken (globally) along the x_3-axis (or "vertical" axis) and the remaining ("transverse" or "horizontal") coordinates are denoted by (x_1, x_2) or $x_{1,2}$.

The reduced system of equations. Directional decomposition requires a separate handling of the horizontal or transverse component of the particle velocity. From (2.2) and (2.3) we obtain

$$v_{1,2} = -\mathrm{i}\rho^{-1}\omega^{-1}(\partial_{1,2} p - f_1), \tag{2.4}$$

leaving, upon substitution, the matrix differential equation $(I, J = 1, 2)$

$$(\partial_3\delta_{IJ} - \mathrm{i}\omega A_{IJ})\, F_J = N_I, \quad A_{IJ} = A_{IJ}(x_{1,2}, D_{1,2}; x_3), \quad D_{1,2} \equiv -\frac{\mathrm{i}}{\omega}\partial_{1,2}, \tag{2.5}$$

in which the elements of the acoustic field matrix[1] are given by

$$F_1 = p, \qquad F_2 = v_3, \tag{2.6}$$

[1] Present ocean-bottom seismic acquisition technology allows both p and v_3 to be measured.

the elements of the acoustic system's matrix operator by

$$A_{11} = A_{22} = 0, \tag{2.7}$$

$$A_{12} = \rho, \tag{2.8}$$

$$A_{21} = -D_1(\rho^{-1}D_1\,) - D_2(\rho^{-1}D_2\,) + \kappa, \tag{2.9}$$

and the elements of the notional source matrix by

$$N_1 = f_3, \qquad N_2 = D_1(\rho^{-1}f_1) + D_2(\rho^{-1}f_2) + q. \tag{2.10}$$

It is observed that the right-hand side of (2.4) and A_{IJ} contain the spatial derivatives $D_{1,2}$ with respect to the horizontal coordinates only. In the sequel of the paper it will become clear that $D_{1,2}$ has the interpretation of *horizontal slowness* operator. Further, it is noted that A_{12} is simply a multiplicative operator.

The coupled system of one-way wave equations. To distinguish up and downgoing constituents in the wave field, we shall construct an appropriate linear operator L_{IJ} with

$$F_I = L_{IJ}W_J, \tag{2.11}$$

which, with the aid of the commutation relation ([.,.] denotes the commutator)

$$(\partial_3 L_{IJ}) = [\partial_3, L_{IJ}], \tag{2.12}$$

transforms (2.5) into

$$L_{IJ}\,(\partial_3\delta_{JM} - \mathrm{i}\omega\Lambda_{JM})W_M = -(\partial_3 L_{IJ})\,W_J + N_I. \tag{2.13}$$

Transformation (2.11) should result in the diagonalization of the operator A_{IJ} in the sense that

$$A_{IJ}L_{JM} = L_{IJ}\Lambda_{JM}, \tag{2.14}$$

where Λ_{JM} is a diagonal matrix of operators. We denote L_{IJ} as the composition operator and W_M as the wave column matrix. The expression in parentheses on the left-hand side of (2.13) represents the two so-called *one-way* wave operators. The first term on the right-hand side of (2.13) is representative for the scattering due to variations of the medium properties in the vertical direction. The diffraction due to variations of the medium properties in the horizontal directions is contained in Λ_{JM} and, implicitly, in L_{IJ}. This diffraction comprises the multipathing of characteristics that commonly occurs in geophysical configurations.

To investigate whether solutions of (2.14) exist, we introduce the column matrix operators $L_I^{(\pm)}$ according to

$$L_I^{(+)} = L_{I1}, \qquad L_I^{(-)} = L_{I2}. \tag{2.15}$$

Upon writing the diagonal elements of Λ_{JM} as

$$\Lambda_{11} = \Gamma^{(+)}, \qquad \Lambda_{22} = \Gamma^{(-)}, \tag{2.16}$$

(2.14) decomposes into the two systems of equations

$$A_{IJ}L_J^{(\pm)} = L_I^{(\pm)}\Gamma^{(\pm)}. \tag{2.17}$$

By analogy with the case where the medium is translationally invariant in the horizontal directions, we shall denote $\Gamma^{(\pm)}$ as the *vertical slowness* operators. Notice that the operators $L_1^{(\pm)}$ synthesize the acoustic pressure and that the operators $L_2^{(\pm)}$ synthesize the vertical particle velocity. Through mutual elimination, the equations for $L_1^{(\pm)}$ and $L_2^{(\pm)}$ can be decoupled as follows:

$$A_{12}A_{21}L_1^{(\pm)} = L_1^{(\pm)}\Gamma^{(\pm)}\,\Gamma^{(\pm)}, \tag{2.18}$$

$$A_{21}A_{12}L_2^{(\pm)} = L_2^{(\pm)}\Gamma^{(\pm)}\,\Gamma^{(\pm)}. \tag{2.19}$$

The partial differential operators on the left-hand sides differ from one another in the case where the volume density of mass does vary in the horizontal directions.

To ensure that nontrivial solutions of (2.18)–(2.19) exist, one equation must imply the other. To construct a formal solution, an ansatz is introduced in the form of a commutation relation for one of the components $L_J^{(\pm)}$ that restricts the freedom in the choice for the other component. In the *acoustic-pressure normalization* analogue one assumes that $L_2^{(\pm)}$ can be chosen such that

$$[A_{12}L_2^{(\pm)}, A_{12}A_{21}] = 0. \tag{2.20}$$

In view of (2.19), $\Gamma^{(\pm)}$ must then satisfy

$$A_{12}A_{21} - \Gamma^{(\pm)}\,\Gamma^{(\pm)} = 0. \tag{2.21}$$

The commutation relation for $L_1^{(\pm)}$ follows as $[L_1^{(\pm)}, A_{12}A_{21}] = 0$ and a possible solution of (2.17) is

$$L_2^{(\pm)} = A_{12}^{-1}\Gamma^{(\pm)}, \qquad L_1^{(\pm)} = I. \tag{2.22}$$

Since $L_2^{(\pm)}$ as given by (2.22) satisfies (2.20), the ansatz is justified. The solutions of (2.21) are written as

$$\Gamma^{(+)} = -\Gamma^{(-)} = \Gamma = \mathrm{A}^{1/2} \ \text{ with } \ \mathrm{A} = A_{12}A_{21}. \tag{2.23}$$

Thus, the *composition* operator becomes

$$L = \begin{pmatrix} I & I \\ A_{12}^{-1}\Gamma & -A_{12}^{-1}\Gamma \end{pmatrix}. \tag{2.24}$$

Note that we have decomposed the pressure field according to

$$F_1 = F_1^{(+)} + F_1^{(-)} \ \text{ with } \ F_1^{(+)} = W_1, \quad F_1^{(-)} = W_2.$$

In terms of the inverse vertical slowness operator, $\Gamma^{-1} = \mathrm{A}^{-1/2}$, the *decomposition* operator then follows as

$$L^{-1} = \tfrac{1}{2}\begin{pmatrix} I & \Gamma^{-1}A_{12} \\ I & -\Gamma^{-1}A_{12} \end{pmatrix}. \tag{2.25}$$

Using the decomposition operator, (2.13) transforms into

$$(\partial_3\delta_{IM} - \mathrm{i}\omega\Lambda_{IM})\,W_M = -(L^{-1})_{IM}(\partial_3 L_{MJ})W_J + (L^{-1})_{IM}N_M, \tag{2.26}$$

which can be interpreted as a coupled system of one-way wave equations. The propagation is captured by the left-hand side. The coupling between the counter-propagating components, W_1 and W_2, is apparent in the first source-like term on the right-hand side. The waves are excited by the second term on the right-hand side. We have

$$-L^{-1}(\partial_3 L) = \begin{pmatrix} T & R \\ R & T \end{pmatrix}, \tag{2.27}$$

in which T and R represent the *transmission* and *reflection* operators, respectively: let $Y = A_{12}^{-1}\Gamma$ denote the *admittance* operator; then

$$R = -T = \tfrac{1}{2}Y^{-1}\,(\partial_3 Y). \tag{2.28}$$

The two-way Helmholtz equation. Suppose that the medium does *not* vary with x_3. Eliminating F_2 or v_3 from (2.5) then leads to the second-order equation for the pressure,

$$[\partial_3^2 + \omega^2 \mathrm{A}(x_{1,2}, D_{1,2})]\, F_1 = \mathrm{i}\omega\,\rho N_2 + \partial_3 N_1, \tag{2.29}$$

the *two-way* Helmholtz equation, where A is given by (2.23).

3. Decomposition of the configuration into thin slabs. We will now decompose the *medium* into (thin) slabs. Each slab in our three-dimensional configuration is assumed to be *invariant* in the direction of preference, x_3: the compressibility, κ, may vary in the transverse directions, whereas the density is assumed to be constant all together. However, the medium may vary from slab to slab, and hence the vertical coordinate x_3 becomes a parameter that identifies the slab in our further analysis.

The characteristic operator. As mentioned, in our thin-slab analysis, we will consider the following medium profile:

$$\rho = \text{const.}, \tag{3.1}$$

$$\kappa(x_{1,2}) = \kappa_0\, n^2(x_{1,2}); \tag{3.2}$$

thus, setting $\kappa_0 = \rho^{-1}c_0^{-2}$, the wave speed follows from

$$c^{-2}(x_{1,2}) = c_0^{-2} n^2(x_{1,2}),$$

where n denotes the index of refraction. The operator in (2.23) is then given by

$$\mathrm{A}(x_{1,2}, D_{1,2}) = -D_1^2 - D_2^2 + c_0^{-2} n^2(x_{1,2}). \tag{3.3}$$

We will denote A as the transverse Helmholtz or *characteristic* operator.

Factorization, Green's functions. We introduce the well-known Helmholtz equation and "characteristic" Green's function as (cf. (2.29))

$$\begin{aligned}[\partial_3^2 + \omega^2 \mathrm{A}(x_{1,2}, D_{1,2})]\, G(x_{1,2}, x_3 - x_3'; x_{1,2}') \\ = -\delta(x_1 - x_1')\delta(x_2 - x_2')\delta(x_3 - x_3').\end{aligned} \tag{3.4}$$

The vertical slowness operators $\Gamma^{(\pm)}$ factorize the Helmholtz operator (cf. (2.23)):

$$\partial_3^2 + \omega^2 \mathrm{A}(x_{1,2}, D_{1,2}) = [\partial_3 - \mathrm{i}\omega\,\Gamma^{(+)}(x_{1,2}, D_{1,2})]\,[\partial_3 - \mathrm{i}\omega\,\Gamma^{(-)}(x_{1,2}, D_{1,2})]. \tag{3.5}$$

The one-way Green's functions $\mathcal{G}^{(\pm)}$ associated with the two factors satisfy

$$\begin{aligned}[\partial_3 - \mathrm{i}\omega\,\Gamma^{(\pm)}(x_{1,2}, D_{1,2})]\, \mathcal{G}^{(\pm)}(x_{1,2}, x_3 - x_3'; x_{1,2}') \\ = \delta(x_1 - x_1')\delta(x_2 - x_2')\delta(x_3 - x_3').\end{aligned} \tag{3.6}$$

Vertical slowness as phase variable. Note that the Fourier representation of the causal Green's function G yields

$$G(x_{1,2}, x_3 - x_3'; x_{1,2}') = \frac{\omega}{2\pi c_0} \int_{\zeta\in\mathcal{Z}} \tilde{G}(x_{1,2}, x_{1,2}'; \zeta)\, \exp[\mathrm{i}\, \underbrace{(\omega/c_0)}_{k_0}\, |x_3 - x_3'|\zeta]\, \mathrm{d}\zeta. \tag{3.7}$$

Here, $\mathcal{Z}$ follows the real axis in the complex ζ-plane, below it for negative real parts and above it for positive real parts. Since

$$\omega^2 \mathrm{A}(x_{1,2}, D_{1,2}) = \partial_1^2 + \partial_2^2 + (\omega/c_0)^2\, n^2(x_{1,2}), \tag{3.8}$$

$\tilde{G}$ satisfies (cf. (3.4))

$$[\partial_1^2 + \partial_2^2 + (\omega/c_0)^2\, (n^2(x_{1,2}) - \zeta^2)]\, \tilde{G}(x_{1,2}, x_{1,2}'; \zeta) = -\delta(x_1 - x_1')\delta(x_2 - x_2'), \tag{3.9}$$

or, more formally,

$$-\omega^2[\mathrm{A}(x_{1,2}, D_{1,2}) - c_0^{-2}\zeta^2]\, \tilde{G}(x_{1,2}, x_{1,2}'; \zeta) = \delta(x_1 - x_1')\delta(x_2 - x_2'). \tag{3.10}$$

We can deform contour $\mathcal{Z}$ to a contour $\mathcal{Z}'$, say, such that the distance from a zero crossing of $n^2(x_{1,2}) - \zeta^2$ remains finite.

Observe the symmetry $\tilde{G}(x_{1,2}, x_{1,2}'; -\zeta) = \tilde{G}(x_{1,2}, x_{1,2}'; \zeta)$. Hidden inside the integral is a cut-off function in accordance with the microlocal representation of G.

4. Kernel representations in terms of the characteristic Green's function.

The one-way propagator. Using the image principle, we can express the one-way Green's functions in terms of the Green's function of the second-order Helmholtz equation,

$$\mathcal{G}^{(+)}(x_{1,2}, x_3 - x_3'; x_{1,2}') + \mathcal{G}^{(-)}(x_{1,2}, x_3 - x_3'; x_{1,2}') = -2\, \partial_3 G(x_{1,2}, x_3 - x_3'; x_{1,2}'). \tag{4.1}$$

Hence, for $x_3 > x_3'$,

$$\mathcal{G}^{(+)}(x_{1,2}, x_3 - x_3'; x_{1,2}') = -2\, \partial_3 G(x_{1,2}, x_3 - x_3'; x_{1,2}'). \tag{4.2}$$

In fact, $\mathcal{G} \equiv \mathcal{G}^{(+)}$ is the kernel of the (upward) one-way wave propagator. In view of (4.2) this kernel satisfies the property

$$\partial_3^{2j}\mathcal{G} = [-\omega^2 \mathrm{A}(x_{1,2}, D_{1,2})]^j \mathcal{G}, \qquad j = 1, 2, \ldots, \tag{4.3}$$

for $x_3 > x_3'$. We will pay special attention to the so-called thin-slab expansion of $\mathcal{G}$.

The vertical slowness or square-root operator. The vertical slowness or square-root operator Γ (see (2.23)) acts on the wave field as

$$(\Gamma\{W_1, W_2\})(x_{1,2}) = \int_{x_{1,2}'\in\mathbb{R}^2} \mathcal{C}(x_{1,2}, x_{1,2}')\, \{W_1, W_2\}(x_{1,2}')\, \mathrm{d}x_1'\mathrm{d}x_2', \tag{4.4}$$

where $\mathcal{C}$ denotes a Schwartz kernel. From this operator representation, we extract the left vertical slowness symbol through the Fourier transformation

$$\gamma(x_{1,2}, p_{1,2}) = \int_{x_{1,2}'\in\mathbb{R}^2} \mathcal{C}(x_{1,2}, x_{1,2}')\, \exp[-\mathrm{i}\omega(x_\sigma - x_\sigma')p_\sigma]\, \mathrm{d}x_1'\mathrm{d}x_2', \tag{4.5}$$

where the summation convention has been invoked for $\sigma \in \{1,2\}$. The left symbols of the horizontal slowness operators $D_{1,2}$ appear to be simply $p_{1,2}$. The relation between the left vertical slowness symbol and the horizontal slowness symbol constitutes the generalized slowness surface.

We will now focus on finding integral representations for the Schwartz kernel. First, note that the Schwartz kernel can be expressed in terms of the one-way Green's function,

$$\mathcal{C}^{(+)}(x_{1,2}, x'_{1,2}; x'_3) = -\lim_{x_3 \downarrow x'_3} \frac{\mathrm{i}}{\omega} \partial_3 \mathcal{G}^{(+)}(x_{1,2}, x_3 - x'_3; x'_{1,2}), \tag{4.6}$$

$$\mathcal{C}^{(-)}(x_{1,2}, x'_{1,2}; x'_3) = -\lim_{x_3 \uparrow x'_3} \frac{\mathrm{i}}{\omega} \partial_3 \mathcal{G}^{(-)}(x_{1,2}, x_3 - x'_3; x'_{1,2}). \tag{4.7}$$

With (4.2) we find that

$$\mathcal{C}(x_{1,2}, x'_{1,2}; x'_3) = -\lim_{x_3 \downarrow x'_3} \frac{2}{\mathrm{i}\omega}\, \partial_3^2 G(x_{1,2}, x_3 - x'_3; x'_{1,2}). \tag{4.8}$$

Note that $\mathcal{C}$ is dependent on x'_3 through the index of refraction. We will suppress this dependence in our notation.

The inverse vertical slowness operator. The inverse or reciprocal vertical slowness operator admits the kernel identification

$$\mathcal{A}_{-1/2}(x_{1,2}, x'_{1,2}) = -2\mathrm{i}\omega\, G(x_{1,2}, 0; x'_{1,2}). \tag{4.9}$$

From the inverse vertical slowness operator, the higher fractional powers of the characteristic operator can be obtained, viz., through the composition

$$\mathcal{A}^{j-1/2} = \mathrm{A}^j \mathcal{A}_{-1/2}. \tag{4.10}$$

5. Uniform asymptotic expansion of the characteristic Green's function: The absence of caustics.

The inner solution. The inner region is determined by the condition

$$\|(x_1 - x'_1, x_2 - x'_2)\| = \mathcal{O}(k_0^{-1})$$

and corresponds to the behavior of the kernels near their diagonals. The inner region is so close to the "source" at $x'_{1,2}$ that caustics have not (yet) formed.

We reconsider (3.4),

$$[\partial_k \partial_k + k_0^2 n^2(x_{1,2})]\, G(x_{1,2}, x_3 - x'_3; x'_{1,2}) = -\delta(x_1 - x'_1)\delta(x_2 - x'_2)\delta(x_3 - x'_3)$$

and introduce the relative coordinate

$$y_j = x_j - x'_j, \qquad j \in \{1,2,3\}.$$

We expand the index of refraction about (x'_1, x'_2) according to

$$\begin{aligned} n^2(y_{1,2} + x'_{1,2}) &= n^2(x'_{1,2}) + 2n(x'_{1,2})\,([y_1\partial_1 + y_2\partial_2]n)(x'_{1,2}) \\ &\quad + n(x'_{1,2})\,[y_1\partial_1 + y_2\partial_2]^2 n(x'_{1,2}) + (([y_1\partial_1 + y_2\partial_2]n)(x'_{1,2}))^2 + \ldots, \end{aligned} \tag{5.1}$$

where we differentiate $(\partial_{1,2})$ with respect to $x'_{1,2}$ while the argument of n and its derivatives is $x'_{1,2}$. We invoke the expansion of the Green's function in terms of $y_{1,2}$,

$$G = G_0 + G_1 + G_2 + \dots, \tag{5.2}$$

where the subscript indicates the order in $y = (y_1^2 + y_2^2 + y_3^2)^{1/2}$. Then

$$\begin{aligned}
&[\partial_k\partial_k + k_0^2 n^2(x'_{1,2})]\, G_0(x_{1,2}, x_3 - x'_3; x'_{1,2}) \\
&\qquad = -\delta(x_1 - x'_1)\delta(x_2 - x'_2)\delta(x_3 - x'_3), \qquad (5.3)\\
&[\partial_k\partial_k + k_0^2 n^2(x'_{1,2})]\, G_1(x_{1,2}, x_3 - x'_3; x'_{1,2}) \\
&\qquad = -2k_0^2 n(x'_{1,2})\,([y_1\partial_1 + y_2\partial_2]n)(x'_{1,2})\; G_0(x_{1,2}, x_3 - x'_3; x'_{1,2}), \qquad (5.4)\\
&[\partial_k\partial_k + k_0^2 n^2(x'_{1,2})]\, G_2(x_{1,2}, x_3 - x'_3; x'_{1,2}) \\
&\qquad = -2k_0^2 n(x'_{1,2})\,([y_1\partial_1 + y_2\partial_2]n)(x'_{1,2})\; G_1(x_{1,2}, x_3 - x'_3; x'_{1,2}) \qquad (5.5)\\
&\qquad\quad -k_0^2\left[n(x'_{1,2})\,[y_1\partial_1 + y_2\partial_2]^2 n(x'_{1,2})\right. \\
&\qquad\quad \left. +(([y_1\partial_1 + y_2\partial_2]n)(x'_{1,2}))^2\right]\; G_0(x_{1,2}, x_3 - x'_3; x'_{1,2}),
\end{aligned}$$

etc., with solutions obtained recursively as

$$\begin{aligned}
(5.6)\quad & G_0(x_{1,2}, x_3 - x'_3; x'_{1,2}) = \frac{\exp[\mathrm{i}k_0 n\, y]}{4\pi y}, \\
(5.7)\quad & G_1(x_{1,2}, x_3 - x'_3; x'_{1,2}) = \tfrac{1}{2}\mathrm{i}k_0 y\,([y_1\partial_1 + y_2\partial_2]n)\; G_0(x_{1,2}, x_3 - x'_3; x'_{1,2}), \\
& G_2(x_{1,2}, x_3 - x'_3; x'_{1,2}) = \frac{\mathrm{i}k_0 y}{24n}\left\{4n[y_1\partial_1 + y_2\partial_2]^2 n\right. \\
&\qquad +(3\mathrm{i}k_0 n y + 1)([y_1\partial_1 + y_2\partial_2]n)^2 - y^2[(\partial_1 n)^2 + (\partial_2 n)^2] \\
&\qquad \left. +\frac{(\partial_1 n)^2 + (\partial_2 n)^2 - 2n[(\partial_1)^2 + (\partial_2)^2]n}{(\mathrm{i}k_0 n)^2}(\mathrm{i}k_0 n y - 1)\right\} G_0. \qquad (5.8)
\end{aligned}$$

Inner expansion in midpoint coordinates. In the spirit of the Weyl calculus of kernel symbols (see [11, 21.6.5]), we can improve the above result by introducing the midpoint coordinates

$$\bar{x}_j = \tfrac{1}{2}(x_j + x'_j), \qquad j \in \{1, 2, 3\},$$

and re-expand the exponential according to

$$\begin{aligned}
&\exp[\mathrm{i}k_0 n(x'_{1,2})\, y] = \exp[\mathrm{i}k_0 n(\bar{x}_{1,2})\, y]\;\left\{1 - \tfrac{1}{2}\mathrm{i}k_0 y[y_1\partial_1 + y_2\partial_2]n\right. \\
&\qquad \left. + \tfrac{1}{8}\mathrm{i}k_0 y[y_1\partial_1 + y_2\partial_2]^2 n - \tfrac{1}{8}k_0^2 y^2([y_1\partial_1 + y_2\partial_2]n)^2 + \dots\right\}, \qquad (5.9)
\end{aligned}$$

where the argument of n is now $\bar{x}_{1,2}$. The expansion for G (cf. (5.2) and (5.6)–(5.8)) can then be rewritten as

$$\begin{aligned}
G = \frac{\exp[\mathrm{i}k_0 n\, y]}{4\pi y}\Bigg\{1 + \frac{\mathrm{i}k_0 y}{24n}\Bigg[\, & n[y_1\partial_1 + y_2\partial_2]^2 n + ([y_1\partial_1 + y_2\partial_2]n)^2 \\
& - y^2[(\partial_1 n)^2 + (\partial_2 n)^2] \\
& + \frac{(\partial_1 n)^2 + (\partial_2 n)^2 - 2n[(\partial_1)^2 + (\partial_2)^2]n}{(\mathrm{i}k_0 n)^2}(\mathrm{i}k_0 n y - 1)\Bigg] + \dots\Bigg\}. \qquad (5.10)
\end{aligned}$$

Note that the odd order terms (up to this order, G_1) have disappeared. The expansion above has an improved error estimate, here $\mathcal{O}(y^4)$: We now have (cf. (5.2)) $G \simeq G_0 + G_2$ and upon substitution it follows that

$$[\partial_k \partial_k + k_0^2 n^2(x_{1,2})]\, G = G_0(x_{1,2}, x_3 - x_3'; x_{1,2}')\ k_0^2 \mathcal{O}(y^4). \tag{5.11}$$

The outer solution. The outer region is determined by the condition

$$\|(x_1 - x_1', x_2 - x_2')\| = \mathcal{O}(1)$$

and corresponds to the behavior of the kernels away from their diagonals.

We reconsider (3.9),

$$[\partial_1^2 + \partial_2^2 + k_0^2(n^2(x_{1,2}) - \zeta^2)]\, \tilde{G}(x_{1,2}, x_{1,2}'; \zeta) = -\delta(x_1 - x_1')\delta(x_2 - x_2')$$

and we introduce the representation

$$\tilde{G}(x_{1,2}, x_{1,2}'; \zeta) = \mathsf{C}\, \exp(\mathrm{i}k_0 \psi), \tag{5.12}$$

where C is a yet-to-be-determined constant. We expand ψ into phase and amplitude contributions,

$$\psi = \phi + \underbrace{\frac{1}{\mathrm{i}k_0}\phi_1 + \frac{1}{(\mathrm{i}k_0)^2}\phi_2 + \dots}_{\text{amplitude}}. \tag{5.13}$$

Substituting this expansion into the partial differential equation, and collecting equal powers of $(\mathrm{i}k_0)$, results in the eikonal equation

$$p^2 + q^2 + \zeta^2 - n^2(x_{1,2}) = 0, \tag{5.14}$$

for the leading order; here $p \equiv \partial_{x_1}\phi$ and $q \equiv \partial_{x_2}\phi$. The next order terms yield the equation

$$2p\,(\partial_{x_1}\phi_1) + 2q\,(\partial_{x_2}\phi_1) + \partial_{x_1} p + \partial_{x_2} q = 0, \tag{5.15}$$

whereas the final order that we will account for implies the equation

$$2p\,(\partial_{x_1}\phi_2) + 2q\,(\partial_{x_2}\phi_2) + \partial_{x_1}^2\phi_1 + \partial_{x_2}^2\phi_1 + (\partial_{x_1}\phi_1)^2 + (\partial_{x_2}\phi_1)^2 = 0. \tag{5.16}$$

Amplitude expansion. It is convenient to remove the singularities from ϕ_1 and ϕ_2. This is accomplished by the change of functions,

$$\phi_1 = -\tfrac{1}{2}\log\phi + \psi_1, \tag{5.17}$$

$$\phi_2 = \tfrac{1}{8}\phi^{-1} + \psi_2. \tag{5.18}$$

With this change, (5.15)–(5.16) take the form

$$2p\,(\partial_{x_1}\psi_1) + 2q\,(\partial_{x_2}\psi_1) + \phi\,[\partial_{x_1}^2 + \partial_{x_2}^2]\log\phi = 0, \tag{5.19}$$

$$2p\,(\partial_{x_1}\psi_2) + 2q\,(\partial_{x_2}\psi_2) + \partial_{x_1}^2\psi_1 + \partial_{x_2}^2\psi_1 + (\partial_{x_1}\psi_1)^2 + (\partial_{x_2}\psi_1)^2 = 0, \tag{5.20}$$

supplemented with the initial conditions $\psi_1 = \psi_2 = 0$ at $x_{1,2} = x_{1,2}'$.

Expansion in $z = \mathcal{O}(k_0^{-1})$. We now make the assumption that the propagation distance satisfies

$$k_0 \underbrace{|x_3 - x_3'|}_{y_3 = z} = \mathcal{O}(1). \tag{5.21}$$

Thus we guarantee that the stationary point (where $\partial_\zeta \phi = 0$) of the integral representation (3.7) remains at $\zeta = 0$, and that

$$|\exp[\mathrm{i}k_0 |x_3 - x_3'|\zeta]| = \mathcal{O}(1). \tag{5.22}$$

We then expand the relevant functions about $\zeta = 0$, i.e.,

$$\phi = I_0 - \tfrac{1}{2}\zeta^2 I_1 - \tfrac{1}{8}\zeta^4 I_2 + \dots, \tag{5.23}$$

$$\psi_1 = \psi_{10} + \zeta^2 \psi_{11} + \dots, \tag{5.24}$$

$$\psi_2 = \psi_{20} + \dots, \tag{5.25}$$

where I_0, I_1, I_2 and $\psi_{10}, \psi_{11}, \psi_{20}$ are independent of ζ.

The phase function. Invoking expansion (5.23) into (5.14), the equations determining the phase function become

$$P^2 + Q^2 - n^2(x_{1,2}) = 0, \tag{5.26}$$

$$P\,(\partial_{x_1} I_1) + Q\,(\partial_{x_2} I_1) - 1 = 0, \tag{5.27}$$

$$P\,(\partial_{x_1} I_2) + Q\,(\partial_{x_2} I_2) - (\partial_{x_1} I_1)^2 - (\partial_{x_2} I_1)^2 = 0, \tag{5.28}$$

where $P = \partial_{x_1} I_0$ and $Q = \partial_{x_2} I_0$. With eikonal equation (5.26) is associated the Hamilton system

$$\begin{aligned} \frac{\mathrm{d}x_1}{\mathrm{d}\mu} &= P, \qquad \frac{\mathrm{d}P}{\mathrm{d}\mu} = (\partial_1 M)(x_{1,2}), \\ \frac{\mathrm{d}x_2}{\mathrm{d}\mu} &= Q, \qquad \frac{\mathrm{d}Q}{\mathrm{d}\mu} = (\partial_2 M)(x_{1,2}), \end{aligned} \tag{5.29}$$

where $M = \frac{1}{2}n^2$, supplemented by the initial conditions

$$(x_1, x_2)|_0 = (x_1', x_2'), \quad (P, Q)|_0 = (\alpha_1, \alpha_2), \quad \alpha_1^2 + \alpha_2^2 = n^2(x_{1,2}'). \tag{5.30}$$

The additional equations (5.27)–(5.28) comply with the initial conditions at $\mu = 0$: $I_j = 0$, $j = 0, 1, 2, \dots$.

In the Hamilton system (5.29), we expand the right-hand sides into a Taylor series about the "source" coordinates, $x_{1,2}'$:

$$\begin{aligned} \frac{\mathrm{d}P}{\mathrm{d}\mu} &= (\partial_1 M)(x_{1,2}') + y_1 \partial_1 (\partial_1 M)(x_{1,2}') + y_2 \partial_2 (\partial_1 M)(x_{1,2}'), \\ \frac{\mathrm{d}Q}{\mathrm{d}\mu} &= (\partial_2 M)(x_{1,2}') + y_1 \partial_1 (\partial_2 M)(x_{1,2}') + y_2 \partial_2 (\partial_2 M)(x_{1,2}'). \end{aligned} \tag{5.31}$$

We then evaluate the solutions to the Hamilton (see (5.29)–(5.31)) and eikonal (see (5.26)) equations for small values of μ. The parametric representation of the Hamil-

tonian flow follows as

$$
\begin{aligned}
y_1 &= P|_0\mu + \tfrac{1}{2}P_1\mu^2 + \tfrac{1}{3}P_2\mu^3 + \dots,\\
P &= \underbrace{\alpha_1}_{P|_0} + \underbrace{(\partial_1 M)}_{P_1}\,\mu + \tfrac{1}{2}\,\underbrace{[\alpha_1\partial_1 + \alpha_2\partial_2](\partial_1 M)}_{P_2}\,\mu^2 + \dots,\\
y_2 &= Q|_0\mu + \tfrac{1}{2}Q_1\mu^2 + \tfrac{1}{3}Q_2\mu^3 + \dots,\\
Q &= \underbrace{\alpha_2}_{Q|_0} + \underbrace{(\partial_2 M)}_{Q_1}\,\mu + \tfrac{1}{2}\,\underbrace{[\alpha_1\partial_1 + \alpha_2\partial_2](\partial_2 M)}_{Q_2}\,\mu^2 + \dots;
\end{aligned}
\tag{5.32}
$$

in these equations we differentiate $(\partial_{1,2})$ with respect to $x'_{1,2}$ while the argument of $(\partial_{1,2}M)$ is $x'_{1,2}$. For the purpose of the uniform matching, we will re-expand the solution about the transverse midpoint coordinates $\bar{x}_{1,2}$ and give results as needed later.

Solving system (5.32) for μ, α_1, α_2 in terms of y_1, y_2, yields

$$
\begin{aligned}
\mu = \frac{r_2}{n}\Bigg(1 - \frac{1}{2}\frac{[y_1\partial_1 + y_2\partial_2]n}{n} + \frac{1}{3}\left(\frac{[y_1\partial_1 + y_2\partial_2]n}{n}\right)^2\\
+ \frac{1}{8}\left(\frac{[y_1^\perp\partial_1 + y_2^\perp\partial_2]n}{n}\right)^2 - \frac{1}{6}\frac{[y_1\partial_1 + y_2\partial_2]^2 n}{n}\Bigg),
\end{aligned}
\tag{5.33}
$$

$$
\alpha_{1,2} = \frac{n}{r_2}\left(y_{1,2}(1 - \tfrac{1}{2}a_1^2) + y_{1,2}^\perp(a_1 + a_2)\right),
\tag{5.34}
$$

where the argument of n is $x'_{1,2}$,

$$
r_2 = (y_1^2 + y_2^2)^{1/2}
\tag{5.35}
$$

and

$$
y_1^\perp = -y_2, \quad y_2^\perp = y_1,
\tag{5.36}
$$

while

$$
\begin{aligned}
a_1 &= -\frac{[y_1^\perp\partial_1 + y_2^\perp\partial_2]n}{2n},\\
a_2 &= \frac{1}{12}\Bigg(\frac{([y_1^\perp\partial_1 + y_2^\perp\partial_2]n)([y_1\partial_1 + y_2\partial_2]n)}{n^2}\\
&\qquad -2\frac{[y_1^\perp\partial_1 + y_2^\perp\partial_2][y_1\partial_1 + y_2\partial_2]n}{n}\Bigg);
\end{aligned}
\tag{5.37}
$$

note that a_1 and a_2 are of first and second order in y, respectively.

With the aid of relation

$$
P\,\partial_{x_1} I_j + Q\,\partial_{x_2} I_j = \frac{\mathrm{d}I_j}{\mathrm{d}\mu}
$$

valid along a characteristic or ray, (5.26)–(5.28) take the form

$$\frac{\mathrm{d}I_0}{\mathrm{d}\mu} = n^2(x_{1,2}), \tag{5.38}$$

$$\frac{\mathrm{d}I_1}{\mathrm{d}\mu} = 1, \tag{5.39}$$

$$\frac{\mathrm{d}I_2}{\mathrm{d}\mu} = (\partial_{x_1} I_1)^2 + (\partial_{x_2} I_1)^2. \tag{5.40}$$

Explicit expansions of I_j near the "source" (μ small or, equivalently, r_2 small) are readily obtained from (5.38)–(5.40) using system (5.32) and solutions (5.33)–(5.34). (Basically, such a procedure encompasses an expansion of (the argument of) n^2 about the fixed initial point $(x'_{1,2})$ in terms of $y_{1,2}$; we then substitute the small μ expansion (5.32) for $y_{1,2}$ and re-expand the relevant coefficients about $\bar{x}_{1,2}$.) These expansions are only needed for matching the inner and outer solutions. They are given as needed later (see (5.54)–(5.58)).

The amplitude expansion. Invoking expansion (5.23)–(5.25) into (5.19)–(5.20), the equations determining the amplitude become

$$2P\,\partial_{x_1}\psi_{10} + 2Q\,\partial_{x_2}\psi_{10} + I_0[\partial^2_{x_1} + \partial^2_{x_2}]\log I_0 = 0, \tag{5.41}$$

$$2P\,\partial_{x_1}\psi_{20} + 2Q\,\partial_{x_2}\psi_{20} + (\partial_{x_1}\psi_{10})^2 + (\partial_{x_2}\psi_{10})^2 + [\partial^2_{x_1} + \partial^2_{x_2}]\psi_{10} = 0, \tag{5.42}$$

supplemented with the initial conditions

$$\psi_{10} = \psi_{20} = 0 \quad \text{at } x_{1,2} = x'_{1,2}. \tag{5.43}$$

The next order equation, for ψ_{11}, becomes

$$\begin{aligned} &2P\,\partial_{x_1}\psi_{11} + 2Q\,\partial_{x_2}\psi_{11} - (\partial_{x_1} I_1)(\partial_{x_1}\psi_{10}) - (\partial_{x_2} I_1)(\partial_{x_2}\psi_{10}) \\ &\quad - \tfrac{1}{2} I_1[\partial^2_{x_1} + \partial^2_{x_2}]\log I_0 - \tfrac{1}{2} I_0[\partial^2_{x_1} + \partial^2_{x_2}](I_1/I_0) = 0, \end{aligned} \tag{5.44}$$

supplemented with the initial conditions

$$\psi_{11} = 0 \quad \text{at } x_{1,2} = x'_{1,2}. \tag{5.45}$$

In (5.41)–(5.42) and (5.44),

$$P\,\partial_{x_1}\psi_{ij} + Q\,\partial_{x_2}\psi_{ij} = \frac{\mathrm{d}\psi_{ij}}{\mathrm{d}\mu}$$

along a characteristic or ray. Upon solving these equations, about the stationary point at $\zeta = 0$, we obtain the transform-domain expansion for the characteristic Green's function,

$$\begin{aligned} &\tilde{G}(x_{1,2}, x'_{1,2}; \zeta)\, \exp[-\mathrm{i}k_0(x_3 - x'_3)\zeta] = \mathsf{C}\,\frac{1}{\sqrt{I_0}} \exp[\mathrm{i}k_0(I_0 - \tfrac{1}{2}\zeta^2 I_1) + \psi_{10}] \\ &\left\{ 1 - \mathrm{i}k_0\zeta(x_3 - x'_3) + \frac{1}{\mathrm{i}k_0}\left(\frac{1}{8I_0} + \psi_{20} + \mathrm{i}k_0\zeta^2\left(\psi_{11} + \frac{I_1}{4I_0} + \tfrac{1}{2}[\mathrm{i}k_0(x_3 - x'_3)]^2\right)\right.\right. \\ &\qquad \left.\left. - \tfrac{1}{8}(\mathrm{i}k_0\zeta^2)^2 I_2 \right) + \dots \right\}. \end{aligned} \tag{5.46}$$

TABLE 5.1
Relevant equations.

I_0	I_1	I_2	ψ_{10}	ψ_{20}	ψ_{11}
(5.38)	(5.39)	(5.40)	(5.41)	(5.42)	(5.44)

Carrying out the inverse Fourier transform with the method of stationary phase then results in

$$G(x_{1,2}, x_3 - x_3'; x_{1,2}') = \mathsf{C}\left(\frac{-\mathrm{i}k_0}{2\pi}\right)^{1/2} \exp(\psi_{10}) \frac{\exp(\mathrm{i}k_0 I_0)}{(I_0 I_1)^{1/2}}$$
$$\left\{1 + \frac{1}{\mathrm{i}k_0 I_0}\left(\frac{3}{8}\left(1 - \frac{I_2 I_0}{I_1^2}\right) + \left(\frac{\psi_{11}}{I_1} + \psi_{20}\right) I_0 + \tfrac{1}{2}[\mathrm{i}k_0(x_3 - x_3')]^2 \frac{I_0}{I_1}\right) + \dots\right\}. \tag{5.47}$$

Effective index of refraction, effective metric and uniform asymptotic expansion. As in the two-dimensional case [10], for notational convenience, we introduce the *effective* index of refraction and *effective* horizontal distance as

$$\nu \equiv \left[\frac{I_0}{I_1}\right]^{1/2}, \tag{5.48}$$

$$\chi_1 \equiv [I_0 I_1]^{1/2}, \tag{5.49}$$

where the arguments are evaluated along the characteristics, whereas

$$r = [\chi_1^2 + z^2]^{1/2}. \tag{5.50}$$

Then a uniform asymptotic expansion is

$$G(x_{1,2}, x_3 - x_3'; x_{1,2}') = \frac{1}{4\pi r} \exp(\mathrm{i}k_0 \nu r) \exp(\psi_{10} r^2/\chi_1^2) \tag{5.51}$$
$$\left\{ 1 + \frac{r}{\mathrm{i}k_0 \nu \chi_1^2}\left(\frac{3}{8}\left(1 - \frac{\nu^3 I_2}{\chi_1}\right) + \nu(\nu\psi_{11} + \chi_1\psi_{20})\right) \right.$$
$$\left. + \frac{1}{8}\left(1 - \frac{\nu^3 I_2}{\chi_1}\right)\left(\frac{(x_3 - x_3')^2}{\chi_1^2 r^2}[\mathrm{i}k_0 \nu r (x_3 - x_3')^2 + r^2 + \chi_1^2]\right) + \dots \right\}.$$

The equations to be evaluated or solved are listed in Table 5.1.

In the *outer* region, $\chi_1 = \mathcal{O}(1)$, whence

$$\frac{r}{\chi_1} \sim 1 + \frac{(x_3 - x_3')^2}{2\chi_1^2} = 1 + \mathcal{O}(k_0^{-2}), \tag{5.52}$$

$$\nu r = \nu\chi_1 + \nu\frac{(x_3 - x_3')^2}{2\chi_1} + \mathcal{O}(k_0^{-4}), \tag{5.53}$$

and the uniform solution reduces to the outer solution (5.47) with

$$\mathsf{C} = \left(\frac{\mathrm{i}}{8\pi k_0}\right)^{1/2}.$$

On the *inner* region, $\chi_1 = \mathcal{O}(k_0^{-1})$, whence

$$\frac{1}{\chi_1^2}\left(1-\frac{\nu^3 I_2}{\chi_1}\right) \sim -\frac{1}{3}\left[\left(\frac{\partial_1 n}{n}\right)^2 + \left(\frac{\partial_2 n}{n}\right)^2\right], \tag{5.54}$$

$$\frac{\nu}{\chi_1^2}(\nu\psi_{11}+\chi_1\psi_{20}) \sim \frac{1}{12}\left[\frac{[\partial_1^2+\partial_2^2]n}{n} + \left(\frac{\partial_1 n}{n}\right)^2 + \left(\frac{\partial_2 n}{n}\right)^2\right], \tag{5.55}$$

$$\frac{\psi_{10}}{\chi_1^2} \sim \frac{1}{12}\left[-\frac{[\partial_1^2+\partial_2^2]n}{n} + \left(\frac{\partial_1 n}{n}\right)^2 + \left(\frac{\partial_2 n}{n}\right)^2\right], \tag{5.56}$$

$$\begin{aligned}\nu r \sim ny\Bigg(1+\frac{1}{24}\Bigg\{&\frac{[y_1\partial_1+y_2\partial_2]^2 n}{n} + \left(\frac{y_1\partial_1 n}{n}\right)^2 + \left(\frac{y_2\partial_2 n}{n}\right)^2 \\ &+\left[\left(\frac{\partial_1 n}{n}\right)^2 + \left(\frac{\partial_2 n}{n}\right)^2\right]\left(-y^2+\frac{(x_3-x_3')^4}{y^2}\right)\Bigg\}\Bigg),\end{aligned} \tag{5.57}$$

$$\frac{1}{r} \sim \frac{1}{y}\left(1-\frac{1}{24}\left[\left(\frac{\partial_1 n}{n}\right)^2 + \left(\frac{\partial_2 n}{n}\right)^2\right]\frac{r_2^4}{y^2}\right), \tag{5.58}$$

where r_2 was defined in (5.35), and the argument of n is $\bar{x}_{1,2}$. Substitution of these results into the uniform solution yields the inner solution (5.10).

The inner and outer solutions match when $\chi_1 = \mathcal{O}(k_0^{-2/3})$, which scaling defines the boundary layer.

6. Uniform asymptotic expansion of the characteristic Green's function: The presence of a caustic. In the generic case of a heterogeneous slab, caustics will form in the transverse directions. Following the Maslov approach, we note that there will always be two coordinates chosen from (y_1, y_2) and their Fourier duals (η_1, η_2) such that the solution in these coordinates remains asymptotically finite and meaningful. The transition from one doublet of coordinates to another is followed by the Keller–Maslov line bundle [11] that is accounted for in the solution's amplitude through a tensor product. We will discuss the mixed (y_1, η_2) case here; together with the previous section, all necessary combinations can be found by permutation of coordinates.

We reconsider (3.4) once again,

$$[\partial_k\partial_k + k_0^2 n^2(x_{1,2})]\, G(x_{1,2}, x_3 - x_3'; x_{1,2}') = -\delta(x_1-x_1')\delta(x_2-x_2')\delta(x_3-x_3'),$$

and introduce a slight change in notation,

$$y_{1,2} = x_{1,2} - x_{1,2}', \qquad z = x_3 - x_3'.$$

We write the Green's function in the form of an appropriate Fourier integral,

$$G(x_{1,2}, x_3 - x_3'; x_{1,2}') = \frac{k_0}{2\pi}\int_{\mathbb{R}} \hat{G}(y_1, \eta_2, z; x_{1,2}')\, \exp(\mathrm{i}k_0\eta_2 y_2)\, \mathrm{d}\eta_2. \tag{6.1}$$

We now distinguish amplitude and phase according to

$$\hat{G}(y_1, \eta_2, z; x_{1,2}') = A(y_1, \eta_2, z; x_{1,2}')\exp[\mathrm{i}k_0\phi(y_1, \eta_2, z; x_{1,2}')]. \tag{6.2}$$

The inner solution. We expand the index of refraction, $n^2(x'_{1,2}+y_{1,2})$, in the partial differential equation in y_2 about $-q$ where $q\equiv\partial_{\eta_2}\phi$. Upon substituting the Fourier representation into the Helmholtz equation (3.4), after several integrations by parts, we obtain the following equations.

Up to highest order (lowest order in $(\mathrm{i}k_0)^{-1}$), we recover the eikonal equation, viz.,

$$p^2+\eta_2^2+r^2-n^2(x'_1+y_1,x'_2-q)=0, \tag{6.3}$$

where $p\equiv\partial_{y_1}\phi$ and $r\equiv\partial_z\phi$. This is a pseudodifferential equation for ϕ. In the spirit of the solution method of characteristics, we deduce the Hamilton equations for the bicharacteristics,

$$\begin{aligned}
&\frac{\mathrm{d}y_1}{\mathrm{d}\lambda}=p, && \frac{\mathrm{d}p}{\mathrm{d}\lambda}=(\partial_1M)(x'_1+y_1,x'_2-q),\\
&\frac{\mathrm{d}\eta_2}{\mathrm{d}\lambda}=(\partial_2M)(x'_1+y_1,x'_2-q), && \frac{\mathrm{d}q}{\mathrm{d}\lambda}=-\eta_2,\\
&\frac{\mathrm{d}z}{\mathrm{d}\lambda}=r, && \frac{\mathrm{d}r}{\mathrm{d}\lambda}=0,
\end{aligned} \tag{6.4}$$

in which

$$M=\tfrac{1}{2}n^2.$$

The Hamilton system is supplemented with initial conditions at $\lambda=0$:

$$(y_1,\eta_2,z)|_0=(0,\beta_2,0),\quad (p,q,r)|_0=(\beta_1,0,\beta_3),\quad \beta_1^2+\beta_2^2+\beta_3^2=n^2(x'_{1,2}). \tag{6.5}$$

In the next order, we recover the transport-like equation for A, viz.,

$$(\partial_{y_1}^2+\partial_z^2)A+2\mathrm{i}k_0CA-DA=-\delta(y_1)\delta(z), \tag{6.6}$$

in which

$$\begin{aligned}
CA&=[p\,\partial_{y_1}+r\partial_z+(\partial_2M)(x'_1+y_1,x'_2-q)\,\partial_{\eta_2}]\,A\\
&\quad+\tfrac{1}{2}\left[\partial_{y_1}^2\phi+\partial_z^2\phi-(\partial_2^2M)(x'_1+y_1,x'_2-q)\,\partial_{\eta_2}^2\phi\right]A, \qquad (6.7)\\
DA&=\left[(\partial_2^2M)(x'_1+y_1,x'_2-q)\,\partial_{\eta_2}^2-(\partial_{\eta_2}q)(\partial_2^3M)(x'_1+y_1,x'_2-q)\,\partial_{\eta_2}\right]A\\
&\quad+\left[-\tfrac{1}{3}(\partial_{\eta_2}^2q)(\partial_2^3M)(x'_1+y_1,x'_2-q)+\tfrac{1}{4}(\partial_{\eta_2}q)^2(\partial_2^4M)(x'_1+y_1,x'_2-q)\right]A\\
&\quad+\mathcal{O}((\mathrm{i}k_0)^{-1}). \qquad (6.8)
\end{aligned}$$

Observe that on the inner region the y_1 and z derivatives are large, and, hence, the inner transport-like equation reduces to

$$(\partial_{y_1}^2+\partial_z^2)A+2\mathrm{i}k_0CA=-\delta(y_1)\delta(z)+\dots. \tag{6.9}$$

The phase function. First, we evaluate the solutions to the Hamilton (cf. (6.4)) and eikonal (cf. (6.3)) equations for small values of λ. The parametric representation of the Hamiltonian flow follows from (6.4) as

$$\begin{aligned}
&y_1=\beta_1\lambda+\tfrac{1}{2}(\partial_1M)\,\lambda^2+\dots, && p=\beta_1+(\partial_1M)\,\lambda+\dots,\\
&\eta_2=\beta_2+(\partial_2M)\,\lambda+\dots, && q=-\beta_2\lambda-\tfrac{1}{2}(\partial_2M)\,\lambda^2+\dots,\\
&z=\beta_3\lambda, && r=\beta_3
\end{aligned} \tag{6.10}$$

while, through integration of the canonical one-form along the bicharacteristic, the phase function is found to be

$$\phi = (\beta_1^2 + \beta_3^2)\,\lambda + [\beta_1(\partial_1 M) - \tfrac{1}{2}\beta_2(\partial_2 M)]\,\lambda^2 + \dots, \tag{6.11}$$

in which the substitution $(\partial_{1,2}M) = (\partial_{1,2}M)(x'_{1,2})$ is understood.

Solving system (6.10) subject to the constraint in (6.5) for $\lambda, \beta_1, \beta_2, \beta_3$ in terms of y_1, η_2, z yields

$$\lambda = (R/\gamma)[1 - \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1 M) + \eta_2 R(\partial_2 M)) + \dots], \tag{6.12}$$

$$\beta_1 = (\gamma/R)[y_1 + \gamma^{-3}(-\tfrac{1}{2}\gamma z^2(\partial_1 M) + \eta_2 y_1 R(\partial_2 M)) + \dots], \tag{6.13}$$

$$\beta_2 = \eta_2 - (R/\gamma)(\partial_2 M) + \dots, \tag{6.14}$$

$$\beta_3 = (\gamma z/R)[1 + \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1 M) + \eta_2 R(\partial_2 M)) + \dots], \tag{6.15}$$

in which $R \equiv (y_1^2 + z^2)^{1/2}$ and $\gamma \equiv [n^2(x'_{1,2}) - \eta_2^2]^{1/2}$. Substituting these solutions in the remaining equations of system (6.10) gives

$$\begin{aligned} p &= (\gamma/R)[y_1 + \gamma^{-3}(\tfrac{1}{2}\gamma(y_1^2 + R^2)(\partial_1 M) + \eta_2 y_1 R(\partial_2 M)) + \dots], \\ q &= (R/\gamma)[-\eta_2 + \gamma^{-4}\tfrac{1}{2}(\gamma^2 y_1\eta_2(\partial_1 M) + (\gamma^2 + 2\eta_2^2)R(\partial_2 M)) + \dots], \\ r &= (\gamma z/R)[1 + \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1 M) + \eta_2 R(\partial_2 M)) + \dots], \end{aligned} \tag{6.16}$$

whereas the phase function (6.11) takes the form

$$\phi = \gamma R\,[1 + \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1 M) + \tfrac{1}{2}\eta_2 R(\partial_2 M)) + \dots]. \tag{6.17}$$

The amplitude function. Having obtained the solution of the eikonal equation, we now proceed with solving the transport-like equation. First, observe the following property of functions F of $k_0\phi$:

$$\left[\partial_{y_1}^2 + \partial_z^2 + 2\mathrm{i}k_0 C\right] F = k_0^2(p^2 + r^2)$$

$$\left\{F'' + 2\mathrm{i}F' + \frac{1}{k_0\phi}\,(F' + \mathrm{i}F) + \frac{\eta_2(\partial_2 M)(x'_{1,2})}{2k_0\gamma^4}\,(F' + \mathrm{i}F - 4\mathrm{i}k_0\phi F') + \dots\right\}.$$

Using this property, the inner solution of (6.9) is constructed and found to be

$$\begin{aligned} A = \frac{\mathrm{i}}{4}\exp(-\mathrm{i}k_0\phi) \\ \left\{H_0^{(1)}(k_0\phi) + \frac{\eta_2(\partial_2 M)(x'_{1,2})}{2\gamma^4}k_0\phi^2[H_1^{(1)}(k_0\phi) - \mathrm{i}H_2^{(1)}(k_0\phi)] + \dots\right\}. \end{aligned} \tag{6.18}$$

The outer solution. We assume that our wave field is a transient phenomenon with dominant wave number k_0. The outer region is determined by the condition

$$\|(x_1 - x'_1, x_2 - x'_2)\| = \mathcal{O}(1)$$

and corresponds to the behavior of the kernels away from their diagonals.

Amplitude expansion. In the outer region the derivatives of the amplitude A in (6.2) are $\mathcal{O}(1)$. Thus we expand

$$A = \frac{1}{(k_0\phi)^{1/2}}\left\{A_0 + \frac{1}{\mathrm{i}k_0}\left(\frac{A_0}{8\phi} + A_1\right) + \dots\right\}. \tag{6.19}$$

With this definition, A_0 and A_1 are continuous near the "source" (at $x'_{1,2}$). Substitution of (6.19) into (6.6) and setting terms proportional to $k_0^{-n+1/2}$, $n = 0, 1, \ldots$, equal to zero yields the transport equations

$$LA_0 = 0, \tag{6.20}$$

$$\begin{aligned} LA_1 - \phi^{1/2} D(\phi^{-1/2} A_0) + \partial_{y_1}^2 A_0 + \partial_z^2 A_0 \\ + \frac{1}{\phi}(\partial_2 M)(x'_1 + y_1, x'_2 - q) \left(\partial_{\eta_2} A_0 + \frac{3}{4} \frac{q}{\phi} A_0 \right) \\ - \tfrac{1}{2}(\partial_{\eta_2} q)\, (\partial_2^2 M)(x'_1 + y_1, x'_2 - q) A_0 = 0, \end{aligned} \tag{6.21}$$

where

$$\begin{aligned} LA = 2\frac{\mathrm{d}A}{\mathrm{d}\lambda} + \Big\{ \phi\, [\partial_{y_1}^2 + \partial_z^2] \log\phi \\ - \frac{q}{\phi}(\partial_2 M)(x'_1 + y_1, x'_2 - q) - (\partial_{\eta_2} q)(\partial_2^2 M)(x'_1 + y_1, x'_2 - q) \Big\} A. \end{aligned} \tag{6.22}$$

The nonhomogeneous terms in (6.21) are continuous near the "source."

In preparation for matching the inner and outer solutions, we consider the small λ expansion of the solutions to (6.20)–(6.21):

$$\begin{aligned} A_0 &\to A_0|_0 \left(1 - \frac{3\beta_2 \lambda (\partial_2 M)(x'_{1,2})}{4(\beta_1^2 + \beta_3^2)} + \ldots \right) \\ &= A_0|_0 \left(1 - \frac{3\beta_2 (\partial_2 M)(x'_{1,2}) \phi}{4(\beta_1^2 + \beta_3^2)^2} + \ldots \right), \end{aligned} \tag{6.23}$$

$$A_1 \to A_1|_0 + \ldots. \tag{6.24}$$

Thus near the "source," (6.19) takes the form

$$A = \left(\frac{1}{k_0 \phi} \right)^{1/2} \left\{ A_0|_0 \left(1 + \frac{1}{8\mathrm{i} k_0 \phi} - \frac{3\beta_2 (\partial_2 M)(x'_{1,2})}{32(\beta_1^2 + \beta_3^2)^2} \left[8\phi + \frac{1}{\mathrm{i} k_0} \right] \right) + \frac{1}{\mathrm{i} k_0} A_1|_0 + \ldots \right\}. \tag{6.25}$$

Inner solution on the outer scale. In preparation for developing the inner solution on the outer region, we observe the asymptotic behavior of the amplitude given in (6.18): We have

$$A = \left(\frac{\mathrm{i}}{8\pi k_0 \phi} \right)^{1/2} \left\{ 1 + \frac{1}{8\mathrm{i} k_0 \phi} - \frac{3\eta_2 (\partial_2 M)(x'_{1,2})}{4\gamma^4} \left[\phi - \frac{5}{8\mathrm{i} k_0} \right] + \ldots \right\} \tag{6.26}$$

as $k_0 \phi$ becomes large. On the other hand, approaching the "source" as λ (i.e., ϕ) becomes small, in this expression, gives

$$\frac{\eta_2}{\gamma^4} \to \frac{\beta_2}{(\beta_1^2 + \beta_3^2)^2},$$

cf. (6.10).

Uniform asymptotic expansion. *Matching the inner solution on the overlapping region.* The overlapping region is governed by λ small and $k_0\lambda$ large, i.e., ϕ small and $k_0\phi$ large (or $R = \mathcal{O}(k_0^{-1/3})$, where R was defined just below (6.15)). Comparing (6.25) with (6.26) yields the initial conditions for A_0 and A_1,

$$A_0|_0 = \left(\frac{\mathrm{i}}{8\pi}\right)^{1/2}, \tag{6.27}$$

$$A_1|_0 = \left(\frac{\mathrm{i}}{8\pi}\right)^{1/2} \frac{9\beta_2(\partial_2 M)(x'_{1,2})}{16(\beta_1^2+\beta_3^2)^2}. \tag{6.28}$$

Thus the initial conditions for A_0 and A_1 are determined by matching the outer expansion to the inner solution on the overlapping region. It is only now that the outer solution is fully determined.

Uniform expansion. Finally, the uniform expansion is obtained by adding the outer solution ((6.1), (6.2), and (6.19)) to the inner solution ((6.1), (6.2), and (6.18)) and subtracting the matching terms on the overlapping region (equation (6.26)). However, in the inner region caustics will not have developed yet and, hence, there the noncaustic uniform asymptotic expansion of the previous section will apply.

Expansion in $z = \mathcal{O}(k_0^{-1})$. For use of the expansion of G in the kernels of the vertical slowness operator and the thin-slab propagator, we will have to make the assumption that the propagation distance satisfies

$$k_0 \underbrace{|x_3 - x'_3|}_{z} = \mathcal{O}(1). \tag{6.29}$$

Exploiting the small range of propagation to yield the thin-slab propagator, we expand

$$\phi = I_0 + \tfrac{1}{2}z^2 I_1 + \tfrac{1}{8}z^4 I_2 + \dots, \tag{6.30}$$

$$A_0 = A_{00} + z^2 A_{01} + \dots, \tag{6.31}$$

$$A_1 = A_{10} + \dots, \tag{6.32}$$

where I_0, I_1, I_2 and A_{00}, A_{01}, A_{10} are independent of z.

The phase function. Substituting the expansion for ϕ in (6.3) yields up to leading order

$$P^2 + \eta_2^2 - n^2(x'_1 + y_1, x'_2 - Q) = 0, \tag{6.33}$$

where $P = \partial_{y_1} I_0$ and $Q = \partial_{\eta_2} I_0$. The associated Hamilton system, i.e., the counterpart of (6.4) with the preferred (principal) components removed, becomes

$$\begin{aligned} &\frac{\mathrm{d}y_1}{\mathrm{d}\mu} = P, && \frac{\mathrm{d}P}{\mathrm{d}\mu} = (\partial_1 M)(x'_1 + y_1, x'_2 - Q), \\ &\frac{\mathrm{d}\eta_2}{\mathrm{d}\mu} = (\partial_2 M)(x'_1 + y_1, x'_2 - Q), && \frac{\mathrm{d}Q}{\mathrm{d}\mu} = -\eta_2, \end{aligned} \tag{6.34}$$

supplemented by the initial conditions (cf. (6.5))

$$(y_1, \eta_2)|_0 = (0, \alpha_2), \quad (P, Q)|_0 = (\alpha_1, 0), \quad \alpha_1^2 + \alpha_2^2 = n^2(x'_{1,2}). \tag{6.35}$$

The equation for the next order term follows as

$$\frac{\mathrm{d}I_1}{\mathrm{d}\mu} + I_1^2 = 0 \tag{6.36}$$

with solution

$$I_1 = \frac{1}{\mu}. \tag{6.37}$$

(The initial condition has been matched with the inner solution.)

The equation for I_2 follows as

$$\frac{\mathrm{d}I_2}{\mathrm{d}\mu} + 4I_2I_1 + (\partial_{y_1}I_1)^2 - (\partial_2^2M)(x_1' + y_1, x_2' - Q)(\partial_{\eta_2}I_1)^2 = 0. \tag{6.38}$$

This equation simplifies from a computational point of view upon scaling $I_2 = \mu^{-4}\bar{I}_2$; then

$$\frac{\mathrm{d}\bar{I}_2}{\mathrm{d}\mu} + [(\partial_{y_1}I_1)^2 - (\partial_2^2M)(x_1' + y_1, x_2' - Q)(\partial_{\eta_2}I_1)^2]\mu^4 = 0, \tag{6.39}$$

supplemented by the initial condition

$$\bar{I}_2|_0 = 0. \tag{6.40}$$

We evaluate the solutions to the Hamilton (equation (6.34)) and eikonal (equation (6.33)) equations for small values of μ. The parametric representation of the Hamiltonian flow follows as (compare with (6.10))

$$\begin{aligned} y_1 &= \alpha_1\mu + \tfrac{1}{2}(\partial_1M)\,\mu^2 + \ldots, & P &= \alpha_1 + (\partial_1M)\,\mu + \ldots, \\ \eta_2 &= \alpha_2 + (\partial_2M)\,\mu + \ldots, & Q &= -\alpha_2\mu - \tfrac{1}{2}(\partial_2M)\,\mu^2 + \ldots, \end{aligned} \tag{6.41}$$

while the leading-order constituent phase function is found to be (compare with (6.11))

$$I_0 = \alpha_1^2\mu + [\alpha_1(\partial_1M) - \tfrac{1}{2}\alpha_2(\partial_2M)]\,\mu^2 + \ldots, \tag{6.42}$$

in which the substitution $(\partial_{1,2}M) = (\partial_{1,2}M)(x_{1,2}')$ is understood.

Solving system (6.41) subject to the constraint in (6.35) for μ, α_1, α_2 in terms of y_1, η_2 yields

$$\mu = (|y_1|/\gamma)[1 - \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1M) + \eta_2|y_1|(\partial_2M)) + \ldots], \tag{6.43}$$

$$\alpha_1 = (\gamma/|y_1|)[y_1 + \gamma^{-3}\eta_2y_1^2(\partial_2M) + \ldots], \tag{6.44}$$

$$\alpha_2 = \eta_2 - (|y_1|/\gamma)(\partial_2M) + \ldots, \tag{6.45}$$

in which $\gamma = [n^2(x_{1,2}') - \eta_2^2]^{1/2}$ as before. Substituting these solutions into (6.42) then yields (compare with (6.17))

$$I_0 = \gamma|y_1|[1 + \gamma^{-3}(\tfrac{1}{2}\gamma y_1(\partial_1M) + \tfrac{1}{2}\eta_2|y_1|(\partial_2M)) + \ldots]. \tag{6.46}$$

Amplitude expansion. Upon substituting (6.30)–(6.32) into (6.20)–(6.21), and collecting leading-order terms, the equations for A_{00} and A_{10} follow as

$$\widetilde{L}A_{00} = 0, \tag{6.47}$$

$$\widetilde{L}A_{10} + 2A_{01} - \frac{3}{4}\frac{Q}{I_0^2}(\partial_2M)(x_1' + y_1, x_2' - Q)\,A_{00} - \widetilde{D}A_{00} = 0, \tag{6.48}$$

where

$$\widetilde{L}A = 2\frac{\mathrm{d}A}{\mathrm{d}\mu} + \Bigg[I_0\,\partial_{y_1}^2 \log I_0 + I_1 - \frac{Q}{I_0}(\partial_2 M)(x_1' + y_1, x_2' - Q) - (\partial_{\eta_2} Q)(\partial_2^2 M)(x_1' + y_1, x_2' - Q) \Bigg] A, \tag{6.49}$$

$$\begin{aligned}\widetilde{D}A = {} & -\partial_{y_1}^2 A - \frac{1}{I_0}(\partial_2 M)(x_1' + y_1, x_2' - Q)\,\partial_{\eta_2} A \\ & + I_0^{1/2} \Bigg[(\partial_2^2 M)(x_1' + y_1, x_2' - Q) \left(\partial_{\eta_2}^2 + \frac{\partial_{\eta_2} Q}{2I_0} \right) \\ & - (\partial_2^3 M)(x_1' + y_1, x_2' - Q)((\partial_{\eta_2} Q)\partial_{\eta_2} + \tfrac{1}{3}(\partial_{\eta_2}^3 Q)) \\ & + \tfrac{1}{4}(\partial_2^4 M)(x_1' + y_1, x_2' - Q)\tfrac{1}{4}(\partial_{\eta_2} Q)^2 \Bigg] \left(\frac{A}{I_0^{1/2}} \right),\end{aligned} \tag{6.50}$$

supplemented with the initial conditions (compatible with (6.27)–(6.28))

$$A_{00}|_0 = \left(\frac{\mathrm{i}}{8\pi} \right)^{1/2}, \tag{6.51}$$

$$A_{10}|_0 = \left(\frac{\mathrm{i}}{8\pi} \right)^{1/2} \frac{9\beta_2 (\partial_2 M)(x_{1,2}')}{16(\beta_1^2 + \beta_3^2)^2}. \tag{6.52}$$

The next order equation, for A_{01}, yields (cf. (6.20))

$$\widetilde{L}A_{01} + 4I_1 A_{01} + \widetilde{L}_1 A_{00} = 0, \tag{6.53}$$

where

$$\begin{aligned}\widetilde{L}_1 A = {} & (\partial_{y_1} I_1)(\partial_{y_1} A) - (\partial_{\eta_2} I_1)(\partial_2^2 M)(x_1' + y_1, x_2' - Q)(\partial_{\eta_2} A) \\ & + \tfrac{1}{2} \left((\partial_{y_1}^2 I_1) - \frac{2P(\partial_{y_1} I_1)}{I_0} + \frac{P^2 I_1}{I_0^2} + 3I_2 - \frac{2I_1^2}{I_0} \right) A \\ & + \Bigg[\left(\frac{QI_1}{I_0^2} - \frac{(\partial_{\eta_2} I_1)}{I_0} \right) (\partial_2 M)(x_1' + y_1, x_2' - Q) \\ & + \left(\frac{Q(\partial_{\eta_2} I_1)}{I_0} - (\partial_{\eta_2}^2 I_1) \right) (\partial_2^2 M)(x_1' + y_1, x_2' - Q) \\ & + (\partial_{\eta_2} I_1)(\partial_{\eta_2} Q)(\partial_2^3 M)(x_1' + y_1, x_2' - Q) \Bigg] A.\end{aligned} \tag{6.54}$$

This equation simplifies from a computational point of view upon scaling $A_{01} = \mu^{-2} \bar{A}_{01}$; then

$$\widetilde{L}\bar{A}_{01} + \mu^2 \widetilde{L}_1 A_{00} = 0 \tag{6.55}$$

with the initial condition $\bar{A}_{01}|_0 = 0$.

We remark that the inhomogeneous term in (6.55) is continuous at the "source" $(x_{1,2}')$ and

$$A_{01} \to -\frac{3\alpha_2 (\partial_2 M)(x_{1,2}')}{8\alpha_1^4 \mu} A_{00}|_0 \quad \text{as} \quad \mu \to 0,$$

TABLE 6.1
Relevant equations.

I_0	I_1	I_2	A_{00}	A_{10}	A_{01}
(6.33)	(6.37)	(6.39)	(6.47)	(6.48)	(6.55)

cf. (6.41) for Q and (6.42) for I_0. The inhomogeneous term in (6.48) is continuous at the "source" $(x'_{1,2})$ since

$$-\frac{3}{4}\frac{Q}{I_0^2}(\partial_2 M)(x'_1+y_1,x'_2-Q)\to\frac{3}{4}\frac{\alpha_2(\partial_2 M)(x'_{1,2})}{\alpha_1^4\mu}\qquad\text{as}\qquad\mu\to 0.$$

Effective index of refraction and effective metric. Again, we introduce an *effective* index of refraction and *effective* horizontal distance as

$$\nu\equiv[I_0I_1]^{1/2}, \tag{6.56}$$

$$\chi_1\equiv\left[\frac{I_0}{I_1}\right]^{1/2}, \tag{6.57}$$

where the arguments are evaluated along the characteristics, whereas

$$r=[\chi_1^2+z^2]^{1/2}. \tag{6.58}$$

Then

$$\begin{aligned}G(x_{1,2},x_3-x'_3;x'_{1,2})&\\ =\frac{k_0}{2\pi}\int_{\mathbb{R}}\frac{1}{(k_0\nu r)^{1/2}}\exp[\mathrm{i}k_0(\nu r+\eta_2y_2)]&\left\{A_{00}+\frac{1}{\mathrm{i}k_0}\left(\frac{A_{00}}{8\nu r}+A_{10}\right)+\dots\right\}\mathrm{d}\eta_2,\end{aligned} \tag{6.59}$$

cf. (6.1), (6.2), (6.19), which represents the outer solution. The equations to be evaluated or solved are listed in Table 6.1.

7. Uniform asymptotic expansions of the vertical slowness operator and the one-way wave propagator.

The square-root operator kernel. Using (4.8), upon carrying out repeated differentiation, we arrive at the uniform asymptotic expansion of the square-root operator kernel,

$$\begin{aligned}\mathcal{C}(x_{1,2},x'_{1,2};x'_3)=\frac{\mathrm{i}}{2\pi\omega\chi_1^3}\exp(\mathrm{i}k_0\nu\chi_1)\exp(\psi_{10})&\\ \left\{(\mathrm{i}k_0\nu\chi_1+2\psi_{10})\left(1+\frac{1}{\mathrm{i}k_0\nu\chi_1}\left(\frac{3}{8}\left(1-\frac{\nu^3I_2}{\chi_1}\right)+\nu(\nu\psi_{11}+\chi_1\psi_{20})\right)\right)&\right.\\ \left.-\frac{1}{2}\left(1+\frac{\nu^3I_2}{\chi_1}\right)+\dots\right\},&\end{aligned} \tag{7.1}$$

in the absence of caustics, and the outer expansion,

$$\begin{aligned}\mathcal{C}(x_{1,2},x'_{1,2};x'_3)=\frac{\mathrm{i}k_0}{\omega\pi}\int_{\mathbb{R}}\exp[\mathrm{i}k_0(\nu\chi_1+\eta_2y_2)]&\\ \left\{\frac{1}{(\nu\chi_1)^{1/2}\chi_1^2}\left(\left(\mathrm{i}k_0\nu\chi_1-\frac{3}{8}\right)A_{00}+2\chi_1^2A_{01}+\nu\chi_1A_{10}+\dots\right)\right\}\mathrm{d}\eta_2,&\end{aligned} \tag{7.2}$$

in the presence of a caustic, to the order considered.

The propagator kernel. Using (4.2), we arrive at the uniform asymptotic expansion of the one-way propagator kernel,

$$\begin{aligned}(7.3)\quad &\mathcal{G}(x_{1,2}, x_3 - x_3'; x_{1,2}') \\ &= -2(x_3 - x_3')\left\{ \left(\frac{\mathrm{i}k_0\nu}{r} + \frac{2\psi_{10}}{\chi_1^2}\right) G(x_{1,2}, x_3 - x_3'; x_{1,2}') \right. \\ &\quad -\frac{1}{4\pi r^3}\exp(\mathrm{i}k_0\nu r)\exp\left(\frac{\psi_{10}r^2}{\chi_1^2}\right) \\ &\qquad \left.\left[-1 + \frac{1}{8\chi_1^2 r^2}\left(1 - \frac{\nu^3 I_2}{\chi_1}\right)(4\chi_1^4 + (x_3 - x_3')^2(r^2 + \chi_1^2))\right] + \dots \right\}\end{aligned}$$

in the absence of caustics, and the outer expansion,

$$\begin{aligned}(7.4)\quad &\mathcal{G}(x_{1,2}, x_3 - x_3'; x_{1,2}') = -\frac{k_0}{\pi}\int_{\mathbb{R}} \frac{(x_3 - x_3')}{r^2(k_0\nu r)^{1/2}} \\ &\qquad \exp[\mathrm{i}k_0(\nu r + \eta_2 y_2)]\left\{\left(\mathrm{i}k_0\nu r - \frac{3}{8}\right)A_{00} + \nu r A_{10} + 2r^2 A_{01} + \dots\right\}\mathrm{d}\eta_2,\end{aligned}$$

in the presence of a caustic, to the order considered. In both cases, we observe that

$$\lim_{x_3 \downarrow x_3'} \mathcal{G}(x_{1,2}, x_3 - x_3'; x_{1,2}') = \delta(x_{1,2} - x_{1,2}'),$$

as it should.

8. Discussion. One of the main objectives of directional wave field decomposition is the introduction of the concept of "tracing waves." A general theory for this, employing the complete generalized Bremmer coupling series, has been developed before. The application of the series, however, depends on solving an operator composition equation, the characteristic equation, and an associated one-way wave equation. In this paper, in smoothly varying media, we have obtained uniform asymptotic expansions for both solutions valid in the "high- and mid-frequency" wave regime.

The method of uniform asymptotics consists of three components: (i) the construction of a "far-field" or "outer" solution, representing an operator kernel away from its diagonal and obtained by microlocal techniques suppressing locally medium variations in the principal (here vertical) direction; (ii) the construction of a "near-field" or "inner" solution, representing the operator kernel near its diagonal and obtained mostly by Taylor-like expansions; (iii) matching the inner and outer solutions in a boundary layer to all orders considered.

The result is a one-way wave field representation that is truly more general than its microlocal counterpart. For example, the microlocal treatment of the one-way operator solutions to the characteristic equation would require cut-offs removing critical-angle scattering phenomena. Also, modal behavior is naturally included in our framework of uniform asymptotics. Conceptually, our theory is an intermediate between asymptotic-ray and full-wave theories in the sense that our theory is still asymptotic but valid in a much larger frequency band (see also Thomson [12]).

From a computational perspective, the uniform asymptotic one-way wave propagator falls into the category of propagators associated with the paraxial wave equation, the phase-screen or split-step Fourier approximation, the phase-shift-plus-interpolation

method, and so on. However, it does not suffer from any of the limitations of these approaches. A desirable feature of a closed-form solution as presented in this paper is its ease of use, in particular with a view to taking caustics into account. (In this context, for a comparison with a ray tracing approach, see Ziomek [13]).

Hidden in the uniform asymptotic expansions are certain aspects of homogenization: we have introduced an effective index of refraction and an effective metric, which follow from the actual medium variations and are evaluated by means of ray methods.

Throughout the paper, the configuration has been assumed to be three-dimensional. Previous two-dimensional results, obtained by more restrictive arguments, are recovered by assuming that $\partial_2 n \equiv 0$ and integrating the characteristic Green's function over y_2.

As a final remark, we indicate how variable density can be incorporated in the analysis. For details on how it affects the decomposition procedure, see de Hoop [1]. The key in the approach presented in this paper is the introduction of an effective wave speed, $c'^{-2}(x_{1,2},\omega) = c_0^{-2} n'^2(x_{1,2},\omega)$, with

$$n'^2(x_{1,2},\omega) = n^2(x_{1,2}) + c_0^2 \left[\frac{3[(D_1\rho)^2 + (D_2\rho)^2]}{4\rho^2} - \frac{(D_1^2 + D_2^2)\rho}{2\rho} \right], \quad \rho = \rho(x_1, x_2).$$

This change requires some straightforward adjustments of the asymptotic matching.

ANALYTICAL AND NUMERICAL INVESTIGATION OF THE RESOLVENT FOR PLANE COUETTE FLOW*

MATTIAS LIEFVENDAHL† AND GUNILLA KREISS†

Abstract. We present new bounds for the solution of the resolvent equation for plane Couette flow. Both analytic methods and computation, using the Chebyshev tau spectral method, are used. The emphasis is on determining the Reynolds number-dependence of the estimates. The main result is the introduction of a weighted norm, which leads to optimal asymptotic behavior of the resolvent for large Reynolds numbers.

Key words. hydrodynamical stability, resolvent estimate, threshold amplitude

1. Introduction.

Hydrodynamic stability of shear flows is a classic topic in applied mathematics with roots in the 19th century. We refer to the books [14], [1], [3], and [20] for an outline of the field and general background of this work.

In this paper we study plane Couette flow, i.e., flow of a viscous incompressible fluid between two moving planes. It is assumed that there is no pressure gradient, and so the stationary velocity profile is linear. The spectrum for Couette flow was thoroughly investigated in the period 1950–1970. We mention the papers [26], [5], and [7], which are concerned with bounds for the most unstable eigenvalues. These efforts culminated in a paper of Romanov [18], where it is shown that all eigenvalues λ satisfy $\operatorname{Re}\lambda \leq -\delta/R$ for some $\delta > 0$. Here R denotes the Reynolds number. In [18] the fact that the eigenvalues lie in the stable complex half-plane is combined with semigroup theory to prove the nonlinear stability of plane Couette flow for all Reynolds numbers. This is a rather special situation for shear flows; e.g., Poiseuille flow becomes unstable for $R > 5772$. This was shown in [23] and [19]. The accurate value of the critical Reynolds number was obtained in [15] with the same numerical method we use in this paper to study the norm of the resolvent.

Although plane Couette flow is stable to infinitesimal perturbations, it can be excited to turbulence by finite perturbations. There is a threshold value for the size of the perturbations. Below this value the perturbations decay to zero, and above the threshold the perturbation may lead to turbulence. The question of what the threshold value is and its dependence on the Reynolds number is the motivation for the present work. It has been known for a very long time that the threshold decreases with increasing Reynolds number. In the beginning of the 1990s the hypothesis that the threshold is proportional to $R^{-\beta}$ (for some $\beta > 0$) was starting to be investigated [25], [24]. Computations in [16] suggest a β-value of approximately 5/4. The asymptotic analysis of [2] suggests an approximate β-value of 1.

Another approach to this problem is found in [9], where a bound on the resolvent operator in the entire unstable half-plane is used to show nonlinear stability. The resolvent estimate depends on the Reynolds number. In [9] it is proven that Couette

*Received by the editors October 22, 2001; accepted for publication (in revised form) July 5, 2002; published electronically January 17, 2003.
http://www.siam.org/journals/siap/63-3/39675.html
†Department of Numerical Analysis and Computing Science, Royal Intitute of Technology, Stockholm S-100 44, Sweden (mli@nada.kth.se, gunillak@nada.kth.se).

flow is stable to perturbations of amplitude $\leq CR^{-21/4}$. Thus $21/4$ is an upper bound on the exponent β.

The proof in [9] is based on a resolvent estimate which is obtained by computation. In this paper, we analytically derive a resolvent estimate in a sector of the complex (s-)plane, which covers all but a bounded part of the unstable half-plane. In this estimate we include both the dependence on the Reynolds number and the complex number s. For the Fourier transformed resolvent equation we give an estimate in the entire unstable half-plane which holds for certain wave numbers. These results are not sufficient for stability investigations but should be seen as the start of more detailed investigations of the resolvent for Couette flow.

To obtain estimates directly applicable to nonlinear stability, we must resort to numerical methods. An important result of this paper is obtained in this way. The resolvent estimate of [9] is

$$\|\mathbf{u}\| \leq CR^2 \|\mathbf{f}\| . \tag{1.1}$$

Here $\mathbf{u}$ is the velocity field, $\mathbf{f}$ is the forcing, and we use the L^2-norm. It is well known that, with respect to this norm, the resolvent is increasingly nonnormal as R grows. This means that the eigenfunctions of the linear problem are increasingly nonorthogonal and that there exist initial perturbations such that the norm of the solution of the linear problem grows initially. The largest possible growth increases with R. By using a different norm, the normality properties of the resolvent and the orthogonality properties of the eigenfunctions change.

If the resolvent $\mathcal{R}$ is normal with respect to the inner product defining the norm, then with this norm

$$\|\mathcal{R}\|_N = \frac{1}{\operatorname{dist}(\Omega_U, \Sigma)}; \tag{1.2}$$

see [8, p. 277]. Here $\Omega_U = \{s \in \mathbb{C} : \operatorname{Re} s \geq 0\}$ is the unstable half-plane, and Σ is the spectrum. By considering the Fourier transformed eigenvalue problem with streamwise wavenumber equal to zero, it is easy to see that the eigenvalue bound of Romanov is sharp. Thus the right-hand side in (1.2) is proportional to R. If $\mathcal{R}$ is nonnormal, then its norm is larger.

In this paper we introduce new norms by weighting the different velocity components with R-dependent coefficients. We investigate several possibilities, and the best result is

$$\|\mathbf{u}\|_3 \leq CR \|\mathbf{f}\|_3 . \tag{1.3}$$

C denotes a generic constant. The norm with subscript 3 is introduced in section 2.2. We see that we gain a factor R in the right-hand side. By the above argument, this result is optimal in the sense that we can improve only the constant C; the exponent of R cannot be lower than one.

We obtain (1.3) by numerical computations in which we maximize the Fourier transformed resolvent over different wave numbers. The maximum occurs when the streamwise wave number equals zero, corresponding to disturbances without streamwise variations.

In [13], the inequality (1.3) is used to considerably improve the exponent $21/4$ for the threshold mentioned above. In the present paper we also investigate the weighting proposed in [9] and show that it does not lead to an improved exponent.

1.1. Outline of the paper. A definition of the continuous problem and definitions and notation for the various norms we will use are given in section 2.

Section 3 is devoted to the analytical resolvent estimate, which is given in Theorem 3.1. The well-known reformulation of the problem in terms of u_2 and η_2 (the normal component of the vorticity), instead of $\mathbf{u}$ and p, is presented in section 4. The equations are also Fourier transformed. In the same section we state an analytical estimate for the Fourier transformed problem, in Lemma 4.1. After this we turn to numerical methods, which are applied to the reformulated problem.

In section 5 we present results of computations of the different norms of the resolvent. The most important result is the optimal R-exponent in the resolvent estimate for the third modified norm (defined in section 2.2). For the discretization we use the Chebyshev spectral tau method developed in [15] for eigenvalue calculations. Our method is described in detail in [12]. In [17] computations of the norm of the resolvent (or equivalently the pseudospectra; see [17]) were performed for the Orr–Sommerfeld equation. There a Chebyshev spectral method developed in [6] was used. In [25] computation of the pseudospectra for the full Couette problem seems to have been made using the same method as in [17].

Some remarks on estimates of higher order space derivatives are stated in section 6.

2. Statement of the problem. Here we introduce the resolvent PDE. We also define the resolvent operator. (It is not obvious how to do this because of the special role of the pressure.) In section 2.2 we introduce notation for the norms we will use. These norms are constructed as a weighted combination of the norms of the components of the velocity field. The weights depend on the Reynolds number R.

2.1. The resolvent equation. We choose the coordinate system so that (nondimensionalized) Couette flow is given by

$$\mathbf{U} = \begin{pmatrix} x_2 \\ 0 \\ 0 \end{pmatrix} \tag{2.1}$$

in the domain

$$\Omega = \{\mathbf{x} \in \mathbb{R}^3 : -1 < x_2 < 1\}. \tag{2.2}$$

We use bold letters to denote vectors, and subscripts to identify the components, so x_2 is the second component of the vector $\mathbf{x}$.

The resolvent equation is derived by linearizing the Navier–Stokes equations at the flow (2.1) and then applying the Laplace transform. The result is

$$s\mathbf{u} + x_2 \frac{\partial \mathbf{u}}{\partial x_1} + \begin{pmatrix} u_2 \\ 0 \\ 0 \end{pmatrix} + \mathbf{grad}\, p = \frac{1}{R}\Delta \mathbf{u} + \mathbf{f}, \tag{2.3}$$

$$\operatorname{div} \mathbf{u} = 0,$$

with boundary conditions

$$\mathbf{u} = 0, \qquad \mathbf{x} \in \partial\Omega. \tag{2.4}$$

For this problem we are interested in the mapping of $\mathbf{f}$ to $\mathbf{u}$. This function is defined when the problem is uniquely solvable for $\mathbf{u}$. We introduce the notation

$$\mathcal{R}(s) : L^2(\Omega)^3 \to L^2(\Omega)^3, \qquad \mathcal{R}(s) : \mathbf{f} \to \mathbf{u}, \tag{2.5}$$

and call $\mathcal{R}$ the resolvent operator. According to the result in [18], $\mathcal{R}$ is well defined when $\operatorname{Re} s \geq -\delta/R$ for some $\delta > 0$. This means that all eigenvalues for Couette flow correspond to stable modes and have real part less than $-\delta/R$. The focus in this paper is on deriving bounds on the norm of $\mathcal{R}$ in the right half-plane ($\operatorname{Re} s \geq 0$) and tracking the R-dependence of these bounds.

The pressure has a special role in (2.3). It is not uniquely determined, but this is no problem from our point of view. See [11] and [27] for more information on the properties of the pressure. In [27, p. 68] a resolvent estimate, including the pressure, is given in Theorem 6.1. (For that result to hold, an additional condition on the pressure must of course be added to determine it uniquely.)

It suffices to study (2.3) with $\mathbf{f} \in C_0^\infty(\Omega)^3$ such that $\operatorname{div} \mathbf{f} = 0$. Less regular forcing can be treated by the standard closure argument for densely defined continuous operators, once the appropriate estimate has been derived in the smooth case. A forcing which is not solenoidal will be corrected by the pressure so that only the solenoidal part affects the velocity field [27].

2.2. Weighted norms. All norms used in this article are defined by inner products. The L^2-inner product for scalar functions has the following definition and notation:

$$(u, v) = \int_\Omega \overline{u}(x) v(x) dx, \qquad u, v \in L^2(\Omega).$$

We denote the complex conjugate of a function u by $\overline{u}$. For the L^2-inner product of vector functions we have the same notation:

$$(\mathbf{u}, \mathbf{v}) = \sum_{k=1}^{3} (u_k, v_k), \qquad \mathbf{u}, \mathbf{v} \in L^2(\Omega)^3.$$

Which of the above two inner products we have in mind will be clear from the arguments.

In this paper we will also consider norms with R-dependent weights of the components of $\mathbf{u}$. We define the following three modified norms:

$$\|\mathbf{u}\|_1^2 = \|u_1\|^2 + R^2 \|u_2\|^2 + R^2 \|u_3\|^2, \tag{2.6}$$

$$\|\mathbf{u}\|_2^2 = \|u_1\|^2 + R \|u_2\|^2 + \|u_3\|^2, \tag{2.7}$$

$$\|\mathbf{u}\|_3^2 = \|u_1\|^2 + R^2 \|u_2\|^2 + \|u_3\|^2. \tag{2.8}$$

We emphasize that subscripts on norms are always used to identify the different modified norms. The subscripts do NOT indicate p in the L_p-norms.

The modified norm (2.6) was suggested in [9], where it was conjectured that it leads to a more favorable dependence of the Reynolds number in the resolvent estimate. This turns out to be false, as we show in section 5. The two norms with subscripts 2 and 3, respectively, which only weight the second component of the velocity, turn out to be more suited for this purpose; see section 5.

3. The analytical estimate. Here we derive a resolvent estimate in a sector of the complex plane. The result is similar to that of [27, Chapter 1, section 5], the differences being that we track the Reynolds number-dependence of the estimate, we treat a specific flow and domain so that we can give the numerical value of all constants, and finally the domain in our case is unbounded; the result in [27] holds

for bounded domains. To simplify the presentation, we treat only the case $R \geq 1$. In the application to hydrodynamic stability we are interested in the behavior for large Reynolds numbers. When $R < 1$ we have a very viscous fluid. That simple situation is covered by a general and classical result of Serrin [21]; see also [20, section 5.6].

To derive our a priori estimate, we assume that $\mathbf{u}$, p is a smooth solution of (2.3). The estimate we derive will immediately imply uniqueness for the velocity field; the existence of a solution is established by standard methods [11], [22]. Now we scalar multiply the resolvent equation (2.3) with $\overline{\mathbf{u}}$ and integrate over Ω; this leads to

$$s\|\mathbf{u}\|^2 + \left(\mathbf{u}, x_2 \frac{\partial \mathbf{u}}{\partial x_1}\right) + (u_1, u_2) + (\mathbf{u}, \mathbf{grad}\, p) = \frac{1}{R}(\mathbf{u}, \Delta \mathbf{u}) + (\mathbf{u}, \mathbf{f}). \tag{3.1}$$

To simplify this equation, we use the following identities (easily derived by partial integration using the fact that $\mathbf{u} = 0$ on the boundary):

$$(\mathbf{u}, \mathbf{grad}\, p) = -(\operatorname{div} \mathbf{u}, p), \tag{3.2}$$

$$(\mathbf{u}, \Delta \mathbf{u}) = -\sum_{k=1}^{3} \left\| \frac{\partial \mathbf{u}}{\partial x_k} \right\|^2, \tag{3.3}$$

$$\operatorname{Re}\left(\mathbf{u}, x_2 \frac{\partial \mathbf{u}}{\partial x_1}\right) = 0. \tag{3.4}$$

In (3.2) we can use the fact that the velocity field is solenoidal, and thus the pressure disappears from (3.1). This simplification is unique for the L^2-norm.

We use (3.2)–(3.4) in (3.1) and take the real and imaginary parts of the resulting expression. After some rearrangement, we obtain

$$\operatorname{Re} s\|\mathbf{u}\|^2 + \frac{1}{R}\sum_{k=1}^{3} \left\| \frac{\partial \mathbf{u}}{\partial x_k} \right\|^2 = \operatorname{Re}\left[(\mathbf{u}, \mathbf{f}) - (u_1, u_2)\right], \tag{3.5}$$

$$\operatorname{Im} s\|\mathbf{u}\|^2 + \operatorname{Im}\left(\mathbf{u}, x_2 \frac{\partial \mathbf{u}}{\partial x_1}\right) = \operatorname{Im}\left[(\mathbf{u}, \mathbf{f}) - (u_1, u_2)\right]. \tag{3.6}$$

Using these two equations, we will derive the resolvent estimate of Theorem 3.1. Before we state the theorem, we define the following two sectors in the complex plane:

$$\Sigma_R = \left\{ s \in \mathbb{C} : \operatorname{Re} s - 3 + \frac{1}{2R}|\operatorname{Im} s| \geq 0 \right\},$$
$$\Sigma_0 = \{ s \in \mathbb{C} : \operatorname{Re} s - 3 - |\operatorname{Im} s| \geq 0 \}.$$

The sectors are plotted in Figure 3.1.

THEOREM 3.1. *If $s \in \Sigma_R$, then the solution of the resolvent equation satisfies*

$$\|\mathbf{u}\| \leq \frac{4\sqrt{2}R}{|s-3|}\|\mathbf{f}\|. \tag{3.7}$$

If, furthermore, $s \in \Sigma_0$, then we have the R-independent estimate

$$\|\mathbf{u}\| \leq \frac{\sqrt{2}}{|s-3|}\|\mathbf{f}\|. \tag{3.8}$$

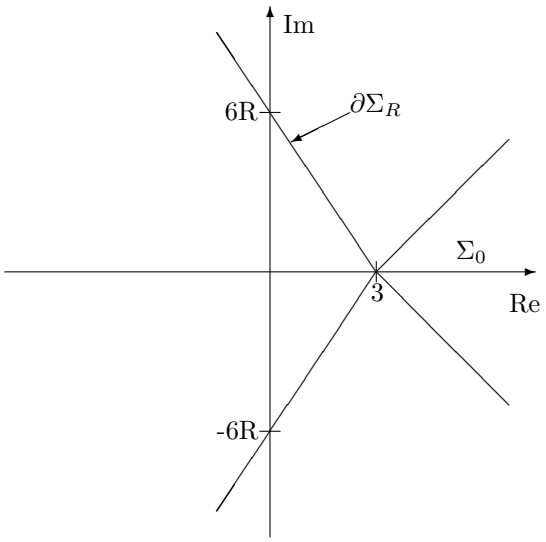

FIG. 3.1. *The sectors of the complex plane in which the estimates of Theorem* 3.1 *holds.*

Proof. Application of the Cauchy–Schwarz inequality and simple manipulations of (3.5) and (3.6) give the following inequalities:

$$(\operatorname{Re} s - 1)\,\|\mathbf{u}\|^2 + \frac{1}{R}\sum_{k=1}^{3}\left\|\frac{\partial \mathbf{u}}{\partial x_k}\right\|^2 \leq \|\mathbf{u}\|\,\|\mathbf{f}\|\,, \tag{3.9}$$

$$(|\operatorname{Im} s| - 1)\,\|\mathbf{u}\|^2 \leq \|\mathbf{u}\|\left\|\frac{\partial \mathbf{u}}{\partial x_1}\right\| + \|\mathbf{u}\|\,\|\mathbf{f}\|\,. \tag{3.10}$$

We first prove (3.8) and thus assume $s \in \Sigma_0$. We drop the derivative terms in (3.9) and cancel $\|\mathbf{u}\|$; this leads to

$$\|\mathbf{u}\| \leq \frac{1}{\operatorname{Re} s - 1}\,\|\mathbf{f}\|\,.$$

The following inequalities hold for $s \in \Sigma_0$:

$$\frac{1}{\operatorname{Re} s - 1} \leq \frac{1}{\operatorname{Re} s - 3} \leq \frac{\sqrt{2}}{|s-3|}.$$

We have now proven (3.8).

We now use the inequality $ab \leq a^2/4 + b^2$ on the first term in the right-hand side of (3.10). After some rearrangement, we obtain

$$\left(|\operatorname{Im} s| - \frac{5}{4}\right)\|\mathbf{u}\|^2 - \left\|\frac{\partial \mathbf{u}}{\partial x_1}\right\|^2 \leq \|\mathbf{u}\|\,\|\mathbf{f}\|\,.$$

We divide this inequality by R and add it to (3.9). This gives

$$\left(\operatorname{Re} s - 1 + \frac{1}{R}|\operatorname{Im} s| - \frac{5}{4R}\right)\|\mathbf{u}\|^2 \leq \left(1 + \frac{1}{R}\right)\|\mathbf{u}\|\,\|\mathbf{f}\|\,.$$

We use the fact that $R \geq 1$ and cancel $\|\mathbf{u}\|$. This leads to

$$\left(\operatorname{Re} s + \frac{1}{R}|\operatorname{Im} s| - \frac{9}{4}\right) \|\mathbf{u}\| \leq 2\,\|\mathbf{f}\|\,.$$

Using the defining inequality for Σ_R, we get

$$\|\mathbf{u}\| \leq \frac{4R}{|\operatorname{Im} s|}\,\|\mathbf{f}\|\,.$$

For $s \in \Sigma_R \setminus \Sigma_0$ we have

$$\frac{1}{|\operatorname{Im} s|} \leq \frac{\sqrt{2}}{|s-3|}.$$

This concludes the proof of (3.7) in $\Sigma_R \setminus \Sigma_0$. Since (3.8) implies (3.7) in Σ_0, the theorem is proven.

Remark. For the modified norms one cannot, in analogy with the above, take the modified inner product of $\mathbf{u}$ with the resolvent equation. The reason for this is that the pressure then is not eliminated. If one instead uses the above manipulations and the equivalence of norms,

$$c(R)\,\|\mathbf{u}\| \leq \|\mathbf{u}\|_X \leq C(R)\,\|\mathbf{u}\| \qquad (X = 1, 2 \text{ or } 3),$$

then a resolvent estimate is obtained in the same regions as in the theorem above. Now, however, the constant in the inequality will, asymptotically for large R, grow faster than in the case of the L^2-norm.

4. Transformation of the problem. The original problem (2.3) is an elliptic system coupled with the divergence "constraint." This is a PDE system with a very special structure. We shall instead consider the useful and well-known reformulation of the problem to one fourth order equation for the normal velocity u_2 and a second order equation for the normal vorticity. See [3] and [20]. Since the coefficients in the PDE do not depend on the x_1- and x_3-coordinates, the problem can be Fourier transformed in these variables. The Fourier transformed equation for the normal velocity is called the Orr–Sommerfeld equation. Following [20], we refer to the Fourier transformed equation for the normal vorticity as the Squire equation. We will also give an analytical estimate for the solution of the transformed problem in Lemma 4.1.

Let $\boldsymbol{\eta} = \mathbf{curl}\,\mathbf{u}$ and $\mathbf{g} = \mathbf{curl}\,\mathbf{f}$. The reduced and transformed system is

$$\begin{pmatrix} L_{OS} & 0 \\ -i\xi_3 & L_{SQ} \end{pmatrix} \begin{pmatrix} \hat{u}_2 \\ \hat{\eta}_2 \end{pmatrix} - s \begin{pmatrix} \hat{\Delta} & 0 \\ 0 & 1 \end{pmatrix} \begin{pmatrix} \hat{u}_2 \\ \hat{\eta}_2 \end{pmatrix} = \begin{pmatrix} -\hat{\Delta}\hat{f}_2 \\ -\hat{g}_2 \end{pmatrix}. \tag{4.1}$$

Here we have introduced the differential operators

$$\begin{aligned} \hat{\Delta} &= \frac{\partial^2}{\partial x_2^2} - k^2, \\ L_{OS} &= \frac{1}{R}\hat{\Delta}^2 - i\xi_1 x_2 \hat{\Delta}, \\ L_{SQ} &= \frac{1}{R}\hat{\Delta} - i\xi_1 x_2 \end{aligned}$$

and the notation $k^2 = \xi_1^2 + \xi_3^2$, where ξ_1 and ξ_3 are the wave numbers in the x_1 and x_3 directions, respectively. The system (4.1) is supplemented with the boundary conditions

$$\hat{u}_2 = \hat{u}_2' = \hat{\eta}_2 = 0, \qquad x_2 = \pm 1. \tag{4.2}$$

The Fourier transforms of the remaining velocity components are given by

$$\hat{u}_1 = \frac{i\xi_1 \hat{u}_2' - i\xi_3 \hat{\eta}_2}{k^2}, \tag{4.3}$$

$$\hat{u}_3 = \frac{i\xi_3 \hat{u}_2' + i\xi_1 \hat{\eta}_2}{k^2}. \tag{4.4}$$

Considering ξ_1 and ξ_3 as parameters, the domain of the problem is $(-1, 1)$ instead of Ω. We will use the same notation for the L^2-norm in this case as in section 2.2. The domain we have in mind will be clear from the argument. For example, we have

$$\|\hat{\mathbf{u}}\|_1^2 = \int_{-1}^{1} \left(|\hat{u}_1|^2 + R^2 |\hat{u}_2|^2 + R^2 |\hat{u}_3|^2 \right) dx_2.$$

Using the expressions (4.3) and (4.4) for $\hat{u}_1$ and $\hat{u}_3$, we obtain for the Fourier transform of the velocity field

$$\|\hat{\mathbf{u}}\|^2 = \int_{-1}^{1} \left(|\hat{u}_2(x)|^2 + \frac{1}{k^2} |\hat{u}_2'(x)|^2 + \frac{1}{k^2} |\hat{\eta}_2(x)|^2 \right) dx. \tag{4.5}$$

This expression allows us to compute $\|\hat{\mathbf{u}}\|$ without explicitly determining $\hat{u}_1$ and $\hat{u}_3$.

From (4.1) we can derive estimates directly, for some parameter values, using only integration by parts, $\operatorname{div} \mathbf{f} = 0$, and the following Poincaré inequality:

$$\|\hat{\mathbf{u}}\| \leq 4 \|\hat{\mathbf{u}}'\|.$$

These estimates are collected in the following lemma.

LEMMA 4.1. *There is a constant C, independent of ξ_1, ξ_3, R, and $\operatorname{Re} s \geq 0$, such that*

$$\|\hat{\eta}_2\|^2 \leq \frac{CR^2}{1 + k^2} \left(\|\hat{u}_2\|^2 + \|\hat{g}_2\|^2 \right).$$

If at least one of the inequalities $|\xi_1| R \leq |\xi_3|^3$, $|\xi_1| R \leq 1/128$, or $\xi_1^2 + \xi_3^2 \geq R$ hold, then we also have the estimate

$$(1 + k^2) \|\hat{u}_2'\|^2 + \|\hat{u}_2\|^2 \leq \frac{CR^2}{1 + k^4} \|\hat{f}_2\|^2,$$

and it follows that there are constants C_0, C_2, and C_3 such that

$$\begin{aligned} \|\hat{\mathbf{u}}\| &\leq C_0 R^2 |\mathbf{f}\|, \\ \|\hat{\mathbf{u}}\|_2 &\leq C_2 R^{\frac{3}{2}} |\mathbf{f}\|_2, \\ \|\hat{\mathbf{u}}\|_3 &\leq C_3 R \|\mathbf{f}\|_3. \end{aligned}$$

We do not give the straightforward proof of the inequalities in Lemma 4.1.

In analogy with (2.5), we introduce notation for the mapping

$$\hat{\mathcal{R}}(s,\xi_1,\xi_3) : L^2(-1,1)^3 \to L^2(-1,1)^3, \qquad \hat{\mathcal{R}}(s,\xi_1,\xi_3) : \hat{\mathbf{f}} \to \hat{\mathbf{u}}.$$

For the L^2-norm we now show that $\|\mathcal{R}(s)\|$ can be determined by maximizing

$$\|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\|$$

with respect to ξ_1 and ξ_3. For the modified norms this is also the case, and it is shown in a similar manner.

We need Plancherel's formula connecting the L^2-norm of the transformed function with that of the original unknown:

$$\|\mathbf{u}\|^2 = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \|\hat{\mathbf{u}}\|^2 \, d\xi_1 d\xi_3.$$

By definition, we have

$$\|\mathcal{R}(s)\|^2 = \sup_{\mathbf{f}\neq 0} \frac{\|\mathbf{u}\|^2}{\|\mathbf{f}\|^2}. \tag{4.6}$$

We also have

$$\|\hat{\mathbf{u}}\| = \|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\hat{\mathbf{f}}\| \le \left(\sup_{\xi_1,\xi_3} \|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\|\right) \|\hat{\mathbf{f}}\|. \tag{4.7}$$

Using (4.7) in Plancherel's formula and then (4.6), we obtain the inequality

$$\|\mathcal{R}(s)\| \le \sup_{\xi_1,\xi_3} \|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\|. \tag{4.8}$$

Now we will show that there is actually equality in (4.8). This is done by constructing a family of functions $\mathbf{f}_\epsilon$, with corresponding solutions $\mathbf{u}_\epsilon$, such that

$$\lim_{\epsilon\to 0} \frac{\|\mathbf{u}_\epsilon\|}{\|\mathbf{f}_\epsilon\|} = \sup_{\xi_1,\xi_3} \|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\|.$$

We denote by $\xi_1^{(0)}$ and $\xi_3^{(0)}$ the values for which the maximum of the norm occurs,[1] and by $\hat{\mathbf{f}}_0$ the corresponding forcing, and thus we have

$$\sup_{\xi_1,\xi_3} \|\hat{\mathcal{R}}(s,\xi_1,\xi_3)\| = \|\hat{\mathcal{R}}(s,\xi_1^{(0)},\xi_3^{(0)})\hat{\mathbf{f}}_0\|.$$

We will use a family of cut-off functions $\varphi_\epsilon \in C_0^\infty(\mathbb{R}^2)$ which satisfy

$$\begin{aligned} \varphi_\epsilon &\ge 0, \\ \int_{\mathbb{R}^2} \varphi_\epsilon^2 dx &= 1, \\ \varphi_\epsilon(\xi_1,\xi_3) &= 0 \qquad \text{if } (\xi_1-\xi_1^{(0)})^2 + (\xi_3-\xi_3^{(0)})^2 \ge \epsilon. \end{aligned}$$

[1] That the supremum is attained follows from the continuity and the decay for large $\xi_1^2+\xi_3^2$, which follow from the estimates of Lemma 4.1.

Now we take as our function $\mathbf{f}_\epsilon$ the inverse Fourier transform of

$$\hat{\mathbf{f}}_\epsilon(\xi_1, x_2, \xi_3) = \hat{\mathbf{f}}_0(x_2)\varphi_\epsilon(\xi_1, \xi_3).$$

We have the following:

$$\begin{aligned}&\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \|\hat{\mathbf{u}}_\epsilon(\cdot, \xi_1, \xi_3)\|^2 \, d\xi_1 d\xi_3 \\ &\quad = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \varphi_\epsilon^2 \|\hat{\mathcal{R}}(s, \xi_1, \xi_3)\hat{\mathbf{f}}_0\|^2 d\xi_1 d\xi_3 \to \|\mathcal{R}(s, \xi_1^{(0)}, \xi_3^{(0)})\hat{\mathbf{f}}_0\|^2\end{aligned}$$

when $\epsilon \to 0$. Using the definition of $\|\mathcal{R}\|$ and Plancherel's formula, we see that we can obtain $\|\mathcal{R}\|$ by maximizing $\|\hat{\mathcal{R}}\|$ over ξ_1 and ξ_3:

$$\|\mathcal{R}(s)\| = \max_{\xi_1, \xi_3} \|\hat{\mathcal{R}}(s, \xi_1, \xi_3)\|. \tag{4.9}$$

5. Numerical results. In this section we numerically determine C and γ in the expression

$$\sup_{\operatorname{Re} s \geq 0} \|\mathcal{R}(s)\| \approx CR^\gamma. \tag{5.1}$$

This is done for the four norms introduced in section 2.2. For this optimization we use (4.9) and maximize

$$\|\hat{\mathcal{R}}(s, \xi_1, \xi_3)\| \tag{5.2}$$

over $\operatorname{Re} s \geq 0$, $\xi_1 \geq 0$, $\xi_3 \geq 0$.

The numerical calculations of the resolvent norm are done by discretizing (4.1) and (4.2) with a spectral Chebyshev tau method. The method is based on the classical paper [15]. In [12] our method is described in detail.

Because of symmetry, it is sufficient to search the first quadrant of the ξ_1-ξ_3 plane. The resolvent cannot have a local maximum (in the resolvent set); this maximum principle is given in [4, p. 230]. The decay estimate of Theorem 3.1 in the sector Σ_R, combined with the maximum principle, implies that the maximization of $\|\hat{\mathcal{R}}(s, \xi_1, \xi_3)\|$ can be restricted to $\operatorname{Re} s = 0$. We thus have to maximize the function over three real variables. However, as was noted in [25] and [9] in the case of the L^2-norm, the maximum seems always to occur for $s = 0$. We believe that this is the case for all norms considered in this paper, and in section 5.1 we present results supporting this fact.

In sections 5.2 and 5.3 we determine the values of C and γ in (5.1) for all four different norms. For all the norms except $\|\cdot\|_1$ the maximum of (5.2) occurs where the second part of Lemma 4.1 is applicable. The exponents of R in the computed resolvents agree with the resolvent bounds in the lemma.

5.1. The maximum occurs for $s = 0$. In this section we present computational results supporting the assumption

$$\sup_{\operatorname{Re} s = 0, \xi_1, \xi_3} \|\hat{\mathcal{R}}(s, \xi_1, \xi_3)\| = \sup_{\xi_1, \xi_3} \|\hat{\mathcal{R}}(0, \xi_1, \xi_3)\|.$$

We have performed extensive computations. In Figure 5.1 we see typical results. For a fixed Reynolds number we have plotted $\|\hat{\mathcal{R}}\|_3$ as a function of σ when $s = i\sigma$ for

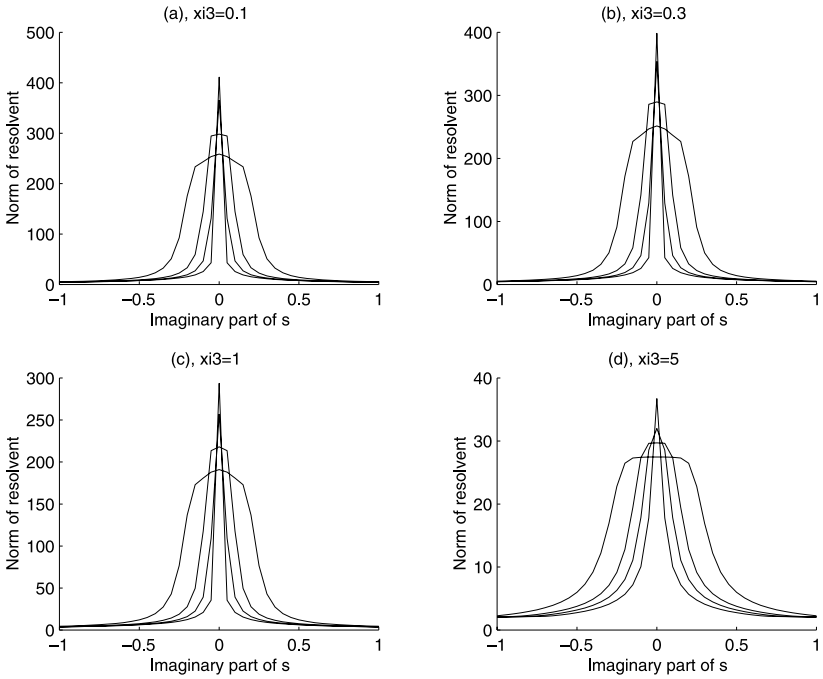

FIG. 5.1. *The value of* $\|\mathcal{R}(i\sigma, \hat{\xi}_1, \xi_3)\|_3$ *for* $R = 1000$. *For each plot,* ξ_3 *is fixed to the value shown above the plot. The four different curves in each plot correspond to* $\xi_1 = 0, 0.1, 0.2,$ *and* 0.4, *respectively. On the horizontal axis we have the imaginary part of* s *for* $\operatorname{Re} s = 0$. *All curves exhibit the typical behavior, with maximum at* $s = 0$. *The peak in plot* (a) *is near the global maximum; compare Table* 5.3.

some different values of ξ_1 and ξ_3. The third modified norm turns out to be the most interesting for our purposes; see section 5.3.

The corresponding computations for other Reynolds numbers and the other norms of this paper have been made with the same result: The maximum occurs for $s = 0$. The assumption is also supported by the fact that the peak at $s = 0$ is so sharp. Furthermore, only a small range of ξ_1 and ξ_3 give values of $\|\hat{\mathcal{R}}\|$ near the peak at $s = 0$; the norm decays quickly for other choices of ξ_1 and ξ_3.

5.2. The L^2- and first modified norms. For the standard norm, the following R-dependence was established in [9]:

$$\max_{\operatorname{Re} s \geq 0} \mathcal{R}(s) = 0.0152R^2. \tag{5.3}$$

From Table 5.1 we conclude that our computations yield the same result. In Figure 5.2 we show $\|\mathcal{R}(0, \hat{\xi}_1, \xi_3)\|$ as a function of ξ_1 and ξ_3. As was noted in [9], the maximum occurs for $\xi_1 = 0$, where the second part of Lemma 4.1 is applicable. Figure 5.2 can be compared with Figure 1 in [9]. There the resolvent, scaled by $k/(\xi_3 R^2)$, is plotted as a function of $\xi_1 R$ and k for $R = 500, 1000$. For a given R a simple change of variables connects $\xi_1 R$ and k to ξ_1 and ξ_3. Note that, along the vertical axis, where $\xi_1 = \xi_1 R = 0$, $k = \xi_3$. As expected, the contour lines of the two figures are very similar.

The object when constructing the modified norms is to find a norm where the normality of the problem does not degenerate as R increases. Such a norm would

TABLE 5.1

The norm of the resolvent for different Reynolds numbers in the L^2-norm and the first modified norm. The value of ξ_3 for which the maximum occurs is also given. The ξ_1-coordinate for the maximum is zero. The values are determined with three significant digits.

L^2-norm

R	ξ_3	$\|\mathcal{R}\|$
350	1.18	1860
1000	1.18	$1.52 \cdot 10^4$
3500	1.18	$1.86 \cdot 10^5$
10^4	1.18	$1.52 \cdot 10^6$

1st modified norm

R	ξ_3	$\|\mathcal{R}\|_1$
350	0	$2.45 \cdot 10^4$
1000	0	$2.00 \cdot 10^5$
3500	0	$2.45 \cdot 10^6$
10^4	0	$2.01 \cdot 10^7$

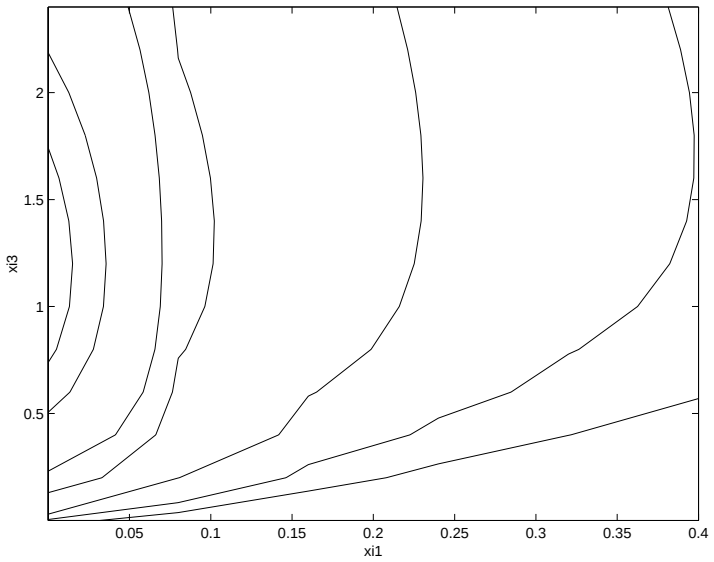

FIG. 5.2. *Contour plot of $\|\hat{\mathcal{R}}(0, \xi_1, \xi_3)\|$ (L^2-norm) for $R = 1000$. The contour lines represent values in the range 300 to 13000. The maximum occurs along the ξ_3-axis.*

yield a smaller exponent γ than in (5.3), where it is two. The first modified norm was suggested in [9] for this purpose. As we show below, however, the exponent is still two in this case.

In Table 5.1 we present $\|\hat{\mathcal{R}}\|_1$ for some values of the Reynolds number. From this table the values of C and γ in (5.3) can be reproduced by a least squares fit, and for the first modified norm we obtain

$$\|\mathcal{R}\|_1 = 0.198 R^{2.00}.$$

We see that the first modified norm gives the same exponent and a larger (worse) constant than the L^2-norm.

There are some difficulties in the investigation for the first modified norm. The maximum occurs for $\xi_1, \xi_3 \to 0$, as can be seen in Figure 5.3. Moreover, we get different limits depending on how we let ξ_1 and ξ_3 tend to zero. To find the maximum, we approach the origin along the ray $\xi_1 = \xi_3$. In Figure 5.4 we show the norm of $\hat{\mathcal{R}}$ on this ray. The peak is sharp, but it is clear that the limiting value is $2.00 \cdot 10^5$ (for $R = 1000$) as is shown in Table 5.1.

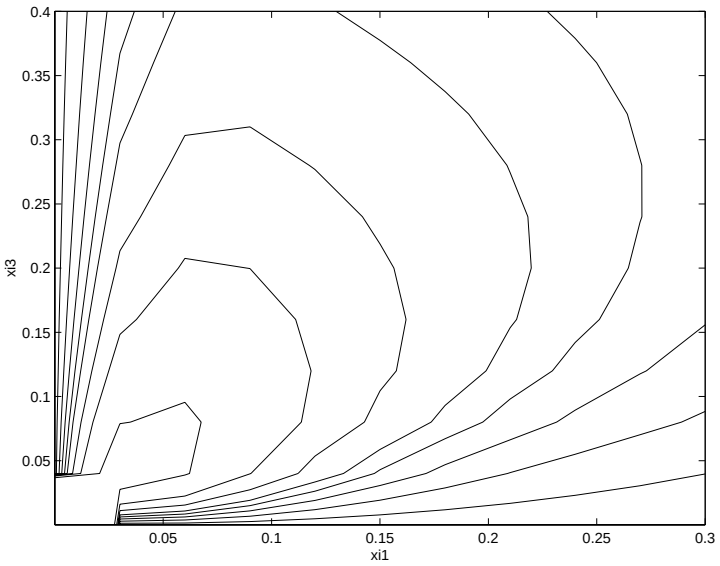

FIG. 5.3. *Contour plot of* $\|\hat{\mathcal{R}}(0,\xi_1,\xi_3)\|_1$ *for* $R = 1000$. *The contour lines represent values in the interval* $(1000, 17000)$. *The region around the origin (*$\xi_1 \leq 0.05$ *and* $\xi_3 \leq 0.05$*) is not resolved. A high peak is located around the origin; as shown in Table* 5.1, *the maximum is* $2 \cdot 10^5$. *See Figure* 5.4 *for the limiting behavior at the origin.*

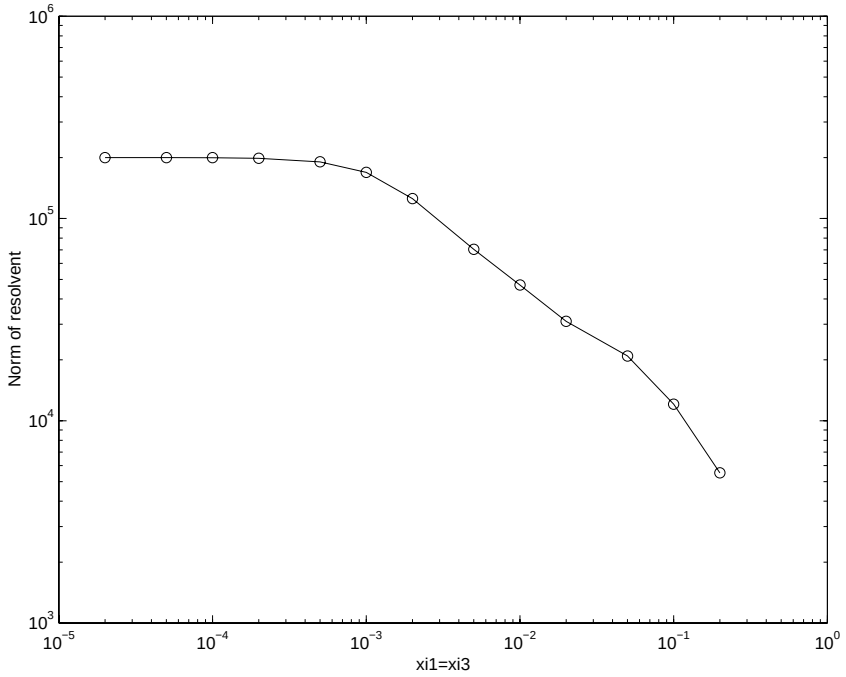

FIG. 5.4. *The values of* $\|\hat{\mathcal{R}}(0,\xi_1,\xi_3)\|_1$ *for* $\xi_1 = \xi_3$ *and* $R = 1000$. *In this logarithmic plot it is evident that the limiting value at* $\xi_1 = \xi_3 = 0$ *is* $2 \cdot 10^5$.

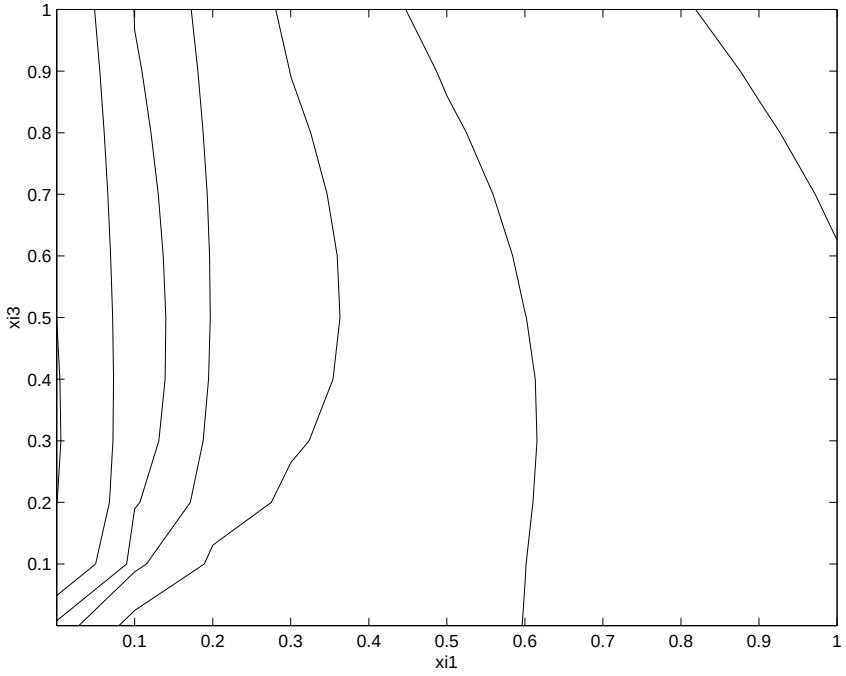

FIG. 5.5. *The values of* $\|\hat{\mathcal{R}}(0,\xi_1,\xi_3)\|_2$ *for* $R = 1000$ *in the* ξ_1*-*ξ_3 *plane. The contour lines represent values in the range* 150 *to* 2000*.*

5.3. The second and third modified norms. In this section we present our investigations of the second and third modified norms which achieve the goal and yield lower (better) exponents γ. In Figures 5.5 and 5.6 we see the plots in the ξ_1-ξ_3 plane for the second and third modified norms, respectively. In both cases the maximum occurs along the ξ_3 axis, where the second part of Lemma 4.1 is applicable. In Table 5.2 we list the values of $\|\mathcal{R}\|_2$ for different values of the Reynolds number. From this table we obtain

$$\|\mathcal{R}\|_2 = 0.056R^{1.52}.$$

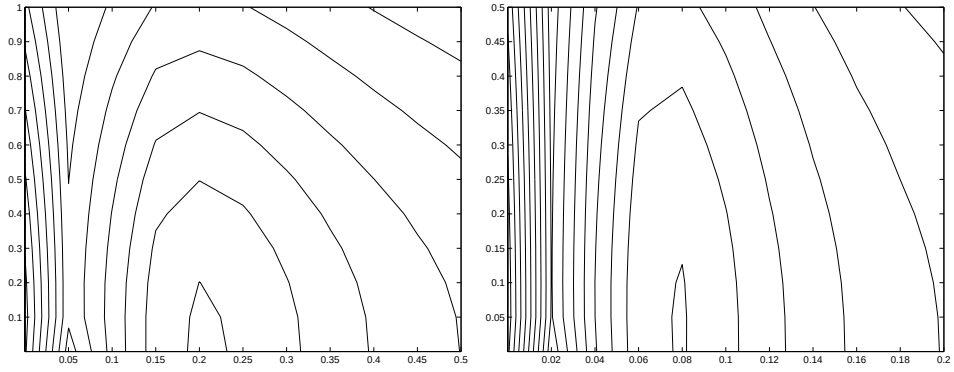

FIG. 5.6. *The values of* $\|\hat{\mathcal{R}}(0,\xi_1,\xi_3)\|_3$*. In the left panel we have* $R = 350$*, and in the right,* $R = 1000$*. The global maximum is along the* ξ_3 *(vertical) axis. Observe the local maximum on the* ξ_1*-axis. See Table* 5.3 *for location and values of the global and local maxima.*

TABLE 5.2

The norm of the resolvent for different Reynolds numbers for the second norm. The value of ξ_3 for which the maximum occurs is also given. The ξ_1-coordinate for the maximum is zero.

2nd modified norm

R	ξ_3	$\|\mathcal{R}\|_2$
350	0.40	420
1000	0.31	2080
3500	0.24	$1.41 \cdot 10^4$
10^4	0.18	$6.92 \cdot 10^4$

TABLE 5.3

The third modified norm. In the first table we have the norm of the resolvent for different Reynolds numbers. The maximum occurs for $\xi_1 = 0$. In the second table we have the local maxima which occur for $\xi_3 = 0$ and the ξ_1-values listed.

Global maxima

R	ξ_3	$\|\mathcal{R}\|_3$
350	0.046	145
1000	0.028	413
3500	0.016	1450
10000	0.009	4130

Local maxima

R	ξ_1	$\|\hat{\mathcal{R}}\|_3$

In Figure 5.6 we see that, in addition to the global maximum on the ξ_3 axis, there is a local maximum on the ξ_1 axis. In Table 5.3 we give the value and locations of the global and local maxima. For increasing Reynolds number both maxima move along the respective axes towards the origin. From the values in Table 5.3 we obtain

$$\|\mathcal{R}\|_3 = 0.413 R^{1.00}, \tag{5.4}$$

in agreement with Lemma 4.1. Note that here we have the optimal exponent $\gamma = 1.00$. The constant and the exponent in (5.4) are determined by a least squares fit of the model function CR^γ to the four values in Table 5.3. The agreement of the curve (5.4) with the computed values is very good.

6. Remarks on regularity. Using a resolvent estimate of the type (1.1) or (1.3), it is possible to derive an elliptic regularity estimate

$$\|\mathbf{u}\|_{H^2} \leq C(R) \|\mathbf{f}\| ,$$

which holds uniformly for $\operatorname{Re} s \geq 0$. Here we have the usual Sobolev H^2-norm in the left-hand side,

$$\|\mathbf{u}\|_{H^2}^2 \stackrel{def}{=} \sum_{|\alpha| \leq 2} \left\| \frac{\partial^\alpha \mathbf{u}}{\partial x^\alpha} \right\|^2 ,$$

where α denotes a multi-index. This will lead to a constant $C(R)$ which asymptotically grows faster than R^γ. Here $\gamma = 2$ for the L^2-norm, and $\gamma = 1$ for the third modified norm. More interesting from our point of view of nonlinear stability is to have an estimate of some second derivatives satisfying the following two criteria. First, the constant in the estimate should be proportional to R^γ. Second, via Sobolev inequalities, it should be possible to bound the supremum norm with the combination

of second and lower order derivatives. One possibility for doing this, used in [9], is

$$\|\mathbf{u}\|_{\tilde{H}}^2 \stackrel{def}{=} \|\mathbf{u}\|^2 + \frac{1}{R}\sum_{k=1}^{3}\left\|\frac{\partial \mathbf{u}}{\partial x_k}\right\|^2 + \frac{1}{R^2}\left(\left\|\frac{\partial^2 \mathbf{u}}{\partial x_1^2}\right\|^2 + \left\|\frac{\partial^2 \mathbf{u}}{\partial x_1 \partial x_2}\right\|^2 + \left\|\frac{\partial^2 \mathbf{u}}{\partial x_2 \partial x_3}\right\|^2 + \left\|\frac{\partial^2 \mathbf{u}}{\partial x_3^2}\right\|^2\right),$$

which bounds the supremum norm according to

$$\sup_{\mathbf{x}\in\Omega} |\mathbf{u}(\mathbf{x})| \leq C_s R^{3/4} \|\mathbf{u}\|_{\tilde{H}};$$

see [10, Appendix 3]. As is shown in [9], this norm also satisfies the first criterion above,

$$\|\mathbf{u}\|_{\tilde{H}} \leq C R^2 \|\mathbf{f}\|.$$

In [13] a variation of this approach is used for the third modified norm.

7. Conclusions. The analytical resolvent estimate of Theorem 3.1 exhibits the expected property, deteriorating as the Reynolds number increases. The sector in which it holds shrinks, and the constant grows. However, in the sector Σ_0, which does not depend on the Reynolds number, the estimate is independent of the Reynolds number.

The result of Theorem 3.1 does not cover the entire unstable half-plane; still, it is known that the resolvent is bounded there. To improve the estimate with analytical techniques, it may be fruitful to consider the reformulated problem of section 4. One such result is Lemma 4.1. It is the reformulated problem which is studied in the investigations of the spectrum referred to in the introduction. We believe, however, that deriving a completely analytical resolvent estimate in the entire unstable half-plane would be extremely complicated.

We therefore employ numerical methods, which yield the estimate implying stability, as was found in [9]. The main result of our computations is the optimal exponent 1.00 of the Reynolds number in (5.4). This is obtained by weighting the second component of the velocity field with a coefficient that depends on the Reynolds number. In [13] we use (5.4) to improve the theoretical bound on the perturbation threshold, as discussed in the introduction.

CONGESTION ON MULTILANE HIGHWAYS*

J. M. GREENBERG†, A. KLAR‡, AND M. RASCLE§

Abstract. We present a new model for traffic on a multilane freeway (with n lanes). Our basic descriptors are the car density ρ (in cars/mile), taken across all lanes in the freeway, and the average car velocity u (in miles/hour). The flux of cars across all lanes is given by $\rho u = \sum_{i=1}^{n} \rho_i u_i$, where ρ_i is the car density in the ith lane, and u_i the velocity of cars in the ith lane. We shall track only ρ and u and not what is going on in each individual lane.

On such multilane freeways, one often observes distinct stable equilibrium relationships between car velocity and density. Prototypical situations involve two equilibria,

$$v = v_1(\rho) > v = v_2(\rho), \quad 0 \le \rho < \rho_{\max},$$

where $v_1(\cdot)$ and $v_2(\cdot)$ are monotone decreasing and satisfy $v_1(\rho_{\max}) = v_2(\rho_{\max}) = 0$. The upper curve is typically stable for densities satisfying $0 \le \rho \le \rho_1$, whereas the lower curve is stable for densities satisfying $\rho_2 \le \rho \le \rho_{\max}$. Our interest is in the situation where $0 < \rho_2 \le \rho_1 < \rho_{\max}$ and $v_2(\rho_2) \le v_1(\rho_1)$.

In this paper we present a model that incorporates both equilibrium curves and a simple switching mechanism which allows cars to transit from one equilibrium curve to the other. This switching mechanism, when combined with the continuity equation, produces relaxation or self-excited oscillations in the system, and these oscillations are what interests us here.

Key words. microscopic and macroscopic traffic models, multiple equilibria, self-excited oscillations, travelling waves

1. Introduction. In this paper we present a new model for traffic on a multilane freeway with n lanes. Our basic descriptors are the car density ρ (in cars/mile), taken across all lanes in the freeway, and the average car velocity u (in miles/hour). The flux of cars across all lanes is given by $\rho u = \sum_{i=1}^{n} \rho_i u_i$, where ρ_i is the car density in the ith lane, and u_i the velocity of cars in the ith lane. We shall track only ρ and u and not what is going on in each individual lane. This model simplification will ultimately yield a one-dimensional model.

On such multilane freeways, one often observes distinct stable equilibrium relationships between auto velocity and density. Prototypical situations involve two equilibria,

$$v = v_1(\rho) > v = v_2(\rho), \quad 0 \le \rho < \rho_{\max}, \tag{1.1}$$

where $v_1(\cdot)$ and $v_2(\cdot)$ are monotone decreasing and satisfy $v_1(\rho_{\max}) = v_2(\rho_{\max}) = 0$. The upper curve is typically stable for densities satisfying $0 \le \rho \le \rho_1$, whereas the

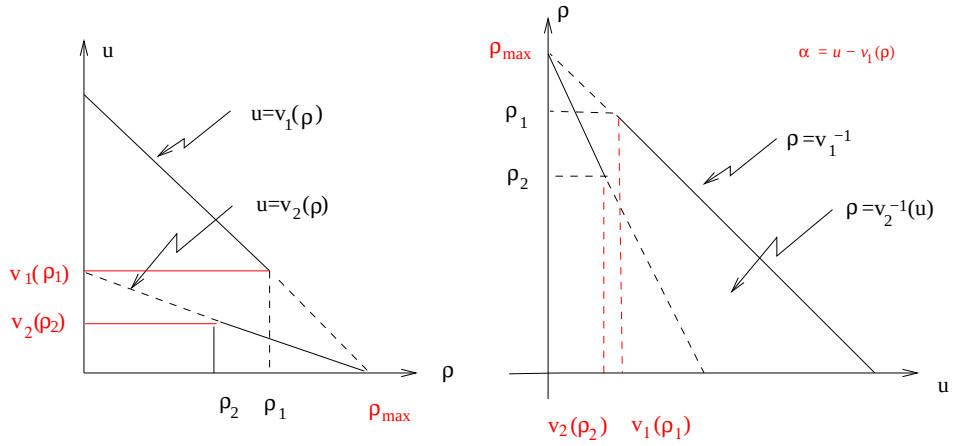

FIG. 1.1. *Two equilibrium curves $v_1(\rho)$ and $v_2(\rho)$.*

lower curve is stable for densities satisfying $\rho_2 \le \rho \le \rho_{\max}$. Our interest is in the situation where $0 < \rho_2 \le \rho_1 < \rho_{\max}$ and $v_2(\rho_2) \le v_1(\rho_1)$; see Figure 1.1.

The explanation for the two curves is quite simple. For high density congested traffic, lane changing and passing is difficult and dangerous, and this yields the slower equilibrium curve. On the other hand, when the traffic is less dense, lane changing and passing becomes easier, and this yields the faster equilibrium curve.

In this paper we present a model that incorporates both equilibrium curves and a simple switching mechanism which allows cars to transit from one equilibrium curve to the other.

Once again, our basic descriptors are the car density ρ and velocity u. We also track

$$\alpha = u - v_1(\rho),$$

which represents the discrepancy between the actual car speed and the uncongested equilibrium speed.

Our governing equations are

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho u) = 0 \tag{1.2}$$

and

$$\frac{\partial \alpha}{\partial t} + u\frac{\partial \alpha}{\partial x} = \begin{cases} \dfrac{-\alpha}{\epsilon}, & \rho < R(u), \\ \dfrac{((v_2 - v_1)(\rho) - \alpha)}{\epsilon}, & \rho \ge R(u). \end{cases} \tag{1.3}$$

Here, $u \to R(u)$ is a monotone nondecreasing function defined on $0 \le u$ and satisfying

$$R(u) = \rho_2, \qquad 0 \le u \le v_2(\rho_2), \qquad \text{and} \quad R(u) = \rho_1,\ v_1(\rho_1) \le u; \tag{1.4}$$

see Figure 1.2.

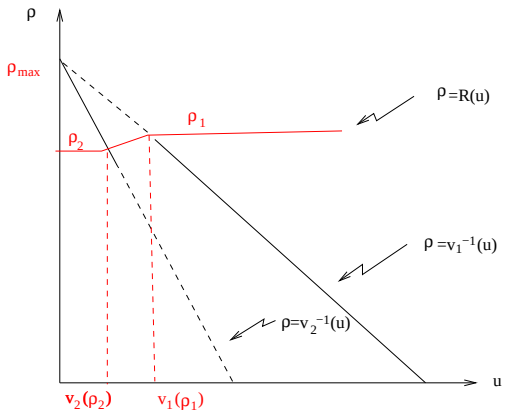

FIG. 1.2. *Switching curve* $R(u)$.

For experimental data and the choice of the switch curve, we refer to the work of Kerner [7, 8]. In his thesis, Sopasakis [9] gave an argument supporting the choice $\rho_2 = \rho_1$ and $R(u) \equiv \rho_2,\ 0 \le u$.

The motivation for system (1.2), (1.3) is as follows:

1. When there is no source term, i.e., the right-hand side of (1.3) is set to zero, our model is the one introduced in [3]. This model turns out to be the rigorous hydrodynamic limit of the microscopic follow-the-leader system (1.20)–(1.23) (see below) with no right-hand side; see [2] and also [10].
2. In the case with a source term of the form $-1/\epsilon(V(\rho) - u)$, the above result remains true; for details, see [6] and [2].
3. At least formally, the system we propose to study here is the limit of the microscopic system (1.23), when the size of cars goes to zero.

We note that (1.2) and (1.3) imply that u satisfies

$$\frac{\partial u}{\partial t} + (u + \rho v_1'(\rho))\frac{\partial u}{\partial x} = \begin{cases} \dfrac{v_1(\rho) - u}{\epsilon}, & \rho < R(u), \\ \dfrac{v_2(\rho) - u}{\epsilon}, & \rho \ge R(u). \end{cases} \tag{1.5}$$

One motivation for the switching mechanism hypothesized here is as follows. We assume that there are two natural modes in which drivers can operate. The first is the fast mode and is characterized by the equilibrium curve $\rho \to v_1(\rho)$, and the second is the slow mode characterized by the slow curve $\rho \to v_2(\rho)$. What we are hypothesizing in (1.5) is that if the current state of traffic, (u, ρ), lies below the switch curve $\rho = R(u)$, drivers' preferences will migrate towards the fast curve $u = v_1(\rho)$, whereas if the traffic state, (u, ρ), lies above $\rho = R(u)$, their preferences will migrate towards the slow curve $u = v_2(\rho)$.

An alternative approach would be to hypothesize that, for all densities $0 \le \rho \le \rho_{\max}$, the preferred state of an average driver is characterized by the homogenized equilibrium curve

$$v(\rho) = a(\rho)v_1(\rho) + (1 - a(\rho))v_2(\rho),$$

where $a(0) = 1$, $a'(\rho) \le 0$ for $0 \le \rho \le \rho_{\max}$, and $a(\rho_{\max}) = 0$. This latter approach has been used in multiclass models of traffic flow; see, for instance, [4, 5] and many other references.

For $0 < \rho \le \rho_{\max}$, the system (1.2), (1.4), (1.5) is strictly hyperbolic, with distinct wave speeds $c_1 = u + \rho v_1'(\rho) < c_2 = u$. Variants of this relaxation model with one equilibrium and no switch curve have been studied by Aw and Rascle [3], Argall et al. [1], Greenberg [6], and Aw et al. [2]. The principal results of those investigations relevant to us here are that for any initial data $\rho_0(\cdot)$ and $u_0(\cdot)$ satisfying

$$0 \le u_0(x) \le v_1(\rho_0(x)) \quad \text{and} \quad 0 \le \rho_0(x) \le \rho_{\max} \tag{1.6}$$

the system (1.2), (1.4), (1.5) has an appropriately defined weak solution satisfying (1.6) for all future times. Thus the model presented here has no signals propagating faster than the car velocities and yields none of the velocity reversals seen in the Payne–Whitham models. These two observations are the basic strength of this class of second-order model.

For simplicity, we restrict our attention to spatially periodic solutions—the ring road scenario. We shall also work with a Lagrangian reformulation of the system. When discretized, this Lagrangian system yields a follow-the-leader–type model.

We let l be the spatial period of our data $\rho_0(\cdot) > 0$ and assume that

$$\int_0^l \rho_0(\xi)d\xi = M \tag{1.7}$$

is an integer. For any real number $m \in [0, M]$ we let $x^0(m)$ be the unique solution of

$$m = \int_0^{x^0(m)} \rho_0(\xi)d\xi \tag{1.8}$$

and $x(m,t)$ be the solution of

$$\frac{\partial x}{\partial t}(m,t) = \bar{u}(m,t) \stackrel{def}{=} u(x(m,t),t) \quad \text{and} \quad x(m,0) = x^0(m). \tag{1.9}$$

Here, ρ and u are solutions of (1.2), (1.4), and (1.5). The continuity equation (1.2), when combined with (1.8) and (1.9), yields

$$m = \int_{x(0,t)}^{x(m,t)} \rho(\xi,t)d\xi, \tag{1.10}$$

and (1.10) in turn implies that

$$\bar{\rho}(m,t) \stackrel{def}{=} \rho(x(m,t),t) \quad \text{and} \quad \bar{\gamma}(m,t) \stackrel{def}{=} \frac{\partial x}{\partial m}(m,t) \tag{1.11}$$

satisfy

$$\bar{\rho}(m,t)\bar{\gamma}(m,t) \equiv 1. \tag{1.12}$$

Additionally, (1.9) implies that $\bar{\gamma}$ and $\bar{u}$ satisfy

$$\frac{\partial \bar{\gamma}}{\partial t}(m,t) = \frac{\partial \bar{u}}{\partial m}(m,t). \tag{1.13}$$

Finally, if we let

$$\bar{\alpha}(m,t) \stackrel{def}{=} \alpha(x(m,t),t) = \bar{u}(m,t) - V_1(\bar{\gamma}(m,t)), \tag{1.14}$$

then (1.3) implies

$$\frac{\partial \bar{\alpha}}{\partial t}(m,t) = \begin{cases} -\dfrac{\bar{\alpha}(m,t)}{\epsilon}, & \bar{\gamma}(m,t) > \dfrac{1}{R(\bar{u}(m,t))}, \\ \dfrac{((V_2 - V_1)(\bar{\gamma}(m,t)) - \bar{\alpha}(m,t))}{\epsilon}, & \bar{\gamma}(m,t) \le \dfrac{1}{R(\bar{u}(m,t))}, \end{cases} \tag{1.15}$$

where

$$V_1(\bar{\gamma}) \stackrel{def}{=} v_1\left(\frac{1}{\bar{\gamma}}\right) \quad \text{and} \quad V_2(\bar{\gamma}) \stackrel{def}{=} v_2\left(\frac{1}{\bar{\gamma}}\right). \tag{1.16}$$

In what follows, we assume that the functions $V_1(\cdot)$ and $V_2(\cdot)$ defined in (1.16) are increasing and concave on $[L \stackrel{def}{=} 1/\rho_{\max}, \infty)$ and satisfy

$$0 = V_2(L^+) = V_1(L^+),$$

$$0 < V_2^{(p)}(\bar{\gamma}) < V_1^{(p)}(\bar{\gamma}) \quad \text{for } L < \bar{\gamma} < \infty \text{ and } p = 0, 1, \tag{1.17}$$

and the limit relations

$$\lim_{\bar{\gamma}\to\infty} (V_i(\bar{\gamma}),\ V_i^{(p)}(\bar{\gamma})) = (v_i^\infty, 0), \qquad i \text{ and } p = 1, 2, \tag{1.18}$$

where $v_2^\infty < v_1^\infty$. The parameter L is interpreted as the length of a typical car on the roadway.

Equations (1.13)–(1.15) also combine to give

$$\frac{\partial \bar{u}}{\partial t}(m,t) - V_1'(\bar{\gamma}(m,t))\frac{\partial \bar{u}}{\partial m}(m,t) = \begin{cases} \dfrac{V_1(\bar{\gamma}(m,t)) - \bar{u}(m,t)}{\epsilon}, & \bar{\gamma}(m,t) > \dfrac{1}{R(\bar{u}(m,t))}, \\ \dfrac{V_2(\bar{\gamma}(m,t)) - \bar{u}(m,t)}{\epsilon}, & \bar{\gamma}(m,t) \le \dfrac{1}{R(\bar{u}(m,t))}. \end{cases} \tag{1.19}$$

1.1. The follow-the-leader model. In [6], Greenberg showed that for the Lagrangian system (1.9)–(1.19) the appropriate stable spatial differencing scheme was downwind; see also [2]. Moreover, such differencing, with $\Delta m = 1$ (recall that cars are discrete), yields

$$\frac{dx_m}{dt} = \bar{u}_m, \tag{1.20}$$

$$\bar{\gamma}_m = x_{m+1} - x_m, \tag{1.21}$$

$$\bar{\rho}_m = \frac{1}{\bar{\gamma}_m}, \tag{1.22}$$

and

$$\frac{d\bar{u}_m}{dt} - V_1'(x_{m+1}-x_m)(\bar{u}_{m+1}-\bar{u}_m)$$

$$= \begin{cases} \dfrac{V_1(x_{m+1}-x_m)-\bar{u}_m}{\epsilon}, & x_{m+1}-x_m > \dfrac{1}{R(\bar{u}_m)}, \\ \dfrac{V_2(x_{m+1}-x_m)-\bar{u}_m}{\epsilon}, & x_{m+1}-x_m \le \dfrac{1}{R(\bar{u}_m)}. \end{cases} \tag{1.23}$$

This latter system implies that

$$\bar{\alpha}_m \stackrel{def}{=} \bar{u}_m - V_1(x_{m+1}-x_m) \tag{1.24}$$

satisfies

$$\frac{d\bar{\alpha}_m}{dt} = \begin{cases} -\dfrac{\bar{\alpha}_m}{\epsilon}, & x_{m+1}-x_m > \dfrac{1}{R(\bar{u}_m)}, \\ \dfrac{((V_2-V_1)(x_{m+1}-x_m)-\bar{\alpha}_m)}{\epsilon}, & x_{m+1}-x_m \le \dfrac{1}{R(\bar{u}_m)}. \end{cases} \tag{1.25}$$

These equations hold for $1 \le m \le M$ and $x_{M+1}(t) = x_1(t) + l$, where again l is the spatial period of our original data $\rho_0(\cdot)$ and $u_0(\cdot)$. The initial positions of the cars are constrained to satisfy

$$x_{m+1}(0) - x_m(0) \ge L \stackrel{def}{=} \frac{1}{\rho_{\max}}, \tag{1.26}$$

and these numbers are related to $\rho_0(\cdot)$ by

$$\int_{x_m(0)}^{x_{m+1}(0)} \rho_0(\xi)\,d\xi \stackrel{def}{=} \bar{\rho}_m^0(x_{m+1}(0)-x_m(0)) = 1. \tag{1.27}$$

In section 2 we analyze a first-order integration scheme for the system (1.20)–(1.22), (1.24), and (1.25). We obtain estimates which guarantee that

$$L \le x_{m+1}(t) - x_m(t) \quad \text{and} \quad 0 \le u_m(t) \le V_1(x_{m+1}(t)-x_m(t)) \tag{1.28}$$

for all $t \ge 0$. These estimates guarantee the consistency of the model. In section 3 we present some simulations with the discrete model. Here we see the persistent periodic wave trains separating congested regions of slow-moving traffic from regions of less dense faster-moving traffic. The waves separating these regions are analyzed in section 4. In that section we revert to continuum model (1.9) and (1.11)–(1.19) because it is analytically easier to work with.

2. A priori estimates. In this section we establish a priori estimates for solutions of (1.20)–(1.22), (1.24), and (1.25). We integrate these equations with a first-order Euler scheme. Specifically, we let Δt be our time step, $t_n = n\Delta t$, and for any function $f_m(\cdot)$ we let f_m^n denote the approximate value of $f_m(\cdot)$ at t_n. Our integration scheme is

$$x_m^{n+1} = x_m^n + \Delta t u_m^n, \tag{2.1}$$

$$\bar{\gamma}_m^{n+1} = x_{m+1}^{n+1} - x_m^{n+1}, \tag{2.2}$$

$$\bar{\rho}_m^{n+1} = \frac{1}{\left(x_{m+1}^{n+1} - x_m^{n+1}\right)}, \tag{2.3}$$

$$\bar{\alpha}_m^{n+1} = \left(\bar{u}_m^{n+1} - V_1(x_{m+1}^{n+1} - x_m^{n+1})\right), \tag{2.4}$$

where

$$\bar{\alpha}_m^{n+1} = \left(1 - \frac{\Delta t}{\epsilon}\right)\bar{\alpha}_m^n + \Delta t(V_2 - V_1)(x_{m+1}^n - x_m^n)H\left(\bar{\rho}_m^n - R(\bar{u}_m^n)\right)/\epsilon \tag{2.5}$$

and

$$H(s) = \begin{cases} 0, & s < 0, \\ 1, & s \geq 0. \end{cases} \tag{2.6}$$

These equations hold for $1 \leq m \leq M$ and

$$x_{M+1}^{n+1} = x_1^{n+1} + l. \tag{2.7}$$

Throughout, we assume that

$$0 \leq \Delta t V_1'(L) \leq \frac{1}{2} \quad \text{and} \quad 0 \leq \frac{\Delta t}{\epsilon} \leq \frac{1}{2}. \tag{2.8}$$

Remark. Recall that in section 1 we assumed $\Delta m = 1$ in order to obtain the follow-the-leader model. If instead we had allowed any $0 < \Delta m$, our (2.2) and (2.3) would have been replaced by $\bar{\gamma}_m^{n+1} = (x_{m+1}^{n+1} - x_m^{n+1})/\Delta m$ and $\bar{\rho}_m^{n+1} = \Delta m/(x_{m+1}^{n+1} - x_m^{n+1})$. Our basic integration scheme (2.1), (2.5) would be the same, but (2.8) would be modified to $\frac{\Delta t}{\Delta m} V_1'(L) \leq \frac{1}{2}$.

THEOREM 2.1. *Suppose that* (2.8) *holds and that for* $1 \leq m \leq M$

$$L \leq x_{m+1}^n - x_m^n \quad \text{and} \quad 0 \leq u_m^n \leq V_1(x_{m+1}^n - x_m^n). \tag{2.9}$$

Then (2.9) *holds for* n *replaced by* $n+1$.

Proof. The identities (2.1)–(2.6) imply that

$$\bar{\gamma}_m^{n+1} = \bar{\gamma}_m^n + \Delta t\left(\bar{u}_{m+1}^n - \bar{u}_m^n\right) \tag{2.10}$$

and

$$\begin{aligned} \bar{u}_m^{n+1} = {} & V_1\left(\bar{\gamma}_m^{n+1}\right) + \left(\bar{u}_m^n - V_1\left(\bar{\gamma}_m^n\right)\right)\left(1 - \frac{\Delta t}{\epsilon}\right) \\ & + \left(V_2 - V_1\right)\left(\bar{\gamma}_m^n\right) H\left(\bar{\rho}_m^n - R\left(\bar{u}_m^n\right)\right)\frac{\Delta t}{\epsilon}, \end{aligned} \tag{2.11}$$

and the inequalities

$$\left.\begin{aligned} & L \leq \bar{\gamma}_m^n, \qquad 1 \leq m \leq M, \\ & 0 \leq \bar{u}_m^n = V_1\left(\bar{\gamma}_m^n\right) + \bar{\alpha}_m^n \ \text{ and } \ \bar{\alpha}_m^n \leq 0, \ \ 1 \leq m \leq M, \end{aligned}\right\} \tag{2.12}$$

imply that

$$\bar{\gamma}_m^{n+1} \geq F\left(\bar{\gamma}_m^n\right) \stackrel{def}{=} \bar{\gamma}_m^n - \Delta t V_1\left(\bar{\gamma}_m^n\right). \tag{2.13}$$

The fact that Δt satisfies (2.8) implies that $F(\cdot)$ is monotone increasing on $[L, \infty)$, and thus (2.9) and (2.13) imply

$$\bar{\gamma}_m^{n+1} \geq F(L) = L, \tag{2.14}$$

as desired. On the other hand, the inequalities

$$\bar{u}_m^n - V_1\left(\bar{\gamma}_m^n\right) \leq 0, \qquad \left(V_2 - V_1\right)\left(\bar{\gamma}_m^n\right) \leq 0, \tag{2.15}$$

and (2.11) imply that

$$\bar{\alpha}_m^{n+1} = \bar{u}_m^{n+1} - V_1\left(\bar{\gamma}_m^{n+1}\right) \leq 0. \tag{2.16}$$

The identity (2.11), when combined with (2.10), yields

$$\begin{aligned} \bar{u}_m^{n+1} = & \left(1 - \frac{\Delta t}{\epsilon}\right)\bar{u}_m^n + \left(V_1\left(\bar{\gamma}_m^n + \Delta t\left(\bar{u}_{m+1}^n - \bar{u}_m^n\right)\right) - V_1\left(\bar{\gamma}_m^n\right)\right) \\ & + \left(\frac{\Delta t}{\epsilon}\right)\left(1 - H\left(\bar{\rho}_m^n - R(\bar{u}_m^n)\right)\right) V_1(\bar{\gamma}_m^n) \\ & + \left(\frac{\Delta t}{\epsilon}\right) H\left(\bar{\rho}_m^n - R(\bar{u}_m^n)\right) V_2(\bar{\gamma}_m^n) \end{aligned} \tag{2.17}$$

or

$$\begin{aligned} \bar{u}_m^{n+1} = & \left(1 - \frac{\Delta t}{\epsilon} - \Delta t V_1'(\delta_m^n)\right)\bar{u}_m^n + \Delta t V_1'(\delta_m^n)\bar{u}_{m+1}^n \\ & + \left(\frac{\Delta t}{\epsilon}\right)\left(1 - H(\bar{\rho}_m^n - R(\bar{u}_m^n))\right)V_1(\bar{\gamma}_m^n) + \left(\frac{\Delta t}{\epsilon}\right) H(\bar{\rho}_m^n - R(\bar{u}_m^n))V_2(\bar{\gamma}_m^n) \end{aligned} \tag{2.18}$$

for some $\delta_m^n \geq \min\left(\gamma_m^{n+1}, \gamma_m^n\right) \geq L$, and (2.18) together with (2.6) and (2.8) and $u_m^n \geq 0$, $1 \leq m \leq M$, imply that $\bar{u}_m^{n+1} \geq 0$. This concludes the proof of Theorem 2.1. □

The estimates contained in Theorem 2.1 guarantee that the densities

$$\rho_m^n = \frac{1}{x_{m+1}^n - x_m^n}, \qquad 1 \leq m \leq M, \tag{2.19}$$

satisfy

$$0 \leq \rho_m^n \leq \rho_{\max}. \tag{2.20}$$

These estimates further imply that the approximate solutions defined in (2.1)–(2.7) converge to solutions of the follow-the-leader model (1.20)–(1.22), (1.24), (1.25) as $\Delta t \to 0^+$.

3. Simulations. All computations in this section were run with the following equilibrium relations:

$$v_1(\rho) = v_1^\infty \left(1 - \frac{\rho}{\rho_{\max}}\right) \quad \text{and} \quad v_2(\rho) = v_2^\infty \left(1 - \frac{\rho}{\rho_{\max}}\right). \tag{3.1}$$

These transform to

$$V_1(\gamma) = v_1^\infty \left(1 - \frac{L}{\gamma}\right) \quad \text{and} \quad V_2(\gamma) = v_2^\infty \left(1 - \frac{L}{\gamma}\right), \tag{3.2}$$

where $L = 1/\rho_{\max}$. The specific parameters used were

$$v_1^\infty = 100 \text{ feet/sec } = \frac{100 \times 3600}{5280} = 68.1818\ldots \text{ mph}, \tag{3.3}$$

$$v_2^\infty = 40 \text{ feet/sec} = \frac{40 \times 3600}{5280} = 27.2727\ldots \text{ mph}, \tag{3.4}$$

and

$$L = 15 \text{ feet}. \tag{3.5}$$

The latter number corresponds to a maximum car density of

$$\rho_{\max} = \frac{1}{15} \text{ cars/foot } = \frac{5280}{15} = 352 \text{ cars/mile}. \tag{3.6}$$

We used the constant switch curve introduced by Sopasakis [9]:

$$\gamma(u) = \gamma_*, \quad 0 \le u, \tag{3.7}$$

with $\gamma_* = 20$ feet. For initial data, we chose three sets of data:

$$x_m^{(k)}(0) = 20m + .1 \sin\left(\frac{km\pi}{200}\right) \tag{3.8}$$

for $-\infty \le m \le \infty$ and $k = 1, 2$, and 3. The observation that

$$x_{400}^{(k)}(0) = 8000 \text{ feet } = 1.5151\ldots \text{ miles} \tag{3.9}$$

and

$$x_{m+400}^{(k)}(0) = x_m^{(k)}(0) + 8000 \tag{3.10}$$

implies that we may interpret the data as initial data for a ring road with 400 cars which is of length 1.5151... miles. We chose constant initial velocities

$$u_m^{(k)}(0) = .5(V_1(\gamma_*) + V_2(\gamma_*)), \quad 1 \le m \le 400, \tag{3.11}$$

or

$$u_m^{(k)}(0) = 17.5 \text{ feet/sec } = 11.931818\ldots \text{ mph}, \quad 1 \le m \le 400. \tag{3.12}$$

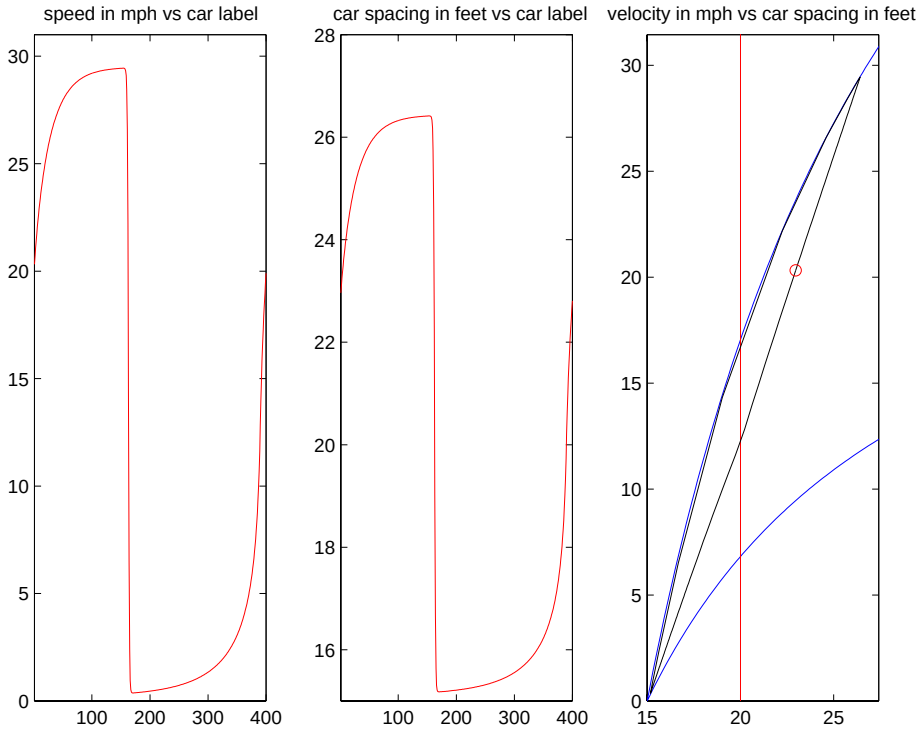

FIG. 3.1. *Periodic solutions at* $t = 2$ *for initial data* $k = 1$.

These data guarantee points on both sides of the switch curve. Simulations were run with relaxation times

$$\epsilon = 1, 2, 4, \text{ and } 8. \tag{3.13}$$

Below, we show the long-time spatially and temporally periodic solutions at time $t = 2$ hours when $\epsilon = 8$ seconds. Figures 3.1, 3.2, and 3.3 correspond to the initial data indexed by $k = 1, 2$, and 3, respectively. At earlier times the solution indexed by each particular k had k discontinuities per period. This phenomenon persisted to $t = 2$ hours for the solution indexed by $k = 2$, but the solution corresponding to the index $k = 3$ converged, by $t = 2$ hours, to a solution with one discontinuity per period.

The first two frames in each figure are self-explanatory. In the third frame of each figure we plot the curve $m \to (\gamma_m = x_{m+1} - x_m, u_m)$. This curve is shown in black. The blue curves are the equilibrium curves $\gamma \to (\gamma, V_1, (\gamma))$ and $\gamma \to (\gamma, V_2(\gamma))$, and the red curve is the image of $u \to (20, u)$. The red circle is the image of (γ_1, u_1). Complete animations of all of these simulations may be found at http://www.math.cmu.edu/∼plin/congestion/. The discontinuities in the profiles propagate at the speed

$$c \simeq 227.6 \pm .1 \text{ cars/minute}. \tag{3.14}$$

An analysis of these solutions may be found in section 4.

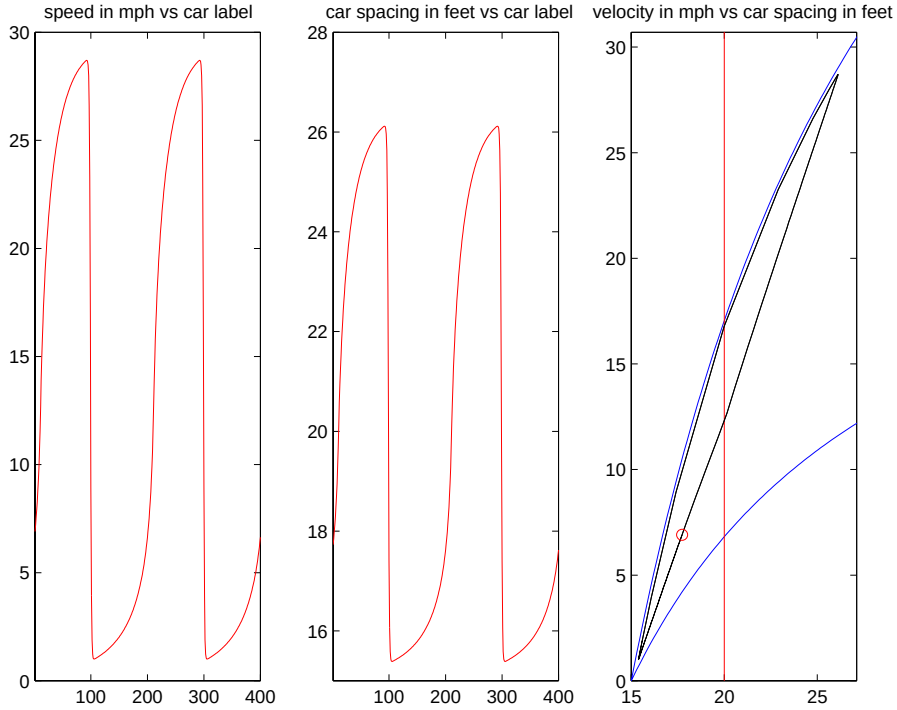

FIG. 3.2. *Periodic solutions at* $t = 2$ *for initial data* $k = 2$.

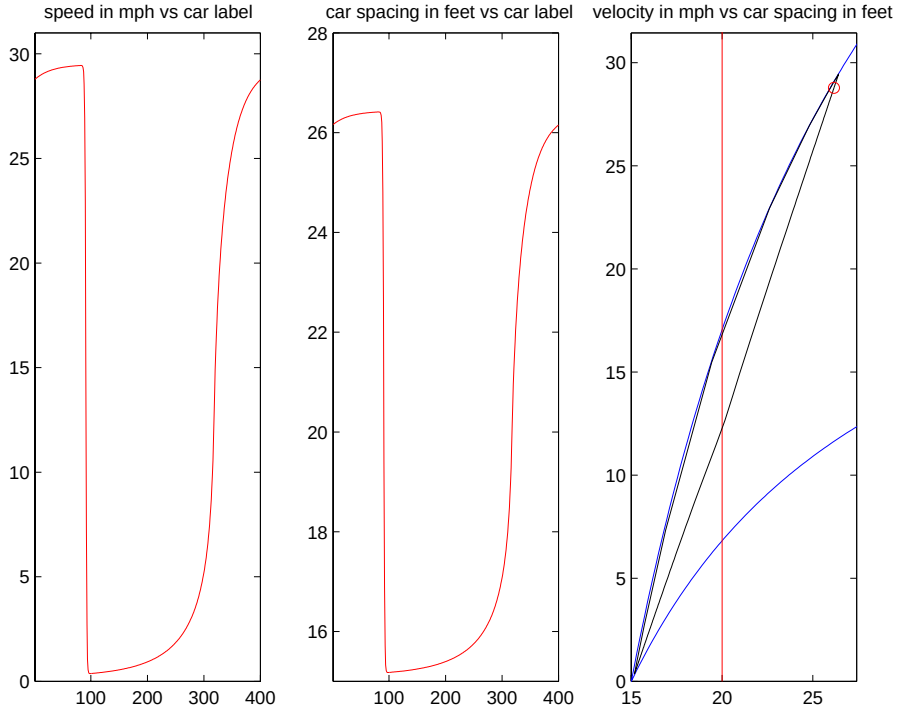

FIG. 3.3. *Periodic solutions at* $t = 2$ *for initial data* $k = 3$.

4. Travelling waves. The wave trains obtained in section 3 are basically discrete approximations to travelling wave solutions to the continuum equations (1.9)–(1.19). In this section our goal is to show that the continuum system (1.9)–(1.19) actually supports such travelling waves. For definiteness we shall assume that the switch curve introduced in (1.4) is the one derived by Sopasakis in [9], namely, the curve

$$R(u) = \rho_*, \quad 0 \le u. \tag{4.1}$$

With this choice of switch curve, the Lagrangian equations become

$$\frac{\partial \bar\gamma}{\partial t} - \frac{\partial \bar u}{\partial m} = 0 \quad \text{and} \quad \frac{\partial \bar u}{\partial t} - V_1'(\bar\gamma)\frac{\partial \bar u}{\partial m} = \begin{cases} \dfrac{V_1(\bar\gamma) - \bar u}{\epsilon}, & \bar\gamma > \gamma_* = \dfrac{1}{\rho_*}, \\[2ex] \dfrac{V_2(\bar\gamma) - \bar u}{\epsilon}, & \bar\gamma \le \gamma_* = \dfrac{1}{\rho_*}. \end{cases} \tag{4.2}$$

Once again,

$$V_1(\bar\gamma) = v_1\left(\frac{1}{\bar\gamma}\right) \quad \text{and} \quad V_2(\bar\gamma) = v_2\left(\frac{1}{\bar\gamma}\right), \tag{4.3}$$

and we assume that both V_1 and V_2 are increasing and concave on $[L, \infty)$ and satisfy

$$0 = V_2(L^+) = V_1(L^+) \quad \text{and} \quad 0 < V_2^{(p)}(\bar\gamma) < V_1^{(p)}(\bar\gamma) \quad \text{for } L < \bar\gamma < \infty \text{ and } p = 0, 1 \tag{4.4}$$

and the limit relations

$$\lim_{\bar\gamma \to \infty} (V_i(\bar\gamma),\ V_i^{(p)}(\bar\gamma)) = (v_i^\infty, 0), \quad i \text{ and } p = 1, 2, \tag{4.5}$$

where $0 < v_2^\infty < v_1^\infty$. L is related to $\rho_{\max}$ by $L = 1/\rho_{\max}$.

We start by describing the portion of the wave trains in which both $\bar\gamma$ and $\bar u$ are increasing in m. These solutions are functions of

$$\xi = m + ct \tag{4.6}$$

and are normalized so that

$$\bar\gamma(0) = \gamma_* \quad \text{and} \quad V_2(\gamma_*) < u_* < V_1(\gamma_*). \tag{4.7}$$

Once again, $\gamma_* = 1/\rho_*$ (see (4.1)). Equation $(4.2)_1$ implies that $\bar u = u_* + c(\bar\gamma - \gamma_*)$, while $(4.2)_2$ yields

$$c\,(c - V_1'(\bar\gamma))\,\frac{d\bar\gamma}{d\xi} = \begin{cases} \dfrac{V_1(\bar\gamma) - u_* - c(\bar\gamma - \gamma_*)}{\epsilon}, & \bar\gamma > \gamma_*, \\[2ex] \dfrac{V_2(\bar\gamma) - u_* - c(\bar\gamma - \gamma_*)}{\epsilon}, & \bar\gamma \le \gamma_*. \end{cases} \tag{4.8}$$

The requirement that $\bar\gamma$ be increasing in ξ implies that $\bar\gamma$ must satisfy $d\bar\gamma/d\xi(0^-) \ge 0$ and $d\bar\gamma/d\xi(0^+) \ge 0$. Equations (4.7) and (4.8) then imply that these latter inequalities may be met only if

$$c = V_1'(\gamma_*). \tag{4.9}$$

In what follows, we let $\Gamma_* > L$ be the unique solution of

$$V_1'(\Gamma_*) = V_2'(L^+). \tag{4.10}$$

If $L < \gamma_* < \Gamma_*$, we let

$$\bar{U} = V_1'(\gamma_*)(\gamma_* - L) \tag{4.11}$$

and note that for $V_2(\gamma_*) < u_* < \bar{U}$ the equation

$$u_* + V_1'(\gamma_*)(\bar{\gamma} - \gamma_*) = V_2(\bar{\gamma}) \tag{4.12}$$

has a unique solution $\gamma_- \in (L, \gamma_*)$ satisfying

$$V_1'(\gamma_*) > V_2'(\gamma_-). \tag{4.13}$$

On the other hand, if $\Gamma_* < \gamma_*$, we let $\gamma_l \in (L, \gamma_*)$ be the unique solution of

$$V_2'(\gamma_l) = V_1'(\gamma_*) \tag{4.14}$$

and

$$\bar{U} = V_1'(\gamma_*)(\gamma_* - \gamma_l) + V_2(\gamma_l) \tag{4.15}$$

and note that, for $V_2(\gamma_*) < u_* < \bar{U}$, (4.11) has a unique solution $\gamma_- \in (\gamma_l, \gamma_*)$ satisfying (4.12).

In what follows, we assume that the parameter u_* in (4.8) satisfies $V_2(\gamma_*) < u_* \leq \bar{U}$, where $\bar{U}$ is defined in (4.10) or (4.14) as appropriate.

We now note that $(4.2)_2$, when combined with (4.8), implies that the profile $\bar{\gamma}$ must satisfy

$$V_1'(\gamma_*)\left(V_1'(\gamma_*) - V_1'(\bar{\gamma})\right)\frac{d\bar{\gamma}}{d\xi} = \begin{cases} \dfrac{V_1(\bar{\gamma}) - u_* - V_1'(\gamma_*)(\bar{\gamma} - \gamma_*)}{\epsilon}, & \bar{\gamma} > \gamma_*, \\ \dfrac{V_2(\bar{\gamma}) - u_* - V_1'(\gamma_*)(\bar{\gamma} - \gamma_*)}{\epsilon}, & \bar{\gamma} \leq \gamma_*. \end{cases} \tag{4.16}$$

Once again, we normalize the profile by insisting that (4.7) hold. Noting that sign $(V_1'(\gamma_*) - V_1'(\bar{\gamma})) =$ sign $(\bar{\gamma} - \gamma_*)$, that

$$V_1(\bar{\gamma}) - u_* - V_1'(\gamma_*)(\bar{\gamma} - \gamma_*) > 0, \quad \gamma_* < \bar{\gamma} < \gamma_+, \tag{4.17}$$

where $\gamma_* < \gamma_+$ is the unique solution of

$$V_1(\gamma_+) - u_* - V_1'(\gamma_*)(\gamma_+ - \gamma_*) = 0, \tag{4.18}$$

and finally that

$$V_2(\bar{\gamma}) - u_* - V_1'(\gamma_*)(\bar{\gamma} - \gamma_*) < 0, \quad \gamma_- < \bar{\gamma} < \gamma_*, \tag{4.19}$$

where γ_- is defined in (4.11), we see that (4.15) and (4.16) have a unique increasing solution defined on $(-\infty, \infty)$. For $\xi < 0$ the solution is given by the quadrature formula

$$\epsilon V_1'(\gamma_*) \int_{\bar{\gamma}(\xi)}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))d\eta}{(u_* + V_1'(\gamma_*)(\eta - \gamma_*) - V_2(\eta))} = -\xi, \tag{4.20}$$

and for $\xi > 0$ the solution is given by

$$\epsilon V_1'(\gamma_*) \int_{\gamma_*}^{\bar{\gamma}(\xi)} \frac{(V_1'(\gamma_*) - V_1'(\eta))d\eta}{(V_1(\eta) - u_* - V_1'(\gamma_*)(\eta - \gamma_*))} = \xi. \tag{4.21}$$

4.1. Periodic profiles. For any $\bar{\gamma} \in (\gamma_-, \gamma_*)$, we let $\Gamma(\bar{\gamma}) > \gamma_*$ be the unique solution of

$$V_1(\Gamma(\bar{\gamma})) - V_1(\bar{\gamma}) = V_1'(\gamma_*)(\Gamma(\bar{\gamma}) - \bar{\gamma}) \tag{4.22}$$

and note that

$$\frac{d\Gamma(\bar{\gamma})}{d\bar{\gamma}} = \frac{(V_1'(\bar{\gamma}) - V_1'(\gamma_*))}{(V_1'(\Gamma(\bar{\gamma})) - V_1'(\gamma_*))} < 0. \tag{4.23}$$

We are now in a position to define the periodic wave trains. For $-|\xi_a| < \xi \le 0$, $\bar{\gamma}(\xi)$ is given by (4.20), and $|\xi_a|$ is given by

$$\epsilon V_1'(\gamma_*) \int_{\bar{\gamma}_a}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))d\eta}{(u_* + V_1'(\gamma_*)(\eta - \gamma_*) - V_2(\eta))} \stackrel{def}{=} |\xi_a|, \tag{4.24}$$

where $\gamma_- < \bar{\gamma}_a < \gamma_*$. For $0 \le \xi \le \xi_{\Gamma(\bar{\gamma}_a)}$, $\bar{\gamma}(\xi)$ is given by (4.21), and $\xi_{\Gamma(\bar{\gamma}_a)}$ is given by

$$\epsilon V_1'(\gamma_*) \int_{\gamma_*}^{\Gamma(\bar{\gamma}_a)} \frac{(V_1'(\gamma_*) - V_1'(\eta))d\eta}{(V_1(\eta) - u_* - V_1'(\gamma_*) * (\eta - \gamma_*))} \stackrel{def}{=} \xi_{\Gamma(\bar{\gamma}_a)}. \tag{4.25}$$

We extend these solutions to all ξ via

$$\bar{\gamma}(\xi) = \bar{\gamma}(\xi + \xi_{\Gamma(\bar{\gamma}_a)} + |\xi_a|). \tag{4.26}$$

The extended solution is a proper weak solution to (4.2). The relations (4.9) and (4.22) imply that the Rankine–Hugoniot relations for (4.2) hold across the discontinuities

$$\xi = m + V_1'(\gamma_*)t = \xi_{\Gamma(\bar{\gamma}_a)} \pm n(\xi_{\Gamma(\bar{\gamma}_a)} + |\xi_a|), \quad n = 0, 1, \ldots . \tag{4.27}$$

Equation (4.22) also implies that

$$V_1'(\bar{\gamma}_a) > V_1'(\gamma_*) = \frac{V_1(\Gamma(\bar{\gamma}_a)) - V_1(\bar{\gamma}_a)}{\Gamma(\bar{\gamma}_a) - \bar{\gamma}_a} > V_1'(\Gamma(\bar{\gamma}_a)), \tag{4.28}$$

and thus across these discontinuities the Lax entropy condition is satisfied. Recalling that the particular solutions of interest to us must be M periodic, we see that (4.24) and (4.25) imply that for some integer $k \ge 1, \bar{\gamma}_a$ and u_* must be such that

$$\begin{aligned} k\epsilon V_1'(\gamma_*) \Bigg[& \int_{\bar{\gamma}_a}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))d\eta}{(u_* + V_1'(\gamma_*)(\eta - \gamma_*) - V_2(\eta))} \\ & + \int_{\gamma_*}^{\Gamma(\bar{\gamma}_a)} \frac{(V_1'(\gamma_*) - V_1'(\eta))d\eta}{(V_1(\eta) - u_* - V_1'(\gamma_*)(\eta - \gamma_*))} \Bigg] = M. \end{aligned} \tag{4.29}$$

The condition that $x(M, t) = x(1, t) + l$ implies that $\bar{\gamma}_a$ and u_* must also satisfy

$$\begin{aligned} k\epsilon V_1'(\gamma_*) \Bigg[& \int_{\bar{\gamma}_a}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))\eta d\eta}{(u_* + V_1'(\gamma_*)(\eta - \gamma_*) - V_2(\eta))} \\ & + \int_{\gamma_*}^{\Gamma(\bar{\gamma}_a)} \frac{(V_1'(\gamma_*) - V_1'(\eta))\eta d\eta}{(V_1(\eta) - u_* - V_1'(\gamma_*)(\eta - \gamma_*))} \Bigg] = l. \end{aligned} \tag{4.30}$$

We conclude this section with an analysis of (4.29) and (4.30). We first note that the integer $k \geq 1$ in these equations is equal to the number of discontinuities of $\bar{\gamma}(\cdot)$ per period. We also note that instead of using u_* and $\bar{\gamma}_a$ as our basic parameters we may instead use γ_- and $\bar{\gamma}_a$. With this choice,

$$\begin{aligned} &u_* + V_1'(\gamma_*)(\eta - \gamma_*) - V_2(\eta) \\ &\qquad = V_2(\gamma_-) + V_1'(\gamma_*)(\eta - \gamma_-) - V_2(\eta) > 0, \quad \gamma_- < \eta < \gamma_*, \end{aligned} \tag{4.31}$$

and

$$\begin{aligned} &V_1(\eta) - u_* - V_1'(\gamma_*)(\eta - \gamma_*) \\ &\qquad = V_1(\eta) - V_2(\gamma_-) - V_1'(\gamma_*)(\eta - \gamma_-) > 0, \quad \gamma_* < \eta < \Gamma(\gamma_-), \end{aligned} \tag{4.32}$$

and solving (4.29) and (4.30) is equivalent to finding $\bar{\gamma}_a \in (\gamma_-, \gamma_*)$ and $\gamma_- < \gamma_*$ such that

$$\begin{aligned} k\epsilon V_1'(\gamma_*) \Bigg[&\int_{\bar{\gamma}_a}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))d\eta}{(V_2(\gamma_-) + V_1'(\gamma_*)(\eta - \gamma_-) - V_2(\eta))} \\ &+ \int_{\gamma_*}^{\Gamma(\bar{\gamma}_a)} \frac{(V_1'(\gamma_*) - V_1'(\eta))d\eta}{(V_1(\eta) - V_2(\gamma_-) - V_1'(\gamma_*)(\eta - \gamma_-))} \Bigg] = M \end{aligned} \tag{4.33}$$

and

$$\begin{aligned} k\epsilon V_1'(\gamma_*) \Bigg[&\int_{\bar{\gamma}_a}^{\gamma_*} \frac{(V_1'(\eta) - V_1'(\gamma_*))\eta d\eta}{(V_2(\gamma_-) + V_1'(\gamma_*)(\eta - \gamma_-) - V_2(\eta))} \\ &+ \int_{\gamma_*}^{\Gamma(\bar{\gamma}_a)} \frac{(V_1'(\gamma_*) - V_1'(\eta))\eta d\eta}{(V_1(\eta) - V_2(\gamma_-) - V_1'(\gamma_*)(\eta - \gamma_-))} \Bigg] = l. \end{aligned} \tag{4.34}$$

In what follows, we let $L_1(\gamma_-, \bar{\gamma}_a, \gamma_*)$ and $L_2(\gamma_-, \bar{\gamma}_a, \gamma_*)$ be the functions defined by the left-hand sides of (4.33) and (4.34), respectively. If $L < \gamma_* < \Gamma_*$ (see (4.9)), the functions L_1 and L_2 are well defined for $\gamma_- \in (L, \gamma_*)$ and $\bar{\gamma}_a \in (\gamma_-, \gamma_*)$, whereas if $\Gamma_* \leq \gamma_*$, these functions are well defined for $\gamma_- \in (\gamma_l, \gamma_*)$ (see (4.13)) and $\bar{\gamma}_a \in (\gamma_-, \gamma_*)$. In either case, the observation that $\lim_{\bar{\gamma}_a \to \gamma_*^-} \Gamma(\bar{\gamma}_a) = \gamma_*$ implies that $L_1(\gamma_-, \gamma_*^-, \gamma_*) = L_2(\gamma_-, \gamma_*^-, \gamma_*) = 0$. We further note that for $\gamma_- < \bar{\gamma}_a < \gamma_*$

$$\begin{aligned} \frac{\partial L_1}{\partial \bar{\gamma}_a}(\gamma_-, \bar{\gamma}_a, \gamma_*) = k\epsilon V_1'(\gamma_*) \Bigg[&\frac{(V_1'(\gamma_*) - V_1'(\bar{\gamma}_a))}{(V_2(\gamma_-) + V_1'(\gamma_*)(\bar{\gamma}_a - \gamma_*) - V_2(\bar{\gamma}_a))} \\ &+ \frac{d\Gamma(\bar{\gamma}_a)}{d\bar{\gamma}_a} \frac{(V_1'(\gamma_*) - V_1'(\Gamma(\bar{\gamma}_a)))}{(V_1(\Gamma(\bar{\gamma}_a)) - V_2(\gamma_-) - V_1'(\gamma_*)(\Gamma(\bar{\gamma}_a) - \gamma_-))} \Bigg]. \end{aligned} \tag{4.35}$$

The last identity, together with $d\Gamma/d\bar{\gamma}_a(\bar{\gamma}_a) < 0$, implies that $\partial L_1/\partial \bar{\gamma}_a(\gamma_-, \bar{\gamma}_a, \gamma_*) < 0$. The fact that

$$\lim_{\bar{\gamma}_a \to \gamma_-^+} L_1(\gamma_-, \bar{\gamma}_a, \gamma_*) = +\infty \tag{4.36}$$

then guarantees that for each $L < \gamma_*$ and admissible γ_- there is a unique $\bar{\gamma}_a(\gamma_-, \gamma_*, M)$ such that (4.33) holds. Thus, solving (4.33) and (4.34) is equivalent to finding an admissible $\gamma_- < \gamma_*$ so that

$$L_2(\gamma_-, \bar{\gamma}_a(\gamma_-, \gamma_*, M), \gamma_*) = l. \tag{4.37}$$

The integral mean-value theorem, when combined with the definition of $\bar{\gamma}_a(\gamma_-, \gamma_*, M)$, guarantees that

$$M\bar{\gamma}_a(\gamma_-, \gamma_*, M) \le L_2(\gamma_-, \bar{\gamma}_a(\gamma_-, \gamma_*, M), \gamma_*) = Mg \tag{4.38}$$

for some $g \in (\bar{\gamma}_a(\gamma_-, \gamma_*, M),\ \Gamma(\bar{\gamma}_a(\gamma_-, \gamma_*, M)))$. These observations, together with $\gamma_- < \bar{\gamma}_a(\gamma_-, \gamma_*, M)$ and $\Gamma(\bar{\gamma}_a(\gamma_-, \gamma_*, M)) < \Gamma(\gamma_-)$, imply that (4.37) has no solutions for

$$l < \begin{cases} ML & \text{if } \gamma_* < \Gamma_* \text{ (see (4.9) and (4.22))}, \\ M\gamma_l & \text{if } \gamma_* \ge \Gamma_* \text{ (see (4.9), (4.13), and (4.22))} \end{cases} \tag{4.39}$$

and

$$l > \begin{cases} M\Gamma(L) & \text{if } \gamma_* < \Gamma_* \text{ (see (4.9) and 4.22))}, \\ M\Gamma(\gamma_l) & \text{if } \gamma_* \ge \Gamma_* \text{(see (4.9), (4.13), and (4.22))}. \end{cases} \tag{4.40}$$

These estimates on the range of $\gamma_- \to L_2(\gamma_-, \bar{\gamma}_a(\gamma_-, \gamma_*, M), \gamma_*)$, though not particularly sharp, are all we could manage with this degree of generality on the functions $V_1(\cdot)$ and $V_2(\cdot)$.

ACOUSTIC PROPAGATION IN DISPERSIONS AND THE GEOMETRIC THEORY OF DIFFRACTION*

O. G. HARLEN†, M. J. HOLMES‡, M. J. W. POVEY‡, AND B. D. SLEEMAN†

Abstract. The ultrasonic characterization of emulsions relies principally upon the theory of thermoacoustic scattering. For a single spherical particle of radius a suspended in a homogeneous medium, the theory provides an exactly soluble solution to the scattering problem. Unfortunately, direct computations with this solution are often ill-conditioned for certain ranges of the acoustic wave number K and thermal wave number L. Recently the authors have developed a low frequency (i.e., $|Ka|, |La| \ll 1$) approach to the theory based on a potential theory technique. This low frequency theory is rapidly convergent and overcomes computation ill-conditioning. In this paper, we pursue the single particle theory and consider the region in which $|Ka| \ll 1$ and $|La| \gg 1$, i.e., the high frequency range of the thermal wavelength. To achieve this, we employ the geometric theory of diffraction. We show that the high frequency solution agrees well with both the experimental measurements and the exact solution in the region where $|Ka| \ll 1$ and $|La| \gg 1$. As in the low frequency case, the high frequency solution may be applied to arbitrary scattering domains.

1. Introduction.

Ultrasound techniques for the characterization of colloidal systems are gaining wide acceptance, and many new ultrasound instruments have recently appeared on the market. The bulk of these instruments claim to accurately measure colloidal particle size distribution, in the case of oil-in-water emulsions at concentrations of up to 30 percent. All these instruments determine particle size from a measurement of ultrasonic attenuation as a function of frequency, together with thermophysical data for the continuous and dispersed phases such as thermal diffusivity. The claims depend on an accurate model of acoustic scattering in such systems. A recent review [1] suggests that the reason for the accuracy of these instruments is that scattering in water based systems is dominated by thermal scattering and that multiple scattering of the thermal field is small. The review authors then suggest that the ECAH model (named for Epstein–Carhart [2] and Allegra–Hawley [3]) upon which most instruments are based is too mathematically complex to be of use in cases where particle-particle interactions are important. In a previous paper [4] we showed that the real deficiency of ECAH is not its complexity but the fact that it is ill-conditioned, thereby leading to unreliability in its numerical predictions, despite the fact that it is an exact theory for a single spherical particle. We demonstrated that, in the case of silicone oil-in-water emulsions, ECAH was accurate to only a few volume percent of the dispersed phase and that the increasing overestimation of the attenuation by ECAH at higher concentrations was a result of unjustifiable approximations made in

the multiple scattering model. In addition, high precision arithmetic was needed to overcome the numerical instability of solutions to ECAH.

To overcome the ill-conditioning in ECAH, we developed in [4] a low frequency solution to the problem of ultrasound propagation in dispersions. We adopted a conventional approach first formulated by Lord Rayleigh [5], refined by Epstein and Carhart [2] and Allegra and Hawley [3]. We call this the ECAH approach, and our low frequency approximation the low frequency potential scattering theory (LFPST). LFPST is based on an asymptotic approach first introduced by Kleinman [6], and we showed that it accurately reproduces experimental results and numerical results from ECAH computed using 24 digit precision arithmetic. The importance of this problem relates to the use of ultrasound for characterizing soft solid and particulate material in a wide range of industries including foods [7, 8] and pharmaceuticals [9]. Since very many such applications lie in the low frequency acoustic limit, an accurate approximation in this limit is of great potential utility. The starting point for LFPST is a set of linearized mass, momentum, and energy equations [4, 10] that reduce to a set of Helmholtz equations, coupled through transmission boundary conditions at the particle surface. It should be pointed out here that this solution at present includes only thermal scattering and that the visco-inertial scattering terms have been omitted for the sake of simplicity. The ECAH solution is not only ill-conditioned [4, 10, 11, 12], but also, because it is based on spherical harmonics, cannot easily be generalized to account for arbitrary particle shape. On the other hand, LFPST is well-conditioned, can provide solutions to arbitrary accuracy, and lends itself to boundary-integral and finite-element techniques that permit solution of the single scattering problem for arbitrary particle shape. In our previous papers [4, 11] we showed that, while it is true that many applications of ultrasound to food and similar emulsions lie in the acoustic low frequency limit, a great proportion of experimental data is high frequency regarding the thermal branch of the problem. In this paper we develop a novel asymptotic description appropriate for the low frequency acoustic limit ($Ka \ll 1$, where K is the acoustic wave vector and a is the particle radius) but where, nevertheless, the problem is high frequency in the thermal field ($La \gg 1$, where L is the thermal wave vector). Examples of such data are given later. We employ the LFPST method for the low frequency acoustic branch (expansion of the acoustic field in powers of iK [4, 11]) and the geometric theory of diffraction (expansion of the thermal field utilizing inverse powers of iL [4]) for the high frequency thermal branch. An iterative system of Poisson equations is formed, whose solution, dependent upon the boundary conditions, provides coefficient values for the field expansions. This approach is not intrinsically constrained by geometrical aspects of the domain. We show, by making an appropriate scaling, that the boundary conditions may be decoupled to second order, significantly simplifying the analysis. In section two, we introduce the problem of thermoacoustic scattering. In section three, we give details of the low frequency perturbation solution, and in section four, we present the geometric theory of diffraction which is applied to the high frequency perturbation solution. In section five, we combine the results of the previous two sections and introduce the form of our perturbation solution together with the associated analytical solution of the problem. Finally, in section six, we present the far field pattern for the solution and compare it with experimental results and the exact solution.

2. Thermoacoustic scattering. We now introduce the model equations and boundary conditions that quantify the problem, keeping our variables consistent with those of [4] as much as possible. As in [4], we consider the scattering of a plane

sound wave of radial frequency ω by a droplet with boundary B that has contrasting thermal and compressive properties. For simplicity we will neglect the effects of viscosity, as these are of secondary importance in oil-water emulsions, though these can be incorporated into the formulation [1]. We define the domains D_1 and D_2 to be regions outside and inside the drop, respectively, and $\mathbf{n}$ to be outward normal on B. The linearized equation for momentum gives

$$i\omega\rho\nabla\Phi + \nabla P = 0, \tag{2.1}$$

where Φ is the velocity potential, P is the pressure perturbation, and ρ is density. Hence the pressure perturbation and velocity potential are related by

$$P = -i\omega\rho\Phi. \tag{2.2}$$

Conservation of energy gives

$$i\omega T + \gamma\sigma\nabla^2 T + \frac{(\gamma-1)}{\beta}\nabla^2\Phi = 0, \tag{2.3}$$

where T is the temperature perturbation, γ the ratio of specific heats, β the coefficient of thermal expansion, and $\sigma = \tau/\rho C_P$ the thermal diffusivity. (τ is thermal conductivity and C_P the specific heat at constant pressure.) Finally, the combination of mass conservation and the first law of thermodynamics gives

$$i\omega P = -\frac{\rho v^2}{\gamma}\nabla^2\Phi + \frac{i\omega v^2\beta\rho}{\gamma}T, \tag{2.4}$$

where v is the adiabatic sound speed. Substituting (2.2) into (2.4) gives

$$\left(\nabla^2 + \frac{\gamma\omega^2}{v^2}\right)\Phi = i\omega\beta T,$$

and substituting for T in (2.3) gives a biharmonic equation for the velocity potential Φ,

$$\nabla^4\Phi + \left(\frac{\omega^2\gamma}{v^2} + i\frac{\omega}{\sigma}\right)\nabla^2\Phi + i\frac{\omega^3}{\sigma v^2}\Phi = 0. \tag{2.5}$$

Equations for the pressure, velocity, density, and temperature variations are obtained from the conservation of mass, momentum, and energy. Equation (2.5) may be factorized as

$$(\nabla^2 + K^2)(\nabla^2 + L^2)\Phi = 0, \tag{2.6}$$

where, in the limit of small $\sigma\omega/v^2$,

$$K \simeq \frac{\omega}{v}\left(1 + i\frac{(\gamma-1)\sigma\omega}{2v^2}\right), \qquad L \simeq \left(\frac{\omega}{2\sigma}\right)^{1/2}(1+i). \tag{2.7}$$

Here the wave number K corresponds to the acoustic wave of length $2\pi v/\omega$ with a small attenuation $\alpha = \omega^2\sigma(\gamma-1)/2v^3$. The wave number L corresponds to a much shorter wavelength disturbance due to heat conduction called the *thermal wave*.

We can therefore express the velocity potential as the sum of a compressional wave potential φ and a thermal wave potential ψ:

$$\Phi = e^{-i\omega t}\left(\varphi + \psi + \varphi_0\right),$$

where $\varphi_0 = e^{iKz}$ is the incoming wave and φ and ψ satisfy separate Helmholtz equations

$$(\nabla^2 + K^2)\varphi = 0 \quad \text{and} \quad (\nabla^2 + L^2)\psi = 0 \quad \text{in} \quad D_1. \tag{2.8}$$

The pressure and temperature perturbations are given by

$$P = -i\omega\rho e^{-i\omega t}(\varphi + \psi + \varphi_0), \qquad T = e^{-i\omega t}(\Gamma_c\varphi + \Gamma_t\psi + \varphi_0),$$

where

$$\Gamma_c = \frac{-iK^2\omega(\gamma-1)}{\beta(\omega + i\gamma\sigma K^2)} \quad \text{and} \quad \Gamma_t = \frac{-iL^2\omega(\gamma-1)}{\beta(\omega + i\gamma\sigma L^2)}.$$

Equivalent equations hold inside the droplet, so that

$$\Phi = e^{-i\omega t}\left(\varphi' + \psi'\right),$$

$$(\nabla^2 + K'^2)\varphi' = 0 \quad \text{and} \quad (\nabla^2 + L'^2)\psi' = 0 \quad \text{in} \quad D_2. \tag{2.9}$$

We use primes to denote quantities in the droplet phase. The wave numbers K' and L' are given by (2.7), but using the parameter values of the droplet. Finally we apply boundary conditions on the potential fields φ, ψ , φ', and ψ', where φ and ψ must satisfy the Sommerfeld radiation condition at infinity (see [15, 17]):

$$\lim_{r\to\infty} r\left(\frac{\partial\varphi}{\partial r} - iK\varphi\right) = 0, \qquad \lim_{r\to\infty} r\left(\frac{\partial\psi}{\partial r} - iL\psi\right) = 0. \tag{2.10}$$

In addition, we require that the normal velocity, pressure, temperature, and heat flux be continuous at the droplet boundary, giving the following four boundary conditions on the boundary B:

(a) normal velocity

$$\frac{\partial}{\partial n}\left(e^{iKz} + \varphi + \psi\right) = \frac{\partial}{\partial n}\left(\varphi' + \psi'\right), \tag{2.11}$$

(b) pressure

$$e^{iKz} + \varphi + \psi = \hat{\rho}\left(\varphi' + \psi'\right), \quad \hat{\rho} = \frac{\rho'}{\rho}, \tag{2.12}$$

(c) temperature

$$\Gamma_c\left(e^{iKz} + \varphi\right) + \Gamma_t\psi = \Gamma'_c\varphi' + \Gamma'_t\psi', \tag{2.13}$$

(d) heat flux

$$\Gamma_c\frac{\partial}{\partial n}\left(e^{iKz} + \varphi\right) + \Gamma_t\frac{\partial}{\partial n}\psi = \hat{\tau}\left(\Gamma'_c\frac{\partial}{\partial n}\varphi' + \Gamma'_t\frac{\partial}{\partial n}\psi'\right), \quad \hat{\tau} = \frac{\tau'}{\tau}. \tag{2.14}$$

For the case of a spherical droplet, a solution for the fields φ, ψ, φ', and ψ' may be found as a Rayleigh series expansion in spherical harmonics (see [1]),

$$\varphi = \sum_{n=0}^{\infty} i^n(2n+1)A_n h_n\,(Kr)\,P_n(\cos\theta), \quad \varphi' = \sum_{n=0}^{\infty} i^n(2n+1)A'_n j_n\,(K'\,r)\,P_n(\cos\theta),$$

$$\psi = \sum_{n=0}^{\infty} i^n(2n+1)B_n h_n\,(Lr)\,P_n(\cos\theta), \quad \psi' = \sum_{n=0}^{\infty} i^n(2n+1)B'_n j_n\,(L'\,r)\,P_n(\cos\theta),$$

$$\varphi_0 = \sum_{n=0}^{\infty} i^n(2n+1)j_n\,(Kr)\,P_n(\cos\theta) = e^{iKz}, \tag{2.15}$$

where $j_n(z)$ and $h_n(z)$ are, respectively, the nth order spherical Bessel and Hankel functions [18]. The coefficients $A_n, B_n, A_n{}', \text{and } B_n{}'$ are found by enforcing the boundary conditions (2.11)–(2.14).

3. Low frequency potential scattering. As mentioned in the introduction, while the ECAH solution given by (2.15) is exact [4], it suffers from a number of limitations, most significantly that its implementation leads to ill-conditioning problems. To eliminate this problem, the authors of [4] sought an asymptotic solution in the limit when the particle size a is such that $|Ka|$ and $|La| \ll 1$. This was achieved by appealing to a method first presented by Kleinman [6] for the solution of low frequency acoustic scattering problems. The method reduced the Helmholtz equation to a sequence of potential problems by taking an integral transformation. We now give a brief outline of the process. First, in solving the Helmholtz equations,

$$\left(\nabla^2 + K^2\right)\varphi = 0 \quad \text{in} \quad D_1, \tag{3.1}$$

$$\left(\nabla^2 + K'^2\right)\varphi' = 0 \quad \text{in} \quad D_2, \tag{3.2}$$

in which φ satisfies the radiation condition at infinity in D_1, we introduce the function

$$\tilde{\varphi} = e^{-iKr}\varphi, \tag{3.3}$$

which is regular at infinity, and we write (3.1) in the form

$$\nabla^2\tilde{\varphi} = -\frac{2iK}{r}\frac{\partial}{\partial r}\,(r\tilde{\varphi}). \tag{3.4}$$

A real valued function is said to be regular at infinity if

$$\lim r \to \infty, \qquad |\, rf(p)\,| < \infty, \qquad \text{and} \quad \lim r \to \infty \left| r^2 \frac{\partial(p)}{\partial r} \right| < \infty,$$

where $r = |x|$ is the magnitude of the position vector x of an arbitrary point. Boundary conditions on the surface connecting the two domains are transformed in terms of the variable $\tilde{\varphi}$. To complete the process, $\tilde{\varphi}$ and φ' are expressed as regular perturbation expansions:

$$\tilde{\varphi} = \sum_{n=0}^{\infty} (iKa)^n\tilde{\varphi}_n, \qquad \varphi' = \sum_{n=0}^{\infty} (iK'a)^n\varphi'_n. \tag{3.5}$$

For $|Ka| < \ln(2)$ this series converges (see [6]), and in practice it is rapidly convergent. This offers a significant improvement on ECAH formulation since the error is bounded by $O(|Ka|^{m+1})$ if an mth order solution is used [4]. In other words, as long as $|Ka|$ is small, we are guaranteed to obtain an accurate estimation of the potential with only a few terms. In contrast, due to the ill-conditioned nature of the ECAH system, it is difficult to know if we have obtained an accurate estimation of the scattered potential.

If we substitute the expansions (3.5) into (3.2) and (3.4), we obtain, for $m \geq 0$, the equivalent system:

$$\nabla^2 \tilde{\varphi}_m = -\frac{2}{ar}\frac{\partial}{\partial r}(r\tilde{\varphi}_{m-1}) \qquad \text{in } D_1, \tag{3.6}$$

together with

$$\nabla^2 \varphi'_m = \frac{1}{a^2}\varphi'_{m-2} \qquad \text{in } D_2, \tag{3.7}$$

with the appropriate modifications to the boundary conditions. In (3.6) and (3.7) we understand that

$$\tilde{\varphi}_{-1} = \tilde{\psi}_{-1} = 0 \quad \text{and} \quad \varphi'_{-1} = \psi'_{-1} = \varphi'_{-2} = \psi'_{-2} = 0.$$

If the fields are given this asymptotic description, then clearly the solution will only be valid in the long wavelength limit. In this paper we also seek to examine the short wavelength limit for which $|La| \gg 1$; this is addressed by the geometric theory of diffraction [13] which we now introduce.

4. The geometric theory of diffraction. Partial differential equations play a crucial part in many branches of mathematics, physics, and industry; however, since explicit exact solutions exist for only relatively few problems, numerical and asymptotic techniques were developed in a bid to elucidate the underlying physics or mechanisms. The notion of asymptotic solutions was first conceived to provide the functional dependence of partial differential equations upon their parameters and data. The main feature of the method relies on *rays*, which are curves along which the terms of the asymptotic expansion satisfy ordinary differential equations. This method was successfully applied by Lewis and Keller [13] to the Helmholtz equation, revealing the phenomenon of diffraction, from which the method gets its name. As a starting point consider the following equation:

$$(\nabla^2 + L^2 n^2(x))\psi = 0; \tag{4.1}$$

here the function $n(x)$ relates to the refractive index of the media. In the case of homogeneous media, $n(x) = constant$ and as such admits plane wave solutions of the form

$$\psi = \tilde{\psi} e^{in(x)\underline{L}\cdot\mathbf{r}}, \tag{4.2}$$

where $\underline{L} = L\hat{L}$ is the propagation vector, $\hat{L}$ the unit vector, and L the wave number. On the basis of (4.2), solutions are sought of the form

$$\psi = \tilde{\psi} e^{iLs(x)}; \tag{4.3}$$

substituting this expression into (4.1) and canceling the factor $\exp(iLs)$ yields

$$-L^2\{(\nabla s)^2 - n^2\}\tilde{\psi} + 2iL\nabla s \cdot \nabla\tilde{\psi} + iL\tilde{\psi}\triangle s + \triangle\tilde{\psi} = 0. \tag{4.4}$$

For large values of L we assume an expansion in inverse powers of iLa of the form

$$\tilde{\psi} = \sum_{m=0}^{\infty} (iLa)^{-m} \tilde{\psi}_m, \tag{4.5}$$

in contrast with the expansions in (3.5). Inserting this expression into (4.4) and equating in powers of m gives

$$-(La)^2\{(\nabla s)^2 - n^2\}\tilde{\psi}_{m+1} + 2iLa\nabla s \cdot \nabla\tilde{\psi}_m + iLa\tilde{\psi}_m \triangle s + a\triangle\tilde{\psi}_{m-1} = 0. \tag{4.6}$$

Again here we understand that $\tilde{\psi_m} = 0$ for $m = -1, -2, \ldots$. For $m = -1$ we have

$$\{(\nabla s)^2 - n^2\}\tilde{\psi}_0 = 0, \tag{4.7}$$

and if $\tilde{\psi}_0 \neq 0$ yields the Eiconal equation,

$$(\nabla s)^2 = n^2(x). \tag{4.8}$$

For $m = 0$, in order to obtain vanishing coefficients, we have

$$2\nabla s \cdot \nabla\tilde{\psi}_0 + \tilde{\psi}_0 \triangle s = 0, \tag{4.9}$$

and for $m = 1, 2, \ldots$,

$$2\nabla s \cdot \nabla\tilde{\psi}_m + \tilde{\psi}_m \triangle s = -\triangle\tilde{\psi}_{m-1}. \tag{4.10}$$

Equations (4.9)–(4.10) are called transport equations and are analogous to (3.6) in the low frequency case. For surfaces of constant phase defined by $s(x) = constant$, curves or rays orthogonal to them provide solutions to the Eiconal equation. One may then express the equation of a ray in the form

$$x = (x_1, x_2, x_3) = x(\zeta), \tag{4.11}$$

and the orthogonality condition is expressed by

$$\frac{dx_j}{d\zeta} = \lambda s_{x_j}, \quad j = 1, 2, 3. \tag{4.12}$$

Here $\lambda(x)$ is an arbitrary proportionality factor and for the choice $\lambda = n^{-1}$ ensures that the parameter ζ is simply the arc length along a ray. Utilizing (4.8) and (4.12), we may write

$$\frac{ds(x)}{d\zeta} = \nabla s \cdot \frac{dx}{d\zeta} = \lambda(\nabla s)^2 = \lambda n^2; \tag{4.13}$$

upon integrating this expression with respect to ζ, we have the solution as

$$s(x(\zeta)) = s(x(\zeta_0)) + \int_{\zeta}^{\zeta_0} \lambda(x(t))n^2(x(t))dt, \tag{4.14}$$

and for the choice $\lambda = n^{-1}$ this reduces to

$$s(\zeta) = s(\zeta_0) + \int_{\zeta}^{\zeta_0} n(t)dt. \tag{4.15}$$

Similarly, the transport equations (4.9)–(4.10) may be expressed in terms of the parameter ζ. The crucial aspect of this formulation is that the original partial differential equation has been confined to the solution of a system of ordinary differential equations, and that the geometry of the problem manifests itself only in terms of the parameter ζ. In this paper we assume our media are homogenous, in the sense that the rays are straight lines. As a simple example to illustrate this, we consider a spherical geometry; this has rays which are simply radial lines, and therefore

$$s(r) = \pm r + constant. \tag{4.16}$$

This furnishes us with the following forms for (4.3):

$$\psi = \tilde{\psi} e^{\pm iLr}. \tag{4.17}$$

A full treatment of the theory is given in [13]. We are now in a position to formulate (2.8)–(2.9) together with the associated boundary conditions (2.11)–(2.14).

5. Formulation. Based on the previous sections, we now apply the following transformations:

$$\tilde{\varphi} = e^{-iK(r-a)}\varphi,$$

$$\tilde{\psi} = e^{-iL(r-a)}\psi, \qquad \tilde{\psi}' = e^{iL'(r-a)}\psi'.$$

Thus (2.8)–(2.9) become

$$\nabla^2\tilde{\varphi} = -\frac{2iK}{r}\frac{\partial}{\partial r}\left(r\tilde{\varphi}\right), \tag{5.1}$$

$$\nabla^2\varphi' + {K'}^2\varphi' = 0, \tag{5.2}$$

$$2iL\nabla s_1 \cdot \nabla\tilde{\psi} + iL\tilde{\psi}\triangle s_1 + \triangle\tilde{\psi} = 0, \tag{5.3}$$

$$2iL'\nabla s_2 \cdot \nabla\tilde{\psi}' + iL'\tilde{\psi}'\triangle s_2 + \triangle\tilde{\psi}' = 0, \tag{5.4}$$

where $s_1(r) = r + constant$ and $s_2(r) = -r + constant$. The boundary conditions of the system now transform to the following:

$$iK\cos\theta e^{iKa\cos\theta} + \left\{iK\tilde{\varphi} + \frac{\partial\tilde{\varphi}}{\partial r}\right\} + \left\{iL\tilde{\psi} + \frac{\partial\tilde{\psi}}{\partial r}\right\} = \frac{\partial\varphi'}{\partial r} + \left\{\frac{\partial\tilde{\psi}'}{\partial r} - iL'\tilde{\psi}'\right\}, \tag{5.5}$$

$$e^{iKa\cos\theta} + \tilde{\varphi} + \tilde{\psi} = \hat{\rho}\{\varphi' + \tilde{\psi}'\}, \tag{5.6}$$

$$\Gamma_c\{e^{iKa\cos\theta} + \tilde{\varphi}\} + \Gamma_t\tilde{\psi} = \Gamma'_c\varphi' + \Gamma'_t\tilde{\psi}', \tag{5.7}$$

$$\Gamma_c\left\{iK\cos\theta e^{iKa\cos\theta}+iK\tilde{\varphi}+\frac{\partial\tilde{\varphi}}{\partial r}\right\}+\Gamma_t\left\{iL\tilde{\psi}+\frac{\partial\tilde{\psi}}{\partial r}\right\}$$

$$=\hat{\tau}\left\{\Gamma_c'\frac{\partial\varphi'}{\partial r}+\Gamma_t'\left\{\frac{\partial\tilde{\psi}'}{\partial r}-iL'\tilde{\psi}'\right\}\right\}. \tag{5.8}$$

We observe that for large La, by dividing the boundary conditions in (5.7)–(5.8) by Γ_t, we have the following ratios:

$$\frac{\Gamma_c}{\Gamma_t}\simeq\frac{(1-\gamma)K^2}{L^2-\gamma K^2}.$$

Thus we define

$$\frac{\Gamma_c}{\Gamma_t}\simeq\frac{G_cK^2}{L^2},$$

where $G_c=(1-\gamma)$, and similarly,

$$\frac{\Gamma_c'}{\Gamma_t}\simeq\frac{G_c'K'^2}{L^2},\qquad G_c'=\frac{(\gamma'-1)\beta}{\beta'},$$

$$\frac{\Gamma_t'}{\Gamma_t}\simeq G_t'=\frac{\sigma\beta}{\sigma'\beta'}.$$

The boundary conditions given in (5.7)–(5.8) now may be written as

$$G_c\frac{(Ka)^2}{(La)^2}\{e^{iKa\cos\theta}+\tilde{\varphi}\}+\tilde{\psi}=G_c'\frac{(K'a)^2}{(La)^2}\varphi'+G_t'\tilde{\psi}', \tag{5.9}$$

$$G_c\frac{(Ka)^2}{(La)^2}\left\{iK\cos\theta e^{iKa\cos\theta}+iKa\tilde{\varphi}+\frac{\partial\tilde{\varphi}}{\partial r}\right\}+\left\{iLa\tilde{\psi}+\frac{\partial\tilde{\psi}}{\partial r}\right\}$$

$$=\hat{\tau}\left\{G_c'\frac{(K'a)^2}{(La)^2}\frac{\partial\varphi'}{\partial r}+G_t'\left\{\frac{\partial\tilde{\psi}'}{\partial r}-iLa'\tilde{\psi}'\right\}\right\}. \tag{5.10}$$

Recognizing this scaling proved to be particularly important in that it simplifies the boundary conditions significantly. Essentially it decouples the thermal field from the acoustic field to low order. One can see that the acoustic potential contributes to the temperature perturbation only at second order in Ka. Consequently the thermal field will be of order $(Ka)^2$, and thus it will only affect the scattered potential at this order.

We now introduce expansions of the following form:

$$\tilde{\varphi}=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\frac{(iKa)^n}{(iLa)^m}\tilde{\varphi}_{nm},\qquad\varphi'=\sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\frac{(iK'a)^n}{(iL'a)^m}\varphi'_{nm}, \tag{5.11}$$

$$\tilde{\psi} = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\frac{(iKa)^n}{(iLa)^m}\tilde{\psi}_{nm}, \qquad \tilde{\psi}' = \sum_{n=0}^{\infty}\sum_{m=0}^{\infty}\frac{(iK'a)^n}{(iL'a)^m}\tilde{\psi}'_{nm}. \tag{5.12}$$

Following the subsequent substitution into (5.1)–(5.4) and the associated boundary conditions (5.5)–(5.6) and (5.9)–(5.10), we obtain the following equivalent transport equations:

$$\nabla^2\tilde{\varphi}_{nm} = -\frac{2}{ar}\frac{\partial}{\partial r}\left(r\tilde{\varphi}_{n-1,m}\right) \qquad \text{in } D_1, \tag{5.13}$$

together with

$$\nabla^2\varphi'_{nm} = \frac{1}{a^2}\varphi'_{n-2,m} \qquad \text{in } D_2, \tag{5.14}$$

$$2\nabla s_1\cdot\nabla\tilde{\psi}_{n0} + \tilde{\psi}_{n0}\triangle s_1 = 0 \qquad \text{in } D_1, \tag{5.15}$$

and, for $m = 1, 2, \ldots,$

$$2\nabla s_1\cdot\nabla\tilde{\psi}_{nm} + \tilde{\psi}_{nm}\triangle s_1 = -a\triangle\tilde{\psi}_{n,m-1} \qquad \text{in } D_1, \tag{5.16}$$

$$2\nabla s_2\cdot\nabla\tilde{\psi'}_{n0} + \tilde{\psi'}_{n0}\triangle s_2 = 0 \qquad \text{in } D_2, \tag{5.17}$$

and, for $m = 1, 2, \ldots,$

$$2\nabla s_2\cdot\nabla\tilde{\psi'}_{nm} + \tilde{\psi'}_{nm}\triangle s_2 = -a\triangle\tilde{\psi'}_{n,m-1} \qquad \text{in } D_2. \tag{5.18}$$

Together with the accompanying sequences for the boundary conditions, the systems of equations (5.13)–(5.18) are well posed. Of course in the above we understand that $\tilde{\varphi}_{-1,m} = 0$, $\varphi'_{-1,m} = \varphi'_{-2,m} = 0$ for all integer values m, and $\tilde{\psi}_{nm} = 0, \tilde{\psi}'_{nm} = 0$ for all integer values n and $m = -1, -2, \ldots$.

5.1. The leading order solutions. The leading order terms in the boundary conditions given in (5.5)–(5.6) and (5.9)–(5.10) are given by

$$iL\tilde{\psi_{n0}} + iL'\tilde{\psi}'_{n0} = 0, \tag{5.19}$$

$$iL\tilde{\psi_{n0}} + iL'\hat{\tau}G'_t\tilde{\psi}'_{n0} = 0, \tag{5.20}$$

and thus, provided that

$$\hat{\tau}G'_t \neq 1, \qquad \text{then} \qquad \tilde{\psi}_{n0} \equiv \tilde{\psi'}_{n0} \equiv 0. \tag{5.21}$$

Similarly, order one terms from (5.5) and $O(La^{-1})$ terms from (5.10) give

$$\tilde{\psi_{n1}} + \tilde{\psi}'_{n1} = 0, \tag{5.22}$$

$$\tilde{\psi_{n1}} + \hat{\tau}G'_t\tilde{\psi}'_{n1} = 0, \tag{5.23}$$

again provided that

$$\hat{\tau}G'_t \neq 1, \qquad \text{then} \qquad \tilde{\psi}_{n1} \equiv \tilde{\psi'}_{n1} \equiv 0, \qquad n = 0, 1, 2, \ldots. \tag{5.24}$$

The remaining order one boundary conditions from (5.5)–(5.6) are

$$\frac{\partial \tilde{\varphi}_{00}}{\partial r} = \frac{\partial \varphi'_{00}}{\partial r}, \tag{5.25}$$

$$1 + \tilde{\varphi}_{00} = \hat{\rho}\varphi'_{00}, \tag{5.26}$$

$$\Rightarrow \varphi'_{00} = \frac{1}{\hat{\rho}}, \qquad \varphi_{00} = 0.$$

In the above we have expanded the incident field as

$$e^{iKz} = \{1 + iKz + \cdots\}$$

and used only the first harmonic. Here we see the decoupling effect of the scaling, as mentioned earlier. The zero order acoustic potentials do not depend upon the thermal potentials. The corresponding transport equations are given by

$$\nabla^2 \tilde{\varphi}_{00} = 0 \qquad \text{in } D_1, \tag{5.27}$$

$$\nabla^2 \varphi'_{00} = 0 \qquad \text{in } D_2, \tag{5.28}$$

$$\tilde{\varphi}_{00} = \frac{A_0^{00} a}{r}, \qquad \varphi'_{00} = C_0^{00}; \tag{5.29}$$

with the associated solutions, (5.25)–(5.26) then yield $A_0^{00} = 0$ and $C_0^{00} = 1/\hat{\rho}$.

In general, from the decomposition of the incident field into spherical harmonics, we can deduce that the associated solutions $\tilde{\varphi}_{nm}, \varphi'_{nm}, \tilde{\psi}_{nm}$, and $\tilde{\psi}'_{nm}$ will contain the first n spherical harmonics. Thus one could expand the incident field into spherical harmonics, given in (2.15), and subsequently deduce that $\tilde{\varphi}$ and φ', which have the associated solutions

$$\tilde{\varphi}_{00} = \sum_{n=0}^{\infty} \frac{A_n^{00} a^{n+1} P_n(\cos\theta)}{r^{n+1}}, \qquad \varphi'_{00} = \sum_{n=0}^{\infty} \frac{C_n^{00} P_n(\cos\theta) r^n}{a^n}, \tag{5.30}$$

yield the solution

$$A_n^{00} = \frac{-I_n n}{n + (n+1)\hat{\rho}}, \qquad C_n^{00} = \frac{I_n (n+1)}{n + (n+1)\hat{\rho}},$$

where $I_n = i^n(2n+1)j_n(Ka)$ and j_n is the nth spherical Bessel function. Thus we have for $n = 0$, $A_0^{00} = 0$ and $C_0^{00} = 1/\hat{\rho}$, as above. In practice, the zero order term dominates the behavior of the solution.

At order (Ka) we have

$$\cos\theta + a\frac{\partial \tilde{\varphi}_{10}}{\partial r} = \frac{K}{K'} a \frac{\partial \varphi'_{10}}{\partial r}, \tag{5.31}$$

$$\cos\theta + \tilde{\varphi}_{10} = \frac{K}{K'} \hat{\rho} \varphi'_{10}, \tag{5.32}$$

together with the associated transport equations

$$\nabla^2 \tilde{\varphi}_{10} = 0 \qquad \text{in } D_1, \tag{5.33}$$

$$\nabla^2 \varphi'_{10} = 0 \qquad \text{in } D_2, \tag{5.34}$$

and solutions

$$\tilde{\varphi}_{10} = \frac{A_0^{10} a}{r} + \frac{A_1^{10} a^2}{r^2} P_1(\cos\theta), \qquad \varphi'_{10} = C_0^{10} + \frac{C_1^{10} r}{a} P_1(\cos\theta), \tag{5.35}$$

where

$$A_0^{10} = C_0^{10} = 0, \qquad A_1^{10} = \frac{\hat{\rho} - 1}{1 + 2\hat{\rho}}, \qquad C_1^{10} = \frac{3}{1 + 2\hat{\rho}},$$

and $P_n(\cos\theta)$ is the nth spherical Legendre polynomial.

To order $((Ka)^2)$ from (5.14)–(5.15), we have the following transport equations:

$$\nabla^2 \tilde{\varphi}_{20} = -\frac{2}{ar} \frac{\partial}{\partial r} (r \tilde{\varphi}_{10}) \qquad \text{in } D_1, \tag{5.36}$$

$$\nabla^2 \varphi'_{20} = \frac{1}{a^2} \varphi'_{00} \qquad \text{in } D_2, \tag{5.37}$$

with solutions of

$$\tilde{\varphi}_{20} = \frac{A_0^{20} a}{r} + \frac{A_1^{20} a^2}{r^2} P_1(\cos\theta) + \frac{A_2^{20} a^3}{r^3} P_2(\cos\theta) - \frac{A_1^{10} a}{r} P_1(\cos\theta),$$

$$\varphi'_{10} = C_0^{20} + \frac{C_1^{20} r}{a} P_1(\cos\theta) + \frac{C_1^{20} r^2}{a^2} P_2(\cos\theta) + \frac{C_0^{00} r^2}{6a^2}, \tag{5.38}$$

where

$$A_0^{20} = \frac{\hat{\rho} - 1}{3\hat{\rho}}, \qquad A_1^{20} = \frac{\hat{\rho} - 1}{1 + 2\hat{\rho}}, \qquad A_2^{20} = \frac{2(\hat{\rho} - 1)}{3(2 + 3\hat{\rho})},$$

$$C_0^{20} = \frac{(3\hat{\rho} - 1)\hat{c}}{6\hat{\rho}^2} - \frac{1}{6\hat{\rho}}, \qquad C_1^{20} = 0, \qquad C_2^{20} = \frac{(5\hat{\rho})}{3(2 + 3\hat{\rho})\hat{\rho}\hat{c}},$$

where $\hat{c} = K'^2/K^2$.

Continuing in this way, we construct the functions $\tilde{\varphi}_{nm}, \varphi'_{nm}, \tilde{\psi}_{nm}$, and $\tilde{\psi}'_{nm}$. At order $(Ka)^2(La)^{-1}$ we observe the first interaction between the thermal and acoustic fields with the following boundary conditions:

$$\tilde{\varphi}_{11} + a \frac{\partial \tilde{\varphi}_{21}}{\partial r} + \tilde{\psi_{22}} = \hat{c}\hat{d} \left\{ a \frac{\partial \varphi'_{21}}{\partial r} - \tilde{\psi'_{22}} \right\}, \tag{5.39}$$

$$\tilde{\varphi}_{21} = \hat{\rho}\, \hat{c}\, \hat{d}\, \varphi'_{21}, \tag{5.40}$$

$$\tilde{\psi}_{22} = -\hat{\tau}\,\hat{c}\,\hat{d}\,G_t'\,\psi_{22}', \tag{5.41}$$

where $\hat{d} = L/L'$. Similar expressions for the order $(Ka)^2(La)^{-2}$ terms together with solutions, developed from the transport equations (5.15)–(5.18), allow determination of the coefficients A_0^{21} and A_0^{22} for the functions

$$\tilde{\varphi}_{21} = \frac{A_0^{21}a}{r} + \frac{A_1^{21}a^2}{r^2}P_1(\cos\theta) + \frac{A_2^{21}a^3}{r^3}P_2(\cos\theta), \tag{5.42}$$

$$\tilde{\varphi}_{22} = \frac{A_0^{22}a}{r} + \frac{A_1^{22}a^2}{r^2}P_1(\cos\theta) + \frac{A_2^{22}a^3}{r^3}P_2(\cos\theta). \tag{5.43}$$

Solutions to the transport equations (5.15) and (5.18) for $n = 2$ and $m = 0, 1, 2$ are of the form

$$\tilde{\psi}_{20} = \frac{D_0^{20}a}{r} + \frac{D_1^{20}a}{r}P_1(\cos\theta) + \frac{D_2^{20}a}{r}P_2(\cos\theta),$$

$$\tilde{\psi}_{21} = \frac{D_0^{22}a}{r} + \frac{D_1^{22}a}{r}P_1(\cos\theta) + \frac{D_2^{22}a}{r}P_2(\cos\theta) - \frac{D_1^{21}a^2}{r^2}P_1(\cos\theta) - \frac{3D_2^{21}a^2}{r^2}P_2(\cos\theta),$$

$$\tilde{\psi}_{22} = \frac{D_0^{22}a}{r} + \frac{D_1^{22}a}{r}P_1(\cos\theta) + \frac{D_2^{22}a}{r}P_2(\cos\theta) - \frac{D_1^{21}a^2}{r^2}P_1(\cos\theta)$$

$$- \frac{3D_2^{21}a^2}{r^2}P_2(\cos\theta) + \frac{3D_2^{20}a^3}{r^3}P_2(\cos\theta),$$

with similar expressions for $\tilde{\psi}'_{2m}$, $m = 0, 1, 2$. However, due to (5.21)–(5.24), considerable simplification is achieved, allowing us to derive the following quantities:

$$A_0^{21} = \left\{\frac{(1-\hat{\tau}G_t')}{\hat{\tau}G_t'}\right\}\left\{\frac{\hat{\tau}(\alpha L^2 G_c' - G_c L'^2\hat{\rho})}{\hat{\rho}L'\,(L'\hat{\tau}+L)}\right\},$$

$$A_0^{22} = \left\{\frac{(L^2 - L'^2\hat{\tau})}{L'(L'\hat{\tau}+L)} - \frac{(\hat{c}-1)\hat{d}}{\hat{\tau}G_t'}\right\}\left\{\frac{\hat{\tau}(\alpha L^2 G_c' - G_c L'^2\hat{\rho})}{\hat{\rho}L'\,(L'\hat{\tau}+L)}\right\}.$$

6. The far field. For the far field we have the following theorem due to Atkinson [15], Barrar and Kay [16], and Wilcox [17].

THEOREM 6.1. *Let u be the radiating solution to the Helmholtz equation,*

$$\bigtriangledown^2 u + k^2 u = 0 \qquad in \quad V_1;$$

then the field scattered from the surface B has an asymptotic form of a spherical wave,

$$u(r) = \frac{e^{ikr}}{r}\sum_{n=0}^{\infty}\frac{f_n(\phi,\Omega)}{r^n}, \tag{6.1}$$

where the series converges absolutely and uniformly for $r > c + \epsilon$, $\epsilon > 0$. Here c is defined as $c = \max_{r\in B} r$. Furthermore, the series may be differentiated term by term

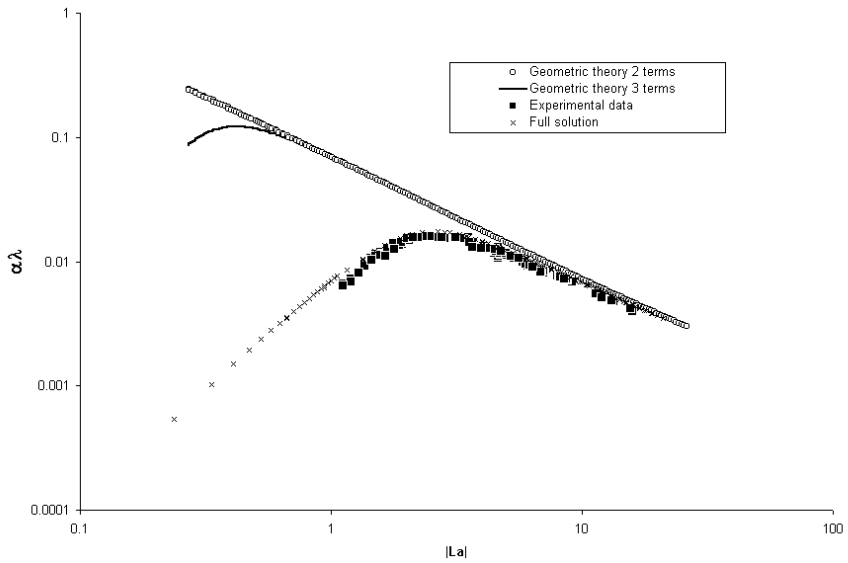

FIG. 6.1. *Plot of $\alpha\lambda$, the attenuation per wavelength, against La, the product of thermal wave number and particle radius, for a silicone (polysiloxane) oil-in-water emulsion. Solid squares denote experimental data for 5% volume concentration of oil, the black line shows the high frequency formulation using the far field pattern in* (6.2)*, and the crosses indicate the ECAH calculation. The open squares show the calculation using only the first two terms in* (6.2)*.*

with r, ϕ, and Ω any number of times, and the resulting series all converge absolutely and uniformly. The functions $f_n(\phi, \Omega)$ are understood to depend on the parameter k, and the function $f_0(\phi)$ is called the far field.

In the above formulation, one can see that the far field pattern for the reflected acoustic field is given by

$$f_0(\phi) = -K^2a^3\left\{A_0^{20} - \frac{iA_0^{21}}{L} - \frac{A_0^{22}}{L^2}\right\} + O(|Ka|^3) \quad \text{as} \quad \mathrm{r} \to \infty, \tag{6.2}$$

where ψ does not contribute due to the nonpropagational character of the thermal wave. The term A_0^{20} contained in the far field pattern derives from the acoustic scattering of the particle, depends upon only the ratio of densities of the two phases, and is independent of the thermal properties. In contrast, the terms A_0^{21} and A_0^{22} are dependent upon the thermal properties of the phases, the former being the dominant term and the coefficient in $(La)^{-1}$. This scaling is seen in Figure 6.1.

6.1. Comparison with experiments. We now compare the high frequency geometric theory of diffraction solution, the ECAH solution, and experimental data. This necessitates the use of multiple particle scattering theory. Lloyd and Berry [14] showed that

$$\left(\frac{B}{K}\right)^2 = 1 + \frac{3\phi f(0)}{K^2a^3} + \frac{9\phi^2 f(0)}{4K^4a^6}\left\{f^2(\pi) - f^2(0) - \int_0^\pi d\theta \frac{1}{\sin(\theta/2)}\frac{d}{d\theta}f^2(\theta)\right\}, \tag{6.3}$$

where B is the wave number of the acoustic wave in the dispersion and $\phi = 4\pi a^3 n_0/3$ is the droplet volume fraction. We have used the above multiple scattering result

TABLE 1
Physical data set for experimental and theoretical emulsions.

	n-Hexadecane	Silicone oil	Aqueous phase
Sound velocity $v(m\ s^{-1})$	1357.9	1004	1482
Density $\rho(kg\ m^{-3})$	773.0	975	998.2
Thermal expansivity $\beta(K^{-1})$	9.1×10^{-4}	9.4×10^{-4}	2.13×10^{-4}
Specific heat $C_p(J\ kg^{-1}K^{-1})$	2215	1460	4182
Thermal conductivity $\tau(W\ m^{-1}K^{-1})$	0.143	0.15	0.591

in what follows, even though we showed in [4] that (6.3) fails to accurately describe multiple scattering in the presence of thermal fields since it assumes that the scatterers are points and neglects the interpenetrating character of the thermal fields. However, we compare our theoretical result with the experimental data only at the lowest concentrations, where the multiple scattering equation (6.3) is most accurate. Figure 6.1 compares experimental data, the theoretical calculations of ECAH, and the above geometric theory of diffraction solution. Since the geometric theory solution is zero order in K, K', one can infer the dominating effect of thermal scattering in acoustic propagation in dispersions, indicating that a significant component of the acoustic attenuation results purely from thermal effects. As can be seen from the figure, the high frequency formulation gives excellent agreement with both experimental results and ECAH for $|La| \gg 1$ and, furthermore, is easy to calculate, providing a very practical solution. The calculations were performed using the parameter values given in Table 1 and compared with experiments performed by Hemar et al. [19]. The data relates to particle sizes in the range 230nm to 760nm for silicone oil-in-water over a range of frequencies from 0.5MHz to 10MHz. For these parameter values the values of Ka ranged from 10^{-4} up to 10^{-2}, and the data satisfy $|Ka| \ll 1$. We present comparisons for the case in which the volume concentration of oil is 5%, since for higher concentrations it is known that multiple scattering of the thermal field makes a significant contribution; see [4].

7. Conclusions. We have obtained an approximation to the ECAH solution for acoustic scattering from a single particle for the acoustic long wavelength regime, when the associated thermal field is in the short wavelength regime. This approximation is well conditioned and well posed and can be computed to arbitrary accuracy. It may be generalized to arbitrary particle shape using boundary-integral and finite-element techniques. This solution for $|La| \gg 1$ complements our previous approximation for $|La| \ll 1$ given in [4]. As noted in [11], since $\sigma\omega/v^2 \ll 1$, $|La| \gg Ka$, and so it is the condition $|La| > 1$ that causes LFPST to fail at higher frequencies even though the acoustic wavelength is still large compared to the particle radius. Together with the LFPST approximation, we now have a set of simple and well-conditioned approximations for the scattering throughout the entire range of low frequency scattering experiments, which provides a further step towards complete understanding of ultrasound propagation through systems of weakly interacting particles in the acoustic long wavelength limit. We have still to address the question raised in [11] concerning the failure of current multiple scattering formulations to adequately deal with thermal scattering.

CONNECTING A DISCRETE IONIC SIMULATION TO A CONTINUUM*

B. NADLER†, T. NAEH†, AND Z. SCHUSS†

Abstract. An important problem in simulating ions in solution is the connection of the finite simulation region to the surrounding continuum bath. In this paper we consider this connection for a simulation of uncharged independent Brownian particles and discuss the relevance of the results to a simulation of charged particles (ions). We consider a simulation region surrounded by a buffer embedded in a continuum bath. We analyze the time course of the exchange process of particles between the simulation region and the continuum, including re-entrances of particles that left the simulation. We partition the particle population into (i) those that have not yet visited the simulation and (ii) those that have. While the arrival process into the simulation of population (i) is Poissonian with known rate, that of population (ii) is more complex. We identify the ordered set of re-entrance times of population (ii) as a superposition of an infinite number of delayed terminating renewal processes, where the renewal periods may be infinite with positive probability. The ordered entrance times of populations (i) and (ii) form the pooled process of injection times of particles into the simulation. We show that while the pooled process is stationary, it is not Poissonian but rather has infinite memory. Yet, under some conditions on the sizes of the simulation and buffer regions, it can be approximated by a Poisson process. This seems to be the first result on the time course of a discrete simulation of a test volume embedded in a continuum.

Key words. stationary stochastic processes, diffusion, renewal theory, simulation of ions

1. Introduction.

Computer simulations of ions in electrolytic solutions are a widely used tool in physical chemistry and are becoming increasingly important in molecular biophysics as well [1], [2], [3], [4], [5], [6], [7], [8], [9], [10], [11], [12], [13], [14], [15], [16]. Since it is impractical to simulate the entire continuum bath, a common approach is to isolate a small finite region of the continuum and simulate only the motion of ions located in this region. The requirements from such a "small" simulation are that the averaged concentrations of the different ionic species in the simulation volume be preserved, the electrostatic forces be correctly reproduced, and the effective measured ionic diffusion coefficients be recovered

Of course, as simulated ions may reach the boundary of the simulation region and nonsimulated bath ions may cross it, the simulation must be *connected* to the surrounding continuum bath. This involves not only the correct computation of the electrostatic field, including the contribution of nonsimulated bath ions, but also the resolution of the two following issues: (i) the imposed boundary behavior on trajectories of simulated ions as they reach the boundary of the simulation region and (ii) the injection scheme (if any) of new ions into the simulation. In this paper we are concerned with these two issues. Specifically, we study the processes of random exit,

entrance, and re-entrance of particles between the simulation region and the continuum bath. We analyze a simulation of *uncharged* particles and discuss the relevance of our results to a simulation with *charged* particles in section 8. The computation of the electrostatic field for a simulation of charged particles will be considered elsewhere.

The total number of simulated ions in a simulation scheme can be either fixed or variable. In simulations with a fixed number of ions, there is no injection scheme of new ions into the simulation, and the imposed boundary conditions on the trajectories of simulated particles are either periodic or reflecting [15], [16]. Simulations with a fixed number of ions, and in particular those with periodic boundary conditions, have serious limitations which have been discussed at length in the literature [17], [18], [19], [20], [21], [22], [23] (and references therein). In particular, density fluctuations are absent in such simulations, and the computation of the electrostatic field is at best problematic.

Density fluctuations are determinants of important properties of an ionic solution [12], [13]. There have been various attempts in the literature to include density fluctuations in simulations with a fixed number of ions. The most common method is the introduction of a *buffer* region between the simulation region and the surrounding continuum bath. The simplest approach, as described in [6], is to run a simulation with a fixed total number of particles in the simulation and buffer region, with reflecting boundary conditions at the outer buffer boundary. In this scheme density fluctuations are of course present in the smaller simulation region, although it is unclear how faithfully they reproduce the actual density fluctuations in the simulation region. Other approaches, as reported in [2] and [8], replace the reflecting boundary conditions at the boundary of the buffer region by "soft" boundary conditions. That is, ions are allowed to leave the buffer region into the bath, but then they are subject to an artificial attracting force, so that they eventually return into the buffer region. In both references, the attracting force was designed to maintain the correct equilibrium density in the simulation region. Once again, while the total number of particles is kept fixed, there are fluctuations in the number of particles in the smaller simulation region. The main problem with these approaches is that the confinement of ions to the simulation by ad hoc artificial attracting forces (or even infinite forces, in the case of reflecting boundaries) imposes unphysical conditions on the simulation and may not necessarily lead to correct time dependent density fluctuations.

Simulations with a variable number of ions also use a buffer region between the simulation and the continuum bath, but replace the reflecting or soft boundary conditions at the boundary of the buffer region by stochastic boundary conditions [7], [8], [9], [10]. These conditions introduce a random exchange mechanism of ions between the simulation and buffer regions with the aim of reproducing the equilibrium density fluctuations. Obviously, different assumptions on the stochastic boundaries lead to different density fluctuations in time and space inside the simulation region. Unfortunately, the stochastic process of equilibrium density fluctuations is unknown in the sense that the joint probability distribution of the number of particles in the simulation volume at different times is unknown. The fluctuation theory proposed by Smoluchowski [11] is valid only for sufficiently long time intervals between observations so that it cannot be applied to a simulation of particles in solution [29]. Yet, these fluctuations affect the physical properties of the solute [12], so proposing a scheme that recovers the correct fluctuations is essential.

In all formulations of stochastic boundaries, the probability laws for the injection times of new particles are *assumed*, rather than derived, from the laws of motion of

ions in solution. The aim of this paper is to *derive* the probability laws of the entrance and re-entrance processes of ions into a finite volume surrounded by a buffer zone as they actually occur in the solution. To derive our results, we make standard general assumptions of physical chemistry about the ionic motion of bath ions.

In our analysis, we consider a finite simulation region surrounded by a buffer region embedded in a practically infinite ionic solution. We assume that all bath ions can be described as *independent* uncharged Brownian particles with an effective diffusion coefficient. This assumption is commonly used in physical chemistry, where ionic solutions are described by an electrochemical potential [12]. This means that, on a large enough time scale, the motions of charged interacting ions in the bath are assumed independent *noninteracting* diffusion processes in a mean field, which reduce to independent Brownian particles for a vanishing mean field.

We consider particle entrances at the boundary of the inner region and their exits at the outer boundary of the buffer zone. In the corresponding simulation, the motion of all particles that enter the inner region is simulated until they cross the outer boundary of the buffer region for the first time. Their motion is simulated once again the next time they enter the inner region, until their next exit at the outer region, and so on. The buffer region in the simulation scheme serves as a separator between the inner simulation region and the surrounding continuum bath, thus avoiding instantaneous re-entrances of Brownian particles at the boundary of the inner region,

To formulate mathematically the problem of introducing particles into the simulation, we divide their entrances into two types: (i) arrivals of "new" particles, which have not visited the simulation region so far, and (ii) arrivals of "returning" particles, which have already visited and exited the simulation region. Obviously, the probability law of the recirculation times is *different* from that of the times between new arrivals, so that particles that leave the simulation at the outer boundary of the buffer zone cannot be returned to the bath on equal footing with particles that have not been in the simulation so far.

In our previous paper [24], we studied the stationary arrival process (i) of new particles. It was shown that in steady state, the interarrival times to an absorbing boundary are exponentially distributed with rate equal to the Smoluchowski flux, rendering the stationary arrival process Poissonian. Apart from its relevance to the problem of connecting a simulation to the surrounding continuum, the study of the arrival problem at an absorbing boundary has many physical applications and a long mathematical history [25], [26].

In this paper, we study the recirculation process (ii) and its role in connecting the simulation to the surrounding bath. We determine stationary probability laws governing the entrance and re-entrance times of all processes (i) and (ii). At any given time in the course of the simulation the particle to be injected next is the one whose arrival time at the inner sphere is the *shortest* among all the particles not currently in the simulation. The candidates for injection are both the new and recirculating particles. In this paper we identify the injection process as a *pooled* process, that is, a superposition of an infinite number of terminating renewal processes and determine some of its statistical properties.

We show that the pooled process converges to a stationary steady state. However, even though in the steady state the process is stationary, its interarrival times are not exponential, not even independent, and have infinite memory. We calculate some of the statistical properties of the pooled process, such as the exact pdf of the residual

first arrival time of the pooled process in steady state, as well as the first and second moments of the pooled process. Our main result is that under some conditions on the size of the simulation and buffer regions, the infinite memory pooled process can be approximated by a Poisson process. This approximation considerably simplifies the simulation. To the best of our knowledge, this work seems to be the first result on the time course of a discrete simulation embedded in a continuum.

The paper is organized as follows. In section 2, we formulate the simulation scheme and identify the entrance process of particles as a pooled process. In section 3, we present a continuum model of the simulation, from which the average flux of the pooled process is calculated. The first two moments of the pooled process are calculated in section 4 by renewal-type considerations. In section 5, we define the entrance times of the pooled process, and in section 6, we calculate the distribution of the residual time till the first particle entrance and the distribution of the subsequent interarrival time. The main result, which asserts that short interarrival times are exponentially distributed and the effective exponential rate is the same as that calculated from the continuum and renewal models, is discussed in section 7. We also present there results of a simulation of the pooled process and discuss its rate of convergence to steady state. Section 8 contains a summary and discussion.

2. Setup of the problem. We consider the following simulation scheme: A practically infinite ionic bath of average density ρ occupies the three dimensional space. Inside this bath, there is a finite simulation region consisting of two concentric spheres of radii a and r_0 ($a < r_0$), centered at the origin (see Figure 1(a)). In the proposed simulation scheme, the motion of all particles that enter the inner sphere is simulated until they cross the outer sphere for the first time. Their motion is simulated once again the next time they enter the inner sphere, until their next exit at the outer sphere, and so on (see Figure 1(b)). The region beyond the outer sphere, $|\boldsymbol{r}| > r_0$, contains no simulated particles and is described by a *continuum* particle density. The annular ring $a < |\boldsymbol{r}| < r_0$ is a *buffer* region that connects the inner region to the surrounding continuum bath in $|\boldsymbol{r}| > r_0$. The buffer region is part continuum and part discrete in the sense that the motions of only some of the particles in it are simulated.

While we do not describe the exact electrostatic interactions between bath ions, we follow the common practice in chemical physics [12] that describes the effective motions of the nonsimulated bath ions as independent diffusions in a mean field. Specifically, for a homogeneous bath with no applied potential, the mean field vanishes, so that exterior of the simulation region can be described as an infinite bath of independent free Brownian particles, with average density ρ. As discussed in the introduction, we assume that the simulation is *self-consistent*. This means that on a large enough time scale the coarse grained motion of simulated ions inside the simulation region can also be described as free diffusion with the same diffusion coefficient as that assumed for the nonsimulated ions in the continuum bath. We further assume that the simulation and buffer regions are large enough so that, for the purpose of calculating the time course of the simulation, all particles, both simulated and nonsimulated, can be described as effectively independent Brownian particles with the above diffusion coefficient. We note that the self-consistency condition is not trivial, and it determines important physical parameters, as discussed in [27].

We introduce the following notation. Particles that have not visited the inner sphere so far are called *blue* particles, and those that have are called *red* particles. The arrival process of blue particles into the simulation is process (i) and the re-

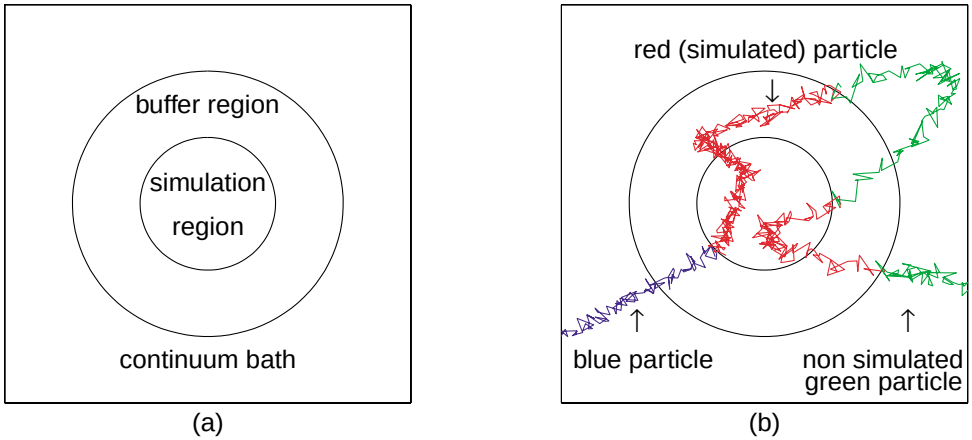

FIG. 1. (a) *The simulation setup.* (b) *The simulated and nonsimulated parts of a typical particle trajectory.*

entrance of the red particles is process (ii).

As shown in [24], in steady state, blue Brownian particles arrive at an absorbing sphere at an exponential rate. A blue particle that reaches the boundary of the inner sphere turns red instantaneously and stays red forever. As long as it is inside the simulation region, its dynamics change from independent Brownian motion, with its effective diffusion coefficient in the ambient solution, to diffusive motion governed by the Langevin equation with electrostatic interactions with the ions in the simulation and with the far field of the ambient solution. The interactions with the nonsimulated ions in the ambient solution outside the outer sphere are replaced by interactions with a mean field, as mentioned above. The assumption of a self-consistent simulation implies that for our purposes the probability distribution of the time a simulated ion spends inside the simulation is identical to that of a free noninteracting Brownian particle.

One way to run this simulation is as follows: Introduce blue particles at exponential interarrival times. Follow the trajectory of each (now red) simulated particle until its first exit at the boundary of the larger sphere. Now, sample a random re-entrance time into the simulation, assuming it performs Brownian motion outside the inner sphere, and store this re-entrance time in a table of all re-entrance times of recirculating particles. In this scheme, the next particle to be injected into the simulation is the one with the *minimal* return time between all particles registered in the table and the next blue particle to be injected into the simulation. There are two main difficulties with this simulation scheme. One is that the table of re-entrance times grows indefinitely with time, because the mean recirculation time of returning particles is infinite (see Proposition A.1 in Appendix A). The other difficulty is that the convergence to steady state of this simulation is extremely slow, as analyzed in section 7. This is due to the fact that as long as the table is finite, all the infinite number of re-entrances of particles that were inside the simulation region *before* the simulation actually started, and are thus not present in this table, are neglected.

This simple example shows that a mechanism to run the simulation in steady state from its start needs to be developed. More specifically, the steady state distribution of return times from this infinite table of recirculated particles has to be calculated.

A key point in this calculation is the well-known feature [28] that for free Brownian motion in three dimensions there is a positive probability that a red particle that just exited the simulation will never return to the inner sphere, so that its recirculation time is infinite. This observation gives rise to the following renewal-type model. The arrivals of blue particles at the inner sphere form a Poisson process [24], [29], as mentioned above. For each arriving particle, its subsequent re-entrance times into the simulation form an independent renewal process. The interarrival times of this process may be infinite with positive probability, thus rendering it a *terminating renewal process* [30]. The renewal processes of different particles start of course at different times, according to their first injection times. A renewal process that starts at a random time with one distribution and is renewed with another is called a *delayed renewal process* [30]. The superposition of all the delayed renewal processes is called the *pooled process*. The steady state of the pooled process is the process of introducing new particles into the simulation, which is the concern of this paper.

3. A continuum model of the simulation. In this section we compute the average *flux* of particle entrances of the pooled process (both blue and red) into the inner simulation region from a continuum model of the above described simulation. To this end, we represent the Brownian particles in the simulation and in the bath as continuum *densities*. Since we consider free Brownian particles, all densities are spherically symmetric and depend only on the radial distance, $r = |\boldsymbol{r}|$, from the center of the simulation spheres. The densities of simulated particles are defined as averages of many different realizations of particle locations of a running simulation.

We start from the radial density of the blue particles, denoted $p_B(r)$. It satisfies the diffusion equation outside the inner sphere [31],

$$\Delta p_B(r) = \frac{d^2 p_B(r)}{dr^2} + \frac{2}{r}\frac{dp_B(r)}{dr} = 0 \qquad \text{for } r > a, \tag{3.1}$$

with absorbing boundary conditions at the boundary of the inner sphere, where blue particles instantaneously turn red,

$$p_B(a) = 0. \tag{3.2}$$

In addition, far away from the simulation region the blue particle density equals the bulk density ρ,

$$\lim_{r\to\infty} p_B(r) = \rho. \tag{3.3}$$

The solution of (3.1)–(3.3) is

$$p_B(r) = \begin{cases} \rho\left(1 - \dfrac{a}{r}\right) & \text{for} \quad r > a, \\ 0 & \text{for} \quad r < a. \end{cases} \tag{3.4}$$

Using (3.4), the continuum flux of blue particles at the inner sphere is given by

$$J_{\text{blue}} = -4\pi a^2 D \frac{d}{dr} p_B(r)\bigg|_{r=a} = 4\pi\rho a D, \tag{3.5}$$

where ρ is the bulk concentration at infinity, and D is the diffusion coefficient of bath particles. Equation (3.5) for the average flux of Brownian particles at an absorbing boundary was already calculated by Smoluchowski in 1917 [25].

Next, we consider the red particle density. According to our assumptions, the total particle density in the bath is uniform and at all locations equals the bulk density ρ. Since the simulation region is an arbitrary region of the bath, the steady state density of the red particles, denoted $p_R(r)$, complements that of the blue particles to the bulk density ρ,

$$p_R(r) = \rho - p_B(r). \tag{3.6}$$

We denote by J_{total} the total flux of particle entrances at the inner sphere. The total flux is the sum of the blue particles flux given by (3.5), and the flux of *returning* red particles, which have exited the simulation through the outer sphere. Since at any given time, only some of the red particles are simulated while others are not, the flux of returning red particles cannot be computed from (3.6). The contribution of red particles to the total incoming flux at the inner sphere comes only from the *nonsimulated* population of red particles. To compute their contribution to the influx, we divide the red particle population into two: simulated red particles, denoted *pink* particles, and nonsimulated red particles, denoted *green* particles. With this notation, the total flux at the inner sphere is given by

$$J_{\text{total}} = J_{\text{blue}} + J_{\text{green}}. \tag{3.7}$$

We denote the steady state densities of the pink and green particles by $p_P(r)$ and $p_G(r)$, respectively. Of course,

$$p_R(r) = p_P(r) + p_G(r).$$

We now calculate the densities of the green and pink particles. Each particle that enters the simulation region at the inner sphere, either new or returning particle, exits it at the outer sphere at some later time with probability one. Once such a particle crosses the outer sphere it immediately becomes green, until its next arrival at the inner sphere, when it becomes pink again. Thus, the green particle density has a *source* at the outer sphere whose strength equals the yet undetermined total absorption flux J_{total} of both blue and returning red particles. That is, the green particle density satisfies the diffusion equation

$$\Delta p_G(r) = \frac{d^2 p_G(r)}{dr^2} + \frac{2}{r}\frac{dp_G(r)}{dr} = J_{\text{total}}\frac{\delta(r-r_0)}{4\pi r_0^2}, \qquad \text{for} \quad r > a, \tag{3.8}$$

with absorbing boundary conditions at the inner sphere,

$$p_G(a) = 0, \tag{3.9}$$

and with the condition that $p_G(r) \to 0$ as $r \to \infty$. The solution for the green particle density, in terms of the yet undetermined parameter J_{total}, is given by

$$p_G(r) = \begin{cases} \dfrac{J_{\text{total}}}{4\pi r_0}\left[\left(1-\dfrac{a}{r}\right) - H(r-r_0)\left(1-\dfrac{r_0}{r}\right)\right], & \text{for} \quad r > a, \\ 0, & \text{for} \quad r < a, \end{cases}$$

where $H(x)$ denotes the Heaviside step function. The averaged densities of the blue, pink, and green particle populations are shown in Figure 2.

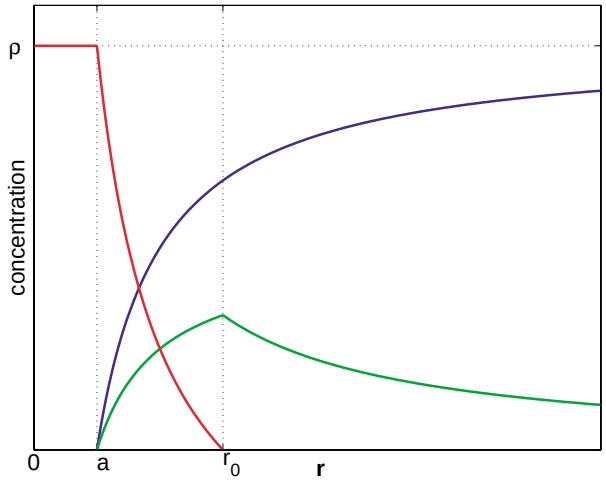

FIG. 2. *The averaged densities of the blue, pink, and green particle population.*

The average influx of green particles at the inner sphere, denoted J_{green}, is thus

$$J_{\text{green}} = 4\pi r^2 \frac{d}{dr} p_G(r)\Big|_{r=a} = \frac{a}{r_0} J_{\text{total}}. \tag{3.10}$$

Note that the flux of green particles into the inner sphere is *smaller* than its source strength J_{total}. This is because there is a positive probability for a green particle that starts its motion at the boundary of the outer sphere to never reach the inner sphere. The ratio between the two fluxes is simply the probability of a free Brownian particle to ever reach the inner sphere from the outer sphere. As shown in section 6, this return probability, denoted p, is given by

$$p = \frac{a}{r_0}. \tag{3.11}$$

The total mean flux of particles into the simulation, denoted Λ, can now be obtained by combining (3.5), (3.7), and (3.10),

$$\Lambda = J_{\text{total}} = J_{\text{blue}} + J_{\text{green}} = \frac{\lambda_B}{1-p}. \tag{3.12}$$

As expected, due to the recirculating red particles, the total flux at the inner sphere is larger than the flux of only the blue particles. For example, in a simulation scheme that inserts only blue particles, absorbs them at the outer sphere and "forgets" about their possible re-entrances, the average particle flux into the simulation region is smaller than it should be. This might have serious effects on the outcome of the simulation.

Finally, note that the flux parameter Λ does not represent a physical quantity, but is rather only a simulation parameter, that depends on the choice of the radii a and r_0 of the simulation spheres. Therefore, all physical parameters that are an outcome of the simulation must not depend on Λ.

4. The mean and variance of the pooled process. In the previous section the total average influx of the steady state pooled process was computed with the

aid of a corresponding continuum model. However, the continuum model is unable to compute other statistical properties of the pooled process, such as the distribution of the interarrival times, or even their variance. Obviously, a simulation scheme should attempt to preserve at least some of these quantities. In this section, we present a statistical renewal model of the pooled process that, in principle, enables the computation of all moments of the pooled process.

For simplicity, we consider a simulation that starts at time $t = 0$ with no particles initially inside the simulation region. Since we are interested in quantities for a simulation that has reached steady state, the results are independent of these initial conditions. We denote by $N^P(t)$ the total number of particle entrances of the pooled process by time t. This includes all entrances of blue particles and re-entrances of returning red particles into the simulation region by time t. We compute the first two moments of $N^P(t)$ and note that the method presented can be applied to compute all higher order moments as well.

THEOREM 4.1. *The average steady state flux of the pooled process is* Λ*, and its variance per unit time is* $\Lambda(1+p)/(1-p)$.

Proof. Let $N^B(t)$ denote the number of arrivals of *blue* particles into the simulation during the time interval $[0,t]$, and let $\{t^i\}_{i=1}^{N^B(t)}$ denote these arrival times. According to [24], the interarrival times of the blue particles are independent identically distributed (i.i.d.) random variables, exponentially distributed with rate λ_B that is equal to the corresponding continuum flux J_{blue} calculated in (3.5). Therefore, the total number of blue arrivals by time t, denoted $N^B(t)$, is a Poisson distributed random variable with parameter $\lambda_B\, t$. For each blue particle we denote by $\xi(t-t^i)$ the (random) number of its re-entrances into the simulation by time t since its first entrance at time t^i. In terms of these random variables, the total number of particle entrances of the pooled process can be written as

$$N^P(t) = \sum_{i=1}^{N^B(t)} \left[1 + \xi(t-t^i)\right]. \tag{4.1}$$

We denote by $\mu_1(t)$ and $\mu_2(t)$ the first two moments of $\xi(t)$,

$$\mu_1(t) = E\left[\xi(t)\right], \qquad \mu_2(t) = E\left[\xi(t)\right]^2. \tag{4.2}$$

Note that $\xi(\infty)$ is the total number of re-entrances of a red particle. Since each particle has probability $p < 1$ of ever returning to the simulation (see (3.11)), the random variable $\xi(\infty)$ follows a *geometric* distribution with parameter p, which gives

$$\mu_1(\infty) = \frac{p}{1-p}, \qquad \mu_2(\infty) = \frac{p}{1-p} + \frac{2p^2}{(1-p)^2}. \tag{4.3}$$

To compute the average of the pooled process, $E[N^P(t)]$, we divide the sum in (4.1) into the first term and the sum of the $N^B(t)-1$ remaining terms,

$$N^P(t) = 1 + \xi(t-t^1) + \sum_{i=2}^{N^B(t)} (1 + \xi(t-t^i)). \tag{4.4}$$

According to our assumptions, the arrival process of blue particles is Poissonian and thus memoryless. In addition, the recirculation processes of different particles are independent and identical, if their starting times are all shifted to an identical initial

time. These two properties imply that given the arrival time of the first blue particle, $t^1 = s$, the sum in (4.4) has the same statistical properties as that of the random variable $N^P(t-s)$. In particular,

$$\Pr\left\{ \sum_{i=2}^{N^B(t)} (1+\xi(t-t^i)) = n \middle| t^1 = s \right\} = \Pr\left\{ \sum_{i=2}^{N^B(t)} [1+\xi\left((t-s)-(t^i-s)\right)] = n \right\}$$

$$= \Pr\left\{ N^P(t-s) = n \right\}. \tag{4.5}$$

Thus, taking expectations in (4.4) and using the exponential distribution of t^1 gives

$$E\left[N^P(t)\right] = \int_0^t E\left[N^P(t)\middle| t^1 = s\right] \lambda_B e^{-\lambda_B s}\, ds$$

$$= \int_0^t \left[1 + \mu_1(t-s) + E \sum_{i=2}^{N^B(t)} [1+\xi((t-s)-(t^i-s))] \right] \lambda_B e^{-\lambda_B s}\, ds,$$

which, according to (4.5), can equivalently be written as a renewal-type integral equation,

$$E\left[N^P(t)\right] = \int_0^t \lambda_B e^{-\lambda_B s} \Big\{ 1 + \mu_1(t-s) + E\Big[N^P(t-s)\Big] \Big\}\, ds, \tag{4.6}$$

along with the initial condition $N^P(0) = 0$. The solution of (4.6) is given by

$$E[N^P(t)] = \int_0^t \lambda_B \left[1 + \mu_1(s)\right]\, ds. \tag{4.7}$$

Therefore, by l′Hôpital′s rule and using (4.3),

$$\lim_{t\to\infty} \frac{E\left[N^P(t)\right]}{t} = \lim_{t\to\infty} \lambda_B \Big[1 + \mu_1(t)\Big] = \lambda_B \Big[1 + \mu_1(\infty)\Big] = \Lambda.$$

As expected, we recover the same total average flux of the pooled process as that computed from the continuum model, (3.12).

Next, we consider the second moment, $E[N^P(t)^2]$. Before computing the expectation, we write $[N^P(t)]^2$ as

$$[N^P(t)]^2 = \sum_{i=1}^{N^B(t)} [1 + 2\xi(t-t^i) + \xi^2(t-t^i)] + 2 \sum_{i=1}^{N^B(t)} [1+\xi(t-t^i)] \sum_{j=i+1}^{N^B(t)} [1+\xi(t-t^j)]$$

$$= H(t) + 2G(t),$$

where

$$H(t) = \sum_{i=1}^{N^B(t)} [1 + 2\xi(t-t^i) + \xi^2(t-t^i)],$$

$$G(t) = \sum_{i=1}^{N^B(t)} [1+\xi(t-t^i)] \sum_{j=i+1}^{N^B(t)} [1+\xi(t-t^j)].$$

The expectations of $H(t)$ and $G(t)$ also satisfy integral equations,

$$E\left[H(t)\right] = \int_0^t \lambda_B e^{-\lambda_B s}\Big\{1 + 2\mu_1(t-s) + \mu_2(t-s) + E\left[H(t-s)\right]\Big\}\, ds,$$
$$E\left[G(t)\right] = \int_0^t \lambda_B e^{-\lambda_B s}\Big\{\big(1 + \mu_1(t-s)\big)E\big[N^P(t-s)\big] + E\left[G(t-s)\right]\Big\}\, ds.$$

The solutions of these equations are

$$E\Big[H(t)\Big] = \int_0^t \lambda_B\Big[1 + 2\mu_1(s) + \mu_2(s)\Big]\, ds,$$
$$E\Big[G(t)\Big] = \int_0^t \lambda_B\Big[1 + \mu_1(s)\Big]E\left[N^P(s)\right]\, ds.$$

The long time behavior of the variance of $N^P(t)$ is found from the identity

$$\lim_{t\to\infty}\frac{\mathrm{Var}[N^P(t)]}{t} = \lim_{t\to\infty}\frac{E\left\{[N^P(t)]^2\right\} - \left\{EN^P(t)\right\}^2}{t}$$
$$= \lim_{t\to\infty}\frac{E[H(t)] + 2E[G(t)] - \left\{E[N^P(t)]\right\}^2}{t}.$$

Inserting the expressions for all quantities, and applying l′Hôpital′s rule, gives

$$\lim_{t\to\infty}\frac{\mathrm{Var}[N^P(t)]}{t} = \Lambda\left[1 + 2\left(\frac{p}{1-p}\right)\right] = \Lambda\,\frac{1+p}{1-p}. \tag{4.8}$$

Note that all moments of the pooled process are independent of the exact distribution of the recirculation time. Rather, they depend only on the return probability p.

Equation (4.8) clearly shows that the pooled process $N^P(t)$ is *not* Poissonian, since the variance per unit time of a Poisson process equals its average rate Λ. The variance of $N^P(t)$ is larger by a factor $(1+p)/(1-p)$, a phenomenon due to the possible re-entrances of exiting particles. In approximating the pooled process by a Poisson process with the same rate, this factor is lost.

5. The entrance times of the pooled process. In the previous section we calculated the first two moments of the pooled process. We now study the actual distribution of the interarrival times of the pooled process, that is, the PDF of the time between the consecutive introductions of particles into the simulation. As discussed above, these entrance times are the ordered union of both entrance times of new blue particles and re-entrance times of red recirculating particles.

Recall that the consecutive arrival times of blue particles were denoted t^j. We denote their interarrival times by $\tau^j = t^j - t^{j-1}$ with the convention that $t^0 = 0$. As shown in [24], the arrival process of blue particles is Poissonian with rate λ_B given by (3.5). Therefore, τ^j are i.i.d. exponential random variables with a common PDF

$$\Pr\{\tau^j \le t\} = F_B(t) = 1 - \exp(-\lambda_B t). \tag{5.1}$$

Next, we consider the recirculation process of red particles. We introduce the following notation for the successive exit and re-entrance times of a red particle. The first entrance time to the inner sphere is denoted by $t_1^j \equiv t^j$. Its first exit time from

the simulation at the outer sphere is denoted θ_1^j, its next re-entrance time t_2^j, and so on. Thus $t_1^j < \theta_1^j < t_2^j < \theta_2^j < \dots$.

The times t_n^j are the consecutive *re-entrance times* of the jth particle into the simulation. We denote $T_1^j = t_1^j$ and set $T_n^j = t_n^j - t_{n-1}^j$ for $n > 1$. The times T_n^j for $n > 1$ are called the *recirculation times* of the jth particle. According to our assumptions, these times are i.i.d. random variables with a positive probability to be infinite. We denote their PDF by

$$F_T(t) = \Pr\{T_n^j \le t\}.$$

Their pdf is given by

$$f_T(t) = f_{\tau_{in}} * f_{\tau_{out}}(t),$$

where τ_{in} is the time a simulated (pink) particle spends in the simulation and τ_{out} is the time a nonsimulated (green) particle spends outside the simulation.

The assumption that the green particles have a positive probability $1-p$ of never returning from the outer sphere to the inner sphere is expressed as

$$\lim_{t\to\infty} F_T(t) = p < 1, \tag{5.2}$$

or, equivalently,

$$\Pr\left\{T_n^j = \infty\right\} = 1 - p > 0 \qquad (n > 1), \tag{5.3}$$

where p is given by (3.11).

Recall that $\xi(t - t^j)$ denoted the number of re-entrances of the jth red particle into the simulation by time t. We denote by $N^j(t)$ its total number of entrances into the simulation by time t, including the first entrance at time t^j,

$$N^j(t) = 1 + \xi(t - t^j).$$

Note that (5.3) implies that $N^j(t)$ is a *terminating renewal process* [30], that is, a renewal process that terminates when an infinite recirculation time occurs.

We now consider the entrance times of the pooled process. By definition, the total number of particle entrances into the simulation by time t, denoted $N^P(t)$, is given by

$$N^P(t) = \sum_{j=1}^{N^B(t)} N^j(t). \tag{5.4}$$

The actual entrance times of the pooled process into the simulation, $\{S_\ell^P\}_{\ell=1}^{N^P(t)}$, are the elements of the set

$$\{S_\ell^P\}_{\ell=1}^{N^P(t)} = \{t_k^j \,|\, 1 \le j \le N^B(t),\, 1 \le k \le N^j(t)\}$$

arranged in *ascending* order.

The times between successive arrivals of the pooled process at the inner sphere, denoted T_ℓ^P, are defined by

$$T_\ell^P = S_{\ell+1}^P - S_\ell^P.$$

With this notation the mathematical problem of simulating the arrivals of ions at the inner sphere is to determine the joint PDF of the times T_ℓ^P (for all ℓ). These times are the interarrival times for introducing new particles into the simulation.

6. The first arrival time of the pooled process. In this section, we calculate the exact PDF of the first arrival time of the pooled process in the steady state. First, we compute the distribution of the *residual* time since start of observation of the simulation till the introduction of the first new particle into the inner sphere. Then, we compute the PDF of the time between consecutive arrivals of the pooled process.

We introduce the following notation. We denote by $\varphi(t)$ the renewal function of the recirculation process of a single particle. It is given by

$$\varphi(t) = \sum_{k=0}^{\infty} f_T^{*k}(t), \tag{6.1}$$

where $f_T^{*k}(t)$ is the k-convolution of the pdf $f_T(t)$ of a single recirculation time, and $f_T^{*0}(t) = \delta(t)$. For future uses, we note that the Laplace transform of φ is

$$\widehat{\varphi}(s) = \sum_{k=0}^{\infty} \widehat{f_T^{*k}}(s) = \sum_{k=0}^{\infty} \left[\widehat{f}_T(s)\right]^k = \frac{1}{1-\widehat{f}_T(s)}, \tag{6.2}$$

and at $s = 0$ we obtain from (5.2)

$$\widehat{\varphi}(0) = \int_0^{\infty} \varphi(t)\, dt = \frac{1}{1-p}. \tag{6.3}$$

Consider a simulation that has been running for an infinite time and is already in steady state. We start to observe the simulation at time $t = 0$, and denote by γ^P the first arrival time of a particle into the simulation after $t = 0$. The first particle to arrive into the simulation may be either a blue particle that has not yet been in the simulation, or a red particle that has visited the simulation in the past and may re-enter the simulation region at the inner sphere after start of observation. Before we compute the exact PDF of γ^P, it is useful to compute the probability that a red particle that initially entered the simulation region at time $-s$ in the past will re-enter the simulation region at time x after start of observation.

LEMMA 6.1. *Let γ_s^R denote the first re-entrance time after $t = 0$ of a red particle that initially entered the simulation at time $-s$. Then*

$$\Pr\left\{\gamma_s^R = x\right\} = \int_0^s \varphi(s-u) f_T(x+u)\, du. \tag{6.4}$$

Proof. Consider a blue particle that entered the simulation at time $t_1 = -s$. In the time interval $[-s, 0]$ this particle may have re-entered the simulation an arbitrary number of times. For a particle that recursed $k-1$ times before time $t = 0$, we denote by t_k its last re-entrance time before $t = 0$ and by t_{k+1} its next re-entrance time after $t = 0$. The event $\left\{\gamma_s^R = x\right\}$ can thus be decomposed into the disjoint union

$$\{\gamma_s^R = x\} = \bigcup_{k=1}^{\infty} \{t_k < 0 \cap t_{k+1} = x \,|\, t_1 = -s\}$$

so that

$$\Pr\left\{\gamma_s^R = x\right\} = \sum_{k=1}^{\infty} \Pr\{t_k < 0 \cap t_{k+1} = x \,|\, t_1 = -s\}. \tag{6.5}$$

The first summand is the probability that the first re-entrance time of the particle occurred at time x. Therefore,

$$\Pr\{t_1 < 0 \cap t_2 = x \,|\, t_1 = -s\} = f_T(s+x). \tag{6.6}$$

The next summand ($k = 2$) is the probability of exactly one recirculation before time $t = 0$ and next re-entrance at time x. To compute this probability, we integrate over all possible times $-u$ for the recirculation time t_2,

$$\begin{aligned}\Pr\{t_2 < 0 \cap t_3 = x \,|\, t_1 = -s\} &= \int_0^s \Pr\{t_2 = -u \cap t_3 = x \,|\, t_1 = -s\}\, du \\ &= \int_0^s f_T(s-u) f_T(u+x)\, du. \end{aligned} \tag{6.7}$$

We now consider the kth term in the sum (6.5). It represents the probability of exactly $k-1$ recirculations before time $t = 0$ and next re-entrance at time x. Let $-u$ denote the last recirculation time prior to time $t = 0$. By assumption, all recirculation times of a particle are i.i.d. random variables with pdf $f_T(t)$. Therefore,

$$\Pr\{t_k = -u \,|\, t_1 = -s\} = f_T^{*(k-1)}(s-u),$$

where f_T^{*k} denotes the kth convolution of the pdf $f_T(t)$. Thus,

$$\Pr\{t_k < 0 \cap t_{k+1} = x \,|\, t_1 = -s\} = \int_0^s f_T^{*(k-1)}(s-u) f_T(u+x)\, du. \tag{6.8}$$

Combining (6.5) with (6.6) and (6.8) and using the definition $f_T^{*0}(t) = \delta(t)$, we obtain that

$$\begin{aligned}\Pr\{\gamma_s^R = x\} &= \int_0^s \sum_{k=0}^{\infty} f_T^{*k}(s-u) f_T(u+x)\, du \\ &= \int_0^s \varphi(s-u) f_T(u+x)\, du, \end{aligned}$$

which concludes the proof of the lemma.

We are now ready to prove the following theorem concerning the PDF of the first arrival time of the pooled process.

THEOREM 6.2. *The stationary PDF of the first arrival time of a steady state pooled process is given by*

$$\Pr\left\{\gamma^P > x\right\} = \exp\{-\Lambda x\} \exp\left\{\Lambda \int_0^x F_T(t)\, dt\right\}. \tag{6.9}$$

Proof. Consider a simulation that has been running for an infinite time which we start to observe at time $t = 0$. The event $\{x < \gamma^P < x + \Delta x\}$ means that no particles arrived into the simulation in the time interval $[0, x]$ and exactly one particle arrived in the short time interval $[x, x + \Delta x]$. This means, of course, that all the remaining particles arrived after time x. The identity of the arriving particle can be either blue or red. Therefore,

$$\begin{aligned}\Pr\{\gamma^P = x\} &= \Pr\left\{\gamma^P > x\right\} \\ &\quad \times [\Pr\{\text{blue arrival at } x\} + \Pr\{\text{red re-entrance at } x\}]. \end{aligned} \tag{6.10}$$

Since the arrivals of blue particles is a memoryless Poisson process with rate λ_B, the probability of the first blue particle to arrive during the time interval $[x, x+\Delta x]$ is approximately $\lambda_B \Delta x$. To compute the re-entrance probability of a red particle at time x, we write

$$\begin{aligned}&\Pr\{\text{red re-entrance at time } x\}\\ &= \int_0^\infty \Pr\{\text{red re-entrance at time } x \,|\, \text{the first entrance time of a red particle}{=}-s\}\\ &\times \Pr\{\text{a red particle first entered the simulation at time } -s\}\, ds.\end{aligned}$$

We consider each term factor in the integral separately. First, we recall that the conditional re-entrance time of this red particle was denoted γ_s^R and its pdf was calculated in the previous lemma. Therefore we write

$$\begin{aligned}&\Pr\{\text{red re-entrance at time } x \,|\, \text{the first entrance time of a red particle}{=}-s\}\\ &= \Pr\{\gamma_s^R = x \,|\, t_1 = -s\}.\end{aligned}$$

Second, by definition,

$$\begin{aligned}&\Pr\{\text{a red particle first entered the simulation at time } -s\}\, ds\\ &= \Pr\{\text{a blue particle entered the simulation at time } -s\}\, ds = \lambda_B\, ds.\end{aligned}$$

Thus, (6.10) can be rewritten as

$$\Pr\left\{\gamma^P = x\right\} = \Pr\left\{\gamma^P > x\right\} \times \lambda_B \left[1 + \int_0^\infty \Pr\{\gamma_s^R = x \,|\, t_1 = -s\}\, ds\right]. \tag{6.11}$$

Inserting (6.4) into (6.11), changing the order of integration in the resulting double integral, and using (6.3) and (5.2) gives

$$\begin{aligned}\Pr\{\gamma^P = x\} &= \lambda_B \Pr\{\gamma^P > x\} \left[1 + \int_0^\infty f_T(x+u)du \int_u^\infty \varphi(s-u)\, ds\right]\\ &= \lambda_B \Pr\{\gamma^P > x\} \left[1 + \frac{F_T(\infty) - F_T(x)}{1-p}\right]\\ &= \lambda_B \Pr\{\gamma^P > x\} \frac{1 - F_T(x)}{1-p}. \qquad (6.12)\end{aligned}$$

Finally, integrating (6.12) with respect to x, we obtain (6.9).

Comment. The fact that the limiting PDF (6.9) is not exponential is yet another manifestation of the non-Poissonian character of the pooled process. The fact that the pooled process is not Poissonian sets this result apart from the known cases of finite mean recurrence times, as analyzed in [33], where the resulting process is Poissonian.

We now show, as mentioned in the introduction, that the pooled process is not a renewal process and has an infinite memory. Therefore its interarrival times are dependent, not identically distributed random variables. Thus, for example, the PDF of the time between the first and the second arrivals after observation begins is not

the same as that of the time between the second and the third arrivals, and so on. The PDF of the interarrival time between the kth and $k+1$th arrivals after observation begins can be calculated as the marginal distribution of the joint distribution of the $k+1$ consecutive interarrival times.

First, we compute the PDF of the time between the first and the second arrivals of the pooled process. Applying considerations similar to the ones in the above computation of the residual first entrance time, it can be shown that

$$\Pr\{\gamma^P = x \cap T_1^P > t\} = \Lambda F_T^c(x) F_T^c(t) \Pr\{\gamma^P > t + x\}.$$

Thus, integrating with respect to x, we obtain

$$\Pr\{T_1^P > t\} = \int_0^\infty \Lambda F_T^c(x) F_T^c(t) \Pr\{\gamma^P > t + x\}\, dx. \tag{6.13}$$

Also, the conditional probability is given by

$$\Pr\{T_1^P > t \,|\, \gamma^P = x\} = \frac{\Lambda F_T^c(x) F_T^c(t) \Pr\{\gamma^P > t + x\}}{\Lambda F_T^c(x) \Pr\{\gamma^P > x\}}. \tag{6.14}$$

A comparison of (6.13) and (6.14) shows that the conditional PDF of T_1^P, given the value of the residual first entrance time γ^P, is *different* than the unconditional PDF of T_1^P. Therefore, the pooled process is not Poissonian, not even a renewal process, but rather has memory. Using similar methods, it is possible to show that the PDF of the kth interarrival time of the pooled process depends on all previous arrival times, which means that the pooled process has infinite memory.

7. Simulation of the pooled process. In this section we present a preliminary statistical analysis of the pooled process and some computer simulation results. First, we estimate the time for convergence of a simulation of the pooled process to steady state. Then, we show both mathematically and numerically that the interarrival times of the pooled process are approximately exponentially distributed. We stress that we study only the pdf of a single interarrival time and not the joint pdf of two or more consecutive interarrival times, nor do we study the time correlations of the pooled process. These issues will be studied in a separate publication.

Consider a computer simulation of the pooled process. As analyzed in section 2, the pooled process is the superposition of many delayed terminating renewal processes. The delayed process is the arrival process of blue particles which is Poissonian with rate λ_B. Thus, the arrival times of the blue particles are easily constructed by sampling their interarrival times from an exponential distribution with rate λ_B. For each blue particle we construct its re-entrance times into the simulation by sampling from the defective distribution F_T. Note that for each blue particle, the total number of its re-entrances follows a geometric distribution with parameter p. Thus, for each blue particle, this sampling procedure results in a *finite* sequence of random re-entrance times. The arrival times of the blue particles are formed by sorting all these entrance and re-entrance times of all particles in increasing order.

7.1. Convergence to steady state. We can estimate the rate of convergence of the pooled process to steady state, starting with no simulated particles inside the inner sphere. Specifically, we determine the minimal time t_S at which

$$\frac{E[N^P(t_S)]}{t_S} = \Lambda(1 - \varepsilon). \tag{7.1}$$

This is a criterion for wide sense convergence to steady state [32]. An explicit expression for $E[N^P(t)]$ was calculated in (4.7) in terms of $\mu_1(s)$, the average number of re-entrances by time s. Since $\mu_1(s)$ is a monotone increasing function, it can be easily seen that $E[N^P(t)]/t$ is also a monotone increasing function. To find a lower bound for t_S, we use the fact that $\mu_1(s)$ satisfies the integral equation [30]

$$\mu_1(s) = \int_0^s f_T(u)[1 + \mu_1(s-u)]du. \tag{7.2}$$

According to (4.3), for all times s,

$$\mu_1(s) < \mu_1(\infty) = \frac{p}{1-p}.$$

Inserting this inequality into (7.2), we obtain a more refined inequality for $\mu_1(s)$,

$$\mu_1(s) < \frac{1}{1-p}F_T(s) < \frac{1}{1-p}\Pr\Big\{\tau_{out} < t\Big\}. \tag{7.3}$$

Combining (A.4) and the inequality

$$\frac{2}{\sqrt{\pi}}\int_x^\infty e^{-u^2}du \le 1 - \frac{2}{\sqrt{\pi}}x \qquad \text{for } x < \frac{1}{\sqrt{2}},$$

we obtain that

$$\Pr\{\tau_{out} < t\} \le \begin{cases} p\left(1 - \dfrac{2}{\sqrt{\pi}}\sqrt{\dfrac{T_b}{t}}\right), & t > 2T_b, \\ \\ p, & t < 2T_b, \end{cases} \tag{7.4}$$

where T_b is defined in (A.5). Inserting (7.4) and (7.3) into (4.7) gives

$$\frac{E[N^P(t)]}{t} \le \Lambda\left(1 - p\frac{4}{\sqrt{\pi}}\sqrt{\frac{T_b}{t}} + p\frac{4\sqrt{2}}{\sqrt{\pi}}\frac{T_b}{t}\right). \tag{7.5}$$

We are now ready to apply the wide sense criteria (7.1). For $\varepsilon \ll 1$, $t_S \gg T_b$, so we can neglect the last term. This gives

$$t_S \ge \frac{16p^2}{\pi}\frac{T_b}{\varepsilon^2}. \tag{7.6}$$

To evaluate whether this time is long or short, consider just the average number of blue particle entrances during this time (neglecting their re-entrances). This number is given by the product $\lambda_B t_S$. Using (3.5) and (7.6) for λ_B and t_S, respectively, gives

$$E[N^B(t_S)] \ge \frac{12(1-p)^2}{\pi}\frac{N_a}{\varepsilon^2}, \tag{7.7}$$

where $N_a = 4/3\pi a^3\rho \gg 1$ denotes the average number of simulated particles in the inner sphere. Therefore, to obtain wide sense convergence up to one percent for a simulation with an average of $N_a = 400$ particles in the inner sphere, the total number of blue particle entrances during this time is of the order of at least $N_a/\varepsilon^2 = 4,000,000$ particles. Note that in a realistic simulation, the time steps of ionic motion are much smaller than the times between consecutive entrances of particles into the simulation. Therefore, (7.7) implies that a simulation that has not started in steady state must be run a prohibitively large number of time steps until convergence to steady state is achieved. Therefore, as discussed in section 2, an algorithm to run the simulation in steady state from the beginning is needed.

7.2. Short interarrival times are approximately exponential. Inserting (6.9) into (6.13) gives the following expression for the distribution of T_1^P:

$$\Pr\{T_1^P > t\} = F_T^c(t) \int_0^\infty \Lambda F_T^c(x) e^{-\Lambda(x+t)} e^{\Lambda \int_0^{t+x} F_T(s) ds} dx. \tag{7.8}$$

We now analyze the short time and long time behavior of this distribution. First we consider short times, $t \ll T_b$. In this case we make a change of variables $x = T_b u$ and $s = T_b w$ in the integrals in (7.8). This gives

$$\Pr\{T_1^P > t\} = F_T^c(t) e^{-\Lambda t} \int_0^\infty \Lambda T_b F_T^c(T_b u) e^{-\Lambda T_b (u - \int_0^{t/T_b + u} F_T(T_b w) dw)}\, du. \tag{7.9}$$

According to our assumptions,

$$\Lambda T_b = \frac{3}{4} \frac{1-p}{p^2} N_a \gg 1.$$

Therefore, applying Laplace's method for the approximation of the integral in (7.9) gives

$$\Pr\{T_1^P > t\} \approx F_T^c(t) e^{-\Lambda t} e^{\Lambda \int_0^t F_T(s)\, ds}.$$

For short times, $t \ll T_b$, $F_T(t) \ll 1$, so that we have the approximation

$$\Pr\{T_1^P > t\} = e^{-\Lambda t}(1 + o(1)) \quad \text{for } t \ll T_b.$$

Next, we consider the long time behavior of $\Pr\{T_1^P > t\}$. For times $t \gg T_b$, we have $F_T(s) \approx p$, and therefore

$$\begin{aligned} \int_0^{x+t} F_T(s)\, ds &= \int_0^x F_T(s)\, ds + \int_x^{x+t} F_T(s)\, ds \\ &\approx \int_0^x F_T(s)\, ds + tp. \end{aligned} \tag{7.10}$$

Inserting (7.10) into (7.8) gives

$$\Pr\{T_1^P > t\} \approx (1-p)\exp(-\lambda_B t) \quad \text{for } t \gg T_b.$$

To conclude, the interarrival time T_1^P is approximately exponential with rate Λ for short times, but due to possible particle recirculations its distribution has a different exponential tail with rate $\lambda_B < \Lambda$. Note, however, that since interarrival times are of the order of $1/\Lambda$, and $1/\Lambda \ll T_b$, all interarrival times of the pooled process are approximately exponentially distributed with rate Λ.

7.3. Simulation results. A simulation of the pooled process for uncharged particles has been run, according to the principles presented at the beginning of this section, with the typical values $a = 50\mathring{A}$, $r_0 = 80\mathring{A}$, $D = 10^{-9}\mathrm{m}^2/\mathrm{sec}$, and $\rho = 0.1\mathrm{M}$. These parameters give a value $p = 0.625$, for the return probability, and a value $N_a = 31$, for the average number of simulated particles inside the inner sphere. The average interarrival time of the pooled process is $1/\Lambda = 10^{-10}\mathrm{sec}$, compared to $T_b = 22.5 \times 10^{-10}\mathrm{sec}$, so that indeed $1/\Lambda \ll T_b$.

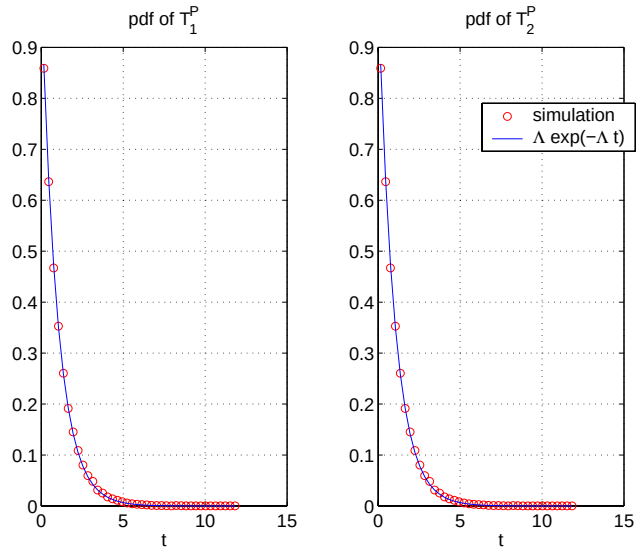

FIG. 3. *The pdfs of T_1^P (left) and T_2^P (right), as computed from the simulation, superimposed on the exponential density with rate Λ.*

In Figure 3 the graphs of the pdfs of T_1^P and T_2^P are superimposed on the exponential pdf with rate Λ. The pdfs of T_1^P and T_2^P are the result of about 250,000 samples of interarrival times of the pooled process. It is apparent that for times shorter than T_b both T_1^P and T_2^P are exponentially distributed with rate Λ. In all of the samples, not even once did an interarrival time longer than T_b occur in the simulation. Therefore, the theoretically predicted exponential tail with rate λ_B cannot be observed in these graphs. Finally, we note that T_1^P and T_2^P are dependent, with a correlation coefficient $r = \mathrm{cov}(T_1^P, T_2^P)/\sigma_1\sigma_2 \approx -0.001$. The fact that the correlation coefficient is negative is not surprising. It reflects the higher probability of recirculation in T_2^P when T_1^P is large. This means that when T_1^P is long there is a higher probability that T_2^P is short. The small correlation coefficient between T_1^P and T_2^P is a consequence of the short interarrival times of the pooled process, $1/\Lambda$, relative to the characteristic time for recirculation, T_b. A detailed analytical and numerical study of the statistical properties of the pooled process will be done elsewhere.

8. Summary and discussion. The time course of the exchange of ions between a test volume embedded in a continuum with a buffer region has been studied. The study of this time course is the basis for a simulation of uncharged and charged particles in a solution. The process of injecting new particles into the simulation has been identified as a stationary pooled process composed of an infinite number of delayed terminating independent renewal processes. While the pooled process converges to a stationary steady state, it is neither a renewal nor a Markov process. We have calculated the first two moments of this process, as well as the probability distribution of its residual time, and the joint distribution of the residual and the next arrival. From these calculations, it is apparent that the pooled process has an infinite memory. Therefore, to run the exact time course of this process in steady state, an infinite record of all past entrances and exits needs to be kept. To avoid this complexity, we have found that under some conditions on the size of the simulation

and buffer regions the pooled process can be approximated by a memoryless Poisson process. This approximation retains the average influx of the pooled process, but underestimates its variance. Our analysis shows how the parameters a and r_0 control the size of the simulation and the accuracy of our proposed approximation.

A closely related mathematical problem is considered in [30, chap. 5, sect. 9], where the renewal periods are assumed to have finite moments, in contrast with the case at hand in which the renewal periods may be infinite with positive probability. In [30], the case of infinitely many uniform sparse renewal processes is considered, and it is shown that under certain conditions on the sparseness, the pooled process becomes Poissonian as the number of processes increases to infinity. As we have seen, in our case the resulting process in not Poissonian.

The application of our results to an actual simulation is different for charged or uncharged particles. The approximations that we derived are not necessary for a simulation of uncharged Brownian particles, though they are necessary for a simulation of charged particles, as discussed below. For uncharged particles the stationary pooled process can be constructed offline to provide the random injection times of particles into the simulation. Such a pooled process has to be constructed for each choice of the parameters λ_B and p, that is, for each set of values for the parameters D, ρ, a, and r_0. With the correct choice of injection times, such a simulation reaches steady state immediately. If a wrong injection time course is adopted, there is a depletion or overcrowding of particles in the simulation region, which renders the simulation not self-consistent.

The simulation of charged particles is completely different from that of uncharged particles. In the uncharged case the mean field is always zero and thus the densities of all species in the bath remain constant throughout the time course of the simulation. In contrast, charged particles cause fluctuations in the net charge inside the simulation volume. The nonzero net charge creates a nonvanishing time dependent electrostatic field outside the simulation region that affects the continuum densities in the bath near the simulation region. Thus, if the net charge in the simulation region is positive, the bath density of positive charges decreases and the density of the negative charges increases in the neighborhood around the simulation region. These changes, in turn, affect the effective entrance rates of the different species into the simulation. Therefore, for charged particles, each configuration of net charge in the simulation region requires the construction of a new table of the pooled process suitable for it. Specifically, each entrance or exit changes the net charge inside the simulation region, which, in turn, changes the entrance rates into the simulation region.

Under the assumption of a *fast bath,*[1] the entrance law of a new ion into the simulation is that of the residual of the pooled process (6.9) that corresponds to the instantaneous concentrations due to the momentary net charge inside the simulation. These conditions change every time an ion enters or exits the simulation. Our analytical expression for the PDF of the residual time eliminates the need to run a simulation of the pooled process (as described in section 7) every time conditions change. In this way, a small portion of the bulk solution can be studied without the need to resort to ad hoc assumptions, such as artificial periodic boundary conditions.

In our model and analysis of a simulation of interacting ions (e.g., charged ions or ions with finite volume), we have used implicitly the concept of a *self-consistent* simulation. This notion is concerned with the detailed laws of ionic motion in the

[1] This means that the time to equilibrate the densities in the bath is shorter than the time between changes in the net charge inside the simulation region.

simulation region and the effective motion of ions in the surrounding continuum. The effective diffusive motion of ions is the result of their thermal interaction with the surrounding solvent and their interactions with each other. Thus, the motion inside the simulation volume is governed by both an unknown diffusion coefficient of ions in infinitely dilute solution and the interionic forces (computed by the simulation). On a sufficiently coarse time scale, the resulting motion of a simulated ion can be viewed as an effective diffusion with an effective diffusion coefficient that can be calculated from statistics of simulated trajectories. This calculated effective diffusion coefficient *must* be equal to the assumed (experimentally measured) diffusion coefficient in the bulk solution. This is a self-consistency requirement from the simulation. In addition, the average concentrations of the ionic species inside the simulation volume must be the same as those assumed in the bulk solution, as mentioned above. This is another self-consistency requirement. Still another self-consistency requirement is concerned with the notion of chemical activity. The concentrations of ions in the presence of an electrostatic field is different than that in the absence of a field, as can be readily seen from the Poisson–Boltzmann theory [12]. To compensate for the replacement of charged particles with independent uncharged particles the notion of activity has been introduced in physical chemistry [12]. More precisely, the change in the chemical potential as a function of particle density is assumed to take a simple form derived from the theory of gases, which replaces the physical density with a larger effective density. The ratio of the two densities is the activity factor. It is a directly measurable physical parameter. In a self-consistent simulation of charged particles, the unknown activity and diffusion coefficients in an infinitely dilute solution have to be chosen in such a way that all the above-mentioned self-consistency conditions are met. Finally, in addition to these self-consistency conditions, the electrostatic field has to be calculated in a self-consistent way at each time step of the simulation. A detailed description of a self-consistent simulation of charged particles will be presented in a separate paper. If the correct time course of the simulation is not followed it may be difficult to meet some of these self-consistency requirements.

Simulations of ions in solution have a wide range of applications. An important one is the theoretical study of permeation of uncharged molecules and ions through protein channels of biological membranes [34], [35]. Protein channels are small natural nano-devices of length in the range of 20–100$\mathring{A}$, and 5–20$\mathring{A}$ diameter. A computer simulation of a channel involves the simulation of the mobile ions both inside the channel and around it, in a volume comparable to the channel size. In the spirit of the theory discussed in this paper, such a simulation must be connected to its surrounding continuum. This leads to a small simulation with large time dependent density and potential fluctuations. The results of this paper are directly applicable to a simulation of permeation of uncharged molecules through protein channels, such as maltoporins that conduct sugar. Although the motion of the sugar molecules inside the maltoporin channel cannot be assumed a diffusion process and has to be simulated by molecular dynamics, the connection of the simulation to the continuum is described by the present work. For channels that conduct ions or other charged molecules, there are additional new elements in their simulation, namely, the presence of an impermeable membrane and a permanent charge profile of the channel itself, inside the simulation volume. The injection process of new particles into the simulation region on both sides of the membrane is similar to that described above. There are many differences, though, between a simulation with and without a channel, that are a subject for a separate study.

Appendix A. The time distribution outside the simulation. We now compute the distribution of τ_{out}, the time a nonsimulated (green) particle spends outside the simulation until its next re-entrance into the simulation. To this end, we denote by $p(r,t\,|\,r_0)$ the (radial) conditional probability density of the particle's location at time t, given that it has exited the simulation at the outer sphere at time $t=0$ and has not yet returned to the inner sphere. Obviously, in terms of this distribution,

$$\Pr\{\tau_{out} > t\} = \int_a^\infty 4\pi r^2 p_{out}(r,t\,|\,r_0)dr. \tag{A.1}$$

According to our assumptions, nonsimulated green particles perform independent free Brownian motion with diffusion coefficient D. Thus, the pdf $p_{out}(r,t\,|\,r_0)$ is the solution of the Fokker–Planck equation [31]

$$\begin{aligned} &\frac{\partial}{\partial t}p_{out}(r,t\,|\,r_0) = D\Delta p(r,t\,|\,r_0), \qquad a<r<\infty,\\ &p_{out}(a,t\,|\,r_0) = 0, \qquad t>0, \\ &p_{out}(r,0\,|\,r_0) = \frac{\delta(r-r_0)}{4\pi r_0^2}, \qquad a<r<\infty. \end{aligned} \tag{A.2}$$

The solution of (A.2) is given by

$$p_{out}\,(r,t\,|\,r_0) = \frac{1}{(4\pi Dt)^{1/2}}\frac{1}{4\pi r_0}\frac{1}{r}\left\{e^{-(r-r_0)^2/4D\,t} - e^{-(r+r_0-2a)^2/4D\,t}\right\}. \tag{A.3}$$

Inserting (A.3) into (A.1) gives

$$\Pr\{\tau_{out} \le t\,|\,r_0\} = p\frac{2}{\sqrt{\pi}}\int_{\sqrt{T_b/t}}^\infty e^{-u^2}\,du, \tag{A.4}$$

where

$$T_b = \frac{(r_0-a)^2}{4D} \tag{A.5}$$

is a characteristic time for the motion of a particle from the outer sphere to reach the inner sphere.

Equation (A.4) shows that τ_{out} can be infinite with probability $1-p>0$, that is, it has a defective probability distribution. It follows that it has an infinite mean value. The pdf of its defective distribution, given by

$$f_{\tau_{out}}(t) = \frac{d}{dt}\Pr\{\tau_{out}\le t\,|\,r_0\} = p\frac{1}{\sqrt{\pi}}\frac{\sqrt{T_b}}{t^{3/2}}\exp\left\{-\frac{T_b}{t}\right\},$$

gives

$$\int_0^\infty t f_{\tau_{out}}(t)\,dt = \infty. \tag{A.6}$$

Moreover, we have the following proposition.

PROPOSITION A.1. *The first moment of τ_{out}, conditioned on $\{\tau_{out} < \infty\}$, is infinite.*

Proof. Since

$$\Pr\{\tau_{out} < t \,|\, \tau_{out} < \infty\} = \frac{\Pr\{\tau_{out} < t,\, \tau_{out} < \infty\}}{\Pr\{\tau_{out} < \infty\}} = \frac{\Pr\{\tau_{out} < t\}}{p},$$

we obtain, in view of (A.6), that

$$\int_0^\infty t d \Pr\{\tau_{out} < t \,|\, \tau_{out} < \infty\} = \frac{1}{\sqrt{\pi}} \int_0^\infty \frac{\sqrt{T_b}}{t^{1/2}} \exp\left\{-\frac{T_b}{t}\right\} dt = \infty.$$

DECAY OF KDV SOLITONS*

HIÊÚ D. NGUYÊÑ†

Abstract. In this paper we develop a linear eigenvalue decomposition for N-soliton solutions of the Korteweg–de Vries equation and use it to obtain a new mathematical explanation of two-soliton interaction in terms of particle decay. We discover that the two-soliton "particles" or pulses which appear in each solution exchange identities upon collision and emit a dual "ghost" particle pair in order to conserve mass and momentum.

Key words. solitons, Korteweg–de Vries (KdV) equation, particle decay, ghost particles

1. Introduction.

It is well known that the Korteweg–de Vries (KdV) equation,

$$u_t - 6uu_x + u_{xxx} = 0,$$

is a model for many wave related phenomena and admits a special family of localized solutions called N-solitons corresponding to reflectionless potentials (cf. [M]). Here, N denotes the number of solitons, i.e., the number of pulses or potential wells, that appear in each solution. One-solitons or solitary waves were first observed by J. Scott Russell along the Union Canal at Edinburgh in 1834 (cf. [M]). Then in 1895, Korteweg and de Vries [KV] published their (KdV) equation as a model for these waves. However, it would require another seventy years before two-soliton interaction was observed by Zabusky and Kruskal [ZK] through numerical calculation; they reported that "solitons 'pass through' one another without losing their identity." The exact interaction of two solitons was then determined numerically by Zabusky [Z] and soon thereafter Lax [La] gave a mathematical proof.

The idea that perhaps solitons actually bounce off each other upon collision dates back to Bowtell and Stuart [BS]. The exchange of mass that occurs then between the two colliding soliton particles allows them to exchange identities. More recent work advocating this viewpoint can be found in [Le] and [MC]. Now, to mathematically investigate such behavior, it is desirable to isolate each particle in any given N-soliton solution. This can be achieved, say, by decomposing the solution into a linear sum, even though the KdV equation itself is nonlinear, so that the superposition principle fails to hold. To this end, various such decompositions can be found in the literature (cf. [GGKM], [HM], [S], [MC]). We shall discuss some of these decompositions in relation to ours at the end of this paper.

In this paper, we develop a linear eigenvalue decomposition of N-soliton solutions for the Korteweg–de Vries equation and use it to obtain a new mathematical explanation of two-soliton interaction in terms of particle decay. This decomposition is obtained through a diagonalization procedure that is applied to the corresponding soliton matrix and has the effect of isolating the decay of each soliton "particle." For two-solitons, the interaction described by Theorem 3.3 suggests a decay phenomenon that occurs frequently in elementary particle physics: the two-soliton particles split

upon collision, resulting in an exchange of identities and the emission of a dual "ghost" particle pair (cf. Figure 1). Theorem 3.4 then shows that each decay process conserves mass and momentum and supports our particle decay interpretation of soliton interaction. Interesting properties of our dual ghost particles are then described in Theorem 3.6. In fact, we like to view each ghost particle as a nonlinear "difference" between two given soliton particles. Lastly, an explicit example is given in section 4 to illustrate our results (cf. Figures 2–4).

2. Soliton particles. Let N be a positive integer and assume that the initial scattering data for $u(x,0)$, obtained through the time-independent Schrodinger equation

$$\psi_{xx} - [\lambda - u(x,0)]\psi = 0, \tag{1}$$

has only a discrete energy spectrum. This means that λ takes on a discrete set of N negative energy eigenvalues $\{\lambda_1 < \lambda_2 < \cdots < \lambda_N < 0\}$ with corresponding eigenfunctions $\{\psi_1, \psi_2, \ldots, \psi_N\}$. It is standard that we normalize these eigenfunctions and compute their normalized factors c_n, commonly referred to as "phase shifts":

$$\int_{-\infty}^{\infty} \psi_n^2 dx = 1, \qquad c_n = \lim_{x \to -\infty} e^{k_n x}\psi_n. \tag{2}$$

The initial scattering data is then used to produce the N-soliton solution of the KdV equation through the determinant formula

$$u(x,t) = -2\frac{\partial^2}{\partial x^2} \log \det(I + A). \tag{3}$$

Here, the $N \times N$ *soliton matrix* A has entries defined by

$$A = (a_{mn}), \qquad a_{mn} = \frac{c_m c_n}{k_m + k_n} e^{(k_m + k_n)x - 4(k_m^3 + k_n^3)t}, \tag{4}$$

where the spectral parameter $k_n > 0$ is defined via the relation $\lambda_n = -k_n^2$. This solution was obtained independently in the early 1970s by Gardner et al. [GGKM] and Wadati and Toda [WT], both groups by means of the inverse scattering method, and by Hirota [H] through his direct method.

We now turn to developing our working definition of a soliton particle. It is well known that A is symmetric and positive definite (cf. [KM], [GGKM], [WT]). This allows us to diagonalize it so that

$$B^{-1}AB = D = \begin{pmatrix} \mu_1(x,t) & 0 & \ldots & 0 \\ 0 & \cdots & & \\ \cdots & & & \\ 0 & & & \mu_N(x,t) \end{pmatrix}. \tag{5}$$

Here, $\{\mu_1 > \cdots > \mu_N\}$ is the (ordered) set of real positive eigenvalues of A and B is the orthogonal matrix consisting of an orthonormal basis of eigenvectors of A. It follows that we can write $u(x,t)$ in terms of $\{\mu_n\}$, which we shall refer to as *decay eigenvalues*:

$$u(x,t) = -2\frac{\partial^2}{\partial x^2} \log \det(I + A) \tag{6}$$

$$= -2\frac{\partial^2}{\partial x^2}\log\det[B^{-1}(I+A)B] \tag{7}$$

$$= -2\frac{\partial^2}{\partial x^2}\log\det(I+D) \tag{8}$$

$$= -2\frac{\partial^2}{\partial x^2}\log\prod_{n=1}^{N}[1+\mu_n(x,t)] \tag{9}$$

$$= \sum_{n=1}^{N} -2\frac{\partial^2}{\partial x^2}\log[1+\mu_n(x,t)]. \tag{10}$$

DEFINITION 2.1. *Define*

$$s_n(\nu_n) \equiv -2k_n^2\operatorname{sech}^2(k_n\nu_n), \qquad n=1,\dots,N, \tag{11}$$

to be the nth soliton particle *of u, where* $\nu_n = x - 4k_n^2 t$ *is the nth moving frame. Then we shall refer to*

$$u_n(x,t) \equiv -2\frac{\partial^2}{\partial x^2}\log[1+\mu_n(x,t)] \tag{12}$$

as the decay function *of* s_n *and to the sum* $u = \sum_{n=1}^{N} u_n$ *as derived in* (10) *as the* decay decomposition *of u. The results of the next section will justify our use of terminology.*

3. Decay of two-solitons. In this section we assume $N = 2$ and investigate the asymptotic behavior of the decay functions u_1 and u_2 as a means of understanding soliton interaction. We begin by writing the matrix A explicitly in terms of the two moving frames ν_1 and ν_2:

$$A = \begin{pmatrix} \frac{c_1^2}{2k_1}e^{2k_1\nu_1} & \frac{c_1c_2}{k_1+k_2}e^{k_1\nu_1+k_2\nu_2} \\ \frac{c_1c_2}{k_1+k_2}e^{k_1\nu_1+k_2\nu_2} & \frac{c_2^2}{2k_2}e^{2k_2\nu_2} \end{pmatrix}. \tag{13}$$

Denoting by $p = \operatorname{Tr}(A)$ and $q = \det(A)$, it follows that the two eigenvalues of A are given by

$$\mu_1 = \frac{1}{2}\left(p + \sqrt{p^2-4q}\right), \tag{14}$$

$$\mu_2 = \frac{1}{2}\left(p - \sqrt{p^2-4q}\right). \tag{15}$$

DEFINITION 3.1. *We define*

$$A_g = \begin{pmatrix} \frac{c_1^2}{2k_1}e^{2k_1\nu_g} & \frac{c_1c_2}{k_1+k_2}e^{(k_1+k_2)\nu_g} \\ \frac{c_1c_2}{k_1+k_2}e^{(k_1+k_2)\nu_g} & \frac{c_2^2}{2k_2}e^{2k_2\nu_g} \end{pmatrix} \tag{16}$$

to be the ghost matrix *of A where* $\nu_g = x - 4k_g^2 t$ *and* $k_g = (k_1^2 + k_1k_2 + k_2^2)^{1/2}$. *In addition, if* γ_1 *and* γ_2 *denote the eigenvalues of* A_g *corresponding to* μ_1 *and* μ_2, *respectively, then we shall refer to*

$$g(\nu_g) \equiv -2\frac{\partial^2}{\partial \nu_g^2}\log[\gamma_1(\nu_g)] \tag{17}$$

as the ghost particle *and*

$$\bar{g}(\nu_g) \equiv -2\frac{\partial^2}{\partial \nu_g^2}\log[\gamma_2(\nu_g)] \tag{18}$$

as the antighost particle *corresponding to the pair* $\{u_1, u_2\}$.

Note that ν_g represents the moving frame of both g and $\bar{g}$ and that $4k_g^2$ represents their velocity and exceeds that of the two-soliton particles. The following lemma assures us that the above-mentioned correspondence between the two sets of eigenvalues is well defined.

LEMMA 3.2. *Denote by* $\hat{k}^2 = k_1^2 k_2 + k_1 k_2^2$. *Then*

$$A = e^{8\hat{k}^2 t} A_g.$$

Moreover, $\mu_n = e^{8\hat{k}^2 t}\gamma_n$ *for* $n = 1, 2$.

Proof. It suffices to prove that every coefficient of A has $e^{8\hat{k}^2 t}$ as a common factor when rewritten in terms of ν_g. This quickly follows from the relation

$$\begin{aligned} e^{k_n(x-4k_n^2 t)} &= e^{k_n(\nu_g + 4k_g^2 t - 4k_n^2 t)} \\ &= e^{k_n\nu_g + 4(k_1^2 k_2 + k_1 k_2^2)t} \\ &= e^{4\hat{k}^2 t} e^{k_n \nu_g}. \end{aligned}$$

The fact that $\mu_n = e^{8\hat{k}^2 t}\gamma_n$ also follows from this relation and can be easily checked by the reader. □

We are now ready to present our theorem describing particle decay of two-solitons. This will justify our use of the terms "particle" and "decay" in referring to s_n and u_n, respectively.

THEOREM 3.3. *The following asymptotic relations hold for* u_1 *and* u_2*:*

(i)

$$\begin{aligned} &u_1 \sim s_1(\nu_1 + \delta_1), && \text{as } t \to -\infty, \\ &u_1 \sim s_2(\nu_2 + \delta_2) + g(\nu_g), && \text{as } t \to \infty, \end{aligned}$$

in the sense that

$$\lim_{\substack{\nu_1 \text{ fixed} \\ t \to -\infty}} u_1 = s_1(\nu_1 + \delta_1), \qquad \lim_{\substack{\nu_2 \text{ fixed} \\ t \to \infty}} u_1 = s_2(\nu_2 + \delta_2), \qquad \lim_{\substack{\nu_g \text{ fixed} \\ t \to \infty}} u_1 = g(\nu_g).$$

Here, the relative phase shifts δ_1 *and* δ_2 *are defined by*

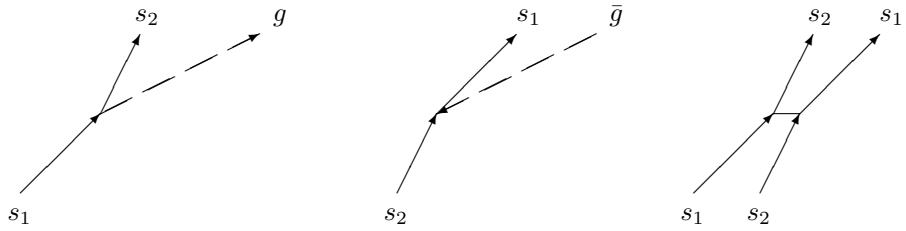
$$e^{2k_1\delta_1} = \frac{c_1^2}{2k_1}, \qquad e^{2k_2\delta_2} = \frac{c_2^2}{2k_2}.$$

(ii)

$$\begin{aligned} &u_2 \sim s_2(\nu_2 + \delta_2 + \Delta), && \text{as } t \to -\infty, \\ &u_2 \sim s_1(\nu_1 + \delta_1 + \Delta) + \bar{g}(\nu_g), && \text{as } t \to \infty. \end{aligned}$$

Here, Δ *is defined by*

$$e^{2k_2\Delta} = \frac{(k_1 - k_2)^2}{(k_1 + k_2)^2}.$$



(a) Diagram of u_1 (b) Diagram of u_2 (c) Diagram of u

FIG. 1. *Space-time plots of two-soliton decay.*

Following the physics literature we shall summarize the decay described by u_1 and u_2 as follows:

$$\begin{aligned} u_1: &\quad s_1 \to s_2 + g, \\ u_2: &\quad s_2 \to s_1 + \bar{g}. \end{aligned}$$

The corresponding space-time plots are drawn in Figure 1. Notice that they describe the exchange of identities between s_1 and s_2 and the fact that the emitted ghost particles (represented by the dashed lines) have velocities greater than both soliton particles.

Proof of Theorem 3.3. (i) Our approach is to analyze u_1 from the perspective of the three moving frames corresponding to the velocities $\nu_1,\ \nu_2$, and ν_g and to treat each as a separate case.

Case I. Assume ν_1 is fixed. We rewrite the trace and determinant of A as

$$\begin{aligned} p &= \mathrm{Tr}(A) \\ &= \tfrac{c_1^2}{2k_1} e^{2k_1\nu_1} + \tfrac{c_2^2}{2k_2} e^{2k_2\nu_2} \\ &= e^{2k_1\nu_1} \left(\tfrac{c_1^2}{2k_1} + \tfrac{c_2^2}{2k_2} e^{2k_2\nu_2 - 2k_1\nu_1} \right) \\ &= e^{2k_1\nu_1} \left(\tfrac{c_1^2}{2k_1} + \tfrac{c_2^2}{2k_2} e^{2(k_2-k_1)\nu_1 + 8k_2(k_1^2-k_2^2)t} \right) \end{aligned}$$

and

$$\begin{aligned} q &= \det(A) \\ &= \left(\tfrac{k_1-k_2}{k_1+k_2} \right)^2 \tfrac{c_1^2 c_2^2}{4k_1k_2} e^{2(k_1\nu_1+k_2\nu_2)} \\ &= e^{2k_1\nu_1} \left(\tfrac{k_1-k_2}{k_1+k_2} \right)^2 \tfrac{c_1^2 c_2^2}{4k_1k_2} e^{2k_2\nu_1 + 8(k_1^2-k_2^2)t} \end{aligned}$$

so that

$$\lim_{\substack{\nu_1 \text{ fixed} \\ t\to-\infty}} p = \frac{c_1^2}{2k_1} e^{2k_1\nu_1}, \qquad \lim_{\substack{\nu_1 \text{ fixed} \\ t\to-\infty}} q = 0.$$

This forces

$$\begin{aligned}\lim_{\substack{\nu_1 \text{ fixed}\\ t\to-\infty}}(1+\mu_1) &= \lim_{\substack{\nu_1 \text{ fixed}\\ t\to-\infty}}\left[1+\frac{1}{2}\left(p+\sqrt{p^2-4q}\right)\right]\\ &= 1+\tfrac{c_1^2}{2k_1}e^{2k_1\nu_1}\end{aligned}$$

and implies

$$\begin{aligned}\lim_{\substack{\nu_1 \text{ fixed}\\ t\to-\infty}}u_1 &= \lim_{\substack{\nu_1 \text{ fixed}\\ t\to-\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(1+\mu_1)\right\}\\ &= -2\tfrac{\partial^2}{\partial x^2}\log(1+\tfrac{c_1^2}{2k_1}e^{2k_1\nu_1})\\ &= \frac{-8k_1c_1^2e^{2k_1\nu_1}}{\left(1+\frac{c_1^2}{2k_1}e^{2k_1\nu_1}\right)^2}\\ &= s_1(\nu_1+\delta_1),\end{aligned}$$

where δ_1 is defined by $e^{2k_1\delta_1} = \frac{c_1^2}{2k_1}$. Note that we have implicitly used the fact $\frac{\partial}{\partial x} = \frac{\partial}{\partial \nu_1}$.

Case II. Assume that ν_2 is fixed. We proceed in the same manner as Case I but factor $e^{2k_2\nu_2}$ instead of $e^{2k_1\nu_1}$ from p and q. It is then a straightforward exercise to show that

$$\lim_{\substack{\nu_2 \text{ fixed}\\ t\to\infty}}u_1 = s_2(\nu_2+\delta_2),$$

where this time δ_2 is defined by $e^{2k_2\delta_2} = \frac{c_2^2}{2k_2}$.

Case III. Assume ν_g is fixed. Applying Lemma 3.2, we obtain, for $t \to -\infty$,

$$\begin{aligned}\lim_{\substack{\nu_g \text{ fixed}\\ t\to-\infty}}u_1 &= \lim_{\substack{\nu_g \text{ fixed}\\ t\to-\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(1+\mu_1)\right\}\\ &= \lim_{\substack{\nu_g \text{ fixed}\\ t\to-\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(1+e^{4\hat{k}^2t}\gamma_1)\right\}\\ &= 0.\end{aligned}$$

On the other hand, for $t \to \infty$,

$$\begin{aligned}\lim_{\substack{\nu_g \text{ fixed}\\ t\to\infty}}u_1 &= \lim_{\substack{\nu_g \text{ fixed}\\ t\to\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(1+e^{4\hat{k}^2t}\gamma_1)\right\}\\ &= \lim_{\substack{\nu_g \text{ fixed}\\ t\to\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log e^{4\hat{k}^2t}+\log(e^{-4\hat{k}^2t}+\gamma_1)\right\}\\ &= \lim_{\substack{\nu_g \text{ fixed}\\ t\to\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(e^{-4\hat{k}^2t}+\gamma_1)\right\}\\ &= -2\tfrac{\partial^2}{\partial \nu_g^2}\log\gamma_1\\ &= g.\end{aligned}$$

This completes the proof of part (i).

(ii) We apply a similar analysis to u_2 by again considering three separate cases.

Case I. Assume ν_2 is fixed. We rewrite p and q as

$$p = e^{8k_1(k_2^2-k_1^2)t}\left(\frac{c_1^2}{2k_1}e^{2k_1\nu_2} + \frac{c_2^2}{2k_2}e^{2k_2\nu_2-8k_1(k_2^2-k_1^2)t}\right),$$
$$q = e^{8k_1(k_2^2-k_1^2)t}\frac{(k_1-k_2)^2}{(k_1+k_2)^2}\frac{c_1^2c_2^2}{4k_1k_2}e^{2(k_1+k_2)\nu_2}.$$

The relations

$$\lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\frac{q}{p} = \frac{(k_1-k_2)^2}{(k_1+k_2)^2}\frac{c_2^2}{2k_2}e^{2k_2\nu_2}, \qquad \lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\frac{q}{p^2} = 0$$

now tell us how μ_2 behaves in the limit once we rationalize it:

$$\begin{aligned}\lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\mu_2 &= \lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\left\{\frac{1}{2}\left(p-\sqrt{p^2-4q}\right)\frac{p+\sqrt{p^2-4q}}{p-\sqrt{p^2-4q}}\right\}\\ &= \lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\left\{\frac{\frac{2q}{p}}{1+\sqrt{1-\frac{4q}{p^2}}}\right\}\\ &= \frac{(k_1-k_2)^2}{(k_1+k_2)^2}\frac{c_2^2}{2k_2}e^{2k_2\nu_2}.\end{aligned}$$

Hence,

$$\begin{aligned}\lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}u_2 &= \lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log(1+\mu_2)\right\}\\ &= \lim_{\substack{\nu_2 \text{ fixed}\\ t\to-\infty}}\left\{-2\frac{\partial^2}{\partial x^2}\log\left[1+\frac{(k_1-k_2)^2}{(k_1+k_2)^2}\frac{c_2^2}{2k_2}e^{2k_2\nu_2}\right]\right\}\\ &= s_2(\nu_2+\delta_2+\Delta),\end{aligned}$$

where Δ is defined by $e^{2k_2\Delta} = \frac{(k_1-k_2)^2}{(k_1+k_2)^2}$.

Case II. Assume that ν_1 is fixed. As the line of argument here is the same as that for Case I with ν_2 fixed, we leave it for the reader to verify that

$$\lim_{\substack{\nu_1 \text{ fixed}\\ t\to\infty}}u_2 = s_1(\nu_1+\delta_1+\Delta).$$

Case III. Assume that ν_g is fixed. The argument establishing

$$\lim_{\substack{\nu_g \text{ fixed}\\ t\to\infty}}u_2 = \bar{g}$$

is exactly the same as that for Case III in (i) and will be left for the reader. This completes the proof of our theorem. □

The following result provides evidence to support our theory of soliton decay.

THEOREM 3.4. (i) *Conservation of mass.*

$$\int_{-\infty}^{\infty}u_n(x,t)dx = -4k_n, \qquad n=1,2.$$

(ii) *Conservation of momentum.*

$$\frac{d}{dt}\int_{-\infty}^{\infty}xu_n(x,t)dx = -16k_n^3, \qquad n=1,2.$$

Proof. (i) For u_1, we have

$$\begin{aligned}\int_{-\infty}^{\infty} u_1(x,t)dx &= \int_{-\infty}^{\infty}\left[-2\tfrac{\partial^2}{\partial x^2}\log(1+\mu_1)\right]dx\\ &= \left[-2\tfrac{\partial}{\partial x}\log(1+\mu_1)\right]_{-\infty}^{\infty}\\ &= -2\left[\tfrac{\mu_1'}{1+\mu_1}\right]_{-\infty}^{\infty}\\ &= -4k_1.\end{aligned}$$

A similar argument applied to u_2 (after first rationalizing μ_2) shows that

$$\int_{-\infty}^{\infty} u_2(x,t)dx = -4k_2.$$

(ii) Integration by parts yields

$$\begin{aligned}\int_{-\infty}^{L} xu_n(x,t)dx &= \left[-2x\tfrac{\partial}{\partial x}\log(1+\mu_n)\right]_{-\infty}^{L} - \int_{-\infty}^{L}\left[-2\tfrac{\partial}{\partial x}\log(1+\mu_n)\right]dx\\ &= -2L\tfrac{\mu_n'(L)}{(1+\mu_n(L)}+2\log(1+\mu_n(L))\\ &\sim -4k_nL+4k_n(L-4k_n^2t+\delta_n)\end{aligned}$$

as $L\to\infty$. It follows that

$$\frac{d}{dt}\int_{-\infty}^{\infty} xu_n(x,t)dx = -16k_n^3, \qquad n=1,2.$$

This completes the proof. □

For $n=1,2$, we define the *center of mass* of u_n to be

$$x_n(t) \equiv \frac{\int_{-\infty}^{\infty} xu_n(x,t)dx}{\int_{-\infty}^{\infty} u_n(x,t)dx}. \tag{19}$$

The next corollary follows immediately from Theorem 3.4.

COROLLARY 3.5. *The center of mass $x_n(t)$ as defined by* (19) *moves with constant velocity $4k_n^2$, i.e.,*

$$\frac{dx_n}{dt} = 4k_n^2, \qquad n=1,2.$$

Let us now investigate our ghost particles a little more closely. We begin with the following theorem which justifies our use of the terms "ghost" and "antighost" for g and $\bar{g}$ as they do not appear in u due to cancellation.

THEOREM 3.6. *The ghost particles g and $\bar{g}$ enjoy the following properties:*

(i) $g+\bar{g}=0$.

(ii) $\int_{-\infty}^{\infty} g(\nu_g)d\nu_g = 4(k_1-k_2)$.

(iii) $g = -32k_1k_2(\frac{p_gq_g}{r_g^{3/2}}) < 0$, *where* $p_g = \mathrm{Tr}(A_g)$, $q_g=\det(A)$, *and* $r_g = p_g^2-4q_g$.

(iv) $g(\nu_g) = O(\mathrm{sech}^2[(k_1-k_2)(\nu_g+\delta_g)])$ *as* $\nu_g\to\pm\infty$, *where δ_g is defined by the relation* $e^{2(k_1-k_2)\delta_g} = \frac{c_1^2k_2}{c_2^2k_1}$.

(v) $|g(\nu_g)| \le (k_1-k_2)^2(k_1+k_2)/\sqrt{k_1k_2}$ *with equality holding precisely when* $\nu_g = -\delta_g$.

Proof. (i) If one recalls that

$$\begin{aligned}\gamma_1\gamma_2 &= \det(A_g)\\ &= \tfrac{(k_1-k_2)^2}{(k_1+k_2)^2}\tfrac{c_1^2c_2^2}{4k_1k_2}e^{2(k_1+k_2)\nu_g},\end{aligned}$$

then it directly follows that

$$\begin{aligned}g+\bar{g} &= -2\tfrac{\partial^2}{\partial\nu_g^2}\log(\gamma_1\gamma_2)\\ &= 0.\end{aligned}$$

(ii) We have

$$\begin{aligned}\int_{-\infty}^{\infty} g(\nu_g)d\nu_g &= \int_{-\infty}^{\infty}\left[-2\tfrac{\partial^2}{\partial\nu_g^2}\log\gamma_1\right]d\nu_g\\ &= \left[-2\tfrac{\gamma_1'}{\gamma_1}\right]_{-\infty}^{\infty}.\end{aligned} \tag{20}$$

Substituting the relations

$$\lim_{\nu_g\to-\infty}\frac{\gamma_1'}{\gamma_1}=2k_2, \qquad \lim_{\nu_g\to\infty}\frac{\gamma_1'}{\gamma_1}=2k_1.$$

into (20) then yields the desired result:

$$\int_{-\infty}^{\infty} g(\nu_g)d\nu_g = 4(k_2-k_1).$$

We note that this result also follows directly from Theorem 3.4 due to conservation of mass of u_1.

(iii) First write γ_1 in the form

$$\gamma_1 = \frac{1}{2}\left(p_g+\sqrt{r_g}\right), \tag{21}$$

where

$$p_g = \mathrm{Tr}(A_g) = \frac{c_1^2}{2k_1}e^{2k_1\nu_g}+\frac{c_2^2}{2k_2}e^{2k_2\nu_g}, \tag{22}$$

$$q_g = \det(A_g) = \frac{(k_1-k_2)^2}{(k_1+k_2)^2}\frac{c_1^2c_2^2}{4k_1k_2}e^{2(k_1+k_2)\nu_g}, \tag{23}$$

$$r_g = p_g^2-4q_g. \tag{24}$$

Then we can express γ_1 in terms of an appropriate hyperbolic cosine function by introducing the identity

$$p_g = \frac{c_1c_2}{\sqrt{k_1k_2}}e^{(k_1+k_2)\nu_g}\cosh[(k_1-k_2)(\nu_g+\delta_g)], \tag{25}$$

where δ_g is defined by the relation $e^{2(k_1-k_2)\delta_g}=\frac{c_1^2k_2}{c_2^2k_1}$. It follows that

$$\begin{aligned}\gamma_1 = \frac{c_1c_2}{\sqrt{k_1k_2}}e^{(k_1+k_2)\nu_g}\Bigg(&\cosh\left[(k_1-k_2)(\nu_g+\delta_g)\right]\\ &+\sqrt{\cosh^2\left[(k_1-k_2)(\nu_g+\delta_g)\right]-\frac{(k_1-k_2)^2}{(k_1+k_2)^2}}\Bigg)\end{aligned} \tag{26}$$

$$= \frac{(k_1-k_2)}{(k_1+k_2)}\frac{c_1c_2}{\sqrt{k_1k_2}}e^{(k_1+k_2)\nu_g}\left(z+\sqrt{z^2-1}\right), \tag{27}$$

where $z = \frac{(k_1+k_2)}{(k_1-k_2)} \cosh[(k_1-k_2)(\nu_g+\delta_g)]$. Therefore,

$$g = -2\frac{\partial^2}{\partial \nu_g^2} \log \gamma_1 \tag{28}$$

$$= -2\frac{\partial^2}{\partial \nu_g^2} \left[\log\left(\frac{(k_1k_2)}{(k_1+k_2)} \frac{c_1c_2}{\sqrt{k_1k_2}} e^{(k_1+k_2)\nu_g} \right) + \log(z+\sqrt{z^2-1}) \right] \tag{29}$$

$$= -2\frac{\partial^2}{\partial \nu_g^2} \cosh^{-1} z \tag{30}$$

$$= -8k_1k_2 \frac{z}{(z^2-1)^{3/2}} \tag{31}$$

$$= -8k_1k_2 \frac{\frac{(k_1+k_2)}{(k_1-k_2)} \cosh[(k_1-k_2)(\nu_g+\delta_g)]}{\left[\frac{(k_1+k_2)^2}{(k_1-k_2)^2} \cosh^2[(k_1-k_2)(\nu_g+\delta_g)] - 1 \right]^{3/2}} \tag{32}$$

$$= -32k_1k_2 \frac{p_g q_g}{r_g^{3/2}}, \tag{33}$$

as desired. Moreover, g is negative because the quantities p_g, q_g, and r_g are all positive.

(iv) It is now easy to deduce from (32) that

$$g(\nu_g) = \mathrm{O}(\mathrm{sech}^2[(k_1-k_2)(\nu_g+\delta_g)])$$

as $\nu_g \to \pm\infty$.

(v) Using (31), we find that $g(\nu_g)$ has the derivative

$$\frac{dg}{d\nu_g} = 8k_1k_2 \frac{2z^2+1}{(z^2-1)^{3/2}} \left(\frac{dz}{d\nu_g} \right). \tag{34}$$

Since $z^2 - 1 > 0$, it follows that $\frac{dg}{d\nu_g}$ is zero precisely when

$$\frac{dz}{d\nu_g} = \frac{(k_1+k_2)^2}{(k_1-k_2)} \sinh[(k_1-k_2)(\nu_g+\delta_g)] \tag{35}$$

is zero, or equivalently, when $\nu_g = -\delta_g$. We can therefore conclude that g has an absolute minimum of

$$g(-\delta_g) = -\frac{(k_1-k_2)^2(k_1+k_2)}{\sqrt{k_1k_2}}$$

at this critical point because of (iv). This completes the proof of Theorem 3.6. □

Remark. Property (iv) of Theorem 3.6 shows that in some sense g can be viewed as a nonlinear difference between the soliton particles s_1 and s_2 as defined by (11). Moreover, $g(\nu_g) \to 0$ as $k_2 \to k_1$ and $g(\nu_g) \to -4k_1\delta(\nu_g)$ as $k_2 \to 0$, where $\delta(\nu_g)$ is the Dirac delta function.

Next, we show that each decay function itself can be decomposed as a sum of a "soliton" term and a "ghost" term:

$$u_n(x,t) = -2\frac{\partial^2}{\partial x^2} \log(1+\mu_n) \tag{36}$$

$$= -2\left[\frac{(1+\mu_n)\mu_n'' - (\mu_n')^2}{(1+\mu_n)^2}\right] \tag{37}$$

$$= -2\frac{\mu_n''}{(1+\mu_n)^2} - 2\left[\frac{\mu_n\mu_n'' - (\mu_n')^2}{\mu_n^2}\right]\left(\frac{\mu_n}{1+\mu_n}\right)^2 \tag{38}$$

$$= -2\frac{\mu_n''}{(1+\mu_n)^2} - 2\left(\frac{\partial^2}{\partial x^2}\log\mu_n\right)\left(\frac{\mu_n}{1+\mu_n}\right)^2 \tag{39}$$

$$= u_n^s + u_n^g. \tag{40}$$

DEFINITION 3.7. *We shall call*

$$u_n^s = -2\frac{\mu_n''}{(1+\mu_n)^2} \tag{41}$$

the soliton component of u_n *and*

$$u_n^g = -2\left(\frac{\partial^2}{\partial x^2}\log\mu_n\right)\left(\frac{\mu_n}{1+\mu_n}\right)^2 \tag{42}$$

the ghost component of u_n*. Moreover, we shall refer to the decomposition given by* (40) *as the splitting decomposition of* u_n*.*

For two-solitons, the following lemma holds.

LEMMA 3.8.

$$u_n^g(x,t) = (-1)^{n-1}g(x-4k_g^2t)\left(\frac{\mu_n(x,t)}{1+\mu_n(x,t)}\right)^2, \quad n=1,2. \tag{43}$$

Remark. The decomposition described in (40) reveals the time-asymmetry of soliton decay in that ghost particles are born at $t=\infty$ and is essentially due to the identity matrix appearing in the N-soliton formula. In particular, the behavior of $\mu_n/(1+\mu_n)\to 0$ as $t\to-\infty$ and $\mu_n/(1+\mu_n)\to 1$ as $t\to\infty$ in (43) indicates that the ghost component u_n^g represents creation of the ghost particle $g(x-4k_g^2t)$ at $t=\infty$. This implies that there is actually interaction between solitons even before "collision" occurs; however, this interaction is insignificant until then. Lastly, it is straightforward to verify that each soliton component u_n^s asymptotically describes an exchange of identities between the two-soliton particles.

4. Two-soliton example. We end our paper with a concrete example to illustrate our results. Let $k_1=c_1=2$ and $k_2=c_2=1$ be the given scattering data. Our soliton matrix A then takes the form

$$A = \begin{pmatrix} e^{4x-64t} & \frac{2}{3}e^{3x-36t} \\ \frac{2}{3}e^{3x-36t} & \frac{1}{2}e^{2x-8t} \end{pmatrix} \tag{44}$$

and has eigenvalues

$$\mu_1 = \frac{1}{12}\left(3e^{2x-8t} + 6e^{4x-64t} + e^{2x-8t}\sqrt{9+28e^{2x-56t}+36e^{4x-112t}}\right), \tag{45}$$

$$\mu_2 = \frac{1}{12}\left(3e^{2x-8t} + 6e^{4x-64t} - e^{2x-8t}\sqrt{9+28e^{2x-56t}+36e^{4x-112t}}\right). \tag{46}$$

The decay functions u_1 and u_2 can now of course be computed through the formula

$$u_n = -2\frac{\partial^2}{\partial x^2}\log(1+\mu_n), \quad n=1,2,$$

but we shall avoid doing this here due to their complicated expressions. The ghost matrix

$$A_g = \begin{pmatrix} e^{4\nu_g} & \frac{2}{3}e^{3\nu_g} \\ \frac{2}{3}e^{3\nu_g} & \frac{1}{2}e^{2\nu_g} \end{pmatrix} \tag{47}$$

has eigenvalues

$$\gamma_1 = \frac{1}{12}\left(3e^{2\nu_g} + 6e^{4\nu_g} + e^{2\nu_g}\sqrt{9 + 28e^{2\nu_g} + 36e^{4\nu_g}}\right), \tag{48}$$

$$\gamma_2 = \frac{1}{12}\left(3e^{2\nu_g} + 6e^{4\nu_g} - e^{2\nu_g}\sqrt{9 + 28e^{2\nu_g} + 36e^{4\nu_g}}\right). \tag{49}$$

Therefore,

$$g = -32k_1k_2\left(\frac{p_g q_g}{r_g^{3/2}}\right) \tag{50}$$

$$= -\frac{384e^{2\nu_g}(1 + 2e^{2\nu_g})}{(9 + 28e^{2\nu_g} + 36e^{4\nu_g})^{3/2}} \tag{51}$$

$$= -\frac{48\cosh(\nu_g + \log\sqrt{2})}{\left[9\cosh^2(\nu_g + \log\sqrt{2}) - 1\right]^{3/2}} \tag{52}$$

and the ghost moving frame is given by $\nu_g = x - 28t$. Of course, we also have $\bar{g} = -g$. Figures 2–4 illustrate the motions of $-u(x,t)$, $-u_1(x,t)$, and $-u_2(x,t)$, respectively, over time through a sequence of six frames corresponding to time steps $t = -0.4, -0.2, \ldots, 0.6$. The soliton particles s_1 and s_2 have amplitudes of 8 and 2, respectively, and velocities of 16 and 4, respectively. The ghost particle g has an amplitude of $3/\sqrt{2} \approx 2.12$ and a velocity of 28. Splitting occurs in the fourth frame at $t = 0.2$ for both u_1 and u_2 as seen in Figures 3 and 4, respectively.

5. Concluding remarks. Our work raises interesting questions some of which deserve comment.

Q1. What happens during collisions of more than two-solitons? Are more ghost particles generated? Can ghost particles from different pairs interact?

A1. It is found that each collision between any two-soliton particles produces a ghost particle pair with the same properties as those described by Theorem 3.6. On the other hand, each collision between two ghost particles where each comes from a different pair will result in their fusion. Because of duality, there is an accompanying fission process which is interpreted as the same fusion process but reversed in time. Moreover, the final states of all ghost particles created is independent of their order of collision (modulo phase shifts). A mathematical theory formulating the creation and interaction of ghost particles will be described in a forthcoming paper.

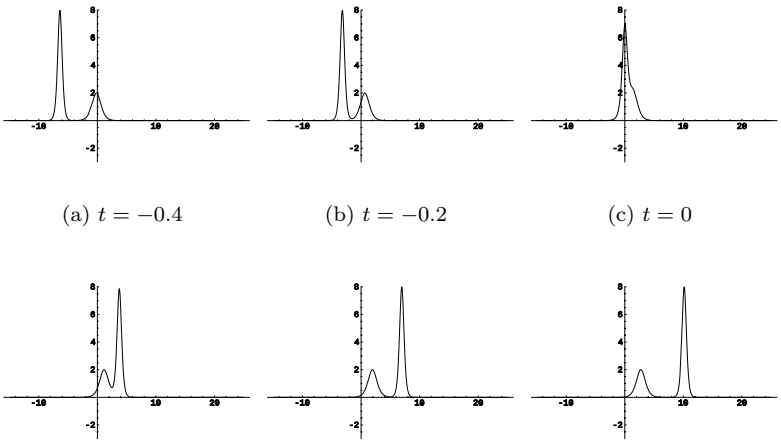
Q2. Do the decay functions $\{u_n\}$ satisfy any partial differential equations?

A2. This is not presently known as we have been unsuccessful at finding such equations. On the other hand, it is known that the eigenvalues $\{\mu_n\}$ of the soliton matrix A which defines $\{u_n\}$ satisfy ordinary differential equations of the form

$$\frac{d\mu_n}{dx} = (E^T \cdot X_n)^2, \quad n = 1, \ldots, N. \tag{53}$$

Here, X_n is a normalized eigenvector of A corresponding to μ_n and

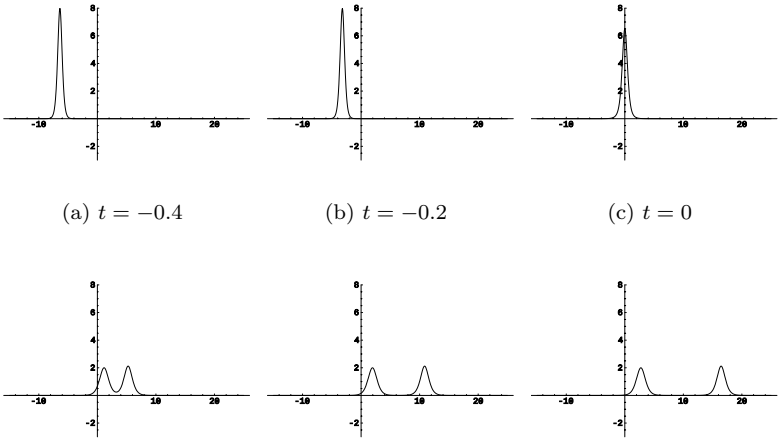
$$E^T = (c_1 e^{k_1\nu_1}, c_2 e^{k_2\nu_2}, \ldots, c_N e^{k_1\nu_1})^T.$$



(a) $t = -0.4$ (b) $t = -0.2$ (c) $t = 0$

(d) $t = 0.2$ (e) $t = 0.4$ (f) $t = 0.6$

FIG. 2. *Plots of* $-u(x,t)$.



(a) $t = -0.4$ (b) $t = -0.2$ (c) $t = 0$

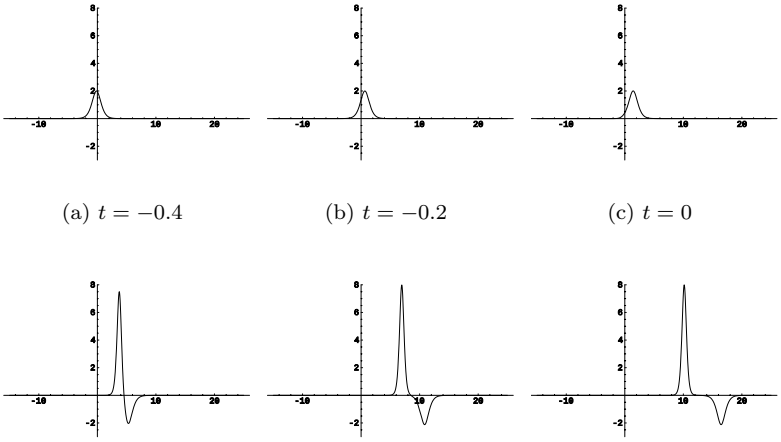
(d) $t = 0.2$ (e) $t = 0.4$ (f) $t = 0.6$

FIG. 3. *Plots of* $-u_1(x,t)$*:* $s_1 \to s_2 + g$.

These differential equations can be easily derived from the symmetry and positive definiteness of A. However, their usefulness is unclear as they do not make direct use of the KdV equation.

Q3. How is the linear eigenvalue decomposition described in this paper related to others in the literature, e.g., Hodnett and Moloney [HM] and Miller and Christiansen [MC]?

A3. Hodnett and Moloney's work in [HM] involves using the Hirota formalism to decompose each N-soliton solution into a linear sum of squares of hyperbolic secant functions having time-dependent amplitudes and phase shifts (a Lie-theoretic gener-



(a) $t = -0.4$ (b) $t = -0.2$ (c) $t = 0$

(d) $t = 0.2$ (e) $t = 0.4$ (f) $t = 0.6$

FIG. 4. *Plots of* $-u_2(x,t)$*:* $s_2 \to s_1 + \bar{g}$.

alization of this decomposition is given by Fuchssteiner in [F]). For two-solitons, this decomposition takes the form

$$u = u_1 + u_2, \tag{54}$$

where

$$u_1 = 2a_1^2 H(\theta_2)\operatorname{sech}^2[\theta_1 + G(\theta_2)], \tag{55}$$

$$u_2 = 2a_2^2 H(\theta_1)\operatorname{sech}^2[\theta_2 + G(\theta_1)]. \tag{56}$$

Here, a_i and θ_i are the spectral parameters and moving frames, respectively. Exact formulas for $H(\nu_1)$ and $G(\nu_2)$ can then be derived by requiring u_1 and u_2 to conserve mass for all times as in Theorem 3.4. In essence, this approach by Hodnett and Moloney views the hyperbolic secant function as the building block for a soliton particle whereas our approach views the eigenvalues of the soliton matrix A as playing this role. As a result, the decomposition of Hodnett and Moloney seems to asymptotically describe only an exchange of soliton identities and not soliton decay as revealed by our decomposition.

As for Miller and Christiansen [MC], they considered soliton solutions of the coupled system

$$\frac{\partial u_k}{\partial t} + \frac{\partial}{\partial x}\left[\frac{u_k}{2}\sum_{j=1}^{N} u_j + \frac{\partial^2 u_k}{\partial x^2}\right] = 0, \qquad k = 1, \ldots, N. \tag{57}$$

This system can be viewed as a multicomponent generalization of the KdV equation and is derived by requiring symmetry and conservation of mass principles. For $N = 2$, numerical solutions for u_1 and u_2 were obtained which indicated an exchange of mass between two given soliton particles after collision. However, there is no prediction of ghost particles, which again is in contrast to our decomposition. In short, we believe our model of soliton interaction to be one that is most consistent with the laws of classical mechanics.

Acknowledgments. The author wishes to sincerely thank Eduardo Flores from Rowan University for his helpful comments and clear explanations of the physical concepts discussed in this paper. The author also wishes to thank the referee for making useful suggestions about this paper and raising the questions addressed above.

THE BIFURCATION STRUCTURE OF THE HOLLING–TANNER MODEL FOR PREDATOR-PREY INTERACTIONS USING TWO-TIMING*

PETER A. BRAZA†

Abstract. The Holling–Tanner model for predator-prey systems has two Hopf bifurcation points for certain parameters. The dependence of the environmental parameters on the underlying bifurcation structure is uncovered using two-timing. Emphasis is on how the bifurcation diagram changes as the Hopf bifurcation points separate. Two degenerate cases require a modification of conventional two-timing. When the two Hopf bifurcation points nearly coalesce, the two stable periodic solution branches are shown to be connected. As a ratio of linear growth rates varies, the Hopf bifurcation points separate further and one limit cycle becomes unstable. This situation can correspond to an outbreak in populations. The modified two-timing analysis analytically captures the unstable and stable limit cycles of the new branch.

1. Introduction.

Predator-prey dynamics continue to be of interest to both applied mathematicians and ecologists. The early Lotka–Volterra model has given way to more sophisticated models from both a mathematical and biological point of view. Although useful for developing some basic intuition about predator-prey systems, the Lotka–Volterra model has the ecologically offensive property of a neutrally stable equilibrium point giving rise to a family of periodic solutions in which initial conditions, rather than environmental parameters, determine long term behavior [1], [2], [3]. As far back as Kolmogorov [4] in 1936, it was suggested that a stable equilibrium or a stable limit cycle should be the result of a wide class of single predator, single prey mathematical models [1]. From an ecological perspective, the fairly regular oscillations seen with the snowshoe hare and lynx in Canada support the isolated periodic solution conclusion (limit cycle) rather then the family of periodic solutions [5].

Robert May developed a model in which he incorporated Holling's rate [6], [7] at which predators remove prey and Leslie's somewhat unconventional equation for predator dynamics [1], [8]. This model, also known as the Holling–Tanner model [9], has been studied both for its mathematical properties and its efficacy for describing real ecological systems such as mite/spider mite, lynx/hare, sparrow/sparrow hawk, etc. by Tanner [10] and Wollkind, Collings, and Logan [11].

The May or Holling–Tanner model for predator-prey interaction is

$$\begin{aligned} \frac{dx}{dt} &= r_1 x\left(1-\frac{x}{k}\right)-\frac{qxy}{x+a}, \\ \frac{dy}{dt} &= r_2 y\left(1-\frac{y}{\gamma x}\right) \end{aligned} \tag{1.1}$$

[1], [9], [10], [11].

The variables $x(t)$ and $y(t)$ denote the prey and predator, respectively. The parameters r_1 and r_2 are the intrinsic growth rates. The value k is the carrying capacity of the prey and γx takes on the role of a prey-dependent carrying capacity for the predator. The parameter γ is a measure of the quality of the prey as food for the predator. The rate at which predators remove the prey, $qx/(x+a)$, is known as a Holling type 2 predator response [1], [6], [9], [12]. The parameter q is the maximum number of prey that can be eaten per predator per time and the parameter a is a saturation value; it corresponds to the number of prey necessary to achieve one half the maximum rate q.

The dynamics of the Holling–Tanner model have proven quite interesting. Thus far the mathematical analysis of the dynamics has generally been either qualitative or numerical. May and Tanner used phase plane stability analysis to find criteria for stable limit cycles [1], [2], [6]. Hsu and Huang [12] discuss global stability questions of the equilibrium point. Sáez and Gonzáles-Olivares [9] develop curves in parameter space that delineate regions of two limit cycles, semistable limit cycles, etc. and discuss bifurcations from an existence viewpoint. Numerical work with AUTO [13] was used in two papers by Collings [14] and Wollkind, Collings, and Logan [11] to illustrate the bifurcations in mite/spider mite systems.

This body of work spurred this author to try to understand the dynamics from a complementary perspective. The point in this paper is to bridge the results on the existence of limit cycles and the numerical work by using techniques to *analytically construct* solutions, applicable to a broad class of predator-prey problems, that describe the underlying bifurcations. A focus is to understand the bifurcation diagram as the two Hopf bifurcation points separate. Two-timing methods will be used to construct the periodic solutions that arise from the Hopf bifurcation points in terms of environmental parameters. Of particular interest will be the ways the two-timing method must be modified to handle the degenerate cases discussed by the authors above. The two branches of periodic solutions are shown to be connected when the Hopf bifurcation points are close. Also, the entire subcritical branch is captured analytically along with conditions for having a semistable limit cycle. The subcritical case is important ecologically since it can correspond to large outbreaks in the populations.

2. Analysis. At the beginning of this section, linear stability results give conditions on the parameters when there will be two Hopf bifurcation points. Then the periodic solutions bifurcating from the two Hopf bifurcation points are found using two-timing. Based on the slow time amplitude equations, it will be shown that one branch is always supercritical while the other one changes from supercritical to subcritical as the parameters are varied.

As a first step in the bifurcation analysis, equations (1.1) are nondimensionalized by defining new predator and prey variables as

$$prey\ \ U = \frac{x}{k}, \qquad predator\ \ V = \frac{y}{\gamma k},$$

along with a new time

$$t_{new} = r_1 t_{old},$$

and parameters

$$r = \frac{r_2}{r_1}, \qquad b = \frac{a}{k}, \qquad c = \frac{q\gamma}{r_1}.$$

Since k is the carrying capacity of the prey and the parameter a is the saturation value of the prey, it only makes sense biologically to consider $b < 1$ [11]. The parameter $r > 0$ is the ratio of linear growth rates of predator to prey and will be an important parameter in the bifurcation analysis to follow. Tanner [10] has field data with estimated intrinsic growth rates for various predator-prey pairs and he notes that cyclic population dynamics only occur when r is small enough relative to other parameters.

With the nondimensional variables and parameters, equations (1.1) become

$$\begin{aligned} \frac{dU}{dt} &= U(1-U) - \frac{cUV}{U+b}, \\ \frac{dV}{dt} &= rV\left(1 - \frac{V}{U}\right). \end{aligned} \tag{2.1}$$

There are two equilibrium solutions. One equilibrium point, given by $U = 1$, $V = 0$, is not of interest since it corresponds to the prey being at its carrying capacity with no predators. In the (U, V) phase plane it is a saddle. The other equilibrium point depends on the parameters b and c and is given implicitly by

$$U^2 + (b + c - 1)U - b = 0 \quad \text{and} \quad V = U. \tag{2.2}$$

A necessary condition for a Hopf bifurcation is that the trace of system (2.1) linearized about the steady state (2.2) be equal to zero. This condition is represented by the equation

$$r = 1 - 2U - \frac{bcU}{(b+U)^2}. \tag{2.3}$$

Of interest is the fact the Hopf bifurcation equation (2.3) depends on the growth rate parameter r whereas the steady state equation (2.2) does not. This will be utilized later when the bifurcations are unfolded.

When (2.2) and (2.3) are solved simultaneously, we get the values of $U = u$ and c where Hopf bifurcations occur:

$$\begin{aligned} u &= \frac{1}{4}\left(1 - b - r \pm \sqrt{(1-b-r)^2 - 8br}\right) \quad \text{and} \\ c &= \frac{1}{4r}\left(2 + r + r^2 - b\,(b+3r) \mp (2+r)\sqrt{(1-b-r)^2 - 8br}\right). \end{aligned} \tag{2.4}$$

The feature to focus on is that there will be two Hopf bifurcation points when $(1-b-r)^2 - 8br > 0$ and none when $(1-b-r)^2 - 8br < 0$. These regions in the (r, b) plane are shown in Figure 1. The degenerate case when $0 < (1-b-r)^2 - 8br \ll 1$ (nearly coalescing Hopf bifurcation points) will be considered in section 3.

The region of Hopf bifurcation points in Figure 1 is in accord with cyclic behavior seen in real ecological systems. May [1] observed that stable limit cycles are likely with weak self-limitation of the prey (large k) and $r_2/r_1 < 1$. The dynamics switch from an attractive fixed point to a stable limit cycle as "life gets better," meaning r_1 or k increases. This corresponds to a smaller r or b. He argues that the work of Baltensweiler [15] on the eight year cyclic behavior of the larch bud moth in Switzerland, which has been observed since 1855, elegantly illustrates this. Tanner [10] and May [1] suggested that the oscillating population of snowshoe hare in subarctic regions as studied by Dolbeer [16] may be due to poor cover since more southerly

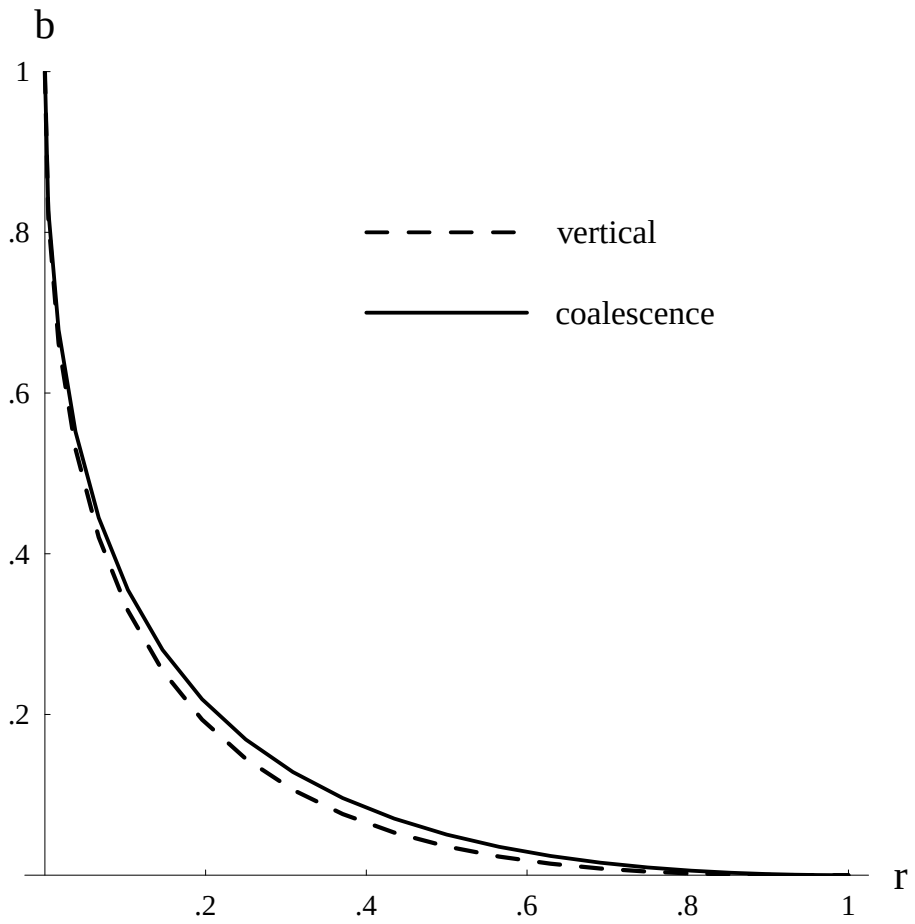

FIG. 1. *The Hopf bifurcation points coalesce for parameters r and b on the solid curve. There are no Hopf bifurcation points in the region above this curve and two Hopf points below it. The dashed curve shows the values of r and b for which the branch of periodic solutions from the right Hopf bifurcation point is vertical.*

populations of snowshoe hare are not cyclic but have more protective cover in the spruce-fir forests of Colorado. Less protective environments mean a smaller value of the parameter $b = a/k$ since a is directly proportional to the time for the predator to search and find the prey [10]. In the same vein, Tanner argues that laboratory experiments by Luckinbill [17] of Paramecium aurelia and its predator Didinium nasutum demonstrate the dependence of population dynamics on the parameter a. He writes, "Cultures of these two species normally exhibited increasing oscillation until one or the other become extinct; an increase in the viscosity of the medium (higher a) strengthened the system's stability, possibly by increasing the predator's searching time." On a different note, Tanner [10] observed that the intrinsic growth rate of the North American mountain lion is larger than its prey, the mule deer (implying $r = r_2/r_1 > 1$), and that these populations are generally near some equilibrium except for natural stochastic variations.

The interrelated influence of ecological parameters on the behavior of a predator-prey system can be complicated to discern. Two-timing will help reveal the depen-

dence of the solutions on the parameters in a fairly explicit way.

In standard two-timing analysis, the bifurcating periodic solutions are found by expanding the variables and bifurcation parameter about the Hopf bifurcation values (2.4). The choice of $c = q\gamma/r_1$ as the primary bifurcation parameter stems from it being a combination of three ecological parameters. Rather than use the values of u and c in (2.4), the analysis will be algebraically simpler if we use the equivalent expressions

$$c_h = \frac{(1-u)^2}{r+u} \quad \text{and} \quad b_h = \frac{u(1-r-2u)}{r+u}, \tag{2.5}$$

also found by solving the steady state (2.2) and Hopf bifurcation (2.3) equations simultaneously, and consider u and r as free parameters. An added benefit is that the local analysis about both Hopf bifurcation points can be done simultaneously by using (2.5) rather than separate analyses using (2.4).

To find the periodic solutions locally about the Hopf bifurcation points, we begin by defining a small parameter ε as a measure of the deviation from the Hopf value of c by

$$c = c_h + P\,\varepsilon^2 \tag{2.6}$$

with $P = \pm 1$ determining the direction of the bifurcation. A slow time is defined by

$$\tau = \varepsilon^2 t, \tag{2.7}$$

and the variables are expanded in a power series in ε as

$$\begin{aligned} U(t,\tau) &= u + \varepsilon u_1(t,\tau) + \varepsilon^2 u_2(t,\tau) + \cdots, \\ V(t,\tau) &= u + \varepsilon v_1(t,\tau) + \varepsilon^2 v_2(t,\tau) + \cdots. \end{aligned} \tag{2.8}$$

When the variables in (2.8), slow time τ, and expressions (2.5) and (2.6) are substituted into the main equations (2.1), we get a sequence of equations at each order of ε.

The $O(\varepsilon)$ equations are

$$\begin{bmatrix} u_{1t} \\ v_{1t} \end{bmatrix} = \begin{bmatrix} r & u-1 \\ r & -r \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix}. \tag{2.9}$$

The periodic solutions, in polar form, are

$$\begin{bmatrix} u_1(t,\tau) \\ v_1(t,\tau) \end{bmatrix} = R(\tau)e^{i\theta(\tau)} \begin{bmatrix} r+i\lambda \\ r \end{bmatrix} e^{i\lambda t} + R(\tau)e^{-i\theta(\tau)} \begin{bmatrix} r-i\lambda \\ r \end{bmatrix} e^{-i\lambda t}. \tag{2.10}$$

The fast time frequency is $\lambda = \sqrt{r(1-u-r)}$. (It is assumed from here on that $1-u-r > 0$.) The amplitude is proportional to $R(\tau)$, which depends on the slow time.

After the $O(\varepsilon^2)$ equations are solved for $u_2(t,\tau)$ and $v_2(t,\tau)$, the differential equations for $R(\tau)$ and $\theta(\tau)$ are obtained by considering the $O(\varepsilon^3)$ equations which are of the form

$$\begin{bmatrix} u_{3t} \\ v_{3t} \end{bmatrix} - \begin{bmatrix} r & u-1 \\ r & -r \end{bmatrix} \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} = \begin{bmatrix} f_3(u_1,u_2,v_1,v_2) - u_{1\tau} \\ g_3(u_1,u_2,v_1,v_2) - v_{1\tau} \end{bmatrix}. \tag{2.11}$$

For periodic solutions to exist, the right-hand side of (2.11) must satisfy a solvability condition:

$$\int_0^{2\pi/\lambda} \begin{bmatrix} f_3 - u_{1\tau} \\ g_3 - v_{1\tau} \end{bmatrix} \cdot \begin{bmatrix} x \\ y \end{bmatrix} dt = 0, \tag{2.12}$$

where $\left[\begin{smallmatrix} x \\ y \end{smallmatrix}\right]$ is any solution of the adjoint homogeneous problem of (2.9),

$$\begin{bmatrix} x_t \\ y_t \end{bmatrix} = \begin{bmatrix} -r & -r \\ 1-u & r \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}. \tag{2.13}$$

The resulting differential equation for $R(\tau)$ is

$$R_\tau = \alpha(r,u)PR + \beta(r,u)R^3. \tag{2.14}$$

The coefficients $\alpha(r,u)$ and $\beta(r,u)$ are given by

$$\begin{aligned} \alpha(r,u) &= \frac{(r+u)(r(r-1)+4ru+2u^2)}{2(1-u)^2(1-r-u)}, \\ \beta(r,u) &= \frac{r(1-r-2u)((1-r)^2r + r(4r-7)u + (5r-4)u^2 + 2u^3)}{2u^2(1-u)(1-r-u)}. \end{aligned} \tag{2.15}$$

The algebra was quite messy so Mathematica [18] was enlisted to help out. There is also an equation for the slow time phase $\theta(\tau)$ but it is not relevant for the purposes here.

The equation (2.14) is the typical cubic form for a Hopf bifurcation. There are two steady states:

$$R = 0 \quad \text{and} \quad R = \sqrt{\frac{-\alpha(r,u)P}{\beta(r,u)}}. \tag{2.16}$$

The value $R = 0$ corresponds to the steady state of (2.1) whereas $R = \sqrt{\frac{-\alpha(r,u)P}{\beta(r,u)}}$ is the amplitude of the bifurcating periodic solutions. It is important to note that there are two values of u from (2.4) which give the nontrivial amplitude, so (2.16) captures the amplitude of the bifurcating periodic solutions from *both* Hopf bifurcation points. The stability of the bifurcating periodic solutions is determined by the signs of $\alpha(r,u)$ and $\beta(r,u)$. Figure 2 delineates regions in the (r,u) plane showing the signs of $\alpha(r,u)$ and $\beta(r,u)$ and the consequent stability.

When there are two Hopf bifurcation points, one arises from the parameters r and u of region A in Figure 2 and the other one comes from region B_1 or B_2. Since $\alpha(r,u) > 0$, $\beta(r,u) < 0$, and $P = 1$ in region A, the bifurcating periodic solution is supercritical (stable). The signs of $\alpha(r,u)$ and $\beta(r,u)$ also determine that the other branch will be stable if it comes from B_1 but that a branch from B_2 will be locally unstable (subcritical). The analysis in section 4 shows that this latter branch becomes stable. In all cases, the branch from either B_1 or B_2 joins the branch from region A. In general, the use of AUTO is required to establish this connection, but the connection of the periodic solution branches from regions A and B_1 is constructed analytically in section 3 in the case of nearly coalescing Hopf bifurcation points. The construction reveals more about the underlying dependence of the bifurcation diagram on the parameters than previous work in which other authors used AUTO exclusively [11], [14].

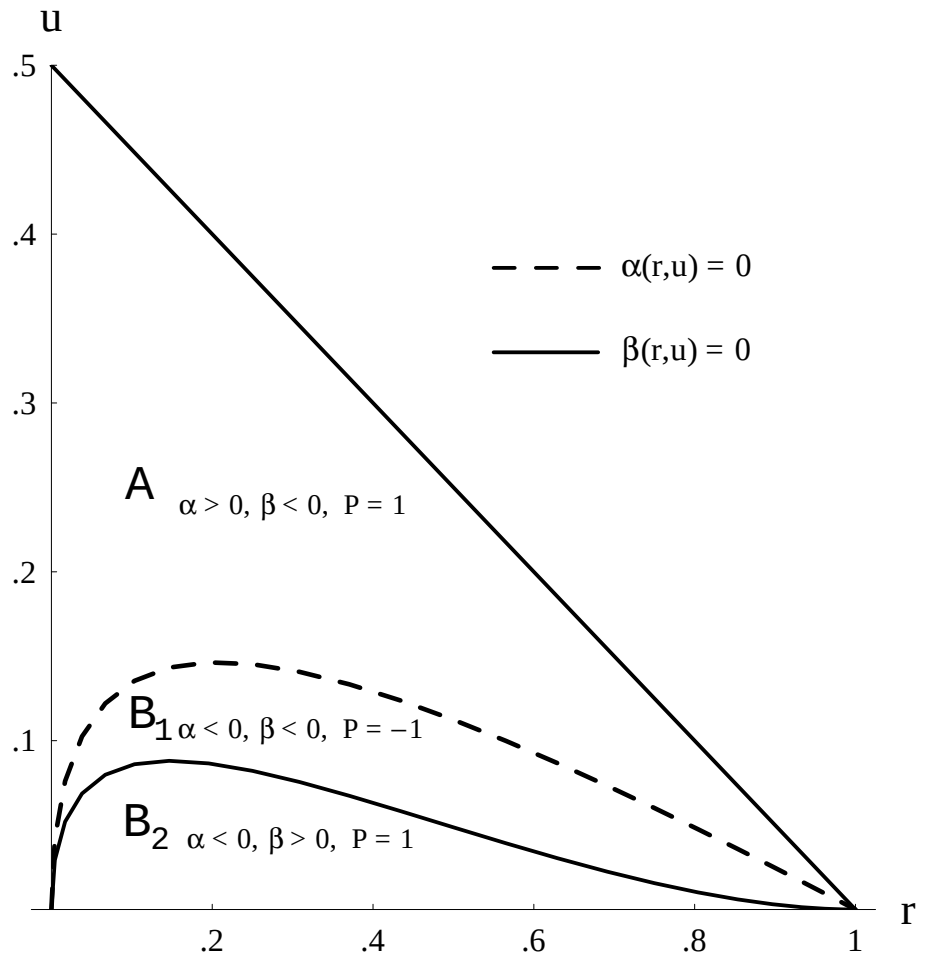

FIG. 2. *The signs of the coefficients $\alpha(r,u)$ and $\beta(r,u)$ of the amplitude equation* (2.15) *are indicated in the three regions of the (r,u) plane. The leftmost Hopf bifurcation point comes from the parameters in region A and the rightmost Hopf point comes from region B_1 or B_2. The resulting branches of periodic solutions are stable from regions A or B_1 and unstable from region B_2.*

In Figure 3, a sequence of pictures was created using AUTO to illustrate how the bifurcation diagrams change as the Hopf bifurcation points separate. The separation of the Hopf bifurcation points increases as ratio of linear growth rate parameter r decreases. In Figure 3, the left Hopf point comes from region A of Figure 2 whereas the right Hopf point comes from region B_1 in Figure 3(a), region B_2 in Figure 3(c), or on the border curve $\beta(r,u) = 0$ in Figure 3(b). The branch of periodic solutions from the left Hopf point is always supercritical but the branch from the right Hopf point is supercritical in Figure 3(a), "vertical" in Figure 3(b), and subcritical in Figure 3(c). The value of R from (2.16) accurately captures the periodic solutions locally. Similar bifurcation diagrams have been found by using AUTO in papers by Collings [14] and Wollkind, Collings, and Logan [11] in regards to mite/spider mite interactions with temperature dependence.

A nice feature about the amplitude equation (2.14) is that the parameters u and r

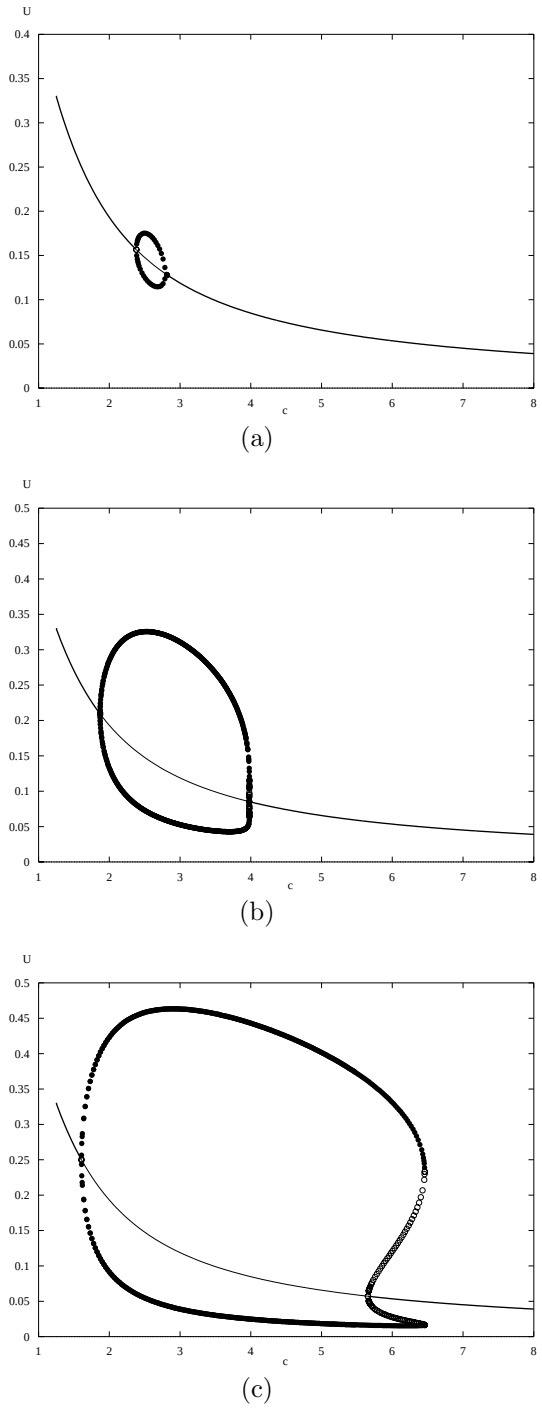

FIG. 3. (a)–(c) *show the bifurcation diagrams (computed with AUTO) of equations* (2.1) *as the Hopf bifurcation points separate. The light line is the unstable steady state and the slightly darker line is the stable steady state. The open circles denote unstable periodic solutions and the solid circles (often appearing as a thick solid curve) are the stable periodic solutions. The parameter b is fixed at* $b = 2/7$ *but* $r = .142$ *in Figure* 3(a), $r = .125$ *in Figure* 3(b), *and* $r = .10$ *in Figure* 3(c). *The coalescence value is* $r = 1/7$.

are not fixed so degeneracies can be readily identified by setting either coefficient $\alpha(r,u)$ or $\beta(r,u)$ of (2.15) equal to zero. The case $\alpha(r,u)=0$, which is equivalent to $(1-b-r)^2-8br=0$, corresponds to the two Hopf bifurcation points coalescing and will be analyzed in detail in the next section. The vertical Hopf bifurcation case occurring when $\beta(r,u)=0$ will be considered in section 4.

3. Nearly coalescing Hopf bifurcation points. Two-timing results generally give only local information about bifurcations. It would be nice to extend the results to show that the periodic solution branches from the two Hopf bifurcation points are connected. This can be done in the case of nearly coalescing Hopf points if the two-timing analysis is appropriately modified. Golubitsky and Langford [19] give the universal unfolding normal form for this case as well as many other degenerate Hopf bifurcations, but that work is not directly of use here.

From (2.4) the Hopf points will coalesce if

$$(1-b-r)^2-8br=0. \tag{3.1}$$

We note from (2.4) and Figure 3 that for a fixed b, as r decreases, the Hopf bifurcation points separate further and the amplitude of the periodic solution increases. This eventually can lead to a destabilization of the system since reductions in minimum population densities can increase the chance of extinction as a result of demographic or environmental stochastic influence [1].

If (3.1) holds, then the linear coefficient, $\alpha(r,u)$, in the amplitude equation (2.14) is zero so the steady state amplitude, $R=\sqrt{\frac{-\alpha(r,u)P}{\beta(r,u)}}$ from (2.16), becomes zero, causing the standard two-timing to break down. To rectify this situation, we begin by splitting the Hopf bifurcation points by defining the small parameter ε in terms of the growth rate parameter by

$$r=\rho-\varepsilon^2 \tag{3.2}$$

and fixing b at the coalescence value

$$b_{coal}=1+3\rho-2\sqrt{2\rho}\sqrt{1+\rho} \tag{3.3}$$

obtained from (3.1) with $\varepsilon=0$. Please note that $\varepsilon=\varepsilon(r)=\sqrt{\rho-r}$ is a measure of how far the growth rate parameter r is from its coalescence value ρ. It is not defined in the conventional way as a deviation from the Hopf value of c as in (2.6). The parameter c will be defined by

$$c=c_{coal}+\varepsilon c_1 \quad \text{with} \quad c_{coal}=-2-2\rho+(2+3\rho)\sqrt{\frac{1+\rho}{2\rho}} \tag{3.4}$$

being the coalescence value of c found by using $r=\rho$ and b_{coal} in expression (2.4). As will be seen, the amplitude and period of the periodic solution will depend on c_1, which measures how far c is from c_{coal}. The parameter c_1 is allowed to vary from 0 to the two Hopf bifurcation values

$$\pm\frac{2+\rho}{2\rho}\sqrt{2+4\rho-3\sqrt{2\rho(1+\rho)}}. \tag{3.5}$$

(These values are the $O(\varepsilon)$ terms in the expansion of c in (2.4) using $r=\rho-\varepsilon^2$ and b_{coal}.) The slow time $\tau=\varepsilon^2 t$ is defined as before. What is not apparent at this

stage is that a slow time frequency shift must be introduced at $O(\varepsilon)$ to account for the near coalescence degeneracy, so a new fast time is introduced as

$$T = (1 + \omega_1 \varepsilon + \cdots)t. \tag{3.6}$$

The variables U and V are expanded about their steady state values, u_s, found by using c from (3.4) and b_{coal} and solving the steady state equation (2.2). Thus we let

$$\begin{aligned} U(T,\tau) &= u_s + \varepsilon u_1(T,\tau) + \varepsilon^2 u_2(T,\tau) + \cdots, \\ V(T,\tau) &= u_s + \varepsilon v_1(T,\tau) + \varepsilon^2 v_2(T,\tau) + \cdots, \end{aligned} \tag{3.7}$$

where

$$u_s = \left(\sqrt{\frac{\rho(1+\rho)}{2}} - \rho\right) - \frac{c_1\rho}{2+\rho}\varepsilon + \frac{2\rho(2\rho + \sqrt{2\rho(1+\rho)}\,)c_1^2}{(2+\rho)^3(1-\rho)}\varepsilon^2 + O(\varepsilon^3). \tag{3.8}$$

The analysis proceeds by substituting the expressions in the above paragraph into the main equations (2.1) to get a sequence of equations at each order of ε. The $O(\varepsilon)$ equations are

$$\begin{bmatrix} u_{1T} \\ v_{1T} \end{bmatrix} = \begin{bmatrix} \rho & \sqrt{\frac{\rho(1+\rho)}{2}} - \rho - 1 \\ \rho & -\rho \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix}. \tag{3.9}$$

The solutions are given by

$$\begin{bmatrix} u_1(T,\tau) \\ v_1(T,\tau) \end{bmatrix} = R(\tau)e^{i\theta(\tau)} \begin{bmatrix} \rho + i\lambda \\ \rho \end{bmatrix} e^{i\lambda T} + R(\tau)e^{-i\theta(\tau)} \begin{bmatrix} \rho - i\lambda \\ \rho \end{bmatrix} e^{-i\lambda T} \tag{3.10}$$

and the fast time frequency is $\lambda = \sqrt{\rho(2 - \sqrt{2\rho(1+\rho)}\,)/2}$.

There are secular terms in the $O(\varepsilon^2)$ equations. This impediment is removed by using a solvability condition similar to (2.12) giving the frequency correction that depends on c_1,

$$\omega_1 = \frac{c_1\rho}{\lambda(2+\rho)(2 - \sqrt{2\rho(1+\rho)}\,)}. \tag{3.11}$$

The solvability condition in this case requires that the right-hand side of the $O(\varepsilon^2)$ equations be orthogonal to the homogeneous solutions of the adjoint problem of (3.9).

As in the general case in the previous section, the equations for the slow time amplitude $R(\tau)$ and phase $\theta(\tau)$ are obtained from the $O(\varepsilon^3)$ equations:

$$\begin{bmatrix} u_{3T} \\ v_{3T} \end{bmatrix} - \begin{bmatrix} \rho & \sqrt{\frac{\rho(1+\rho)}{2}} - \rho - 1 \\ \rho & -\rho \end{bmatrix} \begin{bmatrix} u_3 \\ v_3 \end{bmatrix} = \begin{bmatrix} f_3(u_1,u_2,v_1,v_2) - u_{1\tau} \\ g_3(u_1,u_2,v_1,v_2) - v_{1\tau} \end{bmatrix}. \tag{3.12}$$

With the solvability condition applied to the right-hand side, we get the equation for $R(\tau)$:

$$R_\tau = k_1 R + k_3 R^3 \tag{3.13}$$

with coefficients

$$k_1 = \frac{1}{2} - \frac{2\rho^2 c_1^2}{(2+\rho)^2(2+4\rho-3\sqrt{2\rho(1+\rho)}\,)}, \tag{3.14}$$

$$k_3 = -\frac{\rho(1+\rho+\sqrt{2\rho(1+\rho)}\,)}{1-\rho}.$$

The nontrivial steady state amplitude satisfies

$$R^2 = -\frac{k_1}{k_3} = \frac{(2+\rho)^2(2+4\rho-3\sqrt{2\rho(1+\rho)}\,) - 4\rho^2 c_1^2}{2\rho(2+\rho)^2(2+2\rho-\sqrt{2\rho(1+\rho)}\,)}. \tag{3.15}$$

The coefficient k_3 is always negative since $0 < \rho < 1$. However, $k_1 > 0$ for c_1 satisfying

$$-\frac{2+\rho}{2\rho}\sqrt{2+4\rho-3\sqrt{2\rho(1+\rho)}} < c_1 < \frac{2+\rho}{2\rho}\sqrt{2+4\rho-3\sqrt{2\rho(1+\rho)}}. \tag{3.16}$$

The amplitude R is zero ($k_1 = 0$) at the two outer values of c_1 thus indicating these values correspond to the Hopf bifurcation points. This is in agreement with (3.5). Due to the signs of the coefficients, the analysis shows that the slow time steady state R in (3.15) is stable so the bifurcating periodic solution is stable. It is important to note that, since c_1 varies from both Hopf points, the expression R of (3.15) shows that the periodic solution branches from the two Hopf points are connected. Also, the amplitude is a function of the deviation c_1 from the coalescence value of c. A bifurcation diagram reflecting the analysis in this section is shown in Figure 4.

4. Resolving the vertical branch—the onset of outbreaks. From an ecological viewpoint, the case when the branch of periodic solutions from the right Hopf point is subcritical, as in Figure 3(c), is important since it can correspond to a large cyclic outbreak in the populations. Wollkind, Collings, and Logan [11], in their study of predacious mites and spider mite pests, suggest that events such as reducing the prey population via pesticides may effectively shift the initial conditions so that the system moves from a stable equilibrium to a high amplitude periodic orbit, thus enabling the pest to reach intolerable levels. As a possible control on the populations when the parameters are in a subcritical regime, they discuss artificially increasing r_2 (which is equivalent to increasing r) to stabilize the system. In terms of Figure 1 and (2.4), a larger r value moves the Hopf bifurcation points closer or may remove them entirely. In the former case the system would have smaller amplitude periodic solutions as seen in Figure 3(a) or Figure 4 and, in the latter case, there would only be stable equilibrium populations. Either case would be ecologically preferable to large outbreaks of the spider mite pest that are possible in the subcritical parameter regime.

The ecological ramifications of outbreaks make studying the bifurcation structure in the subcritical case important. In this section the subcritical branch will be analyzed when the parameters correspond to the onset of outbreaks. The amplitude of both the stable and unstable periodic solutions of the subcritical branch are analytically determined and the size of the outbreaks is found as a function of the deviation of the growth rate parameter r from a critical value.

When the R^3 coefficient, $\beta(r,u)$, is zero in the amplitude equation (2.14), the branch of periodic solutions from the rightmost Hopf bifurcation point is "vertical" (on the border between supercritical and subcritical) as in Figure 3(b). The curve

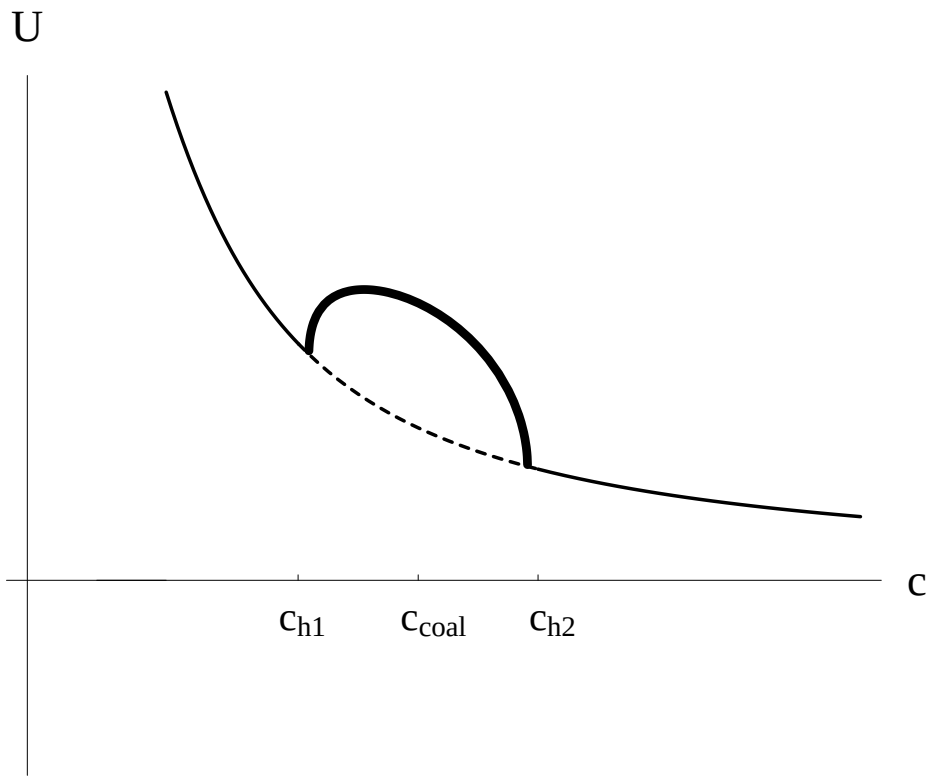

FIG. 4. *The bifurcation diagram in the case of nearly coalescing Hopf bifurcation points, denoted by c_{h1} and c_{h2}, calculated with the modified two-timing results of section* 3. *The thick solid curve shows the maximum amplitude of the stable branch of periodic solutions using the amplitude expression* (3.15). *The dashed (solid) curve is the unstable (stable) steady state. The parameters used were $b = 2/7$ and $r = .13$. The coalescence value is $r = \rho = 1/7$.*

$\beta(r,u) = 0$ is seen in Figure 2 and the corresponding curve in the (r,b) plane is in Figure 1. The two-timing analysis must be modified to address this degeneracy. The steady state amplitude $R = \sqrt{\frac{-\alpha(r,u)P}{\beta(r,u)}}$ from (2.16) suggests a rescaling is necessary in the case when $0 < |\beta(r,u)| \ll 1$.

We proceed by defining the small parameter ε by

$$r = \rho + r_2\,\varepsilon^2, \tag{4.1}$$

where $r_2 = \pm 1$ will determine whether the branch is supercritical or subcritical and ρ is a free parameter. The parameter b is fixed at the value

$$b_v = u_v(1 - \rho - 2u_v)/(\rho + u_v) \tag{4.2}$$

by using (2.5) with u_v satisfying $\beta(\rho, u_v) = 0$ (the subscript v signifies vertical). The parameter c is expanded about the rightmost Hopf bifurcation point of (2.4) as

$$c = c_+(b_v, r) + \varepsilon^4 c_4 \tag{4.3}$$

with c_4 allowed to vary. The amplitude of the periodic solutions will be shown to depend on c_4. The "size" of the outbreaks is defined as the distance from $c_+(b_v, r)$ to

the turning point value of c of the semistable limit cycle. By (4.3) and (4.1), the size is proportional to $(r-\rho)^2$, the square of the difference of the growth rate parameter r from its vertical value ρ.

The variables U and V are expanded about the rightmost Hopf point of (2.4) as

$$\begin{aligned} U(T,\tau) &= u_-(b_v,r) + \varepsilon u_1(T,\tau) + \varepsilon^2 u_2(T,\tau) + \cdots, \\ V(T,\tau) &= u_-(b_v,r) + \varepsilon v_1(T,\tau) + \varepsilon^2 v_2(T,\tau) + \cdots. \end{aligned} \tag{4.4}$$

Note that the expansions in (4.3) and (4.4) will rescale the bifurcating branch to be quartic rather than quadratic as found with the usual scaling (2.6) and (2.8). The quartic branch appropriately accounts for the vertical branch since it is flatter locally. A frequency correction is required in a new fast time, $T = (1+\varepsilon^2\omega_2 + \cdots)t$ and the slow time must be defined by

$$\tau = \varepsilon^4 t \tag{4.5}$$

rather than $\tau = \varepsilon^2 t$, found in the general case of section 2.

As before, with (4.1)–(4.5) substituted into the main equations (2.1), we get a sequence of equations at each power of ε. Unlike the previous analysis, the slow time amplitude equations are found by considering a solvability condition at $O(\varepsilon^5)$ rather than $O(\varepsilon^3)$. Rather than show the general case (the algebra is unwieldy), the method will be illustrated by using specific numerical values for the parameters. The values $\rho = 1/12$ and $u_v = 1/12$ satisfy the vertical condition $\beta(\rho, u_v) = 0$ and give $b_v = 3/8$. With these parameters, the rightmost Hopf bifurcation point occurs at

$$\begin{aligned} u_- &= \frac{1}{12} + \frac{11\,r_2}{5}\varepsilon^2 + \frac{7128}{125}\varepsilon^4 + O(\varepsilon^6) \qquad \text{and} \\ c_+ &= \frac{121}{24} - 121\,r_2\varepsilon^2 + O(\varepsilon^6). \end{aligned} \tag{4.6}$$

The $O(\varepsilon)$ equations are

$$\begin{bmatrix} u_{1T} \\ v_{1T} \end{bmatrix} = \begin{bmatrix} 1/12 & -11/12 \\ 1/12 & -1/12 \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \end{bmatrix} \tag{4.7}$$

and the solutions are given by

$$\begin{bmatrix} u_1(T,\tau) \\ v_1(T,\tau) \end{bmatrix} = R(\tau)e^{i\theta(\tau)} \begin{bmatrix} 1+i\sqrt{10} \\ 1 \end{bmatrix} e^{i\frac{\sqrt{10}}{12}T} + R(\tau)e^{-i\theta(\tau)} \begin{bmatrix} 1+i\sqrt{10} \\ 1 \end{bmatrix} e^{-i\frac{\sqrt{10}}{12}T}. \tag{4.8}$$

A solvability condition applied to the $O(\varepsilon^3)$ equations gives the amplitude-dependent frequency correction, $\omega_2 = \frac{72}{25\sqrt{10}}(17\,r_2 - 1270R^2)$. Finally, the slow time amplitude equation for $R(\tau)$ is obtained by considering the $O(\varepsilon^5)$ equations. The solvability condition gives the fifth order equation

$$R_\tau = \frac{-9797760}{121}\,R^5 - \frac{104976\,r_2}{55}\,R^3 - \frac{c_4}{242}\,R. \tag{4.9}$$

The relevant feature is that there are either one or two nonzero steady states depending on the parameters c_4 and r_2 in addition to the zero steady state. The nonzero steady state(s) satisfy

$$R^2 = \frac{-33r_2 \pm \sqrt{33^2 - \frac{875}{2187}c_4}}{2800}. \tag{4.10}$$

(b)

FIG. 5. *The subcritical branch of periodic solutions as calculated using the expressions in section* 4 *with* $\varepsilon = .02$ *in Figure* 5(a) *and* $\varepsilon = .04$ *in Figure* 5(b). *The thick solid (thick dashed) curve shows the maximum amplitude of the stable (unstable) branch of periodic solutions. The parameters used were* $b = 3/8$ *and* $\rho = 1/12$.

There are different cases to consider. If $r_2 = 1$, then (4.10) gives one real R when $c_4 < 0$ and the branch is supercritical (stable), but there are no real R if $r_2 = 1$ and $c_4 > 0$. If $r_2 = -1$, the branch is subcritical and (4.10) gives two real R when $0 < c_4 < 33^2(2187)/875$. The lesser R value is unstable whereas the greater R value is stable. The branch has a turning point at $c_4^* = 33^2(2187)/875$. This value of c_4 corresponds to the coalescence of the stable and unstable limit cycles forming a semistable limit cycle. For $r_2 = -1$ and $c_4 \leq 0$ the single value of R from (4.10) is stable and represents a continuation of the subcritical branch.

Figure 5 shows the bifurcation diagram with the subcritical branch of periodic solutions using the results of this section. The upper branch of stable periodic solutions corresponds to onset of outbreaks since the populations can achieve a relatively high amplitude oscillation. For the parameters of this example, the outbreak size is $\varepsilon^4 c_4^* = (\rho - r)^2 c_4^* = (1/12 - r)^2 c_4^*$. The analysis in this section is valid when $\varepsilon \ll 1$ so it can only be said to describe the onset of outbreaks. However, as is often the case, the analysis agrees quite well with numerical results when the condition $\varepsilon \ll 1$ is relaxed somewhat. Hence the parametric features of outbreaks (i.e., the size is proportional to $(\rho - r)^2$, etc.) can be extended beyond the onset case.

5. Further comments. The presence of two Hopf bifurcation points in the Holling–Tanner model is ubiquitous. Actual ecological dynamics in the field observed when physical parameters are varied agree qualitatively with features, such as outbreaks, predicted by the model. The two-timing techniques give an organized way to characterize the changes in the bifurcation diagram as the parameters are varied. The modifications required in the degenerate cases have broad applicability to other systems in which two Hopf bifurcations are present.

A TERRAIN-FOLLOWING BOUSSINESQ SYSTEM*

ANDRÉ NACHBIN†

Abstract. A long wave model is derived asymptotically from the nonlinear potential theory equations. The flow regime of interest is incompressible, irrotational, and inviscid. Asymptotic analysis leads to a weakly nonlinear, weakly dispersive (variable coefficient) Boussinesq system valid for a wide class of topographies. The mild slope hypothesis is not required and rapidly varying topographies are also considered. In analogy with atmospheric models we use a terrain-following coordinate system. The novelty is that this coordinate system naturally suggests the weighted averaging of terrain-following velocity components, as opposed to the depth-average of horizontal velocity components found in standard shallow water formulations. Furthermore, a Schwarz–Christoffel toolbox is used to provide additional insight on these new results. Regarding applications, the proposed model can be used for studying solitary waves interacting with fine scale inhomogeneities, a theme of great interest. The terrain-following model also presents potential numerical advantages for Boussinesq solvers.

Key words. dispersive waves, inhomogeneous media, asymptotic theory

1. Introduction.

Shallow water (long wave) models have been known and studied for many years. Among several important partial differential equations that fall into this class are weakly dispersive, weakly nonlinear models such as the KdV equation or the Boussinesq equations [7, 16]. The flow regime considered is incompressible, irrotational, and inviscid. These long wave models can be derived asymptotically from the nonlinear potential theory equations when the leading order terms, in the nonlinearity and dispersion parameters, are retained. Their analysis has received a great deal of attention from both the mathematical theory and applications viewpoints.

Of great research interest are problems involving these models in the presence of heterogeneous media, which can be of different nature depending on the application. Shallow water models are not only of interest in ocean applications but also very common in meteorology [5], where the shallow propagation medium is the atmosphere. Literature is abundant on the mathematical analysis of long wave models, their numerical discretization and behavior, as well as the implementation of oceanic and atmospheric simulators. Reference to some of this work will not be attempted due to the richness of the subject. It is bound to be injudicious.

This work is concerned with the derivation of a long wave model valid in the presence of a wide class of bottom profiles, including rapidly varying topographies. Most of the well-established long wave models are derived under the hypothesis of having mild slope topographies. Among others, we mention three interesting recent works which improve classical shallow water models and include topographic effects. Camassa, Holm, and Levermore [2] derive shallow water equations that have a Hamiltonian principle formulation and which model long-time effects of slowly varying topographies. Milewski [8] considers the propagation of long waves on the surface of a three-

dimensional fluid domain bounded below by a slowly varying topography. Weakly nonlinear wave-topography interaction is studied in two limits giving rise to a variable coefficient KdV equation or a variable coefficient KP (Kadomtsev–Petviashvili) equation. We also mention the work of Schäffer and Madsen [15], who derive a new set of Boussinesq equations which provide improvements for the linear dispersion relation and shoaling characteristics. For rapidly varying topographies it is worth mentioning the earlier work of Rosales and Papanicolaou [14], where effective KdV equations were derived for rapidly varying periodic and (small amplitude) random topographies. But in both cases back-scattering is negligible. Finally we point out the work of Hamilton [6], which is the starting point for the present paper. Hamilton used a conformal mapping technique to derive long wave models on a fluid of rapidly varying depth. In particular, a Boussinesq system is presented [6, equations (A14)–(A15)] in the form of a second order in time 2×2 system. The dependent variables considered are the depth-averaged potential and wave elevation. We derive a first order 2×2 Boussinesq system in terms of the wave elevation and the averaged terrain-following velocity components. For flat channels our system reduces to the standard Boussinesq system found in the literature [7, 16]. Hamilton's conformal mapping technique has also been used by the author to study the reflection-transmission problem over disordered (random) topographies [11, 12, 13].

Moreover, our main result is the derivation of a weakly nonlinear, weakly dispersive (variable coefficient) Boussinesq system valid for a wide class of topographies and multiple scattering problems. The mild slope hypothesis is not required. In analogy with some atmospheric models [3] we use a terrain-following coordinate system for the independent variables. This curvilinear coordinate system is obtained from the theory of conformal mappings as suggested in Hamilton [6]. Hamilton does not use dimensionless variables and performs the asymptotic simplification of equations arguing through chosen length scales. As mentioned above, his formulation of a nonlinear Boussinesq system is briefly outlined in Appendix A [6]. Our approach is to perform the asymptotic simplification of the nonlinear potential theory equations in a systematic way (as in Whitham [16]) by using dimensionless variables and the conformal mapping setting of Hamilton. All steps in the derivation are presented. The curvilinear coordinate system naturally suggests the weighted averaging of terrain-following velocity components, as opposed to the depth-average of horizontal components found in standard shallow water formulations. For rapidly varying topographies the standard depth-average strategy breaks down. As pointed out by Hamilton [6] the truncation term in the near-bottom series expansion will dominate the leading order terms when the bottom is rapidly varying (top of page 292 in [6]). In the dimensionless formulation (given below in section 2) the large truncation term will be caused by the β/γ term in the Neumann condition, when γ is small. In contrast, the asymptotic expansion, for the free surface conditions in the curvilinear coordinates, generates truncation terms that are negligible compared to the leading order ones. The Neumann condition is trivial in this framework, as will be shown in section 4.

Furthermore, our use of dimensionless variables enables a better understanding of the impact of the conformal mapping technique on the asymptotic analysis. Using Driscoll's [4] MATLAB Schwarz–Christoffel toolbox (SC-Toolbox), we provide additional insight on why the terrain-following Boussinesq system is a good model even in the presence of rapidly varying topographies. Using the SC-Toolbox, we graph the curvilinear coordinate system for both slowly and rapidly varying topographies. The average of terrain-following velocity components is clearly seen as a weighted average

along special curves, orthogonal to the topography and to the undisturbed free surface. This weighted averaging naturally adjusts to either slowly varying or rapidly varying topographies, as will be shown graphically with the SC-Toolbox.

Another result of interest is that the nonlinear shallow water equations can be viewed as an $O(\alpha, \sqrt{\beta})$ approximation of the full potential theory equations. The standard notation is used: α is the nonlinearity parameter and β the dispersion parameter. The nonlinear shallow water system is (of course) hyperbolic, but the square root of the dispersion parameter plays a role only on the smoothing of sharp features of the topography. This had been pointed out by Hamilton [6], but the rate of smoothing was not explicitly identified, nor the nonlinear shallow water equation presented.

The proposed model can be used for studying solitary waves over disordered (random) topographies, a theme of great interest [9, 10]. This could not have been done with existing Boussinesq models. We are currently investigating the numerical advantages of working with this model. A potential advantage resides in the fact that within this new framework, the variable ("topographic") coefficient moves away from the dispersive term (a third order derivative) and places itself at first order terms. We have results that indicate the improved performance of Boussinesq solvers [10].

The paper is organized as follows. In section 2 we present the standard scaling [16] and the (dimensionless) nonlinear potential theory equations in Cartesian coordinates. Section 3 describes the conformal mapping theory in full detail along with the calculation of the variable free surface coefficient's leading order term. The (dimensionless) nonlinear potential theory equations, in curvilinear coordinates, are presented in section 4 and the weakly nonlinear, weakly dispersive asymptotic theory in section 5. The applications and conclusions are given in section 6. Appendix A contrasts the terrain-following Boussinesq system with standard Boussinesq formulations.

2. Formulation and scaling. Let variables with physical dimensions be denoted with a tilde. We introduce the length scales σ (a typical pulse width or wavelength), h_0 (a typical depth), a (a typical wave amplitude), l_b (the horizontal length scale for bottom irregularities), and L (the total length of the rough region or the total propagation distance). The acceleration due to gravity is denoted by g and the reference shallow water speed is $c_0 = \sqrt{gh_0}$. Dimensionless variables are then defined in a standard fashion [14, 16] by having

$$\tilde{x} \;=\; \sigma x, \qquad \tilde{y} \;=\; h_0\, y, \qquad \tilde{t} \;=\; \left(\frac{\sigma}{c_0}\right) t,$$

$$\tilde{\eta} \;=\; a\,\eta, \qquad \tilde{\phi} \;=\; \left(\frac{g\sigma a}{c_0}\right)\phi, \qquad \tilde{h} \;=\; h_0\, H\left(\frac{\tilde{x}}{l_b}\right).$$

The velocity potential $\phi(x, y, t)$ and wave elevation $\eta(x, t)$ satisfy the dimensionless equations [16]:

$$\beta\, \phi_{xx} + \phi_{yy} \;=\; 0 \quad \text{for} \quad -H(x/\gamma) < y < \alpha\eta(x, t),$$

with the nonlinear free surface conditions

$$\eta_t + \alpha\phi_x\eta_x - \frac{1}{\beta}\phi_y = 0,$$

$$\eta + \phi_t + \frac{\alpha}{2}\left(\phi_x^2 + \frac{1}{\beta}\phi_y^2\right) = 0$$

at $y = \alpha\eta(x,t)$. The Neumann condition at the impermeable bottom is

$$\phi_y + \frac{\beta}{\gamma}\, H'(x/\gamma)\phi_x = 0.$$

The bottom topography is described by $y = -H(x/\gamma)$, where

$$H(x/\gamma) \;=\; \begin{cases} 1 + n(x/\gamma) & \text{when } \; 0 < x < L, \\ 1 & \text{when } \; x \leq 0 \;\text{ or }\; x \geq L. \end{cases}$$

The bottom profile is described by the (possibly rapidly varying) function $-n(x/\gamma)$. The topography is rapidly varying when $\gamma \ll 1$. The undisturbed depth is given by $y = -1$ and the topography can be of large amplitude provided that $|n| < 1$. We do not need to assume that the fluctuations n are small, nor continuous, nor slowly varying.

The following dimensionless parameters arise:

$\alpha = a/h_0$ (nonlinearity parameter)

$\beta = h_0^2/\sigma^2$ (dispersion parameter)

$\gamma = l_b/\sigma$ (bottom irregularities compared to the wavescale).

Before proceeding with the asymptotic analysis at the level of equations, we first change the underlying Cartesian coordinate system as follows.

3. Conformal mapping. A mapping from a uniform strip onto the fluid domain at rest is constructed analytically. Let the former (computational) domain be defined in the complex w-plane and the rough undisturbed channel (physical domain) be defined in the complex z-plane. Properties of the $z(w)$ mapping will be calculated below. As will be shown, working with a symmetric domain is very convenient for the asymptotic analysis to be performed. This is the reason why we solve the (harmonic) conformal mapping problem in such a symmetric configuration (cf. Figure 3.1). Moreover, instead of referring to the w-plane as our computational domain, we will (equivalently) interpret our formulation as working with orthogonal curvilinear coordinates in the physical domain (the w-plane horizontal and vertical level curves). In Figure 3.1 we superimpose the symmetric domain in the complex z-plane with the curvilinear level curves from the w-plane coordinate system. The polygonal line at the bottom of Figure 3.1 is a schematic representation of the topography.

Following Hamilton [6] we define a symmetric flow domain by reflecting the original one about the undisturbed free surface (cf. Figure 3.1). We denote this domain by Ω_z, where $z = x + i\sqrt{\beta}y$, and consider it as the conformal image of the strip Ω_w, where $w = \xi + i\tilde{\zeta}$ with $|\tilde{\zeta}| \leq \sqrt{\beta}$. Then $z = x(\xi,\tilde{\zeta}) + i\sqrt{\beta}y(\xi,\tilde{\zeta}) = x(\xi,\tilde{\zeta}) + i\tilde{y}(\xi,\tilde{\zeta})$ with x and $\tilde{y}$ a pair of harmonic functions on Ω_w. As will become clear in the following sections (in particular section 5), working with x and y is convenient for long wave (shallow water) asymptotics. The depth is kept fixed in this case. On the other hand, working with x and $\tilde{y}$ is convenient for computing harmonic functions because the parameter β drops from the Laplacian. These are the reasons why we switch from one scaling to the other.

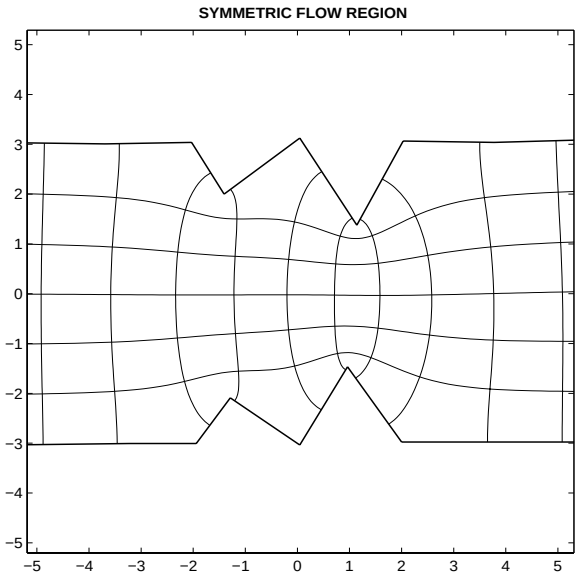

FIG. 3.1. *The symmetric domain in the complex z-plane, where* $z = x(\xi, \tilde{\zeta}) + i\tilde{y}(\xi, \tilde{\zeta})$. *The lower half* ($x \in [-5, 5]$, $y \in [-3, 0]$) *is the physical channel with* $y = \tilde{\zeta} = 0$ *indicating the undisturbed free surface. Superimposed in this complex z-plane domain are the (curvilinear) coordinate level curves from the w-plane system* $\xi\tilde{\zeta}$. *The polygonal line at the bottom of the figure is a schematic representation of the topography (where* $\tilde{\zeta} = \pm\sqrt{\beta}$). *This figure was generated using the SC-Toolbox* [4].

As will become clear, our main goal is to calculate $\tilde{y}_{\tilde{\zeta}}$ along the undisturbed free surface $\tilde{\zeta} = \tilde{y} = 0$. This coefficient is calculated analytically by solving Laplace's equation for the imaginary part of the conformal change of variables. Once this coefficient is obtained we proceed with the derivation of the full potential theory equations in the curvilinear $(\xi, \tilde{\zeta})$ coordinate system.

The imaginary part of the conformal map is the harmonic function that satisfies [6, 11]:

$$\Delta\, \tilde{y}(\xi, \tilde{\zeta}) \;=\; 0 \qquad \text{in } \Omega_w \tag{3.1}$$

with Dirichlet boundary conditions

$$\tilde{y}(\xi, \pm\sqrt{\beta}) \;=\; \pm\, h(x(\xi)) \equiv \pm\sqrt{\beta} H\left(\frac{x(\xi, \pm\sqrt{\beta})}{\gamma}\right). \tag{3.2}$$

Its harmonic conjugate is $x(\xi, \tilde{\zeta})$. The Green's function for problem (3.1)–(3.2) is slightly different from Hamilton's because we introduce dimensionless variables and keep depth effects through the parameter $\sqrt{\beta}$. The Green's function, vanishing along the lines $\tilde{\zeta} = \pm\sqrt{\beta}$, is given by

$$G(w; w_0) = \mathbf{Re}\, \log\, \left((e^{\pi w/2\sqrt{\beta}} - e^{\pi w_0/2\sqrt{\beta}})/(e^{\pi w/2\sqrt{\beta}} + e^{\pi \overline{w_0}/2\sqrt{\beta}})\right), \tag{3.3}$$

where **Re** stands for the real part and the overbar denotes complex conjugation. Near a source point w_0

$$G(w; w_0) \sim\; \mathbf{Re}\, \log(w - w_0),$$

meaning that it behaves like the free-space Green's function. At the solid boundaries $\tilde{\zeta} = \pm\sqrt{\beta}$,

$$G \equiv 0.$$

Additional asymptotic properties are [6]

$$G, \;\; G_\xi \to 0 \;\; \text{as} \;\; \xi \to \pm\infty \;\; \text{in} \;\; -\sqrt{\beta} \leq \tilde{\zeta} \leq \sqrt{\beta}.$$

Using Green's third identity, we have that

$$2\pi \; \tilde{y}(\xi_0, \tilde{\zeta}_0) \;=\; \oint_{\partial\Omega_w} \tilde{y}(\xi, \tilde{\zeta}) \; \frac{dG}{dn}(w; w_0) \; ds.$$

By the conditions above this is the same as

$$2\pi \; \tilde{y}(\xi_0, \tilde{\zeta}_0) \;=\; \int_{-\infty}^{\infty} h(x(\xi)) \; \left(G^+_{\tilde{\zeta}} \;+\; G^-_{\tilde{\zeta}} \right) \; d\xi,$$

where

$$G^+_{\tilde{\zeta}} = \frac{\partial G}{\partial \tilde{\zeta}}(\xi, +\sqrt{\beta}; \xi_0, \tilde{\zeta}_0) \quad \text{and} \quad G^-_{\tilde{\zeta}} = \frac{\partial G}{\partial \tilde{\zeta}}(\xi, -\sqrt{\beta}; \xi_0, \tilde{\zeta}_0).$$

Differentiating this identity with respect to $\tilde{\zeta}_0$ and evaluating at $\tilde{\zeta}_0 = 0$ we get our quantity of interest. Namely we have that at the undisturbed free surface

$$\tilde{y}_{\tilde{\zeta}_0}(\xi_0, 0) \;=\; \frac{1}{2\pi} \int_{-\infty}^{\infty} h(x(\xi)) \left(G^+_{\tilde{\zeta}\tilde{\zeta}_0} \;+\; G^-_{\tilde{\zeta}\tilde{\zeta}_0} \right) d\xi. \tag{3.4}$$

The kernel comes from evaluating

$$G_{\tilde{\zeta}\tilde{\zeta}_0}(\xi, -\sqrt{\beta}; \xi_0, 0) \;+\; G_{\tilde{\zeta}\tilde{\zeta}_0}(\xi, \sqrt{\beta}; \xi_0, 0) \;=\; \frac{2\pi^2}{\beta} \;\; \frac{e^{\frac{\pi}{\sqrt{\beta}}(\xi + \xi_0)}}{(e^{\frac{\pi}{\sqrt{\beta}}\xi} + e^{\frac{\pi}{\sqrt{\beta}}\xi_0})^2} \tag{3.5}$$

$$= \; \frac{\pi^2/\beta}{2 \; \cosh^2 \frac{\pi}{2\sqrt{\beta}}(\xi - \xi_0)},$$

and finally we obtain

$$\tilde{y}_{\tilde{\zeta}_0}(\xi_0, 0) = \; \frac{\pi}{4\beta} \; \int_{-\infty}^{\infty} \; \frac{\sqrt{\beta} H(x(\xi, -\sqrt{\beta})/\gamma)}{\cosh^2 \frac{\pi}{2\sqrt{\beta}}(\xi - \xi_0)} d\xi. \tag{3.6}$$

This expression was obtained by Hamilton [6], but without the $\beta^{1/2}$-scaling. This intermediate $\beta^{1/2}$-scale plays an important role indicating the degree of topography smoothing. The rate of smoothing actually depends on $\beta^{1/2}/\gamma$. Numerical examples of the topography smoothing are presented at the end of this paper (Figures 6.1 and 6.2). We call $\beta^{1/2}$ an intermediate scale because we will work with an integer power expansion in β as in Whitham's [16] derivation of Boussinesq's equations.

In the $(\xi, \tilde{\zeta})$ coordinate system the varying bottom topography is straightened out and a variable coefficient, namely $\tilde{y}_{\tilde{\zeta}}$, will appear in the free surface condition. Before writing the equations in the $(\xi, \tilde{\zeta})$ system note that

$$\int_{-\infty}^{\infty} \frac{\pi}{4\sqrt{\beta}} \operatorname{sech}^2 \left[\frac{\pi}{2\sqrt{\beta}}(x-y) \right] dx \;=\; \frac{1}{2} \tanh \left[\frac{\pi}{2\sqrt{\beta}} x \right]_{-\infty}^{\infty} = 1. \tag{3.7}$$

Hence as $\sqrt{\beta} \downarrow 0$ the kernel in (3.6) goes to a delta function and the bottom is felt at the free surface level without any smoothing. Smoothing takes place only for $\beta^{1/2} > 0$.

At the undisturbed level we define the *variable free surface coefficient*

$$M(\xi) \equiv \tilde{y}_{\tilde{\zeta}}(\xi, 0) = 1 + m(\xi),$$

where

$$m(\xi; \sqrt{\beta}, \gamma) \equiv \frac{\pi}{4\sqrt{\beta}} \int_{-\infty}^{\infty} \frac{n(x(\xi_0, -\sqrt{\beta})/\gamma)}{\cosh^2 \frac{\pi}{2\sqrt{\beta}}(\xi_0 - \xi)} d\xi_0 \;=\; (K * (n \circ x))(\xi). \tag{3.8}$$

The $(\sqrt{\beta}, \gamma)$ parameter dependence will be omitted for brevity. We are ready to rewrite the potential theory equations in the $(\xi, \tilde{\zeta})$ coordinate system. The velocity potential $\phi(\xi, \tilde{\zeta}, t)$ when represented in the curvilinear coordinate system is such that

$$\phi_\xi = \phi_x \; x_\xi(\xi, \tilde{\zeta}) + \phi_{\tilde{y}} \; \tilde{y}_\xi(\xi, \tilde{\zeta})$$

and

$$\phi_{\tilde{\zeta}} = \phi_x \; x_{\tilde{\zeta}}(\xi, \tilde{\zeta}) + \phi_{\tilde{y}} \; \tilde{y}_{\tilde{\zeta}}(\xi, \tilde{\zeta}).$$

In particular, at the undisturbed free surface or for linear problems,

$$\phi_\xi(\xi, 0) = M(\xi) \phi_x$$

and

$$\phi_{\tilde{\zeta}}(\xi, 0) = M(\xi) \phi_{\tilde{y}}.$$

Note that we have used the Cauchy–Riemann equations. Inverting the relation given above, we have

$$\phi_x = \frac{1}{|J|} \left[\tilde{y}_{\tilde{\zeta}} \phi_\xi - \tilde{y}_\xi \phi_{\tilde{\zeta}} \right] \tag{3.9}$$

and

$$\phi_{\tilde{y}} = \frac{1}{|J|} \left[-x_{\tilde{\zeta}} \phi_\xi + x_\xi \phi_{\tilde{\zeta}} \right], \tag{3.10}$$

where

$$|J| = x_\xi \tilde{y}_{\tilde{\zeta}} - \tilde{y}_\xi x_{\tilde{\zeta}} = \tilde{y}_{\tilde{\zeta}}^2 + \tilde{y}_\xi^2.$$

Moreover

$$\phi_x^2 + \phi_{\tilde{y}}^2 = \frac{1}{|J|} \left(\phi_\xi^2 + \phi_{\tilde{\zeta}}^2 \right), \tag{3.11}$$

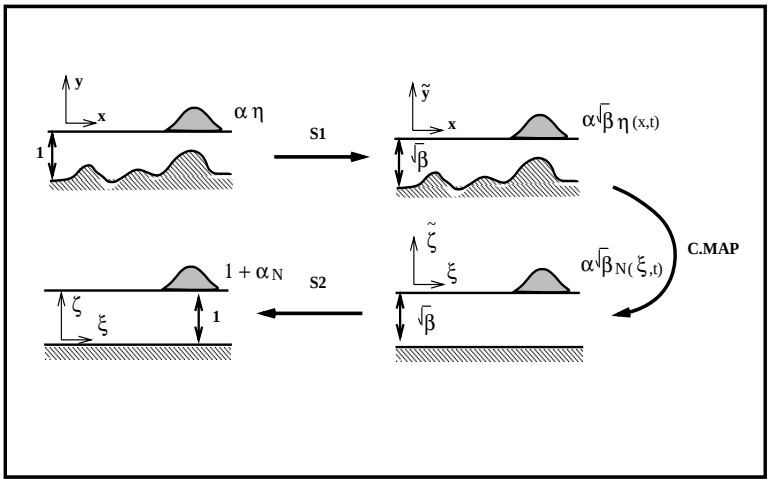

FIG. 3.2. *This is a schematic figure showing the changes of scales performed, indicated by* S1*,* S2*, and the conformal transformation. The geometries on the left are in the shallow water framework (with unit depth). The geometries on the right are used so that the velocity potential solves Laplace's equation in the corresponding variables.*

which relates the speeds in the two coordinate systems.

In the new coordinate system the position of the free surface will be described by some function, here denoted by $N(\xi,t)$, such that

$$\tilde{\zeta} = \alpha\sqrt{\beta}N(\xi,t). \tag{3.12}$$

The new free surface profile, represented by $N(\xi,t)$, does not necessarily resemble $\eta(x,t)$ as indicated in the schematic Figure 3.2. Nevertheless this is a material curve. In the Cartesian coordinates $(x,\tilde{y})$ the dimensionless kinematic condition was given by

$$\sqrt{\beta}\eta_t + \alpha\phi_x\sqrt{\beta}\eta_x - \phi_{\tilde{y}} = 0,$$

which is the same as

$$\frac{D}{Dt}\left(\tilde{y} - \alpha\sqrt{\beta}\eta(x,t)\right) = 0,$$

with the convective derivative

$$\frac{D}{Dt} \equiv \partial_t + \alpha\left(\phi_x\partial_x + \phi_{\tilde{y}}\partial_{\tilde{y}}\right).$$

In the curvilinear coordinates it becomes

$$\frac{\mathcal{D}}{\mathcal{D}t} \equiv \partial_t + \frac{\alpha}{|J|}\left(\phi_\xi\partial_\xi + \phi_{\tilde{\zeta}}\partial_{\tilde{\zeta}}\right),$$

where we have used that $\partial_x = |J|^{-1}(\tilde{y}_{\tilde{\zeta}}\partial_\xi - \tilde{y}_\xi\partial_{\tilde{\zeta}})$ and the corresponding expression for $\partial_{\tilde{y}}$ (cf. (3.9) and (3.10)). The new kinematic condition is obtained by performing

$$\frac{\mathcal{D}}{\mathcal{D}t}\left(\tilde{\zeta} - \alpha\sqrt{\beta}N(\xi,t)\right) = 0$$

and is presented below.

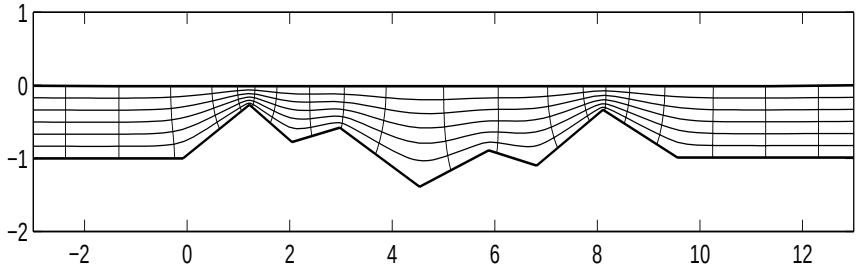

FIG. 4.1. *A schematic figure showing a slowly varying topography in the xy coordinate system together with the ξ and $\tilde{\zeta}$ level-curves. This figure was generated using SC-Toolbox* [4].

4. Nonlinear potential theory equations in terrain-following coordinates. The scaled water wave equations in the fixed orthogonal curvilinear coordinates $(\xi, \tilde{\zeta})$ (cf. Figure 4.1) are

$$\phi_{\xi\xi} + \phi_{\tilde{\zeta}\tilde{\zeta}} = 0, \qquad -\sqrt{\beta} < \tilde{\zeta} < \alpha\sqrt{\beta}N(\xi, t), \tag{4.1}$$

with free surface conditions

$$|J|N_t + \alpha\phi_\xi N_\xi - \frac{1}{\sqrt{\beta}}\phi_{\tilde{\zeta}} = 0 \tag{4.2}$$

and

$$\phi_t + \eta + \frac{\alpha}{2|J|}\left(\phi_\xi^2 + \phi_{\tilde{\zeta}}^2\right) = 0 \tag{4.3}$$

at $\tilde{\zeta} = \alpha\sqrt{\beta}N(\xi, t)$. The bottom condition is

$$\phi_{\tilde{\zeta}} = 0 \quad \text{at} \quad \tilde{\zeta} = -\sqrt{\beta}. \tag{4.4}$$

Regarding the initial conditions note that by starting with a pulse over a region of uniform depth, the initial data are not affected by the conformal mapping (cf. Figure 4.1 at $x \le -1$ and $x \ge 11$). We need only to replace x by ξ in the initial wave conditions. Away from the rough region

$$1 + m(\xi) = \tilde{y}_{\tilde{\zeta}}(\xi, 0) \approx 1,$$

where this adjustment is exponentially fast. Numerical evidence of this adjustment is presented in Figures 6.1 and 6.2. The exponential adjustment rate depends on $\beta^{1/2}$, the important scale we retained in the coefficient (3.8). Hence from the Cauchy–Riemann equations, $x_\xi(\xi, 0) \approx 1$. This was not noticed in Hamilton's work [6] because the analysis was not done in dimensionless variables. Scales were used only to argue which terms could be dropped.

Moreover, it is important to point out that these equations are the same as those obtained by Hamilton [6], using a variational principle. The difference is in our use of dimensionless variables. The corresponding dimensionless variational principle is given below for completeness. Hamilton [6, Appendix A] showed that the $(\xi, \tilde{\zeta})$ change

of variables can be used within the functional given in the books of Whitham [16] and Mei [7]. The variational pressure principle is

$$I = \int \int_{\mathbf{R}} \mathcal{L} dx dt, \tag{4.5}$$

where $\mathbf{R}$ is a region in (x,t) space and the dimensionless Lagrangian is given by

$$\mathcal{L} = -\sqrt{\beta} \int_{-\sqrt{\beta}h(x,y)}^{\alpha\sqrt{\beta}\eta(x,t)} \left[\phi_t + \tilde{y} + \frac{\alpha}{2}\left(\nabla\phi \cdot \nabla\phi\right)\right] d\tilde{y}. \tag{4.6}$$

Under the change of variables the functional becomes

$$I = -\sqrt{\beta} \int \int_{\mathbf{R}} \int_{-\sqrt{\beta}}^{\alpha\sqrt{\beta}N} \left[|J| \left(\phi_t + \frac{1}{\sqrt{\beta}}\tilde{y}(\xi,\tilde{\zeta})\right) + \frac{\alpha}{2}\left(\nabla\phi \cdot \nabla\phi\right)\right] d\tilde{\zeta} d\xi dt, \tag{4.7}$$

where now $\nabla = (\partial_\xi, \partial_{\tilde{\zeta}})$. Minimizing this functional, by taking variations in ϕ and N, Hamilton obtained a system of equations similar to the dimensionless one derived above.

5. Asymptotic theory. The asymptotic theory is performed at the level of equations. We are interested in the shallow water/long wave regime, more specifically in the weakly dispersive, weakly nonlinear regime. As mentioned in section 3 it is convenient to normalize in the vertical direction and work with a unit depth channel (cf. scaling S2, Figure 3.2) when performing a long wave (shallow water) asymptotic analysis. The geometry is kept fixed and we can focus on the leading order terms of the asymptotic expansion. Let the origin of the curvilinear coordinate system be at the bottom and define $\tilde{\zeta} = \sqrt{\beta}(\zeta - 1)$. Substitute in the equations above to get

$$\beta\phi_{\xi\xi} \; + \; \phi_{\zeta\zeta} \; = \; 0 \qquad \text{at} \;\; 0 < \zeta < 1 + \alpha N(\xi,t), \tag{5.1}$$

with free surface conditions

$$|J| N_t + \alpha\phi_\xi N_\xi - \frac{1}{\beta}\phi_\zeta = 0, \tag{5.2}$$

$$\eta + \phi_t + \frac{\alpha}{2|J|}\left(\phi_\xi^2 + \frac{1}{\beta}\phi_\zeta^2\right) = 0 \tag{5.3}$$

at $\zeta = 1 + \alpha N(\xi,t)$ and

$$\phi_\zeta = 0 \qquad \text{at} \;\; \zeta = 0. \tag{5.4}$$

As in Whitham [16] consider a power series expansion near the bottom of the channel in the form

$$\phi(\xi,\zeta,t) = \sum_{n=0}^{\infty} \zeta^n \; f_n(\xi,t). \tag{5.5}$$

This function satisfies the scaled Laplace equation when

$$f_{m+2} = \frac{-\beta}{(m+2)(m+1)} \frac{\partial^2 f_m}{\partial\xi^2}.$$

Moreover, the Neumann condition at the bottom is satisfied when all odd terms (i.e., f_{2m+1}) are zero. Hence by denoting $f_0(\xi,t) = f(\xi,t)$ for simplicity, we have

$$\phi(\xi,\zeta,t) = \sum_{n=0}^{\infty} \frac{(-\beta)^n}{(2n)!}\zeta^{2n}\frac{\partial^{2n} f(\xi,t)}{\partial \xi^{2n}}, \tag{5.6}$$

a power series expansion in β. For this reason the $\beta^{1/2}$-scale was called an intermediate scale earlier. The velocity potential, represented by the power series above, satisfies the scaled Laplace equation and the homogeneous Neumann condition along the bottom. Up to this point we have done exactly the same steps as in Whitham's book [16] for a flat channel in Cartesian coordinates.

We must now satisfy the free surface conditions. At $\zeta = \zeta_{FS} \equiv 1 + \alpha N(\xi,t)$ we have that

$$\phi_\xi(\xi,\zeta_{FS},t) = f_\xi - \frac{\beta}{2}(1+\alpha N)^2 f_{\xi\xi\xi} + O(\beta^2), \tag{5.7}$$

$$\phi_\zeta(\xi,\zeta_{FS},t) = -\beta(1+\alpha N) f_{\xi\xi} + \frac{\beta^2}{3!}(1+\alpha N)^3 f_{\xi\xi\xi\xi} + O(\beta^3), \tag{5.8}$$

and

$$\phi_t(\xi,\zeta_{FS},t) = f_t - \frac{\beta}{2}(1+\alpha N)^2 f_{\xi\xi t} + O(\beta^2). \tag{5.9}$$

Note that both (new) free surface conditions have a time dependent coefficient. This is due to the presence of the Jacobian, of the time independent change of coordinates, evaluated at the time dependent free surface. Within the weakly nonlinear, weakly dispersive approximation considered, it is possible to eliminate this time dependence as will be shown below. Time independent coefficients are better for analysis and computations. As a first step, in this direction, it is worth noticing that at the smooth free surface $\tilde{\zeta}_{FS} = \alpha\sqrt{\beta}N(\xi,t)$ the Jacobian is

$$|J|(\xi,t) = \tilde{y}_\xi^2(\xi,\tilde{\zeta}_{FS}) + \tilde{y}_{\tilde{\zeta}}^2(\xi,\tilde{\zeta}_{FS})$$

and by the Taylor polynomial formula

$$|J|(\xi,t) = \tilde{y}_{\tilde{\zeta}}^2(\xi,0) + \alpha^2 R_J(\xi,\tilde{\zeta}_M) = M(\xi)^2 + O(\alpha^2), \quad 0 < |\tilde{\zeta}_M| < |\tilde{\zeta}_{FS}|. \tag{5.10}$$

The Jacobian can be well approximated by an $O(1)$ time independent coefficient. The time dependent correction term is $O(\alpha^2)$ due to the fact that the curvilinear coordinate system is symmetric about $\tilde{y} = \tilde{\zeta} = 0$. There are no $O(\alpha)$ terms. For the same reason, approximating $\tilde{\zeta}(x,\tilde{y}_{FS})$ in $\tilde{y}$ leads to

$$N(\xi,t) = \frac{1}{M(\xi)}\eta(x(\xi),t) + \alpha^2\beta R_N(\xi,\tilde{y}_M), \quad 0 < |\tilde{y}_M| < |\tilde{y}_{FS}|. \tag{5.11}$$

Substituting expressions (5.7)–(5.11) in the free surface conditions, we get

$$\eta + f_t - \frac{\beta}{2} f_{\xi\xi t} + \frac{\alpha}{2M^2(\xi)} f_\xi^2 = O(\alpha\beta, \beta^2),$$

$$M(\xi)\ \eta_t + \left[\left(1+\frac{\alpha}{M(\xi)}\eta\right) f_\xi\right]_\xi - \frac{\beta}{6} f_{\xi\xi\xi\xi} = O(\alpha^2, \alpha\beta, \beta^2).$$

The variable coefficients are time independent and depend only on $\tilde{y}_{\tilde{\zeta}}(\xi, 0)$ as mentioned before in the conformal mapping section.

As in Whitham [16] it is useful to work with a conveniently averaged velocity component. From (5.7) we have that

$$\phi_\xi(\xi, \zeta_{FS}, t) \equiv u(\xi, \zeta_{FS}, t) = \tilde{u}(\xi, t) - \frac{\beta}{2}\zeta_{FS}^2 \tilde{u}_{\xi\xi}(\xi, t) + O(\beta^2),$$

where $\tilde{u} \equiv f_\xi$ is the "slip-velocity" along the bottom topography. In analogy with the σ-coordinates used in atmospheric flows [5], we call ϕ_ξ the terrain-following velocity component [3]. Its transversal average (along a ξ level-curve) is defined as

$$U(\xi, t) \equiv \frac{1}{\zeta_{FS}} \int_0^{\zeta_{FS}} \phi_\xi(\xi, \zeta, t) d\zeta. \tag{5.12}$$

In physical space this integral represents a weighted average of the terrain-following velocity components. We provide further insight about the averaging in Figure 5.1. Therefore using the potential's power series representation,

$$U(\xi, t) = \sum_{n=0}^{\infty} \frac{(-\beta)^n}{(2n)!} \left[\frac{1}{\zeta_{FS}} \int_0^{\zeta_{FS}} \zeta^{2n} d\zeta\right] \frac{\partial^{2n+1} f(\xi, t)}{\partial \xi^{2n+1}} = \tilde{u} - \frac{\beta}{6}\tilde{u}_{\xi\xi} + O(\alpha\beta, \beta^2).$$

Differentiate the first free surface condition with respect to ξ and substitute for depth-averaged velocity through the expansion

$$\tilde{u} = U + \frac{\beta}{6} U_{\xi\xi} + O(\alpha\beta, \beta^2).$$

We get a *terrain-following Boussinesq system*

$$\begin{cases} M(\xi)\eta_t + \left[(1 + \alpha\eta/M(\xi))\, U\right]_\xi = 0, \\ \\ U_t + \eta_\xi + \frac{\alpha}{2}\left[U^2/M^2(\xi)\right]_\xi - \frac{\beta}{3} U_{\xi\xi t} = 0. \end{cases} \tag{5.13}$$

This is a weakly nonlinear, weakly dispersive system with variable coefficients, all depending on $M(\xi; \sqrt{\beta}, \gamma)$. The $O(\alpha^2, \alpha\beta, \beta^2)$ truncation terms are small and were dropped. This was not the case when working with a Cartesian coordinate system. The truncation terms could be large. Note that working with the terrain-following velocity we generated (formally) a converging asymptotic expansion. This is true even in the presence of rapidly varying topographies ($\gamma \ll 1$), as opposed to the original (nonconverging) expansion in Cartesian coordinates. Our physical interpretation is that the Boussinesq system with weighted terrain-following velocities averages is more representative, as an asymptotic simplification of the full set of equations. Namely, the bulk of the terrain-following velocity components do not deviate too much from their average as opposed to the horizontal components. Figure 5.1 corroborates this interpretation from a graphical perspective. The weighted velocity averages are performed over the ξ level-curves (vertical curves in Figure 5.1; curves over which ζ varies, but ξ is fixed). Note that even with high graphing resolution (Figure 5.1(b)) the effective flow domain penetrates very little into the narrow valleys. The bulk of the average

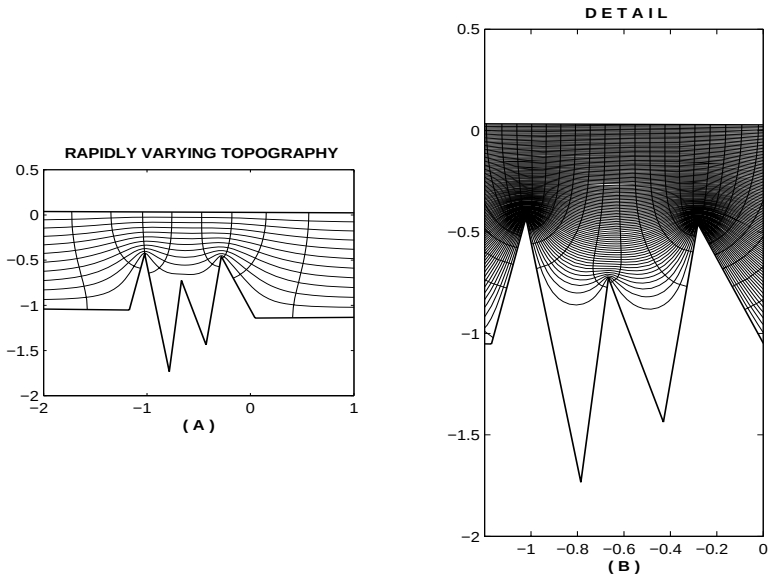

FIG. 5.1. *The effective flow domain. The horizontal resolution is equal to* (a) 10 ζ *level-curves,* (b) 100 ζ *level-curves. This figure was generated using the SC-Toolbox* [4].

is performed over the smoothly varying "outer" terrain-following velocities. In other words the contribution from the highly corrugated valleys is very small: 10% below the lowest ζ level-curve in 5.1(a) and 1% in 5.1(b). Clearly the outer flow prevails in the weighted average (5.12). In contrast if the topography is slowly varying the weights for the inner valley regions will be larger as indicated in Figure 4.1.

Regarding the use of averaged velocities, we do this change of dependent variables because standard long wave models use depth-averaged velocities. Moreover, the use of this dependent variable improves the stability for the high wavenumber regime of the Boussinesq system.

When the channel is flat the *metric term* ($M(\xi) = 1+m(\xi)$) reduces to one and we recover the standard dimensionless Boussinesq system [16]. Note that system (5.13) is different from that obtained by Hamilton (cf. equations (A14) and (A15) in [6]), which has powers of the metric term and an η_{tt} term. A comparison with standard Boussinesq systems is presented in the appendix of the present paper. When linearized they all have the same dispersion relation.

6. Applications and conclusions. We now point out some important features regarding applications with the terrain-following Boussinesq system:

(i) The derivatives of the topography-related coefficients are all well defined, even in the presence of corners or steps along the bottom. The metric term $M(\xi)$ is an analytic function. This is not the case in the classical Boussinesq equations (cf. Appendix A) as pointed out in Hamilton's work [6].

(ii) Under the curvilinear coordinate formulation, the *nonlinear shallow water equations* are viewed as an $O(\alpha, \sqrt{\beta})$ approximation to the full potential theory equations. Dropping the $O(\beta)$ term from system (5.13) above, we are left with a hyperbolic

system, but we are still keeping an $O(\sqrt{\beta})$ term inside the metric term (cf. (3.8)):

$$\begin{cases} M(\xi;\sqrt{\beta},\gamma)\eta_t + \left[\left(1+\alpha\eta/M(\xi;\sqrt{\beta},\gamma)\right)U\right]_\xi = 0, \\ \\ U_t + \eta_\xi + \frac{\alpha}{2}\left[U^2/M^2(\xi;\sqrt{\beta},\gamma)\right]_\xi = 0. \end{cases} \tag{6.1}$$

This has a great advantage in opposition to the $\beta \to 0$ limit used in the standard shallow water derivations. In the limiting $\beta \to 0$ case derivatives at corners along the bottom are not defined. In the present formulation consistency is preserved between the two formulations since in the vanishing β limit the kernel of the metric term goes to a Dirac delta function (cf. (3.7)) and singularities at the bottom are recovered. But retaining the intermediate $O(\sqrt{\beta})$ term leads to a (hyperbolic) shallow water system having a smooth, well-defined coefficient, even if the topography has corners. The degree of smoothing/averaging performed by the metric-kernel is controlled by $\sqrt{\beta}$ and γ (cf. (3.8)). This last point was not observed in Hamilton's work [6] since the metric term was not scaled in terms of depth/wavelength scales. By averaging we mean cases where the bottom is rapidly varying ($\gamma \ll 1$).

A schematic example is presented in Figure 6.1. The conformal mapping was computed numerically [12] as well as the metric term. We considered periodic mountain ranges having identical triangular mountains. The height of each triangle is equal to 0.5 and the base equal to 2.0 units. A natural question to ask is, What is the underlying value of β in this example? As will be discussed below, the averaging effect is related to the ratio between the scales $\sqrt{\beta}$ and γ. This was pointed out in Nachbin [12, p. 366] where a rule was devised in order to incorporate both scales. In order to incorporate these two scales, the Schwarz–Christoffel mapping was performed on mountains varying on the "modified" length scale

$$\tilde{l}_b \equiv l_b/(\sigma\sqrt{\beta}).$$

Note the difference of notations from [12], $l_p \equiv \sigma$ and ($\beta = h_0/\lambda$)—there is the $\sqrt{\beta}$ here. In other words

$$\sqrt{\beta} = \gamma/\tilde{l}_b.$$

Since for the triangular mountains $\tilde{l}_b = 2$, then we have that $\beta = 0.25\gamma^2$. A typical γ for rapidly varying topographies is 0.1 (10 mountain peaks per pulse width).

In the first example we contrast the metric term for a periodic mountain range with 5 mountains with that for a mountain range (of the same period) with 7 mountains. We clearly observe the exponential adjustment mentioned earlier. We also observe the smoothing along the sharp summit of the triangular mountains and the averaging as we put the mountains closer together (cf. Figure 6.2). In this case we have $\tilde{l}_b = 1$ and therefore $\beta = \gamma^2$. As indicated above averaging (in a homogenization sense) takes place as soon as the mountain scale parameter γ is smaller than the support of the sech^2-kernel, controlled by $\beta^{1/2}$ (see (3.7)). Note that the topography's derivative scales like $1/\gamma$ while the metric term's derivative always scales like $1/\sqrt{\beta}$. One of the advantages of this formulation is that the latter is independent of γ. This is a useful fact in the discussion that follows.

(iii) It is worth pointing out that first order derivatives of the metric term are produced. These terms are $O(1/\sqrt{\beta})$ (cf. (3.8)) and are generated by the N_ξ term, in the kinematic condition, and by differentiating Bernoulli's Law with respect to ξ. In particular, these $O(1/\sqrt{\beta})$ terms are present in the $O(\alpha\beta, \beta^2)$ terms that were

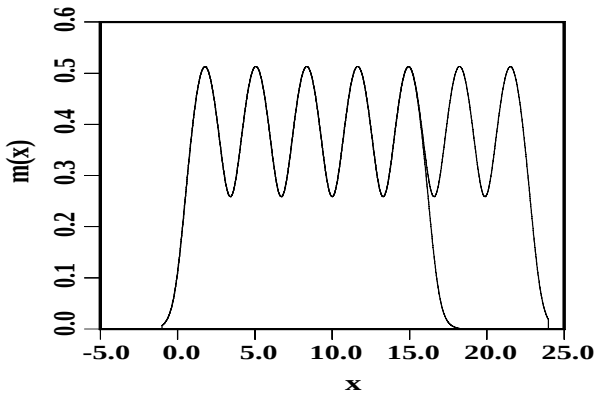

FIG. 6.1. *The metric term* $m(\xi) = M(\xi) - 1$ *for two periodic topographies. One was generated by* 5 *triangular mountains along the bottom while the other by* 7 *triangular mountains. The two metric terms match very well over the first* 5 *mountains, confirming the exponentially fast adjustment mentioned earlier. The* $\beta^{1/2}$*-scale plays a role in this adjustment.*

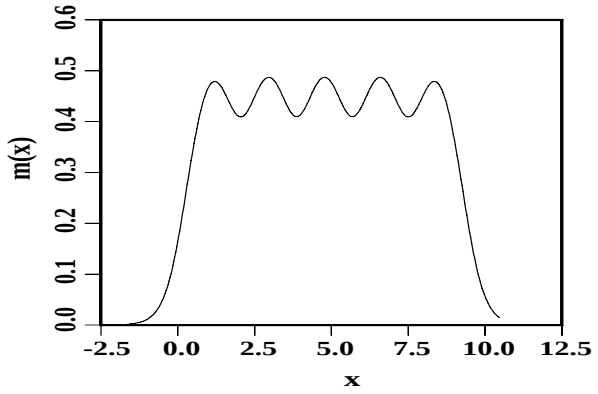

FIG. 6.2. *Averaging observed through the metric term* $m(\xi) = M(\xi) - 1$*. The triangular mountains are closer together, i.e., varying on a faster scale. The base of each triangle is* $1/2$ *of those in Figure* 6.1*.*

dropped from Bernoulli's Law. Nevertheless, one should not be concerned with the loss of validity of the asymptotics. The $O(1/\sqrt{\beta})$ term does not alter the ordering of the terms presented in the asymptotic analysis above. It can be easily verified that when the equation

$$\eta + f_t - \frac{\beta}{2} f_{\xi\xi t} + \frac{\alpha}{2M^2(\xi)} f_\xi^2 = O(\alpha\beta, \beta^2)$$

is differentiated with respect to ξ, the $1/\sqrt{\beta}$ term will only affect the $O(\alpha\beta)$ terms. For example, if we take $O(\alpha\beta)/\sqrt{\beta}$ and compare it to the leading $O(\alpha)$ nonlinearity term, we easily note that reordering takes place only if $\sqrt{\beta} > 1$, which is not the long wave regime we started with. Hence as long as $0 < \beta \ll 1$ the equations derived are valid weakly nonlinear, weakly dispersive approximations to the nonlinear potential theory equations. Namely they are valid as the leading order corrections in α and in β. The question of including the next order terms (in either parameter) was not

relevant to our application of interest [9]. Perhaps there are applications where these terms might play a role. We have not attempted to identify these regimes. Having set that $\beta > 0$ guarantees that the variable coefficients can be differentiated in the standard way. Delta functions do not arise at discontinuities of the topography.

(iv) Regarding applications, these new equations enable the study of the interaction of linear and nonlinear long surface waves with rapidly varying features of the topography. To our knowledge up to the present date, only small amplitude or mild slope topographies have been considered for Boussinesq-type models. The present model expands the regime of applicability and is consistent with previous Cartesian formulations in the case where $\gamma \gg 1$. In this regime the conformal mapping is nearly the identity map at the free surface level.

Many new theoretical and numerical problems can now be addressed with this new curvilinear formulation. A particular theoretical problem that we investigated through this new model is the O'Doherty–Anstey approximation of weakly dispersive waves. This theory characterizes the apparent diffusion of transmitted pulses due to disordered multiple scattering. This theory, initially developed for acoustic waves [1], was generalized to weakly dispersive waves by Muñoz Grajales and Nachbin [9]. Using the terrain-following Boussinesq system, we obtained expressions that capture both the attenuation of the transmitted pulse as well as the forward scattering radiation. Numerical validation experiments include the apparent diffusion of solitary waves in the presence of a highly disordered topography. We are currently also investigating an interesting numerical problem regarding the use of the terrain-following formulation [10]. The classical system (A.2) contains a term difficult to handle numerically in the presence of a topography. This is because the topography-related coefficients multiply the terms with higher order derivatives. In the curvilinear formulation the higher order term has a constant coefficient. We have obtained numerical evidence [10] that the "repositioning" of topography related terms (namely the metric terms) leads to improvements in the performance of Boussinesq solvers. We have also obtained results regarding the time reversed refocusing (i.e., waveform inversion) for weakly dispersive waves [10].

The Boussinesq system (5.13) can be cast into a second order differential equation. Take the system at the stage where we had

$$\eta + f_t - \frac{\beta}{2} f_{\xi\xi t} + \frac{\alpha}{2M^2(\xi)} f_\xi^2 = O(\alpha^2, \alpha\beta, \beta^2),$$

$$M(\xi)\ \eta_t + \left[\left(1 + \frac{\alpha}{M(\xi)}\eta\right) f_\xi\right]_\xi - \frac{\beta}{6} f_{\xi\xi\xi\xi} = O(\alpha^2, \alpha\beta, \beta^2).$$

From these equations we have that

$$\eta_t = -f_{tt} + O(\alpha, \beta), \quad M(\xi)\eta_t = -f_{\xi\xi} + O(\alpha, \beta), \quad \text{and} \quad f_{\xi\xi} = M(\xi) f_{tt} + O(\alpha, \beta).$$

These approximations are used after we calculate the time derivative of the first equation, multiply it by $M(\xi)$, and subtract it from the second equation to get

$$f_{\xi\xi} - M f_{tt} + \frac{\beta}{3} M f_{\xi\xi tt} - \frac{\alpha}{M}\left[f_\xi^2 + \frac{M}{2} f_t^2\right]_t + \alpha\left(\frac{M'}{M^2}\right) f_t f_\xi = O(\alpha^2, \alpha\beta, \beta^2). \tag{6.2}$$

By dropping the $O(\alpha^2, \alpha\beta, \beta^2)$ term we get the second order Boussinesq equation governing the velocity potential along the bottom topography. It is interesting to note

that in the Boussinesq system (5.13) no new terms were generated by the curvilinear coordinates. The only novelty is the presence of the metric term $M(\xi)$. Nevertheless, a new term appears when the system is reduced to a second order differential equation. The new term contains the derivative of the metric term. Again, in the absence of a topography, this differential equation reduces to the standard second order Boussinesq equation [7].

Appendix A. Boussinesq models and their linearization. Consider Peregrine's model (Mei [7, p. 512]):

$$\eta_t + \nabla \cdot [(h+\eta)U] = 0, \tag{A.1}$$

$$U_t + U \cdot \nabla U + g\nabla\eta = \frac{h}{2}\nabla\left[\nabla \cdot (hU_t)\right] - \frac{h^2}{6}\nabla\left[\nabla \cdot U_t\right].$$

Restricting to one-dimensional flows it becomes

$$\eta_t + \partial_x [(h+\eta)U] = 0, \tag{A.2}$$

$$U_t + UU_x + g\eta_x = \frac{h}{2}\left[\partial_x^2(hU_t)\right] - \frac{h^2}{6}U_{xxt}.$$

Linearize this system by letting $\tilde{\eta} = \varepsilon\eta$ and $\tilde{U} = \varepsilon U$. Drop the $\tilde{}$ to get

$$\eta_t + (hU)_x = 0, \tag{A.3}$$

$$U_t + g\eta_x = \frac{h}{2}(hU_t)_{xx} - \frac{h^2}{6}U_{xxt}.$$

Moreover, if the bottom is flat ($h(x) \equiv h_0$),

$$\eta_t + h_0 U_x = 0, \tag{A.4}$$

$$U_t + g\eta_x = \frac{h_0^2}{3}U_{xxt}.$$

The dimensionless Boussinesq equation derived in Whitham (page 467 of [16], using the dispersion relation) is

$$\eta_t + U_x = 0, \tag{A.5}$$

$$U_t + \eta_x = -\frac{\beta}{3}\eta_{xtt}.$$

Moreover, the linearized terrain-following Boussinesq equation is

$$M(\xi)\eta_t + U_\xi = 0, \tag{A.6}$$

$$U_t + \eta_\xi = \frac{\beta}{3}U_{\xi\xi t}.$$

All these Boussinesq systems share *the same dispersion relation*:

$$\omega^2 = \frac{k^2}{1 + \frac{1}{3}\beta k^2}, \tag{A.7}$$

which is stable as $k \to \infty$. In (A.4) the variables are in their original dimensions. Thus, for the sake of comparison, we set $gh_0 = 1$ and $h_0^2 = \beta$. This means that the characteristic wavelength is taken to be equal to one.

ON THE CONVEXITY AND RISK-SENSITIVITY OF THE PRICE OF AMERICAN INTEREST RATE DERIVATIVES*

LUIS H. R. ALVAREZ†

Abstract. We consider the form and sensitivity to risk of the price of perpetual American interest rate derivatives for a broad class of one-factor diffusion models of interest rates. We first present, in terms of the infinitesimal coefficients of the underlying interest rate dynamics, a set of usually satisfied conditions under which the value of the contingent claim is convex, at least on the set where exercising the contract is suboptimal. In line with previous parametrized models considering the valuation of perpetual interest rate derivatives, we find that given our general conditions, the convexity of the exercise payoff is preserved under rational valuation. Consequently, we are able to establish a set of typically satisfied conditions under which increased volatility unambiguously increases the price of the claim and postpones rational exercise by expanding the region where exercising the claim is suboptimal.

Key words. term structure, interest rate derivatives, minimal excessive mappings, convexity, optimal stopping

1. Introduction.

The sign of the relationship between volatility and the value of a contingent contract depends on the form of the value as a function of the current state of the underlying asset. Volatility, being a second-order property, affects the price of the contingent claim through the quadratic variation process and, therefore, increases or decreases the price depending on whether the price is convex or concave. As was proven in [22] and [24], the convexity of the exercise payoff is preserved under risk-neutral valuation for most path-independent claims. Consequently, these authors found that the sign of the relationship between volatility and the arbitrage free price of a contingent contract is positive and, therefore, that increased volatility increases the arbitrage free price of path-independent claims. This property was shown to be valid also for the American-type path-independent contingent claims in both [22] (in the absence of dividends) and [1] (in the presence of dividends). In [2], this result was subsequently shown to be valid for a broad class of path-dependent European interest rate derivatives as well. In [27], the convexity of the price and the positivity of the relationship between volatility and the exercise incentives of a rational investor were established for a special case of the Cox–Ingersoll–Ross model. A similar result was found in [15], which considered the valuation of perpetual variable loan contracts subject to an explicit parametrized short rate model. However, before now not much has been done in considering the robustness of the qualitative results on American interest rate derivatives obtained by applying explicit parametrized interest rate models (cf. [15], [27], and [30]). This is somewhat surprising in light of the large extent of the literature on term structure models of interest rates (see, for example, [7], [8, chapters 15–20], [9], [10], [12], [13, chapter 19], [14], [15], [16], [17], [19], [21], [23], [25],

[26], [27], [30], [31], [32], [34], [35], and [36]) and in light of the fact that this class of valuation problems arises frequently in real option studies considering irreversible investment in the presence of interest rate uncertainty (cf. [18, pp. 48–51] and [27]) and in the valuation of perpetual variable rate loan contracts (cf. [15]). Moreover, as is stated in [30], "...volatility is a key variable in pricing contingent claims such as interest rate options and bonds." Consequently, the sign of the relationship between volatility and the value of interest rate derivatives is an important factor characterizing the exercise incentives of a rational investor as a function of the volatility of the underlying stochastic interest rate dynamics.

Given these arguments, we plan to consider in this study both the form and the comparative static properties of the value of potentially infinitely lived American interest rate derivatives for a broad class of one-factor models of the short rate. For the sake of generality we model the short rate as a linear diffusion with known functional infinitesimal characteristics (i.e., known drift and volatility coefficient). By then applying the classical theory of diffusions, we first demonstrate that given a set of usually satisfied continuity and monotonicity conditions (which are satisfied by, among others, the Black–Karasinski, Cox–Ingersoll–Ross, Dothan, Merton, and Vasiček models), the minimal excessive mappings for the considered one-factor short rate diffusion model are globally convex. Since any nontrivial excessive mapping for the diffusion can be expressed in terms of the minimal ones and the value of an American contingent contract is excessive, we find that the value is convex, at least on the continuation region where waiting is optimal. Consequently, we find that increased volatility increases or leaves unchanged the pre-exercise value of these claims and, therefore, postpones the rational exercise of the contract by expanding or leaving unchanged the continuation region where waiting is optimal. In other words, we are able to demonstrate that increased volatility unambiguously increases the required exercise premium of a rational investor. The main reason for this finding is shown to be the fact that while increased volatility may (as it typically does) increase the value of the underlying payoff, it simultaneously also increases the value of holding the option alive. Since the latter effect dominates the former, we find that the net effect of increased volatility on waiting is unambiguously positive. Moreover, since the curvature of the minimal excessive mappings is independent of the exercise payoff, we also observe that the sign of the relationship between volatility and rational exercise is a process-specific property independent of the form of the underlying payoff. (See [1] for a similar observation in the path-independent case.)

The contents of this study are as follows. In section two we present the one-factor interest rate dynamics and the considered valuation problem (an optimal stopping problem). In section three we then consider the impact of increased volatility on the value of the interest rate derivative. Finally, our principal results are illustrated explicitly in section four.

2. Valuation and optimal stopping. As is well known from the literature on interest rate derivatives, the term structure of interest rates is entirely determined by specifying the dynamic behavior of the short rate of interest under the equivalent martingale measure $\mathbb{Q}$ [7], [8, chapters 16–17], [13, chapter 19], [20], [21]. In line with this argument, consider now the case where the interest rate process $\{r(t); t \geq 0\}$ is described under the risk-neutral measure $\mathbb{Q}$ on the state-space $(a, b) = \mathcal{I} \subseteq \mathbb{R}$ by the time homogeneous stochastic differential equation

$$dr(t) = \mu(r(t))dt + \sigma(r(t))d\hat{W}(t), \quad r(0) = r, \tag{1}$$

where $\hat{W}(t)$ is $\mathbb{Q}$-Brownian motion and the mappings $\mu : \mathcal{I} \mapsto \mathbb{R}$ and $\sigma : \mathcal{I} \mapsto \mathbb{R}_+$ are given sufficiently smooth mappings (at least continuous) for which both the existence and the uniqueness of a solution for (1) are guaranteed (cf. [11, pp. 46–47]). In accordance with most applications, we assume that $\sigma(r) > 0$ for all $r \in \mathcal{I}$ and that the upper boundary $b > 0$ of the state-space $\mathcal{I}$ is unattainable for the diffusion r (typically, $b = \infty$). Thus, even while the short rate may be expected to increase, it is never expected to attain the maximal possible state b in finite time. We will also assume that the lower boundary $a \leq 0$ is either natural (as 0 is for the Dothan and Merton models and $-\infty$ is for the Vasiček model), entrance, exit, or regular. It is also worth pointing out that the boundary behavior of the short rate process $r(t)$ typically depends on the precise parametrization of the model. For example, depending on the relative sizes of the parameters $\kappa, \theta, \sigma \in \mathbb{R}_+$, 0 may be either regular, exit, or entrance for the familiar Cox–Ingersoll–Ross model:

$$dr(t) = \kappa(\theta - r(t))dt + \sigma\sqrt{r(t)}d\hat{W}(t), \quad r(0) = r.$$

Given these assumptions, it is our purpose now to consider the optimal stopping problem

$$V(r) = \sup_{\tau} E_r \left[e^{-\int_0^\tau r(s)ds} \Phi(r(\tau)) \right], \tag{2}$$

where τ is an arbitrary $\mathcal{F}_t$-stopping time and $\Phi : \mathcal{I} \mapsto \mathbb{R}_+$ is a continuous mapping satisfying the intuitively clear boundedness condition

$$E_r \left[e^{-\int_0^t r(s)ds} \Phi(r(t)) \right] < \infty \tag{3}$$

for all $(t, r) \in \mathbb{R}_+ \times \mathcal{I}$. That is, we plan to consider the determination of the value and rational exercise price of a perpetual American contingent claim with exercise payoff $\Phi(r)$. This type of valuation problems arise frequently in studies considering either the pricing of American-type interest rate derivatives or the impact of interest rate uncertainty on real investment opportunities (cf. [27]). It is worth emphasizing that the value $V(r)$ should be viewed as the value of a derivative on a traded asset, since interest rates themselves are not traded. Put somewhat differently, typically $V(r)$ constitutes the value of a compound contingent contract. For example, if $\Phi(r) = (p(r, T) - c)^+$, where $p(r, T)$ is the value of a zero coupon bond maturing T periods from exercise (a T-bond) and $c \in (0, 1)$ is a known strike price of the option (cf. [27]), then $V(r)$ is the value of a perpetual call option on a T-bond. However, since our approach admits more complex contracts as well, we stick to the general notation. Moreover, since the time horizon of the valuation may be finite (as for the Cox–Ingersoll–Ross model), we observe that (2) constitutes a valuation subject to a potentially finite expiration date. In order to analyze the valuation problem (2), we first have to consider the form of the fundamental solutions $\psi : \mathcal{I} \mapsto \mathbb{R}_+$ and $\varphi : \mathcal{I} \mapsto \mathbb{R}_+$ of the ordinary second-order differential equation $(\mathcal{A}u)(r) - ru(r) = 0$, where

$$\mathcal{A} = \frac{1}{2}\sigma^2(r)\frac{d^2}{dr^2} + \mu(r)\frac{d}{dr} \tag{4}$$

denotes the differential operator representing the infinitesimal generator of r in the domain of $\mathcal{A}$. It is known from the classical theory of diffusions that $\psi(r)$ is monotonically increasing and that $\varphi(r)$ is monotonically decreasing on $\mathcal{I}$; that $\lim_{r \to b} \psi'(r)/S'(r) =$

∞ and $\lim_{r\to b}\varphi'(r)/S'(r)=0$, where

$$S'(r)=\exp\left(-\int^{r}\frac{2\mu(y)}{\sigma^2(y)}dy\right)$$

denotes the density of the scale function S of r; and that $\psi'(r)\varphi(r)-\varphi'(r)\psi(r)=BS'(r)$, where B denotes the constant Wronskian of the solutions. (For a thorough characterization of the fundamental solutions, see [11, pp. 18–19]; see also [28, chapter 4 and especially section 4.6].) Moreover, $\psi(r)$ and $\varphi(r)$ are minimal in the sense that any nontrivial excessive function for the interest rate process $r(t)$ killed at the rate r can be written in terms of these mappings (i.e., there is an integral representation for nontrivial excessive mappings in terms of the mappings $\psi(r)$ and $\varphi(r)$; see [11, p. 32]), and for all $r,q\in\mathcal{I}$ we have

$$E_r\left[e^{-\int_0^{\tau(q)}r(t)dt}\right]=\min\left(\frac{\psi(r)}{\psi(q)},\frac{\varphi(r)}{\varphi(q)}\right),$$

where $\tau(q)=\inf\{t\geq 0: r(t)=q\}$ denotes the first hitting time of the short rate process to the state $q\in\mathcal{I}$. Thus, the price of a zero coupon bond expiring at a random date $\tau(q)$ can be expressed in terms of either $\psi(r)$ or $\varphi(r)$, depending on whether the current short rate is below or above the state q.

Define now the mapping $\eta:\mathcal{I}\mapsto\mathbb{R}$ measuring the *net percentage growth rate of the short rate process killed at the rate* r as

$$\eta(r)=\frac{\mu(r)}{r}-r.$$

Our main results characterizing the form of the minimal excessive mappings for the interest rate process $r(t)$ are now summarized in our next theorem.

THEOREM 1. *Assume that the mapping $\eta(r)$ is nonincreasing on $\mathcal{I}$. Then the decreasing fundamental solution $\varphi(r)$ is convex on $\mathcal{I}$. The increasing fundamental solution $\psi(r)$ is convex on $\mathcal{I}$ as well if either a is unattainable for $r(t)$ or a is attainable for $r(t)$ and $\lim_{r\downarrow a}\eta(r)\leq 0$.*

Proof. Applying Dynkin's theorem to the linear mapping $r\mapsto r$ yields (cf. [1] and [3])

$$E_r\left[e^{-\int_0^{\tau(\hat{a},\hat{b})}r(s)ds}r(\tau(\hat{a},\hat{b}))\right]=r+E_r\int_0^{\tau(\hat{a},\hat{b})}e^{-\int_0^{s}r(t)dt}r(s)\eta(r(s))ds, \tag{5}$$

where $\tau(\hat{a},\hat{b})=\{t\geq 0: r(t)\notin(\hat{a},\hat{b})\}$ denotes the first exit time of the interest rate process from the bounded open set $(\hat{a},\hat{b})\subset\mathcal{I}$. Define now the functionals $u_1:\mathcal{I}\mapsto\mathbb{R}$ and $u_2:\mathcal{I}\mapsto\mathbb{R}$ as

$$u_1(r)=E_r\left[e^{-\int_0^{\tau(\hat{a},\hat{b})}r(s)ds}r(\tau(\hat{a},\hat{b}))\right]\quad\text{and}\quad u_2(r)=E_r\int_0^{\tau(\hat{a},\hat{b})}e^{-\int_0^{s}r(t)dt}r(s)\eta(r(s))ds.$$

As is shown in [29, pp. 199–224] (see also chapter 9 in [33]), the functional $u_1(r)$ is on $(\hat{a},\hat{b})$ the solution of the boundary value problem $(\mathcal{A}u_1)(r)=ru_1(r), u_1(\hat{a})=\hat{a}, u_1(\hat{b})=\hat{b}$, and the functional $u_2(r)$ is the solution of the boundary value problem $(\mathcal{A}u_2)(r)-ru_2(r)+r\eta(r)=0, u_2(\hat{a})=u_2(\hat{b})=0$. Consequently, we find that (5) can

be rewritten as

$$\hat{a}\frac{\tilde{\varphi}(r)}{\tilde{\varphi}(\hat{a})}+\hat{b}\frac{\tilde{\psi}(r)}{\tilde{\psi}(\hat{b})}=r+\tilde{B}^{-1}\tilde{\varphi}(r)\int_{\hat{a}}^{r}\tilde{\psi}(y)y\eta(y)m'(y)dy + \tilde{B}^{-1}\tilde{\psi}(r)\int_{r}^{\hat{b}}\tilde{\varphi}(y)y\eta(y)m'(y)dy, \tag{6}$$

where $m'(r) = 2/(\sigma^2(r)S'(r))$ denotes the density of the speed measure m of the diffusion r,

$$\tilde{\varphi}(r)=\varphi(r)-\frac{\varphi(\hat{b})}{\psi(\hat{b})}\psi(r),\quad \tilde{\psi}(r)=\psi(r)-\frac{\psi(\hat{a})}{\varphi(\hat{a})}\varphi(r),$$

and $\tilde{B} = (1-\psi(\hat{a})\varphi(\hat{b})/(\psi(\hat{b})\varphi(\hat{a})))B$ denotes the constant (with respect to the scale) Wronskian of the functions $\tilde{\psi}(r)$ and $\tilde{\varphi}(r)$. Differentiating (6) with respect to r and reordering terms then yield

$$1=\hat{a}\frac{\tilde{\varphi}'(r)}{\tilde{\varphi}(\hat{a})}+\hat{b}\frac{\tilde{\psi}'(r)}{\tilde{\psi}(\hat{b})}-\tilde{B}^{-1}\tilde{\varphi}'(r)\int_{\hat{a}}^{r}\tilde{\psi}(y)y\eta(y)m'(y)dy-\tilde{B}^{-1}\tilde{\psi}'(r)\int_{r}^{\hat{b}}\tilde{\varphi}(y)y\eta(y)m'(y)dy.$$

Dividing this equation first with the term $\tilde{\psi}'(r)$ and then differentiating the resulting equation yield (after a simplification)

$$\tilde{\psi}''(r)=\frac{2rS'(r)}{\sigma^2(r)}\left[\int_{\hat{a}}^{r}\tilde{\psi}(y)y\eta(y)m'(y)dy-\frac{\eta(r)\tilde{\psi}'(r)}{S'(r)}-\frac{\tilde{B}\hat{a}}{\tilde{\varphi}(\hat{a})}\right], \tag{7}$$

since $\tilde{\varphi}''(r)\tilde{\psi}'(r)-\tilde{\psi}''(r)\tilde{\varphi}'(r)=2r\tilde{B}S'(r)/\sigma^2(r)$. Analogously, we can establish that

$$\tilde{\varphi}''(r)=\frac{2rS'(r)}{\sigma^2(r)}\left[\frac{\tilde{B}\hat{b}}{\tilde{\psi}(\hat{b})}-\eta(r)\frac{\tilde{\varphi}'(r)}{S'(r)}-\int_{r}^{\hat{b}}\tilde{\varphi}(y)y\eta(y)m'(y)dy\right]. \tag{8}$$

However, since both $\tilde{\psi}(r)$ and $\tilde{\varphi}(r)$ satisfy the ordinary differential equation $(\mathcal{A}u)(r) = ru(r)$, we find that (cf. [11, p. 18])

$$\frac{\varphi'(\hat{b})}{S'(\hat{b})}-\frac{\varphi'(r)}{S'(r)}=\int_{r}^{\hat{b}}y\varphi(y)m'(y)dy,\quad \frac{\psi'(r)}{S'(r)}-\frac{\psi'(\hat{a})}{S'(\hat{a})}=\int_{\hat{a}}^{r}y\psi(y)m'(y)dy,$$

implying that (7) and (8) can be rewritten as

$$\tilde{\psi}''(r)=\frac{2rS'(r)}{\sigma^2(r)}\left[\int_{\hat{a}}^{r}\tilde{\psi}(y)y(\eta(y)-\eta(r))m'(y)dy-\frac{\eta(r)\tilde{\psi}'(\hat{a})}{S'(\hat{a})}-\frac{\tilde{B}\hat{a}}{\tilde{\varphi}(\hat{a})}\right] \tag{9}$$

and

$$\tilde{\varphi}''(r)=\frac{2rS'(r)}{\sigma^2(r)}\left[\int_{r}^{\hat{b}}\tilde{\varphi}(y)y(\eta(r)-\eta(y))m'(y)dy+\frac{\tilde{B}\hat{b}}{\tilde{\psi}(\hat{b})}-\eta(r)\frac{\tilde{\varphi}'(\hat{b})}{S'(\hat{b})}\right]. \tag{10}$$

The assumed monotonicity of the mapping $\eta(r)$ then implies that

$$\tilde{\psi}''(r)\geq\frac{2rS'(r)}{\sigma^2(r)}\left[-\frac{\eta(r)\tilde{\psi}'(\hat{a})}{S'(\hat{a})}-\frac{\tilde{B}\hat{a}}{\tilde{\varphi}(\hat{a})}\right]\quad\text{and}\quad\tilde{\varphi}''(r)\geq\frac{2rS'(r)}{\sigma^2(r)}\left[\frac{\tilde{B}\hat{b}}{\tilde{\psi}(\hat{b})}+\eta(r)\frac{\tilde{\varphi}'(\hat{b})}{S'(\hat{b})}\right].$$

Observing that $\tilde{\psi}(r) \uparrow \psi(r)$ as $\hat{a} \downarrow a$ and that $\tilde{\varphi}(r) \uparrow \varphi(r)$ as $\hat{b} \uparrow b$ then implies that

$$\psi''(r) \geq -\frac{2rS'(r)}{\sigma^2(r)}\eta(r)\lim_{\hat{a}\downarrow a}\frac{\tilde{\psi}'(\hat{a})}{S'(\hat{a})} \quad \text{and} \quad \varphi''(r) \geq \frac{2rS'(r)}{\sigma^2(r)}\eta(r)\lim_{\hat{b}\uparrow b}\frac{\tilde{\varphi}'(\hat{b})}{S'(\hat{b})} = 0,$$

since $b > 0$ was assumed to be unattainable for r and $a \leq 0$. If a is unattainable for r, then $\lim_{r\downarrow a}\psi'(r)/S'(r) = 0$, proving the convexity of $\psi(r)$ in that case. On the other hand, if a is attainable for r and $\lim_{r\downarrow a}\eta(r) \leq 0$, then $\eta(r) \leq 0$ for all $r \in \mathcal{I}$, proving the convexity of $\psi(r)$ in that case as well. □

Theorem 1 states a set of weak conditions under which the convexity of the minimal excessive mappings $\psi(r)$ and $\varphi(r)$ is always guaranteed. The results of Theorem 1 are very general, since the monotonicity of the mapping $\eta(r)$ is satisfied by almost all models subject to mean reversion and all models subject to decreasing per capita growth rates $\mu(r)/r$. Consequently, our results are valid for, among others, the Black–Karasinski [10], Cox–Ingersoll–Ross [15], [17], [27], Dothan [19], Merton [32], and Vasiček models [36] of interest rates. An interesting implication of Theorem 1 generalizing the conditions under which the convexity of the decreasing fundamental solution $\varphi(r)$ is assured is now summarized in the following. (See [3] for an analogous result in the constant discounting case.)

COROLLARY 1. *Assume that there is a threshold $r_0 \in \mathcal{I}$ such that $\mu(r) \geq 0$ on (a, r_0) and $\eta(r)$ is nonincreasing on (r_0, b). Then $\varphi(r)$ is convex on $\mathcal{I}$.*

Proof. Since $\varphi(r)$ is nonnegative and decreasing, we find that

$$\frac{1}{2}\sigma^2(r)\varphi''(r) = r\varphi(r) - \mu(r)\varphi'(r) \geq 0$$

whenever $r \in (a, r_0)$, that is, whenever $\mu(r) \geq 0$. The convexity of $\varphi(r)$ on (r_0, b) then follows from (10). □

Corollary 1 states a set of weak conditions under which the convexity of the decreasing fundamental solution of the ordinary second-order differential equation $(\mathcal{A}u)(r) = ru(r)$ is always guaranteed. This result is of importance since the decreasing fundamental solution $\varphi(r)$ plays a dominant role in most valuation problems of perpetual interest rate derivatives (cf. [15] and [27]).

It is worth pointing out that the result of Theorem 1 could also be derived for one factor models with *positive rates* (i.e., for which $\mathcal{I} \subseteq \mathbb{R}_+$) by considering the minimal excessive mappings for the diffusion

$$d\tilde{r}(t) = \tilde{\mu}(\tilde{r}(t))dt + \tilde{\sigma}(\tilde{r}(t))d\hat{W}(t), \tag{11}$$

where $\tilde{\mu}(r) = \mu(r)/r$ and $\tilde{\sigma}(r) = \sigma(r)/\sqrt{r}$. Define now the random time change $\beta(t)$ with time change rate r as (cf. [33, pp. 146–151])

$$\beta(t) = \int_0^t r(s)ds$$

and the right-hand inverse process as $\alpha(t) = \inf\{s \in \mathbb{R}_+ : \beta(s) > t\}$. Our assumptions imply that $\alpha(t)$ is continuous, that the random time change $\beta(t)$ is continuous and monotonically increasing, and that $\alpha(\beta(t)) = \beta(\alpha(t)) = t$. Moreover, as is demonstrated in Theorem 8.5.1 of [33] (page 146) the process $\tilde{r}(t)$ coincides in law with the process $r(\alpha(t))$. Consequently, we observe that

$$V(r) = \sup_{\bar{\tau}} E_r\left[e^{-\bar{\tau}}\Phi(\tilde{r}(\bar{\tau}))\right]. \tag{12}$$

In other words, the valuation problem (2) can be solved in terms of the associated stopping problem (12), at least when the lower boundary is unattainable for the interest rate process $r(t)$. This result is, of course, intuitively clear after noticing that the differential operator $\tilde{\mathcal{A}}$ representing the infinitesimal generator of the process $\tilde{r}(t)$ can be written as $\tilde{\mathcal{A}} = \frac{1}{r}\mathcal{A}$. Rewriting the ordinary second-order differential equation $(\mathcal{A}u)(r) = ru(r)$ as $(\tilde{\mathcal{A}}u)(r) = u(r)$ then shows why the minimal excessive mappings for $r(t)$ killed at the rate r and the minimal excessive mappings for $\tilde{r}(t)$ killed at the constant rate 1 coincide and, consequently, why we have the representation (12). It is also worth mentioning at this point that the random time change approach illustrated above applies also when the lower boundary 0 is attainable for the interest rate process $r(t)$. However, in order to apply the time change formula presented above in that case, we have to impose extra boundary conditions for the time-changed process $\tilde{r}(t)$, since the boundary behavior of $\tilde{r}(t)$ typically differs considerably from the boundary behavior of $r(t)$. This is actually a delicate issue which is mostly overlooked in studies considering problems of type (2) (see, for example, [27]). To illustrate this point explicitly, consider problem (2) in the presence of the short rate model (a special case of the Cox–Ingersoll–Ross model corresponding to the continuous time analogue of a branching process; cf. [29, p. 239]):

$$dr(t) = -\mu r(t)dt + \sigma\sqrt{r(t)}d\hat{W}(t), \quad r(0) = r,$$

where $\mu \in \mathbb{R}_+$ and $\sigma > 0$ are exogenously determined constants. Since 0 is an exit and ∞ a natural boundary for the interest rate process $r(t)$, we find that in this case the fundamental solutions of the ordinary second-order differential equation $(\mathcal{A}u)(r) = ru(r)$ read as $\psi(r) = e^{ar} - e^{br}$ and $\varphi(r) = e^{br}$, where $a = \mu/\sigma^2 + \sqrt{\mu^2/\sigma^4 + 2/\sigma^2}$ and $b = \mu/\sigma^2 - \sqrt{\mu^2/\sigma^4 + 2/\sigma^2}$ denote the positive and the negative root of the characteristic equation $\sigma^2 k^2/2 - \mu k - 1 = 0$, respectively. On the other hand, since the operator $\tilde{\mathcal{A}}$ coincides with the differential operator of Brownian motion with drift, we observe, by imposing that $\tilde{r}(t)$ should be killed at 0, that the optimal stopping problem (2) can be rewritten as in (12) with

$$d\tilde{r}(t) = \mu dt + \sigma d\hat{W}(t), \quad \tilde{r}(0) = r,$$

subject to killing at 0. Our main result characterizing the form of the value $V(r)$ is now summarized in the following.

THEOREM 2. *Assume that the conditions of Theorem* 1 *are satisfied. Then the value function $V(r)$ is convex on the continuation region $C = \{r \in \mathcal{I} : V(r) > \Phi(r)\}$. Moreover, if $\Phi(r)$ is convex on $\mathcal{I}$, then $V(r)$ is convex on $\mathcal{I}$ as well.*

Proof. The excessivity of the value function $V(r)$ implies that it is continuous and, therefore, that C is open. Assume that $(x, y) \subset C$ is an arbitrary open subset of C with compact support on $\mathcal{I}$. The harmonicity of the value $V(r)$ on C then implies that if $r \in (x, y)$, then

$$V(r) = E_r\left[e^{-\int_0^{\tau(x,y)} r(s)ds} V(r(\tau(x, y)))\right],$$

where $\tau(x, y) = \inf\{t \geq 0 : r(t) \notin (x, y)\}$ denotes the first exit time from (x, y). As in the proof of Theorem 1, we find that

$$V(r) = \frac{\psi(y)V(x) - V(y)\psi(x)}{\varphi(x)\psi(y) - \varphi(y)\psi(x)}\varphi(r) + \frac{\varphi(x)V(y) - \varphi(y)V(x)}{\varphi(x)\psi(y) - \varphi(y)\psi(x)}\psi(r).$$

However, the excessivity of $V(r)$ implies that $V(x)/V(y) \geq \min(\psi(x)/\psi(y), \varphi(x)/\varphi(y))$ for all $x, y \in \mathcal{I}$ and, therefore, that $\psi(y)V(x) \geq V(y)\psi(x)$ and $\varphi(x)V(y) \geq \varphi(y)V(x)$ (cf. [11, p. 32]). Since the sum of two convex functions is convex, we find that $V(r)$ is convex on C. Moreover, since $V(r) = \Phi(r)$ on the stopping region, we find that if $\Phi(r)$ is convex on $\mathcal{I}$, then $V(r)$ is convex on $\mathcal{I}$ as well. □

Theorem 2 states a set of conditions under which the value is convex, at least in the continuation region C where exercising the option is suboptimal. Interestingly, Theorem 2 also shows that given its conditions, the convexity of the exercise payoff is preserved under valuation. This result is in line with previous results obtained in models considering path-independent American contingent claims (cf. [1] and [22]) and path-dependent European interest rate derivatives (cf. [2]). It is, however, worth emphasizing that *the sufficient conditions for the convexity of the value on the continuation region C do not depend on the payoff $\Phi(r)$ and, therefore, are essentially determined by the infinitesimal coefficients of the diffusion modeling the interest rate dynamics.* This demonstrates that the form of the value of the interest rate derivative on C is *essentially a process-specific and not payoff-specific property* (cf. [1] for similar results in the case of path-independent claims). A set of stronger conditions under which the convexity of the value is also assured is now presented in the following theorem.

THEOREM 3. *Assume that the payoff $\Phi(r)$ is nonincreasing and convex and that*

(a) *$\mu(r)$ is concave,*

(b) *$\mu(r)$ and $\sigma(r)$ are continuously differentiable with Lipschitz-continuous derivatives, and $\sigma'(r)$ satisfies the standard Novikov condition.*

Then the value $V(r)$ is nonincreasing and convex.

Proof. As is shown in [6], given our assumptions (a) and (b), the discount factor $e^{-\int_0^t r(s)ds}$ is decreasing and convex as a mapping of the current short rate r. Therefore, $e^{-\int_0^t r(s)ds} g(r(t))$, being the product of two nonnegative, nonincreasing and convex mappings, is nonnegative, nonincreasing, and convex. Define now the increasing sequence of nonnegative mappings $\{V_n(r)\}_{n\in\mathbb{N}}$ as

$$V_{n+1}(r) = \sup_{t\geq 0} E_r\left[e^{-\int_0^t r(s)ds} V_n(r(t))\right], \quad V_0(r) = \Phi(r).$$

Since $\Phi(r)$ is nonincreasing and convex, and the maximum of a nonincreasing and convex mapping is nonincreasing and convex (by standard duality arguments), we find that $V_n(r)$ is nonincreasing and convex for all n. As is shown in Corollary 10.1.8 of [33], the sequence $V_n(r) \uparrow V(r)$ as $n \to \infty$. Thus, if $q \leq r$ we find that $V(q) \geq V_n(q) \geq V_n(r)$, from which the monotonicity of the value $V(r)$ follows by monotone convergence. Similarly, if $r, q \in \mathcal{I}$ and $\lambda \in [0,1]$ we find that $\lambda V(r) + (1-\lambda)V(q) \geq \lambda V_n(r) + (1-\lambda)V_n(q) \geq V_n(\lambda r + (1-\lambda)q)$, from which the convexity of the value $V(r)$ follows by monotone convergence. □

Theorem 3 states in terms of the drift $\mu(r)$, the volatility coefficient $\sigma(r)$, and the exercise payoff $\Phi(r)$ a set of conditions under which the value of a perpetual American interest rate derivative is nonincreasing and convex as a function of the current short rate. It is worth observing that although the conditions of Theorem 3 are not identical to (and not as general as) the conditions of Theorem 2, the monotonicity condition required in Theorem 2 follows in some cases from the concavity of the drift $\mu(r)$. More precisely, if $\mathbb{R}_+ \subseteq \mathcal{I}$, $\mu(r)$ is concave, and $\lim_{r\downarrow 0} \mu(r) \geq 0$, then $\mu(r)/r$ is decreasing and, therefore, $\eta(r)$ is decreasing as well. An interesting implication of Theorem 3 valid for contracts written on T-bonds (cf. [15] and [27]) is now summarized in the following.

COROLLARY 2. *Denote as $p(r,T)$ the price of a zero coupon bond maturing T periods from exercise, and assume that the mapping $g : \mathbb{R}_+ \mapsto \mathbb{R}_+$ is nondecreasing and convex and that the conditions* (a) *and* (b) *of Theorem* 3 *are satisfied. Then the value*

$$J(r) = \sup_{\tau} E_r \left[e^{-\int_0^\tau r(s)ds} g(p(r(\tau), T)) \right], \tag{13}$$

is nonincreasing and convex.

Proof. The result is a direct implication of Theorem 3. □

Corollary 2 states a set of typically satisfied conditions under which the value of a compound contract written on a T-bond is nonincreasing and convex. Therefore, an important implication of the findings of Corollary 2 is that, given the conditions of Theorem 3, *the value of a call option written on a T-bond is nonincreasing and convex.*

3. The impact of increased volatility. In this section, we plan to consider the comparative static properties of the value function $V(r)$. To accomplish this task, we assume that the interest rate process $\{\hat{r}(t); t \geq 0\}$ evolving on $\mathcal{I}$ is described under the risk-neutral measure $\mathbb{Q}$ by the time homogeneous stochastic differential equation

$$d\hat{r}(t) = \mu(\hat{r}(t))dt + \hat{\sigma}(\hat{r}(t))d\hat{W}(t), \quad \hat{r}(0) = r, \tag{14}$$

where $\hat{\sigma} : \mathcal{I} \mapsto \mathbb{R}_+$ is a given sufficiently smooth (at least continuous) mapping satisfying the condition $\hat{\sigma}(r) \geq \sigma(r)$ for all $r \in \mathcal{I}$. In accordance with the notation in the previous section, we denote the differential operator representing the infinitesimal generator of $\hat{r}$ as

$$\hat{\mathcal{A}} = \frac{1}{2}\hat{\sigma}^2(r)\frac{d^2}{dr^2} + \mu(r)\frac{d}{dr}. \tag{15}$$

We also denote the increasing and decreasing fundamental solutions of the ordinary second-order differential equation $(\hat{\mathcal{A}}u)(r) = ru(r)$ as $\hat{\psi}(r)$ and $\hat{\varphi}(r)$, respectively. Our first important auxiliary result is now summarized in the following lemma.

LEMMA 1. *Assume that the conditions of Theorem* 1 *are satisfied. Then*

$$\min(\hat{\psi}(r)/\hat{\psi}(q), \hat{\varphi}(r)/\hat{\varphi}(q)) \geq \min(\psi(r)/\psi(q), \varphi(r)/\varphi(q))$$

for all $r, q \in \mathcal{I}$. Thus, the class of excessive mappings for the diffusion $\hat{r}(t)$ killed at the rate r belongs into the class of excessive mappings for the diffusion $r(t)$ killed at the rate r.

Proof. Given the conditions of our lemma, we know that $\psi(r)$ and $\varphi(r)$ are convex on $\mathcal{I}$. Thus, we observe that for all $r \in \mathcal{I}$ we have that $(\hat{\mathcal{A}}\psi)(r) - r\psi(r) = ((\hat{\mathcal{A}} - \mathcal{A})\psi)(r) = \frac{1}{2}(\hat{\sigma}(r) - \sigma(r))\psi''(r) \geq 0$ and $(\hat{\mathcal{A}}\varphi)(r) - r\varphi(r) = \frac{1}{2}(\hat{\sigma}(r) - \sigma(r))\varphi''(r) \geq 0$; that is, $\psi(r)$ and $\varphi(r)$ are subharmonic for $\hat{r}(t)$ on $\mathcal{I}$. Consequently, we observe that if $\hat{\tau}(q) = \inf\{t \geq 0 : \hat{r}(t) = q\}$ and $r \leq q$, then

$$\psi(q)\frac{\hat{\psi}(r)}{\hat{\psi}(q)} = E_r \left[e^{-\int_0^{\hat{\tau}(q)} \hat{r}(s)ds} \psi(\hat{r}(\hat{\tau}(q))) \right] \geq \psi(r).$$

Similarly,

$$\varphi(r)\frac{\hat{\varphi}(q)}{\hat{\varphi}(r)} = E_q \left[e^{-\int_0^{\hat{\tau}(r)} \hat{r}(s)ds} \varphi(\hat{r}(\hat{\tau}(r))) \right] \geq \varphi(q),$$

where $\hat{\tau}(r) = \inf\{t \geq 0 : \hat{r}(t) = r\}$. Combining these two inequalities then prove that $\min(\hat{\psi}(r)/\hat{\psi}(q), \hat{\varphi}(r)/\hat{\varphi}(q)) \geq \min(\psi(r)/\psi(q), \varphi(r)/\varphi(q))$ for all $r, q \in \mathcal{I}$.

An arbitrary nontrivial mapping $f : \mathcal{I} \mapsto \mathbb{R}_+$ is excessive for the diffusion $\hat{r}(t)$ killed at the rate r if and only if $f(r)$ is continuous and nonnegative and satisfies for any $(x, y) \subset \mathcal{I}$, $a < x < y < b$ the inequality

$$u(r) = E_r\left[e^{-\int_0^{\hat{\tau}(x,y)} \hat{r}(s)ds} f(\hat{r}(\hat{\tau}(x, y)))\right] \leq f(r),$$

where $\hat{\tau}(x, y) = \inf\{t \geq 0 : \hat{r}(t) \notin (x, y)\}$ (cf. [11, p. 32]). Since $(\hat{\mathcal{A}}u)(r) = ru(r)$ for all $r \in (x, y)$ and $u(r)$ is convex on (x, y) by Theorem 2, we find that $(\mathcal{A}u)(r) - ru(r) = ((\mathcal{A} - \hat{\mathcal{A}})u)(r) = \frac{1}{2}(\sigma^2(r) - \hat{\sigma}^2(r))u''(r) \leq 0$ for all $r \in (x, y)$. Applying Dynkin's theorem to the mapping $r \mapsto u(r)$ and invoking the continuity of the mapping at x and y then imply that

$$f(r) \geq u(r) \geq E_r\left[e^{-\int_0^{\tau(x,y)} r(s)ds} u(r(\tau(x, y)))\right] = E_r\left[e^{-\int_0^{\tau(x,y)} r(s)ds} f(r(\tau(x, y)))\right],$$

which demonstrates that $f(r)$ is excessive for the diffusion $r(t)$ killed at the rate r as well. □

Define now the value of the contingent contract with exercise payoff $\Phi(r)$ and defined with respect to the more volatile interest rate process $\hat{r}(t)$ as

$$\hat{V}(r) = \sup_{\hat{\tau}} E_r\left[e^{-\int_0^{\hat{\tau}} \hat{r}(s)ds} \Phi(\hat{r}(\hat{\tau}))\right], \tag{16}$$

where $\hat{\tau}$ is an arbitrary stopping time. The key implication of our Lemma 1 is now summarized in our main theorem.

THEOREM 4. *Assume that the conditions of Theorem* 1 *are satisfied. Then* $\hat{V}(r) \geq V(r)$ *for all* $r \in \mathcal{I}$ *and* $C = \{r \in \mathcal{I} : V(r) > \Phi(r)\} \subseteq \{r \in \mathcal{I} : \hat{V}(r) > \Phi(r)\} = \hat{C}$.

Proof. As was demonstrated in Lemma 1, the class of excessive mappings for the diffusion $\hat{r}(t)$ killed at the rate r belongs to the class of excessive mappings for the diffusion $r(t)$ killed at the rate r. Thus, $\hat{V}(r)$, being the least excessive majorant of $\Phi(r)$ for the diffusion $\hat{r}(t)$ killed at the rate r, is an excessive majorant of the payoff $\Phi(r)$ for the diffusion $r(t)$ killed at the rate r as well. Since $V(r)$ is the least of such majorants, we find that $\hat{V}(r) \geq V(r)$ for all $r \in \mathcal{I}$. Finally, if $r \in C$, then $\hat{V}(r) \geq V(r) > \Phi(r)$, proving that $r \in \hat{C}$ as well and, therefore, that $C \subseteq \hat{C}$. □

Theorem 4 demonstrates that given the conditions of our Theorem 1, increased volatility increases the value of the contingent claim and postpones the rational exercise of the contingent contract by expanding the continuation region where exercising is suboptimal. Put somewhat differently, Theorem 4 demonstrates that given the conditions of our Theorem 1, the required exercise premium is an increasing function of the volatility of the process (i.e., an increasing mapping of risk). This result is of interest since it demonstrates how a misspecified volatility coefficient affects the value of the considered derivative instruments. If we overestimate the true market volatility, then our theoretical prices will exceed the true ones, and vice versa. An interesting implication of these findings is now summarized in our next corollary.

COROLLARY 3. *Assume that the conditions of Corollary* 2 *are satisfied. Then increased volatility increases the value of derivatives written on zero coupon bonds. Put formally, increased volatility increases the value* $J(r)$ *defined in* (13).

Proof. As was shown in Corollary 2, $J(r)$ is nonincreasing and convex as a function of the current short rate r. Thus, the conditions of Theorem 4 are satisfied, and the alleged result follows. □

Corollary 3 shows that given the general conditions of Corollary 2, increased volatility increases the value of American contingent contracts written on T-bonds. Since increased volatility increases the value of the T-bonds as well, it is not obvious whether the impact of increased volatility on the continuation region is positive or not. Fortunately, there is a broad class of cases for which the positivity of this relationship can be unambiguously established. Our main result on this topic is now proven in the following theorem.

THEOREM 5. *Assume that $\hat{\sigma}(r) = \kappa\sigma(r)$, where $\kappa \in (1, \infty)$ is a known constant. Assume also that the conditions of Corollary 2 are satisfied. Then an increase in the parameter κ increases the value $J(r)$ and postpones rational exercise by expanding the continuation region where exercising the contract is suboptimal.*

Proof. Denote now as $r_\kappa(t)$ the solution of the stochastic differential equation (14) when $\hat{\sigma}(r) = \kappa\sigma(r)$. Denote also as $J_\kappa(r)$ the value $J(r)$ and as $p_\kappa(r,T)$ the price of a T-bond as a function of the known parameter κ. The assumed smoothness of the infinitesimal coefficients $\mu(r)$ and $\sigma(r)$ imply that $r_\kappa(t)$ is continuous as a function of κ. This, in turn, implies that both the value $J_\kappa(r)$ and the price of a T-bond are continuous as functions of the parameter κ. We have already established that $J_\kappa(r) \geq J(r)$ and we also know from [6] that $p_\kappa(r,T) \geq p(r,T)$. Define now the exercise regions $\Gamma = \{r \in \mathcal{I} : J(r) = g(p(r,T))\}$ and $\Gamma_\kappa = \{r \in \mathcal{I} : J_\kappa(r) = g(p_\kappa(r,T))\}$ and let $r \in \Gamma_\kappa$. Then

$$J_\kappa(r) = g(p_\kappa(r,T)) \geq J(r) \geq g(p(r,T)) \Rightarrow g(p_\kappa(r,T)) - g(p(r,T)) \geq J(r) - g(p(r,T)) \geq 0.$$

The continuity of $g(p_\kappa(r,T))$ as a mapping of the parameter κ then implies that there is a sequence $\kappa_n \downarrow 1$ for which the difference $|g(p_{\kappa_n}(r,T)) - g(p(r,T))| < \epsilon/n$ when $n > \bar{N}$. Since $\epsilon > 0$ is arbitrary, we find that $J(r) = g(p(r,T))$ as well and, therefore, that $\Gamma_\kappa \subseteq \Gamma$. Since $C = \{r \in \mathcal{I} : J(r) > g(p(r,T))\} = \mathcal{I}\backslash\Gamma$ and $C_\kappa = \{r \in \mathcal{I} : J_\kappa(r) > g(p_\kappa(r,T))\} = \mathcal{I}\backslash\Gamma_\kappa$, we find that $C \subseteq C_\kappa$, thus proving the alleged claim. □

4. Illustration. It is our purpose in this section to illustrate the results of the two previous sections by considering a class of problems arising frequently in the literature on interest rate derivatives. We assume throughout this section that $\Phi \in C^2(\mathcal{I})$, although this assumption may be relaxed since continuous mappings can be approximated by a sequence of twice continuously differentiable mappings converging uniformly on compacts towards Φ (a mollification of Φ; cf. [4] and [33, pp. 299–302]). Define now the continuous mapping $f : \mathcal{I} \mapsto \mathbb{R}$ as $f(r) = (\mathcal{A}\Phi)(r) - r\Phi(r)$. Our main result is now summarized in the following.

THEOREM 6. *Assume that there is a threshold $\tilde{r} \in (a,b)$ for which $f(r) \gtreqless 0$, when $r \gtreqless \tilde{r}$, that $\lim_{r\uparrow b} \Phi(r) < \infty$, and that*

$$E_r \int_0^\infty e^{-\int_0^s r(t)dt} |f(r(s))| ds < \infty.$$

(A) *If a is either natural or exit for the interest rate process $r(t)$ killed at the rate r, then $\tau(r^*) = \inf\{t \geq 0 : r(t) \leq r^*\}$ is the optimal exercise date and the value reads as*

$$V(r) = \varphi(r) \sup_{q\in(a,r]} \frac{\Phi(q)}{\varphi(q)} = \begin{cases} \Phi(r^*)\frac{\varphi(r)}{\varphi(r^*)}, & r \in (r^*, b), \\ \Phi(r), & r \in (a, r^*], \end{cases} \tag{17}$$

where $r^* = \operatorname{argmax}\{\Phi(r)/\varphi(r)\} \in (a, \tilde{r})$, denoting the optimal exercise price, is the unique root of the smooth pasting condition $\Phi'(r^*)\varphi(r^*) = \Phi(r^*)\varphi'(r^*)$.

(B) *If a is either entrance or killing boundary for the interest rate process $r(t)$ killed at the rate r and the equation $\Phi'(r)\varphi(r) = \Phi(r)\varphi'(r)$ has an interior root on $(a, \tilde{r})$, then the value reads as in* (17) *and $\tau(r^*) = \inf\{t \geq 0 : r(t) \leq r^*\}$ is the optimal exercise date.*

Proof. Denote as $V_p(r)$ the proposed value function. It is then clear that the excessivity of the value $V(r)$ implies that $V(r) \geq V_p(r)$ (cf. [11, p. 32]). To prove the opposite, we first observe that if an optimal threshold r^* exists, then the proposed value function $V_p(r)$ is nonnegative, dominates the exercise payoff $\Phi(r)$, is twice continuously differentiable outside the threshold r^*, and satisfies the variational inequalities $\min\{rV_p(r) - (\mathcal{A}V_p)(r), V_p(r) - \Phi(r)\} = 0$. Thus, we find that if an optimal threshold r^* exists, then the proposed value function $V_p(r)$ is an excessive majorant of the exercise payoff $\Phi(r)$. However, since $V(r)$ is the least of these majorants, we find that $V_p(r) \geq V(r)$ whenever r^* exists. Consequently, it is sufficient to demonstrate that an optimal threshold r^* exists. Applying Dynkin's theorem to the mapping $r \mapsto \Phi(r)$ and following the proof of our Theorem 1 yield that

$$\Phi(\hat{a})\frac{\tilde{\varphi}(r)}{\tilde{\varphi}(\hat{a})} + \Phi(\hat{b})\frac{\tilde{\psi}(r)}{\tilde{\psi}(\hat{b})} = \Phi(r) + \tilde{B}^{-1}\tilde{\varphi}(r)\int_{\hat{a}}^{r} \tilde{\psi}(y)f(y)m'(y)dy + \tilde{B}^{-1}\tilde{\psi}(r)\int_{r}^{\hat{b}} \tilde{\varphi}(y)f(y)m'(y)dy,$$

where $a < \hat{a} < \hat{b} < b$. Dividing this equation with the mapping $\tilde{\varphi}(r)$, differentiating the resulting equation, and reordering terms then yield

$$\frac{\Phi'(r)}{S'(r)}\tilde{\varphi}(r) - \frac{\tilde{\varphi}'(r)}{S'(r)}\Phi(r) = \frac{\Phi(y)}{\tilde{\psi}(\hat{b})}\tilde{B} - \int_{r}^{\hat{b}} \tilde{\varphi}(y)f(y)m'(y)dy.$$

Letting $\hat{b} \uparrow b$ and invoking the assumptions of our theorem then yield

$$\frac{\Phi'(r)}{S'(r)}\varphi(r) - \frac{\varphi'(r)}{S'(r)}\Phi(r) = -\int_{r}^{b} \varphi(y)f(y)m'(y)dy. \tag{18}$$

As is shown in the proof of part B of Theorem 4 in [5], (18) has, under the assumptions of our theorem, a unique root whenever 0 is either natural or exit. Moreover, $\Phi'(r)\varphi(r) \gtreqless \Phi(r)\varphi'(r)$ when $r \lesseqgtr r^*$, demonstrating that $r^* = \operatorname{argmax}\{\Phi(r)/\varphi(r)\}$, thus completing the proof of part (A) of our theorem. The proof of part (B) is then analogous. □

Theorem 6 states a set of typically satisfied conditions under which the optimal stopping problem (2) can always be explicitly solved in terms of the decreasing fundamental solution of the ordinary second-order differential equation $(\mathcal{A}u)(r) - ru(r) = 0$. It is worth observing that the optimal exercise boundary always exists when the lower boundary a is either natural or exit for the interest rate process $r(t)$ killed at the rate r. However, if a is either regular or entrance, then the equation $\Phi'(r)\varphi(r) = \Phi(r)\varphi'(r)$ may or may not have an interior root in $\mathcal{I}$. If such root does not exist, then the contract is never exercised before expiration. An important corollary of our theorem is now summarized in the following corollary.

COROLLARY 4. *Assume that the conditions of Theorems* 1 *and* 6 *are satisfied. Then increased volatility increases the value $V(r)$ and postpones exercise by expanding the continuation region $C = \{r \in \mathcal{I} : V(r) > \Phi(r)\}$ where exercising the contract is suboptimal.*

Proof. The result is a direct consequence of Theorems 4 and 6. □

In line with our theoretical findings, we observe from Theorem 6 and Corollary 4 that the value of the contingent contract is decreasing on $\mathcal{I}$ and convex on C. Consequently, we find that increased volatility increases its value and expands the continuation region where exercising the contract is suboptimal. Moreover, since in the absence of stochasticity (i.e., when $\sigma(r) \equiv 0$) the optimal exercise threshold, denoted now as $\bar{r}$, satisfies the ordinary first-order condition $\mu(\bar{r})\Phi'(\bar{r}) = \bar{r}\Phi(\bar{r})$ and increased volatility increases r^*, we find that increased volatility increases the required exercise premium $r^* - \bar{r}$ as well.

Acknowledgments. The author is grateful to Paavo Salminen and to two anonymous referees for their constructive comments and suggested improvements on earlier versions of this study.

THE COUPLING OF MOTION AND CONDUCTIVE HEATING OF A GAS BY LOCALIZED ENERGY SOURCES*

ANTONIO L. SÁNCHEZ†, JOSÉ L. JIMÉNEZ-ÁLVAREZ†, AND AMABLE LIÑÁN‡

Abstract. This paper investigates the time evolution of the near-isobaric flow field produced in a gas after the sudden application of a constant heat flux from a localized energy source. The problems of plane, line, and point heat sources are all investigated, with a power law for the temperature dependence of the thermal conductivity, after reduction to a quasi-linear heat equation for the temperature. In the planar and spherical cases, the constant heat flux defines scales for the length and time, which are used to nondimensionalize the problem. Numerical integration is used to provide the evolution of the temperature and velocity, and limiting solutions corresponding to small and large rescaled times are obtained. In the axisymmetric case, due to the absence of characteristic length and time scales, the solution is seen to admit a self-similar description in terms of the nondimensional heat flux. Profiles of temperature and radial velocity are provided for different values of this parameter, and the asymptotic limits of both small and large heating rates are addressed separately. The analysis reveals, in particular, the existence of front solutions when the resulting temperatures become much larger than the initial temperature, as occurs for sufficiently large times for the planar source, for sufficiently small times for the point source, and for sufficiently large heating rates for the line source.

1. Introduction.

The expansion accompanying the heating of a gas after the application of an energy source sets the fluid in motion away from the source. The purpose of this paper is to give a description of the associated nonlinear heating process when the induced velocities are much smaller than the velocity of sound, so that one can neglect pressure variations in the first approximation. Furthermore, the analysis treats the energy source as being of negligible size and neglects the effect of gravity, two simplifications that are simultaneously valid when the size of the heated region is much larger than that of the energy source and still sufficiently small so that the buoyancy-induced velocity remains smaller than the thermal-expansion velocity.

We shall consider the one-dimensional transient solutions appearing with plane, line, and point energy sources when a constant heat flux is applied. Numerical and asymptotic techniques will be employed to describe the evolution with time of the temperature and velocity fields. The solution will be seen to depend on the combined effect of outward convection, due to the gas expansion, and of nonlinear heat conduction, associated with the temperature dependence of the thermal conductivity. The results of the analysis should be useful for understanding the ignition process of a reactive gas mixture by a localized energy source, as can be realized in practice by a

laser beam or by passing an electric current through a thin wire.

A simple order-of-magnitude analysis serves to anticipate the characteristic scales of the problem. Consider an energy source located in an infinite gas medium at rest with initial temperature and density T_o and ρ_o, respectively. If a constant energy flux is applied after time $\mathrm{t} = 0$, the characteristic time t_c required to heat a region of characteristic size r_c, so that the temperature is increased by an amount of order T_o, is determined by the energy balance

$$\mathrm{q}_j \mathrm{t}_c \sim \rho_o c_p \mathrm{T}_o \mathrm{r}_c^{j+1}, \tag{1.1}$$

where c_p is the specific heat at constant pressure, assumed to be constant, and the index j takes the values $j = (0, 1, 2)$ for planar, cylindrical, and spherical geometries. Correspondingly, q_0, q_1, and q_2 represent, respectively, the heating rate per unit surface for the planar source, the heating rate per unit length for the line source, and the heating rate of the point source. The above equation must be supplemented by the condition

$$\mathrm{q}_j \sim \mathrm{r}_c^{j-1} k_o \mathrm{T}_o, \tag{1.2}$$

which states that the energy flux is conducted across the heated region, with k_o representing the value of the thermal conductivity at the initial temperature T_o.

For the planar and point sources, the above two balances give the characteristic scales of length and time

$$\mathrm{r}_c \sim \left(\frac{\mathrm{q}_j}{k_o \mathrm{T}_o}\right)^{1/(j-1)} \quad \text{and} \quad \mathrm{t}_c \sim \alpha_o^{-1} \left(\frac{\mathrm{q}_j}{k_o \mathrm{T}_o}\right)^{2/(j-1)}, \tag{1.3}$$

where $\alpha_o = k_o/(\rho_o c_p)$ is the unperturbed thermal diffusivity. On the other hand, the characteristic velocity due to thermal expansion associated with relative changes in density of order unity, which can be anticipated from the continuity equation to be of order $\mathrm{v}_c = \mathrm{r}_c/\mathrm{t}_c$, becomes in this case

$$\mathrm{v}_c \sim \alpha_o \left(\frac{\mathrm{q}_j}{k_o \mathrm{T}_o}\right)^{-1/(j-1)}. \tag{1.4}$$

As shown below, use of these scales enables the problems $j = 0$ and $j = 2$ to be written in a convenient parameter-free form. On the other hand, no characteristic scales can be constructed for the line source, for which the radial extent of the heated region increases with time according to

$$\mathrm{r}_c \sim \left[\frac{\mathrm{q}_1}{(k_o \mathrm{T}_o)}\right]^{1/2} (\alpha_o \mathrm{t})^{1/2}, \tag{1.5}$$

while the characteristic velocity is given by

$$\mathrm{v}_c \sim \left[\frac{\mathrm{q}_1}{(k_o \mathrm{T}_o)}\right]^{1/2} (\alpha_o/\mathrm{t})^{1/2}. \tag{1.6}$$

Because of the absence of characteristic scales, the problem will be seen to admit a similarity solution in terms of the self-similar coordinate $\mathrm{r}/(\alpha_o \mathrm{t})^{1/2}$, with $q = \mathrm{q}_1/(2\pi k_o \mathrm{T}_o)$ entering as a governing parameter.

The ranges of validity for the different assumptions employed in the paper can be delineated by using the above scaling laws (1.3)–(1.6). For instance, the assumption that the source is localized is valid only when r_c is much larger than the size of the energy source, while gravity-induced velocities, of order $(g\mathrm{r}_c)^{1/2}$, can be neglected only when $\mathrm{v}_c \gg (g\mathrm{r}_c)^{1/2}$ for $\mathrm{r}_c \ll (\alpha_o^2/g)^{1/3}$. The assumption of isobaric heating holds only when the induced velocities v_c are much smaller than the velocity of sound, given in order of magnitude by $(c_p\mathrm{T}_o)^{1/2}$, thereby producing pressure variations, of order $\rho_o v_c^2$, that are much smaller than the ambient value. It should also be noted that the above considerations provide, for a given gas mixture, the range of heating rates for which the analyses of the planar and point sources remain accurate. On the other hand, since the characteristic scales given in (1.5)–(1.6) change with time, the above considerations give the time range for which the analysis of the line source holds.

Neither finite-size sources nor buoyancy and compressibility effects are addressed in the present work. When gravity enters, the symmetric solution determined here is expected to evolve to give a steady plume for large times, giving a flow pattern that has been extensively studied in the past (see, e.g., [8, 9] for entries into the literature of thermal plumes from line and point sources). When compressibility effects are significant, a strong shock wave can be expected to form, a phenomenon also observed following the instantaneous localized deposition of a finite amount of energy [18, 19, 20]. This shock wave weakens as it moves away from the source, eventually leading to an acoustic wave as the pressure settles everywhere to the ambient value for sufficiently large times.

The structure of the paper is as follows. After formulating the problem, we will address the similarity solution emerging in the case of a line source. The self-similar temperature and velocity profiles will be given for different values of the heat release rate, and the asymptotic limit of large heat release rates will be described in detail. Next, we will present the solution corresponding to planar and point sources, which involve integration of a parameter-free nonlinear parabolic equation for the temperature. The analysis is extended to include the asymptotic limits of small and large rescaled times. Finally, some concluding remarks will be given.

It should be noted that the problem of near-isobaric heat propagation in a gas from a plane source was addressed previously by Clarke, Kassoy, and Riley in their study of heating of a gas slot confined between infinite parallel walls [5]. In particular, the nonlinear heat equation that governs the problem was derived. They showed that, when the heating rate is applied for a sufficiently long time, the characteristic temperature of the heated region becomes much larger than T_o, so that the thermal wave becomes a front solution with an edge that clearly defines the hot region surrounding the source. We shall see that a front solution also appears with the line source in the limit of large heat release rates and with the point source for sufficiently small times. As seen below, the structure of the solution includes a locally planar thin layer of warm gas, identical for all three configurations, that separates the region of hot gas from the outer cold gas, at temperature $\mathrm{T} = \mathrm{T}_o$. It is worth mentioning that similar front solutions have been previously identified in asymptotic analyses of heat conduction problems when the thermal conductivity depends strongly on the temperature [22], e.g., in electronic conduction in plasmas [16, 23], or in the presence of large temperature variations in gases, as occurs in supercritical droplet evaporation [15]. Front solutions are also encountered in problems of mass diffusion [7] and in flows in porous media [2].

2. Formulation. In the near-isobaric limit considered here, the momentum equation becomes secondary for the computation of the one-dimensional problems addressed, in the sense that the resulting velocity and temperature fields can be determined by integrating the continuity equation

$$\frac{\partial \rho}{\partial \mathrm{t}} + \frac{1}{\mathrm{r}^j}\frac{\partial}{\partial \mathrm{r}}(\mathrm{r}^j \rho \mathrm{v}) = 0 \tag{2.1}$$

and the energy equation

$$\frac{\partial}{\partial \mathrm{t}}(\rho c_v \mathrm{T}) + \frac{1}{\mathrm{r}^j}\frac{\partial}{\partial \mathrm{r}}\left(\mathrm{r}^j \rho \mathrm{v} c_p \mathrm{T} - \mathrm{r}^j k \frac{\partial \mathrm{T}}{\partial \mathrm{r}}\right) = 0, \tag{2.2}$$

supplemented with the equation of state for the ideal gas

$$\rho \mathrm{T} = \rho_o \mathrm{T}_o, \tag{2.3}$$

which is written with pressure differences neglected. These pressure differences, which are much smaller than the ambient pressure in this near-isobaric limit, can be computed a posteriori by integrating the momentum balance equation. In the formulation, ρ, T, and v denote, respectively, the density, temperature, and velocity of the gas, while c_v represents the specific heat at constant volume. For generality, the thermal conductivity k is allowed to vary in our analysis from its initial value k_o, with a temperature dependence given by

$$\frac{k}{k_o} = \left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)^{\sigma}, \tag{2.4}$$

where the exponent σ is typically in the range $0 \le \sigma \le 1$ in gases and takes the value $\sigma = 5/2$ for electronic conduction in plasmas. The initial and boundary conditions for (2.1) and (2.2) corresponding to an infinitesimally small heat source located at $\mathrm{r} = 0$ are

$$\mathrm{t} = 0, \quad \mathrm{r} > 0 : \ \mathrm{T} = \mathrm{T}_o, \quad \rho = \rho_o \tag{2.5}$$

and

$$\mathrm{t} > 0 \begin{cases} \mathrm{r} = 0 : & \mathrm{v} = 0, \ -2^j \pi^{\delta_j} \mathrm{r}^j k \partial \mathrm{T}/\partial \mathrm{r} = \mathrm{q}_j, \\ \mathrm{r} = \infty : & \mathrm{T} = \mathrm{T}_o, \end{cases} \tag{2.6}$$

where $\delta_j = 0$ if $j = 0$ and $\delta_j = 1$ otherwise.

The approximation (2.3) eliminates the time derivative in (2.2), because in this limit of near-isobaric heating, the internal energy does not accumulate locally in the flow field. Integrating the resulting equation, using the boundary condition at $\mathrm{r} = 0$, yields

$$2^j \pi^{\delta_j} \mathrm{r}^j \left(\mathrm{v} \rho_o c_p \mathrm{T}_o - k \frac{\partial \mathrm{T}}{\partial \mathrm{r}}\right) = \mathrm{q}_j. \tag{2.7}$$

As can be seen, the heat released at $\mathrm{r} = 0$ is transported partly by convection and partly by heat conduction. Introducing the dimensionless temperature $T = \mathrm{T}/\mathrm{T}_o = \rho_o/\rho$ and substituting (2.7) into (2.1) finally gives

$$\frac{1}{T^2}\frac{\partial T}{\partial \mathrm{t}} - \frac{1}{\mathrm{r}^j}\frac{\partial}{\partial \mathrm{r}}\left[\frac{\alpha_o}{T}\left(\frac{\mathrm{q}_j}{2^j \pi^{\delta_j} k_o \mathrm{T}_o} + \mathrm{r}^j T^{\sigma}\frac{\partial T}{\partial \mathrm{r}}\right)\right] = 0 \tag{2.8}$$

to be integrated with initial and boundary conditions

$$\left\{ \begin{array}{l} \mathrm{t} = 0 : \ T = 1, \\ t > 0 : \left\{ \begin{array}{l} \mathrm{r} = 0 : \ \mathrm{r}^j T^\sigma \partial T / \partial \mathrm{r} = -\mathrm{q}_j / (2^j \pi^{\delta_j} k_o \mathrm{T}_o), \\ \mathrm{r} = \infty : \ T = 1. \end{array} \right. \end{array} \right. \tag{2.9}$$

This nonlinear heat problem describes the buoyancy-free isobaric evolution of the gas temperature, subject to a localized energy source of rate q_j, which can vary with time.

3. The line source of heat. As previously mentioned, for the line source the solution to (2.8) when the heating rate q_1 is constant is of the self-similar form $T = T(\eta)$, involving the similarity variable $\eta = \mathrm{r}/(\alpha_o \mathrm{t})^{1/2}$, so that $T(\eta)$ is given by the solution of

$$\left[\eta^{-1}(q + \eta T^\sigma T_\eta) - \frac{\eta}{2}\right] T_\eta = T\eta^{-1}(\eta T^\sigma T_\eta)_\eta \left\{ \begin{array}{ll} \eta = 0 : & q + \eta T^\sigma T_\eta = 0, \\ \eta = \infty : & T = 1. \end{array} \right. \tag{3.1}$$

To simplify the notation throughout the text, subscripts will be utilized to denote differentiation with respect to a given variable, so that, for instance, $T_\eta = dT/d\eta$ in the above equation. Apart from the thermal-conductivity exponent σ, only the dimensionless heating rate

$$q = \frac{\mathrm{q}_1}{2\pi k_o T_o} \tag{3.2}$$

enters as a parameter in (3.1). As can be seen, besides the thermal-expansion velocity

$$u = \frac{\mathrm{v}}{(\alpha_o/\mathrm{t})^{1/2}} = \frac{1}{\eta}(q + \eta T^\sigma T_\eta), \tag{3.3}$$

the convective term incorporates an apparent negative velocity $-\eta/2$ due to the growing length scale used in the definition of η.

Sample distributions of $T(\eta)$ are shown in Figure 1 for different values of q, with a value $\sigma = 0.5$ adopted in the calculations for the temperature dependence of the conductivity. Integration by a shooting method was initiated near $\eta = 0$, where the temperature profile is of the form

$$T^{\sigma+1} \simeq -(\sigma + 1) q \ln \eta + B, \tag{3.4}$$

with $B(q, \sigma)$ representing an unknown constant that was varied in the shooting procedure to satisfy the boundary condition $T = 1$ at $\eta = \infty$. The resulting value of B is shown as an inset in Figure 1 for $\sigma = (0, 0.5, 1.0)$. Note that the local high-temperature description (3.4) can be of interest for the analysis of some related problems, such as the ignition of a reactive gas mixture by hot wires or by laser beams [10].

The temperature distribution can be used to determine from (3.3) the gas velocity induced by thermal expansion. This velocity is zero at the heat source and also at $\eta = \infty$ and reaches a maximum at an intermediate location, a result clearly seen in the velocity profiles exhibited in Figure 2. The effect of the heat source on the far field is that of a volumetric source of fluid, inducing radial velocities that decay according to $u \simeq q/\eta$ for $\eta \gg 1$.

The solution corresponding to small heating rates can be determined by introducing an expansion for $T - 1$ in increasing powers of q. Since in this case both ρ and k change by only a small amount from their unperturbed values ρ_o and k_o, the resulting solution is, in the first approximation, that corresponding to a solid with constant

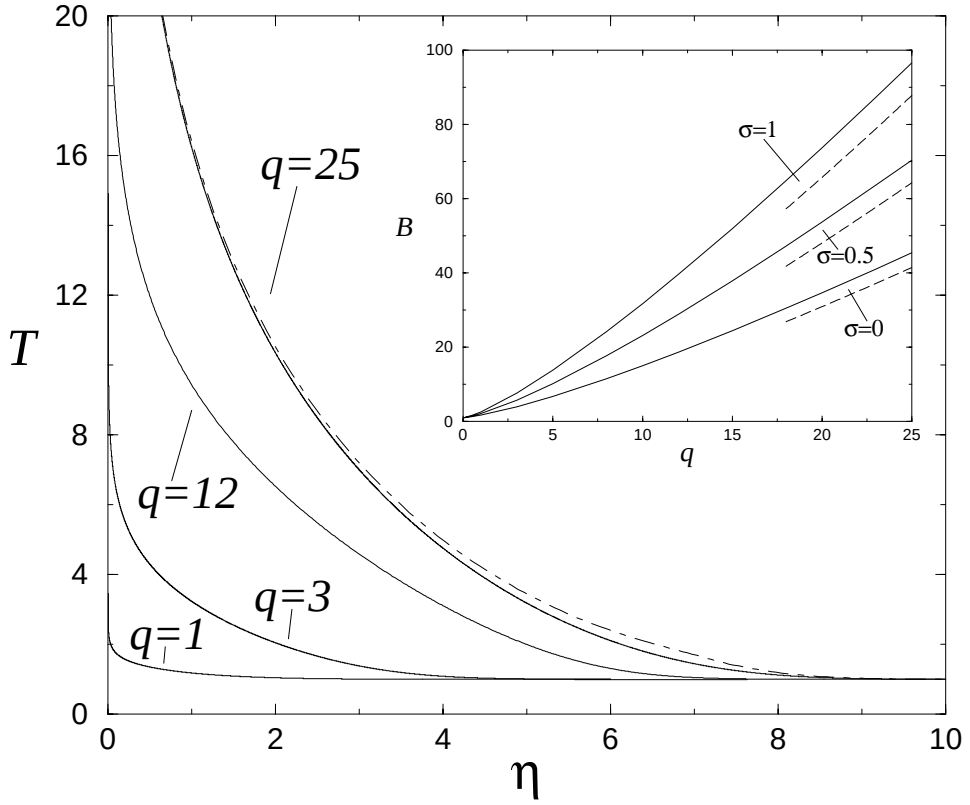

FIG. 1. *The temperature profiles obtained by integration of* (3.1) *with* $\sigma = 0.5$ *(solid lines) and from the large-q composite expansion (dot-dashed lines); the inset shows the variation with q of the constant B, along with the large-q prediction* $B = q[b + (\sigma + 1)\ln(q)/2]$.

thermal conductivity $(T-1)/q = \frac{1}{2}E_1(\eta^2/4)$ (see [4]), where E_1 is the exponential integral function [1]. The effect of the thermal expansion emerges in the solution, giving a small modification of order q^2 to the temperature increment $T-1$ and inducing small radial velocities, of order q, that can be determined from (3.3) to give $u = (q/\eta)[1-\exp(-\eta^2/4)]$. This description can be expected to fail as $T-1$ increases to values of order unity for $\eta \to 0$, in an exponentially small region around the axis corresponding to $\eta \sim \exp(-1/q)$. This region can be studied by employing $\ln(\eta)/q$ as an appropriately stretched coordinate, an analysis that gives $T^{\sigma+1} = 1-(\sigma+1)q\ln\eta$ as the leading-order representation for the temperature. This is in agreement with the results shown in the inset of Figure 1, where the constant B approaches unity as $q \to 0$.

The analysis of the limit of large heat release rates, $q \gg 1$, is more complicated and requires consideration of separate spatial regions. As seen in Figure 1, both the extent of the heated domain and the characteristic value of the temperature grow with increasing values of q. A simple order-of-magnitude analysis of (3.1) reveals that the rescaled variables $\xi = q^{-1/2}\eta$ and $\theta = q^{-1/(\sigma+1)}T$ are appropriate replacements for η and T in this limit of large q. Use of these alternative variables enables (3.1) to

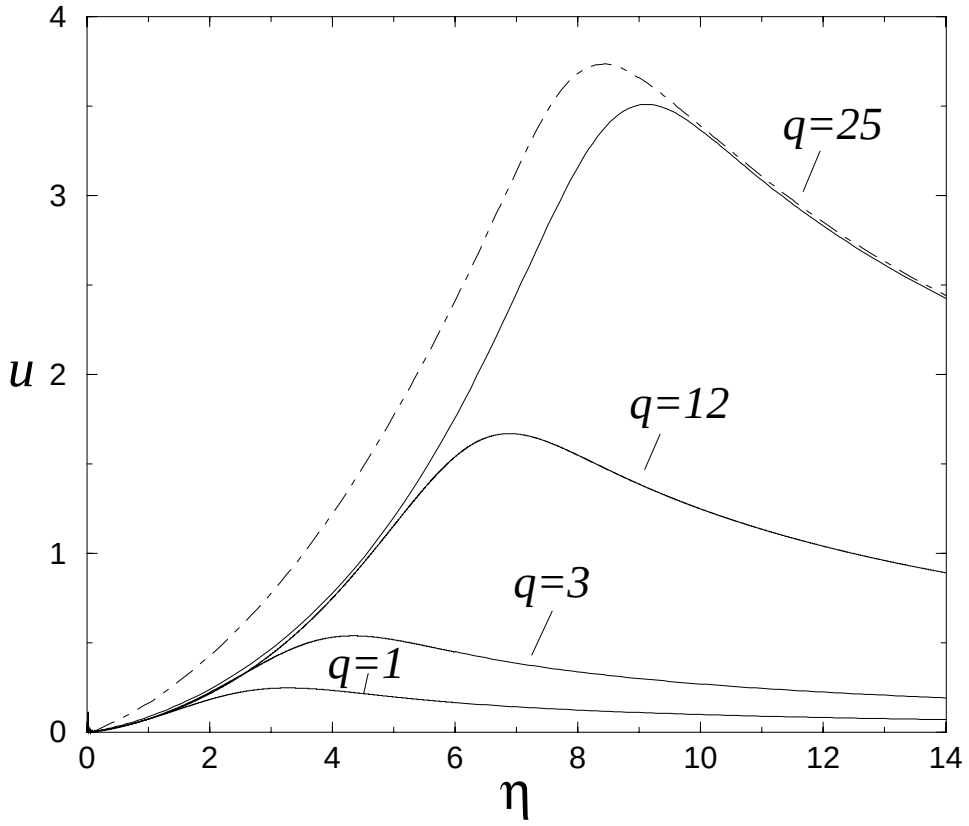

FIG. 2. *The velocity distribution* (3.3) *for* $\sigma = 0.5$ *evaluated with the temperature profiles determined numerically (solid lines) and with the large-q composite expansion (dot-dashed lines).*

be written in the form

$$\left[\xi^{-1}(1+\xi\theta^{\sigma}\theta_{\xi})-\frac{\xi}{2}\right]\theta_{\xi}=\theta\xi^{-1}(\xi\theta^{\sigma}\theta_{\xi})_{\xi}\begin{cases}\xi=0:\xi\theta^{\sigma}\theta_{\xi}=-1,\\ \xi=\infty:\theta=q^{-1/(\sigma+1)}.\end{cases}\tag{3.5}$$

3.1. The high-temperature region. Introducing an expansion of the form

$$\theta=\theta_0+q^{-\mu_1}\theta_1+\cdots\tag{3.6}$$

into (3.5) produces a series of problems that can be solved sequentially, with the order μ_1 for the first-order correction to the leading-order result being determined in the course of the analysis.

The problem emerging at leading order for the function θ_0,

$$\left[\xi^{-1}(1+\xi\theta_0^{\sigma}\theta_{0\xi})-\frac{\xi}{2}\right]\theta_{0\xi}=\theta_0\xi^{-1}(\xi\theta_0^{\sigma}\theta_{0\xi})_{\xi}\begin{cases}\xi=0:\xi\theta_0^{\sigma}\theta_{0\xi}=-1,\\ \xi=\sqrt{2}:\theta_0=0,\end{cases}\tag{3.7}$$

has a front solution that neatly defines the hot region. The location $\xi=\sqrt{2}$ of the front is determined a priori from inspection of (3.7) by noting that heat conduction vanishes as the temperature approaches its zero boundary value, so that convection remains as the only transport mechanism there. Therefore, the leading edge of the

temperature distribution must lie at $\xi = \sqrt{2}$, where the positive thermal-expansion velocity $U = q^{-1/2}u = \xi^{-1}(1 + \xi\theta^{\sigma}\theta_{\xi}) \simeq \xi^{-1}$ equals the negative apparent velocity $-\xi/2$ associated with the growing length scale. The front nature of the solution is clearly a result of the vanishing boundary temperature seen with the scales of this high-temperature region, as occurs in other problems of high-temperature hydrodynamics [13, 15, 22, 23].

The resulting function θ_0 is shown in Figure 3 for four different values of the thermal-conductivity exponent $\sigma = (0, 0.5, 1.0, 2.5)$. The numerical integration was started at $\xi \ll 1$, where $\theta_0^{\sigma+1} \simeq -(\sigma+1)\ln\xi + b$, with $b = (0.0477, 0.1557, 0.2914, 0.7637)$ for $\sigma = (0, 0.5, 1.0, 2.5)$. Note that, in terms of this shooting parameter, the constant B appearing in (3.4) can be expressed in the form $B = q[b + (\sigma + 1)\ln(q)/2]$, an asymptotic prediction tested in the inset of Figure 1. The temperature profiles are seen to approach the cold boundary $\xi = \sqrt{2}$ according to

$$\theta_0 = \left(\frac{1+\sigma}{1-\sigma}\right)^{1/(1+\sigma)} (\sqrt{2} - \xi)^{2/(1+\sigma)} \tag{3.8}$$

if $\sigma < 1$, according to

$$\theta_0 = \sqrt{2}(\sqrt{2} - \xi)\left[\ln\left(\frac{1}{\sqrt{2} - \xi}\right)\right]^{1/2} \tag{3.9}$$

if $\sigma = 1$, and according to

$$\theta_0 = E(\sqrt{2} - \xi)^{1/\sigma} \tag{3.10}$$

if $\sigma > 1$, where E is a constant to be determined as part of the numerical integration (e.g., $E = 2.7449$ for $\sigma = 5/2$).

As previously mentioned, the order μ_1 of the first-order correction to the leading-order results must be determined as part of the solution. Although the boundary condition at $\xi = \infty$ given in (3.5) suggests $\mu_1 = 1/(\sigma + 1)$, corresponding to a correction in temperature T of order unity, it is shown below that the necessary correction is in fact larger when $\sigma < 1$. The cases $\sigma = 1$ and $\sigma > 1$, which give $\mu_1 = 1/(\sigma + 1)$, are treated separately in the appendixes.

The function θ_1 satisfies the equation

$$\left(1 - \frac{\xi^2}{2}\right)\theta_{1\xi} = 2\theta_0(\xi\theta_0^{\sigma-1}\theta_{0\xi})_{\xi}\theta_1 + \theta_0^2(\xi\theta_0^{\sigma-1}\theta_{1\xi})_{\xi} + \theta_0^2(\xi(\sigma-1)\theta_0^{\sigma-2}\theta_{0\xi}\theta_1)_{\xi} \tag{3.11}$$

obtained from linearizing (3.5) about θ_0. The corresponding boundary conditions are

$$\xi = 0: \quad \xi\theta_0^{1+\sigma}\theta_{1\xi} - \sigma\theta_1 = 0 \tag{3.12}$$

and

$$\xi = \sqrt{2}: \quad \theta_1 = 0. \tag{3.13}$$

In addition to the trivial solution $\theta_1 = 0$, for each value of μ_1 the above problem admits a single nontrivial solution that can be determined aside from an arbitrary multiplicative factor. To discriminate the value of μ_1, one needs to investigate the corner layer that appears at distances of order $q^{-1/2}$ about $\xi = \sqrt{2}$, where the temperature becomes of order unity.

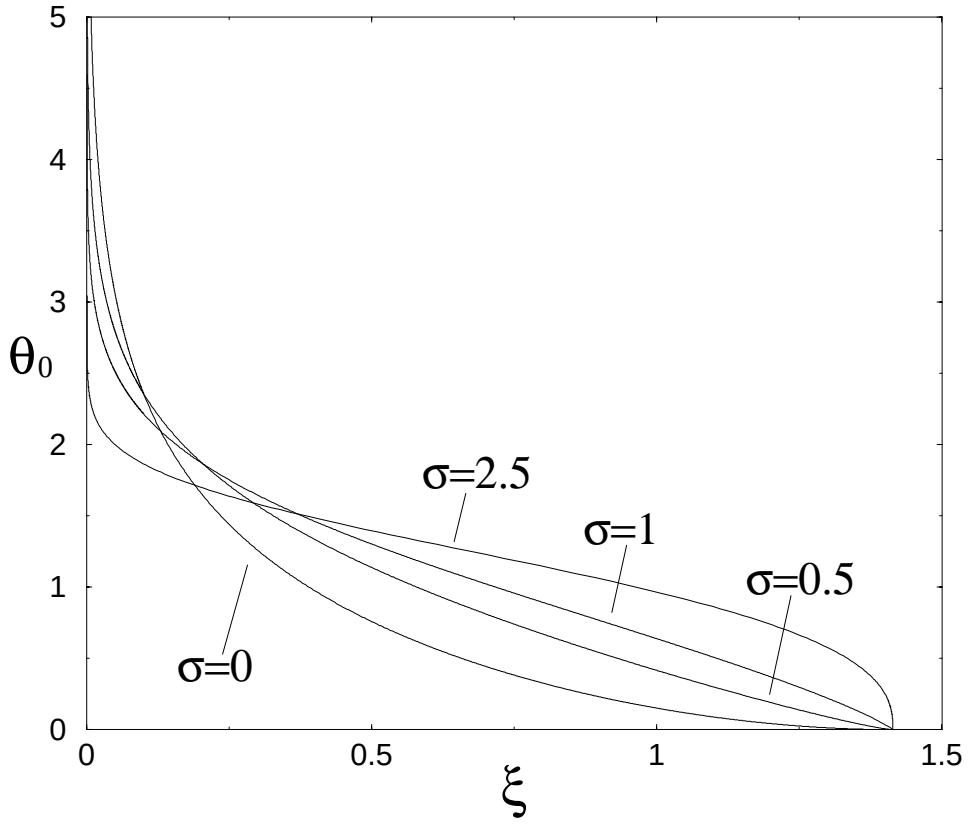

FIG. 3. *The temperature profiles obtained by integration of* (3.7) *for* $\sigma = (0, 0.5, 1.0, 2.5)$.

3.2. The corner layer. Around $\xi = \sqrt{2}$ the temperature must evolve from the cold boundary distribution given in (3.8) to the final asymptotic value $T = 1$. The description of the resulting corner layer must make use of the translated coordinate $\chi = \sqrt{2q} - \eta$. At leading order the problem becomes

$$T^2(T^{\sigma-1}T_\chi)_\chi + \chi T_\chi = 0 \begin{cases} \chi \to -\infty : T = 1, \\ \chi \to \infty : T \to \left(\frac{1+\sigma}{1-\sigma}\right)^{1/(1+\sigma)} \chi^{2/(1+\sigma)}. \end{cases} \tag{3.14}$$

The solution to this problem, which is given in Figure 4, determines in particular the asymptotic behavior for $\chi \to \infty$, where the temperature is seen to approach only slowly its boundary value according to

$$T - \left(\frac{1+\sigma}{1-\sigma}\right)^{1/(1+\sigma)} \chi^{2/(1+\sigma)} = A\chi^{(2-\sigma-\sqrt{2-\sigma^2})/(1+\sigma)}, \tag{3.15}$$

with A being a constant determined as part of the integration. Sample values are $A = (3.816, 4.5080, 5.664, 9.353)$ for $\sigma = (0, 0.25, 0.5, 0.75)$.

3.3. Uniformly valid description. Matching the solution given in (3.15) with the outer expansion $\theta = \theta_0 + t^{-\mu_1}\theta_1 + \cdots$ gives

$$\mu_1 = \frac{\sigma + \sqrt{2 - \sigma^2}}{2(1+\sigma)} \tag{3.16}$$

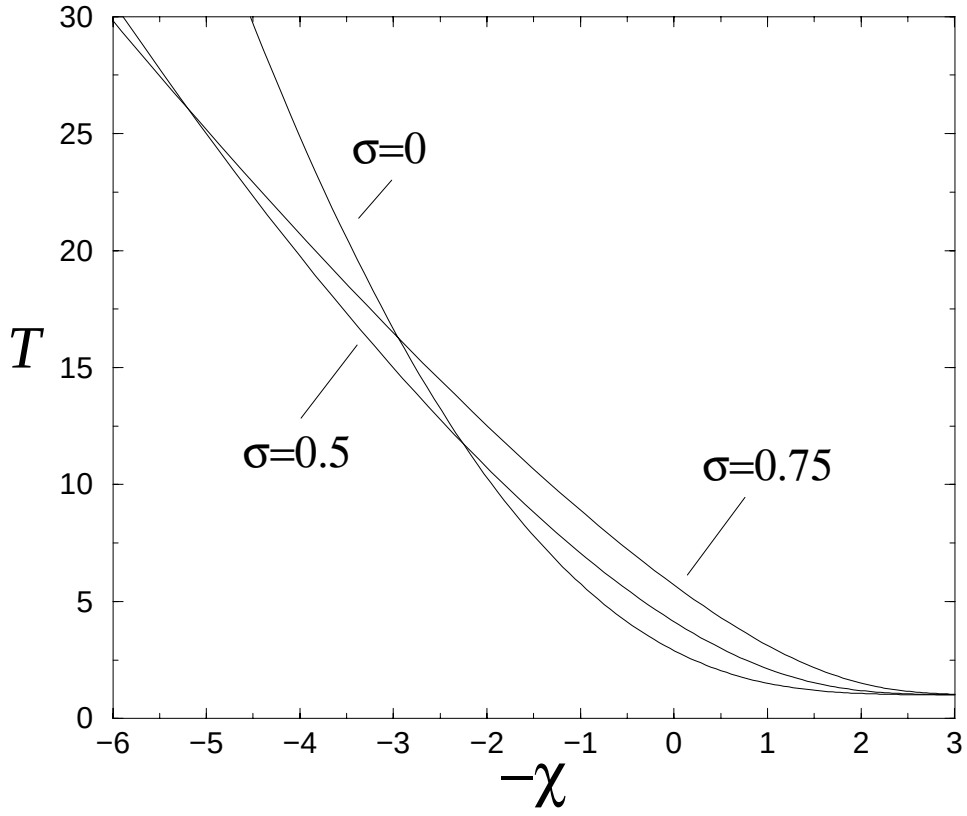

FIG. 4. *The temperature profile across the transition layer for different values of* σ.

for the order of the correction. Furthermore, the matching procedure provides

$$\xi \to \sqrt{2}: \quad \theta_1 = A(\sqrt{2}-\xi)^{(2-\sigma-\sqrt{2-\sigma^2})/(1+\sigma)} \tag{3.17}$$

as a replacement for (3.13), thereby removing all previously noted arbitrariness; i.e., (3.11) subject to (3.12) and (3.17) has a unique solution that must be determined by numerical integration.

A uniformly valid description for the temperature field can be obtained by combining the outer expansion for θ with the corner-layer profile according to the composite expansion

$$\begin{aligned} T(\eta) &= q^{1/(\sigma+1)}\left[\theta_0(\xi)+q^{-\mu_1}\theta_1(\xi)\right] \\ &+ T(\chi) - H(\sqrt{2}-\xi)\left[\left(\frac{1+\sigma}{1-\sigma}\right)^{1/(1+\sigma)}\chi^{2/(1+\sigma)} - A\chi^{(2-\sigma-\sqrt{2-\sigma^2})/(1+\sigma)}\right], \end{aligned} \tag{3.18}$$

where $H(\sqrt{2}-\xi)$ is the Heaviside function with origin $\xi=\sqrt{2}$ and $T(\chi)$ is the temperature profile across the corner layer, with the rescaled variables $\xi = q^{-1/2}\eta$ and $\chi = \sqrt{2q}-\eta$ being those utilized above for the outer region and for the corner layer, respectively. The resulting temperature profile and the accompanying velocity

profile, determined by straightforward substitution of (3.18) into (3.3), are plotted in Figures 1 and 2, showing reasonable agreement for the relatively large value of $q = 25$ considered.

4. Constant heat flux from a plane wall. Use of the characteristic scales identified above in (1.3) and (1.4) provides $t = \alpha_o[\mathrm{q}_0/(k_oT_o)]^2\mathrm{t}$, $r = [\mathrm{q}_0/(k_oT_o)]\mathrm{r}$, and $v = \mathrm{v}/[\mathrm{q}_0\alpha_o/(k_oT_o)]$ as dimensionless variables to describe the planar source. As first shown by Clarke, Kassoy, and Riley [5], the problem then reduces to that of integrating

$$\frac{\partial T}{\partial t} - T^2\frac{\partial}{\partial r}\left[\frac{1}{T}\left(1 + T^\sigma\frac{\partial T}{\partial r}\right)\right] = 0 \tag{4.1}$$

with initial condition

$$t = 0, \qquad 0 \le r < \infty : \quad T = 1 \tag{4.2}$$

and boundary conditions

$$t > 0 \begin{cases} r = 0 : & T^\sigma \partial T/\partial r = -1, \\ r = \infty : & T = 1, \end{cases} \tag{4.3}$$

while the velocity can be computed from (2.7) to give

$$v = 1 + T^\sigma\frac{\partial T}{\partial r}. \tag{4.4}$$

4.1. Temperature and velocity distributions. As can be seen, σ is the only parameter left in the problem. An exact solution is known only for $\sigma = 1$ (see [5]), a case for which the density-weighted coordinate $\mathrm{d}z = T^{-1}\mathrm{d}r$, often introduced for the analysis of variable-density boundary layers [17, 21], reduces (4.1)–(4.3) to the constant-density problem (see [4]), thereby yielding

$$T = 1 + 2t^{1/2}\,\mathrm{i}^1\mathrm{erfc}\left(\frac{z}{2t^{1/2}}\right) \quad \text{and} \quad r = z + t\left[1 - 4\,\mathrm{i}^2\mathrm{erfc}\left(\frac{z}{2t^{1/2}}\right)\right] \tag{4.5}$$

as an implicit representation for the temperature profile $T(r)$, where $\mathrm{i}^1\mathrm{erfc}$ and $\mathrm{i}^2\mathrm{erfc}$ denote repeated integrals of the complementary error function erfc (see [1]). Correspondingly, the velocity profile (4.4) reduces to $v = 1 - \mathrm{erfc}\left[\int_0^r T^{-1}\mathrm{d}r/(2t^{1/2})\right]$.

For $\sigma \neq 1$, the problem needs numerical integration. To handle the unbounded value of $\partial T/\partial t$ at $t = 0$, the initial condition (4.2) must be replaced in the numerical integrations with the leading-order representation of the temperature profile for $t \ll 1$, when the temperature increase from the initial value $T = 1$ is small, of order $t^{1/2}$, and is seen to be confined to a thin layer of characteristic thickness $t^{1/2}$ located in the vicinity of the wall. To describe this initial period it is convenient to introduce the self-similar variables $r/t^{1/2}$ and $(T-1)/t^{1/2}$ into (4.1)–(4.3), yielding in the first approximation the constant-density result (see [4]),

$$\frac{(T-1)}{t^{1/2}} = 2\,\mathrm{i}^1\mathrm{erfc}\left[\frac{r}{(2t^{1/2})}\right], \tag{4.6}$$

while the initial velocity distribution becomes

$$v = 1 - \mathrm{erfc}\left(\frac{r}{2t^{1/2}}\right). \tag{4.7}$$

Characteristic temperature profiles obtained for $\sigma = 0.5$ by numerical integration of (4.1) with boundary conditions (4.3) and with the initial profile (4.6) evaluated at $t \ll 1$ are shown in Figure 5, along with the accompanying velocity profiles determined by evaluating (4.4). The profiles at $t = 0.4$ are compared with the asymptotic predictions

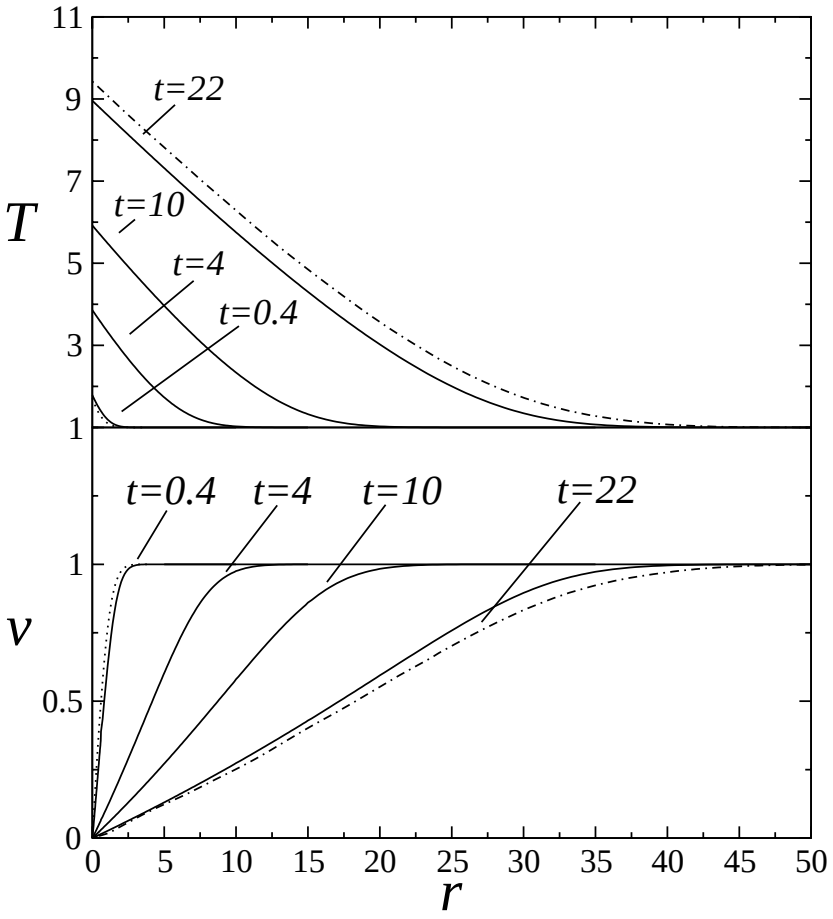

FIG. 5. *The temperature and velocity profiles obtained by integration of* (4.1)–(4.3) *for* $\sigma = 0.5$ *(solid lines); the profiles at* $t = 0.4$ *are compared with the asymptotic predictions given in* (4.6) *and* (4.7) *for* $t \ll 1$, *and the profiles at* $t = 22$ *are compared with the asymptotic predictions for* $t \gg 1$.

for small times given in (4.6) and (4.7), while the profile $t = 22$ is compared with the asymptotic prediction for $t \gg 1$, to be developed below.

In this planar case, the temperature remains bounded everywhere, growing with time. The evolution of the maximum temperature T_w attained at the wall is shown in Figure 6 for $\sigma = 0$ and $\sigma = 0.5$. The numerical solution is compared with the asymptotic description for small t,

$$T_w = 1 + \frac{2}{\pi^{1/2}} t^{1/2}, \tag{4.8}$$

obtained by evaluating (4.6) at $r = 0$, and also with the results given below for $t \gg 1$. Note that (4.8) gives exactly the wall temperature at all times when $\sigma = 1$, as can be seen by evaluating (4.5) at $z = 0$.

4.2. Solution for $t \gg 1$. The solution in this limit parallels that obtained above for the planar case in the limit $q \gg 1$. As previously mentioned, the temperature and the extent of the heated region continues to increase as time progresses. An order-of-magnitude analysis of (4.1) and (4.3) suggests the use of the modified variables

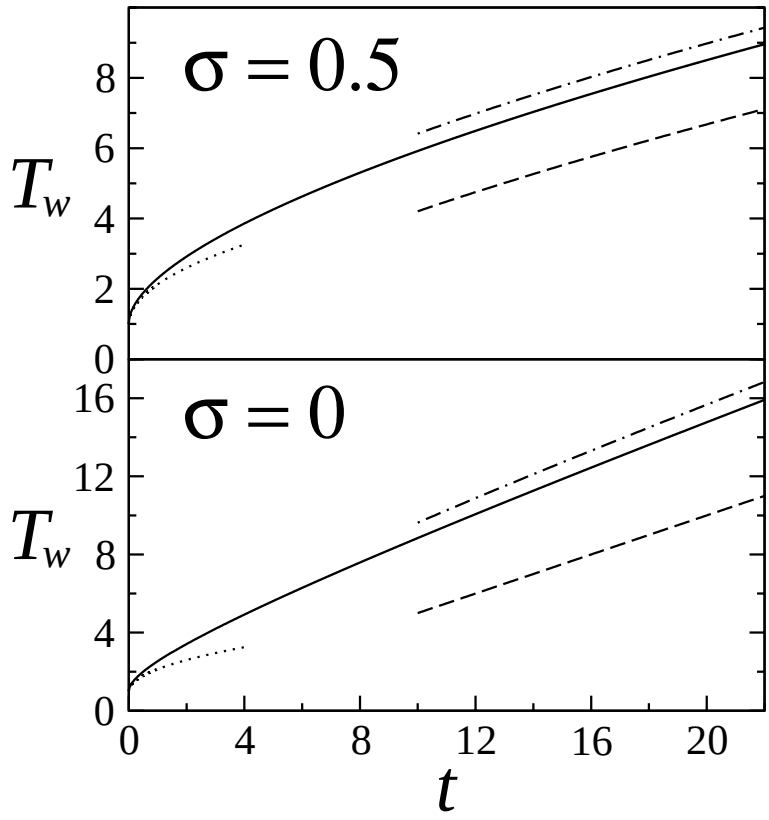

FIG. 6. *The evolution with time of the wall temperature for different values of σ obtained from numerical integration of* (4.1) *(solid lines), from the short-time prediction* (4.8) *(dotted lines), from the leading-order long-time prediction $T_w = \theta_0(0)t^{1/(\sigma+1)}$ (dashed lines), and from the two-term expansion $T_w = t^{1/(\sigma+1)}[\theta_0(0) + \theta_1(0)t^{-\mu_0}]$ (dot-dashed lines).*

$\theta = T/t^{1/(\sigma+1)}$ and $x = r/t$, of order unity, for the analysis of the limit $t \gg 1$, so that (4.1) and (4.3) take the form

$$t\theta_t + (1 + \theta^\sigma\theta_x - x)\theta_x + \frac{\theta}{\sigma+1} = \theta(\theta^\sigma\theta_x)_x \tag{4.9}$$

and

$$\begin{cases} x = 0: & \theta^\sigma\theta_x = -1, \\ x = \infty: & \theta = 1/t^{1/(\sigma+1)}, \end{cases} \tag{4.10}$$

while the velocity is given by $v = 1 + \theta^\sigma\theta_x$. As can be seen, because of the rescaled variables employed in this limit, an additional convective term $-x\theta_x$ appears in (4.9), together with a damping term $\theta/(\sigma+1)$ associated with the growing temperature scale.

Introducing the expansion $\theta(x,t) = \theta_0(x) + t^{-\mu_0}\theta_1(x) + \cdots$ permits us to solve the problem in a sequential manner, with the unknown value of μ_0 being determined as part of the asymptotic development as shown below. The function θ_0 is obtained from

$$(1 + \theta_0^\sigma\theta_{0x} - x)\theta_{0x} + \frac{\theta_0}{\sigma+1} = \theta_0(\theta_0^\sigma\theta_{0x})_x \begin{cases} x = 0: & \theta_0^\sigma\theta_{0x} = -1, \\ x = 1: & \theta_0 = 0. \end{cases} \tag{4.11}$$

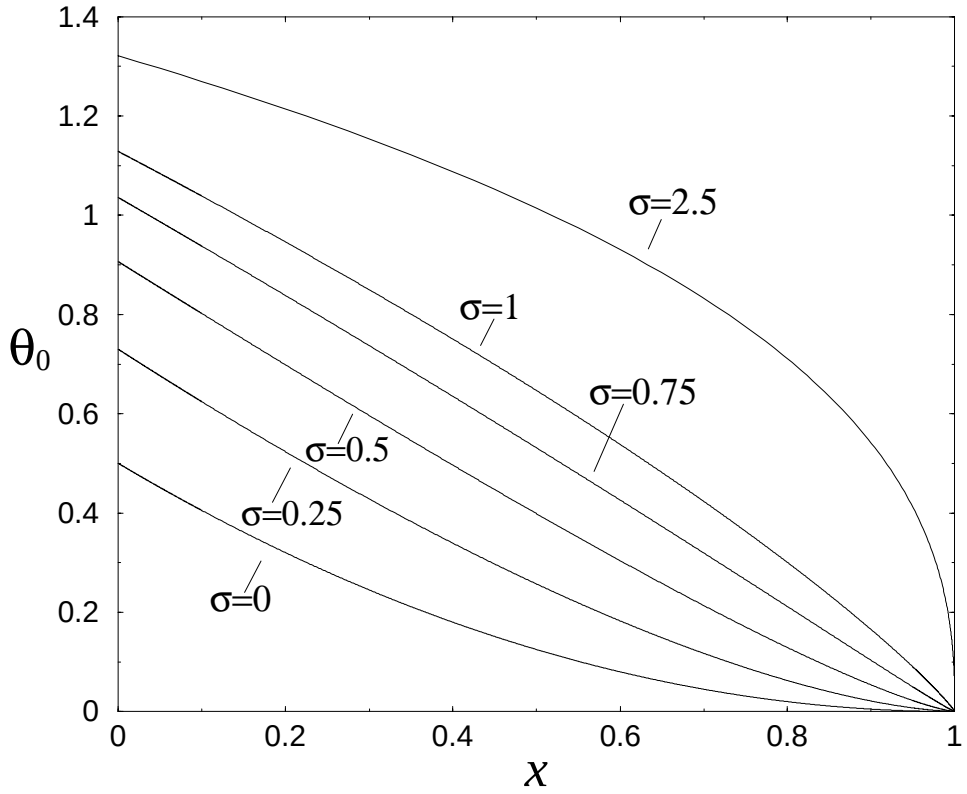

FIG. 7. *The temperature profile* θ_0 *obtained from* (4.9) *for different values of* σ.

The problem (4.11) has a front solution, similar to that seen in the axisymmetric case for $q \gg 1$. Since both the heat-conduction term, $\theta_0(\theta_0^\sigma \theta_{0x})_x$, and the damping term, $\theta_0/(\sigma+1)$, vanish as the temperature approaches its zero boundary value, the front of the temperature distribution must lie at $x = 1$, where the positive velocity due to thermal expansion, $v \simeq 1$, equals the apparent negative velocity $-x$.

When $\sigma = 0$, the problem given in (4.11) has the exact solution (see [5])

$$\begin{cases} \theta_0 = (1-x)^2/2, & v = x, \quad \text{for} \quad 0 < x < 1, \\ \theta_0 = 0, & v = 1, \quad \text{for} \quad 1 < x. \end{cases} \tag{4.12}$$

Another exact solution appears when $\sigma = 1$, as can be seen by rewriting (4.5) in terms of the intermediate coordinate $\bar{z} = z/(2t^{1/2})$ to give the implicit representation [5]

$$\theta_0 = 2\,\mathrm{i}^1\mathrm{erfc}(\bar{z}) \quad \text{and} \quad x = 1 - 4\,\mathrm{i}^2\mathrm{erfc}(\bar{z}). \tag{4.13}$$

Numerical integration is necessary to compute profiles of θ_0 when $\sigma \neq (0, 1)$. The temperature profiles (4.12) and (4.13) are shown in Figure 7 along with the numerical results corresponding to $\sigma = (0.25, 0.5, 0.75, 2.5)$. A shooting technique started at $x = 0$ was used for the integration of (4.11), with $\theta(0)$ utilized as the shooting parameter to be varied in the iteration procedure. This initial value, which equals $\theta_0(0) = 0.5$ for $\sigma = 0$, $\theta_0(0) = 2/\pi^{1/2}$ for $\sigma = 1$, and $\theta_0(0) = (0.7298, 0.9063, 1.0356, 1.3212)$ for $\sigma = (0.25, 0.5, 0.75, 2.5)$, determines the leading-order prediction for the wall temperature

$T_w = \theta_0(0)t^{1/(\sigma+1)}$. The comparisons with the results of the numerical integrations for large times, shown in Figure 6, clearly indicate that the asymptotic description must be carried on to the following order for increased accuracy.

This first-order correction $\theta_1(x)$ must satisfy the conservation equation (4.9) linearized about θ_0

$$\left(\frac{1}{\sigma+1} - \mu_0\right)\theta_1 + (1-x)\theta_{1x} = \theta_0^\sigma \left\{ \left[(\sigma+1)\theta_{0xx} - \sigma(1-\sigma)\frac{\theta_{0x}^2}{\theta_0} \right] \theta_1 - 2(1-\sigma)\theta_{0x}\theta_{1x} + \theta_0\theta_{1xx} \right\}, \tag{4.14}$$

subject to the boundary conditions

$$x = 0: \quad \theta_0^{1+\sigma}\theta_{1x} - \sigma\theta_1 = 0 \tag{4.15}$$

and

$$x = 1: \quad \theta_1 = 0. \tag{4.16}$$

As occurred before with the perturbation problem (3.11)–(3.13), for each value of μ_0 the problem (4.14)–(4.16) admits a single nontrivial solution that can be determined aside from an arbitrary multiplicative factor. The value of μ_0 is determined from matching the first two terms of the high-temperature distribution $\theta = \theta_0 + t^{-1/(\sigma+1)}\theta_1$ with the leading-order temperature representation across the corner layer, located around $x = 1$. It is remarkable that the first-order correction can be determined without taking into account the initial non–self-similar growth period, thereby indicating that memory effects emerge in the asymptotic development for large times only at higher orders. The associated corrections should be computed from matching the asymptotic results with the numerical computations for $t \sim 1$, a development not pursued further here.

As seen before for the line source, the structure of the solution for $\sigma = 1$ and $\sigma > 1$ is different from that encountered with $\sigma < 1$. The analyses of the former solutions, which are given in the appendixes, reveal that $\mu_0 = 1/(\sigma+1)$, corresponding to a correction in temperature T of order unity. The corrections are larger when $\sigma < 1$, when the leading-order temperature profile approaches the boundary $x = 1$ according to the local description

$$\theta_0 = \left(\frac{(1+\sigma)}{2(1-\sigma)}\right)^{1/(\sigma+1)} (1-x)^{2/(\sigma+1)}, \tag{4.17}$$

as can be obtained from (4.11). The corner layer, where the temperature T is of order unity, corresponds to distances $(1-x)$ of order t^{-1}. Introducing the coordinate $\chi = (t/2)^{1/2}(1 - r/t)$ reduces the leading-order problem to that given in (3.14), whose solution matches asymptotically with the boundary distribution (4.17). Furthermore, inspection of (3.15) indicates that the order of the first-order correction must be

$$\mu_0 = \frac{\sigma + \sqrt{2-\sigma^2}}{2(1+\sigma)} \tag{4.18}$$

to complete the matching, and that

$$x = 1: \quad \theta_1 = A[(1-x)/\sqrt{2}]^{(2-\sigma-\sqrt{2-\sigma^2}/(1+\sigma)} \tag{4.19}$$

must replace (4.16) to provide uniqueness for the solution to (4.14). In general, numerical integration is required to compute θ_1, the only exception being the case $\sigma = 0$, for which the exact solution

$$\theta_1 = \left(\frac{A}{2^{1-1/\sqrt{2}}}\right)\left[(1-x)^{2-\sqrt{2}} - \frac{2-\sqrt{2}}{1+\sqrt{2}}(1-x)^{1+\sqrt{2}}\right] \tag{4.20}$$

is available.

The results of the asymptotic analysis can be combined to give a uniformly valid description for the temperature. The corresponding composite expansion is that given in (3.18), with q, ξ, and μ_1 being replaced with t, x, and μ_0, and with the origin for the Heaviside function being $x = 1$. The resulting temperature profile and its accompanying velocity profile are plotted in Figure 5, showing good agreement for the value $t = 22$ considered. The relatively small errors observed, of order unity, correspond to a correction at the following order in the asymptotic analysis, which is not computed here. As seen in Figure 6, an error of order unity is also present in the second-order asymptotic prediction for the wall temperature $T_w = t^{1/(\sigma+1)}(\theta_0(0) + \theta_1(0)t^{-\mu_0})$, where $\theta_1(0) = (2.359, 2.223, 1.927, 1.486)$ for $\sigma = (0, 0.25, 0.5, 0.75)$.

5. The point source of heat. The characteristic scales for this problem, defined in order of magnitude in (1.3) and (1.4), were used to define the dimensionless variables $t = \alpha_o[\mathrm{q}_2/(4\pi k_o T_o)]^{-2}\mathrm{t}$, $r = \mathrm{r}/[\mathrm{q}_2/(4\pi k_o T_o)]$, and $v = \mathrm{v}[\mathrm{q}_2/(4\pi k_o T_o)]/\alpha_o$. The temperature T is determined by integrating

$$\frac{\partial T}{\partial t} - \frac{T^2}{r^2}\frac{\partial}{\partial r}\left[\frac{1}{T}\left(1 + T^\sigma r^2 \frac{\partial T}{\partial r}\right)\right] = 0, \tag{5.1}$$

with initial condition

$$t = 0, \;\; 0 \le r < \infty : \;\; T = 1 \tag{5.2}$$

and boundary conditions

$$t > 0 \begin{cases} r = 0 : & r^2 T^\sigma \partial T/\partial r = -1, \\ r = \infty : & T = 1, \end{cases} \tag{5.3}$$

while the velocity can be computed from

$$v = \frac{1}{r^2}\left(1 + r^2 T^\sigma \frac{\partial T}{\partial r}\right). \tag{5.4}$$

As in the planar case, σ remains as the only parameter left in the problem. Because of the boundary condition at $r = 0$, the temperature profile presents an infinite value at the point source for $t > 0$. Hence, the numerical integration of the problem (5.1)–(5.3) must account for the singular character of the solution near the origin, where

$$T^{\sigma+1} = \frac{(\sigma+1)}{r} + C(t). \tag{5.5}$$

In particular, the initial profile $T = 1$ must be replaced with the leading-order representation emerging for $t \ll 1$.

5.1. Initial temperature growth. As previously anticipated, the structure of the solution in this limit $t \ll 1$ is that found for $q \gg 1$ in the axisymmetric case and for $t \gg 1$ in the planar case, that is, a neatly defined central region of high temperature separated from the outer cold gas at temperature $T = T_o$ by a thin corner layer of warm fluid. The appropriate scales for length and temperature to describe the hot region, $t^{1/3}$ and $t^{-1/[3(\sigma+1)]}$, can be anticipated from the balance of the three terms in (5.1). Correspondingly, the associated rescaled variables $\theta = t^{1/[3(\sigma+1)]}T$ and $y = r/t^{1/3}$ reduce (5.1) and (5.3) to

$$t\theta_t + \left[y^{-2}(1 + y^2\theta^\sigma\theta_y) - \frac{y}{3}\right]\theta_y - \frac{\theta}{3(\sigma+1)} = \theta y^{-2}(y^2\theta^\sigma\theta_y)_y \tag{5.6}$$

and

$$\begin{cases} y = 0: & y^2\theta^\sigma\theta_y = -1, \\ y = \infty: & \theta = t^{1/[3(\sigma+1)]}. \end{cases} \tag{5.7}$$

Because of the growing length scale that has been introduced, besides the rescaled thermal-expansion velocity of order unity, $t^{2/3}v = y^{-2}(1+y^2\theta^\sigma\theta_y)$, there exists in (5.6) a negative apparent velocity $-y/3$. Similarly, the decreasing scale used for the temperature leads to the negative damping term $-\theta/[3(\sigma+1)]$.

Introducing the expansion $\theta(y,t) = \theta_0(y) + t^{\mu_2}\theta_1(y) + \cdots$ yields at leading order

$$\left[y^{-2}(1 + y^2\theta_0^\sigma\theta_{0y}) - \frac{y}{3}\right]\theta_{0y} - \frac{\theta_0}{3(\sigma+1)} = \theta_0 y^{-2}(y^2\theta_0^\sigma\theta_{0y})_y \tag{5.8}$$

to be integrated with boundary conditions

$$\begin{cases} y = 0: & y^2\theta_0^\sigma\theta_{0y} = -1, \\ y = 3^{1/3}: & \theta_0 = 0. \end{cases} \tag{5.9}$$

As before, the balance between the thermal-expansion velocity and the apparent velocity determines the location of the front $y = 3^{1/3}$. A shooting method was used to integrate (5.8). Integration was initiated near $y = 0$, where the temperature profile is of the form $\theta_0^{\sigma+1} = (\sigma+1)/y + c$. The unknown shooting parameter c was varied in the numerical integration to satisfy the boundary condition at $y = 3^{1/3}$, yielding the profiles shown in Figure 8. The negative constant $c = -(0.8390, 1.2173, 1.5806, 2.6397)$ for $\sigma = (0, 0.5.1.0, 2.5)$ provides $C = ct^{-1/3}$ for the initial evolution of the constant C in (5.5).

If $\sigma < 1$, the function θ_0 is seen to approach the boundary according to

$$\theta_0 = \left(\frac{7(1+\sigma)}{6(1-\sigma)}\right)^{1/(1+\sigma)} (3^{1/3} - y)^{2/(1+\sigma)}, \tag{5.10}$$

to be matched with the temperature profile across the transition layer, which is determined at leading order by (3.14), with the similarity coordinate being defined as $\chi = t^{-1/6}(6/7)^{1/2}(3^{1/3} - r/t^{1/3})$. Matching the first two terms in the expansion for θ with (3.15) yields in this case

$$\mu_2 = \frac{\sigma + \sqrt{2 - \sigma^2}}{6(1+\sigma)} \tag{5.11}$$

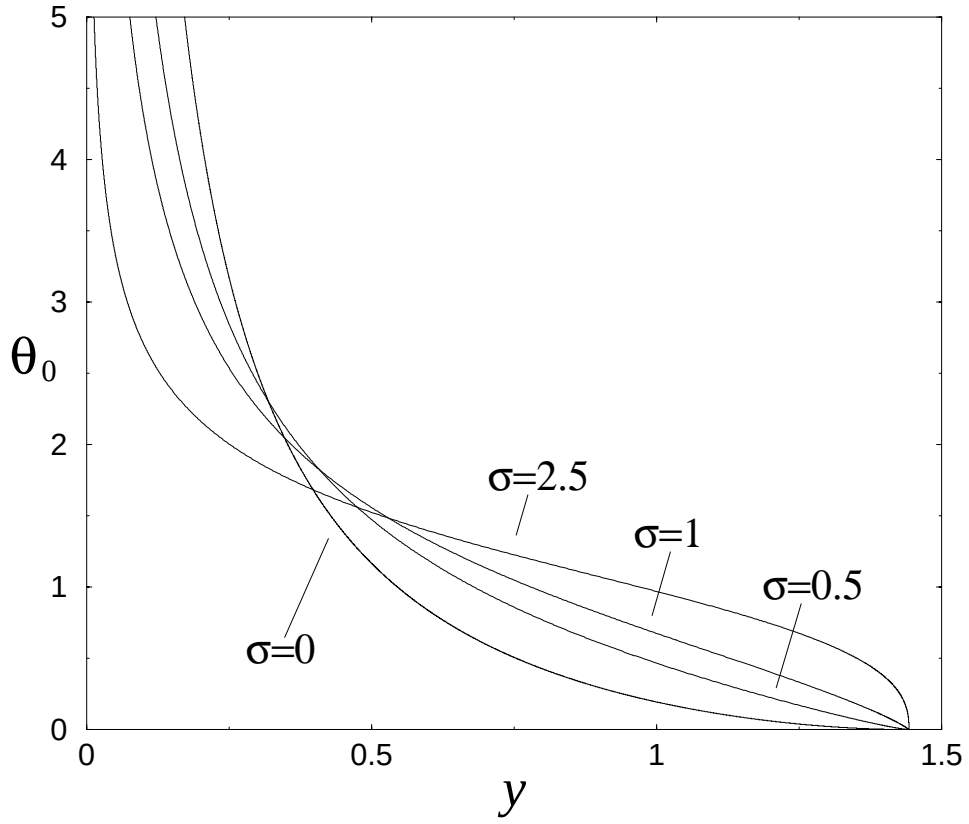

FIG. 8. *The temperature profiles obtained by integration of* (5.8) *for* $\sigma = (0, 0.5, 1.0, 2.5)$.

along with the asymptotic value

$$\theta_1 \to A\left[(7/6)^{1/2}(3^{1/3}-y)\right]^{(2-\sigma-\sqrt{2-\sigma^2})/(1+\sigma)} \tag{5.12}$$

to be used as a boundary condition at $y = 3^{1/3}$ when computing the first-order correction θ_1. The singular case $\sigma = 1$, when

$$\theta_0 = (3^{1/3}-y)\left[\frac{7}{3}\ln\left(\frac{1}{3^{1/3}-y}\right)\right]^{1/2} \tag{5.13}$$

for $0 < 3^{1/3} - y \ll 1$, is described separately in Appendix A, while the the case $\sigma > 1$, when $\theta_0 \propto (3^{1/3}-y)^{1/\sigma}$ near the boundary, is described in Appendix B.

5.2. Temperature and velocity distributions. As previously mentioned, the results of the asymptotic analysis for $t \ll 1$ were employed to enable integrations of (5.1). The two-term expansion $\theta = \theta_0 + t^{\mu_2}\theta_1$ was combined with the solution in the corner layer to provide the corresponding composite expansion, which is that given in (3.18) with the exponents $-1/[3(\sigma+1)]$ and μ_2 and the variables y and t replacing $1/(\sigma+1)$, $-\mu_1$, ξ, and q, respectively, and with the origin for the Heaviside function being $y = 3^{1/3}$. This composite expansion evaluated at $t = 0.01$ was used as an initial condition in the integrations shown in Figure 9, where the temperature

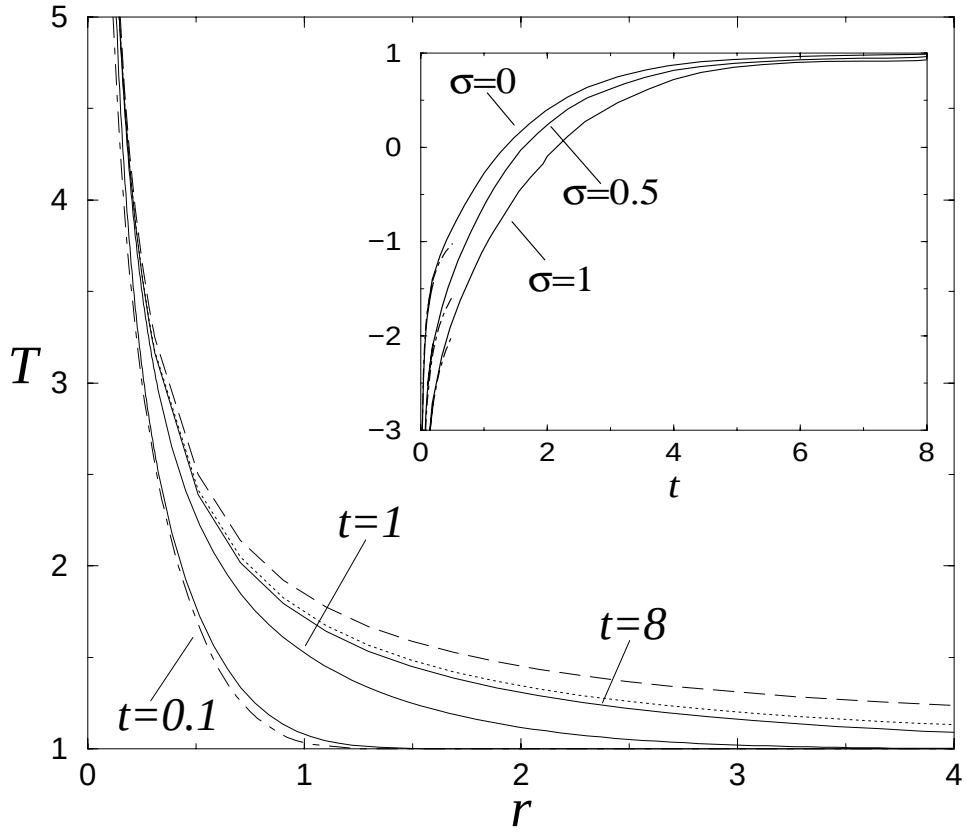

FIG. 9. *The temperature profile corresponding to the final steady solution* (5.14) *with* $\sigma = 0.5$ *(dashed line), along with those obtained by integration of* (5.1) *(solid lines), from the short-time composite expansion (dot-dashed line), and from the long-time quasi-steady expression* (5.16) *(dotted line); the inset shows the variation of the constant* C *together with the short-time prediction* $C = ct^{-1/3}$ *(dot-dashed lines).*

profiles corresponding to $t = (0.1, 1.0, 8.0)$ are shown. As can be observed, the comparison with the short-time composite expansion for $t = 0.1$ still gives reasonably good agreement. For completeness, the plot exhibits in an inset the variation with time of the constant C corresponding to the near-origin temperature distribution (5.5), along with the short-time prediction $C = ct^{-1/3}$.

The temperature profiles can be used in (5.4) to provide the associated velocity profiles, which are shown in Figure 10. The solution is seen to evolve rapidly from the initial large velocities of order $t^{-2/3}$ to the final quasi-stagnant solution corresponding to $t \gg 1$, which is described below.

5.3. Quasi-steady long-time solution. For asymptotically large values of t, the solution evolves to approach the profile

$$T_s = \left(1 + \frac{\sigma + 1}{r}\right)^{1/(\sigma+1)}. \tag{5.14}$$

This steady solution (5.14) and its associated velocity field $v = 0$ are correct to all algebraic orders at distances r of order unity; i.e., the investigation in the limit $t \gg 1$

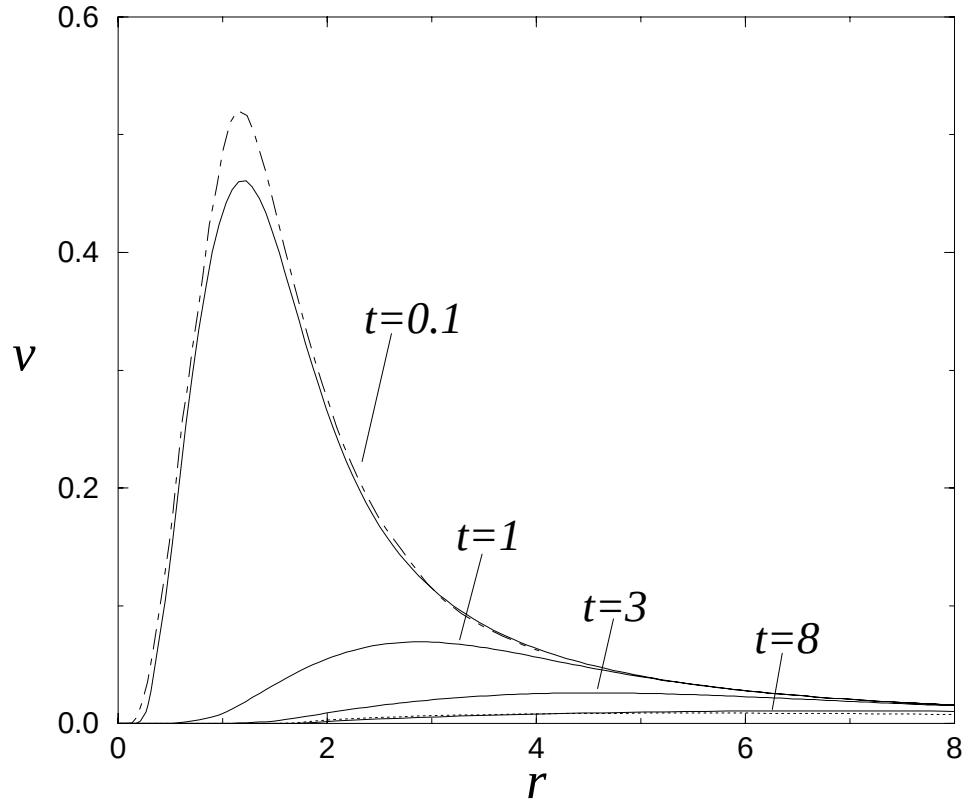

FIG. 10. *The velocity profiles obtained by evaluating* (5.4) *with the numerical temperature profile (solid lines) and with the short-time composite expansion (dot-dashed lines). The dotted line represents the long-time quasi-steady solution* (5.17).

of perturbations of the form $T = T_s(r) + t^{-\alpha}T_\alpha(r)$ yields $T_\alpha = 0$ irrespective of the value of α.

Unsteady effects are seen to enter farther from the heat source, in a far-field region corresponding to distances of order $t^{1/2}$ where only small temperature increments $T - 1$ of order $t^{-1/2}$ exist. To study this far-field region, it is convenient to employ the similarity coordinate $\eta = r/t^{1/2}$, along with the rescaled temperature increment $T - 1 = t^{-1/2}\Theta$, where an expansion of the form $\Theta(\eta, t) = \Theta_0(\eta) + t^{-1/2}\Theta_1(\eta) + \cdots$ is assumed. Introducing these new variables into (5.1) yields at leading order

$$(\eta^2/2)(\Theta_0 + \eta\Theta_{0\eta}) + (\eta^2\Theta_{0\eta})_\eta \begin{cases} \eta \to 0: & \Theta_0 = 1/\eta, \\ \eta \to \infty: & \Theta_0 = 0, \end{cases} \tag{5.15}$$

where the boundary condition as $\eta \to 0$ comes from matching with the steady solution (5.14). Straightforward integration gives $\Theta_0 = \eta^{-1}\mathrm{erfc}(\eta/2)$. Now combining the inner steady-state profile with the far-field transient solution provides the composite expansion $T = T_s + t^{-1/2}(\Theta_0 - 1/\eta)$, which gives the solution for the large-time temperature evolution with errors of order t^{-1}. At the same level of approximation, one may write

$$T = \left[1 + \frac{\sigma + 1}{r}\mathrm{erfc}\left(\frac{r}{2t^{1/2}}\right)\right]^{1/(\sigma+1)} \tag{5.16}$$

for the temperature profile, a compact expression that can be used in (5.4) to obtain the velocity profile

$$v = \frac{1}{r^2}\left[\operatorname{erf}\left(\frac{r}{2t^{1/2}}\right) - \frac{r}{(\pi t)^{1/2}}\exp\left(\frac{-r^2}{4t}\right)\right]. \tag{5.17}$$

Note that, when $\sigma = 0$, (5.16) corresponds to the exact self-similar solution achieved with constant density and constant conductivity [4]. These large-time predictions are compared in Figures 9 and 10 with results of numerical integrations for $t = 8$, yielding reasonably good agreement.

6. Conclusions. The transient, one-dimensional, near-isobaric, buoyancy-free flow field induced by a localized energy source of constant rate has been analyzed for planar, cylindrical, and spherical geometries. The convection induced by thermal expansion is seen to aid the transport of heat away from the source, in a nonlinear process of evolution that has been computed with account taken of the variable thermal conductivity typical of gases. Our study shows a self-similar solution for the line source, with the dimensionless heat release q entering as a parameter, while both the planar source and the point source require consideration of a nonlinear parabolic equation for the time evolution of the temperature.

The analysis reveals that front solutions emerge when the resulting temperatures become much larger than the initial temperature, with the front location being determined a priori from a convective balance. It is shown that the inner structure of the planar thin front, which is identical for all three geometrical configurations, determines the first-order correction in the hot region. Note that front solutions can also be expected to emerge as limiting solutions when a variable heating rate $\mathrm{q_j(t)}$ is applied, a problem to be addressed in future work. In that case, unsteady effects are likely to emerge in the hot region at leading order, while the inner structure of the thin front is expected to evolve in a quasi-steady manner. Also of interest is the investigation of the effect of compressibility on the heat propagation process from point and line sources, as done for planar sources by Clarke, Kassoy, and Riley [6]. Future research should also consider the solution emerging after the heat source is switched off. A related study is that of Meerson [12], who considered the conductive cooling of a gas heated by a localized deposition of heat.

The quantitative information provided here can be of interest, for instance, in analyses of ignition processes of a reactive gas mixture by localized energy sources [10]. The corresponding energy conservation equation should incorporate a heat-release term, and should be supplemented by conservation equations for the chemical species. The ignition process typically involves an initial quasi-frozen period with negligible chemical heat release, in which the description given here holds, followed by a period of significant exothermicity. For instance, for ignition of hydrogen-oxygen mixtures [10, 11], the initial branched-chain explosion [3, 14] produced after the heat source is turned on could be computed with the temperature and velocity fields given above. It can be anticipated that, since ignition often requires temperatures that are much larger than the normal ambient value, the front solutions described above will be particularly useful for these ignition studies.

Appendix A. The front solution for $\sigma = 1$. The structure of the front when $\sigma = 1$ is different from that described in the text for σ in the range $0 \le \sigma < 1$. We give first the solution corresponding to the line source of heat, and describe later the small modifications required for the planar and spherical geometries.

To construct the solution one needs to match the leading-order solution across the corner layer with the the two-term expansion $\theta = \theta_0 + q^{-1/2}\theta_1$, where we already anticipate that the order of the correction is $\mu_1 = 1/2$. The first-order correction θ_1 is determined by integrating

$$\left(1 - \frac{\xi^2}{2}\right)\theta_{1\xi} = 2\theta_0(\xi\theta_{0\xi})_\xi\theta_1 + \theta_0^2(\xi\theta_{1\xi})_\xi, \tag{A.1}$$

with boundary conditions

$$\begin{cases} \xi = 0: & (\theta_0\theta_1)_\xi = 0, \\ \xi = \sqrt{2}: & \theta_1 = 2D\ln[1/(\sqrt{2}-\xi)], \end{cases} \tag{A.2}$$

where D is an unknown constant to be determined as part of the matching procedure. Near the front, the two-term expansion $\theta = \theta_0 + q^{-1/2}\theta_1$ can be written as

$$\theta = \sqrt{2}(\sqrt{2}-\xi)\left[\ln\left(\frac{1}{\sqrt{2}-\xi}\right)\right]^{1/2} + q^{-1/2}2D\ln\left(\frac{1}{\sqrt{2}-\xi}\right), \tag{A.3}$$

where use has been made of (3.9).

Observation of (A.3) reveals that the corner layer, where the temperature becomes of order unity, is a factor $(\ln q)^{-1/2}$ thinner than that found with $\sigma < 1$, and is displaced towards the cold outer gas. More precisely, the front extends over distances of order $q^{-1/2}(\ln q)^{-1/2}$ around $\xi = \sqrt{2} + Dq^{-1/2}(\ln q)^{1/2}$, where D is the unknown constant appearing in (A.2). The appropriate inner coordinate must incorporate both a translation and a dilatation according to $\zeta = q^{1/2}(\ln q)^{1/2}[\sqrt{2} + Dq^{-1/2}(\ln q)^{1/2} - \xi]$. The problem reduces to that of integrating

$$T^2T_{\zeta\zeta} - DT_\zeta = 0 \begin{cases} \zeta \to -\infty: & T - 1 \to 0, \\ \zeta \to \infty: & T_\zeta - 1 \to 0, \end{cases} \tag{A.4}$$

where the boundary condition as $\zeta \to \infty$ comes from matching with (A.3). Integrating once with use made of the boundary condition $T(-\infty) = 1$ yields $T_\zeta = D(1 - 1/T)$, whereas imposing the linear profile on the hot boundary finally determines $D = 1$. This value can be used in (A.2) to complete the boundary conditions necessary to uniquely determine the first-order perturbation θ_1. Note that the second quadrature for the corner-layer equation, $T + \ln(T-1) = \zeta + \zeta_o$, contains an arbitrary translation ζ_o, which could be computed from higher-order terms in the asymptotic expansion.

The solutions encountered for $j = 0$ and $j = 2$ also respond to the same structure. Thus, for the planar heat source, the first-order perturbation θ_1 in the expansion $\theta = \theta_0 + t^{-1/2}\theta_1$ is determined from

$$(1-x)\theta_{1x} = 2\theta_0\theta_{0xx}\theta_1 + \theta_0^2\theta_{1xx} \begin{cases} x = 0: & (\theta_0\theta_1)_x = 0, \\ x = 1: & \theta_1 = 2D\ln[1/(1-x)], \end{cases} \tag{A.5}$$

while for the point source the expansion in the hot region becomes $\theta = \theta_0 + t^{1/6}\theta_1$, where θ_1 satisfies

$$\left(1 - \frac{y^3}{3}\right)\theta_{1y} = 2\theta_0(y^2\theta_{0y})_y\theta_1 + \theta_0^2(y^2\theta_{1y})_y, \tag{A.6}$$

with boundary conditions

$$\begin{cases} y = 0: & (\theta_0\theta_1)_y = 0, \\ y = 3^{1/3}: & \theta_1 = 6D\ln[1/(3^{1/3}-y)]. \end{cases} \tag{A.7}$$

On the other hand, the inner coordinates $\zeta = (t/2)^{1/2}(\ln t)^{1/2}[1+D(t/2)^{-1/2}(\ln t)^{1/2} - x]$ for $j = 0$, and $\zeta = [(7/2)\ln(1/t)]^{1/2}t^{-1/6}\left\{3^{1/3} + [(7/2)\ln(1/t)]^{1/2}t^{1/6}(D/3) - y\right\}$ for $j = 2$, reduce the corner-layer problem to (A.4), indicating that $D = 1$ should be used in (A.5) and (A.7).

Appendix B. The front solution for $\sigma > 1$. The structure of the thermal wave near the edge for $\sigma > 1$ is similar to that described above for $\sigma = 1$. As explained in the text, the asymptotic behavior of the leading-order profile θ_0 near the edge is

$$\theta_0 = E[(j+1)^{1/(j+1)} - \xi]^{1/\sigma}, \tag{B.1}$$

where E is a constant to be determined from the numerical integration, and where ξ should be replaced with x and y for $j = 0$ and $j = 2$, respectively, following the notation used in the text.

As before, we shall first give the solution corresponding to $j = 1$, for which we assume the expansion $\theta = \theta_0 + q^{-1/(\sigma+1)}\theta_1$. The first-order correction θ_1 can be calculated by integrating

$$\left(1 - \frac{\xi^2}{2}\right)\theta_{1\xi} = 2\theta_0(\xi\theta_0^{\sigma-1}\theta_{0\xi})_\xi\theta_1 + \theta_0^2(\xi\theta_0^{\sigma-1}\theta_{1\xi})_\xi + (\sigma-1)\theta_0^2(\xi\theta_0^{\sigma-2}\theta_{0\xi}\theta_1)_\xi, \tag{B.2}$$

with boundary conditions

$$\begin{cases} \xi = 0 : \theta_0\theta_{1\xi} + \sigma\theta_1\theta_{0\xi} = 0, \\ \xi = \sqrt{2} : \theta_1 = D(\sqrt{2} - \xi)^{(1-\sigma)/\sigma}, \end{cases} \tag{B.3}$$

where D is a constant to be determined below. Near the edge, the two-term expansion for θ gives

$$\theta = E(\sqrt{2} - \xi)^{1/\sigma} + D(\sqrt{2} - \xi)^{(1-\sigma)/\sigma}. \tag{B.4}$$

As seen before for $\sigma = 1$, the corner layer that appears is thinner than that corresponding to $\sigma < 1$ and is displaced towards the outer cold gas. Its inner structure can be described by introducing the variable $\zeta = (\sigma/E)q^{\sigma/(\sigma+1)}[\sqrt{2} + (\sigma/E)Dq^{-1/(\sigma+1)} - \xi]$ to yield the problem

$$T^2(T^{\sigma-1}T_\zeta)_\zeta - DT_\zeta = 0 \begin{cases} \zeta \to -\infty : T \to 1, \\ \zeta \to \infty : T_\zeta \to 1/\sigma\zeta^{(1-\sigma)/\sigma}. \end{cases} \tag{B.5}$$

The boundary condition as $\zeta \to -\infty$ can be used in a first quadrature to give us $D[(T-1)/T^\sigma] = T_\zeta$, which can be evaluated as $\zeta \to \infty$ to provide $D = 1/\sigma$ for the value of the unknown constant D.

The same structure appears near the edge of the thermal wave when $j = 0$ and $j = 2$. For the planar case, the first-order correction in the expansion $\theta = \theta_0 + t^{-1/(\sigma+1)}\theta_1$ is determined from

$$(1-x)\theta_{1x} = 2\theta_0(\theta_0^{\sigma-1}\theta_{0x})_x\theta_1 + \theta_0^2(\theta_0^{\sigma-1}\theta_{1x})_x + (\sigma-1)\theta_0^2(\theta_0^{\sigma-2}\theta_{0x}\theta_1)_x, \tag{B.6}$$

with boundary conditions

$$\begin{cases} x = 0 : \theta_0\theta_{1x} + \sigma\theta_1\theta_{0x} = 0, \\ x = 1 : \theta_1 = D(1-x)^{(1-\sigma)/\sigma}. \end{cases} \tag{B.7}$$

Similarly, the expansion for $j = 2$ is $\theta = \theta_0 + t^{1/[3(\sigma+1)]}\theta_1$, where θ_1 is computed by integrating

(B.8)
$$\left(1 - \frac{y^3}{3}\right)\theta_{1y} = 2\theta_0(y^2\theta_0^{\sigma-1}\theta_{0y})_y\theta_1 + \theta_0^2(y^2\theta_0^{\sigma-1}\theta_{1y})_y + (\sigma-1)\theta_0^2(y^2\theta_0^{\sigma-2}\theta_{0y}\theta_1)_y,$$

with boundary conditions

(B.9)
$$\begin{cases} y = 0 : \theta_0\theta_{1y} + \sigma\theta_1\theta_{0y} = 0, \\ y = 3^{1/3} : \theta_1 = 3D(3^{1/3} - y)^{(1-\sigma)/\sigma}. \end{cases}$$

Use of the inner coordinates $\zeta = (\sigma/E)(t/2)^{\sigma/(\sigma+1)}[1 + (\sigma/E)D(t/2)^{-1/(\sigma+1)} - x]$ for $j = 0$, and $\zeta = (\sigma/E)t^{-\sigma/[3(\sigma+1)]}[3^{1/3} + (\sigma/E)(D/3)t^{1/[3(\sigma+1)]} - y]$ for $j = 2$, reduces the description of the corner layer to the problem given in (B.5), so that the value $D = 1/\sigma$ is obtained for the constant D appearing in (B.7) and (B.9).

GENERALIZED TAYLOR–ARIS DISPERSION IN SPATIALLY PERIODIC MICROFLUIDIC NETWORKS. CHEMICAL REACTIONS*

K. D. DORFMAN† AND H. BRENNER‡

Abstract. Macrotransport theory governing solute transport in spatially periodic networks is extended so as to account for first-order, irreversible chemical reactions occurring within the network. The otherwise locally continuous interstices of the spatially periodic medium are modeled as a discrete graphical network by the expedient of dividing the repetitive unit cell into a finite number of subvolume elements i ($i = 1, 2, \ldots, n$) representing the nodes of the graph. The solute is assumed to be depleted at the uniform rate $k(i)$ when present in node i, i.e., each node i is modeled as a continuous stirred-tank flow reactor. The edges of the graph embody the solute transport processes occurring between nodes, either via "piggy-back" entrainment in a flowing fluid or external force-driven animation, or both, as well as by molecular diffusion. A Taylor–Aris-like "method-of-moments" scheme is applied to homogenize the resulting master equation governing solute transport within the network, thereby explicitly furnishing (i) a pair of adjoint matrix eigenvalue problems for computing the node-based macrotransport fields $P_0^\infty(i)$ and $A(i)$ (ultimately required to calculate the mean solute velocity $\bar{\mathbf{U}}^*$), as well as the network-scale, effective first-order irreversible reaction rate constant $\bar{K}^*$; (ii) a matrix equation for computing the third node-based macrotransport field $\mathbf{B}(i)$ (ultimately used to determine the Taylor–Aris solute dispersivity $\bar{\mathbf{D}}^*$); and (iii) edge-based summations of the three preceding nodal fields, used to calculate the network-scale solute velocity vector $\bar{\mathbf{U}}^*$ and dispersivity dyadic $\bar{\mathbf{D}}^*$. The computational simplicity of this graphical network scheme, in contrast with the original interstitially continuous Taylor–Aris macrotransport paradigm, is demonstrated in the context of an elementary geometric model of a porous medium.

Key words. Taylor dispersion, stochastic processes, asymptotics

1. Introduction.

The integration of microscale reaction protocols with downstream microfluidic chromatographic separation techniques has spearheaded the development of miniaturized total analysis systems (μ-TAS) [18, 20, 23] directed towards low-volume (point-of-use) chemical processes and biological assays in microchip environments. Constructing such devices with precision microfabrication techniques enables the creation of highly reproducible periodic microscale structures of any mode of arrangement, whose unit cell configurations can be designed for optimal performance. Concurrently, the relatively new field of "microreaction engineering" [19] has employed these fabrication techniques to produce increasingly complex microscale reactor architectures. Globally interpreting the performance of these devices necessitates knowledge of the three device-scale parameters serving to quantify the effective transport processes, namely, the mean solute depletion rate $\bar{K}^*$, velocity vector $\bar{\mathbf{U}}^*$, and dispersion dyadic $\bar{\mathbf{D}}^*$. Computing these global parameters from knowledge of the detailed microscale (unit cell) parameters characterizing the device necessitates

creating theoretical tools sufficient to do justice to the technological advances implicit therein, while at the same time being sufficiently simple to render the computations tractable. This is the goal of the scheme outlined herein.

A previous contribution [12] demonstrated that graph theoretical models of microfluidic devices could be satisfactorily employed to compute $\bar{\mathbf{U}}^*$ and $\bar{\mathbf{D}}^*$ for nonreactive systems with a degree of rigor consistent with conventional (i.e., interstitially continuous) spatially periodic Taylor–Aris models, the latter models requiring vastly more detailed microscale data and computational resources. Network models of this type prove especially useful in microfluidic contexts due to their ability to straightforwardly incorporate complicated topologies into the requisite analysis. Such graphical network modeling entails subdividing the otherwise continuous solute transport path within the spatially periodic interstitial domain of the device into discrete volume elements. These constitute the nodes of the graph, which are treated simply as "points." Transport between such volume elements occurs within the channels connecting them. These constitute the edges of the graph, regarded simply as "lines" connecting the points, with the transport rates occurring therein quantified by experimentally measurable, albeit averaged, discrete local-scale transport parameters. As such, the requisite internode convective and diffusive transport rates must be specified for each edge of the graph. In addition, a "mixing rule" must be specified to govern the choice of intersectional egress channel for those solute particles instantaneously situated within the channel intersections and about to exit.

In the absence of the present reactive feature, application of a rigorous Taylor–Aris-like "method-of-moments" scheme to the lumped-parameter, local-scale transport processes occurring within the spatially periodic network produced a generic paradigm [12], enabling the calculation of $\bar{\mathbf{U}}^*$ and $\bar{\mathbf{D}}^*$ from knowledge of the prescribed local-scale data. In the present contribution, we extend this nonreactive network scheme to include the depletion of physicochemically reactive solutes within the network, either via chemical reaction or by irreversible adsorption onto the walls of the medium. In the spirit of previous generalized Taylor–Aris analyses [9], we develop a generic computational scheme for extracting the key macroscale parameters, namely, $\bar{K}^*$, $\bar{\mathbf{U}}^*$, and $\bar{\mathbf{D}}^*$, from the prescribed microscale data. Aside from their Lagrangian definitions, the latter trio of parameters also possess Eulerian interpretations as the transport coefficients appearing in the "macrotransport" equation [9],

$$\frac{\partial \bar{P}}{\partial t} + \bar{\mathbf{U}}^* \cdot \bar{\nabla} \bar{P} - \bar{\mathbf{D}}^* : \bar{\nabla} \bar{\nabla} \bar{P} + \bar{K}^* \bar{P} = A\left(i_0\right) \delta\left(\mathbf{R_I} - \mathbf{R_{I_0}}\right) \delta\left(t\right), \tag{1.1}$$

quantifying the asymptotic, long-time transport processes of the reactive solute probability density. (What is meant by long-time will be established in section 4.) In the latter, $\bar{P}$ is a coarse-grained probability density, $\bar{\nabla}$ is a coarse-grained gradient operator, δ is the Dirac delta function, $\mathbf{R_I}$ is the unit cell location (c.f. (2.1)), and i_0 and $\mathbf{R_{I_0}}$, respectively, identify the local and unit cell scale initial locations of the solute pulse. Importantly, the magnitude of the (fictitious) initial condition appearing in the above macrotransport equation is not necessarily equal to that of the true initial condition [7], with the difference quantified by the fictitious initial condition field $A(i)$ (this field will be determined in our asymptotic analysis). Consequently, although the macrotransport coefficients $\bar{K}^*$, $\bar{\mathbf{U}}^*$, and $\bar{\mathbf{D}}^*$ will themselves prove to be independent of the initial condition, at least for long-times validating (1.1), the effective equation still depends upon the initial condition. This memory effect contrasts directly with the Taylor–Aris description of conservative transport processes, wherein the effective equation "forgets" the initial condition. Indeed, the incorporation of the

fictitious initial condition is an essential feature of effective transport equations for nonconservative transport processes [7].

Numerous schemes, displaying varying degrees of rigor and sophistication, have already been proposed in the literature for formulating an effective equation and calculating the coefficients appearing therein. With the existence of sufficient statistical data created from stochastic simulations, approximate values of these global transport rate parameters may be extracted from unidirectional capillary transport models [2, 3, 40], pore-effectiveness factors [17], or other algorithms for simulating particle transport [32]. Alternatively, analytical techniques, such as effective-medium theories [10, 11, 21, 22, 26, 29], multiple-scales analyses [27], volume-averaging [33], center-manifold theory [5, 6], effective stream-tube ensembles [16], and general lumping analyses [25], have been invoked to homogenize the unsteady convection-diffusion-reaction transport equation governing the solute transport through the interstices of the periodic array. These latter techniques are well adapted to characterize disordered ("random") porous media or nonlinear chemical reaction rates (or both), along with the concomitant degree of mathematical and computational complexity accompanying such schemes. Indeed, variations of these schemes have been employed to analyze transport in randomly connected reactive networks [2, 3, 4, 17, 24, 34, 40], in particular near to the percolation limit [3, 34, 39, 40].

In what follows, only first-order, irreversible reactions occurring in the interstices of a regular, spatially periodic "porous medium" are considered. Analogous to our prior analysis of nonreactive media [12], we adapt the spatially periodic moment scheme proposed originally by Dungan, Shapiro, and Brenner [14] to the network model. Such generalized moment analyses constitute physically reasonable methods for homogenizing linear transport equations, while sidestepping the mathematical and computational intractabilities inherent in the aforementioned, more detailed homogenization theories. As a consequence, our analysis, when brought to fruition, furnishes a straightforward matrix equation/edge summation scheme for computing $\bar{K}^*$, $\bar{\mathbf{U}}^*$, and $\bar{\mathbf{D}}^*$. The computational simplicity of the resulting scheme renders parametric studies of the macrotransport processes computationally feasible, even for large networks with complex architectures.

Apart from the explicit μ-TAS and microreaction engineering applications cited above, the generic paradigm to be developed is of broader interest in applications lying outside of these fields. Indeed, various homogenization procedures, albeit devoid of our rigorous Taylor–Aris network formalism, have previously been invoked to study catalysis [3, 17, 31, 33, 34, 39, 40], reduced kinetic models [25], transport in chemical reactors and porous media [2, 6, 14, 15, 16, 17, 27, 28, 30, 34], and irreversible adsorption phenomena [4, 24, 32, 34, 38]. One particularly interesting use of the notion of homogenization involves extracting macroscopically observable reaction rates from molecular-scale models of coupled reaction-diffusion phenomena [10, 11, 21, 22, 26, 29].

This paper is organized as follows. Section 2 outlines the graph construction and concomitant master equation governing the solute (probability density) transport process. Section 3 details an adaptation of the generalized moment scheme [14] to the graphical master equation. Asymptotic long-time moments of the probability density are evaluated in section 4, thereby furnishing a generic paradigm for computing the macrotransport parameters from the prescribed microscale data. This paradigm is applied in section 5 to a relatively straightforward reactive network model, demonstrating thereby the ready applicability of this scheme towards extracting complex, *nonlinear macroscopic* behavior from otherwise nominally *linear microscale* systems.

2. Microscale description. The general protocol for converting an interstitially continuous spatially periodic model into a graphical network model was discussed at length in our prior contribution [12]. Consequently, the exposition which follows is appropriately abbreviated, making adjustments to the prior discretization technique, where necessary, to properly account for the nontrivial feature of (locally) spatially nonuniform chemical reactions. Reference [12] should be consulted for further details.

2.1. Continuous model. Attention is focused exclusively upon convective-diffusive-reactive transport processes occurring in "strongly connected," spatially periodic networks. The spatially periodic medium is characterized by the existence of a repetitive unit cell, extending indefinitely in all directions. The use of infinitely extended networks eliminates the need to explicitly account for "end effects." As real networks are finite in extent, the present analysis is expected to be strictly asymptotically valid only for circumstances where the number, N, of unit cells comprising the real system is large, i.e., $N \gg 1$. While the present unbounded analysis is mathematically consistent, care must be taken in its direct application to bounded systems. Explicitly, it has been shown [5], in the context of center-manifold theory, that Taylor–Aris dispersion models of this type may not be applicable to finite systems when local-space diffusion is not the shortest time scale. Moreover, sufficiently short residence times in bounded systems may fail to satisfy the requisite long-time criteria (see section 4). In the latter case, the present asymptotic analysis will no longer be valid.

The geometry of the (three-dimensional) unit cell is quantified by a trio of base lattice vectors $\{\mathbf{l}_1, \mathbf{l}_2, \mathbf{l}_3\}$, which are subject to the restriction that the magnitude of their scalar triple product, $|\mathbf{l}_1 \times \mathbf{l}_2 \cdot \mathbf{l}_3|$, is equal to the superficial volume, τ_0, of the unit cell [9]. The location of a given unit cell within the infinite array is identified by a triad of integers $\mathbf{I} \equiv (I_1, I_2, I_3)$ ($I_j = 0, \pm 1, \pm 2, \ldots, \pm\infty$; $j = 1, 2, 3$) whereby the centroid of cell $\mathbf{I}$ is vectorially displaced from an arbitrary origin situated at $\mathbf{R}_0 = (0, 0, 0)$ by an amount represented by the discrete position vector

$$\mathbf{R}_\mathbf{I} = \mathbf{l}_1 I_1 + \mathbf{l}_2 I_2 + \mathbf{l}_3 I_3. \tag{2.1}$$

The interstitial domain of the unit cell is decomposed into a finite number of subvolume elements i ($i = 1, 2, \ldots, n$), here represented as the nodes of the graph.[1] Consequently, the instantaneous location of a solute particle on the graph is denoted by the discrete matrix/integer pair $(\mathbf{I}, i)$. Each node i is characterized by its volume, $v(i)$, and its reaction rate constant, $k(i)$ ($k \geq 0$), the latter quantifying the irreversible, first-order rate of solute depletion (if any) occurring therein. Consequently, the periodic network may be envisioned as composed of a strongly connected network of homogeneous, continuous stirred-tank flow reactors (CSTFRs).

Transport between contiguous subvolume elements, say, nodes i' and i, is represented by the edges of the graph. The edge geometry requires specifying the edge length, $l(j)$, corresponding to the distance between the respective centroids of the subvolume elements i' and i (connected by edge j), and the edge's effective channel cross-sectional area, $A(j)$. In addition to molecular diffusion, solute motion within the

[1] In considering purely convective-diffusive transport [12], each subvolume element was defined (for the sake of definiteness) to consist of the volume of a channel intersection plus half the volume of those channels incident to that intersection. This restriction is relaxed in what follows, since we will require later that the reaction rate be uniform within a given subvolume element.

edges of the network is assumed to arise from passive "piggy-back" entrainment in a flowing solvent and/or by the action of an externally applied force acting on the solute molecules. As in our earlier graphical network model [12], these transport mechanisms here are quantified by the mean solute speed, $U(j)$, and dispersivity, $D(j)$, prevailing in edge j. Both are regarded as being scalars within that edge, their tensorial attributes being associated with the spatial direction (orientation) of the channel centerline equipollent to that edge. The edge dispersivity $D(j)$ includes contributions from both molecular diffusion and Taylor–Aris dispersion, the latter arising from any local flow inhomogeneities existing within the channel. For a channel of sufficiently large aspect ratio, the microscale parameters $U(j)$ and $D(j)$ are calculable, at least in principle, from classical macrotransport theory [9]. In lieu of sufficient hydrodynamic data for effecting their calculation, these parameters may also be measured experimentally. Further details regarding their evaluation in such circumstances are available elsewhere [12].

Since multiple edges j are typically associated with a single node i,[2] the preference for the solute to choose a particular edge j upon exiting node i is assumed to be governed quantitatively by a mixing parameter $K(j)$. The numerous models proposed for estimating this parameter are reviewed in our prior, nonreactive contribution [12]. The hypotheses underlying the three most widely prevalent models are (i) perfect mixing ($K(j) = 1$), where the channel intersections are simply envisioned as large mixing volumes; (ii) flow-rate proportionality ($K(j) \propto U(j)A(j)$), where, for convection-dominated flows, it is assumed that the intersection residence time is insufficient for the particle to cross many streamlines within the intersection before exiting; and (iii) thermodynamic partitioning ($K(j) =$ a function of the solute physicochemical properties), where, for diffusion-dominated flows, the longer intersection residence time suffices to establish thermodynamic equilibrium. With use of the preceding geometrical data and transport parameters, the edge convection rate, $c(j)$, and edge diffusion (dispersion) rate, $d(j)$, are defined as the respective volumetric flow rates,

$$c(j) \overset{\text{def.}}{=} K(j)U(j)A(j), \qquad d(j) \overset{\text{def.}}{=} K(j)\frac{D(j)A(j)}{l(j)}. \tag{2.2}$$

2.2. Graphical model. In order to clarify the preceding discussion, as well as to facilitate construction of the requisite graphs, consider by way of example the reactive medium depicted in Figure 1. The network repeats indefinitely in the x-direction, whereby its unidirectional lattice geometry is characterized by the single base lattice vector $\mathbf{l}_x = \hat{\mathbf{x}} l_x$, with $\hat{\mathbf{x}}$ a unit vector in the x-direction and $l_x = |\mathbf{l}_x|$ the period of the unit cell. The single unit cell, indicated by the box, is shaded to correspond to its graphical decomposition into the trio of volume elements, $i = \{a, b, c\}$.

Figure 2(a) depicts the basic graph [12], Γ_b, constructed from the network in Figure 1. The basic graph consists of those nodes contained within a representative cell, say, $\mathbf{I}$, as well as those nodes located in an adjacent cell, $\mathbf{I}'$, possessing an edge directed into cell $\mathbf{I}$.[3] The edge direction is chosen such that the convective flow

[2] A node possessing a single incident edge corresponds to a "dead-end" bond in the network model. The strong connectivity of the network requires that at least one node in the unit cell possess multiple incident edges.

[3] The notation $\mathbf{I}'$ is invoked to generically denote a cell adjacent to $\mathbf{I}$. For networks with multiple adjacent cells, possessing a number of edges entering cell $\mathbf{I}$, the respective cells would be referred to notationally as $\mathbf{I}'$, $\mathbf{I}''$, etc.

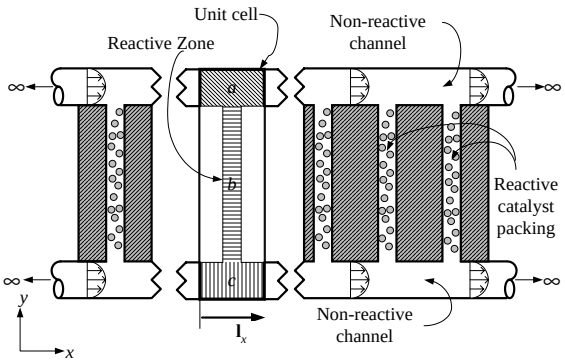

FIG. 1. *Spatially periodic, unidirectional reactive network consisting of two continuous, infinitely extended, nonreactive cylindrical ducts, periodically connected by thin, cylindrical tubes containing a reactive catalyst packing. The periodicity of the network is reflected by the presence of the unit cell, indicated by the highlighted box, with base lattice vector* $\mathbf{l_x}$. *The white portion of the unit cell indicates the inaccessible volume occupied by the blocks separating adjacent reactive domains. The unit cell is subdivided into the three discrete volumetric domains, a, b, and c, so as to facilitate subsequent graphical analysis of the network.*

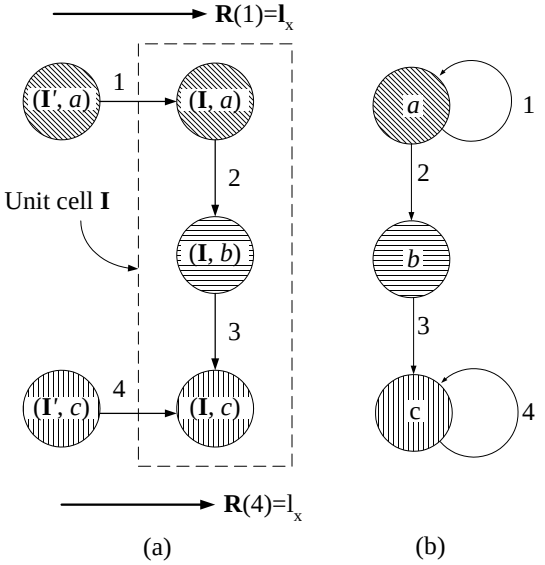

FIG. 2. (a) *Basic graph constructed from the continuous description of Figure* 1. *Vertices* $i = \{a, b, c\}$ *on the basic graph correspond to the volume elements depicted in Figure* 1. *The edges* $j = \{1, 2, 3, 4\}$ *connecting adjacent vertices represent intrachannel transport pathways situated between the individual volume elements* i, *within each edge, in which the solute is transported at the convective rate* $c(j)$ *and diffusive rate* $d(j)$. *The macroscopic jump vector* $\mathbf{R}(j = \{1, 4\}) = \mathbf{l_x}$ *corresponds to a "Darcy-scale" displacement vector drawn between the adjacent cells* $\mathbf{I}'$ *and* $\mathbf{I}$. (b) *Local graph constructed by contracting homologous vertices in the basic graph of Figure* 2(a).

rate, $c(j)$, is positive within that edge, i.e., the edge direction is colinear with the net direction of the flow or the applied force within that edge. (Any edge orientation suffices when $c(j) = 0$.) The basic graph includes all edges that are directed into the unit cell, as well as those edges internal to the cell. Edges entering cell $\mathbf{I}$ from $\mathbf{I}'$ are

assigned the macroscopic jump vector,

$$\mathbf{R}(j) = \mathbf{R}_{\mathbf{I}} - \mathbf{R}_{\mathbf{I}'}, \tag{2.3}$$

corresponding to the discrete "Darcy-scale" vector displacement from cell $\mathbf{I}'$ to cell $\mathbf{I}$. In this case, $\mathbf{R}(1) = \mathbf{R}(4) = \hat{\mathbf{x}} l_x$, whereas $\mathbf{R}(2) = \mathbf{R}(3) = \mathbf{0}$.

Two additional graphs are required to complete the graphical model. The entire infinitely extended periodic medium is captured by the global graph, Γ_g. This graph, which will be used to formulate the master equation, is formed by translations of the basic graph through its basic lattice [1, 12]. The local graph, Γ_l, is constructed by contracting all homologous vertices of the basic graph and removing the edges between them. This graph, depicted in Figure 2(b), is invariant to the choice of unit cell [1]. It will be employed in the moment scheme pursued later.

In order to cast the subsequent Taylor–Aris paradigm into an efficient matrix form, it is necessary to introduce several other graph theoretical entities [8] and transport matrices [12]. Let m denote the number of edges and n the number of nodes on the local graph. The graph connectivity is captured by the $n \times m$ incidence matrix $\mathbf{D}$, whose elements are defined as follows:

$$D_{ij} \overset{\text{def.}}{=} \begin{cases} 1 & \text{if edge } j \text{ has its terminal vertex in node } i, \\ -1 & \text{if edge } j \text{ has its initial vertex in node } i, \\ 0 & \text{otherwise.} \end{cases} \tag{2.4}$$

This matrix can be decomposed into a pair of $n \times m$ matrices,

$$\mathbf{D} = \Pi^{(+)} - \Pi^{(-)}, \tag{2.5}$$

where the nonzero entries of $\Pi^{(+)}$ are the positive entries in $\mathbf{D}$, and the nonzero entries of $\Pi^{(-)}$ constitute the absolute values of the negative entries in $\mathbf{D}$.

Collect the edge transport parameters into the pair of $m \times m$ diagonal matrices,

$$\mathbf{c} = c(j)\delta(i,j), \qquad \mathbf{d} = d(j)\delta(i,j), \tag{2.6}$$

and represent the respective nodal volumes and reaction rates by the pair of $n \times n$ diagonal matrices,

$$\mathbf{v} = v(i)\delta(i,j), \qquad \mathbf{k} = k(i)\delta(i,j). \tag{2.7}$$

Finally, define $\mathbf{R}$ as the $m \times 3$ matrix whose m rows are composed of the macroscopic jump vectors $\mathbf{R}(j)$.

2.3. Probability density on the graph. Consider the conditional reactive-probability density, $P_r(\mathbf{I},i,t \mid i_0) \geq 0$, that the solute "molecule" (particle) being tracked is instantaneously present in cell $\mathbf{I}$ and situated at vertex i at time t, given that the particle was initially introduced into cell $\mathbf{I}_0 = \mathbf{0}$ and vertex i_0 at time $t = 0$. This probability density necessarily obeys the normalized "conservation" equation

$$\sum_{i \in \Gamma g} P_r(\mathbf{I},i,t \mid i_0) = \begin{cases} 0, & t < 0, \\ 1, & t = 0, \\ < 1, & t > 0. \end{cases} \tag{2.8}$$

The last inequality arises from the attenuation of the total amount of solute present in the system at time $t > 0$ caused by its disappearance via chemical reaction or

irreversible adsorption. Indeed, after sufficient time has elapsed, the amount of solute remaining in the system, and hence its probability density, would be expected to be completely depleted (corresponding to $P_r(\mathbf{I},i,t\,|\,i_0)=0$ for all $(\mathbf{I},i)$), a fact which will be subsequently confirmed.

For the case of a reactive solute traversing the network, the reactive probability density is governed by the following convection-diffusion-reaction master equation at each node i on the global graph Γ_g:

$$\begin{aligned} v(i)\frac{dP_r(\mathbf{I},i,t\,|\,i_0)}{dt} &= \delta(\mathbf{I})\delta(i,i_0)\delta(t) - k(i)v(i)P_r(\mathbf{I},i,t\,|\,i_0) \\ &\quad + \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} c(j)P_r(\mathbf{I}',i',t\,|\,i_0) + d(j)\begin{bmatrix} P_r(\mathbf{I}',i',t\,|\,i_0) \\ -P_r(\mathbf{I},i,t\,|\,i_0)\end{bmatrix} \\ &\quad - \sum_{\substack{j\in\Omega^-\\ j=\{i,i'\}}} c(j)P_r(\mathbf{I},i,t\,|\,i_0) + d(j)\begin{bmatrix} P_r(\mathbf{I},i,t\,|\,i_0) \\ -P_r(\mathbf{I}',i',t\,|\,i_0)\end{bmatrix}, \end{aligned} \tag{2.9}$$

with $\delta(\mathbf{I})$ and $\delta(i,i_0)$ Kronecker delta functions, $\delta(t)$ the Dirac delta function, and with $j=\{a,b\}$ denoting an edge whose initial vertex is a and whose terminal vertex is b. Proper interpretations of all but one of the terms appearing in (2.9) are as discussed in [12]. The new term, $k(i)v(i)P_r(\mathbf{I},i,t\,|\,i_0)$, accounts for the CSTFR model of solute depletion, with P_r identified with the volumetric solute concentration (i.e., solute mass per unit volume).

In order to assure that subsequent infinite sums converge [cf. (3.3), (3.11)–(3.12)], all moments of the reactive-probability density are required to decay faster than algebraically, i.e.,

$$|\mathbf{R}|^m P_r(\mathbf{I},i,t\,|\,i_0)\to 0 \quad \text{as} \quad |\mathbf{I}|\to\infty. \tag{2.10}$$

3. Moment scheme.

3.1. Local moments. In order to ultimately arrive at the desired paradigm for computing the macrotransport parameters $\bar{K}^*$, $\bar{\mathbf{U}}^*$, and $\bar{\mathbf{D}}^*$, the generalized moment scheme proposed by Dungan, Shapiro, and Brenner [14] will be adapted to the master equation (2.9) governing solute transport on the graph. In this context, define the "*nonreactive*" solute probability density,

$$P(\mathbf{I},i,t\,|\,i_0) \overset{\text{def.}}{=} \frac{\exp\left(\bar{K}t\right)}{A(i_0)} P_r(\mathbf{I},i,t\,|\,i_0), \tag{3.1}$$

where the time- and position-independent reaction velocity constant $\bar{K}$ (defined globally on the network scale) and vertex field $A(i)$ (defined locally on the unit cell scale) will be determined later. Rescaling the probability density in accord with (3.1) will shortly result in a new transport problem (3.2) which only accounts for those species still present in the system at time t. Consequently, the rescaled problem is not adversely affected by very fast reaction rates which serve to deplete much of the solute mass before satisfying the long-time criteria. Rather, the impact of the fast reaction on the total amount of solute still present in the system at time t will be captured by the (reaction rate) eigenvalues $\bar{K}$, whereas the spatial dependence of the reaction will be reflected in the field $A(i)$, whose physical significance will be discussed in the context of (3.12).

The master equation governing P is derived by substituting (3.1) into (2.9) to obtain

$$\begin{aligned} v(i)\frac{dP(\mathbf{I},i,t\,|\,i_0)}{dt} =& \frac{\delta(\mathbf{I})\delta(i,i_0)\delta(t)}{A(i_0)} + \left[\bar{K}-k(i)\right] v(i)P\left(\mathbf{I},i,t\,|\,i_0\right) \\ &+ \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} c(j)P(\mathbf{I}',i',t\,|\,i_0) + d(j)\left[\begin{array}{c} P(\mathbf{I}',i',t\,|\,i_0) \\ -P(\mathbf{I},i,t\,|\,i_0) \end{array}\right] \\ &- \sum_{\substack{j\in\Omega^-\\ j=\{i,i'\}}} c(j)P(\mathbf{I},i,t\,|\,i_0) + d(j)\left[\begin{array}{c} P(\mathbf{I},i,t\,|\,i_0) \\ -P(\mathbf{I}',i',t\,|\,i_0) \end{array}\right]. \end{aligned} \tag{3.2}$$

Define the nonreactive local moment as the m-adic,

$$\mathbf{P}_m(i,t\,|\,i_0) \overset{\text{def.}}{=} \sum_{\mathbf{I}} \mathbf{R}_{\mathbf{I}}^m P\left(\mathbf{I},i,t\,|\,i_0\right), \tag{3.3}$$

where $\mathbf{R}_{\mathbf{I}}^m \equiv \mathbf{R}_{\mathbf{I}}\mathbf{R}_{\mathbf{I}}\cdots\mathbf{R}_{\mathbf{I}}$ (m-times); the triple sum,

$$\sum_{\mathbf{I}} \overset{\text{def.}}{=} \sum_{I_1=-\infty}^{\infty}\sum_{I_2=-\infty}^{\infty}\sum_{I_3=-\infty}^{\infty}, \tag{3.4}$$

is taken over all unit cells. The equation governing the local moments $\mathbf{P}_m(i)$ (with time and the initial condition suppressed therein for notational simplicity) is obtained upon multiplying (3.2) by $\mathbf{R}_{\mathbf{I}}^m$ and summing over $\mathbf{I}$, thereby obtaining

$$v(i)\frac{d\mathbf{P}_m(i)}{dt} = \frac{\delta(m,0)\delta(i,i_0)\delta(t)}{A(i_0)} + L\left[\mathbf{P}_m\left(i\right)\right] + \Gamma_m(i), \tag{3.5}$$

where $\delta\left(m,0\right)$ is a Kronecker delta function. In the latter, the vertex operator L operating on an arbitrary field $\psi(i)$ is defined as

$$\begin{aligned} L\left[\psi(i)\right] \overset{\text{def.}}{=}& \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} c(j)\psi\left(i'\right) + d(j)\left[\psi(i')-\psi(i)\right] \\ &- \sum_{\substack{j\in\Omega^-\\ j=\{i,i'\}}} c(j)\psi(i) + d(j)\left[\psi(i)-\psi(i')\right] + \left[\bar{K}-k(i)\right] v(i)\psi(i). \end{aligned} \tag{3.6}$$

The first few m-adics $\Gamma_m(i)$ appearing in (3.5) possess the respective forms

$$\Gamma_0(i) = 0, \tag{3.7}$$

$$\Gamma_1(i) = \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} \left[c(j)+d(j)\right]\mathbf{R}\left(j\right)P_0(i') - \sum_{\substack{j\in\Omega^-\\ j=\{i,i'\}}} d(j)\mathbf{R}(j)P_0(i'), \tag{3.8}$$

$$\Gamma_2(i) = 2\ \text{sym}\left\{\begin{array}{l} \displaystyle\sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} \left[c(j)+d(j)\right]\left[\frac{1}{2}\mathbf{R}\left(j\right)\mathbf{R}\left(j\right)P_0(i') + \mathbf{R}\left(j\right)\mathbf{P}_1(i')\right] \\ \quad + \displaystyle\sum_{\substack{j\in\Omega^-\\ j=\{i,i'\}}} d(j)\left[\frac{1}{2}\mathbf{R}\left(j\right)\mathbf{R}\left(j\right)P_0(i') - \mathbf{R}\left(j\right)\mathbf{P}_1(i')\right] \end{array}\right\}, \tag{3.9}$$

where, for an arbitrary dyad $\mathbf{XY}$ (with $\mathbf{X}$ and $\mathbf{Y}$ vectors),

$$\operatorname{sym}(\mathbf{XY}) \stackrel{\text{def.}}{=} \frac{1}{2}(\mathbf{XY} + \mathbf{YX}). \tag{3.10}$$

3.2. Total moments. Define the respective unweighted and weighted *nonreactive* total moments,

$$\mathbf{M}'_m(t \mid i_0) \stackrel{\text{def.}}{=} \sum_{i \in \Gamma_l} v(i)\mathbf{P}_m(i, t \mid i_0), \tag{3.11}$$

$$\mathbf{M}_m(t \mid i_0) \stackrel{\text{def.}}{=} \sum_{i \in \Gamma_l} v(i)A(i)\mathbf{P}_m(i, t \mid i_0). \tag{3.12}$$

In the latter, the node-based field $A(i)$ [cf. (3.1)] arises from the necessity for introducing into macrotransport theory a fictitious initial condition [14], whose significance and defining equation will be established shortly. It is possible to choose the constant $\bar{K}$ appearing in the definition (3.1) such that M'_0 is conserved for sufficiently long-times [36] (see (4.7)). However, transients arising from the initial placement, i_0, of the particle (within cell $\mathbf{I}_0 = \mathbf{0}$) persist for long times, longer than the time required for the asymptotic theory of Taylor–Aris to constitute an accurate global representation of the transport phenomena. By way of example, consider the classical case of solute entrainment in a flow between parallel, reactive plates [9]. If the initial solute pulse is near the plates, then much of the solute mass only samples the slow moving streamlines near the wall before being depleted. In contrast, if the pulse is placed in the midplane, then the solute mass will have the opportunity to sample many streamlines before being depleted. This residual transient thereby impacts nontrivially upon the network-scale transport processes [7] and is captured by the fictitious initial condition field $A(i)$. To properly correct for such transients, as was done in the original derivation [14], we will derive a difference equation for the fictitious initial condition $A(i)$ (in place of the literal initial condition). This scheme insures that M_0 too is conserved for all times, thereby allowing a conventional Taylor–Aris moment analysis [14], involving the use of weighted moments. It will be shown that the rates of change of the weighted and unweighted moments differ only by exponentially small temporal terms, at least for sufficiently long times. As a consequence, the distinction between the two types of total moments, $\mathbf{M}'_m$ and $\mathbf{M}_m$, defined above proves irrelevant in the final macrotransport results.

The differential equation governing M_0 is derived by forming the product of $A(i)$ and (3.5) (with $m = 0$ and (3.7)), and summing over $i \in \Gamma_l$ to obtain

$$\begin{aligned}\frac{dM_0}{dt} = {} & \delta(t) + \sum_{i \in \Gamma_l} \left[\bar{K} - k(i)\right] v(i)A(i)P_0(i) \\ & + \sum_{\substack{j \in E\Gamma_l \\ j \in \Omega^+}} c(j)A(i)P_0(i') + d(j)A(i)\left[P_0(i') - P_0(i)\right] \\ & - \sum_{\substack{j \in E\Gamma_l \\ j \in \Omega^-}} c(j)A(i)P_0(i) + d(j)A(i)\left[P_0(i) - P_0(i')\right].\end{aligned} \tag{3.13}$$

Here and hereafter, the following compact summation notation will be employed:

$$\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^+}} \overset{\text{def.}}{=} \sum_{i\in V\Gamma_l} \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}}, \qquad \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^-}} \overset{\text{def.}}{=} \sum_{i\in V\Gamma_l} \sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}}. \tag{3.14}$$

The strong connectivity of the graph furnishes the pair of identities,

$$\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^+}} \epsilon(j)\phi(i') = \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^-}} \epsilon(j)\phi(i), \tag{3.15}$$

$$\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^+}} \epsilon(j)\phi_1(i')\phi_2(i) = \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^-}} \epsilon(j)\phi_1(i)\phi_2(i'), \tag{3.16}$$

where $\phi_k(i)$ and $\epsilon(j)$ are, respectively, node- and edge-based quantities. With use of these identities, (3.13) may be reformulated as

$$\begin{aligned}\frac{dM_0}{dt} &= \delta(t) + \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^+}} P_0(i)d(j)\left[A(i') - A(i)\right] + \sum_{i\in\Gamma_l}\left[\bar{K} - k(i)\right]v(i)A(i)P_0(i)\\ &\quad + \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^-}} P_0(i)\left[c(j) + d(j)\right]\left[A(i') - A(i)\right].\end{aligned} \tag{3.17}$$

In order that M_0 be conserved for all times, the summations appearing on the right-hand side of (3.17) must vanish; explicitly,

$$\begin{aligned}&\sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} d(j)\left[A(i') - A(i)\right] + \sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}} \left[c(j) + d(j)\right]\left[A(i') - A(i)\right]\\ &\qquad + \left[\bar{K} - k(i)\right]v(i)A(i) = 0.\end{aligned} \tag{3.18}$$

Equation (3.18), governing $A(i)$, may be restated in compact form as

$$\left\{\mathbf{k} - \mathbf{v}^{-1}\cdot\left[\mathbf{D}\cdot\mathbf{d} - \Pi^{(-)}\cdot\mathbf{c}\right]\cdot\mathbf{D}^{\dagger}\right\}\cdot\mathbf{A} = \bar{K}\mathbf{A}, \tag{3.19}$$

where $\mathbf{A}$ is an $n\times 1$ column vector whose elements are the fictitious initial nodal conditions embodied in $A(i)$ $(i = 1, 2, \ldots, n)$. Equation (3.19) constitutes an eigenvalue problem for simultaneously computing the eigenvalues $\bar{K}$ and eigenvectors $A(i)$. The scheme for identifying the one, physically relevant eigenvalue $\bar{K}$, as well as the required normalization of the corresponding physically relevant eigenvector $\mathbf{A}$, will be specified in the following section.

With use of (3.18), temporal integration of (3.17) demonstrates that

$$M_0 = \begin{cases} 0, & t < 0,\\ 1, & t \geq 0,\end{cases} \tag{3.20}$$

whereupon M_0 is indeed seen to be conserved for all times (independently of i_0). A generic equation governing the weighted total moments may also be derived with use of (3.18). To do so, multiply (3.5) by $A(i)$, sum over $i\in\Gamma_l$, and use (3.15) and (3.16), thereby obtaining the expression

$$\frac{d\mathbf{M}_m}{dt} = \delta(m,0)\delta(t) + \sum_{i\in\Gamma_l} A(i)\Gamma_m(i). \tag{3.21}$$

4. Asymptotic, long-time limits. The following section furnishes the asymptotic, long-time limits of the first few local and total moments of the nonreactive probability density. By "long-time" is meant that the residence time, t_R, of the solute in the network is long compared with the diffusion time scale; that is, $t_R \gg l^2/D_m$, where l denotes a characteristic linear dimension of the unit cell (typically the magnitude of a macroscopic jump vector, $|\mathbf{R}(j)|$) and D_m is the molecular diffusivity of the solute [9]. A further criterion imposed upon the definition of long-time behavior will be established later [cf. (4.4)].

4.1. Zero-order moments. For sufficiently long times, the zeroth-order local moment (3.3) assumes the asymptotic form

$$P_0(i,t\,|\,i_0) \approx P_0^{\infty}(i) + \exp \tag{4.1}$$

for all i_0, where "exp" denotes temporal terms that are exponentially small for sufficiently long times. The asymptotic probability density, $P_0^{\infty}(i)$, is independent of time as well as of the initial local position, i_0. The validity of (4.1) has been established [35, 37] via the use of eigenfunction expansions.

Substitute (4.1) into (3.5), set $m = 0$, and use (3.7) to obtain the difference equation governing $P_0^{\infty}(i)$, namely,

$$L\,[P_0^{\infty}(i)] = 0. \tag{4.2}$$

The latter may be recast into the compact matrix form,

$$\left\{\mathbf{k} - \mathbf{v}^{-1}\cdot\mathbf{D}\cdot\left[(\mathbf{c}+\mathbf{d})\cdot\left(\Pi^{(-)}\right)^{\dagger} - \mathbf{d}\cdot\left(\Pi^{(+)}\right)^{\dagger}\right]\right\}\cdot\mathbf{P} = \bar{K}\mathbf{P}, \tag{4.3}$$

where $\mathbf{P}$ is the $n\times 1$ column vector composed of the asymptotic probability densities, $P_0^{\infty}(i)$ $(i = 1, 2, \ldots, n)$. Similar to (3.19), (4.3) constitutes an eigenvalue problem posed for $P_0^{\infty}(i)$ and $\bar{K}$. The eigenvalue with the smallest real part (corresponding to the slowest decaying mode of the full solution) is identified as the effective reaction rate $\bar{K}^*$ [14, 35, 37].[4] For all physical circumstances, the eigenvalue possessing the smallest real part is pure real [35, 37]. Moreover, the solution of this eigenvalue problem furnishes a second criterion quantifying what is meant by the phrase "long-time behavior." Upon denoting the second smallest eigenvalue of (4.3) as $\bar{K}_1$, we require the residence time to satisfy the inequality

$$t_R \gg \left(\bar{K}^*\right)^{-1} - \bar{K}_1^{-1}, \tag{4.4}$$

whereupon the effective transport process is dominated by the eigenvalue with the smallest real part, $\bar{K}^*$.

As shown below, the eigenvalue problems posed for $P_0^{\infty}(i)$ (4.2) and $A(i)$ (3.18) are adjoint. Thus, let $\bar{K}_P$ and $\bar{K}_A$, respectively, be eigenvalues of (4.2) and (3.18). Upon multiplying (3.18) by $P_0^{\infty}(i)$, (4.2) by $A(i)$, and summing both results over $i \in \Gamma_l$, we see that $\bar{K}_P = \bar{K}_A$. Consequently, the appropriate fictitious initial condition $A(i)$ is the eigenvector of (3.18) corresponding to the eigenvalue $\bar{K} = \bar{K}^*$.

[4] By way of example, Batycky, Edwards, and Brenner [7] illustrate the dominance of the slowest decaying mode by comparing the (asymptotic) macrotransport solution for a nonadiabatic unsteady heat transfer process with its exact trigonometric function expansion. Moreover, their analysis clearly illustrates the necessity for incorporating the notion of a fictitious initial condition into effective-medium models, such as in the present macrotransport model.

The eigenvalue problems governing $P_0^\infty(i)$ and $A(i)$ only specify each of these two fields to within arbitrary, constant multipliers. These multipliers may be uniquely determined by applying the normalization conditions [14], namely,

$$\sum_{i\in\Gamma_l} v(i)P_0^\infty(i) = 1, \tag{4.5}$$

$$\sum_{i\in\Gamma_l} v(i)A(i)P_0^\infty(i) = 1. \tag{4.6}$$

To verify that the weighted and unweighted zeroth-order total moments are indistinguishable at long times, substitute the asymptotic solution (4.1) into (3.11), together with the normalization condition (4.5). This demonstrates that our choice of $\bar{K}$ and $A(i_0)$ conserves M_0' for long times, at least to within exponentially small terms; explicitly,

$$M_0' \approx 1 + \exp \tag{4.7}$$

for all i_0. Moreover, the ability to formulate consistent results for M_0, (3.20) and M_0', (4.7) verifies the change in variables (3.1), thereby confirming our prior assertion that the solute is eventually depleted completely at each and every node, and hence throughout the network as a whole.

4.2. First-order moments.

4.2.1. Mean velocity. The mean velocity of the reactive tracer through the network is determined from knowledge of the asymptotic limit of the rate of growth of the first total moment via the generic expression [14],

$$\bar{\mathbf{U}}^* = \lim_{t\to\infty} \frac{d\mathbf{M}_1}{dt}. \tag{4.8}$$

Substitute (3.8) into (3.21), set $m = 1$, and use (3.16) and (4.1) to obtain

$$\bar{\mathbf{U}}^* = \sum_{\substack{j\in E\Gamma_l \\ j\in\Omega^+}} c(j)\mathbf{R}(j)\,A(i)P_0^\infty(i') + d(j)\mathbf{R}(j)\left[A(i)P_0^\infty(i') - A(i')P_0^\infty(i)\right]. \tag{4.9}$$

4.2.2. Derivation of the B-equation. Subject to a posteriori verification, assume the following trial solution for the first-order local moment:

$$\mathbf{P}_1(i) \approx P_0^\infty(i)\left[\bar{\mathbf{U}}^* t + \mathbf{B}(i)\right] + \exp, \tag{4.10}$$

where $\mathbf{B}(i)$ is a node-based field to be determined. Substitution of (4.10) into (3.12), together with the choice $m = 1$, furnishes the weighted first-order total moment,

$$\mathbf{M}_1 \approx \bar{\mathbf{U}}^* t + \sum_{i\in\Gamma_l} v(i)A(i)P_0^\infty(i)\mathbf{B}(i) + \exp. \tag{4.11}$$

The difference equation governing $\mathbf{B}(i)$ is derived by substituting the trial solution (4.10) into (3.5), setting $m = 1$, and using (3.8). Elimination of time-dependent terms via (4.2), and reactive terms via the product of $\mathbf{B}(i)$ with (4.2), eventually yields

$$\begin{aligned}\sum_{\substack{j\in\Omega^+(i) \\ j=\{i',i\}}} &[c(j)+d(j)]\,P_0^\infty(i')\left[\mathbf{B}(i') - \mathbf{B}(i)\right] \\ &- \sum_{\substack{j\in\Omega^-(i) \\ j=\{i,i'\}}} d(j)P_0^\infty(i')\left[\mathbf{B}(i) - \mathbf{B}(i')\right] = v(i)P_0^\infty(i)\bar{\mathbf{U}}^* - \alpha(i),\end{aligned} \tag{4.12}$$

with $\alpha(i)$ the node-based vector,

$$\alpha(i) = \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} [c(j)+d(j)]\,\mathbf{R}(j)\,P_0^\infty(i') - \sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}} d(j)\mathbf{R}(j)P_0^\infty(i'). \tag{4.13}$$

Equation (4.12) defines the **B**-field only to within an arbitrary additive constant vector [9], whose value ultimately proves irrelevant when computing the dispersivity [cf. (4.32)]. Consequently, the resulting degree of freedom may be utilized so as to conveniently allow an arbitrary reference node, say i^*, to be chosen such that $\mathbf{B}(i^*) = \mathbf{0}$. With the latter specification, the $(n-1)$ equations generated by (4.12) for $i \neq i^*$ suffice to determine the remaining vectors $\mathbf{B}(i)$.[5]

Subsequent calculations [cf. (4.32)] necessitate introducing the edge-based vector field,

$$\mathbf{b}(j) \overset{\text{def.}}{=} \mathbf{B}(i) - \mathbf{B}(i'), \quad \{j \in \Omega^+(i)\}, \tag{4.14}$$

defined such that edge j has its initial vertex at i' and its terminal vertex at i. The m vectors, $\mathbf{b}(j)$, may be computed from the solution of the $(n-1)$ equations generated by (4.12), together with the m definitions from (4.14). Alternatively, a difference equation may be derived for $\mathbf{b}(j)$ by substituting (4.14) into (4.12), so as to obtain

$$\sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}} d(j)P_0^\infty(i')\mathbf{b}(j) - \sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} [c(j)+d(j)]\,P_0^\infty(i')\mathbf{b}(j) = v(i)P_0^\infty(i)\bar{\mathbf{U}}^* - \alpha(i). \tag{4.15}$$

However, the n equations contained in (4.15) generally prove insufficient to solve for all m vectors $\mathbf{b}(j)$, since, for all but the most trivial networks, $m > n$. Consequently, it is necessary to augment the (nonsquare) coefficient matrix by noting that the sum of the **b** vectors vanishes along any cycle of the graph [12],

$$\sum_{j\in\text{cycle}} \mathbf{b}(j) = \mathbf{0}. \tag{4.16}$$

Superposition of the n equations provided by (4.15), together with the $(m-n)$-independent cycles chosen from (4.16), completely specifies the **b** vectors.

To reformulate the **B**-equations in matrix form, define the pair of $n \times m$ conditioned connectivity matrices,

$$\tilde{\Pi}_{ij}^{(+)} \overset{\text{def.}}{=} \begin{cases} P_0^\infty(i') & \text{if edge } j \text{ is directed from } i' \text{ to } i,\\ 0 & \text{otherwise;}\end{cases} \tag{4.17}$$

$$\tilde{\Pi}_{ij}^{(-)} \overset{\text{def.}}{=} \begin{cases} P_0^\infty(i') & \text{if edge } j \text{ is directed from } i \text{ to } i',\\ 0 & \text{otherwise.}\end{cases} \tag{4.18}$$

With use of the latter, the (nonsquare) equation set (4.15) governing **b** adopts the form

$$\left[\tilde{\Pi}^{(-)}\cdot\mathbf{d} - \tilde{\Pi}^{(+)}\cdot(\mathbf{c}+\mathbf{d})\right]\cdot\mathbf{b} = \mathbf{v}\cdot\mathbf{P}\cdot\bar{\mathbf{U}}^* - \left[\tilde{\Pi}^{(+)}\cdot(\mathbf{c}+\mathbf{d}) - \tilde{\Pi}^{(-)}\cdot\mathbf{d}\right]\cdot\mathbf{R}. \tag{4.19}$$

[5] In the nonreactive network theory [12], the cocycle space was invoked to provide a formal mechanism for choosing the reference node i^*. While this technique remains valid for the present reactive case, subsequent simplifications of the **B**-equations render the utility of such a formalism moot.

Conversion between $\mathbf{b}$ and $\mathbf{B}$ is accomplished via the transformation

$$\mathbf{b} = \mathbf{D}^{\dagger} \cdot \mathbf{B}, \tag{4.20}$$

whereupon (4.12) adopts the matrix form,

$$\left[\tilde{\Pi}^{(-)} \cdot \mathbf{d} - \tilde{\Pi}^{(+)} \cdot (\mathbf{c}+\mathbf{d})\right] \cdot \mathbf{D}^{\dagger} \cdot \mathbf{B} = \mathbf{v} \cdot \mathbf{P} \cdot \bar{\mathbf{U}}^{*} - \left[\tilde{\Pi}^{(+)} \cdot (\mathbf{c}+\mathbf{d}) - \tilde{\Pi}^{(-)} \cdot \mathbf{d}\right] \cdot \mathbf{R}. \tag{4.21}$$

The time-independence of (4.12) and (4.15) confirms a posteriori the assumed trial solution (4.10) for $\mathbf{P}_1$ as well as the resulting expression (4.11) for $\mathbf{M}_1$. Consequently, the unweighted first-order total moment may be computed from (3.11) (with $m = 1$) together with (4.5) and (4.10), yielding

$$\mathbf{M}_1' \approx \bar{\mathbf{U}}^{*} t + \bar{\mathbf{B}} + \text{exp}, \tag{4.22}$$

where the time- and position-independent vector $\bar{\mathbf{B}}$ is of the form

$$\bar{\mathbf{B}} = \sum_{i \in \Gamma_l} v(i) P_0^{\infty}(i) \mathbf{B}(i). \tag{4.23}$$

Differentiation of (4.11) and (4.22) with respect to time reveals that the temporal rates of change of $\mathbf{M}_1$ and $\mathbf{M}_1'$ differ only by exponentially small terms at long times.

4.3. Second-order moments. The difference equation governing the weighted second-order total moment, $\mathbf{M}_2$, is derived from (3.21) with $m = 2$, upon making use of (3.9), (3.16), (4.1), (4.9), and (4.10), thereby obtaining

$$\begin{aligned} \frac{d\mathbf{M}_2}{dt} \approx{}& 2\bar{\mathbf{U}}^{*}\bar{\mathbf{U}}^{*} t + 2 \text{ sym} \left\{ \sum_{\substack{j \in E\Gamma_l \\ j \in \Omega^{+}}} [c(j) + d(j)]\, A(i) P_0^{\infty}(i') \begin{bmatrix} \frac{1}{2}\mathbf{R}(j)\mathbf{R}(j) \\ +\mathbf{R}(j)\mathbf{B}(i') \end{bmatrix} \right\} \\ &+ 2 \text{ sym} \left\{ \sum_{\substack{j \in E\Gamma_l \\ j \in \Omega^{+}}} \left\{ d(j) A(i') P_0^{\infty}(i) \begin{bmatrix} \frac{1}{2}\mathbf{R}(j)\mathbf{R}(j) \\ -\mathbf{R}(j)\mathbf{B}(i) \end{bmatrix} \right\} \right\} + \text{exp}. \end{aligned} \tag{4.24}$$

Subject to a posteriori verification, assume a trial solution for the second-order local moment, $\mathbf{P}_2$, of the form

$$\mathbf{P}_2(i) \approx P_0^{\infty}(i) \left\{ \bar{\mathbf{U}}^{*}\bar{\mathbf{U}}^{*} t^2 + 2 \text{ sym} \left[\bar{\mathbf{U}}^{*}\mathbf{B}(i)\right] t + 2\bar{\mathbf{D}}^{*} t + \mathbf{H}(i) \right\} + \text{exp}, \tag{4.25}$$

with the constant dyadic $\bar{\mathbf{D}}^{*}$ and dyadic field $\mathbf{H}(i)$ to be determined forthwith.

To compute $\bar{\mathbf{D}}^{*}$, form the weighted second-order total moment from (3.12), with order $m = 2$, and (4.25), and differentiate the resulting expression with respect to time, so as to obtain

$$\frac{d\mathbf{M}_2}{dt} \approx 2\bar{\mathbf{U}}^{*}\bar{\mathbf{U}}^{*} t + 2\bar{\mathbf{D}}^{*} + 2 \text{ sym} \sum_{i \in \Gamma_l} v(i) P_0^{\infty}(i) A(i) \bar{\mathbf{U}}^{*} \mathbf{B}(i) + \text{exp}. \tag{4.26}$$

The summation appearing in (4.26) may be simplified by forming the product of (4.12) with $A(i)\mathbf{B}(i)$, and subsequently summing the result over $i \in \Gamma_l$, thereby yielding

(4.27)
$$2\ \mathrm{sym}\left[\sum_{i\in\Gamma_l} v(i)P_0^{\infty}(i)A(i)\bar{\mathbf{U}}^{*}\mathbf{B}(i)\right] = 2\ \mathrm{sym}\left[\sum_{i\in\Gamma_l}\alpha(i)A(i)\mathbf{B}(i)\right] + 2\ \mathrm{sym}\,(\mathbf{E})\,,$$

where $\mathbf{E}$ is the constant dyadic

$$\begin{aligned}\mathbf{E} = &\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{+}}} [c(j)+d(j)]\,P_0^{\infty}(i')A(i)\mathbf{B}(i)\,[\mathbf{B}\,(i')-\mathbf{B}(i)]\\ &-\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{-}}} d(j)P_0^{\infty}(i')A(i)\mathbf{B}(i)\,[\mathbf{B}(i)-\mathbf{B}(i')]\,.\end{aligned} \tag{4.28}$$

The dyadic $\mathbf{E}$ may itself be simplified upon multiplying (4.2) by $A(i)\mathbf{B}(i)\mathbf{B}(i)$ and (3.18) by $P_0^{\infty}(i)\mathbf{B}(i)\mathbf{B}(i)$, summing both results over $i \in \Gamma_l$ with use of (3.16), and forming their difference, so as to obtain the expression

(4.29)
$$\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{+}}} \{[c(j)+d(j)]\,A(i)P_0^{\infty}(i') - d(j)A(i')P_0^{\infty}(i)\}\,[\mathbf{B}(i)\mathbf{B}(i)-\mathbf{B}(i')\mathbf{B}(i')] = \mathbf{0}.$$

Upon adding the null result (4.29) to (4.28), and using the definition (4.14), the symmetric portion of $\mathbf{E}$ is found to possess the form

$$2\ \mathrm{sym}\,(\mathbf{E}) = -\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{+}}} \{[c(j)+d(j)]\,A(i)P_0^{\infty}(i') + d(j)A(i')P_0^{\infty}(i)\}\,\mathbf{b}(j)\mathbf{b}(j). \tag{4.30}$$

Equation (4.27) may be further simplified by using (4.13) jointly with the identity (3.16) to show that

$$\sum_{i\in\Gamma_l}\alpha(i)A(i)\mathbf{B}(i) = \sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{+}}} \left\{ \begin{array}{c} [c(j)+d(j)]\,\mathbf{R}(j)A(i)P_0^{\infty}(i')\mathbf{B}(i) \\ -d(j)\mathbf{R}(j)A(i')P_0^{\infty}(i)\mathbf{B}(i') \end{array} \right\}. \tag{4.31}$$

Upon comparing (4.24) with our trial solution (4.26), and making use of (4.27), (4.30), and (4.31), as well as the identity (3.16), there results the expression

$$\bar{\mathbf{D}}^{*} = \frac{1}{2}\sum_{\substack{j\in E\Gamma_l\\ j\in\Omega^{+}}} \{c(j)A(i)P_0^{\infty}(i') + d(j)\,[A(i)P_0^{\infty}(i') + A(i')P_0^{\infty}(i)]\}\,\tilde{\mathbf{b}}(j)\tilde{\mathbf{b}}(j), \tag{4.32}$$

where the vector $\tilde{\mathbf{b}}(j)$ is defined as

$$\tilde{\mathbf{b}}(j) \overset{\text{def.}}{=} \mathbf{R}(j) - \mathbf{b}(j). \tag{4.33}$$

Moreover, we see that $\bar{\mathbf{D}}^{*}$ represents the solute dispersivity dyadic, inasmuch as $\bar{\mathbf{D}}^{*}$ may also calculated from its definition [14], namely,

$$\bar{\mathbf{D}}^{*} = \frac{1}{2}\lim_{t\to\infty}\frac{d}{dt}\left(\mathbf{M}_2 - \mathbf{M}_1\mathbf{M}_1\right). \tag{4.34}$$

The latter is seen to accord with the result (4.32) upon use of (4.11) and (4.26).

Equation (4.32) enforces an equality between the trial solution $\mathbf{M}_2$, (4.26), and its derived formula (4.24). Consequently, a posteriori verification of (4.25) is completed by deriving a solvable difference equation for $\mathbf{H}(i)$ [37]. To do so, substitute the trial solution (4.25) into (3.5), with $m = 2$, and use (3.9). Removing the time-dependent terms via (4.2) and (4.12), and subsequently substituting for the reaction term upon multiplying (4.2) by $\mathbf{H}(i)$, ultimately furnishes the governing equation for $\mathbf{H}(i)$, namely,

(4.35)
$$\sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} [c(j)+d(j)]\,P_0^\infty(i')\,[\mathbf{H}(i')-\mathbf{H}(i)] - \sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}} d(j)P_0^\infty(i')\,[\mathbf{H}(i)-\mathbf{H}(i')] = \beta(i),$$

with $\beta(i)$ the symmetric forcing function

$$\beta(i) = 2\ \mathrm{sym}\left\{\begin{array}{l} v(i)P_0^\infty(i)\left[\bar{\mathbf{U}}^*\mathbf{B}(i)+\bar{\mathbf{D}}^*\right] \\ -\displaystyle\sum_{\substack{j\in\Omega^+(i)\\ j=\{i',i\}}} [c(j)+d(j)]\,P_0^\infty(i)\left[\frac{1}{2}\mathbf{R}(j)\mathbf{R}(j)+\mathbf{R}(j)\mathbf{B}(i')\right] \\ -\displaystyle\sum_{\substack{j\in\Omega^-(i)\\ j=\{i,i'\}}} d(j)P_0^\infty(i')\left[\frac{1}{2}\mathbf{R}(j)\mathbf{R}(j)-\mathbf{R}(j)\mathbf{B}(i')\right] \end{array}\right\}. \tag{4.36}$$

Inasmuch as the structure of (4.35) is identical to that of (4.12), (4.35) will possess a solution if (4.12) itself possesses a solution. As was the case in the original development [36] of this moment technique, computing $\mathbf{H}$ proves unnecessary. Indeed, we have already derived formulas for all the relevant macrotransport parameters without prior knowledge of $\mathbf{H}$. Rather, the demonstrated existence of the latter time-independent, solvable equation (4.35) simply completes the a posteriori verification of (4.25).

The latter verification permits computing $\mathbf{M}_2'$ by substituting (4.25) into (3.11), choosing $m = 2$, and invoking (4.5) and (4.23). Thereby, one obtains

$$\mathbf{M}_2' \approx \bar{\mathbf{U}}^*\bar{\mathbf{U}}^* t^2 + 2\ \mathrm{sym}\left(\bar{\mathbf{B}}\bar{\mathbf{U}}^*\right) t + 2\bar{\mathbf{D}}^* t + \sum_{i\in\Gamma_l} v(i)P_0^\infty(i)\mathbf{H}(i) + \mathrm{exp.} \tag{4.37}$$

Differentiation of the latter with respect to time, followed by subsequent comparison of the resulting expression with (4.26), reveals that the time rates of change of $\mathbf{M}_2$ and $\mathbf{M}_2'$ differ only by exponentially small terms at long times.

5. Example.

5.1. Kinematics. In the following detailed example, the general paradigm developed above is applied to the network depicted in Figure 3. This medium may be envisioned as being composed of a pair of infinitely extended parallel rows of wells, where the wells are connected via thin capillary tubes in the manner indicated in the figure. The centroids of the wells are separated by a distance l. When solute is present in well a, it is assumed to be depleted by a chemical reaction at the uniform rate k. The capillaries connecting these wells possess respective cross-sectional areas A and lengths λl ($\lambda < 1$). Transport occurs within all channels by molecular diffusion, quantified by the diffusion coefficient D_m. Application of the externally applied force F

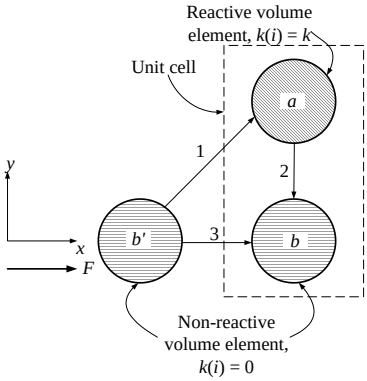

FIG. 3. *Basic graph of a model reactive porous medium. The unit cell, indicated by the dashed box, consists of two nodes, labeled a and b, connected by edges* $j = \{1, 2, 3\}$. *A reactive solute molecule possessing molecular diffusivity* D_m *is assumed not to react when present in subvolume element* $v(b)$, *owing, say, to the absence of a catalyst there, and to be consumed at the rate* k *when present in subvolume element* $v(a)$, *owing, say, to the presence of a catalyst. Application of an externally applied force of magnitude* F *in the* x*-direction gives rise to deterministic solute transport exclusively through edge* 3.

gives rise to solute transport in the x-direction. The solute is assumed to be point-size, whereupon no contribution arises from capillary-scale Taylor–Aris dispersion owing to the absence of a solvent velocity field.

The present example possesses an alternate interpretation as a model of solute transport via bulk flow (through edge 3) with periodic sites for (potentially irreversible) adsorption to the walls. Transport through edge 1 corresponds to diffusive transport from the bulk to adsorption site, while reversibly adsorbed solutes are returned to the bulk flow by diffusion through edge 2. (The depletion "reaction" corresponds to irreversible adsorbtion.) In such a model, the volume of node a, when scaled with the volumetric flow rate in edge 3, corresponds to the (average) residence time of the reversible adsorption process, while the volume of node b represents the volume of a period of the bulk channel containing one adsorption site. In essence, this model is equipollent with our previous analysis of entropic trapping [13], where the retention in the traps is analogous to the present irreversible adsorption process.

The periodic unit cell, indicated by the dashed box, consists of the pair of nodes, $i = \{a, b\}$, characterized by the parameters

$$\mathbf{v} = \tau_0 \begin{bmatrix} \phi_a & 0 \\ 0 & \phi_b \end{bmatrix}, \qquad \mathbf{k} = \begin{bmatrix} k & 0 \\ 0 & 0 \end{bmatrix}, \tag{5.1}$$

where $\tau_0 = v(a) + v(b)$ is the (accessible) volume of the unit cell, and ϕ_a and ϕ_b are the volume fractions of nodes a and b, respectively. The nodes are connected by a trio of edges, $j = \{1, 2, 3\}$, whose edge transport rates (2.6) and macroscopic jump vector are, respectively, given by

$$\mathbf{c} = \frac{D_m F A}{kT} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{d} = \frac{D_m A}{\lambda l} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{R} = l \begin{bmatrix} \hat{\mathbf{x}} \\ 0 \\ \hat{\mathbf{x}} \end{bmatrix}, \tag{5.2}$$

with kT the Boltzmann factor.

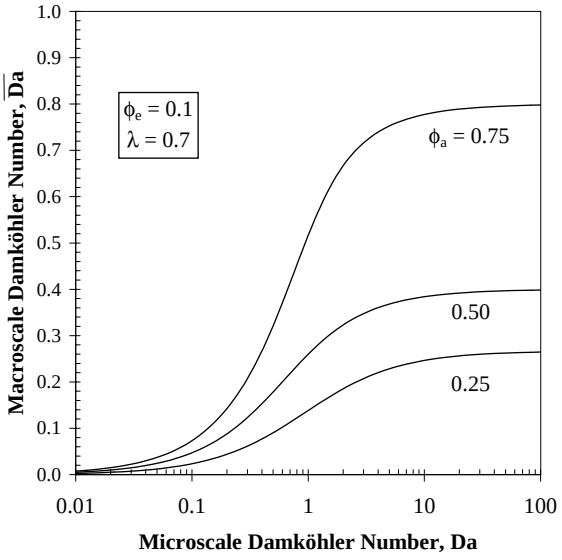

FIG. 4. *Plot of the macroscale Damköhler number, $\overline{Da}$, as a function of the microscale Damköhler number, Da, for several values of the volume fraction of the reactive well, ϕ_a, and for the specified geometric attributes shown in the inset.*

In what follows, it is useful to define the dimensionless parameters

$$\phi_e \overset{\text{def.}}{=} \frac{Al}{\lambda\tau_0}, \quad \mathrm{Da} \overset{\text{def.}}{=} \frac{kl^2}{D_m}, \quad \mathrm{Pe} \overset{\text{def.}}{=} \frac{Fl}{kT}, \tag{5.3}$$

which, respectively, correspond to the volume fraction of the edges, and the microscale Damköhler and Peclét numbers.

5.2. Macrotransport solution. With the geometrical and phenomenological microscale transport data now specified, the eigenvalue problem (4.3) may be rendered in dimensionless form as

$$\begin{bmatrix} 2\frac{\phi_e}{\phi_a} + \mathrm{Da} & -2\frac{\phi_e}{\phi_a} \\ -2\frac{\phi_e}{\phi_b} & 2\frac{\phi_e}{\phi_b} \end{bmatrix} \begin{bmatrix} P_0^\infty(a) \\ P_0^\infty(b) \end{bmatrix} = \frac{\bar{K}l^2}{D_m} \begin{bmatrix} P_0^\infty(a) \\ P_0^\infty(b) \end{bmatrix}. \tag{5.4}$$

Upon defining the macroscopic Damköhler number as

$$\overline{\mathrm{Da}} \overset{\text{def.}}{=} \frac{\bar{K}^* l^2}{D_m}, \tag{5.5}$$

the solution of the eigenvalue problem (5.4) reveals that

$$\overline{\mathrm{Da}} = \frac{\phi_e}{\phi_a\phi_b} + \frac{\mathrm{Da}}{2} - \left[\left(\frac{\phi_e}{\phi_b} - \mathrm{Da}\right)^2 + \frac{\phi_e}{\phi_a}\mathrm{Da} + \frac{\phi_e^2}{\phi_a^2\phi_b}(1+\phi_a)\right]^{\frac{1}{2}}. \tag{5.6}$$

From inspection, we see that $\overline{\mathrm{Da}}$ vanishes with Da; likewise, $\overline{\mathrm{Da}}$ approaches infinity linearly as Da approaches infinity. (Of course, this corresponds to the uninteresting limit where all of the solute mass is depleted instantaneously [5].) Figure 4 displays

numerical values of $\overline{\mathrm{Da}}$ (as a function of Da) for several different values of ϕ_a. $\overline{\mathrm{Da}}$ is seen to increase with Da (the apparent asymptotes appearing at Da ≈ 10 being artifacts of the semilog plot). Owing to the fact that molecular diffusion is the sole mechanism for transporting solute into the reactive well, the overall reaction rate is much slower than that prevailing in well a. By increasing the volume of the reactive well, thereby increasing the solute residence time therein, $\overline{\mathrm{Da}}$ will increase monotonically, all other things being equal.

With use of (4.5), the normalized (dimensionless) eigenvectors corresponding to the smallest eigenvalue (5.6) are, respectively,

$$P_0^{\infty}(a)\tau_0 = \frac{\phi_a - \gamma}{\phi_a\,(1-\gamma)}, \tag{5.7}$$

$$P_0^{\infty}(b)\tau_0 = (1-\gamma)^{-1}, \tag{5.8}$$

where γ denotes the following combination of dimensionless parameters:

$$\gamma \equiv \frac{\phi_a \phi_b}{2\phi_e}\overline{\mathrm{Da}}. \tag{5.9}$$

Substitution of (5.6) into (3.19), together with explicitly incorporating the normalization condition (4.6) in the first row (in lieu of the equation corresponding to $i = a$), furnishes the following matrix equation for the $A(i)$:

$$\begin{bmatrix} \phi_a P_0^{\infty}(a)\tau_0 & \phi_b P_0^{\infty}(b)\tau_0 \\ 2\phi_e & \phi_b\overline{\mathrm{Da}} - 2\phi_e \end{bmatrix} \begin{bmatrix} A(a) \\ A(b) \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}. \tag{5.10}$$

Solution of (5.10) yields the respective fictitious initial conditions,

$$A(a) = \beta\,(1-\gamma)\,(\phi_a - \gamma)\,, \tag{5.11}$$

$$A(b) = \phi_a \beta\,(1-\gamma)\,, \tag{5.12}$$

where β is the following combination of dimensionless parameters:

$$\beta^{-1} \equiv \phi_a - 2\phi_a\gamma + \gamma^2. \tag{5.13}$$

It is readily verified that the solutions (5.11)–(5.12) satisfy (3.18) for $i = a$. Moreover, $A(a) = A(b) = 1$ in the nonreactive limit, Da$\rightarrow 0$, as would be expected.

Armed with knowledge of $A(i)$ and $P_0^{\infty}(i)$, the mean velocity may be calculated from the summation (4.9), yielding

$$\bar{\mathbf{U}}^* = \hat{\mathbf{x}} D_m A \left\{ \mathrm{Pe} A(b) P_0^{\infty}(b) + \lambda^{-1}\left[A(a)P_0^{\infty}(b) - A(b)P_0^{\infty}(a)\right]\right\}. \tag{5.14}$$

The latter result may be simplified and rendered dimensionless via use of (5.7)–(5.8) and (5.11)–(5.12), yielding

$$\bar{\mathbf{U}}^* = \hat{\mathbf{x}}\left(\frac{D_m F}{kT}\right)\hat{U}^*, \tag{5.15}$$

in which $\hat{U}^*$ is the dimensionless scalar coefficient (i.e., speed)

$$\hat{U}^* = \lambda\beta\phi_a\phi_e. \tag{5.16}$$

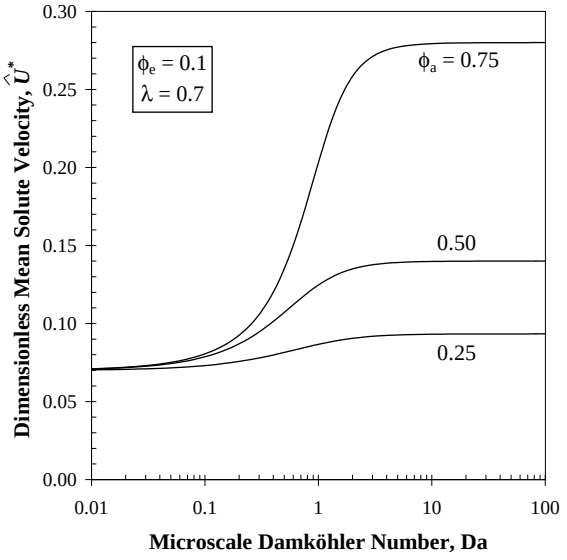

FIG. 5. *Plot of the dimensionless mean solute velocity, $\hat{U}^*$, as a function of the microscale Damköhler number, Da, for several values of the volume fraction of the reactive well, ϕ_a, and for the specified geometric attributes shown in the inset.*

The latter result reduces to $\hat{U}^* = \lambda\phi_e$ in the nonreactive Da$\rightarrow$ 0 limit, in accord with the mean velocity computed from nonreactive network theory [12]. The dimensionless mean velocity is plotted for nonzero values of Da in Figure 5. Since the solute is able to sample the tortuous diffusion path through well a, the (dimensionless) speed $\hat{U}^*$ is less than unity. The mean velocity increases with increasing reaction rate, since the solute entering well a is then depleted at a greater rate, thereby reducing its contribution to the overall transport rate. Similarly, increasing the residence time in well a causes $\hat{U}^*$ to increase. In the limit of infinite reaction rate, one would expect that no solute entering well a could contribute to the overall solute velocity, thereby leading to the value $\hat{U}^* = 1$. This contrasts with a naïve limit of (5.16), which would seem to imply that $\hat{U}^* = 0$. The latter incorrect limit derives from the singularity of (5.4) at Da$\rightarrow \infty$. While not essential to this illustrative example, the proper limiting behavior could be analyzed by rescaling the problem, i.e., solving for the ratio $\bar{K}^*/k$.

The existence of numerous candidates ((4.12), (4.15), (4.19), and (4.21)) for computing the **B**-field makes the choice of its solution protocol flexible. Upon noting that the edge subsets $j = \{1, 2\}$ and $j = \{3\}$ are independent cycles on the local graph, it follows from (4.16) that

$$\mathbf{b}(1) = -\mathbf{b}(2), \tag{5.17}$$

$$\mathbf{b}(3) = \mathbf{0}. \tag{5.18}$$

Use of (4.15) with $i = a$ furnishes the algebraic equation,

$$\phi_e P_0^\infty(b)\tau_0 \frac{\mathbf{b}(2)}{l} - \phi_e P_0^\infty(b)\tau_0 \frac{\mathbf{b}\,(1)}{l} = \phi_a P_0^\infty(a)\tau_0 \mathrm{Pe}\bar{\mathbf{U}}^* \left(\frac{kT}{D_m F}\right) - \hat{\mathbf{x}}\phi_e P_0^\infty(b)\tau_0. \tag{5.19}$$

Together with (5.7)–(5.8), (5.16), and (5.17), this furnishes the solution

$$\frac{\mathbf{b}(1)}{l} = \frac{\hat{\mathbf{x}}}{2}\left[1 - \mathrm{Pe}\lambda\beta\phi_a\left(\phi_a - \gamma\right)\right]. \tag{5.20}$$

It is readily verified that (5.17), (5.18), and (5.20) satisfy (4.15) with $i = b$.

From (4.33), $\tilde{\mathbf{b}}(j) = \hat{\mathbf{x}}\tilde{b}(j)l$, wherein the dimensionless scalar coefficients $\tilde{b}(j)$ possess the respective functional forms,

$$\tilde{b}(1) = 1/2\left[1 + \mathrm{Pe}\lambda\beta\phi_a\left(\phi_a - \gamma\right)\right], \tag{5.21}$$

$$\tilde{b}(2) = 1/2\left[1 - \mathrm{Pe}\lambda\beta\phi_a\left(\phi_a - \gamma\right)\right], \tag{5.22}$$

$$\tilde{b}(3) = 1. \tag{5.23}$$

The dispersivity is calculated from (4.32) as

$$\bar{\mathbf{D}}^* = \hat{\mathbf{x}}\hat{\mathbf{x}}\frac{DAl}{2\lambda}\left\{\begin{array}{c}\left[A(a)P_0^{\infty}(b) + A(b)P_0^{\infty}(a)\right]\left[\tilde{b}^2(1) + \tilde{b}^2(2)\right] \\ + \left(\lambda\mathrm{Pe} + 2\right)A(b)P_0^{\infty}(b)\tilde{b}^2(3)\end{array}\right\}, \tag{5.24}$$

which, with use of (5.7)–(5.8), (5.11)–(5.12), and (5.21)–(5.23), ultimately furnishes the dispersivity dyadic,

$$\bar{\mathbf{D}}^* = \hat{\mathbf{x}}\hat{\mathbf{x}}D_m\hat{D}^*, \tag{5.25}$$

with $\hat{D}^*$ the dimensionless scalar dispersivity,

$$\hat{D}^* = \frac{\phi_e\beta}{2}\left[3\phi_a - \gamma + \phi_a\lambda\mathrm{Pe} + \left(\phi_a\lambda\beta\right)^2\left(\phi_a - \gamma\right)^3\mathrm{Pe}^2\right]. \tag{5.26}$$

In the nonreactive limit,

$$\lim_{\mathrm{Da}\to 0}\hat{D}^* = \frac{\phi_e}{2}\left[3 + \lambda\mathrm{Pe} + \left(\lambda\phi_a\right)^2\mathrm{Pe}^2\right], \tag{5.27}$$

which is identical to the dispersivity calculated directly from the nonreactive theory [12].

Figure 6 portrays the dispersivity $\hat{D}^*$ as a function of Da for several different values of Pe. As is typically the case [9], the dispersivity increases with increasing Peclét number, all other things being equal. The latter effect owes its origin to the "mechanical" dispersion [12] arising from the "delay time" introduced by the tortuous path through node a. The magnitude of latter effect, which measures the "spread" between one solute particle which takes the tortuous path $b' \to a \to b$ and a second particle which takes the path $b' \to b$, depends upon the rate of convection and increases with increasing Pe.

For circumstances wherein $\mathrm{Da} < 1$, the dispersivity gradually increases from its nonreactive value, (5.27). Indeed, normalizing (5.26) for $\hat{D}^*$ with the nonreactive value (5.27) collapses the data for $\mathrm{Da} < 1$ onto a relatively thin band. This increase arises from the increase in the mean velocity over the same range of Da. Explicitly, the dispersivity is a measure of the deviations from the mean solute motion. As Da increases linearly, $\hat{U}^*$ increases dramatically (see Figure 5). Consequently, the mechanical dispersion caused by transport through a increases. Moreover, this increase more than offsets the decrease in dispersion which occurs from solute depletion.

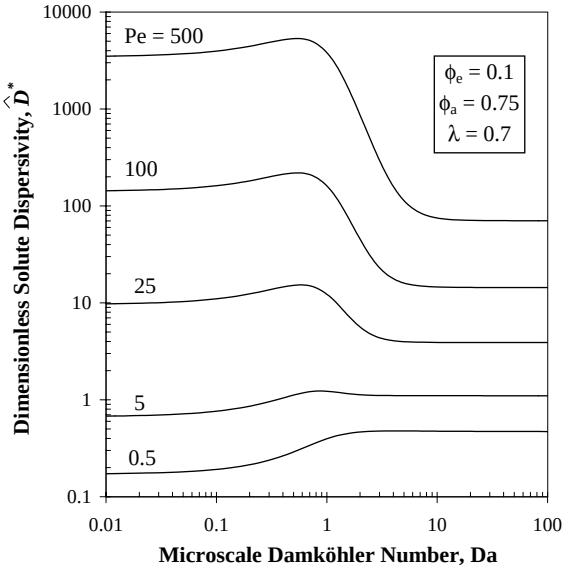

FIG. 6. *Plot of the dimensionless dispersivity, $\hat{D}^*$, as a function of the microscale Damköhler number, Da, for several values of the Peclét number, Pe, and for the specified geometric attributes shown in the inset.*

At Da $= 1$, the dispersion either levels off or undergoes a precipitous drop. When $\hat{D}^* < 1$ at Da $= 1$, the dispersion begins approaching its asymptotic value of $\hat{D}^* = 1$. The latter corresponds to the case where the only source of dispersion is from node b, since all solute molecules entering node a are depleted. When $\hat{D}^* > 1$ at Da $= 1$, the dispersivity decreases since the increasing reaction rate (at a fixed convection rate) serves to diminish the mechanical dispersion arising from the tortuous path through a. As Da $\to \infty$, the only contributions to $\hat{D}^*$ would be expected to arise from molecular diffusion in the nonreactive channels and mechanical dispersion resulting from the mixing process in well b. As was the case with the mean velocity, the singular nature of this limit prevents recovery of the proper limiting behavior directly from (5.26).

REALIZABLE (AVERAGE STRESS, AVERAGE STRAIN) PAIRS IN A PLATE WITH HOLES*

G. W. MILTON†, S. K. SERKOV†, AND A. B. MOVCHAN‡

Abstract. Here a complete characterization is given of the set of all possible (average stress, average strain) pairs that can exist in a plate containing a fixed volume fraction f of holes. Specifically, for a given average stress, the range of values the average strain takes as the microgeometry is varied (while keeping f fixed) is determined. It is shown that multiple rank laminate materials suffice to generate all possible values of the average strain. When the microgeometry is restricted to be a periodic array of holes, with only one hole per unit cell, the average strain takes a smaller range of values as the hole shape is varied. A certain necessary condition for optimality must be satisfied if the hole is such that the average strain is on the boundary of this range. Numerical results are obtained for the range in the limit where the holes are well separated and occupy a small volume fraction. Optimal hole shapes, associated with average strains on the boundary of the range of admissible values, are identified. Analytical expressions are obtained for certain optimal holes, called critical holes, for which the tangential stress is zero along the smooth portions of their boundary.

1. Introduction.

The objective of this paper is to cast light on the realizable (average stress, average strain) pairs that can occur in planar two phase composites, when one phase is void and the other phase is isotropic. Specifically, for a given fixed applied stress $\boldsymbol{\sigma}_*$ we ask: What is the range $R(f, \boldsymbol{\sigma}_*)$ of values that the average strain $\boldsymbol{\epsilon}_*$ takes as the microgeometry is varied over all possible configurations that have a fixed volume fraction f of the void phase? Also, what microgeometries are associated with average strains $\boldsymbol{\epsilon}_*$ that lie on or near the boundary of the range $R(f, \boldsymbol{\sigma}_*)$? Putting it another way, how should one punch out a fixed area fraction of holes in a stressed plate to obtain an extreme average strain $\boldsymbol{\epsilon}_*$?

Characterizing the range $R(f, \boldsymbol{\sigma}_*)$ and identifying microgeometries associated with the boundary is important for structural design problems. Consider, for example, the following optimal design problem, analogous to one treated by Gibiansky, Lurie, and Cherkaev (1988) for conductivity. A planar body contains a fixed total volume fraction p of voids in an isotropic plate material. The body is subject to given displacement boundary conditions. How should the voids be configured so that the net force on a given segment of the boundary is maximized (or minimized)? This is a tricky computational problem, since the answer might be that it is best to have infinitely many voids distributed in some microstructure. A solution is to consider the relaxed problem, where one allows for composites in the body, and not just plate or void phase. Thus one looks for the best macroscopic stress field $\boldsymbol{\sigma}_*(\mathbf{x})$ and associated macroscopic strain field $\boldsymbol{\epsilon}_*(\mathbf{x})$ compatible with the displacement boundary conditions

such that the relation $\boldsymbol{\epsilon}_*(\mathbf{x}) \in R(f(\mathbf{x}), \boldsymbol{\sigma}_*(\mathbf{x}))$ holds everywhere in the body for some choice of the function $f(\mathbf{x})$ whose average over the body is p, with $1 \geq f(\mathbf{x}) \geq 0$ for all $\mathbf{x}$. Once this problem is solved, one introduces voids into the body so that the microstructure in the vicinity of each point $\mathbf{y}$ has a local volume fraction $f(\mathbf{x})$ of voids and is such that application to it of a local average stress $\boldsymbol{\sigma}_*(\mathbf{y})$ produces the local average strain $\boldsymbol{\epsilon}_*(\mathbf{y})$.

The relation between the average strain $\boldsymbol{\epsilon}_*$ and average stress $\boldsymbol{\sigma}_*$ takes the form

$$\boldsymbol{\epsilon}_* = \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}_*, \tag{1.1}$$

where $\boldsymbol{\mathcal{S}}_*$ is the effective compliance tensor which is a fourth order tensor. This relation can also be expressed in the equivalent form

$$\begin{pmatrix} \epsilon_{11}^* \\ \epsilon_{22}^* \\ \sqrt{2}\epsilon_{12}^* \end{pmatrix} = \mathbf{S}_* \begin{pmatrix} \sigma_{11}^* \\ \sigma_{22}^* \\ \sqrt{2}\sigma_{12}^* \end{pmatrix}, \tag{1.2}$$

where the ϵ_{ij}^* and σ_{ij}^* are the elements of the average strain $\boldsymbol{\epsilon}_*$ and average stress $\boldsymbol{\sigma}_*$ in Cartesian coordinates. In this representation the fourth order effective compliance tensor $\boldsymbol{\mathcal{S}}_*$ is represented by the symmetric 3×3 matrix $\mathbf{S}_*$.

This question of characterizing $R(f, \boldsymbol{\sigma}_*)$ is nontrivial because we do not know the range of values that the effective compliance matrix $\mathbf{S}_*$ can take as the microgeometry is varied. The set of all possible compliance matrices is known as the G-closure at constant volume fraction (see Cherkaev (2000) and references therein) and is denoted as $G_f U$, in which U represents the set of compliance matrices of the two component phases. If we use the elements of the $\mathbf{S}_*$ as coordinates, $G_f U$ is represented (for a fixed volume fraction f) by a set in a six-dimensional space. However, there is one degree of rotational invariance associated with this set, due to the fact that if we rotate the microgeometry, then the effective compliance matrix is transformed in the obvious manner. Due to this invariance we can represent $G_f U$ as a set in a five-dimensional space. In contrast, it requires only four dimensions to represent (for a fixed volume fraction f) all of the sets $R(f, \boldsymbol{\sigma}_*)$ that are generated as $\boldsymbol{\sigma}_*$ varies. To see this we can assume without loss of generality (by choosing the coordinate axes and normalizing the stress appropriately) that the tensor $\boldsymbol{\sigma}_*$ takes the form

$$\boldsymbol{\sigma}_* = \begin{pmatrix} \sigma & 0 \\ 0 & 1 \end{pmatrix} \quad \text{with} \quad |\sigma| \leq 1. \tag{1.3}$$

For each value of σ the range $R(f, \boldsymbol{\sigma}_*)$ can be represented as a set in a three-dimensional space with ϵ_{11}^*, ϵ_{22}^*, and ϵ_{12}^* as coordinates. Thus the entire collection of sets $R(f, \boldsymbol{\sigma}_*)$ obtained as σ is varied can be represented by a single set in a four-dimensional space with σ, ϵ_{11}^*, ϵ_{22}^*, and ϵ_{12}^* as coordinates. Due to the reduction in dimensionality it is anticipated that the task of characterizing all the sets $R(f, \boldsymbol{\sigma}_*)$ should be easier than that of characterizing the G-closure at constant volume fraction.

For linear conductivity the analogous problem has been completely solved for a d-dimensional composite containing an arbitrary number n of anisotropic or anisotropic conducting phases, mixed in fixed proportions by Tartar (1995), following earlier work of Raĭtum (1983) and Murat and Tartar (1985) for the case of composites containing two isotropic phases. For a given fixed applied electric field $\mathbf{e}_*$, the problem is to find the range $R(f_1, \ldots, f_n, \mathbf{e}_*)$ of values that the average current field $\mathbf{j}_*$ takes as the microstructure is varied (allowing for arbitrary spatial variations in the orientation of

each phase), while keeping the volume fractions $f_1, \ldots, f_n$ of the phases fixed. For fixed values of the volume fraction, this range turned out to be simply a sphere in the space with the components j_1^*, j_2^*,$\ldots$,j_d^* of $\mathbf{j}_*$ as coordinates. (It can alternatively be represented as a set in a two-dimensional space with the invariants $\mathbf{j}_* \cdot \mathbf{e}_*/(\mathbf{e}_* \cdot \mathbf{e}_*)$ and $\mathbf{j}_* \cdot \mathbf{j}_*/(\mathbf{e}_* \cdot \mathbf{e}_*)$ as coordinates.) Moreover, average currents on the boundary of the range $R(f_1, \ldots, f_n, \mathbf{e}_*)$ were associated with simple laminates of the n phases. The phases are oriented so that the axes with minimum conductivity are aligned parallel to the direction of lamination $\mathbf{n}$, and so the axes with maximum conductivity are aligned in another perpendicular direction, with the fields $\mathbf{j}_*$ and $\mathbf{e}_*$ both lying in the plane spanned by these two directions. As the angle between $\mathbf{n}$ and $\mathbf{e}_*$ is varied, the vector $\mathbf{j}_*$ ranges over the entire boundary of the sphere $R(f_1, \ldots, f_n, \mathbf{e}_*)$. Laminates appear naturally as the optimal composites since they are the best microgeometries for guiding current in desired directions. In some sense the optimal microstructures we seek in this paper can be regarded as the best microgeometries for guiding stress.

For nonlinear conductivity less is known. The case of composites of two isotropic phases, with one phase occupying a fixed volume fraction f, has been investigated by Milton and Serkov (2000). The set $R(f, \mathbf{e}_*)$ (of all possible average current fields $\mathbf{j}_*$ associated with a given applied electric field $\mathbf{e}_*$) is no longer a sphere, and there are other microstructures besides simple laminates which are needed to generate currents $\mathbf{j}_*$ on the boundary of $R(f, \mathbf{e}_*)$. Curiously, to generate the maximum current in the direction of $\mathbf{e}_*$, it is sometimes necessary to use a simple laminate with its layers oriented perpendicular (rather than parallel) to the field.

The structure of the present paper can be summarized as follows:

- Section 2 gives an essentially complete characterization of the range $R(f, \boldsymbol{\sigma}_*)$ of values that $\boldsymbol{\epsilon}_*$ takes as the microstructure varies over all conceivable configurations. Microgeometries corresponding to values of $\boldsymbol{\epsilon}_*$ on or near the boundary of $R(f, \boldsymbol{\sigma}_*)$ are identified.
- Section 3 considers periodic arrays of holes with only one simply connected hole per unit cell occupying a fixed volume fraction f. A condition for optimality is derived which must necessarily hold if $\boldsymbol{\epsilon}_*$ is at the boundary of its range of admissible values for this restricted class of microgeometry.
- Section 4 presents numerical results for the range of values of $\boldsymbol{\epsilon}_*$ for periodic arrays of well separated holes occupying a fixed infinitesimal volume fraction f. Hole shapes are identified which correspond to values of $\boldsymbol{\epsilon}_*$ at the boundary of its range of admissible values for this restricted class of microgeometry.
- Section 5 gives analytical expressions for the shape of certain holes, which we call critical holes. These have the property that the tangential stress is zero along all smooth portions of the boundary of the hole, for at least one loading. Such holes satisfy the optimality criterion, and the numerical evidence suggests that they are optimal holes.

Throughout the paper we will assume that the plate is in a state of plane stress (i.e., the plate contracts or expands in thickness so that the normal component of the stress on the plate surface remains zero). The formulae are easily adapted to the case of plane strain (where the thickness of the plate is constrained to be constant) by making the standard adjustments to the moduli entering the formulae.

The characterization of $R(f, \boldsymbol{\sigma}_*)$ given in section 2 can be generalized to three-dimensional porous media. The only difficult part is constructing porous "pentamode" materials for which the effective elasticity tensor has one finite nonzero eigenvalue and five zero eigenvalues. The structures given in Figure 5 of Milton and Cherkaev (1995)

provide a basis for constructing such pentamode materials. However, to ensure that one eigenvalue is nonzero, the junctions between the linkages have to be appropriately modified. The three-dimensional case will be analyzed in detail in a forthcoming paper.

2. The essentially complete characterization of $R(f, \boldsymbol{\sigma}_*)$. The characterization of $R(f, \boldsymbol{\sigma}_*)$ is a delicate question because strange effective behaviors can result when one phase is void (Khruslov (1978), Briane (1998), Briane and Mazliak (1998)). Additionally, nonlinear effects, such as the buckling of the layers in a laminate of the matrix and void phases, cannot be ignored. To avoid these technical issues, we will suppose that the void phase is not really void but has a nonzero isotropic elasticity matrix $\mathbf{C}_V$. Then the set $G_f U$ of all possible compliance matrices is well defined, and its associated set $G_f U \boldsymbol{\sigma}_*$ consisting of all strain tensors $\boldsymbol{\epsilon}_*$ such that $\boldsymbol{\epsilon}_* = \mathbf{S}_* \boldsymbol{\sigma}_*$ for some $\mathbf{S}_* \in G_f U$ is also well defined. We define $R(f, \boldsymbol{\sigma}_*)$ as the set which $G_f U \boldsymbol{\sigma}_*$ approaches in the limit as $\mathbf{C}_V$ approaches zero. (It remains to show that this set does not depend upon the path of isotropic positive definite fourth order tensors that $\mathbf{C}_V$ follows as it approaches zero, but the ensuing analysis suggests that this is the case.)

The main result of this section is the following theorem.

THEOREM 1. *The set $R(f, \boldsymbol{\sigma}_*)$ includes all strain tensors $\boldsymbol{\epsilon}_*$ such that*

$$\boldsymbol{\epsilon}_* : \boldsymbol{\sigma}_* > \lim_{\mathbf{C}_V \to 0} \left[\min_{\mathbf{S}_* \in G_f U} \boldsymbol{\sigma}_* : \mathbf{S}_* \boldsymbol{\sigma}_* \right], \tag{2.1}$$

in which the right-hand side (when divided by 2) can be identified with the lower bound on the elastic energy for which an explicit expression is available (Gibiansky and Cherkaev (1984), *Allaire and Kohn* (1993*a*, 1993*b*)*). Hence any tensor $\boldsymbol{\epsilon}_*$ for which $\boldsymbol{\epsilon}_* : \boldsymbol{\sigma}_*$ is less than the right-hand side of* (2.1) *is not contained in $R(f, \boldsymbol{\sigma}_*)$. When* $\det(\boldsymbol{\sigma}_*) \geq 0$*, the set $R(f, \boldsymbol{\sigma}_*)$ also contains those strain tensors $\boldsymbol{\epsilon}_*$ such that equality holds in* (2.1).

This theorem does not quite provide a complete characterization of $R(f, \boldsymbol{\sigma}_*)$, because when $\det(\boldsymbol{\sigma}_*) < 0$ it is still uncertain as to whether tensors $\boldsymbol{\epsilon}_*$ such that equality holds in (2.1) belong to $R(f, \boldsymbol{\sigma}_*)$.

In establishing Theorem 1, we skip many of the technical details. During much of the proof we treat the void phase as being truly void, and then at the end we discuss how the argument needs to be modified when one correctly takes the limit $\mathbf{C}_V \to 0$.

Let $\mathbf{S} = \mathbf{S}(E, \nu)$ be the compliance matrix of the original plate, which for plane stress is given by

$$\mathbf{S}(E, \nu) = \begin{pmatrix} 1/E & -\nu/E & 0 \\ -\nu/E & 1/E & 0 \\ 0 & 0 & (1+\nu)/E \end{pmatrix}, \tag{2.2}$$

where E and ν are the Young's modulus and Poisson's ratio of the isotropic plate material, respectively. Rather than characterizing the set $R(f, \boldsymbol{\sigma}_*)$ of possible average strains $\boldsymbol{\epsilon}_*$ associated with a given average stress, it is simpler to consider the equivalent problem of characterizing the set

$$D(f, \boldsymbol{\sigma}_*) = \frac{R(f, \boldsymbol{\sigma}_*)}{f} - \frac{\mathbf{S}\boldsymbol{\sigma}_*}{f} \tag{2.3}$$

of possible values of

$$\boldsymbol{\epsilon}_V = \frac{[\boldsymbol{\epsilon}_* - \mathbf{S}\boldsymbol{\sigma}_*]}{f} = [\mathbf{S}_*(E, \nu) - \mathbf{S}(E, \nu)] \frac{\boldsymbol{\sigma}_*}{f}, \tag{2.4}$$

when the average stress $\boldsymbol{\sigma}_*$ and the void volume fraction f are fixed. This tensor $\boldsymbol{\epsilon}_V$ can be regarded as the average strain within the void phase. To justify this interpretation, suppose that the void phase was not really void but had elasticity matrix $\mathbf{C}_V$. Let $\boldsymbol{\epsilon}_V$ and $\boldsymbol{\sigma}_V$ represent the average strain and stress in this phase, and let $\boldsymbol{\epsilon}_P$, $\boldsymbol{\sigma}_P$ represent the average strain and stress in the remaining plate. Then we have

$$\begin{aligned}\boldsymbol{\epsilon}_* &= f\boldsymbol{\epsilon}_V + (1-f)\boldsymbol{\epsilon}_P = f\boldsymbol{\epsilon}_V + (1-f)\mathbf{S}\boldsymbol{\sigma}_P \\ &= f\boldsymbol{\epsilon}_V + \mathbf{S}(\boldsymbol{\sigma}_* - f\boldsymbol{\sigma}_V) = f(\mathbf{I} - \mathbf{S}\mathbf{C}_V)\boldsymbol{\epsilon}_V + \mathbf{S}\boldsymbol{\sigma}_*.\end{aligned} \tag{2.5}$$

This relation implies that $\boldsymbol{\epsilon}_V$ is given by (2.4) in the limit $\mathbf{C}_V \to 0$.

The set $D(f, \boldsymbol{\sigma}_*)$ of possible average strains within the void phase must have a rather trivial dependence on E and ν. It has been established (Day et al. (1992), Cherkaev, Lurie, and Milton (1992), Zheng and Hwang (1996, 1997), Hu and Weng (2001)) that $E[\mathbf{S}_*(E,\nu) - \mathbf{S}(E,\nu)]$ is independent of the moduli E and ν of the plate. It follows that $E\boldsymbol{\epsilon}_V$ is independent of the moduli of the plate. Consequently the set $D(f, \boldsymbol{\sigma}_*)$ must be independent of ν and must rescale in proportion to $1/E$ as the Young's modulus E of the plate is varied.

Some elementary bounds on the set $D(f, \boldsymbol{\sigma}_*)$ follow immediately from optimal bounds on the elastic energy $\boldsymbol{\epsilon}_* : \boldsymbol{\sigma}_*/2$, due to Allaire and Kohn (1993a) (see also Gibiansky and Cherkaev (1984) and Allaire and Kohn (1993b) for related energy bounds in planar elasticity). Without loss of generality let us suppose that $\boldsymbol{\sigma}_*$ takes the form (1.3). Then their bounds imply

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* \geq B(\sigma), \quad \text{where} \quad B(\sigma) = \frac{(1+|\sigma|)^2}{(1-f)E} \tag{2.6}$$

for any $\boldsymbol{\epsilon}_V \in D(f, \boldsymbol{\sigma}_*)$. Here we will establish that any $\boldsymbol{\epsilon}_V$ satisfying this bound as an inequality can be identified with the average strains within the void phase of a particular multiple rank laminate composite. The only open question is the minor point of whether those $\boldsymbol{\epsilon}_V$ satisfying the bound as an equality are realizable. We can answer this affirmatively only when σ is nonnegative.

First let us consider the case when $\sigma > 0$. It is well known that second rank laminates attain the energy bound. These second rank laminates are obtained by laminating the void phase with the plate phase, and then laminating this structure (on a much larger length scale, with a different direction of lamination) with the plate phase again. In an appropriately chosen second rank laminate subject to the applied stress $\boldsymbol{\sigma}_*$, the average strain $\boldsymbol{\epsilon}_V$ in the void phase is such that (2.6) holds as an equality. Our aim is to show the stronger result that, for every $\boldsymbol{\epsilon}_V$ such that (2.6) holds as an equality, there exists a second rank laminate such that $\boldsymbol{\epsilon}_V$ is the average strain in the void phase. Geometrically the set of $\boldsymbol{\epsilon}_V$ such that (2.6) holds as an equality represents a plane in the space with ϵ^*_{11}, ϵ^*_{22}, and ϵ^*_{12} as coordinates, and we want to show that every point on this plane corresponds to some second rank laminate. Second rank laminates are special, in that their associated effective elasticity matrix $\mathbf{C}_* = \mathbf{S}_*^{-1}$ has one zero eigenvalue. Consequently two different average strains can produce the same average stress. They are unimode materials in the sense of having one easy mode of deformation (Milton and Cherkaev, 1995). A line of average strains (rather than a single average strain) is associated with a given average stress $\boldsymbol{\sigma}_*$. This line lies in the plane $\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = B(\sigma)$. The orientation of the line in this plane varies as one changes the structure of the second rank laminate, while still attaining the bound.

We will now prove that the structure can be adjusted so that the line passes through any desired point in the plane $\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = B(\sigma)$.

Explicit formulae are available for the effective elasticity or compliance tensor of second rank laminates (Francfort and Murat (1986), Gibiansky and Cherkaev (1987)), but we do not need these formulae in the ensuing analysis. Consider a simple laminate of the plate phase and the void phase, mixed in proportions $(1-p)$ and p, with the average strain in the void phase being $\boldsymbol{\epsilon}_V$ and with the interfaces being oriented parallel to a unit vector $\mathbf{t}_1$. The stress $\boldsymbol{\sigma}_P^{(1)}$ and strain $\boldsymbol{\epsilon}_P^{(1)}$ in the plate phase must be

$$\boldsymbol{\sigma}_P^{(1)} = E(\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1)\mathbf{t}_1 \otimes \mathbf{t}_1, \quad \boldsymbol{\epsilon}_P^{(1)} = \mathbf{S}\boldsymbol{\sigma}_P^{(1)} \tag{2.7}$$

to ensure compatibility of stresses and strains at each interface. (Here $\mathbf{t}_1 \otimes \mathbf{t}_1$ denotes the rank-1 matrix $\mathbf{t}_1\mathbf{t}_1^T$, in which the row vector $\mathbf{t}_1^T$ is the transpose of the column vector $\mathbf{t}_1$.) The resulting average stress and strain in the entire laminate are therefore $\boldsymbol{\sigma}_*^{(1)} = p\boldsymbol{\sigma}_P^{(1)}$ and $\boldsymbol{\epsilon}_*^{(1)} = p\boldsymbol{\epsilon}_P^{(1)} + (1-p)\boldsymbol{\epsilon}_V$. Next suppose that this laminate has been layered (on a much larger length scale) with new layers of the plate phase, in proportions $(1-q)$ and q, with the new interfaces being oriented parallel to a unit vector $\mathbf{t}_2$. The stress $\boldsymbol{\sigma}_P^{(2)}$ and strain $\boldsymbol{\epsilon}_P^{(2)}$ in the new layers of the plate phase must be

$$\boldsymbol{\sigma}_P^{(2)} = \boldsymbol{\sigma}_*^{(1)} + E(1-p)(\mathbf{t}_2 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_2)\mathbf{t}_2 \otimes \mathbf{t}_2, \quad \boldsymbol{\epsilon}_P^{(2)} = \mathbf{S}\boldsymbol{\sigma}_P^{(2)} \tag{2.8}$$

to ensure compatibility of the stresses $\boldsymbol{\sigma}_P^{(2)}$ and $\boldsymbol{\sigma}_*^{(1)}$ and compatibility of the associated strains, $\mathbf{S}\boldsymbol{\sigma}_P^{(2)}$ and $\boldsymbol{\epsilon}_*^{(1)}$. The total average stress in this rank-2 laminate is therefore

$$\boldsymbol{\sigma}_* = (1-f)E[c_1(\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1)\mathbf{t}_1 \otimes \mathbf{t}_1 + c_2(\mathbf{t}_2 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_2)\mathbf{t}_2 \otimes \mathbf{t}_2], \tag{2.9}$$

where $f = (1-p)(1-q)$ is the volume fraction of void in the second rank laminate and c_1 and c_2 are the nonnegative lamination parameters

$$c_1 = \frac{p}{1-f} = \frac{p}{p+q-pq}, \qquad c_2 = \frac{q(1-p)}{1-f} = \frac{q(1-p)}{p+q-pq} \tag{2.10}$$

introduced by Tartar (1985), satisfying $c_1 + c_2 = 1$. For any fixed value of f, $c_1 = 1 - c_2$ can take any value between 0 and 1. Now if $\boldsymbol{\epsilon}_V$, $\mathbf{t}_1$, and $\mathbf{t}_2$ are such that

$$\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1 = \mathbf{t}_2 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_2 = \frac{1+\sigma}{(1-f)E}, \tag{2.11}$$

then $\boldsymbol{\sigma}_*$ will have the desired trace $1+\sigma$, and

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = (1-f)E[c_1(\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1)^2 + c_2(\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1)^2] = \frac{(1+\sigma)^2}{(1-f)E}. \tag{2.12}$$

In other words, the bound (2.6) will be satisfied as an equality. (Note that $\boldsymbol{\sigma}_*$ given by (2.9) necessarily has eigenvalues of the same sign when (2.11) holds.) To ensure that $\boldsymbol{\sigma}_*$ is diagonal we choose

$$c_1 = \frac{-\cos\theta_2 \sin\theta_2}{\cos\theta_1 \sin\theta_1 - \cos\theta_2 \sin\theta_2}, \qquad c_2 = \frac{\cos\theta_1 \sin\theta_1}{\cos\theta_1 \sin\theta_1 - \cos\theta_2 \sin\theta_2}, \tag{2.13}$$

where θ_1 and θ_2 are the angles of the layers, in terms of which

$$\mathbf{t}_1 = \begin{pmatrix} \sin\theta_1 \\ \cos\theta_1 \end{pmatrix}, \quad \mathbf{t}_2 = \begin{pmatrix} \sin\theta_2 \\ \cos\theta_2 \end{pmatrix}. \tag{2.14}$$

Both c_1 and c_2 will be positive if we take θ_1 between 0 and $\pi/2$, and θ_2 between $\pi/2$ and π. To ensure that the diagonal elements of $\boldsymbol{\sigma}_*$ are σ and 1 we take

$$\tan\theta_2 = -\frac{\sigma}{\tan\theta_1}. \tag{2.15}$$

Next note that any $\boldsymbol{\epsilon}_V$ satisfying equality in (2.6) can be represented in the form

$$\boldsymbol{\epsilon}_V = \frac{(1+\sigma)\mathbf{I}}{(1-f)E} + \mathbf{A} \quad \text{with} \quad \mathbf{A} = \begin{pmatrix} a & b \\ b & -a\sigma \end{pmatrix} \tag{2.16}$$

for some choice of the constants a and b. The condition (2.11) then requires that $\mathbf{t}_1$ and $\mathbf{t}_2$ be chosen with

$$\mathbf{t}_1 \cdot \mathbf{A}\mathbf{t}_1 = \mathbf{t}_2 \cdot \mathbf{A}\mathbf{t}_2 = 0. \tag{2.17}$$

This will be satisfied if $\tan\theta_2$ is given by (2.15), and if $\tan\theta_1$ is the unique nonnegative root of the quadratic

$$a(\tan\theta_1)^2 + 2b\tan\theta_1 - a\sigma = 0, \tag{2.18}$$

which always has such a root. By choosing the parameters according to (2.13), (2.15), and (2.18), we have obtained a laminate such that $\boldsymbol{\epsilon}_V$ is the average strain in the void phase and $\boldsymbol{\sigma}_*$ given by (1.3) is the average stress. In the special case when $a = 0$ we have $\theta_1 = 0$ and $\theta_2 = \pi$, and (2.13) is not sufficient to determine c_1 and c_2. (The tensor $\boldsymbol{\sigma}_*$ given by (2.9) is always diagonal.) In this case we choose $c_1 = \sigma/(1+\sigma)$ and $c_2 = 1/(1+\sigma)$ to ensure that the diagonal elements of $\boldsymbol{\sigma}_*$ are σ and 1. In another special case when $b = 0$ the equations are solved with $\tan\theta_1 = -\tan\theta_2 = \sqrt{\sigma}$ and $c_1 = c_2 = 1/2$.

When $\sigma = 0$ a simple laminate of the void and plate phases with its layers parallel to the x_2-axis suffices to generate all values of $\boldsymbol{\epsilon}_V$ on the boundary of $D(f, \boldsymbol{\sigma}_*)$. The effective elasticity matrix $\mathbf{C}_* = \mathbf{S}_*^{-1}$ of such a laminate has two zero eigenvalues. It is a bimode material in the sense of having two easy modes of deformation. A plane of average strains (rather than a single average strain) is associated with a given average stress $\boldsymbol{\sigma}_*$. It is easy to check that the associated plane of values of $\boldsymbol{\epsilon}_V$ is

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = \frac{1}{(1-f)E}, \tag{2.19}$$

which, according to (2.6), is the boundary of $D(f, \boldsymbol{\sigma}_*)$.

When $\sigma < 0$ it is known that the energy bound is attained by rank-2 laminates with $\theta_1 = 0$ and $\theta_2 = \pi$. Indeed, by choosing these values of θ_1 and θ_2 and

$$\mathbf{t}_1 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_1 = -\mathbf{t}_2 \cdot \boldsymbol{\epsilon}_V \mathbf{t}_2 = -\frac{1-\sigma}{(1-f)E}, \quad c_1 = \frac{-\sigma}{1-\sigma}, \quad c_2 = \frac{1}{1-\sigma}, \tag{2.20}$$

we see that $\boldsymbol{\sigma}_*$ given by (2.9) is diagonal with elements σ and 1, and that the bound (2.6) is achieved. In contrast to the case when $\sigma > 0$, these are the only rank-2 laminates which attain the bound. The constraint (2.20) on $\boldsymbol{\epsilon}_V$ forces it to have the form

$$\boldsymbol{\epsilon}_V = \begin{pmatrix} -k & c \\ c & k \end{pmatrix}, \quad \text{where} \quad k = \frac{1-\sigma}{(1-f)E}, \tag{2.21}$$

which generates only one line on the boundary of $D(f,\boldsymbol{\sigma}_*)$ as c is varied. What saves us is the fact that there are many other laminate structures which come close to attaining the bound.

Suppose we want to find a multiple rank laminate for which the average stress $\boldsymbol{\epsilon}_V$ within the void phase is close to boundary of $D(f,\boldsymbol{\sigma}_*)$. We can express $\boldsymbol{\epsilon}_V$ in the form

$$\boldsymbol{\epsilon}_V = \begin{pmatrix} a-k-\delta & b \\ b & k+\delta-a\sigma \end{pmatrix}, \tag{2.22}$$

where δ is a small positive parameter, and a and b can have any real values.

Now it was established by Milton and Cherkaev (1995) (see also section 30.7 in Milton (2002)) that for any given tensor $\boldsymbol{\sigma}_*$ with negative determinant there exists a rank-4 laminate which is bimode and supports the stress $\boldsymbol{\sigma}_*$. The associated plane of values of $\boldsymbol{\epsilon}_V$ necessarily takes the form

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = (1-\sigma)h, \tag{2.23}$$

where h is a fixed constant with $h > k$. This plane is parallel to the boundary of $D(f,\boldsymbol{\sigma}_*)$. Let us assume that δ is small enough so that $h > k+\delta$. Our aim is to show that, by laminating together (on a very large length scale) this bimode material with the second rank laminate achieving the energy bound, we can attain the desired value (2.22) of $\boldsymbol{\epsilon}_V$.

In general the set $R(f,\boldsymbol{\sigma}_*)$ has the property that

$$\boldsymbol{\epsilon}_*^C = p\boldsymbol{\epsilon}_*^A + (1-p)\boldsymbol{\epsilon}_*^B \in R(f,\boldsymbol{\sigma}_*) \tag{2.24}$$

for all $p \in (0,1)$, whenever $\boldsymbol{\epsilon}_*^A$ and $\boldsymbol{\epsilon}_*^B$ are such that

$$\boldsymbol{\epsilon}_*^A \in R(f,\boldsymbol{\sigma}_*), \quad \boldsymbol{\epsilon}_*^B \in R(f,\boldsymbol{\sigma}_*), \quad \text{and} \quad \mathbf{t}\cdot\boldsymbol{\epsilon}_*^A\mathbf{t} = \mathbf{t}\cdot\boldsymbol{\epsilon}_*^B\mathbf{t} \tag{2.25}$$

for some choice of $\mathbf{t} \neq 0$. The condition that $\boldsymbol{\epsilon}_*^A$ and $\boldsymbol{\epsilon}_*^B$ lie in $R(f,\boldsymbol{\sigma}_*)$ implies that there exist composites A and B of the two phases, with the void phase occupying the volume fraction f in each composite, such that if an average stress $\boldsymbol{\sigma}_*$ is applied to these composites, then the resulting average strains will be $\boldsymbol{\epsilon}_*^A$ and $\boldsymbol{\epsilon}_*^B$, respectively. The last condition in (2.25) ensures compatibility of the average strains. The associated composite C is a laminate of the two composites A and B, laminated (on a length scale much larger than the microstructure of composites A and B) in proportions p and $1-p$, respectively, with its layers being parallel to $\mathbf{t}$. When an average stress $\boldsymbol{\sigma}_*^C$ is applied to this laminate, the elasticity equations are solved with the stress field within composites A and B having the same average value of $\boldsymbol{\sigma}_*$ resulting in an average strain of $\boldsymbol{\epsilon}_*^C$ in composite C.

When mapped to the set $D(f,\boldsymbol{\sigma}_*)$ (which is just $R(f,\boldsymbol{\sigma}_*)$ shifted and rescaled) this property implies

$$\boldsymbol{\epsilon}_V^C = p\boldsymbol{\epsilon}_V^A + (1-p)\boldsymbol{\epsilon}_V^B \in D(f,\boldsymbol{\sigma}_*) \tag{2.26}$$

for all $p \in (0,1)$, whenever $\boldsymbol{\epsilon}_V^A$ and $\boldsymbol{\epsilon}_V^B$ are such that

$$\boldsymbol{\epsilon}_V^A \in D(f,\boldsymbol{\sigma}_*), \quad \boldsymbol{\epsilon}_V^B \in D(f,\boldsymbol{\sigma}_*), \quad \text{and} \quad \mathbf{t}\cdot\boldsymbol{\epsilon}_V^A\mathbf{t} = \mathbf{t}\cdot\boldsymbol{\epsilon}_V^B\mathbf{t} \tag{2.27}$$

for some choice of $\mathbf{t} \neq 0$. We want to find $\boldsymbol{\epsilon}_V = \boldsymbol{\epsilon}_V^A$ of the form (2.21) and $\boldsymbol{\epsilon}_V = \boldsymbol{\epsilon}_V^B$ satisfying (2.23), such that $\boldsymbol{\epsilon}_V^C$ matches $\boldsymbol{\epsilon}_V$ in (2.22). First note that if the last

condition in (2.27) holds, then necessarily

$$0 = \mathbf{t} \cdot (\boldsymbol{\epsilon}_V^C - \boldsymbol{\epsilon}_V^A)\mathbf{t} = \mathbf{t} \cdot \begin{pmatrix} \delta - a & c - b \\ c - b & a\sigma - \delta \end{pmatrix} \mathbf{t}. \tag{2.28}$$

Letting θ denote the angle of the layers in the final lamination, so that $\mathbf{t} = (\sin\theta, \cos\theta)$, this last condition becomes

$$(\delta - a)(\tan\theta)^2 + 2(c - b)\tan\theta + a\sigma - \delta = 0. \tag{2.29}$$

We are free to select any value of θ such that $\tan\theta$ is nonzero and finite, and we set

$$c = b + \frac{(a - \delta)(\tan\theta)^2 + \delta - a\sigma}{2\tan\theta} \tag{2.30}$$

so that (2.29) is satisfied. Having found c and $\mathbf{t}$, we choose

$$\boldsymbol{\epsilon}_V^B = \frac{(\boldsymbol{\epsilon}_V^C - p\boldsymbol{\epsilon}_V^A)}{(1 - p)} \quad \text{with} \quad p = \frac{h - k - \delta}{h - k} \tag{2.31}$$

so that (2.26) holds, so that $\boldsymbol{\epsilon}_V = \boldsymbol{\epsilon}_V^B$ satisfies (2.23), and so that the last condition in (2.27) holds. The average strain in the void phase in the resulting composite then matches (2.22).

So far, for each positive, zero, or negative value of σ, we have found composites realizing values of $\boldsymbol{\epsilon}_V$ such that (2.6) is satisfied, or almost satisfied, as an equality. It remains to find composites realizing the remaining values of $\boldsymbol{\epsilon}_V$ satisfying the inequality (2.6). These composites have average strain in the void phase matching any $\boldsymbol{\epsilon}_V$ in the interior of $D(f, \boldsymbol{\sigma}_*)$. Given any α between 1 and $1/f$, consider the set of composites we have found that have values of $\boldsymbol{\epsilon}_V$ on or close to the boundary of $D(\alpha f, \boldsymbol{\sigma}_*)$. These have a volume fraction αf of the void phase, and are such that

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* \approx \frac{(1 + |\sigma|)^2}{(1 - \alpha f)E}. \tag{2.32}$$

Now we can reduce the volume fraction of the void phase down to f in each of these composites by inserting islands of the plate phase into the void spaces. Inside these islands both the stress and the strain will be zero. The stress field and hence the average stress field $\boldsymbol{\sigma}_*$ will remain unchanged. The displacement field $\mathbf{u}(\mathbf{x})$ in the original part of the plate phase (excluding the new islands) will also remain invariant. Since $\mathbf{u}(\mathbf{x})/\|\mathbf{x}\|$ approaches $\boldsymbol{\epsilon}_*\mathbf{x}/\|\mathbf{x}\|$ as $\|\mathbf{x}\| \to \infty$, it follows that the average strain will remain unchanged when we insert the islands. The average strain $\boldsymbol{\epsilon}_V$ in the void phase, given by (2.4), will be multiplied by the factor α because the volume fraction of void is reduced by the factor α. In this way we obtain composites, with the void phase occupying the volume fraction f, which realize or come close to realizing any $\boldsymbol{\epsilon}_V$ satisfying

$$\boldsymbol{\epsilon}_V : \boldsymbol{\sigma}_* = \alpha \frac{(1 + |\sigma|)^2}{(1 - \alpha f)E}. \tag{2.33}$$

As α is varied from 1 to $1/f$, this plane of values of $\boldsymbol{\epsilon}_V$ sweeps across the entire range allowed by (2.6).

There is one technical point which remains. That is, the results seem very sensitive to perturbations. In particular, a small change in the structure of a bimode material

may cause the zero eigenvalues of its effective elasticity matrix to become nonzero, and the associated set of values of $\boldsymbol{\epsilon}_V$, for a given applied stress $\boldsymbol{\sigma}_*$, changes from a plane of values to just a single value. Also, to rigorously justify our analysis, we should really take the void phase to have a nonzero Young's modulus E_V (so that it is not void) and then take the limit as $E_V \to 0$. But for any $E_V > 0$ the effective elasticity matrix will have nonzero eigenvalues, and so there will be just a single value of $\boldsymbol{\epsilon}_V$ for a given $\boldsymbol{\sigma}_*$ in any unimode or bimode material. It looks like our analysis falls apart.

However, the key observation to make is that while these perturbations make large changes to the effective compliance matrix $\mathbf{S}_*$, they make small changes to the effective elasticity matrix $\mathbf{C}_*$. For a given fixed applied strain $\boldsymbol{\epsilon}_*$ let us consider the range $S(f, \boldsymbol{\epsilon}_*)$ of values that the average stress $\boldsymbol{\sigma}_*$ takes as the microgeometry is varied over all possible configurations that have a fixed volume fraction f of the void phase. When the structure of a material is slightly perturbed, the value of $\boldsymbol{\sigma}_*$ will not change by much. Characterizing all the sets $S(f, \boldsymbol{\epsilon}_*)$ and characterizing all the sets $R(f, \boldsymbol{\sigma}_*)$ are clearly equivalent problems. The energy bounds imply

$$\boldsymbol{\epsilon}_* : \boldsymbol{\sigma}_* \geq \boldsymbol{\sigma}_* : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}_* + \frac{f(|\lambda_1| + |\lambda_2|)^2}{(1-f)E}, \tag{2.34}$$

where λ_1 and λ_2 are the eigenvalues of $\boldsymbol{\sigma}_*$ and $\boldsymbol{\mathcal{S}}$ is the fourth order compliance tensor of the plate (represented by the matrix $\mathbf{S}$ given by (2.2)). The set of $\boldsymbol{\sigma}_*$ consistent with these bounds for a given value of $\boldsymbol{\epsilon}_*$ does not have a simple geometrical interpretation in the space with σ_{11}^*, σ_{22}^*, and σ_{12}^* as coordinates, although its intersection of its boundary with the region $\det \boldsymbol{\sigma}_* \geq 0$ is an ellipsoidal surface. To find a microstructure associated with a given $\boldsymbol{\sigma}_*$ in this set, we use the same construction as before, that is, we look for the microstructure associated with $\boldsymbol{\epsilon}_*$ when the average stress $\boldsymbol{\sigma}_*$ is applied. Now, however, $\boldsymbol{\sigma}_*$ will be only slightly perturbed if we make E_V very small and positive. Since the structure of the material associated with a given $\boldsymbol{\sigma}_*$ changes continuously as $\boldsymbol{\sigma}_*$ is varied in the regions $\det \boldsymbol{\sigma}_* > 0$ and $\det \boldsymbol{\sigma}_* < 0$, we can realize any $\boldsymbol{\sigma}_*$ satisfying the strict inequality (2.34) for sufficiently small values of E_V, provided that $\det \boldsymbol{\sigma}_* \neq 0$. If $\det \boldsymbol{\sigma}_* = 0$ and E_V is fixed but very small, then we consider the microstructures A and B associated with $\boldsymbol{\sigma}_*^A$ and $\boldsymbol{\sigma}_*^B$, where

$$\boldsymbol{\sigma}_*^A = \boldsymbol{\sigma}_* + \delta \mathbf{t} \otimes \mathbf{t}, \qquad \boldsymbol{\sigma}_*^B = \boldsymbol{\sigma}_* - \delta \mathbf{t} \otimes \mathbf{t}, \tag{2.35}$$

where δ is small and the unit vector $\mathbf{t}$ is chosen so that $\det \boldsymbol{\sigma}_*^A \neq 0$. Then $\det \boldsymbol{\sigma}_*^B = -\det \boldsymbol{\sigma}_*^A$ is also nonzero. By laminating together the microstructures A and B in equal proportions with the layer interfaces being oriented parallel to $\mathbf{t}$, we obtain a composite having the average stress $\boldsymbol{\sigma}_*$.

3. A necessary condition for optimality for a periodic array of holes. Although we have completely characterized the range $R(f, \boldsymbol{\sigma}_*)$ and identified optimal (or almost optimal) microgeometries, the solution is unsatisfactory from a practical viewpoint. Multiple rank laminates are difficult to construct, and when one phase is void we expect that buckling of the layers and contact between adjacent layers could be a serious problem. Instead of allowing all possible microgeometries, it makes sense to consider a restricted class of more realistic microgeometries, such as periodic composites comprised of a regular array of holes with one simply connected hole per unit cell. We focus on this problem since a periodic composite with only one hole per unit cell should be much easier to manufacture than a composite with multiple

(or perhaps infinitely many) holes per unit cell. The holes occupy a (possibly large) volume fraction f in the plate. We let $\widetilde{R}(f, \boldsymbol{\sigma}_*)$ denote the range of values that the average strain $\boldsymbol{\epsilon}_*$ takes as the boundary Γ of the hole in the unit cell is varied, while keeping f fixed. (The range $\widetilde{R}(f, \boldsymbol{\sigma}_*)$ will depend on our choice of primitive vectors of the unit cell.)

A first step towards determining $\widetilde{R}(f, \boldsymbol{\sigma}_*)$ is to find its convex hull. This is obtained from its Legendre transform

$$g(f, \boldsymbol{\sigma}_*^0, \boldsymbol{\sigma}_*) = \min_{\boldsymbol{\epsilon}_* \in \widetilde{R}(f, \boldsymbol{\sigma}_*)} \boldsymbol{\sigma}_*^0 : \boldsymbol{\epsilon}_*. \tag{3.1}$$

Knowing $g(f, \boldsymbol{\sigma}_*^0, \boldsymbol{\sigma}_*)$ for given values of f, $\boldsymbol{\sigma}_*^0$, and $\boldsymbol{\sigma}_*$ allows one to compute a tangent plane to the set $\widetilde{R}(f, \boldsymbol{\sigma}_*)$ (with the tangent plane having normal $\boldsymbol{\sigma}_*^0$). By varying $\boldsymbol{\sigma}_*^0$ and taking the envelope of the resulting family of tangent lines, one recovers the convex hull of $\widetilde{R}(f, \boldsymbol{\sigma}_*)$. When $\boldsymbol{\sigma}_*^0 = \boldsymbol{\sigma}_*$, the quantity $\boldsymbol{\sigma}_*^0 : \boldsymbol{\epsilon}_*/2$ is simply the elastic energy stored in the composite when it is subject to the average stress $\boldsymbol{\sigma}_*$, and so $g(f, \boldsymbol{\sigma}_*, \boldsymbol{\sigma}_*)/2$ represents a sharp bound on the elastic energy of a periodic array of holes, with the void phase occupying the volume fraction f. The bound (2.34) clearly implies

$$g(f, \boldsymbol{\sigma}_*, \boldsymbol{\sigma}_*) \geq \boldsymbol{\sigma}_* : \boldsymbol{\mathcal{S}} \boldsymbol{\sigma}_* + \frac{f(|\lambda_1| + |\lambda_2|)^2}{(1-f)E}, \tag{3.2}$$

where λ_1 and λ_2 are the eigenvalues of $\boldsymbol{\sigma}_*$. This inequality becomes an equality only when $\det \boldsymbol{\sigma}_* \geq 0$, and the hole shapes attaining the minimum value of the elastic energy are those found by Vigdergauz (1986, 1994, 1996, 1999) (see also Grabovsky and Kohn (1995)). These holes approach ellipses as the volume fraction f approaches zero. When $\det \boldsymbol{\sigma}_*$ is negative, Allaire and Aubry (1999) have proved that there is a definite gap between the left- and right-hand sides of the above equation. The assumption of only one hole per unit cell represents a significant restriction on the set of microstructures being considered. Cherkaev et al. (1998), following preliminary work of Cherkaev and Vigdergauz (1986), have shown that in the limit as $f \to 0$ the hole minimizing the elastic energy is almost rectangular in shape when $\det \boldsymbol{\sigma}_* < 0$.

Here we consider what happens when the boundary Γ of the hole is varied, while keeping f fixed, so as to minimize the bilinear form

$$\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}_*, \tag{3.3}$$

where $\boldsymbol{\sigma}_*^0$ and $\boldsymbol{\sigma}_*$ are fixed tensors. The value of the minimum is of course $g(f, \boldsymbol{\sigma}_*^0, \boldsymbol{\sigma}_*)$, the function we seek to find. It is conceivable that the minimum value is never achieved. The boundary of the hole could become increasingly convoluted as the minimum is approached. Alternatively, the boundary of the optimal shaped hole could touch itself along certain intervals, corresponding to slits or infinitesimally thin bridges. For the moment let us ignore these possibilities and assume that the minimum is achieved by a simply connected hole, with a boundary that does not touch itself and that additionally does not touch the boundary of the unit cell.

We will show that if the shape of hole is such that this bilinear form is minimized, then the following necessary condition for optimality holds:

$$\sigma_{tt}^0(\mathbf{x}) \sigma_{tt}(\mathbf{x}) = \text{constant on all smooth portions of } \Gamma. \tag{3.4}$$

Here, $\sigma^0_{tt}(\mathbf{x})$ and $\sigma_{tt}(\mathbf{x})$ are the tangential components of the periodic stress tensor fields $\boldsymbol{\sigma}^0(\mathbf{x})$ and $\boldsymbol{\sigma}(\mathbf{x})$ that are generated when average stresses $\boldsymbol{\sigma}^0_*$ and $\boldsymbol{\sigma}_*$, respectively, are applied to the composite. Thus the stress tensor field $\boldsymbol{\sigma}^0(\mathbf{x})$, defined to be zero within each hole, has average value

$$\langle \boldsymbol{\sigma}^0 \rangle = \boldsymbol{\sigma}^0_* \tag{3.5}$$

and satisfies the equilibrium equation

$$\nabla \cdot \boldsymbol{\sigma}^0(\mathbf{x}) = 0 \tag{3.6}$$

and the boundary condition

$$\boldsymbol{\sigma}^0(\mathbf{x}) \cdot \mathbf{n}(\mathbf{x}) = 0, \quad \mathbf{x} \in \Gamma, \tag{3.7}$$

where $\mathbf{n}(\mathbf{x})$ is the outward normal to the surface Γ at the point $\mathbf{x}$. Additionally, this stress is related to the associated strain tensor field

$$\boldsymbol{\epsilon}^0(\mathbf{x}) = \frac{1}{2}(\nabla \mathbf{u}^0(\mathbf{x}) + (\nabla \mathbf{u}^0(\mathbf{x}))^T) \tag{3.8}$$

through the constitutive law

$$\boldsymbol{\epsilon}^0(\mathbf{x}) = \boldsymbol{\mathcal{S}} \boldsymbol{\sigma}^0(\mathbf{x}). \tag{3.9}$$

By deleting the superscript 0 in these formulae, one obtains the equations satisfied by the stress tensor field $\boldsymbol{\sigma}(\mathbf{x})$. By definition, the effective compliance tensor $\boldsymbol{\mathcal{S}}_*$ governs the relations

$$\boldsymbol{\epsilon}^0_* = \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}^0_*, \qquad \boldsymbol{\epsilon}_* = \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}_* \tag{3.10}$$

between the average strain, $\boldsymbol{\epsilon}^0_*$ or $\boldsymbol{\epsilon}_*$, and the average stress, $\boldsymbol{\sigma}^0_*$ or $\boldsymbol{\sigma}_*$. Since the local strains $\boldsymbol{\epsilon}^0(\mathbf{x})$ and $\boldsymbol{\epsilon}(\mathbf{x})$ are undefined within each hole, the statement that the average strains are $\boldsymbol{\epsilon}^0_*$ and $\boldsymbol{\epsilon}_*$ holds in the sense that

$$\mathbf{u}^0(\mathbf{x}) - \boldsymbol{\epsilon}^0_* \mathbf{x} \text{ and } \mathbf{u}(\mathbf{x}) - \boldsymbol{\epsilon}_* \mathbf{x} \text{ are periodic in } \mathbf{x}. \tag{3.11}$$

Now let Ω denote the region occupied by the plate within the unit cell, excluding the hole. Then from (3.10) we have the useful identity

$$\begin{aligned}
\int_\Omega \boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}} \boldsymbol{\sigma}(\mathbf{x}) d\mathbf{x} &= \int_\Omega \boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\epsilon}(\mathbf{x}) d\mathbf{x} \\
&= \int_{\text{boundary of the cell}} \mathbf{n} \cdot \boldsymbol{\sigma}^0(\mathbf{x}) \mathbf{u}(\mathbf{x}) dl + \int_\Gamma \mathbf{n} \cdot \boldsymbol{\sigma}^0(\mathbf{x}) \mathbf{u}(\mathbf{x}) dl \\
&= \int_{\text{boundary of the cell}} \mathbf{n} \cdot \boldsymbol{\sigma}^0(\mathbf{x}) [\boldsymbol{\epsilon}_* \mathbf{x}] dl \\
&= \int_\Omega \boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\epsilon}_* d\mathbf{x} \\
&= \boldsymbol{\sigma}^0_* : \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}_*,
\end{aligned} \tag{3.12}$$

where we have used the fact that $\mathbf{n} \cdot \boldsymbol{\sigma}^0(\mathbf{x})$ vanishes on the boundary Γ and the fact that on opposite sides of the unit cell $\mathbf{n} \cdot \boldsymbol{\sigma}^0(\mathbf{x})$ takes opposite values, while $\mathbf{u}(\mathbf{x}) - \boldsymbol{\epsilon}_* \mathbf{x}$ takes the same value, implying that their scalar product integrates to zero.

To establish (3.4) we introduce a Lagrange multiplier c and look for the stationary points of

$$\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_* \boldsymbol{\sigma}_* + cf \tag{3.13}$$

as the boundary of the hole is varied. For simplicity, let us assume that the unit cell is square with sides of unit length.

Let $\lambda\gamma(\mathbf{x})$ be the perturbation of the interface in the normal direction; that is, the new boundary $\Gamma(\lambda)$ consists of points

$$\mathbf{y} = \mathbf{x} + \lambda\gamma(\mathbf{x})\mathbf{n}(\mathbf{x}), \quad \mathbf{x} \in \Gamma, \tag{3.14}$$

where $\mathbf{n}(\mathbf{x})$ is the outward normal to the original surface Γ at the point $\mathbf{x}$.

Our aim is to evaluate

$$\frac{d}{d\lambda}(\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_*(\lambda)\boldsymbol{\sigma}_* + cf(\lambda))\bigg|_{\lambda=0}. \tag{3.15}$$

The derivative of $f(\lambda)$ is simply

$$\frac{d}{d\lambda} f(\lambda)\bigg|_{\lambda=0} = \int_\Gamma \gamma(\mathbf{x}) dl. \tag{3.16}$$

Also from (3.12) we see that the remaining derivative in (3.15) splits into the sum of three terms:

$$\begin{aligned}\frac{d}{d\lambda}(\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_*(\lambda)\boldsymbol{\sigma}_*)\bigg|_{\lambda=0} &= \int_\Omega \frac{d\boldsymbol{\sigma}^0(\mathbf{x})}{d\lambda}\bigg|_{\lambda=0} : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x}) d\mathbf{x} + \int_\Omega \boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}} \frac{d\boldsymbol{\sigma}(\mathbf{x})}{d\lambda}\bigg|_{\lambda=0} d\mathbf{x} \\ &\quad + \int_\Gamma \boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x})\gamma(\mathbf{x}) dl,\end{aligned} \tag{3.17}$$

where the last term arises because the domain of integration $\Omega(\lambda)$ depends on λ. The first term can be equated with the derivative that we seek to find through a calculation similar to that given in (3.12):

$$\begin{aligned}\int_\Omega \frac{d\boldsymbol{\sigma}^0(\mathbf{x})}{d\lambda}\bigg|_{\lambda=0} : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x}) d\mathbf{x} &= \int_\Omega \frac{d\boldsymbol{\epsilon}^0(\mathbf{x})}{d\lambda}\bigg|_{\lambda=0} : \boldsymbol{\sigma}(\mathbf{x}) d\mathbf{x} \\ &= \int_{\text{boundary of the cell}} \mathbf{n} \cdot \boldsymbol{\sigma}(\mathbf{x}) \frac{d\mathbf{u}^0(\mathbf{x})}{d\lambda} dl + \int_\Gamma \mathbf{n} \cdot \boldsymbol{\sigma}(\mathbf{x}) \frac{d\mathbf{u}^0(\mathbf{x})}{d\lambda} dl \\ &= \int_{\text{boundary of the cell}} \mathbf{n} \cdot \boldsymbol{\sigma}(\mathbf{x}) \left[\frac{d\boldsymbol{\epsilon}_*^0}{d\lambda}\mathbf{x}\right] dl \\ &= \int_\Omega \boldsymbol{\sigma}(\mathbf{x}) \frac{d\boldsymbol{\epsilon}_*^0}{d\lambda} d\mathbf{x} \\ &= \frac{d}{d\lambda}(\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_*(\lambda)\boldsymbol{\sigma}_*)\bigg|_{\lambda=0}.\end{aligned} \tag{3.18}$$

Similarly, the second term can also be equated with this derivative, and so we deduce that

$$\frac{d}{d\lambda}(\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{S}}_*(\lambda)\boldsymbol{\sigma}_* + cf(\lambda))\bigg|_{\lambda=0} = \int_\Gamma (-\boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x}) + c)\gamma(\mathbf{x}) dl. \tag{3.19}$$

For this to be zero for all choices of $\gamma(\mathbf{x})$ we must have

$$\boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x}) = c \quad \text{on all smooth portions of } \Gamma. \tag{3.20}$$

But the only nonzero components of $\boldsymbol{\sigma}^0(\mathbf{x})$ and $\boldsymbol{\sigma}(\mathbf{x})$ on the boundary of the hole are the tangential components σ^0_{tt} and σ_{tt}. It follows that

$$\boldsymbol{\sigma}^0(\mathbf{x}) : \boldsymbol{\mathcal{S}}\boldsymbol{\sigma}(\mathbf{x}) = \sigma^0_{tt}[(\mathbf{t}\otimes\mathbf{t}) : \boldsymbol{\mathcal{S}}(\mathbf{t}\otimes\mathbf{t})]\sigma_{tt}, \tag{3.21}$$

where $\mathbf{t}$ is the unit vector tangential to the hole boundary. Finally, since $\boldsymbol{\mathcal{S}}$ is rotationally invariant, $(\mathbf{t}\otimes\mathbf{t}) : \boldsymbol{\mathcal{S}}(\mathbf{t}\otimes\mathbf{t})$ is a constant independent of the direction of $\mathbf{t}$. In conclusion, we arrive at (3.4).

4. Possible stress-strain pairs for a dilute array of holes. Here we consider a periodic array of holes in a plate having isotropic compliance matrix $\mathbf{S}(E,\nu)$. It is assumed there is only one hole per unit cell, occupying a very small volume fraction f of the unit cell. Additionally the hole is assumed to be well separated from the holes in adjoining cells, so that interaction effects can be neglected. Let $\widetilde{D}(\boldsymbol{\sigma}_*)$ denote the range of values that $\boldsymbol{\epsilon}_V$ takes as the hole shape is varied, in the limit $f \to 0$. Our aim is to find $\widetilde{D}(\boldsymbol{\sigma}_*)$ and to identify the optimal hole shapes that correspond to values of $\boldsymbol{\epsilon}_V$ on the boundary of $\widetilde{D}(\boldsymbol{\sigma}_*)$. In some sense these optimal holes have the greatest effect on the average strain when a given (small) volume fraction of them is inserted into a plate which is subject to the applied loading $\boldsymbol{\sigma}_*$.

To the first order in f the effective compliance matrix is given by

$$\mathbf{S}_* = \mathbf{S} + f\mathbf{E} + \mathcal{O}(f^2), \tag{4.1}$$

where the compliance polarizability matrix $\mathbf{E}$ is obtained by solving the planar elasticity equations for a single hole in an infinite plane, subject to uniform applied stresses. Associated with the matrix $\mathbf{E}$ is a fourth order compliance polarizability tensor $\boldsymbol{\mathcal{E}}$. (The tensor $f\boldsymbol{\mathcal{E}}$ has been called the hole compliance tensor or H-tensor by Kachanov (1993) and Shafiro and Kachanov (1999), and the inverse of $\mathbf{E}$ has been called the Pólya–Szegö matrix by Movchan and Serkov (1997).)

To a first approximation, the average strain $\boldsymbol{\epsilon}_V$ in the void phase, as defined by (2.4), is given by

$$\boldsymbol{\epsilon}_V \approx \mathbf{E}\boldsymbol{\sigma}_*. \tag{4.2}$$

Thus the problem of determining the set $\widetilde{D}(\boldsymbol{\sigma}_*)$ reduces to finding the range of values that $\mathbf{E}\boldsymbol{\sigma}_*$ takes as the hole shape is varied.

Now in the periodic array, $\mathbf{S}_* - \mathbf{S} \approx f\mathbf{E}$ should remain virtually unchanged when we insert into each hole an island of plate material that is connected to the surrounding plate by a very thin bridge of plate material (to ensure that the hole in the unit cell remains simply connected). This reduces the volume fraction of void f by some factor, and $\mathbf{E}$ must accordingly increase by the same factor. We deduce that

$$\lambda\boldsymbol{\epsilon}_V \in \widetilde{D}(\boldsymbol{\sigma}_*) \quad \text{for all } \lambda \geq 1, \quad \text{provided } \boldsymbol{\epsilon}_V \in \widetilde{D}(\boldsymbol{\sigma}_*). \tag{4.3}$$

This obviously implies that the set $\widetilde{D}(\boldsymbol{\sigma}_*)$ is unbounded in some directions.

Our goal is to numerically compute this set and to identify the hole shapes which correspond to values of $\boldsymbol{\epsilon}_V$ on the boundary of $\widetilde{D}(\boldsymbol{\sigma}_*)$. The approach we take is similar to one successfully used by Cherkaev et al. (1998) to find hole shapes which minimize the elastic energy under a given loading $\boldsymbol{\sigma}_*$. For values of $\boldsymbol{\sigma}_*$ with positive determinant they recovered the known result that the optimal hole is an ellipse,

while for values of $\boldsymbol{\sigma}_*$ with negative determinant they found that the optimal hole is almost rectangular in shape. The first step in these computations is to determine the compliance polarizability matrix $\mathbf{E}$ for a given shaped hole.

4.1. Compliance polarizability matrices for a dilute array of holes. For an arbitrary shaped hole Movchan and Serkov (1997) (see also Serkov (1998)) show how the calculation of $\mathbf{E}$ can be reduced to solving a system of linear equations. In this section we briefly summarize the main points of their analysis and also show how it can be used to obtain the elastic fields in the vicinity of each hole.

Let the shape of the hole be specified by the image of the exterior of the unit circle under the conformal map

$$z = \omega(\xi), \tag{4.4}$$

where $z = x_1 + ix_2$, and the complex variable ξ is associated with the unit circle. Without loss of generality we can assume that $\omega(\xi) \approx \xi$ when $|\xi|$ is very large. The complex valued function ω can be expanded in a Laurent series, and, after truncation, one has

$$z = \omega(\xi) = \xi + \sum_{n=1}^{N} c_{-n}\xi^{-n}, \tag{4.5}$$

with the c_i being complex coefficients that determine the shape of the hole. We consider the response to an applied stress (representing the stress at a large distance from the hole)

$$\boldsymbol{\sigma}_* = \begin{pmatrix} \sigma_{11}^* & \sigma_{12}^* \\ \sigma_{12}^* & \sigma_{22}^* \end{pmatrix} \tag{4.6}$$

as the loading coefficients σ_{11}^*, σ_{22}^*, and σ_{12}^* are varied. The solution to this planar elasticity problem is naturally expressed in terms of the Kolosov–Muskhelishvili complex potentials ϕ and ψ (Muskhelishvili (1953)). For plane stress they determine the two-dimensional displacement field $\mathbf{u}(\mathbf{x})$ through the relation

$$u_1 + iu_2 = \frac{[(3-\nu)\phi(z)/(1+\nu) - z\overline{\phi'(z)} - \overline{\psi(z)}]}{(2\mu)}, \tag{4.7}$$

in which ν is Poisson's ratio, μ is the shear modulus, and the overline denotes complex conjugation. The associated stress field $\boldsymbol{\sigma}(\mathbf{x})$ has components σ_{11}, σ_{22}, and σ_{12} given by

$$\sigma_{11} + \sigma_{22} = 4\,\mathrm{Re}[\phi'(z)], \quad \sigma_{22} - \sigma_{11} + 2i\sigma_{12} = 2[\overline{z}\phi''(z) + \psi'(z)]. \tag{4.8}$$

The potential $\phi(\xi)$ can be shown (see the formulae between (3.11) and (3.13) in Movchan and Serkov (1997)) to satisfy the integral equation

$$\phi(\xi) - \frac{1}{2\pi i}\int_{|t|=1} \frac{\omega(t)\overline{\phi'(t)}}{\overline{\omega'(t)}(t-\xi)}dt = \alpha\xi - \overline{\gamma}\xi^{-1}, \tag{4.9}$$

where the real coefficient α and the complex coefficient γ are determined from the loading coefficients:

$$\alpha = \frac{(\sigma_{11}^* + \sigma_{22}^*)}{4}, \quad \gamma = \frac{(\sigma_{22}^* - \sigma_{11}^* + 2i\sigma_{12}^*)}{2}. \tag{4.10}$$

Now the complex potential $\phi(\xi)$ can be expanded in a Laurent series in powers of ξ, and the coefficients of this series must depend linearly on the applied stress, that is, linearly on α and linearly on the real and imaginary parts of γ. Also when ξ is large, $\phi(\xi)$ approaches $\alpha\xi$. Accordingly, the potential $\phi(\xi)$ has the representation

$$\phi(\xi) = \alpha\xi - \overline{\gamma}\xi^{-1} - \alpha\sum_{n=1}^{\infty} a_n^{\alpha}\xi^{-n} - \mathrm{Re}(\gamma)\sum_{n=1}^{\infty} a_n^{\gamma}\xi^{-n} - \mathrm{Im}(\gamma)\sum_{n=1}^{\infty} a_n^{\tau}\xi^{-n}, \tag{4.11}$$

where the minus signs and the additional term $-\overline{\gamma}\xi^{-1}$ are introduced to simplify subsequent equations. This serves to define the three sets of coefficients a_n^j, $j = \alpha, \gamma, \tau$, each set being associated with a different loading. By substituting (4.11) back into (4.9) and using the residue theorem to evaluate the contour integrals, one finds that

$$a_n^{\alpha} = a_n^{\gamma} = a_n^{\tau} = 0 \quad \text{for all } n > N, \tag{4.12}$$

and that the remaining coefficients satisfy the system of linear equations

$$\begin{aligned}
a_m^{\alpha} - \sum_{k=1}^{N-m-1} \rho_{N-m-k-1} k \overline{a}_k^{\alpha} &= \rho_{N-m}, \qquad a_m^{\alpha} \in \mathbb{C}, \\
a_m^{\gamma} - \sum_{k=1}^{N-m-1} \rho_{N-m-k-1} k \overline{a}_k^{\gamma} &= \rho_{N-m-2}, \qquad a_m^{\gamma} \in \mathbb{C}, \\
a_m^{\tau} - \sum_{k=1}^{N-m-1} \rho_{N-m-k-1} k \overline{a}_k^{\tau} &= \rho_{N-m-2} i, \qquad a_m^{\tau} \in \mathbb{C},
\end{aligned} \tag{4.13}$$

for $m = 1, 2, 3, \ldots, N$, where $\rho_k = 0$ for $k < 0$, $\rho_0 = c_{-N}$, and

$$\rho_k = \frac{1}{k!}\frac{d^k}{d\xi^k}\left[\frac{\xi^{N+1} + \sum_{n=1}^{N} c_{-n}\xi^{N-n}}{1 - \sum_{n=1}^{N} n\overline{c}_{-n}\xi^{n+1}}\right]\Bigg|_{\xi=0} \tag{4.14}$$

for $k > 0$.

This system can be written in the matrix form

$$\mathbf{X}^{(i)} - \mathbf{A}\overline{\mathbf{X}^{(i)}} = \mathbf{B}^{(i)}, \qquad i = \alpha, \gamma, \tau, \tag{4.15}$$

where

$$\mathbf{X}^{(\alpha)} = \begin{pmatrix} a_1^{\alpha} \\ a_2^{\alpha} \\ \vdots \\ a_{N-2}^{\alpha} \\ a_{N-1}^{\alpha} \\ a_N^{\alpha} \end{pmatrix}, \quad \mathbf{X}^{(\gamma)} = \begin{pmatrix} a_1^{\gamma} \\ a_2^{\gamma} \\ \vdots \\ a_{N-2}^{\gamma} \\ a_{N-1}^{\gamma} \\ a_N^{\gamma} \end{pmatrix}, \quad \mathbf{X}^{(\tau)} = \begin{pmatrix} a_1^{\tau} \\ a_2^{\tau} \\ \vdots \\ a_{N-2}^{\tau} \\ a_{N-1}^{\tau} \\ a_N^{\tau} \end{pmatrix},$$

$$\mathbf{B}^{(\alpha)} = \begin{pmatrix} \rho_{N-1} \\ \rho_{N-2} \\ \vdots \\ \rho_2 \\ \rho_1 \\ \rho_0 \end{pmatrix}, \quad \mathbf{B}^{(\gamma)} = \begin{pmatrix} \rho_{N-3} \\ \rho_{N-4} \\ \vdots \\ \rho_0 \\ 0 \\ 0 \end{pmatrix}, \quad \mathbf{B}^{(\tau)} = i\mathbf{B}^{(\gamma)} \tag{4.16}$$

are N-dimensional vectors and

$$\mathbf{A} = \begin{pmatrix} \rho_{N-3} & 2\rho_{N-4} & \cdots & (N-2)\rho_0 & 0 & 0 \\ \rho_{N-4} & 2\rho_{N-5} & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ \rho_1 & 2\rho_0 & \cdots & 0 & 0 & 0 \\ \rho_0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & \cdots & 0 & 0 & 0 \end{pmatrix} \tag{4.17}$$

is an $N \times N$ matrix. It helps to rewrite (4.15) in the equivalent form

$$(\mathbf{I} - \mathbf{A}\overline{\mathbf{A}})\mathbf{X}^{(i)} = \mathbf{B}^{(i)} + \mathbf{A}\overline{\mathbf{B}^{(i)}}, \qquad i = \alpha, \gamma, \tau, \tag{4.18}$$

which may be solved directly for the unknown vectors $\mathbf{X}^{(i)}$.

From the solution for the coefficients a_n^j, $j = \alpha, \gamma, \tau$, we can find the potential $\phi(z)$ for an arbitrary applied stress and hence determine the tangential stresses on the boundary of the hole:

$$\sigma_{tt} = \text{Trace}(\boldsymbol{\sigma}) = 4\,\text{Re}[\Phi(\mathbf{x})] \ \text{ on } \Gamma, \ \text{ where } \Phi(\mathbf{x}) = \frac{\phi'(\xi)}{\omega'(\xi)}. \tag{4.19}$$

This is useful because in order to check if the optimality condition (3.4) is satisfied (or approximately satisfied) we need to determine stress fields at the boundary of the hole.

Also, once the potential $\phi(\xi)$ has been determined, the potential $\psi(\xi)$ can be found from the relation

$$\psi(\xi) = \gamma\xi - \alpha\xi^{-1} + \frac{1}{2\pi i}\int_{|t|=1} \frac{\overline{\omega(t)}\phi'(t)}{\omega'(t)(t-\xi)}dt, \tag{4.20}$$

which directly follows from the formulae between (3.11) and (3.13) in Movchan and Serkov (1997). By substituting the series expansion (4.11) for $\phi(\xi)$ in (4.9) and using the residue theorem to evaluate the contour integrals, one finds that $\psi(\xi)$ is given by the series expansion

$$\psi(\xi) = \gamma\xi - \alpha\xi^{-1} - \alpha\sum_{n=1}^{\infty} a_{-n}^{\alpha}\xi^{-n} - \text{Re}(\gamma)\sum_{n=1}^{\infty} a_{-n}^{\gamma}\xi^{-n} - \text{Im}(\gamma)\sum_{n=1}^{\infty} a_{-n}^{\tau}\xi^{-n}, \tag{4.21}$$

where the coefficients a_{-n}^{α}, a_{-n}^{γ}, and a_{-n}^{τ} are obtained by setting $m = -n$ in the formulae (4.13). It is curious that the series expansion for the potential $\phi(\xi)$ terminates at $n = N$, whereas the series expansion for $\psi(\xi)$ has an infinite number of terms. Having obtained the potentials $\phi(\xi)$ and $\psi(\xi)$, the displacement field $\mathbf{u}(\mathbf{x})$ around the hole can be computed using (4.7).

The compliance polarizability matrix $\mathbf{E}$ is determined by the area of the hole and by the far field behavior of the potentials ϕ and ψ in the z-plane. This far field behavior in the z-plane is in turn determined first by the far field behavior of ϕ and ψ in the ξ plane, which to leading order is governed by the six coefficients a_1^j and a_{-1}^j with $j = \alpha, \gamma, \tau$, and second by the dependence of z on ξ when $|\xi|$ is large, which to leading order is governed by the coefficient c_{-1}. Explicit calculation shows that the compliance polarizability matrix is given by the formula

$$\mathbf{E} = \frac{-1}{E(1 - \sum_{n=1}^{\infty} n|c_{-n}|^2)} \begin{pmatrix} -2\Omega + \Sigma - \frac{1}{2}\Xi & 2\Omega - \frac{1}{2}\Xi & \Lambda - 2\Theta \\ 2\Omega - \frac{1}{2}\Xi & -2\Omega - \Sigma - \frac{1}{2}\Xi & \Lambda + 2\Theta \\ \Lambda - 2\Theta & \Lambda + 2\Theta & 2\Upsilon \end{pmatrix}, \tag{4.22}$$

where E is the Young's modulus and

$$\begin{aligned}
&\Omega = 1 + \mathrm{Re}(a_1^\gamma), \qquad \Sigma = 2\,\mathrm{Re}(c_{-1}) + \mathrm{Re}(a_1^\alpha) + \mathrm{Re}(a_{-1}^\gamma),\\
&\Xi = 1 + \mathrm{Re}(a_{-1}^\alpha), \qquad \Upsilon = -2 + 2\,\mathrm{Im}(a_1^\tau),\\
&\Theta = \sqrt{2}\,\mathrm{Im}(a_1^\gamma), \qquad \Lambda = \sqrt{2}\,\mathrm{Im}(c_{-1}) + \sqrt{2}\,\mathrm{Im}(a_1^\alpha).
\end{aligned} \tag{4.23}$$

The expression (4.22) for the compliance polarizability matrix $\mathbf{E}$ differs from the one given in formula (4.8) of Movchan and Serkov (1997) by the prefactor of

$$V = \pi\left(1 - \sum_{n=1}^{\infty} n|c_{-n}|^2\right), \tag{4.24}$$

which represents the area of a hole which is the image of the unit circle $|\xi| = 1$ under the conformal map (4.5). This additional factor is needed to normalize with respect to the area of the hole so that (4.1) gives the correct estimate for the effective compliance tensor of a dilute periodic array of these holes.

4.2. Explicit formulae for elliptical holes. For elliptical holes the formulae (4.22) and the whole algorithm can be simplified. An ellipse of arbitrary eccentricity and arbitrary orientation can be generated by a conformal map of the form

$$z = \omega(\xi) = \xi + c_{-1}\xi^{-1}, \quad c_{-1} \in \mathbb{C}, \quad |c_{-1}| < 1. \tag{4.25}$$

By selecting

$$c_{-1} = \frac{1-r}{1+r}e^{2i\beta}, \quad \beta \in [0,\pi], \quad r > 0, \tag{4.26}$$

the boundary of the unit disc $|\xi| = 1$ is mapped onto the boundary of an ellipse with semiaxis lengths a and $b = 2-a$ having a desired ratio $r = b/a$, and with axes oriented at desired angles of β and $\beta + \pi/2$.

The formulae for coefficients Ω, Σ, Ξ, Υ, Θ, and Λ can be reduced to the form

$$\begin{aligned}
&\Omega = 1, \qquad \Xi = 2\left(1 + \left(\frac{1-r}{1+r}\right)^2\right), \qquad \Upsilon = -2,\\
&\Sigma = 4\frac{1-r}{1+r}\cos 2\beta, \qquad \Lambda = 2\sqrt{2}\frac{1-r}{1+r}\sin 2\beta, \qquad \Theta = 0,
\end{aligned} \tag{4.27}$$

and consequently the compliance polarizability matrix is

$$\mathbf{E} = \frac{-1}{Er}\begin{pmatrix} -(1+r+r^2) + (1-r^2)\cos 2\beta & r & \frac{1}{\sqrt{2}}(1-r^2)\sin 2\beta \\ r & -(1+r+r^2) - (1-r^2)\cos 2\beta & \frac{1}{\sqrt{2}}(1-r^2)\sin 2\beta \\ \frac{1}{\sqrt{2}}(1-r^2)\sin 2\beta & \frac{1}{\sqrt{2}}(1-r^2)\sin 2\beta & -\frac{1}{2}(1+r)^2 \end{pmatrix}. \tag{4.28}$$

Without loss of generality we can assume that $\boldsymbol{\sigma}_*$ has the form (1.3). Then straightforward calculations give the following analytical formulae for $\boldsymbol{\epsilon}_V = (\epsilon_{11}^V, \epsilon_{22}^V, \sqrt{2}\epsilon_{12}^V)$ when the applied stress $\boldsymbol{\sigma}_*$ is given by (1.3):

$$\begin{aligned}
\epsilon_{11}^V &= \frac{1}{Er}\left\{\sigma(r+1)^2 + \sigma(r^2-1)\cos 2\beta - r(\sigma+1)\right\},\\
\epsilon_{22}^V &= \frac{1}{Er}\left\{(r+1)^2 + (1-r^2)\cos 2\beta - r(\sigma+1)\right\},\\
\epsilon_{12}^V &= \frac{1}{2Er}(\sigma+1)(r^2-1)\sin 2\beta.
\end{aligned} \tag{4.29}$$

The formulae (4.28) and (4.29) were obtained by Kachanov (1993) as a limiting case of Eshelby's results for an ellipsoidal cavity.

In particular, when $\sigma = -1$ (which corresponds to a pure shear applied stress) we see that ϵ_{12}^V is necessarily zero for all orientations and eccentricities of the ellipse. However, as shown in Figure 10 (see section 5 below), ϵ_{12}^V is nonzero for other inclusion shapes. Thus, when $\sigma = -1$, the maximum value that $|\epsilon_{12}^V|$ attains as an inclusion is rotated can be taken as a measure of its nonellipticity.

Also when $\sigma = 0$ (which corresponds to an applied uniaxial stress), we see that $\epsilon_{11}^V = -1/E$ for all orientations and eccentricities of the ellipse.

4.3. Numerical results for arbitrary shaped holes. Without loss of generality we can take $E = 1$ and assume that $\boldsymbol{\sigma}_*$ has the form (1.3). The convex hull of the set $\widetilde{D}(\boldsymbol{\sigma}_*)$ can be computed from its Legendre transform, which is the minimum value (in the limit $N \to \infty$) of

$$\boldsymbol{\sigma}_*^0 : \boldsymbol{\epsilon}_V = \sigma_{11}^0 \epsilon_{11}^V + \sigma_{22}^0 \epsilon_{22}^V + 2\sigma_{12}^0 \epsilon_{12}^V = \begin{pmatrix} \sigma_{11}^0 \\ \sigma_{22}^0 \\ \sqrt{2}\sigma_{12}^0 \end{pmatrix} \mathbf{E}(c_{-1}, c_{-2}, \ldots, c_{-N}) \begin{pmatrix} \sigma \\ 1 \\ 0 \end{pmatrix} \tag{4.30}$$

as the complex coefficients c_{-1}, c_{-2}, ..., c_{-N}, representing the hole shape, are varied over their admissible range. One has to avoid those sets of coefficients such that the mapping $w(\xi)$ from the exterior of the unit circle onto its image is not one-to-one.

Under the 180° rotation $\mathbf{x} \to -\mathbf{x}$, the tensors $\boldsymbol{\sigma}_*^0$ and $\boldsymbol{\sigma}_*$ remain invariant. Since the bilinear form $\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_*$ remains invariant under this rotation, we expect (unless there is symmetry breaking) that the hole shape minimizing this bilinear form should also be invariant under this rotation. Consequently we restrict our attention to conformal maps satisfying

$$\omega(\xi) = -\omega(-\xi), \tag{4.31}$$

or equivalently to complex sets of coefficients c_{-n} which are zero for all even values of n.

By varying $\boldsymbol{\sigma}_*^0$ we could in principle recover the convex hull of the set $\widetilde{D}(\boldsymbol{\sigma}_*)$. However, we decided to first focus on finding the convex hull of the projection of the set $\widetilde{D}(\boldsymbol{\sigma}_*)$ onto the $(\epsilon_{11}^V, \epsilon_{22}^V)$ plane. This projection, which we denote by $\widetilde{D}_1$, represents the set of possible values of $(\epsilon_{11}^V, \epsilon_{22}^V)$. Its convex hull is obtained by taking, say,

$$\boldsymbol{\sigma}_*^0 = \begin{pmatrix} \sigma^0 & 0 \\ 0 & 1 \end{pmatrix} \tag{4.32}$$

and computing the minimum value of the bilinear form (4.30) for varying values of σ^0. Our numerical results suggest that we can associate hole shapes with every point on the boundary of the convex hull. This indicates that $\widetilde{D}_1$ is itself convex, in which case it would coincide with its convex hull. In any case, the convex hull of $\widetilde{D}_1$ is itself important: it represents the set of possible values of $\boldsymbol{\epsilon}_V$ in a plate containing well-separated holes having a mixture of different shapes and sizes, with the holes occupying an infinitesimal average volume fraction f.

The downhill simplex method (see, for example, Press et al. (1986)) was initially used for the minimization, giving quite satisfactory results. Then to obtain more refined results we used the gradient flow method for the minimization as this was faster than the downhill simplex method. The question of uniqueness of the hole shape

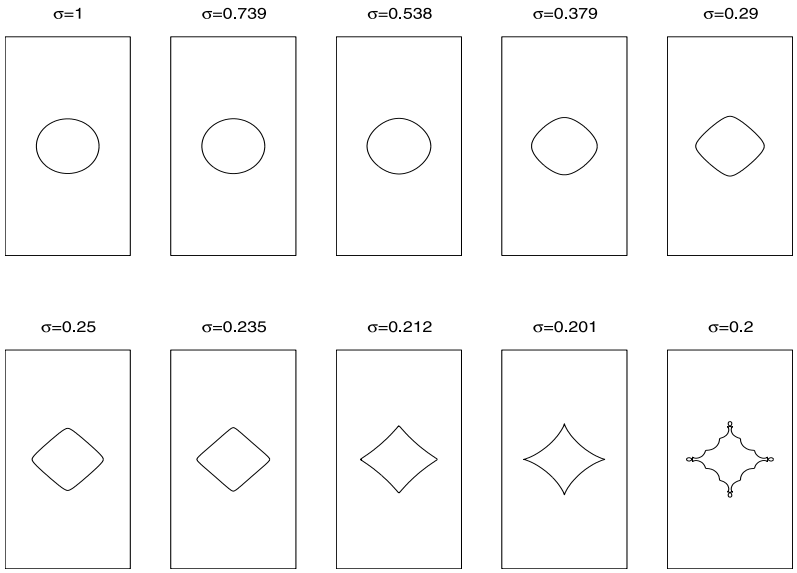

FIG. 1. *Evolution of the optimal hole shapes minimizing the bilinear form with* $\sigma^0 = 1/\sigma$. *The numerical method for finding the hole shapes breaks down in the last plot.*

minimizing the bilinear form and the question of whether the numerically obtained hole shape is a global (and not just local) minimizer of the bilinear form was not studied. Attention was paid to the constraint that the coefficients c_{-n} be admissible only at the end of the calculation. If the hole boundary turned out to self-intersect, we redid the calculation with a smaller step size, which sometimes (but not always) corrected the problem. In the numerical experiments described below, we took $N = 21$ and did the minimization over the 11 complex coefficients c_{-1}, $c_{-3}, \ldots$, c_{-21}. As a check, we also took $N = 23$ in a few test cases and found little change in the shape of the optimal hole. Since the tensors $\boldsymbol{\sigma}_*^0$ and $\boldsymbol{\sigma}_*$ remain invariant under the reflections $x_1 \to -x_1$ and $x_2 \to -x_2$, we expected that the optimal holes would also have this symmetry, i.e., that the minimizing coefficients c_{-n} would turn out to be real. This was found to be the case. After finding an optimal hole (for given values of $\boldsymbol{\sigma}_*^0$ and $\boldsymbol{\sigma}_*$), we calculated the associated value of $\boldsymbol{\epsilon}_V = \mathbf{E}\boldsymbol{\sigma}_*$ lying on the boundary of $\widetilde{D}(\boldsymbol{\sigma}_*)$ and the associated tangent plane to this set having normal $\boldsymbol{\sigma}_*^0$.

An additional simplification occurs in the special case when $\sigma^0 = 1/\sigma$. Then under a 90° rotation the tensor $\boldsymbol{\sigma}_*^0$ is transformed to $\boldsymbol{\sigma}_*/\sigma$, while $\boldsymbol{\sigma}_*^0$ is transformed to $\sigma\boldsymbol{\sigma}_*^0$. Thus the bilinear form $\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_*$ remains invariant if we rotate the hole by 90° or if we reflect it about the axes. Unless there is symmetry breaking we expect that the hole shape minimizing this bilinear form should also be invariant under these transformations, that is, it should have square symmetry. Consequently we expect that the minimizing coefficients c_{-n} should all be real and zero unless $n+1$ is a multiple of 4. Figure 1 shows our numerical results for the evolution of optimal shapes as σ is increased. The case $\sigma = 1$ corresponds to a circular hole, which is known to minimize the elastic energy under hydrostatic loading. Figure 2 shows plots of the product $\sigma_{tt}^0(\mathbf{x})\sigma_{tt}(\mathbf{x})$ of the tangential components of the stress field around the boundary of the inclusion. One can see that the optimality criterion (3.4) is approximately satisfied, at least for values of σ which are not too small. The results

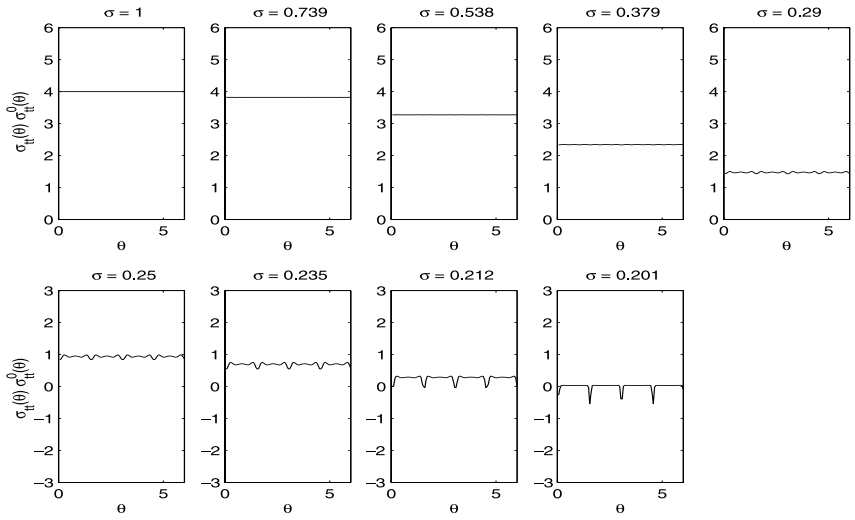

FIG. 2. *Product of the tangential stresses $\sigma^0_{tt}(\theta)$ and $\sigma_{tt}(\theta)$ along the hole boundary for the holes of Figure* 1 *as a function of the angle θ, where $\xi = e^{i\theta}$.*

indicate that the optimal shaped hole becomes nonconvex for sufficiently small σ and that its boundary develops cusps when $\sigma \approx 0.2$. In the next subsection we will provide an analytical formula for what we believe is the optimal hole shape when $\sigma = 0.2$. Below this critical value of σ the method fails; the algorithm produces a nonsensical self-intersecting boundary, as illustrated in the last plot of Figure 1.

In Figures 3–9 (parts (a)), the solid curves are numerical results representing a portion of the boundary of $\widetilde{D}_1$ for various values of σ. The dots represent values of $(\epsilon^V_{11}, \epsilon^V_{22})$ associated with elliptical holes of varying eccentricity and orientation. They are calculated using the analytical formulae (4.29). Parts (b) of Figures 3–9 display the shapes of the optimal holes corresponding to marked points on the solid curves.

For a hydrostatic load, with $\sigma = 1$, Figure 3(a) shows that elliptical shaped holes cover almost the entire set $\widetilde{D}_1$. However, among the ellipses, only the circular hole is optimal for this loading, and it minimizes the elastic energy. One can check that the optimality condition (3.4) is not satisfied for an elliptical hole unless it is a circle. Indeed the optimal shaped holes shown in diagrams A–D and F–L of Figure 3(b) are not exactly ellipses. For this particular loading, the set $\widetilde{D}_1$ is sufficient to allow us to determine the entire set $\widetilde{D}(\boldsymbol{\sigma}_*)$. This is because when $\boldsymbol{\sigma}_* = \mathbf{I}$, we can choose our coordinates so that $\boldsymbol{\epsilon}^V$ is diagonal. Thus the set $\widetilde{D}_1$ also represents the set of possible eigenvalue pairs (λ_1, λ_2) of the matrix $\boldsymbol{\epsilon}^V$.

When σ and σ^0 are both close to 1, the optimal hole is close to being circular in shape. Suppose that the boundary of the hole is the curve traced by $x_1 + ix_2 = r(\theta)e^{i\theta}$ as θ is varied. This serves to define $r(\theta)$, which parameterizes the hole shape. A straightforward but tedious perturbation analysis shows that when

$$\sigma = 1 + c\varepsilon, \quad \sigma^0 = 1 + c_0\varepsilon \tag{4.33}$$

(in which ε is a small parameter and c and c_0 are constants), the optimality condition (3.4) is satisfied when

$$r(\theta) = 1 + \varepsilon\left(\frac{c + c_0}{4}\right)\cos 2\theta + \varepsilon^2\left(\frac{c - c_0}{4}\right)^2\left[\frac{\cos 4\theta}{6} - \cos 2\theta\right] + \mathcal{O}(\varepsilon^3). \tag{4.34}$$

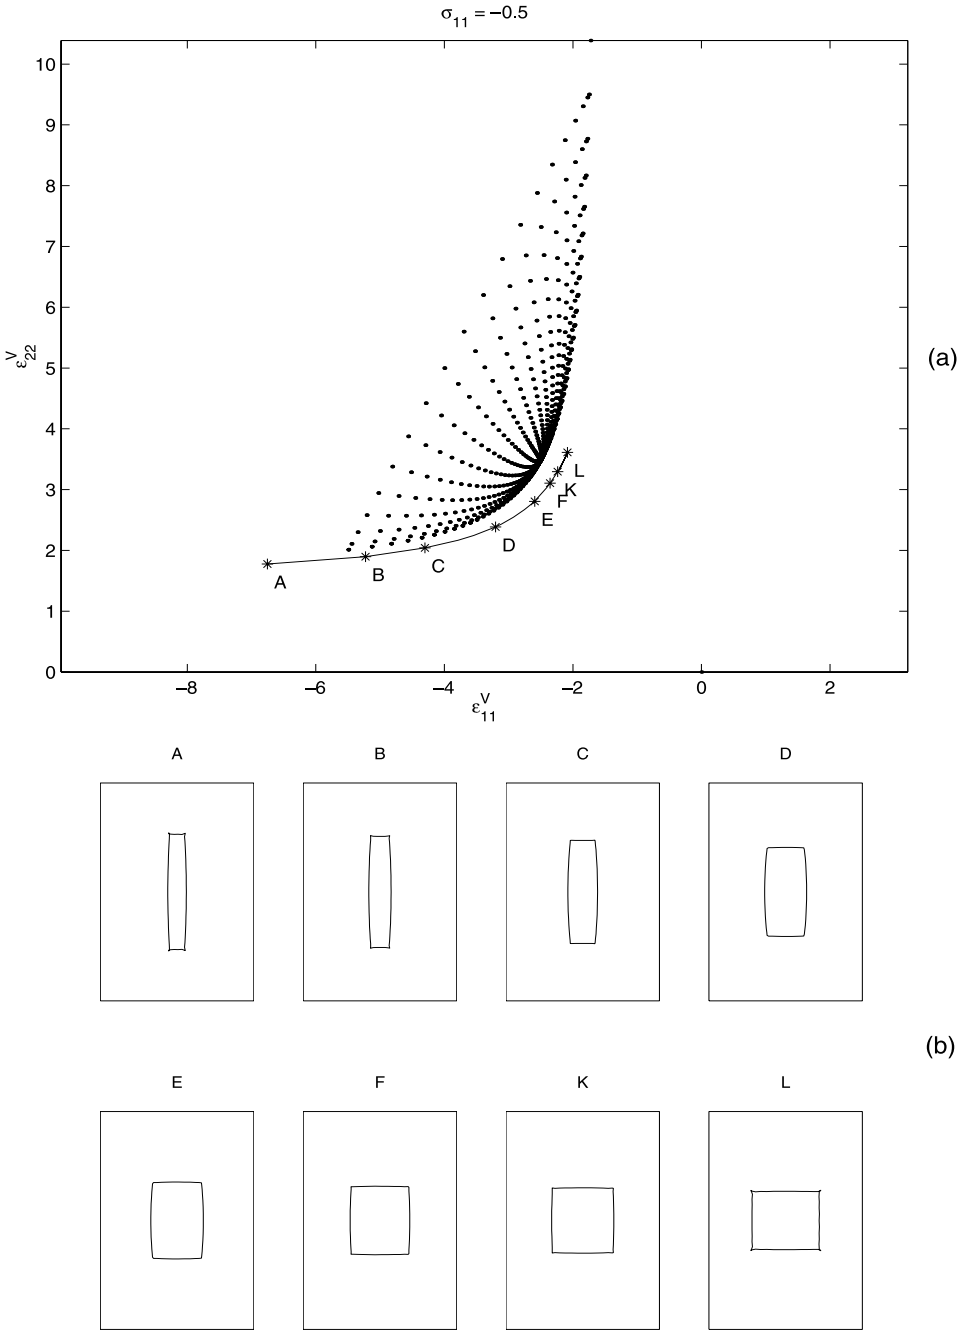

FIG. 8. *As for Figure* 3, *but for biaxial loading with* $\sigma = -0.5$.

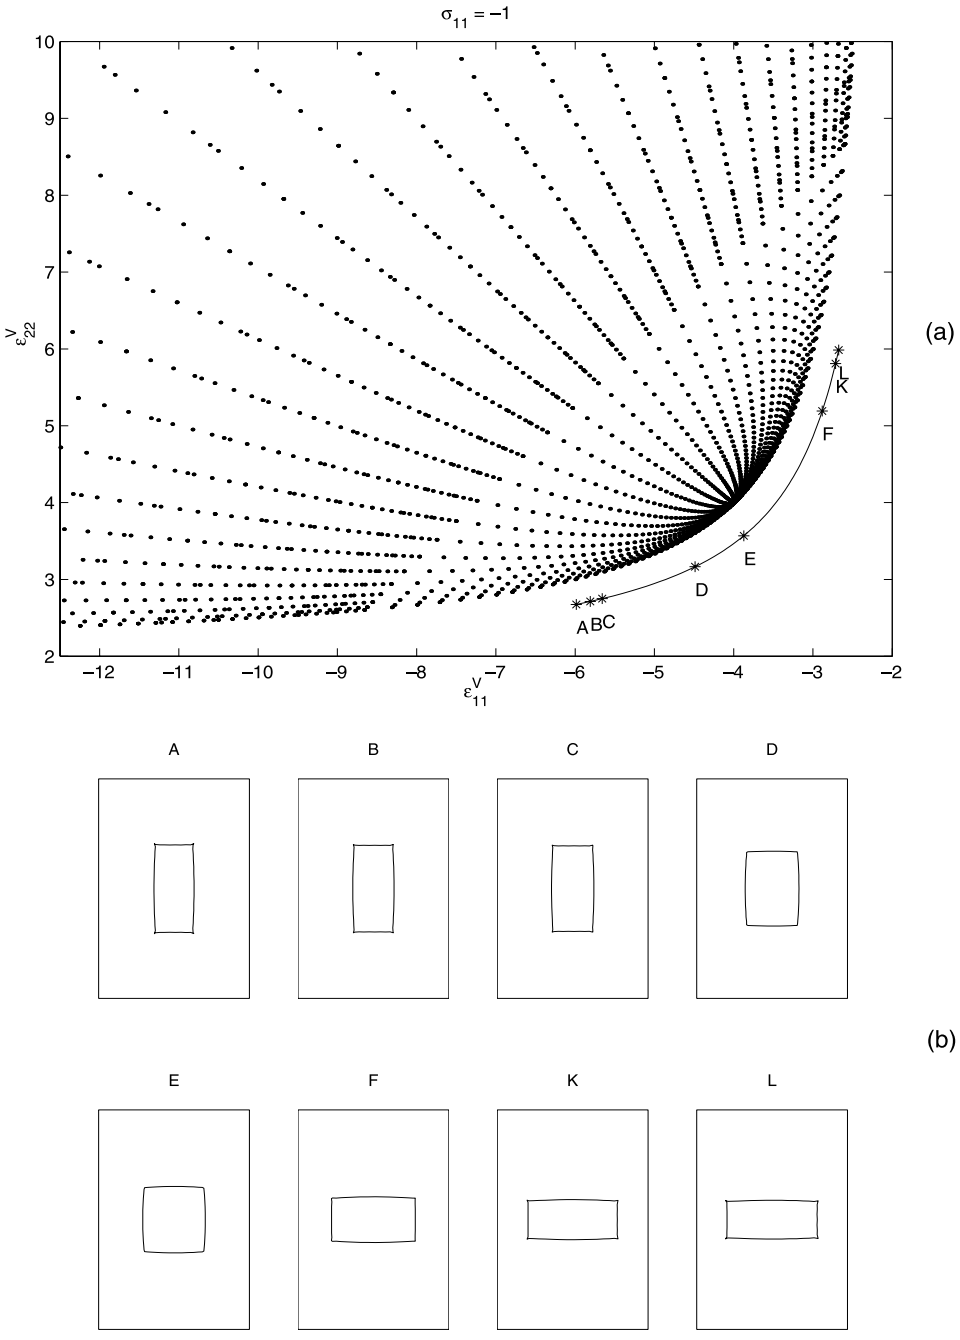

FIG. 9. *As for Figure* 3, *but for pure shear loading with* $\sigma = -1$.

This perturbation analysis and the numerical results suggest that the optimal hole is smooth when ε is sufficiently small, and that it is elliptical or circular to the first order in ε but nonelliptical to the second order in ε (unless $c_0 = c$, in which case the bilinear form is the energy and is minimized by elliptical holes for all $\varepsilon > -1/c$). When $c_0 = -c + c^2\varepsilon$, which corresponds to $\sigma^0 \approx 1/\sigma$, the terms involving $\cos 2\theta$ cancel, and the resulting hole has fourfold symmetry, in agreement with Figure 1.

When σ is less than 1, there are values of $\boldsymbol{\epsilon}_*$ associated with elliptical holes such that $\lambda\boldsymbol{\epsilon}_*$ is not associated with any elliptical hole for some $\lambda > 1$ (but is associated with an elliptical hole with an island in it). In particular, as illustrated in Figures 4, 5, 6, for $\sigma = 0.5$, $\sigma = 0.2$, and $\sigma = 0.01$, respectively, ϵ_{11}^V can be negative for elliptical holes but cannot be arbitrarily large and negative. It follows from (4.29) that $\epsilon_{11}^V \geq \sigma - 1$ for all elliptical holes in a plate with $E = 1$, with the bound being achieved with $\beta = \pi/2$ in the limit $r \to \infty$. Thus the values of $(\epsilon_{11}^V, \epsilon_{22}^V)$ associated with elliptical holes no longer adequately cover $\widetilde{D}_1$. Accordingly, as illustrated in the diagrams A–L of Figures 5(b) and 6(b), the optimal shaped holes are sometimes quite different from elliptical in shape.

For $\sigma = 0$ the algorithm did not produce any reliable results. This case may be rather singular. When σ is infinitesimal and positive, it is possible to find an elliptical hole with an island in it (connected to the surrounding plate by a thin bridge) matching any given value of $(\epsilon_{11}^V, \epsilon_{22}^V)$ with $\epsilon_{11}^V + \epsilon_{22}^V > 0$ and $\epsilon_{22}^V > 1$. Unless $\epsilon_{11}^V \approx -1$, the required hole will be very elongated in shape and aligned at a slight angle to the x_2 axis. When σ is infinitesimal and negative, it is possible to find an elliptical hole matching any given value of $(\epsilon_{11}^V, \epsilon_{22}^V)$ with $\epsilon_{11}^V < -1$ and $\epsilon_{22}^V > 1$. Again unless $\epsilon_{11}^V \approx -1$, the required ellipse will be very elongated in shape and aligned at a slight angle to the x_2 axis. When $\sigma = 0$, the bound on the elastic energy implies that $\epsilon_{22}^V \geq 1$ for any shaped hole.

For negative values of σ the optimal shaped holes change to being almost rectangular in shape. This is illustrated in Figures 7, 8, and 9, for $\sigma = -0.01$, $\sigma = -0.5$, and $\sigma = -1$, respectively.

We also obtained some results for the projection of the set $\widetilde{D}(\boldsymbol{\sigma}_*)$ onto the $(\sigma\epsilon_{11}^V + \epsilon_{22}^V, \epsilon_{12}^V)$ plane. (The prefactor of σ is added to ϵ_{11}^V so that nontrivial projections are obtained for both positive and negative values of σ.) This projection, which we denote as $\widetilde{D}_2$, represents the set of possible values of $(\sigma\epsilon_{11}^V + \epsilon_{22}^V, \epsilon_{12}^V)$. The convex hull of this projection is obtained by taking

$$\boldsymbol{\sigma}_*^0 = \begin{pmatrix} \sigma & \delta \\ \delta & 1 \end{pmatrix} \tag{4.35}$$

and varying δ. For the hydrostatic load $\sigma = 1$ the results for $\widetilde{D}_1$ in Figure 3(a) (representing the set of possible eigenvalue pairs of the matrix $\boldsymbol{\epsilon}_*$) can be used to determine $\widetilde{D}_2$. The optimal holes associated with the boundary of $\widetilde{D}_2$ are obtained by rotating the optimal holes associated with the boundary of $\widetilde{D}_1$. For the loading with $\sigma = -1$ the tensors $\boldsymbol{\sigma}_*$ and $\boldsymbol{\sigma}_*^0$ are transformed under a 90° rotation to $-\boldsymbol{\sigma}_*$ and $-\boldsymbol{\sigma}_*^0$, respectively, leaving the bilinear form $\boldsymbol{\sigma}_*^0 : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_*$ invariant. Unless there is symmetry, breaking the optimal hole should also have this symmetry; that is, the minimizing complex coefficients c_{-n} should be zero unless $n + 1$ is a multiple of 4. Numerical results for $\widetilde{D}_2$ are presented in Figure 10(a). As discussed in section 4.2, elliptical holes necessarily have $\epsilon_{12}^V = 0$ when $\sigma = -1$. The optimal shaped holes are roughly rotated squares, as illustrated in the diagrams A–L of Figure 10(b). The shape changes slightly from one diagram to the next, and is not just a rotation of the

same hole. Indeed a hole which satisfies the optimality condition (3.4) is generally not going to satisfy the condition for any choice of $\boldsymbol{\sigma}^0_*$ when $\boldsymbol{\sigma}_*$ is rotated.

The calculations described above are based on numerical experiments where we have minimized over a finite set of conformal mapping coefficients c_n, treating them as controls. It is possible that we have not adequately explored the set of admissible shapes, and it is possible that the shapes found are only local minimizers and not global minimizers. These are difficult questions that one always faces when trying to approximate an infinite-dimensional minimization problem by a finite-dimensional one. Since relatively large perturbations to the boundary sometimes produce small changes in $\boldsymbol{\epsilon}_V$, we believe our sets of admissible values of $\boldsymbol{\epsilon}_V$ to be generally more reliable than our results for the shapes of the optimal holes.

5. Critical holes. Consider the graphs in Figure 2 of the tangential stress product $\sigma^0_{tt}\sigma_{tt}$ around the boundary of the hole. As σ approaches its critical value $\sigma \approx 0.2$, the product approaches zero. Further numerical investigations (see Figure 11) showed that both σ_{tt} and σ^0_{tt} approach zero on all smooth portions on the boundary, and that σ_{tt} blows up to infinity at two opposing corner points, while σ^0_{tt} blows up to infinity at the remaining two opposing corner points. Certainly the optimality criterion (3.4) will be satisfied if σ_{tt} (or alternatively σ^0_{tt}) is zero on all smooth portions of the boundary

Γ. Let us try to find holes having this property, which we will call critical holes. It was a surprise to us to discover that such holes exist, with the stress field $\boldsymbol{\sigma}(\mathbf{x})$ (or $\boldsymbol{\sigma}^0(\mathbf{x})$) being zero along the boundary except at the corner points. To our knowledge they have not been previously studied.

Without loss of generality let us suppose that the two corner points where σ_{tt} blows up correspond to $\xi = 1$ and $\xi = -1$. (We no longer assume that $\boldsymbol{\sigma}_*$ has the diagonal form (1.3).) The analytic function $\Phi(\xi)$, which determines σ_{tt} through (4.19), must have zero real part on the unit circle $|\xi| = 1$, except at the points $\xi = 1$ and $\xi = -1$, where it must have a delta function singularity. Also it must approach α in the limit $\zeta \to \infty$ because $\phi'(\xi)/\omega'(\xi)$ approaches 1 in this limit. These considerations imply that $\Phi(\xi)$ is given by the expression

$$\Phi(\xi) = \lim_{\epsilon \to 0} \left[\alpha + \frac{\alpha}{\xi + \varepsilon - 1} - \frac{\alpha}{\xi + 1 - \varepsilon} \right] = \frac{\alpha(\xi - 1)}{2(\xi + 1)} + \frac{\alpha(\xi + 1)}{2(\xi - 1)}. \tag{5.1}$$

In the ensuing calculations one should think of ϵ as being infinitesimal and strictly positive, so that the singularities of $\Phi(\xi)$ lie inside the unit circle, even though we will be looking at what happens in the limit $\epsilon \to 0$. (The only place one has to be careful in making the distinction between zero ϵ and infinitesimal ϵ is in evaluating the integral (5.4).)

To obtain $\omega(\xi)$ from $\Phi(\xi)$ we follow the approach of Cherkaev et al. (1998), who solve this type of problem with a different $\Phi(\xi)$. By differentiating (4.9) and using the relation $\overline{\Phi(t)} = -\Phi(t) + 2\,\mathrm{Re}\,\Phi(t)$, we see that

$$\omega'(\xi)\Phi(\xi) + \frac{1}{2\pi i} \int_{|t|=1} \frac{\omega(t)\Phi(t)}{(t - \xi)^2} dt - \frac{1}{\pi i} \int_{|t|=1} \frac{\omega(t)\,\mathrm{Re}\,\Phi(t)}{(t - \xi)^2} dt = \alpha + \overline{\gamma}\xi^{-2}. \tag{5.2}$$

The first integral can be evaluated using the Cauchy integral theorem,

$$\frac{1}{2\pi i} \int_{|t|=1} \frac{\omega(t)\Phi(t)}{(t - \xi)^2} dt = \alpha - \frac{d}{d\xi}[\omega(\xi)\Phi(\xi)] = \alpha - \omega'(\xi)\Phi(\xi) + \frac{4\alpha\xi\omega(\xi)}{(\xi^2 - 1)^2} \tag{5.3}$$

in which the leading constant α comes from the integral around a circle of very large radius. The second integral can be making the substitution (5.1), keeping ε finite, and taking the limit $\varepsilon \to 0$, giving

$$\frac{1}{\pi i} \int_{|t|=1} \frac{\omega(t)\,\mathrm{Re}\,\Phi(t)}{(t - \xi)^2} dt = \frac{\omega(1)\alpha}{(\xi - 1)^2} - \frac{\omega(-1)\alpha}{(\xi + 1)^2}. \tag{5.4}$$

Assuming $\omega(-1) = -\omega(1)$ and substituting (5.3) and (5.4) back into (5.2) results in a simple expression for $\omega(\xi)$ involving $\omega(1)$. The constant $\omega(1)$ can then be determined from the constraint that $\omega(\xi)/\xi$ approaches 1 as $\xi \to \infty$. In this way we see that necessarily

$$\omega(\xi) = \xi + (1 - 3k)\xi^{-1} + k\xi^{-3}, \quad \text{where } k = \frac{\overline{\gamma}}{4\alpha}. \tag{5.5}$$

This is an exact formula, not an approximation. The requirement that the mapping from the exterior of the unit disk onto its image be one-to-one will be satisfied if and only if k lies inside the intersection of the disk of radius $1/3$ with the region Q whose boundary is the curve traced out by

$$k = \frac{e^{i\eta}(1 - e^{i\eta})}{1 + 3e^{i\eta}} \tag{5.6}$$

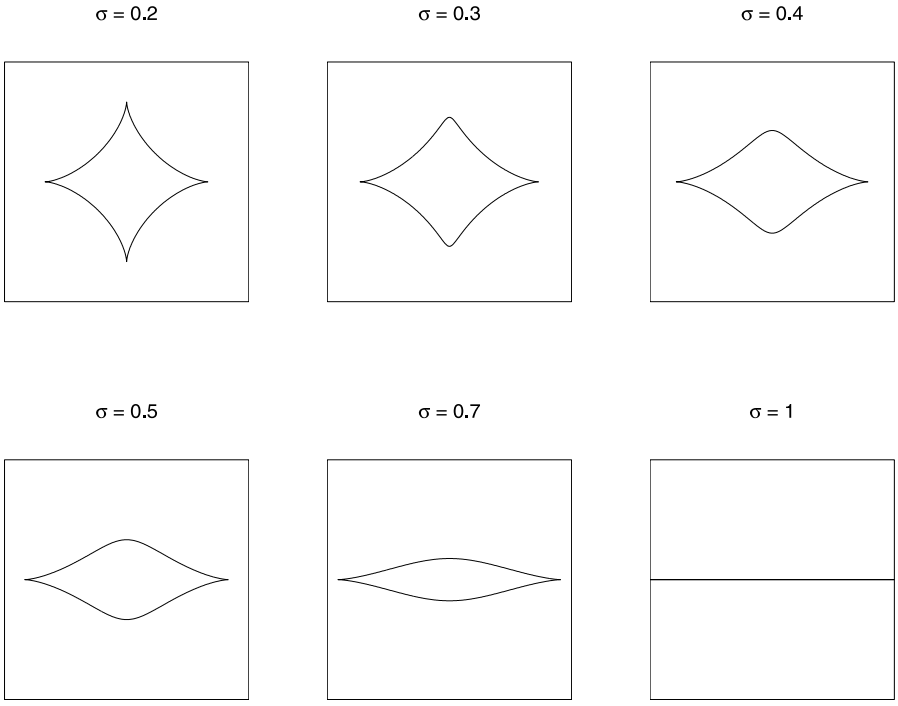

FIG. 12. *Critical holes associated with various values of* σ *between* 0.2 *and* 1. *The tangential stress* $\sigma_{tt}(\theta)$, *and hence all components of the stress field* $\mathfrak{E}(\mathbf{x})$, *are zero along the smooth portions of the boundary.*

as η varies between 0 and 2π. The constraint that $|k| \leq 1/3$ ensures that $\omega'(\xi)$ is nonzero when $|\xi| > 1$, while the constraint that $k \in Q$ ensures that the image of the circle $|\xi| = 1$ does not intersect itself and that $\omega(e^{i\theta})$ moves anticlockwise around the boundary as θ is increased from 0 to 2π. When k is real, these restrictions force k to lie between 0 and 1/3. Figure 12 shows examples of the hole shapes for $k = \overline{\gamma}/(4\alpha) = (1-\sigma)/[2(1+\sigma)]$ (corresponding to the loading (1.3)) as σ varies between 0.2 and 1. Notice that the hole shape for $\sigma = 0.2$ matches the hole shape found numerically in the next to last plot in Figure 1. Figure 13 shows examples of the hole shapes for complex values of k ranging over the boundary of admissible values. These unusual hole shapes might have been seen in our numerical simulations, had we explored the full range $\widetilde{D}(\boldsymbol{\sigma}_*)$ of values of $\boldsymbol{\epsilon}_V$, and not just the range $\widetilde{D}_1$ of values of the pair $(\epsilon_{11}^V, \epsilon_{22}^V)$.

By integrating $\phi'(\xi) = \omega'(\xi)\Phi(\xi)$, using (4.20) and the fact that $\overline{t} = 1/t$ when $|t| = 1$, one finds that the potentials ϕ and ψ are given by the expressions

$$\begin{aligned} \phi &= \alpha[\xi - (1+3k)\xi^{-1} - k\xi^{-3}] = \alpha z + Az^{-1} + \mathcal{O}(z^{-3}), \\ \psi &= 4\alpha\overline{k}\xi + \frac{4\alpha(\overline{k}-1)\xi}{(\xi^2-1)} = 4\alpha\overline{k}z + Bz^{-1} + \mathcal{O}(z^{-3}), \end{aligned} \tag{5.7}$$

in which the coefficients

$$A = -2\alpha, \quad B = 4\alpha(3|k|^2 - 1) \tag{5.8}$$

govern the leading corrections to the far field behavior in the z-plane. The average

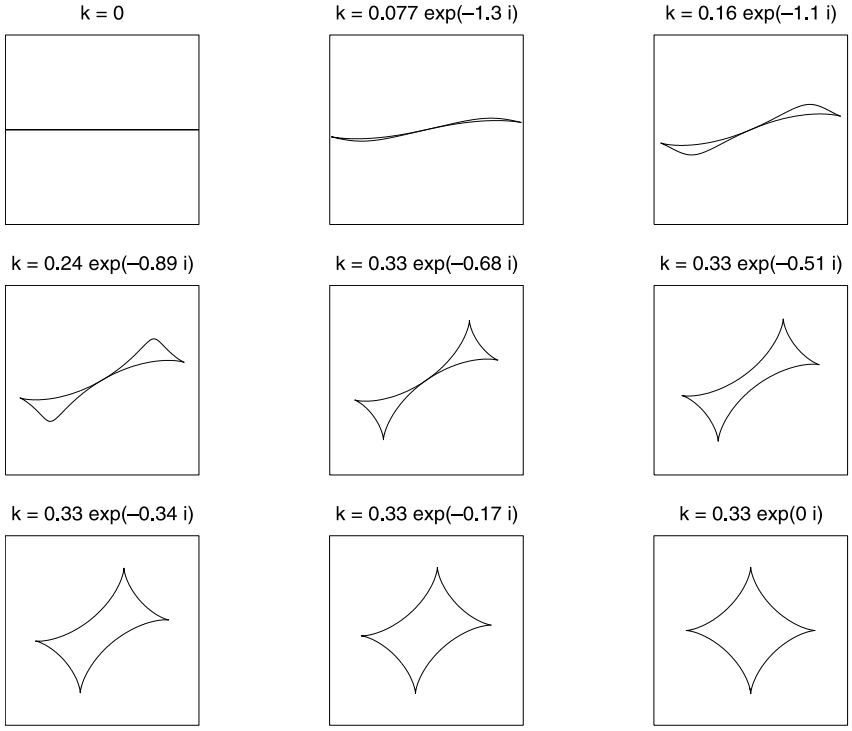

FIG. 13. *Critical holes associated with values of k at the boundary of its range of admissible values.*

strain in the void phase is determined by these coefficients and by the area V of the hole, given by (4.24). A straightforward computation (similar to the one given by Movchan and Serkov (1997) for determining $\mathbf{E}$) shows that

$$\boldsymbol{\epsilon}_V = \frac{\pi}{V}\begin{pmatrix} 2\,\mathrm{Re}(2A-B) & 4\,\mathrm{Im}(A) \\ 4\,\mathrm{Im}(A) & -2\,\mathrm{Re}(2A+B)\end{pmatrix}, \tag{5.9}$$

giving

$$\boldsymbol{\epsilon}_V = \frac{4\alpha}{3\,\mathrm{Re}(k)-6|k|^2}\begin{pmatrix} -3|k|^2 & 0 \\ 0 & 2-3|k|^2\end{pmatrix}. \tag{5.10}$$

For the loading (1.3), which corresponds to $\alpha = (1+\sigma)/4$ and $k = (1-\sigma)/[2(1+\sigma)]$, the formula (5.10) implies

$$\epsilon_{11}^V = -\frac{(1-\sigma^2)}{4\sigma}, \qquad \epsilon_{22}^V = \frac{(1+\sigma)(5+22\sigma+5\sigma^2)}{12\sigma(1-\sigma)}, \tag{5.11}$$

and the restrictions on k force σ to lie between 0.2 and 1. This average stress within the void phase is represented by the small square in Figures 4 and 5.

Suppose that the hole generated by (5.5) for a fixed value of k is subject to a different loading $\boldsymbol{\sigma}_*^0$ having loading coefficients

$$\alpha^0 = \frac{(\sigma_{11}^{*0}+\sigma_{22}^{*0})}{4}, \qquad \gamma^0 = \frac{(\sigma_{22}^{*0}-\sigma_{11}^{*0}+2i\sigma_{12}^{*0})}{2}. \tag{5.12}$$

The integral equation (4.9) (with α and γ being replaced by the new loading coefficients) can be solved for $\phi(\xi)$, giving

$$\phi(\xi) = \alpha^0\zeta - \frac{\overline{\gamma^0} + \alpha^0(1-k)}{\xi} + \frac{(4\alpha^0\overline{k} - \gamma^0)k - (4\alpha^0 k - \overline{\gamma^0})|k|^2}{(1-|k|^2)\xi} - \frac{\alpha^0}{\xi^3}, \tag{5.13}$$

which agrees with (5.7) when $\alpha^0 = \alpha$ and $\gamma^0 = 4\alpha\overline{k}$.

Now the optimality criterion (3.4) seems to say nothing about σ^0_{tt} when σ_{tt} is zero on all smooth portions of the boundary of Γ. However, here we will present a plausibility argument to suggest that σ^0_{tt} should be finite at $\xi = 1$ and $\xi = -1$. Assume otherwise, and suppose that there exist small perturbations of the loadings $\boldsymbol{\sigma}_*$ and $\boldsymbol{\sigma}^0_*$ that result in the optimal hole minimizing the bilinear form $\boldsymbol{\sigma}^0_* : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_*$ having a completely smooth boundary. The functions σ_{tt} and σ^0_{tt} should remain approximately the same with sharp peaks at $\xi = 1$ and $\xi = -1$. But then the product $\sigma^0_{tt}\sigma_{tt}$ cannot be constant around the boundary, and we have a contradiction. On the other hand, assume that σ^0_{tt} was originally finite, taking the value s^0 at $\xi = 1$ and at $\xi = -1$. The product $\sigma^0_{tt}\sigma_{tt}$ will equal some small constant ε, and therefore $\sigma^0_{tt} = \varepsilon/\sigma_{tt}$ will have a sharp dip (with a minimum close to zero) after the perturbation. If σ_{tt} is of the order of ε away from its peak, then we can see that σ^0_{tt} could remain approximately equal to s^0 in the vicinity of $\xi = 1$ and $\xi = -1$, but away from the dip at these points. The dip can be regarded as being due to a small multiple of σ_{tt} being subtracted from the unperturbed potential σ^0_{tt} because of the slightly different loading. In the special case when $s^0 = 0$ the argument has to be modified, but everything works out if, for example, σ_{tt} is of the order of $\sqrt{\varepsilon}$ away from its peak. This is only a plausibility argument because it breaks down if all small perturbations of loading result in optimal holes having nonsmooth boundaries. However, the results we obtain by assuming that σ^0_{tt} is finite at $\xi = 1$ and $\xi = -1$ justify this assumption.

The potential $\Phi(\xi) = \phi'(\xi)/\omega'(\xi)$ will have a finite real part at $\xi = 1$ and at $\xi = -1$ if $\phi'(\xi)$ is zero at these points. This cancels the effect of $\omega'(\xi)$ being zero at these points. Thus the tangential stress component σ^0_{tt} will be finite at the cusp points when

$$\gamma^0 = 2\alpha^0(3|k|^2 - 1), \tag{5.14}$$

in which case $\boldsymbol{\sigma}^0_*$ takes the form

$$\boldsymbol{\sigma}^0_* = 2\alpha^0 \begin{pmatrix} 2 - 3|k|^2 & 0 \\ 0 & 3|k|^2 \end{pmatrix}. \tag{5.15}$$

Consequently we have

$$\boldsymbol{\sigma}^0_* : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_* = \boldsymbol{\sigma}^0_* : \boldsymbol{\epsilon}_V = 0, \tag{5.16}$$

and if this represents the minimum value of the bilinear form $\boldsymbol{\sigma}^0_* : \boldsymbol{\mathcal{E}}\boldsymbol{\sigma}_*$, then we can place an island of plate material inside the inclusion (connected to the surrounding plate by a very thin bridge of plate material) without disturbing the minimum. Thus there would be a whole family of optimal holes minimizing the bilinear form, with values of $\boldsymbol{\epsilon}_V$ that are λ times the $\boldsymbol{\epsilon}_V$ given by (5.10), with $\lambda \geq 1$. Certainly the optimality criterion (3.4) is satisfied for such holes, since the product $\sigma^0_{tt}\sigma_{tt}$ is zero around the boundary of the hole including at the shore of the island (where both σ^0_{tt} and σ_{tt} are zero).

By substituting (5.14) back into (5.13), using (4.20) and the fact that $\bar{t} = 1/t$ when $|t| = 1$, one obtains the potentials ϕ and ψ associated with the loading $\boldsymbol{\sigma}_*^0$:

$$\begin{aligned}\phi &= \alpha^0\zeta + \alpha^0(1+3k)\xi^{-1} - \alpha^0\xi^{-3} = \alpha^0 z + A^0 z^{-1} + \mathcal{O}(z^{-3}),\\ \psi &= 2\alpha^0(3|k|^2-1)\xi - \frac{2\alpha^0[9|k|^2(k+1)-3k+1]\xi}{\xi^2+3k}\\ &= 2\alpha^0(3|k|^2-1)z + B^0 z^{-1} + \mathcal{O}(z^{-3}),\end{aligned} \tag{5.17}$$

in which

$$A^0 = 6k\alpha^0, \quad B^0 = -24|k|^2\alpha^0. \tag{5.18}$$

The associated average stress within the void phase by direct analogy with (5.9) is

$$\boldsymbol{\epsilon}_V^0 = \frac{1}{6\,\mathrm{Re}(k) - 12|k|^2}\begin{pmatrix} 2\,\mathrm{Re}(2A^0 - B^0) & 4\,\mathrm{Im}(A^0) \\ 4\,\mathrm{Im}(A^0) & -2\,\mathrm{Re}(2A^0 + B^0)\end{pmatrix}. \tag{5.19}$$

One can check that $\boldsymbol{\sigma}_* : \boldsymbol{\epsilon}_V^0 = 0$, which agrees with (5.16).

In the special case in which the loadings $\boldsymbol{\sigma}_*$ and $\boldsymbol{\sigma}_*^0$ take the forms (1.3) and (4.32), corresponding to $\alpha^0 = 1/(6|k|^2)$ and $k = (1-\sigma)/[2(1+\sigma)]$, we have

$$\sigma^0 = 2\alpha^0(2 - 3|k|^2) = \frac{5 + 22\sigma + 5\sigma^2}{3(1-\sigma)^2}, \tag{5.20}$$

and the constraint that σ lies between 0.2 and 1 forces σ^0 to lie between 5 and infinity. According to the formula (5.18) and (5.19) the matrix $\boldsymbol{\epsilon}_V^0$ has elements

$$\begin{aligned}\epsilon_{11}^{0V} &= \frac{1+\sigma^0}{\sigma} = \frac{(1+\sigma^0)(3\sigma^0-5)}{3\sigma^0 + 11 - 4\sqrt{6(\sigma^0+1)}},\\ \epsilon_{22}^{0V} &= -(1+\sigma^0), \quad \epsilon_{12}^{0V} = 0,\end{aligned} \tag{5.21}$$

where we have used (5.20) to express these elements entirely in terms of the constant σ^0 associated with the applied loading. Now let us rotate the hole by 90°, rotate $\boldsymbol{\sigma}_*^0$ and $\boldsymbol{\epsilon}_V^0$ by 90°, and divide both matrices by σ^0. Then, by relabelling $1/\sigma^0$ as σ, we see that the applied loading (1.3) with σ between 0 and 0.2 can produce an average stress $\boldsymbol{\epsilon}_V$ within the void phase having elements

$$\epsilon_{11}^V = -(1+\sigma), \quad \epsilon_{12}^V = 0, \quad \epsilon_{22}^V = \frac{(1+\sigma)(3-5\sigma)}{3 + 11\sigma - 4\sqrt{6\sigma(1+\sigma)}}. \tag{5.22}$$

This average stress within the void phase is represented by the small circle in Figure 6.

For negative values of σ, Figures 7, 8, and 9 suggest that the optimal holes are somewhat rectangular in shape. Accordingly, it makes sense to study critical holes for which the tangential stress (and hence the real part of $\Phi(\xi)$) vanishes except at four points on the boundary of the unit circle $|\xi| = 1$, which we take to be the points p, $-p$, $\overline{p} = 1/p$, and $-\overline{p} = -1/p$, where $p = e^{i\beta}$. Assuming that the applied loading is diagonal (i.e., γ is real), that σ_{tt} around the hole boundary has delta function singularities at the four points, and that the hole shape and potentials have inversion and reflection symmetry, which implies

$$\begin{aligned}&\omega(-\xi) = -\omega(\xi), \quad \phi(-\xi) = -\phi(\xi), \quad \Phi(-\xi) = \Phi(\xi),\\ &\overline{\omega(\xi)} = \omega(\overline{\xi}), \quad \overline{\phi(\xi)} = \phi(\overline{\xi}), \quad \overline{\Phi(\xi)} = \Phi(\overline{\xi}),\end{aligned} \tag{5.23}$$

the function $\Phi(\xi) = \phi'(\xi)/\omega'(\xi)$ is easily deduced to be

$$\begin{aligned}\Phi(\xi) &= \lim_{\varepsilon\to 0}\left[\alpha + \frac{\alpha p}{\xi+\varepsilon-p} - \frac{\alpha p}{\xi+p-\varepsilon} + \frac{\alpha\overline{p}}{\xi+\varepsilon-\overline{p}} - \frac{\alpha\overline{p}}{\xi+\overline{p}-\varepsilon}\right]\\ &= \frac{\alpha(\xi-p)}{4(\xi+p)} + \frac{\alpha(\xi+p)}{4(\xi-p)} + \frac{\alpha(\xi-\overline{p})}{4(\xi+\overline{p})} + \frac{\alpha(\xi+\overline{p})}{4(\xi-\overline{p})}.\end{aligned} \tag{5.24}$$

In the appendix we calculate the final form of $\omega(\xi)$, the area of the hole, and the strain in the void. It turns out that the loading can produce zero tangential stress along the smooth portions of the boundary only when $|\gamma/\alpha| \le C_1$, where $C_1 \approx 1.5$, i.e., when $1/C_2 > \sigma \ge C_2$, where $C_2 = (2-C_1)/(2+C_1) \approx 1/7$. Thus such holes are unlikely to be optimal when σ is negative. These calculations are presented in the appendix.

One reason why this analysis failed may be our assumption that σ_{tt} has simple delta function singularities at the four points, p, $-p$, $\overline{p}$, and $-\overline{p}$. When σ is negative, the tangential stress around the boundary of an optimal hole can take both positive and negative values. This is most easy to see when one minimizes the compliance energy $\boldsymbol{\sigma}_* : \boldsymbol{\mathcal{S}}_*\boldsymbol{\sigma}_*$. Cherkaev et al. (1998) have shown that the tangential stress changes sign at the four corner points but keeps constant magnitude around the boundary. Accordingly, the assumption that σ_{tt} is a positive valued measure around the boundary is probably too strong. Relaxing this constraint permits other forms of $\Phi(\xi)$, such as

$$\begin{aligned}\Phi(\xi) &= \frac{\alpha(\xi-p)}{4(\xi+p)} + \frac{\alpha(\xi+p)}{4(\xi-p)} + \frac{\alpha(\xi-\overline{p})}{4(\xi+\overline{p})} + \frac{\alpha(\xi+\overline{p})}{4(\xi-\overline{p})}\\ &\quad + \frac{i\beta(\xi-p)^2}{(\xi+p)^2} + \frac{i\beta(\xi+p)^2}{(\xi-p)^2} - \frac{i\beta(\xi-\overline{p})^2}{(\xi+\overline{p})^2} - \frac{i\beta(\xi+\overline{p})^2}{(\xi-\overline{p})^2},\end{aligned} \tag{5.25}$$

where β is an arbitrary real constant. This satisfies the symmetry constraints (5.23) and has zero real part except at the corner points. It would be interesting to see the hole shapes associated with this form of $\Phi(\xi)$. We did not do this, as the preliminary analysis was more involved than for the case $\beta = 0$ (treated in the appendix), which was already quite difficult.

Appendix. Here we calculate the final form of $\omega(\xi)$, the area of the hole, and the strain in the void when $\Phi(\xi)$ takes the form (5.24) and $p = e^{i\beta}$. These calculations are quite complicated and are best done with the aid of an algebraic manipulator, such as Maple. We follow the same procedure as used in section 5. We easily find that

$$\frac{1}{\pi i}\int_{|t|=1} \frac{\omega(t)\,\mathrm{Re}\,\Phi(t)}{(t-\xi)^2}\,dt = \frac{\alpha g}{2(\xi-p)^2} + \frac{\alpha g}{2(\xi+p)^2} + \frac{\alpha\overline{g}}{2(\xi-\overline{p})^2} + \frac{\alpha\overline{g}}{2(\xi+\overline{p})^2}, \tag{A.1}$$

where $g = p\omega(p)$. This leads to

(A.2)

$$\omega(\xi) = \frac{-g(i\xi^2+1/q)^2(i\xi^2+q)\xi^2 - \overline{g}(i\xi^2-q)^2(i\xi^2-1/q)\xi^2 + i(\gamma/\alpha)(i\xi^2-q)^2(i\xi^2+1/q)^2}{2\xi^3[(q-1/q)(\xi^4+1) - 4i\xi^2]},$$

in which $q = ip^2 = e^{i\tau}$ and $\tau = 2\beta + \pi/2$ have been introduced to simplify subsequent formulae. The denominator of $\omega(\xi)$ is zero when $\xi = 0$ and additionally when

$$\xi^2 = r_1 \equiv \frac{i(q+1)}{q-1} = \frac{1+\cos(\tau)}{\sin(\tau)} \quad \text{or} \quad \xi^2 = r_2 \equiv \frac{1}{r_1} = \frac{1-\cos(\tau)}{\sin(\tau)}. \tag{A.3}$$

Without loss of generality we can assume that $p = e^{i\beta}$ lies in the first quadrant with $\pi/2 \geq \beta \geq 0$, so that $3\pi/2 \geq \tau \geq \pi/2$. Then r_1 will lie inside the unit circle, while r_2 will lie outside it. In order for $\omega(\xi)$ to be analytic outside the unit disk, we require that the numerator of (A.2) be zero when $\xi^2 = r_2$. This imposes the constraint that

$$g(1-\overline{q})(q-\overline{q}+2) + \overline{g}(1-q)(\overline{q}-q+2) + \left(\frac{\gamma}{\alpha}\right)(q^2+\overline{q}^2+2) = 0, \tag{A.4}$$

in which $\overline{q} = 1/q$ is the complex conjugate of q. Additionally we have the constraint that

$$1 = \lim_{\xi\to\infty} \frac{\omega(\xi)}{\xi} = \frac{g + \overline{g} + \gamma/\alpha}{2i(\overline{q}-q)}. \tag{A.5}$$

These two real valued constraints can be used to solve for the complex constant g, giving

$$g = \frac{-2i(q-1)^2(q^2-2q-1) + (\gamma/\alpha)(3q^2-2q+1)}{(q-1)(q^2-4q+1)}, \tag{A.6}$$

which, when substituted back into the expression (A.2), gives

$$\omega(\xi) = \frac{2i\xi^2(q-1)^2(a_1\xi^4 + a_2\xi^2 + a_3) + i(\gamma/\alpha)q(b_1\xi^4 + b_2\xi^2 + b_3)}{2\xi^3 q(q-1)(q^2-4q+1)[i\xi^2(q-1)+q+1]} \tag{A.7}$$

with coefficients

$$\begin{aligned} &a_1 = q(q^2-4q+1), \quad a_2 = -i(q^4-1), \quad a_3 = q(q^2+4q+1), \\ &b_1 = 3q(3q^2-4q+3), \quad b_2 = i(q^2-1)(3q^2-8q+3), \quad b_3 = q(q^2-4q+1). \end{aligned} \tag{A.8}$$

Thus for a given loading, i.e., for given real values of α and γ, there is a one-parameter family of holes (parameterized by τ, with $q = e^{i\tau}$) such that the tangential stress is zero along the smooth portions of the boundary of each hole in the family. When $p = 1$, that is, $q = i$, the above expression for $\omega(\xi)$ reduces to (5.5), as it should. Also when $\gamma/\alpha = -4\sin(\tau)/3$, the expression for $\omega(\xi)$ reduces to

$$\omega(\xi) = \xi + 2\sin(\tau)\xi^{-1} - \frac{\xi^{-3}}{3}, \tag{A.9}$$

which corresponds to the inclusion generated from (5.5) with $k = -e^{2i\beta}/3$, rotated by an angle of $-\beta/2$. (One makes this substitution for k, multiplies the entire expression by $e^{-i\beta/2}$, and replaces ξ with $e^{i\beta/2}\xi$ to recover (A.9).) Another special case is for $q = -1$, and the expression for $\omega(\xi)$ reduces to

$$\omega(\xi) = \xi - \frac{\xi^{-3}}{3} - \left(\frac{\gamma}{\alpha}\right)\frac{(5\xi^{-1}+\xi^{-5})}{8}. \tag{A.10}$$

Of course there are restrictions on β which are necessary to ensure that the mapping $\omega(\xi)$ from the exterior of the unit disk onto its image is one-to-one. Differentiating (A.7) with respect to ξ gives

$$\omega'(\xi) = \frac{i(i\xi^2 q+1)(i\xi^2-q)(a\xi^4+b\xi^2+c)q^{3/2}}{\xi^4(q-1)(q^2-4q+1)[i\xi^2(q-1)+q+1]^2}, \tag{A.11}$$

where a, b, and c are the real valued coefficients

$$\begin{aligned}
a &= -i(q-1)^3(q^2-4q+1)q^{-5/2} = 2[\sin(5\tau/2) - 7\sin(3\tau/2) + 16\sin(\tau/2)],\\
b &= (q+1)(q-1)^2(q^2+4q+1)q^{-5/2} + 3i(\gamma/\alpha)(q-1)(3q^2-4q+3)]q^{-3/2}/2\\
&= 2[\cos(5\tau/2) + 3\cos(3\tau/2) - 4\cos(\tau/2)] - 3(\gamma/\alpha)[3\sin(3\tau/2) - 7\sin(\tau/2)],\\
c &= 3(\gamma/\alpha)(q+1)(q^2-4q+1)q^{-3/2}/2\\
&= 3(\gamma/\alpha)[\cos(3\tau/2) - 3\cos(\tau/2)].
\end{aligned} \tag{A.12}$$

The conformality constraint that $\omega'(\xi)$ be nonzero outside the unit disk is satisfied if and only if the quadratic $a\xi^4 + b\xi^2 + c$ has no root lying outside the unit disk, which holds if and only if

$$1 \geq \frac{c}{a} \geq \left|\frac{b}{a}\right| - 1. \tag{A.13}$$

Another restriction on the values that β can take arises from the constraints that $\omega(1)$ must lie on the positive real axis, and that $\omega(i)$ must lie on the positive imaginary axis, implying that

$$\begin{aligned}
0 &\leq 16[\sin(\tau/2)]^2[\sin(\tau/2) + \cos(\tau/2)]^3\\
&\quad +(\gamma/\alpha)[3\sin(3\tau/2) - 3\cos(3\tau/2) - 15\sin(\tau/2) + \cos(\tau/2)],\\
0 &\leq 16[\sin(\tau/2)]^2[\sin(\tau/2) - \cos(\tau/2)]^3\\
&\quad +(\gamma/\alpha)[-3\sin(3\tau/2) - 3\cos(3\tau/2) + 15\sin(\tau/2) + \cos(\tau/2)].
\end{aligned} \tag{A.14}$$

The constraints (A.13) and (A.14) confine the pair $(\gamma/\alpha, \tau)$ to lie within the region shown in Figure 14. One can see that this forces $|\gamma/\alpha|$ to be less than $C_1 \approx 1.5$. If $|\gamma/\alpha|$ is greater than this value, then the constraints cannot be satisfied for any choice of τ.

The potential ψ is obtained by substituting $\phi'(t) = \omega'(t)\Phi(t)$ into (4.20), using (5.24) and (A.7) and the fact that $\overline{\omega(t)} = \omega(\bar{t}) = \omega(1/t)$, and calculating the contour integral using the method of residues, giving

$$\psi = \frac{2i\xi\alpha(q-1)^2 s_1 + i\xi^3\gamma q s_2}{(q-1)(q^2-4q+1)(i\xi^2 q+1)(i\xi^2-q)}, \tag{A.15}$$

where

$$\begin{aligned}
s_1 &= -i\xi^2(q-1)(q^2+4q+1) + (q+1)(q^2-4q+1),\\
s_2 &= i\xi^2(q-1)(q^2-4q+1) + (q+1)(3q^2-4q+3).
\end{aligned} \tag{A.16}$$

The coefficients A and B appearing in the series expansions,

$$\phi = \alpha z + Az^{-1} + \mathcal{O}(z^{-3}), \quad \psi = \gamma z + Bz^{-1} + \mathcal{O}(z^{-3}), \tag{A.17}$$

of the potentials in powers of $1/z$ are found to be

(A.18)

$$\begin{aligned}
A &= -\lim_{\xi\to\infty} \xi^2[\omega(\xi)\Phi(\xi) - \alpha] - \alpha c_{-1} = i\alpha\left(q - \frac{1}{q}\right),\\
B &= \lim_{\xi\to\infty} \xi[\phi(\xi) - \gamma\xi] - \gamma c_{-1} = \frac{-4\alpha^2(q-1)^4(q^2+4q+1) - 3\gamma^2 q^2(3q^2-4q+3)}{2\alpha q(q-1)^2(q^2-4q+1)},
\end{aligned}$$

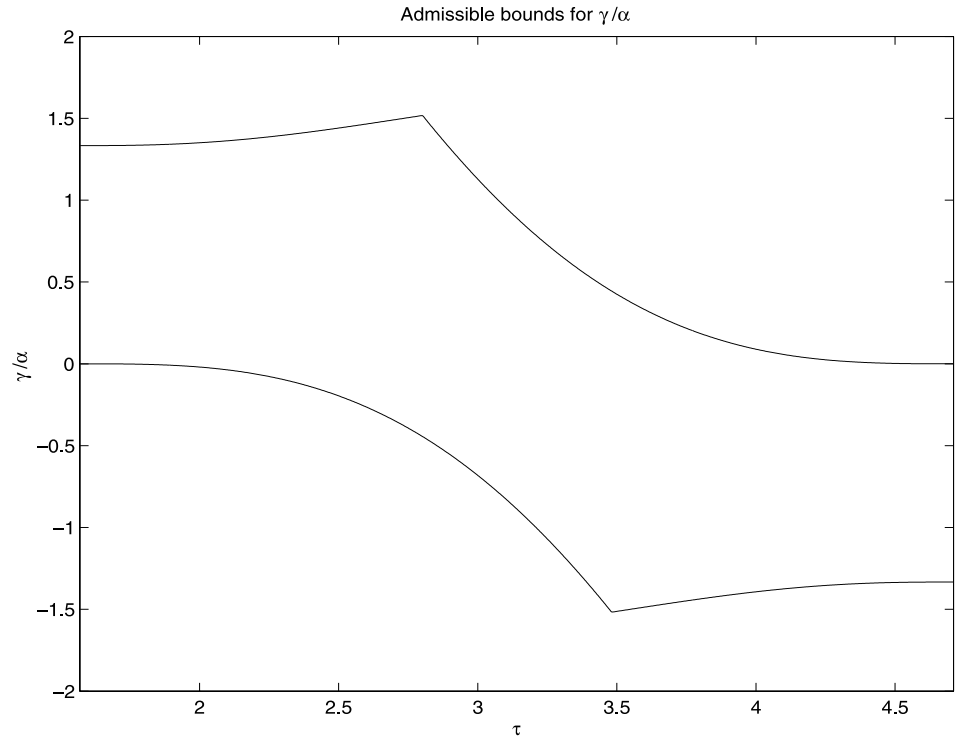

FIG. 14. *According to the constraints* (A.13) *and* (A.14), *the pair* $(\gamma/\alpha, \tau)$ *must lie within the region between these curves.*

where c_{-1} is the value of $\xi[\omega(\xi) - \xi]$ in the limit as $\xi \to \infty$. Substituting these expressions into (5.9) gives

$$\begin{aligned}
\epsilon_{11}^V &= \frac{4\alpha(1+i)(q-1)^3(q-i)^3 + 3(\gamma^2/\alpha)q^2(3q^2-4q+3)}{(V/\pi)q(q-1)^2(q^2-4q+1)} \\
&= \frac{8\alpha[1-\cos(\tau)-\sin(\tau)]^3 + 3(\gamma^2/\alpha)(3\cos(\tau)-2)}{(V/\pi)[5-6\cos(\tau)+\cos(2\tau)]}, \\
\epsilon_{22}^V &= \frac{4\alpha(1-i)(q-1)^3(q+i)^3 + 3(\gamma^2/\alpha)q^2(3q^2-4q+3)}{(V/\pi)q(q-1)^2(q^2-4q+1)} \\
&= \frac{8\alpha[1-\cos(\tau)+\sin(\tau)]^3 + 3(\gamma^2/\alpha)(3\cos(\tau)-2)}{(V/\pi)[5-6\cos(\tau)+\cos(2\tau)]},
\end{aligned} \tag{A.19}$$

in which V is the area of the inclusion. The area of the inclusion (assuming $\overline{\omega(\xi)} = \omega(\overline{\xi})$) is given by the contour integral

$$V = \frac{1}{2i}\int_{|\xi|=1} \overline{\omega(\xi)}\omega'(\xi)d\xi = \frac{1}{2i}\int_{|\xi|=1} \omega(1/\xi)\omega'(\xi)d\xi. \tag{A.20}$$

Substituting (A.7) and (A.11) into this formula and using the method of residues to evaluate the integral gives

$$\left(\frac{V}{\pi}\right) = v_1 + v_2\left(\frac{\gamma}{\alpha}\right) + v_3\left(\frac{\gamma}{\alpha}\right)^2, \tag{A.21}$$

where

$$
\begin{aligned}
v_1 &= \frac{-3(q^2+1)^3}{q(q^2-4q+1)^2} = \frac{-6[\cos(\tau)]^3}{[2-\cos(\tau)]^2},\\
v_2 &= \frac{-3i(q+1)(q^8-5q^7+17q^6-39q^5+48q^4-39q^3+17q^2-5q+1)}{q(q-1)^3(q^2-4q+1)^2}\\
&= \frac{3\cos(\tau/2)[\cos(4\tau)-5\cos(3\tau)+17\cos(2\tau)-39\cos(\tau)+24]}{8[\sin(\tau/2)]^3[2-\cos(\tau)]^2},\\
v_3 &= \frac{3(3q^8-3q^7-32q^6+87q^5-134q^4+87q^3-32q^2-3q+3)}{4(q-1)^4(q^2-4q+1)^2}\\
&= \frac{3[3\cos(4\tau)-3\cos(3\tau)-32\cos(2\tau)+87\cos(\tau)-67]}{128[\sin(\tau/2)]^4[2-\cos(\tau)]^2}. \qquad \text{(A.22)}
\end{aligned}
$$

DOUBLE HOPF BIFURCATIONS IN THE DIFFERENTIALLY HEATED ROTATING ANNULUS*

GREGORY M. LEWIS† AND WAYNE NAGATA‡

Abstract. We study a mathematical model of the differentially heated rotating fluid annulus experiment. In particular, we analyze the double Hopf bifurcations that occur along the transition between axisymmetric steady solutions and nonaxisymmetric rotating waves. The model uses the Navier–Stokes equations in the Boussinesq approximation. At the bifurcation points, center manifold reduction and normal form theory are used to deduce the local behavior of the full system of partial differential equations from a low-dimensional system of ordinary differential equations.

It is not possible to compute the relevant eigenvalues and eigenfunctions analytically. Therefore, the linear part of the equations is discretized, and the eigenvalues and eigenfunctions are approximated from the resulting matrix eigenvalue problem. However, the projection onto the center manifold and reduction to normal form can be done analytically. Thus, a combination of analytical and numerical methods is used to obtain numerical approximations of the normal form coefficients, from which the dynamics are deduced.

The results indicate that, close to the transition, there are regions in parameter space where there are multiple stable waves. Hysteresis of these waves is predicted. The validity of the results is shown by their consistency with experimental observations.

Key words. differentially heated rotating fluid experiment, axisymmetric to nonaxisymmetric transition, hysteresis of rotating waves, center manifold reduction, numerical approximation of normal form coefficients

1. Introduction.

Laboratory experiments that isolate the effects of differential heating and rotation have long been regarded as useful tools for studying the behavior of large scale geophysical fluids, such as the atmosphere. The dynamic similarity of the various experiments to actual geophysical flows indicates that the form of the differential heating, the geometry of the system, the properties of the fluid, and the boundary conditions play a secondary role [13]. This is evidence that the character of large scale geophysical fluid flows is determined, to a large extent, by the differential heating and rotation. Consequently, the investigation of a mathematical model of a laboratory experiment itself can provide insight into the dynamical properties of large scale geophysical fluids. Furthermore, models of the experiments can be tractable, and the model and the method of analysis can be quantitatively validated via comparison with experimental observations. In contrast, a quantitative validation is not possible when studying direct, simplified models of large scale flows.

We study a model of a particular laboratory experiment in which the changes in the flow patterns in a differentially heated rotating annulus are observed as the imposed temperature gradient and rate of rotation are varied. We use an accurate

mathematical model that is able to quantitatively reproduce some of the experimental observations [18], [19]. In the laboratory experiments, for small differential heating and rotation, a steady axisymmetric pattern is observed, i.e., the pattern is invariant under rotation. As the parameter values are increased, this relatively simple pattern becomes unstable and a wave motion appears. It is this transition from axisymmetric to nonaxisymmetric flow that is of interest here.

We study the transition by directly analyzing the partial differential equations (PDEs) that describe the fluid flow in the rotating annulus. In particular, we study the double Hopf bifurcations that are found at isolated points along the transition. These double Hopf bifurcation points occur when the linearization about the steady axisymmetric solution has two pairs of complex conjugate eigenvalues that simultaneously cross the imaginary axis as the parameters are varied. Center manifold reduction is used to find the dynamics of the PDEs close to the bifurcation point. This is a method of simplifying the equations in a way that takes into account all of the nonlinear interactions. The results are valid for parameter values close to the bifurcation point and when the bifurcating solutions are, in some sense, small. This method is sometimes referred to as weakly nonlinear analysis, because the nonlinear terms in the equations are assumed to be small but not negligible. Essentially, the technique is able to show the existence and stability of the bifurcating solutions and to give a first-order estimate of the solution itself, but it is not able to determine whether the solution persists for values of the parameters far from the bifurcation point.

This type of bifurcation analysis has been successful in other applications to fluid flow. One of the best known is the onset of motion in a layer of fluid heated from below, Rayleigh–Bénard convection (see, e.g., [24]). Another application of note is the Couette–Taylor problem (see [1] and the references contained therein), which is a fluid annulus experiment (without differential heating) where the inner and outer cylinders rotate at different rates, generating a shear flow in the fluid. A rich variety of behavior has been found by experiment, some of which can be explained with bifurcation theory. In addition, bifurcation analysis has made several predictions of flow patterns that were subsequently confirmed by experimental results. In the geophysical fluid dynamics literature, an asymptotic method, formally equivalent to center manifold reduction, was used to analyze "weakly nonlinear" wave-wave interactions (double Hopf bifurcations) in the two layer quasi-geostrophic potential vorticity equations in [20], [21], and [25] (see also [2] and [10]). The results indicated bistability and hysteresis of the wave solutions. For all of these models, it is possible to find the results analytically.

In the field of geophysical fluid dynamics, few models exist that can be studied purely analytically. Since the model we study does not fall into this category, we use an analytical-numerical hybrid analysis technique. Using center manifold reduction, it is possible to analytically reduce the time-dependent nonlinear PDEs to a series of steady linear PDE problems. These linear systems are then solved numerically, which results in numerical approximations for the coefficients of the normal form equations, from which the local dynamics can be deduced. Not only are the linear problems less difficult to numerically approximate, but also the validity of the approximations is more easily verified. Thus, although numerical approximations must be made, this method of analysis gives evidence that the predicted dynamics corresponds to those of the PDEs. Essentially equivalent methods are used in the Couette–Taylor problem [1] and in [7], where a double Hopf bifurcation was analyzed in a barotropic quasi-

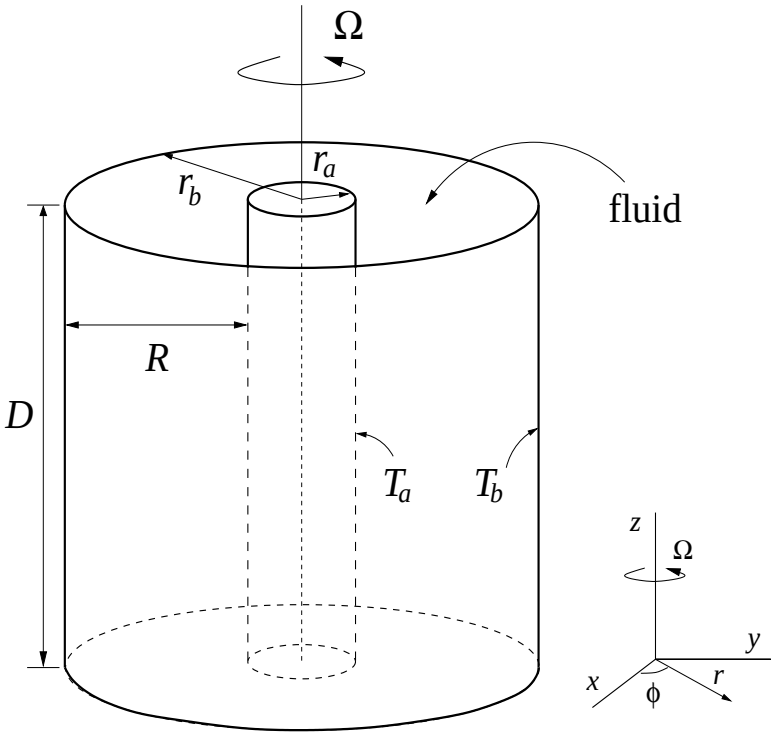

FIG. 1. *The differentially heated rotating annulus experiment, where the annulus is rotated at rate Ω and the inner wall is held at the fixed temperature T_a and the outer wall at temperature T_b, creating a differential heating $\Delta T = T_b - T_a$. Here r_a and r_b are the radii of the inner and outer cylinders, $R = r_b - r_a$, and D is the height of the annulus.*

geostrophic model. It should be noted that although similar methods were used in these problems, the numerics are substantially less intensive than those presented here. In fact, until recently, the numerics of this work would not have been possible on a personal computer.

In the next section, we describe the experiments in more detail. We discuss some general experimental results, and in so doing, introduce some of the flow features that our model reproduces. In section 3, the dynamical equations are written explicitly. The methods of analysis are discussed in the following two sections, where the analytical methods are presented in section 4 and the numerical methods are presented in section 5. In section 6, the results are described and discussed. A conclusion follows.

2. Experimental observations. Many different experiments have been performed in an attempt to develop an understanding of differentially heated rotating fluid systems (see, e.g., [13], [15], and [5]). The experiments often take the form of studying fluid flow in a rotating cylindrical annulus, where differential heating is obtained by maintaining the inner and outer walls of the annulus at different temperatures; see Figure 1. The experiments consist of finding the various stable flow patterns that occur at different values of the rotation rate and differential heating. The results are typically given in a diagram where the transitions between the different flow types are plotted in parameter space in terms of the Taylor number $\mathcal{T}$ and

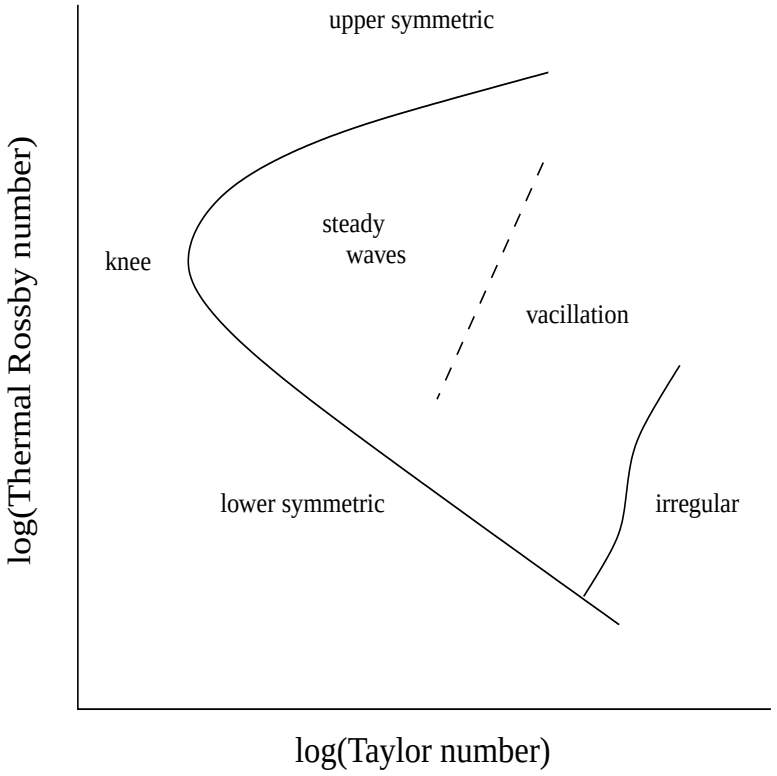

FIG. 2. *A schematic diagram depicting general experimental results; see, e.g.,* [13]. *To the left of all the curves is the axisymmetric regime, which is separated into three (dynamically similar) regions: lower symmetric, knee, and upper symmetric. To the right of the curve is the nonaxisymmetric regime, which is separated into three dynamically distinct regimes: steady waves, vacillation, and irregular flow.*

the thermal Rossby number $\mathcal{R}$ (see [4], [13]). The Taylor number

$$\mathcal{T} = \frac{4\Omega^2 R^4}{\nu^2}$$

is a dimensionless parameter measuring the relative importance of rotation to viscosity, where Ω is the rate of rotation, R is the gap width of the annulus, and ν is the kinematic viscosity of the fluid. The thermal Rossby number

$$\mathcal{R} = \frac{\alpha g D \Delta T}{\Omega^2 R^2}$$

is another dimensionless parameter measuring the relative importance of rotation to the differential heating, where ΔT is the difference in temperature between the inner and outer walls of the annulus, α is the coefficient of thermal expansion of the fluid, D is the depth, and g is the gravitational acceleration. If all other parameters are held fixed, there is a one-to-one relationship between these two dimensionless parameters and the two physical parameters that are varied during experiments: the differential heating ΔT and rate of rotation Ω.

Most of the experiments find four main flow regimes in different regions of parameter space (see Figure 2). (1) *Axisymmetric flow*: this flow is characterized by its

azimuthal invariance. (2) *Steady waves*: the flow in this region is nonaxisymmetric and resembles a rotating wave with constant amplitude and phase. Different wavelengths are seen in different subregions, with the possibility of observing stable waves of different wavelengths within the same subregion. The transitions between the subregions exhibit hysteresis. (3) *Vacillation*: in this region, the amplitude or structure of the observed wave varies apparently periodically in time. (4) *Irregular flow*: this region is characterized by its irregular nature in both space and time.

All of the observed flows have their counterparts in the Earth's atmosphere [6], [13]. The axisymmetric flow resembles the Hadley cell, which is observed in the atmosphere near the equator where the "local" rotation rate and differential heating are relatively small. In midlatitude regions of the Earth, the flow sometimes has wave characteristics that resemble the steady waves and vacillations seen in the experiments. Here, in both the atmosphere and experiments, the flow trajectories are curved, and vertical motion is inhibited.

Of particular interest to us are the transition from the axisymmetric to wave regime and the hysteresis of the waves which is observed in the steady wave regime. The hysteresis occurs between waves whose wave numbers differ by the integer one. By quantifying the double Hopf bifurcations that occur along the transition, we give evidence of the mechanism by which the hysteresis occurs.

3. Model equations. The dynamical equations of the fluid are taken to be the Navier–Stokes equations in the Boussinesq approximation. In particular, we consider the variations of all fluid properties to be negligible, and the equation of state of the fluid is assumed to be

$$\rho = \rho_0[1 - \alpha\,(T - T_0)], \tag{1}$$

where ρ is the density of the fluid, T is the temperature, α is the (constant) coefficient of thermal expansion, ρ_0 is the density at the reference temperature T_0, and $\alpha\,(T - T_0)$ is assumed to be small. A significant simplification due to the Boussinesq approximation is that the fluid can be considered incompressible. For the temperature evolution, we take the heat equation, with an advection term that couples the fluid velocity to the temperature. The boundaries are the inner wall of the cylindrical annulus with radius r_a, the outer wall with radius r_b, as well as a rigid flat bottom and top. At the boundaries, the no-slip condition is imposed on the fluid, and the temperature is T_a and T_b at the inner and outer walls, respectively, while the bottom and top are thermally insulating. The equations are written in circular cylindrical coordinates in a frame of reference corotating with the annulus at rate Ω. The radial, azimuthal, and vertical (or axial) coordinates are denoted r, φ, and z, respectively, with unit vectors $\mathbf{e}_r$, $\mathbf{e}_\varphi$, and $\mathbf{e}_z$ (see Figure 1).

We make a change of variables

$$r = Rr', \qquad z = Dz', \tag{2}$$

where $R = r_b - r_a$ is the gap width and D is the height of the annulus; write the fluid temperature as

$$T = T'(r', \varphi, z', t) + \Delta T\left(r' - \frac{r_a}{R}\right) + T_a, \tag{3}$$

where $\Delta T = T_b - T_a$ is the imposed temperature difference; and write the fluid pressure as

$$p = p'(r', \varphi, z', t) + \rho_0 g D(1 - z') + \frac{\rho_0 \Omega^2 R^2 (r')^2}{2}. \tag{4}$$

Then we drop the primes to obtain equations describing the evolution of the fluid velocity $\mathbf{u} = u(r,\varphi,z,t)\mathbf{e}_r + v(r,\varphi,z,t)\mathbf{e}_\varphi + w(r,\varphi,z,t)\mathbf{e}_z$, pressure deviation $p = p(r,\varphi,z,t)$, and temperature deviation $T = T(r,\varphi,z,t)$:

$$\frac{\partial \mathbf{u}}{\partial t} = \nu_s \nabla_s^2 \mathbf{u} - \frac{1}{R\rho_0}\nabla_s p - 2\Omega \mathbf{e}_z \times \mathbf{u} + \left(g\mathbf{e}_z - \Omega^2 R r \mathbf{e}_r\right)\alpha\left[T + \Delta T\left(r - \frac{r_a}{R}\right) + T_a - T_0\right] - \frac{1}{R}\left(\mathbf{u}\cdot\nabla_s\right)\mathbf{u}, \tag{5}$$

$$\frac{\partial T}{\partial t} = \kappa_s \nabla_s^2 T + \kappa_s \frac{\Delta T}{r} - \frac{\Delta T}{R}u - \frac{1}{R}\left(\mathbf{u}\cdot\nabla_s\right)T, \tag{6}$$

$$\nabla_s \cdot \mathbf{u} = \frac{\partial u}{\partial r} + \frac{u}{r} + \frac{\partial v}{\partial \varphi} + \frac{1}{\delta}\frac{\partial w}{\partial z} = 0, \tag{7}$$

where $\delta = D/R$, $\nu_s = \nu/R^2$, ν is the kinematic viscosity, $\kappa_s = \kappa/R^2$, κ is the coefficient of thermal diffusivity, g is the gravitational acceleration,

$$\nabla_s^2 = \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial \varphi^2} + \frac{1}{\delta^2}\frac{\partial^2}{\partial z^2},$$

$$\nabla_s = \mathbf{e}_r\frac{\partial}{\partial r} + \mathbf{e}_\varphi\frac{1}{r}\frac{\partial}{\partial \varphi} + \mathbf{e}_z\frac{1}{\delta}\frac{\partial}{\partial z},$$

$$\begin{aligned}\left(\mathbf{u}_1\cdot\nabla_s\right)\mathbf{u}_2 = {} & \left(u_1\frac{\partial u_2}{\partial r} + \frac{v_1}{r}\frac{\partial u_2}{\partial \varphi} + \frac{1}{\delta}w_1\frac{\partial u_2}{\partial z} - \frac{v_1 v_2}{r}\right)\mathbf{e}_r \\ & + \left(u_1\frac{\partial v_2}{\partial r} + \frac{v_1}{r}\frac{\partial v_2}{\partial \varphi} + \frac{1}{\delta}w_1\frac{\partial v_2}{\partial z} + \frac{u_1 v_2}{r}\right)\mathbf{e}_\varphi \\ & + \left(u_1\frac{\partial w_2}{\partial r} + \frac{v_1}{r}\frac{\partial w_2}{\partial \varphi} + \frac{1}{\delta}w_1\frac{\partial w_2}{\partial z}\right)\mathbf{e}_z\end{aligned}$$

for velocity fields $\mathbf{u}_j = u_j(r,\varphi,z,t)\mathbf{e}_r + v_j(r,\varphi,z,t)\mathbf{e}_\varphi + w_j(r,\varphi,z,t)\mathbf{e}_z$, $j = 1, 2$, and

$$\left(\mathbf{u}\cdot\nabla_s\right)T = u\frac{\partial T}{\partial r} + \frac{v}{r}\frac{\partial T}{\partial \varphi} + \frac{1}{\delta}w\frac{\partial T}{\partial z}.$$

The domain is $r_a/R < r < r_b/R$, $0 \le \varphi < 2\pi$, $0 < z < 1$, and the boundary conditions are

$$\begin{aligned}\mathbf{u} &= 0 \quad \text{on} \quad r = \frac{r_a}{R},\ \frac{r_b}{R} \ \text{ and } \ z = 0, 1, \\ T &= 0 \quad \text{on} \quad r = \frac{r_a}{R},\ \frac{r_b}{R}, \\ \frac{\partial T}{\partial z} &= 0 \quad \text{on} \quad z = 0, 1,\end{aligned} \tag{8}$$

with 2π-periodicity in φ for $\mathbf{u}$, T, and p.

The solutions will not depend explicitly on the value of the reference temperature T_0. However, there is implicit dependence because the values of ν, κ, and ρ_0 are chosen to be those of the fluid at T_0. It is assumed that the difference between the temperature of the fluid and T_0 is everywhere small enough so that ν and κ can be considered as constants.

4. Analytical methods. We choose as the parameters of interest the rotation rate Ω and the temperature difference ΔT between the inner and outer annulus walls. These are the physical quantities (external variables) that are easily varied in an experiment. The other parameters describe the geometry of the annulus or properties of the fluid. Another choice is to use the dimensionless parameters, the Taylor number $\mathcal{T}$ and the thermal Rossby number $\mathcal{R}$ (see section 2), which have a one-to-one correspondence with Ω and ΔT. Our results are quoted in terms of these dimensionless parameters because experimental results are usually presented on a log-log plot of $\mathcal{T}$ versus $\mathcal{R}$. However, the analysis was carried out using the parameters Ω and ΔT, because nondimensionalization did not significantly simplify the equations (see [18]). The choice of parameters will not change the procedure or the results.

A summary of the main steps of the analysis is as follows:

1. Plot the neutral stability curves, by
   (a) calculating the steady axisymmetric solution at a particular location in parameter space,
   (b) solving the eigenvalue problem for this solution to find its linear stability,
   (c) repeating steps (a) and (b) at various locations in parameter space to find the parameter values at which the solution is neutrally stable.
2. Localize the point in parameter space where the double Hopf bifurcation occurs (find the intersections of the neutral stability curves; see below).
3. Calculate the eigenvalues and eigenfunctions at the bifurcation point.
4. Compute the appropriate normal form coefficients, which involves
   (a) calculating the adjoint eigenfunctions,
   (b) calculating the center manifold coefficients.

An analytical form for the steady axisymmetric solution is not known, and, therefore, numerical approximations must be made. This is also the case for the eigenvalues and eigenfunctions. In the analysis, this is dealt with by leaving the unknown functions unresolved when deriving the formulae for the normal form coefficients. That is, we write the normal form coefficients in terms of the unresolved functions. Then, for the numerical approximation of the normal form coefficients, the values of the unknown functions are needed only at specific locations (the grid points), and numerical approximations are used. We postpone discussion of the numerical methods until the next section, and for the remainder of this section we discuss the analytical methods. In particular, we discuss the equations necessary for the computation of the axisymmetric solution and the eigenfunctions, and we discuss briefly how center manifold reduction is used to derive the formulae for the normal form coefficients of interest. For a more detailed explanation of the center manifold reduction and normal form equations in the context of this model, see [18], and for a general context, see, e.g., [11].

4.1. The steady axisymmetric solution. The analysis begins with the computation of a steady axisymmetric solution. That is, we look for a solution of (5)–(7), with the boundary conditions (8), in the form

$$\mathbf{u} = \mathbf{u}^{(0)}(r,z) = u^{(0)}(r,z)\mathbf{e}_r + v^{(0)}(r,z)\mathbf{e}_\varphi + w^{(0)}(r,z)\mathbf{e}_z,$$

$$p = p^{(0)}(r,z), \qquad T = T^{(0)}(r,z),$$

independent of φ and t. The solution also depends on the parameters, but we do not indicate this dependence explicitly. We assume that such a solution exists, is unique and regular, and depends smoothly on the parameters, at least for the parameter

values of interest. We have not attempted to prove this, but we believe that, using standard techniques, it would be a feasible if lengthy digression to do so (see, for example [3]).

A stream function $\xi^{(0)}$ is introduced, so that the incompressibility condition (7) is automatically satisfied. The pressure terms can then be eliminated, and we obtain three equations in the three unknown functions $\xi^{(0)}$, $v^{(0)}$, and $T^{(0)}$. The resulting equations, computed using the Maple symbolic computation package, are sufficiently complicated that no insight is gained by explicitly writing them here. For more details, see [18]. In section 5, we describe how $\xi^{(0)}$, $v^{(0)}$, and $T^{(0)}$ are computed numerically.

4.2. The perturbation equations. Next, perturbation equations are required. It is on this system that the center manifold reduction is performed. We write

$$\mathbf{u} = \mathbf{u}^{(0)} + \hat{\mathbf{u}}, \quad p = p^{(0)} + \hat{p}, \quad T = T^{(0)} + \hat{T}, \tag{9}$$

where $(\mathbf{u}^{(0)}, p^{(0)}, T^{(0)})$ is the steady axisymmetric solution, substitute (9) into (5)–(7), and drop the hats, to obtain the perturbation equations

$$\begin{aligned}\frac{\partial \mathbf{u}}{\partial t} = {} & \nu_s \nabla_s^2 \mathbf{u} - \frac{1}{R\rho_0} \nabla_s p - 2\Omega \mathbf{e}_z \times \mathbf{u} + \left(g\mathbf{e}_z - \Omega^2 R r \mathbf{e}_r\right) \alpha T \\ & - \frac{1}{R}\left(\mathbf{u}^{(0)} \cdot \nabla_s\right)\mathbf{u} - \frac{1}{R}\left(\mathbf{u} \cdot \nabla_s\right)\mathbf{u}^{(0)} - \frac{1}{R}\left(\mathbf{u} \cdot \nabla_s\right)\mathbf{u},\end{aligned} \tag{10}$$

$$\frac{\partial T}{\partial t} = \kappa_s \nabla_s^2 T - \frac{\Delta T}{R} u - \frac{1}{R}\left(\mathbf{u}^{(0)} \cdot \nabla_s\right) T - \frac{1}{R}\left(\mathbf{u} \cdot \nabla_s\right) T^{(0)} - \frac{1}{R}\left(\mathbf{u} \cdot \nabla_s\right) T, \tag{11}$$

$$\nabla_s \cdot \mathbf{u} = 0, \tag{12}$$

with the boundary conditions (8). The trivial solution $\mathbf{u} = \mathbf{0}$, $p = 0$, $T = 0$ now satisfies these equations and corresponds to the steady axisymmetric solution of (5)–(7).

The perturbation equations (10)–(12) can be put into a suitable abstract form for which some important theoretical properties have been established. Following Henry [12, pp. 79–81], we can define a space $\mathcal{X}$ of vector functions $U = [\mathbf{u}, T]$ so that the incompressibility condition (12) and boundary conditions (8) are satisfied as part of the definition of the space. Then there is an abstract projection operator onto the space $\mathcal{X}$ that eliminates the pressure terms, and the system (10)–(12) together with boundary conditions (8) can be written as an abstract evolution equation in the space $\mathcal{X}$,

$$\dot{U} = \mathbf{L}\, U + \mathbf{N}(U), \tag{13}$$

where $\mathbf{L}\, U$ is the linear part of the equation (observe that $\mathbf{L}$ depends on the parameters, through the steady axisymmetric solution), and $\mathbf{N}(U)$ is the nonlinear part (it has the form $\mathbf{N}(U) = \mathbf{M}(U, U)$, where $\mathbf{M}$ is bilinear). If we assume that the steady axisymmetric solution of (5)–(8) exists, is unique, is regular, and depends smoothly on the parameters, then at least locally near $U = 0$ the initial-value problem for (13) in $\mathcal{X}$ has a unique solution $U(t)$, $t \geq 0$, that depends smoothly on initial conditions and parameters [12, Chapter 3]. Moreover, the principle of linearized stability holds, and the stability of the trivial solution $U = 0$ of (13) can be determined from the spectrum of the linearization $\mathbf{L}$ [12, Chapter 5].

4.3. The eigenvalue problem. The linearized stability of the steady axisymmetric solution is determined by the spectrum of the linearization of (10)–(12) about the trivial solution. Since $\mathbf{L}$ is the sum of a self-adjoint operator and a bounded linear operator, it is sectorial. The spatial domain is bounded, so the spectrum consists entirely of isolated eigenvalues of finite multiplicity. The eigenvalue problem is formally obtained by assuming that the unknown functions may be written as $\mathbf{u} = \mathbf{u}(r, \varphi, z, t) = e^{\lambda t}\tilde{\mathbf{u}}_m(r, z)e^{im\varphi}$, with m an integer, and likewise for T and p, and then linearizing (10)–(12). A linear eigenvalue problem for the eigenvalues λ and the eigenfunctions $[\tilde{\mathbf{u}}_m(r, z), \tilde{T}_m(r, z)]e^{im\varphi}$ is obtained for each azimuthal wave number m. By the principle of linearized stability, if all eigenvalues λ have negative real parts, then the steady axisymmetric solution is asymptotically stable, while if any eigenvalue λ has a positive real part, then the steady axisymmetric solution is unstable. We are especially interested in locating critical parameter values, where a finite number of eigenvalues have zero real parts and the rest have negative real parts. The solution is then neutrally stable, and we expect a bifurcation of solutions of the nonlinear equations as parameters are varied near the critical values. The azimuthal wave numbers m of the eigenfunctions corresponding to the eigenvalues that have zero real part at the critical parameter values are defined as the critical wave numbers.

If $m \neq 0$, it is possible to eliminate the pressure and azimuthal velocity terms. The resulting three equations in the three remaining unknowns $\tilde{u}_m(r, z)$, $\tilde{w}_m(r, z)$, and $\tilde{T}_m(r, z)$ may be written in the form of a generalized linear eigenvalue problem

$$\lambda \mathbf{A}_m \tilde{U}_m = \mathbf{L}_m \tilde{U}_m, \tag{14}$$

where

$$\tilde{U}_m = \begin{pmatrix} \tilde{u}_m \\ \tilde{w}_m \\ \tilde{T}_m \end{pmatrix}$$

and $\mathbf{A}_m$ and $\mathbf{L}_m$ are 3×3 matrices of linear operators. If $m = 0$, a stream function method can be used in exactly the same manner as in the calculation of the axisymmetric solution. Again the equations were calculated using Maple and are too lengthy to write here.

Finally, the adjoint eigenvalue problem is necessary to calculate the adjoint eigenfunctions. The adjoint operators are calculated using the inner product, which for two vector functions $U_1 = [\mathbf{u}_1, T_1]$ and $U_2 = [\mathbf{u}_2, T_2]$ is taken to be

$$\langle U_1, U_2 \rangle = \int_0^1 \int_0^{2\pi} \int_{\frac{r_a}{R}}^{\frac{r_b}{R}} \left(\mathbf{u}_1 \cdot \overline{\mathbf{u}}_2 + T_1 \overline{T}_2 \right) r \; dr \; d\varphi \; dz, \tag{15}$$

where the overbar denotes complex conjugation. The adjoint eigenfunctions have the form $[\tilde{\mathbf{u}}^*_m(r, z), \tilde{T}^*_m(r, z)]e^{im\varphi}$.

4.4. Normal form coefficients. The numerical results, presented in section 6, predict that there are critical parameter values at which the linear eigenvalue problem has two complex conjugate pairs of eigenvalues with zero real parts, while the other eigenvalues have negative real parts. Therefore, suppose that the critical parameter values occur at $\Omega = \Omega_0$ and $\Delta T = \Delta T_0$, so that for Ω near Ω_0 and ΔT near ΔT_0 the eigenvalue problem has eigenvalues

$$\lambda_1 = \mu_1 + i\omega_1, \quad \overline{\lambda}_1, \quad \lambda_2 = \mu_2 + i\omega_2, \quad \overline{\lambda}_2, \tag{16}$$

and when $\Omega = \Omega_0$ and $\Delta T = \Delta T_0$, we have $\mu_1 = \mu_2 = 0$. Also, assume that all the other eigenvalues have negative real parts, with the real parts uniformly bounded below zero.

The eigenfunctions corresponding to the above eigenvalues are

$$\Phi_1, \quad \overline{\Phi}_1, \quad \Phi_2, \quad \overline{\Phi}_2,$$

where they have the form

$$\Phi_j = [\tilde{\mathbf{u}}_{m_j}(r,z), \tilde{T}_{m_j}(r,z)]e^{im_j\varphi},$$

with m_j ($j = 1, 2$, $m_1 \neq m_2$) being the azimuthal wave number corresponding to Φ_j. The center eigenspace E^c is the span of the eigenfunctions corresponding to the eigenvalues with zero real parts when $\Omega = \Omega_0$ and $\Delta T = \Delta T_0$,

$$E^c = \text{span}\{\Phi_1, \overline{\Phi}_1, \Phi_2, \overline{\Phi}_2\}.$$

The stable eigenspace E^s is the span of all the other eigenfunctions, which are the eigenfunctions that correspond to eigenvalues with negative real parts. The adjoint eigenfunctions corresponding to the Φ_j are denoted by Φ_j^*, where the Φ_j^* are found from the adjoint eigenvalue problem. The eigenfunctions and their adjoints are normalized so that their inner products satisfy

$$\langle \Phi_j, \Phi_j^* \rangle = 1 \tag{17}$$

for $j = 1, 2$. Due to a rescaling (see below), the results do not depend on the way in which the second normalization constant is determined.

The projection of U onto the center eigenspace E^c is given by

$$PU = \langle U, \Phi_1^* \rangle \Phi_1 + \langle U, \overline{\Phi}_1^* \rangle \overline{\Phi}_1 + \langle U, \Phi_2^* \rangle \Phi_2 + \langle U, \overline{\Phi}_2^* \rangle \overline{\Phi}_2. \tag{18}$$

Using this projection, we may then decompose U as follows:

$$U = z_1\Phi_1 + \overline{z}_1\overline{\Phi}_1 + z_2\Phi_2 + \overline{z}_2\overline{\Phi}_2 + \Psi, \tag{19}$$

where $PU = z_1\Phi_1 + \overline{z}_1\overline{\Phi}_1 + z_2\Phi_2 + \overline{z}_2\overline{\Phi}_2 \in E^c$, $(I - P)U = \Psi \in E^s$, and I is the identity operator. This implies that the complex amplitudes z_1 and z_2 are given by the inner products $z_1 = z_1(t) = \langle U, \Phi_1^* \rangle$ and $z_2 = z_2(t) = \langle U, \Phi_2^* \rangle$.

Taking the projection of (13), we get

$$\begin{aligned} \dot{z}_1 &= \lambda_1 z_1 + \langle \mathbf{N}(U), \Phi_1^* \rangle, \\ \dot{z}_2 &= \lambda_2 z_2 + \langle \mathbf{N}(U), \Phi_2^* \rangle, \end{aligned} \tag{20}$$

where U is given by (19). The complex conjugate equations contain redundant information, and so are omitted. For (20), we use center manifold theory to write U solely in terms of the center eigenspace variables z_1 and z_2, and in so doing we decouple the system.

Given that the assumptions stated above for (13) and the eigenvalues for the linearization are valid, then, for $(\Omega, \Delta T)$ in a neighborhood of $(\Omega_0, \Delta T_0)$, the center manifold theorem [12, p. 168] implies that there exists a differentiable center manifold for (13):

$$W_{loc}^c = \left\{ U = z_1\Phi_1 + \overline{z}_1\overline{\Phi}_1 + z_2\Phi_2 + \overline{z}_2\overline{\Phi}_2 + H(z_1\Phi_1, \overline{z}_1\overline{\Phi}_1, z_2\Phi_2, \overline{z}_2\overline{\Phi}_2) \right\}, \tag{21}$$

where $H : E^c \to E^s$ is defined for $\|z_1\Phi_1 + \overline{z}_1\overline{\Phi}_1 + z_2\Phi_2 + \overline{z}_2\overline{\Phi}_2\|$ small and $\|\cdot\|$ is the norm that corresponds to the inner product (15). The local center manifold W^c_{loc} is locally invariant, is tangent to the center eigenspace E^c at $U = 0$ when $\Omega = \Omega_0$ and $\Delta T = \Delta T_0$, and is locally exponentially attracting.

Therefore, on the center manifold, we can write

$$\Psi = H(z_1, \overline{z}_1, z_2, \overline{z}_2) = O(|z_1, \overline{z}_1, z_2, \overline{z}_2|^2) \tag{22}$$

and then expand the center manifold function H in a Taylor series as

$$\begin{aligned} H(z_1, \overline{z}_1, z_2, \overline{z}_2) = {} & H_{2000}z_1^2 + H_{1100}z_1\overline{z}_1 + H_{0020}z_2^2 + H_{0011}z_2\overline{z}_2 \\ & + H_{1010}z_1z_2 + H_{1001}z_1\overline{z}_2 + c.c. + O(3), \end{aligned} \tag{23}$$

where H_{ijkl} are the Taylor series coefficients of H, $O(n) = O(|z_1, \overline{z}_1, z_2, \overline{z}_2|^n)$, and *c.c.* denotes the complex conjugates of the previous terms that are written explicitly. We also write

$$\begin{aligned} N(z_1, \overline{z}_1, z_2, \overline{z}_2) = {} & N_{2000}z_1^2 + N_{1100}z_1\overline{z}_1 + N_{0020}z_2^2 + N_{0011}z_2\overline{z}_2 \\ & + N_{1010}z_1z_2 + N_{1001}z_1\overline{z}_2 + c.c. + O(3), \end{aligned} \tag{24}$$

where $N(z_1, \overline{z}_1, z_2, \overline{z}_2)$ is the nonlinear term of (13) written in terms of $z_1, \overline{z}_1, z_2$, and $\overline{z}_2$, using the decomposition of U given in (19), and with Ψ written using (22) and (23). With the nonlinear part written as (24), the system is decoupled, and (20) reduces to a four-dimensional ODE that describes the dynamics on the center manifold. Because the center manifold is locally exponentially attracting, the behavior of the original PDEs, close to the bifurcation point, can be deduced from the reduced system.

The normal form for the nonresonant case is

$$\begin{aligned} \dot{z}_1 &= \lambda_1 z_1 + G_{11}z_1^2\overline{z}_1 + G_{12}z_1z_2\overline{z}_2 + O(4), \\ \dot{z}_2 &= \lambda_2 z_2 + G_{21}z_1\overline{z}_1z_2 + G_{22}z_2^2\overline{z}_2 + O(4), \end{aligned} \tag{25}$$

where $\lambda_j{=}\lambda_j(\Omega, \Delta T)$, and the normal form coefficients G_{kl} are given by

$$\begin{aligned} G_{11} &= \langle N_{2100}, \Phi_1^* \rangle, \\ G_{12} &= \langle N_{1011}, \Phi_1^* \rangle, \\ G_{21} &= \langle N_{1110}, \Phi_2^* \rangle, \\ G_{22} &= \langle N_{0021}, \Phi_2^* \rangle. \end{aligned} \tag{26}$$

The normal form (25) is obtained from (20) by using a series of near-identity coordinate transformations (see, e.g., [26]). This normal form requires the nonresonance condition that the imaginary parts of the eigenvalues, ω_1 and ω_2, satisfy $n_1\omega_1 + n_2\omega_2 \neq 0$ for all integers n_1 and n_2 with $|n_1| + |n_2| \leq 4$ at the critical parameter values $\Omega = \Omega_0$ and $\Delta T = \Delta T_0$.

In general, the formulae (26) for the normal form coefficients also depend on the coefficients of the terms that are quadratic in z_1 and z_2 (e.g., N_{2000}). However, in our case these terms vanish in the projection (20) because, due to their φ-dependence, they are orthogonal to the adjoint eigenfunctions. In the same manner it can be shown that to find the normal form coefficient $G_{11} = \langle N_{2100}, \Phi_1^* \rangle$, only $\tilde{N}_{2100}^{(m_1)}$ is needed, where $\tilde{N}_{ijkl}^{(m_1)}$ is defined as the coefficient of $e^{im_1\varphi}$ in the expansion $N_{ijkl}(r, \varphi, z) = \sum_m \tilde{N}_{ijkl}^{(m)}(r, z)\, e^{im\varphi}$. That is, all terms with a factor $e^{im\varphi}$, $m \neq m_1$, vanish in the

inner product because they are orthogonal to Φ_1^*. Furthermore, due to the form of the nonlinear part, only the eigenfunctions Φ_1, $\overline{\Phi}_1$ and the particular coefficients of the center manifold function, $\tilde{H}_{1100}^{(0)}$ and $\tilde{H}_{2000}^{(2m_1)}$, appear in the formula for $\tilde{N}_{2100}^{(m_1)}$, where the $\tilde{H}_{ijkl}^{(m)}$ are defined in a manner similar to the $\tilde{N}_{ijkl}^{(m)}$, i.e., $H_{ijkl}(r,\varphi,z) = \sum_m \tilde{H}_{ijkl}^{(m)}(r,z)\, e^{im\varphi}$.

Thus, in addition to the eigenfunctions, the normal form coefficient

- G_{11} can be written as a function of only the coefficients $\tilde{H}_{1100}^{(0)}$ and $\tilde{H}_{2000}^{(2m_1)}$.

Similarly, in addition to the eigenfunctions, the normal form coefficients

- G_{12} can be written as a function of only the coefficients, $\tilde{H}_{0011}^{(0)}$, $\tilde{H}_{1001}^{(m_1-m_2)}$, and $\tilde{H}_{1010}^{(m_1+m_2)}$;
- G_{21} can be written as a function of only the coefficients $\tilde{H}_{1100}^{(0)}$, $\tilde{H}_{0110}^{(m_2-m_1)}$, and $\tilde{H}_{1010}^{(m_1+m_2)}$;
- G_{22} can be written as a function of only the coefficients $\tilde{H}_{0011}^{(0)}$ and $\tilde{H}_{0020}^{(2m_2)}$.

The equations satisfied by the $H_{ijkl}(r,\varphi,z)$ are derived using the local invariance of the center manifold (see [11]). From these equations, it follows that the relevant $\tilde{H}_{ijkl}^{(m)}(r,z)$ satisfy

$$
\begin{aligned}
\left[2\lambda_1\mathbf{I} - \tilde{\mathbf{L}}^{(2m_1)}\right]\tilde{H}_{2000}^{(2m_1)} &= \tilde{N}_{2000}^{(2m_1)},\\
\tilde{\mathbf{L}}^{(0)}\tilde{H}_{1100}^{(0)} &= -\tilde{N}_{1100}^{(0)},\\
\left[2\lambda_2\mathbf{I} - \tilde{\mathbf{L}}^{(2m_2)}\right]\tilde{H}_{0020}^{(2m_2)} &= \tilde{N}_{0020}^{(2m_2)},\\
\tilde{\mathbf{L}}^{(0)}\tilde{H}_{0011}^{(0)} &= -\tilde{N}_{0011}^{(0)},\\
\left[(\lambda_1+\lambda_2)\,\mathbf{I} - \tilde{\mathbf{L}}^{(m_1+m_2)}\right]\tilde{H}_{1010}^{(m_1+m_2)} &= \tilde{N}_{1010}^{(m_1+m_2)},\\
\left[\left(\lambda_1+\overline{\lambda}_2\right)\mathbf{I} - \tilde{\mathbf{L}}^{(m_1-m_2)}\right]\tilde{H}_{1001}^{(m_1-m_2)} &= \tilde{N}_{1001}^{(m_1-m_2)},
\end{aligned}
\tag{27}
$$

where the $\tilde{\mathbf{L}}^{(m)}$ are defined by $\mathbf{L}[\tilde{U}(r,z)e^{im\varphi}] = e^{im\varphi}[\tilde{\mathbf{L}}^{(m)}\tilde{U}(r,z)]$ and $\mathbf{I}$ is the identity operator. For $m \neq 0$, the same solution method that is used for the eigenvalue problem can be used here (i.e., elimination of the pressure term and one velocity component). For $m = 0$, the stream function method (as for the axisymmetric solution) can be used.

We write $z_1 = \rho_1 e^{i\theta_1}/\sqrt{|G_{11}^r|}$ and $z_2 = \rho_2 e^{i\theta_2}/\sqrt{|G_{22}^r|}$, where G_{ij}^r is the real part of the normal form coefficients G_{ij}, and substitute these expressions into (25). In these scaled polar coordinates, the truncated normal form equations are

$$
\begin{aligned}
\dot{\rho}_1 &= \rho_1\left(\mu_1 + a\rho_1^2 + b\rho_2^2\right),\\
\dot{\rho}_2 &= \rho_2\left(\mu_2 + c\rho_1^2 + d\rho_2^2\right),\\
\dot{\theta}_1 &= \omega_1,\\
\dot{\theta}_2 &= \omega_2,
\end{aligned}
\tag{28}
$$

where

$$
\begin{aligned}
a &= \frac{G_{11}^r}{|G_{11}^r|} = \pm 1,\\
b &= \frac{G_{12}^r}{|G_{22}^r|},\\
c &= \frac{G_{21}^r}{|G_{11}^r|},
\end{aligned}
\tag{29}
$$

$$d = \frac{G_{22}^r}{|G_{22}^r|} = \pm 1,$$

and $\lambda_j = \mu_j + i\omega_j$. The $O(|\rho_1, \rho_2|^4)$ terms are ignored in the $\dot{\rho}_j$ equations, and the $O(|\rho_1, \rho_2|^2)$ terms are ignored in the $\dot{\theta}_j$ equations. Ignoring these terms does not affect the local dynamics, except for fine details of the dynamics on invariant tori.

In summary, given m_1 and m_2, the coefficients of the scaled normal form equations a, b, c, d can be written in terms of the following functions, which are all functions only of the two spatial variables r and z:

- the eigenfunctions and adjoint eigenfunctions

$$\tilde{\Phi}_{m_1}, \quad \tilde{\Phi}^*_{m_1}, \quad \tilde{\Phi}_{m_2}, \quad \tilde{\Phi}^*_{m_2},$$

  where $\Phi_j(r, \varphi, z) = \tilde{\Phi}_{m_j}(r, z)e^{im_j\varphi}$, $j = 1, 2$;
- certain Taylor series coefficients of the center manifold function

$$\tilde{H}^{(0)}_{1100}, \quad \tilde{H}^{(2m_1)}_{2000}, \quad \tilde{H}^{(m_1-m_2)}_{1001}, \quad \tilde{H}^{(m_1+m_2)}_{1010}, \quad \tilde{H}^{(0)}_{0011}, \quad \text{and} \quad \tilde{H}^{(2m_2)}_{0020},$$

where $H_{ijkl}(r, \varphi, z) = \sum_m \tilde{H}^{(m)}_{ijkl}(r, z)e^{im\varphi}$. The eigenfunctions are found from the eigenvalue problem (14), and the coefficients of the center manifold function are found from (27).

5. Numerical methods. In order to find values of the normal form coefficients, the axisymmetric solution, the eigenfunctions, and the Taylor series coefficients of the center manifold function must be known. Because analytic solutions of these are not known, they are approximated numerically. Upon discretization, the axisymmetric solution is approximated from a system of nonlinear algebraic equations, while the partial differential eigenvalue problems become matrix eigenvalue problems and the partial differential boundary value problems for finding the coefficients of the center manifold function become systems of linear equations. In all cases, the discretization leads to large sparse systems, and thus we seek appropriate solution techniques.

In this section, we discuss some of the details of the numerical approximations, including the discretization and solution techniques. Also included is a brief discussion of convergence for the approximation.

5.1. The mesh: Nonuniform spacing. We employ centered finite differencing to discretize the spatial derivatives. The values of the unknown functions in the interior of the domain are approximated at $N \times N$ grid points, labeled by $(r, z) = (r_k, z_l)$, with $1 \le k \le N$ and $1 \le l \le N$, where N, k, l are positive integers. We define $r_0 = r_a/R$, $r_{N+1} = r_b/R$, $z_0 = 0$, and $z_{N+1} = 1$. This leads to a discretized solution vector of size $3N^2 + 2N$ (because $T(r_k, z_0)$ and $T(r_k, z_{N+1})$ are also unknown for $1 \le k \le N$).

With the no-slip boundary conditions and the small parameter ν multiplying a second derivative term, boundary layers form in the fluid flow. For this reason, a scaling method is used to choose the locations of the grid points. This consists of making a change of coordinates and calculating the solutions on a uniform grid in the new coordinates. The transformation is chosen such that its inverse takes a uniform grid to a grid with many points near the boundary. The transformation that takes the new coordinates (x, y) to the original coordinates (r, z) is given by

$$r = \frac{\tan^{-1}(\eta x)}{2\tan^{-1}\left(\frac{\eta}{2}\right)} + \frac{1}{2} + \frac{r_a}{R}, \qquad z = \frac{\tan^{-1}(\eta y)}{2\tan^{-1}\left(\frac{\eta}{2}\right)} + \frac{1}{2}, \tag{30}$$

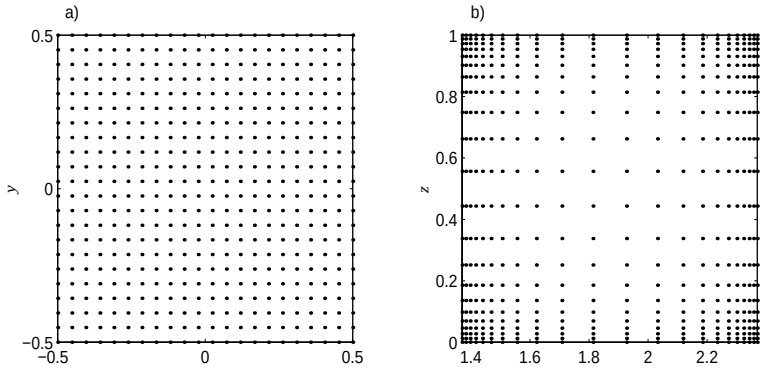

FIG. 3. *The transformation of the grid points.* (a) *A uniform grid (equally spaced grid points) of* $N = 20$, (b) *the grid obtained by applying the change of coordinates* (30) *with* $\eta = 6$.

where η is a scaling factor that determines the magnitude of compression near the boundary; see Figure 3. The domain $r_a \leq r \leq r_b/R$, $0 \leq z \leq 1$ is mapped to $-1/2 \leq x \leq 1/2$, $-1/2 \leq y \leq 1/2$, and the solutions are approximated on a uniform grid in the (x, y) coordinates.

The boundary layers observed in the eigenfunctions are not as severe as those in the axisymmetric solutions. In fact, significant errors are introduced in the eigenvalues and eigenfunctions if the points in the interior are too sparse. This occurs even if the axisymmetric solutions appear to be well resolved. This suggests that different scaling factors should be used for the axisymmetric and eigenvalue problems. However, errors introduced in interpolation seem to negate the potential benefit of using different scaling factors. In the calculations presented, the scaling factor $\eta = 6$ is used. This is the smallest value that leads to qualitatively good results for the axisymmetric problem when $N = 20$; for smaller values of η, the boundary layer is not resolved well enough. Also, for larger values of η (for $N = 20$), there is an insufficient number of interior points to adequately describe the eigenfunctions. However, for larger values of N, the results are consistent and not as sensitive to the choice of η.

5.2. Solution techniques. For the computation of the axisymmetric solution we use Newton's method. This method can be combined with a predictor-corrector continuation technique to find the axisymmetric solution for a wide range of parameter values. If $\Omega = 0$ and $\Delta T = 0$, then the trivial solution satisfies the axisymmetric equations. Thus for Ω and ΔT small, the trivial solution is a reasonable prediction of the solution, and Newton's method is used for the correction. For small increments in the parameter values, the previous solution is a reasonable prediction. To make larger increments in the parameter values, a secant line approximation can be used for the prediction.

Each point on a neutral stability curve is found using an iterative secant method, where the real part of the eigenvalue with largest real part is considered as a function of the parameters. The iterative procedure for the localization of the double Hopf points uses the fact that the points occur at intersections of two neutral stability curves. In both procedures, iteration continues until the magnitudes of the real parts of the relevant eigenvalues are less than a specified tolerance (10^{-8} for the results presented below).

The discretized transformed equations and the entries of the coefficient matrices

are computed symbolically using Maple. The generalized matrix eigenvalue problem, which results from the discretization of (14), is solved in Matlab using the implicitly restarted Arnoldi method [17], which is a memory-efficient iterative method for finding a specified number of eigenvalues with the largest magnitudes. A generalized Cayley transformation is made so that the Arnoldi iteration finds the eigenvalues with largest real parts [8]. The parameters of the transformation can also be chosen to improve convergence properties. In particular, the generalized Cayley transformation

$$\mathbf{C}(\mathbf{L},\mathbf{A}) = (\mathbf{L} - \alpha_1 \mathbf{A})^{-1} (\mathbf{L} - \alpha_2 \mathbf{A}) \tag{31}$$

maps eigenvalues λ of the generalized matrix eigenvalue problem $\lambda \mathbf{A} v = \mathbf{L} v$ to eigenvalues σ of the transformed matrix $\mathbf{C}(\mathbf{L},\mathbf{A})$, such that the eigenvalues λ with $\mathrm{Real}(\lambda) > (\alpha_1 + \alpha_2)/2$ are mapped to the eigenvalues σ with $|\sigma| > 1$, where α_1 and α_2 are the real parameters of the Cayley transformation. The matrix $\mathbf{C}(\mathbf{L},\mathbf{A})$ does not have to be formed explicitly, because the Arnoldi iteration only requires matrix-vector products involving $\mathbf{C}(\mathbf{L},\mathbf{A})$; see [17]. Thus, the sparseness properties of $\mathbf{L}$ and $\mathbf{A}$ can be exploited, and computer memory requirements can be reduced.

5.3. Convergence. For the centered differencing that was used, the local truncation error is $O(h^2)$ (i.e., approximately a constant times h^2, as $h \to 0$), where h is the mesh size. Given this and a few standard assumptions, the accuracy of the approximations for the boundary value problems will be $O(h^2)$. In addition, if the approximate solution and the differencing scheme for the derivative are both $O(h^2)$, then the approximations of derivatives of the solutions are also $O(h^2)$. However, for the present application, although the approximation of the partial differential eigenvalue problem by the matrix eigenvalue problem can be assumed to converge, the order of this convergence is unknown. Considering this, it is reasonable to assume that the approximations of the normal form coefficients converge, even though we could not say to what order.

An additional comment should be made concerning the eigenfunction approximation. It is obvious that a finite-dimensional approximation is not able to approximate all the solutions of the infinite-dimensional continuous eigenvalue problem. We expect that it is the highly oscillatory high wave number eigenfunctions that the matrix problem is unable to resolve. Because the critical eigenfunctions of interest have relatively low wave numbers and are not highly oscillatory, we expect that these functions are resolved and that the errors in the differencing are relatively small.

Our results, which are presented in the next section, indicate that the approximation of the normal form coefficients seems to be convergent. However, the mesh size h could not be taken small enough to obtain an accurate estimate of the order of convergence.

6. Results. The results of our study are presented in this section. The parameter values specifying the geometry of the annulus and fluid properties are listed in Table 1. These values correspond to the experiments performed by Fein [4]. Our results are compared with those obtained in that study.

6.1. The axisymmetric solution. An example of the axisymmetric solution is plotted in Figure 4. Qualitatively, the form of the solution is the same for all values of the parameters. The figure shows that the fluid velocity in the interior of the fluid is predominantly in the azimuthal direction. The radial velocity is almost zero everywhere except near the upper and lower boundaries, where it is negative and positive, respectively. The vertical velocity is largest at the inner and outer walls,

that, at the upper and lower boundaries, the inward and outward motion is deflected to the right. Although quantitative information of the experimental axisymmetric flow was not available, the computed flow profile qualitatively reproduces all the features of the experimental flow.

6.2. Neutral stability and transition curves. The neutral stability curves are presented in Figure 5. There is a separate curve for each azimuthal wave number. The curves consist of points in the parameter space where, for the given wave number, there is one pair of complex conjugate eigenvalues with zero real part while all other eigenvalues associated to that wave number have negative real part. Wave numbers from $m = 2$ to 10 were calculated, and it was found that $m = 3$ to 8 were the only critical wave numbers. Therefore, only these values are shown in Figure 5. It is not possible to calculate the neutral stability curves of all wave numbers, but it can be argued that the higher wave numbers will not be critical in the parameter range of interest. We refer the interested reader to [18] and here justify investigation of only a

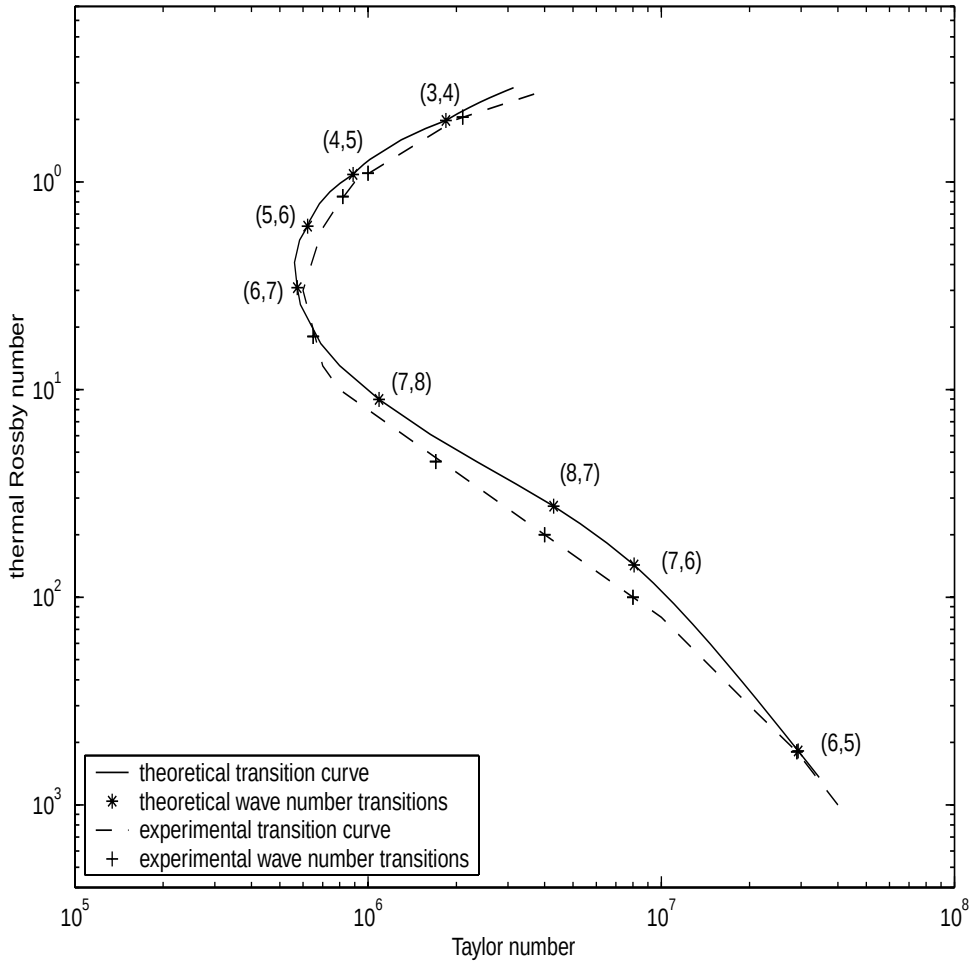

FIG. 6. *Transition curves for theory and experiment delineating the axisymmetric from the nonaxisymmetric regimes. The critical wave number transitions (double Hopf bifurcation points), labeled as* (m_1, m_2)*, are also plotted along the curve.*

finite number of wave numbers by comparison with the experimental results. A 25×25 grid was used for the calculations of all curves shown.

In Figure 6, the curve that separates the axisymmetric regime from the nonaxisymmetric regime is plotted. To the left of this curve, the axisymmetric solution is linearly stable (to perturbations of all wave numbers), while to the right, it is unstable. Along this curve it can be seen that there are transitions of the critical wave number. These transitions occur at intersections of the neutral stability curves and correspond to the double Hopf bifurcation points; i.e., at these points there are two complex conjugate pairs of eigenvalues with zero real parts. Also plotted in Figure 6 is the experimentally observed transition curve taken from Fein [4], with critical wave number transitions. This is the curve along which a transition from the axisymmetric to steady wave flow was observed. All curves are plotted on a log-log graph of the Taylor number $\mathcal{T}$ versus the thermal Rossby number $\mathcal{R}$ (see section 2).

Linear analysis reproduces many of the experimental observations. By inspection

TABLE 2

Numerical results for double Hopf bifurcation points; $a = -1$ and $d = -1$ for all N. Here, m_1 and m_2 are the critical wave numbers, N is the number of grid points on one side, $(\Omega_0, \Delta T_0)$ is the location in parameter space where the bifurcation occurs, ω_1 and ω_2 are the imaginary parts of the eigenvalues at $(\Omega_0, \Delta T_0)$, and a,b,c, and d are the normal form coefficients.

of Figure 6, it can be seen that there is a good correspondence between the numerical and experimental transition curves. It has also been shown, via comparison with experimentally measured wave speeds at the transition, that the imaginary parts of the eigenvalues are also in agreement. See [19] for further discussion.

6.3. Double Hopf normal form coefficients: Hysteresis. The numerical results are presented in Table 2. Included are the locations of the double Hopf bifurcation points and the values of the normal form coefficients, as well as the values of

the imaginary parts of the critical eigenvalues at the bifurcation point. The double Hopf points are labeled in terms of the associated critical wave numbers m_1 and m_2. For all double Hopf points, the critical wave numbers m_1 and m_2 differ by the integer one, and the normal form coefficients satisfy $a = -1$, $b < 0$, $c < 0$, and $d = -1$, as well as the condition $A = ad - bc < 0$.

The dynamics are found from an investigation of the fixed points of the equations obtained by ignoring the θ_j in the normal form equations (28). To lowest order, the $\dot{\theta}_j$ equations add a constant rotation for each corresponding dimension. See [9] for a complete analysis of the normal form equations (28). Here, there are fixed points when

(i) $\rho_1 = \rho_2 = 0$,
(ii) $\rho_2 = 0$ and $\rho_1 = \rho_p = \sqrt{\mu_1/-a}$,
(iii) $\rho_1 = 0$ and $\rho_2 = \rho_q = \sqrt{\mu_2/-d}$,
(iv) $\rho_1 = \rho_1^{(T)} = \sqrt{(-d\mu_1 + b\mu_2)/A}$ and $\rho_2 = \rho_2^{(T)} = \sqrt{(c\mu_1 - a\mu_2)/A}$,

where $A = ad - bc$, and with the condition that the quantities inside the square root signs must be positive.

Fixed point (i) is a fixed point of the normal form equations for all values of the parameters. By inspection of the normal form equations (28), it is fairly easy to see that, regardless of the values of the coefficients, for small ρ_1 and ρ_2, $\dot{\rho}_1$ and $\dot{\rho}_2$ will have the same sign as μ_1 and μ_2, respectively. This means that solution (i) will be stable if both μ_1 and μ_2 are negative, and unstable if either one is greater than zero. In the fluid annulus, this solution corresponds to the steady axisymmetric flow. Fixed points (ii) and (iii) correspond to periodic solutions of the normal form equations and exist when $\mu_1 > 0$ and $\mu_2 > 0$, respectively (because we have $a = -1$ and $d = -1$). In the fluid, these solutions correspond to nonaxisymmetric steadily rotating waves. The fixed point (iv) corresponds to a 2-torus for the normal form equations and exists when $(-d\mu_1 + b\mu_2)/A > 0$ *and* $(c\mu_1 - a\mu_2)/A > 0$. Because we have $A < 0$, $a = -1$, $b < 0$, $c < 0$, and $d = -1$, the 2-torus exists in the wedge in (μ_1, μ_2) parameter space given by $d\mu_1/b < \mu_2 < c\mu_1/a$, $\mu_1 > 0$, $\mu_2 > 0$. These solutions correspond to modulated wavy flow in the fluid.

A linear stability analysis of fixed points (ii), (iii), and (iv) gives the local behavior near the bifurcation points; see Figure 7 for the bifurcation diagram. The results indicate that both of the bifurcating waves, corresponding to the fixed points (ii) and (iii), are stable in the wedge where the 2-torus exists. Thus, the boundaries of the wedge $\mu_2 = d\mu_1/b$ and $\mu_2 = c\mu_1/a$ give the boundaries of the region of bistability of the wave solutions. Furthermore, because only one of the bifurcating waves loses stability on each of the boundaries of the wedge, there is hysteresis. The results also indicate that the 2-torus is always unstable. In Figure 9, the approximate boundaries of the region of bistability are drawn. The bifurcation diagram in Figure 8 shows the hysteresis that occurs when a one-parameter path through the parameter space crosses the region of bistability. The parameter s could be either Ω or ΔT or a function of both, depending on the particular circumstances. An example of such a path is indicated on Figure 7.

Quantitative verification of the predicted hysteresis is not currently possible due to the lack of experimental data for the specific annulus studied here. Furthermore, although the extent of hysteresis has been mapped for other transitions in other regions of parameter space (see, e.g., [5], [14], [16], and [4]), there is relatively little data concerning the hysteresis that occurs in the transitions between steady waves near the axisymmetric regime. Also, many experimental results in the steady wave

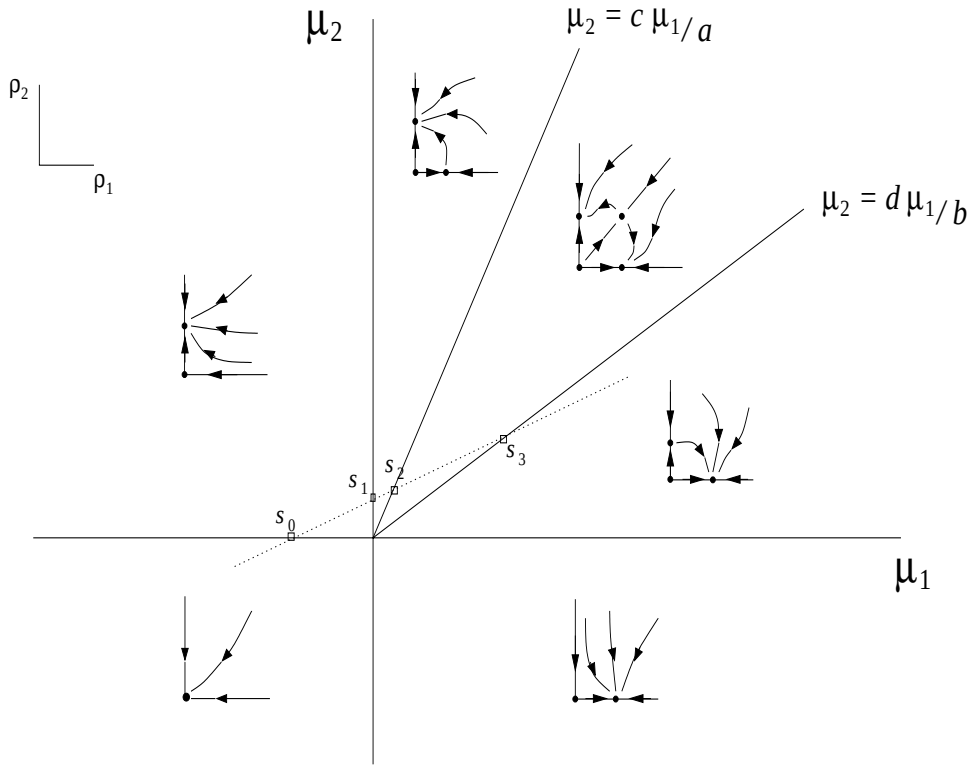

FIG. 7. *The two-dimensional bifurcation diagram. The diagram is displayed using the real parts of the critical eigenvalues μ_1, μ_2 as the bifurcation parameters. The regions of different character are separated by solid lines. In each region, the corresponding phase portrait is drawn, where the phase portraits are presented in ρ_1, ρ_2 coordinates. The θ_1 and θ_2 equations in* (28) *add a constant rotation to each coordinate. The dotted line indicates a possible one-parameter path which will lead to hysteresis. The bifurcation points along this path are indicated by s_0, s_1, s_2, and s_3 (see Figure* 8*).*

regime are quoted in terms of the wave number that is most likely to occur. Our analysis cannot predict this.

It can be seen in Table 2 that the numerical differences between the normal form coefficients at the different levels of discretization decrease with increasing discretization level. This is an indication of the convergence of the numerical approximations. However, it appears that N is not large enough for us to make an estimation of the order of convergence. Yet, the differences in the normal form coefficients at different N are quite small, which is evidence that these results are at least qualitatively accurate. To say this with more certainty, the analysis must be performed using higher levels of discretization. This was not possible with the available resources. Because the results accurately reproduce the experimental results, we conclude that the approximations are satisfactory.

The results for the $(m_1, m_2) = (3, 4)$ and $(m_1, m_2) = (4, 5)$ double Hopf points are not complete (see Table 2). For these wave number pairs with $N = 20$, the eigenfunctions are not well resolved, and the eigenvalues are inaccurate. Also, the evidence of convergence of the normal form coefficients (see Table 2) is weaker for the double Hopf points at higher differential heating. It seems that the increase in numerical difficulty is not caused by the difficulty of resolving the boundary layer in

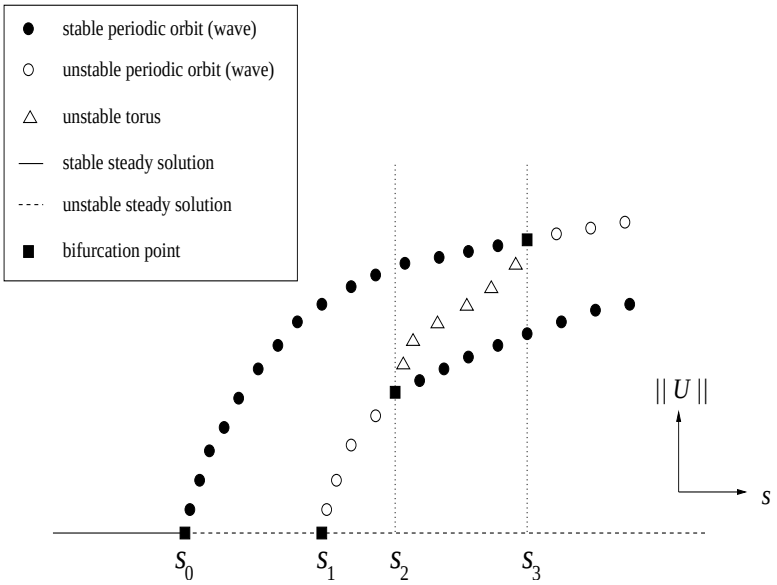

FIG. 8. *The one-dimensional bifurcation diagram depicting the bifurcation observed along the path indicated with the dotted line in Figure* 7. *The bifurcation points are labeled as* s_0, s_1, s_2, *and* s_3. $\|U\|$ *is a measure of the size of the solution, and* s *is the bifurcation parameter.*

the axisymmetric solution, but rather by the difficulty of resolving the eigenfunctions in the interior of the domain.

6.4. The eigenfunctions: Bifurcating wave form. An example of an eigenfunction is plotted in Figure 10. This is the eigenfunction with wave number $m = 6$ that is observed at the $(m_1, m_2) = (6, 7)$ double Hopf point (see Table 2). From (28), the periodic orbit corresponding to the wave with wave number m_1, to lowest order in μ_1, is given by

$$\begin{aligned} \rho_1 &= \sqrt{\frac{-\mu_1}{a}} + O(\mu_1), \\ \theta_1 &= \omega_1 t + O(\mu_1) \end{aligned} \tag{32}$$

or, in terms of z_1,

$$z_1 = \sqrt{\frac{-\mu_1}{G_{11}^r}} e^{i\omega_1 t} + O(\mu_1), \tag{33}$$

which describes a near-circular periodic orbit. The periodic orbit corresponding to the wave with wave number m_2 is given by a similar expression. In terms of the variables of the perturbation equations (10)–(12), to lowest order, the periodic solution corresponding to (32) is given by $U = [\mathbf{u}, T] = z_1\Phi_1 + \overline{z}_1\overline{\Phi}_1 = \mathrm{Re}\,(z_1\Phi_1)$. That is,

$$\begin{aligned} U &= \mathrm{Re}\left[\sqrt{\frac{-\mu_1}{G_{11}^r}} e^{i\omega_1 t}\tilde{\Phi}_{m_1} e^{im_1\varphi}\right] + O(\mu_1) \\ &= \sqrt{\frac{-\mu_1}{G_{11}^r}}\left[\tilde{\Phi}_{m_1}^r \cos(m_1\varphi + \omega_1 t) - \tilde{\Phi}_{m_1}^i \sin(m_1\varphi + \omega_1 t)\right] + O(\mu_1), \end{aligned} \tag{34}$$

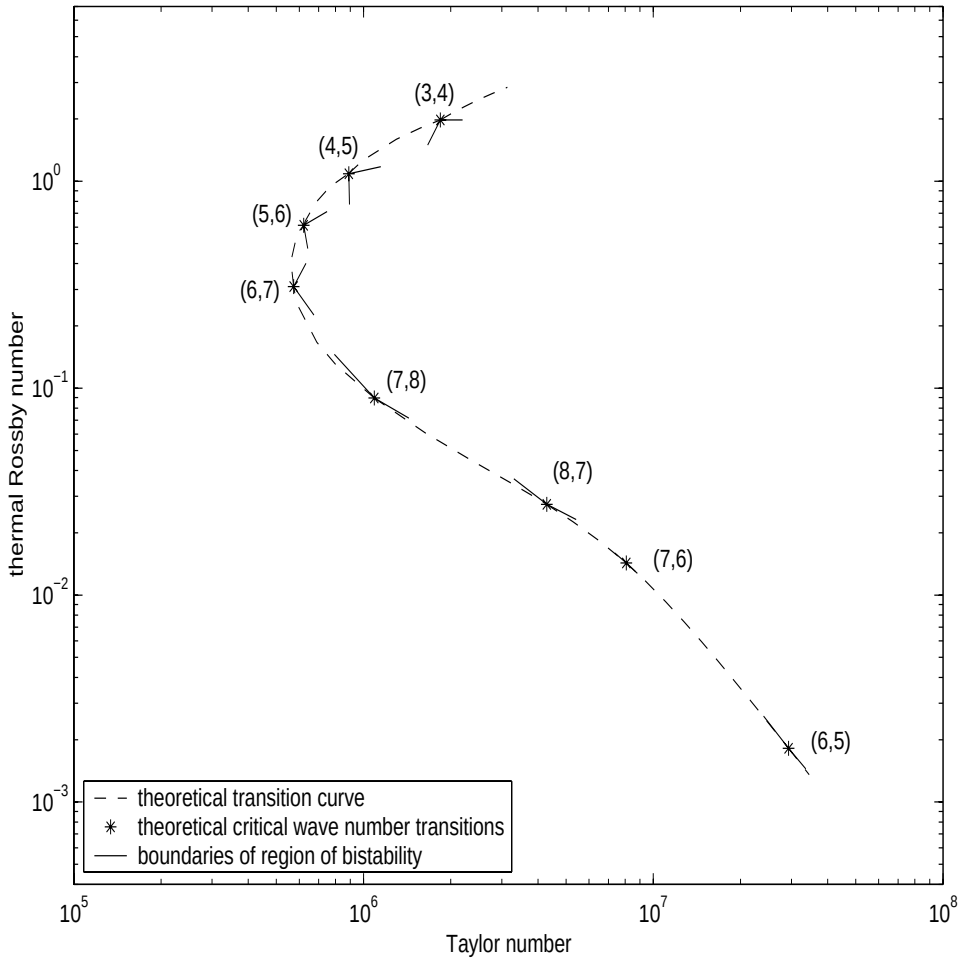

FIG. 9. *Theoretical transition curve between the axisymmetric and the nonaxisymmetric regimes including the boundaries of the region of bistability. The boundaries are the solid lines attached to the double Hopf points. For each double Hopf point, the area between the boundaries is the region where there is bistability of wave solutions.*

i.e., a rotating wave, where $\Phi_1 = \tilde{\Phi}_{m_1} e^{im_1\varphi}$ and where $\tilde{\Phi}^r_{m_1}$ and $\tilde{\Phi}^i_{m_1}$ denote the real and imaginary parts of $\tilde{\Phi}_{m_1}$, respectively. In terms of the variables of the original equations (5)–(7), the solution U corresponds to deviations from the axisymmetric solution $[\mathbf{u}^{(0)}, T^{(0)}]$ of the same equations. Also, if t is fixed, then at different φ, the periodic solution is a different linear combination of $\tilde{\Phi}^r_{m_1}$ and $\tilde{\Phi}^i_{m_1}$, and thus, the form of the eigenfunction gives the form of the bifurcating wave to the lowest order of approximation. That is, the approximation is valid for parameter values that are close to the axisymmetric-to-wave transition curve.

The form of the bifurcating wave is consistent with previous results. Measurements, from experiments with the same annulus geometry as is used for our results, indicate that the temperature has a maximum at midradius middepth [4]. Furthermore, the coarse features of the wave form are consistent with the detailed experimental and numerical results of [15], as well as the numerical results of [27], even

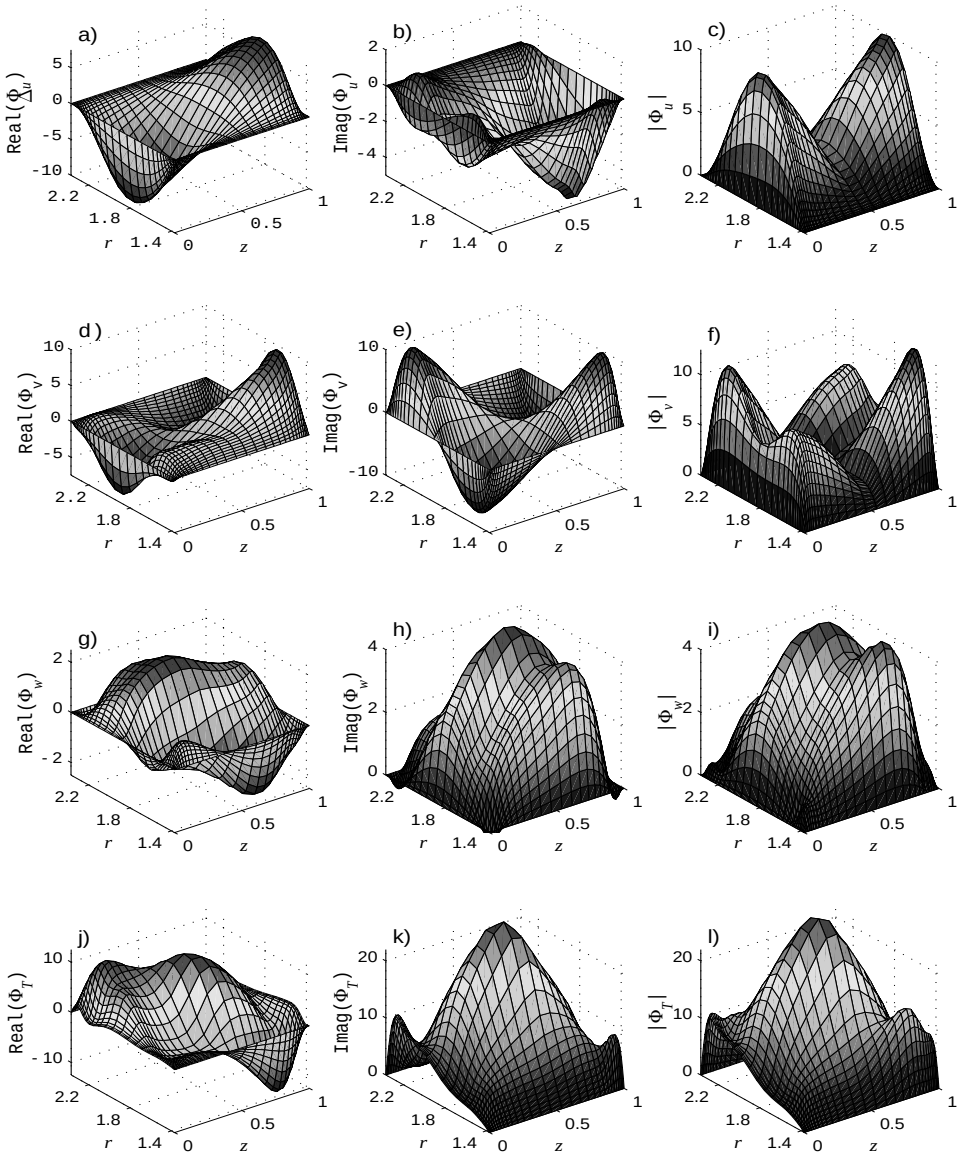

FIG. 10. *An example of the radial and vertical dependence of an eigenfunction with* $m = 6$ *and* $N = 30$ *at* $\Omega = 0.5838$ *and* $\Delta T = 0.6944$: (a) *real part,* (b) *imaginary part, and* (c) *amplitude of the radial component of the eigenfunction;* (d) *real part,* (e) *imaginary part, and* (f) *amplitude of the azimuthal component of the eigenfunction;* (g) *real part,* (h) *imaginary part, and* (i) *amplitude of the vertical component of the eigenfunction;* (j) *real part,* (k) *imaginary part, and* (l) *amplitude of the temperature component of the eigenfunction. though different annulus geometries, waves with different dominant wave numbers, and waves far from the axisymmetric-to-wave transition curve are studied. This includes (see Figures 5 and 6 of [15]) the radial dependence of the Fourier amplitude of the dominant wave number of the radial velocity at various heights, and the radial dependence of the Fourier amplitude of the dominant wave number of the azimuthal velocity at middepth. In our case, the square of the Fourier amplitude is given by

$(\tilde{\Phi}^r_{m_j})^2 + (\tilde{\Phi}^i_{m_j})^2$. See also Figure 8 in [27] for the vertical dependence of the deviations from the azimuthally averaged flow of both temperature and velocity for the (numerical) wave forms in an annulus without a rigid lid. However, compared to our bifurcating waves (34), the waves of these experimental and numerical studies show a relative decrease in the amplitude at midradius of the azimuthal average of the azimuthal velocity (i.e., the wave number zero Fourier component of the azimuthal velocity). In our case, the azimuthal average to first order is given by the axisymmetric solution $[\mathbf{u}^{(0)}, p^{(0)}, T^{(0)}]$ (see Figure 4). The waves studied in [15] and [27] are observed in regions of parameter space far from the axisymmetric-to-wave transitions, where the higher-order terms in (34), which we have ignored, may be important. Although these higher-order terms do not produce a significant qualitative change in the deviations from the azimuthally averaged flow, they do seem to produce a small, but noticeable, qualitative difference on the the azimuthal averaged flow itself. In order to study this effect, the bifurcating waves (34) would have to be calculated for parameter values far from the transition curve.

7. Conclusion. In this paper, we study the transitions from axisymmetric steady solutions to nonaxisymmetric waves in a Navier–Stokes model of the differentially heated rotating annulus experiment. An analytical-numerical center manifold reduction is used to analyze the double Hopf bifurcation points that occur at this transition. The results, which are obtained by numerically approximating the coefficients of the normal form equations, show that there are stable waves that bifurcate from the axisymmetric solution via a Hopf bifurcation, and that hysteresis (and bistability) of the bifurcating waves occurs near critical wave number transitions. Associated with the hysteresis is the existence of an unstable torus. Approximate boundaries to the region of bistability are drawn. The results are consistent with laboratory experiments, which supports not only the validity of the model, but also the validity of the analysis. Although the convergence of the numerical approximations cannot be proven, the evidence of convergence and the correspondence with experimental results supports the claim that the behavior that is predicted by our results occurs in the full PDE model.

The behavior seen in the model of the experiment is qualitatively the same as that seen in the models of the analytical studies discussed in the first section. This is very interesting because the models of these analytical studies are simplified models of atmospheric circulation, and so they are of a very different scale from that of the experiment. That is, the method of analysis is able to highlight the dynamical similarity of two geophysical fluid models of vastly different scales. The similarity is evidence for the usefulness of studying the models of both scales and for the statement that both types of models incorporate the fundamental properties of differentially heated rotating systems.

The study presented here is a beginning, and there are many possible directions future work could take. The models of atmospheric circulation of the analytical studies mentioned above are quite simplified. The success of the numerical computations of the present study gives confidence that analysis of this type could be applied to more realistic atmospheric models, such as that presented in [3]. Also, in the analysis of the annulus experiment, there is the possibility of resonant behavior close to an experimentally observed "triple-point," which is a point in parameter space that is shared by three regimes (the axisymmetric, the wave, and the irregular regimes; see Figure 2). The $(m_1, m_2) = (6, 5)$ double Hopf point, which occurs in a similar region in parameter space as does the experimentally observed triple-point, is close to being

resonant; i.e., the imaginary parts of the two complex conjugate pairs of eigenvalues with largest real part are nearly equal. Thus, a strongly resonant double Hopf bifurcation might be found by varying a third parameter, and in this case the dynamics found close to the resonant bifurcation may explain the existence of the triple-point.

Another interesting direction would be to attempt to follow the bifurcating solutions as the parameters move away from the bifurcation point. Two interesting flows that are observed in the annulus (both experimentally and numerically) are amplitude vacillation and wave dispersion [14], [22]. It has been hypothesized that the mechanism responsible for both of these flows is an interaction of two waves via a stable torus, where amplitude vacillation results from an interaction of two waves of the same dominant azimuthal wave number, while wave dispersion results from an interaction of waves with different dominant azimuthal wave numbers [23], [21]; see also [5] for experimental evidence.

The unstable torus, which we have shown to exist in the steady wave regime, is such an interaction of two waves with different wave numbers. Thus, it is possible that if the unstable torus could be followed further into the steady wave regime, a bifurcation to a stable torus (and wave dispersion) might be discovered. Alternatively, if the stable periodic orbits corresponding to the wave solutions could be followed further into the wave regime, a bifurcation to a stable torus might occur, which might result in the discovery of either amplitude vacillation or wave dispersion. At the moment, such a study seems computationally prohibitive. However, if the curvature of the annulus is neglected, a symmetry of the resulting system leads to a bifurcation to a steady solution as opposed to a periodic orbit. In this case, the computation may be possible.

The comparison of theoretical and experimental results that took place in the investigation of the Taylor–Couette flow led to many more discoveries about the system than otherwise would have occurred. The work presented here begins such a comparison for the differentially heated rotating annulus flow. Some of our results are confirmed by comparison with experiments, and some predictions, concerning the boundaries of the region of bistability, have yet to be verified. For future work, we expect that the use of such techniques will lead to further discovery of new dynamics, both theoretical and experimental, which in turn will lead to a better general understanding of differentially heated rotating fluid systems.

DEPINNING TRANSITIONS IN DISCRETE REACTION-DIFFUSION EQUATIONS*

A. CARPIO† AND L. L. BONILLA‡

Abstract. We consider spatially discrete bistable reaction-diffusion equations that admit wave front solutions. Depending on the parameters involved, such wave fronts appear to be pinned or to glide at a certain speed. We study the transition of traveling waves to steady solutions near threshold and give conditions for front pinning (propagation failure). The critical parameter values are characterized at the depinning transition, and an approximation for the front speed just beyond threshold is given.

Key words. discrete reaction-diffusion equations, traveling wave fronts, propagation failure, wave front depinning

AMS subject classifications. 34E15, 92C30

1. Introduction.

Spatially discrete systems describe physical reality in many different fields: atoms adsorbed on a periodic substrate [13], motion of dislocations in crystals [32], propagation of cracks in a brittle material [35], microscopic theories of friction between solid bodies [18], propagation of nerve impulses along myelinated fibers [23, 24], pulse propagation through cardiac cells [24], calcium release waves in living cells [6], sliding of charge density waves [19], superconductor Josephson array junctions [39], or weakly coupled semiconductor superlattices [3, 9]. No one really knows why, but spatially discrete systems of equations often have smooth solutions of the form $u_n(t) = u(n - ct)$, which are monotone functions approaching two different constants as $(n - ct) \to \pm\infty$. Existence of such *wave front* solutions has been proved for particular discrete systems having dissipative dynamics [40]. In the case of discrete systems with conservative dynamics, a wave front solution was explicitly constructed by Flach, Zolotaryuk, and Kladko [16]. However, a general proof of wave front existence for discrete conservative systems with bistable sources is lacking.

A distinctive feature of spatially discrete reaction-diffusion systems (not shared by continuous ones) is the phenomenon of wave front pinning: for values of a control parameter in a certain interval, wave fronts joining two different constant states fail to propagate [24]. When the control parameter surpasses a threshold, the wave front depins and starts moving [23, 19, 32, 9]. The existence of such thresholds is thought to be an intrinsically discrete fact, which is lost in continuum approximations. The characterization of propagation failure and front depinning in discrete systems is thus an important problem, which is not yet well understood despite the numerous inroads made in the literature [23, 6, 19, 32, 25, 26, 28, 30, 27, 36, 37, 38].

In this paper, we study front depinning for infinite one-dimensional nonlinear spatially discrete reaction-diffusion (RD) systems. When confronted with a spatially discrete RD system, a possible strategy is to approximate it by a continuous RD system. For generic nonlinearities, the width of the pinning interval is exponentially small as the continuum limit is approached. Pinning in the continuum limit has been analyzed by many authors using exponential asymptotics, also known as asymptotics beyond all orders. As far as we can tell, usage of these techniques for discrete equations goes back to two classic papers by Indenbom [22] (for the FK potential) and by Cahn [7] (for the double-well potential). In both cases, an exponential formula for the critical field was derived by means of the Poisson sum rule. In the context of dislocation motion, exponential formulas for the depinning shear stress of the Peierls–Nabarro (PN) model were found earlier by Peierls [33] and Nabarro [31]. Descriptions of wave front pinning near the continuum limit can also be found in more recent work [20, 25, 27].

Analyzing the continuum limit of a discrete system by means of exponential asymptotics is a costly strategy for describing pinning for two reasons. It is not numerically accurate as we move away from the continuum limit, and it ceases to be useful if convective terms [11] or disorder [12] alter the structure of the discrete system (quite common in applications). Thus other authors have tried to describe the opposite strongly discrete limit. For discrete RD equations, Erneux and Nicolis [14] studied a finite discrete RD equation with a cubic nonlinearity, a Dirichlet boundary condition at one end, and a Neumann boundary condition at the other end. They considered a particular limit in which two of the three zeroes of the cubic nonlinearity coalesced as diffusivity went to zero. Erneux and Nicolis's calculation is essentially a particular case of our active point approximation that involves only one active point and makes an additional assumption on the nonlinearity (not needed in our calculations). They found that the wave front velocity scales as the square root of $(d-d_c)$ (d is the diffusivity and d_c its critical value at which wave fronts are pinned). Essentially the same results can be found in the appendix of [27]. Kladko, Mitkov, and Bishop [28] introduced an approximation called the single active site theory. In this approximation, the wave front is described by two linear tails (solution of the RD equation linearized about each of the two constants joined by the front) *patched* at one point. This approximation is used to estimate the critical field for wave front depinning.

By a combination of numerical and asymptotic calculations, we arrive at the following description [10, 11]. The nature of the depinning transition depends on the nonlinearity of the model and is best understood as propagation failure of the traveling front. Usually, but not always, the wave front profiles become less smooth as a parameter F (external field) decreases. They become *discontinuous* at a critical value F_c. Below F_c, the front is pinned at discrete positions corresponding to a stable steady state. As a consequence of the maximum principle for spatially discretized parabolic equations, stationary and moving wave fronts cannot simultaneously exist for the same value of F (see [8]). This is *not* the case for chains with conservative dynamics, which are spatially discretized hyperbolic equations without a maximum principle. For chains with conservative Hamiltonian dynamics, an inverse method due to Flach, Zolotaryuk, and Kladko [16] explicitly shows that stationary and moving wave fronts may coexist for the same value of the parameters.

We consider chains of diffusively coupled overdamped oscillators in a potential V, subject to a constant external force F:

$$\frac{du_n}{dt} = u_{n+1} - 2u_n + u_{n-1} + F - A\,g(u_n). \tag{1.1}$$

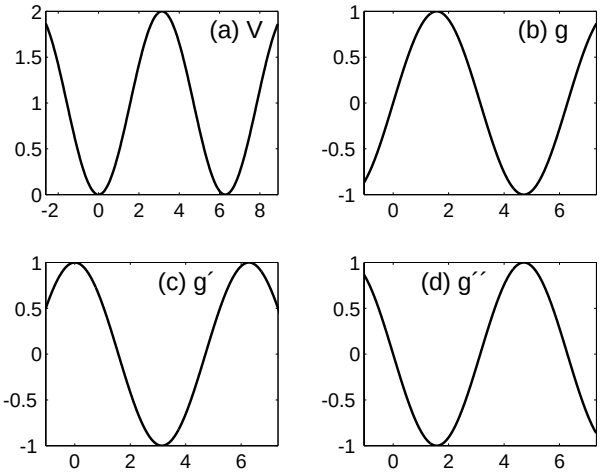

FIG. 1.1. *FK model:* (a) *potential* $1-cos(x)$, (b) *source term* $g(u) = \sin(u)$, (c) $g'(u) = \cos(u)$, (d) $g''(u) = -\sin(u)$.

Here $g(u) = V'(u)$ is at least C^1, and it presents a "cubic" nonlinearity (see Figure 1.1), such that $A\,g(u) - F$ has three zeroes, $U_1(F/A) < U_2(F/A) < U_3(F/A)$ in a certain force interval ($g'(U_i(F/A)) > 0$ for $i = 1, 3$, $g'(U_2(F/A)) < 0$). Provided that $g(u)$ is odd with respect to $U_2(0)$, there is a symmetric interval $|F| \le F_c$ where the discrete wave fronts joining the stable zeroes $U_1(F/A)$ and $U_3(F/A)$ are pinned [23, 8]. For $|F| > F_c$, there are smooth traveling wave fronts, $u_n(t) = u(n - ct)$, with $u(-\infty) = U_1$ and $u(\infty) = U_3$, as proved in [40, 8]. The velocity $c(A, F)$ depends on A and F, and it satisfies $cF < 0$ and $c \to 0$ as $|F| \to F_c$ (see [8]). Examples are the overdamped Frenkel–Kontorova (FK) model ($g = \sin u$; see Figure 1.1) [17] and the quartic double well potential ($V = (u^2 - 1)^2/4$). Less symmetric nonlinearities yield a nonsymmetric pinning interval, and our analysis applies to them with trivial modifications. Note that coexistence of fronts traveling in opposite directions can occur in the case of conservative systems, but not for (1.1) due to the maximum principle (which is the basis of comparison techniques) [8].

For the overdamped FK model given by (1.1) with $g = \sin u$, Figure 1.2 shows wave front profiles near the critical field. Individual points undergo abrupt jumps at particular times, which gives the misleading impression that the motion of the discrete fronts proceeds by successive jumps. Actually, the points remain very close to their stationary values at $F = F_c$, say $u_n(A, F_c)$, during a very long time interval of order $|F - F_c|^{-\frac{1}{2}}$. Then, at a specific time, *all* the points $u_n(t)$ jump to a vicinity of $u_{n+1}(A, F_c)$. The method of matched asymptotic expansions can be used to describe this two-stage motion of the points $u_n(t)$. Then the wave front profile can be reconstructed by using the definition $u_n(t) = u(n - ct)$. The slow stage of front motion is described by the normal form of a saddle-node bifurcation, and it yields an approximation to the wave front velocity, which scales with the field as $|F-F_c|^{\frac{1}{2}}$. This scaling has been mentioned by other authors: it was found numerically in [1], and by means of exponential asymptotics in the limit A small in [27]. It is also conjectured in [26] on the correct basis that the depinning transition consists of a saddle-node bifurcation (a similar claim was stated in [30] for continuous reaction diffusion equations with localized sources). However, the derivation of the *local* saddle-node normal form and

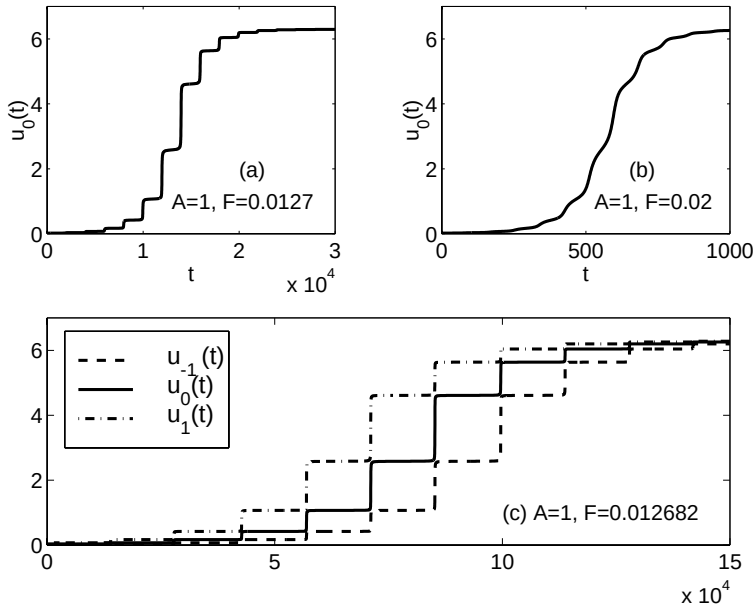

FIG. 1.2. *Wave front profiles for the overdamped FK model when* $A = 1$ *near* F_c.

the correct description of the *global* saddle-node bifurcation involving matching with a fast stage during which the front jumps abruptly one lattice period were apparently omitted by the authors of [26], who used energy arguments. Our picture of the wave front depinning transition has essentially been corroborated in the continuum limit (as an appropriate dimensionless lattice length goes to zero) by King and Chapman, who used asymptotics beyond all orders [27]. An independent confirmation follows from Fáth's calculations for a spatially discrete reaction-diffusion equation with a piecewise linear source term [15] (except that the velocity should scale differently with $|F - F_c|$ in this case).

For exceptional nonlinearities, the wave front does not lose continuity as the field decreases. In this case, there is a continuous transition between wave fronts moving to the left for $F > 0$ and moving to the right for $F < 0$; as for continuous systems, front pinning occurs at only a single field value $F = 0$ (see [27, 16, 36, 37, 38]). Wave front velocity then scales linearly with the field. We discuss the characterization of the critical field (including analytical formulas in the strongly discrete limit), describe depinning anomalies (discrete systems having zero critical field [36, 37, 38, 16]), and give a precise characterization of stationary and moving fronts near depinning (including front velocity) by singular perturbation methods. Our approximations show excellent agreement with numerical simulations.

The rest of the paper is organized as follows. In section 2, we characterize wave front depinning. We also explain that pinning of wave fronts normally occurs at force values belonging to an interval with nonzero length. However, there are nonlinearities for which pinning occurs only at $F = F_c = 0$. In section 3, we present a theory of wave front depinning for the strongly discrete case (A large). This theory enables us to predict the critical field and the speed and shape of the wave fronts near threshold. The main ideas of our theory are very simple. First, a wave front profile $u_n(t) =$

$u(n-ct)$ can be reconstructed if we follow the motion of one point during a sufficiently long time interval. Secondly, the analysis of (1.1) is complicated by the presence of the discrete diffusion term $u_{n+1}-2u_n+u_{n-1}$. Previous authors have tried to approximate this term by its continuum limit (corresponding to $A \to 0$), which leads to using exponential asymptotics [27]. (See also [25] on using exponential asymptotics for the Hamiltonian version of our model.) However, we are only interested in constructing solutions of (1.1) joining constant values. For sufficiently large A (say, $A = 0.1$ for the FK model), u_i is approximately either $U_1(F/A)$ or $U_3(F/A)$ except for a finite number of points (the *active* points). Then we can approximate the infinite system (1.1) by a closed system of ordinary differential equations (only one equation for $A \geq 10$ in the FK model). The depinning transition is a global bifurcation of this system, as explained in section 3. Some auxiliary technical results are collected in the appendix.

2. Front pinning as propagation failure. To describe monotone stationary solutions of (1.1) joining $U_1(F/A)$ and $U_3(F/A)$ for $|F| \leq F_c$, it is better to start by considering traveling wave fronts for $|F| > F_c$. It has been proved (and corroborated by numerical calculations) that traveling wave fronts and stationary profiles cannot coexist at the same value of F (see [9]). Furthermore, numerical computations of wave fronts near the critical fields F_c for the FK and other usual potentials show staircase-like wave front profiles, which sharpen as F approaches F_c. At $F = F_c$, a series of gaps open up, and one is left with a discontinuous stationary profile $s(x)$ solving

$$\begin{aligned} s(x+1) - 2s(x) + s(x-1) &= Ag(s(x)) - F_c, \quad x \in \mathbb{R}, \\ s(-\infty) = U_1\left(\frac{F_c}{A}\right), &\quad s(\infty) = U_3\left(\frac{F_c}{A}\right). \end{aligned} \tag{2.1}$$

The profile $s(x)$ is increasing and piecewise constant. The sequence of constant values attained by $s(x)$ defines a steady solution u_n of (1.1) with $F = F_c$. A stationary solution can thus be understood as a wave front that fails to propagate and is *pinned* at discrete values. Figure 1.2 illustrates the pinning transition for the FK model with $A = 1$. As F decreases from 0.02 to 0.0127, a series of steps are formed. Figure 1.2(c) depicts the paths described by three consecutive points. All profiles look identical and are obtained by shifting any one of them some multiple of a certain constant length. This implies that the length of all steps in the profile is the same and that all the points $u_n(t)$ in (1.1) proceed to climb the next step in the staircase at the same time. This behavior indicates that the wave front is a traveling wave, $u_n(t) = u(n - ct)$. Proofs of this fact for some sources can be found in [40].

2.1. Limiting front profile at the critical field. Let us start by showing that the limit of the traveling waves as $F \to F_c$ is singular if $F_c > 0$. This fact can be guessed from the differential-difference equations satisfied by the wave profiles. The traveling waves for $|F| > F_c$ have the form $u_n(t) = u(n - ct)$, where the profile $u(z)$ solves (see [8])

$$\begin{aligned} -cu_z &= u(z+1) - 2u(z) + u(z-1) - Ag(u(z)) + F, \quad z \in \mathbb{R}, \\ u(-\infty) = U_1\left(\frac{F}{A}\right), &\quad u(\infty) = U_3\left(\frac{F}{A}\right). \end{aligned} \tag{2.2}$$

The solution u is as smooth as allowed by $g(u)$. (u is C^{k+1} if $g(u)$ is C^k, with $k \geq 1$.) Then multiplying (2.2) by u_z and integrating it, we get

$$-c\int_{-\infty}^{\infty} u_z^2 dz = F\left[U_3\left(\frac{F}{A}\right) - U_1\left(\frac{F}{A}\right)\right]. \tag{2.3}$$

A first obvious conclusion is that the sign of c is opposite to the sign of F. Let F_c be positive. As $F \to F_c$, $c \to 0$ and $F\,[U_3(F/A) - U_1(F/A)] \to F_c\,[U_3(F_c/A) - U_1(F_c/A)] \neq 0$. Therefore the integrals $\int u_z^2 dz \to \infty$ as $F \to F_c$. Thus the limiting profile must be discontinuous if $F_c > 0$.

If $F_c = 0$, the relation (2.3) can be used to show that (2.1) has a smooth solution. In fact, provided that $c \sim -K\,F$ $(K > 0)$ as $F \to 0$, we can use (2.3) to uniformly bound the derivatives of the solutions u in (2.2) for $F \neq 0$. Then we obtain a smooth solution of (2.1) in the limit as $F \to 0$. We will come back to this question later on in subsection 2.3. Note that the stationary equation $s(x+1)-2s(x)+s(x-1) = Ag(s)-F$ has no continuous solutions joining $U_1(F/A)$ to $U_3(F/A)$ unless $F = 0$. To see this [8], we multiply the equation by s_x (in the sense of distributions if necessary) and integrate to get $F = 0$.

2.2. Characterization of the critical field. Some results are available in the continuum limit $A \to 0$. For $g = \sin u$, it is well known that F_c vanishes exponentially fast as A goes to zero. An exponential formula for F_c was first found by Indenbom [22] using the Poisson sum rule (following the calculations of the PN energy barrier for the PN model by Peierls [33] and Nabarro [31]) and numerically checked by Hobart [21] in the context of the Peierls stress and energy for dislocations. For the discrete bistable RD equation, Cahn [7] derived an exponential dependence of F_c by a similar technique. Related ideas can be found in Kladko, Mitkov, and Bishop [28]. These arguments can be used for other potentials and suggest that $F_c \sim C\,e^{-\eta/\sqrt{A}}$ as $A \to 0+$ (with positive C and η independent of A) holds for a large class of nonlinearities. Using exponential asymptotics, King and Chapman [27] have obtained precise formulas for the critical field and the wave front velocity of a discrete RD equation. Particularized to the FK potential, their formulas for the critical field and for the wave front velocity after depinning are $F_c \sim \Lambda\, e^{-\pi^2/[2\sinh^{-1}(\sqrt{A}/2)]}$, $\Lambda \approx 356.1$, and $c \sim D\,\sqrt{(F^2 - F_c^2)/A}$, respectively. This latter result agrees with the scaling law $c \sim |F - F_c|^{\frac{1}{2}}$, found in a large class of discrete RD equations [9, 10, 11, 26] and in continuous equations with localized sources [30]. However, exponential asymptotics [27] does not work for A large. We shall therefore follow a different approach. We shall begin by considering stationary increasing discrete front profiles and study under which conditions they start moving. Since stationary fronts are pinned wave fronts, we can call the transition from stationary to moving fronts the *depinning transition*.

Two facts distinguish the depinning transition: (i) the smallest eigenvalue of (1.1) linearized about a stable stationary profile becomes zero (see below), and (ii) stationary and moving wave fronts cannot coexist for the same values of the field. First, the following comparison principle [23] for (1.1) can be used to show that stationary and traveling wave fronts cannot coexist for the same value of F (see [8]).

Comparison principle. Assume that we have two configurations $w_n(t)$ and $l_n(t)$. If initially $w_n(0) \geq l_n(0)$ for all n, and at any later time $t > 0$

$$\frac{dw_n}{dt} \geq w_{n+1} - 2w_n + w_{n-1} - Ag(w_n) + F, \tag{2.4}$$

$$\frac{dl_n}{dt} \leq l_{n+1} - 2l_n + l_{n-1} - Ag(l_n) + F \tag{2.5}$$

for all $n \in \mathbb{Z}$, then necessarily $w_n(t) \geq l_n(t)$ for all n and t. Here w_n satisfying (2.4) is said to be a supersolution, and l_n satisfying (2.5) is said to be a subsolution.

Front pinning can be proved using stationary sub- and supersolutions, which can be constructed, provided that the stationary solution is linearly stable. The

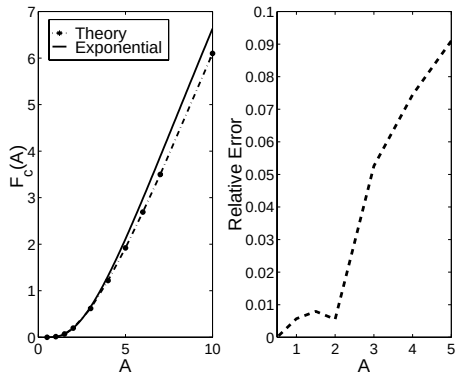

FIG. 2.1. (a) *Critical field, $F_c(A)$, for $A \in (\frac{1}{2}, 10)$. We have compared the result of approximately solving $\lambda_1(A, F) = 0$ for F as a function of A (see the appendix) to the asymptotic result $F_c \sim 356.1\, e^{-\pi^2/[2\sinh^{-1}(\sqrt{A}/2)]}$ of* [27]. (b) *Relative error of the exponential asymptotics approximation.*

smallest eigenvalue of the linearization of (1.1) about a stationary profile $u_n(A, F)$, $u_n(t) = u_n(A, F) + v_n e^{-\lambda t}$, is given by

$$\lambda_1(A, F) = \min \frac{\sum[(v_{n+1} - v_n)^2 + Ag'(u_n(A, F))v_n^2]}{\sum v_n^2}, \tag{2.6}$$

over a set of functions v_n, which decay exponentially as $n \to \pm\infty$. We show in the appendix that the minimum is attained at a positive eigenfunction.

The critical field can be uniquely characterized by $\lambda_1(A, F_c) = 0$ and $\lambda_1(A, F) > 0$ for $|F| < F_c$. The details are given in the appendix. Notice that $\lambda_1(A, F) > 0$ implies that (2.1) does not have smooth solutions $s(x)$; otherwise, $v_n = s'(n)$ is an eigenfunction corresponding to $\lambda_1 = 0$ as it happens in the continuum limit. The previous characterization is the basis of a procedure for calculating $F_c(A)$. In section 3, we shall show that wave fronts near the depinning transition are described by a reduced system of equations for a finite number of points $u_n(t)$ which "jump" from about a discrete value corresponding to the stationary solution, $u_n(A, F_c)$, to the next one, $u_{n+1}(A, F_c)$, during front motion. The smallest eigenvalue for the linearization of the reduced system of equations about a stationary solution approximates λ_1 well. The critical field obtained by this procedure has been depicted in Figure 2.1 for the FK potential and compared to King and Chapman's asymptotic result (obtained by keeping two terms in their formulas). Notice that the asymptotic result loses accuracy as A increases.

Equation (2.6) shows that the critical field is positive for large A and typical nonlinearities. In fact, consider the FK potential. For $F = 0$ there are two one-parameter families of stationary solutions which are symmetric with respect to U_2 (see Figure 2.2), one taking on the value U_2 (unstable dislocation), and the other one having $u_n \neq U_2$ (stable dislocation) [21, 8]. The centers of two stable (or two unstable) dislocations differ in an integer number of lattice periods. Except for a possible rigid shift, the stable dislocation, $u_n(A, 0)$, is a dynamically stable stationary solution towards which step-like initial conditions evolve. Figures 2.3(a) and (b) show two initial conditions that evolve (exponentially fast) towards the stable dislocation. Half the initial points $u_n(0)$ have been selected to be below U_2, and the other half are above this value. In Figure 2.3(a), $u_n(0) - u_n(A, 0) = \epsilon_n$, where ϵ_n are real random

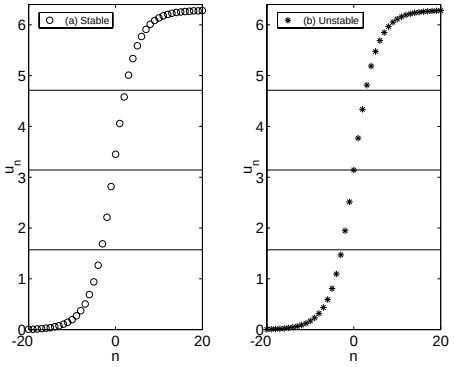

FIG. 2.2. *Stable and unstable dislocations for the FK model when* $F = 0$ *and* $A = 0.1$.

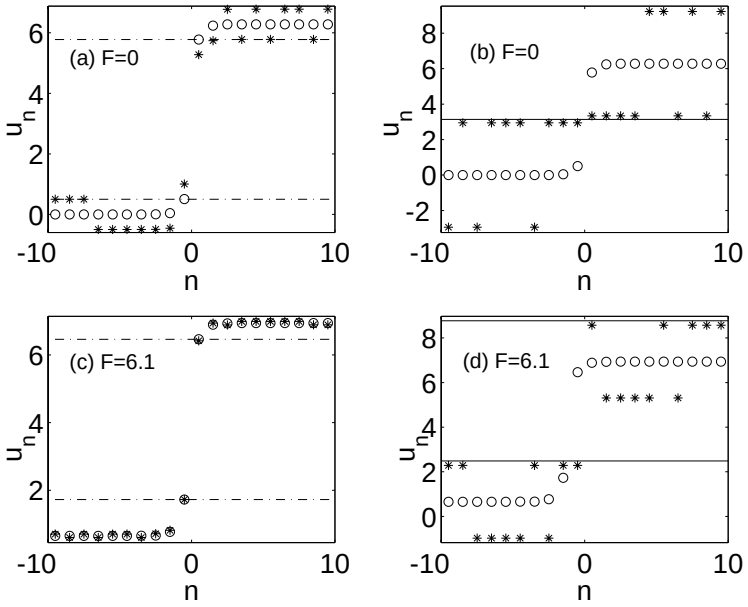

FIG. 2.3. *Initial condition* $u_n(0)$ *(asterisks) and its large time limit, the stable dislocation (circles), for the FK model with* $A = 10$*;* $F = 0$ *for* (a) *and* (b)*, and* $F = 6.1 < F_c$ *for* (c) *and* (d)*. The initial points are selected as indicated in the text.*

numbers with $|\epsilon_n| < 0.5$. In Figure 2.3(b), $u_n(0) - U_{1,3} = \delta_n B$, $0 < B = U_2 - U_1 - 0.2$, and δ_n randomly takes on the values 1 or -1. By using comparison methods, it is possible to prove that a small disturbance of the stable dislocation evolves towards it. The same results hold for the stable stationary solution $u_n(A, F)$ for $0 < |F| < F_c$. As $|F|$ increases, a disturbance of the stable stationary solution typically evolves towards the same stationary solution displaced an integer number of lattice periods unless the disturbance is sufficiently small. See Figure 2.3(d) for an example of this phenomenon for F slightly smaller than F_c. Carefully selecting the initial condition avoids this, as in Figure 2.3(c).

For large A, the stable dislocation has $g'(u_n) > 0$ for all n, and (2.6) gives

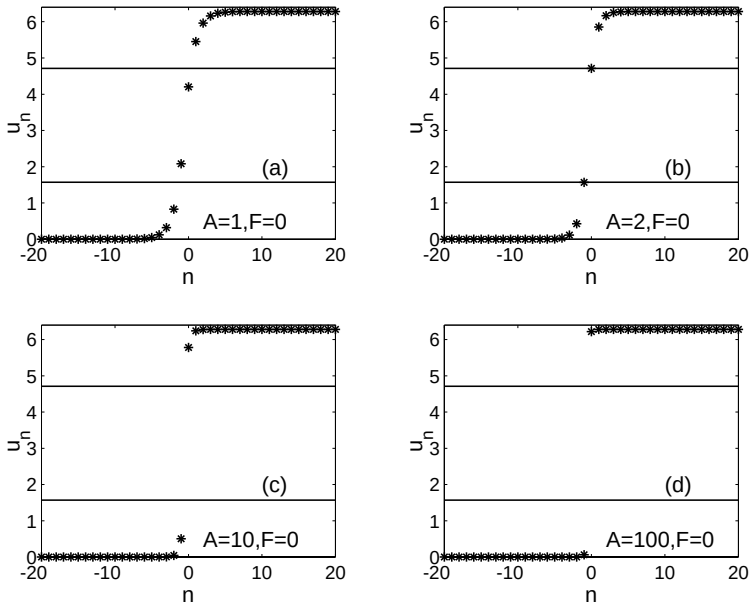

FIG. 2.4. *Stationary solutions for the FK model when* $A = 1, 2, 10, 100$.

$\lambda_1(A, 0) > 0$. Since $\lambda_1(A, F_c) = 0$, this implies that the critical field is nonzero. (Different proofs are given in [23, 9].) As $A > 0$ decreases, several u_n may enter the region of negative slope $g'(u)$: the number of points with $g'(u_n) < 0$ increases as A decreases; see Figures 2.2 and 2.4. It should then be possible to have $\lambda_1(A, 0) = 0$, i.e., $F_c = 0$, for a discrete system! Examples of this *pinning anomaly* will be given next.

2.3. Pinning failure. Despite widespread belief, it is not true that the critical field is positive for all discrete systems. This point was already raised by Hobart [21], who proposed the following numerical criterion to check whether for a given source g the critical field for (1.1) is zero.

Let us assume for the sake of simplicity that g is odd about 0. Then $U_2(0) = 0$ and $U_1(0) = -U_3(0)$. For any $x \in (U_1(0), U_3(0))$, we can compute numerically a unique value $y(x)$ such that the sequence u_n defined by $u_0 = x$, $u_1 = y(x)$, and $u_n = 2u_{n-1} - u_{n-2} + g(u_{n-1}), n > 1$, tends to $U_3(0)$ as $n \to \infty$. Hobart conjectured that $F_c = 0$ for a given nonlinearity g, provided that the function $y(x)$ satisfies

$$y^{-1}(x) = -y(-x), \quad y(x) - y(-x) = 2x + g(x) \tag{2.7}$$

for $x \in (U_1(0), U_3(0))$. It is fairly easy to construct examples of nonlinearities $g(x)$ for which (2.7) holds. It suffices to choose some smooth odd increasing function $u(x)$ such that $u(x) \to \pm a$ as $x \to \pm\infty$ for some $a > 0$. We define $g(u(x)) = u(x+1) - 2u(x) + u(x-1)$ so that $g(z) = u(u^{-1}(z) + 1) - 2z + u(u^{-1}(z) - 1)$ and $y(z) = u(u^{-1}(z) + 1)$. Choosing $u(x) = \tanh(x)$ (see [34, 5, 16]), we get an explicit formula for g: $g(z) = -2\gamma z(1 - z^2)/(1 - \gamma z^2)$ with $\gamma = \tanh^2(1)$. Notice that one or two points of the stationary solutions, $u_n = \tanh(n + p)$ (p is any constant), enter the region where $g' < 0$; see Figure 2.5(a).

By following this procedure, we find examples of bistable source terms for which

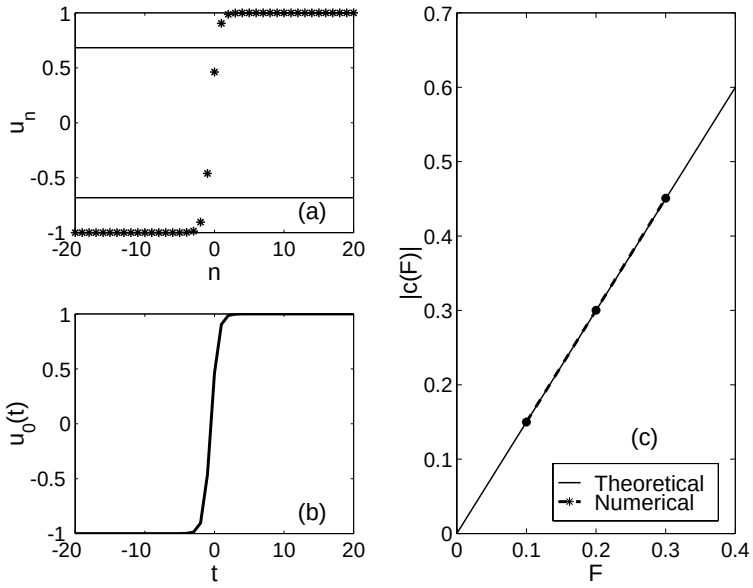

FIG. 2.5. (a) *Stationary solution* $u_n = \tanh(n)$, (b) *wave front for* F *small,* (c) *numerically calculated versus predicted speed for* $g(u) = -2\gamma u(1-u^2)/(1-\gamma u^2)$, *with* $\gamma = \tanh^2(1)$.

(1.1) has a uniparametric family of continuous stationary solutions, $u_n = u(n+p)$, $0 \le p < a$, satisfying $u_{n+1} - 2u_n + u_{n-1} = g(u_n)$ and $u_{-\infty} = -a$, $u_\infty = a$. In this case, (1.1) does not have stationary solutions joining $U_1(F/A)$ and $U_3(F/A)$ unless $F = 0$ (see [8]). The existence of continuous steady solutions for $F = 0$ implies that there is a continuous transition from wave fronts traveling to the left ($c < 0$) for $F > 0$ to wave fronts traveling to the right ($c > 0$) for $F < 0$. Only at $F = 0$ are wave fronts stationary (pinned). This pinning anomaly is stated more precisely as follows.

THEOREM 2.1. *Let* $g \in C^2$ *be as in the Introduction with* $g(0) = 0$, *and let* $\mathcal{L}(F)$ *be the operator*

$$\mathcal{L}(F)\, v_n = A\, g'(u_n) v_n + 2v_n - v_{n+1} - v_{n-1}, \tag{2.8}$$

corresponding to the evolution equation (1.1) *linearized about the stationary solution* $u_n = u_n(A, F)$ *at field* F. *Let us assume that for* $F = 0$ *there exists a differentiable increasing stationary solution* $u(x)$ *such that* $u(x) \to \pm U_3(0)$ *as* $x \to \pm\infty$. *Then,*

1. *zero is the smallest eigenvalue of the operator* $\mathcal{L}_0 = \mathcal{L}(0)$, *corresponding to the evolution equation* (1.1) *linearized about the stationary solution* $u_n(A, 0) = u(n)$;

2. $F_c(A) = 0$ *for* (1.1);

3. *traveling wave fronts exist for all* $F \neq 0$. *Furthermore, their speed increases linearly with the force for small* F. *We have*

$$c \sim -F\, \frac{U_3(0) - U_1(0)}{\int_{-\infty}^{\infty} \left(\frac{du}{dx}\right)^2 dx} \tag{2.9}$$

as $F \to 0$.

Moreover, statement 3 *implies the existence of steady differentiable solutions* $u(x)$ *of* (1.1) *such that* $u(x) \to \pm U_3(0)$ *as* $x \to \pm\infty$ *for* $F = 0$.

It is not our goal here to give a rigorous proof of this result, but to sketch the main ideas. First of all, note that the derivative $v_n = u_x(n) > 0$ is a *positive* eigenfunction of the elliptic operator $\mathcal{L}_0$ corresponding to the eigenvalue $\lambda = 0$ and decaying exponentially at infinity. Statement 1 immediately follows. This fact can be used to construct propagating sub- and supersolutions for (1.1) which forbid pinning for any $F \neq 0$. Thus, $F_c = 0$, which is statement 2. For $F = \epsilon > 0$ sufficiently small, the propagating subsolutions are $l_n(t) = l(n+\epsilon c_0 t)$, with $c_0 > 0$ and $l(x) = u(x)+\epsilon u_x(x)$. For $F = -\epsilon$, the propagating supersolutions are $w_n(t) = w(n-\epsilon c_0 t)$, with $c_0 > 0$ and $w(x) = u(x) - \epsilon u_x(x)$. In both cases, we have to choose $c_0 < 1/\max(u_x)$. A subsolution traveling to the left "pushes" the fronts to the left. Similarly, the supersolutions traveling to the right "push" the fronts to the right.

Let us now obtain statement 3. If $|F| > 0$, we have traveling wave front solutions $u_n(t) = \mathcal{U}(n - ct)$ of (1.1), whose profile $\mathcal{U}(z)$ satisfies the differential-difference equation

$$-c\frac{d\mathcal{U}}{dz}(z) = \mathcal{U}(z+1) - 2\mathcal{U}(z) + \mathcal{U}(z-1) - g(\mathcal{U}(z)) + F, \tag{2.10}$$

and $\mathcal{U}(\pm\infty) = \pm U_3(0)$; see [8]. Let $F = F_0\epsilon$ with $0 < \epsilon \ll 1$. The traveling wave solution can be written as $\mathcal{U}(n-ct) = u(n-ct) + \epsilon w(n-ct) + o(\epsilon)$, where $u(x)$ is the smooth stationary profile. Let $z = n - ct$ and $c = c_0\epsilon + o(\epsilon)$. Then w obeys

$$w(z+1) - 2w(z) + w(z-1) - Ag'(u(z))w(z) = -c_0\frac{du}{dz}(z) - F_0,$$

$$w(-\infty) = w(\infty) = \frac{1}{g'(U_1)} = \frac{1}{g'(U_3)}.$$

By the Fredholm alternative, this linear nonhomogeneous equation has a solution if the left-hand side $-c_0 du/dz - F_0$ is orthogonal to the eigenfunction du/dz, which yields (2.9).

In section 3, we show that the wave front speed c scales as $|F-F_c|^{\frac{1}{2}}$ if $F_c > 0$. Our linear scaling (2.9) of the velocity in statement 3 therefore implies that $F_c = 0$. The linear scaling (2.9) with $F_c = 0$ implies the existence of smooth stationary solutions at $F = 0$ as discussed in the first subsection.

Remark 1. We conjecture that the three statements in Theorem 2.1 are equivalent. To prove this, it would be enough to show that $F_c = 0$ implies the linear scaling of the speed of the waves (statement 3). Then, existence of differentiable stationary solutions follows. This implies statement 1 ($\lambda_1(A, 0) = 0$), which implies statement 2 ($F_c = 0$), as we showed above.

Remark 2. When stationary wave front solutions have smooth profiles, pinning failure occurs for discrete RD equations and for discrete equations with conservative dynamics. In the latter case, translation-invariant smooth profiles have the same energy, and therefore the PN energy barrier (defined as the smallest energy barrier that must be overcome for a kink or wave front to move [4]) vanishes. Pinning of a wave front usually results if the energy difference between the stable and the unstable front solutions (see Figure 2.2) is not zero. This energy difference provides an estimation of the PN energy barrier. Discussions of the PN potential and the PN barrier can be found in section 2.3 of [4] and in section III.B of [16]. The mathematical meaning and usefulness of the PN barrier for an infinite system with conservative dynamics are worth studying.

Remark 3. Speight and Ward [36] and Speight [37, 38] have developed a technique to discretize some continuum conservative models in such a way that kink-like initial

profiles may propagate without getting trapped. Their idea is to seek a discrete version of the potential energy which admits minimals satisfying a first order difference equation called the Bogomol'nyi equation so that there is no PN barrier. On the other hand, the difference operators in Speight and Ward [36] discretized equations of motion have a structure different from discrete diffusion and are hard to justify physically.

Remark 4. In discrete RD equations, moving and pinned fronts cannot coexist for the same value of the applied field. For chains with conservative Hamiltonian dynamics, the situation is less clear. In fact, it is possible to have two stationary front solutions with a positive energy difference between them (which would imply a nonzero critical field and therefore wave front pinning according to general belief), and yet a moving wave front may coexist with the stationary fronts for the same parameter values. An explicit example of this situation has been constructed by Flach, Zolotaryuk, and Kladko using an inverse method [16].

3. Asymptotic theory of wave front depinning. In this section we introduce a systematic procedure for deriving analytic expressions for the critical field $F_c > 0$ as a function of A, and for the front profiles and their velocity as functions of $F - F_c$ and A. Our methods work best in the strongly discrete case for large A. Our ideas are quite general and may be applied successfully to more complex discrete models [11]. We shall assume that $g \in C^2$ throughout this section.

3.1. Theory with a single active point. We choose A large enough for the stable dislocation in Figure 2.2 not to enter the region where $g' < 0$; see Figure 2.4. When $F > 0$, this solution is no longer symmetric with respect to U_2. If F is not too large, all $u_n(A, F)$ avoid the region of negative slope $g'(u) < 0$. For larger F and generic potentials (FK, double-well, ...), we have observed numerically that $g' < 0$ for a single point, labelled $u_0(A, F)$. This property persists until F_c is reached; see Figure 3.1.

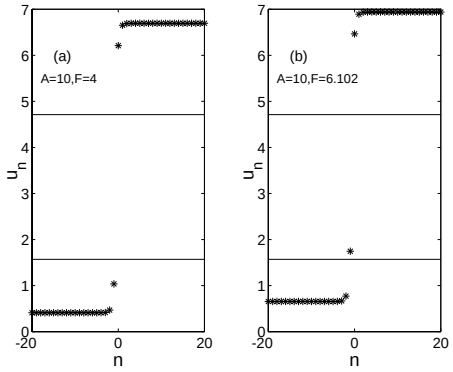

FIG. 3.1. *Stationary solutions for the FK model with* $A = 10$*:* (a) *No points are found in the region* $g' < 0$ *for sufficiently small* F*;* (b) *one point enters the region* $g' < 0$ *for sufficiently large* $F < F_c$*.*

First, consider the symmetric stationary profile with $u_n \neq U_2$ for $F = 0$. The front profile consists of two tails with points very close to U_1 and U_3, plus two symmetric points u_0, u_1 in the gap region between U_1 and U_3. As $F > 0$ increases, this profile changes slightly: the two tails are still very close to $U_1(F/A)$ and $U_3(F/A)$. As for the two middle points, u_1 gets closer and closer to U_3, whereas u_0 moves away from

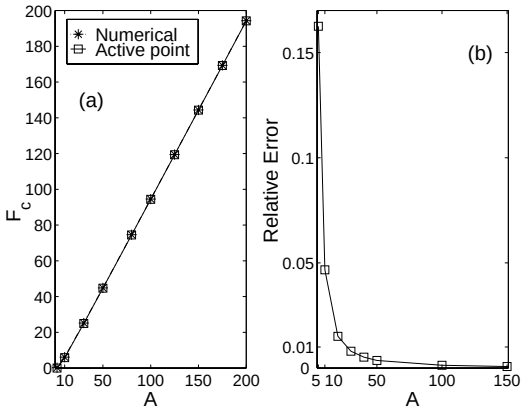

FIG. 3.2. *Approximation of* (1.1) *by the equation with one active point for the FK potential and* $A > 2$*:* (a) *critical force versus* A, (b) *error in the approximation of* $F_c(A)$.

U_1. This structure is preserved by the traveling fronts above the critical field: there is only one active point most of the time, which we can adopt as our u_0. Then the wave front profile (2.2) can be calculated as $u(-ct) = u_0(t)$. In (1.1), we can approximate $u_{-1} \sim U_1$, $u_1 \sim U_3$, thereby obtaining

$$\frac{du_0}{dt} \approx U_1\left(\frac{F}{A}\right) + U_3\left(\frac{F}{A}\right) - 2u_0 - A\,g(u_0) + F. \tag{3.1}$$

This equation has three stationary solutions for $F < F_c$, two stable and one unstable, and only one stable stationary solution for $F > F_c$. Let us consider $F < F_c$. Only two out of the three solutions of (3.1) approximate stationary fronts for the exact system: those having smaller values of u_0. The one having smallest u_0 approximates the stable stationary front; the other one approximates the unstable stationary front. Recall that the unstable front had a value $u_0 = [U_1(0) + U_3(0)]/2$ at the middle of the gap for $F = 0$. As $F > 0$ increases, u_0 decreases towards $U_1(F/A)$. Thus one active point will also approximate the profile of the unstable stationary front. The stationary solution of (3.1) having the largest value of u_0 (slightly below $U_3(F/A)$) is not consistent with the assumptions we made to derive (3.1), and therefore it does not approximate a physically existing stationary front. If $F > F_c$, the only stationary solution of (3.1) is the unphysical one. The critical field F_c is such that the expansion of the right-hand side of (3.1) about the two coalescing stationary solutions has zero linear term, $2 + Ag'(u_0) = 0$, and

$$2u_0 + A\,g(u_0) \sim U_1\left(\frac{F_c}{A}\right) + U_3\left(\frac{F_c}{A}\right) + F_c. \tag{3.2}$$

These equations for F_c and $u_0(A, F_c)$ have been solved for the FK potential, for which $u_0 = \cos^{-1}(-2/A)$ and $U_1 + U_3 = 2\sin^{-1}(F_c/A) + 2\pi$. The results are depicted in Figure 3.2 and show excellent agreement with those of direct numerical simulations for $A > 10$. Our approximation performs less well for smaller A, and it breaks down at $A = 2$ with the wrong prediction $F_c = 0$. Notice that $F_c(A)/A \sim 1$ as A increases. In practice, only steady solutions are observed for very large A.

Let us now construct the profile of the traveling wave fronts after depinning for

F slightly above F_c. Then $u_0(t) = u_0(A, F_c) + v_0(t)$ obeys the following equations:

$$\frac{dv_0}{dt} = \alpha\,(F - F_c) + \beta\, v_0^2, \tag{3.3}$$

$$\alpha = 1 + \frac{1}{A\,g'(U_1(F_c/A))} + \frac{1}{A\,g'(U_3(F_c/A))}\,, \tag{3.4}$$

$$\beta = -\frac{A}{2}\,g''(u_0), \tag{3.5}$$

where we have used $2 + Ag'(u_0) = 0$ and (3.2) and ignored terms of order $(F - F_c)\,v_0$ and higher. These terms are negligible after rescaling $v_0 = (F - F_c)^{\frac{1}{2}}\varphi$ and $\tau = (F - F_c)^{\frac{1}{2}}t$. The coefficients α and β are positive because $g'(U_i) > 0$ for $i = 1, 3$ and $g''(u_0) < 0$ since $u_0 \in (U_1(0), U_2(0))$. For the FK potential, $\alpha = 1 + 2/\sqrt{A^2 - F_c^2}$ and $\beta = \sqrt{A^2 - F_c^2}/2$. Equation (3.3) has the (outer) solution

$$v_0(t) \sim \sqrt{\frac{\alpha(F - F_c)}{\beta}}\,\tan\left(\sqrt{\alpha\beta\,(F - F_c)}\,(t - t_0)\right), \tag{3.6}$$

which is very small most of the time, but it blows up when the argument of the tangent function approaches $\pm\pi/2$. Thus the outer approximation holds over a time interval $(t - t_0) \sim \pi/\sqrt{\alpha\beta\,(F - F_c)}$, which equals $\pi\sqrt{2/\alpha}(A^2 - 4)^{-\frac{1}{4}}(F - F_c)^{-\frac{1}{2}}$ for the FK potential. The reciprocal of this time interval yields an approximation for the wave front velocity,

$$c(A, F) \sim -\frac{\sqrt{\alpha\beta\,(F - F_c)}}{\pi}\,, \tag{3.7}$$

or $c \sim -(A^2 - 4)^{\frac{1}{4}}(1 + 2/\sqrt{A^2 - F_c^2})^{\frac{1}{2}}(F - F_c)^{\frac{1}{2}}/(\pi\sqrt{2})$ for an FK potential. The minus sign reminds us that wave fronts move towards the left for $F > F_c$. In Figures 3.3(a) and (b) we compare this approximation with the numerically computed velocity for $A = 100$ and $A = 10$.

When the solution begins to blow up, the outer solution (3.6) is no longer a good approximation, for $u_0(t)$ departs from the stationary value $u_0(A, F_c)$. We must go back to (3.1) and obtain an inner approximation to this equation. As F is close to F_c and $u_0(t) - u_0(A, F_c)$ is of order 1, we numerically solve (3.1) at $F = F_c$ with the matching condition that $u_0(t) - u_0(A, F_c) \sim 2/[\pi\sqrt{\beta/[\alpha\,(F - F_c)]} - 2\beta\,(t - t_0)]$ as $(t - t_0) \to -\infty$. This inner solution describes the jump of u_0 from $u_0(A, F_c)$ to values on the largest stationary solution of (3.1), which is close to U_3. During this jump, the motion of u_0 forces the other points to move. Thus, $u_{-1}(t)$ can be calculated by using the inner solution in (1.1) for u_0, with $F = F_c$ and $u_{-2} \approx U_1$. A composite expansion [2] constructed with these inner and outer solutions is compared to the result of direct numerical simulations in Figure 3.4.

Notice that (3.3) is the normal form associated with a saddle-node bifurcation in a one-dimensional phase space. The wave front depinning transition is a *global* bifurcation with generic features: each individual point $u_n(t)$ spends a long time, which scales as $|F - F_c|^{-\frac{1}{2}}$, near discrete values $u_n(A, F_c)$, and then jumps to the next discrete value on a time scale of order 1. The traveling wave ceases to exist for $F \le F_c$.

3.2. Theory with several active points. The approximations to $F_c(A)$ and the wave front speed provided by the previous asymptotic theory break down for small

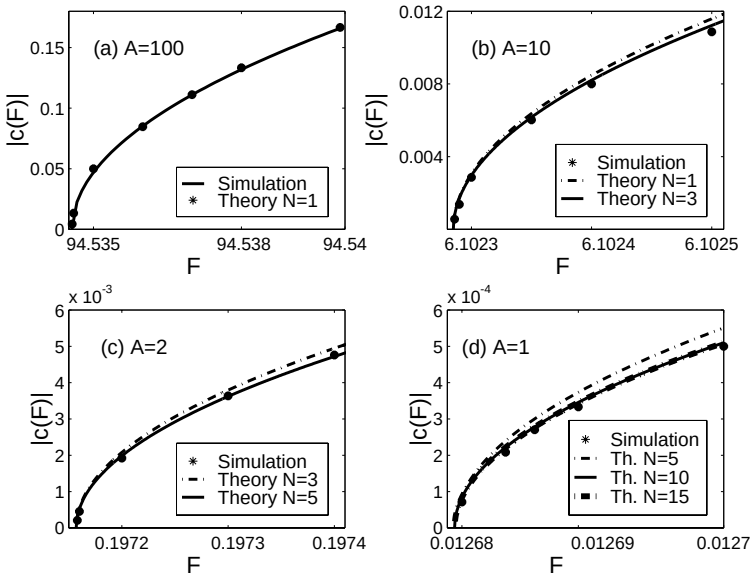

FIG. 3.3. *Comparison of theoretically predicted and numerically calculated wave front velocities near F_c for the FK model with N active points and the following values of the parameter A:* (a) $A = 100$, (b) $A = 10$, (c) $A = 2$, (d) $A = 1$.

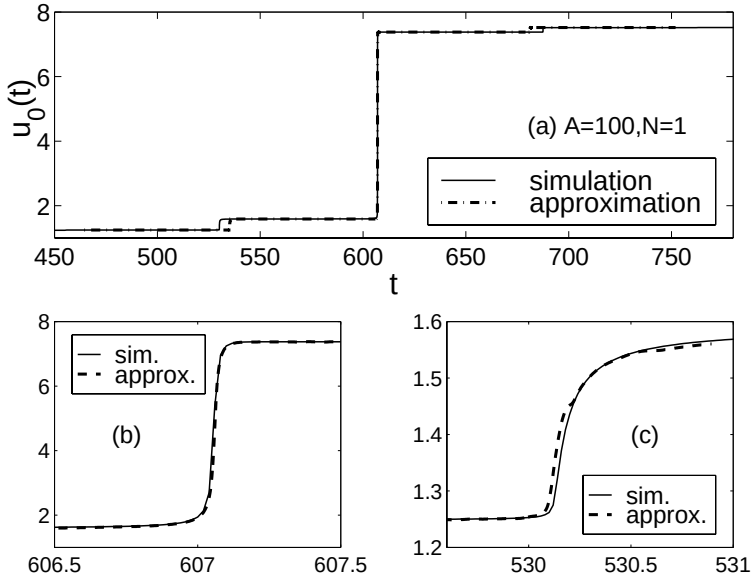

FIG. 3.4. *Comparison of asymptotic and numerically calculated wave front profiles near F_c:* (a) *Complete wave front profile as indicated by the trajectory $u_0(t)$.* (b) *Zoom near the largest jump in the profile.* (c) *Zoom near the jump preceding the largest one after translating the asymptotic profile. This last has been calculated by inserting the approximate $u_0(t)$ in the equation for $u_{-1}(t)$.*

A. In particular, for the FK potential and $A < 2$, no double zeroes of $2x + A\sin(x) - (F + U_1 + U_3)$ are found for $F = F_c$. What happens is that we need more than one point to approximate wave front motion. Depinning is then described by a reduced

system of more than one degree of freedom corresponding to active points. There is a saddle-node bifurcation in this reduced system whose normal form is of the same type as (3.3). The jump of the active points after blow up is found by solving the reduced system with a matching condition [10].

We explain our procedure for a finite number of active points. The front is formed by two tails, very close to $U_1(F/A)$ and $U_3(F/A)$, respectively, and several intermediate points $u_{-L}, \ldots, u_M$. The reduced system describing the dynamics of the front for $F > F_c$ is

$$\begin{aligned} &\frac{du_i}{dt} = u_{i+1} - 2u_i + u_{i-1} - Ag(u_i) + F, \quad i = -L, \ldots, M, \\ &u_{-L-1} = U_1(F/A), \qquad u_{M+1} = U_3(F/A). \end{aligned} \tag{3.8}$$

At $F = F_c$ this system has a stationary solution $u_{-L}, \ldots, u_M$. Writing $u_i(t) = u_i + v_i(t)$, we obtain for v_i

$$\begin{aligned} &\frac{dv_i}{dt} = v_{i+1} - 2v_i + v_{i-1} - Ag'(u_i)v_i - \frac{A}{2}g''(u_i)v_i^2 + F - F_c, \quad i = -L, \ldots, M, \\ &v_{-L-1} \sim \frac{F - F_c}{Ag'(U_1(F_c/A))}, \qquad v_{M+1} \sim \frac{F - F_c}{Ag'(U_3(F_c/A))}. \end{aligned} \tag{3.9}$$

The tridiagonal matrix $\mathcal{M}$ defined as

$$\begin{pmatrix} 2 + Ag'(u_{-L}) & -1 & & & & & \\ -1 & 2 + Ag'(u_{1-L}) & -1 & & & & \\ & \cdot & \cdot & \cdot & & & \\ & & \cdot & \cdot & \cdot & & \\ & & & \cdot & \cdot & \cdot & \\ & & & & -1 & 2 + Ag'(u_{M-1}) & -1 \\ & & & & & -1 & 2 + Ag'(u_M) \end{pmatrix} \tag{3.10}$$

has $L + M$ strictly positive eigenvalues plus a smallest eigenvalue $\lambda \sim 0$ with an associate positive eigenfunction V. We choose V such that $\sum_{i=-L}^{M} V_i^2 = 1$ and write an eigenfunction expansion for v as follows:

$$v(t) = \varphi\, V + \sum_{i=-L, i\neq 0}^{M} W_i \varphi_i \exp(-\lambda_i t). \tag{3.11}$$

Thus $v(t) \sim V\varphi(t)$ as time increases. Let $D = -\frac{A}{2}$ diag $(g''(u_{-L}), \ldots, g''(u_M))$, $V^2 = (V_{-L}^2, \ldots, V_M^2)$, and

$$w = (F - F_c)\left(1 + \frac{1}{Ag'(U_1(F_c/A))}, 1, \ldots, 1, 1 + \frac{1}{Ag'(U_3(F_c/A))}\right).$$

Then system (3.9) becomes

$$\frac{d\varphi}{dt}\, V \sim \varphi\, \mathcal{M}V + \varphi^2\, DV^2 + w \sim \varphi^2\, DV^2 + w \tag{3.12}$$

as time increases. Multiplying by the transpose of V, we get an evolution equation for the amplitude $\varphi(t)$:

$$\frac{d\varphi}{dt} = \alpha\,(F - F_c) + \beta\,\varphi^2, \tag{3.13}$$

where now α and β are

$$\alpha = \sum_{i=-L}^{M} V_i + \frac{V_{-L}}{Ag'(U_1(F_c/A))} + \frac{V_M}{Ag'(U_3(F_c/A))} > 0,$$

$$\beta = -\frac{A}{2} \sum_{i=-L}^{M} g''(u_i) V_i^3 > 0.$$

The coefficient α is positive because $g'(U_i) > 0$ for $i = 1, 3$. We have checked numerically that $\beta > 0$ for different nonlinearities and values of A. An intuitive explanation follows. First, notice that $g''(u) > 0$ for $u \in (U_2(0), U_3(0))$, and $g''(u) < 0$ for $u \in (U_1(0), U_2(0))$. For large A, the largest component is V_0, the others are negligible, and we have one active point as in the previous subsection; see Figure 3.4. Then $\beta \sim -g''(u_0(A, F_c))V_0^3 > 0$ because $u_0 < U_2(0)$, which implies $g''(u_0) < 0$. As A decreases, V_0 is still the largest component and $g''(u_0(A, F_c)) < 0$. Now there may be other terms with $g''(u_i(A, F_c)) > 0$, and we have only numerical evidence that $\beta > 0$, not a proof.

Notice that (3.13) is the normal form of a saddle-node bifurcation. Its solution is again (3.6), which blows up at times $(t - t_0) = \pm 1/(2c)$, where

$$c(A, F) \sim -\frac{1}{\pi} \sqrt{\alpha\beta(F - F_c)}, \tag{3.14}$$

as discussed before. c is the wave front speed near F_c, approximately given by the reciprocal of the time during which the outer solution holds.

Figures 2.1, 3.3, and 3.5 show the critical field, wave front velocities, and profiles for different values of $A \in (1, 10)$ corresponding to the FK model. We have compared results of direct numerical simulations to those of our theory for $N = L+M+1$ active points. Provided that $N = L + M + 1$ active points have been selected, we find the smallest eigenvalue of the matrix $\mathcal{M}$ and move F until $\lambda(F, A; N) = 0$, $N = L+M+1$, which yields an approximation for $F_c(A)$; see Figure 2.1. The wave front velocities can be calculated by means of (3.14) and have been depicted in Figure 3.3.

The wave front profiles near F_c can be determined as follows. We start with an initial condition, $u_n(0) \approx u_n(A, F_c)$ or $\varphi(0) = 0$ in (3.11). The active points blow up at $t \sim \pm(2c)^{-1}$, for example as

$$u_n(t) \sim u_n(A, F_c) + \frac{1}{\beta(\pm\frac{1}{2c} - t)} V, \tag{3.15}$$

provided $t \to \pm 1/(2c)$. At these times, we should insert a fast stage during which the $u_n(t)$ are no longer close to $u_n(A, F_c)$, as an inner layer. The inner layer variables $u_n(t)$ obey (1.1) with $F = F_c$ and the boundary conditions $u_n(t) \to u_n(A, F_c)$ (according to (3.15)) as $t \to -\infty$, and $u_n(t) \to u_{n+1}(A, F_c)$ as $t \to \infty$. To get a uniform approximation, we notice that the blow up times are $t_m = (2c)^{-1} + m/c$, $m \in \mathbb{Z}$. Let us denote by $u_n^{(m)}(\tau)$, $\tau = (t - t_m)$, the solution of (1.1) with $F = F_c$ and the boundary conditions $u_n^{(m)}(\tau) \to u_{n+m}(A, F_c)$ as $\tau \to -\infty$, and $u_n^{(m)}(\tau) \to u_{n+m+1}(A, F_c)$ as $\tau \to \infty$. During the time interval $(t_{-L-n-1}, t_{M-n}) = (-(2c)^{-1} - (L+n)/c, (2c)^{-1} + (M - n)/c)$ that $u_n(t)$ needs to go from $U_1(F_c/A)$ to $U_3(F_c/A)$, the uniform approximation

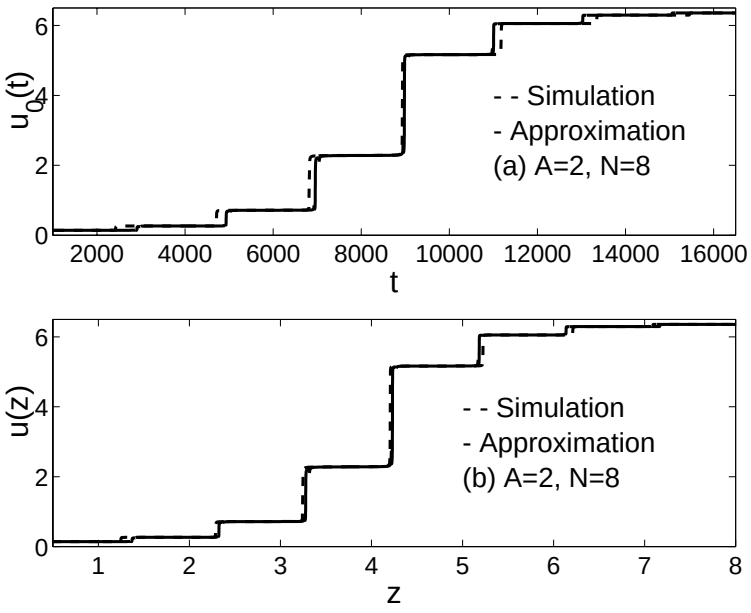

FIG. 3.5. *Comparison of theoretically predicted and numerically calculated wave fronts near F_c for $A = 2$ using $N = 8$ active points:* (a) *trajectory of one point,* (b) *wave front profile,* $u(z) = u_0(z/|c|)$.

to the wave front is

$$u_n(t) \sim \sum_{m=-n-L-1}^{M-n} \Big\{ u_n^{(m)}(t-t_m) + u_n^{(m-1)}(t-t_{m-1}) - u_{n+m}(A,F_c) + \left[\varphi\left(t - \frac{m}{c}\right) - \frac{1}{\beta\,(t_m - t)} + \frac{1}{\beta\,(t-t_{m-1})} \right] V \Big\} \chi_{(t_{m-1},t_m)}. \tag{3.16}$$

Then $u_n(t_{-L-n-1}) \sim U_1(F_c/A)$ and $u_n(t_{M-n}) \sim U_3(F_c/A)$. In (3.16), the indicator function $\chi_{(t_{m-1},t_m)}$ is 1 if $t_{m-1} < t < t_m$ and 0 otherwise. Therefore, $\chi_{(t_{m-1},t_m)} = \theta(t_m - t) - \theta(t_{m-1} - t)$, where $\theta(x) = 1$ if $x > 0$ and 0 otherwise. Written in terms of the variable $z = n - ct$ such that $u_n(t) = u(z)$, $u(z) = u_n((n-z)/c) = u_0(-z/c)$. Then (3.16) becomes

$$\begin{aligned} u(z) \sim \sum_{m=-L-1}^{M} & \Big\{ u_0^{(m)}\left(-\frac{z+m+\frac{1}{2}}{c}\right) + u_0^{(m-1)}\left(-\frac{z+m-\frac{1}{2}}{c}\right) - u_m(A,F_c) \\ & + \left[\varphi\left(-\frac{z+m}{c}\right) - \frac{c}{\beta\,(z+m+\frac{1}{2})} - \frac{c}{\beta\,(z+m-\frac{1}{2})} \right] V \Big\} \\ & \times \left[\theta\left(z+m+\frac{1}{2}\right) - \theta\left(z+m-\frac{1}{2}\right) \right] \end{aligned} \tag{3.17}$$

for $-M - 1/2 < z < L + 1/2$. We have $u(L + 1/2 + 0) \sim U_1(F_c/A)$ and $u(-M - 1/2 - 0) \sim U_3(F_c/A)$, and therefore (3.17) approximates the wave front profile. In Figure 3.5, we have depicted the wave front profile in two ways, by drawing $u_0(t)$ and $u(z) = u_0(-z/c)$. Notice that the largest source of discrepancy between numerical

calculations and our asymptotic approximation is the error in determining the wave speed. The discrepancies are more evident for $u_0(t)$ because of the different horizontal scale used to depict $u(z)$.

How do we determine the optimal number of active points? For large enough $N = L + M + 1$ and a given A, the eigenvector V corresponding to the smallest eigenvalue of the matrix $\mathcal{M}$ in (3.10) has a certain number of components that are of order one, whereas all others are very small. The number of components of normal size determines the optimal number of active points: only one point if A is larger than 10, five if $A = 2$, etc. Keeping less active points than the optimal number results in larger errors, whereas keeping more active points than optimal does not result in a significantly better approximation. The eigenvector of the reduced system of equations for the active points is a good approximation to the large components of the eigenvector corresponding to the complete system. As we approach the continuum limit, more and more points enter the reduced system of equations, and exponential asymptotic methods become a viable alternative to our methods.

3.3. Depinning transition as a global bifurcation. We have shown that the depinning transition is a global bifurcation in a reduced system of equations corresponding to the active points. Starting from a stable stationary solution, the smallest eigenvalue of the system linearized about the stationary solution becomes zero at the (approximate) critical field, and its associated eigenfunction is positive. The stationary solution disappears as the critical field is surpassed. Beyond it, the active points $u_n(t)$ spend a long time, of order $(F - F_c)^{-\frac{1}{2}}$, near the stationary values $u_n(A, F_c)$, and then jump to $u_{n+1}(A, F_c)$ on an order 1 time scale. Near the critical field, the depinning transition is described *locally* by the normal form of a saddle-node bifurcation. For $F > F_c$ (or $F < -F_c$), the bifurcation amplitude blows up in finite time, on a time scale of order $||F| - F_c|^{-\frac{1}{2}}$. The construction of the wave front profile is completed, matching the outer solution given by the saddle-node normal form to a solution of the reduced system of active points at $F = F_c$. (A mathematically related phenomenon occurs in a mean-field model of sliding charge-density waves [2].)

We conjecture that the depinning transition in the infinite system (1.1) is a global bifurcation of the same type as for the reduced system of active points. At the critical field, two stationary solutions of (1.1) (one stable, the other unstable) coalesce and disappear. For $F > F_c$ (or $F < -F_c$), the wave front profile is constructed as indicated above for the reduced system. To prove this conjecture, we could repeat our construction in section 3.2 for an infinite number of points. This is possible because we know that the infinite system, linearized about the "stable" steady solution $u_i(A, F_c)$ at $F = F_c$, has a zero eigenvalue and an associated positive exponentially decaying eigenfunction V. Using V, we obtain the normal form equation (3.13), where now

$$\alpha = \sum_{i=-\infty}^{\infty} V_i > 0, \qquad \beta = -\frac{A}{2} \sum_{i=-\infty}^{\infty} g''(u_i) V_i^3. \tag{3.18}$$

We should now prove that the coefficient β is positive and that the infinite system has solutions connecting $u_n(A, F_c)$ to $u_{n+1}(A, F_c)$ and satisfying the matching condition. We justified that $\beta > 0$ for the finite system in subsection 3.2, and we show in Proposition A.4 (in the appendix) that the eigenfunction for the infinite system can be approximated by the corresponding eigenfunction of the reduced system with a finite number of active points. The existence of traveling wave solutions for $F > F_c$ ensures that the infinite system has solutions connecting $u_n(A, F_c)$ to $u_{n+1}(A, F_c)$.

The velocity of a wave front in the infinite system is again given by (3.14) with the coefficients (3.18).

Remark 5. By using comparison techniques, it is possible to prove that solutions of discrete RD equations with finitely many points and Dirichlet boundary conditions approximate solutions of the same equations with infinitely many points. In the continuum limit, the wave fronts approach constant values exponentially fast as $i \to \pm\infty$. This exponential decay justifies the active point approximation in two ways. First, the number of active points needed to approximate well the wave fronts of the infinite system decreases as A increases. It is usually better to add another active point to the approximate system than to patch rigid tails to the last active points of a wave front by generalizing Kladko, Mitkov, and Bishop's active site approximation [28]. Secondly, exponential decay at the ends of a wave front causes the operator of the linearized problem about the wave front to be compact and therefore to have a discrete spectrum (see the appendix). This fact justifies that the normal form we calculate by using active points approximates the correct local normal form of the depinning global bifurcation.

4. Conclusions. In this paper, we have studied depinning of wave fronts in discrete RD equations. Pinned (stationary) and traveling wave fronts cannot coexist for the same value of the forcing term. There are two different depinning transitions, i.e., two different ways in which a pinned front may start moving. The normal depinning transition can be viewed as a loss of continuity of traveling front profiles as the critical field is approached: below the critical field, the fronts become pinned stationary profiles with discontinuous jumps at discrete values u_n. The wave front velocity scales as $|F - F_c|^{\frac{1}{2}}$ near the critical field F_c. For sufficiently large A (far from the continuum limit), the critical field and these fronts can be approximated by singular perturbation methods which show excellent agreement with numerical simulations. These methods are based upon the fact that the wave front motion can be described by a reduced system of equations corresponding to the dynamics of only a finite number of points, the active points.

Besides the normal depinning transition, certain nonlinearities present anomalous pinning (pinning failure): the velocity of the wave fronts is not zero except at zero forcing, just as for continuous RD equations. These nonlinearities are characterized by smooth profiles of stationary and moving wave fronts, by having zero critical field, and by a linear scaling of wave front velocity with field.

Appendix. Characterization of the depinning threshold. In this section we establish the "depinning criterion," which provides a characterization of $F_c(A)$ as follows.

THEOREM A.1. *Set $F = 0$ and $A > 0$. Assume that the nonlinearity $g \in C^3$ has three zeroes U_i, $U_1 < U_2 < U_3$, is odd about U_2, and satisfies $g'(U_1) = g'(U_3) > 0$. Let u_n be a stationary increasing solution of* (1.1)*, symmetric about U_2 and such that $u_{-\infty} = U_1$ and $u_\infty = U_3$. Let $\lambda_1(A, 0)$ be the smallest eigenvalue of the zero field operator $\mathcal{L}_0$ of* (2.8) *at $F = 0$:*

$$\begin{aligned} -(v_{n+1} - 2v_n + v_{n-1}) + Ag'(u_n)v_n &= \lambda_1(A,0)v_n, \\ v_{\pm n} \to 0 \text{ exponentially as } n \to \infty. \end{aligned} \tag{A.1}$$

If $\lambda_1(A, 0) > 0$, then $F_c(A) > 0$, and for $|F| \le F_c(A)$ there exist increasing stationary solutions $u_n(A, F)$ of (1.1) *with $u_{-\infty} = U_1(F/A)$ and $u_\infty = U_3(F/A)$. Moreover, the smallest eigenvalues of the operator $\mathcal{L}(F)$, corresponding to the linearization of* (1.1)

about $u_n(A,F)$,

$$\begin{aligned} -(v_{n+1}-2v_n+v_{n-1})+Ag'(u_n(A,F))v_n &= \lambda_1(A,F)v_n, \\ v_{\pm n} &\to 0 \text{ exponentially as } n\to\infty, \end{aligned} \tag{A.2}$$

are strictly positive for $|F|<F_c(A)$. *We can characterize* $F_c(A)$ *as the zero of the smallest eigenvalue,* $\lambda_1(A,F_c(A))=0$.

This theorem will be proved in subsection A.2. To calculate $\lambda_1(A,F)$ and $F_c(A)$, we approximate the infinite tridiagonal matrix in (A.2) by an $N\times N$ matrix, where N is the number of active points. Similar truncation approximations were used in [29] to calculate the lowest eigenvalue of an infinite tridiagonal matrix. For values of A which are not too small, numerical simulations show that the matrices $\mathcal{M}$ in (3.10) have positive eigenvalues. The eigenvector $V(A,F,N)$ (chosen to have norm 1), corresponding to the smallest eigenvalue $\lambda(A,F,N)$, is positive, and it is "concentrated" in the central components $V_{-m(A)},\ldots,V_{m(A)}$. All other components are very small. The number of significant components $m(A)$ does not change as N increases, but it increases as A decreases. For large A, $m(A)=0$, and only V_0 is significant. Provided N is large enough, the eigenvalues $\lambda(A,F,N)$ and the eigenvectors $V(A,F,N)$ approximate well the smallest eigenvalue and associated eigenfunction of the infinite problem, as we indicate in the next subsection. For a fixed value of N, the eigenvalues $\lambda(A,F,N)$ decrease as A decreases. For fixed N and A, they decrease as F increases from $F=0$ to values close to $F_c(A)$. In the next subsection, we collect several results on eigenvalues for this type of problem.

A.1. Eigenvalue problems. Before proving Theorem A.1, we should make sure that our linear operators do have eigenfunctions and eigenvalues. We consider the real valued and symmetric operators $\mathcal{L}(F)\,v_n = Ag'(u_n)v_n-(v_{n+1}-2v_n+v_{n-1})$ in spaces of sequences decaying exponentially at infinity. Their spectra are discrete and real (these operators are compact), and we would like to make sure that they are not empty. Since we are interested mainly in the smallest eigenvalue, we shall use its variational characterization, prove that this eigenvalue exists, and characterize its dependence on the parameters A and F. We shall also describe finite-dimensional approximations of eigenvalues and eigenfunctions.

Let us first look for necessary conditions for $\lambda(A,F)$ to exist. Let $\lambda\in\mathbb{R}$ be an eigenvalue of $\mathcal{L}(F)$ with eigenfunction V_n. Multiplying $\mathcal{L}(F)\,V_n-\lambda V_n$ by V_n and summing over n, we obtain

$$\begin{aligned} 0 &= \sum_n (V_{n+1}-V_n)^2+[Ag'(u_n)-\lambda]V_n^2 \\ &\geq \sum_n (V_{n+1}-V_n)^2+([A\min_n g'(u_n)]-\lambda)\sum_n V_n^2. \end{aligned} \tag{A.3}$$

Thus, $\lambda=\sum_n[(V_{n+1}-V_n)^2+Ag'(u_n)V_n^2]/\sum V_n^2 > A\min_n g'(u_n)$. This inequality implies that λ is positive if u_n does not take on values in the region where g' is negative, which occurs for large enough $A>0$. In general, we can say only that $\lambda>Ag'(U_2)$ for g' attains its minimum value in $[U_1,U_3]$ at U_2. Similarly,

$$\begin{aligned} 0 &= \sum_n (V_{n+1}-V_n)^2+[Ag'(u_n)-\lambda]V_n^2 \\ &\leq [4+A\max_n(g'(u_n))-\lambda]\sum_n V_n^2. \end{aligned} \tag{A.4}$$

Therefore, $\lambda < Ag'(U_1) + 4 = Ag'(U_3) + 4$ for $g'(u)$ attains its maximum value in $[U_1, U_3]$ at the end points, $u = U_1$ and $u = U_3$.

The smallest eigenvalue λ is given by the Rayleigh formula

$$\lambda = \min \frac{\sum_n (w_{n+1} - w_n)^2 + Ag'(u_n) w_n^2}{\sum_n w_n^2}, \tag{A.5}$$

where the infimum is taken over our space of exponentially decaying functions. That minimum is attained at an eigenfunction V_n solving (A.1). Now, (A.1) may have solutions decaying at $\pm\infty$ only if the difference equation

$$V_{n+1} + (-2 - Ag'(U_1) + \lambda) V_n + V_{n-1} = 0 \tag{A.6}$$

has solutions of the form r^n with $r < 1$. This happens when $(-2 - Ag'(U_1) + \lambda)^2 > 4$. Thus either $\lambda > 4 + Ag'(U_1) > 0$ (excluded above) or $\lambda < Ag'(U_1)$. We conclude that $\lambda < Ag'(U_1)$ is a necessary condition to attain the minimum (A.5) at a positive eigenfunction decaying exponentially at infinity.

We now establish sufficient conditions for the minimum (A.5) to exist.

LEMMA A.2 (Conditions for the existence of positive decaying eigenfunctions). *Let $F = 0$, $A > 0$, and let the nonlinearity g satisfy the hypotheses in Theorem* A.1. *Let u_n be a stationary increasing solution of* (1.1) *such that $u_{-\infty} = U_1(0)$ and $u_\infty = U_3(0)$. Given an exponentially decaying sequence $w = w_n$, we define*

$$J(w) = \frac{\sum_n [(w_{n+1} - w_n)^2 + Ag'(u_n) w_n^2]}{\sum_n w_n^2}.$$

Let us suppose that there is a sequence w_n such that $J(w_n) < Ag'(U_1)$. Then the infimum

$$\lambda = \inf_{\sum_n r_0^{-2|n|} v_n^2 < \infty} \frac{\sum_n [(v_{n+1} - v_n)^2 + Ag'(u_n) v_n^2]}{\sum_n v_n^2} \tag{A.7}$$

is attained at a positive function V_n which decays as $r(A,\lambda)^{|n|}$ at infinity, with $0 < r(A,\lambda) = [2 + Ag'(U_1) - \lambda - \sqrt{(-2 - Ag'(U_1) + \lambda)^2 - 4}]/2 < r_0 < 1$. Now $\lambda = \lambda_1(A, 0)$, and v_n solves (A.1).

Remark 6. The value $0 < r_0 < 1$ is determined in the proof. Note that $r(A,\lambda)$ is a decreasing function of A but an increasing function of λ.

Remark 7. We have shown above that $Ag'(U_2) < \lambda < Ag'(U_1)$. Thus the smallest eigenvalue shrinks to zero as $A \to 0$, although we do not have proof that it does so monotonically.

Proof. Clearly $J(w)$ is bounded from below by $A \min_n(g'(u_n))$. We choose $r_0 = r(A, J(w_n)) \in (0,1)$ and define $\|w\|_0 = \sum r_0^{-2|n|} |w_n|^2$. Let $w^m = w_n^m$, $m > 0$, be a sequence minimizing $J(w)$: $\|w^m\|_0 < \infty$ and let $J(w^m) \to \lambda$ when $m \to \infty$. We replace w^m with $v^m = v_n^m = w_n^m / \|w^m\|_0$. Then, $\|v^m\|_0 = 1$ and $J(v^m) = J(w^m) \to \lambda$. $\|v^m\|_0 = 1$ implies that, uniformly in m, $|v_n^m| \le r_0^{|n|}$ and $\sum_{n > n(\epsilon)} |v_n^m|^2 < \epsilon$ for $n(\epsilon)$ large enough. Thus, a subsequence v^m tends to some limit $V = V_n$ such that $|V_n| \le r_0^{|n|}$ and $\sum_n |v_n^m - V_n|^2$ tends to zero as m tends to infinity. Therefore, $J(v^m) \longrightarrow J(V) = \lambda$ and the infimum is attained at the sequence $V = V_n$. Moreover, $V = V_n$ satisfies the Euler equation (A.1) for the minimization problem, which then implies that V_n decays as stated in the lemma.

On the other hand, $J(|V_n|) \le J(V_n)$, and we can choose nonnegative V_n. But then λ has to be the smallest eigenvalue $\lambda_1(A,0)$.

LEMMA A.3 (Choice of the sequence w_n with $J(w_n) < Ag'(U_1)$). *Let $F = 0$, $A > 0$, and u_n be as in Lemma* A.2. *Let $u(x)$ be the solution of the boundary value problem $d^2u/dx^2 = g(u)$, with $u(-\infty) = U_1$, $u(\infty) = U_3$ such that $u(0) = U_2$.*

- *For sufficiently small $A < 1$, we have*

$$|u_{n+1} - u_n| \max_{[u_n, u_{n+1}]} |g''| < 2g'(U_1) \quad \forall n, \tag{A.8}$$

and $w_n = u_{n+1} - u_n$ satisfies $J(w_n) < Ag'(U_1)$. An estimation of the appropriate values of A indicates that they should be smaller than

$$A < \left(\frac{2g'(U_1)}{\max_{[U_1,U_3]}|g''| \max_{\mathbb{R}}|du/dx|} \right)^2 .$$

- *For $A > 2\,g'''(U_1)$, we can choose $w_n = 0$ for $|n| > M \ge 0$, $w_n = r^n$ for $n \ge 0$, and $w_n = r^{n+1}$ for $n < 0$.*

Proof. The function $w_n = u_{n+1} - u_n$ is a solution of

$$w_{n+1} - 2w_n + w_{n-1} = A \frac{g(u_{n+1}) - g(u_n)}{u_{n+1} - u_n} w_n$$

that decays at infinity as $r(A,0)^{|n|}$. Multiplying this equation by w_n and adding over n, we obtain

$$\sum_n \left((w_{n+1} - w_n)^2 + A \frac{g(u_{n+1}) - g(u_n)}{u_{n+1} - u_n} w_n^2 \right) = 0. \tag{A.9}$$

This result can be used to calculate $J(w_n)$:

$$J(w_n) = A \frac{\sum \left(g'(u_n) - \frac{g(u_{n+1}) - g(u_n)}{u_{n+1} - u_n} \right) w_n^2}{\sum w_n^2} = -\frac{A}{2} \frac{\sum g''(\xi_n) w_n^3}{\sum w_n^2} , \tag{A.10}$$

by the mean value theorem. Thus, $J(w_n) \le (A/2) \max_n (|u_{n+1} - u_n| \max_{[u_n, u_{n+1}]} |g''|)$. For sufficiently small A, $|u_{n+1} - u_n| \le C\sqrt{A}$, so that $J(w_n) < CA^{\frac{3}{2}} \max|g''|/2 < Ag'(U_1)$. More precisely, for small A, $w_n = u_{n+1} - u_n \simeq u((n+1)\sqrt{A}) - u(n\sqrt{A}) \simeq \sqrt{A} u'(\xi)$. Then $|w_n| \le \max |du/dx| \sqrt{A}$.

To prove the other case, we observe that $J(w_n) = (r-1)^2 + A \sum_{i=0}^{\infty} g'(u_n) r^{2n}$ is smaller than $Ag'(u_1)$, provided that $(1-r)/(1+r) < A\,g'''(U_1)/[2\,(1 - (r(A,0)r)^2)]$, with $r(A,\lambda)$ defined as in Lemma A.2. The last inequality holds if $A > 2\,g'''(U_1)$.

Remark 8. For the FK nonlinearity, the first condition of the lemma holds for $A < 0.9$, and the second condition for $A > 2$. For intermediate values, numerical simulations show that $w_n = u_{n+1} - u_n$ satisfies $J(w_n) < Ag'(U_1)$.

PROPOSITION A.4 (Finite-dimensional approximations). *Let $u_n(A,F)$ be a stationary solution of* (1.1) *under the hypotheses in Theorem* A.1 *for $|F| \le F_c(A)$. Let $\lambda_1(A,F)$ be the smallest eigenvalue of the operator $\mathcal{L}(F)$ (linearized about $u_n(A,F)$) and $\lambda(A,F,N)$ be the smallest eigenvalues of the matrices* (3.10). *Then, $\lambda(A,F,N) \to \lambda_1(A,F)$ as $N \to \infty$. As a consequence, if $V > 0$ is an eigenfunction associated to $\lambda_1(A,F)$ with $\sum_n V_n^2 = 1$ and if $V(N) > 0$ are eigenvectors associated to $\lambda(A,F,N)$ such that $\sum_n V_n(N)^2 = 1$, then $V(N) \to V$ as $N \to \infty$.*

Proof. It follows from the Rayleigh characterizations for the smallest eigenvalues:

$$\lambda_1(A,F) = \min_{\sum r^{-2|n|} w_n^2} \frac{\sum_{-\infty}^{\infty} [(w_{n+1}-w_n)^2 + Ag'(u_n(A,F))w_n^2]}{\sum_{-\infty}^{\infty} w_n^2}, \tag{A.11}$$

$$\lambda(A,F,N) = \min \frac{\sum_{-L}^{M} [(v_{n+1}-v_n)^2 + Ag'(u_n(A,F))v_n^2]}{\sum_{-L}^{M} v_n^2}. \tag{A.12}$$

Letting $w_n = v_n$ for $n = -L, \ldots, M$ and $w_n = 0$ otherwise, we see that $\lambda_1(A,F) \leq \lambda(A,F,N)$, $N = L + M + 1$. Now let w_n be an eigenfunction for $\lambda_1(A,F)$ such that $\sum_{-\infty}^{\infty} w_n^2 = 1$. Then,

$$\lambda(A,F,N) \leq \frac{\lambda_1(A,F) - \sum_{n<-L,\, n>M} [(w_{n+1}-w_n)^2 + Ag'(u_n(A,F))w_n^2]}{\sum_{-L}^{M} w_n^2}.$$

We conclude that $\lambda(A,F,N) \to \lambda_1(A,F)$ as $N \to \infty$. This and the exponential decay of V prove the convergence of the eigenvectors.

A.2. Proof of Theorem A.1. The theorem will be proved in two steps and, for simplicity, in the particular case of periodic g. In this case, $U_3(F/A) - U_3(0) = U_1(F/A) - U_1(0)$, which allows us to use symmetric sub- and supersolutions. Small modifications are required in the general case.

Step 1: $F_c(A) > 0$. We use the existence of a positive eigenfunction v_n associated with a positive eigenvalue $\lambda_1(A,0)$ to construct stationary supersolutions for (1.1) when $F > 0$ is small. The known solution u_n provides a stationary subsolution.

We look for a supersolution of the form

$$w_n = u_n + (1+\delta)\left(U_1\left(\frac{F}{A}\right) - U_1(0)\right) + \epsilon v_n, \tag{A.13}$$

with $\delta > 0$ to be chosen and ϵ, F small to be determined. Let us check that

$$w_{n+1} - 2w_n + w_{n-1} \leq g(w_n) - F, \qquad w_\infty > U_3(F/A), w_{-\infty} > U_1(F/A) \tag{A.14}$$

holds. The conditions at infinity are satisfied for any $\delta > 0$. Provided

$$\left|(1+\delta)\left(U_1\left(\frac{F}{A}\right) - U_1(0)\right)\right| \leq k\epsilon, \tag{A.15}$$

inequality (A.14) holds if

$$\epsilon\,(v_{n+1} - 2v_n + v_{n-1}) < Ag'(u_n)\left[\epsilon v_n + (1+\delta)\left(U_1\left(\frac{F}{A}\right) - U_1(0)\right)\right] - F + O(A\epsilon^2).$$

Using (A.1), we are left with

$$F < \epsilon\lambda_1(A,0)v_n + A(1+\delta)g'(u_n)\left(U_1\left(\frac{F}{A}\right) - U_1(0)\right).$$

Now, $U_1(F/A) = g^{-1}(F/A)$, the inverse being taken near $U_1(0)$, in the region with $g' > 0$. Using $g^{-1}(x) \sim g^{-1}(x_0) + (g^{-1})'(x_0)(x - x_0)$, we obtain

$$U_1\left(\frac{F}{A}\right) = g^{-1}\left(\frac{F}{A}\right) \sim U_1(A,0) + \frac{F}{A\,g'(U_1(0))}. \tag{A.16}$$

Thus, the condition for w_n to be a supersolution is

$$F < \epsilon\lambda_1(A,0)v_n + g'(u_n)\frac{1+\delta}{g'(U_1(0))}F.$$

Let M be sufficiently large. We distinguish two different ranges of indices n:

- For $|n| > M$, $g'(u_n) > 0$ and $v_n \ll 1$. Then the right-hand side of the previous inequality is dominated by the second term. We choose δ large enough to ensure $F < g'(u_n)(1+\delta)\,F/g'(U_1(0))$, that is, $1+\delta > g'(U_1(0))/g'(u_M)$.
- For small $|n|$, $g'(u_n) < 0$. The previous inequality is satisfied, provided we choose F so small that

$$\left(1 + |g'(u_n)|\frac{1+\delta}{g'(U_1(0))}\right) F < \epsilon\lambda_1(A,0)v_n$$

  for a fixed value of δ.

With these choices, w_n satisfies (A.14). Note that these choices are compatible with condition (A.15). Using (A.16), (A.15) becomes $(1+\delta)\,F/[A\,g'(U_1(0))] < k\,\epsilon$. This holds for small enough F.

Let $F > 0$ be small enough for a w_n defined in (A.13) to be a supersolution with δ, ϵ adequately selected. Now, let $h_n(t)$ be a solution to (1.1) for such $F > 0$ with initial datum $h_n(0)$ satisfying $u_n < h_n(0) < w_n$. Then, $u_n < h_n(t) < w_n$ for all $t > 0$. Therefore, propagation is excluded and the solutions are pinned.

Stationary solutions $u_n(A,F)$ for such $F > 0$ can be obtained as long time limits of solutions $h_n(t)$ to (1.1) when $h_n(0)$ is increasing, tends exponentially to $U_1(A,F)$ (resp., $U_3(A,F)$) at $-\infty$ (resp., ∞), and $u_n < h_n(0) < w_n$. We conclude that $F_c(A) > 0$.

Step 2: $\lambda_1(A,F) > 0$ for $|F| < F_c(A)$ and $\lambda_1(A,F_c(A)) = 0$. To fix ideas, we take $F > 0$. The case $F < 0$ follows by symmetry. From Step 1, we know that $F_c(A) > 0$, and there are stationary solutions $u_n(A,F)$ of (1.1) existing for $F > 0$ small that are increasing from $U_1(F/A)$ to $U_3(F/A)$.

In an analogous way as we did for $F = 0$, we get

$$\lambda_1(A,F) = \min_{\sum r_0^{-2|n|} w_n^2 < \infty} \frac{\sum_n [(w_{n+1} - w_n)^2 + A g'(u_n(A,F)) w_n^2]}{\sum w_n^2}\,. \tag{A.17}$$

This formula defines $\lambda_1(A,F)$ as a continuous function of F. That $\lambda_1(A,0) > 0$ implies $\lambda_1(A,F) > 0$ up to some F_c at which $\lambda_1(A,F_c) = 0$. As long as $\lambda_1(A,F_1) > 0$, we can obtain stationary solutions for $F > F_1$ (close to F_1), as done in Step 1. This procedure cannot continue forever since such stationary solutions do not exist for F close to A: eventually $g(U) = F/A$ ceases to have three solutions, and the stationary wave fronts cannot be constructed. Thus, we must reach a value F_c at which $\lambda_1(A,F_c) = 0$.

Acknowledgments. The authors are indebted to J. M. Vega for a critical reading of the manuscript and helpful comments, and to V. Hakim for pointing out to them the relevance of [7]. A. C. thanks S. P. Hastings and J. B. McLeod for fruitful discussions.

AN ASYMPTOTIC MODEL OF NONADIABATIC CATALYTIC FLAMES IN STAGNATION-POINT FLOW*

STEPHEN B. MARGOLIS† AND TIMOTHY J. GARDNER‡

Abstract. A formal asymptotic model is derived for a nonadiabatic catalytic flame in stagnation-point flow. In the present context, the premixed reaction in the bulk gas is augmented by a surface catalytic reaction on the stagnation plane, where conductive heat losses are allowed to occur. In addition, the thermal effects of a finite-volume combustor are accounted for by allowing for volumetric heat losses from the bulk gas. The analysis exploits the near-equidiffusional limit corresponding to near-unity Lewis numbers, and yields a general nonsteady nonplanar model for the reactionless outer flow subject to boundary conditions that reflect both surface catalysis and distributed chemical reaction in a thin boundary layer. For the case of steady planar combustion, the surface-temperature response indicates the possibility of multiple solution branches, which are shown to be linearly stable, and a corresponding extension of the extinction limit that demonstrates how the presence of a surface catalyst can counterbalance the extinguishing effects of heat loss and stretch in nonadiabatic strained flames. The present model is particularly relevant for small-volume combustors, where the increased surface-to-volume ratio can lead to extinction of the nonadiabatic flame in the absence of a catalyst.

1. Introduction.

The effects of catalysis in combustion problems have long been of interest because of a catalyst's ability to enhance what would otherwise be slow and/or incomplete chemical reactions. Combustion applications include the use of catalysts to increase fuel efficiency, accelerate the conversion of intermediate pollutant species, increase the rate of production of desirable products, and allow flames to be sustained in nonadiabatic environments. The last of these is of particular concern in the present work, which is motivated by a growing interest in the use of catalysts to extend extinction limits in small-volume reactors, or microcombustors. Because such a combustor is characterized by relatively large surface-to-volume ratios, the degree of nonadiabaticity associated with conductive and/or radiative heat losses through the walls of the device is a limiting factor in determining its minimum size. Depending on the geometry, coating one or more surfaces with a catalyst can allow combustion to proceed at lower temperatures than would otherwise be possible.

The geometry of the model problem considered here corresponds to a nonadiabatic stretched flame in stagnation-point flow against a catalytic surface. This is illustrated in Figure 1, where the nonadiabatic effects associated with the finite volume of an actual microcombustor are modeled by a volumetric heat-loss term in the energy

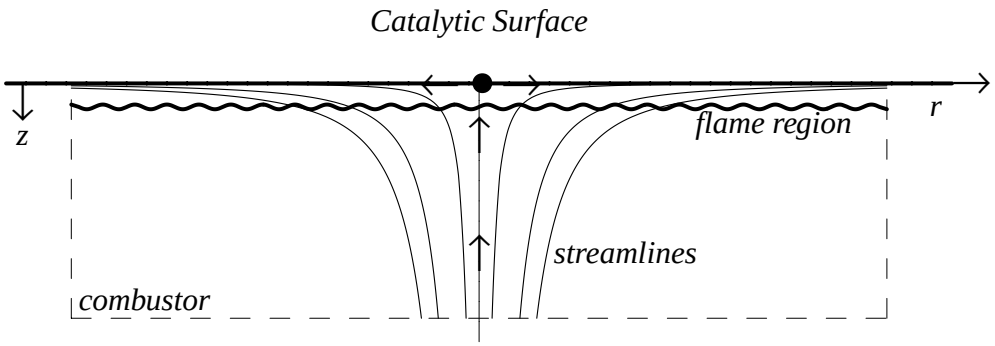

FIG. 1. *Model geometry for a nonadiabatic premixed flame in stagnation-point flow. Heat loss is modeled both volumetrically and by conduction at the catalytic surface. Near extinction, the reaction region is assumed to lie adjacent to the catalytic surface.*

equation and a conductive loss at the catalytic surface. In the absence of heat losses, the semi-infinite geometry depicted in Figure 1 is similar to that considered by others (cf. Law and Sivashinsky [1], Giovangigli and Candel [2], Warnatz et al. [3]), who have analyzed the corresponding adiabatic problem both analytically and numerically. In addition to previous experimental investigations (cf. Law, Ishizuka, and Mizomoto [4], Ikeda, Sato, and Williams [5]), this geometry is also suggested by more recent experiments (Mowery et al. [6]) on small-volume combustors. In the latter application, such a combustor (nominally $2500\mu \times 2500\mu \times 400\mu$) is fed by an inlet tube that blows against a catalytic surface (platinum mounted on a titanium/silicon wafer) and is vented by one or more outlet ports on either the opposite ($2500\mu \times 2500\mu$) face or sides. In those experiments, it was demonstrated, following ignition by the heated catalytic surface, that a nearly flat flame could be sustained under the inlet port, close to the catalytic surface, without further heat addition. In the absence of the catalyst, the level of heat loss was apparently sufficient to extinguish the flame.

The above experimental result was supported by our recent study (Margolis and Gardner [7]) that analyzed the steady-state response of the nonadiabatic semi-infinite problem. In that work, which was restricted to volumetric heat losses, it was shown that a sufficiently strong catalytic effect produced an extension of the extinction limit, allowing a degree of nonadiabaticity that would otherwise extinguish the flame. The present work extends these results by deriving a formal asymptotic model valid for a general nonsteady nonplanar flame. In addition, nonadiabaticity in the present model arises not only from a volumetric heat-loss term in the conservation equation for temperature, but also from a conductive loss term in the boundary condition at the catalytic surface. An analysis of the solution response corresponding to steady planar burning again predicts the possibility of multiple solutions, which are now shown to be linearly stable, and an extension of the extinction limit for sufficiently strong catalytic influences. In the current model, this extinction limit is shown to depend on two parameters associated with the effects of catalysis and on one other parameter that incorporates the combined effects of volumetric heat losses, conductive heat losses at the catalytic surface, and thermal/diffusive effects associated with the deviation in the Lewis number from unity.

2. Model formulation. Based on the above overall description of the model problem, the flame is assumed to be stabilized in a cylindrically symmetric stagnation-point flow field that occupies the domain $0 < \tilde{z} < \infty$, $0 < \tilde{r} < \infty$, where $\tilde{z}$ and $\tilde{r}$ are

the axial and radial coordinates, respectively, and the tildes denote dimensional quantities. The catalytic surface, across which conductive heat transfer is allowed, thus corresponds to the plane $\tilde{z} = 0$, and the effects of heat loss arising from the remaining finite dimensions of the actual combustor are represented in a volumetric fashion. Although one may consider the portion of the flow field of interest to be governed by a boundary-layer formulation (cf. [1]), it turns out that qualitatively identical results are obtained if potential flow and weak thermal expansion are assumed [7]. We thus make these assumptions for simplicity, resulting in the specified classical flow field $(\tilde{u}, \tilde{w}) = \tilde{\nabla}\tilde{\phi}$, where $\tilde{u}$ and $\tilde{w}$ are the radial and axial velocities, respectively, $\tilde{\phi} = -\tilde{a}(\tilde{z}^2 - \tilde{r}^2/2)$ is the velocity potential, and $\tilde{a}$ is the strain rate. Equivalently, $\tilde{u}(\tilde{r}, \tilde{z}) = -\tilde{r}^{-1}\partial\tilde{\psi}/\partial\tilde{z} = \tilde{a}\tilde{r}$ and $\tilde{w}(\tilde{r}, \tilde{z}) = \tilde{r}^{-1}\partial\tilde{\psi}/\partial\tilde{r} = -2\tilde{a}\tilde{z}$, where $\tilde{\psi}(\tilde{r}, \tilde{z}) = -\tilde{a}\tilde{r}^2\tilde{z}$ is the stream function.

Given this flow field, a closed problem for the temperature $\tilde{T}$ and mass fraction Y of the deficient component of the mixture (i.e., the mass fraction of fuel if the initial composition is lean, and the mass fraction of oxidizer if it is rich) in the region $0 < \tilde{z} < \infty$ can be specified. This is conveniently written in dimensionless form by first introducing a characteristic flame temperature $\tilde{T}_f$ (to be determined) and the nondimensional quantities

$$z = \sqrt{\frac{\tilde{a}}{\tilde{\lambda}}}\,\tilde{z}, \quad t = \tilde{a}\tilde{t}, \quad y = \frac{Y}{Y_u}, \quad \Theta = \frac{\tilde{T} - \tilde{T}_u}{\tilde{T}_f - \tilde{T}_u}, \quad \sigma = \frac{\tilde{T}_{sub} - \tilde{T}_u}{\tilde{T}_f - \tilde{T}_u},$$

$$T_f = \frac{\tilde{T}_f}{\tilde{T}_u}, \quad Le = \frac{\tilde{\lambda}}{\tilde{\lambda}_m}, \quad q = \frac{Y_u\tilde{Q}}{\tilde{T}_f - \tilde{T}_u}, \quad H = \frac{\tilde{H}}{\tilde{a}}, \quad K = \frac{\tilde{K}}{\sqrt{\tilde{a}\tilde{\lambda}}}, \tag{1}$$

$$\beta = \frac{\tilde{E}_g}{\tilde{R}^\circ\tilde{T}_f}\big(1 - \tilde{T}_u/\tilde{T}_f\big), \quad \nu = \frac{\tilde{E}_s}{\tilde{E}_g},$$

where ϑ is the angular coordinate, $\tilde{T}_u$ and Y_u are the unburned (ambient) temperature and mass fraction of the fresh mixture, $\tilde{\lambda}$ and $\tilde{\lambda}_m$ are the thermal and mass diffusivities, respectively, $\tilde{Q}$ is the heat release (in units of temperature), $\tilde{E}_g$ is the activation energy of the gas-phase reaction, $\tilde{A}_g$ and n are the rate coefficient and reaction order, respectively, $\tilde{R}^\circ$ is the gas constant, and $\tilde{H}$ is a volumetric heat-loss rate coefficient. The last of these, which is represented in the last term of (3) below, reflects a phenomenological volumetric representation of heat losses across the noncatalytic surfaces of an actual finite-volume combustor. An approximation for $\tilde{H}$ may be obtained from a knowledge of the corresponding surface heat-transfer coefficients and the surface-to-volume ratio of the combustor. Other quantities that arise in the specification of the boundary conditions include Y_s and $\tilde{T}_s$, which represent values at $\tilde{z} = 0$ that are to be determined. (It is assumed that the catalytic surface is highly conductive in the transverse direction, so that $\tilde{T}_s$ and Y_s are independent of $\tilde{r}$ and ϑ.) The temperature $\tilde{T}_{sub}$, on the other hand, is the temperature of the catalyst-coated substrate and is allowed to differ from the ambient temperature $\tilde{T}_u$. The boundary conditions given below also model the catalyst as an exothermic reaction at the surface $\tilde{z} = 0$, distinguished from the reaction rate in the bulk gas by a surface rate coefficient $\tilde{A}_s$ and a different activation energy $\tilde{E}_s$. In this work, the catalytic surface is explicitly allowed to be nonadiabatic ($\tilde{K}$ is the corresponding surface heat-transfer coefficient), with $\tilde{T}_s > (<)\ \tilde{T}_{sub}$ corresponding to a thermal loss (gain). The latter scenario can occur if, for example, the substrate is heated, but aside from this loss (gain), heat produced by the catalytic surface reaction is conducted normal to the

surface into the bulk gas. (There is no convective contribution since $\tilde{w} = 0$ at the surface.) The catalytic effect itself is modeled by assuming that $\tilde{E}_s < \tilde{E}_g$, thus allowing the surface reaction to take place at lower temperatures and consequently raising the temperature of the surrounding region such that the gas-phase reaction, if relatively weak in the absence of catalysis, is further encouraged. Finally, it is also useful to define the reaction-rate parameters Λ_s, Λ_g and their ratio τ as

$$\Lambda_s = \frac{\tilde{A}_s Y_u^{n-1}}{\sqrt{\tilde{a}\tilde{\lambda}}}\, e^{-\tilde{E}_s/\tilde{R}^\circ \tilde{T}_f}, \quad \Lambda_g = \frac{\tilde{A}_g Y_u^{n-1}}{\tilde{a}}\, e^{-\tilde{E}_g/\tilde{R}^\circ \tilde{T}_f},$$
$$\tau = \frac{\Lambda_s}{\Lambda_g} = \sqrt{\frac{\tilde{a}}{\tilde{\lambda}}}\, \frac{\tilde{A}_s}{\tilde{A}_g}\, e^{(\tilde{E}_g - \tilde{E}_s)/\tilde{R}^\circ \tilde{T}_f}. \tag{2}$$

With these definitions, the nondimensional forms of the energy and species conservation equations are given by

$$\frac{\partial \Theta}{\partial t} + r\frac{\partial \Theta}{\partial r} - 2z\frac{\partial \Theta}{\partial z} = \nabla^2 \Theta + q\Lambda_g y^n\, e^{\beta(\Theta-1)/[T_f^{-1} + (1 - T_f^{-1})\Theta]} - H\Theta, \quad 0 < z < \infty, \tag{3}$$

$$\frac{\partial y}{\partial t} + r\frac{\partial y}{\partial r} - 2z\frac{\partial y}{\partial z} = Le^{-1}\nabla^2 y - \Lambda_g y^n\, e^{\beta(\Theta-1)/[T_f^{-1} + (1 - T_f^{-1})\Theta]}, \quad 0 < z < \infty, \tag{4}$$

subject to the boundary conditions

$$\Theta \to 0, \quad y \to 1 \quad \text{as} \ \ z \to \infty, \tag{5}$$

$$\left.\frac{\partial \Theta}{\partial z}\right|_{z=0} = -q\tau\Lambda_g y_s^n\, e^{\nu\beta(\Theta_s - 1)/[T_f^{-1} + (1 - T_f^{-1})\Theta_s]} + K(\Theta_s - \sigma),$$
$$Le^{-1}\left.\frac{\partial y}{\partial z}\right|_{z=0} = \tau\Lambda_g y_s^n\, e^{\nu\beta(\Theta_s - 1)/[T_f^{-1} + (1 - T_f^{-1})\Theta_s]}, \tag{6}$$

where Θ_s and y_s denote the values of Θ and y at $z = 0$ and $\nabla^2 = \partial^2/\partial r^2 + r^{-1}\partial/\partial r + r^{-2}\partial^2/\partial \vartheta^2 + \partial^2/\partial z^2$. Thus, in addition to the distributed chemical reaction and volumetric heat losses represented by the nondiffusive terms on the right-hand sides of (3) and (4), surface combustion and conductive thermal losses across the catalytic surface are also specifically accounted for in the present model by the terms on the right-hand sides of the boundary conditions (6).

3. Asymptotic analysis of the model. It is assumed in the present work that the Zel'dovich number $\beta \gg 1$ and that $\nu \sim \mathrm{O}(1)$. Thus, the activation energies of both the bulk-gas and catalytic reactions are taken to be large, although it is logically expected that $\nu < 1$, implying that the catalytic surface reaction can be sustained at lower temperatures than the distributed gas-phase reaction. In this realistic asymptotic limit, there are two possible burning regimes, corresponding to a thin gaseous reaction zone that is either adjacent to the catalytic surface or an O(1) distance away. Both regimes have been discussed in the context of the adiabatic problem (cf. [1], [2]), where it has been heuristically argued, based on the strained nature of the flow field, that as the strain rate increases toward extinction, the gas flame will tend to either intrude onto the catalytic surface for $Le < 1$ or remain at an O(1) standoff distance for $Le > 1$ [1]. This conclusion is based on the physical argument that a

planar flame gains chemical energy and loses thermal energy by diffusion in the normal direction with respect to the flame, whereas convection, which is nonnormal to the flame, supplies chemical energy but removes thermal energy. Consequently, if energy losses from the flame to the diverging flow via thermal diffusion outweigh energy gains to the flame from mass diffusion ($Le > 1$), the flame temperature T_f would be expected to decrease and the flame would tend to extinguish prior to being pushed against the catalytic surface. On the other hand, if $Le < 1$, T_f would tend to increase and extinction would only tend to occur (due to sufficiently reduced residence time) after the flame had intruded against the surface. However, a detailed analysis [2] suggests more generally that the flame will lie adjacent to the stagnation surface prior to extinction either when the Lewis number is less than a critical value that is somewhat greater than unity or when the activation-energy ratio $\nu < 1/2$, corresponding to a sufficiently low surface activation energy and hence a more active catalytic reaction. It is only in this regime that catalysis can play a significant role because, if the bulk-gas reaction goes to completion at a finite standoff distance, reactants are depleted before reaching the surface and the catalyst then plays no role.

As in our previous study [7], the present work seeks in part to investigate the role of catalysis in counterbalancing the extinguishing effects of heat loss. We thus restrict our analysis to the intrusive regime in which the thin distributed reaction zone lies adjacent to the catalytic surface. Based on previous asymptotic studies of nonadiabatic combustion problems (cf. Matkowsky and Olagunju [8], Booty, Margolis, and Matkowsky [9], Kaper et al. [10], Margolis and Johnston [11]), it is clear that extinction then occurs for $O(\beta^{-1})$ values of the heat-loss parameters H and K. Accordingly, we define the corresponding scaled parameters h and k as

$$H = \frac{h}{\beta}, \qquad K = \frac{k}{\beta}, \tag{7}$$

where extinction is expected to occur for sufficiently large values of h and k. In addition, it will prove useful, for the purpose of deriving a closed asymptotic model (cf. Matkowsky and Sivashinsky [12]), to realistically restrict consideration to the near-equidiffusional regime

$$Le = 1 + \frac{l}{\beta}, \tag{8}$$

where l is the scaled departure of the Lewis number from unity.

Based on the preceding discussion, there are now two regions to consider in the asymptotic limit $\beta \gg 1$; namely, an outer reactionless region $z > 0$, in which temperatures are sufficiently low that the reaction terms in (3) and (4) become exponentially small, and a thin distributed reaction zone adjacent to the surface $z = 0$, on which the catalytic reaction occurs. Considering first the outer region, where z and $1 - \Theta$ are both $O(1)$, we seek solutions in the expanded form

$$\Theta^{(o)} \sim \Theta_0 + \beta^{-1}\Theta_1 + \cdots, \qquad y^{(o)} \sim y_0 + \beta^{-1}y_1 + \cdots. \tag{9}$$

Substituting these scalings and expansions into the reactionless version of (8)–(10), we obtain, at the zeroth order, the equations

$$\begin{aligned} &\frac{\partial \Theta_0}{\partial t} + r\frac{\partial \Theta_0}{\partial r} - 2z\frac{\partial \Theta_0}{\partial z} = \nabla^2 \Theta_0, \\ &\frac{\partial y_0}{\partial t} + r\frac{\partial y_0}{\partial r} - 2z\frac{\partial y_0}{\partial z} = \nabla^2 y_0, \quad 0 < z < \infty, \end{aligned} \tag{10}$$

subject to

$$\Theta_0 \to 0, \quad y_0 \to 1 \ \text{ as } \ z \to \infty, \qquad \Theta_0 \to 1, \quad y_0 \to 0 \ \text{ as } \ z \to 0, \tag{11}$$

where the boundary conditions at $z = 0$ are immediately deduced from the form of the inner expansions given below. Defining the enthalpy variable $S_0 = \Theta_0 + y_0$ and summing (10) and (11) thus determines a closed problem for S_0 as

$$\frac{\partial S_0}{\partial t} + r\frac{\partial S_0}{\partial r} - 2z\frac{\partial S_0}{\partial z} = \nabla^2 S_0, \qquad 0 < z < \infty, \tag{12}$$

$$S_0 \to 1 \ \text{ as } \ z \to 0, \ \infty. \tag{13}$$

Assuming compatible initial conditions (those that are consistent with the result (14) below), the solution to (12) and (13) is simply $S_0 = 1$, and thus

$$S_0 = y_0 + \Theta_0 = 1. \tag{14}$$

At the first order, the equations for Θ_1 and y_1 are given by

$$\begin{aligned} \frac{\partial \Theta_1}{\partial t} + r\frac{\partial \Theta_1}{\partial r} - 2z\frac{\partial \Theta_1}{\partial z} &= \nabla^2 \Theta_1 - h\Theta_0, \\ \frac{\partial y_1}{\partial t} + r\frac{\partial y_1}{\partial r} - 2z\frac{\partial y_1}{\partial z} &= \nabla^2 y_1 - l\nabla^2 y_0, \qquad 0 < z < \infty, \end{aligned} \tag{15}$$

subject to

$$\Theta_1 \to 0, \quad y_1 \to 0 \ \text{ as } \ z \to \infty, \tag{16}$$

and appropriate matching conditions, given below, as $z \to 0$. Defining the second-order enthalpy variable $S_1 = \Theta_1 + y_1$, the equation for S_1, obtained from summing the equations of (15) and the use of (14), is given by

$$\frac{\partial S_1}{\partial t} + r\frac{\partial S_1}{\partial r} - 2z\frac{\partial S_1}{\partial z} = \nabla^2 S_1 + l\nabla^2 \Theta_0 - h\Theta_0, \qquad 0 < z < \infty, \tag{17}$$

where

$$S_1 \to 0, \quad \Theta_0 \to 0 \ \text{ as } \ z \to \infty. \tag{18}$$

In the inner region adjacent to the surface $z = 0$, we introduce the stretched coordinate η and the scaled rate coefficients $\hat{\lambda}$ and $\hat{\tau}$ according to

$$\eta = \beta z, \quad \Lambda_g = \beta^{n+1}\hat{\lambda}, \quad \tau = \beta^{-1}\hat{\tau}, \tag{19}$$

and seek solutions in the expanded form

$$\Theta^{(i)} \sim 1 + \beta^{-1}\theta_1 + \beta^{-2}\theta_2 + \cdots, \qquad y^{(i)} \sim \beta^{-1}\zeta_1 + \beta^{-2}\zeta_2 + \cdots. \tag{20}$$

Substituting these expansions and scalings into (3), (4), and (6), we obtain the first-order inner problem as

$$\frac{\partial^2 \theta_1}{\partial \eta^2} + q\hat{\lambda}\zeta_1^n e^{\theta_1} = 0, \qquad \frac{\partial^2 \zeta_1}{\partial \eta^2} - \hat{\lambda}\zeta_1^n e^{\theta_1} = 0, \tag{21}$$

subject to the inner boundary and matching conditions

$$\left.\frac{\partial\theta_1}{\partial\eta}\right|_{\eta=0} = -q\hat{\tau}\hat{\lambda}\zeta_s^n e^{\nu\theta_s}, \quad \left.\frac{\partial\zeta_1}{\partial\eta}\right|_{\eta=0} = \hat{\tau}\hat{\lambda}\zeta_s^n e^{\nu\theta_s}, \tag{22}$$

$$\theta_1 \sim \Theta_1\big|_{z=0} + \eta\left.\frac{\partial\Theta_0}{\partial z}\right|_{z=0}, \quad \zeta_1 \sim y_1\big|_{z=0} + \eta\left.\frac{\partial y_0}{\partial z}\right|_{z=0}, \tag{23}$$

where θ_s and ζ_s, respectively, denote θ_1 and ζ_1 evaluated at $\eta = 0$. Combining the equations of (21) so as to eliminate the reaction term and integrating the result, we thus obtain

$$\frac{\partial\theta_1}{\partial\eta} + q\frac{\partial\zeta_1}{\partial\eta} = 0, \tag{24}$$

where the boundary conditions (22) have been used to evaluate the constant of integration. Applying the matching conditions (23) and using the result (14) then gives the requirement

$$\left.\frac{\partial\Theta_0}{\partial z}\right|_{z=0} + q\left.\frac{\partial y_0}{\partial z}\right|_{z=0} = (q-1)\left.\frac{dy_0}{dz}\right|_{z=0} = 0. \tag{25}$$

Since y_0 must satisfy the problem given by (10) and (11), the last equality can only be satisfied in general if $q = 1$, which, based on the definition of q in (1), determines the characteristic flame temperature $\tilde{T}_f$ as the adiabatic flame temperature $\tilde{T}_f = \tilde{T}_u + Y_u\tilde{Q}$. Using this result and integrating (24) then gives, upon applying the matching conditions (23), the relation

$$\theta_1 + \zeta_1 = S_1\big|_{z=0}. \tag{26}$$

Returning to the first equation in (21), we substitute (26) for ζ_1 into the reaction-rate expression to obtain a scalar equation for θ_1 as

$$\frac{\partial^2\theta_1}{\partial\eta^2} + \hat{\lambda}\big(S_1\big|_{z=0} - \theta_1\big)^n e^{\theta_1}. \tag{27}$$

Multiplying this result by $\partial\theta_1/\partial\eta$ and integrating, we obtain, upon use of the matching condition for θ_1, the first integral

$$\left(\frac{\partial\theta_1}{\partial\eta}\right)^2 + 2\hat{\lambda}\int_{-\infty}^{\theta_1}\big(S_1\big|_{z=0} - \bar{\theta}_1\big)^n e^{\bar{\theta}_1}d\bar{\theta}_1 = \left(\left.\frac{\partial\Theta_0}{\partial z}\right|_{z=0}\right)^2. \tag{28}$$

Thus, evaluating (28) at $\eta = 0$ according to the first boundary condition in (22) yields an implicit relation for θ_s given by

$$\hat{\tau}^2\hat{\lambda}^2\big(S_1\big|_{z=0} - \theta_s\big)^{2n} e^{2\nu\theta_s} + 2\hat{\lambda}G_n\big(\theta_s; S_1\big|_{z=0}\big) = \left(\left.\frac{\partial\Theta_0}{\partial z}\right|_{z=0}\right)^2, \tag{29}$$

where (26) implies (since the surface mass fraction $\zeta_1 \geq 0$) the physical restriction $\theta_s \leq S_1\big|_{z=0}$ and

$$G_n\big(\theta_s; S_1\big|_{z=0}\big) = \int_{-\infty}^{\theta_s}\big(S_1\big|_{z=0} - \bar{\theta}_1\big)^n e^{\bar{\theta}_1}d\bar{\theta}_1 = \int_{-\theta_s}^{\infty}\big(\chi + S_1\big|_{z=0}\big)^n e^{-\chi}\,d\chi. \tag{30}$$

An additional relation that will be needed is obtained from a consideration of the second-order inner problem, which, since $q = 1$, is given by

$$\begin{aligned} &\frac{\partial^2\theta_2}{\partial\eta^2} + \hat{\lambda} f(\zeta_1, \zeta_2, \theta_1, \theta_2; n) e^{\theta_1} = 0, \\ &\frac{\partial^2\zeta_2}{\partial\eta^2} - l\frac{\partial^2\zeta_1}{\partial\eta^2} - \hat{\lambda} f(\zeta_1, \zeta_2, \theta_1, \theta_2; n) e^{\theta_1} = 0, \end{aligned} \tag{31}$$

$$\begin{aligned} &\left.\frac{\partial\theta_2}{\partial\eta}\right|_{\eta=0} = -\hat{\tau}\hat{\lambda} g(\zeta_s, \hat{\zeta}_s, \theta_s, \hat{\theta}_s; n) e^{\nu\theta_s} + k(1-\sigma), \\ &\left.\frac{\partial\zeta_2}{\partial\eta}\right|_{\eta=0} - l\left.\frac{\partial\zeta_1}{\partial\eta}\right|_{\eta=0} = \hat{\tau}\hat{\lambda} g(\zeta_s, \hat{\zeta}_s, \theta_s, \hat{\theta}_s; n) e^{\nu\theta_s}, \end{aligned} \tag{32}$$

$$\begin{aligned} &\theta_2 \sim \Theta_2\big|_{z=0} + \eta\left.\frac{\partial\Theta_1}{\partial z}\right|_{z=0} + \frac{1}{2}\eta^2\left.\frac{\partial^2\Theta_0}{\partial z^2}\right|_{z=0}, \\ &\zeta_2 \sim y_2\big|_{z=0} + \eta\left.\frac{\partial y_1}{\partial z}\right|_{z=0} + \frac{1}{2}\eta^2\left.\frac{\partial^2 y_0}{\partial z^2}\right|_{z=0}, \end{aligned} \tag{33}$$

where $\hat{\theta}_s$ and $\hat{\zeta}_s$, respectively, denote θ_2 and ζ_2 evaluated at $\eta = 0$, $f(\zeta_1, \zeta_2, \theta_1, \theta_2; n) = n\zeta_2\zeta_1^{n-1} + \zeta_1^n\big[\theta_2 - (1 - T_f^{-1})\theta_1^2\big]$, and $g(\zeta_s, \hat{\zeta}_s, \theta_s, \hat{\theta}_s; n) = n\hat{\zeta}_s\zeta_s^{n-1} + \nu\zeta_s^n\big[\hat{\theta}_s - (1 - T_f^{-1})\theta_s^2\big]$. Integrating the sum of (31) and applying the boundary conditions (32), we obtain

$$\frac{\partial\theta_2}{\partial\eta} + \frac{\partial\zeta_2}{\partial\eta} + l\frac{\partial\theta_1}{\partial\eta} = k(1-\sigma), \tag{34}$$

where we have used the result (24) with $q = 1$. Applying the matching conditions (33) thus yields the condition

$$\left.\frac{\partial S_1}{\partial z}\right|_{z=0} = -l\left.\frac{\partial\Theta_0}{\partial z}\right|_{z=0} + k(1-\sigma). \tag{35}$$

Collecting the preceding results, we have thus succeeded in deriving a closed asymptotic model for the outer temperature- and enthalpy-perturbation variables Θ_0 and S_1, and the surface-temperature coefficient θ_s. In particular, solutions for these variables are determined from the first equality of (10) and from (17) in the half-space $0 < z < \infty$, the corresponding boundary conditions (11) and (18) at $z = 0$ and as $z \to \infty$, and the derived conditions (29) and (35) at $z = 0$. In what follows, we apply this model to obtain multiple basic solutions corresponding to steady planar flames, as well as corresponding extinction limits beyond which no solutions of this type exist.

4. Steady plane-flame solutions. The basic solution $\bar{\Theta} = \Theta_0(z)$, $\bar{S} = S_1(z)$, and $\bar{\theta}_s = \theta_s = const.$, corresponding to steady planar combustion, is governed by the time-independent, one-dimensional version of (17) and the first equality of (10), subject to (11), (18), (29), and (35). In particular,

$$-2z\frac{d\bar{\Theta}}{\partial z} = \frac{d^2\bar{\Theta}}{dz^2}, \quad -2z\frac{d\bar{S}}{dz} = \frac{d^2\bar{S}}{dz^2} + l\frac{d^2\bar{\Theta}}{dz^2} - h\bar{\Theta}, \quad 0 < z < \infty, \tag{36}$$

$$\bar{S} \to 0, \quad \bar{\Theta} \to 0 \ \text{ as } \ z \to \infty. \tag{37}$$

$$\bar{\Theta}(0) = 1, \quad \left.\frac{d\bar{S}}{dz}\right|_{z=0} = -l \left.\frac{d\bar{\Theta}}{dz}\right|_{z=0} + k(1-\sigma), \tag{38}$$

$$\hat{\tau}^2 \hat{\lambda}^2 \left[\bar{S}(0) - \bar{\theta}_s\right]^{2n} e^{2\nu\bar{\theta}_s} + 2\hat{\lambda} G_n\left(\bar{\theta}_s; \bar{S}(0)\right) = \left(\left.\frac{d\bar{\Theta}}{dz}\right|_{z=0} \right)^2, \quad \bar{\theta}_s \le \bar{S}(0). \tag{39}$$

We remark that while (36)–(38) are sufficient to determine $\bar{\Theta}$ and $\bar{S}$, the requirement that (39) produce physical solutions for the surface-temperature coefficient $\bar{\theta}_s$ will yield parameter limits associated with extinction.

The solution for $\bar{\Theta}$ satisfying the first equation of (36) and the boundary conditions in (37) and (38) is easily obtained as

$$\bar{\Theta}(z) = \operatorname{erfc}(z) = 1 - \frac{2}{\sqrt{\pi}} \int_0^z e^{-\bar{z}^2} d\bar{z}. \tag{40}$$

Substituting this result into the second equation of (36) then gives an inhomogeneous equation for $\bar{S}$ as

$$\frac{d^2\bar{S}}{dz^2} + 2z \frac{d\bar{S}}{dz} = h \operatorname{erfc}(z) - \frac{4l}{\sqrt{\pi}}\, z\, e^{-z^2}. \tag{41}$$

Homogeneous solutions of (41) are 1 and $\operatorname{erfc}(z)$, and thus a particular solution of (41) is obtained, using the variation-of-parameters formula, as

$$\begin{aligned} \bar{S}_p = \frac{\sqrt{\pi}}{2} \Bigg\{ & - \int_z^\infty \operatorname{erfc}(\bar{z}) \left[h \operatorname{erfc}(\bar{z}) - \frac{4l}{\sqrt{\pi}} \bar{z}\, e^{-\bar{z}^2} \right] e^{\bar{z}^2} d\bar{z} \\ & - \operatorname{erfc}(z) \int_0^z \left[h \operatorname{erfc}(\bar{z}) - \frac{4l}{\sqrt{\pi}} \bar{z}\, e^{-\bar{z}^2} \right] e^{\bar{z}^2} d\bar{z} \Bigg\}. \end{aligned} \tag{42}$$

Hence, using the fact that $4\int_z^\infty \bar{z} \operatorname{erfc}(\bar{z})\, d\bar{z} = (1-2z^2)\operatorname{erfc}(z) + (2/\sqrt{\pi})\, z \exp(-z^2)$, the complete solution of (41) can be written as

$$\begin{aligned} \bar{S}(z) = c_1 + c_2 \operatorname{erfc}(z) - \frac{\sqrt{\pi}}{2} h \left[\int_z^\infty e^{\bar{z}^2} \operatorname{erfc}^2(\bar{z})\, d\bar{z} + \operatorname{erfc}(z) \int_0^z e^{\bar{z}^2} \operatorname{erfc}(\bar{z})\, d\bar{z} \right] \\ + \frac{l}{2} \left[\operatorname{erfc}(z) + \frac{2}{\sqrt{\pi}}\, z\, e^{-z^2} \right], \end{aligned} \tag{43}$$

where application of the boundary conditions (37) and (38) for $\bar{S}$ determines c_1 and c_2 as

$$c_1 = 0, \qquad c_2 = -l - \frac{\sqrt{\pi}}{2}\, k(1-\sigma). \tag{44}$$

The solutions $\bar{\Theta}$ and $\bar{S}$ are displayed in Figure 2.

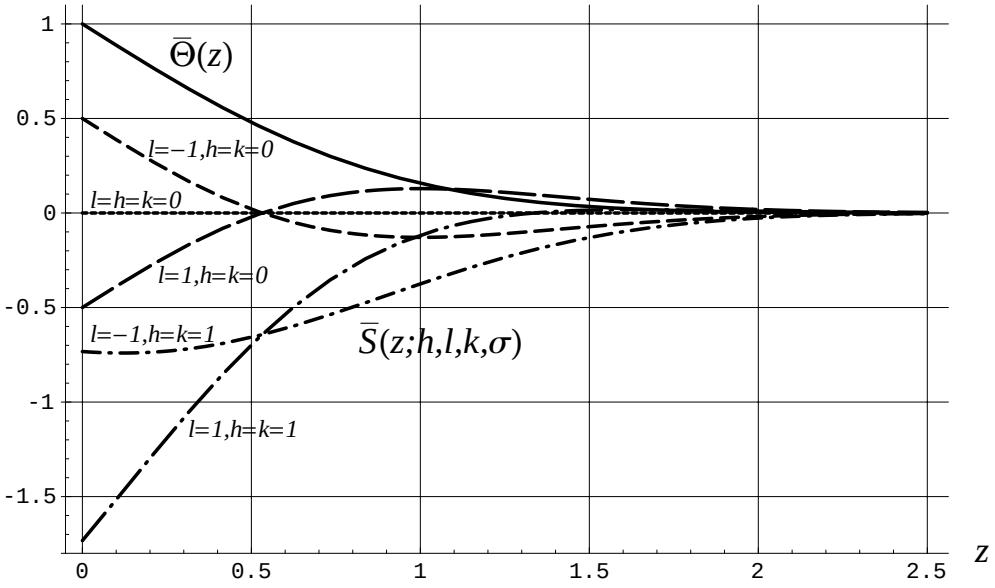

FIG. 2. *Outer solution profiles* $\bar{\Theta}(z)$ *and* $\bar{S}(z;h,l,k,\sigma)$. *The several curves for* $\bar{S}$ *were drawn for* $\sigma = 0$ *and various values of the parameters* h, l, *and* k *as indicated.*

From (40), (43), and (44), we note that $\bar{S}(0)$ is given by

$$\bar{S}(0) = -\frac{l}{2} - \frac{\sqrt{\pi}}{2}\big[k(1-\sigma)+\gamma h\big], \qquad \gamma = \int_0^\infty e^{\bar{z}^2}\operatorname{erfc}^2(\bar{z})\,d\bar{z} \doteq 0.391066. \tag{45}$$

Substituting this result and $d\bar{\Theta}/dz|_{z=0} = -2/\sqrt{\pi}$ into (39) then gives the condition for $\bar{\theta}_s$ as

$$\frac{2}{\pi\hat{\lambda}} = \left[G_n(\bar{\theta}_s;-\Psi) + \frac{1}{2}\hat{\tau}^2\hat{\lambda}(-\bar{\theta}_s-\Psi)^{2n}e^{2\nu\bar{\theta}_s}\right], \quad -\bar{\theta}_s \geq \Psi, \tag{46}$$

where

$$\Psi \equiv \frac{l}{2} + \frac{\sqrt{\pi}}{2}\big[k(1-\sigma)+\gamma h\big] = -\bar{S}(0) \tag{47}$$

and the restriction $-\bar{\theta}_s \geq \Psi$ follows from (26) evaluated at $z = 0$ and the fact that the leading-order mass-fraction coefficient $\zeta_1 \geq 0$. The parameter group Ψ represents a sum of parametric influences arising from conductive losses ($k > 0$) at the catalytic surface, volumetric heat losses ($h > 0$) associated with the finite size of the combustor, and unequal rates of thermal and mass diffusion ($l \neq 0$). We note that Ψ is generally positive for sufficiently large values of the heat-loss coefficients, which, given our present focus on nonadiabaticity, is the main regime of interest here. However, for sufficiently small values of these parameters and a Lewis number less than unity ($l < 0$), Ψ can take on negative values as well. In that case, the minimum value $-\bar{\theta}_s = \Psi$ corresponds to a surface temperature that exceeds the adiabatic flame temperature for freely-propagating flames, consistent with the known dependence of the flame temperature on Lewis number in the present strained geometry (cf. [1], [7]).

Equation (46) provides a relationship for the surface-temperature coefficient $\bar{\theta}_s$, which, according to (20), reflects the scaled leading-order temperature perturbation

at the nonadiabatic catalytic surface from the normalized flame temperature of unity. As discussed in detail in the following section, (46) also admits a physical solution for $\bar{\theta}_s$ only for parameter values that do not exceed a critical condition, and thus (46) also defines an extinction criterion for steady planar burning, beyond which the present solution does not exist. As will also be shown below, the result (46) is consistent with our previous analysis [7], which was restricted to a steady, planar flame at the outset, with $k = 0$ and $Le \sim \mathrm{O}(1)$.

5. Extinction limits for steady planar combustion. The integral represented by $G_n(\bar{\theta}_s; -\Psi)$, which can also be expressed in terms of the incomplete gamma function $\Gamma(b, x) = \int_x^\infty t^{b-1}e^{-t}\,dt$ as $G_n(\bar{\theta}_s; -\Psi) = e^{-\Psi}\Gamma(n+1, -\bar{\theta}_s - \Psi)$, can be evaluated explicitly for integer values of the reaction order n. In particular, we have

$$G_0(\bar{\theta}_s; \Psi) = e^{\bar{\theta}_s}, \quad G_1(\bar{\theta}_s; -\Psi) = \big(1 - \bar{\theta}_s - \Psi\big)e^{\bar{\theta}_s}, \qquad G_2(\bar{\theta}_s; -\Psi) = \big[1 + \big(1 - \bar{\theta}_s - \Psi\big)^2\big]e^{\bar{\theta}_s}, \ldots. \tag{48}$$

Hence, restricting further consideration to the case $n = 1$, (46) may be written as

$$\alpha_1 = (1 - \bar{\theta}_s - \Psi)e^{\bar{\theta}_s} + \alpha_2(-\bar{\theta}_s - \Psi)^2 e^{2\nu\bar{\theta}_s}, \quad -\bar{\theta}_s \geq \Psi, \tag{49}$$

where we have defined the parameters α_1 and α_2 as

$$\alpha_1 = \frac{2}{\pi\hat{\lambda}}, \qquad \alpha_2 = \frac{1}{2}\hat{\tau}^2\hat{\lambda}. \tag{50}$$

Here, α_1, which is inversely proportional to $\hat{\lambda}$ and hence Λ_g, may be regarded, according to the definition of Λ_g in (2), as a measure of either the strain rate $\tilde{a}$ or the reciprocal of the gas-phase reaction rate. On the other hand, α_2, which is proportional to $\hat{\tau}^2\hat{\lambda}$ or to $(\Lambda_s/\Lambda_g)^2\Lambda_g$, is independent of $\tilde{a}$ but does represent a relative scaled measure of the surface reaction-rate coefficient with respect to that of the bulk gas (in units of the gas-phase rate). Equation (49) is thus an implicit relation for $\bar{\theta}_s$ as a function of the four parameter groups α_1, α_2, ν, and Ψ.

Before proceeding, we note that (49) is similar in form to that derived previously in the absence of heat losses (cf. [1]) and in the presence of volumetric heat losses only [7]. In the latter case, the results are equivalent, provided we set $k = 0$ in the definition of Ψ and restrict Le, which was regarded as O(1) in [7], to be an $\mathrm{O}(1/\beta)$ perturbation of unity, as in the present study. Indeed, setting $k = 0$ and defining $\theta_s^* = \bar{\theta}_s + l/2$, $\hat{\alpha}_1 = \alpha_1 e^{l/2}$, and $\hat{\alpha}_2 = \alpha_2 e^{l/2-\nu l}$, we recover, to O(1), the corresponding expression obtained in [7]. In deriving this result, we note that because $T_f = 1 + Q/\sqrt{Le}$ (cf. [1], [7]), where $Q = \tilde{Y}_u\tilde{Q}/\tilde{T}_u$, the Lewis number enters into the definition of both Λ_g and Λ_s (or τ) such that, to O(1), $\hat{\alpha}_1$ and $\hat{\alpha}_2$ are equivalent to the α_1 and α_2 defined in [7].

The surface-temperature response predicted by (49) is briefly summarized as follows. In particular, rather than consider the implicit solution of (49) for $\bar{\theta}_s$, it is convenient to instead analyze the explicit algebraic behavior of $\alpha_1(\bar{\theta}_s; \alpha_2, \Psi, \nu)$.Thus, in the absence of catalysis ($\alpha_2 = 0$), equation (49) is reduced to

$$\alpha_1 = (1 - \bar{\theta}_s - \Psi)e^{\bar{\theta}_s}, \tag{51}$$

where we again note that physical solutions are always restricted to $-\bar{\theta}_s \geq \Psi$, where the lower limit corresponds, according to (26), to complete consumption of reactants

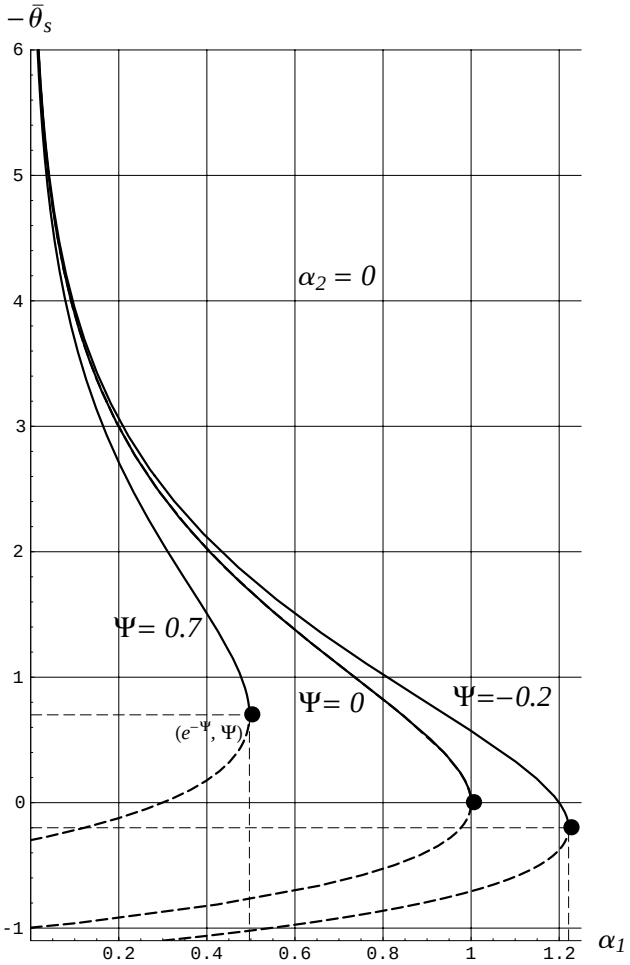

FIG. 3. *Solution response in the absence of catalysis ($\alpha_2 = 0$) for reaction order $n = 1$. Physical solutions (solid curve) are restricted to $-\bar{\theta}_s \geq \Psi$. A steady planar solution does not exist for $\alpha_1 > \alpha_1^e$, where α_1^e is the extinction limit.*

by the gas-phase reaction (i.e., $\zeta_s = 0$). The solution curve $\alpha_1(-\bar{\theta}_s)$, plotted as $\bar{\theta}_s(\alpha_1)$, is shown in Figure 3. Since no steady planar solution exists for $\alpha_1 > e^{-\Psi}$, we interpret this critical value of the strain-rate parameter α_1 as an extinction limit. According to the definition (47) of Ψ, this limit decreases exponentially with increasing values of the heat-loss parameters h and k, and with increasing values of the Lewis-number perturbation from unity. As indicated above, the latter reflects the decrease in flame temperature associated with increased thermal losses via diffusion to the strained flow field. In terms of Ψ, the critical condition for extinction is thus $\Psi > -\ln \alpha_1$, so that smaller values of the strain rate allow the flame to tolerate larger thermal losses.

For the more general response in the presence of catalysis ($\alpha_2 > 0$), we first calculate $d\alpha_1/d(-\bar{\theta}_s)$ from (49) as

$$\frac{d\alpha_1}{d(-\bar{\theta}_s)} = (-\bar{\theta}_s - \Psi)e^{-(-\bar{\theta}_s)} \left\{ -1 + 2\alpha_2 \left[1 - \nu(-\bar{\theta}_s - \Psi) \right] e^{(1-2\nu)(-\bar{\theta}_s)} \right\}. \tag{52}$$

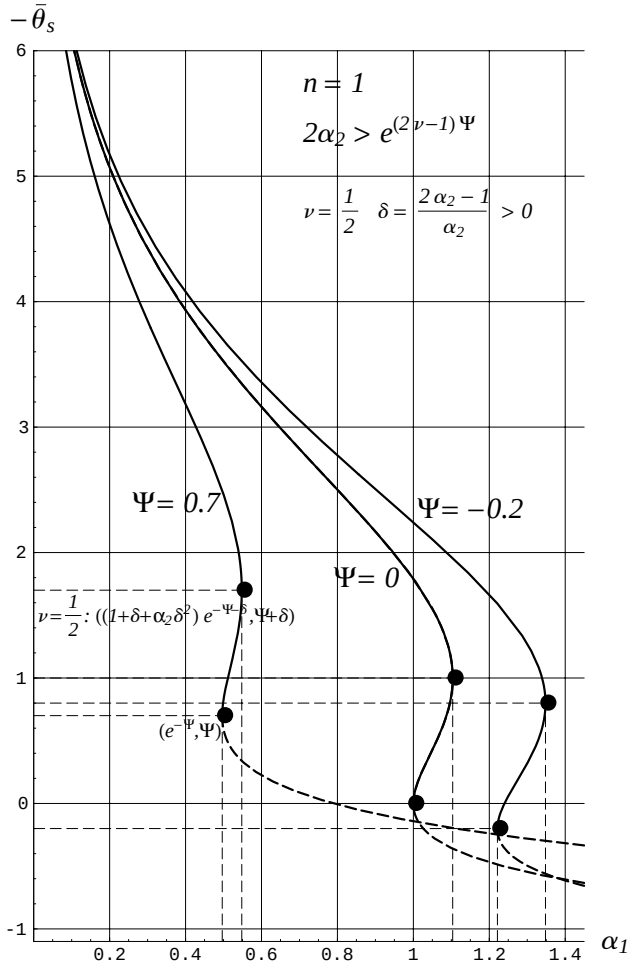

FIG. 4(a). *Solution response for activation-energy ratio $\nu = 1/2$ and $\alpha_2 > 1/2$. For $\alpha_2 > 1/2$, corresponding to a relatively strong surface reaction, an extension of the extinction limit to the higher value $\alpha_1^e = (1 + \delta + \alpha_2\delta^2)\, e^{-\Psi-\delta}$ is realized. The curves were drawn for $\alpha_2 = 1$ and the indicated values of Ψ.*

From (52) we thus conclude that $d\alpha_1/d(-\bar{\theta}_s) = 0$ at $-\bar{\theta}_s = \Psi$, corresponding to $\alpha_1 = e^{-\Psi}$, and may also be zero at value(s) of $-\bar{\theta}_s$ that satisfy the condition

$$2\alpha_2\big[1 - \nu(-\bar{\theta}_s - \Psi)\big] = e^{(2\nu-1)(-\bar{\theta}_s)}. \tag{53}$$

For example, if $\nu = 1/2$, corresponding to the case in which the activation energy of the catalytic surface reaction is half that of the distributed reaction in the bulk gas, (53) is satisfied when $-\bar{\theta}_s = \Psi + \delta$, where $\delta = (2\alpha_2 - 1)/\alpha_2$. Thus, for $\alpha_2 > 1/2$ (i.e., for $\delta > 0$), there exists a second physical solution of (49), corresponding to $\alpha_1 = \alpha_1^e = (1 + \delta + \alpha_2\delta^2)e^{-\Psi-\delta}$, for which $d\alpha_1/d(-\bar{\theta}_s) = 0$. On the other hand, for $\alpha_2 < 1/2$ (i.e., for $\delta < 0$), this additional solution is unphysical since it occurs for $-\bar{\theta}_s < \Psi$. The consequences of a physical root of (53) are evident from Figures 4(a) and 4(b), which are drawn for the case $\nu = 1/2$ just described. For $\alpha_2 > 1/2$, corresponding to a sufficiently vigorous surface reaction, the extinction limit is increased (since

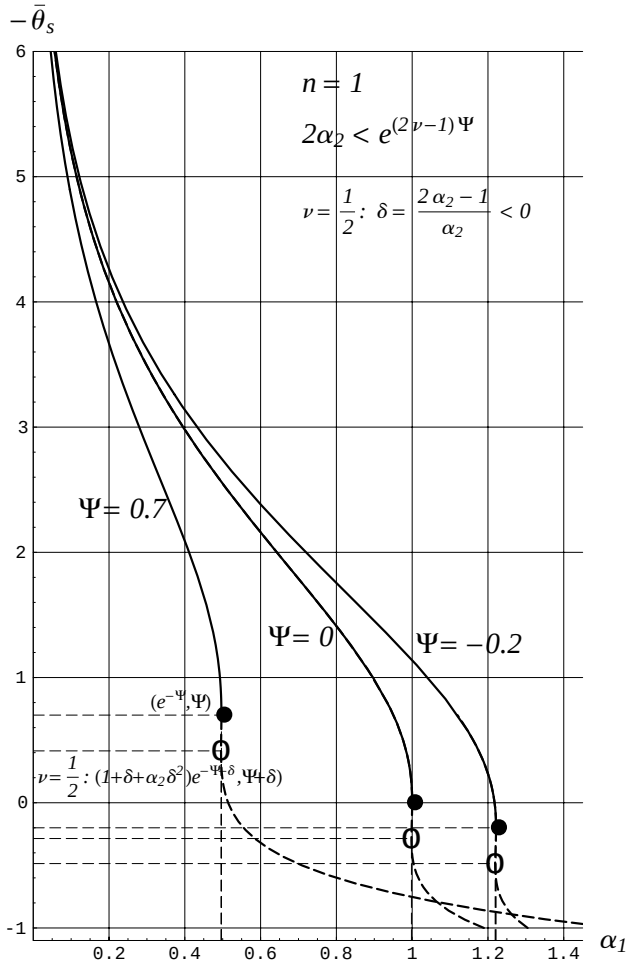

FIG. 4(b). *Solution response for activation-energy ratio $\nu = 1/2$ and $2\alpha_2 < 1$. For $\alpha_2 < 1/2$, corresponding to a relatively weak catalytic influence, the solution response is modified accordingly, but the extinction limit is the same as that obtained in the absence of catalysis. The curves were drawn for $\alpha_2 = 7/16$ and the indicated values of Ψ.*

$d^2\alpha_1/d(-\bar{\theta}_s)^2|_{-\bar{\theta}_s=\Psi} > 0$) to the value $\alpha_1 = \alpha_1^e$ given above (Figure 4(a)). In addition, the solution becomes multivalued for $e^{-\Psi} < \alpha_1 < \alpha_1^e$, implying both a high- and low-temperature solution (corresponding to a small and large value of $-\bar{\theta}_s$, respectively) for α_1 within this range. On the other hand, for $\alpha_2 < 1/2$ (Figure 4(b)), which corresponds to a relatively weak surface reaction, the extinction limit $\alpha_1 = e^{-\Psi}$ remains the same as that in the complete absence of a catalytic reaction. That is, even though a weak catalytic reaction does modify the solution response relative to the noncatalytic case, the maximum possible value of α_1 is unchanged.

The preceding discussion for the case $\nu = 1/2$ implies that the effects of a sufficiently active surface reaction at a reduced activation energy allows for a lower flame temperature (i.e., a larger value of $-\bar{\theta}_s$), thereby extending the extinction limit. That is, reactants that pass through the gas-phase reaction region due to higher rates of strain and/or lower gas-phase reactivity are still able to undergo at least partial conversion at the catalytic surface and thus contribute to the overall heat release. If the

catalytic reaction is weak or absent altogether, this additional opportunity for conversion is reduced or eliminated, and consequently, the gas flame cannot sustain itself at values of the strain-rate parameter α_1 that are larger than the critical value corresponding to extinction in the noncatalytic case. In terms of the parameter group Ψ, the critical value corresponding to extinction is raised from $\Psi = -\ln \alpha_1$ for $\alpha_2 < 1/2$ to $\Psi = \Psi^e = -\ln \alpha_1 + \ln(1+\delta+\alpha_2\delta^2) - \delta$. As δ decreases to zero from above (i.e., as α_2 approaches $1/2$), the maximum rate of heat loss that can be tolerated for a given value of α_1 is reduced to the same limit as for the noncatalytic problem.

These results are readily extended beyond the special case $\nu = 1/2$ as follows. First, it is useful to differentiate (52) to obtain

$$\left.\frac{d^2\alpha_1}{d(-\bar{\theta}_s)^2}\right|_{-\bar{\theta}_s=\Psi} = e^{-\Psi}\left[2\alpha_2\, e^{(1-2\nu)\Psi} - 1\right]. \tag{54}$$

Thus, at the minimum value $-\bar{\theta}_s = -\bar{\theta}_s^0 = \Psi$, it is seen that $d^2\alpha_1/d(-\bar{\theta}_s)^2$ is either positive or negative, depending on whether $2\alpha_2$ is greater or less than $e^{(2\nu-1)\Psi}$. In the first case, since $d\alpha_1/d(-\bar{\theta}_s)$ is zero at $-\bar{\theta}_s = -\bar{\theta}_s^0$, α_1 will increase with increasing $-\bar{\theta}_s$ until it reaches a maximum at the value of $-\bar{\theta}_s$ that corresponds to the single root of (53). This argument holds for all values of ν since, at $-\bar{\theta}_s = -\bar{\theta}_s^0$, the left-hand side of (53) exceeds the value of the right-hand side, leading to a single intersection when the linear left-hand and exponential right-hand sides of (53) are plotted against $-\bar{\theta}_s$. Consequently, for $2\alpha_2 > e^{(2\nu-1)\Psi}$, the qualitative behavior will be identical to Figure 4(a), indicating an extension of the extinction limit relative to the noncatalytic case. On the other hand, for $2\alpha_2 < e^{(2\nu-1)\Psi}$, we have that $d^2\alpha_1/d(-\bar{\theta}_s)^2$ is negative at $-\theta_1 = -\bar{\theta}_s^0$ and hence α_1 decreases as $-\bar{\theta}_s$ increases from that value. The qualitative nature of the solution response then depends on whether $\nu \geq 1/2$ or $\nu < 1/2$.

If, for the case $2\alpha_2 < e^{(2\nu-1)\Psi}$, we have $\nu \geq 1/2$, the right-hand side of (53) is either exponentially increasing or constant, whereas the left-hand side is a linearly decreasing function of $-\bar{\theta}_s$. In this instance, the left-hand side of (53) is less than the value of the right-hand side at $-\bar{\theta}_s = -\bar{\theta}_s^0$ and there are no physical roots of (53). The solution response is then qualitatively similar to Figure 4(b) and there is no catalytic extension of the extinction limit. This situation persists as ν decreases below the value $1/2$ (at which point the right-hand side of (53) transitions from a growing to a decaying exponential) until at some point the linearly decreasing left-hand side of (53) intersects the exponentially-decaying right-hand side tangentially in at first one, and then two, places. The first of these roots, if it occurs for $-\bar{\theta}_s > -\bar{\theta}_s^0$, then corresponds to a relative minimum in the $\alpha_1(-\bar{\theta}_s)$ response, while the second corresponds to a relative maximum and hence an extension of the extinction limit, provided that this root occurs in the physical range $-\bar{\theta}_s > -\bar{\theta}_s^0$ and the relative maximum value of α_1 exceeds the value at $-\bar{\theta}_s^0$. In the two-root case just described, the solution response is triple-valued for a range of α_1 values, corresponding to low-, intermediate- and high-temperature solution branches.

The various scenarios just described for $\nu < 1/2$, which illustrate how different effects can counterbalance one another, are illustrated in Figures 5(a)–(c). In particular, the $\Psi = 0$ curve in Figure 5(a) demonstrates both the aforementioned relative minimum and maximum for $2\alpha_2 < e^{(2\nu-1)\Psi}$, while the other two curves for $\Psi > 0$ exhibit only the relative maximum in the physical range $-\bar{\theta}_s > -\bar{\theta}_s^0$ as the increase in Ψ eventually leads to the parameter regime $2\alpha_2 > e^{(2\nu-1)\Psi}$. In Figure 5(b), which

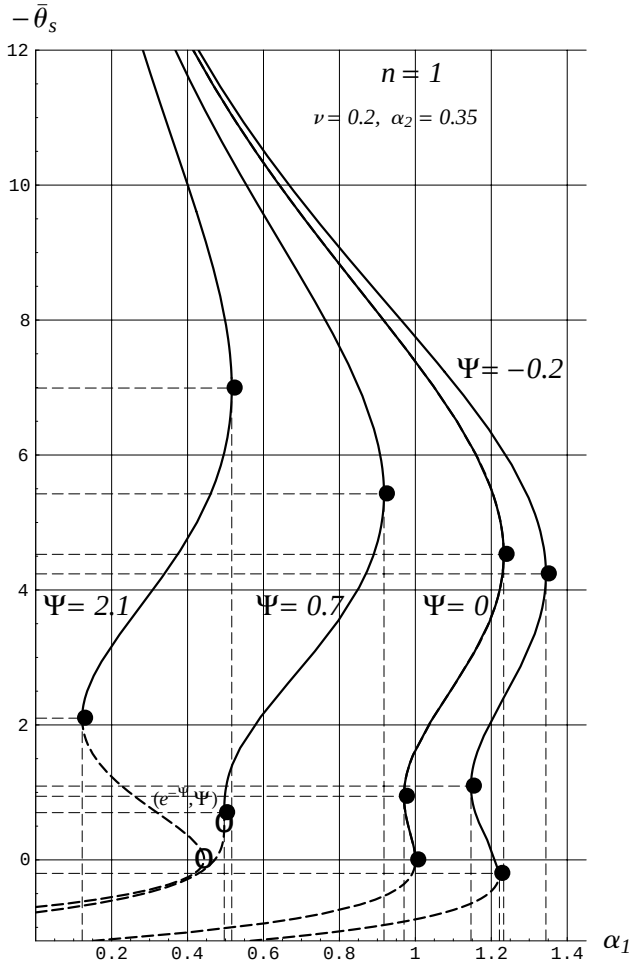

FIG. 5(a). *Solution response for $\nu < 1/2$ and several values of Ψ: $\nu = 0.2$ and $\alpha_2 = 0.35$. Larger values of α_2 and smaller values of ν have a tendency to extend the extinction limit and can thus compensate for the extinguishing effects of larger heat losses.*

is qualitatively similar to Figure 5(a), the surface activation-energy parameter ν has been decreased further with respect to its previous value, leading to a greater catalytic effect and a consequently greater extension of the extinction limit. This same effect is achieved by increasing the surface reaction-rate parameter α_2 to the value used in Figure 5(c), where there is now no relative minimum in any of the solution responses since the value of α_2 is now sufficiently large that $2\alpha_2 > e^{(2\nu-1)\Psi}$. Hence, decreasing ν and increasing α_2 have the same qualitative effect on the extension of the extinction limit. With respect to the heat-loss parameters h and k, we note from the definition (47) that the extinction limit corresponds to larger values of these parameters for smaller Lewis numbers. Thus, for example, flames whose Lewis numbers are less than unity ($l < 0$) can tolerate larger thermal losses than those whose Lewis numbers are greater then unity ($l > 0$).

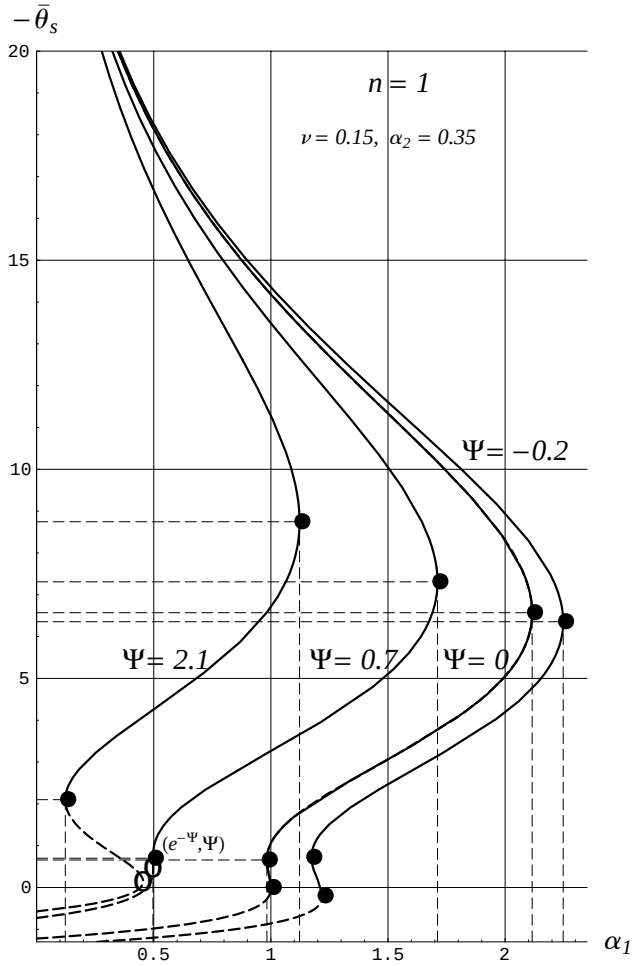

FIG. 5(b). *Solution response for $\nu < 1/2$ and several values of Ψ: $\nu = 0.15$ and $\alpha_2 = 0.35$. Larger values of α_2 and smaller values of ν have a tendency to extend the extinction limit and can thus compensate for the extinguishing effects of larger heat losses.*

6. Stability of the basic solution. The possibility of multiple steady plane-flame solutions, as illustrated in Figures 4(a) and 5(a)–(c), suggests the need for a stability analysis to determine which portions of the solution response correspond to stable combustion states, as well as to indicate the possible existence of additional nonsteady and/or nonplanar solutions. Accordingly, we introduce perturbations u, v, and τ about the basic state $\bar{\Theta}$, $\bar{S}$, and $\bar{\theta}_s$ according to

$$\Theta_0 = \bar{\Theta}(z) + u(r, \vartheta, z, t), \quad S_1 = \bar{S}(z) + v(r, \vartheta, z, t), \quad \theta_s = \bar{\theta}_s + \tau(r, \vartheta, t), \tag{55}$$

where $\bar{\Theta}$ and $\bar{S}$ are given by (40), (43), and (44), and $\bar{\theta}_s$ is determined from (46) and (47). Substituting these definitions into the closed problem given by (17) and the first equation of (10), subject to (11), (18), (29), and (35), we obtain, after linearizing

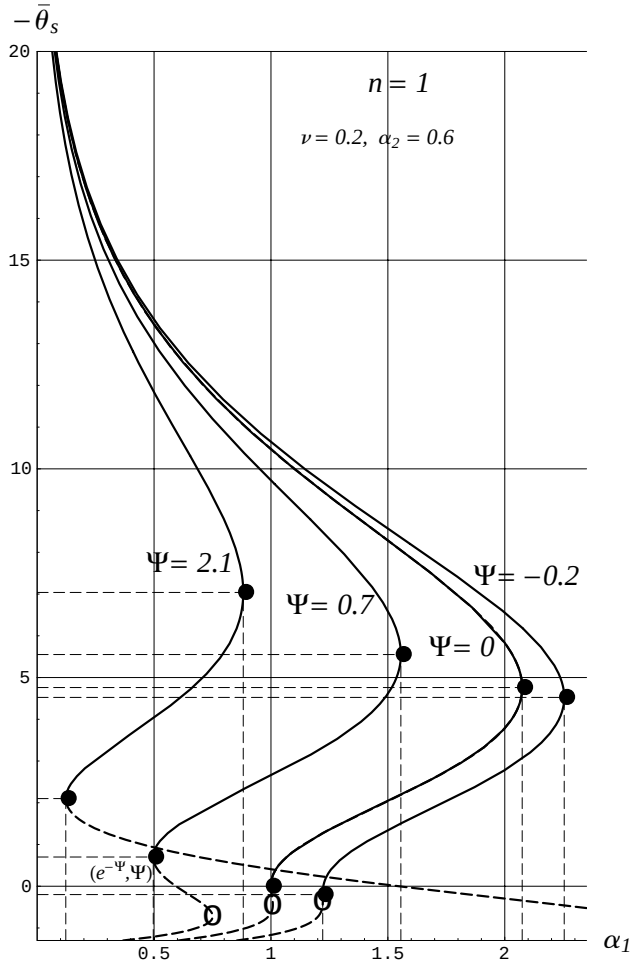

FIG. 5(c). *Solution response for $\nu < 1/2$ and several values of Ψ: $\nu = 0.2$ and $\alpha_2 = 0.6$. Larger values of α_2 and smaller values of ν have a tendency to extend the extinction limit and can thus compensate for the extinguishing effects of larger heat losses.*

about the basic solution, the linear stability problem

$$\begin{aligned} &\frac{\partial u}{\partial t} + r\frac{\partial u}{\partial r} - 2z\frac{\partial u}{\partial z} = \nabla^2 u, \\ &\frac{\partial v}{\partial t} + r\frac{\partial v}{\partial r} - 2z\frac{\partial v}{\partial z} = \nabla^2 v + l\nabla^2 u - hu, \quad 0 < z < \infty, \end{aligned} \tag{56}$$

$$u\big|_{z=0} = 0, \quad \left.\frac{\partial v}{\partial z}\right|_{z=0} = -l\left.\frac{\partial u}{\partial z}\right|_{z=0}, \qquad u,\ v \to 0 \ \text{ as } \ z \to \infty, \tag{57}$$

$$\begin{aligned} -\sqrt{\pi}\,\alpha_1 \left.\frac{\partial u}{\partial z}\right|_{z=0} &= \left[v\big|_{z=0} + \tau(-\Psi - \bar{\theta}_s)\right] e^{\bar{\theta}_s} + 2\alpha_2(-\Psi - \bar{\theta}_s) \\ &\quad \times \ \left[v\big|_{z=0} + \ \nu\tau(-\Psi - \bar{\theta}_s - \nu^{-1})\right] e^{2\nu\bar{\theta}_s}. \end{aligned} \tag{58}$$

In obtaining (58), the reaction order n has been taken to be unity, and the preceding results were used to evaluate $\bar{S}(0) = -\Psi$, $d\bar{\Theta}/dz\big|_{z=0} = -2/\sqrt{\pi}$ and, from (30), to calculate

$$\begin{aligned} G_1\big(\theta_s; S_1\big|_{z=0}\big) &= \big(1 + S_1\big|_{z=0} - \theta_s\big)\, e^{\theta_s} \\ &= \big(1 - \Psi + v\big|_{z=0} - \bar{\theta}_s - \tau\big)\, e^{\bar{\theta}_s + \tau} \\ &\sim \big(1 - \Psi - \bar{\theta}_s\big)\, e^{\bar{\theta}_s} + \big(1 - \Psi - \bar{\theta}_s\big)\, e^{\bar{\theta}_s}\tau \\ &\quad + \big(v\big|_{z=0} - \tau\big)\, e^{\bar{\theta}_s} + \cdots . \end{aligned} \tag{59}$$

An investigation of the linear stability of the basic solution may now proceed by seeking solutions of (56)–(58) proportional to $e^{i(\omega t \pm m\theta)}$ times appropriate functions of kr and z, where $i\omega$ is the complex growth rate and m and k are the angular and radial wavenumbers, respectively. However, because it is reasonable to assume a high conductivity for the catalytic surface relative to the gas, which would consequently not support a nonuniform temperature distribution at $z = 0$, we may, in that case, set the radial and angular wavenumbers to zero. That is, only planar perturbations of the basic state are admissible, and harmonic solutions are thus restricted to the form

$$u = f(z)\, e^{i\omega t}, \quad v = g(z)\, e^{i\omega t}, \quad \tau = c_1 e^{i\omega t}. \tag{60}$$

Here, choosing the preexponential coefficient to be unity in the last expression would normalize any nontrivial solution to the linear stability problem, with stability of the basic state determined by the sign of the real part of $i\omega$. Substituting (60) into (56)–(58) thus gives a closed problem for the complex unknowns $f(z)$, $g(z)$, and $i\omega$ as

$$i\omega f - 2z\frac{df}{dz} = \frac{d^2 f}{dz^2}, \quad i\omega g - 2z\frac{dg}{dz} = \frac{d^2 g}{dz^2} + l\frac{d^2 f}{dz^2} - hf, \qquad 0 < z < \infty, \tag{61}$$

$$f(0) = 0, \quad \frac{dg}{dz}\bigg|_{z=0} = -l\frac{df}{dz}\bigg|_{z=0}, \qquad f,\ g \to 0 \ \text{ as } \ z \to \infty, \tag{62}$$

$$\begin{aligned} -\sqrt{\pi}\,\alpha_1 \frac{df}{dz}\bigg|_{z=0} &= \big[g(0) + c_1(-\Psi - \bar{\theta}_s)\big]\, e^{\bar{\theta}_s} + 2\alpha_2(-\Psi - \bar{\theta}_s) \\ &\quad \times \ \big[g(0) + \nu c_1(-\Psi - \bar{\theta}_s - \nu^{-1})\big]\, e^{2\nu\bar{\theta}_s}. \end{aligned} \tag{63}$$

We proceed with an analysis of (61)–(63) by noting that the subproblems for f and g may be solved sequentially in terms of $i\omega$. We also consider only solutions for which $\Re(i\omega) \geq 0$, since solutions with $\Re(i\omega) < 0$ correspond to decaying perturbations and hence stability of the basic solution.

It is readily verified that the transformation $x = -z^2$ converts the first of (61) into the standard form of the confluent hypergeometric equation $x\, d^2f/dx^2 + (b - x)\, df/dx - af = 0$ with $b = 1/2$ and $a = -i\omega/4$. For noninteger values of b, two independent solutions for f are therefore ${}_1F_1(a; b; x)$ and $x^{1-b}{}_1F_1(1 + a - b; 2 - b; x)$, where ${}_1F_1(a; b; x) = \sum_{n=0}^{\infty}[(a)_n/(b)_n]x^n/n! = \big\{\Gamma(b)/[\Gamma(b-a)\Gamma(a)]\big\} \int_0^1 e^{xt}t^{a-1} \times (1 - t)^{b-a-1}dt$ is the confluent hypergeometric (Kummer) function (cf. Slater [13]). Thus, in terms of z, the general solution of the first equality in (61) may be written as

$$f(z) = C_1 \cdot {}_1F_1\left(-\frac{i\omega}{4}; \frac{1}{2}; -z^2\right) + C_2\, z \cdot {}_1F_1\left(\frac{1}{2} - \frac{i\omega}{4}; \frac{3}{2}; -z^2\right), \tag{64}$$

where C_1 and C_2 are constants of integration. Requiring that $f(0) = 0$ thus implies $C_1 = 0$, while the boundary condition $f \to 0$ as $z \to \infty$ requires, when $\Re(i\omega) \geq 0$, that $C_2 = 0$ as well, where the latter is deduced from the asymptotic behavior ${}_1F_1(a; b; x) \sim [\Gamma(b)/\Gamma(b-a)](-x)^{-a}[1 + \mathrm{O}(|x|^{-1})]$ as $|x| \to \infty$ for $\Re(x) < 0$ (cf. [13]). Hence, $f(z) \equiv 0$ so that no nontrivial solution for f corresponding to neutral or growing perturbations is admissible.

A similar argument can be applied to the determination of $g(z)$. In particular, because $f = 0$, the second equation of (61) for g is identical to the equation for f, and thus the general solution for $g(z)$ is also given by the right-hand side of (64). In this case, the boundary condition $\partial g/\partial z = l\partial f/\partial z = 0$ at $z = 0$ implies that $C_2 = 0$ in the corresponding general solution for g, while the condition that g vanish as $z \to \infty$ requires, based on the above asymptotic behavior of ${}_1F_1$, that $C_1 = 0$ as well. Thus, for $\Re(i\omega) \geq 0$, both $f(z)$ and $g(z)$ are identically zero. Equation (63) then reduces to

$$c_1(-\Psi - \bar{\theta}_s)\left[1 + 2\alpha_2\nu(-\Psi - \bar{\theta}_s - \nu^{-1})\, e^{(1-2\nu)(-\bar{\theta}_s)}\right] = 0, \tag{65}$$

which is generally satisfied only if $c_1 = 0$. An exception occurs at values of $-\bar{\theta}_s$ for which $d\alpha_1/d(-\bar{\theta}_s) = 0$ (i.e., at the relative extrema in Figures 3–5), in which case, based on (52) and (53), c_1 is indeterminate. However, all other points on the basic solution response correspond to either decaying harmonic perturbations or to the absence of a nontrivial solution to the linear stability problem. We thus conclude that, at least in the classical sense, all branches of the basic solution are linearly stable. Consequently, in parameter regimes where multiple solutions exist, the observed solution is likely to depend on the initial conditions, which appears to be the case in actual experiments [6]. We remark, however, that relaxing the assumption of high surface conductivity so as to allow for transverse perturbations might, as in the case of strictly gaseous flames in stagnation-point flow, permit instability for sufficiently small values of the strain-rate parameter (cf. Sivashinsky, Law, and Joulin [14]).

7. Conclusion. The present work has presented a formal asymptotic model of a nonadiabatic catalytic flame in stagnation-point flow. The thermal/diffusive model, which was derived under the assumptions of large activation energies and near-unity Lewis numbers, considers both surface and volumetric heat losses, where the former occurs at the catalytic surface and the latter approximates conductive and/or radiative losses across the remaining surfaces. Assuming combustion to occur in the near-surface region where catalytic effects are felt, it was shown that the presence of a catalytic surface has the potential to significantly extend the extinction limits arising from the effects of flame stretch and heat loss. In particular, reactants that leak through the distributed portion of the gas flame, due to larger strain rates and/or larger rates of heat loss that lower the reaction rate, have an additional opportunity to react under the influence of a catalyst at the surface. Such an influence is particularly desirable from the standpoint of building small combustors that have relatively large surface-to-volume ratios, and the present work has therefore focused on further extending earlier studies to the nonadiabatic regime. Indeed, recent experiments indicate that microcombustors on the order of a cubic millimeter or less are feasible when the stagnation surface is coated with a catalyst.

The solution response of the model problem is parameterized by the nondimensional strain rate, the ratios of the surface reaction rate and activation energy to those of the distributed reaction in the bulk gas, and a parameter that represents a linear combination of the effects of surface and volumetric heat losses and those associated with nonunity Lewis numbers. The main results demonstrate how, in certain

parameter regimes associated with a strongly catalytic effect, the solution response is modified from that of the noncatalytic problem to allow for larger values of the strain rate, rate of heat loss, and/or Lewis number than would be the case in the absence of catalysis. In such regimes, the solution response exhibits an extinction limit at a value of the strain rate (or heat-loss coefficient) that is larger than the corresponding value in the absence of catalysis, resulting in a catalytic extension of the extinction limit. In addition, multiple solution branches appear, corresponding to high, low, and, in some cases, intermediate surface temperatures. A linear stability analysis suggests, consistent with recent experiments, that in the limit of high surface conductivity each branch is locally stable so that it should be possible to observe different solutions depending on the initial conditions.

RADIAL STRUCTURE OF TRAVELING WAVES IN THE INNER EAR*

HONGXUE CAI† AND RICHARD CHADWICK†

Abstract. We develop a hybrid approach for modeling the cochlea, in which we let the WKB method determine the axial propagation of waves and restrict the numerics to transverse planes, where we solve a fluid-solid interaction eigenvalue problem. The cochlear fluid is treated as viscous and incompressible. Viscous effects are confined to oscillatory boundary layers and the thin gap between the reticular lamina (RL) and the lower surface of the tectorial membrane (TM). Our model includes axial fluid coupling and also axial elastic coupling via a basilar membrane (BM) modeled as an orthotropic clamped plate. Three-dimensional (3D) flow is solved in two-dimensional (2D) domains, with interactions with 2D elastic domains representing the organ of Corti (OC) and the TM. The OC contains inhomogeneities representing discrete cellular structures. We have computed the interaction between the BM, TM, OC, and the cochlear fluid to find the complex-valued wavenumber-frequency relation and vibrational modes. The details of the cochlear fluid flow and pressure fields are calculated, along with displacements of the elastic structures. Simulation of passive radial modes in the apical region of a guinea pig cochlea for frequencies less than 1 kHz indicates monophasic vibration of the BM and a synchronous rotation of three rows of outer hair cell stereocilia induced by a shearing motion between the RL and TM.

Key words. cochlear mechanics, traveling wave, fluid-solid interaction, radial modes

1. Introduction.

Modeling the radial structure of traveling waves in the inner ear is timely because of new experimental observations that require interpretation. Experimental observations can now resolve the vibratory patterns across the width of the organ of Corti (OC). Both monophasic and multiphasic radial modal patterns have been reported, depending on the method of stimulation, axial location, and frequency [11, 16, 25, 26, 29]. These patterns, representing the radial structure of the traveling wave, are critical to understanding the stimulation of inner and outer hair cells (IHCs and OHCs). An excellent recent review of experimental cochlear mechanics can be found in Robles and Ruggero [31]. A reliable computational model would be very useful in sorting out the variety of reported responses. Here we begin by developing a passive model.

The detailed cochlear fluid flow and micromechanical movements of the tectorial membrane (TM) and cellular structures relative to one another within the OC have interested many auditory researchers [1, 3, 4, 12, 22, 24, 39, 40]. Most models in the literature use simple lumped elements (lever, spring, damper, transformer, etc.). While these lumped-parameter models have been very useful, they oversimplify the dynamics by neglecting fluid mass coupling in the micromechanics. They also make assumptions concerning the kinematics that can now be computed rather than as-

sumed. Toward this end we develop a *physically realistic* OC geometry and model the OC as an elastic body whose *inhomogeneities* are due to discrete cellular elements including IHCs, OHCs, Deiter's cells (DCs), pillar cells (PCs), and the reticular lamina (RL). Accordingly, the OC has a material property map with each subdomain having the Young's modulus (E) and Poisson's ratio (ϑ) of the corresponding cell structures (see Appendix B).

The excessive computational cost of incorporating radial structure and fluid-solid interaction into models of traveling waves complicates the study of cochlear mechanics. Straightened models with three-dimensional (3D) flow including radial variation of the traveling wave have been studied using the WKB method [8, 17, 33, 34] and by fully numerical methods [19, 28]. Manoussaki and Chadwick [23] developed a hybrid approach to study the effects of cochlear curvature. But these types of models considered the basilar membrane (BM) only and did not attempt to consider the complications of other true degrees of freedom in the cochlear partition (CP). Actually there are very few calculations for which the radial variation of BM transverse deflection is computed and not assumed. Other modeling efforts [7, 20, 38] used full 3D finite elements or finite differences, with some critique offered by Steele [32]. In his hybrid 3D model of the cochlea, which includes structural details of the OC modeled as orthotropic shell elements and discrete fluid domains modeled as equivalent rectangles, Steele reported different propagation modes in different fluid domains. Here we develop a hybrid approach that provides a single propagating mode with a single wavenumber applicable to the entire cross section. Like Steele [32], we let the WKB method deal with the axial propagation of the wave, and we restrict the numerics to the transverse plane. We use finite elements for both fluid and solid components, and we compute fluid-solid interaction in a physically realistic complex geometry of the cochlear cross section. Modes and displacements of the OC are analyzed, and the details of the cochlear fluid flow are calculated. This approach avoids a full 3D computation and allows for greater resolution in a cochlear cross section. In our cochlear model, we carry out only the first step in the reduction of the 3D hydroelastic problem to a sequence of eigenvalue problems in transverse planes. The WKB-numerical hybrid approach allows this reduction and provides the formalism for connecting the solution in different transverse planes via an energy transport equation. That part of the solution is beyond the scope of the present work.

2. Model description. The coordinates (X, Y, Z) respectively denote the "radial," "transverse," and "axial" (along the duct length) directions. The transverse plane of the cochlea is divided into fluid and elastic domains (Figure 2.1). Discrete structural elements are embedded in the two-dimensional (2D) continuum of the OC. The TM and OC solid domains are coupled by cochlear fluid and OHC stereocilia. The OC rests on an orthotropic clamped plate that represents the BM, whose axial coupling is considered via the plate Green's function (see section 3 for details). The axial fluid flow and coupling are also retained by WKB expansion on all fluid domains: scala tympani (ST) and the combined scala media and scala vestibuli (SM+SV). The cross section of the cochlea is bounded by rigid walls, represented by circular arcs and straight segments in Figure 2.1.

2.1. Fluid domains. The fluid velocity $\tilde{\mathbf{V}} = (\tilde{V_X}, \tilde{V_Y}, \tilde{V_Z})$ and pressure $\tilde{P}$ satisfy the linearized Navier–Stokes and mass conservation equations (see [5])

$$\rho \frac{\partial \tilde{\mathbf{V}}}{\partial t} = -\nabla \tilde{P} + \mu \nabla^2 \tilde{\mathbf{V}}, \tag{2.1}$$

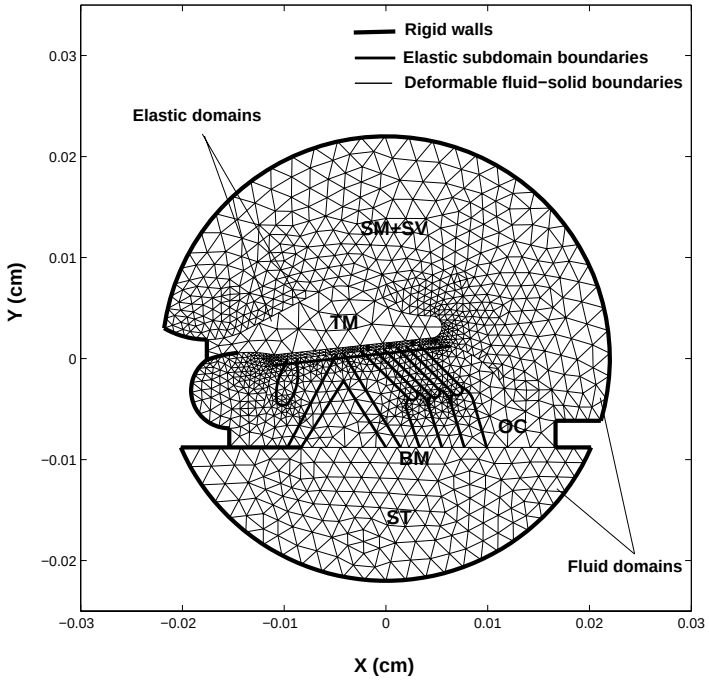

FIG. 2.1. *Model representation of a cochlear cross section. Tectorial membrane (TM) and organ of Corti (OC) are represented by 2D elastic domains. The former is homogeneous, while the latter contains different subdomains representing discrete cellular structures. The OC has the reticular lamina (RL, not labeled) as its top boundary and rests on the basilar membrane (BM), which is represented by an orthotropic clamped plate. A narrow fluid-filled gap exists between the RL and the lower surface of the TM. Stereocilia elastically couple the RL and TM. The scala tympani (ST) is the fluid compartment on the lower side, while the upper fluid region is the combined scala media and scala vestibuli (SM+SV). (For the present calculation without the Reissner's membrane, the scala media and scala vestibuli contain the same fluid.) Scale is in cm.*

$$\nabla \cdot \tilde{\mathbf{V}} = 0, \tag{2.2}$$

where ∇ is the gradient operator, ∇^2 is the Laplacian operator, and ρ and μ are the density and viscosity of the cochlear fluid. From (2.1) and (2.2), it follows that the pressure is harmonic:

$$\nabla^2 \tilde{P} = 0. \tag{2.3}$$

Boundary conditions for pressure can be obtained for a viscous fluid following Holmes and Cole [17]. For thin oscillatory boundary layers the dominant boundary conditions are those for an inviscid fluid,

$$\mathbf{n} \cdot \nabla \tilde{P} = 0 \tag{2.4}$$

on rigid walls, where $\mathbf{n}$ is the outward unit normal. Since $\tilde{\mathbf{V}} = \partial \tilde{\mathbf{U}}/\partial t$,

$$\mathbf{n} \cdot \nabla \tilde{P} = -\rho \frac{\partial \tilde{\mathbf{V}}_{\mathbf{n}}}{\partial t} = -\rho \frac{\partial^2 \tilde{\mathbf{U}}_{\mathbf{n}}}{\partial t^2} \tag{2.5}$$

on deformable boundaries, where $\tilde{\mathbf{U}} = (\tilde{U}_X, \tilde{U}_Y, 0)$ is the displacement vector of a deformable boundary.

2.2. Solid domains. We solved a structural mechanics plane strain problem for the TM and OC solid domains. The stress-strain relation can be written, assuming isotropic and isothermal conditions (see [35]), as

$$\begin{pmatrix} \tilde{\sigma}_X \\ \tilde{\sigma}_Y \\ \tilde{\tau}_{XY} \end{pmatrix} = \frac{E}{(1+\vartheta)(1-2\vartheta)} \begin{pmatrix} 1-\vartheta & \vartheta & 0 \\ \vartheta & 1-\vartheta & 0 \\ 0 & 0 & (1-2\vartheta)/2 \end{pmatrix} \begin{pmatrix} \tilde{\epsilon}_X \\ \tilde{\epsilon}_Y \\ \tilde{\gamma}_{XY} \end{pmatrix}, \tag{2.6}$$

where $\tilde{\sigma}_X$ and $\tilde{\sigma}_Y$ are the stresses in the X and Y directions and $\tilde{\tau}_{XY}$ is the shear stress. The material properties are expressed as a combination of E (Young's modulus) and ϑ (Poisson's ratio). The strains are defined as

$$\tilde{\epsilon}_X = \frac{\partial \tilde{U}_X}{\partial X}, \quad \tilde{\epsilon}_Y = \frac{\partial \tilde{U}_Y}{\partial Y}, \quad \tilde{\gamma}_{XY} = \frac{\partial \tilde{U}_X}{\partial Y} + \frac{\partial \tilde{U}_Y}{\partial X}. \tag{2.7}$$

For the vibratory 2D elastic domains, the equation of motion, neglecting gravity, is given by

$$-\nabla \cdot \tilde{\sigma} + \rho_s \frac{\partial^2 \tilde{\mathbf{U}}}{\partial t^2} = 0, \tag{2.8}$$

where ρ_s is the density of the solid domains. Combining (2.6), (2.7), and (2.8), we can arrive at a PDE system involving the displacements. The Young's modulus and Poisson's ratio are incorporated into the PDE coefficient matrices; thus we can handle the inhomogeneities of the OC by discretizing its mechanical properties (E and ϑ) on corresponding subdomains (see Appendix B).

There are four types of boundary conditions on the 2D solid domains. Boundary segments contiguous with rigid domains are subject to a homogeneous Dirichlet condition with zero displacements: $\tilde{U}_X = \tilde{U}_Y = 0$. The OC boundary segment contiguous with the BM is an inhomogeneous Dirichlet condition: $\tilde{U}_X = 0$ and $\tilde{U}_Y = \tilde{Y}_b$, where $\tilde{Y}_b$ is the BM displacement. $\tilde{Y}_b$ can be calculated via a plate Green's function integral (see section 3). Deformable boundary segments in contact with fluid are subject to the stress vector $\tilde{\sigma}_{\mathbf{n}}$:

$$\tilde{\sigma}_{\mathbf{n}} = \tilde{\sigma} \cdot \mathbf{n} = -\tilde{P}\mathbf{n} + \tilde{\tau}\mathbf{s}, \tag{2.9}$$

where $\mathbf{s}$ is the unit tangential vector in the transverse plane and $\tilde{\tau}$ is the tangential surface traction due to an oscillatory boundary layer. The stress vector $\tilde{\sigma}_{\mathbf{n}}$ can be expressed in terms of solid displacements via (2.6) and (2.7), so that (2.9) is an inhomogeneous Neumann condition; this will be discussed further in section 2.3. Finally, the thin gap region bounded by the lower surface of the TM and the upper surface of the RL is given special treatment in the present model. Here we adopt the analysis of Chadwick, Dimitriadis, and Iwasa [9], who showed using lubrication theory that there is no squeezing of the gap, but only a relative tangential motion between the TM and RL, as was originally proposed by Allen [1, 3]. In the present context this leads to the inhomogeneous Dirichlet condition $\tilde{U}_{TM,n} = \tilde{U}_{RL,n}$.

2.3. WKB expansion. The axial coordinate is normalized by the cochlear length L ($z = Z/L$), and the other two coordinates are normalized by a characteristic cross-sectional radius R_0 ($x = X/R_0$, $y = Y/R_0$). We express all dependent variables in the form $\tilde{\Phi}(x, y, z, t) = \Phi(x, y, z)\exp[i(\omega t - \epsilon^{-1} \int k(z)dz)]$, where k is the dimensionless complex-valued wavenumber normalized by R_0 (i.e., $k = \tilde{k}R_0$, where

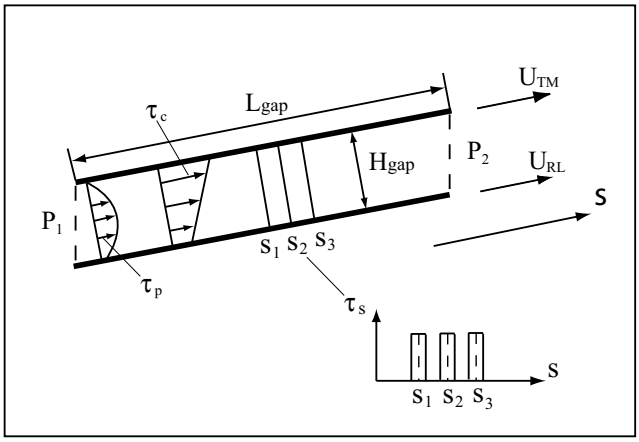

FIG. 2.2. *RL-TM gap tangential stresses. τ_p is the Poiseuille flow-induced tangential stress, τ_c is the Couette flow-induced tangential stress, and τ_s is the tangential stress contributed by hair bundle stiffness.*

$\tilde{k}$ is the dimensional wavenumber), $\epsilon = R_0/L_c \ll 1$, and ω is the radian frequency. The slowly varying wave approximation requires the expansion of the amplitude Φ of each dependent variable: $\Phi = \Phi_0 + \epsilon\Phi_1 + \cdots$. The dominant equation of the WKB expansion of (2.3) gives us

$$\nabla_T^2 P_0 = k^2 P_0, \tag{2.10}$$

where the Laplacian operator is defined in the normalized transverse plane: $\nabla_T^2 = \partial^2/\partial x^2 + \partial^2/\partial y^2$. The WKB expansion of (2.4) and (2.5) gives the following dominant boundary condition for the fluid domains:

$$\frac{\partial P_0}{\partial n_T} = \rho\omega^2 R_0 U_{n_T 0}, \tag{2.11}$$

where the fluid-solid interface normal displacement $U_{n_T 0} = \mathbf{U_0} \cdot \mathbf{n_T}$. After solving the inviscid problem, the pressure acting on a deformable boundary can be corrected for viscous effects in an oscillatory boundary layer [5] by adding a small correction term to the boundary pressure [9]: $P_c = \rho\omega^2 U_{n_T 0}\sqrt{-i\nu/\omega}$, where $\nu = \mu/\rho$ is the kinematic viscosity.

The dominant WKB expansion of (2.8) is

$$\nabla_T \cdot \sigma_{\mathbf{0}} + R_0\rho_s\omega^2 \mathbf{U_0} = 0, \tag{2.12}$$

with boundary condition at a deformable surface

$$\sigma_{n_T 0} = \sigma_{\mathbf{0}} \cdot \mathbf{n_T} = -P_0 \mathbf{n_T} + \tau \mathbf{s}. \tag{2.13}$$

Solid damping is included in the model by assuming a Voigt solid and replacing E by $E + i\omega E'$, where E' is a damping parameter [19]. For the TM-RL gap boundary segments, $\tau = \tau_p + \tau_c + \tau_s$ (see Figure 2.2), where $\tau_p = \frac{1}{2}\Delta P_0 H_{gap}/L_{gap}$ is the Poiseuille flow-induced tangential stress due to the pressure difference ΔP_0 between the two ends of the gap of length L_{gap} and thickness H_{gap}, $\tau_c = i\mu\omega\Delta U_{s0}/H_{gap}$ is

the Couette flow-induced tangential stress due to the difference between the TM and RL tangential displacements ΔU_{s0}, and τ_s is the tangential stress contributed by the hair bundle stiffness (K_s). We model τ_s as a rectangular wave over the normalized OHC diameter with amplitude $K_s \Delta U_{s0}/A_s$, where A_s is the effective area of stress ($15 \times 15 \mu m^2$) of the hair bundle. Couette and Poiseuille flow in the gap was proposed by Allen [1, 3]. For the nongap boundary segments, $\tau = \sqrt{i\omega\nu}(\frac{1}{i\omega R_0}\frac{\partial P_0}{\partial s} + i\rho\omega U_{s0})$, where U_{s0} is either the TM or OC segment tangential displacement (see Appendix A). All boundary conditions are linearized and applied on their undeformed locations.

3. Computation. We fix ω and solve the above eigenvalue problem for the wavenumber, fluid pressure, and solid displacement fields using the MATLAB PDE Toolbox on an SGI workstation with an R12000 processor. We define the geometry and the boundary conditions by directly editing MATLAB geometry and boundary condition matrices. Each boundary segment (straight line or arc) corresponds to a column in the geometry matrix, and each column in the geometry matrix must correspond to a column in the boundary condition matrix. A boundary condition must be expressed in a special MATLAB string representation, which contains the 2D coordinates x and y, the outward normal vector components n_x and n_y, and a normalized arc length parameter s. Since the boundary string expressions must be continuous functions, we define the boundaries using polynomial curve-fits. Meshes of the 2D domains are generated and refined by MATLAB. For clarity, the meshes shown in Figure 2.1 are coarser than those we used in our actual calculations. Our algorithm iterates between elliptic, 2D plane strain, and eigenvalue solvers in the PDE Toolbox (see Appendix B). First we guess values of the wavenumber k and of the displacements of the TM, OC, and BM, and we solve the elliptic problems in the upper and lower fluid chambers (see Figure 2.1) for the fluid pressure field P_0. Then we solve the 2D plane strain problems sequentially for the OC and TM. We calculate the updated deflection of the BM via the plate Green's function G:

$$Y_b(x) = R_0 \int_{b_1}^{b_2} G(x, x')\Delta\sigma_n(x')dx', \tag{3.1}$$

where b_1 and b_2 are the radial coordinates of the BM endpoints and $\Delta\sigma_n$ is the difference between the pressure at the lower surface of the BM and the negative of the normal stress at the lower surface of the OC. Considering the axial coupling of the BM [2, 18, 21, 36], the orthotropic plate Green's function $G(x, x')$ satisfies

$$D_x \frac{\partial^4 G}{\partial x^4} - 2(D_x D_z)^{1/2} k^2 \frac{\partial^2 G}{\partial x^2} + (-R_0^4 \rho_b H_b \omega^2 + D_z k^4)G = \delta(x - x')R_0^4, \tag{3.2}$$

with the following boundary conditions for an orthotropic clamped plate: $G_L(b_1) = G_R(b_2) = 0$, $G'_L(b_1) = G'_R(b_2) = 0$, $G_L(x') = G_R(x')$, $G'_L(x') = G'_R(x')$, $G''_L(x') = G''_R(x')$, and $G'''_L(x') - G'''_R(x') = R_0^3/D_x$, where $G_L(x)$ and $G_R(x)$ are defined as $G_L(x) = G(x, x')$ for $x < x'$ and $G_R(x) = G(x, x')$ for $x > x'$. Note that $D_x = (E_b + i\omega E_b^{'})I_b$ is the complex radial rigidity of the BM, D_z is the axial rigidity of the BM, and $\rho_b H_b$ is the mass per unit area of the BM. The plate Green's function is determined analytically in Mathematica and imported into MATLAB. More specifically, $G_R(x)$ and $G_L(x)$ are each the sum of four exponential functions with multiplicative constants. The boundary conditions lead to an 8×8 linear system, which is solved analytically.

The impedances of deformable surfaces are defined to be $Z_n = -P_0/U_{n0}$. The impedances are also determined as continuous functions using polynomial fits. This

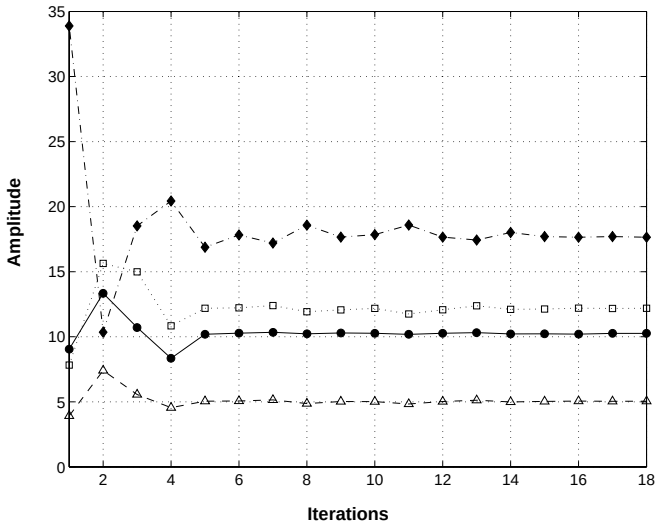

FIG. 3.1. *Convergence of the algorithm. Plots versus iteration number of the absolute values of the dimensional wavenumber* $\tilde{k}$ $[cm^{-1}]$ *(solid circle) and point impedances Z: middle of BM lower surface (open triangle), middle of RL (open square), and middle of TM lower surface (solid diamond). provides the eigenvalue solver with the mixed homogeneous boundary condition: $\partial P_0/\partial n + \rho\omega^2 R_0 Z_n P_0 = 0$. The eigenvalue solver gives the updated wavenumber $k_{eig} = \xi + i\eta$. This value of k_{eig} is used in the elliptic solver for the next iteration of pressure, and so on. The algorithm selects the k_{eig} that corresponds to a propagating mode, and rejects eigenvalues that correspond to evanescent waves with η large and negative. Iteration is stopped when both the real part and imaginary part of k_{eig} given by the eigenvalue solver satisfy the convergence conditions: $(\xi_m - \xi_{m-1})/\xi_m < tolerance$ and $(\eta_m - \eta_{m-1})/\eta_m < tolerance$, where m is the iteration cycle number. For the present calculation, we use $tolerance = 0.01$. Figure 3.1 shows that the algorithm is convergent. We also note that k_{eig} in the upper and lower chambers agree within a few percent.

4. Results and discussion. In this paper we concentrate on developing an algorithm to determine the wavenumber and *relative* motions in fluid and elastic domains as a function of frequency in a single transverse plane. This problem is not without interest in itself, since experiments measuring the motions of the BM and other structures are typically made in a single plane, with the frequency of the stimulus being varied. Thus in our calculation, the cross-sectional geometry is chosen to model the apex of guinea pig cochlea (see Figure 2.1). Parameters used in the computation are listed in Table 4.1. An elasticity map for the model is depicted in Figure 4.1.

Figure 4.2 shows the real part and the imaginary part of the complex-valued dimensional wavenumber $\tilde{k}$ of the propagating wave as a function of frequency f. The real part of $\tilde{k}$ is related to phase or wavelength of the traveling wave, while the imaginary part of $\tilde{k}$ is related to the damping of the traveling wave: as the real part of $\tilde{k}$ increases, the axial wavelength (λ) decreases ($\lambda = 2\pi/Re[\tilde{k}]$), and as the imaginary part of $\tilde{k}$ becomes more negative, the axial damping of the wave increases. A traveling wave with a positive real part and a negative imaginary part of $\tilde{k}$ represents a damped

TABLE 4.1
Parameters used for the apical turn of the guinea pig cochlea.

Symbol	Value and unit	Meaning
ρ	1 g/cm^3	Fluid density
ρ_b	1 g/cm^3	BM density
ρ_t	1 g/cm^3	TM density
ρ_c	1 g/cm^3	OC density
μ	0.01 g/(cm $\cdot$ s)	Fluid viscosity
$E_b{}'$	6e4 dyn $\cdot$ s/cm^2	BM damping
$E_t{}'$	0.3 dyn $\cdot$ s/cm^2	TM damping
$E_c{}'$	0.01 dyn $\cdot$ s/cm^2	OC damping
H_b	0.00015 cm	BM thickness
E_b	2e9 dyn/cm^2	BM Young's modulus
E_t	1e4 dyn/cm^2	TM Young's modulus
E_c	4e2 dyn/cm^2	OC Young's modulus
E_i	4e4 dyn/cm^2	IHCs Young's modulus
E_o	6e4 dyn/cm^2	OHCs Young's modulus
E_d	1e5 dyn/cm^2	DCs Young's modulus
E_p	4e5 dyn/cm^2	PCs Young's modulus
E_r	3e5 dyn/cm^2	RL Young's modulus
ϑ_t	0.49	TM Poisson's ratio
ϑ_c	0.49	OC Poisson's ratio
$b_2 - b_1$	0.025 cm	BM width
H_{gap}	0.00058 cm	Gap thickness
L_{gap}	0.015 cm	Gap length
K_s	1 dyn/cm	Hair bundle stiffness
D_z/D_x	0.1	BM axial coupling parameter

FIG. 4.1. *Elasticity map of the model. Scale is* $log_{10}E$, *where* E (dyn/cm^2) *has the values listed in Table* 4.1.

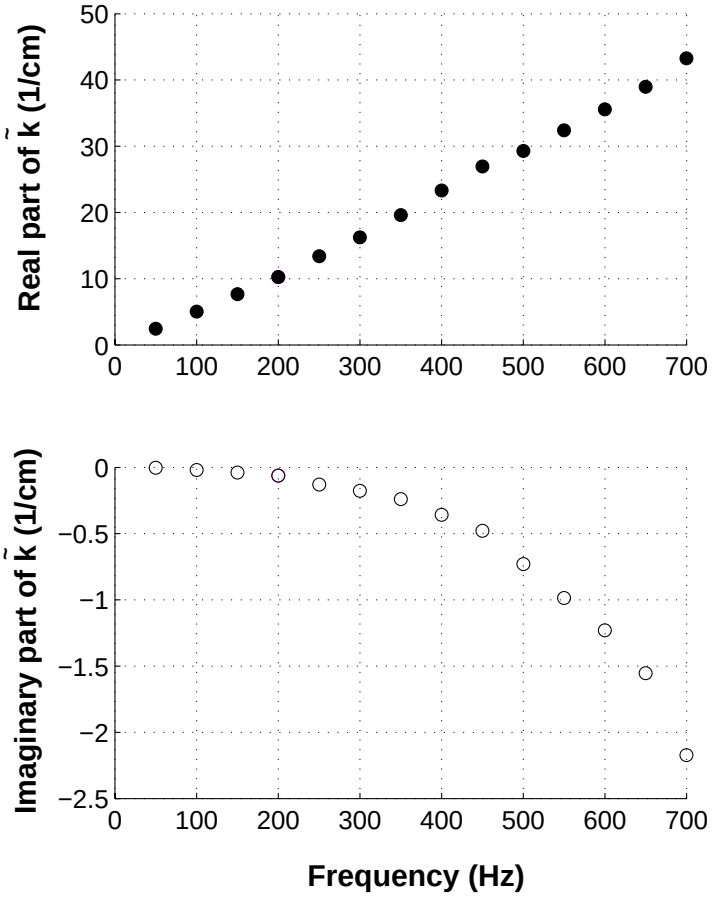

FIG. 4.2. *Dimensional wavenumber $\tilde{k}$. Real (solid circle) and imaginary (open circle) parts.*

right-running wave. von Békésy [6] shows 200 Hz waveforms on the cochlear partition inferred from measurements of amplitude and phase at the apex of human cadaver cochlea. Those waveforms have $\lambda \sim 0.6$cm. From Figure 4.2 we also find $\lambda \sim 2\pi/10 \sim 0.6$cm. At 700 Hz we find $\lambda \sim 2\pi/43 \sim 0.15$cm, which can be compared with the 0.155cm measurement made near the apex of the guinea pig cochlea at 1 kHz by Cooper and Rhode [10].

Modal pressure fields and CP displacements at 200 Hz and 700 Hz are shown in Figures 4.3 and 4.4, respectively. The spatial distribution of the fluid pressure is much more uniform at lower frequency (200 Hz) than at higher frequency (700 Hz). Our calculated pressure distribution in the ST at 700 Hz exhibits a pressure gradient similar to that measured by Olson [27]. In either case, the axial fluid velocity and pressure satisfy $\rho \frac{\partial \tilde{V}_Z}{\partial t} = -\frac{\partial \tilde{P}}{\partial Z}$ when the viscous boundary layer effect is neglected. The WKB approximation of this relation gives $\rho i\omega V_{0Z} = i\tilde{k}P_0$. Thus axial velocity is proportional to the product of wavenumber and fluid pressure at fixed frequency ($V_Z = \tilde{k}P_0/(\rho\omega)$). Because a single wavenumber $\tilde{k}$ exists in both the upper and lower chambers, the mass conservation condition for axial flow is $\langle P_{0u}\rangle A_u + \langle P_{0l}\rangle A_l = 0$, where $\langle\rangle$ denotes the area average. The pressure fields shown in Figures 4.3 and 4.4

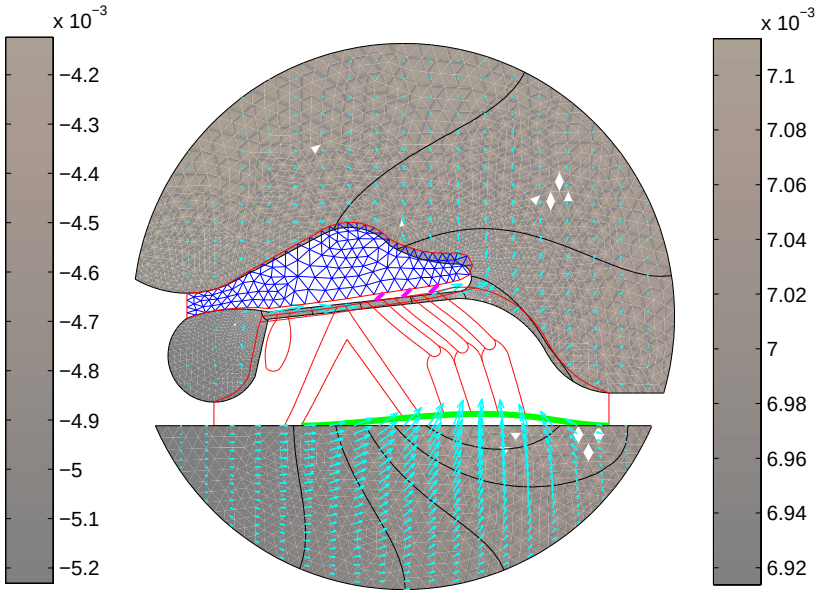

FIG. 4.3. *Snapshot of the real parts of modal pressure fields and CP displacements in an apical cross section at* 200 *Hz. The left and right grayscale maps represent the spatial distribution of the cochlear fluid pressure in the upper and lower chambers, respectively. Axial velocity is proportional to the pressure. Fluid velocity leads pressure gradient by* $\pi/2$ *radians, except in the gap, where flow is opposite to pressure gradient.*

satisfy this relation. We can also estimate the axial flow in the spiral sulcus (SS) and the radial flow in the gap. A radial flow in the gap is induced by the pressure gradient existing along the gap. This flow would be important for the stimulation of the IHCs whose stereocilia (not shown) are not in contact with the TM. Note that this Poiseuille flow, estimated as $Q_R \simeq H_{gap}^3 \lambda \Delta P_0/(48\mu L_{gap})$, is much smaller than the axial fluid flow in SS ($Q_Z \simeq \tilde{k} P_{0ss} A_{ss}/(\rho\omega)$). Note also that ΔP_0 is the pressure difference across the gap length, and P_{0ss} and A_{ss} are spiral sulcus pressure and area. Using $\nu = 0.01\text{cm}^2/s, A_{ss} = 0.009^2\text{cm}^2, f = 700$ Hz, $\tilde{k} = 43\text{cm}^{-1}$ (Figure 4.2), $H_{gap} = 6 \times 10^{-4}\text{cm}, Lgap = 0.015\text{cm}$, and $P_{0ss}/\Delta P_0 \simeq 2$ in Figure 4.4, we get $Q_Z/Q_R \simeq 360$.

von Békésy [6] observed the passive BM radial vibrational mode of the guinea pig cochlea near the helicotrema. He found that no vibrational subdivision of the BM by the pillar cells occurred at low frequencies. Our calculated CP vibrational modes agree with his findings (see Figures 4.3 and 4.4). When we increase the Young's modulus of the pillar cells by an order of magnitude, the BM retains its monophasic mode shape.

Figure 4.5 shows the detailed movements within the OC and TM at 700 Hz. We have found similar patterns at lower frequencies. An upward transverse movement of the BM develops into a leftward radial component at the RL. We find that the TM essentially rotates like a rigid body about its attachment to the bone, with little radial motion. This leads to a shear movement between TM and RL which causes a clockwise rotation of the stereocilia, as is commonly believed. This pattern of motion agrees with the experimental findings of Ulfendahl, Khanna, and Heneghan [37] and Hemmert, Zenner, and Gummer [14] at the apex of the guinea pig cochlea, and with the observation of Richter et al. [30] in the hemicochlear preparation. Gummer, Hemmert, and Zenner [13] and Hemmert, Zenner, and Gummer [15] measured a resonant TM radial motion that was rather sharply tuned to a frequency $\sim 1/2$ octave below the BM characteristic frequency. This radial TM resonance was not found by Ulfendahl, Khanna, and Heneghan [37], so there is some experimental disagreement concerning this finding. Lumped-parameter micromechanical models by Allen [3], which involved TM radial stiffness, and by Zwislocki [39], which involved OHC stereocilia stiffness, introduced the idea of a radial TM resonance or "second filter" to reconcile neural and mechanical tuning curves. The present calculations do not show a significant radial TM motion. It would be premature, however, to rule out the possibility that such a motion might be found.

Allen and Sondhi [2] showed that a small amount of axial rigidity reduces the high-frequency slope of the tuning curve. We have included axial elastic coupling in the model via an orthotropic plate model of the BM (see (3.2)). However, it turns out that small elastic coupling ($D_z/D_x = 0.1$) has a negligible effect on the radial mode shape and only slightly decreases the wavenumber. This decrease was previously found by Holmes and Cole [17]. Increasing stereocilia stiffness slightly reduced the real part of the wavenumber, while increasing fluid viscosity slightly increased the imaginary part of the wavenumber. Neither stereocilia stiffness nor viscosity changes seemed to affect the radial mode shapes.

Figure 4.6 shows the shear stresses along the lower surface of the TM in the gap at 700 Hz. The shear stresses due to Couette flow (τ_c) and Poiseuille flow (τ_p) are small relative to the pressure along the gap surface, but the shear stress induced by stereocilia (τ_s) is of the same order as the gap pressure.

In the future we would like to extend the model to include fluid domains in the OC.

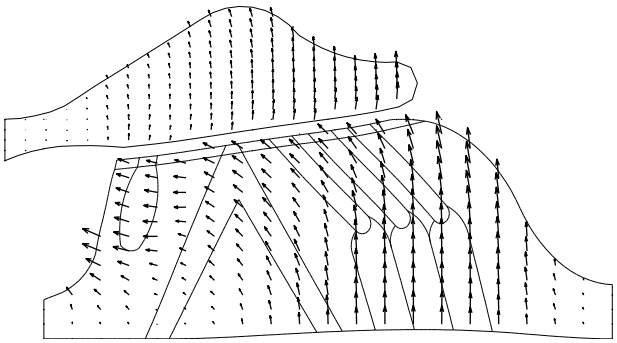

FIG. 4.5. *Detailed movements within the OC and TM. The direction and size of the arrows denote the velocity direction and amplitude of OC and TM movements. A shear movement is present between the TM and RL.*

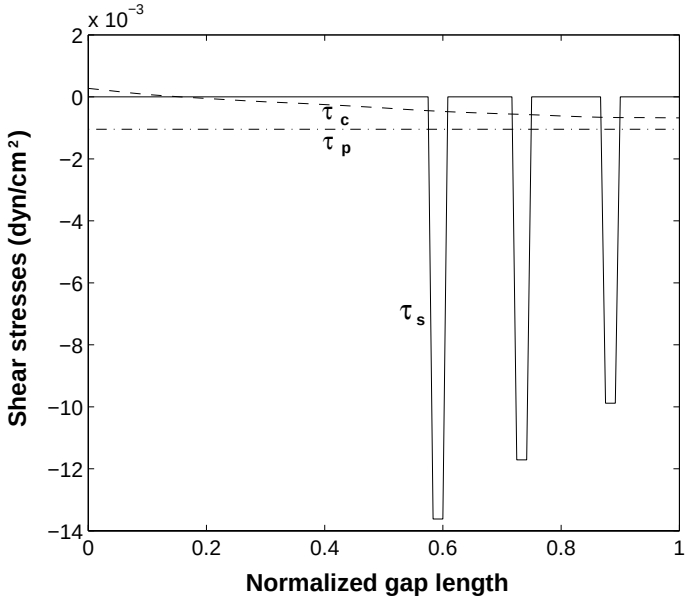

FIG. 4.6. *Shear stresses along the lower surface of the TM in the gap at* 700 *Hz.* τ_p*: Poiseuille flow-induced shear stress,* τ_c*: Couette flow-induced shear stress,* τ_s*: shear stress due to stereocilia stiffness.*

A preliminary effort in that direction has been made by Steele [32], who concluded that leakages between OC fluid domains must be important to mitigating the very high pressures that would otherwise develop inside the OC. A preliminary study of the effect of including the inner tunnel of Corti in our model corroborates that finding. Modeling the basal turn at high frequencies would obviously be desirable, but that presents difficulties in meshing the smaller OC and TM domains with the large fluid domains (ST, SM+SV).

Our results show that the hybrid WKB-numerical approach is a good choice for modeling the cochlea. It avoids a full 3D computation, and the number of transverse sections required for good axial resolution in our hybrid method is far less than the number of axial nodes required in full 3D numerics. This enables us to treat wave

propagation in the complex cochlear geometry with cellular resolution (10 microns) using a desktop workstation. Typical runtimes for a convergent solution at fixed frequency in a single cross section are in the range of 5–20 minutes, depending on initial guesses, while hours of computing time on a high-end computer are needed for a full 3D numerical model [28].

Appendix A. Tangential fluid stress on a deformable boundary segment. Within a thin fluid layer near a deformable boundary other than the TM-RL gap (Figure A.1), the tangential fluid velocity (q_0) and pressure (P_0) satisfy the linearized oscillatory boundary layer equation

$$\rho i\omega q_0 = -R_0^{-1}\frac{\partial P_0}{\partial s} + \mu R_0^{-2}\frac{\partial^2 q_0}{\partial n^2}, \tag{A.1}$$

where ρ and μ are the density and viscosity of the cochlear fluid, and n and s represent the outward normal and tangential direction of the deformable boundary, respectively. Let $q_0^* = V_{s0} - q_0$, where V_{s0} is the local inviscid tangential fluid velocity. Then

$$\mu R_0^{-2}\frac{\partial^2 q_0^*}{\partial n^2} - \rho i\omega q_0^* = -\frac{\partial P_0}{\partial s}R_0^{-1} - \rho i\omega V_{s0} = 0, \tag{A.2}$$

where ω is the radian frequency and $i = \sqrt{-1}$. Therefore,

$$R_0^{-2}\frac{\partial^2 q_0^*}{\partial n^2} - \frac{i\omega}{\nu}q_0^* = 0, \tag{A.3}$$

with $q_0^* \to 0$ as $n \to \infty$, and $q_0^* = V_{s0} - i\omega U_{s0}$ on $n = 0$, where U_{s0} is the boundary segment tangential displacement and $\nu = \mu/\rho$ is kinematic viscosity. Thus

$$q_0^* = (V_{s0} - i\omega U_{s0})e^{-nR_0\sqrt{i\omega/\nu}}, \tag{A.4}$$

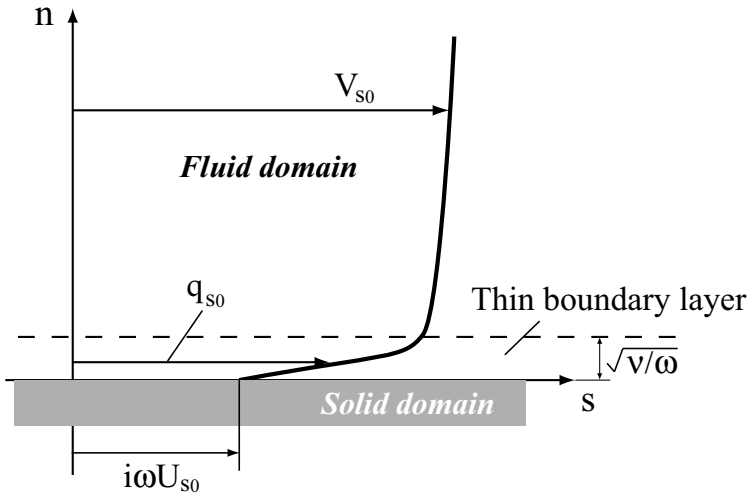

FIG. A.1. *Dominant WKB expansion of the tangential fluid velocity profile in a fluid domain with a deformable boundary segment.* $V_{s0} = -\frac{1}{\rho i\omega R_0}\frac{\partial P_0}{\partial s}$ *is the local inviscid tangential fluid velocity;* q_0 *is the tangential fluid velocity within the thin layer near the deforming boundary;* U_{s0} *is the boundary segment tangential displacement, and* $i\omega U_{s0}$ *is the tangential velocity.*

and the shear stress may be calculated from

$$\tau = \mu R_0^{-1} \frac{\partial q_0^*}{\partial n}\bigg|_{n=0} = \sqrt{i\omega\nu}\left(\frac{1}{i\omega R_0}\frac{\partial P_0}{\partial s} + i\rho\omega U_{s0}\right). \tag{A.5}$$

Appendix B. MATLAB numerical solvers. The MATLAB PDE Toolbox can solve elliptic and eigenvalue problems of the forms

$$-\nabla\cdot(c\nabla P_0) + aP_0 = f \tag{B.1}$$

and

$$-\nabla\cdot(c\nabla P_0) + aP_0 = \lambda d P_0 \tag{B.2}$$

in bounded domain Ω, where c, a, f, d, and the unknown P_0 are scalar, complex-valued functions on Ω, and λ is an unknown eigenvalue. The following boundary conditions are defined for scalar P_0:

(1) Dirichlet: $hP_0 = r$ on the boundary $\partial\Omega$.

(2) Generalized Neumann: $\mathbf{n}\cdot(\nabla P_0) + qP_0 = g$ on $\partial\Omega$,

where $\mathbf{n}$ is the outward unit normal. Here g, q, h, and r are complex-valued functions defined on $\partial\Omega$.

Note that, for solving the elliptic pressure P_0^{elli} of a fluid domain (see (2.10)), we let $c = -1$, $a = k^2$, and $f = 0$ in (B.1), and for solving eigenvalue k^2 and eigenvalue pressure P_0^{eigen} (see (2.10)), we let $c = -1$, $d = -1$, and $a = 0$ in (B.2). We define $q = 0$, and $g = 0$ and $g = -\rho\omega^2 R_0 U_{n_T 0}$ for rigid and deformable boundaries, respectively, to provide the elliptic solver boundary conditions (see (2.11)). For the eigenvalue solver we let $g = 0$ and $q = \rho\omega^2 Z_n$, where $Z_n = -P_0/U_{n0}$ is the impedance of deformable surfaces.

For the OC and TM solid domains, we use the following MATLAB Plane Strain solver:

$$-\nabla\cdot(\underline{\mathbf{c}}\otimes\nabla\mathbf{U_0}) + \mathbf{aU_0} = \mathbf{f}, \tag{B.3}$$

where $\underline{\mathbf{c}}$ is a rank-four tensor, which can be written as four 2-by-2 matrices c_{11}, c_{12}, c_{21}, c_{22}:

$$c_{11} = \begin{pmatrix} 2G+\zeta & 0 \\ 0 & G \end{pmatrix}, \qquad c_{12} = \begin{pmatrix} 0 & \zeta \\ G & 0 \end{pmatrix}, \tag{B.4}$$

$$c_{21} = \begin{pmatrix} 0 & G \\ \zeta & 0 \end{pmatrix}, \qquad c_{22} = \begin{pmatrix} G & 0 \\ 0 & 2G+\zeta \end{pmatrix},$$

where G, the shear modulus, is defined by $G = E/2(1+\vartheta)$, and ζ in turn is defined by $2G\vartheta/(1-2\vartheta)$. $\mathbf{f} = (f_x, f_y)^T$ are volume forces. By the notation $\nabla\cdot(\underline{\mathbf{c}}\otimes\nabla\mathbf{U_0})$, we mean the 2-by-1 vector with $(i,1)$-component:

$$\sum_{j=1}^{2}\left(\frac{\partial}{\partial x}c_{ij11}\frac{\partial}{\partial x} + \frac{\partial}{\partial x}c_{ij12}\frac{\partial}{\partial y} + \frac{\partial}{\partial y}c_{ij21}\frac{\partial}{\partial x} + \frac{\partial}{\partial y}c_{ij22}\frac{\partial}{\partial y}\right)U_{0j}. \tag{B.5}$$

When constructing the geometry of the OC, we define the left and right subdomain numbers of each segment in the geometry matrix. Three matrices of fixed format contain the information about mesh points, the boundary segments, and the triangles

when a triangular mesh is built on the domain Ω by MATLAB mesh generating and refining facilities. The MATLAB function pdesdt can provide indices of the triangles inside a subdomain. Thus we can discretize the above PDE coefficients c_{ij} and boundary conditions on Ω to obtain a linear system which will give the approximate solution at the mesh points of the unknown displacements (U_{0x} and U_{0y}). Because the PDE coefficients c_{ij} contain the Young's modulus E and the Poisson's ratio ϑ, the inhomogeneities of the OC are introduced by its E-map discretized on Ω. (Note that the Poisson's ratio ϑ is constant on all subdomains.)

Acknowledgments. The authors thank E. K. Dimitriadis, K. Iwasa, and B. Shoelson for their helpful comments.

SIMULATION OF WAVE INTERACTIONS AND TURBULENCE IN ONE-DIMENSIONAL WATER WAVES*

KURT M. BERGER† AND PAUL A. MILEWSKI‡

Abstract. The weak- or wave-turbulence problem consists of finding statistical states of a large number of interacting waves. These states are obtained by forcing and dissipating a conservative dispersive wave equation at disparate scales to model physical forcing and dissipation, and by predicting the spectrum, often as a Kolmogorov-like power law, at intermediate scales. The mechanism for energy transfer in such systems is usually triads or quartets of waves. Here, we first derive a small-amplitude nonlinear dispersive equation (a finite-depth Benney–Luke-type equation), which we validate, analytically and numerically, by showing that it correctly captures the main deterministic aspects of gravity wave interactions: resonant quartets, Benjamin–Feir-type wave-packet stability, and wave-mean flow interactions. Numerically, this equation is easier to integrate than either the full problem or the Zakharov integral equation. Some additional features of wave interaction are discussed such as harmonic generation in shallow water. We then perform long time computations on the forced-dissipated model equation and compute statistical quantities of interest, which we compare to existing predictions. The forward cascade yields a spectrum close to the prediction of Zakharov, and the inverse cascade does not.

1. Introduction.

The weak- or wave-turbulence problem consists of finding statistical states of a large number of interacting waves. These states are obtained by forcing and dissipating a conservative dispersive wave problem at disparate scales and predicting the spectrum, often as a Kolmogorov-like power law, at intermediate scales. In dispersive waves, the energy transfer between waves occurs mostly amongst *resonant* sets of waves, usually triads or quartets of waves. Here we consider only quartets since triads do not exist in surface gravity waves. Quartet resonances occur when the product of a pair of waves has a component with the same frequency and wavenumber as the product of two other waves. For simple waves $e^{i(\mathbf{k}_j\cdot\mathbf{x}-\omega(\mathbf{k}_j)t)}$, this means

$$\mathbf{k}_1+\mathbf{k}_2=\mathbf{k}_3+\mathbf{k}_4, \tag{1.1}$$

$$\omega(\mathbf{k}_1)+\omega(\mathbf{k}_2)=\omega(\mathbf{k}_3)+\omega(\mathbf{k}_4). \tag{1.2}$$

In dispersive problems, these resonant sets are sparse, in contrast to nondispersive problems, where interactions are dense in Fourier space ((1.2) is always satisfied). The deterministic dynamics of *isolated* resonant quartets are modeled by sets of coupled nonlinear differential equations for the wave amplitudes and are well understood (see [10]). The dynamics of quartets which are not isolated (allowed to interact with other quartets) are poorly understood. In the limit in which all possible quartets are active, statistical theories of wave turbulence apply.

‡Department of Mathematics, University of Wisconsin, 480 Lincoln Dr., Madison, WI 53706 (milewski@math.wisc.edu). The research of this author was partially supported by NSF-DMS and a Sloan Research Fellowship.

The initial work on wave turbulence was done by Hasselmann [14], Benney and Saffmann [7], and Benney and Newell [5], who introduced the statistical closures based on the resonant wave interactions. Zakharov [29], through conformal transformations, solved the resulting kinetic equation and obtained the power law for the Kolmogorov spectrum. The particular physical context for these initial results was the ocean surface gravity wave spectrum.

Majda, McLaughlin, and Tabak [19] started the numerical investigation of the predictions of weak turbulence theory using a nonlinear Schrödinger-like (NLS) model equation. Adding large-scale forcing and dissipation to their one-dimensional model, they investigated the turbulent cascades of energy and initially showed that Zakharov's [29] prediction for the energy spectrum did not hold, proposing a simpler, yet unrigorous quartet-based scaling to explain their results. More recent work by Cai et al. [9] and Zakharov et al. [30] shows that several meta-stable spectra can coexist in the system, with the Zakharov spectra being among those observed.

Classical, small-amplitude periodic gravity waves, discovered by Stokes, are unstable to small modulations through the Benjamin–Feir instability. This result was derived independently by Lighthill [15], Benjamin [1], and Whitham [26], and confirmed experimentally by Benjamin and Feir [2]. One can obtain the result by analyzing the slow modulation of gravity waves and deriving an NLS equation for the evolution of the wave envelope (see Hasimoto and Ono [13] and Zakharov [28], among others). A plane wave solution of the NLS equation corresponds to the Stokes wave, and it can be shown for waves of wavelength $\frac{2\pi}{k}$ in water of depth H to be unstable when $kH > 1.363$. (Waves in deeper water are unstable, and the NLS switches from "defocusing" to "focusing.") Davey and Stewartson [11] generalized this result to two spatial dimensions, deriving a more complicated NLS-type equation. This result for two-dimensional waves was derived independently a few years earlier, however, by Benney and Roskes [6], albeit in a slightly different form.

Here we investigate wave interaction and turbulence numerically for an equation describing small-amplitude gravity water waves. We perform wave interaction experiments and long time wave turbulence computations using a finite-depth Benney–Luke (fBL) equation [21]. To validate this model, we first show, analytically and numerically, that the fBL equation correctly captures the main deterministic aspects of resonant gravity wave interactions: resonant quartets and the Benjamin–Feir-type wave-packet stability. Some additional features of our numerical results are discussed: the generation of harmonics in shallow water and the long time frequency downshift of unstable wavepackets. For the wave-turbulence experiments, we compare the computed wave spectrum to predicted spectra. We note that the use of a single partial differential equation, rather than the full water wave equations, makes computing complex surface wave dynamics possible. All of our work is for a one-dimensional free surface. Although the computation of the two-dimensional free surface problem is not fundamentally different, we restrict our attention to the one-dimensional problem because of computational time constraints.

We note that there is a fundamental difference in the wave interaction problem between the one-dimensional and two-dimensional free surface. In two dimensions and infinite depth, the fundamental interaction mechanism is resonant quartets. The quartet interaction coefficients, however, vanish as the waves become parallel to each other, and therefore, for one-dimensional infinite depth, quartets are not important. Thus in a one-dimensional deep water system, the strongest mechanism for energy exchange between Fourier modes is the Benjamin–Feir instability, which is local in Fourier space, and the slower quintet interaction, which requires quartic terms in the

equations to be modeled correctly. The Benjamin–Feir instability is also relevant for two-dimensional free surface problems.

For a one-dimensional free surface over water of finite depth, there exist quartet interactions (which vanish as $|\mathbf{k}| \to \infty$ to agree with the deep water limit). Therefore the one-dimensional finite depth problem is a computationally accessible useful test for the more relevant two-dimensional problem. That is why we restrict our numerical calculations to waves that are long enough to be influenced by the bottom.

The remainder of this paper is organized as follows. In section 2, we derive the fBL equation. Next, in section 3, we derive the nonlinear Schrödinger equation from the one-dimensional fBL equation using a multiple-scales approach, in a manner similar to Hasimoto and Ono, who started from the full water wave equations. This NLS equation correctly predicts the Benjamin–Feir instability limit, which we verify numerically using the fBL equation. In section 4 we derive a set of new partial differential equations that describe the coupled evolution of quartets and the induced mean flow for one-dimensional finite-depth gravity waves. We then show that solutions to these quartet equations closely match numerical solutions of the fBL equation, when initialized with four waves that satisfy the resonance conditions. We also study a model of the interaction of a primary wave and its quasi-resonant second harmonic in shallow water to explain the quartet simulation results. Finally, in the last section, we investigate wave turbulence numerically using the fBL model.

2. The Benney–Luke equation for gravity waves in finite depth. The Benney–Luke equation [4] describes the evolution of three-dimensional, weakly nonlinear waves in shallow water. Recently Milewski and Keller [22] derived a more general Benney–Luke model for waves in water of finite depth, shown here in a slightly different (and corrected) form:

$$u_{tt} + \mathcal{L}u + \epsilon\mathcal{N}_1(u,u) + \epsilon^2\mathcal{N}_2(u,u,u) = 0 \tag{2.1}$$

with quadratic terms

$$\mathcal{N}_1 = (\nabla u)_t^2 + (\mathcal{L}u)_t^2 + u_t\Delta u - u_t\mathcal{L}u_{tt} \tag{2.2}$$

and cubic terms

$$\mathcal{N}_2 = \frac{1}{6}\nabla\cdot(\nabla u\,(\nabla u)^2) + (\Delta u - \mathcal{L}^2 u)\left(u_t\mathcal{L}u_t - \frac{1}{2}(\mathcal{L}u)^2\right) + 2u_t\Delta u_t\mathcal{L}u$$

$$- 2u_t(\nabla u\cdot\nabla\mathcal{L}u)_t + 2\mathcal{L}u(\nabla u\cdot\nabla\mathcal{L}u) + \frac{1}{2}\mathcal{L}^2u(\nabla u)^2. \tag{2.3}$$

In this equation, $\epsilon = a/H \ll 1$ is the ratio of wave amplitude a to depth H, $u(x,y,t)$ is the velocity potential at the undisturbed free surface $z = H$, and $\mathcal{L}$ is the operator $\mathcal{L} = (-\Delta)^{\frac{1}{2}}\tanh[(-\Delta)^{\frac{1}{2}}]$, resulting in the dispersion relation $\omega^2 = |\mathbf{k}|\tanh(|\mathbf{k}|)$. The water surface is given by $H + \eta(x,y,t)$, where, to leading order, $\eta = -u_t$. The fBL is derived as follows. Using the depth H as both the horizontal and vertical length scale, a as the scale for typical free surface displacements, $a\sqrt{gH}$ as the velocity potential scale, and $\sqrt{H/g}$ as the time scale, the dimensionless water wave equations can be written in terms of the velocity potential $\phi(x,y,z,t)$ and free

surface displacement $\eta(x,y,t)$ as

$$\Delta\phi + \phi_{zz} = 0, \quad 0 < z < 1 + \epsilon\eta, \tag{2.4}$$

$$\phi_z = 0, \quad z = 0, \tag{2.5}$$

$$\eta_t + \epsilon(\nabla\eta \cdot \nabla\phi) - \phi_z = 0, \quad z = 1 + \epsilon\eta, \tag{2.6}$$

$$\phi_t + \frac{\epsilon}{2}(\nabla\phi)^2 + \frac{\epsilon}{2}\phi_z^2 + \eta = 0, \quad z = 1 + \epsilon\eta. \tag{2.7}$$

Expanding the two surface boundary conditions about $z = 1$ and eliminating η leads to a single boundary condition in ϕ at $z = 1$, correct to $\mathrm{O}(\epsilon^2)$:

$$\phi_{tt} + \phi_z + \epsilon\mathcal{Q}_1(\phi,\phi) + \epsilon^2\mathcal{Q}_2(\phi,\phi,\phi) = 0, \tag{2.8}$$

where the quadratic terms are

$$\mathcal{Q}_1(\phi,\phi) = \left[\frac{1}{2}((\nabla\phi)^2 + \phi_z^2) - \phi_t\phi_{tz}\right]_t + \nabla\cdot(\phi_t\nabla\phi) \tag{2.9}$$

and the cubic terms are

$$\begin{aligned}\mathcal{Q}_2(\phi,\phi,\phi) = &\left[-\frac{1}{2}\phi_t((\nabla\phi)^2 + \phi_z^2)_z + \phi_t\phi_{tz}^2 + \frac{1}{2}\phi_{tzz}\phi_t^2\right]_t \\ &+ \nabla\cdot\left[\frac{1}{2}(\nabla\phi)((\nabla\phi)^2 + \phi_z^2) - (\nabla\phi)\phi_t\phi_{tz} - \frac{1}{2}(\nabla\phi_z)\phi_t^2\right].\end{aligned} \tag{2.10}$$

Next, we solve Laplace's equation with the bottom boundary condition, obtaining

$$\phi(x,y,z,t) = \cosh[z(-\Delta)^{\frac{1}{2}}]\Phi(x,y,t), \tag{2.11}$$

with

$$u(x,y,t) = \phi(x,y,1,t) = \cosh[(-\Delta)^{\frac{1}{2}}]\Phi(x,y,t) \tag{2.12}$$

being the velocity potential at $z = 1$. With this notation, it follows that $\phi_z(x,y,1,t) = \mathcal{L}u$ and $\phi_{zz}(x,y,1,t) = -\Delta u$, where $\mathcal{L}$ is defined as $\mathcal{L} = (-\Delta)^{\frac{1}{2}}\tanh[(-\Delta)^{\frac{1}{2}}]$ and has the symbol $\hat{\mathcal{L}}(\mathbf{k}) = |\mathbf{k}|\tanh(|\mathbf{k}|)$. Thus if $\hat{u}(\mathbf{k},t)$ is the Fourier transform of $u(\mathbf{x},t)$, then

$$\mathcal{L}u = \frac{1}{2\pi}\int_{-\infty}^{\infty} |\mathbf{k}|\tanh(|\mathbf{k}|)e^{i\mathbf{k}\cdot\mathbf{x}}\hat{u}(\mathbf{k},t)d\mathbf{k}. \tag{2.13}$$

Substitution into the boundary condition (2.8) yields, after some simplification, the fBL equation (2.1).

We note that since ϵ is the ratio of the amplitude of the free surface displacement to depth, the wave slope appears to be arbitrary. However, note that for $|\mathbf{k}|$ large the wave slope $\hat{\eta}_x = O(|\mathbf{k}|^{3/2}\hat{u})$ and that in (2.1), $\mathcal{N}_j = O(|\mathbf{k}|^{(1+3/2j)}\hat{u}^j)$, thus implying that solutions of the fBL are relevant only if the wave slope is also small as waves get short compared to depth. For the shallow limit, $|\mathbf{k}|$ small, $\hat{\eta} = O(|\mathbf{k}|\hat{u})$, $\hat{\eta}_x = O(|\mathbf{k}|^2\hat{u})$, and $\mathcal{N}_j = O(|\mathbf{k}|^{(2+j)}\hat{u}^j)$, requiring only that η be small.

A similar equation applies for gravity waves in water of infinite depth, now with ϵ being the wave slope (ratio of the amplitude of the surface displacement to a characteristic length scale), and $\hat{\mathcal{L}} = |k|$. Therefore, $\mathcal{L} = (-\Delta)^{\frac{1}{2}}$, which, in the case of one horizontal dimension, is $\mathcal{L} = -\partial_x \mathcal{H}$, where $\mathcal{H}$ is the Hilbert transform. For the deep-water limit, the derivation must be modified slightly. The origin of the vertical axis is shifted to the undisturbed fluid level, and the bottom boundary condition becomes $|\nabla\phi| \to 0, z \to -\infty$. Expanding the two surface boundary conditions about $z = 0$ and eliminating η again leads to (2.8). Solving Laplace's equation with the new bottom boundary condition modifies the depth dependence of the velocity potential:

$$\phi(x, y, z, t) = e^{z(-\Delta)^{\frac{1}{2}}} \Phi(x, y, t). \tag{2.14}$$

Correspondingly, the velocity potential at $z = 0$ is just

$$u(x, y, t) = \phi(x, y, 0, t) = \Phi(x, y, t), \tag{2.15}$$

and $\mathcal{L}$ is now defined as $\mathcal{L} = (-\Delta)^{\frac{1}{2}}$ and has the symbol $\hat{\mathcal{L}}(\mathbf{k}) = |\mathbf{k}|$.

In the remainder of this paper we assume that the free surface is one-dimensional.

3. Nonlinear modulation of gravity waves. We consider the slow modulation of one-dimensional gravity waves in water of finite depth using the fBL equation, obtaining an NLS equation, in agreement with earlier results. This equation predicts instability for $kH > 1.363$. Of critical importance in the derivation of this NLS equation is a wave-induced mean flow, which vanishes in the deep water limit.

3.1. Derivation of an NLS equation. In what follows, we employ the method of multiple scales, introducing the slow space and time scales $X = \epsilon x$, $T = \epsilon t$, and $\tau = \epsilon^2 t$. The NLS equation governs the evolution of wave packets or, alternatively, of a narrowly peaked Fourier spectrum centered at k_c. Thus one expands the governing equations with $k = k_c + \epsilon\Delta k$. The equation in physical space is then recovered with the duality $\partial_X \leftrightarrow i\epsilon\Delta k$. Thus, in (2.1) we make the substitutions $\partial_t \to \partial_t + \epsilon\partial_T + \epsilon^2\partial_\tau$ and $\partial_x \to \partial_x + \epsilon\partial_X$ and, for $\mathcal{L}$,

$$\mathcal{L} \to \mathcal{L} - \epsilon i \frac{\partial \hat{\mathcal{L}}}{\partial k}\partial_X - \frac{1}{2}\epsilon^2 \frac{\partial^2 \hat{\mathcal{L}}}{\partial k^2}\partial_{XX}, \tag{3.1}$$

where k_c is denoted k. The dispersion relation is

$$\omega^2(k) = \hat{\mathcal{L}} = |k| \tanh(|k|), \tag{3.2}$$

and

$$\frac{\partial \hat{\mathcal{L}}}{\partial k} = 2\omega c_g(k), \tag{3.3}$$

$$\frac{\partial^2 \hat{\mathcal{L}}}{\partial k^2} = 2c_g^2 + 2\omega \frac{\partial c_g}{\partial k}, \tag{3.4}$$

where $c_g(k)$ is the group velocity.

After substitution, we have the following equation for $u(x, t, X, T, \tau)$:

$$\begin{aligned} &u_{tt} + \mathcal{L}u + \epsilon\left(2u_{tT} - i\frac{\partial \hat{\mathcal{L}}}{\partial k}u_X + \mathcal{N}_1(u, u)\right) \\ &\quad + \epsilon^2\left(2u_{t\tau} + u_{TT} - \frac{1}{2}\epsilon^2 \frac{\partial^2 \hat{\mathcal{L}}}{\partial k^2}u_{XX} + \mathcal{N}_2(u, u, u) + \mathcal{M}(u, u)\right) = 0, \end{aligned} \tag{3.5}$$

where

$$\mathcal{M}(u,u) = u_T(u_{xx} - \mathcal{L}u_{tt}) + 2u_t(u_{xX} - \mathcal{L}u_{tT}) + iu_t\frac{\partial\hat{\mathcal{L}}}{\partial k}u_{ttX} + 2u_x(u_{xT} + u_{Xt})$$
$$+ 2u_Xu_{xt} - 2i\mathcal{L}u\frac{\partial\hat{\mathcal{L}}}{\partial k}u_{tX} + 2\mathcal{L}u\mathcal{L}u_T - 2i\frac{\partial\hat{\mathcal{L}}}{\partial k}u_X\mathcal{L}u_t. \tag{3.6}$$

Next, we expand u in the small parameter ϵ as $u = u_0 + \epsilon u_1 + \epsilon^2 u_2 + \cdots$ and look for a single plane wave of slowly varying amplitude and wavelength $\frac{2\pi}{k}$:

$$u_0(x,t,X,T,\tau) = A(X,T,\tau)e^{i\theta} + * + B(X,T,\tau), \tag{3.7}$$

where $\theta = kx - \omega t$, B is the "mean-flow" component, and the $*$ denotes the complex conjugate of the preceding terms. We note that although the waves are $O(\epsilon)$, the mean flow B_x is $O(\epsilon^2)$. Substitution into (3.5) leads to a series of equations at various orders of ϵ. The O(ϵ) equation is

$$u_{1tt} + \mathcal{L}u_1 = -\left(2u_{0tT} - i\frac{\partial\hat{\mathcal{L}}}{\partial k}u_{0X}\right) - \mathcal{N}_1(u_0,u_0). \tag{3.8}$$

The first terms on the right of the above equation are secular and impose that A is moving at the group velocity. Thus, with $\xi = X - c_gT$, the right-hand side becomes $3i\omega|k|^2(\sigma^2-1)A^2e^{2i\theta} + *$, where $\sigma = \tanh(|k|)$, $A = A(\xi,\tau)$, and

$$u_1 = \frac{3i|k|^2(1-\sigma^4)}{4\sigma^2\omega}A(\xi,\tau)^2e^{2i\theta} + *. \tag{3.9}$$

Proceeding to O(ϵ^2) terms, the equation is

$$u_{2tt} + \mathcal{L}u_2 = \left(2u_{1tT} - i\frac{\partial\hat{\mathcal{L}}}{\partial k}u_{1X}\right) - \left(2u_{0t\tau} + u_{0TT} - \frac{1}{2}\frac{\partial^2\hat{\mathcal{L}}}{\partial k^2}u_{0XX}\right)$$
$$- \left(\mathcal{N}_1(u_0,u_1) + \mathcal{N}_1(u_1,u_0) + \mathcal{M}(u_0,u_0) + \mathcal{N}_2(u_0,u_0,u_0)\right). \tag{3.10}$$

In this equation, eliminating the secular terms in $e^{i\theta}$ and mean flows (e^{i0}) leads to the two equations

$$B_{\xi\xi} = \frac{\gamma}{c_g^2 - 1}(AA^*)_\xi \tag{3.11}$$

and

$$iA_\tau + \alpha A_{\xi\xi} = \bar{\beta}|A|^2A + \frac{\gamma}{2\omega}B_\xi A, \tag{3.12}$$

where

$$\gamma(k) = 2k\omega + c_g|k|^2(1-\sigma^2),$$
$$\alpha(k) = \frac{1}{2}\frac{\partial c_g}{\partial k},$$
$$\bar{\beta}(k) = \frac{9 - 12\sigma^2 + 13\sigma^4 - 2\sigma^6}{4\omega\sigma^2}|k|^4.$$

Integrating (3.11) to obtain the induced horizontal mean flow $B_\xi = \frac{\gamma}{c_g^2-1}|A|^2$ (we ignore the constant of integration, which would correspond to an imposed weak flow)

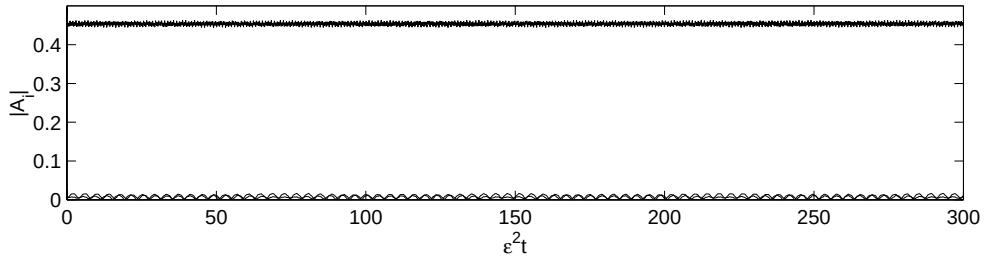

FIG. 3.1. *Evolution of a single plane wave and two small side-bands using the one-dimensional fBL equation. Here* $kH = 1.344 < 1.363$, *and stability is expected.*

and substituting into (3.12) yields a nonlinear Schrödinger equation for the complex amplitude $A(\xi, \eta)$:

$$iA_\tau + \alpha A_{\xi\xi} = \beta |A|^2 A, \tag{3.13}$$

with

$$\beta(k) = \bar{\beta} + \frac{\gamma^2}{2\omega(c_g^2 - 1)}. \tag{3.14}$$

The well-known fact that the mean flow vanishes in the deep water limit can be obtained by writing the mean flow in dimensional variables and taking $H \to \infty$.

3.2. Benjamin–Feir instability. The plane wave solution of the NLS equation $A = A_0 e^{-i\beta|A_0|^2\tau}$ for constant A_0 corresponds to the Stokes wave train to $O(\epsilon^2)$ (see [13]). Moreover, linear stability analysis (see [10] and [13]) shows that a plane wave solution to (3.13) will be unstable if the product $\alpha\beta < 0$. Given the finite-depth dispersion relation, we find $\alpha(k) < 0$ for all k, and $\beta(k)$ changes sign at $k \approx 1.363$, becoming positive for k larger than this value. This is the well-known Benjamin–Feir instability criterion. Note that the induced mean-flow plays an important result in this derivation, and in the deep-water limit this flow is not present.

To verify the stability predictions of this NLS equation, we numerically solve the fBL equation with initial condition $u(x, 0) = Ae^{ikx} + a(e^{i(k+\Delta k)x} + e^{i(k-\Delta k)x}) + *$ corresponding to a primary plane wave of wavenumber k and two side-bands of the next adjacent wavenumbers. We use a relative amplitude of $a = 0.01A$ with $\Delta k = \frac{1}{32}$. Dimensionally, our wavenumber k corresponds to kH, and we take two values on either side of the $kH = 1.363$ limit. Figures 3.1 and 3.2 show the results for $kH = 1.344$ and $kH = 1.438$, respectively, on the long time scale $\tau = \epsilon^2 t$. Note the instability of the primary mode and the side-bands in the second figure. The calculations do not show cyclic modulation and demodulation (or recurrence, present for some limits of the Benjamin–Feir instability) due to the relatively large amplitude of the carrier wave.

The extension to two dimensions (two-dimensional instabilities of plane waves) is straightforward, and the fBL equation is an appropriate starting point for an asymptotic study (such as that of Davey and Stewartson and of Benney and Roskes) or numerical experiments.

We note that in our calculations of the unstable Benjamin–Feir regime it is the lower Fourier side-bands that dominate the spectrum. This "frequency downshift"

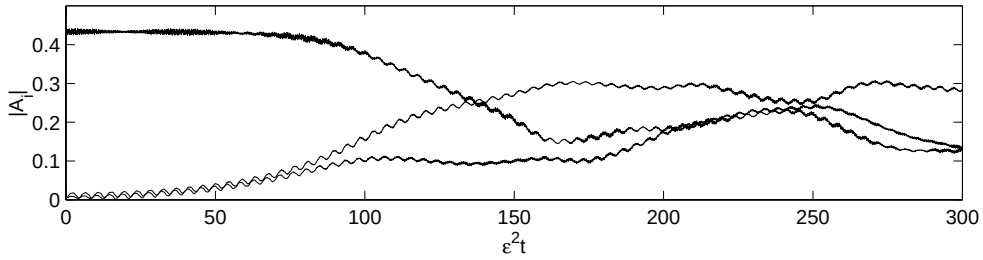

FIG. 3.2. *Evolution of a single plane wave and two small side-bands using the one-dimensional fBL equation. Here* $kH = 1.438 > 1.363$, *and growth of the side-bands is observed.*

has been observed experimentally [18] and is thought to be a three-dimensional phenomenon requiring a combination of nonlinear wave modulation and dissipation [25]. We do not perform here detailed calculations of this phenomenon; however, we believe that the equations used here (at least for two-dimensional free surface waves) could be used for this purpose.

4. Resonant interaction of gravity waves. Nonlinear resonance, an important mechanism for the transfer of energy among periodic wave trains, was pioneered by Phillips, Benney, Longuet-Higgins, and others in the 1960s (see below). The basic idea is that two or more distinct wave trains can combine to produce a perturbation with a frequency that corresponds to the natural frequency of a free wave with the same wavenumber. When this occurs, we have resonance, and the amplitude of the response grows linearly. Resonance with three waves, known collectively as a *triad*, is only possible when the dispersion curve has an inflection point (such as in capillary-gravity waves). For pure gravity waves, resonance is possible only among sets of four waves, known as *quartets*.

The idea of resonance for dispersive waves was first suggested by Phillips [24], who showed that three gravity surface waves could resonantly force a fourth wave, forming a quartet. Using the method of multiple scales, Benney [3] derived a coupled set of ordinary differential equations describing the amplitude evolution of a quartet of deep water gravity waves. Bretherton [8] showed that these types of coupled ordinary differential equations could be solved exactly using Jacobi elliptic functions. Experimental confirmation of the existence and importance of resonant water wave interactions was provided by Longuet-Higgins and Smith [17] and McGoldrick et al. [20]. Hammack and Henderson [12] provide a review of experimental results concerning resonant interaction theory for water waves, while the book by Craik [10] gives a comprehensive treatment of wave interactions in general, including triads and quartets in surface waves.

Here we derive a set of equations describing the resonant interaction of four gravity waves in water of finite depth using the fBL equation. The derivation of these "quartet equations" will closely parallel that of the NLS equation in the previous section, except that we will consider the amplitudes of *four* surface waves as well as the induced mean flow. A similar derivation in infinite depth leads to a set of equations whose primary interaction coefficients are zero, indicating that there is *no* quartet interaction in the one-dimensional "deep water" case. This is predicted by the analysis of Longuet-Higgins [16] and shown analytically by Zahkarov [27]. This is not true of two-dimensional infinite-depth gravity waves, nor of the one-dimensional *finite-depth* waves, which we consider here (although the quartet coefficients vanish for $|k| \to \infty$).

4.1. Derivation of quartet/mean-flow equations. Beginning with the one-dimensional fBL equation (2.1), we proceed with the method of multiple scales as before, obtaining (3.5). Again, we expand u in the small parameter ϵ as

$$u = u_0 + \epsilon u_1 + \epsilon^2 u_2 + \cdots \tag{4.1}$$

but now consider a set of plane waves of slowly varying amplitude:

$$u_0(x,t,X,T,\tau) = B(X,T,\tau) + \sum_{j=1}^{4} A_j(X,T,\tau) e^{i(k_j x - \omega_j t)} + *. \tag{4.2}$$

Furthermore, we assume that the four plane waves form a resonant quartet satisfying (1.1)–(1.2). Using the notation $\theta = kx - \omega(k)t$, the resonance condition is $\theta_1 + \theta_2 = \theta_3 + \theta_4$. Substitution into (3.5) again leads to a series of equations at various orders of ϵ. The $O(\epsilon)$ equation is (3.8), and we introduce four frames $\xi_j = X - c_g(k_j)T$ moving at the four group velocities $c_g(k_j)$ and assume that $A_j = A_j(\xi_j, \tau)$.

The quadratic term $\mathcal{N}_1$ is the product of two sums of eight terms each (four plane waves and their conjugates). We need to keep track of only a subset of the sixty-four possible quadratic terms, since we are interested in only those terms that can combine to form quartets at the next order. We will ignore the creation of the conjugate modes, since they are derivable from the main result for the primary modes. For example, at this order we need to account for the $\theta_1 + \theta_2$ term, since $\theta_4 = \theta_1 + \theta_2 - \theta_3$, but can ignore the $-\theta_1 - \theta_2$ term, since this is used only in forming the conjugate of the $e^{i\theta_4}$ wave. With this in mind, the $O(\epsilon)$ problem can be written

$$u_{1tt} + \mathcal{L} u_1 = -i \sum_{a,b} G(a,b) A_a A_b e^{i(\theta_a + \theta_b)}, \tag{4.3}$$

in which

$$G(a,b) = \omega_a (k_b^2 - \omega_b^2 \hat{\mathcal{L}}(k_b)) + 2\omega_b (k_a k_b - \hat{\mathcal{L}}(k_a)\hat{\mathcal{L}}(k_b)) \tag{4.4}$$

and $a, b \in \{1, -1, 2, -2, 3, -3, 4, -4\}$, with the notation $k_{-1} = -k_1$, $\omega_{-1} = -\omega_1$, $A_{-1} = A_1^*$, etc. Here the sum is over those combinations of (a,b) that are relevant to forming quartets, and it varies for which of the four waves is being created.

A particular solution to the $O(\epsilon)$ equation (4.3) is

$$u_1 = -i \sum_{a+b \neq 0} \frac{G(a,b)}{\hat{\mathcal{L}}(k_a + k_b) - (\omega_a + \omega_b)^2} A_a A_b e^{i(\theta_a + \theta_b)}, \tag{4.5}$$

where, again, the details of the sum (discussed below) depend on the primary wave being formed. The restriction on the sum ($a + b \neq 0$) is added because both numerator and denominator vanish (there is no mean flow generated at this order). Proceeding to $O(\epsilon^2)$ terms, the equation is

$$\begin{aligned} u_{2tt} + \mathcal{L} u_2 = &\left(2u_{1tT} - i \frac{\partial \hat{\mathcal{L}}}{\partial k} u_{1X} \right) - \left(2u_{0t\tau} + u_{0TT} - \frac{1}{2} \frac{\partial^2 \hat{\mathcal{L}}}{\partial k^2} u_{0XX} \right) \\ &- \left(\mathcal{N}_1(u_0, u_1) + \mathcal{N}_1(u_1, u_0) + \mathcal{M}(u_0, u_0) + \mathcal{N}_2(u_0, u_0, u_0) \right). \end{aligned} \tag{4.6}$$

In this equation, we seek to eliminate the secular terms in $e^{i\theta_j}, j = 1, \ldots, 4$, and the zero-mode terms (e^{i0}). Upon transforming to the moving frame $\xi_j = X - c_g(k_j)T$, the linear terms on the right-hand side reduce to

$$\left(-2i\omega_j A_{j\tau} - \omega_j \frac{\partial c_g}{\partial k}(k_j) A_{j\xi_j\xi_j}\right) e^{i\theta_j} + B_{TT} - B_{XX}, \tag{4.7}$$

where $j = 1, \ldots, 4$.

On the right-hand side, the terms $\mathcal{N}_1(u_0, u_1) + \mathcal{N}_1(u_1, u_0)$ will yield cubic terms, since u_1 contains quadratic terms (4.5) and u_0 has the original plane waves. We are interested in only combinations that yield a member of the quartet, i.e., terms in $e^{i\theta_j}$. No e^{i0} terms are created here. The relevant contributions of the terms $\mathcal{N}_1(u_0, u_1) + \mathcal{N}_1(u_1, u_0)$ can be written

$$\sum_{a,b,c} \frac{G(a,b)\,[G(a+b,c) + G(c,a+b)]}{\hat{\mathcal{L}}(k_a + k_b) - (\omega_a + \omega_b)^2} A_a A_b A_c e^{i(\theta_a+\theta_b+\theta_c)} + *, \tag{4.8}$$

in which we keep the notation $a, b, c \in \{1, -1, 2, -2, 3, -3, 4, -4\}$. Note that c always comes from the u_0 term, and a and b come from the u_1 term that was solved at $\mathrm{O}(\epsilon)$. Also, we keep the restriction that $a + b \neq 0$. The notation $G(a + b, c)$ means to use $k_a + k_b$ and $\omega_a + \omega_b$ for k_a and ω_a in the expression (4.4).

The term $e^{i(\theta_a+\theta_b+\theta_c)}$ will be equal to $e^{i\theta_j}$ for one of the original θ_j when a, b, and c are chosen appropriately. For example, to form terms in $e^{i\theta_1}$, we are interested in the six permutations of the set $\{-2, 3, 4\}$ since $\theta_1 = -\theta_2 + \theta_3 + \theta_4$. Evaluating the sum in (4.8) with these six sets of a, b, c yields the term $q_1 A_2^* A_3 A_4 e^{i\theta_1}$, where q_1 is a coefficient. However, we must also consider permutations of the sets $\{1, 1, -1\}$, $\{1, 2, -2\}$, $\{1, 3, -3\}$, and $\{1, 4, -4\}$, since they also lead to terms in $e^{i\theta_1}$. (In using these values of a, b, c, however, care must be taken to avoid duplicates and the cases when $a + b = 0$.) Thus, the contribution of $\mathcal{N}_1(u_0, u_1) + \mathcal{N}_1(u_1, u_0)$ to the quartet equations will be

$$\left(q_j A_l^* A_m A_n + \sum_{k=1}^{4} p_{jk} |A_k|^2 A_j\right) e^{i\theta_j} \tag{4.9}$$

for $j = 1, \ldots, 4$, where l, m, and n depend on j and satisfy $\theta_j + \theta_l = \theta_m + \theta_n$.

The contributions of the cubic terms $\mathcal{N}_2(u_0, u_0, u_0)$ are very similar to those of the quadratic terms $\mathcal{N}_1(u_0, u_1) + \mathcal{N}_1(u_1, u_0)$, except that they come from u_0 directly. We again sum over five distinct groups of six permutations and obtain the same twenty terms as in (4.9), but with different coefficients. We add these coefficients to those obtained from the quadratic terms. The contribution of $\mathcal{N}_2(u_0, u_0, u_0)$ is

$$\sum_{a,b,c} H(a,b,c) A_a A_b A_c e^{i(\theta_a+\theta_b+\theta_c)} + *, \tag{4.10}$$

in which

$$\begin{aligned} H(a,b,c) = {} & \omega_a\omega_b\hat{\mathcal{L}}(k_b)(k_c^2 + \hat{\mathcal{L}}^2(k_c)) + 2\omega_a\omega_b\hat{\mathcal{L}}(k_c)(k_b\omega_b - k_c\omega_b - k_c\omega_c) \\ & + \frac{1}{2}k_a^2(3k_bk_c + \hat{\mathcal{L}}(k_b)\hat{\mathcal{L}}(k_c)) + \frac{1}{2}\hat{\mathcal{L}}^2(k_a)(\hat{\mathcal{L}}(k_b)\hat{\mathcal{L}}(k_c - k_bk_c) - 2k_ak_c\hat{\mathcal{L}}(k_b)\hat{\mathcal{L}}(k_c)). \end{aligned}$$

Note that, like the quadratics, the cubics do not contribute any terms in e^{i0}.

Finally, $\mathcal{M}(u_0, u_0)$ gives both terms in $e^{i\theta_j}$ and "mean-flow" terms in e^{i0}:

$$\begin{aligned}&\sum_{j=1}^{4}(-2k_j\omega_j - c_g(k_j)(k_j^2 - \hat{\mathcal{L}}^2(k_j)))(A_jA_j^*)_{\xi_j}\\ &+\sum_{j=1}^{4}(2k_j\omega_j B_X + (\hat{\mathcal{L}}^2(k_j) - k_j^2)B_T)A_j e^{i\theta_j}.\end{aligned} \tag{4.11}$$

Equating terms from (4.6) in like powers of $e^{i\theta}$ leads to a coupled set of *five* partial differential equations governing the evolution of the resonant quartet and the "mean-flow" term B:

$$B_{TT} - B_{XX} = \sum_{j=1}^{4}(2k_j\omega_j + c_g(k_j)(k_j^2 - \hat{\mathcal{L}}^2(k_j)))(A_jA_j^*)_{\xi_j}, \tag{4.12}$$

$$\begin{aligned}iA_{j\tau} + \frac{1}{2}\frac{\partial c_g}{\partial k}(k_j)A_{j\xi_j\xi_j} &= \frac{\alpha_j}{2\omega_j}A_l^*A_mA_n + \frac{1}{2\omega_j}\left(\sum_{k=1}^{4}\beta_{jk}|A_k|^2A_j\right)\\ &+ \frac{1}{2\omega_j}(2k_j\omega_jB_X + (\hat{\mathcal{L}}^2(k_j) - k_j^2)B_T)A_j\end{aligned} \tag{4.13}$$

for $j = 1, \ldots, 4$, where $\theta_j + \theta_l = \theta_m + \theta_n$. Note that we have intentionally glossed over some notational inconsistency by using X, T, and ξ_j as independent variables in (4.12). Furthermore, the induced mean flows on any particular member of the quartet from the other three members are rapidly varying on the time scale of (4.13), unless group velocities are close. However, we will not be concerned with initial conditions for (4.12) and (4.13) that involve spatial modulation of the four primary waves and will thus treat (4.13) as a set of ordinary differential equations (see below).

Historically, the derivation of quartet equations was done for deep water, for which *spatial* modulation effects are ignored since the mean-flow is known to be zero. Thus (4.12) would not be present, $B = 0$ in (4.13), and these equations become ordinary differential equations. Of course the dispersion relation $\omega^2 = \hat{\mathcal{L}}$ also changes for deep water. As noted by Bretherton [8] for the two-dimensional deep-water case, the primary interaction coefficients α_i turn out to be *equal*. This is also true for finite-depth quartet equations, which we have confirmed using the fBL model. For deep water we find $\alpha_i = 0$, as expected. Since the α_i are primarily responsible for the exchange of energy among the four waves (the β_{jk} modify the period and amplitude), there is no interaction in the one-dimensional deep-water case.

4.2. Quartet simulations. To verify that (4.12) and (4.13) correctly capture the finite-depth quartet interactions, we compare the solutions to these equations to a simulation using the fBL equation. Since computing with these five coupled partial differential equations is computationally intensive, we seek a simpler special case. By choosing an initial condition in which the amplitude of the four primary waves is not spatially modulated, we ignore the second term in (4.13) and (4.12) altogether, leaving a set of four coupled ordinary differential equations. Although an exact solution involving Jacobi elliptic functions is known for a set of ordinary differential equations of this form (see [8]), we solve them numerically using a fourth-order Runge–Kutta method, while we evolve the fBL equation in time using a pseudospectral method. The

initial condition for both computations is the same. We pick four plane waves among a discrete set of wavenumbers that satisfy the resonance conditions $k_1 + k_2 = k_3 + k_4$ and $\omega_1 + \omega_2 = \omega_3 + \omega_4$, and give them each an initial amplitude. The quartet equations govern the four amplitudes as a function of $\tau = \epsilon^2 t$, while the simulation of the fBL equation computes the evolution of *all* the Fourier modes.

The pseudospectral method used here was developed by Milewski and Tabak [23] and involves the factoring of the fBL equation. Equation (2.1) can be also written as

$$(\partial_{tt} + L^2)u = \mathcal{G}(u), \tag{4.14}$$

in which $L^2 = \mathcal{L} = (-\partial_{xx})^{\frac{1}{2}} \tanh[(-\partial_{xx})^{\frac{1}{2}}]$ and $\mathcal{G}(u) = -\epsilon\mathcal{N}_1(u,u) - \epsilon^2\mathcal{N}_2(u,u,u)$. We factor the left-hand side by introducing $U(x,t) = (\partial_t - iL)u(x,t)$ and recast the equation in terms of U as

$$U_t + iLU = \mathcal{G}(U). \tag{4.15}$$

Thus the free surface is, to leading order, $\eta = -u_t = -Re(U)$. To solve (4.15), we transform it to Fourier space, introduce an integrating factor, and numerically integrate using a Runge–Kutta scheme. Since we compute with U directly and not u, we choose to initially set the quartet amplitudes to have equal values *in terms of* U. The conversion to the amplitudes of u is straightforward. If $u(x,t) = \sum_{j=1}^{4} A_j e^{i\theta_j} + *$, then $U(x,t) = \sum_{j=1}^{4} -2i\omega_j A_j e^{i\theta_j}$ and $\eta(x,t) = \sum_{j=1}^{4} i\omega_j A_j e^{i\theta_j} + *$. In the figures below, we graph the absolute value of the relevant Fourier modes of $U(x,t)$, i.e., $|U_j| = 2\omega_j |A_j|$.

A slight modification to the fBL equation (2.1) must be made before using our pseudospectral method. The problem lies with the $O(\epsilon)$ quadratic terms which have the term $-u_t \mathcal{L} u_{tt}$. Because of this term, we cannot integrate (2.1) in the form given. With the substitution $u_{tt} = -\mathcal{L}u - \epsilon\mathcal{N}_1(u,u) + O(\epsilon^2)$, the quadratic term becomes

$$\bar{\mathcal{N}}_1(u,u) = 2u_x u_{xt} + 2\mathcal{L}u\mathcal{L}u_t + u_t u_{xx} + u_t \mathcal{L}^2 u, \tag{4.16}$$

and there is an additional cubic term in the equation which becomes

$$u_{tt} + \mathcal{L}u + \epsilon\bar{\mathcal{N}}_1(u,u) + \epsilon^2 \left(\mathcal{N}_2(u,u,u) + u_t \mathcal{L}[\bar{\mathcal{N}}_1(u,u)]\right) = 0. \tag{4.17}$$

These modifications are similar to the formal manipulations that one uses to "regularize" the Korteweg–de Vries (KdV) equation and obtain the Benjamin–Bona–Mahoney (BBM) equation. There are also corresponding changes to the details of the quartet equations, in particular to the definitions of the functions $G(a,b)$ and $H(a,b,c)$ in (4.4) and (4.11), respectively. The new cubic term adds

$$\omega_a\omega_b(k_c^2 - \hat{\mathcal{L}}(k_c))\hat{\mathcal{L}}(k_b + k_c) + 2\omega_a\omega_c(k_b k_c - \hat{\mathcal{L}}(k_b)\hat{\mathcal{L}}(k_c))\hat{\mathcal{L}}(k_b + k_c) \tag{4.18}$$

to the function H.

Figure 4.1 shows the numerical solution of the four coupled quartet equations using a fourth-order Runge–Kutta scheme. We use the quartet wavenumbers $(k_1, k_2, k_3, k_4) = (81, 46, 142, -15)\Delta k$, where $\Delta k = \frac{1}{64}$, and the corresponding frequencies ω_j to precompute the twenty quartet coefficients. The initial amplitude of each mode U_j is 0.2. For this quartet, energy is periodically exchanged between the four waves which is inherently on the $\tau = \epsilon^2 t$ time scale. The total energy, given by $\sum_{j=1}^{4} \frac{1}{\alpha_j}|A_j|^2$, remains constant.

Figure 4.2 shows the pseudospectral simulation of the fBL equation initialized with energy only in the same four wavenumbers considered above. We use a total of

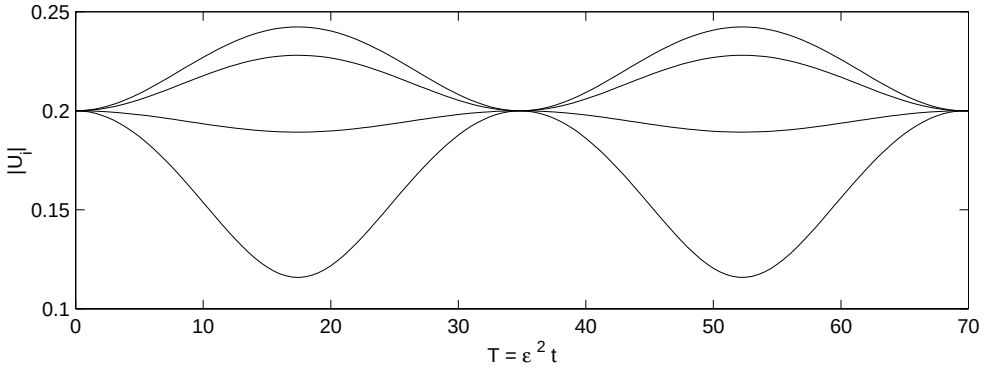

FIG. 4.1. *Numerical solution of the quartet equations using a fourth-order Runge–Kutta scheme. The wavenumbers are* $(k_1, k_2, k_3, k_4) = (81, 46, 142, -15)\Delta k$, *where* $\Delta k = \frac{1}{64}$. *The initial amplitude is* $U_j = 0.2$.

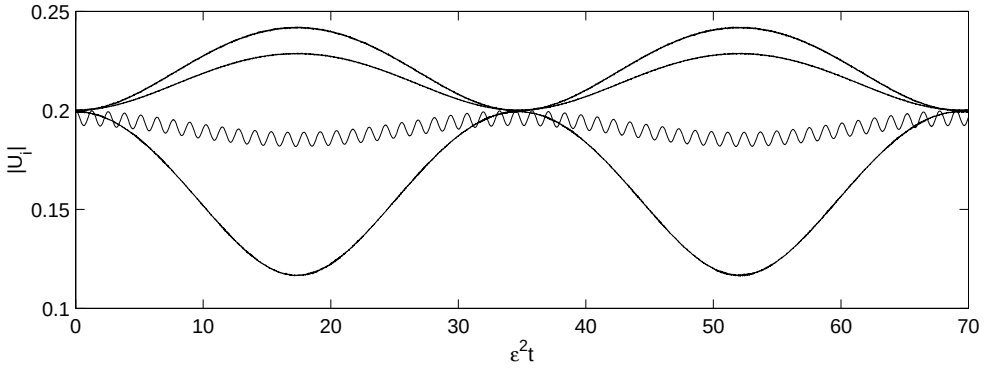

FIG. 4.2. *Simulation of the fBL equation initialized with four waves of the same initial amplitude. The wavenumbers are* $(k_1, k_2, k_3, k_4) = (81, 46, 142, -15)\Delta k$, *where* $\Delta k = \frac{1}{64}$. *The initial amplitude is* $U_j = 0.2$, $\epsilon = .05$, *and* $\Delta t = 0.1$. *We use* 1024 *wavenumbers in this computation.*

1024 wavenumbers with the initial amplitude of each member of the quartet being $U_j = 0.2$. Note that energy is periodically exchanged between the four waves on the long time scale $\tau = \epsilon^2 t$, as predicted (here $\epsilon = .05$). On a shorter time scale, the longest wave in the quartet $k_4 = -15/64$ periodically exchanges energy with its near-resonant second harmonic, the $k = -30/64$ mode. This accounts for the smaller oscillations in the amplitude of this mode. In the next section, we derive the equations governing this interaction and show that they can be combined with the quartet equations to correctly predict the simulation results.

Quartets containing wavenumbers closer to the shallow water regime ($kH < 1$) will exhibit prominent second harmonic interaction, as the dispersion curve is nearly linear in this range. This draws energy from the primary quartet and may account for the slight variation in period between the two quartet graphs. Quartets without this second-harmonic interaction do not exist for this one-dimensional model because quartets containing many larger wavenumbers ($kH > 1$) are very weakly coupled since the $\alpha_j \to 0$ as $H \to \infty$, and other mechanisms such as nonresonant interactions and Benjamin–Feir instability are relatively more significant.

4.3. Derivation of second-harmonic interaction. Beginning with the one-dimensional fBL equation (2.1), we proceed with the method of multiple scales. We restrict our attention to the slow time scale $T = \epsilon t$ since we expect the interaction to occur on this scale. We also ignore slow spatial variation, consistent with our integration of the quartet equations above. With the substitution $\partial_t \to \partial_t + \epsilon\partial_T$ we have the following equation for $u(x,t,T)$:

$$u_{tt} + \mathcal{L}u + \epsilon\left(2u_{tT} + \mathcal{N}_1(u,u)\right) = 0, \tag{4.19}$$

where higher-order terms are unnecessary. Next, we expand u as $u = u_0 + \epsilon u_1 + \cdots$ with

$$u_0(x,t,T) = A_1(T)e^{i(kx-\omega t)} + A_2(T)e^{i(2kx-\omega(2k)t)} + *. \tag{4.20}$$

With the notation $\omega_1 = \omega(k)$, $\omega_2 = \omega(2k)$, $\theta_1 = kx - \omega_1 t$, and $\theta_2 = 2kx - \omega_2 t$, the balance of terms at $\mathrm{O}(\epsilon)$ in (4.19)

$$2\omega_1 A_{1T}e^{i\theta_1} + 2\omega_2 A_{2T}e^{i\theta_2} + * = \sum_{a,b} G(a,b)A_a A_b e^{i(\theta_a+\theta_b)}, \tag{4.21}$$

in which the function $G(a,b)$ is the same as that derived before for the quadratic terms (4.4). We can only get terms in e^{2ik} with $a = b = 1$, for which the right-hand side becomes $G(1,1)A_1^2 e^{i(2kx-2\omega_1 t)} = G(1,1)A_1^2 e^{i\theta_2}e^{-i\Delta t}$, where the frequency mismatch is $\Delta = 2\omega_1 - \omega_2$. In a similar way, we can create terms in e^{ik} with $(a,b) = (-1,2)$ or $(2,-1)$, giving a right-hand side of $(G(-1,2) + G(2,-1))A_1^* A_2 e^{i\theta_1}e^{i\Delta t}$. Thus the wave-second-harmonic interaction equations are

$$\frac{dA_1}{dT} = \delta_1 A_1^* A_2 e^{i\Delta t}, \qquad \delta_1 = \frac{G(-1,2)+G(2,-1)}{2\omega_1} < 0, \tag{4.22}$$

$$\frac{dA_2}{dT} = \delta_2 A_1^2 e^{-i\Delta t}, \qquad \delta_2 = \frac{G(1,1)}{2\omega_2} > 0. \tag{4.23}$$

For $k \ll 1$, $\Delta = k^3$, $\delta_1 = -3k^2$, and $\delta_2 = (3/2)k^2$. The transformations $A_1 \to A_1 e^{i\Delta t}$, $A_2 \to A_2 e^{i\Delta t}$ remove the periodic coefficient (detuning term), yielding

$$\frac{dA_1}{dT} = -i\Delta A_1 + \delta_1 A_1^* A_2 e^{i\Delta t}, \qquad \frac{dA_2}{dT} = -i\Delta A_2 + \delta_2 A_1^2 e^{-i\Delta t}. \tag{4.24}$$

These equations for $\epsilon = O(\Delta)$ can be solved analytically. Writing $A_1 = \rho_1 e^{i\phi_1}$, $A_2 = \rho_2 e^{i\phi_2}$, the equations (4.22), (4.23) conserve

$$E = -\frac{1}{\delta_1}\rho_1^2 + \frac{1}{\delta_2}\rho_2^2, \tag{4.25}$$

$$H = \rho_1^2\rho_2\sin(\phi_2 - 2\phi_1) - \frac{\Delta}{4}\left(\frac{1}{\delta_1}\rho_1^2 + \frac{1}{\delta_2}\rho_2^2\right), \tag{4.26}$$

where H is the Hamiltonian in appropriate coordinates. From these, one can conclude $|A_1|^2 = \delta_1 I(t) + c_1$, $|A_2|^2 = \delta_2 I(t) + c_2$, where

$$\left(\frac{dI}{dT}\right)^2 = 4(\delta_1 I + c_1)^2(\delta_2 I + c_2) - 4\left(H + \frac{\Delta}{2\delta_2}(\delta_2 I + c_2)\right)^2. \tag{4.27}$$

The solution can be written in terms of elliptic functions. For the results described below, $I(0) = 0$, $c_1 = -\delta_1 E$, $c_2 = 0$, and $H + (\Delta/4)E = 0$.

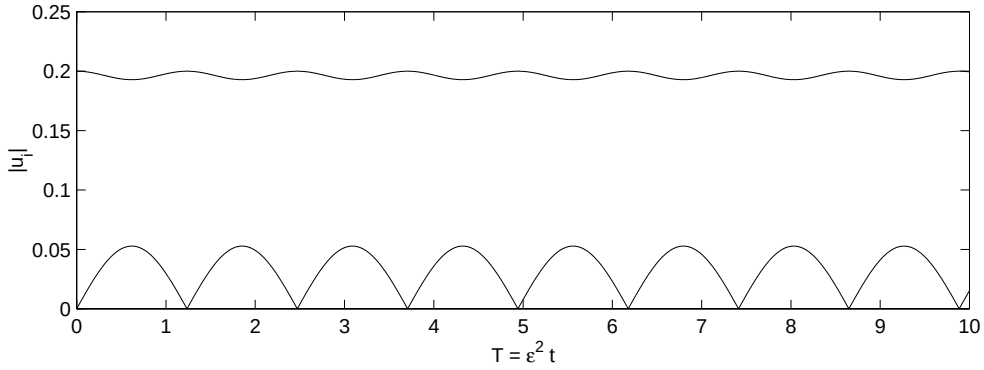

FIG. 4.3. *Solution of the second-harmonic interaction equations with* $k = -15/64$. *The initial amplitude is* $U_1 = 0.2$ *for the primary mode and* $U_2 = 0$ *for the second harmonic.* ($\epsilon = .05$.)

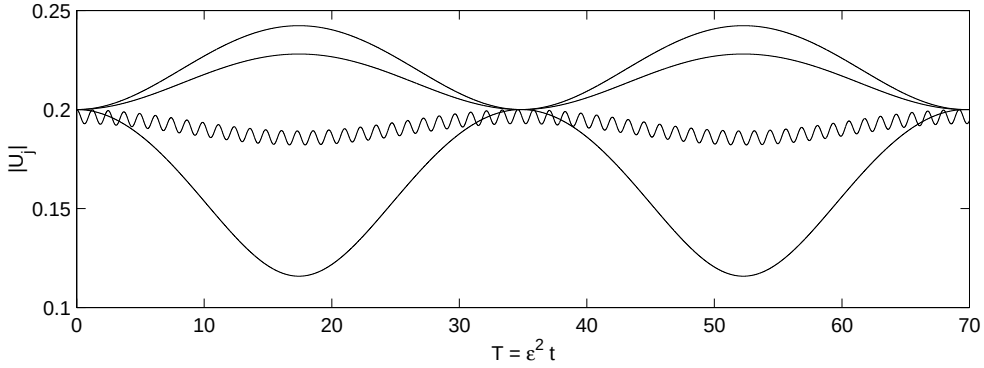

FIG. 4.4. *Numerical solution of the quartet equations with second-harmonic interaction using a fourth-order Runge–Kutta scheme. The wavenumbers are* $(k_1, k_2, k_3, k_4) = (81, 46, 142, -15)\Delta k$, *where* $\Delta k = \frac{1}{64}$. *The initial amplitude is* $U_j = 0.2$.

For the quartet of waves that we consider here, only the mode $k_4 = -\frac{15}{64}$ will generate significant second harmonic energy. Figure 4.3 shows the solution of (4.22), (4.23). The primary mode is $k = -\frac{15}{64}$ with initial amplitude $U_1 = 0.2$, as in the quartet simulation. The $2k$ mode has zero initial amplitude. (Note that, for consistency, we show the results in terms of our computational variable $U = (\partial_t - iL)u$, as discussed above.)

A pseudospectral simulation of the fBL equation initialized with energy in only the single mode $k = -\frac{15}{64}$ yields a virtually identical result.

Finally we augment the quartet equations (4.13) with the second-harmonic interaction term (for the $k_4 = -\frac{15}{64}$ mode only) and the second harmonic equation (4.23). Although these equations combine two time scales and thus are not formally correct, they give results virtually identical (see Figure 4.4) to those of the fBL simulation of Figure 4.2.

5. Gravity wave turbulence simulations. Since we have shown that the one-dimensional fBL equation captures the deterministic dynamics of the water wave problem, we turn our attention to the simulation of dispersive wave turbulence using

this equation. Statistical dispersive wave-turbulence theory relies on a closure (see [14], [7], [5], [29]) that, in essence, restricts the dynamics to the resonant set of waves satisfying (1.1), (1.2). Briefly, the closure is based on writing (4.15) in Fourier space,

$$\hat{U}_t + i\omega\hat{U} = \int Q(k_1,k_2,k_3,k)\hat{U}_1\hat{U}_2\hat{U}_3\delta(k_1+k_2+k_3-k)dk_1dk_2dk_3, \tag{5.1}$$

where $\hat{U}_1 = \hat{U}(k_1,t)$. The expression for the "collision" kernel Q is essentially the quartet coefficients computed previously. From (5.1) one obtains the equation for the second-order moment $n_k = \langle\hat{U}(k,t)\hat{U}^*(k,t)\rangle$:

$$\frac{dn_k}{dt} = \int 2\ \mathrm{Re}\ Q\langle\hat{U}_1\hat{U}_2\hat{U}_3\hat{U}^*\rangle\delta(k_1+k_2+k_3-k)dk_1dk_2dk_3, \tag{5.2}$$

where $\langle\cdot\rangle$ denotes the ensemble average. Next, one writes the equation for the evolution of the fourth-order moments appearing in the integrand of (5.2) in terms of sixth-order moments. The closure consists in reducing these sixth-order moments to products of second-order moments (a quasi-Gaussianity assumption). This leads to a relation of the form

$$\langle\hat{U}_1\hat{U}_2\hat{U}_3\hat{U}^*\rangle \sim Q\frac{n_2n_3n_k + n_1n_3n_k + n_1n_2n_k - n_1n_2n_3}{i(\omega_1+\omega_2+\omega_3-\omega_k)}. \tag{5.3}$$

Now, substituting (5.3) into (5.2) and replacing the reciprocal of the sum of frequencies by $\delta(\omega_1+\omega_2+\omega_3-\omega_k)$, one obtains a closed equation that concentrates the dynamics on the resonant set. (The difference in the sign in front of k_3 and ω_3 in these delta functions and in (1.1), (1.2) is just a matter of convention.)

The steady state ($\frac{dn_k}{dt} = 0$) of this resulting equation has two types of solutions: solutions in statistical equilibrium and solutions with finite fluxes (cascades) of energy. The latter have been of particular interest in attempts to describe the ocean's wave spectrum.

Since these cascades require that the governing equation (4.15) be forced and dissipated, we augment the equation by adding forcing and dissipation terms (which are meant to model physical processes such as wind forcing, viscous damping, etc.) at various ranges of wavenumbers. Then, from long time computations, we observe the evolution of the energy spectrum until a statistical steady state is reached. Since both energy and wave action are conserved in this system, we must dissipate at both ends of the Fourier spectrum and force at some intermediate scale. Thus, the factored form of the fBL equation (4.15) in Fourier space, with forcing and dissipation, becomes

$$\hat{U}_t + i\hat{L}\hat{U} = \hat{G}(\hat{U}) + \hat{F}, \tag{5.4}$$

in which we define the forcing-dissipation function $\hat{F}$ as

$$\hat{F}(k) = \begin{cases} f_r\hat{U} & \text{for } k_{fl}\Delta k \le |k| \le k_{fh}\Delta k, \\ d_{r1}|k|^{-2}\hat{U} & \text{for } k_{dl}\Delta k \le |k| \le k_{dh}\Delta k, \\ d_{r2}|k|^2\hat{U} & \text{for } |k| \ge K_d\Delta k, \\ 0 & \text{otherwise.} \end{cases} \tag{5.5}$$

Here k_{fl}, k_{fh}, k_{dl}, k_{dh}, and K_d are integers which define the range of forcing and the two dissipation ranges, the latter being $|k| > K_d\Delta k$. The forcing rate f_r is positive, while the dissipation rates d_{r1} and d_{r2} should be negative. The closure theory

described above appears insensitive on the particular form of the forcing, and this is confirmed by the numerical simulations. Various forms of forcing (both deterministic and random) and dissipation ("standard" viscosity and "hyper" viscosity) were experimented with, and the results did not change appreciably. Our approach is similar to that of Majda and coworkers (see [19] and [9]), who perform computations with a simpler NLS-like model equation.

6. Direct cascades. To generate a direct (or forward) cascade over a significant range, we force at low wavenumbers and dissipate at both the lowest and highest wavenumbers. We construct the experiment such that the *finite-depth* regime lies in the inertial range (the range of wavenumbers that are neither forced nor dissipated) for reasons mentioned in the introduction. Figure 6.1 compares the dispersion relations of the shallow water ($\omega = k$), infinite-depth ($\omega = |k|^{\frac{1}{2}}$), and arbitrary-depth ($\omega = (|k| \tanh |k|)^{\frac{1}{2}}$) problems. We will arbitrarily denote the range $0.5 < k < 2.5$ as the finite-depth regime and indicate this range in our numerical result.

We compute the correlation function

$$p(k) = \overline{\hat{u}(k,t)\hat{u}^*(k,t)}, \tag{6.1}$$

where the overbar denotes time average (after a statistical steady state is reached). It can be shown that

$$p(k) \sim \frac{1}{2\pi} \int_{-\infty}^{\infty} \overline{u(x,t)u(x+r,t)} e^{-ikr} dr, \tag{6.2}$$

when correlations are spatially independent.

Figure 6.2 shows a typical weak turbulence spectrum that we obtain using the one-dimensional fBL model. The computation uses 2048 dealiased modes with $\Delta k = \frac{1}{100}$. The parameters chosen are $\epsilon = 0.05$, $f_r = 0.00001$, $d_{r1} = -0.0009$, and $d_{r2} = -0.01$. Initially, the system has significant energy only in the lower wavenumbers $\hat{U}(4\Delta k \leq k \leq 12\Delta k) = 0.5$. All other modes are initialized to $\hat{U}(k) = 0.00001$. We show the average spectrum from $t = 150,000$ to $t = 200,000$, computed with the methods described earlier with $\Delta t = 0.1$.

There are six regions of the spectrum divided by five vertical dotted lines. From left to right, these are (1) the low wavenumber dissipation range, (2) the forcing range, (3) the "shallow" inertial range, (4) the "finite depth" inertial range, (5) the "infinite depth" inertial range, (6) the high wavenumber dissipation range.

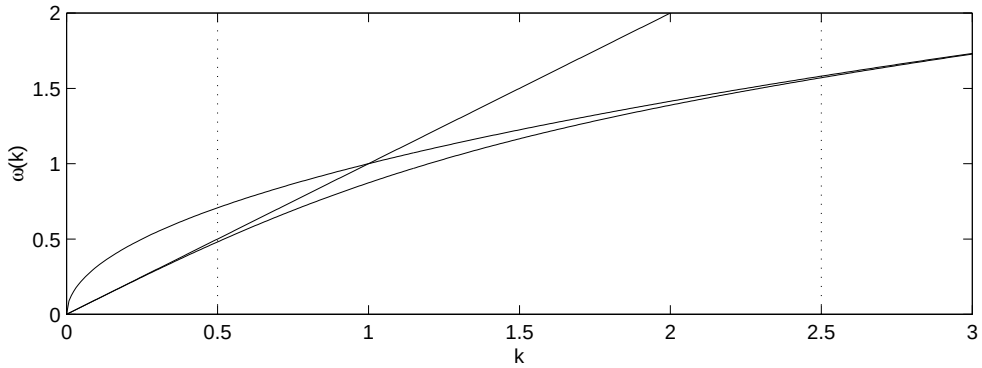

FIG. 6.1. *Finite-depth dispersion relation* $\omega(k) = (|k| \tanh(|k|))^{\frac{1}{2}}$. *As indicated in the figure,* $\omega \sim |k|$ *as* $k \to 0$, *and* $\omega \sim (|k|)^{1/2}$ *for* k *large. The vertical lines in the figure reflect an arbitrary choice for the transition region* $(0.5 < k < 2.5)$ *between these two power laws.*

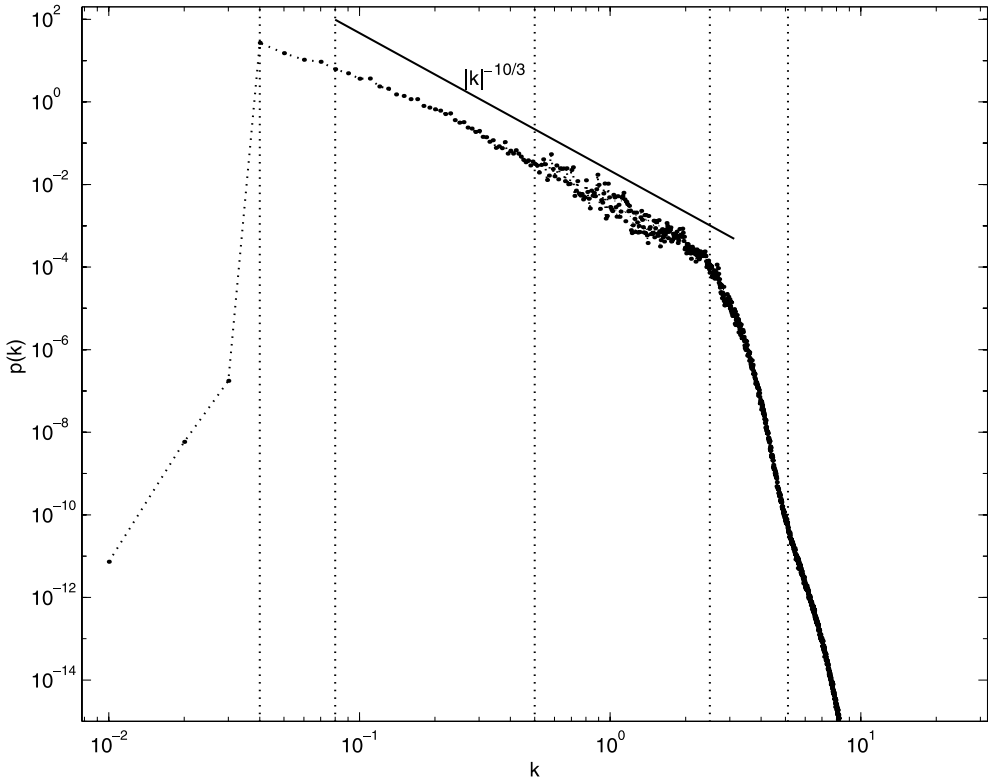

FIG. 6.2. Experiment 1. *Direct cascade using the fBL model with forcing between* $k = 4\Delta k$ *and* $k = 8\Delta k$ *and dissipation from* $k = \Delta k$ *to* $k = 3\Delta k$ *and for* $k > 512\Delta k$. *Here* $\Delta k = \frac{1}{100}$ *and* $\epsilon = 0.05$. *We estimate* $p(k)$ *by the time average of* $\hat{u}(k,t)\hat{u}^*(k,t)$ *for* $t = 150,000$ *to* $t = 200,000$ *with data every* $t = 500$.

We note that some features of the spectrum seem to change in correlation with the shape of the dispersion curve. In the shallow and finite-depth regimes, there is a good agreement with the weak turbulence theory of Zakharov [27] described above. He predicts a direct cascade of $p(k) \sim |k|^{-10/3}$ (in the present variables), subject to some strict conditions on the wave amplitudes (which are not strictly satisfied in the computations). Using least-square interpolation of the data yields $p(k) \sim |k|^{\alpha}$ with $-3 > \alpha > -3.4$, depending on where the endpoints of the inertial range are chosen. The Zakharov slope is shown in Figure 6.2 for comparison. We also note that in the finite-depth region (region 4) the data is more spread. This is probably because in this regime the discrete quartets are sparser, whereas in shallower water, wave interaction is denser, and nondispersive wave steepening plays a more important role.

6.1. Inverse cascade. To obtain an inverse cascade (from high to low wavenumbers) we modified the forcing and dissipation parameters from the previous experiment. We force near the deep water regime, between wavenumbers 2.25 and 2.50. Again, we use 2048 dealiased modes, now with $\Delta k = \frac{1}{200}$, $\epsilon = 0.05$, $f_r = 0.0006$, $d_{r1} = -0.75$, and $d_{r2} = -0.50$. Initially, all modes are initialized to $\hat{U}(k) = 0$. We show the average spectrum from $t = 150,000$ to $t = 200,000$, computed with the methods described earlier with $\Delta t = 0.1$.

The results are shown in Figure 6.3. The results here are less clear. In the shallow water regime there appears to be a region with $p(k) \sim |k|^{\alpha}$, with $-2.2 > \alpha > -2.4$.

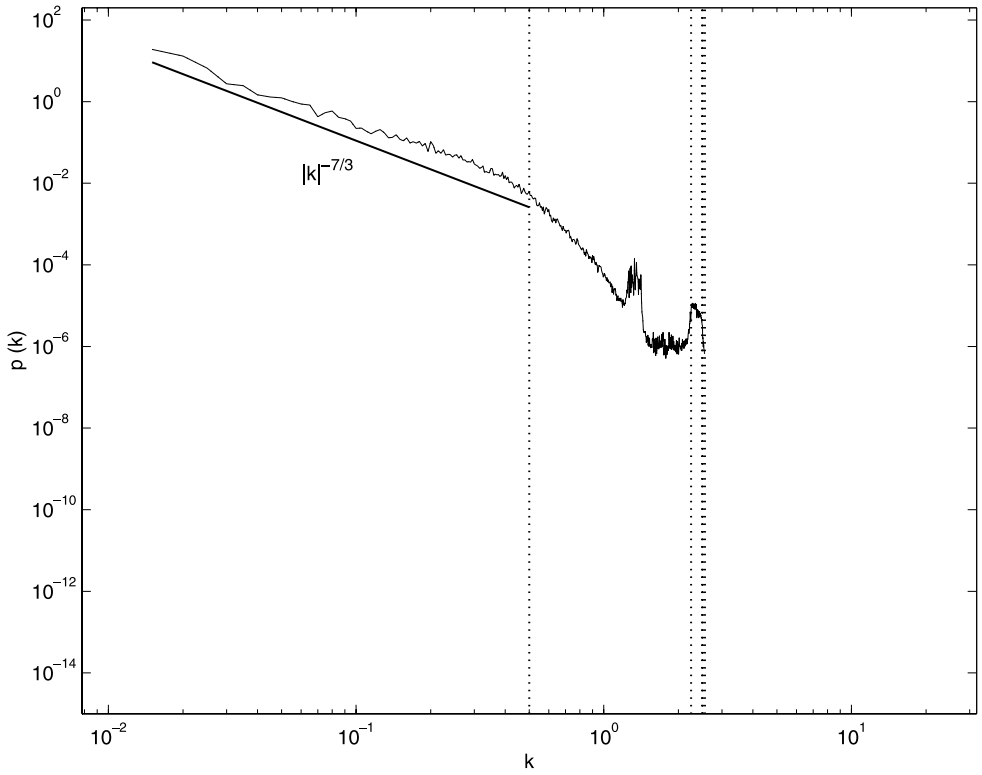

FIG. 6.3. *Inverse cascade using the fBL model with forcing between* $k = 450\Delta k$ *and* $k = 500\Delta k$ *and dissipation from* $k = \Delta k$ *to* $k = 2\Delta k$ *and for* $k > 512\Delta k$. *Here* $\Delta k = \frac{1}{200}$ *and* $\epsilon = 0.05$. *We estimate* $p(k)$ *by the time average of* $\hat{u}(k,t)\hat{u}^*(k,t)$ *for* $t = 250,000$ *to* $t = 300,000$ *with data every* $t = 1000$.

(We show a slope of $\alpha = -7/3$ for reference.) Zakharov's [27] prediction for the shallow water inverse cascade is $|k|^{-3.0}$. The reasons for this difference may be related to the generation of coherent structures (solitons) which are excluded from the theory (by assuming sufficiently small amplitudes compared to dispersive effects). In fact, the more recent work on NLS [9], [30] explores the role of coherent structures in the various spectra observed.

At finite depth, our computed spectrum drops much more steeply. The two visible peaks in the spectrum are due to the forcing: the peak at higher wavenumbers is over the forcing region, and the second peak is a direct subharmonic generation from the forced modes.

7. Conclusion. We have derived a Benney–Luke model for waves in arbitrary depth and verified its utility by demonstrating its accuracy in important deterministic water wave phenomena: Benjamin–Feir wave packet instability, resonant quartet interactions, and harmonic generation in shallow water. We have then used the model, together with forcing and dissipation, to simulate wave turbulence. The numerical spectra that we obtain agree with Zakharov's prediction for the direct cascades but not for inverse cascades. Possible reasons for the departure from Zakharov's prediction include the narrow range of applicability of his theory in this regime to avoid solitons. The present work validates the use of the fBL equation for the more interesting problem of two-dimensional turbulent simulations.

OPTIMIZATION OF ACOUSTIC SOURCE STRENGTH IN THE PROBLEMS OF ACTIVE NOISE CONTROL*

J. LONČARIĆ† AND S. V. TSYNKOV‡

Abstract. We consider a problem of eliminating the unwanted time-harmonic noise on a predetermined region of interest. The desired objective is achieved by active means, i.e., by introducing additional sources of sound called control sources, which generate the appropriate annihilating acoustic signal (antisound). A general solution for the control sources has been obtained previously in both continuous and discrete formulation of the problem. In the current paper, we focus on optimizing the overall absolute acoustic source strength of the control sources. Mathematically, this amounts to the minimization of multivariable complex-valued functions in the sense of L_1 with conical constraints, which are only "marginally" convex. The corresponding numerical optimization problem appears very challenging even for the most sophisticated state-of-the-art methodologies, and even when the dimension of the grid is small and the waves are long.

Our central result is that the global L_1-optimal solution can, in fact, be obtained without solving the numerical optimization problem. This solution is given by a special layer of monopole sources on the perimeter of the protected region. We provide a rigorous proof of global L_1 minimality for both continuous and discrete optimization problems in the one-dimensional case. We also provide numerical evidence that corroborates our result in the two-dimensional case, when the protected domain is a cylinder. Even though we cannot fully justify it, we believe that the same result holds in the general case, i.e., for multidimensional settings and domains of arbitrary shape. We formulate this notion as a conjecture at the end of the paper.

Key words. noise cancellation, control sources, minimization of amplitude, volume velocity, surface monopoles

1. Introduction.

The area of active control of sound has a rich history of development, both as a chapter of theoretical acoustics and in the perspective of many different applications. Any attempt to adequately overview this extensive area in the framework of a focused research publication would obviously be deficient. Therefore, we simply refer the reader to monographs [3, 5, 11] that, among other things, contain a detailed survey of the literature.

The formulation of the problem that we use in the current paper has been introduced and studied in our previous work [7]; here, we analyze this formulation from the standpoint of optimization. Let Ω be a given domain, $\Omega \subset \mathbb{R}^n$, where the space dimension $n = 2$ or $n = 3$. (These two cases are most interesting for applications.) The domain Ω can be either bounded or unbounded; for reasons of simplicity we will further assume that Ω is bounded. Let Γ be the boundary of Ω: $\Gamma = \partial\Omega$. Both on Ω and on its (unbounded) complement $\Omega_1 = \mathbb{R}^n \backslash \Omega$ we consider the time-harmonic acoustic

field $u = u(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^n$, governed by the nonhomogeneous Helmholtz equation:

$$\boldsymbol{L}u \equiv \Delta u + k^2 u = f. \tag{1.1}$$

Equation (1.1) is subject to the Sommerfeld radiation boundary conditions at infinity, which for $n = 2$ are formulated as

$$u(\boldsymbol{x}) = O(|\boldsymbol{x}|^{-1/2}), \quad \frac{\partial u(\boldsymbol{x})}{\partial |\boldsymbol{x}|} + iku(\boldsymbol{x}) = o(|\boldsymbol{x}|^{-1/2}) \quad \text{as} \quad |x| \longrightarrow \infty, \tag{1.2a}$$

and for $n = 3$ as

$$u(\boldsymbol{x}) = O\left(|\boldsymbol{x}|^{-1}\right), \quad \frac{\partial u(\boldsymbol{x})}{\partial |\boldsymbol{x}|} + iku(\boldsymbol{x}) = o\left(|\boldsymbol{x}|^{-1}\right) \quad \text{as} \quad |\boldsymbol{x}| \longrightarrow \infty. \tag{1.2b}$$

The Sommerfeld boundary conditions specify the direction of wave propagation and distinguish between the incoming and outgoing waves at infinity by prescribing the outgoing direction only; they guarantee the unique solvability of the Helmholtz equation (1.1) for any compactly supported right-hand side $f = f(\boldsymbol{x})$. We define $\operatorname{supp} f = \{\boldsymbol{x} | f(\boldsymbol{x}) \neq 0\}$.

The source terms $f = f(\boldsymbol{x})$ in (1.1) can be located on both Ω and its complement $\Omega_1 = \mathbb{R}^n \backslash \Omega$; to emphasize the distinction, we define

$$f = f^+ + f^-, \tag{1.3}$$

where the sources f^+ are interior, $\operatorname{supp} f^+ \subset \Omega$, and the sources f^- are exterior, $\operatorname{supp} f^- \subset \Omega_1$, with respect to Ω. Accordingly, the overall acoustic field $u = u(\boldsymbol{x})$ can be represented as the sum of two components:

$$u = u^+ + u^-, \tag{1.4}$$

where

$$\boldsymbol{L}u^+ = f^+, \tag{1.5a}$$

$$\boldsymbol{L}u^- = f^-. \tag{1.5b}$$

Note that both $u^+ = u^+(\boldsymbol{x})$ and $u^- = u^-(\boldsymbol{x})$ are defined on the entire $\mathbb{R}^n$; the superscripts "+" and "−" refer to the sources that drive each of the field components, rather than to the domains of these components. The setup described above is schematically shown in Figure 1.1.

Hereafter, we will call the component u^+ of (1.4), (1.5a) *sound*, or the "friendly" part of the total acoustic field; the component u^- of (1.4), (1.5b) will accordingly be called *noise*, or the "adverse" part of the total acoustic field. In the formulation that we are presenting, Ω will be a (predetermined) region of space to be shielded. This means that we would like to eliminate the noise inside Ω while leaving the sound component there unaltered. In the mathematical framework that we have adopted, the component u^- of the total acoustic field, i.e., the response to the adverse sources f^- (see (1.3), (1.4), (1.5)), will have to be cancelled on Ω, whereas the component u^+, i.e., the response to the friendly sources f^+, will have to be left unaffected on Ω. A physically more involved but conceptually easy-to-understand example can be given to illustrate the foregoing idea of shielding: inside the passenger compartment of an aircraft we would like to eliminate the noise coming from the propulsion system

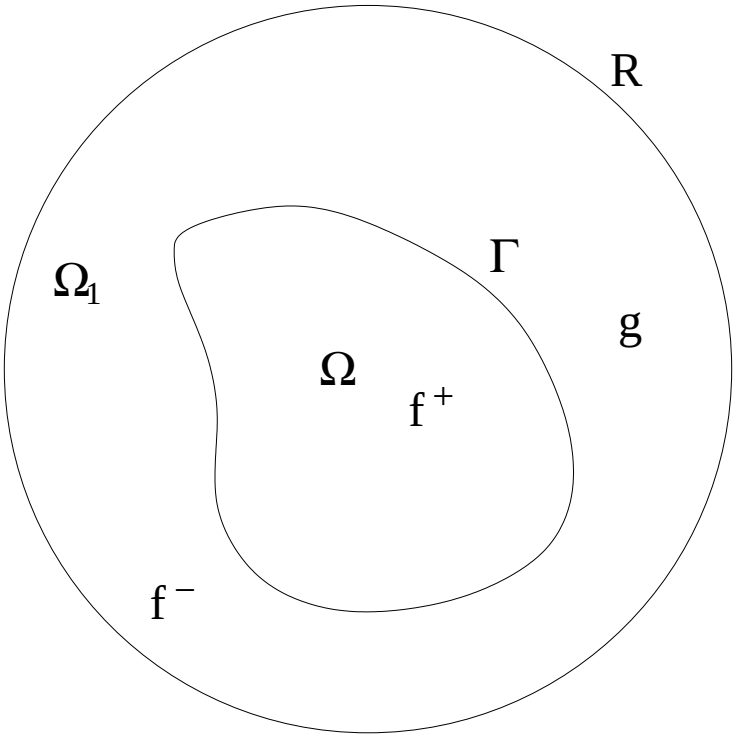

FIG. 1.1. *Geometric setup.*

located outside the fuselage, while not interfering with the ability of the passengers to listen to the in-flight entertainment programs or to converse.

The concept of *active noise control* that we will be discussing implies that the component u^- is to be suppressed on Ω by introducing additional sources of sound $g = g(\boldsymbol{x})$ exterior with respect to Ω, $\operatorname{supp} g \subset \Omega_1$, so that the total acoustic field $\tilde{u} = \tilde{u}(\boldsymbol{x})$ can now be governed by the equation (cf. formulae (1.1), (1.3))

$$\boldsymbol{L}\tilde{u} = f^+ + f^- + g \tag{1.6}$$

and coincide with only the friendly component u^+ on the domain Ω:

$$\tilde{u}|_{\boldsymbol{x}\in\Omega} = u^+|_{\boldsymbol{x}\in\Omega}. \tag{1.7}$$

The new sources $g = g(\boldsymbol{x})$ of (1.6)—see Figure 1.1—will hereafter be referred to as the *control sources* or simply *controls.* An obvious solution for these control sources is $g = -f^-$. This solution, however, is excessively expensive. One one hand, the excessiveness comes from the information-type considerations, as the solution $g = -f^-$ requires explicit and detailed knowledge of the structure and location of the sources f^-. As shown in [7], this knowledge is, in fact, superfluous. On the other hand, the implementation of the solution $g = -f^-$ may encounter most serious technical difficulties. In the example above, it is obviously not feasible to directly counter the actual noise sources, which are aircraft propellers or turbofan jet engines located on, or underneath, the wings. Therefore, solutions of this noise control problem

other than the most obvious one may be preferable from both the theoretical and practical standpoints. The general solution for the control sources g was obtained in our previous work [7], and we describe it in section 2.

Before proceeding, let us note only that in the current paper we focus on the case of the standard constant-coefficient Helmholtz equation (1.1), which governs the acoustic field and is valid throughout the entire space $\mathbb{R}^n$. This allows us to make subsequent analysis most straightforward. As a matter of fact, other, more complex, cases that involve variable coefficients and possibly nonlinearities in the governing equations over some regions, as well as different types of far-field behavior, discontinuities in the material properties, etc., can be considered as well. Approaches to obtaining solutions for active controls in these cases are outlined in our previous paper [7] for the continuous formulation of the problem, and in the monograph by Ryaben'kii [15, Part VIII] for the discrete formulation of the problem.

The material in the rest of the paper is organized as follows. In section 2, we introduce the control sources for the continuous formulation of the problem. In section 3, we obtain the control sources in the discrete formulation of the problem, i.e., on the grid. In section 4, we discuss minimization of the overall acoustic source strength of active controls that we have constructed, which mathematically amounts to the optimization in the sense of L_1. We present convincing two-dimensional numerical evidence, as well as a rigorous one-dimensional proof, of the global L_1-optimality of a particular layer of monopole sources concentrated on the perimeter of the protected region. We believe that the combination of computations in two space dimensions and general proof in one space dimension cannot be a mere coincidence. As such, even though we cannot fully justify it, we formulate the corresponding general result on global L_1-optimality of surface monopoles as a conjecture in the concluding section 5. This conjecture basically implies that the aforementioned L_1-optimization problem can be solved without using any numerical optimization techniques.

2. Continuous control sources.

2.1. General solution. As demonstrated in [7], the general solution for the control sources $g = g(\boldsymbol{x})$ is given by the following formula ($\Omega_1 = \mathbb{R}^n \backslash \Omega$):

$$g(\boldsymbol{x}) = -\boldsymbol{L}w\Big|_{\boldsymbol{x}\in\Omega_1}, \tag{2.1}$$

where $w = w(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega_1$, is a special auxiliary function-parameter that parameterizes the family of controls (2.1). The requirements that the function $w(\boldsymbol{x})$ must meet are, in fact, relatively "loose." At infinity, it has to satisfy the Sommerfeld boundary conditions (1.2a) or (1.2b). At the interface Γ, the function w and its normal derivative have to coincide with the corresponding quantities that pertain to the total acoustic field u given by formula (1.4):[1]

$$w\Big|_\Gamma = u\Big|_\Gamma, \qquad \frac{\partial w}{\partial \boldsymbol{n}}\Big|_\Gamma = \frac{\partial u}{\partial \boldsymbol{n}}\Big|_\Gamma. \tag{2.2}$$

Other than that, the function $w(\boldsymbol{x})$ used in (2.1) is arbitrary, and consequently formula (2.1) defines a large family of control sources, which, as will be seen in section 4, provides ample room for optimization. To make the discussion in the current paper

[1] In practice, the quantities u and $\frac{\partial u}{\partial \boldsymbol{n}}$ on Γ can be measured and supplied to the control system as the input data.

self-contained, we briefly outline below the justification for formula (2.1) as a general solution for controls, while referring the reader to [7] for further detail.

Introducing the fundamental solution $G = G(\boldsymbol{x})$ of the Helmholtz operator $\boldsymbol{L}$ of (1.1) for $n = 2$,

$$G(\boldsymbol{x}) = -\frac{1}{4i} H_0^{(2)}(k|\boldsymbol{x}|), \tag{2.3a}$$

where $H_0^{(2)}(z) = J_0(z) - iY_0(z)$ is the Hankel function of the second kind, and for $n = 3$,

$$G(\boldsymbol{x}) = -\frac{e^{-ik|\boldsymbol{x}|}}{4\pi|\boldsymbol{x}|}, \tag{2.3b}$$

we can obviously represent the sound portion $u^+ = u^+(\boldsymbol{x})$ of the overall acoustic field that satisfies (1.5a) everywhere on $\mathbb{R}^n$ as follows:

$$u^+(\boldsymbol{x}) = \int_\Omega G(\boldsymbol{x} - \boldsymbol{y}) f^+(\boldsymbol{y}) d\boldsymbol{y} = \int_\Omega G(\boldsymbol{x} - \boldsymbol{y}) \boldsymbol{L} u^+(\boldsymbol{y}) d\boldsymbol{y}, \quad \boldsymbol{x} \in \mathbb{R}^n. \tag{2.4}$$

Consequently, applying the classical Green's formula (see, e.g., [18] or [24]) to the function $u^+ = u^+(\boldsymbol{x})$ on Ω, we have

$$\int_\Gamma \left(u^+ \frac{\partial G}{\partial \boldsymbol{n}} - \frac{\partial u^+}{\partial \boldsymbol{n}} G \right) ds_{\boldsymbol{y}} = 0, \quad \boldsymbol{x} \in \Omega, \tag{2.5}$$

where integrals in (2.5) are, again, convolutions. Similarly, applying the same Green's formula on Ω to $u^- = u^-(\boldsymbol{x})$ and using (2.5), we obtain

$$u^-(\boldsymbol{x}) = \int_\Gamma \left(u^- \frac{\partial G}{\partial \boldsymbol{n}} - \frac{\partial u^-}{\partial \boldsymbol{n}} G \right) ds_{\boldsymbol{y}} = \int_\Gamma \left(u \frac{\partial G}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}} G \right) ds_{\boldsymbol{y}}, \quad \boldsymbol{x} \in \Omega. \tag{2.6}$$

Therefore, from (2.6) we can conclude that the desired annihilating acoustic signal $v = v(\boldsymbol{x})$ that cancels out the unwanted noise on Ω can be obtained as

$$v(\boldsymbol{x}) = -\int_\Gamma \left(u \frac{\partial G}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}} G \right) ds_{\boldsymbol{y}}, \tag{2.7}$$

so that for $\boldsymbol{x} \in \Omega$ we indeed have

$$[u(\boldsymbol{x}) + v(\boldsymbol{x})]_{\boldsymbol{x} \in \Omega} = u^+(\boldsymbol{x}).$$

To actually implement the annihilating signal v of (2.7), we introduce the auxiliary function $w = w(\boldsymbol{x})$ on $\mathbb{R}^n$ that satisfies the aforementioned conditions at the interface Γ and at infinity, and apply the Green's formula to w, which yields

$$w(\boldsymbol{x}) - \int_\Omega G \boldsymbol{L} w d\boldsymbol{y} = \int_\Gamma \left(w \frac{\partial G}{\partial \boldsymbol{n}} - \frac{\partial w}{\partial \boldsymbol{n}} G \right) ds_{\boldsymbol{y}}, \quad \boldsymbol{x} \in \Omega. \tag{2.8}$$

As $w(\boldsymbol{x})$ satisfies the Sommerfeld conditions (1.2a) or (1.2b), we obviously have $w(\boldsymbol{x}) = \int_{\mathbb{R}^n} G \boldsymbol{L} w d\boldsymbol{y}$, $\boldsymbol{x} \in \mathbb{R}^n$, which, along with formulae (2.2) and (2.7), allows us to transform equality (2.8) to

$$v(\boldsymbol{x}) = -\int_{\Omega_1} G \boldsymbol{L} w d\boldsymbol{y}. \tag{2.9}$$

Equation (2.9) implies that for any $w = w(\boldsymbol{x})$ chosen as described above, formula (2.1) describes an appropriate control function.

Conversely, assume that $g = g(x)$, $\operatorname{supp} g \subset \Omega_1$, is a control field such that the solution $\tilde{u} = \tilde{u}(\boldsymbol{x})$ of (1.6) subject to the Sommerfeld conditions (1.2a) or (1.2b) satisfies equality (1.7). Then, by choosing $w = w(\boldsymbol{x})$, $\boldsymbol{x} \in \mathbb{R}^n$, as the solution to the nonhomogeneous equation

$$-\boldsymbol{L}w = g - f^+,$$

subject to the corresponding Sommerfeld condition, (1.2a) or (1.2b), one can represent g in the form (2.1); see [7]. Altogether, we obtain that formula (2.1) describes the general solution for controls. In other words, for any $w(\boldsymbol{x})$, formula (2.1) provides an appropriate control field $g(\boldsymbol{x})$, and any appropriate control field $g(\boldsymbol{x})$ can be represented in the form (2.1) with some particular choice of $w(\boldsymbol{x})$.

Let us emphasize several important properties of controls (2.1). First of all, from the foregoing derivation we can see that to obtain these controls one needs no knowledge of the actual exterior sources of noise f^-. In other words, neither their location, nor structure, nor strength are required. All one needs to know is u and $\frac{\partial u}{\partial \boldsymbol{n}}$ on the perimeter Γ of the protected region Ω. As has been mentioned, in a practical setting $u|_\Gamma$ and $\frac{\partial u}{\partial \boldsymbol{n}}|_\Gamma$ can be interpreted as measurable quantities that are supplied to the control system as the input data. Moreover, these measurable quantities refer to the overall acoustic field u, rather than only to its unwanted component u^-. In other words, the methodology can automatically distinguish between the signals coming from the exterior and interior sources, and can tune the controls so that they cancel only the unwanted exterior signal. This capability is extremely important, as in many applications the overall acoustic field always contains a component that needs to be suppressed along with the part that needs to be left intact. Alternatively, one can say that the control sources (2.1) are insensitive to the interior sound $u^+(\boldsymbol{x})$. Indeed, given a function $w(\boldsymbol{x})$ that satisfies interface conditions (2.2) and the radiation boundary conditions at infinity, we can take instead $\tilde{w}(\boldsymbol{x}) = w(\boldsymbol{x}) - u^+(\boldsymbol{x})$; this new function will satisfy the interface conditions (2.2) with u replaced by u^- and the same Sommerfeld conditions at infinity. Most important, the control sources generated by $\tilde{w}(\boldsymbol{x})$ will be the exact same control sources as those generated by $w(\boldsymbol{x})$ because $\boldsymbol{L}\tilde{w}(\boldsymbol{x}) = \boldsymbol{L}[w(\boldsymbol{x}) - u^+(\boldsymbol{x})] = \boldsymbol{L}w(\boldsymbol{x})$ for $\boldsymbol{x} \in \Omega_1$.

Let us also note that in a more general framework, formula (2.9) (with (2.2) taken into account) can be interpreted as a particular case of the generalized potential of Calderon's type with the vector density $-\big(u, \frac{\partial u}{\partial \boldsymbol{n}}\big)|_\Gamma$. This more general framework allows us to analyze more complex formulations of the active noise control problem (see [7]) such as those that involve variations in material properties and alternative types of far-field behavior of the solution. We refer the reader to the original work by Calderon [2] and Seeley [16], as well as to the monograph by Ryaben'kii [15], for general concepts related to Calderon's potentials and associated pseudodifferential boundary projection operators. As concerns the aforementioned more advanced formulations of the noise control problem, the key result is basically the same as above. The general solution for control sources is still given by formula (2.1), where the auxiliary function $w(\boldsymbol{x})$ should still satisfy the interface conditions (2.2) and the problem-specific far-field boundary conditions (in case they differ from the previously mentioned Sommerfeld conditions). The operator $\boldsymbol{L}$ in formula (2.1) will, however, no longer be the constant-coefficient Helmholtz operator of (1.1); it will rather be the problem-specific variable-coefficients operator that accounts for the particular variations in material properties, etc. However, since formula (2.1) for controls does not

change (see [7]), we immediately conclude that we, in fact, do not need to know the operator $\boldsymbol{L}$ on Ω. In other words, for obtaining the control sources we do not need to know the material properties of the sound-conducting medium inside the protected region. This result (see [7]), which at first seems counterintuitive, has, in fact, a straightforward physical explanation. We only need to realize that the noise we want to suppress, and the output of controls that is supposed to annihilate this noise, propagate across one and the same medium, and we do not need to know what this medium is (under some relatively nonrestrictive limitations; see [7]). It is also interesting to mention that the aforementioned Calderon boundary projection operators essentially render the decomposition of the wave field $u(\boldsymbol{x})$ on the boundary Γ into its incoming and outgoing component with respect to the domain Ω; see [7]. Subsequently, the controls (2.1) can be interpreted as either sources cancelling the incoming wave field for the domain to be shielded, i.e., Ω, or alternatively, as sources cancelling the outgoing wave field for the domain complementary to the one to be shielded, i.e., $\Omega_1 = \mathbb{R}^n \backslash \Omega$. The latter interpretation is often more versatile; see [7].

Another important thing to notice is that the control sources $g(\boldsymbol{x})$ of (2.1) are defined, generally speaking, on the entire complementary domain $\Omega_1 = \mathbb{R}^n \backslash \Omega$. For the analysis of specific problems, especially when the protected region Ω is bounded and the complementary region Ω_1 is unbounded, as in Figure 1.1, it may be convenient to consider compactly supported control sources, i.e., the control sources concentrated in the vicinity of the interface Γ. To obtain such controls, one needs to narrow down the class of functions $w(\boldsymbol{x})$ used in formula (2.1). Namely, instead of considering arbitrary $w(\boldsymbol{x})$ subject only to constraints (2.2) and Sommerfeld boundary conditions at infinity, one needs to consider $w(\boldsymbol{x})$ that become a solution to the homogeneous Helmholtz equation everywhere outside some larger domain that fully contains the protected region Ω. In so doing, the area outside Ω that supports the controls $g(\boldsymbol{x})$ of (2.1) will stretch from Γ to the outer boundary of the aforementioned larger domain, and may basically look like a curvilinear strip adjacent to Γ from the exterior side. This strip may, in principle, be made as narrow as desired and may eventually shrink completely, thus reducing to only the interface Γ itself. As will be seen, the sources $g(\boldsymbol{x})$ supported only on the perimeter Γ represent an important class of active controls. Such distributions $g(\boldsymbol{x})$ include monopole and dipole layers as special cases, which are idealizations of pulsating or vibrating membranes.

2.2. Artificial boundary conditions and compactly supported controls. To actually obtain compactly supported controls $g(\boldsymbol{x})$ in a particular setting, it is often convenient to use the methodology known as artificial boundary conditions (see the review paper [19]) for the selection of the appropriate function $w(\boldsymbol{x})$ in formula (2.1). Assume that $w(\boldsymbol{x})$ satisfies the homogeneous Helmholtz equation $\boldsymbol{L}w = 0$ outside some outer artificial boundary, which is a closed surface (curve) with an interior that fully contains Ω. In Figure 1.1, we schematically represent this outer boundary as a sphere (circle) of radius R. It turns out that one can equivalently replace the homogeneous equation $\boldsymbol{L}w = 0$ along with the Sommerfeld boundary conditions at infinity by the special artificial boundary conditions (ABCs) at the outer boundary. For the outer boundary of a general shape, this can be done most efficiently using the same apparatus of Calderon's pseudodifferential boundary projection operators (see [15, 19]) that has been mentioned before. For the particular case of a regular spherical or circular outer boundary (see Figure 1.1), which is convenient due to the simplicity of the analysis, the construction of the ABCs is described below. We emphasize that the forthcoming boundary conditions are exact. In other words, they

are set at a finite artificial boundary and are fully equivalent to the Sommerfeld boundary conditions set at infinity. They also appear to be nonlocal. High accuracy (exactness) and nonlocality of the ABCs that we introduce and use hereafter present a notable distinction compared to many approximate methods, which are typically local but not as accurate; see, e.g., [19].

We will use spherical coordinates (ρ, θ, ϕ) in $\mathbb{R}^n$, $n = 3$, and assume that $\boldsymbol{L}w = 0$ for $|\boldsymbol{x}| \equiv \rho \geq R$; see Figure 1.1. In addition, we will assume that $w(\boldsymbol{x})$ satisfies the Sommerfeld boundary condition (1.2b). Expanding $w(\boldsymbol{x})$ with respect to spherical functions Y_l^m, $l = 0, 1, 2, \ldots$, $m = 0, \pm 1, \ldots, \pm l$, and separating the variables in the differential operator $\boldsymbol{L}$, we arrive at the following collection of second-order ordinary differential equations:

$$\begin{aligned} &\frac{d^2\hat{w}_{lm}}{d\rho^2} + \frac{2}{\rho}\frac{d\hat{w}_{lm}}{d\rho} + \left[k^2 - \frac{l(l+1)}{\rho^2}\right]\hat{w}_{lm} = 0, \\ &\rho \geq R, \quad l = 0, 1, 2, \ldots, \quad m = 0, \pm 1, \ldots, \pm l, \end{aligned} \tag{2.10}$$

for the unknown radial modes $\hat{w}_{lm}$. These modes are also supposed to satisfy boundary conditions at infinity

$$\hat{w}_{lm}(\rho) = O\left(\rho^{-1}\right), \quad \frac{d\hat{w}_{lm}(\rho)}{d\rho} + ik\hat{w}_{lm}(\rho) = o\left(\rho^{-1}\right) \quad \text{as} \quad \rho \longrightarrow \infty, \tag{2.11}$$

which immediately follow from the Sommerfeld condition (1.2b). For any given pair (l, m) the general solution of (2.10) is given by

$$\hat{w}_{lm} = \frac{c_1}{\sqrt{\rho}} H^{(1)}_{l+1/2}(k\rho) + \frac{c_2}{\sqrt{\rho}} H^{(2)}_{l+1/2}(k\rho), \tag{2.12}$$

where c_1 and c_2 are arbitrary constants and $H^{(1)}_{l+1/2}(k\rho)$ and $H^{(2)}_{l+1/2}(k\rho)$ are Hankel functions of the first and second kind, respectively. Taking into account the asymptotic expressions for the Hankel functions for a fixed order ν and large values of ρ (see, e.g., [24]),

$$\begin{aligned} H^{(1)}_\nu(\rho) &= \sqrt{\frac{2}{\pi\rho}} \exp\left[i\left(\rho - \frac{\pi}{2}\nu - \frac{\pi}{4}\right)\right] + O\left(\rho^{-3/2}\right), \\ H^{(2)}_\nu(\rho) &= \sqrt{\frac{2}{\pi\rho}} \exp\left[-i\left(\rho - \frac{\pi}{2}\nu - \frac{\pi}{4}\right)\right] + O\left(\rho^{-3/2}\right), \end{aligned}$$

we conclude that only $\rho^{-1/2}H^{(2)}_{l+1/2}(k\rho)$ satisfies boundary conditions (2.11), and consequently the constant c_1 (see (2.12)) in any particular solution that satisfies the Sommerfeld conditions at infinity has to be equal to zero. As the two functions $\rho^{-1/2}H^{(1)}_{l+1/2}(k\rho)$ and $\rho^{-1/2}H^{(2)}_{l+1/2}(k\rho)$ form a fundamental system of solutions for the linear homogeneous second-order ODE (2.10), requiring that only one of them, $\rho^{-1/2}H^{(2)}_{l+1/2}(k\rho)$, be present in the actual solution $\hat{w}_{lm}$ is equivalent to requiring that $\hat{w}_{lm}(\rho)$ be parallel to $\rho^{-1/2}H^{(2)}_{l+1/2}(k\rho)$ for $\rho \geq R$ in the sense of the corresponding Wronskian vanishing at $\rho = R$:

$$\det \begin{bmatrix} \hat{w}_{lm} & \rho^{-1/2}H^{(2)}_{l+1/2}(k\rho) \\ \frac{d}{d\rho}\hat{w}_{lm} & \frac{d}{d\rho}\left(\rho^{-1/2}H^{(2)}_{l+1/2}(k\rho)\right) \end{bmatrix}\Bigg|_{\rho=R} = 0. \tag{2.13}$$

Obviously, equality (2.13) enforced at $\rho = R$ implies that it will hold for all $\rho \geq R$ as well. Equality (2.13) is a linear homogeneous relation between a given Fourier component $\hat{w}_{lm}$ of the solution $w(\boldsymbol{x})$ and the corresponding Fourier component $\frac{d}{d\rho}\hat{w}_{lm}$ of its normal derivative $\frac{d}{d\rho}w(\boldsymbol{x})$ on the spherical surface $\rho = R$. The entire family of such relations for all $l = 0, 1, 2, \ldots$ and $m = 0, \pm 1, \ldots, \pm l$ set at $\rho = R$ is equivalent to saying that the function $w = w(\boldsymbol{x})$ originally defined inside the sphere, i.e., for $\rho \leq R$, can be smoothly extended to the region $\rho \geq R$ so that the extension will solve the homogeneous equation $\boldsymbol{L}w = 0$ for $\rho \geq R$ and have a proper far-field behavior, i.e, satisfy the Sommerfeld condition (1.2b). Hereafter, we will refer to relations (2.13) for $l = 0, 1, 2, \ldots$ and $m = 0, \pm 1, \ldots, \pm l$ as *the artificial boundary conditions* for the three-dimensional Helmholtz equation on the spherical surface $\rho = R$.

The ABCs for the two-dimensional case on the circular external artificial boundary $\rho = R$ can be obtained similarly. We introduce polar coordinates (ρ, θ) in $\mathbb{R}^n$, $n = 2$, use standard Fourier expansion in the circumferential direction with respect to the complex exponents $e^{-il\theta}$, $l = 0, \pm 1, \pm 2, \ldots$, and arrive at the following collection of second-order ordinary differential equations:

$$\frac{d^2\hat{w}_l}{d\rho^2} + \frac{1}{\rho}\frac{d\hat{w}_l}{d\rho} + \left[k^2 - \frac{l^2}{\rho^2}\right]\hat{w}_l = 0, \quad \rho \geq R, \quad l = 0, \pm 1, \pm 2, \ldots, \tag{2.14}$$

for the unknown radial modes $\hat{w}_l$. These modes are also supposed to satisfy boundary conditions at infinity

$$\hat{w}_l(\rho) = O(\rho^{-1/2}), \quad \frac{d\hat{w}_l(\rho)}{d\rho} + ik\hat{w}_l(\rho) = o(\rho^{-1/2}) \quad \text{as} \quad \rho \longrightarrow \infty, \tag{2.15}$$

which immediately follow from the Sommerfeld condition (1.2a). For every given l, (2.14) is the Bessel equation and has general solution

$$\hat{w}_l = c_1 H_l^{(1)}(k\rho) + c_2 H_l^{(2)}(k\rho), \tag{2.16}$$

where c_1 and c_2 are, again, arbitrary constants. The asymptotics of the Hankel functions for large ρ's indicates that to satisfy (2.15) one must have $c_1 = 0$ in any particular solution that satisfies the radiation conditions at infinity. This requirement leads to the following ABCs for the two-dimensional Helmholtz equation:

$$\det \begin{bmatrix} \hat{w}_l & H_l^{(2)}(k\rho) \\ \frac{d}{d\rho}\hat{w}_l & \frac{d}{d\rho}H_l^{(2)}(k\rho) \end{bmatrix}\Bigg|_{\rho=R} = 0, \tag{2.17}$$

where relations (2.17) should be considered for all $l = 0, \pm 1, \pm 2, \ldots$. We refer the reader to the review article [19] for further detail on the construction of ABCs for different equations in different settings. Let us also reiterate that once the ABCs (2.13) or (2.17) are satisfied for all radial modes, then we can consider $\boldsymbol{L}w = 0$ for $\rho \geq R$, and as such, the resulting control sources $g(\boldsymbol{x})$ given by (2.1) will be compactly supported between the interface Γ and the external artificial boundary $\rho = R$.

2.3. Types of control sources. Let us now analyze the continuous control sources from the standpoint of their geometric location and the type of acoustic excitation that they provide. To put this analysis into a mathematical perspective, it will be convenient to use the apparatus of distributions; see, e.g., [24].

In our original derivation of formula (2.1), we have implicitly assumed that the function $w(\boldsymbol{x})$ was sufficiently smooth so that the operator $\boldsymbol{L}$ could be applied in the classical sense everywhere on $\Omega_1 = \mathbb{R}^n \backslash \Omega$. In this case, the function $g(\boldsymbol{x})$ is locally absolutely integrable, $g \in \boldsymbol{L}_1^{(\mathrm{loc})}(\Omega_1)$, and can be interpreted as a regular distribution. As for any other distribution, it can be represented as a convolution of its own self with the δ-function: $g = \delta * g$. This means that from the mathematical standpoint the control field $g(\boldsymbol{x})$ can be viewed as an expansion in terms of the elementary point monopoles $g(\boldsymbol{y})\delta(\boldsymbol{x}-\boldsymbol{y})$ with regular density g:

$$g(\boldsymbol{x}) = \delta * g = \int_{\mathbb{R}^n} g(\boldsymbol{y})\delta(\boldsymbol{x}-\boldsymbol{y})d\boldsymbol{y}. \tag{2.18}$$

Next, we recall that, by definition of the fundamental solution $\boldsymbol{L}G = \delta(\boldsymbol{x})$, the response to every such elementary monopole $g(\boldsymbol{y})\delta(\boldsymbol{x}-\boldsymbol{y})$ will be given by $g(\boldsymbol{y})G(\boldsymbol{x}-\boldsymbol{y})$, and consequently, the overall control output

$$G * g = \int_{\mathbb{R}^n} g(\boldsymbol{y})G(\boldsymbol{x}-\boldsymbol{y})d\boldsymbol{y} \tag{2.19}$$

will be interpreted as superposition of the foregoing elementary responses, i.e., solutions generated by the aforementioned point monopoles. Altogether we see that the original formula (2.1) provides the general solution for controls in the class of regular distributions $\boldsymbol{L}_1^{(\mathrm{loc})}(\Omega_1)$, which corresponds to the volumetric control sources of monopole type on the complementary domain $\Omega_1 = \mathbb{R}^n \backslash \Omega$. Compactly supported controls discussed in section 2.2 obviously fall into this category. Later on we will see that this class of functions contains, in fact, all meaningful volumetric excitations.

In many cases it may also be desirable to consider surface controls, i.e., the control sources that are concentrated only on the interface Γ. Let us first assume that there are no interior sources, which means that $u^+(\boldsymbol{x}) = 0$, and the acoustic field we want to control consists only of its adverse component, $u(\boldsymbol{x}) \equiv u^-(\boldsymbol{x})$. After the control, the overall acoustic field has to be equal to zero on the domain Ω. As shown in [20], the general solution for surface controls is given by

$$g^{(\mathrm{surf})} = -\left[\frac{\partial w}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma) - \frac{\partial}{\partial \boldsymbol{n}}\big([w-u]_\Gamma \delta(\Gamma)\big), \tag{2.20}$$

where $w = w(\boldsymbol{x})$, as before, denotes the auxiliary function-parameter that in this case has to satisfy the homogeneous Helmholtz equation on the complementary domain, $\boldsymbol{L}w = 0$ for $\boldsymbol{x} \in \Omega_1$, and the Sommerfeld boundary condition (1.2a) or (1.2b) at infinity. Expressions in rectangular brackets in formula (2.20) denote discontinuities of the corresponding quantities across the interface Γ. The first term on the right-hand side of (2.20) represents the density of a single-layer potential, which is a layer of monopoles on the interface Γ, and the second term on the right-hand side of (2.20) represents the density of a double-layer potential, which is a layer of dipoles on the interface Γ.

A detailed justification of formula (2.20) as general solution for surface controls can be found in [20]. Here we mention only that it basically amounts to proving that a given solution $u(\boldsymbol{x})$ of the homogeneous equation $\boldsymbol{L}u = 0$ on Ω can be represented as a combination of a single-layer potential and a double-layer potential if and only if the densities of the aforementioned potentials are defined as $\left[\frac{\partial w}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma)$ and

$\frac{\partial}{\partial \boldsymbol{n}}\left([w-u]_\Gamma \delta(\Gamma)\right)$, respectively (cf. formula (2.20)). The direct implication is easy to establish by applying the operator $\boldsymbol{L}$ to the discontinuous function

$$v(\boldsymbol{x}) = \begin{cases} u(\boldsymbol{x}) & \text{for } \boldsymbol{x} \in \Omega, \\ w(\boldsymbol{x}) & \text{for } \boldsymbol{x} \in \Omega_1, \end{cases} \tag{2.21}$$

in the sense of distributions (see [24]), which yields

$$\boldsymbol{L}v = \left[\frac{\partial w}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma) + \frac{\partial}{\partial \boldsymbol{n}}\big([w-u]_\Gamma \delta(\Gamma)\big), \tag{2.22}$$

and subsequently reconstructing $u(\boldsymbol{x})|_{\boldsymbol{x}\in\Omega} = v(\boldsymbol{x})|_{\boldsymbol{x}\in\Omega}$ as a convolution with the fundamental solution. The inverse implication requires explicitly obtaining $w(\boldsymbol{x})$ for a given $u(\boldsymbol{x})$ and given surface densities, which is done in [20], again, in the form of a special surface integral. Then, the control sources (2.20) are obtained by simply taking (2.22) with the opposite sign, which guarantees the cancellation of $u(\boldsymbol{x})$ on Ω by $-v(\boldsymbol{x})$.

In the family of surface controls (2.20) we identify two important particular cases. First, the cancellation of $u(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega$, can be achieved by using only the surface monopoles, i.e., by employing only a single-layer potential as the annihilating signal. To do that, we need to find $w(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega_1$, such that the overall function $v(\boldsymbol{x})$ of (2.21) would have the discontinuity on Γ only in its normal derivative and not in the function itself. This $w(\boldsymbol{x})$ will then be a solution of the following external Dirichlet problem:

$$\begin{aligned} \boldsymbol{L}w = 0, \quad & \boldsymbol{x} \in \Omega_1, \\ w\big|_\Gamma = u\big|_\Gamma, \quad & \end{aligned} \tag{2.23}$$

subject to the appropriate Sommerfeld boundary condition (1.2a) or (1.2b). Problem (2.23) is always uniquely solvable on $\Omega_1 = \mathbb{R}^n \backslash \Omega$. Second, one can employ only the double-layer potential to cancel out $u(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega$, i.e., use only surface dipoles as the control sources. In this case, the function $w(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega_1$, has to be such that $v(\boldsymbol{x})$ given by (2.21) would have discontinuity on Γ only in the function itself and not in its normal derivative. This $w(\boldsymbol{x})$ should then solve the following external Neumann problem:

$$\begin{aligned} \boldsymbol{L}w = 0, \quad & \boldsymbol{x} \in \Omega_1, \\ \frac{\partial w}{\partial \boldsymbol{n}}\Big|_\Gamma = \frac{\partial u}{\partial \boldsymbol{n}}\Big|_\Gamma, \quad & \end{aligned} \tag{2.24}$$

again, subject to the appropriate Sommerfeld condition at infinity, (1.2a) or (1.2b); the latter guarantees the solvability of (2.24).

In a more general case, when interior sources are present, the results, in fact, do not change. Assume, as before, that the overall acoustic field is the sum of its friendly and adverse components (see (1.4)), $u(\boldsymbol{x}) = u^+(\boldsymbol{x}) + u^-(\boldsymbol{x})$, and we want to cancel out $u^-(\boldsymbol{x})$ on Ω. Then, formula (2.20), where u shall now be interpreted as in (1.4) and w is a function-parameter, will still provide the general solution for surface controls. Indeed, since $\boldsymbol{L}u^+ = 0$ on Ω_1 and, moreover, $u^+(x)$ and $\frac{\partial u^+}{\partial \boldsymbol{n}}(\boldsymbol{x})$ are continuous across the interface Γ, then (2.20) simply reduces to

$$g^{(\mathrm{surf})} = -\left[\frac{\partial \tilde{w}}{\partial \boldsymbol{n}} - \frac{\partial u^-}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma) - \frac{\partial}{\partial \boldsymbol{n}}\big([\tilde{w}-u^-]_\Gamma \delta(\Gamma)\big), \tag{2.25}$$

where the new function-parameter $\tilde{w}$ is given by $\tilde{w}(\boldsymbol{x}) = w(\boldsymbol{x}) - u^+(\boldsymbol{x})$ and, as such, satisfies the aforementioned general requirements of w's. This means that the control sources $g^{(\mathrm{surf})}(\boldsymbol{x})$, $\boldsymbol{x} \in \Gamma$, defined by (2.20), or equivalently (2.25), appear insensitive to the friendly component $u^+(\boldsymbol{x})$ of the acoustic field, and will precisely annihilate $u^-(\boldsymbol{x})$ on the domain Ω. Furthermore, the entire family of surface controls (2.25) is obviously the exact same family as we would have obtained if there were no interior sources and the overall acoustic field consisted of only $u^-(\boldsymbol{x})$. It is also clear that the same reasoning will apply to the particular cases of purely monopole and purely dipole controls. Namely, if in problems (2.23) and (2.24) we interpreted the boundary data u and $\frac{\partial u}{\partial \boldsymbol{n}}$ (respectively) in the sense of (1.4), then the solution w of either problem would obviously be $w(\boldsymbol{x}) = \tilde{w}(\boldsymbol{x}) + u^+(\boldsymbol{x})$, where $\tilde{w}(\boldsymbol{x})$ is the solution that corresponds to $u^+(\boldsymbol{x}) \equiv 0$. This means that both the monopole and the dipole layers constructed using the respective solution $w(\boldsymbol{x})$ would be the exact same monopole or dipole layer that suppresses $u^-(\boldsymbol{x})$ on Ω in the case of no interior sources and no interior sound.

Altogether we conclude that, as indicated by formula (2.20), surface control sources are combinations of monopole and dipole layers, with the two "extreme" cases corresponding to either only monopoles (see (2.23)) or only dipoles (see (2.24)). From the standpoint of physics, the monopole and dipole sources provide different types of excitation to the surrounding sound-conducting medium. A point monopole source can be interpreted as a vanishingly small pulsating sphere that radiates acoustic waves symmetrically in all directions, whereas a point dipole source resembles a small oscillating membrane that has a particular directivity of radiation (see, e.g., [11] for a more detailed discussion on the properties of different sources). This distinction basically warrants a separate consideration of the monopole- and dipole-type sources as far as the pointwise or surface excitation may be concerned. However, in the context of volumetric excitation, a separate consideration of dipole fields appears, in effect, superfluous.

Indeed, a point dipole is characterized by its (complex) magnitude b and direction $\boldsymbol{m}$ (cf. formula (2.20)):

$$-b\frac{\partial \delta}{\partial \boldsymbol{m}} = -b\langle \boldsymbol{m}, \nabla\delta\rangle = -\langle \boldsymbol{b}, \nabla\delta\rangle, \tag{2.26}$$

where the definition of $\nabla\delta$ is standard, i.e., for any test function $\phi \in \mathcal{D}$ we have $(\nabla\delta, \phi) = -(\delta, \nabla\phi) = -\nabla\phi(0)$, $\langle\cdot,\cdot\rangle$ denotes a conventional real scalar product, and the complex n-dimensional vector $\boldsymbol{b} \equiv b\boldsymbol{m}$ is called the dipole moment.[2] Let us now consider a volumetric distribution of dipoles, i.e., a right-hand side to the Helmholtz equation given in the following convolution form (cf. formula (2.18)):

$$b(\boldsymbol{x}) = -\int_{\mathbb{R}^n} \langle \boldsymbol{b}(\boldsymbol{y}), \nabla\delta(\boldsymbol{x}-\boldsymbol{y})\rangle d\boldsymbol{y} = -\sum_{i=1}^{n} b_i * \nabla_i\delta, \tag{2.27}$$

where $\boldsymbol{b}$ is a regular vector field. Since the convolution of any distribution with the δ-function always exists [24], we can rewrite (2.27) as

$$b(\boldsymbol{x}) = -\sum_{i=1}^{n} \nabla_i b_i * \delta = -\int_{\mathbb{R}^n} \mathrm{div}\boldsymbol{b}(\boldsymbol{y})\delta(\boldsymbol{x}-\boldsymbol{y})d\boldsymbol{y} = -\mathrm{div}\boldsymbol{b} * \delta = -\mathrm{div}\boldsymbol{b}. \tag{2.28}$$

[2]We emphasize that $\boldsymbol{b}$ is not a most general complex vector, but rather a product of a single complex quantity b and a real n-dimensional vector $\boldsymbol{m}$.

Formula (2.28) implies that if we additionally require that the vector field $\boldsymbol{b}(\boldsymbol{y})$ be somewhat more regular than simply $\boldsymbol{b} \in L_1^{(\mathrm{loc})}(\Omega_1)$, namely, $\mathrm{div}\boldsymbol{b} \in L_1^{(\mathrm{loc})}(\Omega_1)$, then the volumetric distribution of dipoles can be reduced to an equivalent volumetric distribution of monopoles as in (2.18).

Next, by differentiating the relation $\boldsymbol{L}G = \delta$, we obtain that the response to the point dipole excitation (2.26) is given by $-\langle \boldsymbol{b}, \nabla G\rangle$. Accordingly, the solution that corresponds to the distribution of sources (2.27) or (2.28) is given by (cf. formula (2.19))

$$
\begin{aligned}
u(\boldsymbol{x}) &= -\int_{\mathbb{R}^n} \langle \boldsymbol{b}(\boldsymbol{y}), \nabla G(\boldsymbol{x}-\boldsymbol{y})\rangle d\boldsymbol{y} = -\sum_{i=1}^{n} b_i * \nabla_i G \\
&= -\sum_{i=1}^{n} \nabla_i b_i * G = -\int_{\mathbb{R}^n} \mathrm{div}\boldsymbol{b}(\boldsymbol{y}) G(\boldsymbol{x}-\boldsymbol{y}) d\boldsymbol{y}.
\end{aligned} \tag{2.29}
$$

Note that, for the representation via the divergence operator to hold, we need to require that the convolutions $b_i * G$ exist in $\mathcal{D}'$; see [24]. A convenient sufficient condition for that may be $\boldsymbol{b}$ having compact support, which, as we have seen in section 2.2, does not present a significant restriction of generality from the standpoint of active control of sound. To make sure that the function $u(\boldsymbol{x})$ of (2.29) does solve the equation $\boldsymbol{L}u = b$, we apply the operator $\boldsymbol{L}$ of (1.1) to it:

$$
\begin{aligned}
\boldsymbol{L}u(\boldsymbol{x}) &= -\boldsymbol{L}\left[\sum_{i=1}^{n} b_i * \nabla_i G\right] = -\sum_{i=1}^{n} \boldsymbol{L}\left[b_i * \nabla_i G\right] \\
&= -\sum_{i=1}^{n} b_i * \boldsymbol{L}\nabla_i G = -\sum_{i=1}^{n} b_i * \nabla_i \boldsymbol{L}G = -\sum_{i=1}^{n} b_i * \nabla_i \delta = b(\boldsymbol{x}).
\end{aligned}
$$

Again, for the foregoing chain of equalities to hold, we need to require the existence of some convolutions in $\mathcal{D}'$, this time $b_i * \nabla_i G$, $i = 1, \ldots, n$. This is guaranteed by the same sufficient condition of $\mathrm{supp}\boldsymbol{b}$ being compact.

From the previous discussion we see that mathematically we can describe volumetric sources of time-harmonic sound only in terms of monopoles. In a real-life acoustic setting, however, both the actual monopole and the dipole sources may be present. It is instrumental to see how those sources that have different physical interpretation enter the right-hand side of the Helmholtz operator. We postpone the corresponding discussion till section 4.1, in which we provide the motivation for selecting a particular optimization criterion. In the meantime, let us emphasize that in the rest of the paper we are going to analyze only one type of the control sources, namely, the monopoles. This class includes all of the volumetric controls (2.1), i.e., monopoles distributed in space, and their limiting case given by the monopole layer on the surface Γ (cf. formula (2.20)):

$$
g^{(\mathrm{surf})}_{\mathrm{monopole}} = -\left[\frac{\partial w}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}}\right]_{\Gamma} \delta(\Gamma), \tag{2.30}
$$

where $w = w(\boldsymbol{x})$ in (2.30) solves the Dirichlet problem (2.23).[3] In other words, we have narrowed down the class of admissible controls by excluding the surface

[3] As has been mentioned (see section 4.1), volumetric monopoles considered in the mathematical perspective may include contributions from both actual physical monopoles and dipoles.

dipoles. Clearly, having only one and the same type of sources greatly facilitates their description and comparison using the same quantitative characteristics, e.g., acoustic strength (see [11] for the definition and section 4 for more detail). In particular, it allows us to formulate (see section 4.1) and solve (see sections 4.2 and 4.3) the optimization problem for the control sources with the overall absolute acoustic source strength being the cost function. Moreover, the solution of this optimization problem, i.e., the global minimum (more precisely, largest lower bound) in the class of all volumetric controls that guarantee the exact cancellation of noise, happens to be the uniquely defined single layer (2.30), (2.23) on the interface Γ. In this framework, surface dipoles naturally fall out of consideration.

There are, however, optimization criteria that employ physically meaningful quantities other than the total source strength, which naturally justify using combinations of both monopole and dipole control sources. These criteria would typically compare outputs of controls rather than the controls themselves. For example, in the forthcoming paper [8] we employ one such criterion, which is based on the power required by the control system. It turns out that the corresponding analysis necessarily involves interaction between the sources of sound and the surrounding acoustic field. Even though it may seem counterintuitive at a first glance, one can build a control system (a particular combination of monopoles and dipoles) that would require no power input for operation and would even produce a net power gain while providing exact noise cancellation. This, of course, comes at the expense of having the original sources of noise produce even more energy; see [8].

3. Discrete control sources. Similarly to the continuous constructions of the previous section, one can discretize the problem on the grid and obtain the control sources for the discrete formulation. From the standpoint of applications this is, of course, preferred, because any practical design of a noise control system can contain only a finite number of elements or devices (acoustic sensors and actuators) that will be associated with the grid nodes in the discrete case. Details regarding the discrete formulation of the noise control problem can be found in the monograph by Ryaben'kii [15, Part VIII], as well as in the papers [22, 23]; here we provide only a brief account of the corresponding work. The analysis hereafter will not be limited to any specific type of the grid. In particular, no adaptation or grid fitting to either the shape of the protected region Ω (i.e., interface Γ) or that of the external artificial boundary will generally be required. In some cases, though, it may simply be convenient and inexpensive to use a regular grid of an appropriate geometry. For example, as we discuss later, having a polar or spherical grid may greatly simplify setting the ABCs on the circle or sphere, respectively, of radius R in the discrete framework.

3.1. Grids and discretization. Let us now introduce a finite-difference grid $\mathbb{N}$ that would span both Ω and Ω_1. In the discrete formulation, the grid never stretches all the way to infinity; it is always truncated by the external artificial boundary, which implies that the discrete control sources that we obtain will always be compactly supported. Later in section 3.3, we will discuss how to set the appropriate ABCs for the discrete formulation. Now let $u^{(h)}$ be a representation of the acoustic field on the grid, and $\boldsymbol{L}^{(h)}$ be a finite-difference approximation of the differential operator $\boldsymbol{L}$ of (1.1). To accurately define the approximation, we will need to introduce another grid $\mathbb{M}$ along with the previously defined $\mathbb{N}$. On the grid $\mathbb{M}$, we will consider the residuals of the operator $\boldsymbol{L}^{(h)}$, and subsequently the right-hand sides to the corresponding inhomogeneous finite-difference equation. We will use the notations n and m for the

individual nodes of the grids $\mathbb{N}$ and $\mathbb{M}$, respectively, and the notation $\mathbb{N}_m$ for the stencil of the discrete operator $\boldsymbol{L}^{(h)}$ centered at a given $m \in \mathbb{M}$, so that

$$\boldsymbol{L}^{(h)} u^{(h)}\big|_m = \sum_{n \in \mathbb{N}_m} a_{mn} u_n^{(h)}, \tag{3.1}$$

where a_{nm} are the coefficients associated with particular nodes of the stencil. There are no limitations to the type of discrete operators that one may use. We only require that the difference operator $\boldsymbol{L}^{(h)}$ of (3.1) approximate the differential operator $\boldsymbol{L}$ of (1.1) with the accuracy sufficient for a particular application.

Next, we introduce the following subsets of the grids $\mathbb{M}$ and $\mathbb{N}$, which will allow us to accurately distinguish between the interior and exterior domains, interior and exterior sources, and interior and exterior solutions on the discrete level:

$$\begin{gathered} \mathbb{M}^+ = \mathbb{M} \cap \Omega, \quad \mathbb{M}^- = \mathbb{M} \backslash \mathbb{M}^+ = \mathbb{M} \cap \Omega_1, \\ \mathbb{N}^+ = \bigcup_{m \in \mathbb{M}^+}, \quad \mathbb{N}^- = \bigcup_{m \in \mathbb{M}^-} \mathbb{N}_m, \\ \gamma = \mathbb{N}^+ \cap \mathbb{N}^-, \quad \gamma^+ = \mathbb{N}^- \cap \Omega, \quad \gamma^- = \mathbb{N}^+ \cap \Omega_1. \end{gathered} \tag{3.2}$$

We emphasize that the grid $\mathbb{M}$ that pertains to the residuals of the finite-difference operator $\boldsymbol{L}^{(h)}$ is partitioned into $\mathbb{M}^+$ and $\mathbb{M}^-$ directly, i.e., following the geometry of Ω and Ω_1. In contradistinction to that, the grid $\mathbb{N}$ is not partitioned directly; we rather consider the collection of all nodes of $\mathbb{N}$ swept by the stencil $\mathbb{N}_m$ when its center belongs to $\mathbb{M}^+$, and call this subgrid $\mathbb{N}^+$; see (3.2). Obviously, some of the nodes of $\mathbb{N}^+$ obtained by this approach happen to be outside Ω, i.e., in Ω_1, and these nodes are called γ^-. The sets $\mathbb{N}^-$ and γ^+ are defined similarly starting from $\mathbb{M}^-$. The key idea is that whereas the grids $\mathbb{M}^+$ and $\mathbb{M}^-$ do not overlap, the grids $\mathbb{N}^+$ and $\mathbb{N}^-$ do overlap, and their overlap is denoted γ; obviously, $\gamma = \gamma^+ \cup \gamma^-$. The subset of grid nodes γ is called *the grid boundary*; it is a fringe of nodes that is located near the continuous boundary Γ and in some sense straddles it. The specific structure of γ obviously depends on the construction of the operator $\boldsymbol{L}^{(h)}$ of (3.1) and the stencil $\mathbb{N}_m$. For example, for the conventional second-order central-difference Laplacians on rectangular grids, γ will be a two-layer fringe of grid nodes located near Γ, as shown schematically in Figure 3.1. Further specifics on the construction of grid boundaries can be found in the monograph [15].

3.2. Discrete noise control problem and its general solution. Having introduced the discretization (3.1) and grid subsets (3.2), we can formulate and solve the noise control problem on the grid. We will reproduce below the key results of [15, Part VIII]; see also [22, 23] for detail.

The discrete noise control problem is formulated similarly to the continuous one; see section 1. Let $f_m^{(h)+}$, $m \in \mathbb{M}^+$, and $f_m^{(h)-}$, $m \in \mathbb{M}^-$, be the interior and exterior discrete acoustic sources, respectively. Let $u_n^{(h)+}$, $n \in \mathbb{N}$, and $u_n^{(h)-}$, $n \in \mathbb{N}$, be the corresponding solutions, i.e., $\boldsymbol{L}^{(h)} u^{(h)+} = f^{(h)+}$ and $\boldsymbol{L}^{(h)} u^{(h)-} = f^{(h)-}$. Using the same terminology as before, we will call $u^{(h)+}$ the discrete sound and $u^{(h)-}$ the discrete noise. The overall discrete acoustic field $u^{(h)}$ is the sum of its sound and noise components, $u^{(h)} = u^{(h)+} + u^{(h)-}$ on $\mathbb{N}$, and obviously satisfies the equation $\boldsymbol{L}^{(h)} u^{(h)} = f^{(h)} \equiv f^{(h)+} + f^{(h)-}$. The goal is to obtain the discrete control sources $g^{(h)} = g_m^{(h)}$ so that the solution $\tilde{u}^{(h)}$ of the equation $\boldsymbol{L}^{(h)} \tilde{u}^{(h)} = f^{(h)+} + f^{(h)-} + g^{(h)}$ will be equal to only the sound component $u^{(h)+}$ on the subgrid $\mathbb{N}^+$.

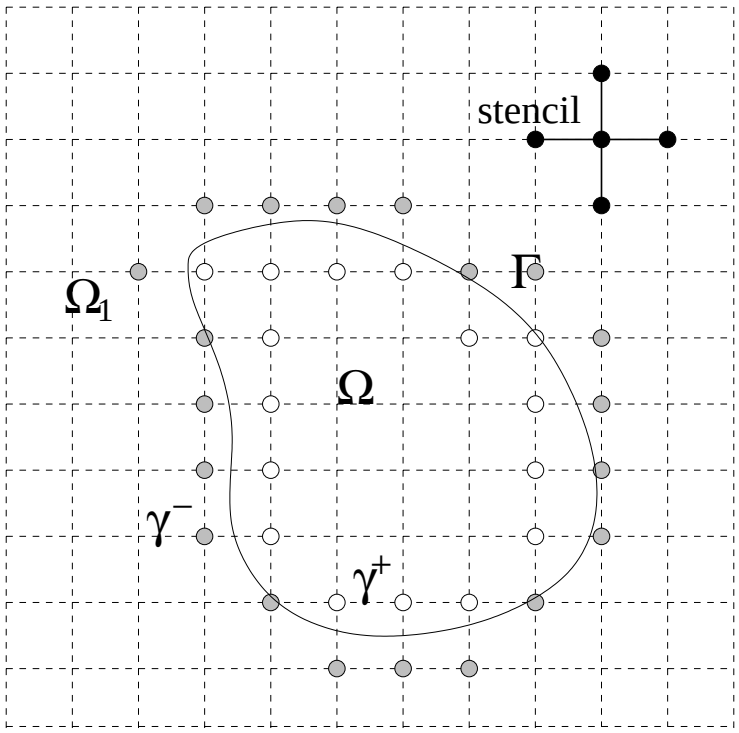

FIG. 3.1. *Schematic geometry of the domains, the stencil, and the grid boundary* $\gamma = \gamma^+ \cup \gamma^-$*: Hollow circles denote* γ^+*, filled circles denote* γ^-*.*

Let us now recall that, in the continuous case, the unique solvability of the governing differential equation (inhomogeneous Helmholtz' equation) was guaranteed by the Sommerfeld radiation conditions (1.2a) or (1.2b) at infinity. In the discrete case, we also need to guarantee the unique solvability of the foregoing finite-difference equations, but we obviously cannot directly set the boundary conditions at infinity. Therefore, the Sommerfeld radiation conditions have to be replaced by some other boundary conditions set at a finite location. To preserve the physics of the model that involves the propagation of waves toward infinity, one may choose to set the appropriate ABCs at the external artificial boundary that truncates our domain.[4] We emphasize that previously, i.e., in the continuous case, we have introduced and used the ABCs (see section 2.2) only for the purpose of obtaining compactly supported controls. Those ABCs were applied to the auxiliary function-parameter $w(\boldsymbol{x})$ (see (2.13) or (2.17)). In the discrete case, the ABCs should apply to the actual solutions $u^{(h)}$, $u^{(h)+}$, $u^{(h)-}$, and $\tilde{u}^{(h)}$, which represent the acoustic fields on the grid. For the purpose of constructing the controls, however, we will never need to implement the ABCs for the acoustic solutions on the grid explicitly. We will only need to know that these boundary conditions can be obtained (a variety of different approaches can be found, e.g., in [19]) and that they will guarantee the solvability of the difference equations involved.

[4]These ABCs would guarantee that the interior solution can be extended beyond the artificial boundary, so that the extension solves the Helmholtz equation and displays the correct far-field behavior.

There will, of course, be an explicit role for the ABCs in the discrete framework as well. We will employ these boundary conditions in the same capacity as we have used the original continuous ABCs (see section 2.2). Namely, when obtaining compactly supported controls, the ABCs will truncate the corresponding discrete function-parameter $w^{(h)}$. A specific approach to constructing the discrete ABCs that we use in this work is based on discretization of the continuous ABCs of section 2.2, and we discuss it in section 3.3. Altogether, both the discrete acoustic fields and the discrete-function parameter that is used for constricting the control sources (see formula (3.3) below) are going to satisfy the same ABCs. This is similar to the continuous case, when both the solution itself (i.e., acoustic field) and the function-parameter w satisfied the same Sommerfeld radiation conditions at infinity.

The general solution for the discrete control sources $g^{(h)} = g_m^{(h)}$ that eliminate the unwanted noise $u^{(h)-}$ on $\mathbb{N}^+$ is given by the following formula (cf. formula (2.1)):

$$g_m^{(h)} = -\boldsymbol{L}^{(h)} w^{(h)}\big|_{m\in\mathbb{M}^-}, \tag{3.3}$$

where $w^{(h)} = w_n^{(h)}$, $n \in \mathbb{N}^-$, is a special auxiliary grid function-parameter that parameterizes the family of controls (3.3). The requirements that this function $w^{(h)}$ must satisfy are, again, rather "loose," and can be considered natural discrete counterparts of the corresponding requirements of the continuous function-parameter $w(\boldsymbol{x})$; see the discussion around formula (2.2) in section 2.1. Namely, at the grid boundary γ the function $w^{(h)}$ has to coincide with the overall acoustic field $u^{(h)}$ to be controlled:

$$w_n^{(h)}\big|_{n\in\gamma} = u_n^{(h)}\big|_{n\in\gamma}. \tag{3.4}$$

We note that since, e.g., for the second-order discretizations the grid boundary γ contains two layers of nodes, γ^+ and γ^- (see Figure 3.1), then specifying the corresponding nodal values on γ is in some sense equivalent to specifying the function and its normal derivative on Γ in the continuous case; see (2.2). Of course, this is not a rigorous statement from the standpoint of approximation; we will address the approximation-related issues later on. We also note that when creating practical designs, the boundary data $u_n^{(h)}\big|_{n\in\gamma}$ shall be interpreted as measurable quantities that provide input for the control system. In other words, we can think of a microphone at every node of γ; these microphones measure the characteristics of the actual acoustic field and generate the input signal $u_n^{(h)}\big|_{n\in\gamma}$.

The other requirement of $w^{(h)}$, besides the interface boundary conditions (3.4), has already been mentioned. The function $w^{(h)}$ must satisfy the appropriate discrete ABCs at a finite external artificial boundary. The role of the discrete ABCs is the same as that of the continuous ABCs—to provide a replacement for the Sommerfeld radiation boundary conditions. This is done in the same approximate sense as the operator $\boldsymbol{L}^{(h)}$ approximates $\boldsymbol{L}$; see section 3.3. Other than the two aforementioned requirements, the function $w^{(h)}$ is arbitrary and, as such, parameterizes a substantial variety of discrete control sources; see (3.3). The latter will provide the search space for optimization in section 4.

The justification for formula (3.3) as the general solution for the discrete control sources is based on the theory of difference potentials; see [15]. In the framework of this theory one can show that the solution $v^{(h)} = v_n^{(h)}$ of the equation $\boldsymbol{L}^{(h)} v^{(h)} = g^{(h)}$ subject to the appropriate ABCs, where $g^{(h)}$ is defined according to (3.3) and (3.4), will be equal to exactly $-u^{(h)-}$ on the interior subgrid $\mathbb{N}^+$: $v_n^{(h)}|_{n\in\mathbb{N}^+} = -u^{(h)-}|_{n\in\mathbb{N}^+}$.

In other words, when the controls $g^{(h)}$ of (3.3) are added to the original source terms of the governing finite-difference equation, they annihilate the unwanted noise on the domain of interest in the discrete sense, i.e., on the grid. The aforementioned solution $v_n^{(h)}\big|_{n\in\mathbb{N}^+}$ is called the generalized difference potential with the density $-u_n^{(h)}\big|_{n\in\gamma}$ defined on the grid boundary γ. It is shown in the theory of difference potentials (see [15]) that the potential depends only on its density $-u_n^{(h)}|_{n\in\gamma}$ and not on the values of the function-parameter outside γ: $w_n^{(h)}|_{n\in\mathbb{N}^-\setminus\gamma}$. Consequently, all possible controls $g^{(h)}$ obtained according to (3.3), with different $w^{(h)}$'s subject only to (3.4) and the corresponding ABCs (see section 3.3), will produce identical output on $\mathbb{N}^+$ that will cancel out the unwanted noise $u_n^{(h)-}|_{n\in\mathbb{N}^+}$. This provides room for optimization of the discrete control sources; see section 4. It can also be shown that every discrete control source $g_m^{(h)}|_{m\in\mathbb{M}^-}$ that cancels out $u_n^{(h)-}|_{n\in\mathbb{N}^+}$ can be represented in the form (3.3) with some function $w^{(h)} = w_n^{(h)}$, $n \in \mathbb{N}^-$, that satisfies (3.4) and the external boundary conditions (ABCs). Similarly to the continuous case, this is done by explicitly constructing the appropriate $w^{(h)}$ for a given $g^{(h)}$ and $u_n^{(h)}|_{n\in\gamma}$; we refer the reader to [15, Part VIII] and [22, 23] for detail.

As has been mentioned, the cancellation of noise in the discrete framework is obtained on the grid $\mathbb{N}^+$. It is important to understand in what sense this discrete cancellation models the continuous cancellation described in section 2. This is basically the question of approximation of the continuous generalized potentials by the discrete ones. To that effect, the theory of difference potentials (see [15]) says that, under certain natural conditions, the difference potential $v^{(h)} = v_n^{(h)}$, $n \in \mathbb{N}^+$, i.e., the solution to $\boldsymbol{L}^{(h)}v^{(h)} = g^{(h)}$ with $g^{(h)}$ given by (3.3), approximates the continuous Calderon's potential $v = v(\boldsymbol{x})$, $\boldsymbol{x} \in \Omega$ (see (2.9)), i.e., the solution to $\boldsymbol{L}v = g$ with g given by (2.1). The aforementioned natural conditions include first the consistency and stability of the finite-difference scheme for the Helmholtz equation. Consistency and stability will guarantee convergence as the grid size vanishes. In addition, the discrete boundary data $u_n^{(h)}|_{n\in\gamma}$ of (3.4) have to approximate the continuous boundary data $(u, \frac{\partial u}{\partial \boldsymbol{n}})|_\Gamma$ of (2.2) in the following sense. Once the continuous function u and its first-order normal derivative $\frac{\partial u}{\partial \boldsymbol{n}}$ are known at the boundary Γ, normal derivatives of higher orders can be obtained via the differential equation itself, and the near-boundary values $u_n^{(h)}|_{n\in\gamma}$ can be calculated using Taylor's expansion; the order of accuracy of the latter calculation with respect to the grid size h has to be at least as high as the order of accuracy of the interior scheme. In this case, the quality of approximation, i.e., the rate of convergence of the discrete potential to the continuous one with respect to h, will be the same as prescribed by the finite-difference scheme itself. For the second-order central-difference schemes discussed in sections 3.3 and 4, this rate is $O(h^2)$. In other words, when designing an active control system following the finite-difference approach, one can expect to have the actual noise cancellation in the same approximate sense as the solution of the finite-difference equation approximates the corresponding solution of the original differential equation. Note that in any particular practical setting we will need to require sufficient wave resolution on the grid, i.e., the waves of length $\lambda = 2\pi/k$, where k is the wavenumber in (1.1), will have to be well resolved by the specific discretization.

3.3. Specific discretization and discrete artificial boundary conditions. As has been mentioned, one can use different approaches to construct discrete ABCs (see, e.g., [19]) that are needed to obtain compactly supported controls. The most

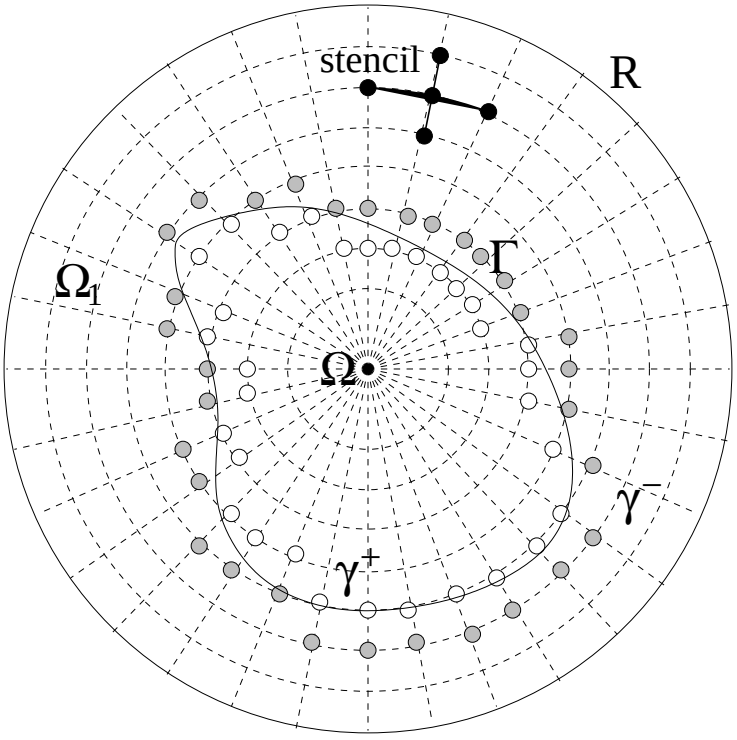

FIG. 3.2. *Schematic geometry of the domains, the stencil, and the grid boundary* $\gamma = \gamma^+ \cup \gamma^-$ *in polar coordinates: Hollow circles denote* γ^+*, filled circles denote* γ^-*.*

straightforward technique, which is adopted in the current study, although it is apparently not the most general one, is to directly approximate the continuous boundary conditions (2.13) or (2.17) with sufficient order of accuracy. For that, we will need a grid that would be fitted to the shape of the external artificial boundary, i.e., a polar or spherical grid. An example of the corresponding grid subsets γ^+ and γ^- for polar coordinates is schematically shown in Figure 3.2.

In all numerical experiments that follow in section 4, we use a two-dimensional setup. Accordingly, we introduce a polar grid that has J cells in the radial direction with the nodes $\rho_j = j\Delta\rho$, $j = 0, \dots, J$, so that $\rho_0 = 0$ and $\rho_J = R$, and L cells in the circumferential direction with the nodes $\theta_s = s\Delta\theta$, $s = 0, \dots, L$, so that $\theta_0 = 0$ and $\theta_L = 2\pi$. For simplicity, it is convenient to assume that the grid sizes $\Delta\rho = R/J$ and $\Delta\theta = 2\pi/L$ are constant; in applications, the grid in the radial direction may be stretched; see section 4.2.

The Helmholtz equation is discretized on this grid with second-order accuracy by central differences:

$$\begin{aligned} \boldsymbol{L}^{(h)} w^{(h)}\big|_{s,j} \equiv \frac{1}{\rho_j}\frac{1}{\Delta\rho}\left(\rho_{j+\frac{1}{2}}\frac{w^{(h)}_{s,j+1}-w^{(h)}_{s,j}}{\Delta\rho} - \rho_{j-\frac{1}{2}}\frac{w^{(h)}_{s,j}-w^{(h)}_{s,j-1}}{\Delta\rho}\right) \\ + \frac{1}{\rho_j^2}\frac{w^{(h)}_{s+1,j}-2w^{(h)}_{s,j}+w^{(h)}_{s-1,j}}{\Delta\theta^2} + k^2 w^{(h)}_{s,j} = 0. \end{aligned} \tag{3.5}$$

The left-hand side of (3.5) is a particular realization of the operator (3.1) that employs the five-node stencil shown in Figure 3.2. This operator will be used in section 4 for obtaining optimal discrete control sources.

To construct the finite-difference ABCs at $\rho = R$, we will also consider a semi-discrete form of the homogeneous equation in the far field:

$$\frac{1}{\rho}\frac{d}{d\rho}\left(\rho\frac{dw_s}{d\rho}\right) + \frac{1}{\rho^2}\frac{w_{s+1} - 2w_s + w_{s-1}}{\Delta\theta^2} + k^2 w_s = 0, \quad s = 0, \ldots, L-1. \tag{3.6}$$

Introducing the direct and inverse discrete Fourier transforms, $l = -L/2+1, \ldots, L/2$, $s = 0, \ldots, L-1$,

$$\hat{w}_l = \frac{1}{L}\sum_{s=0}^{L-1} w_s e^{-ils\Delta\theta}, \qquad w_s = \sum_{l=-L/2+1}^{L/2} \hat{w}_l e^{ils\Delta\theta}, \tag{3.7}$$

we reduce (3.6) to the following system of ordinary differential equations with respect to $\hat{w}_l = \hat{w}_l(\rho)$:

$$\frac{1}{\rho}\frac{d}{d\rho}\left(\rho\frac{d\hat{w}_l}{d\rho}\right) - \frac{\alpha_l^2}{\rho^2}\hat{w}_l + k^2\hat{w}_l = 0, \quad \alpha_l^2 = \frac{4}{\Delta\theta^2}\sin^2\frac{l\Delta\theta}{2}, \quad \rho \geq R, \tag{3.8}$$

where again $l = -L/2+1, \ldots, L/2$. Equations (3.8) are the same as (2.14), except that in the discrete case the range for l is finite, and l^2 in (2.14) has been replaced by α_l^2 in (3.8). Therefore, we can use the same boundary conditions (2.17) for $l = -L/2+1, \ldots, L/2$,

$$\frac{d}{d\rho}\hat{w}_l\bigg|_{\rho=R} = \hat{w}_l(R)\frac{\frac{d}{d\rho}H_{\alpha_l}^{(2)}(kR)}{H_{\alpha_l}^{(2)}(kR)}, \tag{3.9}$$

only with the Hankel functions of order l replaced by the Hankel functions of the order α_l. For implementation in the foregoing discrete framework, boundary conditions (3.9) for all $l = -L/2+1, \ldots, L/2$ have to be approximated with second-order accuracy, which can be easily done as follows:

$$\frac{\hat{w}_{l,J} - \hat{w}_{l,J-1}}{\Delta\rho} - \beta_l\frac{\hat{w}_{l,J} + \hat{w}_{l,J-1}}{2} = 0, \qquad \beta_l = \frac{\frac{d}{d\rho}H_{\alpha_l}^{(2)}(kR)}{H_{\alpha_l}^{(2)}(kR)}. \tag{3.10}$$

Finally, relations in (3.10) for all $l = -L/2+1, \ldots, L/2$ can be rewritten in the matrix form:

$$\boldsymbol{w}_{\cdot,J} = \boldsymbol{F}^{-1}\mathrm{diag}\left\{-\left(\frac{1}{\Delta\rho} + \beta_l\right)\left(\frac{1}{\Delta\rho} - \beta_l\right)^{-1}\right\}\boldsymbol{F}\,\boldsymbol{w}_{\cdot,J-1} \equiv \boldsymbol{T}\,\boldsymbol{w}_{\cdot,J-1}, \tag{3.11}$$

where $\boldsymbol{F}$ and $\boldsymbol{F}^{-1}$ are matrices of the direct and inverse discrete Fourier transforms of (3.7), and $\boldsymbol{w}_{\cdot,J}$ and $\boldsymbol{w}_{\cdot,J-1}$ are L-dimensional vectors of components $w_{s,J}^{(h)}$ and $w_{s,J-1}^{(h)}$, respectively, $s = 0, 1, \ldots, L-1$.

In the three-dimensional case, instead of the discrete Fourier transforms (3.7) one can use expansions with respect to the so-called finite-difference spherical functions (see [15, Part IV, Chapter 4]) that form a full orthogonal system of eigenvectors for the spherical part of the discrete Laplacian. Other than that, the construction of the

discrete three-dimensional ABCs will be similar to the foregoing two-dimensional construction. We do not expand on it here because we do not conduct three-dimensional computations in this paper. Let us also mention that for small l the difference between l^2 and the corresponding α_l^2 (see (3.8)) will obviously be small as well. Therefore, for smooth functions w, for which the short-wave part of the spectrum (large l's) is insignificant, one may not even have to replace l in (2.17) by α_l in (3.9). We have observed this type of behavior in the previous paper [14], in which we studied similar questions for the Poisson equation.

3.4. Types of discrete control sources. Similarly to the continuous case (see section 2.3) let us now identify some particular types of discrete control sources. First, we define another subset of the grid $\mathbb{M}$ (more precisely, of $\mathbb{M}^-$):

$$\mathbb{M}^-_{\text{int}} = \left\{ m \in \mathbb{M}^- \middle| \mathbb{N}_m \cap \gamma^+ = \emptyset \right\}.$$

Basically, $\mathbb{M}^-_{\text{int}}$ is the interior subset of $\mathbb{M}^-$ such that, when the center of the stencil sweeps this subset, the stencil itself does not touch γ^+; see Figures 3.1 and 3.2. In other words, we can say that $\mathbb{M}^-_{\text{int}}$ is a subset of $\mathbb{M}^-$ such that

$$\bigcup_{m \in \mathbb{M}^-_{\text{int}}} \mathbb{N}_m = \mathbb{N}^- \backslash \gamma^+.$$

Having defined this new subset $\mathbb{M}^-_{\text{int}}$, we now introduce the auxiliary function $w^{(h)} = w_n^{(h)}$, $n \in \mathbb{N}^-$, for (3.3) as follows:

$$w_n^{(h)}\big|_{n\in\gamma^+} = u_n^{(h)}\big|_{n\in\gamma^+}, \tag{3.12a}$$

and

$$\begin{aligned} &w_n^{(h)}\big|_{n\in\gamma^-} = u_n^{(h)}\big|_{n\in\gamma^-}, \\ &\boldsymbol{L}^{(h)} w^{(h)} = 0 \ \text{ on } \ \mathbb{M}^-_{\text{int}}. \end{aligned} \tag{3.12b}$$

As before, we also assume that $w^{(h)}$ satisfies the appropriate discrete ABCs; see, e.g., (3.11). Definition (3.12a) means that on the interior part of the grid boundary γ^+ we simply set $w^{(h)}$ equal to the given $u^{(h)}$: $w_n^{(h)}|_{n\in\gamma^+} = u_n^{(h)}|_{n\in\gamma^+}$. Definition (3.12b) is actually a discrete exterior boundary-value problem of the Dirichlet type. Indeed, everywhere on and "outside" the exterior part of the grid boundary γ^-, i.e., on $\mathbb{N}^-\backslash\gamma^+$, the grid function $w^{(h)}$ is obtained as a solution of the homogeneous equation $\boldsymbol{L}^{(h)} w^{(h)} = 0$ (enforced at the nodes $\mathbb{M}^-_{\text{int}}$) supplemented by the boundary data on γ^-: $w_n^{(h)}\big|_{n\in\gamma^-} = u_n^{(h)}\big|_{n\in\gamma^-}$, which is specified for the unknown function $w^{(h)}$ itself. Note, relation (3.12a) and the first relation (3.12b) together are obviously equivalent to (3.4). Therefore, the function $w^{(h)}$ defined via (3.12a), (3.12b) falls into the general class of $w^{(h)}$'s used for obtaining the discrete control sources; see section 3.2.

Problem (3.12b) can clearly be considered a finite-difference counterpart to the continuous Dirichlet problem (2.23). Therefore, it is natural to call the control sources $g^{(h)} \equiv g^{(\text{h,surf})}_{\text{monopole}}$ obtained by formulae (3.3), (3.12a), (3.12b) *the discrete surface monopoles.* Indeed, because of the definition of $w^{(h)}$ given by (3.12a) and (3.12b), these $g^{(\text{h,surf})}_{\text{monopole}}$ may, generally speaking, differ from zero only on the grid set $\mathbb{M}^-\backslash\mathbb{M}^-_{\text{int}}$, which is a single "curvilinear" layer of nodes of grid $\mathbb{M}$ that follows the geometry

of Γ. Accordingly, the output of these controls can be called the discrete single-layer potential; it was first introduced and analyzed in our recent paper [20]. Let us emphasize that unlike the continuous surface monopoles (2.30), which belong to a different class of functions rather than the volumetric sources (2.1) and (2.2) (singular δ-type distributions vs. regular locally integrable functions), the foregoing discrete surface monopoles belong to the same original class of discrete control sources (3.3) and (3.4). They can be considered as the ultimate reduction of the volumetric discrete controls (3.3) and (3.4) to the surface. In section 4, the discrete surface monopoles will play a fundamental role for the analysis of the optimization problems.

Besides the discrete surface monopoles and the corresponding single-layer potential, one can also define the discrete surface dipoles and, accordingly, the double-layer potential; see [20]. Grid dipoles are introduced for the pairs of neighboring nodes so that the nodes in the pair are assigned values equal in magnitude and opposite in sign. The control sources in the form of discrete surface dipoles can be obtained by solving a special Neumann-type discrete exterior boundary-value problem for the auxiliary function $w^{(h)}$, which would be analogous to the continuous problem (2.24). The construction of surface dipoles, however, is somewhat more elaborate than the foregoing definition of surface monopoles. And because in this paper we basically focus on the monopole-type sources only, we are not going to further elaborate here on the issue of discrete surface dipoles, but will rather refer the reader to our paper [20] for detail.

4. Optimization of control sources. Once the general solution for controls is available, in either continuous (2.1) or discrete (3.3) formulation, the next step is to decide what particular element of this large family of functions will be optimal for a specific setting. There is a multitude of possible criteria for optimality that one can use; we discuss some of them in the forthcoming papers [8, 9]. We should also emphasize that in many practical problems the cancellation of noise is only approximate, and, as such, the key criterion for optimization (or sometimes, the key constraint) is the quality of this cancellation, i.e., the extent of noise reduction. In contradistinction to that, in this paper we are considering ideal, or exact, cancellation; i.e., every particular control field from either the continuous (2.1) or discrete (3.3) family completely eliminates the unwanted noise on the domain of interest. Consequently, the criteria for optimality of the controls that we can employ will not include the level of the residual noise as a part of the corresponding function of merit, and should rather depend only on the control sources themselves. We realize, of course, that at a later stage of the work we will also need to look into the issues of approximate, rather than exact, noise cancellation, for the reason of further reducing the costs. In this case, optimal solutions found in the framework of the exact cancellation are likely to provide good initial guesses for subsequent optimization in the approximate framework. Moreover, it will probably be possible to use some results from the approximation theory to deal with the issues of approximate noise cancellation once we have solutions for the exact cancellation. We expect that this approach will be much faster than any algorithm of combinatorial type. A similar reduction in computational complexity of optimization was outlined in our earlier work [6] on the optimal distributed control of the exterior Stokes flow.

4.1. Optimization in the sense of L_1. To derive a meaningful criterion for optimization of the control sources, let us first discuss the physical meaning of the quantities involved in the formulation of the problem. The most natural way to interpret the field variable $u = u(\boldsymbol{x})$ (as well as its discrete counterpart $u_n^{(h)}$) is to call it acoustic pressure. Indeed, acoustic pressure is the quantity which is directly measured

by the sensing devices (microphones), and as such can be immediately supplied as the required boundary input data for the control system; see formulae (2.2) and (3.4). We now recall that in the current paper we only analyze a single-frequency formulation of the noise control problem. To better understand the nature of the source terms in the Helmholtz equation that governs the time-harmonic pressure $u = u(\boldsymbol{x})$, we will now examine the original unsteady acoustic formulation. Let $p = p(\boldsymbol{x}, t)$ be the actual acoustic pressure, and $\boldsymbol{v} = \boldsymbol{v}(\boldsymbol{x}, t)$ be the velocity of fluid particles. Then, the acoustics system can be written as

$$\begin{aligned} \frac{\partial \rho(\boldsymbol{x}, t)}{\partial t} + \rho_0 \operatorname{div} \boldsymbol{v}(\boldsymbol{x}, t) &= \rho_0 q_{\mathrm{vol}}(\boldsymbol{x}, t), \\ \rho_0 \frac{\partial \boldsymbol{v}(\boldsymbol{x}, t)}{\partial t} + \operatorname{grad} p(\boldsymbol{x}, t) &= \boldsymbol{b}_{\mathrm{vol}}(\boldsymbol{x}, t), \end{aligned} \tag{4.1}$$

where ρ_0 is the density of the ambient fluid. The quantity q_{vol} on the right-hand side of the continuity equation in (4.1) is known as the volume velocity per unit volume; see, e.g., [10, 11]. It is defined through the actual volume velocity $q = \int_S v_n d\sigma$, which is the integral of the normal component of the fluid particles' velocity v_n evaluated over a closed surface S; then $q_{\mathrm{vol}} = \lim_{V \to +0} \frac{1}{V} \int_S v_n d\sigma$, where V is the volume enclosed by S. The physical meaning of the sources $\rho_0 q_{\mathrm{vol}}$ is that they excite the medium by altering the balance of mass in the system, i.e., by injecting/draining certain amounts of fluid. Clearly, in the time-harmonic context the process of injecting/draining the fluid has to be periodic.

Similarly, the quantity $\boldsymbol{b}_{\mathrm{vol}}$ on the right-hand side of the second equation of (4.1) shall be interpreted as the force per unit volume. Obviously, it excites the medium by altering the balance of momentum in the system; and again, in the time-harmonic context the net force applied to the fluid particles has to be periodic. Altogether, we see that two types of sources can be introduced in unsteady acoustics that are distinctly different from the standpoint of physics. Next, we will see that they can be interpreted as monopoles and dipoles, respectively, as introduced in section 2.3.

We apply the adiabatic law $p = c^2 \rho$, where c is the speed of sound (constant), differentiate the first equation of (4.1) with respect to time, take the divergence of the second equation of (4.1), and substitute into the first one, which yields the inhomogeneous wave equation for the acoustic pressure:

$$-\frac{1}{c^2} \frac{\partial^2 p(\boldsymbol{x}, t)}{\partial t^2} + \Delta p(\boldsymbol{x}, t) = \operatorname{div} \boldsymbol{b}_{\mathrm{vol}}(\boldsymbol{x}, t) - \rho_0 \frac{\partial q_{\mathrm{vol}}(\boldsymbol{x}, t)}{\partial t}. \tag{4.2}$$

The second term on the right-hand side of (4.2) is the volume acceleration per unit volume multiplied by the ambient fluid density. The Helmholtz equation for the time-harmonic pressure is obtained by Fourier transforming (4.2) in time, which formally amounts to replacing the temporal derivatives $\frac{\partial}{\partial t}(\,\cdot\,)$ by $-i\omega(\,\cdot\,)$. For simplicity we will keep all the notations the same except that the time-harmonic problem quantities will depend only on $\boldsymbol{x}$ and not on t, and we will also use the previous notation $u(\boldsymbol{x})$ for the Fourier transformed pressure $p(\boldsymbol{x}, t)$:

$$\Delta u(\boldsymbol{x}) + k^2 u(\boldsymbol{x}) = \operatorname{div} \boldsymbol{b}_{\mathrm{vol}}(\boldsymbol{x}) + i\omega \rho_0 q_{\mathrm{vol}}(\boldsymbol{x}). \tag{4.3}$$

The wavenumber k in the Helmholtz equation (4.3) is given by $k = \omega/c$, where ω is the frequency of the original temporal oscillations.

Clearly, (4.3) is basically the same as (1.1), except that in (4.3) we provide a detailed description of the source terms based on their physical origin. Namely, we see that the scalar sources q_{vol} that alter the acoustic balance of mass (see (4.1)) enter the

right-hand side of the Helmholtz equation directly (up to a multiplicative constant), whereas the sources $\boldsymbol{b}_{\rm vol}$ that alter the acoustic balance of momentum (see (4.1)) enter the right-hand side of the Helmholtz equation through a divergence operator. Therefore, the analysis of section 2.3 allows us to interpret $q_{\rm vol}(\boldsymbol{x})$ as genuine volumetric monopoles and $\boldsymbol{b}_{\rm vol}(\boldsymbol{x})$ as volumetric dipoles that are rewritten as equivalent monopoles $\mathrm{div}\boldsymbol{b}_{\rm vol}(\boldsymbol{x})$ for mathematical convenience.

The latter operation, namely, recasting the physical dipoles into the monopole form, allows us to qualitatively study and optimize both types of sources in a uniform manner. In acoustics (see [10]), the overall right-hand side $f(\boldsymbol{x}) = \mathrm{div}\boldsymbol{b}_{\rm vol}(\boldsymbol{x}) + i\omega\rho_0 q_{\rm vol}(\boldsymbol{x})$ of (4.3) is often referred to as *the acoustic source density*. As we have seen, the meaning of this right-hand side is excitation per unit volume. Accordingly, the integral of this quantity over a given region, $\int_V f d\boldsymbol{x}$, is referred to as *the acoustic source strength* that pertains to the sources in this region, and the integral of its magnitude, $\int_V |f| d\boldsymbol{x}$, is known as *the absolute acoustic source strength.* If the actual sources involved in the consideration were only monopoles, then the acoustic source strength would obviously coincide with the overall volume velocity q, and the acoustic source density would coincide with the volume velocity per unit volume $q_{\rm vol}$.

For distributed sources, the acoustic source density is assumed to be finite; in particular, for distributed genuine monopoles the associated volume velocity per unit volume is assumed to be finite. In the case of an isolated point monopole, i.e., a δ-type source (see section 2.3), which can be represented as a vanishingly small oscillating sphere of radius ϵ with surface velocity v_ϵ, the volume velocity can be introduced as $q = \lim_{\epsilon\to+0} v_\epsilon 4\pi\epsilon^2$. When the strength q of this isolated monopole is finite, the associated source density is formally infinite (which is natural to expect for a δ-type source). In the case of a continuous distribution of sources, the relationship between the source density and source strength is standard (like that between the mass density and total mass, electric charge density and total charge, etc.) and basically says that the integral of the source density over a given region is equal to the overall source strength associated with this region. In other words, the acoustic source density is equal to the acoustic source strength per unit volume.

Obviously, the physical meaning of the quantity $g = g(\boldsymbol{x})$ of (2.1) that describes the control sources is the same as that of the original right-hand side $f = f(\boldsymbol{x})$ of (1.1) that we have recently specified according to (4.3). Namely, $g(\boldsymbol{x})$ shall be interpreted as *the acoustic source strength per unit volume* (up to a multiplicative constant) of the control sources. It is important to mention that as we are studying the time-harmonic traveling waves, all the quantities involved in the formulation of the problem are complex-valued. This is essential, as otherwise it would not have been possible to account for the key phenomenon of the variation of phase between different spatial locations.

Having identified the physical meaning of the variables involved in the noise control model that we have adopted, we would argue in the current paper for selecting the optimal control sources based on minimization of their *overall absolute acoustic source strength.* Mathematically, this translates into the minimization of the L_1 norm of the control sources:

$$\|g\|_1 \equiv \int_{\mathrm{supp}\, g} |g(\boldsymbol{x})| d\boldsymbol{x} \longrightarrow \min, \tag{4.4}$$

where the search space for minimization in (4.4) includes all the appropriate auxiliary functions $w(\boldsymbol{x})$, by means of which the controls $g(\boldsymbol{x})$ are defined (see formulae (2.1), (2.2), and the discussion in the beginning of section 2.1). The advantage of using

this criterion for optimization is that it has a clear physical interpretation, and the quantities involved, the volume velocity as well as the force applied to fluid particles, actually characterize the corresponding engineering devices (actuators in the active noise control system). For comparison, we note that the criterion based on the L_2 norm,

$$\|g\|_2 \equiv \sqrt{\int_{\operatorname{supp} g} |g(\boldsymbol{x})|^2 d\boldsymbol{x}} \longrightarrow \min,$$

does not have a similar clear physical interpretation, although as indicated below (see also our forthcoming paper [9]), the corresponding numerical optimization problem is much easier to solve. Another advantage of using the L_1 norm, or in other words, the overall absolute acoustic source strength, as the cost function for optimization (minimization) is that it characterizes only the control sources themselves. This is a convenient distinction compared, e.g., to the power-based criteria, which, as has been mentioned, would always involve interaction between the sources and the field they operate in. This interaction is often referred to as the "load" on the sources by the field (see [11]), and may lead to certain types of degeneration when solving the optimization problem; see [8].

In the discrete framework, the L_1 minimization problem that corresponds to (4.4) is formulated as follows:

$$\|g^{(h)}\|_1 \equiv \sum_{m \in \mathbb{M}^- \cap \{\rho < R\}} V_m |g_m^{(h)}| \longrightarrow \min, \tag{4.5}$$

where V_m accounts for the volume in three dimensions or area in two dimensions of a particular grid cell, and again, the search space includes all the appropriate auxiliary grid functions $w^{(h)}$ through which $g^{(h)}$ is defined; see formula (3.3). The function $w^{(h)}$ is supposed to satisfy boundary conditions (3.4) on the interface, and the selected ABCs at the external artificial boundary; for the two-dimensional examples analyzed in the following section 4.2 the latter will be boundary conditions (3.11).

Let us now return to the definition (3.3) of the discrete control sources $g^{(h)}$ and adopt the polar framework of section 3.3. The finite-difference operator $\boldsymbol{L}^{(h)}$ can obviously be interpreted as a matrix with N columns and M rows, where N is the number of nodes $n \equiv (s, j)$ of the grid $\mathbb{N}^-$ such that the corresponding radial coordinate $\rho_j \le R$, i.e., $j \le J$, and M is the number of nodes $m \equiv (s, j)$ of the grid $\mathbb{M}^-$ such that the corresponding radial coordinate $\rho_j < R$, i.e., $j \le J - 1$. Denote by $\boldsymbol{w}$ the vector of N components $w_n^{(h)} \equiv w_{s,j}^{(h)}$ such that $n \in \mathbb{N}^-$ and $j \le J$. The components of $\boldsymbol{w}$ can obviously be arranged in a particular way so that this vector can then be decomposed into four subvectors:

$$\boldsymbol{w} = [\boldsymbol{w}_\gamma, \boldsymbol{w}_0, \boldsymbol{w}_{\cdot,J-1}, \boldsymbol{w}_{\cdot,J}]^T, \tag{4.6}$$

where $\boldsymbol{w}_\gamma$ contains all those and only those $w_n^{(h)}$ for which $n \in \gamma$, $\boldsymbol{w}_{\cdot,J}$, and $\boldsymbol{w}_{\cdot,J-1}$ correspond to the outermost and second-to-last circles of the polar grid, respectively, as in formula (3.11), and $\boldsymbol{w}_0$ contains all the remaining components of $\boldsymbol{w}$. In accordance with (4.6), the matrix $\boldsymbol{L}^{(h)}$ can be decomposed into four submatrices:

$$\boldsymbol{L}^{(h)} = [\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{C}, \boldsymbol{D}], \tag{4.7}$$

where the number of rows in all four is the same and equal to M, $\boldsymbol{A}$ has as many columns as there are nodes in γ (we denote this number $|\gamma|$), $\boldsymbol{C}$ and $\boldsymbol{D}$ each have L columns (see section 3.3), and the number of columns in $\boldsymbol{B}$ is obviously $N - |\gamma| - 2L$.

Using representations (4.6) and (4.7), one can rewrite the optimization problem (4.5) as follows:

$$\| \boldsymbol{V}(\boldsymbol{A}\boldsymbol{w}_\gamma + \boldsymbol{B}\boldsymbol{w}_0 + \boldsymbol{C}\boldsymbol{w}_{\cdot,J-1} + \boldsymbol{D}\boldsymbol{w}_{\cdot,J}) \|_1 \longrightarrow \min, \tag{4.8}$$

where the norm in (4.8) is a conventional L_1 norm on complex M-dimensional vectors, and $\boldsymbol{V}$ is an $M \times M$ diagonal matrix with the entries given by the corresponding cell areas V_m. Next, we recall that the search space for optimization (4.5) is composed of all the appropriate grid functions $w^{(h)}$, which means that the vector $\boldsymbol{w}$ in the optimization formulation (4.8) is, in fact, subject to a number of equality-type constraints that come from the interface conditions (3.4) and ABCs (3.11). More precisely, the first subvector $\boldsymbol{w}_\gamma$ in (4.6) is known and fixed because of (3.4), and we can rewrite (3.4) as $\boldsymbol{w}_\gamma = \boldsymbol{u}_\gamma$, where $\boldsymbol{u}_\gamma$ is given. The last subvector $\boldsymbol{w}_{\cdot,J}$ in (4.6) is a function of $\boldsymbol{w}_{\cdot,J-1}$ according to (3.11). Therefore, we can conclude that only $\boldsymbol{w}_0$ and $\boldsymbol{w}_{\cdot,J-1}$ contain free variables that provide the search space for optimization, and as such rewrite (4.8) as

$$\min_{\boldsymbol{w}_0, \boldsymbol{w}_{\cdot,J-1}} \| \boldsymbol{V}(\boldsymbol{B}\boldsymbol{w}_0 + (\boldsymbol{C} + \boldsymbol{D}\boldsymbol{T})\boldsymbol{w}_{\cdot,J-1} + \boldsymbol{A}\boldsymbol{w}_\gamma) \|_1 \equiv \min_{\boldsymbol{z}} \| \boldsymbol{E}\boldsymbol{z} - \boldsymbol{f} \|_1, \tag{4.9}$$

where $\boldsymbol{E} = \boldsymbol{V}[\boldsymbol{B}, \boldsymbol{C} + \boldsymbol{D}\boldsymbol{T}]$ is an $M \times (N - |\gamma| - L)$ given matrix, $\boldsymbol{z} = [\boldsymbol{w}_0, \boldsymbol{w}_{\cdot,J-1}]^T$ is an $(N - |\gamma| - L)$-dimensional vector of unknowns, and $\boldsymbol{f} = -\boldsymbol{V}\boldsymbol{A}\boldsymbol{w}_\gamma$ is an M-dimensional known vector of the right-hand side. Minimization problem (4.9) is, in fact, a problem of finding a weak solution in the sense of L_1 of an overdetermined complex linear system $\boldsymbol{E}\boldsymbol{z} = \boldsymbol{f}$.

Let us first note that the most conventional weak formulation for an overdetermined system $\boldsymbol{E}\boldsymbol{z} = \boldsymbol{f}$ would be that in the sense of L_2, rather than (4.9). The L_2 minimization problem $\| \boldsymbol{E}\boldsymbol{z} - \boldsymbol{f} \|_2 \longrightarrow \min$ has proven easy to solve numerically even for rather complex geometries. It does not require the Moore–Penrose-type arguments and can be conveniently solved by a standard QR algorithm; we report the corresponding results in our forthcoming paper [9]. As has been mentioned, though, this formulation lacks a convincing physical interpretation and therefore, hereafter we concentrate on solving the L_1 optimization problem (4.9).

By introducing M additional real variables $t_i \in \mathbb{R}$, $i = 1, \ldots, M$, one can reduce problem (4.9) to the following optimization problem with equality-type constraints,

$$\begin{gathered} \min \sum_i t_i, \\ \left| \sum_j e_{ij} z_j - f_i \right| - t_i = 0, \quad i = 1, \ldots, M, \end{gathered} \tag{4.10}$$

which is equivalent to the problem with inequality-type constraints:

$$\begin{gathered} \min \sum_i t_i, \\ \left| \sum_j e_{ij} z_j - f_i \right| - t_i \le 0, \quad i = 1, \ldots, M. \end{gathered} \tag{4.11}$$

If all the quantities involved in the formulation (4.9) were real, then problem (4.11) would, in turn, be equivalent to the linear programming problem (see [21, Chapter 12, section 4]):

$$\begin{aligned} &\min \sum_i t_i, \\ &-t_i \le \sum_j e_{ij} z_j - f_i \le t_i, \quad i = 1, \dots, M, \end{aligned} \tag{4.12}$$

which nowadays can be solved efficiently even for large dimensions. However, complex entries in $\boldsymbol{E}$, $\boldsymbol{z}$, and $\boldsymbol{f}$ (see (4.9)) are essential in order to account for traveling waves, so we will actually need to solve *a nonlinear problem* (4.11) rather than a linear problem (4.12).

The most obvious disadvantage of optimizing in the sense of L_1 is that the foregoing problem (4.11) appears very difficult to solve numerically. Besides being nonlinear, the constraints are obviously nonsmooth. Moreover, strictly speaking, those constraints are not convex either. Indeed, for every $i = 1, \dots, M$, the inequality $|\sum_j e_{ij} z_j - f_i| - t_i \le 0$ defines a cone in the space of variables t_i, $\Re(\sum_j e_{ij} z_j - f_i)$, and $\Im(\sum_j e_{ij} z_j - f_i)$. As we are only considering the upper half of the cone, this set is geometrically convex. However, algebraically the function $|\sum_j e_{ij} z_j - f_i|^2 - t_i^2$ of variables z_j, t_i obviously cannot be convex. And the algebraic convexity (i.e., positive semidefiniteness of the Hessian) is exactly what distinguishes between the convex and nonconvex programming problems, with the latter being substantially more difficult to treat in a numerical setting; see [21, Chapter 24]. Of course, problem (4.11) can be reformulated so that the constraints will become truly convex:

$$\begin{aligned} &\min \sum_i \sqrt{t_i}, \\ &\left| \sum_j e_{ij} z_j - f_i \right|^2 - t_i \le 0, \quad i = 1, \dots, M. \end{aligned} \tag{4.13}$$

However, in the formulation (4.13) the most "harmless" cost function that one can think of, i.e., the linear function $\sum_i t_i$, has been replaced by the function $\sum_i \sqrt{t_i}$ that has singular derivatives at the optimum. Experimentally, we have observed that this presents even more severe problems for a numerical optimizer.

Altogether, the combination of nonlinearity, nonsmoothness, and only "marginal" convexity (optimization over cones) makes problem (4.11) a serious challenge even for the most sophisticated state-of-the-art approaches to numerical optimization—the approaches that are typically based on interior point methods [12, 21]. The difficulties are further exacerbated by the large dimension of the grid on which the problem is formulated. Even for the aforementioned state-of-the art methods the maximum number of constraints that they can handle is typically on the order of hundreds. And in problem (4.11), the number of constraints is the same as the number of grid nodes M. As such, one can easily encounter an orders of magnitude difference between the number of constraints that the numerical optimizer will handle and the number of grid nodes that will make the formulation of an active noise control problem practically interesting. This is especially true for three-dimensional problems.

In spite of all difficulties, we have still managed to obtain numerical solutions in two space dimensions for some simple test cases. All numerical experiments that we have conducted indicate a very consistent behavior of the L_1-optimal solution for control sources; it happens to be the discrete layer of monopoles on the surface $g^{(\mathrm{h,\,surf})}_{\mathrm{monopole}}$ described in section 3.4. Recall, this solution is obtained by applying formula (3.3) to the auxiliary function $w^{(h)}$ defined by (3.12a), (3.12b). In the following section 4.2, we report the corresponding computational results, and in the subsequent section 4.3, we provide a general proof of the global L_1-optimality of this surface monopole solution in the case of one space dimension. Overall, the combination of the two-dimensional numerical evidence and the one-dimensional general proof prompts us to put forward a conjecture (see section 5) that the foregoing uniquely defined layer of surface monopoles always provides the control sources with minimal total absolute strength. This conjecture implies that the difficult procedure of numerical optimization in the sense of L_1 *can actually be bypassed* when building the L_1-optimal control sources; the latter can be obtained by simply solving the boundary-value problem (3.12b), which is an easy task. In other words, assuming that our arguments toward global minimality of surface monopoles are sufficiently convincing (see sections 4.2 and 4.3), we can claim that finding the L_1-optimal controls will now take only a most straightforward computation, apparently even easier than optimization in the sense of L_2; see [9]. Of course, comparison of the different optimization strategies in the framework of an approximate, rather than exact, noise cancellation will require a through future study.

4.2. Numerical solution of the L_1-optimization problem. For our numerical simulations, we have considered the simplest possible two-dimensional geometric setup, with the protected domain Ω in the form of a disk of radius $r = 1$ centered at the origin. The external artificial boundary was a circle of radius $R > r$, as in section 3.3. As such, the resulting discrete control sources were concentrated within the annular region $r \le \rho \le R$.

In contradistinction to section 3.3, here we have used a polar grid, which was stretched in the radial direction. This allowed us to keep the cell aspect ratio constant. The grid is first built in the coordinates $(\ln\rho, \theta)$; it has equal square cells $\frac{2\pi}{L} \times \frac{2\pi}{L}$ and is constructed on the rectangle $[-\frac{2\pi}{L}, \ln R] \times [0, 2\pi]$. Then, the conformal mapping $e^{\ln\rho + i\theta}$ maps it onto a polar grid with uniform angular spacing $\theta_s = s\Delta\theta$, where $\Delta\theta = \frac{2\pi}{L}$ and $s = 0, \ldots, L$, so that $\theta_0 = 0$ and $\theta_L = 2\pi$, and nonuniform radial spacing $\rho_j = \exp\big(\frac{2\pi}{L} \cdot j\big)$, $j = -1, 0, \ldots, J$, so that $\rho_{-1} = \exp\big(-\frac{2\pi}{L}\big)$, $\rho_0 = 1 = r$, and $\rho_J = R$. It is convenient to define the grid sizes in the radial direction as $\Delta\rho_j \equiv \rho_j - \rho_{j-1} = \exp\big(\frac{2\pi}{L} \cdot j\big) - \exp\big(\frac{2\pi}{L} \cdot (j-1)\big)$, $j = 0, \ldots, J$. The Helmholtz operator can be easily approximated on this new nonuniform grid with the second order of accuracy using the same five-node stencil as shown in Figure 3.2. This involves little change compared to the approximation (3.5), which works for uniform grids, and we refer the reader to our paper [14] for detail. The discrete ABCs (3.10) or (3.11) do not change, except that $\Delta\rho_J$ needs to be substituted instead of $\Delta\rho$.

As we are building our control sources outside of the protected region $\Omega = \{(\rho, \theta) \,|\, \rho < r = 1\}$, i.e., on $\Omega_1 = \mathbb{R}^2 \backslash \Omega$, we do not need to be concerned with the structure of the grid inside Ω. For our constructions, we will only need to use one grid circle inside Ω. This will be the innermost circle $j = -1$. The second to innermost circle $j = 0$ already represents the interface $\Gamma = \partial\Omega = \{(\rho, \theta) \,|\, \rho = r = 1\}$.

Adopting the definition (3.2) of the grid subsets introduced in section 3.1, we obtain

(4.14)
$$\mathbb{M}^+ = \{(\rho_j, \theta_s)\,|\,j = -1\}, \quad \mathbb{M}^- = \{(\rho_j, \theta_s)\,|\,0 \le j \le J-1\},$$
$$\mathbb{N}^+ = \{(\rho_j, \theta_s)\,|\,j = -1, 0\}, \quad \mathbb{N}^- = \{(\rho_j, \theta_s)\,|\,-1 \le j \le J\},$$
$$\gamma = \{(\rho_j, \theta_s)\,|\,j = -1, 0\}, \quad \gamma^+ = \{(\rho_j, \theta_s)\,|\,j = -1\}, \quad \gamma^- = \{(\rho_j, \theta_s)\,|\,j = 0\}.$$

For all definitions in (4.14), we assume $s = 0, \ldots, L-1$.

In the computational experiments, we have used grids with four times the number of cells in the circumferential direction compared to the radial direction. Specific grid dimensions were: $L = 32$ and $L = 48$, and accordingly, $J = 7$ and $J = 11$. (Note, as $j = -1, 0, \ldots, J$, the number of cells in the radial direction is $J+1$.) The wavenumber k in the Helmholtz equation (1.1) was chosen as $k = 0.5$. The excitation, i.e., the acoustic field $u^{(h)}$ that drives the control system, was taken in the analytic form of a shifted fundamental solution (see formula (2.3a)), as if it were generated by the point source $\delta(\boldsymbol{x} - \boldsymbol{x}_1)$, where $\boldsymbol{x}_1 = (\rho\cos\theta, \rho\sin\theta) = (5, 0)$. We reemphasize that our approach does not require an explicit knowledge of the exterior sources of noise. We only need this function $u^{(h)}$ as a sample field to be used as given data in formula (3.4).

We have also considered another case: $L = 48$, $J = 9$; for this case, we have selected $k = 0.9$. The excitation was produced by two point sources, $\delta(\boldsymbol{x} - \boldsymbol{x}_1) + \delta(\boldsymbol{x} - \boldsymbol{x}_2)$, where $\boldsymbol{x}_1 = (5, 0)$ and $\boldsymbol{x}_2 = (1, 2)$. Note, as for the wavenumber we have $k = \omega/c$, where ω is the temporal frequency and c is the speed of sound (see section 4.1). We also obtain the following relation between the wavelength λ and the wavenumber: $\lambda = 2\pi/k$. This means that in both cases, $k = 0.5$ and $k = 0.9$, we consider long waves relative to the diameter of the protected region Ω, which has been found advantageous from the standpoint of convergence of the numerical optimization algorithm.

The matrices and vectors involved in the formulation of the optimization problem (4.9) were constructed in accordance with the chosen geometric setup. Namely, the dimension of $\boldsymbol{L}^{(h)}$ (see (4.7)) was $M \times N \equiv (L \cdot J) \times (L \cdot (J+2))$; the dimension of $\boldsymbol{A}$, which corresponds to the variables on γ, was $M \times 2 \cdot L \equiv (L \cdot J) \times 2 \cdot L$; the dimension of $\boldsymbol{B}$ was $M \times (N - 4L) \equiv (L \cdot J) \times (L \cdot (J-2))$; and the dimension of either $\boldsymbol{C}$ or $\boldsymbol{D}$ was $M \times L \equiv (L \cdot J) \times L$.

We have tried several numerical approaches for solving the corresponding minimization problems (4.11), starting with the algorithms available as a part of the standard optimization toolbox in MATLAB. However, our best numerical results were obtained with the software package SeDuMi by J. F. Sturm.[5] This is a numerical algorithm for optimization over cones [17]; it employs the ideas of interior point methods and the self-dual embedding technique of [25]; see also [13]. The algorithm allows for complex-valued entries, which is very important in our framework, and also for quasi-convex quadratic and positive semidefinite constraints. Of course, all the cases that we have been able to compute using SeDuMi (see above) can still be treated only as simple model examples on the scale of potential applications for noise control (see section 4.1). However, the optimal solutions that we have obtained all demonstrate a very coherent behavior that we discuss below. On Figures 4.1(a), 4.2(a), and 4.3(a) we plot magnitudes of the L_1 optimal solutions computed with SeDuMi [17]. Let us also note that SeDuMi is, in fact, a rather general procedure, and one may expect

better numerical performance from more focused algorithms, such as the one proposed by Andersen et al. in [1]. In the future, we may try the algorithm of [1] for solving the foregoing L_1 minimization problem.

Apparently, the most obvious observation that one can make by looking at Figures 4.1(a), 4.2(a), and 4.3(a) is that in all cases the optimal solution (i.e., the L_1 minimum) is concentrated on a single circumferential layer of grid nodes. This is the second to innermost circle of the grid $\mathbb{N}^-$ (see (4.14)), i.e., the grid line $j = 0$. It corresponds to the outer portion of the grid boundary γ^- (see (4.14)), and, in the continuous case, to the interface Γ itself, $\Gamma = \partial\Omega = \{(\rho, \theta) \,|\, \rho = r = 1\}$. In other words, the L_1-optimal solutions for control sources that we have computed can all be interpreted as layers of monopole sources on the perimeter of the protected region Ω. This clearly calls for comparing these optimal solutions with the densities of discrete

single-layer potentials introduced in section 3.4.

To conform the general definitions of section 3.4 to the specific geometric setup analyzed here, we need to construct on $\mathbb{N}^- \backslash \gamma^+$ the solution $w^{(h)}$ of the discrete exterior Dirichlet problem (3.12b) for the case when γ^- is the grid circle $j = 0$. (In this case, $\mathbb{M}^-_{\mathrm{int}}$ corresponds to $j > 0$.) Then, the operator $\boldsymbol{L}^{(h)}$ of (3.5) needs to be applied to the overall resulting function $w^{(h)}$, including its definition (3.12a) on the inner part γ^+ of the grid boundary: $w^{(h)}_n|_{n\in\gamma^+} = u^{(h)}_n|_{n\in\gamma^+}$. Since we know ahead of time that the resulting controls will differ from zero only on γ^- (which is an equivalent of $\mathbb{M}^- \backslash \mathbb{M}^-_{\mathrm{int}}$ in this case), we need not consider $w^{(h)}$ anywhere beyond $j = 1$. Consequently, for the purpose of constructing surface monopoles, we may simply set $J = 1$ and consider $w^{(h)}$ on three grid circles only: $j = -1$, $j = 0 \equiv J - 1$, and $j = 1 \equiv J$. In so doing, we obviously have to specify the ABCs (3.11) right on the interface; in other words, the input for the ABCs will be on γ^-, i.e., at $j = 0$, and the output will be on the outermost circle $j = J = 1$. Clearly, specifying the ABCs on γ^- allows us to reconstruct $w^{(h)}_{s,j}$ for $j = J$ directly by formula (3.11), i.e., without actually solving the aforementioned exterior Dirichlet problem. And once we know $w^{(h)}$ for $j = -1$, 0, and 1, we can easily obtain the discrete surface monopole controls on γ^-, i.e., for $j = 0$. As in section 3.4, we will denote these control sources $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$.

In Figures 4.1(b), 4.2(b), and 4.3(b), we plot magnitudes of the discrete surface controls $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$ for the exact same cases, for which we have explicitly computed the L_1 minimal solutions using SeDuMi. Visually comparing Figures 4.1(a), 4.2(a), and 4.3(a) with respective Figures 4.1(b), 4.2(b), and 4.3(b), we conclude that there is virtually no difference between them. In other words, the L_1-optimal solutions coincide with the surface monopole control sources $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$. To further corroborate this conclusion, we evaluate the L_1 norm of the difference on the grid $\mathbb{M}^-$ between each L_1-optimal solution and the corresponding surface monopole layer $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$, assuming that $g^{(\mathrm{h,surf})}_{\mathrm{monopole}} = 0$ everywhere except on γ^-. The results are presented in Table 4.1.

The data in Table 4.1, which take into account both magnitude and phase, do

TABLE 4.1
Comparison of the computed L_1-optimal solutions with surface monopoles.

Case	$\min_{w^{(h)}} \|g^{(h)}\|_{1,\mathbb{M}^-}$	$\|g^{(\mathrm{h,surf})}_{\mathrm{monopole}}\|_{1,\mathbb{M}^-}$	$\|g^{(h)}_{\mathrm{min}} - g^{(\mathrm{h,surf})}_{\mathrm{monopole}}\|_{1,\mathbb{M}^-}$	Relative diff.
Figure 4.1	0.5764	0.5761	0.0067	0.0117
Figure 4.2	0.5769	0.5761	0.0036	0.0063
Figure 4.3	0.9760	0.9750	0.0083	0.0085

corroborate that the respective solutions are close to one another. Moreover, by comparing the second and third rows in Table 4.1, we can apparently observe the phenomenon of grid convergence. Indeed, the case of Figure 4.2 is computed on a grid which is 1.5 times finer in each direction than the grid of Figure 4.1. For a second-order scheme, we can consequently expect a drop in the error by a factor of ~ 2.25, which we indeed see in Table 4.1 for both the absolute and relative difference between the L_1 minimum $g^{(h)}_{\mathrm{min}}$ and surface monopoles $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$. Even though the solutions that we are computing are obviously not smooth, and thus the grid convergence may be difficult to justify analytically, the foregoing experimental observation certainly makes our point about the coincidence of $g^{(h)}_{\mathrm{min}}$ and $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$ even more convincing.

Summarizing the foregoing numerical results, we can see that in all the cases analyzed the minimum for the L_1 norms of the control sources $g^{(h)}$ on $\mathbb{M}^-$ (see (4.5)) is actually given by the L_1 norm of $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$:

$$\min_{w^{(h)}} \|g^{(h)}\|_{1,\mathbb{M}^-} = \|g^{(\mathrm{h,surf})}_{\mathrm{monopole}}\|_{1,\mathbb{M}^-}.$$

The right-hand side of the previous equality can be recast into a more natural form by noticing that surface controls $g^{(\mathrm{h,surf})}_{\mathrm{monopole}}$ are defined only on γ^-. Then we can replace the L_1 norm over the two-dimensional grid domain $\mathbb{M}^-$ by the L_1 norm over the "one-dimensional" grid subset γ^-. This will bring about a factor of $\Delta\rho_1$ because obviously the cell areas V_m (see (4.5)) that correspond to nodes $j = 0$ are all equal and proportional to $\Delta\rho_1$. As such, we obtain

$$\min_{w^{(h)}} \|g^{(h)}\|_{1,\mathbb{M}^-} = \|g^{(\mathrm{h,surf})}_{\mathrm{monopole}}\|_{1,\gamma^-} \Delta\rho_1. \tag{4.15}$$

Equality (4.15) basically conjectures *global minimality of the surface monopole solution for active controls in the sense of* L_1.

As of yet, of course, we can only claim that equality (4.15) holds because it has been corroborated by a particular collection of numerical experiments that we have conducted. However, motivated by the consistency of our experimental observations that all suggest (4.15) (see Figures 4.1, 4.2, and 4.3 and Table 4.1), we have been able to prove a general result on the global L_1-optimality of the surface monopole solution for controls in both continuous and discrete formulation in the one-dimensional case. As has already been mentioned, we interpret the combination of the foregoing numerical results and the forthcoming analytic one-dimensional proof as an indication that surface monopoles may provide a universal global optimum in the sense of L_1. This, in particular, means that no numerical optimization will be needed for constructing the L_1-optimal control sources; they can simply be obtained by solving the boundary-value problem (3.12b) for the generating function $w^{(h)}$.

4.3. One-dimensional proof of global L_1-optimality. It will be convenient to consider simultaneously both the continuous and discrete formulations of the one-dimensional noise control problem. Let's denote the independent variable $x \in \mathbb{R}$ and

introduce the one-dimensional Helmholtz equation for the field variable $u = u(x)$ (cf. (1.1)):

$$\boldsymbol{L}u \equiv \frac{d^2u}{dx^2} + k^2u = f(x). \tag{4.16}$$

Then we introduce a uniform grid $x_n = n \cdot h$, $n = 0, \pm 1, \pm 2, \dots$, of variable x, and approximate (4.16) with the second-order central-difference scheme

$$\boldsymbol{L}^{(h)}u^{(h)} = \frac{u^{(h)}_{n+1} - 2u^{(h)}_n + u^{(h)}_{n-1}}{h^2} + k^2u^{(h)}_n = f^{(h)}_n. \tag{4.17}$$

Note that here we are using the same subscript "n" for both the discrete unknown function $u^{(h)}$ and the discrete right-hand side $f^{(h)}$, because for the particular scheme (4.17) they are defined on the same grid. We will still need to distinguish, however, between the grids $\mathbb{M}$ and $\mathbb{N}$ when constructing the necessary grid subsets.

Let us assume that our protected region Ω corresponds to $x < 0$ and accordingly, the complementary region Ω_1 corresponds to $x \geq 0$. Then, the continuous control sources will be given by (cf. formula (2.1))

$$g(x) = -\frac{d^2w}{dx^2} - k^2w\bigg|_{x\geq 0}, \tag{4.18}$$

where the auxiliary function $w(x)$, $x \geq 0$, is supposed to satisfy the interface conditions (cf. formula (2.2))

$$w(0) = u(0), \qquad \frac{dw}{dx}\bigg|_{x=0} = \frac{du}{dx}\bigg|_{x=0} \tag{4.19}$$

and the appropriate ABC, i.e., the radiation boundary condition, as $x \longrightarrow +\infty$. The quantities $u(0)$ and $\frac{du}{dx}\big|_{x=0}$ in (4.19) are assumed to be given.

Next, applying the definitions of section 3.1 to a particular stencil given by (4.17), we will have $\mathbb{M}^+ = \{m \,|\, m \equiv n = -1, -2, \dots\}$, $\mathbb{M}^- = \{m \,|\, m \equiv n = 0, 1, 2, \dots\}$, $\mathbb{N}^+ = \{n \,|\, n = 0, -1, -2, \dots\}$, $\mathbb{N}^- = \{n \,|\, n = -1, 0, 1, 2, \dots\}$, and $\gamma = \{n \,|\, n = -1, 0\}$. Accordingly, the discrete one-dimensional control sources will be given by (cf. formula (3.3))

$$g^{(h)}_n = -\frac{w^{(h)}_{n+1} - 2w^{(h)}_n + w^{(h)}_{n-1}}{h^2} - k^2w^{(h)}_n\bigg|_{n\geq 0}, \tag{4.20}$$

where the auxiliary grid function $w^{(h)}_n$ is supposed to satisfy the interface conditions on $\gamma = \{n \,|\, n = -1, 0\}$ (cf. formula (3.4))

$$w^{(h)}_{-1} = u^{(h)}_{-1}, \qquad w^{(h)}_0 = u^{(h)}_0, \tag{4.21}$$

and the appropriate ABC at infinity, or in other words, for large n's. Again, the quantities $u^{(h)}_{-1}$ and $u^{(h)}_0$ in (4.21) are considered as given.

To obtain the continuous ABC, we assume that the auxiliary function $w(x)$ satisfies the homogeneous version of (4.16): $\boldsymbol{L}w = 0$ for $x \geq X > 0$. This equation has two linearly independent solutions: e^{-ikx} is a right-traveling wave, and e^{ikx} is a left-traveling wave. In the one-dimensional framework, we obviously need to treat

the right-traveling wave as outgoing for the artificial outer boundary $x = X$. Therefore, employing the same mode selection principle as in section 2.2, we arrive at the following ABC (cf. formulae (2.13) and (2.17)):

$$\left.\frac{dw}{dx}\right|_{x=X} = -ikw(X), \tag{4.22}$$

which guarantees that only one of the two aforementioned linearly independent modes, namely e^{-ikx}, will remain in the composition of $w(x)$ for $x \geq X$. Note that boundary condition (4.22) can, in fact, be interpreted as the Sommerfeld radiation condition. In the one-dimensional case, it can be specified at a finite location, in contradistinction to the multidimensional case when these boundary conditions can only be specified at infinity; see formulae (1.2a), (1.2b). Altogether, the continuous auxiliary function $w = w(x)$ that defines the control sources $g(x)$ by formula (4.18) is specified on the interval $[0, X]$ and satisfies boundary conditions (4.19) and (4.22).

To obtain the discrete one-dimensional ABC, we will not approximate (4.22) with finite differences, as we did in section 3.3 for the polar case, when it was basically the only option. We will rather use a genuine finite-difference approach, which has shown efficient in many cases (see the review [19]), and which was studied in our recent paper [4] for a more complex formulation that involves a high-order approximation to the Helmholtz equation. Let's assume that the auxiliary grid function $w^{(h)}$ satisfies the homogeneous version of (4.17): $\boldsymbol{L}^{(h)} w^{(h)}\big|_n = 0$ for $n \geq N > 0$ (one may think that $X = (N-1) \cdot h$). This homogeneous finite-difference equation has two linearly independent solutions: q^n and q^{-n}, where q and q^{-1} are roots of the corresponding algebraic characteristic equation

$$q^2 - (2 - k^2h^2)q + 1 = 0. \tag{4.23}$$

These roots are given by the formulae:

$$q = 1 - \frac{1}{2}k^2h^2 - ikh\sqrt{1 - \frac{1}{4}k^2h^2}, \qquad q^{-1} = 1 - \frac{1}{2}k^2h^2 + ikh\sqrt{1 - \frac{1}{4}k^2h^2}. \tag{4.24}$$

It is easy to see from (4.24) that for small h the discrete wave q^n approximates the continuous right-traveling wave e^{-ikx}, and the discrete wave q^{-n} approximates the continuous left-traveling wave e^{ikx}. Therefore, the solution q^n shall be interpreted as a discrete outgoing wave, and q^{-n} shall be interpreted as a discrete incoming wave, for the external artificial boundary $n = N$. To guarantee the radiation of waves, we need to select q^n and prohibit q^{-n}, or in other words, require that $w_n^{(h)} = c \cdot q^n$ for $n \geq N$, where $c = \text{const}$. Accordingly, we arrive at the following discrete ABC:

$$w_N^{(h)} = q \cdot w_{N-1}^{(h)}, \tag{4.25}$$

which guarantees that only one of the two aforementioned linearly independent solutions, namely q^n, will remain in the composition of $w_n^{(h)}$ for $n \geq N$. Altogether, the auxiliary grid function $w^{(h)} = w_n^{(h)}$ that defines the control sources $g^{(h)}$ by formula (4.20) is specified on the grid subset $\{n \,|\, n = -1, 0, 1, \ldots, N\}$ and satisfies boundary conditions (4.21) and (4.25).

From now on, we will be considering only the situation with no interior sources. In other words, the only field present in the model *before control* will be the incoming field with respect to the protected region $\Omega = \{x \in \mathbb{R} \,|\, x < 0\}$. In the continuous case it can be expressed as $u(x) \equiv u^-(x) = Ae^{ikx}$, and in the discrete case as $u_n^{(h)} \equiv u_n^{(h)-} = Aq^{-n}$, where $A = \text{const}$. This restriction, in fact, presents no loss of generality. Indeed, if we had both components, $u(x) = u^-(x) + u^+(x) = Ae^{ikx} + Be^{-ikx}$, and had chosen $w(x)$ according to (4.19) and (4.22), then we could have replaced this

$w(x)$ by $\tilde{w}(x) = w(x) - Be^{-ikx} \equiv w(x) - u^+(x)$. The function $\tilde{w}(x)$ would satisfy the new interface conditions $\tilde{w}(0) = u^-(0)$, $\frac{d\tilde{w}}{dx}\big|_{x=0} = \frac{du^-}{dx}\big|_{x=0}$ instead of (4.19), and the same original ABC (4.22). Most important, the control sources generated by this new auxiliary function according to (4.18) will be the exact same control sources as those generated by $w(x)$: $\boldsymbol{L}w = \boldsymbol{L}[\tilde{w} + Be^{-ikx}] = \boldsymbol{L}\tilde{w}$, $x \geq 0$. Similarly in the discrete case, if we had $u_n^{(h)} = u_n^{(h)-} + u_n^{(h)+} = Aq^{-n} + Bq^n$, then the auxiliary functions $w_n^{(h)}$ and $\tilde{w}_n^{(h)} = w_n^{(h)} - Bq^n \equiv w_n^{(h)} - u_n^{(h)+}$ would generate the exact same discrete control sources according to (4.20). Of course, the foregoing argument is in complete agreement with the general discussion of section 2 on insensitivity of the control sources to the interior sound.

In the continuous one-dimensional case, the interface between the protected region $\Omega = \{x \in \mathbb{R} \,|\, x < 0\}$ and its complement $\Omega_1 = \{x \in \mathbb{R} \,|\, x \geq 0\}$ is obviously one point, $x = 0$. To construct the corresponding "surface" monopole controls, we consider a special form of the auxiliary function $w(x)$. Namely, if the original field to be controlled is the left-traveling wave that propagates into Ω, $u(x) = u^-(x) = Ae^{ikx}$, $x < 0$, then we take $w(x)$ in the form of the right-traveling wave: $w(x) = Ae^{-ikx}$, $x \geq 0$. Obviously, this function $w(x)$ solves the homogeneous equation on Ω_1, $\boldsymbol{L}w = 0$, $x \geq 0$, and satisfies the ABC (4.18). It also satisfies the Dirichlet boundary condition at the interface $x = 0$: $w(0) = u(0)$. Altogether, we see that $w(x)$ selected this way solves the one-dimensional counterpart of the exterior Dirichlet problem (2.23) that we used in section 2.3 to obtain the control sources in the form of surface monopoles. According to the analysis of section 2.3, surface monopoles are obtained by applying the operator $-\boldsymbol{L}$ to the function v of (2.21), which has discontinuous first derivative across the interface. In the specific one-dimensional case that we are studying here, this function is given by

$$v(x) = \begin{cases} Ae^{ikx} & \text{for } x < 0, \\ Ae^{-ikx} & \text{for } x \geq 0. \end{cases} \tag{4.26}$$

Applying the operator $-\boldsymbol{L}$ (see (4.16)) to the function $v(x)$ of (4.26) in the sense of distributions (see [24]), we obtain the following "surface" (in fact, point) monopole control source (cf. formula (2.30)):

$$g_{\text{monopole}}^{(\text{surf})} = 2Aik\delta(x). \tag{4.27}$$

To obtain the discrete "surface" monopoles in the one-dimensional case, we need to consider $u_n^{(h)} = Aq^{-n}$ for $n \leq 0$, and $w_n^{(h)} = Aq^n$ for $n \geq 0$; we also set $w_{-1}^{(h)} = u_{-1}^{(h)}$. The aforementioned $w_n^{(h)}$ solves the discrete homogeneous equation $\boldsymbol{L}^{(h)}w^{(h)} = 0$ for $n > 0$, satisfies the discrete ABC (4.25), and the interface conditions $w_\gamma^{(h)} = u_\gamma^{(h)}$, or equivalently (4.21). In other words, the selected $w^{(h)}$ solves the one-dimensional version of the exterior Dirichlet-type problem (3.12b), (3.12a) that we used in section 3.4 to derive surface monopole controls in the discrete framework. Applying the operator $-\boldsymbol{L}^{(h)}$ (see (4.17)) to the foregoing function $w^{(h)}$, we obtain the discrete surface control source

$$g_{\text{monopole}}^{(h,\,\text{surf})} = \begin{cases} -A\left(2\frac{q-1}{h^2} + k^2\right) & \text{for} \quad n = 0, \\ 0 & \text{for} \quad n > 0. \end{cases} \tag{4.28}$$

We are now prepared to formulate our central result on the global L_1-optimality of surface monopoles in the one-dimensional discrete framework. For any function $w^{(h)} = w_n^{(h)}$ that satisfies the ABC (4.25) and the interface conditions (4.21), where $u_n^{(h)} = Aq^{-n}$, $n \leq 0$, the L_1 norm of the corresponding control sources (4.20) will

always be greater than or equal to the magnitude of the surface monopole (4.28) times the grid size h: $\|g^{(h)}\|_1 \geq |g^{(h,\,\mathrm{surf})}_{\mathrm{monopole}}|h$. In the case $w^{(h)}_n = Aq^n$ the equality is achieved, and thus $\min_{w^{(h)}} \|g^{(h)}\|_1 = |g^{(h,\,\mathrm{surf})}_{\mathrm{monopole}}|h$. In other words, the following theorem holds.

THEOREM 4.1. *Let a complex-valued function $w^{(h)} = w^{(h)}_n$ be defined on the grid $n = -1, 0, 1, \ldots, N$, where $N > 0$ can be arbitrary. Let $w^{(h)}_0 = A$, where $A \in \mathbb{C}$ is a given constant, and $w^{(h)}_{-1} = qw^{(h)}_0$ and $w^{(h)}_N = qw^{(h)}_{N-1}$, where q is defined by formula (4.24). Then,*

$$\min_{w^{(h)}_n} \sum_{n=0}^{N-1} \left| \frac{w^{(h)}_{n+1} - 2w^{(h)}_n + w^{(h)}_{n-1}}{h^2} + k^2 w^{(h)}_n \right| = |A| \left| 2\frac{q-1}{h^2} + k^2 \right|. \tag{4.29}$$

Proof. Let us introduce new quantities p_0, $p_1, \ldots, p_{N-2}$ so that $w^{(h)}_1 = p_0 w^{(h)}_0$, $w^{(h)}_2 = p_1 w^{(h)}_1, \ldots, w^{(h)}_{N-1} = p_{N-2} w^{(h)}_{N-2}$. Then the sum on the left-hand side of (4.29) can be recast in the following form (taking into account that $w^{(h)}_{-1} = qw^{(h)}_0$ and $w^{(h)}_N = qw^{(h)}_{N-1}$):

$$\begin{aligned}
&\sum_{n=0}^{N-1} \left| \frac{w^{(h)}_{n+1} - 2w^{(h)}_n + w^{(h)}_{n-1}}{h^2} + k^2 w^{(h)}_n \right| \\
&\quad = |A| \left| \frac{p_0 + q - 2}{h^2} + k^2 \right| + |A| \left| \frac{p_0 p_1 - 2p_0 + 1}{h^2} + k^2 p_0 \right| \\
&\quad + |A||p_0| \left| \frac{p_1 p_2 - 2p_1 + 1}{h^2} + k^2 p_1 \right| + |A||p_0||p_1| \left| \frac{p_2 p_3 - 2p_2 + 1}{h^2} + k^2 p_2 \right| + \cdots \\
&\quad + |A||p_0||p_1| \cdots |p_{N-3}| \left| \frac{p_{N-2} q - 2p_{N-2} + 1}{h^2} + k^2 p_{N-2} \right|.
\end{aligned}$$

Next, we introduce new notations: $p_0 = q + z_0$, $p_1 = q + z_1, \ldots, p_{N-2} = q + z_{N-2}$, where q is defined by (4.24) and all the quantities are generally assumed to be complex. Using these new notations, we can rewrite the generic term on the right-hand side of the previous equality as follows:

$$\begin{aligned}
&|A||p_0||p_1| \cdots |p_n| \left| \frac{p_{n+1} p_{n+2} - 2p_{n+1} + 1}{h^2} + k^2 p_{n+1} \right| \\
&\quad = |A||q + z_0||q + z_1| \cdots |q + z_n| \left| \frac{(q + z_{n+1})(q + z_{n+2}) - 2(q + z_{n+1}) + 1}{h^2} \right. \\
&\qquad\qquad \left. + k^2 (q + z_{n+1}) \right| \\
&\quad = |A||q + z_0||q + z_1| \cdots |q \\
&\qquad + z_n| \Bigg| \underbrace{\frac{q^2 - 2q + 1}{h^2} + k^2 q}_{0} + \frac{z_{n+1} z_{n+2} + q(z_{n+1} + z_{n+2}) - 2z_{n+1}}{h^2} + k^2 z_{n+1} \Bigg| \\
&\quad = |A||q + z_0||q + z_1| \cdots |q + z_n| \left| \frac{z_{n+2}(q + z_{n+1})}{h^2} + z_{n+1} \left(\frac{q-2}{h^2} + k^2 \right) \right| \\
&\quad = |A||q + z_0||q + z_1| \cdots |q + z_n| \left| \frac{z_{n+2}(q + z_{n+1})}{h^2} + \frac{z_{n+1}}{h^2} \mu \right|.
\end{aligned}$$

In the last chain of equalities, expression $\frac{q^2-2q+1}{h^2} + k^2 q$ turns into zero by virtue of the characteristic equation (4.23), and $\mu = q - 2 + k^2h^2$. Using the definition of q from (4.24), we can obtain

$$|\mu|^2 = \left|-1 - \frac{1}{2}k^2h^2 - ikh\sqrt{1 - \frac{1}{4}k^2h^2} + k^2h^2\right| = \left|-1 + \frac{1}{2}k^2h^2 - ikh\sqrt{1 - \frac{1}{4}k^2h^2}\right|$$

$$= \left(-1 + \frac{1}{2}k^2h^2\right)^2 + k^2h^2\left(1 - \frac{1}{4}k^2h^2\right) = 1 - k^2h^2 + \frac{1}{4}k^4h^4 + k^2h^2 - \frac{1}{4}k^4h^4 = 1.$$

Finally, collecting all terms, we can now have

$$\sum_{n=0}^{N-1}\left|\frac{w_{n+1}^{(h)} - 2w_n^{(h)} + w_{n-1}^{(h)}}{h^2} + k^2 w_n^{(h)}\right|$$

$$= |A|\left|\frac{z_0}{h^2} + 2\frac{q-1}{h^2} + k^2\right| + |A|\left|\frac{z_1(q+z_0)}{h^2} + \frac{z_0}{h^2}\mu\right|$$

$$+ |A||q+z_0|\left|\frac{z_2(q+z_1)}{h^2} + \frac{z_1}{h^2}\mu\right| + |A||q+z_0||q+z_1|\left|\frac{z_3(q+z_2)}{h^2} + \frac{z_2}{h^2}\mu\right| + \cdots$$

$$+ |A||q+z_0||q+z_1|\ldots|q+z_{N-3}|\left|\frac{z_{N-2}}{h^2}\mu\right|$$

$$\geq |A|\left|2\frac{q-1}{h^2} + k^2\right| - |A|\left|\frac{z_0}{h^2}\right| + |A|\left|\frac{z_0}{h^2}\right||\mu| - |A||q+z_0|\frac{|z_1|}{h^2} + |A||q+z_0|\frac{|z_1|}{h^2}|\mu|$$

$$- |A||q+z_0||q+z_1|\frac{|z_2|}{h^2} + |A||q+z_0||q+z_1|\frac{|z_2|}{h^2}|\mu| - \cdots$$

$$+ |A||q+z_0||q+z_1|\ldots|q+z_{N-3}|\frac{|z_{N-2}|}{h^2}|\mu|$$

$$= |A|\left|2\frac{q-1}{h^2} + k^2\right|.$$

In other words, we have obtained the inequality

$$\sum_{n=0}^{N-1}\left|\frac{w_{n+1}^{(h)} - 2w_n^{(h)} + w_{n-1}^{(h)}}{h^2} + k^2 w_n^{(h)}\right| \geq |A|\left|2\frac{q-1}{h^2} + k^2\right|. \tag{4.30}$$

To establish the result of the theorem, i.e., formula (4.29), it remains to show only that there will be a particular $w^{(h)} = w_n^{(h)}$ for which inequality (4.30) transforms into the equality. Clearly, the equality in formula (4.30) is achieved for $w_n^{(h)} = Aq^n$, $n \geq 0$, because in this case $z_0 = z_1 = \cdots = z_{N-2} = 0$. This completes the proof. ∎

Let us also recall that if we multiply the sum on the left-hand side of either formula (4.29) or formula (4.30) by the grid size h, we obtain the discrete L_1 norm of the control sources $g^{(h)}$. Therefore, inequality (4.30) transforms into

$$\left\|g^{(h)}\right\|_1 \geq \left|g_{\text{monopole}}^{(h,\,\text{surf})}\right| h, \tag{4.31}$$

and consequently, we have, in effect, demonstrated the global L_1 minimality of the surface control sources:

$$\min_{w^{(h)}}\left\|g^{(h)}\right\|_1 = \left|g_{\text{monopole}}^{(h,\,\text{surf})}\right| h. \tag{4.32}$$

Equality (4.32) is a one-dimensional counterpart of (4.15), but unlike the experimentally established formula (4.15), equality (4.32) has been proven rigorously.

The foregoing proof of Theorem 4.1 also reveals the mechanism of discrepancy between the optimal control $g^{(h,\,\mathrm{surf})}_{\mathrm{monopole}}$ and all other suboptimal controls. Namely, every time the auxiliary function $w^{(h)}_n$ "departs" from the pure right-traveling wave Aq^n, which is equivalent to having $z_n \neq 0$, we may pick up additional value of $\|g^{(h)}\|_1$ in case the actual estimate based on the triangle inequality that we use,

$$|A||q+z_0||q+z_1|\cdots|q+z_n|\left|\frac{z_{n+2}(q+z_{n+1})}{h^2}+\frac{z_{n+1}}{h^2}\mu\right|$$

$$\geq |A||q+z_0||q+z_1|\cdots|q+z_n|\frac{|z_{n+1}|}{h^2}|\mu|$$

$$-|A||q+z_0||q+z_1|\cdots|q+z_n||q+z_{n+1}|\frac{|z_{n+2}|}{h^2},$$

happens to be "strictly greater" rather than "greater or equal" for this given term. It is also interesting to look into the role of the ABC (4.25). This boundary condition "swallows" the last term in the sum so that all the previous terms can cancel one another in pairs, and only the first term $|g^{(h,\,\mathrm{surf})}_{\mathrm{monopole}}|$ will remain.

Next, we will analyze the continuous case. Assume that $w(x)$ is a regular smooth function, which is defined on the interval $[0, X]$ and satisfies boundary conditions (4.19) and (4.22). Let us also assume that the grid function $w^{(h)} = w^{(h)}_n$, $n = 0, 1, \ldots, N-1$, is the trace of $w(x)$ on the aforementioned uniform grid with size h: $w^{(h)}_n = w(x_n) \equiv w(n \cdot h)$. Note that we need to require sufficient smoothness of $w(x)$ in order to guarantee the consistency of the finite-difference scheme: $\boldsymbol{L}^{(h)}w^{(h)} = \boldsymbol{L}w + O(h^2)$ (see (4.16) and (4.17)). Let us additionally define $w^{(h)}_{-1} = qw^{(h)}_0$ and $w^{(h)}_N = qw^{(h)}_{N-1}$, in accordance with the boundary conditions (4.21) and (4.25), respectively, like in the formulation of Theorem 4.1. Then for small h we can disregard the quadratic terms in the definition of q (see (4.24)) and have for the right endpoint

$$\frac{w^{(h)}_N - w^{(h)}_{N-1}}{h} = -ikw^{(h)}_{N-1},$$

which is obviously an approximation of the continuous ABC (4.22) with the accuracy $O(h)$. Similarly, for the left endpoint we obtain

$$\frac{w^{(h)}_0 - w^{(h)}_{-1}}{h} = ikw^{(h)}_0,$$

which is an $O(h)$ accurate approximation of the second boundary condition (4.19) under the assumption that the field to be controlled is $u(x) = u^-(x) = Ae^{ikx}$, $x < 0$, and consequently, $\frac{du}{dx}\big|_{x=0} = iku(0)$. Altogether, we have constructed a grid function $w^{(h)} = w^{(h)}_n$, $n = -1, 0, \ldots, N$, that satisfies the conditions of Theorem 4.1 and also approximates on the grid all the continuous requirements of the function $w = w(x)$.

Let us now again multiply both sides of inequality (4.30) by the positive quantity h and consider independently the limit on its right-hand side and the limit on its left-hand side as $h \longrightarrow +0$. First, we obtain

$$|A|\left|2\frac{q-1}{h^2}+k^2\right|h = |A|\left|-k^2-\frac{2ik}{h}\sqrt{1-\frac{1}{4}k^2h^2}+k^2\right|h \longrightarrow 2|A|k \quad \text{as} \quad h \longrightarrow +0.$$

Note that the limit is equal to the magnitude of the surface monopole in the continuous formulation (see (4.27)). Next, on the left-hand side we have

$$\sum_{n=0}^{N-1}\left|\frac{w_{n+1}^{(h)}-2w_n^{(h)}+w_{n-1}^{(h)}}{h^2}+k^2w_n^{(h)}\right|h=\sum_{n=0}^{N-1}\left|\frac{d^2w}{dx^2}(x_n)+k^2w(x_n)\right|h+O(h^2)$$

$$\longrightarrow\int_0^X\left|\frac{d^2w}{dx^2}(x)+k^2w(x)\right|dx\qquad\text{as}\quad h\longrightarrow+0.$$

Note that the limit is equal to the L_1 norm $\|g\|_1$ of the continuous control sources $g(x)$ defined by formula (4.18). As inequality (4.30) holds for any given value of h, we can claim that it will also hold in the limit $h\longrightarrow+0$. Therefore, we have arrived at the following result.

COROLLARY 4.2. *Let a complex-valued function $w=w(x)$ be defined on $[0,X]$. Let $w(0)=A$, where $A\in\mathbb{C}$ is a given constant, and $w'(0)=ikw(0)$ and $w'(X)=-ikw(X)$. Then,*

$$\int_0^X\left|\frac{d^2w}{dx^2}(x)+k^2w(x)\right|dx\geq 2|A|k. \tag{4.33}$$

It is easy to see that the requirements of $w(x)$ formulated in Corollary 4.2 are equivalent to the conditions that guarantee the appropriateness of $w(x)$ for constructing the control sources $g(x)$ using (4.18); see formulae (4.19) and (4.22). Therefore, the result of Corollary 4.2, i.e., inequality (4.33), can be recast as

$$\|g\|_1\geq 2|A|k. \tag{4.34}$$

On the right-hand side of inequality (4.34) we have the magnitude of the "surface" monopole $g_{\text{monopole}}^{(\text{surf})}$ defined by formula (4.27). Note that, unlike in the previously considered discrete case, when the minimal solution $g_{\text{monopole}}^{(h,\,\text{surf})}$ of (4.28) was an element of the same class of control sources $g^{(h)}$ defined by (4.20), here the minimum $g_{\text{monopole}}^{(\text{surf})}(x)$ defined by (4.27) belongs to a different class of functions, namely, singular (i.e., δ-type) distributions, as opposed to regular (i.e., $L_1^{(\text{loc})}$) distributions. In other words, $g_{\text{monopole}}^{(\text{surf})}(x)\notin L_1(\mathbb{R})$, and not even $L_1^{(\text{loc})}(\mathbb{R})$. As such, we cannot introduce the L_1 norm of $g_{\text{monopole}}^{(\text{surf})}(x)$. Therefore, inequality (4.34) formally has to stay the way it is. However, symbolically we can, of course, write

$$\int_{\mathbb{R}}\left|g_{\text{monopole}}^{(\text{surf})}(x)\right|dx=\int_{\mathbb{R}}|2Aik\delta(x)|\,dx=2|A|k, \tag{4.35}$$

which allows us to "informally" interpret inequality (4.34) as if $g_{\text{monopole}}^{(\text{surf})}(x)$ of (4.27) provided a lower bound in L_1 for all the control sources $g(x)$ defined by (4.18). Let us also note that "integration" with respect to x in (4.35), which "removes" the δ-function itself and leaves only its magnitude $2k|A|$, is a continuous analogue of multiplication by h on the right-hand side of formulae (4.31) or (4.32). Therefore, we conclude that the continuous inequality (4.34) is a direct counterpart of the discrete inequality (4.31).

Even though $g_{\text{monopole}}^{(\text{surf})}(x)\notin L_1^{(\text{loc})}(\mathbb{R})$, we will still show that there are regular control sources $g(x)\in L_1^{(\text{loc})}(\mathbb{R})$ that are arbitrarily close to $g_{\text{monopole}}^{(\text{surf})}(x)$ in the weak

sense. More precisely, we will construct a sequence of regular auxiliary functions $w_\epsilon(x)$ such that the corresponding $g_\epsilon(x)$ obtained according to (4.18) will converge to $g^{(\mathrm{surf})}_{\mathrm{monopole}}(x)$ of (4.27) in the sense of distributions. This will allow us to claim that although the minimal solution $g^{(\mathrm{surf})}_{\mathrm{monopole}}(x)$ is singular, it is, in fact, "on the borderline" of the class of regular solutions. In other words, it is a limiting point, in the sense of weak convergence, of the space of all $g(x)$ defined by formula (4.27). In addition, we will also show that the L_1 norms $\|g_\epsilon\|$ converge to the magnitude $2k|A|$ of the "surface" monopole $g^{(\mathrm{surf})}_{\mathrm{monopole}}(x)$ of (4.27). This will allow us to formulate in the continuous case the result similar to the minimality (4.32) but in the sense of "infimum" rather than "minimum."

Consider a regular function $w_\epsilon = w_\epsilon(x)$ that is defined on $[0, X]$ and satisfies boundary conditions (4.19) and (4.22) with $u(x) = Ae^{ikx}$ for $x < 0$. In addition, let us assume that not only for $x > X$, but also in between some (small) $\epsilon < X$ and X, the function $w_\epsilon(x)$ already coincides with a right-traveling wave: $w_\epsilon(x) = w_\epsilon(\epsilon)e^{-ik(x-\epsilon)}$, $\epsilon \le x \le X$. In other words, we require that $w_\epsilon(0) = A$, $w'_\epsilon(0) = ikA$, and $w'_\epsilon(\epsilon) = -ikw_\epsilon(\epsilon)$. For the purpose of obtaining the aforementioned convergent sequence, we will subsequently let $\epsilon \longrightarrow +0$. The control sources $g_\epsilon(x)$ are defined according to formula (4.18): $g_\epsilon(x) = -w''_\epsilon(x) - k^2 w_\epsilon(x)$, $0 \le x \le \epsilon$, and for $x > \epsilon$ we have $g_\epsilon(x) = 0$. If $\varphi = \varphi(x)$ is a test function on $\mathbb{R}$, i.e., a compactly supported infinitely smooth function (see [24]), then the corresponding functional, i.e., the distribution g_ϵ itself, can be represented as follows:

$$(g_\epsilon, \varphi) = \int_{\mathbb{R}} g_\epsilon(x)\varphi(x)dx = \int_0^\epsilon [-w''(x) - k^2 w(x)]\varphi(x)dx$$

$$= w(\epsilon)\varphi'(\epsilon) - w(0)\varphi(0) - [\varphi(\epsilon)w'(\epsilon) - \varphi(0)w'(0)] + \int_0^\epsilon [-w(x)\varphi''(x) + k^2 w(x)\varphi(x)]dx.$$

As $w(x) \in L_1^{(\mathrm{loc})}(\mathbb{R})$ and $\varphi(x)$ is a test function, the integral on the right-hand side of the previous equality vanishes as $\epsilon \longrightarrow +0$. Let us now additionally assume that the functions $w_\epsilon = w_\epsilon(x)$ are constructed so that $w_\epsilon(\epsilon) \longrightarrow w_\epsilon(0)$ when $\epsilon \longrightarrow +0$. In other words, we assume continuity at $x = 0$. Then, because of the boundary condition (4.22) at $x = \epsilon$, we have $w'_\epsilon(\epsilon) \longrightarrow -ikA$ as $\epsilon \longrightarrow +0$. Altogether, we obtain

$$(g_\epsilon, \varphi) \longrightarrow 2ikA\varphi(0) \quad \text{as} \quad \epsilon \longrightarrow +0. \tag{4.36}$$

The limit (4.36) implies that in the sense of distributions

$$g_\epsilon(x) \longrightarrow g^{(\mathrm{surf})}_{\mathrm{monopole}}(x) \equiv 2ikA\delta(x) \quad \text{as} \quad \epsilon \longrightarrow +0. \tag{4.37}$$

Let now specify a particular form of $w_\epsilon(x)$:

$$w_\epsilon(x) = \frac{-ikA}{\epsilon}x^2 + ikAx + A, \qquad x \in [0, \epsilon]. \tag{4.38}$$

For this function, we have $w_\epsilon(0) = w_\epsilon(\epsilon) = A$, $w'_\epsilon(0) = ikA$, and $w'_\epsilon(\epsilon) = -ikA$, and consequently, $w_\epsilon(x)$ of (4.38) meets all the previous conditions. For the L_1 norm of the corresponding control $g_\epsilon(x)$, we obtain

$$\|g_\epsilon\|_1 = \int_0^\epsilon |w''_\epsilon(x) + k^2 w_\epsilon(x)|dx = \int_0^\epsilon |A| \left[k^2 + \left(-\frac{k^3}{\epsilon}x^2 + k^3 x - \frac{2k}{\epsilon}\right)^2\right]^{1/2} dx.$$

As we always have $0 \le x \le \epsilon$, the dominant term in the last integral for small ϵ is $\frac{2k}{\epsilon}$, and therefore

$$\|g_\epsilon\|_1 \longrightarrow 2k|A| \quad \text{as} \quad \epsilon \longrightarrow +0. \tag{4.39}$$

Putting together the result of Corollary 4.2 with the limits (4.37) and (4.39), we arrive at the following result.

THEOREM 4.3. *Let a complex-valued function $w = w(x)$ be defined on $[0, X]$. Let $w(0) = A$, where $A \in \mathbb{C}$ is a given constant, and $w'(0) = ikw(0)$ and $w'(X) = -ikw(X)$. Then, in the class of regular control sources $g(x)$ defined by formula* (4.18) *for all such $w(x)$, one can identify a sequence $g_\epsilon(x)$ that would converge in the sense of distributions to the point monopole $g^{(\mathrm{surf})}_{\mathrm{monopole}}(x)$ defined by formula* (4.27):

$$g_\epsilon(x) \longrightarrow g^{(\mathrm{surf})}_{\mathrm{monopole}}(x) \equiv 2ikA\delta(x) \quad \textit{as} \quad \epsilon \longrightarrow +0.$$

Besides, the magnitude of the point monopole $g^{(\mathrm{surf})}_{\mathrm{monopole}}(x)$ of (4.27) *provides the greatest lower bound for L_1 norms of all the control sources $g(x)$ of* (4.18):

$$\inf_{w(x)} \|g\|_1 = 2k|A|. \tag{4.40}$$

Clearly, estimate (4.40) can be interpreted as global L_1 minimality of the "surface" control (4.27) among the continuous one-dimensional control sources (4.18). It is a continuous version of the previously established discrete result (4.32).

5. Discussion. For the problem of active control of sound, we have systematically described time-harmonic general solutions for the volume and surface control sources in the continuous and discrete formulation of the problem. These control sources guarantee the identical cancellation of unwanted noise on a predetermined region of interest. We have also proposed a criterion for optimization of the resulting control sources. This criterion chooses the overall absolute acoustic source strength as the cost function for minimization, and as such admits a clear physical interpretation. Mathematically, it translates into minimization of complex-valued functions in the sense of L_1, which is a very challenging problem from the standpoint of numerical implementation. We have still managed, though, to compute several two-dimensional numerical solutions using the algorithm SeDuMi. All these solutions demonstrate a coherent behavior—the minimum is achieved on the surface of the protected region. In other words, the minimum is delivered by the appropriate surface monopole controls. Therefore, the numerical evidence that we have received indicates that surface monopoles may provide a global L_1 minimum for the control sources in the general setting. We have been able to rigorously prove this result in the one-dimensional case for both continuous and discrete formulation of the problem. Even though we have not yet been able to prove a similar result for a general multi-dimensional framework, we still believe that it is true, because a combination of the two-dimensional numerical evidence and a one-dimensional accurate proof cannot, in our opinion, be a mere coincidence. Therefore, we put forward the minimization result in the form of a conjecture. Let us recall that according to (2.30) the surface monopole controls are given by

$$g^{(\mathrm{surf})}_{\mathrm{monopole}}(\boldsymbol{x}) = -\left[\frac{\partial w}{\partial \boldsymbol{n}} - \frac{\partial u}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma) = -\left[\frac{\partial \tilde{w}}{\partial \boldsymbol{n}} - \frac{\partial u^-}{\partial \boldsymbol{n}}\right]_\Gamma \delta(\Gamma) \equiv \nu(\boldsymbol{x})|_{\boldsymbol{x}\in\Gamma} \cdot \delta(\Gamma), \tag{5.1}$$

where $\tilde{w}(x) = w(\boldsymbol{x}) - u^+(\boldsymbol{x})$, as before, and $w(\boldsymbol{x})$ is a solution to the exterior Dirichlet problem (2.23). Then, we can formulate the following.

CONJECTURE 5.1. *Let a complex-valued function $w = w(\boldsymbol{x})$ be defined on $\Omega_1 = \mathbb{R}^n \backslash \Omega$, and let it be sufficiently smooth so that the operator $\boldsymbol{L}$ of* (1.1) *can be applied to $w(\boldsymbol{x})$ on its entire domain in the classical sense, and the result $\boldsymbol{L}w$ can be locally absolutely integrable. Let, in addition, $w(\boldsymbol{x})$ satisfy the interface conditions* (2.2)*, where $u = u(\boldsymbol{x})$ is a given field to be controlled, and the appropriate Sommerfeld radiation boundary conditions at infinity,* (1.2a) *or* (1.2b)*. Then the greatest lower bound for the L_1 norms of all the control sources $g(\boldsymbol{x})$ obtained with such auxiliary functions $w(\boldsymbol{x})$ using formula* (2.1) *is given by the L_1 norm on Γ of the magnitude of surface monopoles* (5.1)*:*

$$\inf_{w(\boldsymbol{x})} \int_{\Omega_1} |g(\boldsymbol{x})| d\boldsymbol{x} = \int_{\Gamma} |\nu(\boldsymbol{x})| ds. \tag{5.2}$$

Alternatively, we can rewrite (5.2) as

$$\inf_{w(\boldsymbol{x})} \|g(\boldsymbol{x})\|_{1,\Omega_1} = \|\nu\|_{1,\Gamma}. \tag{5.3}$$

Equality (5.3) is a multidimensional generalization of (4.40). Let us also notice that equality (4.15), which was obtained on the basis of experimental observations in two space dimensions, can be considered a discrete two-dimensional prototype of (5.3).

In the formulation of Conjecture 5.1, we did not include the results on the convergence of a sequence of volumetric controls to the surface layer $\nu\delta(\Gamma)$ (see (5.1)) and on the convergence of the corresponding L_1 norms, as we did in Theorem 4.3 for the one-dimensional case. We believe, though, that these results can be easily formulated and justified in the multidimensional framework using an approach similar to the one that we have used in the one-dimensional case. The key missing part, however, that does not yet allow us to transform Conjecture 5.1 into a theorem, is proving that surface monopoles provide *a lower bound* for the volumetric controls in the sense of L_1, whereas showing that this is the greatest lower bound is more straightforward. The analysis of this problem will be a subject of our future research. In this connection we can mention only that, at least in the two-dimensional case, the geometry of the protected region Ω should not be a limitation when constructing a general proof. If one can prove the result for a constant-width linear strip with periodic boundary conditions on its sides, and with the interface Γ being a segment of the straight line normal to the sides of the strip, then for any other shape the same result can likely be obtained with the help of a conformal mapping.

Acknowledgments. It is our pleasure to acknowledge most useful discussions with Jan Hesthaven, Wu Li, Michael Overton, and Victor Ryaben'kii. We would also like to thank the reviewer of the paper, who drew our attention to several important points and thereby helped make the revised manuscript a substantial improvement over its original version.

INTERMITTENCY IN THE TRANSITION TO TURBULENCE*

A. C. FOWLER† AND P. D. HOWELL†

Abstract. It is commonly known that the intermittent transition from laminar to turbulent flow in pipes occurs because, at intermediate values of a prescribed pressure drop, a purely laminar flow offers too little resistance, but a fully turbulent one offers too much. We propose a phenomenological model of the flow, which is able to explain this in a quantitative way through a hysteretic transition between laminar and turbulent "states," characterized by a disturbance amplitude variable that satisfies a natural type of evolution equation. The form of this equation is motivated by physical observations and derived by an averaging procedure, and we show that it naturally predicts disturbances having the characteristics of slugs and puffs. The model predicts oscillations similar to those which occur in intermittency in pipe flow, but it also predicts that stationary "biphasic" states can occur in sufficiently short pipes.

Key words. intermittency, transition, turbulence, slugs, puffs

1. Introduction.

Ever since Reynolds's (1883) seminal paper on the transition to turbulence in pipe flow, it has been known that the transition occurs in an intermittent fashion. As the Reynolds number increases beyond a value of around 2000 (although the precise value depends on the pipe used and on the experimental conditions at the inlet), intermittent flashes of turbulence can be seen in the pipe. Furthermore, the reason for this intermittency is well known, at least in a crude way (Prandtl and Tietjens (1934, pp. 36f.)). Turbulent flow at a given flow rate has a higher drag than laminar flow, and so, as the pressure drop driving the flow is increased, there arises a critical interval of flow rate within which laminar flow offers too low a resistance to the pressure drop but turbulent flow provides too high a resistance. In this intermediate case, the flow cycles between the two types of flow, and this is manifested in the pipe through the regular occurrence of turbulent "flashes"; this is Reynolds's term, but it has now become more customary to call the flashes "slugs" or "puffs" (Wygnanski and Champagne (1973)), depending on their provenance. The resultant flow then oscillates, producing an oscillatory (and indeed, periodic) outlet flow (Prandtl and Tietjens (1934, p. 37)).

It is perhaps unsurprising that there have been few attempts to recover these observations theoretically. Of necessity, any putative model must be semiempirical, and those that have been put forward (Bohr and Rand (1991), Deissler (1987a,b), Sakaguchi and Brand (1996)) serve as qualitative analogues rather than quantitative ones, and their aim has been to explain qualitatively the existence of turbulent slugs, rather than to draw a quantitative comparison; in addition, the resulting periodic solutions have not been found, although Deissler (1987b) hints at a mechanism similar to that suggested here.

Our aim in this paper is to provide a simple model which avoids the detailed complexities of three-dimensional turbulent flow, but which is nevertheless built solidly on

*Received by the editors March 10, 2000; accepted for publication (in revised form) August 9, 2002; published electronically March 26, 2003.

observed features of turbulence, and in particular, on the experimentally determined drag law. Although our motivating aim is to provide a predictive mechanism for intermittency and flow oscillations, we also find that we can make detailed comparisons with slug and puff dynamics. Wygnanski and Champagne (1973) distinguished these on the basis that slugs occurred at higher Reynolds number (above about 2700), were caused by low amplitude disturbances, and spread longitudinally as they propagated, the front and rear travelling at speeds respectively greater and less than the mean flow speed u, at least for large enough Reynolds number. In a very careful study, Lindgren (1957) showed that the front and rear wave speeds of slugs appeared to approach a value of about $0.9u$ as the Reynolds number decreased towards a value R_k (equal to about 2400 in his experiments), although in fact distinct slug measurements could be made only down to Reynolds number 2700.

At lower Reynolds number (below 2700 in Wygnanski and Champagne's experiments, presumably below 2400 in Lindgren's), puffs are seen. In contrast to slugs, puffs are generated by large amplitude disturbances at the inlet, and unlike slugs, which have relatively sharp leading and trailing edges, puffs have only a sharp trailing edge and a diffuse front. The trailing edge migrates backwards relative to the mean flow, with the difference between their two speeds tending to zero as the Reynolds number decreases towards a value $\underline{R}$ (about 2050 in Lindgren's experiments). Lindgren identifies a further Reynolds number $\overline{R}_k$, above which slugs grow as they propagate; presumably this is the Reynolds number at which stable slugs become viable. A final critical value is $\overline{R}$, above which fully developed turbulence can be maintained throughout the pipe.

2. A model for intermittency in turbulent flow.

2.1. Behavior of the wall friction. The Reynolds number for flow in a pipe of diameter d is

$$Re = \frac{\rho u d}{\mu}, \tag{2.1}$$

where u is the mean flow velocity, ρ is the density, and μ is the viscosity. In a pipe of length l, the pressure drop along its length in conditions of steady flow is given by

$$F = \frac{\Delta p}{l} = \frac{\lambda \rho u^2}{2d}, \tag{2.2}$$

where the drag coefficient λ is a function of the Reynolds number (Schlichting (1979)). In conditions of fully developed laminar flow, which pertain for $Re \lesssim 2300$,

$$\lambda_L = \frac{64}{Re}, \tag{2.3}$$

whereas Blasius's (1913) empirical relation for fully developed turbulent flow is

$$\lambda_T = \frac{0.3164}{Re^{1/4}} \tag{2.4}$$

and is approximately valid for $3300 < Re < 10^5$. At higher Reynolds number, a more sophisticated result based on Prandtl's mixing length theory can be used to define λ implicitly, but (2.4) will suffice for the present purpose, where such high Reynolds numbers are not relevant.

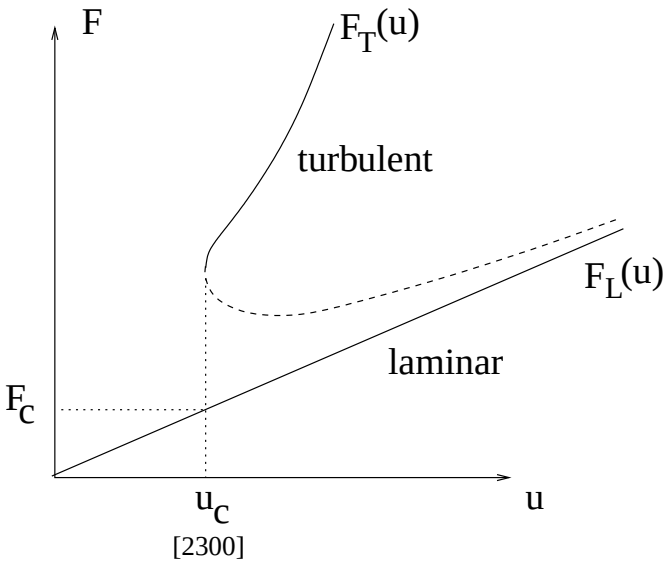

FIG. 1. *Schematic drag law for laminar and turbulent flow. The experimentally determined laminar and turbulent values are the solid curves, and we hypothesize that an unstable (dashed) branch separates the two, as shown.*

Between the onset of transition at $Re = 2300$ and the attainment of fully developed turbulence (throughout the pipe) at $Re \approx 3300$,[1] there is a region in which λ *increases* with Re. This odd behavior is associated with the phenomenon of *intermittency*. At Reynolds numbers above 2300, fluid can exist locally in a turbulent state, but for $Re < 3300$, turbulent slugs of fluid are interspersed with laminar plugs. The intermittency factor γ (the fraction of time at a fixed location for which the flow is turbulent) grows with distance downstream, and also with Reynolds number (Rotta (1956), Wygnanski and Champagne (1973)).

We wish to place a specific interpretation on this observed behavior. The local cross-sectionally averaged wall friction in a tube of diameter d is given from (2.2) by

$$F_L = \frac{32\mu u}{d^2} \tag{2.5}$$

for laminar flow (using (2.3)) and

$$F_T \approx \frac{0.16\rho^{3/4}\mu^{1/4}u^{7/4}}{d^{5/4}} \tag{2.6}$$

for turbulent flow.

As shown in Figure 1, the turbulent friction $F_T(u)$ exists as a local description down to Reynolds numbers of 2300, while the laminar expression $F_L(u)$ exists as a solution for all values of u. In particular, at values of Re above 2300, both behaviors are possible as locally stable solutions of the Navier–Stokes equation.

[1] This numerical value and that of the "onset" at 2300 depend on the level of the inlet disturbance, as well as the particular experimental set-up; these values are adopted from inspection of experimental drag measurements—see Schlichting (1979, Figure 20.1)—and will be used as typical values. In due course, we will relate them to the critical values discussed by Lindgren (1957).

Although it is not in fact essential to our argument, the existence of a jump in F between the two accessible solution branches suggests strongly that there is a third intermediate branch which joins the laminar and turbulent branches, as shown in Figure 1, and this is supported by other experimental work also (Huang and Huang (1989), Wygnanski and Champagne (1973), Darbyshire and Mullin (1995)). Moreover, the existence of an unstable intermediate branch is analogous to the existence of unstable equilibria in the transition to turbulence of plane and pipe Poiseuille flow (Orszag and Patera (1980), (1983)), and this lends support to the concept embodied in Figure 1.

We take the form of the dashed part of the $F(u)$ curve in Figure 1 as a hypothesis. It is then convenient to think of the local friction F as a state variable (rather like enthalpy), and to suppose that it is a measure of the laminar or turbulent "phase" of the fluid. And, rather like a phase change, the intermediate state is not accessible. In a fluid, boiling leads to dispersed phases at intermediate enthalpies, and transition to turbulence leads to intermittency at intermediate flow rates.

From the point of view of dynamical systems theory, the existence of a state variable F demarcating laminar and turbulent phases with a multiple valued equilibrium suggests that the simplest model beyond the mixing length theory which can describe transitions between laminar and turbulent states is one which embodies an evolution equation for F. In order to see how such an equation might be proposed, we need to study the way in which the basic mixing length theory produces the equilibrium structure of Figure 1.

2.2. Averaging. We start with the Navier–Stokes equations

$$\frac{\partial u_i}{\partial x_i} = 0,$$

$$\rho\left[\frac{\partial u_i}{\partial t} + \frac{\partial}{\partial x_j}(u_i u_j)\right] = -\frac{\partial p}{\partial x_i} + \mu\nabla^2 u_i. \tag{2.7}$$

Following common procedure (Mathieu and Scott (2000)), we define

$$u_i = \bar{u}_i + u_i', \tag{2.8}$$

where $\bar{u}_i$ is a local time average of u_i, and u_i' represents the fluctuating part. More specifically,

$$\bar{u}_i = \frac{1}{2T}\int_{t-T}^{t+T} u_i\, dt, \tag{2.9}$$

and we suppose formally that u_i' varies on a time scale $\ll T$, while we allow $\bar{u}_i$ to vary on times $\gg T$. (The necessity for this assumption can be removed by taking ensemble averages instead.)

Averaging of (2.7) thus leads to

$$\frac{\partial \bar{u}_i}{\partial x_i} = 0,$$

$$\rho\left[\frac{\partial \bar{u}_i}{\partial t} + \frac{\partial}{\partial x_j}(\bar{u}_i \bar{u}_j)\right] = -\frac{\partial \bar{p}}{\partial x_i} + \mu\nabla^2 \bar{u}_i + \frac{\partial}{\partial x_j}(-\rho\overline{u_i' u_j'}). \tag{2.10}$$

Next we define the cross-sectional average over the pipe as

$$\hat{h} = \frac{1}{S}\int_S h\, dS, \tag{2.11}$$

where S denotes the cross-sectional area. If we let $x\ (= x_1)$ denote distance down the pipe axis, then also

$$\widehat{\frac{\partial f_j}{\partial x_j}} = \frac{\partial \hat{f}_1}{\partial x} - \frac{1}{R}\langle f_n \rangle_w, \tag{2.12}$$

where $R = S/P$ is the hydraulic radius, P is the pipe perimeter, $f_n = \mathbf{f}.\mathbf{n}$ denotes the *inwards* normal component of $\mathbf{f}$ ($\mathbf{n}$ is the unit inward normal) and $\langle\ \rangle_w$ denotes the circumferential average,

$$\langle g \rangle_w = \frac{1}{P}\int_{\partial S} g\, ds. \tag{2.13}$$

We take a cross-sectional average of (2.10). We must have $\langle \bar{u}_n \rangle_w = 0$, thence $\partial \hat{\bar{u}}_1/\partial x = 0$; i.e., the mean flow is

$$\hat{\bar{u}}_1 = u(t), \tag{2.14}$$

say, and thus, considering the x component only,

$$\rho \dot{u} = -\frac{\partial p}{\partial x} - F + \frac{\partial}{\partial x}(-\rho \widehat{\overline{u_1'^2}}), \tag{2.15}$$

where we write $\hat{\bar{p}} = p$, and

$$F = \frac{\mu}{R}\left\langle \frac{\partial \bar{u}_1}{\partial n} \right\rangle_w + \frac{1}{R}\langle -\rho \overline{u_1' u_n'} \rangle_w. \tag{2.16}$$

Strictly, the second term on the right-hand side of (2.16) can be neglected, since $u_i' = 0$ at the wall. However, it is more common to define the "wall" in (2.13) to lie just outside the laminar sublayer, so that although $\bar{\mathbf{u}} \approx 0$ there, we allow the Reynolds stresses $(-\rho \overline{u_1' u_j'})$ to be nonzero at the wall. (In particular, this allows us to deal with rough walls.) We follow this practice here.

In conditions of steady uniform flow, (2.16) defines the wall drag, and Figure 1 represents the observed variation of F with u. In laminar flow,

$$\left\langle \frac{\partial \bar{u}_1}{\partial n} \right\rangle_w = \frac{8u}{d}, \tag{2.17}$$

while Prandtl's mixing length theory for turbulent flow also leads to $\langle \partial \bar{u}_1/\partial n \rangle_w \propto u/d$, although with a different coefficient. We will suppose that (2.17) applies in both cases, partly for simplicity, and partly because the laminar contribution is small in turbulent flow, so that the inaccuracy of (2.17) in that case is inconsequential. (A more realistic prescription for $\langle \partial \bar{u}_1/\partial n \rangle_w$ would be $L(A)u/d$, but we will persevere with (2.17).)

Given our constitutive prescription (2.17) for $\langle \partial \bar{u}_1/\partial n \rangle_w$, we now define a fluctuation velocity

$$A = \frac{d}{8\mu}\langle -\rho \overline{u_1' u_n'} \rangle_w. \tag{2.18}$$

It follows from (2.16) and (2.17) that (since the hydraulic radius of a pipe is $d/4$)

$$F = \frac{8\mu}{dR}[u + A]. \tag{2.19}$$

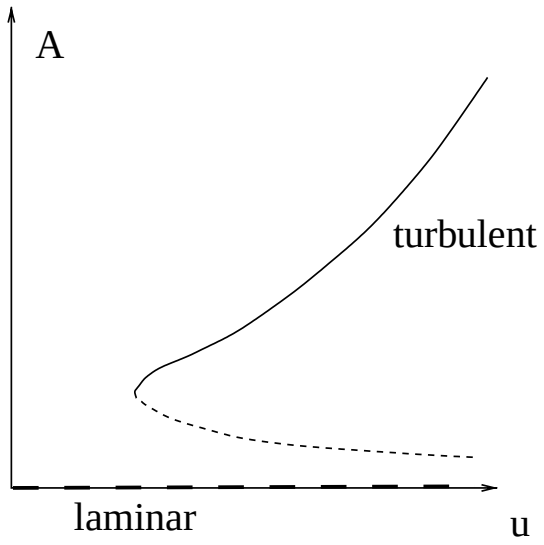

FIG. 2. *Diagram equivalent to Figure* 1 *for the postulated equilibrium, showing "amplitude" A versus flow rate u (or equivalently, Reynolds number).*

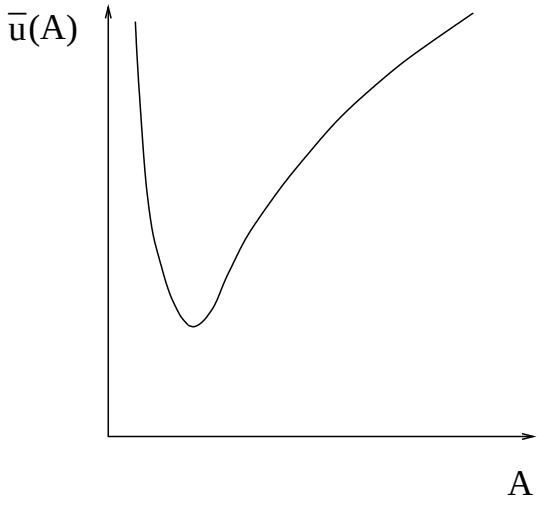

FIG. 3. *The function* $\bar{u}(A)$ *defined by reversing the axes in Figure* 2.

In terms of A, the equilibrium friction diagram Figure 1 now takes the form shown in Figure 2, and thus defines a single valued function $\bar{u}(A)$, such that in Figure 2, $u = \bar{u}(A)$ for $A \neq 0$, as shown in Figure 3.

The closure problem of turbulence is that of determining the Reynolds stresses $(-\rho\overline{u_i' u_j'})$. The idea of an eddy viscosity μ_T involves the closure assumption

$$-\rho\overline{u_i' u_j'} = \mu_T \left(\frac{\partial \bar{u}_i}{\partial x_j} + \frac{\partial \bar{u}_j}{\partial x_i} \right) - \frac{2}{3}\rho k \delta_{ij}, \tag{2.20}$$

where

$$k = \frac{1}{2}\overline{u_i' u_i'} \tag{2.21}$$

is the turbulent kinetic energy per unit mass. In unidirectional flows, Prandtl's mixing length hypothesis takes the form

$$\mu_T \propto \rho n^2 \left| \frac{\partial \bar{u}_1}{\partial n} \right|, \tag{2.22}$$

n representing distance from the wall. In a circular pipe, Schlichting (1979) shows that this empirical assumption actually leads to virtually perfect agreement with experimental measurements of wall drag. That is to say, in a steady uniform flow, F given by (2.16) together with an empirical assumption of eddy viscosity type for turbulent flow (and the equivalent exact molecular viscosity rule for laminar flow) is able to match the upper and lower branches in Figure 1 very well.

Prescription of (2.20) with (2.22) is an example of a zero-dimensional model closure. Such a closure is not good for three-dimensional flows, and this led to the development of more complicated "one-equation" or "two-equation" models. A typical example is the famous "k-ε" model (Mathieu and Scott (2000)), in which (2.20) is still used; one assumes (for example) that

$$\mu_T = \frac{Ck^2}{\varepsilon_D}, \tag{2.23}$$

where

$$\varepsilon_D = \frac{\mu}{2\rho} \overline{\left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i} \right) \left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i} \right)} \tag{2.24}$$

is the rate of dissipation of turbulent kinetic energy, and the model is closed by posing two evolution equations for k and ε_D (hence the term, two-equation model). In view of its similarity to the model we propose below, we give an example of a typical closure for k:

$$\frac{\partial k}{\partial t} + \bar{u}_k \frac{\partial k}{\partial x_k} = \Pi - \varepsilon_D + \frac{\partial}{\partial x_k} \left(\frac{\mu_T}{\sigma \rho} \frac{\partial k}{\partial x_k} \right); \tag{2.25}$$

Π is prescribed in terms of $\bar{u}$, σ is a constant. Note the basic type of advection-diffusion equation with source and sink terms.

In an analogous way, our purpose now is to consider how one might model slow time and space evolution of the fluctuation amplitude A. Derivation of an equation for A is not easy, nor is it our main purpose, and we will confine ourselves to providing a motivation for the form such an equation might take. We begin with the equations for the fluctuations u_i',

$$\frac{\partial u_i'}{\partial x_i} = 0,$$

$$\rho \left[\frac{\partial u_i'}{\partial t} + \frac{\partial}{\partial x_k} \{ \bar{u}_i u_k' + u_i' \bar{u}_k + u_i' u_k' - \overline{u_i' u_k'} \} \right] = -\frac{\partial p'}{\partial x_i} + \mu \nabla^2 u_i'. \tag{2.26}$$

Multiplying the second equation by u_j' and its u_j' equivalent by u_i', adding the two, and time averaging leads to the evolution equation for the Reynolds stress tensor

$$R_{ij} = -\rho\overline{u_i'u_j'} \tag{2.27}$$

in the form (see Launder, Reece, and Rodi (1975))

$$\begin{aligned}\frac{\partial R_{ij}}{\partial t} + \frac{\partial}{\partial x_k}[\bar{u}_k R_{ij}] = &-\left[R_{jk}\frac{\partial \bar{u}_i}{\partial x_k} + R_{ik}\frac{\partial \bar{u}_j}{\partial x_k}\right] + 2\mu\overline{\boldsymbol{\nabla} u_i' . \boldsymbol{\nabla} u_j'} - \overline{p'\left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i}\right)} \\ &+ \frac{\partial}{\partial x_k}(\rho\overline{u_i'u_j'u_k'}) + \frac{\partial}{\partial x_k}[\overline{p'(u_i'\delta_{jk} + u_j'\delta_{ik})}] + \frac{\mu}{\rho}\nabla^2 R_{ij}.\end{aligned} \tag{2.28}$$

Launder, Reece, and Rodi (1975) characterize the terms in this equation in the following way. Of the six terms on the right-hand side of (2.28), the first represents generation and the second, dissipation; the last three represent transport, while the fourth (pressure strain) term is characterized by a spatial integral of the fluctuating velocity field. To see this, we take the divergence of the Navier–Stokes equation to find

$$\nabla^2 p = -\rho\frac{\partial^2(u_i u_j)}{\partial x_i \partial x_j}, \tag{2.29}$$

whence the fluctuating pressure field p' satisfies

$$\nabla^2 p' = -\rho\frac{\partial^2}{\partial x_i \partial x_j}[\bar{u}_i u_j' + u_i'\bar{u}_j + u_i'u_j' - \overline{u_i'u_j'}], \tag{2.30}$$

and p' can be written as a spatial integral convolving a suitable Green's function with the right-hand side of (2.30).

From (2.18), $A = (d/8\mu)\langle R_{1n}\rangle_w$, and in the absence of swirling motion, $\langle g\rangle_w = g$ for any of the terms g in (2.28). Also, on the wall $\bar{u}_i = 0$, and $\partial\bar{u}_1/\partial n$ is the only nonvanishing velocity derivative term ($\partial\bar{u}_n/\partial n = -\partial\bar{u}_1/\partial x = 0$). Setting $i = 1$, $j = n$, a wall average leads to

$$\begin{aligned}&\frac{\partial}{\partial t}\langle -\rho\overline{u_1'u_n'}\rangle_w + \frac{\partial}{\partial x}\langle -\rho\overline{u_1'^2u_n'}\rangle_w \\ &\qquad = \langle\rho\overline{u_n'^2}\rangle_w\left\langle\frac{\partial\bar{u}_1}{\partial n}\right\rangle_w + 2\mu\langle\overline{\boldsymbol{\nabla} u_1' . \boldsymbol{\nabla} u_n'}\rangle_w \\ &\qquad\quad - \left\langle\frac{\partial}{\partial n}(-\rho\overline{u_1'u_n'^2}) - \overline{u_1'\frac{\partial p'}{\partial n}} + \overline{p'\frac{\partial u_1'}{\partial n}} + \frac{\mu}{\rho}\frac{\partial^2}{\partial n^2}(-\rho\overline{u_1'u_n'})\right\rangle_w \\ &\qquad\quad + \frac{\partial}{\partial x}\left\langle\overline{p'u_n'}\right\rangle_w + \frac{\mu}{\rho}\frac{\partial^2}{\partial x^2}\langle -\rho\overline{u_1'u_n'}\rangle_w.\end{aligned} \tag{2.31}$$

It is not so easy to characterize the nature of the terms in (2.31) as we did for (2.28), because some of the transport terms in (2.28) involving normal derivatives can no longer be so categorized. Such terms, together with the pressure strain terms, form the third term on the right-hand side of (2.31). The other terms have direct analogy with those in (2.28). The second term on the left-hand side of (2.31) is a transport term and arises from the fourth term on the right-hand side of (2.28). The first and second terms on the right-hand side of (2.31) are source and sink terms, arising from the corresponding generation and dissipation terms in (2.28). The final two terms in (2.31) are transport terms.

2.3. Closure assumptions. We now face the daunting task of choosing constitutive laws for the various terms in (2.31). In choosing an eddy viscosity model, we specifically supposed (cf. (2.20))

$$\langle -\rho\overline{u_1' u_n'}\rangle_w = \mu_T \left(\frac{\partial \bar{u}_1}{\partial n} + \frac{\partial \bar{u}_n}{\partial x} \right)\Bigg|_w , \tag{2.32}$$

where μ_T itself depends on $\bar{u}_1$. In uniform flow ($\partial/\partial t = \partial/\partial x = 0$), this subsequently leads via Prandtl's mixing length theory to a functional relation between u and A. Given that we suppose u and A to be defined via (2.17) and (2.18), that is,

$$u = \frac{d}{8}\left\langle \frac{\partial \bar{u}_1}{\partial n} \right\rangle_w , \qquad A = \frac{d}{8\mu}\langle -\rho\overline{u_1' u_n'}\rangle_w , \tag{2.33}$$

it is natural to relate fluctuating terms in (2.31) to A, and terms in $\bar{u}_1$ to u. Furthermore, if we neglect $\partial/\partial t$ and $\partial/\partial x$, we should regain the equilibrium curve (with $A > 0$) of Figure 2, which we will suppose is written in the form $u = \bar{u}(A)$. At this point, we specifically ignore the problem of constituting the pressure fluctuation terms. As discussed above, we expect such terms to give rise to convolution integrals, but their omission will clarify the subsequent discussion without compromising the results. The above comments suggest (given (2.33)) that we choose

$$\begin{aligned} \langle \rho\overline{u_n'^2}\rangle_w \left\langle \frac{\partial \bar{u}_1}{\partial n} \right\rangle_w - \left\langle \frac{\partial}{\partial n}(-\rho\overline{u_1' u_n'^2}) - 2\mu\overline{\boldsymbol{\nabla} u_1' . \boldsymbol{\nabla} u_n'} + \frac{\mu}{\rho}\frac{\partial^2}{\partial n^2}(-\rho\overline{u_1' u_n'}) \right\rangle_w \\ = \frac{8\mu}{d} r(A)[u - \bar{u}(A)], \end{aligned} \tag{2.34}$$

where

$$r(A) = \frac{1}{\mu}\langle \rho\overline{u_n'^2}\rangle_w \tag{2.35}$$

is a positive function, with $dr/dA > 0$ and $r = 0$ when $A = 0$. The last term in (2.31) is a laminar diffusion term,

$$\frac{\mu}{\rho}\frac{\partial^2}{\partial x^2}\langle -\rho\overline{u_1' u_n'}\rangle_w = \frac{\mu}{\rho}.\frac{8\mu}{d}\frac{\partial^2 A}{\partial x^2}, \tag{2.36}$$

and it is plausible to expect an equivalent turbulent diffusive term to exist also.

There are two ingredients that we might expect to find in $\langle -\rho\overline{u_1'^2 u_n'}\rangle_w$. If we follow the (apparently arbitrary) recipe (2.32), which relates $\langle\overline{u_1' u_n'}\rangle_w$ to $\partial\bar{u}_1/\partial n$ and $\partial\bar{u}_n/\partial x$, we would equivalently write

$$\langle\overline{(-\rho u_1' u_n')u_1'}\rangle_w = -\frac{\mu_T}{\rho}\frac{\partial}{\partial x}\langle -\rho\overline{u_1' u_n'}\rangle_w + \cdots , \tag{2.37}$$

but also

$$\langle -\rho\overline{u_1'^2 u_n'}\rangle_w = \mu_T \frac{\partial}{\partial n}\langle\overline{u_1'^2}\rangle_w + \cdots . \tag{2.38}$$

The simplest choice is then

$$\langle -\rho\overline{u_1'^2 u_n'}\rangle_w = \frac{\mu_T}{\rho}\frac{\partial}{\partial x}\langle -\rho\overline{u_1' u_n'}\rangle_w + \mu_T\frac{\partial}{\partial n}\langle\overline{u_1'^2}\rangle_w . \tag{2.39}$$

Finally, it seems reasonable to propose

$$\mu_T \frac{\partial}{\partial n}\langle\overline{u_1'^2}\rangle_w = \frac{8\mu}{d}W(A,u), \tag{2.40}$$

with $W \geq 0$ as we expect $\partial\overline{u'^2}/\partial n$ to be positive at the wall: as for $r(A)$, we expect $W = 0$ when $A = 0$ and $\partial W/\partial A > 0$.

Multiplying (2.31) by $d/8\mu$, we have (ignoring the pressure fluctuation terms)

$$\begin{aligned}\frac{\partial A}{\partial t} + \frac{\partial}{\partial x}\left[-\frac{\mu_T}{\rho}\frac{\partial A}{\partial x} + W(A,u)\right]\\ = r(A)[u - \bar{u}(A)] + \frac{\mu}{\rho}\frac{\partial^2 A}{\partial x^2}.\end{aligned} \tag{2.41}$$

The functions $W(A,u)$ and $r(A)$ in (2.41) are matters of conjecture. To be specific, we now define

$$U = \frac{\partial W}{\partial A} = \frac{\partial\left[\mu_T \frac{\partial}{\partial n}\langle\overline{u_1'^2}\rangle_w\right]}{\partial\langle-\rho\overline{u_1' u_n'}\rangle_w}, \tag{2.42}$$

so that $U > 0$ is an advection velocity. If we define

$$D = \frac{(\mu + \mu_T)}{\rho} \tag{2.43}$$

in (2.41), then our simple model for A is

$$A_t + UA_x = r[u - \bar{u}(A)] + (DA_x)_x, \tag{2.44}$$

where $\bar{u}(A)$ indicates the single valued equilibrium curve with $A \neq 0$ in Figure 2. This equation represents the idea that A evolves with time while the fluid is advected, seeking the equilibria in Figure 2. The principal difference that a more detailed prescription might make would be the inclusion of integral terms in (2.44) corresponding to the pressure fluctuation terms which we have ignored.

We now discuss suitable choices for U, r, and D. It is generally thought that pipe Poiseuille flow is linearly stable at all Reynolds numbers (Drazin and Reid (1981)), although the smallest disturbance decay rates tend to zero as $Re \to \infty$. This will be the case here if $r\bar{u} \propto A$ and $r = o(A)$ as $A \to 0$. Experimental measurements (Wygnanski and Champagne (1973), Darbyshire and Mullin (1995)) are suggestive of an asymptotic relationship $\bar{u} \sim A^{-2}$ as $\bar{u} \to \infty$ (see Figure 4), and we will make this assumption here. It then follows that an appropriate choice for r is

$$r = kA^3. \tag{2.45}$$

Then (2.44) allows $A = 0$ to be linearly stable. An issue here concerns the measurement of experimental disturbance amplitudes. Darbyshire and Mullin (1995) indicate absolute amplitudes, whereas Wygnanski and Champagne's (1973) data (in Figure 4) apparently measures amplitude ratios. There are two points of observation to make. The first is that the data points at higher Re in Figure 4 will place the entire pipe flow in the inlet region, which jeopardizes the interpretation of the amplitude as a perturbation to fully developed flow. The other is that if the amplitude ratio did indeed decrease as weakly as suggested by Figure 4, then the absolute amplitude would

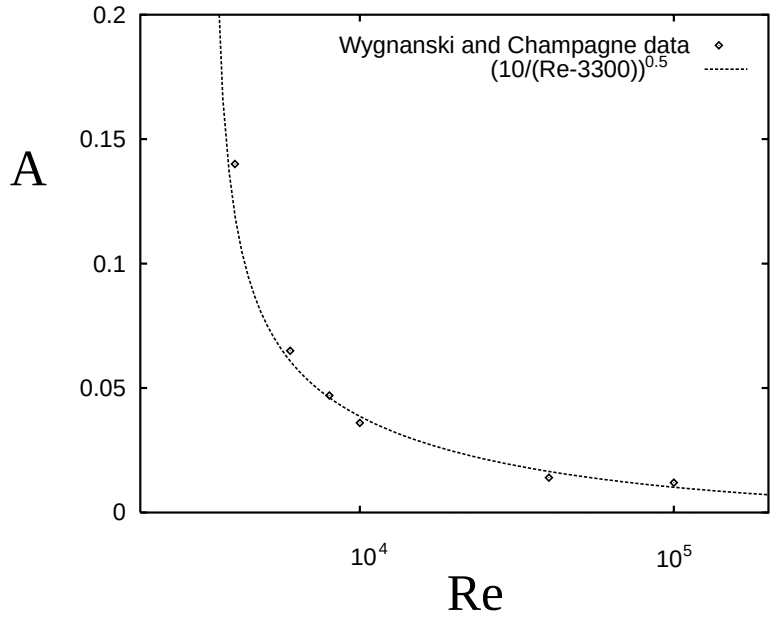

FIG. 4. *Data taken by hand from the lower threshold of the slug transition curve of Wygnanski and Champagne* (1973) *indicating threshold values of A (percent), together with the fitted curve* $A = \{10/(Re - 3300)\}^{1/2}$.

eventually increase with Re. This does not seem to be suggested by experiment, and is inconsistent with linear theory. We therefore hold to our interpretation of A in (2.44) as an absolute amplitude.

The constant k should represent the idea that the laminar-turbulent transition is associated with a rapid inviscid three-dimensional instability of slowly decaying two-dimensional disturbances (Orszag and Patera (1980)). This suggests that $t \sim d/u \sim 1/kA^2u$, and it is thus suitable to choose (for example)

$$k = \frac{1}{[A]^2 d}\,, \tag{2.46}$$

where $[A]$ is a representative value of A near transition.

The amplitude equation (2.44) is then in fact, when $A \ll u$, exactly that which can be derived using multiple scale methods (Davey and Nguyen (1971)), although the correctness of such equations is in doubt (Itoh (1977), Davey (1978)). However, it does seem likely that some such unstable solution branch bifurcates from infinity, as is suggested by the work of Rosenblat and Davis (1979) and Smith and Bodonyi (1982). We do not claim that (2.44) represents the last word in modelling slowly varying fluctuations, but its form is consistent with what is known about pipe flow. As a model, it serves the same purpose as Burgers's (1948) model, and indeed it bears some resemblance, although Burgers's model was more concerned with cross-stream transport of energy. The model (2.44) is also analogous (and serves a similar purpose) to the Swift–Hohenberg-type amplitude model, which has been used by some authors with a purpose similar to that of the present paper (Sakaguchi and Brand (1996), Deissler (1987a)).

The diffusion coefficient D in (2.43) has two parts representative of a laminar

and a (larger) turbulent diffusivity, and so we take $D \sim ud$ to represent the latter quantity. However, we should also allow D to depend on A, since when A is small, D is represented by molecular viscosity. We will find that the diffusive term allows for the existence of convectively growing slugs (Bohr and Rand (1991), Deissler (1987b)), with front and rear ends which travel respectively faster and slower than the mean flow, as is observed in practice.

The choice of a suitable advection velocity U is less clear. Most simply, we would take $U = u$, the mean flow. However, for marginally stable modes at high Re, the relevant linear stability advection velocity (Drazin and Reid (1981)) is less than u, and we therefore allow U to be less than u and to depend on A.

2.4. A model for intermittency. We can then provide a putative model for intermittent turbulent flow as follows. For an incompressible (thus $u = u(t)$) fluid flow subject to a mean pressure gradient F_m in a pipe $0 < x < l$, we solve

$$A_t + UA_x = kA^3[u - \bar{u}(A)] + (DA_x)_x. \tag{2.47}$$

In (2.15) we neglect the term $\frac{\partial}{\partial x}(-\rho\widehat{\overline{u_1'^2}})$, partly because we expect it to be small and partly because the natural constitution of $\overline{u_1'^2} \propto u^2$ leads to its absence, since $u = u(t)$. Then u and p satisfy

$$\begin{aligned} \rho\dot{u} &= -p_x - F, \\ \int_0^l -p_x\,dx &= F_m l, \end{aligned} \tag{2.48}$$

which together imply (using the definition of F in (2.19))

$$\rho\dot{u} = F_m - \frac{32\mu}{d^2}\left[u + \frac{1}{l}\int_0^l A\,dx\right]. \tag{2.49}$$

Deissler (1987b) has suggested that if F_m is prescribed, then the pressure drop feedback (i.e., (2.49)) may cause intermittency; we will seek to establish this suggestion here.

The pair of equations (2.47) and (2.49) require two boundary conditions for A (as well as initial conditions for A and u). A primary observation of transition in pipe flow ever since the experiments of Reynolds (1883) is that the level of inlet disturbance is instrumental in determining the nature of the flow. Therefore we prescribe

$$A = A_0 \quad \text{at } x = 0, \tag{2.50}$$

and we expect that the value of A_0 will be important in determining the dynamics of the flow.

The outlet condition is required only if the diffusion term is included, and, in order to exclude physically inappropriate boundary layers at the channel outlet, we prescribe the passive condition

$$A_x = 0 \quad \text{at } x = l \tag{2.51}$$

there.

2.5. Nondimensionalization. We choose scales $[F]$, $[A]$, $[u]$, $[t]$, $[x]$ as follows: $[F]$ is chosen as the critical value $F_c = 32\mu u_c/d^2$ in Figure 1, where the laminar flow can become unstable to turbulent bursts, and $[u] = u_c$ is the corresponding mean flow. Then we choose $[A] = [u]$, $[t] = \rho[u]/[F]$, and $[x] = [u][t]$; the advection velocity U is scaled with $[u]$. We then find that

$$[x] = \frac{d}{\varepsilon}, \tag{2.52}$$

where

$$\varepsilon = \frac{32}{[Re]}, \tag{2.53}$$

and the Reynolds number scale is

$$[Re] = \frac{\rho[u]d}{\mu}; \tag{2.54}$$

since $\varepsilon \ll 1$ ($\varepsilon \approx 0.015$ for $[Re] = 2300$), we see that $[x] \gg d$. The scale $[x]$, in fact, describes the inlet region of the pipe (Goldstein (1938, pp. 299f.)). The dimensionless model becomes (using the same notation for the dimensionless variables)

$$\begin{aligned} \varepsilon[A_t + UA_x] &= A^3[u - \bar{u}(A)] + \varepsilon^2(\kappa A_x)_x, \\ \dot{u} &= F^* - u - \frac{1}{L}\int_0^L A\,dx, \end{aligned} \tag{2.55}$$

where the dimensionless parameters are

$$L = \frac{\varepsilon l}{d}, \quad \kappa = \frac{D}{d[u]}, \quad F^* = \frac{F_m}{F_c}, \tag{2.56}$$

and, in keeping with (2.46), we have defined

$$k = \frac{1}{u_c^2 d}. \tag{2.57}$$

The dimensionless drag F is given for laminar flow by $F = u$, and Blasius's law for turbulent flow (2.6) is

$$F \approx \frac{[Re]^{3/4}}{200}u^{7/4} \approx 1.66\,u^{7/4} \tag{2.58}$$

for $u \gtrsim 1$, where the Reynolds number scale is taken to be 2300, by choice of $[u]$. This yields

$$A \approx 1.66\,u^{7/4} - u \quad \text{for} \quad u \gtrsim 1 \tag{2.59}$$

for the upper part of the curve in Figure 2. Over the range $1 \lesssim u \lesssim 4$, corresponding to Reynolds numbers up to 10^4, (2.59) is well approximated by $A \approx u^2 - \frac{1}{4}u$, i.e., $u \approx \frac{1}{8} + (A + \frac{1}{64})^{1/2}$ for $0.75 \lesssim A \lesssim 15$, and this in turn is well approximated by $u \approx 0.7 + 0.6\,A^{0.64}$. Our choice for $\bar{u}(A)$ is thus motivated by this expression, with an extra term $\propto 1/A^2$ added (in order to provide the unstable branch in Figure 2, and to

ensure linear decay at small A), with a coefficient δ chosen so that $\bar{u}$ has a minimum at $\bar{u} = 1$. Thus, we choose

$$\bar{u}(A) = a + bA^s + \frac{\delta}{A^2}, \tag{2.60}$$

and the values of the parameters motivated by the above discussion are

$$a = 0.7, \quad b = 0.6, \quad s = 0.64, \quad \delta = 0.0035. \tag{2.61}$$

It is a happy fact that the resulting decay rate of small disturbances $A \ll 1$ is $\dot{A}/A \approx -\delta$, which corresponds to the slow viscous decay rate ($\delta \sim \varepsilon \approx 0.014$), as is appropriate. Figure 16.3 of Schlichting (1979) indicates that a natural pipe length scale over which the intermittency factor γ grows is $l/d \sim 300$. For such pipe lengths (in a 1 cm diameter pipe this is $l = 3$ m), $L \approx 4.5$, so that values of $L \gtrsim 1$ are appropriate.

The choice of the advection velocity U and the diffusivity κ are as follows. For turbulent flow, we expect $\mu_T \sim \rho[u]d$; hence (2.43) implies $\kappa \sim 1$, but for small A it should be $O(\varepsilon)$, corresponding to the laminar viscosity term. The simplest choice compatible with these criteria is

$$\kappa = A + \varepsilon, \tag{2.62}$$

although in our numerical illustrations we will be content with the choice $\kappa = 1$. For the advection velocity, the choice $U = u$ corresponds to the mean flow. We define

$$U = u - V(A) \tag{2.63}$$

and will find that the corrective term to the mean flow allows us to include a realistic description of puffs within this simple theory, providing $V > 0$, as we expect.

3. Analysis.

3.1. Constant velocity.

We begin our analysis of (2.55) by supposing that the inlet velocity u is constant. We write the amplitude equation in the form

$$\varepsilon(A_t + UA_x) = f(A; u) + \varepsilon^2(\kappa A_x)_x, \tag{3.1}$$

where $U = u - V(A)$, $\kappa = A + \varepsilon$, and

$$f(A; u) = (u - a)A^3 - bA^{3+s} - \delta A. \tag{3.2}$$

The form of slugs. Clearly, A evolves locally over a rapid time scale of $O(\varepsilon)$ to a steady state of (3.1), i.e., to $A = 0$ (laminar) or to the stable (turbulent) branch of $u = \bar{u}(A)$ (see Figure 2). As shown in Figure 5, f is pseudocubic, and for $u > 1$ (the minimum value of $\bar{u}(A)$, corresponding here to $Re = 2300$) there are three roots of f: $A = 0$ and the stable and unstable branches, which are defined to be $A = A_m(u)$ and $A_M(u)$, respectively.

We change coordinates to the local moving frame coordinates (X, T) given by

$$x = ut + \varepsilon X, \quad t = \varepsilon T, \tag{3.3}$$

whence (3.1) becomes

$$A_T - V(A)A_X = f(A) + \{\kappa(A)A_X\}_X. \tag{3.4}$$

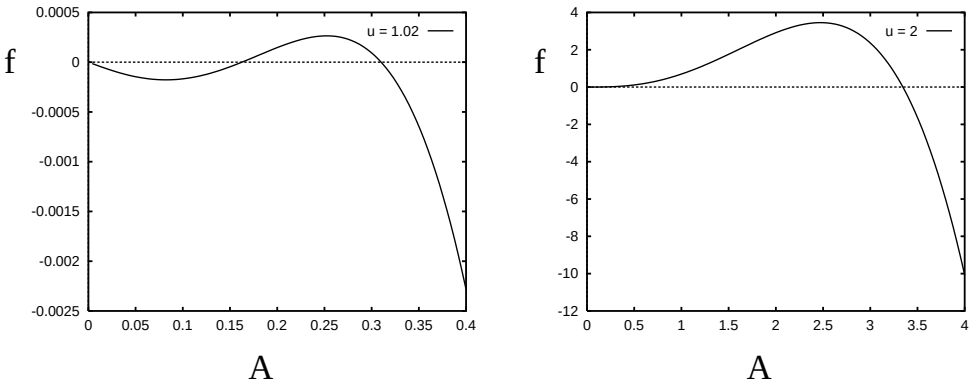

FIG. 5. *The function $f(A,u)$ for $u = 1.02$ and $u = 2$. Note the different vertical and horizontal scales.*

It is well known from reaction-diffusion theory (Murray 1993) that a local perturbation $A > A_m$ will evolve to a slug within which $A = A_M$, and the front and rear move *outward* at speeds v_+ and v_-, respectively, given by

$$v_\pm = \frac{\int_0^{A_M} \kappa(A) f(A)\,dA \mp \int_{-\infty}^{\infty} \kappa(A) V(A) A'^2\,dz}{\int_{-\infty}^{\infty} \kappa(A) A'^2\,dz}, \tag{3.5}$$

where $A(z)$ is the wave front solution of

$$-v_\pm A' \mp V(A)A' = f(A) + \{\kappa(A)A'\}', \tag{3.6}$$

together with

$$\begin{aligned} A &\to A_M \quad \text{as} \quad z \to -\infty, \\ A &\to 0 \qquad \text{as} \quad z \to +\infty. \end{aligned} \tag{3.7}$$

Note that the two wave front profiles are different if $V \neq 0$ (and then $v_+ \neq v_-$). The coordinate $z = \pm X - v_\pm T$ is the wave front variable. From (2.30), we define the front and rear slug boundary speeds u_f and u_r as

$$\begin{aligned} u_f &= u + v_+, \\ u_r &= u - v_-. \end{aligned} \tag{3.8}$$

If $V = 0$, so that the wave profiles are symmetric, then $v_+ = v_-$ and the mean slug speed is that of the mean flow; however, this is not observed.

The data in Figure 7 of Wygnanski and Champagne (1973), and in Figure 4.15 of Lindgren (1957), can be used to constrain, to some extent, our choices for $\kappa(A)$ and, particularly, $V(A)$. First, note that if $v_+ + v_- < 0$, then slugs contract and are not viable. If V is small, then this occurs if $\int_0^{A_M} \kappa(A) f(A)\,dA < 0$. We can see from the form of Figure 5 that there will be a critical value of $u = u^* > 1$ where $\int_0^{A_M(u^*)} \kappa(A) f(A;u^*)\,dA = 0$, so that slugs are only viable if $u > u^*$. For $V \neq 0$, we can expect u^* to depend on V. In Wygnanski and Champagne's data, the corresponding Reynolds number is 2700, whence $u^* \approx 1.17$ (based on a Reynolds number scale of 2300). This is also the minimum value for which Lindgren provides identifiable slug data. For $u > u^*$, the data indicate that u_f/u and u_r/u are functions

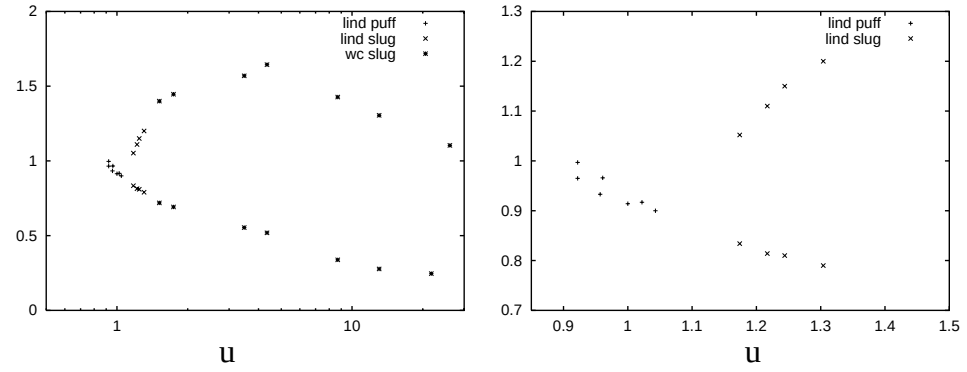

FIG. 6. *Estimates for the relative front and rear speeds u_f/u and u_r/u, redrawn from the data of Wygnanski and Champagne* (1973) *and Lindgren* (1957). *On the right is a close-up of (some of) Lindgren's data.*

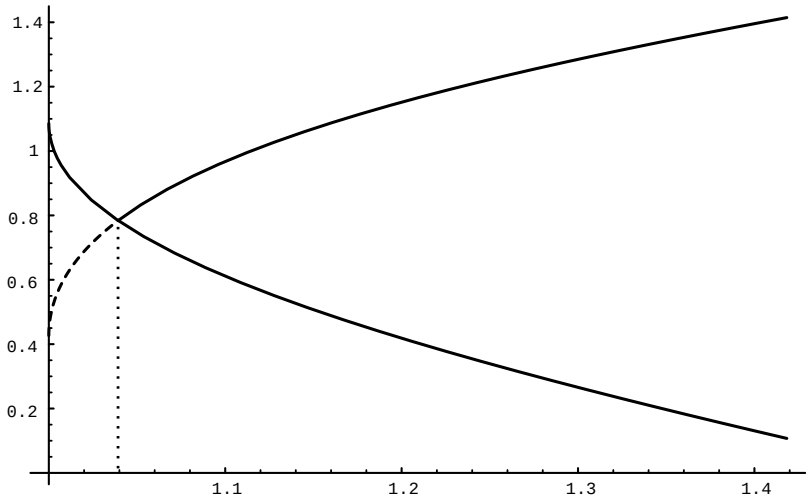

FIG. 7. *Front and rear relative wave speeds u_f/u and u_r/u, as a function of u. The parameter values used are $b = 0.6$, $s = 0.64$, and $\delta = 0.1$, with the drift velocity $V(A)$ being taken as $V = 0.4A$ and the diffusivity $\kappa = 1$. The critical value at which the two speeds coalesce is approximately* 1.04 *in this case, and the critical relative speed is about* 0.8. *With* $[Re] = 2300$, *this corresponds to a value of R_k (in Lindgren's* (1957) *notation) of* 2392.

of u, as shown in Figure 6; they appear to coalesce when $Re = R_k \approx 2400$, at a value of about 0.9. We have solved the travelling wave equation numerically, to reproduce data equivalent to that shown in Figure 6. Figure 7 shows the results of these calculations; they are in good qualitative agreement with Lindgren's (1957) results.

A feature of a slug is its sharp interface. In the travelling wave solutions of (3.6), this sharpness is represented both by the short wavelength ε (corresponding to a tube diameter) and also by the fact that (approximately) $\kappa \to 0$ as $A \to 0$; the diffusivity is degenerate and this causes A to reach (approximately) zero in a finite distance.

It is straightforward to compute the value of u^* (if $V = 0$) explicitly from the

expression (3.2) for f. We suppose $\kappa = A$, so that A_M and u^* are determined from

$$\begin{aligned} &(u-a)A^3 - bA^{3+s} - \delta A = 0, \\ &\frac{(u-a)}{5}A^5 - \frac{b}{5+s}A^{5+s} - \frac{\delta A^3}{3} = 0; \end{aligned} \tag{3.9}$$

from these we find

$$\begin{aligned} A_M &= \left[\frac{2\delta(5+s)}{3sb}\right]^{\frac{1}{2+s}}, \\ u^* &= a + 5(2+s)\left(\frac{\delta}{3s}\right)^{\frac{s}{2+s}}\left(\frac{b}{2(5+s)}\right)^{\frac{2}{2+s}}, \end{aligned} \tag{3.10}$$

and for the numerical values given in (2.61), we find $u^* \approx 1.01$, $A_M \approx 0.28$.

In this theory, u^* is the critical velocity required for slug propagation. Because $\delta \ll 1$, we see that, for $u > u^*$, the unstable zero A_m of f is approximately given by

$$A_m \approx \left(\frac{\delta}{u-a}\right)^{1/2}. \tag{3.11}$$

Note the similarity to the fitted curve in Figure 4. Thus small amplitude disturbances of $O(\delta^{1/2})$ spontaneously generate slugs, which grow as they propagate.

The form of puffs. When $u < u^*$, slugs cannot be maintained. In this case, large disturbances will cause puffs to propagate. These migrate slowly backwards relative to the mean flow, with a sharp trailing edge and a diffuse advancing boundary. In order to explain their characteristics, we observe first that when $u < u^*$, then f is small and A_M is as well (see Figure 5). In fact, (3.10) suggests that we write

$$A = \delta^{\frac{1}{2+s}}\alpha, \quad u - a = \delta^{\frac{s}{2+s}}w \tag{3.12}$$

in this case, and then

$$\begin{aligned} f(A,u) &= \delta^{\frac{3+s}{2+s}}F(\alpha,w), \\ F &= w\alpha^3 - b\alpha^{3+s} - \alpha, \end{aligned} \tag{3.13}$$

and (3.4) is

$$\alpha_T - V[\delta^{\frac{1}{2+s}}\alpha]\alpha_X = \delta F(\alpha,w) + \{\kappa[\delta^{\frac{1}{2+s}}\alpha]\alpha_X\}_X. \tag{3.14}$$

Now let us suppose, for example, that $V(A) = cA$ (as in Figure 7), $\kappa(A) \approx A$. If we define the slow time scale τ by

$$T = \frac{\tau}{\delta^{\frac{1}{2+s}}}, \tag{3.15}$$

then α satisfies the approximate equation

$$\alpha_\tau - c\alpha\alpha_X = (\alpha\alpha_X)_X + \delta^{\frac{1+s}{2+s}}F(\alpha;w), \tag{3.16}$$

which is, to leading order, a degenerate nonlinear diffusion equation of Burgers type.

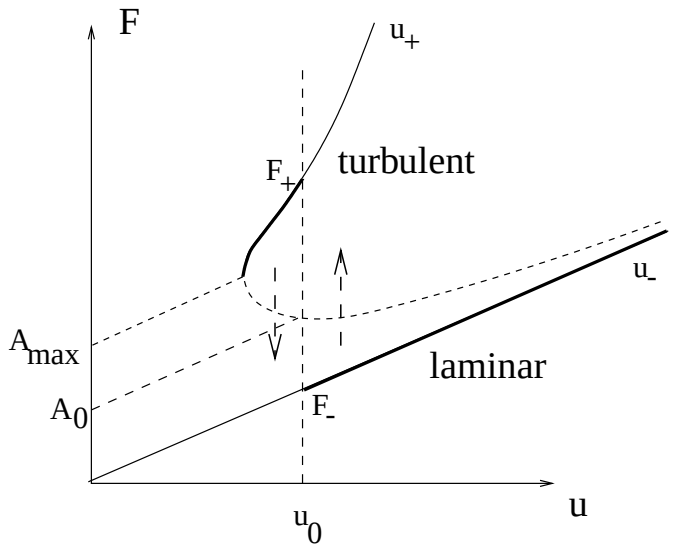

FIG. 8. *Diagrammatic representation of intermittency. The inlet disturbance amplitude A_0 determines a threshold velocity u_0 on the unstable branch, such that the turbulent branch is stable for $u > u_0$ and the laminar branch is stable for $u < u_0$, as indicated by the arrows. If the prescribed pressure drop F^* lies between the corresponding intersection values $F_\pm$ of $u = u_0$ with the turbulent and laminar branches, then an intermittent flow will ensue.*

Solutions behave as follows. Let $\alpha_m = O(1)$ denote the lower positive zero of F in (3.13). For prolonged perturbations to A in excess of $\delta^{\frac{1}{2+s}}\alpha_m$, a puff will form. The turbulent flow within the puff will be locally stable, but will eventually disappear by wastage of the profile. However, before this happens, the disturbance amplitude α will evolve over a time scale $\tau \sim 1$, i.e., $T \sim 1/\delta^{\frac{1}{2+s}}$, according to

$$\alpha_\tau - c\alpha\alpha_X = (\alpha\alpha_X)_X, \tag{3.17}$$

and thus into a profile with a sharp upstream (shock) profile and a diffuse downstream profile. The speed of the upstream front, relative to the mean velocity, is negative and of order $dX/dT \sim \delta^{\frac{1}{2+s}}$. All of these features are consistent with puffs. In particular, note that the necessary disturbance amplitude is $O(\delta^{\frac{1}{2+s}})$, as opposed to the smaller threshold $O(\delta^{1/2})$ for slugs. The formation of a backward propagating puff relative to the mean flow relies on the sign of V being positive. If this is the case, then the simple theory based on (3.4) is sufficient to explain many of the pertinent facts concerning slugs and puffs.

3.2. A mechanism for intermittency. The above discussion indicates that the amplitude evolution equation (3.1) can explain both artificially generated slugs and puffs if the flow rate is constant. In order to explain how intermittency can arise spontaneously, we must return to the pressure driven flow model given by (2.55).

Suppose that the inlet disturbance level is $A = A_0$. Since f is an increasing function of u, there is a unique value $u = u_0$ for which $A_m(u_0) = A_0$. Suppose that $u < u_0$. Then $A \to 0$ in $x > 0$ (see Figure 8), and (eventually) $u \to F^*$ from (2.55). However, if $F^* > u_0$, then at some point u reaches u_0, and for $u > u_0$, $A \to A_M(u)$ near the inlet: a slug is generated. Again (eventually) u tends to the positive root

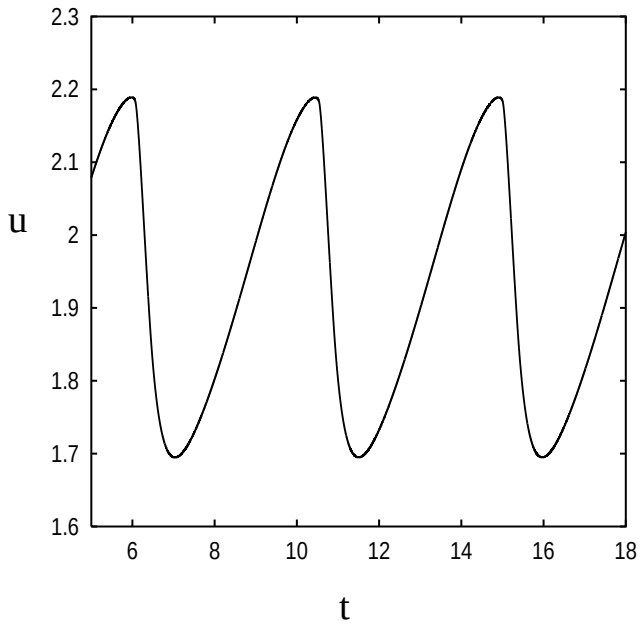

FIG. 9. *Mean velocity fluctuations in the solution of* (2.55). *The parameter values used are* $L = 4$, $A_0 = 0.3$, $\varepsilon = 0.05$, $\kappa(A) = 1$, $U(A,u) = u$, $a = 0.7$, $b = 0.6$, $s = 0.64$, $\delta = 0.1$, $F^* = 3$, $u(0) = 3.1$. *The space step was* 0.01, *and the time step was* 0.001.

of $F^* = u + A_M(u)$. (Note that this is simply the upper branch of the $F(u)$ curve in Figure 1.) But if the corresponding value of $u < u_0$, then again A decreases towards zero (a slug is terminated). It is fairly clear that this sequence will continue to oscillate, and also that the dependence of u on the spatial integral of A will cause a finite sequence of slugs to propagate downstream. The intermittency factor γ of Rotta (1956) will increase with x due to the spreading of the slugs.

Figure 8 illustrates this description graphically. Observe that the preceding paragraph indicates that $u \to u_-(F^*)$ if $u < u_0(A_0)$ and $u \to u_+(F^*)$ if $u > u_0(A_0)$, where $u_\pm(F^*)$ are the turbulent and laminar branches of Figure 8. Thus, intermittency should occur, given F^* and A_0, if

$$u_+(F^*) < u_0(A_0) < u_-(F^*) \tag{3.18}$$

in Figure 8. This depends on both the prescribed pressure drop F^* *and* the inlet disturbance amplitude A_0. The level curves of A $(= F - u)$ are simply lines parallel to the laminar branch u_-. Furthermore, $u_0(A_0)$ is simply the unstable branch of the $\bar{u}(A)$ curve. Thus, given A_0, we determine u_0 as the value of u at which the line $F = u + A_0$ intersects the unstable branch in Figure 8. So long as $A_0 < A_{\max}$ (the value of $F - u$ at the nose of the curve), the value u_0 defines two values F_+ and F_- on the stable turbulent and laminar branches, respectively. Intermittency then occurs if

$$F_- < F^* < F_+, \tag{3.19}$$

which is equivalent to (3.18).

Numerical results. We have solved the system (2.55) numerically, taking $U = u$ and $\kappa = 1$. Figure 9 shows the resulting periodic variations in the mean velocity. This

figure can be favorably compared with Figure 19 of Prandtl and Tietjens (1934). We have not had to tune the model, and so we believe this behavior to be robust. The choice of functions U and κ is immaterial to the phenomenon of intermittency; the advection U affects the specific form of puffs, while we avoid the degenerate $\kappa = A$ in order to avoid numerical awkwardness at slug boundaries. Similarly we choose a relatively high value of ε (0.05) (and hence also δ) in order to avoid the demands of excessively small space steps.

Figure 10 shows the space-time evolution of $A(x,t)$ for the same parameter values as used in Figure 9. After an initial transient, a periodic sequence of slugs is generated at some distance from the inlet and propagates downstream towards the outlet.

4. Discussion. Our primary purpose in this paper was to develop a simple model which could predict the intermittent transition to turbulence which is seen in pipe flow, and we have shown that this can be done using the observed fact that there is a sudden increase in friction at the onset of turbulent flow. We associate this with a hysteretic transition between laminar and turbulent states, characterized by a turbulent fluctuation amplitude A. We have then used the observed drag law to build the simplest evolution equation for A that is consistent with both the drag law and an inferred linear stability at small amplitudes. We have also shown that this form of amplitude equation is consistent with a one-equation closure of the time-averaged Navier–Stokes equations resembling those of R_{ij}-ε type (Launder, Reece, and Rodi (1975), Mathieu and Scott (2000)).

The inclusion of realistic diffusive and advective terms then allows us to describe, within the confines of this evolution equation model, phenomena which can be characterized as slugs or puffs, and we have shown that many of their peculiar features arise naturally from the simple ingredients of the model.

In this discussion, we wish to focus further on two particular experimental observations of the parameter ranges in which laminar, intermittent, or turbulent behavior occurs.

Lindgren (1957) identified four particular transition values of the Reynolds number, which he denoted as $\underline{R}$, R_k, $\overline{R}_k$, and $\overline{R}$. The value of $\underline{R}$ occurs when the first self-maintaining puffs are seen (i.e., with an identifiable tail velocity). In Lindgren's experiments, this value is about 2050. The value of R_k (about 2400) occurs when slugs are first seen (with identifiable fronts), and the value of $\overline{R}_k$ (about 2700) is where these become coherent, that is, they do not split as they propagate. Finally, $\overline{R}$ (about 3300?) denotes the onset of fully developed turbulence. The first three of these values correspond in Figure 6 to values $u \approx 0.9$, $u \approx 1.04$, and $u \approx 1.17$. In our model (cf. Figure 5) we can identify two critical values of u (and hence Re). Denoting the smaller and larger positive roots of (3.2) by $A_m(u)$ and $A_M(u)$, respectively, there is a critical value u_1 at which $A_m = A_M$, and a larger value u_2 for which the wave speeds v_+ and v_- given by (3.6) and (3.7) sum to zero. When V is small, $u_2 \approx u^*$, as discussed following (3.8), and explicit formulae for these critical values are

$$u_1 = a + (2+s)\left(\frac{\delta}{s}\right)^{\frac{s}{2+s}}\left(\frac{b}{2}\right)^{\frac{2}{2+s}},$$

$$u_2 \approx u^* = a + 5(2+s)\left(\frac{\delta}{3s}\right)^{\frac{s}{2+s}}\left(\frac{b}{2(5+s)}\right)^{\frac{2}{2+s}}. \tag{4.1}$$

We identify the values of u_1 with $\underline{R}$, and u_2 with R_k. There is no mechanism in our model for slug splitting, and we cannot produce any equivalent for $\overline{R}_k$. Finally, the onset of fully developed turbulence at $\overline{R}$ necessarily must depend on the inlet

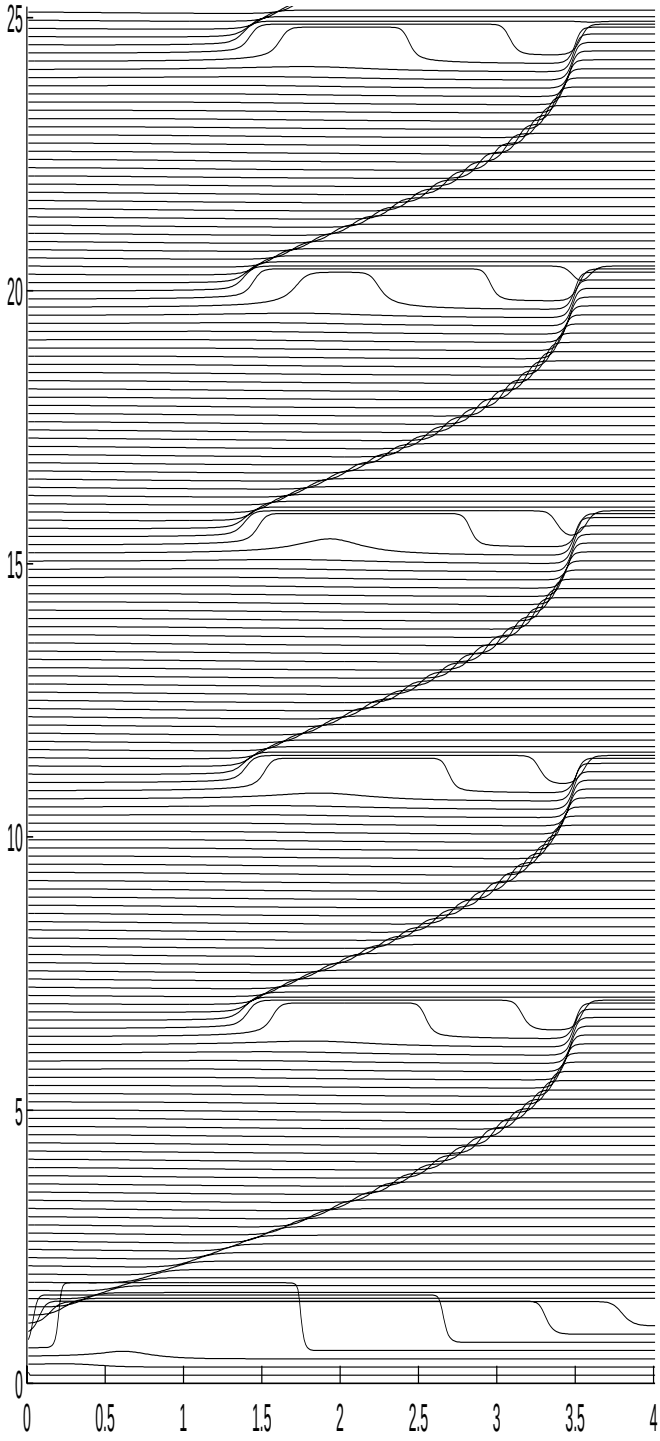

FIG. 10. *Space-time plot of $A(x,t)$, using the same parameters as in Figure 9. A sequence of slugs is generated midway down the pipe, each of which grows rapidly and then propagates down the pipe.*

disturbance amplitude level A_0 (since if this is zero, then the flow may be maintained as laminar indefinitely). In our model, this defines a third transition value u_4 (the missing u_3 would correspond to $\overline{R}_k$), such that $A_m(u_4) = A_0$, and thus

$$u_4 = a + \frac{\delta}{A_0^2} + bA_0^s. \tag{4.2}$$

This u_4 is a monotonically decreasing function of A_0 in the admissible range $0 < A < A_{\max}$, which is where $A_m = A_M$ and $u_4 = u_1$. Lindgren's apparent value of 3300 corresponds to $u_4 = 1.43$, and when A_0 is small, (3.11) applies, so that the inferred corresponding inlet disturbance amplitude is ≈ 0.02. It is also evident that, by adjusting the parameters b, a, s, and particularly δ, we could find reasonably accurate values for the predicted u_1 and u_2; such an exercise is rather alien to our present purpose, however.

The second comparison we want to make is to the amplitude-velocity transition curve in Figure 2 of Wygnanski and Champagne (1973). This figure plots inlet disturbance amplitude versus Reynolds number and delineates a laminar region from a fully turbulent region. The demarcation boundary essentially consists of two separate curves, between which the flow is intermittent. At high Re (and low A_0), slugs occur in the intermittent region, while at low Re (and high A_0), puffs occur. The slug and puff regions become "uncertain" around $Re = 2700$, corresponding in our model to the value $u = u_2$.

In our model, the critical inlet amplitude, which separates flows that can be fully laminar from those that can be fully turbulent, is $A_0 = A_m(u)$. However, whether fully developed turbulent or laminar flow can be obtained throughout the pipe depends on the applied pressure drop F^*, and it is appropriate to use this as the control variable. Denote the turbulent and laminar branches of the pressure drop curve as $F_T(u)$ and $F_L(u)$, these being given by (2.60) and $F_L = u$, respectively. Our predictions for the upper and lower transition curves in A_0-F^* space are then, for the upper curve,

$$\begin{aligned} F^* &= F_T(u), \\ A_0 &= A_m(u), \end{aligned} \tag{4.3}$$

and for the lower,

$$\begin{aligned} F^* &= F_L(u), \\ A_0 &= A_m(u). \end{aligned} \tag{4.4}$$

These curves are portrayed in Figure 11, and they show qualitative agreement with Wygnanski and Champagne's (1973) figure (bearing in mind that theirs is a log-linear plot). Indeed we have already seen (compare Figure 4 and (3.11)) that there is some quantitative resemblance also.

The fact that the very simple model used here compares so well with experimental observations is encouraging, but it must be pointed out that the guts of the process are entirely missing, that is to say, the generation of the turbulent chaotic eddies themselves. What we have shown is that some macroscopic features of the transition to turbulence in pipe flow can be understood more or less entirely through the well-founded postulate of a hysteretic transition between laminar and turbulent "states" of the fluid. Precisely what the turbulent state consists of is not addressed in this theory.

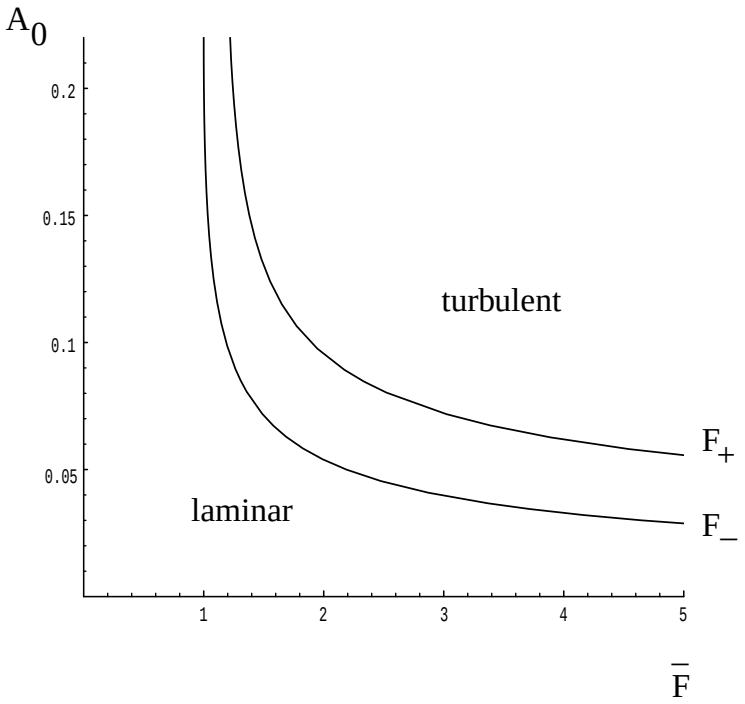

FIG. 11. *Parameter space of inlet disturbance A_0 versus applied pressure drop F^*, with $b = 0.6$, $s = 0.64$, $\delta = 0.0035$. Intermittency occurs for points between the two solid curves. Of these, the bottom is $F_- = a + bA_0^s + \delta/A_0^2$; the top is given by $F_+ = a + A_M + bA_0^s + \delta/A_0^2$, where A_M is the solution $> A_0$ of $bA_M^s + \delta/A_M^2 = bA_0^s + \delta/A_0^2$.*

WHITE NOISE ANALYSIS OF COUPLED LINEAR-NONLINEAR SYSTEMS*

DUANE Q. NYKAMP†

Abstract. We present an asymptotic analysis of two coupled linear-nonlinear systems. Through measuring first and second input-output statistics of the systems in response to white noise input, one can completely characterize the systems and their coupling. The proposed model is similar to a widely used phenomenological model of neurons in response to sensory stimulation and may be used to help characterize neural circuitry in sensory brain regions.

Key words. neural networks, correlations, Weiner analysis, white noise

1. Introduction.

Most electrophysiology data from intact mammalian brains is recorded using an extracellular electrode which remains outside the neurons. When the electrode is positioned near a neuron, it can record the neuron's output events, called spikes, because spike magnitudes are sufficiently large. The internal state of a neuron, including small fluctuations in response to its inputs, cannot be measured.

When only output spikes are measurable, one cannot directly measure the effect of a connection from one neuron to another. If neuron 1 is connected to neuron 2, then an output spike of neuron 1 will perturb the internal state of neuron 2. If the internal state cannot be measured, this perturbation can be inferred only via its effect on the spike times of neuron 2. In general, the spike times of a neuron will be a function of many inputs coming from many other neurons. This complexity makes reliable inferences on the structure of neuronal circuits from spike time data a formidable challenge.

Explicit mathematical models may lead to tools that can address this challenge. Through model analysis, one may develop methods to infer aspects of network structure from spike times, subject to the validity of the underlying model. In this paper, we derive a method for reconstructing the connectivity between two isolated neurons based on a simple linear-nonlinear model (see below) of neural response to white noise. Although this model greatly simplifies the reality of the brain's neural networks, the results from this analysis can be used to analyze neurophysiology data, provided that they are interpreted within the limitations of the model [12].

Numerous researchers have used white noise analysis to describe the response of neurons to a stimulus. The most common use of white noise analysis has been to analyze the response properties of single neurons [11, 4, 5, 8, 9, 2, 3, 16, 18, 7, 6]. Recently, researchers have begun to apply the techniques of white noise analysis to simultaneous measurements of multiple neurons [15, 1, 19], although without explicitly modeling neural connectivity. In [12], we showed how, in white noise experiments, interpretation of spike time data is especially difficult because standard correlation

measures confound stimulus and connectivity effects. We demonstrated correlation measures that remove the stimulus effects based on the linear-nonlinear model.

In this paper, we present the asymptotic analysis of the linear-nonlinear model that underlies the correlation measures of [12]. Subject to a first order approximation in the coupling magnitude, we derive a method to completely reconstruct the coupled system from first and second input-output statistics. As a consequence of this reconstruction, we obtain a correlation measure, which we call $\mathcal{W}$, that approximates the neuronal coupling.

Although the analysis below can be used for any pair of coupled linear-nonlinear systems, we refer to the systems as *neurons* since neuroscience was the motivation for this analysis and because this choice simplifies the description.

In section 2, we describe the linear-nonlinear model. In section 3, we derive expressions for the input-output statistics for the case when the neurons are uncoupled. We derive the corresponding expressions for the cases of unidirectional coupling in section 4 and generalize the results to mutual coupling in section 5. We demonstrate the method with simulations in section 6 and discuss the results in section 7.

2. The model. The standard model underlying most white noise analyses of neural function is the linear-nonlinear model of neural response to an input $\mathbf{X}$,

$$\Pr\big(R^i = 1 \big| \mathbf{X} = \mathbf{x}\big) = g(\mathbf{h}^i \cdot \mathbf{x}), \tag{2.1}$$

where the response R^i at discrete time point i is one if the neuron spiked, and zero otherwise. The neural response depends on the convolution of the kernel $\mathbf{h}$ with the stimulus. The stimulus $\mathbf{X}$ is a vector whose components represent the spatio-temporal sequence of stimulus values, such as the sequence of pixel values for each refresh of a computer monitor.

The neural response depends on the convolution of a stimulus with a kernel $\mathbf{h}$, normalized so that $|\mathbf{h}| = 1$. The kernel can be viewed as sliding along the stimulus with time; it represents the spatio-temporal stimulus features to which the neuron responds. We let $\mathbf{h}^i$ denote the kernel shifted for time point i and write the convolution of the kernel with the stimulus as the dot product $\mathbf{h}^i \cdot \mathbf{X}$ (implicitly viewing the temporal index of the stimulus as going backward in time). The function $g(\cdot)$ is the neuron's output nonlinearity (representing, for example, its spike generating mechanism). Although the linear-nonlinear system is only a phenomenological approximation of complex biology, it can be simply characterized by standard white noise analysis [13]. The ease of an explicit mathematical analysis is a prime motivation for choosing the linear-nonlinear model and white noise input.

We propose a model that augments the linear-nonlinear framework to include the effects of neural connections between two neurons. After neuron q spikes, the probability that neuron p spikes j time steps later is modified by the connectivity factor $\bar{W}^j_{qp}$. In a caricature of synaptic input acting at subthreshold levels (of the voltage, or internal state, of a neuron), the term $\bar{W}^j_{qp}$ is added underneath the nonlinearity so that

$$\Pr\big(R^i_p = 1 \big| \mathbf{X} = \mathbf{x}, \mathbf{R}_q = \mathbf{r}_q\big) = g_p\bigg(\mathbf{h}^i_p \cdot \mathbf{x} + \sum_{j \geq 0} \bar{W}^j_{qp} r^{i-j}_q\bigg), \tag{2.2}$$

where $p, q \in \{1, 2\}$ represent the index of the neurons, $q \neq p$, and $R^i_p \in \{0, 1\}$ is the response of neuron p at time i.[1]

[1] With the exceptions of W and T, we will use capital variables to denote random quantities. In addition, we will use subscripts to denote neuron index, and superscripts to denote temporal indices.

We assume that the output nonlinearity can be approximated as an error function

$$g_p(s) = \frac{\hat{r}_p}{2}\left[1 + \operatorname{erf}\left(\frac{s - \bar{T}_p}{\epsilon_p\sqrt{2}}\right)\right], \tag{2.3}$$

where $\hat{r}_p$ is the maximum firing rate, $\bar{T}_p$ is the threshold, ϵ_p defines the steepness of the nonlinearity, and $\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$. Note that $\lim_{x\to\infty} g_p(x) = \hat{r}_p$ and $\lim_{x\to-\infty} g_p(x) = 0$. The error function nonlinearity is assumed so that we can derive analytic results. As demonstrated in section 6, the results apply to more general nonlinearities.

So that the input $\mathbf{X}$ is a discrete approximation of temporal or spatio-temporal white noise, we let each of its n components be standard normal random variables. We do not explicitly distinguish spatial versus temporal components of the input in our notation because they are treated identically in the analysis. To keep the notation simple, time is represented only by the temporal index of the kernels $\mathbf{h}_p^i$ and the spikes R_p^i. With this convention, the probability density function of $\mathbf{X}$ is simply

$$\rho_{\mathbf{X}}(\mathbf{x}) = \frac{1}{(2\pi)^{n/2}} e^{-|\mathbf{x}|^2/2}. \tag{2.4}$$

In the next sections, we consider special cases of the coupling $\bar{W}$. For each case, we calculate the expected values of the responses $E\{R_p^i\}$, the "correlation"[2] between the stimulus and the spikes of each neuron $E\{\mathbf{X}R_p^i\}$, and the "correlation" between the spikes of the two neurons $E\{R_1^i R_2^{i-k}\}$. Since these statistics can be estimated when one can obtain only the spike times from the neurons, they are readily measurable in neurophysiology experiments. We base our reconstruction of the linear-nonlinear system of (2.2) on these input-output statistics. Most importantly, we will reconstruct the coupling terms $\bar{W}_{pq}^j$.

3. Uncoupled neurons. In this section, we assume that the neurons are uncoupled so that the responses of neurons are independent conditioned on the input.[3] In this case, the response probabilities obey (2.2) and (2.3) with $\bar{W}_{pq}^j = 0$.

The analysis of the single neuron statistics reduces to the case of individual neurons. As detailed in [13], the first two input-output statistics are given by

$$E\{R_p^i\} = \frac{\hat{r}_p}{2}\operatorname{erfc}\left(\frac{\delta_p \bar{T}_p}{\sqrt{2}}\right) \tag{3.1}$$

and

$$E\{\mathbf{X}R_p^i\} = \frac{\delta_p}{\sqrt{2\pi}} e^{-\frac{\delta_p^2 \bar{T}_p^2}{2}} \mathbf{h}_p^i, \tag{3.2}$$

where

$$\delta_p = \frac{1}{\sqrt{1+\epsilon_p^2}} \tag{3.3}$$

[2] We recognize that the statistics $E\{\mathbf{X}R_p^i\}$ and $E\{R_1^i R_2^{i-k}\}$ are not actually correlations. We use the term since these statistics are consistently called correlations in the neuroscience literature. We hope the reader will forgive our loose use of the term. The stimulus-spike correlation $E\{\mathbf{X}R_p^i\}$ can be thought of as the average stimulus that precedes each spike of neuron p.

[3] Meaning $\Pr(R_1^i = 1 \,\&\, R_2^j = 1|\mathbf{X}) = \Pr(R_1^i = 1|\mathbf{X})\Pr(R_2^j = 1|\mathbf{X})$.

and $\operatorname{erfc}(x) = 1 - \operatorname{erf}(x)$. Note that, since both the input and the system are stationary, the results are independent of time index i (except for the temporal index of the linear kernel). Assuming that one knew $\hat{r}_p$, the nonlinearities $g_p(\cdot)$ could be computed by estimating ϵ_p and $\bar{T}_p$ from these statistics [13]. One could also obtain the unit vectors $\mathbf{h}_p^i$ from $E\{\mathbf{X}R_p^i\}/|E\{\mathbf{X}R_p^i\}|$. In this simple case, one does not even need to measure $E\{R_1^i R_2^{i-k}\}$ to reconstruct the system.

Before we calculate an expression for $E\{R_1^i R_2^{i-k}\}$, we define the angles between the linear kernels, which turn out to be the only important geometry of the kernels for white noise input. Let $\bar{\theta}_{pq}^k$ be the angle between kernel q and kernel p shifted k units in time

$$\cos\bar{\theta}_{pq}^k = \mathbf{h}_p^{i-k} \cdot \mathbf{h}_q^i. \tag{3.4}$$

This angle is of course independent of time index i. (The inner product can be represented as a cosine because kernels were normalized to be unit vectors.) Note that $\bar{\theta}_{qp}^{-k} = \bar{\theta}_{pq}^k$. We always define the corresponding sine by $\sin\theta = \sqrt{1-\cos^2\theta}$ so that $\sin\theta \geq 0$.

For a given time shift k, without loss of generality, assume that $\mathbf{h}_1^i$ is the first unit vector $\mathbf{e}_1$ (in stimulus space) and $\mathbf{h}_2^{i-k}$ is a linear combination of the first two unit vectors:[4]

$$\begin{aligned}\mathbf{h}_1^i &= \mathbf{e}_1,\\ \mathbf{h}_2^{i-k} &= \mathbf{e}_1\cos\bar{\theta}_{21}^k + \mathbf{e}_2\sin\bar{\theta}_{21}^k.\end{aligned}$$

Assuming that the nonlinearities satisfy

$$\lim_{x\to-\infty} g_p(x) = 0, \tag{3.5}$$

we compute the correlation between the spikes of neuron 1 and the spikes of neuron 2 by changing variables and integrating by parts twice. In each integration by parts, one boundary term disappears due to (3.5), and the other boundary term is incorporated into the complementary error functions:

$$\begin{aligned}E\{R_1^i R_2^{i-k}\} &= \frac{1}{2\pi}\int g_1(x_1)g_2(x_1\cos\bar{\theta}_{21}^k + x_2\sin\bar{\theta}_{21}^k)e^{-\frac{x_1^2+x_2^2}{2}}\,dx_1\,dx_2\\ &= \frac{1}{2\pi}\int g_1(u)g_2(v)\exp\left(-\frac{u^2}{2} - \frac{(v-u\cos\bar{\theta}_{21}^k)^2}{2\sin^2\bar{\theta}_{21}^k}\right)\frac{du\,dv}{\sin\bar{\theta}_{21}^k}\\ &= \frac{1}{4}\int g_1'(u)g_2'(v)\operatorname{derfc}\left(\frac{u}{\sqrt{2}},\frac{v}{\sqrt{2}},\cos\bar{\theta}_{21}^k\right)du\,dv,\end{aligned} \tag{3.6}$$

where we have defined a double complementary error function

$$\operatorname{derfc}(a,b,c) = \frac{4}{\pi}\int_a^\infty dy\,e^{-y^2}\int_{\frac{b-cy}{\sqrt{1-c^2}}}^\infty dz\,e^{-z^2}. \tag{3.7}$$

The function derfc is a two dimensional analogue of the complementary error function. The integral is taken over the intersection of the two half-planes $\mathbf{x}\cdot\mathbf{u} > a$

[4]Since the stimulus is rotationally invariant, we can rotate the axis so that $\mathbf{h}_1^i$ is parallel to the first axis and $\mathbf{h}_2^{i-k}$ lies in the span of the first two axes. Recall that $|\mathbf{h}_p^i| = 1$.

and $\mathbf{x} \cdot \mathbf{v} > b$, where $\mathbf{u}$ and $\mathbf{v}$ are two unit vectors with inner product $\mathbf{u} \cdot \mathbf{v} = c$. (Here, $\mathbf{x}$ represents a generic vector.) Note that $\operatorname{derfc}(a, b, 0) = \operatorname{erfc}(a)\operatorname{erfc}(b)$ and $\operatorname{derfc}(a, b, c) = \operatorname{derfc}(b, a, c)$.

When the nonlinearity is an error function (i.e., (2.3)), we substitute into (3.6) and use formula (B.8) to obtain

$$E\{R_1^i R_2^{i-k}\} = \frac{\hat{r}_1 \hat{r}_2}{4} \operatorname{derfc}\left(\frac{\delta_1 \bar{T}_1}{\sqrt{2}}, \frac{\delta_2 \bar{T}_2}{\sqrt{2}}, \delta_1 \delta_2 \cos \bar{\theta}_{21}^k\right). \tag{3.8}$$

Equations (3.1), (3.2), and (3.8) are the expressions for the input-output statistics for the simple case of uncoupled neurons.

4. Unidirectional coupling. Let the coupling from neuron 2 to neuron 1 ($\bar{W}_{21}^j$) be nonzero, but keep $\bar{W}_{12}^j = 0$. Then the probability of a spike of neuron 1 at time k is dependent not only on the input but also on the spikes of neuron 2 for times before k, as given by (2.2). The probability of neuron 2's spiking remains the same as in section 3, and thus the input-output statistics $E\{R_2^i\}$ and $E\{\mathbf{X}R_2^i\}$ are unchanged.

In what follows, we calculate expressions for the remaining input-output statistics. We first show that effective parameters of the system can be calculated from $E\{R_p^i\}$ and $E\{\mathbf{X}R_p^i\}$. We next show how the coupling $\bar{W}_{21}^j$ can be calculated from $E\{R_1^i R_2^{i-k}\}$.

We assume that $\bar{W}_{21}^j$ is small and compute a first order approximation by dropping terms that are second order or higher in $\bar{W}_{21}^j$. Since from now on all equalities will be within $O(\bar{W}^2)$, we will, for simplicity, use $=$ to mean equal within $O(\bar{W}^2)$.

4.1. Mean rate of neuron 1. In this section, we show that the mean rate of neuron 1 is nearly identical to the uncoupled case of (3.1), only with the original threshold $\bar{T}_1$ replaced with an effective threshold T_1 to be defined below.

The general expression for the mean rate of neuron 1, calculated in Appendix A.3, is

$$E\{R_1^i\} = \frac{1}{\sqrt{2\pi}} \int g_1(u) e^{-\frac{u^2}{2}} du + \sum_{j \geq 0} \frac{\bar{W}_{21}^j}{2\sqrt{2\pi}} \int g_1'(u) g_2'(v) e^{-\frac{u^2}{2}} \operatorname{erfc}\left(\frac{v - u \cos \bar{\theta}_{21}^k}{\sqrt{2} \sin \bar{\theta}_{21}^k}\right) du\, dv. \tag{4.1}$$

Note that the mean rate $E\{R_1^i\}$ is independent of i (as it must be).

When the nonlinearities are error functions (e.g., (2.3)), the first term is the uncoupled mean rate (i.e., (3.1)). We use formula (B.5) to simplify the $\bar{W}_{21}^j$ term so that the mean rate of neuron 1 is

$$E\{R_1^i\} = \frac{\hat{r}_1}{2} \operatorname{erfc}\left(\frac{\delta_1 \bar{T}_1}{\sqrt{2}}\right) + \frac{\hat{r}_1 \hat{r}_2 \delta_1}{2\sqrt{2\pi}} e^{-\frac{\delta_1^2 \bar{T}_1^2}{2}} \sum_{j \geq 0} \bar{W}_{21}^j \operatorname{erfc}\left(\frac{\delta_2 \bar{T}_2 - \delta_1^2 \delta_2 \bar{T}_1 \cos \bar{\theta}_{21}^j}{\sqrt{1(1 - \delta_1^2 \delta_2^2 \cos^2 \bar{\theta}_{21}^j)}}\right).$$

Using the Taylor series for $\operatorname{erfc}(\frac{\delta_1 \bar{T}_1 + x}{\sqrt{2}})$, we pull the second term into the error function (making only an $O(\bar{W}^2)$ error), obtaining

$$E\{R_1^i\} = \frac{\hat{r}_1}{2} \operatorname{erfc}\left(\frac{\delta_1 T_1}{\sqrt{2}}\right), \tag{4.2}$$

where we let $T_2 = \bar{T}_2$ and have defined the effective threshold for neuron 1:

$$T_1 = \bar{T}_1 - \sum_{j\geq 0} \frac{\hat{r}_2 \bar{W}_{21}^j}{2} \operatorname{erfc}\left(\frac{\delta_2 T_2 - \delta_1^2 \delta_2 \bar{T}_1 \cos\bar{\theta}_{21}^j}{\sqrt{2(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}} \right). \tag{4.3}$$

The mean rate of neuron 1 is identical to that of an uncoupled neuron with the effective threshold T_1.

4.2. Correlation of spikes of neuron 1 with the stimulus. We calculate the general expression for the correlation between the spikes of neuron 1 with the stimulus in Appendix A.4, obtaining

$$\begin{aligned} E\{\mathbf{X}R_1^i\} = \frac{1}{\sqrt{2\pi}} \Bigg[& \int g_1'(u) e^{-\frac{u^2}{2}} du \\ & + \sum_{j\geq 0} \frac{\bar{W}_{21}^j}{2} \int g_1'(u) g_2'(v) u e^{-\frac{u^2}{2}} \operatorname{erfc}\left(\frac{v - u\cos\bar{\theta}_{21}^k}{\sqrt{2}\sin\bar{\theta}_{21}^k} \right) du\, dv \Bigg] \mathbf{h}_1^i \\ & + \sum_{j\geq 0} \frac{\bar{W}_{21}^j}{2\pi} \int g_1'(u) g_2'(v) \exp\left(- \frac{u^2 - 2\cos\bar{\theta}_{21}^j uv + v^2}{2\sin^2\bar{\theta}_{21}^j} \right) du\, dv\, \overset{\perp ji}{\mathbf{h}}_{21}, \end{aligned} \tag{4.4}$$

where we define $\overset{\perp ji}{\mathbf{h}}_{21}$ as the component of $\mathbf{h}_2^{i-j}$ that is perpendicular to $\mathbf{h}_1^i$,

$$\overset{\perp ji}{\mathbf{h}}_{21} = \frac{\mathbf{h}_2^{i-j} - \cos\bar{\theta}_{21}^j \mathbf{h}_1^i}{\sin\bar{\theta}_{21}^j}. \tag{4.5}$$

Because of the coupling, $E\{\mathbf{X}R_1^i\}$ is no longer parallel to the linear kernel $\mathbf{h}_1^i$. Each term in the last sum of (4.4) indicates how the coupling $\bar{W}_{21}^j$ leads to a component of $E\{\mathbf{X}R_1^i\}$ that is perpendicular to $\mathbf{h}_1^i$.

When the nonlinearities are error functions (e.g., (2.3)), we use (4.5) and formulas (B.1), (B.6), and (B.2) to obtain the following expression for the correlation between the stimulus and the spikes of neuron 1:

$$\begin{aligned} E\{\mathbf{X}R_1^i\} = \mu_1^0 & \left[1 - \sum_{j\geq 0} \frac{\hat{r}_2 \bar{W}_{21}^j \delta_1^2 \delta_2 \cos\bar{\theta}_{21}^j}{\sqrt{2\pi(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}} \exp\left(-\frac{[\delta_2 T_2 - \delta_1^2\delta_2 T_1 \cos\bar{\theta}_{21}^j]^2}{2(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)} \right) \right] \mathbf{h}_1^i \\ & + \mu_1^0 \sum_{j\geq 0} \frac{\hat{r}_2 \bar{W}_{21}^j \delta_2}{\sqrt{2\pi(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}} \exp\left(-\frac{[\delta_2 T_2 - \delta_1^2\delta_2 T_1 \cos\bar{\theta}_{21}^j]^2}{2(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)} \right) \mathbf{h}_2^{i-j}, \end{aligned} \tag{4.6}$$

where

$$\mu_p^0 = \frac{\hat{r}_p \delta_p}{\sqrt{2\pi}} e^{-\frac{\delta_p^2 T_p^2}{2}}. \tag{4.7}$$

One key to obtaining (4.6) was using the exponential's Taylor series to bring the effective threshold T_1 (4.3) into the exponential of the first term. We let $T_2 = \bar{T}_2$ and simply replaced $\bar{T}_1$ with T_1 in all other terms (making an $O(\bar{W}^2)$ error).

4.3. Reconstruction from the mean rate and stimulus-spike correlations. Equations (4.2) and (4.6) give expressions for the first two input-output statistics of the linear-nonlinear system (2.2) with unidirectional coupling. These equations

show that the coupling has both changed the effective threshold and altered the direction of $E\{\mathbf{X}R_1^i\}$ so that it is no longer parallel to the kernel $\mathbf{h}_1^i$.

Because of these modifications, we can no longer recover $\bar{T}_1$ or $\mathbf{h}_1^i$ (or $\cos\bar{\theta}_{21}^j$) from $E\{R_1^i\}$ and $E\{\mathbf{X}R_1^i\}$ as outlined in section 3. Nonetheless, subject to one more assumption, one can recover the effective threshold T_1, the original δ_1, and an effective angle between the kernels. As shown below, one simply views the neurons as uncoupled and reconstructs the neuron parameters as in section 3. This procedure does not use $E\{R_1^iR_2^{i-k}\}$. We will be able use this last statistic to determine the coupling $\bar{W}_{21}^j$.

4.3.1. Effective angle between kernels. When the neurons were uncoupled, the linear kernel $\mathbf{h}_1^i$ could be determined by the normalized stimulus-spike correlation $E\{\mathbf{X}R_1^i\}/|E\{\mathbf{X}R_1^i\}|$. Although this measurement no longer yields the kernel, we can treat it as an effective kernel and define the effective angle between kernels by

$$\cos\theta_{pq}^k = \frac{E\{\mathbf{X}R_p^{i-k}\}}{\left|E\{\mathbf{X}R_p^{i-k}\}\right|}\cdot\frac{E\{\mathbf{X}R_q^i\}}{\left|E\{\mathbf{X}R_q^i\}\right|}. \tag{4.8}$$

In this case of unidirectional coupling, neuron 2 is unaffected, and the effective angle between neurons 1 and 2 is $\cos\theta_{21}^k = \mathbf{h}_2^{i-k}\cdot E\{\mathbf{X}R_1^i\}/|E\{\mathbf{X}R_1^i\}|$.

We rewrite (4.2) and (4.6) in terms of the measurable effective angle as follows. The magnitude of the stimulus-spike correlation, within $O(\bar{W}^2)$, is

$$\left|E\{\mathbf{X}R_1^i\}\right| = \mu_1^0\left[1+\sum_{j\geq 0}\frac{\hat{r}_2\bar{W}_{21}^j(1-\delta_1^2)\delta_2\cos\bar{\theta}_{21}^j}{\sqrt{2\pi(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}}\exp\left(-\frac{[\delta_2T_2-\delta_1^2\delta_2T_1\cos\bar{\theta}_{21}^j]^2}{2(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}\right)\right] \tag{4.9}$$

so that

$$\cos\theta_{21}^k = \cos\bar{\theta}_{21}^k + \sum_{j\geq 0}\frac{\hat{r}_2\bar{W}_{21}^j\delta_2(\cos\theta_{22}^{k-j}-\cos\bar{\theta}_{21}^j\cos\bar{\theta}_{21}^k)}{\sqrt{2\pi(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}}\exp\left(-\frac{[\delta_2T_2-\delta_1^2\delta_2T_1\cos\bar{\theta}_{21}^j]^2}{2(1-\delta_1^2\delta_2^2\cos^2\bar{\theta}_{21}^j)}\right).$$

Since $\cos\theta_{21}^k$ is within $O(\bar{W})$ of $\cos\bar{\theta}_{21}^k$, we can replace $\cos\bar{\theta}_{21}^k$ by $\cos\theta_{21}^k$ in the last terms (making only an $O(\bar{W}^2)$ error), and write $\cos\bar{\theta}_{21}^k$ in terms of $\cos\theta_{21}^k$:

$$\cos\bar{\theta}_{21}^k = \cos\theta_{21}^k - \sum_{j\geq 0}\bar{W}_{21}^jC_{21}^{jk}, \tag{4.10}$$

where

$$C_{pq}^{jk} = (\cos\theta_{pp}^{k-j} - \cos\theta_{pq}^j\cos\theta_{pq}^k)\mu_{pq}^j, \tag{4.11}$$

$$\mu_{pq}^k = \frac{\hat{r}_p\delta_p\exp\left(-\frac{1}{2}[\lambda_{pq}^k]^2\right)}{\sqrt{2\pi(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k)}}, \tag{4.12}$$

and

$$\lambda_{pq}^k = \frac{\delta_pT_p-\delta_p\delta_q^2T_q\cos\theta_{pq}^k}{\sqrt{1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k}}. \tag{4.13}$$

Note that $\mu_p^0\mu_{pq}^k = \mu_q^0\mu_{qp}^{-k}$.

We now make an $O(\bar{W}^2)$ error by replacing $\cos\bar{\theta}_{21}^k$ with $\cos\theta_{21}^k$ in the stimulus-spike correlation

$$E\{\mathbf{X}R_1^i\} = \mu_1^0\left[\left(1 - \sum_{j\geq 0}\bar{W}_{21}^j\delta_1^2\cos\theta_{21}^j\mu_{21}^j\right)\mathbf{h}_1^i + \sum_{j\geq 0}\bar{W}_{21}^j\mu_{21}^j\mathbf{h}_2^{i-j}\right] \tag{4.14}$$

and in the expression for the effective threshold (4.3),

$$\bar{T}_1 = T_1 + \sum_{j\geq 0}\bar{W}_{21}^j\eta_{21}^j, \tag{4.15}$$

where

$$\eta_{pq}^k = \frac{\hat{r}_p}{2}\operatorname{erfc}\left(\frac{\lambda_{pq}^k}{\sqrt{2}}\right). \tag{4.16}$$

4.3.2. Effective nonlinearity parameters. As shown above, $\cos\theta_{21}^k$, not the original $\cos\bar{\theta}_{21}^k$, is the measurable inner product between the kernels. We next show that, with one additional mild assumption, the parameters T_1 and δ_1 are the nonlinearity parameters measured from $E\{\mathbf{X}R_1^i\}$ and $E\{R_1^i\}$ when treating neuron 1 as an independent neuron as in section 3.

The magnitude of $E\{\mathbf{X}R_1^i\}$ is

$$\left|E\{\mathbf{X}R_1^i\}\right| = \mu_1^0\left(1 + \sum_{j\geq 0}\bar{W}_{21}^j(1-\delta_1^2)\cos\theta_{21}^j\mu_{21}^j\right). \tag{4.17}$$

This expression simplifies to μ_1^0 if we assume that $\bar{W}_{21}^j\delta_1\delta_2(1-\delta_1^2)\cos\theta_{21}^j$ is small enough to ignore. Since we have already assumed that $\bar{W}_{21}^j$ is small, we simply need to assume that $\delta_2(1-\delta_1^2)\cos\theta_{21}^j$ is small to have an expression that is second order in a small parameter. This expression is the product of three factors that are each less than one. It will be small if the nonlinearities are not very sharp or if the kernels of the neurons are not nearly aligned.

With this approximation, the stimulus-spike correlation is

$$\left|E\{\mathbf{X}R_1^i\}\right| \approx \mu_1^0 = \frac{\hat{r}_1\delta_1}{\sqrt{2\pi}}e^{-\frac{\delta_1^2T_1^2}{2}}. \tag{4.18}$$

Recall that the mean rate of neuron 1 (see (4.2)) is

$$E\{R_1^i\} = \frac{\hat{r}_1}{2}\operatorname{erfc}\left(\frac{\delta_1T_1}{\sqrt{2}}\right).$$

These results are the same as (3.1) and (3.2) for an uncoupled neuron with nonlinearity parameters δ_1 and T_1. One can determine δ_1 and T_1 from these equations (assuming that $\hat{r}_1$ is known).

Using only $E\{R_p^i\}$ and $E\{\mathbf{X}R_p^i\}$ in this manner, one can calculate effective nonlinearity parameters of both neuron 1 and neuron 2, as well as the effective angle between the linear kernels. We next show how the connectivity $\bar{W}_{21}$ can be determined from the remaining input-output statistic $E\{R_1^iR_2^{i-k}\}$.

4.4. Correlation between spikes of neurons 1 and 2. We calculate the general expression for the correlation between the spikes of neurons 1 and 2 in Appendix A.5, obtaining the complicated expression

$$\begin{aligned} E\{R_1^i R_2^{i-k}\} &= \frac{1}{4}\int g_1'(u_1)g_2'(u_2)\,\mathrm{derfc}\left(\frac{u_1}{\sqrt{2}},\frac{u_2}{\sqrt{2}},\cos\bar\theta_{21}^k\right)du_1du_2 \\ &\quad+\frac{\bar W_{21}^k}{2\sqrt{2\pi}}\int g_1'(u_1)g_2'(u_2)e^{-\frac{u_1^2}{2}}\,\mathrm{erfc}\left(\frac{u_2-u_1\cos\bar\theta_{21}^k}{\sqrt{2}\sin\bar\theta_{21}^k}\right)du_1du_2 \\ &\quad+\sum_{j\ge0,\,j\ne k}\frac{\bar W_{21}^j}{4\sqrt{2\pi}}\int du_1du_2du_3\,g_1'(u_1)g_2'(u_2)g_2'(u_3)e^{-\frac{u_1^2}{2}} \\ &\quad\times\mathrm{derfc}\left(\frac{u_2-u_1\cos\bar\theta_{21}^k}{\sqrt{2}\sin\bar\theta_{21}^k},\frac{u_3-u_1\cos\bar\theta_{21}^j}{\sqrt{2}\sin\bar\theta_{21}^j},\frac{\cos\theta_{22}^{k-j}-\cos\bar\theta_{21}^j\cos\bar\theta_{21}^k}{\sin\bar\theta_{21}^j\sin\bar\theta_{21}^k}\right). \end{aligned} \tag{4.19}$$

When the nonlinearities are error functions (e.g., (2.3)), we simplify this expression using three formulas ((B.8), (B.9), and (B.5)) and (4.10), (4.15), (4.7), (4.16), and (4.11). We use the following Taylor series expansions of $\mathrm{derfc}(a,b,c)$,

$$\begin{aligned} \mathrm{derfc}(a+x,b,c) &= \mathrm{derfc}(a,b,c)-\frac{2x}{\sqrt{\pi}}e^{-a^2}\,\mathrm{erfc}\left(\frac{b-ca}{\sqrt{1-c^2}}\right)+O(x^2), \\ \mathrm{derfc}(a,b,c+x) &= \mathrm{derfc}(a,b,c)+\frac{2x}{\pi\sqrt{1-c^2}}e^{-\frac{a^2-2abc+b^2}{1-c^2}}+O(x^2), \end{aligned}$$

to pull terms for the effective threshold T_1 and effective kernel inner product $\cos\theta_{21}^j$ into the first term. All other terms are $O(\bar W)$, so we can simply drop the bars from $\bar T_1$ and $\cos\bar\theta_{21}^j$.

Defining

$$\nu_{pq}^k=\frac{\hat r_p\hat r_q}{4}\,\mathrm{derfc}\left(\frac{\delta_pT_p}{\sqrt{2}},\frac{\delta_qT_q}{\sqrt{2}},\delta_p\delta_q\cos\theta_{pq}^k\right), \tag{4.20}$$

$$\tilde\nu_{pq}^{kj}=\begin{cases}\eta_{pq}^k & \text{for } j=k,\\ \frac{(\hat r_p)^2}{4}\,\mathrm{derfc}\left(\frac{\lambda_{pq}^k}{\sqrt{2}},\frac{\lambda_{pq}^j}{\sqrt{2}},\xi_{pq}^{kj}\right) & \text{otherwise,}\end{cases} \tag{4.21}$$

and

$$\xi_{pq}^{kj}=\frac{\delta_p^2\cos\theta_{pp}^{k-j}-\delta_p^2\delta_q^2\cos\theta_{pq}^j\cos\theta_{pq}^k}{\sqrt{(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^j)(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k)}}, \tag{4.22}$$

the correlation between the spikes of neurons 1 and 2 becomes

$$E\{R_1^iR_2^{i-k}\}=\nu_{21}^k+\sum_{j\ge0}A_{21}^{kj}\bar W_{21}^j, \tag{4.23}$$

where

$$A_{pq}^{kj}=\mu_q^0\big[\tilde\nu_{pq}^{kj}-\eta_{pq}^k\eta_{pq}^j+(\cos\theta_{pq}^k\cos\theta_{pq}^j-\cos\theta_{pp}^{k-j})\mu_{pq}^k\mu_{pq}^j\big] \tag{4.24}$$

and μ_p^0, μ_{pq}^k, λ_{pq}^k, and η_{pq}^k are defined in (4.7), (4.12), (4.13), and (4.16), respectively. The term ν_{21}^k in (4.23) is analogous to the correlation observed in the uncoupled case (3.8), and the sum represents additional correlations due to the coupling terms $\bar W_{21}^j$. A discussion of some properties of A_{pq}^{kj} is given in the next section.

The important fact to note about (4.23) is that, with the exception of the $\bar{W}_{21}^j$, every factor on the right-hand side can be calculated from the mean rates $E\{R_p^i\}$ and stimulus-spike correlations $E\{\mathbf{X}R_p^i\}$. Equation (4.23) can then be solved to determine the $\bar{W}_{21}^j$.

5. Mutual coupling. Let both $\bar{W}_{21}^j$ and $\bar{W}_{12}^j$ be nonzero so that the neurons are mutually coupled. Then the probability of a spike of neuron p at time k depends not only on the input but also on the spikes of neuron q for times before k, as given by (2.2).

Since we assume that $\bar{W}_{pq}^j$ is small and compute a first order approximation, the mutual interaction results are identical to the unidirectional results of section 4 applied in both directions. The effect of neuron p on neuron q is $O(\bar{W})$, so the effect of neuron p on itself through neuron q is $O(\bar{W}^2)$ and can be ignored. We can ignore second (and higher) order interactions.

The mutual coupling case involves no more work beyond that for the unidirectional case. The statistics for neuron 1 are unchanged, and the statistics for neuron 2 become analogous to those for neuron 1. The expression for $E\{R_1^i R_2^{i-k}\}$ simply adds a sum in terms of the $\bar{W}_{12}^j$ coupling.

We summarize the model and resulting equations. We are given the system

$$\Pr\bigl(R_p^i = 1 \bigm| \mathbf{X} = \mathbf{x}, \mathbf{R}_q = \mathbf{r}_q\bigr) = g_p\biggl(\mathbf{h}_p^i \cdot \mathbf{x} + \sum_{j\geq 0} \bar{W}_{qp}^j r_q^{i-j}\biggr) \tag{5.1}$$

for $p, q \in \{1, 2\}$, $q \neq p$, with

$$g_p(x) = \frac{\hat{r}_p}{2}\biggl[1 + \operatorname{erf}\biggl(\frac{x - \bar{T}_p}{\epsilon_p\sqrt{2}}\biggr)\biggr]. \tag{5.2}$$

We assume we know $\hat{r}_p$. We can reconstruct the system from the following input-output statistics: $E\{R_p^i\}$, $E\{\mathbf{X}R_p^i\}$, and $E\{R_1^i R_2^{i-k}\}$.

First, we calculate $\delta_p = 1/\sqrt{1+\epsilon_p^2}$ and an effective threshold T_p from $E\{R_p^i\}$ and $|E\{\mathbf{X}R_p^i\}|$ using the equations[5]

$$E\{R_p^i\} = \frac{\hat{r}_p}{2}\operatorname{erfc}\biggl(\frac{\delta_p T_p}{\sqrt{2}}\biggr) \tag{5.3}$$

and

$$\bigl|E\{\mathbf{X}R_p^i\}\bigr| \approx \mu_p^0 = \frac{\hat{r}_p\delta_p}{\sqrt{2\pi}}\exp\biggl(-\frac{\delta_p^2 T_p^2}{2}\biggr). \tag{5.4}$$

Then, we calculate the effective angle between the kernels by

$$\cos\theta_{pq}^k = \frac{E\{\mathbf{X}R_p^{i-k}\}\cdot E\{\mathbf{X}R_q^i\}}{\bigl|E\{\mathbf{X}R_p^{i-k}\}\bigr|\bigl|E\{\mathbf{X}R_q^i\}\bigr|}. \tag{5.5}$$

The last step is to calculate the coupling $\bar{W}$ from the spike correlations with delays $k = -N, \ldots, N$,

$$E\{R_1^i R_2^{i-k}\} = \nu_{21}^k + \sum_{j\geq 0} A_{21}^{kj}\bar{W}_{21}^j + \sum_{j\geq 0} A_{12}^{-kj}\bar{W}_{12}^j, \tag{5.6}$$

[5]The fact that T_p and $E\{\mathbf{X}R_p^i\}$ are given by equations analogous to (4.15) and (4.14) is not needed for the reconstruction.

where

$$A_{pq}^{kj} = \mu_q^0\big[\tilde{\nu}_{pq}^{kj} - \eta_{pq}^k\eta_{pq}^j + (\cos\theta_{pq}^k\cos\theta_{pq}^j - \cos\theta_{pp}^{k-j})\mu_{pq}^k\mu_{pq}^j\big],$$

$$\nu_{pq}^k = \frac{\hat{r}_p\hat{r}_q}{4}\operatorname{derfc}\left(\frac{\delta_pT_p}{\sqrt{2}}, \frac{\delta_qT_q}{\sqrt{2}}, \delta_p\delta_q\cos\theta_{pq}^k\right),$$

$$\tilde{\nu}_{pq}^{kj} = \begin{cases} \eta_{pq}^k & \text{for } j = k, \\ \frac{(\hat{r}_p)^2}{4}\operatorname{derfc}\left(\frac{\lambda_{pq}^k}{\sqrt{2}}, \frac{\lambda_{pq}^j}{\sqrt{2}}, \xi_{pq}^{kj}\right) & \text{otherwise,} \end{cases}$$

$$\eta_{pq}^k = \frac{\hat{r}_p}{2}\operatorname{erfc}\left(\frac{\lambda_{pq}^k}{\sqrt{2}}\right),$$

$$\mu_{pq}^k = \frac{\hat{r}_p\delta_p\exp\left(-\frac{1}{2}[\lambda_{pq}^k]^2\right)}{\sqrt{2\pi(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k)}},$$

$$\lambda_{pq}^k = \frac{\delta_pT_p - \delta_p\delta_q^2T_q\cos\theta_{pq}^k}{\sqrt{1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k}},$$

and

$$\xi_{pq}^{kj} = \frac{\delta_p^2\cos\theta_{pp}^{k-j} - \delta_p^2\delta_q^2\cos\theta_{pq}^j\cos\theta_{pq}^k}{\sqrt{(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^j)(1-\delta_p^2\delta_q^2\cos^2\theta_{pq}^k)}}.$$

We assume that we have chosen the number of delays (given by $k = -N, \dots, N$) so that W_{21}^j and W_{12}^j for $j = 0, \dots, N$ are all the nonzero connectivity terms of the system. Unfortunately, even though the $\bar{W}$ are the only unknowns left in the system (5.6), we still have $2N+2$ unknowns with only $2N+1$ equations.

To reduce the number of unknowns, we simply do not attempt to distinguish $\bar{W}_{21}^0$ from $\bar{W}_{12}^0$. Although there is no reason these should be identical, the best we can do is calculate their sum. To solve the equations, we define a new $\bar{W}^j$ by

$$\bar{W}^j = \begin{cases} \bar{W}_{12}^{-j} & \text{for } j < 0, \\ \bar{W}_{12}^0 + \bar{W}_{21}^0 & \text{for } j = 0, \\ \bar{W}_{21}^j & \text{for } j > 0. \end{cases} \tag{5.7}$$

Our new equation for the $\bar{W}$ is then

$$E\{R_1^iR_2^{i-k}\} = \nu_{21}^k + \sum_j \tilde{A}^{kj}\bar{W}^j, \tag{5.8}$$

where

$$\tilde{A}^{kj} = \begin{cases} A_{12}^{-k,-j} & \text{for } j < 0, \\ \frac{1}{2}(A_{12}^{-k0} + A_{21}^{k0}) & \text{for } j = 0, \\ A_{21}^{kj} & \text{for } j > 0. \end{cases} \tag{5.9}$$

If we let $\mathcal{S}^k = E\{R_1^i R_2^{i-k}\} - \nu_{21}^k$, we can write the solution of (5.8) for $\bar{W}^j$ in matrix-vector notation as $\bar{W} = \tilde{A}^{-1}\mathcal{S}$, where $\tilde{A}^{-1}$ denotes the matrix inverse of $\tilde{A}$. This solution of (5.8) for $\bar{W}^j$ modifies the correlations in $E\{R_1^i R_2^{i-k}\}$ in two ways. First, the subtraction of ν_{21}^k removes correlations due solely to the fact that neurons are responding to the same stimulus. (See [12] for a detailed discussion.) Second, inverting the matrix $\tilde{A}$ eliminates the filtering of $\bar{W}$ by the temporal structure of $\mathbf{h}_1^i$ and $\mathbf{h}_2^i$.

The relevant temporal structure of the kernels is captured by $\cos\bar{\theta}_{pq}^k = \mathbf{h}_p^{i-k} \cdot \mathbf{h}_q^i$. Clearly, $\cos\bar{\theta}_{pp}^0 = |\mathbf{h}_p^i|^2 = 1$. If, with this exception, $\cos\bar{\theta}_{pq}^k = 0$ (so that the kernels are orthogonal to each other and temporal shifts of themselves), then the effects of $\bar{W}$ are not filtered by the kernels. $\hat{A}$ is a diagonal matrix, and inverting $\tilde{A}$ simply scales the measured correlations. (Too see this fact, recall that $\operatorname{derfc}(a, b, 0) = \operatorname{erfc}(a)\operatorname{erfc}(b)$ and that we can interchange $\cos\bar{\theta}_{pq}^k$ and $\cos\theta_{pq}^k$ in expressions defining A since it appears in $O(\bar{W})$ terms.)

As the inner products $\cos\bar{\theta}_{pq}^k$ increase, the off-diagonal elements of $\tilde{A}$ grow. In fact, the inner products of the kernels with themselves ($\cos\bar{\theta}_{pp}^k$) will be close to 1 for k near 0 if the structure of the kernels changes slowly with time. Typically, the off-diagonal elements of $\tilde{A}$ will still be substantially less than the diagonal elements even with large $\cos\bar{\theta}_{pp}^k$, and inversion of $\tilde{A}$ will be stable. However, close examination of equations defining $\tilde{A}$ reveals that off-diagonals could become equal to the diagonal in the extreme case of very sharp nonlinearities and other parameter limits. (Parameters needed are $\epsilon_1 = \epsilon_2 = 0$ so that $\delta_1 = \delta_2 = 1$, as well as $\hat{r}_1 = \hat{r}_2 = 1$, $\cos\bar{\theta}_{pp}^k = 1$ for $k \neq 0$, and $\cos\bar{\theta}_{pq}^j = 0$ for $p \neq q$.)[6] In this case, the matrix $\tilde{A}$ could become almost singular, and its inversion would not be stable.

Outside this extreme case, the matrix $\tilde{A}$ is well conditioned, and solving (5.8) for $\bar{W}$ removes the filtering caused by the temporal structure of the kernels. Subject to the validity of the model (5.1), the result will faithfully reconstruct the underlying connectivity.

6. Results. To demonstrate the reconstruction procedure, we simulate a pair of coupled linear-nonlinear neurons (see (5.1)) responding to white noise input and use the above method to estimate the parameters. We assume that the maximum output rates $\hat{r}_p$ are known using alternative methods such as those described in [13]. Then, from the responses R_p^i and the discrete white noise input X, one can estimate $E\{R_p^i\}$, $E\{\mathbf{X}R_p^i\}$, and $E\{R_1^i R_2^{i-k}\}$ for $p = 1, 2$ and $k = -N, \ldots, N$. The maximum delay parameter N must be chosen large enough so that the $E\{R_1^i R_2^{i-k}\}$ capture the effects of the $\bar{W}^j$. In the examples, we set $N = 30$.

The calculations depend on estimating the inner products $E\{\mathbf{X}R_p^i\} \cdot E\{\mathbf{X}R_q^{i-k}\}$. We estimate each correlation by $E\{\mathbf{X}R_p^i\} \approx \langle \mathbf{X}R_p^i \rangle$, where $\langle\cdot\rangle$ represents averaging over a data set. A naive estimate of the inner product by $E\{\mathbf{X}R_p^i\} \cdot E\{\mathbf{X}R_q^{i-k}\} \approx \langle \mathbf{X}R_p^i \rangle \cdot \langle \mathbf{X}R_q^{i-k} \rangle$ will be highly biased, especially when the dimension of the kernels $\mathbf{h}_p^i$ and $\mathbf{h}_q^i$ is large. To reduce the bias, we estimate the covariance between the factors of each term defining $\langle \mathbf{X}R_p^i \rangle \cdot \langle \mathbf{X}R_q^{i-k} \rangle$ and subtract it from the estimate.[7]

For our simulations, we used kernels $\mathbf{h}_p^i$ that mimic linear kernels of neurons in

[6] Note that $\lim_{c\to 1} \operatorname{derfc}(a, a, c) = 2\operatorname{erfc}(a)$.

[7] This bias reduction is equivalent to estimating the product of expected values of two random variables Y and Z using the formula for covariance $E\{YZ\} - \operatorname{cov}(Y, Z) = E\{Y\}E\{Z\}$. For more details on bias reduction of inner products, see Appendix B of [13].

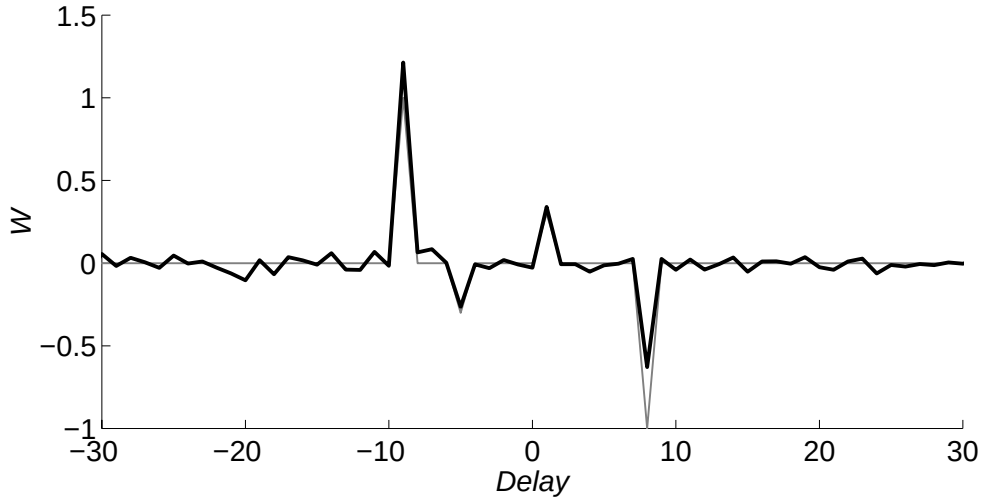

FIG. 1. *Estimated connectivity $\mathcal{W}$ (thick black line) when the nonlinearities are error functions. For comparison, the simulated connectivity $\bar{W}$ is shown with a thin gray line. $\mathcal{W}$ agrees quantitatively with $\bar{W}$, though the magnitudes of the large peaks differ. Delay is in units of time and is the spike time of neuron 1 minus the spike time of neuron 2.*

visual cortex [10]. We used the spatio-temporal linear kernels of the form

$$h_p(\mathbf{j},t) = \begin{cases} te^{-t/5}\exp\left(-\frac{|\mathbf{j}|^2}{50}\right)\sin(0.5(j_1\cos\phi_p + j_2\sin\phi_p)) & \text{for } t>0, \\ 0 & \text{otherwise,} \end{cases} \tag{6.1}$$

where $\mathbf{j} = (j_1, j_2)$ is the spatial grid point and t is time. We set the spatial axis parameters to be $\phi_1 = 0$ and $\phi_2 = \pi/4$. We sampled $h_p(\mathbf{j},t)$ on a $32 \times 32 \times 32$ grid and normalized it to form the unit vector $\mathbf{h}_p^i$. All units are in grid points. The detailed structure of the kernels is insignificant as the only relevant parameters from the kernels are their inner products $\cos\bar{\theta}_{pq}^k$.

In the first example, we set the parameters of the error function nonlinearity (i.e., (5.2)) to $\hat{r}_1 = \hat{r}_2 = 0.5$, $\bar{T}_1 = 1.5$, $\bar{T}_2 = 2.0$, $\epsilon_1 = 0.5$, and $\epsilon_2 = 1.0$. The precise parameter values are arbitrary; we chose them so that the neuron firing rates would be low as observed in white noise experiments. The results are not sensitive to these parameter choices. Just to illustrate the method, we set an artificial coupling of $\bar{W}_{21}^1 = 0.3$, $\bar{W}_{21}^8 = -1.0$, $\bar{W}_{12}^5 = -0.3$, and $\bar{W}_{12}^9 = 1.0$. All other coupling terms were set to zero. We simulated the system for 250,000 units of time, obtaining about 10,000 spikes from each neuron, a realistic number of spikes in white noise experiments [17].

To analyze the results, we assumed that we knew that $\hat{r}_p = 0.5$, and calculated all other parameters from the input-output statistics using the proposed method. We focus on the estimate of the simulated connectivity $\bar{W}$, denoting by $\mathcal{W}$ our estimate of the connectivity. As shown in Figure 1, the estimate $\mathcal{W}$ captures all the qualitative features of $\bar{W}$. For the lower magnitude coupling (with $|\bar{W}| = 0.3$), $\mathcal{W}$ also estimates the magnitudes accurately. However, when $|\bar{W}| = 1.0$, the first order approximation breaks down enough to cause $\mathcal{W}$ to overestimate the positive coupling by 20% and underestimate the magnitude of the negative coupling by nearly 40%. (The asymmetry between positive and negative coupling is most likely due to the low average firing rates of 0.04 spikes per unit time; cf. [14].)

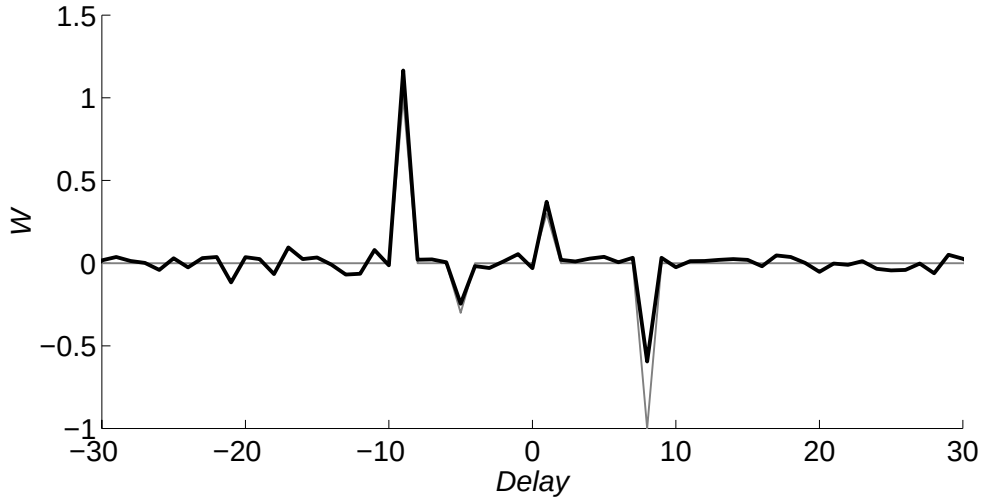

FIG. 2. *Estimated connectivity $\mathcal{W}$ (thick black line) when simulated power law nonlinearities are analyzed as error functions. $\mathcal{W}$ agrees with the simulated connectivity $\bar{W}$ (thin gray line) just as well as in the error function case of Figure* 1.

Since the stimulus standard deviation is assumed to be one, we have effectively scaled $\mathbf{X}$, and likewise $\bar{W}$, $\bar{T}_p$, and ϵ_p, by the stimulus standard deviation. When $|\bar{W}^j| = 1$, it is equal in magnitude to the standard deviation of $\mathbf{h}_p^i \cdot \mathbf{X}$. Since in this case the contribution of $\bar{W}^j$ in (5.1) is the same order of magnitude as the contribution of $\mathbf{h}_p^i \cdot \mathbf{X}$, one cannot expect the first order approximation to be valid. Not only are estimation errors, such as those shown in Figure 1, possible when the coupling magnitude is sufficiently large, but $\mathcal{W}$ can also show additional peaks due to the second order interactions that we ignored in section 5 (not shown).

For a second example, we demonstrate the robustness of the analysis to deviations in the form of the nonlinearities g_p. We repeat the first example, but rather than using an error function nonlinearity, we use a power law nonlinearity,

$$g_p(y) = \begin{cases} A_p y^{\beta_p} & \text{if } y > 0, \\ 0 & \text{otherwise,} \end{cases}$$

with $A_1 = 0.07$, $A_2 = 0.04$, $\beta_1 = 2.5$, and $\beta_2 = 2.0$ (we truncate so that $g_p(x) \leq 1$). Using the same $\bar{W}$ as above, we simulated the system for 250,000 units of time, obtaining approximately 10,000 spikes from neuron 1 and 5,000 spikes from neuron 2.

We analyze the output of the system identically to the first example. We assume that each nonlinearity was an error function nonlinearity with $\hat{r}_p = 1$ and calculate the error function parameters from $E\{R_P^i\}$ and $|E\{\mathbf{X}R_p^i\}|$. The resulting error function parameters (which include the effects from the connectivity) were $\epsilon_1 = 0.76$, $\epsilon_2 = 1.1$, $T_1 = 2.2$, and $T_2 = 3.0$. As shown in Figure 2, the method estimated the connectivity just as well as when the simulated nonlinearity really was an error function. The results were not sensitive to the selection of the maximum firing rate parameters, as the calculated $\mathcal{W}$ was virtually identical if we set $\hat{r}_p = 0.5$ or $\hat{r}_p = 2$ and repeated the analysis.

We repeated this test for simulations based on a wide variety of power law parameters A_p and β_p. We were unable to find an example for which the calculation of $\mathcal{W}$

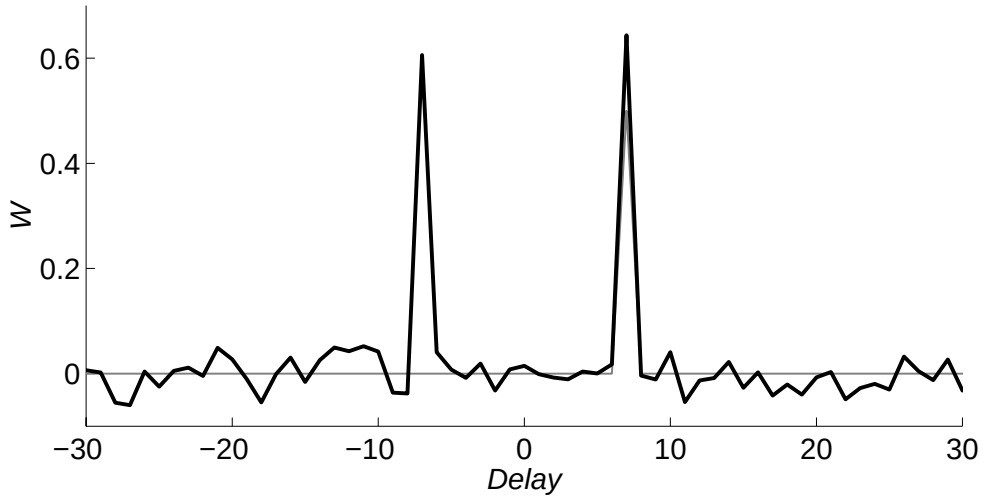

FIG. 3. *Estimated connectivity $\mathcal{W}$ (thick black line) when the two neurons receive common input from a third neuron. The peak at a delay of 7 units of time is due to the simulated connectivity $\bar{W}$ (thin gray line). However, the peak of $\mathcal{W}$ at a delay of -7 is due not to connectivity between the two neurons ($\bar{W} = 0$) but rather to the common input from the third neuron.*

was significantly worse than in Figure 2. Even with $\beta_p < 1$ so that the derivative of $g_p(y)$ was infinite at $y = 0$, the results were similar. The method simply is not sensitive to the detailed form of the nonlinearity.

The measure $\mathcal{W}$ cannot distinguish between correlations caused by the connectivity assumed in (5.1) and correlations caused by other mechanisms. For example, if the two neurons received common input from a third, unmeasured, neuron, that connectivity would appear in the calculation of $\mathcal{W}$.

To demonstrate, we simulated three coupled linear-nonlinear neurons analogous to (5.1). We used (6.1) with $\phi_3 = \pi/2$ for the linear kernel of the third neuron. All three neurons had error function nonlinearities with $\bar{T}_1 = 2$, $\bar{T}_2 = 2.5$, $\bar{T}_3 = 2$, $\epsilon_1 = 0.5$, $\epsilon_2 = 1$, and $\epsilon_2 = 0.7$. We created a connection from neuron 3 to both neurons 1 and 2, as well as a connection from neuron 2 to neuron 1. (We set $\bar{W}_{31}^1 = 1.5$, $\bar{W}_{32}^8 = 1.5$, and $\bar{W}_{21}^7 = 0.5$, leaving the other connectivity terms at zero.) We simulated the system for 250,000 units of time, obtaining approximately 12,000–13,000 spikes per neuron, and then analyzed the system as above by ignoring the output of neuron 3.

As shown in Figure 3, $\mathcal{W}$ has a peak at the delay of 7 corresponding to the connection from neuron 2 to neuron 1 ($\bar{W}_{21}^7$). However, $\mathcal{W}$ also has a peak at a delay of -7. This second peak does not correspond to any direct connection between neuron 1 and neuron 2 ($\bar{W}_{12}^7 = 0$). Instead, the peak is created because the connection from neuron 3 to neuron 2 is 7 units of time delayed compared to the connection from neuron 3 to neuron 1. Since $\mathcal{W}$ cannot distinguish between direct connections and common input, it must be interpreted with care. It cannot be viewed as representing the connectivity between the two measured neurons unless one could somehow rule out a mutual connection from any unmeasured neurons.

7. Discussion. We derived a method for analyzing a pair of coupled linear-nonlinear systems driven by white noise. Through measuring first and second order input-output statistics, one can characterize the systems. In particular, one can

reconstruct the coupling between the systems if the coupling is assumed to be of a particular form (see (5.1)).

We demonstrated that the method is robust to variations in the detailed form of the nonlinearity. We believe this robustness is due to the smoothing by the white noise input. Each input-output statistic depends on the nonlinearities $g_p(\cdot)$ only through expected values over the white noise. The effect of this smoothing is most clearly seen in the initial expression for each statistic in Appendix A. The $g_p(\cdot)$ appear in the integrals as either $g_p(\mathbf{h}_p^i \cdot \mathbf{x})$ or $g_p'(\mathbf{h}_p^i \cdot \mathbf{x})$. Since the kernels are unit vectors, the arguments of the nonlinearity are standard normals. Only the integrals of the $g_p(\cdot)$ over the probability density function of standard normals, not pointwise evaluation of the $g_p(\cdot)$, affect the input-output statistics. These integrals smooth out minor differences between nonlinearity shapes.

Since the method is a first order approximation in the coupling magnitude, measurements of large $\mathcal{W}$ (on the order of the standard deviation of an input component) must be viewed cautiously. According to our simulation results, the breakdown of the first order approximation typically leads only to deviations in the magnitude of the estimated connectivity. However, in extreme cases, large connectivity could lead to the emergence of second order effects in the form of additional peaks in $\mathcal{W}$ that do not reflect the connectivity $\bar{W}$.

More importantly, the method cannot distinguish between the assumed mutual coupling of the model and other mechanisms for creating correlations between the responses, such as common input from outside sources. Measurements of $\mathcal{W}$ would be evidence of mutual coupling only if other mechanisms for correlations could be ruled out. Nonetheless, even if the source of $\mathcal{W}$ cannot be definitively determined, measurement of $\mathcal{W}$ still could provide evidence about the time scale and magnitudes of the interactions in the underlying neural network.

The proposed method was developed to analyze multielectrode recordings of neurons in response to a white noise stimulus. However, the linear-nonlinear model assumed by the analysis is only a crude, phenomenological approximation to the biology. To better interpret the results of the method, one must be able to assign significance to nonzero measurements of $\mathcal{W}$. One future challenge is to develop methods for identifying cases in which nonzero measurements of $\mathcal{W}$ are due simply to deviations from the linear-nonlinear model.

Appendix A. Details of derivation for unidirectional coupling.

A.1. Probability of a spike in neuron 1. Under the first order approximation in $\bar{W}$, we can simplify (2.2) for neuron 1 to

$$\begin{aligned}\Pr\bigl(R_1^i = 1 \bigm| \mathbf{X} = \mathbf{x}, \mathbf{R}_2 = \mathbf{r}_2\bigr) &= g_1\biggl(\mathbf{h}_1^i \cdot \mathbf{x} + \sum_{j \geq 0} \bar{W}_{21}^j r_2^{i-j}\biggr) \\ &= g_1(\mathbf{h}_1^i \cdot \mathbf{x}) + g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) \sum_{j \geq 0} \bar{W}_{21}^j r_2^{i-j}. \end{aligned} \tag{A.1}$$

The probability of a spike in neuron 1 is then

$$\begin{aligned}\Pr\bigl(R_1^i = 1 \bigm| \mathbf{X} = \mathbf{x}\bigr) &= \sum_{\mathbf{r}_2} \Pr\bigl(R_1^i = 1 \bigm| \mathbf{X} = \mathbf{x}, \mathbf{R}_2 = \mathbf{r}_2\bigr) \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \bigm| \mathbf{X} = \mathbf{x}\bigr) \\ &= g_1(\mathbf{h}_1^i \cdot \mathbf{x}) \sum_{\mathbf{r}_2} \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \bigm| \mathbf{X} = \mathbf{x}\bigr) \\ &\quad + g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) \sum_{j \geq 0} \bar{W}_{21}^j \sum_{\mathbf{r}_2} r_2^{i-j} \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \bigm| \mathbf{X} = \mathbf{x}\bigr). \end{aligned} \tag{A.2}$$

The sum is over all values of $\mathbf{r}_2$, where each component $r_2^{\tilde{\jmath}}$ can be either one or zero; i.e., this sum is over every possible spike combination of neuron 2. The product reflects the assumption that, since $\bar{W}_{12} = 0$, the responses of neuron 2, when conditioned on the stimulus, are independent.

The total probability of any spike combination of neuron 2 must equal one,

$$\sum_{\mathbf{r}_2} \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \big| \mathbf{X} = \mathbf{x}\bigr) = 1. \tag{A.3}$$

Moreover, since $r_2^{i-j} \in \{0,1\}$, only terms where $r_2^{i-j} = 1$ make a contribution in the coefficient of $\bar{W}_{21}^j$:

$$\begin{aligned}\sum_{\mathbf{r}_2} r_2^{i-j} \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \big| \mathbf{X} = \mathbf{x}\bigr) \\ = \Pr\bigl(R_2^{i-j} = 1 \big| \mathbf{X} = \mathbf{x}\bigr) \sum_{\mathbf{r}_2 \text{ except } r_2^{i-j}} \prod_{\tilde{\jmath} \neq j} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \big| \mathbf{X} = \mathbf{x}\bigr) \\ = g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}). \qquad \text{(A.4)}\end{aligned}$$

In the last step, we used a generalization of (A.3) excluding the $i - j$ time interval.

Combining (A.2), (A.3), and (A.4), the probability of a spike in neuron 1 is

$$\Pr\bigl(R_1^i = 1 \big| \mathbf{X} = \mathbf{x}\bigr) = g_1(\mathbf{h}_1^i \cdot \mathbf{x}) + \sum_{j \geq 0} \bar{W}_{21}^j g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}), \tag{A.5}$$

where $=$ indicates equality within $O(\bar{W}^2)$.

A.2. Probability of spike pairs. In the case of unidirectional coupling, the probability of a spike pair is

$$\begin{aligned}\Pr\bigl(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \big| \mathbf{X} = \mathbf{x}, \mathbf{R}_2 = \mathbf{r}_2\bigr) &= g_1\left(\mathbf{h}_1^i \cdot \mathbf{x} + \sum_{j \geq 0} \bar{W}_{21}^j r_2^{i-j}\right) r_2^{i-k} \qquad \text{(A.6)} \\ &= g_1(\mathbf{h}_1^i \cdot \mathbf{x}) r_2^{i-k} + g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) r_2^{i-k} \bar{W}_{21}^k + g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) r_2^{i-k} \sum_{\substack{j \geq 0 \\ j \neq k}} \bar{W}_{21}^j r_2^{i-j}.\end{aligned}$$

Note that $(r_2^{i-k})^2 = r_2^{i-k}$ since $r_2^{i-k} \in \{0,1\}$.

If we repeat the same procedure as in the previous section,

$$\begin{aligned}\Pr\bigl(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \big| \mathbf{X} = \mathbf{x}\bigr) \qquad \text{(A.7)} \\ = \sum_{\mathbf{r}_2} \Pr\bigl(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \big| \mathbf{X} = \mathbf{x}, \mathbf{R}_2 = \mathbf{r}_2\bigr) \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \big| \mathbf{X} = \mathbf{x}\bigr),\end{aligned}$$

the only new term will be

$$\sum_{\mathbf{r}_2} r_2^{i-j} r_2^{i-k} \prod_{\tilde{\jmath}} \Pr\bigl(R_2^{i-\tilde{\jmath}} = r_2^{i-\tilde{\jmath}} \big| \mathbf{X} = \mathbf{x}\bigr) = g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}). \tag{A.8}$$

Therefore,

$$\begin{aligned}\Pr\bigl(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \big| \mathbf{X} = \mathbf{x}\bigr) = g_1(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) \\ + \bar{W}_{21}^k g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) \\ + \sum_{\substack{j \geq 0 \\ j \neq k}} \bar{W}_{21}^j g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}). \qquad \text{(A.9)}\end{aligned}$$

A.3. Mean rate of neuron 1. The mean rate of neuron 1 (see (A.5)) is given by

$$\begin{aligned} E\{R_1^i\} &= \frac{1}{(2\pi)^{n/2}} \int \Pr\bigl(R_1^i = 1 \bigm| \mathbf{X} = \mathbf{x}\bigr) e^{-|\mathbf{x}|^2/2} d\mathbf{x} \\ &= \frac{1}{(2\pi)^{n/2}} \int g_1(\mathbf{h}_1^i \cdot \mathbf{x}) e^{-|\mathbf{x}|^2/2} d\mathbf{x} \\ &\quad + \sum_{j \ge 0} \frac{\bar{W}_{21}^j}{(2\pi)^{n/2}} \int g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}) e^{-|\mathbf{x}|^2/2} d\mathbf{x}. \end{aligned} \tag{A.10}$$

The first term is identical to the uncoupled case. For the rest of the terms, we use a different coordinate system for each j. The first unit vector is $\mathbf{e}_1 = \mathbf{h}_1^i$, and the second unit vector is the component of $\mathbf{h}_2^{i-j}$ that is perpendicular to $\mathbf{h}_1^i$, so that $\mathbf{h}_2^{i-j} = \mathbf{e}_1 \cos\bar{\theta}_{21}^j + \mathbf{e}_2 \sin\bar{\theta}_{21}^j$.

We change variables and integrate by parts (assuming (3.5)) to simplify the jth term:

$$\begin{aligned} &\frac{\bar{W}_{21}^j}{2\pi} \int g_1'(x_1) g_2(x_1 \cos\bar{\theta}_{21}^j + x_2 \sin\bar{\theta}_{21}^j) e^{-\frac{x_1^2+x_2^2}{2}} dx_1 dx_2 \\ &\quad = \frac{\bar{W}_{21}^j}{2\pi} \int g_1'(u) g_2(v) \exp\biggl(-\frac{u^2}{2} - \frac{(v - u\cos\bar{\theta}_{21}^j)^2}{2\sin^2\bar{\theta}_{21}^j}\biggr) \frac{du\,dv}{\sin\bar{\theta}_{21}^j} \\ &\quad = \frac{\bar{W}_{21}^j}{2\sqrt{2\pi}} \int g_1'(u) g_2'(v) e^{-\frac{u^2}{2}} \operatorname{erfc}\biggl(\frac{v - u\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j}\biggr) du\,dv. \end{aligned} \tag{A.11}$$

The mean rate of neuron 1 is thus

$$\begin{aligned} E\{R_1^i\} = \frac{1}{\sqrt{2\pi}} &\int g_1(u) e^{-\frac{u^2}{2}} du \\ &+ \sum_{j \ge 0} \frac{\bar{W}_{21}^j}{2\sqrt{2\pi}} \int g_1'(u) g_2'(v) e^{-\frac{u^2}{2}} \operatorname{erfc}\biggl(\frac{v - u\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j}\biggr) du\,dv. \end{aligned} \tag{A.12}$$

A.4. Correlation of spikes of neuron 1 with the stimulus. The stimulus-spike correlation of neuron 1 (see (A.5)) is

$$\begin{aligned} E\{\mathbf{X}R_1^i\} &= \frac{1}{(2\pi)^{n/2}} \int \mathbf{x} \Pr\bigl(R_1^i = 1 \bigm| \mathbf{X} = \mathbf{x}\bigr) e^{-|\mathbf{x}|^2/2} d\mathbf{x} \\ &= \frac{1}{(2\pi)^{n/2}} \int \mathbf{x} g_1(\mathbf{h}_1^i \cdot \mathbf{x}) e^{-|\mathbf{x}|^2/2} d\mathbf{x} \\ &\quad + \sum_{j \ge 0} \frac{\bar{W}_{21}^j}{(2\pi)^{n/2}} \int \mathbf{x} g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}) e^{-|\mathbf{x}|^2/2} d\mathbf{x}. \end{aligned} \tag{A.13}$$

The first term is identical to the uncoupled case, becoming

$$\frac{1}{\sqrt{2\pi}} \int g_1'(u) e^{-\frac{u^2}{2}} du\, \mathbf{h}_1^i$$

with an integration by parts. For the rest of the terms, just as in the previous section, we will use a different coordinate system for each j, with $\mathbf{e}_1 = \mathbf{h}_1^i$ and with $\mathbf{e}_2$ being

the component of $\mathbf{h}_2^{i-j}$ that is perpendicular to $\mathbf{h}_1^i$. We will denote this second unit vector by

$$\overset{\perp ji}{\mathbf{h}}_{21} = \frac{\mathbf{h}_2^{i-j} - \cos\bar{\theta}_{21}^j \mathbf{h}_1^i}{\sin\bar{\theta}_{21}^j}. \tag{A.14}$$

Note that $\mathbf{h}_2^{i-j} = \mathbf{h}_1^i \cos\bar{\theta}_{21}^j + \overset{\perp ji}{\mathbf{h}}_{21} \sin\bar{\theta}_{21}^j$. The jth term thus has two nonzero components,

$$\begin{aligned}
&\frac{\bar{W}_{21}^j}{2\pi} \int (x_1 \mathbf{h}_1^i + x_2 \overset{\perp ji}{\mathbf{h}}_{21}) g_1'(x_1) g_2(x_1 \cos\bar{\theta}_{21}^j + x_2 \sin\bar{\theta}_{21}^j) e^{-\frac{x_1^2+x_2^2}{2}} dx_1 dx_2 \\
&\qquad = \bar{W}_{21}^j (I_{j,1} \mathbf{h}_1^i + I_{j,2} \overset{\perp ji}{\mathbf{h}}_{21}),
\end{aligned} \tag{A.15}$$

where the above defines $I_{j,1}$ and $I_{j,2}$. We change variables and integrate by parts (assuming (3.5)) to simplify the first component:

$$\begin{aligned}
I_{j,1} &= \frac{1}{2\pi} \int u g_1'(u) g_2(v) \exp\left(-\frac{u^2}{2} - \frac{(v - u\cos\bar{\theta}_{21}^j)^2}{2\sin^2\bar{\theta}_{21}^j} \right) \frac{du\,dv}{\sin\bar{\theta}_{21}^j} \\
&= \frac{1}{2\sqrt{2\pi}} \int g_1'(u) g_2'(v) u e^{-\frac{u^2}{2}} \operatorname{erfc}\left(\frac{v - u\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j} \right) du\,dv.
\end{aligned} \tag{A.16}$$

To simplify $I_{j,2}$, we first integrate by parts in the x_2 variable, then change variables:

$$\begin{aligned}
I_{j,2} &= \frac{1}{2\pi} \int g_1'(x_1) g_2'(x_1 \cos\bar{\theta}_{21}^j + x_2 \sin\bar{\theta}_{21}^j) \sin\bar{\theta}_{21}^j e^{-\frac{x_1^2+x_2^2}{2}} dx_1 dx_2 \\
&= \frac{1}{2\pi} \int g_1'(u) g_2'(v) \exp\left(-\frac{u^2 - 2\cos\bar{\theta}_{21}^j uv + v^2}{2\sin^2\bar{\theta}_{21}^j} \right) du\,dv.
\end{aligned} \tag{A.17}$$

Combining these results, the stimulus-spike correlation of neuron 1 is

$$\begin{aligned}
E\{\mathbf{X} R_1^i\} = \frac{1}{\sqrt{2\pi}} \Bigg[&\int g_1'(u) e^{-\frac{u^2}{2}} du \\
&+ \sum_{j\ge 0} \frac{\bar{W}_{21}^j}{2} \int g_1'(u) g_2'(v) u e^{-\frac{u^2}{2}} \operatorname{erfc}\left(\frac{v - u\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j} \right) du\,dv \Bigg] \mathbf{h}_1^i \\
&+ \sum_{j\ge 0} \frac{\bar{W}_{21}^j}{2\pi} \int g_1'(u) g_2'(v) \exp\left(-\frac{u^2 - 2\cos\bar{\theta}_{21}^j uv + v^2}{2\sin^2\bar{\theta}_{21}^j} \right) du\,dv\, \overset{\perp ji}{\mathbf{h}}_{21}.
\end{aligned} \tag{A.18}$$

A.5. Correlation between spikes of neurons 1 and 2. The correlation between spikes of neuron 1 and neuron 2 is (see (A.9))

$$\begin{aligned}
E\{R_1^i R_2^{i-k}\} &= \frac{1}{(2\pi)^{n/2}} \int \Pr\big(R_1^i = 1 \,\&\, R_2^{i-k} = 1 \big| \mathbf{X} = \mathbf{x}\big) e^{-\frac{|\mathbf{x}|^2}{2}} d\mathbf{x} \\
&= \frac{1}{(2\pi)^{n/2}} \int \Bigg[g_1(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) \\
&\qquad + g_1'(\mathbf{h}_1^i \cdot \mathbf{x}) g_2(\mathbf{h}_2^{i-k} \cdot \mathbf{x}) \left(\bar{W}_{21}^k + \sum_{j\ge 0,\, j\ne k} \bar{W}_{21}^j g_2(\mathbf{h}_2^{i-j} \cdot \mathbf{x}) \right) \Bigg] e^{-\frac{|\mathbf{x}|^2}{2}} d\mathbf{x}.
\end{aligned} \tag{A.19}$$

The first term is identical to the uncoupled case (i.e., (3.6)). The $\bar{W}_{21}^k$ term is identical to (A.11).

For the $\bar{W}_{21}^j$ terms with $j \neq k$, we let $\mathbf{e}_1 = \mathbf{h}_1^i$ and $\mathbf{e}_2 = \overset{\perp ki}{\mathbf{h}}_{21}$, and let the third unit vector be the component of $\mathbf{h}_2^{i-j}$ perpendicular to both $\mathbf{e}_1$ and $\mathbf{e}_2$ so that

$$\mathbf{h}_2^{i-j} = \mathbf{e}_1 \cos\bar{\theta}_{21}^j + \mathbf{e}_2 c_{21}^{kj} \sin\bar{\theta}_{21}^j + \mathbf{e}_3 \sin\bar{\theta}_{21}^j \sqrt{1-(c_{21}^{kj})^2},$$

where

$$c_{21}^{kj} = \overset{\perp ki}{\mathbf{h}}_{21} \cdot \overset{\perp ji}{\mathbf{h}}_{21} = \frac{\cos\theta_{22}^{k-j} - \cos\bar{\theta}_{21}^k \cos\bar{\theta}_{21}^j}{\sin\bar{\theta}_{21}^k \sin\bar{\theta}_{21}^j}.$$

Denoting the $\bar{W}_{21}^j$ terms in (A.19) by $\bar{W}_{21}^j I_{kj}$ and changing variables, we compute

$$\begin{aligned} I_{kj} &= \frac{1}{(2\pi)^{3/2}} \int g_1'(x_1) g_2(x_1\cos\bar{\theta}_{21}^k + x_2 \sin\bar{\theta}_{21}^k) \\ &\qquad \times g_2\Big(x_1\cos\bar{\theta}_{21}^j + x_2 c_{21}^{kj}\sin\bar{\theta}_{21}^j + x_3 \sin\bar{\theta}_{21}^j\sqrt{1-(c_{21}^{kj})^2}\Big) e^{-\frac{x_1^2+x_2^2+x_3^2}{2}}\, dx_1 dx_2 dx_3 \\ &= \frac{1}{(2\pi)^{3/2}} \int \frac{du_1 du_2 du_3\, g_1'(u_1) g_2(u_2) g_2(u_3)}{\sin\bar{\theta}_{21}^k \sin\bar{\theta}_{21}^j \sqrt{1-(c_{21}^{kj})^2}} \\ &\qquad \times \exp\left(-\frac{u_1^2}{2} - \frac{(u_2 - u_1\cos\bar{\theta}_{21}^k)^2}{2\sin^2\bar{\theta}_{21}^k} - \frac{\left[\frac{u_3 - u_1\cos\bar{\theta}_{21}^j}{\sin\bar{\theta}_{21}^j} - c_{21}^{kj}\frac{u_2 - u_1\cos\bar{\theta}_{21}^k}{\sin\bar{\theta}_{21}^k}\right]^2}{2[1-(c_{21}^{kj})^2]} \right). \end{aligned}$$

Using (3.5) and integrating by parts twice as in the derivation of (3.6), we simplify this expression to

$$\begin{aligned} I_{kj} = \frac{1}{4\sqrt{2\pi}} &\int g_1'(u_1) g_2'(u_2) g_2'(u_3) e^{-\frac{u_1^2}{2}} \\ &\times \operatorname{derfc}\left(\frac{u_2 - u_1\cos\bar{\theta}_{21}^k}{\sqrt{2}\sin\bar{\theta}_{21}^k}, \frac{u_3 - u_1\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j}, c_{21}^{kj} \right) du_1 du_2 du_3. \end{aligned} \tag{A.20}$$

The correlation between spikes of neuron 1 and neuron 2 is therefore

$$\begin{aligned} E\{R_1^i R_2^{i-k}\} &= \frac{1}{4}\int g_1'(u_1) g_2'(u_2) \operatorname{derfc}\left(\frac{u_1}{\sqrt{2}}, \frac{u_2}{\sqrt{2}}, \cos\bar{\theta}_{21}^k\right) du_1 du_2 \\ &\quad + \frac{\bar{W}_{21}^k}{2\sqrt{2\pi}} \int g_1'(u_1) g_2'(u_2) e^{-\frac{u_1^2}{2}} \operatorname{erfc}\left(\frac{u_2 - u_1\cos\bar{\theta}_{21}^k}{\sqrt{2}\sin\bar{\theta}_{21}^k}\right) du_1 du_2 \\ &\quad + \sum_{j\geq 0,\, j\neq k} \frac{\bar{W}_{21}^j}{4\sqrt{2\pi}} \int du_1 du_2 du_3\, g_1'(u_1) g_2'(u_2) g_2'(u_3) e^{-\frac{u_1^2}{2}} \\ &\quad \times \operatorname{derfc}\left(\frac{u_2 - u_1\cos\bar{\theta}_{21}^k}{\sqrt{2}\sin\bar{\theta}_{21}^k}, \frac{u_3 - u_1\cos\bar{\theta}_{21}^j}{\sqrt{2}\sin\bar{\theta}_{21}^j}, \frac{\cos\theta_{22}^{k-j} - \cos\bar{\theta}_{21}^j\cos\bar{\theta}_{21}^k}{\sin\bar{\theta}_{21}^j\sin\bar{\theta}_{21}^k} \right). \end{aligned} \tag{A.21}$$

Appendix B. Formulas used in derivations. In all formulas, each sine is assumed to be positive.

The formulas

$$\frac{1}{\epsilon_p\sqrt{2\pi}}\iint \exp\left(-\frac{(x-T_p)^2}{2\epsilon_p^2}-\frac{x^2}{2}\right)dx = \delta_p e^{-\frac{\delta_p^2 T_p^2}{2}} \tag{B.1}$$

and

$$\begin{aligned}\frac{1}{2\pi\epsilon_p\epsilon_q}\iint \exp\left(-\frac{(x-T_p)^2}{2\epsilon_p^2}-\frac{(y-T_q)^2}{2\epsilon_q^2}-\frac{x^2-2xy\cos\theta+y^2}{2\sin^2\theta}\right)dx\,dy \\ = \frac{\delta_p\delta_q\sin\theta}{\sqrt{1-\delta_p^2\delta_q^2\cos^2\theta}}\exp\left(-\frac{\delta_p^2T_p^2-2\delta_p^2\delta_q^2T_pT_q\cos\theta+\delta_q^2T_q^2}{2(1-\delta_p^2\delta_q^2\cos^2\theta)}\right),\end{aligned} \tag{B.2}$$

where $\delta_q = 1/\sqrt{1+\epsilon_q^2}$, follow from the application of

$$\int \exp(-[ax^2+bx+c])\,dx = \sqrt{\frac{\pi}{a}}\exp\left(\frac{b^2}{4a}-c\right)$$

for $a>0$.

For the following two formulas, change variables in the double integral so that one of the new variables is parallel to the line $u = dx+f$ (where u is the integration variable of the $\operatorname{erfc}(\cdot)$). By completing the square in the resulting integrands, one can derive both

$$\int \exp(-[ax^2+bx+c])\operatorname{erfc}(dx+f)\,dx = \sqrt{\frac{\pi}{a}}\exp\left(\frac{b^2}{4a}-c\right)\operatorname{erfc}\left(\frac{2af-bd}{2\sqrt{a(a+d^2)}}\right) \tag{B.3}$$

and

$$\begin{aligned}&\int x\exp(-[ax^2+bx+c])\operatorname{erfc}(dx+f)\,dx \\ &\quad = -\frac{1}{a}\exp\left(\frac{b^2}{4a}-c\right)\left[\frac{d\exp\left(-\frac{(2af-bd)^2}{4a(a+d^2)}\right)}{\sqrt{a+d^2}}+\frac{b\sqrt{\pi}}{2\sqrt{a}}\operatorname{erfc}\left(\frac{2af-bd}{2\sqrt{a(a+d^2)}}\right)\right]\end{aligned} \tag{B.4}$$

for $a>0$. By applying (B.3) twice, one can show that

$$\begin{aligned}\frac{1}{2\pi\epsilon_p\epsilon_q}\iint \exp\left(-\frac{(x-T_p)^2}{2\epsilon_p^2}-\frac{(y-T_q)^2}{2\epsilon_q^2}-\frac{x^2}{2}\right)\operatorname{erfc}\left(\frac{y-x\cos\theta}{\sqrt{2}\sin\theta}\right)dx\,dy \\ = \delta_p e^{-\frac{\delta_p^2T_p^2}{2}}\operatorname{erfc}\left(\frac{\delta_qT_q-\delta_p^2\delta_qT_p\cos\theta}{\sqrt{2(1-\delta_p^2\delta_q^2\cos^2\theta)}}\right),\end{aligned} \tag{B.5}$$

and by applying both (B.3) and (B.4), one can show that

$$\begin{aligned}&\frac{1}{2\pi\epsilon_p\epsilon_q}\iint x\exp\left(-\frac{(x-T_p)^2}{2\epsilon_p^2}-\frac{(y-T_q)^2}{2\epsilon_q^2}-\frac{x^2}{2}\right)\operatorname{erfc}\left(\frac{y-x\cos\theta}{\sqrt{2}\sin\theta}\right)dx\,dy \\ &\quad = \delta_p^3T_pe^{-\frac{\delta_p^2T_p^2}{2}}\operatorname{erfc}\left(\frac{\delta_qT_q-\delta_p^2\delta_qT_p\cos\theta}{\sqrt{2(1-\delta_p^2\delta_q^2\cos^2\theta)}}\right) \\ &\qquad + \frac{2\delta_p\delta_q(1-\delta_p^2)\cos\theta}{\sqrt{2\pi(1-\delta_p^2\delta_q^2\cos^2\theta)}}\exp\left(-\frac{\delta_p^2T_p^2-2\delta_p^2\delta_q^2T_pT_q\cos\theta+\delta_q^2T_q^2}{2(1-\delta_p^2\delta_q^2\cos^2\theta)}\right).\end{aligned} \tag{B.6}$$

For the following formula, let u be the integration variable of the $\operatorname{erfc}(\cdot)$. Then change variables in the triple integral so that the first variable is parallel to the line $y = dx + f$, and a linear combination of the first and second variables is parallel to the line $u = gx + h - ky$. By repeatedly completing the square in the integrand, one can derive that

$$\int dx \exp(-[ax^2 + bx + c]) \int_{dx+f}^{\infty} dy\, e^{-y^2} \operatorname{erfc}(gx + h - ky)$$

(B.7)

$$= \sqrt{\frac{\pi}{a}} e^{(\frac{b^2}{4a} - c)} \int_{\frac{2af - bd}{2\sqrt{a(a+d^2)}}}^{\infty} e^{-u^2} \operatorname{erfc}\left(\frac{(2ha - bg)\sqrt{a + d^2} - 2\sqrt{a}(gd + ka)u}{2a\sqrt{(kd - g)^2 + a + d^2}} \right) du$$

for $a > 0$. Repeated application of (B.7), combined with extensive algebra, yields

$$\text{(B.8)} \quad \frac{1}{2\pi\epsilon_p\epsilon_q} \iint \exp\left(-\frac{(x - T_p)^2}{2\epsilon_p^2} - \frac{(y - T_q)^2}{2\epsilon_q^2} \right) \operatorname{derfc}\left(\frac{x}{\sqrt{2}}, \frac{y}{\sqrt{2}}, \cos\theta \right) dx\, dy$$
$$= \operatorname{derfc}\left(\frac{\delta_p T_p}{\sqrt{2}}, \frac{\delta_q T_q}{\sqrt{2}}, \delta_p \delta_q \cos\theta \right)$$

and

$$\frac{1}{(2\pi)^{3/2}\epsilon_p\epsilon_q^2} \iiint \exp\left(-\frac{(x - T_p)^2}{2\epsilon_p^2} - \frac{(y - T_q)^2}{2\epsilon_q^2} - \frac{(z - T_q)^2}{2\epsilon_q^2} - \frac{x^2}{2} \right)$$
$$\times \operatorname{derfc}\left(\frac{z - x\cos\theta}{\sqrt{2}\sin\theta}, \frac{y - x\cos\phi}{\sqrt{2}\sin\phi}, \frac{\cos\psi - \cos\theta\cos\phi}{\sin\theta\sin\phi} \right) dx\, dy\, dz$$

(B.9)

$$= \delta_p e^{-\frac{\delta_p^2 T_p^2}{2}} \operatorname{derfc}\left(\frac{\delta_q T_q - \delta_p^2 \delta_q T_p \cos\theta}{\sqrt{2(1 - \delta_p^2\delta_q^2\cos^2\theta)}}, \frac{\delta_q T_q - \delta_p^2 \delta_q T_p \cos\phi}{\sqrt{2(1 - \delta_p^2\delta_q^2\cos^2\phi)}}, \frac{\delta_q^2\cos\psi - \delta_p^2\delta_q^2\cos\theta\cos\phi}{\sqrt{(1 - \delta_p^2\delta_q^2\cos^2\theta)(1 - \delta_p^2\delta_q^2\cos^2\phi)}} \right),$$

where $\operatorname{derfc}(\cdot)$ is defined by (3.7).

Acknowledgments. The author thanks Dario Ringach for numerous helpful discussions throughout the development of this research and Charlie Peskin and Dan Tranchina for constructive criticism on an early version of these ideas.

HYPERBOLIC HOMOGENIZED MODELS FOR THERMAL AND SOLUTAL DISPERSION*

VEMURI BALAKOTAIAH† AND HSUEH-CHIA CHANG‡

Abstract. We formulate a general theory, based on a Lyapunov–Schmidt expansion, for averaging thermal and solutal dispersion phenomena in multiphase reactors, with specific attention to the important Taylor mechanism due to transverse intraphase and interphase capacitance-weighted velocity gradients. We show that the classical Taylor dispersion phenomena are better described in terms of low dimensional models that are hyperbolic and contain an effective local time or length scale in place of the traditional Taylor dispersion coefficient. This description eliminates the use of an artificial exit boundary condition associated with parabolic homogenized equations as well as the classical upstream-feedback and infinite propagation speed anomalies. Our approach is also applicable for describing steady dispersion in the presence of reaction and thermal generation or consumption. For two-phase systems, maximum dispersion is found to exist at an optimum fraction ϵ_f of the lower-capacitance phase. For the disparate phase capacities of most reactors, thermal or solutal dispersion is shown to have the scaling $\frac{\epsilon_f p^2}{(1-\epsilon_f)\Gamma}\alpha_f$, where α_f is the thermal diffusivity of the low-capacitance phase, Γ is the capacitance ratio, and p is the transverse Peclet number.

Key words. solutal dispersion, thermal dispersion, averaging, Liapunov–Schmidt reduction, multiphase reactors

1. Introduction.

A major goal of the discipline of chemical engineering known as reaction engineering is to combine the complex kinetics, flow fields, and geometries of multiphase reacting systems (such as a packed bed) into accurate low dimensional homogenized convection-diffusion-reaction models that contain all the pertinent transport and kinetic effects of the above complications. It was realized very early that flow turbulence, tortuosity of the interstitial streamlines, velocity gradient of the flowing phase, adsorption onto a stationary phase (as in a chromatograph), and accumulation near stagnation points or stagnant dead zones can give rise to anomalously high solutal dispersion, orders of magnitude higher than molecular diffusion, that must somehow be modeled and included in the homogenized model as a dispersion term $D_{eff}\frac{\partial^2 c}{\partial z^2}$ with the dispersion coefficient D_{eff}. That such a term stipulates that two boundary conditions be provided for the parabolic homogenized model has also introduced considerable confusion. The classical Danckwerts boundary conditions and many other inconsistent ones provide one boundary condition at each end of the reactor (Danckwerts (1953), Choi and Perlmutter (1976), Wehner and Wilhelm (1956)) and have recently been "justified" by Roberts (1989) using center manifold theory. There are, however, fundamental difficulties with this parabolic equation and the Danckwerts boundary conditions. This model introduces infinitely fast diffusive spreading of a

localized concentration perturbation and upstream diffusive propagation (Hinduja, Sundaresan, and Jackson (1980), Sundaresan, Anderson, and Aris (1980)). Both phenomena are not observed experimentally as the flow-induced dispersion mechanisms are hyperbolic in nature (Hiby (1962), Chang (1982)). As a result, the homogenized parabolic equation and Danckwerts boundary conditions cannot describe the observed dispersion phenomena in finite length reactors.

Local turbulent dispersion can be estimated using classical homogeneous turbulent mixing theory. Dispersion in periodic as well as random velocity fields has been reviewed by Majda and Kramer (1999). These authors also present an excellent review of homogenization methods for the convective diffusion equation with periodic velocity fields.

In many applications such as chromatographs and reactors involving packed beds, the flow is laminar, and the more important larger scale dispersion effects that occur over several reactor radii are mostly due to a Taylor–Aris dispersion mechanism (Taylor (1953), Aris (1959), Brenner and Edwards (1993)). This mechanism occurs when a macroscopic transverse velocity gradient, like Poiseuille flow in a tube or macroscopic flow nonuniformity in a packed bed, induces longitudinal dispersion as transverse diffusion lands molecules onto streamlines or flow channels of different velocity. Adsorption onto a stationary solid phase also can trigger this effect as the solid phase has a velocity (zero) different from the flowing phase. Adsorption-induced Taylor–Aris dispersion is responsible for the dispersion of chromatograph signals (Balakotaiah and Chang (1995)). It is also a main problem in biochemical assays on chip-scale laboratories and reactors using microfluidics (Culbertson, Jacobson, and Ramsey (1998)).

Several theories have been developed to predict solutal Taylor–Aris dispersion in packed beds. In the limit of extremely high Peclet number p in an unbounded medium when diffusion is unimportant in the bulk of the flowing phase, Koch and Brady used a diffusive boundary layer cutoff to show that D_{eff} scales as $p \ln p$ (Koch and Brady (1985)). Roberts (1989) and Balakotaiah and Chang (1995) used center manifold theory to show that reaction can affect the dispersion coefficient in a long reactor whose length is much longer than its transverse dimension (radius) such that diffusion dominates in the transverse direction.

Another confusion concerning dispersion is whether a homogenized model remains valid at steady state and whether D_{eff} and its underlying dispersion mechanism are still in play at steady state. While Taylor's classical theory (Taylor, 1953), Koch and Brady's high-p dispersion mechanism in an unbounded medium, and Roberts's and Balakotaiah and Chang's reactive dispersion theory in a long reactor are clearly for transient dispersion, it seems physically intuitive that the same transverse gradient in longitudinal velocity can affect steady-state reactor conversion or performance (Chang, 1982). In fact, it is common practice to use the homogenized model for both steady and transient reactors (Westerterp, Dilman, and Kronberg (1995)). Steady dispersion, however, lacks theoretical justification. An apparent steady dispersion will be shown here to exist, but its description is fundamentally different from that of the transient one.

Even more important than solutal dispersion is thermal dispersion, a subject that is only recently being scrutinized in detail. It is well known in the reaction engineering literature (Balakotaiah (1996), Subramanian and Balakotaiah (1996)) that reactor dynamics and steady-state multiplicity are extremely sensitive to thermal dispersion. Empirical studies and recent analyses have shown that reactor ignition, extinction, hot spot formation, and thermal runaways of most important (and difficult to control) reactors for exothermic reactions are also extremely sensitive to thermal dispersion

(Balakotaiah, Kodra, and Nyugen (1995), Leighton and Chang (1995), and Keith, Leighton, and Chang (1999)). To compound the problem, thermal dispersion is more sensitive to packing and flow geometries and is far more difficult to estimate than solutal dispersion. Two major difficulties are that the thermal penetration depth into the solid phase is deeper than the solutal one, and that the stationary and mobile capacitances are more disparate. As a result, interphase dispersion due to discrepancies in the phase-averaged thermal velocities can enhance and even dominate the intraphase dispersion mechanism in the flowing phase due to transverse flow velocity gradient. The addition of interphase dispersion, distinct from Taylor's intraphase dispersion, renders the analysis more difficult. Vortmeyer and Schaefer (1974), Leighton and Chang (1995), and Balakotaiah and Dommeti (1999) obtained interphase dispersion coefficients based on lumped models with heat transfer coefficients. Leighton and Chang (1995) showed that the ignition location and light-off time of a catalytic converter is determined mostly by this thermal dispersion mechanism. Keith, Leighton, and Chang (1999) used metal inserts to enhance thermal dispersion of a reverse-flow reactor to prevent thermal runaway. Without including the intraphase dispersion mechanism due to flow nonuniformity, they found that an optimum void fraction of intermediate value and with maximum dispersion exists when the heat capacity ratio Γ is near unity, but none exists for realistic void fractions for disparate capacities. In fact, for the more common case of disparate capacities, a generic scaling seems to exist. This would be a significant general result as most reactors have disparate capacities and complex flow fields. It would be desirable to obtain general dispersion scalings insensitive to the flow fields. However, the omission of intraphase dispersion will be shown here to be valid only for disparate capacities. Greatly enhanced dispersion still exists near unit Γ and at an optimum flowing-phase fraction, but the actual dispersion coefficient must include intraphase dispersion and a detailed description of the macroscopic flow fields.

A general solutal/thermal Taylor–Aris dispersion theory will be formulated here to clearly delineate the intraphase and interphase contributions. The proper limit when the former can be omitted and the simpler lumped-phase models can be utilized is also defined. The theory also shows that dispersion phenomena are better described in terms of reduced (low dimensional) models that are hyperbolic in the longitudinal coordinate and time, and with an effective transfer or exchange time constant between the master (slowly varying) mode and slave (local) modes, in contrast to the traditional parabolic models with an effective dispersion coefficient. The reduced models derived based on the present theory eliminate the classical problems of upstream diffusion and infinite propagation speed associated with the parabolic-type averaged equations derived in the prior literature. The theory utilizes the Lyapunov–Schmidt reduction technique of classical bifurcation theory and is based on a perturbation expansion near zero eigenvalue(s).

2. Packed-bed heat transfer. To illustrate the concept of interphase dispersion (due to transfer or exchange between the phases) and some key ideas in our approach, we first consider a very simple model of a packed bed in which the solid is stationary and the fluid moves (Figure 1). The classical heat transfer model of this system ignores the (transverse) gradients within each phase as well as conduction in the axial direction in each phase. The model is described by the following pair of hyperbolic equations for the solid and fluid temperatures:

$$\epsilon_f \, (\rho c_p)_f \left[\frac{\partial T_f}{\partial t'} + u_0 \frac{\partial T_f}{\partial z'} \right] = h a_v (T_s - T_f), \tag{2.1a}$$

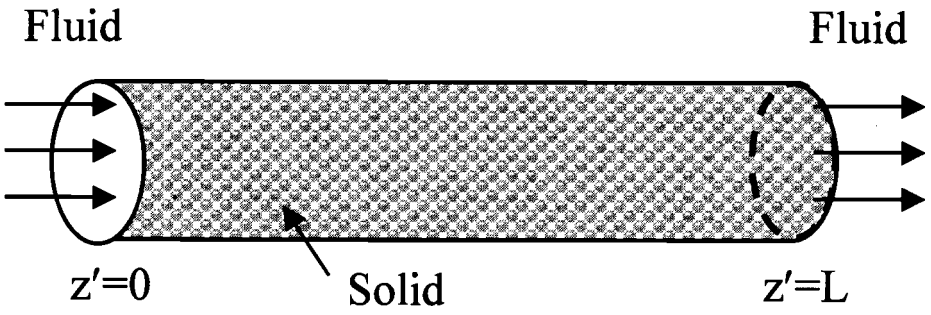

FIG. 1. *Schematic diagram of a packed-bed reactor in which solid and fluid phases interact.*

$$(1-\epsilon_f\ )(\rho c_p)_s \frac{\partial T_s}{\partial t'} = -h a_v (T_s - T_f), \tag{2.1b}$$

with initial and boundary conditions

$$T_f = f_0(t'), \qquad z' = 0,\ t' > 0, \tag{2.1c}$$

$$T_f = T_f^0(z'), \qquad t' = 0,\ z' > 0, \tag{2.1d}$$

$$T_s = T_s^0(z'), \qquad t' = 0,\ z' > 0. \tag{2.1e}$$

Here, u_0 (assumed to be a constant) is the interstitial fluid velocity, ϵ_f is the void fraction of the bed (available for flow), $(\rho c_p)_s$ ($(\rho c_p)_f$) is the solid (fluid) heat capacity per unit volume, h is the interphase heat transfer coefficient, and a_v is the (interphase) transfer area per unit bed volume. Assuming that the bed has a length L, we define

$$z = \frac{z'}{L}, \qquad t = \frac{u_0 t'}{L}, \qquad \Gamma = \frac{(\rho c_p)_s}{(\rho c_p)_f}, \qquad Pe = \frac{(\rho c_p)_f u_0}{L h a_v}, \tag{2.2}$$

and write (2.1a) and (2.1b) in dimensionless form as

$$A \begin{pmatrix} T_f \\ \\ T_s \end{pmatrix} = Pe \begin{pmatrix} \frac{\partial T_f}{\partial t} + \frac{\partial T_f}{\partial z} \\ \\ \frac{\partial T_s}{\partial t} \end{pmatrix}, \tag{2.3a}$$

where the matrix operator A is defined by

$$A = \begin{pmatrix} -\frac{1}{\epsilon_f} & \frac{1}{\epsilon_f} \\ \frac{1}{\Gamma(1-\epsilon_f)} & -\frac{1}{\Gamma(1-\epsilon_f)} \end{pmatrix}. \tag{2.3b}$$

(As shown later, A can be made symmetric by defining an inner product weighted with respect to the relative capacitances of the phases.) We note that the Peclet number Pe is the ratio of interphase transfer time ($\frac{(\rho c_p)_f}{h a_v}$) to the convection time ($\frac{L}{u_0}$), Γ is the ratio of solid to fluid heat capacities, and time is nondimensionalized with respect to the convection time. It is assumed that the Peclet number is small, or equivalently, that the interphase transfer time is much smaller compared to the

convection time. The matrix A is singular with the following null eigenvector and slave eigenvector (with eigenvalue $-\frac{1}{\epsilon_f} - \frac{1}{\Gamma(1-\epsilon_f)}$):

$$\phi_0 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}, \qquad \phi_1 = \begin{pmatrix} \Gamma(1-\epsilon_f) \\ -\epsilon_f \end{pmatrix}. \tag{2.4}$$

Writing

$$\begin{pmatrix} T_f \\ T_s \end{pmatrix} = \begin{pmatrix} 1 & \Gamma(1-\epsilon_f) \\ 1 & -\epsilon_f \end{pmatrix} \begin{pmatrix} T_m \\ T_d \end{pmatrix} \tag{2.5a}$$

or

$$\begin{pmatrix} T_m \\ T_d \end{pmatrix} = \begin{pmatrix} \frac{\epsilon_f}{[\epsilon_f+\Gamma(1-\epsilon_f)]} & \frac{\Gamma(1-\epsilon_f)}{[\epsilon_f+\Gamma(1-\epsilon_f)]} \\ \frac{1}{[\epsilon_f+\Gamma(1-\epsilon_f)]} & \frac{-1}{[\epsilon_f+\Gamma(1-\epsilon_f)]} \end{pmatrix} \begin{pmatrix} T_f \\ T_s \end{pmatrix}, \tag{2.5b}$$

we observe that T_m is the capacitance-weighted (average) temperature, while T_d is the local temperature difference. In terms of these variables, the model may be written as

$$[\epsilon_f + \Gamma(1-\epsilon_f)]\frac{\partial T_m}{\partial t} + \epsilon_f \frac{\partial T_m}{\partial z} = -\epsilon_f(1-\epsilon_f)\Gamma\frac{\partial T_d}{\partial z}, \tag{2.6a}$$

$$T_d = -\frac{Pe\epsilon_f(1-\epsilon_f)\Gamma}{[\epsilon_f+\Gamma(1-\epsilon_f)]^2}\left[\frac{\partial T_m}{\partial z} + \epsilon_f\frac{\partial T_d}{\partial t} + \Gamma(1-\epsilon_f)\left(\frac{\partial T_d}{\partial t} + \frac{\partial T_d}{\partial z}\right)\right]. \tag{2.6b}$$

For $Pe = 0$, the solid and fluid temperatures are in equilibrium, and the average temperature evolves according to (2.6a) with its right-hand side set to zero. For small values of the Peclet number, we have from (2.6b)

$$T_d = -\frac{Pe\epsilon_f(1-\epsilon_f)\Gamma}{[\epsilon_f+\Gamma(1-\epsilon_f)]^2}\left(\frac{\partial T_m}{\partial z}\right) + O(Pe^2). \tag{2.7}$$

Thus, the temperature difference T_d is slaved to the average temperature. Substituting (2.7) into (2.6a) and writing the resulting averaged equation in dimensional form, we obtain

$$\frac{\partial T_m}{\partial t'} + \langle u\rangle \frac{\partial T_m}{\partial z'} = \alpha_{eff}\frac{\partial^2 T_m}{\partial z'^2}, \tag{2.8a}$$

$$\langle u\rangle = u_0\frac{\epsilon_f}{[\epsilon_f+\Gamma(1-\epsilon_f)]}, \qquad \alpha_{eff} = \frac{u_0^2(\rho c_p)_f\ \Gamma^2\ \epsilon_f^2(1-\epsilon_f)^2}{ha_v[\epsilon_f+\Gamma(1-\epsilon_f)]^3}. \tag{2.8b}$$

Here, $\langle u\rangle$ and α_{eff} are the capacitance-weighted velocity and effective thermal diffusivity of the bed, respectively. From the above derivation, it is clear that the reduced model is valid only when $t' \gg \frac{(\rho c_p)_f}{ha_v}$ and $z' \gg u_0\frac{(\rho c_p)_f}{ha_v}$, i.e., when there is a short transient that escapes the effective equation. During this transient, the two phases equilibrate, and the appropriate initial condition for T_m is simply the capacitance-weighted average of the initial conditions of T_s and T_f,

$$T_m(t'=0) = \frac{\epsilon_f\ T_f(t'=0) + \Gamma(1-\epsilon_f)T_s(t'=0)}{[\epsilon_f\ +\Gamma(1-\epsilon_f)]}. \tag{2.8c}$$

This is valid even though $t' = 0$ on the two sides of (2.8c) corresponds to slightly different instants in time. The two boundary conditions for (2.8a) are more problematic, as the original equation only offers one boundary condition at $z' = 0$. Thus, one obvious one (from (2.1b) and (2.1c)) is that

$$T_m(z' = 0, t') = f_0(t') + \frac{(\rho c_p)_s \ \Gamma(1-\epsilon_f)^2}{h a_v [\epsilon_f + \Gamma(1-\epsilon_f)]} \left(\frac{\partial f_0(t')}{\partial t'} \right). \tag{2.8d}$$

In the engineering and the Taylor dispersion theory literature (Danckwerts (1953), Vortmeyer and Schaeffer (1974), Roberts (1992)), the other boundary condition is imposed at the exit $z' = L$, and the often-used exit (Danckwerts) boundary condition is

$$\frac{\partial T_m}{\partial z'}(z' = L, t') = 0. \tag{2.8e}$$

This is clearly not acceptable since the original problem does not possess any boundary condition at the exit. There is also a more fundamental problem associated with the form of the reduced model given by (2.8a). In this form, the reduced model is a parabolic equation, and imposing an artificial exit boundary condition leads to infinite propagation speed for inlet signals. Again, this is certainly not true for the original equations (2.1a) and (2.1b), which may be combined to obtain a single hyperbolic equation for T_f, T_s, or any linear combination of these. For example, without any assumptions on the length or time scales, it is easily seen that the temperature T_i ($i = f, s$, or m) satisfies the hyperbolic equation

$$\frac{\partial T_i}{\partial t'} + \langle u \rangle \frac{\partial T_i}{\partial z'} + \frac{(\rho c_p)_s \ \epsilon_f (1-\epsilon_f)}{h a_v [\epsilon_f + \Gamma(1-\epsilon_f)]} \frac{\partial}{\partial t'} \left[\frac{\partial T_i}{\partial t'} + u_0 \frac{\partial T_i}{\partial z'} \right] = 0. \tag{2.9}$$

For $i = m$, the initial and boundary conditions for (2.9) are the same as those defined by (2.8c) and (2.8d), respectively. Thus, the parabolic form of the reduced equation given by (2.8a) is not preferable as it leads to nonphysical phenomena such as upstream diffusion and infinite speed of propagation. This is certainly not true for the initial model, (2.9), which predicts finite propagation speed for all inlet and initial signals and no upstream diffusion. (This can be seen more clearly by comparing the analytical solutions of the exact and reduced equations for a unit step or impulse inputs. These analytical solutions can be expressed in terms of modified Bessel functions.) The origin of the second spatial derivative term in the reduced equation and the interpretation of the coefficient α_{eff} as an effective (Taylor) diffusivity can be traced back to the paper of Taylor on shear dispersion (Taylor (1953)). We present here an alternate form of the reduced equation (and interpretation of the local coefficients) that eliminates the above-mentioned inconsistencies of the classical Taylor dispersion theory.

We note that, when the interphase transfer time is small, the leading order approximation

$$\frac{\partial T_m}{\partial t'} = - \langle u \rangle \frac{\partial T_m}{\partial z'} + O\left(\frac{(\rho c_p)_f}{h a_v} \right) \tag{2.10}$$

may be used to write the reduced equation in three different forms: as a parabolic equation in z' (i.e., (2.8a)), a parabolic equation in t', or a hyperbolic equation in z' and t'. We also note that the local (2.7) written in terms of either $\frac{\partial T_m}{\partial t'}$ or $\frac{\partial T_m}{\partial z'}$ defines a characteristic time (that is proportional to $\frac{(\rho c_p)_f}{h a_v}$) for heat exchange between the

slowly varying mode T_m and the slave (local) mode T_d. Thus, we write the averaged model as

$$\frac{\partial T_m}{\partial t'} + \langle u \rangle \frac{\partial T_m}{\partial z'} + \langle u \rangle t_H \frac{\partial^2 T_m}{\partial z' \partial t'} = 0, \tag{2.11}$$

where t_H is the characteristic local exchange time (between the two modes) defined by

$$t_H = \frac{(\rho c_p)_s \ (1-\epsilon_f)^2 \Gamma}{h a_v [\epsilon_f + \Gamma(1-\epsilon_f)]}. \tag{2.12}$$

We also define a local length scale as $\ell_H = \langle u \rangle \ t_H$ and note that the reduced model is valid for $z' \gg \ell_H$ and $t' \gg t_H$. In this form, the reduced model defines both the local length and time scales (their ratio being $\langle u \rangle$), and the local effective diffusivity is given by $\alpha_{eff} = \frac{\ell_H^2}{t_H} = \langle u \rangle^2 \ t_H$.

This hyperbolic form of the reduced equation is favored for the following reasons: (i) Since the initial model is hyperbolic, the reduced model should also be hyperbolic; (ii) writing the reduced model as a parabolic equation either in z' or t' requires an artificial boundary or initial condition; (iii) the hyperbolic (2.11) defines a characteristic initial value problem for T_m and hence only T_m needs to be specified along the characteristic curves $z' =$ constant and $t' =$ constant. (In contrast, for the general Cauchy problem, both the function and the normal derivative should be specified along a noncharacteristic curve.) The initial and boundary conditions for (2.11) are the same as those defined by (2.8c) and (2.8d), respectively. Now, no artificial boundary or initial conditions are required, and the reduced model does not lead to any nonphysical phenomena. This hyperbolic form of the reduced model also replaces the concept of an effective (Taylor) diffusivity by that of an effective local time or length scale.

The perturbation expansion can be carried out to higher orders in Pe, and the reduced model (with appropriate initial and boundary conditions) can be expressed in hyperbolic form, but we do not pursue this calculation here. The conditions under which the perturbation expansion converges may also be obtained (for this specific example) in terms of the spatial or time scales appearing in the initial and boundary conditions. We consider it only briefly here and refer to Balakotaiah and Dommeti (1999) for more details.

We note that the local equation (2.6b) may be written as

$$\left[1 + \frac{Pe \ \epsilon_f (1-\epsilon_f)\Gamma}{[\epsilon_f + \Gamma(1-\epsilon_f)]} \left(\frac{\partial}{\partial t}\right)\right] T_d = \frac{Pe \ (1-\epsilon_f)\Gamma}{[\epsilon_f + \Gamma(1-\epsilon_f)]} \left(\frac{\partial T_m}{\partial t}\right). \tag{2.13}$$

Thus, if we consider the special case in which only the inlet conditions are varied, then by taking a Laplace transform, we can reduce the local equation to a linear algebraic equation in terms of the forcing frequency. This equation has a convergent power series expansion in Pe, provided the dimensionless forcing frequency (ω) satisfies the criterion

$$\frac{Pe \ \epsilon_f \ (1-\epsilon_f)\Gamma\omega}{[\epsilon_f + \Gamma(1-\epsilon_f)]} < 1. \tag{2.14}$$

In dimensional terms, (2.14) may be written as

$$\omega' t_H < \frac{(1-\epsilon_f)\Gamma}{\epsilon_f}. \tag{2.15}$$

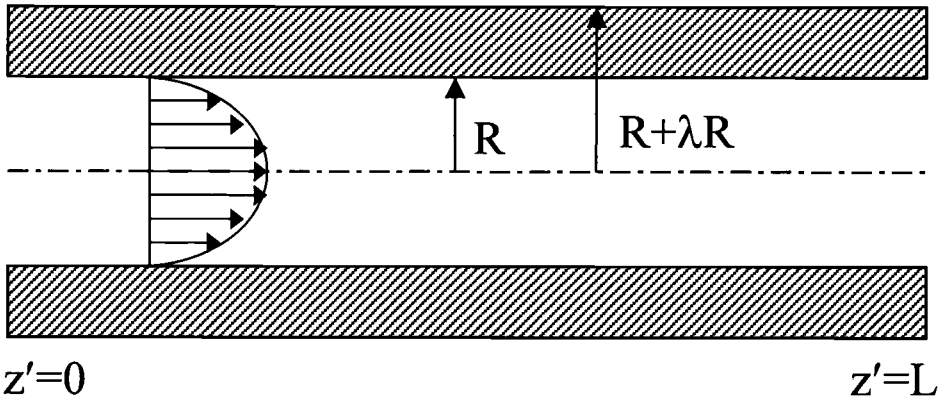

FIG. 2. *Schematic diagram illustrating the classical Taylor solutal dispersion in laminar flow in a circular tube.*

This convergence criterion has a simple physical meaning for the special case in which the volumetric heat capacities of the phases are equal (when the right-hand side of (2.15) is equal to unity): the reduced model exists only if the forcing frequency is less than that defined by the characteristic local exchange time ($\omega' < \frac{1}{t_H}$).

3. Taylor's solutal dispersion theory revisited. In this section, we consider the classical Taylor problem that illustrates intraphase dispersion due to transverse velocity gradients and show that the inconsistencies associated with the parabolic form of the reduced model can be removed by expressing the reduced model in a hyperbolic form. Our approach also shows the similarity between the inter- and intraphase dispersion and the superiority of the hyperbolic models for describing these phenomena.

The dispersion of a nonreactive solute in a circular tube of constant cross section (see Figure 2 for notation) in which the flow is laminar is described by the convective-diffusion equation

$$\frac{\partial C}{\partial t'} + 2\langle u\rangle\left(1-\frac{r^2}{R^2}\right)\frac{\partial C}{\partial z'} = \frac{D}{r}\frac{\partial}{\partial r}\left(r\frac{\partial C}{\partial r}\right),\ 0<r<R,\ z'>0,\ t'>0, \tag{3.1a}$$

$$\frac{\partial C}{\partial r} = 0 @ r = 0, R, \tag{3.1b}$$

$$I.C : C(z', r, 0) = f(z', r), \tag{3.1c}$$

$$B.C : C(0, r, t') = g(r, t'). \tag{3.1d}$$

In writing (3.1a), it is assumed that longitudinal diffusion can be neglected (this assumption is relaxed later on). Here, $\langle u\rangle$ is the average velocity in the pipe, R is the radius, and D is the diffusivity of the species. Defining dimensionless variables

$$z = \frac{z'}{L}, \quad t = \frac{\langle u\rangle t'}{L}, \quad \xi = \frac{r}{R}, \quad Pe = \frac{R^2\langle u\rangle}{LD}, \tag{3.2}$$

we can write (3.1a) and (3.1b) as

$$\pounds C \equiv \frac{1}{\xi}\frac{\partial}{\partial\xi}\left(\xi\frac{\partial C}{\partial\xi}\right) = Pe\left[\frac{\partial C}{\partial t} + 2\left(1-\xi^2\right)\frac{\partial C}{\partial z}\right], \qquad \frac{\partial C}{\partial\xi} = 0 @ \xi = 0, 1. \tag{3.3}$$

We note that the transverse operator $\mathcal{L}$ is symmetric with respect to the inner product

$$(v, w) = \int_0^1 2\xi v(\xi) w(\xi) d\xi.$$

It has a zero eigenvalue with normalized eigenfunction $\phi_0 = 1$. We define the mixing-cup (velocity weighted) and spatial average concentrations by

$$C_m = \int_0^1 4\xi(1-\xi^2) C(\xi, z, t) d\xi, \tag{3.4a}$$

$$\langle C \rangle = \int_0^1 2\xi C(\xi, z, t) d\xi. \tag{3.4b}$$

Transverse averaging of (3.3) gives

$$\frac{\partial \langle C \rangle}{\partial t} + \frac{\partial C_m}{\partial z} = 0. \tag{3.5}$$

We note that when $Pe = 0$, $\langle C \rangle = C_m$, and substitution of this into (3.5) gives the leading order evolution equation for the averaged concentration. Writing

$$C(\xi, z, t) = \langle C \rangle (z, t) + W(\xi, z, t), \qquad W \in \ker\ \mathcal{L}, \tag{3.6}$$

we can solve for the slave variable $W(\xi, z, t)$ in terms of $\langle C \rangle (z, t)$ using a perturbation expansion in Pe (and the Fredholm alternative):

$$\mathcal{L}W - Pe\left[\frac{\partial W}{\partial t} + 2\left(1-\xi^2\right)\frac{\partial W}{\partial z}\right] = Pe\left[\frac{\partial \langle C \rangle}{\partial t} + 2\left(1-\xi^2\right)\frac{\partial \langle C \rangle}{\partial z}\right], \tag{3.7a}$$

$$\frac{\partial W}{\partial \xi} = 0 @ \xi = 0, 1. \tag{3.7b}$$

To leading order, we have

$$W(\xi, z, t) = Pe \frac{\partial \langle C \rangle}{\partial t}\left[\frac{1}{12} - \frac{\xi^2}{4} + \frac{\xi^4}{8}\right] + O(Pe^2). \tag{3.8}$$

Substitution of this into (3.6) and transverse averaging (after multiplying by the velocity profile) gives the local equation relating C_m and $\langle C \rangle$:

$$C_m - \langle C \rangle = \frac{Pe}{48}\frac{\partial \langle C \rangle}{\partial t} + O(Pe^2) = \frac{Pe}{48}\frac{\partial C_m}{\partial t} + O(Pe^2). \tag{3.9}$$

As in the packed-bed problem, this local equation (when written in dimensional form) defines a characteristic transfer time between the slowly evolving mode C_m(or $\langle C \rangle$) and the slave mode $C_m - \langle C \rangle$. Equations (3.5) and (3.9) complete the reduced model to leading order. In this form, the reduced model for intraphase diffusion is similar to the two-mode packed-bed model of interphase diffusion. We can combine the two equations to obtain a single equation for either C_m or $\langle C \rangle$. Since the mixing-cup concentration (which is often measured in experiments) is more relevant in applications, the reduced model in terms of C_m in dimensional form is given by

$$\frac{\partial C_m}{\partial t'} + \langle u \rangle \frac{\partial C_m}{\partial z'} + \langle u \rangle\ t_D \frac{\partial^2 C_m}{\partial z' \partial t'} = 0, \qquad t' \gg t_D,\ z' \gg \ell_D, \tag{3.10}$$

where the local diffusion or mixing time is defined by

$$t_D = \frac{R^2}{48D}. \tag{3.11}$$

The corresponding length scale and local diffusivity are given by $\ell_D = \langle u \rangle\, t_D$, $D_{eff} = \langle u \rangle^2 t_D$. As noted earlier, in the Taylor dispersion literature, (3.10) is written as a parabolic equation with an effective dispersion coefficient D_{eff}, which requires an artificial boundary condition at the exit of the tube (Roberts (1992)). Below we present a solution of (3.10) for general inlet and initial conditions and show that it can describe dispersion for long times as well as the parabolic model. However, unlike the classical parabolic equation over an infinite domain, (3.10) can accommodate an inlet boundary condition. Once again, since (3.10) defines a characteristic initial value problem, to complete the model, we need to specify C_m only along the characteristic curves $z' = 0$ and $t' = 0$. Thus, the initial and boundary conditions for the reduced model are obtained by taking the mixing-cup averages of (13.c) and (13.d):

$$C_m(z', t' = 0) = \int_0^1 4\xi(1-\xi^2)\ f(z', R\xi)d\xi \equiv f_m(z'), \tag{3.12a}$$

$$C_m(z' = 0, t') = \int_0^1 4\xi(1-\xi^2)\ g(R\xi, t')d\xi \equiv g_m(t'). \tag{3.12b}$$

Equations (3.10) and (3.12) complete the hyperbolic model to order Pe. As in the packed-bed example, the perturbation expansion can be carried out to higher orders, and it can be shown that it converges, provided $t_D\omega_t' < 0.858$ and $\ell_D\omega_z' < 0.288$, where $\omega_t'(\omega_z')$ is the temporal (spatial) frequency contained in the inlet or initial conditions. (For details, see Chakraborty and Balakotaiah (2002), Balakotaiah and Chang (1995), and Mercer and Roberts (1990).)

The above analysis can be extended to the general case in which axial diffusion is included in (13.a). In this case, the reduced model may be shown to be

$$\frac{\partial \langle C \rangle}{\partial t'} + \langle u \rangle \frac{\partial C_m}{\partial z'} = D\frac{\partial^2 \langle C \rangle}{\partial z'^2}, \tag{3.13a}$$

$$\langle C \rangle - C_m = -\ t_D \frac{\partial \langle C \rangle}{\partial t'}. \tag{3.13b}$$

We can combine these equations to obtain a single hyperbolic equation for $\langle C \rangle$:

$$\frac{\partial \langle C \rangle}{\partial t'} + \langle u \rangle \frac{\partial \langle C \rangle}{\partial z'} + \langle u \rangle\ t_D \frac{\partial^2 \langle C \rangle}{\partial z' \partial t'} = D\frac{\partial^2 \langle C \rangle}{\partial z'^2}. \tag{3.14}$$

(We note that C_m or any other weighted average concentration also satisfies the same equation (3.14). This is due to the fact that the original conservation equation is linear in the concentration.) We note that when $D \ll \langle u \rangle^2\ t_D$, or equivalently, the radial Peclet number $p = \frac{\langle u \rangle\ R}{D} \gg 6.93$, axial diffusion can be neglected. (Note that the perturbation Peclet number Pe, which is equal to p times the aspect ratio $\left(\frac{R}{L}\right)$, can be small even when $p \gg 6.93$, provided that the aspect ratio is sufficiently small. The conditions $p \gg 6.93$ and $Pe \ll 1$ are usually satisfied for well-designed reactors or chromatographic columns.)

3.1. Solution of the hyperbolic model. In this section, we present the solution of the hyperbolic model defined by (3.10) and (3.12) and compare these solutions to those of the classical parabolic model. We use the local time and length scales to nondimensionalize the variables and write the hyperbolic model in the following form:

$$\frac{\partial C_m}{\partial t} + \frac{\partial C_m}{\partial z} + \frac{\partial^2 C_m}{\partial z \partial t} = 0, \qquad t \gg 1,\ z \gg 1, \tag{3.15a}$$

$$C_m(z, t = 0) = f(z), \tag{3.15b}$$

$$C_m(z = 0, t) = g(t). \tag{3.15c}$$

(With this scaling, the reciprocal of the nondimensional time is the Peclet number.) The substitution

$$C_m = W \exp(-z - t) \tag{3.16a}$$

reduces (3.15a) to the canonical form

$$\frac{\partial^2 W}{\partial z \partial t} - W = 0. \tag{3.16b}$$

The fundamental solution (Riemann function) of (3.16b) is given by (see Garabedian (1964))

$$W_g(z, t, \xi, \eta) = I_0\left(2\sqrt{(z - \xi)(t - \eta)}\right), \tag{3.16c}$$

where I_0 is the modified Bessel function of order zero. Using this fundamental solution, we may express the solution of (3.15) as

$$\begin{aligned} C_m(z, t) = e^{-z-t} \Bigg\{ & c_0 I_0(2\sqrt{zt}) + \int_0^z \frac{dF(\xi)}{d\xi} I_0\left(2\sqrt{t(z - \xi)}\right) d\xi \\ & + \int_0^t \frac{dG(\eta)}{d\eta} I_0\left(2\sqrt{z(t - \eta)}\right) d\eta) \Bigg\}, \end{aligned} \tag{3.17a}$$

where

$$F(z) = e^z f(z), \tag{3.17b}$$

$$G(t) = e^t g(t), \tag{3.17c}$$

$$c_0 = \frac{f(0) + g(0)}{2}. \tag{3.17d}$$

Below, we use this analytical solution to show that the solution of the hyperbolic model, (3.15a)–(3.15c), remains positive for arbitrary but positive inlet and initial conditions. We also compare the solutions of the hyperbolic model with those of the parabolic model for some special cases.

3.2. Positivity of the solutions to the hyperbolic model. We note that (3.15) as well as the general solution given by (3.17) have the permutational symmetry in z and t; i.e., they are invariant to the transformation $(z,t,f) \to (t,z,g)$. Thus, to prove the positivity of the solution of (3.15), it is sufficient to consider the case of $g(t) = 0$ and $f(z) \neq 0$. Now, for the special case of $f(z) = \delta(z - z_0)$ and $g(t) = 0$, the general solution given by (3.17) simplifies to

$$C_{mg}(z,z_0,t) = \begin{cases} I_1\left(2\sqrt{t(z-z_0)}\right) e^{z_0-z-t}\sqrt{\frac{t}{z-z_0}}, & z > z_0, \\ 0, & z < z_0. \end{cases} \tag{3.18}$$

Since this Green's function is positive, the solution given by (3.17) remains positive for all positive inlet and initial conditions. In fact, an alternate form of the analytical solution to (3.15) makes this obvious:

$$C_m(z,t) = \begin{cases} \int_0^z I_1\left(2\sqrt{t(z-z_0)}\right) e^{z_0-z-t}\sqrt{\frac{t}{z-z_0}} f(z_0)dz_0 \\ \qquad + \int_0^t I_1\left(2\sqrt{z(t-t_0)}\right) e^{t_0-t-z}\sqrt{\frac{z}{t-t_0}} g(t_0)dt_0, & z > 0,\ t > 0, \\ 0, & z < 0 \text{ or } t < 0. \end{cases} \tag{3.19}$$

3.3. Comparison of the dispersion curves for parabolic and hyperbolic models. As stated earlier, it is of interest to determine how the solution of the hyperbolic model differs from that of the parabolic models used in the literature to describe solutal dispersion in nonreacting systems. In the engineering literature, the solution of the averaged model to a unit impulse (Delta function) input is known as the dispersion curve. For the parabolic model, this is the standard Gaussian curve given by

$$E_p(z,t) = \frac{1}{\sqrt{4\pi t}} \exp\left\{-\frac{(z-t)^2}{4t}\right\}. \tag{3.20}$$

Thus, the parabolic model predicts a peak in the dispersion curve at $z = t$ and a variance that increases linearly with time. The dispersion curve for the hyperbolic model is obtained by taking $z_0 = 0$ in (3.18):

$$E_h(z,t) = \begin{cases} e^{-z-t}\sqrt{\frac{t}{z}} I_1(2\sqrt{tz}), & z > 0, \\ 0, & z < 0. \end{cases} \tag{3.21}$$

Examination of this curve shows that it has a peak at $z = 0$ for $t \leq 2$. This is consistent with physical observation that, for short times, transverse diffusion has not acted on the initial delta function input and hence the peak should be at the injection point. For $t \gg 1$, (3.21) may be written as

$$E_h(z,t) \approx \left(\frac{t}{z}\right)^{\frac{3}{4}} \frac{1}{\sqrt{4\pi t}} \exp\left\{-\frac{(z-t)^2}{(\sqrt{t}+\sqrt{z})^2}\right\}. \tag{3.22}$$

Thus, the dispersion curves predicted by the two models are close to each other near $t = z$ (and $t \gg 1$), but the hyperbolic model predicts an asymmetric curve with a slightly higher peak at $z = t - \frac{3}{2}$. In addition, as noted earlier, the parabolic model predicts upstream diffusion (since $E_p(z,t)$ is not zero for $z < 0$) and infinite propagation speed. Neither of these nonphysical phenomena is present in the hyperbolic

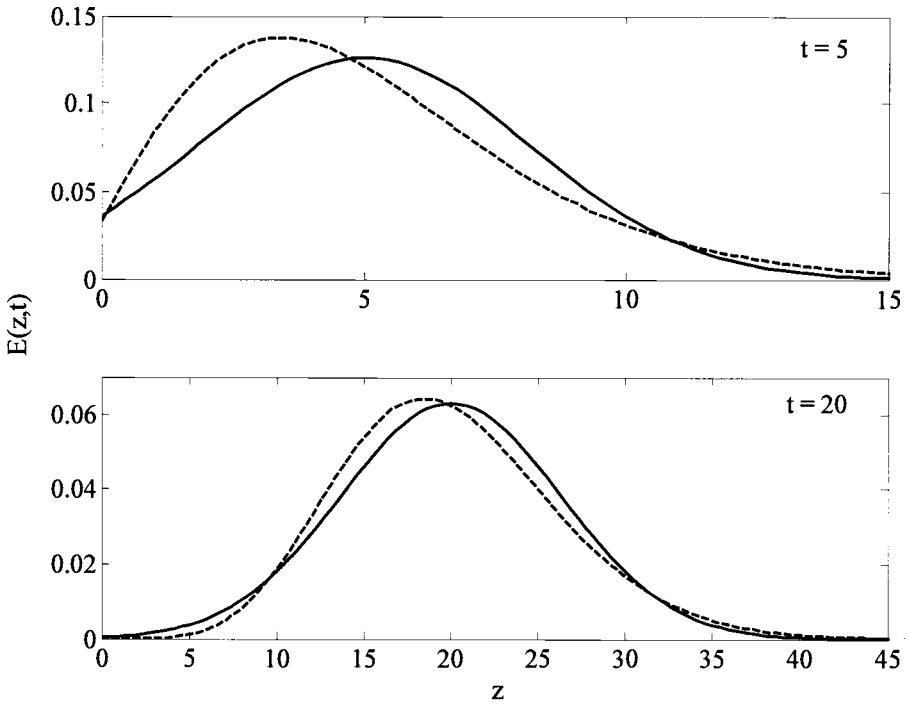

FIG. 3. *Comparison of the dispersion curves predicted by the parabolic and hyperbolic models at* $t = 5$ *and* 20. *The symmetric curve with peak at* $t = z$ *is for the parabolic model, while the asymmetric curve with peak at* $z \approx t - \frac{3}{2}$ *is for the hyperbolic model.*

model. Figure 3 compares the two solutions at two different times, $t = 5$ and $t = 20$. While the two curves are extraordinarily close for large times, they intersect three times (for all $t > 4.84$), and the dispersion curve predicted by the hyperbolic model has a nonzero skewness at all finite times. We note that this skewness can also be predicted by the parabolic-type models as done by Chatwin (1970), but higher order terms (like $\frac{\partial^3 C_m}{\partial z^3}$) have to be included in the perturbation expansion. The hyperbolic model captures the asymmetry at the lowest order.

4. General thermal/solutal dispersion theory. We now extend the theory to the general case of a multiphase system in which the individual phases may be stationary or moving and the capacitance varies with transverse coordinates; i.e., dispersion is due to combined inter- and intraphase mechanisms. We assume a long reactor with weak longitudinal variation of temperature or concentration (due to the small aspect ratio) and strong longitudinal (laminar) flow $w(x, y)$. We retain only transverse molecular solutal or thermal diffusion in x and y. Conversely, only longitudinal convection is appreciable to balance transverse diffusion. The general governing equation for the reactor temperature or concentration in dimensionless form is then

$$F(\theta, Pe) \equiv \frac{1}{\rho c_p} \nabla \cdot k \nabla \theta - Pe \left(\frac{\partial \theta}{\partial t} + w \frac{\partial \theta}{\partial z} \right) = 0, \tag{4.1}$$

where the ∇ operator is only for the transverse direction $\nabla = (\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, 0)^T$ and both the dimensionless conductivity k and the heat or solutal capacity ρc_p are functions of the transverse coordinates x and y within the transverse cross section Ω. The Peclet number in (4.1) is again defined as the ratio of the transverse diffusion or local exchange time ($\frac{R^2}{\alpha_0}$) to the convection time ($\frac{L}{u_0}$). (We note here that the thermal conductivity, heat capacitance per unit volume, and the velocity are nondimensionalized using some reference values k_0, $(\rho c_p)_0$, and u_0, which can be chosen conveniently for each application. Here, $Pe = \frac{R^2 u_0}{L\alpha_0}$, where $\alpha_0 = \frac{k_0}{(\rho c_p)_0}$.) When $\rho c_p = 1$ is uniform throughout Ω, the transport problem (4.1) reduces to mass transport with uniform capacitance. However, the solutal diffusivity can vary from phase to phase and is hence a function of (x, y). Similarly, the transport coefficients w and k do not have to be constant within each phase but can vary continuously with respect to (x, y).

Equation (4.1) must be solved in the transverse direction with continuity in θ and $k\frac{\partial \theta}{\partial n}$ at the phase boundaries. We shall also impose a no-flux boundary condition at the transverse reactor boundary $\partial\Omega$,

$$\left.\frac{\partial \theta}{\partial n}\right|_{\partial\Omega} = 0. \tag{4.2}$$

It is then clear that, at $Pe = 0$, a particular solution to (4.1) is $\theta = \langle\theta\rangle$, the capacitance-weighted transverse average of θ, independent of the transverse coordinates x and y. We then seek correction to $\langle\theta\rangle$ for small Pe. To leading order, one obtains the linear operator in Ω,

$$D_\theta F(\langle\theta\rangle, 0) \cdot v = \frac{1}{\rho c_p}\nabla \cdot k\nabla v \equiv \pounds v, \tag{4.3}$$

with Neumann boundary conditions on the outer boundary $\partial\Omega$, $\frac{\partial v}{\partial n}|_{\partial\Omega} = 0$. This transverse diffusion operator contains a transverse-dependent conductivity k and capacitance ρc_p that change from phase to phase. The operator is self-adjoint with respect to the inner product

$$[u, v] = \frac{1}{\Omega_{cp}} \int_\Omega \rho c_p \; u \; v \; d\Omega, \tag{4.4a}$$

$$\Omega_{cp} = \int_\Omega \rho c_p \; d\Omega. \tag{4.4b}$$

It has a zero eigenvalue with a constant null eigenfunction ϕ_0, which can be chosen as unity. The other eigenfunctions $\phi_n(x, y)$ all have zero integral (transverse average) from a simple application of divergence theorem to $\pounds\phi_n = -\lambda_n\phi_n$ with the Neumann boundary condition to $\partial\Omega$:

$$[\phi_n, \phi_0] = \langle\phi_n\rangle = \frac{1}{\Omega_{cp}} \int_\Omega \rho c_p \phi_n d\Omega = 0. \tag{4.5}$$

(We point out that (4.5) defines the capacitance-weighted transverse average of any function. We also define $\langle\rho c_p\rangle = \Omega_{cp}/|\Omega|$.)

We expand θ in terms of $\{\phi_n\}_{n=0}^{\infty}$,

$$\theta = \langle\theta\rangle + \theta'(x, y, z, t), \tag{4.6}$$

where $\langle\theta\rangle$ represents the null eigenfunction ϕ_0 component without (x, y)-dependence, while $\theta' \perp \ker \pounds$ represents the complement spanned by the other eigenfunctions.

Since $\mathcal{L}$ is self-adjoint with respect to the Hilbert inner product and $\theta' \perp \ker \mathcal{L}$, we have

$$\langle \theta' \rangle = 0. \tag{4.7}$$

In the terminology of bifurcation theory, the equation satisfied by $\langle\theta\rangle$ is the so-called branching equation at a simple zero eigenvalue. (In the engineering literature, this is often referred to as the homogenized equation, reduced model, averaged equation, pseudohomogeneous model, etc.) This reduced equation can be obtained by applying the implicit function theorem to eliminate θ' from the equation $EF(\langle\theta\rangle + \theta', Pe) = 0$. (Here, E is the projection operator onto *range* $\mathcal{L}$.) This Lyapunov–Schmidt reduction can be done by expanding θ' in terms of the small parameter Pe and solving a linear equation at each order by using the Fredholm alternative. Writing

$$\theta' = Pe\theta_1 + Pe^2\theta_2 + \cdots, \tag{4.8}$$

the leading order equation is given by

$$\mathcal{L}\theta_1 - \left(\frac{\partial \langle\theta\rangle}{\partial t} + w \frac{\partial \langle\theta\rangle}{\partial z} \right) = 0. \tag{4.9}$$

Before we solve for θ' in terms of $\langle\theta\rangle$ to obtain the reduced model, we invoke a unique relationship between the capacitance-weighted average $\langle\theta\rangle$ and the mixing-cup average defined by

$$\theta_m = \frac{1}{\Omega_{cp}} \int_\Omega \rho c_p \; w \; \theta \; d\Omega = \frac{[w\theta, \phi_0]}{[w, \phi_0]} = \frac{\langle w\theta \rangle}{\langle w \rangle}, \tag{4.10a}$$

where $\langle w \rangle$ is the capacitance-weighted average dimensionless velocity, i.e.,

$$\langle w \rangle = \frac{1}{\Omega_{cp}} \int_\Omega \rho c_p \; w \; d\Omega. \tag{4.10b}$$

We note that, only in the degenerate case in which w is uniform over Ω, $\theta_m = \langle\theta\rangle$. In all other cases, $\theta_m \neq \langle\theta\rangle$. Integrating (4.1) over the transverse cross-section Ω and invoking the Neumann condition (4.2), one obtains

$$\frac{\partial \langle\theta\rangle}{\partial t} + \langle w \rangle \frac{\partial \theta_m}{\partial z} = 0. \tag{4.11}$$

This relationship is exact and is valid for all orders in Pe. A second relation between $\langle\theta\rangle$ and θ_m may be obtained by multiplying (4.6) by w and taking the inner product with the null eigenfunction ϕ_0:

$$\theta_m = \langle\theta\rangle + Pe \; \frac{[w\theta_1, \phi_0]}{\langle w \rangle} + O(Pe^2). \tag{4.12}$$

Thus, to leading order, the mixing-cup and capacitance-weighted average temperatures are equal, and the evolution equation (4.11) for $\langle\theta\rangle$ reduces to

$$\frac{\partial \langle\theta\rangle}{\partial t} + \langle w \rangle \frac{\partial \langle\theta\rangle}{\partial z} + O(Pe) = 0. \tag{4.13}$$

To obtain the evolution equation to order Pe, we insert (4.13) into (4.9) and define η as

$$\theta_1 \sim \eta \frac{\partial \langle \theta \rangle}{\partial z} \tag{4.14}$$

to reduce (4.9) to the following convenient form:

$$\pounds \eta = w - \langle w \rangle , \tag{4.15a}$$

with no-flux condition at $\partial\Omega$

$$\left. \frac{\partial \eta}{\partial n} \right|_{\partial\Omega} = 0 \tag{4.15b}$$

and the usual continuity of η and $k\frac{d\eta}{dn}$ at the phase boundaries within Ω. Substitution of (4.14) into (4.11) and (4.12) gives the reduced model

$$\frac{\partial \theta_m}{\partial t} + \langle w \rangle \frac{\partial \theta_m}{\partial z} + Pe\Lambda \frac{\partial^2 \theta_m}{\partial z \partial t} = 0, \tag{4.16}$$

where the numerical coefficient Λ is given by

$$\Lambda = - \frac{[w\eta, \phi_0]}{\langle w \rangle} = - \frac{\langle w\eta \rangle}{\langle w \rangle}. \tag{4.17}$$

In dimensional form, (4.16) becomes

$$\frac{\partial \theta_m}{\partial t'} + \langle u \rangle \frac{\partial \theta_m}{\partial z} + \ell_H \frac{\partial^2 \theta_m}{\partial z' \partial t'} = 0, \tag{4.18}$$

where $\langle u \rangle$ is the capacitance-weighted average velocity and the effective local length scale ℓ_H is defined by

$$\ell_H = \Lambda \frac{R^2 u_0}{\alpha_0}. \tag{4.19}$$

The corresponding time scale and the dimensional effective dispersion coefficient are given by $t_H = \frac{\ell_H}{\langle u \rangle}$ and $\alpha_{eff} = \frac{\ell_H^2}{t_H} = \Lambda \frac{R^2 u_0 \langle u \rangle}{\alpha_0}$, respectively. Again, we note that (4.18) is valid only for $t' \gg t_H$ and $z' \gg \ell_H$. Dispersion can still occur for $0 < t' < t_H$ or $0 < z' < \ell_H$ or even when w is uniform in Ω. However, in these higher order cases, the expansion must be carried to higher orders in Pe so that the averaged model can capture this early dispersion. Similarly, as pointed out by Mercer and Roberts (1990) and Young and Jones (1991), early dispersion effects due to point sources or sinks can be captured at order Pe^2 and higher. We shall not discuss these higher order special cases here as they are not very common in reactors and are also specific to each problem.

The initial and boundary conditions for the general equation (4.18) may be derived in the same manner as for the two specific examples illustrated earlier. We now consider the local equation and various special cases of thermal and solutal dispersion.

4.1. The local equation. As noted above, the local equation (4.15) must be solved before we can determine the numerical coefficient Λ and hence the effective local length or time scales. It is clear that the inhomogeneous term on the right-hand side of (4.15a) satisfies the solvability condition for the singular operator. Also, since $\eta \perp \ker \mathcal{L}$,

$$\langle \eta \rangle = 0, \tag{4.20}$$

which can be used to solve for η uniquely.

Multiplying (4.15a) by η, taking the inner product with the null eigenfunction, and using (4.20), one obtains

$$\begin{aligned} \Lambda &= -[\eta w, \phi_0] \\ &= -[\eta \mathcal{L} \eta, \phi_0] \\ &= -\tfrac{1}{\Omega_{cp}} \textstyle\int_\Omega \eta \nabla \cdot k \nabla \eta \, d\Omega. \end{aligned} \tag{4.21}$$

Using (4.15b) and the divergence theorem (integration by parts), (4.21) then yields

$$\Lambda = \frac{1}{\Omega_{cp}} \int_\Omega k \nabla \eta \cdot \nabla \eta \, d\Omega, \tag{4.22}$$

which is always positive. This quadratic form for Λ is more convenient for some of our derivations and could possibly be used in a variational numerical scheme for η.

In the case of single-phase thermal transport or multiphase solutal transport when ρc_p is uniform throughout Ω, (4.22) simplifies to

$$\Lambda = \frac{1}{|\Omega|} \int_\Omega \alpha \nabla \eta \cdot \nabla \eta \, d\Omega, \tag{4.23}$$

where α is the dimensionless local diffusivity. If, in addition, α is independent of the transverse coordinates (x, y) and is normalized to unity, then Λ depends on only the velocity profile and the geometry of Ω. This clearly shows that, for the single-phase limit and for uniform-capacitance solutal transport, dispersion occurs when a transverse gradient in the longitudinal velocity exists.

The interphase dispersion seen in the packed-bed example arises from the different thermal or capacitance-weighted velocities of each phase and hence contributes to dispersion even if the longitudinal velocity w_j is gradientless within each phase j. This limit is particularly interesting, as the local equation has the following algebraic form for each phase Ω_j in Ω:

$$\sum_j A_{ij} \, \eta_j = (w_i - \langle w \rangle), \tag{4.24a}$$

where A is the matrix defining the coupling between the phases. The numerical coefficient Λ takes the simple and explicit form

$$\Lambda = \frac{\sum_j w_j \eta_j \, (\rho c_p)_j \;\; \epsilon_j}{\sum_j \, (\rho c_p)_j \;\; \epsilon_j}, \tag{4.24b}$$

where ϵ_i is the volume fraction of phase i. For the two-phase example of section 2, with A defined by (2.3b) and $w_1 = 1, w_2 = 0$, we have

$$\begin{aligned} \eta &= \frac{\epsilon_f (1 - \epsilon_f) \Gamma}{[\epsilon_f + (1 - \epsilon_f)\Gamma]^2} \begin{pmatrix} -(1 - \epsilon_f)\Gamma \\ \epsilon_f \end{pmatrix}, \\ \Lambda &= \frac{-w_1 \eta_1 \epsilon_f}{[\epsilon_f + (1 - \epsilon_f)\Gamma]} = \frac{\epsilon_f^2 (1 - \epsilon_f)^2 \Gamma^2}{[\epsilon_f + (1 - \epsilon_f)\Gamma]^3}. \end{aligned} \tag{4.25}$$

This interphase dispersion mechanism arises as solutal or heat "molecules" are transported to different phases through transverse thermal random walks. Once arrived, molecules at each phase are caused to propagate longitudinally by different thermal or capacitance-weighted velocities. The proportion of molecules in each phase is determined by the local diffusivity and the size of Ω_i. Hence, the capacitance-weighted longitudinal phase thermal velocities (as defined by (4.24)) simply yield the thermal dispersion.

4.2. Thermal/solutal dispersion with diffusion into the wall. We next examine thermal and solutal dispersion in a cylindrical pipe of radius R with a solid wall of thickness λR ($\lambda > 0$); see Figure 2. The diffusivity in the wall (α_s) is assumed to be distinct from that in the fluid phase. Here, we take the pipe radius (R), the average fluid velocity ($\langle u_f \rangle$), the fluid heat capacitance $(\rho c_p)_f$, and fluid thermal diffusivity (α_f) to nondimensionalize the variables. The velocity field is now

$$w(\xi) = \begin{cases} 2\left[1-\xi^2\right] & \text{in} \quad \Omega_f,\ 0<\xi<1, \\ 0 & \text{in}\ \ \Omega_s,\ 1<\xi<1+\lambda, \end{cases} \tag{4.26}$$

with

$$\langle w \rangle = \frac{\epsilon_f}{\epsilon_f + \Gamma(1-\epsilon_f)},$$

$$\epsilon_f = \frac{1}{(1+\lambda)^2}.$$

The local equation is now

$$\frac{1}{\xi}\frac{\partial}{\partial \xi}\left(\xi \frac{\partial \eta_f}{\partial \xi}\right) = w - \langle w \rangle \quad \text{in } \Omega_f, \tag{4.27a}$$

$$\frac{1}{\mu}\frac{1}{\xi}\frac{\partial}{\partial \xi}\left(\xi \frac{\partial \eta_s}{\partial \xi}\right) = w - \langle w \rangle \quad \text{in } \Omega_s, \tag{4.27b}$$

with boundary conditions

$$\frac{\partial \eta_f}{\partial \xi} = 0, \quad \xi = 0, \tag{4.28a}$$

$$\frac{\partial \eta_s}{\partial \xi} = 0, \quad \xi = (1+\lambda), \tag{4.28b}$$

$$\eta_f = \eta_s, \quad \xi = 1, \tag{4.28c}$$

$$\frac{\Gamma}{\mu}\frac{\partial \eta_s}{\partial \xi} = \frac{\partial \eta_f}{\partial \xi}, \quad \xi = 1, \tag{4.28d}$$

where $\mu = \alpha_f/\alpha_s$ is the ratio between the diffusivities.

Some algebraic manipulation immediately yields

$$\eta_f = \left\{ \frac{1}{2}\xi^2 - \frac{1}{8}\xi^4 - \frac{\langle w \rangle}{4}\xi^2 + s_f \right\}, \tag{4.29a}$$

$$s_f = -\frac{5}{24}\epsilon_f - \frac{3}{8}(1-\epsilon_f) - \langle w \rangle \left\{ (\mu - 1)\frac{(1-\epsilon_f)}{4} - \frac{\epsilon_f}{8} + \frac{\mu}{2} f(\epsilon_f) \right\}, \tag{4.29b}$$

$$f(\epsilon_f) = \frac{\epsilon_f^2 + 2\epsilon_f - 3 - 2ln\epsilon_f}{4\epsilon_f}, \tag{4.29c}$$

$$\eta_s = \left(\frac{\mu}{2}\right) \langle w \rangle \left\{ (1+\lambda)^2 \ln(\xi) - \frac{1}{2}\xi^2 + s_s \right\}, \tag{4.29d}$$

$$s_s = \frac{1}{2} + \frac{s_f + \frac{3}{8} - \frac{1}{4}\langle w \rangle}{\frac{\mu}{2}\langle w \rangle}. \tag{4.29e}$$

Substituting into (4.17), we obtain

$$\Lambda = \frac{\beta_1 \epsilon_f}{\epsilon_f + \Gamma(1-\epsilon_f)} + \frac{(\Gamma - 1)\beta_2 \epsilon_f^2 (1-\epsilon_f)}{[\epsilon_f + \Gamma(1-\epsilon_f)]^2}, \tag{4.30}$$

$$\begin{aligned} \beta_1 = {} & \frac{11 - 8\epsilon_f}{48} + \left(\frac{\epsilon_f}{\epsilon_f + \Gamma(1-\epsilon_f)} \right) \left(\frac{6\epsilon_f - 8}{48} \right) \\ & + \frac{\mu}{4} \left(\frac{\epsilon_f}{\epsilon_f + \Gamma(1-\epsilon_f)} \right) (2f(\epsilon_f) + 1 - \epsilon_f), \end{aligned} \tag{4.31a}$$

$$\beta_2 = \frac{1}{6} + \frac{-\epsilon_f(1-\epsilon_f) + \mu(4\epsilon_f - \epsilon_f^2 - 3 - 2ln\epsilon_f)}{8(1-\epsilon_f)(\epsilon_f + \Gamma(1-\epsilon_f))}. \tag{4.31b}$$

Several limits are of interest. As $\epsilon_f \to 1$, we obtain Taylor's result $\Lambda = \frac{1}{48}$ for solutal dispersion. In the limit of $\Gamma(1-\epsilon_f) \gg \epsilon_f$, for intermediate ϵ_f values away from unity we obtain

$$\Lambda = \frac{\alpha_{eff}}{p^2 \alpha_f} = \frac{11}{48} \frac{\epsilon_f}{\Gamma(1-\epsilon_f)}, \tag{4.32}$$

where $p = \langle u_f \rangle R/\alpha_f$ is the transverse Peclet number. The coefficient 11/48 is also consistent with Leighton and Chang (1995), using the lumped-phase approach. (Note that $\frac{48}{11}$ is the asymptotic Nusselt number, Nu_∞, for laminar flow in a tube with a constant flux boundary condition on the tube wall.) In Figure 4 we plot the product of Γ and the normalized dispersion coefficient Λ given by (4.30) for Γ values of 100 and 1000, with μ varying from 10^{-1} to 10^2. It is obvious that all of them are independent of μ and collapse nicely into the specific scaling of (4.32) except near $\epsilon_f = 1$, where (4.32) is singular. Thus, the high-Γ limit yields a scaling that is insensitive to geometric and

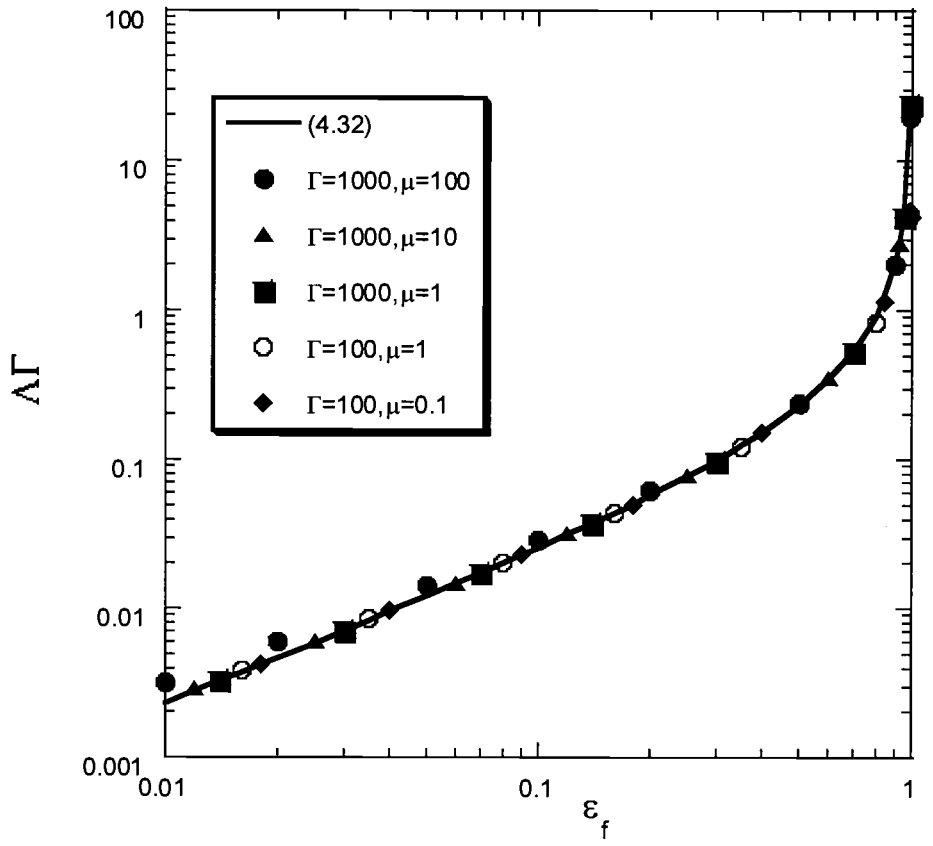

FIG. 4. *High-*Γ *dispersion for various values of diffusivity (*μ*) and capacitance ratio (*Γ*). The curves for various* μ *and* Γ *collapse nicely into the* μ*-independent limit of* (4.32).

flow details and is independent of α_s. The dispersion is small in this limit at $O(\Gamma^{-1})$ and increases sharply with ϵ_f.

For $\epsilon_f \ll 1$ and Γ of unit order, one can deduce from (4.30) that the flowfield-sensitive intraphase term with the β_1 coefficient dominates over the other interphase term. A simple calculation then yields

$$\frac{\alpha_{eff}}{p^2\alpha_f} = \left(\frac{\mu}{4\Gamma^2}\right)\epsilon_f \ln\left(\frac{1}{\epsilon_f}\right), \tag{4.33}$$

with a different Γ scaling from (4.32).

For ϵ_f close to unity, the interphase term becomes equally important as the intraphase term. The high effective dispersion near $\Gamma(1-\epsilon_f) \sim \epsilon_f$ is verified in Table 1, where we have used (4.30) to determine the optimum ϵ_f for various μ and Γ values. Figure 5 shows a plot of the maximum value of the normalized dispersion coefficient that can be obtained for the optimum volume fraction ϵ_f of the low capacitance phase. All these curves approach an asymptotic value for $\Gamma > 10$. This asymptote may be found from (4.30) in the limit of $\Gamma \gg 1$ and $\delta = \Gamma(1-\epsilon_f)$ finite. This simplification

50	0.98	0.98	0.98

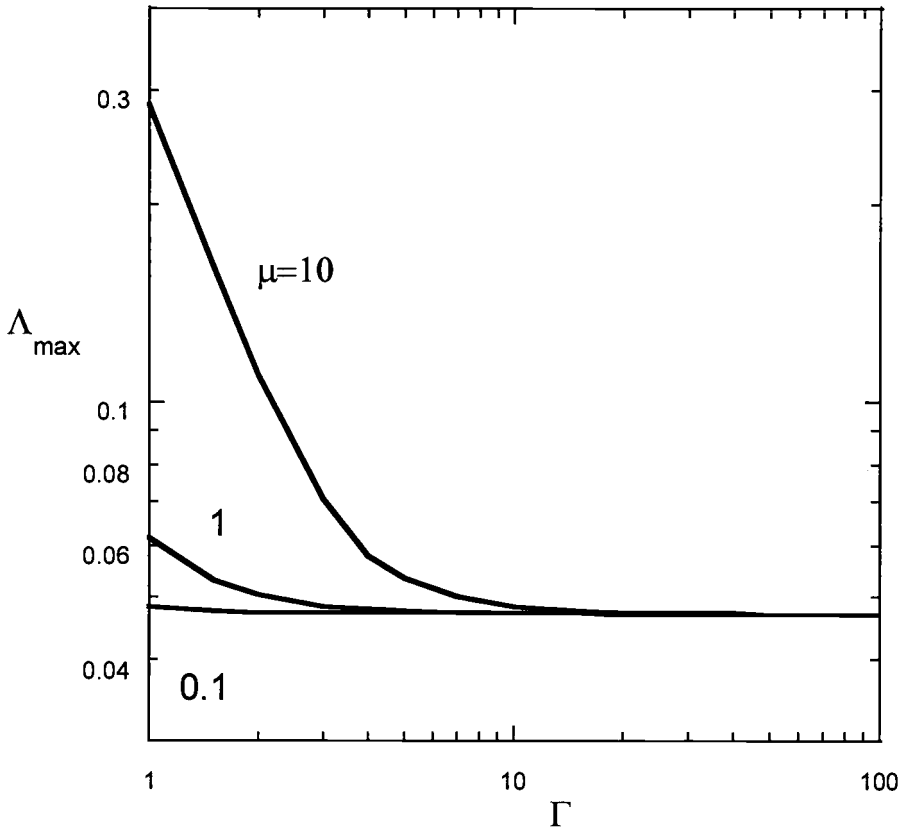

FIG. 5. *Maximum dispersion coefficient obtained at an optimum ϵ_f as a function of Γ for various μ values.*

gives

$$\Lambda = \frac{1 + 6\delta + 11\delta^2}{48(1+\delta)^3}. \tag{4.34}$$

This is the expression derived by Golay (1958) for capillary chromatography with a retentive layer. It follows from (4.34) that $\Lambda_{\max} = 0.047$ at $\delta = 1.15$. As is evident from Figure 5, the optimum normalized dispersion $\Lambda_{\max}$ relative to ϵ_f becomes independent of Γ and μ for Γ beyond 10, as is consistent with (4.30). However, this

optimum dispersion is highest for Γ below 10, near unit order Γ. Hence, the largest dispersion occurs near unit order Γ with a dispersion magnitude that is 3 to 4 times the high Γ limit. Unfortunately, we cannot use the lumped model approach with heat transfer coefficients for these high dispersion reactors. Their dispersion coefficient is highly sensitive to flow distribution/packing, in contrast to the generic limit at high Γ.

Finally, we consider the case of $\Gamma = 1$, which corresponds to the solutal dispersion in a pipe and into the porous wall or particles as in a catalytic monolith or packed-bed reactor, respectively. Here, the phases have equal capacities and, as reasoned above, D_{eff} should be sensitive to details in geometry and flow. For $\Gamma = 1$, (4.30) simplifies to

$$\Lambda = \frac{1}{48} g_1(\epsilon_f) + \frac{\mu}{8} g_2(\epsilon_f), \tag{4.35a}$$

$$\begin{aligned} g_1(\epsilon_f) &= \epsilon_f(6\epsilon_f^2 - 16\epsilon_f + 11), \\ g_2(\epsilon_f) &= \epsilon_f(4\epsilon_f - \epsilon_f^2 - 3 - 2\ln(\epsilon_f)). \end{aligned} \tag{4.35b}$$

We note that the function $g_1(\epsilon_f)$ has a maximum value of 2.26 at $\epsilon_f = 0.465$, while $g_2(\epsilon_f)$ has a maximum value of 0.206 at $\epsilon_f = 0.15$. As μ increases from 0 to ∞, the optimum ϵ_f decreases from 0.465 to 0.206. This is verified in Figure 6, where we have plotted Λ as a function of ϵ_f for different μ values. As expected, Λ is sensitive to both μ and ϵ_f.

5. Reactive and steady dispersion. It is clear from (4.18) that, at steady state, the mixing-cup temperature θ_m remains constant along the reactor—dispersion disappears at steady state. However, steady dispersion can exist under reactive conditions. As transverse diffusion and a longitudinal velocity gradient can produce transient longitudinal dispersion, steady reactive conversion differences across streamlines due to the transverse velocity gradient can also trigger transverse steady diffusive flux. The latter can, in turn, alter the overall conversion and produce an apparent steady dispersion. We shall examine this case here for the simplest scalar case—a single step irreversible reaction for solutal transport or a zeroth order reaction (with excess reactants) for thermal transport valid under thermal ignition conditions (Zeldovich et al. (1985)). Equation (4.1) can then be modified to

$$F(\theta, Pe) \equiv \frac{1}{\rho c_p} \nabla \cdot k \nabla \theta - Pe \left(\frac{\partial \theta}{\partial t} + w \frac{\partial \theta}{\partial z} \right) - PeKf(\theta) = 0, \tag{5.1}$$

where the Damköhler number $K(x, y, z, t)$ reflects the different activity in different phases (e.g., due to varying catalytic activity caused by nonuniform distribution of the catalytic agent and catalyst decay in time), and the nonlinear function $f(\theta)$ captures the temperature or concentration dependence of the reaction rate. (Note also that, unlike the previous cases, $F(\theta, Pe)$ is now nonlinear in θ.) Both $K(x, y, z, t)$ and $f(\theta)$ are of unit order with respect to Pe. The function $f(\theta)$ can be positive or negative, corresponding to solutal/thermal consumption or generation, respectively.

With this scaling, the transverse diffusion operator $\pounds$ remains the dominant linear operator. Moreover, the decomposition into a capacitance-weighted transverse average $\langle\theta\rangle$ and a θ' component, with $\langle\theta'\rangle = 0$, remains valid. However, the overall transverse balance now becomes

$$\frac{\partial \langle\theta\rangle}{\partial t} + \langle w \rangle \frac{\partial \theta_m}{\partial z} + \langle Kf(\theta) \rangle = 0. \tag{5.2}$$

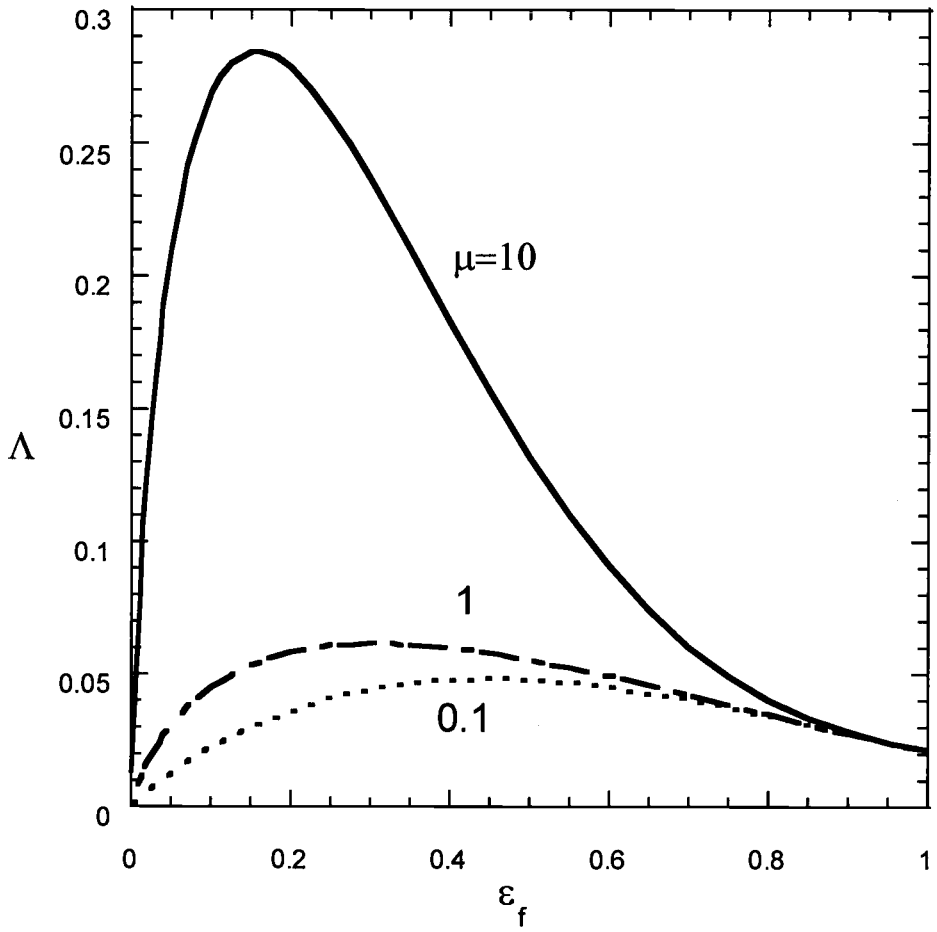

FIG. 6. *Unit order* Γ *dispersion as a function of* ϵ_f *for various* μ *values.*

To leading order, (5.2) reduces to

$$\frac{\partial \langle\theta\rangle}{\partial t} + \langle w\rangle \frac{\partial \langle\theta\rangle}{\partial z} + \langle K\rangle f(\langle\theta\rangle) + O(Pe) = 0. \tag{5.3}$$

The equation for θ' then becomes, to leading order in Pe,

$$\pounds\ \theta' = Pe(w - \langle w\rangle)\frac{\partial \langle\theta\rangle}{\partial z} + Pe(K - \langle K\rangle) f(\langle\theta\rangle). \tag{5.4}$$

We then require the decomposition of θ' into two components

$$\theta' = Pe\left[\eta \frac{\partial \langle\theta\rangle}{\partial z} + \chi f(\langle\theta\rangle)\right] + O(Pe^2); \tag{5.5}$$

the first term containing η is the transient dispersion contribution considered earlier. The reactive (source or sink) contribution is captured by χ as defined by

$$\pounds\ \chi = K - \langle K\rangle\,, \tag{5.6}$$

where $\langle\chi\rangle = 0$ as for η. The other boundary conditions are $\frac{\partial\chi}{\partial n} = 0$ on $\partial\Omega$ and continuity of χ and $k\frac{\partial\chi}{\partial n}$ across the phase boundaries $\partial\Omega_i$.

The homogenized model then becomes

$$\frac{\partial\langle\theta\rangle}{\partial t} + \langle w\rangle\frac{\partial\theta_m}{\partial z} + \langle K\rangle f(\langle\theta\rangle) + Pe\ f'(\langle\theta\rangle)\left(\delta\frac{\partial\langle\theta\rangle}{\partial z} + \kappa f(\langle\theta\rangle)\right) = 0, \tag{5.7a}$$

$$\theta_m = \langle\theta\rangle - Pe\left[\Lambda\frac{\partial\langle\theta\rangle}{\partial z} + \gamma f(\langle\theta\rangle)\right], \tag{5.7b}$$

where Λ is defined earlier by (4.17) and the new constants are

$$\gamma = -\frac{\langle w\chi\rangle}{\langle w\rangle}, \qquad \delta = \langle K\eta\rangle, \qquad \kappa = \langle K\chi\rangle.$$

We can combine (5.7a) and (5.7b) into a single equation for either $\langle\theta\rangle$ or θ_m. However, the coefficients that appear in the resulting equation are no longer constants but depend on the source function. As in the nonreactive case, representing the dispersion terms as second derivatives in z and interpretation of their coefficients as Taylor dispersion coefficients leads to further conceptual difficulties (in addition to the upstream diffusion, infinite propagation speed anomalies, and extra boundary or initial condition needed). Now, the capacitance-weighted average velocity and the dispersion coefficient are no longer constants but depend on the source function and its derivative. (They can be negative and hence lose their physical meaning!) Our approach based on the local length or times scales is still applicable here, the only difference being the additional length or time scales that appear due to the source or sink terms. Thus, in this case, it is preferable to leave the model in the two-mode form, the two modes being the mixing-cup and capacitance-weighted average temperature or concentration. The model is still hyperbolic as in the nonreactive case and reduces to (4.16) when the Damköhler number $K \equiv 0$. The initial and boundary conditions on (5.7) may also be derived in the same manner as in the nonreactive case.

We note that the reduced model now contains four effective local constants that are of the same order of magnitude. It can be seen that the two terms in (5.7b) (containing the constants Λ and γ) represent dispersion effects due to velocity gradients, while the two terms in (5.7a) (containing the constants δ and κ) represent dispersion effects due to a nonuniform reaction rate. The three new terms with coefficients γ, δ, and κ represent reactive dispersion effects (commonly known as mixing effects in the engineering literature), where as the nonreactive term with coefficient Λ may be interpreted as the traditional velocity gradient-induced dispersion. (This term may be interpreted as the so-called micromixing effect; see Chakraborty and Balakotaiah (2002) for more details.) We now examine various special cases.

The first case we consider is that in which $f(\theta)$ is a constant (say, $f(\theta) = -1$). This corresponds to the nonreactive situation, with a source term added to the classical Taylor problem or the thermal dispersion problem. For this case, three of the source-induced dispersion terms vanish, and (5.7) reduces to

$$\frac{\partial\theta_m}{\partial t} + \langle w\rangle\frac{\partial\theta_m}{\partial z} + \Lambda Pe\frac{\partial^2\theta_m}{\partial z\partial t} = \langle K\rangle. \tag{5.8}$$

Thus, the addition of a slowly varying source term simply adds its capacitance-weighted transverse average to the reduced model.

Next, we consider the case in which the Damköhler number K is constant (independent of transverse coordinates and time). Again, the three constants γ, δ, and κ vanish, and the model reduces to

$$\frac{\partial \theta_m}{\partial t} + \langle w \rangle \frac{\partial \theta_m}{\partial z} + \Lambda Pe \frac{\partial^2 \theta_m}{\partial z \partial t} = K\ f\left(\theta_m + \Lambda Pe \frac{\partial \theta_m}{\partial z}\right). \tag{5.9}$$

In this case, in addition to the transient dispersion term, we also have a source correction term, and the reduced model is different from the standard models used in the literature. These earlier literature models were obtained by just adding the source term to the nonreactive reduced model. Such models are clearly invalid as they exclude the correction term which appears in (5.9). (This was first noted by Balakotaiah and Dommeti (1999) using lumped resistance models. This correction term is also missing in the averaged models of Westerterp, Dilman, and Kronberg (1995) and Westerterp et al. (1995) using a heuristic approach.)

The third case we consider is that of a two-phase system in which the low capacitance fluid phase is moving and the solid phase is stationary. We also assume that $K = 0$ in the fluid phase and $K = 1$ in the solid phase. (This is a generalization of the packed-bed model with heat generation in the solid phase.) For this case, it may be seen that $\gamma > 0$, $\kappa > 0$, and $\delta < 0$. If $f'(\langle\theta\rangle) > 0$ (exothermic reaction), this corresponds to a decrease in the capacitance-weighted average velocity and an increase in the source strength in the reduced model.

The last case we consider is that of steady-state dispersion under reactive conditions. Now, since K is independent of t and since the time derivative in (5.2) is zero, we redo the Liapunov–Schmidt reduction. The reduced model is now given by the pair of equations

$$\langle w \rangle \frac{d\theta_m}{dz} + \langle K \rangle f(\langle\theta\rangle) + Pe\ \langle K\chi \rangle f'(\langle\theta\rangle) f(\langle\theta\rangle) = 0, \tag{5.10a}$$

$$\theta_m = \langle\theta\rangle + Pe\ \frac{\langle w\chi \rangle}{\langle w \rangle} f(\langle\theta\rangle), \tag{5.10b}$$

where χ is distinct from the transient version (5.6) and is now defined by

$$\pounds \chi = K - \frac{w}{\langle w \rangle} \langle K \rangle, \tag{5.11a}$$

$$\frac{\partial \chi}{\partial n} = 0 \qquad \text{on } \partial\Omega. \tag{5.11b}$$

The boundary condition to be used on (5.10) is

$$\theta = \theta_{m0} \qquad \text{at } z = 0. \tag{5.12}$$

The reduced model is a differential-algebraic system, and there is no second derivative term. (We note that the reduced model is not an initial value problem in z! For the case of an exothermic reaction, it is an index infinity differential-algebraic system and can have multiple (in fact, an infinite number of) solutions whenever the local equation (5.10b) has multiple solutions. This can happen when the kinetics is autocatalytic. For more details, see Chakraborty and Balakotaiah (2002).) The

steady-state reactive correction/dispersion term $-\langle w\chi\rangle$ is different from the transient reactive and nonreactive dispersion coefficient $-\langle w\eta\rangle$. For the special case of uniform activity (K is independent of transverse coordinates) it is easily seen that

$$\chi = -\frac{K}{\langle w\rangle}\eta, \tag{5.13}$$

where η is as defined in the nonreactive case. For this special case, the steady-state model (5.10) simplifies to

$$\langle w\rangle \frac{d\theta_m}{dz} + K\ f(\langle\theta\rangle) = 0, \tag{5.14a}$$

$$\theta_m = \langle\theta\rangle - \ Pe\frac{K\Lambda}{\langle w\rangle^2} f(\langle\theta\rangle), \tag{5.14b}$$

with initial/boundary condition (5.12). This reduced model is very different from the standard pseudohomogeneous model with Danckwerts boundary conditions. We note that while the numerical coefficient Λ that appears in the above steady-state model is the same as that in the Taylor's transient solutal dispersion problem, there is also a correction to the source term containing the same coefficient (see also (5.9)). In addition, it should be emphasized again that the reduced model is a differential-algebraic system rather than a two-point boundary value problem as in the following classical Danckwerts model:

$$\Lambda\frac{d^2\theta_m}{dz^2} - \langle w\rangle \frac{d\theta_m}{dz} - K\ f(\theta_m) = 0, \tag{5.15a}$$

$$\langle w\rangle\,\theta_{m0} = \langle w\rangle\,\theta_m\ - \Lambda\ \frac{d\theta_m}{dz} \qquad \text{at } z = 0, \tag{5.15b}$$

$$\frac{d\theta_m}{dz} = 0 \qquad \text{at } z = L. \tag{5.15c}$$

In this model, the exit boundary condition (5.15c) is imposed rather than derived from the original two-dimensional model.

6. Discussion. We have shown in this work that dispersion caused by transverse gradients can be described by reduced models that are hyperbolic in the longitudinal coordinate and time and that contain an effective local length or time scale. Our method also overcomes the main deficiencies of the previous approaches to averaging based on the moments method and the center manifold theorem. The former is applicable only to linear problems, while the latter describes the asymptotic behavior close to a fixed point (such as a trivial solution $\theta(x, y, z, t) = 0$). In contrast, our method is based on expansion around a state $\langle\theta\rangle(z, t)$ that is only independent of the transverse coordinates and can be applied to both steady-state and transient problems.

We have presented here the averaged models to only the lowest order in Pe. However, the extension to obtain higher order averaged models is straightforward. For example, for the solutal/thermal dispersion problem, it is easily seen that the reduced model to all orders (in Pe or t_H) is of the form

$$\frac{\partial\langle\theta\rangle}{\partial t'} + \langle u\rangle \frac{\partial\theta_m}{\partial z'} = 0, \tag{6.1a}$$

$$\langle\theta\rangle - \theta_m + \sum_{i=1}^{\infty} \beta_i (t_H)^i \frac{\partial^i \langle\theta\rangle}{\partial t^i} = 0, \tag{6.1b}$$

where t_H is the local time scale and β_i are numerical constants that depend on the velocity profile $w(x, y)$ and the geometry of Ω. Appropriate inlet and initial conditions may also be derived for (6.1).

The present approach may also be extended in many ways. Instead of the no-flux outer wall, we can allow an isothermal wall or a mixed boundary condition with a wall heat transfer coefficient. In such cases, the operator $\mathcal{L}$ is no longer singular and $\langle\theta\rangle$ does not strictly correspond to the null eigenfunction. However, if the transverse gradient remains small (and $\mathcal{L}$ has a discrete spectrum), the invariant manifold approach of Roberts (1989) and Balakotaiah and Chang (1995) can be used to extend the Lyapunov–Schmidt technique presented here.

Acknowledgments. We thank two anonymous referees for many helpful comments.

EVANS FUNCTION STABILITY OF COMBUSTION WAVES*

V. GUBERNOV†, G. N. MERCER†, H. S. SIDHU†, AND R. O. WEBER†

Abstract. In this paper we investigate the linear stability and properties, such as speed, of the planar travelling combustion front. The speed of the front is estimated both analytically, using the matched asymptotic expansion, and numerically, by means of the shooting and relaxation methods. The Evans function approach extended by the compound matrix method is employed to numerically solve the linear stability problem for the travelling wave solution.

1. Introduction.

Problems involving combustion waves are characterized by strong dependence of the reaction rate, which is usually modelled by the Arrhenius law, on the temperature. This sharp dependence of the reaction rate naturally divides the structure of the travelling front into three regions. Ahead of the combustion wave, in a preheat zone, the temperature is low and there is almost no reaction. When the temperature becomes sufficiently high, the reaction rate increases exponentially and the fuel is converted into heat very quickly. This takes place in a narrow region called the reaction zone. Finally, behind the front, in a product zone, all fuel is consumed, no reaction occurs, and the temperature is constant. The temperature and the amount of fuel change rapidly in the reaction zone. The above picture in some sense is close to the boundary layer problem. Therefore similar methods of analysis, like the matched asymptotic expansion (MAE), apply in both cases.

The analysis of steady propagating planar combustion fronts is usually based on MAE. According to this method, in the limit of high activation energy, we seek the travelling wave solution in the form of a series in all three regions; then on the boundaries of these zones the expansions are matched in each order of a small parameter. The asymptotic procedure in principle allows us to find the solution with any desired accuracy and for arbitrary Lewis number. As a rule, only the leading order is considered [1, 2, 3, 4, 5]; however, the higher order approximations can also be obtained [6]. The method of MAE is valid in the limit of large activation energy, and the properties of the steady combustion front, such as speed, can be found only numerically for general values of activation energy. Numerical analysis is mostly focused on solving the system of partial differential equations (PDE) that describe the problem [7, 8]. However, PDE can always be reduced to a system of ordinary differential equations (ODE) for steady propagating planar waves. In this paper we take advantage of the ODE formulation of the problem, which is usually more convenient for numerical analysis. We use shooting and relaxation methods to investigate the dependence of the speed of the front on the parameters of the problem. Besides the benefits of technical implementation, an ODE formulation does not depend on the

†School of Mathematics and Statistics, University of New South Wales at the Australian Defence Force Academy, Canberra, ACT 2600, Australia (vlad@ma.adfa.edu.au, g.mercer@adfa.edu.au, hss@ma.adfa.edu.au, r.weber@adfa.edu.au).

stability of the travelling wave and therefore allows us to continue the solution branch over a broader parameter range.

As we vary the parameters of the problem, a steady propagating planar front can lose stability, giving rise to either pulsating or cellular flames [5, 9]. Analytical investigation of the stability using the MAE leads to the so-called closure problem. In contrast to steady travelling waves, in this case the leading order equations depend on first order corrections, first order equations include second order terms of the asymptotic expansion, etc. In order to find the solution to the leading order problem, an infinite number of equations have to be investigated. One of the ways of overcoming this obstacle is just to truncate the expansion [1, 2, 3, 4, 5, 9]. This yields a closed problem with a replacement of the Arrhenius reaction rate by a delta-function source depending on the temperature at the reaction front. The truncated model has been used extensively for the stability analysis of combustion waves [1, 2, 3, 4]. However, the model with the delta-function source suffers from inconsistencies, as was noted in [5, 9]. The inverse of the small parameter of the expansion appears explicitly in the exponential terms describing the strength of the source. In other words, temperature variations behind the front are considered to be small in the exponential terms and of leading order elsewhere.

An asymptotically consistent approach was proposed in [5] for the system with the Lewis number of the order of unity. In this case the enthalpy does not change at the leading order. A closed problem was derived for the leading order temperature and the first order enthalpy. However, until recently [9], there has not been a consistent approach that treats the model with arbitrary Lewis number.

In [9] a generalization of the MAE method was introduced. The coefficients in the expansions are allowed to depend on the expansion parameter. This enables the correct scaling of the temperature variations ahead of and behind the reaction zone; namely, a restriction is imposed connecting the leading order temperature in the preheat zone and the first two terms of the asymptotic expansion in the product zone. The constraint reflects the fact that small temperature variations behind the front change the leading order terms in the preheat zone. The resulting model includes equations for the leading order variables ahead of the reaction zone and for the first order temperature variations in the product zone, together with matching and boundary conditions. There is no restriction on the range of the Lewis number values.

However, the models describing the propagation of the steady planar combustion waves were derived only in the leading order of the expansion parameter of the asymptotic procedure. In other words the papers mentioned above analyze the linear stability of models which are different from the original one with the Arrhenius kinetics. This is fully justified by the complexity of the problem and reveals the lack of alternative methods to MAE. Fortunately, recent advances in the application of the Evans function [10] to stability analysis of solitary waves and fronts [11, 12, 13, 14, 15] provide us with a powerful tool for the semianalytical investigation of travelling front stability.

The linear stability problem can always be formulated as an eigenvalue problem for some differential operator. The Evans function was first introduced in [10] to study the stability of nerve pulses as an analytical function whose zeros correspond to the isolated eigenvalues of this differential operator. In some specific cases the Evans function can be found explicitly, and the Evans function being zero gives the dispersion relation. In other cases, like solitary waves of a generalized Kordeweg–deVries (KdV) equation [16] and generalized nonlinear Schrödinger equation [17], the

asymptotic behavior of the Evans function can be found using the results obtained in [16], where the derivative of the Evans function was connected to the Melnikov integral [18]. The knowledge of asymptotics allowed the authors to localize zeros of the Evans function and to solve the stability problem analytically.

The asymptotic form of the Evans function for the combustion problem was derived in [15] in the limit of large activation energy and Lewis number of the order of unity. The results of [15] agree with the predictions of the MAE analysis of [5]. Zeros of the Evans function and therefore the stability of the combustion front can be found only numerically for general parameter values. Previously, this problem was solved by direct integration of the governing PDE [7, 8]. We cannot expect this method to be accurate near the critical parameter values, where the rate of instability is weak and a long integration time is needed to detect it. Furthermore, this method is relatively difficult for computational implementation in comparison with the numerical estimation of the Evans function proposed in [19], which is based on ODE integration. However, the latter method is applicable only for problems with a specific type of geometry, such as the linear stability problem for the KdV equation, and fails to work for stiff systems [12], such as in our case.

In the present paper we apply the Evans function method to the stability analysis of the planar combustion front. The linear stability problem associated with the travelling combustion wave is an example of a stiff problem. We extend the conventional algorithm for calculating the Evans function [19] by the compound matrix method [12, 13, 20, 21, 22], which was first employed for analysis of the hydrodynamic stability for the Orr–Sommerfeld equation. This method eliminates the stiffness and makes the linear stability problem numerically tractable.

In this paper we use the combination of shooting-relaxation and the Evans function method (extended by the compound matrix method) as a consistent approach for numerical investigation of both properties and stability of the travelling planar front, based on the ODE formulation of the combustion problem. We show that the method is valid for a wide range of the parameter values.

The paper is organized as follows. The model and governing equations are introduced in section 2. In section 3 we show how MAE can be used to derive travelling wave solutions in the limit of large activation energy, and we compare these solutions with the solutions obtained by shooting and relaxation methods. The linear stability problem is formulated in section 4, whereas the relation to the Evans function is discussed in section 5. In section 6 we quote the asymptotic results of [15] for the Evans function. Numerical stability analysis is carried out in section 7. Finally, concluding remarks can be found in section 8.

2. Model. We consider a premixed fuel in one dimension. The heat loss is neglected. We assume that the rate of exothermic combustion is well described by the Arrhenius law. In nondimensional coordinates, the equations governing this process can be found in [7] and are given as

$$u_t = u_{xx} + ve^{-1/u}, \qquad v_t = \tau v_{xx} - \beta ve^{-1/u}, \tag{2.1}$$

where u and v are the nondimensional temperature and mass fraction of the fuel, respectively; τ is the inverse Lewis number (the ratio of the diffusion rates of mass and heat); and β is the ratio of the activation energy to heat release.

We consider the ambient temperature to be equal to zero. This approximation simplifies the problem, decreasing the number of parameters. As is noted in [7], this is a way to circumvent the "cold-boundary problem" and does not change the behavior of

the system. It is not an appropriate simplification when considering ignition problems. Parameter τ varies from zero, for solid fuel, to unity, for gaseous fuels. The parameter β is of the order of unity or larger.

We consider system (2.1) subject to the following boundary conditions:

$$\begin{array}{llll} u(x,t) \to \beta^{-1}, & v(x,t) \to 0 & \text{as} & x \to -\infty, \\ u(x,t) \to 0, & v(x,t) \to 1 & \text{as} & x \to +\infty. \end{array} \tag{2.2}$$

On the right boundary we have a cold ($u = 0$) and unburned ($v = 1$) state, whereas the opposite limit corresponds to the hot ($u = \beta^{-1}$) and burned ($v = 0$) state.

3. Travelling wave solution. Let us consider the case $\tau \sim O(1)$. We will seek the solution of (2.1) in a form of the front travelling with a constant speed c

$$u(x,t) = u(\xi), \qquad v(x,t) = v(\xi), \tag{3.1}$$

where we have introduced a moving coordinate frame $\xi = x - ct$. After substituting (3.1) into (2.1), it is easy to obtain two second order differential equations

$$u_{\xi\xi} + cu_\xi + ve^{-1/u} = 0, \qquad \tau v_{\xi\xi} + cv_\xi - \beta ve^{-1/u} = 0 \tag{3.2}$$

and boundary conditions

$$\begin{array}{llll} u = \beta^{-1}, & v = 0 & \text{as} & \xi \to -\infty, \\ u = 0, & v = 1 & \text{as} & \xi \to +\infty. \end{array} \tag{3.3}$$

Now let us make the reaction terms in (3.1) symmetric by introducing new variables $\widetilde{u} = \beta u$, $\widetilde{v} = v$ and scale the coordinate $z = c\xi$. This gives us the equations

$$\widetilde{u}_{zz} + \widetilde{u}_z + \beta^2 Q\widetilde{v}e^{\beta(1-1/\widetilde{u})} = 0, \qquad \tau\widetilde{v}_{zz} + \widetilde{v}_z - \beta^2 Q\widetilde{v}e^{\beta(1-1/\widetilde{u})} = 0, \tag{3.4}$$

where $Q = (\beta c^2 e^\beta)^{-1}$ is a flame speed eigenvalue, which has to be found. Boundary conditions are modified as follows:

$$\begin{array}{llll} \widetilde{u} = 1, & \widetilde{v} = 0 & \text{as} & z \to -\infty, \\ \widetilde{u} = 0, & \widetilde{v} = 1 & \text{as} & z \to +\infty. \end{array} \tag{3.5}$$

In the new variables the reaction zone is of the order of β^{-1}. Outside this zone the reaction terms of (3.4) become negligible. Hence in the outer region (3.4) can be written as

$$\widetilde{u}_{zz} + \widetilde{u}_z = 0, \qquad \tau\widetilde{v}_{zz} + \widetilde{v}_z = 0, \tag{3.6}$$

subject to boundary conditions (3.5).

We seek the solution of problem (3.6) in the form of a series, with β^{-1} being a small parameter, and hence we postulate

$$\begin{aligned} \widetilde{u} &= U_0 + \beta^{-1}U_1 + \cdots, \\ \widetilde{v} &= V_0 + \beta^{-1}V_1 + \cdots, \\ Q &= Q_0 + \beta^{-1}Q_1 + \cdots. \end{aligned} \tag{3.7}$$

In the zeroth order, the solution of equations (3.6) is

$$U_0 = \begin{cases} 1, & z < 0, \\ e^{-z}, & z > 0, \end{cases} \quad \text{and} \quad V_0 = \begin{cases} 0, & z < 0, \\ 1 - e^{-z/\tau}, & z > 0. \end{cases} \tag{3.8}$$

In order to find Q_0 we should match the solution (3.8) with the solution of the inner problem.

Let us consider (3.4) in a thin boundary layer where the reaction occurs. We introduce the stretched coordinate $y = \beta z$ and seek solutions of the form

$$\begin{aligned} \widetilde{u} &= 1 + \beta^{-1}u_1 + \beta^{-2}u_2 + \cdots, \\ \widetilde{v} &= \beta^{-1}v_1 + \beta^{-2}v_2 + \cdots, \\ Q &= Q_0 + \beta^{-1}Q_1 + \cdots. \end{aligned} \tag{3.9}$$

After substituting (3.9) into (3.4) and leaving the leading terms of the order $O(\beta)$, we obtain the equations

$$\ddot{u}_1 + Q_0 v_1 e^{u_1} = 0, \qquad \tau\ddot{v}_1 - Q_0 v_1 e^{u_1} = 0, \tag{3.10}$$

with the dot denoting derivative $\partial/\partial y$. In deriving (3.10) we have assumed that $\tau \sim O(1)$ and $Q_0 \sim O(1)$. On the boundaries we can require that the following matching conditions be satisfied:

$$\begin{aligned} &\lim_{y\to\pm\infty}[u_1(y) - U_1(0\pm) - U_{0z}(0\pm)y] = 0, \\ &\lim_{y\to\pm\infty}[v_1(y) - V_1(0\pm) - V_{0z}(0\pm)y] = 0. \end{aligned} \tag{3.11}$$

On the left boundary from (3.8) it follows that $U_{0z}(0-) = V_{0z}(0-) = 0$, and we can rewrite (3.11) in the form

$$\begin{aligned} &u_1 = U_1(0-), \quad v_1 = V_1(0-) \\ &\dot{u}_1 = 0, \qquad\quad \dot{v}_1 = 0 \end{aligned} \qquad \text{as} \quad y \to -\infty. \tag{3.12}$$

System (3.10) has the integral

$$u_1 + \tau v_1 = C_1 + D_1 y. \tag{3.13}$$

Applying the matching condition (3.12), it can be shown that $D_1 = 0$ and $C_1 = U_1(0-) + \tau V_1(0-)$. Using this integral system, (3.10) can be reduced to a single equation

$$\ddot{\theta} - k\theta e^{-\theta} = 0, \tag{3.14}$$

where $\theta = C_1 - u_1$, $k = Q_0/\tau e^{C_1}$. Equation (3.14) can be treated as the equation of motion of a point particle with unit mass in the potential $W(\theta) = k(1+\theta)e^{-\theta}$. The potential $W(\theta)$ has a maximum only for $\theta = 0$. Conditions (3.12) imply that $\dot{\theta}(-\infty) = 0$. This is possible only if the energy $E = \dot{\theta}^2/2 + W(\theta)$ is equal to the maximal value of the potential $W(0) = k$. Therefore, $\theta = 0$ as $y \to -\infty$, and consequently, $C_1 = U_1(0-)$ and $V_1(0-) = 0$. On the other hand, as $y \to +\infty$ the potential $W(y)$ decays exponentially and $\dot{\theta} \to \sqrt{2k}$.

Returning to the original problem, the left boundary conditions can be written as

$$\begin{aligned} &u_1 = U_1(0-), \quad v_1 = 0 \\ &\dot{u}_1 = 0, \qquad\quad \dot{v}_1 = 0 \end{aligned} \qquad \text{as} \quad y \to -\infty. \tag{3.15}$$

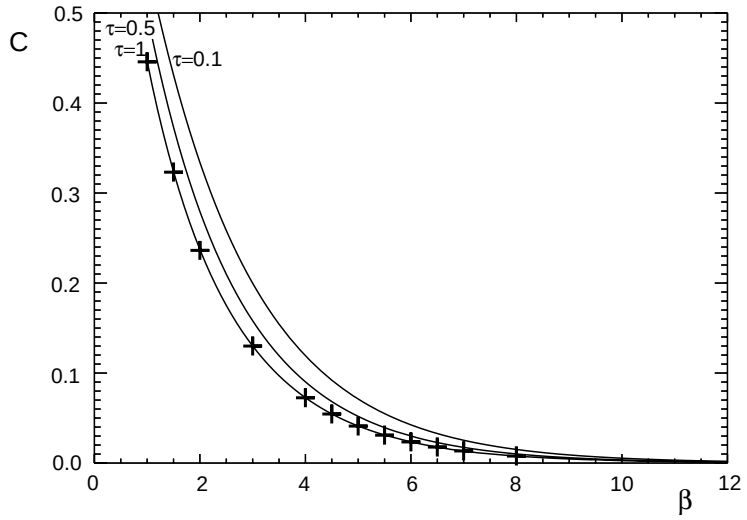

FIG. 1. *Numerically determined speed of the travelling front as a function of β. Solid lines correspond to the results obtained by shooting and relaxation methods for values of parameter $\tau =$ 0.1, 0.5, and 1.0 (right to left). Crosses represent the speed of the front calculated by direct PDE integration of* (2.1) *for* $\tau = 1.0$.

On the right boundary, it follows from (3.11) and (3.13) that

$$\left(\frac{\partial U_0}{\partial z}\right)_{z=0+} = -\tau \left(\frac{\partial V_0}{\partial z}\right)_{z=0+} = -\sqrt{\frac{2Q_0}{\tau e^{U_1(0-)}}}. \tag{3.16}$$

For planar front solution $U_1(0-) = 0$ and from (3.8) we have $(\partial U_0/\partial z)_{z=0+} = -1$. Taking into account the definition of Q, we can obtain the following estimation of the speed:

$$c = \sqrt{2\tau^{-1}\beta^{-1}} e^{-\beta/2}, \tag{3.17}$$

which agrees with the results of [7, 8] in the limit of large β. Note that a similar expression for the front speed was first found in [6].

We also solved (3.2) numerically. As in [23], we used the shooting method to obtain the guess solution, and then the results were corrected with a more accurate method, namely, relaxation. Combination of these methods allowed us to numerically obtain the dependence of the travelling front velocity on the parameters β and τ. In Figure 1 we plot the speed of the front as a function of β for three different values of τ. The results are compared to the predictions obtained in [7] by direct PDE integration of (2.1). The accordance between these two approaches is excellent.

In Figure 2 we compare the prediction of the asymptotic formula (3.17) for the speed of the front with the results obtained numerically. As can be seen, the correspondence is quite good for $\tau = 1$ and large values of β. However, when we decrease the value of τ, the approximation of the speed (3.17), which is valid for $\tau \sim O(1)$, becomes unsatisfactory. For example, when $\tau = 0.1$, the difference between the analytical and numerical results becomes significant.

The stability analysis of the steady propagating combustion front carried out in the following sections is based on how accurately we can approximate the solution of

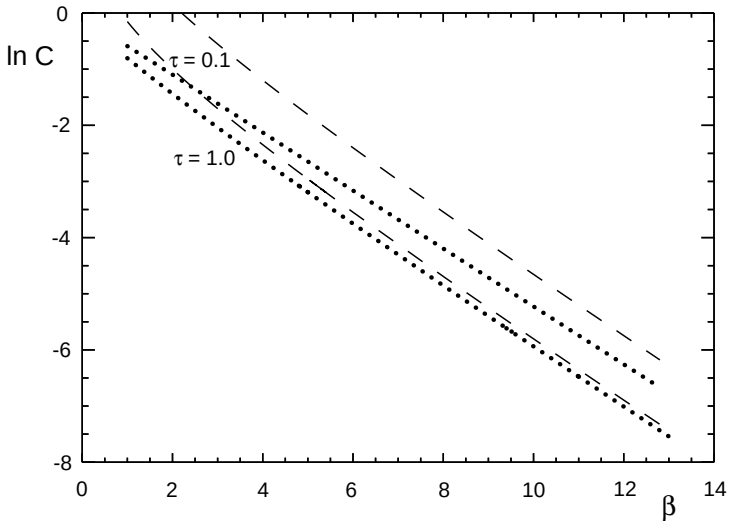

FIG. 2. *Logarithm of the speed of the travelling front as a function of β for values of parameter $\tau = 0.1$ and 1.0. Dots correspond to the numerical results, whereas dashed lines represent the approximation of the speed according to the formula* (3.17). *In each case the upper line is for $\tau = 0.1$ and the lower line for $\tau = 1.0$.*

(3.2). Standard relaxation routine (see [23] and references therein) allows us to control the average local correction made on each iteration step. The solution is considered to be resolved if the correction is less than 10^{-15}. We also tested the accuracy of the method independently by changing the step of the grid and comparing the resulting variations in the values of the front speed. For example, a fourfold mesh refinement changes the value of the front speed in the ninth significant digit. Therefore we assume that the numerical procedure outlined here works reasonably well.

4. Stability of a travelling front. As a first step in the analysis of travelling wave stability, we linearize (2.1) around the front solution (3.1):

$$u(x,t) = u(\xi) + \varphi(\xi,t), \qquad v(x,t) = v(\xi) + \chi(\xi,t), \tag{4.1}$$

where φ and χ are linear perturbation terms. After substitution of (4.1) into (2.1) it is straightforward to derive

$$\begin{pmatrix} \partial\varphi/\partial t \\ \partial\chi/\partial t \end{pmatrix} = \hat{L} \begin{pmatrix} \varphi \\ \chi \end{pmatrix}, \tag{4.2}$$

where

$$\hat{L} = \begin{pmatrix} \partial_\xi^2 + vu^{-2}e^{-1/u} + c\partial_\xi & e^{-1/u} \\ -\beta vu^{-2}e^{-1/u} & \tau\partial_\xi^2 - \beta e^{-1/u} + c\partial_\xi \end{pmatrix}. \tag{4.3}$$

The stability of the travelling front is then defined from the spectra of $\hat{L}$. It is easy to show that the essential spectrum of this operator always lies in the left half-plane and therefore the discrete spectrum is solely responsible for the transition to instability (see [24]). We will seek the solution of (4.2) of the form

$$\varphi(\xi,t) = \varphi(\xi)e^{\lambda t}, \qquad \chi(\xi,t) = \chi(\xi)e^{\lambda t}, \tag{4.4}$$

where λ is a spectral parameter (in combustion literature it is sometimes referred to as the growth rate eigenvalue). Substituting (4.4) into (4.2) and introducing a vector with the components $z_1 = \varphi,\ z_2 = \varphi_\xi,\ z_3 = \chi,\ z_4 = \chi_\xi$, we obtain the system of ODE in the form

$$\dot{\mathbf{z}} = \mathbf{A}\mathbf{z}, \tag{4.5}$$

where

$$\mathbf{A}(\xi,\lambda) = \begin{pmatrix} 0 & 1 & 0 & 0 \\ \lambda - vu^{-2}e^{-1/u} & -c & -e^{-1/u} & 0 \\ 0 & 0 & 0 & 1 \\ \beta\tau^{-1}vu^{-2}e^{-1/u} & 0 & \tau^{-1}(\lambda + \beta e^{-1/u}) & -\tau^{-1}c \end{pmatrix}. \tag{4.6}$$

We use (4.5) to investigate the stability of the travelling front. Following [12], we will say that the travelling front is linearly unstable if, for some fixed complex λ with $Re(\lambda) > 0$, there exists a solution of (4.5) which decays exponentially as $\xi \to \pm\infty$. We will refer to this λ as an eigenvalue and to the corresponding solution as an eigenmode.

5. Evans function. Let us introduce the limit matrices

$$\mathbf{A}_\pm(\lambda) \equiv \lim_{\xi\to\pm\infty} \mathbf{A}(\xi,\lambda). \tag{5.1}$$

The explicit form of $\mathbf{A}_\pm$ can be found from the boundary conditions (3.3). The limit matrices have eigenvalues

$$\begin{aligned} &\mu^-_{1,2}(\lambda) = \tfrac{-c\mp\sqrt{c^2+4\lambda}}{2}, && \mu^+_{1,2} = \mu^-_{1,2}, \\ &\mu^-_{3,4}(\lambda) = \tfrac{-c\mp\sqrt{c^2+4\tau(\lambda+\beta e^{-\beta})}}{2\tau}, && \mu^+_{3,4}(\lambda) = \mu^-_{3,4}(\lambda - \beta e^{-\beta}), \end{aligned} \tag{5.2}$$

with corresponding eigenvectors $\mathbf{k}^\pm_i$ (for $i = 1,\dots,4$). Equations (5.2) imply that $\mathbf{A}_-$ has two eigenvalues $\mu^-_{2,4}$ with positive real parts and two eigenvalues $\mu^-_{1,3}$ with negative real parts. Similarly, for $\mathbf{A}_+$ we have $Re(\mu^+_{2,4}) > 0$ and $Re(\mu^+_{1,3}) < 0$. Therefore, for any value of λ there exist two linearly independent solutions $\mathbf{z}^-_{2,4}(\xi,\lambda)$ of (4.5) corresponding to unstable subspaces of $\mathbf{A}_-$ satisfying the conditions

$$\lim_{\xi\to-\infty} \exp(-\mu^-_i\xi)\mathbf{z}^-_i(\xi,\lambda) = \mathbf{k}^-_i, \qquad i = 2,4, \tag{5.3}$$

and two linearly independent solutions $\mathbf{z}^+_{1,3}(\xi,\lambda)$ of (4.5) corresponding to stable subspaces of $\mathbf{A}_+$ satisfying the conditions

$$\lim_{\xi\to+\infty} \exp(-\mu^+_i\xi)\mathbf{z}^+_i(\xi,\lambda) = \mathbf{k}^+_i, \qquad i = 1,3. \tag{5.4}$$

Now we can consider a space of solutions of (4.5) bounded as $\xi \to -\infty$ and a space of solutions bounded as $\xi \to +\infty$. If these spaces intersect nontrivially for some value λ, then λ is an eigenvalue. We will call the function which measures whether these spaces intersect the Evans function. Geometrically this means that for some value of λ and any value of coordinate ξ the plane defined by the vectors $\mathbf{z}^-_{2,4}$ intersects nontrivially with the plane defined by the vectors $\mathbf{z}^+_{1,3}$. We can also say that λ is an eigenvalue if and only if the solutions $\mathbf{z}^-_{2,4}$ and $\mathbf{z}^+_{1,3}$ are linearly dependent or, equivalently, the Wronskian evaluated on these solutions (a matrix whose columns

are $\mathbf{z}^-_{2,4}(\xi)$ and $\mathbf{z}^+_{1,3}(\xi)$) is equal to zero. One of the Evans function definitions is given in [15] via this Wronskian, which is evaluated for definiteness at $\xi = 0$. Let $\mathbf{e}_i$ be the orthonormal basis in four dimensional space $\mathbf{C^4}$ of system (4.5) solutions. In this basis the vectors $\mathbf{z}^\pm_i$ have coordinates $(z^\pm_{i1}, z^\pm_{i2}, z^\pm_{i3}, z^\pm_{i4})^T$, and the Evans function is defined as

$$D(\lambda) = \begin{vmatrix} z^-_{21}(0,\lambda) & z^-_{41}(0,\lambda) & z^+_{11}(0,\lambda) & z^+_{31}(0,\lambda) \\ z^-_{22}(0,\lambda) & z^-_{42}(0,\lambda) & z^+_{12}(0,\lambda) & z^+_{32}(0,\lambda) \\ z^-_{23}(0,\lambda) & z^-_{43}(0,\lambda) & z^+_{13}(0,\lambda) & z^+_{33}(0,\lambda) \\ z^-_{24}(0,\lambda) & z^-_{44}(0,\lambda) & z^+_{14}(0,\lambda) & z^+_{34}(0,\lambda) \end{vmatrix}. \tag{5.5}$$

In what follows we will also require an alternative definition of the Evans function. Returning to the geometrical picture, we can say that to find the eigenvalues we do not have to seek the solutions $\mathbf{z}^-_{2,4}$ and $\mathbf{z}^+_{1,3}$, but it is sufficient to determine the orientation of the planes, constructed on corresponding pairs of vectors, in space $\mathbf{C^4}$ of system (4.5) solutions.

If we take two linear independent vectors in $\mathbf{C^n}$, then the orientation of a plane containing both vectors can be determined by a wedge product of them. (Two vectors are linear dependent if and only if their wedge product is equal to zero.) If $n = 3$, a wedge product coincides with a vector product, and the result of the operation is a vector belonging to $\mathbf{C^3}$. However, in the general case the result of a wedge product of two vectors is a vector lying in $\bigwedge^2(\mathbf{C^n})$, where $\bigwedge^2(\mathbf{C^n})$ is the second exterior power of $\mathbf{C^n}$. It has dimension $\dim[\bigwedge^2(\mathbf{C^n})] = n!/2!(n-2)!$.

In our case a plane can be defined by a six component vector; for instance, we define

$$\mathbf{V}^- = \mathbf{z}^-_2 \wedge \mathbf{z}^-_4, \qquad \mathbf{V}^+ = \mathbf{z}^+_1 \wedge \mathbf{z}^+_3, \tag{5.6}$$

where $\mathbf{V}^\pm \in \bigwedge^2(\mathbf{C^4})$ and $\wedge$ stands for wedge product. If λ is an eigenvalue, the planes associated with the vectors $\mathbf{V}^+$ and $\mathbf{V}^-$ intersect nontrivially. This means that $\mathbf{V}^+$ and $\mathbf{V}^-$ are linear dependent and a wedge product $\mathbf{V}^+ \wedge \mathbf{V}^-$ equals zero. Now we can make use of the Evans function definition given in [25] as

$$\widetilde{D}(\lambda) = \exp\left[-\int_0^\xi Tr(\mathbf{A}(s,\lambda))\right] \mathbf{V}^+(\xi,\lambda) \wedge \mathbf{V}^-(\xi,\lambda). \tag{5.7}$$

For the sake of further consideration it is convenient to take $\xi = 0$ in the definition (5.7). As was shown in [12], in this case we can rewrite (5.7) as

$$\widetilde{D}(\lambda) = D(\lambda)\Gamma, \tag{5.8}$$

where $\Gamma = \mathbf{e}_1 \wedge \mathbf{e}_2 \wedge \mathbf{e}_3 \wedge \mathbf{e}_4$ is a standard volume in $\mathbf{C^4}$ and

$$D(\lambda) = [\mathbf{V}^+, \Sigma\overline{\mathbf{V}^-}]. \tag{5.9}$$

Here, the overline denotes the complex conjugate, $[\cdot,\cdot]$ is the complex inner product in $\mathbf{C^6}$, and Σ is the operator that in a basis

$$\begin{aligned} &\mathbf{v}_1 = \mathbf{e}_1 \wedge \mathbf{e}_2, \quad \mathbf{v}_2 = \mathbf{e}_1 \wedge \mathbf{e}_3, \quad \mathbf{v}_3 = \mathbf{e}_1 \wedge \mathbf{e}_4, \\ &\mathbf{v}_4 = \mathbf{e}_2 \wedge \mathbf{e}_3, \quad \mathbf{v}_5 = \mathbf{e}_2 \wedge \mathbf{e}_4, \quad \mathbf{v}_6 = \mathbf{e}_3 \wedge \mathbf{e}_4, \end{aligned} \tag{5.10}$$

is represented by the matrix

$$\Sigma = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}. \tag{5.11}$$

In the basis (5.10) the components of vector $\mathbf{V}^-$ can be shown to be

$$\begin{array}{ll} \mathbf{V}_1^- = z_{21}z_{42} - z_{41}z_{22}, & \mathbf{V}_4^- = z_{22}z_{43} - z_{42}z_{23}, \\ \mathbf{V}_2^- = z_{21}z_{43} - z_{41}z_{23}, & \mathbf{V}_5^- = z_{22}z_{44} - z_{42}z_{24}, \\ \mathbf{V}_3^- = z_{21}z_{44} - z_{41}z_{24}, & \mathbf{V}_6^- = z_{23}z_{44} - z_{43}z_{24}. \end{array} \tag{5.12}$$

A similar relation holds for $\mathbf{V}^+$. Using these expressions for $\mathbf{V}^\pm$, we can show (by means of direct substitution) that definitions (5.5) and (5.9) are identical.

The vectors $\mathbf{V}^\pm$ can be also called the second compounds of the matrices formed from a pair $\mathbf{z}_{2,4}^-$ or $\mathbf{z}_{1,3}^+$, respectively, and were considered in [20, 21, 22] in relation with the Orr–Sommerfeld equation. The definition (5.5) is the simpler of the two, but the importance of the second definition (5.9) will be revealed in section 7.

6. Evans function for $\tau \sim O(1)$ and $\beta \gg 1$. Let us return to the definition (5.5) of the Evans function. In [15] it was shown that in the case of $\tau \sim 1$ and $\beta \gg 1$ the Evans function can be approximated analytically with good accuracy. In this section we assume that $\tau = 1 - \beta^{-1}\ell$, where $\ell \sim 1$.

First, let us rewrite the spectral problem (4.2)–(4.3) for the operator $\hat{L}$ in the symmetric form. By introducing the variables $\widetilde{u} = \beta u$, $\widetilde{v} = v$, $\widetilde{\varphi} = \beta\varphi$, $\widetilde{\chi} = \chi$, and the scaled coordinate $z = c\xi$ defined in section 3, we can obtain

$$\hat{L}\begin{pmatrix} \widetilde{\varphi} \\ \widetilde{\chi} \end{pmatrix} = \widetilde{\lambda}\begin{pmatrix} \widetilde{\varphi} \\ \widetilde{\chi} \end{pmatrix}, \tag{6.1}$$

where $\widetilde{\lambda} = \lambda/c^2$ and

$$\hat{L} = \begin{pmatrix} \partial_z^2 + \partial_z + \beta^3 Q\widetilde{v}\widetilde{u}^{-2}e^{\beta(1-1/\widetilde{u})} & \beta^2 Q e^{\beta(1-1/\widetilde{u})} \\ -\beta^3 Q\widetilde{v}\widetilde{u}^{-2}e^{\beta(1-1/\widetilde{u})} & \tau\partial_z^2 + \partial_z - \beta^2 Q e^{\beta(1-1/\widetilde{u})} \end{pmatrix}. \tag{6.2}$$

A similar type of equation was considered in [15]. The solutions $\widetilde{\mathbf{z}}_{2,4}^-$ and $\widetilde{\mathbf{z}}_{1,3}^+$ of (6.1), having the same meaning as in the previous section, were found. Using the definition (5.5), the Evans function can be shown to be approximated in the limit $\beta \to \infty$ as

$$D(\widetilde{\lambda}, \ell) = 2\Gamma^2(\Gamma - 1) - \ell(2\widetilde{\lambda} - \Gamma + 1), \tag{6.3}$$

where $\Gamma = \sqrt{1 + 4\widetilde{\lambda}}$. As ℓ crosses $\ell_c = 4(1+\sqrt{3}) \approx 10.92$, a pair of complex conjugate eigenvalues $\pm i\widetilde{\lambda}_c$, where $\widetilde{\lambda}_c \approx 0.6356$, passes into the right half of the complex plane, giving rise to a Hopf bifurcation. The same result was obtained in [4, 5] using the matched asymptotic expansion. Now we can estimate the boundary of stability of the planar front as $\beta = \ell_c/(1-\tau)$ and the Hopf frequency $\lambda = c^2\widetilde{\lambda}_c$. Unfortunately, we cannot expect this prediction to be quantitatively accurate, because in the beginning of the consideration it was assumed that $\ell \sim O(1)$, whereas ℓ_c has been found to be much greater.

7. Numerics and the compound matrix method. The method of calculating the Evans function was proposed in [19]. The idea is based on the definition (5.5). According to (5.5) it is necessary to determine the solutions $\mathbf{z}^-_{2,4}$ or $\mathbf{z}^+_{1,3}$ at $\xi = 0$. In order to numerically trace the solution, for example, growing as we integrate forward, the coordinate is exponentially scaled so as to eliminate the maximal rate of exponential growth. However, the numerical algorithm introduced in [19] allows us to find only the solutions which correspond to maximal (minimal) rates of exponential growth (decay) as $\xi \to \pm\infty$.

In our case we need to obtain two pairs of solutions: one pair bounded as ξ tends to $+\infty$, another as $\xi \to -\infty$. Let us consider for definiteness $\xi < 0$. From the analysis developed in section 5 it follows that system (4.5) has two solutions $\mathbf{z}^-_{2,4}$ bounded as $\xi \to -\infty$ and two solutions $\mathbf{z}^-_{1,3}$ unbounded as $\xi \to -\infty$ which are of no interest. In order to neglect $\mathbf{z}^-_{1,3}$ we have to numerically integrate the system (4.5) from $\xi = -l_1$ to $\xi = 0$ (where l_1 is chosen sufficiently large). Integrating forward we can find only $\mathbf{z}^-_4$, because $\mu^-_2 < \mu^-_4$ and the solution $\mathbf{z}^-_2$ is always ruled out due to errors of the numerical scheme. The same obstacles remain in the limit $\xi \to +\infty$. Systems with this kind of behavior are called stiff. The stiffness makes the direct calculation using (5.5) impossible, and some procedure of orthogonalization is required. The compound matrix method, which we employed in order to avoid this type of difficulty, is described below and will be seen to be closely related to the definition (5.9) introduced in section 5.

Let $\mathbf{z}_1$ and $\mathbf{z}_2$ be two solutions of (4.5); then the vector $\mathbf{V} = \mathbf{z_1} \wedge \mathbf{z_2}$ is the solution of the equation

$$\dot{\mathbf{V}} = \mathbf{B}\mathbf{V}, \tag{7.1}$$

where $\mathbf{B}$ is a 6×6 matrix whose elements can be found from the matrix $\mathbf{A}$ (see [13, 20, 21, 22] for details). It can be shown that the eigenvalues $s^\pm_i$ of $\mathbf{B}$ in the limits $\xi = \pm\infty$ are given via eigenvalues $\mu^\pm_i$ of $\mathbf{A}_\pm$ as

$$\begin{aligned} s^\pm_1 &= \mu^\pm_1 + \mu^\pm_2, \quad s^\pm_4 = \mu^\pm_2 + \mu^\pm_3, \\ s^\pm_2 &= \mu^\pm_1 + \mu^\pm_3, \quad s^\pm_5 = \mu^\pm_2 + \mu^\pm_4, \\ s^\pm_3 &= \mu^\pm_1 + \mu^\pm_4, \quad s^\pm_6 = \mu^\pm_3 + \mu^\pm_4. \end{aligned} \tag{7.2}$$

Therefore $\mathbf{V}^-(\xi)$, defined by (5.6), is the solution of (7.1) corresponding to the largest rate of exponential growth s^-_5 as we integrate forward from $\xi = -\infty$ to $\xi = 0$. Similarly $\mathbf{V}^+(\xi)$, defined by (5.6), is the solution of (7.1) corresponding to the largest rate of exponential growth s^+_2 as we integrate backward from $\xi = +\infty$ to $\xi = 0$. These solutions can always be found numerically by means of the method introduced in [19], and then we use definition (5.9) to calculate the Evans function numerically.

The problem of stability of the travelling front of (2.1) then reduces to the search for zeros of the Evans function (5.9) located in the right half-plane. Zeros of $D(\lambda)$ can be calculated using an argument principle. The number of zeros in the right half-plane equals the number of times the image of the imaginary axis under $D(it)$, $t \in R$, winds (wraps) around the origin. Graphs of $D(it), t \in R$, are called Nyquist plots [19].

Figure 3 shows Nyquist plots for $\tau = 0.1$ and $\beta = 6.8,\ 7.026,\ 7.2$. For $\beta = 6.8$ the curve does not encircle the origin, and hence the travelling front is stable. Transition to instability occurs for $\beta = 7.026$, when two complex conjugate eigenvalues cross the imaginary axes and the curve passes through the origin three times. The front

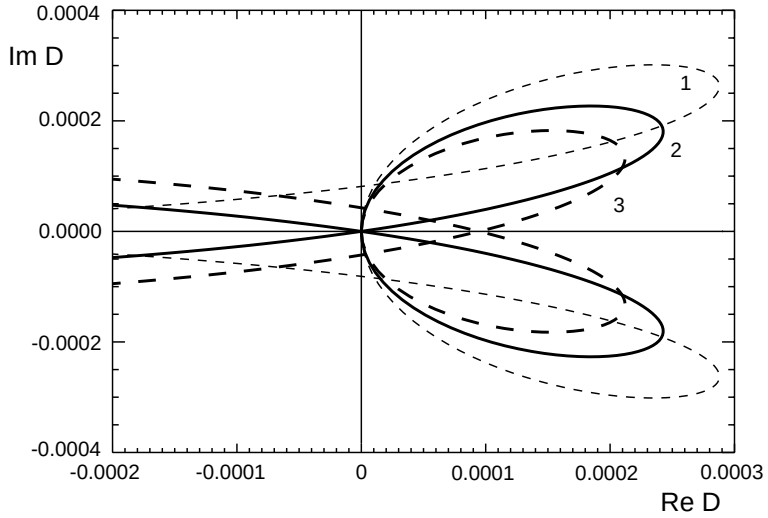

FIG. 3. *Transition to instability. The image of the imaginary axis $D(it)$ near the origin for $\tau = 0.1$ and for $\beta = 6.8$ (curve 1), 7.026 (curve 2), 7.2 (curve 3). Note that curve 1 does not encircle the origin, curve 2 is the transition, and curve 3 encircles the origin two times.*

is clearly unstable for $\beta = 7.2$, when the curve encircles the origin two times, and therefore there are two points of discrete spectra in the right half-plane.

The Nyquist plot technique allows us to obtain the criterion of transition to instability. Using this criterion, we can conclude whether the travelling front is stable or not for some fixed parameter values. However, it is quite difficult to calculate the critical parameter values. More detailed information can be collected by means of the Newton–Raphson method, which we apply to the equation $D(\lambda) = 0$. This allows us to locate the zeros of the Evans function on the complex plane for any given values of β and τ. In Figure 4 it is shown how two complex conjugate eigenvalues move from the left half-plane to the right half-plane, resulting in Hopf bifurcation at the parameter values when λ is purely imaginary. To determine the critical value β_c, when a pair of eigenvalues is located exactly on the imaginary axis, we consider the equation $Re\lambda = 0$ together with $D(\lambda) = 0$ and solve this system using the Newton–Raphson method. We start the iteration process with appropriate guess values for λ and β. We repeat the process until the zero is found with an accuracy of 10^{-12}. This gives us $\beta_c = 7.02609...$ for $\tau = 0.1$. While searching for the zeros of the Evans function, we checked the credibility of the method by decreasing the integration step by a factor of four. This results in the variation of the critical value of β in the ninth significant figure.

It is clear that we can use the procedure described above to find the dependence of the critical value β_c on τ. In Figure 5 the stability boundary is plotted in the parameter plane (β, τ). In section 6 we showed that as we increase τ towards 1, the corresponding value β_c tends to infinity. At the same time, according to (3.17) and the results of section 6, the speed of the front and the Hopf frequency tends to zero. As a result, the travelling front becomes flatter, and we should infinitely increase the interval of integration. For example, when $\tau = 0.6$, the critical values become $\beta_c = 21.087$, $c = 9.509 \times 10^{-6}$, $\lambda_c = 6.969 \times 10^{-11}$, and the interval of integration is about 10^6. In addition, it is numerically difficult to trace such small

values of λ_c. This implies that we can find the boundary of stability only on the interval $\tau \in [0, 0.6]$. As a result, it is extremely difficult to verify the asymptotic formula for $\beta_c(\tau)$ derived in section 6, as this is valid for $\tau \sim 1$. In Figure 5 we also plot the prediction obtained with the truncation model [9]. As can be seen, the discrepancy between the theoretical and numerical results is large for both asymptotic models. The generalized MAE developed in [9] gives the best correspondence with

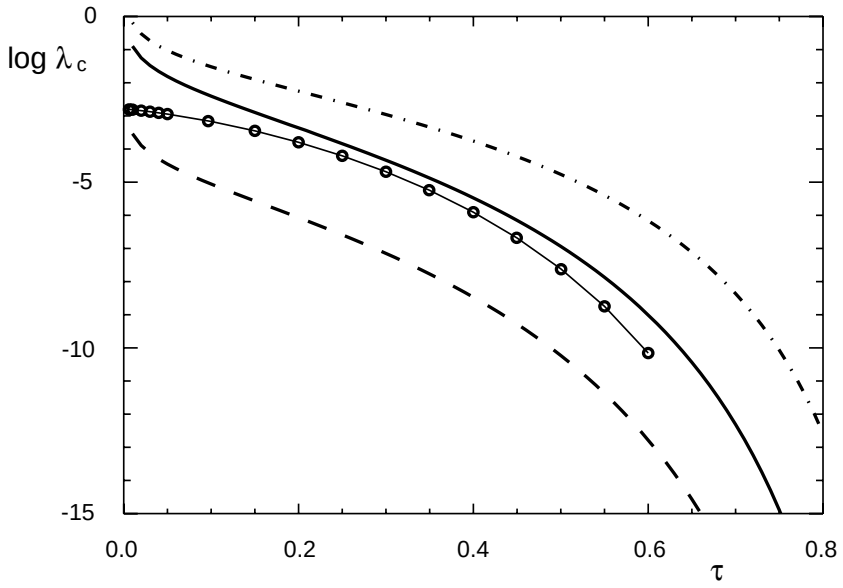

FIG. 6. *The logarithm of the Hopf frequency as a function of τ. Dots connected with a thin solid curve correspond to numerical results. the numerical data for $\tau \in [0.1, 0.5]$. In Figure 6 we plot the logarithm of the Hopf frequency as a function of τ for $\beta = \beta_c$. As in the previous figure, the generalized MAE estimation best fits the numerical results.

Finally, using the compound matrix method, we can find the eigenmodes of the system (4.2)–(4.3) by inverting the relations (5.12) for $\mathbf{V}^-$ and similarly for $\mathbf{V}^+$. In Figures 7 and 8 we show the eigenmodes obtained for $\tau = 0.3$ for the critical value $\beta_c = 9.7404$, when two eigenvalues lie on the imaginary axis. These eigenmodes can be used, for example, in perturbation analysis when we want to investigate properties of the solution, bifurcating from the steady propagating front (see [24] for details).

8. Conclusion. The speed of planar combustion fronts was investigated using the shooting and relaxation methods for different values of Lewis number and different values of β (the ratio of the activation energy to heat release). We have compared the numerical results with the asymptotic estimation of the speed of the combustion front. Derivation of the speed estimation is given in section 3 and agrees with the results of [5, 7, 8]. The correspondence between the numerical and analytical results is good for large β and $\tau \sim 1$, whereas for moderate values of β the difference becomes significant. This is expected, as the asymptotic formula for speed of the front was derived in the leading order of the asymptotic expansion with β being a small parameter. It is also important to note that as we decrease the value of τ up to the order of β^{-1} the asymptotic prediction of the front speed becomes unsatisfactory even for sufficiently large values of β. This reveals the fact that, in the asymptotic treatment of the problem, τ was considered to be of the order of units, and therefore the asymptotic approach fails to work for $\tau \sim \beta^{-1}$. It is interesting to note that the dependence of speed on β seems to be correct, whereas the dependence of c on τ is valid only for $\tau \sim 1$. Excellent correspondence of the numerical results obtained with the integration of the

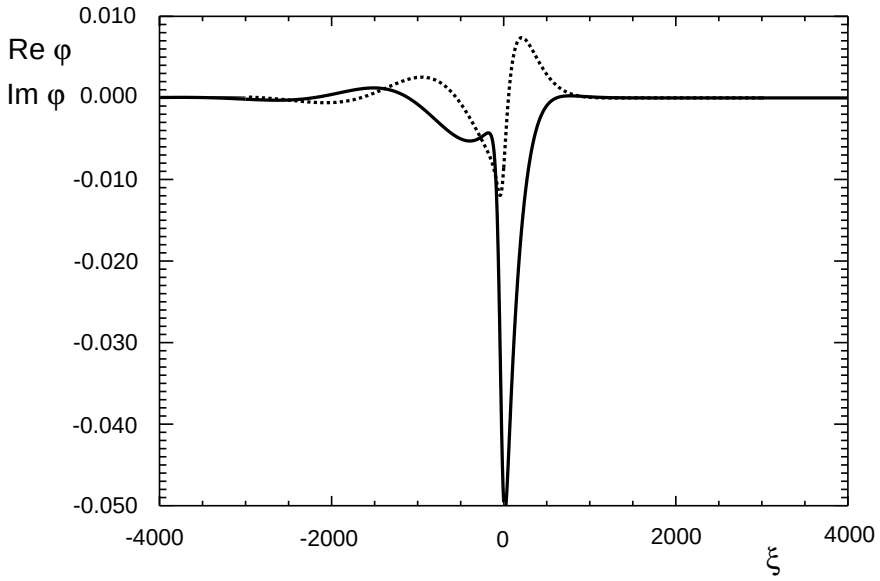

FIG. 7. *The eigenmode $\varphi(\xi)$ of the system* (4.2)–(4.3) *for $\tau = 0.3$, $\beta = \beta_c = 9.7404$, and purely complex eigenvalue $\lambda = i\lambda_c$. The solid line corresponds to Re φ, and the dashed line denotes Im φ.*

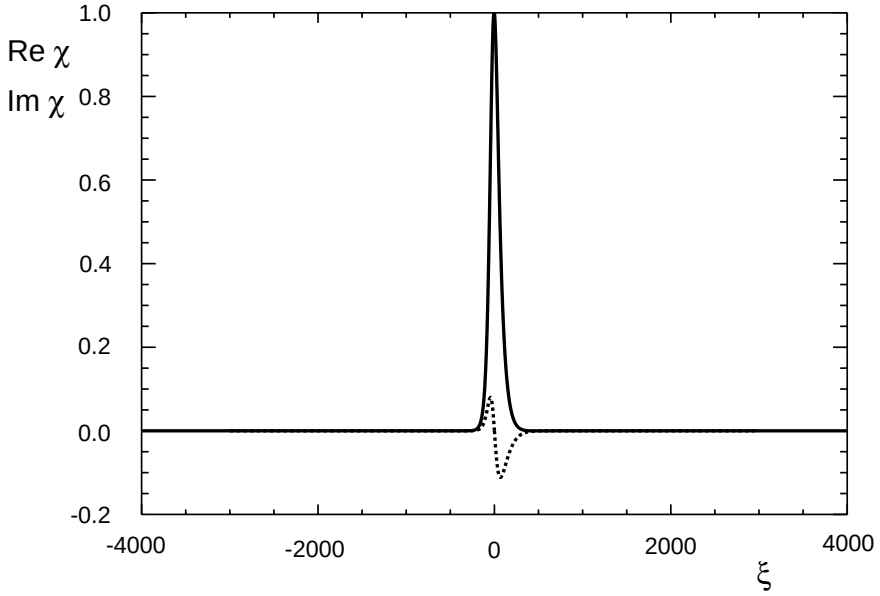

FIG. 8. *The eigenmode $\chi(\xi)$ of the system* (4.2)–(4.3) *for $\tau = 0.3$, $\beta = \beta_c = 9.7404$, and purely complex eigenvalue $\lambda = i\lambda_c$. The solid line corresponds to Re χ, and the dashed line denotes Im χ.*

governing PDE and corresponding ODE supports the credibility of both methods (the difference was found in the third significant digit). At the same time, we believe that the shooting and relaxation methods are preferable, as they require fewer computer resources, are more accurate, and do not depend on the stability of the solution.

The Evans function method was employed to examine the linear stability problem.

In this paper we consider only pulsating instabilities. Methods used in this paper are able to treat cellular instabilities as well (see [14]), and this is the subject of a separate paper. It was shown in section 7 that the conventional method for calculating the Evans function fails in our case. We demonstrated that the compound matrix method significantly expands the applicability of the Evans function approach. The results obtained with the compound matrix method were compared to the predictions of the asymptotic models. It appears that classic asymptotic models derived with truncated series are able to give only qualitative behavior for the front stability. We cannot expect the model derived in [4, 5] to give good quantitative results for $\tau \in [0, 0.6]$ considered in this paper, as it is valid for $\tau \simeq 1$. We would like to mention that it is very difficult to check the results of the asymptotic analysis for $\tau \to 1$ both numerically and experimentally, because the pulsating instability manifests itself only for extremely large values of β in this case. To the best of our knowledge β values of less than 30, considered in this paper while analyzing the stability of the travelling front, cover most of the combustion reactions. It turns out that the results obtained with the generalized matched asymptotic expansion method in [9] best correspond to the numerical data found in the present paper.

The compound matrix method not only allowed us to obtain a simple numerical criterion for the transition to instability for steady propagating solutions, but also provided us with more detailed information about the eigenvalues and eigenmodes. We located the eigenvalues, responsible for transition to instability, on the complex plane and found corresponding eigenmodes for the linear stability problem. This information can be useful, for example, in the analysis of the bifurcating solutions and their stability.

Finally, we would like to say a few words regarding the ambient temperature, which was taken to be equal to zero in this paper. The main disadvantage of this approach is the fact that the ambient temperature is a convenient control parameter used in experiments. This parameter is also ruled out in the asymptotic theories mentioned earlier. Therefore it is of clear interest to investigate the effect of this parameter on the stability of the combustion front. In the future we will be applying the methods described in this paper to models with finite ambient temperature and taking heat loss into consideration.

Acknowledgments. The authors thank S. J. A. Malham and K. Y. Kolossovski for helpful discussions, and the anonymous referees for their useful comments.

ANISOTROPIC POLARIZATION TENSORS AND DETECTION OF AN ANISOTROPIC INCLUSION*

HYEONBAE KANG†, EUNJOO KIM†, AND KYOUNGSUN KIM†

Abstract. We introduce the notion of (generalized) anisotropic polarization tensors and prove that they are symmetric and positive-definite. We also estimate the eigenvalues of the anisotropic polarization tensor in terms of the volume of the given domain. We apply these properties to an electrical impedance tomography problem to detect a single anisotropic inhomogeneity of small size. The goal is to detect an unknown inclusion when anisotropic conductivities of the background and the inclusion are known. Three results of computational experiments for the detection of an inclusion are given. One experiment is to assure the validity of the algorithm, while the other two are to see how anisotropy plays a role in the detection procedure.

Key words. anisotropic conductivity, anisotropic polarization tensor, asymptotic expansion, far-field, electrical impedance tomography

1. Introduction.

Let B be a bounded Lipschitz domain in $\mathbb{R}^d$, $d = 2, 3$. Suppose that the conductivity of B is different from that of background, $\mathbb{R}^d \setminus B$; the polarization tensor (PT) describes to the first order changes in the voltage potential due to the presence of the inhomogeneity B. For cases when the conductivities are isotropic, i.e., when they are independent of direction, the concept of PT was introduced by Schiffer and Szegö [18] and Pólya and Szegö [17]. If the conductivity is zero, namely, if B is insulated, the PT tensor is called the virtual mass. This concept of PT was extensively studied by many authors [17], [13], [8], [16], [6] for various purposes. In [6], Cedio-Fengya, Moskow, and Vogelius proved the symmetry and positive-definiteness of PT, and these properties became essential ingredients in recent development on the electrical impedance tomography (EIT) problem for detecting small inhomogeneities; see, for example, Cedio-Fengya, Moskow, and Vogelius [6], Brühl, Hanke, and Vogelius [5], and Ammari and Seo [4]. There are other works on locating inclusions from EIT data, such as [9], [10], [19]. The concept of PT was recently generalized by Ammari and Kang to the higher orders for the purpose of derivation of the complete asymptotic expansion of the voltage potential, and some of the important properties of PT were obtained [1], [2].

In this paper, we introduce the notion of (generalized) *anisotropic polarization tensor* (APT) and establish the symmetry and positive-definiteness of the first order tensor. We note that, in the anisotropic case, polarization occurs due to not only the presence of discontinuity, but also the difference of the anisotropy. These tensors are defined in the same way as the generalized isotropic polarization tensor in [1] and [2]. We also estimate the eigenvalues of the APT in terms of the volume of B.

We then apply these properties of APT to the EIT problem to detect an inhomogeneity inclusion with anisotropic conductivity. Let Ω be a bounded domain in

$\mathbb{R}^d$, $d = 2, 3$, with a connected Lipschitz boundary $\partial\Omega$. Suppose that Ω contains a single small inhomogeneity D of the form $D = z + \epsilon B$, where B is a bounded Lipschitz domain in $\mathbb{R}^d$ containing the origin, ϵ is small and approximately the order of magnitude of D, and z is a point in D. We assume that D is well separated from the boundary of Ω, namely, there exists a constant $c_0 > 0$ such that $\text{dist}(z, \partial\Omega) \geq c_0$. We also assume that the background $\Omega \setminus D$ has homogeneous anisotropic conductivity A, and D has homogeneous anisotropic conductivity $\tilde{A}$, where A and $\tilde{A}$ are constant $d \times d$ positive-definite symmetric matrices. Thus the conductivity profile of the body Ω is

$$\gamma(x) = \chi(\Omega \setminus D)A + \chi(D)\tilde{A}, \tag{1.1}$$

where $\chi(D)$ is the characteristic function of D. We also assume that $A - \tilde{A}$ is either positive- or negative-definite. (For this, see the remark immediately following the proof of Lemma 3.2.) The EIT problem we consider is to determine D from a finite number of pairs of applied current and measured voltage on $\partial\Omega$, when A and $\tilde{A}$ are known.

Let N be the unit normal to $\partial\Omega$. For a given $g \in L^2_0(\partial\Omega) := \{f \in L^2(\partial\Omega) : \int_{\partial\Omega} f d\sigma = 0\}$, let u_ϵ denote the steady-state voltage potential in the presence of the conductivity inhomogeneities, i.e., the solution to

$$\begin{cases} \nabla \cdot (\gamma(x)\nabla u(x)) = 0 & \text{in } \Omega, \\ \langle A\nabla u, N\rangle|_{\partial\Omega} = g & \left(\int_{\partial\Omega} u d\sigma = 0\right). \end{cases} \tag{1.2}$$

We first consider asymptotic expansion of u_ϵ as $\epsilon \to 0$ in terms of the background potential and APTs. The background potential U is the steady-state voltage potential in the absence of the conductivity inhomogeneities, i.e., the solution to

$$\begin{cases} \nabla \cdot (A\nabla U) = 0 & \text{in } \Omega, \\ \langle A\nabla U, N\rangle|_{\partial\Omega} = g & \left(\int_{\partial\Omega} U d\sigma = 0\right). \end{cases} \tag{1.3}$$

We follow the lines in [1] to derive the asymptotic formula of u_ϵ on $\partial\Omega$ (Theorem 4.1). Then using a simple formula found in [1] relating the Neumann function and the fundamental solution, we convert this asymptotic formula to that of a function determined by boundary measurements outside Ω to calculate the far-field relation (Theorem 4.3). We then use this relation to derive an algorithm for finding APT, the order of magnitude, and z. In this process, those properties of APT proved in earlier sections will play essential roles. This method is similar to the one proposed in [3] for detecting single isotropic inhomogeneity. We also present a different algorithm for finding the center z based on an idea of [15] and [4].

Using the algorithm, we perform three computational experiments. The first one is computational validation of the reconstruction formula with and without noise. The formula or algorithm of reconstruction is derived under the assumption that $\tilde{A} - A$ is either positive- or negative-definite. However, there are practical situations in which the conductivity is high in one direction and low in another. The second experiment is to see what happens if $\tilde{A} - A$ has eigenvalues of mixed signs. The results of this experiment show that, even in this case, algorithms find the inclusion fairly well. Unlike the isotropic case, there is difficulty in understanding what the

limiting case of extreme conductivity is. The purpose of the third experiment is to see what happens if the condition number of $\tilde{A} - A$ is very large. The result indicates that if the condition number of $\tilde{A} - A$ becomes large, so does the error of the reconstruction. During these experiments, we compare the performance of two algorithms. Theoretically, the first algorithm gives better precision of $O(\epsilon^d)$ in finding the center. However, computational results show that the second algorithm works better under the presence of noise in the data.

This paper is organized as follows. In section 2, we briefly review the layer potentials for the operator $\nabla \cdot A\nabla$. In section 3, APTs are defined, and symmetry, positive-definiteness, and estimation of eigenvalues are proved. In section 4, we derive reconstruction formulas for finding APT, the order of magnitude of the inclusion, and the center. Section 5 is for presentation of the computational experiments.

2. Layer potentials. Let D be a bounded domain in $\mathbb{R}^d, d = 2, 3$. We assume that ∂D is Lipschitz. Let A be a positive-definite symmetric matrix and A_* be the positive-definite symmetric matrix such that $A^{-1} = A_*^2$. Let $\Gamma(x)$ be the fundamental solution of the operator $\nabla \cdot A\nabla$:

$$\Gamma(x) = \begin{cases} \dfrac{1}{2\pi\sqrt{|A|}} \ln \|A_* x\|, & d = 2, \\ -\dfrac{1}{4\pi\sqrt{|A|}\|A_* x\|}, & d = 3, \end{cases} \tag{2.1}$$

where $|A|$ is the determinant of A. The single and double layer potentials associated with A of the density function ϕ on D are defined by

$$\mathcal{S}_D\phi(x) := \int_{\partial D} \Gamma(x - y)\phi(y)d\sigma(y), \quad x \in \mathbb{R}^d, \tag{2.2}$$

$$\mathcal{D}_D\phi(x) := \int_{\partial D} \frac{\partial}{\partial \nu_y}\Gamma(x - y)\phi(y)d\sigma(y), \quad x \in \mathbb{R}^d \setminus \partial D, \tag{2.3}$$

where $\frac{\partial u}{\partial \nu} := \langle AN, \nabla u\rangle$, and N is the outward unit normal to ∂D.

We now suppose that D is compactly contained in a bounded domain Ω. Suppose that the background conductor $\Omega \setminus D$ has anisotropic conductivity A, and D has $\tilde{A}$. We always suppose that $\tilde{A} - A$ is either positive-definite or negative-definite. $\tilde{\mathcal{S}}_D$ and $\mathcal{S}_D$ denote the single layer potentials on D corresponding to $\tilde{A}$ and A, respectively. We also denote $\frac{\partial u}{\partial \tilde{\nu}} := \langle \tilde{A}N, \nabla u\rangle$. The subscript $+$ in the notation $u|_+$ denotes the limit to the boundary from the outside of a given domain, and $-$ indicates the limit from the inside. The following result of Escauriaza and Seo [7] is an essential ingredient of the present paper.

THEOREM 2.1. *For each $(F, G) \in L_1^2(\partial D)\times L^2(\partial D)$, there exists a unique solution $(f, g) \in L^2(\partial D) \times L^2(\partial D)$ of the integral equation*

$$\begin{cases} \tilde{\mathcal{S}}_D f - \mathcal{S}_D g = F \\ \dfrac{\partial}{\partial \tilde{\nu}}\tilde{\mathcal{S}}_D f\Big|_- - \dfrac{\partial}{\partial \nu}\mathcal{S}_D g\Big|_+ = G \end{cases} \quad \text{on } \partial D. \tag{2.4}$$

Moreover, there exists a constant C depending on only the largest and smallest eigenvalues of $\tilde{A}$, A, and $\tilde{A} - A$, and the Lipschitz character of D such that

$$\|f\|_{L^2(\partial D)} + \|g\|_{L^2(\partial D)} \le C(\|F\|_{L_1^2(\partial D)} + \|G\|_{L^2(\partial D)}). \tag{2.5}$$

3. The APT. We will be using the usual notation for multiindices: for multiindex $\alpha = (\alpha_1, \dots, \alpha_d)$, $x^\alpha := x_1^{\alpha_1} \cdots x_d^{\alpha_d}$, $\partial^\alpha := \partial_1^{\alpha_1} \cdots \partial_d^{\alpha_d}$, etc.

As in [1], (generalized) APTs are defined as follows.

DEFINITION 3.1. *Let B be a bounded Lipschitz domain in $\mathbb{R}^d$, and $\tilde{A}$ and A be the anisotropic conductivities of B and $\mathbb{R}^d \setminus \overline{B}$, respectively. For a multiindex α, let $(f_\alpha, g_\alpha) \in L^2(\partial B) \times L^2(\partial B)$ be the unique solution of*

$$\begin{cases} \tilde{\mathcal{S}}_B f_\alpha - \mathcal{S}_B g_\alpha = x^\alpha \\ \dfrac{\partial}{\partial \tilde{\nu}} \tilde{\mathcal{S}}_B f_\alpha \Big|_- - \dfrac{\partial}{\partial \nu} \mathcal{S}_B g_\alpha \Big|_+ = \frac{\partial}{\partial \nu} x^\alpha \end{cases} \quad \text{on } \partial B. \tag{3.1}$$

For a pair of multiindices α, β, define the anisotropic polarization tensors *(APTs) associated with the domain B and anisotropic conductivities $\tilde{A}$ and A by*

$$m_{\alpha\beta} = \int_{\partial B} y^\beta g_\alpha(y) d\sigma. \tag{3.2}$$

The first order APT ($|\alpha| = |\beta| = 1$) is particularly important. In this section, we prove those properties of the first order APT which play significant roles in detection of an inhomogeneity inclusion, such as symmetry, positive-definiteness, and estimation of the eigenvalues. When $|\alpha| = |\beta| = 1$, denote $m_{\alpha\beta}$ by m_{ij}, $i, j = 1, \dots, d$, i.e.,

$$m_{ij} = \int_{\partial B} y_j g_i(y) d\sigma, \tag{3.3}$$

where $f_i = f_\alpha$ and $g_i = g_\alpha$ with $\alpha = e_i$. Here and throughout this section we drop the subscript B from the notation of single layer potentials. Define

$$\phi_i(x) := \begin{cases} \mathcal{S} g_i(x), & x \in \mathbb{R}^d \setminus B, \\ \tilde{\mathcal{S}} f_i(x), & x \in B. \end{cases}$$

Then ϕ_i is the unique solution of the following transmission problem:

$$\begin{cases} \nabla \cdot (A \nabla \phi_i) = 0 & \text{in } \mathbb{R}^d \setminus B, \\ \nabla \cdot (\tilde{A} \nabla \phi_i) = 0 & \text{in } B, \\ \phi_i|_- - \phi_i|_+ = x_i & \text{on } \partial B, \\ \dfrac{\partial \phi_i}{\partial \tilde{\nu}} \Big|_- - \dfrac{\partial \phi_i}{\partial \nu} \Big|_+ = \dfrac{\partial x_i}{\partial \nu} & \text{on } \partial B, \\ \phi_i(x) = O(|x|^{-d+1}) & \text{as } |x| \to \infty. \end{cases}$$

By the jump relation of the single layer potential, $g_i = \frac{\partial (\mathcal{S} g_i)}{\partial \nu}\big|_+ - \frac{\partial (\mathcal{S} g_i)}{\partial \nu}\big|_-$. Thus it

follows from (3.1) that

$$\begin{aligned}\int_{\partial B} y_j g_i d\sigma &= \int_{\partial B} y_j \left[\frac{\partial(\mathcal{S}g_i)}{\partial \nu}\Big|_+ - \frac{\partial(\mathcal{S}g_i)}{\partial \nu}\Big|_- \right] d\sigma \\ &= \int_{\partial B} y_j \left[\frac{\partial(\tilde{\mathcal{S}}f_i)}{\partial \tilde{\nu}}\Big|_- - \frac{\partial y_i}{\partial \nu} - \frac{\partial(\mathcal{S}g_i)}{\partial \nu}\Big|_- \right] d\sigma \\ &= \int_{\partial B} \left[\frac{\partial y_j}{\partial \tilde{\nu}} \tilde{\mathcal{S}} f_i - \frac{\partial y_j}{\partial \nu}\big(y_i + \mathcal{S}g_i\big) \right] d\sigma \\ &= \int_{\partial B} \left[\frac{\partial y_j}{\partial \tilde{\nu}} - \frac{\partial y_j}{\partial \nu} \right] \phi_i|_-(y) d\sigma.\end{aligned}$$

Therefore,

$$m_{ij} = \left\langle (\tilde{A} - A)e_j, \int_B \nabla \phi_i(y) dy \right\rangle, \tag{3.4}$$

or equivalently,

$$m_{ij} = \langle (\tilde{A} - A)e_j, e_i \rangle |B| + \int_{\partial B} \langle (\tilde{A} - A)N, e_j \rangle \phi_i|_+(y) d\sigma. \tag{3.5}$$

In particular, if $\tilde{A}$ and A are isotropic, say $\tilde{A} = \tilde{\mu} I$ and $A = \mu I$, then one can easily check that

$$m_{ij} = \left(1 - \frac{\mu}{\tilde{\mu}}\right) \left[\tilde{\mu} \delta_{ij} |B| + \tilde{\mu} \int_{\partial B} y_j \left. \frac{\partial \phi_i}{\partial \nu} \right|_+ \right],$$

which is the polarization tensor studied in [6].

Let $M = (m_{ij})$. Suppose that $d = 3$ for convenience. The two dimensional case can be treated in the same way without change. Let A_* be the unique positive-definite symmetric matrix such that $A^{-1} = A_*^2$. Then $A_* \tilde{A} A_*$ is also symmetric positive-definite. Let λ_j and v_j, $j = 1, 2, 3$, be eigenvalues and corresponding eigenvectors of $A_* \tilde{A} A_*$, respectively. Let $w_j = A_* v_j$, $j = 1, 2, 3$. Since $A_* \tilde{A} A_* v_j = \lambda_j v_j$, we have $\tilde{A} w_j = \lambda_j A w_j$. Therefore, we get

$$(\tilde{A} - A) w_j = (\lambda_j - 1) A w_j = \frac{\lambda_j - 1}{\lambda_j} \tilde{A} w_j. \tag{3.6}$$

Note that $\lambda_j > 1$ (< 1) if $\tilde{A} - A$ is positive (negative)-definite. Let $f_i^* := w_i \cdot (f_1, f_2, f_3)$ and $g_i^* := w_i \cdot (g_1, g_2, g_3)$, $i = 1, 2, 3$. Then (f_i^*, g_i^*) is the unique solution of

$$\begin{cases} \tilde{\mathcal{S}} f_i^*(x) - \mathcal{S} g_i^*(x) &= w_i \cdot x \\ \left. \dfrac{\partial}{\partial \tilde{\nu}} \tilde{\mathcal{S}} f_i^* \right|_-(x) - \left. \frac{\partial}{\partial \nu} \mathcal{S} g_i^* \right|_+(x) &= \dfrac{\partial}{\partial \nu}(w_i \cdot x) \end{cases} \quad \text{on } \partial B. \tag{3.7}$$

For a domain D and positive-definite symmetric matrix A, define a bilinear form

$$(f, g)_D^A := \int_D \langle A \nabla f, \nabla g \rangle dx,$$

and let Q_D^A denote the corresponding quadratic form.

LEMMA 3.2.

$$\int_{\partial B}(w_j\cdot y)g_i^*d\sigma=\int_{\partial B}(w_i\cdot y)g_j^*d\sigma,\quad i,j=1,2,3, \tag{3.8}$$

and

$$\begin{aligned}\frac{\lambda_j+1}{\lambda_j-1}\int_{\partial B}(w_j\cdot y)g_i^*d\sigma&=(\tilde{\mathcal{S}}f_j^*,\tilde{\mathcal{S}}f_i^*)_B^{\tilde{A}}+(\mathcal{S}g_j^*,\mathcal{S}g_i^*)_{\mathbb{R}^3\setminus B}^A\\&\quad+(w_j\cdot y,w_i\cdot y)_B^A-(\mathcal{S}g_j^*,w_i\cdot y)_B^A+(w_j\cdot y,\mathcal{S}g_i^*)_B^A.\end{aligned} \tag{3.9}$$

Proof. In the same way as before, we can show that

$$\int_{\partial B}(w_j\cdot y)g_i^*d\sigma=\int_{\partial B}\left[\frac{\partial(w_j\cdot y)}{\partial\tilde{\nu}}-\frac{\partial(w_j\cdot y)}{\partial\nu}\right]\tilde{\mathcal{S}}f_i^*d\sigma. \tag{3.10}$$

Note that, by (3.6),

$$\frac{\partial(w_j\cdot y)}{\partial\tilde{\nu}}-\frac{\partial(w_j\cdot y)}{\partial\nu}=\langle N,(\tilde{A}-A)w_j\rangle=\begin{cases}(\lambda_j-1)\dfrac{\partial(w_j\cdot y)}{\partial\nu},\\[2mm]\dfrac{\lambda_j-1}{\lambda_j}\dfrac{\partial(w_j\cdot y)}{\partial\tilde{\nu}}.\end{cases} \tag{3.11}$$

It then follows from (3.7) and the first relation in (3.11) that

$$\begin{aligned}\frac{1}{\lambda_j-1}\int_{\partial B}(w_j\cdot y)g_i^*d\sigma&=\int_{\partial B}\frac{\partial(w_j\cdot y)}{\partial\nu}\tilde{\mathcal{S}}f_i^*d\sigma\\&=\int_{\partial B}\frac{\partial(w_j\cdot y+\mathcal{S}g_j^*)}{\partial\nu}\bigg|_-(w_i\cdot y+\mathcal{S}g_i^*)d\sigma-\int_{\partial B}\frac{\partial\mathcal{S}g_j^*}{\partial\nu}\bigg|_-(w_i\cdot y+\mathcal{S}g_i^*)d\sigma\\&=\int_{\partial B}\frac{\partial(w_j\cdot y+\mathcal{S}g_j^*)}{\partial\nu}\bigg|_-(w_i\cdot y+\mathcal{S}g_i^*)d\sigma-\int_{\partial B}(\mathcal{S}g_j^*)\frac{\partial(w_i\cdot y+\mathcal{S}g_i^*)}{\partial\nu}\bigg|_-d\sigma.\end{aligned} \tag{3.12}$$

On the other hand, by (3.7) and the second relation in (3.11), we get

$$\begin{aligned}\frac{\lambda_j}{\lambda_j-1}\int_{\partial B}(w_j\cdot y)g_i^*d\sigma&=\int_{\partial B}\frac{\partial(w_j\cdot y)}{\partial\tilde{\nu}}\tilde{\mathcal{S}}f_i^*d\sigma=\int_{\partial B}(w_j\cdot y)\,\frac{\partial(\tilde{\mathcal{S}}f_i^*)}{\partial\tilde{\nu}}\bigg|_-d\sigma\\&=\int_{\partial B}\tilde{\mathcal{S}}f_j^*\,\frac{\partial(\tilde{\mathcal{S}}f_i^*)}{\partial\tilde{\nu}}\bigg|_--\int_{\partial B}\mathcal{S}g_j^*\,\frac{\partial\mathcal{S}g_i^*}{\partial\nu}\bigg|_+-\int_{\partial B}\mathcal{S}g_j^*\frac{\partial(w_i\cdot y)}{\partial\nu}.\end{aligned} \tag{3.13}$$

Subtracting (3.12) from (3.13), we get

$$\begin{aligned}\int_{\partial B}(w_j\cdot y)g_i^*d\sigma&=-\int_{\partial B}\frac{\partial(w_j\cdot y+\mathcal{S}g_j^*)}{\partial\nu}\bigg|_-(w_i\cdot y+\mathcal{S}g_i^*)\\&\quad+\int_{\partial B}\tilde{\mathcal{S}}f_j^*\,\frac{\partial(\tilde{\mathcal{S}}f_i^*)}{\partial\tilde{\nu}}\bigg|_--\int_{\partial B}\mathcal{S}g_j^*\left[\frac{\partial\mathcal{S}g_i^*}{\partial\nu}\bigg|_+-\frac{\partial\mathcal{S}g_i^*}{\partial\nu}\bigg|_-\right]\\&=-(w_j\cdot y+\mathcal{S}g_j^*,w_i\cdot y+\mathcal{S}g_i^*)_B^A+(\tilde{\mathcal{S}}f_j^*,\tilde{\mathcal{S}}f_i^*)_B^{\tilde{A}}-\int_{\partial B}\mathcal{S}g_j^*g_i^*d\sigma.\end{aligned}$$

Since $\int_B \mathcal{S}g_j^* g_i^* d\sigma = \int_B g_j^* \mathcal{S}g_i^* d\sigma$, we have (3.8).

To prove (3.9) we write (3.12) in slightly different way: By (3.7), we get

$$\frac{1}{\lambda_j - 1}\int_{\partial B}(w_j \cdot y) g_i^* d\sigma = \int_{\partial B}\frac{\partial (w_j \cdot y)}{\partial \nu}\mathcal{S}g_i^* d\sigma + \int_{\partial B}\frac{\partial (w_j \cdot y)}{\partial \nu}(w_i \cdot y) d\sigma. \tag{3.14}$$

Adding (3.13) with (3.14), we get (3.9). This completes the proof. □

Remark. Let $M := (m_{ij})$. If $\tilde{A} - A$ is positive- or negative-semidefinite, not definite, then some $\lambda_j = 1$. Suppose $\lambda_j = 1$. Then (3.10) and (3.6) show that

$$\langle w_i, M w_j\rangle = \int_{\partial B}(w_j \cdot y) g_i^* d\sigma = 0, \quad i = 1, 2, 3.$$

Since w_1, w_2, w_3 are linearly independent, $Mw_j = 0$. In particular, M is singular. This is the reason why we are assuming that $\tilde{A} - A$ is positive- or negative-definite.

THEOREM 3.3. *The anisotropic polarization tensor M is symmetric, and for each $a \neq 0 \in \mathbb{R}^d$ there exists $\bar{a} \in \mathbb{R}^d$ such that $\langle \bar{a}, Ma\rangle > 0$. In fact, if $a = \sum_i a_i^* w_i$, then*

$$\bar{a} = \sum_i \frac{\lambda_i + 1}{\lambda_i - 1} a_i^* w_i. \tag{3.15}$$

Proof. Let $a, b \in \mathbb{R}^3$, let $a = \sum_i a_i^* w_i$ and $b = \sum_i b_i^* w_i$. Then

$$\langle b, Ma\rangle = \int_{\partial B}(a \cdot y)(b \cdot g)(x) d\sigma = \sum_{i,j=1}^{d} a_j^* b_i^* \int_{\partial B}(w_j \cdot y)(w_i \cdot g)(y) d\sigma,$$

where $g = (g_1, g_2, g_3)$. Thus, by (3.8), we obtain

$$\begin{aligned}\langle b, Ma\rangle &= \sum_{i,j=1}^{d} a_j^* b_i^* \int_{\partial B}(w_j \cdot y)(w_i \cdot g)(y) d\sigma \\ &= \sum_{i,j=1}^{d} a_j^* b_i^* \int_{\partial B}(w_i \cdot y)(w_j \cdot g)(y) d\sigma \\ &= \int_{\partial B}(b \cdot y)(a \cdot g)(y) d\sigma = \langle a, Mb\rangle.\end{aligned}$$

For a given a, define $\bar{a}$ as (3.15). Then

$$\langle \bar{a}, Ma\rangle = \sum_{i,j=1}^{d} \frac{\lambda_j + 1}{\lambda_j - 1} a_i^* a_j^* \int_{\partial B}(w_j \cdot y)(w_i \cdot g)(y) d\sigma.$$

Let $f_a = \sum_i a_i^* f_i^* = a \cdot f$ and $g_a = \sum_i a_i^* g_i^* = a \cdot g$. It then follows from (3.9) that

$$\begin{aligned}\langle \bar{a}, Ma\rangle &= (\tilde{\mathcal{S}} f_a, \tilde{\mathcal{S}} f_a)_B^{\tilde{A}} + (\mathcal{S} g_a, \mathcal{S} g_a)_{\mathbb{R}^3 \setminus B}^{A} \\ &\quad + (a \cdot y, a \cdot y)_B^A - (\mathcal{S} g_a, a \cdot y)_B^A + (a \cdot y, \mathcal{S} g_a)_B^A \\ &= Q_B^{\tilde{A}}(\tilde{\mathcal{S}} f_a) + Q_{\mathbb{R}^d \setminus B}^{A}(\mathcal{S} g_a) + \langle a, Aa\rangle |B|.\end{aligned} \tag{3.16}$$

Thus the proof is complete. □

Without loss of generality, let us suppose that $\tilde{A} - A$ is positive-definite so that $\lambda_j > 1$, $j = 1, 2, 3$. One can immediately observe from (3.16) that

$$C_1 \|a\|^2 |B| \leq \langle \bar{a}, Ma \rangle \tag{3.17}$$

for some constant C_1 depending only on A.

Fix a point $z \in B$. Since $\int_{\partial B} g_i(y) d\sigma = 0$, we get from the definition of APT that

$$\begin{aligned} |m_{ij}| &\leq \left(\int_{\partial B} (y_j - z_j)^2 d\sigma \right)^{1/2} \left(\int_{\partial B} |g_i(y)|^2 d\sigma \right)^{1/2} \\ &\leq \operatorname{diam}(B) |\partial B|^{1/2} \|g_i\|_{L^2(\partial B)}. \end{aligned}$$

It then follows from (2.5) that

$$|m_{ij}| \leq C \operatorname{diam}(B) |\partial B| \leq C|B|,$$

where the dependence of the constant C is the same as that in Theorem 2.1. Thus we obtain

$$\langle \bar{a}, Ma \rangle \leq C|B| \|a\| \|\bar{a}\| \leq C_2 |B| \|a\|^2$$

for some C_2. Therefore we get

$$C_1 \|a\|^2 |B| \leq \langle \bar{a}, Ma \rangle \leq C_2 \|a\|^2 |B|. \tag{3.18}$$

Define constant matrices W and Λ by

$$W := [w_1, w_2, w_3]^T \quad \text{and} \quad \Lambda := \operatorname{diag}[\mu_1, \mu_2, \mu_3], \quad \mu_j := \frac{\lambda_j + 1}{\lambda_j - 1}. \tag{3.19}$$

We also define

$$V := [v_1, v_2, v_3]^T. \tag{3.20}$$

Note that W is nonsingular, $W = A_* V$, and W and Λ are determined by A and $\tilde{A}$. One can easily check that $\bar{a}$ defined by (3.15) can be written as

$$\bar{a} = W^{-1} \Lambda W a. \tag{3.21}$$

Thus (3.18) reads

$$C_1 |B| \|a\|^2 \leq \langle W^{-1} \Lambda W a, Ma \rangle \leq C_2 |B| \|a\|^2.$$

Let $b = Wa$. Then we have

$$C_1 |B| \|b\|^2 \leq \langle W^{-1} \Lambda b, M W^{-1} b \rangle = \langle \Lambda b, (W^{-1})^T M W^{-1} b \rangle \leq C_2 |B| \|b\|^2. \tag{3.22}$$

Here constants C_1 and C_2 are different from previous ones. However, their dependence is the same. Let v be an eigenvector of the symmetric matrix $(W^{-1})^T M W^{-1}$ and μ be the corresponding eigenvalue. Then $\mu > 0$ and

$$\langle \Lambda v, (W^{-1})^T M W^{-1} v \rangle = \langle \Lambda v, \mu v \rangle = \mu \|\Lambda^{1/2} v\|^2.$$

It then follows from (3.22) that

$$C_1|B|\|v\|^2 \le \mu\|\Lambda^{1/2}v\|^2 \le C_2|B|\|v\|^2,$$

and hence

$$C_1|B| \le \mu \le C_2|B|. \tag{3.23}$$

Therefore, $(W^{-1})^T M W^{-1}$ is positive-definite and

$$C_1|B|\|b\|^2 \le \langle b, (W^{-1})^T M W^{-1} b\rangle \le C_2|B|\|b\|^2 \quad \forall b \in \mathbb{R}^d.$$

Hence, by letting $a = W^{-1}b$, we get

$$C_1|B|\|a\|^2 \le \langle a, Ma\rangle \le C_2|B|\|a\|^2 \quad \forall a \in \mathbb{R}^d.$$

As a consequence, we obtain the following estimation of the eigenvalues of M.

THEOREM 3.4. *If $\tilde{A} - A$ is positive(negative)-definite, so is M. If μ is an eigenvalue of M, then*

$$C_1|B| \le |\mu| \le C_2|B| \tag{3.24}$$

for some constants C_1 and C_2, whose dependence is the same as that in Theorem 2.1.

4. Detection of an inclusion. Recall that $D = z + \epsilon B$. Let $N(x,y)$, $x \in \partial\Omega$, $y \in \Omega$, be the Neumann function for $\nabla \cdot A\nabla$ on Ω, and $m_{\alpha\beta}$ the APTs. Following the same lines of derivation used in [1], one can prove the following asymptotic expansion of the solution u_ϵ to (1.2) on $\partial\Omega$.

THEOREM 4.1. *For $x \in \partial\Omega$,*

$$u_\epsilon(x) = U(x) - \epsilon^d \sum_{|\alpha|=1}^{d} \sum_{|\beta|=1}^{d-|\alpha|+1} \frac{\epsilon^{|\alpha|+|\beta|-2}}{\alpha!\beta!} \partial^\alpha U(z) m_{\alpha\beta} \partial_z^\beta N(x,z) + O(\epsilon^{2d}), \tag{4.1}$$

where the remainder $O(\epsilon^{2d})$ is dominated by $C\epsilon^{2d}$ for some C independent of $x \in \partial\Omega$ and z.

In fact, as in [1], one can represent the solution u_ϵ in terms of layer potentials and the Neumann functions, and then obtain the expansion (4.1). We note that if there are well-separated multiple inclusions, then an asymptotic formula can be obtained by adding formula (4.1).

We now define a function $H[g]$ for $g \in L_0^2(\partial\Omega)$ by

$$H[g](x) = -\mathcal{S}_\Omega(g)(x) + \mathcal{D}_\Omega(u_\epsilon|_{\partial\Omega})(x), \quad x \in \mathbb{R}^d \setminus \overline{\Omega}. \tag{4.2}$$

Substituting (4.1) into (4.2), one can see that

$$H[g](x) = -\mathcal{S}_\Omega(g)(x) + \mathcal{D}_\Omega(U|_{\partial\Omega})(x) - \epsilon^d \sum_{|\alpha|=1}^{d} \sum_{|\beta|=1}^{d-|\alpha|+1} \frac{\epsilon^{|\alpha|+|\beta|-2}}{\alpha!\beta!} \partial^\alpha U(z) m_{\alpha\beta} \partial_z^\beta \mathcal{D}_\Omega(N(\cdot,z))(x) + O\left(\frac{\epsilon^{2d}}{|x|^{d-1}}\right).$$

We then observe two simple but important facts. First, observe that $-\mathcal{S}_\Omega(g)(x) + \mathcal{D}_\Omega(U|_{\partial\Omega})(x) = 0$ if $x \in \mathbb{R}^d \setminus \overline{\Omega}$. Second, in the same way as that used for the proof of Lemma 2.3 of [1], we can show that

$$\mathcal{D}_\Omega(N(\cdot,z))|_+(x) = \Gamma(x-z) \quad \text{modulo constants} \quad \forall x \in \partial\Omega,\ \forall z \in \Omega. \tag{4.3}$$

Thus we obtain the following asymptotic expansion of $H[g]$ outside Ω.

THEOREM 4.2. *For $x \in \mathbb{R}^d \setminus \overline{\Omega}$,*

$$H[g](x) = -\epsilon^d \sum_{|\alpha|=1}^{d} \sum_{|\beta|=1}^{d-|\alpha|+1} \frac{\epsilon^{|\alpha|+|\beta|-2}}{\alpha!\beta!} \partial^\alpha U(z) m_{\alpha\beta} \partial_z^\beta \Gamma(x,z) + O\left(\frac{\epsilon^{2d}}{|x|^{d-1}}\right). \tag{4.4}$$

Suppose now that $g = \langle AN, a\rangle$ for a constant vector $a \in \mathbb{R}^d$. Then $U(x) = a \cdot x$ and the formula (4.4) takes the form

$$H[g](x) = -\epsilon^d \sum_{|\alpha|=1} \sum_{|\beta|=1}^{d} \frac{\epsilon^{|\beta|-1}}{\beta!} \partial^\alpha U(z) m_{\alpha\beta} \partial_z^\beta \Gamma(x,z) + O\left(\frac{\epsilon^{2d}}{|x|^{d-1}}\right). \tag{4.5}$$

Then by explicitly computing $\partial_z^\beta \Gamma(x,z)$, one can show that

$$H[g](x) = \frac{1}{\omega_d} \left\langle a, \epsilon^d M A_* \frac{A_*(x-z)}{|A_*(x-z)|^d} \right\rangle + O\left(\frac{\epsilon^d}{|x|^d}\right) + O\left(\frac{\epsilon^{2d}}{|x|^{d-1}}\right), \tag{4.6}$$

where $\omega_d = 2\pi$ if $d = 2$, and $\omega_d = 4\pi$ if $d = 3$, and $M = (m_{ij})$ is the first order APT.

For a general Neumann datum g, we have

$$H[g](x) = \frac{1}{\omega_d} \left\langle \nabla U(z), \epsilon^d M A_* \frac{A_*(x-z)}{|A_*(x-z)|^d} \right\rangle + O\left(\frac{\epsilon^d}{|x|^d}\right) + O\left(\frac{\epsilon^{d+1}}{|x|^{d-1}}\right). \tag{4.7}$$

Since $\frac{A_*(x-z)}{|A_*(x-z)|^d} = \frac{A_* x}{|A_* x|^d} + O(|x|^{-d})$, we obtain from (4.6) and (4.7) the following far-field relations.

THEOREM 4.3. *For $g \in L_0^2(\partial\Omega)$, let U_g be the solution of* (1.3). *Then, for $|x| = O(\epsilon^{-1})$,*

$$\omega_d |A_* x|^{d-1} H[g](x) = \left\langle \nabla U_g(z), \epsilon^d M A_* \frac{A_* x}{|A_* x|} \right\rangle \quad \textit{modulo } O(\epsilon^{d+1}). \tag{4.8}$$

If $g = \langle AN, a\rangle$, then for $|x| = O(\epsilon^{-d})$

$$\omega_d |A_* x|^{d-1} H[g](x) = \left\langle a, \epsilon^d M A_* \frac{A_* x}{|A_* x|} \right\rangle \quad \textit{modulo } O(\epsilon^{2d}). \tag{4.9}$$

We note that (4.8) is a general far-field relation, while (4.9) is a formula with better precision.

Using (4.6), (4.8), and (4.9), we can detect APT, the order of magnitude of D, and z.

Detection of APT. Now let $a = e_i$, or equivalently, $g = \langle AN, e_i\rangle$, and choose $b_j = O(\epsilon^{-d})$ so that

$$A_* \frac{A_* b_j}{|A_* b_j|} = e_j, \quad i, j = 1, \dots, d. \tag{4.10}$$

It then follows from (4.9) that

$$\epsilon^d m_{ij} = \omega_d |A_* b_j|^{d-1} H[g](b_j) \quad \text{modulo } O(\epsilon^{2d}). \tag{4.11}$$

Since ϵ is not known a priori, in actual computations we find unit vectors b_j satisfying (4.10) and then compute $\omega_d |t A_* b_j|^{d-1} H[g](t b_j)$ as $t \to \infty$. Since the first order APT is invariant under translation, as one can easily check, $\epsilon^d M$ is the first order APT for the domain D.

Detection of order of magnitude. Having found $\epsilon^d M$, we proceed to find the order of magnitude ϵ and the center z. Using (3.24), we can determine the order of magnitude of D. Let μ be the smallest (in absolute value) eigenvalue of $\epsilon^d M$. Then, by Theorem 3.4, $\epsilon^d|B| \approx |\mu|$. Considering the ambiguity of representation of $D = z + \epsilon B$, $\epsilon^d|B|$ or $\epsilon|B|^{1/d}$ seems the right notion of the order of magnitude.

Detection of center—Method 1. Let v_j, $j = 1, \dots, d$, be orthonormal eigenvectors of the symmetric matrix $A_*(\epsilon^d M)A_*$ with the corresponding eigenvalue λ_j, and $a_j := A_* v_j$ and $g_j := \langle AN, a_j \rangle$. Let $x(t) := ta_j + O(\epsilon^{-1})a_j^\perp$, where $a_j^\perp$ is a vector perpendicular to a_j. Then $|x(t)| = O(\epsilon^{-1})$, and hence, by (4.6), we get

$$H[g_j](x(t)) = \frac{\lambda_j}{\omega_d} \frac{|a_j|^2 t - a_j \cdot z}{|A_*(x(t) - z)|^d} \quad \text{modulo } O(\epsilon^{2d}). \tag{4.12}$$

Find the unique zero, call it t_j, of $H[g_j](x(t))$ as a function of t for $j = 1, \dots, d$. Let $\bar{z} = t_1 a_1 + \cdots + t_d a_d$. This $\bar{z}$ is the center. In fact, by the same argument as in [4], we can prove that

$$|\bar{z} - z| = O(\epsilon^d).$$

Detection of center—Method 2. Let b_j, $j = 1, \dots, d$, be the unit vector defined by (4.10). Then, from (4.8), we get

$$\omega_d |tA_* b_j|^{d-1} H[g](tb_j) = \langle \nabla U_g(z), \epsilon^d M e_j \rangle \quad \text{modulo } O(\epsilon^{d+1}). \tag{4.13}$$

Let $g = \frac{\partial U}{\partial \nu}$, where U is a second order homogeneous harmonic polynomial. By computing $\omega_d |tA_* b_j|^{d-1} H[g](tb_j)$ as $t \to \infty$, we recover $\langle \nabla U(z), \epsilon^d M e_j \rangle$, $j = 1, \dots, d$. From this we now recover $\nabla U_g(z)$, and hence the center z modulo $O(\epsilon^1)$.

The precision of this method is $O(\epsilon^1)$, which is worse than Method 1. However, numerical experiments in the next section show that this method performs better when there is noise in the data.

5. Computational experiments. This section presents results of numerical experiments of finding the inhomogeneity, $D \subset \Omega \subset \mathbb{R}^2$. In the following, Ω is assumed to be the disk centered at $(0, 0)$, with radius $r = 2$ and the background conductivity $A = I$. We also assume that $D = z + \epsilon B$, where B is the unit disk centered at $(0, 0)$. We note that in the anisotropic case, D being a disk does not provide a special advantage. Moreover, in the process of solving the inverse problem, we don't use any a priori knowledge of D being a disk.

Direct problem. Let u be the solution of (1.2). In order to collect the data $u|_{\partial\Omega}$, we solve the direct problem (1.2) as follows: In the same way as in [12], it can be proved that u is represented by

$$u(x) = \begin{cases} \mathcal{D}_\Omega u(x) - \mathcal{S}_\Omega g(x) + \mathcal{S}_D \phi(x) & \text{in } \Omega \setminus D, \\ \tilde{\mathcal{S}}_D \psi(x) & \text{in } D, \end{cases}$$

where $u|_{\partial\Omega}$, ϕ, and ψ satisfy the following relations:

$$\begin{aligned} & u = \mathcal{D}_\Omega u\big|_- - \mathcal{S}_\Omega g\big|_- + \mathcal{S}_D \phi \qquad \text{on } \partial\Omega, \\ & \mathcal{D}_\Omega u - \mathcal{S}_\Omega g + \mathcal{S}_D \phi\big|_+ = \tilde{\mathcal{S}}_D \varphi\big|_- \qquad \text{on } \partial D, \\ & \frac{\partial}{\partial \nu} \mathcal{D}_\Omega u - \frac{\partial}{\partial \nu} \mathcal{S}_\Omega g + \frac{\partial}{\partial \nu} \mathcal{S}_D \phi \Big|_+ = \frac{\partial}{\partial \tilde{\nu}} \tilde{\mathcal{S}}_D \varphi \Big|_- \qquad \text{on } \partial D. \end{aligned}$$

We solve this integral equation using the collocation method (see [14]) and obtain $u|_{\partial\Omega}$ on $\partial\Omega$ for given data g. We also add some noise to the computed data. Adding $p\%$ noise means that we have

$$u(1 + p \cdot \mathrm{rand}(1))$$

as the measured Dirichlet data. Here rand(1) is the random number in $(-1, 1)$.

Reconstruction Algorithm 1.

Step 1. Obtain Dirichlet data u on $\partial\Omega$ for given Neumann data $g_j = \langle N, e_j \rangle$, $j = 1, 2$.

Step 2. For $i, j = 1, 2$, calculate $\lim_{t\to\infty} \omega_2 t H[g_i](te_j)$ to obtain the matrix $\epsilon^2 M$.

Step 3. Find orthonormal eigenvectors v_1, v_2 and corresponding eigenvalues μ_1, μ_2 of $\epsilon^2 M$. Let μ be the minimum of μ_1, μ_2. The order of magnitude of D is $\epsilon = \sqrt{\mu |B|^{-1}}$.

Step 4. Let $g_j' = \langle N, v_j \rangle$ and $x_j(t) = tv_j + \frac{1}{\epsilon} v_j^{\perp}$, $j = 1, 2$. Find the zero, say t_j, of $H[g_j'](x_j(t)) = v_j \cdot e_1 H[g_1](x_j(t)) + v_j \cdot e_2 H[g_2](x_j(t))$ as a function of t. We obtain the center $\bar{z} = t_1 v_1 + t_2 v_2$.

Reconstruction Algorithm 2. Step 4 in the above algorithm is replaced with

Step 4′. For $g = \frac{\partial(x_1 x_2)}{\partial\nu}$, compute $h_j = \lim_{t\to\infty} \omega_2 t H[g](te_j)$, $j = 1, 2$. Then

$$(z_1, z_2) = (h_1, h_2) \begin{pmatrix} \epsilon^2 m_{12} & \epsilon^2 m_{22} \\ \epsilon^2 m_{11} & \epsilon^2 m_{12} \end{pmatrix}^{-1}.$$

We add the same amount of random noise in this step as well.

We now present the results of computational experiments. The first experiment is when $\tilde{A} - A$ is positive-definite; the second one is when $\tilde{A} - A$ is *not* positive-definite; the third one is to investigate the role of the condition number of $\tilde{A} - A$ in the reconstruction process.

Numerical table for Figure 2. *See explanations for Table* 1.

z	r	noise(%)	$\bar{r}$	$\bar{z_1}$ / $\bar{z_2}$	$\lvert z-\bar{z_1}\rvert$ / $\lvert z-\bar{z_2}\rvert$
$(0,1)$	0.2	0	0.1557	$(-0.0000, 0.9999)$	1.2316e-004
				$(-0.0000, 0.9998)$	1.6690e-004
		2	0.1417	$(-0.1421, 1.1468)$	0.2043
				$(0.0288, 1.0771)$	0.0823
		5	0.1689	$(-0.3499, 1.1841)$	0.3954
				$(0.1036, 0.7906)$	0.2336

Experiment 1. Let $\tilde{A} = \left(\begin{smallmatrix} 10 & 2 \\ 2 & 5 \end{smallmatrix}\right)$ and the actual inhomogeneity $D = (-1,-1) + 0.2B$. Note that $\tilde{A} - A$ is positive-definite. Figure 1 shows the results when there are 0%, 2%, and 5% random noise. Figure 2 is the result when $\tilde{A} = \left(\begin{smallmatrix} 10 & 1 \\ 1 & 2 \end{smallmatrix}\right)$ and $D = (0,1) + 0.2B$.

These results show that both Algorithms 1 and 2 detect the order of magnitude of the inclusion fairly well even with the presence of noise. However, Algorithm 2 performs better than Algorithm 1 in detecting the center when there is noise. A probable cause for this is that the zeros of functions in (4.12), which is already small, are sensitive to the noise.

Figure 3 shows that the location of the unknown inclusions does not affect the performance of the algorithms as long as they are away from $\partial\Omega$.

Experiment 2. This experiment is designed to determine whether the algorithms work in the case when $\tilde{A} - A$ is neither positive- nor negative-definite. Let $\tilde{A} = \left(\begin{smallmatrix} 2 & 0 \\ 2 & 1/2 \end{smallmatrix}\right)$ and $D = (1,0) + 0.2B$. Figure 4 shows the result. The algorithms seem to be working equally well for this case. It would be interesting to prove that the reconstruction formulas in this paper hold even when $\tilde{A} - A$ is neither positive- nor negative-definite. In this example as well, Algorithm 2 performs better in detection of the center.

Experiment 3. This experiment is designed to determine how the condition number of $\tilde{A} - A$ affects the precision of the algorithm. Suppose $A = I$. We first take $\tilde{A} = \left(\begin{smallmatrix} \lambda & 0 \\ 0 & 2 \end{smallmatrix}\right)$ and observe how the relative error $\frac{|z-\bar{z}|}{\epsilon^2}$ changes as λ increases. We then take $\tilde{A} = \left(\begin{smallmatrix} \lambda+1 & 0 \\ 0 & \lambda \end{smallmatrix}\right)$ and make the same observations. Figure 5 compares changes of relative errors of these two cases when $\lambda = 10, 10^2, 10^4, 10^5, 10^6$. It exhibits a clear difference: In the first case, when the condition number of $\tilde{A} - A$ increases as λ increases, the relative error is increasing, while in the second case, when the condition number does not change, the error is stabilized. The second case is somewhat similar to the isotropic case, and this kind of result is expected (see [11] or [2]). It is known

that long and thin inclusions, or cracklike inclusions (inclusions of high Lipschitz character) are hard to detect; see, for example, [4]. This experiment suggests that in addition to these geometric obstructions, in the anisotropic case there is another obstruction of high condition number of $\tilde{A}-A$.

Conclusion. Numerical results show that the second reconstruction algorithm performs better in the presence of noise. They also show that the reconstruction procedure works well even when $A-\tilde{A}$ is neither positive- nor negative-definite, and that the error of reconstruction increases as the condition number of $A-\tilde{A}$ increases. It would be interesting to investigate these points in a mathematically rigorous way.

THE NO RESPONSE TEST—A SAMPLING METHOD FOR INVERSE SCATTERING PROBLEMS*

D. RUSSELL LUKE† AND ROLAND POTTHAST‡

Abstract. We describe a novel technique, which we call the no response test, to locate the support of a scatterer from knowledge of a far field pattern of a scattered acoustic wave. The method uses a set of sampling surfaces and a special test response to detect the support of a scatterer without a priori knowledge of the physical properties of the scatterer. Specifically, the method does not depend on information about whether the scatterer is penetrable or impenetrable nor does it depend on any knowledge of the nature of the scatterer (absorbing, reflecting, etc.). In contrast to previous sampling algorithms, the techniques described here enable one to locate obstacles or inhomogeneities from the far field pattern of only one incident field—the no response test is a one-wave method. We investigate the theoretical basis for the no response test and derive a one-wave uniqueness proof for a region containing the scatterer. We show how to find the object within this region. We demonstrate the applicability of the method by reconstructing sound-soft, sound-hard, impedance, and inhomogeneous medium scatterers in two dimensions from one wave with full and limited aperture far-field data.

1. Introduction.

Inverse scattering is concerned with recovering information about a medium and its embedded objects by exciting or illuminating the medium with acoustic or electromagnetic fields and measuring the resulting field. One of the fundamental problems is to determine the location and shape of scatterers that are either buried or located in some inaccessible region of a medium. Applications range from geoscience to medical imaging.

Over the past decade, several innovative and successful methods have been introduced into the area of inverse scattering. Here, we add to the list a methodology that we call the *no response test* and demonstrate its applicability. The idea of the method is to test the hypothesis that a scatterer lies within a given test domain given the far field data. We sample by construction the set of incident fields that are small on the test domain and large outside. The far field patterns corresponding to these incident fields are then calculated using the given far field data. We call the calculated far field patterns *responses*. If all the responses are small, then the unknown scatterer is shown to be a subset of the test domain, that is, the hypothesis is true. The unknown scatterer is located within the union of all test domains for which the hypothesis is true. Since small, rather than large, responses indicate the location of the scatterer, the methodology is called the "no response" method.

To place this methodology relative to other reconstruction techniques, we give a brief review of the different reconstruction approaches. The evolutionary tree of inverse scattering algorithms is diverse enough that some taxonomy is in order. We

separate reconstruction algorithms into three classes: *iterative*, *decomposition*, and *sampling/probe* methods.

Category	Methods
I	Iterative techniques
	Newton method Landweber scheme Least squares fits (depending on the setup) Conjugate gradient method
II	Decomposition techniques
	Colton–Monk method / dual space method Kirsch–Kress method Potthast / point source method
III	Probe and sampling techniques
	Colton–Kirsch method / linear sampling method Kirsch / factorization method Potthast / singular sources method Ikehata / probe method Ikehata / enclosure method Luke–Potthast / no response test

Iterative methods (category I in [16]) use the model of the full forward problem, or an appropriate approximation thereof, for the solution of the inverse problem. These techniques have the advantage that they use all information about the forward problem for the solution of the inverse problem, and they usually deliver quite good reconstructions. However, due to the need to solve the forward problem many times, they can be computationally intensive. Also, obtaining a localized reconstruction in a limited data setting is problematic since full data for solving the forward problem is presumed. Indeed, at the very least it is presumed that one knows *which* model the data should satisfy. Well-known examples of iterative techniques are the *Newton method*, the *Landweber method*, and various versions of *least squares fits*.

Decomposition algorithms (category II in [16]) consist of methods that split the inverse problem into an ill-posed part to reconstruct the scattered field and a well-posed part to find the unknown scatterer due to some boundary condition. Representatives of this type of method are the *dual space method* proposed by Colton and Monk [3, 4] and the technique of Kirsch and Kress [2], but also newer strategies like the *point source method* of Potthast [14, 15, 16], which turns out to be a type of adjoint method to the Kirsch–Kress technique.

Sampling and probe methods comprise the third and most recent class of algorithms (category III in [16]). These involve testing a given region with a model mapping the data to a point in the test region and locating the boundary of the unknown scatterer as the points where some unusual or characteristic behavior (usually some resolvable type of blow-up) occurs in the model functions. Where these techniques differ is in the construction of the model functions, which leads to fundamentally different algorithms. These methods share the advantage that they can be applied without knowing whether the scatterer is an impenetrable (sound-soft or sound-hard) or an inhomogeneous medium. The no response test belongs to this class. We discuss in more detail the different strategies within this class that have been proposed since 1995.

A scatterer is denoted by its support $\Omega \subset \mathbb{R}^m$ ($m = 2$ or 3) where Ω is bounded. For our purposes we need only assume that the boundary of the scatterer $\partial\Omega$ is Lipschitz; however, this introduces mathematical technicalities that cloud the central

ideas here. We therefore limit our discussion to twice continuously differentiable (C^2) boundaries. Readers interested in the details of boundaries with corners, or more generally Lipschitz boundaries, are referred to [11, 12]. We denote by $\nu(x_0)$ the *unit outward normal* to Ω at the point $x_0 \in \partial\Omega$, that is, $|\nu(x_0)| = 1$ and the vector product $(y - x_0, \nu(x_0)) \leq 0$ for every $y \in \overline{\Omega}$.

Let $u, u^s : \mathbb{R}^m \to \mathbb{C}$ and $u^\infty : \mathbb{S} \to \mathbb{C}$ denote the *total*, *scattered*, and *far* fields, respectively, due to excitation from an *incident plane wave* u^i at a fixed wavenumber $\kappa > 0$. Here $\mathbb{S} := \{x \in \mathbb{R}^m \mid |x| = 1\}$. We parameterize these fields by the *direction of incidence* $\hat{y}$ of the incident plane wave $u^i(x, \hat{y}) := e^{i\kappa x \cdot \hat{y}}$, $x \in \mathbb{R}^m$, $\hat{y} \in \mathbb{S}$, where $i = \sqrt{-1}$ in the exponential. Similarly we write the dependence on the direction of incidence explicitly in the argument of the other fields as $u(x, \hat{y})$, $u^s(x, \hat{y})$, and $u^\infty(\hat{x}, \hat{y})$, respectively. Here and elsewhere, the hat indicates a unit vector, $\hat{x} := \frac{x}{|x|}$. When the far field data is known only on an open subset Γ of $\mathbb{S}$, we call the data *limited aperture* data.

Method	Amount of far field data needed	Assumptions on the physical nature of the scatterer
Colton–Kirsch / linear sampling method	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x}, \hat{y} \in \Gamma \subset \mathbb{S}$	none
Kirsch / factorization method	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x}, \hat{y} \in \mathbb{S}$	none
Potthast / singular sources method	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x}, \hat{y} \in \Gamma \subset \mathbb{S}$	none
Ikehata / probe method	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x}, \hat{y} \in \mathbb{S}$	none
Ikehata / enclosure method	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x} \in \mathbb{S}$ one $\hat{y} \in \mathbb{S}$	none
Luke–Potthast / no response test	$u^\infty(\hat{x}, \hat{y})$ $\forall \hat{x} \in \Gamma \subset \mathbb{S}$ one $\hat{y} \in \mathbb{S}$	none

The *linear sampling method* of Colton and Kirsch [1] characterizes the domain of an unknown scatterer by the behavior of the solution to the integral equation of the first kind:

$$\int_{\mathbb{S}} u^\infty(\hat{x}, \hat{y}) g(\hat{y}) ds(\hat{y}) = e^{i\kappa \hat{x} \cdot z}, \qquad \hat{x} \in \mathbb{S}. \tag{1.1}$$

Here a regularized solution g is calculated for all points z on a sampling grid $\mathcal{G}$. The unknown boundary is found where $||g(z)||$ becomes unbounded.

Kirsch [10] proposed a modified version of this method by constructing a spectral decomposition of the operator

$$(Fg)(\hat{x}) := \int_{\mathbb{S}} u^\infty(\hat{x}, \hat{y}) g(\hat{y}) ds(\hat{y}), \qquad \hat{x} \in \mathbb{S},$$

used in (1.1). He proposed to solve the equation

$$(F^* F)^{1/4} g(\hat{x}) = e^{i\kappa \hat{x} \cdot z}, \qquad \hat{x} \in \mathbb{S},$$

for all $z \in \mathcal{G}$ and showed that the equation is solvable if and only if z is in the interior of the unknown scatterer. This technique of Kirsch is known as the *modified linear sampling* or *factorization method*.

Ikehata and Potthast have independently proposed two related algorithms, the *probe method* [6] and the *method of singular sources* [16], respectively. These techniques are distinct from the (modified) linear sampling methods above in that they use different quantities that blow up when approaching the boundary of some scatterer.

The probe method of Ikehata uses Green's formula to define an indicator function that blows up when the virtual source touches the unknown obstacle. Let Λ be the Dirichlet-to-Neumann map for the boundary value problem in a domain B with the unknown domain $\Omega \subset B$ and Λ_0 be the Dirichlet-to-Neumann map for B without the existence of Ω. Ikehata proposed considering

$$I(z,f) := \int_{\partial B} \overline{(\Lambda - \Lambda_0)f} \cdot f ds$$

for specially constructed functions f. It can be shown that $I(z,f)$ tends to infinity if z tends to the boundary of the unknown domain. The Dirichlet-to-Neumann map can be calculated from the far field patterns $u^\infty(\hat{x},\hat{y})$ for all $\hat{x},\hat{y} \in \mathbb{S}$, i.e., from the far field pattern for scattering of all plane waves of one fixed frequency.

The singular sources method of Potthast uses a different functional which also blows up at the boundary of the obstacle. This functional is defined as the magnitude of the *scattered field* $\Psi^s(z,z)$ of singular sources $\Psi(\cdot,z)$ and is calculated by backprojection of the form

$$\Psi^s(y,z) \approx \int_{\mathbb{S}}\int_{\mathbb{S}} u^\infty(\hat{x},\hat{y}) g(\hat{x},y) g(-\hat{y},z) ds(\hat{y}) ds(\hat{x}), \qquad y,z \in \mathbb{R}^m \setminus \Omega,$$

for explicitly constructed kernels $g(\cdot,\cdot)$.

All of the linear sampling and probe methods share the advantage that no knowledge about the boundary condition of the unknown scatterer is needed. With the exception of the Kirsch factorization method, these methods are valid in the limited aperture case, where the far field data is not known on the full sphere but only on an open subset $\Gamma \subset \mathbb{S}$. The principle disadvantage of sampling and probe techniques, however, is that they all require the knowledge of far field patterns for a large number of incident plane waves. The current challenge facing these algorithms is to reduce the amount of data needed for reliable reconstructions.

Recent work by Ikehata has made significant progress toward the development of reconstruction algorithms using very limited data. His *enclosure method* [7, 8] enables one to find the support of convex polygons from the knowledge of one measured field. Ikehata uses a special harmonic incident field,

$$v = e^{\tau x \cdot (\omega + i\omega^\perp)},$$

to construct the following indicator function:

$$I_\omega(\tau,t) = e^{-\tau t}\left\{ \left\langle \left.\frac{\partial u}{\partial \nu}\right|_{\partial G}, v|_{\partial G} \right\rangle - \left\langle \left.\frac{\partial v}{\partial \nu}\right|_{\partial G}, u|_{\partial G} \right\rangle \right\}, \qquad \tau > 0, \quad t \in \mathbb{R}, \tag{1.2}$$

where $\omega \in \mathbb{S}$ is a direction vector, u is the unknown, weak solution to the scattering problem, and G is some domain containing the unknown scatterer, $\Omega \subset \operatorname{int} G$ the interior of G. Ikehata shows that at the corners of polygonal scatterers this indicator function becomes unbounded. He then exploits this property to uniquely reconstruct the scatterer. For details on implementation, see [9]. While for the purposes of analysis the presentation of the enclosure method is limited to specific settings, it appears that in practice the method is independent of the material properties of the scatterer.

In this work we propose another technique for locating a scatterer from a single incident wave that also exploits the behavior of a special indicator function in the

neighborhood of a scatterer. Since we look, rather, for where the indicator function does *not* become unbounded, we call the method the no response test. Like the enclosure method, the no response test can be used to locate scatterers from only one incident wave. Moreover, neither the enclosure method nor the no response test require a priori knowledge of the material properties of the scatterer. However, the indicator function in the no response test is a different functional on the measured data than that of Ikehata. Also, we do not make use of, nor place any particular constraints on, the geometric properties of the scatterer.

It is often the case that numerical algorithms precede by many years their mathematical justification. The absence of analytical results for a particular application does not preclude the successful implementation and numerical study of algorithms. At the expense of mathematical analysis limited to narrow settings, we have chosen to highlight the robustness of the no response test in a variety of settings by focusing on numerical results. We leave many questions unanswered; however, the demonstration of the applicability of the techniques discussed here helps to motivate and formulate the analysis that must follow. In section 3 we provide preliminary theoretical results to motivate the method. A convergence proof for one-wave reconstructions would include a one-wave uniqueness result. These results are not yet available. However, we can show that a set (depending on some test domain Ω_t^0) surrounding the unknown scatterer, which we call its *corona*, is uniquely determined by the one-wave far field pattern independent of the boundary condition.

The no response algorithm is given in section 4. In the same section we show reconstructions for scattering from scatterers with *Dirichlet*, *Neumann*, or *impedance* boundary conditions or for scattering from an inhomogeneous medium. We show results from each of these scatterers with full and limited aperture data. Preparatory to this, we briefly review in section 2 the fundamental scattering models for sound-soft, sound-hard, and mixed obstacles as well as inhomogeneous media.

2. Dirichlet, Neumann, impedance, and medium scattering problems. This section serves to review briefly the key elements of scattering by bounded objects or media and to provide some tools for the inversion method described in section 3. We also describe how we solved the forward problems to produce the data used for the demonstration of the no response test.

Scattering review. Let v^i be an incident field that satisfies the Helmholtz equation,

$$\triangle v + \kappa^2 v = 0,$$

with wave number $\kappa > 0$ on $\mathbb{R}^m$. The incident field produces a scattered field v^s that solves the Helmholtz equation on the exterior of the scatterer Ω and satisfies the *Sommerfeld radiation condition*

$$r^{\frac{m-1}{2}}\Big(\frac{\partial}{\partial r} - i\kappa\Big)v(x) \to 0, \qquad r = |x| \to \infty$$

uniformly in all directions. For impenetrable scatterers we consider cases where the scatterer is either sound-soft (a perfect conductor), sound-hard (a perfect reflector), or some mixture of these. Each of these types of scatterers is modeled by a total field,

$$v = v^i + v^s,$$

that satisfies either *Dirichlet*, *Neumann*, or *impedance* boundary conditions. These boundary conditions are given, respectively, as

$$v|_{\partial\Omega} = 0, \qquad \frac{\partial v}{\partial \nu}|_{\partial\Omega} = 0, \qquad \frac{\partial v}{\partial \nu}|_{\partial\Omega} + \lambda v|_{\partial\Omega} \ = \ 0,$$

with the impedance function $\lambda \in C(\partial\Omega)$. We also treat penetrable scatterers, where the inhomogeneity is modeled by a nonnegative refractive index $n : \mathbb{R}^m \to \mathbb{R}_+$ and where $n(x) := 1$ for $x \in \mathbb{R}^m \setminus \Omega$. Then the total field $v \in H^2_{loc}(\mathbb{R}^m)$ solves the inhomogeneous Helmholtz equation,

$$\triangle v + \kappa^2 n v = 0,$$

in $\mathbb{R}^m$, and $v^s = v - v^i$ satisfies the Sommerfeld radiation condition.

The following result enables us to calculate the scattered and far fields of any reasonable incident field as the weighted superposition of the corresponding fields generated by scattering from incident plane waves. This result is fundamental to the no response test.

THEOREM 2.1. *Let Γ be an open subset of $\mathbb{S}$, the unit sphere on $\mathbb{R}^m$ ($m = 2, 3$), and let $\Omega \subset \mathbb{R}^m$ denote the bounded support of a scattering body with C^2 boundary. Denote by $u^s : \mathbb{R}^m \to \mathbb{C}$ and $u^\infty : \mathbb{S} \to \mathbb{C}$ the scattered and far fields, respectively, due to excitation from an incident plane wave u^i at a fixed wavenumber $\kappa > 0$ with direction $-\hat{y}$, $u^i(x, -\hat{y}) := e^{i\kappa x\cdot(-\hat{y})}$, $x \in \mathbb{R}^m$, $\hat{y} \in \mathbb{S}$. Consider the superposition of plane waves*

$$v^i(x) \ = \ \int_\Gamma e^{i\kappa x\cdot(-\hat{y})} g(-\hat{y}) ds(\hat{y}), \qquad x \in \mathbb{R}^m, \tag{2.1}$$

where $g \in L^2(-\Gamma)$. The corresponding solution to the scattering problem with Dirichlet, Neumann, or impedance boundary conditions or scattering by an inhomogeneous medium is given by $v = v^i + v^s$, where

$$v^s(x) \ = \ \int_\Gamma u^s(x, -\hat{y}) g(-\hat{y}) ds(\hat{y}), \qquad x \in \mathbb{R}^m \setminus \overline{\Omega}.$$

The corresponding far field pattern is given by

$$v^\infty(\hat{x}) \ = \ \int_\Gamma u^\infty(\hat{x}, -\hat{y}) g(-\hat{y}) ds(\hat{y}), \qquad \hat{x} \in \mathbb{S}. \tag{2.2}$$

Proof. The proof relies only on the linearity and boundedness of the particular scattering problem. Linearity implies that the sum of two incident fields is scattered onto the sum of the single scattered fields. By boundedness of the scattering operator from $C(\Omega)$ into $C_{loc}(\mathbb{R}^m \setminus \overline{\Omega})$, the limit for the integration can be performed and we obtain the stated results. ∎

The signs in the expressions for v^i, v^s, and v^∞ above have been chosen so that the backprojection mapping between the far field measurements and the scattered field, which we derive below, has a natural interpretation in terms of a physical aperture in the far field. Note that the function g is defined on $-\Gamma$, where $-\Gamma$ is the mirror image of the interval Γ: $\hat{y} \in \Gamma \iff -\hat{y} \in -\Gamma$. Using the standard far field reciprocity relation $u^\infty(\hat{x}, -\hat{y}) = u^\infty(\hat{y}, -\hat{x})$ $(\hat{x}, \hat{y} \in \mathbb{S})$ we see that the far field is defined on Γ with any incident wave direction $-\hat{x}$. When $\Gamma = \mathbb{S}$ this virtual aperture is not as apparent. The incident field v^i given by (2.1) is called a *Herglotz wave function*. Since this function depends on the density g, we write this explicitly as $v^i[g](x)$. We denote the scattered field for scattering of a Herglotz wave function $v^i[g](x)$ by $v^s[g](x)$. Similarly, the corresponding far field pattern is given by $v^\infty[g](\hat{x})$.

Numerical considerations. As a basis both for the theoretical discussion and the implementations (that is, the generation of the simulated data), we briefly sketch the solution of the above scattering problems. For all proofs and a detailed discussion we refer to [2] and [16].

For the solution of the Dirichlet problem we represent the scattered field as a combined single- and double-layer potential

$$v^s(x) = \int_{\partial\Omega} \left\{ \frac{\partial\Phi(x,y)}{\partial\nu(y)} - i\Phi(x,y) \right\} \varphi(y) ds(y), \qquad x \in \mathbb{R}^m \setminus \partial\Omega.$$

For this representation of the scattered field and the boundary condition, the density φ must satisfy the integral equation

$$\varphi + K\varphi - iS\varphi = -2v^i, \tag{2.3}$$

where $\mathcal{S}$ is the single-layer operator,

$$(S\varphi)(x) := 2\int_{\partial\Omega} \Phi(x,y)\varphi(y) ds(y), \qquad x \in \partial\Omega,$$

and K is the double-layer operator,

$$(K\varphi)(x) := 2\int_{\partial\Omega} \frac{\partial\Phi(x,y)}{\partial\nu(y)}\varphi(y) ds(y), \qquad x \in \partial\Omega.$$

The equation has a unique solution that depends continuously on the right-hand side in $C(\partial\Omega)$.

For the Neumann problem we use the modified approach due to Panich [13]:

$$v^s(x) = \int_{\partial\Omega} \left\{ \Phi(x,y)\varphi(y) + i\frac{\partial\Phi(x,y)}{\partial\nu(y)}(S_0^2\varphi)(y) \right\} ds(y), \qquad x \in \mathbb{R}^m \setminus \partial\Omega, \tag{2.4}$$

where S_0 denotes the single-layer operator in the case $\kappa = 0$. For this representation of the scattered field, the density φ can be shown to satisfy the boundary integral equation

$$\varphi - K'\varphi - iTS_0^2\varphi = 2\frac{\partial v^i}{\partial\nu}, \tag{2.5}$$

where

$$(K'\varphi)(x) := 2\int_{\partial\Omega} \frac{\partial\Phi(x,y)}{\partial\nu(x)}\varphi(y) ds(y), \qquad x \in \partial\Omega,$$

and

$$(T\varphi)(x) := 2\frac{\partial}{\partial\nu(x)}\int_{\partial\Omega} \frac{\partial\Phi(x,y)}{\partial\nu(y)}\varphi(y) ds(y), \qquad x \in \partial\Omega.$$

Both (2.3) and (2.5) have unique solutions that depend continuously on the incident field in $C(\partial\Omega)$.

For the impedance boundary value problem we follow the same approach using the representation (2.4). An application of the jump relations leads to the equation

$$\left[I - K' - iTS_0^2 - \lambda S - i\lambda(I+K)S_0^2 \right]\varphi = 2\frac{\partial v^i}{\partial\nu} + 2\lambda v^i. \tag{2.6}$$

Under suitable assumptions on the impedance λ (basically ensuring uniqueness of the impedance scattering problem) the integral equation (2.6) has a unique solution which depends continuously on the incident field in $C(\partial\Omega)$.

For the penetrable inhomogeneous medium we use Green's formula applied to the total field to recast the solution to the scattering problem as the solution to the *Lippmann–Schwinger* equation

$$v(x) \;=\; v^i - \kappa^2 \int_{\mathbb{R}^m} \Phi(x,y) m(y) v(y), \qquad x \in \mathbb{R}^m,$$

where $m(y) := 1 - n(y)$ for the index of refraction $n : \mathbb{R}^m \to \mathbb{R}_+$. The Lippmann–Schwinger equation has a unique solution in $C(\Omega)$ that depends continuously on the incident field v^i.

3. The inverse problem and the no response test. The *inverse problem* we consider is to locate the scatterer Ω given an incident plane wave u^i and the far field data restricted to the aperture $u^\infty|_\Gamma$, where $\Gamma \subset \mathbb{S}$ is some open set. The solution to the inverse problem is often called the *reconstruction* of the scatterer. The no response method is a reconstruction algorithm that uses only one incident wave and does not use any a priori information about the physical characteristics of the scatterer.

We consider the hypothesis that a scatterer lies within a given domain. The no response test is a way to determine whether or not this hypothesis is true. We begin with a heuristic description of the reconstruction method based on this test. An explicit formulation of the full algorithm is given in the next section.

The scattering test response. Let $\Omega_t \subset \mathbb{R}^m$ be a bounded test domain with a C^2 boundary. Sample by construction (see (2.1)) the set of incident fields that are small on the test domain Ω_t and large outside. The far field patterns corresponding to these incident fields are then calculated via (2.2). We call the magnitude of the calculated far field patterns *responses*. If the maximum of the sampled responses is small, we show that this is an indication that the unknown scatterer is a subset of the test domain Ω_t. While general geometric properties of the test domain are not important (e.g., convexity, symmetry, and so forth), it is critical that the test domain be large enough that by translation the scatterer is contained in the interior. The no response algorithm makes use of a template test domain Ω_t^0 that is rotated and translated around the computational domain. The location and shape of the scatterer is then recovered by the behavior, with respect to these test domains, of the sampled *scattering test response*, that is, the supremum over all responses for a fixed test domain. This is defined below.

DEFINITION 3.1 (scattering test response). *Given the far field pattern u^∞ due to an incident plane wave u^i with direction $-\hat{x}$ and a scatterer Ω as in Theorem* 2.1*, let $v^i[g]$ denote a Herglotz wave function defined by* (2.1) *and $v^\infty[g]$ denote the corresponding far field pattern given by* (2.2)*. We define the* scattering test response *for the test domain Ω_t by*

$$\mu_\epsilon(\Omega_t, \Omega, \hat{x}) := \sup\left\{ |v^\infty[g](\hat{x})| : \;\; g \in L^2(-\Gamma) \text{ such that } ||v^i[g]||_{C(\Omega_t)} \le \epsilon \right\}. \tag{3.1}$$

We keep the direction $\hat{x}$ fixed in what follows, so to reduce notational clutter we drop the argument and use the notation $\mu_\epsilon(\Omega_t, \Omega)$ whenever there is no chance for confusion.

To calculate μ_ϵ from the far field pattern $u^\infty|_\Gamma$ for scattering of a plane wave u^i with direction $-\hat{x}$, we use the reciprocity relation $u^\infty(\hat{x},-\hat{y}) = u^\infty(\hat{y},-\hat{x})$ $(\hat{x},\hat{y}\in\mathbb{S})$ and Theorem 2.1 to obtain

$$\begin{aligned} v^\infty(\hat{x}) &= \int_\Gamma u^\infty(\hat{x},-\hat{y})g(-\hat{y})ds(\hat{y}) \\ &= \int_\Gamma u^\infty(\hat{y},-\hat{x})g(-\hat{y})ds(\hat{y}). \end{aligned} \tag{3.2}$$

Thus, from knowledge of the far field pattern $u^\infty(\hat{y},-\hat{x})$, $\hat{y}\in\Gamma$, for one wave with direction of incidence $-\hat{x}$, we can reconstruct $\mu_\epsilon(\Omega_t,\Omega)$ for any domain Ω_t by construction of appropriate kernels g of the (limited aperture) Herglotz wave functions. Before discussing in detail the construction of the densities g and the test domains Ω_t, we prove some basic results about the behavior of the scattering test response that motivate our numerical methods.

The no response test is built upon two observations. First, when the scatterer Ω is contained in the *interior* of the test domain Ω_t, the value $\mu_\epsilon(\Omega_t,\Omega)$ is *small or bounded*. Second, if the scatterer is in the *exterior* of the test domain, then $\mu_\epsilon(\Omega_t,\Omega)$ is *large or unbounded*. These facts are used to locate the support Ω of the scatterer as a region contained in the union of test domains where the scattering test response μ_ϵ is bounded. We summarize this critical behavior in the following theorem.

THEOREM 3.2 (behavior of the scattering test response). *If $\Omega\subset\Omega_t$, then there is a constant $c\in\mathbb{R}$ such that*

$$\mu_\epsilon(\Omega_t,\Omega)\le c\epsilon.$$

On the other hand, if $\overline{\Omega}\cap\overline{\Omega}_t=\emptyset$, and $\mathbb{R}^m\setminus(\overline{\Omega}\cup\overline{\Omega}_t)$ is connected, then we have

$$\mu_\epsilon(\Omega_t,\Omega)=\infty.$$

Proof. When $\Omega\subset\Omega_t$ the boundedness of the scattering map $v^i\mapsto v^\infty$ implies the existence of a constant c such that for all v^i satisfying

$$||v^i||_{C(\Omega_t)}\le\epsilon,$$

we have

$$||v^\infty||_{C(\mathbb{S})}\le c\epsilon.$$

This completes the proof of the first statement.

To prove the second statement, we consider two disjoint domains, Ω_t' and Ω', satisfying $\Omega_t\subset\Omega_t'$, $\Omega\subset\Omega'$, and $\overline{\Omega_t'}\cap\overline{\Omega'}=\emptyset$. We further require that the interior homogeneous Dirichlet problems for Ω_t' and Ω' have only the trivial solution. Then the Herglotz wave operator $H: L^2(-\Gamma)\to L^2(\partial(\Omega_t'\cup\Omega'))$, defined by

$$(Hg)(x) := v^i[g](x)\Big|_{\partial(\Omega_t'\cup\Omega')},$$

has dense range. This can be shown in a similar fashion to the proof of Lemma 3.1.2 of [16]. Choose $y\notin\overline{\Omega_t'}\cup\overline{\Omega'}$ such that the far field pattern $w^\infty(\hat{x},y)$ for scattering of $\Phi(\cdot,y)$ by Ω is not zero. This is always possible since, by the mixed reciprocity relation [16, Theorem 2.1.4], we have

$$w^\infty(\hat{x},y)=\gamma u^s(y,-\hat{x})$$

and $u^s(\cdot,-\hat{x})$ cannot vanish on an open subset of $\mathbb{R}^m$. Next, construct $v^i[g](x)$ satisfying

$$||v^i[g](x)||_{C(\Omega_t')} \leq \epsilon, \qquad ||v^i[g](x) - \beta\Phi(\cdot,y)||_{C(\Omega')} \leq \epsilon.$$

Then since $\Omega_t \subset \Omega_t'$, we have

$$\mu_\epsilon(\Omega_t,\Omega) \geq |v^\infty[g](\hat{x})|.$$

By definition $\Omega \subset \Omega'$; thus

$$\left|v^\infty[g](\hat{x}) - \beta w^\infty(\hat{x},y)\right| \leq c\epsilon,$$

with some constant c, which, by the triangle inequality, yields

$$|v^\infty[g](\hat{x})| \geq \beta|w^\infty(\hat{x},y)| - c\epsilon.$$

Thus we have

$$\mu_\epsilon(\Omega_t,\Omega) \geq \beta|w^\infty(\hat{x},y)| - c\epsilon$$

for all $\beta \in \mathbb{R}$. This completes the proof. ∎

REMARK 3.3. *In general we would like to know if the implication*

$$\Omega \not\subset \Omega_t \implies \mu_\epsilon(\Omega_t,\Omega) = \infty$$

is true. It would immediately yield a convergence proof of the no response test to find the support of unknown scatterers. This implication is strongly linked to the uniqueness question for the inverse scattering problem under consideration, for which to date there is no proof. Colton and Sleeman [5] *have proven uniqueness for the problem with Dirichlet boundary data given a finite number of incident fields and a priori information about the size of the scatterer. The number of incident fields required depends on the size of the scatterer and the wavelength of the incident field. Alternatively, we could try to prove*

$$\Omega \not\subset \Omega_t \implies \mu_\epsilon(\Omega_t,\Omega) > C$$

for the smallest constant $C = c\epsilon$ for which Theorem 3.2 *is true. This would also lead to a convergence proof for the no response test under the condition that the right constant C is chosen appropriately for the judgment about a test domain. Both problems will be part of future research.*

In the following corollary to Theorem 3.2, we use (3.2) to show that the far field pattern on a limited aperture Γ resulting from excitation by a single incident field uniquely determines the union of all translations of a fixed test domain Ω_t^0 for which μ_ϵ is finite. This is stated precisely below.

DEFINITION 3.4 (corona of Ω corresponding to Ω_t^0). *Let Ω_t^0 denote a fixed, bounded test domain with C^2 boundary. Denote translations of Ω_t^0 by $\Omega_t^0(z) := \Omega_t^0 + z$ for $z \in \mathbb{R}^m$. Define the* corona *of the scatterer Ω by*

$$M(\Omega_t^0,\Omega,\hat{x}) := \bigcup\left\{\Omega_t^0(z) : \ z \in \mathbb{R}^m, \mu_\epsilon(\Omega_t^0(z),\Omega,\hat{x}) < \infty\right\}. \tag{3.3}$$

COROLLARY 3.5 (uniqueness and bounds for the corona). *Let $\Omega_t^0 \subset \mathbb{R}^m$ with $\mathbb{R}^m \setminus \overline{\Omega_t^0}$ connected be a bounded domain large enough that there is some $z \in \mathbb{R}^m$ for which $\Omega \subset \Omega_t^0(z)$, where Ω denotes the support of the scatterer. Then we have*

$$M(\Omega_t^0,\Omega,\hat{x}) \subset \bigcup\left\{\Omega_t^0(z) : \ z \in \mathbb{R}^m, \overline{\Omega_t^0}(z) \cap \overline{\Omega} \neq \emptyset\right\} \tag{3.4}$$

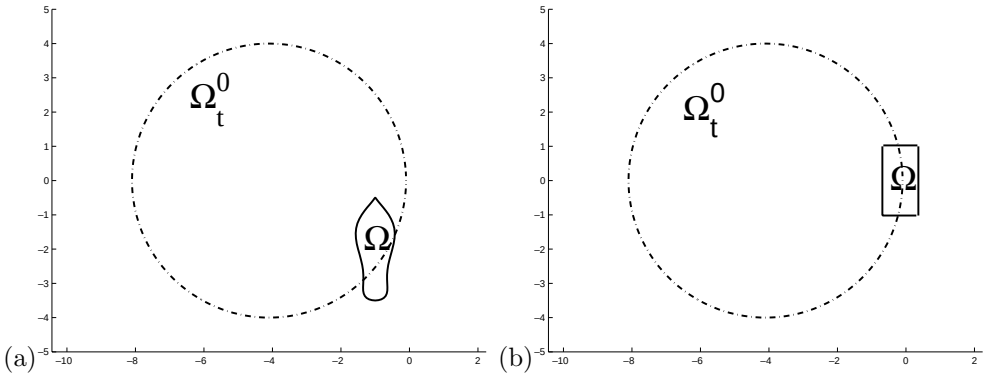

FIG. 1. *Scatterer Ω and test domain Ω_t^0 used in reconstruction simulations. The obstacle Ω in* (a) *is used for Dirichlet, Neumann, and impedance obstacle reconstructions. The scatterer shown in* (b) *is used for inhomogeneous media reconstructions.*

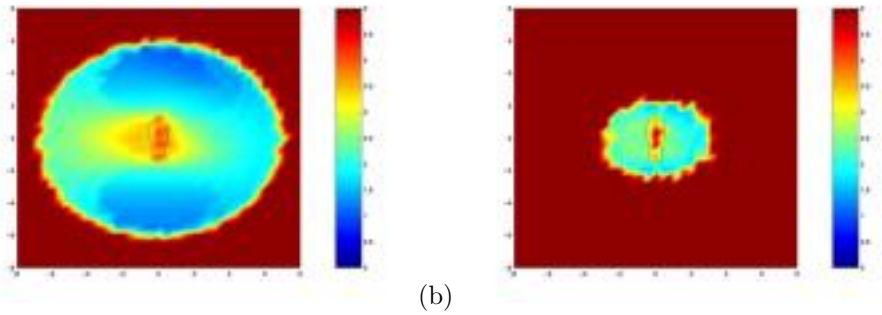
and the scatterer Ω is a subset of its corona, $M(\Omega_t^0, \Omega, \hat{x})$. Moreover, the corona is uniquely determined by the far field pattern for scattering of one plane wave with direction of incidence $-\hat{x}$.

Proof. For points z with $\mu_\epsilon(\Omega_t^0(z)) < \infty$, we apply Theorem 3.2 to conclude that $\overline{\Omega_t^0}(z) \cap \overline{\Omega} \neq \emptyset$, from which we immediately obtain the relation (3.4). For $\Omega \subset \Omega_t^0(z)$ we have $\mu_\epsilon(\Omega_t^0(z)) < \infty$ and thus the support of the scatterer is a subset of its corona: $\Omega \subset M$.

Using (3.2) the values of $\mu_\epsilon(\Omega_t^0(z), \Omega, \hat{x})$ can be calculated directly from the limited aperture far field pattern $u^\infty(\hat{y}, -\hat{x})$, $\hat{y} \in \Gamma$; that is, for fixed test domain Ω_t^0 and direction $\hat{x}$, the scattering test response $\mu_\epsilon(\Omega_t^0(z), \Omega, \hat{x})$ is a scalar-valued mapping of $\hat{x}$. Since the direction of incidence of a plane wave uniquely determines the far field pattern $u^\infty(\cdot, -\hat{x})$, then the corona is uniquely determined by the far field pattern u^∞. ∎

The corona corresponding to the circular test domain of a boat-shaped scatterer (see Figure 1) is shown in Figure 2. From the above uniqueness theorem we know that the unknown scatterer—whatever its physical nature might be—is located in the corona. Note that, at the very least, we can use the center of the corona for a single incident wave as an estimate for the center of the obstacle. In our experiments here, however, we are able to extract even more information about the scatterer from the corona. Recall from Remark 3.3 that we cannot say anything specific about the behavior of μ_ϵ for $\overline{\Omega} \cap \overline{\Omega_t^0}(z) \neq \emptyset$ when $\Omega \not\subset \Omega_t^0(z)$. We observe numerically that the value of the scattering test response increases as the intersection $\overline{\Omega} \cap \overline{\Omega_t^0}(z) \neq \emptyset$ becomes smaller. We therefore propose a technique that allows us to detect these increases, and thereby detect the location and shape of the scatterer within the corona. We begin by describing the choice of the test domain and the calculation of the scattering test response. Details for efficient implementation together with the algorithm are given in the following section.

The test domain Ω_t^0. For fixed scatterers Ω and incident wave directions $\hat{x}$, the scattering test response μ_ϵ takes as input the test domains $\Omega_t^0(z)$ and returns a scalar value as output. We would like to know which test domains $\Omega_t^0(z)$ yield small values for μ_ϵ without having to work with the unwieldy domains themselves. For this, we construct a mapping from the domain $\Omega_t^0(z)$ to the point $z' \in \Omega_t^0(z)$ and assign to



(a) (b)

FIG. 2. *The figure demonstrates the calculated corona and the corresponding bound for the location of the unknown obstacle when* Ω_t^0 *is a circle with radius* $r_t = 4$ *as shown in Figure* 1(a). *For this bound we do not need to know the physical nature of the scatterer and only* one *scattered wave is necessary. Here we used the wave number* $\kappa = 5$, *aperture opening* $\theta = 0.9\pi$, *regularization parameter* $\alpha = 10^{-11}$ *for an incident wave with direction* $(-1, 0)$. *The far field pattern contains* 1–2% *errors. The figure demonstrates the change in the corona for different choices of the approximation domain:* (a) *shows the corona for an approximation domain of radius* $r_t = 4$, (b) *shows the corona for an approximation domain of radius* $r_t = 1.3$.

that point the corresponding value of μ_ϵ. It is how we choose the point z' that allows us to get much more information about the obstacle than we would expect.

The key property that we exploit is the observation that μ_ϵ grows as the intersection $\Omega \cap \Omega_t^0(z)$ becomes smaller. We emphasize that this observation is *empirical*, since at this time we cannot prove anything about the behavior of μ_ϵ in this situation. In order to detect this growth, assign the domain $\Omega_t^0(z)$ to a point z' on the *boundary* $\partial\Omega_t^0(z)$. To avoid keeping track of more points than necessary, we construct the generating domain Ω_t^0 such that $0 \in \partial\Omega_t^0$ and map the translated domain $\partial\Omega_t^0(z)$ to the point $z' = z$. When $z \in \Omega$, the scatterer will not to fall entirely within the domain $\Omega_t^0(z)$. In this case we observe that the scattering test response μ_ϵ is significantly higher than when z is in the parts of the corona that do not intersect with the scatterer, representing the situation where $\Omega \subset \Omega_t^0(z)$.

We now describe a special realization of the no response test. We assign to the point z the value of the scattering test response

$$f^*(z; \Omega_t^0) := \mu_\epsilon(\Omega_t^0(z), \Omega). \tag{3.5}$$

However, by restriction to the point z from the full set $\overline{\Omega_t^0}(z)$, we lose information: we obtain small values for $f^*(z; \Omega_t^0)$ only on one side of the unknown object as shown in Figure 3, where $f^*(z; \Omega_t^0)$ is plotted. The full information is recovered by rotating the generating domain Ω_t^0 around the origin and repeating the above procedure. This is described in detail next.

Rotations or other variations of the test domain are necessary because of our choice of the mapping from $\Omega_t^0(z)$ to the point $z' \in \Omega_t^0(z)$. Had we chosen a radially symmetric generating domain Ω_t^0 and mapped this domain to its center, rotations would not be necessary. However, in this case the image does not directly reflect the behavior of the test response that we use to reconstruct the obstacle, not just its corona, that is, the behavior of the test response when the boundary of the test domain intersects the scatterer. Note that the idea of monitoring the behavior at the boundary of the test domain also appears in the enclosure method, where the test domain is a half-space and the behavior of the indicator function (1.2) indicates which

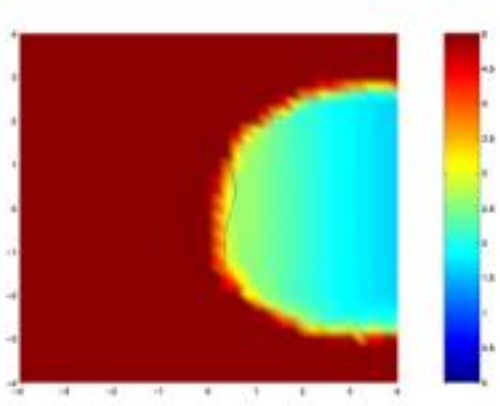


FIG. 3. *The figure shows a plot of the function* $f^*(z;\Omega_t^0)$ *given by* (3.5) *on a grid containing the unknown scatterer. The scatterer is indicated by the black curve. Here, we used a Dirichlet boundary condition.*

half-space the obstacle belongs to [6, 9]. Alternatively, we could use an arbitrary set of generating domains Ω_t^0 with $0 \in \partial\Omega_t^0$; however, it is much more convenient to work with a single generating domain rotated about the origin.

The value $f^*(z;\Omega_t^0)$ assigned to the point z via (3.5) at one rotation of the domain Ω_t^0 does not necessarily correspond to the value of the same point at a different rotation. To see this, suppose that the scatterer Ω is contained in a small circle of radius 1 centered at the point $(-1,0)$. Suppose further that Ω_t^0 is a circle of radius 2 with center $(-2,0)$. In this case $\Omega \subset \Omega_t^0$ and $f^*(0;\Omega_t^0)$ will therefore be small. If we rotate Ω_t^0 about the origin by 180° and denote the resulting domain by $\widetilde{\Omega_t}^0$, then $\Omega \cap \widetilde{\Omega_t}^0 = \{0\}$. In this case we observe that the corresponding value for $f^*(0;\widetilde{\Omega_t}^0)$ will be large. In each case we assign a value to the point $z = 0$, but clearly the values do not correspond to the same situation. In order to prevent the large values of one orientation from drowning out the information contained in the small values from other rotations, we take the minimum of the values assigned to the points z over all rotations.

Let R_θ denote the rotation operator mapping the domain Ω_t^0 onto the rotated domain $R_\theta\Omega_t^0$. If at a point z the value $F(z;\Omega_t^0)$,

$$F(z;\Omega_t^0) := \inf_{\theta\in[0,2\pi]} f^*(z;R_\theta\Omega_t^0), \tag{3.6}$$

is large, then we suppose that the unknown obstacle lies partly outside all rotations of the test domain about this point. In this way, by sampling all points z in and around the unknown scatterer Ω we are able to reconstruct aspects of the shape, location, and size of Ω. Details about how we implement this are given next.

4. Implementation and numerical demonstrations.

Calculating the densities g. As prescribed in (3.1), we construct incident fields that are small on the test domain $\Omega_t^0(z)$. For this we approximate the fundamental solution to the Helmholtz equation $\Phi(x,y)$ where the singularity is located at a point $y \in \mathbb{R}^m$ sufficiently far away from $\Omega_t^0(z)$. To construct the densities g corresponding

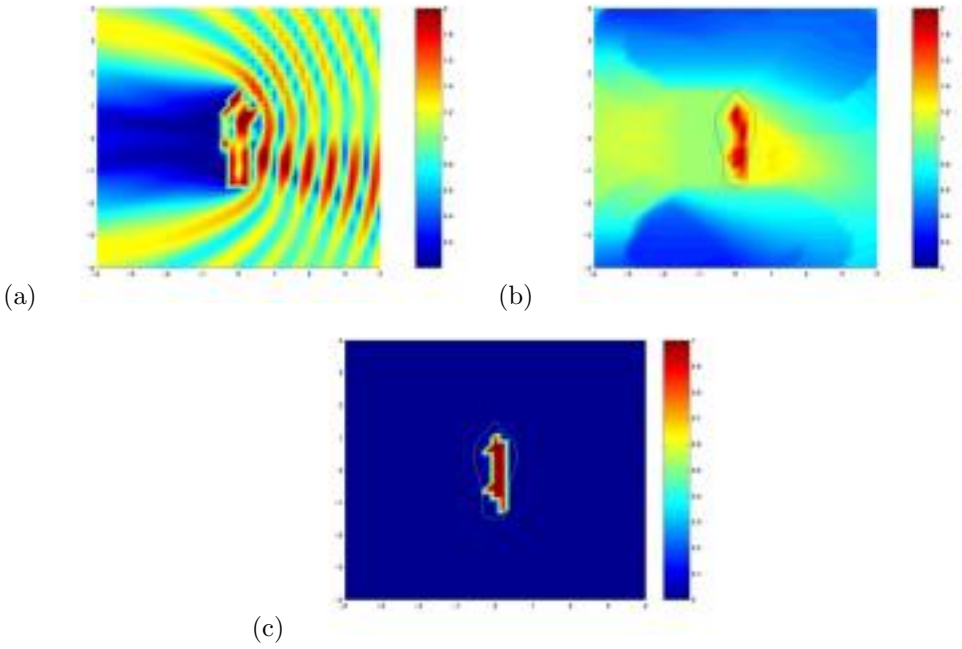

FIG. 4. (a) *Original total field for scattering by a Dirichlet obstacle.* (b) *A plot of the function* $F(z)$ *defined by* (3.6) *for* $z \in \mathcal{G}$*, the computational grid.* (c) *Thresholded version of the function* F *with* $C = 1.4$ *(see Algorithm* 4.1*). Here we used the wave number* $\kappa = 5$*, aperture opening* $\theta = 1.8\pi$*, regularization parameter* $\alpha = 10^{-11}$ *for an incident wave with direction* $(-1, 0)$*. The far field pattern contains* 1–2% *errors.*

to these incident fields, we use Tikhonov regularization to approximately solve the ill-posed equation

$$\Big(H_z g(\cdot, y)\Big)(x) = \Phi(x, y) \qquad \text{for } x \in \partial\Omega_t^0(z),$$

where $H_z : L^2(\Gamma) \to L^2(\partial\Omega_t^0(z))$ is a (limited angle) Herglotz wave operator defined by

$$(H_z g)(x) := \int_\Gamma e^{i\kappa x\cdot(-\hat{y})} g(-\hat{y}) ds(\hat{y}), \qquad x \in \partial\Omega_t^0(z). \tag{4.1}$$

Specifically, for the regularization parameter $\alpha > 0$, we define

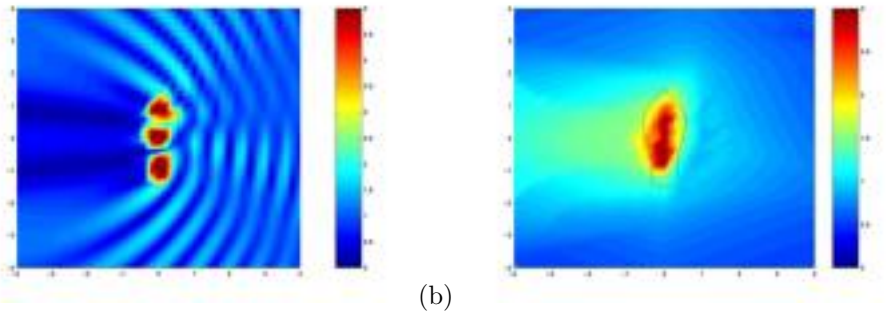
$$g_{z,\alpha}(\cdot, y) := (\alpha I + H_z^* H_z)^{-1} H_z^* \Phi(\cdot, y), \tag{4.2}$$

where the argument y of the density $g_{z,\alpha}$ denotes the dependence of the density on the location of the singularity in Φ. The subscripts z and α on g denote the dependence of the density on the regularization parameter α and the test domain $\Omega_t^0(z)$. This yields

$$v^i[g_{z,\alpha}(\cdot, y)](\cdot) \approx \Phi(\cdot, y) \quad \text{on } \partial\Omega_t^0(z).$$

On $\Omega_t^0(z)$, for $d(y, \Omega_t^0(z)) \geq \rho$ we have, for all $\alpha \in [0, \alpha_0]$ for fixed α_0 sufficiently small,

$$|v^i[g_{z,\alpha}(x, y)]| \leq \begin{cases} \frac{c}{\sqrt{\rho}}, & m = 2, \\ \frac{c}{\rho}, & m = 3, \end{cases} \qquad x \in \Omega_t^0(z), \tag{4.3}$$



(a) (b)

FIG. 5. (a) *Original total field for scattering by an impedance obstacle with* $\lambda = i$. (b) *A plot of the function* $F(z)$ *defined by* (3.6) *for* $z \in \mathcal{G}$, *the computational grid. Here we used the wave number* $\kappa = 5$, *aperture opening* $\theta = 1.8\pi$, *regularization parameter* $\alpha = 10^{-11}$ *for an incident wave with direction* $(-1, 0)$. *The far field pattern contains* 1–2% *errors.*

with some constant c that is typically of size smaller than 10^1. Thus by knowing the value of $v^i[g_{z,\alpha}]$ at the point closest to the source point we obtain upper bounds on the size of the incident field on all of $\Omega_t^0(z)$. This is used in the calculation of the scattering test response μ_ϵ. On the exterior region $\mathbb{R}^m \setminus \overline{\Omega}_t$ the magnitude of $v^i[g_{z,\alpha}]$ is in the range of $c/2\alpha$. For example, $|v^i[g_{z,\alpha}]|$ is of size 50 if $c = 1$ and $\alpha = 10^{-2}$. This corresponds to a data error of one percent.

Translations of the test domain. We describe a quick method to calculate lower estimates for the test response μ_ϵ for a large number of translated test domains $\Omega_t^0(z)$ with generating domain Ω_t^0. In the moving reference frame of the test domain, spatial translations look like translations of the incident field. We use this and the fact that phase shifts in the far field correspond to spatial translations in the near field in order to translate the generating domain Ω_t^0 around the computational domain.

Let Ω_t^0 be a generating test domain and define $\Omega_t^0(z) = \Omega_t^0 + z$ to be the corresponding translated test domain. Translations of the Herglotz wave function $v^i[g]$ can be easily performed by the multiplication of the density g by the complex factor $e^{-i\kappa z \cdot d}$. At points $z \in \mathbb{Q}$ covering the area where the unknown scatterer is supposed to be (that is, $\mathbb{Q}$ is the computational domain and satisfies $\Omega \subset \mathbb{Q}$) we calculate translations $\Omega_t^0(z)$ of the test domain Ω_t^0 by the corresponding translation of the Herglotz wave function $v^i[g]$:

$$v^i[g](x - z) = v^i[e^{-i\kappa z \cdot (\cdot)} g(\cdot)](x), \qquad x \in \mathbb{R}^m. \tag{4.4}$$

We define the function $|v^\infty[g](\hat{x}, z)|$ to be the far field pattern at the point $\hat{x} \in \mathbb{S}$ for scattering of the shifted incident field $v^i[g](x - z)$. Then from Theorem 2.1 and (3.2) we obtain

$$|v^\infty[g](\hat{x}, z)| = \left| \int_\Gamma u^\infty(\hat{y}, -\hat{x}) e^{i\kappa z \cdot \hat{y}} g(-\hat{y}) ds(\hat{y}) \right|. \tag{4.5}$$

In words, the magnitude of the far field v^∞ at the point $\hat{x} \in \mathbb{S}$ with test domain $\Omega_t^0(z)$ is given by the magnitude of the weighted superposition of the measured far field pattern due to a single incident plane wave excitation; the weight $g(-\hat{y})$ is determined by the generating domain Ω_t^0 and the phase shift is determined by the translation of Ω_t^0.

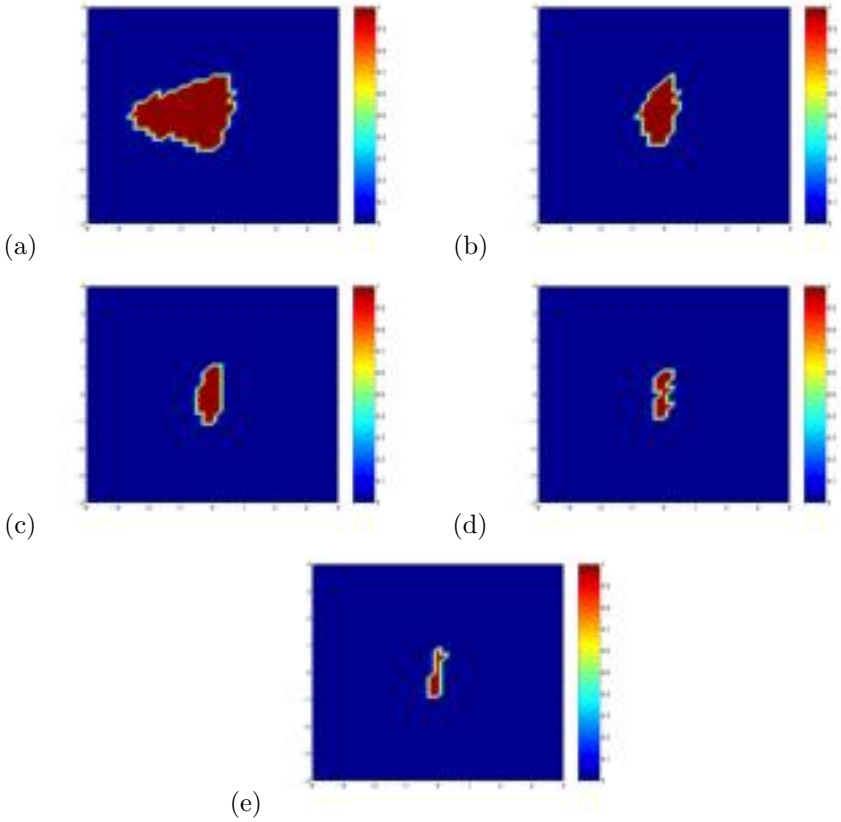


FIG. 6. *We show different thresholded versions of the reconstruction to demonstrate the influence of the cut-off parameter C. The wave number is $\kappa = 5$, aperture opening $\theta = 1.8\pi$, regularization parameter $\alpha = 10^{-11}$ for an incident wave with direction $(-1, 0)$; that is, the incident wave is coming from the right-hand side. The far field pattern contains 1–2% errors.*

Sampling the scattering test response. The scattering test response $\mu_\epsilon(\Omega_t^0(z), \Omega)$ is the supremum over $|v^\infty[g](\hat{x}, z)|$, where $g \in L^2(\Gamma)$ is chosen such that

$$||v^i[g]||_{C(\Omega_t^0(z))} \leq \epsilon. \tag{4.6}$$

We choose a finite subset $\{g_1, \ldots, g_{n_y}\}$ of densities g such that (4.6) is satisfied and calculate the maximum of the values $|v^\infty[g_j](\hat{x}, z)|$ for $j = 1, \ldots, n_y$ via (4.5). To obtain different densities g, we solve (4.2) at the points y_j, $j = 1, \ldots, n_y$, in the exterior of $\Omega_t^0(z)$. In our experiments we chose $n_y \approx 20$. Using the efficient translations in (4.4), we need only solve (4.2) for g with Ω_t^0 for each $j = 1, \ldots, n_y$, rather than solving for g for every translated domain $\Omega_t^0(z)$. Also, from the discussion following (4.3), if we choose the points y_j appropriately, there is no need to check explicitly if condition (4.6) is satisfied.

The no response algorithm. We finish this section with a detailed prescription for using the no response test to locate an unknown obstacle.

ALGORITHM 4.1 (no response test).

- *Choose an appropriate test domain Ω_t^0 with $0 \in \partial\Omega_t^0$ that is large enough such that translations of Ω_t^0 and its rotated versions may contain the unknown*

(a) (b)

(c) (d)

FIG. 9. (a)–(d) *We show several thresholded versions of the function* F *for the reconstruction of an inhomogeneous medium, where we used the thresholds* $C = 0.1$, $C = 0.06$, $C = 0.05$, *and* $C = 0.045$.

- *Calculate the minimum with respect to the rotations* θ_l, *that is, the sampled version of* (3.6)*:*

$$F(z; \Omega_t^0) := \min_{l=1,\ldots,n_r} f^*(z; R_{\theta_l} \Omega_t^0), \qquad z \in \mathcal{G}.$$

- *Choose a threshold* C *and calculate*

$$\Omega_{rec} := \{ z \in \mathcal{G} : \ F(z; \Omega_t^0) \geq C \}.$$

Now, an approximation for the support Ω *of the unknown scatterer is given by the components of* Ω_{rec} *that are not connected with infinity.*

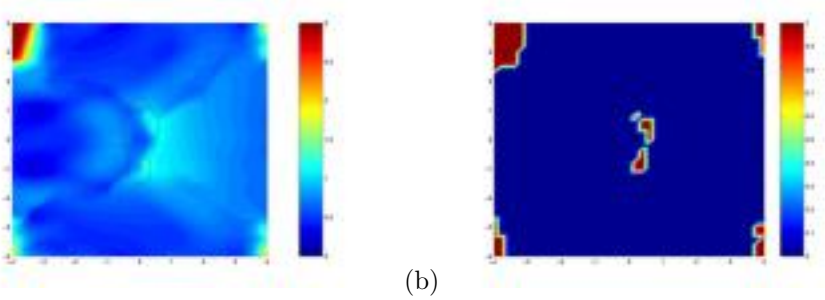

FIG. 10. *Limited aperture reconstruction of a Dirichlet obstacle.* (a) *A plot of the function* $F(z)$ *defined by* (3.6) *for* $z \in \mathcal{G}$*, the computational grid.* (b) *Thresholded version of the function* F*. Here we used the wave number* $\kappa = 5$*, aperture opening* $\theta = 0.6\pi$*, regularization parameter* $\alpha = 10^{-11}$ *for an incident wave with direction* $(-1, 0)$*. The far field pattern contains* 1–2% *errors.*

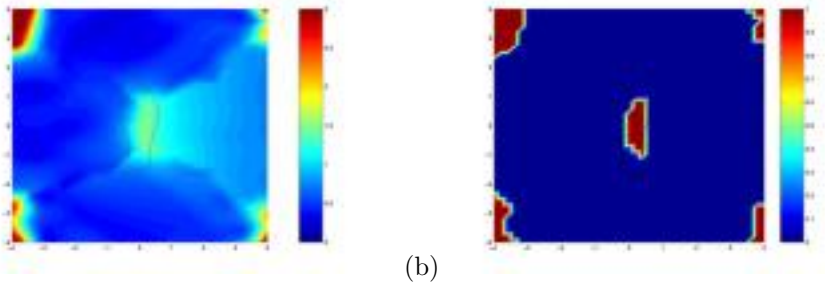

FIG. 11. *Limited aperture reconstruction of a Neumann obstacle.* (a) *A plot of the function* $F(z)$ *defined by* (3.6) *for* $z \in \mathcal{G}$*.* (b) *Thresholded version of the function* F*. Here we used the wave number* $\kappa = 5$*, aperture opening* $\theta = 0.6\pi$*, regularization parameter* $\alpha = 10^{-11}$ *for an incident wave with direction* $(-1, 0)$*. The far field pattern contains* 1–2% *errors.*

For the choice of the constant C we propose dynamical thresholding on the image $F(z)$ that is informed by a priori knowledge about the approximate size of the object.

Numerical results. All the following numerical reconstruction procedures are based on the same algorithm independent of the boundary condition or physical nature of the scatterer. All reconstructions use the far field data for *one* wave only. We show results for full and limited aperture data.

To compare different reconstructions for obstacles with different boundary condition for all the following pictures, we used the far field pattern for one wave with direction of incidence $(-1, 0)$. We first show results for full aperture and demonstrate the influence of the cut-off parameter (Figures 4–9).

In a second part, we restrict our measurements to a limited aperture. Here, we would like to show that even with limited aperture the method yields reasonable results. Figures 10 to 13 show limited aperture reconstructions for the Dirichlet, Neumann, and impedance boundary condition and for the inhomogeneous medium. We used $\kappa = 5$ and an aperture of 0.6π, or $108°$.

5. Concluding remarks. The no response test is a novel sampling technique for reconstructing the support of unknown scatterers. The method does not require a priori knowledge about the physical or geometric properties of the unknown scatterer. Reconstructions can be obtained from the far field pattern for scattering of a single

incident wave. The method appears to be robust and can be used in limited aperture settings. The results and open questions discussed in this work offer a new perspective on some old questions (for example, the uniqueness question for one wave) and provide new directions for future research, both in numerical techniques and analysis.

VIRUS DYNAMICS: A GLOBAL ANALYSIS*

PATRICK DE LEENHEER† AND HAL L. SMITH†

Abstract. Exploiting the fact that standard models of within-host viral infections of target cell populations by HIV, developed by Perelson and Nelson [*SIAM Rev.*, 41 (1999), pp. 3–44] and Nowak and May [*Virus Dynamics*, Oxford University Press, New York, 2000], give rise to competitive three dimensional dynamical systems, we provide a global analysis of their dynamics. If the basic reproduction number $R_0 < 1$, the virus is cleared and the disease dies out; if $R_0 > 1$, then the virus persists in the host, solutions approaching either a chronic disease steady state or a periodic orbit. The latter can be ruled out in some cases but not in general.

Key words. virus dynamics, global stability, oscillations, HIV

1. Introduction.

Recently there has been a substantial effort in the mathematical modeling of virus dynamics, primarily motivated by the AIDS epidemic and HIV; see, e.g., [9, 11, 15]. Perelson and Nelson [14] and Nowak and May [12] provide excellent reviews and many more citations. The latter has a somewhat broader focus, also treating SIV (the simian version of HIV) and the hepatitis B viral infections. These models focus on the disease dynamics within an infected individual and contrast with an earlier parallel literature on the dynamics within the human population. Simple HIV models have played a significant role in the development of a better understanding of the disease and the various drug therapy strategies used against it. For example, they provided a quantitative understanding of the level of virus production during the long asymptomatic stage of HIV infection; see [13, 14, 12].

We focus primarily on HIV models here but note, following [12], that the basic model applies to many other viral infections. Moreover, similar models exist which describe infections of marine bacteria by bacteriophages; see [1].

A brief review of the salient features of the role of HIV in the disease will be useful. The course of an HIV infection is as follows. First, HIV enters its target, a T cell. Inside this cell it makes a DNA copy of its viral RNA; hence it falls into the class of so-called retroviruses. In this process it needs the enzyme reverse transcriptase (RT). The viral DNA is then inserted into the DNA of the T cell, which will henceforth produce viral particles that can bud off the cell to infect other uninfected T cells. Before leaving the host cell, the virus particle is equipped with protease, an enzyme used to cleave a long protein chain. If this feature is lost, the virus particle is not capable of successfully infecting other T cells.

The models considered in [14, 12] have three state variables: T, the concentration of uninfected T cells; T^*, the concentration of productively infected T cells; and V, the concentration of free virus particles in the blood. In chemical reaction notation, the model can be written

$$T + V \to T^* \to NV,$$

because mass action reaction terms are used and each infected T cell is assumed to produce N viral particles over its lifespan. The interaction between these cells and virus particles is then given by the following equations:

$$\begin{aligned} \dot{T} &= f(T) - kVT, \\ \dot{T}^* &= -\beta T^* + kVT, \\ \dot{V} &= -\gamma V + N\beta T^*, \end{aligned} \tag{1}$$

where we have relabeled many of the parameters used in [14, 12]. The functional form of f is defined differently by different authors:

1. Perelson and Nelson [14]: $f(T) = f_1(T) \equiv \delta - \alpha T + pT(1 - \frac{T}{T_{max}})$.
2. Nowak and May [12]: $f(T) = f_2(T) \equiv \delta - \alpha T$.

The parameters α, β, γ, δ, k, N, p, and $T_{\max}$ are positive.

We briefly summarize the interpretation of the different parameters in the model. Parameters α, β, and γ are the death rates of the uninfected T cells, the infected T cells, and the virus particles, respectively. k is the contact rate between uninfected T cells and virus particles. δ represents a constant production of T cells in the thymus. In the literature this process is not assumed to be constant, but to depend on virus loads. Usually δ is then replaced by a decreasing function of the concentration of virus particles; see, e.g., [15]. N is the average number of virus particles produced by an infected T cell. In the case $f = f_1$, healthy T cells are assumed to proliferate logistically, although the control mechanisms for T cell proliferation are largely unknown. The p and $T_{\max}$ are the growth rate (respectively, carrying capacity) associated with a logistic growth of uninfected T cells in the absence of virus particles, infected T-cells, and natural body sources such as the thymus. Note that simplification of the logistic term $pT(1 - (T + T^*)/T_{\max})$ to $pT(1 - T/T_{\max})$ is not always performed; see, e.g., [15]. From a mathematical point of view, this simplification leads to a competitive system, which opens up a whole arsenal of tools in the subsequent analysis. We will elaborate on this below. Another simplification, found in all models in the literature, is that (logistic) proliferation of T^* cells has been neglected.

Both Perelson and Nelson and Nowak and May ignore the loss term $-kVT$, which should appear in the V equation, i.e.,

$$\dot{V} = -\gamma V + N\beta T^* - kVT, \tag{2}$$

representing the loss of a free virus particle once it enters the target cell, arguing that this small term can be absorbed into the loss term $-\gamma V$. We will consider (1) with and without this added term.

An important feature of this model is that it ignores the reaction of the immune system, and therefore the model describes a worst-case scenario in some sense; see [12, 11] for models which include an immune response to the virus. More realistic models also include a compartment for latently infected T cells [14, 12, 15], which are capable of but not actively producing virus. A related modeling approach consists of incorporating a delay term describing the delay between the time of infection of a T cell and the time of emission of virus particles from this cell [3]. Our model also neglects virus mutations, which occur very frequently and on a fast time-scale. Some of these mutations cause drug resistance, which makes effective treatment very difficult.

System (1), with or without the $-kVT$ term in the V equation, is competitive with respect to the cone $K := \{(X, Y, Z) \in R^3 | \, X, Z \geq 0, Y \leq 0\}$—see p. 49 in [16]—and thus solutions with initial states ordered according to the order of K (i.e., their

difference is a vector in K) remain ordered for backward time. Indeed, the Jacobian matrix of system (1) (respectively of system (1) with the V-equation replaced by (2)) at an arbitrary point of R^3_+ possesses the following structures:

$$\begin{pmatrix} * & 0 & - \\ + & * & + \\ 0 & + & * \end{pmatrix}, \quad \begin{pmatrix} * & 0 & - \\ + & * & + \\ - & + & * \end{pmatrix}, \tag{3}$$

where some of the + and − signs can actually be zero for points on the boundary of R^3_+. Note that these matrices are sign-symmetric; i.e., for every $i \neq j$, the product of the (i, j)th and the (j, i)th entry of these matrices is nonnegative. The incidence graph associated with this matrix, where edges between the nodes are furnished with a + or a − sign, depending on the sign of one of the corresponding entries in the above Jacobian matrix, satisfies the following property: Every closed loop in this graph possesses an odd number of edges with − signs. This property implies that the system is competitive. Alternatively, the change of variables $T^* \to -T^*$ results in a system the Jacobian for which has nonpositive off-diagonal terms on the relevant domain and hence is competitive in the usual sense. The theory of competitive (and cooperative) systems was initiated by Hirsch in a series of six well-known papers, of which we list [5, 6, 7, 8]. Contributions to this theory were also made by Smith, e.g., [17, 18, 20]; see [16] for a review. A particular consequence of the theory of competitive systems is a generalization of the Poincaré–Bendixson theorem to dimension 3; see, e.g., [5, 6] or Theorem 4.1 in [16]: A compact limit set of a competitive system in R^3 which contains no steady states is a periodic orbit. Furthermore, a periodic orbit of a competitive system in R^3 must contain a steady state inside a certain topological closed ball on the surface of which lies the periodic orbit; see Theorem 2.4 in [17]. These results will play a major role in our analysis.

We will also exploit the "isomorphism" between system (1) with $f = f_2$ and the standard SEIR model with constant population size, analyzed by Li and Muldowney in their well-known paper [10]. Although this isomorphism breaks down when $f \neq f_2$ or when the $-kVT$ term is included in the V equation, the method used by Li and Muldowney to prove orbital asymptotic stability of any periodic orbit, and thereby to derive a contradiction to their existence, extends under suitable restrictions.

We identify a basic reproduction number R_0 for the model, which gives the number of infected T cells produced by a single infected T cell in a healthy individual. Our main results are formulated in terms of this number and extend the existing ones in the following five directions:

1. If $R_0 < 1$, we show that the virus is cleared.
2. If $R_0 > 1$, then a chronic disease steady state exists which is globally asymptotically stable under certain conditions. In particular, these conditions are satisfied for the special case $f = f_2$ using parameter values appropriate for HIV.
3. For $f = f_1$, orbitally asymptotically stable periodic orbits are shown to exist and to attract almost all solutions under suitable conditions if $R_0 > 1$. These conditions are apparently not satisfied for HIV. We note that sustained oscillations were observed from numerical simulations by Perelson, Kirschner, and de Boer [15] in a four dimensional model including a compartment of latently infected T cells.
4. Since the function f, which models healthy T cell dynamics, is poorly understood, we start analyzing our model with only minimal assumptions on f. We

show that particular choices for f may lead to different qualitative behavior. For example, for $f = f_2$ the chronic disease steady state, if it exists, is always locally asymptotically stable, while for $f = f_1$ this steady state may be unstable and sustained oscillations may occur. This sensitivity of the behavior to f, in particular, calls for a better understanding of the mechanisms of T cell proliferation.

5. Applications are made to drug therapy following Perelson and Nelson's treatment in [14].

2. Main results. We consider a model of a virus infecting a target cell population. Denoting by T the target cell and using the same symbol for its concentration in the appropriate bodily fluid, we assume that the target cell population is regulated in a healthy individual according to some dynamics given by

$$\dot{T} = f(T),$$

where f is a smooth function. We expect homeostasis to be maintained in a healthy individual with T cell levels at some positive steady state $\bar{T} > 0$. Therefore, assume that f satisfies

$$f(T) > 0,\ 0 \le T < \bar{T}, \quad f(\bar{T}) = 0, \quad f'(\bar{T}) < 0, \quad \text{and} \quad f(T) < 0,\ T > \bar{T}. \tag{4}$$

Consider an individual infected with a virus V which attacks target cells, producing productively infected cells T^*, which, in turn, produce on average N virus particles during their life spans. Following [14, 12], we obtain the following system for the dynamics of T, T^*, V:

$$\begin{aligned} \dot{T} &= f(T) - kVT, \\ \dot{T}^* &= -\beta T^* + kVT, \\ \dot{V} &= -\gamma V + N\beta T^* - ikVT, \end{aligned} \tag{5}$$

where $i = 0$ if we choose, following [14, 12], to ignore the loss of a viral particle when it enters a target cell, or $i = 1$ when we do not.

The basic reproduction number for the model is intuitively determined by considering the fate of a single productively infected cell in an otherwise healthy individual with normal target cell level $T = \bar{T}$. This infected cell produces N virions, each with life span γ^{-1}, which will infect $k\bar{T}N\gamma^{-1}$ healthy target cells. Thus we expect the amplification factor to be $k\bar{T}N\gamma^{-1}$. In fact, a local stability calculation, carried out in the proof of Lemma 3.2 below, leads to

$$R_0 = \frac{k\bar{T}(N - i)}{\gamma}, \tag{6}$$

reflecting the loss of the original productively infected cell if $i = 1$. In any case, as N is typically large, this is a minor point.

Our main result, proved in a series of results in the next section, shows that the global dynamics is largely determined by R_0.

THEOREM 2.1.

1. *For $R_0 < 1$ the only steady state is the disease-free state $E_0 \equiv (\bar{T}, 0, 0)$, and it is globally attracting; the virus is cleared.*

2. *For $R_0 > 1$, in addition to the disease-free state, which is unstable, there is a "chronic disease" steady state $E_e \equiv (T_e, T_e^*, V_e)$ given by*

$$T_e = \frac{\gamma}{k(N-i)}(\equiv \bar{T}/R_0), \quad T_e^* = \frac{\gamma V_e}{(N-i)\beta}, \quad V_e = \frac{f(T_e)}{kT_e}, \tag{7}$$

which is locally attracting if $f'(T_e) \le 0$, e.g., when $f = f_2$.
In particular, with R_0 as a bifurcation parameter, E_0 exchanges its local stability properties with E_e when R_0 passes through 1, making E_e locally attracting if $R_0 > 1$ and $R_0 - 1$ small.
The disease persists in the sense that there exist $\epsilon > 0$ and $M > 0$, independent of initial data (T_0, T_0^*, V_0) satisfying $T_0^* + V_0 > 0$, such that

$$\epsilon < T(t), T^*(t), V(t) < M$$

for all large t.
The omega limit set of every solution with initial conditions as restricted above either contains E_e or is a nontrivial periodic orbit.
If $f'(T) < 0$ for $T \in [0, \bar{T}]$, and denoting $0 < \alpha^* = -\max_{T\in[0,\bar{T}]} f'(T)$, E_e is a globally asymptotically stable steady state for system (5) with respect to initial conditions not on the T axis in case $i = 0$ or in case $i = 1$ and $kf(0) - \min(\alpha^*, \beta)\beta < 0$.
In the special case $f = f_1$, for both $i = 0, 1$ there exist parameter values for which E_e is unstable with a two dimensional unstable manifold (see Lemma 3.4). In this case, there exists an orbitally asymptotically stable periodic orbit; every solution except those with initial data on the one dimensional stable manifold of E_e or on the T axis converges to a nontrivial periodic orbit.

Observe that, as $f(T) > 0$ only if $T < \bar{T}$, the positivity of V_e requires that $T_e < \bar{T}$, or equivalently, $R_0 > 1$.

Our main result says that if a typical productively infected target cell, introduced into an otherwise healthy individual where $T = \bar{T}$, cannot replace itself by producing virus that infects at least one healthy target cell, then the virus is eventually cleared and the individual returns to the disease-free state. However, if the infected cell can replace itself, then the disease persists indefinitely into the future in the sense that the viral load is ultimately bounded from below by an initial-condition-independent value. Moreover, the omega limit set either contains the chronic disease state E_e, coinciding with it in case it is locally attracting, or is a nontrivial periodic orbit. In the latter case, the viral load and the target cell populations cycle periodically.

If $f = f_2$ and $R_0 > 1$, then $f' = -\alpha < 0$ is automatically satisfied and therefore E_e is globally asymptotically stable if $i = 0$ or if $i = 1$ and $kf_2(0) - \min(\alpha^*, \beta)\beta = k\delta - \min(\alpha, \beta)\beta < 0$. In case of HIV, $\alpha \le \beta$ is expected to hold, reflecting the fact that removal rates for healthy target cells are lower than those for infected target cells, and thus the last condition reduces to $k\delta - \alpha\beta < 0$, which is easily verified for the (biologically plausible) numerical data for HIV in [15].

In the special case $f = f_1$, E_e is asymptotically stable when $R_0 > 1$ and $R_0 - 1$ is small, but this stability can be lost for certain parameter values. In Figure 1 below, we show that periodic oscillations in the viral load and T cell populations are possible. The parameter values are not chosen to match those for a particular viral infection; they are chosen simply to establish the possibility for oscillations. As in [15], time is measured in days and T, T^*, V have units mm^{-3}. See Lemma 3.4 for more information about parameter ranges for which periodic solutions are expected.

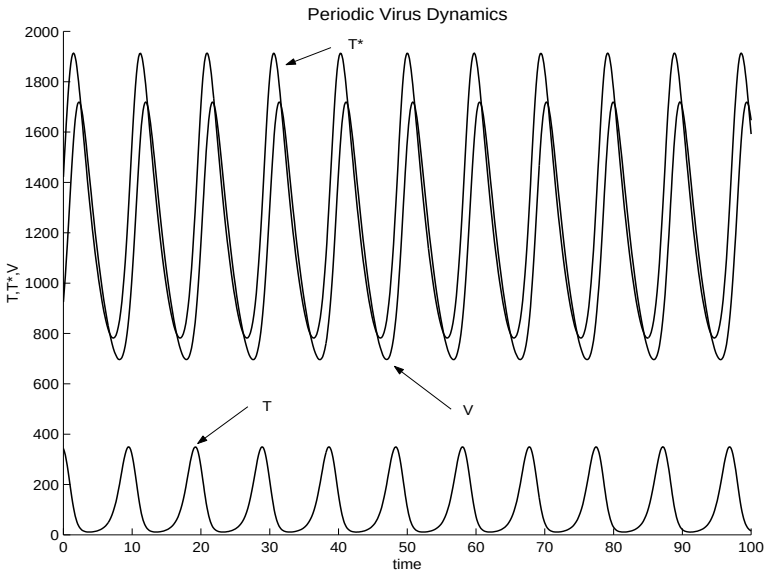

FIG. 1. *Periodic solution for* $f = f_1$. *Parameters:* $\delta = 10day^{-1}mm^{-3}, \alpha = 0.02day^{-1}$, $p = 3day^{-1}$, $T_{max} = 1500mm^{-3}$, $\beta = 0.24day^{-1}$, $\gamma = 2.4day^{-1}$, $k = 0.0027mm^3day^{-1}$, $N = 10$, *and* $i = 1$.

Our results can be used to give a mathematically rigorous justification for the plausible approximation arguments employed by Perelson and Nelson [14] to show that combination drug therapy can be effective in clearing the virus. Currently, the main drugs are RT inhibitors and protease inhibitors, and in practice, cocktails of several of these drugs have been most successful. The first type inhibits the copying of viral RNA to DNA and results in unsuccessful infection of the T cell by the virus. The second type results in virus particles that are noninfectious. Following [14], the short-term behavior after infection is given by the following system describing uninfected and infected T cells, infectious virus V_I, and noninfectious virus V_{NI}:

$$\begin{aligned} \dot{T} &= f(T) - k(1-\eta_{RT})V_I T, \\ \dot{T}^* &= -\beta T^* + k(1-\eta_{RT})V_I T, \\ \dot{V}_I &= -\gamma V_I + N\beta(1-\eta_{PI})T^* - ikV_I T, \\ \dot{V}_{NI} &= -\gamma V_{NI} + N\beta\eta_{PI}T^*, \end{aligned} \tag{8}$$

where, again, $i = 0$ corresponds to the system treated in [14], and $i = 1$ takes account of the loss of a virus particle when it enters a target cell (whether or not the virus is able to convert its RNA to DNA and insert itself in the host genome). The "effectiveness" coefficients η_{RT} for RT inhibitor and η_{PI} for protease inhibitor are assumed to lie somewhere between zero, meaning totally ineffective, and one, which represents 100% effectiveness.

Of course, the primary focus of drug therapy is on the possibility of clearing the virus. Observing that the first three equations are decoupled from the last one and that this subsystem is essentially similar to (5), we can calculate the basic reproduction number R_0^c under combination therapy by linearizing about the disease-free state E_0

to obtain

$$R_0^c = \frac{k\bar{T}[N(1-\eta_{RT})(1-\eta_{PI}) - i]}{\gamma}. \tag{9}$$

Comparing this with (6), we see that, in essence, N has been reduced to $N(1-\eta_{RT})(1-\eta_{PI})$. As i is typically much smaller than N and can be neglected, we see that the two inhibitors act in concert to reduce R_0 in (6) by the factor $(1-\eta_{RT})(1-\eta_{PI})$. If $R_0^c < 1$, the virus is cleared.

COROLLARY 2.2. *If $R_0^c < 1$, then the disease-free steady state E_0 is globally attracting. If $R_0^c > 1$, then E_0 is unstable.*

Assuming that current treatment does not allow for HIV eradication in an individual, this result implies one of the following: The efficiency of drugs is never high enough to make $R_o^c < 1$, or model (8) is not appropriate to describe HIV dynamics in a treated individual. It is argued in the recent paper by Callaway and Perelson that the first explanation is not viable. The second is adopted instead, and modified models are proposed to bring reality and theory closer to each other; see [2] for details.

3. Proofs.

3.1. Boundedness and stability of the disease-free steady state. First we show that solutions of model (5) are bounded.

LEMMA 3.1. *The closed positive orthant is positively invariant for* (5) *and there exists $M > 0$ such that all solutions satisfy $T(t), T^*(t), V(t) < M$ for all large t.*

Proof. The positive invariance of the positive orthant is trivial; we sketch the ultimate boundedness argument. Since $\dot{T} < f(T)$, we see that $T(t) < \bar{T} + 1$ for all large t, say $t > t_0$. Let $S = \max_{T \geq 0} f(T)$. Adding the first two equations gives $\dot{T} + \dot{T}^* = f(T) - \beta T^* \leq S - \beta T^*$. Let $A > 0$ be such that $\beta A > S + 1$. Then, so long as $T(t) + T^*(t) \geq A + \bar{T} + 1$ and $t > t_0$, we have $\dot{T} + \dot{T}^* < -1$. Clearly, there must exist $t_1 > t_0$ such that $T(t) + T^*(t) < A + \bar{T} + 1$ for all $t > t_1$.

The asymptotic bound for $T^*(t)$, namely, $T(t)^* \leq A + \bar{T} + 1$, together with the differential inequality $\dot{V} \leq -\gamma V + N\beta[A + \bar{T} + 1]$, which holds for large t, leads immediately to the asymptotic bound $V(t) \leq \gamma^{-1} N\beta[A + \bar{T} + 1]$. ∎

Next we consider the local stability behavior of (5) at the disease-free steady state E_0.

LEMMA 3.2. *If $R_0 < 1$, then the disease-free state E_0 is a locally asymptotically stable steady state of system* (5)*; if $R_0 > 1$, then it is unstable.*

Proof. The Jacobian matrix of the vector field corresponding to system (5), evaluated at E_0, is

$$J_0 := \begin{pmatrix} f'(\bar{T}) & 0 & -k\bar{T} \\ 0 & -\beta & k\bar{T} \\ 0 & N\beta & -\gamma - ik\bar{T} \end{pmatrix}. \tag{10}$$

Here $f'(\bar{T}) < 0$ is an eigenvalue, and the remaining eigenvalues derive from the two-by-two lower right submatrix, whose trace is negative and determinant is $\beta\gamma[1 - R_0]$. The result follows immediately. ∎

We remark that the same result holds for (8) with drug therapy, where R_0^c replaces R_0.

The following result deals with the global stability behavior of the disease-free steady state E_0.

LEMMA 3.3. *If $R_0 < 1$, then all solutions approach the disease-free state E_0.*

Proof. On consideration of the competitive vector field given by (5) on the three faces of the positive orthant, we see that any nontrivial periodic orbit must lie entirely in the interior of the positive orthant. If P denotes such a nontrivial periodic orbit, then it follows that the smallest box B containing P whose sides are parallel to the coordinate planes must also lie interior to the positive orthant. We can express B as $B = [p, q]_K$, where K denotes the cone $K \equiv \{(T, T^*, V) : T, V \geq 0, T^* \leq 0\}$. Indeed, if X^P (respectively, X_P) denotes the maximum (respectively, minimum) of coordinate $X = T, T^*, V$ on the periodic orbit P, then $p = (T_P, T^{*P}, V_P)$ and $q = (T^P, T^*_P, V^P)$. By Proposition 4.3 of [16], B must contain a steady state of (5). However, E_0 is the only steady state and $E_0 \notin B$. We conclude that no nontrivial periodic orbit exists. By the Poincaré–Bendixson theory for three dimensional competitive systems and the local stability of E_0, all solutions must approach E_0 in the limit. ∎

The same result holds for (8), with R_0^c in place of R_0. The entirely similar argument uses the fact that an endemic steady state exists only when the disease-free state is unstable ($R_0^c > 1$).

3.2. Local stability of the disease steady state. The local stability of the disease steady state is discussed next.

LEMMA 3.4. *Let $R_0 > 1$ and $f'(T_e) \leq 0$; then the nontrivial steady state $E_e \in \mathrm{int}(R^3_+)$ is locally asymptotically stable for system (5), for $i = 0, 1$. If $R_0 > 1$ and $f = f_1$, then E_e is unstable with a two dimensional unstable manifold under each of the following conditions:*

(a) *$i = 0$ with T_{max} large enough and (19) holds.*

(b) *$i = 1$ with kT_{max} large (see (20)) and p large enough.*

Proof. A calculation shows that the Jacobian matrix of the vector field corresponding to system (5), evaluated at E_e, takes the following form:

$$J_1 := \begin{pmatrix} -a & 0 & -kT_e \\ kV_e & -\beta & kT_e \\ -ikV_e & N\beta & -c \end{pmatrix}, \tag{11}$$

where

$$a := -f'(T_e) + kV_e \quad \text{and} \quad c := \gamma + ikT_e. \tag{12}$$

The characteristic equation associated with J_1 is given by

$$\lambda^3 + (a + \beta + c)\lambda^2 + [a(\beta + \gamma) - ikT_e f'(T_e)]\lambda + k\beta\gamma V_e = 0, \tag{13}$$

where we have used the expressions (6), (7) to simplify the coefficient of first and zeroth order. If $f'(T_e) \leq 0$, then it is easy to see that all coefficients are positive.

To finish the proof by means of the Routh–Hurwitz criterion, we need to show that

$$\Delta \equiv (a + \beta + c)(a(\beta + \gamma) - ikT_e f'(T_e)) - k\beta\gamma V_e \tag{14}$$

is positive. Using (12), it follows that

$$\begin{aligned} \Delta &= (-f'(T_e) + kV_e + \beta + \gamma + ikT_e)[(-f'(T_e) + kV_e)(\beta + \gamma) - ikT_e f'(T_e)] - k\beta\gamma V_e \\ &= (\beta + \gamma)^2(kV_e - f'(T_e)) - (\beta + \gamma)ikT_e f'(T_e) + (\beta + \gamma)ikT_e(kV_e - f'(T_e)) \\ &\quad - (ikT_e)^2 f'(T_e) + (\beta + \gamma)(kV_e - f'(T_e))^2 - ikT_e f'(T_e)(kV_e - f'(T_e)) \\ &\quad - k\beta\gamma V_e. \end{aligned} \tag{15}$$

If $f'(T_e) \leq 0$, then all terms in (15) are nonnegative except the last. However, the very first term $(\beta+\gamma)^2(kV_e - f'(T_e))$ can be expanded, yielding a term $2\beta\gamma kV_e$, which exceeds the last term $-k\beta\gamma V_e$. This implies that Δ is positive.

Hereafter, we consider the case in which $f = f_1$. A calculation yields

$$a = \frac{\delta}{T_e} + \frac{pT_e}{T_{max}} > 0, \tag{16}$$

and thus the coefficients of the zero and second powers of λ in the characteristic polynomial are positive. Together with the claim (which is proved below) that the Jacobian matrix has a real eigenvalue which is strictly less than the real parts of any other eigenvalue, it follows that if the Jacobian is hyperbolic and unstable, then there can be only one eigenvalue with negative real part (in fact it is negative) and two with positive real part. Further, hyperbolicity can only fail by a pair of pure imaginary eigenvalues and one negative eigenvalue.

Proof of claim. We prove that the Jacobian matrix possesses a real eigenvalue which is strictly less than the real part of the other eigenvalues. This follows from an application of the Perron–Frobenius theorem. Recall that the Perron–Frobenius theorem holds for nonnegative matrices and states that these matrices possess a real eigenvalue which is nonnegative. In addition, the modulus of every eigenvalue is not larger than this real eigenvalue. Now notice that the linear transformation $(x, y, z) \to (x, -y, z)$ puts J_1 in the following form:

$$\tilde{J}_1 := \begin{pmatrix} -a & 0 & -kT_e \\ -kV_e & -\beta & -kT_e \\ -ikV_e & -N\beta & -c \end{pmatrix}. \tag{17}$$

Of course, the eigenvalues of J_1 and $\tilde{J}_1$ are the same. Finally, observe that $-\tilde{J}_1$ is a nonnegative matrix for which the Perron–Frobenius theorem holds. The claim then follows immediately since the eigenvalues of $-\tilde{J}_1$ are the opposites of the eigenvalues of J_1.

If $i = 0$ and $f = f_1$, then all coefficients of (13) are positive as noted above. Inserting (16) and the values of V_e, T_e into (15) leads to

$$\begin{aligned} \Delta &= (\beta+\gamma)^2 a + (\beta+\gamma)a^2 - k\beta\gamma V_e \\ &= m\left(\frac{p}{T_{max}}\right)^2 + n\frac{p}{T_{max}} + q, \end{aligned} \tag{18}$$

where

$$\begin{aligned} m &= \frac{(\beta+\gamma)\gamma^2}{(Nk)^2}, \\ n &= \frac{(\beta+\gamma)^2\gamma}{Nk} + 2\delta(\beta+\gamma) - \beta\gamma T_{max} + \frac{\beta\gamma^2}{Nk}, \\ q &= (\beta+\gamma)^2\frac{Nk\delta}{\gamma} + (\beta+\gamma)\frac{(Nk\delta)^2}{\gamma^2} - \beta\delta Nk + \beta\gamma\alpha. \end{aligned}$$

Clearly, $m > 0$ and, less obviously, $q > 0$ since the first term exceeds the third in absolute value. By choosing T_{max} large, we may make $n < 0$ and as large in absolute value as we desire. In particular, if $n < 0$ and $n^2 > 4om$, then the quadratic (18) in

p/T_{max} is negative for an interval of values of p/T_{max} centered on

$$\frac{p}{T_{max}} = \frac{-n}{2m}, \tag{19}$$

ensuring that $\Delta < 0$. It follows that E_e is hyperbolic and unstable with a two dimensional unstable manifold.

If $i = 1$ and $f = f_1$, then a straightforward calculation shows that the coefficient of λ in (13) is given by

$$a_2 \equiv \frac{\gamma p}{N-1}\left[\frac{\beta+\gamma}{kT_{max}} + \frac{2\gamma}{k(N-1)T_{max}} - 1\right] + \frac{\gamma\alpha}{N-1} + \frac{(\beta+\gamma)\delta(N-1)k}{\gamma},$$

which can be negative when the term in brackets is negative, provided that p is large enough. Fixing kT_{max} so large that

$$kT_{max} > \beta + \gamma + \frac{2\gamma}{N-1} \tag{20}$$

ensures that the term in brackets is negative. Then, provided that p is large enough, it follows that E_e is hyperbolic and unstable with a two dimensional unstable manifold. □

3.3. Disease persistence. We discuss persistence of the disease next.

LEMMA 3.5. *If $R_0 > 1$, then there exists $\epsilon > 0$, independent of initial conditions satisfying $T^*(0) + V(0) > 0$, such that $\liminf_{t\to\infty} X(t) > \epsilon$ for $X = T, T^*, V$.*

Proof. The result follows from an application of Theorem 4.6 in [19], with $X_1 = \text{int}(R^3_+)$ and $X_2 = \text{bd}(R^3_+)$. This choice is in accordance with the conditions stated in this theorem. Furthermore, note that by virtue of Lemma 3.1 there exists a compact set B in which all solutions of system (5) initiated in R^3_+ ultimately enter and remain forever after. The compactness condition $(C_{4.2})$ is easily verified for this set B. Denoting the omega limit set of the solution $x(t, x_0)$ of system (5) starting in $x_0 \in R^3_+$ by $\omega(x_0)$ (which exists by Lemma 3.1), we need to determine the following set:

$$\Omega_2 = \cup_{y\in Y_2}\omega(y), \quad \text{where } Y_2 = \{x_0 \in X_2 |\, x(t, x_0) \in X_2, \forall t > 0\}. \tag{21}$$

From the system equations (5) it follows that all solutions starting in $\text{bd}(R^3_+)$ but not on the T axis leave $\text{bd}(R^3_+)$ and that the T axis is an invariant set, implying that $Y_2 = \{(T, T^*, V)^T \in \text{bd}(R^3_+) |\ T^* = V = 0\}$. Furthermore, it is easy to see that $\Omega_2 = \{E_0\}$ as all solutions initiated on the T axis converge to E_0. Then E_0 is a covering of Ω_2, which is isolated (since E_0 is a hyperbolic steady state under the assumption of the theorem) and acyclic (because there is no nontrivial solution in $\text{bd}(R^3_+)$ which links E_0 to itself). Finally, if it is shown that E_0 is a weak repeller for X_1, the proof will be done.

By definition, E_0 is a weak repeller for X_1 if for every solution starting in $x_0 \in X_1$

$$\limsup_{t\to+\infty} d(x(t, x_0), E_0) > 0. \tag{22}$$

We claim that (22) is satisfied if the following holds:

$$W^s(E_0) \cap \text{int}(R^3_+) = \emptyset, \tag{23}$$

where $W^s(E_0)$ denotes the stable manifold of E_0. To see this, suppose that (22) does not hold for some solution $x(t, x_0)$ starting in $x_0 \in X_1$. In view of the fact that the closed positive orthant is positively invariant for system (5) (recall Lemma 3.1), it follows that $\liminf_{t\to+\infty} d(x(t, x_0), E_0) = \limsup_{t\to+\infty} d(x(t, x_0), E_0) = 0$ and thus that $\lim_{t\to+\infty} x(t, x_0) = E_0$, which is clearly impossible if (23) holds.

What remains to be shown is that (23) holds. To that end, recall that the Jacobian matrix of system (5) at E_0, given in (10), is unstable if $R_0 > 1$. In particular, J_0 possesses one eigenvalue with positive real part, which we denote as λ_+, and two eigenvalues with negative real part, $f'(\bar{T})$, and an eigenvalue which we denote as λ_-. (Note that λ_- may be equal to $f'(\bar{T})$.) We proceed by determining the location of $E^s(E_0)$, the stable eigenspace of E_0. Clearly $(1, 0, 0)^T$ is an eigenvector of J_0 associated to $f'(\bar{T})$. If $\lambda_- \neq f'(\bar{T})$, then the eigenvector associated to λ_- has the following structure: $(0, p_2, p_3)^T$, where p_2 and p_3 satisfy the eigenvector equation

$$\begin{pmatrix} -\beta & k\bar{T} \\ N\beta & -\gamma - ik\bar{T} \end{pmatrix} \begin{pmatrix} p_2 \\ p_3 \end{pmatrix} = \lambda_- \begin{pmatrix} p_2 \\ p_3 \end{pmatrix}. \tag{24}$$

If $\lambda_- = f'(\bar{T})$, then λ_- is a repeated eigenvalue, and an associated generalized eigenvector will possess the following structure: $(*, p_2, p_3)^T$, where the value of $*$ is irrelevant for what follows and p_2 and p_3 also satisfy (24).

We claim that in both cases (i.e., $\lambda_- \neq f'(\bar{T})$ and $\lambda_- = f'(\bar{T})$) the vector $(p_2, p_3)^T \notin R^2_+$. The matrix in (24) is an irreducible Metzler matrix. A Metzler matrix is a matrix with nonnegative off-diagonal entries. For the definition of an irreducible matrix, see [4]. Observe that adding a sufficiently large positive multiple of the identity matrix to the matrix in (24) results in a nonnegative irreducible matrix for which the Perron–Frobenius theorem [4] holds. Consequently, the matrix in (24) possesses a simple real eigenvalue which is larger than the real part of any other eigenvalue, also called the *dominant eigenvalue*. Clearly, the dominant eigenvalue here is λ_+. But the Perron–Frobenius theorem also implies that every eigenvector that is not associated with the dominant eigenvalue does not belong to the closed positive orthant. Applied here, this means that $(p_2, p_3) \notin R^2_+$. Consequently, $E_s(E_0) \cap \mathrm{int}(R^3_+) = \emptyset$, and therefore also $W^s(E_0) \cap \mathrm{int}(R^3_+) = \emptyset$, which concludes the proof. □

3.4. Oscillations. Lemma 3.4 provides sufficient conditions for the Jacobian at E_e to have two eigenvalues with positive real part and one negative eigenvalue. The dynamical consequences of this are described in the following result.

LEMMA 3.6. *If $R_0 > 1$, the omega limit set of a solution which is not initiated on the T axis either contains E_e or is a nontrivial periodic orbit. If $R_0 > 1$ and if the Jacobian matrix at E_e has two eigenvalues with positive real part and one negative eigenvalue, then there exists an orbitally asymptotically stable periodic orbit. Every solution except those with initial data on the one dimensional stable manifold of E_e or on the T axis approaches a nontrivial periodic orbit.*

Proof. For $R_0 > 1$ it follows from the persistence result in Lemma 3.5 that the omega limit set of a solution which is not initiated on the T axis cannot contain a point on the T axis. Since there is only one steady state E^e which does not belong to the T axis, the first statement of the theorem follows from the generalized Poincaré–Bendixson theorem for competitive systems in dimension 3.

The assertions regarding the existence of an orbitally asymptotically stable periodic orbit follow from Theorem 1.2 in [20] and the fact that nonlinearities in (5) are analytic. In order to apply that result, we take the domain for (5) to be the interior of the positive orthant, in which the only steady state is E_e. Lemmas 3.1 and 3.5

imply that the dissipativity hypothesis of Theorem 1.2 is satisfied. The negativity of the Jacobian determinant, also required for Theorem 1.2, follows from our hypotheses concerning the eigenvalues. The assertion that suitably restricted forward orbits approach a periodic orbit follows from Theorem 4.2 in [16]. That result is stated for systems which are competitive in the traditional sense and so it applies to (5) since it can be transformed to a system which is competitive in the traditional sense. See also the remarks following Theorem 4.2, where it is noted that the second hypothesis of Theorem 4.2 holds if the Jacobian matrix is irreducible. □

3.5. Global asymptotic stability of the disease steady state. Finally we provide sufficient conditions preventing oscillations and leading to a globally asymptotically stable disease steady state.

LEMMA 3.7. *Suppose that* $R_0 > 1$, $f'(T) < 0$ *for* $T \in [0, \bar{T}]$, *and denote* $0 < \alpha^* = -\max_{T\in[0,\bar{T}]} f'(T)$. *If* $i = 0$ *or if* $i = 1$ *and* $kf(0) - \min(\alpha^*, \beta)\beta < 0$, *then* E_e *is a globally asymptotically stable steady state for system* (5) *with respect to initial conditions not on the* T *axis.*

Proof. The proof is based on an extension of the Poincaré–Bendixson theorem for the class of three dimensional competitive systems [16] and a powerful theory of second compound equations to prove asymptotic orbital stability of periodic solutions; see [10] and references cited therein. We do not wish to repeat the details of a precise proof here, because many of the arguments are the same as in [10], where a global stability result for a related epidemiological model is proved. Instead we provide only a sketch of the proof and go into details only where our proof is different. Under the assumptions of this lemma, system (5) possesses a steady state $E_e \in \text{int}(R^3_+)$, which is unique in $\text{int}(R^3_+)$. Moreover, from the proof of Lemma 3.5 it follows that the omega limit sets of solutions not initiated on the T axis are in $\text{int}(R^3_+)$. We claim that the only possible omega limit sets of solutions of system (5) are E_e or nontrivial periodic orbits. Indeed, if an omega limit set of a solution does not possess E_e, then it cannot contain another steady state (E_e is the unique steady state in $\text{int}(R^3_+)$), and thus it must be a nontrivial periodic orbit according to the extension of the Poincaré–Bendixson theorem for competitive systems. On the other hand, if an omega limit set does contain E_e, it *is* $\{E_e\}$, because E_e is a locally asymptotically stable steady state of system (5) according to Lemma 3.4 (notice that the condition needed to apply this Lemma, $f'(T_e) \le 0$, is satisfied here because $T_e = \bar{T}/R_0 < \bar{T}$ and $f' < 0$ in $[0, \bar{T}]$ by assumption), which establishes the claim. Finally we will show below that if system (5) possesses a nontrivial periodic solution, then this solution must be asymptotically orbitally stable. This fact will imply that E_e is a globally asymptotically stable steady state of system (5) with respect to initial conditions not on the T axis, which concludes the proof of this theorem. A proof of this implication can be found in [10]. The argument is that if E_e would not be globally asymptotically stable, then there would have to be a nontrivial periodic solution in $\text{int}(R^3_+)$. But it can then be shown that the region of attraction of E_e would have nonempty intersection with the region of attraction of the periodic solution, a contradiction. We prove the following: If system (5) possesses a nontrivial period solution, then this solution is asymptotically orbitally stable. Denote the periodic solution by $p(t) \equiv (p_1(t), p_2(t), p_3(t))^T$ and suppose that its minimal period is $\omega > 0$. Recall that from the proof of Lemma 3.1

$$0 \le p_1(t) \le \bar{T} \qquad \forall t \in [0, \omega]. \tag{25}$$

To establish asymptotic orbital stability of a periodic solution, we resort to the so-called method of the second compound equation; see [10] and references cited therein.

The second compound equation is the following periodic linear system:

$$\dot{z} = \frac{\partial f^{[2]}}{\partial x}(p(t))z, \tag{26}$$

where $z = (z_1, z_2, z_3)^T$ and $\frac{\partial f^{[2]}}{\partial x}$ is derived from the Jacobian matrix of system (5) and defined as follows:

$$\begin{aligned}\frac{\partial f^{[2]}}{\partial x} &:= \begin{pmatrix} j_{11}+j_{22} & j_{23} & -j_{13} \\ j_{32} & j_{11}+j_{33} & j_{12} \\ -j_{31} & j_{21} & j_{22}+j_{33} \end{pmatrix} \\ &= \begin{pmatrix} f'(T)-\beta-kV & kT & kT \\ N\beta & f'(T)-\gamma-k(iT+V) & 0 \\ ikV & kV & -\beta-\gamma-ikT \end{pmatrix}, \end{aligned} \tag{27}$$

where j_{kl} is the (k, l)th entry of the Jacobian matrix associated with system (5). The importance of the second compound equation is that if system (26) is asymptotically stable, then the periodic solution $p(t)$ is asymptotically orbitally stable for system (5); see [10]. We will show that the function

$$V(z_1, z_2, z_3; p(t)) := \sup\left\{|z_1|, \frac{p_2(t)}{p_3(t)}(|z_2|+|z_3|)\right\} \tag{28}$$

is a Lyapunov function for system (26). This function is positive, but not differentiable everywhere. Fortunately, this lack of differentiability can be remedied by using the right derivative of V, denoted as $D_+V(t)$. We have

$$D_+(|z_1(t)|) \le -(-f'(p_1(t)) + \beta + kp_3(t)).|z_1(t)| + k\frac{p_1(t)p_3(t)}{p_2(t)}.\frac{p_2(t)}{p_3(t)}(|z_2(t)|+|z_3(t)|) \tag{29}$$

and

$$\begin{aligned} D_+\left(\frac{p_2(t)}{p_3(t)}(|z_2(t)|+|z_3(t)|)\right) &= \left(\frac{\dot{p}_2(t)}{p_2(t)} - \frac{\dot{p}_3(t)}{p_3(t)}\right).\frac{p_2(t)}{p_3(t)}(|z_2(t)|+|z_3(t)|) \\ &\quad + \frac{p_2(t)}{p_3(t)}D_+(|z_2(t)|+|z_3(t)|) \\ &\le \left(\frac{p_2(t)}{p_3(t)}(N\beta + ikp_3(t))\right).|z_1(t)| \\ &\quad + \left(\frac{\dot{p}_2(t)}{p_2(t)} - \frac{\dot{p}_3(t)}{p_3(t)} - \gamma - ikp_1(t)\right).\frac{p_2(t)}{p_3(t)}(|z_2(t)|+|z_3(t)|) \\ &\quad - \frac{p_2(t)}{p_3(t)}(-f'(p_1(t))|z_2(t)| + \beta|z_3(t)|) \\ &\le \left(\frac{p_2(t)}{p_3(t)}(N\beta + ikp_3(t))\right).|z_1(t)| \\ &\quad + \left(\frac{\dot{p}_2(t)}{p_2(t)} - \frac{\dot{p}_3(t)}{p_3(t)} - \gamma - ikp_1(t) \right. \\ &\qquad \left. - \min(\alpha^*, \beta)\right).\frac{p_2(t)}{p_3(t)}(|z_2(t)|+|z_3(t)|), \end{aligned}$$

where the last inequality was obtained using the definition of α^* and (25).

Defining the following functions,

$$g_1(t) = -(-f'(p_1(t)) + \beta + kp_3(t)) + k\frac{p_1(t)p_3(t)}{p_2(t)}$$

$$= -(-f'(p_1(t)) + kp_3(t)) + \frac{\dot{p}_2(t)}{p_2(t)}, \tag{30}$$

$$g_2(t) = \frac{p_2(t)}{p_3(t)}(N\beta + ikp_3(t)) + \frac{\dot{p}_2(t)}{p_2(t)} - \frac{\dot{p}_3(t)}{p_3(t)} - \gamma - ikp_1(t) - \min(\alpha^*, \beta)$$

$$= ikp_2(t) + \frac{\dot{p}_2(t)}{p_2(t)} - \min(\alpha^*, \beta), \tag{31}$$

where the second equalities in (30) and (31) stem from the fact that $p(t)$ satisfies the system equations (5), we obtain that

$$D_+V(t) \le \sup(g_1(t), g_2(t))V(t). \tag{32}$$

Using the definition of α^* and (25), it follows from (30) that $g_1(t) \le -\alpha^* + \dot{p}_2(t)/p_2(t)$, and thus that $g_1(t) \le g_2(t)$. Then (32) can be rewritten as

$$D_+V(t) \le g_2(t)V(t). \tag{33}$$

We claim that the following holds:

$$\int_0^\omega g_2(t)dt < 0. \tag{34}$$

If this is established, it will follow from (33) that V is a Lyapunov function for system (26), and this will conclude the proof of the theorem.

(a) When $i = 0$, (34) is immediate from (31).

(b) When $i = 1$, using the fact that $p(t)$ is a periodic solution of (5), we see that

$$\int_0^\omega \beta p_2(t)dt = \int_0^\omega kp_3(t)p_1(t)dt = \int_0^\omega f(p_1(t))dt \le f(0)\omega$$

because, by assumption, $f'(T) < 0$ for all $T \in [0, \bar{T}]$ and since (25) holds. Consequently,

$$\int_0^\omega g_2(t)dt = \int_0^\omega [kp_2(t) - \min(\alpha^*, \beta)]dt \le \left[k\frac{f(0)}{\beta} - \min(\alpha^*, \beta)\right]\omega, \tag{35}$$

and it follows, under the assumption that $kf(0) - \min(\alpha^*, \beta)\beta < 0$, that (34) holds as claimed. □

HIGH FREQUENCY BEHAVIOR OF THE FOCUSING NONLINEAR SCHRÖDINGER EQUATION WITH RANDOM INHOMOGENEITIES*

ALBERT FANNJIANG†, SHI JIN‡, AND GEORGE PAPANICOLAOU§

Abstract. We consider the effect of random inhomogeneities on the focusing singularity of the nonlinear Schrödinger equation in three dimensions, in the high frequency limit. After giving a phase space formulation of the high frequency limit using the Wigner distribution, we derive a nonlinear diffusion equation for the evolution of the wave energy density when random inhomogeneities are present. We show that this equation is linearly stable even in the case of a focusing nonlinearity, provided that it is not too strong. The linear stability condition is related to the variance identity for the nonlinear Schrödinger equation in an unexpected way. We carry out extensive numerical computations to get a better understanding of the interaction between the focusing nonlinearity and the randomness.

Key words. focusing NLS, semiclassical limit, Wigner transformation, random media, diffusion approximation

1. Introduction.

The nonlinear Schrödinger equation (NLS)

$$i\frac{\partial\phi}{\partial t}+\frac{1}{2}\Delta\phi-\beta|\phi|^2\phi=0, \qquad \phi(0,\mathbf{x})=\phi_0(\mathbf{x}), \tag{1}$$

with $\mathbf{x}$ in three dimensions, arises as the subsonic limit of the Zakharov model of Langmuir equations in plasma physics [20] and in many other contexts. The NLS (1) is in dimensionless form, with β a parameter that measures the strength of the nonlinearity relative to wave dispersion. When $\beta<0$ the nonlinearity is focusing, and when $\beta>0$ it is defocusing. An important property of the NLS is that, in three dimensions, the solution in the focusing case may develop a singularity at some finite time. This result is based on the existence of two invariants with respect to time: the *mass*

$$M=\int_{R^3}|\phi(t,\mathbf{x})|^2\,d\mathbf{x} \tag{2}$$

and the *energy*

$$H=\int_{R^3}\left(\frac{1}{2}|\nabla\phi(t,\mathbf{x})|^2+\frac{1}{2}\beta|\phi(t,\mathbf{x})|^4\right)d\mathbf{x}, \tag{3}$$

together with the *variance identity*

$$\frac{d^2}{dt^2}\int_{R^3}|\mathbf{x}|^2|\phi(t,\mathbf{x})|^2\,d\mathbf{x} = 4H + \beta\int_{R^3}|\phi(t,\mathbf{x})|^4\,d\mathbf{x}. \tag{4}$$

In the focusing case $\beta < 0$ and with a negative energy $H < 0$, the solution cannot remain bounded for all time. More precisely, it follows from the variance identity and the uncertainty inequality that the L^2 norm of the gradient of the solution blows up in finite time [6]. Many other properties of the NLS can be found in [18].

The goal of this paper is to investigate the effect of random inhomogeneities on the focusing NLS in the *high frequency* regime. In the high frequency limit the dimensionless time and propagation distance are long compared to the scale of variation of the potential $V(\mathbf{x})$. To make this precise we introduce slow time and space variables $t \to t/\epsilon$, $\mathbf{x} \to \mathbf{x}/\epsilon$, with ϵ a small parameter, and the scaled wave function $\phi^\epsilon(t,\mathbf{x}) = \phi(t/\epsilon, \mathbf{x}/\epsilon)$, which satisfies the scaled Schrödinger equation

$$\begin{aligned} &i\epsilon\phi^\epsilon_t + \frac{\epsilon^2}{2}\Delta\phi^\epsilon - V(t,\mathbf{x})\phi^\epsilon = 0,\\ &V(t,\mathbf{x}) = \beta|\phi(t,\mathbf{x})|^2 + V_0(\mathbf{x}). \end{aligned} \tag{5}$$

In the absence of the regularizing effect of the random inhomogeneities, the initial value problem for the focusing NLS is, in this regime, catastrophically ill-posed, even if the original NLS does not blow up. The random inhomogeneities are modeled by a potential that is a zero mean, stationary random function with correlation length comparable to the wavelength and with small variance. It takes the form of $v_0(\mathbf{x}) = \sqrt{\epsilon}\,V_1(\frac{\mathbf{x}}{\epsilon})$ since the wavelength is of order ϵ. Here $V(t,\mathbf{x})$ is the slowly varying background, without the nonlinear part, and $V_1(\mathbf{y})$ is a mean zero, stationary random function with correlation length of order one. This scaling allows the random potential to interact fully with the waves. We shall also assume that the fluctuations are statistically homogeneous and isotropic so that

$$\langle V_1(\mathbf{x})V_1(\mathbf{y})\rangle = R(|\mathbf{x}-\mathbf{y}|), \tag{6}$$

where $\langle,\rangle$ denotes statistical averaging and $R(|\mathbf{x}|)$ is the covariance of random fluctuations. The power spectrum of the fluctuations is defined by

$$\hat{R}(\mathbf{k}) = \left(\frac{1}{2\pi}\right)^3\int e^{i\mathbf{k}\cdot\mathbf{x}}R(\mathbf{x})\,d\mathbf{x}. \tag{7}$$

When (6) holds, the fluctuations are isotropic and $\hat{R}$ is a function only of $|\mathbf{k}|$. Because of the statistical homogeneity, the Fourier transform of the random potential V_1 is a generalized random process with orthogonal increments

$$\langle\hat{V}_1(\mathbf{p})\hat{V}_1(\mathbf{q})\rangle = \hat{R}(\mathbf{p})\delta(\mathbf{p}+\mathbf{q}). \tag{8}$$

Using the Wigner phase space form of the Schrödinger equation, we derive a nonlinear mean field transport approximation, in the high frequency and weak fluctuation limit. When, moreover, the transport mean free path is small, this nonlinear phase space transport equation can be further approximated by a nonlinear degenerate diffusion equation (e.g., (76)). This is the main result of this paper, and it captures in a precise way the interaction between the focusing nonlinearity and the random medium,

in the high frequency limit. A linear stability analysis of this diffusion equation reveals in a simplified but physically clear way the form of the nonlinearity-randomness interaction. We find that the condition that the linearized diffusion equation be stable reduces to the *positivity of the right-hand side of the variance identity* (4) *of the NLS*, in the high frequency limit (e.g., (94)). This is a surprising result because it is precisely the opposite of this condition, a negative right-hand side for (4), which produces a focusing singularity in NLS (1). We see that this condition, or rather its opposite

$$4H + \beta \int_{R^3} |\phi(t, \mathbf{x})|^4 \, d\mathbf{x} > 0, \tag{9}$$

becomes a *stability* condition, in a well defined high frequency regime, provided that the focusing mechanism is regularized by random inhomogeneities.

The paper is organized as follows. In section 2 we briefly review the nonlinear high frequency limit in its usual form, and in section 3 we reconsider that limit in its phase space form, using the Wigner distribution. In section 4 the random initial data is discussed. In section 5 we introduce random inhomogeneities and describe the mean field transport approximation for the Wigner distribution. In section 6 we rewrite the nonlinear transport equation in parity form, introducing the odd and even parts of the Wigner distribution, and in section 7 we derive the diffusion approximation in the small mean free path limit. The linearized stability condition for this degenerate nonlinear diffusion equation is obtained in section 8.

In section 9 we introduce a numerical scheme for the mean field nonlinear transport equation and present the results of several numerical calculations. In section 10 we do the same for the degenerate nonlinear diffusion equation for the wave energy density. Our numerical results indicate that in the high frequency regime the random inhomogeneities slow down the propagation of wave energy, in both the linear and defocusing cases. In the focusing case, the randomness is able to interact fully with the focusing nonlinearity as long as the nonlinearity is not too strong. In the diffusive regime, the randomness interacts fully with the focusing or defocusing nonlinearity, in a diffusive way, provided that the stability condition (94) holds. We end with section 11, which contains a brief summary and conclusions.

2. Nonlinear high frequency limit. We briefly review the high frequency asymptotic analysis for solutions of (1) with oscillatory initial data. The potential has the nonlinear part from the NLS and a linear part that we may add since it does not affect the analysis as long as it does not depend on ϵ. In the usual high frequency approximation [11] we consider initial data of the form

$$\phi^\epsilon(0, \mathbf{x}) = e^{iS_0(\mathbf{x})/\epsilon} A_0(\mathbf{x}) \tag{10}$$

with a smooth real valued initial phase function $S_0(\mathbf{x})$ and a smooth compactly supported complex valued initial amplitude $A_0(\mathbf{x})$. We then look for an asymptotic solution of (5) in the same form as the initial data (10), with evolved phase and amplitude

$$\phi^\epsilon(t, \mathbf{x}) \sim e^{iS(t,\mathbf{x})/\epsilon} A(t, \mathbf{x}). \tag{11}$$

Inserting this form into (5) and equating powers of ϵ, we get approximate evolution equations for the phase and amplitude

$$S_t + \frac{1}{2}|\nabla S|^2 + V(t, \mathbf{x}) = 0, \qquad S(0, \mathbf{x}) = S_0(\mathbf{x}) \tag{12}$$

and

$$(|A|^2)_t + \nabla \cdot (|A|^2 \nabla S) = 0, \qquad |A(0,\mathbf{x})|^2 = |A_0(\mathbf{x})|^2. \tag{13}$$

The phase equation (12) is the *eiconal* and the amplitude equation (13) the *transport* equation. The terminology for the latter is standard in the high frequency approximation but should not be confused with the radiative transport equation that will be derived later. These equations can be rewritten using the high frequency dispersion relation ω of the Schrödinger equation

$$\omega(t,\mathbf{x},\mathbf{k}) = \frac{1}{2}|\mathbf{k}|^2 + V(t,\mathbf{x}). \tag{14}$$

The energy in the high frequency regime is obtained by using the ansatz (11) in the energy (3) so that for small ϵ

$$H \approx \int_{R^3} \left(\frac{1}{2}|\nabla S|^2 + \frac{\beta}{2}|A|^2 + V_0 \right) |A|^2 \, d\mathbf{x}. \tag{15}$$

The potential is $V(t,\mathbf{x}) = \beta|A(t,\mathbf{x})|^2 + V_0(\mathbf{x})$. Even when it does not depend on the amplitude $|A|$, in the linear case, the eiconal equation (12) is nonlinear, and its solution exists in general only up to some time t^* that depends on the initial phase $S_0(\mathbf{x})$ and $V_0(\mathbf{x})$. This solution can be constructed by the method of characteristics, and singularities form when these characteristics (rays) cross. The eiconal and the transport equations are decoupled in the linear case.

To see more clearly the form of the eiconal and transport equations in the NLS case, we let $\rho = |A|^2$, $\mathbf{u} = \nabla S$, take the gradient of (12), with only the nonlinear potential $V(t,\mathbf{x}) = \beta|A(t,\mathbf{x})|^2$, and rewrite this differentiated eiconal and (13) in conservation law form:

$$\rho_t + \nabla \cdot (\rho \mathbf{u}) = 0, \tag{16}$$

$$(\rho \mathbf{u})_t + \nabla \cdot (\rho \mathbf{u}\mathbf{u}) + \nabla p(\rho) = 0, \tag{17}$$

where

$$p(\rho) = \frac{\beta}{2}\rho^2. \tag{18}$$

Now the eiconal and transport equations are fully coupled. When $\beta > 0$, this system of conservation laws are the isentropic gas dynamics equations, with equation of state given by (18) (γ-law gas with $\gamma = 2$). It is hyperbolic, and the solution may become discontinuous at a finite time. The velocity $\mathbf{u}$ is irrotational since it is a gradient, so $\nabla \times \mathbf{u} = 0$. The eiconal equation (12) is the Bernoulli form of the momentum conservation law (17) for time dependent and irrotational flows. Another form of the momentum conservation law is

$$\rho(\mathbf{u}_t + \mathbf{u} \cdot \nabla \mathbf{u}) + \nabla p = 0, \tag{19}$$

and the conservation of energy is exactly as in (15), with $V_0 = 0$, which we rewrite in the fluid variables

$$\frac{\partial}{\partial t} H = \frac{\partial}{\partial t} \int_{R^3} \left(\frac{1}{2}\rho|\mathbf{u}|^2 + p \right) d\mathbf{x} = 0. \tag{20}$$

In the one-dimensional defocusing case, the nonlinear high frequency limit was analyzed in detail in [9, 10]. In the higher-dimensional defocusing case, mathematical results are available only for the more regular Schrödinger–Poisson high frequency equations [5, 14, 7, 21]. When $\beta < 0$, the system of conservation laws (16)–(17) has complex characteristics, and the initial value problem is catastrophically ill-posed. This is the case even if the original NLS does not have solutions that blow up, when the Hamiltonian $H > 0$, for example. The high frequency limit for the focusing NLS has been studied only in the one-dimensional case with analytical initial data [12].

3. The Wigner distribution. An essential step in deriving phase space transport equations from wave equations is the introduction of the Wigner distribution [19, 15]. We begin with a brief review of some basic facts and then give the phase space form of the high frequency limit.

For any smooth function ϕ, rapidly decaying at infinity, the Wigner distribution is defined by

$$W(\mathbf{x},\mathbf{k}) = \left(\frac{1}{2\pi}\right)^3 \int_{R^3} e^{i\mathbf{k}\cdot\mathbf{y}} \phi\left(\mathbf{x}-\frac{\mathbf{y}}{2}\right) \overline{\phi}\left(\mathbf{x}+\frac{\mathbf{y}}{2}\right) d\mathbf{y}, \tag{21}$$

where $\bar{\phi}$ is the complex conjugate of ϕ. The Wigner distribution is defined on phase space and has many important properties. It is real, and its $\mathbf{k}$-integral is the modulus square of the function ϕ,

$$\int_{R^3} W(\mathbf{x},\mathbf{k})\, d\mathbf{k} = |\phi(\mathbf{x})|^2, \tag{22}$$

so we may think of $W(\mathbf{x},\mathbf{k})$ as wave number–resolved mass density. This is not quite right though, because $W(\mathbf{x},\mathbf{k})$ is not always positive, but it does become positive in the high frequency limit. The energy flux is expressed through $W(\mathbf{x},\mathbf{k})$ by

$$\mathcal{F} = \frac{1}{2i}(\phi\nabla\overline{\phi} - \overline{\phi}\nabla\phi) = \int_{R^3} \mathbf{k} W(\mathbf{x},\mathbf{k})\, d\mathbf{k}, \tag{23}$$

and its second moment in $\mathbf{k}$ is

$$\int |\mathbf{k}|^2 W(\mathbf{x},\mathbf{k})\, d\mathbf{k} = |\nabla\phi(\mathbf{x})|^2. \tag{24}$$

The Wigner distribution possesses an important $\mathbf{x}$-to-$\mathbf{k}$ duality given by the alternative definition

$$W(\mathbf{x},\mathbf{k}) = \int e^{i\mathbf{p}\cdot\mathbf{x}} \hat{\phi}\left(-\mathbf{k}-\frac{\mathbf{p}}{2}\right) \overline{\hat{\phi}\left(-\mathbf{k}+\frac{\mathbf{p}}{2}\right)}\, d\mathbf{p}, \tag{25}$$

where $\hat{\phi}$ is the Fourier transform of ϕ,

$$\hat{\phi}(\mathbf{k}) = \frac{1}{(2\pi)^3} \int e^{i\mathbf{k}\cdot\mathbf{x}} \phi(\mathbf{x})\, d\mathbf{x}. \tag{26}$$

These properties make the Wigner distribution a good quantity for analyzing the evolution of wave energy in phase space.

Given a wave function of the form (11), that is, an inhomogeneous wave with phase $S(t,\mathbf{x})/\epsilon$, its scaled Wigner distribution has the weak limit

$$W^\epsilon(\mathbf{x},\mathbf{k}) = \frac{1}{\epsilon^3} W\left(\mathbf{x},\frac{\mathbf{k}}{\epsilon}\right) \to |A(\mathbf{x})|^2 \delta(\mathbf{k}-\nabla S(\mathbf{x})), \tag{27}$$

as a generalized function, as $\epsilon \to 0$. This suggests that the correct scaling for the high frequency limit is

$$W^\epsilon(t,\mathbf{x},\mathbf{k}) = \left(\frac{1}{2\pi}\right)^3 \int e^{i\mathbf{k}\cdot\mathbf{y}} \phi^\epsilon\left(t,\mathbf{x}-\frac{\epsilon\mathbf{y}}{2}\right)\overline{\phi^\epsilon\left(t,\mathbf{x}+\frac{\epsilon\mathbf{y}}{2}\right)}\,d\mathbf{y}, \tag{28}$$

where ϕ^ϵ satisfies (5). From (27) we conclude that, as $\epsilon \to 0$, the scaled Wigner distribution of the solution $\phi^\epsilon(t,\mathbf{x})$ of (5) with initial data (10) is given by

$$W(t,\mathbf{x},\mathbf{k}) = |A(t,\mathbf{x})|^2 \delta(\mathbf{k}-\nabla S(t,\mathbf{x})), \tag{29}$$

where $S(t,\mathbf{x})$ and $A(t,\mathbf{x})$ are solutions of the eiconal and transport equations (12) and (13), respectively.

We will now sketch the derivation of the high frequency approximation of the scaled Wigner distribution directly from the Schrödinger equation. Let us assume that the initial Wigner distribution $W_0^\epsilon(\mathbf{x},\mathbf{k})$ tends to a smooth function $W_0(\mathbf{x},\mathbf{k})$ that has compact support. Note that this is not the case with the Wigner function corresponding to $\phi^\epsilon(0,\mathbf{x})$ given by (10), but it may be the case for random initial wave functions. We explain this briefly in the next section. The evolution equation for $W^\epsilon(t,\mathbf{x},\mathbf{k})$ corresponding to the Schrödinger equation (5) is the *Wigner equation*

$$W_t^\epsilon + \mathbf{k}\cdot\nabla_{\mathbf{x}} W^\epsilon + \mathcal{L}^\epsilon W^\epsilon = 0. \tag{30}$$

Here the operator $\mathcal{L}^\epsilon$ is defined by

$$\mathcal{L}^\epsilon Z(\mathbf{x},\mathbf{k}) = i\int_{R^3} e^{-i\mathbf{p}\cdot\mathbf{x}}\hat{V}(\mathbf{p})\frac{1}{\epsilon}\left[Z\left(\mathbf{x},\mathbf{k}+\frac{\epsilon\mathbf{p}}{2}\right) - Z\left(\mathbf{x},\mathbf{k}-\frac{\epsilon\mathbf{p}}{2}\right)\right]d\mathbf{p} \tag{31}$$

on any smooth function Z in phase space. The Fourier transform of V is $\hat{V}$.

From (31) we can easily find the limit of the operator $\mathcal{L}^\epsilon$ as $\epsilon \to 0$, in the linear case where the potential V does not depend on the solution. For any smooth and decaying function $Z(\mathbf{x},\mathbf{k})$ we have

$$\mathcal{L}^\epsilon Z(\mathbf{x},\mathbf{k}) \to -\nabla_{\mathbf{x}} V\cdot\nabla_{\mathbf{k}} Z. \tag{32}$$

Thus, the limit Wigner equation is the *Liouville equation* in phase space,

$$W_t + \mathbf{k}\cdot\nabla_{\mathbf{x}} W - \nabla V\cdot\nabla_{\mathbf{k}} W = 0, \tag{33}$$

with the initial condition $W(0,\mathbf{x},\mathbf{k}) = W_0(\mathbf{x},\mathbf{k})$. When the initial Wigner distribution has the form

$$W_0(\mathbf{x},\mathbf{k}) = |A_0(\mathbf{x})|^2\delta(\mathbf{k}-\nabla S_0(\mathbf{x})), \tag{34}$$

then it is easy to see that, up to the time of singularity formation, the solution of (33) is given by

$$W(t,\mathbf{x},\mathbf{k}) = |A(t,\mathbf{x})|^2\delta(\mathbf{k}-\nabla S(t,\mathbf{x})), \tag{35}$$

where $S(t,\mathbf{x})$ and $A(t,\mathbf{x})$ are solutions of the eiconal and transport equations (12) and (13), respectively. If the $W_0(\mathbf{x},\mathbf{k})$ and $V(\mathbf{x})$ are smooth, so will be the solution of (32), in the linear case.

In the nonlinear case the potential depends on the solution. The Liouville, or *Liouville–Vlasov*, equation is a nonlinear partial differential equation since

$$V = \beta\rho(t,\mathbf{x}) + V_0(\mathbf{x}) \quad \text{and} \quad \rho = \int_{R^3} W\, d\mathbf{k}. \tag{36}$$

For the initial conditions (34) it is better to use the fluid variables

$$\rho(t,\mathbf{x}) = |A(t,\mathbf{x})|^2 \quad \text{and} \quad \rho(t,\mathbf{x})\mathbf{u}(t,\mathbf{x}) = \rho(t,\mathbf{x})\nabla S(t,\mathbf{x}) = \int_{R^3} \mathbf{k} W\, d\mathbf{k}, \tag{37}$$

which solve the conservation laws (16)–(17). In the defocusing case, up to the time of shock formation the solution to the Liouville–Vlasov equation is given by

$$W(t,\mathbf{x},\mathbf{k}) = \rho(t,\mathbf{x})\delta(\mathbf{k} - \mathbf{u}(t,\mathbf{x})). \tag{38}$$

We see, therefore, that from the Wigner distribution we can recover all the information about the high frequency approximation, when it makes sense. In addition, it provides flexibility to deal with initial data that are not of the form (34).

4. Random initial data. Let us consider initial wave functions of the form $\phi_0(\frac{\mathbf{x}}{\epsilon},\mathbf{x})$, where $\phi_0(\mathbf{y},\mathbf{x})$ is a stationary random field in $\mathbf{y}$ for each $\mathbf{x}$ with mean zero and covariance

$$\langle \phi_0(\mathbf{y}_1,\mathbf{x}_1)\bar{\phi}_0(\mathbf{y}_2,\mathbf{x}_2)\rangle = R_0(\mathbf{y}_1 - \mathbf{y}_2, \mathbf{x}_1, \mathbf{x}_2). \tag{39}$$

Then with

$$W_0^\epsilon(\mathbf{x},\mathbf{k}) = \frac{1}{(2\pi)^3}\int e^{i\mathbf{k}\cdot\mathbf{y}}\phi_0\left(\frac{\mathbf{x}}{\epsilon} - \frac{\mathbf{y}}{2}, \mathbf{x} - \frac{\epsilon\mathbf{y}}{2}\right)\bar{\phi}_0\left(\frac{\mathbf{x}}{\epsilon} + \frac{\mathbf{y}}{2}, \mathbf{x} + \frac{\epsilon\mathbf{y}}{2}\right) d\mathbf{y} \tag{40}$$

we have that

$$\langle W_0^\epsilon(\mathbf{x},\mathbf{k})\rangle \to \hat{R}_0(\mathbf{k},\mathbf{x},\mathbf{x}) \tag{41}$$

pointwise in $\mathbf{k}$ and $\mathbf{x}$. Here $\hat{R}_0(\mathbf{k},\mathbf{x},\mathbf{x})$ is the diagonal part of the power spectral density of R_0, that is, its Fourier transform in $\mathbf{y}$ with $\mathbf{x}_1 = \mathbf{x}_2 = \mathbf{x}$. We also have that for any test function $\psi(\mathbf{x},\mathbf{k})$

$$\int W_0^\epsilon(\mathbf{x},\mathbf{k})\psi(\mathbf{x},\mathbf{k})\, d\mathbf{x}\, d\mathbf{k} \to \int \hat{R}_0(\mathbf{k},\mathbf{x},\mathbf{x})\psi(\mathbf{x},\mathbf{k})\, d\mathbf{x}\, d\mathbf{k} \tag{42}$$

in probability as $\epsilon \to 0$. This means that W_0^ϵ converges to $\hat{R}_0$ weakly in probability. However, it does not converge in mean square; that is, the mean fluctuation $\langle ||W_0^\epsilon - \hat{R}_0||_{L^2}^2\rangle$ does not go to zero. This can be seen from the fact that $\langle ||W_0^\epsilon||_{L^2}^2\rangle$ does not tend to $||\hat{R}_0||_{L^2}^2$.

From the above example we see how smooth and compactly supported initial Wigner functions can arise. For linear waves in random media there are no additional complications when dealing with random initial data that are statistically independent from the medium. The situation is much more complicated in the case of nonlinear waves and essentially unexplored mathematically.

5. High frequency limit with random inhomogeneities. We now consider small random perturbations of the potential $V(t,\mathbf{x})$. It is well known that, in one space dimension, linear waves in a random medium get localized even when the random perturbations are small [16], so our analysis is restricted to three dimensions. The two-dimensional case is difficult because the mean field approximation that we use in three dimensions is most likely incorrect.

We consider the linear case first. We assume that the correlation length of the random perturbation is of the same order as the wavelength, so the potential has the form $V(t,\mathbf{x}) + \sqrt{\epsilon}\, V_1(\frac{\mathbf{x}}{\epsilon})$ since the wavelength is of order ϵ. Here $V(t,\mathbf{x})$ is the slowly varying background, without the nonlinear part, and $V_1(\mathbf{y})$ is a mean zero, stationary random function with correlation length of order one. This scaling allows the random potential to interact fully with the waves. We shall also assume that the fluctuations are statistically homogeneous and isotropic so that

$$\langle V_1(\mathbf{x}) V_1(\mathbf{y})\rangle = R(|\mathbf{x}-\mathbf{y}|), \tag{43}$$

where $\langle , \rangle$ denotes statistical averaging and $R(|\mathbf{x}|)$ is the covariance of random fluctuations. The power spectrum of the fluctuations is defined by

$$\hat{R}(\mathbf{k}) = \left(\frac{1}{2\pi}\right)^3 \int e^{i\mathbf{k}\cdot\mathbf{x}} R(\mathbf{x})\, d\mathbf{x}. \tag{44}$$

When (43) holds, the fluctuations are isotropic and $\hat{R}$ is a function only of $|\mathbf{k}|$. Because of the statistical homogeneity, the Fourier transform of the random potential V_1 is a generalized random process with orthogonal increments

$$\langle \hat{V}_1(\mathbf{p}) \hat{V}_1(\mathbf{q})\rangle = \hat{R}(\mathbf{p})\delta(\mathbf{p}+\mathbf{q}). \tag{45}$$

If the amplitude of these fluctuations is strong, then scattering will dominate and waves will be localized [4], at least in the linear case. This means that we cannot assume that the fluctuations in the random potential $V_1(\mathbf{y})$ are large. If the random fluctuations are too weak, they will not affect energy transport at all. In order that the scattering produced by the random potential and the influence of the slowly varying background affect energy transport in comparable ways, the fluctuations in the random potential must be of order $\sqrt{\epsilon}$. This makes the transport mean free time, the reciprocal of Σ below, of order one and independent of ϵ. The scaled equation (5) becomes

$$\begin{aligned} &i\epsilon \frac{\partial \phi^\epsilon}{\partial t} + \frac{\epsilon^2}{2}\Delta\phi^\epsilon - \left(V(t,\mathbf{x}) + \sqrt{\epsilon}\, V_1\left(\frac{\mathbf{x}}{\epsilon}\right)\right)\phi^\epsilon = 0, \\ &\phi^\epsilon(0,\mathbf{x}) = \phi_0\left(\frac{\mathbf{x}}{\epsilon},\mathbf{x}\right). \end{aligned} \tag{46}$$

To describe the passage from (46) to the transport equation in its simplest form, we will set $V(t,\mathbf{x}) = 0$. A smooth and ϵ independent potential $V(t,\mathbf{x})$ that is not zero will not change the scattering terms in the phase space transport equation. It will affect only the Liouville part in the linear case. Now (30) for W^ϵ has the form

$$\frac{\partial W^\epsilon}{\partial t} + \mathbf{k}\cdot\nabla_{\mathbf{x}} W^\epsilon + \frac{1}{\sqrt{\epsilon}}\mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W^\epsilon = 0, \tag{47}$$

where the operator $\mathcal{L}_{\frac{\mathbf{x}}{\epsilon}}$, a rescaled form of (31), is given by

$$\mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} Z(\mathbf{x},\mathbf{k}) = i\int e^{-i\mathbf{p}\cdot\mathbf{x}/\epsilon}\hat{V}_1(\mathbf{p})\left(Z\left(\mathbf{x},\mathbf{k}+\frac{\mathbf{p}}{2}\right) - Z\left(\mathbf{x},\mathbf{k}-\frac{\mathbf{p}}{2}\right)\right) d\mathbf{p}. \tag{48}$$

The behavior of this operator as $\epsilon \to 0$ is very different from (32) when V_1 is slowly varying. We can find the correct results by a formal multiscale analysis (see [15]).

Let $\mathbf{y} = \mathbf{x}/\epsilon$ be a fast space variable (on the scale of the wavelength), and introduce an expansion of W^ϵ of the form

$$W^\epsilon(t,\mathbf{x},\mathbf{k}) = W(t,\mathbf{x},\mathbf{k}) + \epsilon^{1/2}W^{(1)}(t,\mathbf{x},\mathbf{y},\mathbf{k}) + \epsilon W^{(2)}(t,\mathbf{x},\mathbf{y},\mathbf{k}) + \cdots, \tag{49}$$

with $\mathbf{y} = \mathbf{x}/\epsilon$ on the right. We assume that the leading term does not depend on the fast scale and that the initial Wigner distribution $W^\epsilon(0,\mathbf{x},\mathbf{k})$ tends to a smooth function $W_0(\mathbf{x},\mathbf{k})$, which is decaying fast enough at infinity. Then the average of the Wigner distribution, $\langle W^\epsilon \rangle$ is close to W, which satisfies the transport equation

$$\begin{aligned} &\frac{\partial W}{\partial t} + \mathbf{k}\cdot\nabla_{\mathbf{x}}W - \nabla_{\mathbf{x}}V\cdot\nabla_{\mathbf{k}}W, = \overline{\mathcal{L}}W, \\ &W(0,\mathbf{x},\mathbf{k}) = W_0(\mathbf{x},\mathbf{k}), \end{aligned} \tag{50}$$

where we have inserted on the left the term due to the potential V in (36). The linear operator $\overline{\mathcal{L}}$ is given by

$$\overline{\mathcal{L}}W(\mathbf{x},\mathbf{k}) = 4\pi \int_{R^3} \hat{R}(\mathbf{p}-\mathbf{k})\delta(\mathbf{k}^2-\mathbf{p}^2)[W(\mathbf{x},\mathbf{p}) - W(\mathbf{x},\mathbf{k})]\, d\mathbf{p}. \tag{51}$$

The left-hand side of (50) has precisely the form (33) of the Liouville equation. The right-hand side is the linear transport operator with differential scattering cross section $\sigma(\mathbf{k},\mathbf{k}')$ given by

$$\sigma(\mathbf{k},\mathbf{p}) = 4\pi\hat{R}(\mathbf{p}-\mathbf{k})\delta(\mathbf{k}^2-\mathbf{p}^2), \tag{52}$$

and total scattering cross section $\Sigma(\mathbf{k})$ given by

$$\Sigma(\mathbf{k}) = 4\pi \int_{R^3} \hat{R}(\mathbf{k}-\mathbf{p})\delta(\mathbf{k}^2-\mathbf{p}^2)\, d\mathbf{p}. \tag{53}$$

Note also that the transport equation (50) has two important properties. First, the total energy

$$E(t) = \iint_{R^3\times R^3} W(t,\mathbf{x},\mathbf{k})\, d\mathbf{k}\, d\mathbf{x} \tag{54}$$

is conserved, and second, the positivity of the solution $W(t,\mathbf{x},\mathbf{k})$ is preserved; that is, if the initial Wigner distribution $W_0(\mathbf{x},\mathbf{k})$ is nonnegative, then $W(t,\mathbf{x},\mathbf{k}) \geq 0$ for $t > 0$.

The physical meaning of the transport approximation for the linear Schrödinger equation with random potential is as follows. The characteristic wavelength introduced by the initial data is comparable with the scale of the inhomogeneities of the random potential. When we observe the wave energy far from the source and after a long time, it appears to evolve in phase space according to a radiative transport equation with a mean free path that is comparable to the distance from the source of the waves. This kind of behavior is captured with the ϵ scaling that we have introduced. The scaling of the size of the fluctuations by $\sqrt{\epsilon}$ is introduced so that the mean free path between macroscopic scatterings is comparable to the propagation distance.

The mathematical analysis of the passage from waves to transport in the linear case is considered in [2, 3, 8, 17]. The paper of Ho, Landau, and Wilkins [8] has

extensive references, and the paper of Erdös and Yau [3] gives a result that is global in time.

In the nonlinear case the potential $V(t,\mathbf{x}) = V^\epsilon(t,\mathbf{x})$ in (46) depends on the solution. In terms of the Wigner function, the potential is $\beta\rho^\epsilon(t,\mathbf{x}) + V_0(\mathbf{x})$ with $\rho^\epsilon = \int W^\epsilon\, d\mathbf{k}$. We will make a *mean field* hypothesis here, which says that in the transport limit $\epsilon \to 0$ the nonlinear potential keeps its form in the transport equation (50). This amounts to assuming that $\rho^\epsilon \to \rho$ in a strong sense. Some evidence for this is provided in the appendix. However, the mean field hypothesis is very difficult to prove. It is also difficult to test numerically, since the fact that we are in three dimensions is expected to play an important role. There are no mathematical results that deal with the mean field approximation.

5.1. A linear stability analysis. Let $\boldsymbol{\xi}$ be the unit vector in the direction of $\mathbf{k}$, i.e., $\mathbf{k} = k\boldsymbol{\xi}$, where $k = |\mathbf{k}|$. For simplicity, in the remainder of the paper we assume that the power spectral density of the inhomogeneities is

$$\hat{R} = \frac{\alpha}{2\pi}$$

with α a constant. Then (50)–(51) can be written as

$$\partial_t W + \mathbf{k}\cdot\nabla_{\mathbf{x}} W - \nabla_{\mathbf{x}} V\cdot\nabla_{\mathbf{k}} W = \alpha \int_{|\boldsymbol{\xi}'|=1} W(t,\mathbf{x},k,\boldsymbol{\xi}')\, d\boldsymbol{\xi}' - 4\pi\alpha W, \tag{55}$$

with

$$V = \beta\rho \quad \text{and} \quad \rho = \int_{R^3} W\, d\mathbf{k}. \tag{56}$$

The initial condition (34) is now rewritten as

$$W(0,\mathbf{x},k,\boldsymbol{\xi}) = \frac{1}{4\pi k^2}\delta(k - |\nabla S_0(\mathbf{x})|)\delta\left(\boldsymbol{\xi} - \frac{\nabla S_0(\mathbf{x})}{|\nabla S_0(\mathbf{x})|}\right)|A_0(\mathbf{x})|^2. \tag{57}$$

In order to carry out a linear stability analysis we first take the first two moments of (55). Multiplying (55) by 1 and $\mathbf{k}$, respectively, and integrating over $\mathbf{k}$, we have

$$\partial_t\rho + \nabla_{\mathbf{x}}\cdot\rho\mathbf{u} = 0, \tag{58}$$

$$\partial_t\rho\mathbf{u} + \nabla_{\mathbf{x}}\cdot\int \mathbf{k}\mathbf{k}W\, d\mathbf{k} - \int \mathbf{k}\nabla_{\mathbf{x}} V\cdot\nabla_{\mathbf{k}} W\, d\mathbf{k} = -4\pi\alpha\rho\mathbf{u}. \tag{59}$$

Thus the random inhomogeneity contributes a damping effect. Of course, these equations are not closed since high moments are undefined. However, they can be used in the linear stability analysis.

First we note that

$$\rho_0 \equiv \bar{\varrho}, \quad u_0 \equiv 0, \qquad W_0 \equiv \delta(\mathbf{k})\bar{\varrho},$$

with $\bar{\varrho}$ a constant, is a solution of the moment equations (58)–(59). We look for a solution near these constant states, in the form

$$\rho = \overline{\rho} + \rho^{(1)}, \qquad \mathbf{u} = \mathbf{u}^{(1)}, \tag{60}$$

where

$$\rho^{(1)} \ll \overline{\rho}, \qquad |\mathbf{u}^{(1)}| \ll 1. \tag{61}$$

We also set

$$W = \delta(\mathbf{k} - \mathbf{u})\rho. \tag{62}$$

With this ansatz, the moment equations can be closed to give

$$\partial_t \rho^{(1)} + \nabla_{\mathbf{x}} \cdot \rho \mathbf{u}^{(1)} = 0, \tag{63}$$

$$\partial_t \rho \mathbf{u}^{(1)} + \nabla_{\mathbf{x}} \cdot \mathbf{u}^{(1)} \mathbf{u}^{(1)} \rho + \beta \rho \nabla_{\mathbf{x}} \rho = -4\pi\alpha\rho\mathbf{u}^{(1)}. \tag{64}$$

Using (61) and ignoring higher order terms, we obtain the leading order equations

$$\partial_t \rho^{(1)} + \overline{\rho} \nabla_{\mathbf{x}} \cdot \mathbf{u}^{(1)} = 0, \tag{65}$$

$$\partial_t \mathbf{u}^{(1)} + \beta \nabla_{\mathbf{x}} \rho^{(1)} = -4\pi\alpha\mathbf{u}^{(1)}. \tag{66}$$

This system is hyperbolic if $\beta \geq 0$ and so is stable in the linear and defocusing cases. However, in the focusing case $\beta < 0$, the system is elliptic. A dispersion relation analysis for (65)–(66) shows that there are three negative eigenvalues

$$-1, \quad -1, \quad -2\pi\alpha - \sqrt{4\pi^2\alpha^2 - \beta\overline{\rho}|\boldsymbol{\eta}|^2},$$

where $\boldsymbol{\eta}$ is the wave number, and a fourth one

$$-2\pi\alpha + \sqrt{4\pi^2\alpha^2 - \beta\overline{\rho}|\boldsymbol{\eta}|^2}.$$

This last one is always negative when $\beta > 0$, and zero when $\beta = 0$, suggesting stability in the defocusing and linear cases. It is always negative when $\beta < 0$. The focusing case near uniform solutions with $\mathbf{u} = 0$ is, therefore, linearly unstable.

This means that the only hope for linear stability in the focusing case is to have a nonzero $\mathbf{u}$. This is consistent with the linear stability of the diffusion approximation in the focusing case, which will be derived next.

6. The parity formulation. It is convenient to use the parity formulation of the transport equation (50). This allows us to obtain the diffusion approximation in a transparent way.

To get the parity form of (55), we split it into two equations, one for $\mathbf{k}$ and one for $-\mathbf{k}$:

$$\begin{aligned}\partial_t W(\mathbf{k}) + \mathbf{k} \cdot \nabla_{\mathbf{x}} W(\mathbf{k}) - \nabla_{\mathbf{x}} V \cdot \nabla_{\mathbf{k}} W(\mathbf{k}) \\ = \alpha \int_{|\boldsymbol{\xi}'|=1} W(t, \mathbf{x}, k, \boldsymbol{\xi}')\, d\boldsymbol{\xi}' - 4\pi\alpha W(\mathbf{k}),\end{aligned} \tag{67}$$

$$\begin{aligned}\partial_t W(-\mathbf{k}) - \mathbf{k} \cdot \nabla_{\mathbf{x}} W(-\mathbf{k}) + \nabla_{\mathbf{x}} V \cdot \nabla_{\mathbf{k}} W(-\mathbf{k}) \\ = \alpha \int_{|\boldsymbol{\xi}'|=1} W(t, \mathbf{x}, k, \boldsymbol{\xi}')\, d\boldsymbol{\xi}' - 4\pi\alpha W(-\mathbf{k}).\end{aligned} \tag{68}$$

Define the even and odd parities as

$$W^+ = \frac{1}{2}[W(t, \mathbf{x}, \mathbf{k}) + W(t, \mathbf{x}, -\mathbf{k})],$$

$$W^- = \frac{1}{2}[W(t, \mathbf{x}, \mathbf{k}) - W(t, \mathbf{x}, -\mathbf{k})].$$

Adding and subtracting (67) and (68) gives the parity form of the transport equation

$$\partial_t W^+ + \mathbf{k}\cdot\nabla_{\mathbf{x}} W^- - \nabla_{\mathbf{x}} V\cdot\nabla_{\mathbf{k}} W^- = \alpha \int_{|\boldsymbol{\xi}'|=1} W^+(t,\mathbf{x},k,\boldsymbol{\xi}')\,d\boldsymbol{\xi}' - 4\pi\alpha W^+, \tag{69}$$

$$\partial_t W^- + \mathbf{k}\cdot\nabla_{\mathbf{x}} W^+ - \nabla_{\mathbf{x}} V\cdot\nabla_{\mathbf{k}} W^+ = -4\pi\alpha W^-. \tag{70}$$

The parity formulation has the advantage that the diffusion approximation can be derived easily, as will be shown in the next section.

7. Nonlinear diffusion limit. The diffusion approximation is obtained from the parity equations (69) and (70) in the small mean free time limit $1/\alpha \to 0$, and with the time stretched $t \to \alpha t$. Then (69) implies that for α large

$$W^+(t,\mathbf{x},\mathbf{k}) = \frac{1}{4\pi}\int_{|\boldsymbol{\xi}'|=1} W^+(t,\mathbf{x},k,\boldsymbol{\xi}')\,d\boldsymbol{\xi}' \equiv W_0(t,\mathbf{x},k), \tag{71}$$

and so the leading term of W^+ is independent of $\boldsymbol{\xi}$. From (70) we have that

$$W^- = -\frac{1}{4\pi\alpha}(\mathbf{k}\cdot\nabla_{\mathbf{x}} W_0 - \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}} W_0), \tag{72}$$

where

$$\rho_0(t,\mathbf{x}) = \int k^2 W_0\,dk$$

and where the time derivative can be neglected on the long time scale. Using (72) in (69), we get

$$\begin{aligned}\partial_t W_0 - \mathbf{k}\cdot\nabla_{\mathbf{x}}\frac{1}{4\pi\alpha}&(\mathbf{k}\cdot\nabla_{\mathbf{x}} W_0 - \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}} W_0)\\ &+ \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}}\frac{1}{4\pi\alpha}(\mathbf{k}\cdot\nabla_{\mathbf{x}} W_0 - \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}} W_0) = 0.\end{aligned} \tag{73}$$

Taking the $\boldsymbol{\xi}$ average $\frac{1}{4\pi}\int_{|\boldsymbol{\xi}|=1}\cdot\,d\boldsymbol{\xi}$ in (73) yields

$$\begin{aligned}\frac{\partial W_0}{\partial t} &- \frac{k^2}{4\pi}\frac{1}{4\pi\alpha}\int_{|\boldsymbol{\xi}|=1}\boldsymbol{\xi}\cdot\nabla_{\mathbf{x}}(\boldsymbol{\xi}\cdot\nabla_{\mathbf{x}} W_0)\,d\boldsymbol{\xi} + \beta\frac{1}{4\pi}\frac{k}{4\pi\alpha}\int_{|\boldsymbol{\xi}|=1}\boldsymbol{\xi}\cdot\nabla_{\mathbf{x}}(\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}} W_0)\,d\boldsymbol{\xi}\\ &+ \beta\frac{1}{4\pi\alpha}\nabla_{\mathbf{x}}\rho_0\cdot\frac{1}{4\pi}\int_{|\boldsymbol{\xi}|=1}\nabla_{\mathbf{k}}(\mathbf{k}\cdot\nabla_{\mathbf{x}} W_0)\,d\boldsymbol{\xi}\\ &- \frac{\beta^2}{4\pi}\nabla_{\mathbf{x}}\rho_0\cdot\frac{1}{4\pi\alpha}\int_{|\boldsymbol{\xi}|=1}\nabla_{\mathbf{k}}(\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{k}} W_0)\,d\boldsymbol{\xi} = 0.\end{aligned} \tag{74}$$

By straightforward manipulations, (74) becomes

$$\begin{aligned}\alpha\frac{\partial W_0}{\partial t} &- \frac{1}{12\pi}k^2\Delta W_0 + \beta\frac{k}{12\pi}\nabla_{\mathbf{x}}\cdot\left(\frac{\partial W_0}{\partial k}\nabla_{\mathbf{x}}\rho_0\right)\\ &+ \beta\frac{1}{12\pi}\nabla_{\mathbf{x}}\rho_0\cdot\left[\nabla_{\mathbf{x}}\frac{\partial}{\partial k}(kW_0) + 2\nabla_{\mathbf{x}} W_0\right]\\ &- \frac{\beta^2}{12\pi}|\nabla_{\mathbf{x}}\rho_0|^2\left[\frac{\partial^2 W_0}{\partial k^2} + \frac{2}{k}\frac{\partial W_0}{\partial k}\right] = 0.\end{aligned} \tag{75}$$

This is the diffusion approximation of the transport equation (55) and can also be written in the form

$$\alpha\frac{\partial W_0}{\partial t} - \frac{1}{12\pi}\begin{pmatrix} \nabla_{\mathbf{x}} \\ \frac{\partial}{\partial k} \end{pmatrix}\cdot\begin{pmatrix} k^2 I_3 & -\beta k\nabla_{\mathbf{x}}\rho_0 \\ -\beta k\,(\nabla_{\mathbf{x}}\rho_0)^T & \beta^2|\nabla_{\mathbf{x}}\rho_0|^2 \end{pmatrix}\begin{pmatrix} \nabla_{\mathbf{x}} W_0 \\ \frac{\partial W_0}{\partial k} \end{pmatrix}$$
$$+\beta\frac{1}{6\pi}\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{x}}W_0 - \frac{\beta^2}{6\pi k}|\nabla_{\mathbf{x}}\rho_0|^2\frac{\partial W_0}{\partial k} = 0. \tag{76}$$

Here I_3 is the 3×3 identity matrix. The diffusion coefficient matrix in (76) is

$$D = \frac{1}{12\pi}\begin{pmatrix} k^2 I_3 & -\beta k\nabla_{\mathbf{x}}\rho_0 \\ -\beta k(\nabla_{\mathbf{x}}\rho_0)^T & \beta^2|\nabla_{\mathbf{x}}\rho_0|^2 \end{pmatrix}, \tag{77}$$

and it is symmetric and nonnegative semidefinite. However, since $\det D = 0$, the diffusion matrix is degenerate. This is because the scattering operator in (51) is concentrated on the unit sphere. The derivation of the nonlinear diffusion equation (76) is the main result of this paper.

The diffusion equation (75) or (76) can be rewritten into a very simple form (see [1]). Let

$$e = \frac{k^2}{2}, \qquad \tilde{\nabla} = \nabla_{\mathbf{x}} - \beta\nabla_{\mathbf{x}}\rho\frac{\partial}{\partial e}; \tag{78}$$

then (75) becomes

$$12\pi\alpha\frac{\partial W_0}{\partial t} - \tilde{\nabla}\cdot(2e\tilde{\nabla}W_0) + \beta\nabla_{\mathbf{x}}\rho_0\cdot\tilde{\nabla}W_0 = 0. \tag{79}$$

We can get equations for moments of W_0 which, however, are not closed. First we multiply (75) by k^2, integrate over k, and then integrate by parts to get

$$12\pi\alpha\frac{\partial\rho_0}{\partial t} - 3\beta\nabla_{\mathbf{x}}\cdot(\rho_0\nabla_{\mathbf{x}}\rho_0) = -\Delta\int k^4 W_0\,dk. \tag{80}$$

This gives mass conservation

$$\frac{\partial}{\partial t}\int\rho_0(t,\mathbf{x})\,d\mathbf{x} = 0.$$

Let u_0 be given by

$$u_0 = \frac{1}{\rho_0}\int k^3 W_0(t,\mathbf{x}\,k)\,dk. \tag{81}$$

To get an equation for the second moment, we multiply (75) by k^3 and integrate over k. After integrating by parts, we obtain

$$\frac{\partial\rho_0 u_0}{\partial t} - \Delta\int k^5 W_0\,dk - 4\beta\nabla_{\mathbf{x}}\cdot(\rho_0 u_0\nabla_{\mathbf{x}}\rho_0) - \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{x}}\rho_0 u_0$$
$$-2\beta^2|\nabla_{\mathbf{x}}\rho_0|^2\int kW_0\,dk = 0. \tag{82}$$

Note that (80) and (82) are not closed since they involve higher k moments of W_0.

As in the usual diffusion theory of the transport equation, an initial layer analysis gives the initial condition for W_0 as

$$W_0(0,\mathbf{x},k) = \frac{1}{k^2}\delta(k - |\nabla S_0(\mathbf{x})|)\,|A_0(\mathbf{x})|^2. \tag{83}$$

8. Linear stability condition for the nonlinear diffusion equation. In this section we carry out a linear stability analysis on the diffusion equation (75). This stability analysis gives a simplified but clear picture of how the nonlinear and random effects interact.

We use the moment equations (80) and (82) for the stability analysis. First we note that

$$\rho_0 \equiv \bar{\varrho}, \quad u_0 \equiv \overline{u}, \qquad W_0 \equiv \frac{1}{k^2}\delta(k-\overline{u})\bar{\varrho},$$

where $\bar{\varrho}, \overline{u}$ are constants, is a solution of the moment equations (80) and (82). We look for a solution near these constant states, in the form

$$\rho_0 = \overline{\rho} + \rho^{(1)}, \qquad u_0 = \overline{u} + u^{(1)}, \tag{84}$$

where

$$\rho^{(1)} \ll \overline{\rho}, \qquad u^{(1)} \ll \overline{u}.$$

We also set

$$W_0 = \frac{1}{k^2}\delta(k-u_0)\rho_0. \tag{85}$$

With this ansatz, the moment equations can be closed to give

$$12\pi\alpha\frac{\partial\rho_0}{\partial t} - \Delta\rho_0 u_0^2 - 3\beta\nabla_{\mathbf{x}}\cdot(\rho_0\nabla_{\mathbf{x}}\rho_0) = 0, \tag{86}$$

$$\begin{aligned} 12\pi\alpha\frac{\partial\rho_0 u_0}{\partial t} &- \Delta\rho_0 u_0^3 - 4\beta\nabla_{\mathbf{x}}\cdot(\rho_0 u_0\nabla_{\mathbf{x}}\rho_0) \\ &- \beta\nabla_{\mathbf{x}}\rho_0\cdot\nabla_{\mathbf{x}}\rho_0 u_0 - 2\beta^2|\nabla_{\mathbf{x}}\rho_0|^2\frac{\rho_0}{u_0} = 0. \end{aligned} \tag{87}$$

With the linearization (84), the last two terms in (87) are insignificant and so will be neglected. The moment equations thus become

$$12\pi\alpha\frac{\partial\rho_0}{\partial t} - \Delta\rho_0 u_0^2 - 3\beta\nabla_{\mathbf{x}}\cdot(\rho_0\nabla_{\mathbf{x}}\rho_0) = 0, \tag{88}$$

$$12\pi\alpha\frac{\partial\rho_0 u_0}{\partial t} - \Delta\rho_0 u_0^3 - 4\beta\nabla_{\mathbf{x}}\cdot(\rho_0 u_0\nabla_{\mathbf{x}}\rho_0) = 0. \tag{89}$$

We now do the linearization (84) and, keeping only the leading terms, obtain the coupled system of linear diffusion equations

$$12\pi\alpha\frac{\partial\rho_1}{\partial t} = (\overline{u}^2 + 3\beta\bar{\varrho})\Delta\rho_1 + 2\overline{\varrho u}\Delta u_1, \tag{90}$$

$$12\pi\alpha\frac{\partial u_1}{\partial t} = \beta\overline{u}\Delta\rho_1 + \overline{u}^2\Delta u_1. \tag{91}$$

8.1. Linear stability from the diffusion matrix. The diffusion coefficient matrix of (90) and (91),

$$A = \begin{pmatrix} \overline{u}^2 + 3\beta\bar{\varrho} & 2\overline{\varrho u} \\ \beta\overline{u} & \overline{u}^2 \end{pmatrix}, \tag{92}$$

has two eigenvalues:

$$\lambda_\pm = \overline{u}^2 + \frac{3}{2}\beta\bar{\varrho} \pm \frac{1}{2}\sqrt{8\beta\overline{\varrho u}^2 + 9\beta^2\overline{u}^2}. \tag{93}$$

Clearly, $Re(\lambda_\pm) > 0$ if and only if

$$\overline{u}^2 + \frac{3}{2}\beta\bar{\varrho} > 0. \tag{94}$$

This means that the right-hand side of the variance identity (4) in the high frequency limit, where H has the form (15) or (20) in the $\rho, \mathbf{u}$ variables, must be positive for stability. Therefore, even in the focusing case $\beta < 0$, the initial value problems for the linear diffusion equations (90) and (91) are well posed as long as (94) is satisfied.

It is surprising that the stability condition (94) does not depend on the strength α of the random inhomogeneities, although the diffusion rate does. It is also surprising that the right-hand side of the variance identity comes up as a *stability* condition, while in the analysis of the NLS equation it is used to get focusing solutions (instability) when (9) is negative.

8.2. Linear stability for the energy. We now study the stability of (90)–(91) in the energy norm. In the linear case when $\beta = 0$, it is obvious that (90)–(91) is stable. We analyze the defocusing and focusing cases separately.

In the defocusing case, $\beta > 0$, we multiply (90) by $\beta\rho$, and (91) by $\bar{\varrho}u$, and then add the resulting equations and integrate over $\mathbf{x}$. Upon integration by parts, we obtain

$$\begin{aligned}
12\pi\alpha\frac{\partial}{\partial t}\int\left(\frac{\beta}{2}\rho^2 + \frac{1}{2}\bar{\varrho}u^2\right)d\mathbf{x} &= -\int \beta(\overline{u}^2 + 3\beta\bar{\varrho})|\nabla\rho|^2 + 3\beta\overline{\varrho u}\nabla\rho\cdot\nabla u + \overline{\varrho u}^2|\nabla u|^2\,d\mathbf{x} \\
&= -\int \beta\left(\overline{u}^2 + \frac{3}{4}\beta\bar{\varrho}\right)|\nabla\rho|^2\,d\mathbf{x} \\
&\quad -\int \frac{9}{4}\beta^2\bar{\varrho}|\nabla\rho|^2 + 3\beta\overline{\varrho u}\nabla\rho\cdot\nabla u + \overline{\varrho u}^2|\nabla u|^2\,d\mathbf{x} \\
&= -\int \beta\left(\overline{u}^2 + \frac{3}{4}\beta\bar{\varrho}\right)|\nabla\rho|^2\,d\mathbf{x} - \int \bar{\varrho}\left|\frac{3}{2}\beta\nabla\rho + \overline{u}\nabla u\right|^2 d\mathbf{x} \\
&\le 0. \qquad (95)
\end{aligned}$$

Thus, in the defocusing case the system (90)–(91) is always stable.

In the focusing case, $\beta < 0$, we again multiply (90) by $\beta\rho$, and (91) by $2\bar{\varrho}u$. We then *subtract* the first equation from the second one. By integrating over $\mathbf{x}$ and integrating by parts, we obtain

$$12\pi\alpha\frac{\partial}{\partial t}\int\left(\bar{\varrho}u^2 - \frac{\beta}{2}\rho^2\right)d\mathbf{x} = -2\overline{\varrho u}^2\int|\nabla u|^2\,d\mathbf{x} + \beta\int(\overline{u}^2 + 3\beta\bar{\varrho})|\nabla\rho|^2\,d\mathbf{x}. \tag{96}$$

Clearly, a sufficient condition for the above term to be nonpositive is

$$\overline{u}^2 + 3\beta\bar{\varrho} \ge 0. \tag{97}$$

This means that the coefficient of $\Delta\rho$ in (90) should be nonnegative, which means that the diagonal entries of the matrix A should be nonnegative.

9. Numerical solution of the nonlinear transport equation. In this section we will present some numerical results for the nonlinear transport equation (55)–(56). In order to have good resolution, we assume spherical symmetry and use a second order nonoscillatory upwind scheme [13]. The solution depends only on $r = |\mathbf{x}|$, k, and $\theta = \cos^{-1} \frac{\mathbf{x}\cdot\mathbf{k}}{rk}$, the angle between $\mathbf{x}$ and $\mathbf{k}$. In these variables, (55) and (56) become

$$\begin{aligned} &\frac{\partial W}{\partial t} + \mathrm{k}\cos\theta \frac{\partial W}{\partial r} - \frac{k}{r}\sin\theta \frac{\partial W}{\partial \theta} - \beta \frac{\partial V}{\partial r}\left(\cos\theta \frac{\partial W}{\partial k} - \frac{\sin\theta}{k}\frac{\partial W}{\partial \theta}\right) \\ &\qquad = 2\pi\alpha \int_0^\pi W \sin\theta \, d\theta - 4\pi\alpha W, \\ &V = V(\rho), \qquad \rho = \int_0^\infty \int_0^{2\pi} W k^2 \sin\theta \, dk \, d\theta. \end{aligned} \tag{98}$$

In terms of the direction cosine $-1 \le \mu = \cos\theta \le 1$, (98) can be rewritten in conservation form as

$$\begin{aligned} &\frac{\partial W}{\partial t} + \frac{\partial}{\partial r}(\mu k W) + \frac{\partial}{\partial k}\left(-\beta\mu \frac{\partial V}{\partial r} W\right) + \frac{\partial}{\partial \mu}\left[(1-\mu^2)\left(\frac{k}{r} - \frac{\beta}{k}\frac{\partial V}{\partial r}\right) W\right] \\ &\qquad = 2\pi\alpha \int_{-1}^1 W(t,r,k,\mu') \, d\mu' - 4\pi\alpha W, \\ &V = V(\rho), \qquad \rho = \int_0^\infty \int_{-1}^1 W k^2 \, dk \, d\mu, \end{aligned} \tag{99}$$

where $W = W(t, r, k, \mu)$. The initial condition for (99) is

$$W(0, r, k, \mu) = \frac{1}{k^2}\delta(k - u_0(r))\delta(\mu - a_0(r))\rho_0(r). \tag{100}$$

9.1. The numerical method. We will use a second order upwind scheme for spatial discretizations. This is a natural choice since (99) is a hyperbolic equation. We use the composite midpoint rule for angular integration, and the second order explicit Runge–Kutta method for time discretization. The overall accuracy is of second order.

Let $r_{i+1/2}$ $(0 \le i \le I)$ be the grid points in the r-direction, and likewise define $k_{j+1/2}$ $(0 \le j \le J)$ and $\mu_{l+1/2}$ $(0 \le l \le L)$. Let r_i, k_j, μ_l be the midpoints (for example, $r_i = \frac{1}{2}(r_{i+1/2} + r_{i-1/2})$). Let $\Delta r = r_{i+1/2} - r_{i-1/2}$, $\Delta k = k_{j+1/2} - k_{j-1/2}$, and $\Delta\mu = \mu_{l+1/2} - \mu_{l-1/2}$ be the uniform grid sizes in each direction. Let W_{ijl} be the numerical approximation of W at (r_i, k_j, μ_l), and $W_{i+1/2,j,l}$ be the approximation of W at $(r_{i+1/2}, s_j, \mu_l)$. We define $W_{i,j+1/2,l}$ and $W_{ij,l+1/2}$ in a similar way. A second order conservative approximation for (99) is

$$\begin{aligned} &\frac{\partial}{\partial t} W_{ijl} + \frac{\mu_l k_j}{\Delta r}(W_{i+1/2,j,l} - W_{i-1/2,j,l}) - \frac{\mu_l}{\Delta k}\frac{\partial V_i}{\partial r}(W_{i,j+1/2,l} - W_{i,j-1/2,l}) \\ &\qquad + \frac{1-\mu_l^2}{\Delta\mu}\left(\frac{k_j}{r_i} - \frac{1}{k_j}\frac{\partial V_i}{\partial r}\right)(W_{i,j,l+1/2} - W_{i,j,l-1/2}) \\ &\qquad = 2\pi\alpha \int_{-1}^1 W_{ij}(t,r,k,\mu') - 4\pi\alpha W_{ijl}. \end{aligned} \tag{101}$$

To get the flux $W_{i+1/2,jl}$ from the known quantity W_{ijl}, we use the second order

upwind scheme due to van Leer (see [13]):

$$W_{i+1/2,jl} = W_{ijl} + \frac{\Delta r}{2}\sigma_i^r \qquad \text{if} \quad \mu_l > 0, \tag{102}$$

$$W_{i+1/2,jl} = W_{i+1,jl} - \frac{\Delta r}{2}\sigma_{i+1}^r \qquad \text{if} \quad \mu_l < 0. \tag{103}$$

Here σ_i^r is the limited slope (see [13])

$$\sigma_i^r = \frac{1}{\Delta r}(W_{i+1,jl} - W_{ijl})\phi(\theta^r), \tag{104}$$

$$\theta^r = \frac{W_{ijl} - W_{i-1,jl}}{W_{i+1,jl} - W_{ijl}}, \tag{105}$$

$$\phi(\theta) = \frac{|\theta| + \theta}{1 + |\theta|}. \tag{106}$$

A limited slope scheme is necessary, especially for the defocusing case, since moments of the nonlinear transport equation are close to the gas dynamics equations. Without a limited slope the numerical solutions become oscillatory when shocks develop. We define the flux in the k-direction in a similar way:

$$W_{i,j+1/2,l} = W_{ijl} + \frac{\Delta k}{2}\sigma_j^k \qquad \text{if} \quad -\mu_l \frac{\partial V_i}{\partial r} > 0, \tag{107}$$

$$W_{i,j+1/2,l} = W_{i,j+1,l} - \frac{\Delta k}{2}\sigma_{j+1}^k \qquad \text{if} \quad -\mu_l \frac{\partial V_i}{\partial r} < 0, \tag{108}$$

where σ_i^k is defined as in (104). The flux in the μ-direction is given by

$$W_{i,j,l+1/2} = W_{ijl} + \frac{\Delta \mu}{2}\sigma_l^\mu \qquad \text{if} \quad \frac{k_j}{r_i} - \frac{1}{k_j}\frac{\partial V}{\partial r} > 0, \tag{109}$$

$$W_{i,j,l+1/2} = W_{i,j,l+1} - \frac{\Delta \mu}{2}\sigma_{l+1}^\mu \qquad \text{if} \quad \frac{k_j}{r_i} - \frac{1}{k_j}\frac{\partial V}{\partial r} < 0, \tag{110}$$

where σ_l^μ is defined as in (104).

To find $\frac{\partial V_i}{\partial r}$, given that $V'(r) = V'(\rho)\frac{\partial \rho}{\partial r}$, we need to evaluate $\frac{\partial \rho_i}{\partial r}$. We use the centered difference

$$\begin{aligned} \frac{\partial \rho_i}{\partial r} &\approx \frac{\rho_{i+1/2} - \rho_{i-1/2}}{\Delta r} \\ &= \frac{1}{\Delta r}\left(\int_0^\infty \int_{-1}^1 W_{i+1/2}(t,k,\mu)\, dk\, d\mu - \int_0^\infty \int_{-1}^1 W_{i-1/2}(t,k,\mu)\, dk\, d\mu\right) \\ &\approx \frac{\Delta k \Delta \mu}{\Delta r} \sum_{j,l} (W_{i+1/2,j,l} - W_{i-1/2,j,l}). \end{aligned} \tag{111}$$

Here we have used the composite midpoint rule to approximate the integral. It has second order accuracy in k and μ. We can use the flux $W_{i+1/2,j,l}$ already obtained from (103) in (111). To recover $V_{i+1/2}$, we use the integral

$$\rho_{i+1/2} = \rho_{1/2} + \int_0^{r_{i+1/2}} \frac{\partial \rho}{\partial r}\, dr \approx \rho_{1/2} + \sum_{j=0}^{i} \frac{\partial \rho_j}{\partial r}\Delta r, \tag{112}$$

where the composite midpoint rule has again been used.

Time discretization. We use the second order Runge–Kutta method.

Boundary conditions. Since the numerical flux has a five-point stencil, it is necessary to have two fictitious points outside the physical boundaries. To define W on the left of $r = 0$ we use the condition

$$W(t, -r, k, \mu) = W(t, r, k, -\mu). \tag{113}$$

This makes sense physically because (99) remains unchanged if we simultaneously replace r by $-r$ and μ by $-\mu$. To define W to the left of $k = 0$, we use a similar condition

$$W(t, r, -k, \mu) = W(t, r, k, -\mu). \tag{114}$$

The scattering term in (99) is small near $k = 0$. At outer boundaries of r and k we use outgoing boundary conditions. For the computations the domain in k is large enough so that at the outer boundary W is nearly zero. At $\mu = \pm 1$ we simply use the reflecting boundary condition $\frac{\partial W}{\partial \mu} = 0$.

More precisely, we fix the numerical boundary conditions at $r = 0$ as follows. If $\frac{\partial V}{\partial r} < 0$, we first extrapolate W to second order for $\mu < 0$ from the interior value of W to get $W_{-1/2,jl}$ and $W_{-2/3,jl}$, where $r_{-1/2} = -r_{1/2}$ and $r_{-3/2} = -r_{3/2}$ are the fictitious points. To obtain W at the fictitious points for $\mu > 0$, we use the condition (113) numerically, i.e., $W_{-1/2.jl} = W_{1/2,j,L-l+1}$ and $W_{-3/2,jl} = W_{3/2,j,L-l+1}$. If $\frac{\partial V}{\partial r} > 0$ we reverse this process. This corresponds to extrapolation in an upwind direction, which is necessary for a hyperbolic equation. At $k = 0$ we impose a similar boundary condition. At the outer boundaries we always assume zero incoming flux, and the outgoing flux is simply the outflow boundary condition.

9.2. Numerical results. We will now present the results of some numerical experiments for the nonlinear transport equation (99). We want to see the effect of randomness, which in (99) is the scattering term, on the focusing nonlinearity. We use the potential

$$V(\rho) = \beta\rho.$$

The initial energy density is

$$W(0, r, k, \mu) = \frac{1}{k^2}\delta(k-1)\delta(\mu)\rho_0(r), \tag{115}$$

but in the numerical computations we use the Gaussian

$$W(0, r, k, \mu) = \frac{\lambda^2}{\pi}\frac{1}{k^2}e^{-\lambda^2((k-1)^2+\mu^2)}\rho_0(r), \tag{116}$$

which gives

$$\rho_0(r) = e^{-\lambda^2 r^2} + 0.5. \tag{117}$$

This initial density regularizes the *delta*-function. The smoothing effect of the parameter λ is explored numerically below. The nonlinear transport equation with *delta*-function initial data is quite singular, and there is no theoretical justification for expecting it to correspond to the limiting behavior $\lambda \to \infty$ of the regularized solutions.

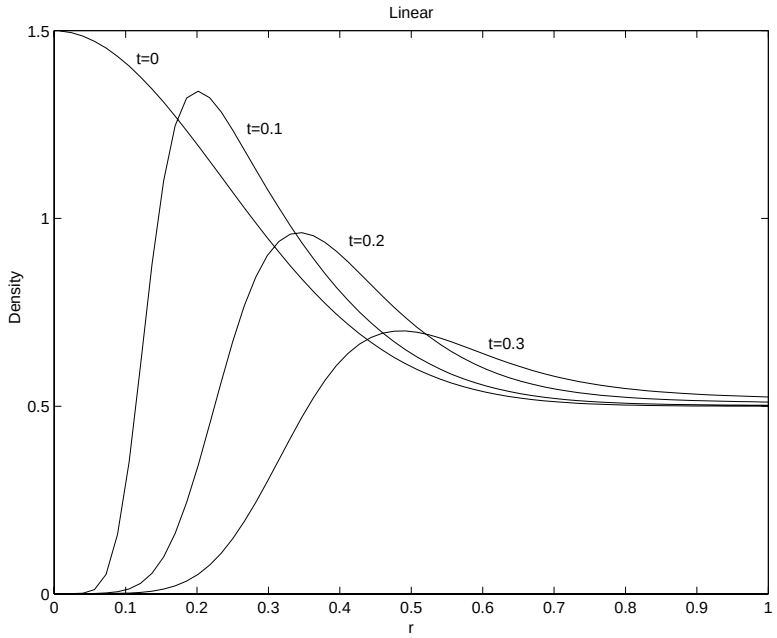

FIG. 1. *The density $\rho(t,r)$ versus r for the linear case without randomness;* ($\alpha = \beta = 0$) *and* $\lambda = 3$. *Note that the energy is propagating away from the origin.*

The computational domain in r, k, μ space is $[0,2] \times [0,2] \times [-1,1]$. We use 120 cells in r, 120 cells in k, and 40 cells in μ. We use $\Delta t = 10^{-4}$ for the linear case, $\Delta t = 5 \times 10^{-6}$ for the defocusing case, and $\Delta t = 10^{-5}$ for the focusing cases. In the focusing case the solution is less diffusive, and the CFL condition allows a slightly larger Δt than in the defocusing case. We first use $\lambda = 3$.

1. The linear case ($\beta = 0$). If there is no randomness ($\alpha = 0$), wave energy moves away from the origin, as in Figure 1. By turning on the random terms ($\alpha = 0.7$), we see that it tends to slow down the spreading of the energy, as shown in Figure 2.
2. The defocusing case ($\beta = 1$). The energy density without randomness ($\alpha = 0$) is shown in Figure 3. It propagates away from the origin much faster than in the linear case, Figure 1. In Figure 4 we show the energy density in the defocusing case with randomness ($\alpha = 0.7$). The solution is more spread out than in the linear case.
3. The focusing case. If there is no randomness ($\alpha = 0$), the numerical solution becomes highly oscillatory (one wave length per grid point; see Figure 5), reflecting the unstable nature of the problem. By turning on the randomness, for example, at $\alpha = 0.7$, numerical results are stable, at least when $|\beta|$ is not too large. We compare the results of $\beta = -0.2$ and $\beta = -0.5$ in Figures 6 and 7, respectively. In both cases the solutions spread out more slowly than in the linear case, and larger $|\beta|$ slows down the spreading of the solution. We also consider the smoothing effect of the initial data. In Figures 8 and 9 we compare numerical solutions with $\lambda = 6$ and $\lambda = 9$, respectively. The solutions are quite close to each other. The larger λ slows down spreading a bit, but the qualitative behavior of the numerical solutions remains the same.

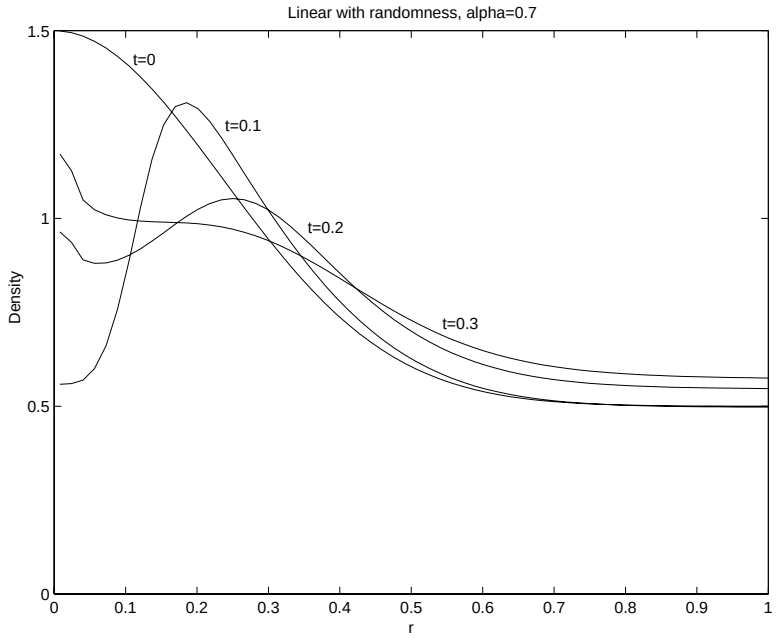

FIG. 2. *The density $\rho(t,r)$ versus r for the linear case with randomness $\alpha = 0.7$ and $\lambda = 3$. Wave energy spreading is slower than that of Figure 1 without randomness.*

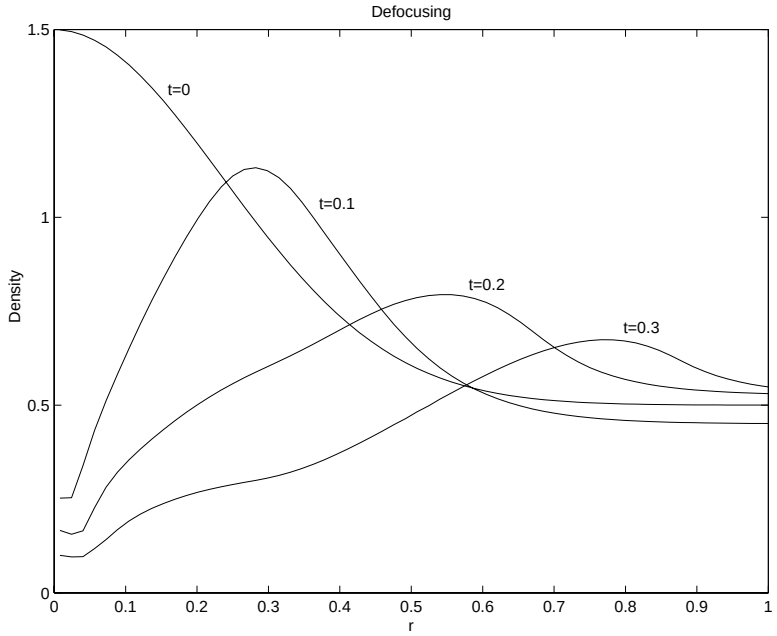

FIG. 3. *The density $\rho(t,r)$ versus r for the defocusing case with no randomness ($\alpha = 0$, $\beta = 1$) and $\lambda = 3$. The wave energy propagates away from the origin much faster than in the linear case.*

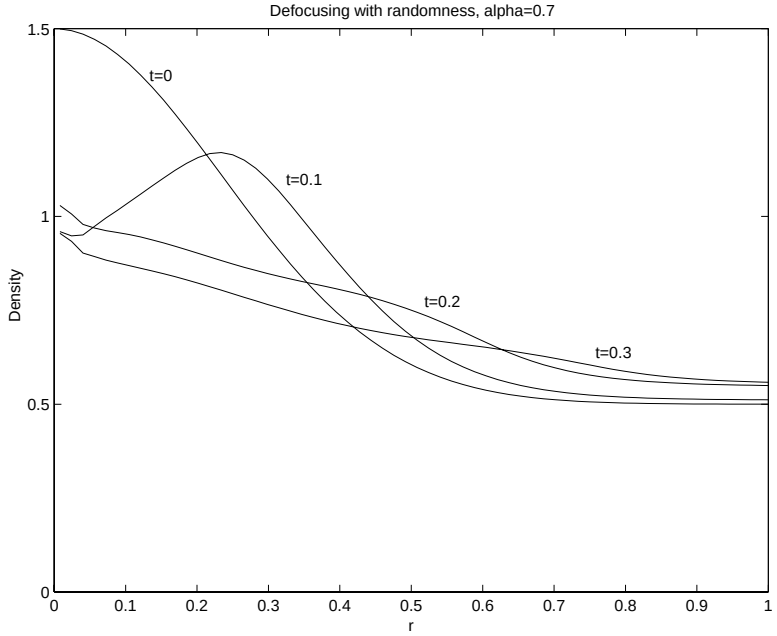

FIG. 4. *The energy density $\rho(t,r)$ versus r in the defocusing case with randomness ($\alpha = 0.7$, $\beta = 1$) and $\lambda = 3$. The density is more spread out.*

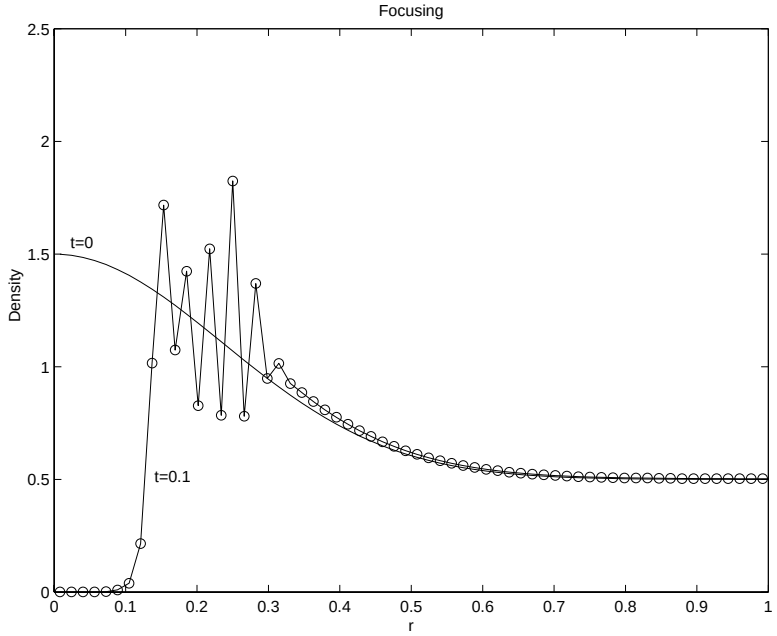

FIG. 5. *The energy density $\rho(t,r)$ versus r for the focusing case with no randomness. Here $\beta = -0.2$ and $\lambda = 3$.*

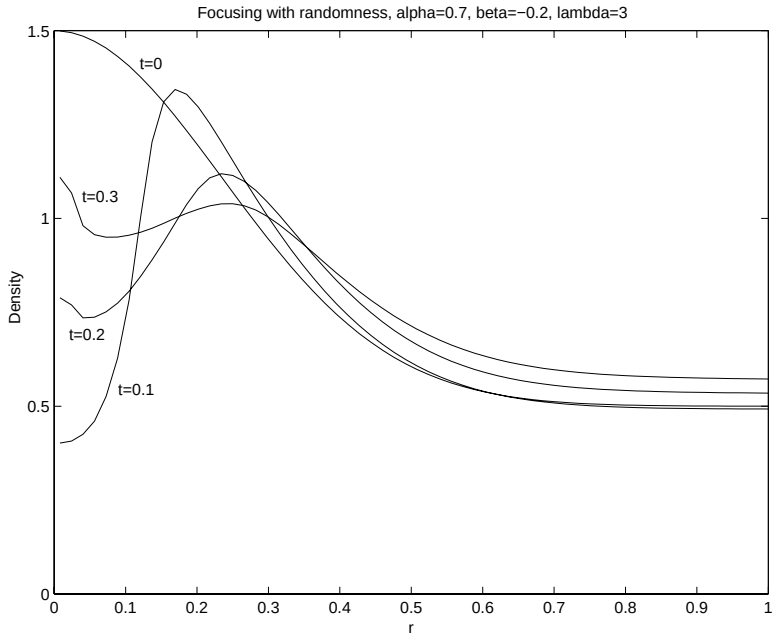

FIG. 6. *The energy density $\rho(t,r)$ versus r for the focusing case with randomness. Here $\alpha = 0.7$, $\beta = -0.2$, and $\lambda = 3$.*

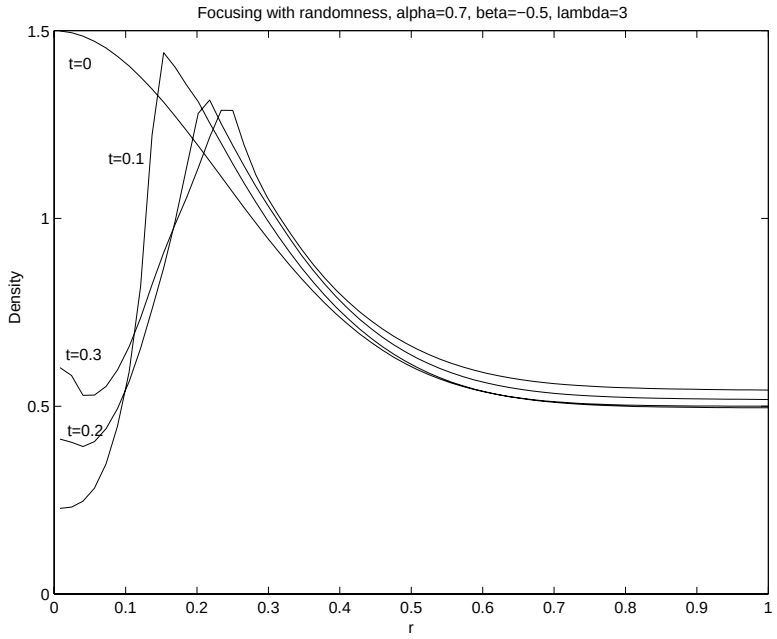

FIG. 7. *The energy density $\rho(t,r)$ versus r for the focusing case with randomness. Here $\alpha = 0.7$, $\beta = -0.5$, and $\lambda = 3$.*

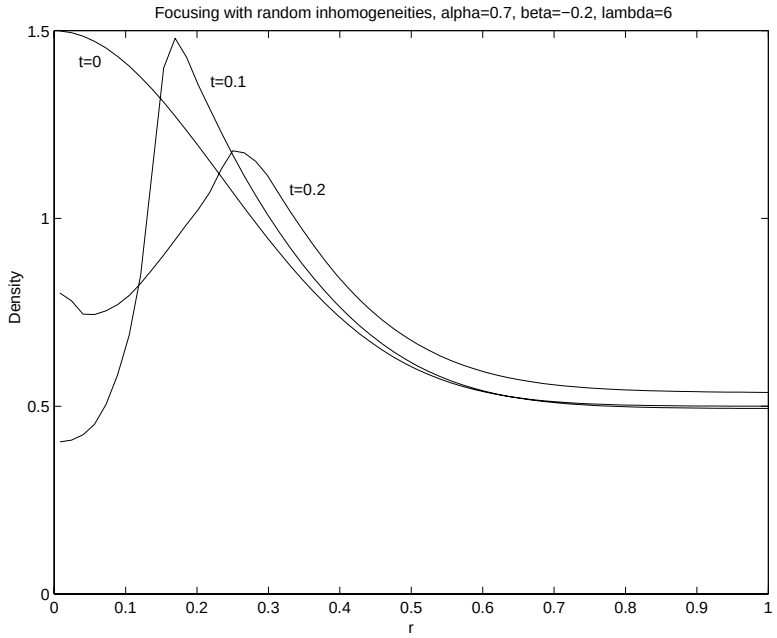

FIG. 8. *The energy density $\rho(t,r)$ versus r for the focusing case with randomness. Here $\alpha = 0.7$, $\beta = -0.2$, and $\lambda = 6$.*

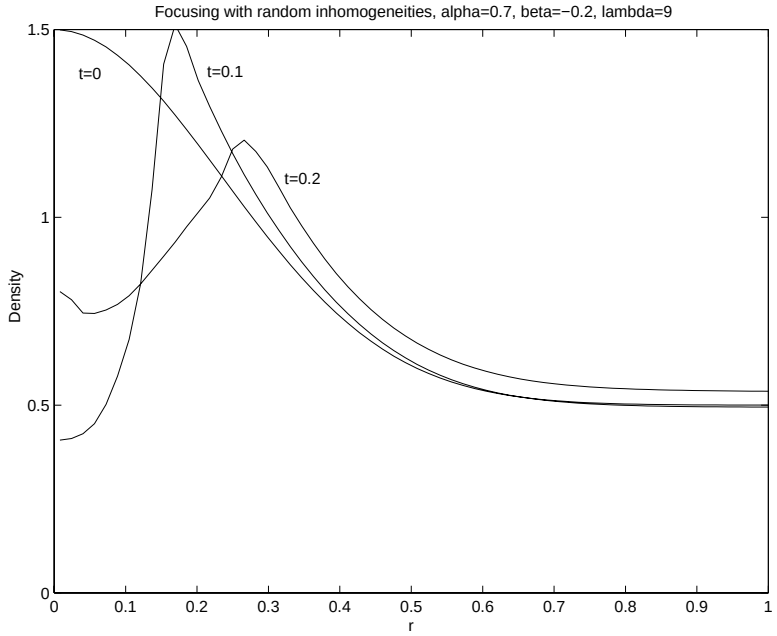

FIG. 9. *The energy density $\rho(t,r)$ versus r for the focusing case with randomness. Here $\alpha = 0.7$, $\beta = -0.2$, and $\lambda = 9$.*

It still remains an important issue to investigate the quantitative relation among α, β, and λ and how it effects the stability of the physical problem. This will be a topic for future research.

10. Numerical solution of the nonlinear diffusion equation. We also numerically solve the nonlinear diffusion equation (75). We rescale the time variable so that α disappears. We have four independent variables, but we will assume spherical symmetry to reduce them to two. Let $r = |\mathbf{x}|$ and $W(t, \mathbf{x}, k) = W(t, r, k)$. The diffusion equation (75) in polar coordinates is

$$\begin{aligned}&\frac{\partial W_0}{\partial t} - \frac{1}{12\pi}\frac{k^2}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial W_0}{\partial r}\right) + \frac{k}{12\pi}\frac{\partial W_0}{\partial k}\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial V}{\partial r}\right) + \frac{k}{6\pi}\frac{\partial^2 W_0}{\partial r\partial k}\frac{\partial V}{\partial r}\\ &\quad + \frac{1}{4\pi}\frac{\partial V}{\partial r}\frac{\partial W_0}{\partial r} - \frac{1}{12\pi}\left(\frac{\partial V}{\partial r}\right)^2\frac{\partial^2 W_0}{\partial k^2} - \frac{1}{6\pi k}\left(\frac{\partial V}{\partial r}\right)^2\frac{\partial W_0}{\partial k} = 0,\\ &\qquad V(\rho) = \beta\rho,\end{aligned} \tag{118}$$

with the initial condition

$$W_0(0, r, k) = \frac{1}{k^2}\delta(k - u_0(r))\rho_0(r). \tag{119}$$

We use a second order centered difference scheme for spatial derivatives and a composite midpoint rule to approximate $\rho_0(r)$. Let $W_{i,j}$ denote the spatial discretization of W_0. The spatially discretized form of (118) is

$$\begin{aligned}&\frac{\partial W_{i,j}}{\partial t} - \frac{1}{12\pi}\frac{k_j^2}{r_i^2(\Delta r)^2}(r_{i+1/2}^2(W_{i+1,j} - W_{i,j}) - r_{i-1/2}^2(W_{i,j} - W_{i-1,j}))\\ &\quad + \frac{k}{12\pi r_i^2}\left(\frac{W_{i,j+1} - W_{i,j-1}}{2\Delta k}\right)\frac{1}{(\Delta r)^2}[r_{i+1/2}^2(V_{i+1} - V_i) - r_{i-1/2}^2(V_i - V_{i-1})]\\ &\quad + \frac{k_j}{6\pi}\left(\frac{V_{i+1} - V_{i-1}}{2\Delta r}\right)\frac{1}{4\Delta r\Delta k}(W_{i+1,j+1} - W_{i+1,j-1} - W_{i-1,j+1} + W_{i-1,j-1})\\ &\quad + \frac{1}{4\pi}\left(\frac{V_{i+1} - V_{i-1}}{2\Delta r}\right)\frac{W_{i+1,j} - W_{i-1,j}}{2\Delta r}\\ &\quad - \frac{1}{12\pi}\left(\frac{V_{i+1} - V_{i-1}}{2\Delta r}\right)^2\frac{1}{\Delta k^2}(W_{i,j+1} - 2W_{i,j} + W_{i,j-1})\\ &\quad - \frac{1}{6\pi k_j}\left(\frac{V_{i+1} - V_{i-1}}{2\Delta r}\right)^2\frac{W_{i,j+1} - W_{i,j-1}}{2\Delta k} = 0.\end{aligned} \tag{120}$$

Here we define $r_{i+1/2} = (r_i + r_{i+1})/2$ and $k_{j+1/2} = (k_j + k_{j+1})/2$. To get V_i from W we use the composite midpoint rule. For time discretization we use the second order Runge–Kutta method. At $r = 0$ or $k = 0$ we use reflecting boundary conditions. At the outer boundaries we use vanishing flux conditions. It is important to have a domain in k that is large enough so that W is very small at the outer boundary of k. We choose the initial data

$$W_0(0, r, k) = \frac{1}{k^2}e^{-9((k-1)^2 + r^2)}. \tag{121}$$

The domain of integration is $[0, 1] \times [0, 2]$. We take 32 points in r, 64 points in k, and $\Delta t = 10^{-4}$. The numerical results for linear, defocusing, and focusing (with

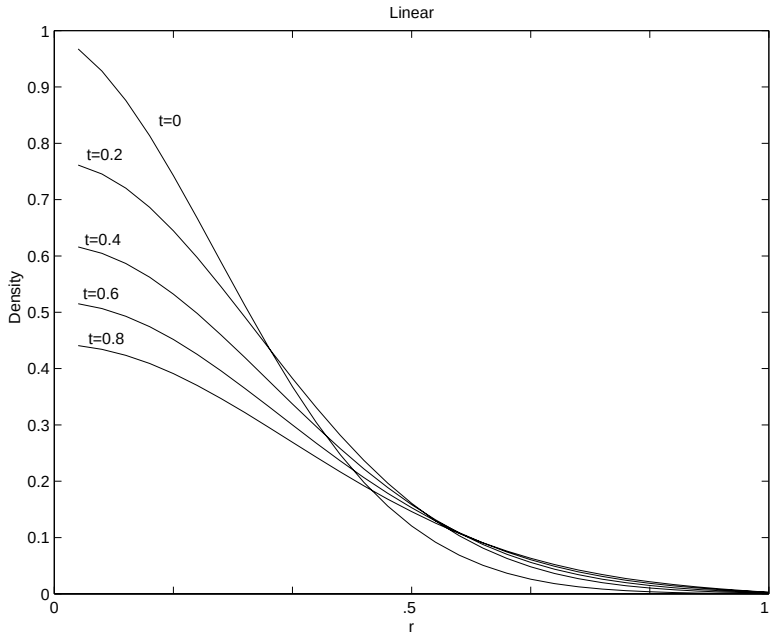

FIG. 10. *The energy density $\rho(t,r)$ in the diffusion approximation in the linear case, plotted as a function of r with $\Delta t = 0.0001$.*

$\beta = -1$ and $\beta = -0.5$) cases are shown in Figures 10, 11, 12, 13, respectively. In the linear case there is less diffusion than in the defocusing case, while in the focusing case diffusion is quite reduced. In fact, in the focusing case with $\beta = -1$ the stability condition (94) is not satisfied in part of the domain, and $\rho(t,r)$ grows locally as the solution tends to focus. In Figure 12 we show the solution until it is about to blow up (at $t \approx 0.51$). By decreasing Δt we may compute the solution to a slightly longer time, but it still breaks down numerically. For a stable solution we have to take a smaller $|\beta|$. In Figure 13 we show ρ with $\beta = -0.5$ so that the stability condition (94) is satisfied in the whole domain. The solution is stable and diffuses, at a slower rate than in the linear case. Our numerical results support the linear stability analysis that leads to (94). If (94) holds at every point of the domain initially, then the nonlinear diffusion equation is stable in time.

In Figure 14 we plot the diffusivity

$$\sigma(t) = \int_0^\infty \int_0^\infty W_0 r^4 k^2 \, dr \, dk \tag{122}$$

as a function of time, where the integrals are computed numerically with the composite midpoint rule. We see more clearly what we observed in the previous figures. The slope of $\sigma(t)$, the rate of diffusion, decreases as we go from the defocusing to the linear and to the focusing ($\beta = -0.5$) case.

11. Summary and conclusions. We have studied the interaction of nonlinear waves, solutions of the nonlinear Schrödinger equation (NLS), and random inhomogeneities, which have mean zero, are stationary, and have correlation length comparable to the wavelength. Using the Wigner phase space form of the Schrödinger equation, we formally derive a nonlinear mean field transport approximation in the

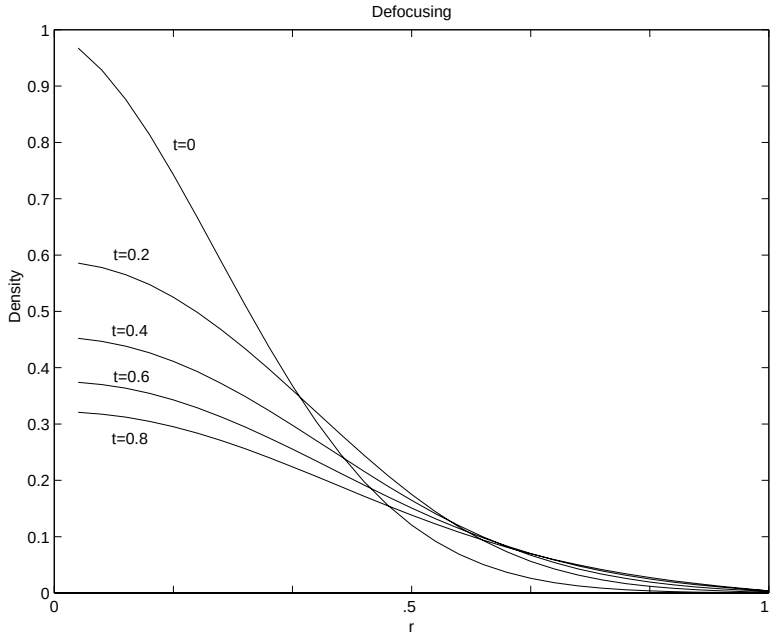

FIG. 11. *The energy density $\rho(t,r)$ in the diffusion approximation in the defocusing case ($\beta = 1$), plotted as a function of r with $\Delta t = 0.0001$.*

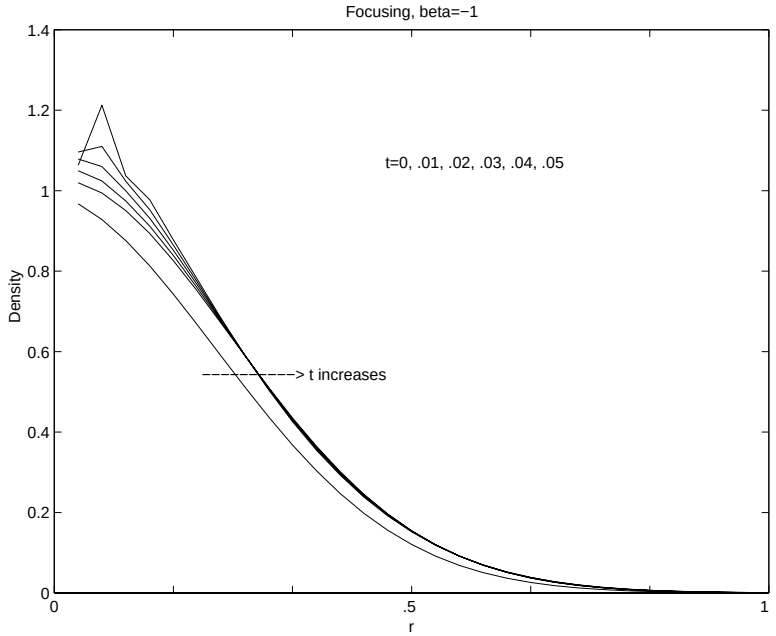

FIG. 12. *The energy density $\rho(t,r)$ in the diffusion approximation in the focusing case with $\beta = -1$, plotted as a function of r with $\Delta t = 0.0001$. Note the onset of instability where condition* (94) *is violated.*

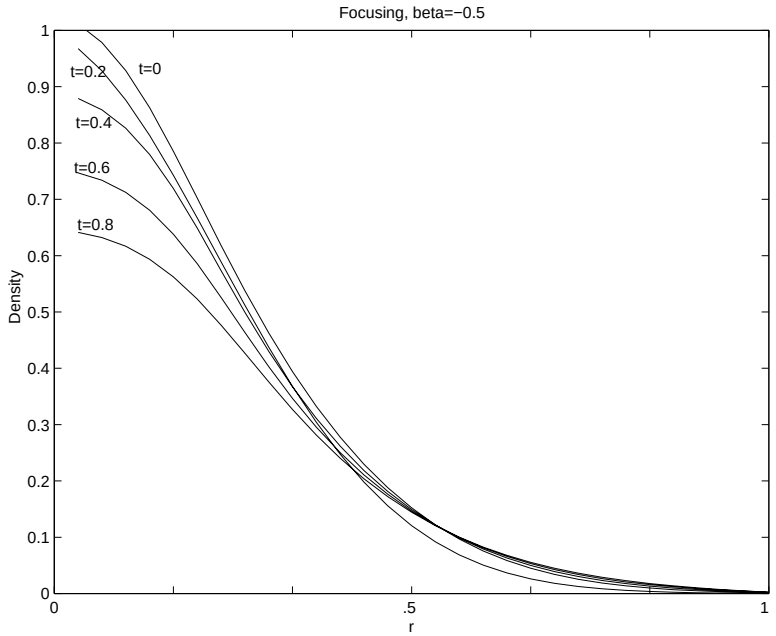

FIG. 13. *The energy density $\rho(t,r)$ in the diffusion approximation in the focusing case with $\beta = -0.5$, plotted as a function of r with $\Delta t = 0.0001$. Now the condition* (94) *holds everywhere so there is no instability.*

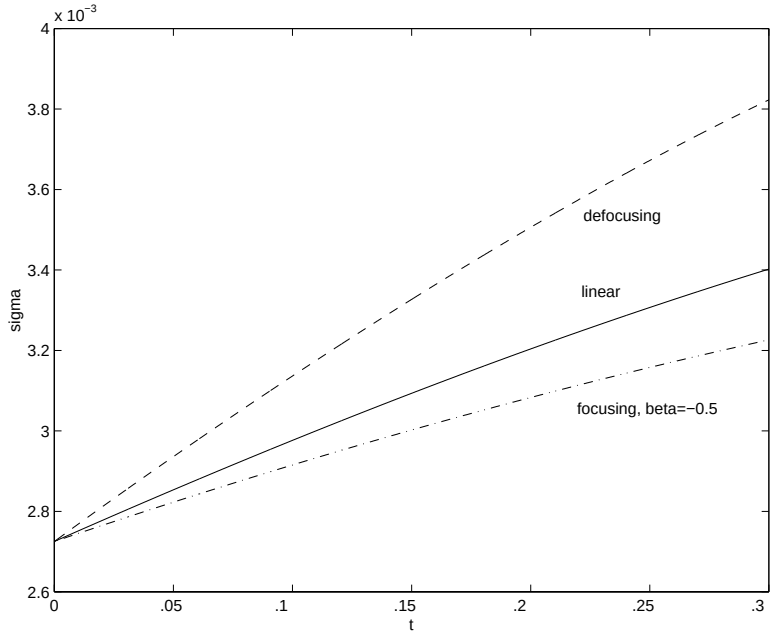

FIG. 14. *A comparison of the diffusivity $\sigma(t)$ defined in* (122) *for the linear, defocusing, and focusing cases.*

high frequency limit, and then get the diffusion approximation of this nonlinear transport equation. A linear stability analysis of the nonlinear diffusion equation shows in a simplified way how the nonlinearity and randomness interact. The focusing nonlinearity has an antidiffusive effect (see (94) with $\beta < 0$), but as long as it is not very strong the diffusion equation is linearly stable. The linear stability condition (94) has a surprising connection with the variance identity of the NLS (4): it is the right-hand side of this identity in the high frequency limit.

We then use suitable numerical schemes for both the mean field transport equation and its nonlinear diffusion approximation, and obtain numerical solutions for these two equations. Our results indicate that in the high frequency regime the random inhomogeneities prevent the wave energy from propagating in the linear and defocusing cases, but they are not strong enough to interact fully with the focusing nonlinearity. However, in the diffusive regime, randomness and nonlinearity interact fully, in a diffusive way, in all cases, defocusing and focusing. More precisely, we find that the following hold:

1. In the high frequency regime, for the linear and defocusing Schrödinger equation, the presence of random inhomogeneities prevents the wave energy from propagating and damps its amplitude. In the focusing case, the random inhomogeneities can stabilize the focusing nonlinearity if the nonlinearity is not too strong.
2. In the diffusive regime the defocusing nonlinearity enhances the overall diffusivity. The focusing nonlinearity is antidiffusive. However, when the strength of the nonlinearity is within a stability threshold given by (94), the random diffusivity dominates and the overall solution is diffusive. Thus, if the original focusing NLS does not blow up because the right-hand side of the variance identity (4) is negative, then the random inhomogeneities can stabilize it in the high frequency and diffusive regimes.

Appendix A. The mean field approximation and the correctors. In this appendix, we provide some evidence supporting the mean field approximation invoked in section 5 by analyzing the behavior of the correctors $W^{(1)}, W^{(2)}, \ldots$ in the multiscale expansion (49).

In the linear case, Spohn [17] has proved local-in-time convergence of the solution of the linear Schrödinger equation to that of the linear transport equation. Erdös and Yau [3] have improved the result so that the convergence is global in time. Both results involve detailed analysis of graphs corresponding to multiple scattering.

There are no rigorous results for the nonlinear case. The fact that the corrector analysis predicts the same limiting scattering kernel and the dimension ($d \geq 3$) required for convergence as proved by Erdös and Yau [3] is probably not a coincidence. The extent to which the correctors tell us about the *fluctuation* around the mean field in the limit $\epsilon \to 0$ remains to be tested and needs further investigation.

The terms in the expansion (49) are determined by substituting into the Wigner equation (47) and collecting terms of same orders in ϵ:

$$O\left(\frac{1}{\epsilon}\right): \qquad \mathbf{k} \cdot \nabla_{\mathbf{y}} W = 0, \tag{123}$$

$$O\left(\frac{1}{\sqrt{\epsilon}}\right): \qquad \mathbf{k} \cdot \nabla_{\mathbf{y}} W^{(1)} + \mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W = 0, \tag{124}$$

$$O(1): \qquad \frac{\partial W}{\partial t} + \mathbf{k} \cdot \nabla_{\mathbf{x}} W + \mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W^{(1)} = -\mathbf{k} \cdot \nabla_{\mathbf{y}} W^{(2)}. \tag{125}$$

Equation (123) means that $W = W(t, \mathbf{x}, \mathbf{k})$ does not depend on the fast variable $\mathbf{y}$. Equation (124) is the corrector equation for $W^{(1)}$, which is degenerate. With a standard regularization, (124) becomes

$$\epsilon W_\epsilon^{(1)} + \mathbf{k} \cdot \nabla_{\mathbf{y}} W_\epsilon^{(1)} + \mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W = 0, \tag{126}$$

which has the solution

$$W_\epsilon^{(1)} = i \int d\mathbf{p}\, \hat{V}(\mathbf{p}) \frac{e^{-i\mathbf{p}\cdot\mathbf{y}}}{\epsilon - i\mathbf{k}\cdot\mathbf{p}} \left[W\left(t, \mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(t, \mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right]. \tag{127}$$

Substituting (127) into (125), taking expectation, and passing to the limit $\epsilon \to 0$, we get the transport equation (50) for W. We see from (125) that the second order corrector $W^{(2)}$ satisfies the equation

$$\mathbf{k} \cdot \nabla_{\mathbf{y}} W^{(2)} + \mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W^{(1)} - \langle \mathcal{L}_{\frac{\mathbf{x}}{\epsilon}} W^{(1)} \rangle = 0,$$

which again should be regularized as in (127). Higher order correctors can be determined similarly. We focus on the first corrector $W^{(1)}$.

As pointed out in section 4, the initial data for the Wigner function does not converge strongly; thus neither the solution W^ϵ of the Wigner equation nor the corrector $W_\epsilon^{(1)}$ is expected to converge strongly. This is, indeed, the case, as stated next.

PROPOSITION A.1. *Suppose that $W(t, \mathbf{x}, \mathbf{k})$ is such that the function*

$$f(\mathbf{k}, \mathbf{p}) = \hat{R}(\mathbf{p}) \int d\mathbf{x} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right]^2$$

is continuous and its zero set does not contain the set $\{(\mathbf{k}, \mathbf{p}) : \mathbf{k} \cdot \mathbf{p} = 0\}$. Then, $\epsilon \iint \langle |W_\epsilon^{(1)}|^2 \rangle \, d\mathbf{x}\, d\mathbf{k}$ does not vanish as $\epsilon \to 0$, in any dimension.

Proof. A straightforward calculation leads to

$$\begin{aligned}
&\epsilon \iint \langle |W_\epsilon^{(1)}|^2 \rangle \, d\mathbf{x}\, d\mathbf{k} \\
&= \int d\mathbf{p}\, \hat{R}(\mathbf{p}) \int d\mathbf{k}\, \frac{\epsilon}{\epsilon^2 + (\mathbf{k}\cdot\mathbf{p})^2} \int d\mathbf{x} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right]^2 \\
&\geq \frac{1}{2\epsilon} \int d\mathbf{k} \int_{|\mathbf{k}\cdot\mathbf{p}| \leq \epsilon} d\mathbf{p}\, \hat{R}(\mathbf{p}) \int d\mathbf{x} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right]^2 \\
&\geq \frac{1}{2\epsilon} \int d\mathbf{k} \int_{|\mathbf{k}\cdot\mathbf{p}| \leq \epsilon} d\mathbf{p}\, f(\mathbf{k}, \mathbf{p}). \qquad (128)
\end{aligned}$$

As the set $\{\mathbf{k} \in R^d : |\mathbf{k} \cdot \mathbf{p}| \leq \epsilon\} \bigcap \mathrm{supp}\{f(\mathbf{k}, \mathbf{p})\}$ has a measure of order ϵ for W satisfying the stated assumption, the expression (128) does not vanish in the limit $\epsilon \to 0$, as we wanted to show.

We note that "generic" functions W that are *not* spherically symmetric in $\mathbf{k}$ satisfy the condition stated in Proposition A.1.

However, $\sqrt{\epsilon}\, W_\epsilon^{(1)}$ does vanish strongly (in $\mathbf{x}$) if it is first integrated against a test function of $\mathbf{k}$, as stated in the next proposition. This provides some reason for using the mean field hypothesis in the derivation of the transport equation.

PROPOSITION A.2. *For $d \geq 3$ and any differentiable $W(\mathbf{x}, \mathbf{k})$ with a compact support, we have*

$$\lim_{\epsilon \to 0} \epsilon \int d\mathbf{x} \left\langle \left| \int d\mathbf{k}\, W_\epsilon^{(1)} \phi(\mathbf{k}) \right|^2 \right\rangle = 0 \quad \forall \phi(\mathbf{k}) \in C_c^\infty. \tag{129}$$

Proof. After taking the expectation, the expression on the left-hand side of (129) becomes

$$\epsilon \int d\mathbf{p}\, \frac{\hat{R}(\mathbf{p})}{|\mathbf{p}|^2} \int d\mathbf{x} \left| \int d\mathbf{k}\, \frac{\phi(\mathbf{k})}{\epsilon - i\mathbf{k}\cdot\hat{\mathbf{p}}} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right] \right|^2 , \tag{130}$$

where $\hat{\mathbf{p}} = \mathbf{p}/|\mathbf{p}|$. Since $\phi(\mathbf{k})[W(\mathbf{x}, \mathbf{k} - \mathbf{p}/2) - W(\mathbf{x}, \mathbf{k} + \mathbf{p}/2)]$ is differentiable, we have

$$\begin{aligned} &\lim_{\epsilon\to 0} \int d\mathbf{k}\, \frac{\phi(\mathbf{k})}{\epsilon - i\mathbf{k}\cdot\hat{\mathbf{p}}} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right] \\ &= \lim_{\epsilon\to 0} \int_{|\mathbf{k}\cdot\hat{\mathbf{p}}|>\epsilon} d\mathbf{k}\, \frac{\phi(\mathbf{k})}{-i\mathbf{k}\cdot\hat{\mathbf{p}}} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right] \\ &= i \int d\mathbf{k}_\perp(\hat{\mathbf{p}}) \fint d(\mathbf{k}\cdot\hat{\mathbf{p}})\, \frac{\phi(\mathbf{k})}{\mathbf{k}\cdot\hat{\mathbf{p}}} \left[W\left(\mathbf{x}, \mathbf{k} - \frac{\mathbf{p}}{2}\right) - W\left(\mathbf{x}, \mathbf{k} + \frac{\mathbf{p}}{2}\right) \right], \end{aligned} \tag{131}$$

with $\mathbf{k}_\perp(\hat{\mathbf{p}})$ the orthogonal projection of $\mathbf{k}$ onto the plane normal to $\mathbf{p}$. Here $\fint$ stands for the Cauchy principal value integral. Since $|\mathbf{p}|^{-2}$ in (130) is an integrable singularity in three or more dimensions, the expression in (129) is $O(\epsilon)$ as $\epsilon \to 0$, as we wanted to show.

APPROXIMATION OF THE INTEGRAL BOUNDARY LAYER EQUATION BY THE KURAMOTO–SIVASHINSKY EQUATION*

HANNES UECKER†

Abstract. In suitable parameter regimes the integral boundary layer equation (IBLe) can be formally derived as a long wave approximation for the flow of a viscous incompressible fluid down an inclined plane. For very long waves with small amplitude, the IBLe can be further reduced to the Kuramoto–Sivashinsky equation (KSe). Here we justify this reduction of the IBLe to the KSe. Using energy estimates, we show that solutions of the KSe approximate solutions of the IBLe over sufficiently long time scales. This is a step towards understanding the approximation properties of the KSe for the full Navier–Stokes system describing the inclined film flow.

Key words. inclined film flow, integral boundary layer equation, Kuramoto–Sivashinsky equation, energy estimates

1. Introduction and statement of result.

For typical flow conditions the so-called Nusselt flow of a viscous incompressible fluid down an inclined plane is subject to long wave surface instabilities, and trains of solitary waves develop on the free surface. Starting from the Navier–Stokes equations (NSe), a number of reduced equations have been formally derived to describe the evolution of the free surface and in particular to understand the formation of these wavetrains. See [3] for an extensive review and [12] for experiments on inclined film flows, and the comprehensive monograph [4] for a wealth of further information.

Here we study analytically the relationship between two of the approximate equations. The first one is the so-called integral boundary layer equation (IBLe), which is derived from the NSe using a long wave expansion followed by an averaging over the film height. In Appendix B we briefly review this derivation of the IBLe.

By a small amplitude and second long wave expansion in the IBLe, corresponding to a small amplitude and very long wave expansion of the NSe, the IBLe can be further reduced to the Kuramoto–Sivashinsky equation (KSe). This second reduction is justified in this paper; we show that the Kuramoto–Sivashinsky (KS) dynamics can be observed in the IBLe; see Theorem 1.1.

Using the time and space scales of the NSe, the IBLe we consider reads

(1.1)
$$\begin{aligned} h_t &= -q_x, \\ q_t &= -\frac{6}{5}\partial_x\left(\frac{q^2}{h}\right)+\frac{2}{\mathrm{R}}\left(h-\frac{3q}{2h^2}-h_x h\cot\theta\right)+\mathrm{W}\varepsilon^{-2}h\left(\partial_x^3 h-\frac{3}{2}\partial_x^3 h h_x^2-3h_{xx}^2 h_x\right) \\ &\quad +\frac{1}{\mathrm{R}}\left(\frac{7}{2}q_{xx}-\frac{9q_x h_x}{h}+\frac{6qh_x^2}{h^2}-\frac{9qh_{xx}}{2h}\right), \end{aligned}$$

where $x \in \mathbb{R}$ and $t > 0$. Here we remark that, in contrast to the Shkadov model [23], (1.1) is a parabolic system due the dissipative term $\frac{7}{2\mathrm{R}}\partial_x^2 q$ on the right-hand side; see Remarks 1.4 and Appendix B.3 for further discussion.

In (1.1), h is the film height, q describes the flow, $0 < \theta \leq \pi/2$ is the inclination angle, R is the Reynolds number, W is a normalized Weber number, and $0 < \varepsilon \ll 1$ is a small parameter. In the derivation of (1.1) it is assumed that the Weber number $\mathrm{W}_e = \mathrm{W}\varepsilon^{-2} = \mathcal{O}(\varepsilon^{-2})$, while $\mathrm{R} = \mathcal{O}(1)$ and $\cot\theta = \mathcal{O}(1)$. The latter means that the plane may not be close to horizontal. However, a vertical plane, i.e., $\cot\theta = 0$, is allowed. The parameter W could be adsorbed into ε, but we think the analysis becomes more transparent by keeping W. As noted, see Appendix B for the underlying scalings.

In the IBLe the Nusselt solution of the inclined film problem corresponds to $(h, q) = (1, 2/3)$. Since we are interested in the instability of this solution, we will assume throughout that R is larger than the critical Reynolds number (see [2]), i.e.,

$$\mathrm{R} > \mathrm{R}_c = \frac{5}{4}\cot\theta. \tag{1.2}$$

With an abuse of notation we set $h = 1 + \eta, q = 2/3 + q$, and expand (1.1) up to quadratic terms, since from previous work, e.g., [10], it is well known and can also readily be seen in the analysis below that cubic and higher order terms play no role in the justification of the long wave/small amplitude approximation for (1.1). See, however, Remarks 1.3, 3.2, and A.5 for changes in the function spaces if cubic and higher order terms are included.

We write the quadratic expansion as

$$\eta_t = -q_x, \tag{1.3}$$

$$q_t = a_0(\eta)\eta + a_1(\eta, q)\eta_x + a_2(\eta, q)\eta_{xx} + \varepsilon^{-2}a_3(\eta)\eta_{xxx} - b_0(\eta)q - b_1(\eta, q)q_x + b_2 q_{xx}, \tag{1.4}$$

where

$$\begin{aligned} &a_0(\eta) = \frac{6-6\eta}{\mathrm{R}}, \quad a_1(\eta, q) = \left(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta - \frac{8}{5}\eta + \frac{8}{5}q + \frac{6}{\mathrm{R}}\eta_x\right), \\ &a_2(\eta, q) = \frac{1}{\mathrm{R}}\left(-3 + \frac{9}{2}\eta - \frac{9}{2}q\right), \quad a_3(\eta) = \mathrm{W}(1+\eta), \\ &b_0(\eta) = \frac{3}{\mathrm{R}}(1-2\eta), \quad b_1(\eta, q) = \frac{8}{5} - \frac{8}{5}\eta + \frac{12}{5}q + \frac{9}{\mathrm{R}}\eta_x, \quad b_2 = \frac{7}{2\mathrm{R}}. \end{aligned} \tag{1.5}$$

Splitting (1.3) and (1.4) into linear and nonlinear terms, we write

$$U_t = A_0 U + F(U), \tag{1.6}$$

$$U = \begin{pmatrix} \eta \\ q \end{pmatrix}, \quad A_0 = A_0(\partial_x) = \begin{pmatrix} 0 & -\partial_x \\ a_{00} + a_{10}\partial_x + a_{20}\partial_x^2 + \varepsilon^{-2}a_{30}\partial_x^3 & -b_{00} - b_{10}\partial_x + b_{20}\partial_x^2 \end{pmatrix},$$

where $a_{00} = a_0(0), a_{10} = a_1(0, 0), \ldots$, and where F contains the quadratic terms.

Inserting $U = \mathrm{e}^{\mu t + \mathrm{i}kx}U(k)$ into (1.6), we obtain the dispersion relation

$$\begin{aligned} \mu_{1,2}(k) = &-\frac{1}{2}\left(\frac{7}{2\mathrm{R}}k^2 + \frac{8}{5}\mathrm{i}k + \frac{3}{\mathrm{R}}\right) \\ &\pm\sqrt{\frac{1}{4}\left(\frac{7}{2\mathrm{R}}k^2 + \frac{8}{5}\mathrm{i}k + \frac{3}{\mathrm{R}}\right)^2 - \frac{6}{\mathrm{R}}\mathrm{i}k - \left(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta\right)k^2 + \frac{3}{\mathrm{R}}\mathrm{i}k^3 - \mathrm{W}\varepsilon^{-2}k^4}. \end{aligned} \tag{1.7}$$

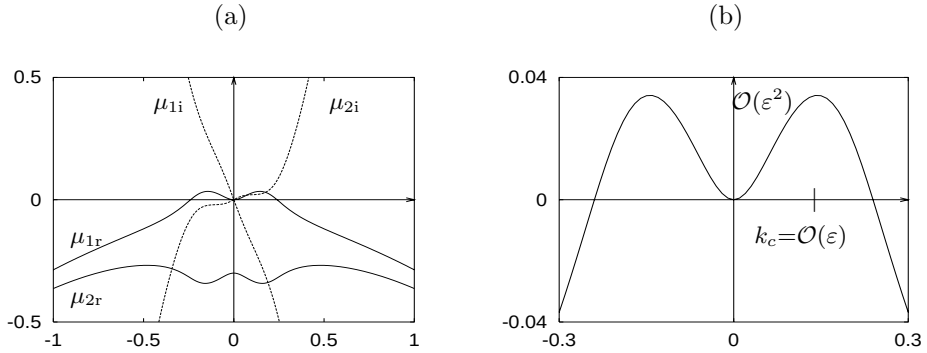

FIG. 1.1. *The dispersion relation* $\mu_j = \mu_{j\mathrm{r}} + \mathrm{i}\mu_{j\mathrm{i}}$, $j = 1, 2$, *for the IBLe;* $\varepsilon = 0.2$, $W = 1$, $\mathrm{R} = 10$, $\theta = \pi/2$. (a) *The two curves of eigenvalues* $\mu_{1,2}$; (b) *blowup of* $\mu_{1\mathrm{r}}(k)$ *near* $k = 0$.

This spectrum of the operator $A_0(\mathrm{i}k)$ is sketched in Figure 1.1. In particular, from μ_1 we recover the instability criterion (1.2): for $\mathrm{R} > \mathrm{R}_c$ we have a long wave instability with maximum growth rate $\mathrm{Re}\mu_1(k_c) = \mathcal{O}(\varepsilon^2)$, $k_c = \mathcal{O}(\varepsilon)$. Moreover, for $|k| \to \infty$ we have

$$\begin{aligned}\mu_{1,2}(k) &= \left(-\frac{7}{4\mathrm{R}} \pm \sqrt{\left(\frac{7}{4\mathrm{R}}\right)^2 - \mathrm{W}\varepsilon^{-2}}\right) k^2 + \mathcal{O}(|k|^{3/2}) \\ &= \left(-\frac{7}{4\mathrm{R}} \pm \mathrm{i}(\varepsilon^{-1}\sqrt{\mathrm{W}} + \mathcal{O}(\varepsilon))\right) k^2 + \mathcal{O}(|k|^{3/2}),\end{aligned} \tag{1.8}$$

where in the second equality we have assumed for simplicity that $(\frac{7}{4\mathrm{R}})^2 < \mathrm{W}\varepsilon^{-2}$. This shows the parabolic damping (and the very fast oscillations) of the high wavenumber modes.

In fact, A_0 generates an analytic semigroup e^{tA_0} with

$$\|e^{tA_0}U\|_Y \le C\mathrm{e}^{C\varepsilon^2 t}\|U\|_Y, \tag{1.9}$$

where as phase-space Y we choose, for instance, the Hilbert space $Y{=}H^2(\mathbb{R}){\times}H^1(\mathbb{R})$ equipped with the norm

$$\|U\|_Y^2 = \frac{1}{2}\int_{\mathbb{R}} \left\{q^2{+}c_1\eta^2{-}2c_2q\eta{-}2c_3\eta_x q{+}c_4q_x^2{+}\varepsilon^{-2}\mathrm{W}(\eta_x^2{+}c_4\eta_{xx}^2)\right\}\mathrm{d}x. \tag{1.10}$$

Here we must choose $c_2 = 2$, and c_1, c_3, c_4 can be chosen as

$$c_1 = 9, \quad c_3 = -\frac{11\mathrm{R}}{5} + \frac{2\cot\theta}{3}, \quad c_4 = \mathrm{R}^2; \tag{1.11}$$

see section 2.1, where we also motivate the choice of $\|\cdot\|_Y$. The strong weighting of derivatives of η in (1.10) reflects the fact that in (1.6) the small parameter ε appears in a rather unusual way, namely as an inverse power in front of the damping by the surface tension. This is inherited from the fact that in the underlying Navier–Stokes equations we consider the limit of large surface tension; see Appendix B.2.

Assuming very long waves with a small amplitude, the KSe for the film height η can be formally derived from the NSe. Accordingly, the KSe can also be derived from the IBLe, namely by the ansatz

$$\eta(t,x) = \varepsilon\eta_1(T,X) + \mathcal{O}(\varepsilon^3), \qquad q(t,x) = \varepsilon q_1(T,X) + \varepsilon^2 q_2(T,X) + \mathcal{O}(\varepsilon^3), \tag{1.12}$$

where $T = \varepsilon^2 t$ and $X = x - ct$ are the very slow timescale and the very long space scale in a frame moving with the speed c. These time and space scalings follow directly from the dispersion relation (1.7) for A_0. Plugging (1.12) into (1.6), we obtain the hierarchy of equations

$$\begin{aligned}
&\mathcal{O}(\varepsilon(1.4)): \quad q_1 = 2\eta_1,\\
&\mathcal{O}(\varepsilon^2(1.3)): \quad -c\eta_{1X} = -q_{1X} = -2\eta_{1X} \quad \Rightarrow \quad c = 2,\\
&\mathcal{O}(\varepsilon^2(1.4)): \quad -cq_{1X} = -\frac{8}{5}q_{1X} + \left(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta\right)\eta_{1X} + \mathrm{W}\partial_X^3\eta_1 - \frac{3}{\mathrm{R}}q_2 + \frac{6}{\mathrm{R}}(\eta_1 q_1 - \eta_1^2),\\
&\qquad\qquad \Rightarrow q_2 = \left(\frac{8\mathrm{R}}{15} - \frac{2}{3}\cot\theta\right)\eta_{1X} + \frac{1}{3}\mathrm{RW}\partial_X^3\eta_1 + 2\eta_1^2; \qquad (1.13)
\end{aligned}$$

that is, q_1, q_2 are given as functions of η_1. At $\mathcal{O}(\varepsilon^3(1.3))$ we find $\partial_T\eta_1 = -\partial_X q_2$, which gives the KSe

$$\partial_T\eta_1 = -\left(\frac{8\mathrm{R}}{15} - \frac{2}{3}\cot\theta\right)\partial_X^2\eta_1 - \frac{1}{3}\mathrm{RW}\partial_X^4\eta_1 - 4\eta_1\partial_X\eta_1 \qquad (1.14)$$

for η_1. Note that the coefficient of $\partial_X^2\eta_1$ is less than zero iff $\mathrm{R} > \mathrm{R}_c$.

Obviously (1.14) is a much simpler equation than (1.6) since it is a semilinear scalar parabolic equation, while the IBLe is a quasilinear system. Moreover, the KSe is a generic long wave equation; see, e.g., [13] for a basic review and, e.g., [14] for the existence and smoothness of solutions $\eta_1 \in C([0, T_0], H^m(\mathbb{R}))$ to initial conditions $\eta_1(0) \in H^m(\mathbb{R})$.

We define the approximation

$$\varepsilon\psi(t,x) = \begin{pmatrix} \varepsilon q_1(T,X) + \varepsilon^2 q_2(T,X) \\ \varepsilon\eta_1(T,X) \end{pmatrix}, \qquad (1.15)$$

with q_1, q_2 given by (1.13), and the spaces

$$H^{r,s}((0,t_0)\times\mathbb{R}) = L^2((0,t_0), H^r(\mathbb{R})) \cap H^s((0,t_0), L^2(\mathbb{R}))$$

and show the following result.

THEOREM 1.1. *Assume that $\eta_1 \in C([0,T_0], H^9(\mathbb{R}))$ is a solution of the KSe. Then for all $C_1 > 0$ there exist $\varepsilon_0, C_2 > 0$ such that for all $\varepsilon \in (0, \varepsilon_0)$ the following holds. If*

$$\|U(0,\cdot) - \varepsilon\psi(0,\cdot)\|_Y \le C_1\varepsilon^{3/2}, \qquad (1.16)$$

then there exists a unique solution $U = (\eta, q)$ of the IBLe up to large time $t_0 = T_0/\varepsilon^2$,

$$\eta \in H^{3,3/2}((0,t_0)\times\mathbb{R}), \quad q \in H^{2,1}((0,t_0)\times\mathbb{R}). \qquad (1.17)$$

For $t > 0$ the solution is smooth, and it fulfills

$$\sup_{0\le t\le t_0} \|U(t,\cdot) - \varepsilon\psi(t,\cdot)\|_Y \le C_2\varepsilon^{3/2}. \qquad (1.18)$$

Remark 1.2. The properties of the spaces $H^{r,s}((0,t_0)\times\mathbb{R})$ are reviewed in Appendix A. Here we remark that $H^{3,3/2}((0,t_0)\times\mathbb{R})\times H^{2,1}((0,t_0)\times\mathbb{R}) \subset C([0,t_0], Y)$ such that (1.18) makes sense. Note that C_1, C_2 in Theorem 1.1 do not depend on

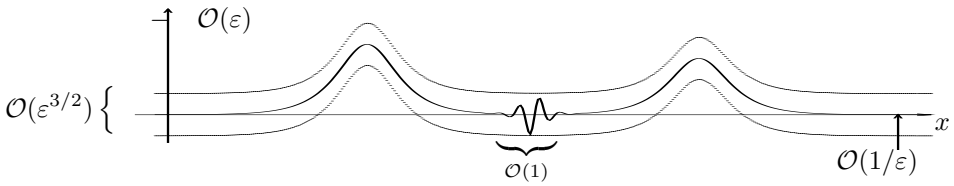

FIG. 1.2. *Sketch of the initial data. For q_0 we may allow small oscillations on the original scale.*

$\varepsilon \in (0, \varepsilon_0)$. However, ε_0, C_1, C_2 do depend on R and W in such a way that, for instance, $\mathrm{R}_2 \geq \mathrm{R}_1$ gives $\varepsilon_0(\mathrm{R}_2) \leq \varepsilon_0(\mathrm{R}_1)$ and similarly for C_1, C_2, but we do not work this out in detail.

From (1.18) we obtain $\sup_{0\leq t\leq t_0} \|U(t,\cdot) - \varepsilon\psi(t,\cdot)\|_{L^\infty} \leq C_2\varepsilon^{3/2}$. Thus, the error is small compared to the size of the solution. Moreover, the error for η_x is much smaller, i.e., $\sup_{0\leq t\leq t_0} \|\partial_x\eta(t,\cdot) - \varepsilon\partial_x\psi_1(t,\cdot)\|_{C^0} \leq C_2\varepsilon^{7/2}$. On the other hand, we must impose the same condition on the initial condition. This means that η_0 must be a long wave in a much stricter sense than q_0. For q_0 we may allow small perturbations of $\varepsilon\psi_1$ on the original scale. Such "fast" oscillations in η_0 would violate (1.16). This situation is sketched in Figure 1.2.

Remark 1.3. Theorem 1.1 also holds in higher order Sobolev spaces; see Remark 3.2. In fact, if cubic terms were included in (1.6), then in order to control the nonlinearity we would *have* to work in $H^3 \times H^2$, due to the term $\eta_{xx}^2\eta_x$; cf. Remark A.5.

Remark 1.4. As already said, our IBLe differs from previously derived *hyperbolic* IBLe, IBL_h, also called the Shkadov model [23] (see Appendix B.3), in that the linearization of (1.1) around Nusselt's solution is *sectorial*. Heuristically, this can be seen from the dispersion relation (1.7) (cf.(1.8)): the spectrum of A_0 lies in a sector around the negative real axis; the additionally needed resolvent estimates are given in Lemma A.3.

A parabolic IBLe has also been derived in [16] (see also [4, section 3.3]), under the assumption of $\mathrm{W} = \mathcal{O}(\varepsilon^{-2})$, $\mathrm{R} = \mathcal{O}(\varepsilon^{-1})$, and small θ.

Remark 1.5. Numerical simulations of the free boundary problem for the governing NSe of IBL_h and of the KSe suggest that for high but finite Weber numbers, corresponding to finite $\varepsilon > 0$, IBL_h is valid as an approximation for NSe up to intermediate Reynolds numbers. We conclude that this also holds true for our IBLe (1.1), since (1.1) is derived as a higher order approximation of the NSe than IBL_h. On the other hand, the KSe gives good results only for smaller Reynolds numbers; for details, see [3] and the references therein. See also [17] for comparison of solutions of the IBLe with experimental results and extensive numerical studies of the NSe.

Remark 1.6. One major reason for the reduction of the inclined film problem to the IBLe or to the KSe is to gain understanding of the formation of solitary and periodic waves on the free surface of the film. For the existence and properties of solitary waves for IBL_h and the KSe, see, again [3, 4] and the references therein. In a somewhat different scaling, a generalized KSe or KdV-KS equation with third order dispersion can be derived from the NSe (see [25]). For this KdV-KSe there are analytical results and extensive numerical studies concerning the stability and dynamics of solitary waves [15, 7, 5]. Our result does not contribute to the understanding of these waves but says that the (periodic or solitary) waves of the KSe can be seen as small amplitude waves in the IBLe over long times.

Remark 1.7. The IBLe itself is only formally derived from the NSe. Error

estimates in the sense of Theorem 1.1 seem to be very difficult for this reduction. Instead, we suggest studying directly the reduction of the NSe to the KSe. This will be the subject of future work. Since the linearization around Nusselt's solution in the NSe is also sectorial [1, 24], we can use similar methods as in the present paper.

Finally, we remark that a result like Theorem 1.1 is not obvious. There are counterexamples where formally derived amplitude equations make wrong predictions about the dynamics in the original system [20, 8]. Moreover, the question of which simplified equation, dependent on the parameter regime, still describes the inclined film problem is not settled. Here we contribute to the answer in the sense that for $\mathcal{O}(1)$ Reynolds numbers and in the limit of (very) large Weber number the KSe accurately captures the IBLe dynamics for long small amplitude waves over the right time scale.

Similarly to our result, the validity of multiple scale approximations to the NSe in a fixed domain, where the instability is located at a finite nonzero wavenumber, has been shown in [18, 21]. See also, e.g., [22] for the water wave problem, and [19] for such approximation results in simpler settings, i.e., for scalar semilinear parabolic problems.

To explain the difficulty for the proof of Theorem 1.1 we write the IBLe (1.6) as

$$U_t = A_0 U + B(U,U), \tag{1.19}$$

where $B(U,V)$ is a symmetric bilinear form representing the quadratic terms in (1.6). For a $\beta > 1$ we set

$$U = \varepsilon\psi + \varepsilon^\beta R, \tag{1.20}$$

and obtain the equation

$$\partial_t R = A_0 R + 2\varepsilon B(\psi, R) + \varepsilon^\beta B(R,R) + \varepsilon^{-\beta}\mathrm{Res}(\varepsilon\psi) \tag{1.21}$$

for the error R, where the so-called residual

$$\mathrm{Res}(\varepsilon\psi) = \varepsilon(-\partial_t\psi + A_0\psi + \varepsilon B(\psi,\psi)) \tag{1.22}$$

contains the terms that do not vanish after inserting (1.12) into (1.6). We essentially have to show (a) that solutions to (1.21) for initial conditions $R_0 = R|_{t=0}$ of order $\mathcal{O}(1)$ exist locally, and (b) that the solutions exist and stay $\mathcal{O}(1)$-bounded up to times $t = T_0/\varepsilon^2$. In order to show (a) for the quasilinear parabolic system (1.21), we use the maximal regularity techniques from [11]. To achieve (b), we first define an improved approximation $\varepsilon\tilde{\psi}$ such that the residual is sufficiently small and then derive an energy estimate similar to (1.9). Note that a priori we would expect a growth rate like $\mathrm{e}^{C\varepsilon t}$ for solutions of (1.21) due to the term $2\varepsilon B(\tilde{\psi}, R)$ in (1.21). Moreover, because of the term $\varepsilon^{-\beta}\mathrm{Res}(\varepsilon\tilde{\psi})$, we would like to choose β small, while in order to handle the nonlinear term $\varepsilon^\beta B(R,R)$, we would like to have β large. The approach turns out to work with $\beta = 3/2$.

In section 2 we give the calculation leading to the energy estimate (1.9) for the linearized problem and define the improved approximation. The proof of Theorem 1.1 follows in section 3. The local existence of solutions to (1.6) is shown in Appendix A, which also yields the local existence of solutions to the error equation. In Appendix B we give a brief review of the underlying physical problem, show how the parabolic IBLe (1.1) can be formally derived from the governing NSe, and end with a brief discussion of the hyperbolic Shkadov model.

2. Preparations.

2.1. The linearized energy estimate. Here we show the straightforward calculations leading to the energy estimate (1.9). In section 3 we extend these to the quasilinear problem (1.21). We fix $c_1 = 9$, $c_2 = 2$, $c_4 = \mathrm{R}^2$ in (1.10) and show how $c_3 = -11\mathrm{R}/5 + 2\cot\theta/3$ yields (1.9). Using

$$|ab| \le \delta a^2 + \frac{1}{4\delta} b^2, \quad \delta > 0, \tag{2.1}$$

it is clear that, for ε sufficiently small, $\|\cdot\|_Y$ is equivalent to $\|\cdot\|_{Y_0}$ with

$$\|(\eta, q)\|_{Y_0}^2 = \frac{1}{2}\int_{\mathbb{R}} q^2 + q_x^2 + \eta^2 + \varepsilon^{-2}(\eta_x^2 + \eta_{xx}^2)\,\mathrm{d}x,$$

and hence a norm on $H^2(\mathbb{R}) \times H^1(\mathbb{R})$. By Fourier transform it is obvious that the solution U of the linearized equation $U_t = A_0 U$, with A_0 from (1.6), exists and is smooth. We then obtain

$$\begin{aligned}
\frac{\mathrm{d}}{\mathrm{d}t}\|U\|_Y^2 = \int_{\mathbb{R}} \Big\{ & (q - 2\eta - c_3\eta_x - \mathrm{R}^2 q_{xx})\Big[\frac{6}{\mathrm{R}}\eta + \Big(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta\Big)\eta_x - \frac{3}{\mathrm{R}}\eta_{xx} \\
& \qquad + \varepsilon^{-2}\mathrm{W}\eta_{xxx} - \frac{3}{\mathrm{R}}q - \frac{8}{5}q_x + \frac{7}{2\mathrm{R}}q_{xx}\Big] \\
& - 9\eta q_x + \varepsilon^{-2}\mathrm{W}\big(\eta_{xx}q_x + \mathrm{R}^2\eta_{xxx}q_{xx}\big) - c_3 q_x^2\Big\}\,\mathrm{d}x \\
= \int_{\mathbb{R}} \Big\{ & -\frac{3}{\mathrm{R}}q^2 + \frac{12}{\mathrm{R}}q\eta - \frac{12}{\mathrm{R}}\eta^2 + \Big(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta - \frac{16}{5} + 9 + \frac{3}{\mathrm{R}}c_3\Big)\eta_x q \\
& + \Big(-c_3 - 3\mathrm{R} - \frac{7}{2\mathrm{R}}\Big)q_x^2 + \Big(6\mathrm{R} + \frac{8}{5}c_3 + \frac{10}{\mathrm{R}}\Big)q_x\eta_x \\
& + \Big(-c_3\Big(\tfrac{4}{5} - \tfrac{2}{3}\cot\theta\Big) - \tfrac{6}{\mathrm{R}}\Big)\eta_x^2 + \Big(\mathrm{R}^2\Big(\tfrac{4}{5} - \tfrac{2}{3}\cot\theta\Big) + \tfrac{7c_3}{2\mathrm{R}}\Big)q_x\eta_{xx} \\
& - \frac{7\mathrm{R}}{2}q_{xx}^2 + 3\mathrm{R}q_{xx}\eta_{xx} + \varepsilon^{-2}\mathrm{W}c_3\eta_{xx}^2\Big\}\,\mathrm{d}x.
\end{aligned}$$

The quadratic form in η, q without derivatives is nonpositive. For $c_3 = -11\mathrm{R}/5 + 2\cot\theta/3$ the coefficient of $\eta_x q$ vanishes. Moreover, the coefficients of q_x^2, q_{xx}^2 are negative definite, and the coefficient of η_{xx}^2 is negative definite with strong weight ε^{-2}. Note that $c_3 < 0$ due to (1.2). The terms with η_x, q_x yield $\frac{\mathrm{d}}{\mathrm{d}t}\|U\|_Y^2 \le C_1\|\eta_x\|_{L^2}^2$, but since η_x^2 appears in $\|U\|_Y$ with weight ε^{-2}, we nevertheless obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}\|U\|_Y^2 \le C_1\varepsilon^2\|U\|_Y^2 - C\|q_x\|_{H^1}^2. \tag{2.2}$$

On the other hand, the coefficient of $q\eta_x$ has to vanish identically, since we have no negative definite term in q^2 and cannot have one, as is clear from the dispersion relation. Therefore we have to introduce c_3 in (1.10). From (2.2) we get (1.9) using Gronwall's lemma. The dissipation in $\partial_x q$ in (2.2) will be important for the quasilinear problem (1.21).

2.2. The residual. For notational convenience and without loss of generality for our purposes, we assume in the following that we have a vertically falling film such

that $\cot\theta = 0$. Then the critical Reynolds number is $\mathrm{R}_c = 0$, and we may further assume without loss of generality that

$$\mathrm{R} = W = 1. \tag{2.3}$$

In order to get a small residual in (1.21), we define an improved approximation by

$$\varepsilon\tilde{\psi}(t,x) = \begin{pmatrix} \varepsilon\eta_1(T,X) \\ \sum_{j=1}^3 \varepsilon^j q_j(T,X) \end{pmatrix}, \quad T = \varepsilon^2, \quad X = \varepsilon(x-2t). \tag{2.4}$$

Plugging (2.4) into (1.3), (1.4), we first obtain (1.13) and (1.14) as before, and then

$$\begin{aligned} \mathcal{O}(\varepsilon^3(1.4)): \quad q_{1T} - 2q_{2X} &= \frac{8}{5}\eta_{1X}\eta_1 + \frac{7}{2}q_{1XX} + \eta_1\eta_{1XXX} - 3\eta_{1XX} - 3q_3 \\ &\quad + 6\eta_1 q_2 - \frac{8}{5}q_{2X} - \frac{12}{5}q_1 q_{1X} + \frac{8}{5}\eta_1\eta_{1X} \\ \Rightarrow q_3 &= \frac{1}{3}\left(\frac{4}{5}\partial_X^4\eta_1 + 3\eta_{1X}\eta_1 + \frac{52}{25}\eta_{1XX}\eta_1 + \frac{112}{5}\eta_{1X}\eta_1 + 12\eta_1^3\right). \end{aligned} \tag{2.5}$$

With q_3 given by (2.5), all terms up to order $\mathcal{O}(\varepsilon^3)$ vanish in the residual

$$\mathrm{Res}(\varepsilon\tilde{\psi}) = \varepsilon^4 f = \varepsilon^4 \begin{pmatrix} f_1 \\ f_2 \end{pmatrix}. \tag{2.6}$$

To leading order in derivatives we have

$$\begin{aligned} f_1 &= -q_{3X} = -\frac{4}{15}\partial_X^5\eta_1 + \tilde{f}_1, \\ f_2 &= -\varepsilon q_{3T} + \tilde{f}_2 = -\frac{4\varepsilon}{15}\partial_X^4\partial_T\eta_1 + \tilde{f}_2 = \frac{4\varepsilon}{45}\partial_X^8\eta_1 + \tilde{f}_2. \end{aligned} \tag{2.7}$$

Later we need

$$(f_1, f_2) \in C\left(\left[0, \varepsilon^2 T_0\right], H^2(\mathbb{R}) \times H^1(\mathbb{R})\right) \tag{2.8}$$

and therefore

$$\eta_1 \in C([0,T_0], H^9(\mathbb{R})) \tag{2.9}$$

in Theorem 1.1. The (nonlinear) functions $\tilde{f}_{1,2}$ in (2.7) contain lower order derivatives of η_1, and it can be easily checked that (2.8) holds if (2.9) does.

In order to estimate the residual in Y, we finally need to take care of how scaling affects the L^2 norm, i.e., $\|u(\varepsilon\cdot)\|_{L^2} = \varepsilon^{-1/2}\|u(\cdot)\|_{L^2}$. This loss of $\varepsilon^{-1/2}$ is the reason that we cannot choose $\beta = 2$ in (1.20), which would be more convenient in order to control the nonlinear terms in (1.21).

We summarize our results as follows.

LEMMA 2.1. *Assume that $\eta_1 \in C([0,T_0], H^9(\mathbb{R}))$. Then*

$$\sup_{0\le t<T_0/\varepsilon^2} \|\varepsilon\tilde{\psi} - \varepsilon\psi\|_Y \le C\varepsilon^{5/2} \quad \text{and} \quad \sup_{0\le t\le T_0/\varepsilon^2} \|\mathrm{Res}(\varepsilon\tilde{\psi})\|_Y \le C\varepsilon^{7/2}.$$

Due to the first estimate in Lemma 2.1 we can use $\varepsilon\tilde{\psi}$ instead of $\varepsilon\psi$ in the proof of Theorem 1.1, and in order to simplify symbols we drop the $\tilde{}$ in the following. Also we write $\psi = (\psi_1, \psi_2)$ and $\psi_j' = \partial_X\psi_j$.

3. Proof of Theorem 1.1. In the following many constants which are independent of ε and t are denoted by C, and C_1, C_2 are the constants from Theorem 1.1.

From the local existence of solutions to the IBLe in Theorem A.1 we directly obtain the following local existence of solutions to (1.21).

COROLLARY 3.1. *Let $R_0 \in H^2(\mathbb{R}) \times H^1(\mathbb{R})$ and $0 < t_1 \le T_0/\varepsilon^2$. Then there exists an $\varepsilon_1 > 0$ such that for all $\varepsilon \in (0, \varepsilon_1)$ there exists a unique solution $R \in H^{3,3/2}((0,t_1)\times\mathbb{R}) \times H^{2,1}((0,t_1)\times\mathbb{R})$ of the error equation (1.21) with $R(0) = R_0$.*

Proof. For ε_1 sufficiently small we have

$$\|U_0\|_{H^2\times H^1} = \|(\varepsilon\psi + \varepsilon^{3/2}R)|_{t=0}\|_{H^2\times H^1} \le \rho$$

for all $\varepsilon \in (0, \varepsilon_1)$, with $\rho > 0$ from Theorem A.1. Therefore there exists a unique solution $U \in H^{3,3/2}((0,t_1)\times\mathbb{R}) \times H^{2,1}((0,t_1)\times\mathbb{R})$ of (1.6). Using the smoothness of η_1 we find that the solution $R = \varepsilon^{-3/2}(U - \varepsilon\psi)$ of (1.21) has the same regularity. ∎

The proof of Theorem 1.1 now works as follows: due to Corollary 3.1 we have a local solution $R \in C([0,t_1), H^2 \times H^1)$ of (1.21). Thus we may choose t_1 so small that $\sup_{0\le t\le t_1} \|R\|_Y \le 2\|R_0\|_Y \le 2C_1$. This implies

$$\sup_{0\le t\le t_1} (\|r\|_\infty + \|\xi\|_\infty + \varepsilon^{-1}\|\partial_x\xi\|_\infty) \le 2CC_1, \tag{3.1}$$

where $C > 0$ comes from Sobolev embedding. Using (3.1), we derive an energy estimate that implies $\|R(t_1)\|_Y \le \mathrm{e}^{C\varepsilon^2 t_1}\|R_0\|_Y$. Thus, using Corollary 3.1 again, the solution can be continued and stays $\mathcal{O}(1)$-bounded in Y until $t_1 = t_0 = T_0/\varepsilon^2$.

It will be convenient to write (1.21) as

$$R_t = A(t,R)R + \varepsilon^2 f, \tag{3.2}$$

where, with $a_0, \dots, b_1$ from (1.5),

$$R = \begin{pmatrix}\xi\\ r\end{pmatrix}, \quad A(t,R) = \begin{pmatrix} 0 & -\partial_x \\ \tilde a_0 + \tilde a_1\partial_x + \tilde a_2\partial_x^2 + \varepsilon^{-2}\tilde a_3\partial_x^3 & -\tilde b_0 - \tilde b_1\partial_x + \tilde b_2\partial_x^2 \end{pmatrix},$$

$$\tilde a_0 = \tilde a_0(t,\xi) = a_0(\varepsilon\psi_1 + \varepsilon^{3/2}\xi) - \frac{8}{5}\varepsilon^2\psi_1' + \frac{9}{2}\varepsilon^3\psi_1'' + \varepsilon^4\psi_1''' + 6\varepsilon\psi_2 + \frac{8}{5}\varepsilon^2\psi_2' + 3\varepsilon^3\psi_2''',$$
$$\tilde a_1 = \tilde a_1(t,R) = a_1(\varepsilon\psi + \varepsilon^{3/2}R) - 2\varepsilon^2\psi_1', \quad \tilde a_2 = \tilde a_2(t,\xi) = a_2(\varepsilon\psi_1 + \varepsilon^{3/2}\xi),$$
$$\tilde a_3 = \tilde a_3(t,\xi) = a_3(\varepsilon\psi_1 + \varepsilon^{3/2}\xi),$$
$$\tilde b_0 = \tilde b_0(t,\xi) = b_0(\varepsilon\psi_1 + \varepsilon^{3/2}\xi) - \frac{8}{5}\varepsilon^2\psi_1' + \frac{12}{5}\varepsilon^2\psi_2' + \frac{9}{2}\varepsilon^3\psi_1'',$$
$$\tilde b_1 = \tilde b_1(t,R) = b_1(\varepsilon\psi + \varepsilon^{3/2}R) - \varepsilon^2\psi_1', \quad \tilde b_2 = b_2 = \frac{7}{2}.$$

The main idea for obtaining the energy estimate is to define an equivalent norm $N_Y(R,t)$ on Y that depends on time and the solution itself in such a way that high order and strongly weighted mixed products like $\varepsilon^{-2}\partial_x^2 q\partial_x^3\eta$ still cancel after integration by parts in $\frac{\mathrm{d}}{\mathrm{d}t}\|R\|^2_{N_Y(R,t)}$. This can be achieved by dividing all terms in (1.10) involving r by $\tilde a_3$. Moreover, we need correction terms that eliminate terms of order $\mathcal{O}(\varepsilon)$ and $\mathcal{O}(\varepsilon^{3/2})$ in $\frac{\mathrm{d}}{\mathrm{d}t}\|R\|_{N(t,R)}$ without derivatives that come from $2\varepsilon B(\tilde\psi, R) + \varepsilon^{3/2}B(R,R)$ in (1.21).

Thus, with coefficients $\gamma_1, \dots, \gamma_4 \in \mathbb{R}$ to be determined, we define

$$\|R\|^2_{N_Y(t,R)} = E + F_1 + F_2, \tag{3.3}$$

$$E = \frac{1}{2}\int_{\mathbb{R}} \left\{ \frac{1}{\tilde a_3}\left[r^2 - 4r\xi - 2c_3 r\xi_x + r_x^2\right] + 9\xi^2 + \varepsilon^{-2}\left[\xi_x^2 + \xi_{xx}^2\right] \right\} \mathrm{d}x,$$

$$F_1 = \int \frac{1}{\tilde a_3}\varepsilon\eta_1\left[\gamma_1 r^2 + \gamma_2 \xi r\right] \mathrm{d}x, \quad F_2 = \int \frac{1}{\tilde a_3}\varepsilon^{3/2} r\left[\gamma_3 r\xi + \gamma_4 \xi^2\right] \mathrm{d}x,$$

where for notational convenience we keep writing c_3 for $-11/5$. Due to (3.1) we have

$$1 - C\varepsilon \le \sup_{0\le t\le t_0, x\in\mathbb{R}} |a_3| = \sup_{0\le t\le t_0, x\in\mathbb{R}} |1 + \varepsilon\psi_1 + \varepsilon^{3/2}\xi| \le 1 + C\varepsilon. \tag{3.4}$$

Therefore $N_Y(t,R)$ is still an equivalent norm on Y if ε is sufficiently small. Moreover, space and time derivatives of $\tilde a_0, \tilde a_1, \dots, \tilde b_2$ produce terms of order $\mathcal{O}(\varepsilon^{3/2})$, and in particular we have

$$\frac{\mathrm{d}}{\mathrm{d}x}\tilde a_0 = 6\varepsilon^{3/2}\xi_x + \varepsilon^2 h_1, \quad \frac{\mathrm{d}}{\mathrm{d}x}\tilde b_0 = 3\varepsilon^{3/2}\xi_x + \varepsilon^2 h_2, \tag{3.5}$$

$$\frac{\mathrm{d}}{\mathrm{d}x}\tilde a_3 = \varepsilon^{3/2}\xi_x + \varepsilon^2 h_3, \quad \frac{\mathrm{d}}{\mathrm{d}t}\tilde a_3 = \varepsilon^{3/2}\xi_t + \varepsilon\frac{\mathrm{d}}{\mathrm{d}t}\psi_1 = -\varepsilon^{3/2} r_x + h_4, \tag{3.6}$$

with $\|h_j\|_{L^\infty} = \mathcal{O}(\varepsilon^2)$, $j = 1,2,3,4$. Hence we can estimate terms like, for instance, $(\frac{\mathrm{d}}{\mathrm{d}x}\frac{\tilde b_0}{\tilde a_3})r\xi$ that show up during integration by parts in $\frac{\mathrm{d}}{\mathrm{d}t}\|R\|^2_{N(t,R)}$ as

$$\begin{aligned}\int \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{\tilde b_0}{\tilde a_3}\right) r\xi \,\mathrm{d}x &= \int \frac{1}{3\tilde a_3}(\varepsilon^{3/2}\xi_x r\xi) - 6\frac{\tilde b_0}{\tilde a_3^2}(\varepsilon^{3/2} r_x r\xi) + \mathcal{O}(\varepsilon^2)|r\xi| \,\mathrm{d}x \\ &\le C\|\xi\|_\infty \int \varepsilon\xi_x^2 + \varepsilon r_x^2 + \varepsilon^2(\xi^2 + r^2)\,\mathrm{d}x + C\varepsilon^2 \int r^2 + \xi^2 \,\mathrm{d}x,\end{aligned} \tag{3.7}$$

and similarly for $(\frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{\tilde a_3})(r^2 - 4r\xi)$; see (3.10). The first term on the right-hand side of (3.7) is estimated by $\varepsilon^3\varepsilon^{-2}\xi_x^2$, and the second term is well behaved since we will have an $\mathcal{O}(1)$ negative definite term $-Cr_x^2$ in $\frac{\mathrm{d}}{\mathrm{d}t}\|R\|^2_{N_Y(t,R)}$. This is essentially the first reason why the estimate (2.2) can be carried over to the quasilinear problem (3.2). The second reason is that the coefficients $\gamma_1, \dots, \gamma_4$ can be chosen in such a way that the terms r^2, ξ^2 without derivatives in $\frac{\mathrm{d}}{\mathrm{d}t}\|R\|^2_{N_Y(t,R)}$ have $\mathcal{O}(\varepsilon^2)$ coefficients. This is possible again due to the fact that the small parameter ε does not as usual enter (1.6) as a coefficient of the low order terms but in inverse power as coefficient of the high order damping term.

We start with $\frac{\mathrm{d}}{\mathrm{d}t}E$. Using $2\int g f_x f \,\mathrm{d}x = -\int g_x f^2 \,\mathrm{d}x$, we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}E = d_1 + d_2 + d_3 + d_4, \tag{3.8}$$

$$\begin{aligned} d_1 = \int \Bigg\{ &\left[r - 2\xi \; - c_3\xi_{xx} - r_{xx} - \tilde a_3 \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{1}{\tilde a_3}\right) r_x\right] \\ &\left[\frac{\tilde a_0}{\tilde a_3}\xi + \frac{\tilde a_1}{\tilde a_3}\xi_x + \frac{\tilde a_2}{\tilde a_3}\xi_{xx} + \varepsilon^{-2}\xi_{xxx} - \frac{\tilde b_0}{\tilde a_3} r - \frac{\tilde b_1}{\tilde a_3} r_x + \frac{\tilde b_2}{\tilde a_3} r_{xx} + \varepsilon^2 \frac{f_2}{\tilde a_3}\right] \Bigg\} \mathrm{d}x, \\ d_2 = \int &-9\xi r_x + \varepsilon^{-2}(\xi_{xx} r_x + \xi_{xxx} r_{xx}) + 9\xi\varepsilon^2 f_1 + \varepsilon^{-2}\varepsilon^2\left(\xi_x f_{1x} + \xi_{xx} f_{1xx}\right) \mathrm{d}x, \\ d_3 = \int \frac{1}{\tilde a_3}\left[2r r_x + c_3 r r_{xx}\right] \mathrm{d}x, \quad &d_4 = \int \left(\frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{\tilde a_3}\right)\left[r^2 - 4r\xi - 2c_3 r\xi_x + r_x^2\right] \mathrm{d}x. \end{aligned}$$

Integration by parts yields

(3.9)
$$\begin{aligned} d_1+d_2+d_3 = \int\Big\{ & \frac{1}{\tilde a_3}\big[-\tilde b_0 r^2+(\tilde a_0+2\tilde b_0)r\xi-2\tilde a_0\xi^2\big]+\mathcal{O}(\varepsilon^2)(r^2+\xi^2) \\ & + \frac{1}{\tilde a_3}\big[\tilde a_1-2\tilde b_1+9+c_3\tilde b_0+\mathcal{O}(\varepsilon)\big]r\xi_x+\frac{1}{\tilde a_3}\big[-c_3-\tilde b_0-\tilde b_2+\mathcal{O}(\varepsilon)\big]r_x^2 \\ & + \frac{1}{\tilde a_3}\big[\tilde a_0+c_3\tilde b_1-\tilde a_2+2\tilde b_2+\mathcal{O}(\varepsilon)\big]r_x\xi_x+\frac{1}{\tilde a_3}\big[-c_3\tilde a_1+2\tilde a_2+\mathcal{O}(\varepsilon)\big]\xi_x^2 \\ & + \big[c_3\varepsilon^{-2}+\mathcal{O}(\varepsilon)\big]\xi_{xx}^2+\frac{1}{\tilde a_3}\big[\tilde a_1+c_3\tilde b_2+\mathcal{O}(\varepsilon)\big]r_x\xi_{xx}-\frac{\tilde b_2}{\tilde a_3}r_{xx}^2-\frac{2\tilde a_2}{\tilde a_3}r_{xx}\xi_{xx} \\ & + \varepsilon^2 f_2[r-2\xi-c_3\xi_{xx}-r_{xx}+\mathcal{O}(\varepsilon)r_x]+9\varepsilon^2 f_1\xi+f_{1x}\xi_x+f_{1xx}\xi_{xx}\Big\}\,\mathrm{d}x, \end{aligned}$$

where the order symbol $\mathcal{O}(\varepsilon)$ always refers to terms estimated in L^∞. The coefficient of $r\xi_x$ in (3.9) is $\mathcal{O}(\varepsilon)$ due to the choice of c_3 and (3.1). Similarly to (3.7), d_4 can be estimated as

$$\begin{aligned} d_4 \le{}& C\|r\|_\infty\int\varepsilon^{3/2}(|r_x r|+|r_x\xi|)\,\mathrm{d}x+C\varepsilon^2\int r^2+\xi^2\,\mathrm{d}x \\ & + C\varepsilon^{3/2}\|r_x\|_\infty\int\big[-2c_3 r\xi_x+r_x^2\big]\,\mathrm{d}x, \end{aligned} \tag{3.10}$$

and therefore (3.9) and (3.10), except for the first term on the right-hand side of (3.9), can be estimated by $C\varepsilon^2 E+C_{\mathrm{res}}\varepsilon^2$.

Thus, we now have

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\|R\|_{N_Y(t,R)}^2 &= \frac{\mathrm{d}}{\mathrm{d}t}E+\frac{\mathrm{d}}{\mathrm{d}t}F_1+\frac{\mathrm{d}}{\mathrm{d}t}F_2 \\ &\le \int\frac{1}{\tilde a_3}\big[-\tilde b_0 r^2+(\tilde a_0+2\tilde b_0)r\xi-2\tilde a_0\xi^2\big]\,\mathrm{d}x+\frac{\mathrm{d}}{\mathrm{d}t}F_1+\frac{\mathrm{d}}{\mathrm{d}t}F_2+C\varepsilon^2E+\varepsilon^2C_{\mathrm{res}}. \end{aligned} \tag{3.11}$$

To control the first three terms on the right-hand side of (3.11), we calculate

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}F_1 &= \int\frac{\varepsilon\eta_1}{\tilde a_3}\big[2\gamma_1 r(6\xi-3r)+\gamma_2\xi(6\xi-3r)\big]\,\mathrm{d}x+h_1, \\ \frac{\mathrm{d}}{\mathrm{d}t}F_2 &= \int\frac{\varepsilon^{3/2}\xi}{\tilde a_3}\big[2\gamma_2 r(6\xi-3r)+\gamma_4\xi(6\xi-3r)\big]\,\mathrm{d}x+h_2, \end{aligned}$$

where h_1 and h_2 contain terms like, for instance, $h_1=-\varepsilon\eta_1 r_x r^2/\tilde a_3+\cdots$, that can be controlled by the negative definite terms in $\frac{\mathrm{d}}{\mathrm{d}t}E$ as in (3.7) and (3.10). Since

$$\tilde b_0 = 3-6\varepsilon\eta_1-6\varepsilon^{3/2}\xi+\mathcal{O}(\varepsilon^2),\qquad \tilde a_0 = 6-18\varepsilon\eta_1-6\varepsilon^{3/2}\xi+\mathcal{O}(\varepsilon^2), \tag{3.12}$$

we thus obtain

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\|R\|_{N_Y(t,R)}^2 \le{}& \int\frac{1}{\tilde a_3}\Big\{\big(-3+6\varepsilon(1-\gamma_1)\eta_1+6\varepsilon^{3/2}\xi(1-\gamma_3)\varepsilon^{3/2}\xi\big)r^2 \\ & + \big(12-3(10-4\gamma_1+\gamma_2)\varepsilon\eta_1-3(6-4\gamma_3+\gamma_4)\varepsilon^{3/2}\xi\big)r\xi \\ & - \big(12-6(6+\gamma_2)\varepsilon\eta_1-6(2+\gamma_4)\varepsilon^{3/2}\xi\big)\xi^2\Big\}\,\mathrm{d}x \\ & + C\varepsilon^2E+C_{\mathrm{res}}\varepsilon^2. \end{aligned} \tag{3.13}$$

Choosing $\gamma_1 = 1, \gamma_2 = -6, \gamma_3 = 1, \gamma_4 = -2$, the $\mathcal{O}(\varepsilon)$ and $\mathcal{O}(\varepsilon^{3/2})$ coefficients in the integral vanish, and since $\int \frac{1}{\bar{a}_3}\left[-3r^2 + 12r\xi - 12\xi^2\right] \mathrm{d}x \le 0$, we finally obtain

$$\frac{\mathrm{d}}{\mathrm{d}t}\|R\|^2_{N_Y(t,R)} \le C\varepsilon^2 E + C_{\mathrm{res}}\varepsilon^2 \le C\varepsilon^2 \|R\|^2_{N_Y(t,R)} + C_{\mathrm{res}}\varepsilon^2. \tag{3.14}$$

This gives $\|R\|^2_{N_Y(t,R)} \le \mathrm{e}^{C\varepsilon^2 t}\|R|_{t=0}\|^2_{N_Y(t,R)} + C(\mathrm{e}^{C\varepsilon^{2t}-1})$, using Gronwall's lemma. The proof of Theorem 1.1 is now complete. □

Remark 3.2. Theorem 1.1 also holds in higher order Sobolev spaces. For $m \ge 3$ we can define $Y_m = H^m(\mathbb{R}) \times H^{m-1}(\mathbb{R})$, with $\|\cdot\|_{Y_m}$ defined in a way similar to $\|\cdot\|_Y$; i.e., for $\cot\theta = 0$, R = W = 1,

$$\|U\|^2_{Y_3} = \frac{1}{2}\int_{\mathbb{R}} \Big\{ q^2 + 9\eta^2 - 4q\eta - \frac{22}{5}\eta_x q + 2q_x\eta_{xx} + q_x^2 + q_{xx}^2 + 2q_x\eta_{xx} + \varepsilon^{-2}(\eta_x^2 + \eta_{xx}^2 + \eta_{xxx}^2) \Big\} \mathrm{d}x.$$

Then for $\|U(0,\cdot) - \varepsilon\psi(0,\cdot)\|_{Y_m} \le C_1\varepsilon^{3/2}$ and $\eta_1 \in H^{m+6}(\mathbb{R})$ we obtain a solution $U \in H^{m+1,(m+1)/2} \times H^{m,m/2}$ with $\sup_{0\le t\le t_0}\|U(t,\cdot) - \varepsilon\psi(t,\cdot)\|_{Y_m} \le C_2\varepsilon^{3/2}$. The local existence of solutions in these higher order spaces is already shown in Theorem A.1, and from the above proof of Theorem 1.1 it can be seen that the high order terms are uncritical in the energy estimates.

Appendix A. Local existence of solutions for the IBLe. To treat the initial value problem for the IBLe (1.6), we use the spaces

$$H^{r,s} = H^{r,s}((0,t_0)\times\mathbb{R}) = L^2((0,t_0), H^r(\mathbb{R})) \cap H^s((0,t_0), L^2(\mathbb{R})),$$

defined for $r, s \ge 0$. Because we have a parabolic system, we will always have $s = r/2$, and therefore we introduce the notation $K^r = K^r((0,t_0)\times\mathbb{R}) = H^{r,r/2}((0,t_0)\times\mathbb{R})$. We recall a few facts on the spaces $H^{r,r/2}((0,t_0)\times\mathbb{R})$, mainly from [11].

If $u \in H^{r,s}$ and $j,k \in \mathbb{N}$ with $1 - (j/r + k/s) \ge 0$, then $\partial_t^k\partial_x^j u \in H^{\mu,\nu}$ with $\mu/r = \nu/s = 1-(j/r+k/s)$; see [11, Proposition 4.2.3]. Especially, if $u \in K^r$ and $1-(j/r+2k/r) \ge 0$, then $\partial_t^k\partial_x^j u \in K^{r-j-2k}$. For $k < r/2 - 1/2$ we have traces $\partial_t^k u(0,\cdot) \in H^{r-2k-1}(\mathbb{R})$; see [11, Proposition 4.2.1]. Conversely, if these traces are given at $t = 0$, then there exists a bounded extension operator such that $u \in K^r$; see [11, Theorem 4.2.3]. Similarly, there exists a bounded extension operator from $K^r = K^r((0,t_0)\times\mathbb{R})$ into $K^r(\mathbb{R}\times\mathbb{R})$; see [24, Lemma 3.1].

For $u \in K^r(\mathbb{R}\times\mathbb{R}^n)$ let $\hat{\hat{u}}(\tau,k) = \iint \mathrm{e}^{-\mathrm{i}(\tau t + k\cdot x)}u(t,x)\,\mathrm{d}k\,\mathrm{d}t$ be the Fourier transform in time and space of u. Then we have the equivalence of norms

$$\|u\|^2_{K^r(\mathbb{R}\times\mathbb{R}^n)} \sim \iint |\hat{\hat{u}}(\tau,\xi)|^2(1+|k|^2+|\tau|)^r\,\mathrm{d}k\,\mathrm{d}\tau. \tag{A.1}$$

From this it follows easily that if $u \in K^r(\mathbb{R}\times\mathbb{R}^n)$ with $r > (n+2)/2$, then u is bounded and continuous. Finally, we need the special subspace

$$K_0^r = K_0^r((0,t_0)\times\mathbb{R}) = \{u \in K^r((0,t_0)\times\mathbb{R}) : \partial_t^k u(0,\cdot) = 0 \text{ for } k\in\mathbb{N}, k < r/2 - 1/2\}.$$

For $u \in K_0^r((0,\infty)\times\mathbb{R})$ the continuation by $u(t) = 0$ for $t < 0$ is in $K^r(\mathbb{R}\times\mathbb{R})$; see [11, Theorem 1.11.5]. In addition to the full space-time transform of $u \in K^r$ we also

use the Fourier transform in time only, denoted by $\hat{u}(\tau,x)=\int \mathrm{e}^{-\mathrm{i}\tau t}u(t,x)\,\mathrm{d}t$. For $u\in K_0^r((0,\infty)\times\mathbb{R})$ we then obtain the equivalence

$$\|u\|^2_{K^r((0,\infty)\times\mathbb{R})}\sim\int\|\hat{u}(\tau,\cdot)\|^2_{H^r}+|\tau|^r\|\hat{u}(\tau,\cdot)\|^2_{L^2}\,\mathrm{d}\tau. \tag{A.2}$$

We introduce the shorthand $\mathcal{K}^r=K^r\times K^{r-1}$. Also, in this section we write $|u|_r$ for the Sobolev norm in the spacial variable x (or its dual k), i.e., $|u|_r{=}\|u\|_{H^r(\mathbb{R})}$, and, e.g., $|\hat{u}(1{+}k^2)|_0$ for the L^2 norm of the function $k\mapsto\hat{u}(1{+}k^2)$. In the proof of Theorem 1.1 we use the following local existence theorem for the solutions of the IBLe (1.6) with $r=2$; however, here we state a more general case.

THEOREM A.1. *Let $2\le r<4$, $\varepsilon>0$, and $t_0>0$ be fixed. Then there exists a $\rho>0$ such that for all $U_0=(\eta_0,q_0)\in H^r(\mathbb{R})\times H^{r-1}(\mathbb{R})$ with $|U_0|_{H^r\times H^{r-1}}\le\rho$ there exists a unique solution*

$$U=(\eta,q)\in\mathcal{K}^{r+1} \tag{A.3}$$

of the IBLe (1.6) with $U|_{t=0}=U_0$ and $\|U\|_{\mathcal{K}^{r+1}}\le C|U_0|_{H^r\times H^{r-1}}$, where the constant $C>0$ depends only on ε and t_0. Moreover, for all $0<t_1<t_0$ and all $k>0$ we have $U\in\mathcal{K}^{r+k+1}((t_1,t_0)\times\mathbb{R})$; i.e., U is smooth for $t>0$.

Remark A.2. Examining the proof of Theorem A.1, we obtain that ρ may be chosen independently of $\varepsilon\in(0,\varepsilon_0)$. Theorem A.1 is used in Corollary 3.1 in this sense, but for simplicity we do not keep track of this here. Also, the upper bound $r<4$ is only for notational convenience, i.e., to avoid the formulation of higher order trace conditions at $t=0$; see (A.12).

The proof of Theorem A.1 consists of two steps. First we consider the linear inhomogeneous version of (1.6) with zero initial data, i.e., the equation

$$LU=F(t),\quad U(0)=0,\quad LU=U_t-A_0U,\quad F\in\mathcal{K}_0^{r-1}, \tag{A.4}$$

and estimate its solutions in $\mathcal{K}_0^{r+1}$. Then we write the solution U of (1.6) as $U=\tilde{U}{+}U^{(1)}$, where $\tilde{U}\in\mathcal{K}^{r+1}$ fulfills $\tilde{U}(0)=U_0$ and some (further) trace conditions at $t=0$; see (A.12). Then $U^{(1)}$ has to solve the equation

$$LU^{(1)}=G(U^{(1)}),\quad U^{(1)}(0)=0,\quad G(U^{(1)})=F(\tilde{U}+U^{(1)})-L\tilde{U}. \tag{A.5}$$

We show that for $U^{(1)}\in\mathcal{K}_0^{r+1}$ we have $G(U^{(1)})\in\mathcal{K}_0^{r-1}$, and use the estimates for (A.4), estimates for the nonlinearity, and the contraction mapping theorem to solve (A.5).

LEMMA A.3. *Let $r\ge2$, $\varepsilon>0$, and $t_0>0$. For every $F\in\mathcal{K}_0^{r-1}$ there exists a unique solution $U\in\mathcal{K}_0^{r+1}$ of (A.4) with $\|U\|_{\mathcal{K}^{r+1}}\le C\|F\|_{\mathcal{K}^{r-1}}$, where $C>0$ depends only on ε,t_0.*

Proof. We identify F with its extension to $\mathcal{K}^{r-1}(\mathbb{R}\times\mathbb{R})$, with $F(t)=0$ for $t\le0$. Then $\mathrm{e}^{-\sigma t}F\in L^1(H^{r-1})\cap L^2(H^{r-1})$ for $\mathrm{Re}\sigma>0$, and therefore $\hat{F}(\tau)$ has an analytic extension into $\mathrm{Im}\tau<0$. We write $\lambda=\sigma+\mathrm{i}\tau$ and consider the Fourier transform in t (i.e., the Laplace transform) of (A.4),

$$\begin{aligned}&\lambda\hat{\eta}=-\hat{q}_x+\hat{f}_1\quad\Leftrightarrow\quad\hat{\eta}=\frac{-\hat{q}_x+\hat{f}_1}{\lambda},\\&\lambda\hat{q}=\frac{1}{\lambda}\big(a_{00}{+}a_{10}\partial_x{+}a_{20}\partial_x^2{+}\varepsilon^{-2}a_{30}\partial_x^3\big)(-\hat{q}_x{+}\hat{f}_1){-}b_{00}\hat{q}{-}b_{10}\hat{q}_x{+}b_{20}\hat{q}_{xx}{+}\hat{f}_2.\end{aligned} \tag{A.6}$$

Now choose $\sigma_0 > 0$ such that $\mathrm{Re}\mu_{1,2}(k) < \sigma_0$ for all $k \in \mathbb{R}$. For $\mathrm{Re}\lambda = \sigma > \sigma_0$ we obtain

$$|\hat\eta|_{r+1} + |\lambda|^{(r+1)/2}|\hat\eta|_0 \le C\big(|\hat f_1|_{r-1} + |\lambda|^{(r-1)/2}|\hat f_1|_0 + |\hat f_2|_{r-2} + |\lambda|^{(r-2)/2}|\hat f_2|_0\big), \tag{A.7}$$

$$|\hat q|_r + |\lambda|^{r/2}|\hat q|_0 \le C\big(|\hat f_1|_{r-1} + |\lambda|^{(r-1)/2}|\hat f_1|_0 + |\hat f_2|_{r-2} + |\lambda|^{(r-2)/2}|\hat f_2|_0\big); \tag{A.8}$$

see below. Moreover, since $\hat F$ is analytic in λ, so is $\hat U = (\hat\eta, \hat q)$ for $\mathrm{Re}\lambda > \sigma_0$. Let

$$U(t) = \frac{1}{2\pi}\int \mathrm{e}^{\sigma_0 t}\mathrm{e}^{\mathrm{i}\tau t}\hat U(\sigma_0 + \mathrm{i}\tau)\,\mathrm{d}\tau.$$

Then $\mathrm{e}^{-\sigma_0 t}U$ is the inverse Fourier transform of the function $\tilde\lambda \mapsto \hat U(\sigma_0 + \tilde\lambda)$, which is analytic for $\mathrm{Re}\tilde\lambda > 0$. Thus, by the Paley–Wiener theorem [26, Theorem 6.4.2], we have $U(t) = 0$ for $t < 0$, and from (A.2), (A.7), and (A.8) we obtain $\mathrm{e}^{-\sigma_0 t}U \in \mathcal{K}_0^{r+1}(\mathbb{R}_+ \times \mathbb{R})$. Since t_0 is finite, we thus have $U \in \mathcal{K}_0^{r+1} = \mathcal{K}_0^{r+1}((0,t_0)\times\mathbb{R})$ with $\|U\|_{\mathcal{K}^{r+1}} \le C\|F\|_{\mathcal{K}^{r-1}}$, where C obviously depends only on t_0 and σ_0, and hence on t_0 and ε.

It remains to show (A.7), (A.8). This is essentially a direct consequence of the parabolic shape of the spectrum. After Fourier transform in x and sorting terms, (A.6) becomes

$$\hat{\hat\eta} = \frac{-\mathrm{i}k\hat{\hat q} + \hat{\hat f}_1}{\lambda}, \qquad g(\lambda,k)\hat{\hat q} = g_0(k)\hat{\hat f}_1 + \lambda\hat{\hat f}_2, \tag{A.9}$$

where

$$g(\lambda,k) = \lambda^2 + \lambda g_1(k) + \mathrm{i}k g_0(k), \quad g_1(k) = b_{20}k^2 + b_{10}\mathrm{i}k + b_{00},$$
$$g_0(k) = a_{00} + a_{10}\mathrm{i}k - a_{20}k^2 - a_{30}\mathrm{i}k^3.$$

Since $g(\lambda,k) = \det(\lambda\mathrm{Id} - A_0(\mathrm{i}k)) = (\lambda-\mu_1(k))(\lambda-\mu_2(k))$, with $\mu_{1,2}$ from (1.7), we have

$$|g(\lambda,k)| \ge C(|\lambda|^2 + (1+k^2)^2).$$

Thus we can estimate

$$\begin{aligned}
|\hat q|_r &\le C|\hat{\hat q}(1+k^2)^{r/2}|_0 \le C\left(\left|\frac{\hat{\hat f}_1 g_0(k)(1+k^2)^{r/2}}{g(\lambda,k)}\right|_0 + \left|\frac{\hat{\hat f}_2\lambda(1+k^2)^{r/2}}{g(\lambda,k)}\right|_0\right)\\
&\le C\left(|\hat{\hat f}_1(1+k^2)^{(r-1)/2}|_0 + |\hat{\hat f}_2(1+k^2)^{(r-2)/2}|_0\right) \le C(|\hat f_1|_{r-1} + |\hat f_2|_{r-2}),
\end{aligned}$$

$$|\lambda|^{r/2}|\hat q|_0 \le C|\lambda|^{r/2}\left|\frac{\hat{\hat f}_1 g_0(k)}{g(\lambda,k)}\right|_0 + \left|\frac{\hat{\hat f}_2\lambda}{g(\lambda,k)}\right|_0 \le C|\lambda|^{(r-2)/2}(|\hat{\hat f}_1|_0 + |\hat{\hat f}_2|_0),$$

$$\begin{aligned}
|\eta|_{r+1} &\le C\left|\frac{(-\mathrm{i}k\hat{\hat q} + \hat{\hat f}_1)(1+k^2)^{(r+1)/2}}{\lambda}\right|_0\\
&= C\left|\frac{(-\mathrm{i}k g_0(k) + g(\lambda,k))\hat{\hat f}_1 - \mathrm{i}k\lambda\hat{\hat f}_2}{\lambda g(\lambda,k)}(1+k^2)^{(r+1)/2}\right|_0\\
&= C\left|\frac{(\lambda + g_1(k))\hat{\hat f}_1 - \mathrm{i}k\hat{\hat f}_2}{g(\lambda,k)}(1+k^2)^{(r+1)/2}\right|_0 \le C(|\hat f_1|_{r-1} + |\hat f_2|_{r-2}),
\end{aligned}$$

$$|\lambda|^{(r+1)/2}|\eta|_{r+1} \le C\left|\frac{(-\mathrm{i}k\hat{\hat q} + \hat{\hat f}_1)}{\lambda}\right|_0 \le C(|\lambda|^{(r-1)/2}|\hat{\hat f}_1|_0 + |\lambda|^{(r-2)/2}|\hat{\hat f}_2|_0).$$

Here we have used the typical parabolic splitting of the domain, for instance,

$$\left|\frac{\hat{\hat{f}}_2 k}{g(\lambda,k)}\right|_0^2 = \left|\frac{\hat{\hat{f}}_2 k}{g(\lambda,k)}\right|^2_{L^2(\{k^2\le|\lambda|\})} + \left|\frac{\hat{\hat{f}}_2 k}{g(\lambda,k)}\right|^2_{L^2(\{k^2\ge|\lambda|\})}$$
$$\le \left|\frac{k\hat{\hat{f}}_2}{|\lambda|^2}\right|^2_{L^2(\{k^2\le|\lambda|\})} + \left||\lambda|^{-3/2}\frac{\hat{\hat{f}}_2 k|\lambda|^{3/2}}{(|\lambda|^2+(1+k^2)^2)}\right|^2_{L^2(\{k^2\ge|\lambda|\})} \le C|\lambda|^{-3}|\hat{f}_2|_0^2.$$

The proof of Lemma A.3 is now complete. ∎

The nonlinear terms in (A.5) can be controlled using the following result, the proof of which follows via extension from $\|uv\|_{K^s(\mathbb{R}\times\mathbb{R}^n)} \le C\|u\|_{K^r(\mathbb{R}\times\mathbb{R}^n)}\,\|v\|_{K^s(\mathbb{R}\times\mathbb{R}^n)}$ if $r > (n+2)/2$.

LEMMA A.4. *Let $r > 3/2$, $0 \le s \le r$. Then there exists a $C > 0$ such that for all $u \in K^r, v \in K^s$ we have $uv \in K^s$ and*

$$\|uv\|_{K^s} \le C\|u\|_{K^r}\|v\|_{K^s}. \tag{A.10}$$

Proof of Theorem A.1. Lemma A.4 applied to F gives

$$\begin{aligned}\|F(U)\|_{\mathcal{K}^{r-1}} &\le C\|U\|^2_{\mathcal{K}^{r+1}},\\ \|F(U)-F(V)\|_{\mathcal{K}^{r-1}} &\le C\|U-V\|_{\mathcal{K}^{r+1}}(\|U\|_{\mathcal{K}^{r-1}} + \|V\|_{\mathcal{K}^{r-1}}).\end{aligned} \tag{A.11}$$

Due to [11, Theorem 4.2.3] there exists an extension $\tilde{U} \in \mathcal{K}^{r+1}$ of $U_0 \in H^r \times H^{r-1}$. We have to choose $\tilde{U} = (\tilde{\eta}, \tilde{q})$ in such a way, that for $U^{(1)} \in \mathcal{K}_0^{r+1}$ the right-hand side $G = F(\tilde{U} + U^{(1)}) - L\tilde{U}$ of (A.5) is in $\mathcal{K}_0^{r-1}$, i.e.,

$$\begin{aligned}\partial_t^k G_1|_{t=0} &= 0 \quad \text{for} \quad 0 \le k < \frac{r}{2} - 1,\\ \partial_t^k G_2|_{t=0} &= 0 \quad \text{for} \quad 0 \le k < \frac{r}{2} - \frac{3}{2}.\end{aligned} \tag{A.12}$$

For $r = 2$ these conditions are trivially true. For $2 < r \le 3$, again due to [11, Theorem 4.2.3], we may choose $\tilde{\eta}$ in such a way that $\partial_t\tilde{\eta}|_{t=0} = -\partial_x q_0 \in H^{r-2}(\mathbb{R})$. Similarly, for $3 < r \le 4$ we additionally choose $\tilde{q}$ such that $\partial_t\tilde{U}|_{t=0} = A(U_0)U_0 \in H^{r-2} \times H^{r-3}$. Thus, in each case, $L\tilde{U} = F(\tilde{U}) = F(\tilde{U} + U^{(1)})$ at $t = 0$, and so $G \in \mathcal{K}_0^{r-1}$.

Thus, we finally consider the mapping

$$\Phi(U^{(1)}) = L_0^{-1}(F(\tilde{U} + U^{(1)}) - L\tilde{U}), \tag{A.13}$$

where $L_0^{-1} : \mathcal{K}_0^{r-1} \to \mathcal{K}_0^{r+1}$ is the solution operator of (A.4). If ρ is sufficiently small, it is easy to see via Lemma A.3, (A.11), and the contraction mapping theorem that Φ has a fixed point $U^{(1)}$ with $\|U^{(1)}\|_{\mathcal{K}^{r+1}} \le C|U_0|_{H^r\times H^{r-1}}$, which gives us the solution $U = \tilde{U} + U^{(1)}$ of the IBLe.

The proof of the regularity result is standard: $U \in L^2((0,t_0), H^{r+1}\times H^r)$ implies $U \in H^{r+1}\times H^r$ for almost every $t > 0$, and, starting again at some such t_1, we obtain $U \in \mathcal{K}^{r+2}((t_1,t_0)\times\mathbb{R})$. The necessary trace conditions at $t = t_1$ are automatically fulfilled. ∎

Remark A.5. (A.11) holds for $r \ge 2$ due to the special form of F, namely, due to the absence of terms of the form $\eta_{xx}(\eta_{xx} + \eta_{xxx})$ and $q_x(q_x + q_{xx})$. If, for instance, (1.1) is expanded to cubic terms, then we obtain a term $-3\varepsilon^{-2}\eta_{xx}^2\eta_x$ in (1.6), and then we would need $r > 5/2$ in Theorem A.1 and therefore $m = 3$ in Theorem 1.1.

Appendix B. Formal derivation of the IBLe. In order to make the paper sufficiently self-contained, and to point out the influence of dissipation, we give here a brief overview of the physical problem underlying (1.1) and describe how (1.1) is formally derived. Details of this calculus can be found in, e.g., [4] and the references therein.

B.1. The inclined film problem. We consider a two dimensional viscous liquid film flowing down an inclined "plane" with inclination angle θ. Using the thickness h_0 of the flat film as the characteristic length and the surface velocity $u_N = u_N(h_0) = gh_0^2 \sin\theta/2\nu$ of the basic Nusselt solution

$$(u, v, p) = (u_N, 0, p_N), \quad u_N(y) = \frac{g\sin\theta}{2\nu}(2h_0 y - y^2), \quad p_N = \rho g \cos\theta(h_0 - y)$$

as characteristic velocity, the governing dimensionless NSe and the continuity equation read

$$\mathbf{u}_t + (\mathbf{u}\cdot\nabla)\mathbf{u} = -\nabla p + \frac{1}{\mathrm{R}}\Delta\mathbf{u} + \frac{2}{\mathrm{R}}\mathbf{g}, \qquad \operatorname{div}\mathbf{u} = 0. \tag{B.1a}$$

Here $\mathbf{u} = (u, v)$ is the velocity field; $\mathrm{R} = u_N h_0/\nu$ is the Reynolds number; ν, ρ, g are the viscosity, density, and gravitational constant; and $\mathbf{g} = (1, -\cot\theta)$. At the free surface $y = h(t, x)$ we have the kinematic condition

$$h_t + h_x u = v \tag{B.1b}$$

and the tangential and normal stress conditions

$$4h_x u_x + (h_x^2 - 1)(u_y + v_x) = 0, \qquad p - \frac{2}{\mathrm{R}}\frac{h_x u_x - h_x(u_y + v_x) + v_y}{1 + h_x^2} = -\mathrm{W}_e K(h), \tag{B.1c}$$

where $\mathrm{W}_e = \sigma/(\rho u_N^2 h_0)$ is the Weber number, σ is the coefficient of surface tension, and $K(h) = h_{xx}(1 + h_x^2)^{-3/2}$ is the interfacial curvature. A constant atmospheric pressure p_a has been adsorbed into p. Finally, at the rigid wall we prescribe the no-slip condition

$$\mathbf{u} = 0 \quad \text{at} \quad y = 0. \tag{B.1d}$$

For $\mathrm{R} > \mathrm{R}_c = \frac{5}{4}\cot\theta$ Nusselt's solution is unstable to long wave perturbations [2], and in order to analyze this long wave instability a number of reduced equations for (B.1) have been derived. We briefly describe the derivation of (1.1).

B.2. Derivation of the IBLe. We assume that the Weber number is large, $\mathrm{W}_e = \mathrm{W}\varepsilon^{-2}$, where $0 < \varepsilon \ll 1$ is a small parameter, while the Reynolds number is $\mathcal{O}(1)$, and let

$$u(t, x, y) = \tilde{u}(\tau, \xi, y), \quad v(t, x, y) = \varepsilon^{2/3}\tilde{v}(\tau, \xi, y), \quad \tau = \varepsilon^{2/3}t, \quad \xi = \varepsilon^{2/3}x,$$
$$p(t, x, y) = \varepsilon^{-2/3}\tilde{p}(\tau, \xi, y), \quad h(t, x) = \tilde{h}(\tau, \xi).$$

Substituting this long wave ansatz into the free boundary value problem (B.1) and retaining terms up to order $\mathcal{O}(\varepsilon^{4/3})$, we obtain

$$\text{(B.2a)} \qquad \text{in } \Omega: \quad \varepsilon^{2/3}\big(\tilde{u}_\tau+\tilde{u}_\xi\tilde{u}+\tilde{u}_y\tilde{v}\big) = -\tilde{p}_\xi+\frac{\varepsilon^{4/3}\tilde{u}_{\xi\xi}+\tilde{u}_{yy}+2}{\mathrm{R}},$$

$$\text{(B.2b)} \qquad 0 = -\tilde{p}_y - \frac{2\varepsilon^{2/3}\cot\theta}{\mathrm{R}}+\frac{\varepsilon^{4/3}\tilde{v}_{yy}}{\mathrm{R}},$$

$$\text{(B.2c)} \qquad \tilde{u}_\xi = -\tilde{v}_y,$$

$$\text{(B.2d)} \qquad \text{at } y=\tilde{h}(t,\xi): \quad \tilde{h}_\tau+\tilde{h}_\xi\tilde{u} = \tilde{v},$$

$$\text{(B.2e)} \qquad -\tilde{u}_y+\varepsilon^{4/3}\big(\tilde{h}_\xi\tilde{u}_\xi+\tilde{h}_\xi^2\tilde{u}_y-\tilde{v}_\xi\big) = 0,$$

$$\text{(B.2f)} \qquad \tilde{p} - \frac{2\varepsilon^{4/3}(-\tilde{u}_\xi - \tilde{h}_\xi\tilde{u}_y)}{\mathrm{R}} = -\mathrm{W}\tilde{h}_{\xi\xi}\bigg(1-\frac{3}{2}\varepsilon^{4/3}\tilde{h}_\xi^2\bigg),$$

$$\text{(B.2g)} \qquad \text{at } y=0: \quad \tilde{u}=\tilde{v}=0.$$

In order to derive the IBLe, we define the flow rate

$$\text{(B.3)} \qquad \tilde{q}(\tau,\xi) = \int_0^{\tilde{h}(\tau,\xi)} \tilde{u}(\tau,\xi,y)\,\mathrm{d}y$$

such that $\partial_\tau\tilde{h} = -\partial_\xi\tilde{q}$. Following [23], we assume that the velocity field is slaved to the elevation $\tilde{h}$ and the flow $\tilde{q}$ in a Nusselt-like fashion, i.e.,

$$\text{(B.4)} \qquad \tilde{u} = \frac{3\tilde{q}}{2\tilde{h}^3}(2\tilde{h}y-y^2).$$

Substituting (B.3) and (B.4) into (B.2), we obtain

$$\begin{aligned}\tilde{q}_\tau = &-\frac{6}{5}\partial_\xi\bigg(\frac{\tilde{q}^2}{\tilde{h}}\bigg)+\varepsilon^{-2/3}\bigg[\tilde{h}\mathrm{W}\bigg(\tilde{h}_{\xi\xi\xi}\bigg(1-\frac{3\varepsilon^{4/3}\tilde{h}_\xi^2}{2}\bigg)-3\varepsilon^{4/3}\tilde{h}_{\xi\xi}^2\tilde{h}_\xi\bigg)+\frac{(2\tilde{h}-3\tilde{q}/\tilde{h}^2)}{\mathrm{R}}\bigg]\\ &-\frac{2\cot\theta\tilde{h}_\xi\tilde{h}}{\mathrm{R}}+\frac{\varepsilon^{2/3}}{\mathrm{R}}\bigg[\bigg(\frac{7}{2}\bigg)\tilde{q}_{\xi\xi}-\frac{9\tilde{q}_\xi\tilde{h}_\xi}{\tilde{h}}+\frac{6\tilde{q}\tilde{h}_\xi^2}{\tilde{h}^2}-\frac{9\tilde{q}\tilde{h}_{\xi\xi}}{2\tilde{h}}\bigg].\end{aligned}$$

This, together with $\partial_\tau\tilde{h} = -\partial_\xi\tilde{q}$, is (1.1) when scaling back to t,x, i.e., defining $h(t,x) = \tilde{h}(\varepsilon^{-2/3}\tau,\varepsilon^{-2/3}\xi)$ and $q(t,x) = \tilde{q}(\varepsilon^{-2/3}\tau,\varepsilon^{-2/3}\xi)$.

Remark B.1. Evaluating the assumption (B.4) mathematically seems rather difficult. Note that, with this assumption and defining $\tilde{v}(\tau,\xi,y) = -\int_0^y \tilde{u}_\xi(\tau,\xi,\tilde{y})\,\mathrm{d}\tilde{y}$, the no-slip boundary condition (B.2g) is fulfilled, but the condition (B.2e) for the tangential stress holds only up to order $\mathcal{O}(\varepsilon^{4/3})$. See also the following subsection.

B.3. Remarks on first order boundary layer theory. If in (B.2) we keep terms only up to order $\mathcal{O}(\varepsilon^{2/3})$, we obtain the so-called boundary layer equation (see [6])

$$\text{(B.5a)} \qquad \text{in } \Omega: \quad \tilde{u}_\tau+\tilde{u}_\xi\tilde{u}+\tilde{u}_y\tilde{u} = \frac{\varepsilon^{-2/3}}{\mathrm{R}}\big[\tilde{u}_{yy}+2+\mathrm{RW}\tilde{h}_{\xi\xi\xi}\big]-\frac{2\cot\theta\tilde{h}_\xi}{\mathrm{R}},$$

$$\text{(B.5b)} \qquad \tilde{u}_\xi = -\tilde{v}_y,$$

$$\text{(B.5c)} \qquad \text{at } y=\tilde{h}(t,\xi): \quad \tilde{h}_\tau+\tilde{h}_\xi\tilde{u} = \tilde{v}, \quad \tilde{u}_y = 0,$$

$$\text{(B.5d)} \qquad \text{at } y=0: \quad \tilde{u}=\tilde{v}=0.$$

In this case, the ansatz (B.3) and (B.4) gives

$$\begin{aligned} \tilde{h}_\tau &= -\tilde{q}_\xi, \\ \tilde{q}_\tau &= -\frac{6}{5}\partial_\xi\left(\frac{\tilde{q}^2}{\tilde{h}}\right) + \frac{\varepsilon^{-2/3}}{\mathrm{R}}\left[2\tilde{h} - \frac{3\tilde{q}}{\tilde{h}^2} + \mathrm{RW}\tilde{h}\partial_\xi^3\tilde{h}\right] - \frac{2\cot\theta\tilde{h}_\xi\tilde{h}}{\mathrm{R}}, \end{aligned} \tag{B.6}$$

and the reduction of (B.5) to (B.6) is exact; i.e., every solution of (B.6) gives an exact solution of (B.5) via (B.4). In other words, the solutions of (B.6) define an invariant manifold for (B.5). Moreover, (B.6) reduces to the KSe (1.14) in just the same way as (1.1) does.

However, (B.6) is a quasilinear *hyperbolic* system, as can be seen from the dispersion relation

$$\mu_{1,2}(k) = -\frac{1}{2}\left(\frac{3}{\mathrm{R}} + \frac{8}{5}\mathrm{i}k\right) \pm \sqrt{\frac{1}{4}\left(\frac{3}{\mathrm{R}} + \frac{8}{5}\mathrm{i}k\right)^2 - \frac{6}{\mathrm{R}}\mathrm{i}k - \left(\frac{4}{5} - \frac{2}{\mathrm{R}}\cot\theta\right)k^2 - \mathrm{W}\varepsilon^{-2}k^4} \tag{B.7}$$

for the linearization of (B.6) (after rescaling to t, x coordinates) around $(q, h) = (2/3, 1)$. In particular, for $|k| \to \infty$, this yields (in contrast to (1.8))

$$\mu_{1,2}(k) = -\frac{3}{2\mathrm{R}} \pm \mathrm{i}\left(\varepsilon^{-1}\sqrt{W}k^2 + \mathcal{O}(|k|)\right), \tag{B.8}$$

such that the high wave number modes are just uniformly damped but there is no dissipation.

The derivation of the KSe from (1.1) and from (B.6) is the same, since the dissipation terms first show up in the q-equation at order $\mathcal{O}(\varepsilon^3)$. In other words, the linear part of the KSe is determined from the local expansion of $\mu_1(k)$ at $k = 0$.

However, due to (B.8), the linearization of (B.6) around $(h, q) = (1, 2/3)$ generates only a strongly continuous semigroup. The local existence of solutions to (B.6) can still be shown, for instance, using the methods from [9], but with our method we cannot prove an approximation result like Theorem 1.1 for the reduction of (B.6) to the KSe. The reason for this is that, due to the lack of dissipation, our energy estimate for the quasilinear problem breaks down.

Acknowledgment. The author thanks R. L. Pego for helpful discussions and remarks.

BIFURCATION ANALYSIS OF A PREY-PREDATOR COEVOLUTION MODEL*

FABIO DERCOLE†, JEAN-OLIVIER IRISSON‡, AND SERGIO RINALDI§

Abstract. We show in this paper how numerical bifurcation analysis can be used to study the evolution of genetically transmitted phenotypic traits. For this, we consider the standard Rosenzweig–MacArthur prey-predator model [*The American Naturalist,* 97 (1963), pp. 209–223] and, following the so-called adaptive dynamics approach, we derive from it a second-order evolutionary model composed of two ODEs, one for the prey trait and one for the predator trait. Then, we perform a detailed bifurcation analysis of the evolutionary model with respect to various environmental and demographic parameters. Surprisingly, the evolutionary dynamics turn out to be much richer than the population dynamics. Up to three evolutionary attractors can be present, and the bifurcation diagrams contain numerous global bifurcations and codimension-2 bifurcation points. Interesting biological properties can be extracted from these bifurcation diagrams. In particular, one can conclude that evolution of the traits can be cyclic and easily promote prey species diversity.

Key words. bifurcation analysis, coevolution, evolution, evolutionary dynamics, Lotka–Volterra model, monomorphism, prey-predator model

Introduction. One of the most important notions in biology, namely evolution, is now recognized to be of primary importance in many fields of science. Evolution of markets, institutions, technologies, languages, and social rules are relevant examples. Thus, a well-founded mathematical theory of evolution is now needed more than ever.

Evolving systems are in general composed of N homogeneous subsystems identified by two features: dimension n_i and characteristic trait x_i. For example, in ecology, the subsystems are interacting plant and animal populations, n_i is the number of individuals of each population or, equivalently, the density of the population, and x_i is a genetically transmitted phenotypic trait (e.g., body size). Both features vary in time, but densities can vary at much faster rates than traits. This means that an evolving system has two distinct timescales: one is fast and concerns only the densities, which vary while traits remain practically constant, and the other concerns the slow variation of the traits entraining slow variations of the densities. In some favorable cases, these slow variations of the traits can be described by a standard ODE model (called the evolutionary model).

The theoretical work developed so far has shown that evolutionary dynamics can be extremely complex. For example, cyclic regimes [7] (called *Red Queen dynamics*, as in [27]) and chaotic regimes [3] are possible, as well as evolutionary suicides and murders, which occur when the variation of the trait of a population entails the extinction of the same or another population [20, 10]. Moreover, an evolving system

can also have alternative evolutionary attractors, in which case the fate of the system is determined by its ancestral conditions.

Once an evolutionary model is available, the powerful machinery of numerical bifurcation analysis can be applied to it. This is mandatory if the aim is to detect the impact of some strategic parameters on the evolution of the system. Systematic bifurcation analysis with respect to key environmental parameters could, for example, explain why ecosystems differ at various latitudes, altitudes, and depths. The few bifurcation studies performed to date on evolutionary models (see, for example, [19, 21, 7]) are far from satisfactory: they are inaccurate because they have been mainly carried out through simulation, and they are incomplete because they refer to non-generic cases or point out only some aspects of the full bifurcation diagram. In this article we therefore present an accurate and detailed bifurcation analysis of a typical evolutionary model. The problem we tackle is the coevolution of prey and predator traits, a subject that has received a great deal of attention in the last decade (see [1] for a review). We consider two populations (prey and predator) and two traits (one for each population), and the bifurcation analysis of the evolutionary model is performed with respect to pairs of parameters. The results we obtain are of rather limited biological value because they refer to a specific prey-predator coevolution model. However, the methodology is very general and could be applied to other models in order to obtain, through a suitable comparative analysis, general conclusions on the coevolution of prey-predator communities.

The paper is organized as follows. In the next section we recall how, under suitable assumptions on the mutation and selection processes, a canonical evolutionary model can be derived from a general population model [6, 5]. Then, we focus on the well known Rosenzweig–MacArthur prey-predator model [26], showing how the canonical evolutionary model can be explicitly derived from it. Finally, we present the bifurcation analysis of the evolutionary model and demonstrate how interesting biological conclusions can be extracted from it. Some comments and comparisons with the literature close the paper.

The canonical equation of monomorphic evolutionary dynamics. Consider two interacting populations, hereafter called *prey* and *predator* populations, with densities n_1 and n_2 and phenotypic traits x_1 and x_2.

At ecological timescale (fast dynamics), the traits are constant while the densities vary according to two ODEs of the form

$$\begin{aligned} \dot{n}_1 &= n_1 F_1(n_1, n_2, x_1, x_2), \\ \dot{n}_2 &= n_2 F_2(n_1, n_2, x_1, x_2), \end{aligned} \tag{1}$$

where F_i is the net per capita growth rate of the ith population. In the following, model (1), called the *resident model*, is assumed to have one strictly positive and globally stable equilibrium $\bar{n}(x_1, x_2)$ for each (x_1, x_2) belonging to a set of the trait space called the *stationary coexistence region*. This condition is not strictly necessary, but it simplifies the discussion.

At evolutionary timescale (slow dynamics), the traits vary according to two ODEs called the *evolutionary model:*

$$\begin{aligned} \dot{x}_1 &= k_1 G_1(x_1, x_2), \\ \dot{x}_2 &= k_2 G_2(x_1, x_2), \end{aligned} \tag{2}$$

where k_1 and k_2 are suitable constant parameters determined by size and frequency

of mutations. However, population densities vary slowly with the traits because, at evolutionary timescale, model (1) is always at the equilibrium $\bar{n}(x_1, x_2)$.

Some authors discuss evolutionary problems by assigning particular forms to the functions G_1 and G_2 in model (2) without connecting them with a population model (see [2] and references therein). More frequently, model (2) is derived from model (1) through various arguments [16, 2]. This is a little surprising, since the dynamics of the traits should reflect the characteristics of the mutation and selection processes, which, however, are not included in the resident model (1). In fact, the most transparent approach for deriving the evolutionary model (2) is the so-called *adaptive dynamics* approach [15, 22, 6, 13, 12] based on the *resident-mutant models*, which describe the interactions among three populations, namely, the two resident populations and a mutant population with trait x_1' or x_2'. (Notice that this approach rules out the possibility that prey and predator mutants are present at the same time.) When the prey population is split into two subpopulations (resident and mutant) with densities n_1 and n_1' and traits x_1 and x_1', the model is

$$\begin{aligned} \dot{n}_1 &= n_1 f_1(n_1, n_2, n_1', x_1, x_2, x_1'), \\ \dot{n}_2 &= n_2 f_2(n_1, n_2, n_1', x_1, x_2, x_1'), \\ \dot{n}_1' &= n_1' f_1'(n_1, n_2, n_1', x_1, x_2, x_1'). \end{aligned} \tag{3}$$

The initial value of n_1' in these equations is very small because a mutant population is initially composed of one or a few individuals. A similar third-order model involving the mutant trait x_2', the density n_2', and the function f_2' describes the case in which the mutant is a predator. In the ecological literature, models like model (3) are often called "competition models" because they describe the competition between two similar populations. Obviously, model (3), together with its companion model for the predator mutation, contains more information than the resident model (1). Indeed, the latter can be immediately derived from the former by disregarding the mutant equation and letting $n_1' = n_2' = 0$, thus obtaining

$$F_i(n_1, n_2, x_1, x_2) = f_i(n_1, n_2, 0, x_1, x_2, x_i'),$$

where the function $f_i(n_1, n_2, 0, x_1, x_2, x_i')$ does not depend on x_i'. The functions f_i and f_i', identifying the right-hand sides of the resident-mutant models, are called *fitness functions*, and they enjoy a number of structural properties. Function f_i, $i = 1, 2$, satisfies the condition

$$f_i(n_1, n_2, n_1', x_1, x_2, x_1) = F_i(n_1 + n_1', n_2, x_1, x_2)$$

because, when $x_1 = x_1'$, resident and mutant individuals do not differ, so that only the total number of prey $(n_1 + n_1')$ matters. Function f_1' is defined by

$$f_1'(n_1, n_2, n_1', x_1, x_2, x_1') = f_1(n_1', n_2, n_1, x_1', x_2, x_1)$$

because either one of the two prey subpopulations can be considered as mutant, provided the other is considered as resident. Of course, the same properties hold for the functions f_1, f_2, and f_2' appearing in the competition model for the predator mutation.

Now that we have defined the resident model (1) and the resident-mutant model (3), we can show how the evolutionary model (2) can be derived following the adaptive dynamics approach. For this, assume that the resident population model (1) with

traits x_1 and x_2 is at its equilibrium $\bar{n}(x_1, x_2)$ when a mutant appears. If mutations are rare at ecological timescale, the initial conditions $(\bar{n}_1(x_1, x_2), \bar{n}_2(x_1, x_2), n_1')$ can be used in model (3) to determine the fate of the mutant population. If the mutant population does not invade, i.e., if

$$f_1'(\bar{n}_1(x_1, x_2), \bar{n}_2(x_1, x_2), n_1', x_1, x_2, x_1') < 0 \tag{4}$$

for all small $n_1' > 0$, then it becomes extinct and the final result is still a pair of resident populations with traits x_1 and x_2 and densities $\bar{n}_1(x_1, x_2)$ and $\bar{n}_2(x_1, x_2)$. By contrast, it can be proved [11] that if (4) holds with the opposite inequality sign and if mutations are small (i.e., x_1' differs only slightly from x_1), then the resident population generically becomes extinct and is replaced by the mutant population with density $\bar{n}_1(x_1', x_2)$. In other words, each mutation brings a new trait into the system, but competition between resident and mutant populations selects the winner, namely, the trait that remains in the system. This kind of evolution of the traits is called *monomorphic evolution*. This process of mutation and selection can be further specified by making suitable assumptions on the frequency and distribution of small mutations [6, 5], and the conclusion is that the rate at which the trait x_i varies at evolutionary timescale is given by the following ODE, called the *canonical equation of adaptive dynamics*:

$$\dot{x}_i = k_i \bar{n}_i(x_1, x_2) \left. \frac{\partial f_i'}{\partial x_i'} \right|_{\substack{n_1=\bar{n}_1(x_1,x_2) \\ n_2=\bar{n}_2(x_1,x_2) \\ n_i'=0; x_i'=x_i}} , \tag{5}$$

where k_i is proportional to the frequency and variance of mutations, $\bar{n}_i(x_1, x_2)$ is the equilibrium density of the resident model, and $\partial f_i'/\partial x_i'$ is the derivative of the fitness of the mutant, called the *selective derivative*. Equation (5), written for the prey and for the predator, gives two ODEs that form the evolutionary model (2) with

$$G_i(x_1, x_2) = \bar{n}_i(x_1, x_2) \left. \frac{\partial f_i'}{\partial x_i'} \right|_{\substack{n_1=\bar{n}_1(x_1,x_2) \\ n_2=\bar{n}_2(x_1,x_2) \\ n_i'=0; x_i'=x_i}} . \tag{6}$$

Thus, model (5) describes the monomorphic coevolution of the traits under the assumption of rare and random mutations of small effects. Monomorphic evolutionary dynamics are usually presented by drawing a few trajectories of model (5) in the stationary coexistence region. This set of trajectories, called the *coevolutionary portrait*, points out, as sketched in Figure 1, all relevant invariant sets (equilibria, limit cycles, and saddle separatrices). Some trajectories of the coevolutionary portrait (see gray regions in Figure 1) reach the boundary of the stationary coexistence region, thus implying the extinction of one of the two populations.

Figure 2 schematically summarizes monomorphic evolution and highlights the different roles played by the three models we have introduced. The ecological literature mainly deals with the resident model (1) since ecologists are interested in the short-term dynamics of the populations and usually do not even consider the possibility of having a mutant population involved in the game. By contrast, theoretical studies on evolution are based on formal evolutionary models (2), or on verbal theories that can be considered as a sort of surrogate of these models. Figure 2 points out two facts. The first is that both the resident model (1) and the evolutionary model (2) are needed if one is interested in the population dynamics entrained at evolutionary timescale by the dynamics of the traits. The second is that the resident-mutant

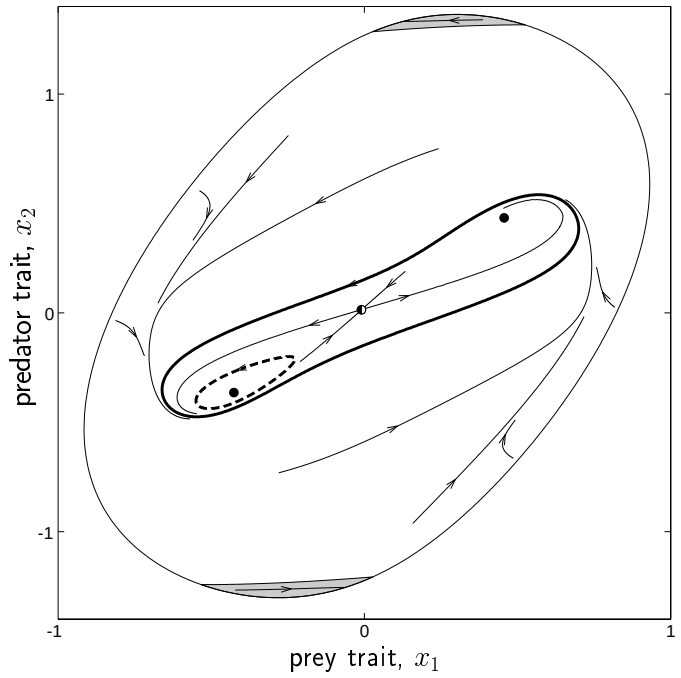

FIG. 1. *Example of a coevolutionary portrait in the stationary coexistence region. The portrait is characterized by three equilibria (two stable foci (filled circles) and one saddle (half-filled circle)) and two limit cycles (one stable (thick line) and one unstable (dashed line)).*

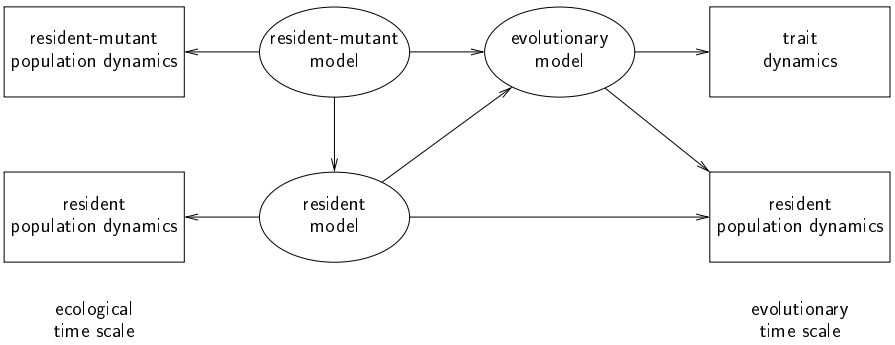

FIG. 2. *Flow chart demonstrating the relationships among resident-mutant models, the resident model, and the evolutionary model.*

model (3) is a "source" model, namely, a model that contains the information needed to answer all questions. Unfortunately, the scheme of Figure 2 is not always taken into account, and evolutionary models (2) are often derived directly from the resident model through arguments, which at best give the same result that a hidden equivalent resident-mutant model would give.

Once monomorphic dynamics has found a halt at a stable monomorphic equilibrium $\bar{x}$, one can look at the second-order terms in the Taylor expansion of the mutant fitness function to establish whether the equilibrium is a *branching point* [13] or not.

More precisely, a stable equilibrium $\bar{x}$ is said to be a branching point if

$$\left.\frac{\partial^2 f_i'}{\partial x_i'^2}\right|_{\substack{n_1=\bar{n}_1(\bar{x}_1,\bar{x}_2)\\ n_2=\bar{n}_2(\bar{x}_1,\bar{x}_2)\\ n_i'=0;x_i'=x_i;x=\bar{x}}} > 0 \tag{7}$$

and

$$\left.\frac{\partial^2 f_i'}{\partial x_i' \partial x_i}\right|_{\substack{n_1=\bar{n}_1(\bar{x}_1,\bar{x}_2)\\ n_2=\bar{n}_2(\bar{x}_1,\bar{x}_2)\\ n_i'=0;x_i'=x_i;x=\bar{x}}} < 0 \tag{8}$$

for i equal to 1 or 2, since small mutations of the ith population invade and coexist, at equilibrium, with the former resident [12]. Thus, branching points are the origin of dimorphism. Of course, after a branching has occurred, there are three resident populations, and one can continue the analysis by deriving the three corresponding canonical equations.

A model of prey-predator coevolution. In this section we specify the prey-predator coevolution problem, which is analyzed in what follows. First we present the resident prey-predator model that has most often been used in the last few decades to predict prey and predator abundances at ecological timescales in the absence of mutations. We then extend this model to a scenario in which a mutant population is also present, by adding a third ODE for the mutant population and by specifying the dependence of the demographic parameters upon the traits of the resident and mutant populations. This produces a resident-mutant population model from which, following the scheme described in the previous section, we finally derive an evolutionary model of the form (2) (details are relegated to the appendix).

The population model we consider is the well-known Rosenzweig–MacArthur prey-predator model [26]:

$$\begin{aligned} \dot{n}_1 &= n_1\left(r - cn_1 - \frac{a}{1+ahn_1}n_2\right),\\ \dot{n}_2 &= n_2\left(e\frac{an_1}{1+ahn_1} - d\right), \end{aligned} \tag{9}$$

where r is prey growth rate per capita, c is prey intraspecific competition, a is predator attack rate, h is predator handling time (namely, the time needed by each predator to handle and digest one unit of prey), e is efficiency (namely, a conversion factor transforming each unit of predated biomass into predator newborns), and d is predator death rate. The reader interested in more details on the biological interpretation of the parameters can refer to [23]. The six positive parameters of the model (r, c, a, h, e, d) could be reduced to three through rescaling. However, we do not follow this option because it would complicate the biological interpretation of the dependence of the parameters upon the prey and predator traits. In order to have a meaningful problem, one must assume that $e > dh$, because otherwise the predator population cannot grow even in the presence of an infinitely abundant prey population.

For any meaningful parameter setting, model (9) has a global attractor in $\mathbb{R}^2_+$, namely,

(a) the trivial equilibrium $(r/c, 0)$ if $d/a(e-dh) \geq r/c$,

(b) the strictly positive equilibrium

$$\bar{n}_1 = \frac{d}{a(e-dh)}, \qquad \bar{n}_2 = \frac{c}{a}\left(\frac{r}{c} - \frac{d}{a(e-dh)}\right)\left(1 + ah\frac{d}{a(e-dh)}\right) \tag{10}$$

if

$$\frac{rah-c}{2ahc} \le \frac{d}{a(e-dh)} < \frac{r}{c}, \tag{11}$$

(c) a strictly positive limit cycle if $d/a(e-dh) < (rah-c)/(2ahc)$.

The transition from (a) to (b) is a transcritical bifurcation (which is generic in the class of positive systems of the form (9)), while the transition from (b) to (c) is a supercritical Hopf bifurcation (see [17] for a proof).

If we now imagine that a mutant population is also present, we can enlarge model (9) by adding a third ODE and by slightly modifying the equations of the resident populations in order to take the mutant population into account. Of course we also need to specify how the parameters depend upon the traits x_1, x_2, x_1', x_2'. The number of possibilities is practically unlimited, because even for well-identified prey and predator species there are many meaningful options. Thus, at this level of abstraction, it is reasonable to limit the number of parameters sensitive to the traits, and to avoid trait dependencies that could give rise to biologically unrealistic evolutionary dynamics, like the unlimited growth of a trait (so-called runaway). Our choice has been to assume that the parameters r, e, and d are independent of the traits, because this will allow us to compare our results with those obtained in [7]. Thus, in the case of a mutation in the prey population, the resident-mutant model is

$$\begin{aligned}
\dot{n}_1 &= n_1\Bigg(r - c(x_1,x_1)n_1 - c(x_1,x_1')n_1' \\
&\qquad - \frac{a(x_1,x_2)}{1+a(x_1,x_2)h(x_1,x_2)n_1 + a(x_1',x_2)h(x_1',x_2)n_1'}n_2\Bigg), \\
\dot{n}_2 &= n_2\left(e\frac{a(x_1,x_2)n_1 + a(x_1',x_2)n_1'}{1+a(x_1,x_2)h(x_1,x_2)n_1 + a(x_1',x_2)h(x_1',x_2)n_1'} - d\right), \\
\dot{n}_1' &= n_1'\Bigg(r - c(x_1',x_1)n_1 - c(x_1',x_1')n_1' \\
&\qquad - \frac{a(x_1',x_2)}{1+a(x_1,x_2)h(x_1,x_2)n_1 + a(x_1',x_2)h(x_1',x_2)n_1'}n_2\Bigg).
\end{aligned} \tag{12}$$

The traits are assumed to be real variables obtained from the actual phenotypic traits through a suitable nonlinear scaling that maps the positive interval of the phenotype into the real axis. Thus, the maximum and minimum values of the prey (predator) phenotype correspond to the limit values ∞ and $-\infty$ of x_1 (resp., x_2). Similarly, in the case of a mutation in the predator population, the resident-mutant model is

$$\begin{aligned}
\dot{n}_1 &= n_1\Bigg(r - c(x_1,x_1)n_1 \\
&\qquad - \frac{a(x_1,x_2)}{1+a(x_1,x_2)h(x_1,x_2)n_1}n_2 - \frac{a(x_1,x_2')}{1+a(x_1,x_2')h(x_1,x_2')n_1}n_2'\Bigg), \\
\dot{n}_2 &= n_2\left(e\frac{a(x_1,x_2)n_1}{1+a(x_1,x_2)h(x_1,x_2)n_1} - d\right), \\
\dot{n}_2' &= n_2'\left(e\frac{a(x_1,x_2')n_1}{1+a(x_1,x_2')h(x_1,x_2')n_1} - d\right).
\end{aligned} \tag{13}$$

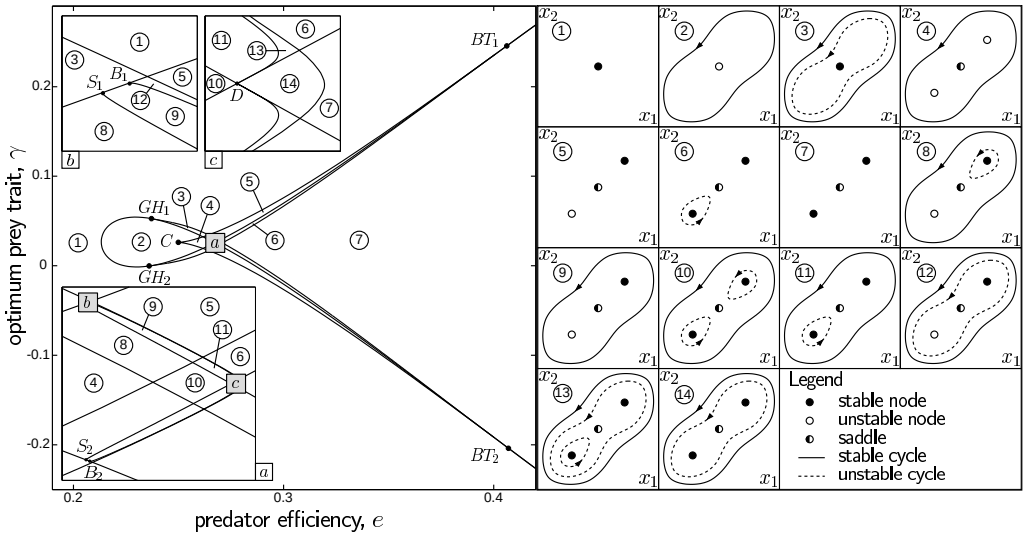

FIG. 3. *Bifurcation diagram of evolutionary model* (5) *with respect to predator efficiency* e *and optimum prey trait* γ *and corresponding sketches of coevolutionary state portraits. Panels a, b, and c are magnified views of the bifurcation diagram. Parameter values are* $r = 0.5$, $d = 0.05$, $k_1 = k_2 = 1$, $\gamma_0 = 0.01$, $\gamma_1 = 0.5$, $\gamma_2 = 1$, $\alpha = 1$, $\alpha_0 = 0.01$, $\alpha_1 = 1$, $\alpha_2 = 1$, $\alpha_3 = 0.6$, $\theta = 0.9$, $\theta_1 = \theta_2 = 0.5$, $\theta_3 = \theta_4 = 1$.

The functional forms specifying the parameters' dependence upon the traits are reported in the appendix and are such that the left-hand inequality of condition (11) (i.e., $(rah - c)/(2ahc) \leq d/(a(e - dh))$) is always satisfied. (This excludes the possibility of population cycles.) Thus, the boundary of the stationary coexistence region is simply the set of pairs (x_1, x_2) for which $d/(a(e-dh)) = r/c$ (see (11)). This means that on that boundary $\bar{n}_2(x_1, x_2) = 0$; i.e., the predator population becomes extinct if the traits reach the boundary of the stationary coexistence region.

At this point, (6) can be used to derive the evolutionary model (2), since the strictly positive equilibrium $\bar{n}(x_1, x_2)$ is known (see (10)). The analytic expressions of the selective derivatives and of the second-order derivatives needed for evaluating the branching conditions (7), (8) are not reported because they are very long. In any case, they can be easily derived by means of any software for symbolic computation.

Bifurcation analysis. The evolutionary model derived in the previous section has been studied through numerical bifurcation analysis. Local and global codimension-1 bifurcations with respect to various parameters have been obtained by means of specialized software based on continuation techniques [9, 8, 18]. Moreover, two-dimensional bifurcation diagrams have been produced by focusing on codimension-2 bifurcation points [17].

The first surprising result is that the evolutionary model is much richer than the resident population model. In fact, while the latter is characterized by two bifurcations, in the former twelve bifurcations have been detected. Figure 3 shows these bifurcations in the space (e, γ), where e is predator efficiency and γ is the prey trait value (called optimum) at which intraspecific competition is minimum. In general, both parameters are influenced by environmental factors. For example, the efficiency of an herbivore (predator) depends upon the caloric content of its prey (grass), which, in turn, is mainly fixed by humidity, temperature, and soil composition. Figure 3

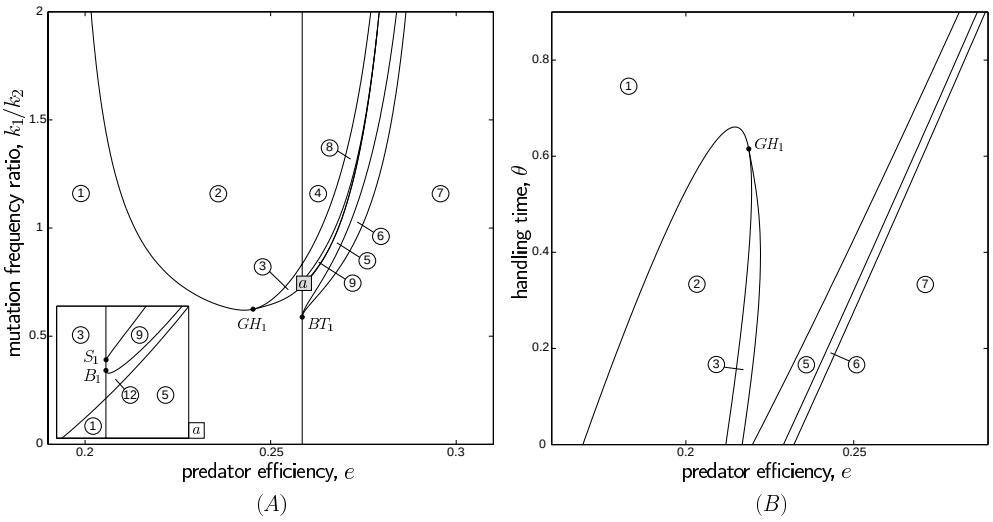

FIG. 4. *Bifurcation diagram of evolutionary model* (5) *with respect to predator efficiency* e *and mutation frequency ratio* k_1/k_2 (A) *and handling time* θ (B). *See Figure* 3 *for coevolutionary state portraits and parameter values.*

points out that there are fourteen subregions in the parameter space characterized by different coevolutionary portraits. In each one of them, for simplicity, the boundary of the stationary coexistence region, where the predator population becomes extinct, is not shown. This, however, fails to point out, graphically, that evolutionary extinction of the predator population occurs in all cases, as shown in Figure 1, which is actually the coevolutionary portrait corresponding to subregion 11. It is worth noticing that this form of evolutionary extinction is always an evolutionary murder. In fact, on the boundary of the stationary coexistence region $\dot{x}_2 = 0$, because $\bar{n}_2 = 0$ in (5); i.e., the predator trait is locally constant while the prey trait varies.

Coevolutionary attractors can be equilibria or limit cycles, and the existence of alternative attractors is rather common. When they exist, attracting cycles surround all equilibria. Actually, there can be up to three alternative attractors (two equilibria and one cycle), as shown by the coevolutionary portraits 10, 11, 13, and 14. There are ten codimension-2 bifurcation points, namely a cusp (C), two generalized Hopf (GH_1 and GH_2), two Bogdanov–Takens (BT_1 and BT_2), four noncentral saddle-node homoclinic loops (S_1, S_2, B_1, and B_2), and a double homoclinic loop (D) (see [17]).

No other bifurcation curves and codimension-2 bifurcation points are present in the two extra bifurcation diagrams presented in Figure 4, where the coevolutionary portraits are intentionally not shown to stress that they are exactly as in Figure 3. The parameter on the horizontal axis of these two bifurcation diagrams is still the efficiency of the predator, while the parameter on the vertical axis is related to two important characteristics of the mutation and predation processes, namely, the ratio k_1/k_2 between the frequencies of prey and predator mutations, and the predator handling time θ corresponding to the maximum attack rate (see the appendix).

The bifurcation diagrams are very useful for deriving interesting biological properties concerning the impact of various factors on coevolution. For example, one could be interested in identifying the factors favoring the so-called Red Queen dynamics, namely, the possibility of cyclic coevolution of the traits. For this, one should extract

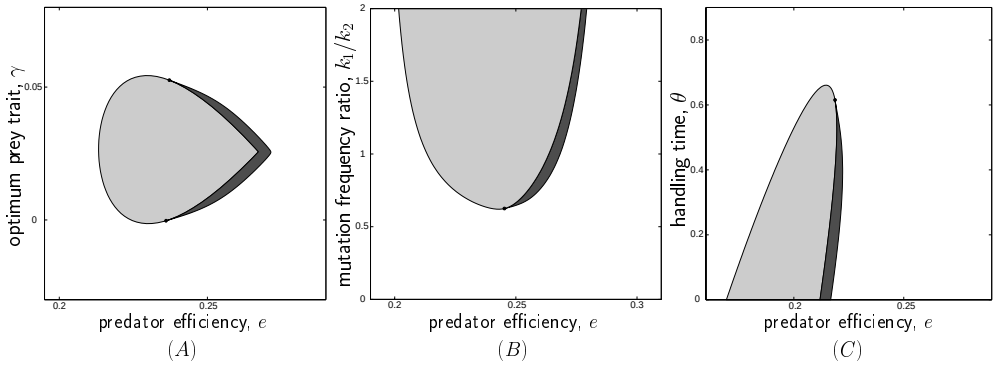

FIG. 5. *Red Queen dynamics: in the white regions cyclic coevolution is not possible, while in the gray regions it is the only long-term form of coevolution. In the black regions both stationary and cyclic coevolution are possible. Panels* (A), (B), *and* (C) *are extracted from the bifurcation diagrams of Figures* 3, 4(A), *and* 4(B), *respectively.*

from each bifurcation diagram the subregions 2–4, 8–14, where at least one of the coevolutionary attractors is a limit cycle. The result is Figure 5, which shows where cyclic coevolution is the only possible outcome (gray regions) and where stationary coevolution is also possible (black regions). Figure 5 indicates that Red Queen dynamics occur only for intermediate values of predator efficiency. Thus, slow environmental drifts entraining slow but continuous variations of predator efficiency can promote the disappearance of Red Queen dynamics. However, if efficiency decreases, Red Queen dynamics disappear smoothly through a supercritical Hopf bifurcation (where the attracting evolutionary cycle shrinks to a point). By contrast, if efficiency increases, Red Queen dynamics disappear discontinuously through a catastrophic bifurcation (tangent bifurcation of limit cycles). Figure 5 also indicates other biologically relevant properties, such as the fact that Red Queen dynamics are facilitated by high (low) frequency of prey (predator) mutation, and by low predator handling times. This last result shows that the highest chances for cyclic coevolution are obtained when $\theta = 0$, i.e., when the Rosenzweig–MacArthur model degenerates into the Lotka–Volterra model. This brings us to the following rather intriguing conclusion: the Lotka–Volterra assumptions (which do not give rise to population cycles) can easily explain coevolutionary cycles, while the Rosenzweig–MacArthur assumptions (which can easily give rise to population cycles) can hardly support Red Queen dynamics.

Extra information can be added to the bifurcation diagrams of Figures 3 and 4 by specifying whether the stable monomorphic equilibria $(\bar{x}_1, \bar{x}_2)$ are branching points (B) or not (NB). This can be easily done by computing (through continuation) the curves where conditions (7), (8) are critical. Thus, any region of parameter space characterized by only one stable monomorphic equilibrium can, in principle, be partitioned into four subregions: in one of these subregions monomorphism is the only form of coevolution, while in the other three regions dimorphism is possible through the branching of one of the two populations or of both. However, in all of the numerical experiments that we have performed, only prey branching occurred. This is consistent with the well-known principle of "competitive exclusion" [14]. In fact, if the predator population would branch, the system would converge to an equilibrium with two slightly different predators and one prey, in contrast with the competitive exclusion principle. In conclusion, there are only two possibilities: $(\bar{x}_1, \bar{x}_2)$ is not a

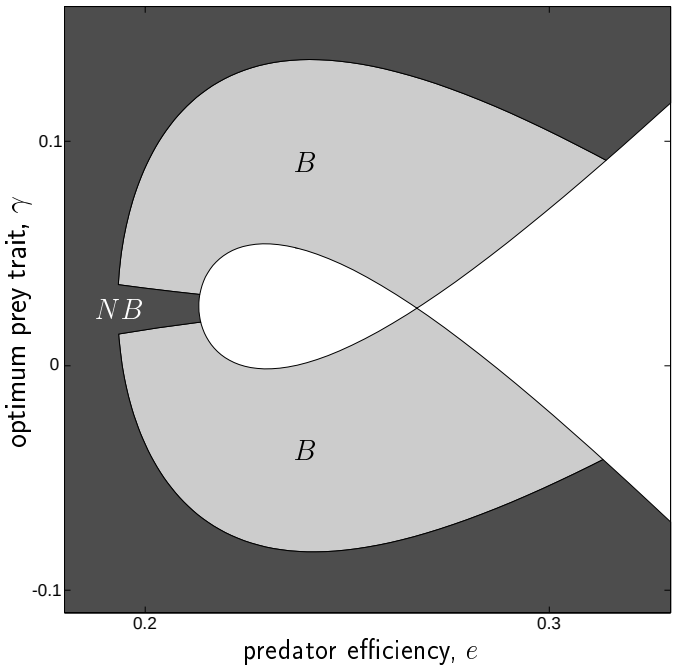

FIG. 6. *In the gray and black regions (extracted from Figure* 3*) the evolutionary model* (5) *has only one stable equilibrium, which is either a branching point (B) for the prey population or not (NB).*

branching point or it is a branching point for the prey population. In other words, our findings are in line with biological principles and support the idea [4] that predators are promoters of prey species diversity. Figure 6 shows how the region characterized by a unique stable equilibrium $(\bar{x}_1, \bar{x}_2)$ is partitioned into B and NB subregions. The result is rather interesting if it is complemented with what has already been discovered about the disappearance of Red Queen dynamics induced by variations of predator efficiency. In fact, the overall conclusion is that Red Queen dynamics disappear abruptly if predator efficiency increases, and smoothly if predator efficiency decreases. However, in the latter case, as soon as Red Queen dynamics disappear, dimorphism can occur in the prey population. Thus, environmental drifts of any sign can give rise to discontinuities in the dynamics of the traits. This observation proves once more that coevolution is an astonishingly complex dynamic process.

Discussion and conclusions. The problem of prey-predator coevolution has been investigated in this paper from a purely mathematical point of view. For this, the classic Rosenzweig–MacArthur model (logistic prey and predator with saturating functional response) has first been transformed into a resident-mutant model by adding a third equation for the mutant population. Then, an evolutionary model describing the slow dynamics of the traits has been derived from the resident-mutant model through the standard adaptive dynamics approach [15, 22, 6, 13, 12]. The bifurcation analysis of the evolutionary model has shown that the dynamics of the traits at evolutionary timescale are much more complex than the dynamics of the populations at ecological timescale. The numerically produced bifurcation diagrams have proved to be powerful tools for extracting qualitative information on the impact

of various factors on coevolution. Conclusions like those we have obtained on the impact of environmental drifts on evolutionary cycles (so-called Red Queen dynamics) could not have been derived without performing a detailed bifurcation analysis of an evolutionary model. A generally encouraging message emerging from this study is that other very important biological problems, such as the evolution of mutualism, cannibalism, and parasitism, could most likely be studied successfully through the bifurcation analysis of the canonical evolutionary model. But the same approach should also be very effective for studying relevant problems in social sciences and economics, where mechanisms somewhat similar to biological mutation and selection can sometimes be identified.

Limiting the discussion to the problem of prey-predator coevolution, we can say that the results presented in this paper are far more complete than those available in the literature. Indeed, the only comparable result is the bifurcation analysis presented in [7], where a bifurcation diagram similar to that of Figure 4(A) was obtained through simulation. That bifurcation diagram is incomplete and derived for a quite degenerate case, i.e., for a Lotka–Volterra model ($\theta = 0$ in our model) with a very special parameter combination reducing the number of bifurcation curves to six. However, despite this double degeneracy, the analysis in [7] points out Red Queen dynamics, multiple evolutionary attractors, and evolutionary murder. A comparison with the nonmathematical literature (see, for example, [24, 25] and [1]) neither contradicts nor supports our findings.

Even if what we have presented in this paper might seem rather general, the analysis should first be repeated for many other prey-predator models and for different assumptions on the trait dependence of the demographic parameters, and a comparative analysis should be performed in order to extract biologically significant results. Moreover, there are a number of possible interesting extensions. First, one could investigate the dynamics of dimorphism by applying the bifurcation approach followed in this paper to more complex population assemblies, composed, for example, of one resident predator population and two resident prey populations. The outcome of such a study could be that a predator branching generating a second resident predator population is possible, because this outcome is not in conflict with the principle of competitive exclusion. Second, while remaining in the simple context of monomorphism, one could be interested in detecting the prey-predator coevolutionary dynamics under the assumption that the two populations can coexist by cycling at ecological timescale. This extension is absolutely not trivial, because the derivation of the evolutionary model is rather difficult in this case. However, the problem is of great interest because its analysis could perhaps help to answer the very intriguing question: does coevolution destabilize populations? Third, one could be interested in extending the analysis to the coevolution of tritrophic food chains composed of a prey, a predator, and a superpredator population. From the results obtained in this paper, showing that evolutionary dynamics of ditrophic food chains (composed of a prey and a predator population) are much more complex than the corresponding population dynamics, one should naturally be inclined to conjecture that chaotic coevolutionary dynamics should be possible in tritrophic food chains. The proof of this conjecture would be a great result.

Appendix. In this appendix we specify how the prey intraspecific competition c, the predator attack rate a, and the predator handling time h, appearing in the resident-mutant models (12), (13), depend upon the resident and mutant traits. Due to our definition of the traits, which are scaled measures of the phenotypes, c, a, and

h are bounded functions of the traits. Unless otherwise stated, all the parameters appearing in these functions are assumed to be positive.

Prey intraspecific competition c is given by

$$c(x_1, x_1') = \frac{\gamma_1 + \gamma_2 (x_1 - \gamma)^2}{1 + \gamma_0(\gamma_1 + \gamma_2 (x_1 - \gamma)^2)}. \tag{A1}$$

Notice that c depends only upon its first argument. This means that resident prey individuals face the same competition when they are opposed to other resident individuals or to mutant individuals. The parameter γ, which can be either positive or negative, is the value of the prey trait x_1 (called *optimum prey trait*) at which intraspecific competition is minimum (and equal to $\gamma_1/(1+\gamma_0\gamma_1)$). For prey traits x_1 far from γ, intraspecific competition saturates at $1/\gamma_0$.

The predator attack rate a is the bell-shaped function

$$a(x_1, x_2) = \alpha_0 + \alpha \exp\left(- \left(\frac{x_1}{\alpha_1}\right)^2 + 2\alpha_3 \left(\frac{x_1}{\alpha_1}\right)\left(\frac{x_2}{\alpha_2}\right) - \left(\frac{x_2}{\alpha_2}\right)^2 \right), \tag{A2}$$

where $\alpha_3 < 1$. If prey and predator traits are tuned, i.e., if $x_1 = x_2 = 0$, the predator attack rate is maximum (and equal to $\alpha_0 + \alpha$). When prey and predator traits are far from being tuned, the predator attack rate drops to α_0.

The predator handling time is the product of an increasing sigmoidal function of the prey trait x_1 and of a decreasing sigmoidal function of the predator trait x_2,

$$h(x_1, x_2) = \theta \left[1 + \theta_1 - \frac{2\theta_1}{1 + \exp(\theta_3 x_1)}\right] \left[1 + \theta_2 - \frac{2\theta_2}{1 + \exp(-\theta_4 x_2)}\right], \tag{A3}$$

where θ is the handling time corresponding to the tuned situation ($(x_1, x_2) = (0, 0)$), referred to as handling time in Figures 4(B) and 5(C).

Finally, we have fixed r, d, and all the parameters of the functions c, a, and h at the values indicated in the caption of Figure 3, and we have limited θ from above and e from below so that the following two inequalities hold for all (x_1, x_2):

$$e - dh(x_1, x_2) > 0, \qquad \frac{r}{c(x_1)} \leq \frac{1}{a(x_1, x_2)h(x_1, x_2)}.$$

These conditions guarantee that the left-hand inequality of condition (11) holds. Thus, population cycles are ruled out from our study.

ANALYSIS OF A MODEL FOR MULTICOMPONENT MASS TRANSFER IN THE CATHODE OF A POLYMER ELECTROLYTE FUEL CELL*

M. VYNNYCKY† AND E. BIRGERSSON†

Abstract. A chief factor that is thought to limit the performance of polymer electrolyte fuel cells (PEFCs) is the hydrodynamics associated with the cathode. In this paper, a two-dimensional model for three-component (oxygen, nitrogen, water) gaseous flow in a PEFC cathode is derived, nondimensionalized, and analyzed. The fact that the geometry is slender allows the use of a narrow-gap approximation leading to a simplified formulation. In spite of the highly nonlinear coupling between the velocity variables and the mole fractions, an asymptotic treatment of the problem indicates that oxygen consumption and water production can be described rather simply in the classical lubrication theory limit with the reduced Reynolds number as a small parameter. In general, however, the reduced Reynolds number is $O(1)$, requiring a numerical treatment; this is done using the Keller–Box discretization scheme. The analytical and numerical results are compared in the limit mentioned above, and further results are generated for varying inlet velocity and gas composition, channel width and porous backing thickness, pressure and current density. Also, a novel, compact way to present fuel cell performance, which takes into account geometrical, hydrodynamical, and electrochemical features, is introduced.

1. Introduction.

There is at present a rapidly increasing interest in improving the design of fuel cells, that is, electrochemical devices that convert the chemical energy of a fuel with an oxidant directly into electricity. Fuel cells have a variety of applications; for instance, the alkaline fuel cell (AFC) was mainly used in space exploration, while the phosphoric acid fuel cell (PAFC), the solid oxide fuel cell (SOFC), and the molten carbonate fuel cell (MCFC) are most suited to stationary applications. Of the several types of fuel cells that are currently under development, perhaps the one that has received the most attention, particularly from the point of view of commercialization in the automotive industry, has been the polymer electrolyte fuel cell (PEFC), also often referred to as the proton-exchange membrane (PEM) fuel cell or the solid polymer fuel cell (SPFC); the merit of this type of fuel cell over others for this particular application is that it can generate the high current densities that are required to power a vehicle, as well as the fact that it operates at comparatively low temperatures (often no higher than 100°C).

A schematic diagram of a PEFC is given in Figure 1. Essentially, this entails a polymer membrane sandwiched between two gas-diffusion electrodes, which are each adjacent to flow channels contained within bipolar plates. The oxidant, usually oxygen from air which is either dry or humidified to some extent, is fed in at the inlet of the channel on the cathode side and is transported to the electrolyte/cathode interface; the fuel, on the other hand, normally hydrogen, is fed at the anode channel inlet and is transported to the electrolyte/anode interface. Both interfaces contain a catalyst,

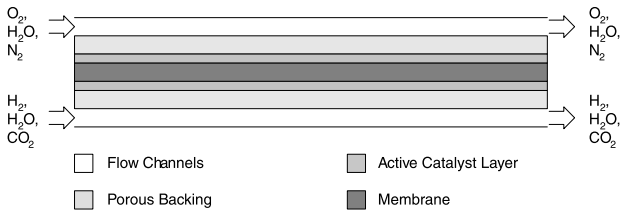

FIG. 1. 2*D PEFC.*

often platinum, to accelerate the reactions

$$2H_2 \rightarrow 4H^+ + 4e^- \quad \text{at the anode,} \tag{1.1}$$

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O \quad \text{at the cathode,} \tag{1.2}$$

in the course of which an electric current is produced to drive a given load. In particular, the reaction at the cathode also produces both heat and water as by-products, the latter of which may be present throughout the system as either vapor or liquid or both; the production of the former can lead to temperatures at the catalytic layer in the order of 80–90°C. Optimal fuel cell performance is achieved at typical voltages of around 0.5 V at current densities of about 1 Acm^{-2}.

Recent years have seen the appearance of mathematical models for some or all of the parts of a typical fuel cell described above. Modeling proves necessary because of an, as yet, incomplete understanding of several important phenomena:

1. mass transport limitations, that is, to ensure that sufficient amounts of oxygen reach the catalytic layer at the cathode in order that a desired current is sustained;
2. water management, that is, to ensure that the water flow in the system is great enough to keep the membrane adequately hydrated but low enough to prevent flooding;
3. thermal management, that is, to ensure that the cell does not overheat, which may well occur as the result of the heat produced by electrochemical reactions in the catalyst layer.

Since the full problem is highly three-dimensional (3D), nonisothermal, multiphase, multicomponental, and most likely time-dependent in nature, numerous simplifications have been made in existing models to ensure some element of tractability. Perhaps the first one-dimensional (1D) models to provide a simplified treatment were developed by Bernardi and Verbrugge [5, 6] and Springer, Zawodzinski, and Gottesfeld [37]; a recent contribution is due to Gurau, Barbir, and Lui [20]. 1D treatments, whilst they are able to address some aspects of the three issues related to fuel cell performance mentioned above, are not able to address these questions at a local level: that is to say, where oxygen depletion occurs or where there is flooding or inadequate heat removal. Subsequent pseudo–two-dimensional (2D) models have tackled some of these issues [12, 17, 31, 44] with varying assumptions about the nature of the flow; in these so-called along-the-channel models, the resulting equations are ordinary differential equations with the coordinate along the fuel cell as the independent variable. Most recently, techniques of computational fluid dynamics have been used. Amongst models assuming single-phase gaseous flow, there are 2D isothermal models for the cathode [25, 45], 2D isothermal models for the whole cell [18, 19, 23, 36], 3D isother-

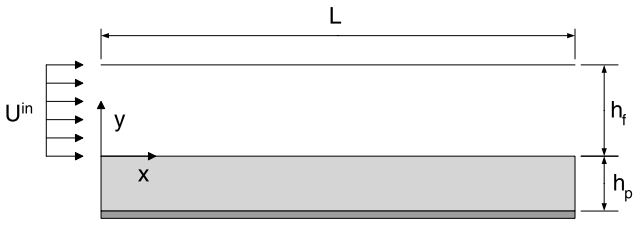

FIG. 2. *The cathode of a PEFC.*

mal models for the whole cell [14, 15], and 3D nonisothermal models for the whole cell [35]; generally speaking, there does not appear to be any experimental evidence that fuel cells are isothermal, although this assumption may indeed be valid for either small cells or large cells from which heat is removed at an adequate rate. In addition, two-phase flow at the cathode has also begun to receive attention [22, 31, 41].

This paper primarily addresses the first issue of the three given above. In addition, one of the goals is to steer between 1D models and full computational fluid dynamics to derive a 2D formulation that does not sacrifice too many geometrical features, yet on the other hand does not demand excessive computing time either. We focus here on the isothermal, three-component, gas-phase, 2D flow in a gas channel and adjacent porous gas backing of a PEFC cathode (Figure 2), although we note that the problem of multicomponent flow is a generic one, appearing not only in both electrodes of a PEFC (the gases are $(O_2,\ N_2,\ H_2O)$ at the cathode and (H_2, CO_2, H_2O) at the anode), but also in electrodes of other types of fuel cells [7, 21]. The geometry is assumed to be slender, as is typically the case in practice. Air, possibly humidified, is fed in at the inlet at the left (Figure 2); oxygen that reaches the catalytic layer reacts to produce water vapor, which is transported, along with oxygen and nitrogen, out at the outlet. The approach used here, however, differs from previous ones in that we use scaling arguments, nondimensionalization, and asymptotics to identify the main governing parameters and, subsequently, to obtain a reduced model. The benefits of this are the availability of closed-form analytical solutions in certain limits, as well as a model that is cheap to compute away from those limits; this feature is important from the point of view of extension to fuel cell stacks where transport in as many as 125 such assemblies may need to be computed (see, e.g., [27, 28, 29, 39]). The solution of this benchmark problem is useful from several other points of view:

- as a basis for later work and comparison when two-phase flow is introduced;
- to elucidate features that might not be obvious from simply solving the full equations.

Regarding the second point, it is clear from the majority of cathode studies that the mole fraction of O_2 decreases monotonically along the channel, while the mole fraction of H_2O increases, with the two slopes in some way dependent on physical and operating parameters. Among the results of the present treatment are closed-form expressions for these in certain limits.

The mathematical model is formulated in section 2. This consists of mass, momentum, and species transport equations and allows for the possibility of varying mixture density, as well as the crossed diffusion of species. A nondimensional analysis of the governing equations in section 3 provides an indication of the qualitative features one would expect in a multicomponent flow; there are found to be similarities with classical lubrication theory, in view of the slenderness of the geometry, except

that the reduced Reynolds number is typically $O(1)$. Furthermore, transport in the porous backing is found, to a reasonable approximation, to be 1D. In section 4, the first term in an asymptotic series in the reduced Reynolds number is derived: at leading order, the mole fractions are found to be solely a function of the distance along the fuel cell. Section 5 provides a description of a numerical scheme that is subsequently used when the reduced Reynolds number is $O(1)$; the scheme is verified in the lubrication theory limit for which closed-form solutions can be secured. Section 6 presents the results. A novel feature which we demonstrate here is that the traditional method for evaluating fuel cell performance, namely through the use of polarization curves, can be supplemented by the concept of a "polarization surface," whereby the average current density is plotted not as a function of cell potential but as a function of two dimensionless parameters which depend on cell potential, channel geometry, and inlet velocity; consequently, individual polarization curves are then paths along a "polarization surface." The implications of these results for a PEFC are also considered, in particular, as regards the limitations of the formulation with respect to liquid water formation, and conclusions are drawn in section 7.

2. Mathematical formulation.

2.1. Basics of multicomponent flow. We define the local mass average velocity, $\mathbf{v}$, of an n-component gas by

$$\mathbf{v} = \frac{\sum_{i=1}^{n} \rho_i \mathbf{v}_i}{\sum_{i=1}^{n} \rho_i},$$

where $\mathbf{v}_i$ denotes the velocity of species i with respect to stationary coordinate axes, and ρ_i is the mass concentration (the mass of species i per unit of volume of solution). For each component, the mass flux with respect to a coordinate system fixed in space is given by

$$\mathbf{n}_i = \rho\omega_i\mathbf{v} + \mathbf{j}_i, \quad i = 1, \ldots, n,$$

with

$$\rho = \sum_{i=1}^{n} \rho_i,$$

where ω_i is the mass fraction of species i, given by $\omega_i = \rho_i/\rho$, $\mathbf{j}_i$ is the mass diffusive flux relative to the mass-averaged velocity, and ρ_i denotes the density of species i. If we consider just concentration diffusion for an ideal gas mixture [8], we have

$$\mathbf{j}_i = \frac{c^2}{\rho} \sum_{j=1}^{n} M_i M_j D_{ij} \nabla x_j, \quad i = 1, \ldots, n; \tag{2.1}$$

here $(M_i)_{i=1,\ldots,n}$ are the molecular weights, $(D_{ij})_{i,j=1,\ldots,n}$ are the multicomponent diffusion coefficients, and $(x_i)_{i=1,\ldots,n}$ is the mole fraction of species i and is given by $x_i = c_i/c$, where c_i is the molar concentration of species i in moles per m^3 ($c_i = \rho_i/M_i$) and

$$c = \sum_{i=1}^{n} c_i.$$

Useful additional identities are $c = \rho/M$, where $M = \sum_{i=1}^{n} x_i M_i$ and a relation between the mass and mole fractions

$$\omega_i = x_i c M_i/\rho.$$

In general, $(D_{ij})_{i,j=1,\ldots,n}$ are strongly dependent on composition but can be expressed in terms of the Stefan–Maxwell diffusion coefficients, $(\mathcal{D}_{ij})_{i,j=1,\ldots,n}$, which are independent of composition. For a three-component system, as will be the case here, the relations are of the form [8]

$$D_{ij} = \mathcal{D}_{ij}\left\{1 + \frac{x_k\left[(M_k/M_j)\,\mathcal{D}_{ik} - \mathcal{D}_{ij}\right]}{x_i\mathcal{D}_{jk} + x_j\mathcal{D}_{ik} + x_k\mathcal{D}_{ij}}\right\}, \quad i,j,k = 1,2,3 \ \ (i \neq j)\,. \tag{2.2}$$

$(\mathcal{D}_{ij})_{i,j=1,\ldots,n}$ can in principle be measured experimentally [8, 38].

For the mixture density, we use the constitutive relation for an ideal gas,

$$\rho = \frac{pM}{RT}, \tag{2.3}$$

where p is the pressure, T is the temperature, and R is the universal gas constant (8.314 $\mathrm{kgm^2s^{-2}mol^{-1}K^{-1}}$). We note, in addition, the possibility that the mixture viscosity, μ_{mix}, will not necessarily be constant either, although we treat it to be so here.

2.2. Channel. Consider the 2D steady flow of a three-component gas in a channel of height h_f, adjacent to a porous medium of length L and height h_p (see Figure 2). The equations of continuity of mass and momentum for the mixture are taken as

$$\nabla.\,(\rho\mathbf{v}) = 0, \tag{2.4}$$

$$\nabla.\,(\rho\mathbf{v}\otimes\mathbf{v}) = -\nabla\left(p + \frac{2\mu}{3}\nabla.\mathbf{v}\right) + \mu\nabla^2\mathbf{v} - \rho g\mathbf{j}, \tag{2.5}$$

where g is the acceleration due to gravity and $\mathbf{j}$ is the unit vector in the positive y-direction; for later use, it is also convenient to define p', the modified pressure, given by

$$p' = p + \frac{2}{3}\mu\nabla.\mathbf{v}.$$

The continuity equation for each of the species,

$$\nabla.\mathbf{n}_i = 0, \quad i = 1,\ldots,3, \tag{2.6}$$

can be recast as, for the cathode of a fuel cell, with $n = 3$ in the form of two transport equations

$$\nabla.\left(\frac{\rho\mathbf{v}}{M}\begin{bmatrix} x_{O_2} \\ x_{H_2O}\end{bmatrix}\right) = \nabla.\left(\frac{\rho}{M^2}\mathbf{M}\begin{bmatrix}\nabla x_{O_2} \\ \nabla x_{H_2O}\end{bmatrix}\right), \tag{2.7}$$

where

$$\mathbf{M} = M_{N_2}\begin{pmatrix} D_{O_2,N_2} & D_{O_2,N_2} \\ D_{H_2O,N_2} & D_{H_2O,N_2}\end{pmatrix} - \begin{pmatrix} 0 & M_{H_2O}D_{O_2,H_2O} \\ M_{O_2}D_{H_2O,O_2} & 0\end{pmatrix}.$$

Here, use has been made of the relation $x_{O_2} + x_{N_2} + x_{H_2O} = 1$ to eliminate x_{N_2}, with the diffusion coefficients D_{O_2,H_2O}, D_{H_2O,O_2}, D_{H_2O,N_2}, and D_{O_2,N_2} given by (2.2).

2.3. Porous backing. For the porous region, volume-averaging of (2.4)–(2.7) along the lines of De Vidts and White [13] or Whitaker [43] is required. We present this at a moderate level of detail in order to sketch how the transport equations that are normally used, (2.23) below, can be arrived at; fuller details of analogous equations can be found elsewhere [13, 43]. First, let B be a quantity (either scalar, vector, or tensor) associated with the gas phase, and let the quantity $\langle B\rangle$ be the local volume (or superficial) average of B,

$$\langle B\rangle \equiv \frac{1}{\mathcal{V}}\int_{\mathcal{V}^{(\mathrm{g})}} B d\mathcal{V}, \tag{2.8}$$

and let $\langle B\rangle^{(\mathrm{g})}$ be the intrinsic volume average of B in the gas phase,

$$\langle B\rangle^{(\mathrm{g})} \equiv \frac{1}{\mathcal{V}^{(\mathrm{g})}}\int_{\mathcal{V}^{(\mathrm{g})}} B d\mathcal{V}. \tag{2.9}$$

Also, let γ be the porosity, given by $\gamma = \mathcal{V}^{(\mathrm{g})}/\mathcal{V}$. A comparison of (2.8) and (2.9) shows that the local and intrinsic volume average for the gas phase is given by

$$\langle B\rangle = \gamma \langle B\rangle^{(\mathrm{g})}. \tag{2.10}$$

Taking the superficial average of (2.4) gives

$$\langle \nabla.(\rho \mathbf{v})\rangle = 0, \tag{2.11}$$

whilst the superficial average of (2.5) gives (cf. [42])

$$\langle \mathbf{v}\rangle = -\frac{\mathbf{K}}{\mu}.\left(\nabla \langle p'\rangle^{(\mathrm{g})} + \langle \rho\rangle^{(\mathrm{g})} g\mathbf{j}\right) + \mathbf{K}.\nabla^2\left(\frac{\langle \mathbf{v}\rangle}{\gamma}\right) - \mathbf{F}.\langle \mathbf{v}\rangle, \tag{2.12}$$

where $\mathbf{K}$ is the Darcy Law permeability tensor and $\mathbf{F}$ is the Forchheimer correction tensor. Writing $\widetilde{D}_{ij} = c^2 D_{ij}/\rho$, we have

$$\nabla.\langle c_i \mathbf{v}\rangle + \frac{1}{\mathcal{V}}\int_{A_{gs}} c_i \mathbf{n}_{gs}.\mathbf{v} dA + \sum_{j=1}^{n} M_i M_j \nabla.\left(\left\langle \widetilde{D}_{ij}\right\rangle\left[\nabla\langle x_j\rangle + \frac{1}{\mathcal{V}}\int_{A_{gs}} x_j \mathbf{n}_{gs} dA\right]\right)$$

$$+\frac{1}{\mathcal{V}}\sum_{j=1}^{n} M_i M_j \widetilde{D}_{ij}\int_{A_{gs}} \mathbf{n}_{gs}.\nabla x_j dA = 0, \tag{2.13}$$

where $\mathbf{n}_{gs}$ represents the unit normal vector pointing from the gas phase to the solid phase, and A_{gs} represents the area of the gas-solid interface contained within $\mathcal{V}$. In the absence of surface reactions and zero normal velocity (passive dispersion), this reduces to

$$\nabla.\langle c_i \mathbf{v}\rangle + \sum_{j=1}^{n} M_i M_j \nabla.\left(\left\langle \widetilde{D}_{ij}\right\rangle\left[\nabla\langle x_j\rangle + \frac{1}{\mathcal{V}}\int_{A_{gs}} x_j \mathbf{n}_{gs} dA\right]\right) = 0, \tag{2.14}$$

and then

$$\nabla.\langle c_i \mathbf{v}\rangle + \sum_{j=1}^{n} M_i M_j \nabla.\left(\widetilde{D}_{ij}\left[\nabla\left(\gamma\langle x_j\rangle^{(\mathrm{g})}\right) + \frac{1}{\mathcal{V}}\int_{A_{gs}} x_j \mathbf{n}_{gs} dA\right]\right) = 0, \tag{2.15}$$

where we have used the fact that $\widetilde{D}_{ij}$ changes slowly with temperature and mole fraction within the representative elementary volume in order to be able to write

$$\nabla . \left\langle \widetilde{D}_{ij} \nabla x_j \right\rangle = \nabla . \left(\widetilde{D}_{ij} \left\langle \nabla x_j \right\rangle \right). \tag{2.16}$$

To ascertain this, we generalize the reasoning given by Whitaker [43] as follows. With

$$\begin{aligned} \widetilde{D}_{ij} &= \frac{pD_{ij}}{RTM} \\ &= \frac{p\mathcal{D}_{ij}}{RTM} \left\{ 1 + \frac{x_k \left[\left(M_k / M_j \right) \mathcal{D}_{ik} - \mathcal{D}_{ij} \right]}{x_i \mathcal{D}_{jk} + x_j \mathcal{D}_{ik} + x_k \mathcal{D}_{ij}} \right\}, \end{aligned}$$

we require

$$\frac{l_\gamma}{\widetilde{D}_{ij}} \left(\left. \frac{\partial \widetilde{D}_{ij}}{\partial p} \right]_{\langle p \rangle^{(\mathrm{g})}} \nabla \langle p \rangle^{(\mathrm{g})} + \left. \frac{\partial \widetilde{D}_{ij}}{\partial T} \right]_{\langle T \rangle^{(\mathrm{g})}} \nabla \langle T \rangle^{(\mathrm{g})} + \sum_{l=1}^{n} \left. \frac{\partial \widetilde{D}_{ij}}{\partial x_l} \right]_{\langle x_l \rangle^{(\mathrm{g})}} \nabla \langle x_l \rangle^{(\mathrm{g})} \right) \ll 1,$$

where l_γ is the pore length scale. Also, for later use, we need to be able to justify that within the representative elementary volume,

$$\begin{aligned} \nabla . \langle c_i \mathbf{v} \rangle &= \nabla . \left(\frac{p}{RT} \langle x_i \mathbf{v} \rangle \right) \\ &= \nabla . \left(\frac{\rho}{M} \langle x_i \mathbf{v} \rangle \right) \\ &= \nabla . \left(\frac{\langle \rho \rangle}{\langle M \rangle} \langle x_i \mathbf{v} \rangle \right); \end{aligned}$$

this would be justified if

$$\frac{l_\gamma}{D_\gamma} \left(\left. \frac{\partial D_\gamma}{\partial p} \right]_{\langle p \rangle^{(\mathrm{g})}} \nabla \langle p \rangle^{(\mathrm{g})} + \left. \frac{\partial D_\gamma}{\partial T} \right]_{\langle T \rangle^{(\mathrm{g})}} \nabla \langle T \rangle^{(\mathrm{g})} \right) \ll 1,$$

where $D_\gamma = p/RT$. Thus, we would require

$$l_\gamma \left(\frac{\nabla \langle p \rangle^{(\mathrm{g})}}{p} - \frac{\nabla \langle T \rangle^{(\mathrm{g})}}{T} \right) \ll 1; \tag{2.17}$$

we verify that this relation is indeed satisfied in section 3.2.

Now, decomposing according to

$$\phi = \langle \phi \rangle^{(\mathrm{g})} + \phi',$$

where $\phi = (x_j, c_j, \mathbf{v}, \rho)$ and the primed quantities denote spatial fluctuations, (2.11) and (2.15) can be shown to become, respectively,

$$\nabla . \left(\langle \rho \rangle^{(\mathrm{g})} \langle \mathbf{v} \rangle \right) = -\nabla . \left(\langle \rho' \mathbf{v}' \rangle \right), \tag{2.18}$$

$$\nabla.\left(\frac{\gamma\left\langle\rho\right\rangle^{(\mathrm{g})}\left\langle x_i\right\rangle^{(\mathrm{g})}\left\langle\mathbf{v}\right\rangle^{(\mathrm{g})}}{\left\langle M\right\rangle^{(\mathrm{g})}}\right)$$
$$+\sum_{j=1}^{n}M_iM_j\nabla.\left(\widetilde{D}_{ij}\left[\nabla\left(\gamma\left\langle x_j\right\rangle^{(\mathrm{g})}\right)+\frac{1}{\mathcal{V}}\int_{A_{gs}}x_j'\mathbf{n}_{gs}dA\right]\right)$$
$$-\nabla.\left(\frac{\left\langle\rho\right\rangle^{(\mathrm{g})}}{\left\langle M\right\rangle^{(\mathrm{g})}}\left\langle\mathbf{v}'x_i'\right\rangle\right)=0,$$

(2.19)

where we again use analysis due to Whitaker [43, pp. 14–20]. To keep the ongoing discussion simple, we assume henceforth that γ is constant. Eventually, we arrive at

(2.20)
$$\nabla.\left(\frac{\gamma\left\langle\rho\right\rangle^{(\mathrm{g})}\left\langle x_i\right\rangle^{(\mathrm{g})}\left\langle\mathbf{v}\right\rangle^{(\mathrm{g})}}{\left\langle M\right\rangle^{(\mathrm{g})}}\right)+\sum_{j=1}^{n}M_iM_j\nabla.\left(\left[\mathbf{D}_{ij}^{\mathrm{eff}}+\gamma\mathbf{D}_j^{\mathrm{hyd}}\delta_{ij}\right]\nabla\left\langle x_j\right\rangle^{(\mathrm{g})}\right)=0,$$

where $\mathbf{D}_{ij}^{\mathrm{eff}}$ is an effective diffusivity tensor given by

$$\mathbf{D}_{ij}^{\mathrm{eff}}=\gamma\widetilde{D}_{ij}\left(1+\frac{1}{\mathcal{V}^{(\mathrm{g})}}\int_{A_{gs}}\mathbf{n}_{gs}\mathbf{b}_gdA\right),$$

and δ_{ij} is the Kronecker delta; here, $\mathbf{b}_g$ is referred to as the closure variable and is found from the so-called closure problem. $\mathbf{D}_j^{\mathrm{hyd}}$ is called the hydrodynamic dispersion tensor and is defined by

$$\mathbf{D}_j^{\mathrm{hyd}}:=-\frac{\left\langle\rho\right\rangle^{(\mathrm{g})}}{\left\langle M\right\rangle^{(\mathrm{g})}}\left\langle\mathbf{v}'x_j'\right\rangle^{(\mathrm{g})}.$$

For gas diffusion electrodes, the following is often used [3, 5, 6, 45]:

$$\mathbf{D}_{ij}^{\mathrm{eff}}=\widetilde{D}_{ij}\gamma^{\frac{3}{2}};$$

this would imply

$$\left(1+\frac{1}{\mathcal{V}^{(\mathrm{g})}}\int_{A_{gs}}\mathbf{n}_{gs}\mathbf{b}_gdA\right)=\gamma^{\frac{1}{2}}.$$

For the cathode, with $i=O_2,N_2$, and H_2O, we have in more expedient form, on assuming the permeability to be isotropic and constant and neglecting the Forchheimer correction term in (2.12) and dispersion terms in (2.18) and (2.19) (see section 3.4),

$$\nabla.\left(\left\langle\rho\right\rangle^{(\mathrm{g})}\left\langle\mathbf{v}\right\rangle\right)=0, \tag{2.21}$$

$$\left\langle\mathbf{v}\right\rangle=-\frac{\kappa}{\mu}\left(\nabla\left\langle p'\right\rangle^{(\mathrm{g})}+\left\langle\rho\right\rangle^{(\mathrm{g})}g\mathbf{j}\right)+\frac{\kappa}{\gamma}\nabla^2\left\langle\mathbf{v}\right\rangle, \tag{2.22}$$

(2.23)
$$\nabla.\left(\frac{\left\langle\rho\right\rangle^{(\mathrm{g})}\left\langle\mathbf{v}\right\rangle}{\left\langle M\right\rangle^{(\mathrm{g})}}\begin{bmatrix}\left\langle x_{O_2}\right\rangle^{(\mathrm{g})}\\ \left\langle x_{H_2O}\right\rangle^{(\mathrm{g})}\end{bmatrix}\right)=\nabla.\left(\frac{\gamma^{\frac{3}{2}}\left\langle\rho\right\rangle^{(\mathrm{g})}}{\left(\left\langle M\right\rangle^{(\mathrm{g})}\right)^2}\left\langle\mathbf{M}\right\rangle^{(\mathrm{g})}\begin{bmatrix}\nabla\left\langle x_{O_2}\right\rangle^{(\mathrm{g})}\\ \nabla\left\langle x_{H_2O}\right\rangle^{(\mathrm{g})}\end{bmatrix}\right),$$

where

$$\langle \mathbf{M} \rangle^{(\mathrm{g})} = M_{N_2} \begin{pmatrix} \langle D_{O_2,N_2} \rangle^{(\mathrm{g})} & \langle D_{O_2,N_2} \rangle^{(\mathrm{g})} \\ \langle D_{H_2O,N_2} \rangle^{(\mathrm{g})} & \langle D_{H_2O,N_2} \rangle^{(\mathrm{g})} \end{pmatrix} - \begin{pmatrix} 0 & M_{H_2O} \langle D_{O_2,H_2O} \rangle^{(\mathrm{g})} \\ M_{O_2} \langle D_{H_2O,O_2} \rangle^{(\mathrm{g})} & 0 \end{pmatrix},$$

with

$$\langle D_{ij} \rangle^{(\mathrm{g})} = \mathcal{D}_{ij} \left\{ 1 + \frac{\langle x_k \rangle^{(\mathrm{g})} \left[(M_k/M_j)\, \mathcal{D}_{ik} - \mathcal{D}_{ij} \right]}{\langle x_i \rangle^{(\mathrm{g})} \mathcal{D}_{jk} + \langle x_j \rangle^{(\mathrm{g})} \mathcal{D}_{ik} + \langle x_k \rangle^{(\mathrm{g})} \mathcal{D}_{ij}} \right\};$$

(2.21)–(2.23) are then akin to the governing equations for the porous backing used by most authors, although with more attention having been paid here to the distinction between intrinsic and superficial variables, the possibility of nonconstant diffusion coefficients, and the inclusion of crossed diffusion terms.

2.4. Boundary conditions.

2.4.1. Inlet, outlet, upper wall, vertical walls. For boundary conditions in the channel, we prescribe inlet velocity and gas composition at $x = 0$, $0 \le y \le h_f$, so that

$$u = U^{in}, \quad v = 0, \quad x_{O_2} = x^{in}_{O_2}, \quad x_{H_2O} = x^{in}_{H_2O}, \tag{2.24}$$

where $\mathbf{v} = (u, v)$. At the upper channel wall ($0 \le x \le L$, $y = h_f$), there is no slip, no normal flow, and no componental flux, so that

$$u = v = \frac{\partial x_{O_2}}{\partial y} = \frac{\partial x_{H_2O}}{\partial y} = 0. \tag{2.25}$$

At the outlet at $x = L, 0 \le y \le h_f$, we have constant pressure, and no diffusive componental flux, so that

$$p = p^{out}, \quad \frac{\partial v}{\partial x} = \frac{\partial x_{O_2}}{\partial x} = \frac{\partial x_{H_2O}}{\partial x} = 0. \tag{2.26}$$

At the vertical walls of the porous electrode ($x = 0, L, -h_p \le y \le 0$), we prescribe no normal flow, no tangential shear, and no mass flux for the gas components, so that

$$\langle u \rangle = \frac{\partial \langle v \rangle}{\partial x} = \frac{\partial \langle x_{O_2} \rangle^{(\mathrm{g})}}{\partial x} = \frac{\partial \langle x_{H_2O} \rangle^{(\mathrm{g})}}{\partial x} = 0, \tag{2.27}$$

where $\langle \mathbf{v} \rangle = (\langle u \rangle, \langle v \rangle)$.

2.4.2. Channel/porous backing interface. In addition, matching conditions are required for the fluid-porous interface at $y = 0$, $0 \le x \le L$. The conditions for continuity of normal velocity and normal stress are given, respectively, as

$$v = \langle v \rangle, \tag{2.28}$$

$$p - \mu \frac{\partial v}{\partial y} = \langle p \rangle^{(\mathrm{g})} - \mu_{eff} \frac{\partial \langle v \rangle}{\partial y}, \tag{2.29}$$

where $\mu_{eff}\,(=\mu/\gamma)$ is termed the effective viscosity of the porous medium. The remaining two conditions that are required have been the subject of longstanding debate ever since the work of Beavers and Joseph [4]; a recent contribution is due to Jäger and Mikelić [24]. A summary of possible options for the momentum equation is given by Alazmi and Vafai [1], of which the most relevant for this application, and indeed most consistent in view of our use of the full Navier–Stokes equations for the fluid and a Darcy/Brinkman/Forchheimer formulation for the porous medium, is one due to Ochoa-Tapia and Whitaker [32] when inertial effects are important:

$$u = \langle u \rangle\,, \tag{2.30}$$

$$\frac{\mu}{\gamma}\frac{\partial \langle u \rangle}{\partial y} - \mu\frac{\partial u}{\partial y} = \frac{\beta_1 \mu}{\kappa^{\frac{1}{2}}}u + \beta_2 \rho u^2, \tag{2.31}$$

respectively. Here, β_1 and β_2 are $O\,(1)$ constants which would need to be determined experimentally, although it turns out here that the leading order problem is dictated more by (2.30) than by (2.31) .

Finally, volume-averaging techniques at the interface analogous to those used for heat transfer by [33] are required for the mole fraction transport equations. We do not pursue the details but simply assume the point values for the mole fractions of O_2 and H_2O in the channel to be equal to their intrinsic values in the porous backing, so that

$$\langle x_{O_2} \rangle^{(\mathrm{g})} = x_{O_2}, \quad \langle x_{H_2O} \rangle^{(\mathrm{g})} = x_{H_2O} \text{ at } y = 0, \tag{2.32}$$

and, in addition, that the point values for the mole fraction fluxes of O_2 and H_2O are equal to their superficial values in the porous medium, so that

$$\mathbf{n}_{O_2}.\mathbf{n} = \langle \mathbf{n}_{O_2}.\mathbf{n} \rangle\,, \quad \mathbf{n}_{H_2O}.\mathbf{n} = \langle \mathbf{n}_{H_2O}.\mathbf{n} \rangle\,;$$

using (2.28) and (2.32) , we arrive at

$$\gamma^{\frac{3}{2}}\frac{\partial}{\partial y}\begin{bmatrix} \langle x_{O_2} \rangle^{(\mathrm{g})} \\ \langle x_{H_2O} \rangle^{(\mathrm{g})} \end{bmatrix} = \frac{\partial}{\partial y}\begin{bmatrix} x_{O_2} \\ x_{H_2O} \end{bmatrix}, \tag{2.33}$$

respectively.

2.4.3. Catalyst/porous backing interface. At $y = -h_f$, we would expect $\langle u \rangle\,, \langle v \rangle\,, \langle x_{O_2} \rangle^{(\mathrm{g})}$, and $\langle x_{H_2O} \rangle^{(\mathrm{g})}$ to match to their counterparts in the catalytic layer, although naturally this approach would require us to model the catalyst layer and then by extension the membrane and the corresponding regions on the anode side. This has been done to varying degrees by various authors [5, 6, 14, 17, 18, 19, 20, 23, 31, 35, 36, 37]. An alternative approach, often adopted when the flow field in the porous backing and gas channels rather than the electrochemistry in the catalyst and the membrane is of interest [25, 30, 45, 41], is to prescribe a current density, I, at this interface. Using Faraday's Law, the superficial mass flux of oxygen is given as a function of current density, so that

$$\langle \mathbf{n}_{O_2}.\mathbf{n} \rangle = -\frac{M_{O_2} I}{4F}, \tag{2.34}$$
