ESTIMATE OF TURBULENT EDDY DIFFUSION BY EXACT RENORMALIZATION*

ALEXANDRA INDEIKINA† AND HSUEH-CHIA CHANG†

Abstract. By using a Lagrangian renormalization formulation, the effective diffusion equation is rigorously derived for a tracer in a homogeneous, isotropic, stationary, multidimensional and zero-mean Gaussian velocity field with a known two-point/two-time correlation tensor. The basic idea is to find the appropriate representation for the averaged small-scale solute distribution, to express it in terms of large-scale variables, and then to evaluate the limit of the infinite separation between the dissipation and the integral scales of turbulence. Key to the derivation is the validation of Corrsin's independence hypothesis for the selected velocity field at any diffusion time. The requirement of the nontrivial limiting behavior for the averaged solute distribution then results in the determination of the appropriate time scale for the averaged effective large-scale long-time spreading problem and in the evaluation of the effective transport coefficient. Unlike the simple shear flow case of Avellaneda and Majda, multidimensional velocity fluctuations ensure a constant eddy diffusivity in the limit of infinite time for any spectral parameters. By adjusting a single decorrelation time spectral parameter for a velocity field with Kolmogorov spectrum, the effective evolution equation is shown to produce the same time-evolution of the lateral mean-square displacement as a numerical simulation of planar flow and experimental heat-transfer data in turbulent pipe flow. The predicted constant asymptotic eddy diffusivity at infinite time, $E_D = 7.26 \times 10^{-3} \nu Re^{7/8}$, agrees with experimental data for eddy diffusivities in pipes and ducts over three decades of Reynolds numbers.

1. Introduction.

It is well known that the effective diffusivity of a turbulent flow can be a thousand times larger than the molecular transport coefficient. Hence, the computation of eddy diffusivity in a fully developed turbulence is an extremely important practical problem in both engineering and environmental science. Macroscopic description of the dispersion enhancement is a complex problem due to large fluctuations in the scalar field caused by the turbulent flow, where the velocity involves a continuous range of excited space and/or time scales and admits only a statistical description. The goal of eddy diffusivity theories is to assess the effects of the continuum of energetic smaller scales on the large scales through an effective equation without resolving this effect explicitly. Mathematically, it requires the statistical averaging of the small-scale fluctuations and then the determination of new appropriate time scales for the resulting effective transport equation such that the desired solution behaves nontrivially in the large-scale long-time limit.

Unfortunately, because of the presence of convective term $\mathbf{u} \cdot \boldsymbol{\nabla}(\dots)$ in transport equations, all statistical quantities are coupled up to infinite order. To find the average value $\langle C \rangle$, for example, one needs to know the correlation $\langle Cu \rangle$; if one tries to write down the equation for $\langle Cu \rangle$, terms like $\langle Cuu \rangle$ will appear in it, and so on. Hence, one needs to close somehow this infinite hierarchy of statistical moments. The fluctuations

in turbulent flows are typically large, however, and the usual perturbation expansions, which simply neglect higher-order moments, will completely fail to predict something reasonable for problems of such kind. Instead, these problems have been attacked through a wide variety of renormalized perturbation theories that mimic ideas from field theory and the renormalization group theory from critical phenomena, both involving partial summation of the perturbation series.

The basic idea of the renormalized perturbation theories (RPT) is in the replacement, after ensemble averaging, of the zero-order terms in a formal widely divergent perturbation expansion by the exact values. It should be mentioned that convergence is not ensured for the renormalized perturbation series. However, even if it does not converge, it is much more accurate than widely divergent primitive perturbation series. The application of renormalized perturbation theories to turbulence has been pioneered by Kraichnan in a series of papers during the late 1950s, cumulating in the direct interaction approximation (DIA). (See Kraichnan [16], for example.) The "direct interaction principle" means that the strongest coupling occurs between the "nearest neighbors" in the wavenumber space. Consequently, only terms responsible for such interactions should be taken into account, summed, and averaged. As a result, the renormalized perturbation series is truncated at the second order.

Note that in its original formulation, DIA fails even to reproduce the Kolmogorov "$k^{-5/3}$" energy spectrum and results instead in a $k^{-3/2}$ decay for the inertial range of wavenumbers. Further development of this theory that includes reformulation in mixed Eulerian Lagrangian coordinates (see Kraichnan [17]) results in at least qualitative agreement with spectral measurements. Unfortunately, as the performance improves, the length and complexity of the final equations grow dramatically. Until now, different modifications of DIA remain the most popular among all renormalized perturbation theories. As an example of the application of DIA to scalar transport problems, one can mention the study of Koch and Brady [14]. They use DIA to predict the rate of growth of the variance of a tracer for a slowly decaying velocity covariance $\sim x^{-\gamma}$. Their analysis indicates that the spread will be nondiffusive with the mean-square displacement growing like $t^{4/(2+\gamma)}$ as $t \to \infty$ for $0 < \gamma \leq 2$, and this result is qualitatively consistent with numerical simulation. However, higher-order moments obtained from this approximation are incorrect.

In general, the strength of the renormalized perturbation theories lies in their generality and the absence of ad hoc assumptions or disposable constants. However, the unpredictable error of all RPT's (because of unknown mathematical properties of renormalized perturbation series) on one hand, and the enormous complexity when formulated for inhomogeneous turbulence on the other, restrict using these theories in both fundamental and engineering applications. A partial answer to the first of these problems lies within the renormalization group approach, which is quite distinct from RPT.

The renormalization group method (RNG) already has some success when applied to problems in critical phenomena. The pioneers in the development of the RNG for turbulence are Forster, Nelson, and Stephen [9]. Their theory is later generalized by De Dominicis and Martin [6]. The RNG involves iterative averaging over the small bands of modes and progressive scaling away from the highest wavenumbers (short waves), whose effect on the lowest wavenumbers (long waves) can be retained in an average form as a contribution to the transport coefficients. If the system becomes invariant under the mode elimination procedure, the scaling transformation is said to have reached a fixed point. One can then eliminate all fluctuations, and

the value of the new transport coefficient at the fixed point corresponds to enhanced diffusivity. Using the RNG, Yakhot and Orszag [23] obtain the turbulent viscosity and the relation between turbulent Prandtl number and turbulent viscosity for unbounded homogeneous turbulence and applied these results to heat transfer in a pipe, using an empirical model for the viscosity in a wall region (Yakhot, Orszag, and Yakhot [24]). It has been reported that the proposed formula gives good agreement with experimental data in a wide range of Prandtl number, $10^{-2} < Pr < 10^{6}$.

From both a physical and mathematical point of view, the RNG is more rigorous than the RPT, and at the same time, the RNG is simpler: at the end, the mathematical problem reduces to the study of a system of first-order ordinary differential equations. However, it should be mentioned that the RNG mode elimination procedure is valid to any order only if the neglected higher-order terms (they are truly negligible only when the first band of modes is eliminated) remain negligible after scaling transformations. In turbulent flow calculations, the above condition often requires the space dimension to be "slightly higher than 3," with the best performance, for example, in seven-dimensional space (Yakhot and Orszag [23]). Consequently, it is hard to expect the RNG to give the correct prediction for any case, Yakhot, Orszag, and Yakhot's claim notwithstanding.

For scalar transport problems, perhaps the most rigorous and accurate approach has been suggested by Avellaneda and Majda [1]. They consider an advection-diffusion of a passive scalar in a simple shear flow $\mathbf{u} = (0, u_2(x_1, t), 0)$, where $u_2(x_1, t)$ has stationary Gaussian statistics. This model problem admits an explicit representation of the solution through the Lagrangian formulation. Using the above representation and some properties of stochastic differential equations, Avellaneda and Majda develop a complete renormalization theory for this exactly solvable model with full mathematical rigor. They found several regimes of anomalous diffusion that depend on the parameters of the velocity spectrum, such as time-dependent diffusivities and even an effective equation with a random nonlocal diffusion coefficient.

With this exact result, the capability of the RNG, Lagrangian RPT, and DIA in predicting turbulent transport for the same model flow is also examined (Avellaneda and Majda [2]). It is found that all these approximate theories give incorrect predictions for some regions of renormalization, which depend on the parameters defining the velocity spectrum.

The RNG always predicts a simple local diffusion equation with constant diffusivity and often erroneously determines the appropriate time scale for the effective transport problem. More importantly, it has been found that the RNG is barely acceptable for velocity spectra pertinent to turbulent transport problems. The important example of the Kolmogorov velocity spectrum belongs to the boundary of applicability of the RNG, where this method can still give the correct long time scale for the effective diffusion problem. However, in this case RNG can only provide the infinite-time asymptotic value of effective diffusivity and cannot resolve the time-evolution of the mean-square displacement. Hence, the application of the results of Yakhot and Orszag [23] to nonsteady turbulent transport problems seems questionable.

In contrast, both RPT always reproduce the correct time scale for effective diffusion problems. However, the resulting effective equations can vary from the simple wave equation to some complicated integro-differential equation instead of the local diffusion equation with time-dependent diffusivity predicted by the exact renormalization theory of Avellaneda and Majda [1].

For the more general case of turbulent transport by isotropic homogeneous ran-

dom velocity fields, Avellaneda and Majda [3] investigate a part of the spectral parameter space in the vicinity of the Kolmogorov value. They find that the anomalous long-time scale for the effective transport process remains the same as for a simple shear flow model considered earlier [1], regardless of flow dimensions. The governing equation may, however, differ. If the temporal fluctuations are not irrelevant in the large-scale long-time limit, Avellaneda and Majda suggest a nonlocal diffusion equation but do not present details in their report [3].

Recently, Fannjiang [8] invokes variational principles to analyze scalar transport by the same three-dimensional turbulent flow for the entire range of spectral parameters. He also investigates the effect of the cut-off wavenumber on the resulting scaling laws. (In fact, this introduces a third dimension in the parameter space.) While this method produces a long time scale for anomalous diffusion, consistent with earlier results of Avellaneda and Majda [3] at identical values of the parameters, it provides only an upper bound for the effective diffusion coefficient. The limiting long time scale is found to be dependent on the wavenumber scaling. However, it should be noted that the actual wavenumber range, important for the scalar transport, is not arbitrary. Instead, it should be determined from physical arguments (as has been done by Avellaneda and Majda [1]) like the velocity spectrum, spatial scales of initial data, requirement of finite (not only bounded) eddy diffusivity, etc. Hence, the applicability of Fannjiang's results [8] to practical turbulent transport is quite limited.

It also should be noted that none of the earlier works relate the main scaling parameter (the ratio of dissipation to integral length scales of turbulence) to other typically reported physical quantities (like Reynolds number, friction velocity, pipe diameter, etc.). For the Kolmogorov spectrum, this relation is well known (see McComb [19], for example, or any other textbook on turbulence), but it is not obvious for other spectra. Also, there are almost no comparisons of suggested theories with experimental data. The only exceptions are the work of Yakhot, Orszag, and Yakhot [24] and in the fundamental book of McComb [19], where some of the predicted infinite-time asymptotic values of effective diffusivities are compared to data. If, however, the theory suggests time-dependent eddy diffusivity or nonlocal scalar transport, one needs to use data on the time-evolution of mean-square displacement to check the prediction adequately.

The investigation of full two-dimensional (2-D) and three-dimensional (3-D) turbulent transport using an extension of exact renormalization theory of Avellaneda and Majda is the subject of this report. With the usual idealization for the turbulent core, the zero-mean unbounded turbulent flow in the inertial range of length scales is assumed to be stationary, homogeneous, and isotropic. The spreading of the pulse of the solute in 2-D or 3-D isotropic random flow is examined as the simplest example, allowing the derivation of large-scale long-time effective transport equation and the associated effective diffusivity, which is time-dependent in general, in terms of parameters defining the velocity statistics.

The basic idea is to find the appropriate representation for the averaged small-scale solute distribution, to express it in terms of large-scale variables, and then to evaluate the limit of the infinite separation between the dissipation and the integral scales of turbulence. (In fact, this is the limit of infinite Reynolds number). The requirement of the nontrivial limiting behavior for the averaged solute distribution (it is never equal to zero nor the initial data) then results in the determination of the appropriate time scale for the averaged effective large-scale long-time spreading problem and in the evaluation of the effective transport coefficient.

Since the whole idea of renormalization in this case is based on the appropriate rescaling, the initial nondimensionalization of the small-scale transport problem and the statistics of the random velocity field are defined precisely in sections 2 and 3.

Section 4 describes the Lagrangian formulation of the advection-diffusion problem through Ito's stochastic differential equation. It provides the solution for the distribution of the evolved concentration field that, however, has to be averaged over the distribution of random velocity field and over the Brownian motion that represents the molecular diffusion effect in Ito's formulation.

This averaging is completed in section 5, and it is shown that the resulting averaged concentration distribution and the evolution equation for the effective diffusivity are exact for the selected stationary homogeneous isotropic Gaussian velocity field. With some physically plausible assumptions, the above result also can be applied to the more important case of non-Gaussian velocity statistics.

In section 6 the rescaling of the derived equations is carried out. The large-scale long-time limiting behavior of the averaged solute distribution is evaluated and the effective diffusion equation is derived, provided that the effective diffusivity can be properly renormalized.

The renormalization procedure for different parameters of the velocity spectrum is described in section 7. It includes the evaluation of the distinguishing limit for the evolution of rescaled enhanced diffusivity and hence the determination of the appropriate time-rescaling function for the effective large-scale long-time diffusion equation.

The summary and discussion of results of the renormalization analysis are offered in section 8. The Kolmogorov velocity spectrum is chosen to compare the predicted transport coefficient with experimental data on turbulent scalar transport and with earlier numerical simulation. Both quantitative and qualitative agreement seem to be satisfactory, taking into account the strong limitation of the assumed homogeneous and isotropic Gaussian statistics.

2. Initial nondimensionalization for the transport problem. Consider the dispersion of a solute/temperature field by a well-developed turbulent flow. Away from the boundaries, in a turbulent core, the mean velocity profile is often assumed to be flat. Consequently, such mean flow results only in the translation of the initial solute distribution. Hence, in a frame of reference moving with the constant mean flow, the spreading of the pulse is governed by the advection-diffusion equation

$$\frac{\partial C'}{\partial t'} + \mathbf{u}' \cdot \boldsymbol{\nabla}' C' = D_0' \boldsymbol{\nabla}'^2 C', \qquad C'(\mathbf{x}', 0) = C_0'(\mathbf{x}'), \tag{2.1}$$

where $\mathbf{u}'(\mathbf{x}', t')$ is the random velocity field with zero mean, D_0' is the molecular diffusivity and primes denote dimensional variables. Because only the turbulent core will be considered here, no boundary conditions are imposed. Since the goal of this study is to average the effect of all inertial range fluctuations of the velocity field, the problem should be made nondimensional with the smallest possible scale of turbulence initially. Hence, the dissipation length scale L_d for the fluctuation velocity field $\mathbf{u}'$ is taken as the characteristic length. The characteristic velocity U_d is then defined by the requirement that the dissipation Reynolds number $R_d = U_d L_d/\nu$ is equal to 1, such that $U_d = \nu/L_d$. This results in the characteristic time $\tau_d = L_d/U_d = {L_d}^2/\nu$, which corresponds to the viscous dissipation time scale. The inverse of the Schmidt number defines the nondimensional diffusivity $D_0 = D_0'/\nu = Sc^{-1}$.

For the renormalization procedure, it also is necessary to define the macroscopic scales for the problem. The macroscopic length scale L_0 is defined as the integral length scale of the turbulence. For the realistic systems, L_0 is of the order of the lateral dimension of the flow. Since the effect of constant mean flow in this idealized problem has been eliminated and only the inertial range of the turbulence will be considered, the large-scale Reynolds number $R_0 = U_0 L_0/\nu$ is defined through the root-mean-square velocity U_0 for the large-eddy motion.

The ratio between the dissipation and the integral length scales increases with R_0 and it is represented by the small parameter $\delta = L_d/L_0 \ll 1$. The actual dependence of δ on the large-scale Reynolds number R_0 depends on the spectrum of the velocity fluctuation and will be specified later.

The advection-diffusion problem (2.1) is linear in C' and, because there are no boundary conditions, the characteristic value of the concentration difference $\triangle C'$ used for nondimensionalization is not important. However, several restrictions should be imposed on the initial nondimensional solute distribution $C_0 = C_0'/\triangle C'$. Since (2.1) describes the solute dispersion in the unbounded domain, $C_0(\mathbf{x}')$ should decay to infinity fast enough such that the integral of the initial distribution over the entire n-dimensional space is finite,

$$0 < {L'}^{-n} \int_{-\infty}^{\infty} C_0(\mathbf{x}') d^n\mathbf{x}' < \infty,$$

where an appropriate length scale L' is added for dimensional reasons. Consequently, $C_0(\mathbf{x}')$ can be defined by its Fourier integral

$$C_0(\mathbf{x}') = (2\pi/L')^{-n} \int_{-\infty}^{\infty} \hat{C}_0(\mathbf{K}') \exp(\imath \mathbf{K}'\mathbf{x}') d^n\mathbf{K}', \tag{2.2}$$

where $\mathbf{K}'$ is the n-dimensional wavevector.

If one would like to describe a large-scale long-time behavior of the spreading process, it is necessary to assume large-scale initial data for the advection-diffusion problem (2.1). This implies that $C_0(\mathbf{x}')$ varies only over the integral length scale L_0. Consequently, one should set $L' = L_0$ in (2.2) such that $C_0(\mathbf{x}') = C_0(\mathbf{x}'/L_0)$ and $\hat{C}_0(\mathbf{K}') = \hat{C}_0(\mathbf{K})$, where $\mathbf{K} = \mathbf{K}' L_0$ is the large-scale nondimensional wavevector.

Hence, with the nondimensionalization on dissipation length and time scales L_d and τ_d, the governing equation (2.1) and the initial distribution (2.2) becomes

$$\frac{\partial C}{\partial t} + \mathbf{u} \cdot \boldsymbol{\nabla} C = D_0 \boldsymbol{\nabla}^2 C, \tag{2.3}$$

$$C(\mathbf{x}, 0) = C_0(\delta \mathbf{x}) = (2\pi)^{-n} \int_{-\infty}^{\infty} \hat{C}_0(\mathbf{K}) \exp(\imath \delta \mathbf{K}\mathbf{x}) d^n\mathbf{K}, \tag{2.4}$$

and all nondimensional variables and parameters introduced in this section are summarized below:

$$\begin{array}{llll} \mathbf{x} = \mathbf{x}'/L_d, & \mathbf{u} = \mathbf{u}'/U_d, & \mathbf{K} = \mathbf{K}' L_0, & t = t'/\tau_d, \\ \tau_d = L_d/U_d = {L_d}^2/\nu, & D_0 = D_0'/\nu = Sc^{-1}, & & \\ R_d = U_d L_d/\nu = 1, & R_0 = U_0 L_0/\nu \gg 1, & \delta = L_d/L_0 \ll 1. & \end{array}$$

3. Velocity statistics. Let us specify the random velocity field $\mathbf{u}(\mathbf{x},t)$. The fluid is assumed to be incompressible, such that the continuity equation $\boldsymbol{\nabla}\cdot\mathbf{u}'=0$ holds. With the usual idealization for the turbulent core, the zero-mean unbounded turbulent flow in the inertial range of length scales ($L_d \ll L' \ll L_0$ or, in nondimensional form, $1 \ll L' \ll 1/\delta$) is assumed to be stationary, homogeneous, and isotropic.

It also is assumed that the random flow field $\mathbf{u}(\mathbf{x},t)$ has Gaussian statistics. In general, this is a very strong and, moreover, nonphysical assumption for the turbulent flow. It is well known that real turbulence is never Gaussian. More importantly, the nonzero triple correlation $\langle u_i(\mathbf{x},t)u_j(\mathbf{x},t)u_k(\mathbf{y},t)\rangle$ is responsible for turbulent energy transfer. At the same time, the Gaussian statistics for zero-mean $\mathbf{u}(\mathbf{x},t)$ immediately leads to the vanishing of all odd-order moments. For the problem of a scalar transport, however, this is a rather common approximation (see Kimura and Kraichnan [13], Koch and Shaqfeh [15], or Avellaneda and Majda [2], for example) if one is not interested in how the random flow field has been created and sustained.

With the above assumptions, the m-dimensional Gaussian velocity field $\mathbf{u}(\mathbf{x},t)$ is specified by the spectral form of two-point two-time correlation tensor $\mathbf{R}$,

$$\begin{aligned}\langle u_i(\mathbf{x},t)u_j(\mathbf{y},s)\rangle &= R_{ij}(|\mathbf{x}-\mathbf{y}|,|t-s|)\\ &= (2\pi)^{-m}\int_{-\infty}^{\infty}\hat{Q}(k,|t-s|)\hat{P}_{ij}(\mathbf{k})\exp(\imath\mathbf{k}(\mathbf{x}-\mathbf{y}))d^m\mathbf{k},\end{aligned}\tag{3.1}$$

where $k=|\mathbf{k}|$, $\hat{P}_{ij}(\mathbf{k})=\delta_{ij}-k_ik_j/k^2$, and the spectral amplitude $\hat{Q}(k,|t-s|)$ is defined in the inertial range of wavenumbers

$$\begin{aligned}&\hat{Q}(k,|t-s|)=\alpha^2k^{1-m-\epsilon}\exp(-ak^z|t-s|), && \delta\le k\le 1,\\ &\hat{Q}(k,|t-s|)\equiv 0 && \text{otherwise.}\end{aligned}\tag{3.2}$$

One should mention that the correlation of the Fourier-component of the velocity field is given by

$$\begin{aligned}\langle\hat{u}_i(\mathbf{k},t)\hat{u}_j(\mathbf{q},s)\rangle &= \delta(\mathbf{k}+\mathbf{q})\hat{R}_{ij}(\mathbf{k},|t-s|)\\ &= \delta(\mathbf{k}+\mathbf{q})\hat{Q}(k,|t-s|)\hat{P}_{ij}(\mathbf{k}).\end{aligned}\tag{3.3}$$

Note that for the simple shear flow considered by Avellaneda and Majda [1] ($m=1$, $\mathbf{u}(\mathbf{x},t)=(0,u_2(x_1,t),0)$, $\mathbf{k}=(k_1,0,0)$) the spectral correlation tensor $\hat{\mathbf{R}}(\mathbf{k},|t-s|)$ reduces to a single component $\hat{R}_{22}=\hat{Q}(k,|t-s|)$ and in this case the requirement of the isotropy of the velocity field should be omitted.

For the realistic turbulent core, the spatial dimensions m and n for the velocity and concentration field should always be set equal to 3 because fluctuations are always 3-D. However, the general form of the isotropic spectrum (3.2) and the initial conditions (2.4) with $m=n=2$ or 3 will be considered, keeping in mind other possible applications and the comparison with earlier works.

If the experimental data on the two-point two-time correlation are available, all parameters in the model spectrum, as well as the value of the scale ratio δ, can be determined directly. However, most velocity measurements provide only the energy spectrum. Hence, it is useful to discuss the physical meaning of the parameters of the model spectrum (3.2) and to establish some relations between values of these parameters and more common measurable quantities, like the Reynolds number, for example. The parameters ϵ and α are related to the kinetic energy spectrum (per

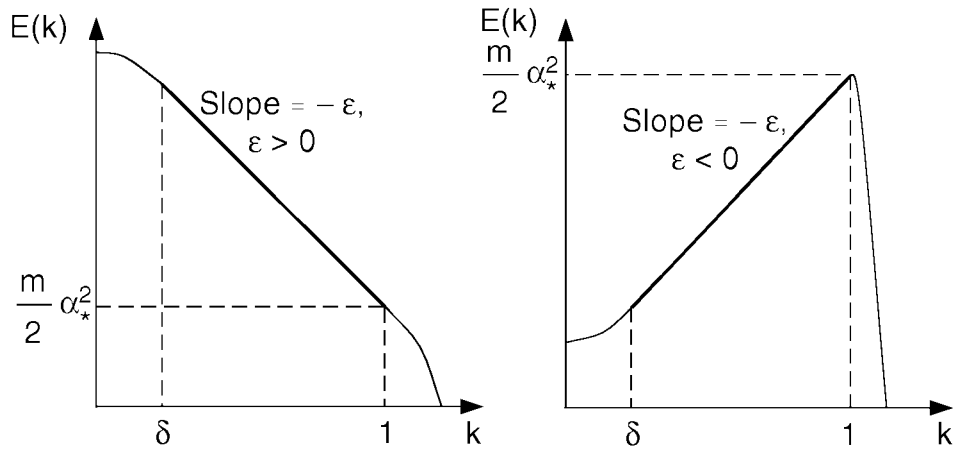

FIG. 1. *Schematic of the model energy spectrum (log-log plot).* (a) *For positive ϵ, the energy is supplied by the large-eddy motion, with $k < \delta$, and is dissipated in small-scale fluctuations $k > 1$, with the energy cascade along the spectrum.* (b) *In the case of negative ϵ, the spectrum should necessarily have a peak, where some additional stochastic forcing is applied.*

unit mass of liquid)

$$\hat{E}(k)dk = \frac{1}{2}\mathrm{tr}\hat{\mathbf{R}}(\mathbf{k},0)k^{m-1}\frac{S^{(m)}}{(2\pi)^m}dk, \tag{3.4}$$

where $S^{(m)} = 2\pi^{m/2}/\Gamma(m/2)$ is the area of the m-dimensional unit sphere. For 2-D or 3-D flow, the model energy spectrum (3.4) becomes

$$\hat{E}(k)dk = \frac{\alpha^2(m-1)}{4\pi^{m-1}}k^{-\epsilon}dk, \qquad \delta \le k \le 1, \quad m = 2, 3. \tag{3.5}$$

The energy spectrum (3.5) is shown schematically in Figure 1(a) for positive values of the exponent ϵ. Hence, ϵ defines the strength of the infra-red divergence of the kinetic energy at low wavenumbers, and α is the nondimensional amplitude parameters which are assumed to be independent on the separation of scales δ. The values of $\epsilon = 5/3$, $m = 3$, and $\alpha^2(m-1)/(4\pi^{m-1}) = \alpha_0$ in (3.5) provide the nondimensional version for the Kolmogorov energy spectrum

$$\hat{E}'_{(K)}(k')dk' = \alpha_0\varepsilon^{2/3}k'^{-5/3}dk', \tag{3.6}$$

where $\alpha_0 \approx 1.5$ is the Kolmogorov constant and ε is the energy dissipation rate.

With the nondimensionalization on the dissipation length scale, the kinetic energy of the small-scale fluctuations ($k, dk \sim O(1)$) should be of the order of $O(1)$. Consequently, the amplitude for the energy spectrum $\alpha^2(m-1)/(4\pi^{m-1}) \sim O(1)$. The universality of the spectrum in the inertial range of wavenumbers implies that (3.5) should remain invariant under the scaling transformations ($L_d \leftrightarrow L_0, U_d \leftrightarrow U_0$). Consequently, in the large-scale limit ($k, dk \sim O(\delta)$) expression (3.5) should provide the kinetic energy for the largest eddies included in consideration, without rescaling of the amplitude α. This requirement gives the relation between the integral and dissipation scales

$$\frac{{U_0}^2}{{U_d}^2} \sim \delta^{1-\epsilon} \tag{3.7}$$

or, in terms of the Reynolds number for the large-eddy motion,

$$\delta \sim {R_0}^{-2/(\epsilon+1)}. \tag{3.8}$$

With $\epsilon = 5/3$, (3.8) reduces to $\delta \sim {R_0}^{-3/4}$, i.e., provides the correct dependence for the scales ratio δ on the Reynolds number of the large-eddy motion for well-developed isotropic turbulence.

Several remarks should be made here. As is evident from (3.7), a physically meaningful spectrum for the flow with an energy cascade from the large to the small scales should have $\epsilon > 1$. It is unlikely for the speed of the large-eddy motion U_0 to be smaller than the root-mean-square velocity of the smallest scales U_d, unless some additional small-scale stochastic forcing is applied. In such a case, when the system presents both "slow" large eddies and "fast" small fluctuations, (3.8) provides another restriction: $\epsilon > -1$ because the separation of scales δ should increase with R_0. For negative values of ϵ, the spectrum should necessarily have a peaked shape, like in Figure 1(b), and the functional form of the decaying part of the spectrum may be important.

The integration over k in (3.5) results in the total kinetic energy of the inertial-range fluctuations

$$E = \int_0^\infty \hat{E}(k)dk = \frac{1}{2}\mathrm{tr}\mathbf{R}(0,0) = \frac{m}{2}\frac{U_{rms}^2}{U_d^2}$$

and provides the relation for the parameters of the model spectrum with the root-mean-square velocity U_{rms},

$$\frac{U_{rms}^2}{U_d^2} = \frac{\alpha^2(m-1)}{2m\pi^{m-1}} \begin{cases} \frac{1}{\epsilon-1}(\delta^{1-\epsilon}-1) & \epsilon \neq 1, \\ -\ln\delta & \epsilon = 1, \end{cases} \tag{3.9}$$

or, in terms of the root-mean-square Reynolds number $R_{rms} = U_{rms}L_0/\nu$,

$$R_{rms}^2 = \frac{\alpha^2(m-1)}{2m\pi^{m-1}} \begin{cases} \frac{1}{\epsilon-1}(\delta^{-(1+\epsilon)}-\delta^{-2}) & \epsilon \neq 1, \\ -\delta^{-2}\ln\delta & \epsilon = 1. \end{cases} \tag{3.10}$$

In the limit $\delta \to 0$, (3.8) and/or (3.10) allow us to relate the amplitude parameter α in the model and the ratio of scales δ with R_{rms} and R_0 for ϵ different from Kolmogorov's 5/3 value.

Now let us consider the time-dependent part of the two-point two-time correlation (3.2). The decorrelation time $T = 1/ak^z$ corresponds to the turnover time for different spatial modes. The parameter $z > 0$ represents the fact that low-wavenumber modes have larger turnover times than the short waves. Larger values of z increase the separation of the decorrelation times for long and short waves. The nonnegative parameter a defines the decorrelation time $1/a$ for the shortest waves with $k = 1$. The value of $a = 0$ corresponds to the spatially random steady flow $\mathbf{u} = \mathbf{u}(\mathbf{x})$. The limiting value $a \to \infty$ (provided that α^2 scales as a) corresponds to fluctuations that are completely decorrelated in time. In such a case, the exponential term should be replaced by a delta-function $\delta(k^z(t-s)) = k^{-z}\delta(t-s)$. Similar to the amplitude of the spectrum α, a is assumed to be independent of the scale ratio δ.

The physical association of T with the turnover time for different modes $\hat{\mathbf{u}}(\mathbf{k})$ implies that $1/T \sim ku(k)$. Since the speed of the mode $u(k)$ can be estimated as a

root-mean-square fluctuation velocity in the range of wavenumbers $q > k$,

$$u(k) \sim \left(\int_k^\infty \hat{E}(q) dq \right)^{1/2},$$

the kinetic energy spectrum (3.5) results in the estimate for $1/T$,

$$1/T = ak^z \sim \alpha k^{(3-\epsilon)/2}, \tag{3.11}$$

and, consequently,

$$a \sim \alpha, \qquad z = \frac{3-\epsilon}{2}. \tag{3.12}$$

The above estimate prescribes the particular relationship (3.12) between z and ϵ. Note that, according to the Kolmogorov similarity hypothesis, in the inertial range of wavenumbers, T can depend only on the energy dissipation rate ε and the wavenumber itself. Dimensional analysis then leads to the well-known result for the frequency-response function $\omega'(k') \sim 1/T'$ and turbulent viscosity $\nu_T(k')$:

$$\omega'(k') = \nu_T(k') k'^2 \sim 1/T' \sim \varepsilon^{1/3} k'^{2/3}. \tag{3.13}$$

As can be easily seen, for the Kolmogorov value of the exponent $\epsilon = 5/3$, (3.11) is just a nondimensional version of (3.13).

Measurement of the decorrelation time T from two-time correlations are rare. Hence, (3.12) provides a welcomed estimate of z from ϵ. However, the spectral parameter a remains unknown as $a \sim \alpha$ is only an order estimate. We shall determine a parameter a empirically in section 8.

Hence, the Kolmogorov energy spectrum (3.6) corresponds to $\epsilon = 5/3$, $z = 2/3$, $m = 3$, $\alpha^2(m-1)/(4\pi^{m-1}) = \alpha_0 \approx 1.5$, and $a \sim O(1)$ in the model spectrum (3.2). However, regardless of solute dispersion by a well-developed turbulent flow, different "velocity" statistics are possible. In a subsequent analysis, the general form of the two-point two-time correlation function (3.1)–(3.2) for the isotropic stationary Gaussian velocity field $\mathbf{u}(\mathbf{x}, t)$ will be used. The possible values of parameters in (3.2) are $m = \{2; 3\}$, $-1 < \epsilon < 3$, $z \geq 0$, $a \geq 0$, $\alpha \sim O(1)$.

4. Lagrangian formulation for statistical advection-diffusion problem. The advection-diffusion problem (2.3)–(2.4) for the concentration field $C(\mathbf{x}, t)$ is essentially the Fokker–Planck equation for the probability density function to find a fluid particle in a particular location $\mathbf{x}$ at time t for given initial condition $C(\mathbf{x}, 0) = C_0(\delta\mathbf{x})$. The equivalent representation for a Fokker–Planck equation is an Ito stochastic differential equation for the trajectory of the fluid particle

$$\begin{aligned} &d\mathbf{X}(s) = \mathbf{u}(\mathbf{X}(s), s)ds + \sqrt{2D_0} d\mathbf{W}(s), \\ &\mathbf{X}(s=0) = \mathbf{x}, \end{aligned} \tag{4.1}$$

where the Gaussian white noise $\mathbf{W}(s)$ represents the displacement of the fluid particle due to molecular diffusion. Hence, equation (4.1) is, in fact, the Lagrangian formulation of the advection-diffusion problem (2.3)–(2.4), where the molecular diffusion is replaced by a random walk $\sqrt{2D_0}\mathbf{W}(s)$ of a fluid particle. Note that the Lagrangian velocity $\mathbf{u}(\mathbf{X}(s), s)$ depends on $\mathbf{W}(s)$ while the realization of the Eulerian velocity field $\mathbf{u}(\mathbf{x}, s)$ is, of course, independent of molecular diffusion. The goal

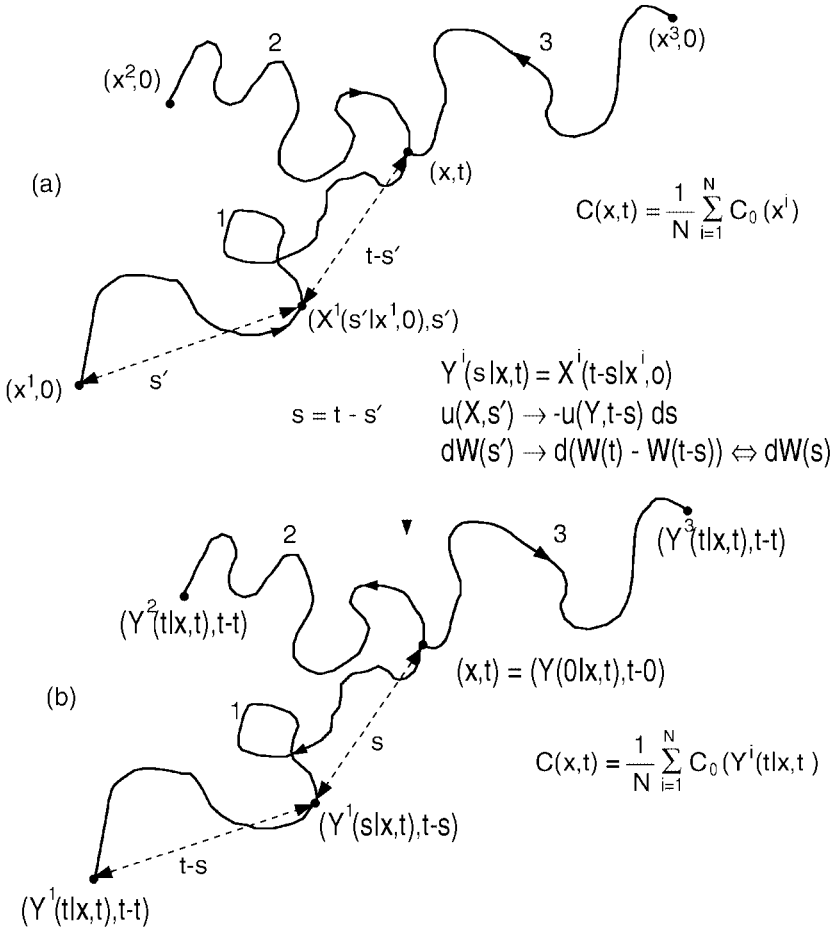

FIG. 2. *Schematic of the Lagrangian formulation for the advection-diffusion problem.* (a) *The concentration in point x at time t is determined by the initial solute distribution, averaged over all possible initial points $x^{(i)}$ of fluid particles trajectories $X^{(i)}(t) = x$.* (b) *Transition to the inverse problem allows us to find the distribution of the initial points $(x^{(i)}, 0)$ with respect to the final state (x, t).*

now is to find the representation for the average concentration distribution for any $\mathbf{x}$ and t. For each fixed realization (i) of the "composed" random "velocity field" $\mathbf{V} = \mathbf{u} + \sqrt{2D_0}\dot{\mathbf{W}}$ (of course, $\dot{\mathbf{W}}$ is only a formal notation because the trajectories of the Brownian motion are nondifferentiable), there exists a particular trajectory $\mathbf{X}^{(i)}(s|\mathbf{x}^{(i)}, 0)$ which begins at some initial point $\mathbf{x}^{(i)}$ at $s = 0$ and arrives at $\mathbf{x}$ at time $s = t$, such that $\mathbf{x} = \mathbf{X}^{(i)}(s|\mathbf{x}^{(i)}, 0)$, as shown schematically in Figure 2(a). Since in such formulation (2.3)–(2.4) is reduced to a pure convection problem, the concentration does not change along the trajectory $\mathbf{X}^{(i)}(s|\mathbf{x}^{(i)}, 0)$ and is equal to $C_0(\delta\mathbf{x}^{(i)})$. The corresponding realization of the random concentration field is then

$$C^{(i)}(\mathbf{x}, t) = C(\mathbf{X}^{(i)}(s|\mathbf{x}^{(i)}, 0)) = C_0(\delta\mathbf{x}^{(i)}),$$

and the averaging over all possible trajectories gives the solute distribution

$$\overline{C(\mathbf{x},t)} = \frac{1}{N}\lim_{N\to\infty}\sum_{i=1}^{N} C_0(\delta\mathbf{x}^{(i)}). \tag{4.2}$$

In order to compute (4.2) one needs to determine the evolution of the initial points $(\mathbf{x}^{(i)},0)$ with respect to the final state $(\mathbf{x},t) = (\mathbf{X}^{(i)}(t|\mathbf{x}^{(i)},0),t)$—in other words, to find the inverse trajectories $\mathbf{Y}^{(i)}(s) = \mathbf{Y}^{(i)}(s|\mathbf{x},t)$, which begin at $(\mathbf{x},t)$ at $s=0$ and come to $(\mathbf{x}^{(i)},0)$ at $s=t$. The schematic of the inverse problem is shown in Figure 2(b): for any fixed realization of $\mathbf{u}$ and $\mathbf{W}$ one can go on the trajectory $\mathbf{X}^{(i)}(s|\mathbf{x}^{(i)},0)$ in the opposite direction, such that the inverse trajectory $\mathbf{Y}^{(i)}(s|\mathbf{x},t) = \mathbf{X}^{(i)}(t-s|\mathbf{x}^{(i)},0)$, and, consequently,

$$\overline{C(\mathbf{x},t)} = \frac{1}{N}\lim_{N\to\infty}\sum_{i=1}^{N} C_0(\delta\mathbf{Y}^{(i)}(t|\mathbf{x},t)). \tag{4.3}$$

Hence, it is possible to write down the stochastic differential equation for the inverse problem:

$$\begin{aligned} &d\mathbf{Y}(s) = -\mathbf{u}(\mathbf{Y}(s),t-s)ds + \sqrt{2D_0}d\mathbf{W}(s),\\ &\mathbf{Y}(s=0) = \mathbf{x}. \end{aligned} \tag{4.4}$$

The solution for the average concentration distribution is then given by (4.3) and (2.4) with the replacement of the empirical averaging in (4.3) by the averaging over the distribution of trajectory $Y(t|\mathbf{x},t)$,

$$\begin{aligned} \overline{C(\mathbf{x},t)} &= (2\pi)^{-n}\int_{-\infty}^{\infty}\hat{C}_0(\mathbf{K})\langle\exp(\imath\delta\mathbf{K}\mathbf{Y}(t|\mathbf{x},t))\rangle_Y d^n\mathbf{K}\\ &= (2\pi)^{-n}\int_{-\infty}^{\infty}\hat{C}_0(\mathbf{K})\langle\langle\exp(\imath\delta\mathbf{K}\mathbf{Y}(t|\mathbf{x},t))\rangle\rangle_{u,W} d^n\mathbf{K}. \end{aligned} \tag{4.5}$$

Note that since $Y(s|\mathbf{x},t)$ is related to $\mathbf{u}$ and $\mathbf{W}$ by (4.4), the above averaging is equivalent to the averaging over independent distributions of the Eulerian velocity field $\mathbf{u}$ and $\mathbf{W}$, $\langle\dots\rangle_Y = \langle\langle\dots\rangle_{Y(u|W)}\rangle_W = \langle\langle\dots\rangle_{Y(W|u)}\rangle_u = \langle\langle\dots\rangle_u\rangle_W = \langle\langle\dots\rangle_W\rangle_u$.

The representation of the advection-diffusion problem (2.3)–(2.4) by (4.4)–(4.5) is exact regardless of whether the velocity field is stochastic or not. For example, in the case of time-periodic linear planar flow field ($\mathbf{u}_{\text{linear}} = \mathbf{A}\mathbf{x}\cos\omega t$), where the constant matrix $\mathbf{A}$ has zero trace), equation (4.4) describes a 2-D time-dependent Ornstein–Uhlenbeck process (see Gardiner [10], for example). The solution of (4.4) then becomes

$$\mathbf{Y}_{\text{linear}}(s=t) = \mathbf{B}(\mathbf{t})\mathbf{x} + \sqrt{(2/Pe)}\int_0^t \mathbf{B}(t-s)d\mathbf{W}(s),$$

where the matrix $\mathbf{B}(t) = \exp(-\mathbf{A}\sin\omega t/\omega)$. Since $\mathbf{Y}_{\text{linear}}$ is linear in $d\mathbf{W}$, and $\mathbf{B}(\mathbf{t})$ is nonstochastic, $\mathbf{Y}_{\text{linear}}$ is a Gaussian random process. The averaging over W in (4.5) then gives a solute distribution (equation (6) of Indeikina and Chang [12]) in terms of the Fourier transform.

5. Evaluation of the partially-averaged enhanced diffusivity tensor. Unfortunately, explicit solution of the stochastic differential equations can be easily done only for several special cases, mostly including linear equations or some simple explicit form of coefficients. In the present case, the random velocity field is specified by the spectral correlation function (3.1) and hence (4.4) is, in fact, a system of coupled stochastic integro-differential equations. Hence, one should make some possible simplifications.

Note that the "final" time t is only a parameter in (4.4) containing only $\mathbf{u}(\mathbf{Y}(s), t-s)$ and that $\mathbf{u}(\mathbf{Y}(0), t-0) = \mathbf{u}(\mathbf{x}, t)$. Hence, because of the stationarity of the random velocity field (everything depends only on $|(t-s)-(t-0)| = s$), the statistical properties of the random function $\mathbf{Y}(s|\mathbf{x}, t)$ also cannot be dependent on t. Consequently, the replacement of $\mathbf{u}(\mathbf{Y}(s), t-s)$ on $\mathbf{u}(\mathbf{Y}(s), s)$ in (4.4) changes nothing in the statistics of $\mathbf{Y}$. It can be easily shown that the absence of the mean flow and the requirement of the homogeneity of the velocity field leads to $\langle\langle \mathbf{Y}(s|\mathbf{x}, t)\rangle\rangle_{u,W} = \langle\langle \mathbf{Y}(s|\mathbf{x}, t)\rangle_u\rangle_W = \mathbf{x}$. The homogeneity of the velocity field then gives rise to the independence of all statistical properties of the zero-mean function $\mathbf{Y}(s|\mathbf{x}, t) - \mathbf{x}$ on $\mathbf{x}$. Also one can partially separate the influence of Brownian motion $\mathbf{W}$ and focus first on the averaging over the distribution of Eulerian velocity $\mathbf{u}$ in (4.5). Hence, (4.4) can be rewritten as

$$\mathbf{Y}(s|\mathbf{x}, t) = \mathbf{x} + \sqrt{2D_0}\mathbf{W}(s) + \mathbf{Z}(\mathbf{s}, \mathbf{W}(\mathbf{s})), \tag{5.1a}$$

$$d\mathbf{Z}(s) = -\mathbf{u}(\mathbf{x} + \sqrt{2D_0}\mathbf{W}(s) + \mathbf{Z}(\mathbf{s}), s)ds, \tag{5.1b}$$

$$\mathbf{Z}(s = 0) = 0, \tag{5.1c}$$

and, without loss of generality, one can set $x = 0$ in (5.1b) for $\mathbf{Z}$. It should be emphasized that all these changes are possible only for the stationary and homogeneous velocity field with zero mean. For example, the linear flow field of Indeikina and Chang [12] does not satisfy the homogeneity condition and one should use (4.4).

Invoking the representation of Eulerian velocity $\mathbf{u}(\mathbf{x}, t)$ by the spatial Fourier transform, one can formally integrate (5.1b)–(5.1c) to get

$$\mathbf{Z}(t) = (2\pi)^{-m/2} \int_0^t \int_{-\infty}^{\infty} \hat{\mathbf{u}}(\mathbf{k}, s) \exp(\imath\sqrt{2D_0}\mathbf{k}\mathbf{W}(s)) \exp(\imath\mathbf{k}\mathbf{Z}(s)) d^m\mathbf{k}ds. \tag{5.2}$$

With the representation of trajectory $\mathbf{Y}(s|\mathbf{x}, t)$ by (5.1a) and (5.2), the averaging in (4.5) also can be partially decomposed on the independent averaging over distributions of $\hat{\mathbf{u}}$ and $\mathbf{W}$:

$$\begin{aligned}\langle\langle \exp(\imath\delta\mathbf{K}\mathbf{Y}(t|\mathbf{x}, t))\rangle\rangle_{u,W} = \\ \exp(\imath\delta\mathbf{K}\mathbf{x})\langle \exp(\imath\delta\sqrt{2D_0}\mathbf{K}\mathbf{W}(t))\langle \exp(\imath\delta\mathbf{K}\mathbf{Z}(t, \mathbf{W}(t)))\rangle_{Z(u|W)}\rangle_W,\end{aligned} \tag{5.3}$$

where the averaging over $\hat{\mathbf{u}}$ should be made first.

For the simple shear flow $\mathbf{u}(\mathbf{x}, t) = (0, u_2(x_1, t), 0)$, analyzed by Avellaneda and Majda [1], integral (5.2) provides the exact solution. In this case, without coupling of the fluctuations of the velocity field, $\mathbf{Z}(t)$ is a Gaussian random variable in the sense of averaging over the distribution of $\hat{\mathbf{u}}$ because $\hat{\mathbf{u}}$ is assumed Gaussian. In several dimensions, the nonlinear coupling of the fluctuations in different directions may result in the deviation of the distribution of trajectories from Gaussian at intermediate times. However, according to the central limit theorem, in the long-time limit, $\mathbf{Z}(t)$ again approaches a Gaussian variable regardless of the distribution of $\hat{\mathbf{u}}$ as a result of the summation of a large number of random steps (McComb [19, pp. 446–447], Gardiner

[10, pp. 37–38]) and this fact is well supported by numerous experiments on turbulent transport of passive scalar (for example, Shlien and Corrsin [21], McComb and Rabie [18], Groenhof [11], and many others).

Hence, one can simply assume that the Gaussian distribution of trajectories $\mathbf{Z}(t,\mathbf{W}(t))$ for a fixed $\mathbf{W}(t)$, that is strictly valid in the long-time limit (and it is the topic of interest), is not in great error also at intermediate times. In such a case, the averaging over the distribution of the velocity field in (4.5) reduces to

$$\langle \exp(\imath\delta\mathbf{KZ})\rangle_{Z(u|W)} = \exp\left(-\frac{\delta^2}{2}\langle(\mathbf{KZ})^2\rangle_{Z(u|W)}\right) = \exp\left(-\frac{\delta^2}{2}K_i\tilde{Z^2_{ij}}K_j\right), \tag{5.4}$$
$$\tilde{Z^2_{ij}} = \tilde{Z^2_{ij}}(t,\mathbf{W}(t)) = \langle Z_i(t,\hat{\mathbf{u}},\mathbf{W}(t))Z_j(t,\hat{\mathbf{u}},\mathbf{W}(t))\rangle_{\hat{u}},$$

where the tensor of "convective" mean-square displacement $\tilde{Z^2_{ij}}$ is obviously symmetric.

Now it is necessary to determine the partially averaged tensor $\tilde{Z^2_{ij}}$. As is evident from (5.2), it requires the evaluation of the quantity

$$\langle \hat{u}_i(\mathbf{k},s_1)\hat{u}_j(\mathbf{q},s_2)\exp(\imath(\mathbf{kZ}(s_1)+\mathbf{qZ}(s_2)))\rangle_{\hat{u},Z|W} \tag{5.5}$$

if one cannot solve (5.1) explicitly. Unfortunately, $\mathbf{Z}$ and $\hat{\mathbf{u}}$ are dependent and, in general, one cannot separate the averaging in (5.5) into two independent averagings $\langle\hat{u}_i\hat{u}_j\rangle_{\hat{u}}\langle\exp(\cdots)\rangle_{Z|W}$, as is suggested by Corrsin's independence hypothesis for long-time turbulent diffusion (Corrsin [5]).

However, we show (details are given in Appendices A and B) that, for the selected *stationary homogeneous isotropic Gaussian* Eulerian velocity field $\mathbf{u}$, (5.4) provides the exact result. (We invoke the symmetry of the velocity field and the factorization property of higher-order moments of the Gaussian distribution to show the Gaussian distribution of trajectories $\mathbf{Z}(t,\mathbf{W}(t))$ at fixed $\mathbf{W}(t)$.) By introducing the "deviation variables" for trajectories and velocity and utilizing the stationarity of both Eulerian and Lagrangian Gaussian velocity fields, we also have shown (see Appendix C for details) that, despite the dependence of $\mathbf{Z}$ on $\hat{\mathbf{u}}$, averaging in (5.5) leads to the same expression for $\tilde{Z^2_{ij}}$ as if Corrsin's independence hypothesis holds for any diffusion time. Hence, using the above result and the two-point two-time correlation (3.1)–(3.3) yields the representation for $\tilde{Z^2_{ij}}$ in terms of the enhanced diffusivity tensor $\tilde{D_{ij}}(t) \equiv \tilde{D_{ij}}(t,\mathbf{W}(t))$. In the 3-D case ($m=3$ below) it is given by (see Appendix C)

$$\frac{1}{2}\tilde{Z^2_{ij}}(t,\mathbf{W}(t)) = \int_0^t \tilde{D_{ij}}(s)ds, \tag{5.6}$$

$$\tilde{D_{ij}}(s) = \frac{\alpha^2}{(2\pi)^m}\int_{-\pi}^{\pi}\int_0^{2\pi}\int_\delta^1 k^{-\epsilon}\tilde{F}(\mathbf{k},s)\left(\delta_{ij}-\frac{k_ik_j}{k^2}\right)dkd\phi d\theta, \tag{5.7a}$$

$$d\tilde{F}(s) = (1-[ak^z+k^2D_0+k_i\tilde{D_{ij}}(s)k_j]\tilde{F})ds - \tilde{G}\sqrt{2D_0}k_ndW_n(s), \tag{5.7b}$$

$$d\tilde{G}(s) = -[ak^z+k^2D_0+k_i\tilde{D_{ij}}(s)k_j]\tilde{G}ds + \tilde{F}\sqrt{2D_0}k_ndW_n(s), \tag{5.7c}$$

$$\tilde{D_{ij}}(0)=0, \qquad \tilde{F}(\mathbf{k},0)=0, \qquad \tilde{G}(\mathbf{k},0)=0, \tag{5.7d}$$

and for 2-D flow one should set $m=2$ and omit integration over θ in (5.7a).

Note that without molecular diffusion ($D_0=0$), the enhanced diffusivity tensor, as well as the concentration distribution, is already fully averaged. After the integration of angular dependence in (5.7a), $\tilde{D_{ij}}(s)$ reduces to an isotropic one, $\tilde{D_{ij}}(s) =$

$\delta_{ij}\overline{D(s)}$, and, consequently, $k_i\tilde{D_{ij}}(s)k_j = k^2\overline{D(s)}$, as it should be because of the isotropy of the velocity field. It is clear that, since the Brownian motion $\mathbf{W}(t)$ also is isotropic, there does not exist any interaction that can create some preferred direction. However, formally one cannot integrate out the angular dependence in (5.7a) and hence reduce the tensor to a single scalar before the molecular diffusion effect is averaged or neglected because of the presence of the last term in the right-hand side of (5.7b).

Hence, invoking (5.3) and (5.6), one obtains for the average concentration distribution (4.5):

$$\begin{aligned}\overline{C(\mathbf{x},t)} &= (2\pi)^{-n}\int_{-\infty}^{\infty}\hat{C}_0(\mathbf{K})\exp(\imath\delta\mathbf{K}\mathbf{x})\\ &\times\left\langle\exp\left(\imath\delta\mathbf{K}\mathbf{W}(t)\sqrt{2D_0}-\delta^2\int_0^t K_i\tilde{D_{ij}}(s)K_j ds\right)\right\rangle_W d^n\mathbf{K},\end{aligned}\tag{5.8}$$

where $\tilde{D_{ij}}$ is given by (5.7).

As also is evident from (5.7b) and (5.7c), in the limit of infinite time, the average value of F approaches fixed point value $[ak^z + k^2D_0 + k^2\tilde{D}_\infty]^{-1}$ while the average value of $G \to 0$. The dispersion of F, which is determined by $k^2D_0\langle G^2\rangle_W$, can remain finite in general or even large in comparison with $(\langle F\rangle_W)^2$. Such an effect has been found by Avellaneda and Majda [1] for the simple shear flow for some range of spectral parameters that are, however, very far from the region of interest of turbulent problems. Fortunately, this is not the case for isotropic 2- or 3-D flow. In several dimensions the coupling of fluctuations in different directions results, from one side, in a larger enhanced dissipation and, from the other side, in the necessary existence of the "random walk" limit with constant diffusivity. Hence, any nonlocal behavior due to the interaction of the flow with molecular diffusion, as in the Avellaneda and Majda [1] case, can only be a transient effect.

It has been specially checked that in the large-scale long-time limit the contribution of dW_m terms in $\tilde{D}$ and, consequently, the dispersion always remains negligible in comparison with the average for all values of spectral parameters. This means that the fluctuations of $\tilde{D}$ due to the interaction with the molecular diffusion are the higher-order effect and only the mean value affects the solute distribution (5.8). Hence, in order to simplify the presentation of the renormalization procedure, the averaging in (5.7) and (5.8) will be taken independently now since the cross-interaction terms always become irrelevant in the large-scale long-time limit. As a result, (5.7) and (5.8) become

$$\overline{D(s)} = \frac{\alpha^2(m-1)}{2m\pi^{m-1}}\int_\delta^1 k^{-\epsilon}\overline{F}(k,s)dk,\tag{5.9a}$$

$$\frac{\partial\overline{F}}{\partial s} = 1 - [ak^z + k^2D_0 + k^2\overline{D(s)}]\overline{F},\tag{5.9b}$$

$$\overline{D(0)} = 0, \qquad \overline{F(k,0)} = 0,\tag{5.9c}$$

$$\begin{aligned}\overline{C(\mathbf{x},t)} &= (2\pi)^{-n}\int_{-\infty}^{\infty}\hat{C}_0(\mathbf{K})\exp(-\imath\delta\mathbf{K}\mathbf{x})\\ &\times\exp\left[-\delta^2K^2\left(D_0t+\int_0^t\overline{D(s)}ds\right)\right]d^n\mathbf{K}.\end{aligned}\tag{5.10}$$

6. Large-scale long-time behavior of the averaged concentration distribution. It should be recalled that all variables in (5.9)–(5.10), except the initial data wavevector $\mathbf{K}$, are made dimensionless in the dissipation length scale, while the topic of interest is the integral-scale averaged solute distribution. Consequently, in order to find this large-scale long-time limiting behavior of the spreading process, one should rescale other variables in (5.9)–(5.10),

$$\mathbf{x} = \mathbf{x}^*/\delta, \qquad k = k^* g(\delta), \qquad t = t^*/\rho^2(\delta), \tag{6.1}$$

such that new nondimensional space and time variables become

$$\mathbf{x}^* = \mathbf{x}'/L_0, \quad k^* = k' L_0 \left[\frac{\delta}{g(\delta)}\right], \quad t^* = t'/\tau, \quad \text{where } \tau = \frac{L_0^2}{\nu}\left[\frac{\delta}{\rho(\delta)}\right]^2. \tag{6.2}$$

The scaling functions $\rho(\delta)$ and $g(\delta)$ then must be determined from the requirement that the averaged concentration distribution has nontrivial limiting behavior, namely, it is never equal to zero nor the initial data,

$$\overline{C^*(\mathbf{x}^*, t^*)} = \lim_{\delta\to 0} \overline{C\left(\mathbf{x}^*/\delta, t^*/\rho^2(\delta)\right)}; \tag{6.3a}$$

$$\overline{C^*(\mathbf{x}^*, t^*)} \neq 0, \qquad \overline{C^*(\mathbf{x}^*, t^*)} \neq C_0(\mathbf{x}^*). \tag{6.3b}$$

Note that the scaling $\rho(\delta) = \delta$ results in the diffusion time scale $\tau = L_0^2/\nu$ and scalings $\rho(\delta) = \delta^b$ with $b < 1$ correspond to shorter time scales. This means that the spreading occurs faster than pure diffusion motion.

The application of rescaling (6.1) to (5.9)–(5.10) then gives the representation for the averaged solute distribution

$$\overline{C^*(\mathbf{x}*, t^*)} = \int_{-\infty}^{\infty} \hat{C}_0(\mathbf{K}) \exp\left[-\imath \mathbf{K}\mathbf{x}^* - K^2 \int_0^{t^*} \overline{D_*(s^*)} ds^*\right] \frac{d^n\mathbf{K}}{(2\pi)^n}, \tag{6.4}$$

which corresponds to the large-scale effective diffusion equation

$$\frac{\partial \overline{C^*}}{\partial t^*} = \overline{D_*(t^*)} \boldsymbol{\nabla_*}^2 \overline{C^*}, \qquad C^*(x^*, 0) = C_0(x^*) \tag{6.5}$$

in nondimensional variables specified by (6.2). The conditions in (6.3b) imply that the effective diffusivity $\overline{D_*(t^*)}$ must satisfy $0 < \overline{D_*(t^*)} < \infty$ and it is then defined by the large-scale limit

$$\begin{aligned} \overline{D_*(t^*)} &= \lim_{\delta\to 0}\left[\frac{\delta}{\rho(\delta)}\right]^2 \left(D_0 + \overline{D\left(t^*/\rho^2(\delta), \delta, g(\delta)\right)}\right) \\ &= \lim_{\delta\to 0}\left[\frac{\delta}{\rho(\delta)}\right]^2 D_0 + \triangle D(t^*), \end{aligned} \tag{6.6}$$

where

$$\triangle D(t^*) = \lim_{\delta\to 0} \frac{\delta^2 g^{1-\epsilon}(\delta)}{\rho^4(\delta)} \alpha_*^2 \int_{\delta/g(\delta)}^{1/g(\delta)} k^{*-\epsilon} \overline{F}(k^*, t^*, \delta) dk^*, \tag{6.7a}$$

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(\frac{g^z}{\rho^2} a k^{*z} + \frac{g^2}{\rho^2} k^{*2} D_0 + \frac{g^2}{\delta^2} k^{*2} \triangle D(t^*)\right) \overline{F}, \qquad \overline{F}(k^*, 0) = 0, \tag{6.7b}$$

$$0 < \triangle D(t^*) < \infty, \tag{6.7c}$$

and the new amplitude constant

$$\alpha_*^2 = \frac{\alpha^2(m-1)}{2m\pi^{m-1}} \tag{6.8}$$

is introduced only to simplify the notation since the spectral amplitude α^2 is assumed to be independent of δ.

In the next section the limits (6.6) and (6.7) will be evaluated with an appropriate choice of scaling functions for all possible values of exponents $-1 < \epsilon < 3$ and $z \geq 0$ of the velocity spectrum (3.2).

7. Renormalization for different parameters of the velocity spectrum.

7.1. Mean field regime (region 1). This regime corresponds to the case when the standard diffusive scaling $\rho(\delta) = \delta$ describes a large-scale long-time behavior of the average concentration field. Hence, one can expect that the molecular diffusion also will make a contribution into the effective diffusion coefficient. With the choice $\rho(\delta) = \delta$ and $g(\delta) = 1$ in (6.6) and (6.7) one obtains

$$\overline{D_*} = \triangle D + D_0, \tag{7.1a}$$

$$\triangle D(t^*) = \lim_{\delta \to 0} \frac{1}{\delta^2} \alpha_*^2 \int_\delta^1 k^{*-\epsilon} \overline{F}(k^*, t^*, \delta) dk^*, \tag{7.1b}$$

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(a k^{*z} + k^{*2} D_0 + k^{*2} \triangle D(t^*) \right) \frac{\overline{F}}{\delta^2}, \qquad \overline{F}(k^*, 0) = 0, \tag{7.1c}$$

$$0 < \triangle D(t^*) < \infty. \tag{7.1d}$$

It is evident from (7.1c) that as $\delta \to 0$ the fixed point value $\overline{F}_\infty/\delta^2 = [a k^{*z} + k^{*2} D_0 + k^{*2} \triangle D(\infty)]^{-1}$ is reached exponentially fast. Hence, for any $t^* > 0$ one can set the enhanced diffusivity equal to the limiting value $\triangle D(t^*) = \triangle D(\infty)$. Consequently, (7.1b) and the fixed point value from (7.1c) provide the expression for $\triangle D(\infty)$:

$$\triangle D(\infty) = \alpha_*^2 \int_0^1 \frac{k^{*-\epsilon} dk^*}{a k^{*z} + k^{*2} D_0 + k^{*2} \triangle D(\infty)}. \tag{7.2}$$

The integral in (7.2) is finite for $\epsilon < 1 - z$ and $z < 2$ or for $\epsilon < -1$ and $z \geq 2$ which, together with the lowest allowable value of $\epsilon > -1$ define the boundary of the mean field regime: $-1 < \epsilon < 1 - z$. For such spectra, there is no infra-red divergence of the kinetic energy and the contributions of the individual fluctuations are, in fact, simply summed. Instead, because the upper limit of integration in (7.2) remains finite, the ultraviolet cut-off, which corresponds to the decaying part of the spectrum at large wavenumbers in Figure 1(b), is important. Consequently, the simple cut-off by setting the velocity correlation tensor equal to zero above some highest wavenumber may be inappropriate for peaked spectra.

7.2. Superdiffusive regimes. These regimes describe spreading that is faster than pure diffusion motion. As has been already mentioned, such dispersion requires the shorter time scale in (6.2),

$$\frac{\delta}{\rho(\delta)} \to 0 \quad \text{as} \quad \delta \to 0. \tag{7.3}$$

Physically, this corresponds to convection-dominant spreading and to spectra with infra-red divergence of kinetic energy of fluctuations. Hence, one can expect that

molecular diffusion will be negligible under such conditions. Indeed, the term containing D_0 in (6.6) vanishes in this limit and the effective diffusivity $\overline{D_*} = \triangle D(t^*)$. However, since for larger values of ϵ the infinite-time enhanced diffusivity (7.2) diverges at low wavenumbers, one needs to introduce a nontrivial wavenumber rescaling

$$g(\delta) \neq 1, \quad g(\delta) \to 0 \quad \text{as} \quad \delta \to 0 \tag{7.4}$$

in order to reach the convergence of the integral in (6.7a) and hence to satisfy the condition of the existence of the nontrivial solution (6.7c). Consequently, for some values of $g(\delta)$, the molecular diffusion coefficient still can enter into the expression for $\overline{D_*}$ through (6.7b).

However, let us consider first the natural choice of $g(\delta) = \delta$ which is stipulated by the infra-red cut-off of the spectrum. In this case, because of the requirement (7.3), the molecular diffusion term in (6.7b) vanishes and the governing equations for renormalization become

$$\triangle D(t^*) = \lim_{\delta \to 0} \frac{\delta^{3-\epsilon}}{\rho^4(\delta)} \alpha_*^2 \int_1^{1/\delta} k^{*-\epsilon} \overline{F}(k^*, t^*, \delta) dk^*, \tag{7.5a}$$

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(\frac{\delta^z}{\rho^2} a k^{*z} + k^{*2} \triangle D(t^*) \right) \overline{F}, \qquad \overline{F}(k^*, 0) = 0, \tag{7.5b}$$

$$0 < \triangle D(t^*) < \infty. \tag{7.5c}$$

Because the dependence on δ still remains in (7.5b), it is necessary to analyze three separate cases:

$$\frac{\delta^z}{\rho^2} \to \infty, \qquad \frac{\delta^z}{\rho^2} \to 0, \qquad \text{and} \quad \frac{\delta^z}{\rho^2} \equiv 1 \quad \text{as} \quad \delta \to 0$$

I. $\frac{\delta^z}{\rho^2} \to \infty$ (region 2). Under such conditions, the fixed point value in (7.5b) is again reached infinitely fast. Hence, similar to the mean field regime, the enhanced diffusivity is effectively time-independent and can be set equal to its limiting value for any $t^* > 0$. The substitution of the fixed point value $\overline{F}_\infty = \rho^2/(\delta^z a k^{*z})$ of (7.5b) into (7.5a) and the straightforward integration gives the renormalized enhanced diffusivity

$$\triangle D(t^* > 0) = \triangle D(\infty) = \frac{\alpha_*^2}{a[z + \epsilon - 1]} \lim_{\delta \to 0} \frac{\delta^{3-\epsilon-z}}{\rho^2(\delta)}. \tag{7.6}$$

The requirement of the nontriviality solution (7.5c) implies that $\triangle D(\infty)$ should be positive and that the limit in the right-hand side of (7.6) should be finite. Without loss of generality, one can set it equal to one, because any constant value can be included into ρ or $\triangle D$.

Hence, these restrictions together with the definition of the case define the time-rescaling function $\rho(\delta)$ and the boundaries for region 2 of renormalization

$$\rho(\delta) = \delta^{(3-\epsilon-z)/2} \qquad \text{for} \qquad 1 - z < \epsilon < 3 - 2z \tag{7.7}$$

with the effective diffusivity

$$\overline{D_*} = \triangle D(\infty) = \frac{\alpha_*^2}{a[z + \epsilon - 1]}. \tag{7.8}$$

II. $\frac{\delta^z}{\rho^2} \to 0$ (region 3). In this case (7.5b) is independent on δ and hence the time-rescaling function $\rho(\delta)$ can be determined directly from the limit in (7.5a) that gives $\rho(\delta) = \delta^{(3-\epsilon)/4}$, provided that the integral over k converges. Note that the integral should converge for any time, $0 \le t^* < \infty$, since (7.5) predicts the time-dependent effective diffusivity in this regime. The estimate of the limiting behavior of the enhanced diffusivity at small time, $t^* \to 0$, gives

$$\triangle D(t^* \to 0) \approx \frac{t^* \alpha_*^2}{\epsilon - 1} \left(1 - \delta^{\epsilon - 1}\right),$$

and the requirement (7.5c) then provides the lower bound for ϵ, $\epsilon > 1$. The restriction for the superdiffusive scaling (7.3) and the definition of the case give another bound: $3 - 2z < \epsilon \le 3$. Consequently, region 3 of the renormalization is finally defined by

$$\rho(\delta) = \delta^{(3-\epsilon)/4} \qquad \text{for} \qquad \max\{1, 3 - 2z\} < \epsilon \le 3, \tag{7.9}$$

$$\overline{D_*} = \triangle D(t^*) = \alpha_*^2 \int_1^\infty k^{*-\epsilon} \overline{F}(k^*, t^*) dk^*, \tag{7.10}$$

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - k^{*2} \triangle D(t^*) \overline{F}, \qquad \overline{F}(k^*, 0) = 0, \tag{7.11}$$

with the following limiting behavior at short and long time:

$$\triangle D(t^* \to 0) \approx \frac{t^* \alpha_*^2}{\epsilon - 1}, \qquad \triangle D(t^* \to \infty) \to \frac{\alpha_*}{\sqrt{\epsilon + 1}}. \tag{7.12}$$

III. $\frac{\delta^z}{\rho^2} \equiv 1$ (Kolmogorov boundary). This case corresponds to the boundary between the regions 2 and 3 and it is defined by $\epsilon = 3 - 2z$, $z < 1$, where both scaling functions (7.7) and (7.9) collapse into $\rho(\delta) = \delta^{z/2}$. From the order-of-magnitude and dimensional analysis of section 3 one can conclude that the physically plausible velocity correlation, which can provide the energy cascade and remain invariant under the scaling transformations, should belong to this boundary. The Kolmogorov velocity spectrum with $\epsilon = 5/3$ and $z = 2/3$ also corresponds to this regime and that is why this region is called the "Kolmogorov boundary." The effective diffusivity $\overline{D_*}$ is hence given by (7.10), but (7.11) for $\overline{F}(k^*, t^*)$ becomes different,

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(a k^{*z} + k^{*2} \triangle D(t^*)\right) \overline{F}, \tag{7.13}$$

and in such a case one obtains the widest dependence on the parameters of the spectrum. The small-time asymptote in (7.12) does not change on this boundary, but in the large-time limit $t^* \to \infty$ the evaluation of the integral in (7.10) with $\epsilon = 3 - 2z$ and $\overline{F}_\infty = \left(a k^{*z} + k^{*2} \triangle D(\infty)\right)^{-1}$ results in the following implicit expression for $\triangle D(\infty)$:

$$\frac{a^2 (2 - z)}{\alpha_*^2} = \frac{a}{\triangle D(\infty)} - \ln\left(1 + \frac{a}{\triangle D(\infty)}\right). \tag{7.14}$$

As is evident from (7.14), for any fixed z (or ϵ), $\triangle D(\infty)/a$ depends, in fact, on one parameter, a^2/α_*^2. It should be noted that, as has been established in section 3 (equations (3.11)–(3.12)), in this regime $a \sim \alpha_*$ and the proportionality constant should not depend much on flow conditions, as is stipulated by the Kolmogorov similarity hypothesis. The parameters α_* and δ also are related to the root-mean-square

velocity and the large-scale Reynolds number through (3.7)–(3.10). Hence, in fact, in the dimensional version of (7.14), there are no free parameters to play with in order to fit any experimental data.

Intermediate wavenumber scaling $\frac{\delta}{g(\delta)} \to 0$ as $\delta \to 0$ (region 4). The diffusive ($g(\delta) = 1$) and convective ($g(\delta) = \delta$) wavenumber scalings have already been considered. However, it still remains the part of ϵ–z plane, $\max\{-1, 3-2z\} < \epsilon \leq 1$, where these scalings do not give successful renormalization. Consequently, one should select some intermediate wavenumber scaling, something like $g(\delta) = \delta^b$ with $b < 1$, such that $\delta/g(\delta) \to 0$ as $\delta \to 0$ slower than for pure diffusive scaling.

For simple shear flow (Avellaneda and Majda [1]), the requirement $\delta/g(\delta) \to 0$ splits this remaining part of the ϵ–z plane into two regions by the line $z = 2$. In both cases the integration over k in (6.7a) is extended from 0 to ∞ such that both cut-offs are negligible, and the analysis of Avellaneda and Majda [1] results in an effective diffusivity that grows as a noninteger power of time, $\triangle D \sim t^c$ with $0 < c < 1$. The coefficient of proportionality is determined by time-correlation of the velocity fluctuations (ak^{*z} term in (6.7b)) for $z < 2$. For $z > 2$, random nonlocal diffusivity has been obtained because of nonlinear interaction of the velocity field with Brownian motion $\sqrt{2D_0}dW(t)$, which describes the molecular diffusion.

In 2- or 3-D flow, however, the mathematical consequence of the coupling of the fluctuations is the term $\triangle D(t^*)k^{*2}g^2/\delta^2$ in (6.7b) for $\overline{F}$ and, consequently, for $\triangle D(t^*)$ because they also are related by (6.7a). It can be easily seen that, under the conditions of the superdiffusive time-scaling $\delta/\rho \to 0$ as $\delta \to 0$, for any choice of the wavenumber scale satisfying $\delta/g(\delta) \to 0$, this "feedback" term immediately leads to the achievement of infinite-time limit in (6.7b). Hence, it is quite possible that the effective diffusivity grows like a noninteger power of time at the beginning of the spreading process, but in two or three dimensions this is a transient effect, and for large-scale initial data the infinite-time limiting behavior will be seen for any $t^* > 0$. However, if the initial data vary in some intermediate scale between L_d and L_0, it also will require the rescaling of the initial data wavevector $\mathbf{K}$. This rescaling should reduce the "feedback" term, such that the above transient behavior can become visible from the point of view of large-scale motion. However, since such assumption effectively adds a third dimension to ϵ–z parameter space, this analysis will not be pursued here, mostly because this region of renormalization is far away from the turbulent transport problems.

Instead, without changing the assumption of the integral-scale initial data, the fixed-point value $\overline{F}_\infty = (\delta/g(\delta))^2[k^{*2}\triangle D(\infty)]^{-1}$ is utilized to determine the scaling function $\rho(\delta)$. The integration in (6.7a) then results in the same scaling law as for region 3 and the effective diffusivity is equal to the infinite-time asymptote in (7.12). Because there is no convergence problem on the boundary $\epsilon = 1$ with region 3 and the scaling law also is continuous, this boundary can be included in region 4. The remaining boundaries, however, should be considered separately.

Boundaries $\{\epsilon = 1 - z,\ z < 2\}$ and $\{\epsilon = 3 - 2z,\ 1 \leq z < 2\}$. Since all these boundaries separate regions with constant effective diffusivity, one can expect their behavior will not be different. In all these cases, the integral in (7.10) can be evaluated explicitly with $\overline{F}(k^*, t^*) = \overline{F}_\infty$ and the requirement of the large-scale long-time distinguishing limit provides expressions for the effective diffusivity and time-rescaling function.

For the continuation of the Kolmogorov boundary into the region $1 \leq z < 2$, the scaling function is continuous on the boundary between regions 2 and 4, and the

enhanced diffusivity corresponds to the infinite-time limit (7.14) of the Kolmogorov boundary.

For the boundary between regions 1 and 2 the analysis results in the logarithmic dependence for ρ^2,

$$\rho(\delta) = \delta(-\ln\delta)^{1/2}, \qquad \overline{D_*} = \triangle D(\infty) = \frac{\alpha_*^2}{a} \quad \text{for} \quad \epsilon = 1 - z,\ z < 2, \tag{7.15}$$

and, consequently, (7.15) can be used at finite scale ratio δ only if δ is so small that $(-\ln\delta)^{1/2}$ is a large number.

8. Comparison and discussion. From the renormalization analysis of the advection-diffusion problem (2.1) with Gaussian random velocity field defined by two-point two-time correlation (3.1)–(3.2), it has been found that in the large-scale long-time limit the averaged spreading process can be described by the effective diffusion equation (6.5),

$$\frac{\partial \overline{C^*}}{\partial t^*} = \overline{D_*(t^*)} \boldsymbol{\nabla_*}^2 \overline{C^*}, \qquad C^*(x^*, 0) = C_0(x^*),$$

where nondimensional variables are specified by (6.2):

$$\mathbf{x}^* = \frac{\mathbf{x}'}{L_0}, \qquad t^* = \frac{t'}{\tau}, \quad \tau = \frac{L_0^2}{\nu}\left[\frac{\delta}{\rho(\delta)}\right]^2 = \tau_{diff}\left[\frac{\delta}{\rho(\delta)}\right]^2.$$

The effective diffusivity $\overline{D_*(t^*)} = \overline{D_*}(t^*, \epsilon, z, a, \alpha_*)$ and the scaling function $\rho(\delta)$ have been determined for different spectral parameters. It has been found that the functional forms of $\overline{D_*}$ and $\rho(\delta)$ depend only on the exponents ϵ and z of two-point two-time correlation (3.2) and several different regions of renormalization in ϵ–z have been determined. The regions of renormalization are shown in Figure 3 and the values of $\overline{D_*}$, $\rho(\delta)$ and $\tau(\delta)$ are summarized below:

Region 1. $-1 < \epsilon < 1 - z$.

$$\rho(\delta) = \delta, \quad \tau = \tau_{diff}, \quad \overline{D_*} = D_0 + \triangle D, \quad \triangle D = \int_0^1 \frac{\alpha_*^2 k^{*-\epsilon} dk^*}{ak^{*z} + k^{*2}(D_0 + \triangle D)}.$$

Boundary 1–2. $\epsilon = 1 - z$, $0 \le z < 2$.

$$\rho(\delta) = \delta(-\ln\delta)^{1/2}, \quad \tau = \tau_{diff}/(-\ln\delta), \quad \overline{D_*} = \triangle D = \frac{\alpha_*^2}{a}.$$

Region 2. $1 - z < \epsilon < 3 - 2z$.

$$\rho(\delta) = \delta^{(3-\epsilon-z)/2}, \quad \tau = \tau_{diff}\delta^{\epsilon+z-1}, \quad \overline{D_*} = \triangle D = \frac{\alpha_*^2}{a[z + \epsilon - 1]}.$$

Kolmogorov boundary (regions 2–3). $\epsilon = 3 - 2z$, $\epsilon > 1$, $z < 1$.

$$\rho(\delta) = \delta^{(3-\epsilon)/4} = \delta^{z/2}, \quad \tau = \tau_{diff}\delta^{(1+\epsilon)/2}, \quad \overline{D_*} = \triangle D(t^*),$$

$$\triangle D(t^*) = \alpha_*^2 \int_1^\infty k^{*-\epsilon} \overline{F}(k^*, t^*) dk^*,$$

$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(ak^{*z} + k^{*2}\triangle D(t^*)\right)\overline{F}, \quad \overline{F}(k^*, 0) = 0.$$

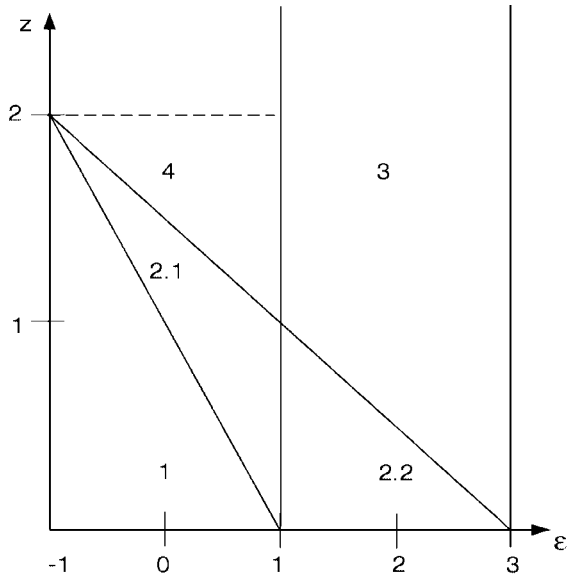

FIG. 3. *The regions of renormalization in the ϵ–z parameter plane. The dashed line corresponds to the split of region 4 in the 1-D case. The separation of region 2 occurs only in terms of Reynolds number because of the different dependence on the scale ratio δ for spectra with and without infra-red divergence of kinetic energy.*

Region 3. $\max\{1, 3-2z\} < \epsilon \le 3$.

$$\rho(\delta) = \delta^{(3-\epsilon)/4}, \quad \tau = \tau_{diff}\delta^{(1+\epsilon)/2}, \quad \overline{D_*} = \triangle D(t^*),$$
$$\triangle D(t^*) = \alpha_*^2 \int_1^\infty k^{*-\epsilon}\overline{F}(k^*, t^*)dk^*,$$
$$\frac{\partial \overline{F}}{\partial t^*} = 1 - k^{*2}\triangle D(t^*)\overline{F}, \quad \overline{F}(k^*, 0) = 0.$$

Region 4. $\max\{1, 3-2z\} < \epsilon \le 1$.

$$\rho(\delta) = \delta^{(3-\epsilon)/4}, \quad \tau = \tau_{diff}\delta^{(1+\epsilon)/2}, \quad \overline{D_*} = \triangle D = \frac{\alpha_*}{\sqrt{\epsilon+1}}.$$

Boundary 2–4. $\epsilon = 3-2z, \quad -1 < \epsilon \le 1, \quad 1 \le z < 2$.

$$\rho(\delta) = \delta^{(3-\epsilon)/4}, \quad \tau = \tau_{diff}\delta^{(1+\epsilon)/2}, \quad \overline{D_*} = \triangle D,$$
$$\frac{a^2(2-z)}{\alpha_*^2} = \frac{a}{\triangle D} - \ln\left(1 + \frac{a}{\triangle D}\right).$$

The case of spatially random steady flow $\mathbf{u} = \mathbf{u}(\mathbf{x})$ ($a = 0$) corresponds to the line $z = 2$ on the ϵ–z plane shown in Figure 1, because one should preserve the convergence of all integrals with only diffusive terms $\sim k^2$. There also is no need to set $a = 0$, because in regions 3 and 4 the effective diffusivity and the time-rescaling function are independent of both a and z.

If $\mathbf{u}$ is a white noise in time ($a \to \infty, \alpha^2 \sim a$), one should cross the ϵ–z diagram by the line $z = 0$ and evaluate the above limit for regions 1 and 2. Note that in

the present analysis the exponent of the spectral correlation function $\hat{Q} \sim k^{1-m-\epsilon}$, introduced by (3.2), is defined in a manner that depends on the space dimension m in such a way that the kinetic energy spectrum (per unit mass of liquid) depends only on ϵ. Hence, 2-D and 3-D cases have the same ϵ–z diagram, and only the amplitude constant α_*^2 of (6.8) depends on the space dimension. If one would like to work in terms of exponent of the spectral correlation function instead of kinetic energy, one simply has to move the ϵ–z diagram of Figure 3 to the right along the ϵ axis by one or two units and make corresponding changes of notation in the definitions of the time scale.

The ϵ–z diagram of Figure 3 is identical to that obtained by Avellaneda and Majda [1] for the simple shear flow with appropriate changes of notation ($\epsilon \leftrightarrow \tilde{\epsilon} - 1$, such that the left boundary of the mean field regime corresponds to $\tilde{\epsilon} = 0$) except for region 4. The effective diffusivities for two or three dimensions are different everywhere except in region 2. There the enhanced diffusivity is completely determined by strongly correlated (low z) high-wavenumber fluctuations of the velocity field. The above results also are consistent with earlier findings of Avellaneda and Majda [3] and Fannjiang [8] for multidimensional flows.

In general, the one-dimensional (1-D) analysis of Avellaneda and Majda [1] provides a small-time asymptote for the spreading process in 2-D or 3-D flow when enhanced diffusivity is small: a linear growth of effective diffusivity in time for region 3 and Kolmogorov boundary and noninteger power growth in time for two different parts of region 4. Later on, coupling of fluctuations in several dimensions necessarily results in the random walk limit, while this does not always happen in the 1-D simple shear flow. However, for region 3 and the Kolmogorov boundary, Avellaneda and Majda [3] suggest an effective nonlocal diffusion equation, while our analysis gives the usual diffusion equation with a time-dependent coefficient (which approaches a constant as $t \to \infty$). At the least, our infinite-time limit for the Kolmogorov spectrum (i.e., for usual turbulence) is well supported by numerous experimental data (see, for example, McComb [19, pp. 470–471] or Sherwood, Pigford, and Wilke [20, pp. 124–125] for data collections). Below, we also will compare our predicted time-evolution of mean-square displacement with available data, which will provide additional support for our results.

It has been shown in section 2 that the scale ratio δ and the spectral amplitude α_* are related to the large-eddy Reynolds number $R_0 = U_0 L_0/\nu$ and with the root-mean-square Reynolds number $R_{rms} = U_{rms} L_0/\nu$ by equations (3.7)–(3.10), and these dependencies are different for $\epsilon \ >, <, = \ 1$. It also is established in section 2 that, at least for the Kolmogorov boundary, a is of the order α. Hence, it also is useful to provide the expressions for the time scale τ and the effective diffusivity $\overline{D_*}$ in terms of the above Reynolds numbers. This summary is given below, where all time scales are defined with respect to the convective time scale of the fluctuations $\tau_{conv} = L_0/U_{rms}$ instead of the diffusion time scale $\tau_{diff} = L_0^2/\nu$, and the typically unknown spectral parameter a has been replaced by

$$\beta = a/\alpha_* \tag{8.1}$$

such that β is unit order coefficient.

Region 1. $-1 < \epsilon < 1 - z$.

$$\tau = \tau_{conv} R_0^{2/(\epsilon+1)}, \quad \overline{D_*} = \frac{D_0}{\tilde{\alpha}} + \triangle D, \quad \tilde{\alpha} = \frac{R_{rms}}{R_0^{-2/(\epsilon+1)}},$$

$$\triangle D = \int_0^1 \frac{(1-\epsilon) k^{*-\epsilon} dk^*}{\beta k^{*z} + k^{*2}(D_0/\tilde{\alpha} + \triangle D)}.$$

Region 2.1. $1 - z < \epsilon < 3 - 2z, \quad \epsilon < 1.$

$$\tau = \tau_{conv} R_0^{2(2-\epsilon-z)/(\epsilon+1)}, \quad \overline{D_*} = \frac{1-\epsilon}{\beta[z+\epsilon-1]}.$$

Region 2.2. $1 - z < \epsilon < 3 - 2z, \quad \epsilon > 1.$

$$\tau = \tau_{conv} R_0^{2(3-\epsilon-2z)/(\epsilon+1)}, \quad \overline{D_*} = \frac{\epsilon-1}{\beta[z+\epsilon-1]}.$$

Boundary 2.1–2.2. $\epsilon = 1, \quad 0 < z < 1.$

$$\tau = \tau_{conv} R_0^{1-z} \ln R_0, \quad \overline{D_*} = \frac{1}{\beta z}.$$

Kolmogorov boundary (regions 2–3). $\epsilon = 3 - 2z, \quad \epsilon > 1, \quad z < 1.$

$$\tau = \tau_{conv}, \quad \overline{D_*}(t^*) = (\epsilon - 1) \int_1^\infty k^{*-\epsilon} \overline{F}(k^*, t^*) dk^*,$$
$$\frac{\partial \overline{F}}{\partial t^*} = 1 - \left(\beta k^{*z} + k^{*2} \overline{D_*}(t^*) \right) \overline{F}, \quad \overline{F}(k^*, 0) = 0.$$

Region 3. $\max\{1, 3 - 2z\} < \epsilon \leq 3.$

$$\tau = \tau_{conv}, \quad \overline{D_*}(t^*) = (\epsilon - 1) \int_1^\infty k^{*-\epsilon} \overline{F}(k^*, t^*) dk^*,$$
$$\frac{\partial \overline{F}}{\partial t^*} = 1 - k^{*2} \overline{D_*}(t^*) \overline{F}, \quad \overline{F}(k^*, 0) = 0.$$

Region 4. $\max\{1, 3 - 2z\} < \epsilon < 1.$

$$\tau = \tau_{conv} R_0^{(1-\epsilon)/(1+\epsilon)}, \quad \overline{D_*} = \sqrt{\frac{1-\epsilon}{\epsilon+1}}.$$

Boundary 2–4. $\epsilon = 3 - 2z, \quad -1 < \epsilon < 1, \quad 1 < z < 2.$

$$\tau = \tau_{conv} R_0^{(1-\epsilon)/(1+\epsilon)}, \quad \frac{\beta^2(2-z)}{2(z-1)} = \frac{\beta}{\overline{D_*}} - \ln\left(1 + \frac{\beta}{\overline{D_*}}\right).$$

The boundary 1–2 with logarithmic scaling with respect to δ is not included in this summary because the accuracy of the logarithmically distinguished limit is already too low. It also should be mentioned that the above analysis is valid in the limit of infinite (i.e., very large, in practice) Reynolds number. This is especially true for spectra with weak infra-red divergence, when ϵ is close to 1. In such a case, the $|\epsilon - 1|$ factor in the expressions for the effective diffusivity should be replaced on $|(\epsilon - 1)/(1 - R_0^{(\epsilon-1)/(\epsilon+1)})|$, and this will make transitions across regime boundaries continuous.

Hence, depending on the data available, one can use any of these summaries to scale variables in the effective diffusion equation (6.5). It should be emphasized, however, that the integral scales L_0 and R_0 correspond to the largest possible eddies of the inertial range and are not the same as the mean flow parameters of the real flows. Because the lower limit of integration over k in the superdiffusive regimes has been set equal to 1, the integral length scale L_0 corresponds to the inverse of the maximal

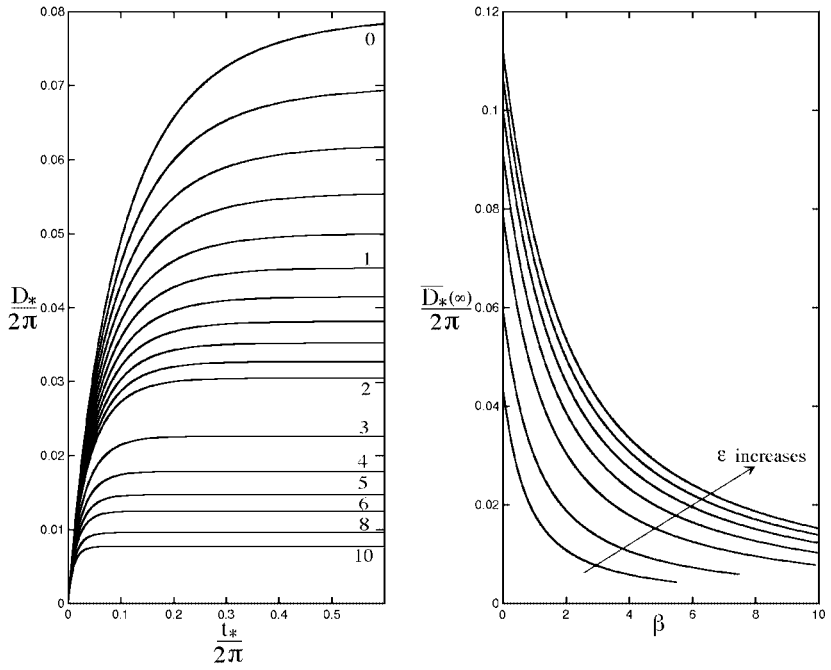

FIG. 4. *Effective diffusivity at the Kolmogorov boundary* $\epsilon = 3 - 2z$. (a) *Time-evolution of the effective diffusivity for the Kolmogorov spectrum* ($\epsilon = 5/3$) *with indicated values of* β. *In the range from* 0 *to* 2, β *increases with a* 0.2 *increment.* (b) *The dependence of* $\overline{D}_*(\infty)$ *on* β *for* $\epsilon = 7/6$; 4/3; 5/3; 2; 7/3; 8/3; 3.

possible wavenumber. Hence, by the usual convention for spectral methods, one can set $L_0 = L'/2\pi$ in the definition of the convective time scale, $\tau_{conv} = L_0/U_{rms} = L'/2\pi U_{rms}$, where L' is the conventional spatial dimension of the real flow (pipe diameter, for example).

The most interesting regions for turbulence are the Kolmogorov boundary and region 3, where the time scale τ does not depend on R_0, as it should be in the limit of the infinite Reynolds number. In other regions of renormalization, the physics that cause the lower infra-red divergence of the spectrum should be invoked to determine large-eddies characteristics.

The effective diffusivity depends on the molecular one only for the mean field regime (region 1), which corresponds to the slowest rate of spreading. In the superdiffusive regimes (regions 2–4), the transport process is faster than pure diffusion motion. The integral time scale for these cases takes the form $\tau = \tau_{diff}\delta^b$ or $\tau = \tau_{conv}R_0^c$, where $b > 0,\ 0 \le c < 1$. The shortest pure convective time scale belongs to region 3 and to the Kolmogorov boundary. These regions have the largest values of the parameter ϵ, which defines the strength of the infra-red divergence of the velocity spectrum. For these regions, time-dependent effective diffusivity is obtained.

It is well known, beginning from the classical work of Taylor [22], that the mean-square displacement of fluid particles $\langle X^2(t)\rangle$ by turbulent flow is defined by the convective scaling $\langle X^2(t)\rangle = \langle V^2\rangle t^2$ initially and approaches the random walk limit $\langle X^2(t)\rangle = 2\langle V^2\rangle T_L t$ for long diffusion time. Figure 4(a) shows the dependence of the effective diffusivity on time for the Kolmogorov spectrum for the different values

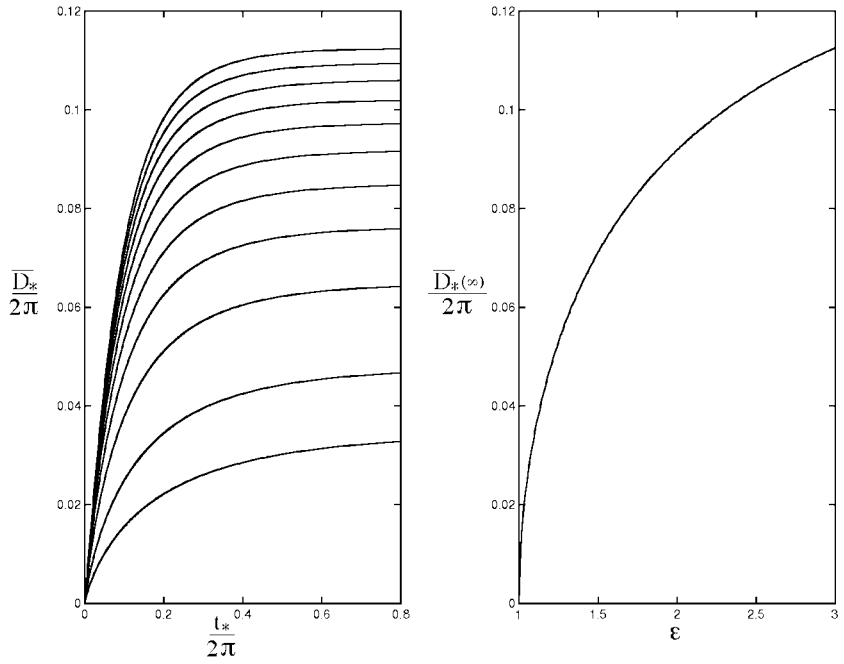

FIG. 5. *Effective diffusivity in region* 3. (a) *Time-evolution of the effective diffusivity. The lowest line corresponds to* $\epsilon = 1.1$ *and others correspond to the increasing values of* ϵ *from* 1.2 *to* 3 *with* 0.2 *increment.* (b) *The dependence of* $\overline{D}_*(\infty)$ *on* ϵ.

of the parameter β. Recalling the definition of the effective diffusivity through the "convective" mean-square displacement by (5.6),

$$\overline{Z}^2 = 2\int_0^t \overline{D_*(s)}ds,$$

one can conclude that the time-evolution of the effective diffusivity is qualitatively consistent with the classical result: linear growth of $\overline{D_*}(t)$ at $t \to 0$ and approach to the constant value $\overline{D_*}(\infty)$ at large times for all values of β. For other values of $\epsilon = 3 - 2z$ at the Kolmogorov boundary, the time-evolution of the effective diffusivity occurs in a similar manner, as shown in Figure 4(a).

Increasing the parameter β corresponds to decreasing the correlation time for the fluctuation of the velocity field. As one can see in Figure 4(a), the random walk limit is reached faster when the correlation time decreases. The largest diffusivity enhancement corresponds to the steady flow case $\beta = 0$, which produces the $D_*(t)$ dependence of region 3 for the corresponding value of ϵ. The dependence of the infinite-time asymptotic diffusivity $\overline{D_\infty} = \overline{D_*}(\infty)/2\pi$ on β for the Kolmogorov boundary $\epsilon = 3 - 2z$ is shown in Figure 4(b) for several values of ϵ.

The dependence $\overline{D_*}(t)$ for region 3 has a similar shape as that for the Kolmogorov boundary and is shown in Figure 5(a) for several values of ϵ. The stronger infra-red divergence of the spectrum (higher ϵ) results in larger effective diffusivity and shorter time to reach the random walk limit. The dependence of infinite-time asymptote $\overline{D_\infty}$ on ϵ in Figure 5(b) confirms that the boundary $\epsilon = 1$ does not belong to this region, since $\overline{D_\infty}(\epsilon = 1) = 0$, and a different, slower time scale should be imposed in this

case. Note that, for fixed β, the dependence of the effective diffusivity on ϵ for the spectra from the Kolmogorov boundary is similar to one shown in Figure 5.

The superdiffusive regimes in regions 2 and 4 correspond to intermediate time scales between diffusion and convection. In these time scales, the transition period for $\overline{D_*} = \overline{D_*}(t)$ is short and one immediately sees the limiting value $\overline{D_*}(\infty)$ in the integral time scale.

We shall compare our theoretical predictions to experimental data for the transverse (normal) diffusivity for turbulent channel flows. Due to the zero-mean velocity assumption, we cannot capture the downstream diffusivity of the most common turbulent flows. In order to make a comparison with earlier experimental and numerical works on turbulent transport, the Kolmogorov spectrum is chosen, which is defined by $\epsilon = 5/3$, $z = 2/3$. Unfortunately, experimental measurements of the two-point two-time correlation in well-developed isotropic turbulence has not been found. Different spectral theories suggest different relations between the value of β and the Kolmogorov constant α_0 (mostly like $\beta = c\alpha_0^2$, where the constant c varies from one theory to another) and, at the same time, predict the value of the Kolmogorov constant that is several factors off [19]. Hence, instead of selecting the appropriate value of β from existing theoretical predictions, we shall determine it empirically from the asymptotic diffusivity at infinite time.

Note that the values of $\overline{D} = \overline{D_*}/2\pi$ and $t = t_*/2\pi$ shown in Figure 4 are already rescaled according to the conventional choice $L_0 = L'/2\pi$, such that the dimensional effective diffusivity and time are

$$\overline{D}' = \overline{D} U_{rms} L', \qquad t' = \frac{tL'}{U_{rms}},$$

where L' is the appropriate spatial dimension for the real turbulent flow. For pipe flows, for example, the long-time effective diffusivity in the transverse direction scaled on the friction velocity and a pipe diameter is about $[3-4]\times 10^{-2}$ [11], [18], [19].

Hence, it is already evident in Figure 4(b) that the infinite time asymptotic $\overline{D_\infty}$ for the Kolmogorov spectrum provides a correct order-of-magnitude estimate for any $\beta < 10$. Because the root-mean-square velocity near the center of the pipe is typically about 0.8 of the friction velocity U_τ [19], one can expect a quantitative agreement with the choice of $\beta \approx 1-2$, and the selected value of β should not vary from one particular set of data to another. Figure 6 reproduces experimental data collection from the book of Sherwood, Pigford, and Wilke [20, Figure 4.11, p. 125]. The solid line $E_D = \overline{D}'_\infty$ is calculated using the value of $\beta = 1$ for the Kolmogorov spectrum, which gives $\overline{D}_\infty = 4.55\times 10^{-2}$ and the typical value 0.8 for the ratio U_{rms}/U_τ. Hence, in terms of the friction velocity, the long-time effective diffusivity becomes

$$\overline{D}'_\infty = 0.8\overline{D}_\infty(\epsilon = 5/3, z = 2/3, \beta = 1) U_\tau d = 3.64\times 10^{-2} U_\tau d,$$

where d is the pipe diameter. To express the friction velocity in terms of the average velocity U_{av}, the well-known expression for the friction factor in a pipe flow has been invoked,

$$U_\tau = U_{av}\sqrt{f/2}, \qquad f = 0.067\left(\frac{U_{av}d}{\nu}\right)^{-1/4},$$

because most of the data in the high Reynolds number part of the figure has been taken for air flow in pipes. Hence, in variables of Figure 6, the line $E_D = \overline{D}'_\infty(U_{av}d)$

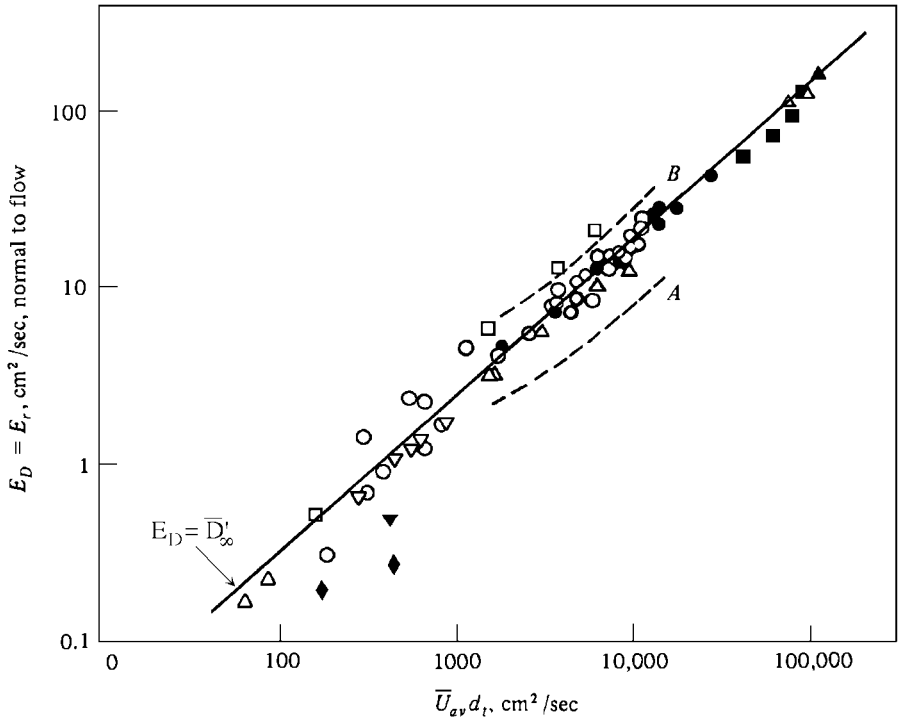

FIG. 6. *Eddy diffusion coefficient for transport normal to the flow direction in pipes and flat ducts. The data are taken from Sherwood, Pigford, and Wilke* [20, *Figure* 4.11, *p.* 125]. *The solid line indicated* $E_D = \overline{D}'_\infty$ *uses the Kolmogorov velocity spectrum with* $\beta = 1$.

is given by

$$E_D = 7.26 \times 10^{-3} \nu Re^{7/8} = 7.26 \times 10^{-3} \nu^{1/8} (U_{av} d)^{7/8} = 5.73 \times 10^{-3} (U_{av} d)^{7/8},$$

where in the last equality $\nu = 0.15$ cm^2/sec for air has been used and, consequently, $U_{av}d$ should be taken in the same units.

It is evident from Figure 6 that the choice of $\beta = 1$ gives a reasonable representation for the long-time effective diffusivity over a wide range of Reynolds numbers. Lower values of β quickly lift up the calculated line, while a slightly higher number, say $\beta = 1.2$, still gives a good representation. For $\beta = 2$, however, the $E_D = \overline{D}'_\infty$ line is already outside most of data points in Figure 6. These data hence allow us to select a very specific coefficient β for the decorrelation time spectral parameter. We shall use this value of $\beta = 1$ in all subsequent comparisons, without further adjustment to the particular flow conditions.

The usual measurable time-dependent quantity in turbulent transport experiments is the solute/temperature profile. For diffusion from a point or line source, it is well represented by a Gaussian shape. This allows the determination of the mean-square displacement $Z^2(t)$, and the slope of the long-time path of the curve $Z^2(t)/2$ gives the long-time value of effective diffusivity. Unfortunately, the mean-square displacement data are not reported so often as the long-time diffusivity and the resolution of the small-time region are typically low.

The solid line in Figure 7 shows the small-time evolution of the nondimensional mean-square displacement for the Kolmogorov spectrum with $\beta = 1$, and the dashed

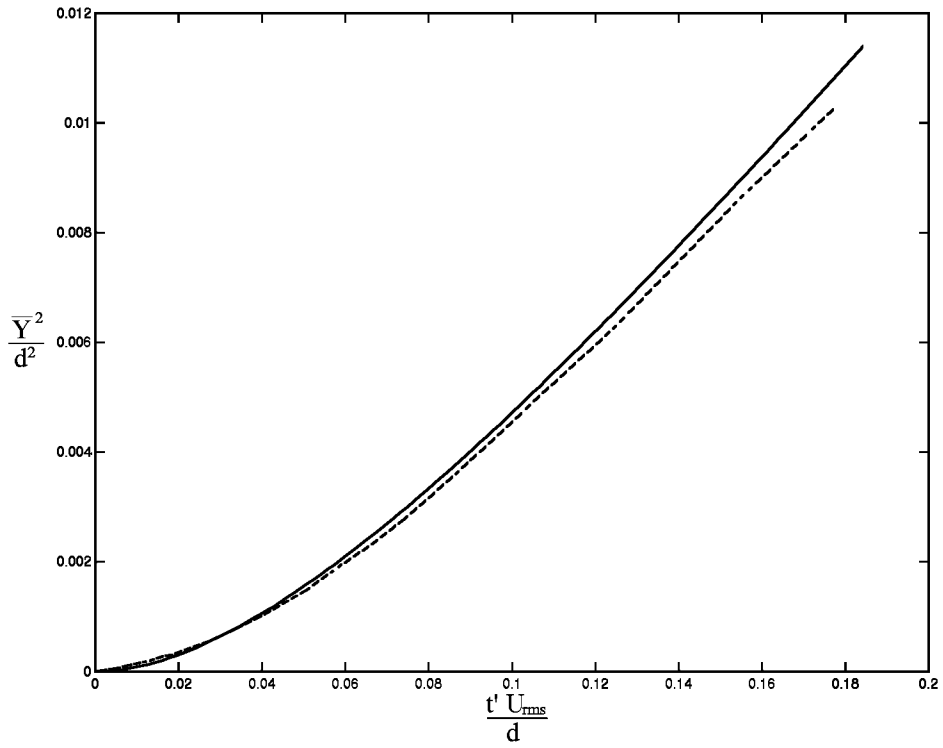

FIG. 7. *Mean-square displacement of fluid particles by turbulent flow.* (—) *Current theory with Kolmogorov velocity spectrum and* $\beta = 1$. (- -) *Experimental heat-transfer data of Baldwin and Walsh* [4] *in turbulent pipe flow, scaled by the reported values of the root-mean-square velocity and the pipe diameter.*

line corresponds to one of the data point from Figure 6 (the lowest black square in the high-Re range [4]). The experimental curve is scaled according to the suggestion of the present theory, on the reported values of the root-mean-square velocity ($U_{rms} \approx 0.035U$ with $U = 22$ m/sec), and the pipe diameter (20 cm). It is evident that small-time evolution of the mean-square displacement also is reproduced by the current theory with reasonable accuracy.

Near the axis of the pipe, turbulence is approximately isotropic. In the numerical experiment of Deardorff and Peskin [7], the trajectories of the fluid particles, released at 1/4 of the channel height and well within the region of mean shear for a turbulent plane air flow, have been calculated. The different statistical quantities, like mean-square displacements in different directions, correlation functions, mean-square particles separation, and so on, have been obtained by averaging the results for different sets of particles. All results are reported in nondimensional form, scaled on the friction velocity and channel height.

Since diffusion starts from a region of appreciable shear, the effective ratio of the root-mean square to friction velocity can vary significantly with time, even if spreading in a spatially homogeneous lateral direction is considered. This is because of the cross-influence of the fluctuations in different directions, included in the present theory and also apparent in reported results of Deardorff and Peskin [7] for the mean-square displacements in different directions for different sets of particles, before the

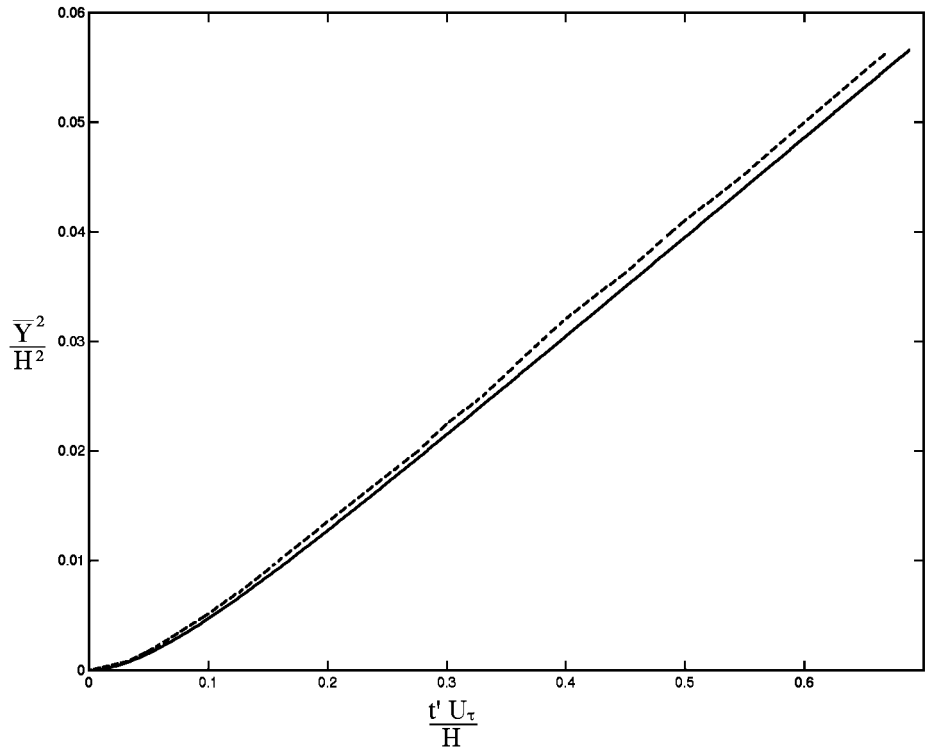

FIG. 8. *Mean-square displacement of the fluid particles by turbulent flow.* (—) *Current theory with Kolmogorov velocity spectrum and* $\beta = 1$. (- -) *Numerical experiment of Deardorff and Peskin* [7]*, mean-square displacement in the lateral direction of a shear flow in a plane channel.*

final averaging.

In Figure 8 the solid line again corresponds to the prediction of the present theory, and the dashed line now represents the Deardorff and Peskin [7] numerical result for the mean-square displacement in the lateral direction with no additional rescaling for the adjustment of the root-mean-square to friction velocity. The agreement again is quite good. Hence, one can expect that the above renormalization theory to yield satisfactory prediction from the spectral data for the transport properties of nearly isotropic random flows.

Appendix A. Distribution of convective trajectories (5.4). First of all, let us establish some statistical properties for the Lagrangian velocity field $\mathbf{U}(t) = -\mathbf{u}(\sqrt{2D_0}\mathbf{W}(t) + \mathbf{Z}(\mathbf{t}), t)$. Invoking the representation of the Eulerian velocity $\mathbf{u}(\mathbf{x}, t)$ by its spatial Fourier transform, one can represent $\mathbf{U}(t)$ by

$$\mathbf{U}(t) = -(2\pi)^{-m/2} \int_{-\infty}^{\infty} \hat{\mathbf{u}}(\mathbf{k}, t) g_w(\mathbf{k}, t) f(\mathbf{k}, t) d^m\mathbf{k}, \tag{A.1}$$

where

$$g_w(\mathbf{k}, t) = \exp(\imath\sqrt{2D_0}\mathbf{k}\mathbf{W}(t)),$$
$$f(\mathbf{k}, t) = \exp(\imath\mathbf{k}\mathbf{Z}(t)) = \exp\left(\imath\mathbf{k}\int_0^t \mathbf{U}(s)ds\right),$$

and the value of $\langle f(\delta\mathbf{K},t)\rangle_{U|W}$ gives the characteristic function of the distribution of "convective" trajectories $\mathbf{Z}(t)$. The product of any N number of the components of $\mathbf{U}(t)$ is then given by

$$\prod_{n=1}^{N} U_{i_n}(t) = \frac{(-1)^N}{(2\pi)^{\frac{mN}{2}}} \int g_w\left(\sum_{n=1}^{N}\mathbf{k}^n,t\right) f\left(\sum_{n=1}^{N}\mathbf{k}^n,t\right) \prod_{n=1}^{N} \hat{u}_{i_n}(\mathbf{k}^n,t)d^m\mathbf{k}^n. \tag{A.2}$$

Hence, in order to express any analytic function of the Lagrangian velocity $\mathbf{U}(t)$ in terms of known random functions $\hat{\mathbf{u}}$ and $\mathbf{W}(t)$, one needs to find such representation for $f(\mathbf{k},t)$.

Time-evolution of $f(\mathbf{k},t)$ can be described by the equation

$$df = \imath\mathbf{k}\mathbf{U}(t)f(\mathbf{k},t)dt, \quad f(\mathbf{k},0)=1,$$

and formal integration with $\mathbf{U}(t)$ given by (A.1) yields

$$f(\mathbf{k},t) = 1 - \int_0^t \int_{-\infty}^{\infty} \imath\mathbf{k}\hat{\mathbf{u}}(\mathbf{q},s)f(\mathbf{k}+\mathbf{q},s)g_w(\mathbf{q},s)\frac{d^m\mathbf{q}}{(2\pi)^{m/2}}ds. \tag{A.3}$$

Equation (A.3) is a linear integral equation for f with random but continuous and, in the mean-square sense, bounded kernel. It should be recalled that $\hat{\mathbf{u}}(\mathbf{q},s)$ is defined on the domain $\delta < q < 1$ and the dispersion of $\hat{\mathbf{u}}$, as is given by (3.3), is bounded for any finite δ. The probability for $\hat{\mathbf{u}}(\mathbf{q},s)$ to exceed essentially $\langle\hat{\mathbf{u}}\hat{\mathbf{u}}\rangle^{1/2}$ is really small because a Gaussian distribution has an exponentially small tail. Consequently, one can expect that the analogue of the Neumann expansion for (A.3) will converge, at least for some finite values of t and δ.

Hence, by iterative substitution of $f(\mathbf{k}+\mathbf{q},s)$ into (A.3) one can write the series solution for f in terms of $\hat{u}$ and $\mathbf{W}$:

$$\begin{aligned} f(\mathbf{k},t) &= 1 - \int_0^t \int_{-\infty}^{\infty} \imath k_{j_1}\hat{u}_{j_1}(\mathbf{q}^1,s_1)g_w(\mathbf{q}^1,s_1)\frac{d^m\mathbf{q}^1}{(2\pi)^{\frac{m}{2}}}ds_1 \\ &- \int_0^t ds_1 \int_0^{s_1} ds_2 \int_{-\infty}^{\infty} k_{j_1}\hat{u}_{j_1}(\mathbf{q}^1,s_1)(k+q^1)_{j_2}\hat{u}_{j_2}(\mathbf{q}^2,s_2) \\ &\qquad \times g_w(\mathbf{q}^1,s_1)g_w(\mathbf{q}^2,s_2)\frac{d^m\mathbf{q}^1 d^m\mathbf{q}^2}{(2\pi)^m} + \cdots \\ &+ \frac{(-\imath)^p}{(2\pi)^{\frac{mp}{2}}} \int_{-\infty}^{\infty} \prod_{k=1}^{p} \int_0^{s_{k-1}} \left(\sum_{l=0}^{k-1} q_{j_k}^l\right) \hat{u}_{j_k}(\mathbf{q}^k,s_k)g_w(\mathbf{q}^k,s_k)d^m\mathbf{q}^k ds_k + \cdots, \end{aligned} \tag{A.4}$$

where $s_0 = t$ and $\mathbf{q}^0 = \mathbf{k}$ in the representation of general terms in (A.4). The convergence of this Neumann series is established in Appendix B.

The substitution of (A.4) into (A.2) and averaging over $\hat{u}$ immediately gives that all terms in the series, except the first one (which is equal to 1), vanish because of the homogeneity of the Eulerian velocity field $\mathbf{u}$ and the continuity equation. Indeed, with $\mathbf{q}^0 = \mathbf{k} = \sum_{m=1}^{N}\mathbf{k}^m$ in (A.4), the general "pth" term in the product of "N" U-components in (A.2) becomes

$$\cdots \prod_{n=1}^{N} \hat{u}_{i_n}(\mathbf{k}^n,t) \prod_{k=1}^{p} \left(\sum_{m=1}^{N} k_{j_k}^m + \sum_{l=1}^{k-1} q_{j_k}^l\right) \hat{u}_{j_k}(\mathbf{q}^k,s_k)\cdots, \tag{A.5}$$

where only dependencies on $\hat{u}$ and wavevectors are shown. The homogeneity requirement implies that only terms with

$$\sum_{m=1}^{N} \mathbf{k}^m + \sum_{l=1}^{p} \mathbf{q}^l = 0$$

can give nonzero average (compare with the $\delta(\mathbf{k}+\mathbf{q})$ term in the spectral form of velocity correlation (3.3)) and, consequently, one can set

$$\sum_{m=1}^{N} \mathbf{k}^m + \sum_{l=1}^{p-1} \mathbf{q}^l = -\mathbf{q}^p$$

in (A.5). The last two factors in the product (A.5) then become

$$\left(\sum_{m=1}^{N} k^m + \sum_{l=1}^{p-1} q^l \right)_{j_p} \hat{u}_{j_p}(\mathbf{q}^p, s_p) = -q^p_{j_p} \hat{u}_{j_p}(\mathbf{q}^p, s_p) \equiv 0$$

because of the continuity equation. Hence, only $f_0(\mathbf{k}, t) = 1$ contributes to the average of (A.2), and the homogeneity restriction for the remaining term, $\sum_{n=1}^{N} \mathbf{k}^n = 0$, also leads to the disappearance of the dependence on $\mathbf{W}(t)$,

(A.6)
$$\begin{aligned}
\left\langle \prod_{n=1}^{N} U_{i_n}(t) \right\rangle &= \frac{(-1)^N}{(2\pi)^{\frac{mN}{2}}} \int \exp\left(\imath \sqrt{2D_0} \sum_{n=1}^{N} \mathbf{k}^n \mathbf{W}(t) \right) \left\langle \prod_{n=1}^{N} \hat{u}_{i_n}(\mathbf{k}^n, t) \right\rangle d^m\mathbf{k}^n \\
&= \frac{(-1)^N}{(2\pi)^{\frac{mN}{2}}} \int \left\langle \prod_{n=1}^{N} \hat{u}_{i_n}(\mathbf{k}^n, t) \right\rangle d^m\mathbf{k}^n = (-1)^N \left\langle \prod_{n=1}^{N} u_{i_n}(0, t) \right\rangle \\
&= (-1)^N \left\langle \prod_{n=1}^{N} u_{i_n}(\mathbf{x}, T-t) \right\rangle = (-1)^N \left\langle \prod_{n=1}^{N} u_{i_n}(0, 0) \right\rangle.
\end{aligned}$$

The last two identities follow from the original definition of the inverse trajectory and from the stationarity of the Eulerian velocity field $\mathbf{u}(\mathbf{x}, t)$.

Because any analytic function of the Lagrangian velocity can be represented by a power series in the velocity components, it follows from (A.6) that

$$\langle \phi(\mathbf{U}(s)) \rangle_U = \langle \phi(-\mathbf{u}(\mathbf{x}, t-s)) \rangle_u$$

for any arbitrary analytic function $\phi(\mathbf{U}(s))$. This implies that $\mathbf{U}(s)$ and $-\mathbf{u}(\mathbf{x}, t-s)$ have the same distribution. Because $\mathbf{u}$ is assumed Gaussian, $\mathbf{U}(t)$ and the convective trajectory $\mathbf{Z}(t)$, which is linear in $\mathbf{U}$, also are Gaussian. Consequently, equation (5.4),

(A.7)
$$\begin{aligned}
&\langle \exp(\imath\delta\mathbf{K}\mathbf{Z}) \rangle_{Z(u|W)} = \exp\left(-\frac{\delta^2}{2} \langle (\mathbf{K}\mathbf{Z})^2 \rangle_{Z(u|W)} \right) = \exp\left(-\frac{\delta^2}{2} K_i \tilde{Z^2_{ij}} K_j \right), \\
&\tilde{Z^2_{ij}} = \tilde{Z^2_{ij}}(t, \mathbf{W}(t)) = \langle Z_i(t) Z_j(t) \rangle_{\hat{u}} = \int_0^t \int_0^t \langle \mathbf{U}_i(s) \mathbf{U}_j(s') \rangle_U ds ds',
\end{aligned}$$

provides the exact representation for the characteristic function $\langle \exp(\imath\delta\mathbf{K}\mathbf{Z}) \rangle$ at any time t for the selected stationary homogeneous isotropic Gaussian Eulerian velocity field $\mathbf{u}$.

Appendix B. Convergence of Neumann series (A.4) for the characteristic function. For all the results in Appendix A to be correct, one needs to establish the convergence of the series (A.4) for $f(\mathbf{k},t)$. In fact, it is enough to estimate the average of a general even term, $|\langle f(\mathbf{k},t)_{2p}\rangle|$. The absolute convergence of the series $\langle f(\mathbf{k},t)_{2p}\rangle$ will then guarantee the convergence of (A.4) in the mean-square sense because of the structure of even and odd terms and because of the previously discussed fast decay of the tail of Gaussian distribution. Hence, let us consider the detailed structure of $|\langle f(\mathbf{k},t)_{2p}\rangle|$,

$$
\begin{aligned}
|\langle f(\mathbf{k},t)_{2p}\rangle| = \Bigg| & \frac{(-1)^p}{(2\pi)^{mp}} \int_0^t ds_1 \int_0^{s_1} ds_2 \ldots \int_0^{s_{2p-1}} ds_{2p} \int_{-\infty}^{\infty} d^m\mathbf{q}^1 d^m\mathbf{q}^2 \ldots d^m\mathbf{q}^{2p} \\
& \times \exp\left(\imath\sqrt{2D_0}\sum_{i=1}^{2p}\mathbf{q}^i\mathbf{W}(s_i)\right) \\
& \times k_{j_1}(k+q^1)_{j_2}(k+q^1+q^2)_{j_3}\ldots\left(k+\sum_{i=1}^{2p-1}q^i\right)_{j_{2p}} \\
& \times \langle \hat{u}_{j_1}(\mathbf{q}^1,s_1)\hat{u}_{j_2}(\mathbf{q}^2,s_2)\hat{u}_{j_3}(\mathbf{q}^3,s_3)\ldots\hat{u}_{j_{2p}}(\mathbf{q}^{2p},s_{2p})\rangle\Bigg|.
\end{aligned}
\tag{B.1}
$$

To calculate the average in the last line of (B.1), one can invoke the factorization property of high-order moments of Gaussian distribution

$$
\underbrace{\langle \hat{u}_i\hat{u}_j\hat{u}_k\hat{u}_m\ldots\rangle}_{2p} = \frac{2p!}{p!2^p}\left(\underbrace{\langle\hat{u}_i\hat{u}_j\rangle\langle\hat{u}_k\hat{u}_m\rangle\ldots}_{p\text{ 2-nd moments}}\right)_{\text{sym}},
\tag{B.2}
$$

where the subscript "sym" denotes the arithmetic mean of all symmetrized products of the $\hat{u}_i\hat{u}_j$. For example, the fourth-order moment is

$$
\langle \hat{u}_i\hat{u}_j\hat{u}_k\hat{u}_m\rangle = \frac{4!}{2!2^2}\left(\frac{1}{3}\left[\langle\hat{u}_i\hat{u}_j\rangle\langle\hat{u}_k\hat{u}_m\rangle + \langle\hat{u}_i\hat{u}_k\rangle\langle\hat{u}_j\hat{u}_m\rangle + \langle\hat{u}_i\hat{u}_m\rangle\langle\hat{u}_j\hat{u}_k\rangle\right]\right).
\tag{B.3}
$$

With the factorization (B.2) and the correlation of the Fourier-component of the velocity field given by (3.3),

$$
\begin{aligned}
&\langle \hat{u}_{j_i}(\mathbf{q}^i,s_i)\hat{u}_{j_n}(\mathbf{q}^n,s_n)\rangle = \\
&\qquad \delta(\mathbf{q}^i+\mathbf{q}^n)\left[\delta_{j_ij_n} - \frac{q^i_{j_i}q^i_{j_n}}{(q^i)^2}\right]\alpha^2(q^i)^{1-m-\epsilon}\exp(-a(q^i)^z|s_i-s_n|)
\end{aligned}
\tag{B.4}
$$

for $\delta \le q^i \equiv |\mathbf{q}^i| = |\mathbf{q}^n| \le 1$; $\langle \hat{u}_{j_i}(\mathbf{q}^i,s_i)\hat{u}_{j_n}(\mathbf{q}^n,s_n)\rangle \equiv 0$ otherwise, (B.1) becomes

$$|\langle f(\mathbf{k},t)_{2p}\rangle| = \frac{\alpha^{2p}}{(2\pi)^{mp}}\frac{2p!}{p!2^p}\prod_{k=1}^{p}\int_1^{\delta}(\tilde{q}^k)^{-\epsilon}d\tilde{q}^k\int_0^t ds_1\int_0^{s_1} ds_2\ldots\int_0^{s_{2p-1}} ds_{2p}$$

$$\times\Bigg|\Bigg\{\exp\left(-a\sum_{i=1}^{p}(\tilde{q}^i)^z\triangle_i s\right)\int_{\text{angles}}\cdots\int\exp\left(\imath\sqrt{2D_0}\sum_{i=1}^{2p}\tilde{\mathbf{q}}^i\triangle_i\mathbf{W}\right)$$

$$\times k_{j_1}(k+q^1)_{j_2}(k+q^1+q^2)_{j_3}\ldots\left(k+\sum_{i=1}^{2p-1}q^i\right)_{j_{2p}} \tag{B.5}$$

$$\times\underbrace{\left[\ldots\delta(\mathbf{q}^l+\mathbf{q}^n)\left(\delta_{j_l j_n}-\frac{q^l_{j_l}q^l_{j_n}}{(q^l)^2}\right)\ldots\right]}_{p\text{ factors}}\Bigg\}_{\text{sym}}\Bigg|,$$

where the symbolic notations $\triangle_i s$, $\triangle_i\mathbf{W}$, and $\tilde{\mathbf{q}}^i$ correspond to the ordering of terms in the symmetrized product

$$\tilde{\mathbf{q}}^1=\mathbf{q}^1,\quad \triangle_1 s=s_1-s_k,\quad \triangle_1\mathbf{W}=\mathbf{W}(s_1)-\mathbf{W}(s_k),$$

$$\tilde{\mathbf{q}}^2=\begin{cases}\mathbf{q}^2, & \triangle_2 s=s_2-s_i,\quad \triangle_2\mathbf{W}=\mathbf{W}(s_2)-\mathbf{W}(s_i) \quad \text{for } k\neq 2,\\ \mathbf{q}^3, & \triangle_3 s=s_3-s_i,\quad \triangle_3\mathbf{W}=\mathbf{W}(s_3)-\mathbf{W}(s_i) \quad \text{for } k=2,\end{cases}$$

and so on.

It is evident that the homogeneity requirement and the fluid incompressibility (product of p delta-functions and $[\delta_{j_l j_n}-q^l_{j_l}q^l_{j_n}/(q^l)^2]$ factors, respectively, in the last line of (B.5)) effectively eliminate most of the "q" terms in the third line of (B.5). The symmetry condition of the velocity field, however, cannot be invoked completely until Brownian motion effect is averaged or neglected. By explicit consideration of angular integration for the fourth and sixth moments (they are relatively short but already contain all representative combinations of even and odd powers of $\tilde{q}^i$), it can be shown that interaction with nonaveraged effect of molecular diffusion leads to factors $|\tilde{g}^i_w|<1$, like

$$\tilde{g}^i_w=\frac{\sin(\sqrt{2D_0}\tilde{q}^i|\triangle_i\mathbf{W}|)}{\sqrt{2D_0}\tilde{q}^i|\triangle_i\mathbf{W}|}\quad\text{and /or}\quad \tilde{g}^i_w\frac{\triangle_i\mathbf{W}}{|\triangle_i\mathbf{W}|},\quad \tilde{g}^m_w\tilde{g}^i_w\frac{\triangle_i\mathbf{W}+\triangle_m\mathbf{W}}{|\triangle_i\mathbf{W}+\triangle_m\mathbf{W}|}$$

in the 3-D case, for example. More importantly, the first one with a nonzero average always corresponds to terms with even powers in $\tilde{q}^i$ in the third line of (B.5). The others, which contain an odd power of $\mathbf{W}$ and hence will vanish after averaging, always appear only if odd powers in $\tilde{q}^i$ are present, i.e., they correspond to terms like $k_j\tilde{q}^i_j$ and $\tilde{q}^i_j\tilde{q}^m_j$ with $i\neq m$ and their odd powers in (B.5). Hence, the interaction of random symmetric convection with molecular diffusion does not induce net coupling between nonsymmetric terms $\tilde{q}^i_j\tilde{q}^m_j$ with $i\neq m$ in (B.5) and it cannot lead to net nonsymmetric effects.

Consequently, one can set $|\exp(\imath\sqrt{2D_0}\dots)| = 1$ in (B.5) before the angular integration. As a result, the absolute value of the integral over angles in (B.5) yields

$$\left| \int_{\text{angles}} \cdots \int \dots \right| \le C^p k^{2p}, \tag{B.6}$$

where the numerical constant C depends on the space dimension but is independent on p. Now, because $\exp\left(-a\sum_{i=1}^{p}(\tilde{q}^i)^z \triangle_i s\right)$ is always less than 1, one can replace it by 1 in the second line of (B.5) and complete the integration over s and $\tilde{q}^i$. The resulting estimate for $|\langle f(\mathbf{k},t)_{2p}\rangle|$ is

$$\begin{aligned} |\langle f(\mathbf{k},t)_{2p}\rangle| &\le \frac{\alpha^{2p}}{(2\pi)^{mp}} \frac{2p!}{p!2^p} \left(\frac{\delta^{1-\epsilon}-1}{\epsilon-1}\right)^p \frac{t^{2p}}{2p!} C^p k^{2p} \\ &= \frac{1}{p!}\left[\frac{C(kt\alpha)^2}{2(2\pi)^m}\left(\frac{\delta^{1-\epsilon}-1}{\epsilon-1}\right)\right]^p. \end{aligned} \tag{B.7}$$

With the Stirling's formula, $p! \approx p^p e^{-p}\sqrt{2\pi p}$, it is evident that for any fixed $t < \infty$, $k < \infty$, and $\delta > 0$

$$|\langle f(\mathbf{k},t)_{2p}\rangle|^{1/p} \le \frac{e}{p}\left[\frac{C(kt\alpha)^2}{2(2\pi)^m}\left(\frac{\delta^{1-\epsilon}-1}{\epsilon-1}\right)\right] \to 0 \text{ as } p \to \infty. \tag{B.8}$$

Hence, according to the Cauchy criteria, the average of series (A.4), $\langle f(\mathbf{k},t)\rangle = \langle f(\mathbf{k},t)_{2p}\rangle$, converges absolutely, regardless of the value of the exponent ϵ. Because of the exponentially small tail of the Gaussian distribution, this leads to the convergence of the unaveraged series (A.4).

It should be mentioned that (B.7) strongly overestimates $|\langle f(\mathbf{k},t)_{2p}\rangle|$ at large values of t because $\exp\left(-a\sum_{i=1}^{p}(\tilde{q}^i)^z \triangle_i s\right)$ in (B.5) has been set equal to 1, which corresponds to small-time behavior. Hence, it is not surprising that larger and larger values of p are needed in order for the right-hand side of (B.7) to decay in the large-scale, long-time limit for arbitrary values of ϵ. However, this does not yet mean that the actual convergence of (A.4) is not as rapid at large time. In fact, one of the goals of the subsequent renormalization analysis is to reach the uniform convergence of (A.4) in the above limit. In any case, (B.8) is valid for any finite $t < \infty$, $k < \infty$, and $\delta > 0$, and it is valid to replace the characteristic function with series (A.4).

Appendix C. Effective diffusivity tensor (5.7). It should be emphasized that establishing that the trajectories are Gaussian distributed tells us only that the characteristic function can be expressed through the mean-square displacement tensor alone as it is given by (A.7) (which is the same as (5.4)), but it does not yet provide the expression for $\tilde{Z}_{ij}^2$. It is evident that (A.7) involves the two-time correlation $\langle \mathbf{U}_i(s)\mathbf{U}_j(s')\rangle_U$, and only relations among the single-time moments $\langle \prod_{n=1}^{N} U_{i_n}(t)\rangle$ and $\langle \prod_{n=1}^{N} u_{i_n}(0,t)\rangle$ have been established by (A.6).

While estimate (B.7) for $|\langle f(\mathbf{k},t)_{2p}\rangle|$ is quite straightforward, it is difficult or even can be impossible to obtain the exact expression for $\tilde{Z}_{ij}^2$ by directly averaging and summing series (A.4) for $f(\delta\mathbf{K},t)$. Using the averaged version of (A.4) instead of (A.6) for any practical purposes also is difficult since (B.7) and (B.8) strongly overestimate the number of terms that is required for the convergence of the series (A.4) in the long-time limit. Hence, another approach will be used to obtain the

evolution equation (5.7) for the effective diffusivity $\tilde{D_{ij}}(s)$, which is related to $\tilde{Z_{ij}^2}$ by definition (5.6),

$$\frac{1}{2}\tilde{Z_{ij}^2}(t,\mathbf{W}(t)) = \int_0^t \tilde{D_{ij}}(s)ds. \tag{C.1}$$

Note that $\mathbf{Z}(t)$ is Gaussian, $\mathbf{Z}(0) = 0$, and $\langle \mathbf{Z}(t)\rangle_U = 0$. Then one can introduce the appropriate m-dimensional white noise $\mathbf{z}(t)$ with the usual autocorrelation properties, $dz_n(t)dz_k(t) = \delta_{nk}dt$ and $dz_n(t)dz_k(s) = 0$ for $t \neq s$, such that $\mathbf{Z}(t)$ can be represented by Ito's stochastic integral

$$Z_i(t) = \int_0^t U_i(s')ds' = \int_0^t A_{in}(s,\mathbf{W}(s))dz_n(s), \tag{C.2}$$

where the matrix $A_{in}(s,\mathbf{W}(s))$ does not depend explicitly on $\mathbf{z}(t)$. It, however, depends on $\hat{\mathbf{u}}$. The Gaussian random processes $\mathbf{z}(t)$ and $\mathbf{W}(t)$, as well as $\mathbf{z}(t)$ and $\int \ldots \hat{\mathbf{u}}(\mathbf{k},t)d^m\mathbf{k}$, also are dependent in general. For example, the dependence of $\mathbf{A}$ on $\hat{\mathbf{u}}$ is evident from relation (A.6) among the statistical properties of Eulerian and Lagrangian velocities that suggests $\mathbf{A} \sim \langle \mathbf{u}(0,0)\mathbf{u}(0,0)\rangle^{1/2}$. The general dependence, of course, is not limited by this simple relation.

However, according to the definition of Ito's stochastic integral, $\mathbf{z}(s)$, $\mathbf{W}(s)$, and $\hat{\mathbf{u}}(\mathbf{k},s)$ are statistically independent of $d\mathbf{z}(t)$ for $t \geq s$ (this also is true for $d\mathbf{W}(t)$). It should be emphasized that only independence on $d\mathbf{z}(t)$ is implied, but not on $\mathbf{z}(t)$; for example, $\langle \hat{u}_i(\mathbf{k},s)dz_j(t)\rangle = 0$ for $t \geq s$, but $\langle \hat{u}_i(\mathbf{k},s)z_j(t)\rangle \neq 0$ in general, regardless of the relative values of t and s. Physically, this means that all these physical quantities at time s "do not know what happens in the future," i.e., how the white noise $\mathbf{z}$ will change at the next instant in time. Hence, from definitions (C.1) and (C.2) and the above properties of $d\mathbf{z}$, it follows that because

$$\begin{aligned}\tilde{Z_{ij}^2}(t) = \langle Z_i(t)Z_j(t)\rangle_{\hat{u}} &= \left\langle \int_0^t A_{in}(s,\mathbf{W}(s))dz_n(s) \int_0^t A_{kj}(s',\mathbf{W}(s'))dz_k(s') \right\rangle_{\hat{u}} \\ &= \int_0^t \langle A_{in}(s,\mathbf{W}(s))A_{nj}(s,\mathbf{W}(s))\rangle_{\hat{u}}ds = 2\int_0^t \tilde{D_{ij}}(s)ds,\end{aligned}$$

the two-time correlation $\langle Z_i(t_1)Z_j(t_2)\rangle_{\hat{u}}$ becomes

$$\begin{aligned}\langle Z_i(t_1)Z_j(t_2)\rangle_{\hat{u}} &= \int_0^{\min\{t_1,t_2\}} \langle A_{in}(s,\mathbf{W}(s))A_{nj}(s,\mathbf{W}(s))\rangle_{\hat{u}}ds \\ &= 2\int_0^{\min\{t_1,t_2\}} \tilde{D_{ij}}(s)ds = \tilde{Z_{ij}^2}(\min\{t_1,t_2\}).\end{aligned} \tag{C.3}$$

Another important consequence of (C.2) and these properties of $d\mathbf{z}$ is the statistical independence of both $\mathbf{Z}(s)$ and $\hat{\mathbf{u}}(\mathbf{q},s)$ on

$$\begin{aligned}\triangle^Z(\mathbf{k}, t \geq t') = k_m(Z_m(t) - Z_m(t')) &= k_m \int_{t'}^t A_{mn}(s',\mathbf{W}(s'))dz_n(s') \\ &= k_m \int_{t'}^t U_m(s'')ds''\end{aligned} \tag{C.4}$$

for any $\mathbf{k}$, $\mathbf{q}$, and $t \geq t' \geq s$.

It also should be noted that the two-point two-time Eulerian velocity correlation (3.3) (same as (B.4)) yields

$$\begin{aligned}\langle \hat{u}_i(\mathbf{k},t)\hat{u}_j(\mathbf{q},s)\rangle &= \exp(-ak^z|t-s|)\langle \hat{u}_i(\mathbf{k},s)\hat{u}_j(\mathbf{q},s)\rangle \\ &= \exp(-ak^z|t-s|)\langle \hat{u}_i(\mathbf{k},0)\hat{u}_j(\mathbf{q},0)\rangle\end{aligned} \tag{C.5}$$

such that

$$\langle [\hat{u}_i(\mathbf{k},t) - \exp(-ak^z(t-s))\hat{u}_i(\mathbf{k},s)]\,\hat{u}_j(\mathbf{q},s)\rangle \equiv 0 \tag{C.6}$$

for any pairs of $\{\mathbf{k},\mathbf{q}\}$, $\{i,j\}$, and $t \geq s$. For further analysis, it is convenient to introduce the notation

$$\triangle_i^u(\mathbf{k}, t \geq t') = \hat{u}_i(\mathbf{k},t) - \exp(-ak^z(t-t'))\hat{u}_i(\mathbf{k},t'), \tag{C.7}$$

where, similar to (C.4), t should be $\geq t'$. Using (C.5) and definition (C.7), it can be easily shown that

$$\langle \triangle_i^u(\mathbf{k}, t \geq t')\hat{u}_j(\mathbf{q},s)\rangle \equiv 0 \tag{C.8}$$

for any $\{\mathbf{k},\mathbf{q}\}$, $\{i,j\}$, and $t \geq t' \geq s$.

This means that $\hat{\mathbf{u}}(\mathbf{q},s)$ is statistically independent of $\triangle^{\mathbf{u}}(\mathbf{k}, t \geq t')$ for $t' \geq s$. According to (C.2), $\mathbf{Z}(s)$ also can be defined through the Lagrangian velocity $\mathbf{U}(s')$ with $s' \leq s$, which, in turn, depends only on $\hat{\mathbf{u}}(\mathbf{q}^l, s_l)$ at different instants of time $s_l \leq s'$ because of the series solution (A.4). Consequently, $\mathbf{Z}(s)$ also is statistically independent of $\triangle^{\mathbf{u}}(\mathbf{k}, t \geq t')$ for $t' \geq s$. It is hence useful to summarize the established independence properties:

$$\langle \triangle_i^u(\mathbf{k}, t \geq t')\hat{u}_j(\mathbf{q},s)\rangle \equiv 0, \quad \langle \triangle_i^u(\mathbf{k}, t \geq t')Z_j(s)\rangle \equiv 0, \tag{C.9}$$

$$\begin{aligned}&\langle \triangle^Z(\mathbf{k}, t \geq t')\hat{u}_j(\mathbf{q},s)\rangle \equiv 0, \quad \langle \triangle^Z(\mathbf{k}, t \geq t')Z_j(s)\rangle \equiv 0 \\ &\text{for any} \quad \{\mathbf{k},\mathbf{q}\}, \quad \{i,j\}, \quad \text{and} \quad t \geq t' \geq s,\end{aligned} \tag{C.10}$$

where $\triangle^Z$ and $\triangle_i^u$ are defined by (C.4) and (C.7), respectively.

Now let us consider the two-time correlation for the Lagrangian velocity components

$$\begin{aligned}\langle U_i(t)U_j(s)\rangle_{\hat{u}} = (2\pi)^{-m} \iint \exp\left[\imath\sqrt{2D_0}(\mathbf{k}\mathbf{W}(t) + \mathbf{q}\mathbf{W}(s))\right] \\ \times \langle \hat{u}_i(\mathbf{k},t)\hat{u}_j(\mathbf{q},s)\exp\left[\imath(\mathbf{k}\mathbf{Z}(t) + \mathbf{q}\mathbf{Z}(s))\right]\rangle_{\hat{u}} d^m\mathbf{k}d^m\mathbf{q},\end{aligned} \tag{C.11}$$

where, without loss of generality, one can set $t \geq s$. The next step is to find the proper decomposition for the average in the last line of (C.11) in order to complete the averaging without obtaining the explicit solution for $\mathbf{Z}$. Using definitions (C.4) and (C.7) and the independence properties (C.9)–(C.10), one obtains

$$\begin{aligned}&\langle \hat{u}_i(\mathbf{k},t)\hat{u}_j(\mathbf{q},s)\exp\left[\imath(\mathbf{k}\mathbf{Z}(t) + \mathbf{q}\mathbf{Z}(s))\right]\rangle \\ &= \langle \{\triangle_i^u(\mathbf{k}, t \geq s) + \exp(-ak^z(t-s))\hat{u}_i(\mathbf{k},s)\}\,\hat{u}_j(\mathbf{q},s) \\ &\quad \times \exp\left[\imath\left\{\triangle^Z(\mathbf{k}, t \geq s) + (\mathbf{k}+\mathbf{q})\mathbf{Z}(s)\right\}\right]\rangle \\ &= \langle \triangle_i^u(\mathbf{k}, t \geq s)\exp\left[\imath\triangle^Z(\mathbf{k}, t \geq s)\right]\rangle\langle \hat{u}_j(\mathbf{q},s)\exp\left[\imath(\mathbf{k}+\mathbf{q})\mathbf{Z}(s)\right]\rangle \\ &+ \langle \exp\left[\imath\triangle^Z(\mathbf{k}, t \geq s)\right]\rangle \exp(-ak^z(t-s))\langle \hat{u}_i(\mathbf{k},s)\hat{u}_j(\mathbf{q},s)\exp\left[\imath(\mathbf{k}+\mathbf{q})\mathbf{Z}(s)\right]\rangle \\ &\equiv \{1\} + \{2\}.\end{aligned} \tag{C.12}$$

The second term $\{2\}$ in (C.12) can now be averaged explicitly. One can use two-time correlation (C.3) for $\mathbf{Z}$ in the first average, which involves only $\triangle^Z(\mathbf{k}, t \geq s) = \mathbf{k}(\mathbf{Z}(t) - \mathbf{Z}(s))$. The second $\langle \dots \rangle$ in $\{2\}$, which contains only s-dependent quantities, is exactly the same as $\langle \dots \rangle$ in the average of (A.2) for the single-time second moment of Lagrangian velocity $\langle U_i(s) U_j(s) \rangle_u$. Consequently, (A.6) and the Eulerian velocity correlation (B.4) allow the completion of this averaging. The result is

$$\begin{aligned}\{2\} &= \exp\left[-\frac{1}{2} k_m \left\{\tilde{Z}^2_{mn}(t) - \tilde{Z}^2_{mn}(s)\right\} k_n\right] \exp(-ak^z(t-s)) \langle \hat{u}_i(\mathbf{k}, 0) \hat{u}_j(\mathbf{q}, 0) \rangle \\ &= \delta(\mathbf{k}+\mathbf{q}) \alpha^2 k^{1-m-\epsilon} \left(\delta_{ij} - \frac{k_i k_j}{k^2}\right) \exp\left[-ak^z(t-s) - k_m \int_s^t \tilde{D}_{mn}(s') ds' k_n\right],\end{aligned} \tag{C.13}$$

$$k = |\mathbf{k}|, \quad \delta < k < 1,$$

where the definition of $\tilde{D}_{mn}$ in (C.1) also has been used. Note that (C.13) gives exactly the same result as that from invoking Corrsin's independence hypothesis, namely, the independent averaging of $\langle \hat{u}\hat{u} \rangle$ and $\langle \exp[\dots] \rangle$ in (C.11). The decomposition (C.12) for the averaging in (C.11), however, also contains the term $\{1\}$, which will be considered below.

The second average in $\{1\}$, which contains all $\mathbf{q}$-dependent factors and quantities, and depends only on s but not t, is not of great interest. Including $\exp[\imath \mathbf{q} \mathbf{W}(s)]$ from the first line of (C.11) (which remains invariant under the averaging over $\hat{u}$) into this $\langle \dots \rangle$ and integrating over $\mathbf{q}$ reduce it to $\langle U_j(s) \exp[\imath \mathbf{k} \mathbf{Z}(s)] \rangle_U$, which is some nonzero function of s and $\mathbf{k}$ in general.

Now let us examine the first average in $\{1\}$, which depends only on wavevector $\mathbf{k}$ and "differences" $\triangle^u_i$ and $\triangle^Z$, $\langle \triangle^u_i(\mathbf{k}, t \geq s) \exp\left[\imath \triangle^Z(\mathbf{k}, t \geq s)\right] \rangle$. Using the definition of $\triangle^Z$ by (C.4), one can write the stochastic differential equations (with respect to variable t) for the exponential factor

$$\begin{aligned} f^{\triangle}(\mathbf{k}, t \geq s) &= \exp\left[\imath \triangle^Z(\mathbf{k}, t \geq s)\right] \\ &= \exp\left[\imath \mathbf{k}(\mathbf{Z}(t) - \mathbf{Z}(s))\right] = \exp\left[\imath \mathbf{k} \int_s^t \mathbf{U}(s') ds'\right] \end{aligned} \tag{C.14}$$

both in terms of Lagrangian velocity and the new white noise $z(t)$:

$$df^{\triangle}(\mathbf{k}, t \geq s) = \imath \mathbf{k} \mathbf{U}(t) f^{\triangle}(\mathbf{k}, t \geq s) dt, \tag{C.15}$$

$$df^{\triangle}(\mathbf{k}, t \geq s) = \imath \mathbf{k} \mathbf{A}(t) f^{\triangle}(\mathbf{k}, t \geq s) d\mathbf{z}(t) - \mathbf{k} \tilde{\mathbf{D}}(t) \mathbf{k} f^{\triangle}(\mathbf{k}, t \geq s) dt. \tag{C.16}$$

Now, similar to (A.3), let us formally integrate (C.15), multiply it by $\triangle^{\mathbf{u}}(\mathbf{k}, t \geq s)$, and average the result:

$$\begin{aligned} \langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) f^{\triangle}(\mathbf{k}, t \geq s) \rangle &= \langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) \rangle \\ &\quad + \left\langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) \int_s^t \imath \mathbf{k} \mathbf{U}(t') f^{\triangle}(\mathbf{k}, t' \geq s) dt' \right\rangle \\ &= \left\langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq t') \int_s^t \imath \mathbf{k} \mathbf{U}(t') f^{\triangle}(\mathbf{k}, t' \geq s) dt' \right\rangle \\ &\quad + \left\langle \int_s^t \exp(-a|\mathbf{k}|^z (t-t') \triangle^{\mathbf{u}}(\mathbf{k}, t' \geq s)) \imath \mathbf{k} \mathbf{U}(t') f^{\triangle}(\mathbf{k}, t' \geq s) dt' \right\rangle, \end{aligned} \tag{C.17}$$

where the useful property of $\triangle^{\mathbf{u}}$,

$$\triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) = \triangle^{\mathbf{u}}(\mathbf{k}, t \geq t') + \exp(-a|\mathbf{k}|^z(t-t'))\triangle^{\mathbf{u}}(\mathbf{k}, t' \geq s)$$
$$\text{for any} \qquad t \geq t' \geq s,$$

which can be easily obtained from its definition (C.7), has been invoked. The first term in the right-hand side of (C.17) vanishes because, as is evident from (A.3), both $\mathbf{U}(t')$ and $f^{\triangle}(\mathbf{k}, t' \geq s)$ contain only $\hat{\mathbf{u}}(\mathbf{q}^{\mathbf{l}}, t_l \leq t')$, and because of the independence properties (C.9). In order to average the second term, one can invoke the equivalent representation of $df^{\triangle}(\mathbf{k}, t \geq s) = \imath\mathbf{k}\mathbf{U}(t)f^{\triangle}(\mathbf{k}, t \geq s)dt$ by (C.16):

$$\begin{aligned}
&\exp(a|\mathbf{k}|^z t)\langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) f^{\triangle}(\mathbf{k}, t \geq s)\rangle \\
&= \left\langle \int_s^t \exp(a|\mathbf{k}|^z t')\imath\mathbf{k}\mathbf{A}(t')\triangle^{\mathbf{u}}(\mathbf{k}, t' \geq s) f^{\triangle}(\mathbf{k}, t' \geq s) d\mathbf{z}(t') \right\rangle \\
&\qquad - \int_s^t \mathbf{k}\tilde{\mathbf{D}}(t')\mathbf{k}\langle \triangle^{\mathbf{u}}(\mathbf{k}, t' \geq s) f^{\triangle}(\mathbf{k}, t' \geq s)\rangle dt' \\
&= -\int_s^t \exp(a|\mathbf{k}|^z t')\mathbf{k}\tilde{\mathbf{D}}(t')\mathbf{k}\langle \triangle^{\mathbf{u}}(\mathbf{k}, t' \geq s) f^{\triangle}(\mathbf{k}, t' \geq s)\rangle dt',
\end{aligned} \tag{C.18}$$

where both sides also have been multiplied by $\exp(a|\mathbf{k}|^z t)$. The first term in (C.18) again vanishes because it is linear in $dz(t')$. Consequently, the time-evolution of the average value $\langle \triangle^{\mathbf{u}} f^{\triangle}\rangle$ is described by the simple equation

$$\frac{d\langle \triangle^{\mathbf{u}} f^{\triangle}\rangle}{dt} = -\left[a|\mathbf{k}|^z + \mathbf{k}\tilde{\mathbf{D}}(t)\mathbf{k}\right]\langle \triangle^{\mathbf{u}} f^{\triangle}\rangle, \qquad \langle \triangle^{\mathbf{u}} f^{\triangle}\rangle(t \leq s) \equiv 0, \tag{C.19}$$

which has the only trivial solution $\langle \triangle^{\mathbf{u}} f^{\triangle}\rangle = \langle \triangle^{\mathbf{u}}(\mathbf{k}, t \geq s) f^{\triangle}(\mathbf{k}, t \geq s)\rangle \equiv 0$.

Hence, term {1} in (C.12) vanishes exactly, and term {2} gives the same average as if the Corrsin's independence hypothesis had been invoked during the averaging of (C.11). This is essentially due to Gaussian distribution of the trajectories and stationarity of both Eulerian and Lagrangian Gaussian velocity fields. All these properties lead to the statistical independence of "changes" in the Eulerian velocity field, $\triangle^{\mathbf{u}}(\mathbf{k}, t \geq s)$, and in the distribution of "differences in trajectories," $f^{\triangle}(\mathbf{k}, t \geq s)$, despite the interdependence of $\mathbf{Z}$ and $\mathbf{u}$.

The substitution of expression (C.13) for the "effectively independent" term {2} into (C.11) hence gives the two-time Lagrangian velocity correlation for $t \geq s$:

$$\begin{aligned}
\langle U_i(t)U_j(s)\rangle_{\hat{u}} &= RL_{ij}(t,s) \\
&= \frac{\alpha^2}{(2\pi)^m}\int_{\delta<k<1} k^{1-m-\epsilon}\exp(-ak^z(t-s))\left(\delta_{ij} - \frac{k_i k_j}{k^2}\right) \\
&\qquad \times \exp\left[-k_m \int_s^t \tilde{D}_{mn}(s')ds' k_n\right] \\
&\qquad \times \exp\left[\imath\sqrt{2D_0}\mathbf{k}(\mathbf{W}(t) - \mathbf{W}(s))\right] d^m\mathbf{k}.
\end{aligned} \tag{C.20}$$

The derivation of the evolution equation for the effective diffusivity now becomes straightforward. According to the definition of effective diffusivity by (C.1),

$$\frac{1}{2}d\tilde{Z}_{ij}(t) = \tilde{D}_{ij}(t)dt = \left\{\int_0^t \left[RL_{ij}(t,s) + RL_{ij}(s,t)\right] ds\right\} dt, \tag{C.21}$$

where (C.20) provides the expressions for $RL_{ij}(t,s)$ and $RL_{ij}(s,t)$ under the condition $t \geq s$. The resulting expression for $\tilde{D}_{ij}(t)$ is

$$\tilde{D}_{ij}(t) = \frac{\alpha^2}{(2\pi)^m} \int_{\delta<k<1} k^{1-m-\epsilon} \tilde{F}(\mathbf{k},t,\mathbf{W}(t)) \left(\delta_{ij} - \frac{k_i k_j}{k^2}\right) d^m\mathbf{k}, \tag{C.22a}$$

$$\tilde{F}(\mathbf{k},t,\mathbf{W}(t)) = \int_0^t \exp\left(-ak^z(t-s) - k_m \int_s^t \tilde{D}_{mn}(s')ds' k_n\right) \times \cos\left[\sqrt{2D_0} k_l (W_l(t) - W_l(s))\right] ds. \tag{C.22b}$$

The averaging of all quantities involving $\tilde{D}_{ij}(t)$ over $\mathbf{W}(t)$ and the analysis of their time-evolution becomes easier if one can write down the governing differential equation for the real-valued function $\tilde{F}(\mathbf{k},t,\mathbf{W}(t))$. Invoking Ito's stochastic differentiation,

$$df\,(t,\mathbf{W}(t)) = \left[\frac{\partial f}{\partial t} + \frac{1}{2}\nabla_W^2 f\right] dt + \frac{\partial f}{\partial W_i} dW_i(t),$$

one can write the evolution equation for $\tilde{F}(\mathbf{k},t,\mathbf{W}(t))$ defined in (C.22b):

$$\begin{aligned} d\tilde{F} &= \left[1 - \left(ak^z + k^2 D_0 + k_m \tilde{D}_{mn}(t) k_n\right) \tilde{F}\right] dt - \tilde{G}\sqrt{2D_0} k_l dW_l(t), \\ d\tilde{G} &= -\left[ak^z + k^2 D_0 + k_m \tilde{D}_{mn}(s) k_n\right] \tilde{G} dt + \tilde{F}\sqrt{2D_0} k_l dW_l(t), \\ \tilde{F}(\mathbf{k},0,\mathbf{W}(0)) &= 0, \qquad \tilde{G}(\mathbf{k},0,\mathbf{W}(0)) = 0, \end{aligned} \tag{C.23}$$

where

$$\begin{aligned} \tilde{G} = \tilde{G}(\mathbf{k},t,\mathbf{W}(t)) &= -\frac{\partial \tilde{F}}{\partial (k_l W_l(t))} \\ &= \int_0^t \exp\left(-ak^z(t-s) - k_m \int_s^t \tilde{D}_{mn}(s')ds' k_n\right) \\ &\qquad \times \sin\left[\sqrt{2D_0} k_l (W_l(t) - W_l(s))\right] ds. \end{aligned}$$

It is evident that (C.22a) and (C.23) are exactly the same as equations (5.7a)–(5.7d).

SELF-SIMILAR SOLUTIONS FOR WEAK SHOCK REFLECTION*

ALLEN M. TESDALL† AND JOHN K. HUNTER‡

Abstract. We present numerical solutions of a two-dimensional Riemann problem for the unsteady transonic small disturbance equations that provides an asymptotic description of the Mach reflection of weak shock waves. We develop a new numerical scheme to solve the equations in self-similar coordinates and use local grid refinement to resolve the solution in the reflection region. The solutions contain a remarkably complex structure: there is a sequence of triple points and tiny supersonic patches immediately behind the leading triple point that is formed by the reflection of weak shocks and expansion waves between the sonic line and the Mach shock. An expansion fan originates at each triple point, thus resolving the von Neumann paradox of weak shock reflection. These numerical solutions raise the question of whether there is an infinite sequence of triple points in an inviscid weak shock Mach reflection.

Key words. weak shock reflection, self-similar solutions, unsteady transonic small disturbance equation, two-dimensional Riemann problems, von Neumann paradox

1. Introduction.

Experimental observations of the Mach reflection of weak shock waves off a wedge show a pattern that closely resembles a single Mach reflection, in which the incident, reflected, and Mach shocks meet at a triple point. The von Neumann theory of shock reflection [10, 16] shows that a standard triple point configuration, consisting of three shocks and a contact discontinuity, is impossible for sufficiently weak shocks. This apparent conflict between theory and experiment for weak shock reflection has been a long-standing puzzle and is often referred to as the triple point, or von Neumann, "paradox" (see section I.17 of [2], for example).

Guderley [8, 9] proposed that there is a supersonic region behind the triple point in a steady weak shock Mach reflection, in which case there is an additional expansion fan at the triple point, resolving the apparent paradox. There was, however, no evidence of a supersonic region or an expansion fan in experimental observations [3, 18, 19] or numerical solutions [4, 5, 20] of weak shock reflections off a wedge, until Hunter and Brio [12] obtained a numerical solution of a shock reflection problem for the unsteady transonic small disturbance equation that contained a supersonic region behind the triple point. The region is extremely small, which is why it had not been detected previously. Subsequently, Zakharian et al. [24] found a supersonic region in a numerical solution of a shock reflection problem for the full Euler equations, using local grid refinement near the triple point, for a set of parameter values corresponding to those in [12].

The solutions in [12, 24] are for a single set of parameter values, and they are not sufficiently well resolved to show an expansion fan at the triple point directly, or to show the structure of the flow inside the supersonic region. In this paper, we present

high-resolution numerical solutions of the shock reflection problem for the unsteady transonic small disturbance equations for a range of parameter values. There is a supersonic region behind the triple point in all of the numerical solutions obtained here. This region consists of a sequence of supersonic patches formed by a sequence of expansion fans and shock waves that are reflected between the sonic line and the Mach shock (see Figures 5 and 6, for example). Each of the reflected shocks intersects the Mach shock, resulting in a sequence of triple points, rather than a single triple point. The numerical results raise the question of whether there is an infinite sequence of triple points in an inviscid weak shock Mach reflection.

The total size of the repeating structure of supersonic patches is approximately the same as that of the supersonic region in the solution obtained in [12], at the same parameter value, by a different numerical scheme. Other important quantities, including the strength of the reflected shock and the location of the triple point, agree closely with this solution, providing an independent check on the self-similar solutions presented here.

There are, at the moment, no experimental observations of a supersonic region behind the triple point in a weak shock Mach reflection. As we discuss in section 5, the small size of the region and the effect of viscosity may make it very difficult to detect experimentally. A structure similar to the one in the solutions presented here has been observed in shock-boundary layer interactions in transonic flows over an airfoil [1, 13] (see Figures 245 and 247 in [6]). The shock reflects off a laminar boundary layer as an expansion wave, leading to a sequence of reflected shock and expansion waves inside the supersonic bubble on the airfoil.

The numerical solutions of weak shock reflection in [5, 12, 20, 24] were obtained by solving an initial-value problem for the unsteady equations. The problem of inviscid shock reflection off a wedge is self-similar, and there are a number of advantages to solving the problem in self-similar, rather than unsteady, form. In the unsteady formulation the equations are time-marched, and any waves present move through the computational domain, complicating algorithms for local grid refinement near the triple point. By contrast, a solution of the self-similar equations is stationary, making local grid refinement algorithms much easier to implement. Moreover, a global grid refinement strategy is possible, in which a partially converged solution on a coarse grid is interpolated onto a fine grid, and then converged on the fine grid. This process may be repeated recursively until the desired resolution is obtained.

In this paper, we present numerical solutions of the shock reflection problem for the unsteady transonic small disturbance equations computed in self-similar coordinates. Samtaney [17] developed a scheme for the solution of the Euler equations in self-similar coordinates, but his scheme does not apply to the unsteady transonic small disturbance equations, and a different approach is required. In our approach, we introduce special self-similar variables in which the self-similar transonic small disturbance equations have the form of the usual transonic small disturbance equations modified by lower-order terms. What makes the use of the unsteady transonic small disturbance equations worthwhile is the fact that, with the same computational resources, we can obtain a much more finely resolved solution than for the Euler equations.

This paper is organized as follows. In section 2, we describe the shock reflection problem for the unsteady transonic small disturbance equation, and in section 3 we give the details of our numerical method. In section 4, we present our numerical solutions. In section 5, we discuss some of the questions raised by these solutions and consider the effect of physical viscosity on the inviscid solutions. We summarize our

conclusions in section 6.

2. The asymptotic shock reflection problem. The asymptotic shock reflection problem [11, 12, 14, 20] consists of the unsteady transonic small disturbance equation

$$\begin{aligned} &u_t + \left(\frac{1}{2}u^2\right)_x + v_y = 0, \\ &u_y - v_x = 0 \end{aligned} \tag{2.1}$$

in the half space $y > 0$ with the initial and boundary conditions

$$u(x, y, 0) = \begin{cases} 0 & \text{if } x > ay, \\ 1 & \text{if } x < ay, \end{cases} \tag{2.2}$$

$$v(x, y, t) = 0 \qquad \text{if } x > \sigma(y, t), \tag{2.3}$$

$$v(x, 0, t) = 0. \tag{2.4}$$

Here, $x = \sigma(y, t)$ is the location of the incident and Mach shocks. The location of the incident shock is given by

$$x = ay + \left(\frac{1}{2} + a^2\right) t. \tag{2.5}$$

The incident shock strength, as measured by the jump in u, is normalized to one. This problem depends on a single parameter a, the inverse slope of the incident shock.

These equations may be derived by a systematic asymptotic expansion of the shock reflection problem for the full Euler equations for weak shock reflection off thin wedges [12]. The variables $u(x, y, t)$, $v(x, y, t)$ are proportional to the x, y fluid velocity components, respectively, and pressure perturbations are proportional to u. The flow is irrotational and isentropic to leading order in the shock strength.

If the Mach number of the incident shock is M, and the wedge angle in radians is θ_w, then (2.1)–(2.4) is obtained in the limit $M \to 1$ and $\theta_w \to 0$, with

$$a = \frac{\theta_w}{2\sqrt{M - 1}} \tag{2.6}$$

fixed. Because of transonic similarity, the asymptotic problem depends on a single combination of the incident shock strength and the wedge angle. A regularly reflected solution of (2.1)–(2.4) is impossible when $a < \sqrt{2}$, and triple point solutions of (2.1), in which three plane shocks separated by constant states meet at a point, do not exist.

The problem (2.1)–(2.4) is self-similar, so the solution depends only on the similarity variables

$$\xi = \frac{x}{t}, \qquad \eta = \frac{y}{t}.$$

Writing (2.1) in terms of ξ, η, and a pseudo-time variable $\tau = \log t$, we get

$$\begin{aligned} &u_\tau - \xi u_\xi - \eta u_\eta + \left(\frac{1}{2}u^2\right)_\xi + v_\eta = 0, \\ &u_\eta - v_\xi = 0. \end{aligned} \tag{2.7}$$

As $\tau \to +\infty$, solutions of (2.7) converge to a pseudo-steady, self-similar solution that satisfies

$$\begin{aligned} &-\xi u_\xi - \eta u_\eta + \left(\frac{1}{2}u^2\right)_\xi + v_\eta = 0, \\ &u_\eta - v_\xi = 0. \end{aligned} \tag{2.8}$$

Equation (2.8) is hyperbolic when $u < \xi + \eta^2/4$, corresponding to supersonic flow in a self-similar coordinate frame, and is elliptic when $u > \xi + \eta^2/4$, corresponding to subsonic flow. The equation changes type across the sonic line given by

$$\xi + \frac{\eta^2}{4} = u(\xi, \eta). \tag{2.9}$$

3. The numerical method. In order to solve (2.7) numerically, we write it in terms of parabolic coordinates

$$\begin{aligned} &r = \xi + \frac{1}{4}\eta^2, \qquad \theta = \eta, \\ &\widetilde{u} = u - \left(\xi + \frac{1}{4}\eta^2\right), \qquad \widetilde{v} = v - \frac{1}{2}\eta u, \end{aligned} \tag{3.1}$$

which gives

$$\begin{aligned} &\widetilde{u}_\tau + \left(\frac{1}{2}\widetilde{u}^2\right)_r + \widetilde{v}_\theta + \frac{3}{2}\widetilde{u} + \frac{1}{2}r = 0, \\ &\widetilde{u}_\theta - \widetilde{v}_r = 0. \end{aligned} \tag{3.2}$$

With respect to these variables, the self-similar equations have the form of the usual transonic small disturbance equations modified by lower-order terms, and they can be solved by a standard numerical scheme. We introduce a potential $\varphi(r, \theta, \tau)$ such that

$$\widetilde{u} = \varphi_r, \qquad \widetilde{v} = \varphi_\theta, \tag{3.3}$$

and we write (3.2) in the potential form

$$\varphi_{r\tau} + \left(\frac{1}{2}\varphi_r^2\right)_r + \varphi_{\theta\theta} + \frac{3}{2}\varphi_r + \frac{1}{2}r = 0. \tag{3.4}$$

We define a nonuniform grid r_i in the r direction and θ_j in the θ direction, where $r_{i+1} = r_i + \Delta r_{i+1/2}$ and $\theta_{j+1} = \theta_j + \Delta\theta_{j+1/2}$. We also define $(r_{i-1/2}, r_{i+1/2})$ as the neighborhood of the point r_i, with length $\Delta r_i = \frac{1}{2}(\Delta r_{i-1/2} + \Delta r_{i+1/2})$, where $r_{i+1/2} = \frac{1}{2}(r_{i+1} + r_i)$. Similar definitions apply for the nonuniform grid θ_j. We denote an approximate solution of (3.4) by

$$\varphi_{i,j}^n \approx \varphi(r_i, \theta_j, n\Delta\tau),$$

where $\Delta\tau$ is a fixed time step, and we discretize (3.4) in time τ using

$$\frac{\varphi_r^{n+1} - \varphi_r^n}{\Delta\tau} + \varphi_{\theta\theta}^{n+1} + f(\varphi_r)_r^n + \frac{3}{2}\varphi_r^{n+1} + \frac{1}{2}r = 0, \tag{3.5}$$

where the flux function f is defined by

$$f(\widetilde{u}) = \frac{1}{2}\widetilde{u}^2. \tag{3.6}$$

We solve (3.5) by sweeping from right to left in r, using the spatial discretization

(3.7)

$$\begin{aligned}
&\varphi_{i,j}^{n+1} - \Delta r_{i+1/2}\Delta\tau \left(\frac{\frac{\varphi_{i,j+1}-\varphi_{i,j}}{\Delta\theta_{j+1/2}} - \frac{\varphi_{i,j}-\varphi_{i,j-1}}{\Delta\theta_{j-1/2}}}{\Delta\theta_j} \right)^{n+1} + \frac{3}{2}\Delta\tau\varphi_{i,j}^{n+1} \\
&\quad = \varphi_{i+1,j}^{n+1} - \varphi_{i+1,j}^{n} + \varphi_{i,j}^{n} + \Delta\tau \left(F(\widetilde{u}_{i+1/2,j}, \widetilde{u}_{i+3/2,j})^n - F(\widetilde{u}_{i-1/2,j}, \widetilde{u}_{i+1/2,j})^n \right) \\
&\qquad + \frac{3}{2}\Delta\tau\varphi_{i+1,j}^{n+1} + \frac{1}{2}\Delta\tau\Delta r_{i+1/2}\,\hat{r}_{i+1/2}.
\end{aligned}$$

Here, F is a numerical flux function, and

$$\widetilde{u}_{i-1/2,j} = \frac{\varphi_{i,j} - \varphi_{i-1,j}}{\Delta r_{i-1/2}}.$$

The variable $\hat{r}_{i+1/2}$ is the value of r at which the source term $\frac{1}{2}r$ is evaluated, and in most of the calculations we used the definition $\hat{r}_{i+1/2} = r_i$. We tried a number of different treatments of the source term and obtained similar results with them all. See [21] for a detailed discussion.

In most of the computations, we used an Engquist–Osher numerical flux function. Dropping the θ-subscript j, which is constant in the following definitions, the Engquist–Osher flux for (3.6) is

$$F^{EO}(\widetilde{u}_{i-1/2}, \widetilde{u}_{i+1/2}) = \frac{1}{2}\max(\widetilde{u}_{i-1/2}, 0)^2 + \frac{1}{2}\min(\widetilde{u}_{i+1/2}, 0)^2.$$

In our highest resolution computations for $a = 0.5$, we used a second-order, flux-limiter scheme [23], with a Lax–Wendroff flux as the higher-order flux, and an Engquist–Osher flux as the lower-order flux. The numerical flux function for this scheme is given by

$$F(\widetilde{u}_{i-1/2}, \widetilde{u}_{i+1/2}) = \psi(\varrho)F^{LW}(\widetilde{u}_{i-1/2}, \widetilde{u}_{i+1/2}) + (1 - \psi(\varrho))F^{EO}(\widetilde{u}_{i-1/2}, \widetilde{u}_{i+1/2}),$$

$$\varrho = \begin{cases}
\dfrac{\left(\left|\frac{\widetilde{u}_{i-3/2}+\widetilde{u}_{i-1/2}}{2}\right| - \frac{\Delta\tau}{\Delta r_i}\left(\frac{\widetilde{u}_{i-3/2}+\widetilde{u}_{i-1/2}}{2}\right)^2\right)(\widetilde{u}_{i-1/2} - \widetilde{u}_{i-3/2})}{\left(\left|\frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2}\right| - \frac{\Delta\tau}{\Delta r_i}\left(\frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2}\right)^2\right)(\widetilde{u}_{i+1/2} - \widetilde{u}_{i-1/2})}, & \frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2} \geq 0, \\[2ex]
\dfrac{\left(\left|\frac{\widetilde{u}_{i+1/2}+\widetilde{u}_{i+3/2}}{2}\right| - \frac{\Delta\tau}{\Delta r_i}\left(\frac{\widetilde{u}_{i+1/2}+\widetilde{u}_{i+3/2}}{2}\right)^2\right)(\widetilde{u}_{i+3/2} - \widetilde{u}_{i+1/2})}{\left(\left|\frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2}\right| - \frac{\Delta\tau}{\Delta r_i}\left(\frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2}\right)^2\right)(\widetilde{u}_{i+1/2} - \widetilde{u}_{i-1/2})}, & \frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2} < 0,
\end{cases}$$

where ψ is a minmod flux-limiter,

$$\psi(\varrho) = \begin{cases} 0, & \varrho \leq 0, \\ \varrho, & 0 < \varrho < 1, \\ 1, & \varrho \geq 1. \end{cases}$$

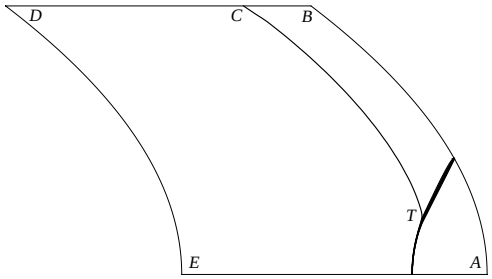

FIG. 1. *A schematic diagram of the computational domain. EA is the wall and ABDE is the numerical boundary. The incident shock enters the computational domain through AB. The incident, reflected, and Mach shocks meet at the triple point T.*

The Lax–Wendroff flux for (3.6) is given by

$$F^{LW}(\widetilde{u}_{i-1/2},\widetilde{u}_{i+1/2}) = \frac{1}{4}(\widetilde{u}^2_{i-1/2}+\widetilde{u}^2_{i+1/2}) - \frac{1}{2}\frac{\Delta\tau}{\Delta r_i}\left(\frac{\widetilde{u}_{i-1/2}+\widetilde{u}_{i+1/2}}{2}\right)^2(\widetilde{u}_{i+1/2}-\widetilde{u}_{i-1/2}).$$

We evolve the solution of (3.7) forward in time τ until it converges to a steady state, using line relaxation. The direction of sweep, from right to left in r, is consistent with the direction of propagation of the characteristics for (2.8), which is in the $-r$ direction.

3.1. Boundary conditions. We computed solutions of the half-space problem (2.1)–(2.4) in the finite computational domain

$$r^L \le r \le r^R, \qquad 0 \le \theta \le \theta^T,$$

shown schematically in Figure 1. The left and right boundaries of the computational domain are parabolic because of the use of the coordinates in (3.1). We use a nonuniform grid that has a locally refined area of uniform grid very close to the triple point, and is stretched exponentially away from the triple point toward the outer numerical boundaries and the wall. In the solutions shown below, the nonuniform grids are stretched by amounts between 0.5% and 1.5%, and the total number of grid points in our largest grid is approximately 3×10^6.

We impose the physical no-flow condition (2.4), which implies that $\varphi_\theta = 0$, on the wall EA. In addition, we require numerical boundary conditions on the outer computational boundaries.

On the right boundary AB, we impose Dirichlet data corresponding to the incident shock solution in (2.2)–(2.3). Using (3.1) in (2.5), we find that the incident shock location with respect to the transformed self-similar coordinates is given by

$$r = a\theta + \frac{1}{4}\theta^2 + \frac{1}{2} + a^2.$$

Thus, the incident shock location is a parabola with respect to the transformed coordinates, instead of a straight line. Ahead of the incident shock we have $(u,v) = (0,0)$, and behind the incident shock we have $(u,v) = (1,-a)$. Hence, using (3.1), (3.3), and

the requirement that the potential is continuous across the shock, we find that the potential for the incident shock solution is given by

$$\varphi(r,\theta) = \begin{cases} -\frac{1}{2}r^2, & r > a\theta + \frac{1}{4}\theta^2 + \frac{1}{2} + a^2, \\ r - a\theta - \frac{1}{4}\theta^2 - \frac{1}{2}r^2 - \frac{1}{2} - a^2, & r < a\theta + \frac{1}{4}\theta^2 + \frac{1}{2} + a^2. \end{cases} \tag{3.8}$$

We impose (3.8) as a boundary condition for (3.4) on AB.

The asymptotic behavior of the solution of the shock reflection problem at large distances from the reflection point is given by the solution of the linearized shock reflection problem [12]. We use this result to formulate a numerical boundary condition on the subsonic boundary CDE. In self-similar variables, the linearized solution for φ_r behind the reflected wavefront $r = 1$ is

$$\varphi_r = 1 - r + \frac{1}{\pi}\tan^{-1}\left(\frac{2a\sqrt{1-r}}{1 - r + \frac{1}{4}\theta^2 - a^2}\right), \quad r < 1. \tag{3.9}$$

We impose (3.9) as a Neumann condition on the left boundary DE. Writing (3.9) as $\varphi_r = f(r,\theta)$, we discretize it as

$$\frac{\varphi_{i+1,j} - \varphi_{i,j}}{\Delta r_{i+1/2}} = f(r_{i+1/2}, \theta_j).$$

On the top boundary BD, we impose the Dirichlet condition (3.8) when $r > 1$, corresponding to the segment BC, and the condition (3.9) when $r < 1$, corresponding to the segment CD. The exact location of the reflected shock is slightly different from the point $r = 1$, where we switch the numerical boundary conditions, and the exact solution differs slightly from the linearized solution, but we found that the disturbance originating from the top boundary was small provided that the boundary was far enough away from the triple point (see Figure 9). We tried a number of other numerical boundary conditions, but (3.8)–(3.9) gave the most satisfactory results.

4. Numerical results. We computed numerical solutions of (2.1)–(2.4) for a equal to 0.3, 0.4, 0.5, 0.6, 0.65, 0.7, 0.75, and 0.8. In the following figures, we present solutions for the values 0.3, 0.5, 0.6, and 0.8. The solutions for the other values of a are similar to the ones presented here. Figure 2 shows u-contour plots of the global solutions as a function of $(x/t, y/t)$. From (2.6), increasing a corresponds to increasing the wedge angle while fixing the Mach number of the incident shock, or decreasing the Mach number while fixing the wedge angle. Hence, the sequence of plots in Figure 2(a)–(d) is a numerical representation of a series of shock reflection experiments in which the wedge angle is increased, while the Mach number is held constant at a value near one.

The numerical solutions closely resemble a single Mach reflection. The Mach shock becomes shorter and stronger as a increases, and the strength of the reflected shock near the triple point, which is very weak for smaller values of a, also increases with a (see Table 4.1). For a fixed value of a, the strength of the Mach shock increases as it moves away from the triple point, reaching a maximum at the wall $y = 0$. The strength of the reflected shock increases initially as it moves away from the triple point, then decreases, approaching zero as $y \to +\infty$. The thickening of the incident shock as it moves away from the triple point in Figure 2(a)–(d) is caused by the use of a stretched grid.

In Figure 3, we show the u-contours and the numerically computed location of the sonic line (2.9) near the triple point for the values of a shown in Figure 2. All of

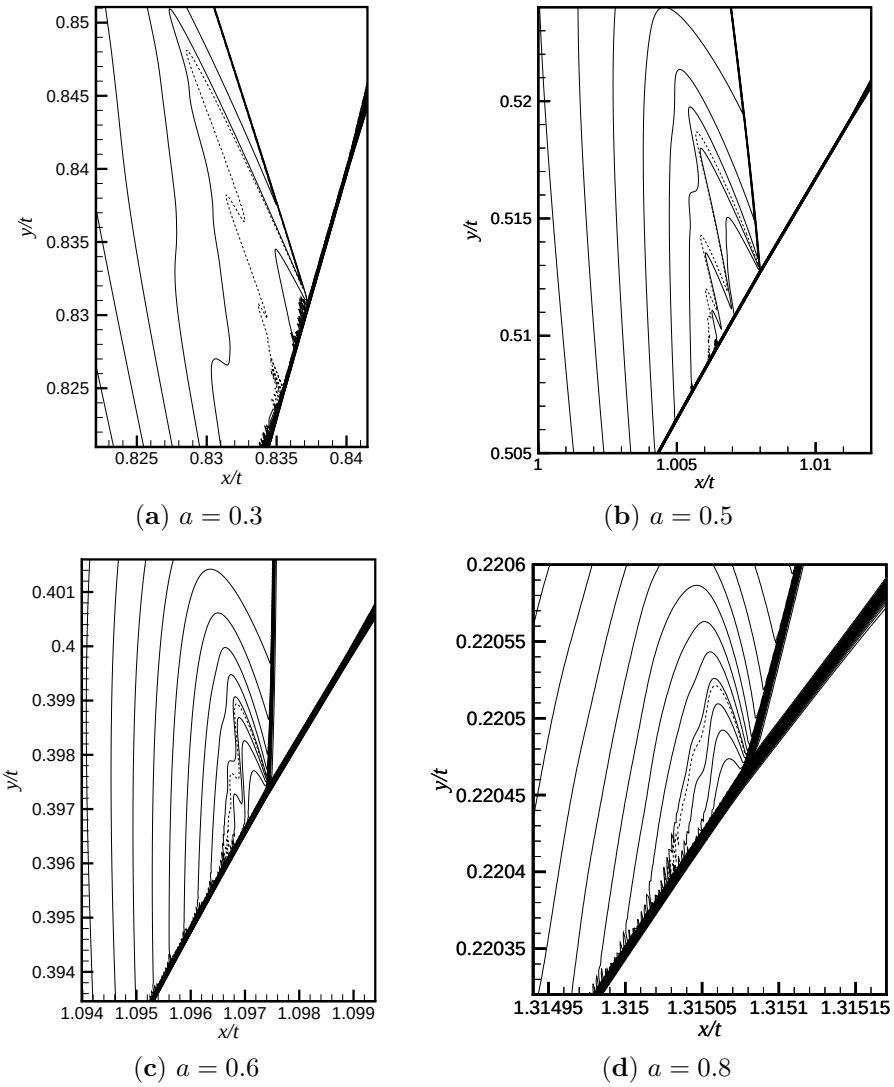
the solutions contain a small region of supersonic flow behind the triple point, the size of which decreases rapidly with increasing a. Table 4.1 gives the size of the supersonic region in the numerical solution for each value of a. The height $\Delta(y/t)$ is a numerical estimate of the difference between the maximum value of y/t on the sonic line and the minimum value of y/t at the rear sonic point on the Mach shock. The width $\Delta(x/t)$ is an estimate of the width of the supersonic region at the value of y/t corresponding to the triple point. In detailed plots of our most refined solution with $a = 0.5$ (see Figures 5 and 6, for example), the expansion fan generated by the collision of the reflected shock with the incident shock at the triple point can be clearly seen. Behind the leading triple point, there is a sequence of shocks and expansion fans. These shocks are less apparent in the less resolved solutions, such as Figure 3(c), and in



(**a**) $a = 0.3$ (**b**) $a = 0.5$

(**c**) $a = 0.6$ (**d**) $a = 0.8$

FIG. 3. *Contour plots of u near the triple point for increasing values of a. The u-contour spacing is* 0.005 *in* (a)*, and* 0.01 *in* (b)–(d)*. The dotted line is the sonic line. The regions shown contain the refined uniform grids, which have the following numbers of grid points:* (a) 620×480*;* (b) 768×608*;* (c) 346×260*;* (d) 245×150.

Figure 3(d) they cannot be seen at all.

The area covered by the most refined uniform grid fits inside the region shown in Figure 3(a)–(d); the actual refined grid area would appear as a sheared rectangle because the equations are discretized with respect to the parabolic coordinates in (3.1). The figure caption gives the number of grid points in the most refined area of the grid. The small numerical oscillations immediately behind the Mach shock (see Figure 3(a) and (d), for example) seem to be caused by the lack of alignment of the shock with the grid.

We found that, for a given value of a, a certain minimum grid resolution was required to resolve the supersonic region behind the triple point. As we refined the

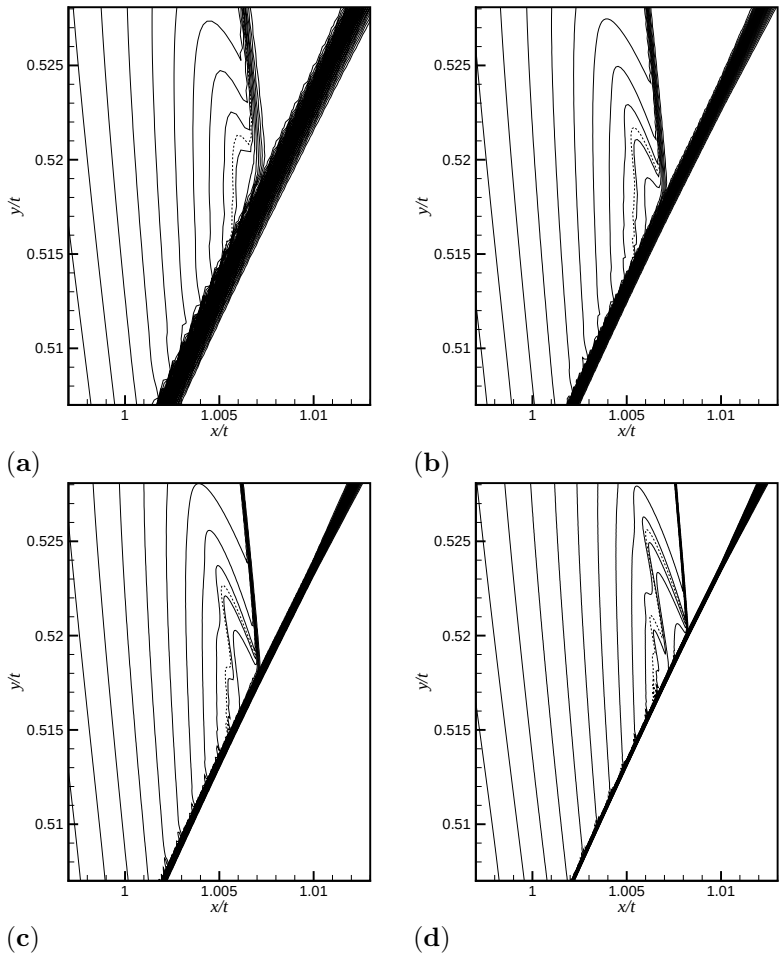


FIG. 4. *A sequence of contour plots illustrating the effect of increasing grid resolution on the numerical solution. The solutions plotted here are for* $a = 0.5$. *The figures show the* u*-contours in the refined grid area near the triple point, with a* u*-contour spacing of* 0.01. *Each grid is refined by a factor of two in both* x/t *and* y/t *in relation to the previous grid. The region shown includes the refined uniform grid area. The dotted line is the sonic line. In* (a), *the refined uniform grid contains* 64×42 *grid points. A supersonic region is visible as a bump in the sonic line, but it is poorly resolved. In* (b), *the refined uniform grid area contains* 128×84 *grid points. The supersonic region appears to be smooth. In* (c), *the refined uniform grid area contains* 256×168 *grid points. There is an indication of a shock wave behind the leading triple point. The refined uniform grid in* (d) *contains* 512×336 *grid points. Two shock waves are visible behind the leading triple point.*

grid beyond this minimum level, a detailed flowfield structure in the region emerged. Figure 4 shows the u-contours and the sonic line near the triple point for a sequence of solutions for $a = 0.5$ computed on successively refined grids. In this sequence, we refined each grid by a factor of two in x/t and y/t in relation to the previous grid. The resolution of the locally refined areas is indicated on the plots. In Figure 4(a)–(b), the sonic line appears fairly smooth. The supersonic region in Figure 4(b) is similar in size, shape, and resolution to the one obtained in [12]. At the next level of refinement, shown in Figure 4(c), there is an indication of the coalescence of u-contours at the rear of the supersonic region and evidence of a second reflected shock there. Finally,

in Figure 4(d), the second reflected shock is better defined, with an indication of a third, weaker shock following it. Further shocks appear in our most refined solution in Figure 3(b).

Returning to Figure 3, we can explain the qualitative differences between the solutions for different values of a in terms of their numerical resolution. As shown in Table 4.1, the size of the supersonic region decreases with increasing a. We therefore had to use more refined grids for higher values of a. For example, the solution shown in Figure 3(d) for $a = 0.8$ was computed using a grid that was a factor of 16 times more refined in x/t and y/t than the grid used in the solution for $a = 0.5$ shown in Figure 3(b). However, the supersonic region in Figure 3(d) is smaller than the one in Figure 3(b) by a linear factor of about 90, resulting in a lower relative resolution. Consequently, the detailed flowfield near the triple point is not visible in Figure 3(d), similar to the under-resolved solutions shown in Figure 4(a)–(b). By contrast, the solutions for $a = 0.3, 0.5, 0.6$ in Figure 3(a)–(c) contain a sequence of shocks and expansions, evident from the pronounced bumps in the sonic line.

There is a small discrepancy between the numerically computed location of the triple point in these figures and the theoretical location of the incident shock in (2.5). The reason for this discrepancy is that the numerical boundary conditions did not give an incident shock that was of exactly constant strength and exactly straight in $(x/t, y/t)$-coordinates. The deviation of the numerical solution for the incident shock from the exact uniform solution was, however, very small. For example, in our numerical solution for $a = 0.5$, the nonuniformity in u and v in the state behind the incident shock is less than 0.4%, and the numerically computed value of the x/t-coordinate of the triple point differs by 0.15% from the theoretical value obtained from (2.5) using the numerically computed value of y/t. We tried a number of different implementations of the numerical scheme and boundary conditions, but none of them gave an exactly straight incident shock. Nevertheless, we saw a supersonic region and the same structure of reflected shocks and expansion fans inside it for all of the implementations.

In Figure 5, we plot closely spaced u-contours, and more widely spaced v-contours, to give a detailed picture of the sequence of shock and expansion waves for $a = 0.5$. Figure 6 is an enlargement of the solution shown in Figure 5 over a very small area close to the leading triple point, which shows the expansion wave that originates at the triple point. The expansion wave is in the family opposite to the shock waves, and it reflects off the sonic line as a compression wave (cf. the discussion in [9]). This compression wave forms a shock that hits the Mach shock and reflects as the next expansion wave. The result is a sequence of triple points, rather than a single triple point. The variables u and v decrease smoothly across the expansion wave at the front of a patch from sonic to supersonic values, moving from right to left in the downstream direction; then u and v jump from supersonic to subsonic values across the shock at the rear of a patch. A very weak wave is visible behind the incident shock in Figure 5(b). This wave is a numerical artifact that is generated when the incident shock crosses from the stretched grid into the uniform grid.

Each shock-expansion pair in the sequence is smaller and weaker than the one preceding it. Four reflected shocks appear to be visible in Figures 5–6. From the numerical data, their approximate strengths, beginning with the leading reflected shock, are

$$[u]_1 \approx 0.08, \qquad [u]_2 \approx 0.02, \qquad [u]_3 \approx 0.01, \qquad [u]_4 \approx 0.003.$$

Here, the jump $[u]$ in u across a reflected shock is measured at the point where the flow

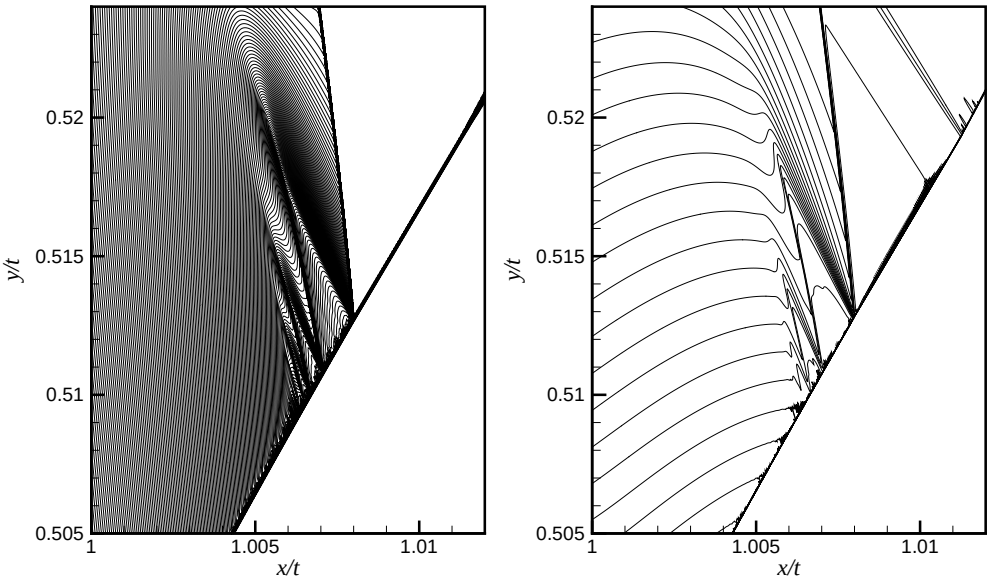

FIG. 5. *A detailed contour plot of* (a) u *and* (b) v *near the triple point for* $a = 0.5$. *The* u*-contour spacing is* 0.0005 *and the* v*-contour spacing is* 0.001. *The sonic line is plotted in Figure* 3(b) *and Figure* 6. *The figure shows a sequence of shock and expansion waves. Each expansion wave is centered at a triple shock intersection and reflects off the sonic line into a compression wave. The compression wave forms a shock wave that intersects the Mach shock, resulting in a sequence of triple points. Three shock-expansion wave pairs and triple points are visible in the plots, with indications of a fourth. The region shown contains the refined uniform grid, which has* 768×608 *grid points.*

behind the shock is sonic. This point is very close to the corresponding triple point on the Mach shock, as shown in Figure 6. It is not possible, however, to determine from the numerical solution whether or not this sonic point coincides exactly with the triple point, as argued by Guderley [9] in the case of steady weak shock Mach reflections.

Three shocks and an expansion fan appear to connect four states at the leading triple point. We label these states 1–4 in Figure 6. Table 4.2 gives values of u and v for each of the states, computed from the numerical solution. For states 2–4, these values were computed at the locations indicated in the figure. The values of (u, v) for state 3 behind the reflected shock were computed close to the point where the flow behind the shock is sonic. This ensures that states 2 and 3 are connected by the reflected shock and not by any part of the expansion fan, which connects states 3 and 4. For state 1, the values for (u, v) were computed at a location sufficiently far ahead of the incident shock so that they were not influenced by the effects of numerical diffusion near the shock.

The velocity components $(\bar{u}, \bar{v})$ in a reference frame moving with the triple point are given by [12] as

$$\bar{u} = u - \left(\xi_* + \frac{1}{4}\eta_*^2\right), \qquad \bar{v} = v - \frac{1}{2}\eta_* u, \tag{4.1}$$

where (ξ_*, η_*) are the (ξ, η)-coordinates of the triple point. From the numerical solu-

tion shown in Figure 6, we obtain $\xi_* = 1.008$, $\eta_* = 0.5128$. We show the corresponding values of $(\bar{u}, \bar{v})$ in Table 4.2. In Figure 7(a), we plot the shock and rarefaction curves for the steady transonic small disturbance equation [12] through each of the four states for $(\bar{u}, \bar{v})$. The plot in Figure 7(b) is an enlarged view of the shock and rarefaction curves for the states 2, 3, and 4. The curves coincide almost exactly with those of a triple point with an expansion fan. We show similar curves through the numerical values of the analogous states at the second triple point in Figure 7(c)–(d). These

TABLE 4.2

Numerically computed values for the four states at the leading and second triple points, from the solution for $a = 0.5$ (see Figure 6). The state ahead of the incident shock is denoted by 1, the state behind the incident shock by 2, the state behind the reflected shock by 3, and the state behind the Mach shock by 4. The states $1'$–$4'$ are the four analogous states at the second triple point. The variables $\bar{u}$ and $\bar{v}$ are defined in (4.1), with $\xi_* = 1.008$, $\eta_* = 0.5128$ for states 1–4, corresponding to the leading triple point, and $\xi_* = 1.007$, $\eta_* = 0.5108$ for states $1'$–$4'$, corresponding to the second triple point.

State	u	v	$\bar{u}$	$\bar{v}$
1	0	0	-1.074	0
2	0.997	-0.5000	-0.077	-0.756

$3'$	1.072	-0.5047	0.000	-0.778
$4'$	1.060	-0.5088	-0.012	-0.779

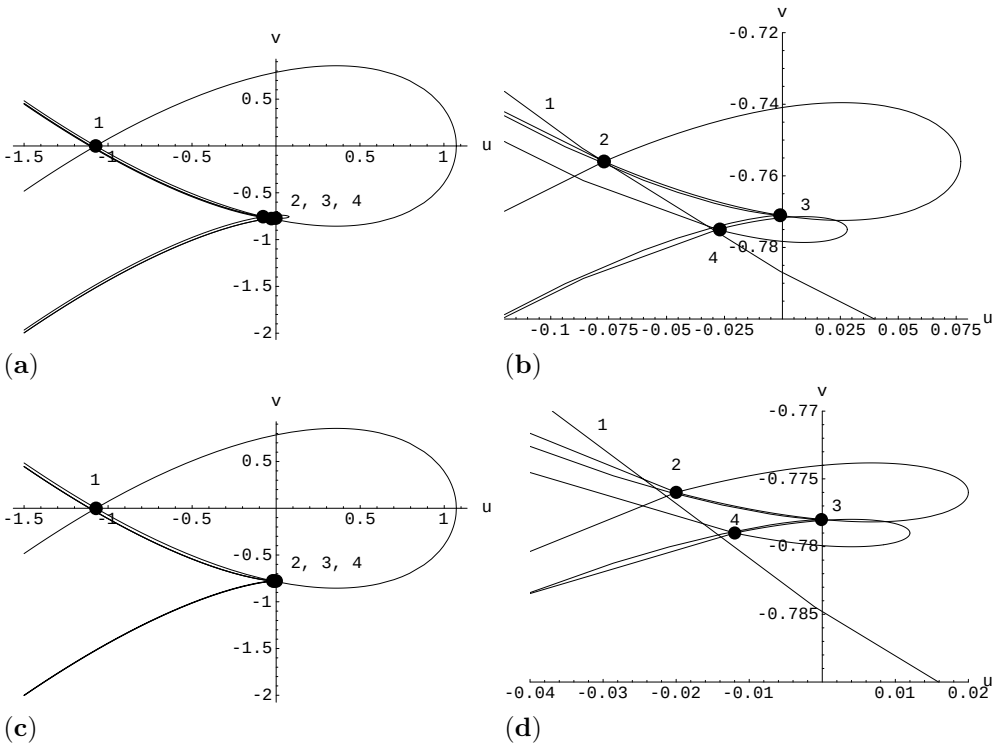

FIG. 7. *The plots in* (a)–(b) *show the theoretical shock and rarefaction curves through each of the four states for $(\bar{u}, \bar{v})$ at the leading triple point (see Figure 6). Their numerical values are given in Table 4.2. (The bars have been omitted from the axis labels.) The curves correspond almost exactly to those of a triple point with an expansion fan. The plots in* (c)–(d) *show similar shock and rarefaction curves for the second triple point. The states 2 and 4 lie slightly off the shock curve of 1; nevertheless, the overall agreement with the curves of a triple point with an expansion fan is excellent.*

plots show that the triple points with expansion fans that we observe numerically are consistent with theory.

To accelerate the convergence of the solution on a very refined grid, we partially

The sharp local peaks correspond to interpolations onto more refined grids. The computation on the most refined grid begins at approximately* $n = 30000$. *The final stage of convergence to a value for the maximum norm of the residual of less than* 10^{-9} *is not shown in the plot.*

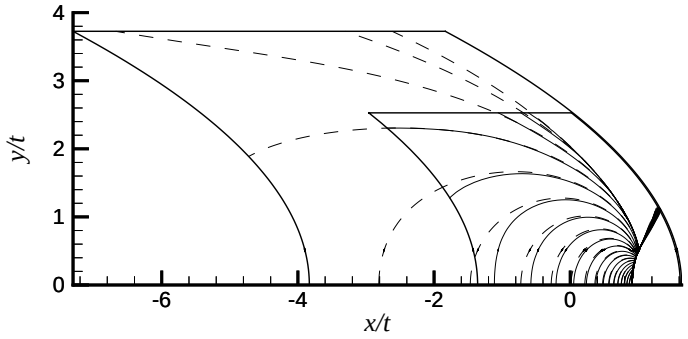

FIG. 9. *A check of the sensitivity of the solutions to the size of the numerical domain, showing* u*-contours for two solutions computed on different sized domains, for* $a = 0.5$. *The full numerical domains are shown, with* u*-contours for the large domain solution (dashed lines) and the small domain solution (solid lines) plotted at the same values of* u. *Contour lines for* u *and* v *near the triple point for both solutions shown here are compared in Figure* 10.

converged the solution on a coarse grid, interpolated the solution onto a refined grid, and repeated this process until the desired resolution was obtained. For example, Figure 4 shows a sequence of solutions obtained on four consecutive intermediate grids during the computation for $a = 0.5$. In Figure 8, we plot the maximum norm of the residual for a typical computation, in which nine grids were used. The sharp local peaks correspond to interpolations onto more refined grids. In the computation shown, the solution on each intermediate grid was converged until the maximum norm of the residual was less than 10^{-7}. The solution on the final grid in a computation was converged until no further change was observed in the details of the solution near the triple point, which typically occurred when the maximum norm of the residual was less than 10^{-9}.

We performed checks to determine the sensitivity of the solutions to the placement of the top and left numerical boundaries, which intersect the region where (2.8) is elliptic. In Figure 9, we plot u-contours for two solutions for $a = 0.5$ computed on

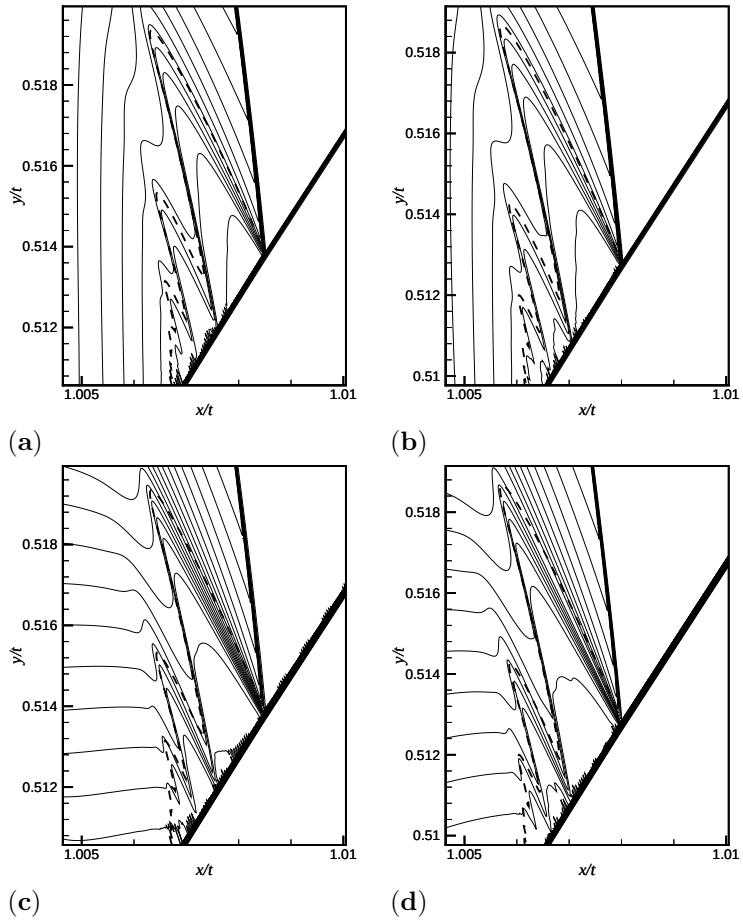

FIG. 10. *A comparison of u- and v-contours near the triple point for the two solutions shown in Figure* 9. *The plots in* (a) *and* (b) *show u-contours for the solutions computed on the larger and smaller domains, respectively, plotted at the same levels of u. The plots in* (c) *and* (d) *show v-contours for the solutions computed on the larger and smaller domains, respectively, plotted at the same levels of v. The dashed line in* (a)–(d) *is the sonic line. The u-contour spacing in* (a)–(b) *is* 0.005*, and the v-contour spacing in* (c)–(d) *is* 0.001.

different sized domains. In this study, the top and left numerical boundaries of the smaller domain were extended, as indicated in the figure, to approximately double the distance from these boundaries to the triple point. The contour lines are plotted at the same values of u for both solutions, with the dashed lines representing the u-contours of the solution on the larger domain. The contour lines approach each other and almost coincide near the triple point.

Figure 10 is an enlargement of the solutions near the triple point, showing u-contours and v-contours for the solutions on the larger and smaller domains. The u-contours in Figure 10(a)–(b) and the v-contours in Figure 10(c)–(d) are plotted at the same values of u and v, respectively, and the sizes of the regions shown in these plots are the same. The dashed line in Figure 10(a)–(d) is the sonic line. The structure of reflected shocks and expansion waves, supersonic patches, and repeating triple points did not change as a result of enlarging the computational domain, and the size of the supersonic region is nearly identical for the two solutions. The main

effect of extending the boundaries is a slight shift in the location of the leading triple point. The shift is approximately 0.05% in x/t and 0.2% in y/t.

5. Discussion. These numerical results raise the question of whether there is an infinite sequence of triple points in an inviscid weak shock Mach reflection. Gamba, Rosales, and Tabak [7] prove, under some mild assumptions, that the flow behind a triple point cannot be strictly subsonic for the unsteady transonic small disturbance equation. Therefore, if there were a finite sequence of supersonic triple points, there would presumably have to be a smooth transition from supersonic to subsonic flow at the rear of the final supersonic patch. Such a smooth transition appears unlikely to occur, however, because the resulting nonlinear mixed-type boundary value problem would be overdetermined [9, 15].

The most plausible alternative to a finite sequence of triple points terminated by a shock-free supersonic patch is an infinite sequence of more closely spaced triple points, weaker shock-expansion pairs, and smaller supersonic patches that accumulate at the rear sonic point of the supersonic region on the Mach shock. In this structure, the shock and expansion waves would reflect back and forth infinitely many times between the Mach shock and the sonic line, into the rear sonic point. The inviscid equations do not define a length scale so solutions may, in principle, develop arbitrarily small structures. We do not know, however, of a way to confirm or deny the existence of an infinite sequence of patches whose size shrinks to zero.

A remarkable feature of the numerical solutions is the extraordinarily small size of the supersonic region, especially for larger values of a. For example, when $a = 0.8$, the height of the supersonic region is approximately 0.05% of the height of the Mach shock. Once the inverse shock slope a is fixed, there are no further parameters in the problem, so the small size of the region cannot be explained by the dependence of the solution on a small parameter. The shock reflection pattern is produced by the requirement that the y-velocity component v, which is equal to $-a$ behind the incident shock, must return to zero at the wall $y = 0$. Thus, a global scale for v_η is

$$\alpha = \frac{a}{(y/t)_{\text{t.p.}}},$$

where $(y/t)_{\text{t.p.}}$ is the (y/t)-location of the triple point. The supersonic region is produced by the expansion fan that is formed when the leading reflected shock collides with the incident shock. If Δv is the change in v across this fan, then a local scale for v_η near the triple point is

$$\beta = \frac{\Delta v}{\Delta(y/t)},$$

where $\Delta(y/t)$ is the height of the supersonic region. From the numerical data, we find that α is much less than β for larger values of a, corresponding to a rapid change in the solution near the triple point and a tiny supersonic region. For example, when $a = 0.5$, we find from the numerical data that $\alpha/\beta \approx 1.0$, but when $a = 0.8$, we find that $\alpha/\beta \approx 0.05$. Since the largest value of a that we investigated is 0.8, we neither know if solutions for higher values of a contain a supersonic region with a sequence of triple points over the entire range $0.8 < a < \sqrt{2}$, nor know if the transition between regular and Mach reflection occurs exactly at $a = \sqrt{2}$.

A repeating structure of supersonic patches and triple points with expansion fans appears to provide a resolution of von Neumann's triple point paradox within

the framework of inviscid shock theory, and viscosity is not required to explain the structure of a weak shock Mach reflection. Nevertheless, in view of the extremely small size of the supersonic region, it is important to consider the likely effect of physical viscosity on the inviscid description. Since the triple point lies in the interior of the fluid, it is reasonable to expect that boundary layer effects do not influence the local structure of the solution. Thus, the main effect of viscosity is to thicken the shocks. If the size of the supersonic region is smaller than the viscous thickness of the reflected shock, then the sonic line is embedded inside the viscous profile of the reflected shock, and the local structure of the solution near the triple point is dominated by viscous effects. Since the numerical scheme includes numerical viscosity, which mimics the effect of physical viscosity, the plots in Figure 4 of the solution with increasing numerical resolution presumably indicate the effect of decreasing physical viscosity on the solution. At resolutions lower than the ones shown in Figure 4, the supersonic region disappears completely, and the sonic line runs down the inside of the reflected shock, through the triple point, and down the Mach shock.

To compare the width of the supersonic region with the viscous shock thickness, we suppose that the reflected shock Mach number is M_r and the mean free path in the gas is λ. The thickness δ of the reflected shock is then approximately given by [22]:

$$\delta = \frac{3\lambda}{M_r - 1}.$$

The incident and Mach shocks are thinner than the reflected shock because they are stronger. If the width of the supersonic region in x/t in the solution of the unsteady transonic small disturbance equation is $\Delta(x/t)$, then, from [12], the asymptotic width d of the supersonic region parallel to the wall in physical variables is given by

$$d = 2(M-1)\Delta(x/t)L.$$

Here, L is the distance traveled by the Mach shock along the wall, from the corner of the wedge to the reflection point, and M is the Mach number of the incident shock. Hence

$$\frac{d}{\delta} = c(M-1)^2\frac{L}{\lambda},$$

where the dimensionless constant c is defined by

$$c = \frac{2}{3}\Delta\left(\frac{x}{t}\right)[u]_r, \tag{5.1}$$

and $[u]_r$ is the ratio of the reflected and incident shock strengths,

$$[u]_r = \frac{M_r - 1}{M - 1}.$$

The supersonic region is much larger than the reflected shock structure if $d \gg \delta$, meaning that

$$L \gg \frac{\lambda}{c(M-1)^2}.$$

The value of c in (5.1) may be estimated from the numerical data in Table 4.1. The supersonic region is easier to observe for larger values of c, and the largest value of

c for the results obtained here is $c \approx 6 \times 10^{-5}$ for $a = 0.5$. For smaller values of a, the reflected shock becomes very weak and thick, while for larger values of a, the supersonic region becomes extremely small. The mean free path in argon at standard conditions is approximately $\lambda = 6 \times 10^{-5}$ mm. Therefore, for a shock reflection in argon with $a = 0.5$, we estimate that the supersonic region separates from the viscous profile of the reflected shock when $L \gg (M-1)^{-2}$ mm. Even for a relatively strong weak shock with $M = 1.1$, this estimate gives $L \gg 100$ mm. Thus, in order to observe the supersonic region in a shock tube experiment, the test section of the tube would have to be significantly longer than 100 mm.

It is striking that such a complex inviscid structure forms on a length scale that is comparable with, or less than, the viscous shock thickness in typical experiments.

6. Conclusion. We have presented numerical evidence of a structure of reflected shocks and expansion waves and a sequence of triple points and supersonic patches in a tiny region behind the leading triple point of an inviscid weak shock Mach reflection. The presence of the expansion fans at the triple points resolves the von Neumann paradox of weak shock reflection. Qualitative arguments, based on the well-posedness of mixed-type boundary value problems, suggest that there may be an infinite sequence of triple points and patches in an inviscid reflection, but a proof or disproof of this suggestion is lacking. The numerical solutions provide an estimate of the size of the supersonic region, which may enable its experimental detection.

MULTIPLE BUMPS IN A NEURONAL MODEL OF WORKING MEMORY*

CARLO R. LAING†, WILLIAM C. TROY‡, BORIS GUTKIN§, AND G. BARD ERMENTROUT‡

Abstract. We study a partial integro-differential equation defined on a spatially extended domain that arises from the modeling of "working" or short-term memory in a neuronal network. The equation is capable of supporting spatially localized regions of high activity which can be switched "on" and "off" by transient external stimuli. We analyze the effects of coupling between units in the network, showing that if the connection strengths decay monotonically with distance, then no more than one region of high activity can persist, whereas if they decay in an oscillatory fashion, then multiple regions can persist.

Key words. short-term memory, integro-differential equation, coupling, homoclinic orbits

1. Introduction.

Working memory, which involves the holding and processing of information on the time scale of seconds, is a much studied area of neuroscience [3, 9, 24, 35, 37]. Experiments in primates [8, 15, 29] have shown that there exist neurons in the prefrontal cortex that have elevated firing rates during the period in which an animal is "remembering" the spatial location of an event before acting on the information being remembered. Realistic models for this type of activity have involved spatially extended systems of coupled neural elements and the study of spatially localized areas of high activity in these systems. Previous studies have involved "rate" models [1, 19, 22, 37] in which a neural element is described by a single scalar variable, e.g., a firing rate and more complicated "spiking" models [9, 24, 35], which take into account the intrinsic dynamics of single neurons.

In this paper we extend the 1977 work of Amari [1] who found *single* spatially localized regions of high activity ("bumps") in rate models of the form

$$\frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} w(x-y) f(u(y,t))\, dy + s(x,t) + h. \tag{1.1}$$

Equation (1.1) models a single layer of neurons. The function $u(x,t)$ denotes the "synaptic drive" or "synaptic input" to a neural element at position $x \in (-\infty, \infty)$ and time $t \geq 0$. The connection function $w(x)$ determines the coupling between elements, and the nonnegative function $f(u)$ gives the firing rate, or activity, of a neuron with input u. Neurons at a point x are said to be active if $f(u(x,t)) > 0$. The function $s(x,t)$ represents a variable external stimulus. Finally, the parameter h denotes a *constant* external stimulus applied uniformly to the entire neural field. Although

the model we study has been used to model working memory, similar equations arise in neural theory as applied to vision and robotic navigation [17], head direction systems [39], and cognitive development in infants [32]. We also mention recent analyses of wave propagation when inhomogeneities are present in the underlying neural substrate [4] and also in neural networks with axo-dendritic synaptic interactions [10].

Our goal is to extend Amari's results in two ways. First, in the next section we will extend the analysis of the original model in which $w(x)$ is assumed to have exactly one zero in $(0,\infty)$, and $f(u)$ is a step function. We will determine a simple set of assumptions on w and f for which (1.1) has stationary "single-bump" solutions. Our assumptions will allow us to obtain a more precise description of the shape of solutions. We will also investigate the existence of "double-bump" solutions.

In section 3 we relax the restrictions on w and f to include both oscillatory connection functions which change sign infinitely often and *continuous* firing rate functions. Our goal here is to show that "multi-bump" solutions of (1.1) exist over an appropriate range of parameters. The extension of $f(u)$ to a continuous function will allow us to derive an ordinary differential equation, specific solutions of which are steady-states of (1.1). This differential equation, which is derived in section 5, will be invaluable in proving the existence or otherwise of such "multi-bump" solutions. Sections 6 and 7 are devoted to studies of its N-bump solutions. In section 8 we extend the model to two space dimensions and present numerical evidence for multi–bumps solutions. Sections 9 and 10 contain proofs of two theorems stated in the text, and a summary of our results is given in section 11.

2. "Mexican hat" coupling. We begin with a description of the assumptions and conclusions obtained by Amari [1] where the coupling function $w(x)$ satisfies the following:

(H_1) $w(x)$ is symmetric, i.e., $w(-x) = w(x)$ for all $x \in \mathbf{R}$;
(H_2) $w(x) > 0$ on an interval $(-\bar{x}, \bar{x})$, and $w(-\bar{x}) = w(\bar{x}) = 0$;
(H_3) $w(x)$ is decreasing on $(0, \bar{x}]$;
(H_4) $w < 0$ on $(-\infty, -\bar{x}) \cup (\bar{x}, \infty)$.

An additional condition which Amari uses but does not explicitly state is

(H_5) w is continuous on $\mathbf{R}$, and $\int_{-\infty}^{\infty} w(y)\,dy$ is finite.

A coupling satisfying (H_2) and (H_4) produces "lateral inhibition" [14]. That is, condition (H_2) means that nearby neural elements excite one another, but (H_4) results in an "inhibitory effect" if the distance between neural elements is greater than a certain value, $\bar{x}$. Conditions (H_1), (H_3) and (H_5) are general requirements which allow for a tractable mathematical analysis of (1.1). In order to rigorously determine the shape of steady-state solutions of (1.1), we make one final assumption on the coupling function $w(x)$:

(H_6) $w(x)$ has a unique minimum on $\mathbf{R}^+$ at a point $x_0 > \bar{x}$, and $w(x)$ is strictly increasing on (x_0, ∞).

A connection function which satisfies conditions (H_1)–(H_6) is

$$w(x) = Ke^{-k|x|} - Me^{-m|x|}, \tag{2.1}$$

where $0 < M < K$ and $0 < m < k$. An example of this "Mexican hat" type function is given in Figure 1 for $K = 3.5$, $M = 3$, $k = 1.8$, and $m = 1.52$. For simplicity, Amari assumes (see Figure 1) that the firing rate $f(u)$ is the Heaviside step function

$$f(u) = \begin{cases} 0, & u \le 0, \\ 1, & u > 0. \end{cases} \tag{2.2}$$

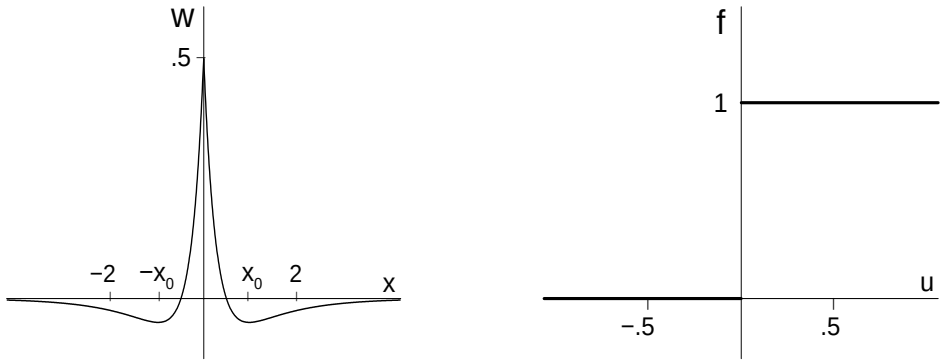

FIG. 1. *Mexican hat function* (2.1) *for parameters given in the text, and the Heaviside firing rate function* (2.2).

The effect of (2.2) is that a neuron fires at its maximum rate when the input exceeds the threshold value $u = 0$ and does not fire otherwise. Thus, (2.2) can be viewed as modeling neural elements whose firing rates "saturate" immediately, since increasing the input further does not cause the firing rate to increase, provided the input is above the threshold value.

Under assumptions (H_1)–(H_5), Amari analyzes the existence and stability of equilibrium solutions of (1.1) under the assumption that there is no "inhomogeneous" external stimulus $s(x,t)$. That is, he sets $\partial u(x,t)/\partial t = 0$ and $s(x,t) = 0$. This reduces (1.1) to the time independent equation

$$u(x) = \int_{-\infty}^{\infty} w(x-y) f(u(y))\, dy + h. \tag{2.3}$$

Solutions of (2.3) are called equilibrium or *stationary* solutions. An important observation is that the neural system is still subject to the constant external stimulus h applied uniformly to the entire neural field. Note that if $h \leq 0$, then the constant function $u = h$ is a solution of (2.3).

Single-bump solutions: For a given distribution $u(x)$, Amari defines its region of excitation to be the set

$$R(u) = \{x | u(x) > 0\}.$$

He then defines a *localized excitation* to be a pattern $u(x)$ whose region of excitation is a *finite* interval, i.e., $R(u) = (a_1, a_2)$. If $R(u)$ is connected, we refer to the pattern as a "single-bump", or "1-bump" solution. Furthermore, because (2.3) is homogeneous, it is easily verified that $u(x-a)$ is a solution whenever $u(x)$ is a solution. Thus, without loss of generality, we assume that the region of excitation for a single-bump solution has the form

$$R(u) = (0, a).$$

Remark. If (2.3) has a solution whose region of excitation consists of $N > 1$ disjoint, finite connected intervals, the solution is called an *N-bump* solution. A major goal of this paper is to show that multi-bump solutions exist for (2.3) when the restrictions on $w(x)$ and $f(u)$ are relaxed.

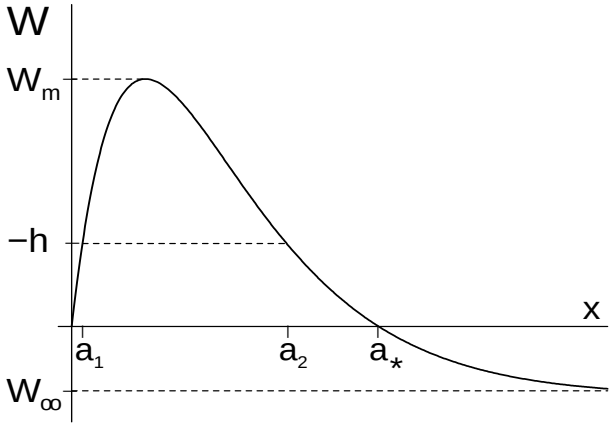

FIG. 2. $W(x)$, (2.4), *for parameters given in the text. We have chosen* h *to be negative, so that* $W_\infty < 0 < -h < W_m$.

In his analysis of single-bump solutions, Amari makes use of the function

$$W(x) = \int_0^x w(y)\,dy \tag{2.4}$$

and the related quantities

$$W_m = \max_{x>0} W(x) \quad \text{and} \quad W_\infty = \lim_{x\to\infty} W(x). \tag{2.5}$$

Conditions (H_1) and (H_5) imply that $W(x)$ is odd, and that W_∞ is finite, respectively. Amari observes that if (2.3) has a single-bump solution $u(x)$ whose region of excitation is given by $R(u) = (0, a)$, then $u(x)$ satisfies

$$u(x) = \int_0^a w(x-y)\,dy + h = W(x) - W(x-a) + h. \tag{2.6}$$

At the value $x = a$, (2.6) reduces to

$$W(a) = -h \tag{2.7}$$

since $W(x)$ is odd and $u(0) = u(a) = 0$. In turn, Amari claims that if $a > 0$ and $h < 0$ satisfy (2.7), then

$$u(x) = W(x) - W(x-a) + h \tag{2.8}$$

is a single-bump solution of (2.3) for which $R(u) = (0, a)$.

For a given $h \le 0$, (2.7) may have zero, one or two positive solutions. The exact number is determined by the relative values of W_∞, W_m, and h. In Figure 2 we construct the $W(x)$ corresponding to the Mexican hat function illustrated in Figure 1. That is, we use the formula for $w(x)$ given in (2.1) for the specific values $K = 3.5$, $k = 1.8$, $M = 3$, and $m = 1.52$. In Figure 2 we see that if $W_\infty < 0 < -h < W_m$, then there are two values, a_1 and a_2, which satisfy (2.7). Setting $a = a_1$ and $a = a_2$ in (2.8)

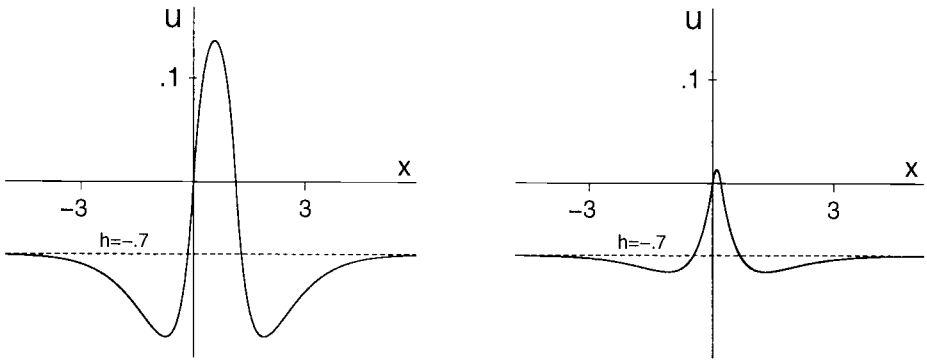

FIG. 3. *Stable (left) and unstable (right) single-bump solutions of* (2.3) *for the functions* w *and* f *shown in Figure* 1 *and* $h = -0.7$.

gives the corresponding single-bump solutions of (2.3). In Figure 3 we illustrate these two solutions for the value $h = -0.7$. Amari gives arguments that indicate that the large amplitude solution corresponding to $a = a_2$ (i.e., the first solution in Figure 3) is stable, while the second, smaller amplitude solution in Figure 3 corresponding to $a = a_1$ is unstable. Furthermore, as Figure 2 indicates, if $h = 0$, then (2.7) holds only at the positive value $a = a_2 = a_*$. Setting $a = a_*$ and $h = 0$ in (2.8), one can easily show that the resulting function is still a single-bump solution of (2.3).

We note that if (2.7) has a solution for some $a > 0$ and $h > 0$, then (2.8) implies that $u(x) > 0$ for all large x, contradicting the supposition that $R(u) = (0, a)$ is finite. Thus, single-bump solutions do not exist if $h > 0$.

Finally, we make a few observations concerning the *shape* of nonconstant single-bump solutions (see Figure 3). First, we conclude from hypotheses (H_1)–(H_4) and (2.8) that $u(x)$ is symmetric with respect to $x = a/2$ and that $u(x)$ is increasing on $(0, a/2)$ and decreasing on $(a/2, a)$. When we consider the additional hypotheses (H_5) and (H_6), it follows from standard analysis that the solution $u(x)$ has a unique minimum on $(0, \infty)$, and that $u(x) \to h$ from below as $x \to \infty$.

Double-bump solutions: We now consider the possible existence of double-bump solutions. A solution $u(x)$ of (2.3) is called a double-bump, or 2-bump, solution if there are values $0 < a < b < c$ such that

$$\begin{cases} u > 0 \quad \text{on} \quad (0, a) \cup (b, c), \\ u(0) = u(a) = u(b) = u(c) = 0, \\ u < 0 \quad \text{otherwise.} \end{cases} \tag{2.9}$$

Thus, a 2-bump solution is one whose region of excitation consists of two disjoint, connected intervals. The quantity $b - a$ is the distance between bumps. Our goal is to prove the existence or nonexistence of double-bump solutions of (2.3) which satisfy property (2.9). In general, a rigorous resolution of this problem is very difficult. Before stating our first result, we recall that x_0 denotes the unique positive value at which the coupling function $w(x)$ attains its global minimum and that $w(x)$ is strictly increasing on (x_0, ∞) (see Figure 1). In the following result we eliminate a class of 2-bump solutions.

THEOREM 2.1. *Under hypotheses* (H_1)–(H_6) *there is no value* $h \in \mathbf{R}$ *for which the problem* (2.2)–(2.3) *has a* 2*-bump solution such that the distance between bumps satisfies* $b - a \geq x_0$.

Remark. Theorem 2.1 does not completely eliminate the existence of all double-bump solutions. For example, our proof does not address the existence of general 2-bump solutions such that the distance $b - a$ satisfies $b - a < x_0$. However, it can be shown that under the assumptions $c - b = a$, i.e., equal width bumps, and $W_\infty < 0$, (2.2)–(2.3) can support (possibly unstable) 2-bump solutions [33] (and see [18]). We also have no results concerning existence or nonexistence of N-bump solutions where $N \geq 3$. The resolution of these problems remains open.

Because the proof of Theorem 2.1 is somewhat technical, we postpone the details until section 9. We proceed in the next section to describe the main focus of our investigation.

3. Statement of main results. The main goal of our investigation is to extend the analysis in section 2 and determine conditions on the connection and firing functions so that the integral equation (1.1) has stable *N-bump* solutions. For this we choose a specific $w(x)$ which changes sign infinitely often, and we let $f(u)$ be a continuous extension of the Heaviside function. For simplicity it is assumed that both $s(x,t) = 0$ and $h = 0$. Setting $h = 0$ will be compensated for by including a threshold in f. Thus, we study the problem

$$\frac{\partial u(x,t)}{\partial t} = -u(x,t) + \int_{-\infty}^{\infty} w(x-y) f(u(y,t))\, dy, \tag{3.1}$$

where

$$w(x) = e^{-b|x|}(b \sin|x| + \cos x) \tag{3.2}$$

and

$$f(u) = 2e^{-r/(u-th)^2} H(u - th). \tag{3.3}$$

Here $th > 0$, $b > 0$, and $r > 0$ are constants. The parameter b controls the rate at which the oscillations in w decay with distance. As shown in Figure 4, they decay more rapidly as b is increased. It is hoped that this oscillatory form of coupling better represents the connectivity known to exist in the prefrontal cortex, where labeling studies have shown that coupled groups of neurons form spatially approximately periodic stripes [16, 26, 27]. Interestingly, it has been proposed that disruption of this "lattice" of connectivity may be responsible for some of the symptoms of schizophrenia [27]. Note that we are not addressing the processes involved in the *formation* of these stripes, but are interested in the possible patterns of neural activity that can exist in the system once these patterns are in place. Also, although $w(x)$ does not have finite support we know that in the brain, connections cannot exist over arbitrarily large distances, so this is obviously an approximation to reality. It would be an interesting problem to analyze (3.1) with a function $w(x)$ that had more than one zero crossing for $x > 0$ yet had finite support. Finally, it is interesting to observe that the coupling given in (3.2) is differentiable at $x = 0$, and that $w'(0) = 0$. This is proved in [23] and easily follows from the formal definition of derivative. In contrast, the lateral inhibition coupling given in (2.1) is not differentiable at $x = 0$. However, we believe that the only significant feature for analysis of the models is continuity of w at $x = 0$.

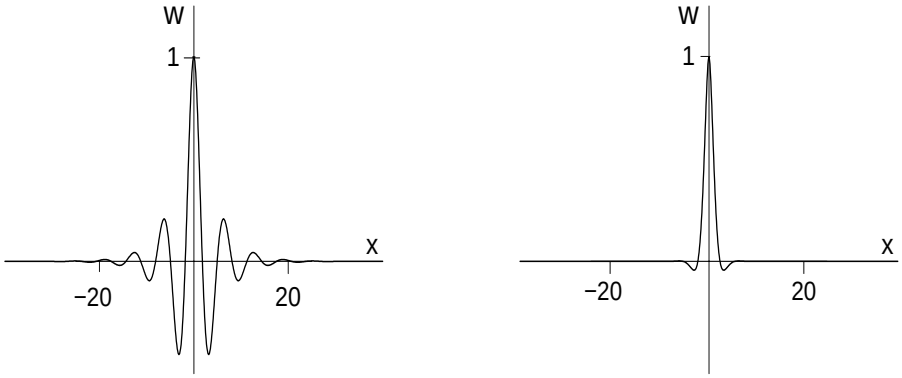

FIG. 4. $w(x)$, (3.2), *for* $b = 0.25$ *(left) and* $b = 1.0$ *(right).*

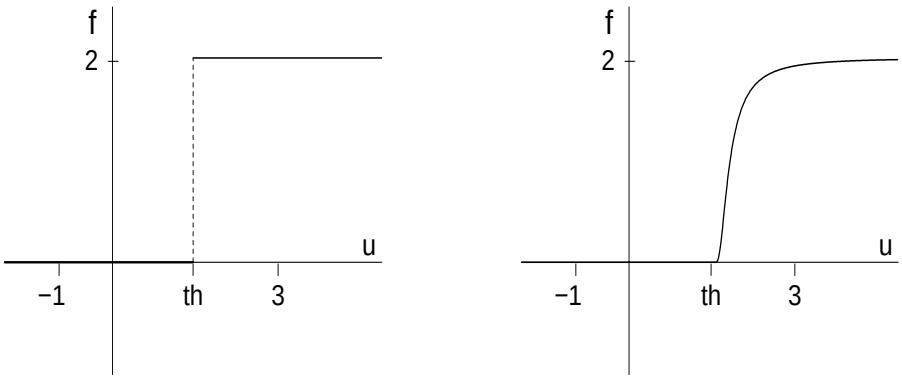

FIG. 5. $f(u)$, (3.3), *for* $r = 0$ *(left) and* $r = 0.1$ *(right), with* $th = 1.5$.

The parameter th denotes the *threshold* that is now included in $f(u)$. The coefficient of 2 in (3.3) was chosen merely for convenience. We note that $f(u) = 0$ if and only if $u \leq th$. Furthermore, $f(u)$ is a C^∞ function when $r > 0$, and r controls the rate of increase of $f(u)$ for u just past threshold. The differentiability of f will be useful when we derive a differential equation, specific solutions of which are equivalent to steady-state solutions of (3.1). In Figure 5 we set $th = 1.5$ and graph $f(u)$ for $r = 0$ (left) and $r = 0.1$ (right). When $r = 0$, $f(u)$ is just twice the Heaviside function. For $r > 0$, $f(u)$ is a *continuous* function which rapidly approaches 2 from below as u increases past th.

The choice of the functions (3.2) and (3.3) had some arbitrariness to it. The important features of (3.3) are that $f(u) = 0$ for $u \leq th$ and that $f(u)$ is sufficiently differentiable. The choice of (3.2) was made not only because it has the appropriate shape (decaying oscillations, with approximately the same distance between successive maxima), but also because the form of its Fourier transform makes the ordinary differential equation derived in section 5 particularly simple. Our hope is that the

qualitative details of the following results do not depend on the exact form of (3.2) and (3.3).

As before, we define a "stationary solution" to be a time independent solution of (3.1)–(3.3). Thus, a stationary solution satisfies the equation

$$u(x) = \int_{-\infty}^{\infty} w(x-y) f(u(y)) dy. \tag{3.4}$$

Before proceeding with our study of N-bump stationary solutions, we need to make precise the definition of the "region of excitation." For a solution of (3.4), we define its region of excitation to be the set

$$R(u) = \{x | u(x) > th\}. \tag{3.5}$$

A solution of (3.4) is an N-bump solution if its region of excitation consists of exactly N disjoint, finite connected intervals.

In the next section we begin our investigation of N-bump stationary solutions by considering the limiting value $r = 0$. As $r \to 0^+$ we note that the firing function tends to the discontinuous step function depicted in Figure 5 (left). In sections 5–7 we extend our studies to the case $r > 0$, for which the firing function $f(u)$ is *continuous.* As mentioned above, when $r > 0$ we find that there is an equivalent differential equation, some of whose solutions are solutions of (3.4). In section 5 we derive this fourth order equation and state our second theorem which determines a range of parameter values over which N-bump solutions can possibly exist. The differential equation will be especially useful to us in sections 6 and 7 where we give an extensive numerical investigation of the global behavior of entire families of N-bump solutions as parameters vary. Section 6 consists of a study of families of N-bump solutions for odd values of N, while section 7 covers even values of N.

4. The limiting problem: $r = 0$. It is natural to begin our investigation by considering the case $r = 0$ where $f(u)$ reduces to a multiple of the Heaviside function. In order to understand this case, we investigate the existence of N-bump solutions for a specific choice of the parameters b and th. For convenience we set $th = 1.5$ and $b = 0.25$ (see Figures 4 and 5 in the previous section). At these values our computations suggest that the problem (3.1)–(3.3) has at least four *stable* N-bump solutions. These are shown on the *left* in Figures 6–9, where the initial profile $u(x, 0)$ is represented by the dashed curve, and the solid curve represents $u(x, t)$ at $t = 60$. The formula for $u(x, 0)$ is given by

$$u(x,0) = \cos\left(\frac{Lx}{12.5\pi}\right) \exp\left(-\left(\frac{Lx}{12.5\pi}\right)^2\right), \quad -12.5\pi < x < 12.5\pi. \tag{4.1}$$

The parameter $L > 0$ allows us to vary the initial profile $u(x, 0)$. Equation (3.1) was numerically solved by spatially discretizing it on a uniform grid and then moving forward in time with an Euler step until convergence. The integral was approximated by a Reimann sum; note that the convolution can be performed more efficiently with a fast Fourier transform.

In the left panel in Figures 6 and 7 we set $L = 6$ and $L = 2.5$, and find that $u(x, t)$ approaches stable 1-bump and 2-bump solutions, respectively, as $t \to \infty$. Our computations imply that these also are solutions of

$$u(x) = \int_{-\infty}^{\infty} w(x-y) f(u(y)) dy. \tag{4.2}$$

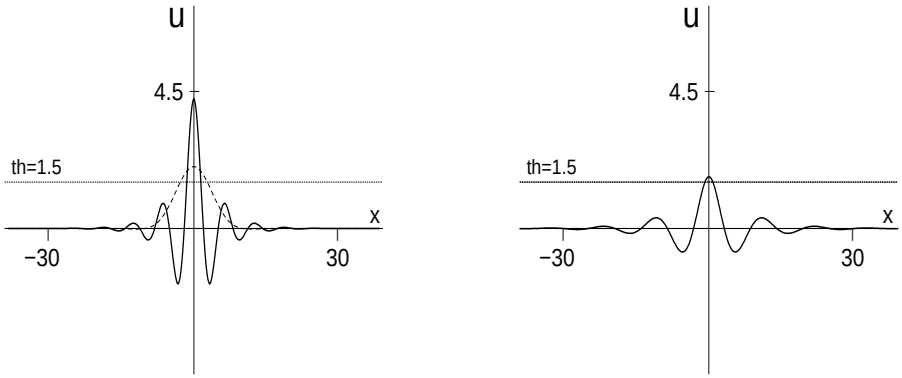

FIG. 6. *Stable (left) and unstable (right)* 1*-bump solutions:* $r = 0,\ th = 1.5,\ b = 0.25$.

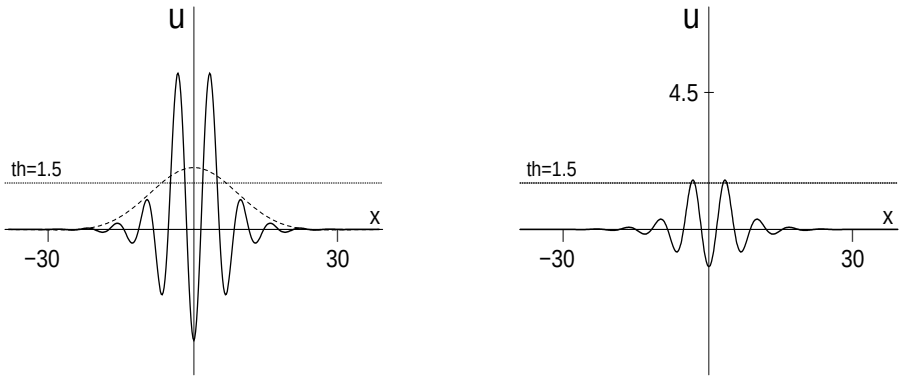

FIG. 7. *Stable (left) and unstable (right)* 2*-bump solutions:* $r = 0,\ th = 1.5,\ b = 0.25$.

Our computations also indicate that there exist *unstable* 1-bump and 2-bump stationary solutions. These are shown in the right panel in Figures 6 and 7. It is interesting to compare these unstable solutions with the unstable single-bump solution of the original Amari model described in section 2 (see Figure 3). Some of the stable solutions in Figures 6–9, Figures 14–17, Figure 19, Figure 23, Figures 25–28, and Figure 30 were found by numerically integrating (3.1) to a steady state, and the continuation program Auto97 [12, 13] was used to find the unstable solutions and reconfirm some of the stable solutions already found. We provide more detail in section 6.

Even though the system (3.1)–(3.3) is defined on an infinite domain, when numerically integrating (3.1) it must be finite. We have chosen a domain size of 25π, centered at $x = 0$. While it is unlikely that the boundaries have a significant effect on the spatially localized solutions shown in Figures 6 and 7, they will have a greater effect on broader solutions such as those in Figures 8 and 9. When comparing homoclinic orbits for the differential equation derived in section 5 (which represent solutions on an infinite domain) with solutions obtained from the numerical integration of (3.1),

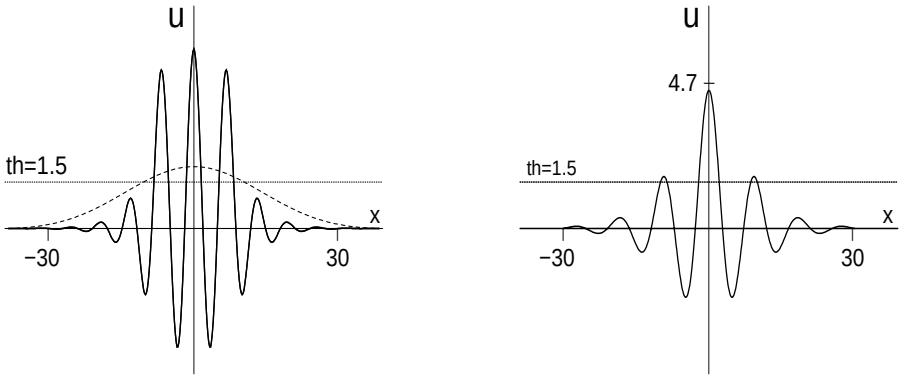

FIG. 8. *Stable (left) and unstable (right)* 3*-bump solutions:* $r = 0,\ th = 1.5,\ b = 0.25$.

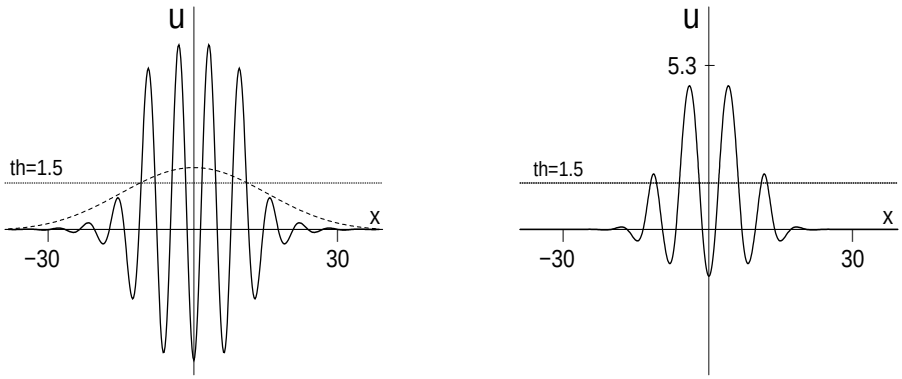

FIG. 9. *Stable (left) and unstable (right)* 4*-bump solutions:* $r = 0,\ th = 1.5,\ b = 0.25$.

the difference in domains should be kept in mind.

In the left panel of Figures 8 and 9 we let $L = 1.6$ and $L = 1.5$, respectively, and found that $u(x,t)$ tended to stable 3-bump and 4-bump stationary solutions as $t \to \infty$. Again, our computations indicate that there exist corresponding *unstable* 3-bump and 4-bump stationary solutions. These are shown in the right panels of Figures 8 and 9. Although we do not show the results, our computations indicate that if $L = 1$, then $u(x,t)$ tends to a stable 5-bump stationary solution as $t \to \infty$. For the values $r = 0$, $b = 0.25$, and $th = 1.5$, and a sufficiently large domain, we conjecture that both stable and unstable N-bump stationary solutions exist for each $N \geq 1$. We leave the resolution of this conjecture as an open problem.

We now develop a necessary mathematical criterion for the existence of 1-bump solutions of (4.2) when $r = 0$. In this case the firing function $f(u)$ defined in (3.3) reduces to twice the Heaviside function, as shown in the left panel of Figure 5. The solutions computed in Figures 6–9 are symmetric with respect to $x = 0$. Thus, we first look for single-bump *symmetric* solutions. We assume that there is a value $a > 0$

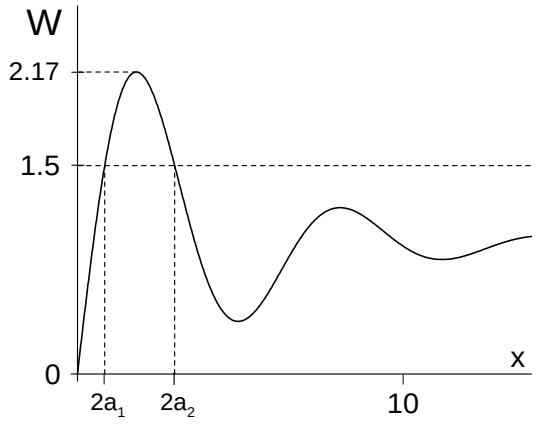

FIG. 10. $W(x)$, (4.4): $th = 1.5,\ b = 0.25$.

such that $u(x) > th$ on $(-a, a)$ and $u(x) < th$ if $|x| > a$. Under these assumptions, (4.2) reduces to

$$u(x) = \int_{-a}^{a} 2w(x-y)\,dy. \tag{4.3}$$

In analogy with section 2, we define

$$W(x) \equiv \int_{0}^{x} 2w(y)\,dy, \tag{4.4}$$

and note that $W(0) = 0$. From (4.3) and (4.4) it follows that

$$u(x) = W(x+a) - W(x-a). \tag{4.5}$$

Thus, we conclude that the condition $u(a) = th$ can be written as

$$W(2a) = th. \tag{4.6}$$

Figure 10 shows that, when $b = 0.25$ and $th = 1.5$, there are exactly two positive values, a_1 and a_2, for which (4.6) is satisfied. In Figure 11 we keep $th = 1.5$ and decrease b from $b = 0.25$. The left panel shows that there is a critical $b \approx 0.057$ at which a third value $a = a_3$ appears which satisfies $W(2a_3) = th$. For $0 < b < 0.057$ there are *at least* four solutions of (4.6). For example, we set $b = 0.03$ and illustrate this property in the right panel of Figure 11. As b decreases further, the number $\nu = \nu(b)$ of solutions of (4.6) (i.e., the number of symmetric 1-bump solutions of (4.2)) continues to increase, with $\nu(b) \to +\infty$ as $b \to 0^+$. In Figure 12 we see that the number $\nu(b)$ of solutions of (4.6) also increases if we keep b fixed at $b = 0.25$ and then lower the value of th from $th = 1.5$. Here we find that there is a critical value $th^* \equiv W(\infty) = 4b/(b^2+1)$ such that $\nu(b) \to +\infty$ as $th \to th^*$. We conjecture that each solution of (4.6) corresponds to a single-bump solution of the integral equation

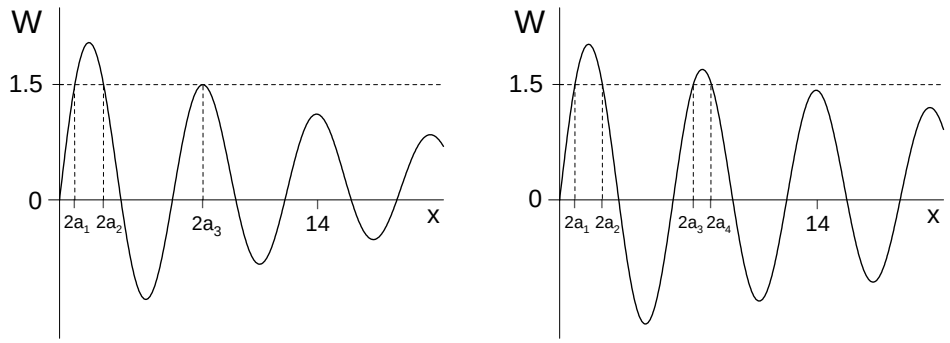

FIG. 11. $W(x)$, (4.4): $th = 1.5$; $b = 0.057$ *(left) and* $b = 0.03$ *(right).*

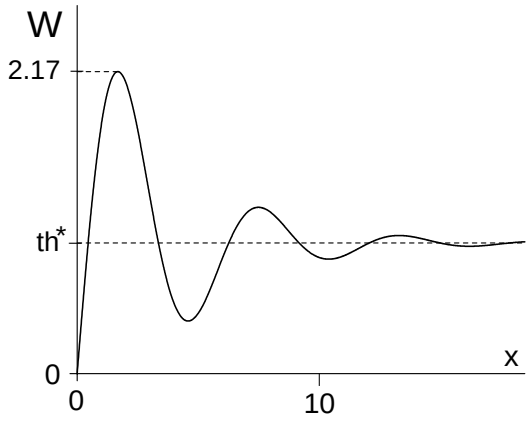

FIG. 12. $W(x)$, (4.4): $b = 0.25$, $th^* = 0.94$.

(4.2). In order to prove this conjecture, one would need to check that for all values of a satisfying (4.6), the function defined in (4.5) satisfied

$$u(x) > th \text{ for } -a < x < a \text{ and } u(x) < th \text{ for } x < -a \text{ or } a < x, \tag{4.7}$$

i.e., that the form of $u(x)$ given in (4.5) is actually a 1-bump solution. It would also be interesting to develop a criterion for the existence of N-bump solutions when $N > 1$. We leave these questions as open problems for future research.

5. The continuous case: $r > 0$. We now turn to the case $r > 0$, for which $f(u)$ is a *continuous* function. Thus, we study the existence of N-bump solutions of the equation

$$u(x) = \int_{-\infty}^{\infty} w(x-y) f(u(y))\, dy, \tag{5.1}$$

where $w(x)$ is given in (3.2) and $f(u)$ is given by (3.3), with $r > 0$. When $r > 0$, both the mathematical and computational analysis of (5.1) become more tractable. This is due to the fact that N-bump solutions of an associated differential equation problem also are solutions of (5.1). To derive the differential equation we make use of the Fourier transform, defined by

$$\mathrm{F}(g) = \int_{-\infty}^{\infty} e^{-i\alpha\eta} g(\eta)\, d\eta, \tag{5.2}$$

where $g \in L^1(\mathbf{R})$ and $\alpha \in \mathbf{R}$. Note that $\mathrm{F}(g)$ is a function of α.

We assume that u is a solution of (5.1), that u, u', u'', u''', and u'''' are continuous on $\mathbf{R}$, and that

$$(u, u', u'', u''') \to (0, 0, 0, 0) \tag{5.3}$$

exponentially fast as $x \to \pm\infty$. Under these assumptions, an application of the Fourier transform to (5.1) is justified and gives

$$\mathrm{F}(u) = \mathrm{F}(w)\mathrm{F}(f(u)). \tag{5.4}$$

An evaluation of $\mathrm{F}(w)$ converts (5.4) to

$$\mathrm{F}(u) = \frac{4b(b^2+1)}{\alpha^4 + 2\alpha^2(b^2-1) + (b^2+1)^2}\mathrm{F}(f(u)). \tag{5.5}$$

Next, multiply both sides of (5.5) by the denominator of $\mathrm{F}(w)$ and use the identities

$$\mathrm{F}(u'''') = \alpha^4\mathrm{F}(u) \quad \text{and} \quad \mathrm{F}(-u'') = \alpha^2\mathrm{F}(u) \tag{5.6}$$

to obtain

$$\mathrm{F}[u'''' - 2(b^2-1)u'' + (b^2+1)^2 u - 4b(b^2+1)f(u)] = 0. \tag{5.7}$$

We claim that (5.7) is satisfied if u is a solution of the problem

$$\begin{cases} u'''' - 2(b^2-1)u'' + (b^2+1)^2 u = 4b(b^2+1)f(u), \\ \lim_{x\to\pm\infty}(u, u', u'', u''') = (0, 0, 0, 0). \end{cases} \tag{5.8}$$

Because $r > 0$, it follows from the definition of $f(u)$ and standard analysis that if u is a solution of (5.8), then u, u', u'', u''', and u'''' are continuous on $\mathbf{R}$, hence (5.7) holds. It then follows that properties (5.4)–(5.7) also hold. From this we conclude that any solution of (5.8) also is a solution of the integral equation (5.1). This reduces the problem of finding N-bump solutions of (5.1) to the study of N-bump solutions of (5.8).

The first goal of our investigation of (5.8) is to extend the results of the previous section where we considered the special case $r = 0$. Thus, we keep $th = 1.5$ and choose an $r > 0$. Our numerical experiments for the case $r = 0$ indicate the existence of even solutions. Thus, when $r > 0$ we will restrict our attention to even solutions of (5.8). These satisfy

$$u'(0) = u'''(0) = 0. \tag{5.9}$$

In the next two sections we use the program AUTO97 [12, 13] to obtain an understanding of the global behavior of families of N-bump solutions of (5.8) as the parameter b varies.

Our second goal is to give global estimates on the range of r, th, and b for which N-bump solutions of (5.8) can exist. We have the following result.

THEOREM 5.1. *Let $r > 0$ and $th > 0$. If there is a value $b > 0$ for which* (5.8) *has a nonconstant solution, then*

$$0 < b \leq \frac{4 + \sqrt{|16 - th^2|}}{th}. \tag{5.10}$$

Remarks. (i) It would be interesting to extend the results of Theorem 5.1 to the special case $r = 0$. When $r = 0$ the function $f(u)$ is discontinuous and the differential equation in (5.8) no longer has a continuous right-hand side. However, since $f(u)$ will now be piecewise constant and the left-hand side of the differential equation is linear, it may be possible to solve (5.8) over restricted domains, piecing together these solutions into a continuous solution for all $x \in (-\infty, \infty)$. We leave this as an open problem.

(ii) The proof of Theorem 5.1 will be postponed until section 10.

(iii) As will be seen in section 6, the upper bound for b in Theorem 5.1 is not particularly tight, but the main purpose of this theorem is to show that there do not exist nonconstant solutions for all positive b.

The differential equation in (5.8) is fourth order, and for $th > 0$ it has a fixed point at the origin. The eigenvalues of the linearization of (5.8) about the origin are $b \pm i$ and $-b \pm i$. Thus, in (u, u', u'', u''') phase space, solutions of (5.8) are homoclinic orbits leading to the bifocus-type fixed point $(u, u', u'', u''') = (0, 0, 0, 0)$ [25]. We note that the differential equation is not generic since the sum of the eigenvalues is zero for all parameter values. This is a simple consequence of the fact that the differential equation in (5.8) is conservative and, in fact, Hamiltonian. This is easily verified, since solutions $u(x)$ satisfy the first integral

$$u'u''' - \frac{(u'')^2}{2} - (b^2 - 1)(u')^2 + (b^2 + 1)^2 Q(u) = 0, \tag{5.11}$$

where $Q(u)$ is defined by

$$Q(u) \equiv \int_0^u \left(s - \left(\frac{8b}{b^2 + 1} \right) e^{-r/(s-th)^2} H(s - th) \right) ds. \tag{5.12}$$

We also note that the differential equation is *reversible* since it contains only even order derivatives.

In recent years, higher order reversible, Hamiltonian equations have played an increasingly important role in modeling pattern formation in physical systems. We mention, for example, the encyclopedic paper by Cross and Hohenberg [11] which describes a wide array of higher order scalar equations. In two recent survey papers, Champneys [5, 6] gives a dynamical systems approach to the analysis of multi-bump, homoclinic orbits in higher order reversible models arising in physics, fluid mechanics, and optics. We also mention the recent book by Peletier and Troy [30] in which methods of analysis of pattern formation in higher order equations are developed from the alternative topological shooting point of view. In the models considered in these works, families of N-bump homoclinic orbits often arise through a Hamiltonian–Hopf

bifurcation from a constant solution. Furthermore, in many of these models the terms involving u are polynomials of degree greater than one. Thus, these terms exhibit *superlinear* growth as $|u| \to \infty$. However, in the model proposed in this paper, the terms involving u exhibit only *linear* growth for large $|u|$. In addition, the rapidly increasing sigmoidal function $f(u)$ given in (3.3) is poorly approximated by polynomials. Finally, as we shall see in the next two sections, our numerical investigation of (5.8) indicates that families of N-bump solutions do not come into existence through a Hamiltonian–Hopf bifurcation from a constant solution. Because of these fundamental differences from other higher order equations, a rigorous proof of existence of N-bump solutions of problem (5.8) should prove to be a challenging problem.

6. Families of N-bump solutions: N odd. In this section we use AUTO97 [12, 13] to determine the global behavior of families of even 1-bump, 3-bump, and 5-bump solutions of the problem

$$\begin{cases} u'''' - 2(b^2-1)u'' + (b^2+1)^2 u = 4b(b^2+1)f(u) \\ \lim_{x\to\pm\infty}(u, u', u'', u''') = (0,0,0,0), \end{cases} \tag{6.1}$$

where

$$f(u) = 2e^{-r/(u-th)^2} H(u-th), \tag{6.2}$$

and $th > 0$, $b > 0$, and $r > 0$ are constants.

In Figure 13 we set $th = 1.5$ and $r = 0.095$, and let b vary, and compute the bifurcation curve for families of even 1-bump and 3-bump solutions of (6.1)–(6.2). The horizontal axis is b and the vertical axis gives the global maximum of u for the corresponding solutions. Figures 14–17 show solutions at specific points $P_0, \ldots, P_7$ on the curve.

Using MATLAB [28], we numerically integrate (3.1)–(3.3) to a steady state, choosing an initial condition which evolves, as $t \to \infty$, into a 1-bump solution at $b = 0.25$. This solution, which we conjecture to be stable, is labeled P_4 on the bifurcation diagram, and is illustrated in the right panel of Figure 16. We then use AUTO97 to continue this solution as b varies. Figure 13 shows 1-bump solutions along the lower branch ${\Gamma_1}^-$ *between* P_1 and P_3. We conjecture that these solutions are unstable. Solutions at P_2 and P_3 are shown in Figure 15. As b decreases along ${\Gamma_1}^-$, solutions cease to be 1-bump solutions at P_1 (the right panel in Figure 14). As b decreases towards zero, solutions acquire arbitrarily many bumps. For example, the point P_0 corresponds to the 3-bump solution shown in the left panel of Figure 14. Note that when $b = 0$, the only bounded even solution of the ordinary differential equation (ODE) in (6.1) is $u(x) = \cos x$, and it is to this that solutions tend as $b \to 0$.

Remark. The first solution in Figure 15 is computed at $b = 0.25$. As $r \to 0^+$, our computations indicate that this solution tends to the 1-bump solution shown in the right panel of Figure 6 in section 4.

Next, we consider the middle branch ${\Gamma_1}^+$ in Figure 13. Along ${\Gamma_1}^+$ we find a second family of 1-bump solutions, some of which we conjecture are stable, *between* P_5 and P_3. As b decreases along ${\Gamma_1}^+$, solutions cease to be 1-bump solutions at P_5 (the left panel in Figure 16). The solution in the right panel of Figure 16 was computed at $b = 0.25$. As $r \to 0^+$, our computations indicate that this solution is stable and tends to the 1-bump solution shown in the left panel of Figure 6 in section 4.

We let ${\Gamma_3}^-$ denote the upper branch of the diagram in Figure 13. Along this branch our computations indicate that solutions are *unstable* 3-bump solutions. Specific solutions at P_6 and P_7 are given in Figure 17. The solution at P_6 is computed

at $b = 0.25$, and as $r \to 0^+$ our computations indicate that it tends to the solution shown in the right panel of Figure 8.

We have also investigated the existence of 3-bump and 5-bump solutions. Our computations show that these solutions lie on yet another branch leading to the original bifurcation curve in Figure 13. This branch of solutions is labeled $\Gamma_3{}^+$ and $\Gamma_5{}^-$ in Figure 18. In Figure 19 we give specific solutions on $\Gamma_3{}^+$ and $\Gamma_5{}^-$ at $b = 0.25$. Our computations indicate that the solution in the left panel of Figure 19 is stable. Furthermore, as $r \to 0^+$ this solution tends to the solution in the left panel of Figure 8.

We can use data from Figures 13 and 18 to compare the largest values of b for which nonconstant solutions exist with the upper bound given in Theorem 5.1.

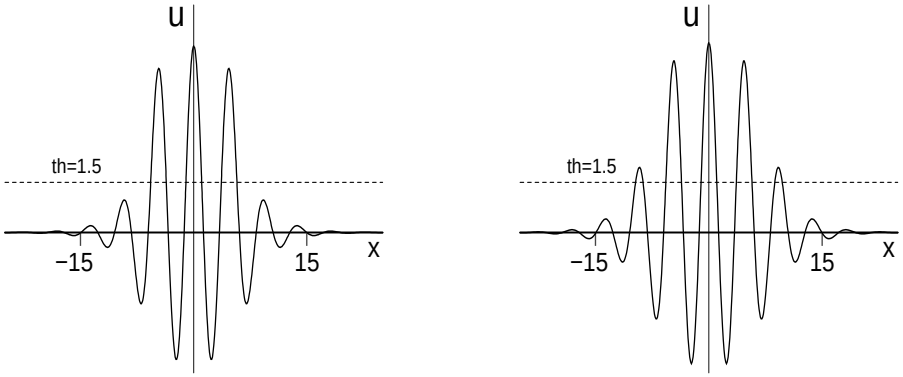

FIG. 19. *Solutions on the curves* $\Gamma_3{}^+$ *(left) and* $\Gamma_5{}^-$ *(right) at* $b = 0.25$ *in Figure* 18.

In Figure 20 we show saddle-node bifurcations of 1-, 3-, and 5-bump solutions in the b, th plane for $r = 0.095$. The curve γ_1 is the continuation of the point P_3 in Figure 13, and the curves γ_3 and γ_5 are the corresponding continuations for 3- and 5-bump homoclinic orbits, respectively. The dashed line (A) is the function given by the equality in (5.10), i.e., the value of b above which Theorem 5.1 states that no nonconstant solutions of (6.1)–(6.2) can exist. We see that the solutions studied in this section are compatible with Theorem 5.1, but that the bound given there is not particularly tight.

We have done one further experiment which shows how quickly the global behavior of solutions can change. In Figures 13 and 18 we set $th = 1.5$ and $r = 0.095$ and found that two "cusps" form on the left side of the bifurcation diagram. In Figure 21 we have increased r from $r = 0.095$ to $r = 0.1$ and repeated our computations. In

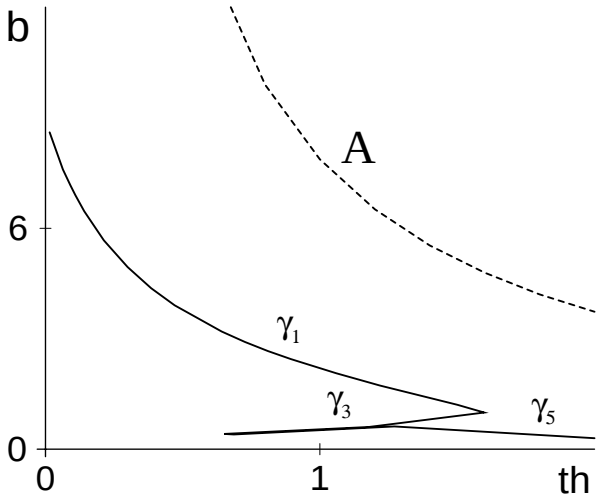

FIG. 20. *The continuation of the saddle-node bifurcations marking the largest values of b for which various orbits exist, compared with the upper bound given in Theorem* 5.1. γ_1 *is the continuation of the point* P_3 *in Figure* 13, *while* γ_3 *and* γ_5 *are continuations of the corresponding points for* 3- *and* 5-*bump homoclinic orbits. The curve "A" is the function* $b = (4+\sqrt{|16-th^2|})/th$, *given in* (5.10).

this case we find that the cusps have now joined and the 1-bumps solutions lie on an isolated closed curve. The lower branch Γ_1^- consists of small amplitude 1-bump solutions, which are conjectured to be unstable. The upper branch Γ_1^+ consists of large amplitude 1-bump solutions, some of which are conjectured to be stable. In order to see the separation of curves more clearly, in Figure 22 we have redrawn the bifurcation diagram of Figure 21 but now we have replaced u_{max} on the vertical axis with the L^2 norm of the solution (the default L^2 norm of AUTO97 is used). Figure 22 suggests that a "snaking" phenomenon occurs in the branches of the bifurcation curve and that solutions acquire more bumps as the L^2 norm increases (e.g., see Figure 23). Similar snaking phenomena occur in other physical systems modeled by higher order scalar equations [21, 30, 38], as well as in systems where homoclinic orbits are present [20].

7. Families of *N*-bump solutions: *N* even. In this section we determine the global behavior of families of 2-bump, 4-bump, and 6-bump solutions of the problem

$$\begin{cases} u'''' - 2(b^2-1)u'' + (b^2+1)^2 u = 4b(b^2+1)f(u), \\ \lim_{x\to\pm\infty}(u,u',u'',u''') = (0,0,0,0), \end{cases} \tag{7.1}$$

where

$$f(u) = 2e^{-r/(u-th)^2}H(u-th). \tag{7.2}$$

Here $H(\cdot)$ is the Heaviside function, $th > 0$ is the threshold, and $b > 0$, $r > 0$ are constants.

In Figure 24 we again keep $th = 1.5$ and $r = 0.095$, and let b vary, and compute the bifurcation curve for families of even 2-bump and 4-bump solutions of (7.1)–(7.2).

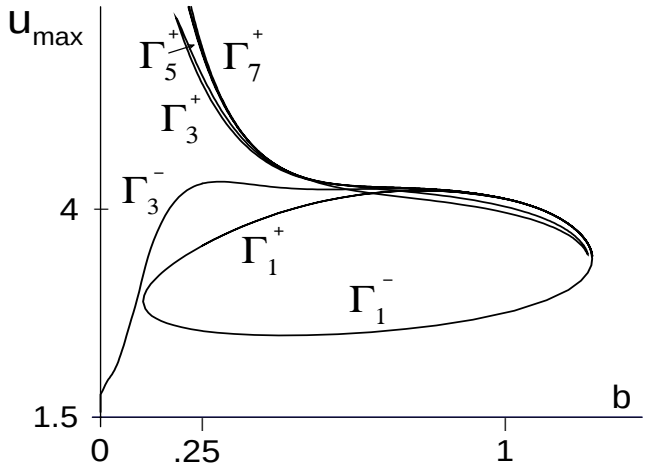

FIG. 21. *Bifurcation curve for* (6.1)–(6.2) *showing* 1-, 3-, 5-, *and* 7-*bump solutions. Parameters are* $th = 1.5$ *and* $r = 0.1$. *Compare this with Figure* 18.

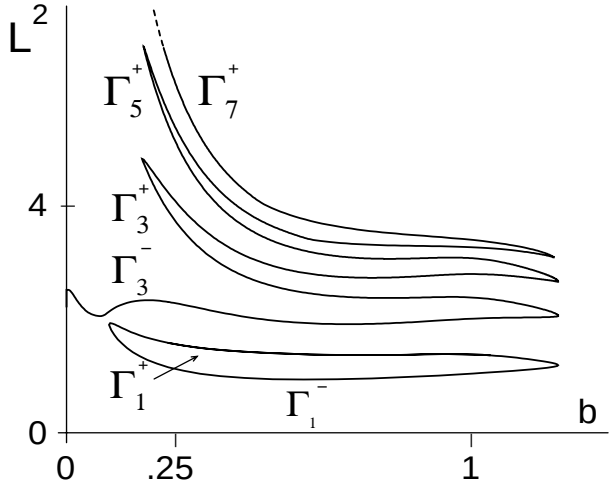

FIG. 22. *The same curves as in Figure* 21*, but the vertical axis is now the* L^2 *norm of the solutions.*

Figures 25–28 show solutions at specific points $P_0, \ldots, P_7$ on this curve. To compute the curve in Figure 24 we first set $b = 0.25$ and integrate (3.1)–(3.3) with an initial condition chosen so that the solution converges, as $t \to \infty$, to the 2-bump (apparently stable) solution indicated by point P_4, and illustrated in the right panel of Figure 27. We then use AUTO97 to continue this solution as b varies. In Figure 24 we find 2-bump solutions, which are conjectured to be unstable, along the lower branch $\Gamma_2{}^-$

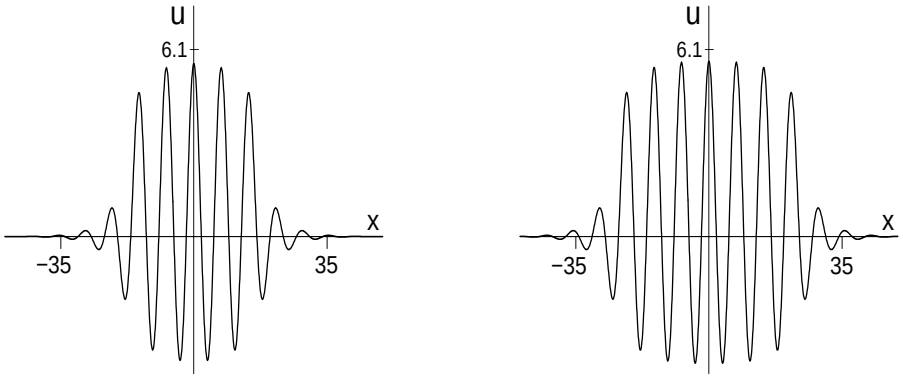

FIG. 23. *Solutions on the curves* Γ_5^+ *(left) and* Γ_7^+ *(right) in Figure* 22. *Parameters are* $r = 0.1$, $th = 1.5$, and $b = 0.25$.

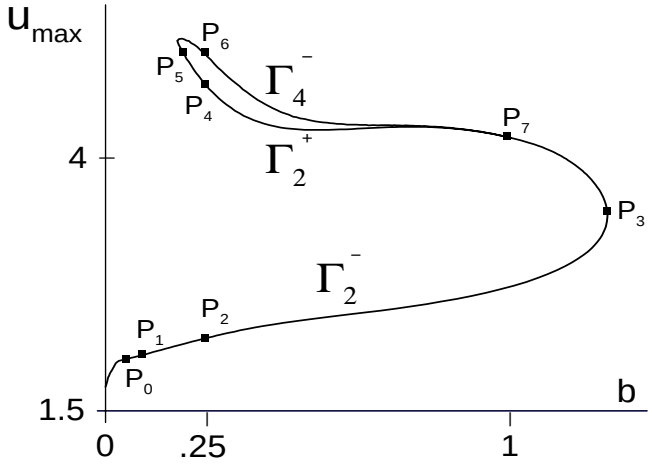

FIG. 24. *Bifurcation curve of* 2*-bump and* 4*-bump solutions for* (7.1)–(7.2). *Solutions at the points* $P_0, \ldots, P_7$ *are shown in Figures* 25–28. *Parameters are* $r = 0.095$, $th = 1.5$. *Compare with Figure* 13.

between P_1 ($b = 0.045$) and P_3 ($b = 1.23$). Solutions at P_2 ($b = 0.25$) and P_3 are shown in Figure 26. As b decreases along $\Gamma_2{}^-$, solutions cease to be 2-bump solutions at P_1 (right panel in Figure 25). To the left of P_1 our computations imply that solutions acquire arbitrarily many bumps as $b \to 0^+$, as was the case for bumps with N odd. For example, at $b = 0.03$ the point P_0 corresponds to the 4-bump solution in the left panel of Figure 25.

Remark. The solution in the left panel of Figure 26 is computed at $b = 0.25$. As $r \to 0^+$, our computations indicate that this solution is unstable and tends to the 2-bump solution shown in the right panel of Figure 7.

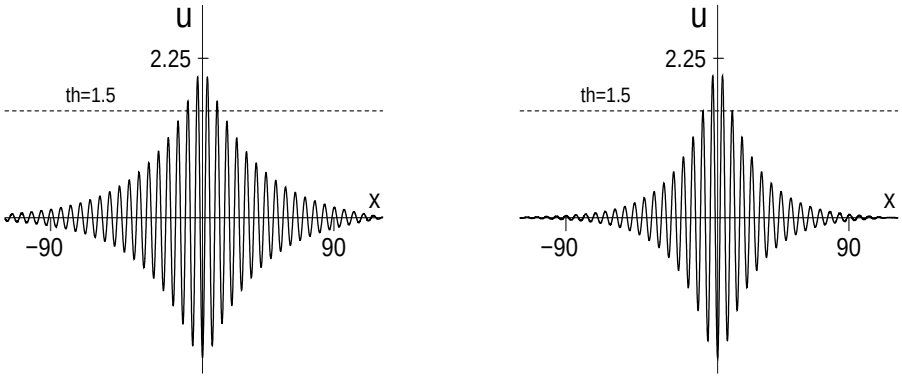

FIG. 25. *Solutions on* $\Gamma_2{}^-$ *at* P_0 *(left) and* P_1 *(right) in Figure* 24.

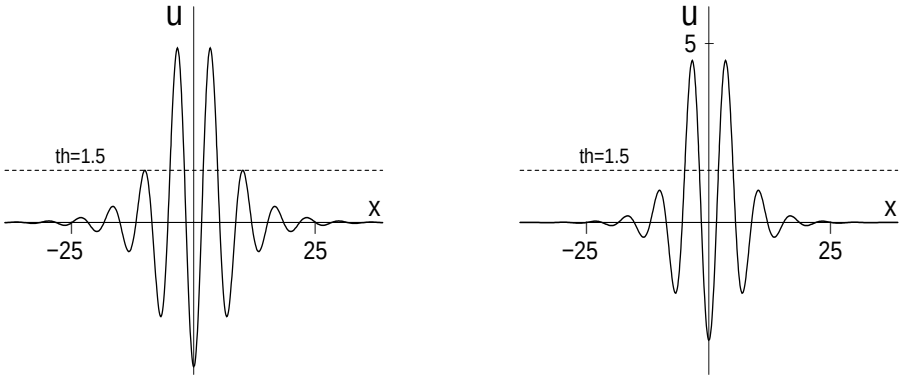

FIG. 27. *Solutions on* $\Gamma_2{}^+$ *at* P_5 *(left) and* P_4 *(right) in Figure* 24.

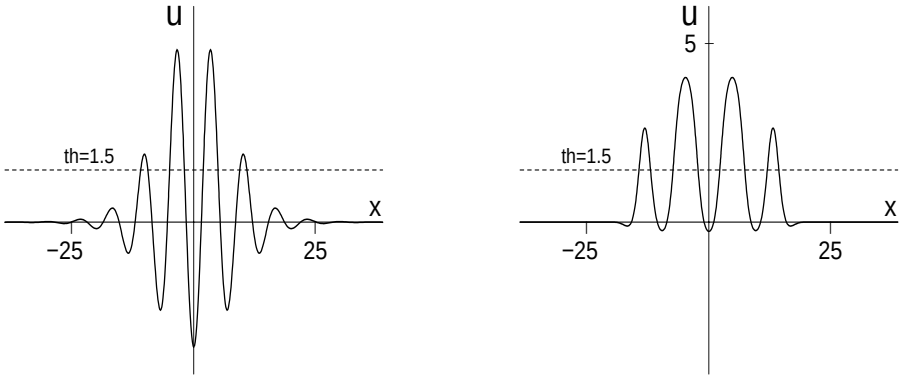

FIG. 28. *Solutions on* $\Gamma_4{}^-$ *at* P_6 *(left) and* P_7 *(right) in Figure* 24.

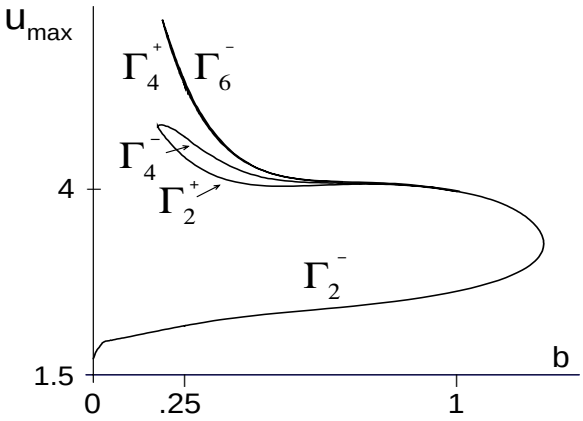

FIG. 29. *Bifurcation curve for* 2, 4, *and* 6*-bump solutions of* (7.1)–(7.2). *This figure is an extension of Figure* 24.

Next, along the middle branch $\Gamma_2{}^+$ in Figure 24 we find a family of 2-bump solutions, some of which are conjectured to be stable, between P_5 ($b = 0.187$) and P_3 ($b = 1.23$). As b decreases along $\Gamma_2{}^+$, solutions cease to be 2-bump solutions at P_5 (shown in the left panel of Figure 27). The solution in the right panel of Figure 27 corresponds to P_4 ($b = 0.25$) in Figure 24. As $r \to 0^+$ this solution tends to the 2-bump solution shown in the left panel of Figure 7.

We let $\Gamma_4{}^-$ denote the upper branch in Figure 24. Along this branch our computations indicate that solutions are *unstable* 4-bump solutions. The solutions at P_6 ($b = 0.25$) and P_7 ($b = 0.99$) are shown in Figure 28. We have also found another family of 4-bump solutions, as well as 6-bump solutions. These solutions lie on a second branch leading to the original curve in Figure 24. The lower and upper curves on this branch are given by $\Gamma_4{}^+$ and $\Gamma_6{}^-$ in Figure 29. In Figure 30 we give specific solutions on $\Gamma_4{}^+$ and $\Gamma_6{}^-$ at $b = 0.25$. Our computations indicate that the solution in the left panel of Figure 30 is stable and tends to the solution in the left panel of Figure 9 as $r \to 0^+$.

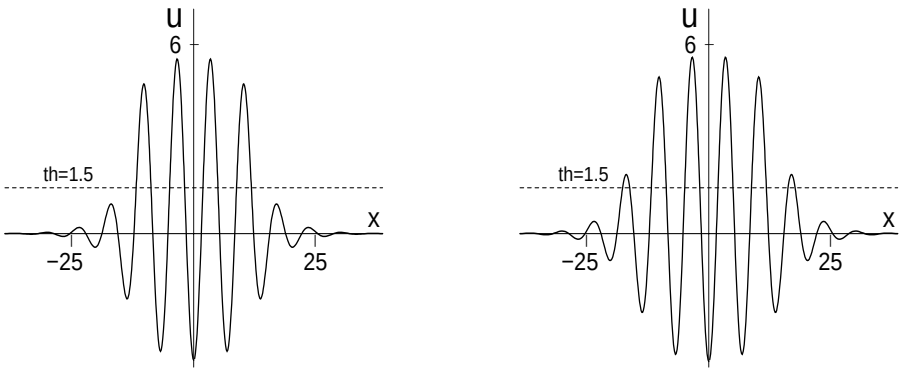

FIG. 30. *Solutions on* $\Gamma_4{}^+$ *(left) and* $\Gamma_6{}^-$ *(right) at* $b = 0.25$ *in Figure* 29.

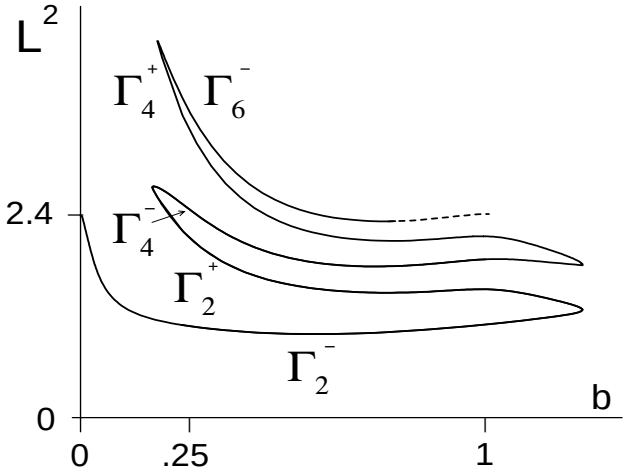

FIG. 31. *The same curves as in Figure* 29, *but the vertical axis is now the* L^2 *norm of the solutions.*

As in the previous section, we redraw in Figure 31 the bifurcation curve shown in Figure 29 but using the L^2 norm for the vertical axis. This allows us to see the separation of branches and, once again, a snaking diagram results.

While we have only looked at multi-bump solutions for which successive maxima of u monotonically increase and then decrease as a function of x, there may also exist "$(n + m)$-bumps" for integer $n, m \geq 1$. These would have the approximate form of an n-bump "glued" to an m-bump, with sufficient low-amplitude oscillations between them. The linearization of (5.8) about the origin has the form necessary for these "composite" orbits to exist, and to confirm this conjecture one would need to check that the N-bump orbits studied above were formed by transverse intersections of the stable and unstable manifolds of the origin (a generic property). See [7] and references

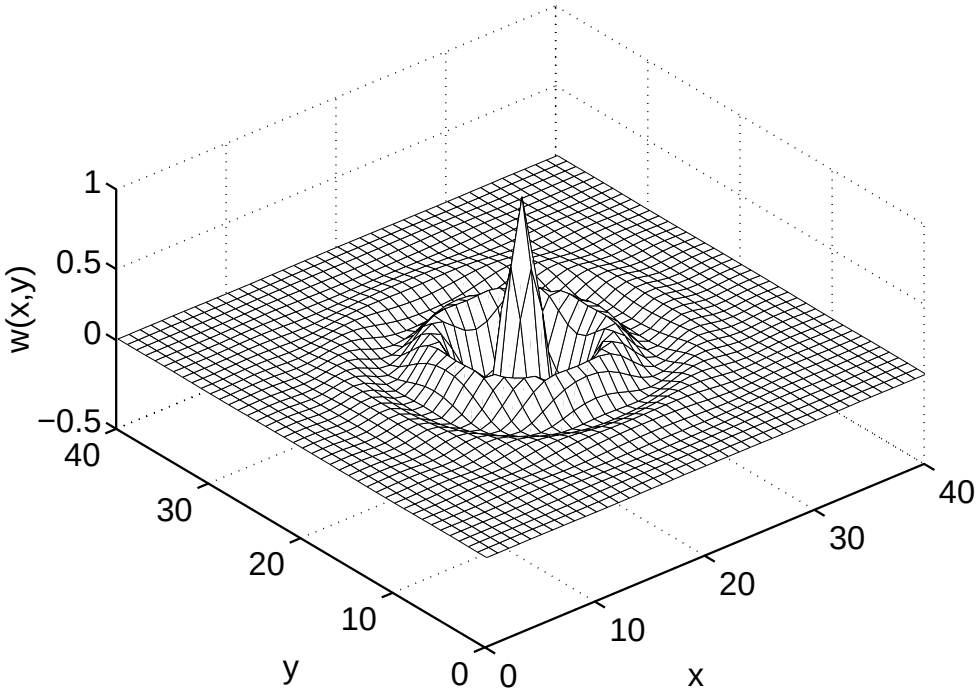

FIG. 32. *Coupling function $w(x, y)$, (8.2), for $b = 0.3$, centered at the center of the domain.*

therein for more details.

8. Extension to two space dimensions. In this section we extend our model to include two spatial dimensions. The system we study, an analogy of (3.1)–(3.3), is the following:

$$\frac{\partial u(x,y,t)}{\partial t} = -u(x,y,t) + \iint_{\Omega} w(x-q, y-s) f(u(q,s,t))\, dq\, ds, \tag{8.1}$$

where

$$w(x,y) = e^{-b\sqrt{x^2+y^2}} \left(b \sin\left(\sqrt{x^2+y^2}\right) + \cos\left(\sqrt{x^2+y^2}\right)\right), \tag{8.2}$$

and

$$f(u) = 2e^{-r/(u-th)^2} H(u-th). \tag{8.3}$$

The coupling function (8.2) is the same as (3.2), with distance in one dimension now replaced by distance in two dimensions. An example is shown in Figure 32. The rate function, (8.3), is identical to (3.3).

A typical stable solution of (8.1)–(8.3) is shown in Figure 33 for the parameters $r = 0.1$, $th = 1.5$, and $b = 0.45$. The initial condition was $u(x, y, 0) = 5$ for $16 < x < 25.6$ and $8 < y < 24$, and $u(x, y, 0) = 0$ otherwise. The domain, Ω, is a square of side-length 40, discretized by a regular 50×50 grid, with open boundaries; i.e., there are no constraints on u or any of its derivatives at the boundaries, and the integral

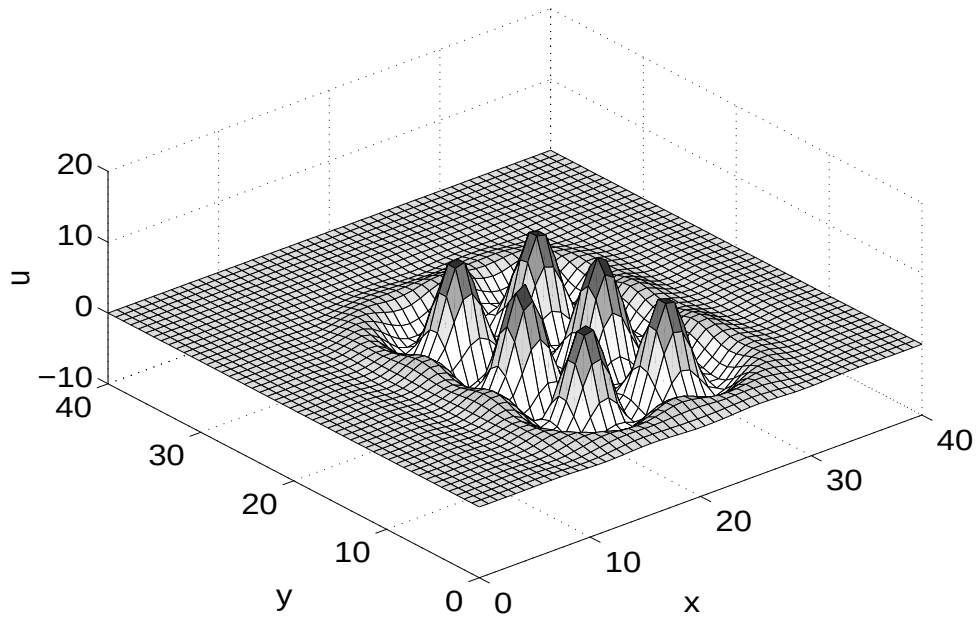

FIG. 33. *A "6-bump" stable solution of* (8.1)–(8.3). *Parameters are* $b = 0.45$, $r = 0.1$, $th = 1.5$.

in (8.1) is taken over only Ω. Note that while the coupling function (8.2) is radially symmetric, the domain is not, and so we do not expect the resulting solutions to have radial symmetry. The equation (8.1) was integrated using an Euler step until the solution converged to a steady state, and at each time step the double integral was approximated by a Riemann integral using the values of u on the grid mentioned above. Note that the convolution can be performed more efficiently by using the two-dimensional fast Fourier transform.

Figure 33 shows the resultant 6-bump solution, and the distance between local maxima is approximately the same as the distance between successive maxima of the coupling function (2π). The regularity is a reflection of the initial condition; more irregular initial conditions lead to an irregular cluster of bumps with similar spacing between local maxima (not shown). That is, keeping $r = 0.1$, $th = 1.5$, and $b = 0.45$, it is possible to find other stable clusters with small numbers of bumps, with the exact number and position being determined by the initial condition. This is analogous with the one-dimensional model (3.1)–(3.3) where stable multi-bump solutions coexist for $b = 0.25$ (see Figure 19 (left), Figure 23, Figure 27 (right), and Figure 30 (left)). In the two-dimensional model, as b is decreased from $b = 0.45$ it seems more difficult to find localized clusters of multi-bump solutions. Instead, for smaller b, either an initial set of u values will die down to $u = 0$ if b is too small or else the entire domain will be filled with bumps. An example with $b = 0.3$ and the other parameters the same (i.e., $r = 0.1$ and $th = 1.5$) is shown in Figure 34. This "progressive recruitment" phenomenon is the same as that seen by Gutkin, Ermentrout, and O'Sullivan in a one-dimensional model [16]. Similar patterns were also found by Usher, Stemmler, and Olami [34] in a neural model with short-range excitation and long-range inhibition.

For larger b, stable attractors also form, but they do not seem to retain the structure of a cluster of bumps observed in Figure 33. However, there still appears

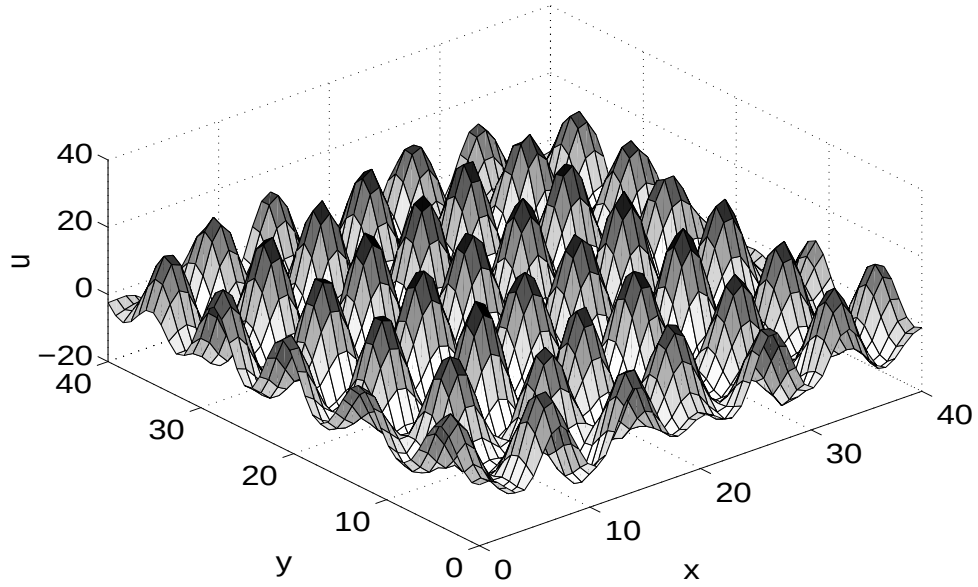

FIG. 34. *A stable solution of* (8.1)–(8.3). *Parameters are* $b = 0.3$, $r = 0.1$, $th = 1.5$. *The initial* u *was spatially localized.*

to be a characteristic length similar to the interbump spacing seen for lower b. In Figure 35, keeping $r = 0.1$ and $th = 1.5$, we increase b to $b = 0.7$ and illustrate an example of this type of stable attractor. For still larger b values, the whole domain becomes active and there are no structures with characteristic length 2π. This is probably due to the lack of a significant inhibitory component to w when b is large—see Figure 4, right panel, for an illustration of this effect in the one-dimensional setting.

In this section, we have presented only numerical results. We leave the possible derivation of a differential equation problem whose solutions describe steady states of (8.1)–(8.3), and any further analysis, as open problems. Although few mathematical results exist for two-dimensional neural models, some interesting results have been obtained relating to the study of circular stationary solutions [2, 31, 36].

9. Proof of Theorem 2.1. In this section we prove Theorem 2.1 concerning the nonexistence of a class of 2-bump solutions of problem (2.2)–(2.3). Recall from section 2 that $u(x)$ is a 2-bump solution of (2.2)–(2.3) if there are values $0 < a < b < c$ such that

$$\begin{cases} u > 0 \quad \text{on} \quad (0,a) \cup (b,c), \\ u(0) = u(a) = u(b) = u(c) = 0, \\ u < 0 \quad \text{otherwise.} \end{cases} \tag{9.1}$$

We define the "distance between bumps" to be $b - a$. Also, we recall from section 2 that under hypotheses (H_1)–(H_6), the function $w(x)$ is symmetric with respect to $x = 0$, that $w(x)$ attains a unique local minimum on $\mathbf{R}^+$ at a value $x_0 > 0$, and that $w(x)$ is *increasing* on (x_0, ∞) (see Figure 1). We will use these properties in our proof of the following result (a restatement of Theorem 2.1).

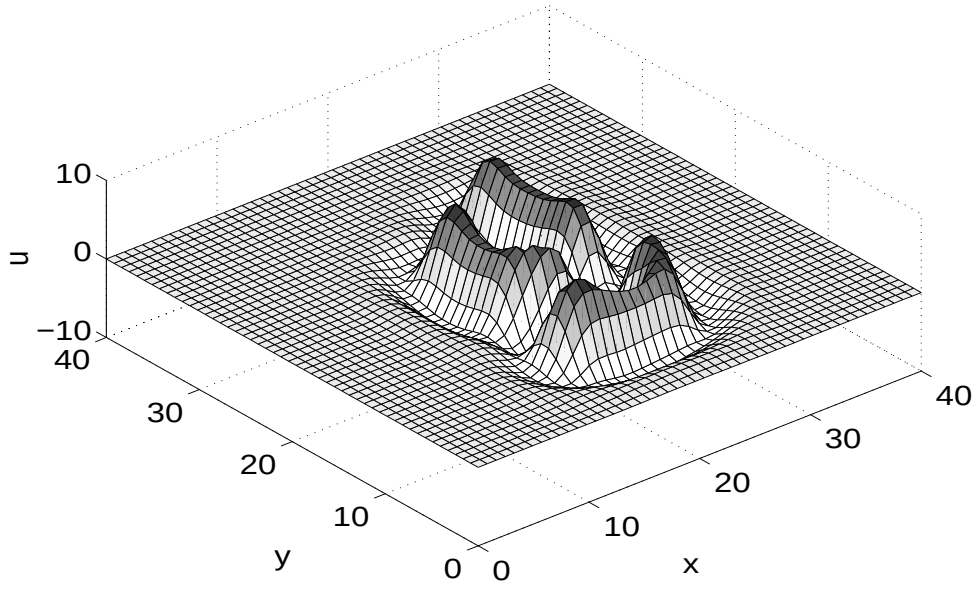

FIG. 35. *A stable solution of* (8.1)–(8.3). *Parameters are* $b = 0.7$, $r = 0.1$, $th = 1.5$. *The initial condition was random but spatially localized.*

THEOREM 9.1. *Under hypotheses* (H_1)–(H_6) *there is no value* $h \in \mathbf{R}$ *for which the problem* (2.2)–(2.3) *has a* 2*-bump solution satisfying* (2.9) *such that the distance between bumps satisfies* $b - a \geq x_0$.

Proof. We assume that there is an $h \in \mathbf{R}$ for which (2.2)–(2.3) has a solution satisfying (2.9), with $b - a \geq x_0$. Using (H_1)–(H_6), we will obtain a contradiction of this assumption. From (2.2), (2.3) and (2.9), it follows that $u(x)$ can be written in the form

$$u(x) = \int_0^a w(x-y)\,dy + \int_b^c w(x-y)\,dy + h \qquad \forall x \in \mathbf{R}. \tag{9.2}$$

Next, recall from (2.4) that $W(x)$ is defined by

$$W(x) = \int_0^x w(y)\,dy \qquad \forall x \in \mathbf{R}. \tag{9.3}$$

Hypotheses (H_1)–(H_6) imply that $W(x)$ is odd. That is,

$$W(x) = -W(-x) \qquad \forall x \in \mathbf{R}. \tag{9.4}$$

Using (9.3), we write (9.2) as

$$u(x) = W(x) - W(x-a) + W(x-b) - W(x-c) + h. \tag{9.5}$$

Because $u(b) = u(c) = W(0) = 0$, it follows from (9.5) that

$$u(c) = W(c) - W(c-a) + W(c-b) + h = 0, \tag{9.6}$$

and

$$u(b) = W(b) - W(b-a) - W(b-c) + h = 0. \tag{9.7}$$

We note that $W(c-b) = -W(b-c)$ since $W(x)$ is odd. Thus, a subtraction of (9.7) from (9.6) leads to

$$W(c) - W(b) = W(c-a) - W(b-a). \tag{9.8}$$

Recalling the definition of $W(x)$ from (9.3), we write (9.8) as

$$\int_b^c w(y)dy = \int_{b-a}^{c-a} w(y)dy. \tag{9.9}$$

Also, our hypothesis that $b - a \geq x_0$ implies that

$$x_0 \leq b - a < c - a. \tag{9.10}$$

We need to consider two cases to complete the proof. The first case is

$$x_0 \leq b - a < c - a \leq b < c. \tag{9.11}$$

From (H_6) and (9.10) we conclude that $w(x)$ is increasing on $(b-a, c)$. Thus, $w(x) > w(b)$ on (b, c), and $w(x) < w(c-a)$ on $(b-a, c-a)$. This implies that

$$\int_b^c w(y)dy > w(b)(c-b), \tag{9.12}$$

and

$$\int_{b-a}^{c-a} w(y)dy < w(c-a)(c-b). \tag{9.13}$$

Combining (9.9), (9.11), (9.12), and (9.13), we conclude that

$$w(b) < w(c-a). \tag{9.14}$$

However, since (H_6) implies that $w(x)$ is nondecreasing on $[c-a, b]$, it follows that $w(b) \geq w(c-a)$, contradicting (9.14). The second case we need to consider is

$$x_0 \leq b - a < b < c - a < c. \tag{9.15}$$

Then (9.9) can be written as

$$\int_b^{c-a} w(y)dy + \int_{c-a}^{c} w(y)dy = \int_{b-a}^{b} w(y)dy + \int_b^{c-a} w(y)dy.$$

This reduces to

$$\int_{c-a}^{c} w(y)dy = \int_{b-a}^{b} w(y)dy. \tag{9.16}$$

Again, we use the fact that $w(x)$ is increasing on (x_0, c), together with (9.15), and conclude that

$$\int_{c-a}^{c} w(y)dy > w(c-a)a \tag{9.17}$$

and

$$\int_{b-a}^{b} w(y)dy < w(b)a. \tag{9.18}$$

From (9.16)–(9.18) it follows that $w(b) > w(c-a)$. However, this is a contradiction since $w(x)$ increases on $(b, c-a)$. The proof of Theorem 2.1 is now complete.

10. Proof of Theorem 5.1. In this section we prove Theorem 5.1 and determine a global parameter regime over which nonconstant solutions of the problem

$$\begin{cases} u'''' - 2(b^2-1)u'' + (b^2+1)^2 u = 4b(b^2+1)f(u), \\ \lim_{x\to\pm\infty}(u,u',u'',u''') = (0,0,0,0) \end{cases} \tag{10.1}$$

might possibly exist. We recall that $f(u)$ is defined by

$$f(u) = 2e^{-r/(u-th)^2}H(u-th), \tag{10.2}$$

where $H(u-th)$ is the Heaviside function (see Figure 5). For convenience we restate our result (Theorem 5.1) below.

THEOREM 10.1. *Let $r > 0$ and $th > 0$. If there is a value $b > 0$ for which (10.1)–(10.2) has a nonconstant solution, then*

$$0 < b \le \frac{4+\sqrt{|16-th^2|}}{th}.$$

Proof. Suppose that $u(x)$ is a nonconstant solution of (10.1)–(10.2) for some

$$r > 0,\ th > 0, \quad \text{and} \quad b > \frac{4+\sqrt{|16-th^2|}}{th}. \tag{10.3}$$

We will obtain a contradiction of this assumption. First, we observe that

$$\frac{4+\sqrt{|16-th^2|}}{th} \ge 1 \qquad \forall\ th > 0. \tag{10.4}$$

It then follows from (10.3) and (10.4) that $b > 1$. Next, from (10.1)–(10.2) it is easily verified that $u(x)$ must satisfy the first integral

$$u'u''' - \frac{(u'')^2}{2} - (b^2-1)(u')^2 + (b^2+1)^2 Q(u) = 0, \tag{10.5}$$

where $Q(u)$ is defined by

$$Q(u) \equiv \int_0^u \left(s - \left(\frac{8b}{b^2+1}\right) e^{-r/(s-th)^2} H(s-th) \right) ds. \tag{10.6}$$

Over the range given in (10.3), we claim that the integrand in (10.6) satisfies

$$u - \left(\frac{8b}{b^2+1}\right) e^{-r/(u-th)^2} H(u-th) > 0 \qquad \forall u > 0. \tag{10.7}$$

First, suppose that $0 < u \le th$. Then $f(u) = 0$ by (10.2), and therefore the left side of (10.7) must be positive. If $u > th$, then

$$u - \left(\frac{8b}{b^2+1}\right) e^{-r/(u-th)^2} H(u-th) > th - \frac{8b}{b^2+1} > 0,$$

since we assume that $th > 0$, $r > 0$, and $b > (4+\sqrt{|16-th^2|})/th$. Thus (10.7) is proved. From (10.6) and (10.7) we conclude that $Q(0) = 0$,

$$Q(u) > 0 \quad \text{if} \quad |u| > 0, \qquad \lim_{|u|\to\infty} Q(u) = \infty, \tag{10.8}$$

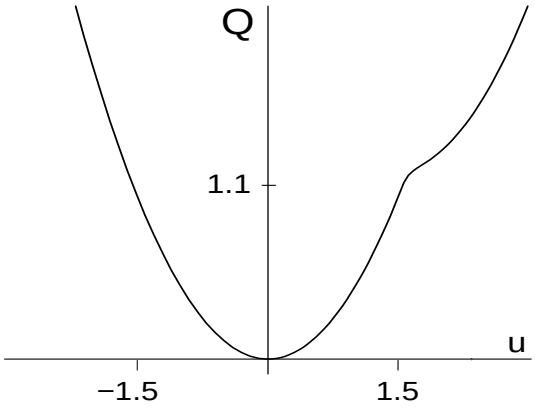

FIG. 36. $Q(u)$, (10.6), *for parameter values* $r = 0.005,\ th = 1.5,\ b = 5.2$.

and

$$\frac{dQ}{du} < 0 \qquad \forall u < 0, \qquad \frac{dQ}{du} > 0 \qquad \forall u > 0. \tag{10.9}$$

For example, the parameters $r = 0.005$, $th = 1.5$, and $b = 5.2$ satisfy (10.3), and in Figure 36 we graph the corresponding $Q(u)$.

Next, because (10.1)–(10.2) is autonomous, we may assume that the solution $u(x)$ attains its global maximum at $x = 0$. We claim that $u(0) > th$. If, on the contrary, $u(0) \le th$, then $u(x) \le th$ for all $x \in \mathbf{R}$, and it follows from (10.2) that $f(u) = 0$ for all $x \in \mathbf{R}$. This reduces the integral equation (5.1) to $u(x) = 0$, and we arrive at a contradiction since we assume that $u(x)$ is a *nonconstant* solution of (10.1)–(10.2), and solutions of (10.1)–(10.2) also are solutions of (5.1). Thus, at $x = 0$ it must be the case that

$$u(0) > th,\ u'(0) = 0, \quad \text{and} \quad u''(0) \le 0. \tag{10.10}$$

Substituting (10.10) into (10.5), and using (10.8), we conclude that

$$u''(0) = -(b^2 + 1)\sqrt{2Q(u(0))} < 0. \tag{10.11}$$

Without loss of generality we may assume that $u'''(0) \le 0$. Otherwise, if $u'''(0) > 0$, then it would suffice to consider the function $v(x) = u(-x)$ which also is a solution of (10.1)–(10.2) and satisfies the initial conditions

$$v(0) > th,\ v'(0) = 0,\ v''(0) < 0, \quad \text{and} \quad v'''(0) < 0.$$

Thus, it may be assumed that the solution $u(x)$ satisfies

$$u(0) > th,\ u'(0) = 0,\ u''(0) < 0, \quad \text{and} \quad u'''(0) \le 0. \tag{10.12}$$

Our goal in the remainder of the proof is to show that there is an $\bar{x} > 0$ such that $u(\bar{x}) > u(0)$. This will contradict the fact that $u(x)$ attains its global maximum

at $x = 0$. Thus, we need to follow the solution as x increases from $x = 0$. Throughout we will make extensive use of the first integral (10.5) and the associated functional $Q(u(x))$. In Figures 37 and 38 we follow $u(x)$ and $Q(u(x))$, respectively, and keep track of the points where the solution $u(x)$ attains its maxima and minima.

From (10.1)–(10.4), (10.7), and (10.12) it follows that $u''''(0) < 0$. This and (10.12) imply that $u'''(x) < 0$ on an interval $(0, \epsilon)$. We set

$$\sigma = \sup\{\hat{x} > 0 | u'''(x) < 0 \quad \forall x \in (0, \hat{x})\}. \tag{10.13}$$

If $\sigma = \infty$, then $u''(x) < u''(0) < 0$ for all $x > 0$, hence $u''(\infty) < 0$, contradicting the condition $u''(\infty) = 0$ given in (10.1). Thus, it must be the case that $\sigma < \infty$, $u'''(\sigma) = 0$, and

$$u(x) < u(0),\ u'(x) < 0, \quad \text{and} \quad u''(x) < u''(0) < 0 \qquad \forall x \in (0, \sigma]. \tag{10.14}$$

Next, it follows from (10.8) and (10.9) that there is a unique, negative value $u_1 < 0$ (see Figure 38) such that

$$Q(u) < Q(u(0)) \qquad \forall u \in (u_1, u(0)), \quad \text{and} \quad Q(u_1) = Q(u(0)). \tag{10.15}$$

We need to show that $u(\sigma) < u_1$. If $u(\sigma) \geq u_1$, then from (10.11), (10.14), and (10.15) it follows that $(u'')^2$ *increases* on $(0, \sigma)$ so that

$$\frac{(u(x)'')^2}{2} > (b^2 + 1)^2 Q(u(x)) \qquad \forall x \in (0, \sigma]. \tag{10.16}$$

Setting $x = \sigma$ in (10.5), and using (10.3), (10.4), (10.14), and (10.16), we obtain

$$-(u'(\sigma))^2(b^2 - 1) > 0,$$

a contradiction since $u'(\sigma) < 0$ and $b > 1$. Therefore it must be the case that $u(\sigma) < u_1$. Thus, there is an $x_1 \in (0, \sigma)$ such that (see Figure 37)

$$u'(x) < 0,\ u''(x) < 0,\ u'''(x) < 0 \qquad \forall x \in (0, x_1], \quad \text{and} \quad u(x_1) = u_1. \tag{10.17}$$

Since $u(\infty) = 0$, it follows from (10.17) that there is an $x_2 > x_1$ such that

$$u'(x) < 0 \qquad \forall x \in [x_1, x_2), \quad \text{and} \quad u'(x_2) = 0. \tag{10.18}$$

We conclude from (10.5) and (10.18) that

$$u(x_2) < u_1 < 0,\ u'(x_2) = 0, \text{ and } u''(x_2) = (b^2 + 1)\sqrt{2Q(u(x_2))} > 0. \tag{10.19}$$

We need to determine the sign of $u'''(x_2)$. Because $u''(x_1) < 0$ and $u''(x_2) > 0$, there is an $\tilde{x} \in (x_1, x_2)$ where $u''(\tilde{x}) = 0$ and $u'''(\tilde{x}) \geq 0$. This, (10.3), (10.4), and (10.18) give

$$u'''(\tilde{x}) - 2(b^2 - 1)u'(\tilde{x}) > 0. \tag{10.20}$$

Next, because $u(x) < u_1 < 0$ on $[\tilde{x}, x_2]$, it follows from (10.1)–(10.2) that

$$(u''' - 2(b^2 - 1)u')' = -(b^2 + 1)^2 u > 0 \qquad \forall x \in [\tilde{x}, x_2]. \tag{10.21}$$

From (10.19), (10.20), and (10.21) we conclude that

$$u'''(x_2) > 0. \tag{10.22}$$

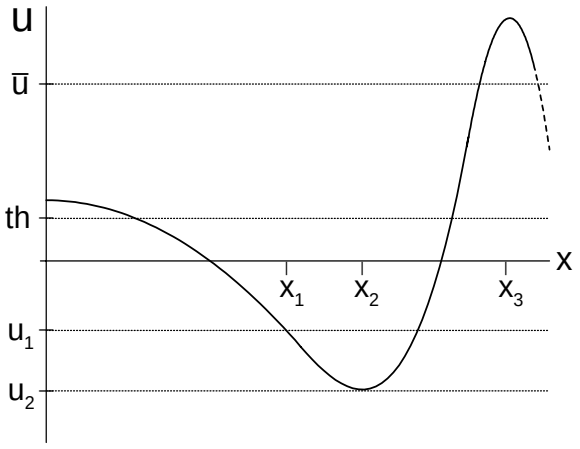

FIG. 37. *A sketch of* $u(x)$ *for* (10.1)–(10.2): $u(x_1) = u_1,\ u(x_2) = u_2$, *and* $u(x_3) > \bar{u}$.

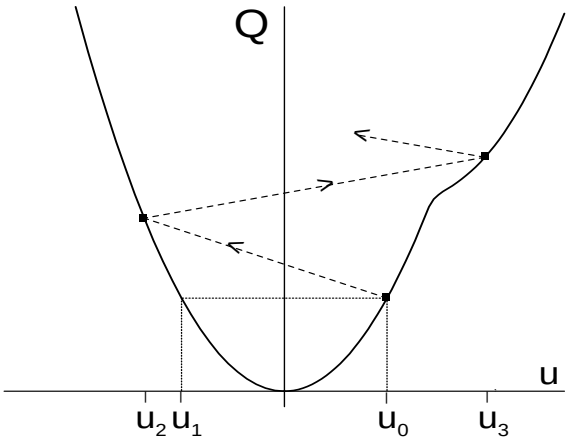

FIG. 38. $Q(u)$, (10.6): $u_0 = u(0),\ u_1 = u(x_1) = u_0,\ u_2 = u(x_2),\ u_3 = u(x_3)$.

In Figure 38 we set $u_1 = u(x_1)$ and $u_2 = u(x_2)$. As $u(x)$ decreases from u_1 to u_2, properties (10.8) and (10.9) imply that $Q(u)$ *increases*, and therefore

$$Q(u(x_2)) > Q(u_1) = Q(u(0)). \tag{10.23}$$

In the final step of the proof we follow $u(x)$ as x increases from $x = x_2$, and we show that there is an $x_3 > x_2$ such that $u(x_3) = u_3 > u(0)$ (see Figures 37 and 38). We first observe from (10.8)–(10.9) that there is a unique $\bar{u} > 0$ such that $Q(\bar{u}) = Q(u(x_2))$.

It follows from (10.23), and the fact that $Q(u)$ is increasing for $u > 0$, that

$$\bar{u} > u(0). \tag{10.24}$$

Next, define

$$x_3 = \sup\{\hat{x} > x_2 | u'''(x) > 0 \ \forall x \in (x_2, \hat{x})\}. \tag{10.25}$$

Because of (10.24), if we show that $u(x_3) > \bar{u}$, we will obtain a contradiction of the fact that $u(x)$ has its global maximum at $x = 0$. From (10.19), (10.22), and (10.25) it follows that

$$u'(x) > 0, \quad u''(x) > u''(x_2) = (b^2+1)\sqrt{2Q(u(x_2))} > 0 \qquad \forall x \in (x_2, x_3]. \tag{10.26}$$

If $x_3 = \infty$, then (10.26) implies that $u''(\infty) > 0$, contradicting the condition $u''(\infty) = 0$ given in (10.1). Thus, $x_3 < \infty$ and it follows from (10.25) that

$$u'''(x_3) = 0. \tag{10.27}$$

Finally, suppose that

$$u(x_2) < u(x) \leq \bar{u} \qquad \forall x \in (x_2, x_3).$$

Then (10.8) and (10.9) imply that

$$0 \leq Q(u(x)) \leq Q(u(x_2)) \qquad \forall x \in (x_2, x_3). \tag{10.28}$$

Combining (10.26), (10.27), and (10.28), and setting $x = x_3$ in (10.5), we obtain

$$-(b^2-1)(u'(x_3))^2 = \frac{(u''(x_3))^2}{2} - (b^2+1)^2 Q(u(x_3)) > 0,$$

a contradiction since $u'(x_3) > 0$ and $b > 1$. Thus, it must be the case that $u(x_3) > \bar{u} > u(0)$ as claimed. However, as described earlier, this contradicts the fact that $u(x)$ has its global maximum at $x = 0$. This completes the proof.

11. Summary. In this paper we have studied steady states of a partial integro-differential equation that has been used to model working memory in a neuronal network. We have extended previous results for "Mexican hat" coupling to the case where the connectivity function changes sign infinitely often, in the hope of more realistically modeling the connectivity known to exist in the prefrontal cortex. Our main results include (a) a proof of the nonexistence of a type of "multiple bump" solution when the connectivity is of Mexican hat type, (b) an upper bound on the decay rate of an oscillatory connectivity function, above which only trivial solutions exist, and (c) a numerical investigation of the possible solutions and the bifurcations they undergo for a particular oscillatory connectivity function.

For the one-dimensional model, many of the numerical results were obtained as a result of noting that stationary solutions of the partial integro-differential equation (5.1) are equivalent to homoclinic orbits in the related fourth order ordinary differential equation problem (5.8). This property allowed us to use the software package AUTO97 [12, 13], with its facilities for continuing homoclinic orbits, to follow both stable and unstable solutions as parameters were varied. We are presently pursuing a rigorous proof of existence of the families of N-bump solutions found here. Already,

it has been proved in [23] that any bounded solution of the ordinary differential equation in (5.8) also is a solution of the integral equation (5.1). Thus, in addition to homoclinic orbits, we are also investigating the existence of other families of solutions, including periodic, aperiodic, and chaotic solutions. While many of our results were derived by exploiting the specific form of an oscillatory connectivity function, we believe that the qualitative aspects of our results will hold for any qualitatively similar function.

For the two-dimensional extension of our model we used a MATLAB [28] code to generate stable multi-bump solutions. For appropriate parameter values we found that N-bump solutions exist and that they retain many of the characteristic qualities of solutions of the one-dimensional model. However, we also found stable solutions which were not predicted by our one-dimensional studies. In future research we will continue our investigation of the different types of stable patterns of solutions of the two-dimensional problem.

DESORPTION OVERSHOOT IN POLYMER-PENETRANT SYSTEMS: ASYMPTOTIC AND COMPUTATIONAL RESULTS*

DAVID A. EDWARDS† AND RICHARD A. CAIRNCROSS‡

Abstract. Many practically relevant polymers undergoing desorption change from the rubbery (saturated) to the glassy (nearly dry) state. The dynamics of such systems cannot be described by the simple Fickian diffusion equation due to viscoelastic effects. The mathematical model solved numerically is a set of two coupled PDEs for concentration and stress. Asymptotic solutions are presented for a moving boundary-value problem for the two states in the short-time limit. The solutions exhibit *desorption overshoot*, where the penetrant concentration in the interior is less than that on the surface. In addition, it is shown that if the underlying time scale of the equations is ignored when postulating boundary conditions, nonphysical solutions can result.

Key words. asymptotic expansions, desorption, moving boundary-value problems, perturbation methods, polymer-penetrant systems, finite-element method

1. Introduction.

Over the past few decades, much experimental and theoretical work has been devoted to the study of polymer-penetrant systems. In particular, the desorption of penetrants from saturated polymer matrices has been examined due to its wide industrial applicability. One unusual feature of such systems is the change in the polymer from a *rubbery* state when it is nearly saturated to a *glassy* state when it is nearly dry. As part of the drying process, a glassy *skin* often develops at the exposed surface of a polymer whose properties are significantly different from the rest of the polymer-penetrant solution [1], [2], [3], [4], [5]. This phenomenon, called *skinning* [6], [7], [8], has many industrial applications [8], [9], [10], [11], [12], [13], [14], [15], [16].

There are many different theories for why the skinning process occurs, including phase separation [17], crystallization [18], and diffusion-induced convection [19]. Nevertheless, for the systems we wish to study, most scientists agree that one important factor is a viscoelastic stress in the polymer entanglement network, which can be as important to the transport process as the well-understood Fickian dynamics [20], [21], [22]. The size of this stress is related to the *relaxation time* of the viscoelastic polymer matrix. In the glassy skin, the relaxation time is finite, so the stress is an important effect, but in the rubbery region the relaxation time is nearly zero [15], [20], [23]. Nevertheless, we will show that in order for the mathematical model to yield physically meaningful results, at some level the short relaxation time in the rubber must also be taken into account.

Numerical and analytical solutions are derived here for model equations for the

system described above. Our equations are the same, to leading order, as those for general polymer-penetrant systems derived in detail by Edwards and Cohen [24], [25], Edwards [26], Cairncross and Durning [8], Durning [27], and Durning and Tabor [28]. These models, which are presented in section 2, consist of a set of coupled PDEs for the concentration and stress. The parameters in the numerical simulation vary smoothly with concentration, so the glass-rubber interface $x = s(t)$ between the two states is simply an isocline of concentration. In contrast, the parameters in the analytical model are assumed to be piecewise constant in the rubber and glass. Thus, a moving boundary-value problem similar to a Stefan problem results. In each of the regions a different partial differential operator holds, and continuity conditions at the glass-rubber interface dictate its motion.

In section 3 we construct a perturbation solution to the equations. The solutions are expressed as integrals of Green's functions convolved with fictitious boundary conditions which provide the new unknowns for which we must solve. In section 4 we construct short-time asymptotic solutions of the concentration and stress fields. The form of the short-time solutions necessitates a corner layer, where the full system of equations holds. The solutions exhibit *desorption overshoot*, where the minimum in the concentration occurs in the interior of the domain.

In addition, if we use a standard high-mass-transfer-coefficient approximation common in diffusion and heat conduction problems, it is possible for the concentration to become negative. This result is confirmed numerically in section 5. In section 6 it is explained that the unphysical negative concentration appears because the limit of high mass transfer coefficient imposes a jump in the exterior concentration faster than the underlying time scales of the operator. Physically, the polymer is *self-regulating* for desorption as well as sorption [24]. A new boundary condition is postulated which incorporates the time scale in the stress evolution equation, and it is shown that such a boundary condition does not lead to negative concentrations.

2. Preliminaries.

2.1. Governing equations.

We examine the following dimensionless system of equations for anomalous desorption in a polymer of finite dimensionless length L:

$$\frac{\partial C}{\partial t} = \frac{\partial}{\partial x}\left(D(C)\frac{\partial C}{\partial x} + \frac{\partial \sigma}{\partial x}\right), \qquad 0 \le x \le L, \tag{2.1a}$$

$$\frac{\partial \sigma}{\partial t} + \frac{\beta(C)}{\beta_{\mathrm{g}}}\sigma = \gamma\epsilon C + \frac{\partial C}{\partial t}, \tag{2.1b}$$

where C is the dimensionless concentration of penetrant in the polymer, γ is a dimensionless constant, and L is the length of the slab scaled with the length scale of stress evolution [29].

The system is described in general in [29] and specialized in [26], but some discussion is required. The flux in (2.1a) can be derived by postulating that the chemical potential is a function of both C and σ [24], which in one dimension corresponds to the stress in the polymer network [24], [30], [31], [32]. In (2.1b), the coefficient of $\partial\sigma/\partial x$ has been chosen constant, in contrast to the models of Durning and colleagues [8], [28], [33].

$D(C)$ is a normalized diffusion coefficient measuring the ratio of the Fickian to non-Fickian effects in the flux. Also $\beta(C)$ is the inverse of the relaxation time, which measures the speed at which changes in one part of the polymer are communicated

to other parts of the polymer. Both increase dramatically as the polymer goes from the glassy to rubbery state [15], [20], [23], [34], [35], [36]. In contrast, the differences in these parameters *within* states are qualitatively negligible. Therefore, for our numerical work we assume the following forms for these functions:

$$\begin{aligned} D(C) &= D_{\mathrm{g}} - \frac{D_{\mathrm{g}} - D_{\mathrm{r}}}{2}\left[1 + \tanh(\alpha(C - C_*))\right], \\ \beta(C) &= \beta_{\mathrm{g}} - \frac{\beta_{\mathrm{g}} - \beta_{\mathrm{r}}}{2}\left[1 + \tanh(\alpha(C - C_*))\right], \end{aligned} \qquad \alpha \gg 1, \tag{2.2}$$

where C_* is the value of the concentration at which the glass-rubber transition occurs. Other physically appropriate forms for β and D are presented in [4], [8], [28], [33], [34], [35], [36], [37].

We examine a polymer that is initially saturated (and hence rubbery) and unstressed, which leads to the initial conditions

$$C^{\mathrm{r}}(x,0) = 1, \qquad \sigma^{\mathrm{r}}(x,0) = 0. \tag{2.3}$$

The end $x = L$ is insulated, while at the exposed surface $x = 0$, the flux is proportional to the difference between the surface concentration and the environment concentration C_{ext}:

$$\left(D(C)\frac{\partial C}{\partial x} + \frac{\partial \sigma}{\partial x}\right)(L,t) = 0, \tag{2.4a}$$

$$\left(D(C)\frac{\partial C}{\partial x} + \frac{\partial \sigma}{\partial x}\right)(0,t) = k[C(0,t) - C_{\mathrm{ext}}], \tag{2.4b}$$

where k is a constant measuring the mass transfer coefficient of the exposed interface.

2.2. Two-state formulation. We solve (2.1)–(2.4) numerically in section 5, but in order to obtain direct dependence of our solution on the physical parameters in the system, we will solve the problem analytically, which necessitates some simplifications.

As $\alpha \to \infty$, the parameters in (2.2) become piecewise constant:

$$\begin{aligned} D(C) &= \begin{cases} D_0\epsilon, & 0 \le C \le C_*, \\ D_{\mathrm{r}}, & C_* \le C \le 1, \end{cases} \\ \beta(C) &= \begin{cases} \beta_{\mathrm{g}}, & 0 \le C \le C_*, \\ \beta_{\mathrm{r}}, & C_* < C \le 1. \end{cases} \end{aligned} \tag{2.5}$$

The rubber is closest to the Fickian regime because the relaxation time is almost instantaneous; thus $\beta_{\mathrm{g}}/\beta_{\mathrm{r}} = \epsilon \ll 1$. It has been shown experimentally [16] that the diffusion coefficient in the glassy region is quite small, so we let $D_{\mathrm{g}} = D_0\epsilon$, where D_0 is an $O(1)$ constant.

With the functional forms in (2.5), it is natural to model the physical system as a two-state problem with a moving boundary $x = s(t)$ representing the glass-rubber interface. Thus, making our substitutions into (2.1), we obtain the following in the glassy region:

$$\frac{\partial C^{\mathrm{g}}}{\partial t} = D_0\epsilon\frac{\partial^2 C^{\mathrm{g}}}{\partial x^2} + \frac{\partial^2 \sigma^{\mathrm{g}}}{\partial x^2}, \tag{2.6a}$$

$$\frac{\partial \sigma^{\mathrm{g}}}{\partial t} + \sigma^{\mathrm{g}} = \gamma\epsilon C^{\mathrm{g}} + \frac{\partial C^{\mathrm{g}}}{\partial t}, \tag{2.6b}$$

while in the rubbery region we have

$$\frac{\partial C^{\mathrm{r}}}{\partial t} = D_{\mathrm{r}} \frac{\partial^2 C^{\mathrm{r}}}{\partial x^2} + \frac{\partial^2 \sigma^{\mathrm{r}}}{\partial x^2}, \tag{2.7a}$$

$$\frac{\partial \sigma^{\mathrm{r}}}{\partial t} + \frac{\sigma^{\mathrm{r}}}{\epsilon} = \gamma \epsilon C^{\mathrm{r}} + \frac{\partial C^{\mathrm{r}}}{\partial t}. \tag{2.7b}$$

With such a formulation, we must have conditions that hold at $x = s(t)$. We impose continuity of concentration at the glass-rubber transition value C_*:

$$C^{\mathrm{r}}(s(t), t) = C^{\mathrm{g}}(s(t), t) = C_*. \tag{2.8}$$

In addition, we require continuity of stress and flux:

$$\sigma^{\mathrm{r}}(s(t), t) = \sigma^{\mathrm{g}}(s(t), t), \tag{2.9a}$$

$$\left(D_{\mathrm{r}} \frac{\partial C^{\mathrm{r}}}{\partial x} + \frac{\partial \sigma^{\mathrm{r}}}{\partial x} \right)(s(t), t) = \left(D_0 \epsilon \frac{\partial C^{\mathrm{g}}}{\partial x} + \frac{\partial \sigma^{\mathrm{g}}}{\partial x} \right)(s(t), t). \tag{2.9b}$$

3. Perturbation solution. We assume perturbation expansions for our dependent variables in ϵ, the small ratio of the relaxation times:

$$C \sim C_0 + O(\epsilon), \qquad \sigma \sim \sigma_0 + O(\epsilon), \tag{3.1}$$

where the same expansions hold for the rubber and glass.

3.1. The glassy region. Substituting (3.1) into (2.6) yields

$$\frac{\partial C_0^{\mathrm{g}}}{\partial t} = \frac{\partial^2 \sigma_0^{\mathrm{g}}}{\partial x^2}, \tag{3.2a}$$

$$\frac{\partial \sigma_0^{\mathrm{g}}}{\partial t} + \sigma_0^{\mathrm{g}} = \frac{\partial C_0^{\mathrm{g}}}{\partial t}. \tag{3.2b}$$

It is simpler to solve for the stress in the glassy region first; hence we combine (3.2) to obtain

$$\frac{\partial \sigma_0^{\mathrm{g}}}{\partial t} + \sigma_0^{\mathrm{g}} = \frac{\partial^2 \sigma_0^{\mathrm{g}}}{\partial x^2}, \qquad 0 < x < s(t). \tag{3.3}$$

In many industrial applications, fast drying is desirable in order to reduce production time and cost. Thus, we consider the case where $k \to \infty$, which corresponds to high mass transfer coefficient or large driving force. (In certain scaling limits, this can also correspond to thick films.) Making this substitution in (2.4b), we obtain

$$C_0^{\mathrm{g}}(0, t) = C_{\mathrm{ext}} < C_*, \tag{3.4}$$

which locates the glass-rubber interface at the origin for $t = 0$. This sort of Dirichlet condition is routinely used in diffusion or heat conduction problems, instead of the more physically realistic flux or activity balance conditions. Nevertheless, we shall see that in this context, imposing such a simple boundary condition can produce unphysical results.

Equation (3.4) implies that the concentration jumps discontinuously at the origin from 1 to C_{ext}, so we have the following:

$$\frac{dC}{dt}(0,t) = (C_{\text{ext}} - 1)\delta(t), \tag{3.5}$$

and upon substituting this result into (3.2b) evaluated at $x = 0$, we obtain

$$\sigma_0^{\text{g}}(0,t) = (C_{\text{ext}} - 1)e^{-t}. \tag{3.6}$$

Note the exponential decay of surface stress from its initial value, reflecting the memory effects in the glassy polymer.

In order to solve the problem, we use an integral method first introduced by Boley [38] and used extensively in this context by Edwards and Cohen [24] and Edwards [26], [29], [39], [40]. Essentially, we wish to write the solution of (3.3) and (3.6) as a Green's function convolved with a *fictitious* initial condition $\sigma_0^{\text{g}}(x,0) = f^{\text{i}}(x)$. This condition is fictitious because the polymer is not glassy at $t = 0$. Thus we extend our domain beyond the region $0 < x < s(t)$. By writing our solution in this form, we reduce the problem from a PDE to an integrodifferential equation.

Since all expressions for $x > s(t)$ are fictitious anyway, we embed the problem in the semi-infinite domain $x > 0$. The solution then is found to be

$$\sigma_0^{\text{g}}(x,t) = (C_{\text{ext}} - 1)e^{-t}\operatorname{erfc}\left(\frac{x}{2\sqrt{t}}\right)$$

$$+\frac{e^{-t}}{2\sqrt{\pi t}}\int_0^\infty f^{\text{i}}(z)\left\{\exp\left[-\frac{(x-z)^2}{4t}\right] - \exp\left[-\frac{(x+z)^2}{4t}\right]\right\}dz. \tag{3.7}$$

3.2. The rubbery region. In the rubbery region we substitute (3.1) into (2.7b) to obtain

$$\sigma_0^{\text{r}}(x,t) = 0. \tag{3.8}$$

Since the γ term does not contribute to the dynamics in either the glassy or the rubbery regions, our model (2.1) contains exactly those dynamical processes as in the models of Cairncross and Durning [8], Durning [27], and Durning and Tabor [28].

Substituting (3.1) and (3.8) into (2.7a) yields

$$\frac{\partial C_0^{\text{r}}}{\partial t} = D_{\text{r}}\frac{\partial^2 C_0^{\text{r}}}{\partial x^2}, \qquad s(t) < x < L, \quad 0 < t < t_L, \tag{3.9a}$$

where $s(t_L) = L$. To use Boley's method to rewrite our solution, we note that upon substituting (3.1) and (3.8) into (2.4a), we obtain

$$\frac{\partial C_0^{\text{r}}}{\partial x}(L,t) = 0, \tag{3.9b}$$

and hence $x = L$ is a line of symmetry. Thus by the method of images

$$C_0^{\text{r}}(x,t) = 1 - [T^{\text{r}}(x,t) + T^{\text{r}}(2L - x,t)] \tag{3.10a}$$

is a solution to (3.9) and (2.3) if $T^{\text{r}}(x,t)$ is a solution of the heat equation. Since the rubber occupies the region $s(t) < x < L$, the fictitious condition is $T^{\text{r}}(0,t) = f^{\text{b}}(t)$, so T^{r} is given by

$$T^{\text{r}}(x,t) = \frac{x}{2\sqrt{D_{\text{r}}\pi}}\int_0^t \frac{f^{\text{b}}(z)}{(t-z)^{3/2}}\exp\left[-\frac{x^2}{4D_{\text{r}}(t-z)}\right]dz. \tag{3.10b}$$

Substituting (3.1) and (3.8) into (2.8) and (2.9), we obtain

$$C_0^{\mathrm{r}}(s(t),t) = C_0^{\mathrm{g}}(s(t),t) = C_*, \tag{3.11a}$$

$$\sigma_0^{\mathrm{g}}(s(t),t) = 0, \tag{3.11b}$$

$$D_{\mathrm{r}}\frac{\partial C_0^{\mathrm{r}}}{\partial x}(s(t),t) = \frac{\partial \sigma_0^{\mathrm{g}}}{\partial x}(s(t),t). \tag{3.12}$$

Upon substitution of (3.7) and (3.10) into (3.11) and (3.12), we will obtain three integrodifferential equations for the unknowns f^{i}, f^{b}, and s.

4. Short-time solutions.

4.1. The outer solution. We examine the small-time asymptotics of our analytic solution as in Edwards [26] by letting

$$f^{\mathrm{i}}(x) \sim f_0^{\mathrm{i}}, \qquad f^{\mathrm{b}}(t) \sim f_0^{\mathrm{b}}, \qquad s(t) = 2s_0 t^n, \qquad t \to 0, \quad x \to 0. \tag{4.1}$$

We substitute (4.1) into (3.10) and (3.7) to obtain expressions for our unknowns for $L = O(1)$. Substituting these expressions into (3.11) and (3.12), we obtain

$$C_* \sim 1 - f_0^{\mathrm{b}} \operatorname{erfc}\left(\frac{s_0 t^{n-1/2}}{\sqrt{D_{\mathrm{r}}}}\right), \tag{4.2a}$$

$$0 \sim (C_{\mathrm{ext}} - 1)\operatorname{erfc}(s_0 t^{n-1/2}) + f_0^{\mathrm{i}} \operatorname{erf}(s_0 t^{n-1/2}), \tag{4.2b}$$

$$\frac{D_{\mathrm{r}} f_0^{\mathrm{b}}}{\sqrt{\pi D_{\mathrm{r}} t}} \exp\left(-\frac{s^2}{4D_{\mathrm{r}} t}\right) \sim [f_0^{\mathrm{i}} - (C_{\mathrm{ext}} - 1)]\frac{e^{-t}}{\sqrt{\pi t}} \exp\left(-\frac{s^2}{4t}\right). \tag{4.3}$$

Equation (4.2a) can be satisfied if and only if $n \geq 1/2$. Equation (4.2b) can be satisfied if and only if $n \leq 1/2$. Therefore $n = 1/2$ and initially the front moves in a purely Fickian way because the nonlinear memory effects have not yet had time to develop. Using this result, we obtain

$$g_1(s_0) \equiv \sqrt{D_{\mathrm{r}}}\frac{1 - C_*}{\operatorname{erfc}(s_0/\sqrt{D_{\mathrm{r}}})} \exp\left(-\frac{s_0^2}{D_{\mathrm{r}}}\right) = \frac{1 - C_{\mathrm{ext}}}{\operatorname{erf} s_0} \exp\left(-s_0^2\right) \equiv g_2(s_0). \tag{4.4}$$

Figure 4.1 shows plots of $g_2 - g_1$ for various values of C_*. The s_0-intercept marks the value of the front speed. Note that as C_* increases, the front speed increases since not as much penetrant has to desorb to move the front along.

Figure 4.2 shows the variance in the front speed as D_{r} and C_{ext} vary. Note that as C_{ext} decreases, the front speed increases because of a larger driving force. In addition, as D_{r} increases, the front speed decreases because it is easier to diffuse penetrant to the front.

Using (4.4), we may derive the value of f_0^{b} and hence obtain

$$C_0^{\mathrm{r}}(x,t) = 1 - \frac{1 - C_*}{\operatorname{erfc}(s_0/\sqrt{D_{\mathrm{r}}})}\left[\operatorname{erfc}\left(\frac{x}{2\sqrt{D_{\mathrm{r}} t}}\right) + \operatorname{erfc}\left(\frac{2L - x}{2\sqrt{D_{\mathrm{r}} t}}\right)\right]. \tag{4.5}$$

As $L \to \infty$, the second term drops out and we are left with exactly the expression in Edwards [26] for the case of a semi-infinite domain. In addition, as $t \to 0$ the second term modeling "reflections" from $x = L$ is negligible.

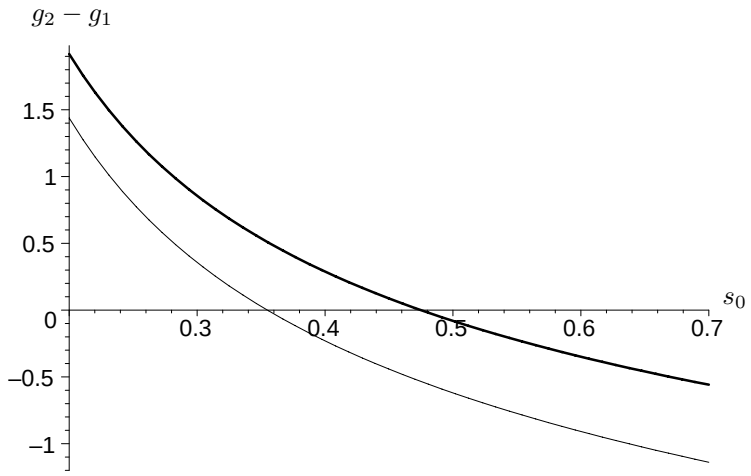

FIG. 4.1. $g_2 - g_1$ *versus* s_0 *for* $D_\mathrm{r} = 7$, $C_\mathrm{ext} = 1/3$. *Thin line:* $C_* = 1/2$. *Thick line:* $C_* = 2/3$.

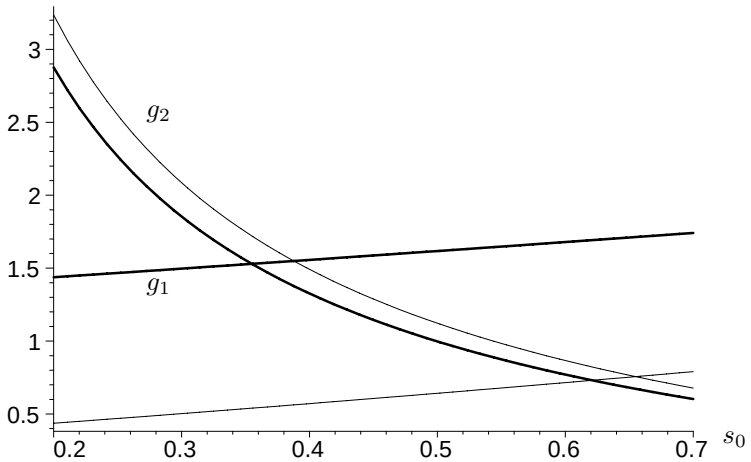

FIG. 4.2. g_1 *and* g_2 *versus* s_0 *for* $C_* = 1/2$. *Thick lines:* $D_\mathrm{r} = 0.4$, $C_\mathrm{ext} = 1/4$. *Thin lines:* $D_\mathrm{r} = 7$, $C_\mathrm{ext} = 1/3$.

We may also use (4.4) to derive the value of f_0^i and hence obtain

$$\sigma_0^\mathrm{g}(x,t) \sim (C_\mathrm{ext} - 1)e^{-t}\left[1 - \frac{1}{\operatorname{erf} s_0}\operatorname{erf}\left(\frac{x}{2\sqrt{t}}\right)\right]. \tag{4.6}$$

Substituting (4.6) into (3.2a) and solving using (3.11a), we have the following:

$$\begin{aligned} C^\mathrm{g}(x,t) = C_* + \frac{C_\mathrm{ext} - 1}{2\operatorname{erf} s_0}\Bigg\{ & e^{-x}\left[\operatorname{erfc}\left(-\sqrt{t} + \frac{x}{2\sqrt{t}}\right) - \operatorname{erfc}\left(s_0 - \frac{x}{2s_0}\right)\right] \\ & + e^{x}\left[\operatorname{erfc}\left(\sqrt{t} + \frac{x}{2\sqrt{t}}\right) - \operatorname{erfc}\left(s_0 + \frac{x}{2s_0}\right)\right]\Bigg\}, \end{aligned} \tag{4.7}$$

where the x/s_0 terms come from the asymptotic expansion of $s^{-1}(x)$, the inverse function for the front position:

$$s^{-1}(x) \sim \left(\frac{x}{2s_0}\right)^2, \qquad x \to 0. \tag{4.8}$$

Unfortunately, we note that if we substitute $x = 0$ into (4.7), we obtain

$$\lim_{x\to 0} C_0^{\mathrm{g}}(x,t) = C_* + C_{\mathrm{ext}} - 1 \neq C_{\mathrm{ext}} = C^{\mathrm{g}}(0,t). \tag{4.9}$$

The discontinuity near $x = 0$ must be resolved by a boundary layer, but even the solution to the full problem near $x = 0$ will be less than C_{ext}. We call this excessive drying near the exposed surface *desorption overshoot*, as the minimum of the concentration now occurs inside the film. The terminology is motivated by the related phenomenon of *sorption overshoot*, where the concentration rises above its equilibrium value during a sorption experiment [41].

Moreover, it is certainly possible for $C_* + C_{\mathrm{ext}} - 1 < 0$, which would yield the physically unrealistic result of a negative concentration. This unphysical aspect is not an artifact of the asymptotics; rather it is the direct result of the Dirichlet condition (3.4), as discussed in section 6.

4.2. The corner layer. The discontinuity about $x = 0$ is caused by the form of the operator in (3.2a). As long as the evolution equation for C has only a $\partial C/\partial t$ term in it, then σ and C will differ *everywhere* only by a function of x. Since both C and σ_0^{r} are constants along the front, that difference must also be a constant at the front. This causes a discontinuity because

$$\lim_{t\to 0} C(s(t),t) \neq \lim_{t\to 0} C(0,t).$$

σ_0^{r} does not vary along the front due to the ϵ^{-1} term in (2.7b). This term can be counteracted if we introduce a corner layer near the origin *via* the following substitutions:

$$C^{\mathrm{r}}(x,t) = C^+(\xi,\tau), \qquad \sigma^{\mathrm{r}}(x,t) = \sigma^+(\xi,\tau), \qquad \xi = \frac{x}{\epsilon^{1/2}}, \qquad \tau = \frac{t}{\epsilon}. \tag{4.10}$$

Substituting (4.10) into (2.7), we obtain

$$\frac{\partial C^+}{\partial \tau} = D_{\mathrm{r}} \frac{\partial^2 C^+}{\partial \xi^2} + \frac{\partial^2 \sigma^+}{\partial \xi^2}, \tag{4.11a}$$

$$\frac{\partial \sigma^+}{\partial \tau} + \sigma^+ = \frac{\partial C^+}{\partial \tau}, \tag{4.11b}$$

which is just the full system (2.7) without the γ term. Hence even in the corner layer, our model matches that of Cairncross and Durning [8], Durning [27], and Durning and Tabor [28]. Note that τ is the time scale for relaxation in the rubber.

To solve this system, we must proceed numerically. Nevertheless, we note that due to the exponential decay inherent in (4.11b), curves of constant C are not curves of constant σ. This fact will remove the discontinuity, which was caused by the fact that the front was an isocline for both outer solutions.

5. Numerical computations. We compare our asymptotic results to those from a finite-element code previously used to solve a similar model [8]. The code solves (2.1)–(2.4) using finite elements with quadratic basis functions. In order to resolve the boundary layer, the domain was discretized into sixty fixed but unequally spaced elements, with more elements placed near $x = 0$.

Application of the finite element method to the model results in a system of nonlinear coupled ODEs for the nodal values of concentration and stress. The system of ODEs was integrated in time using a stiff DAE solver, DASSL [42]. DASSL uses an Adams–Bashforth–Moulton predictor-corrector algorithm with a variable-order backward differentiation formula. The corrector is implicit and the nonlinear system is solved by Newton's method with an analytical Jacobian matrix. The time step is automatically updated to control the estimated error within a specified tolerance. The error tolerance and number and distribution of elements were adjusted until the results were insensitive to the size of these parameters.

5.1. Comparison with asymptotics. The parameters chosen for use in both the analytical model and the numerical simulations were as follows:

$$C_* = 1/2, \qquad D_{\mathrm{r}} = 4, \qquad C_{\mathrm{ext}} = 1/4, \qquad L = 3, \qquad D_{\mathrm{g}} = 4 \times 10^{-4}, \tag{5.1a}$$

$$\beta_{\mathrm{g}} = 1, \qquad \beta_{\mathrm{r}} = 10^4, \qquad \alpha = 80, \qquad k = 1.33 \times 10^4. \tag{5.1b}$$

These parameters essentially correspond to an ϵ value of 10^{-4}. Also, with these parameters, $s_0 \approx 0.4550$.

Figure 5.1 shows a comparison of the asymptotic and numerical predictions of the front position for small time. The speed of the front decreases with time as predicted by both methods. The agreement between the asymptotic and numerical results is excellent.

In Figure 5.2 we show a graph of the concentration for the parameters in (5.1) and the times listed. The interval in x is restricted near $x = 0$; the grid spacing decreases as we reach that endpoint. There is excellent agreement between the numerical and outer solutions in the region away from the boundary layer, and the discontinuity in

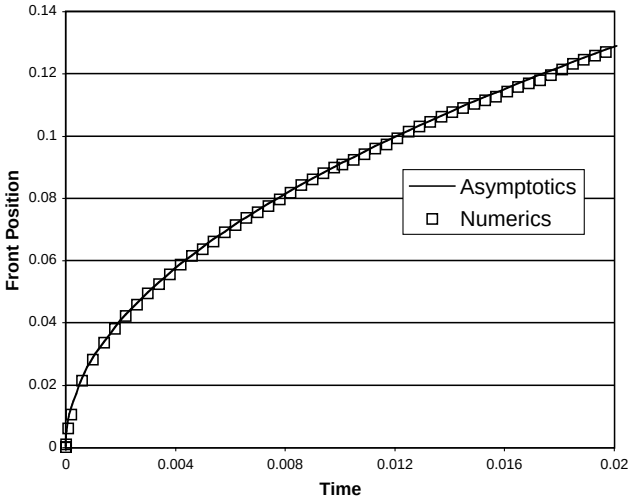

FIG. 5.1. *Asymptotic and numerical calculations of $s(t)$ for the parameters in* (5.1).

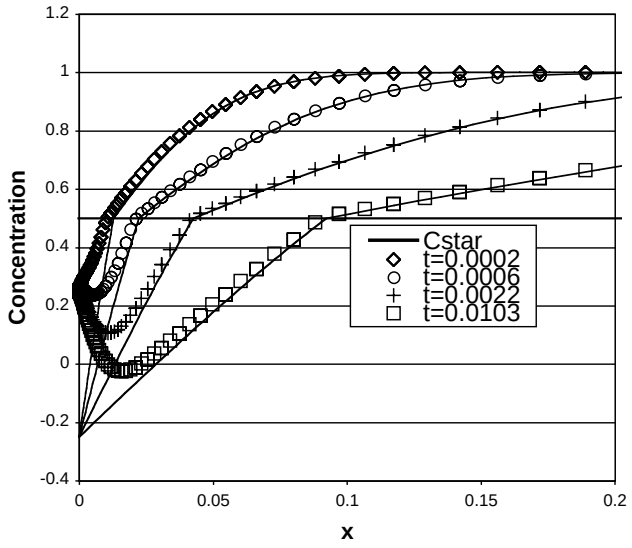

FIG. 5.2. *Aymptotic solution $C_0(x,t)$ (lines) and numerical solution (symbols) versus x. The numerical and asymptotic solutions are indistinguishable beyond $x = 0.2$.*

$\partial C/\partial x$ at the glass-rubber transition is accurately predicted by both techniques. Note that at $t = 0.0103$ even the numerical solution goes negative, so we have confirmed that negative concentration values are not an artifact of the asymptotic solution. We shall examine the root causes of this phenomenon in the next section.

Figure 5.3 shows a graph of the stress versus x for the times listed. There is excellent agreement between the asymptotic and numerical solutions for the glassy stress. In addition, the zero-stress approximation (3.8) and the numerical calculation

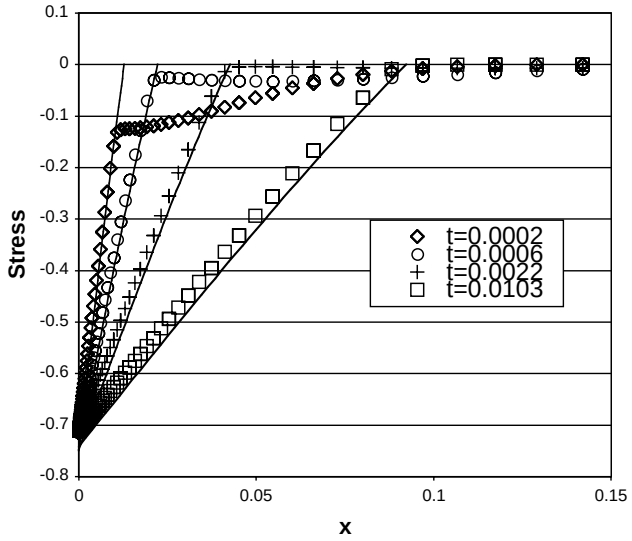

FIG. 5.3. *Aymptotic solution $\sigma_0^{\mathrm{g}}(x,t)$ (lines) and numerical solution (symbols) versus x. The rubbery stress is zero. The numerical and asymptotic solutions are indistinguishable beyond $x = 0.15$.*

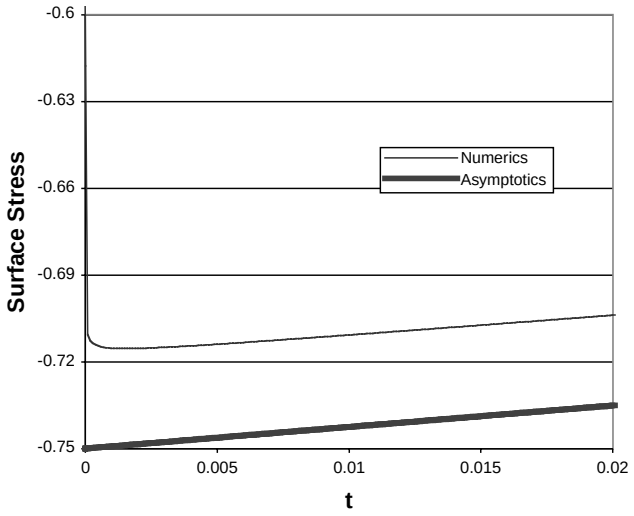

FIG. 5.4. *Comparison of asymptotic (from equation* (3.6)*) and numerical expressions for surface stress.*

in the rubbery region match for larger times. From the graph at $t = 2 \times 10^{-4}$ we see that due to the rapid drop in C at the surface, the stress in the rubbery region is initially $O(1)$, as shown in section 4.2. For longer times, the stress decays exponentially as predicted by (4.11b), until at $t = 2.2 \times 10^{-3}$, the numerical calculation is virtually indistinguishable from (3.8).

Figure 5.4 shows a graph of the surface stress at $x = 0$. Though the outer and numerical solutions decay on the same e^{-t} scale, there is a persistent gap because the outer solution in (3.6) assumes an instantaneous change in C at $t = 0$, while the numerical simulations follow (2.4b). Thus, initially the surface concentration and surface stress evolve on a time scale roughly proportional to k^{-1}. This time scale will become important later on when we examine the reason for the negative concentration values.

5.2. Long-time results. Though the validity of the asymptotics ends for moderate times, we can certainly continue the numerical calculations into that region. Figure 5.5 shows the computed concentration profiles for various times. Note that between $t = 2$ and $t = 4$, the film becomes entirely glassy. (For more discussion of the time at which the front reaches the back of the film, see the appendix.) Since the glass has a longer relaxation time, the change in the concentration between $t = 2$ and $t = 4$ is relatively small.

The unphysical negative concentration is not a brief anomaly; it continues for moderate time, and the size of the dip actually increases. It should be noted that the desorption overshoot disappears if k is smaller, which corresponds to a slower change in the surface concentration. For more discussion of this topic, see section 6.

Figure 5.6 shows the computed stress profiles for the same series of times. The nearly linear stress in the glassy region implies a constant non-Fickian flux. Thus, the evolution of the concentration in this region is dominated by the Fickian flux. Note that the surface stress continues its exponential decay to a final limiting value of zero.

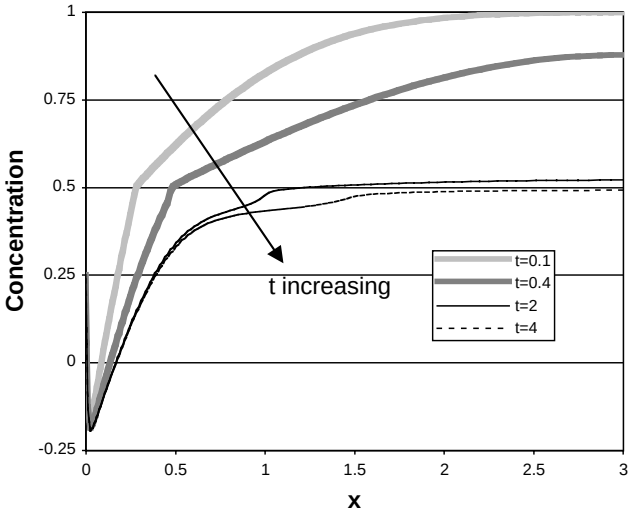

FIG. 5.5. *Computed concentration profiles versus x for the times listed in the legend.*

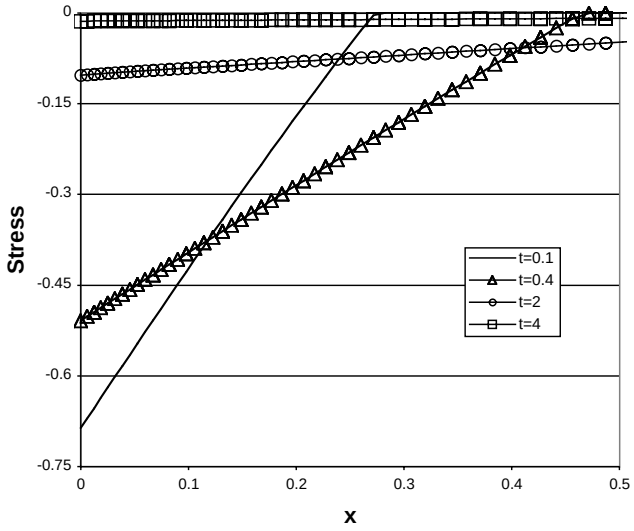

FIG. 5.6. *Computed stress profiles versus x for the times listed in the legend.*

6. Explaining negative concentrations. The unphysical negative concentration is not an artifact of the asymptotics, as the numerical solutions in Figure 5.2 show. To explain the phenomenon, we solve (2.6b) for short times, using (3.6) and (3.2). After some work, we obtain the following expression:

$$\lim_{x\to 0} C_0^{\mathrm{g}}(x,t) = \lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) + C_*. \tag{6.1}$$

Hence the discontinuity *in the outer solution* exists for all time unless

$$\lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) = C_{\mathrm{ext}} - C_*. \tag{6.2}$$

Moreover, the concentration will go negative whenever

$$\lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) < -C_*. \tag{6.3}$$

How then to avoid satisfying this condition?

Following common practice for diffusion and heat transfer problems, we took $k \to \infty$ in (2.4b) to obtain the Dirichlet condition (3.4). The resulting discontinuous jump at $t = 0$ forces $\sigma(0, 0^+) = C_{\mathrm{ext}} - 1$, as can be seen from (3.6), and this value can violate (6.3). Why does the standard Dirichlet trick not work for this model?

In a standard diffusion problem, lines of constant t are characteristics. Thus these equations transmit disturbances with infinite signal speed to the entire domain. As can be intuited from the leading-order outer equations (3.3) and (3.9a), the same is true for this model. This explains why the solution does not break down in any mathematical sense; it just goes negative, which offends our physical sensibilities.

The key difference rather is the delay term inherent in (2.1b). When a jump occurs very quickly, the stress cannot relax fast enough (even with an $O(\epsilon)$ relaxation time in the rubber) to equilibrate it. Once a large stress gradient has been introduced at the exposed surface, there is no mechanism in (3.2a) to stop the concentration from going negative. This is related to the observation in [41] that other models for anomalous diffusion will have negative concentration values if a "retardation time" is not included.

There are several mechanisms one can introduce to moderate the concentration dip. For instance, consider the case where the $\partial\sigma/\partial x$ term in (2.1a) is multiplied by a "stress diffusion coefficient" $E(C)$, where $E(0) = 0$. This term would remain at leading order in the equation analogous to (3.2a), causing $\partial C_0^{\mathrm{g}}/\partial t(C = 0) = 0$ and preventing the concentration from going negative. Moreover, preliminary numerical calculations indicate that if $E(C) \ll 1$ in the glassy region, this change can eliminate negative concentrations while maintaining desorption overshoot.

Another remedy is to slow the change so that it occurs on the fast relaxation time scale of the rubbery polymer. Thus we replace (3.4) by

$$C(0,\tau) = C_{\mathrm{ext}} + (1 - C_{\mathrm{ext}})e^{-\lambda\tau}, \qquad \lambda \neq 1, \tag{6.4}$$

where τ is the time scale defined in (4.10). The exponential form is chosen to match the analysis in Edwards [24] and the forms in Hui et al. [34] and Long and Richman [43]; $\lambda \neq 1$ is taken for simplicity. As λ increases, the driving force increases and the transition between rubber and glass steepens.

As given by (6.4), the interface is now rubbery for some interval. We may substitute (6.4) into the leading orders of (2.6b) and (2.7b) and solve to obtain the stress boundary condition. Since τ is an initial-layer variable, we may take the limit of this condition as $\tau \to \infty$ to find the limiting value of the outer boundary condition. This is found to be

$$\lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) = -\frac{C_* - C_{\mathrm{ext}}}{1-\lambda} + \frac{\lambda(1 - C_{\mathrm{ext}})}{1-\lambda}\left(\frac{C_* - C_{\mathrm{ext}}}{1 - C_{\mathrm{ext}}}\right)^{1/\lambda}. \tag{6.5}$$

Thus our matching condition, and hence $C^{\mathrm{g}}(x, 0)$, depends on λ. As $\lambda \to \infty$, (6.4) approaches a step function and our result from section 3 holds:

$$\lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) = -(1 - C_{\mathrm{ext}}), \qquad \lambda \to \infty. \tag{6.6a}$$

If instead $\lambda \to 0$, we obtain the following:

$$\lim_{t\to 0} \sigma^{\mathrm{g}}(0,t) = -(C_* - C_{\mathrm{ext}}), \quad \lambda \to 0, \tag{6.6b}$$

which from (6.2) is exactly the condition required to eliminate the boundary layer at the exposed surface. In this case the exterior concentration varies on a time scale slower than that of the rubber relaxation time, so the *entire* polymer can equilibrate to the exterior.

Last, we note that from (6.3) that in order to maintain a positive concentration, the expression in (6.5) must be greater than $-C_*$. Hence the generation of negative concentrations in our model can be remedied by imposing more physically realistic boundary conditions. If changes in the exterior happen on a faster time scale than the rubber relaxation time scale, the surface cannot immediately equilibrate. Thus, the polymer exhibits a sort of "self-regulation" which puts restrictions on the speed at which the surface concentration can change. This sort of self-regulation has been seen in similar models of sorption processes [24].

7. Conclusions. During the desorption of saturated polymers near the glass-rubber transition temperature, a glassy skin will form near the exposed surface. One mechanism for the formation of such a skin is viscoelastic relaxation in the polymer network. The mathematical model presented here has captured this behavior in previous numerical [5], [8] and analytical [26], [29] studies. However, never before has the model been studied in both ways simultaneously. This merging of techniques involved restricting the analytical study to a more realistic finite domain and adapting the numerical parameter scheme to approximate a piecewise-constant approach. By approaching the solution in two ways, we validated both approaches. In particular, we established that negative concentrations were the result of neither a computational bug nor an erroneous asymptotic approximation, but were rather the predictable and robust result of a mathematically simple, but physically unrealistic, boundary condition.

In the asymptotic work, the parameters are taken as piecewise constant and the system is treated in a manner similar to a Stefan problem. Since the system is not amenable to similarity solutions, an integral method based on the one in Boley [38] is used. The finite domain is extended to a semi-infinite one in both cases, and the method of images is used to handle the insulated boundary condition at $x = L$.

The asymptotic and numerical results match well, showing a quick transition to the glassy region near the exposed surface. The glass-rubber interface initially moves like $t^{1/2}$, reflecting the fact that the viscoelastic memory effects have not yet had time to develop. The numerical solutions demonstrated desorption overshoot, where a minimum in the concentration occurs in the interior of the domain. This is mirrored in the asymptotic outer solution, which is less than the imposed surface concentration as $x \to 0$.

The overshoot can be traced to our replacement of a flux balance condition with a Dirichlet condition. Such approximations are routinely used in diffusion and heat conduction problems instead of the more complicated (but physically realistic) activity or flux conditions. However, in our case taking the limit of large k leads to negative concentrations. Essentially, we are attempting to force the surface concentration to vary faster than the polymer can adapt. The intrinsic time scale in the model then reduces the set of boundary conditions that can lead to physically meaningful results.

In section 6 we proposed two remedies for negative concentrations. A stress diffusion coefficient can be introduced which shuts down further penetrant diffusion

when the polymer is dry. Alternatively, if we vary the surface concentration on the fast τ time scale, we eliminate the negative concentrations. Essentially, the τ-variance is the fastest that the actual physical system can accommodate. This type of self-regulation has been demonstrated in sorption models [24].

Though the numerical and asymptotic profiles match well for small t, the appendix shows that due to the diffusive nature of the operators considered, the fictitious boundary conditions must be approximated very closely to guarantee accurate results for moderate t. Nevertheless, the agreement for small time provides a sturdy background on which to base further work. Not only do the asymptotic solutions verify the numerics, but they also demonstrate parameter ranges which produce unphysical results.

Appendix. Some remarks on the intersection point. We conclude by examining the solution near the time $t = t_L$ where $s(t_L) = L$. Due to the symmetry about the line $x = L$, $s^{-1}(x)$ should be even about $x = L$, so the first terms in our expansion for $s(t)$ should be

$$s(t) \sim L - s_1\sqrt{r}, \qquad r = t_L - t > 0, \qquad s_1 > 0. \tag{A.1}$$

Using (3.10a) and (A.1) in (3.11), we may construct an expansion in r, eventually reaching the following terms at $O(r)$:

$$(s_1^2 - 2D_{\mathrm{r}})\frac{\partial^2 T^{\mathrm{r}}}{\partial x^2}(L, t_L) = 0, \tag{A.2a}$$

$$\left(\frac{s_1^2}{2} - 1\right)\frac{\partial^2 \sigma_0^{\mathrm{g}}}{\partial x}(L, t_L) = 0. \tag{A.2b}$$

It can be shown that if the second derivative of T^{r} vanishes at $x = L$, *all* even derivatives of T^{r} must vanish there. But the numerical solutions shown later in Figure A.1 do not support this transcendental vanishing. Thus, we set $s_1 = \sqrt{2D_{\mathrm{r}}}$.

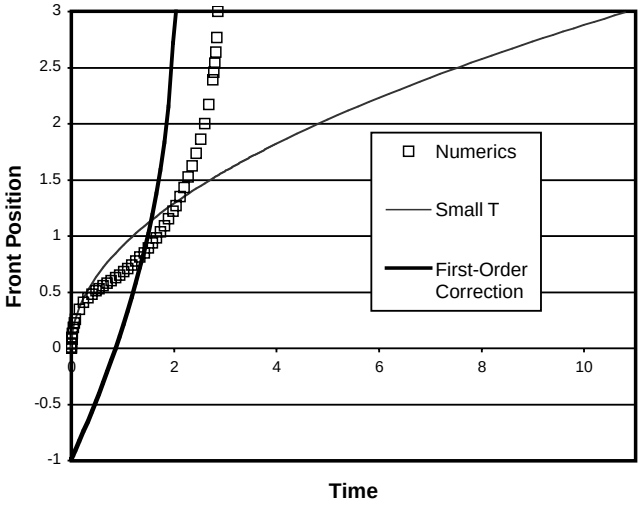

FIG. A.1. *Comparison of short- and intersection-time expressions for $s(t)$ with true front position. Here $s_1 = \sqrt{8}$, $s_L = 1.0634$, and $t_L = 1.990$.*

(Formally, this must be done in a limiting way by setting the stress in the glass equal to a small quantity representing σ_1^{r}, then taking that term to zero.)

To determine t_L, we introduce another degree of freedom into our fictitious condition as follows:

$$f^{\mathrm{i}}(x) \sim f_0^{\mathrm{i}} + f_1^{\mathrm{i}} x. \tag{A.3}$$

Substituting (A.3) into (3.10a) using (4.8), we may combine the resulting equations to obtain the following equation involving t_L:

$$\operatorname{erf} s_0 = \operatorname{erf} s_L - \frac{2s_L}{\sqrt{\pi}} e^{-s_L^2}, \qquad s_L = \frac{L}{2\sqrt{t_L}}. \tag{A.4}$$

Note the underlying parabolic nature of the operator, as evidenced by the relationship between the definition of s_L and the diffusion equation similarity variable. It can be shown that (A.4) has exactly one root s_L. In addition, $s_L > s_0$, so the front must speed up as time passes. Figure A.1 shows a graph of the short- and intersection-time expressions for $s(t)$ as compared with the numerical calculations.

By replacing the one-term expansion for $f^{\mathrm{i}}(x)$ with a two-term expression, we obtain closer agreement near $x = L$, as desired. In particular, we note that by combining the asymptotic results, we obtain the change in concavity of the graph and an acceptable estimate of the inflection time.

Unfortunately, though the two-term expansion provides an improved estimate of t_L, it is still not very accurate. Due to the diffusive nature of the underlying problem, the estimate of the initial condition must be highly accurate to obtain reasonable predictions for moderate t. In addition, the constructed solution does not work well for small times ($r = O(1)$). Thus, as a next step one should construct a three-term expansion for $f^{\mathrm{i}}(x)$ that satisfies the leading-order conditions at both $x = 0$ and $x = L$. This sort of iterative process, where one continually improves the form of f^{i}, should converge to the correct solution on finite domains. Infinite domains are fundamentally different since $t \to \infty$. This case can be treated asymptotically using appropriately chosen expansion functions [26], [29], [39], [40].

Acknowledgments. We thank the reviewers for many helpful comments that improved the manuscript.

A SIMPLE PREDICTION ALGORITHM FOR THE LAGRANGIAN MOTION IN TWO-DIMENSIONAL TURBULENT FLOWS*

LEONID I. PITERBARG† AND TAMAY M. ÖZGÖKMEN‡

Abstract. A new algorithm is suggested for prediction of a Lagrangian particle position in a stochastic flow, given observations of other particles. The algorithm is based on linearization of the motion equations and appears to be efficient for an initial tight cluster and small prediction time. A theoretical error analysis is given for the Brownian flow and a stochastic flow with memory. The asymptotic formulas are compared with simulation results to establish their applicability limits. Monte Carlo simulations are carried out to compare the new algorithm with two others: the center-of-mass prediction and a Kalman filter–type method. The algorithm is also tested on real data in the tropical Pacific.

Key words. stochastic flow, Lagrangian motion, prediction, stochastic simulations, oceanographic applications

1. Introduction.

The problem discussed is motivated by applications to rescue and search operations in the sea. An important part of such operations is to properly narrow the search area based on the best possible prediction of the position of a lost object, given its approximate initial position (Schneider (1998)). It is hard to make a reasonable prediction based only on knowledge of the mean current, because of strong velocity fluctuations drifting the object away from the path indicated by the mean velocity field. One can expect more realistic help from other floating objects in the same area, like debris or drifters (human-made floats), which can be observed from planes or satellites. We consider here a simplified model of such a situation, as follows. Several current following floats are released simultaneously at different known positions in a stochastic flow. One of the floats, called the predictand, is unobservable, while the remaining floats, called the predictors, are observed. The problem is to predict the position of the unobservable float, given the above observations. In addition to practical needs, this problem is of great importance from a theoretical viewpoint since it addresses the predictability issue for the Lagrangian motion in turbulent flows. Here, by turbulent flows, we mean velocity fields with fluctuations described by stochastic differential equations. Thus, a kinematic approach is employed: given flow statistics one should conclude with the mean square error of a prediction algorithm. The mathematical framework we set up here is as follows.

Let $\mathbf{u}(t, \mathbf{r})$ be a random velocity field varying in time. By the method of applications we consider only the two-dimensional case: $\mathbf{u}, \mathbf{r} \in R^2$. Consider $M > 1$ Lagrangian (current following) particles starting at time $t = 0$ from different positions

$\mathbf{r}_1^0, \mathbf{r}_2^0, \ldots, \mathbf{r}_M^0$. Their motion is covered by the following system of $2M$ equations:

$$\frac{d\mathbf{r}_j}{dt} = \mathbf{u}(t, \mathbf{r}_j) \ , \qquad \mathbf{r}_j(0) = \mathbf{r}_j^0, \tag{1}$$

$j = 1, \ldots, M$. Assume that trajectories of the first $p = M-1$ particles $\mathbf{r}_1(t), \mathbf{r}_2(t), \ldots, \mathbf{r}_p(t)$ are completely observed during time interval $(0, T)$, while the trajectory of the last one, $\mathbf{r}_M(t)$, is not observed. The problem is to find a reasonable prediction of the position of the unobserved particle, given the above predictor observations and the initial predictand position. The optimal prediction in the mean square sense,

$$E|\widehat{\mathbf{r}}_M(T) - \mathbf{r}_M(T)|^2 \to \min,$$

is given by the conditional expectation (e.g., Liptser and Shiryaev (1978))

$$\hat{\mathbf{r}}_M(T) = E\left(\mathbf{r}_j(T) \mid \mathbf{r}_1(t), \mathbf{r}_2(t), \ldots, \mathbf{r}_p(t), \quad 0 \le t \le T\right),$$

based on all the observations. Alas, this general formula gives too little in the considered situation. Normally, this conditional expectation cannot be explicitly found even in the simplest case when the velocity fluctuations are delta-correlated in time. However, it can be approximated (with an uncertain accuracy) for some Markov models of stochastic flows (Piterbarg (2001b)). This approximation resulted in a Kalman filter–type prediction algorithm which was tested on synthetic (Özgökmen et al. (2000), Piterbarg (2001b)) and real (Castellari et al. (2001), Özgökmen et al. (2001)) data. In general, that algorithm, called henceforth the KF algorithm, performs well, but its essential drawback is that it requires knowledge of some statistics of the underlying stochastic flow such as the Lagrangian correlation time and the space correlation radius of the Eulerian velocity field.

The goal of this paper is to introduce and investigate a new model-independent prediction algorithm. At first glance, the suggested prediction method looks a little bit naive. Roughly, we linearize (1) in a vicinity of the initial cluster, obtain a linear regression model where regressors are the initial particle positions, then estimate the regression coefficients at any given moment based on the observations of the predictor positions, and, finally, use them for predicting the unknown particle. The idea for the new algorithm emerged when we found from real data that the position of the cluster center of mass is a not bad alternative to the KF algorithm. The trouble is that the center-of-mass algorithm (CM) performs poorly at the initial stage if the predictor is located far from the cluster center of mass. In fact, the suggested algorithm, called here the regression algorithm (RA), can be viewed as a CM algorithm adjusted to the initial position of the predictand. As it will be shown, the RA performs very well at the initial stage if the cluster diameter is essentially less than the space correlation radius of the velocity fluctuations and performs as well as the CM algorithm in the long term. The good predictive skill of RA demonstrated in real data processing has had an impact on development of theoretical and Monte Carlo error analysis for RA. Such an analysis is based on investigating the second moment $\rho(t, \mathbf{r}_0)$ of the difference between positions of two particles initially separated by $\mathbf{r}_0$, called the separation process. The quantity $\rho(t, \mathbf{r}_0)$ can be effectively studied for two important models: the well-known Brownian flow and a stochastic model with memory recently developed in (Piterbarg (2001a)).

The Brownian stochastic flow arises when the Eulerian velocity field is delta-correlated in time. In this case a closed partial differential equation for $\rho(t, \mathbf{r}_0)$ is

readily written and the asymptotical prediction error is obtained for a tight initial cluster by expanding the equation solution in $\mathbf{r}_0$. It is interesting that the prediction error is not determined by the second Lyapunov moment, but rather by the fourth order term in $\mathbf{r}_0$. Asymptotical behavior of the error for large t is determined by the top Lyapunov exponent of the stochastic flow. In the case of a positive Lyapunov exponent, the behavior of the mean square error is close to that of the dispersion, $\sqrt{2Dt}$, where D is an effective diffusivity. In fact, it is even a little bit worse due to the bias between the predictand initial position and the cluster center of mass. For a negative Lyapunov exponent the growth order is $\sqrt{t/\log t}$. It is worthwhile to notice that our algorithm is not designed for long-term prediction.

Being an important mathematical example, the Brownian stochastic flow is not a realistic model for upper ocean turbulence. We focus instead on the second model in which a joint vector of the positions and velocities form a Markov process. For this reason it is called the first-order Markov model to distinguish it from the zero-order model determined by the Brownian flow. The first-order model implies an additional important parameter, the Lagrangian correlation time τ, which can be estimated well from real data (Griffa et al. (1995)). In the framework of the model, the Lagrangian velocity of a single particle is an Ornstein–Uhlenbeck process with parameter τ. In this case the variance of the separation process $\rho(t, \mathbf{r}_0, \mathbf{v}_0)$ also depends on the difference of the initial velocities. As a consequence, the prediction error for close initial positions and velocities is determined by the expansion coefficient of ρ at $\mathbf{v}_0^2$. The equation for ρ in the first-order model is a standard Kolmogorov equation. An expansion of the solution in both $\mathbf{r}_0$ and $\mathbf{v}_0$ results in an approximate mean square error for the prediction. The proposed approximation is in good agreement with simulations. A special focus is on a linear shear mean flow determined by the stretch and rotation parameters γ and ω, respectively. It is shown that the relative prediction error decreases as γ and ω increase. Comparison with the KF algorithm shows that the RA performs essentially better in the presence of a deterministic linear shear flow, while for a pure stochastic flow they are equivalent or KF is better.

The main points of this work are (1) formulation of the new prediction algorithm (section 2); (2) formulas for the prediction error which are in very good agreement with stochastic simulations (sections 3–5); (3) comparative analysis of RA and KF performance based on synthetic and real data (sections 6 and 7).

The main investigation tools used are stochastic simulations, together with standard diffusion process analytic techniques. For the simulations we take real values of model parameters and show the error in dimension units to give an idea of the usefulness of the real prediction.

2. Prediction formula. Assume the following classical regression model for motion of M particles:

$$\mathbf{r}_i(t) = \mathbf{A}(t)\mathbf{r}_i(0) + \mathbf{b}(t) + \mathbf{y}_i(t), \tag{2}$$

where $\mathbf{A}(t)$ and $\mathbf{b}(t)$ are an unknown, random in general, 2×2 matrix and 2-vector, respectively, and $\mathbf{y}_j(t)$ are stochastic processes with zero mean uncorrelated for any fixed t. Notice that this model does not follow from the model (1) in the general case. Moreover, it even contradicts (1) for a nonlinear velocity field. The idea is to construct a prediction algorithm based on (2) and then forget (2) and investigate the algorithm performance for some important particular cases of the model (1). The reason to expect a good performance is that the system (1) can be linearized on short times, and then the obtained formula would be useful for the short-term prediction.

Recall that the first $p = M - 1$ particles (predictors) are supposed to be observed and the Mth one is to be predicted. To identify six unknown parameters at each time (four entries of $\mathbf{A}$ and two entries of $\mathbf{b}$) one should have $p \geq 3$. We accept this assumption for the rest of the paper. The underdetermined situation $p = 2$ is of practical interest as well, but it requires a special consideration which is outside the scope of this paper. The least square estimators of $\mathbf{A}(t)$ and $\mathbf{b}(t)$ based on the observed particles at the moment t are given by

$$\hat{\mathbf{A}}(t) = \mathbf{S}(t)\mathbf{S}(0)^{-1}, \quad \hat{\mathbf{b}}(t) = \mathbf{r}_c(t) - \hat{\mathbf{A}}(t)\mathbf{r}_c(0),$$

where

$$\mathbf{r}_c(t) = \frac{1}{p}\sum_{i=1}^{p} \mathbf{r}_i(t)$$

is the center of mass of the predictor cluster and

$$\mathbf{S}(t) = \sum_{i=1}^{p} (\mathbf{r}_i(t) - \mathbf{r}_c(t))(\mathbf{r}_i(0) - \mathbf{r}_c(0))^T,$$

the superscript T stands for transposition, the vectors mean column-vectors, and it is assumed that $p > 2$ to have nondegenerate matrix $S(0)$. The obtained estimators then are used to predict the unobservable particle

$$\hat{\mathbf{r}}_M(t) = \mathbf{r}_c(t) + \mathbf{S}(t)\mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)). \tag{3}$$

This prediction formula is optimal in the framework of the model (2) if $\mathbf{A}$ and $\mathbf{b}$ are supposed to be deterministic. Further we reject the regression model and study its performance for some specific models of the velocity field $\mathbf{u}(t, \mathbf{r})$ appearing in (1).

If the velocity field is smooth enough in time, then it is worthwhile to include the initial velocities as regressors as well. We do not do that in the present paper for two reasons: first, this does not make any sense when considering the Brownian flow since it implies infinite velocities, and second, determining initial velocities in practice is a very hard problem. However, a study of an initial velocity–based formula is of theoretical interest and will be considered in a further work.

Once again we underscore that the prediction formula (3) does not include any parameters except the initial particle positions. Of course, it is not always a strength. Including well-known parameters would probably improve prediction essentially, but the problem is that statistical estimates of mean currents and turbulence parameters are often not reliable in oceanic conditions. Therefore, apparently, sometimes it is better to use a rough prediction algorithm than fine algorithms with misspecified parameters. Further we try to evaluate limits of this "roughness."

3. General error analysis. Let

$$s^2(t) = E|\hat{\mathbf{r}}_M(t) - \mathbf{r}_M(t)|^2 \tag{4}$$

be the mean square error of the prediction (3). Introduce the variance of the separation process by

$$\rho_{ij}(t) = E|\mathbf{r}_i(t) - \mathbf{r}_j(t)|^2.$$

For the sake of brevity we call ρ_{ij} the separation. Then (see appendix)

(5)

$$s^2(t) = \frac{1}{p}\sum_{k=1}^{p}\rho_{kM}(t) - \frac{1}{2p^2}\sum_{k,l=1}^{p}\rho_{kl}(t) - \frac{1}{p}\sum_{k,l=1}^{p} b_k\rho_{kl}(t) + \sum_{k=1}^{p} b_k\rho_{kM}(t) - \frac{1}{2}\sum_{k,l=1}^{p} b_k b_l\rho_{kl}(t),$$

where coefficients

$$b_i = (\mathbf{r}_i(0) - \mathbf{r}_c(0))^T \mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)) \tag{6}$$

are defined by the initial positions only, while the behavior of $\rho_{ij}(t)$ also depends on the flow properties. Notice that the deviation $E|\mathbf{r}_c(t) - \mathbf{r}_M(t)|^2$ of the predictand from the cluster center of mass is determined by the first two terms in (5).

In the next two sections we will consider two different asymptotics of (4): first, small initial distances between particles and, second, the long time asymptotic. As one will see, in the first case the problem is reduced to a factorized separation

$$\rho_{ij}(t) \sim \rho_0(t)c_{ij},$$

where ρ_0 is independent on the initial configuration and c_{ij} are completely determined by the initial conditions. In the second case under common conditions, the separation is independent of the initial conditions:

$$\rho_{ij}(t) \sim \rho(t)(1 - \delta_{ij}),$$

where δ_{ij} is the Kronecker delta. Hence, in the first case (5) becomes

$$s^2(t) \sim C_0\rho_0(t), \tag{7}$$

where

$$C_0 = \frac{1}{p}\sum_{k=1}^{p} c_{kM} - \frac{1}{2p^2}\sum_{k,l=1}^{p} c_{kl} - \frac{1}{p}\sum_{k,l=1}^{p} b_k c_{kl} + \sum_{k=1}^{p} b_k c_{kM} - \frac{1}{2}\sum_{k,l=1}^{p} b_k b_l c_{kl} \tag{8}$$

is a function of the initial conditions only. A similar formula appears in the second case:

$$s^2(t) \sim C\rho(t), \tag{9}$$

with

$$C = \frac{1}{2} + \frac{1}{2p} + \frac{1}{2}(\mathbf{r}_M(0) - \mathbf{r}_c(0))^T \mathbf{S}(0)^{-1}(\mathbf{r}_M(0 - \mathbf{r}_c(0)). \tag{10}$$

Notice that this algorithm is not designed for long time prediction and the formula (9) is of theoretical interest only.

4. Brownian flow. Assume that the velocity field is decomposed into mean circulation and fluctuation:

$$\mathbf{u}(t, \mathbf{r}) = \mathbf{U}(t, \mathbf{r}) + \mathbf{u}'(t, \mathbf{r}), \tag{11}$$

where $\mathbf{U}_0(t,\mathbf{r})$ is a deterministic velocity field and $\mathbf{u}'(t,\mathbf{r})$ is a random vector field with zero mean, $E\mathbf{u}'(t,\mathbf{r})=0$. The Brownian flow is determined by the assumption that the velocity fluctuation $\mathbf{u}'(t,\mathbf{r})$ is a Gaussian white noise in t, i.e.,

$$E\mathbf{u}'(t,\mathbf{r})=0,\quad E\mathbf{u}'(t_1,\mathbf{r}_1)\mathbf{u}'(t_2,\mathbf{r}_2)^T=\delta(t_1-t_2)\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)\ , \tag{12}$$

where $\delta(t)$ is the Dirac delta-function and $\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)$ is the spatial covariance tensor of the velocity field. Introduce the state, drift, and noise vectors:

$$\mathbf{z}=\begin{pmatrix}\mathbf{r}_1\\ \mathbf{r}_2\\ \dots\\ \mathbf{r}_M\end{pmatrix},\quad \mathbf{A}(t,\mathbf{z})=\begin{pmatrix}\mathbf{U}(t,\mathbf{r}_1)\\ \mathbf{U}(t,\mathbf{r}_2)\\ \dots\\ \mathbf{U}(t,\mathbf{r}_M)\end{pmatrix},\quad \mathbf{W}(t)=\begin{pmatrix}\mathbf{w}_1\\ \mathbf{w}_2\\ \dots\\ \mathbf{w}_M\end{pmatrix},$$

where $\mathbf{r}_j(t)$ are the positions of M particles at time t starting from different locations and $\mathbf{w}_j(t)$ are independent standard Wiener processes. Then a rigorous interpretation of (11), (12) is as follows. The process $\mathbf{z}(t)$ is a $2M$-dimensional Markov process satisfying the stochastic Ito differential equation (Kunita (1990))

$$d\mathbf{z}=\mathbf{A}(t,\mathbf{z})dt+\mathbf{D}(\mathbf{z})^{1/2}d\mathbf{W}(t),$$

where the $2M\times 2M$ diffusion matrix is given by

$$\mathbf{D}(\mathbf{z})=(\mathbf{B}(\mathbf{r}_i,\mathbf{r}_j)).$$

Another equivalent formulation of this model is as follows: $\mathbf{z}(t)$ is a Markov process with the generator given by

$$L=\mathbf{U}(t,\mathbf{r}_i)\cdot\nabla_{\mathbf{r}_i}+\frac{1}{2}\nabla_{\mathbf{r}_i}\cdot\mathbf{B}(\mathbf{r}_i,\mathbf{r}_j)\nabla_{\mathbf{r}_j}.$$

In the homogeneous case characterized by the assumptions that the mean flow is constant $\mathbf{U}(t,\mathbf{r})\equiv\mathbf{U}$ and that the covariance is a function of the position difference $\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)=\mathbf{B}(\mathbf{r}_1-\mathbf{r}_2)$, the separation process $\mathbf{r}(t)=\mathbf{r}_1(t)-\mathbf{r}_2(t)$ (the difference between displacements of two different particles) is also a Markov process with the generator

$$L_s=\nabla_{\mathbf{r}}\cdot(\mathbf{B}(\mathbf{0})-\mathbf{B}(\mathbf{r})))\nabla_{\mathbf{r}}.$$

Further we assume that the velocity field is isotropic (that is, $\mathbf{U}\equiv 0$) and the entries $b_{ij}(\mathbf{r})$ of $\mathbf{B}(\mathbf{r})$ are given by (Monin and Yaglom (1975))

$$b_{ij}(\mathbf{r})=b_N(r)\delta_{ij}+\frac{x_ix_j}{r^2}(b_L(r)-b_N(r)),$$

where $r=|\mathbf{r}|$, $\mathbf{r}=(x_1,x_2)$. Assume that the longitudinal and normal covariances are four times continuously differentiable:

$$\begin{aligned}b_L(r)&=D-\tfrac{1}{2}\beta_Lr^2+\tfrac{1}{2}\gamma_Lr^4+O(r^6),\\ b_N(r)&=D-\tfrac{1}{2}\beta_Nr^2+\tfrac{1}{2}\gamma_Nr^4+O(r^6),\end{aligned} \tag{13}$$

where $D,\beta_L,\gamma_L,\beta_N,\gamma_N$ are positive parameters whose physical meaning is explained below. For the isotropic Brownian flow the squared dispersion is expressed as

$$d^2(t)\equiv E(\mathbf{r}(t)-\mathbf{r}(0))^2=2Dt; \tag{14}$$

hence, D means a diffusivity. Introduce the space correlation radius of the velocity field by

$$R^2 = D/\beta_L$$

and set $\mathbf{r}_{ij} = \mathbf{r}_i(0) - \mathbf{r}_j(0)$, $r_{ij} = |\mathbf{r}_{ij}|$. First, consider the "tight cluster" asymptotic characterized by

$$r_{ij} \ll R, \quad i, j = 1, M.$$

Under this approximation each separation $\rho_{ij}(t) = \rho(t, r_{ij})$ is expressible in form

$$\rho(t, r) = \rho_1(t) r^2 - \rho_0(t) r^4 + O(r^6), \tag{15}$$

where (see appendix)

$$\rho_1(t) = \exp(\overline{\beta} t), \quad \rho_0(t) = K(\exp(\beta_0 t) - \exp(\overline{\beta} t)), \tag{16}$$

where

$$\beta_0 = 2\beta_N + 6\beta_L, \quad \overline{\beta} = \beta_L + \beta_N, \quad K = \frac{\overline{\gamma}}{5\beta_L + \beta_N}, \quad \overline{\gamma} = \gamma_L + \gamma_N.$$

After substitution of the expansion (15) into (5) the terms quadratic in r_{ij} disappear, and we get

$$s^2(t) \sim C_0 \rho_0(t), \tag{17}$$

where C_0 is given by (8) with

$$c_{kl} = |\mathbf{r}_k(0) - \mathbf{r}_l(0)|^4$$

and $\rho_0(t)$ is given in (16)

For the incompressible Brownian flow, characterized by $b_N(r) = (d/dr)(r b_L(r))$, with the longitudinal covariance

$$b_L(r) = D \exp(-r^2/R^2),$$

we have

$$\rho_1(t) = \exp(8Dt/R^2), \quad \rho_0(t) = \frac{3}{8R^2}(\exp(24Dt/R^2) - \exp(8Dt/R^2)).$$

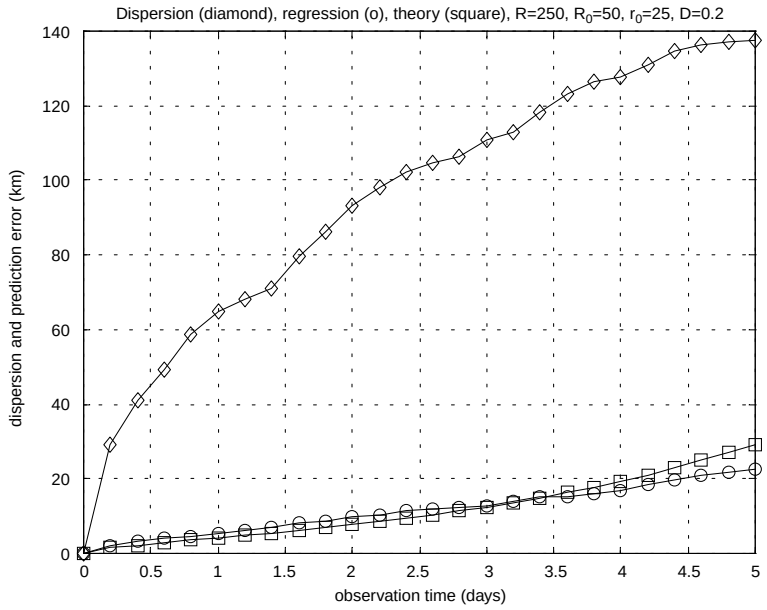
Assume that initially the predictors are located at the vertices of a right polygon at a distance R_0 from the center and the predictand is at a distance r_0 from the center. We call such an initial configuration perfect. In this case (17) becomes

$$s^2(t) \sim (3r_0^4 + 2R_0^4 - 4r_0^2 R_0^2)\rho_0(t) \tag{18}$$

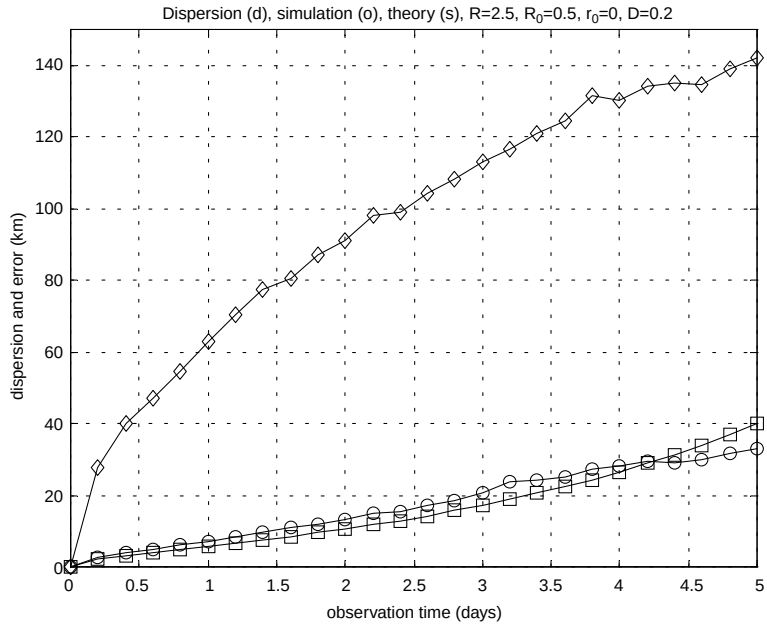
for $p > 3$ and

$$s^2(t) \sim (3r_0^4 + 2R_0^4 - 3r_0^2 R_0^2 - 2R_0 r_0^3 \cos(3\alpha))\rho_0(t)$$

for $p = 3$, where α is the angle between the directions from the center to the predictand and from the center to one of the predictors. The approximation (18) was checked via simulations, and the results are presented in Figure 1(a) and (b). For the simulation



(a)



(b)

FIG. 1. (a) *Dependence of the dispersion,* $d(t)$ (*diamonds*) *and prediction error,* $s(t)$, *obtained from simulations* (*circles*) *and from theory* ((18), *squares*) *on the observation time for the Brownian stochastic flow.* 100 *independent runs are used for* $d(t)$ *and* $s(t)$. *The diffusivity* $D = 2 \times 10^3\, km^2/day$, *number of predictors* $p = 6$, *initial hexagon radius* $R_0 = 50\, km$, *velocity space correlation radius* $R = 250\, km$, *distance of the predictand from the hexagon center* $r_0 = 25$ *km.* (b) *Same as in* (a) *with* $r_0 = 0$.

it was assumed that $R = 250$ km, $R_0 = 50$ km, and $D = 2000$ km^2/day. In the first case the predictor is distanced by $r_0 = 25$ km from the center, and in the second case it is initially located at the center. The dispersion $d(t)$ (diamonds) and experimental prediction error $s(t)$ (circles) are obtained from the simulations by averaging over 100 independent runs. A modest sample size is used on purpose to illustrate graphically how large the noise is under a moderate sample volume typical in oceanographic measurements. The line marked by squares expresses the suggested error formula (18). This approximation performs pretty well up to $T = 5$ days. After that the theoretical curve sharply diverges from the experimental one. The simulated dispersion is in good agreement with formula (14): it behaves as $\sqrt{t}$ and the value $d(5) \approx 139$ is very close to that of given by (14), $d(5) = 100\sqrt{2}$. In the second case (Figure 1(b)) the prediction is slightly worse in full agreement with (18). Notice that the relative prediction error for small t is approximately constant:

$$s_r(t) \equiv \frac{s(t)}{d(t)} \sim \frac{\sqrt{3(3r_0^4 + 2R_0^4 - 4r_0^2R_0^2)}}{2R^2}.$$

As for large t, we have two different situations depending of the sign of the Lyapunov exponent for the underlying flow. The Lyapunov exponent, λ, characterizes the exponential divergence (convergence) of initially close particles. It can be expressed in terms of the flow parameters (Baxendale and Harris (1986)):

$$\lambda = (\beta_N - \beta_L)/2.$$

If $\lambda > 0$, then for large t the difference between the positions of two particles goes to infinity with probability 1, and the mean square distance between them grows as

$$\rho(t) \sim 4Dt.$$

From (9), (10) it follows that the relative error is also approximately constant,

$$s_r(t) \sim \sqrt{1 + \frac{1}{p} + (\mathbf{r}_M(0) - \mathbf{r}_c(0))^T \mathbf{S}(0)^{-1} (\mathbf{r}_M(0 - \mathbf{r}_c(0))},$$

and greater than one.

In the opposite case $\lambda < 0$, the picture is more sophisticated: the difference goes to zero with probability 1; however, the mean square distance still grows, but at a lower rate (see Zirbel and Cinlar (1996)):

$$\rho(t) \sim \frac{ct}{\log t}$$

with constant c depending on the initial distance. Thus, the relative error goes to zero slowly as t goes to infinity:

$$s_r(t) \sim C\sqrt{\frac{1}{\log t}}$$

with constant C depending on the initial cluster configuration.

5. Stochastic flow with memory. As we already noticed, the Brownian flow is not an appropriate model for the upper ocean turbulence, since it is based on the white noise assumption for Lagrangian velocity. In fact, numerous observations clearly

demonstrate that Lagrangian velocity is well approximated by the first-order Markov process (Thomson (1986), Griffa (1996)). The following model of multiparticle motion suggested by Piterbarg (2001a), (2001b) generalizes the above experimental fact.

In addition to the decomposition (11) assume that there is a deterministic acceleration $\mathbf{a}(\mathbf{v},\mathbf{r})$ depending in general on the particle velocity and position such that the motion equations take the form

$$\begin{aligned} d\mathbf{r} &= (\mathbf{U}(t,\mathbf{r})+\mathbf{v})dt, \\ d\mathbf{v} &= \mathbf{a}(\mathbf{v},\mathbf{r})dt + d\mathbf{w}(t,\mathbf{r}), \end{aligned} \tag{19}$$

where

$$E\mathbf{w}(t,\mathbf{r}) = 0, \qquad E\mathbf{w}(t_1,\mathbf{r}_1)\mathbf{w}(t_2,\mathbf{r}_2)^T = \min(t_1,t_2)\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)\ .$$

In other words, now the velocity field is not a white noise itself but rather is driven by a white noise with a space covariance structure determined by tensor $\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)$. A rigorous formulation of (19) is given in the above-mentioned references. For a cluster of M particles, introduce a state vector containing the particle velocities as well as positions and a drift vector:

$$\mathbf{z} = \begin{pmatrix} \mathbf{v}_1 \\ \mathbf{r}_1 \\ \mathbf{v}_2 \\ \mathbf{r}_2 \\ \cdots \\ \mathbf{v}_M \\ \mathbf{r}_M \end{pmatrix}, \qquad \mathbf{A}(t,\mathbf{z}) = \begin{pmatrix} \mathbf{a}_1 \\ \mathbf{U}_1+\mathbf{v}_1 \\ \mathbf{a}_2 \\ \mathbf{U}_2+\mathbf{v}_2 \\ \cdots \\ \mathbf{a}_M \\ \mathbf{U}_M+\mathbf{v}_M \end{pmatrix},$$

where $\mathbf{U}_m = \mathbf{U}(t,\mathbf{r}_m)$, $\mathbf{a}_m = \mathbf{a}(\mathbf{v}_m,\mathbf{r}_m)$. The model (19) implies that the motion of any M particles is a Markov process in $4M$ dimensions described by a stochastic differential equation. Namely,

$$d\mathbf{z} = \mathbf{A}(t,\mathbf{z})dt + \mathbf{D}(\mathbf{z})^{1/2}d\mathbf{W},$$

where $\mathbf{W}(t)$ is a standard Wiener process in $4M$ dimensions and the diffusion matrix $\mathbf{D}(\mathbf{z})$ is given by

$$\mathbf{D}(\mathbf{z}) = (\mathbf{D}_{ij}(\mathbf{z}))$$

with 4×4 blocks

$$\mathbf{D}_{ij} = \begin{pmatrix} \mathbf{B}(\mathbf{r}_i,\mathbf{r}_j) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}.$$

Recall that now $\mathbf{B}(\mathbf{r}_1,\mathbf{r}_2)$ is the covariance tensor of the forcing, not the Eulerian velocity field itself. The equivalent formulation is given by the generator

$$L = (\mathbf{U}(t,\mathbf{r}_i)+\mathbf{v}_i)\cdot\nabla_{\mathbf{r}_i} + \mathbf{a}_i\cdot\nabla_{\mathbf{v}_i} + \frac{1}{2}\nabla_{\mathbf{v}_i}\cdot\mathbf{B}(\mathbf{r}_i,\mathbf{r}_j)\nabla_{\mathbf{v}_j}.$$

For our purposes the following homogeneous case is most important:

$$\mathbf{a}(\mathbf{v},\mathbf{r}) = -\tau^{-1}\mathbf{v}, \quad \mathbf{U}(\mathbf{r}) = \mathbf{U}+\mathbf{G}\mathbf{r}, \quad \mathbf{B}(\mathbf{r}_1,\mathbf{r}_2) = \mathbf{B}(\mathbf{r}_1-\mathbf{r}_2),$$

$$\mathbf{G} = \begin{pmatrix} \gamma & \omega \\ -\omega & -\gamma \end{pmatrix},$$

where τ is the Lagrangian correlation time and the mean velocity field is a divergence-free linear shear flow characterized by constant drift $\mathbf{U}$, stretching parameter γ, and rotation parameter ω. The one-particle motion in this case is described by the well-known Langevin equation for the Lagrangian velocity and the standard motion equation for the displacement

$$\begin{aligned} d\mathbf{v} &= -\tau^{-1}\mathbf{v}dt + \sigma_v\tau^{-1/2}d\mathbf{w}(t), \\ d\mathbf{r} &= (\mathbf{U} + \mathbf{G}\mathbf{r} + \mathbf{v})dt\ , \end{aligned} \tag{20}$$

where $\mathbf{w}(t)$ is a two-dimensional Brownian motion and $\sigma_v^2 = E\mathbf{v}^2$ is the velocity variance. To obtain (20) we assumed that $\mathbf{B}(\mathbf{0}) = (\sigma_v^2/2\tau)\mathbf{I}$. In particular, for the dispersion we get (see appendix)

(21)
$$d^2(t) \equiv\ E(\mathbf{r}(t) - \mathbf{r}(0))^2 = d_0^2(t) + \sigma_v^2 \int_0^t \int_0^t \cosh(\sqrt{\gamma^2(2t - s_1 - s_2)^2 - \omega^2(s_1 - s_2)^2}) \exp(-|s_1 - s_2|/\tau) ds_1 ds_2,$$

where $d_0(t)$ is determined by the mean flow and initial position $\mathbf{r}_0$ only. An explicit expression is given in the appendix. Further we assume that $\mathbf{U} = 0$ and $\mathbf{r}_0 = 0$, which results in $d_0^2(t) = 0$. Notice two partial cases of (21): if $\omega = 0$, then

$$d^2(t) = \frac{\sigma_v^2\tau}{1 - \gamma^2\tau^2}(\gamma^{-1}\ \sinh(2\gamma t) - \tau\cosh(2\gamma t) - \tau + 2\tau\cosh(\gamma t)\exp(-t/\tau)); \tag{22}$$

if $\gamma = 0$, then

$$d^2(t) = \frac{\sigma_v^2\tau}{1 + \omega^2\tau^2}\left(t - \frac{\tau(1 - \omega^2\tau^2)}{1 + \omega^2\tau^2}\ (1 - \exp(-t/\tau)\cos(\omega t)) - \frac{2\omega\tau^2}{1 + \omega^2\tau^2}\exp(-t/\tau)\sin(\omega t)\right).$$

Finally, for the zero shear (Zambianchi and Griffa (1994))

$$d^2(t) = \sigma_v^2\tau\,(t - \tau\ (1 - \exp(-t/\tau)))\,. \tag{23}$$

The stochastic equations for the separation process,

$$\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2, \quad \mathbf{v} = \mathbf{v}_1 - \mathbf{v}_2,$$

take the form

$$\begin{aligned} d\mathbf{v} &= -\tau^{-1}\mathbf{v}dt + (2(\mathbf{B}(\mathbf{0}) - \mathbf{B}(\mathbf{r})))^{1/2}d\mathbf{w}(t), \\ d\mathbf{r} &= (\mathbf{G}\mathbf{r} + \mathbf{v})dt. \end{aligned}$$

In other words, the generator of the separation process is

$$L_s = (\mathbf{G}\mathbf{r} + \mathbf{v}) \cdot \nabla_{\mathbf{r}} - \tau^{-1}\mathbf{v} \cdot \nabla_{\mathbf{v}} + \nabla_{\mathbf{v}} \cdot (\mathbf{B}(\mathbf{0}) - \mathbf{B}(\mathbf{r})))\nabla_{\mathbf{v}}. \tag{24}$$

Assume that the forcing is isotropic, i.e.,

$$b_{ij}(\mathbf{r}) = b_N(r)\delta_{ij} + \frac{x_i x_j}{r^2}(b_L(r) - b_N(r)),$$

with twice differentiable covariances

$$b_L(r) = \frac{\sigma_v^2}{2\tau} - \frac{1}{2}\beta_L r^2 + O(r^4), \quad b_N(r) = \frac{\sigma_v^2}{2\tau} - \frac{1}{2}\beta_N r^2 + O(r^4). \tag{25}$$

Let $\rho = \rho(t,u,v,x,y) = E\mathbf{r}(t)^2$, where $\mathbf{r}(0) = (x,y), \mathbf{v}(0) = (u,v)$. For small x, y, u, v expand

$$\rho = a_1x^2 + 2a_2xy + a_3y^2 + a_4u^2 + 2a_5uv + a_6v^2 + a_7xu + a_8xv + a_9yu + a_{10}yv \tag{26}$$

and set $\mathbf{a} = (a_1, a_2, \ldots, a_{10})$. It is shown in the appendix that

$$\frac{d\mathbf{a}}{dt} = \mathbf{A}\mathbf{a}, \quad \mathbf{a}|_{t=0} = \mathbf{a}_0, \tag{27}$$

where matrix $\mathbf{A}$ and vector $\mathbf{a}_0$ are given. In particular, for the zero shear

$$\rho(t) = \rho(t, \mathbf{r}, \mathbf{v}) = \rho_1(t)\mathbf{r}^2 + \rho_{10}(t)(\mathbf{r}\cdot\mathbf{v}) + \rho_0(t)\mathbf{v}^2, \tag{28}$$

where

$$\begin{aligned} \frac{d\rho_0(t)}{dt} &= -2\tau^{-1}\rho_0(t) + \rho_{10}(t), \\ \frac{d\rho_1(t)}{dt} &= 2\overline{\beta}\rho_0(t), \\ \frac{d\rho_{10}(t)}{dt} &= -\tau^{-1}\rho_{10}(t) + 2\rho_1(t), \end{aligned} \tag{29}$$

where $\overline{\beta} = \beta_L + \beta_N$. Assume that the initial velocities are Gaussian random values with zero mean and independent components with the same variance σ_0^2. Additionally assume that the velocities are independent for different particles and are independent of the forcing. Averaging (28) over the ensemble of initial values gives

$$\rho_{ij}(t) = \rho(t, \mathbf{r}_{ij}, \mathbf{v}_{ij}) = \rho_1(t)r_{ij}^2 + 2\rho_0(t)\sigma_0^2(1-\delta_{ij}). \tag{30}$$

After substituting (30) into (5), the terms containing the distances disappear, and for the "tight cluster" asymptotic in the case of the perfect predictor, we get the initial configuration

$$s^2(t) \sim 2\sigma_0^2\left(1 + \frac{1}{p} + \frac{4r_0^2}{pR_0^2}\right)\rho_0(t), \tag{31}$$

where $\rho_0(t)$ is obtained from (29). In the presence of the mean shear flow we get a similar formula:

$$s^2(t) \sim \sigma_0^2\left(1 + \frac{1}{p} + \frac{4r_0^2}{pR_0^2}\right)(a_4(t) + a_6(t)), \tag{32}$$

where $a_4(t), a_6(t)$ are obtained from (27). The asymptotic (31) is compared with simulations in Figure 2(a) and (b). For the simulations we used Lagrangian correlation time $\tau = 3$ days, the velocity variance $\sigma_v^2 = 0.12 \times 10^4$ km^2/day^2, initial velocity variance $\sigma_0^2 = 0.25 \times 10^2$ km^2/day^2, number of predictors $p = 6$, initial hexagon radius $R_0 = 50$ km, velocity space correlation radius $R = 250$ km. In Figure 2(a) the

FIG. 2. (a) *Dependence of the dispersion,* $d(t)$ (*diamonds*) *and prediction error,* $s(t)$*, obtained from simulations* (*circles*) *and from theory* ((31), *squares*) *on the observation time, for the stochastic flow with memory. The Lagrangian correlation time* $\tau = 3\,days$*, the velocity variance* $\sigma_v^2 = 12 \times 10^2\,km^2/day^2$*, initial velocity variance* $v_0^2 = 0.25 \times 10^2\,km^2/day^2$*, number of predictors* $p = 6$*, initial hexagon radius* $R_0 = 50\,km$*, velocity space correlation radius* $R = 250\,km$*, distance of the predictand from the hexagon center* $r_0 = 25$ *km.* (b) *Same as in* (a) *with* $r_0 = 0$.

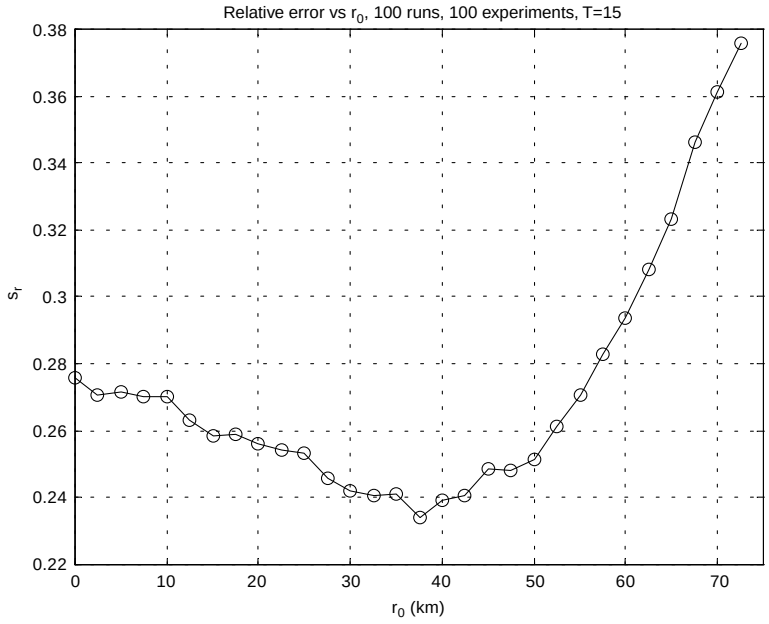

FIG. 3. *Dependence of the relative error s_r on r_0 for the observation time $T = 15$ days. The remaining parameters are the same as those as in Figure* 2(a).

predictand is distanced from the hexagon center by $r_0 = 25$ km, while in Figure 2(b) it is located exactly at the center. We take σ_0 much less than σ_v because the approximation (31) requires both small initial distances and small initial velocity differences. The dispersion $d(t)$ is shown as diamonds; the prediction error, $s(t)$, obtained from simulations, as circles; and the prediction error asymptotic (31) as squares. First, notice a good qualitative agreement of the simulated dispersion (100 runs) with the theoretical formula (23): for small t we have the ballistic regime ($d \sim t$), and for larger time the diffusion regime ($d \sim \sqrt{t}$). The quantitative agreement is also satisfactory. Then these figures show that the theoretical error formula works well for the ratio cluster radius/velocity correlation radius of less than 5 and for prediction periods of fewer than 15 days. The agreement is clearly better in the first case. In this regard, notice that unlike the Brownian flow case, the suggested approximation (31) does not give a correct dependence of the prediction error on the initial distance r_0 from the center. Indeed, in accordance with (31) the error in the second case should be less, but the simulations show the opposite. To get a correct dependence one should account for terms of higher order in the expansion of ρ. We do not do that here but instead study the dependence of the relative prediction error s_r on r_0 by the Monte Carlo method. Figure 3 demonstrates this dependence. The curve was obtained by averaging over 100 experiments with the same parameters $\tau = 3$ days, $\sigma_v^2 = 0.12 \times 10^4$ km^2/day^2, $\sigma_0^2 = 0.25 \times 10^2$ km^2/day^2, $p = 6$, $R_0 = 50$ km, $R = 250$ km, while each experiment included 100 runs to obtain s_r. This figure supports the previous observations that the error first decreases as r_0 increases, then assumes a minimum between 0 and R_0, and finally increases approaching R_0. For $r_0 > R_0$ the prediction worsens drastically. The obtained curve is affected by sampling variability, and the exact dependence s_r on r_0 is still to be investigated. It is interesting that the analytical dependence of s_r on the ratio $x = r_0^2/R_0^2$ obtained for the zero-order model

(19) describes pretty well the experimental curve for the first-order model. Indeed, from (19) $f(x) \equiv s(x)/s(0) = 1.5x^2 - 2x + 1$ assumes $f(0.5) = 0.375, f(2/3) = 1/3$ (minimum point), and $f(1) = 0.5$. Approximately the same values for that ratio follow from the curve in Figure 3. The reason is that for $T \gg \tau$ the first-order model approaches the Brownian flow.

Having sufficiently good agreement between (31) and the simulations, at least for values of r_0 close to $R_0/2$, we investigate the dependence of the prediction error on the model parameters using the analytical formulas (31) and (32). Figure 4(a) illustrates the dependence of the relative error $s_r(T)$ on τ for $R = 200, 250, 300, 350, 400, 450$ km with the zero mean flow and $T = 15$ days obtained from (21), (29), (31). The curves line up with R: the larger the R, the better the prediction. As for the Lagrangian correlation time, the error decreases with τ whenever $\tau/T > 0.5$. The effect of the error increasing for small value of τ is due to the regime changing in the dispersion behavior from ballistic to diffusive. As before, $R_0 = 50$ km and $p = 6$.

Figure 4(b) shows the dependence of s_r on γ and ω for fixed $\tau = 3$ days, $T = 15$ days, and $R = 250$ km, obtained from (21), (27), (32). The values of other parameters are indicated in the figure captions. Obviously, $s_r(\gamma, \omega)$ as a function of the shear parameters is even in both of them. The maximum relative error corresponds to $\gamma = 0$ because of a strong growth of the dispersion with γ (21), (22).

In the next series of experiments with zero mean flow we try a different initial configuration of predictors and a different velocity initialization to determine how the initialization affects the prediction skill. An eventual goal is to find an initial predictor configuration ensuring the best prediction. This problem is very complex and is beyond the scope of this paper. The goal of the present experiments with randomly distributed predictors is to understand the extent of the prediction error's dependence on the initial configuration and velocities. Namely, the alternative configuration we consider is a random initial configuration of predictors with the uniform distribution in a square with side of a. Now we compare four cases, the first two of which were discussed before: (1) perfect configuration ($R_0 = 50$ km) with the predictand $r_0 = 25$ km from the cluster center; (2) perfect configuration with the predictand at the center ($r_0 = 0$); (3) random configuration with $a = 2R_0$ and predictand $r_0 = 25$ km from the square center; (4) random configuration with $a = 2R_0$ and predictand at the square center ($r_0 = 0$). First, we consider the dependence of the error on the number of predictors for these four cases (Figure 5). As one can see there is not much difference in the algorithm performance when the number of predictors is 6 or more. It is worth noting that the random case is slightly worse than the perfect case for low p, but they quickly converge at $p = 6$ and do not change much as p increases. The error does not decrease significantly as p grows for all the initializations. This is in agreement with the theoretical formula (31).

Next we compare the statistical moments and histograms of the prediction error for 6 predictors and prediction time of 15 days (Table 1 and Figure 6(a)). The table gives the statistical moments of the relative deviation $\xi = |r_M - \widehat{r_M}|/d$, and the histograms are histograms of ξ. Thus, $s_r = \sqrt{E\xi^2}$, and it is also given in the table even though it can be found from the first two columns. First, it can be seen that for the perfect predictor configuration (series 1a, 2a) the initial location of the predictand is essential. Approaching the predictand to the predictors ($r_0 = 25$ km, series 1a) diminishes the mean from 0.275 to 0.249. This is in agreement with the previous experiments shown in Figures 2, 3, and 5. As for the random distribution of predictors, the initial position of the predictand almost does not make a difference,

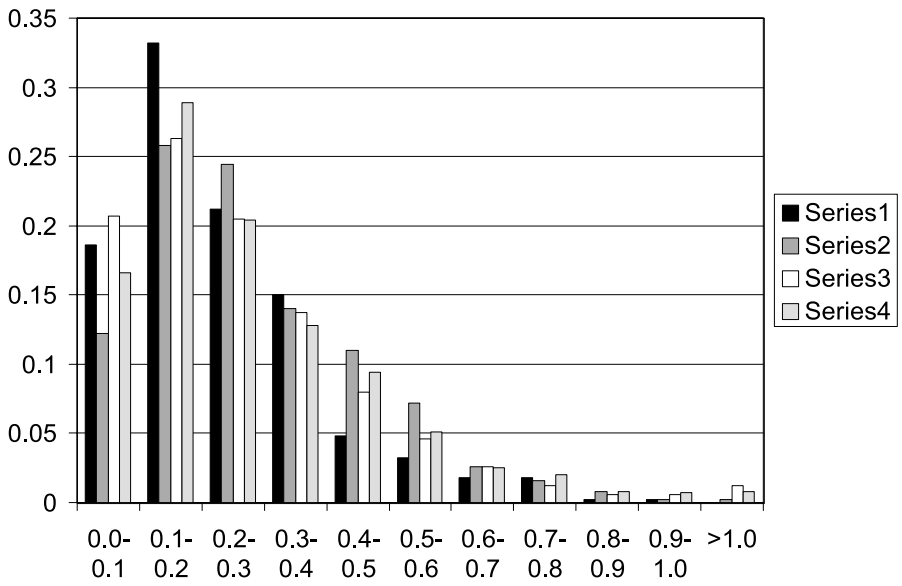
as can also be seen from the histogram (series 3 and 4). In contrast, the histograms in the case of perfect configuration (series 1 and series 2) look quite different. The mode of the first distribution is essentially higher, and the tail decays much faster.

Now introduce the alternative method of the velocity initialization as follows:

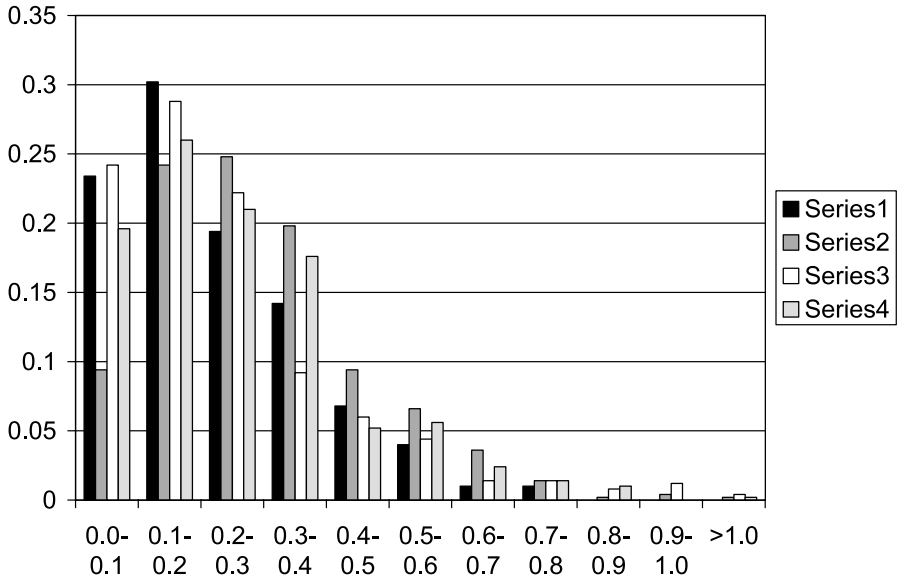
$$\mathbf{v}_j(0) = k\mathbf{r}_j(0), \tag{33}$$

where k is a constant independent of $j = 1, 2, \ldots, M$.

For the experiments we took $k = 0.1$ day^{-1} to have the same order of the initial velocities as in the case of the random initialization. Table 1 and Figure 6(b) demonstrate the statistical moments and histograms for the four cases discussed above, corresponding to the new velocity initialization (33). Regarding the predictand location, the conclusion is as before: for the perfect configuration of the predictors it is better to distance the predictor from the center, and for the random configuration it does not matter.



(a)



(b)

FIG. 6. (a) *Histograms of the relative prediction error for* 500 *runs with different initial configurations and random initial velocities:* (1) *perfect configuration with the biased predictand* (*series* 1), (2) *perfect configuration with the predictand at the center* (*series* 2), (3) *uniformly distributed predictors with the biased predictand* (*series* 3), (4) *uniformly distributed predictors with the predictand at the center* (*series* 4). (b) *Same as in* (a) *with the initial velocities proportional to the positions:* $\mathbf{v}_j(0) = k\mathbf{r}_j(0)$.

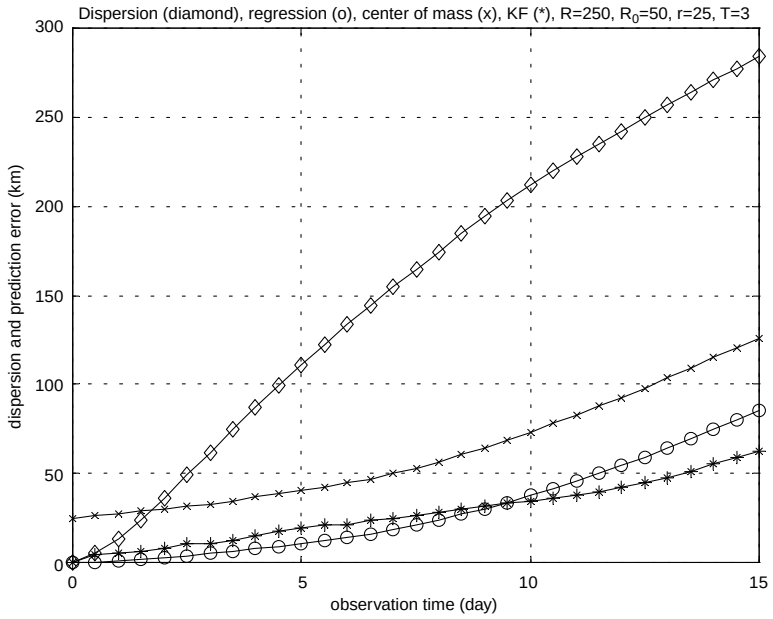
In general, there is not any visible difference in the prediction skill for the different velocity initializations. However, this conclusion is relevant only to 15 days' prediction. In practice we are more interested in a 3- to 5-day forecast, and in such time scales, the difference could be essential.

6. Comparison with KF and CM algorithms (simulations). The goal of the experiments discussed in this section is to compare the performance of RA and KF in both cases: the zero mean flow and a linear shear mean flow. The KF algorithm is based on the system of stochastic differential equations (19) for the M-particle motion. Since the diffusion matrix depends on the state variable $\mathbf{z}$, the classical Kalman filter cannot be applied to this system. What was proposed and studied in Özgökmen et al. (2000), (2001) and Piterbarg (2001b) is as follows. Pretend that the diffusion matrix is constant and write the KF equations for the optimal prediction of the unobserved particle velocity and position. Of course, these equations include the diffusion matrix. Then recall that it depends on the positions of all the particles and simply plug the observed positions for predictors and predictand forecast at the previous time step. We call this procedure a Kalman filter–type algorithm or, for short, the KF algorithm. An exact theoretical error analysis for the KF is very difficult. A Monte Carlo study showed that it gives a reasonable prediction if the model parameters are known (Piterbarg (2001b)). We follow the same approach here: the Lagrangian correlation time τ and the forcing covariance tensor $\mathbf{B}(\mathbf{r}_1, \mathbf{r}_2)$ are the same for generating Lagrangian trajectories and prediction formulas. However, the time steps are different: 1 hour for simulations and 12 hours for prediction. Thus, the KF has a big advantage over the RA, which does not use any information on the flow statistics.

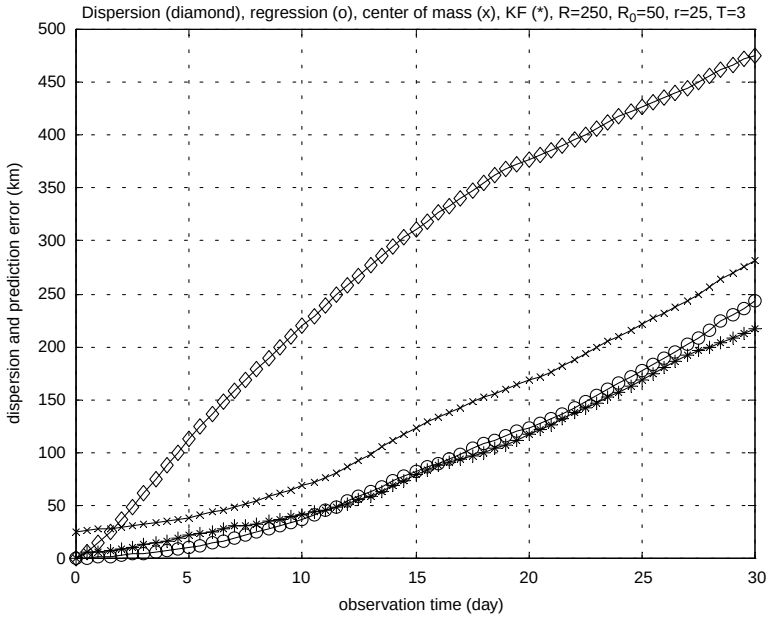
In the first series of experiments we considered the zero mean flow and fixed $\tau = 3$ days, $R = 250$ km, $R_0 = 50$ km, $M = 7$. Initially, the predictors are located in the vortices of the right hexagon, and the velocities are proportional to the position vectors; that is, the initialization (33) and the perfect configuration were used.

If the predictand is placed some distance from the center ($r_0 = 25$ km), then the mean square error of the regression algorithm is slightly lower than that of the KF (Figure 7(a)). Both algorithms are doing quite well compared with the dispersion (diamonds). This is because the initial cluster radius is 5 times less than the spatial correlation radius. The center of mass prediction (crosses) gives clearly worse prediction. After 22 days the performance of KF and regression is pretty much the same (Figure 7(b)).

If the predictand is placed at the center under the same experimental conditions, then the KF prediction turns out to be better (Figure 8(a)). As we mentioned before and which follows from the analytical formulas, the regression and center of mass methods give the same result in this case. For the midterm prediction (up to 30 days), this trend is confirmed (Figure 8(b)). For observation time $T = 30$ days the KF error is about 165 km, while the regression error is around 270 km under the dispersion 450 km. After changing τ to 2.5 days the general picture almost did not change (Figure 9(a)) and the conclusion is the same: KF performs better. However, if we introduce a mean flow, not very strong, the picture changes drastically. For a gyre given by $\omega = 0.1$ and $\gamma = 0$ the performance of KF is very poor (Figure 9(b)). The error reaches 160 km for a 15-day forecast, almost 80% of the dispersion (230 km), while the error of the regression algorithm is acceptable (60 km). Consider a different shear with no rotation: $\omega = 0$ and $\gamma = 0.05$. The conclusion is the same: the performance of the regression is clearly better (Figure 9(c)). The error of KF is



(a)



(b)

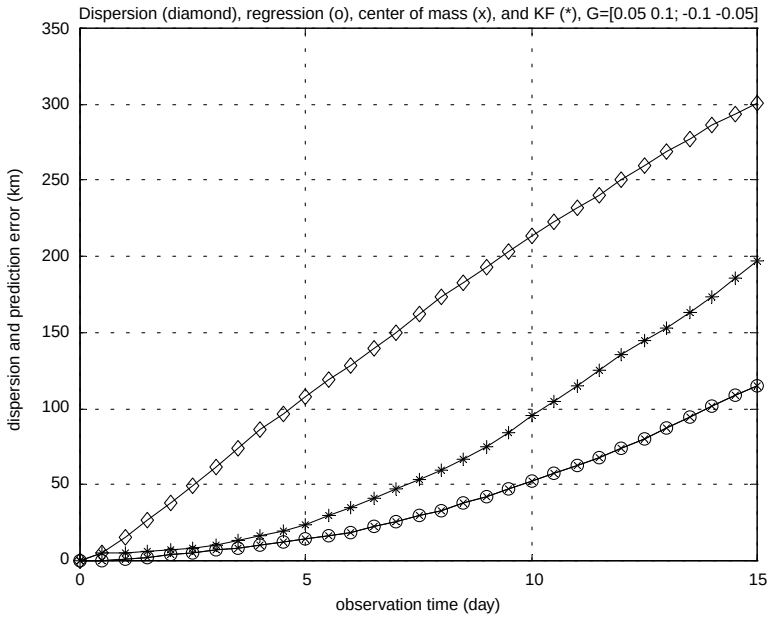
(c)



(d)

FIG. 9. (c) *Same as in Figure* 9(a) *for a nonzero shear:* $\gamma = 0$, $\omega = 0.1\,day^{-1}$. (d) *Same as in Figure* 9(a) *for a nonzero shear:* $\gamma = 0.05$, $\omega = 0.1\,day^{-1}$.

about 140 km, while for the regression it is the same: 60 km. Finally, combining both cases ($\omega = 0.1$ and $\gamma = 0.05$) we observe that the KF error is almost twice as much as the RA error (Figure 9(d)). Thus, with no doubt the regression algorithm performs better in the presence of a deterministic linear shear flow. This is because it is based on the assumption of linear dependence of the particle current position on the initial position. In fact, for purely linear flow the RA gives the exact prediction. Thus, the presence of the mean flow implies the better performance of the regression algorithm.

7. Comparison with KF and CM algorithms (real data). The final stage in this study is to apply RA to predict the motion of oceanic drifters released in a cluster and compare its performance with that of the simulations. It was found in Özgökmen et al. (2001) that during the period in which drifters remain close to one another as a tight cluster (quantified by the number of drifters within the velocity space correlation scale R), the CM method is a simple yet effective means of predicting the drifter location. However, how the prediction accuracy of RA compares to that of CM and the far more complicated technique KF for oceanic drifters needs to be investigated.

The drifter data are obtained from the NOAA Atlantic Oceanographic and Meteorological Laboratory, Global Drifter Center, by searching the entire 1988–1996 data set for a group of 5 or more drifters released within the velocity space correlation scale R. The drifter data are used as provided by the Global Drifter Center, which lists the drifter positions in six-hour intervals after standard quality control procedures (e.g., Hansen and Poulain (1996)) and no further processing has been applied. A total of 7 clusters, each consisting of 5–10 drifters, has been analyzed. In the following, we concisely present results from 3 of these clusters, since the main conclusions remain the same for others. These 3 drifter clusters have been released in the tropical Pacific Ocean, which is a region characterized by strong currents and shears and lacking the effect of coastlines or boundaries. The mean currents (Figure 10) are calculated using the technique described in Bauer et al. (1999) from the entire drifter data set collected under the World Ocean Circulation Experiment (WOCE) during 1988–1996. This figure depicts the general circulation pattern in this region, which is governed by the westward North Equatorial Current north of $10°N$, the eastward North Equatorial

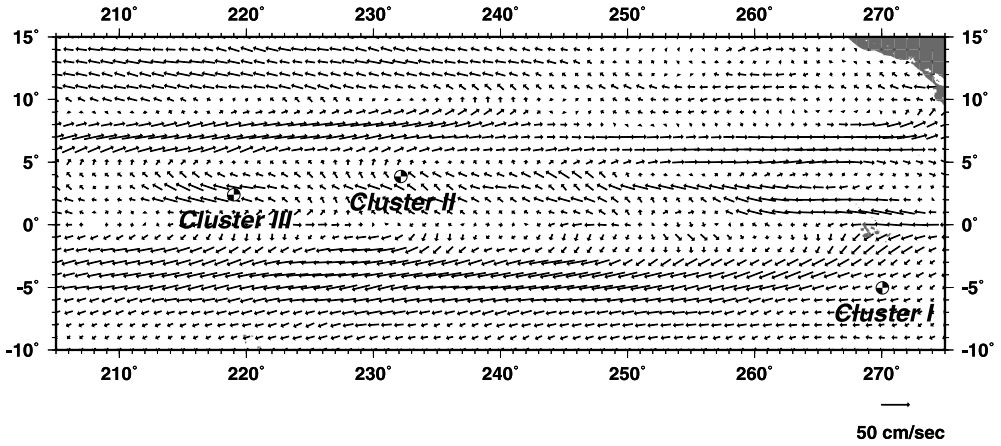


FIG. 10. *The climatological mean flow field depicting the major currents in the tropical Pacific Ocean and the initial release locations of clusters* I, II, *and* III.

Countercurrent between $4°N$ and $9°N$, and the westward South Equatorial Current, which extends across the equator to $10°S$. Drifters in the first cluster (cluster I) have been released in the South Equatorial Current, whereas the others in clusters II and III have been launched just south of the North Equatorial Countercurrent. The mean currents, however, are not a good indicator of drifter motion (Özgökmen et al. (2000), (2001)) and are discussed here only to provide the general surface flow characteristics of this oceanic region. It is also important to point out that in order to be able to deploy these drifters on tight grids, a real-time analysis of a variety of data sets, including current meter profilers and satellite data images, has been necessary for a detailed dynamical analysis due to strong currents in this region (e.g., Flament et al. (1996)). Finally, the space correlation radius of the velocity field in the tropical Pacific Ocean is taken as the Rossby deformation radius $R = 250$ km (Cushman-Roisin (1994)), and the Lagrangian correlation time is taken as $\tau = 3$ days, based on the analysis of drifter motion in the WOCE data set (Bauer et al. (1999)).

Clusters I–III are sorted according to the difficulty of prediction, quantified by the initial scale of the cluster, the velocity variance and prediction period. Cluster I consists of 5 drifters launched within a scale ($\sim R_0$) of approximately 10 km from each other (Figure 11(a)), and the prediction algorithms are applied for 7 days of particle motion, during which the velocity variance is approximately $\sigma_v^2 = 430$ km^2/day^2. During 7 days of motion, these drifters do not spread apart significantly. Given $R_0 \ll R$ and the low velocity variance, one can anticipate very good performance by RA based on the results from theory and stochastic simulations. Dispersion $d(t)$ and prediction errors $s(t)$ from RA, CM, and KM are calculated by sequentially selecting each drifter as predictand and the remaining others in the cluster as predictors, corresponding to the root mean square of that of all cluster particles. The results are shown in Figure 11(b) for cluster I for an observation time of 7 days. This figure shows that prediction errors of both KF and RA are less than that of CM during the observation period and that RA is as accurate as KF. More quantitatively, dispersion reaches approximately 51 km at $T = 7$ days, error from CM is 8 km ($s_r = 0.16$), and error from KF and RA is about 5 km ($s_r = 0.1$).

Cluster II consists of 7 drifters that are also released with a mean diameter of approximately 10 km, but disperses much faster than Cluster I due to a higher velocity variance of $\sigma_v^2 = 720$ km^2/day^2, and the mean cluster diameter reaches 25 km and 50 km after 7 and 14 days of observation time, respectively (Figure 12(a)). Dispersion and prediction errors for cluster II over an observation period of 14 days are shown in Figure 12(b), and the conclusion remains the same as for cluster I; prediction errors of both KF and RA are less than that of CM during the observation period, and RA is as accurate as KF. Dispersion reaches approximately 136 km at $T = 14$ days, error from CM is 44 km ($s_r = 0.32$), and errors from KF and RA are about 26 km ($s_r = 0.19$). The sensitivity of the prediction accuracy of RA to the number of predictors p is investigated by randomly eliminating drifters from cluster II. Figure 12(c) shows the dispersion curve based on the entire cluster and prediction errors calculated for $p = 6$ (same as in Figure 12(b)), $p = 5$, $p = 4$, and $p = 3$. When $p = 3$, a drastic reduction of prediction accuracy takes place, which is found to be independent of the combination of chosen predictors in this cluster. Otherwise, the prediction accuracy gradually decreases as the number of predictors is decreased from 6 to 4, but the accuracy of the method using 4 to 6 predictors remains essentially constant for $T \leq \tau$ or for $T \leq 3$ days.

The motion of cluster III, consisting of 10 drifters, is investigated for 21 days

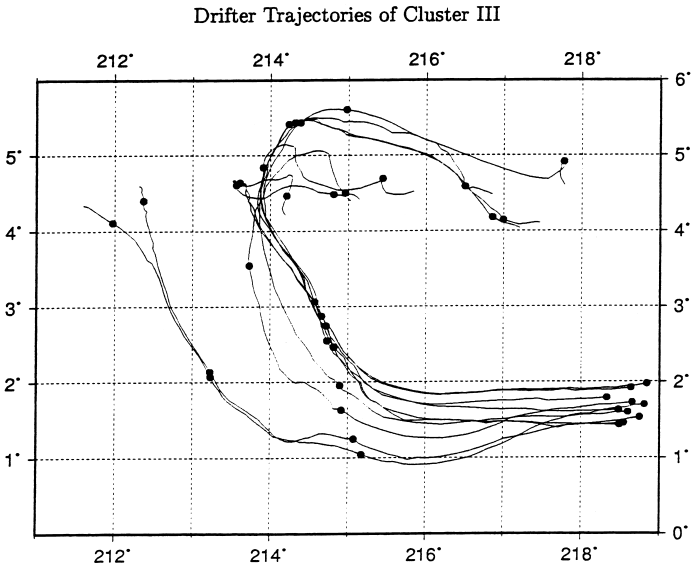
FIG. 12. (c) *Sensitivity of the prediction error of RA to the number of predictors in cluster* II.

during which velocity variance is $\sigma_v^2 = 2240$ km^2/day^2, or the highest of the three clusters. These drifters were released over an area with an approximate diameter of 30 km, but this scale increases to approximately 100, 180, and 250 km after 7, 14, and 21 days, respectively (Figure 13(a)). Dispersion and prediction errors for cluster III are shown in Figure 13(b). During the first 10 days, prediction errors of both KF and RA are approximately the same and less than that of CM, but during the second half of the observation period, the error of KF increases faster than that of RA. This increase appears to be related to the inability of the KF algorithm to follow the bifurcation of some drifters in a larger group as effectively as the RA technique. Dispersion is 426 km (543 km), error from CM is 99 km (235 km) or $s_r = 0.23$ ($s_r = 0.43$), error from KF is 55 km (176 km) or $s_r = 0.13$ ($s_r = 0.32$), and error from RA is 54 km (80 km) or $s_r = 0.13$ ($s_r = 0.15$) at $T = 7$ days ($T = 21$ days).

All in all, the real data comparison of different prediction algorithms is in good qualitative agreement with the simulation results. Even the prediction error values are of the same order, as our simple error theory concludes. Deviations are related to oversimplifications accepted in the considered stochastic model such as the shear flow linearity and fluctuations isotropy.

In summary, the algorithm described in this study presents several important simplifications with respect to the KF method developed and investigated by Piterbarg (2001b) and Özgökmen et al. (2000), (2001): (i) This algorithm does not require any parameters, such as the Lagrangian parameters describing the characteristics of the underlying flow, the velocity correlation space scale R, and the Lagrangian correlation time scale τ. (ii) RA does not utilize the mean flow field, the calculation of which requires large data sets and the associated subgrid scale interpolation introduces further errors. (iii) RA does not need to be initialized with turbulent velocity fluctuations at



(a)

the launch location. (iv) RA is not based on the integration of velocity field to estimate the particle position, which necessarily leads to accumulation of velocity errors as errors of drifter location. (v) Consequently RA is computationally far simpler than KF. Despite these simplifications, it is found on the basis of several oceanic clusters that RA outperforms CM and that RA is as accurate as KF. Also, predictions from RA appear to remain applicable over a time scale of $T \gg \tau$, or much longer than one would anticipate. In future studies, it will be investigated theoretically and numerically how this method performs when $R_0 \approx R$, which is likely to be the case in mid- and high-latitude oceans and for bifurcating clusters.

Appendix.

A.1. Prediction error in terms of separation. Using the definition (4) and expression (6) for b_k, obtain

$$\begin{aligned} s^2 &= E|\hat{\mathbf{r}}_M(t) - \mathbf{r}_M(t)|^2 \\ &= E\{(\mathbf{r}_c(t) + \mathbf{S}(t)\mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)) - \mathbf{r}_M(t))^T(\mathbf{r}_c(t) \\ &\quad + \mathbf{S}(t)\mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)) - \mathbf{r}_M(t))\} \\ &= E\{(\mathbf{r}_c(t) - \mathbf{r}_M(t))^T(\mathbf{r}_c(t) - \mathbf{r}_M(t))\} \\ &\quad + 2E\{(\mathbf{r}_c(t) - \mathbf{r}_M(t))^T\mathbf{S}(t)\}\mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)) \\ &\quad + (\mathbf{r}_M(0) - \mathbf{r}_c(0))^T\mathbf{S}(0)^{-1}E\{\mathbf{S}(t)^T\mathbf{S}(t)\}\mathbf{S}(0)^{-1}(\mathbf{r}_M(0) - \mathbf{r}_c(0)) \\ &= E\{(\mathbf{r}_c(t) - \mathbf{r}_M(t))^T(\mathbf{r}_c(t) - \mathbf{r}_M(t))\} \\ &\quad + 2\textstyle\sum_{k=1}^{p} b_k E\{(\mathbf{r}_c(t) - \mathbf{r}_M(t))^T(\mathbf{r}_k(t) - \mathbf{r}_c(t))\} \\ &\quad + \textstyle\sum_{k,l=1}^{p} b_k b_l E\{(\mathbf{r}_k(t) - \mathbf{r}_c(t))^T(\mathbf{r}_l(t) - \mathbf{r}_c(t))\}. \end{aligned} \tag{A1}$$

Then, dropping the time argument for brevity,

$$\begin{aligned} E\{(\mathbf{r}_k - \mathbf{r}_c)^T(\mathbf{r}_l - \mathbf{r}_c)\} &= \tfrac{1}{p^2}\textstyle\sum_{i,j=1}^{p} E\{(\mathbf{r}_k - \mathbf{r}_i)^T(\mathbf{r}_l - \mathbf{r}_j)\} \\ &= -\tfrac{1}{2p^2}\textstyle\sum_{i,j=1}^{p}(\rho_{kl} + \rho_{ij} - \rho_{ki} - \rho_{lj}) \\ &= -\tfrac{1}{2}\rho_{kl} + \tfrac{1}{2p}\textstyle\sum_{i=1}^{p}(\rho_{ki} + \rho_{li}) - \tfrac{1}{2p^2}\textstyle\sum_{i,j=1}^{p}\rho_{ij}. \end{aligned} \tag{A2}$$

In the latter we used the relation

$$E\{\mathbf{r}_k{}^T\mathbf{r}_l\} = \frac{1}{2}(-\rho_{kl} + E\{\mathbf{r}_k{}^T\mathbf{r}_k\} + E\{\mathbf{r}_l{}^T\mathbf{r}_l\}).$$

By substituting (A2) into (A1), using the obvious relation

$$\sum_{k=1}^{p} b_k = 0,$$

and changing the summation indexes, we obtain (5).

A.2. Separation for Brownian flow (close initial positions). The function

$$\rho(t, r) = E\{(\mathbf{r}_1(t) - \mathbf{r}_2(t))^2\},$$

where $|\mathbf{r}_1(0) - \mathbf{r}_2(0)| = r$, satisfies

$$\frac{\partial \rho}{\partial t} = L_s\rho\ , \qquad \rho(0, r) = r^2, \tag{A3}$$

where in the isotropic case the generator for the separation process is

$$L_s = \frac{b_0 - b_N(r)}{r}\frac{\partial}{\partial r} + (b_0 - b_L(r))\frac{\partial^2}{\partial r^2}\ .$$

Substitute expansions (13), (15) into (A3). The result is

$$\frac{d\rho_1}{dt} = \overline{\beta}\rho_1, \quad \rho_1(0) = 1, \qquad \frac{d\rho_0}{dt} = \beta_0\rho_0 + \overline{\gamma}\rho_1, \quad \rho_0(0) = 0,$$

where

$$\overline{\beta} = \beta_N + \beta_L, \quad \beta_0 = 2\beta_N + 6\beta_L, \qquad \overline{\gamma} = \gamma_N + \gamma_L.$$

Solving the latter equations we obtain (16).

A.3. Dispersion for the flow with memory in presence of linear shear flow. For simplicity assume $\mathbf{U} = 0$. From (20) it follows that

$$\mathbf{r}(t) = \bar{\mathbf{r}}(t) + \int_0^t \exp(\mathbf{G}(t-s))\mathbf{v}(s)ds,$$

where $\mathbf{v}(t)$ is a two-dimensional Ornstein–Uhlenbeck process with the covariance $\sigma_v^2\exp(-t/\tau)\mathbf{I}$ and

$$\bar{\mathbf{r}} = \exp(\mathbf{G}t)\mathbf{r}_0 + (\exp(\mathbf{G}t) - \mathbf{I})\mathbf{G}\mathbf{U}.$$

Set

$$d_0^2 = (\bar{\mathbf{r}} - \mathbf{r}_0)^2;$$

then

$$d^2 = d_0^2 + \sigma_v^2\int_0^t\int_0^t Sp(\exp(\mathbf{G}(t-s_1))\exp(\mathbf{G}^T(t-s_2)))\exp(-|s_1-s_2|/\tau)ds_1ds_2,$$

where $Sp(\mathbf{A})$ means the race of matrix A. Then we use the following relations:

$$Sp(\mathbf{A}) = \lambda_1(\mathbf{A}) + \lambda_2(\mathbf{A}), \quad \lambda(\exp(\mathbf{A})) = \exp\lambda((\mathbf{A})),$$

where $\lambda(\mathbf{A})$ is an eigenvalue of $\mathbf{A}$ and arrive at (21).

A.4. Separation for the flow with memory (close initial positions and velocities). In the case considered, the separation satisfies

$$\frac{\partial\rho}{\partial t} = L_s\rho, \quad \rho|_{t=0} = x^2 + y^2, \tag{A4}$$

with the generator (24) written in the coordinatewise form

$$\begin{aligned} L_s = {} & (\gamma y + \omega x + u)\frac{\partial}{\partial x} - (\gamma y + \omega x + v)\frac{\partial}{\partial y} - \frac{1}{\tau}u\frac{\partial}{\partial u} - \frac{1}{\tau}v\frac{\partial}{\partial v} \\ & + (b_0 - b_N(r) - \frac{x^2}{r^2}(b_L(r) - b_N(r))\frac{\partial^2}{\partial u^2} + (b_0 - b_N(r) - \frac{y^2}{r^2}(b_L(r) - b_N(r))\frac{\partial^2}{\partial v^2} \\ & - \frac{2xy}{r^2}(b_L(r) - b_N(r))\frac{\partial^2}{\partial u\partial v}. \end{aligned}$$

Substituting expansions (25), (27) into (A4) we obtain (27), where

$$\mathbf{A} = \begin{pmatrix} 2\gamma & -2\omega & 0 & 2\beta_L & 0 & 2\beta_N & 0 & 0 & 0 & 0 \\ \omega & 0 & -\omega & 0 & -2\beta & 0 & 0 & 0 & 0 & 0 \\ 0 & 2\omega & -2\gamma & 2\beta_N & 0 & 2\beta_L & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & -2/\tau & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & -2/\tau & 0 & 0 & 1/2 & 0 & 1/2 \\ 0 & 0 & 0 & 0 & 0 & -2/\tau & 0 & 0 & 0 & 1 \\ 2 & 0 & 0 & 0 & 0 & 0 & \gamma - 1/\tau & 0 & -\omega & 0 \\ 0 & 2 & 0 & 0 & 0 & 0 & 0 & \gamma - 1/\tau & 0 & -\omega \\ 0 & 2 & 0 & 0 & 0 & 0 & \omega & 0 & -\gamma - 1/\tau & 0 \\ 0 & 0 & 2 & 0 & 0 & 0 & 0 & \omega & 0 & -\gamma - 1/\tau \end{pmatrix},$$

where $\beta = \beta_N - \beta_L$,

$$\mathbf{a}_0 = (1\ 0\ 1\ 0\ 0\ 0\ 0\ 0\ 0\ 0)^T.$$

For the zero mean flow $\gamma = 0$, $\omega = 0$, and (27) reduces to (29) for $\rho_0 = a_4 + a_6$, $\rho_1 = a_1 + a_3$, and $\rho_{01} = a_7 + a_{10}$.

A RIGOROUS TREATMENT OF A FOLLOW-THE-LEADER TRAFFIC MODEL WITH TRAFFIC LIGHTS PRESENT*

BRENNA ARGALL†, EUGENE CHELESHKIN†, J. M. GREENBERG†, COLIN HINDE†, AND PEI-JEN LIN†

Abstract. Traffic flow on a unidirectional roadway in the presence of traffic lights is modeled. Individual car responses to green, yellow, and red lights are postulated and these result in rules governing the acceleration and deceleration of individual cars. The essence of the model is that only specific cars are directly affected by the lights. The other cars behave according to simple follow-the-leader rules which limit their speed by the spacing between them and the car directly ahead. The model has a number of desirable properties; namely, cars do not run red lights, cars do not smash into one another, and cars exhibit no velocity reversals. In a situation with multiple lights operating in-phase, we get, after an initial start-up period, a constant number of cars through each light during any green-yellow period. Moreover, this flux is less by one or two cars per period than the flux obtained in discretized versions of the idealized Lighthill–Whitham–Richards model which allows for infinite accelerations.

Key words. traffic flow, follow-the-leader, relaxation models, conservation laws

1. Introduction, model description, and statement of results. In this note we examine the behavior of traffic on a unidirectional highway when multiple traffic lights are present. For simplicity we assume the lights operate in-phase.

The model postulates the dynamics of individual cars but may also be thought of as a coarse discretization of a continuum model introduced recently by Greenberg [1], Aw and Rascle [2], Aw, Klar, Materne, and Rascle [3], and Zhang [9] (details of this correspondence may be found in section 4, (4.6)–(4.8)).

We assume we are presented with an empirically determined function $s \to \mathcal{V}(s)$ on $L \leq s$ which satisfies

$$\mathcal{V}(L^+) = 0, \tag{1.1}$$

$$\frac{d\mathcal{V}}{ds}(s) > 0 \text{ and } \frac{d^2\mathcal{V}}{ds^2}(s) < 0, \qquad L \leq s < \infty, \tag{1.2}$$

and

$$\lim_{s\to\infty} \left(\mathcal{V}(s),\ \frac{d\mathcal{V}}{ds}(s),\ \frac{d^2\mathcal{V}}{ds^2}(s) \right) = (\mathcal{V}_\infty > 0, 0, 0). \tag{1.3}$$

The independent variable s is interpreted as the spacing between cars, L is the minimum car spacing (a lower bound for L is the length of typical car), and $\mathcal{V}_\infty > 0$

is the maximum allowable speed of a car. A typical function, and one we shall use in simulations, is

$$\mathcal{V}(s) = \mathcal{V}_\infty \left(1 - \frac{L}{s}\right), \qquad L \le s < \infty. \tag{1.4}$$

In this classic Lighthill–Whitham–Richards model [4, 5, 6, 7] the function $\mathcal{V}(\cdot)$ gives the velocity of individual cars; in ours it provides an upper bound for the velocity of an individual car. An extensive discussion of suitable functions $\mathcal{V}(\cdot)$ may be found in [8, Chapter 4] and the references contained therein. Suffice it to say that the functions $\mathcal{V}(\cdot)$ in our model are consistent with those used in practice.

In this model $x_k(t), 1 \le k \le N$, denotes the position of the kth car at time t, and $0 \le u_k(t)$ is the velocity of the kth car. Throughout,

$$\frac{dx_k}{dt} = u_k, \qquad 1 \le k \le N, \tag{1.5}$$

and the cars are ordered so that $(x_{k+1} - x_k)(t) \ge L$, $1 \le k \le N-1$. During time intervals where the lights are green we assume that

$$u_k = \mathcal{V}((x_{k+1} - x_k)(t)) + \alpha_k, \qquad 1 \le k \le N, \tag{1.6}$$[1]

where $\alpha_k(t) \le 0$ satisfies

$$\epsilon \frac{d\alpha_k}{dt} = -\alpha_k, \qquad 1 \le k \le N. \tag{1.7}$$

The parameter $\epsilon > 0$ may be thought of as a relaxation time. Equations (1.6) and (1.7) imply that during the green light periods the velocities, u_k, satisfy

$$\frac{du_k}{dt} = \mathcal{V}'(x_{k+1} - x_k)(u_{k+1} - u_k) + \frac{(\mathcal{V}(x_{k+1} - x_k) - u_k)}{\epsilon}, \qquad 1 \le k \le N-1, \tag{1.7a}$$

and

$$\frac{du_N}{dt} = \frac{(\mathcal{V}_\infty - u_N)}{\epsilon}. \tag{1.7b}$$

The interesting feature of our model is how yellow or red lights effect the dynamics of an individual car. Our traffic lights cycle from green to yellow to red, and the numbers $0 < TG$, $0 < TY$, and $0 < TR$ denote the duration of the green, yellow, and red lights. At time $t = 0$ we assume we have a sequence of N cars located at

$$x_k(0) = (k - k_0)L_1, \qquad 1 \le k \le N, \tag{1.8}$$

where $L_1 \ge L$ (again L is the minimum allowable auto spacing), and we assume these cars are all at rest; i.e.,

$$u_k(0) = 0, \qquad 1 \le k \le N. \tag{1.9}$$

Finally, we assume they are at traffic lights located at $x = l_I, 1 \le I \le M$, where

$$(N - k_0)L_1 < l_1 < l_2 < \cdots < l_M. \tag{1.10}$$

[1] When $k = N$, $u_N = \mathcal{V}_\infty + \alpha_N$.

We further assume that each intersection is of width $w > 0$ and let

$$t_m = (m-1)(TG + TY + TR), \qquad m = 1, 2, \ldots, \tag{1.11}$$

denote the start of the mth light cycle.

During the time interval $t_m \le t \le t_m + TG$ all cars satisfy (1.5)–(1.7). At time $t_y \stackrel{def}{=} t_m + TG$, the green lights turn yellow, and this will have an effect on the traffic flow.

We start by describing what happens to the lead car, the one indexed by N, when it encounters a light at $x = l$. We assume that

$$x_N(t_y) < l. \tag{1.12}$$

If

$$x_N(t_y) + u_N(t_y)TY \ge l + w + L, \tag{1.13}$$

then the lead car will be able to completely clear the intersection if it travels at its current speed $u_N(t_y)$. We allow it to clear the intersection by following its standard dynamics; that is, over the time interval $t_y \le t \le t_{m+1}$ the Nth car satisfies

$$\frac{dx_N}{dt} = u_N, \tag{1.14}$$

where

$$u_N = \mathcal{V}_\infty + \alpha_N \tag{1.15}$$

and $\alpha_N \le 0$ satisfies

$$\epsilon \frac{d\alpha_N}{dt} = -\alpha_N. \tag{1.16}$$

Following these dynamics the lead car accelerates through the intersection.

On the other hand, if

$$x_N(t_y) + u_N(t_y)TY < l + w + L, \tag{1.17}$$

then it will be impossible for the Nth car to clear the intersection during the yellow phase if it continues to travel at its current speed. If

$$x_N(t_y) + u_N(t_y)(TY + TR) \le l, \tag{1.18}$$

then over the time interval $t_y \le t \le t_{m+1}$ we require it satisfies the modified dynamics

$$\frac{dx_N}{dt} = u_N \quad \text{and} \quad \frac{du_N}{dt} = 0; \tag{1.19}$$

i.e., we insist that it travels at its current speed. This strategy avoids the Nth car accelerating and then possibly having to decelerate as it nears the light.

If (1.17) holds and (1.18) is violated, the lead car will have to slow down and possibly stop. When it satisfies the additional inequality

$$x_N(t_y) + u_N(t_y)(TY + TR)/2 > l, \tag{1.20}$$

the lead car is mandated to satisfy

$$\frac{dx_N}{dt} = u_N \quad \text{and} \quad \frac{du_N}{dt} = \begin{cases} \dfrac{-u_N^2(t_y)}{2(l - x_N(t_y))}, t_y \le t \le t_y + \dfrac{2(l - x_N(t_y))}{u_N(t_y)} \\ \\ 0, t_y + \dfrac{2(l - x_N(t_y))}{u_N(t_y)} \le t \le t_{m+1}.^2 \end{cases} \tag{1.21}$$

This constant deceleration strategy brings the Nth car to rest at $x = l$ at $t = t_y + \frac{2(l - x_N(t_y))}{u_N(t_y)} \le t_{m+1}$, and it then sits at the light until $t = t_{m+1}$.

Finally, when

$$x_N(t_y) + u_N(t_y)(TY + TR) > l \quad \text{and} \quad x_N(t_y) + u_N(t_y)(TY + TR)/2 \le l, \tag{1.22}$$

the lead car is mandated to satisfy

$$\frac{dx_N}{dt} = u_N(t) \quad \text{and} \quad \frac{du_N}{dt} = \frac{-2(x_N(t_y) + u_N(t_y)(TY + TG) - l)}{(TY + TG)^2}$$

over the whole interval $t_y \le t \le t_{m+1}$. This strategy brings the car to the light at $x = l$ at t_{m+1} with velocity

$$u_N(t_{m+1}) = \frac{2(l - x_N(t_y))}{(TY + TR)} - u_N(t_y) > 0. \tag{1.23}$$

We note that if the lead car satisfies (1.17), then the cars with indices $k \le N - 1$ follow their standard dynamics (1.5)–(1.7) over $[t_y, t_{m+1}]$ unless they happen to be influenced by some other light at $x = l' < l$.

Having described what happens when the lead car encounters a yellow light at $x = l$, we turn our attention to what happens when other cars encounter the same light. We let $k_l \le N - 1$ be the largest integer so that

$$x_{k_l}(t_y) < l, \tag{1.24}$$

and we let $p_l \le k_l$ be the largest integer so that

$$x_{p_l}(t_y) + \min_{p_l \le j \le k_l} u_j(t_y)TY < l + w + L. \tag{1.25}$$

The p_lth car will be the first one that does not get through the light at $x = l$.

We first consider the situation when $p_l < k_l$. We assume the existence of a number $\lambda \ge 1$ such that cars travelling with the maximum speed $\mathcal{V}_\infty$ can safely brake at a constant deceleration rate $a = \frac{-\mathcal{V}_\infty^2}{2\lambda L}$ over a road segment of length λL.

We first focus our attention on the situation in which

$$x_{p_l}(t_y) < l - \lambda L. \tag{1.26}$$

[2]The dynamics described by (1.21) are equivalent to

$$\frac{dx_N}{dt} = \frac{u_N(t_y)(l - x_N(t))^{1/2}}{2(l - x_N(t_y))^{1/2}}, \ t_y \le t \le t_y + \frac{2(l - x_N(t_y))}{u_N(t_y)}$$

and

$$\frac{dx_N}{dt} = 0, t_y + \frac{2(l - x_N(t_y))}{u_N(t_y)} \le t \le t_{m+1}.$$

Our basic strategy is to let cars with indices $k \geq p_l+1$ follow their standard dynamics (1.5)–(1.7) over $t_y \leq t \leq t_{m+1}$. The cars with indices $p_l + 1 \leq k \leq k_l$ will clear the intersection by $t_m + TG + TY \stackrel{def}{=} t_r$; i.e., they will satisfy $x_k(t_r) \geq l + w + L$. This follows from the observation that local spatial minima in the velocity are nondecreasing in t (for details see (2.79)–(2.81)).

Rules for the p_lth car. So long as $t_y \leq t \leq t_r$ and $x_{p_l}(t) < l - \lambda L$ we let the p_lth car follow its standard dynamics (1.5)–(1.7). If there is a first $t_{p_l} < t_r$ so that $x_{p_l}(t_{p_l}) = l - \lambda L$, then the driver must decide what to do. In the unlikely event that

$$u_{p_l}(t_{p_l})(t_{m+1} - t_{p_l}) \leq \lambda L, \tag{1.27}$$

then over the interval $[t_{p_l}, t_{m+1}]$ the p_lth car is required to satisfy

$$\frac{dx_{p_l}}{dt} = \min\left(u_{p_l}(t_y),\ U_{p_l}(t)\right) \stackrel{def}{=} u_{p_l}(t)$$

and

$$\begin{aligned}\frac{dU_{p_l}}{dt} &= \mathcal{V}'\left(x_{p_l+1} - x_{p_l}\right)\left(u_{p_l+1} - U_{p_l}\right) \\ &\quad + \frac{\left(\mathcal{V}\left(x_{p_l+1} - x_{p_l}\right) - U_{p_l}\right)}{\epsilon}\end{aligned} \tag{1.28}$$

and

$$U_{p_l}(t_y) = u_{p_l}(t_y).$$

On the other hand, if

$$u_{p_l}(t_{p_l})(t_{m+1} - t_{p_l}) > \lambda L, \tag{1.29}$$

then the p_lth car will have to slow down and possibly stop.

When the p_lth car satisfies the additional inequality

$$u_{p_l}(t_{p_l})(t_{m+1} - t_{p_l})/2 > \lambda L, \tag{1.30}$$

the p_lth car is required to satisfy

$$\frac{dx_{p_l}}{dt} = \min\left(\frac{u_{p_l}(t_{p_l})(l - x_{p_l})^{1/2}}{2(\lambda L)^{1/2}},\ U_{p_l}\right) \stackrel{def}{=} u_{p_l}, \tag{1.31}$$

where

$$\frac{dU_{p_l}}{dt} = \mathcal{V}'(x_{p_l+1} - x_{p_l})(u_{p_l+1} - U_{p_l}) + \frac{(\mathcal{V}(x_{p_l+1} - x_{p_l}) - U_{p_l})}{\epsilon} \tag{1.32}$$

and

$$x_{p_l}(t_{p_l}) = l - \lambda L \ \text{ and } \ U_{p_l}(t_{p_l}) = u_{p_l}(t_{p_l}). \tag{1.33}$$

When (1.31) reduces to

$$\frac{dx_{p_l}}{dt} = \frac{u_{p_l}(t_{p_l})(l - x_{p_l})^{1/2}}{2(\lambda L)^{1/2}} \stackrel{def}{=} v_{p_l}, \tag{1.34}$$

we see that

$$\frac{dv_{p_l}}{dt} = -\frac{u_{p_l}^2(t_{p_l})}{2\lambda L} \leq -\frac{\mathcal{V}_\infty^2}{2\lambda L}, \tag{1.35}$$

and thus we apply this constant braking strategy over $t_{p_l} \leq t \leq t_{p_l} + \frac{2\lambda L}{u_{p_l}(t_{p_l})}$ and the strategy $x_{p_l}(t) = l$ over $t_{p_l} + \frac{2\lambda L}{u_{p_l}(t_{p_l})} \leq t \leq t_{m+1}$.

If instead of (1.30) the p_lth car satisfies

$$u_{p_l}(t_{p_l})(t_{m+1} - t_{p_l})/2 \leq \lambda L, \tag{1.36}$$

the p_lth car is required to satisfy

$$\begin{aligned} \tfrac{dx_{p_l}}{dt} &= \min\left(u_{p_l}(t_{p_l}) + \tfrac{2\lambda L - u_{p_l}(t_{p_l})(t_{m+1}-t_{p_l})}{(t_{m+1}-t_{p_l})^2}(t - t_{p_l}), U_{p_l}\right) \\ &\overset{def}{=} u_{p_l},\ t_{p_l} \leq t \leq t_{m+1} \end{aligned} \tag{1.37}$$

and (1.33), and again U_{p_l} satisfies (1.32) and $(1.33)_2$.

The dynamics for U_{p_l} postulated in (1.28) and (1.32) might seem a bit strange. What we are insisting is that the p_lth car must travel no faster than the minimum of its braking speed and the speed that it would travel at if it disregarded the light and allowed its velocity to be determined by the car ahead. The latter speed U_{p_l} is computed from the standard dynamics equation (see (1.6), (1.7), (1.7a), and (1.7b)).

If there is no such time $t_{p_l} < t_r$ so that $x_{p_l}(t_{p_l}) = l - \lambda L$, then we know that $x_{p_l}(t_r) \leq l - \lambda L$. In this situation we replace t_{p_l} in (1.27)–(1.37) by t_r and the terms λL in all inequalities and identities by $l - x_{p_l}(t_r)$.

Finally, if (1.26) does not hold, i.e., if

$$l - \lambda L \leq x_{p_l}(t_y) < l, \tag{1.38}$$

we set t_{p_l} to t_y in (1.27)–(1.37) and replace λL in these formulas by $l - x_{p_l}(t_y)$.

The rules when $p_l = k_l$ are similarly amended.

The cars with indices $p_{l-1} \leq k \leq p_l - 1$ are required to satisfy their standard dynamics over $[t_y, t_{m+1}]$.

Our first result deals with the model's consistency; we shall show that for all $t \geq 0$ and all indices, $L \leq (x_{k+1} - x_k)(t)$ and $0 \leq u_k(t) < \mathcal{V}((x_{k+1} - x_k)(t))$. We also have the theorem that no cars run any red lights. With two in-phase lights, the number of cars through an intersection during the green and yellow phases is, after a start-up period, a constant. This constant is less than the constant obtained with models which allow for infinite accelerations, i.e., discrete Lagrangian versions of the Lighthill–Whitham–Richards model [4, 5, 6, 7].

One surprising observation about the model just described is that the largest decelerations are not necessarily associated with the cars indexed by p_l but rather cars with indices $k \leq p_l - 1$ which are forced to slow down because the p_lth car has stopped. Equation (1.7a) implies that the latter cars' decelerations are determined by the negative velocity gradients $u_{k+1} - u_k$.

Finally, we note that though we have been quite specific in postulating our stopping rules for the p_lth car, it would have sufficed to have chosen any rule of the form

$$\frac{dx_{p_l}}{dt} = \min\left(v_{p_l}, U_{p_l}\right) \overset{def}{=} u_{p_l}, \qquad t_{p_l} \leq t \leq t_{m+1},$$

where U_{p_l} satisfies

$$\frac{dU_{p_l}}{dt} = \mathcal{V}'(x_{p_{l+1}} - x_{p_l})(u_{p_{l+1}} - U_{p_l}) + (\mathcal{V}(x_{p_{l+1}} - x_{p_l}) - U_{p_l})\epsilon$$

and $U_{p_l}(t_y) = u_{p_l}(t_y)$ if $p_l \leq N-1$, and

$$\frac{dU_N}{dt} = \frac{(\mathcal{V}_\infty - U_N)}{\epsilon} \text{ and } U_N(t_y) = u_{p_l}(t_y)$$

if $p_l = N$, and where $v_{p_l} \geq 0$ is chosen so that if

$$\frac{dx_{p_l}}{dt} = v_{p_l}, \qquad t_y \leq t \leq t_{m+1} \text{ and } x_{p_l}(t_y) < l,$$

then $x_{p_l}(t) \leq l$, $t_y \leq t \leq t_{m+1}$.

2. Model consistency. In this section we turn our attention to the issue of model consistency. The central issue before us is to show that for $1 \leq k \leq N-1$ and $0 \leq t$

$$L \leq (x_{k+1} - x_k)(t) \text{ and } 0 \leq u_k(t) < \mathcal{V}((x_{k+1} - x_k)(t)) \tag{2.1}$$

and that for $k = N$ and $0 \leq t$

$$0 \leq u_N(t) \leq \mathcal{V}_\infty. \tag{2.2}$$

We are also interested in knowing that the distinguished cars indexed by p_l do not run the red lights over the intervals $t_r \overset{def}{=} (m-1)(TG+TY+TR)+TG+TY \leq t \leq m(TG+TY+TR) \overset{def}{=} t_{m+1}$ and that the (p_l+1)st car clears the intersection by t_r, i.e., satisfies

$$x_{p_l+1}(t_r) \geq l + w + L. \tag{2.3}$$

Once again $x = l$ is supposed to be the leading edge of the intersection, w the width of the intersection, and L the length of a car.

There are two natural approaches that one can take to establish the above claims. The first is to show that the desired conclusions follow directly from the governing differential equations and initial and constraining conditions while the second is to show that approximate solutions, generated by numerical discretization, satisfy the desired consistency results. Noting then that these consistency results are sufficient to guarantee that the approximate solutions converge (as $\Delta t \to 0$) to solutions of the original model, we are guaranteed that these limiting solutions satisfy the same consistency results. We adopt the latter procedure here since in the next section we shall perform computations with the discrete approximating system.

Throughout, Δt will denote our time step and the quantities $(x_k^n, u_k^n, \alpha_k^n)$ will denote the values of the approximate solutions at $t_n = n\Delta t$. To keep matters simple we shall assume that the numbers $TG/\Delta t$, $TY/\Delta t$, $TR/\Delta t$, and $\epsilon/\Delta t$ are all integers and we shall assume that $\Delta t \leq \min(\epsilon, (\mathcal{V}'(L) = \max_{L \leq s} \mathcal{V}'(s))^{-1})$.

Our first result deals with the traffic flow over the time intervals

$$t_m \overset{def}{=} (m-1)(TG+TY+TR) \leq t_n = n\Delta t \leq t_y \overset{def}{=} t_m + TG \tag{2.4}$$

when all lights are green. Over such intervals we replace (1.5) by

$$x_k^{n+1} = x_k^n + u_k^n \Delta t, \qquad 1 \le k \le N, \tag{2.5}$$

and this yields

$$s_k^{n+1} = s_k^n + (u_{k+1}^n - u_k^n)\Delta t, \qquad 1 \le k \le N-1, \tag{2.6}$$

where

$$s_k^n = (x_{k+1}^n - x_k^n) \ \text{ and } \ s_k^{n+1} = (x_{k+1}^{n+1} - x_k^{n+1}). \tag{2.7}$$

The u's and s's are related by

$$u_k^n = \mathcal{V}(s_k^n) + \alpha_k^n \tag{2.8}$$

and

$$u_k^{n+1} = \mathcal{V}(s_k^{n+1}) + \left(1 - \frac{\Delta t}{\epsilon}\right) \alpha_k^n. \tag{2.9}$$

These updates hold for indices n satisfying

$$(m-1)(TG + TY + TR)/\Delta t \stackrel{def}{=} n_m \le n \le n_m + TG/\Delta t - 1. \tag{2.10}$$

THEOREM 1. *Suppose that*

$$L \le s_k^{n_m} \quad \textit{and} \quad 0 \le u_k^{n_m} \le \mathcal{V}(s_k^{n_m}), \qquad 1 \le k \le N-1, \tag{2.11}$$

and

$$0 \le u_N^{n_m} \le \mathcal{V}_\infty = \lim_{s \to \infty} \mathcal{V}(s). \tag{2.12}$$

Then, the same inequalities hold for

$$n_m \le n \le n_m + TG/\Delta t \stackrel{def}{=} n_y. \tag{2.13}$$

Proof. The identity (2.6) implies that if $s_k^n \ge L$ and $u_{k+1}^n - u_k^n \ge 0$, then $s_k^{n+1} \ge s_k^n \ge L$. In the situation in which $u_{k+1}^n - u_k^n < 0$, (2.6) implies that

$$s_k^{n+1} = s_k^n + (u_{k+1}^n - \alpha_k^n - \mathcal{V}(s_k^n))\Delta t \tag{2.14}$$

and the natural induction hypotheses $\alpha_k^n \le 0$, $0 \le u_k^n \le \mathcal{V}(s_k^n)$, and $s_k^n \ge L$ imply that $u_{k+1}^n - \alpha_k^n \ge 0$. In the situation in which $0 \le u_{k+1}^n - \alpha_k^n < \mathcal{V}_\infty$ we are guaranteed a unique $\bar{s}_{k+1}^n \in [L, \infty)$ satisfying

$$u_{k+1}^n - \alpha_k^n = \mathcal{V}(\bar{s}_{k+1}^n), \tag{2.15}$$

and here (2.14) reduces to

$$s_k^{n+1} = s_k^n + \left(\mathcal{V}(\bar{s}_{k+1}^n) - \mathcal{V}(s_k^n)\right) \Delta t \tag{2.16}$$

or

$$s_k^{n+1} = (1 - \mathcal{V}'(s_*)\Delta t) s_k^n + \mathcal{V}'(s_*)\Delta t \bar{s}_k^n \tag{2.17}$$

for some $s_* \in (\min(s_k^n, \bar{s}_{k+1}^n),\ \max(s_k^n, \bar{s}_{k+1}^n))$. The latter identity, together with

$$\Delta t \mathcal{V}'(L) \le 1 \quad \text{and} \quad \min(s_k^n, \bar{s}_{k+1}^n) \ge L, \tag{2.18}$$

yields $s_k^{n+1} \ge L$. When $u_{k+1}^n - u_k^n < 0$ and $u_{k+1}^n - \alpha_k^n \ge \mathcal{V}_\infty$, the identity (2.14) implies that

$$s_k^{n+1} \ge s_k^n + (\mathcal{V}_\infty - \mathcal{V}(s_k^n))\Delta t. \tag{2.19}$$

The inequality $(2.18)_1$ guarantees that $s \to s + (\mathcal{V}_\infty - \mathcal{V}(s))\Delta t$ is strictly increasing on $[L, \infty)$ and thus (2.19) implies that $s_k^{n+1} \ge L + \mathcal{V}_\infty \Delta t \ge L$ as desired.

The induction hypothesis $\alpha_k^n \le 0$ together with $\Delta t/\epsilon \le 1$ and (2.9) guarantees that $u_k^{n+1} \le \mathcal{V}(s_k^{n+1})$. What remains to be shown is that $u_k^{n+1} \ge 0$. To establish this assertion we combine (2.8) and (2.9) to obtain

$$u_k^{n+1} = \mathcal{V}(s_k^n + (u_{k+1}^n - u_k^n)\Delta t) + \left(1 - \frac{\Delta t}{\epsilon}\right)(u_k^n - \mathcal{V}(s_k^n)).$$

Noting that

$$\mathcal{V}(s_k^n + (u_{k+1}^n - u_k^n)\Delta t) = \mathcal{V}(s_k^n) + \mathcal{V}'(s_\#)(u_{k+1}^n - u_k^n)\Delta t$$

for some $s_\# \ge L$, we find that

$$u_k^{n+1} = \mathcal{V}'(s_\#)\Delta t u_{k+1}^n + \frac{\Delta t}{\epsilon}(\mathcal{V}(s_k^n) - u_k^n) + (1 - \mathcal{V}'(s_\#)\Delta t)u_k^n.$$

The last identity, when combined with

$$\Delta t \mathcal{V}'(s_\#) \le 1, \quad \Delta t/\epsilon \le 1, \quad u_k^n \ge 0, \quad u_{k+1}^n \ge 0, \quad \text{and} \quad \mathcal{V}(s_k^n) - u_k^n \ge 0,$$

yields $u_k^{n+1} \ge \min(u_k^n, u_{k+1}^n) \ge 0$ as desired. □

We now turn our attention to what happens over the yellow and red phases, i.e., when

$$t_y \overset{def}{=} (m-1)(TG + TY + TR) + TG \le t_n = n\Delta t < t_{m+1} \overset{def}{=} m(TG + TY + TR). \tag{2.20}$$

The results of Theorem 1 imply that when $n = n_y \overset{def}{=} (m-1)(TG+TY+TR)+TG/\Delta t$ the following inequalities are valid:

$$L \le s_k^{n_y} \quad \text{and} \quad 0 < u_k^{n_y} \le \mathcal{V}(s_k^{n_y}), \qquad 1 \le k \le N-1, \tag{2.21}$$

and

$$0 \le u_N^{n_y} \le \mathcal{V}_\infty = \lim_{s \to \infty} \mathcal{V}(s). \tag{2.22}$$

Our next goal is to show that (2.21) and (2.22) hold for indices

$$n_y \le n \le n_{m+1} \overset{def}{=} m(TG + TY + TR). \tag{2.23}$$

For definiteness we assume the lights are located at $l_1 < l_2 < \cdots < l_M$ where $M << N$ and that $L << l_{I+1} - l_I$, $1 \le I \le M-1$. For $1 \le I \le M$, k_I will be the largest integer less than or equal to N, so that

$$x_{k_I}^{n_y} < l_I \tag{2.24}$$

and p_I will be the largest integer less than or equal to k_I so that

$$x_{p_I}^{n_y} + \left(\min_{p_I \le j \le k_I} u_j^{n_y} \right) TY < l_I + w + L. \tag{2.25}$$

It can and does happen that for some $I < M$

$$p_I = p_{I+1} = \cdots = p_M = N. \tag{2.26}$$

Our first task is to establish the desired inequalities for indices $(p_{I-1}+1) \le k \le p_I = N$ for $n_y \le n \le n_{m+1}$. This is the situation that is obtained when the lead car, indexed by N, has passed the $(I-1)$st light but not the Ith light.

The rules laid out in (1.17)–(1.23) imply that $x_N(\cdot)$ satisfies

$$\frac{dx_N}{dt} = \min\,(v_N, U_N) \stackrel{def}{=} u_N, \qquad t_y \le t \le t_{m+1}, \tag{2.27}$$

where U_N satisfies

$$\frac{dU_N}{dt} = \frac{(\mathcal{V}_\infty - U_N)}{\epsilon} \;\text{ and }\; U_N(t_y) = u_N(t_y), \tag{2.28}$$

and $v_N(\cdot) \ge 0$ is chosen so that if $x_N(\cdot)$ satisfies

$$\frac{dx_N}{dt} = v_N \;\text{ and }\; x_N(t_y) < l_I, \tag{2.29}$$

then $x_N(t_{m+1}) \le l_I$. We replace this system with its discrete analogue,

$$x_N^{n+1} = x_N^n + u_N^n \Delta t, \qquad n_y \le n \le n_{m+1} - 1, \tag{2.30}$$

$$U_N^{n+1} = \mathcal{V}_\infty + \left(1 - \frac{\Delta t}{\epsilon}\right)(U_N^n - \mathcal{V}_\infty), \qquad n_y \le n \le n_{m+1} - 1, \tag{2.31}$$

and these are solved subject to the initial conditions

$$x_N^{n_y} < l_I \;\text{ and }\; 0 \le u_N^{n_y} \le U_N^{n_y} \le \mathcal{V}_\infty. \tag{2.32}$$

The discrete velocity u_N^n is given by

$$u_N^n = \min\,(v_N^n, U_N^n), \tag{2.33}$$

and $v_N^n \ge 0$ is a discretization of v_N with the property that if

$$x_N^{n+1} = x_N^n + v_N^n \Delta t \;\text{ and }\; x_N^{n_y} < l_I \tag{2.34}$$

for $n_y \le n \le n_{m+1} - 1$, then

$$x_N^{n_{m+1}} \le l_I. \tag{2.35}$$

The identities (2.31), $(2.32)_2$, and (2.33) guarantee that

$$0 \le u_N^n \le \mathcal{V}_\infty, \qquad n_y \le n \le n_{m+1}. \tag{2.36}$$

If we assume that $(p_{I-1}+1) \le N-1$, then the $(N-1)$st car will follow the standard dynamics (1.5)–(1.7) on $t_y \le t \le t_{m+1}$, and thus for $n_y \le n \le n_{m+1}-1$ we have the approximating discrete system:

$$\begin{aligned} x_{N-1}^{n+1} &= x_{N-1}^n + u_{N-1}^n \Delta t, \qquad u_{N-1}^n = \mathcal{V}(s_{N-1}^n) + \alpha_{N-1}^n, \\ \text{and} \quad u_{N-1}^{n+1} &= \mathcal{V}(s_{N-1}^{n+1}) + \left(1 - \tfrac{\Delta t}{\epsilon}\right) \alpha_{N-1}^n, \end{aligned} \tag{2.37}$$

where

$$s_{N-1}^n = x_N^n - x_{N-1}^n \quad \text{and} \quad s_{N-1}^{n+1} = x_N^{n+1} - x_{N-1}^{n+1} = s_{N-1}^n + (u_N^n - u_{N-1}^n)\Delta t. \tag{2.38}$$

The inequalities (2.21) and (2.22) imply that $\alpha_{N-1}^{n_y} \le 0$, $\alpha_N^{n_y} \le 0$, and $s_{N-1}^{n_y} \ge L$. The identities (2.37) and (2.38) imply that

$$s_{N-1}^{n+1} = s_{N-1}^n + \left(u_N^n - \left(1 - \frac{\Delta t}{\epsilon}\right)^n \alpha_{N-1}^{n_y} - \mathcal{V}(s_{N-1}^n) \right) \Delta t, \tag{2.39}$$

and $(2.37)_2$ and (2.39), together with

$$L \le s_{N-1}^{n_y}, \quad \alpha_{N-1}^{n_y} \le 0, \quad u_N^n \ge 0, \quad \Delta t \mathcal{V}'(L) \le 1, \quad \text{and} \quad \Delta t \le \epsilon \tag{2.40}$$

and the arguments used to establish Theorem 1, imply that

$$L \le s_{N-1}^n, \qquad n_y \le n \le n_{m+1}. \tag{2.41}$$

The arguments used to establish Theorem 1 along with (2.40) and (2.41) also yield $0 \le u_{N-1}^n \le \mathcal{V}(s_{N-1}^n)$, $n_y \le n \le n_{m+1}$. An induction on k for indices $(p_{I-1}+1) \le k$ then yields

$$L \le s_k^n = (x_{k+1}^n - x_k^n) \quad \text{and} \quad 0 \le u_k^n \le \mathcal{V}(s_k^n), \qquad n_y \le n \le n_{m+1}. \tag{2.42}$$

This situation when $p_{I-1} = N-1$ is handled similarly, provided that one adopts the proper first order integration scheme for U_{N-1}. The governing equation for U_{N-1} is

$$\frac{dU_{N-1}}{dt} = \mathcal{V}'(x_N - x_{N-1})(u_N - U_{N-1}) + \frac{(\mathcal{V}(x_N - x_{N-1}) - U_{N-1})}{\epsilon}, \tag{2.43}$$

where

$$\frac{d(x_N - x_{N-1})}{dt} = u_N - u_{N-1}, \tag{2.44}$$

and $v_{N-1} \ge 0$ is chosen so that if

$$\frac{dx_N}{dt} = v_{N-1} \quad \text{and} \quad x_{N-1}(t_y) < l_I, \tag{2.45}$$

then

$$x_{N-1}(t_{m+1}) \le l_I. \tag{2.46}$$

Additionally

$$u_{N-1} \stackrel{def}{=} \min(v_{N-1}, U_{N-1}). \tag{2.47}$$

The integration scheme we use is

$$U_{N-1}^{n+1} = \mathcal{V}(s_{N-1}^n + (u_N^n - U_{N-1}^n)\Delta t) + \left(1 - \frac{\Delta t}{\epsilon}\right)(U_{N-1}^n - \mathcal{V}(s_{N-1}^n)),^3 \tag{2.48}$$

where

$$s_{N-1}^n = x_N^n - x_{N-1}^n. \tag{2.49}$$

To complete the proof one does an induction on the index I, first replacing I by $I-1$. One knows that the car with index $(p_{I-1}+1)$ has a velocity $u_{(p_{I-1}+1)}^n$ satisfying

$$0 \le u_{(p_{I-1}+1)}^n \le \mathcal{V}(s_{p_{I-1}+1}^n), \qquad n_y \le n \le n_{m+1}. \tag{2.50}$$

We first focus on the p_{I-1}st car and note that

$$\frac{dx_{p_{I-1}}}{dt} = \min\,(v_{p_{I-1}}, U_{p_{I-1}}) \stackrel{def}{=} u_{p_{I-1}}, \tag{2.51}$$

and

$$\frac{ds_{p_{I-1}}}{dt} = (u_{(p_{I-1}+1)} - u_{p_{I-1}}). \tag{2.52}$$

The rules laid out in (1.7)–(1.23) imply that

$$\frac{dU_{p_{I-1}}}{dt} = \mathcal{V}'(s_{(p_{I-1})})(u_{(p_{I-1}+1)} - U_{p_{I-1}}) + \frac{(\mathcal{V}(s_{(p_{I-1}+1)}) - U_{p_{I-1}})}{\epsilon} \tag{2.53}$$

and that the velocity field $0 \le v_{p_{I-1}}$ is chosen so that if $x_{p_{I-1}}$ evolves as

$$\frac{dx_{p_{I-1}}}{dt} = v_{p_{I-1}} \quad \text{and} \quad x_{p_{I-1}}(t_y) < l_I, \tag{2.54}$$

then

$$x_{p_{I-1}}(t_{m+1}) \le l_{I-1}. \tag{2.55}$$

The discretization we apply to the p_{I-1}st car is

$$x_{p_{I-1}}^{n+1} = x_{p_{I-1}}^n + u_{p_{I-1}}^n \Delta t \quad \text{and} \quad s_{p_{I-1}}^{n+1} = s_{p_{I-1}}^n + \left(u_{(p_{I-1}+1)}^n - u_{p_{I-1}}^n\right)\Delta t \tag{2.56}$$

for $n_y \le n \le n_{m+1} - 1$. Moreover, for some $n_y \le n_0 \le n_y + TY/\Delta t - 1$

$$u_{p_{I-1}}^{n+1} = \mathcal{V}(s_{p_{I-1}}^{n+1}) + \left(1 - \frac{\Delta t}{\epsilon}\right)(u_{p_{I-1}}^n - \mathcal{V}(s_{p_{I-1}}^n)) \tag{2.57}$$

and

$$U_{p_{I-1}}^{n+1} = u_{p_{I-1}}^{n+1}, \tag{2.58}$$

[3]This scheme is essentially a first order Euler scheme applied to (2.43). The scheme implies that

$$U_{N-1}^{n+1} = U_{N-1}^n + \Delta\, t\mathcal{V}'\left(s_{N-1}^n\right)\left(u_N^n - U_{N-1}^n\right) + \frac{\Delta t}{\epsilon}\left(\mathcal{V}\left(s_{N-1}^n\right) - U_{N-1}^n\right) + 0(\Delta t)^2.$$

whereas for $n_0 \le n \le n_{m+1} - 1$

$$u^n_{p_{I-1}} = \min\,(v^n_{p_{I-1}}, U^n_{p_{I-1}}), \tag{2.59}$$

$$U^{n+1}_{p_{I-1}} = \mathcal{V}(s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - U^n_{p_{I-1}})\Delta t) + \left(1 - \frac{\Delta t}{\epsilon}\right)(U^n_{p_{I-1}} - \mathcal{V}(s^n_{p_{I-1}})),^4 \tag{2.60}$$

and

$$U^{n_0}_{p_{I-1}} = u^{n_0}_{p_{I-1}} \quad \text{and} \quad x^{n_0}_{p_{I-1}} < l_I. \tag{2.61}$$

Finally $v^n_{p_{I-1}}$ is chosen so that if

$$x^{n+1}_{p_{I-1}} = x^n_{p_{I-1}} + v^n_{p_{I-1}}\Delta t, \qquad n_0 \le n \le n_{m+1} - 1, \tag{2.62}$$

then

$$x^{n_{m+1}}_{p_{I-1}} \le l_I. \tag{2.63}$$

The arguments employed to establish Theorem 1 guarantee that for $n_y \le n \le n_0$

$$L \le s^n_{p_{I-1}} \quad \text{and} \quad 0 \le u^n_{p_{I-1}} \le \mathcal{V}(s^n_{p_{I-1}}) \tag{2.64}$$

and that for $n = n_0$

$$0 \le u^{n_0}_{p_{I-1}} \le U^{n_0}_{p_{I-1}} \le \mathcal{V}(s^{n_0}_{p_{I-1}}). \tag{2.65}$$

LEMMA 1. *For* $n_0 \le n \le n_{m+1}$

$$L \le s^n_{p_{I-1}} \quad \textit{and} \quad 0 \le u^n_{p_{I-1}} \le U^n_{p_{I-1}} \le \mathcal{V}(s^n_{p_{I-1}}). \tag{2.66}$$

Proof. The identities (2.56) and (2.60) imply that

$$\begin{aligned}
\mathcal{V}(s^{n+1}_{p_{I-1}}) - U^{n+1}_{p_{I-1}} &= \mathcal{V}(s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - u^n_{p_{I-1}})\Delta t) \\
&\quad - \mathcal{V}(s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - U^n_{p_{I-1}})\Delta t) \\
&\quad + \left(1 - \frac{\Delta t}{\epsilon}\right)(\mathcal{V}(s^n_{p_{I-1}}) - U^n_{p_{I-1}}) \\
&= \Delta t \mathcal{V}'(s_\#)\left(U^n_{p_{I-1}} - u^n_{p_{I-1}}\right) + \left(1 - \frac{\Delta t}{\epsilon}\right)(\mathcal{V}(s^n_{p_{I-1}}) - U^n_{p_{I-1}})
\end{aligned} \tag{2.67}$$

for some $s_\# \ge \min\,(s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - u^n_{p_{I-1}})\Delta t, s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - U^n_{p_{I-1}})\Delta t)$. If we now make the induction hypotheses that

$$L \le s^n_{p_{I-1}} \quad \text{and} \quad 0 \le U^n_{p_{I-1}} \le \mathcal{V}(s^n_{p_{I-1}}), \tag{2.68}$$

then (2.59) implies that

$$0 \le u^n_{p_{I-1}} \le U^n_{p_{I-1}} \le \mathcal{V}(s^n_{p_{I-1}}) \tag{2.69}$$

[4] See Footnote 3.

and (2.69) and (2.42) with $k = p_{I-1} + 1$ implies that

$$\begin{aligned} &\min\left(s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - u^n_{p_{I-1}})\Delta t,\ s^n_{p_{I-1}} + (u^n_{(p_{I-1}+1)} - U^n_{p_{I-1}})\Delta t\right) \\ &\geq s^n_{p_{I-1}} - \mathcal{V}(s^n_{p_{I-1}})\Delta t \stackrel{def}{=} \mathcal{F}(s^n_{p_{I-1}}). \end{aligned} \tag{2.70}$$

This constraint $\Delta t\mathcal{V}'(s) \leq 1$, $L \leq s$ guarantees $\mathcal{F}(\cdot)$ in nondecreasing on $L \leq s$, and this fact, together with $\mathcal{F}(L) = L$, guarantees that $s^{n+1}_{p_{I-1}}$ and $s_\#$ are both greater than or equal to L. Moreover, (2.67) also yields $U^{n+1}_{p_{I-1}} \leq \mathcal{V}(s^n_{p_{I-1}})$. The defining relation (2.60) and (2.70) and $u^n_{(p_{I-1}+1)} \geq 0$ also implies that

$$U^{n+1}_{p_{I-1}} = \Delta t\mathcal{V}'(s_*)u^n_{(p_{I-1}+1)} + (1 - \Delta t\mathcal{V}'(s_*))U^n_{p_{I-1}} + \frac{\Delta t}{\epsilon}(\mathcal{V}(s^n_{p_{I-1}}) - U^n_{p_{I-1}}) \tag{2.71}$$

for some $s_* \geq L$ and (2.71) guarantees that $U^{n+1}_{p_{I-1}} \geq 0$. The last inequality and (2.59), with $n+1$, guarantees that

$$0 \leq u^{n+1}_{p_{I-1}} \leq U^{n+1}_{p_{I-1}} \leq \mathcal{V}(s^{n+1}_{p_{I-1}}), \tag{2.72}$$

and this completes the proof of Lemma 1. ∎

Once again an induction on k for indices $(p_{I-2} + 1) \leq k$ yields

$$L \leq s^n_k = (x^n_{k+1} - x^n_k) \ \text{ and } \ 0 \leq u^n_k \leq \mathcal{V}(s^n_k) \tag{2.73}$$

and additionally yields the following theorem.

THEOREM 2. *For $n_y \leq n \leq n_{m+1} = m(TG + TY + TR)$*

$$L \leq s^n_k \ \textit{and} \ \ 0 \leq u^n_k \leq \mathcal{V}(s^n_k), \qquad 1 \leq k \leq N-1, \tag{2.74}$$

and

$$0 \leq u^n_N \leq \mathcal{V}_\infty = \lim_{s\to\infty} \mathcal{V}(s). \tag{2.75}$$

Moreover, for $1 \leq I \leq M$

$$x^{n_{m+1}}_{p_I} \leq l_I. \qquad \square \tag{2.76}$$

Theorems 1 and 2 go a long way towards establishing the consistency of our model. What remains to be shown is that cars with index $p_I + 1$ clear the light, i.e., that they satisfy

$$x^{n_y + \frac{TY}{\Delta t}}_{(p_I+1)} \geq l_I + w + L. \tag{2.77}$$

The reader should recall that the cars with these indices satisfy

$$x^{n_y}_{(p_{I+1})} < l_I \ \text{ and } \ x^{n_y}_{(p_I+1)} + \left(\min_{(p_I+1)\leq j\leq k_I} u^{n_y}_j\right) TY \geq l_I + w + L \tag{2.78}$$

and that cars with indices $(p_I + 1) \leq k \leq k_I$ evolve by the standard discrete dynamics for $n_y \leq n \leq n_y + TY/\Delta t - 1$; i.e.,

$$x^{n+1}_k = x^n_k + u^n_k\Delta t \ \text{ and } \ u^n_k = \mathcal{V}(s^n_k) + \left(1 - \frac{\Delta t}{\epsilon}\right)^{n-n_y}(u^{n_y}_k - \mathcal{V}(s^{n_y})),$$

where

$$0 \le u_k^{n_y} \le \mathcal{V}(s_k^{n_y}) \quad \text{and} \quad L \le s_k^n.$$

It is a straightforward calculation to show that cars with these indices also satisfy

$$u_k^{n+1} = \mathcal{V}(s_k^n + (u_{k+1}^n - u_k^n)\Delta t) + \left(1 - \frac{\Delta t}{\epsilon}\right)(u_k^n - \mathcal{V}(s_k^n))$$
$$= \Delta t \mathcal{V}'(s_\#) u_{k+1}^n + (1 - \Delta t \mathcal{V}'(s_\#)) u_k^n + \frac{\Delta t}{\epsilon}(\mathcal{V}(s_k^n) - u_k^n)$$

from some $s_\# \ge L$, and that this identity, along with

$$\Delta t \mathcal{V}'(L) \le 1, \qquad \Delta t \le \epsilon, \quad \text{and} \quad 0 \le \mathcal{V}(s_k^n) - u_k^n$$

implies

$$u_k^{n+1} \ge \min\,(u_k^n, u_{k+1}^n). \tag{2.79}$$

We now note that at $t = t_y$ (equivalently $n = n_y$) the cars with indices $p_I \le k$ typically satisfy

$$\min_{p_I \le j \le k_I} u_j^{n_y} = u_{k_0}^{n_y}, \quad \text{where} \quad (p_I + 1) \le k_0 \le k_I, \tag{2.80}$$

and

$$u_{k+1}^{n_y} - u_k^{n_y} \ge 0, \qquad k_0 \le k \le k_\#, \tag{2.81}$$

where $k_\#$ is greater than k_I. Moreover, if the spacing of the lights is sufficiently large, then the spatial monotonicity of the velocities is preserved for $n_y \le n \le n_y + TY/\Delta t$ and $k_0 \le k \le k_\#$. When this is the case, the inequalities (2.78)–(2.81) guarantee (2.77).

3. Simulations. In this section we present some simulations of the system outlined in section 1. We chose

$$\mathcal{V}_\infty = 50f/s, \quad L = 20f, \quad L_1 = 25f, \quad \lambda = 5, \quad \epsilon = 5s \text{ and } N = 600.$$

Our maximal velocity was given by

$$\mathcal{V}(s) = \mathcal{V}_\infty \left(1 - \frac{L}{s}\right), \qquad L \le s.$$

We restrict our attention to a roadway with two in-phase lights located at

$$l_1 = 1 \text{ mile } = 5280f \quad \text{and} \quad l_2 = 2 \text{ miles } = 10,560f,$$

and we assume that the width of each intersection is

$$w = 20f.$$

Finally, the durations of the green, yellow, and red lights were chosen to be

$$TG = 25s, \qquad TY = 5s, \quad \text{and} \quad TR = 30s.$$

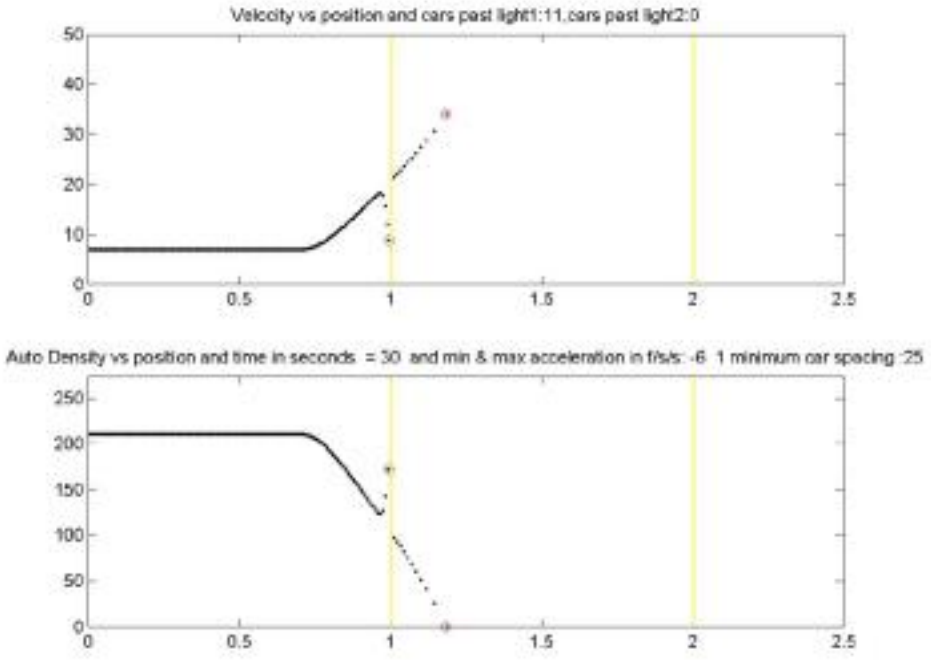

FIG. 1.

Our initial data are taken to be

$$x_k(0) = 25(k - 400) \quad \text{and} \quad u_k(0) = 0,\ 1 \le k \le 600.$$

Snapshots of the solution are shown at times 30, 147, 151, 179, and 191 seconds in Figures 1–5, respectively, and a film may be seen at http://www.math.cmu.edu/users/plin/21380/traffic.html.

In the first frame of each snapshot we plot the auto velocity u_k (in miles/hour) versus current auto position x_k (in miles), and in the second frame we plot the empirical density $\rho_k = \frac{1}{x_{k+1}-x_k}$ (in cars/mile) versus current auto position x_k (in miles).

After an initial startup period we are able to get 18 cars through each light during each green-yellow-red cycle. This number should be contrasted with what one obtains in the singular limit, where $\epsilon = 0^+$, $TY = 0s$, $TG = 30s$, $w = 0f$, and $\lambda = 5$. In this limit

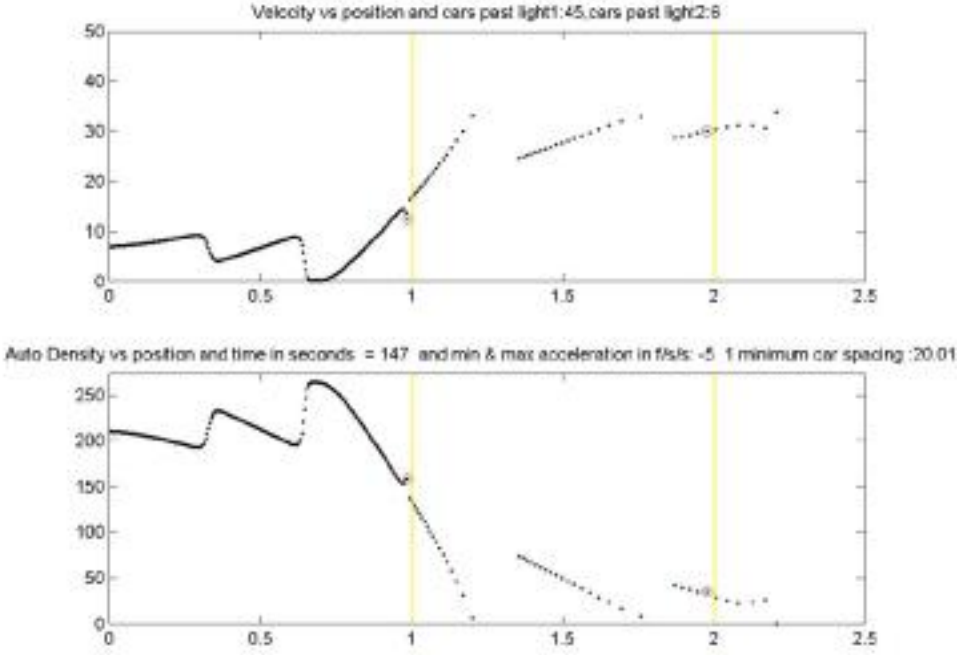
$$u_k \equiv \mathcal{V}_\infty \left(1 - \frac{L}{x_{k+1} - x_k}\right),$$

and if, perchance, we have a car satisfying

$$x_k((t_m + TG)^-) = l_I, \qquad I = 1 \text{ or } 2,$$

and

$$u_k((t_m + TG)^-) > 0,$$



Velocity vs position and cars past light1:45.cars past light2:6

FIG. 5.

then for times $t_m + TG < t \le t_m + TG + TR$,

$$x_k(t) = l \text{ and } u_k(t) \equiv 0.$$

For this singular model we declare a car through the light at l if $x_k(t_y) > l$. The singular model has the potential for infinite accelerations. In steady state the singular model allows us to get 20 cars through an intersection during each green-red cycle.

We note that our choice of which car must stop is made at times $t_y = t_m + TG$ (when a green light turns yellow) and is conservative when the car chosen to stop satisfies $x_{p_l}(t_y) < l - \lambda L$. A more aggressive strategy would have been to allow the p_lth car to follow its standard dynamics until time $t_{p_l} < t_y + TY$, where $x_{p_l}(t_{p_l}) = l - \lambda L$, and then reevaluate whether the p_lth car can get through the light in the remaining time $t_y + TY - t_{p_l}$, i.e., check whether

$$x_{p_l}(t_{p_l}) + \min_{p_l \le k \le k_l(t_{p_l})} u_k(t_{p_l})(t_y + TY - t_{p_l}) \ge l + w + L.$$

If the latter inequality holds, the aggressive strategy would allow the p_lth car through and stop the $(p_l - 1)$st car. We avoided this strategy because it did not seem to be worth the effort to get one more car through the intersection during the green-yellow-red cycle.

The attentive reader will by now realize that once we have determined which car will slow down or stop at a given light the particular braking strategy adopted is immaterial; all that is required is that the velocity associated with the braking strategy, v_{p_l}, be such that if x_{p_l} satisfies

$$\frac{dx_{p_l}}{dt} = v_{p_l} \quad \text{and} \quad x_{p_l}(t_y) < l,$$

then $x_{p_l}(t_{m+1}) \le l$. We adopted constant braking strategies here because they were simple and realistic.

4. Concluding remarks. There are some obvious connections between the discrete model studied in this paper and the continuum or macroscopic models of Aw, Klar, Materne, and Rascle [3].

If one assumes that the maximal velocity $\mathcal{V}(\cdot)$ introduced in (1.1)–(1.3) is actually a function of $\gamma = \frac{s}{L}$ defined on $\gamma = \frac{s}{L} \ge 1$, i.e.,

$$\mathcal{V}(s) = W\left(\frac{s}{L}\right), \tag{4.1}$$

then (1.1) and (1.7) take the form

$$\frac{dx_k}{dt} = u_k \quad \text{and} \quad \frac{du_k}{dt} = W'(\gamma_k)\left(\frac{u_{k+1} - u_k}{L}\right) + \frac{(W(\gamma_k) - u_k)}{\epsilon}, \tag{4.2}$$

where again

$$\gamma_k = \frac{(x_{k+1} - x_k)}{L} \tag{4.3}$$

and

$$\frac{d\gamma_k}{dt} = \frac{u_{k+1} - u_k}{L}. \tag{4.4}$$

The connection between the follow-the-leader system (4.1)–(4.4) is now clear. One introduces reference coordinates

$$X_k = kL, \tag{4.5}$$

lets

$$\mathcal{X}(X_k, t) = x_k(t) \quad \text{and} \quad u(X_k, t) = u_k(t), \tag{4.6}$$

and interprets γ_k and $\frac{u_{k+1}-u_k}{L}$ as the downwind finite difference approximations to $\frac{\partial \mathcal{X}}{\partial X}$ and $\frac{\partial u}{\partial X}$ at the reference point X_k; i.e.,

$$\frac{\partial \mathcal{X}}{\partial X}(X_k, t) = \gamma_k = \frac{x_{k+1} - x_k}{L} \quad \text{and} \quad \frac{\partial U}{\partial X}(X_k, t) = \frac{u_{k+1} - u_k}{L}. \tag{4.7}$$

With these identifications one obtains, at least formally, the Lagrangian traffic equations

$$\frac{\partial \mathcal{X}}{\partial t}(X, t) = u(X, t) \quad \text{and} \quad \frac{\partial \mathcal{X}}{\partial X} = \gamma(X, t), \tag{4.8}$$

where

$$\frac{\partial \gamma}{\partial t} = \frac{\partial u}{\partial X} \quad \text{and} \quad \frac{\partial u}{\partial t} = W'(\gamma)\frac{\partial u}{\partial X} + \frac{(W(\gamma) - u)}{\epsilon}. \tag{4.9}$$

This correspondence is faithful if one restricts one's attention to initial value problems exclusively. We have not seen how to incorporate the traffic light problem into a continuum format.

AN ASYMPTOTIC FINITE DEFORMATION ANALYSIS FOR AN ISOTROPIC COMPRESSIBLE HYPERELASTIC HALF-SPACE SUBJECTED TO A TENSILE POINT LOAD*

DEBRA POLIGNONE WARNE† AND PAUL G. WARNE†

Abstract. The nonlinearly elastic Boussinesq problem is to find the deformation produced in a homogeneous, isotropic, elastic half-space by a point force normal to the undeformed boundary, using the exact equations of elasticity. For this core problem of elasticity and engineering, the 1885 linear elasticity solution of Boussinesq is still used in a variety of applications. In [*SIAM J. Appl. Math.*, 62 (2001), pp. 107–128], we addressed the case of a tensile point load under the constraint of incompressible finite elasticity. Here we consider an analogous asymptotic analysis of this problem within the context of compressible finite elasticity. Asymptotic tests are developed to determine whether an isotropic hyperelastic material can support a finite deflection under a tensile point load. The results are then applied to a variety of particular constitutive models for compressible nonlinearly elastic materials. It is found that, for many of the well-known strain energy models for compressible hyperelastic materials proposed in the literature, a tensile point load cannot be supported. For models which may sustain a tensile point load, we determine the remaining equations and conditions for the asymptotic solution, and numerically compute this solution for a particular case.

1. Introduction.

In this paper, we continue to study the axisymmetric deformation of an isotropic, nonlinearly elastic half-space subjected to a *tensile* point force normal to its undeformed boundary. The present authors have considered this problem in the context of incompressible hyperelasticity [1] and here treat the unconstrained problem. In 1885, Boussinesq solved the analogous problem within the linear theory of elasticity, determining the following nondimensional solution to the linearized equations in the case of a unit point load (see, e.g., [2] for a discussion of the linear Boussinesq problem and solution):

$$r(R,Z) = R - \frac{(1-2\nu)}{4\pi R}\left[\frac{Z}{\sqrt{R^2+Z^2}} - 1 + \frac{1}{(1-2\nu)}\frac{R^2 Z}{\sqrt{(R^2+Z^2)^3}}\right], \tag{1}$$

$$z(R,Z) = Z - \frac{1}{4\pi}\left[\frac{Z^2}{\sqrt{(R^2+Z^2)^3}} + \frac{2(1-\nu)}{\sqrt{R^2+Z^2}}\right]. \tag{2}$$

As discussed in [3], the classical Boussinesq solution is deficient in that it not only predicts an infinite displacement under the point load, thereby violating the basic premise of linear elasticity, but also implies, in the case of compressive loads, that some particles on the line of action of the load pass through one another. To rectify these fundamental physical defects, Simmonds and Warne [3] treat the concentrated

tensile load problem posed within the nonlinear theory of elastostatics and also further study additional interesting aspects of this core problem. In [3], the authors invoke two hypotheses (H1 and H2), which describe the role played by (1), (2) in the context of the fully nonlinear, exact formulation and provide for unique asymptotic solutions near the point load. We shall again adopt these hypotheses as we did in [1], and list them below:

H1: As the dimensionless distance from the point load grows, the solution(s) of the nonlinear Boussinesq problem approaches the solution of the linear Boussinesq problem.

H2: The strain-energy density is bounded everywhere except at the point load; the displacements are bounded everywhere.

In [3], Simmonds and Warne use the principle of stationary potential energy to derive the associated Euler equations from a variational formulation, and then employ known conservation laws of elastostatics [4] and a third hypothesis (H3), successfully used by Knowles and Sternberg [5, 6] for asymptotic analysis of the finite-deformation elastostatic field near a crack tip. In [3] it is shown that the special Blatz–Ko material cannot support a point load and that the generalized neo-Hookean material considered by Knowles [7] with dimensionless stiffening parameter k can support a finite deflection under a point load provided that the material is sufficiently stiffer ($k > \frac{3}{2}$) than the conventional neo-Hookean material ($k = 1$).

In [1], we address the nonlinearly elastic Boussinesq problem using a material formulation of the governing equations in terms of nominal stresses. Upon invoking the hypotheses which proved useful in [3], simple criteria to determine if a hyperelastic material can support a point load are developed in [1] for incompressible isotropic materials, and the results are then applied to a variety of models in the literature. There have been very few works considering the nonlinear Boussinesq problem. The related problem of a tensile concentrated load acting on a cone composed of a particular compressible hyperelastic material proposed by Gao has been treated asymptotically by Gao and Liu [8]. In [3], a case-by-case asymptotic analysis of the governing equations was carried out, and there it was noted that much remains to be done for this problem, including determination of criteria of the type established in [1]. Thus, in this paper, we consider the corresponding problem to that considered in [1] for compressible finite elasticity and establish, in this context, asymptotic tests which allow for a much simpler way to determine whether a compressible hyperelastic material can support a finite deflection under a point load. In subsequent work, we shall similarly address the even more complex problem of an inward (compressive) point load.

In section 2, we briefly review our material formulation of this traction boundary-value problem (developed in [1]) which, in the authors' view, sets up this problem in a rather tractable and explicable form, and then give the governing equations of equilibrium in terms of nominal stress components. Section 3 considers hyperelasticity and restates the basic boundary-value problem for compressible nonlinearly elastic materials upon using a representation for the strain energy which proves more convenient than the standard principal isotropic invariant expression. In section 4, we exploit our material formulation of this problem together with several conservation laws for nonlinear elastostatics, and upon linearizing and invoking H1 as in [1], implications of the linear solution (1), (2) for the conservation integrals are obtained. In section 5, the development and use of simple asymptotic tests for compressible materials is presented, and many of the strain-energy density functions proposed in the literature for compressible hyperelastic material models are tested for the ability to support a finite deflection under tensile point load.

2. Problem formulation. We consider, from the outset, nondimensionalized quantities (see, e.g., [3]), where the position vector $\mathbf{x}$ in the deformed configuration of the body has cylindrical polar coordinates (r, θ, z) and the position vector $\mathbf{X}$ in the reference configuration, the half-space defined by $Z \geq 0$, can be described in terms of cylindrical polar coordinates (R, Θ, Z) or spherical polars (ξ, Φ, Θ). Our interest is thus in axisymmetric deformation fields given by

$$r = r(R, Z) \quad \text{or} \quad r = r(\xi, \Phi), \tag{3}$$

$$\theta = \Theta, \tag{4}$$

$$z = z(R, Z) \quad \text{or} \quad z = z(\xi, \Phi), \tag{5}$$

where the orthonormal bases $(\mathbf{E}_R, \mathbf{E}_\Theta, \mathbf{E}_Z)$ or $(\mathbf{E}_\xi, \mathbf{E}_\Phi, \mathbf{E}_\Theta)$ in the reference configuration are such that

$$\mathbf{E}_R = \cos\Theta\mathbf{E}_X + \sin\Theta\mathbf{E}_Y, \qquad \mathbf{E}_\Theta = -\sin\Theta\mathbf{E}_X + \cos\Theta\mathbf{E}_Y$$

and

$$\mathbf{E}_\xi = \sin\Phi\mathbf{E}_R + \cos\Phi\mathbf{E}_Z, \qquad \mathbf{E}_\Phi = \cos\Phi\mathbf{E}_R - \sin\Phi\mathbf{E}_Z,$$

respectively, and $R = \xi\sin\Phi$, $Z = \xi\cos\Phi$. In the deformed configuration, we thus have orthonormal bases $(\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z)$ with

$$\mathbf{e}_r = \cos\theta\mathbf{e}_x + \sin\theta\mathbf{e}_y, \qquad \mathbf{e}_\theta = -\sin\theta\mathbf{e}_x + \cos\theta\mathbf{e}_y,$$

and $\mathbf{x} = r\mathbf{e}_r + z\mathbf{e}_z$. In the above, $(\mathbf{E}_X, \mathbf{E}_Y, \mathbf{E}_Z)$ and $(\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z)$ are orthonormal Cartesian bases for the reference and deformed configurations, respectively.

The corresponding deformation gradient tensor $\mathbf{F}$ referred to the appropriate right-handed coordinate system is then given by either

$$\mathbf{F} = \begin{bmatrix} r_{,R} & 0 & r_{,Z} \\ 0 & \dfrac{r}{R} & 0 \\ z_{,R} & 0 & z_{,Z} \end{bmatrix} \quad \text{or} \quad \mathbf{F} = \begin{bmatrix} r_{,\xi} & z_{,\xi} & 0 \\ 0 & 0 & \dfrac{r}{\xi\sin\Phi} \\ \dfrac{1}{\xi}r_{,\Phi} & \dfrac{1}{\xi}z_{,\Phi} & 0 \end{bmatrix}, \tag{6}$$

where here and elsewhere a comma denotes differentiation.

The point load is applied via a dimensionless tensile concentrated load normal to the surface $Z = 0$, and thus the dimensionless applied surface traction vector in a cylindrical basis is given by

$$\mathbf{s}(R) = \frac{-\delta(R)}{2\pi R}\mathbf{e}_z \quad \text{on } Z = 0. \tag{7}$$

This implies a boundary condition for the *nominal stress tensor* $\mathbf{S}$ $(= (\det\mathbf{F})\mathbf{F}^{-1}\mathbf{T}$; see, e.g., Ogden [9]) of the form

$$\begin{aligned} \mathbf{s} = \mathbf{S}^T\mathbf{N} &= \mathbf{S}^T(-\mathbf{E}_Z) \\ &= -S_{Zr}\mathbf{e}_r - S_{Zz}\mathbf{e}_z, \end{aligned}$$

as the component forms of $\mathbf{S}$ are similar to those of $\mathbf{F}$ in that they contain the same null components. Thus, the boundary conditions at $Z = 0$ in terms of components of the nominal stress tensor referred to a cylindrical polar basis are

$$S_{Zr} = 0 \quad \text{and} \quad S_{Zz} = \frac{\delta(R)}{2\pi R} \quad \text{on } Z = 0. \tag{8}$$

As determined in [1], the equations of equilibrium $\operatorname{Div}\mathbf{S} \equiv \nabla \cdot \mathbf{S} = \mathbf{0}$ governing deformation fields of the type $(3)_2$, (4), $(5)_2$, where $\mathbf{S}$, represented in a mixed basis, takes the form

$$\mathbf{S} = S_{\xi r}\mathbf{E}_\xi \otimes \mathbf{e}_r + S_{\xi z}\mathbf{E}_\xi \otimes \mathbf{e}_z + S_{\Phi r}\mathbf{E}_\Phi \otimes \mathbf{e}_r + S_{\Phi z}\mathbf{E}_\Phi \otimes \mathbf{e}_z + S_{\Theta\theta}\mathbf{E}_\Theta \otimes \mathbf{e}_\theta$$

and ∇ is the usual spherical gradient operator, reduce to the two equations

$$\sin\Phi(\xi^2 S_{\xi r})_{,\xi} + \xi(\sin\Phi S_{\Phi r})_{,\Phi} - \xi S_{\Theta\theta} = 0 \tag{9}$$

and

$$\sin\Phi(\xi^2 S_{\xi z})_{,\xi} + \xi(\sin\Phi S_{\Phi z})_{,\Phi} = 0. \tag{10}$$

Equation (10) can be written in divergence form and implies the existence of a function $v(\xi, \Phi)$ such that

$$v_{,\Phi} = \xi^2 \sin\Phi S_{\xi z} \quad \text{and} \quad -v_{,\xi} = \xi \sin\Phi S_{\Phi z}, \tag{11}$$

while regularity requirements at the origin $\xi = 0$ and along the axis of symmetry $\Phi = 0$ give

$$v(0^+, \Phi) = 0 \quad \text{and} \quad v(\xi, 0^+) = 0. \tag{12}$$

Also, converting the boundary condition $(8)_1$, we obtain

$$\cos\Phi S_{\xi r} - \sin\Phi S_{\Phi r} = 0 \quad \text{at } \Phi = \frac{\pi}{2}, \tag{13}$$

$$\Rightarrow \quad S_{\Phi r} = 0 \quad \text{at } \Phi = \frac{\pi}{2}, \quad \xi > 0. \tag{14}$$

The implications of the boundary condition $(8)_2$ will be considered in section 4.

3. Hyperelasticity, equilibrium equations, and boundary conditions. We now consider the implications of hyperelasticity and thus assume the existence of a (dimensionless) stored-energy density function $W(\mathbf{F})$ such that

$$\mathbf{S} = \frac{\partial W}{\partial \mathbf{F}} \quad \text{and} \quad S_{ij} = \frac{\partial W}{\partial F_{ji}}. \tag{15}$$

Then the equilibrium equations (9) and (11) become

$$\sin\Phi(\xi^2 W_{,(r,\xi)})_{,\xi} + \xi^2(\sin\Phi W_{,(r,\Phi)})_{,\Phi} - \xi^2 \sin\Phi W_{,r} = 0 \tag{16}$$

and

$$v_{,\Phi} = \xi^2 \sin\Phi W_{,(z,\xi)} \quad \text{and} \quad -v_{,\xi} = \xi^2 \sin\Phi W_{,(z,\Phi)}, \tag{17}$$

recovering the Euler equations derived in [3] (see [3, (18) and (24)]).

For isotropic hyperelastic materials, the stored-energy function is such that

$$W = W(I_1, I_2, I_3),$$

where I_1, I_2, I_3 are the standard principal isotropic invariants of the left and right Cauchy–Green deformation tensors $\mathbf{F}\mathbf{F}^T$ and $\mathbf{F}^T\mathbf{F}$, respectively. We note that the usual normalization conditions,

$$W(3,3,1) = 0 \quad \text{and} \quad \left(\frac{\partial W}{\partial I_1} + \frac{2\partial W}{\partial I_2} + \frac{\partial W}{\partial I_3}\right)\bigg|_{I_1=I_2=3, I_3=1} = 0,$$

require that both the strain energy and the stress, respectively, vanish in the reference configuration. Upon computing the invariants I_1, I_2, I_3 with $\mathbf{F}$ given by $(6)_2$, it is convenient, as in [1] and [3], to use the representation

$$I_1 = A + C, \tag{18}$$

$$I_2 = AC + B^2, \tag{19}$$

$$I_3 = B^2 C, \tag{20}$$

where

$$A = r_{,\xi}^2 + z_{,\xi}^2 + \xi^{-2}(r_{,\Phi}^2 + z_{,\Phi}^2), \tag{21}$$

$$B = \xi^{-1}(r_{,\Phi}\, z_{,\xi} - r_{,\xi}\, z_{,\Phi}), \tag{22}$$

$$C = (\xi \sin\Phi)^{-2} r^2. \tag{23}$$

We consider a general nondimensionalized representation of the strain-energy density function for compressible isotropic hyperelastic materials given by

$$W = W(A, B, C), \tag{24}$$

where here and elsewhere we shall neglect to introduce a new symbol for W on the right-hand side for ease of notation. Then the equilibrium equations (16) and (17) and the boundary condition (14) become

$$\sin\Phi(2\xi^2 r_{,\xi}\, W_A - \xi z_{,\Phi}\, W_B)_{,\xi} + [(2r_{,\Phi}\, W_A + \xi z_{,\xi}\, W_B)\sin\Phi]_{,\Phi} - 2r\csc\Phi W_C = 0, \tag{25}$$

$$v_{,\Phi} = \sin\Phi(2\xi^2 z_{,\xi}\, W_A + \xi r_{,\Phi}\, W_B), \qquad -v_{,\xi} = \sin\Phi(2z_{,\Phi}\, W_A - \xi r_{,\xi}\, W_B), \tag{26}$$

and

$$2r_{,\Phi}\, W_A + \xi z_{,\xi}\, W_B = 0 \quad \text{at } \Phi = \tfrac{\pi}{2}, \quad \xi > 0, \tag{27}$$

respectively, where here and subsequently $W_A \equiv \frac{\partial W}{\partial A}$, and similarly for W_B, W_C.

4. Conservation laws and implications of the linearly elastic Boussinesq problem. We next consider three integral identities which have proven useful in the asymptotic analyses carried out in [1] and [3] for this problem. The first, a direct application of the divergence theorem

$$\int_{\partial\Omega} \mathbf{S}^T \mathbf{N}\, dA = \int_{\Omega} \operatorname{Div} \mathbf{S} dV$$

and equilibrium ($\operatorname{Div}\mathbf{S} = \mathbf{0}$), states that

$$\int_{\partial\Omega} \mathbf{S}^T \mathbf{N} dA = \mathbf{0}, \tag{28}$$

where here and subsequently we take Ω to be the hemisphere of radius $\xi = a$ which is centered at the source, and thus the unit outward normal to the top surface of the hemisphere is $\mathbf{N} = -\mathbf{E}_Z$, while the unit outward normal to the lateral surface is $\mathbf{N} = \mathbf{E}_\xi = \sin\Phi\mathbf{E}_R + \cos\Phi\mathbf{E}_Z$. Thus, as in [1], the above along with $(8)_2$ yields

$$1 = 2\pi a^2 \int_0^{\frac{\pi}{2}} S_{\xi z} \sin\Phi d\Phi, \tag{29}$$

which expresses, in dimensionless form, overall force equilibrium. As before, $(11)_1$, $(12)_2$, and (29) further imply that

$$v\left(\xi, \frac{\pi}{2}\right) = \frac{1}{2\pi} \quad \text{at } \xi = a. \tag{30}$$

The second conservation law, related to Eshelby's energy-momentum tensor, is derived from an application of the divergence theorem to the tensor $W\mathbf{I} - \mathbf{SF}$. As the divergence of this tensor also vanishes (see Chadwick [4]), we obtain

$$\int_{\partial\Omega} (W\mathbf{I} - \mathbf{SF})\mathbf{N}\, dA = \mathbf{0}, \tag{31}$$

which, as shown in [1], results in

$$\begin{aligned} &\int_0^a WR dR - \frac{1}{2\pi} z_{,Z}\,(R = 0, Z = 0) \\ &\quad = \int_0^{\frac{\pi}{2}} \left[\cos\Phi W + S_{\xi r}\left(\frac{\sin\Phi}{a} r_{,\Phi} - \cos\Phi r_{,\xi}\right)\right. \\ &\qquad \left. + S_{\xi z}\left(\frac{\sin\Phi}{a} z_{,\Phi} - \cos\Phi z_{,\xi}\right)\right] a^2 \sin\Phi d\Phi. \end{aligned} \tag{32}$$

The third relation we shall use is the integral identity

$$3\int_\Omega W dV = \int_{\partial\Omega} [W\mathbf{X}\cdot\mathbf{N} + (\mathbf{S}^T\mathbf{N})\cdot(\mathbf{x} - \mathbf{FX})] dA, \tag{33}$$

which is contained among conservation laws of elastostatics derived by Chadwick [4] from the energy-momentum tensor used above. Specializing to the problem under consideration here, we recall from [1] that this determines the relation

$$\begin{aligned} &3\int_0^a \int_0^{\frac{\pi}{2}} W\xi^2 \sin\Phi d\xi d\Phi + \frac{1}{2\pi} z(R = 0, Z = 0) \\ &\quad = a^2 \int_0^{\frac{\pi}{2}} [aW + S_{\xi r}(r - a r_{,\xi}) + S_{\xi z}(z - a z_{,\xi})] \sin\Phi d\Phi. \end{aligned} \tag{34}$$

To conclude this section, we restate the implications of the linearly elastic Boussinesq problem solution (1), (2) for this problem. The solution (1), (2) can be represented as

$$\begin{aligned} r(\xi, \Phi) &= \xi \sin\Phi + \frac{1}{4\pi\xi}[(1 - 2\nu)\csc\Phi(1 - \cos\Phi) - \sin\Phi\cos\Phi], \\ z(\xi, \Phi) &= \xi\cos\Phi + \frac{1}{4\pi\xi}[2(\nu - 1) - \cos^2\Phi]. \end{aligned}$$

Invoking H1 and letting $a \longrightarrow \infty$, we have the following asymptotic results for the terms contained in the above conservation laws:

$$W \longrightarrow O(a^{-4}), \tag{35}$$

$$\mathbf{S} \longrightarrow O(a^{-2}), \tag{36}$$

$$(r - \xi r_{,\xi})|_{\xi = a} \longrightarrow O(a^{-1}), \tag{37}$$

$$(z - \xi z_{,\xi})|_{\xi=a} \longrightarrow O(a^{-1}), \tag{38}$$

$$\left(\frac{\sin\Phi}{\xi} r_{,\Phi} - \cos\Phi r_{,\xi}\right)|_{\xi=a} \longrightarrow O(a^{-2}), \tag{39}$$

$$\left(\frac{\sin\Phi}{\xi} z_{,\Phi} - \cos\Phi z_{,\xi}\right)|_{\xi=a} \longrightarrow -1 + O(a^{-2}). \tag{40}$$

On converting the conservation law results (32) and (34) to spherical representations in the reference configuration, letting $a \longrightarrow \infty$, and employing the above, we obtain

$$0 < 2\pi \int_0^\infty W|_{\Phi=\frac{\pi}{2}} \xi d\xi + 1 = z_{,\xi}\,(0^+, 0) \tag{41}$$

and

$$6\pi \int_0^\infty \int_0^{\frac{\pi}{2}} W\xi^2 \sin\Phi d\xi d\Phi = -z(0^+, 0), \tag{42}$$

respectively. The results (41) and (42), which relate the deflection of the half-space and its partial derivative at the point of application of the load to the stored-energy function, will be useful (as in [1, 3]) in the asymptotic analysis to follow.

5. Asymptotics. We now adopt a third hypothesis (H3) successfully used previously for asymptotic analyses of problems involving singularities in finite elasticity (see [1, 3, 5, 6]):

H3: The unknowns r, z, and v have the following asymptotic forms as $\xi \longrightarrow 0$:

$$r(\xi, \Phi) = \xi^\alpha F(\Phi) + o(\xi^\alpha) \quad \text{with } F(0) = 0, \quad F(\Phi) > 0 \quad \text{for } 0 < \Phi \leq \tfrac{\pi}{2}, \tag{43}$$

$$z(\xi, \Phi) = z(0^+, 0) + \xi^\beta G(\Phi) + o(\xi^\beta), \quad G(0) \neq 0, \tag{44}$$

$$v(\xi, \Phi) = \xi^\delta I(\Phi) + o(\xi^\delta), \quad I(\Phi) \not\equiv 0. \tag{45}$$

Partial derivatives also have analogous asymptotic forms.

As discussed in [3], the above restrictions on F ensure that particles on the z-axis remain there and that particles do not pass through the z-axis, while the restriction on $G(0)$ follows from (41). Additionally, the exponents in (43)–(45) must be such that

$$\alpha > 0, \tag{46}$$

$$\beta > 0, \tag{47}$$

$$\beta \leq 1, \tag{48}$$

$$\delta = 0. \tag{49}$$

These restrictions result from requiring no cavity to form beneath the point load, a finite deflection under the point load, (41), and (30), respectively.

Following the development of [1, 3], we define for brevity

$$\sigma(x) = \begin{cases} 1, & x \geq 0, \\ 0, & x < 0, \end{cases} \tag{50}$$

$$\omega = \min\{\alpha, \beta\}, \tag{51}$$

and thus from (21)–(23) and the above, we have that, as $\xi \longrightarrow 0+$,

$$A \longrightarrow \xi^{2(\omega-1)} \bar{A}(F, F', G, G'), \tag{52}$$

$$B \longrightarrow \xi^{\alpha+\beta-2}\bar{B}(F, F', G, G'), \tag{53}$$

$$C \longrightarrow \xi^{2(\alpha-1)}F^2 \csc^2\Phi, \tag{54}$$

where $\bar{A}$ and $\bar{B}$ are defined for convenience as

$$\bar{A} \equiv \sigma(\beta-\alpha)[\alpha^2F^2 + F'^2] + \sigma(\alpha-\beta)[\beta^2G^2 + G'^2], \tag{55}$$

$$\bar{B} \equiv \beta F'G - \alpha FG' \not\equiv 0 \tag{56}$$

and the final restriction on $\bar{B}$ is necessary to preclude the unacceptable conclusion that $F \equiv 0$. Similarly to [1], we consider the asymptotic forms for the partial derivatives of a strain energy function $W(A, B, C)$, given generally as

$$W_A \longrightarrow \xi^{n(\alpha,\beta)}N(F, F', G, G', \sin\Phi), \tag{57}$$

$$W_B \longrightarrow \xi^{m(\alpha,\beta)}M(F, F', G, G', \sin\Phi), \tag{58}$$

$$W_C \longrightarrow \xi^{p(\alpha,\beta)}P(F, F', G, G', \sin\Phi), \tag{59}$$

where m, n, and p are functions of α and β and M, N, and P are functions of the arguments shown.

5.1. Asymptotic tests: Derivation. We consider now general compressible hyperelastic materials and derive in what follows some simple asymptotic tests on the form of its stored energy to determine whether such a material can support a tensile point load. In section 5.2, we apply our tests to a variety of well-known material models. We remind the reader that the equilibrium equations and boundary condition for this problem are given by (25)–(27), respectively. We now consider the asymptotic implications of these equations.

On substituting (43)–(45) and (57)–(59) into (25), differentiating, and collecting like powers of ξ, we obtain the following asymptotic form of the equilibrium equation (25):

$$\begin{aligned} &2\xi^{n+\alpha}[\alpha(n+\alpha+1)\sin\Phi FN + (\sin\Phi F'N)'] - 2\xi^{p+\alpha}\csc\Phi FP \\ &\quad + \xi^{m+\beta}[(\beta\sin\Phi GM)' - (m+\beta+1)\sin\Phi G'M] = 0. \end{aligned} \tag{60}$$

Next, substituting from (43)–(45), the asymptotic forms of (26) are

$$I' = (2\beta\xi^{n+\beta+1}GN + \xi^{m+\alpha+1}F'M)\sin\Phi \tag{61}$$

and

$$0 = 2\xi^{n+\beta}G'N - \alpha\xi^{m+\alpha}FM, \tag{62}$$

respectively. Finally, the boundary condition (27) becomes

$$2\xi^{n+\alpha}F'N + \beta\xi^{m+\beta}GM = 0 \quad \text{at } \Phi = \tfrac{\pi}{2}, \quad \xi > 0. \tag{63}$$

In addition, the Jacobian

$$J = \det\mathbf{F} = I_3^{\frac{1}{2}}$$

for the deformation of concern here is given by the above, (20), (22), and (23) as

$$J = \frac{r}{\xi^2\sin\Phi}(r_{,\Phi}\, z_{,\xi} - r_{,\xi}\, z_{,\Phi}\,). \tag{64}$$

On substituting from (43) and (44), we have that asymptotically

$$J \longrightarrow \xi^{2\alpha+\beta-3} F(\beta F' G - \alpha F G') \csc\Phi \quad \text{as } \xi \longrightarrow 0. \tag{65}$$

Thus, to maintain the fundamental physical and mathematical restrictions that $\det \mathbf{F}$ is positive and bounded, we must have

$$2\alpha + \beta - 3 = 0 \Rightarrow \alpha = \frac{3-\beta}{2} \tag{66}$$

and, noting $(43)_{2,3}$ and (56),

$$\bar{B} \equiv \beta F' G - \alpha F G' > 0, \qquad F\bar{B} \csc\Phi \text{ bounded}. \tag{67}$$

Recall from (47), (48) that $0 < \beta \leq 1$, and thus (66) requires $1 \leq \alpha < \frac{3}{2}$, and so $\beta \leq \alpha$ and $\beta = 1 \Leftrightarrow \alpha = 1$. Thus from (51)–(54), A, B, and C are independent of ξ when $\alpha = \beta = 1$, and hence the invariants (18)–(20) would not depend asymptotically on ξ, which is clearly unphysical. Thus we restrict attention to values of β such that

$$0 < \beta < 1, \tag{68}$$

which together with (66) gives $1 < \alpha < \frac{3}{2}$, and so by (51), $\omega = \beta$. Thus the asymptotic forms (52)–(54) of A, B, and C reduce to

$$A \longrightarrow \xi^{2(\beta-1)} \bar{A}(F, F', G, G'), \tag{69}$$

$$B \longrightarrow \xi^{\frac{\beta-1}{2}} \bar{B}(F, F', G, G'), \tag{70}$$

$$C \longrightarrow \xi^{(1-\beta)} \bar{C}, \tag{71}$$

where, using $\omega = \beta$, (50), (55), (56), and (67),

$$\bar{A} \equiv \beta^2 G^2 + G'^2, \tag{72}$$

$$\bar{B} \equiv \beta F' G - \alpha F G' > 0, \tag{73}$$

$$\bar{C} \equiv F^2 \csc^2\Phi, \tag{74}$$

and α is given in terms of β by (66). The asymptotic forms for the partial derivatives of a strain energy function $W(A, B, C)$ can then be given generally as

$$W_A \longrightarrow \xi^{n(\beta)} N(F, F', G, G', \sin\Phi), \tag{75}$$

$$W_B \longrightarrow \xi^{m(\beta)} M(F, F', G, G', \sin\Phi), \tag{76}$$

$$W_C \longrightarrow \xi^{p(\beta)} P(F, F', G, G', \sin\Phi). \tag{77}$$

Consider (62) first. As $\xi \longrightarrow 0+$, if $m + \alpha < n + \beta$, then the coefficient of $\xi^{m+\alpha}$ dominates, implying

$$0 = F(\Phi) M.$$

However, recalling $(43)_3$ and (75), $F(\Phi)$ is not identically zero, nor should W_B be identically zero for a reasonable strain energy. Thus

$$m + \alpha \geq n + \beta. \tag{78}$$

In view of (78) then, the $\xi^{n+\beta+1}$ term(s) dominate the right-hand side of (61). Thus we must determine now whether the exponent $n+\beta+1$ can be >0, <0, or $=0$. If $n+\beta+1>0$, then the term on the left in (61) dominates as $\xi \longrightarrow 0+$, resulting asymptotically in $I'=0$ so that

$$I = I_0, \tag{79}$$

where I_0 is an unknown constant. However, $(12)_2$ and (30) asymptotically imply via (45) and (49) that

$$I(0^+) = 0 \quad \text{and} \quad I\left(\frac{\pi}{2}\right) = \frac{1}{2\pi}, \tag{80}$$

and thus (79) is not possible. If $n+\beta+1<0$, then terms on the right of (61) dominate as $\xi \longrightarrow 0+$, and hence I has no influence asymptotically on the solution of the problem since (61) is the only governing equation containing I. However, by $(8)_2$, the point load is applied through S_{Zz}, and

$$S_{Zz} = \cos\Phi S_{\xi z} - \sin\Phi S_{\Phi z} = \xi^{-2}\cot\Phi v_{,\Phi} + \xi^{-1} v_{,\xi} \tag{81}$$

upon using (11). Therefore, by (45) and (49), the point load manifests itself through I, making the above alternative for the case $n+\beta+1<0$ unacceptable. Thus, in a manner analogous to [1], we arrive at the important result that

$$n+\beta+1=0. \tag{82}$$

Recalling that $n=n(\beta)$ was introduced in (74), the function $n(\beta)$ is known for a given strain energy function W, and thus (82) is an equation to determine β. This brings us to our first result, which is analogous to the situation for incompressible hyperelastic solids treated in [1]: *For a given strain energy function W, if β calculated through* (82) (*where n is determined from* (74)) *does not fall in the range* $0<\beta<1$ *given by* (68), *then the material modeled by W cannot sustain a point load.*

We now continue our analysis under the assumption that β satisfying (82) is consistent with (68); i.e., $n(\beta)+\beta+1=0$ and $0<\beta<1$. Recall that by (78) determined above, $m+\alpha \geq n+\beta$. We consider first the possibility that

$$m+\alpha = n+\beta \tag{83}$$

so that the two terms on the right-hand sides of (61) and (62) balance. We will show below that (83) can occur *only* for special material models. The final case of when strict inequality holds in (78) will be treated last in the section.

We proceed under the requirement of (82) and suppose that (83) holds as well. Then (61) and (62) reduce asymptotically to

$$I' = (2\beta GN + F'M)\sin\Phi \tag{84}$$

and

$$0 = 2G'N - \alpha FM, \tag{85}$$

respectively, where by (66), $\alpha = \frac{3-\beta}{2}$. Similarly, the powers of ξ appearing in (60) are given by

$$n+\alpha = \frac{1}{2} - \frac{3}{2}\beta, \quad m+\beta = \frac{3}{2}\beta - \frac{5}{2}, \quad \text{and} \quad p+\alpha = p + \frac{3}{2} - \frac{1}{2}\beta, \tag{86}$$

and so (60) takes the form

$$
\begin{aligned}
(87)\qquad & 2\xi^{\frac{1}{2}-\frac{3}{2}\beta}\left[\frac{3}{4}(3-\beta)(1-\beta)\sin\Phi FN+(\sin\Phi F'N)'\right]-2\xi^{p+\frac{3}{2}-\frac{1}{2}\beta}\csc\Phi FP\\
&+\xi^{\frac{3}{2}\beta-\frac{5}{2}}\left[(\beta\sin\Phi GM)'-\frac{3}{2}(\beta-1)\sin\Phi G'M\right]=0.
\end{aligned}
$$

In view of (68), the $\xi^{\frac{3}{2}\beta-\frac{5}{2}}$ term dominates the $\xi^{\frac{1}{2}-\frac{3}{2}\beta}$ term in (87). Now if the $\xi^{p+\frac{3}{2}-\frac{1}{2}\beta}$ term dominates the $\xi^{\frac{3}{2}\beta-\frac{5}{2}}$ term, then

$$\csc\Phi FP=0. \tag{88}$$

However, as before, $F(\Phi)$ is not identically zero, nor should W_C be identically zero for a reasonable strain energy. On the other hand, if the $\xi^{\frac{3}{2}\beta-\frac{5}{2}}$ term dominates the $\xi^{p+\frac{3}{2}-\frac{1}{2}\beta}$ term in (87), the final term in brackets must be zero, which results in the equation

$$\alpha(\sin\Phi M)G'+\beta G(\sin\Phi M)'=0. \tag{89}$$

Solving (89) yields

$$G=\kappa(\sin\Phi M)^{-\frac{\beta}{\alpha}}=\kappa(\sin\Phi M)^{-\frac{2\beta}{3-\beta}}, \tag{90}$$

where κ is a constant of integration. However, the boundary condition (63) will contradict this possibility. Using (68) and $(86)_{1,2}$, we have $m+\beta<n+\alpha$, and thus the second term on the left in (63) dominates, implying that either

$$G\left(\frac{\pi}{2}\right)=0\quad\text{or}\quad M|_{\Phi=\frac{\pi}{2}}=0. \tag{91}$$

The latter of (91) would imply from (90) that $G(\frac{\pi}{2})\to\pm\infty$, which violates our second hypothesis H2 and thus is unacceptable. The former of (91) is equally unrealistic, as this would imply from (44) that $z(\xi,\frac{\pi}{2})=z(0^+,0)$, and thus in some neighborhood of the origin, the deflection of the top surface of the half-space would be exactly the same as the deflection at the point of application of the point load. Thus, for (83) to hold, the $\xi^{p+\frac{3}{2}-\frac{1}{2}\beta}$ and $\xi^{\frac{3}{2}\beta-\frac{5}{2}}$ terms in (87) must balance, requiring

$$p=2\beta-4. \tag{92}$$

In this case, (87) becomes

$$-2\csc\Phi FP+\alpha(\sin\Phi M)G'+\beta G(\sin\Phi M)'=0. \tag{93}$$

In view of (92), however, $p(\beta)$, introduced in (76), is a *specific* function of β for a given strain energy, and (82), which determines β, has already been derived. Thus if p does not satisfy (92), then (83) is not possible. From (92) and (82), (83) is thus *possible only* in the special case where p and n are related by

$$p=-2(n+3). \tag{94}$$

Thus, in the special case of the material model where (94) occurs and thus p does satisfy (92), the above asymptotic analysis gives a system of coupled first-order ordinary differential equations for F, G, and I introduced in (43)–(45) with hypothesis H3.

This system consists of (93), (84), and (85), which followed from asymptotic analysis of the governing equations (25) and (26), where (66)–(68), (82), and (83) also hold. This system is subject to the boundary conditions in (43), (44), (80), and $(91)_2$. Accordingly, here and subsequently, we have that near the point load, the deformed radius $r(\xi,\Phi)$, deflection $z(\xi,\Phi)$, and $v(\xi,\Phi)$ are such that

$$r \longrightarrow O(\xi^{\frac{3}{2}-\frac{1}{2}\beta}), \qquad z \longrightarrow z(0^+,0)+O(\xi^{\beta}), \qquad v \longrightarrow O(\xi^0) \quad \text{as } \xi \longrightarrow 0^+. \tag{95}$$

This concludes our study of the case (83) since if (92) does not hold, then this, together with our previous analysis, precludes the possibility of (83). Thus it remains to consider the case of (78) when strict inequality holds, assuming that (92) is violated.

Given the above discussion, we now assume (92) does not hold, and hence, neither does (83). Thus, from (78),

$$m+\alpha > n+\beta. \tag{96}$$

Before proceeding, we remind the reader that the exact governing equations (25) and (26) and boundary condition (27) have resulted in (60)–(63). Consider first (62), for which the inequality (96) implies that the first term on the right dominates, resulting in

$$2G'N = 0. \tag{97}$$

We note that $N \not\equiv 0$, as this would imply from (61) (see (99) below) that I is constant, which violates (80). Thus (97) results in

$$G(\Phi) = G_0 \neq 0, \tag{98}$$

where G_0 is an unknown constant with the latter restriction following from (44).

We next consider (61). The inequality (96) further indicates that the first term on the right in (61) also dominates. Since β must be chosen so that (82) holds, (61) gives

$$I' = 2\beta GN\sin\Phi, \tag{99}$$

which along with (98) implies that

$$I = 2\beta G_0\int \bar{N}\sin\Phi d\Phi + I_0, \tag{100}$$

where I_0 is an unknown constant and the expression $\bar{N}$ indicates that the arguments of N are to be evaluated at G, given by (98), and F, which is yet to be determined. Assuming that the integrand in (100) can be integrated, we express I in the form

$$I = 2\beta G_0\Psi(\Phi) + I_0. \tag{101}$$

Imposing the boundary condition $(80)_1$, we have

$$I_0 = -2\beta G_0\Psi(0^+), \tag{102}$$

while $(80)_2$ determines

$$G_0 = \frac{1}{4\pi\beta\left(\Psi\left(\frac{\pi}{2}\right)-\Psi(0^+)\right)}. \tag{103}$$

We remark that by virtue of (44), $G_0 > 0$. Thus I is given in terms of $\Psi(\Phi) = \int \bar{N}(\Phi) \sin\Phi d\Phi$ as

$$I = \frac{(\Psi(\Phi) - \Psi(0^+))}{2\pi\left(\Psi\left(\frac{\pi}{2}\right) - \Psi(0^+)\right)}. \tag{104}$$

Thus G and I of hypothesis H3 are completely determined in terms of Ψ.

What now remains is to determine $F(\Phi)$ and to consider (60) and the boundary condition (63). We first note that the second term of (60) cannot dominate the other two, as this would imply that $P = 0$ and thus W would not depend on C, which is unacceptable. Similarly, the third term of (60) cannot dominate the other two, as this would imply that $M = \frac{K}{\sin\Phi}$, $K \neq 0$ constant, while (63) would in turn require $M|_{\Phi=\frac{\pi}{2}} = 0$, which is contradictory. Thus five remaining possibilities exist for (60), corresponding to all three terms balancing, pairs of terms balancing, and the first term dominating. However, our representation of the strain-energy density function in terms of A, B, C or I_1, I_2, I_3 is also advantageous to rule out two of these five possibilities. In view of (18)–(20), we have

$$\begin{aligned} W_A &= W_1 + CW_2, \\ W_B &= 2B(W_2 + CW_3), \\ W_C &= W_1 + AW_2 + B^2W_3, \end{aligned}$$

where the usual notation $W_i = \frac{\partial W}{\partial I_i}$ is employed. Since $W_1 \longrightarrow \xi^\gamma$, $W_2 \longrightarrow \xi^\eta$, $W_3 \longrightarrow \xi^\delta$ for some γ, η, δ, the above along with (66), (68), (69)–(71), and (75)–(77) can be used to determine that the $\xi^{n+\alpha}$ term in (60) cannot dominate alone, nor can the $\xi^{n+\alpha}$ and $\xi^{m+\beta}$ terms balance and dominate the remaining term.[1] Thus the only remaining cases are the following: the $\xi^{n+\alpha}$ and $\xi^{p+\alpha}$ terms balance and dominate the remaining term (case I), all three terms of (60) balance (case II), and the $\xi^{p+\alpha}$ and $\xi^{m+\beta}$ terms balance and dominate the remaining term (case III).

Consider first case I. Then the asymptotic form of (60) yields the following ordinary differential equation for F:

$$\frac{3}{4}(1-\beta)(3-\beta)\sin\Phi F\bar{N} + (\sin\Phi F'\bar{N})' - \csc\Phi F\bar{P} = 0. \tag{105}$$

In addition, the boundary condition (63) for this case becomes

$$\bar{N}|_{\Phi=\frac{\pi}{2}} = 0. \tag{106}$$

Thus, for a given material model, (105) and (106) provide a first-order ordinary differential equation and boundary condition to determine the final unknown F in the asymptotic solution of this problem. In case II, the asymptotic form of (60) implies that

$$\frac{3}{2}(1-\beta)(3-\beta)\sin\Phi F\bar{N} + 2(\sin\Phi F'\bar{N})' - 2\csc\Phi F\bar{P} + \beta G_0(\sin\Phi\bar{M})' = 0 \tag{107}$$

[1] We note that if $W = W(I_3)$ only, then $W_A \equiv 0$. Reanalysis of $(26)_1$ immediately results in $I(\Phi) =$ constant, which violates (80), and thus compressible materials of this form cannot support a tensile point load. As a related matter, this paper will not consider special compressible materials of the form $W = W(I_1)$ only.

while the boundary condition (63) gives

$$2F'\left(\frac{\pi}{2}\right)\bar{N}|_{\Phi=\frac{\pi}{2}} + \beta G_0 \bar{M}|_{\Phi=\frac{\pi}{2}} = 0. \tag{108}$$

Finally, case III gives

$$-2\csc\Phi F\bar{P} + \beta G_0(\sin\Phi\bar{M})' = 0 \tag{109}$$

along with the boundary condition

$$\bar{M}|_{\Phi=\frac{\pi}{2}} = 0. \tag{110}$$

We remark that the superposed bars on M, N, P denote that these are to be evaluated at G given by (103). Note that $\bar{M}$, $\bar{N}$, $\bar{P}$ also depend on the unknown $F(\Phi)$ and its derivative. In addition, in each of the above three cases, F must satisfy $(43)_{2,3}$ and (67), and thus we collect below the additional conditions, which require

$$F(0) = 0, \;\; F(\Phi) > 0, \;\; \text{and} \;\; F'(\Phi) > 0 \;\; \text{for } 0 < \Phi \leq \tfrac{\pi}{2}, \;\; FF'\csc\Phi \text{ bounded}. \tag{111}$$

On using (66), (82), and (96), we note that

$$m + \alpha > n + \beta \Leftrightarrow m > \frac{1}{2}\beta - \frac{5}{2} \Leftrightarrow m > -\frac{1}{2}n - 3, \tag{112}$$

and thus the three cases above correspond to

$$\begin{cases} \text{I:} & m > \dfrac{1}{2} - \dfrac{5}{2}\beta & \text{and} \quad p = -\beta - 1, \\ \text{II:} & m = \dfrac{1}{2} - \dfrac{5}{2}\beta & \text{and} \quad p = -\beta - 1, \\ \text{III:} & m \in \left(\dfrac{1}{2}\beta - \dfrac{5}{2}, \dfrac{1}{2} - \dfrac{5}{2}\beta\right) & \text{and} \quad p = m + \dfrac{3}{2}(\beta - 1). \end{cases} \tag{113}$$

Alternatively, in view of (82), we may write the above equivalently as

$$\begin{cases} \text{I:} & m > \dfrac{5}{2}n + 3 & \text{and} \quad p = n, \\ \text{II:} & m = \dfrac{5}{2}n + 3 & \text{and} \quad p = n, \\ \text{III:} & m \in \left(-\dfrac{1}{2}n - 3, \dfrac{5}{2}n + 3\right) & \text{and} \quad p = m - \dfrac{3}{2}n - 3. \end{cases} \tag{114}$$

We recall that it was shown earlier (see the discussion and analysis containing (83)–(94)) that a material for which $m < \frac{1}{2}\beta - \frac{5}{2}$ or, equivalently, $m < -\frac{1}{2}n - 3$ cannot support a tensile point load. When $m = \frac{1}{2}\beta - \frac{5}{2} = -\frac{1}{2}n - 3$, the material must be such that $p = 2\beta - 4 = -2(n + 3)$ to sustain the point load. We present below tables summarizing the main tests to determine whether a material can sustain a tensile point load (Table 1) and the remaining differential equation(s) and boundary condition(s) to solve for the complete asymptotic solution when the point load can be supported (Tables 2 and 3). We remind the reader that n, m, and p are determined from a given material model W via (74)–(76), respectively, and that β is determined from (82), i.e., $n + \beta + 1 = 0$, which always applies.

TABLE 1
Asymptotic tests for the ability of a compressible material to support a tensile point load.

$n(\beta)+\beta+1=0$	Material may sustain a point load	Material cannot sustain a point load
β	$\in(0,1)$	$\notin(0,1)$
m	$\geq \frac{1}{2}\beta-\frac{5}{2}=-\frac{1}{2}n-3$	$<\frac{1}{2}\beta-\frac{5}{2}=-\frac{1}{2}n-3$
$m=\frac{1}{2}\beta-\frac{5}{2}=-\frac{1}{2}n-3$	$p=2\beta-4$ $=-2(n+3)$ (Case IV)	$p\neq 2\beta-4$ $=-2(n+3)$
$m\in(\frac{1}{2}\beta-\frac{5}{2},\frac{1}{2}-\frac{5}{2}\beta)$ $=(-\frac{1}{2}n-3,\frac{5}{2}n+3)$	$p=m+\frac{3}{2}(\beta-1)$ $=m-\frac{3}{2}n-3$ (Case III)	$p\neq m+\frac{3}{2}(\beta-1)$ $=m-\frac{3}{2}n-3$
$m=\frac{1}{2}-\frac{5}{2}\beta=\frac{5}{2}n+3$	$p=-\beta-1=n$ (Case II)	$p\neq-\beta-1=n$
$m>\frac{1}{2}-\frac{5}{2}\beta=\frac{5}{2}n+3$	$p=-\beta-1=n$ (Case I)	$p\neq-\beta-1=n$

TABLE 2
Asymptotic equations when a material may support a point load.

Case	m	p	Unknown(s)	ODE(s)	BC(s)
I	$>\frac{1}{2}-\frac{5}{2}\beta$	$=-\beta-1$	$F(\Phi)$	(105)	(106)
II	$=\frac{1}{2}-\frac{5}{2}\beta$	$=-\beta-1$	$F(\Phi)$	(107)	(108)
III	$\in(\frac{1}{2}\beta-\frac{5}{2},\frac{1}{2}-\frac{5}{2}\beta)$	$=m+\frac{3}{2}(\beta-1)$	$F(\Phi)$	(109)	(110)
IV	$=\frac{1}{2}\beta-\frac{5}{2}$	$=2\beta-4$	$F(\Phi)$, $G(\Phi)$, $I(\Phi)$	(93), (85), (84)	$(43)_2$, $(44)_2$, (80), $(91)_2$

TABLE 3
Asymptotic equations when a material may support a point load.

Case	m	p	Unknown(s)	ODE(s)	BC(s)
I	$>\frac{5}{2}n+3$	$=n$	$F(\Phi)$	(105)	(106)
II	$=\frac{5}{2}n+3$	$=n$	$F(\Phi)$	(107)	(108)
III	$\in(-\frac{1}{2}n-3,\frac{5}{2}n+3)$	$=m-\frac{3}{2}n-3$	$F(\Phi)$	(109)	(110)
IV	$=-\frac{1}{2}n-3$	$=-2(n+3)$	$F(\Phi)$, $G(\Phi)$, $I(\Phi)$	(93), (85), (84)	$(43)_2$, $(44)_2$, (80), $(91)_2$

Table 1 should be interpreted as presenting sequential tests on the material to determine whether it may sustain a tensile point load. Thus, in testing a particular material, one must first ensure that $\beta\in(0,1)$, then determine if $m\geq\frac{1}{2}\beta-\frac{5}{2}=-\frac{1}{2}n-3$, and based on this result, continue with the appropriate test(s) for cases I–IV. If a material is not excluded somewhere along this process, then the material can support the point load provided that the remaining ordinary differential equation(s), boundary condition(s), and restrictions following Tables 2 and 3 can be satisfied. Tables 2 and 3 summarize the remaining differential equation(s) and boundary condition(s) when the material modeled by W may sustain a point load. Categories in Table 2 present the results when comparing m, p with β, while Table 3 presents the results when comparing m, p, and n.

For cases I–III, G and I are given by (103)–(104). In addition, we have the additional conditions in (111) for cases I–III, while for case IV, $(43)_3$ and (67) must hold.

5.2. Asymptotic tests: Applications. The asymptotic tests derived above can easily be applied to particular constitutive models in order to test a material's ability to support a finite deflection under a tensile point load. Below we present the results obtained from invoking our tests. The remainder of this subsection is divided into two sections according to hyperelastic materials that (i) cannot sustain the point load and (ii) may sustain the point load. The materials tested encompass many well-known compressible material models proposed in the literature.

5.2.1. Materials that cannot support a tensile point load: Examples.
(a) Special Hadamard materials of the form

$$W = c_1(I_1 - 3) + H(I_3), \quad c_1 > 0 \text{ constant}, \tag{115}$$

with $H(1) = 0$ and $c_1 + H'(1) = 0$ for vanishing stored-energy and stress, respectively, in the undeformed state: On substituting from (18) and (20) we can see directly that $W_A = c_1$, and thus by (75), $n = 0$ for materials of the form (115). However, from Table 1, (82) ($n + \beta + 1 = 0$) implies that $\beta = -1 \notin (0, 1)$, and thus we can immediately conclude that compressible materials of the form (115) cannot support a finite deflection under a tensile point load. A variety of strain-energy functions proposed in the literature, including models of Blatz, Ogden, and Christensen (see [10] and references cited therein), have the form (115).

(b) The generalized Blatz–Ko material [11]:

$$\begin{aligned} W = {} & \frac{\mu}{2} f \left(I_1 - 1 - \frac{1}{\nu} + \frac{1-2\nu}{\nu} I_3^{\frac{-\nu}{1-2\nu}} \right) \\ & + \frac{\mu}{2}(1-f) \left(\frac{I_2}{I_3} - 1 - \frac{1}{\nu} + \frac{1-2\nu}{\nu} I_3^{\frac{\nu}{1-2\nu}} \right) \\ & \text{with } \mu > 0, \quad 0 < \nu < \frac{1}{2}, \quad 0 \le f \le 1. \end{aligned} \tag{116}$$

On substituting from (18)–(20), differentiating, and employing (70), we have

$$W_A = \frac{\mu}{2}[f + (1-f)B^{-2}] \longrightarrow \frac{\mu}{2}[f + (1-f)\xi^{(1-\beta)}\bar{B}^{-2}]. \tag{117}$$

Considering (75), $f = 1$ implies $n = 0$, which was ruled out in (a) above, while $f = 0$ implies that $n = 1 - \beta$, which clearly violates (82). Finally, since by (68) we have $0 < \beta < 1$, the remaining case $0 < f < 1$ implies again that $n = 0$. Thus the generalized Blatz–Ko material cannot support a finite deflection under a tensile point load for *any* range of its parameters. We note that for the special Blatz–Ko material ($f = 0$, $\nu = \frac{1}{4}$) given by

$$W = \frac{\mu}{2} \left(\frac{I_2}{I_3} + 2I_3^{\frac{1}{2}} - 5 \right), \quad \mu > 0, \tag{118}$$

this result was obtained by a different argument in [3]. Here it follows immediately as a consequence of the above asymptotic tests. As another example, we note that the polynomial material proposed by Levinson and Burgess (see [10, reference [24]]) also contains parameters μ, ν, f and has W_A given exactly as in (117). Thus for the polynomial material, we obtain the same conclusion as that for the generalized Blatz–Ko material, regardless of the choice of material parameters.

(c) Generalized Hadamard materials:

$$W = H_1(I_3)(I_1 - 3) + H_2(I_3)(I_2 - 3) + H_3(I_3), \tag{119}$$

with $H_3(1) = 0$, $H_1(1)+2H_2(1)+H_3'(1) = 0$, and $H_1(1)+H_2(1) > 0$. Using (18)–(20) and (69)–(71), it follows that

$$W_A = H_1(B^2C) + H_2(B^2C)C \longrightarrow H_1(\bar{B}^2\bar{C}) + H_2(\bar{B}^2\bar{C})\xi^{(1-\beta)}\bar{C}. \tag{120}$$

From (68) and (75) it is follows immediately that $n = 0$ if $H_1(I_3) \not\equiv 0$, while $n = 1-\beta$ if $H_1(I_3) \equiv 0$, $H_2(I_3) \not\equiv 0$, and thus as before, we see that generalized Hadamard materials *cannot* support a tensile point load.

(d) A model proposed by Gao (see [8]):[2]

$$W = a\left[\left(\frac{I_1}{I_3^{\frac{1}{3}}}\right)^k - 3^k\right] + b(I_3-1)^j I_3^{-q}, \quad a,k>0, \quad b,j,q \geq 0. \tag{121}$$

The material (121) is used by Gao and Liu [8] in an asymptotic analysis of a rubber cone under a concentrated tensile force. On substituting from (18) and (20) into (121) and differentiating, we obtain

$$W_A = \frac{ak}{(B^2C)^{\frac{1}{3}}}\left[\frac{A}{(B^2C)^{\frac{1}{3}}} + \left(\frac{C}{B}\right)^{\frac{2}{3}}\right]^{k-1}, \tag{122}$$

while employing (69)–(71) and factoring results in

$$W_A \longrightarrow \xi^{2(\beta-1)(k-1)}\frac{ak}{(\bar{B}^2\bar{C})^{\frac{1}{3}}}\left[\frac{\bar{A}}{(\bar{B}^2\bar{C})^{\frac{1}{3}}}\right]^{k-1}[1+\eta]^{k-1}, \tag{123}$$

where

$$\eta = \xi^{3(1-\beta)}\left(\frac{\bar{C}}{\bar{B}}\right)^{\frac{2}{3}}\frac{(\bar{B}^2\bar{C})^{\frac{1}{3}}}{\bar{A}}. \tag{124}$$

Thus, in view of (68) and expanding (123) in powers of η, we obtain that, as $\xi \longrightarrow 0^+$, the asymptotic form (75) for W_A yields

$$n = 2(\beta-1)(k-1), \qquad N = \frac{ak\bar{A}^{k-1}}{(\bar{B}^2\bar{C})^{\frac{k}{3}}}, \tag{125}$$

where $\bar{A}$, $\bar{B}$, $\bar{C}$ are given by (72)–(74), respectively. Solving (82) determines

$$\beta = \frac{2k-3}{2k-1}, \quad \text{and so} \quad 0<\beta<1 \Leftrightarrow k > \frac{3}{2}. \tag{126}$$

Thus proceeding with Table 1, we must now determine m (see (76)) and test for $m \geq \frac{1}{2}\beta - \frac{5}{2}$ or, equivalently, $m \geq -\frac{1}{2}n - 3$. Calculating W_B, factoring, expanding, and taking the dominant term imply that for the material (121) we have (76) with

$$m = \frac{(\beta-1)(4k-1)}{2}, \qquad M = -\frac{2\bar{A}N}{3\bar{B}}, \tag{127}$$

[2]We note that the variable K is used in place of I_3 for the material model in [8]; however, K is readily seen to be equivalent to the I_3 in this paper by application of the Cayley–Hamilton theorem.

where β, k, N are as above. It is simple to check that $m = \frac{1-4k}{2k-1} = -\frac{n}{2} - 3$, which then determines that the remaining conditions are those of case IV. Thus we must next determine p (see (77)) and test for $p = 2\beta - 4$ or, equivalently, $p = -2(n+3)$. In a similar manner, we consider W_C and determine that the material (121) implies that (77) is such that

$$p = (\beta - 1)(2k + 1), \qquad P = -\frac{\bar{A}N}{3\bar{C}}, \tag{128}$$

from which it then follows that $p = -2\frac{(2k+1)}{2k-1} = -2(n+3)$, and so case IV is satisfied. Thus, turning to Tables 2 and 3, we must be able to satisfy the system of ordinary differential equations and boundary conditions imposed for this material, as well as the additional conditions $(43)_3$ and (67). However, one can deduce that this is not possible by examining the boundary condition $(91)_2$ (traction-free condition on the surface of the half-space), which from $(125)_2$ and $(127)_2$ becomes

$$M|_{\Phi=\frac{\pi}{2}} = \left.\frac{-2ak\bar{A}^k}{3\bar{B}(\bar{B}^2\bar{C})^{\frac{k}{3}}}\right|_{\Phi=\frac{\pi}{2}} = 0. \tag{129}$$

In view of $(43)_3$, $(44)_2$, (67), (72)–(74), and $(121)_2$, the traction-free boundary condition (129) is satisfied only if $\bar{B} \longrightarrow \pm\infty$ as $\Phi \longrightarrow \frac{\pi}{2}$; however, (67) and continuity of F would then imply that $F(\frac{\pi}{2}) = 0$, which violates $(43)_3$. Thus, under the hypotheses of this paper, a half-space consisting of the material (121) cannot support a finite deflection under a tensile point load and maintain a traction-free boundary.

(e) A model for biological tissue (see [10, 16] and references cited therein):

$$W = \frac{\gamma}{2}[f(I_3)e^{k(I_1-I_2)}(I_1 - 3) + g(I_3)e^{-k(I_1-I_2)}(I_2 - 3) + h(I_3)],$$

where $\gamma > 0, k \neq 0$ are constants, $h(1) = 0$, $f(1)+2g(1)+h'(1) = 0$, and $f(1)+g(1) > 0$. As was the case in [1] for the incompressible biological material model of Fung, W and its partial derivatives go to infinity faster than ξ raised to any power, and thus W is not integrable, which from (42) violates our second hypothesis H2 (displacements must be bounded everywhere). Thus the biological tissue model given above cannot support a tensile point load.

We remark that, as we shall continue to see in the remainder of this subsection, a great utility of the present treatment is the ability to test large classes of materials and quite simply determine whether they may be capable of sustaining the point load. As demonstrated above, many of the well-known models for compressible hyperelastic materials are *not* able to support a finite deflection under a tensile point load. This seems to be consistent with the results of [1] in the sense that, in [1], it was noted that incompressible hyperelastic materials were able to sustain the point load only when they were sufficiently stiff, and thus it is not surprising that many compressible materials fail to do so. To consider the variety of materials treated in this paper (or, similarly, in [1]) within the contexts of the analyses of [3] or [8] would require complete rederivations of the asymptotic forms of the governing equations and subsequent reanalysis for each material model.

5.2.2. Materials that may support a tensile point load: Examples.

(a) An Antman [12] material:

$$W = k_1\left(\frac{I_2}{I_3}\right)^{\mu_1} + k_2\left(\frac{I_1}{I_3}\right)^{\mu_2} + k_3 I_3^{-\mu_3} + k_4 I_1^{\frac{\nu}{2}} + k_5(I_1^2 - 2I_2) + k_6 I_2 + k_7 I_3, \tag{130}$$

where the k_i, μ_j, and ν are all constants satisfying the usual conditions for normalization and physically reasonable response (which we omit for our purposes here). The material (130) is used in [12] to study a class of boundary-value problems for nonlinearly elastic deformations, and it is also attractive for the problem considered in this paper. At this time, we shall not make an exhaustive study of the material (130) for our tensile point load problem, as the potential cases are too numerous for our purposes here, and instead determine the varied possibilities for the exponents n, m, p of (75)–(77). On substituting from (18)–(20), we represent (130) in the form

$$\begin{aligned} W = {} & k_1\left(\frac{A}{B^2}+\frac{1}{C}\right)^{\mu_1} + k_2\left(\frac{A}{B^2C}+\frac{1}{B^2}\right)^{\mu_2} + k_3(B^2C)^{-\mu_3} + k_4(A+C)^{\frac{\nu}{2}} \\ & + k_5(A^2-B^2+C^2) + k_6(AC+B^2) + k_7B^2C. \end{aligned} \tag{131}$$

On computing W_A, substituting from (69)–(71), factoring, and expanding, we obtain the asymptotic form

$$\begin{aligned} W_A \longrightarrow {} & \frac{k_1\mu_1}{\bar{B}^2}\left(\frac{\bar{A}}{\bar{B}^2}+\frac{1}{\bar{C}}\right)^{\mu_1-1}\xi^{(\beta-1)(\mu_1-2)} + \frac{k_2\mu_2}{\bar{B}^2\bar{C}}\left(\frac{\bar{A}}{\bar{B}^2\bar{C}}\right)^{\mu_2-1}\xi^{2(\beta-1)(\mu_2-1)} \\ & + \frac{1}{2}k_4\nu\bar{A}^{\frac{\nu-2}{2}}\xi^{(\beta-1)(\nu-2)} + 2k_5\bar{A}\xi^{2(\beta-1)} + k_6\bar{C}\xi^{1-\beta}. \end{aligned} \tag{132}$$

In view of (68), the final term in (132) can never be dominant and so the asymptotic form of (132) depends on which of the four remaining terms balance and/or dominate the others. There are 15 such possibilities, corresponding to the various cases within each of the four categories below:

$$\begin{cases} (n_1): & n = 2(\beta-1) \Rightarrow \beta = \dfrac{1}{3}, & \nu \le 4, & \mu_1 \le 4, & \text{and} & \mu_2 \le 2, \\ (n_2): & n = (\beta-1)(\nu-2) \Rightarrow \beta = \dfrac{\nu-3}{\nu-1}, & \nu > 4, & \mu_1 \le \nu, & \text{and} & \mu_2 \le \dfrac{\nu}{2}, \\ (n_3): & n = 2(\beta-1)(\mu_2-1) \Rightarrow \beta = \dfrac{2\mu_2-3}{2\mu_2-1}, & \nu < 2\mu_2, & \mu_1 \le 2\mu_2, & \text{and} & \mu_2 > 2, \\ (n_4): & n = (\beta-1)(\mu_1-2) \Rightarrow \beta = \dfrac{\mu_1-3}{\mu_1-1}, & \nu < \mu_1, & \mu_1 > 4, & \text{and} & \mu_2 < \dfrac{\mu_1}{2}. \end{cases} \tag{133}$$

In each equation of (133), we have $\beta \in (0,1)$, while N will vary depending on the case (n_1)–(n_4) and the particular combinations of restrictions placed on ν, μ_1, and μ_2. Next, to determine m, we calculate the asymptotic form of W_B, which yields

$$\begin{aligned} W_B \longrightarrow {} & -\frac{2k_1\mu_1\bar{A}}{\bar{B}^3}\left(\frac{\bar{A}}{\bar{B}^2}+\frac{1}{\bar{C}}\right)^{\mu_1-1}\xi^{\frac{1}{2}(\beta-1)(2\mu_1-1)} \\ & - \frac{2k_2\mu_2}{\bar{B}^{2\mu_2+1}}\left(\frac{\bar{A}}{\bar{C}}\right)^{\mu_2}\xi^{\frac{1}{2}(\beta-1)(4\mu_2-1)} \\ & + 2(k_6-2k_5)\bar{B}\xi^{\frac{1}{2}(\beta-1)}. \end{aligned} \tag{134}$$

The asymptotic form of (134) depends on which of its three terms balance and/or dominate the others, creating seven such possibilities corresponding to the follow-

ing cases:

$$
\begin{cases}
(m_1): & m = \dfrac{1}{2}(\beta-1), & \mu_1 \le 1, & \text{and} & \mu_2 \le \dfrac{1}{2}, \\
(m_2): & m = \dfrac{1}{2}(\beta-1)(4\mu_2-1), & \mu_1 \le 2\mu_2, & \text{and} & \mu_2 > \dfrac{1}{2}, \\
(m_3): & m = \dfrac{1}{2}(\beta-1)(2\mu_1-1), & \mu_1 > 1, & \text{and} & \mu_2 < \dfrac{\mu_1}{2}.
\end{cases} \tag{135}
$$

Again, M will vary with each of the cases (m_1)–(m_3) and the particular combinations of restrictions placed on μ_1 and μ_2. Finally, to determine p, the asymptotic form of W_C results in

$$
\begin{aligned}
W_C \longrightarrow\ & \frac{-k_1\mu_1}{\bar{C}^2}\left(\frac{\bar{A}}{\bar{B}^2}+\frac{1}{\bar{C}}\right)^{\mu_1-1}\xi^{(\beta-1)(\mu_1+1)} - \frac{k_2\mu_2}{\bar{C}}\left(\frac{\bar{A}}{\bar{B}^2\bar{C}}\right)^{\mu_2}\xi^{(\beta-1)(2\mu_2+1)} \\
& + \frac{1}{2}k_4\nu\bar{A}^{\frac{\nu-2}{2}}\xi^{(\beta-1)(\nu-2)} + k_6\bar{A}\xi^{2(\beta-1)},
\end{aligned} \tag{136}
$$

and thus we have four possibilities for p corresponding to the 15 combinations of the parameters ν, μ_1, and μ_2 (and thus P) given below:

(137)

$$
\begin{cases}
(p_1): & p = 2(\beta-1), & \nu \le 4, & \mu_1 \le 1, & \text{and} & \mu_2 \le \dfrac{1}{2}, \\
(p_2): & p = (\beta-1)(\nu-2), & \nu > 4, & \mu_1 \le \nu-3, & \text{and} & \mu_2 \le \dfrac{\nu-3}{2}, \\
(p_3): & p = (\beta-1)(2\mu_2+1), & \nu < 2\mu_2+3, & \mu_1 \le 2\mu_2, & \text{and} & \mu_2 > \dfrac{1}{2}, \\
(p_4): & p = (\beta-1)(\mu_1+1), & \nu < \mu_1+3, & \mu_1 > 1, & \text{and} & \mu_2 < \dfrac{\mu_1}{2}.
\end{cases}
$$

Thus the material (130) offers an array of possibilities for study of the asymptotic equations associated with this problem, which, as mentioned above, we shall explore elsewhere.

(b) A recent model due to Gao [13]:[3]

$$
W = a\left(I_1^k + \left(\frac{I_2}{I_3}\right)^k\right), \quad a, k > 0 \text{ constants.} \tag{138}
$$

Gao [13] studies the asymptotic large deformation elastostatic field near a crack tip for a compressible hyperelastic material described by (138). For the material (138), the asymptotic form (75) for W_A is such that

$$
n = 2(\beta-1)(k-1), \qquad N = ak\bar{A}^{k-1}, \tag{139}
$$

where $\bar{A}$ is given by (72). Solving (82) determines

$$
\beta = \frac{2k-3}{2k-1}, \quad \text{and so} \quad 0 < \beta < 1 \Leftrightarrow k > \frac{3}{2}. \tag{140}
$$

[3]We remark that this material does not satisfy the usual normalization condition of zero strain-energy in the undeformed state ($W(3,3,1) = 0$). A simple remedy would be, e.g., to include a term of the form $-2a3^k$ in (138) or replace I_1, I_2 with $I_1 - 3$, $I_2 - 3$, respectively.

Thus, for the point load to be supported, we must have $k > \frac{3}{2}$ in (138). In continuing with the asymptotic tests, one finds that when $\frac{3}{2} < k < 3$, the corresponding m and p satisfy case III; when $k = 3$, m and p satisfy case II; and when $k > 3$, m and p satisfy case I. However, upon further examination, one finds that the boundary conditions (106) and (110) consistent with cases I and III, respectively, cannot be satisfied for the associated $\bar{N}$ and $\bar{M}$ in these cases. Thus, under the hypotheses of this paper, a half-space consisting of the material (138) with $\frac{3}{2} < k < 3$ or $k > 3$ cannot support a finite deflection under a tensile point load and maintain a traction-free boundary. The boundary condition (108) for the case $k = 3$, however, is not incompatible with the associated $\bar{N}$ and $\bar{M}$. In this case, it can be seen that

$$k = 3 \Rightarrow \beta = \frac{3}{5}, \qquad m = -1, \qquad n = p = -\frac{8}{5}, \qquad \alpha = \frac{6}{5} \tag{141}$$

and that

$$\bar{N} = 3a\bar{A}^2, \quad \bar{M} = -6a\frac{\bar{A}}{\bar{B}^3}\left(\frac{\bar{A}}{\bar{B}^2} + \frac{1}{\bar{C}}\right)^2, \quad \bar{P} = 3a\left[\bar{A}^2 - \frac{1}{\bar{C}^2}\left(\frac{\bar{A}}{\bar{B}^2} + \frac{1}{\bar{C}}\right)^2\right], \tag{142}$$

where

$$\bar{A} = (\beta G_0)^2 = (12\pi a)^{-\frac{2}{5}}, \tag{143}$$

$$\bar{B} = \beta G_0 F'(\Phi) = (12\pi a)^{-\frac{1}{5}} F'(\Phi), \tag{144}$$

$$\bar{C} = \frac{F^2(\Phi)}{\sin^2 \Phi} \tag{145}$$

and

$$G(\Phi) \equiv G_0 = \frac{5}{3}(12\pi a)^{-\frac{1}{5}}, \tag{146}$$

$$I(\Phi) = \frac{1}{2\pi}(1 - \cos\Phi). \tag{147}$$

The remaining equations and conditions that must be satisfied are the ordinary differential equation (107), which in this case results in the nonlinear second-order differential equation for $F(\Phi)$ given by

$$\begin{aligned}(12\pi a)^{-\frac{4}{5}} &\left[2(\sin\Phi F')' + \frac{36}{25}\sin\Phi F - \frac{2F}{\sin\Phi}\right] \\ &+ 2\left\{\left(\frac{\sin\Phi}{F}\right)^3\left[\frac{1}{(F')^2} + \frac{\sin^2\Phi}{F^2}\right]^2 - \left(\frac{\sin\Phi}{(F')^3}\left[\frac{1}{(F')^2} + \frac{\sin^2\Phi}{F^2}\right]^2\right)'\right\} = 0;\end{aligned} \tag{148}$$

the traction-free boundary condition (108), which implies that

$$(12\pi a)^{-\frac{2}{5}}\left[F'\left(\frac{\pi}{2}\right)\right]^2 = \frac{1}{\left[F'\left(\frac{\pi}{2}\right)\right]^2} + \frac{1}{\left[F\left(\frac{\pi}{2}\right)\right]^2}; \tag{149}$$

and the conditions contained in (111), namely,

$$F(0) = 0, \quad F(\Phi) > 0, \quad \text{and} \quad F'(\Phi) > 0 \quad \text{for } 0 < \Phi \le \tfrac{\pi}{2}, \quad FF'\csc\Phi \text{ bounded}. \tag{150}$$

(c) A Jiang–Ogden [14] material:

$$W = f(I_1)h_1(I_3) + h_2(I_3), \tag{151}$$

where $f(3)h_1(1) + h_2(1) = 0$, $f'(3)h_1(1) + f(3)h_1'(1) + h_2'(1) = 0$, and $f'(3)h_1(1) > 0$. Jiang and Ogden [14] consider materials of the form (151) in their study of azimuthal shear of circular cylindrical tubes, where the function $f(I_1)$ has the form $f(I_1) = c_1(I_1 - 1)^j$ with $j \geq \frac{1}{2}$. Here we shall similarly treat materials of the form (151) with $f(I_1) = c_1(I_1 - 1)^k$, $k > 0$ constant. Thus we consider

$$W = c_1(I_1 - 1)^k h_1(I_3) + h_2(I_3), \quad k > 0, \tag{152}$$

for which the asymptotic tests developed earlier determine the following:

$$n = 2(\beta - 1)(k - 1), \qquad N = c_1 k \bar{A}^{k-1} h_1(\bar{B}^2\bar{C}), \tag{153}$$

where $\bar{A}$, $\bar{B}$, $\bar{C}$ are given by (72)–(74), respectively. Solving (82) determines

$$\beta = \frac{2k-3}{2k-1}, \quad \text{and so} \quad 0 < \beta < 1 \Leftrightarrow k > \frac{3}{2}, \tag{154}$$

and via (66), $\alpha = \frac{3-\beta}{2}$. We note that [14] treats four special cases of (152) with $k = \frac{1}{2}$, 1, $\frac{3}{2}$, $\frac{3}{4}$, and thus by $(154)_2$, none of these special cases can support a tensile point load. Continuing with $k > \frac{3}{2}$, it can be seen that

$$m = \frac{(\beta-1)(4k-1)}{2} = \frac{1}{2}\beta - \frac{5}{2}, \qquad M = 2c_1\bar{A}^k\bar{B}\bar{C}h_1'(\bar{B}^2\bar{C}) \tag{155}$$

and

$$p = (\beta - 1)(2k + 1) = 2\beta - 4, \qquad P = c_1\bar{A}^k\bar{B}^2h_1'(\bar{B}^2\bar{C}), \tag{156}$$

and thus case IV is satisfied. By Tables 2 and 3, we must then satisfy the system of ordinary differential equations and boundary conditions imposed for this material, as well as the additional conditions $(43)_3$ and (67). We note here that the material (121) is a special case of (151), and we recall from section 5.2.1(d) that the traction-free boundary condition $(91)_2$ ($M|_{\Phi=\frac{\pi}{2}} = 0$) could not be satisfied for (121). Noting $(155)_2$ and the fact that $\bar{A}$, $\bar{B}$, and $\bar{C}$ are all strictly positive at $\Phi = \frac{\pi}{2}$, $(91)_2$ can then be seen as a condition on the form of the function $h_1(I_3)$ such that a traction-free boundary is possible. As an example, note that $I_3 = B^2C = \bar{B}^2\bar{C}$ and that

$$I_3|_{\Phi=\frac{\pi}{2}} = c \tag{157}$$

for some $c > 0$ constant. Suppose now that

$$h_1(I_3) = \frac{1}{c}I_3\left[\ln\left(\frac{I_3}{c}\right) - 1\right], \tag{158}$$

and so

$$h_1'(I_3) = \frac{1}{c}\ln\left(\frac{I_3}{c}\right), \tag{159}$$

which, in turn, implies via (157) that

$$h_1'(\bar{B}^2\bar{C})|_{\Phi=\frac{\pi}{2}} = 0, \tag{160}$$

and thus the traction-free boundary condition $(91)_2$ is identically satisfied for the material (152) with $h_1(I_3)$ given by (158), where c is as in (157). With this choice for $h_1(I_3)$ and N, M, P, β, and α given above, the remaining equations to be satisfied are (93), (85), and (84), along with boundary conditions $(43)_2$, $(44)_2$, and (80), with the additional conditions $(43)_3$ and (67).

(d) A Beatty–Jiang-type material [15]:

(161)
$$\begin{aligned} W = {} & H_1(I_3)(I_1-3) + H_2(I_3)(I_2-3) + H(I_3) \\ & + c_3(I_1-3)^2 + c_4(I_2-3)^2 + c_5(I_1-3)(I_2-3) + c_6(I_1-3)^3 \\ & + c_7(I_2-3)^3 + c_8(I_1-3)(I_2-3)^2 + c_9(I_1-3)^2(I_2-3) + c_{10}(I_1-3)(I_2-3)^3, \end{aligned}$$

where the c_i are all constants. Beatty and Jiang [15] consider the material (161) with $c_{10} = 0$ in their study of azimuthal shear of nonlinearly elastic compressible solids. When $c_{10} = 0$, the material (161) satisfies the conditions on n, β, m, and p for case III; however, again we find that the associated traction-free boundary condition (110) cannot be satisfied. Thus we augment the material considered in [15] by including the c_{10} term so that (110) might be satisfied. Following the considerations of [15], we require $H_3(1) = 0$, $H_1(1) + 2H_2(1) + H_3'(1) = 0$, $H_1(1) + H_2(1) > 0$, $c_3 + c_4 + c_5 \geq 0$, and $c_6 + c_7 + c_8 + c_9 + c_{10} \geq 0$ for physically reasonable material response. Proceeding with our analysis, we find that

$$n = 4(\beta - 1), \qquad N = 3c_6\bar{A}^2, \tag{162}$$

while solving (82) determines

$$\beta = \frac{3}{5} \Rightarrow n = -\frac{8}{5} \quad \text{and} \quad \alpha = \frac{6}{5}. \tag{163}$$

In addition, one can determine that

$$m = \frac{9}{2}(\beta - 1) = -\frac{9}{5}, \qquad M = 2\bar{A}\bar{B}[c_9\bar{A} + 3c_{10}(\bar{A}\bar{C} + \bar{B}^2)^2], \tag{164}$$

where we recall that $\bar{A}$, $\bar{B}$, $\bar{C}$ are given by (72)–(74), respectively, and

$$\begin{aligned} p &= 6(\beta - 1) = -\frac{12}{5} = m + \frac{3}{2}(\beta - 1), \\ P &= \bar{A}^2[c_9\bar{A} + 3c_{10}(\bar{A}\bar{C} + \bar{B}^2)^2] = \frac{\bar{A}}{2\bar{B}}M. \end{aligned} \tag{165}$$

Thus case III is satisfied, and it then follows that

$$G(\Phi) \equiv G_0 = \frac{5}{3}(12\pi c_6)^{-\frac{1}{3}}, \tag{166}$$

$$I(\Phi) = \frac{1}{2\pi}(1 - \cos\Phi). \tag{167}$$

Further, from Tables 2 and 3, $F(\Phi)$ must then satisfy the conditions in (111) as well as the ordinary differential equation (109) and traction-free boundary condition (110), which for the material (161) become

$$\begin{aligned} & -\frac{F}{\sin\Phi}\left[c_9 + 3c_{10}\beta^2 G_0^2\left(\frac{F^2}{\sin^2\Phi} + F'^2\right)^2\right] \\ & \quad + \left\{\sin\Phi F'\left[c_9 + 3c_{10}\beta^2 G_0^2\left(\frac{F^2}{\sin^2\Phi} + F'^2\right)^2\right]\right\}' = 0 \end{aligned} \tag{168}$$

and

$$\left[F^2\left(\frac{\pi}{2}\right)+F'^2\left(\frac{\pi}{2}\right)\right]^2=-\frac{c_9}{3c_{10}\beta^2G_0^2}, \tag{169}$$

respectively, where by $(163)_1$ and (166), $\beta^2G_0^2=(12\pi c_6)^{-\frac{2}{3}}$. To conclude this paper, we consider the special case of (168), (169) when

$$\frac{F^2}{\sin^2\Phi}+F'^2=c^2,\quad c\neq 0 \text{ constant}, \tag{170}$$

and

$$c_9=-3c_{10}\beta^2G_0^2c^4. \tag{171}$$

Since (168), (169) follow automatically if (170), (171) hold, we will take c_9 in (161) to be given by (171) and consider the first-order nonlinear ordinary differential equation (170) subject to the conditions in (111), which we repeat here as

$$F(0)=0,\quad F(\Phi)>0,\quad \text{and}\quad F'(\Phi)>0\quad \text{for } 0<\Phi\leq\tfrac{\pi}{2},\quad FF'\csc\Phi \text{ bounded}. \tag{172}$$

While (170) is a significant simplification over (168) and appears deceptively simple, we have not found (170) to be amenable to analysis for determining a closed-form solution. Instead, we present in Figures 1 and 2 plots of the direction fields along with the solutions of (170) satisfying $(172)_1$, as well as the remaining conditions in (172), for representative values of the constant $c>1$. We remark that Figures 1 and 2 were generated for simplicity using Maple. The solutions plotted for various c agree with data obtained from computing a numerical solution implementing a fourth-order Runge–Kutta backwards shooting method.

Thus with our numerical solution for $F(\Phi)$, the unknown functions and parameters from (43)–(45) are determined according to (163) for α and β and (166) and (167) for G and I, respectively, where we recall $\delta=0$ from (49). In addition, with (170), (171), we have $\bar{M}=\bar{P}=0$, and thus the asymptotic forms of the nonzero stress components are as follows (where we note that $S_{\Phi z}=0$, $S_{\Theta\theta}=0$):

$$S_{\xi r}\longrightarrow \xi^{-\frac{7}{5}}\frac{12}{5}\bar{N}F(\Phi), \tag{173}$$

$$S_{\xi z}\longrightarrow \xi^{-2}\frac{6}{5}\bar{N}G_0, \tag{174}$$

$$S_{\Phi r}\longrightarrow \xi^{\frac{1}{5}}2\bar{N}F'(\Phi), \tag{175}$$

where by (162), (73), and (166), $\bar{N}=3c_6\bar{A}^2=3c_6(\beta G_0)^4$ is constant. The asymptotic forms of the nonzero stress components, on using the more traditional cylindrical polar coordinates and bases for both the undeformed and deformed configurations, are then computed for this problem as

$$S_{Rr}\longrightarrow \sin\Phi S_{\xi r}, \tag{176}$$

$$S_{Rz}\longrightarrow \sin\Phi S_{\xi z}, \tag{177}$$

$$S_{Zr}\longrightarrow \cos\Phi S_{\xi r}, \tag{178}$$

$$S_{Zz}\longrightarrow \cos\Phi S_{\xi z}, \tag{179}$$

where $S_{\xi r}$, $S_{\xi z}$ are given in (173)–(174) and $\xi\sin\Phi=R$, $\xi\cos\Phi=Z$, $\xi^2=R^2+Z^2$.

HYDRODYNAMIC CLEANSING OF PULMONARY ALVEOLI*

DAPHNE ZELIG† AND SHIMON HABER‡

Abstract. The inside wall of the pulmonary alveolus is lined with a thin viscous fluid layer and a monolayer of surfactants. Inhaled foreign particles that reach the lung alveoli are normally neutralized by macrophages and remain inside the lung. Nevertheless, Podgorski and Gradon [*Ann. Occup. Hyg.*, 37 (1993), pp. 347–365] suggested that a hydrodynamic cleansing mechanism may exist in which particles are swept out by the net fluid flow from the alveolar viscous layer to the adjacent airways. Hawgood [*The Lung: Scientific Foundations*, 2nd ed., R. G. Crystal and J. B. West, eds., Lippincott-Raven, Philadelphia, 1997, pp. 557–571] has also reported that surfactants exit the alveoli during every breathing period. Based upon the foregoing observations, we examine a possible mechanism of hydrodynamic cleansing and predict its effectiveness. Our central assumption is that the amount of surfactant remains periodic during breathing and that a certain regulatory mechanism exists that causes excess surfactant (reported by Hawgood) to leave the alveoli. Owing to the latter, surfactant concentration gradients are induced inside the alveoli, which in turn generate fluid motion (a Marangoni effect) and concomitant fluid discharge. Our analysis predicts that a typical value of the outflow velocity is 10^{-9}[m/sec]; i.e., it takes a fluid particle almost two days to travel a distance equal to an alveolar radius. It is also shown that the outflow velocity depends almost linearly on the discharge rate of the surfactants. Hence, a small artificial addition of surfactants into the lung may enhance alveolar cleansing, provided that a biological mechanism exists that maintains normal surfactant concentration over the lining fluid layer.

1. Introduction.

Zeltner et al. [29] observed that a nonuniform pattern of particle deposition exists within the rodent lung. Specifically, the density of particles deposited on the alveolar entrance rim is five times higher than that on septal alveolar surfaces. Are hydrodynamic forces driving the particles from their initial deposition locations toward the entrance rim? The fluid dynamical problem addressed in this paper is motivated by the search for such a possible cleansing mechanism inside the lung alveoli.

Environmental and occupational hazards resulting from aerosol inhalation have been the subject of intensive research (see Harvey and Crystal [14]). An understanding of aerosol kinetics may also prove to be a meaningful step towards improving diagnostic and therapeutic methods [1], [5]. In humans, the respiratory airway system consists of the nasal cavity, the throat, the voice box, the trachea, the two primary bronchi that bifurcate from the trachea, the bronchi, and bronchiole that divide and subdivide, becoming steadily smaller until there are about 20–23 generations of branching. From the sixteenth generation, the airways become increasingly alveolated. The bronchioles terminate with berry-shaped group of sacs and acinar ducts (the acinus). During breathing, the alveoli and the alveolar ducts expand and contract in a way roughly consistent with geometric similarity. Thus, all dimensions scale approximately as the 1/3 power of the lung volume (Gil and Weibel [8], Gil et al. [7]; Weibel [27]; Ardila,

Horie, and Hildebrandt [2]). Tsuda, Henry, and Butler [25], Tsuda, Otani, and Butler [26], and recently Haber et al. [12] considered the effect of alveolar expansion and contraction on the fluid flow inside the alveoli. In [25] and [26], the authors assumed that the pulmonary acinus could be viewed as a self-similar expanding axisymmetric thoroughfare surrounded by a toroidal sac, a configuration that simplified the numerical calculations. In [12], the alveolus was geometrically approximated by a self-similar expanding spherical cap attached at its rim to the alveolar duct (see also Gil et al. [7]), a geometry that is likely to represent a more faithful portrayal of the acinus.

Little attention has been paid in the past to the effect of alveolar expansion and contraction, since in the case of gas exchange the Peclet number controlling the transport of the gas molecules is much smaller than unity. Thus, convection due to the acinar flow is negligibly small when compared with the diffusive transport. (It takes only a few milliseconds for a gas molecule to reach the alveolar wall from its entrance ring.) However, in the case of aerosol transport, the Peclet number is much larger, and particle convection and diffusion may play a comparable role. Under normal conditions, particles 0.5 to 4 μm in diameter may often reach the acinus and pose the greatest hazard to human health (see, e.g., Dockery et al. [6]).

Particles that enter the respiratory system and are deposited over the airway walls are mechanically removed by the rhythmical motion of cilia (Sleigh, Blake, and Liron [20]). Particles are forced upwards along the bronchiolar tree and are finally removed from the respiratory system by forced convection of air (coughing). Nonetheless, a similar cleansing mechanism does not exist within the acinus. Generally, particles that reach the alveoli are neutralized by macrophages [4] and remain deposited inside the acinus. Indeed, several experimental studies (e.g., Zeltner et al. [29], Heyder et al. [16], Schultz et al. [24]) have investigated such aerosol mixing and deposition. However, Gradon and Podgorski [11] proposed that a purely hydrodynamic effect may assist in cleansing the alveoli. They suggested that gradients in surfactant concentrations induce the thin fluid lining that covers the inner alveolar wall to flow slowly outside the alveolus rim. Thus, particles deposited on the alveolar wall are carried with the fluid toward the entrance rim. They predicted a characteristic clearance time of about one hour.

Scarpelli [23] described the main stages of the surfactant's transition between the air-fluid interface and the fluid body as follows: During expiration, the alveolus contracts and the distance between the surfactant molecules decreases; in other words, their concentration increases and consequently the surface tension diminishes. When the alveolar radius reaches a threshold value, some of the molecules of the surfactant leave the interface and penetrate the fluid. During inspiration, the alveolus expands, the concentration of the surfactant decreases, and concomitantly, the surface tension increases. In addition, surfactants return to the interface from the bulk of the fluid by diffusion. More detailed models for surfactant transition can be found in [9], [10].

In [15], the metabolism of surfactants is explained, and the secretion rate is evaluated. There is clear evidence for the existence of a regulatory mechanism for surfactant production and clearance rates that keeps it from excessive accumulation or dilution [15]. Surfactants are created in Type II cells, which form part of the alveolus wall. After diffusing to the interface, most of them (about 80%) return to these cells and are then recycled for additional use. About 10–20% are consumed by macrophages, which lie at the alveolar wall, and the remaining few percent exit the alveolus.

In this article the alveolar hydrodynamic clearance mechanism is analyzed. We adopt the spherical model that has been extensively used in the past (e.g., Podgorski

and Gradon [22] and Haber et al. [12]) to describe the alveolus configuration. We also use measured experimental data for alveoli expansion/contraction rates and the known measured correlation between surfactant concentration and surface tension. We focus on the dynamical behavior of the surfactants, the main mechanism that controls the lining fluid flow, and assume that no surfactants are accumulated or depleted inside the alveolus during a breathing cycle. The boundary condition at the alveolar rim is based upon the known experimental value of the small amount of surfactant exiting the alveolus per breathing cycle. An open and valid question is what the specific mechanism that causes surfactant to exit the alveolus might be. One might assume, for instance, that airflow in the adjacent airway contributes to the sweeping effect, and reformulate the boundary conditions accordingly. Another possibility is that there is a biological mechanism that discharges excess surfactant from inside the alveolus. We try to avoid such ad hoc assumptions and focus on a cleansing mechanism that is based upon known and validated experimental data. The solution methodology is based on the assumption that, had no fluid been driven through the alveolus opening, surfactant concentration would have been uniform and the lining fluid would have expanded and contracted in a radially symmetric manner to conserve fluid mass. Thus, scaling of the cleansing mechanism is based upon the amount of surfactant leaving the alveolus, a markedly different approach from that used by Podgorski and Gradon [22], who relate the continuity of the fluid and the surfactant layers at the alveolar rim. A source term is also added to the surfactant mass conservation equation to account for surfactants entering or leaving the interface from the bulk fluid, and this facilitates the condition that no mass accumulation or depletion of surfactants per cycle occurs. As a result, the whole set of equations and the solution differ markedly from that obtained by Podgorski and Gradon [22].

In section 2, we define the geometrical, kinematical, and physiological parameters that scale the variables of the problem. In section 3, we obtain the resulting governing equations, boundary conditions, and parameters that control the problem. In section 4, we present the asymptotic expansion of the flow variables in terms of two smallness parameters and obtain the equations and boundary conditions that govern the zero and first order approximations. In section 5.1, we present the analytic solution of the zero order approximation, and in section 5.2, a finite element analysis is utilized to obtain a solution for the first order approximation. In section 6, we discuss our results, and we present our concluding remarks in section 7.

2. The alveolus model: Configuration and typical parameters. Assume that the alveolus can be approximated by a hollow spherical cap of radius $R(t)$ attached at its rim to the alveolar duct (see Figure 1). Typical alveolar mean radius ranges between 40 and 200μm. The alveolus is rhythmically expanding and contracting with a breathing rate of 12–14 breaths per minute for adults and about 33 breaths per minute for infants. The expansion amplitude is about 0.1 alveolar radius. The dependence of R on time is based on experimental data described in Podgorski and Gradon [22] and approximated here by a natural cubic spline interpolation to achieve continuity of its time derivatives (see Figure 2(a)).

A spherical coordinate system (r, θ, ϕ) is located at the center of the spherical cap, where r stands for the radial coordinate and θ and ϕ denote the latitude and azimuthal angles, respectively.

The alveolus rim location is defined by the half-cone angle θ_b. (Henceforth, we assume that $\theta_b = 60^0$ and that the subscript "b" denotes evaluation at the rim.) The inside wall of the alveolus is lined with a thin fluid layer of thickness $h(\theta, \phi, t)$. The

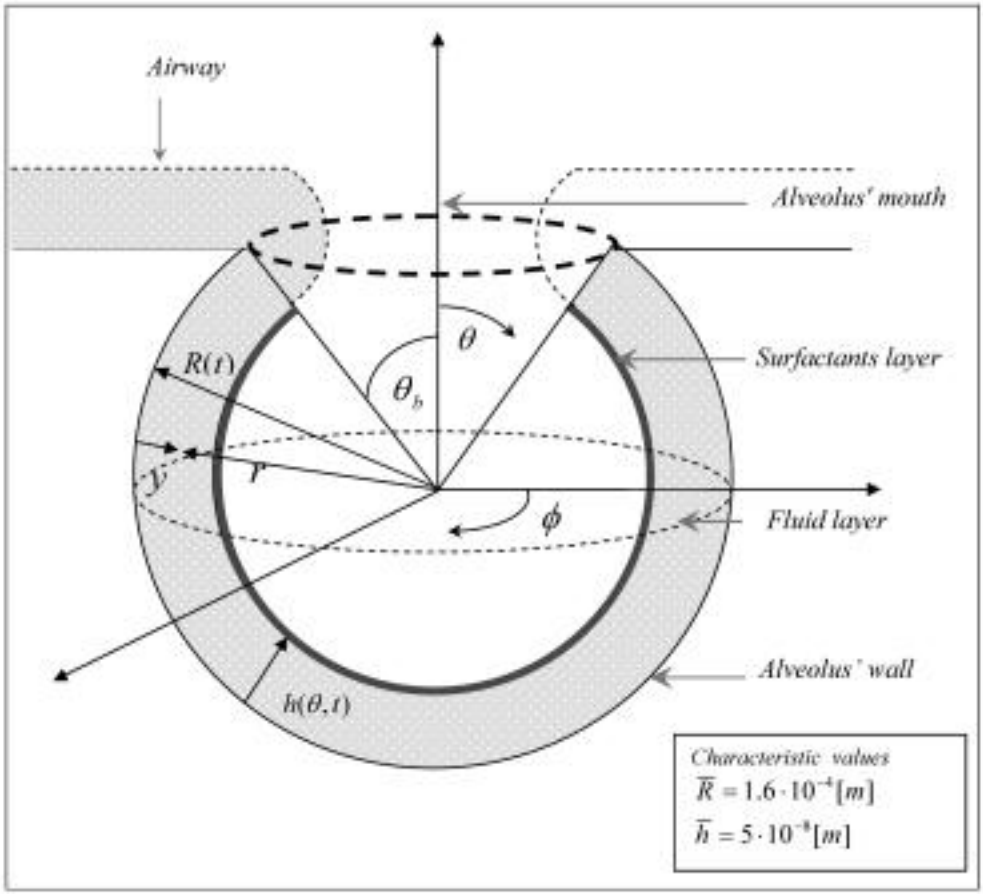

FIG. 1. *A schematic description of the alveolus.*

fluid layer is lined with a single layer of surfactant that lies at the fluid-air interface.

During expansion, additional surfactants are produced at the alveolus wall and diffuse through the fluid bulk into the fluid-air interface. Most of these retract to the fluid layer when the alveolus contracts. A residual part is cleared through the alveolar rim at $\theta = \theta_b$. Thus, a useful partition of the total rate of surfactant production $F(t)$ is

$$F(t) = \frac{\overline{m}(\lambda_b F_b(t) + \lambda_{ec} F_{ec}(t))}{T},$$

where T stands for the breathing period and $\overline{m}$ is the time-averaged amount of surfactants found in the alveolus. (Henceforth, the overhead-bar sign denotes either an average or a typical value.) The first term $\overline{m}\lambda_b F_b(t)/T$ is the rate of production of surfactants that are cleared from the alveolus rim at $\theta = \theta_b$. The prefactor $\overline{m}\lambda_b/T$ is used to scale the production rate so that the time dependent function $F_b(t)$ is of order unity.

The second term $\lambda_{ec}\overline{m}F_{ec}(t)/T$ is a periodic function with zero mean that stands for the rate of transit of surfactant between the fluid bulk and the air-fluid interface during the expansion and contraction process. The prefactor $\lambda_{ec}\overline{m}/T$ scales its

amplitude.

Hawgood [15] provided experimental data pertaining to the total amount of surfactant cleared from the rim during a breathing cycle. However, there is practically no data on how the production rate $F(t)$ varies with time and location. With no such prior knowledge, we believe that a leading order approximation can be obtained if we assume that $F(t)$ is expanded in a time Fourier series with period T and consider only the first two leading terms with $F_b(t) \equiv 1$ and $F_{ec}(t) = \sin(\frac{2\pi t}{T})$. This is equivalent to assuming that surfactants are uniformly produced at the alveolus wall and that the rate of excess surfactants leaving the rim is fixed and scales with $\overline{g} = \overline{m}\lambda_b/T$.

According to [15], the amount of surfactant secretion per hour is about 10–40% of the total amount of the surfactant present at the alveolus. If we pick $T = 4$ sec, the amount of surfactant produced per breathing cycle is about $1.1 \cdot 10^{-4}\overline{m}$ to $4.4 \cdot 10^{-4}\overline{m}$. Hawgood [15] also reported that 1–10% of the secreted amount is cleared from the alveolus. Thus, the range of λ_b is $1 \cdot 10^{-6}$–$4 \cdot 10^{-5}$, and that of λ_{ec} is $9 \cdot 10^{-5}$–$3.9 \cdot 10^{-4}$. Henceforth, we set $\lambda_b = 1 \cdot 10^{-5}$ and $\lambda_{ec} = 1.9 \cdot 10^{-4}$ as appropriate scaling values.

The surfactant surface concentration γ scales with $\overline{\gamma} = \overline{m}/2\pi(\overline{R} - \overline{h})^2 d$, where $d = 1 + \cos(\theta_b)$ and thus $\overline{g} = 2\pi\overline{R}^2 d\lambda_b\overline{\gamma}/T$. The velocity of the lining fluid and the diffusion at the interface layer govern the surfactant flux through the rim. Thus, the amount of surfactant leaving the alveolus per unit time is $g = 2\pi(R-h)\sin(\theta_b)(\gamma u_\theta - D\frac{\partial}{\partial\theta}\gamma)_{r=R-h,\theta=\theta_b}$, where $D = 10^{-10}\mathrm{m}^2/\mathrm{sec}$ is the surfactant surface diffusion coefficient (provided in [22]) and u_θ is the tangential surface velocity. Hence, the surface velocity scales with $\overline{u}_\theta = \lambda_b\frac{\overline{R}}{T} \approx 10^{-9}$ m/sec since the flux due to diffusion is of a lesser effect.

Table 1 furnishes a summary of all the additional physical parameters that are employed in the analysis with mean numerical values taken from [10], [15], and [22].

3. Flow equations, boundary conditions, dimensionless parameters and controlling variables. The differential equations that govern the flow of the lining fluid layer are the following:

(a) The continuity equation for an incompressible fluid,

$$\nabla \cdot \mathbf{u} = 0. \tag{1}$$

(b) The quasi-steady linear momentum equation (neglecting body forces and the disjoint pressure),

$$\mu\nabla^2\mathbf{u} = \nabla p. \tag{2}$$

Here, the local acceleration and convection terms have been neglected since the Reynolds numbers, $R_{eT} = \overline{h}^2/Tv = 5 \times 10^{-10}$, $R_{e\theta} = \overline{u}_\theta\overline{h}/v = 4 \times 10^{-11}$, and $R_{er} = |(\overline{u}_r - \dot{\overline{R}})\overline{h}/v| = 10^{-6}$, are much smaller than unity. The disjoint pressure effect may be neglected since the time scale of an instability (Oron, Davis, and Bankoff [18]) that may cause rupture of the thin lining layer is of the order $96\pi^3\overline{h}^5\rho v\overline{\sigma}/A^2 = 100$ sec (for a Hamaker constant A of the order of 10^{-20} J and surface tension as low as $\overline{\sigma} = 1$ dyne/cm), a much slower process than the breathing cycle of 4 seconds. In addition, Wit, Gallez, and Christov [28] concluded that the cutoff wave number is independent of the Marangoni effect.

(c) The mass conservation equation for the surfactant layer is (see Aris [3, p. 86] for the Reynolds transport theorem in a two-dimensional curved space)

TABLE 1
Geometrical and phenomenological properties.

Description	**Typical Value [units]**
Lining fluid thickness	$\overline{h} = 5 \cdot 10^{-8}$ [m]
Alveolar radius	$\overline{R} = 1.6 \cdot 10^{-4}$ [m]
Breathing period	$\overline{t} = 4$ [sec]
Lining fluid outflow velocity	$\overline{u}_\theta = \dfrac{\lambda_b \overline{R}}{\overline{t}} \approx 10^{-9}$ [m/sec]
Surface tension	$\overline{\sigma} = 2.5 \cdot 10^{-2}$ [N/m]
Surfactant concentration at the fluid-air-interface	$\overline{\gamma} = 3.3 \cdot 10^{-6}$ [mol/m^2]
Capillary pressure	$\overline{P} = \dfrac{\overline{\sigma}}{\overline{R}} \approx 156$ [N/m^2]
Amount of surfactants in the lining fluid interface	$\overline{m} = 2\pi \overline{R}^2 d\overline{\gamma} \approx 5 \cdot 10^{-13} d$ [mol]
Ratio of lining fluid thickness to alveolar radius	$\varepsilon = \dfrac{\overline{h}}{\overline{R}} \approx 3 \cdot 10^{-4}$
Ratio of amount of surfactant leaving the alveolus during a breathing period to $\overline{m}$	$\lambda_b = 10^{-5}$
Ratio of amount of surfactant staying in the lining fluid to $\overline{m}$	$\lambda_{ec} = 1.9 \cdot 10^{-4}$
Diffusion coefficient of the surfactants at the fluid interface	$D = 10^{-10}$ [m^2/sec]
Modified capillary number	$\overline{C}_a = \dfrac{\mu \overline{R}^2}{\overline{h}\overline{\sigma} T} = 0.0614$
Alveolus fluid viscosity	$\mu = 12 \cdot 10^{-3}$ [Pa $\cdot$ sec]

$$\mathbf{n} \cdot \frac{\partial(\gamma \mathbf{n})}{\partial t} + \mathbf{u}_s \cdot \nabla_s(\gamma \mathbf{n}) \cdot \mathbf{n} - \gamma \mathbf{n} \cdot (\nabla \mathbf{u}) \cdot \mathbf{n} = D \nabla_s^2 \gamma + \frac{F(t)}{2\pi (R-h)^2 d}, \tag{3}$$

where $\mathbf{n}$ is a unit vector perpendicular to the interface, $\nabla_s = (\mathbf{I} - \mathbf{nn}) \cdot \nabla$ is the surface gradient, $\mathbf{u}_s = (\mathbf{I} - \mathbf{nn}) \cdot \mathbf{u}$ is the surface velocity, and $\mathbf{I}$ is the idem dyadic. The second term on the right-hand side of (3) is a source term that accounts for the amount of surfactant entering the interface from the fluid bulk.

(d) The equation that governs the fluid layer interface location $h(\theta, t)$ is

$$\frac{\partial E}{\partial t} + \mathbf{u} \cdot \nabla E = 0, \tag{4}$$

where $E = r - R(t) + h(\theta, t) = 0$, $\mathbf{n} = \nabla E / |\nabla E|$, and the time derivative is taken for r and θ held fixed.

Assuming that the problem is axisymmetric, (1)–(4) constitute an appropriate set of equations for the five unknown fields p, γ and h, u_r, and u_θ. The latter fields are subject to the following boundary conditions:

$$u_r = \dot{R} - \frac{\lambda_b \overline{R} \hat{U}(t)}{T}, \quad u_\theta = 0, \qquad r = R(t), \tag{5a,b}$$

$$\text{(6a,b)} \qquad \frac{\partial u_r}{\partial \theta} = 0, \quad u_\theta = 0, \qquad\qquad \theta = \pi,$$

$$\text{(7)} \qquad \mathbf{n} \cdot \boldsymbol{\tau} \cdot \mathbf{t} = \mathbf{t} \cdot \nabla \sigma, \qquad\qquad r = R - h,$$

$$\text{(8)} \qquad p - p_a - \mathbf{n} \cdot \boldsymbol{\tau} \cdot \mathbf{n} - \sigma \nabla \cdot \mathbf{n} = 0, \qquad\qquad r = R - h,$$

$$\text{(9)} \qquad \frac{\partial \gamma}{\partial \theta} = 0, \qquad\qquad \theta = \pi, \quad r = R - h,$$

$$\text{(10)} \qquad 2\pi r \sin(\theta_b) \left[\gamma u_\theta - \left(\frac{D}{r} \right) \frac{\partial \gamma}{\partial \theta} \right] = -\frac{\overline{m} \lambda_b}{T}, \qquad \theta = \theta_b, \quad r = R - h,$$

where σ stands for the surface tension at the surfactant layer, $\boldsymbol{\tau} = \mu[\nabla \mathbf{u} + (\nabla \mathbf{u})^T]$ is the viscous part of the stress tensor, and $\mathbf{t}$ stands for a unit vector tangential to the interface.

Equation (5a) accounts for the unknown velocity of lining fluid $U = \lambda_b \overline{R} \hat{U}(t)/T$ that is generated at the alveolus boundary and compensates for fluid leaving the alveolus every period. We made here the reasonable assumptions that the production rate scales with the amount of surfactants leaving the alveolus and that the fluid is generated uniformly at the alveolus wall. Equation (5b) is a manifestation of the no-slip condition imposed on the flow, (6a,b) and (9) result from the geometrical symmetry of the alveolus, and (7) represents the jump condition in the tangential component of the stress tensor due to surface tension gradients. Equation (8) considers the jump condition in the normal component of the stress tensor stemming from interface curvature, and (10) demonstrates that a given amount of surfactant leaves the alveolus during every breathing period. (That excess amount is produced at the alveolus wall and diffuses through the lining fluid toward the interface.)

To achieve closure of the problem, it seems that we need an additional boundary condition at $\theta = \theta_b$. However, for very thin fluid layers, lubrication theory applies, and such a condition is redundant. The initial conditions are

$$\text{(11)} \qquad h = \overline{h}, \qquad \gamma = \overline{\gamma},$$

where $\overline{h}$ and $\overline{\gamma}$ are constants and stand for the respective fluid layer thickness and surfactant concentration evaluated at time $t = \overline{t}$ at which the alveolar radius R assumes the value $\overline{R}$.

It shall be demonstrated that a periodic solution is readily obtained for any physical values of $\overline{h}$ and $\overline{\gamma}$. A specific set of initial conditions is required to initiate the numerical scheme but is of no consequence in the final periodic solution. For the sake of convenience, we shall assume that $\overline{t} = 0$.

Based upon experimental observations (Philips and Chapman [21]), a constitutive equation $\sigma = \sigma(\gamma)$ was suggested by Gradon and Podgorski [11], which correlates surface tension to the concentration of DPPC (diacylphosphatidylcholine). The correlation function (Figure 2(b)) includes two smooth regions and a dividing point (A) at which the function is not differentiable. The latter fact results in an aphysical, discontinuous velocity solution near the dividing point. To circumvent this difficulty, we employ a smooth, natural, cubic spline interpolation function that matches well with the Podgorski and Gradon [22] data outside A, predicts a slightly higher value near A, and is differentiable everywhere (see Figure 2(b)).

To render the differential equations and boundary conditions dimensionless, we define the following dimensionless variables (denoted henceforth with a caret symbol):

$$\hat{y} = \frac{(R-r)}{\overline{h}}, \qquad \hat{t} = \frac{t}{T}, \qquad \hat{\nabla}_s = \overline{R}\nabla_s, \qquad \hat{R} = \frac{R(\hat{t})}{\overline{R}},$$

$$\hat{u}_y = \frac{(\dot{R}-u_r)T}{\overline{h}}, \qquad \hat{\sigma} = \frac{\sigma}{\overline{\sigma}}, \qquad \hat{u}_\theta = \frac{u_\theta T}{\overline{R}}, \tag{12}$$

$$\hat{p} = \frac{(p_a-p)\overline{R}}{\overline{\sigma}}, \qquad \hat{\gamma} = \frac{\gamma}{\overline{\gamma}}, \qquad \hat{h} = \frac{h}{\overline{h}}.$$

Substituting (12) into (1)–(11) yields an equivalent set of dimensionless equations and boundary conditions, where the dimensionless unknowns depend on the independent variables $\hat{y}$, θ, $\hat{t}$ and parameters λ_b, λ_{ec}, ε, P_e, C_a, θ_b. Here $\varepsilon = \overline{h}/\overline{R} = 3 \times 10^{-4}$ is the lining fluid depth ratio, $P_e = \overline{R}^2/DT = 64$ stands for the Peclet number, and $C_a = \mu\overline{u}_\theta/\overline{\sigma} = 4.8 \times 10^{-11}$ is the capillary number. Equations (1)–(4) are highly nonlinear and couple the velocity field with surfactant concentration and the location of the interface. In the next chapter, we employ an asymptotic expansion in the two smallness parameters λ_b, ε, which makes it possible to solve the problem semianalytically.

4. The asymptotic formulation. A possible clue for a coherent asymptotic representation of the unknown functions is that the cleansing mechanism results from the generation of an excess amount of surfactant determined by λ_b, a parameter that plays a paramount role in the solution. The value of λ_b is of the order of 10^{-5}; thus gradients in surface tension driving the flow are expected to be very small, albeit not zero, resulting in a nonzero small tangential velocity. Had λ_b vanished, the lining fluid would have remained inside the alveolus at all times, covered the alveolus wall uniformly, and grown thicker during exhalation and thinner during inhalation to conserve mass. In this case, the unknown functions h, γ, σ, p, and $\mathbf{u}$ would have been radially symmetric, i.e., depended upon t but not upon θ. Consequently, the following regular asymptotic expansions in λ_b and ε are suggested:

$$\hat{u}_y = \overset{0}{u}_y\,(\hat{y},\hat{t};\varepsilon) + \lambda_b[\hat{U}_y(\hat{y},\theta,\hat{t}) + \varepsilon\hat{U}_y^{(1)}(\hat{y},\theta,\hat{t}) + \cdots] + O(\lambda_b^2), \tag{13a}$$

$$\hat{u}_\theta = \lambda_b[\hat{U}_\theta(\hat{y},\theta,\hat{t}) + \varepsilon\hat{U}_\theta^{(1)}(\hat{y},\theta,\hat{t}) + \cdots] + O(\lambda_b^2), \tag{13b}$$

$$\hat{h} = \overset{0}{h}\,(\hat{t};\varepsilon) + \lambda_b[\hat{H}(\theta,\hat{t}) + \varepsilon\hat{H}^{(1)}(\theta,\hat{t}) + \cdots] + O(\lambda_b^2), \tag{13c}$$

$$\hat{\gamma} = \overset{0}{\gamma}\,(\hat{t};\varepsilon) + \lambda_b[\hat{\Gamma}(\theta,\hat{t}) + \varepsilon\hat{\Gamma}^{(1)}(\theta,\hat{t}) + \cdots] + O(\lambda_b^2), \tag{13d}$$

$$\hat{\sigma} = \overset{0}{\sigma}\,(\hat{t};\varepsilon) + \lambda_b[\hat{\Sigma}(\theta,\hat{t}) + \varepsilon\hat{\Sigma}^{(1)}(\theta,\hat{t}) + \cdots] + O(\lambda_b^2), \tag{13e}$$

$$\hat{p} = \overset{0}{p}\,(\hat{t};\varepsilon) + \lambda_b[\hat{P}(\theta,\hat{t}) + \varepsilon\hat{P}^{(1)}(\theta,\hat{t}) + \cdots] + O(\lambda_b^2). \tag{13f}$$

Here, the naught symbol denotes the radially symmetric solution, and uppercase symbols are used to denote asymptotic, first order fields in λ_b. Notice that the leading term $\overset{0}{u}_\theta$ vanishes identically in expansion (13b); i.e., a tangential velocity component stems solely from excess production of surfactant (see also section 3).

Henceforth, we shall focus our attention on the first two terms in the foregoing expansions and neglect the contribution of the third, order $O(\lambda_b\varepsilon)$, much smaller term. Substituting (13) into the dimensionless form of (1)–(11) and collecting the zero and first order terms in λ_b results in two respective sets of dimensionless differential equations and boundary conditions.

4.1. The zero order approximation. For the zero order, radially symmetric fields, the equations are as follows:
the continuity equation,

$$\frac{\partial}{\partial\hat{y}}\left[(\hat{R}-\varepsilon\hat{y})^2\left(\frac{d\hat{R}}{d\hat{t}}-\varepsilon\overset{0}{u}_y\right)\right]=0, \tag{14a}$$

the radial momentum equation,

$$\frac{1}{(\hat{R}-\varepsilon\hat{y})^2}\left\{\frac{\partial}{\partial\hat{y}}\left[(\hat{R}-\varepsilon\hat{y})^2\frac{\partial\overset{0}{u}_y}{\partial\hat{y}}\right]+2\varepsilon\left(\frac{d\hat{R}}{d\hat{t}}-\varepsilon\overset{0}{u}_y\right)\right\}=-\left(\frac{\overline{T}\overline{\sigma}}{\mu\overline{R}}\right)\frac{\partial\overset{0}{p}}{\partial\hat{y}}, \tag{14b}$$

the mass conservation equation of surfactants,

$$\frac{\partial\overset{0}{\gamma}}{\partial\hat{t}}-\overset{0}{\gamma}\left.\frac{\partial\overset{0}{u}_y}{\partial\hat{y}}\right|_{\hat{y}=\overset{0}{h}}=\frac{1}{(\hat{R}-\varepsilon\overset{0}{h})^2}\lambda_{ec}\sin(2\pi\hat{t}), \tag{14c}$$

and the kinematic condition for interface location,

$$\frac{\partial\overset{0}{h}}{\partial\hat{t}}=\left.\overset{0}{u}_y\right|_{\hat{y}=\overset{0}{h}}. \tag{14d}$$

The appropriate boundary conditions are

$$\overset{0}{u}_y=0,\qquad \hat{y}=0, \tag{15a}$$

$$\overset{0}{p}=\frac{2\overset{0}{\sigma}}{(\hat{R}-\varepsilon\overset{0}{h})},\qquad \hat{y}=\overset{0}{h}. \tag{15b}$$

The initial conditions are replaced by the requirement that the solution be periodic.

Notice that the foregoing equations are not expanded with respect to ε, since, as shall be demonstrated in the next section, an exact solution of (14) is feasible for any value of ε.

4.2. The first order approximation. Substituting (13) into (1)–(10) and collecting first order terms in λ_b yields the following set of equations and boundary conditions:
the continuity equation,

$$\hat{R}\frac{\partial}{\partial\hat{y}}\hat{U}_y+\frac{\partial}{\partial\theta}\hat{U}_\theta+\cot(\theta)\hat{U}_\theta=0, \tag{16a}$$

the momentum equation in the radial direction,

$$\frac{\partial \hat{P}}{\partial \hat{y}} = 0, \tag{16b}$$

the momentum equation in the tangential direction,

$$\frac{\partial^2 \hat{U}_\theta}{\partial \hat{y}^2} = 0, \tag{16c}$$

the mass conservation equation of surfactants,

$$\hat{R}^2 \frac{\partial \hat{\Gamma}}{\partial \hat{t}} + 2\hat{R}\hat{\Gamma}\frac{d\hat{R}}{d\hat{t}} - \frac{\partial \hat{U}_y}{\partial \hat{y}} - \frac{1}{P_e}\left[\frac{\partial^2 \hat{\Gamma}}{\partial \theta^2} + \cot(\theta)\frac{\partial \hat{\Gamma}}{\partial \theta}\right] = 1, \tag{16d}$$

and the kinematic condition for interface location,

$$\frac{\partial \hat{H}}{\partial \hat{t}} = [\hat{U}_y]_{\hat{y}=\overset{0}{h}}. \tag{16e}$$

Notice that time derivatives in (16d,e) are carried out for y and θ held fixed. The appropriate boundary conditions are

$$\hat{U}_y = \hat{U}, \qquad \hat{y} = 0, \tag{17a}$$

$$\hat{U}_\theta = 0, \qquad \hat{y} = 0, \tag{17b}$$

$$\frac{\partial \hat{\Gamma}}{\partial \theta} = 0, \qquad \theta = \pi, \tag{17c}$$

$$\frac{\partial \hat{U}_y}{\partial \theta} = 0, \qquad \theta = \pi, \tag{17d}$$

$$\hat{U}_\theta = 0, \qquad \theta = \pi, \tag{17e}$$

$$\overline{C}_a^{-1}\frac{\partial \hat{\Sigma}}{\partial \theta} - \hat{R}\frac{\partial \hat{U}_\theta}{\partial \hat{y}} = 0, \qquad \hat{y} = \frac{1}{\hat{R}^2}, \tag{17f}$$

$$\hat{P} = 0, \qquad \hat{y} = \frac{1}{\hat{R}^2}, \tag{17g}$$

$$\hat{R}\left[\overset{0}{\gamma}\hat{U}_\theta - \frac{1}{P_e\hat{R}}\frac{\partial \hat{\Gamma}}{\partial \theta}\right] = -\cot\left(\frac{\theta_b}{2}\right), \qquad \theta = \theta_b,\ r = R - h, \tag{17h}$$

where $\overline{C}_a = \frac{\mu \overline{R}/T}{\overline{\sigma}}\frac{\overline{R}}{\overline{h}} = 0.0614$ is the modified capillary number whose inverse scales the Marangoni effect. Notice that $\overline{C}_a$ is the governing capillary number that results from the balance between the shear forces and the surface tension gradients at the interface (17f). A velocity scale defined by $\overline{R}/T$ would be improper since it governs the zero order radially symmetric fields.

In the next section, solutions for the zero and first order approximation fields are addressed.

5. The solution of the zero and first order perturbations.

5.1. The zero order, radially symmetric solution. The exact solutions for the radially symmetric fields (14a–d) are[1]

$$\overset{0}{u}_y = \frac{1}{\varepsilon}\frac{d\hat{R}}{d\hat{t}}\left(1 - \frac{\hat{R}^2}{(\hat{R}-\varepsilon\hat{y})^2}\right) = -2\frac{\hat{y}}{\hat{R}}\frac{d\hat{R}}{d\hat{t}} + O(\varepsilon), \tag{18a}$$

$$\overset{0}{p} = \frac{2\hat{\sigma}(\overset{0}{\gamma})}{(\hat{R}-\varepsilon\overset{0}{h})}, \tag{18b}$$

$$\overset{0}{h} = \frac{1}{\varepsilon}[\hat{R} - (\hat{R}^3 - 1 + (1-\varepsilon)^3)^{1/3}] = \frac{1}{\hat{R}^2} + O(\varepsilon), \tag{18c}$$

$$\overset{0}{\gamma} = \frac{(1-\varepsilon)^2}{(\hat{R}-\varepsilon\overset{0}{h})^2}\left(1 - \frac{\lambda_{ec}}{2\pi}\cos\left[2\pi\left(\hat{t} - \frac{\bar{t}}{T}\right)\right]\right) = \frac{1}{\hat{R}^2} + O(\lambda_{ec}) + O(\varepsilon). \tag{18d}$$

Notice that the radially symmetric pressure is uniform across the lining layer and that for small values of ε the leading terms of the radially symmetric solutions are of order unity.

5.2. The first order perturbation in $\boldsymbol{\lambda_b}$. The solution of (16a–e)–(17a–h) is divided into two consecutive steps. First, an analytic expression is obtained for the velocity $\hat{U}_\theta$, which is substituted into (16d). A numerical scheme is then employed, in which a finite-element method is utilized along θ and a finite difference predictor-corrector method is employed along t to solve the transformed equation (16d).

Integrating (17f) and (16c) and employing boundary condition (17b) yields

$$\hat{U}_\theta = \hat{W}(\theta,\hat{t})\hat{y}. \tag{19a}$$

From (16d), the unknown function $\hat{W}(\theta,\hat{t})$ can easily be determined in terms of $\hat{\Sigma}$ or $\hat{\Gamma}$:

$$\hat{W}(\theta,t) = \frac{\overline{C}_a^{-1}}{\hat{R}}\frac{\partial\hat{\Sigma}}{\partial\theta} = \frac{\overline{C}_a^{-1}}{\hat{R}}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2}\frac{\partial\hat{\Gamma}}{\partial\theta}. \tag{19b}$$

The latter equality stems from the known constitutive relation between surface tension and surfactant concentration.

Introducing (16a) into (16d) and employing (19a) and (19b) yields the second order partial differential equation in $\hat{\Gamma}$,

$$\frac{\partial(\hat{R}^2\hat{\Gamma})}{\partial\hat{t}} + \left[\frac{\overline{C}_a^{-1}}{\hat{R}^4}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2} - \frac{1}{P_e}\right]\left[\frac{\partial^2\hat{\Gamma}}{\partial\theta^2} + \cot(\theta)\frac{\partial\hat{\Gamma}}{\partial\theta}\right] = 1, \tag{20a}$$

subject to the boundary conditions

$$\frac{\partial\hat{\Gamma}}{\partial\theta} = 0, \qquad \theta = \pi, \tag{20b}$$

[1] An easy route to obtaining the exact solutions is to consider the problem from a global point of view in which the total fluid and surfactant mass during breathing is conserved.

$$\left(\frac{\overline{C}_a^{-1}}{\hat{R}^4}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2} - \frac{1}{P_e}\right)\frac{\partial\hat{\Gamma}}{\partial\theta} = -\cot\left(\frac{\theta_b}{2}\right), \qquad \theta=\theta_b, \tag{20c}$$

and the initial condition

$$\hat{\Gamma} = 0. \tag{20d}$$

Notice that since $\partial\hat{\sigma}/\partial\hat{\gamma}$ is invariably negative, (20a) possesses the form of a diffusion equation with an effective time dependent diffusion coefficient that is always positive.

To simplify the finite-element formulation of the problem, we rewrite (20a) and (20c):

$$A(\hat{t})\frac{\partial\hat{\Gamma}}{\partial\hat{t}} + B(\hat{t})\hat{\Gamma} + C(\hat{t})\left(\frac{\partial^2}{\partial\theta^2}\hat{\Gamma} + \cot(\theta)\frac{\partial\hat{\Gamma}}{\partial\theta}\right) = 1, \qquad \pi<\theta<\theta_b, \tag{21a}$$

$$\frac{\partial\hat{\Gamma}}{\partial\theta} = G(\hat{t}), \qquad \theta=\theta_b, \tag{21b}$$

where

$$\begin{aligned} A(\hat{t}) &= \hat{R}^2, \\ B(\hat{t}) &= 2\hat{R}\frac{d\hat{R}}{d\hat{t}}, \\ C(\hat{t}) &= \frac{\overline{C}_a^{-1}}{\hat{R}^4}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2} - \frac{1}{P_e}, \\ G(\hat{t}) &= -\left(\frac{\overline{C}_a^{-1}}{\hat{R}^4}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2} - \frac{1}{P_e}\right)^{-1}\cot\left(\frac{\theta_b}{2}\right). \end{aligned} \tag{21c}$$

The equation governing the deviation of the interface from its spherical shape $\hat{H}$ is obtained from (16a,e) and (19a,b),

$$\frac{\partial\hat{H}}{\partial\hat{t}} = \frac{\hat{U}}{\hat{R}} - \frac{\overline{C}_a^{-1}}{2\hat{R}^6}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2}\left(\frac{\partial^2\hat{\Gamma}}{\partial\theta^2} + \cot(\theta)\frac{\partial\hat{\Gamma}}{\partial\theta}\right). \tag{22}$$

Little is known about the spatial distribution and the time evolution of $\hat{U}$. A global mass-conservation requires that the amount of fluid generated at the alveolus wall equal the amount exiting the alveolus during a single breathing period. Consequently,

$$\int_0^T\left(2\pi R\sin(\theta_b)\int_0^h u_\theta dy\right)dt = \lambda_b\frac{\overline{R}}{T}\int 2\pi R^2[1+\cos(\theta_b)]\hat{U}dt. \tag{23}$$

Substituting (19a,b) into (23) yields

$$\int_0^1 \hat{R}^2\hat{U}d\hat{t} = \frac{1}{2}\varepsilon\overline{C}_a^{-1}\tan\left(\frac{\theta_b}{2}\right)\int_0^1\frac{1}{\hat{R}^4}\frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2}\left[\frac{\partial\hat{\Gamma}}{\partial\theta}\right]_{\theta=\theta_b}dt. \tag{24}$$

Hence $\hat{U}$ is of order ε, and the second term in (22) determines the time evolution and spatial distribution of $\hat{H}$. Fortunately, the equations for $\hat{\Gamma}$ and $\hat{H}$ are decoupled, and we focus on solving $\hat{\Gamma}$, which makes it possible to predict the tangential velocity.

A weak form of the equation for $\hat{\Gamma}$ is obtained by integrating (21a) over the solution domain

$$\int_{\theta=\theta_b}^{\pi} w\left[A(\hat{t})\frac{\partial\hat{\Gamma}}{\partial\hat{t}}+B(\hat{t})\hat{\Gamma}+C(\hat{t})\left(\frac{\partial^2\hat{\Gamma}}{\partial\theta^2}+\cot(\theta)\frac{\partial\hat{\Gamma}}{\partial\theta}\right)-1\right]d\theta=0, \tag{25}$$

where w is any differentiable weighting function. Integrating (25) by parts and utilizing boundary conditions (20b) and (21b) yields

$$\begin{aligned}&\int_{\theta=\theta_b}^{\pi}\left\{w\left[A(\hat{t})\frac{\partial\hat{\Gamma}}{\partial\hat{t}}+B(\hat{t})\hat{\Gamma}+C(\hat{t})\cot(\theta)\frac{\partial\hat{\Gamma}}{\partial\theta}\right]-C(t)\frac{\partial w}{\partial\theta}\frac{\partial\hat{\Gamma}}{\partial\theta}\right\}d\theta\\&=\int_{\theta=\theta_b}^{\pi}wd\theta+w(\theta_b)C(\hat{t})G(\hat{t}).\end{aligned} \tag{26}$$

An element mesh is formed over the solution domain, and w and $\hat{\Gamma}$ are expanded in the following Galerkin sums (see, for example, [17]) for arbitrary c_A's:

$$\begin{aligned}w&=\sum_{A\in\Omega}c_AN_A(\theta),\\\hat{\Gamma}&=\sum_{B\in\Omega}d_B(\hat{t})N_B(\theta),\end{aligned} \tag{27}$$

where Ω denotes the nodes index group and N_A and N_B are the shape functions, $N_1(\theta)$ being the shape function of an element located at the alveolus opening. The unknown time dependent functions $d_B(\hat{t})$ are to be determined as follows. Substituting (27) into (26) yields

$$\begin{aligned}&\sum_{B\in\Omega}\frac{d}{d\hat{t}}d_B\int_{\theta=\theta_b}^{\pi}N_AA(\hat{t})N_Bd\theta\\&\quad+\sum_{B\in\Omega}d_B\int_{\theta=\theta_b}^{\pi}\left\{\begin{array}{l}N_AB(\hat{t})N_B+N_AC(\hat{t})\cot(\theta)\dfrac{dN_B}{d\theta}\\[2ex]-C(\hat{t})\dfrac{dN_A}{d\theta}\dfrac{dN_B}{d\theta}\end{array}\right\}d\theta\\&\quad=\int_{\theta=\theta_b}^{\pi}N_Ad\theta+N_1(\theta_b)C(\hat{t})G(\hat{t}).\end{aligned} \tag{28}$$

Thus (28) possesses the form

$$M\frac{d}{d\hat{t}}d(\hat{t})+Kd(\hat{t})=V, \tag{29}$$

where d is a vector consisting of the unknown functions $d_A(A\in\Omega)$, M and K are

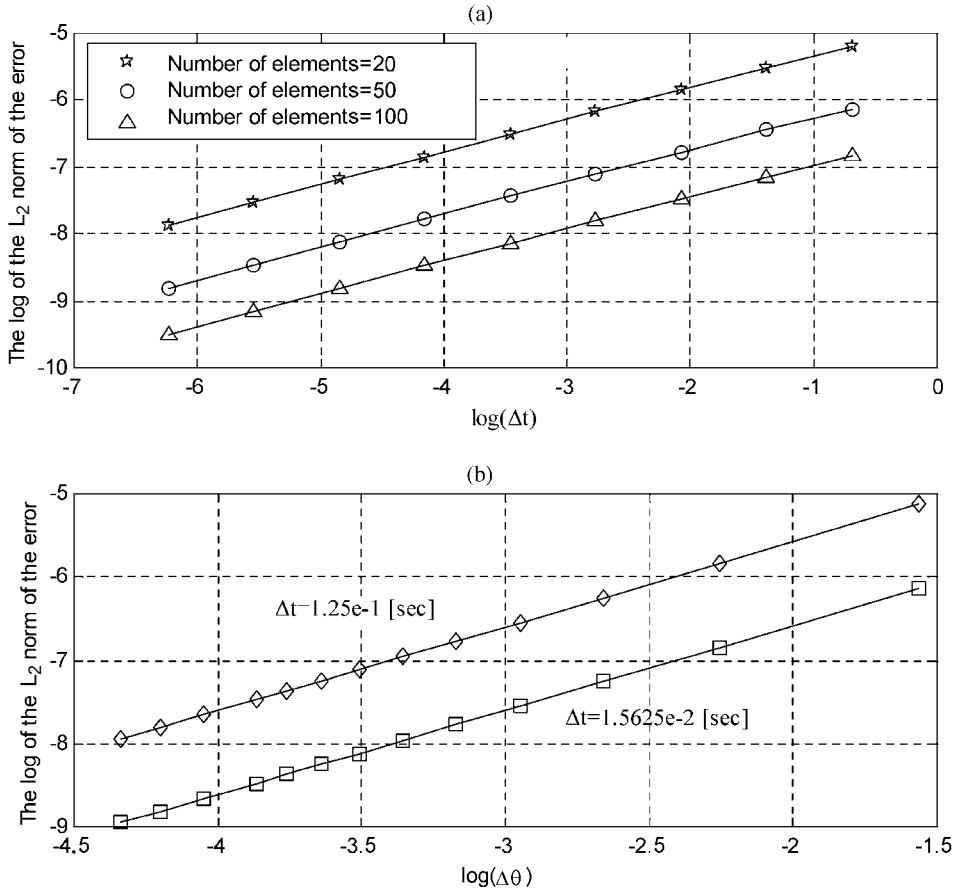

FIG. 3. *Error evaluation for various* (a) *mesh-sizes,* (b) *time-steps. The error is defined by the equation* $L\Gamma_{\text{calculated}} = \text{error}$*, where* L *is the differential operator defined in* (21a).

coefficient matrices, and V is a vector defined as follows:

$$
\begin{aligned}
M_{AB} &= \int_{\theta=\theta_b}^{\pi} N_A A(\hat{t}) N_B d\theta, \\
K_{AB} &= \int_{\theta=\theta_b}^{\pi} \left\{ N_A B(\hat{t}) N_B + N_A C(\hat{t}) \cot(\theta) \frac{dN_B}{d\theta} - C(t) \frac{dN_A}{d\theta} \frac{dN_B}{d\theta} \right\} d\theta, \\
V_A &= \int_{\theta=\theta_b}^{\pi} N_A d\theta + N_1(\theta_b) C(\hat{t}) G(\hat{t}).
\end{aligned} \tag{30}
$$

Choosing linear shape functions N_A, the matrices $M = [M_{AB}]$, $K = [K_{AB}]$ and the vector $V = [V_A]$ can be numerically calculated.

The time evolution equation (29) is numerically solved by a predictor-corrector code. Convergence and error properties of the numerical scheme, the time evolution of the surfactant distribution, the tangential velocities, and the effect of varying the phenomenological parameters are all addressed in the next section.

6. Results. We examined the convergence and accuracy of the numerical scheme; the results are illustrated in Figures 3–5. An L_2 norm was utilized to evaluate errors

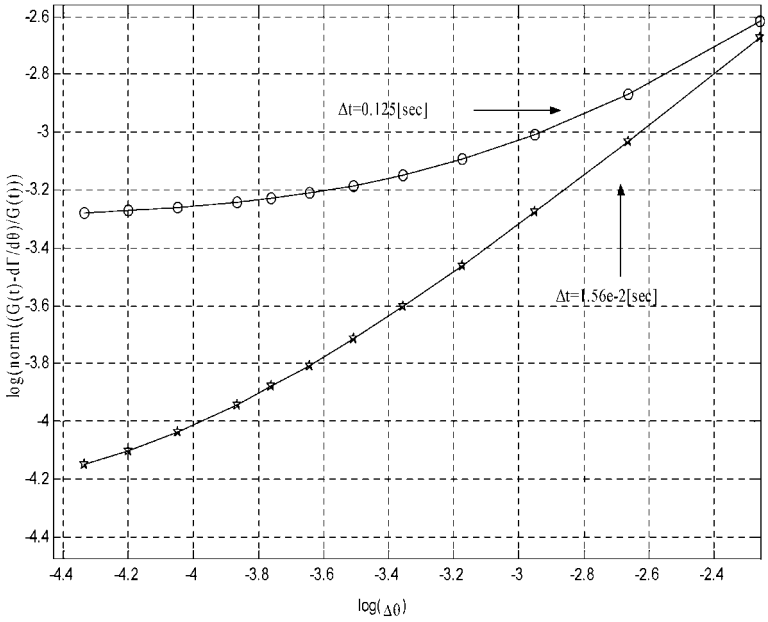

FIG. 4. *The relative error between the calculated derivative* $\partial\Gamma/\partial\theta$ *at* θ_b *and its known exact value from boundary conditions* (21b,c).

in the solution for $\hat{\Gamma}$. To that end, we used the parameter values defined in Table 1; the solution domain was defined by $\pi/3 \leq \theta \leq \pi$; and comparisons were made for the time interval $16 \leq t \leq 20$ sec. The chosen time span, the fifth breathing cycle, was picked to avoid transient effects that may exist at earlier times and are affected by the particular choice of initial conditions. The calculations were repeated for refined time-steps and elements in the θ-direction. We tested grids having 10 to 160 elements in the θ-direction, and time-step sizes ranging between 0.5 sec and $1.95 \cdot 10^{-3}$ sec. The results are summarized in Figure 3, which demonstrates that the estimated error decreases for both time and grid refinements. The best error estimate can be achieved at the boundaries, where a comparison can easily be made between known exact values of the derivatives of $\hat{\Gamma}$ and the respective numerical predictions (see Figure 4). The figure makes clear that the error decreases monotonically with reduced values of time-steps and increased number of elements.

To evaluate the convergence rate of the solution, an L_2 norm was also calculated for the difference between consecutive refined solutions (see Figure 5(a,b)). The figures illustrate vividly that convergence is achieved even for high values of time-steps (of order 0.1) and a small number of elements (of order 20).

Since the solution is approximated up to order ε, no greater precision than 10^{-4} is required. Consequently, from Figures 3–5, a time-step size of 0.015 sec was selected, and the θ-domain was divided into 100 elements, a parameter set that yields a converging solution with an estimated absolute error of order ε or less.

The time evolution of the surfactants and velocity fields is illustrated in Figures 6–10. Since $R(t)$ is a periodic function and, consequently, the time dependent coefficients

of (20a–d) are periodic, we expect a periodic steady-state solution to the problem. Indeed, Figure 6 demonstrates that $\hat{\Gamma}$ reaches a steady state after a short transient period of less than a single breathing cycle.

During every breathing period, $\hat{\Gamma}$ (at θ_b) possesses a two-peak pattern (see Figures 7 and 8). We use, henceforth, the dimensional form of $\hat{\Gamma}$, namely, $\Gamma = \lambda_b \overline{\gamma} \hat{\Gamma}$, to describe the small perturbation in surfactant concentration. The peaks occur during inhalation and exhalation when the derivative of the surface tension with respect to surfactant concentration varies abruptly as γ crosses point A in Figure 2(b) (see Figure 9). The value of Γ remains negative throughout the breathing process. Thus, the total surfactant concentration $\gamma = \overline{\gamma} \overset{0}{\gamma} + \Gamma$ is lower than its radially symmetric concentration $\overline{\gamma} \overset{0}{\gamma}$. This is reflected in a higher than average surface tension at θ_b and a net fluid motion toward the alveolar edge. The latter conclusion is also illustrated in Figure 10, in which the time dependence of the tangential velocity at the interface is depicted. Notice that a negative value for u_θ means a flow direction toward the alveolar edge (Figure 1). It demonstrates that the velocity is a time-periodic function that possesses a negative mean; namely, there is a net flow exiting the alveolus.

Figures 11 and 12 illustrate a smooth spatial distribution of Γ and u_θ for various values of θ_b. Figure 11 validates the former conclusion that surfactant concentration is lowest (surface tension is highest) at θ_b, namely, fluid is drawn toward the alveolar edge. Figure 12 illustrates that the tangential velocity increases (in absolute value) as

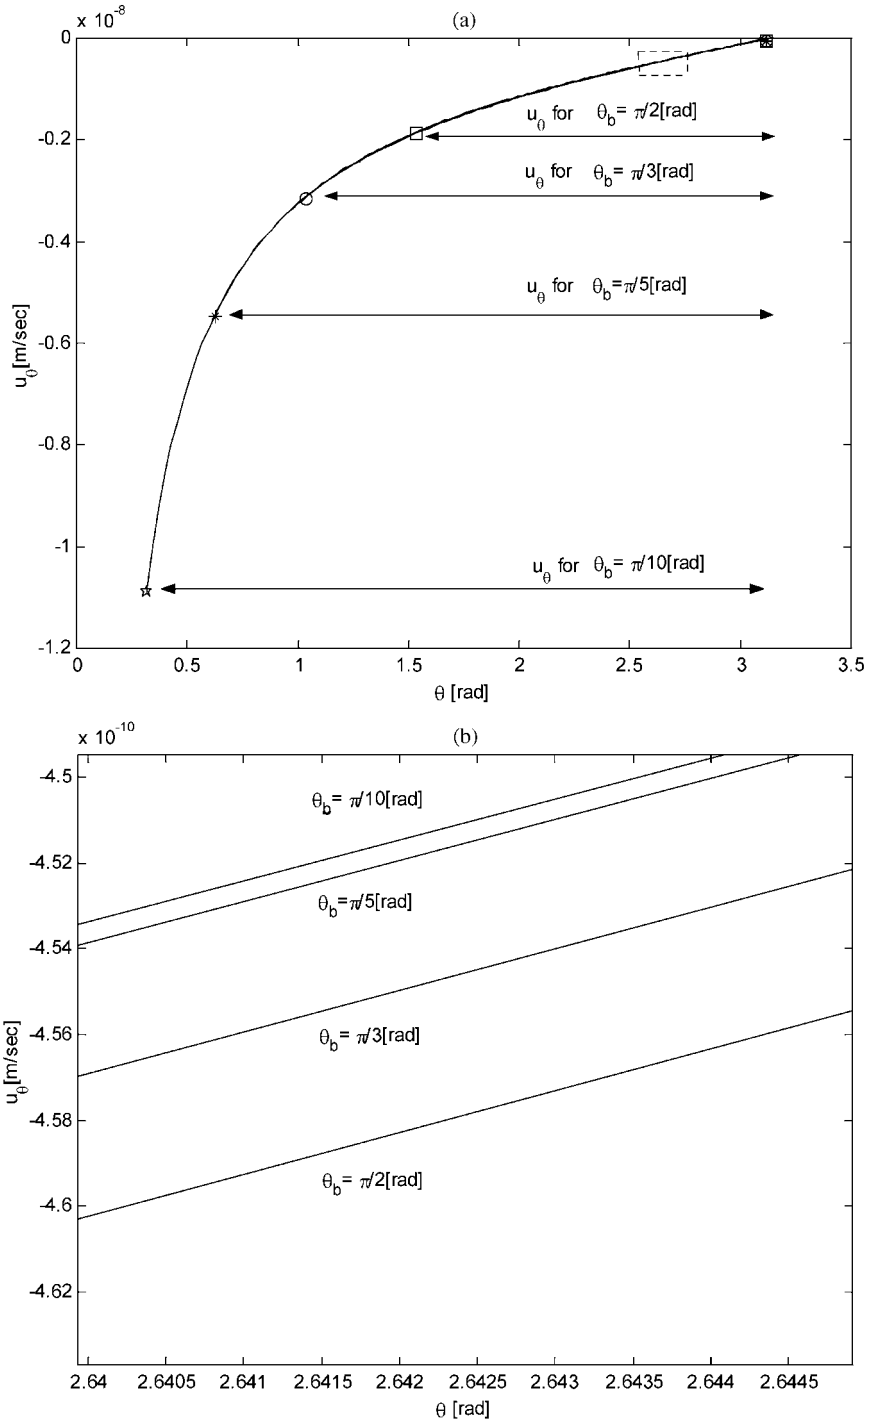

FIG. 12. (a) *The spatial distribution of the tangential velocity for various values of* θ_b. (b) *A blowup of the dotted small rectangle shown in* (a) *that manifests the small contribution of the angle* θ_b.

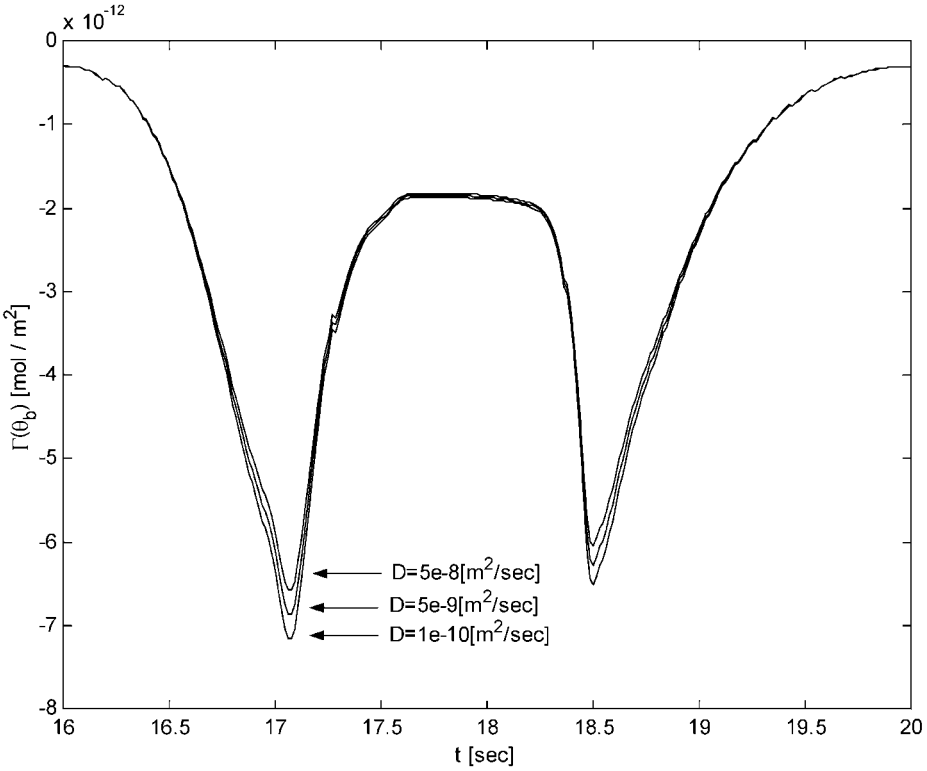

FIG. 13. *The temporal evolution of surfactant concentration* Γ *at* θ_b *for various values of the diffusion coefficient* D.

θ gets closer to θ_b. This result is consistent with the assumption that the fluid excess is generated uniformly at the alveolar surface.

The surfactant concentration and the tangential velocity dependence upon θ and θ_b are also illustrated in Figures 11 and 12, respectively. Figure 11 illustrates that $\gamma = \overline{\gamma} \overset{0}{\gamma} + \Gamma$ decreases and the surfactant concentration gradient increases as θ_b decreases. Hence, smaller values of θ_b yield a nonlinear increase in the magnitude of u_θ at the alveolar rim. This result is not surprising since, from (17h), if the Peclet number is large, u_θ varies like $\cot(\theta_b/2)$. Figure 12 illustrates how u_θ increases (in absolute value) as we approach the alveolar rim. It also illustrates that different values of θ_b result in almost identical values of u_θ, namely, all lines seem to collapse into a single graph within their mutual domain. However, a blowout of a small domain (shown by a small rectangle in the upper right corner of Figure 12) indicates that small deviations do exist between different values of θ_b (Figure 12(a)), with slightly smaller values of u_θ for smaller θ_b's.

The effect of the Peclet number upon surfactant distribution and the tangential velocity field is summarized in Figures 13–14. Figure 13 illustrates a double peaked pattern that results from the abrupt change in surface tension gradients at point A of Figure 2(b). Figure 14 illustrates dependence of u_θ upon time, with the highest (absolute) value occurring at the end of inhalation and the beginning of exhalation. Varying the diffusion coefficient has a minor effect on the results. This is not surprising since the Peclet number is quite high (Pe = 64) and the inverse of the capillary

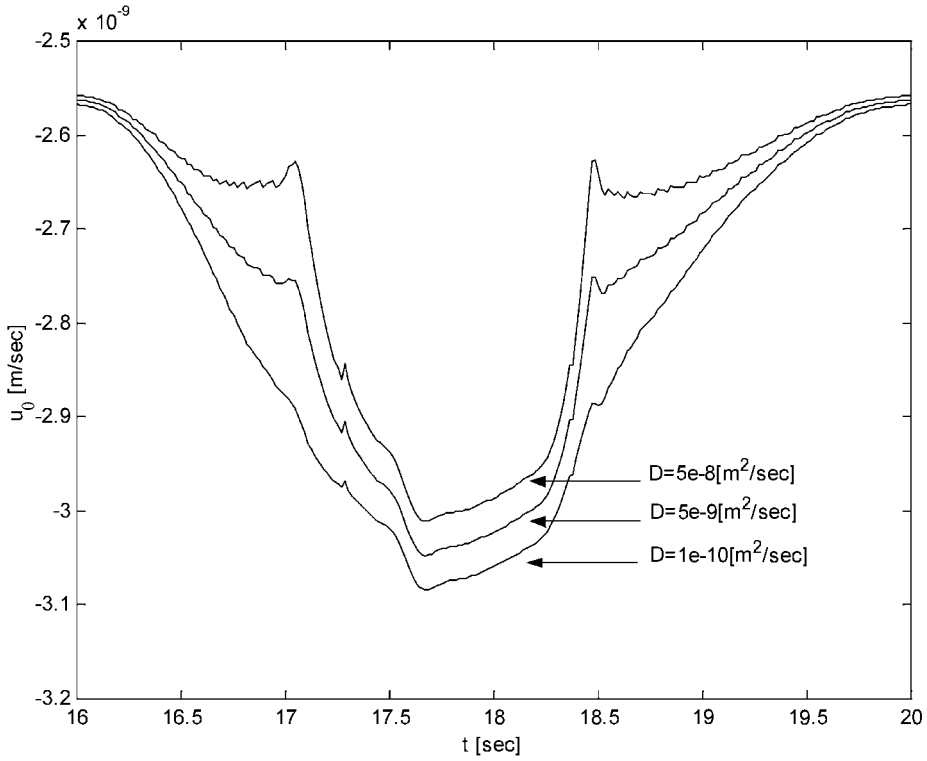

FIG. 14. *The temporal evolution of the tangential velocity U_θ at θ_b for various values of the diffusion coefficient D.*

number is about 16. A more significant effect would occur were D of the order of $D = 5 \times 10^{-8}$ m^2/sec, a much greater value than the estimated physical value of $D = 10^{-10}$ m^2/sec.

Finally, the surfactant production rate, λ_b, has a most significant effect on the tangential velocity. An increase in the production rate causes a concomitant increase in the tangential velocity.

7. Discussion and conclusions. The results in section 6 demonstrate that gradients in surfactant concentration at the lining layer interface induce tangential flow toward the alveolar edge (the Marangoni effect). Based upon experimental observations, we assumed that during every breathing cycle an excess amount of surfactant was secreted at the alveolus wall and removed to the adjacent airway. This excess amount is a given percentage of the existing average amount of surfactant that is embedded inside the lining layer. The removal of surfactants and the concomitant concentration gradients induce tangential flow inside the lining layer so that a small amount of the lining fluid exits the alveolus with a typical low rate on the order of 10^{-9} m/sec. The flow rate varies periodically with time and depends strongly upon how widely open the alveoli are. Pathologically wide cone angles θ_b result in a strong reduction in $\hat{U}_\theta$ and vice versa. However, since $u_\theta \sim \lambda_b \hat{U}_\theta$, the actual tangential velocity may either increase or decrease with θ_b. To make a rigorous conclusion, additional experimental evidence is required to correlate the flux of surfactant exiting the alveolus (proportional to λ_b) with the cone angle θ_b.

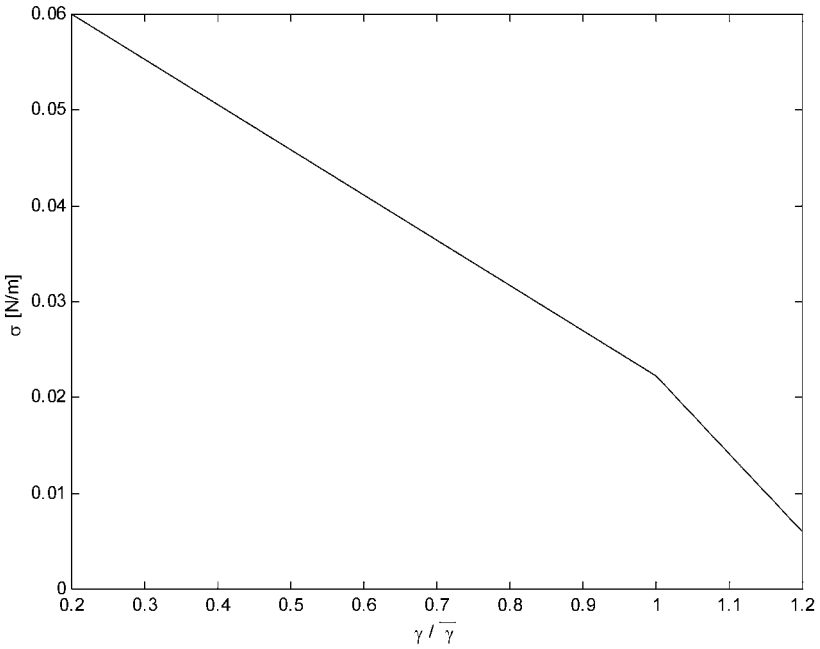

FIG. 15. *Surface tension dependency upon concentration of surfactant TA from Otis et al.* [19].

Particles that are deposited over the alveolus wall are subject to hydrodynamic drag and may be swept out of the alveolus due to the induced tangential velocity. The hydrodynamic cleansing rate is determined by particle velocity that, generally, need not be equal to the fluid velocity. However, the predicted fluid tangential velocity at the alveolar rim may provide a reasonable measure of the rate of hydrodynamic cleansing. With an average sweeping rate, it will take a particle about two days to move a distance equal to one alveolar radius, a very small rate indeed.

The effect of particle diffusion may add to the cleansing rate. However, this effect may be quite small. The diffusion coefficient of a particle 1μm in diameter in an *unbounded* lining flow field is $D_p = 3.8^{*}10^{-14}$ m^2/sec, based on the Stokes–Einstein equation. Thus, it seems that the time it takes a particle to travel a distance equal to one alveolar radius $R = 10^{-4}$m is of the order of $R^2/4D_p \sim 10^5$s, a value similar to the convection time. Notwithstanding this idea, Happel and Brenner [13] show that, due to the close proximity of the particle to the alveolar walls, the hydrodynamic drag coefficient can be several order of magnitudes higher than $6\pi\mu r_p$ (here r_p is the particle radius). Consequently, the value for the diffusion coefficient would be smaller and the resulting diffusion time longer.

We also tried to compare DPPC with an artificial surfactant TA (also known as Survanta; Ross Laboratories, Columbus, OH), widely used clinically to treat respiratory distress syndrome. From Otis et al. [19], a surfactant TA isotherm, relating the surface tension to surface concentration, is obtained (Figure 15) and approximated by two straight lines. Figures 16 and 17 illustrate the behavior of surfactant TA vis-à-vis DPPC, provided that their Peclet number is of similar order.[2] The time evolution of Γ differs markedly from that of DPPC; however, the calculated u_θ at θ_b is very similar.

[2]Note that synthetic surfactants do not undergo cellular secretion and adsorption. Thus, the results may depend on the time protocol by which TA is provided, but this is left for future work.

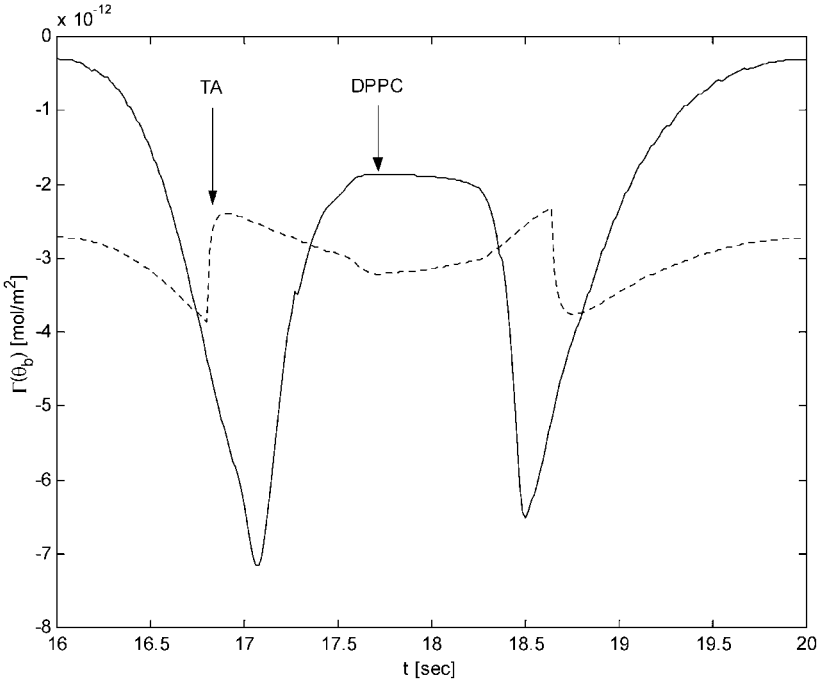

FIG. 16. *The temporal evolution of surfactant concentration* Γ *for DPPC and surfactant TA at* $\theta_b = \pi/3$.

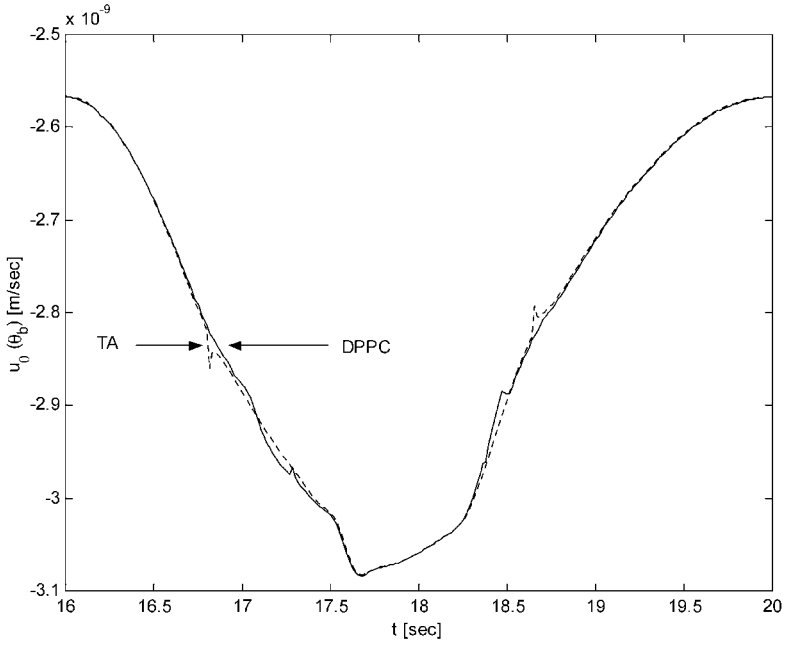

FIG. 17. *The temporal evolution of the tangential velocity for DPPC and surfactant TA at* $\theta_b = \pi/3$.

The small deviations stem from the discontinuity in $\partial\hat{\sigma}/\partial\hat{\gamma}$ assumed for surfactant TA. In fact, U_θ at θ_b should depend approximately linearly upon $\hat{R}$. Since, from (19a) and (19b), at $\hat{y} = 1/\hat{R}^2$ we obtain that

$$\hat{U}_\theta = \frac{\hat{W}}{\hat{R}^2} = \frac{\overline{C}_a^{-1}}{\hat{R}^3} \frac{\partial\hat{\sigma}}{\partial\hat{\gamma}}\bigg|_{\hat{\gamma}=1/\hat{R}^2} \frac{\partial\hat{\Gamma}}{\partial\theta},$$

consequently, at the alveolus edge $\theta = \theta_b$, for large Peclet numbers, boundary condition (21c) results in $\hat{U}_\theta|_{\theta=\theta_b} \sim -\hat{R}\cot(\theta_b/2)$. Thus, the major difference in the tangential velocity $u_\theta \sim \lambda_b \hat{U}_\theta$ between DPPC and surfactant TA stems from λ_b, provided that they possess similar diffusion coefficients.

In summary, a significant enhanced hydrodynamic cleansing can occur if the mechanism that keeps the surfactants from excessive accumulation or dilution functions over a wide range of surfactant concentrations. Notice that a very small deviation in surfactant concentration from the radially symmetric distribution is sufficient to induce flow in the lining layer. Thus, artificial stimulation of surfactant production at the alveolar wall tissue, or artificially administering a small excess amount of surfactant by inhalation, may result in an increased flow of surfactants exiting the alveoli and a concomitant sweeping flow of the lining layer. More research is required to investigate what the physiological mechanisms might be that cause surfactants to exit the alveolus and thereby determine/control the important parameter λ_b for various values of alveolus cone angle θ_b and surfactant composition. We hope that an artificial process can be devised and experimentally tested so that people exposed to a severe polluted environment could utilize the mechanism of enhanced hydrodynamic cleansing to reduce particle deposition of hazardous materials inside the lung alveoli.

Acknowledgments. The authors would like to thank Professor L. Gradon for his helpful explanations and Dr. A. Tsuda for illuminating discussions.

ASYMPTOTIC SOLUTION TO AN INVERSE PROBLEM FOR A SHARED UNBUFFERED RESOURCE*

JOHN A. MORRISON† AND K. G. RAMAKRISHNAN‡

Abstract. We consider an unbuffered resource having capacity C, which is shared by several different services. Calls of each service arrive in a Poisson stream and request a fixed, integral amount of capacity, which depends on the service. An arriving call is blocked and lost if there is not enough free capacity. Otherwise, the capacity of the call is held for the duration of the call, and the holding period is generally distributed. The inverse problem of determining the traffic intensities in terms of the measured values of the carried loads for each service is investigated. It is assumed that C and the traffic intensities are commensurately large. The inverse problem is solved asymptotically in the critically loaded regime, and it involves the unique real solution of a nonlinear equation. An iterative solution of this equation is shown to lead to a contraction mapping and to monotonic and geometric convergence. A separate analysis is given for the overloaded regime, and it is shown that the result matches asymptotically with that for the critically loaded regime. Numerical results are presented for two examples.

1. Introduction.

We consider an unbuffered resource having capacity C, which is shared by S different services. Calls of service s ($s = 1, 2, \ldots, S$) arrive in a Poisson stream with mean rate λ_s and request capacity d_s. An arriving call is blocked and lost if there is less than d_s free capacity. Otherwise, the call capacity d_s is held for the duration of the call, and the holding period is generally distributed with mean $1/\mu_s$ and independent of earlier arrival and holding times. The traffic intensity of calls of service s is $\nu_s = \lambda_s/\mu_s$, and the product form and the insensitivity property hold (see [4], [5], [7]); i.e., the joint stationary distribution of the number of active calls of each service depends on the distributions only through ν_s.

Let $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$ denote the loss probability for each service s, where $\mathbf{d} = (d_1, d_2, \ldots, d_S)$ and $\boldsymbol{\nu} = (\nu_1, \nu_2, \ldots, \nu_S)$. Then the carried loads are $Y_s = \nu_s[1 - \mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)]$, $s = 1, 2, \ldots, S$. Of practical importance is the inverse problem of determining the traffic intensities $\boldsymbol{\nu}$ from the measured values of the carried loads Y_s ($s = 1, 2, \ldots, S$). Once the traffic intensities are known, the loss probabilities are readily determined.

A particular application of such resource sharing is in telecommunication networks, where the provider wants to ensure that service level agreements with customers are met [1], [2]. Specifically, the loss probabilities should not exceed prescribed values. At the same time, the provider wants to verify that customers do not exceed agreed-upon peak traffic intensities.

The model considered above applies to each link of the network. The results for links influence the design of the network and the routing of traffic through the network, so as to optimize revenue while meeting the service level agreements with customers [11], [12], [13]. The model also applies in policing, shaping, access, and call admission control of customer traffic at the edge of the network [17].

In this paper we assume that the capacity C and the traffic intensities $\boldsymbol{\nu}$ are commensurately large and that C is an integer. We also assume that d_s $(s = 1, 2, \ldots, S)$ are positive integers, not large relative to C, and, without loss of generality, that the greatest common divisor of $d_1, \ldots, d_S$ is 1. There are three regimes in which the behavior of the loss probabilities differs. The resource is overloaded, critically loaded, or underloaded depending on whether the total traffic intensity $\sum_{s=1}^{S} d_s \nu_s$ exceeds, is close to, or is less than its capacity C, respectively.

In section 2 we consider the critically loaded regime in which $C - \sum_{s=1}^{S} d_s \nu_s = \delta\sqrt{C}$, where $\delta = O(1)$ may have either sign. The lowest order asymptotic approximation (see [3], [10], [16]) to $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$ implies that $\nu_s \sim Y_s(1 + d_s\beta/\sqrt{C})$, $s = 1, 2, \ldots, S$, where β is independent of s. Both δ and β are determined asymptotically in terms of Y_r $(r = 1, 2, \ldots, S)$, where $0 < C - \sum_{r=1}^{S} d_r Y_r = O(\sqrt{C})$, from the unique real solution of a nonlinear equation. This leads to a critically loaded asymptotic approximation (CLAA) to the traffic intensities. We then use a refined approximation to $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$, which is obtained by specializing the uniform asymptotic approximation [10] to the critically loaded regime. This leads to a refined critically loaded asymptotic approximation (RCLAA) to the traffic intensities.

In section 3 we present an iterative refinement procedure for solving the nonlinear equation and show that it leads to a contraction mapping and to monotonic and geometric convergence. We also establish the connection between our iterative refinement procedure and the one proposed by Mitra [9] for the case of general loading.

In section 4 we consider the overloaded regime in which $0 > C - \sum_{s=1}^{S} d_s \nu_s = O(C)$. It is shown that asymptotically $\nu_s \sim Y_s[(1 + \gamma)/\gamma]^{d_s}$, where $0 < \gamma = C - \sum_{r=1}^{S} d_r Y_r = O(1)$. It is also shown that this result matches asymptotically with those for the critically loaded regime for $\gamma \gg 1$ and $0 < \gamma/\sqrt{C} \ll 1$.

In section 5 we present numerical results for the two examples considered in [14]. We first compare the CLAA and the RCLAA to the traffic intensities with the exact results. We emphasize that both the CLAA and RCLAA are valid only in the critically loaded regime, and that the former uses $O(1)$ and $O(1/\sqrt{C})$ terms, while the latter also includes the $O(1/C)$ term in the expansion. The CLAA gives moderately accurate values in the critically loaded regime, but less so in the overloaded regime. On the other hand, the RCLAA gives quite accurate values in the critically loaded regime, and moderately accurate results in the overloaded regime. Overall, the RCLAA provides a significant improvement of the CLAA, with only minimal additional numerical computations. Both results do become quite accurate in the underloaded regime, since the loss probabilities, although not well approximated there by the CLAA or RCLAA, are exponentially small. We also present the results of some numerical experiments using the iterative procedure proposed by Mitra [9]. The number of iterations required to obtain the required accuracy increases significantly with the load.

The above asymptotic approximations may be applied to each link of a multirate loss network [11] to determine the reduced load offered to the link.

2. Critically loaded regime. In the critically loaded regime,

$$C - \sum_{s=1}^{S} d_s \nu_s = \delta\sqrt{C}, \tag{2.1}$$

where $C \gg 1$, $\nu_s = O(C)$, $s = 1, 2, \ldots, S$, and $\delta = O(1)$ may have either sign. In Appendix A we derive a refined asymptotic approximation to the loss probability $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$ for service s. The approximation is obtained by specializing the uniform asymptotic approximation [10] to the critically loaded regime.

Let

$$\sigma^2 C = 2\sum_{s=1}^{S} d_s^2 \nu_s, \quad \sigma > 0, \qquad \eta C = \sum_{s=1}^{S} d_s^3 \nu_s, \tag{2.2}$$

so that $\sigma = O(1)$ and $\eta = O(1)$, since $\nu_s = O(C)$, $s = 1, 2, \ldots, S$, and

$$\beta = \frac{2e^{-(\delta/\sigma)^2}}{\sigma\sqrt{\pi}\,\mathrm{Erfc}\,(-\delta/\sigma)}, \tag{2.3}$$

where the complementary error function is given by

$$\mathrm{Erfc}\,(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-u^2}\, du\,. \tag{2.4}$$

Then, asymptotically,

$$\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C) \sim \frac{d_s\beta}{\sqrt{C}} \left\{ 1 + \frac{\delta}{\sigma^2\sqrt{C}} \left[\frac{2\eta}{\sigma^2} \left(\frac{2\delta^2}{3\sigma^2} - 1 \right) + d_s - 1 \right] \right. \\ \left. - \frac{\beta}{2\sqrt{C}} \left[1 + \frac{2\eta}{3\sigma^2} \left(1 - \frac{2\delta^2}{\sigma^2} \right) \right] + \cdots \right\}. \tag{2.5}$$

Hence, asymptotically,

$$\begin{aligned} \nu_s &= \frac{Y_s}{[1 - \mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)]} \\ &\sim Y_s \left\{ 1 + \frac{d_s\beta}{\sqrt{C}} + \frac{d_s\beta\delta}{\sigma^2 C} \left[\frac{2\eta}{\sigma^2} \left(\frac{2\delta^2}{3\sigma^2} - 1 \right) + d_s - 1 \right] \right. \\ &\quad \left. - \frac{d_s\beta^2}{2C} \left[1 + \frac{2\eta}{3\sigma^2} \left(1 - \frac{2\delta^2}{\sigma^2} \right) \right] + \frac{d_s^2\beta^2}{C} + \cdots \right\}. \end{aligned} \tag{2.6}$$

We expand in powers of $1/\sqrt{C}$ and let

$$\delta \sim \delta_0 + \frac{\delta_1}{\sqrt{C}} + \cdots, \qquad \sigma \sim \sigma_0 + \frac{\sigma_1}{\sqrt{C}} + \cdots \tag{2.7}$$

and

$$\beta \sim \beta_0 + \frac{\beta_1}{\sqrt{C}} + \cdots, \qquad \eta \sim \eta_0 + \cdots. \tag{2.8}$$

Then, from (2.1)–(2.3) and (2.6), to lowest order,

$$\delta_0\sqrt{C} = C - \sum_{s=1}^{S} d_s Y_s - \frac{\beta_0}{\sqrt{C}} \sum_{s=1}^{S} d_s^2 Y_s, \tag{2.9}$$

$$\sigma_0^2 C = 2\sum_{s=1}^{S} d_s^2 Y_s, \quad \sigma_0 > 0, \qquad \eta_0 C = \sum_{s=1}^{S} d_s^3 Y_s, \tag{2.10}$$

and

$$\beta_0 = \frac{2e^{-(\delta_0/\sigma_0)^2}}{\sigma_0\sqrt{\pi}\,\mathrm{Erfc}\,(-\delta_0/\sigma_0)}\,. \tag{2.11}$$

If we divide (2.9) by $\sigma_0\sqrt{C}$ and use (2.10) and (2.11), we obtain

$$\frac{\delta_0}{\sigma_0} + \frac{e^{-(\delta_0/\sigma_0)^2}}{\sqrt{\pi}\,\mathrm{Erfc}\,(-\delta_0/\sigma_0)} = \frac{\left(C - \sum_{s=1}^{S} d_s Y_s\right)}{\sqrt{2\sum_{s=1}^{S} d_s^2 Y_s}}\,. \tag{2.12}$$

Intuitively, $\sum_{s=1}^{S} d_s Y_s < C$, i.e., the total carried capacity is less than that of the resource. We let

$$a \triangleq \frac{(C - \sum_{s=1}^{S} d_s Y_s)}{\sqrt{2\sum_{s=1}^{S} d_s^2 Y_s}} > 0 \tag{2.13}$$

and

$$g(x) = \frac{e^{-x^2}}{\sqrt{\pi}\,\mathrm{Erfc}\,(x)} - x. \tag{2.14}$$

To lowest order, the inverse problem is asymptotically equivalent to solving the equation $g(\xi) = a$ for $\xi = -\delta_0/\sigma_0$. Then, from (2.11)–(2.13),

$$\beta_0\sigma_0 = 2(\xi + a), \tag{2.15}$$

and, from (2.6) and (2.10), we obtain the first order asymptotic approximation to the traffic intensities ν_s in terms of the carried loads Y_s,

$$\nu_s \sim Y_s\left(1 + \frac{d_s\beta_0}{\sqrt{C}}\right) = Y_s\left[1 + \frac{2d_s(\xi + a)}{\sqrt{2\sum_{r=1}^{S} d_r^2 Y_r}}\right]. \tag{2.16}$$

We note, from (2.14), that $g(0) = 1/\sqrt{\pi}$. We show in Appendix B that $g(-\infty) = \infty$, $g(\infty) = 0$, and $g'(x) < 0$ for $x < \infty$. Hence, there is a unique real solution to $g(\xi) = a > 0$. Since $g(-a) > a$, it follows that $\xi > -a$. In Figure 2.1, $\xi + a$ is depicted as a function of a. Because of the monotonicity, the equation for ξ may be solved numerically by any simple procedure, such as bisection or iterative refinement. In the next section we present an iterative refinement procedure for solving the equation, which leads to a contraction mapping and to monotonic and geometric convergence. This is important, since Mitra [9] has conjectured that his

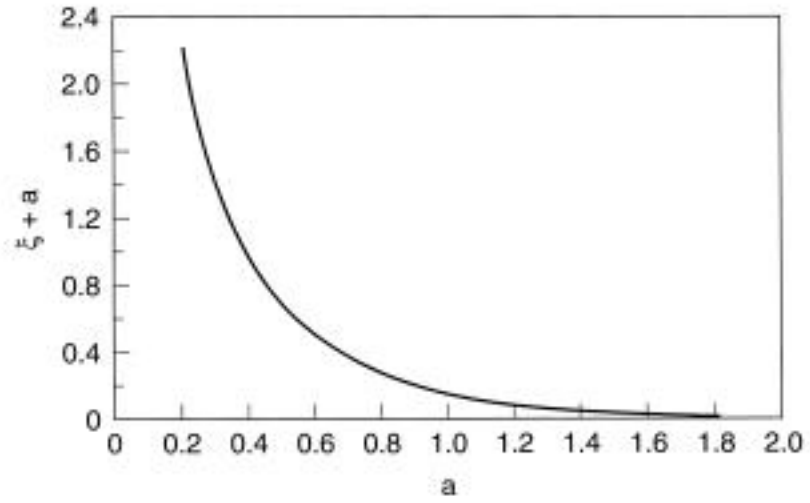

FIG. 2.1. *Plot of $\xi + a$ as a function of a, where $g(\xi) = a$.*

proposed iterative procedure, for the case of general loading, leads to a contraction mapping.

To the next order, from (2.6)–(2.8), we have

$$\nu_s \sim Y_s\left\{1 + d_s\left(\frac{\beta_0}{\sqrt{C}} + \frac{\beta_1}{C}\right) + \frac{d_s\beta_0\delta_0}{\sigma_0^2 C}\left[\frac{2\eta_0}{\sigma_0^2}\left(\frac{2\delta_0^2}{3\sigma_0^2} - 1\right) + d_s - 1\right]\right. \\ \left. - \frac{d_s\beta_0^2}{2C}\left[1 + \frac{2\eta_0}{3\sigma_0^2}\left(1 - \frac{2\delta_0^2}{\sigma_0^2}\right)\right] + \frac{d_s^2\beta_0^2}{C} + \cdots\right\}. \tag{2.17}$$

Hence, from (2.1), (2.9), and (2.10), we obtain

$$\delta_1 = -\frac{1}{2}\sigma_0^2\beta_1 + \frac{1}{2}\beta_0\delta_0 + \frac{1}{4}\beta_0^2\sigma_0^2 - \frac{1}{3}\beta_0\eta_0\left(\frac{5}{2}\beta_0 + \frac{\beta_0\delta_0^2}{\sigma_0^2} + \frac{2\delta_0^3}{\sigma_0^4}\right). \tag{2.18}$$

It follows that

$$\nu_s \sim Y_s\left[1 + \frac{d_s\beta_0}{\sqrt{C}} - \frac{2\delta_1 d_s}{\sigma_0^2 C} + \frac{\beta_0}{C}\left(\beta_0 + \frac{\delta_0}{\sigma_0^2}\right)d_s\left(d_s - \frac{2\eta_0}{\sigma_0^2}\right) + \cdots\right]. \tag{2.19}$$

Also, from (2.2), we obtain

$$\sigma_0\sigma_1 = \beta_0\eta_0. \tag{2.20}$$

Next,

$$\frac{\delta}{\sigma} \sim \frac{1}{\sigma_0}\left[\delta_0 + \frac{1}{\sqrt{C}}\left(\delta_1 - \frac{\delta_0\sigma_1}{\sigma_0}\right) + \cdots\right] \tag{2.21}$$

and

$$\beta\sigma \sim \beta_0\sigma_0 + \frac{1}{\sqrt{C}}(\sigma_0\beta_1 + \beta_0\sigma_1) + \cdots. \tag{2.22}$$

Hence, from (2.3), (2.4), and (2.11), after a straightforward calculation, it is found that

$$\sigma_0\beta_1 + \beta_0\sigma_1 = -\beta_0\left(\delta_1 - \frac{\delta_0\sigma_1}{\sigma_0}\right)\left(2\frac{\delta_0}{\sigma_0} + \beta_0\sigma_0\right). \tag{2.23}$$

If we use (2.18) and (2.20) to eliminate β_1 and σ_1 from (2.23), we obtain

$$\begin{aligned}\delta_1\left[1 - \frac{1}{2}\beta_0\sigma_0\left(2\frac{\delta_0}{\sigma_0} + \beta_0\sigma_0\right)\right] \\ = \frac{1}{2}\beta_0\delta_0 + \frac{1}{4}\beta_0^2\sigma_0^2 - \frac{1}{2}\beta_0^3\delta_0\eta_0 - \frac{\beta_0\eta_0}{3\sigma_0^2}\left(\beta_0\sigma_0^2 + 4\beta_0\delta_0^2 + 2\frac{\delta_0^3}{\sigma_0^2}\right).\end{aligned} \tag{2.24}$$

Since $\delta_0/\sigma_0 = -\xi$, it follows from (2.15) that

$$(1 - 2a^2 - 2a\xi)\delta_1 = (\xi + a)\left[a + \frac{4\eta_0}{3\sigma_0^2}(2a\xi^2 + 3a^2\xi - \xi - a)\right], \tag{2.25}$$

and from (2.19) that

$$\nu_s \sim Y_s\left\{1 + \frac{2d_s(\xi + a)}{\sigma_0\sqrt{C}} - \frac{2d_s}{\sigma_0^2 C}\left[\delta_1 + (\xi + a)(\xi + 2a)\left(\frac{2\eta_0}{\sigma_0^2} - d_s\right)\right]\right\}. \tag{2.26}$$

Hence, from (2.10), we obtain the refined asymptotic approximation

$$\begin{aligned}\nu_s \sim Y_s\Bigg\{1 + \frac{2d_s(\xi + a)}{\sqrt{2\sum_{r=1}^S d_r^2 Y_r}} + \frac{d_s(\xi + a)}{\sum_{r=1}^S d_r^2 Y_r}\left[d_s(\xi + 2a) - \frac{a}{(1 - 2a^2 - 2a\xi)}\right] \\ + \frac{d_s(\xi + a)\left(\sum_{r=1}^S d_r^3 Y_r\right)}{3\left(\sum_{r=1}^S d_r^2 Y_r\right)^2}\left[\frac{a(1 + 2a^2)}{(1 - 2a^2 - 2a\xi)} - (\xi + 5a)\right]\Bigg\}.\end{aligned} \tag{2.27}$$

We note, from (2.4) and (2.14), that

$$g'(\xi) = 2g(\xi)[g(\xi) + \xi] - 1. \tag{2.28}$$

Since $g(\xi) = a$, it follows that

$$1 - 2a^2 - 2a\xi = -g'(\xi) > 0. \tag{2.29}$$

Once ξ has been computed, the numerical calculation of the refined approximation (2.27) is straightforward.

3. Iterative refinement procedure. Let $f(x) = g(x) + x$, where $g(x)$ is given by (2.14). Then, the inverse problem is asymptotically equivalent to solving the equation

$$f(\xi) - \xi = a. \tag{3.1}$$

We consider the algorithm

$$\xi(m + 1) = f(\xi(m)) - a, \quad m = 0, 1, \ldots, \qquad \xi(0) < \infty. \tag{3.2}$$

In order to establish that this is a contraction mapping, we make use of the following, which is proved in Appendix C.

LEMMA 3.1. *Let*

$$f(x) = \frac{e^{-x^2}}{\sqrt{\pi}\,\mathrm{Erfc}\,(x)} = \frac{e^{-x^2}}{2\int_x^\infty e^{-u^2}du}. \tag{3.3}$$

Then $f'(x) > 0$ *and* $f''(x) > 0$ *for* $-\infty < x < \infty$.

We remark that this lemma is of importance in another problem. Reiman [15] observed that $h(x) = \sqrt{2}\,f(x/\sqrt{2})$ is the hazard rate of a standard (mean 0, variance 1) normal random variable. He made use of his assertion that h is strictly increasing and strictly convex, but provided no proof of the latter.

From (3.1) and (3.2), we have

$$\xi(m+1) - \xi = f(\xi(m)) - f(\xi). \tag{3.4}$$

Since $f'(x) > 0$, $\xi(m) \geq \xi \Rightarrow \xi(m+1) \geq \xi$ and $\xi(m) \leq \xi \Rightarrow \xi(m+1) \leq \xi$. By induction,

$$\xi(0) \geq \xi \Rightarrow \xi(m) \geq \xi, \quad m = 0, 1, \ldots, \tag{3.5}$$

and

$$\xi(0) \leq \xi \Rightarrow \xi(m) \leq \xi, \quad m = 0, 1, \ldots . \tag{3.6}$$

Now $f'(x) = g'(x) + 1 < 1$, since $g'(x) < 0$ for $x < \infty$. We suppose first that $\xi(0) \geq \xi$. Then,

$$0 \leq \xi(m+1) - \xi = \int_\xi^{\xi(m)} f'(x)dx \leq \xi(m) - \xi, \tag{3.7}$$

so that $\xi(m)$ is a monotonically nonincreasing function of m, and $\xi(m) \leq \xi(0)$, $m = 0, 1, \ldots$. Hence, since $f''(x) > 0$, we have

$$\xi(0) \geq \xi \Rightarrow |\xi(m+1) - \xi| \leq f'[\xi(0)]\ |\xi(m) - \xi|, \quad m = 0, 1, \ldots . \tag{3.8}$$

On the other hand, if $\xi(0) \leq \xi$, then

$$0 \leq \xi - \xi(m+1) = \int_{\xi(m)}^{\xi} f'(x)dx \leq \xi - \xi(m), \tag{3.9}$$

so that $\xi(m)$ is a monotonically nondecreasing function of m. Hence, from (3.6), since $f''(x) > 0$, we have

$$\xi(0) \leq \xi \Rightarrow |\xi(m+1) - \xi| \leq f'(\xi)\ |\xi(m) - \xi|, \quad m = 0, 1, \ldots . \tag{3.10}$$

We let

$$\alpha = \max\{f'(\xi), f'[\xi(0)]\} = f'\{\max[\xi, \xi(0)]\} < 1. \tag{3.11}$$

Then, from (3.8) and (3.10), we obtain

$$|\xi(m+1) - \xi| \leq \alpha|\xi(m) - \xi|, \quad m = 0, 1, \ldots . \tag{3.12}$$

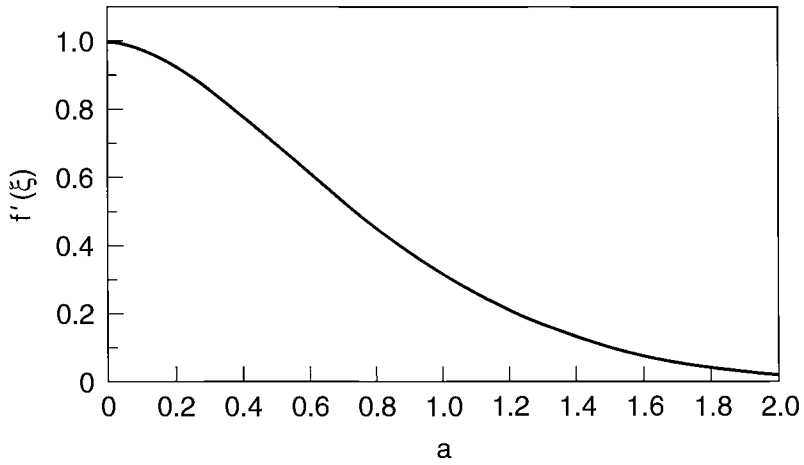

FIG. 3.1. *Plot of the convergence factor $f'(\xi)$ as a function of a.*

Hence $\xi(m)$ converges geometrically and monotonically to ξ. We note, in particular, that if $\xi(0) = -a$, then $\xi > \xi(0)$ and $\alpha = f'(\xi)$. In Figure 3.1, $f'(\xi)$ is depicted as a function of a. Since $f'(\xi) \to 1$ as $a \to 0$, $\xi(m)$ converges slowly for small values of a. Note, from (2.13), that as $a \to 0$ the total carried capacity approaches the capacity of the resource, and we are exiting the critically loaded regime and entering the overloaded one. Consequently, in the next section we analyze the overloaded regime, in which $0 < C - \sum_{s=1}^{S} d_s Y_s = O(1)$.

We conclude this section by establishing the connection between the algorithm (3.2) and the iterative procedure proposed by Mitra [9] for the case of general loading. The general algorithm is

$$\nu_s(m+1) = Y_s + \nu_s(m)\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}(m), C), \quad m = 0, 1, \ldots . \tag{3.13}$$

Mitra conjectured that (3.13) leads to a contraction mapping, but its convergence for any initial guess is an open question. If we multiply this equation by d_s and sum on s, we obtain, from (2.1),

$$\begin{aligned} \delta(m+1)\sqrt{C} &= C - \sum_{s=1}^{S} d_s \nu_s(m+1) \\ &= C - \sum_{s=1}^{S} d_s Y_s - \sum_{s=1}^{S} d_s \nu_s(m)\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}(m), C). \end{aligned} \tag{3.14}$$

But, from (2.5) and (2.6), to lowest order,

$$\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}(m), C) \sim \frac{d_s \beta(m)}{\sqrt{C}}, \qquad \nu_s(m) \sim Y_s, \tag{3.15}$$

and, from (2.2),

$$\sigma(m) \sim \sqrt{\frac{2}{C} \sum_{s=1}^{S} d_s^2 Y_s} \sim \sigma(m+1). \tag{3.16}$$

Hence, asymptotically, from (3.14)–(3.16), we obtain

$$\frac{\delta(m+1)}{\sigma(m+1)} + \frac{1}{2}\sigma(m)\beta(m) \sim \frac{\left(C - \sum_{s=1}^{S} d_s Y_s\right)}{\sqrt{2\sum_{s=1}^{S} d_s^2 Y_s}}. \tag{3.17}$$

From (2.3) and (2.13), we have

$$\frac{\delta(m+1)}{\sigma(m+1)} + \frac{e^{-[\delta(m)/\sigma(m)]^2}}{\sqrt{\pi}\,\mathrm{Erfc}\,[-\delta(m)/\sigma(m)]} \sim a. \tag{3.18}$$

Since $\xi(m) \sim -\delta(m)/\sigma(m)$, this corresponds asymptotically to (3.2), in view of (3.3).

4. Overloaded regime. In the overloaded regime, $0 > C - \sum_{s=1}^{S} d_s\nu_s = O(C)$, and the loss probability $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$ for service s is asymptotically given by (see [6], [10])

$$\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C) = 1 - (z^*)^{d_s} + O\left(\frac{1}{C}\right), \tag{4.1}$$

where z^* is the unique positive solution of

$$\sum_{s=1}^{S} d_s\nu_s(z^*)^{d_s} = C, \quad 0 < z^* < 1. \tag{4.2}$$

Hence,

$$Y_s = \nu_s[1 - \mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)] = \nu_s(z^*)^{d_s} + O(1) \tag{4.3}$$

and

$$0 < \gamma \triangleq C - \sum_{s=1}^{S} d_s Y_s = O(1). \tag{4.4}$$

To determine z^* in terms of Y_s ($s = 1, 2, \ldots, S$), we derive an asymptotic approximation to the correction term in (4.4). In Appendix D we establish that

$$\gamma = C - \sum_{s=1}^{S} d_s Y_s \sim \frac{z^*}{(1 - z^*)}. \tag{4.5}$$

Hence,

$$z^* \sim \frac{\gamma}{(1+\gamma)}, \tag{4.6}$$

and, from (4.3), it follows that

$$\nu_s \sim Y_s \left(\frac{1+\gamma}{\gamma}\right)^{d_s}. \tag{4.7}$$

We will show that this result matches asymptotically with those for the critically loaded regime for $\gamma \gg 1$ and $0 < \gamma/\sqrt{C} \ll 1$. But $\gamma = a\sigma_0\sqrt{C}$, from (2.10), (2.13),

and (4.4), so this corresponds to $0 < a \ll 1$. Since $g(\xi) = a$, it follows from (2.14) and (B.1) that

$$\xi = \frac{1}{2a}[1 - 4a^2 + O(a^4)]\,, \tag{4.8}$$

so that

$$1 - 2a^2 - 2a\xi = 2a^2 + O(a^4). \tag{4.9}$$

Hence, from (2.10) and (2.27), we obtain for small a

$$\nu_s \sim Y_s \left\{ 1 + \frac{d_s}{a\sigma_0\sqrt{C}}[1 + O(a^2)] + \frac{d_s}{2a^2\sigma_0^2 C}[d_s - 1 + O(a^2)] \right\}. \tag{4.10}$$

This matches with (4.7) for $\gamma = a\sigma_0\sqrt{C} \gg 1$.

5. Numerical results. The CLAA to the traffic intensities ν_s, in terms of the carried loads Y_r $(r = 1, \ldots, S)$, is given by (2.16), where $\xi > -a$ satisfies $f(\xi) - \xi = a$, and a and $f(x)$ are given by (2.13) and (3.3). Numerical values of ξ were obtained by the iterative refinement procedure (3.2), with $\xi(0) = -a$. The stopping criterion $|[\xi(m+1) - \xi(m)]/[\xi(m+1) + a]| \le 10^{-4}$ was used. The RCLAA is given by (2.27).

We present numerical results for the two examples considered in [14]. The first example has capacity $C = 96$ and two services with call capacities $d_1 = 1$ and $d_2 = 6$. In Table 1, the CLAA and RCLAA to the traffic intensities ν_1 and ν_2 are compared with the values from which the carried loads Y_1 and Y_2 were calculated, using the exact values of the loss probabilities tabulated in [14]. These values are $\nu_1 = 0.86\nu/1.7$ and $\nu_2 = 0.14\nu/1.7$, where the total traffic intensity $\nu = \nu_1 + 6\nu_2 = 96 + \beta\sqrt{96}$, and $\beta = -6(1)3$, ranging from an underloaded resource to an overloaded one. The CLAA gives moderately accurate values in the critically loaded regime, but less so in the overloaded regime. The RCLAA, however, gives significantly better results in these regimes. Errors of more than 1% are indicated in parentheses in Table 1. The results become quite accurate in the underloaded regime, since the loss probabilities, although not well approximated by CLAA or RCLAA there, are exponentially small. Also listed in Table 1 is the number of iterations required to obtain $\xi + a$ to the desired accuracy, which increases significantly with the load.

Similar comparisons are made in Table 2 for the second example, which has capacity $C = 130$, and three services with call capacities $d_1 = 1$, $d_2 = 3$, and $d_3 = 10$. The traffic intensities from which the carried loads Y_1, Y_2, and Y_3 were calculated exactly are $\nu_1 = 2\nu/13 = \nu_2$ and $\nu_3 = \nu/26$, where the total traffic intensity is $\nu = \nu_1 + 3\nu_2 + 10\nu_3$, and $\nu = 46.8(20.8)171.6$, again ranging from an underloaded resource to an overloaded one. (For $\nu = 67.6$, the exact value of $\mathbb{L}_3$ in [14] should be 4.9623×10^{-3}.) Similar comments apply to the CLAA and RCLAA here as for the first example. Errors of more than 1% are indicated in parentheses in Table 2. Also listed in Table 2 is the number of iterations required to obtain $\xi + a$ to the desired accuracy. All computations were performed with double precision.

The overloaded asymptotic approximation (4.7) gives less accurate results than the RCLAA, even for the heaviest loads considered for the two examples. Thus, for $\nu = 125.4$ in Table 1, (4.7) gives the approximations 64.9 and 11.3 for ν_1 and ν_2, respectively. For $\nu = 171.6$ in Table 2, (4.7) gives the approximations 26.8, 27.6, and 7.23 for ν_1, ν_2, and ν_3, respectively.

TABLE 1

Comparisons of the CLAA and RCLAA to the traffic intensities ν_1 and ν_2 with the exact results for two services with $C = 96$, $d_1 = 1$ and $d_2 = 6$, and total traffic intensity $\nu = \nu_1 + 6\nu_2$.

5.2494	8.81	(14.7)	9.98	(3.4)	10.33		

We also performed some numerical experiments using the algorithm (3.13) proposed by Mitra [9]. The loss probabilities $\mathbb{L}_s$ were evaluated by means of the refined uniform asymptotic approximation (RUAA) derived in [14], which was shown to be very accurate for the two examples considered. The initial values $\nu_s(0)$, $s = 1, 2, \ldots, S$, were chosen either as Y_s (calculated exactly) or as $Z_s = Y_s[(1+\gamma)/\gamma]^{d_s}$, where γ is given by (4.4), corresponding to the approximation (4.7) for the overloaded regime.

In Table 3 we compare the results of the iterative procedure with the (more precisely listed) exact values of the traffic intensities ν_1 and ν_2 for the first example. The corresponding carried loads are given in Table 1. Also listed is the number of iterations required to obtain the desired accuracy. As indicated by our critically loaded asymptotic analysis, the number of iterations increases significantly with the load. For the most heavily loaded case considered, 8 fewer iterations were required when $\nu_s(0) = Z_s$ than when $\nu_s(0) = Y_s$, $s = 1, 2$.

In Table 4 we compare the results of the iterative procedure with the exact values of the traffic intensities ν_1, ν_2, and ν_3 for the second example. The corresponding carried loads are given in Table 2. Similar comments apply to the number of iterations required.

Appendix A. We derive here the refined asymptotic approximation (2.5) to the loss probability $\mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)$ for service s, by specializing the uniform asymptotic

TABLE 2

Comparisons of the CLAA and RCLAA to the traffic intensities ν_1, ν_2, and ν_3 with the exact results for three services with $C = 130$, $d_1 = 1$, $d_2 = 3$, and $d_3 = 10$, and total traffic intensity $\nu = \nu_1 + 3\nu_2 + 10\nu_3$.

approximation [10] to the critically loaded regime. Let

$$\nu_s = \alpha_s C, \quad s = 1, 2, \ldots, S, \tag{A.1}$$

where $C \gg 1$ and $\alpha_s > 0$ is $O(1)$ and bounded away from zero. Also, let

$$f(z) = \sum_{s=1}^{S} \alpha_s (z^{d_s} - 1) - \log z. \tag{A.2}$$

There is a unique positive solution z^* of $f'(z) = 0$ so that

$$\sum_{s=1}^{S} \alpha_s d_s (z^*)^{d_s} = 1, \quad z^* > 0. \tag{A.3}$$

It follows from (A.2) and (A.3) that

$$v \triangleq (z^*)^2 f''(z^*) = \sum_{s=1}^{S} \alpha_s d_s^2 (z^*)^{d_s}. \tag{A.4}$$

We define

$$K = \frac{1}{(1 - z^*)} - \frac{\sqrt{v}\,\mathrm{sgn}\,(1 - z^*)}{\sqrt{-2f(z^*)}}, \quad z^* \neq 1, \tag{A.5}$$

TABLE 3

Comparison of the final iterated values of the traffic intensities ν_1 and ν_2 with the exact results for two services with $C = 96$, $d_1 = 1$ and $d_2 = 6$, and total traffic intensity $\nu = \nu_1 + 6\nu_2$.

ν	Exact	$\nu_s(0) = Y_s$	# of iter.	$\nu_s(0) = Z_s$	# of iter.

125.4	63.435 10.327	63.429 10.320	57	63.442 10.333	49

$$K = \frac{1}{2} + \frac{1}{6v}\sum_{s=1}^{S} \alpha_s d_s^3, \quad z^* = 1, \tag{A.6}$$

and

$$M = \frac{1}{2}\,\mathrm{Erfc}\left[\mathrm{sgn}\,(1-z^*)\sqrt{-Cf(z^*)}\right] + \frac{Ke^{Cf(z^*)}}{\sqrt{2\pi Cv}}\,. \tag{A.7}$$

Then (see [10]),

$$\mathbb{L}_s(\mathbf{d},\boldsymbol{\nu},C) = \frac{e^{Cf(z^*)}[(z^*)^{d_s}-1]}{\sqrt{2\pi Cv}(z^*-1)M}\left[1 + O\left(\frac{1}{C}\right)\right]. \tag{A.8}$$

Since $f(1) = 0$ and $f'(z^*) = 0$, it follows from (A.4) that the expression for K in (A.5) remains finite as $z^* \to 1$, and its limiting value is given by (A.6).

In the critically loaded regime corresponding to (2.1), z^* is close to 1 and we expand in powers of $1/\sqrt{C}$ and let

$$z^* \sim 1 + \frac{c_1}{\sqrt{C}} + \frac{c_2}{C} + \cdots. \tag{A.9}$$

TABLE 4

Comparison of the final iterated values of the traffic intensities ν_1, ν_2, and ν_3 with the exact results for three services with $C = 130$, $d_1 = 1$, $d_2 = 3$, and $d_3 = 10$, and total traffic intensity $\nu = \nu_1 + 3\nu_2 + 10\nu_3$.

171.6	26.4	26.3985	57	26.4017	49
	26.4	26.395		26.405	
	6.6	6.595		6.604	

Then, from (2.1), (A.1), and (A.3), we obtain

$$\frac{\delta}{\sqrt{C}} \sim \frac{c_1}{\sqrt{C}} \sum_{s=1}^{S} \alpha_s d_s^2 + \frac{1}{C} \sum_{s=1}^{S} \alpha_s d_s^2 \left[c_2 + \frac{1}{2} c_1^2 (d_s - 1) \right] + \cdots . \tag{A.10}$$

Hence, from (2.2), we find that

$$c_1 = \frac{2\delta}{\sigma^2}, \qquad c_2 = -\frac{4\delta^2}{\sigma^6} \left(\eta - \frac{1}{2}\sigma^2 \right) . \tag{A.11}$$

Also, from (A.4) and (A.6),

$$v \sim \frac{1}{2}\sigma^2 + \frac{2\delta\eta}{\sigma^2\sqrt{C}} + \cdots, \qquad K \sim \frac{1}{2} + \frac{\eta}{3\sigma^2} + \cdots . \tag{A.12}$$

Since $f'(z^*) = 0$,

$$0 = f(1) = f(z^*) + \frac{1}{2}(1 - z^*)^2 f''(z^*) + \frac{1}{6}(1 - z^*)^3 f'''(z^*) + \cdots . \tag{A.13}$$

However, from (A.2), we obtain

$$z f''(z) + f'(z) = \sum_{s=1}^{S} \alpha_s d_s^2 z^{d_s - 1} \tag{A.14}$$

and

$$zf'''(z) + 2f''(z) = \sum_{s=1}^{S} \alpha_s d_s^2 (d_s - 1) z^{d_s - 2} . \tag{A.15}$$

From (2.2), (A.4), (A.9), (A.11), and (A.15), after some algebra, it is found that

$$f''(z^*) \sim \frac{1}{2}\sigma^2 + \frac{2\delta}{\sigma^2\sqrt{C}}(\eta - \sigma^2) + \cdots \tag{A.16}$$

and

$$f'''(z^*) \sim \eta - \frac{3}{2}\sigma^2 + \cdots . \tag{A.17}$$

It then follows from (A.13) that

$$-Cf(z^*) \sim \frac{\delta^2}{\sigma^2} - \frac{4\delta^3\eta}{3\sigma^6\sqrt{C}} + \cdots . \tag{A.18}$$

Hence, since $z^* < 1$ if $\delta < 0$,

$$\operatorname{sgn}(1 - z^*)\sqrt{-Cf(z^*)} \sim -\frac{\delta}{\sigma}\left(1 - \frac{2\delta\eta}{3\sigma^4\sqrt{C}} + \cdots\right) . \tag{A.19}$$

It follows from (A.18) that

$$e^{Cf(z^*)} \sim e^{-(\delta/\sigma)^2}\left(1 + \frac{4\delta^3\eta}{3\sigma^6\sqrt{C}} + \cdots\right) . \tag{A.20}$$

Also, from (2.4) and (A.19), we obtain

$$\operatorname{Erfc}\left[\operatorname{sgn}(1 - z^*)\sqrt{-Cf(z^*)}\right] \sim \operatorname{Erfc}\left(-\frac{\delta}{\sigma}\right) - \frac{4\delta^2\eta}{3\sigma^5\sqrt{\pi C}} e^{-(\delta/\sigma)^2} + \cdots , \tag{A.21}$$

and hence, from (A.7) and (A.12),

$$M \sim \frac{1}{2}\operatorname{Erfc}\left(-\frac{\delta}{\sigma}\right) + \frac{e^{-(\delta/\sigma)^2}}{\sigma\sqrt{\pi C}}\left[\frac{1}{2} + \frac{\eta}{3\sigma^2}\left(1 - \frac{2\delta^2}{\sigma^2}\right)\right] + \cdots . \tag{A.22}$$

Consequently, with β given by (2.3),

$$\frac{e^{-(\delta/\sigma)^2}}{M\sigma\sqrt{\pi}} \sim \beta\left\{1 - \frac{\beta}{2\sqrt{C}}\left[1 + \frac{2\eta}{3\sigma^2}\left(1 - \frac{2\delta^2}{\sigma^2}\right)\right] + \cdots\right\} . \tag{A.23}$$

Next, from (A.12),

$$\frac{1}{\sqrt{2v}} \sim \frac{1}{\sigma}\left(1 - \frac{2\delta\eta}{\sigma^4\sqrt{C}} + \cdots\right) . \tag{A.24}$$

Finally, from (A.9) and (A.11),

$$\begin{aligned} \frac{\left[(z^*)^{d_s} - 1\right]}{(z^* - 1)} &= \sum_{n=0}^{d_s - 1} (z^*)^n \\ &\sim \sum_{n=0}^{d_s - 1}\left(1 + \frac{2n\delta}{\sigma^2\sqrt{C}} + \cdots\right) \\ &\sim d_s + \frac{\delta}{\sigma^2\sqrt{C}} d_s(d_s - 1) + \cdots . \end{aligned} \tag{A.25}$$

From (A.8), (A.20), and (A.23)–(A.25), we obtain the approximation (2.5).

Appendix B. We here establish that $g(-\infty) = \infty$, $g(\infty) = 0$, and $g'(x) < 0$ for $x < \infty$, where $g(x)$ is given by (2.14), and $\mathrm{Erfc}\,(x)$ by (2.4). First (see [8]), $\mathrm{Erfc}\,(-\infty) = 2$, so that $g(-\infty) = \infty$, and

$$\mathrm{Erfc}\,(x) \sim \frac{e^{-x^2}}{\sqrt{\pi}x}\left[1 - \frac{1}{2x^2} + \frac{3}{4x^4} + O\left(\frac{1}{x^6}\right)\right], \quad x \gg 1. \tag{B.1}$$

Hence $g(\infty) = 0$. Next, we define

$$\omega(x) = \frac{\sqrt{\pi}}{2} e^{x^2}\,\mathrm{Erfc}\,(x) = e^{x^2}\int_x^\infty e^{-u^2}du = \int_0^\infty e^{-v^2}e^{-2xv}dv. \tag{B.2}$$

Then, $\omega(x) > 0$ for $x < \infty$, and

$$g(x) = \frac{1}{2\omega(x)} - x, \qquad g'(x) = -\frac{\omega'(x)}{2[\omega(x)]^2} - 1. \tag{B.3}$$

From (B.2) we obtain

$$[\omega(x)]^2 = \int_0^\infty \int_0^\infty e^{-(v^2+w^2)}\, e^{-2x(v+w)}\, dv\, dw. \tag{B.4}$$

If we make the transformation of variables

$$v = \frac{1}{\sqrt{2}}(\eta - \zeta), \qquad w = \frac{1}{\sqrt{2}}(\eta + \zeta), \tag{B.5}$$

then

$$[\omega(x)]^2 = \int_0^\infty \int_{-\eta}^{\eta} e^{-(\eta^2+\zeta^2)}\, e^{-2\sqrt{2}\,x\eta}\, d\zeta\, d\eta. \tag{B.6}$$

Also, from (B.2),

$$\frac{1}{2}\omega'(x) = -\int_0^\infty ve^{-v^2}\, e^{-2xv}dv = -2\int_0^\infty \eta e^{-2\eta^2}\, e^{-2\sqrt{2}\,x\eta}\, d\eta. \tag{B.7}$$

Hence,

$$\frac{1}{2}\omega'(x) + [\omega(x)]^2 = \int_0^\infty e^{-\eta^2}\, e^{-2\sqrt{2}\,x\eta}\, \psi(\eta)d\eta, \tag{B.8}$$

where

$$\psi(\eta) = \int_{-\eta}^{\eta} e^{-\zeta^2}d\zeta - 2\eta\, e^{-\eta^2} > 0, \quad \eta > 0\,. \tag{B.9}$$

It follows, from (B.3), (B.8), and (B.9), that $g'(x) < 0$ for $x < \infty$.

Appendix C. Here we prove Lemma 3.1. We consider $-\infty < x < \infty$. Then, from (3.3) and (B.2),

$$f(x) = \frac{1}{2\omega(x)}, \qquad f'(x) = -\frac{\omega'(x)}{2[\omega(x)]^2} > 0. \tag{C.1}$$

Next,

$$f''(x) = \frac{[\omega'(x)]^2}{[\omega(x)]^3} - \frac{\omega''(x)}{2[\omega(x)]^2}\,. \tag{C.2}$$

But, from (B.7),

$$\frac{1}{2}\omega''(x) = 2\int_0^\infty v^2\, e^{-v^2}\, e^{-2xv}\, dv. \tag{C.3}$$

Hence, from (B.2) and (B.7),

$$\begin{aligned}[\omega'(x)]^2 - \frac{1}{2}\omega(x)\omega''(x) \\ = \int_0^\infty \int_0^\infty (4vw - v^2 - w^2) e^{-(v^2+w^2)}\, e^{-2x(v+w)}\, dv\, dw,\end{aligned} \tag{C.4}$$

where we have expressed $\omega(x)\omega''(x)$ in a symmetric form.

If we make the transformation of variables (B.5), then

$$[\omega'(x)]^2 - \frac{1}{2}\omega(x)\omega''(x) = \int_0^\infty e^{-\eta^2}\, e^{-2\sqrt{2}\,x\eta}\, \chi(\eta)\, d\eta, \tag{C.5}$$

where

$$\chi(\eta) = \int_{-\eta}^{\eta} (\eta^2 - 3\zeta^2)\, e^{-\zeta^2}\, d\zeta. \tag{C.6}$$

Hence, from (B.9),

$$\chi'(\eta) = 2\eta\, \psi(\eta) > 0, \quad \eta > 0. \tag{C.7}$$

Since $\chi(0) = 0$, it follows that $\chi(\eta) > 0$ for $\eta > 0$. Hence, from (C.2) and (C.5), since $\omega(x) > 0$, we have established that $f''(x) > 0$ for $-\infty < x < \infty$, and the proof of the lemma is complete.

Appendix D. We here establish the asymptotic approximation in (4.5). Let

$$G(\mathbf{d}, \boldsymbol{\nu}, C - n) = \frac{1}{2\pi i} \int_{|z|<1} \frac{z^{n-1} e^{Cf(z)}}{(1-z)} dz \tag{D.1}$$

for integer values of n, where the integral is taken in a counterclockwise direction around a circle of radius less than 1, and, from (A.1) and (A.2),

$$Cf(z) = \sum_{s=1}^{S} \nu_s (z^{d_s} - 1) - C \log z. \tag{D.2}$$

Then (see [14]),

$$1 - \mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C) = \frac{1}{2\pi i G(\mathbf{d}, \boldsymbol{\nu}, C)} \int_{|z|<1} \frac{z^{d_s - 1} e^{Cf(z)}}{(1-z)} dz. \tag{D.3}$$

From (D.2) it follows that

$$\sum_{s=1}^{S} d_s \nu_s z^{d_s} = C[zf'(z) + 1]. \tag{D.4}$$

Hence, since $Y_s = \nu_s[1 - \mathbb{L}_s(\mathbf{d}, \boldsymbol{\nu}, C)]$,

$$C - \sum_{s=1}^{S} d_s Y_s = -\frac{C}{2\pi i G(\mathbf{d}, \boldsymbol{\nu}, C)} \int_{|z|<1} \frac{f'(z)}{(1-z)} e^{Cf(z)} dz. \tag{D.5}$$

However,

$$\frac{d}{dz}\left[\frac{e^{Cf(z)}}{(1-z)}\right] = \left[\frac{Cf'(z)}{(1-z)} + \frac{1}{(1-z)^2}\right] e^{Cf(z)}. \tag{D.6}$$

It follows that

$$C - \sum_{s=1}^{S} d_s Y_s = \frac{1}{2\pi i G(\mathbf{d}, \boldsymbol{\nu}, C)} \int_{|z|<1} \frac{e^{Cf(z)}}{(1-z)^2} dz. \tag{D.7}$$

From (4.2) and (D.4), $f'(z^*) = 0$. Moreover (see [10]), $|z| = z^*$ is a saddle-point contour, and if $h(z)$ is analytic in a domain containing $|z| = z^*$, then

$$\frac{1}{2\pi i} \int_{|z|=z^*} h(z) e^{Cf(z)} dz = \frac{e^{Cf(z^*)}}{\sqrt{2\pi C f''(z^*)}} \left[h(z^*) + O\left(\frac{1}{C}\right)\right]. \tag{D.8}$$

If we deform the contour of integration to $|z| = z^*$ and set $n = 0$ in (D.1), we obtain the asymptotic approximations

$$G(\mathbf{d}, \boldsymbol{\nu}, C) \sim \frac{e^{Cf(z^*)}}{\sqrt{2\pi C f''(z^*)}\ z^*(1 - z^*)} \tag{D.9}$$

and

$$\frac{1}{2\pi i} \int_{|z|<1} \frac{e^{Cf(z)}}{(1-z)^2} dz \sim \frac{e^{Cf(z^*)}}{\sqrt{2\pi C f''(z^*)}\ (1 - z^*)^2}. \tag{D.10}$$

The result in (4.5) follows from (D.7), (D.9), and (D.10).

Acknowledgments. The authors are indebted to Debasis Mitra for posing the general problem and suggesting this investigation. They are also grateful to the referees for suggestions that improved the presentation.

DERIVATION OF A CONTINUUM MODEL FOR EPITAXIAL GROWTH WITH ELASTICITY ON VICINAL SURFACE*

YANG XIANG†

Abstract. In heteroepitaxial growth, the mismatch between the lattice constants in the film and the substrate causes misfit strain in the film, making a flat surface unstable to small perturbations. This morphological instability is called Asaro–Tiller–Grinfeld (ATG) instability, which can drive the film to self-organize into nanostructures such as quantum wires or quantum dots. In practice, most devices are fabricated on vicinal surfaces which consist of steps and terraces. In this case, the misfit strain causes step bunching, and traditional continuum models for the ATG instability do not apply directly. In this paper, we derive a continuum model for step bunching by taking the continuum limit of the discrete models proposed by Duport, Politi, andVillain [*J. Phys.* I, 5 (1995), pp. 1317–1350] and Tersoff et al. [*Phys. Rev. Lett.*, 75 (1995), pp. 2730–2733].

1. Introduction.

Nanostructures such as quantum wires and quantum dots exhibit novel electronic and optical properties and have important potential applications in semiconductor technology. How to fabricate them efficiently has raised intense interest recently. One promising way is to employ the self-organization process during heteroepitaxial growth of thin films where they are under stress. The mismatch between the lattice constants in the film and in the substrate causes misfit strain and stress in the film, driving the self-organization of surface morphology (see, e.g., [44, 46]). Therefore understanding the mechanism of misfit related self-organization is an important step to make this technology a reality.

The stress-driven morphological instability was first studied by Asaro and Tiller [1] and later independently by Grinfeld [17, 18] and Srolovitz [43]. It is called Asaro–Tiller–Grinfeld (ATG) instability or Grinfeld instability. These authors studied the linear instability of a planar surface of a stressed solid to small perturbations and found that the planar surface is unstable for wavenumbers less than a critical value. This instability is manifested by a mass transport via surface diffusion. The stress in the solid is a destabilizing factor while the surface energy is a stabilizing one. This linear instability was also studied by Gao [15], Spencer, Voorhees, and Davis [42], Freund and Jonsdottir [14], Grilhe [16], and others.

The nonlinear evolution of the stress-driven instability for thick films will result in the formation of cusps. It was studied by Yang and Srolovitz [54], Chiu and Gao [5], Spencer and Meiron [40], and Kassner and Misbah [20]. If the films are thin and wet the substrates, Stranski–Krastanow wetting islands will form. The steady states of island shapes were studied by Spencer and Tersoff [41], Kukta and Freund [23], Spencer [39], Rudin and Spencer [33], and Shanahan and Spencer [36], and others. The nonlinear evolution of the surfaces of thin films and the formation of islands were

studied by Chiu and Gao [6], Zhang and Bower [55].

These authors treated the surface as a continuum, neglecting the presence of steps. This can be true only at relatively high temperature above the roughening transition, when the surface can change continuously. The normal temperature for epitaxial growth is below the roughening transition, when the surface will consist of steps and terraces (see, e.g., [30]). In this case, the surface cannot continuously change, and it has been shown that there is an activation barrier for the nucleation of steps [48, 53]. Therefore the continuum theories mentioned above do not apply directly. In practice, most semiconductor devices are fabricated on vicinal surfaces. Such surfaces are cut at a small angle to the atomic planes, creating a succession of terraces separated by atomic-height steps. The self-organization driven by misfit elasticity is achieved by step bunching [26, 28]. These bunches have uniform size and spacing, and they are much straighter than single steps, which tend to meander (Bales–Zangwill instability [3]) due to the Schwoebel barrier [35]. Therefore they can serve as superior templates for growth of quantum wires and nucleation of clusters [32, 45].

The understanding of step bunching induced by misfit strain is not as complete as that of the traditional ATG instability for a continuous surface. One important model was proposed by Tersoff et al. [49] and Liu, Tersoff, and Lagally [24] describing the dynamics of each step based on Burton, Cabrera, and Frank (BCF) theory [4]. In their model, the elastic effect of a step on a thick film is modeled by a force monopole caused by misfit stress in the bulk and a force dipole caused by the step [47]. The force monopole causes attractive interaction between successive steps, which destabilizes a uniform step train. The force dipole causes repulsive interaction between successive steps, which stabilizes a uniform step train. They analyzed the linear instability toward step bunching from a uniform step train with small perturbations and showed that it evolves by progressive coalescence of step bunches [49]. They also studied the kinetic debunching effect and demonstrated numerically how to control the size of bunches [24]. Another important model was proposed by Duport, Nozieres, and Villain [8], Duport, Politi, and Villain [9], and Duport [7]. Besides the two elastic effects between the steps considered by Tersoff et al., they also considered the elastic interaction between adatoms and steps and the Schwoebel barrier. The elastic interaction between adatoms and steps is stabilizing or destabilizing depending on the sign of the misfit. The Schwoebel barrier is always stabilizing. Additional work was done on the shapes of the islands which consist of steps. Duport, Priester, and Villain [10] computed the equilibrium shapes of pyramid-like islands. Kaganer and Ploog [19] studied the two-dimensional island shapes and growth kinetics of step bunches by modifying Tersoff et al.'s model. All these models are two-dimensional based on the observation that the steps are very straight in bunches. Kukta and Bhattacharya [22] proposed a three-dimensional model for step-flow-mediated crystal growth under stress. As far as we know, there is no continuum model for step bunching induced by misfit strain.

There are three different levels of models for epitaxial growth: kinetic Monte Carlo (e.g., [38]), BCF theory [4], and continuum theories, with length scales ranging from atomic size, to terrace width, to mound size ([13], see also [11]). In most cases, a continuum model is desired when we are interested only in the shapes of step bunches or islands. The existing continuum models for the traditional ATG instability follow Mullins' chemical potential argument [27]. They do not incorporate the atomic structure of the underlying crystal which plays an important role in epitaxial growth.

In this paper, we derive a continuum model for the elastically driving step bunch-

ing by taking the continuum limit from the discrete models of Duport, Politi, and Villian [9] and Tersoff et al. [49]. The underlying atomic features of epitaxial growth reflected in the discrete models are kept in our model. This method of deriving continuum models from small scale models has been used in the literature to obtain continuum models for epitaxial growth without elasticity [50, 2, 31, 21, 29] (from BCF models), [34, 12, 25] (from BCF models coupled with adatom density) and [51] (from kinetic Monte Carlo models).

The rest of the paper is organized as follows. In section 2, we review the concept of epitaxial growth on vicinal surfaces and the BCF model, and we present the discrete models of Duport, Politi, and Villian [9] and Tersoff et al. [49]. In section 3, we derive our continuum model from these discrete models. In section 4, we summarize our results.

2. Epitaxial growth on vicinal surface and BCF-like models. In this section, we review the concept of epitaxial growth on vicinal surfaces and BCF theory, and we present the discrete models for elastically driving step bunching.

Epitaxial growth is the growth of crystalline film on a crystalline substrate following the same structure as the substrate. A vicinal surface consists of a succession of terraces separated by atomic-height steps, and the angle between the surface and the crystallographic plane is small. According to the BCF theory [4], the adatoms diffuse on the terraces until they meet the steps and get incorporated into the steps. The surface then grows (see Figure 2.1). The best way to grow a good crystal is to grow it on an infinite vicinal surface with parallel, equidistant steps (uniform step train) [30].

Steps and adatoms can interact elastically. The elastic interaction may be due to different kinds of mechanisms. One mechanism is the broken bond mechanism, which originates from the force dipole exerted by adatoms or steps due to the broken bonds of the adatoms or along the steps. The other mechanism is the misfit mechanism, which originates from the misfit between the lattice constants of the film and the substrate. The misfit strain and stress exist in the bulk of the film. If the modulation of the surface is small, the effect of this mechanism is equivalent to a surface stress

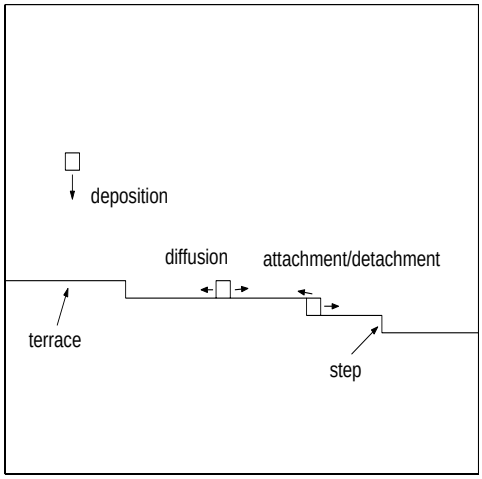

FIG. 2.1. *Schematic picture for the BCF theory.*

acting on a flat surface proportional to the modulation of the surface and the misfit. In the case of isotropic misfit and Hooke's law, the surface stress due to the misfit is given by

$$\eta_{xx} = \eta_{yy} = \frac{\delta a}{a}\frac{E}{1-\nu}\delta h, \tag{2.1}$$

where a is the lattice constant in the substrate, $a + \delta a$ is the lattice constant in the film, E is the Young modulus, ν is the Poisson ratio, and δh is the modulation of the surface.

The elastic interactions between adatoms and steps affect the diffusion of the adatoms on terraces. The elastic interactions between steps modify the equilibrium adatom density on steps and therefore modify the incorporating process of adatoms into the steps if we assume the adatoms incorporated into the steps can detach from them.

As far as diffusion alone is concerned, the adatoms prefer to go to the upper step rather than to the lower step, since an energy barrier exists near the lower step; this is called the Schwoebel barrier [35].

Now we present the model given by Duport, Politi, and Villain in [9] for a 1+1-dimensional vicinal surface based on the BCF theory. The 1+1-dimensional model assumes that the steps are straight and parallel, and the diffusion on the terrace is uniform in the direction parallel to the steps. The vicinal surface is assumed to be infinite and monotonic in the direction perpendicular to the steps. Without loss of generality, it is assumed that the terrace on the left of a step is higher than the terrace on the right. Letting $\{x_n\}$ with $\cdots < x_{n-1} < x_n < x_{n+1} < \cdots$ be the step train, the equations describing the adatom diffusion and step motion can be written as

$$\begin{cases} \dfrac{\partial \rho_n}{\partial t} = D\dfrac{\partial}{\partial x}\left(\dfrac{\partial \rho_n}{\partial x} + \dfrac{\rho_n}{k_B T}\dfrac{\partial U}{\partial x}\right) + F, \quad x_n < x < x_{n+1}, \\ D\left(\dfrac{\partial \rho_n}{\partial x} + \dfrac{\rho_n}{k_B T}\dfrac{\partial U}{\partial x}\right) = k^+(\rho_n - \rho_n^0), \quad x = x_n, \\ D\left(\dfrac{\partial \rho_n}{\partial x} + \dfrac{\rho_n}{k_B T}\dfrac{\partial U}{\partial x}\right) = -k^-(\rho_n - \rho_{n+1}^0), \quad x = x_{n+1}, \\ \dfrac{dx_n(t)}{dt} = a^2[k^+(\rho_n|_{x=x_n^+} - \rho_n^0) + k^-(\rho_{n-1}|_{x=x_n^-} - \rho_n^0)], \end{cases} \tag{2.2}$$

where ρ_n is the adatom density on the terrace between the nth step and the $(n+1)$st step, F is the deposition flux, D is the diffusion constant on terrace, k_B is the Boltzmann constant, T is the temperature, and k^+ and k^- are the hopping rates of an adatom to the upward step and downward step, respectively; the Schwoebel effect stipulates

$$k^+ \geq k^-. \tag{2.3}$$

ρ_n^0 is the equilibrium adatom density on the nth step; it is equal to the equilibrium adatom density on a step in the absence of elastic interactions ρ_0 with a local correction due to elasticity

$$\rho_n^0 = \rho_0 e^{-\frac{1}{k_B T}(U(x_n) - f_n)}. \tag{2.4}$$

The function $U(x)$ is the elastic energy due to the interaction between an adatom and the steps

$$U(x) = -\sum_{m=-\infty}^{+\infty} \frac{\alpha_0}{x_m - x} \tag{2.5}$$

and f_n describes the elastic interaction between the nth step and all other steps

$$f_n = -\sum_{m\neq n}\left(\frac{\alpha_1}{x_m - x_n} - \frac{\alpha_2}{(x_m - x_n)^3}\right). \tag{2.6}$$

The constants $\alpha_1, \alpha_2 > 0$, α_0 may be either positive or negative, and

$$\alpha_0 = \frac{2}{\pi}(1+\nu)\frac{\delta a}{a}\mu_a a^3, \tag{2.7}$$

$$\alpha_1 = \frac{2E}{\pi}\frac{1+\nu}{1-\nu}\left(\frac{\delta a}{a}\right)^2 a^4, \tag{2.8}$$

$$\alpha_2 = \frac{4}{\pi E}(1-\nu^2)\mu_s^2 a^4, \tag{2.9}$$

where $a^2\mu_a$ is the force dipole moment due to the broken bond mechanism for an adatom, $a\mu_s$ is the force dipole moment due to the broken bond mechanism along a step.

The first equation in the system (2.2) describes the deposition and diffusion processes of adatoms on a terrace. The second and third equations describe the incorporating process of adatoms into the steps, which serve as the boundary conditions of the diffusion problem. The fourth equation gives the velocity of the steps.

The function $U(x)$ describes the elastic interaction between one adatom and the steps. In this expression, the adatom has the broken bond effect and the steps have the misfit effect, which is dominant among all possible combinations. The sign of α_0 can be either positive or negative depending on the sign of $\mu_a\delta a$. The case of $\mu_a\delta a > 0$ means that the elastic interaction between an adatom with the broken bond effect and a step with the misfit effect is repulsive for upper steps and is attractive for lower steps. Thus the adatoms on a terrace prefer to go to the lower step than to the upper step. On the other hand, $\mu_a\delta a < 0$ means that the elastic interaction between an adatom with the broken bond effect and a step with the misfit effect is attractive for upper steps and is repulsive for lower steps. Thus the adatoms on a terrace prefer to go to the upper step than to the lower step.

The function f_n describes the elastic interaction between steps. The first term in it comes from the elastic interaction between steps in the step train due to the misfit mechanism. It is an attractive interaction. The second term comes from the elastic interaction between steps in the step train due to the broken bond mechanism. It is a repulsive interaction. Here we do not consider the interactions between a step with the broken bond effect and another step with the misfit effect, since they cancel. In fact, consider two successive steps, one is higher than the other. Due to the misfit mechanism (2.1), the higher step generates a surface stress with a sign the same as δa and the lower step generates a surface stress with a sign the same as $-\delta a$. However, due to the broken bond mechanism, the two steps generate force dipole moments with the same sign. Therefore the elastic interactions between one step with the broken bond mechanism and another step with the misfit mechanism cancel and we do not need to take them into consideration. In Duport, Politi, and Villain's paper [9], they did not notice this and they omitted these interactions by assuming either the broken bond mechanism or the misfit mechanism is dominant.

Now we solve the system (2.2). Usually in epitaxial growth, the deposition process is much slower than the diffusion process, which means that the step velocity is very small compared with the adatom hopping velocity. Therefore the quasi-static approximation can be made:

$$\frac{\partial \rho_n}{\partial t} \approx 0. \tag{2.10}$$

Under this assumption, we can get an explicit solution for the step velocity:

$$\begin{aligned}
\frac{1}{a^2}\frac{dx_n(t)}{dt} &= F\frac{l_n + l_{n-1}}{2} \\
&+ \frac{\rho_n^- e^{\frac{U(x_{n+1})}{k_BT}} - \rho_n^+ e^{\frac{U(x_n)}{k_BT}}}{\frac{e^{\frac{U(x_n)}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_{n+1})}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_n}^{x_{n+1}} e^{\frac{U(y)}{k_BT}}dy} \\
&- \frac{\rho_{n-1}^- e^{\frac{U(x_n)}{k_BT}} - \rho_{n-1}^+ e^{\frac{U(x_{n-1})}{k_BT}}}{\frac{e^{\frac{U(x_{n-1})}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_n)}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_{n-1}}^{x_n} e^{\frac{U(y)}{k_BT}}dy} \\
&+ \frac{\frac{Fl_n}{2}\left(\frac{e^{\frac{U(x_{n+1})}{k_BT}}}{k^-} - \frac{e^{\frac{U(x_n)}{k_BT}}}{k^+}\right)}{\frac{e^{\frac{U(x_n)}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_{n+1})}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_n}^{x_{n+1}} e^{\frac{U(y)}{k_BT}}dy} \\
&- \frac{\frac{Fl_{n-1}}{2}\left(\frac{e^{\frac{U(x_n)}{k_BT}}}{k^-} - \frac{e^{\frac{U(x_{n-1})}{k_BT}}}{k^+}\right)}{\frac{e^{\frac{U(x_{n-1})}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_n)}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_{n-1}}^{x_n} e^{\frac{U(y)}{k_BT}}dy} \\
&+ \frac{\frac{F}{D}\int_{x_n}^{x_{n+1}}\left(y - \frac{x_{n+1}+x_n}{2}\right)e^{\frac{U(y)}{k_BT}}dy}{\frac{e^{\frac{U(x_n)}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_{n+1})}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_n}^{x_{n+1}} e^{\frac{U(y)}{k_BT}}dy} \\
&- \frac{\frac{F}{D}\int_{x_{n-1}}^{x_n}\left(y - \frac{x_n+x_{n-1}}{2}\right)e^{\frac{U(y)}{k_BT}}dy}{\frac{e^{\frac{U(x_{n-1})}{k_BT}}}{k^+} + \frac{e^{\frac{U(x_n)}{k_BT}}}{k^-} + \frac{1}{D}\int_{x_{n-1}}^{x_n} e^{\frac{U(y)}{k_BT}}dy},
\end{aligned} \tag{2.11}$$

where

$$l_n \equiv x_{n+1} - x_n \tag{2.12}$$

is the width of the terrace between the nth step and the $(n+1)$st step.

If it is further assumed that the elastic energies are very small compared to the thermal energy

$$f_n, U(x) << k_BT, \tag{2.13}$$

keeping the leading order terms of $1/k_BT$ for each effect, respectively, we can write the step velocity as

$$
\begin{aligned}
\frac{1}{a^2}\frac{dx_n(t)}{dt} &= F\frac{l_n+l_{n-1}}{2} + \frac{\rho_0}{k_BT}\cdot\frac{l_n}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_n}{D}}\cdot\frac{f_{n+1}-f_n}{l_n} \\
&\quad - \frac{\rho_0}{k_BT}\cdot\frac{l_{n-1}}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_{n-1}}{D}}\cdot\frac{f_n-f_{n-1}}{l_{n-1}} \\
&\quad + \frac{\frac{Fl_n}{2}\left(\frac{1}{k^-}-\frac{1}{k^+}\right)}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_n}{D}} - \frac{\frac{Fl_{n-1}}{2}\left(\frac{1}{k^-}-\frac{1}{k^+}\right)}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_{n-1}}{D}} \\
&\quad + \frac{\frac{F}{D}\int_{x_n}^{x_{n+1}}\left(y-\frac{x_{n+1}+x_n}{2}\right)\frac{U(y)}{k_BT}dy}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_n}{D}} \\
&\quad - \frac{\frac{F}{D}\int_{x_{n-1}}^{x_n}\left(y-\frac{x_n+x_{n-1}}{2}\right)\frac{U(y)}{k_BT}dy}{\frac{1}{k^+}+\frac{1}{k^-}+\frac{l_{n-1}}{D}}.
\end{aligned}
\tag{2.14}
$$

This step motion equation is simpler than that derived in Duport, Politi, and Villain [9]. We keep only the leading order terms of $1/k_BT$ for each effect, respectively. (We neglect the $O(1/k_BT)$ corrections to the hopping rates $k^{\pm}$, while they kept all $O(1/k_BT)$ terms.)

If we consider only the attractive and repulsive elastic interactions between steps and neglect the elastic interaction between adatoms and steps, as well as the Schwoebel barrier, as was done in Tersoff et al. [49] and Liu, Tersoff, and Lagally [24], then we have

$$
\frac{1}{a^2}\frac{dx_n}{dt} = F\frac{l_n+l_{n+1}}{2} + \frac{\rho_0 D}{k_BT}\left(\frac{f_{n+1}-f_n}{l_n} - \frac{f_n-f_{n-1}}{l_{n-1}}\right). \tag{2.15}
$$

This corresponds to the case $U(y)\equiv 0$ and $k^+ = k^- = +\infty$ in (2.14).

3. Continuum equation. In this section, we derive our continuum model governing the elastically driving step bunching by taking the continuum limit from the modified Duport et al.'s discrete model (2.14), of which Tersoff et al.'s discrete model (2.15) is a special case.

Assume the lattice constant a is very small compared with the length scale in which we are interested; then the surface can be considered as a continuous function $h(x)$. As in the discrete models, we assume that the overall slope of the surface is negative. We also assume that the surface has only a bounded deviation from a flat surface representing a uniform step train, so that those summations of the $1/r$ elastic interactions in (2.5) and (2.6) are defined in the sense of principal value. More precisely, we assume that $h(x)\in C^4(\mathbf{R})$ satisfies the following:

$$
\begin{cases}
h_x, h_{xx}, h_{xxx}, \text{ and } h_{xxxx} \text{ are bounded,} \\
h_x < 0, \\
h(x) = -Ax + \text{a bounded smooth function,}
\end{cases}
\tag{3.1}
$$

where $A > 0$ is a constant.

Due to the monotonicity, we can also consider x as a function of h. Due to the asymptotic property of $h(x)$, we know that $x(h)$ is defined for all h and therefore has a similar asymptotic property. More precisely, $x(h)$ satisfies the following:

$$\begin{cases} x(h) \text{ has up to fourth order bounded derivatives,} \\ x_h < 0, \\ x(h) = -\dfrac{h}{A} + \text{a bounded smooth function.} \end{cases} \tag{3.2}$$

The step motion equation (2.14) can be considered as a numerical scheme for a differential equation of $x(h,t)$ with the grid constant a. We have the following relations:

$$x_n = x(h_n, t) \tag{3.3}$$

$$h_{n+1} - h_n = -a, \tag{3.4}$$

where x_n is the position of the nth step, h_n is the height of the terrace between the $(n-1)$st step and the nth step. See Figure 3.1.

We obtain our continuum equation by letting $a \to 0$ in the step motion equation (2.14). We will first compute the continuum limit of each summation representing each elastic effect and then derive the continuum equation.

3.1. Continuum limit of the $1/r^3$ interaction between steps. In this subsection, we compute the continuum limit of $\sum_{m\neq n} \frac{a^2}{(x_m - x_n)^3}$ as $a \to 0$.

First, we have

$$\begin{aligned} & \sum_{m\neq n} \frac{a^2}{(x_m - x_n)^3} \\ = & \sum_{m=1}^{+\infty} \left(\frac{a^2}{(x_{n+m} - x_n)^3} - \frac{a^2}{(x_n - x_{n-m})^3} \right) \\ = & \sum_{m=1}^{+\infty} \frac{\dfrac{2x_n - x_{n+m} - x_{n-m}}{a^2}}{\left(\dfrac{x_{n+m} - x_n}{a}\right)^3 \left(\dfrac{x_n - x_{n-m}}{a}\right)^3} \\ & \cdot \left(\left(\frac{x_n - x_{n-m}}{a}\right)^2 + \frac{x_n - x_{n-m}}{a} \frac{x_{n+m} - x_n}{a} + \left(\frac{x_{n+m} - x_n}{a}\right)^2 \right) \\ \equiv & \sum_{m=1}^{+\infty} a_m. \end{aligned} \tag{3.5}$$

For each a_m, we can compute its limit

$$\lim_{a\to 0} a_m = -\frac{3}{m^2} \frac{x_{hh}}{x_h^4} = \frac{3}{m^2} h_x h_{xx}. \tag{3.6}$$

By the assumption of $x(h)$ (3.2)

$$a_m = O\left(\frac{1}{m^2}\right). \tag{3.7}$$

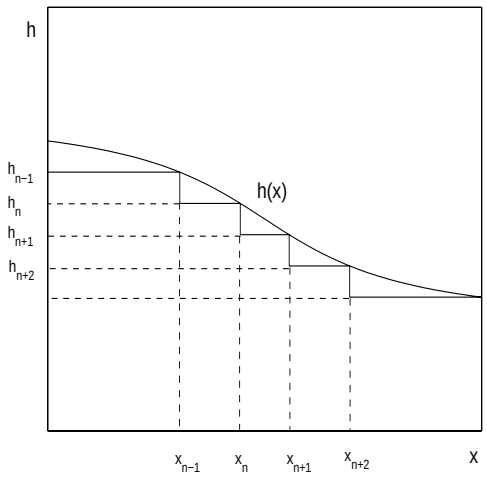

FIG. 3.1. *Continuous surface profile $h(x)$ and positions of steps.*

Therefore the summation converges absolutely, and we can change the order of the summation and the limit to get

$$\lim_{a\to 0}\sum_{m\neq n}\frac{a^2}{(x_m-x_n)^3}=\sum_{m=1}^{+\infty}h_xh_{xx}\frac{3}{m^2}=\frac{\pi^2}{2}h_xh_{xx}. \tag{3.8}$$

3.2. Continuum limit of the $1/r$ interaction between steps. In this subsection, we compute the continuum limit of $\sum_{m\neq n}\frac{a}{x_m-x_n}$ as $a\to 0$.

We use the following theorem obtained by Sidi and Israeli in [37]. They derived it to estimate the error of computing a Cauchy principal value integral using the trapezoidal rule.

THEOREM [37]. *Let $g(x)$ be $2N$ times differentiable on $[a,b]$. The interval $[a,b]$ is divided into n small intervals with $\Delta x=(b-a)/n$, $x_j=a+(j-1)*\Delta x$, $j=0,1,\ldots,n+1$. Let $G(x)=g(x)/(x-t)$, where $t=x_{j_0}$ for some $j_0\neq 0,n+1$. Then as $\Delta x\to 0$,*

$$\begin{aligned}\int_a^b G(x)dx &= \Delta x\left(\frac{1}{2}G(a)+\sum_{x_j\neq t,1\le j\le n}G(x_j)+\frac{1}{2}G(b)\right)+\Delta x g'(t)\\ &\quad+\sum_{\mu=1}^{N-1}\frac{B_{2\mu}}{(2\mu)!}(G^{(2\mu-1)}(a)-G^{(2\mu-1)}(b))\Delta x^{2\mu}+R_{2N}[G;(a,b)],\end{aligned} \tag{3.9}$$

where the B_μ's are the Bernoulli numbers and

$$|R_{2N}[G;(a,b)]|\le M_{2N}\Delta x^{2N}\int_a^b\left|\frac{d^{2N}}{dx^{2N}}\left(\frac{g(x)-g(t)}{x-t}\right)\right|dx \tag{3.10}$$

for a constant M_{2N} not depending on $G(x)$ and $[a,b]$.

Now without loss of generality, assume $x(0)=x_n$ and consider the function $G(h)=1/(x(h)-x(0))$. Choosing the grid constant to be our lattice constant a and

$N = 1$, using the theorem in $(-\infty, +\infty)$, we have

$$\int_{-\infty}^{+\infty} \frac{dh}{x(h) - x(0)} = \sum_{m \neq n} \frac{a}{x_m - x_n} - \frac{a}{2} \frac{x_{hh}}{x_h^2} + O(a^2), \tag{3.11}$$

where the integral on the left is in the sense of the Cauchy principal value at 0 and ∞. It is defined by

$$\int_{-\infty}^{+\infty} \frac{dh}{x(h) - x(0)} \equiv \lim_{H \to +\infty,\ \epsilon \to 0} \left(\int_{-H}^{-\epsilon} \frac{dh}{x(h) - x(0)} + \int_{\epsilon}^{H} \frac{dh}{x(h) - x(0)} \right). \tag{3.12}$$

Here we have used the assumption of $x(h)$ (3.2) to guarantee the existence of the Cauchy principal values at 0 and ∞ and the convergence of the integral in the error term (3.10).

Therefore we have

$$\sum_{m \neq n} \frac{a}{x_m - x_n} = \int_{-\infty}^{+\infty} \frac{dh}{x(h) - x(0)} + \frac{a}{2} \frac{x_{hh}}{x_h^2} + O(a^2). \tag{3.13}$$

Now we show that change of variable from h to x does not affect the Cauchy principal value integral. In fact,

$$\begin{aligned} \int_{\epsilon}^{H} \frac{dh}{x(h) - x(0)} &= \int_{x(\epsilon)}^{x(H)} \frac{h_x}{x - x_n} dx \\ &= -\left(\int_{x(H)}^{x_n - \frac{H}{A}} + \int_{x_n - \frac{H}{A}}^{x_n + x_h(0)\epsilon} + \int_{x_n + x_h(0)\epsilon}^{x(\epsilon)} \right) \frac{h_x}{x - x_n} dx. \end{aligned} \tag{3.14}$$

Since

$$\int_{x_n + x_h(0)\epsilon}^{x(\epsilon)} \frac{h_x}{x - x_n} dx = \int_{x_n + x_h(0)\epsilon}^{x_n + x_h(0)\epsilon + O(\epsilon^2)} \frac{h_x}{x - x_n} dx = O(\epsilon), \tag{3.15}$$

$$\int_{x(H)}^{x_n - \frac{H}{A}} \frac{h_x}{x - x_n} dx = \left| x_n - x(H) - \frac{H}{A} \right| \cdot O\left(\frac{1}{H} \right) = O\left(\frac{1}{H} \right), \tag{3.16}$$

we have

$$\int_{\epsilon}^{H} \frac{dh}{x(h) - x(0)} = -\int_{x_n - \frac{H}{A}}^{x_n + x_h(0)\epsilon} \frac{h_x}{x - x_n} dx + O(\epsilon) + O\left(\frac{1}{H} \right). \tag{3.17}$$

Similarly, we have

$$\int_{-H}^{-\epsilon} \frac{dh}{x(h) - x(0)} = -\int_{x_n - x_h(0)\epsilon}^{x_n + \frac{H}{A}} \frac{h_x}{x - x_n} dx + O(\epsilon) + O\left(\frac{1}{H} \right). \tag{3.18}$$

Therefore a change of variable from h to x does not affect the Cauchy principal value integral. From (3.13) we have as $a \to 0$,

$$\sum_{m \neq n} \frac{a}{x_m - x_n} = -\int_{-\infty}^{+\infty} \frac{h_x}{x - x_n} dx - \frac{a}{2} \frac{h_{xx}}{h_x} + O(a^2). \tag{3.19}$$

The integral is in the sense of the Cauchy principal value at 0 and ∞.

We keep the $O(a)$ term here because it has the same order as the $1/r^3$ interaction.

Summarizing the results, we have shown that as $a \to 0$,

$$a^2 f_n \approx a\alpha_1 \int_{-\infty}^{+\infty} \frac{h_x}{x - x_n} dx + \frac{1}{2} a^2 \alpha_1 \frac{h_{xx}}{h_x} + \frac{\pi^2}{2} \alpha_2 h_x h_{xx}. \tag{3.20}$$

3.3. Continuum limit of the interaction between adatoms and steps. In this subsection, we compute the continuum limit of the interaction between the steps and the adatoms on the terrace between steps x_n and x_{n+1}:

$$\lim_{a\to 0}\frac{1}{a}\int_{x_n}^{x_{n+1}}\left(y-\frac{x_n+x_{n+1}}{2}\right)\sum_m\frac{1}{x_m-y}dy. \tag{3.21}$$

This integral has singularities at the endpoints x_n and x_{n+1}. Duport, Nozieres, and Villain [8], Duport, Politi, and Villain [9], and Duport [7] overcame this difficulty by computing the integral on the interval $[x_n+a, x_{n+1}-a]$. One reason for this truncation of the integration interval is that the nearest lattice site to the step is one lattice constant away from the step. Here we also use this approximation.

First, we compute

$$\int_{x_n}^{x_{n+1}}\left(y-\frac{x_n+x_{n+1}}{2}\right)\frac{1}{x_m-y}dy. \tag{3.22}$$

For $m\neq n, n+1$

$$\int_{x_n}^{x_{n+1}}\left(y-\frac{x_n+x_{n+1}}{2}\right)\frac{1}{x_m-y}dy=-l_n+\left(x_m-\frac{x_n+x_{n+1}}{2}\right)\log\frac{x_m-x_n}{x_m-x_{n+1}}. \tag{3.23}$$

For $m=n$

$$\int_{x_n+a}^{x_{n+1}}\left(y-\frac{x_n+x_{n+1}}{2}\right)\frac{1}{x_n-y}dy=-l_n+\frac{l_n}{2}\log\frac{l_n}{a}. \tag{3.24}$$

For $m=n+1$

$$\int_{x_n}^{x_{n+1}-a}\left(y-\frac{x_n+x_{n+1}}{2}\right)\frac{1}{x_{n+1}-y}dy=-l_n+\frac{l_n}{2}\log\frac{l_n}{a}. \tag{3.25}$$

Therefore we have

$$\begin{aligned}
&\frac{1}{a}\int_{x_n}^{x_{n+1}}\left(y-\frac{x_n+x_{n+1}}{2}\right)\sum_m\frac{1}{x_m-y}dy\\
=\;&\sum_{m=1}^{+\infty}\left(-\frac{l_n}{a}+\left(\sum_{k=1}^{m}\frac{l_{n+k}}{a}+\frac{l_n}{2a}\right)\log\frac{\displaystyle\sum_{k=1}^{m}\frac{l_{n+k}}{a}+\frac{l_n}{a}}{\displaystyle\sum_{k=1}^{m}\frac{l_{n+k}}{a}}\right)\\
&+\sum_{m=1}^{+\infty}\left(-\frac{l_n}{a}+\left(\sum_{k=1}^{m}\frac{l_{n-k}}{a}+\frac{l_n}{2a}\right)\log\frac{\displaystyle\sum_{k=1}^{m}\frac{l_{n-k}}{a}+\frac{l_n}{a}}{\displaystyle\sum_{k=1}^{m}\frac{l_{n-k}}{a}}\right)\\
&-2\frac{l_n}{a}+\frac{l_n}{a}\log\frac{l_n}{a}\\
\equiv\;&\sum_{m=1}^{+\infty}a_m+\sum_{m=1}^{+\infty}b_m-2\frac{l_n}{a}+\frac{l_n}{a}\log\frac{l_n}{a}.
\end{aligned} \tag{3.26}$$

Rewrite a_m as

$$a_m = -\frac{l_n}{a} + \frac{l_n}{2a} \cdot \frac{1}{\theta_m} \log \frac{1+\theta_m}{1-\theta_m}, \tag{3.27}$$

where

$$\theta_m \equiv \frac{\dfrac{l_n}{2a}}{\displaystyle\sum_{k=1}^{m} \frac{l_{n+k}}{a} + \frac{l_n}{2a}}. \tag{3.28}$$

Using the assumption of $x(h)$ (3.2), we can prove that

$$\theta_m = O\left(\frac{1}{m}\right) \tag{3.29}$$

and

$$a_m = O\left(\frac{1}{m^2}\right). \tag{3.30}$$

That means that $\sum_{m=1}^{+\infty} a_m$ is uniformly convergent with respect to a. Therefore

$$\lim_{a\to 0} \sum_{m=1}^{+\infty} a_m = \sum_{m=1}^{+\infty} \lim_{a\to 0} a_m = \sum_{m=1}^{+\infty} \left(1 - \left(m+\frac{1}{2}\right) \log \frac{m+1}{m}\right) \frac{1}{h_x(x_n)}. \tag{3.31}$$

Similarly, we can prove that

$$\lim_{a\to 0} \sum_{m=1}^{+\infty} b_m = \sum_{m=1}^{+\infty} \lim_{a\to 0} b_m = \sum_{m=1}^{+\infty} \left(1 - \left(m+\frac{1}{2}\right) \log \frac{m+1}{m}\right) \frac{1}{h_x(x_n)}. \tag{3.32}$$

It is easy to compute the continuum limit of the other terms in (3.26):

$$\lim_{a\to 0} \left(-2\frac{l_n}{a} + \frac{l_n}{a} \log \frac{l_n}{a}\right) = \frac{2 + \log |h_x(x_n)|}{h_x(x_n)}. \tag{3.33}$$

Using the relation

$$1 + \sum_{m=1}^{+\infty} \left(1 - \left(m+\frac{1}{2}\right) \log \frac{m+1}{m}\right) = \frac{1}{2} \log 2\pi, \tag{3.34}$$

which can be found in Duport, Politi, and Villain's paper [9], we have

$$\lim_{a\to 0} \frac{1}{a} \int_{x_n}^{x_{n+1}} \left(y - \frac{x_n + x_{n+1}}{2}\right) \sum_m \frac{1}{x_m - y} dy = \frac{1}{h_x(x_n)} \log(2\pi |h_x(x_n)|). \tag{3.35}$$

Therefore as $a \to 0$, we have

$$\frac{1}{a} \int_{x_n}^{x_{n+1}} \left(y - \frac{x_n + x_{n+1}}{2}\right) U(y) dy \approx -a\alpha_0 \frac{1}{h_x(x_n)} \log(2\pi |h_x(x_n)|). \tag{3.36}$$

3.4. Derivation of continuum equation. Now we have the continuum limit of f_n (3.20) and the continuum limit of the integral containing $U(x)$ (3.36) as $a \to 0$. To get our continuum limit equation, we approximate the finite differences in the discrete model (2.14) by derivatives:

$$l_n = x_{n+1} - x_n = -x_h a + O(a^2) = -\frac{a}{h_x} + O(a^2), \tag{3.37}$$

$$\begin{aligned} & l_n + l_{n-1} \\ = \;& x_{n+1} - x_{n-1} \\ = \;& -2x_h a - \tfrac{1}{3} x_{hhh} a^3 + O(a^5) \\ = \;& -\frac{2}{h_x} a - \frac{1}{6} \frac{\partial^2}{\partial x^2} \left(\frac{1}{h_x^2} \right) a^3 + O(a^5), \end{aligned} \tag{3.38}$$

$$\frac{G_{n+1} - G_n}{l_n} = \frac{G(x_n + l_n) - G(x_n)}{l_n} = G_x + O(l_n) = G_x + O(a), \tag{3.39}$$

and therefore

$$G_{n+1} - G_n = -a \frac{G_x}{h_x} + O(a^2), \tag{3.40}$$

where G is any smooth function of x and $G_n = G(x_n)$.

We keep only the leading order terms of a in each finite difference, respectively, to keep the main contribution from each effect, except for the term $F(l_n + l_{n-1})/2$. Its leading order term of a is the average growth rate of the surface due to the deposition flux, and we keep a higher order term which has the same order as the term of elastic interactions between steps.

We also use the relation

$$\frac{Dh}{Dt} = \frac{\partial h}{\partial t} + \frac{\partial h}{\partial x} \frac{dx}{dt} = 0, \tag{3.41}$$

where Dh/Dt is the material derivative. It means that adatoms can move only in the horizontal direction.

Now letting $a \to 0$, we get the continuum equation

$$\begin{aligned} h_t \;=\; & a^3 F \left(1 + \frac{a^2}{12} \frac{\partial^2}{\partial x^2} \left(\frac{1}{h_x^2} \right) \right) \\ & + \frac{a^2 \pi \alpha_1 \rho_0 D}{k_B T} \frac{\partial}{\partial x} \left(\frac{1}{1 - (L/a) h_x} \frac{\partial f}{\partial x} \right) \\ & + \frac{1}{2} a^3 F (l_- - l+) \frac{\partial}{\partial x} \left(\frac{1}{1 - (L/a) h_x} \right) \\ & + \frac{a^3 F \alpha_0}{k_B T} \frac{\partial}{\partial x} \left(\frac{\log(2\pi |h_x|)}{1 - (L/a) h_x} \right), \end{aligned} \tag{3.42}$$

where

$$f(x) = -\frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{h_x(y)}{x - y} dy + \frac{a}{2\pi} \frac{h_{xx}}{h_x} + \frac{\pi l_e^2}{2a} h_x h_{xx} \tag{3.43}$$

and parameters

$$l_e = \sqrt{\frac{\alpha_2}{\alpha_1}}, \tag{3.44}$$

$$l_{\pm} = \frac{D}{k^{\pm}}, \tag{3.45}$$

$$L = l_+ + l_-. \tag{3.46}$$

The parameter l_e represents the equilibrium distance between two successive steps under the attractive misfit interaction and the repulsive broken bond interaction, l_+ and l_- represent the strength of the upward and downward step edge barriers, respectively, and

$$l_- \geq l_+ \tag{3.47}$$

due to the Schwoebel effect.

The first term in $f(x)$ is the Hilbert transform of h_x with a negative sign. The Hilbert transform of a function $u(x)$ is defined by

$$H(u) = \frac{1}{\pi} \int_{-\infty}^{+\infty} \frac{u(y)}{x-y} dy. \tag{3.48}$$

We can write our continuum equation in a more convenient form:

$$h_t = \bar{F} + \alpha \frac{\partial^2}{\partial x^2} \left(\frac{1}{h_x^2} \right) + \frac{\partial}{\partial x} \left[\frac{1}{1 - \bar{L} h_x} \left(\beta \frac{\partial f}{\partial x} + \lambda + \sigma \log(2\pi |h_x|) \right) \right], \tag{3.49}$$

$$f = -H(h_x) + \eta \left(\frac{1}{h_x} + \gamma h_x \right) h_{xx}, \tag{3.50}$$

where $H(h_x)$ is the Hilbert transform of h_x and

$$\bar{F} = a^3 F, \tag{3.51}$$

$$\alpha = \frac{a^5 F}{12}, \tag{3.52}$$

$$\bar{L} = \frac{L}{a}, \tag{3.53}$$

$$\beta = \frac{a^2 \pi \alpha_1 \rho_0 D}{k_B T}, \tag{3.54}$$

$$\lambda = \frac{1}{2} a^3 F (l_- - l_+), \tag{3.55}$$

$$\sigma = \frac{a^3 F \alpha_0}{k_B T}, \tag{3.56}$$

$$\eta = \frac{a}{2\pi}, \tag{3.57}$$

$$\gamma = \frac{\pi^2 l_e^2}{a^2}, \tag{3.58}$$

where all the constants are positive except σ, which may be either positive or negative.

The constant $\bar{F}$ and the $\frac{\partial^2}{\partial x^2}(\frac{1}{h_x^2})$ term are due to the deposition flux, where $\bar{F}$ is the average growth rate of the surface and the $\frac{\partial^2}{\partial x^2}(\frac{1}{h_x^2})$ term is the correction due to the local surface profile. The function f represents the elastic interactions between steps. The Hilbert transform term and the h_{xx}/h_x term come from the $1/r$ misfit elastic interaction. The $h_x h_{xx}$ term comes from the $1/r^3$ broken bond elastic interaction. The constant λ and the factor $1/(1-\bar{L}h_x)$ come from the step edge barriers; λ is positive due to the Schwoebel effect. The constant λ also depends on the deposition flux. The $\log(2\pi|h_x|)$ term is due to the elastic interaction between adatoms and steps. Its coefficient σ also depends on the deposition flux. Its sign can be positive or negative depending on the sign of α_0. Recall that $\alpha_0 > 0$ means the elastic interaction between an adatom and a step is repulsive for upper steps and is attractive for lower steps. Thus the adatoms on a terrace prefer to go to the lower step than to the upper step. On the other hand, $\alpha_0 < 0$ means the elastic interaction between an adatom and a step is attractive for upper steps and is repulsive for lower steps. Thus the adatoms on a terrace prefer to go to the upper step rather than to the lower step.

We can also write the continuum equation as

$$h_t = a^3 F - \frac{\partial}{\partial x} J(x,t), \tag{3.59}$$

where the surface flux $J(x,t)$ is

$$J(x,t) = -\alpha \frac{\partial}{\partial x}\left(\frac{1}{h_x^2}\right) + \frac{1}{1-\bar{L}h_x}\left(\beta \frac{\partial f}{\partial x} + \lambda + \sigma \log(2\pi|h_x|)\right). \tag{3.60}$$

If we neglect the Schwoebel barrier and the elastic interaction between adatoms and steps, the continuum equation becomes

$$h_t = \bar{F} + \alpha \frac{\partial^2}{\partial x^2}\left(\frac{1}{h_x^2}\right) + \beta \frac{\partial^2}{\partial x^2}\left[-H(h_x) + \eta\left(\frac{1}{h_x} + \gamma h_x\right) h_{xx}\right]. \tag{3.61}$$

It is the continuum limit of Tersoff et al.'s model (2.15).

If we do not take into consideration the deposition flux, in other words, we consider only the elastic interaction between steps, the continuum equation becomes

$$h_t = \frac{\partial^2}{\partial x^2}\left[-H(h_x) + \eta\left(\frac{1}{h_x} + \gamma h_x\right) h_{xx}\right]. \tag{3.62}$$

Here we have rescaled the time by β.

Equation (3.62) has a variational form. It can be written as

$$h_t = \mu_{xx}, \tag{3.63}$$

where the chemical potential μ is the variation of the total elastic energy

$$\mathcal{E} = \int \left(-\frac{1}{2}\tilde{h}H(h_x) + \eta|h_x|\log|h_x| + \frac{\eta\gamma}{6}|h_x|^3\right) dx. \tag{3.64}$$

Here $\tilde{h} = h - (-Ax)$ is the deviation from the reference planar surface (see assumption (3.1)).

Results on the linear instability, nonlinear evolution, and steady states using our continuum equation are presented in [52].

4. Summary. We have derived a continuum model governing the epitaxial growth with elasticity on a $1+1$-dimensional vicinal surface where the surface profile is monotonic. We obtained our model by taking the continuum limit from the discrete models of Duport, Politi, and Villain [9] and Tersoff et al. [49]. Compared with the existing continuum models for epitaxial growth on a vicinal surface, our model includes the effect of elasticity. Compared with the existing continuum models for surface morphology instability induced by elasticity, our model incorporates the atomic features of the stepped surface.

Acknowledgments. The author would like to thank Professor Weinan E of Princeton University and Professor Robert V. Kohn of New York University for helpful discussions.

DERIVATION OF CONTINUUM TRAFFIC FLOW MODELS FROM MICROSCOPIC FOLLOW-THE-LEADER MODELS*

A. AW†, A. KLAR‡, T. MATERNE‡, AND M. RASCLE†

Abstract. In this paper we establish a connection between a microscopic follow-the-leader model based on ordinary differential equations and a semidiscretization of a macroscopic continuum model based on a conservation law. Naturally, it also turns out that the natural discretization of the conservation law in Lagrangian coordinates is equivalent to a straightforward time discretization of the microscopic model. We also show *rigorously* that, at least in the homogeneous case, the macroscopic model can be viewed as the limit of the time discretization of the microscopic model as the number of vehicles increases, with a scaling in space and time (a zoom) for which the density and the velocity remain fixed. Moreover, a numerical investigation and comparison is presented for the different models.

Key words. microscopic and macroscopic traffic models, Godunov scheme, hydrodynamic limit

1. Introduction.

Microscopic modeling of vehicular traffic is usually based on so-called follow-the-leader models; see [16], [6]. A system of ordinary differential equations is used to model the response of vehicles to their leading vehicle. These models usually consist of a system of second order ordinary differential equations. For instance (a more general nonlinearity could be considered as well), we consider

$$\begin{aligned} \dot{x}_i &= v_i, \\ \dot{v}_i &= C\frac{v_{i+1}-v_i}{(x_{i+1}-x_i)^{\gamma+1}} + A\frac{1}{T_r}\left[V\left(\frac{\Delta X}{x_{i+1}-x_i}\right)-v_i\right], \end{aligned} \tag{1.1}$$

where $x_i(t)$, $v_i(t), i = 1, \ldots,$ are location and speed of the vehicles at time $t \in \mathbb{R}^+$, and ΔX is the length of a car. The basic idea is that the acceleration at time t depends on the relative speeds of the vehicle and its leading vehicle at time t and the distance between the vehicles. The constants $C > 0$, $A > 0$, $\gamma \geq 0$ and the relaxation time T_r are given parameters. In the *homogeneous* case $A = 0$ we recover the usual form of microscopic follow-the-leader models. For $A > 0$ a relaxation term is added, driving the velocity of the car to an equilibrium velocity V, which depends on macroscopic properties of the flow ahead of the driver. T_r is the corresponding relaxation time, different from (and typically much larger than) the reaction time of individual drivers. The constants C, γ are fitted to special situations (see [6]). A common choice is, for example, $\gamma = 0$. This case has to be treated separately from $\gamma > 0$; see below. Initial values $x_i(0) = x_i^0$, $v_i(0) = v_i^0$ have to be described with $v_i^0 \geq 0$ and $x_{i+1}^0 > x_i^0$. Sometimes, a time lag is included in the equations to account for the reaction times of the drivers.

Macroscopic modeling of vehicular traffic started with the work of Whitham [21]. He considered the continuity equation for the density ρ, closing the equation by an equilibrium assumption on the mean velocity v. The equation is

$$\partial_t \rho + \partial_x(\rho V(\rho)) = 0,$$

where $V = V(\rho)$ describes the dependence of the velocity with respect to the density for an *equilibrium* situation. An additional velocity equation has been introduced by Payne [15] and Whitham [21] as an analogy to fluid dynamics. Recently Daganzo [5] has pointed out some severe drawbacks of the Payne/Whitham-type models in certain situations. In [2] Aw and Rascle did develop a new heuristic continuum model avoiding these inconsistencies:

$$\begin{aligned} \partial_t \rho + \partial_x(\rho v) &= 0, \\ \partial_t(\rho v) + \partial_x(\rho v^2) - \rho^2 P'(\rho)\partial_x v &= A\,\frac{\rho}{T_r}\left[V(\rho) - v\right], \end{aligned}$$

where $P(\rho)$ is a given function describing the anticipation of road conditions in front of the drivers, and P' denotes its derivative with respect to ρ. In [2], the authors considered the case of the homogeneous system $A = 0$, but one can also consider in particular the case $A > 0$; see [17] and also [8]. Using the new variable

$$w = v + P(\rho)$$

the model can be written in conservative form as follows:

$$\begin{aligned} \partial_t \rho + \partial_x(\rho v) &= 0, \\ \partial_t(\rho w) + \partial_x(v\rho w) &= A\,\frac{\rho}{T_r}\left[V(\rho) - v\right]. \end{aligned}$$

Initial conditions have to be prescribed: $\rho(x,0) = \rho^0(x) \geq 0$ and $v(x,0) = v^0(x) \geq 0$. We note that the coefficients in the above models can be prescribed in an a priori way or derived from microscopic considerations. See, e.g., [11] for a derivation from a kinetic traffic flow equation.

In the present paper we show how the Aw–Rascle model can be viewed as the limit of a time discretization of a microscopic follow-the-leader model. In particular, the macroscopic coefficient $P = P(\rho)$ is determined from the microscopic model. The paper is arranged in the following way: in section 2 microscopic follow-the-leader models and the Aw–Rascle continuum model are considered in more details. In section 3 scaling limits of the microscopic equation are considered and the formal connection between microscopic and macroscopic model is established. Section 4 contains the full space-time discretization of both models and rigorous relations between the models. Section 5 considers numerically the convergence of the discretized system towards the conservation law in the limit of small time steps and large number of vehicles. We refer to [17] for a related discussion. Finally, when finishing this paper, we received from J. Greenberg—whom we thank—a very recent preprint [8], based on quite similar ideas; see section 4.1 for some comments and a comparison of the results. We have also learned about closely related ideas in [22]. Clearly, these kind of ideas are on the rise.

2. The models. In this section we discuss the microscopic and macroscopic models in more detail.

2.1. The microscopic model. We reconsider the microscopic equations (1.1) with constant $C = C_\gamma$. We introduce a new variable, the distance between, say, the tails of two vehicles following each other:

$$l_i = x_{i+1} - x_i.$$

One obtains the system

$$\begin{aligned} \dot{x}_i &= v_i, \\ \dot{v}_i &= C_\gamma \frac{(v_{i+1} - v_i)}{l_i^{\gamma+1}} + A\frac{1}{T_r}(V(\rho_i) - v_i), \end{aligned}$$

where the local "density around vehicle i" and its inverse (the local (normalized) "specific volume") are, respectively, defined by

$$\rho_i = \frac{\Delta X}{l_i} \quad \text{and} \qquad \tau_i = \frac{1}{\rho_i} = \frac{l_i}{\Delta X}.$$

REMARK 1. *The density is often defined as the* number *of cars per unit length; here* $\nu := 1/l_i$*, and therefore has the dimension of the inverse of a length. With our definition, the density is already* normalized, $\rho = \nu.\Delta X := \nu/\nu_m$*, and is therefore dimensionless, so that the* maximal *density is* $\rho_m = 1/\tau_m = 1$*, when cars are "nose to tail." We will often write expressions like* ρ/ρ_m *or* τ/τ_m *to emphasize this normalization.*

Now define the constant C_γ by

$$C_\gamma = v_{ref}(\Delta X/\ \rho_m)^\gamma = v_{ref}(\Delta X\ \tau_m)^\gamma = \ v_{ref}\Delta X^\gamma,$$

where $v_{ref} > 0$ is a reference velocity, and the coefficient $(\Delta X\ \tau_m)^\gamma$ allows us to recognize in (1.1) the derivative of function $\tilde{P}(\tau)$ defined below in (2.2). One obtains the microscopic model

$$\begin{aligned} \dot{x}_i &= v_i, \\ \dot{v}_i &= \frac{1}{\Delta X}\,(v_{i+1} - v_i)\frac{v_{ref}\tau_m^\gamma}{\tau_i^{\gamma+1}} + A\,\frac{1}{T_r}\,(V(\rho_i) - v_i)\,, \end{aligned} \tag{2.1}$$

where again $\tau_m = 1$ with our definition. We have

$$\dot{l}_i = v_{i+1} - v_i \quad \text{or} \qquad \dot{\tau}_i = \frac{1}{\Delta X}\,(v_{i+1} - v_i).$$

Using the new variable

$$w_i :=\ v_i +\ \tilde{P}(\tau_i)\ \text{ with }\ \tilde{P}(\tau_i) := \begin{cases} \frac{v_{ref}}{\gamma}\ (\frac{\tau_m}{\tau_i})^\gamma, & \gamma > 0, \\ -v_{ref}\ln(\frac{\tau_i}{\tau_m}), & \gamma = 0, \end{cases} \tag{2.2}$$

we get

$$\dot{w}_i = A\,\frac{1}{T_r}\,(V(\rho_i) - v_i)\,.$$

Altogether, one notices that (2.1) can be rewritten in the form

$$\begin{aligned} \dot{\tau}_i &= \frac{1}{\Delta X}\,(v_{i+1} - v_i), \\ \dot{w}_i &= A\,\frac{1}{T_r}\,(V(\rho_i) - v_i)\,. \end{aligned} \tag{2.3}$$

The initial conditions are $\tau_i(0) = \tau_i^0 > 0$, $v_i(0) = v_i^0 \geq 0$.

2.2. The macroscopic model. In conservative form, the macroscopic system under consideration is given by the following equations:

$$\begin{aligned} \partial_t \rho + \partial_x \rho v &= 0, \\ \partial_t \rho w + \partial_x v \rho w &= A\, \frac{\rho}{T_r}\, \left[V(\rho) - v\right], \end{aligned} \tag{2.4}$$

where ρ is again defined as the (normalized) density, i.e., the (local) dimensionless fraction of space occupied by the cars, and v denotes the macroscopic velocity of the cars. Moreover, $A = 0$ in the case of the homogeneous model and A is a positive constant, say $A = 1$, for the relaxed model, and

$$w = v + P(\rho). \tag{2.5}$$

The hyperbolic part of the above system is written as

$$\begin{aligned} \partial_t \rho + \partial_x (\rho v) &= 0, \\ \partial_t (\rho w) + \partial_x (v \rho w) &= 0. \end{aligned} \tag{2.6}$$

In the following, we consider a special class of functions $P(\rho) := \tilde{P}(1/\rho)$, where $\tilde{P}$ is defined in (2.2). In other words, for $\rho > 0$,

$$P(\rho) = \begin{cases} \frac{v_{ref}}{\gamma} \left(\frac{\rho}{\rho_m}\right)^{\gamma}, & \gamma > 0, \\ v_{ref} \ln\left(\frac{\rho}{\rho_m}\right), & \gamma = 0, \end{cases} \tag{2.7}$$

where, as in the previous subsection, $\rho_m = 1$ and v_{ref} is a given reference velocity. The function P is not a pressure. In fact, it is homogeneous to a velocity [11], [17]. In the context of gas dynamics—completely irrelevant here; see [5], [2]—this pseudopressure P would be homogeneous to the enthalpy, so that the exponent γ here plays the role of the usual $(\gamma - 1)$. In particular, the case $\gamma = 0$ here would correspond to the isothermal case, with the same mathematical advantages and difficulties; e.g., one of the Riemann invariants is unbounded near regions of local vacuum; see section 4.1. To obtain a well-defined problem for the case with relaxation—$A > 0$—we choose the function $V = V(\rho)$, $\rho > 0$, such that

$$-P'(\rho) \le V'(\rho) \le 0 \tag{2.8}$$

is fulfilled for all $\rho > 0$. This is the so-called *subcharacteristic condition*; see, e.g., [21], [3], [7]. A typical choice would be $V(\rho) = -c\,(P(\rho) - P(\rho_m))$, $0 \le c \le 1$, and a description of the equilibrium curve $v = V(\rho)$ in the (w, v) plane is shown in Figure 2.1 (left) for the case $\gamma > 0$ and in Figure 2.2 (left) for $\gamma = 0$. Of particular interest is the *characteristic* case, where the equality holds in one of the above inequalities. More precisely, if $\gamma > 0$, we assume that

$$V'(\rho) = -P'(\rho) \text{ (resp., 0) for } \rho \le \rho_* \text{ (resp., } \rho_* \le \rho \le \rho_m), \tag{2.9}$$

where ρ_* is some positive intermediate value between $\rho = 0$ and the maximal value ρ_m of ρ. The equilibrium curve is shown in Figure 2.1 (right); see [17].

In contrast, if $\gamma = 0$, then in the characteristic case we will assume that

$$\begin{aligned} &V(\rho) = v_m \text{ (resp., } -P(\rho)) \text{ (resp., 0)} \\ &\text{for } 0 \le \rho \le \rho_* \text{ (resp., } \rho_* \le \rho \le \rho_{**}) \text{ (resp., } \rho_{**} \le \rho \le \rho_m), \end{aligned} \tag{2.10}$$

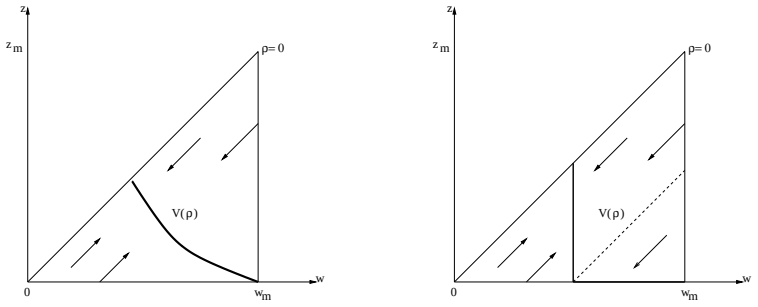

FIG. 2.1. *Invariant region* R *and equilibrium curve* $v = V(\rho)$ *for* $\gamma > 0$*, in the* $(w, z) = (w, v)$ *plane, in the subcharacteristic case (left) and in the characteristic case (right). In the first case, the convexity of the equilibrium curve could be arbitrary.*

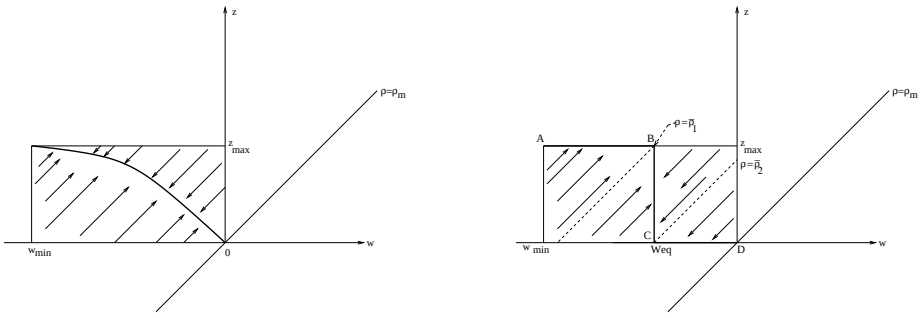

FIG. 2.2. *Invariant region* R *and equilibrium curve* $v = V(\rho)$ *for* $\gamma = 0$*, in the* (w, v) *plane, in the subcharacteristic case (left) and in the characteristic case (right).*

where ρ_* and ρ_{**} are two positive intermediate densities; see Figure 2.2 (right). In this case $\gamma = 0$, Figure 2.3 shows examples of the *same* equilibrium curve and associated bounded region (in the $(\rho,\ \rho\ v)$ plane), which are *invariant* for the *full* system (2.4) in the *subcharacteristic* case Figure 2.3 (left) and in the *characteristic* case Figure 2.3 (right).

Moreover, let $\tau := \rho^{-1}$ be the specific volume, and define the associated functions

$$\tilde{P}(\tau) = P\left(\frac{1}{\tau}\right), \qquad \tilde{V}(\tau) = V\left(\frac{1}{\tau}\right), \qquad w = v + \tilde{P}(\tau). \tag{2.11}$$

We note that

$$\tilde{P}'(\tau) = -\frac{v_{ref}\tau_m^{\gamma}}{\tau^{\gamma+1}}, \qquad \gamma \geq 0,$$

where $\tilde{P}'$ denotes the derivative of $\tilde{P}$ with respect to τ and, as in Remark 1, $\tau_m := \rho_m^{-1} = 1$. For $\rho > 0$ we have $\tilde{P}' < 0$ and $\tilde{P}'' > 0$. For $\rho > 0$, using the specific volume τ, we now transform (2.4): we change the Eulerian coordinates (x, t) into Lagrangian "mass" coordinates (X, T) (see [4]) with

$$\partial_x X = \rho, \qquad \partial_t X = -\rho v, \qquad T = t$$

or

$$\partial_X x = \rho^{-1} = \tau, \qquad \partial_X t = 0, \qquad \partial_T x = v, \qquad \partial_T t = 1.$$

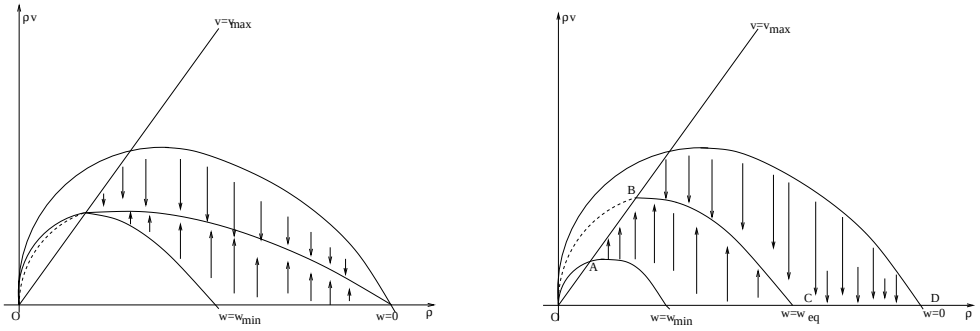

FIG. 2.3. *Invariant region* R *and equilibrium curve* $v = V(\rho)$ *for* $\gamma = 0$*, in the* $(\rho,\ \rho\, v)$ *plane, in the subcharacteristic case (left) and in the characteristic case (right).*

Thus, $X = \int^x \rho(y,t)dy$ is not a mass. In fact, it describes the total space occupied by cars up to point x. We obtain

$$\partial_T \tau - \partial_X v = 0, \tag{2.12}$$
$$\partial_T w = A\,\frac{1}{T_r}\left[V(\rho) - v\right].$$

Since $w = v + \tilde{P}(\tau)$, this is a hyperbolic system to the unknown functions w and τ, with relaxation term if $A > 0$. We add initial conditions $\tau^0(x) > 0$ and $v^0(x) \geq 0$.

We note that, as in the case of gas dynamics [20], even for *weak* (L^∞) solutions, this new system is equivalent to (2.4). This equivalence holds *even* in the vacuum case, where the map $x \to X$ is not invertible, so that $\partial_X x = \tau$ contains a delta-function. However, in this case one must admit for (2.12) a larger class of test-functions, which is an additional difficulty. In the numerical schemes described below, each cell moves between two trajectories, so that the total mass inside this cell remains constant. Therefore in each nonvoid cell, the (usual) weak solutions to (2.4) and (2.12) are the same.

3. Scaling and formal macroscopic limit of the microscopic equations. According to (2.3) the microscopic system can be written as

$$\dot{\tau}_i = \frac{1}{\Delta X}(v_{i+1} - v_i),$$
$$\dot{w}_i = A\,\frac{1}{T_r}\left(V(\rho_i) - v_i\right),$$

where $w_i = v_i + \tilde{P}(\tau_i)$ is defined in (2.2). On the other hand, denoting time by t as in Eulerian coordinates, the Lagrangian macroscopic system (2.12) is rewritten as

$$\partial_t \tau = \partial_X v,$$
$$\partial_t w = A\,\frac{1}{T_r}\left[V(\rho) - v\right],$$

with again $w = v + \tilde{P}(\tau)$. Clearly, (2.3) is at least a rough *semi*discretization of (2.12).

Now let us introduce the scaling. Obviously a macroscopic description for traffic flow is only valid if we consider a large number of vehicles on a long stretch of the highway. Therefore we introduce a scaling such that the size of the domain under

consideration goes to infinity, as well as the number of vehicles, whereas the length of cars shrinks to 0.

In other words, we "make a zoom," i.e., we introduce a small parameter ε, and we multiply the space and time units by $1/\varepsilon$; i.e., we shrink space and time coordinates x and t to

$$x' := \varepsilon\, x \qquad \text{and} \qquad t' := \varepsilon\, t.$$

In particular, the length of a car is now $\Delta X' := \varepsilon.\Delta X$.

Practically, the parameter ε is proportional to the inverse of the maximal possible number of cars per (new) unit length. The space and time derivatives are multiplied by ε. Similarly, since X is the primitive of ρ in x, it is replaced by $X' := \varepsilon\ X$, and therefore the derivatives in X are also multiplied by ε. On the other hand, the normalized density and specific volume are unchanged, as well as the velocity and the other Riemann invariant $w = v + \tilde{P}(\tau)$:

$$\rho' = \rho\ , \qquad \tau' = \tau\ , \qquad v' = v\ , \qquad w' = w.$$

Dropping the primed notation for these unchanged dependent variables, system (2.12) becomes

$$\begin{aligned} \frac{\partial \tau}{\partial t'} &= \frac{\partial v}{\partial X'}\ , \\ \frac{\partial w}{\partial t'} &= A\ \frac{1}{\varepsilon\ T_r}\left[V(\rho) - v\right]. \end{aligned} \tag{3.1}$$

Now let us look at the microscopic system, with the same scaling. The only additional modification is $l_i' = \varepsilon\ l_i$, and the relation $\tau_i = l_i/\Delta X$ is preserved with the primed variables. Again dropping the primes for the unchanged dependent variables, system (2.3) becomes

$$\begin{aligned} \frac{d\tau_i}{dt'} &= \frac{1}{\Delta X'}(v_{i+1} - v_i) \\ \frac{dw_i}{dt'} &= \frac{A}{\varepsilon\ T_r}\ \left(V(\rho_i) - v_i\right). \end{aligned} \tag{3.2}$$

Now let us discuss the consequences of the above scaling on the *equations.* There are two cases.

The homogeneous case $A = 0$. In this case, not surprisingly, the hyperbolic system and the microscopic system remain unchanged with this self-similar scaling. The only (*important*) difference is that in the new coordinates, the mesh size (see the next section) $\Delta X' = \varepsilon \Delta X$ tends to 0 when the zoom parameter ε tends to 0.

Therefore, at least *formally,* the microscopic system "converges" to the macroscopic one when ε tends to 0. More precisely, in this homogeneous case $A = 0$, (3.2) can be viewed as the natural semidiscretization of (3.1); see section 4—finer and finer when ε tends to 0. Obviously, the scaling changes the *initial data*, see Remark 3 below.

The relaxed case $A > 0$. Then there are two possibilities. First, assume that the positive constant A in front of the relaxation time depends nicely on some macroscopic scale and is, in fact, proportional to ε. In other words, let us assume that the relaxation time is comparable in size to the number of cars per (rescaled)

unit length. We note that for numerical purposes, we do not really need to let ε tend to 0, but we need only to consider a "small" ε, so that the semidiscretization (3.2) is "fine enough"; see Remark 2 below. In this case, the conclusion is the same as in the homogeneous case: the macroscopic system is at least the *formal* limit of the microscopic one. Second, on the contrary, assume that this constant A is unchanged in the scaling; then we formally end up with a scalar Lighthill–Whitham–Richards-type equation, but then the limit we are considering is the limit $(\Delta X', \Delta t') = (\Delta X, \Delta t)\ \varepsilon \to\ (0,0)$, with ΔX and Δt constant.

REMARK 2. *The size of the physical quantities allows for various possibilities to scale nicely the equations, with relatively small (but* finite*) values of ε, possibly with* different *scaling constants in x and t. For instance, assume that the "old" units are meter and second. Then, choose as "new" units (or reference length and time)* 1500 *m (or a mile) and* 1 *minute, with $\Delta X = 5$ m. Then we rescale as follows:*

$$x' = \frac{x}{1500}, \qquad t' = \frac{t}{60}.$$

On the other hand, a typical velocity is 90 *km/h, i.e.,* 25 *m/s, or* 1500 *m per mn, i.e.,* 1 *in the new units, which is perfect. Moreover, in these new units, the length of a car is $\Delta X' = 5/1500 = 1/300$, whereas a good time step in the time discretization, of the same order as the reaction time of the drivers, would be $\Delta t = 1/5$ second $= 1/300$ of the new time unit. Thus, in such a system of units, a typical (maximal?) velocity is of order* 1*, as well as the maximal (normalized) density, whereas typical space and time steps are of the order of* 1/300 *of the corresponding unit, subject of course to the CFL condition; see the next section. On the other hand, the relaxation time is typically found to be around* 30 *seconds, i.e.,* 0.5 *in the new units; see, for example,* [12]*. In such a scaling, the rescaled relaxation time, i.e., $\frac{A}{\varepsilon T}$, would still remain* finite*, and therefore we would still be far away from the zero-relaxation limit, i.e., from the Lighthill–Whitham–Richards model.*

REMARK 3. *So far, we have not discussed the problem of the* initial data*. Let us restrict ourselves to the* homogeneous *case $A = 0$, say, in Lagrangian coordinates. (The discussion would be the same in Eulerian coordinates.) In this case, as we said, the scaling preserves the system* (2.12) *(with $A = 0$), which we rewrite in the general form*

$$\frac{\partial U}{\partial t'} + \frac{\partial F(U)}{\partial X'} = 0, \tag{3.3}$$

with $U := U^\varepsilon := (\tau^\varepsilon,\ w^\varepsilon)$. However, this scaling modifies the initial data, where there are obviously (at least) two scales: the microscopic one, i.e., the length of a car (a few meters), and the macroscopic one (say, one kilometer). Therefore, it is natural to extend the microscopic initial data defined in section 2.1 *and to assume, for instance, that in rescaled Lagrangian coordinates the initial data are written as*

$$U_0^\varepsilon(X') = \sum_j \overline{U_j^0}\chi_j(X'), \tag{3.4}$$

where the characteristic function χ_j satisfies $\chi_j(X') = 1$ if and only if $X' \in I_j := (X'_{j-1/2},\ X'_{j+1/2})$, with $X'_l := l\Delta X'$, and $\overline{U_j^0}$ is the average value of a "macroscopic" function U_0 over the same interval.

When $\varepsilon \to 0$, the initial data (3.4) provide initial numerical data to approximate the solution of the initial value problem (3.3), (3.5), with

$$U(X', 0) = U_0(X'). \tag{3.5}$$

4. Rigorous relations between the microscopic and macroscopic equations. In this section microscopic and macroscopic discretizations are discussed as well as different convergence results.

4.1. The discretized models. In this section we will show that a standard explicit Euler discretization of the microscopic model is equivalent to the classical Godunov scheme applied to the macroscopic model. Moreover, this discretization is investigated in more detail.

The discretized microscopic model. We first introduce an explicit Euler time discretization of the *new* microscopic model, (3.2), using the *rescaled* time step $\Delta t'$. With the above scaling we note that the *new* Δt and ΔX tend to zero when ε tends to 0, with a *fixed* ratio $\lambda := \Delta t/\Delta X$. Neglecting the primed notation, i.e., writing Δt and ΔX instead of $\Delta t'$ and $\Delta X'$, we obtain

$$\tau_i^{n+1} = \tau_i^n + \frac{\Delta t}{\Delta X}(v_{i+1}^n - v_i^n), \tag{4.1}$$

with

$$v_i^{n+1} = w_i^{n+1} - \tilde{P}(\tau_i^{n+1}),$$

and if $A > 0$, the relaxation is approximated by

$$w_i^{n+1} = w_i^n e^{\frac{-A\,\Delta t}{\varepsilon T_r}} + (\tilde{V}(\tau_i^{n+1}) + \tilde{P}(\tau_i^{n+1}))(1 - e^{\frac{-A\,\Delta t}{\varepsilon T}}), \tag{4.2}$$

with $\rho_i^n = 1/\tau_i^n$. Of course, (4.2) contains the homogeneous case—if $A = 0$, then

$$w_i^{n+1} = w_i^n. \tag{4.3}$$

On the other hand, if $A > 0$, the relaxation term is correctly treated for ε small, i.e., for small relaxation times, where the equations are becoming stiff. Now let us discretize the macroscopic model.

The discretized macroscopic model. As above, we consider the macroscopic model (3.1) in rescaled variables x', t', with corresponding steps $\Delta t'$, $\Delta X'$, and we again drop the primed notations. Then (3.1) is discretized using a splitting scheme which treats separately the convection and the relaxation terms. Consider

$$\begin{aligned} \partial_t \tau - \partial_X v &= 0, \\ \partial_t w &= 0 \quad \text{if } A = 0, \end{aligned} \tag{4.4}$$

and

$$\partial_t w = \frac{A}{\varepsilon T}\,[V(\rho) - v] \quad \text{if } A \neq 0. \tag{4.5}$$

The most natural discretization to treat the convection part is the Godunov scheme. The relaxation part is treated by the same time discretization as for the microscopic model. Before writing Godunov's method for the hyperbolic equation, we need a brief description of the solution to the Riemann problem.

We consider the system (4.4), or the equivalent system (2.6) in Eulerian coordinates. We recall that $w = v + \tilde{P}(\tau)$. First, the eigenvalues of the system (4.4) are

$\lambda_1 = \tilde{P}'(\tau) < 0$ and $\lambda_2 = 0$. The Riemann invariants are w and $z := v$. They satisfy, for smooth solutions,

$$\partial_t v + \lambda_1 \partial_x v = 0, \qquad \partial_t w + \lambda_2 \partial_x w = 0.$$

Now, since $\tilde{P}''(\tau) > 0$, it turns out that the first eigenvalue λ_1 is genuinely nonlinear (GNL), i.e., for all (w, v), $\partial\lambda_1/\partial v \neq 0$. On the contrary, $\partial\lambda_2/\partial w \equiv 0$; i.e., $\lambda_2 = 0$ is linearly degenerate (LD), as for the original system (2.6) in Eulerian coordinates.

Now let us denote the left and right Riemann data by (w_L, v_L) and (w_R, v_R), respectively. Since the first characteristic speed is genuinely nonlinear, a state (w, v) can be connected on its left (in the (X, T) plane) to (w_L, v_L), either by a backward 1-shock if $v < v_L$, which corresponds to *braking*, or by a backward 1-rarefaction (acceleration) wave if $v > v_L$.

Moreover, see [2], these equivalent systems (2.6) and (4.4) are sometimes called *Temple* systems [19]; see also [10]. Their shock curves and rarefaction curves coincide. Therefore, *even in the case of a shock*, we have $w = w_L$.

On the other hand, (w, v) can be connected on its right to (w_R, v_R) by a stationary 2-contact discontinuity $v = v_L$. Hence, two states (w_L, v_L) and (w_R, v_R) can be connected through a constant intermediate state (w_0, v_0), which is connected to (w_L, v_L) by a 1-shock (braking) if $v_R < v_L$, or by a (continuous) 1-rarefaction wave (acceleration) if $v_R > v_L$ and to (w_R, v_R) by a 2-contact discontinuity. Moreover, w, v are monotone functions of X/t for all values of this variable, whereas τ is only monotone inside *each* elementary wave. In general, $(w_0, v_0) := (w_L, v_R)$, so that we can easily solve graphically the Riemann problem in the coordinates of Figure 2.1 or 2.2.

PROPOSITION 1. *We consider here the system* (4.4), *or the equivalent system* (2.6) *in Eulerian coordinates, with the above data* (w_L, v_L) *and* (w_R, v_R). *Then we have the following:*

1. *No local extremum of* w *or* v *is created for* $t > 0$. *Therefore, the* total variation *in space of* each *Riemann invariant is* nonincreasing *in time. More precisely,*

$$|f_+ - f_0| + |f_0 - f_-| = |f_+ - f_-|, \quad f := w \text{ or } v.$$

2. *In the case* $\gamma > 0$, *the density is nonnegative if and only if* $w - v = P(\rho) \geq 0$. *Consequently, the intermediate state is at* vacuum *if the cars in front are "too fast" with respect to the following cars, namely, if*

$$v_R > w_L = v_L + \tilde{P}(\tau_L).$$

In this case, $\rho = 1/\tau = 0$, v *and* w *are not physically defined, but if we insist and* mathematically *define, for instance,* $v_0 = w_0 = w_L$, *then statement* 1 *remains true.*

3. *In the same case* $\gamma > 0$, *any region defined by the Riemann invariants*

$$\mathcal{T} := \{0 \leq v \leq w \leq w_m = P(\rho_m)\}$$

is bounded *and* invariant *for the Riemann problem and corresponds to bounded nonnegative densities and velocities. An example of such a region is the triangle represented in Figure* 2.1. *Moreover, any rectangle*

$$\mathcal{R} := \{(w, v); 0 \leq w_{min} \leq w \leq w_m = P(\rho_m)\ ,\ 0 \leq v_{min} \leq v \leq v_{max}\} \tag{4.6}$$

inside $\mathcal{T}$ *also is* invariant *for the Riemann problem, away from vacuum if* $w_{min} - v_{max} > 0$.

4. *In the case $\gamma = 0$, vacuum corresponds to $w = -\infty$. Therefore,* any *rectangle*

$$\mathcal{R} := \{-\infty < w_m \le w \le 0 \le v \le v_m\} \tag{4.7}$$

is invariant *for the Riemann problem and corresponds to bounded nonnegative velocities and densities bounded from below by* positive *quantities.*

Proof. Statements 2 and 3 are related to the case $\gamma > 0$, which has been studied in detail in [2]. Statement 1 is then obvious, including if vacuum appears. Now, let us consider the case $\gamma = 0$, which is often considered in the literature on microscopic models; see, e.g., [16], [6]. In this case, it also is easy to check statement 4 again using the relations $w_0 = w_-$, $v_0 = v_+$. So the proof is complete. ∎

REMARK 4. *In the case $\gamma = 0$, when solving the Riemann problem, it is easy to check that the maximal possible speed that cars can reach in an acceleration wave emanating from (w_L, v_L) is infinite. Therefore, the cars behind can always catch up with the cars in front of them, without having to reach the vacuum; compare the numerical results in Figures* 5.2 *and* 5.3 *in section* 5 *below.* ∎

Now (4.4) is discretized using the Godunov method for the hyperbolic problem: We introduce grids in time and mass coordinates with (rescaled) stepsize Δt and ΔX and grid points t_n and $X_{i+1/2}$. Let f_i^n denote the approximation of the function $f(t, X)$ for $X \in [X_{i-1/2}, X_{i+1/2})$, $t \in [t_n, t_{n+1})$. Let $\lambda = \frac{\Delta t}{\Delta X}$ be the grid ratio.

In view of the above discussion, the Godunov method for system (4.4) is given by

$$\begin{aligned} w_i^{n+1} &= w_i^n, \\ \tau_i^{n+1} &= \tau_i^n + \lambda(v_{i+1/2}^n - v_{i-1/2}^n) \\ &= \tau_i^n + \lambda(v_{i+1}^n - v_i^n). \end{aligned} \tag{4.8}$$

And if $A \neq 0$, the full discretization is then

$$\begin{aligned} \tau_i^{n+1} &= \tau_i^n + \lambda(v_{i+1}^n - v_i^n), \\ w_i^{n+1} &= w_i^n e^{\frac{-A\,\Delta t}{\varepsilon T_r}} + (V(\rho_i^{n+1}) + P(\rho_i^{n+1}))(1 - e^{\frac{-A\,\Delta t}{\varepsilon T_r}}), \end{aligned} \tag{4.9}$$

so that we recover exactly the above system (4.2) (or (4.1) when $A = 0$). We have therefore shown the equivalence between the discretizations of the microscopic and the macroscopic system.

By the way, in the macroscopic view of this scheme it will be clear in Theorem 4.1 below that the (sub)characteristic condition is necessary for the stability. This is far from obvious in the microscopic interpretation.

Classically, the above numerical scheme consists of three successive steps, described here in Lagrangian coordinates for nonvoid cells:

1. Starting from piecewise-constant data $U_i^n := (\tau_i^n, w_i^n)$ in each cell, solve the Riemann problem for $t_n < t < t_{n+1}$ assuming that the CFL condition is satisfied. Let $U_h(X, t) := (\tau_h, w_h)(X, t)$ denote the corresponding solution. In fact, the index h stands for the couple $(\Delta X, \Delta t)$, and plays the role of the scaling parameter ε in section 3. We note that the intermediate state $U_{i+1/2}^n$ in the Riemann problem satisfies

$$w_{i+1/2}^n = w_{i+1/2}^n, \qquad v_{i+1/2}^n = v_{i+1}^n. \tag{4.10}$$

2. At time t_{n+1}, average this solution on each cell, i.e., solve (4.1). If $A \neq 0$, let us denote the average values of conservative variables by $(\tau_i^{n+1/2}, w_i^{n+1/2})$.

3. If $A \neq 0$, approximate the ordinary differential equation as above to obtain $(\tau_i^{n+1}, w_i^{n+1})$ from (4.9).

Again, the formulas would be the same in Eulerian coordinates, except that now the cells $x_{i-1/2}, x_{i+1/2}$ would be moving with time. Since $v_{i+1/2}^n = v_{i+1}^n$, we refresh the position by

$$x_{i+1/2}^{n+1} = x_{i+1/2}^n + \Delta t v_{i+1}^n.$$

Now let $I(a,b) := [\min(a,b), \max(a,b))$. Using Proposition 1 and standard ideas, we obtain the first important result.

THEOREM 4.1. *We consider the above algorithm, under the CFL condition, assuming that if $A \neq 0$, the (sub)characteristic condition is satisfied and that the initial data lie in an invariant rectangle $\mathcal{R}$, away from vacuum. Then we have the following.*

1. *We first assume that $A = 0$. Then, as in Proposition* 1, *in each Riemann problem the total variation of w_h is nonincreasing in time. Moreover, in each cell w_h remains constant: $w_h(x,t) \equiv w_i^n$. Consequently, v_h and also τ_h are monotone in each cell. Moreover, $(w_h(X,t), v_h(X,t))$ remains in the invariant region $\mathcal{R}$ for $t_n \leq t \leq t_{n+1}$.*
2. *In step* 2, *$w_i^{n+1/2} = w_i^n$. On the other hand, since in each cell w_h is constant and τ_h monotone, the average $\tau_i^{n+1/2}$ is in $I(\tau_i^n, \tau_{i+1/2}^n)$. By monotonicity the same result is true for the velocity. In fact,*

$$v_i^{n+1/2} \in I(v_i^n, v_{i+1/2}^n) = I(v_i^n, v_{i+1}^n).$$

3. *Finally, the invariant rectangle $\mathcal{R}$ also is invariant for the Godunov scheme. Moreover the total variation of the Riemann invariants, $\sum_j |f_{i+1}^n - f_i^n|$, $f =$ w or v, in space is still decreasing with respect to n. Since w_h is constant and v_h monotone in each cell, the total variation in* time *of w_h and of $\tilde{v}_h$: $(x,t) \to v_i^n + \Delta t(v_i^{n+1} - v_i^n)$ also is controlled from above.*
4. *On any time interval (t_n, t_{n+1}) the solution U_h satisfies the (discrete)* entropy inequality *in the sense of Lax: for any convex entropy $\eta(U) = \eta(\tau, w)$ associated with the entropy flux $q(U)$, and for any n and j,*

$$\eta(U_j^{n+1}) \leq \eta(U_j^n) - (\Delta t/\Delta X)(q(U_{j+1/2}^n) - q(U_{j-1/2}^n)). \tag{4.11}$$

5. *Now we consider the full problem, and we assume that the invariant rectangle $\mathcal{R}$ is constructed as in Figure* 2.1 *or* 2.2, *e.g., in the subcharacteristic case its upper left and lower right corner are at equilibrium. Then the region $\mathcal{R}$ also is invariant by* (2.12, 2) *and by step* 3, *i.e., by* (4.2). *Moreover, under the (sub)characteristic assumption, the* sum *of the total variations in space of the Riemann invariants, $\sum_j (\, |w_{j+1}^n - w_j^n| + |v_{j+1}^n - v_j^n| \,)$, is still nonincreasing in time, and the other conclusions of* (3) *remain valid for* (4.2). *Consequently, since the inverse function $\tilde{P}^{-1}$ is Lipschitz (away from vacuum), the total variation of τ_h also remains uniformly bounded in time.*

Proof. Statements (1) to (3) exploit, in particular, the monotonicity of v between v_j^n and v_{j+1}^n, which is obvious since w_h is constant in each cell, so that there is only one simple wave per cell. Note that v is not a conserved variable, so that an *Eulerian* classical Godunov scheme the averaging step would *not* preserve the total variation and the invariant regions.

Statement (4) is classical: on any time interval (t_n, t_{n+1}) the solution U_h is constructed by the Riemann problem and thus satisfies the *entropy inequality* in the sense

of Lax [13]. Therefore, by the Jensen inequality, the new average values U_j^{n+1} satisfy (4.11).

Finally, besides the above-mentioned references, it is an exercise to show (5). Indeed, in (4.9), compute the differences $(w_{i+1}^{n+1} - w_i^{n+1})$ and $(v_{i+1}^{n+1} - v_i^{n+1})$ in terms of the previous values $f_j^{n+1/2}$, $f = w$ or v, multiply each difference by its sign and add them. Then use the (sub)characteristic assumption to show the result. In the *characteristic* case (see [8]) we note that the evolution of w in each cell does *not* depend on the other cells, so that the total variation of each Riemann invariant w and v is nonincreasing in time, whereas in the subcharacteristic case (see [1], [14]) we can only control the *sum* of these total variations. □

4.2. Convergence results and hydrodynamic limit. There are three levels of description: the fully discrete system (4.9), or (4.1), (4.3), the follow-the-leader model (1.1), and the continuous system (4.4). In this section we discuss first the limit from the fully discrete level (4.8) to the continuous macroscopic model. Moreover, passing from the fully discrete level (4.8) to the semidiscrete one (1.1) and passing from the latter to the continuous level (4.4) are considered.

With the above scaling, we *state* a first *rigorous* result of convergence of the Godunov scheme when $\varepsilon \to 0$; i.e., we state a result dealing with the limit of (4.8) to (4.4) when the rescaled Δt and ΔX tend to 0 with a fixed ratio λ, fulfilling the CFL condition.

For simplicity, we consider the *homogeneous* case $A = 0$, away from vacuum, and we state the result in *rescaled* Lagrangian coordinates, again dropping the primed notations. However, our result also is valid for system (3.1), in rescaled variables, in the (less realistic) case where A is proportional to ε, i.e., $A_0\,\varepsilon$ instead of A. Similarly, the result also is the same for the two corresponding systems in *Eulerian* coordinates. Using the above and standard compactness results, as well as standard results to control the error in the projection steps, we obtain the following theorem.

THEOREM 4.2. *Let us consider the rescaled initial data* (3.5), *and assume that the associated Riemann invariants* w_0 *and* v_0 *are bounded, have a bounded total variation, and lie in an invariant rectangle* $\mathcal{R}$, *away from vacuum.*

Then, using the piecewise-constant initial data (3.4) *as initial data for this scheme, at least a subsequence* $U_h := (w_h, \tau_h)$ *produced by the numerical scheme* (4.1) *converges to a weak entropy solution to the initial value problem* (3.3), (3.5) *as the rescaled* Δt *and* ΔX *tend to* 0 *with a fixed ratio* λ, *fulfilling the CFL condition, as the zoom parameter* $\varepsilon \to 0$.

The above result deals with passing directly from (4.8) to (4.4). It strongly suggests studying the two other natural limits: passing from the fully discrete level (4.8) to the semidiscrete one (1.1), and passing from the latter to the continuous level (4.4). Again we restrict ourselves to the case $A = 0$, away from vacuum.

THEOREM 4.3. *Under the above assumptions, i.e.,* $A = 0$, *and the initial data lie in an invariant rectangle* $\mathcal{R}$, *away from vacuum, we consider in Lagrangian coordinates the values* $U_i^n := (\tau_i^n, w_i^n)$ *constructed by* (4.8) *or* (4.1), (4.3), *but now we rescale only the time step. Therefore the rescaled time step* Δt *vanishes, with a* fixed *space mesh size* ΔX.

Moreover, we assume that the initial data are constant for X *large enough, so that there is a "first" car. Then we have the following:*

1. *The IVP for the (infinite) follow-the-leader system* (1.1) *(with* $A = 0$*) has a unique solution* $U(t)$ *defined at least locally in time. Its natural first order*

approximation (4.1), (4.3) *is stable and consistent, and therefore the whole sequence is convergent for any* fixed ΔX.

2. *The values* U_i^n *stay in the invariant bounded region* $\mathcal{R}$ *and satisfy the uniform* BV*-estimates as in Theorem* 4.1. *Consequently, the solution* U *of* (1.1) *is globally defined and satisfies the same uniform estimates.*
3. *Moreover, set* $U_i := (\tau_i, w_i)$ *and let* $F_{i+1/2} := G(U_i, U_{i+1}) := F(U_{i+1/2}) = F(U_{i+1}) := (v_{i+1}(t),\ 0) = (w_{i+1} - \tilde{P}(\tau_{i+1}),\ 0)$ *denote the (well-defined) Godunov flux at the interface* $X = X_{i+1/2}$. *This nonlinear relation is preserved in the limit* $\Delta t \to 0$*: for all* $t \geq 0$, $F_{i+1/2}(t) := G(U_i(t), U_{i+1}(t)) = (v_{i+1},\ 0) = F(U_{i+1}(t))$. *Finally* (1.1) *is the semidiscretization of* (4.4)*: for any* $t \geq 0$,

$$\frac{dU_i}{dt}(t) = -(\Delta X)^{-1}\,(F_{i+1/2}(t) - F_{i-1/2}(t)). \tag{4.12}$$

Proof. The first part of this result can be adapted from standard textbooks (see, e.g., [18]) to the case of infinite-dimensional systems of ordinary differential equations, here with the l^∞ norm. The other results use the discrete BV estimates (in space and in time) inherited from the Godunov scheme. ∎

Now, define $\mathcal{U}_h(X,t) := \sum_j (\tau_i(t), w_i(t))\,\chi_i(X)$, where χ is defined as in (3.4). We have the following theorem.

THEOREM 4.4. *Under the same assumptions as in Theorem* 4.3*, consider the IVP for the follow-the-leader system* (1.1) *(with* $A = 0$*), and let* ΔX *tend to* 0. *Then at least a subsequence of the sequence* $\mathcal{U}_h$ *converges boundedly almost everywhere to an entropy weak solution* $U := (\tau, w)$ *to the macroscopic system,* (4.4) *for any smooth* $\phi(X,t)$ *with compact support,*

$$\begin{aligned}&\int_0^{+\infty} \sum_i \int_{I_i} [\,U(X,t)\,\partial_t\phi(X,t) \;+\; F(U(X,t))\,\partial_X\phi(X,t)]\,dX\,dt\\ &+\sum_i \int_{I_i} U_0(X)\,\phi(X,0)dX := A + B + D \;=\; 0,\end{aligned} \tag{4.13}$$

and similarly the entropy inequality in the sense of Lax holds for any convex entropy.

Proof. Multiply (4.12) by an arbitrary test-function $\phi(X,t)$, make a (discrete) integration by parts in X and t, and let ΔX tend to 0. We obtain, for any smooth function $\phi(X,t)$ with compact support contained in $[-L,L]\mathrm{x}[0,T]$,

$$\begin{aligned}&\int_0^{+\infty} \sum_i \int_{I_i} [\,U_i(t)\partial_t\phi(X,t) \;+ (\Delta X^{-1})F_{i+1/2}(t)(\phi(X+\Delta X,t) - \phi(X,t))]dXdt\\ &+\sum_i \int_{I_j} U_i(0)\phi(X,0)dX \;:= A_h + B_h + D_h = 0.\end{aligned} \tag{4.14}$$

By compactness, A_h and D_h, respectively, tend to A and D when $h \to 0$. As to B_h, with an obvious first order Taylor expansion, we see that for any ϕ, $|B_h - E_h| \leq C\ \Delta X$, where

$$E_h := \int_0^{+\infty} \sum_i \int_{I_i} F_{i+1/2}(t)\partial_X\phi(X,t)dXdt,$$

and C depends on the L^∞ norm of $F(U)$ and on $L\,T||\partial_X^2\phi||_\infty$.

Now (see Theorem 4.3), $F_{i+1/2}(t) = F(U_{i+1}(t))$, and F is Lipschitz continuous. Therefore, adding and subtracting $F(U_i(t))$, we obtain $|E_h - G_h| \le C'\,\Delta X$, where

$$G_h := \int_0^{+\infty} \sum_i \int_{I_i} F(U_i(t))\partial_X\phi(X,t)dXdt = \int_0^{+\infty} \int_{\setminus} F(\mathcal{U}_h)(X,t)\partial_X\phi(X,t)dXdt$$

and $|C'| \le T\,||\partial_X\phi||_\infty.\,||F'||_\infty.\,\sup_t\{\sum_i |U_{i+1}(t) - U_i(t)|\}$.

Finally, by compactness, G_h tends to B when $\Delta X \to 0$, which shows that U is a weak solution of (4.4). We would establish the entropy inequality in a similar way. First, when $\Delta t \to 0$ as in Theorem 4.3, the fully discrete entropy inequality (4.11) is preserved at the limit and provides the *semidiscrete* entropy inequality, i.e., a relation similar to (4.14), with U, $F(U)$, and the equality sign, respectively, replaced by $\eta(U)$, $q(U)$, and the same *inequality* sign as in (4.11), which implies the Lax entropy inequality by compactness as $\Delta X \to 0$. □

REMARK 5. *In other words, at least in the homogeneous case $A = 0$, and away from vacuum, we have shown that the macroscopic system is the limit of a large number of vehicles on a long stretch of a highway and a large time scale of the same order. For a study of more general cases, we refer to* [1]. *We note, by the way, that in this limit situation the time lag mentioned in the introduction vanishes.*

In contrast, in the relaxed case $A > 0$, with a fixed constant A, we have to study the limit of (4.1) *and* (4.2) *when the three parameters Δt, ΔX, and ε tend to* 0 *together, with fixed ratios, and, of course, satisfy the CFL condition. So far, we have not studied this limit.*

REMARK 6. *In terms of modeling, here we explicitly relate the semidiscretization of the macroscopic system to the microscopic system* (1.1) *directly, i.e., without any intermediate kinetic description. Although we already mentioned the derivation of* (2.4) *from kinetic models* [11], *our* direct *derivation is conceptually important: just imagine a similar result in gas dynamics! For the relation between weak solutions in Eulerian and Lagrangian mass coordinates, we again refer to* [20]. *Finally, we have also learned very recently of a preprint* [22] *with exactly the same formal derivation of the same model.*

5. Numerical methods and examples. For numerical investigations we consider the equations in Eulerian and Lagrangian form. The time discretized microscopic equations (4.1), (4.2) or, equivalently, the Godunov method in Lagrangian coordinates (4.9) can be viewed as a particle method for the conservation law. Computing

$$\begin{aligned} \tau_i^{n+1} &= \tau_i^n + \lambda(v_{i+1}^n - v_i^n), \\ w_i^{n+1} &= w_i^n e^{\frac{-\Delta t}{T(\rho_i^{n+1})}} + (V(\rho_i^{n+1}) + P(\rho_i^{n+1}))(1 - e^{\frac{-\Delta t}{T(\rho_i^{n+1})}}), \end{aligned} \tag{5.1}$$

one obtains the location of the vehicles as follows:

$$x_i^{n+1} = x_i^n + \Delta t v_i^n. \tag{5.2}$$

The density in Eulerian coordinates at the point x_i is then given by the interpolation $\rho_i = \frac{\Delta x}{x_{i+1} - x_i}$. For discretization steps Δt and ΔX tending to 0, one obtains an approximation of the conservation law (2.4) in Eulerian coordinates. From the particle point of view this means that we have to increase the number of vehicles to obtain the desired approximation of the conservation law. However, one could as well use any

other methods to resolve the limiting conservation law in Eulerian coordinates. For example, any second order shock capturing scheme could be used for the macroscopic equations (2.4). Using such a scheme will lead to the same results as the solution of the above discrete equations with a large number of vehicles. We use a relaxation method as developed in [9]. The method is adapted to include the relaxation term on the right-hand side of (2.4). This can be done in a straightforward way that preserves the second order approximation.

In the following we will compare the microscopic particle approach and the above second order scheme using two test problems.

In all cases the equilibrium velocity $V = V(\rho)$ is chosen as a function fitting to experimental data:

$$V(\rho) = U\left(\frac{\rho}{\rho_m}\right)$$

with

$$U(\rho) = v_m \frac{\frac{\pi}{2} + \arctan(11\frac{\rho - 0.22}{\rho - 1})}{\frac{\pi}{2} + \arctan(11 \cdot 0.22)},$$

where ρ_m is the maximal density and v_m is the maximal velocity. The function $P(\rho)$ is chosen by setting $\gamma = 0$ and $\gamma = 1$, i.e., $m_2 = 1$ and $m_2 = 2$, respectively. In order to fulfill the subcharacteristic condition (2.8), we choose the function P as $P(\rho) = 2\ln(\rho/\rho_m)$ and $P(\rho) = 6\rho/\rho_m$. The first test problem is the following: We consider normalized quantities with maximal speed v_m equal to 1 and maximal density ρ_m equal to 1. From the macroscopic point of view we consider a Riemann problem with left and right states given by $\rho_L = 0.05$, $\rho_L v_L = 0.0025$, $v_L = 0.05$, and $\rho_R = 0.05$, $\rho_R v_R = 0.025$, $v_R = 0.5$. The discontinuity is located at $x = 0$. Note that $v_R > w_L = v_L + P(\rho_L)$. Thus, vacuum states appear during the evolution for the continuous conservation law for $\gamma = 1$; see [2].

The discretization size is chosen as $\Delta x = \Delta X = \frac{1}{40}$. This leads to an initial number of cars equal to 800. They are initially distributed equally, spaced with the velocities 0.05 or 0.5, respectively. The time step is chosen according to the CFL condition.

Figure 5.1 shows density ρ and flux $q = \rho u$ at a fixed time for the particle and second order methods for $\gamma = 1$ without the relaxation term. Figure 5.2 shows the same for $\gamma = 0$. Figure 5.3 shows the evolution for $\gamma = 1$ with the relaxation term, where V and T are given by $V(\rho) = U(\rho)$ and $T(\rho) = \text{constant} = 20$. Figure 5.4 shows the same for $\gamma = 0$.

Finally, Figure 5.5 shows the results of our second test case, which is a more complicated situation: The evolution at a bottleneck at $x = 0$ is simulated. The number of lanes is reduced from three to two. This is achieved by setting the maximal density equal to the number of lanes. This means that the fundamental diagram is given by $V(\rho) = U(\frac{\rho}{\rho_m})$, where inside the bottleneck the maximal density ρ_m is reduced from 3 to 2. The boundary data on the left-hand side are chosen such that the flux in the three-lane region is slightly above the maximal possible flux in the two-lane region which creates the traffic jam. ΔX and Δx are chosen as $\frac{1}{4}$, which yields a number of cars around 5000 during the evolution. Figure 5.5 shows the evolution for the microscopic particle method at different times. In particular, the development of a traffic jam is observed in the figure. Identical results are obtained if the second order method for the Eulerian equations is used.

DIFFUSION APPROXIMATION OF A SCATTERING MATRIX MODEL OF A SEMICONDUCTOR SUPERLATTICE*

PIERRE DEGOND† AND KAIJUN ZHANG‡

Abstract. In this paper we derive a diffusion equation for electron transport in a superlattice. The starting model is a quantum scattering matrix model which relates the phase space density of each superlattice cell to that of the neighboring cells. Then, in the limit of a large number of cells, a diffusion equation for the particle number density in the position-energy space is obtained, which is of the "SHE" (spherical harmonics expansion) type. The diffusion constant retains the memory of the quantum scattering characteristics of the superlattice elementary cell (like, e.g., transmission resonances). An example is treated, for which the diffusion constants are analytically computed.

Key words. superlattices, scattering matrix model, diffusion approximation, spherical harmonics expansion, drift-diffusion, energy transport, transmission resonance

1. Introduction.

Semiconductor superlattices are processed by growing periodic layers of two different semiconductor materials like GaAs and GaAlAs [25], [37]. The electronic properties of the two materials result in the establishment of a periodic electrostatic potential in the direction of the growth axis, which is discontinuous at each of the interfaces between the two materials. Superlattices possess a number of interesting physical properties, especially with respect to optoelectronics applications [25], [37]. An application to infrared radiation detection is described in [35].

The electronic properties of solids are characterized by the existence of energy bands [1]: the electron kinetic energy cannot take any arbitrary positive value, like in a vacuum, but may only belong to certain intervals, called energy bands. The bands are separated by forbidden energy gaps. Bloch's theory of bands provides the theoretical framework for this observation: it is a purely quantum mechanical effect originating from the periodic potential created by the regular arrangement of atoms in the crystal. In a superlattice, the periodic alternation of the two materials artificially creates a similar periodicity (although on a larger scale). Therefore, it is natural to expect that electron transport along the periodicity direction will exhibit the same kind of "band splitting." In this case, the bands are called "superlattice minibands," because the width of the energy bands is inversely proportional to the lattice period (see [25], [37]). For a recent account of the mathematical theory of bands, see [27].

Being a quantum mechanical phenomenon, the existence of energy bands is tightly connected with the notion of phase coherence: energy bands (or gaps) result from the constructive (or destructive) interference patterns of the electron wave-functions

between neighboring potential periods. A direct observation of the existence of energy minibands in a superlattice can be made through the measurement of Bloch oscillations [25]: electrons subject to a constant electric field undergo a periodic motion in space with zero mean. This is because each time the electron reaches the boundary of the energy band through the action of the field, it reverses direction in position space and goes backwards. Therefore, in theory, no transport in the direction of the field is allowed in a superlattice.

In practice, the situation is not so ideal due to collisions (or scattering). During their motion, electrons can collide against ionized impurities, phonons, etc. [32]. Another source of scattering, which is negligible in bulk semiconductors but which becomes extremely important in superlattices, is scattering by interface roughness [25], [15]. Indeed, at each material interface (and there are at least two of them per superlattice cell), the perfectly periodic arrangement of atoms is broken: the two materials very seldom have the same crystal constants, and this results in crystal defects at the interface. Even if the lattice mismatch (difference of the crystal constants of the two materials) is negligible, the growth process depends highly on the processing conditions and may not produce perfectly clean interfaces. This is particularly true for industrial processes, where cost constraints may contribute to poorer processing conditions.

A first consequence of collisions is that they allow some transport in the field direction, as they allow electrons to jump from one Bloch periodic trajectory to another one. To account for this effect, the reference model for superlattices, developed by Esaki and Tsu [21], is based on the hypothesis that quantum miniband theory applies to electron trajectories between collisions.

However, a second consequence of such collisions, which is not fully accounted for in the Esaki and Tsu model, is the breakdown of the phase coherence of the electron wave-functions. After a few collisions, constructive or destructive interference patterns can no longer be produced because wave-functions between neighboring cells have random phases with respect to each other. Therefore, transport loses its quantum mechanical nature over scales larger than a few mean free paths (the typical distance a particle travels between two collisions) and becomes purely classical; the quantum mechanical miniband theory still remains valid over shorter distances. The larger distance over which quantum mechanical interferences can occur is called the phase-coherence length. If the coherence length is of the order of the superlattice period, or a few superlattice periods, Bloch's theory can no longer be applied straightforwardly. In this case, Esaki and Tsu's model must be corrected to account for the fact that, even between two collisions, electron transport is not purely quantum and does not follow the miniband theory exactly. Instead, transport becomes classical on scales larger than the phase coherence length. The aim of the present paper is to derive a suitable transport model for such a situation.

2. General outline of the present work. Let ℓ denote the superlattice period. For simplicity, we first assume that the phase coherence length is equal to ℓ. We start with a microscopic model that is quantum mechanical over distances less than ℓ and classical over larger distances. For that purpose, we define the electron distribution function $f_{n+\frac{1}{2}}(k,t)$ on a periodic array of points $x_{n+\frac{1}{2}}$ separated by the period ℓ. $f_{n+\frac{1}{2}}(k,t)$ is a purely classical concept and denotes the density of particles at point $x_{n+\frac{1}{2}}$ having wave-vector k at time t. We recall that, in the semiclassical picture of electron kinetics, wave-vectors k and momenta p are related by $p = \hbar k$, where $\hbar$ is the reduced Planck constant.

Between the points $x_{n+\frac{1}{2}}$, the dynamics is quantum mechanical and must be described by means of quantum wave-functions, solutions of the stationary Schrödinger equation in the elementary cell. (We shall comment on this stationarity hypothesis later on.) Among the possible solutions, we focus on the scattering states, which are the quantum mechanical equivalent of the free moving particles. Knowledge of the scattering states gives us access to two important sets of data: the scattering probabilities, i.e., the probabilities with which particles coming into the elementary cell are either reflected or transmitted, and the quantum time delays, i.e., the duration of the reflection or transmission processes. The scattering probabilities reflect the fact that quantum tunneling through the potential structure is enhanced for some specific values of the wave-vector k called transmission resonances. Indeed, for these values of k, the transmission probability becomes close to unity.

The microscopic model consists of relating $f_{n+\frac{1}{2}}(k,t)$ to its neighboring values at previous times $f_{n+\frac{1}{2}\pm 1}(k,t-\tau)$ through the scattering coefficients. The resulting model is referred to in the literature as a "scattering matrix model" [34]. It retains the quantum nature of transport over distances less than or equal to the phase coherence length (i.e., one or a few superlattice periods) through the use of the scattering data, but reduces to a classical model over larger distances through the use of the classical distribution functions.

If the superlattice period ℓ is strictly less than the coherence length, we suppose that the latter is an integer multiple $N\ell$ of the former, and we consider $N\ell$ as the base period rather than ℓ. Therefore, the Schrödinger equation is solved for a potential structure that consists of an array of N elementary superlattice cells. As N increases, the solution comes closer and closer to that of the fully periodic problem. As soon as N passes above unity, the oscillations of the scattering data increase: transmission peaks (i.e., values of k such that the transmission probability is close to unity) due to resonant tunneling grow more numerous. Therefore, even at moderate values of N, the model can capture the highly oscillatory nature of superlattices that is observed in experimental measurements.

From the knowledge of $f_{n+\frac{1}{2}}$, we have access to the electron concentration, to the charge concentration (provided that the positive ion concentration is known), and therefore, to the self-consistent electric potential through the resolution of Poisson's equations. The self-consistent potential, in turn, is involved in the Schrödinger equation which determines the scattering data. In this way, the problem is fully coupled.

It is useful to note that the scattering matrix model is a kind of space and time discrete version of the Boltzmann equation [28]. In the same way that the continuous Boltzmann equation can be viewed as the Liouville equation of a stochastic particle system, the present model can also be viewed as a deterministic version of a random walk process. We shall come back to this point later.

The goal of this paper is to investigate the limit of the scattering matrix model when the total number of cells in the superlattice structure becomes large. Indeed, in practice, superlattices possess a large (but probably not very large) number of cells (on the order of 20), and it can be useful, at least for fast computations, to solve the model obtained by taking the limit of a large number of cells. After space and time rescaling, the scattering matrix problem appears as a perturbation problem which bears strong similarities with diffusion approximation problems in kinetic theory or with diffusion approximations of random walk processes.

We shall show that the limiting equation is a diffusion equation for the electron number density in the position-energy space (or energy distribution function). This

equation belongs to the class of spherical harmonics expansion (SHE) models, which have proved extremely useful in the context of standard semiconductor modeling. The present paper is the first (to our knowledge) to establish the SHE model in the framework of superlattices. Our derivation furnishes a direct connection between the quantum transport characteristics of the superlattice structure and the coefficients of the SHE model. This model provides means to achieve fast simulations of electron transport in superlattices. A related approach based on a continuous (rather than discrete) model can be found in [8].

Alternate macroscopic models for superlattices have also been proposed [25], [12]. They are based on a space-discrete version of pure drift-diffusion in position space only, while the present model deals with diffusion in a combined position-energy space. Our model therefore describes the physics at a more microscopic level and is thus expected to capture the highly oscillating nature of superlattices more accurately. Furthermore, the diffusion constants involved in [12] are phenomenological, while we shall provide an explicit methodology to derive these diffusion constants from the microscopic data (scattering probabilities and time delays). For instance, in [12], the reflection probabilities are ignored; on the other hand, a displacement current term is included in the current equation there. According to the numerical values, it seems that this term is small, and thus it will be neglected in our model. Globally, the present model seems to give access to a finer description of the physics, but it is also more complex in that it involves an additional variable (the particle energy).

We conclude this section with a few bibliographical comments. The diffusion approximation is a theoretical tool which links the evolution of macroscopic quantities like number or energy densities to the microscopic particle dynamics described by a kinetic equation. The diffusion approximation methodology goes back to the work of Hilbert, Chapman, and Enskog (see, e.g., [14] for an introduction to the subject). Its application to bulk semiconductors is reviewed from a physics view point in [32], [16]. The modern mathematical view of the theory was set up in [10] and [2] in the context of neutron transport (the former using a stochastic description of transport, the latter using purely deterministic models), and its application to semiconductors was developed in [30], [24]. In these works, the resulting macroscopic model is the drift-diffusion model, which is the basic tool in semiconductor modeling [28], [33] and which deals with the electron number density in position space.

By analyzing the various collision scales, it has recently been possible to derive a diffusion model for the particle number density in the position-energy space [20], [4], [17]. This model is often referred to in the literature as the SHE model (the term spherical harmonics expansion arises from its early derivation by physicists [36]). It has proved very efficient in semiconductor device modeling [22], [23] and is also used in plasma physics and gas discharge physics (e.g., [18]). An alternate derivation from a stochastic description of individual particle transport is proposed in [13].

The outline of the paper is as follows: the scattering matrix model is proposed in section 3 and appropriately scaled in section 4. Then, the formal diffusion limit is stated in section 5. Comments on the diffusion model and examples are developed in sections 6 and 7. Finally, the derivation of the diffusion model is (formally) proved in the appendix.

3. A scattering-matrix model for superlattices. We now summarize the previous discussion and set up the starting microscopic model. We consider a semiconductor superlattice consisting of layers of several materials periodically arranged in the direction x and generating a permanent periodic potential of period ℓ in this

direction. Since the superlattice period is usually very small (10 to 100 nm), electron motion through such a structure must be described quantum mechanically. However, we assume that various sources of scattering (e.g., interface roughness scattering due to some crystalline disorder at the various interfaces [25], [15]) produce a phase decoherence of the electron wave-functions over distances comparable with the superlattice period. In this context, quantum effects are limited within one superlattice period.

Let us denote the interval occupied by the nth superlattice pattern by $C_n = [(n-\frac{1}{2})\ell, (n+\frac{1}{2})\ell]$. Our assumption is that the state of the electron gas at each pattern boundary $x_{n+\frac{1}{2}} = (n+\frac{1}{2})\ell$ can be described by a classical distribution function $f_{n+\frac{1}{2}}(k,t)$, which represents the number of electrons at time t with wave-vector $k \in \mathbb{R}$ at this point. Then, finding the motion of an electron through the elementary superlattice pattern C_n reduces to a standard quantum mechanical scattering problem. Such a problem is characterized by reflection-transmission coefficients and time delays [29].

To be more specific, we first need to introduce some additional definitions [1]. For simplicity, we restrict our analysis to a one-dimensional geometry and assume that the energy-versus-wave-vector relationship in each material is parabolic, i.e., is of the form

$$\varepsilon(k) = \frac{\hbar^2 k^2}{2m},$$

where ε is the kinetic energy of an electron moving in the crystal with wave-vector $k \in \mathbb{R}$, $\hbar$ is the reduced Planck constant, and m is the electron effective mass. We shall place the points $x_{n+\frac{1}{2}}$ in the middle of the largest layer and denote the corresponding material by A. Unless otherwise specified, m will refer to the electron effective mass in this material, while $m^*(x)$ will refer to the position-dependent effective mass at any point x of the superlattice. (Of course, $m^*(x) = m$ in material A.) The electron velocity $v(k)$ is related to the wave-vector by

$$v(k) = \frac{1}{\hbar}\frac{d\varepsilon}{dk} = \frac{\hbar k}{m}.$$

We assume that the electric potential ϕ is the sum of two contributions $\phi = \phi_{SL} + \phi_{SC}$. The contribution ϕ_{SL} is specific to superlattice structures and derives from the presence of material discontinuities. It is piecewise constant with jump discontinuities at the material interfaces and, of course, has the periodicity of the superlattice structure. To fix it uniquely, we shall assume that it vanishes at the points $x_{n+\frac{1}{2}}$.

The contribution ϕ_{SC} is the self-consistent potential generated by the charges and by the applied bias. ϕ_{SC} is a solution of the Poisson equation

$$-\frac{d}{dx}\left(\epsilon\frac{d\phi_{SC}}{dx}\right) = \rho(x,t), \tag{3.1}$$

where $\rho(x,t)$ is the charge concentration, given in terms of the positive ion concentration $\rho^+(x)$ (supposed known and given) and of the electron concentration $\rho^-(x,t)$ (the expression of which will be given below) by

$$\rho(x,t) = e(\rho^+(x) - \rho^-(x,t)),$$

where e is the elementary (positive) charge. The Poisson equation (3.1) is supplemented by boundary conditions

$$\phi_{SC}(a,t) = 0, \quad \phi_{SC}(b,t) = \phi_{bias}, \tag{3.2}$$

where a and b are the left and right boundaries of the superlattice and ϕ_{bias} is the applied bias. The dielectric constant ϵ is an ℓ-periodic function of x, which may also have jump discontinuities at the material interfaces. ϕ_{SC} is not periodic in general and is time-dependent, as ρ generally is.

Now, we turn to the solution of the Schrödinger equation associated with the nth pattern C_n. Because of our assumption that the correlation length is of the order of ℓ, the wave-functions of electrons belonging to the nth pattern C_n cannot interact with the potential beyond the boundaries of C_n. To take this fact into account, we modify the potential experienced by the electrons in C_n into a constant potential $\bar{\phi}^n(x)$ outside C_n:

$$\bar{\phi}^n(x) = \begin{cases} \phi(x,t) & \forall x \in [x_{n-\frac{1}{2}}, x_{n+\frac{1}{2}}], \\ \phi(x_{n-\frac{1}{2}}) & \forall x \le x_{n-\frac{1}{2}}, \\ \phi(x_{n+\frac{1}{2}}) & \forall x \ge x_{n+\frac{1}{2}}. \end{cases} \tag{3.3}$$

Now we consider t as a frozen time variable, and for $k \in \mathbb{R}$ given we solve the Schrödinger equation on $\mathbb{R}$ for the wave-function $\psi_k(x)$:

$$-\frac{\hbar^2}{2}\frac{d}{dx}\left(\frac{1}{m^*(x)}\frac{d\psi_k}{dx}\right) - e\bar{\phi}^n\psi_k = \left(\frac{\hbar^2 k^2}{2m} - e\Phi_k^n\right)\psi_k, \tag{3.4}$$

where

$$\Phi_k^n = \begin{cases} \phi(x_{n-\frac{1}{2}}) & \text{if } k \ge 0, \\ \phi(x_{n+\frac{1}{2}}) & \text{if } k \le 0. \end{cases}$$

All the present discussion is classical and can be found, for instance, in [29]. We summarize it below for the reader's convenience. To uniquely specify the solution of (3.4), we impose the following additional conditions: for $k > 0$,

$$\psi_k = \begin{cases} e^{ik(x-x_{n-1/2})} + A(k)e^{-ik(x-x_{n-1/2})}, & x < x_{n-\frac{1}{2}}, \\ B(k)e^{ik_+(x-x_{n+1/2})}, & x > x_{n+\frac{1}{2}}, \end{cases}$$

and similarly, for $k < 0$,

$$\psi_k = \begin{cases} e^{-ik(x-x_{n+1/2})} + A(k)e^{ik(x-x_{n+1/2})}, & x > x_{n+\frac{1}{2}}, \\ B(k)e^{-ik_-(x-x_{n-1/2})}, & x < x_{n-\frac{1}{2}}. \end{cases}$$

We have let

$$k_\pm = \sqrt{k^2 \pm \frac{2me}{\hbar^2}\delta\phi^n(t)}, \qquad \delta\phi^n(t) = \phi(x_{n+\frac{1}{2}}, t) - \phi(x_{n-\frac{1}{2}}, t). \tag{3.5}$$

If the quantity inside the square root is negative, the choice of the pure imaginary root is indifferent and leads to the same solution.

These solutions are called the scattering states and describe free moving particles coming from infinity and entering the nth superlattice pattern C_n. The complex numbers A and B are the scattering amplitudes, from which one computes the reflection and transmission probabilities $R(k)$ and $T(k)$ according to

$$R(k) = |A(k)|^2, \qquad T(k) = \begin{cases} \frac{k_+}{k}|B(k)|^2, & k > 0, k_+ \in \mathbb{R}, \\ \frac{k_-}{|k|}|B(k)|^2, & k < 0, k_- \in \mathbb{R}, \\ 0, & \text{otherwise.} \end{cases}$$

The scattering probabilities satisfy the following relations:

$$R+T=1, \qquad \begin{cases} R,T(k)=R,T(-k_+), & k>0, k_+\in\mathbb{R}, \\ R,T(k)=R,T(k_-), & k<0, k_-\in\mathbb{R}. \end{cases} \tag{3.6}$$

Introducing the phases of the complex numbers A and B,

$$A(k)=|A(k)|e^{iS_R(k)}, \qquad B(k)=|B(k)|e^{iS_T(k)},$$

we define the semiclassical reflection and transmission time delays $\tau_R(k)$ and $\tau_T(k)$ according to the following:

$$\tau_R(k)=\frac{1}{v(k)}\frac{dS_R}{dk}, \qquad \tau_T(k)=\frac{1}{v(k)}\frac{dS_T}{dk}.$$

We also have (see [29])

$$\begin{cases} \tau_R,\tau_T(k)=\tau_R,\tau_T(-k_+), & k>0, k_+\in\mathbb{R}, \\ \tau_R,\tau_T(k)=\tau_R,\tau_T(k_-), & k<0, k_-\in\mathbb{R}. \end{cases} \tag{3.7}$$

Of course, all the scattering data depend on the index n, which has been omitted in the previous discussion.

We now establish the dynamics obeyed by the discrete distribution function $f_{n+\frac{1}{2}}(k,t)$. First, consider $f_{n+\frac{1}{2}}(k,t)$ for $k>0$, which corresponds to particles at point $x_{n+\frac{1}{2}}$ moving to the right; let us trace these particles back to previous times. Some of them have been transmitted through the nth pattern and come from point $x_{n-\frac{1}{2}}$ with a momentum $k_-^n>0$ corresponding to the energy shift $-e\delta\phi^n$. The crossing time of the nth pattern being $\tau_T^n(k_-^n)$, the number of these is $T^n(k_-^n)f_{n-\frac{1}{2}}(k_-^n,t-\tau_T^n(k_-^n))$. The other contribution to $f_{n+\frac{1}{2}}(k,t)$ is made of particles reflected by the nth pattern and coming from point $x_{n+\frac{1}{2}}$ with a momentum $-k$. The number of these is $R^n(-k)f_{n+\frac{1}{2}}(-k,t-\tau_R^n(-k))$. Therefore, we obtain the total number $f_{n+\frac{1}{2}}(k,t)$ by summing up these two contributions. For $k>0$, this leads to

$$\begin{aligned} f_{n+\frac{1}{2}}(k,t) &= T^n(k_-^n)f_{n-\frac{1}{2}}(k_-^n,t-\tau_T^n(k_-^n)) \\ &\quad + R^n(-k)f_{n+\frac{1}{2}}(-k,t-\tau_R^n(-k)), \end{aligned} \tag{3.8}$$

and for $k<0$, to

$$\begin{aligned} f_{n-\frac{1}{2}}(k,t) &= T^n(-k_+^n)f_{n+\frac{1}{2}}(-k_+^n,t-\tau_T^n(-k_+^n)) \\ &\quad + R^n(-k)f_{n-\frac{1}{2}}(-k,t-\tau_R^n(-k)). \end{aligned} \tag{3.9}$$

System (3.8)–(3.9) belongs to the class of scattering matrix models which are sometimes used in the literature [34]. These conditions were first proposed by Ben Abdallah [3] as coupling conditions for classical and quantum models (see also [7]).

To preserve causality, we require system (3.8)–(3.9) to be a backwards difference system in time, and consequently we assume that the time delays are positive. We consider that (3.8)–(3.9) describes the evolution of the system for $t>0$, starting from known states for all $t\le 0$, and prescribe the distribution functions for negative times:

$$f_{n-\frac{1}{2}}(k,t)=(f_I)_{n-\frac{1}{2}}(k,t) \qquad \forall t\le 0,\ \forall n\in\mathbb{Z},\ \forall k\in\mathbb{R}, \tag{3.10}$$

where $(f_I)_{n-\frac{1}{2}}$ is given.

For a bounded structure, the incoming distribution function must be prescribed at the boundary. Let us denote by $a = x_{n_a-\frac{1}{2}}$ and $b = x_{n_b+\frac{1}{2}}$ the left and right boundaries of the structure. Then, we prescribe

$$f_{n_a-\frac{1}{2}}(k,t) = f_a(k,t), \quad f_{n_b+\frac{1}{2}}(-k,t) = f_b(-k,t) \qquad \forall t,\ \forall k > 0,$$

where $f_a(k,t)$ and $f_b(-k,t)$ are given functions of $k > 0$. Usually, $f_{a,b}$ are chosen to be equal to thermodynamical equilibrium distribution functions (see the expression in section 6).

In order to complete the model, we must say how the electron concentration is computed. Following [3], we assume that the electron concentration in the nth pattern is the sum of the concentration of the right-going scattering states (for $k > 0$) weighted by the distribution function at the "left entrance" of the cell C_n, i.e., $f_{n-\frac{1}{2}}(k)$, and that of the left-going states (for $k < 0$) weighted by $f_{n+\frac{1}{2}}(k)$. In other words, for $x \in [x_{n-\frac{1}{2}}, x_{n+\frac{1}{2}})$,

$$\rho^-(x,t) = \int_{k>0} f_{n-\frac{1}{2}}(k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi} + \int_{k<0} f_{n+\frac{1}{2}}(k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi}. \tag{3.11}$$

The factor π^{-1} stands for the one-dimensional momentum density of states (see [1]).

Let us now comment on the hypothesis of frozen time in the solution of the quantum problem. This hypothesis is valid only if the time variation of the potential is slow compared with the transit times of the particles through the pattern C_n. If this is not the case, the potential varies significantly while the particle is crossing the pattern, and the resolution of a time-dependent Schrödinger equation becomes necessary. In such a case, not only would the computational cost increase, but the coupling to the semiclassical distribution function would be much more complicated (see, e.g., [5]). However, the frozen time assumption is acceptable in practice since the self-consistent electric field is a highly averaged, and therefore slowly evolving, quantity. In the present paper, we shall focus on this case. Therefore, all the scattering data in formulas (3.8)–(3.9) must be understood as corresponding to time t.

We note that formula (3.11) also relies on the frozen time assumption: the distribution function evolves on a slower time scale than the time delays, and therefore the statistics of particles in the entire pattern C_n can be approximated by the distribution function at its boundaries at the same time. This approximation is consistent with that made in the resolution of the quantum problem and is not in contradiction with (3.8)–(3.9), where the time delays appear. Indeed, that the time delays are small does not prevent the distribution function from evolving on larger time scales, as we will see in the derivation of the macroscopic model (section 5). Also, removing this assumption is possible, as in [5], but requires a much more complex model, which is beyond our scope here.

Obviously, a stochastic interpretation of the dynamical system (3.8)–(3.9) can be given. At a given time t, a particle sitting at point $x_{n-\frac{1}{2}}$ with momentum $k > 0$ (to fix the ideas) can jump to point $x_{n+\frac{1}{2}}$ with a probability T^n or can reverse momentum with probability R^n. The particle can perform its next jump after a certain time delay $\tau_{R,T}$. Therefore, this model is a dynamical system version of a kind of random walk. The connection between stochastic particle processes and kinetic equations is a very active field, and it is not our aim to elaborate on this relation here. Let us simply mention that, conversely, stochastic particle processes lead to efficient numerical algorithms to solve kinetic equations (referred to as Monte Carlo methods). An introductory monograph for this topic is [26].

In view of this stochastic interpretation, we discuss why the time delays are assigned deterministic values instead of random ones. Semiclassical scattering theory, which is based on a high frequency limit [29], gives very few means for exploring the possible random character of the time delays. Random time delays are likely to appear if the high frequency assumption is removed. However, there exists very little physical information on the probabilistic distribution of time delays in this case. In the absence of such information, the simplest choice seems to be the deterministic semiclassical value. Considering random time delays, however, would not lead to major changes to the present work. An integral over the distribution of time delays would appear in (3.8)–(3.9) and in the expression (5.4) of the density-of-states M of the diffusion model (see section 5).

Finally, let us note that we exclude bound states, which could contribute to trapping particles inside a given superlattice cell. If bound states were considered, additional terms involving the populations of these states would have to appear in (3.11). This would require a model of inelastic collisions, since only such collisions can fill these states. Such collisions are discarded in the present work, as are bound states.

4. Scaling. It is convenient to interpolate the discrete quantities into piecewise continuous functions of the position variable x. We define

$$f(x,k,t) = f_{n+\frac{1}{2}}(k,t), \quad f_I(x,k,t) = (f_I)_{n+\frac{1}{2}}(k,t), \quad x \in [n\ell,(n+1)\ell), \tag{4.1}$$

and

$$(R,T,\tau_R,\tau_T)(x,k) = (R^n,T^n,\tau_R^n,\tau_T^n)(k), \quad x \in [x_{n-\frac{1}{2}},x_{n+\frac{1}{2}}). \tag{4.2}$$

Similarly,

$$\delta\phi(x) = \delta\phi^n,\ k_\pm(x,k) = k_\pm^n(k), \quad x \in [x_{n-\frac{1}{2}},x_{n+\frac{1}{2}}). \tag{4.3}$$

With these definitions, system (3.8)–(3.10) is equivalent to the following system: for $k > 0$,

$$\begin{aligned} f\left(x+\frac{\ell}{2},k,t\right) &= T(x,k_-(x,k))f\left(x-\frac{\ell}{2},k_-(x,k),t-\tau_T(x,k_-(x,k))\right) \\ &\quad + R(x,-k)f\left(x+\frac{\ell}{2},-k,t-\tau_R(x,-k)\right), \end{aligned} \tag{4.4}$$

and for $k < 0$,

$$\begin{aligned} f\left(x-\frac{\ell}{2},k,t\right) &= T(x,-k_+(x,k))f\left(x+\frac{\ell}{2},-k_+(x,k),t-\tau_T(x,-k_+(x,k))\right) \\ &\quad + R(x,-k)f\left(x-\frac{\ell}{2},-k,t-\tau_R(x,-k)\right), \end{aligned} \tag{4.5}$$

with the initial condition

$$f(x,k,t) = f_I(x,k,t) \qquad \forall t \le 0,\ \forall (x,k) \in \mathbb{R}^2. \tag{4.6}$$

The electron concentration takes the form

$$\rho^-(x,t) = \int_{k>0} f(x,k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi} + \int_{k<0} f(x+\ell,k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi} \quad \forall x \in [x_{n-\frac{1}{2}}, x_n), \tag{4.7}$$

$$\rho^-(x,t) = \int_{k>0} f(x-\ell,k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi} + \int_{k<0} f(x,k,t)|\psi_k^n(x,t)|^2 \frac{dk}{\pi} \quad \forall x \in [x_n, x_{n+\frac{1}{2}}). \tag{4.8}$$

We now introduce macroscopic position and time coordinates according to

$$\tilde{x} = \alpha x, \qquad \tilde{t} = \alpha^2 t, \tag{4.9}$$

where $\alpha \ll 1$ is a small parameter describing the ratio between the superlattice cell and the typical size of the device. The time scaling characterizes diffusion phenomena.

Now we make the following assumption, which is classical in the homogenization literature [9]. We suppose that the self-consistent potential can be written as a function of the macroscopic variables $(\tilde{x}, \tilde{t})$ and of the microscopic variable x, and that it is periodic with respect to the latter:

$$\phi_{SC}(x,t) = \tilde{\phi}_{SC}(\tilde{x}, x, \tilde{t}), \tag{4.10}$$

where $\tilde{\phi}_{SC}$ is periodic with respect to its second argument. Indeed, the self-consistent potential may have large scale variations (which extend over the entire structure width, like, e.g., the external potential) as well as subcell variations (related, e.g., to the variations of the electron and ion concentrations or to the dielectric constants). By supposing that the small scale variations are periodic, we assume that a departure from periodicity can occur only on large scales or, equivalently, with small gradients relative to the period. This is the key hypothesis that allows the derivation of a macroscopic regime.

The dielectric constant ϵ as well as the superlattice potential ϕ_{SL} are purely periodic functions and therefore depend only on the periodic variable x: $\epsilon(x)$, $\phi_{SL}(x)$. We could consider large scale variations of these quantities as well, but we discard them here for the sake of clarity.

We now investigate how this assumption translates onto the Schrödinger scattering problem. Using that ϕ_{SL} is periodic and vanishes at the boundary of the elementary cell, and that ϕ_{SC} is periodic with respect to its second argument, the potential (3.3) involved in the Schrödinger equation (3.4) now reads

$$\bar{\phi}^n(x) = \begin{cases} \phi_{SL}(x) + \tilde{\phi}_{SC}(\alpha x, x, \alpha^2 t) & \forall x \in [x_{n-\frac{1}{2}}, x_{n+\frac{1}{2}}], \\ \tilde{\phi}_{SC}(\alpha x_{n-\frac{1}{2}}, x_{-\frac{1}{2}}, \alpha^2 t) & \forall x \le x_{n-\frac{1}{2}}, \\ \tilde{\phi}_{SC}(\alpha x_{n+\frac{1}{2}}, x_{-\frac{1}{2}}, \alpha^2 t) & \forall x \ge x_{n+\frac{1}{2}}. \end{cases} \tag{4.11}$$

We consider this potential the following way: for a given value $\tilde{x}$, we look for the cell C_n such that $\alpha\tilde{x} \in C_n$, i.e., $n(\tilde{x}) = [(\tilde{x}/\alpha\ell) + 1/2]$, where $[\cdot]$ denotes the integer part. Then, we solve the Schrödinger equation (3.4) on $\mathbb{R}$ with the potential (4.11), where x is now a variable independent from $\tilde{x}$, the latter appearing only in $n(\tilde{x})$. Therefore, $\tilde{x}$ and $\tilde{t}$ are *frozen variables* in the Schrödinger problem.

Therefore, the wave-functions are such that $\psi_k = \psi_k(\tilde{x}, x, \tilde{t})$ (but ψ_k is *not* periodic with respect to x), and the scattering data satisfy

$$(R,T) = (\tilde{R},\tilde{T})(\tilde{x},k), \quad (\tau_R,\tau_T) = \alpha^2(\tilde{\tau}_R,\tilde{\tau}_T)(\tilde{x},k),$$
$$\delta\phi = \widetilde{\delta\phi}(\tilde{x},\tilde{t}), \quad k_\pm = \tilde{k}_\pm(\tilde{x},k,\tilde{t}).$$

The factor α^2 in front of the time delays follows from the scaling of time (see the last remark of section 3).

By (4.1), the distribution functions are constant over the period width and therefore do not depend on the fast variable x. However, the electron concentration, because it depends on the wave-functions according to (3.11), may depend on x. Similarly, the ion concentration may have variations within a period, and it also depends on x. Both the distribution function and the concentrations are assumed to be small, of order α^2. This hypothesis is required for consistency with (4.10): if the charge concentration is not small, strong potential gradients can occur on small scales, which we want to avoid. Therefore, we assume the following:

$$f(x,k,t) = \alpha^2 \tilde{f}^\alpha(\tilde{x},k,\tilde{t}),$$
$$(\rho^-,\rho^+,\rho)(x,t) = \alpha^2(\tilde{\rho}^{-\alpha},\tilde{\rho}^{+\alpha},\tilde{\rho}^\alpha)(\tilde{x},x,\tilde{t}).$$

We shall now rename the variables to deal with nicer notations: the periodic variable x will be denoted by y, while the rescaled position and time variables $\tilde{x}$ and $\tilde{t}$ will simply be denoted by x and t. The tildes will be dropped, and the dependence on the scaling parameter α will be recalled only when necessary. With this scaling, the problem (4.4), (4.5), (3.1), (3.11) becomes: for $k > 0$,

$$f\left(x+\alpha\frac{\ell}{2},k,t\right) = R(x,-k)f\left(x+\alpha\frac{\ell}{2},-k,t-\alpha^2\tau_R(x,-k)\right) + T(x,k_-(x,k))f\left(x-\alpha\frac{\ell}{2},k_-(x,k),t-\alpha^2\tau_T(x,k_-(x,k))\right), \tag{4.12}$$

and for $k < 0$,

$$f\left(x-\alpha\frac{\ell}{2},k,t\right) = R(x,-k)f\left(x-\alpha\frac{\ell}{2},-k,t-\alpha\tau_R(x,-k)\right) + T(x,-k_+(x,k))f\left(x+\alpha\frac{\ell}{2},-k_+(x,k),t-\alpha^2\tau_T(x,-k_+(x,k))\right), \tag{4.13}$$

with the initial condition

$$f(x,k,t) = f_I(x,k,t) \qquad \forall t \le 0,\ \forall (x,k) \in \mathbb{R}^2. \tag{4.14}$$

The Poisson equation reads

$$\left(\alpha\frac{\partial}{\partial x}+\frac{\partial}{\partial y}\right)\left(\epsilon(y)\left(\alpha\frac{\partial}{\partial x}+\frac{\partial}{\partial y}\right)\phi_{SC}\right) = \alpha^2\rho(x,y,t), \tag{4.15}$$

$$\rho(x,y,t) = e(\rho^+(x,y)-\rho^-(x,y,t)). \tag{4.16}$$

The electron concentration is given by

$$\forall y \in [x_{-\frac{1}{2}},0), \tag{4.17}$$
$$\rho^-(x,y,t) = \int_{k>0} f(x,k,t)|\psi_k(x,y,t)|^2\frac{dk}{\pi} + \int_{k<0} f(x+\alpha\ell,k,t)|\psi_k(x,y,t)|^2\frac{dk}{\pi},$$

$$\forall y \in [0,x_{\frac{1}{2}}), \tag{4.18}$$
$$\rho^-(x,y,t) = \int_{k>0} f(x-\alpha\ell,k,t)|\psi_k(x,y,t)|^2\frac{dk}{\pi} + \int_{k<0} f(x,k,t)|\psi_k(x,y,t)|^2\frac{dk}{\pi}.$$

The goal of the present paper is to find the formal limit of model (4.12)–(4.18) when α tends to zero. We note that, in this problem, all quantities depend on α. We shall use a superscript α when we want to emphasize this dependence. We state the main theorem in the next section.

5. The diffusion limit. The aim of this paper is to prove the following theorem.

THEOREM 5.1 (formal). *Assume that R, the reflection coefficient associated with potential ϕ_{SL}, is nonzero almost everywhere. Then, in the limit $\alpha \to 0$, the solution f^α, ϕ^α_{SC}, $\rho^{-,\alpha}$ converges, at least formally, to f, ϕ_{SC}, ρ^- such that*

(i) *There exists a function $F(x,\varepsilon(k),t)$, which depends only on k through the energy $\varepsilon(k)$, such that $f(x,k,t) = F(x,\varepsilon(k),t)$. Furthermore, F satisfies the following diffusion equation (SHE model):*

$$M(\varepsilon)\frac{\partial F}{\partial t} + \left(\frac{\partial}{\partial x} - eE\frac{\partial}{\partial \varepsilon}\right) J = 0, \tag{5.1}$$

$$J(x,\varepsilon,t) = -D(\varepsilon)\left(\frac{\partial}{\partial x} - eE\frac{\partial}{\partial \varepsilon}\right) F, \tag{5.2}$$

$$F(x,\varepsilon,t=0) = F_I(x,\varepsilon,0), \tag{5.3}$$

where $E = -\partial\phi_{SC}/\partial x$ is the self-consistent electric field. $M(\varepsilon)$ and $D(\varepsilon)$ are defined by

$$M(\varepsilon) = \frac{1}{\ell}[T(k)\tau_T(k) + R(k)\tau_R(k)], \tag{5.4}$$

$$D(\varepsilon) = \frac{\ell}{2}\frac{T(k)}{R(k)}, \tag{5.5}$$

where $k = \sqrt{2m\varepsilon}/\hbar$ and T, R, τ_T, τ_R refer to the scattering data of the Schrödinger problem with potential $\phi = \phi_{SL}$ on the cell C_0 only.

(ii) *$\phi_{SC} = \phi_{SC}(x,t)$ does not depend on the fast variable y and is a solution of the Poisson equation*

$$-\frac{d}{dx}\left(\bar{\epsilon}\frac{d\phi_{SC}}{dx}\right) = \rho(x,t), \tag{5.6}$$

where the charge concentration $\rho(x,t)$ is given by

$$\rho(x,t) = e(\rho^+(x) - \rho^-(x,t)),$$
$$\rho^+(x) = \int_{-\ell/2}^{\ell/2} \rho^+(x,y)\frac{dy}{\ell}\ , \qquad \rho^-(x,t) = \int_{-\ell/2}^{\ell/2} \rho^-(x,y,t)\frac{dy}{\ell},$$

and the average dielectric constant $\bar{\epsilon}$ by

$$\bar{\epsilon}^{-1} = \int_{-\ell/2}^{\ell/2} \frac{1}{\epsilon(y)}\frac{dy}{\ell}.$$

(iii) *The positive ion concentration $\rho^+(x,y)$ is a datum; the electron concentration is given by*

$$\rho^-(x,y,t) = \int_{k\in\mathbb{R}} F(x,\varepsilon(k),t)|\psi_k(x,y,t)|^2\frac{dk}{\pi}. \tag{5.7}$$

The coefficients M and D are, respectively, referred to as the "density-of-states" and the "diffusivity."

Let us comment on boundary conditions. The boundary conditions (3.2) may also be used in conjunction with the Poisson equation (5.6). However, in order to account for boundary layers in the homogenization process, more accurate boundary conditions can be imposed, of Robin (or Fourier) type, namely,

$$(\phi_{SC} - \alpha\lambda_a\phi'_{SC})(a,t) = 0, \qquad (\phi_{SC} + \alpha\lambda_b\phi'_{SC})(b,t) = \phi_{bias}, \tag{5.8}$$

where λ_a, λ_b are positive extrapolation lengths (for expressions of λ_a and λ_b, see, e.g., [9]) and α is the scaling parameter (4.9). Similarly, considerations of kinetic layers lead to the following boundary conditions for F:

$$(F + \alpha\Lambda_a J)(a,\varepsilon,t) = F_a(\varepsilon,t), \qquad (F - \alpha\Lambda_b J)(b,\varepsilon,t) = F_b(\varepsilon,t), \tag{5.9}$$

where $F_a(\varepsilon,t) = f_a(k,t)$, $F_b(\varepsilon,t) = f_b(-k,t)$, and $\Lambda_{a,b} > 0$. We refer to [19] for the theory of boundary layers in the framework of the SHE model and for the computation of $\Lambda_{a,b}$. We shall not dwell on this point here.

The proof of Theorem 5.1 proceeds in three steps. The first consists of showing that f^α formally converges to a function of $(x,\varepsilon(k),t)$ only. The second and third steps correspond to the derivations of the continuity and current equations (5.1), (5.2). To achieve these goals, two methods can be utilized: the Hilbert expansion method [2], [17] and the moment method [24]. We shall choose the latter because it involves more straightforward computations. We shall defer the details of the proof to the appendix. We shall take the existence of solutions for the original discrete model (4.12)–(4.18) as well as the convergence of f^α, ϕ^α_{SC}, $\rho^{-,\alpha}$ for granted, and we shall focus solely on the establishment of the limit model. In fact, proving convergence is a very challenging mathematical problem which is far beyond the scope of the present paper. In the next sections, we comment further on the model obtained and deal with some practical examples.

6. Comments on the diffusion model (5.1)–(5.2). We refer to the introduction for references on the SHE model (5.1)–(5.2). This model is of great practical interest for semiconductor device simulations because it provides information about the electron energy distribution function at a much lower cost than a Monte Carlo simulation of the Boltzmann equation [22], [23]. To our knowledge, the present paper provides the first derivation of this model in the framework of superlattices, when the diffusion is induced by the scattering properties of the quantum potential structure itself.

Another interesting property of this model is that it gives rise to a hierarchy of moment models [4], [17], including the usual drift-diffusion model [28], [33] and the so-called energy-transport model, which is an extension of the drift-diffusion model with an additional energy balance equation (see [6] and references therein). We refer to [4], [17] for the derivation of these models. Here, we first want to discuss the relation between the number and energy densities $n(x,t)$ and $\mathcal{E}(x,t)$ in position space, which are obviously important macroscopic quantities, and the energy distribution F. This relation takes the form

$$\begin{pmatrix} n \\ \mathcal{E} \end{pmatrix} = \int_{\mathcal{R}} F(x,\varepsilon,t) \begin{pmatrix} 1 \\ \varepsilon \end{pmatrix} M(x,\varepsilon)d\varepsilon, \tag{6.1}$$

where, in drift-diffusion or energy-transport models, F is approximated by a Fermi–Dirac distribution (i.e., the quantum thermodynamical equilibrium distribution function of electrons; see [11]) $F_{\mu,T}(\varepsilon) = (\exp((\varepsilon-\mu)/k_BT)+1)^{-1}$. The thermodynamic parameters $\mu = \mu(x,t)$ and $k_BT = k_BT(x,t)$ are the chemical potential and thermal energy and characterize the state of the electron gas. (6.1) furnishes a local relationship between the pairs $(n,\mathcal{E})$ and (μ,T).

Here, the particular form of the density-of-states M makes this relationship fairly different than in bulk semiconductor materials. M can be viewed as an "averaged density-of-states" over the superlattice elementary period. It reduces to the usual one-dimensional density-of-states (up to a constant factor) $M = v(k)^{-1}$ if the potential ϕ_{SL} is constant in the elementary cell (since in this case $T = 1$, $R = 0$, and τ_T is equal to the classical transit time $\ell/v(k)$). But M may significantly differ from this value if ϕ_{SL} is not constant (see section 7).

Because of this particular form of M, the relationship between $(n,\mathcal{E})$ and (μ,T) in the superlattice can significantly depart from that of bulk materials. In particular, at resonant energies (see the example of square potentials below) the time delays are significantly longer than the classical time delays. Symmetrically, at energies away from resonances, they can be shorter. Therefore, in (6.1), M weights the resonant energies more strongly and the nonresonant ones less strongly. The relation $(\mu,T) \to (n,\mathcal{E})$ reflects these effects.

Next we discuss the value of the electron mobility in the superlattice, given by [4], [17]:

$$\mu_{\mathrm{SL}} = \frac{e}{nk_BT}\int_{\mathcal{R}} D(x,\varepsilon)F_{\mu,T}(1-F_{\mu,T})d\varepsilon. \tag{6.2}$$

We recall that the mobility is the coefficient of Ohm's law $j_n = \mu_{\mathrm{SL}} nE$, which is the expression of the drift-diffusion law when the chemical potential μ and the temperature T are constant in space. The mobility is one of the most important transport parameters in semiconductors as it is easily accessible to measurements and characterizes the ability of electrons to react to an external electric field. In the present case, the mobility of the electrons is induced solely by their scattering by the superlattice potential pattern. A realistic expression of the mobility must also include the influence of "bulk interactions" like phonon or impurity interactions. As already pointed out, this is not yet done in full rigor in the present work, but a rough estimate of the total mobility μ_{tot} can be obtained from

$$\frac{1}{\mu_{\mathrm{tot}}} = \frac{1}{\mu_{\mathrm{bulk}}} + \frac{1}{\mu_{\mathrm{SL}}}, \tag{6.3}$$

where μ_{bulk} is the mobility under the influence of bulk collisions alone (see [32], [16]). Formula (6.3) can be understood by a circuit analogy, in which the resistances (proportional to the reciprocal of the mobility) of the bulk and of the superlattice add up in series. It provides a first answer to the problem of determining the electron mobility in the superlattice. This question was left open, for instance, in [35], where by default, the superlattice mobility was assumed to be equal to that of the bulk.

As a conclusion, the diffusion model (5.1)–(5.2) can be used in two ways: either for direct simulations or as a way to access analytical values for the parameters of macroscopic (drift-diffusion or energy-transport) models. In the latter case, the analytical values of M and D give rise to easily computable values of the drift-diffusion mobilities or density versus chemical potential relationships. (See the example in the

next section.) Through the specific values (5.4), (5.5), the obtained parameters of the drift-diffusion model retain information about the quantum nature of transport in the superlattice base cell in a rigorous way.

7. Example: Square wells or barriers. In this section, we analyze the simple case in which ϕ_{SL} is equal to a simple square well or barrier. More precisely, we suppose that the presence of a second material (called B) results in potential and effective mass jumps at the $A-B$ interfaces. We denote by m_A and m_B the effective masses in materials A and B. We denote by V the potential ϕ_{SL} in material B, with $V>0$ if B produces an (energy) potential well, and $V<0$ if it produces a potential barrier. We assume that the B layer has width a. Therefore,

$$\phi_{SL}(x)=\begin{cases} V, & x\in\left(-\frac{a}{2},\frac{a}{2}\right),\\ 0, & x\notin\left(-\frac{a}{2},\frac{a}{2}\right),\end{cases}\qquad m(x)=\begin{cases} m_B, & x\in\left(-\frac{a}{2},\frac{a}{2}\right),\\ m_A, & x\notin\left(-\frac{a}{2},\frac{a}{2}\right).\end{cases}\tag{7.1}$$

We note that

$$\varepsilon(k)=\frac{\hbar^2k^2}{2m_A},\quad \kappa=\left(\frac{m_B}{m_A}(k^2+k_V^2)\right)^{1/2},\quad k_V^2=\frac{2em_A}{\hbar^2}V.\tag{7.2}$$

Note that $k_V^2>0$ and $\kappa^2>k^2$ in the case of a well, and $k_V^2<0$, $\kappa^2<k^2$ in the case of a barrier. In the barrier case, κ^2 can be negative, in which case κ is a pure imaginary number $\kappa=i\tilde{\kappa}$.

The resolution of (3.4) for the scattering states in this case is an elementary quantum mechanics problem, the solution of which can be found in any textbook (see [29], for instance). Here we just note that, to account for the effective mass discontinuity, the continuity of ψ and $m^{-1}\psi'$ must be enforced at the interfaces $x=\pm a/2$.

With (7.1), we find for a well ($k_V^2>0$) and any value of $k>0$, or for a barrier ($k_V^2<0$) and incident energies above the barrier energy $k^2+k_V^2>0$, that

$$T=\frac{1}{1+\chi_0\sin^2(\kappa a)},\qquad \chi_0=\frac{\left((m_B-m_A)k^2-m_Ak_V^2\right)^2}{4m_Am_Bk^2(k^2+k_V^2)}\tag{7.3}$$

and

$$\tau_T=\tau_R:=\tau_{sq}=\frac{1}{v(k)}(\ell-a+d_{sq}),\tag{7.4}$$

with

$$d_{sq}=\frac{a\chi_1(1+\cot^2(\kappa a))-\kappa^{-1}\chi_2\cot(\kappa a)}{\chi_3+\cot^2(\kappa a)},\qquad \chi_1=\frac{(m_A+m_B)k^2+m_Ak_V^2}{2m_A(k^2+k_V^2)},$$
$$\chi_2=\frac{\left((m_A-m_B)k^2+m_Ak_V^2\right)k_V^2}{2m_A(k^2+k_V^2)k^2},\qquad \chi_3=\frac{\left((m_A+m_B)k^2+m_Ak_V^2\right)^2}{4m_Am_Bk^2(k^2+k_V^2)}.$$

The value of d_{sq} has to be compared to the corresponding value d_{cl} for classical motion:

$$d_{cl}=\frac{k}{m_A}\frac{m_B}{(k^2+k_V^2)^{1/2}}a.$$

At resonant energies (i.e., when $\sin(\kappa a)=0$), $\tau_{sq}>\tau_{cl}$, while the reverse inequality holds at nonresonant energies (i.e., when $\cos(\kappa a)=0$); see [29].

In the case of a barrier ($k_V^2 < 0$) and incident energies below the barrier energy $k^2 + k_V^2 < 0$, we find

$$T = \frac{1}{1 + \chi_0 \sinh^2(\tilde{\kappa} a)}, \qquad d_{sq} = \frac{a\chi_1(\coth^2(\tilde{\kappa} a) - 1) + \tilde{\kappa}^{-1}\chi_2 \coth(\tilde{\kappa} a)}{\chi_3 + \coth^2(\tilde{\kappa} a)},$$

with χ_0, χ_1, and χ_3 obtained by changing $k^2 + k_V^2$ into $|k^2 + k_V^2|$ in the denominators of the formulas above and with χ_2 unchanged.

With (7.3) and (7.4), equations (5.4), (5.5) give the expression of the density-of state and diffusivity in the case of square wells or barriers:

$$D = \frac{\ell}{\hbar\pi} \frac{1}{\chi_0 \sin^2(\kappa a)} \quad \text{for } \kappa^2 > 0, \tag{7.5}$$

$$D = \frac{\ell}{\hbar\pi} \frac{1}{\chi_0 \sinh^2(\tilde{\kappa} a)} \quad \text{for } \kappa^2 = -\tilde{\kappa}^2 < 0, \tag{7.6}$$

$$M = \frac{2\tau_{sq}}{\hbar\pi\ell}. \tag{7.7}$$

As already pointed out, the diffusivity has infinite peaks at resonant energies ($\sin(\kappa a) = 0$). These peaks are due to resonant tunneling and are reminiscent of the conduction minibands in an infinite superlattice.

If more than one well or one barrier is present within a period (i.e., when the coherence length is larger than the period), the scattering data become increasingly complicated (but still can be computed numerically) and resemble even more closely the energy band structure of the infinite superlattice.

This example shows that the coefficients M and D of the diffusion model can be computed easily from the resolution of the Schrödinger equation in a single cell. The most important characteristics of quantum transport (like the existence of transmission resonances) translate into specific behaviors (like singularities at resonance energy) of these constants.

8. Conclusion. In this paper, we have presented a scattering matrix model describing electron transport in semiconductor superlattices when the electron phase coherence length is of the order of the superlattice period. Then, we have investigated the limit of a large number of superlattice cells. We have shown that, at the diffusion time scale, the scattering matrix model formally converges to a diffusion model in the position-energy space, the so-called SHE model, and have explained how it can be used to model electron transport in superlattices. In particular, the model takes into account the electric potential self-consistency through a quantum model of the charge concentration. An analytical example shows how the diffusion constants can be explicitly computed from the scattering data of the base cell.

The scientific merit of this model can only be assessed in light of numerical simulations and comparisons with other experiments or numerical models. In the present paper, we have focused on the derivation of the diffusion model and will defer its numerical validation to future work. However, we feel that the present model has promising capabilities. It will be easy to solve numerically, while giving access to finer physical details than conventional drift-diffusion models. In particular, we have shown how the diffusion constants retain some of the essential features of quantum transport in the superlattice base cell. Beyond their use in the SHE model, these diffusion constants can be used in turn to improve our knowledge of diffusion constants of conventional models of the drift-diffusion type when applied to superlattices.

Appendix. Proof of Theorem 5.1. We shall give only the formal calculations below, supposing that all unknowns have a limit in a convenient function space. The proof of this point is a very difficult one (given the nonlinearity of the problem and its highly oscillating character) and will not be tackled here.

A.1. The potential and the Schrödinger equation. It is a classical matter in homogenization theory [9] that

$$\phi^\alpha_{SC}(x,y,t) = \phi_{SC}(x,t) + O(\alpha) \quad \text{as } \alpha \to 0,$$

where $\phi_{SC}(x,t)$ does not depend on y and satisfies the homogenized Poisson equation (5.6).

Then, standard perturbation theory for the Schrödinger equation applies (see [31]), and we get, at least formally,

$$\psi^\alpha_k(x,y,t) \to \psi_k(x,y,t), \quad R^\alpha, T^\alpha, \tau^\alpha_R, \tau^\alpha_T \to R, T, \tau_R, \tau_T, \dots,$$

where ψ_k, R, T, τ_R, τ_T are the wave-function and scattering data associated with the potential $\phi = \phi_{SC}(x,t) + \phi_{SL}(y)$. However, since ϕ_{SC} does not depend on y, the wave-function is deduced from the solution of the Schrödinger equation with potential $\phi_{SL}(y)$ by multiplication by a constant (in y) phase factor (Gauge transformation), and the scattering data are unchanged. Furthermore, a simple coordinate translation allows us to consider the problem in the elementary cell C_0 again without changing the scattering data. Therefore, R, T, τ_R, τ_T do not depend on x. From now on, ψ_k will denote the wave-function associated with the cell C_0, which also does not depend on x.

Now we estimate the potential shift $\delta\phi^\alpha$ across a cell. Following section 4, we consider a point x and let $n = n^\alpha(x) = [(x/\alpha\ell) + 1/2]$, where $[\cdot]$ is the integer part. According to (4.11), across the cell $C_{n^\alpha(x)}$ associated with x, $\delta\phi^\alpha$ is equal to

$$\delta\phi^\alpha = \phi^\alpha_{SC}(\alpha x_{n+\frac12}, x_{-\frac12}, t) - \phi^\alpha_{SC}(\alpha x_{n-\frac12}, x_{-\frac12}, t).$$

We can define δ_- and δ_+ such that

$$\alpha x_{n-\frac12} = \alpha\left(n - \frac12\right)\ell = x + \alpha\delta_-, \qquad \alpha x_{n+\frac12} = \alpha\left(n + \frac12\right)\ell = x + \alpha\delta_+.$$

We obviously have $-\ell \le \delta_- \le 0$, $0 \le \delta_+ \le \ell$, $\delta_+ - \delta_- = \ell$. Therefore,

$$\delta\phi^\alpha = \phi^\alpha_{SC}(x + \alpha\delta_+, x_{-\frac12}, t) - \phi^\alpha_{SC}(x + \alpha\delta_-, x_{-\frac12}, t) = \alpha\ell\frac{\partial\phi^\alpha_{SC}}{\partial x} + O(\alpha^2). \tag{A.1}$$

In particular, $\delta\phi^\alpha \to \delta\phi = 0$. From this, we note that

$$k^\alpha_\pm(x,k) = |k| \pm \alpha\frac{em\ell}{\hbar^2}\frac{1}{|k|}\frac{\partial\phi^\alpha_{SC}}{\partial x} + O(\alpha^2). \tag{A.2}$$

Finally, taking the limit $\alpha \to 0$ in (4.17) and (4.18) leads to (5.7), provided that f is a function of $\varepsilon(k)$ only. This point is proved in the next section.

A.2. f depends only on the energy. We consider problem (4.12), (4.13) and formally let $\alpha \to 0$. We have, using (A.2),

$$f(x,k,t) = R(-k)f(x,-k,t) + T(k)f(x,k,t), \quad k > 0. \tag{A.3}$$

Now, considering that R and T are the scattering data associated with the limit potential, which has no potential shift ($\delta\phi = 0$), formulas (3.6) lead to

$$R + T = 1, \quad R, T(k) = R, T(-k), \quad \tau_R, \tau_T(k) = \tau_R, \tau_T(-k) \qquad \forall k \in \mathbb{R}. \tag{A.4}$$

Using these relations, (A.3) leads to

$$R(k)(f(x,k,t) - f(x,-k,t)) = 0, \quad k > 0. \tag{A.5}$$

With the assumption that $R > 0$ almost everywhere, we deduce that f is even with respect to k or, equivalently, that it is a function of $\varepsilon(k)$. Therefore, we have $f(x,k,t) = F(x,\varepsilon(k),t)$.

A.3. Current equation (5.2). We introduce the current

$$J^\alpha(x,\varepsilon,t) = \frac{1}{2\alpha}\left(f^\alpha(x,k,t) - f^\alpha(x,-k,t)\right), \quad k = \frac{\sqrt{2\varepsilon m}}{\hbar}. \tag{A.6}$$

We show that $J^\alpha \to J$, where J is given by (5.2).

For $k > 0$, we rewrite (4.12) by shifting the position variable by a half-period:

$$\begin{aligned} f^\alpha(x,k,t) = {} & R^\alpha\left(x - \alpha\frac{\ell}{2}, -k\right) f^\alpha(x,-k,t-\alpha^2\tau_R^\alpha) \\ & + T^\alpha\left(x - \alpha\frac{\ell}{2}, k_-^\alpha\right) f^\alpha(x-\alpha\ell, k_-^\alpha, t-\alpha^2\tau_T^\alpha), \end{aligned} \tag{A.7}$$

where we have not repeated the arguments of k_-^α and $\tau_{R,T}^\alpha$. We rewrite (A.7) according to

$$\begin{aligned} f^\alpha(x,k,t) = {} & R^\alpha\left(x - \alpha\frac{\ell}{2}, -k\right) f^\alpha(x,-k,t) + T^\alpha\left(x - \alpha\frac{\ell}{2}, k_-^\alpha\right) f^\alpha(x,k_-^\alpha,t) \\ & + T^\alpha\left(x - \alpha\frac{\ell}{2}, k_-^\alpha\right)\left(-\alpha\ell\frac{\partial f^\alpha}{\partial x}(x,k,t) + (k_-^\alpha - k)\frac{\partial f^\alpha}{\partial k}(x,k,t)\right) + O(\alpha^2). \end{aligned} \tag{A.8}$$

We note that, by (3.6), $T^\alpha(x - \alpha\frac{\ell}{2}, k_-^\alpha) = T^\alpha(x - \alpha\frac{\ell}{2}, -k)$. Now, using (A.2), we deduce from (A.8) that

$$\begin{aligned} & R^\alpha\left(x - \alpha\frac{\ell}{2}, -k\right)\left(f^\alpha(x,k,t) - f^\alpha(x,-k,t)\right) \\ & \quad = -\alpha\ell T^\alpha\left(x - \alpha\frac{\ell}{2}, k_-^\alpha\right)\left(\frac{\partial f^\alpha}{\partial x}(x,k,t) + \frac{em}{\hbar^2}\frac{1}{k}\frac{\partial\phi_{SC}^\alpha}{\partial x}\frac{\partial f^\alpha}{\partial k}(x,k,t)\right) + O(\alpha^2), \end{aligned}$$

or, dividing by R^α,

$$J^\alpha(x,\varepsilon(k),t) = -\frac{\ell}{2}\frac{T^\alpha(x - \alpha\frac{\ell}{2}, k_-^\alpha)}{R^\alpha(x - \alpha\frac{\ell}{2}, k_-^\alpha)}\left(\frac{\partial f^\alpha}{\partial x}(x,k,t) + \frac{em}{\hbar^2}\frac{1}{k}\frac{\partial\phi_{SC}^\alpha}{\partial x}\frac{\partial f^\alpha}{\partial k}(x,k,t)\right) + O(\alpha).$$

Now, taking the limit $\alpha \to 0$ and noting that

$$\frac{\partial f}{\partial k} = \frac{\partial F}{\partial\varepsilon}\frac{\hbar^2 k}{m}, \quad k > 0,$$

we easily obtain (5.2).

A.4. Continuity equation (5.1). To prove the continuity equation (5.1), we evaluate

$$I^\alpha = \frac{1}{\alpha\ell}\left(J^\alpha\left(x+\alpha\frac{\ell}{2},\varepsilon,t\right) - J^\alpha\left(x-\alpha\frac{\ell}{2},\varepsilon-e\delta\phi^\alpha,t\right)\right).$$

First, using (A.1) together with a Taylor expansion, we readily see that

$$I^\alpha = \left(\frac{\partial J^\alpha}{\partial x} + e\frac{\partial\phi^\alpha_{SC}}{\partial x}\frac{\partial J^\alpha}{\partial\varepsilon}\right)(x,\varepsilon,t) + O(\alpha).$$

Now, using (4.12), (4.13), we compute

$$\begin{aligned}
2\alpha^2\ell I^\alpha &= T(x,k^\alpha_-)f\left(x-\alpha\frac{\ell}{2},k^\alpha_-,t-\alpha^2\tau^\alpha_T(x,k^\alpha_-)\right)\\
&\quad + R(x,-k)f\left(x+\alpha\frac{\ell}{2},-k,t-\alpha^2\tau^\alpha_R(x,-k)\right) - f\left(x+\alpha\frac{\ell}{2},-k,t\right)\\
&\quad + T(x,-k)f\left(x+\alpha\frac{\ell}{2},-k,t-\alpha^2\tau^\alpha_T(x,-k)\right)\\
&\quad + R(x,k^\alpha_-)f\left(x-\alpha\frac{\ell}{2},k^\alpha_-,t-\alpha^2\tau^\alpha_R(x,k^\alpha_-)\right) - f\left(x-\alpha\frac{\ell}{2},k^\alpha_-,t\right).
\end{aligned}$$

By Taylor expanding with respect to t and using (3.6), we finally get

$$\begin{aligned}
2\alpha^2\ell I^\alpha &= -\alpha^2\left(T(x,k^\alpha_-)\tau^\alpha_T(x,k^\alpha_-) + R(x,-k)\tau^\alpha_R(x,-k)\right.\\
&\qquad \left. + T(x,-k)\tau^\alpha_T(x,-k) + R(x,k^\alpha_-)\tau^\alpha_R(x,k^\alpha_-)\right)\frac{\partial f^\alpha}{\partial t}(x,k,t) + O(\alpha^3).
\end{aligned}$$

Taking the limit $\alpha\to 0$ and using (A.4) then easily leads to (5.1).

This conclude the proof of Theorem 5.1. □

RELAXATION OSCILLATIONS IN A CLASS OF DELAY DIFFERENTIAL EQUATIONS*

A. C. FOWLER† AND MICHAEL C. MACKEY‡

Abstract. We study a class of delay differential equations which have been used to model hematological stem cell regulation and dynamics. Under certain circumstances the model exhibits self-sustained oscillations, with periods which can be significantly longer than the basic cell cycle time. We show that the long periods in the oscillations occur when the cell generation rate is small, and we provide an asymptotic analysis of the model in this case. This analysis bears a close resemblance to the analysis of relaxation oscillators (such as the Van der Pol oscillator), except that in our case the slow manifold is infinite dimensional. Despite this, a fairly complete analysis of the problem is possible.

Key words. relaxation oscillations, delay differential equations, hematopoiesis, stem cells, chronic myelogenous leukaemia

1. Introduction.

The understanding of periodic behavior in nonlinear ordinary differential equations is reasonably complete. Near Hopf bifurcation, periodic solutions are generically of small amplitude and can be analyzed using the methods of multiple scales. At more extreme parameter values, oscillations are often strongly nonlinear, and it is frequently the case that the dynamics are relaxational, in which case they can be understood through the existence of slow manifolds in phase space and the associated asymptotic analysis of the resulting relaxation oscillators. The classic example is the relaxation oscillation of the Van der Pol oscillator, whose analysis is ably expounded by Kevorkian and Cole (1981).

The situation is much less satisfactory for delay differential equations, which are frequently used to model populations, for example, in ecology (Gurney, Blythe, and Nisbet (1980)) or physiology (Mackey (1997)). One example is the delay recruitment equation

$$\varepsilon \dot{x} = -x + f(x_1), \tag{1.1}$$

where $x_1 = x(t-1)$. For unimodal f (i.e., $f(0) = 0$, $(x - x^*)f'(x) < 0$ for some $x^* > 0$), periodic oscillations can occur for sufficiently small ε. In some circumstances, a singular perturbation analysis of periodic solutions when $\varepsilon \ll 1$ is possible (Chow and Mallet-Paret (1982); Chow, Lin, and Mallet-Paret (1989)), but the results have been limited in scope.

Although linear and weakly nonlinear stability methods are straightforward for delay differential equations, singular perturbation methods appear difficult to implement in general. Much of the work that has been done, such as Chow and Mallet-Paret's work cited above, is concerned with systems with large delay (thus (1.1) or

its generalizations (Chow and Huang (1994); Hale and Huang (1996))). Artstein and Slemrod (2001) place their discussion of relaxation oscillations in the context of slow and fast manifolds familiar from ordinary differential equations and draw a distinction between systems where the delay is "fast" or "slow." (In this context we will find that the delay in our system is fast.)

Actual constructive asymptotic methods are less common. Fowler (1982) analyzed the delayed logistic equation $\varepsilon\dot{x} = x(1 - x_1)$, and Bonilla and Liñan (1984) analyzed a more general system having distributed delay and with diffusion. In a sequence of papers, Lange and Miura (e.g., 1982, 1984) provided asymptotic analyses of models with delays and exhibited boundary layer behavior, although they were exclusively concerned with boundary value problems, and their systems were linear. More recently, Pieroux et al. (2000) analyzed a laser system when the delay was large but dependence on the delayed variable was weak, using multiple scale techniques. In this paper, we show how a constructive relaxational perturbation analysis can be carried out for a particular class of delay differential equations describing stem cell dynamics, when the net proliferation rate is small.

2. A mathematical model of stem cell dynamics. Hematological diseases are interesting and have attracted a significant amount of modeling attention because a number of them are periodic in nature (Haurie, Dale, and Mackey (1998)). Some of these diseases involve only one blood cell type and are due to the destabilization of peripheral control mechanisms, e.g., periodic auto-immune hemolytic anemia (Bélair, Mackey, and Mahaffy (1995); Mahaffy, Bélair, and Mackey (1998)) and cyclical thrombocytopenia (Swinburne and Mackey (2000); Santillan et al. (2000)). Typically, periodic hematological diseases of this type involve periodicities between two and four times the bone marrow production/maturation delay (which is different from the delay considered in this paper).

Other periodic hematological diseases involve oscillations in all of the blood cells (white cells, red blood cells, and platelets). Examples include cyclical neutropenia (Haurie, Dale, and Mackey (1999); Haurie et al. (1999); Haurie et al. (2000)) and periodic chronic myelogenous leukemia (Fortin and Mackey (1999)). These diseases involve very long period dynamics (on the order of weeks to months) and are thought to be due to a destabilization of the pluripotential stem cell (PPSC) compartment from which all of these mature blood cell types are derived.

In Figure 2.1 we have given a pictorial representation of the PPSC compartment and defined the important variables. The dynamics of this PPSC population are governed (Mackey (1978), (1997), (2001)) by the pair of coupled differential delay equations

$$\frac{dP}{d\hat{t}} = -\gamma P + \beta(N)N - e^{-\gamma\tau}\beta(N_\tau)N_\tau \tag{2.1}$$

for the dynamics of the proliferating phase cells and

$$\frac{dN}{d\hat{t}} = -[\beta(N) + \delta]N + 2e^{-\gamma\tau}\beta(N_\tau)N_\tau \tag{2.2}$$

for the nonproliferating (G_0) phase cells. In these equations, $\hat{t}$ is time, τ is the time required for a cell to traverse the proliferative phase, $N_\tau = N(\hat{t} - \tau)$, and the resting to proliferative phase feedback rate β is taken to be a Hill function of the form

$$\beta(N) = \frac{\beta_0\theta^n}{\theta^n + N^n}. \tag{2.3}$$

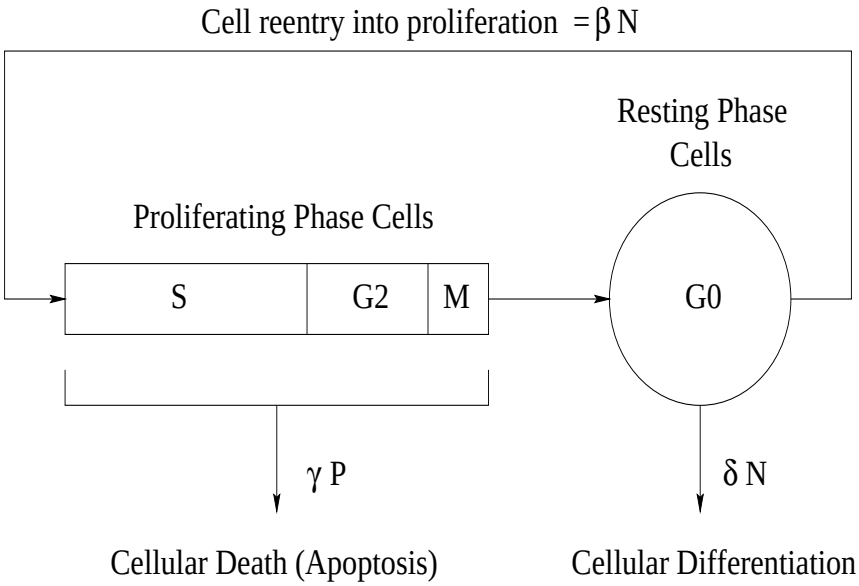

FIG. 2.1. *A schematic representation of the G_0 stem cell model. Proliferating phase cells (P) include those cells in S (DNA synthesis), G_2, and M (mitosis) while the resting phase (N) cells are in the G_0 phase. δ is the rate of differentiation into all of the committed stem cell populations, while γ represents a loss of proliferating phase cells due to apoptosis. β is the rate of cell reentry from G_0 into the proliferative phase, and τ is the duration of the proliferative phase. See Mackey* (1978), (1979), (1997) *for further details.*

The origin of the terms in these equations is fairly obvious. For example, the first term of (2.2) represents the loss of proliferating cells to cell division ($\beta(N)N$) and to differentiation (δN). The second term represents the production of proliferating stem cells, with the factor 2 accounting for the amplifying effect of cell division while $e^{-\gamma\tau}$ accounts for the attenuation due to apoptosis (programmed cell death) at rate γ. It is clear that in investigating the dynamics of the PPSC we need only understand the dynamics of the G_0 phase resting cell population since the proliferating phase dynamics are driven by the dynamics of N.

Typical values of the parameters for humans are given by Mackey (1978), (1997) as

$$\delta = 0.05\,\mathrm{d}^{-1}, \quad \beta_0 = 1.77\,\mathrm{d}^{-1}, \quad \tau = 2.2\,\mathrm{d}, \quad n = 3. \tag{2.4}$$

(The value of θ is 1.62×10^8 cells kg^{-1}, but this is immaterial for dynamic considerations.) For values of γ in the range $0.2\,\mathrm{d}^{-1}$, the consequent steady state is unstable and there is a periodic solution whose period P at the bifurcation ranges from 20–40 days. It is the observation that $P \gg \tau$, which arouses our curiosity, and which we wish to explain. (In differential delay equations, periodic oscillations have periods bounded below by 2τ and under certain circumstances the period may be in the range 2τ to 4τ.)

We rewrite (2.2) in a standard form as follows. First scale the nonproliferating phase cell numbers by θ and the time by τ so that

$$N \to \theta N, \quad \hat{t} = \tau t^*, \tag{2.5}$$

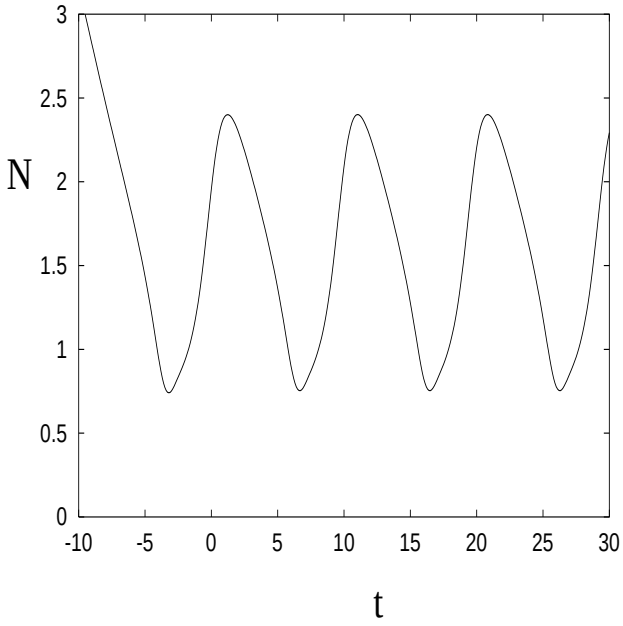

FIG. 2.2. *Solution of* (2.6) *with* $\varepsilon = 0.11$, $b = 3.9$, *and* $\mu = 1.2$.

and (2.2) becomes

$$\dot{N} = g(N_1) - g(N) + \varepsilon[\mu g(N_1) - N], \tag{2.6}$$

where $\dot{N} = dN/dt^*$, $N_1 = N(t^* - 1)$,

$$g(N) = \frac{bN}{1 + N^n}, \tag{2.7}$$

and the parameters are defined by

$$b = \beta_0 \tau, \quad \varepsilon = \delta\tau, \quad \mu = \frac{2e^{-\gamma\tau} - 1}{\delta\tau}. \tag{2.8}$$

The biological interpretation of these is as follows: b represents the rate at which cells migrate round the loop in Figure 2.1, ε represents the rate of loss through differentiation, and μ represents the net proliferation rate round the loop. The dimensionless time t^* is measured in units of the proliferative time spent in the loop. If we take $\gamma \sim 0.2\,\mathrm{d}^{-1}$, then typical values of the parameters are

$$b \sim 3.9, \quad \mu \sim 2.6, \quad \varepsilon \sim 0.11. \tag{2.9}$$

On this basis, we suppose $b, \mu = O(1)$. The long periods are associated with the relatively small value of ε, and so the aim of our analysis is to solve (2.6) when $\varepsilon \ll 1$. Figure 2.2 shows the periodic behavior when $\varepsilon = 0.11$, $b = 3.9$, and $\mu = 1.2$ (the steady state is stable when $\mu = 2.6$).

3. Singular perturbation analysis. The first order delay differential equation (2.6) is an infinite dimensional system. For example, defining the function

$$u_{t^*}(s) = N(t^* + s), \quad s \in [-1, 0], \tag{3.1}$$

we can consider (2.6) as a sequence of ordinary differential equations on the Banach space $C[-1,0]$ of continuous functions on $[-1,0]$. Singular perturbation analysis is therefore not necessarily straightforward, but we shall see that a formal procedure is indeed possible.

The key observation for our investigation is that a solution of (2.6) can be slowly varying, on a slow time scale

$$t = \varepsilon t^*, \tag{3.2}$$

or on a rather loosely defined "slow manifold" on which $N \approx N_1$. In terms of t, which represents time measured in units of the slower differentiation time scale, we have $N(t^* - 1) = N(t - \varepsilon)$; thus (2.6) is ($N' = dN/dt$)

$$N' = \frac{g(N_\varepsilon) - g(N)}{\varepsilon} + \mu g(N_\varepsilon) - N. \tag{3.3}$$

Also, by expanding N_ε for small ε, we have

$$\begin{aligned} N_\varepsilon &= N - \varepsilon N' + \tfrac{1}{2}\varepsilon^2 N'' \dots, \\ g(N_\varepsilon) &= g(N) - [\varepsilon N' - \tfrac{1}{2}\varepsilon^2 N'' + \tfrac{1}{6}\varepsilon^3 N''' \dots]g'(N) + [\tfrac{1}{2}\varepsilon^2 N'^2 \dots]g''(N) + \cdots; \end{aligned} \tag{3.4}$$

note that $N' = dN/dt$, while $g'(N) = dg/dN$. We thus have

$$[1 + g'(N)]N' = \mu g(N) - N + \varepsilon[-\mu g' N' + \tfrac{1}{2}N'' g' + \tfrac{1}{2}N'^2 g''] + \cdots, \tag{3.5}$$

and successive terms in the expansion

$$N \sim N_0 + \varepsilon N_1 + \cdots \tag{3.6}$$

satisfy the equations

$$N_0' = \frac{\mu g(N_0) - N_0}{1 + g'(N_0)}, \tag{3.7}$$

$$\begin{aligned} &[1 + g'(N_0)]N_1' + g''(N_0)N_0'N_1 \\ &\qquad = \mu g'(N_0)N_1 - N_1 + [-\mu g'(N_0)N_0' + \tfrac{1}{2}N_0'' g'(N_0) + \tfrac{1}{2}N_0'^2 g''(N_0)], \end{aligned} \tag{3.8}$$

and so on. Note particularly that in this slow region N_1 denotes the second term in the expansion for N and does *not* represent $N(t^* - 1)$; it will revert to the former meaning when we consider the dynamics in the fast "shock" layer (when the expansion will use u and v as first and second order terms). Equation (3.7) states that the rate of change of the resting stem cell population is due to net proliferation (the first term in the numerator) and loss by differentiation (the second). The effect of the delay in the proliferative cycle is to mediate the rate by the denominator. In our procedure we now begin to follow Kevorkian and Cole's (1981) exposition (pp. 67 and the following ones) quite closely.

The function $g = bN/(1 + N^n)$ is unimodal. If $g' > -1$ everywhere, then N will evolve on the slow time scale to a steady state. Suppose now that

$$b > b_c = \frac{4n}{(n-1)^2}, \tag{3.9}$$

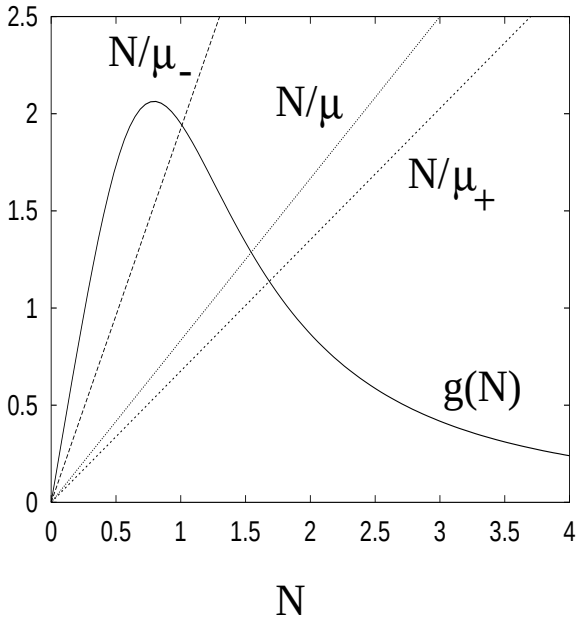

FIG. 3.1. *Graphs of $g(N)$ and N/μ for $b = 3.9$, $n = 3$, and $\mu = 1.2$ in the range $(\mu_-, \mu_+) = (0.52, 1.48)$. Also shown are graphs of N/μ_- and N/μ_+.*

which is the criterion for g' to reach -1. Then there are two values $N_- < N_+$ at which $g' = -1$; for (2.7), we have, explicitly,

$$N_\pm^n = \tfrac{1}{2}(n-1)[b \pm (b^2 - b_c b)^{1/2}] - 1. \tag{3.10}$$

If $\mu b < 1$, $N = 0$ is stable, by consideration of (3.7). If $\mu b > 1$, then there is a positive steady state N^* in which $N^* = \mu g(N^*)$. We define the two values of μ where $N^* = N_\pm$ as $\mu_\pm$; thus,

$$\mu_\pm = \frac{N_\pm}{g(N_\pm)}, \quad \mu_- < \mu_+. \tag{3.11}$$

Using (3.10), we have, explicitly,

$$\mu_\pm = \tfrac{1}{2}(n-1)\left[1 \pm \left(1 - \frac{b_c}{b}\right)^{1/2}\right]. \tag{3.12}$$

The situation which is of interest is when $\mu_- < \mu < \mu_+$, and this is depicted in Figure 3.1. In this situation, the graph of N_0' versus N_0 is as shown in Figure 3.2, and it is apparent that the fixed point in (N_-, N_+) is unstable, because the slope of the graph at the fixed point (where $N' = 0$) is positive. (Conversely, there is a stable fixed point when μ is outside this range.)

Suppose that $N > N_+$ initially. Then N_0 decreases and reaches N_+ at finite time. Define this time to be when $t = 0$; then

$$\int_{N_+}^{N_0} \left\{ \frac{1 + g'(N)}{N - \mu g(N)} \right\} dN = -t. \tag{3.13}$$

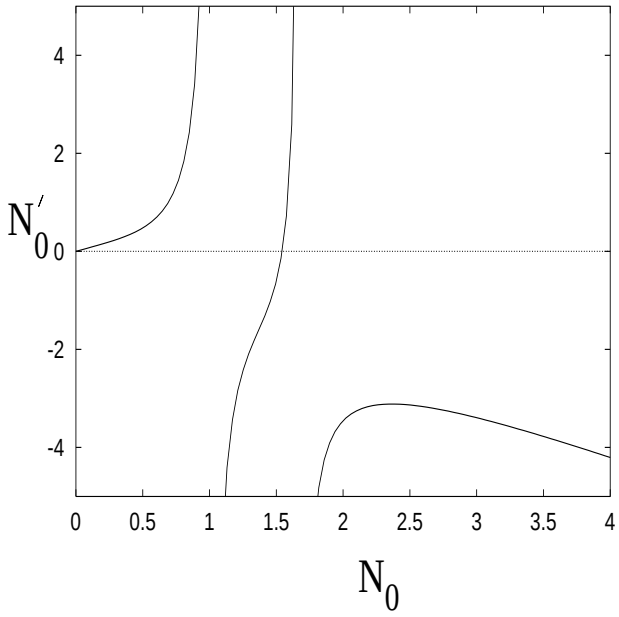

FIG. 3.2. *Graph of* $N_0'(N_0)$ *given by* (3.7) *when* $n = 3$, $b = 3.9$, *and* $\mu = 1.2$.

Since $1+g'(N_+) = 0$, the first term in the expansion of the integral in (3.13) for small $N_0 - N_+$ is quadratic, and from this we find, as $-t \to 0+$,

$$N_0 \sim N_+ + q_1(-t)^{1/2} + q_2(-t) + O[(-t)^{3/2}]. \tag{3.14}$$

Detailed expressions for the coefficients are given in the appendix.

Rearrangement of (3.8) using (3.7) allows N_1 to be obtained in the form

$$N_1 = \left(\frac{N_0 - \mu g(N_0)}{1 + g'(N_0)}\right)\left[A_1 - \frac{g'(N_0)}{2\{1 + g'(N_0)\}} + \int_{N_+}^{N_0} k(N)\, dN + h_+ \ln(N_0 - N_+)\right], \tag{3.15}$$

where $h_+ = h(N_+)$,

$$h(N) = -\frac{g'(N)\{1 - \mu g'(N)\}(N - N_+)}{2\{N - \mu g(N)\}\{1 + g'(N)\}} \tag{3.16}$$

(with the singularity at N_+ removed), and

$$k(N) = \frac{h(N) - h(N_+)}{N - N_+} - \frac{\mu g'(N)}{N - \mu g(N)}. \tag{3.17}$$

In particular,

$$h_+ = \frac{1 + \mu}{2g_+''(N_+ - \mu g_+)}, \tag{3.18}$$

where $g_+ = g(N_+)$, etc. Higher order terms can be obtained in a similar way. Note that, since $N_0 - N_+ \sim (-t)^{1/2}$ as $-t \to 0$, and $g'(N_+) = -1$, it follows that $1+g'(N_0) \sim (-t)^{1/2}$ as $-t \to 0$, and therefore (3.15) implies that $N_1 = O(1/(-t))$ as $-t \to 0+$, and the validity of the expansion breaks down when $(-t)^{1/2} \sim \varepsilon/(-t)$, i.e., when $-t \sim \varepsilon^{2/3}$.

3.1. Transition layer. The solution becomes disordered as $-t \to 0$, and specifically when $-t \sim \varepsilon^{2/3}$. In this section we analyze this "transition" layer. In addition, we might anticipate the existence of a region in which N changes on the fast (delay) time scale t^*, and this will indeed turn out to be the case. However, it transpires that such a fast region cannot be matched directly to the slow outer region, and, just as for the Van der Pol oscillator, the inability to match slow and fast regions also suggests that there is a transition region which joins the two. In terms of the outer time scale t, we shall find that the slow solution is valid for $-t \sim O(1)$, the transition region for $-t \sim O(\varepsilon^{2/3})$, and the fast "shock" layer for $-t \sim O(\varepsilon)$. Indeed, the dynamics of these three regions are essentially the same as those of the corresponding regions in the analysis of the Van der Pol equations, and we follow the exposition in Kevorkian and Cole (1981) closely. In particular, consultation of this book is strongly recommended for those less familiar with the basic procedure of matched asymptotic expansions. (Note that there are some algebraic errors in Kevorkian and Cole's exposition.)

A distinguished limit exists in which we put

$$t = \rho(\varepsilon) + \left(\frac{\varepsilon^{2/3}}{\Omega}\right)\tilde{t}, \tag{3.19}$$

where we assume $\tilde{t}$ is $O(1)$. The definition of Ω is

$$\Omega = (g_+'' q_1)^{2/3}, \tag{3.20}$$

and $\rho(\varepsilon)$ is a (small) origin shift which is introduced to allow matching to be carried out. Since $N - N_+ \sim (-t)^{1/2}$ as $-t \to 0+$, this requires $N - N_+ \sim \varepsilon^{1/3}$, and we define f via

$$N = N_+ + \left(\frac{\varepsilon^{1/3}\Omega}{g_+''}\right) f. \tag{3.21}$$

It is still appropriate to expand the delay term, and we find, from (3.3), that $f(\tilde{t})$ satisfies

$$f'' + 2ff' + 1 = \varepsilon^{1/3}[-\kappa f + \tfrac{1}{3}\Omega f''' + \Omega(f'^2 + ff'') - \lambda f^2 f'] + O(\varepsilon^{2/3}), \tag{3.22}$$

where

$$\lambda = \frac{\Omega g_+'''}{g_+''^2}, \quad \kappa = \frac{2}{\Omega^2}(1+\mu). \tag{3.23}$$

We expand f in powers of $\varepsilon^{1/3}$, thus

$$f \sim f_1 + \varepsilon^{1/3} f_2 + \cdots; \tag{3.24}$$

then from (3.22) we find that

$$\begin{aligned} f_1'' + 2f_1 f_1' + 1 &= 0, \\ f_2'' + 2(f_1 f_2)' &= -\kappa f_1 + \tfrac{1}{3}\Omega f_1''' + \Omega(f_1 f_1')' - \lambda f_1^2 f_1', \end{aligned} \tag{3.25}$$

and so on. The first of these may be integrated to yield

$$f_1' + f_1^2 + \tilde{t} = 0, \tag{3.26}$$

where the constant of integration is absorbed into the time shift $\rho(\varepsilon)$ in (3.19). The solution of the Riccati equation (3.26) is

$$f_1 = \frac{V'(\tilde{t})}{V(\tilde{t})}, \tag{3.27}$$

where V satisfies the modified Airy equation

$$V'' + \tilde{t}V = 0. \tag{3.28}$$

The solutions of (3.28) are $\mathrm{Ai}\,(-\tilde{t})$ and $\mathrm{Bi}\,(-\tilde{t})$, whose leading order behaviors as $\tilde{t} \to -\infty$ are $V \sim \exp\left[\pm\frac{2}{3}(-\tilde{t})^{3/2}\right]$ (minus for Ai). Thus if V contains any Bi, it will dominate as $\tilde{t} \to -\infty$, and hence $f_1 = V'(\tilde{t})/V(\tilde{t}) \sim -(-\tilde{t})^{1/2}$ in this limit. Therefore, in order to obtain $f_1 \sim (-\tilde{t})^{1/2}$ as $\tilde{t} \to -\infty$, which is required for matching purposes, we must suppress the Bi component and choose

$$V(\tilde{t}) = 2\sqrt{\pi}\mathrm{Ai}\,(-\tilde{t}), \tag{3.29}$$

where the premultiplicative constant is chosen for later algebraic convenience (it does not affect the definition of f_1). Since $f_1 \sim (-\tilde{t})^{1/2}$ as $\tilde{t} \to -\infty$, f_1 is monotonically decreasing for large $-\tilde{t}$, and hence from (3.26) $f_1 > (-\tilde{t})^{1/2}$. If f_1' first reaches zero for some value of $\tilde{t} = \tilde{t}_c < 0$, then at that point (3.26) implies that $f_1 = (-\tilde{t})^{1/2}$ and also that (since f_1' is continuous and $f_1 > (-\tilde{t})^{1/2}$ for $\tilde{t} < \tilde{t}_c$) $f_1' < 0$, which contradicts the assertion. Thus $f_1' < 0$ for all $\tilde{t} < 0$, and (3.26) implies this directly for $\tilde{t} > 0$. Thus we find f_1 is monotonically decreasing while it is finite, which is in the region $\tilde{t} < \tilde{t}_0$, where $\tilde{t}_0 \approx 2.338$ is the first zero of $\mathrm{Ai}\,(-\tilde{t})$. The solution will break down as $\tilde{t} \to \tilde{t}_0$, where it will match to an inner region, or shock layer, in which $t^* = O(1)$ (with a suitably chosen origin for t^*).

The first integral of $(3.25)_2$ is (using $f_1 = V'/V$)

$$f_2' + 2f_1 f_2 = -\kappa \ln V + \tfrac{1}{3}\Omega f_1'' + \Omega f_1 f_1' - \tfrac{1}{3}\lambda f_1^3 + C_2, \tag{3.30}$$

where C_2 is constant. By differentiation of (3.26) we find that $-C_2 f_1'$ is a particular solution for (3.30) when only the C_2 term is present on the right-hand side. Using $f_1 = V'/V$, we have

$$(V^2 f_2)' = C_2 V^2 - \kappa V^2 \ln V + \tfrac{1}{3}\Omega V^2 f_1'' + \Omega V^2 f_1 f_1' - \tfrac{1}{3}\lambda V^2 f_1^3. \tag{3.31}$$

Next we make use of the following identities, which can be obtained by integrating by parts and using (3.27) and (3.28):

$$\begin{aligned}
&\int V^2 f_1 f_1' = \tfrac{1}{2}V^2 f_1^2 - \int V^2 f_1^3, \\
&\int V^2 f_1'' = V^2 f_1' - V^2 f_1^2 + 2\int V^2 f_1^3, \\
&\int V^2 f_1^3 = V'^2 \ln V + (V^2 \ln V - \tfrac{1}{2}V^2)\tilde{t} - \int (V^2 \ln V - \tfrac{1}{2}V^2).
\end{aligned} \tag{3.32}$$

The comment after (3.30) implies that

$$\frac{1}{V^2}\int_{-\infty}^{\tilde{t}} V^2 d\tilde{t} = -f_1', \tag{3.33}$$

and use of (3.26) and integration by parts in (3.32) implies that

$$\frac{1}{V^2}\int V^2 f_1^3 = -f_1' \ln V - \frac{1}{V^2}\int V^2 \ln V + \tfrac{1}{2} f_1^2. \tag{3.34}$$

Hence we obtain the solution

$$\begin{aligned} f_2 = f_1'[-C_2 + \tfrac{1}{3}\Omega + \tfrac{1}{3}(\Omega+\lambda)\ln V] - \tfrac{1}{6}\lambda f_1^2 \\ + [\tfrac{1}{3}(\Omega+\lambda) - \kappa]\,\frac{1}{V^2}\int_{-\infty}^{\tilde{t}} V^2 \ln V\, d\tilde{t}, \end{aligned} \tag{3.35}$$

where we have set the integration constant D_2 (in a term D_2/V^2) to zero to prevent exponential growth as $\tilde{t} \to -\infty$.

3.2. Matching. In order to match the outer solution to the transition solution, we expand the latter for large $-\tilde{t}$ and the former for small $-t$. Equation (3.14) gives the behavior of N_0 for small $(-t)$, while if we expand (3.15) for N_0 near N_+, and use (3.14), we find

$$N_1 \sim \frac{r_1}{(-t)} + \frac{r_{21}(A_1) + r_{22}\ln(-t)}{(-t)^{1/2}} + O(1), \tag{3.36}$$

where the constants r_1, r_{21}, r_{22} are given in the appendix; r_1 and r_{22} are known, while r_{21} involves the unknown constant A_1 in (3.15).

Next we need the behavior of f_1 and f_2 as $\tilde{t} \to -\infty$. The function $V = 2\sqrt{\pi}\,\mathrm{Ai}\,(-\tilde{t})$ has the following asymptotic behavior as $\tilde{t} \to -\infty$:

$$V \sim (-\tilde{t})^{-1/4} \exp\left[-\tfrac{2}{3}(-\tilde{t})^{3/2}\right]\left[1 - \frac{5}{48(-\tilde{t})^{3/2}} + \cdots\right]. \tag{3.37}$$

Since $f_1 = V'/V$, we have

$$f_1 \sim (-\tilde{t})^{1/2} + \frac{1}{4(-\tilde{t})} + O[(-\tilde{t})^{-5/2}], \tag{3.38}$$

and thence we find from (3.35) that

$$f_2 \sim s_1(-\tilde{t}) + \frac{s_{21}(C_2) + s_{22}\ln(-\tilde{t})}{(-\tilde{t})^{1/2}} + O\left[\frac{\ln(-\tilde{t})}{(-\tilde{t})^2}\right], \tag{3.39}$$

and the coefficients s_1, s_{22}, and s_{21} are given in the appendix. Again, s_1 and s_{22} are known, and s_{21} involves the unknown constant C_2 in (3.35).

We match in an intermediate region where

$$t = \eta t_\eta + \rho(\varepsilon), \quad \tilde{t} = \left(\frac{\Omega}{\varepsilon^{2/3}}\right)\eta t_\eta, \tag{3.40}$$

and we take $\varepsilon^{2/3} \ll \eta \ll 1$ and also presume that $\eta \gg \rho$. Writing both expansions (3.6) and (3.24) in terms of t_η, the outer expansion is given by

$$\begin{aligned} N \sim N_+ + q_1(-\eta t_\eta)^{1/2} - \frac{\rho q_1}{2(-\eta t_\eta)^{1/2}} \cdots + q_2(-\eta t_\eta) + \cdots \\ + \frac{\varepsilon r_1}{(-\eta t_\eta)} \cdots + \frac{\varepsilon[r_{21} + r_{22}\ln(-\eta t_\eta)\ldots]}{(-\eta t_\eta)^{1/2}} \cdots, \end{aligned} \tag{3.41}$$

while the transition expansion is

$$N \sim N_+ + q_1(-\eta t_\eta)^{1/2} + \frac{\varepsilon}{4g''_+(-\eta t_\eta)}\dots$$
$$+ \frac{s_1\Omega^2}{g''_+}(-\eta t_\eta) + \frac{\varepsilon\Omega^{1/2}}{g''_+}\frac{[s_{21} + s_{22}\{\ln(\Omega/\varepsilon^{2/3}) + \ln(-\eta t_\eta)\}]}{(-\eta t_\eta)^{1/2}}\dots, \tag{3.42}$$

and matching requires

$$r_1 = \frac{1}{4g''_+}, \quad q_2 = \frac{s_1\Omega^2}{g''_+}, \quad r_{22} = \frac{\Omega^{1/2}}{g''_+}s_{22},$$
$$r_{21} = \frac{\Omega^{1/2}}{g''_+}[s_{21} + s_{22}\ln\Omega],$$
$$\rho = \frac{4\Omega^{1/2}s_{22}}{3g''_+q_1}\,\varepsilon\ln\varepsilon. \tag{3.43}$$

The first three of these are satisfied identically (see the appendix), while the fourth and fifth determine s_{21} and ρ, given r_{21} in the outer solution.

3.3. Matching to the shock layer. The transition solution governed by (3.22) breaks down as $\tilde{t} \to \tilde{t}_0$. Near $\tilde{t}_0$, we have that

$$V \approx -K(\tilde{t} - \tilde{t}_0) + \tfrac{1}{6}K\tilde{t}_0(\tilde{t} - \tilde{t}_0)^3 + O[(\tilde{t} - \tilde{t}_0)^4], \tag{3.44}$$

where $K = 2\sqrt{\pi}\mathrm{Ai}'(-\tilde{t}_0) \approx 2.486$, and thus

$$f_1 \sim -\frac{1}{(\tilde{t}_0 - \tilde{t})} + \tfrac{1}{3}\tilde{t}_0(\tilde{t}_0 - \tilde{t})\dots. \tag{3.45}$$

$N - N_+$ becomes of $O(1)$ when $\tilde{t}_0 - \tilde{t} \sim \varepsilon^{1/3}$ (this follows from (3.45) together with (3.21)), and this suggests that we put

$$\tilde{t} = \tilde{t}_0 + \Omega\{\varepsilon^{1/3}t^* + \sigma(\varepsilon)\}, \tag{3.46}$$

and we anticipate that $\sigma \ll 1$. In terms of t,

$$t = \rho(\varepsilon) + \left(\frac{\varepsilon^{2/3}}{\Omega}\right)\tilde{t}_0 + \varepsilon^{2/3}\sigma(\varepsilon) + \varepsilon t^*, \tag{3.47}$$

so that in the transition layer $N(t^*)$ satisfies (2.6), i.e.,

$$\frac{dN}{dt^*} = g(N_1) - g(N) + \varepsilon[\mu g(N_1) - N], \tag{3.48}$$

and N_1 reverts here to its original meaning as $N(t^* - 1)$. The behavior of f_2 as $\tilde{t} \to \tilde{t}_0$ follows from (3.35), which implies

$$f_2 \sim -\tfrac{1}{3}(\Omega + \lambda)\frac{\ln(\tilde{t}_0 - \tilde{t})}{(\tilde{t}_0 - \tilde{t})^2} + \frac{C_3}{(\tilde{t}_0 - \tilde{t})^2}, \tag{3.49}$$

where

$$C_3 = C_2 - \tfrac{1}{3}\Omega - \tfrac{1}{3}(\Omega + \lambda)\ln K - \tfrac{1}{6}\lambda + [\tfrac{1}{3}(\Omega + \lambda) - \kappa]\frac{I_0}{K^2}, \tag{3.50}$$

$$I_0 = \int_{-\infty}^{\tilde{t}_0} V^2 \ln V\, dV. \tag{3.51}$$

If we expand N in a transition region where $\varepsilon^{1/3}t^* = \eta t_\eta \ll 1$, and we suppose $\sigma \ll \eta$, then from (3.45) and (3.49) we find that

$$N \sim N_+ + \frac{\varepsilon^{1/3}}{g''_+}\left[\frac{1}{\eta t_\eta}\left\{1 - \frac{\sigma}{\eta t_\eta}\right\} - \tfrac{1}{3}\Omega^2 \tilde{t}_0(\eta t_\eta + \sigma)\ldots\right]$$
$$+ \frac{\varepsilon^{2/3}}{\Omega g''_+}\frac{1}{(\eta t_\eta)^2}\left[\{C_3 - \tfrac{1}{3}(\Omega+\lambda)\ln\Omega\} - \tfrac{1}{3}(\Omega+\lambda)\ln(-\eta t_\eta)\right]\ldots. \tag{3.52}$$

The presence of the term in $\varepsilon^{2/3}$ formally requires that we expand (3.48) as

$$N \sim u + \varepsilon^{2/3}v + O(\varepsilon) \tag{3.53}$$

and that u, v satisfy

$$\begin{aligned} u' &= g(u_1) - g(u), \\ v' &= g'(u_1)v_1 - g'(u)v, \end{aligned} \tag{3.54}$$

where the suffix 1 indicates a delayed argument.

Evidently, $u \to N_+$ as $t^* \to -\infty$, and its asymptotic behavior can be determined by writing

$$u = N_+ + \phi \tag{3.55}$$

and expanding for small ϕ, together with a Taylor expansion for $\phi_1 \equiv \phi(t^* - 1)$ as $\phi - \phi' + \cdots$. This leads (with the ansatz $\phi \gg \phi' \gg \phi'' \ldots$) to

$$0 = [-\tfrac{1}{2}\phi'' - g''_+\phi\phi'] + [\tfrac{1}{6}\phi''' + \tfrac{1}{2}g''_+(\phi'^2 + \phi\phi'') - \tfrac{1}{2}g'''_+\phi^2\phi'] + \cdots, \tag{3.56}$$

where the brackets enclose terms of similar order. Two terms of the solution of this as $t^* \to -\infty$ yield

$$\phi \sim \frac{1}{g''_+ t^*} + \frac{[E_1 - E_2\ln(-t^*)]}{t^{*2}} + \cdots, \tag{3.57}$$

where E_1 is an arbitrary constant, and E_2 is defined in the appendix. The equation for ϕ is autonomous, and an arbitrary constant can be added to t^*. It is clear that this is equivalent to changing the value of E_1; therefore the value of E_1 fixes the phase of ϕ.

The asymptotic behavior of v can then be found in a similar way, and we find that

$$0 = [-\tfrac{1}{2}v'' - g''_+(\phi v)'] + [\tfrac{1}{6}v''' + \tfrac{1}{2}g''_+(v\phi)'' - \tfrac{1}{2}g'''_+(\phi^2 v)'] + \cdots, \tag{3.58}$$

whence

$$v \sim -E_3[t^* + g''_+E_2\ln(-t^*) - E_4 + \cdots], \tag{3.59}$$

where E_3 is arbitrary and E_4 is given in the appendix. As in the Van der Pol analysis, v has a "homogeneous" solution $v = g'(u)u'$, which is $O(1/t^{*2})$ as $t^* \to -\infty$, and (3.59) comes from the "particular" solution of $(3.54)_2$, which does not tend to zero at $-\infty$.

The behavior of N as $t^* \to -\infty$ is thus

$$N \sim N_+ + \frac{1}{g''_+ t^*} + \frac{[E_1 - E_2\ln(-t^*)]}{t^{*2}} + \cdots$$
$$- \varepsilon^{2/3}E_3[t^* + g''_+E_2\ln(-t^*) - E_4], \tag{3.60}$$

and putting $\varepsilon^{1/3}t^* = \eta t_\eta$ in the matching region gives

$$N \sim N_+ + \frac{\varepsilon^{1/3}}{g''_+\eta t_\eta} + \frac{\varepsilon^{2/3}[E_1 + E_2 \ln \varepsilon^{1/3} - E_2 \ln(-\eta t_\eta)]}{(\eta t_\eta)^2} \cdots$$
$$- \varepsilon^{1/3}E_3(\eta t_\eta) - \varepsilon^{2/3}E_3[g''_+E_2 \ln(-\eta t_\eta) - g''_+E_2 \ln \varepsilon^{1/3} - E_4] \ldots . \tag{3.61}$$

Terms in (3.52) can be matched to the corresponding terms in (3.61) if

$$\begin{aligned} \sigma &= -\varepsilon^{1/3}\left\{\tfrac{1}{3}g''_+E_2 \ln \varepsilon - E_4\right\}, \\ E_1 &= \frac{C_3 - \frac{1}{3}(\Omega + \lambda)\ln \Omega}{\Omega g''_+} - \frac{E_4}{g''_+}, \\ E_3 &= \frac{\Omega^2 \tilde{t}_0}{3g''_+}, \\ E_2 &= \frac{\Omega + \lambda}{3\Omega g''_+}; \end{aligned} \tag{3.62}$$

these determine E_1, E_3, and σ, while the equation for E_2 is satisfied automatically.

3.4. Shock layer. To compute N for $t^* = O(1)$, we must solve for $N = u + \varepsilon^{2/3}v$ the equations

$$\begin{aligned} &u' = g(u_1) - g(u), \\ &u \sim N_+ + \frac{1}{g''_+t^*} + \frac{[E_1 - E_2 \ln(-t^*)]}{t^{*2}} + \cdots \quad \text{as} \quad t^* \to -\infty, \\ &v' = g'(u_1)v_1 - g'(u)v, \\ &v \sim -E_3[t^* + g''_+E_2 \ln(-t^*) - E_4] \quad \text{as} \quad t^* \to -\infty. \end{aligned} \tag{3.63}$$

The solutions of these must be obtained numerically. Note that the value of E_1 determines the origin of t^*, i.e., varying E_1 in $(3.63)_2$ simply phase shifts the solution.

It is at this point that the solution method deviates significantly from the Van der Pol procedure. The Van der Pol shock layer equation admits a first integral, and the solution can be written as a quadrature. The important point, however, is the existence of this first integral. Remarkably, an analogous procedure can be followed for the delay equations (3.63).

First, numerical integration of (3.63) indicates that u tends to a constant as $t^* \to \infty$. This is shown in Figure 3.3. The phase of the solution depends on the location of the initial interval, as shown in Figure 3.4. For the purposes of our analysis, we need to know this constant, and it can be found as follows. A trivial integration of $(3.63)_1$ shows that

$$u(t^*) + \int_{t^*-1}^{t^*} g[u(s)]ds = N_+ + g_+ \tag{3.64}$$

is constant, where the right-hand side is evaluated from the asymptotic expression for u as $t^* \to -\infty$. This immediately implies u is bounded (by $N_+ + g_+ \pm \max g$) as $t \to \infty$, and if we suppose that u tends to a constant N_L (as in Figure 3.3), then the value of the constant is easily found from (3.64) to satisfy

$$N_L + g_L = N_+ + g_+, \tag{3.65}$$

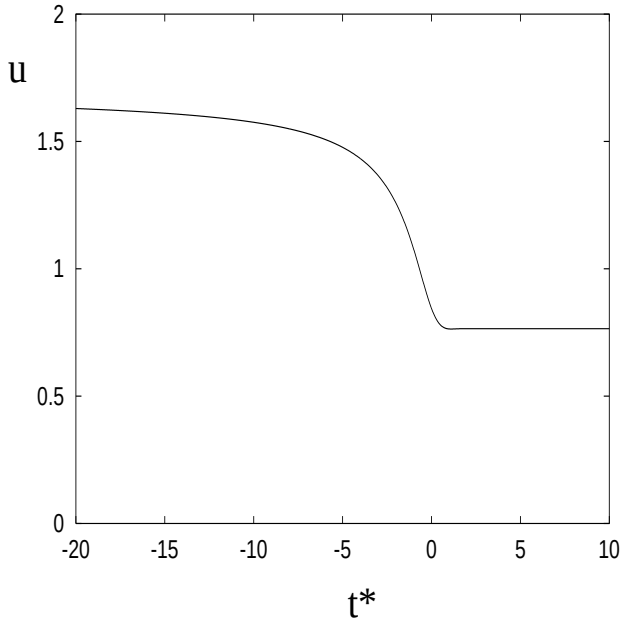

FIG. 3.3. *The solution* $u_\Delta(t^*)$ *of* $(3.63)_1$ *for* u *with the initial data taken from* $(3.63)_2$ *on the interval* $[-\Delta - 1, -\Delta)$. *The solution* $u_{20}(t^*)$ *shown is obtained using* $E_1 = 0$ *and* $\Delta = 20$. *The choice of* Δ *affects the phase of the solution, as indicated in Figure* 3.4. *This phase shift does not affect the analysis since the solution tends to a constant exponentially, so that only exponentially small terms in the slow recovery phase are affected.*

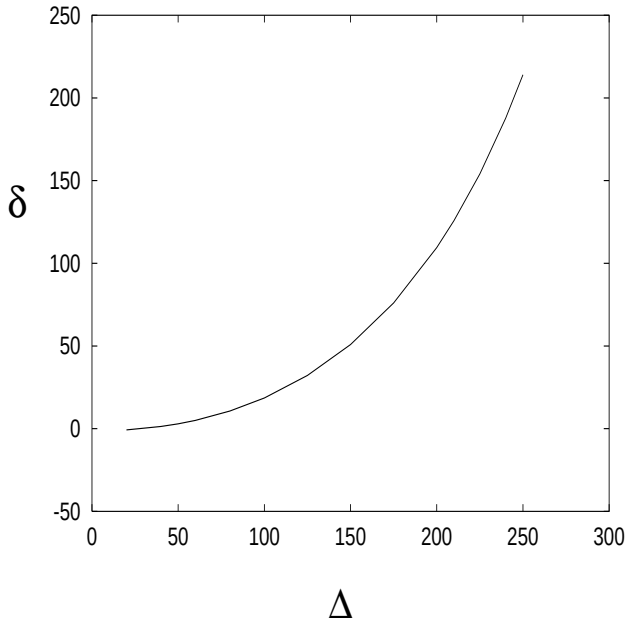

FIG. 3.4. *The variation of the computed value* δ *where* $u = 1$ *(i.e., a measure of the phase of the solution of* $(3.63)_1$*) as a function of the location* Δ *of the initial interval* $[-\Delta - 1, -\Delta)$.

where $g_L = g(N_L)$.

Next, we study the behavior of u near N_L by writing

$$u = N_L + U, \tag{3.66}$$

so that

$$U' \approx g'_L(U_1 - U), \tag{3.67}$$

where $g'_L = g'(N_L)$, and solutions are $e^{-\lambda t^*}$ for a denumerable set $\lambda_1, \lambda_2, \ldots$ of exponents. It is straightforward to show that, if these are assigned in order of increasing real part, then $\operatorname{Re}\lambda_1 > 0$, and $\operatorname{Im}\lambda_k \in ((2k-1)\pi, 2k\pi)$ if $g'_L > 0$, $\operatorname{Im}\lambda_k \in (2(k-1)\pi, (2k-1)\pi)$ if $-1 < g'_L < 0$ (we can assume $g'_L > -1$) except that $\operatorname{Im}\lambda_1 = 0$. In any event $u = N_L$ is stable, and

$$u = N_L + O(e^{-\lambda_1 t^*}) \quad \text{as} \quad t^* \to \infty. \tag{3.68}$$

Integration of $(3.63)_3$ with the matching condition $(3.63)_4$ now shows that

$$N(t) + \int_{t-1}^{t} g'[u(s)]v(s)ds = -E_3\left[\tfrac{3}{2} + g''_+ E_2\right], \tag{3.69}$$

and therefore

$$v = -v_L + O(e^{-\lambda_1 t^*}) \quad \text{as} \quad t^* \to \infty, \tag{3.70}$$

where

$$v_L = \frac{E_3[\frac{3}{2} + g''_+ E_2]}{1 + g'_L}. \tag{3.71}$$

Thus as $t^* \to \infty$,

$$N \sim N_L - \varepsilon^{2/3} v_L + O(\varepsilon, \mathrm{TST}), \tag{3.72}$$

where TST denotes the transcendentally small exponential terms.

3.5. Recovery phase. The second part of the oscillation resembles the first. There follows a slow recovery phase, terminating with transition and shock regions, and then the first slow phase is repeated. As Kevorkian and Cole (1981) point out, it is not worth the effort to compute the $O(\varepsilon \ln \varepsilon)$ terms without also computing the $O(\varepsilon)$ terms, which requires solving for further terms in the expansions. Having shown that the matching procedure does indeed work, we now abandon the $O(\varepsilon \ln \varepsilon)$ terms, and thus we do not require all the detail presented previously. Since the details of the recovery phase are similar to those of the preceding (initiation) phase, we summarize the relevant results much more briefly.

In the recovery phase, we revert to the slow time defined by (3.47):

$$t = \alpha + \varepsilon t^*, \tag{3.73}$$

where

$$\alpha = \frac{\varepsilon^{2/3}\tilde{t}_0}{\Omega} + O(\varepsilon \ln \varepsilon), \tag{3.74}$$

bearing in mind the definitions of ρ and σ. As before, N satisfies (3.5), although the $O(\varepsilon^{2/3})$ term in the shock layer requires a corresponding term in the expansion. However, it is convenient (since there is no forcing term at $O(\varepsilon^{2/3})$) to lump this correction into the $O(1)$ term, accommodating the $O(\varepsilon^{2/3})$ correction by a further phase shift in the time origin. Specifically,

$$N \sim N_0 + \varepsilon N_1 + \cdots, \tag{3.75}$$

and the solution for N_0 can be written as

$$\int_{N_0}^{N_-} \left\{ \frac{1+g'}{\mu g - N} \right\} dN = t_- - t. \tag{3.76}$$

Note that $N_0 \to N_L$ as $t \to \alpha$, and (cf. Figure 3.2) $N_L < N_-$; thus in the recovery phase $1 + g' > 0$ and $\mu g > N$. In (3.70), t_- is the time when the second transition region occurs.

We match (3.76) to the preceding shock layer by writing $N \sim N_0 \sim N_L - \varepsilon^{2/3} v_L$, $t = \alpha + \varepsilon t^*$ in (3.76), and we find that matching requires that

$$t_- = \int_{N_L}^{N_-} \left\{ \frac{1+g'(N)}{\mu g(N) - N} \right\} dN + \varepsilon^{2/3} \left[\frac{\tilde{t}_0}{\Omega} + v_L \left\{ \frac{1+g'_L}{\mu g_L - N_L} \right\} \right] + O(\varepsilon \ln \varepsilon). \tag{3.77}$$

As $t \to t_-$, (3.76) gives, analogously to (3.14),

$$N_0 \sim N_- - Q_1 (t_- - t)^{1/2} + Q_2 (t_- - t) + \cdots, \tag{3.78}$$

and in the transition region at $t = t_-$, we get

$$\begin{aligned} N &= N_- + \frac{\varepsilon^{1/3} \omega}{g''_-} f, \\ t &= t_- + r(\varepsilon) + \frac{\varepsilon^{2/3}}{\omega} \tilde{t}, \end{aligned} \tag{3.79}$$

where

$$\omega = [-g''_- Q_1]^{2/3} \tag{3.80}$$

(note $g''_- < 0$ and $Q_1 > 0$).

This leads directly to (3.22), but with k, l, ω replacing κ, λ, Ω; k and l are defined in the appendix as κ and λ, but with ω, g''_-, g'''_- replacing Ω, g''_+, g'''_+. Hence

$$f \sim \frac{-\mathrm{Ai}'(-\tilde{t})}{\mathrm{Ai}(-\tilde{t})} + O(\varepsilon^{1/3}), \tag{3.81}$$

and matching occurs automatically at leading order (and $r = O(\varepsilon \ln \varepsilon)$).

The transition layer leads to a shock layer where we write, by analogy to (3.47),

$$t = t_- + \frac{\varepsilon^{2/3} \tilde{t}_0}{\omega} + [r(\varepsilon) + \varepsilon^{2/3} s(\varepsilon)] + \varepsilon t^*, \tag{3.82}$$

and $r + \varepsilon^{2/3} s = O(\varepsilon \ln \varepsilon)$. Now, notice that to obtain the $O(\varepsilon^{2/3})$ shift in (3.77), we need to know v_L, and thus E_2 and E_3 in (3.71). Similarly, we find that, putting

$$N \sim u + \varepsilon^{2/3} v + O(\varepsilon) \tag{3.83}$$

in the recovery shock, then

$$u \sim N_- + \frac{1}{g_-'' t^*} + \frac{e_1 - e_2 \ln(-t^*)}{t^{*2}} + \cdots,$$
$$v \sim -e_3[t^* + e_2 g_-'' \ln(-t^*) - e_4 \ldots] \tag{3.84}$$

as $t^* \to -\infty$, and we will need e_2 and e_3. Since the equation for f in the recovery transition region is of the same form as in the first transition region, e_2 and e_3 are found in the same way, and thus

$$e_2 = \frac{\omega + l}{3\omega g_-''}, \quad e_3 = \frac{\omega^2 \tilde{t}_0}{3 g_-''}. \tag{3.85}$$

Finally, as $t^* \to \infty$ in the recovery shock,

$$N \sim N_U - \varepsilon^{2/3} v_U + O(\varepsilon, \mathrm{TST}), \tag{3.86}$$

where

$$N_U + g_U = N_- + g_-,$$
$$v_U = \frac{e_3[\frac{3}{2} + g_-'' e_2]}{1 + g_U'}. \tag{3.87}$$

At this point, we reenter the first slow phase, and if the motion is periodic, with period $P(\varepsilon)$, then we should regain the slow phase solution (3.13) with t replaced by t_+, where

$$t_+ = t - P(\varepsilon); \tag{3.88}$$

thus

$$\int_{N_+}^{N} \left\{ \frac{1 + g'}{N - \mu g} \right\} dN \sim -t_+ = P(\varepsilon) - t, \tag{3.89}$$

and we match this directly to the recovery shock as $t_+ \to 0$. We have $N \sim N_U - \varepsilon^{2/3} v_U$, $t = t_- + \varepsilon^{2/3} \tilde{t}_0/\omega + \varepsilon t^* + O(\varepsilon \ln \varepsilon)$, and matching of the two expressions requires, using (3.77), that

$$P(\varepsilon) = \int_{N_+}^{N_U} \left(\frac{1 + g'}{N - \mu g} \right) dN + \int_{N_L}^{N_-} \left(\frac{1 + g'}{\mu g - N} \right) dN$$
$$+ \varepsilon^{2/3} \left[\tilde{t}_0 \left(\frac{1}{\omega} + \frac{1}{\Omega} \right) + v_L \left(\frac{1 + g_L'}{\mu g_L - N_L} \right) - v_U \left(\frac{1 + g_U'}{N_U - \mu g_U} \right) \right]$$
$$+ O(\varepsilon \ln \varepsilon), \tag{3.90}$$

and this completes our analysis of the periodic solutions.

4. Discussion. The model we have sought to understand is (2.6):

$$\dot{N} = g(N_1) - g(N) + \varepsilon[\mu g(N_1) - N]. \tag{4.1}$$

If written in terms of the slow time $t = \varepsilon t^*$, this is

$$\varepsilon N' = g(N_\varepsilon) - g(N) + \varepsilon[\mu g(N_\varepsilon) - N]. \tag{4.2}$$

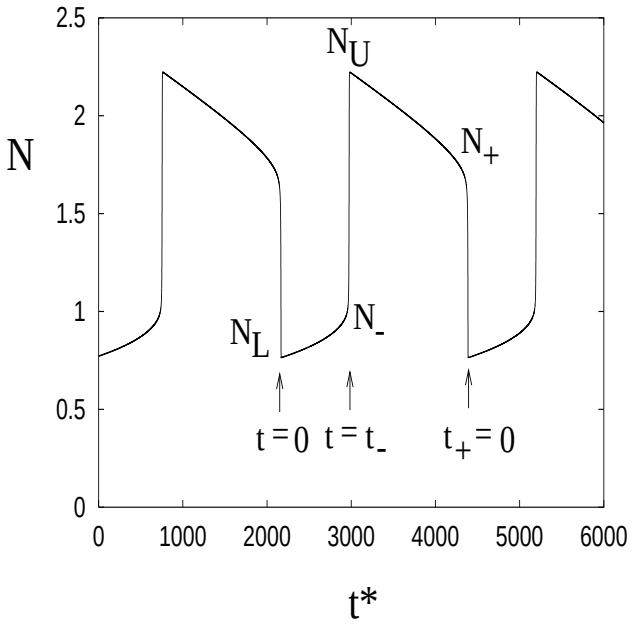

FIG. 4.1. *Numerical solution for $N(t^*)$ when $b = 3.9$, $\mu = 1.2$, $n = 3$, and $\varepsilon = 0.0001$. For a choice of origin for t at the minimum, the subsequent value t_- at the next transition is shown, and also shown is the phase resetting origin for $t_+ = t + P$.*

The analysis applies generally for unimodal functions satisfying $g'(N_\pm) = -1$, and oscillations occur for $\mu \in (\mu_-, \mu_+)$, where

$$\mu_\pm = \frac{N_\pm}{g(N_\pm)}. \tag{4.3}$$

As $\varepsilon \to 0$, we predict periodic solutions having periods (in t^*) of $P(\varepsilon)/\varepsilon$, where P is given by (3.90). The maximum and minimum values are approximately

$$N_{\max} = N_U - \varepsilon^{2/3} v_U \tag{4.4}$$

and

$$N_{\min} = N_L - \varepsilon^{2/3} v_L, \tag{4.5}$$

respectively. Figure 4.1 shows an example of the solution at very low ε, while Table 4.1 and Figures 4.2–4.5 show how these predictions compare with numerical solutions, for the particular choice of $g = bN/(1+N^n)$. It can be seen that the agreement improves, as expected, as ε becomes small.

In terms of the original dimensional quantities of the model, we see that the maximum and minimum values of N depend asymptotically entirely on the form of the function $g(N)$. The dimensional period is given to leading order by $P_0\tau/\varepsilon$, where

$$P_0 = \int_{N_+}^{N_U} \left(\frac{1+g'}{N - \mu g} \right) dN + \int_{N_L}^{N_-} \left(\frac{1+g'}{\mu g - N} \right) dN. \tag{4.6}$$

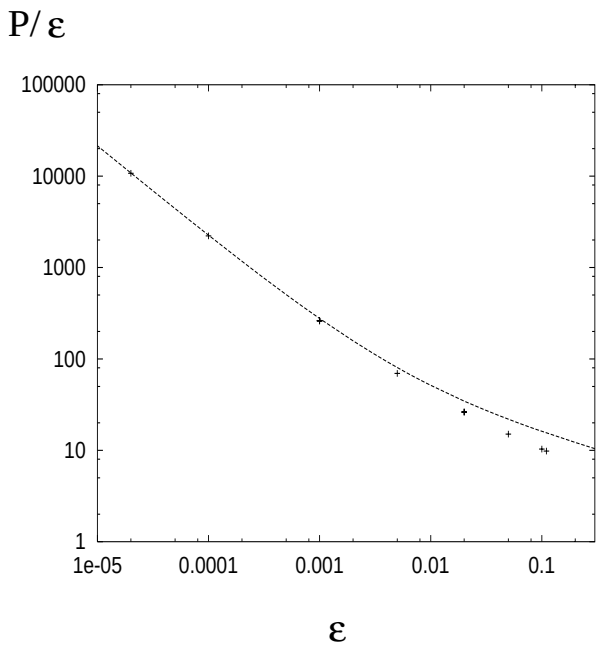

FIG. 4.2. *Variation of the actual period (in* t^**) of the numerical solution (crosses) as a function of* ε, *together with the theoretical prediction (solid curve) from* (3.90), *for* $b = 3.9$, $\mu = 1.2$, $n = 3$.

P_0 essentially depends only on the shape of $g(N)$, and thus the period is

$$P_{\text{dim}} = \frac{P_0}{\delta}, \tag{4.7}$$

that is, it is controlled by the rate of differentiation. However, oscillations do not

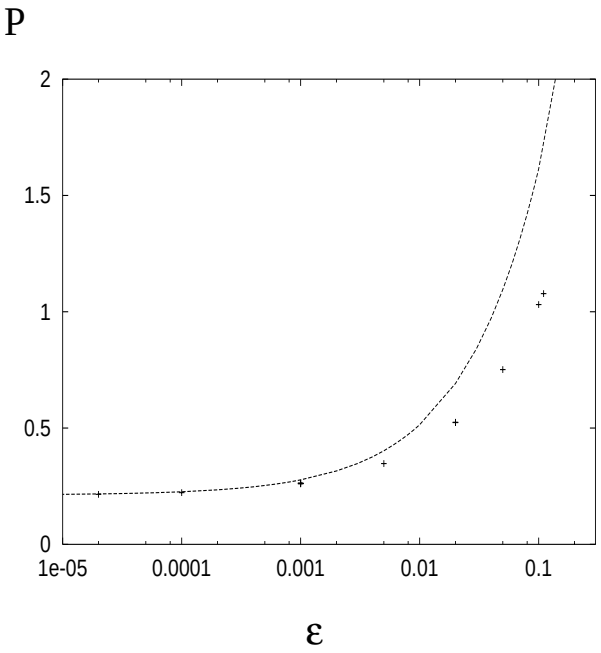

FIG. 4.3. *As for Figure* 4.2, *but plotting the period in* t, P, *versus* ε.

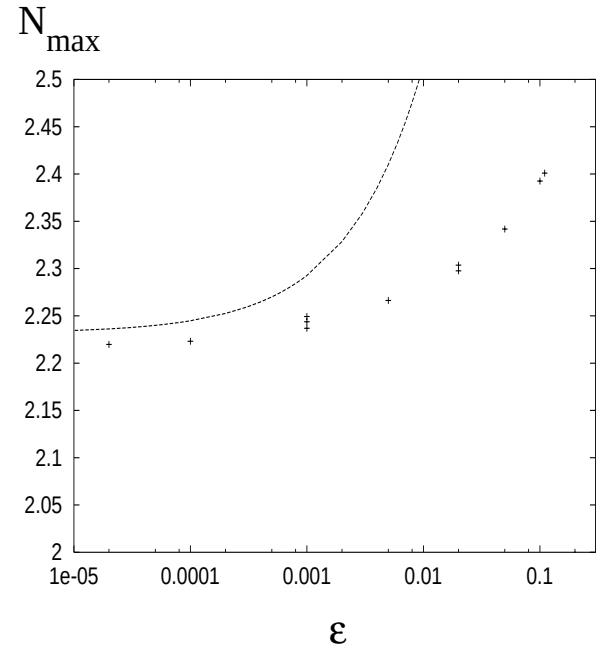

FIG. 4.4. *Numerical values of* $N_{\max}$ *(crosses) and predicted values (solid curve) from* (4.4) *as a function of* ε *for* $b = 3.9$, $\mu = 1.2$, $n = 3$. *When more than one cross is plotted, as at* $\varepsilon = 0.001$, *the different values come from the use of different step sizes in the integrator. Specifically, at* $\varepsilon = 0.001$, *decreasing step sizes* 0.01, 0.005, 0.001 *gave increasing values of* $N_{\max}$.

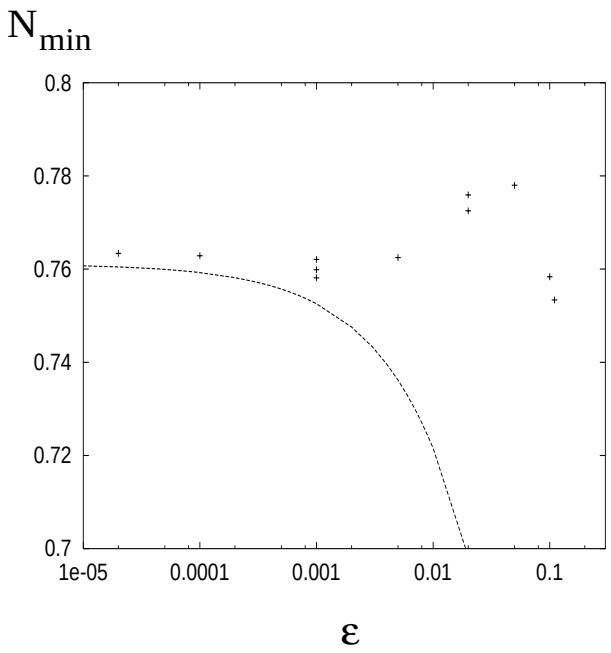

FIG. 4.5. *Computed and predicted values for* $N_{\min}$, *similar to Figure* 4.4. *Here decreasing step size at* $\varepsilon = 0.001$ *leads to decreasing* $N_{\min}$.

occur at all unless μ is a finite range of $O(1)$, and this requires that $\gamma\tau$ is increased over normal values, which can be due either to an increased proliferation delay τ or to an increased apoptotic rate γ.

It is difficult to give a useful characterization of the dimensional maximum and minimum values of N. These are simply $N_{\text{dim}}^{\max} \approx \theta N_U$ and $N_{\text{dim}}^{\min} \approx \theta N_L$. The easiest interpretation of N_U and N_L is that shown graphically in Figure 4.6. We can get a crude idea of the magnitude of the maximum and minimum values, however, if we consider the specific proliferation rate $\beta(N)$ to be adequately represented by the two quantities β_0, which is the maximum specific proliferation rate, and θ, which gives an estimate of the value of N where the proliferation rate "turns off." Our crude estimate idealizes β as being piecewise constant, with a switch off occurring at $N = \theta$, and will generally be reasonably accurate if the switch at $N \approx \theta$ is sharp. Then we have the estimates

$$\begin{aligned} N_{\text{dim}}^{\min} &\approx \frac{\theta}{1+\beta_0\tau}, \\ N_{\text{dim}}^{\max} &\approx (1+\beta_0\tau)\theta, \end{aligned} \tag{4.8}$$

and these could in principle be used to constrain the appropriate form of β in the model. The amplitude of the oscillation is, very roughly, $2\beta_0\tau\theta$.

From a mathematical perspective, the most interesting feature of the analysis is that it is completely analogous to that of a second order relaxational differential equation. In fact, Figure 4.6 indicates the similarity which can be drawn between the present model and that of the simple system

$$\begin{aligned} \varepsilon N' &= v - g(N), \\ N' + v' &= \mu g(N) - N - \varepsilon\mu v'. \end{aligned} \tag{4.9}$$

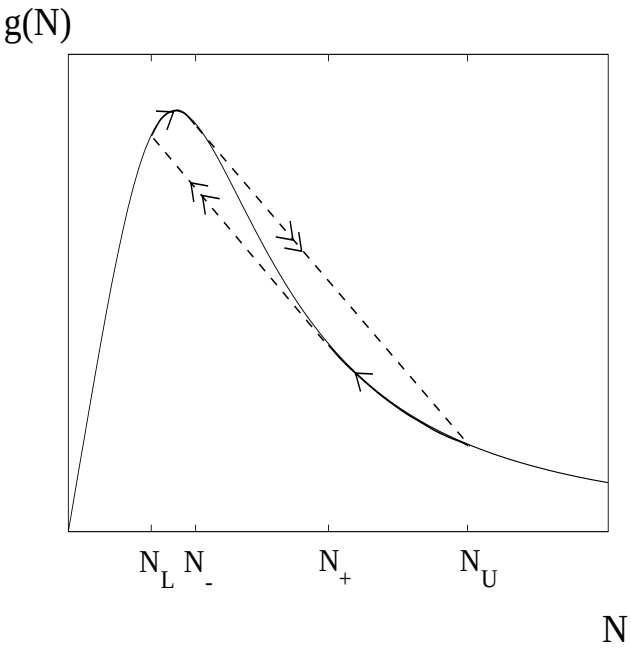

FIG. 4.6. *Phase diagram of the relaxation oscillations of both* (4.9) *and* (4.13). $g(N)$ *is plotted for* $b = 5$, $n = 3$.

In (4.9), the slow manifold is $v = g(N)$, and on this

$$N' \approx \frac{\mu g - N}{1 + g'} \tag{4.10}$$

just as for (4.2). For (4.9), there is a fast phase as $N \to N_+$ or $N \to N_-$, and in the fast phases, $N + v$ is approximately constant; since $v \to g(N)$ at either end we have the same results

$$\begin{aligned} N_+ + g(N_+) &= N_L + g(N_L), \\ N_- + g(N_-) &= N_U + g(N_U), \end{aligned} \tag{4.11}$$

as for (4.2).

The analogy can be slightly tightened by defining the functions

$$\begin{aligned} v &= g(N_\varepsilon) + \varepsilon[\mu g(N_\varepsilon) - N], \\ \hat{v} &= \frac{g(N) - g(N_\varepsilon)}{\varepsilon}. \end{aligned} \tag{4.12}$$

Evidently $\hat{v}$ is functionally dependent on v, and for slowly varying N, we have $v \approx g(N)$, $\hat{v} \approx [g(N)]'$, i.e., $\hat{v} \approx v'$; clearly this is inappropriate when N is rapidly varying. The definitions (4.12) allow us to write (4.2) in the suggestive form

$$\begin{aligned} \varepsilon N' &= v - g(N), \\ N' + \hat{v} &= \mu g(N) - N - \varepsilon\mu\hat{v}, \end{aligned} \tag{4.13}$$

and we see that the functional equation reduces precisely to the second order system (4.9) under the identification $\hat{v} = v'$. What appears to be extraordinary is that the

infinite dimensional breakdown of this approximation in the fast shock layers does not affect the analytical description in any significant way.

Apart from the mathematical novelty of solving a delay differential equation, there are some physiological ramifications of our analysis. The model for stem cell proliferation in (2.2) is a reasonable synopsis of the process, but the rate function of progress through the cycle, $\beta(N)$, is not well constrained. Nor is it possible to access this function directly, since the stem cell population itself is hidden, and oscillations are manifested in the differentiated products, which are themselves dynamically controlled by peripheral controlling mechanisms. Therefore it is useful to be able to characterize the oscillations of the resting stem cell population for a variety of different progression functions $\beta(N)$, and our analysis allows us to do this. It will also allow us in future work to analyze how oscillations in the stem cell population propagate through the maturing cell types, so that in principle we can use resulting observed cell cycles as a constraint on the stem cell dynamics.

Appendix. In (3.14), we find q_1 and q_2:

$$q_1 = \left[\frac{2(N_+ - \mu g_+)}{g''_+}\right]^{1/2}, \tag{A.1}$$

$$q_2 = \tfrac{1}{3} q_1^2 \left[\left(\frac{1+\mu}{N_+ - \mu g_+}\right) - \frac{g'''_+}{2g''_+}\right]; \tag{A.2}$$

h_+ is defined in (3.18):

$$h_+ = \frac{1+\mu}{2g''_+(N_+ - \mu g_+)}; \tag{A.3}$$

Ω is defined in (3.20):

$$\Omega = q_1^{2/3} g_+''^{2/3}; \tag{A.4}$$

κ and λ are defined in (3.23):

$$\kappa = \frac{2}{\Omega^2}(1+\mu), \tag{A.5}$$

$$\lambda = \frac{\Omega g'''_+}{g''^2_+}; \tag{A.6}$$

r_1, r_{21}, and r_{22} are defined in (3.41):

$$r_1 = \frac{1}{4g''_+}, \tag{A.7}$$

$$r_{21} = \frac{q_1}{2}\left[A_1 + \frac{q_2}{2g''_+ q_1^2} - \tfrac{1}{2} - \frac{g'''_+}{4g''^2_+} + h_+ \ln q_1\right], \tag{A.8}$$

$$r_{22} = \tfrac{1}{4} q_1 h_+; \tag{A.9}$$

s_1, s_{21}, and s_{22} are defined in (3.42):

$$s_1 = \tfrac{1}{3}\kappa - \tfrac{1}{6}\lambda, \tag{A.10}$$

$$s_{21} = \tfrac{1}{2} C_2 - \tfrac{1}{4}\Omega - \tfrac{1}{6}\lambda + \tfrac{1}{12}\kappa, \tag{A.11}$$

$$s_{22} = \tfrac{1}{8}\kappa. \tag{A.12}$$

E_2 and E_4 appear in (3.57) and (3.59):

$$E_2 = \frac{1}{3g''_+}\left(1 + \frac{g'''_+}{g''^2_+}\right), \tag{A.13}$$

$$E_4 = \tfrac{1}{2}g''_+E_2 + \frac{g'''_+}{g''^2_+} + g''_+E_1. \tag{A.14}$$

In (3.78) we find Q_1 and Q_2:

$$Q_1 = \left[\frac{2(N_- - \mu g_-)}{g''_-}\right]^{1/2}, \tag{A.15}$$

$$Q_2 = \tfrac{1}{3}Q_1^2\left[\left(\frac{1+\mu}{N_- - \mu g_-}\right) - \frac{g'''_-}{2g''_-}\right], \tag{A.16}$$

and then ω, k, and l are introduced in (3.80) and are restated below:

$$\omega = (-Q_1 g''_-)^{2/3}, \tag{A.17}$$

$$k = \frac{2}{\omega^2}(1+\mu), \tag{A.18}$$

$$l = \frac{\omega g'''_-}{g''^2_-}. \tag{A.19}$$

A FINITE ELEMENT METHOD FOR AN EIKONAL EQUATION MODEL OF MYOCARDIAL EXCITATION WAVEFRONT PROPAGATION*

KARL A. TOMLINSON†, PETER J. HUNTER†, AND ANDREW J. PULLAN†

Abstract. An efficient finite element method is developed to model the spreading of excitation in ventricular myocardium by treating the thin region of rapidly depolarizing tissue as a propagating wavefront. The model is used to investigate excitation propagation in the full canine ventricular myocardium. An eikonal-curvature equation and an eikonal-diffusion equation for excitation time are compared. A Petrov–Galerkin finite element method with cubic Hermite elements is developed to solve the eikonal-diffusion equation on a reasonably coarse mesh. The oscillatory errors seen when using the Galerkin weighted residual method with high mesh Péclet numbers are avoided by supplementing the Galerkin weights with C^0 functions based on derivatives of the interpolation functions. The ratio of the Galerkin and supplementary weights is a function of the Péclet number such that, for one-dimensional propagation, the error in the solution is within a small constant factor of the optimal error achievable in the trial space. An additional no-inflow boundary term is developed to prevent spurious excitation from initiating on the boundary. The need for discretization in time is avoided by using a continuation method to gradually introduce the nonlinear term of the governing equation. A simulation is performed in an anisotropic model of the complete canine ventricular myocardium, with 2355 degrees of freedom for the dependent variable.

Key words. eikonal equation, myocardial excitation, wavefront propagation, Petrov–Galerkin method, Hermite interpolation, numerical continuation

1. Introduction.

In developing a computational model of the electrical behavior of the ventricular myocardium, it would be unreasonable to expect to be able to model every microscopic biological process that occurs within and between each and every cell. Such detail in the model is also unnecessary: the ventricular function and the electrical fields induced in the torso are not so much affected by the activity of one ion or one ion channel or even one cell as by the collective activity of many cells. Instead of resolving the small spatial detail of the microscopic processes, the collective macroscopic effect of these processes can be modelled.

The most intense electrical activity is the depolarization of cells, which leads to the activation of the mechanisms that cause the myocardium to contract and the heart to pump. Depolarization occurs quickly and in only a narrow region of cells at a time, so this narrow region can be considered as a propagating *excitation wavefront*. An eikonal model may be used to approximate the propagation process, describing the motion of the wavefront by the time at which it excites every point in the myocardium.

A finite element method with cubic Hermite elements is developed to determine excitation times on a fairly coarse mesh for large scale simulations. Petrov–Galerkin weighted residual equations, developed in section 2, are supplemented with a no-inflow term, developed in section 3, to prevent spurious excitation on boundaries, and are solved by a continuation method with Newton's method (section 4). employs the computational method to simulate excitation in the complete ventricular myocardium.

1.1. The bidomain model. As a means for collecting together the microscopic functional elements of the myocardium to model their macroscopic effects, Schmitt [21] suggested the concept of two interpenetrating domains. One domain was to represent the volume-averaged properties of the intracellular contents and their interconnections, and the other domain was to represent the volume-averaged properties of the surrounding extracellular tissue and fluid. These domains were to coexist spatially, and the behavior of current flow between them was to be based on the volume-averaged properties of the cell membrane. This approach is now generally referred to as the *bidomain model* [12]. The two domains are referred to as the *intracellular* and *extracellular* domains. Each is treated as a continuum.

A reaction-diffusion system of equations for the potential ϕ_e in the extracellular domain and the difference in potential V_m across the membrane between the domains can be derived from conservation of current under the assumptions that capacitive, inductive, and electromagnetic propagative effects within the domains are negligible and that the current in each domain obeys Ohm's law:

$$\nabla \cdot \left(G^i \nabla V_m\right) = -\nabla \cdot \left((G^i + G^e)\nabla \phi_e\right),$$

$$i_{ion} + c_m \frac{\partial V_m}{\partial t} = -\nabla \cdot (G^e \nabla \phi_e). \tag{1.1}$$

The intracellular potential ϕ_i is the sum of the extracellular potential ϕ_e and the transmembrane potential V_m. G^i and G^e are intra- and extracellular *effective conductivity tensors*. The fibrous and laminar structure of the myocardium is modelled under the assumptions that the conductivities are orthotropic and that they share the same principal axes, $\boldsymbol{a}_l$, $\boldsymbol{a}_t$, and $\boldsymbol{a}_n$, where $\boldsymbol{a}_l$ is parallel to the fibers (longitudinal), $\boldsymbol{a}_t$ is transverse to the fibers but in the plane of the sheets, and $\boldsymbol{a}_n$ is normal to the sheets. i_{ion} represents the sum of the (outward) membrane ionic currents per unit tissue volume, and c_m is the membrane capacitance per unit volume.

It is assumed that the extracellular space is in direct contact with the outside volume. Continuity of the extracellular potential ϕ_e with the potential ϕ_o in the outside volume and conservation of current between the volumes leads to the boundary conditions

$$\phi_e = \phi_o, \tag{1.2}$$

$$\boldsymbol{n} \cdot G^i \nabla(\phi_e + V_m) = 0,$$

$$\boldsymbol{n} \cdot G^e \nabla \phi_e = \boldsymbol{n} \cdot \boldsymbol{j}_o \qquad \text{on } \partial\Omega, \tag{1.3}$$

where $\boldsymbol{n}$ is the unit normal to the boundary and $\boldsymbol{j}_o$ is the current density in the outside volume [15].

If the intra- and extracellular conductivity tensors were related by a constant scalar factor (equal anisotropy), then system (1.1) could be reduced to a simple *monodomain* reaction-diffusion equation in one variable:

$$i_{ion} + c_m \frac{\partial V_m}{\partial t} = \nabla \cdot (G^m \nabla V_m). \tag{1.4}$$

G^m has the same principal axes as G^i and G^e, and the reciprocals of its eigenvalues equal the sums of the reciprocals of the intra- and extracellular principal conductivi-

ties. The boundary condition on V_{m} would be

$$\boldsymbol{n} \cdot \mathrm{G}^{\mathrm{e}} \nabla V_{\mathrm{m}} = -\boldsymbol{n} \cdot \mathrm{G}^{\mathrm{o}} \nabla \phi_{\mathrm{o}} \qquad \text{on } \partial\Omega. \tag{1.5}$$

If the anisotropic ratios are not equal, the monodomain equation (1.4) may still be used as an approximation of the bidomain system (1.1). For plane wave propagation in any of the three principal directions, both (1.1) and (1.4) predict the same propagation speeds, but the predicted speeds may differ for intermediate directions.

It is convenient to scale (1.4) so that the parameters give indications of the important spatial and temporal scales. This can be done by dividing the equation by a characteristic conductance per unit volume. During the depolarization phase of the action potential, consideration of the large difference between the activation and inactivation time constants of the dominating fast sodium current leads to the approximation of i_{ion} as a time-independent function of the transmembrane voltage [5]. That is, $i_{\mathrm{ion}} = i_{\mathrm{ion}}(V_{\mathrm{m}})$. If the transmembrane potential V_{m} is near its resting potential V_{r}, the behavior of the ionic membrane currents can be approximated by assuming the membrane has a passive conductance per unit volume defined by

$$\frac{1}{\mathrm{r_m}} := \frac{\mathrm{d}i_{\mathrm{ion}}}{\mathrm{d}V_{\mathrm{m}}}(V_{\mathrm{r}}). \tag{1.6}$$

(The symbol ":=" denotes definition.) Multiplying the terms in (1.4) by an average (space-independent) value $\bar{\mathrm{r}}_{\mathrm{m}}$ of $\mathrm{r_m}$ gives

$$\bar{\mathrm{r}}_{\mathrm{m}} i_{\mathrm{ion}} + \tau_{\mathrm{m}} \frac{\partial V_{\mathrm{m}}}{\partial t} = \nabla \cdot (\mathrm{M} \nabla V_{\mathrm{m}}), \tag{1.7}$$

where

$$\mathrm{M} := \bar{\mathrm{r}}_{\mathrm{m}} \mathrm{G}^{\mathrm{m}} \qquad \text{and} \qquad \tau_{\mathrm{m}} := \bar{\mathrm{r}}_{\mathrm{m}} \mathrm{c_m} \tag{1.8}$$

are the *coupling tensor*, which has dimensions of space squared, and the *membrane time constant*, which has dimension of time. The eigenvalues of M are squares of the space constants λ_{l}, λ_{t}, and λ_{n} in each of the principal directions. They may be expressed in terms of conductivities using

$$\frac{1}{\lambda_{\mathrm{l}}^2} = \frac{1}{\bar{\mathrm{r}}_{\mathrm{m}}} \left(\frac{1}{\mathrm{g_{il}}} + \frac{1}{\mathrm{g_{el}}} \right), \qquad \text{etc.} \tag{1.9}$$

These space and time constants are appropriate when the behavior of the tissue is largely passive such as in the early stages of the action potential. The behavior in these stages is important for propagation as it initiates the change in transmembrane potential that leads to activation of the active currents. The time and space constants relevant in the fastest stage of depolarization, however, may be different. The magnitude of the maximum slope of $i_{\mathrm{ion}}(V_{\mathrm{m}})$ is much larger than the slope at $V_{\mathrm{m}} = V_{\mathrm{r}}$ used to define $\mathrm{r_m}$ in (1.6). The appropriate multiplier for scaling the system of equations is then smaller than $\bar{\mathrm{r}}_{\mathrm{m}}$, and so the appropriate space and time constants are also smaller. The space constants λ_{l}, λ_{t}, and λ_{n} probably provide an indication of the region of influence that the excitation wavefront has, and, together with τ_{m}, they provide an upper bound on the relevant spatial and temporal scales.

Solution of the reaction-diffusion equation (1.7) is very computationally demanding due to the important spatial scales being much smaller than the dimensions of

the ventricles. As discussed in [23], the space constants for the passive behavior of canine myocardium are probably $\lambda_l \approx 0.8\,\text{mm}$ and $\lambda_n < \lambda_t \approx 0.5\,\text{mm}$. Reasonable approximation of the potential would probably require at least 5 degrees of freedom to represent changes over the distance of a space constant. This implies that at least 5^3 degrees of freedom would be required to represent a volume of about $0.8 \times 0.5 \times 0.5 = 0.2\ \text{mm}^3$. For the full canine ventricular myocardium with a volume of about $0.2 \times 10^6\ \text{mm}^3$, at least 10^8 degrees of freedom would be needed.

1.2. An eikonal approach. Given the difficulty in the numerical solution of a reaction-diffusion equation for transmembrane potential, a governing equation is sought for the motion of the excitation wavefront. It is expected that the speed of propagation can be assumed to vary more slowly and over much larger spatial scales than the transmembrane potential. This assumption is probably reasonable most of the time, but there are abrupt spatial changes in propagation speed where a wavefront collides with the boundary or another wavefront. The fine details of the wavefront shape in these small collision regions are not, however, expected to have much influence on the overall ventricular function.

The wavefront motion can be described by the *excitation time* $u(\boldsymbol{x})$, defined as the time at which the wavefront passes through the point $\boldsymbol{x}$ (or, more specifically, the time at which the transmembrane potential at that point crosses the value midway between its resting and plateau potentials). The position of the wavefront at any time t is then given by the surface along which $u(\boldsymbol{x}) = t$, and the excitation time can be described numerically on a stationary mesh. A governing equation for u is referred to as an *eikonal equation*.

Many myocardial excitation models have been based on Huygens' principle (reviewed in [19]) and are effectively approximating an eikonal equation. In such models, the heart is represented by a matrix of cells or grid points. At fixed time intervals after any cell is excited, its quiescent neighboring cells are excited. The time interval before excitation of each neighboring cell depends on the distance to the cell and the propagation speed for that direction. This method requires little computational effort but has the disadvantage that the numerical treatment of the eikonal equation is very low order and propagation can occur in only a finite number of directions. The result is that the wavefronts generated are polyhedral instead of ellipsoidal.

More accurate numerical solutions for excitation wavefront propagation have been obtained using wavefront propagation equations derived from the reaction-diffusion equation (1.7) under the assumption that the profile of the depolarization upstroke varies slowly in space.

An alternative approach for describing wavefront propagation is to use a function $\varphi(\boldsymbol{x}, t)$, defined so that, at any time t, the level set of points $\boldsymbol{x}$ such that $\varphi(\boldsymbol{x}, t) = 0$ gives the position of the wavefront at that time (see [22]). Keener [13] derived an equation for φ from (1.7) by selecting a moving coordinate system such that V_m is a function of only a spatial variable normal to the wavefront and then requiring the current conservation equation to be satisfied at the wavefront. The resulting equation,

$$\left[c_0 + \nabla \cdot \left(\frac{M\nabla u}{\sqrt{\nabla u \cdot M\nabla u}}\right)\right] \sqrt{\nabla\varphi \cdot M\nabla\varphi} = \tau_m \frac{\partial\varphi}{\partial t}, \tag{1.10}$$

is parabolic and time-dependent. φ has a physical interpretation only at its zero contour, so the selection of initial conditions is unclear. If, however, $\varphi(\boldsymbol{x}, t)$ is chosen

to be $t - u(\boldsymbol{x})$, then (1.10) reduces to a parabolic eikonal equation for excitation time:

$$c_0\sqrt{\nabla u \cdot \mathrm{M}\nabla u} - \sqrt{\nabla u \cdot \mathrm{M}\nabla u}\,\nabla \cdot \left(\frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}\right) = \tau_{\mathrm{m}}. \tag{1.11}$$

The numerical solution to (1.10) was found using finite difference discretizations in space and time. Second-order central differences were initially used for the spatial discretization [13], but [14] later replaced these with first-order upwind differences to stabilize the numerical solution.

An elliptic eikonal equation was derived by Colli Franzone, Guerri, and Rovida [8] and Colli Franzone, Guerri, and Tentoni [9] using singular perturbation techniques. The equivalent eikonal equation for reaction-diffusion equation (1.7) is

$$c_0\sqrt{\nabla u \cdot \mathrm{M}\nabla u} - \nabla \cdot (\mathrm{M}\nabla u) = \tau_{\mathrm{m}}. \tag{1.12}$$

As the equation is elliptic, a boundary condition is required around the entire boundary. Without a model of the surrounding tissue, it is not possible to predict the current flux from the outside domain, and thus the boundary condition (1.5) for the reaction-diffusion system is not helpful. However, experimental evidence suggests that epicardial isochrones are unaffected by surrounding conducting volumes [11]. Without a surrounding volume, boundary condition (1.5) leads to the simple no-flux boundary condition

$$\boldsymbol{n} \cdot \mathrm{M}\nabla u = 0, \tag{1.13}$$

where $\boldsymbol{n}$ is the unit normal to the boundary.

In their numerical solution of the eikonal equation, Colli Franzone and Guerri [6] added a time derivative term to give a related parabolic equation in space and time. The time-dependent equation for (1.12) is

$$\frac{\partial \breve{u}}{\partial t} + c_0\sqrt{\nabla \breve{u} \cdot \mathrm{M}\nabla \breve{u}} - \nabla \cdot (\mathrm{M}\nabla \breve{u}) = \tau_{\mathrm{m}}. \tag{1.14}$$

The steady-state solution for $\breve{u}(\boldsymbol{x}, t)$ is the excitation time $u(\boldsymbol{x})$. To find this solution, spatial discretization was performed using finite element–like integrals of quantities calculated by finite differences, and a finite difference scheme was used to step through time until $\breve{u}$ approached its limiting value. The spatial discretization was later modified [7] so that traditional finite element integrals were used for most terms, but a first-order upwind finite difference was used for the first-order spatial derivatives. A purely explicit finite difference scheme in time gave a method that was similar to Jacobi successive overrelaxation. In order to avoid instability, the time step (or relaxation parameter) had to be small, and thus convergence was very slow.

When compared to the reaction-diffusion equation (1.7), the eikonal equations (1.11) and (1.12) have the advantages that the domain is reduced by one dimension (because the dependent variable is no longer a function of time) and that the important spatial scales are much larger. In order to make use of these advantages, a numerical method needs to be found that requires only a spatial discretization and will work effectively when this discretization is reasonably coarse.

Both the level set and relaxation methods discussed above fail to take advantage of the fact that excitation time depends only on spatial position. The use of either of the time-dependent equations (1.10) or (1.14) increases the size of the domain by one dimension. For this reason, the method investigated here uses numerical

continuation, with Newton's method applied directly to a spatial discretization of an eikonal equation, to converge from an initial guess to the solution. Each Newton iteration requires not much more work than that required in an iteration of an implicit time stepping scheme for either (1.10) or (1.14), yet makes a considerably better attempt to go directly to the required solution.

1.3. Interpretation and comparison of eikonal equations. Interpretations of the two suggested eikonal equations (1.11) and (1.12) for wavefront propagation can be made from each of the terms involved.

The contours of u give the positions of the wavefront at time $t = u$. The gradient of u at any point along one of these contours is therefore normal to that wavefront surface and has magnitude equal to the reciprocal of the speed of that point on the wavefront. That is,

$$\nabla u = \frac{1}{\theta}\,\boldsymbol{p}, \tag{1.15}$$

where θ is the local wavefront speed and $\boldsymbol{p}$ is the unit normal to the wavefront pointing away from depolarized tissue. A space constant ρ in the direction of propagation $\boldsymbol{p}$ may be calculated from the square root of the component of the coupling tensor in that direction:

$$\rho := \sqrt{\boldsymbol{p} \cdot \mathrm{M}\boldsymbol{p}}. \tag{1.16}$$

The first term in both governing equations (1.11) and (1.12) is a nonlinear advection term, which may be written as

$$\mathrm{c}_0 \sqrt{\nabla u \cdot \mathrm{M}\nabla u} = \mathrm{c}_0 \frac{\rho}{\theta}. \tag{1.17}$$

This term is an anisotropic generalization of the left-hand side of the standard eikonal equation $|\nabla u| = 1$ and is a function of the local speed of the wavefront surface.

The second term in the parabolic equation (1.11) may be written as

$$\sqrt{\nabla u \cdot \mathrm{M}\nabla u}\,\nabla \cdot \left(\frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}\right) = \frac{\rho}{\theta}\,\nabla \cdot \left(\frac{1}{\rho}\mathrm{M}\boldsymbol{p}\right) = \frac{\rho}{\theta}\,\kappa, \tag{1.18}$$

where κ is an anisotropic generalization of the mean curvature. It is positive when the wavefront is convex if viewed from ahead of the wavefront. The parabolic equation is therefore called an *eikonal-curvature equation*.

Using expressions (1.17) and (1.18) in the eikonal-curvature equation (1.11) gives

$$\frac{\tau_{\mathrm{m}}}{\rho}\theta = \mathrm{c}_0 - \kappa. \tag{1.19}$$

For a given propagation direction, this equation states that the speed of the wavefront is a linear function of its anisotropic mean curvature. Propagation is faster when the wavefront is concave, and slower when it is convex. This reflects the dependency of tissue depolarization on the diffusion of charge from already depolarized tissue. If there is more depolarized tissue in close proximity to a region of quiescent tissue, then that region will be depolarized faster.

If there is no curvature, the speed of propagation is c_0 space constants per time constant. The constant c_0 is therefore the dimensionless propagation speed for a planar wavefront in homogeneous tissue.

The second term in the eikonal-curvature equation may also be expressed as

(1.20)
$$\sqrt{\nabla u \cdot \mathrm{M}\nabla u}\,\nabla \cdot \left(\frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}\right) = \nabla \cdot (\mathrm{M}\nabla u) - \nabla\sqrt{\nabla u \cdot \mathrm{M}\nabla u} \cdot \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}},$$

where the right-hand side is an anisotropic generalization of the Laplacian of u minus the component of this term in the direction of propagation. The eikonal-curvature equation is parabolic, as it lacks this second derivative in the direction of propagation. Propagation is effectively determined only by information at the wavefront. It is unaffected by boundaries or approaching wavefronts until a collision occurs.

The eikonal equation (1.12) is elliptic, as it contains the full generalized Laplacian. Although it is difficult to comprehend diffusion of excitation time, it is not too surprising that there is a Laplacian in the governing equation, as the propagation process depends heavily on the diffusion of charge. The elliptic eikonal equation is therefore called an *eikonal-diffusion equation*. Under this equation, propagation speed depends not only on information at the wavefront but also on the activity of the surrounding tissue. The constant c_0 is still the dimensionless speed of steady planar wavefront propagation in infinite homogeneous tissue.

It is interesting to investigate three-dimensional analytic solutions to these two governing equations for a wavefront spreading out from the origin in an infinite homogeneous domain. There exist solutions that may be written as functions of only the dimensionless distance from the origin,

(1.21)
$$r := \sqrt{\boldsymbol{x} \cdot \mathrm{M}^{-1}\boldsymbol{x}}.$$

The solutions describe ellipsoidal wavefronts having the same principal axes as the coupling tensor. Both eikonal equations predict that an initial wavefront of this shape will retain the same shape as it propagates. Under the eikonal-curvature equation, the propagation speed $\theta = \rho/\frac{\mathrm{d}u}{\mathrm{d}r}$ satisfies

(1.22)
$$\frac{\tau_{\mathrm{m}}}{\rho}\theta = \mathrm{c}_0\frac{r - \frac{2}{\mathrm{c}_0}}{r},$$

and under the eikonal-diffusion equation,

(1.23)
$$\frac{\tau_{\mathrm{m}}}{\rho}\theta = \mathrm{c}_0\frac{r^2}{r^2 + \frac{2}{\mathrm{c}_0}r + \frac{2}{{\mathrm{c}_0}^2}}.$$

For very large r, both equations predict that the ellipsoid grows at the same constant speed, but for small r the equations differ in the way they predict propagation under large curvature. The eikonal-curvature equation has a change in propagation direction at $r = \frac{2}{\mathrm{c}_0}$, suggesting that the initially depolarized region must have a radius of at least $\frac{2}{\mathrm{c}_0}$ space constants in order for the region to be able to supply enough current to surrounding tissue for propagation to proceed. If the initially depolarized region is smaller than this threshold size, then the equation predicts that the wavefront will retreat and the region will repolarize. The eikonal-diffusion equation, on the other hand, predicts a zero propagation speed only at the origin, suggesting that if enough current has been injected into the tissue to depolarize a region of tissue, then propagation will proceed however small this region may be.

As a wavefront approaches a no-flux boundary or another approaching wavefront, there is less quiescent tissue to drain current from the depolarizing tissue, and thus

the reaction-diffusion model predicts an increase in propagation speed. The eikonal-curvature equation, however, does not include any effects of the boundary or collision on wavefront propagation. Solutions to the eikonal-diffusion equation, on the other hand, much more closely approximate the variations in propagation speed due to another approaching wavefront [8]. The eikonal-diffusion equation is selected as the governing eikonal equation for the work presented here and shall be referred to simply as the eikonal equation.

1.4. Solution spaces and interpolation. In the finite element method the numerical solution $U(\boldsymbol{x})$ is represented by a linear combination of known *interpolation functions* $\psi_i(\boldsymbol{x})$:

$$U(\boldsymbol{x}) := U_i\, \psi_i(\boldsymbol{x}). \tag{1.24}$$

The finite element method selects the unknown parameters U_i in an attempt to approximate the exact solution $u(\boldsymbol{x})$. The domain is divided into a number of *elements* so that, within each element, U depends on only a subset of the parameters. For each element, a local coordinate system $\boldsymbol{\xi}$ is defined, and thus, within that element,

$$U(\boldsymbol{x}(\boldsymbol{\xi})) := U_{\nu(e,j)} \Psi_j(\boldsymbol{\xi}), \tag{1.25}$$

where $\Psi_j(\boldsymbol{\xi})$ are the element's local *basis functions*, and $\nu(e, j)$ is a known function mapping the local parameter j in element e to its corresponding global parameter. The interpolation functions $\psi_i(\boldsymbol{x}(\boldsymbol{\xi}))$ are therefore equal to corresponding basis functions $\Psi_j(\boldsymbol{\xi})$ in elements influenced by U_i and zero elsewhere.

Cubic Hermite elements are used here for discretization of the geometry and dependent variables. One-dimensional basis functions are cubic polynomials that interpolate the value and first derivative of U at the two adjacent nodes. Multidimensional basis functions are obtained from tensor products of the one-dimensional functions. Hermite elements have the advantage over cubic Lagrange elements that all nodes lie on element vertices, and thus parameters can be shared by surrounding elements, and a high-order interpolation is achieved with fewer parameters. This also provides first derivative continuity (C^1) in U.

Because the exact solution u satisfies an elliptic differential equation with predominantly smooth space-dependent coefficients and boundary conditions, it is expected to be sufficiently smooth for the first derivative continuity of the interpolation. Across any surface where the coefficients of the equation are not sufficiently smooth, similar interpolation can be used but with the elements on opposing sides of the surface using separate derivative parameters.

The time and location of excitation wavefront initiation is specified by Dirichlet boundary conditions for excitation time u on Γ_D, where Γ_D denotes the portion of the boundary in which u is known from the initiation process. These boundary conditions are enforced by specifying the values of the parameters U_j that describe U on Γ_D. The set D is defined as the list of indices j for these parameters U_j and their corresponding interpolation functions ψ_j. The set N is defined as the list of indices j for the remaining parameters, which do not influence the value of U on Γ_D and are free to be determined by the finite element method.

The *trial space* S_D^h is defined as the space of possible numerical solutions U sat-

isfying the Dirichlet boundary conditions,

(1.26a)
$$S_{\mathrm{D}}^h := \left\{ V : \exists\, v_j \in \mathbb{R} \text{ for } j \in N \text{ such that (s.t.) } V = \sum_{j \in D} U_j \psi_j + \sum_{j \in N} v_j \psi_j \right\},$$

and the space S_0^h is defined as the space of possible variations in the approximation,

(1.26b)
$$S_0^h := \left\{ V : \exists\, v_j \in \mathbb{R} \text{ for } j \in N \text{ s.t. } V = \sum_{j \in N} v_j \psi_j \right\}.$$

The exact solution u is expected to lie in the Sobolev space $H^1(\Omega)$. The spaces H^1_{D} and $H^1_{\mathrm{D}_0}$ are defined for the exact solution in a manner similar to that for S^h_{D} and S^h_0 for the approximate solution:

(1.27a)
$$H^1_{\mathrm{D}} := \left\{ v \in H^1(\Omega) : v = u \text{ on } \Gamma_{\mathrm{D}} \right\},$$

(1.27b)
$$H^1_{\mathrm{D}_0} := \left\{ v \in H^1(\Omega) : v = 0 \text{ on } \Gamma_{\mathrm{D}} \right\}.$$

Note that for either Lagrange or Hermite interpolation $S^h_0 \subset H^1_{\mathrm{D}_0}$, and, assuming $\sum_{j \in D} U_j \psi_j = u$ on Γ_{D}, $S^h_{\mathrm{D}} \subset H^1_{\mathrm{D}}$. Under these conditions we also have $u - U \in H^1_{\mathrm{D}_0}$.

2. A Petrov–Galerkin finite element method. The space constants in the coupling tensor M for myocardium are several times smaller than the dimensions of the tissue, and thus the advection term in the eikonal equation tends to dominate the diffusion term. Care must be taken in selecting a spatial discretization to prevent oscillatory errors such as those that can occur in numerical solution of the steady-state linear advection-diffusion equation (e.g., [24]). A Petrov–Galerkin finite element method that avoids this problem is developed here for eikonal equation (1.12).

The general Petrov–Galerkin finite element method for determining an approximation U for u may be formulated as finding $U \in S^h_{\mathrm{D}}$ such that

(2.1)
$$B(U, W) = \langle \tau_{\mathrm{m}}, W \rangle \qquad \forall W \in T^h,$$

where T^h is the test space,

(2.2)
$$B(v, w) := \langle \mathrm{c}_0 \sqrt{\nabla v \cdot \mathrm{M} \nabla v}, w \rangle + \langle \mathrm{M} \nabla v, \nabla w \rangle,$$

and $\langle \cdot, \cdot \rangle$ denotes the inner product over the domain Ω.

In this section, a means for estimating the quality of a test space T^h is described, and a set of weighting functions, which form a basis for T^h, is selected on the grounds of keeping the expected error in the solution to a minimum and facilitating numerical solution of the resulting weighted residual equations.

2.1. Approximate symmetrization. The performance of the Galerkin finite element method is poor when diffusion is small due to the asymmetric nature of $B(\cdot, \cdot)$. The object of selecting a Petrov–Galerkin scheme is to choose a mapping from S^h_0 to T^h so that it compensates for this asymmetry. Barrett and Morton [2] showed how an error bound can be derived for a test space T^h if $B(\cdot, \cdot)$ is bilinear. This form is bilinear for the eikonal equation if and only if propagation is in only one direction, but analysis of this simple case leads to one-dimensional weighting functions that can

be extended to higher dimensions. A summary of the key points in the error bound derivation follows.

If $T^h \subset H^1_{\mathrm{D}_0}$, then the exact solution u satisfies the same weighted residual equations (2.1) as the numerical solution U. Therefore, if $B(\cdot,\cdot)$ is bilinear, the error $u-U$ satisfies the orthogonality property

$$B(u-U,W)=0 \qquad \forall W\in T^h. \tag{2.3}$$

The convergence properties implied by this orthogonality property depend on T^h.

If $B_{\mathrm{S}}(\cdot,\cdot)$ is any symmetric continuous coercive bilinear form on $H^1_{\mathrm{D}_0}\times H^1_{\mathrm{D}_0}$, then, from the Riesz representation theorem, there exists a *representer* $R_{\mathrm{S}}\colon H^1_{\mathrm{D}_0}\to H^1_{\mathrm{D}_0}$ such that

$$B(v,w)=B_{\mathrm{S}}(v,R_{\mathrm{S}}w) \qquad \forall v,w\in H^1_{\mathrm{D}_0}. \tag{2.4}$$

Assuming $u-U\in H^1_{\mathrm{D}_0}$, this means that the orthogonality property (2.3) may be written as

$$B_{\mathrm{S}}(u-U,R_{\mathrm{S}}W)=0 \qquad \forall W\in T^h. \tag{2.5}$$

The performance of the method depends on how closely S^h_0 can be approximated by $R_{\mathrm{S}}T^h$. Define the norm $\|\cdot\|_{B_{\mathrm{S}}}$ such that

$$\|v\|^2_{B_{\mathrm{S}}}:=B_{\mathrm{S}}(v,v). \tag{2.6}$$

If $T^h\subset H^1_{\mathrm{D}_0}$ and there exists a constant $\Delta_{\mathrm{S}}\in[0,1)$ such that

$$\inf_{W\in T^h}\|V-R_{\mathrm{S}}W\|_{B_{\mathrm{S}}}\leqslant\Delta_{\mathrm{S}}\|V\|_{B_{\mathrm{S}}} \qquad \forall V\in S^h_0, \tag{2.7}$$

then it is possible to determine a bound for the error in terms of the optimal error and the constant Δ_{S}:

$$\|u-U\|_{B_{\mathrm{S}}}\leqslant\frac{1}{\sqrt{1-\Delta^2_{\mathrm{S}}}}\inf_{Z\in S^h_{\mathrm{D}}}\|u-Z\|_{B_{\mathrm{S}}}. \tag{2.8}$$

The ratio of this bound on the error to the optimal solution error is therefore described by the *error factor* $(1-\Delta^2_{\mathrm{S}})^{-\frac{1}{2}}$. This factor is 1 if the test space T^h is chosen to be equal to $T^{h*}\subset H^1_{\mathrm{D}_0}$ defined such that

$$R_{\mathrm{S}}T^{h*}=S^h_0. \tag{2.9}$$

If the representer R_{S} is known, then the constant Δ_{S} may be calculated for given S^h_0 and T^h. In the Petrov–Galerkin finite element method, S^h_0 and T^h are both of dimension N. Define the N × N matrices A, B, and C with entries

$$\begin{aligned} A_{ij}&:=B_{\mathrm{S}}(R_{\mathrm{S}}w_i,R_{\mathrm{S}}w_j),\\ B_{ij}&:=B_{\mathrm{S}}(R_{\mathrm{S}}w_i,\psi_j)=B(\psi_j,w_i),\\ \text{and}\quad C_{ij}&:=B_{\mathrm{S}}(\psi_i,\psi_j), \end{aligned} \tag{2.10}$$

where the weighting functions w_i (usually based on ψ_i) form a basis for T^h. The error factor $(1-\Delta^2_{\mathrm{S}})^{-\frac{1}{2}}$ is the reciprocal of the square root of the smallest eigenvalue λ of the generalized eigenvalue problem

$$B^{\mathrm{T}}A^{-1}B\boldsymbol{V}=\lambda C\boldsymbol{V}. \tag{2.11}$$

2.2. One-dimensional optimal weighting functions. Consider a one-dimensional problem on a domain of length L with a Dirichlet boundary condition at $x = 0$ and a Neumann boundary condition at $x = \mathrm{L}$ so that wavefront propagation is only in the direction of increasing x. The excitation time $u(x)$ is required to satisfy

$$\mathrm{c}_0\sqrt{\mathrm{M}}u' - \mathrm{M}u'' = \tau_{\mathrm{m}} \quad \text{on } (0, \mathrm{L}), \tag{2.12a}$$

$$u(0) = 0, \qquad \text{and} \qquad \mathrm{M}u'(\mathrm{L}) = 0, \tag{2.12b}$$

where c_0 and M are positive constants and $\cdot'$ denotes the derivative with respect to x.

With propagation in only one direction, the form $B(\cdot,\cdot)$ is bilinear. For constant c_0 and M, it simplifies to

$$B(v, w) := \mathrm{c}_0\sqrt{\mathrm{M}}\langle v', w\rangle + \mathrm{M}\langle v', w'\rangle. \tag{2.13}$$

The second inner product is symmetric and can be used for $B_{\mathrm{S}}(\cdot,\cdot)$:

$$B_{\mathrm{S}}(v, w) := \mathrm{M}\langle v', w'\rangle. \tag{2.14}$$

For this problem the Riesz representer R_{S} may be easily found. From its defining relation (2.4) and definitions of $B(\cdot,\cdot)$ (2.13) and $B_{\mathrm{S}}(\cdot,\cdot)$ (2.14),

$$\begin{aligned} &\mathrm{c}_0\sqrt{\mathrm{M}}\langle v', w\rangle + \mathrm{M}\langle v', w'\rangle = \mathrm{M}\langle v', (R_{\mathrm{S}}w)'\rangle \\ \Longrightarrow\ &\left\langle \mathrm{M}v' \frac{\mathrm{c}_0}{\sqrt{\mathrm{M}}} w + w' - (R_{\mathrm{S}}w)' \right\rangle = 0 \qquad\qquad \forall v, w \in H^1_{\mathrm{D}_0}. \end{aligned}$$

With the Neumann boundary condition at $x = \mathrm{L}$, v is only confined to be zero at $x = 0$, and thus

$$(R_{\mathrm{S}}w)' = \gamma w + w' \qquad \forall w \in H^1_{\mathrm{D}_0}, \tag{2.15}$$

where $\gamma = \frac{\mathrm{c}_0}{\sqrt{\mathrm{M}}}$. This and the boundary condition $(R_{\mathrm{S}}w)(0) = 0$ due to $R_{\mathrm{S}}w \in H^1_{\mathrm{D}_0}$ uniquely determine $R_{\mathrm{S}}w$ for any given w.

If each of the weighting functions w_i^* were chosen such that $R_{\mathrm{S}}w_i^* = \psi_i$, they would form a basis for the optimal test space T^{h*}.

2.3. One-dimensional approximate symmetrization. The expressions for optimal one-dimensional weighting functions w_i^* become rather complicated, particularly for irregular meshes or variable coefficients. Extension to more than one dimension and to the nonlinear eikonal equation does not seem feasible. Instead, therefore, the weighting functions are chosen to be simple combinations of the optimal functions when γ approaches 0 and ∞. For the one-dimensional problem (2.12), the weighting functions are

$$w_i := A_0 w_i^0 + A_\infty w_i^\infty, \tag{2.16}$$

where

$$w_i^0 := \psi_i \qquad \text{and} \qquad w_i^\infty := \gamma^{-1}{\psi_i}', \tag{2.17}$$

and A_0 and A_∞ are functions of the mesh Péclet number,

$$P_{\mathrm{e}} := \frac{\mathrm{c}_0}{\sqrt{\mathrm{M}}} \frac{\mathrm{d}x}{\mathrm{d}\xi}. \tag{2.18}$$

These weighting functions are local and easily evaluated. With the C^1 continuity of cubic Hermite interpolation, they all lie in $H^1_{\mathrm{D}_0}$ except the function corresponding to the derivative at $x = 0$. This will be discussed and corrected below.

2.3.1. Selection of coefficients. The proportionality coefficients A_0 and A_∞ are chosen with the intention of making the factor in the error bound (2.8) as small as possible. This contrasts with the work of Christie et al. [4], in which weighting functions were assembled to cancel truncation errors in difference equations for one-dimensional equal-length elements. The error factor depends on the closeness with which $R_S T^h$ approximates S_0^h as measured by the constant Δ_S in bound (2.7). $(R_S W)'$ is given by expression (2.15), and thus bound (2.7) is equivalent to

$$\inf_{W \in T^h} \|V' - \gamma W - W'\|_{L_2} \leqslant \Delta_S \|V'\|_{L_2} \qquad \forall V \in S_0^h. \tag{2.19}$$

Bounds for error factors in terms of P_e have been obtained for meshes of equal-length one-dimensional linear elements using eigenvalue problem (2.11) (see [17]), but extension to cubic Hermite elements is difficult. Analysis is therefore simplified by considering only the function in S_0^h that is expected to be most poorly approximated by functions in $R_S T^h$.

With cubic Hermite interpolation, each V' for $V \in S_0^h$ is piecewise quadratic with C^0 continuity. V' may have discontinuities in derivatives at element boundaries. If advection dominates (γ is large), each V' must be approximated by a $W \in T^h$. With Galerkin weights ψ_i, each W is piecewise cubic with C^1 continuity and cannot approximate discontinuities in first derivatives. If elements are equally spaced, the function $V \in S_0^h$ with the largest discontinuities in first derivatives of V' relative to $\|V\|_{L_2}$ is

$$\hat{V} := \sum_{j \in N^1} \psi_j, \tag{2.20}$$

where N^1 indexes the interpolation functions corresponding to first derivatives. $\hat{V}'$ is orthogonal to every ψ_i except those corresponding to derivatives at the boundaries. This explains the poor performance of the Galerkin method in advection-dominated problems. Of course, on the other hand, the space spanned by derivative weights ${\psi_i}'$ allows any V' for $V \in S_0^h$ to be represented exactly. If diffusion dominates (γ is small), each V' must be approximated by a W' such that $W \in T^h$. Galerkin weights achieve this exactly because $T^h = S_0^h$. With derivative weights, however, each W' is piecewise linear. These W' are therefore orthogonal to the highest frequency (piecewise-quadratic) function V' such that $V \in S_0^h$. The function that cannot be approximated is again $\hat{V}'$.

Here A_0 and A_∞ are selected so that $\hat{V}'$ is approximated as closely as possible by $\gamma\hat{W} + \hat{W}'$, where $\hat{W}$ is a simple combination of the W's that provide an exact representation when P_e approaches 0 and ∞:

$$\hat{W} := A_0 \hat{V} + A_\infty \gamma^{-1} \hat{V}'. \tag{2.21}$$

The smallest eigenvalue in eigenvalue problem (2.11) is estimated by considering only $\hat{V}$ and $\hat{W}$. This leads to an estimate of the error factor in bound (2.8),

$$\frac{1}{\sqrt{1 - \Delta_S^2}} \approx \frac{\|\hat{V}\|_{B_S} \|R_S \hat{W}\|_{B_S}}{B(\hat{V}, \hat{W})} = \frac{\|\hat{V}'\|_{L_2} \|(R_S \hat{W})'\|_{L_2}}{\langle \hat{V}', (R_S \hat{W})' \rangle},$$

where, from (2.15) and (2.21),

$$(R_S \hat{W})' = \gamma A_0 \hat{V} + (A_0 + A_\infty)\hat{V}' + \gamma^{-1} A_\infty \hat{V}''.$$

If elements are of equal length h and boundary effects are ignored, the integrals may be evaluated to give

$$\frac{1}{\sqrt{1-\Delta_{\mathrm{S}}^2}} \approx \frac{\sqrt{\left(\frac{P_{\mathrm{e}}^2}{42}+1\right)A_0^2+\left(1+\frac{60}{P_{\mathrm{e}}^2}\right)A_\infty^2}}{A_0+A_\infty}. \tag{2.22}$$

This estimate is minimized when

$$\frac{A_\infty}{A_0} = \frac{P_{\mathrm{e}}^2+42}{42(P_{\mathrm{e}}^2+60)}P_{\mathrm{e}}^2. \tag{2.23}$$

With coefficients in this optimum ratio,

$$\frac{1}{\sqrt{1-\Delta_{\mathrm{S}}^2}} \approx \sqrt{\frac{P_{\mathrm{e}}^4+102P_{\mathrm{e}}^2+2520}{P_{\mathrm{e}}^4+84P_{\mathrm{e}}^2+2520}}. \tag{2.24}$$

As expected, the estimate of the error factor approaches 1 as P_{e} approaches ∞ or 0. Its maximum value is $\sqrt{\frac{2\sqrt{70}+17}{2\sqrt{70}+14}} \approx 1.05$, which is predicted at $P_{\mathrm{e}} = \sqrt{6\sqrt{70}} \approx 7.1$.

2.3.2. Dirichlet boundaries. The weighting function corresponding to the derivative at $x = 0$, where the Dirichlet boundary condition is applied, is nonzero on that boundary. This means that the weighted residual equations (2.1) are not satisfied if the exact solution u is substituted for U, and so the error orthogonality property (2.3) does not hold. This is corrected by changing the definition of the derivative term w_i^∞ to include a multiplier $\zeta \in H^1_{\mathrm{D}_0}$ so that all weighting functions lie in $H^1_{\mathrm{D}_0}$:

$$w_i^\infty := \zeta\gamma^{-1}{\psi_i}'. \tag{2.25}$$

The multiplier is chosen to be an exponential ramp,

$$\zeta := \frac{1-\mathrm{e}^{-\gamma x}}{1-\mathrm{e}^{-\gamma h}}, \tag{2.26}$$

in the element adjacent to $x = 0$, and one elsewhere, so that for large γ the behavior of w_i^∞ near $x = 0$ is similar to that of the optimal weighting functions w_i^* in section 2.2. These weighting functions still become optimal when $\gamma \to \infty$.

2.3.3. Verification of error estimates. The estimates of the optimal ratio of A_∞ to A_0 (2.23) and of the error factor (2.24) rely on the assumption that $\hat{V}$ is the function in S_0^h that is most poorly approximated by functions in $R_{\mathrm{S}}T^h$. To investigate the validity of this assumption, error factors were calculated from the smallest eigenvalues of problem (2.11) with the full trial and test spaces for various P_{e} and numbers of elements. The weighting functions w_i in (2.16) were defined using (2.25) for w_i^∞ and (2.17) for w_i^0. $\frac{A_\infty}{A_0}$ was given by (2.23). The resulting error factors are compared with estimates from (2.24) in Figure 2.1.

In all cases investigated, the calculated error factors approached the estimate (2.24) as the number of elements became large. The eigenvector of (2.11) corresponding to the smallest eigenvalue was, in each case, dominated by components corresponding to w_j for $j \in N^1$, which were almost constant in the middle of the domain but smaller nearer the boundaries. This affirms that, without boundary effects, $\hat{V}$ is indeed the most poorly approximated function in S_0^h. Near boundaries, $\hat{V}$ can be approximated better, but the estimate (2.24) based on $\hat{V}$ and ignoring boundary effects appears to provide a good upper bound on the error factor.

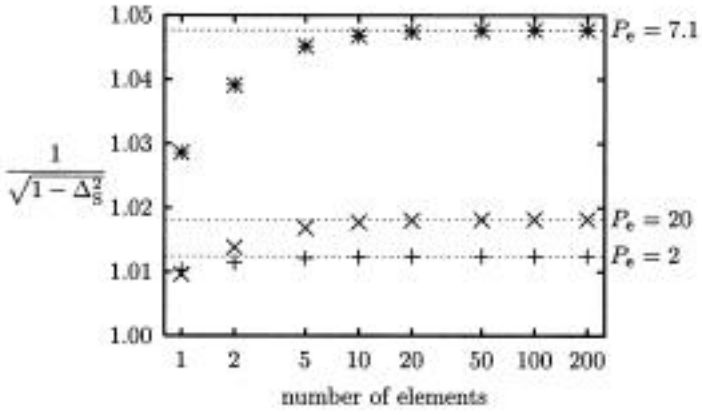

FIG. 2.1. *Comparison of calculated and estimated one-dimensional error factors. The data points are calculated values, and the lines are the estimates from* (2.24).

2.3.4. Variable lengths and coefficients. The terms in the approximately optimal weighting function (2.16) are optimal weights when P_e approaches 0 and ∞, even with unequally spaced elements and variable equation coefficients, but the ratio $\frac{A_\infty}{A_0}$ given in (2.23) is based on constant element lengths and coefficients. With variable lengths or coefficients, the best choices of A_0 and A_∞ are no longer constant. It is assumed that weighting functions (2.16) are still close to optimal if the ratio (2.23) is used, but the variation over x in the total magnitude of A_0 and A_∞ is yet to be determined. Note that with weighting functions (2.16) and propagation only in the direction of increasing x, if boundary effects are ignored, the error orthogonality property (2.3) may be written as

$$\langle u' - U', A_0\gamma \mathrm{M}V\rangle + \langle u' - U', (A_0 + A_\infty)\mathrm{M}V'\rangle + \langle u' - U', A_\infty\gamma^{-1}\mathrm{M}V''\rangle = 0 \qquad \forall V \in S_0^h.$$

If we aim for a small error in the sense of the $\|\cdot\|_{B_S}$ norm, then the left-hand side should resemble $B_S(u-U,V)$. The second term is therefore the desirable term, and its dominance is achieved by appropriate selection of $\frac{A_\infty}{A_0}$ in (2.23). The second term is equivalent to $B_S(u-U,V)$ if

$$A_0 + A_\infty := 1. \tag{2.27}$$

2.4. Extension to three dimensions. For modelling the excitation of the heart, the definitions of the terms in the weighting functions need to be extended to the three-dimensional case with wavefronts travelling in any direction. Weighting functions are still based on the simple combination (2.16) of terms selected for their performance when P_e approaches 0 and ∞, but the Riesz representer theory of section 2.1 can no longer be applied because the form $B(\cdot,\cdot)$ defined in (2.2) is no longer bilinear.

2.4.1. Selection of weight terms. When $P_e \to 0$, $B(\cdot,\cdot)$ becomes bilinear, and thus w_i^0 are defined as the optimal weights in the sense of $\|\cdot\|_{B_S}$, which are still ψ_i. When the advection term is present, its nonlinearity means that the techniques

used in section 2.2 can no longer be used to find a weight that guarantees minimum error in the sense of the $\|\cdot\|_{B_S}$ norm. However, when $P_e \to \infty$, making the residual $c_0\sqrt{\nabla u \cdot M \nabla u} - \tau_m$ orthogonal to the least squares weight $\frac{\nabla U \cdot M \nabla \psi_i}{c_0\sqrt{\nabla U \cdot M \nabla U}}$ minimizes

$$\left\| \sqrt{\nabla U \cdot M \nabla U} - \frac{\tau_m}{c_0} \right\|_{L_2} = \left\| \sqrt{\nabla U \cdot M \nabla U} - \sqrt{\nabla u \cdot M \nabla u} \right\|_{L_2}.$$

These weighting functions compare with the derivative weighting functions of Brooks and Hughes [3] in their solution of the multidimensional steady-state linear advection-diffusion equation with linear elements.

As in the one-dimensional case, a multiplier $\zeta \in H^1_{D_0}$ is included with the least squares weight to ensure that the weighting functions are zero on Dirichlet portions of the boundary. ζ is based on the one-dimensional expression (2.26) and is defined by

$$\zeta := \frac{1 - \exp\left(-\frac{P_e p_\zeta}{k_\zeta}\right)}{1 - \exp\left(-\frac{P_e}{k_\zeta}\right)}, \tag{2.28}$$

where k_ζ is a constant and p_ζ is a simple nonnegative function in $H^1_{D_0}$. In elements adjacent to Dirichlet boundaries, p_ζ is a polynomial function of $\boldsymbol{\xi}$; in other elements, $p_\zeta = 1$. This means that ζ is equal to one over most of the domain, and thus most weights are unaffected by the multiplier. Near Dirichlet boundaries, the weights have similar behavior to one-dimensional optimal weighting functions for large P_e if p_ζ increases from zero at the boundary with slope $|\nabla_{\boldsymbol{\xi}} p_\zeta| = k_\zeta$. A cubic interpolation is used for p_ζ, and k_ζ is set to 3. Away from Dirichlet boundaries, nodal values of p_ζ are set to 1, and derivatives to 0. On Dirichlet boundaries, nodal values are 1, and derivatives are set so that the slope of p_ζ at the boundary is as close to 3 as possible.

The least squares term is discontinuous at wavefront collisions, which makes it difficult to design an integration scheme such that the residuals in the resulting discrete system of nonlinear equations are continuous with respect to the nodal parameters U_j. In order to keep the integration scheme simple, the smooth term,

$$w_i^\infty := \zeta \frac{\nabla U \cdot M \nabla \psi_i}{\sqrt{(1-\alpha_\infty) {c_0}^2 \nabla U \cdot M \nabla U + \alpha_\infty {\tau_m}^2}}, \tag{2.29}$$

is used instead with the constant $\alpha_\infty \in (0,1)$. This term is close to the least squares term when advection dominates and U is close to u. At a collision, however, the denominator remains greater than zero, and so the term vanishes. The best value for α_∞ has not been thoroughly investigated, but $\alpha_\infty = \frac{1}{4}$ seems to work well.

2.4.2. Mesh Péclet number. The one-dimensional expression for P_e in (2.18) included the equation space constant $\sqrt{M}$ and an element spatial scale $\frac{dx}{d\xi}$. In more than one dimension, these quantities are not scalar, and thus the intention is to base P_e on suitable space constants in the direction of propagation.

It is convenient to define at each point in space a dimensionless *natural coordinate system* $\boldsymbol{\upsilon}$ in which the coupling tensor M transforms to the identity matrix and the advection term becomes isotropic:

$$c_0\sqrt{\nabla U \cdot M \nabla U} \equiv c_0 \left| \nabla_{\boldsymbol{\upsilon}} U \right|,$$

where $\nabla_{\boldsymbol{\upsilon}}$ denotes the gradient operator with respect to $\boldsymbol{\upsilon}$ coordinates. The one-dimensional scalar ratio of $\sqrt{\mathrm{M}}$ to $\frac{\mathrm{d}x}{\mathrm{d}\xi}$ corresponds to a multidimensional tensor $\nabla_{\boldsymbol{\upsilon}}\boldsymbol{\xi}$. A scalar quantity is selected from this using the rate of change of $\boldsymbol{\xi}$ arc length with respect to $\boldsymbol{\upsilon}$ arc length in the direction of propagation:

$$\left|\left(\frac{\nabla_{\boldsymbol{\upsilon}} U}{|\nabla_{\boldsymbol{\upsilon}} U|}\cdot\nabla_{\boldsymbol{\upsilon}}\right)\boldsymbol{\xi}\right|. \tag{2.30}$$

A smooth P_{e} is defined by

$$P_{\mathrm{e}} := \frac{\mathrm{c}_0\sqrt{(1-\alpha_\infty)\mathrm{c}_0{}^2\left|\nabla_{\boldsymbol{\upsilon}} U\right|^2+\alpha_\infty\tau_{\mathrm{m}}{}^2}}{\sqrt{(1-\alpha_\infty)\mathrm{c}_0{}^2\left|\left(\nabla_{\boldsymbol{\upsilon}} U\cdot\nabla_{\boldsymbol{\upsilon}}\right)\boldsymbol{\xi}\right|^2+\alpha_\infty\tau_{\mathrm{m}}{}^2\bar{\mu}^{\boldsymbol{\xi}}}}, \tag{2.31}$$

where

$$\bar{\mu}^{\boldsymbol{\xi}} := \frac{1}{3}\frac{\partial\xi_m}{\partial\upsilon_p}\frac{\partial\xi_m}{\partial\upsilon_p} \tag{2.32}$$

(which is an average of the diagonal elements of the coupling tensor in the $\boldsymbol{\xi}$ coordinate system).

2.4.3. Discontinuous derivatives of U. Expressions (2.23) and (2.27) for the coefficients A_0 and A_∞ are only useful if U is C^1 continuous. There are, however, places in the ventricular myocardium where u is not expected to be C^1 continuous [23]. The coefficients in (2.23) and (2.27) and w_i^∞ in (2.29) depend on first derivatives of U, so, with only C^0 continuity in U, the weighting functions (2.16) may be discontinuous. To retain continuity in the weights, A_0 is made constant and p_ζ is set to zero on interelement boundaries where C^1 continuity in U is not expected. The nodal values of p_ζ on interelement boundaries without C^1 continuity are set in the same manner as if they were on Dirichlet boundaries. In this way, $A_0 w_i^0$ retains the C^0 continuity of the interpolation functions, and $A_\infty w_i^\infty$ approaches zero at interelement boundaries where derivatives of U are not expected to be continuous.

With constant A_0, keeping the ratio of A_∞ to A_0 similar to the one-dimensional optimal ratio (2.23) would mean that for large P_{e} the weights would be heavily dependent on the direction of propagation, making the weighted residual equations very nonlinear. Instead, A_0 and A_∞ are defined by

$$A_0 := 1 \qquad \text{and} \qquad A_\infty := \frac{P_{\mathrm{e}}^2}{\mathrm{k}_{\mathrm{lim}}P_{\mathrm{e}}+50}, \tag{2.33}$$

where the constant $\mathrm{k}_{\mathrm{lim}}$ determines the maximum magnitude of the derivative term. It is chosen to be 2 (discussed below). The weighting functions are therefore given by the sum of Galerkin and supplementary weighting functions,

$$w_i = \psi_i + \hat{w}_i, \tag{2.34}$$

where the supplementary weighting functions are defined by

$$\hat{w}_i := \zeta\frac{P_{\mathrm{e}}}{2P_{\mathrm{e}}+50}\frac{\mathrm{c}_0\nabla_{\boldsymbol{\upsilon}} U\cdot\nabla_{\boldsymbol{\upsilon}}\psi_i}{\sqrt{(1-\alpha_\infty)\mathrm{c}_0{}^2\left|\left(\nabla_{\boldsymbol{\upsilon}} U\cdot\nabla_{\boldsymbol{\upsilon}}\right)\boldsymbol{\xi}\right|^2+\alpha_\infty\tau_{\mathrm{m}}{}^2\bar{\mu}^{\boldsymbol{\xi}}}}. \tag{2.35}$$

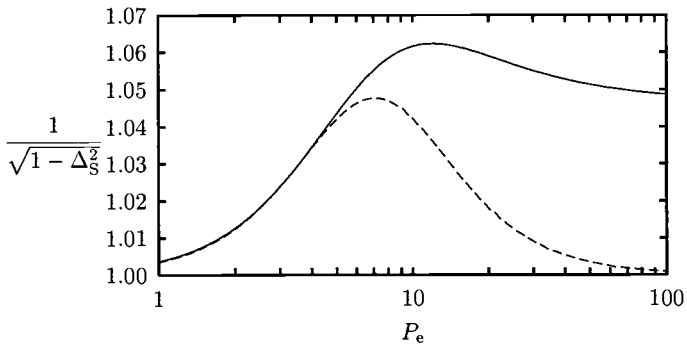

FIG. 2.2. *Comparison of one-dimensional error factor estimates from* (2.22) *with* $\frac{A_\infty}{A_0}$ *determined by the derivative-limited expressions* (2.33) *(solid line) and the optimal expression* (2.23) *(dashed line).*

For large P_e, the magnitude of the supplementary weighting functions, which are dependent on U, is similar to that of the Galerkin weighting functions, which are independent of U. This reduces the effects of nonlinearity in the weighted residual equations, facilitating their solution.

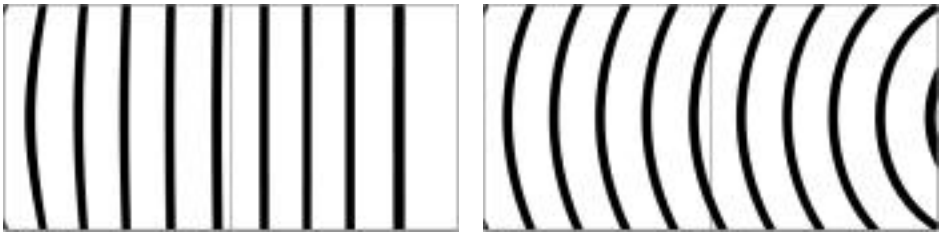
To estimate the error introduced by not using the optimal ratio of A_∞ to A_0 (2.23), one-dimensional error factor estimates for ratios from (2.33) and (2.23) are compared in Figure 2.2. These error factors are calculated from expression (2.22), which is based on constant equation coefficients and assumes a large number of equal-length one-dimensional elements. The maximum predicted error factor with (2.33) is less than two percent greater than the maximum with the optimal ratio (2.23). The constant k_{lim} in (2.33) was set to 2 to keep the nonlinear term in the weight as small as possible while not significantly increasing the expected error factor.

3. No-inflow boundary condition. For large Péclet numbers, the no-flux boundary condition derived from the diffusion of charge is not necessarily enough to sufficiently constrain the solution.

3.1. Inflow boundaries. The lack of stability under large Péclet numbers of the Petrov–Galerkin method developed in the previous section is demonstrated in the situation shown in Figure 3.1. The tissue is stimulated in such a way that the wavefront is initially concave (when viewed from inactive tissue). Note that for $P_e = 10$ the curvature of the wavefront reduces as it propagates across the tissue, but for $P_e = 100$ the curvature increases.

The nature of the solution for $P_e = 100$ is in some ways quite reasonable. The residual in the eikonal equation (1.12) is very small. An inwardly propagating circular wavefront becomes a smaller circle, so an initially concave wavefront becomes more concave. The problem with the solution is that the no-flux boundary condition (1.13) is not satisfied.

The no-flux boundary condition is not very well satisfied on the boundary at the right-hand end of the tissue in the solution for $P_e = 10$ either. Such boundaries where the wavefront extinguishes shall be referred to as *outflow* boundaries. The boundary condition at these boundaries only affects a small boundary layer of tissue, so failure to satisfy the boundary condition does not introduce much error into the



(a) $P_e = 10$ (b) $P_e = 100$

FIG. 3.1. *Excitation contours calculated by the Petrov–Galerkin method for a slice of tissue stimulated unevenly at the left-hand edge. Stimulus times are specified by a quadratic function so that the corners are stimulated first and the center of the edge last. The tissue is represented by two unit square cubic Hermite elements. Equation parameters are selected for unit plane wave speed in any direction. Contours are at intervals of* 0.2.

solution. The boundaries where the wavefronts enter the domain shall be called *inflow* boundaries. The boundary at the left-hand end of the tissue is an inflow boundary because tissue is stimulated on this boundary. In the $P_e = 10$ solution, the no-flux boundary condition on the other boundaries is satisfied very well.

In the $P_e = 100$ solution, the no-flux boundary condition on the boundaries at the top and bottom of the domain is not satisfied. The boundary condition (1.13) is derived from prevention of diffusion of charge across the boundary. For large Péclet numbers, diffusion effects are small, and so the emphasis on satisfying the boundary condition is small. Because the discretization does not allow U to exactly represent u, the numerical method selects a solution that closely satisfies the eikonal equation but almost ignores the boundary condition. As the effects of diffusion are small, the propagation speed should be almost unaffected by curvature and should be almost equal to the unit plane wave speed. This is reflected in the solution through the magnitude of the gradient of activation time which is close to one over the entire domain. Note, however, that the average propagation speed along the top and bottom edges of the domain is about 1.1. This is due to the fact that the method does not recognize that tissue needs to be excited by other excited tissue. It is assumed that the propagation direction is normal to the wavefront, but, because the boundary condition is not strongly enforced, the wavefront normal is not parallel to the boundary. The wavefront is propagating from outside the boundary into the domain, and the boundary is an inflow boundary. Tissue is being excited by nonexistent tissue outside the boundary.

Without a mechanism to prevent wavefronts from entering the domain through unwanted inflow boundaries, excitation can initiate at arbitrary points on the boundary and totally corrupt the numerical solution. This problem occurs when the diffusion term becomes insignificant, and thus the nature of propagation without diffusion is now investigated to determine a prevention mechanism.

3.2. Propagation without diffusion. For large Péclet numbers the numerical scheme behaves as if it is solving the eikonal equation without a diffusion term and without the associated no-flux boundary condition. Without these, the solution to the eikonal equation (1.12) is not unique. To reflect the fact that tissue must be excited by neighboring tissue, the governing equation should instead be

$$\sup_{\boldsymbol{a}\in A(\boldsymbol{x})} \left\{ \lim_{\alpha \searrow 0} \frac{u(\boldsymbol{x}) - u(\boldsymbol{x} - \alpha \boldsymbol{a})}{\alpha} \right\} = \tau_m(\boldsymbol{x}) \qquad \forall \boldsymbol{x} \in \Omega - \Gamma_D, \tag{3.1}$$

where, for m dimensions,

$$A(\boldsymbol{x}) := \left\{\boldsymbol{a} \in \mathbb{R}^m : \boldsymbol{a} \cdot \mathrm{M}^{-1}\boldsymbol{a} = {\mathrm{c}_0}^2;\ \exists\, \alpha \in \mathbb{R} \text{ s.t. } \alpha > 0,\ \boldsymbol{x} - \alpha\boldsymbol{a} \in \Omega\right\}. \tag{3.2}$$

Restricting the vectors $\boldsymbol{a}$ to the set $A(\boldsymbol{x})$ determines the directions in which propagation can occur at the point $\boldsymbol{x}$ and the propagation speeds for these directions.

In regions where the solution is smooth enough, this governing equation is equivalent to

$$\sup_{\boldsymbol{a} \in A} \{\boldsymbol{a} \cdot \nabla u\} = \tau_{\mathrm{m}}. \tag{3.3}$$

(If A is replaced with A_{Ω^0} defined below, this equation is a special case of that used by Falcone, Giorgi, and Loreti [10] in their analysis of front propagation problems.) For a point not on the boundary, the definition of A simplifies to

$$A_{\Omega^0} := \left\{\boldsymbol{a} \in \mathbb{R}^m : \boldsymbol{a} \cdot \mathrm{M}^{-1}\boldsymbol{a} = {\mathrm{c}_0}^2\right\}, \tag{3.4}$$

and the supremum in (3.3) occurs when

$$\boldsymbol{a} = \mathrm{c}_0 \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}.$$

Away from the boundaries, therefore, (3.3) is equivalent to the eikonal equation (1.12) without a diffusion term.

Without diffusion, there is no Neumann boundary condition, but the notation Γ_{N} will be used for $\partial\Omega - \Gamma_{\mathrm{D}}$, the portion of the boundary in which no Dirichlet boundary condition is applied. For a point on this portion of the boundary, A is equivalent to

$$A_{\partial\Omega} := \left\{\boldsymbol{a} \in \mathbb{R}^m : \boldsymbol{a} \cdot \mathrm{M}^{-1}\boldsymbol{a} = {\mathrm{c}_0}^2,\ \boldsymbol{n} \cdot \boldsymbol{a} \geqslant 0\right\}, \tag{3.5}$$

where $\boldsymbol{n}$ is the unit outward-pointing normal to the boundary.

In order to investigate the nature of the solution to (3.3) near boundaries, consider two points, $\boldsymbol{x}_{\partial\Omega} \in \Gamma_{\mathrm{N}}$ and $\boldsymbol{x}_{\Omega^0} \in \Omega - \partial\Omega$, such that $\boldsymbol{x}_{\Omega^0}$ is an infinitesimal distance from $\boldsymbol{x}_{\partial\Omega}$. As discussed above, the solution at $\boldsymbol{x}_{\Omega^0}$ satisfies

$$\mathrm{c}_0 \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}} \cdot \nabla u = \tau_{\mathrm{m}}.$$

If the solution is smooth enough in the vicinity of the points, one would expect that $\nabla u(\boldsymbol{x}_{\partial\Omega})$ is equal to $\nabla u(\boldsymbol{x}_{\Omega^0})$ and should satisfy the same equation. This is only consistent with (3.3) if

$$\mathrm{c}_0 \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}} \in A_{\partial\Omega},$$

and thus the direction of propagation on Γ_{N} is restricted by

$$\boldsymbol{n} \cdot \mathrm{M}\nabla u \geqslant 0. \tag{3.6}$$

If some diffusion is included, it can be assumed that u is smooth enough that the governing equation becomes

$$\sup_{\boldsymbol{a} \in A} \{\boldsymbol{a} \cdot \nabla u\} - \nabla \cdot (\mathrm{M}\nabla u) = \tau_{\mathrm{m}}. \tag{3.7}$$

The limit of the solution to this equation as the diffusion term vanishes satisfies (3.1).

The no-flux boundary condition on Γ_{N} ensures that $\mathrm{M}\nabla u$ is either parallel to the boundary or zero. The supremum in (3.7) therefore occurs when $\boldsymbol{a} = \mathrm{c}_0 \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}$ and (3.7) is equivalent to the eikonal equation (1.12). The limit of the solution to the eikonal equation (1.12) and its no-flux boundary condition (1.13) as the diffusion term vanishes satisfies the diffusionless governing equation (3.1).

3.3. A no-inflow boundary term. Although the exact solution of the eikonal equation (1.12) approaches the solution of the diffusionless propagation equation (3.1), the same is not necessarily true for the numerical solution. Unfortunately, with the Petrov–Galerkin method, when diffusion effects become small, they are swamped by discretization errors. The method behaves as if it were solving an eikonal equation without a diffusion term and without the no-flux boundary condition. Without these, the solution is not unique, and so the scheme becomes unstable. To prevent this, the numerical treatment of the advection term needs to more closely represent the corresponding term in (3.1).

With a finite difference method this is easily done by using an upwind difference scheme [18]. Such schemes can select the grid points used in the difference expressions for the advection term so that the excitation time of each grid point is calculated as the expected time for a wavefront to arrive from neighboring grid points with lower excitation times. As there are only grid points in the domain, the wavefront can only arrive from points in the domain, and there are no unwanted inflow boundaries. None of the so-called upwind finite element methods for steady-state problems provide the same restrictions on the solution. Finite element methods only evaluate the advection term at sample points in the domain, and thus the boundaries have no influence on propagation.

The approach used here to stabilize the Petrov–Galerkin solution of the eikonal equation is to add to the weighted residual equations a boundary integral term that encourages the solution to satisfy the boundary inequality (3.6). If this is satisfied, the supremum in (3.3) occurs when $\boldsymbol{a} = \mathrm{c}_0 \frac{\mathrm{M}\nabla u}{\sqrt{\nabla u \cdot \mathrm{M}\nabla u}}$, and thus the residual in the eikonal equation (1.12) is equivalent to the residual in (3.3).

The satisfaction of boundary inequality (3.6) is encouraged by including a penalty term when it is not satisfied. This penalty term is constructed from minimization of an integral over Γ_{N} of the square of a residual,

$$\int_{\Gamma_{\mathrm{N}}} A_{\mathrm{b}}\, r_{\mathrm{b}}^2 \,\mathrm{d}\Gamma, \tag{3.8}$$

where r_{b} is a residual that is zero if and only if (3.6) is satisfied, and A_{b} is a coefficient independent of U. The minimum occurs when the derivatives with respect to each parameter U_i,

$$\int_{\Gamma_{\mathrm{N}}} A_{\mathrm{b}}\, r_{\mathrm{b}}\, \frac{\partial r_{\mathrm{b}}}{\partial U_i} \,\mathrm{d}\Gamma, \tag{3.9}$$

are zero. These integrals are added to the left-hand side of the Petrov–Galerkin discrete equations (2.1) to encourage the numerical solution U to satisfy the boundary inequality (3.6).

The natural coordinate system $\boldsymbol{v}$ of section 2.4.2 may be used to express inequality (3.6) as

$$\boldsymbol{n}^{\boldsymbol{v}} \cdot \nabla_{\boldsymbol{v}} u \geqslant 0, \tag{3.10}$$

where $\boldsymbol{n}^{\boldsymbol{v}}$ is the unit outward-pointing normal to the boundary in this coordinate system. When r_b was defined as the direct residual in this inequality, the penalty term was found to place too much emphasis on satisfying this inequality at the expense of satisfying the eikonal equation. The expression for r_b was therefore selected to be more closely associated with the advection term. Consider the residual

$$r_\mathrm{b} := |\nabla_{\boldsymbol{v}} U| - \sqrt{|\nabla_{\boldsymbol{v}} U|^2 - \min(\boldsymbol{n}^{\boldsymbol{v}} \cdot \nabla_{\boldsymbol{v}} U, 0)^2}. \tag{3.11}$$

If (3.10) is satisfied, this expression is zero. If (3.10) is not satisfied, the expression is essentially the difference between the advection term and what it would be if it were calculated from only the components of $\nabla_{\boldsymbol{v}} U$ in the surface of the boundary. With this residual, the expression $r_\mathrm{b} \frac{\partial r_\mathrm{b}}{\partial U_i}$ has a discontinuity when $|\nabla_{\boldsymbol{v}} U| = \boldsymbol{n}^{\boldsymbol{v}} \cdot \nabla_{\boldsymbol{v}} U$, which corresponds to propagation into the domain normal to the boundary. It is not likely that this will occur, but, to ensure that the discrete equations are smooth enough for solution by Newton's method, the modified residual

$$r_\mathrm{b} := \sqrt{|\nabla_{\boldsymbol{v}} U|^2 + \alpha_\mathrm{b} \tfrac{{\tau_\mathrm{m}}^2}{{\mathrm{c}_0}^2}} - \sqrt{|\nabla_{\boldsymbol{v}} U|^2 - \min(\boldsymbol{n}^{\boldsymbol{v}} \cdot \nabla_{\boldsymbol{v}} U, 0)^2 + \alpha_\mathrm{b} \tfrac{{\tau_\mathrm{m}}^2}{{\mathrm{c}_0}^2}} \tag{3.12}$$

is used. As with α_∞ in section 2.4, a value of $\frac{1}{4}$ is used for α_b.

The boundary integrands are of similar magnitude to the products of the advection term and the weights in (2.34) and (2.35) if they are multiplied by

$$P_\mathrm{e}^\mathrm{b} \left(1 + \frac{P_\mathrm{e}^\mathrm{b}}{2P_\mathrm{e}^\mathrm{b} + 50} \right).$$

To retain the symmetric and positive semidefinite nature of the boundary terms (3.9), an expression that is independent of U is used for the Péclet number:

$$P_\mathrm{e}^\mathrm{b} := \mathrm{c}_0 \left| \boldsymbol{n}^{\boldsymbol{v}} \cdot \frac{\partial \boldsymbol{v}}{\partial \xi_n} \right|, \tag{3.13}$$

where ξ_n is the local element coordinate that does not vary over the boundary. The expression is based on the spatial properties in the direction normal to the boundary instead of in the direction of propagation used in (2.31).

Even with the integrands dimensionally consistent, there is still a difference between the dimensions of the boundary and domain integrals in the order of one spatial dimension. An appropriate multiplier needs to be found for the boundary term to balance the emphasis on satisfaction of the eikonal equation and of the boundary inequality. This should reflect the depth of the region of influence that the boundary terms should have. The parameters U_j that are included in the boundary terms have a significant direct influence on the solution over about half an element. If the boundary terms are given a multiplier that resembles half the width of the element, then the equations involving these parameters should put even emphasis on satisfaction of the domain equation and the boundary inequality. The multiplier is chosen to be

$$\frac{1}{2} \left| \boldsymbol{n} \cdot \frac{\partial \boldsymbol{x}}{\partial \xi_n} \right|,$$

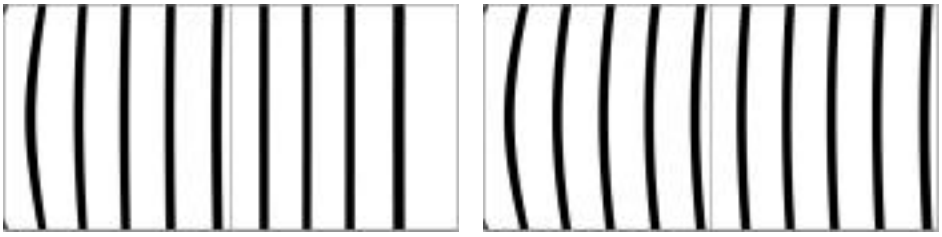


FIG. 3.2. *Excitation contours calculated by the Petrov–Galerkin method with the additional boundary term* (3.9). *The slice of tissue is described in Figure* 3.1.

so that the width of the element is estimated from information at the boundary. The coefficient A_b in the boundary terms (3.9) is therefore

$$A_b := \frac{P_e^b}{2}\left(1 + \frac{P_e^b}{2P_e^b + 50}\right)\left|\boldsymbol{n} \cdot \frac{\partial \boldsymbol{x}}{\partial \xi_n}\right|. \tag{3.14}$$

The numerical solutions obtained by this modified scheme in solving the test problem of section 3.1 are shown in Figure 3.2. For $P_e = 10$, the solution is very similar to the solution in Figure 3.1(a) obtained without the additional boundary term. For $P_e = 100$, the solution satisfies both the eikonal equation (1.12) and boundary condition (3.6) reasonably well, given the coarse discretization. Although the wavefront is not perpendicular to the top and bottom boundaries, the propagation speeds along these boundaries are sensible, and the satisfaction of (3.6) improves with distance from the initiation point.

4. Summary of the method. The numerical method developed for the simulation of excitation propagation in ventricular myocardium uses Newton's method to solve a system of weighted residual equations that are sums of the Petrov–Galerkin weighted residuals of section 2.4 and the no-inflow weighted residual of section 3.3. Newton's method requires a sufficiently good initial guess on which it can iteratively improve. If the diffusion term dominates, the equation is close to linear, and thus almost any initial guess leads to rapid convergence. An initial guess of $U_j = 0\ \forall j \in N$ is sufficient. If the advection term dominates, however, the significant nonlinearities may prevent the method from converging if the initial guess is not good enough. Approximate solutions to equations with more significant diffusion are used as initial guesses for equations with more advection in a numerical continuation method [1] on the continuum of equations,

$$\alpha_c c_0 \sqrt{\nabla u \cdot \mathrm{M} \nabla u} - \nabla \cdot (\mathrm{M} \nabla u) = \alpha_c \tau_m. \tag{4.1}$$

Here α_c is the continuation variable, which is increased from 0 to 1 to transform a diffusion equation into the desired eikonal equation.

From Petrov–Galerkin weighted residual equations (2.1), no-inflow weighted residual equations (3.9), and governing equation continuum (4.1), the weighted residual

equations are

$$\int_{\Omega} \left(\alpha_{\mathrm{c}} (\mathrm{c}_0 \sqrt{\nabla U \cdot \mathrm{M} \nabla U} - \tau_{\mathrm{m}})(\psi_i + \hat{w}_i) + \nabla U \cdot \mathrm{M} \nabla \psi_i - \nabla \cdot (\mathrm{M} \nabla U)\, \hat{w}_i \right) \mathrm{d}\Omega + \int_{\Gamma_{\mathrm{N}}} \left(\boldsymbol{n} \cdot \mathrm{M} \nabla U \hat{w}_i + A_{\mathrm{b}}\, r_{\mathrm{b}}\, \frac{\partial r_{\mathrm{b}}}{\partial U_i} \right) \mathrm{d}\Gamma = 0 \qquad \forall i \in N. \tag{4.2}$$

The boundary inequality residual definition (3.12) is used for r_{b}.

When the value of the continuation variable is less than one, the influence of the diffusion term is increased, and thus the supplementary weights $\hat{w}_i$ and the boundary integral coefficient A_{b} are calculated using the apparent Péclet number. The supplementary weighting functions $\hat{w}_i$ are defined by (2.35), with the Péclet number defined by (cf. (2.31))

$$P_{\mathrm{e}} := \frac{\alpha_{\mathrm{c}} \mathrm{c}_0 \sqrt{(1-\alpha_\infty) {\mathrm{c}_0}^2 \nabla_{\boldsymbol{\xi}} U \cdot \mathrm{M}^{\boldsymbol{\xi}} \nabla_{\boldsymbol{\xi}} U + \alpha_\infty {\tau_{\mathrm{m}}}^2}}{\sqrt{(1-\alpha_\infty) {\mathrm{c}_0}^2 \nabla_{\boldsymbol{\xi}} U \cdot \mathrm{M}^{\boldsymbol{\xi}} \mathrm{M}^{\boldsymbol{\xi}} \nabla_{\boldsymbol{\xi}} U + \alpha_\infty {\tau_{\mathrm{m}}}^2 \bar{\mu}^{\boldsymbol{\xi}}}}. \tag{4.3}$$

The boundary integral coefficient A_{b} is defined by (3.14) with the Péclet number defined by (cf. (3.13))

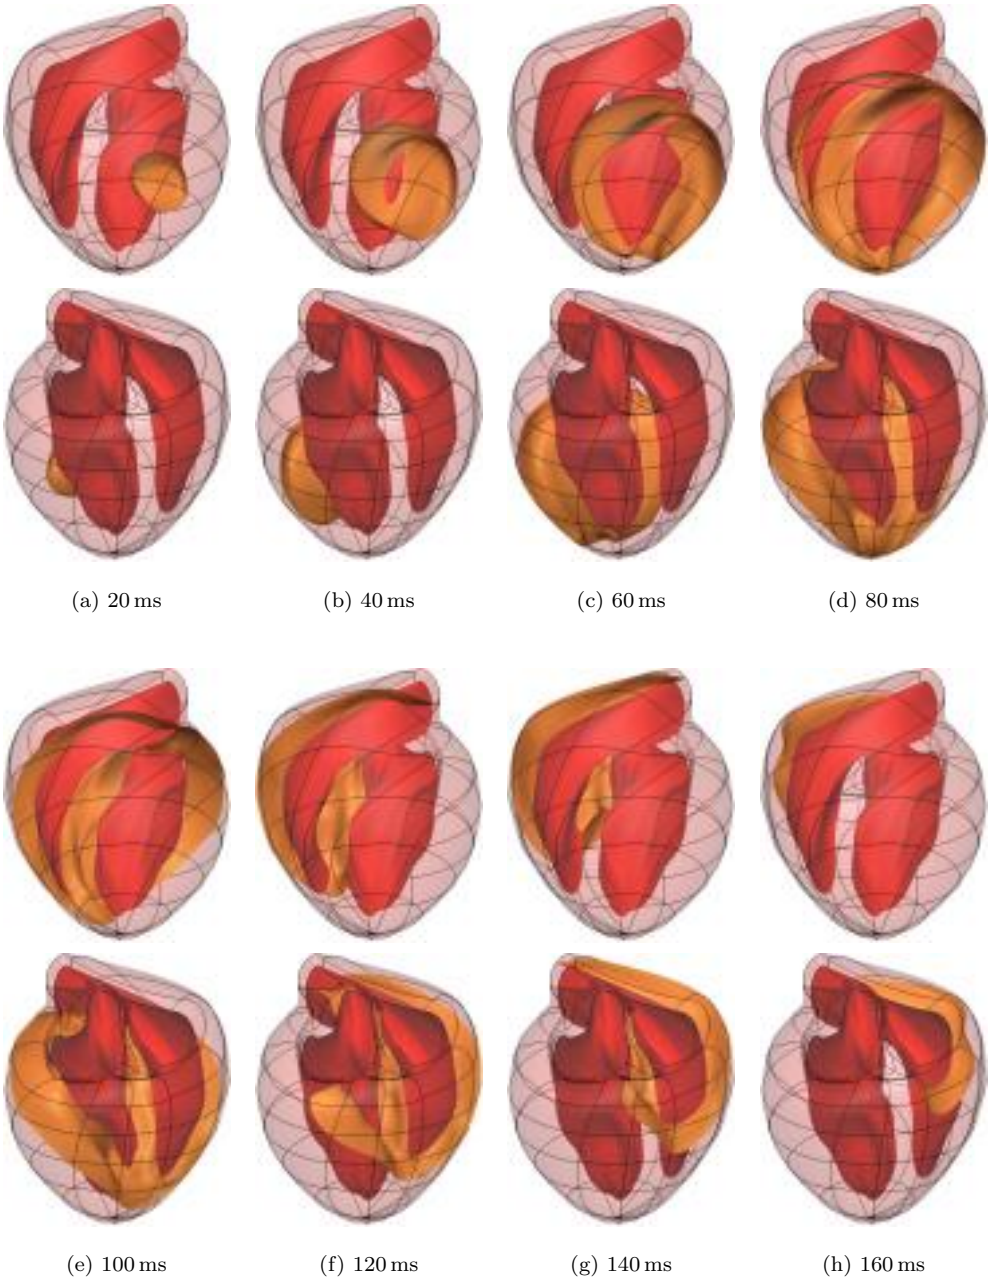
$$P_{\mathrm{e}}^{\mathrm{b}} := \alpha_{\mathrm{c}} \mathrm{c}_0 \left| \boldsymbol{n}^{\boldsymbol{v}} \cdot \frac{\partial \boldsymbol{v}}{\partial \xi_n} \right|. \tag{4.4}$$

The integrals in (4.2) are evaluated using Gauss–Legendre quadrature schemes. A grid of quadrature points with four points in each direction is used within each element. The system of linear equations for each Newton iteration is solved using the generalized minimum residual (GMRES) iterative solver [20] with a simple diagonal preconditioner and no restarts.

5. Simulation. Numerical simulation of excitation propagation through the full canine ventricular myocardium was performed using the method developed here to solve eikonal equation (1.12). The model of the canine ventricular geometry and the selection of material parameters for the governing equation (1.12) are discussed in [23]. Parameters used were $\lambda_{\mathrm{l}} = 0.8\,\mathrm{mm}$, $\lambda_{\mathrm{t}} = \lambda_{\mathrm{n}} = 0.5\,\mathrm{mm}$, $\tau_{\mathrm{m}} = 3\,\mathrm{ms}$, and $\mathrm{c}_0 = 2.5$. There were 2355 degrees of freedom for the dependent variable. The method was programmed primarily in extended FORTRAN 77 as part of the CMISS (an acronym for Continuum Mechanics, Image analysis, Signal processing and System identification) software package. It was executed on one 195 MHz MIPS R10000 processor of a Silicon Graphics Octane.

A point stimulus site was chosen to match the pacing site used for epicardial-sock activation time recordings by Le Grice [16], so that results could be compared with experimental measurements. This site is on the epicardial surface of the anterior aspect of the left ventricular free wall and located at a distance from the apex about one third of that from apex to base.

Snapshots of wavefront locations from the simulation are presented in Figure 5.1. Epicardial isochrones are similar to those from the experimental recordings for times from about 20 ms to 60 ms after stimulation but start to differ considerably outside this interval. Near the stimulus site, experimental recordings showed much slower propagation in the direction transverse to the fibers. The difference in simulation



(a) 20 ms (b) 40 ms (c) 60 ms (d) 80 ms

(e) 100 ms (f) 120 ms (g) 140 ms (h) 160 ms

FIG. 5.1. *Wavefront locations at* 20 *ms time intervals in a simulation of propagation from an epicardial point stimulus at time* 0. *For each sample time, two opposing views are shown.*

results is probably due both to the coarse discretization and to the inability of the eikonal model to reproduce the transient effects near a stimulus. The distance over which slow initial transverse propagation was observed experimentally is less than one quarter of the element length in this direction. For times greater than 65 ms

after stimulation, experimental recordings showed much earlier epicardial excitation, particularly in the more basal and posterior areas on the left ventricular free wall. The region of latest recorded excitation was at the pulmonary conus, which was excited about 125 ms after stimulation. In simulations, the latest excitation occurred about 180 ms after stimulation in the basal posterior region of the right ventricular free wall. The discrepancy is most likely due to the lack of Purkinje fibre representation in the computational model. If the effects of this fast conduction network are not included in the model, results cannot be expected to be realistic. More realistic simulations are presented in [23].

The solution to the discrete system of equations (4.2) was obtained after seventeen Newton iterations and required just less than four minutes of CPU time. One Newton iteration was performed for each increment of the continuation variable α_c until it reached one, then four Newton iterations were required before the relative change in the solution reduced to less than 10^{-5}. The time required for each iteration ranged from 10.7 s to 16.9 s. Of this, the time for calculation of the Jacobian was consistently 7.2 s, but the time for solution of the linear system of equations ranged from 3.0 s when diffusion was significant, to 5.3 s when α_c reached one, to 9.2 s in the final iteration. Most of the remaining 0.5 s in each iteration was spent evaluating the residual in the nonlinear equations.

In the solution of the linear system of equations for each Newton iteration, GMRES iterations were performed until the residual in the linear system was reduced by a factor of 10^{-3}. There was an increasing trend in the number of GMRES iterations required to achieve this, from 111 iterations when diffusion was significant, to 170 when α_c reached one, to 251 in the final Newton iteration. This suggests that the condition number of the Jacobian may increase as the effect of diffusion decreases.

Although convergence in the solution to the nonlinear system was achieved reasonably easily in this simulation with these material parameters, when α_c was increased to represent a reduction in the effects of diffusion, convergence could be achieved for $\alpha_c = 1.06$ but not for $\alpha_c = 1.07$. This means that, if the material parameters were changed so that the relative magnitude of the diffusion term was reduced by more than six percent, artificial diffusion would be required to obtain convergence.

Part of the reason for the inability to achieve convergence when the diffusion term is small may be related to the lack of C^1 continuity in U at certain places in the mesh. A close inspection of the wavefront near the apex in Figure 5.1(c) reveals that the front is starting to form a point as it approaches the apex. This feature of the wavefront vanishes when more diffusion is introduced into the equation.

As discussed in section 3.3, when the diffusion effects become very small, the numerical method behaves as if it were solving an eikonal equation without a diffusion term. The appropriate equation to solve in this situation is the diffusionless propagation equation (3.1). Although the discrepancy between this and the eikonal equation was dealt with on boundaries in section 3.3, it was assumed that inside the domain the residuals in the two equations were equivalent. The residuals are only equivalent, however, if first derivatives are continuous. The C^1 constraint vanishes at the apex because the element widths vanish. Without C^1 continuity, the eikonal equation admits solutions where tissue is not necessarily excited by neighboring tissue. Wavefronts can initiate and spread out from any point in space where C^1 continuity is not enforced. This lack of uniqueness in the solution makes the Jacobian for Newton's method singular and therefore convergence unlikely. If simulations are to be performed with less diffusion, the numerical treatment of the advection term needs to more closely represent its form in (3.1).

If diffusion needs to be added to the equation in order to obtain a stable solution, high-order convergence rates can no longer be expected, and thus one might ask the question of what the advantage of high-order elements might be. To address this question, the cubic Hermite Petrov–Galerkin finite element scheme is compared with a simple finite difference scheme using first-order upwind differences for the advection term. A simple Taylor series analysis of first-order upwind differences shows that the coefficient of numerical diffusion is half the coefficient of the advection term multiplied by the grid point spacing, which resembles $\frac{1}{2}c_0\lambda h$. When doubling the physiological diffusion to stabilize the cubic Hermite scheme, the coefficient of additional diffusion resembles λ^2. In order to make the additional diffusion in the first-order scheme of similar magnitude, the grid point spacing must be given by $h = \frac{2\lambda}{c_0}$, or equivalently, the grid Péclet number P_e must be equal to 2. In the cubic model, the volume average of the geometric mean of the mesh Péclet numbers for each direction is 22, and the maximum Péclet number in any direction at any point is 116. An optimally designed first-order grid would have grid spacings of 0.64 mm in the fibre direction and 0.4 mm in the other directions. The 0.2×10^6 mm^3 myocardial volume would need to be represented by about 2×10^6 grid points. This is a factor of about 10^3 greater than the 2355 degrees of freedom in the cubic Hermite mesh.

6. Conclusions. An efficient computational model has been developed for the excitation process in ventricular myocardium. The need to represent the small-scale ionic activity is eliminated by modelling the excitation process as a propagating wavefront of depolarizing tissue.

A Petrov–Galerkin method using cubic Hermite elements has been developed to enable numerical solution of an eikonal equation for excitation time on a reasonably coarse mesh. The method is a weighted residual method with weights that are linear combinations of Galerkin weights and C^0 continuous supplementary weights based on the derivatives of the interpolation functions in the direction of propagation. For one-directional propagation, the error in the solution is within a small constant factor of the optimal error achievable in the trial space. To estimate the constant factor in the error bound, it was only necessary to consider the function in the trial space with highest frequency first derivative and its corresponding weighting function. A function of the mesh Péclet number was selected for the ratio of the Galerkin and supplementary weights so that this error factor is small for all values of the Péclet number.

For high Péclet numbers, the numerical solution of the eikonal-diffusion equation behaves as if there is no diffusion term. An eikonal equation determines the speed of propagation at each point in space but provides no constraint on the direction of propagation. Without the diffusion term, there is no longer any no-flux boundary condition, and spurious excitation can initiate at any point on the boundary. A no-inflow boundary term has been designed to provide a penalty on such spurious excitation.

Using a continuation method to gradually introduce the nonlinear term of the governing equation, seventeen Newton iterations were required to obtain the solution for a simulation in the full ventricular myocardium. The method showed instabilities when the effect of diffusion was very small, but the level of diffusion required for stability was much less than the level of numerical diffusion that would be introduced in a first-order upwind finite difference scheme with the same number of degrees of freedom.

INTERACTION OF THERMAL EXPLOSION AND NATURAL CONVECTION: CRITICAL CONDITIONS AND NEW OSCILLATING REGIMES*

T. DUMONT†, S. GÉNIEYS†, M. MASSOT†, AND V. A. VOLPERT†

Abstract. In this paper we investigate, numerically as well as analytically, the influence of natural convection on thermal explosion in a two-dimensional square vessel, filled with a reactant mixture, whose vertical walls are adiabatic and horizontal walls are infinitely conducting, preset at an equal temperature T_0. Natural convection enhances the heat losses at the boundaries while large temperatures tend to promote natural convection, thus yielding two competitive phenomena. The governing equations are taken to be the Navier–Stokes equations in the Oberbeck–Boussinesq approximation of low density variations coupled to the heat equation with an exponential chemical source term. This is valid because we consider a 1-step reaction with high heat release, we use the Frank-Kamenetskii transformation under high activation energy asymptotics, and we do not take into account thermo-diffusion as well as the different molar masses of the species. We solve the vorticity-stream function-temperature formulation with an alternating direction numerical method on finite difference approximations. The numerical results show the coexistence of 1-vortex and 2-vortex regimes, from which thermal explosion can occur. New regimes of thermal explosion are found when the Frank-Kamenetskii and Rayleigh parameters are close to the critical conditions for explosion and convection. Periodic-in-time solutions can exist from which thermal explosion can also occur. Linear stability analysis allows us to predict the onset of convection not too close to the explosion limit. Finally, we propose a model problem through a system of two ordinary differential equations which is able to reproduce the bifurcation behavior of the global system close to critical conditions for both explosion and convection.

Key words. thermal explosion, natural convection, stability and bifurcation analysis

1. Introduction.

The theory of thermal explosion has been investigated in numerous works (see [7], [15], [17], [21], [22], [24]). Thermal explosion denotes the rapid buildup of energy in systems subject to exothermic reactions, the rate of which rises with temperature. It is of practical importance in problems of fire and explosion safety.

The theory of thermal explosion begins with the works by van 't Hoff who formulated the basic principles of chemical reactions in the end of the 19th century. The first part of the development of this theory was terminated by 1930 due to the work by Semenov with collaborators (see [21], [22], [24]). They explained the physical mechanism of thermal and chain explosion and offered a simple mathematical model in order to get the critical conditions of explosion with a space-independent temperature.

The next step in the development of the theory begins with the works by Frank-Kamenetskii [7], [8] who proposed to consider a space-dependent temperature distribution with Dirichlet boundary conditions in a motionless fluid. He considered a 1-step reaction in the framework of large activation energy asymptotics under the

Volpert) and by a BQR Grant from the Université Claude Bernard, Lyon 1 (Project Coordinator: M. Massot).

large heat release assumption, so that the reactant depletion can be neglected. Thermal explosion is viewed as the nonexistence imposibility of a stationary solution. The study of this highly unstationary problem is then reduced to the study of the existence of stationary solutions. This approach was developed in a large number of physical and mathematical works (see [2], [17], [24], and the references therein).

Many other models have been developed further to take into account heterogeneous media [1] or coupling with hydrodynamics [15], [18]. This paper is a contribution to the latter. The influence of free convection on thermal explosion has not received much attention yet. In [15], Kagan et al. considered a forced convection in a two-dimensional (2D) vessel with a large aspect ratio and weakly conducting walls. Surprisingly enough, it is shown that convection can promote explosion. Merzhanov and Shtessel in [18] have investigated the influence of natural convection on thermal explosion in a 2D square vessel with infinitely conducting horizontal walls and adiabatic vertical walls. If the fluid is motionless, the maximal temperature is then at the center of the vessel, and if it is large enough, free convection appears. Free convection can inhibit explosion by enhancing the heat losses at the walls. Critical conditions for both explosion and convection have been investigated numerically as well as analytically with simple models using a single variable: the averaged temperature [18].

In this paper, we study the influence of natural convection on critical conditions for thermal explosion and extend the work by Merzhanov and Shtessel [18]. First, from the modeling point of view, we discuss the assumptions underlying the use of the Navier–Stokes equations for a frozen mixture composition under the Oberbeck–Boussinesq approximation with an exponential source term in the temperature equation. Second, for the considered configuration, with an aspect ratio of one, we show the coexistence of 1-vortex and 2-vortex modes and analyze the corresponding bifurcation diagrams; explosion can occur from both of these regimes. Third, the behavior of the system in a neighborhood of the point where the critical conditions of explosion and convection coincide is studied through comprehensive numerical simulation which was impossible 30 years ago. New regimes of thermal explosion are found when the Frank-Kamenestskii parameter is close to the critical one. Periodic-in-time solutions can exist so that thermal explosion can occur either from these oscillating solutions or from a stationary solution where natural convection is present. Numerical simulations in this neighborhood face several difficulties: high parameter sensitivity, possible oscillations, very slow convergence to stationary or periodic solutions, and possible explosion. Fourth, we perform a linear stability analysis on a simplified model which allows us to obtain a good description of the onset of natural convection far from the critical conditions for thermal explosion. We thus validate the code and gain physical insight into the main difference between the present situation, where the chemistry is coupled to the hydrodynamics and the classical Rayleigh–Bénard problem. Fifth, we propose a simplified model in order to describe the complex bifurcation behavior of the system: a system of two ordinary differential equations for the mean temperature and the maximal stream function. In the spirit of Semenov's theory, this simplified system contains a phenomenological heat losses coefficient. We show how the model problem is able to describe the appearance of stable limit cycles and explain the possible explosion either from oscillating or stationary solutions.

The paper is organized as follows: the modeling assumptions are detailed in section 2. Numerical method and simulations obtained with the comprehensive model are presented in section 3. We then propose simplified models in order to describe the observed phenomena. In section 4 we propose a linear stability analysis of a simplified model in order to find the onset of convection away from the critical conditions of

thermal explosion. Finally, section 5 is devoted to the bifurcation analysis of a model problem close to the critical conditions for both explosion and convection, and section 6 provides a discussion which makes the link between sections 3, 4, and 5, thus completely describing the qualitative behavior of the global system by the model problem.

2. General modeling of the problem.

2.1. Configuration. The configuration studied here is a 2D square vessel whose vertical walls are adiabatic and horizontal walls are infinitely conducting, filled with a reactant mixture. An equal constant temperature T_0 is preset at the horizontal walls. This configuration is similar to the one considered by Merzhanov and Shtessel in [18]. At the starting moment the fluid is at rest at temperature T_0. Either the fluid can encounter thermal explosion (a rapid buildup of temperature modeled in the Frank-Kamenetskii theory by a temperature blow-up) or, after a characteristic time, there exists a slowly varying solution (modeled in the Frank-Kamenetskii theory by a stationary solution at frozen composition) where chemical heat release is balanced by the heat losses through the walls. When no gravity is present, the stationary one-dimensional (1D) concave temperature profile possesses an analytical expression, the characteristics of which are given in subsection 2.2.

In the presence of gravity, the upper half-part of the domain is heated from below by the reacting mixture and beyond a certain stability limit, like in the Rayleigh–Bénard problem [6], [11], convection appears and enhances the heat losses.

The purpose of the present study is to couple the heat equation which governs the classical explosion limits to the hydrodynamics through natural convection. Before dealing with the modeling of the coupled problem, let us come back to the classical results.

2.2. Frank-Kamenetskii theory of thermal explosion. In the Frank-Kamenetskii theory, the explosion limit is determined by studying the existence of stationary solutions to the nondimensional heat equation:

$$\partial_\tau \theta = \partial_{zz}\theta + \mathrm{F_K} \exp\left(\frac{\theta}{1+\dfrac{\mathcal{R}T_0}{E}\theta}\right), \qquad z \in [0,2], \qquad \theta(0) = \theta(2) = 0, \tag{2.1}$$

where T is the temperature and $\theta = (T - T_0)/\mathcal{R}T_0^2/E$ is the temperature scaled by the Frank-Kamenetskii temperature $\mathcal{R}T_0^2/E$; t^* is the time variable and $\tau = t^*/\tau_\kappa$ the nondimensional time associated with the diffusion time $\tau_\kappa = L^2/\kappa_0$; $z = z^*/L$, 2L is the size of the domain and z^* the dimensional space variable; $\mathrm{F_K}$ is the Frank-Kamenetskii parameter defined as the ratio of the diffusion time τ_κ and of a chemical ignition time τ_{ch}:

$$\mathrm{F_K} = \frac{\tau_\kappa}{\tau_{ch}}, \qquad \tau_{ch} = \frac{\mathcal{R}T_0^2}{E\,(T_b - T_0)}\frac{1}{B}\exp\left(\frac{E}{\mathcal{R}T_0}\right), \tag{2.2}$$

where κ_0 is the thermal diffusivity at $T = T_0$, $T_b - T_0 = Q/\rho_0 c_{p0}$ is the adiabatic temperature of reaction, Q is the heat of reaction, ρ_0 is the density of the mixture, c_{p0} is the heat capacity at constant pressure, and at $T = T_0$, E is the activation energy, $\mathcal{R}$ the universal gas constant, and B the frequency factor of the Arrhenius-type reaction rate. Reactant depletion has already been neglected due to the fact that the characteristic time of reactant depletion is much longer than the characteristic time of temperature buildup under the assumption of large heat release, $(T_b - T_0)/T_0 >> \mathcal{R}T_0/E$.

The explosion limit will be described by the only Frank-Kamenetskii parameter. Under the assumptions of large activation energy $E/\mathcal{R}T_0 >> 1$, we can perform the Frank-Kamenetskii transform so that the nonlinear reaction rate in (2.1) is taken to be $\mathrm{F_K}\exp(\theta)$ [8], [24].

Thermal explosion is defined as the nonexistence of a stationary solution of equation (2.1) [7], [8], [24]. It can be shown that there exists a critical value $\mathrm{F_{K}}_c$ such that a stationary temperature profile exists if and only if the Frank-Kamenetskii parameter is below the critical value $\mathrm{F_K} \leq \mathrm{F_{K}}_c$. In this case an analytical expression of the stationary temperature profile as well as an exact formula for the maximal temperature as a function of $\mathrm{F_K}$ are available. The value of $\mathrm{F_{K}}_c$ is approximately 0.88. Beyond this value no stationary solution exists and the system is said to encounter thermal explosion. It is worth noting that the maximal temperature increase at the center of the vessel when a stationary solution exists is of the order of magnitude of the Frank-Kamenetskii temperature, which means that it is small compared to T_0 under the large activation energy assumption.

When gravity is present, fluid motion should be taken into account. For large Rayleigh numbers, free convection will possibly increase heat losses through the walls, thus yielding two competitive phenomena. In order to proceed with the study of such situations, we have to first provide a model for both hydrodynamics, dissipative phenomena, and chemical reactions. This is the purpose of the next section.

2.3. Governing equations. The most general set of equations governing multicomponent reactive fluid mixtures is a system of mixed hyperbolic-parabolic equations describing hydrodynamics, complex dissipation phenomena such as viscous dissipation, multicomponent mass, and heat diffusion, as well as chemistry [5], [12], [13].

The model chosen for the chemistry is a 1-step exothermic reaction in the context of negligible composition effects as in the original Frank-Kamenetskii theory. Consequently, out of the various coupled complex phenomena described by the comprehensive equations, we want only to retain hydrodynamics, viscous dissipation, heat conduction, the effect of gravity, and the heat release of the single chemical reaction as a heat source term. Composition effects due to complex chemistry, multicomponent diffusion, thermal diffusion, as well as stratification of the fluid due to the effect of gravity on species of different molecular weights, are out of the scope of this study. We further assume, for the sake of simplicity, that the heat capacities at constant pressure and at constant volume of the various components of the mixture are constant. The thermal conduction coefficient is assumed constant, $\lambda = \lambda_0$, as well as the thermal diffusivity, $\kappa = \kappa_{_0} = \frac{\lambda_0}{\rho_0 c_{p0}}$, the shear viscosity, $\mu = \mu_0$, and the kinematic viscosity, $\nu = \nu_{_0} = \frac{\mu_0}{\rho_0 c_{p0}}$. We neglect the bulk viscosity. The resulting set of equation is the usual compressible Navier–Stokes equations for a single fluid coupled to the heat equation with a chemical source term.

This system of equations is then considered in the limit of small density variations, also called the Oberbeck-Boussinesq approximation:

$$\partial_\tau\theta + u\,\partial_x\theta + v\,\partial_z\theta = \partial_{xx}\theta + \partial_{zz}\theta + \mathrm{F_K}\exp(\theta), \tag{2.3}$$

$$\partial_\tau u + u\,\partial_x u + v\,\partial_z u = -\partial_x\mathcal{P} + \mathrm{Pr}_{_0}(\partial_{xx}u + \partial_{zz}u), \tag{2.4}$$

$$\partial_\tau v + u\,\partial_x v + v\,\partial_z v = -\partial_z\mathcal{P} + \mathrm{Pr}_{_0}(\partial_{xx}v + \partial_{zz}v) + \mathrm{Pr}_{_0}\,\mathrm{Ra}_{_0}\,\theta, \tag{2.5}$$

$$\partial_x u + \partial_z v = 0. \tag{2.6}$$

The nondimensional quantities involved in the problem are

$$\tau = \frac{t^* w_0}{L}, \quad U = (u,v)^t = \frac{U^*}{w_0}, \quad \mathcal{P} = \frac{\mathcal{P}^*}{p_0}, \quad \theta = \frac{T - T_0}{\mathcal{R}T_0^2/E}, \tag{2.7}$$

$$w_0 = \frac{\kappa_0}{L}, \quad p_0 = \rho_0 \frac{\mathcal{R}}{\bar{m}} T_0, \quad \mathrm{Pr}_0 = \frac{\nu_0}{\kappa_0}, \tag{2.8}$$

where t^*, $U^* = (u^*, v^*)^t$, and $\mathcal{P}^*$ are the dimensional quantities, respectively, time, velocity vector, and perturbation of the pressure, and where $\bar{m}$ is the molar mass of the mixture. Also, Pr_0 is the Prandtl number, x and z are the horizontal and the vertical coordinates, u and v are the horizontal and the vertical components of the scaled velocity, and Ra_0 is the Rayleigh number. Denoting by g the gravity acceleration and recalling that the thermal expansion coefficient α of a perfect gas is the inverse of the temperature and that the typical temperature increase is of the order of the Frank-Kamenetskii temperature $\mathcal{R}T_0^2/E$, the Rayleigh number then reads as $\mathrm{Ra}_0 = \frac{gL^3 \mathcal{R}T_0/E}{\kappa_0 \nu_0}$. Problem (2.3)–(2.6) is considered in the square domain $0 \le x \le 2$, $0 \le z \le 2$ with the boundary conditions

$$x = 0, 2: \ \partial_x \theta = 0, u = 0, \partial_x v = 0; \qquad z = 0, 2: \ \theta = 0, \partial_z u = 0, v = 0. \tag{2.9}$$

The justification of the Oberbeck–Boussineq approximation of small density variations has been investigated in many works, under different assumptions on the state law of the fluid and on the geometry of the vessel [14], [19], [20], [23]. In a recent work by two of the authors [9], it is investigated for a general divariant state law, and a unified approach is presented for both liquids and gases. We restate the fundamental assumptions in the framework of thermal explosion in the following proposition.

PROPOSITION 1. *Let us consider a fluid layer of thickness $2L$ under gravity conditions, the vertical temperature field of which $T_S(z)$ is given by a stationary solution of equation* (2.1) *under the assumption $\mathrm{F_K} \le \mathrm{F_{K}}_c$. Let $\chi_0 = \gamma g L / c_0^2$ and assume that*

$$\chi_0 \ll \mathcal{R}T_0/E \ll 1, \tag{2.10}$$

where c_0 is the velocity of sound in the mixture and γ is the ratio of the heat capacity at constant pressure over the heat capacity at constant volume. Then there exists a static solution (i.e., a solution without convection) of the compressible Navier–Stokes equations $(\rho_S, p_S, T_S, U_S = 0)$ with $\partial_z p_S = -\rho_S g$, $z \in [0, 2L]$, $p_S(2L) = p_0$, $p_S = \rho_S \mathcal{R} T_S / \bar{m}$, which satisfies $(\rho_S - \rho_0)/\rho_0 \ll 1$. Further assume that

$$w_0 / \sqrt{gL\mathcal{R}T_0/E} = O(1), \quad \mathrm{Pr}_0 = O(1), \quad \chi_0 = O(\epsilon^{j+1}), \quad j \ge 1, \tag{2.11}$$

where $\epsilon = \frac{\mathcal{R}T_0}{E}$. Then the solution of the nondimensional compressible Navier–Stokes equations can be formally represented in the form

$$\bar{u} = u + O(\epsilon), \qquad \bar{v} = v + O(\epsilon), \qquad \bar{\theta} = \theta + O(\epsilon), \tag{2.12}$$

$$\bar{p} = 1 + p_{j+1}\epsilon^{j+1} + p_{j+2}\epsilon^{j+2} + O(\epsilon^{j+3}), \qquad \bar{\rho} = 1 - \theta\epsilon + O(\epsilon^2), \tag{2.13}$$

where $\partial_{(x,z)} p_{j+1} = -\chi_0 \epsilon^{-(j+1)} e_z$, e_z being the vertical unit vector directed upwards, and where the variables θ, u, v and $\mathcal{P} = \frac{p_{j+2}\epsilon^{j+2} c_0^2}{\gamma w_0^2}$ satisfy the system (2.3)–(2.6). *The nondimensional pressure $1 + p_{j+1}\epsilon^{j+1}$ and density 1 in equations* (2.13) *correspond to the static solutions p_S and ρ_S.*

3. Numerical simulations. For the model introduced in the previous section, we first present the numerical method and devote the next subsection to the results.

3.1. Numerical method. We consider a $\omega - \psi$ formulation of the equations; the problem (2.3)–(2.6) with (2.9) becomes

$$\partial_\tau \theta + u\partial_x \theta + v\partial_z \theta = \partial_{xx}\theta + \partial_{zz}\theta + \mathrm{F_K}\exp(\theta), \tag{3.1}$$

$$\partial_\tau \omega + u\partial_x \omega + v\partial_z \omega = \mathrm{Pr_0}(\partial_{xx}\omega + \partial_{zz}\omega) + \mathrm{Pr_0}\ \mathrm{Ra_0}\ \partial_x \theta, \tag{3.2}$$

$$\partial_{xx}\psi + \partial_{zz}\psi = -\omega, \tag{3.3}$$

where ψ is the stream function, ω the vorticity,

$$u = \partial_z \psi, \quad v = -\partial_x \psi.$$

The free surface boundary conditions become

$$x = 0, 2 :\ \partial_x \theta = 0, \psi = 0, \omega = 0; \qquad z = 0, 2 :\ \theta = 0, \psi = 0,\ \omega = 0. \tag{3.4}$$

Problem (3.1)–(3.4) is discretized using finite differences with an alternating directions method. For (3.1), this yields

$$\frac{\theta_{ij}^{n+1/2} - \theta_{ij}^{n}}{\tau/2} + u_{ij}^{n}\ \frac{\theta_{i+1,j}^{n+1/2} - \theta_{i-1,j}^{n+1/2}}{2h} + v_{ij}^{n}\ \frac{\theta_{i,j+1}^{n} - \theta_{i,j-1}^{n}}{2h}$$

$$= \frac{\theta_{i+1,j}^{n+1/2} - 2\theta_{i,j}^{n+1/2} + \theta_{i-1,j}^{n+1/2}}{h^2} + \frac{\theta_{i,j+1}^{n} - 2\theta_{i,j}^{n} + \theta_{i,j-1}^{n}}{h^2} + \mathrm{F_K}\exp(\theta_{i,j}^{n})$$

and

$$\frac{\theta_{ij}^{n+1} - \theta_{ij}^{n+1/2}}{\tau/2} + u_{ij}^{n}\ \frac{\theta_{i+1,j}^{n+1/2} - \theta_{i-1,j}^{n+1/2}}{2h} + v_{ij}^{n}\ \frac{\theta_{i,j+1}^{n+1} - \theta_{i,j-1}^{n+1}}{2h}$$

$$= \frac{\theta_{i+1,j}^{n+1/2} - 2\theta_{i,j}^{n+1/2} + \theta_{i-1,j}^{n+1/2}}{h^2} + \frac{\theta_{i,j+1}^{n+1} - 2\theta_{i,j}^{n+1} + \theta_{i,j-1}^{n+1}}{h^2} + \mathrm{F_K}\exp(\theta_{i,j}^{n}),$$

where τ is the time step and h the space step. Other equations are discretized similarly.

A continuation method is used to study existence and stability of stable stationary and periodic-in-time solutions. Among the three parameters of the problem $\mathrm{Pr_0}$, $\mathrm{Ra_0}$, and $\mathrm{F_K}$, the last two are more essential. So far, for a fixed value of the Prandtl number ($\mathrm{Pr_0} = 1$) we vary $\mathrm{Ra_0}$ and $\mathrm{F_K}$.

3.2. Numerical results. This subsection can be considered at the heart of our work: it introduces all the new physical behaviors of the considered configuration. We first present the state of the art by recalling the results of Merzhanov and Shtessel [18]. This allows us to roughly identify zones in the $\mathrm{Ra_0} - \mathrm{F_K}$ parameter plane where explosion is to be found. Convection appears as a supercritical bifurcation from a static solution when $\mathrm{F_K} < \mathrm{F_{K}}c$; we present the first results validating our code and emphasize that 1-vortex and 2-vortex convection regimes can coexist for a given value of the Frank-Kamenetskii number. We then focus on the behavior of the system around the bifurcation point of codimension 2 at $\mathrm{F_{K}}c$ and $\mathrm{Ra}_c(\mathrm{F_{K}}c)$, and identify new oscillating regimes, which can be periodic or lead to explosion. We finally present some results on the unstationary behavior of the system in the last subsection.

3.2.1. The diagram of Merzhanov and Shtessel. Let us first come back to the work by Merzhanov and Shtessel and summarize their results. They have shown by direct numerical simulation the existence of four regions in the Rayleigh/Frank-Kamenetskii parameter plane. In region I, there exists a stationary solution in a static fluid while in region II, a stationary solution exists in a moving fluid. In region III, thermal explosion arises from a moving fluid, whereas in region IV thermal explosion arises from a static one. The boundary between regions I and IV is predicted by the Frank-Kamenetskii theory and given by $\mathrm{F_K}_c \approx 0.88$. The interesting scenario takes place in region II for the Frank-Kamenetskii parameter bigger than the critical value. Convection enhances the heat losses at the boundaries, thus inhibiting explosion. The limit between III and IV is difficult to locate since convection is always enhanced by the blow-up of the temperature so that it is difficult to decide if convection started just before or during thermal explosion. These regions were characterized in [18] and several simple models were provided in order to describe the behavior of the solutions in the various regions. However, the only convection regime considered in this paper is a 2-vortex regime. Besides, because of computation limitations, the detailed behavior at the point where the four regions merge is not studied. We first show, in the next subsection, that there exists also a 1-vortex solution. Moreover, 1- and 2-vortex regimes can coexist; explosion can occur from both of these regimes.

3.2.2. Two regimes: One or two vortices. Consider first the case where $\mathrm{F_K} < \mathrm{F_K}_c$. There exists a static solution. For Ra_0 sufficiently large, it loses stability and a convective regime appears. The bifurcation diagram is usual for convection problems. The maximum of the stream function $\psi_{\max}$ is roughly proportional to $\sqrt{\mathrm{Ra}_0 \bar{\theta} - \mathrm{Ra}_c}$ as represented on Figure 1 and as will be shown in subsection 5.5, where Ra_c is the critical value of the Rayleigh number and $\bar{\theta}$ is the averaged temperature in the vessel. The supercritical bifurcation can also be observed on a $(\psi_{\max}, \mathrm{Ra}_0)$-plane. At the same time the mean temperature decreases when Ra_0 increases. As can be expected, an increase of $\mathrm{F_K}$ results in an increase of the mean temperature and of the maximum of the stream function. It decreases the critical Rayleigh number (see Figure 1).

In the present configuration (2D square domain), only 1-vortex and 2-vortex solutions are observed. The solution bifurcating from the static solution has only one vortex which fills practically the whole domain being slightly moved to its upper part. For Ra_0 larger than a critical value $\mathrm{Ra}_{1,2}$, a transition from a 1-vortex solution to a 2-vortex solution is observed. Decreasing Ra_0 and using the 2-vortex regime as an initial condition, we observe a reverse transition to a 1-vortex solution but for $\mathrm{Ra}_{2,1} < \mathrm{Ra}_{1,2}$. Note that the number and position of the vortices depend on the geometry of the vessel and that, in the present situation, there exists a parameter range $\mathrm{Ra}_0 \in [\mathrm{Ra}_{2,1}, \mathrm{Ra}_{1,2}]$, where the two regimes 1-vortex and 2-vortex coexist.

Now consider the case $\mathrm{F_K} > \mathrm{F_K}_c$, which means that no static solution is to be found. For Ra_0 large enough, a 2-vortex solution exists (see Figure 2; $\mathrm{F_K} = 0.9$ and $\mathrm{F_K} = 1.0$). For $\mathrm{F_K} = 0.9$, decreasing Ra_0 leads to a transition to a 1-vortex regime and finally leads to explosion. However, for $\mathrm{F_K} = 1.0$, decreasing Ra_0 directly leads to an explosion from this 2-vortex regime. It can be shown by a proper choice of the initial condition that a 1-vortex solution can still be reached; if we increase Ra_0 from this 1-vortex solution, we jump onto the 2-vortex solution; a decrease of Ra_0 leads to an explosion from this 1-vortex regime. Again, one can observe the existence of a Ra_0 range for which the 1-vortex regime and the 2-vortex regimes coexist. It has to be noticed that the symbols used in Figure 2 for a 1-vortex or a 2-vortex regime do not

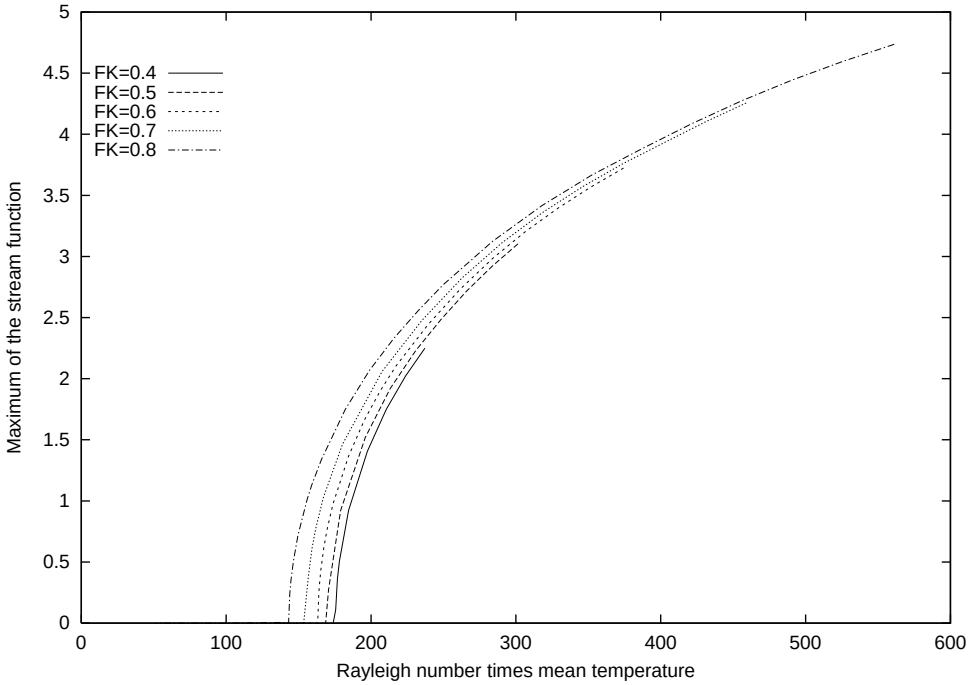

FIG. 1. *Convective regime bifurcating from the static solution for five values of the* $\mathrm{F_K}$ *parameter below the critical conditions: maximum of the stream function versus effective Rayleigh number* $\mathrm{Ra}_0\bar{\theta}$.

reproduce any real temperature or stream function field.

For Frank-Kamanetskii numbers slightly above the critical value for the existence of a stationary solution, a general scenario can be proposed. Decreasing Ra_0 leads to a decrease of the maximum of the stream function (and to an increase of the mean temperature) until a minimum is reached (see Figure 2). A further decrease of Ra_0 yields a great increase of the mean temperature and of the maximal stream function until explosion is obtained and the stationary solution disappears (see Figure 2).

3.2.3. Oscillating thermal explosion around critical conditions. From the previous subsections, one could think that all scenarios have been covered. However, a closer look at the neighborhood of the point $(\mathrm{F_{K}}_c, \mathrm{Ra}_c(\mathrm{F_{K}}_c))$ reveals a rich nonlinear behavior.

We consider three values of $\mathrm{F_K}$, two above $\mathrm{F_{K}}_c$, 0.8775 and 0.88, and one below, 0.875. Starting from values of Ra_0 for which a convective stationary solution is observed numerically, we continue this solution using Ra_0 as a bifurcation parameter.

For $\mathrm{F_K} = 0.88$, decreasing Ra_0 successively yields a decrease and then an increase of $\theta_{\max}$, appearance of a periodic-in-time mode, an increase and then a decrease of the oscillations amplitude, reappearance of a stationary solution, and explosion. For the periodic solution, the maximal temperature also oscillates and can reach the value $\theta_{\max} \simeq 2.0$, which is much larger than the critical value 1.2 of the Frank-Kamenetskii theory (see Figure 3).

For $\mathrm{F_K} = 0.8775$, one again observes the appearance of a periodic solution with an increase of the oscillations, but then there is an explosion from the oscillating solution

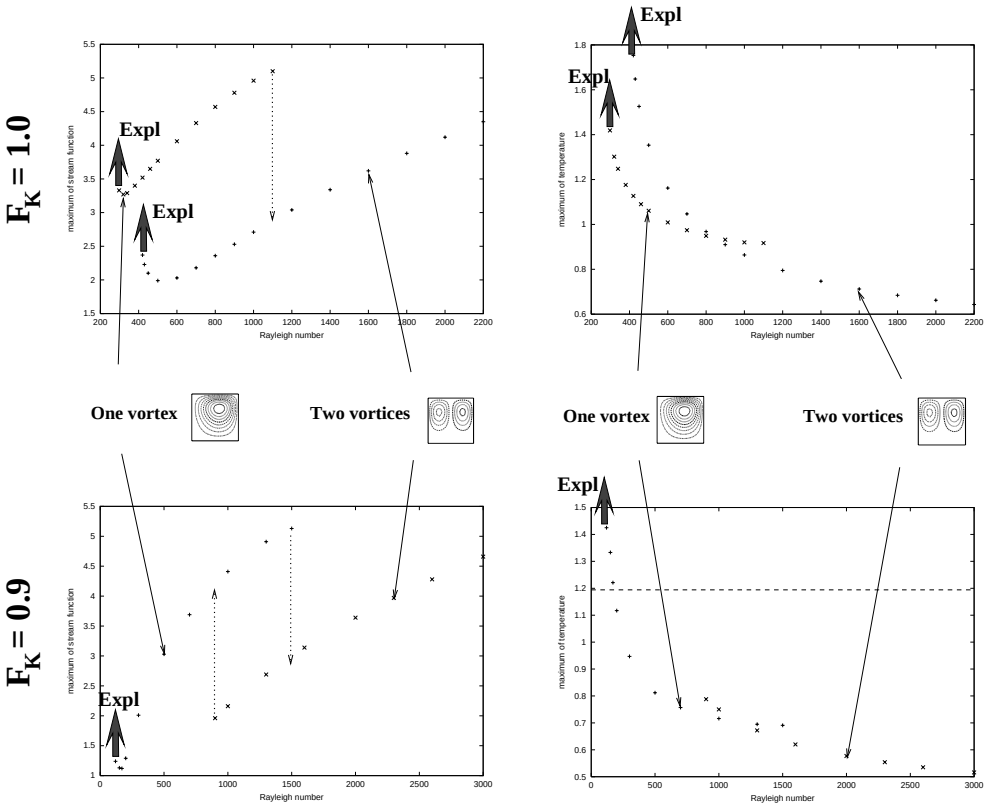

FIG. 2. *Explosion from* 1*-vortex or* 2*-vortex regimes for* $\mathrm{F_K} = 0.9, 1.0$*; on the left the maximal stream function is represented; on the right, the maximal temperature is represented; explosion is indicated by a vertical arrow.*

(see Figure 3). Using proper initial conditions permits us to follow the end of this branch: oscillations decrease, stationary solution appears again, and then explosion occurs from the stationary solution (see Figure 3). Let us mention that for this value of $\mathrm{F_K}$, the period of oscillations is very large as will be seen in the next subsection.

For $\mathrm{F_K} = 0.875$, the branch on the right reaches the nonconvective stationary solution at $\mathrm{Ra}_0 = 163$. Further decreasing the value of the Rayleigh number results in a straight line on Figure 3, since no convection is present and we plot only the maximal value of the temperature profile without convection for various values of Ra_0. We could think that for the parameter range $\mathrm{Ra}_0 \in [110, 163]$, the previous branch is the only branch. However, two striking scenarios also appear for $\mathrm{F_K} = 0.875$ for some Rayleigh numbers smaller than Ra_c. Besides the stable static solution for this value of $\mathrm{F_K}$ below the critical value, other stable solutions exist, both stationary or with periodic oscillations, and can be reached by using proper initial conditions (see Figure 3). One observes thermal explosion either from a periodic oscillating solution (increasing Ra_0) or from a stationary convective solution (decreasing Ra_0). This is all the more surprising since intuition predicts that convection should inhibit explosion by enhancing the heat losses through the boundaries. In this case, convection promotes explosion. An explanation for the presence of this branch of solutions can be suggested. In the situation without convection, for $\mathrm{F_K} < \mathrm{F_K}_c$, there exists two branches of solutions, one stable and one unstable with higher temperature; these

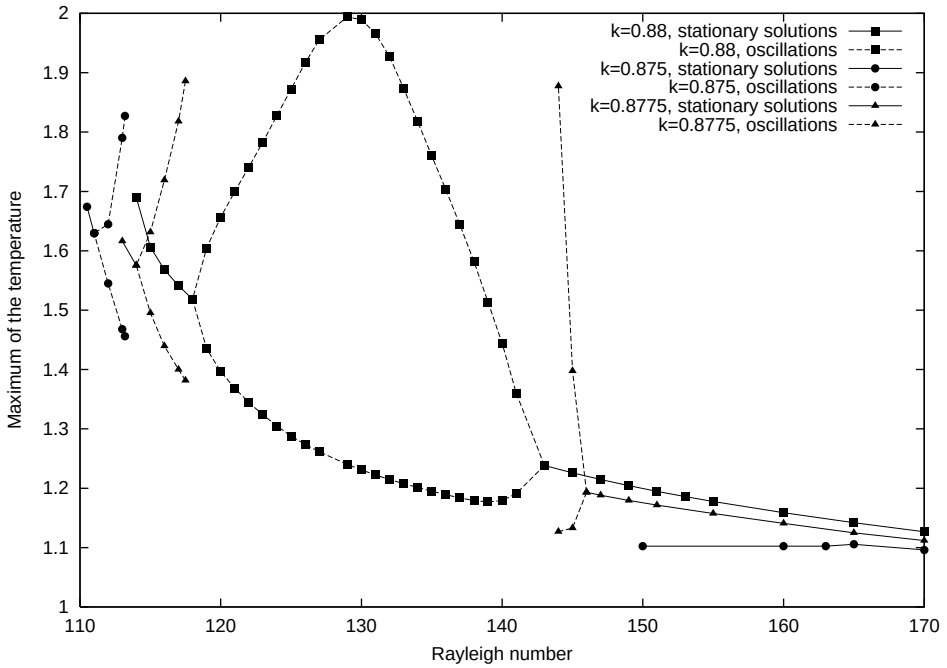

FIG. 3. *Stationary solutions, periodic-in-time solutions, and oscillating explosion. For stationary solutions, only one point is plotted associated with the maximal temperature versus* Ra_0*; for periodic solutions, we have plotted the maximum and the minimum of the maximal temperature in the vessel versus* Ra0 *(the branches of stationary unstable solutions corresponding to these periodic solutions are not represented).*

two branches join at the bifurcation point $\mathrm{F_K} = \mathrm{F_{K}}_c$. The piece of the stable branch observed for small Rayleigh numbers at $\mathrm{F_K} = 0.875$ could be the stabilization by convection of this unstable nonconvective branch for $\mathrm{F_K}$ close to $\mathrm{F_{K}}_c$.

3.2.4. Unstationary behavior. The purpose of this subsection is to describe the unstationary behavior of the oscillating solutions previously identified. We focus on value $\mathrm{F_K} = 0.8775$, the richest scenario.

We first present the growth of the oscillations when we start from a stationary convective solution at $\mathrm{Ra}_0 = 147$ and set at $t = 0$, $\mathrm{Ra}_0 = 145$. Figure 4 describes the path to the periodic oscillating solution. The very slow growth is related to the closeness to the Hopf bifurcation. More interesting is the analysis of the periodic solution; almost all the time (about 90%) the solution is close to a static one and periodically, with a very long period compared to the nondimensional time, it almost explodes, and $\psi_{\max}$ and $\bar{\theta}$ reach their maximal value.

The second point is related to the thermal explosion from a periodic oscillating solution on the other side of the branch at $\mathrm{Ra}_0 = 117.5$. In Figure 5(a) we have represented the mean temperature, the maximal temperature, and the maximal stream function, first for the periodic oscillating solution at $\mathrm{Ra}_0 = 117.5$. We then set, at $t = 0$, $\mathrm{Ra}_0 = 118$, and represent on the second figure Figure 5(b) the evolution of the previous three quantities. The system goes on its periodic trajectory for another period and then it explodes. The explosion behavior is very different from the one on the other side of the branch.

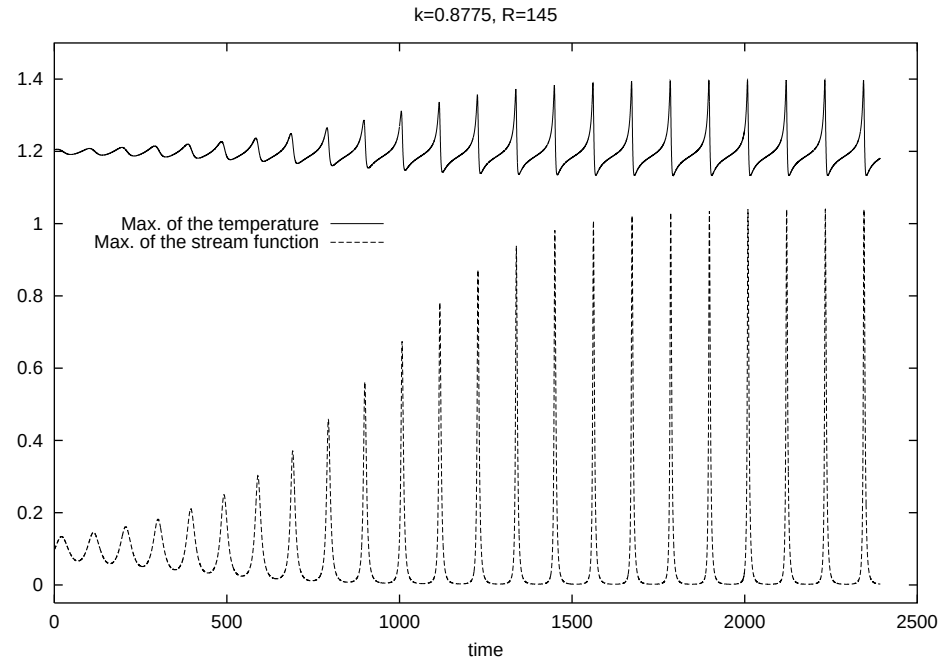

FIG. 4. *Growth and stabilization of the oscillation at* $\mathrm{Ra}_0 = 145$*: maximal temperature (solid line) and maximal stream function (dashed line) versus time.*

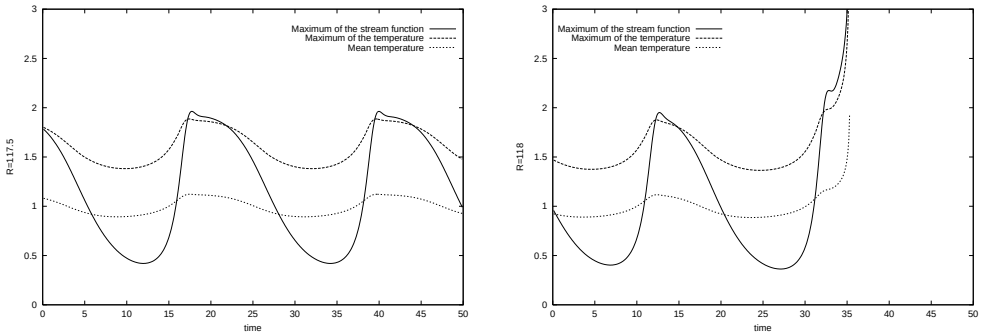

(a) (b)

FIG. 5. (a) *Periodic solution at* $\mathrm{Ra}_0 = 117.5$ *and* (b) *oscillating explosion at* $\mathrm{Ra}_0 = 118$ *(solid line: maximal stream function, dotted line: mean temperature, dashed line: maximal temperature).*

In conclusion, we point out that taking into account fluid motion when studying explosion reveals new phenomena—periodic-in-time solutions and explosion either from these solutions or from stationary solutions. These features happen for $\mathrm{F_K}$ and Ra_0 close to their critical value. A simplified system is proposed in section 5 in order to investigate, analyze, and reproduce these phenomena.

4. Linear stability analysis for a simplified model for $\mathbf{F_K < F_{Kc}}$. The purpose of this section is to perform a linear stability analysis on a simplified model, which allows us to obtain a good estimate of Ra_c (the critical value of Ra_0 for fixed $\mathrm{F_K} < \mathrm{F_{K}}_c$) for the onset of natural convection. It is another validation of the code, but

more specifically it allows us to gain physical insight on the main difference between the present situation, where the chemistry is coupled to the hydrodynamics, and the classical Rayleigh–Bénard problem.

The linear stability analysis of system (3.1)–(3.4) around the nonconvective solution is well known for a nonreactive fluid in the Rayleigh–Bénard configuration (see, e.g., [3], [4], [6], [10], [11]).

We start in the same manner; problem (2.3)–(2.6), (2.9) is linearized about a static solution $\theta_S(z)$, $u = v = 0$, which depends only on the vertical coordinate. Using simple algebra, pressure can be eliminated; it yields

$$\partial_\tau \theta = \Delta\theta + F'(\theta_S)\,\theta - \theta_S' v, \tag{4.1}$$

$$\partial_\tau \Delta v = \mathrm{Pr}_0\,\Delta\Delta v + \mathrm{Pr}_0\,\mathrm{Ra}_0\,\partial_{xx}\theta, \tag{4.2}$$

where $F(\theta_S)$ denotes the reaction rate. In the present section, it is assumed to be affine with respect to θ_S,

$$F(\theta_S) \simeq \mathrm{F_K}\,(1 + \theta_S), \tag{4.3}$$

which is valid for small θ_S and leads to simple computations. The boundary conditions are the same as in the classical analysis [6], [11].

We look for the solution of (4.1)–(4.3) of the form $\theta(x,z,t) = \tilde\theta(z)e^{-\lambda\tau}\cos(kx)$, $v(x,z,t) = \tilde v(z)e^{-\lambda\tau}\cos(kx)$, where $k = \pi m/2$, $m = 1, 2, \ldots$, which yields the eigenvalue problem

$$-\lambda\tilde\theta = \tilde\theta'' - k^2\tilde\theta + \mathrm{F_K}\,\tilde\theta - \theta_S'\tilde v, \tag{4.4}$$

$$-\lambda(\tilde v'' - k^2\tilde v) = \mathrm{Pr}_0\,(\tilde v'''' - 2k^2\tilde v'' + k^4\tilde v) - \mathrm{Pr}_0\,\mathrm{Ra}_0\,k^2\tilde\theta, \tag{4.5}$$

with the boundary conditions

$$z = 0, 2 : \tilde\theta = 0,\ \tilde v = \tilde v'' = 0. \tag{4.6}$$

The convective instability boundary can be found from the condition that the eigenvalue λ with the minimal real part is zero. In the present study, these eigenvalues are not computed exactly but are approximated.

With the approximation (4.3) the static solution $\theta_S(z)$ can be found explicitly. However, even in this case, problem (4.4)–(4.6) does not give a simple expression for λ. Hence $\theta_S(z)$ is approximated by the first term of its Fourier series (it can be verified that the second term is already essentially less than the first one): $\theta_S(z) \simeq \frac{2}{\pi}\sigma\sin(\frac{\pi z}{2})$ so that $\theta_S'(z) \simeq \sigma\cos(\frac{\pi z}{2})$ with $\sigma = \dfrac{8\mathrm{F_K}}{\pi^2 - 4\mathrm{F_K}}$. Note that σ is well defined if $\mathrm{F_K} < \pi^2/4$, which is satisfied for $\mathrm{F_K} < \mathrm{F}_{\mathrm{K}c}$.

We look for the solution $\tilde\theta$ and $\tilde v$ of (4.4)–(4.6) in the form of Fourier series

$$\tilde\theta = \sum_{n=1}^{+\infty} b_n \sin\left(\frac{\pi n z}{2}\right), \qquad \tilde v = \sum_{n=1}^{+\infty} c_n \sin\left(\frac{\pi n z}{2}\right)$$

and assume $\lambda = 0$. It leads to the infinite system for the coefficients c_n:

$$c_2 = -\gamma_1 c_1,$$

$$c_{n-1} + c_{n+1} = -\gamma_n c_n, \qquad n = 2, 3, \ldots.$$

TABLE 1
Values of Ra_c *given by* (4.7) *and by the numerical simulations.*

$\mathrm{F_K}$	0.4	0.5	0.6	0.7	0.8
numerical Ra_c	1025	740	547	408	280
analytical Ra_c	922	735	558	446	340
$658/\theta^{\max}$	2680	1999	1532	1178	879

Here

$$\gamma_n = \frac{\mathrm{Ra}_n}{\mathrm{Pr}_0 \mathrm{Ra}_0}, \quad \mathrm{Ra}_n = \frac{2\mathrm{Pr}_0}{\sigma k^2}\left(\left(\frac{\pi n}{2}\right)^2 + k^2\right)^2 \left(\left(\frac{\pi n}{2}\right)^2 + k^2 - \mathrm{F_K}\right).$$

The critical Rayleigh number Ra_c is given by the condition that the determinant of this infinite system of equations equals zero. To find Ra_c explicitly we have to truncate the system. Taking only two equations ($c_3 = 0$) leads to

$$\mathrm{Ra}_c^2 = \mathrm{Ra}_1 \mathrm{Ra}_2, \tag{4.7}$$

while for three equations ($c_4 = 0$),

$$\mathrm{Ra}_c^2 = \frac{\mathrm{Ra}_1 \mathrm{Ra}_2 \mathrm{Ra}_3}{\mathrm{Ra}_1 + \mathrm{Ra}_3},$$

which is close to $\mathrm{Ra}_1 \mathrm{Ra}_2$ if $\mathrm{Ra}_3 >> \mathrm{Ra}_1$.

It can be easily verified that if $\mathrm{Ra}_{n+1} \gg \mathrm{Ra}_n$, $n = 2, 4, \ldots$, then each successive approximation will be close to the previous one. In the case $k = \pi/2$ ($m = 1$), these conditions are satisfied and one can use the approximation (4.7).

In Table 1, the values of Ra_c given by (4.7) are compared with the numerical results for various values of $\mathrm{F_K}$. It is interesting to note that the agreement is pretty good far from the critical conditions for explosion; it gets worse when we get really close to $\mathrm{F}_{\mathrm{K}c}$ even if the estimate for $\mathrm{F_K} = 0.8$ is still correct up to 20%.

Note that these values of Ra_c are much smaller than $658/\theta^{\max}$ as stated in Merzhanov and Shtessel [18] and given in the third row. (658 is the critical Rayleigh number for the Rayleigh–Bénard problem in an infinite layer with free surface boundary conditions.) Actually, $658/\theta^{\max}$ would be a good approximation of Ra_c if the temperature profile were linear in the upper part of the domain, as it is in the original Rayleigh–Bénard problem. The present study shows that the nonlinear temperature profile yields quite different values of Ra_c.

5. Model problem, bifurcation analysis. In the previous section, we have considered the behavior of the system away from the explosion limit. We investigate, in the present section, a model problem to describe the observed oscillatory instability, the Hopf bifurcations, and the oscillating explosion close to the critical conditions for both convection and explosion (see subsection 3.2.3).

A similar attempt was performed in [18]; however, they wanted only to describe the nonlinear variations of the heat losses at the boundaries due to natural convection. Consequently, the authors used one differential equation on a variable representing the mean temperature, and the heat losses coefficient α was a nonlinear function of this characteristic temperature taking into account the effect of natural convection.

Here we want to describe a complex bifurcation behavior, and a single equation is not able to reproduce, for example, the observed limit cycles. We thus consider the

following model problem of two ordinary differential equations:

$$\mathrm{d}_t\bar{\theta} = F(\bar{\theta}) - \alpha\big(|\psi_{\max}|\big)\bar{\theta}, \tag{5.1}$$

$$\mathrm{d}_t\psi_{\max} = -a\psi_{\max}(\psi_{\max}^2 + \delta^2(\theta_c - \bar{\theta})), \tag{5.2}$$

where $\bar{\theta}$ and $\psi_{\max}$ correspond to the mean value of the temperature and the maximum value of the stream function, and a, δ, and θ_c are positive constants. It has to be noticed that α, a, δ, and θ_c also depend on the parameter Ra_0.

Equation (5.1) describes the heat balance between heat production due to the reaction and heat loss through the boundaries. It is almost the same as in Semenov's theory of thermal explosion with the difference that the coefficient α is not constant; $\alpha(|\psi_{\max}|)$ is now a function of the maximal stream function and depends on the Rayleigh number as a parameter.

Equation (5.2) describes a supercritical bifurcation of convective solutions. If $\bar{\theta} < \theta_c(\mathrm{Ra}_0)$, then there is only one solution $\psi_{\max} = 0$. If $\bar{\theta} > \theta_c$, then there are also two other solutions $\psi_{\max} = \pm\delta\sqrt{\bar{\theta} - \theta_c}$.

In the Rayleigh–Bénard problem, the Rayleigh number reads $\mathrm{Ra} = \dfrac{gL^3\alpha_0\Delta T}{\kappa_0\nu_0}$, where the static temperature profile is a linear function of z leading to a temperature difference of ΔT, where α_0 is the thermal expansion coefficient ($1/T_0$ in the present case of a perfect gas). In the present study, the static temperature profile is highly nonlinear as already observed in the analytical study of the critical Rayleigh number (section 4). We then consider an effective Rayleigh number based on the averaged temperature $\mathrm{Ra} = \dfrac{gL^3\bar{\theta}\mathcal{R}T_0/E}{\kappa_0\nu_0} = \mathrm{Ra}_0\bar{\theta}$, where $\mathrm{Ra}_0 = \dfrac{gL^3\mathcal{R}T_0/E}{\kappa_0\nu_0}$; besides, from subsection 3.2, we know that for a stationary convective solution, $\psi_{\max} = b\sqrt{\mathrm{Ra} - \mathrm{Ra}_c} = b\sqrt{\mathrm{Ra}_0}\sqrt{\bar{\theta} - \bar{\theta}_c}$, with $\bar{\theta}_c = \mathrm{Ra}_c/\mathrm{Ra}_0$, so that $\delta = b\sqrt{\mathrm{Ra}_0}$. We then consider $\tilde{\psi} = \psi_{\max}/\delta$ with $\tilde{a} = a\delta^2$. In what follows we omit the tildes for the equation on $\tilde{\psi}$ and the bars for the equation on $\bar{\theta}$ for the sake of simplicity and the system reads as follows:

$$\mathrm{d}_t\theta = F(\theta) - \alpha\big(|\psi|\big)\theta, \tag{5.3}$$

$$\mathrm{d}_t\psi = -a\psi(\psi^2 + \theta_c - \theta). \tag{5.4}$$

5.1. Various modeling of the heat losses α. In this paper, we consider two models for the description of the heat losses coefficient α. The first one is a very simplified model:

$$\alpha(|\psi|) = \alpha_0(1 + \mu|\psi|^2), \tag{5.5}$$

where μ is the sensitivity of the heat losses coefficient α on convection; it can depend on the parameter Ra_0. For this model, it is possible to define analytically the critical conditions in terms of μ, θ_c, and α_0 (see subsection 5.3). However, even if this model reproduces the existence of stable limit cycles and Hopf bifurcations, it occurs in such a narrow parameter range that it makes the comparison with the original partial differential equation model difficult. This is the reason why we introduce a second model; it is based on the study [18] where a formula is provided in order to approximate the heat losses coefficient in the configuration of high Rayleigh numbers Ra and for a nonreactive problem:

$$\alpha = \alpha_0\left(1 + \frac{\mu\mathrm{Ra}^n}{\mathrm{Ra} + \gamma}\right). \tag{5.6}$$

In the present situation, when Ra_0 is reaching Ra_c, where the supercritical bifurcation is taking place, the modification of α_0 should approach zero so that Ra, in (5.6), has to be replaced by $\mathrm{Ra}_0\theta - \mathrm{Ra}_c$, which can be rewritten for stationary convective solutions: $\mathrm{Ra}_0(\theta - \theta_c) = \mathrm{Ra}_0\psi^2$. Finally we consider the model:

$$\alpha(|\psi|) = \alpha_0\left(1 + \frac{\mu\,\mathrm{Ra}_0^{n-1}|\psi|^{2n}}{|\psi|^2 + \gamma/\mathrm{Ra}_0}\right); \tag{5.7}$$

we will consider essentially $n = 1$ and assume that the sensitivity of the heat losses coefficient to the convection μ depends on the parameter Ra_0.

For this second model, we will show that the parameter range for the existence of a stable limit cycle starting at the Hopf bifurcation is larger; besides, this model is able to reproduce the existence of a stable limit cycle between two Hopf bifurcations, the oscillations amplitude of which are first increasing and then decreasing without leading to explosion (sections 5.4 and 6).

5.2. Conditions for Hopf bifurcation. Let us now study the stability of a stationary solution (θ_S, ψ_S). We will show that the presence of oscillations (as observed in section 4) can be described by the model problem (5.3)–(5.4) under some assumptions. Consider the linearized system

$$\mathrm{d}_t\theta = F'(\theta_S)\theta - \alpha(|\psi_S|)\theta - \alpha'(|\psi_S|)\theta_S\psi, \tag{5.8}$$

$$\mathrm{d}_t\psi = a\psi_S\theta - 2a\psi_S^2\psi. \tag{5.9}$$

It has purely imaginary eigenvalues $\pm i\phi$ if

$$F'(\theta_S) - \alpha(|\psi_S|) - 2a\psi_S^2 = 0, \tag{5.10}$$

$$-2a\psi_S^2(F'(\theta_S) - \alpha(|\psi_S|)) + a\psi_S\alpha'(|\psi_S|)\theta_S = \phi^2. \tag{5.11}$$

Consider first equation (5.10). It cannot have solutions if $\theta_S < \theta^*$, where θ^* is the critical temperature for the Semenov's theory of thermal explosion given by the equalities

$$F(\theta^*) = \alpha^*\theta^*, \qquad F'(\theta^*) = \alpha^*.$$

Indeed, in this case

$$F'(\theta_S) - \alpha(|\psi_S|) < F'(\theta_S) - \alpha^* < 0.$$

If $\theta_S > \theta^*$, then $F'(\theta_S) > \alpha^*$ and (5.10) may be satisfied. We have

$$F'(\theta_S) - \frac{F(\theta_S)}{\theta_S} - 2a(\theta_S - \theta_c) = 0, \tag{5.12}$$

$$-4a^2\psi_S^4 + a\psi_S\alpha'(|\psi_S|)\theta_S = \phi^2. \tag{5.13}$$

Equation (5.12) and the inequality

$$\theta_S > \frac{4a\psi_S^3}{\alpha'(|\psi_S|)}$$

obtained from (5.13) determine conditions when the system (5.8), (5.9) has purely imaginary eigenvalues. These conditions can be satisfied on decreasing branches of the maximal value of the stationary stream function $\psi(\mathrm{Ra}_0)$ due to the fact that θ_c is inversely proportional to Ra_0.

5.3. Analysis of the first model. Let us first define the critical conditions as well as the conditions for Hopf bifurcation in the case of $\alpha(|\psi|) = \alpha_0(1 + \mu|\psi|^2)$. Concerning the critical conditions, θ_{LP} (LP for "limit point" or critical point) satisfies

$$(\theta_{LP} - \theta_c)^2 + (\theta_{LP} - \theta_c)(\beta + \sigma) + \beta\sigma - 1 = 0, \quad \beta = \theta_c - 1, \quad \sigma = 1/\mu - 1, \tag{5.14}$$

which always has real solutions with only one above θ_c,

$$\theta_{LP} - \theta_c = -\frac{\beta + \sigma}{2} + \sqrt{1 + \left(\frac{\beta - \sigma}{2}\right)^2}. \tag{5.15}$$

Conditions for Hopf bifurcation then read as

$$\frac{\exp(\theta_H)}{\theta_H} = \alpha_0(1 + \mu(\theta_H - \theta_c)) = 2a\frac{\theta_H\theta_c}{\theta_H - 1}, \tag{5.16}$$

$$-4a^2\psi_H^4 + 2a\psi_H^2\alpha_0\mu\theta_H = \phi^2, \qquad \theta_H > \frac{2a\psi_H^2}{\alpha_0\mu}, \tag{5.17}$$

where the H subscript corresponds to the point of Hopf bifurcation. The last inequality reduces to $\theta_H < \frac{2a\theta_c}{2a-\alpha_0\mu}$ if $2a - \alpha_0\mu > 0$; it is always true if $2a - \alpha_0\mu \leq 0$. For the Hopf bifurcation to take place, it is then necessary that

$$\left(-\frac{2a}{\alpha_0\mu} + \beta + \frac{1}{\mu}\right)^2 \geq \frac{4\beta}{\mu}. \tag{5.18}$$

The analysis of the trajectories of system (5.3), (5.4) using CONTENT [16] shows that there exist three qualitatively different situations depending on the choice of parameters: decaying oscillations where a trajectory converges to a stable focus (Case A of Figure 6), oscillations with increasing amplitude from an unstable stationary point and an oscillating explosion (Case C of Figure 6), and, in between these two, slowly decreasing oscillations from an unstable limit cycle decaying to a stable focus or slowly increasing oscillations from this unstable limit cycle yielding to explosion (Case B of Figure 6).

Decaying and growing oscillations were also observed for the complete problem (section 3). Stable periodic oscillations apparently observed for it are not found directly for the model problem by simply changing the parameters and following the trajectories. This is due to the fact that the parameter range corresponding to the existence of a stable limit cycle is extremely small even if we know from the Hopf theorem that it is not reduced to an interval of zero length.

We then conducted a more detailed analysis using limit cycle continuation in order to detect the point where an unstable limit cycle is merging with a stable one. The complete bifurcation diagram is given on Figure 6, where the corresponding phase portraits are provided at the bottom.

The main problem with this model is the very narrow parameter range where a stable limit cycle is to be found. It is all the more difficult when α_0 is becoming smaller. The idea was then to switch to another model where the parameter sensitivity is a little lower due to saturation phenomena: model 2.

5.4. Analysis of the second model. The second model is introduced because it brings three new features. The parameter range where stable limit cycles exist is larger. It is also due to the fact that the stable limit cycle reaches the loop of

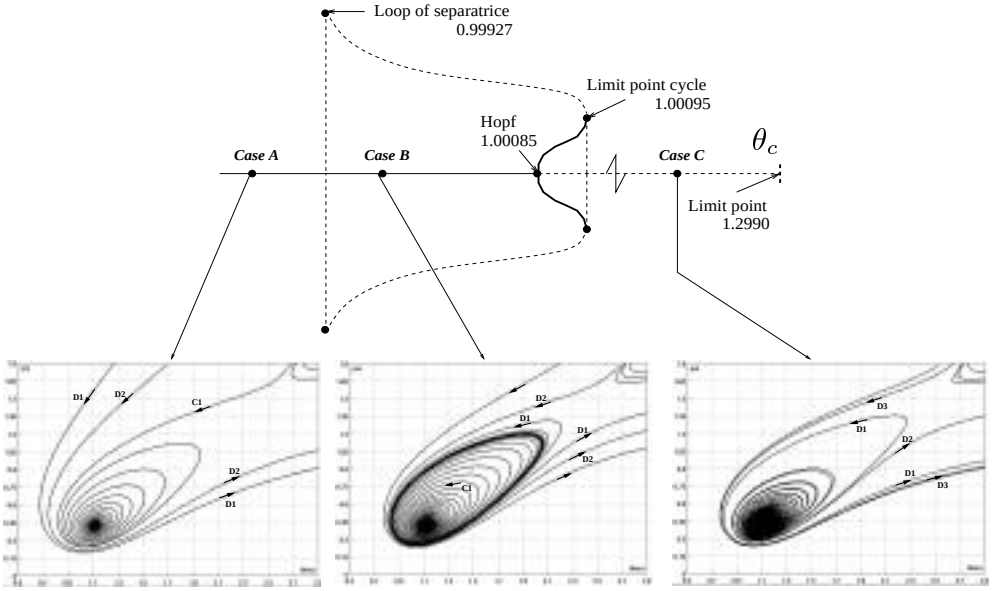

FIG. 6. *Bifurcation diagram for the first model with θ_c as the bifurcation parameter with the various phase portraits (C for converging trajectories and D for diverging trajectories).*

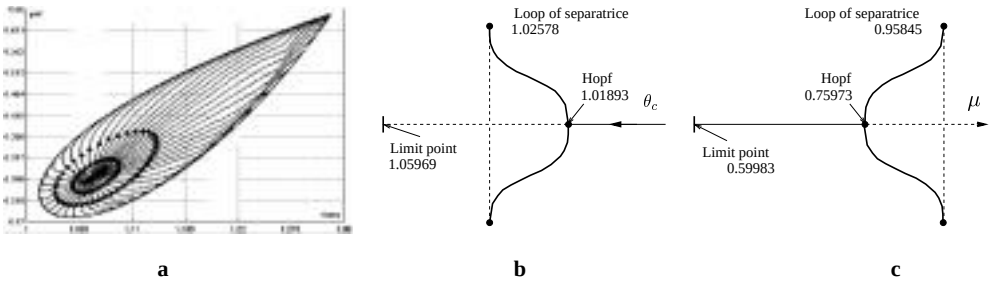

FIG. 7. (a) *Continuation of the limit cycle with θ_c as the continuation parameter in the phase plane (θ, ψ) from the Hopf bifurcation point to the loop of separatrice.* (b) *Bifurcation diagram for the second model with θ_c as the bifurcation parameter.* (c) *Bifurcation diagram for the second model with μ as the bifurcation parameter.*

separatrice associated with the other (saddle) equilibrium instead of meeting with an unstable limit cycle as in the first model (Figure 6). Finally, two Hopf bifurcations are found in the neighborhood of the initial point for both bifurcation parameters θ_c and α_0. The initial point $\alpha_0 = 2.7, \theta_c = 1.0$ is the point we start the continuation of equilibrium from.

We find the two critical points where the equilibria disappear at $\alpha_0 = 2.7, \theta_c = 1.06$ (denoted by "limit point" in Figure 7(b)) and $\alpha_0 = 2.688, \theta_c = 1.0$ (denoted by "limit point" in Figure 7(c)). Besides, two Hopf bifurcations are identified at $\alpha_0 = 2.695, \theta_c = 1$ and at $\alpha_0 = 2.7, \theta_c = 1.019$; at the initial point, the equilibrium is stable and is destabilized through the Hopf bifurcations.

On Figure 7(a), we have used CONTENT [16] in order to represent the continuation of the stable limit cycle with θ_c as the bifurcation parameter. The various lines starting from the Hopf bifurcation point and reaching the loop of separatrice

represent the continuation of one point of the limit cycle. The bifurcation diagram is presented on Figure 7(b), and we see that the stable limit cycle is present from the value $\theta_c = 1.01893$, where the Hopf bifurcation is taking place until $\theta_c = 1.02578$, where the stable limit cycle is merging with the loop of separatrice. Another possible bifurcation parameter which brings a reparametrization of $\dot{\psi} = 0$ is μ, the sensitivity of the heat losses coefficient on convection, instead of α_0. The corresponding bifurcation diagram is presented on Figure 7(c), knowing that the initial point corresponds to $\mu = 0.7$.

5.5. Comparison with direct numerical simulations. The purpose of the present section is to make the link between the direct numerical simulations of section 3, on the one side, and the results on the model problem presented in the first part of this section, on the other side. The fundamental point is to be able to use physical values of the parameters in the model problem. The first step is then to come back to the relationship between the Semenov and Frank-Kamenetskii theories and extend the relationship to the other parameters when convection is present.

The link between the Frank-Kamenetskii and the Semenov theories has already been considered in [24], thus showing that around the critical conditions for explosion, if $\bar{\theta}$ is the averaged temperature in the layer, $\overline{\exp(\theta)} \approx \exp(\bar{\theta})$. Thus, integrating (2.1) in $\bar{z}$ over $[0, 2]$ and changing the temperature scaling from the diffusion time L^2/κ_0 to the chemical time τ_{ch} introduced in subsection 2.2 yields

$$d_{\bar{\tau}}\bar{\theta} = -\Phi + \exp(\bar{\theta}), \qquad \bar{\tau} = t/\tau_{ch} = \mathrm{F_K}.\tau, \tag{5.19}$$

where Φ is the total heat flux through the boundaries, modeled by $\Phi = \alpha_0\bar{\theta}$. However, the critical value of the mean temperature given by the Frank-Kamenetskii theory and denoted $\bar{\theta}_0^*$ is .86, whereas critical conditions for (5.19) yield $\alpha_0^* = e$, $\bar{\theta}_1^* = 1$. Thus, even if $\exp(\bar{\theta})$ is a good approximation of the value in the mean of the chemical source term, it does not provide a good approximation of its derivative as a function of the mean temperature. Consequently, we consider $\eta = \bar{\theta}/\bar{\theta}_0^*$ and approximate $\exp(\bar{\theta})$ by $\bar{\theta}_0^* \exp(\bar{\theta}/\bar{\theta}_0^*)$, so that η satisfies

$$d_{\bar{\tau}}\eta = -\alpha_0\eta + \exp(\eta), \tag{5.20}$$

the critical conditions of which are defined by $\eta^* = 1$, $\alpha_0^* = e$, or $\bar{\theta} = \bar{\theta}_0^* = 0.86$. The change of variable then allows us, by changing the derivative of the chemical source term at critical conditions, to recover critical conditions compatible with the Frank-Kamenetskii theory.

We then have to check that the value of the heat flux at the boundaries is correctly predicted by our numerical model. We have computed the values of the heat flux for various values of the Frank-Kamenetskii number below the critical value, for two spatial discretizations 21 and 51 points, as well as the values predicted by the theory. Numerical results and theory match very well and the error remains below 4%. One can check from these numerical simulations of (2.1) that $\alpha_0 = \partial_{\bar{z}}\bar{\theta}|_{\bar{z}=0} * \bar{\theta}_0^*/\bar{\theta}$ approaches the value e in the neighborhood of the critical conditions.

It was proposed in subsection 3.2 that the convective instability is appearing as a supercritical bifurcation and that the maximum of the stream function is proportional to $\sqrt{\mathrm{Ra} - \mathrm{Ra}_c} = \sqrt{\mathrm{Ra}_0}\sqrt{\theta - \theta_c}$, a property used in the model problem. On Figure 8(a), we check this relationship for $\mathrm{F_K} = 0.6$, $\mathrm{F_K} = 0.875$, and $\mathrm{F_K} = 0.9$; it thus makes the link between the stream function observed with either model and the stream function given by the direct numerical simulations.

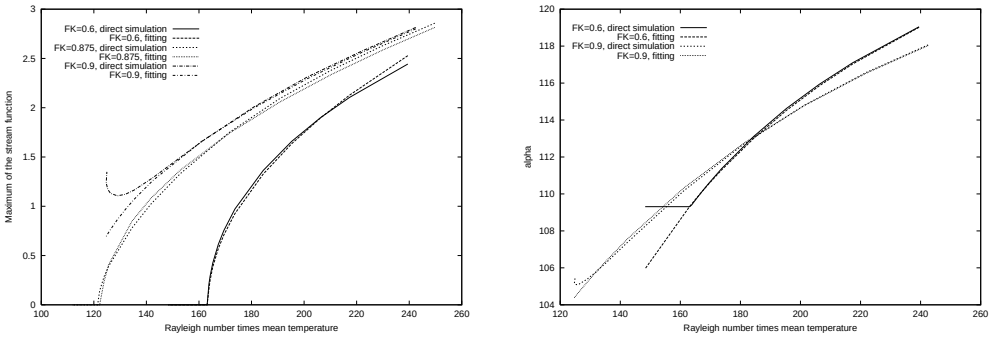

FIG. 8. *Comparison of model and simulations:* (a) $\psi_{\max}$ *at* $\mathrm{F_K} = 0.6, 0.875, 0.9$*;* (b) *heat losses coefficient at* $\mathrm{F_K} = 0.6, 0.9$.

In order to justify the choice of the various models considered for the heat losses coefficients, we have plotted α versus $\mathrm{Ra}_0\theta$ on Figure 8(b), comparing on the one side the ratios of the heat flux over the mean temperature from the simulation and on the other side the values given by the second model.

We have done that for various values of $\mathrm{F_K}$; we isolate two cases on Figure 8(b) for $\mathrm{F_K} = 0.6$, below the critical value, and $\mathrm{F_K} = 0.9$, above the critical value. For the first one, starting from the constant analytical value α_0 which corresponds to the static solution, we can fit very precisely, using the second model, the values coming from the direct numerical simulations and then prove that the choice of a constant value of μ and γ is possible. For the second one, there exists a region of the parameter Ra_0 where the maximum of the stream function has a square root-like behavior; in this region, we can still fit α very precisely as shown on Figure 8(b). However, in the region where the maximum of the stream function separates from the square root-like behavior, the fit for α is not valid anymore and the parameters μ and γ cannot remain fixed.

6. Discussion. In the present section, we discuss three key points: the definition of thermal explosion, the influence of convection on heat losses at the boundaries, and finally the ability of the model problem described in the previous section to reproduce the complete bifurcation diagram of the full partial differential equation system with Ra_0 as the bifurcation parameter at fixed $\mathrm{F_K}$.

Classically, thermal explosion is defined as the nonexistence of a stationary solution for (2.1). When gravity is present and convection interferes with heat production, our study makes it clear that this definition of thermal explosion is not complete. Actually, there is a parameter range where there exists an unstable stationary solution and where thermal explosion can still occur whatever the initial data ($F_K = 0.8775$, which is below the critical value, and for the Rayleigh range between the two Hopf bifurcations yielding oscillatory solutions; see Figure 3), whereas for some parameter range, even if the stationary solution exists and is not stable, there exists periodic oscillations and no thermal explosion is found in the attraction basin of the stable limit cycle; however, the possible domain of initial conditions in order to converge to these stable oscillations is limited. Due to the presence of this oscillatory instability, we have to give a more complete definition: thermal explosion is the blow-up of the temperature; it corresponds to three scenarios: there exists no stationary solution

and no periodic solution; there exists a stable stationary solution or a stable periodic solution with its attraction set of initial data (which can be bounded or not) and the initial solution does not belong to this set; or, finally, there exists unstable stationary solutions and the temperature blows up whatever the initial data.

The second point we want to come back to is the influence of convection on heat losses. The convective instability due to the nonlinear profile of temperature is difficult to relate to the linear one in the Rayleigh–Bénard configuration as shown in section 4, where the critical Rayleigh numbers cannot be correlated. The modeling of the heat losses in the context of thermal explosion coupled to convection was still an open problem. It then becomes clear that using the direct numerical simulations and linear stability analysis, we were able, first, to characterize the critical conditions for the convective instability to appear, and, second, to model the heat losses through an interpolation formula that was to be really precise (using μ and γ) on the square root-like branches (either for $\mathrm{F_K}$ below the critical value or for large Rayleigh numbers). There are two points still to be discussed here: first, what is the influence of the transition from one vortex to two vortices on the heat losses? and, more generally, depending on the aspect ratio, what would be the behavior of heat losses depending on the modes?; second, what is the behavior of the heat losses in the regions of parameters when we are close to thermal explosion and the stationary branch for ψ goes away from a square root-like profile? The latter point will be discussed in the next paragraph: the model problem is able to reproduce the bifurcation behavior of the full system. Finally, we would like to emphasize that we have chosen Dirichlet boundary conditions on part of the boundary, thus influencing the heat losses. It would be necessary to reproduce the same kind of study in the case of Robin boundary conditions.

The last point we want to discuss is the ability of the model problem to describe surprisingly well the bifurcation diagram of the full system of partial differential equations. We have already seen that the heat losses coefficient is well described by the second model proposed in comparison with the direct numerical simulations; the correspondence between the two systems, when the Rayleigh number is small enough, already has been shown by making the link between Semenov and Frank-Kamenetskii theories. However, the bifurcation parameters used in the direct numerical simulation were the Rayleigh number Ra_0 and the Frank-Kamenetskii parameter $\mathrm{F_K}$. The second model system, when $\mathrm{F_K}$ is given, thus setting α_0, Ra_c, and γ, still has two parameters depending on Ra_0: θ_c and μ. We have seen that there can be two causes of Hopf bifurcation: either when θ_c is increasing on a decreasing branch of ψ or when μ is decreasing. It has been shown that μ remains constant on a square root-like branch of the stream function; however, we did not inquire as to what is the behavior of μ when the stream function leaves this square root-like behavior. It can be shown for various values of $\mathrm{F_K} > \mathrm{F_K}_c$ that in the region where the stationary value of ψ as a function of Ra_0 changes its convexity, there is a strong variation of α as a function of ψ. Let us consider, for example, the case when $\mathrm{F_K} = 0.9$, where no oscillations are found. It is shown that for the same value of ψ, the value of α decreases for a smaller Ra_0. We can model this phenomenon by choosing a fixed γ and considering the evolution of μ versus Ra_0. The evolution of the heat losses coefficient sensitivity μ as a function of Ra_0 presents a strong decrease of μ in the considered region. A similar result holds for oscillating solutions.

The very striking fact is that this analysis provides a way of understanding why oscillations can start growing and then decrease onto a stable stationary solution before exploding, as is the case when $\mathrm{F_K} = 0.88$. Let us refer to the bifurcation diagram, Figure 7. It shows that an increase of θ_c (which can be associated with a

decrease of Ra_0) at given μ can initiate the oscillations through a Hopf bifurcation. If, in between the bifurcation point and the loop of separatrice, one encounters a strong decrease of μ, then the amplitude of the limit cycle can decrease until it goes through another Hopf bifurcation so that the stationary solution is stable again. Decreasing μ further leads to an explosion from the stable stationary solution, which is exactly the behavior of the full system for $\mathrm{F_K} = 0.88$. It is interesting to note finally that the model system is able to reproduce all the bifurcation diagram identified using direct numerical simulations.

7. Conclusion. In this paper we have presented a comprehensive simulation, bifurcation analysis, and modeling of the nonlinear interaction of thermal explosion and natural convection in a 2D square configuration. New stable periodic-in-time solutions and oscillating thermal explosion have been identified in the neighborhood of the critical conditions for both explosion and convection. The stable periodic solutions can be modeled by a simple system of two ordinary differential equations. We have justified the modeling of the heat losses depending on the regimes of convection and especially in the neighborhood of the oscillating solutions, where the sensitivity of heat losses to convection encounters a strong decrease. Finally, all the identified regimes and bifurcations can be qualitatively described by the proposed model problem.

A NEW RENORMALIZATION METHOD FOR THE ASYMPTOTIC SOLUTION OF WEAKLY NONLINEAR VECTOR SYSTEMS*

B. MUDAVANHU†‡ AND R. E. O'MALLEY, JR.†

Abstract. This paper considers the asymptotic integration of a special class of initial value problems involving a nonlinear regular perturbation scaled by a small parameter $\epsilon > 0$. For $t = \mathcal{O}(1/\epsilon)$, these problems were classically solved using either the method of averaging or of multiple scales to remove secular terms that arise in the natural power series procedure. Our new ansatz is straightforward and effective. Moreover, it indicates when problems might occur in providing the asymptotic solution on very long time intervals. Other closely related problems are also attacked using renormalization.

Key words. oscillations, asymptotics, renormalization

Background: The rise of secular terms. We shall seek the asymptotic solution $x_\epsilon(t)$ of the initial value problem for the weakly nonlinear nearly autonomous vector system

$$\dot{x} = Mx + \epsilon N(x, t, \epsilon) \tag{1}$$

on the semi-infinite time interval $t \geq 0$ as the small positive parameter ϵ tends to zero. Such problems and their generalizations describe numerous electrical, mechanical, and biological oscillations. Indeed, the asymptotic solution of related boundary value problems for partial differential equations remains of substantial interest and importance. Without further hypotheses, however, one can't predict the time interval on which the solution remains bounded. We shall assume that the matrix M has only imaginary eigenvalues, that the fundamental matrix e^{Mt} for the unperturbed problem has a period $p > 0$, and that the vector N is smooth in its three arguments and p-periodic in t. We could even assume that M is a diagonal matrix having a spectral decomposition $M = iV\Lambda V^{-1}$ with a real diagonal matrix Λ and introduce the transformation $\widetilde{x} = Vx$.

By variation of parameters,

$$z_\epsilon(t) = e^{-Mt} x_\epsilon(t) \tag{2}$$

will satisfy the transformed system

$$\dot{z} = \epsilon f(z, t, \epsilon), \tag{3}$$

analogous to (1) with $M = 0$, for the p-periodic forcing

$$f(z, t, \epsilon) \equiv e^{-Mt} N(e^{Mt} z, t, \epsilon). \tag{4}$$

Indeed, we will say the system (3) is in standard form. Moreover, anticipating that (3) will have a nearly constant solution for bounded times, setting

$$x_\epsilon(t) = e^{Mt}(x(0) + \epsilon u(t, x(0), \epsilon)) \qquad \text{or} \qquad z_\epsilon(t) = x(0) + \epsilon u(t, x(0), \epsilon) \tag{5}$$

shows that the scaled correction vector u will satisfy the nearly linear initial value problem

$$\dot{u} = f(x(0) + \epsilon u, t, \epsilon) \tag{6}$$

on some interval $t \geq 0$ with $u(0, x(0), \epsilon) = 0$.

The natural starting point for obtaining an asymptotic solution $x_\epsilon(t)$ of (1) or $z_\epsilon(t)$ to (3) is to introduce the regular power series expansion

$$u(t, x(0), \epsilon) = u_0(t, x(0)) + \epsilon u_1(t, x(0)) + \epsilon^2 u_2(t, x(0)) + \cdots \tag{7}$$

for u, determining its terms u_j uniquely and successively by equating coefficients of like powers of ϵ in the differential equation (6) and the initial condition. Thus, the u_j's must satisfy the resulting sequence of linear initial value problems

$$\begin{cases} \dot{u}_0 = f(x(0), t, 0), \qquad u_0(0) = 0, \\ \dot{u}_1 = f_x(x(0), t, 0)u_0 + f_\epsilon(x(0), t, 0), \qquad u_1(0) = 0, \\ \dot{u}_2 = f_x(x(0), t, 0)u_1 + \frac{1}{2}[f_{xx}(x(0), t, 0)u_0 + 2f_{x\epsilon}(x(0), t, 0)]u_0 \\ \qquad + \frac{1}{2}f_{\epsilon\epsilon}(x(0), t, 0), \qquad u_2(0) = 0, \\ \text{etc.}, \end{cases} \tag{8}$$

and thus integrating successively immediately provides the coefficients

$$u_0(t, x(0)) = \int_0^t f(x(0), s, 0)ds, \tag{9}$$

$$u_1(t, x(0)) = \int_0^t [f_x(x(0), s, 0)u_0(s, x(0)) + f_\epsilon(x(0), s, 0)]ds, \tag{10}$$

etc., in (7). Using standard Gronwall inequality arguments (cf. Smith (1985) or Murdock (1991)), it becomes clear that the regular power series (7) provides the asymptotic solution $x_\epsilon(t)$ as $\epsilon \to 0$ on bounded t intervals.

Recall, however, that Lagrange, Laplace, Poincaré, and other developers of celestial mechanics knew that ordinary *resonance* implies that these u_j's generally contain secular terms that grow as polynomials in t of degree $j + 1$. This implies that the expansion (7) then loses its asymptotic validity on long time intervals since the terms $\epsilon^{j+1}u_j(t)$ of ϵu all attain the same asymptotic order when $t = \mathcal{O}(1/\epsilon)$. For this reason, the power series (7) was called *naive* by Chen, Goldenfeld, and Oono (1996). Many asymptotic methods have been developed to deal with this dilemma. The most important classical techniques are the Krylov–Bogoliubov *averaging* method, largely developed in Kiev in the 1930s (cf. Bogoliubov and Mitropolsky (1961)), and two-timing or the method of *multiple scales*, developed at Caltech in the 1960s (cf. Kevorkian and Cole (1996), but note independent early contributions of Kuzmak (1959), Cochran (1962), and Mahony (1962)). Our work relates closely to the *renormalization group* method of Chen, Goldenfeld, and Oono (1996) and the *invariance*

condition method of Woodruff (1993, 1995), though averaging and multiple scale concepts remain essential to its development. Readers should note that Oono (2000) and Nozaki and Oono (2001) simplify the earlier renormalization group method and that Jarrad (2001) includes a promising *variational perturbation theory.* Chen, Goldenfeld, and Oono (1996) began their paper by suggesting that "the practice of asymptotic analysis is something of an art." Like them, we seek to show that "the renormalization group approach sometimes seems to be more efficient and accurate than standard methods in extracting global information from the perturbation expansion."

Simple resonance considerations show that u_0 will grow like a multiple of t as $t \to \infty$ if and only if its known forcing $f(x(0), t, 0)$ has a nonzero *average*

$$\langle f(x(0), t, 0)\rangle \equiv \frac{1}{p}\int_0^p f(x(0), s, 0)ds, \tag{11}$$

which conveniently coincides with the leading term in its Fourier series expansion on $0 \le t \le p$. Indeed, if we split $f(x(0), t, 0)$ into its average and supplementary *fluctuating zero-average part*

$$\{f(x(0), t, 0)\} = f(x(0), t, 0) - \langle f(x(0), t, 0)\rangle, \tag{12}$$

the response u_0 analogously splits into the sum

$$u_0(t, x(0)) = ta_0(x(0)) + U_0(x(0), t) \tag{13}$$

of its corresponding secular part $a_0 t$, with the average

$$a_0(x(0)) \equiv \langle f(x(0), t, 0)\rangle \tag{14}$$

as a coefficient and with the *bounded* secular-free part

$$U_0(x(0), t) \equiv \int_0^t \{f(x(0), s, 0)\}ds. \tag{15}$$

Substituting (13) into (10), integrating by parts, and splitting f_x into its average and fluctuating parts, we next get

$$\begin{aligned} u_1(t, x(0)) &= \left(\int_0^t s f_x(x(0), s, 0)ds\right) a_0(x(0)) \\ &\qquad + \int_0^t [f_x(x(0), s, 0)U_0(x(0), s) + f_\epsilon(x(0), s, 0)]ds \\ &= \left(\frac{1}{2}t^2\langle f_x(x(0), t, 0)\rangle + t\frac{\partial U_0}{\partial x}(x(0), t)\right) a_0(x(0)) \\ &\qquad + \int_0^t \left[f_x(x(0), s, 0)U_0(x(0), s) + f_\epsilon(x(0), s, 0)\right. \\ &\qquad\qquad \left. - \frac{\partial U_0}{\partial x}(x(0), s)a_0(x(0))\right] ds. \end{aligned}$$

Thus, u_1 has the predicted polynomial form

$$\begin{aligned} u_1(t, x(0)) &= \frac{1}{2}t^2\langle f_x(x(0), t, 0)\rangle a_0(x(0)) \\ &\qquad + t\left[a_1(x(0)) + \frac{\partial U_0}{\partial x}(x(0), t)a_0(x(0))\right] + U_1(x(0), t), \end{aligned} \tag{16}$$

where the coefficients involve the average

$$a_1(x(0)) \equiv \left\langle f_x(x(0),t,0)U_0(x(0),t) + f_\epsilon(x(0),t,0) - \frac{\partial U_0}{\partial x}(x(0),t)a_0(x(0)) \right\rangle$$

and the supplementary term

$$U_1(x(0),t) \equiv \int_0^t \Big\{ f_x(x(0),s,0)U_0(x(0),s) + f_\epsilon(x(0),s,0) - \frac{\partial U_0}{\partial x}(x(0),s)a_0(x(0)) \Big\} ds \tag{17}$$

that remains bounded for all $t \geq 0$. (Corresponding higher-order first and final coefficients a_j and U_j won't be so directly linked as when $j = 0$ and 1.)

Continuing in this manner, however, we ultimately learn that a bounded asymptotic solution $z_\epsilon(t)$ results on a longer time interval from using only the bounded secular-free (or so-called *bare*) part

$$x(0) + \epsilon U_0(x(0),t) + \epsilon^2 U_1(x(0),t) + \epsilon^3(\cdots)$$

of the regular power series for z_ϵ. Further, we must generally replace the initial vector $x(0)$ by a time-varying amplitude $A_\epsilon(\tau)$ depending on the slow-time

$$\tau = \epsilon t \tag{18}$$

and found by integrating the initial value problem

$$\frac{dA_\epsilon}{d\tau} = a_0(A_\epsilon) + \epsilon a_1(A_\epsilon) + \mathcal{O}(\epsilon^2), \quad A_\epsilon(0) = x(0),$$

on (possibly unbounded) τ intervals where its solution remains bounded. (Observe that one might interpret the replacement of $x(0)$ by the slowly varying $A_\epsilon(\tau)$ as finding an envelope of solutions (cf. Ei, Fujii, and Kunihiro (2000)). Likewise, one could be motivated by Whitham's success in using slowly varying functions to asymptotically solve nonlinear partial differential equations (cf. Whitham (1974) and Debnath (1997)) or by the use of related *amplitude equations* in stability theory (cf. Coullet and Spiegel (1983), Eckhaus (1992), and Promislow (2001)). The basic ploy is to eliminate the secular terms from the naive expansion (7). Moreover, observe that replacing $x(0)$ by $A_\epsilon(\tau)$ also makes our leading-order approximation $e^{Mt}A_\epsilon(\tau)$ to $x_\epsilon(t)$ richer, although such an improvement will not be asymptotically noticeable when t is only finite. We admit that this simple renormalization result still remains largely unmotivated, but we shall now obtain it by using an effective ansatz that could be applied more generally (e.g., in asymptotically stable contexts where M is a stable matrix and $\frac{1}{p}\int_0^p f(x(0),s,0)ds$ converges as $p \to \infty$, allowing us to take an infinite p to again define the averaged equation satisfied by the limiting $A_0(\tau)$. When $M = \left(\begin{smallmatrix} -Q & 0 \\ 0 & iR \end{smallmatrix}\right)$ for an exponentially decaying matrix e^{-Qt} and a periodic e^{iRt}, we would use such a long-time average to approximate the first components of x).

The basic ansatz. We shall begin anew to solve (1) by directly introducing the multiple-scale *ansatz*

$$\begin{cases} x_\epsilon(t) = e^{Mt}z_\epsilon(t) \equiv e^{Mt}[A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau),t,\epsilon)] \\ \text{or} \\ z_\epsilon(t) = A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau),t,\epsilon) \end{cases} \tag{19}$$

corresponding to the *bare* expansion of Chen, Goldenfeld, and Oono (1996). It can be motivated for problem (1), at least for τ finite, by substituting (19) into the differential equation (3). Using the chain rule, we get

$$\frac{1}{\epsilon}\frac{dz_\epsilon}{dt} = \left(I + \epsilon\frac{\partial U}{\partial A_\epsilon}\right)\frac{dA_\epsilon}{d\tau} + \frac{\partial U}{\partial t} = f. \tag{20}$$

We now split $\frac{\partial U}{\partial A_\epsilon}$ and f into sums of their average and mean-free fluctuating parts, respectively, using the leading term and the supplementary sum of their Fourier expansions on $0 \le t \le p$, and asking that A_ϵ account for the nonzero average terms

$$\left(I + \epsilon\left\langle\frac{\partial U}{\partial A_\epsilon}\right\rangle\right)\frac{dA_\epsilon}{d\tau} = \langle f\rangle$$

in (20), while the correction ϵU to A_ϵ in (19) handles its remaining terms

$$\epsilon\left\{\frac{\partial U}{\partial A_\epsilon}\right\}\frac{dA_\epsilon}{d\tau} + \frac{\partial U}{\partial t} = \{f\}$$

with zero averages. (Readers might indeed recall that an analogous decomposition occurs in the early comparison by Morrison (1966) of averaging and two-timing.) Thus, A_ϵ should satisfy the autonomous system

$$\begin{aligned}\frac{dA_\epsilon}{d\tau} &= \left(I + \epsilon\left\langle\frac{\partial U}{\partial A_\epsilon}(A_\epsilon(\tau), t, \epsilon)\right\rangle\right)^{-1}\langle f(A_\epsilon + \epsilon U(A_\epsilon, t, \epsilon), t, \epsilon)\rangle \\ &\equiv a\ (A_\epsilon, \epsilon) \\ &= \langle f(A_\epsilon, t, 0)\rangle \\ &\quad + \epsilon\Bigg[\langle f_x(A_\epsilon, t, 0)U_0(A_\epsilon, t) + f_\epsilon(A_\epsilon, t, 0)\rangle \\ &\qquad - \left\langle\frac{\partial U_0}{\partial A_\epsilon}(A_\epsilon, t)\right\rangle\langle f(A_\epsilon, t, 0)\rangle\Bigg] + \epsilon^2(\cdots)\end{aligned} \tag{21}$$

and the initial condition $A_\epsilon(0) = x(0)$, while U must satisfy

$$\frac{\partial U}{\partial t} = \{f\} - \epsilon\left\{\frac{\partial U}{\partial A_\epsilon}\right\}a(A_\epsilon, \epsilon)$$

and the trivial initial condition $U(A_\epsilon(\tau), 0, \epsilon) = 0$. We shall call the differential equation (21) the *amplitude* or *first level RG (renormalization group) equation*, noting that an analogous evolution equation results when one uses the higher-order method of averaging. The asymptotic integration of (21) on $\tau \ge 0$ is the appropriate candidate problem to replace the integration of (1) after t becomes unbounded. In these differential equations for A_ϵ and U, the times t and τ are taken to be independent variables, as is typical in two-timing. Integrating the latter equation with respect to t shows that U must satisfy the integral equation

$$\begin{aligned}U(A_\epsilon(\tau), t, \epsilon) = &\int_0^t \{f(A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau), s, \epsilon), s, \epsilon)\}ds \\ &- \epsilon\int_0^t\left\{\frac{\partial U}{\partial A_\epsilon}(A_\epsilon(\tau), s, \epsilon)\right\}ds\, a(A_\epsilon(\tau), \epsilon).\end{aligned} \tag{22}$$

That we have obtained the compact formulae (21) and (22) to all orders in ϵ is quite helpful, though we naturally next employ power series methods to get more explicit asymptotic results for bounded τ values. Note, in particular, that $\frac{\partial U}{\partial t}$ has a zero average, so its integral U in (22) will be bounded whenever the amplitude $A_\epsilon(\tau)$ is. The resulting power series expansion

$$U(A_\epsilon(\tau), t, \epsilon) = U_0(A_\epsilon(\tau), t) + \epsilon U_1(A_\epsilon(\tau), t) + \epsilon^2(\cdots) \tag{23}$$

has coefficients successively and unambiguously given by

$$\begin{aligned} U_0(A_\epsilon(\tau), t) &= \int_0^t \{f(A_\epsilon(\tau), s, 0)\} ds, \\ U_1(A_\epsilon(\tau), t) &= \int_0^t \{f_x(A_\epsilon(\tau), s, 0) U_0(A_\epsilon(\tau), s) + f_\epsilon(A_\epsilon(\tau), s, 0)\} ds \\ &\quad - \int_0^t \left\{ \frac{\partial U_0}{\partial A_\epsilon}(A_\epsilon(\tau), s) \right\} ds\, a_0(A_\epsilon(\tau)), \end{aligned}$$

etc., corresponding to the functions previously obtained in (15) and (17) for the non-secular parts of the naive expansion (7). Note that U is p-periodic in t.

The remaining, and still formidable, task is to obtain the asymptotic solution of the initial value problem (21) for the slowly varying amplitude A_ϵ on time intervals where it will determine a bounded solution x_ϵ or z_ϵ via (19) and (22). We naturally first seek $A_\epsilon(\tau)$ as a power series

$$A_\epsilon(\tau) = A_0(\tau) + \epsilon A_1(\tau) + \epsilon^2 A_2(\tau) + \cdots, \tag{24}$$

where (21) implies that its limit A_0 must satisfy the limiting nonlinear problem

$$\frac{dA_0}{d\tau} = a_0(A_0) \equiv \frac{1}{p} \int_0^p f(A_0, s, 0) ds, \quad A_0(0) = x(0), \tag{25}$$

exactly as in classical averaging, while the next term A_1, for example, must satisfy a linearized problem

$$\frac{dA_1}{d\tau} = \frac{da_0(A_0)}{dA_0} A_1 + a_1(A_0), \quad A_1(0) = 0.$$

The uniqueness of A_0 implies the invertibility of the Jacobian matrix $\frac{\partial A_0}{\partial x(0)}$, which satisfies the homogeneous linear matrix system as long as A_0 remains defined. If A_0 ever blows up, we must naturally limit our interval of approximation. Using a variation of parameters, then,

$$A_1(\tau) = \frac{\partial A_0(\tau)}{\partial x(0)} \int_0^\tau \left(\frac{\partial A_0(s)}{\partial x(0)} \right)^{-1} a_1(A_0(s)) ds \tag{26}$$

and later terms A_j also follow successively without complication. Using the regular perturbation expansions for $A_\epsilon(\tau)$ and for $U(A_\epsilon(\tau), t, \epsilon)$ in the ansatz (19) results in an approximation for x_ϵ that agrees asymptotically with the naive expansion on intervals where t is finite, and that extends that approximation to longer intervals, at least as long as τ remains finite and $A_0(\tau)$ is defined. One possible further difficulty is instability of $A_0(\tau)$ as $\tau \to \infty$ (if $x(0)$ isn't restricted to the appropriate stable

manifold). Another is encountering τ-secular terms in the power series generated for $A_\epsilon(\tau)$. Note, indeed, that A_1 will be τ-secular if the forcing term $a_1(A_0)$ contains a nontrivial projection in the range of the fundamental matrix $\frac{\partial A_0(\tau)}{\partial x(0)}$. A bounded τ, indeed, provides the usual time limit for obtaining asymptotic solutions by the classical averaging and two-timing methods, which are quite intimately related (cf. Morrison (1966)). Instability as $\tau \to \infty$ cannot be overcome. If, however, $A_0(\tau)$ exists for all $\tau \geq 0$ and if it decays exponentially to an asymptotically stable rest point or *sink*, the resulting expansion (24) for $A_\epsilon(\tau)$ and the resulting expansion (19) for $x_\epsilon(t)$ are uniformly valid for all $t \geq 0$. Recall that Greenlee and Snow (1975) provided an early discussion of such problems, while Murdock and Wang (1996) called this the Sanchez–Palencia condition, in reference to related results for averaging. Indeed, when $a_0(A_0) \equiv 0$, we can immediately seek the asymptotic solution $x_\epsilon(t)$ on $\mathcal{O}(1/\epsilon^2)$ time intervals, as Sanders and Verhulst (1985) and Murdock and Wang (1996) show for averaging and multiple scales, respectively, by replacing the slow-time τ in (21) by the even slower-time

$$\kappa = \epsilon\tau = \epsilon^2 t. \tag{27}$$

Readers should realize that the successful ansatz (19) can be interpreted as a *near-identity* transformation for z_ϵ. Such transformations, which generalize a classical asymptotic procedure of von Ziepel, were introduced by Neu (1980). They are useful in a variety of contexts, including many where our periodicity assumption doesn't hold. In this sense, the basic method of matched asymptotic expansions (cf. Il'in (1992)) and the boundary function method of Vasil'eva, Butuzov, and Kalachev (1995) can both be considered to be extensions of our renormalization technique, as will be demonstrated below. Note further that the basic ansatz (19) is considerably more direct than traditional two-timing, since the solution is not sought as an arbitrary function of the slow-time τ, but rather as a function of t and the amplitude A_ϵ, which is obtained asymptotically as a function of τ by solving the renormalized equation (21). At any stage, we have available a finite truncation

$$U^n(A_\epsilon(\tau), t, \epsilon) \equiv \sum_{j=0}^{n} \epsilon^j U_j(A_\epsilon(\tau), t)$$

for the correction U to A_ϵ satisfying $U(A_\epsilon(\tau), t, \epsilon) = U^n(A_\epsilon(\tau), t, \epsilon) + \mathcal{O}(\epsilon^{n+1})$. Likewise, we have the truncation

$$A_\epsilon^n(\tau) = \sum_{j=0}^{n} \epsilon^j A_j(\tau)$$

such that $A_\epsilon(\tau) = A_\epsilon^n(\tau) + \mathcal{O}(\epsilon^{n+1})$. Substituting into the integral (22), this implies that

$$U(A_\epsilon(\tau), t, \epsilon) = U^n(A_\epsilon^m(\tau), t, \epsilon) + \mathcal{O}(\epsilon^{n+1}) + \mathcal{O}(\epsilon^{m+2}t) \tag{28}$$

for any positive integers m and n, at least for appropriate bounded values of τ.

Our success in using the ansatz (19) for large times suggests that we might often be able to asymptotically solve the amplitude equation (21) on long time intervals, even when τ-secular terms in the series (24) for the amplitude A_ϵ need to be eliminated, by using a secondary ansatz

$$x(0) = B_\epsilon(\kappa) + \epsilon W(B_\epsilon(\kappa), \tau, \epsilon), \tag{29}$$

analogous to (19), in (19). We can asymptotically solve the resulting second level RG equation for the amplitude $B_\epsilon(\kappa)$ to get the resulting multiscale composite expansion

$$x_\epsilon(t) = e^{Mt}[\mathcal{A}(\tau, B_\epsilon(\kappa) + \epsilon W(B_\epsilon(\kappa), \tau, \epsilon), \epsilon) + \epsilon U(\mathcal{A}(\tau, B_\epsilon(\kappa) + \epsilon W(B_\epsilon(\kappa), \tau, \epsilon), \epsilon), t, \epsilon)],$$

where we have set

$$A_\epsilon(\tau) = \mathcal{A}(\tau, x(0), \epsilon)$$

to emphasize its dependence on the initial vector $x(0)$. This expansion can be expected to be valid at least for bounded κ intervals. Moreover, we can consider the preceding expansion (19) to be an *intermediate* asymptotic expansion in the sense of Barenblatt (1996).

The critical idea behind the traditional (first level) renormalization group method of Chen, Goldenfeld, and Oono (1996) is to replace the initial value $x(0)$ in the naive expansion (7) by a slowly-varying function $A_\epsilon(\tau)$ through a near-identity transformation

$$x(0) = A_\epsilon(\tau) + \epsilon Z(A_\epsilon(\tau), t, \epsilon) \tag{30}$$

to eliminate secular (or *divergent*) terms in the naive expansion (7) by appropriate selection of the correction terms Z_j and to thereby obtain the secular-free expansion (19), where A_ϵ remains to be determined. To lowest orders, we would, for example, obtain the necessary cancellation by taking

$$Z_0(A_\epsilon, t) = -a_0(A_\epsilon)t$$

and

$$Z_1(A_\epsilon, t) = \frac{1}{2}t^2\langle f_x(A_\epsilon, t, 0)\rangle a_0(A_\epsilon) - t\left[\langle f_x(A_\epsilon, t, 0)U_0(A_\epsilon, t, 0) + f_\epsilon(A_\epsilon, t, 0)\rangle - a_0(A_\epsilon)\left\langle \frac{\partial U_0}{\partial x}(A_\epsilon, t)\right\rangle\right].$$

Upon differentiating (30) with respect to t, the *invariance condition* $\frac{dx(0)}{dt} = 0$ and the chain rule immediately imply that $A_\epsilon(\tau)$ will satisfy

$$\frac{dA_\epsilon}{d\tau} = a(A_\epsilon, \epsilon) \equiv -\left(I + \epsilon\frac{\partial Z}{\partial A_\epsilon}\right)^{-1}\frac{\partial Z}{\partial t}. \tag{31}$$

We did not take this approach above because it is more direct to immediately find A_ϵ by asymptotically integrating (21), which turns out to ultimately be independent of the secular correction Z introduced in (30). We nonetheless note how instructive it is to see how the terms of the t-secular function Z can be selected to eliminate successive secular terms in (7) and to learn how the function $a(A_\epsilon, \epsilon)$, generated by using the intermediate Z, coincides with that already defined in (21). In some sense, renormalization corresponds to a summing of secular terms. We note that Nozaki and Oono (2001) get the RG equation from an intermediate proto-RG equation and that they make a distinction between resonant and nonresonant secular terms. Indeed, when no secular terms occur in (7), A_ϵ will remain the constant $x(0)$. Next, τ-secular terms in the resulting series (24) could analogously also be eliminated, if necessary, by

replacing the initial vector $x(0)$ by a slowly varying function $B_\epsilon(\kappa)$ of the slow time $\kappa = \epsilon^2 t$ through use of another near-identity transformation (29), where $B_\epsilon(\kappa)$ must satisfy a second level RG equation

$$\frac{dB_\epsilon}{d\kappa} = b(B_\epsilon, \epsilon) \equiv -\left(I + \epsilon \frac{\partial W}{\partial B_\epsilon}\right)^{-1} \frac{\partial W}{\partial \tau} \tag{32}$$

and $B_\epsilon(0) = x(0)$ (cf. Mudavanhu and O'Malley (2001)). Assuming existence and appropriate stability of $B_0(\kappa)$, this will allow the asymptotic solution for x_ϵ to be defined beyond bounded values of κ. One may again be stopped by either blowup at finite κ, instability as $\kappa \to \infty$, or by κ-secular terms. The latter would require a higher level renormalization, and that could determine the asymptotic solution on a still longer time interval. We thus proceed in a leapfrog fashion. (Related applied work is contained in Moise and Ziane (2001) and Wirosoetisno, Shepherd, and Temam (2002).)

Two simple scalar examples. (a) Consider the simple example

$$\dot{x} = ix + \epsilon x(\alpha + x) \tag{33}$$

for some bounded complex constant α. Direct integration of this Riccati equation provides the exact solution

$$x_\epsilon(t) = e^{(i+\epsilon\alpha)t}\left[1 - \frac{\epsilon x(0)}{i+\epsilon\alpha}(e^{(i+\epsilon\alpha)t} - 1)\right]^{-1} x(0) \tag{34}$$

with a least period $\frac{2\pi}{1-i\epsilon\alpha}$ when $\operatorname{Re}\alpha = 0$. When $\alpha \neq 0$, secular terms become apparent when $e^{\epsilon\alpha t}$ is expanded in its Maclaurin series about $\epsilon = 0$. When $\operatorname{Re}\alpha < 0$, such a naive expansion in powers of ϵ is very misleading, since the actual solution decays exponentially to zero as $\tau = \epsilon t \to \infty$, while the Taylor-expanded series has unbounded secular terms. When $\operatorname{Re}\alpha > 0$, however, the solution blows up algebraically like $-\frac{i}{\epsilon}$ as $\tau \to \infty$. Thus, we can't expect an asymptotic approximation to the solution to be defined on time intervals on which τ becomes unbounded.

If we directly seek a solution to (33) of the form

$$x_\epsilon(t) = e^{it}(x(0) + \epsilon u(t, x(0), \epsilon)), \tag{35}$$

the scaled correction u must satisfy the nonlinear equation

$$\begin{aligned} \dot{u} &= f(x(0) + \epsilon u, t, 0) \\ &\equiv (\alpha + x(0)e^{it})x(0) + \epsilon(\alpha + 2x(0)e^{it})u + \epsilon^2 e^{it}u^2 \end{aligned} \tag{36}$$

and $u(0, x(0), \epsilon) = 0$. The resulting regular perturbation series is determined termwise through the successive linear initial value problems

$$\begin{aligned} \dot{u}_0 &= (\alpha + x(0)e^{it})x(0), \quad u_0(0) = 0, \\ \dot{u}_1 &= (\alpha + 2x(0)e^{it})u_0, \quad u_1(0) = 0, \\ \dot{u}_2 &= (\alpha + 2x(0)e^{it})u_1 + e^{it}u_0^2, \quad u_2(0) = 0, \end{aligned}$$

etc. Integrating termwise, we obtain the naive expansion

$$
\begin{aligned}
x_\epsilon(t) = e^{it}\Big[&x(0) + \epsilon(\alpha t + ix(0)(1-e^{it}))x(0) \\
&+ \epsilon^2 x(0)\Big[\frac{1}{2}\alpha^2 t^2 + i\alpha x(0)t(1-2e^{it}) \\
&\qquad - x(0)(1-e^{it})(\alpha + x(0)(1-e^{it}))\Big] + \mathcal{O}(\epsilon^3)\Big],
\end{aligned} \tag{37}
$$

valid asymptotically for bounded t values. The anticipated secular terms occur, however, for $\alpha \neq 0$, indicating the breakdown of the approximation (37) when $\tau = \epsilon t \to \infty$.

If we instead seek an asymptotic solution $x_\epsilon(t)$ of (33), using our ansatz

$$
x_\epsilon(t) = e^{it}(A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau), t, \epsilon)), \tag{38}
$$

the amplitude A_ϵ and the correction U will have to satisfy (21) and (22), respectively. Since $f(A_\epsilon(\tau), t, 0) = (\alpha + A_\epsilon(\tau)e^{it})A_\epsilon(\tau)$, the average

$$
\langle f(A_\epsilon(\tau), t, 0)\rangle = \alpha A_\epsilon(\tau)
$$

is the leading term of its Fourier series, and it is supplemented by

$$
\{f(A_\epsilon(\tau), t, 0)\} = A_\epsilon^2(\tau)e^{it}.
$$

This implies that both

$$
\frac{dA_\epsilon}{d\tau} = \alpha A_\epsilon + \mathcal{O}(\epsilon)
$$

and

$$
U_0(A_\epsilon(\tau), t) = iA_\epsilon^2(\tau)(1-e^{it}),
$$

and thus

$$
A_\epsilon(\tau) = e^{\alpha\tau}x(0) + \mathcal{O}(\epsilon)
$$

is defined on all $\tau \geq 0$, provided $\operatorname{Re}\alpha \leq 0$. Otherwise, the solution $x_\epsilon(t)$ will be bounded only for finite τ.

The next-order corrections to $\frac{dA_0}{d\tau}$ and U_0 involve the expression

$$
\begin{aligned}
&f_x(A_\epsilon, t, 0)U_0(A_\epsilon, t) - \frac{\partial U_0}{\partial A_\epsilon}(A_\epsilon, t)\langle f(A_\epsilon, t, 0)\rangle \\
&\qquad = (-i\alpha A_\epsilon^2 + 2iA_\epsilon^3 e^{it})(1-e^{it}).
\end{aligned}
$$

Since its average part is $-i\alpha A_\epsilon^2$, the $\mathcal{O}(\epsilon)$ improved approximations satisfy the amplitude equation

$$
\frac{dA_\epsilon}{d\tau} = \alpha A_\epsilon - \epsilon i\alpha A_\epsilon^2 + \mathcal{O}(\epsilon^2), \tag{39}
$$

and the corresponding secular-free correction to A_ϵ is given by

$$
U(A_\epsilon(\tau), t, \epsilon) = iA_\epsilon^2(1-e^{it}) - \epsilon iA_\epsilon^2(1-e^{it})(\alpha + A_\epsilon(1-e^{it})) + \mathcal{O}(\epsilon^2). \tag{40}
$$

As expected, the latter coincides with the secular-free terms of the appropriately truncated naive expansion, with the slowly varying amplitude A_ϵ replacing the initial value $x(0)$.

For $\operatorname{Re}\alpha < 0$, $A_0(\tau)$ will decay exponentially to zero, and this allows us to obtain the asymptotic solution (38) for all $\tau \geq 0$. The most interesting case occurs when $\operatorname{Re}\alpha = 0$. Then, the two-term truncation of the amplitude equation (39) is essentially the same as the original Riccati equation (33). To find the solution for $\kappa = \epsilon^2 t = \mathcal{O}(1)$ generally requires another renormalization, so we will then obtain an asymptotic representation of the solution in terms of the three scales, t, τ, and an amplitude B_ϵ that is a function of κ.

A numerical verification of any presumed approximation X can be carried out by employing the technique of Bosley (1996). We define the absolute error

$$E(t,\epsilon) = |x_{\text{exact}} - X|,$$

although we often employ a carefully computed numerical solution in place of the unknown exact solution. If $E = \mathcal{O}(\epsilon^{n+1})$ for a fixed time, the value of $\log(E)$ as a function of $\log\epsilon$ should be linear with slope $n+1$ in the limit $\epsilon \to 0$. The slope is readily determined by using a linear least squares fit. For the example, interesting results are obtained by considering the three separate cases: $\alpha = 1$, $\alpha = -1$, and $\alpha = i$. (Comparable conclusions on longer time intervals naturally follow for the example

$$\dot{x} = i\epsilon x + \epsilon^2 x(\alpha + x),$$

which we treat by immediately introducing $\tau = \epsilon t$ as a replacement for the given time t.)

Figures 1–3 below are comparisons of the exact solutions in these three cases with, respectively, regular perturbation and RG asymptotic approximations for (33), together with their numerical verifications of asymptotic validity using Bosley's technique for $t = 10$.

(b) We next consider the nonautonomous equation

$$\dot{x} = \epsilon N(x,t) \equiv \epsilon(-x^3 - x^2\cos t + \sin t), \tag{41}$$

introduced by Murdock and Wang (1996), together with a positive initial value $x(0)$. Since $x\dot{x} < 0$ for $|x|$ sufficiently large, the solution $x_\epsilon(t)$ remains bounded for all times. Setting

$$x_\epsilon(t) = x(0) + \epsilon u(t, x(0), \epsilon),$$

it follows that u must satisfy the initial value problem

$$\begin{aligned}\dot{u} = (-x^3(0) + x^2(0)\cos t + \sin t) + \epsilon(-3x^2(0) + 2x(0)\cos t)u \\ + \epsilon^2(-3x(0) + \cos t)u^2, \quad u(0) = 0,\end{aligned}$$

for which a naive expansion could be readily generated. Alternatively, the ansatz (or near-identity transformation)

$$x_\epsilon(t) = A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau), t, \epsilon) \tag{42}$$

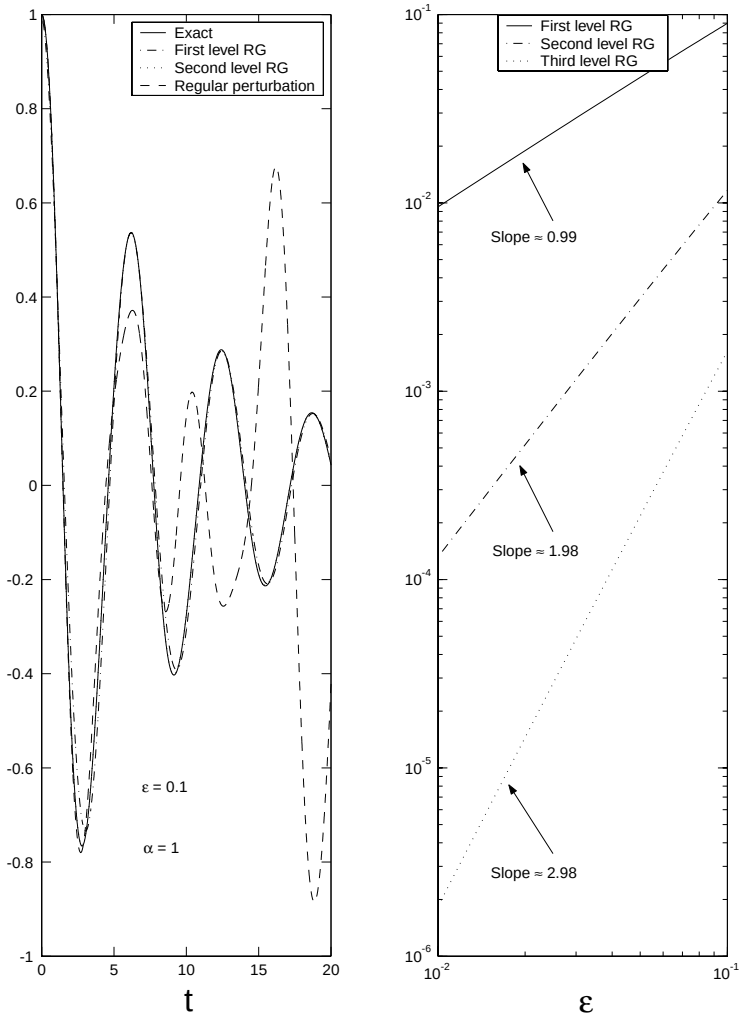

FIG. 1.

involves, to leading order, the amplitude equation

$$\frac{dA_\epsilon}{d\tau} = \langle N(A_\epsilon, t)\rangle + \mathcal{O}(\epsilon) = -A_\epsilon^3 + \mathcal{O}(\epsilon),$$

predicted by averaging, and the secular-free correction term

$$U_0(A_\epsilon, t) = \int_0^t \{N(A_\epsilon, s)\}ds = A_\epsilon^2(\tau)\sin t + 1 - \cos t.$$

Since the resulting limiting amplitude

$$A_0(\tau) = \frac{x(0)}{\sqrt{2\tau x^2(0) + 1}} \tag{43}$$

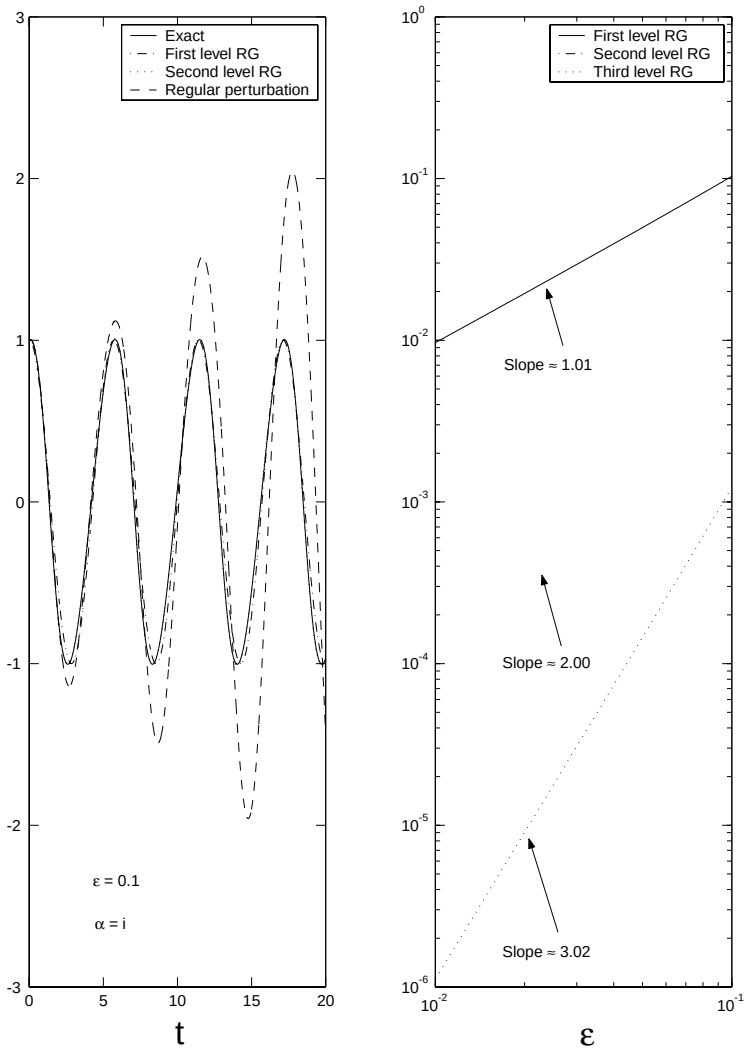

FIG. 2.

decays only algebraically as $\tau \to \infty$, we naturally seek its $\mathcal{O}(\epsilon)$ correction determined by using the average part of the expression

$$N_x(A_0,t)U_0(A_0,t) - \langle N(A_0,t)\rangle U_{0x}(A_0,t) \\ = -(3A_0^2 + A_0) - A_0^4 \sin t + (3A_0^2 + 2A_0)\cos t + A_0^3 \sin 2t - A_0 \cos 2t.$$

Since this implies the more accurate amplitude equation

$$\frac{dA_\epsilon}{d\tau} = -A_\epsilon^3 - \epsilon(3A_\epsilon^2 + A_\epsilon) + \mathcal{O}(\epsilon^2), \tag{44}$$

the regular perturbation series

$$A_\epsilon(\tau) = A_0(\tau) + \epsilon A_1(\tau) + \mathcal{O}(\epsilon^2) \tag{45}$$

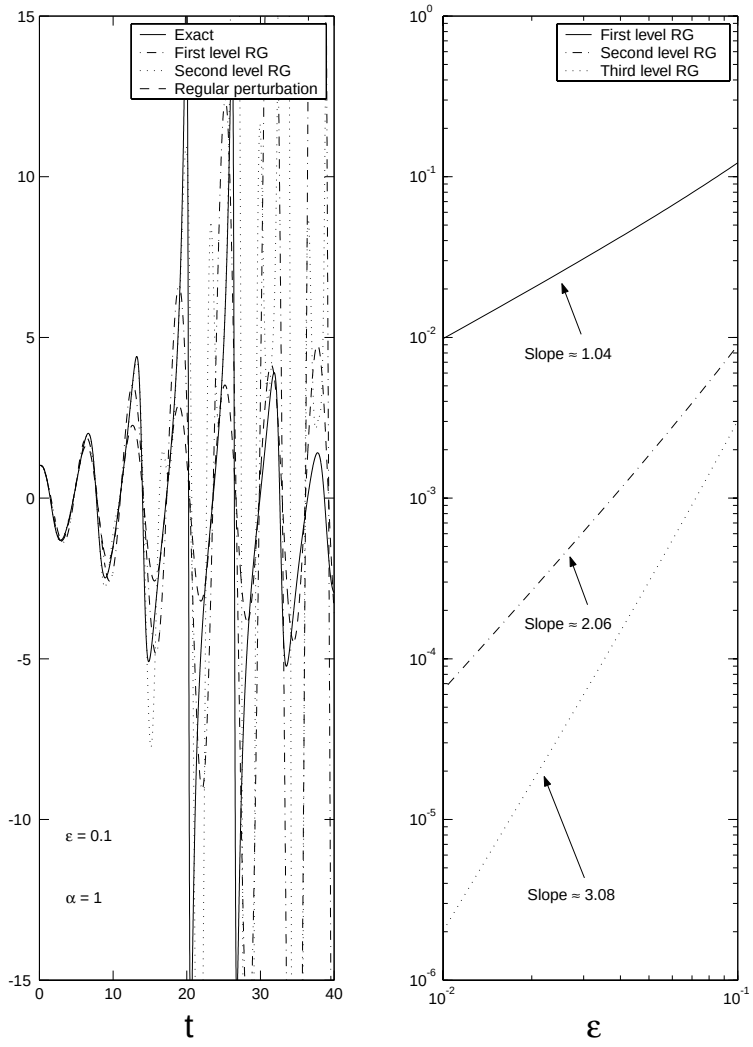

FIG. 3.

will require that the first correction term A_1 satisfy the linear initial value problem

$$\frac{dA_1}{d\tau} = -3A_0^2 A_1 - (3A_0^2 + A_0), \quad A_1(0) = 0.$$

We write its exact solution as

$$A_1(\tau) = -\frac{\sqrt{2\tau x^2(0)+1}}{4x(0)} - 1 + \left(\frac{1}{4x(0)} + 1\right) \frac{1}{(\sqrt{2\tau x^2(0)+1})^3}. \tag{46}$$

Since $|A_1|$ blows up like $\tau^{1/2}$ as $\tau \to \infty$, we shall attempt to eliminate its secular term and later ones in (45) by using a traditional renormalization. Setting

$$x(0) = B_\epsilon(\kappa) + \epsilon W(B_\epsilon(\kappa), \tau, \epsilon) \tag{47}$$

in (45) and using a power series for W, we get the power series expansion

$$A_\epsilon(\tau) = \frac{B_\epsilon + \epsilon W}{\sqrt{2\tau(B_\epsilon+\epsilon W)^2+1}} - \epsilon\left[\frac{\sqrt{2\tau(B_\epsilon+\epsilon W)^2+1}}{4(B_\epsilon+\epsilon W)} - 1 + \cdots\right] + \cdots$$
$$= \frac{B_\epsilon}{\sqrt{2\tau B_\epsilon^2+1}} + \epsilon\left[\frac{W_0}{\sqrt{2\tau B_\epsilon^2+1}} - \frac{2\tau B_\epsilon^2 W_0}{(\sqrt{2\tau B_\epsilon^2+1})^3} - \frac{\sqrt{2\tau B_\epsilon^2+1}}{4B_\epsilon} + \cdots\right] + \cdots.$$

Thus, we can cancel the troublesome τ-secular term at $\mathcal{O}(\epsilon)$ by picking

$$W_0(B_\epsilon,\tau) = \frac{(2\tau B_\epsilon^2+1)^2}{4B_\epsilon}.$$

The resulting second level RG equation (32) is

$$\frac{dB_\epsilon}{d\kappa} = -\frac{\partial W_0}{\partial \kappa} + \mathcal{O}(\epsilon) = -\frac{2}{\epsilon}\kappa B_\epsilon^2 - B_\epsilon + \mathcal{O}(\epsilon).$$

Solving the two-term approximate Riccati equation with the initial value $B_\epsilon(0) = x(0)$ determines the exponentially decaying

$$B_0(\kappa) = \frac{e^{-\kappa}x(0)}{\sqrt{\frac{x^2(0)}{\epsilon}(1-e^{-2\kappa}-2\kappa e^{-2\kappa})+1}} \tag{48}$$

(with admitted abuse of notation) and the corresponding leading-order approximation

$$x_\epsilon(t) = \frac{B_0(\kappa)}{\sqrt{\frac{2\kappa}{\epsilon}B_0^2(\kappa)+1}} + \mathcal{O}(\epsilon) \tag{49}$$

to the decaying solution, which is asymptotically valid for all $t \geq 0$. We note that the regular perturbation expansion is asymptotically correct for t finite, that the series (42) and (45) with τ-secular terms is likewise correct for τ finite, but that the twice-renormalized expansion corresponding to (49) is needed on longer time intervals. The algebraic decay of the limiting solution with $\sqrt{\kappa/\epsilon} = \sqrt{\epsilon t}$ is unexpected, but it follows from renormalization, as does the ultimate exponential decay as $\kappa \to \infty$. Analogous behavior was obtained in Mudavanhu and O'Malley (2001) in solving the second-order equation

$$\ddot{y} + y + \epsilon\dot{y}^3 + 3\epsilon^2\dot{y} = 0,$$

introduced in Morrison (1966).

Figure 4 is a comparison of the numerical solution and the first and second *level* RG asymptotic approximations for the solution of (41). The second level approximation is obtained by renormalizing the second-order amplitude equation as indicated. Figure 5 shows the numerical verifications of the RG approximations using Bosley's technique for $t = 10$.

Second-order scalar equations. Mudavanhu and O'Malley (2001) considered scalar equations of the form

$$\ddot{y} + y + \epsilon g(y,\dot{y},\epsilon) = 0 \tag{50}$$

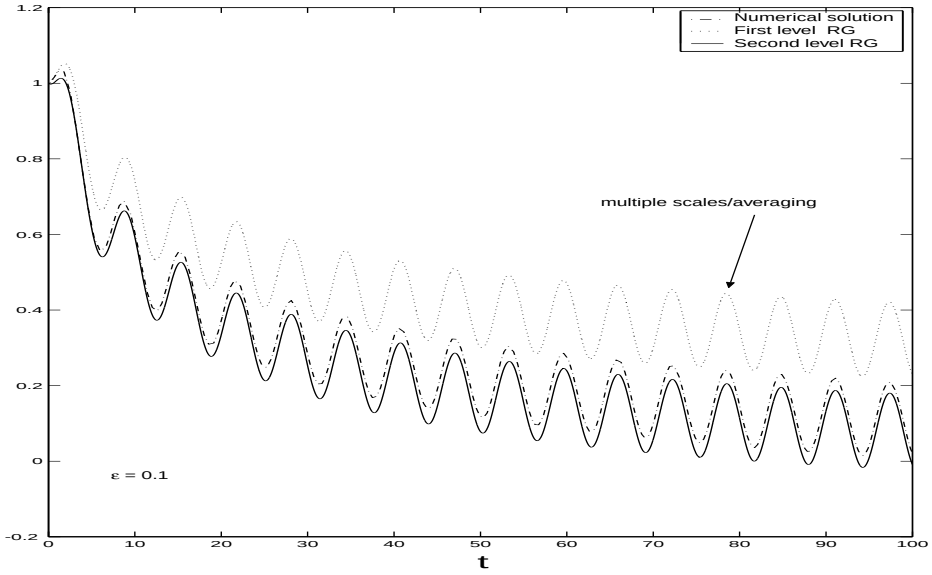

FIG. 4.

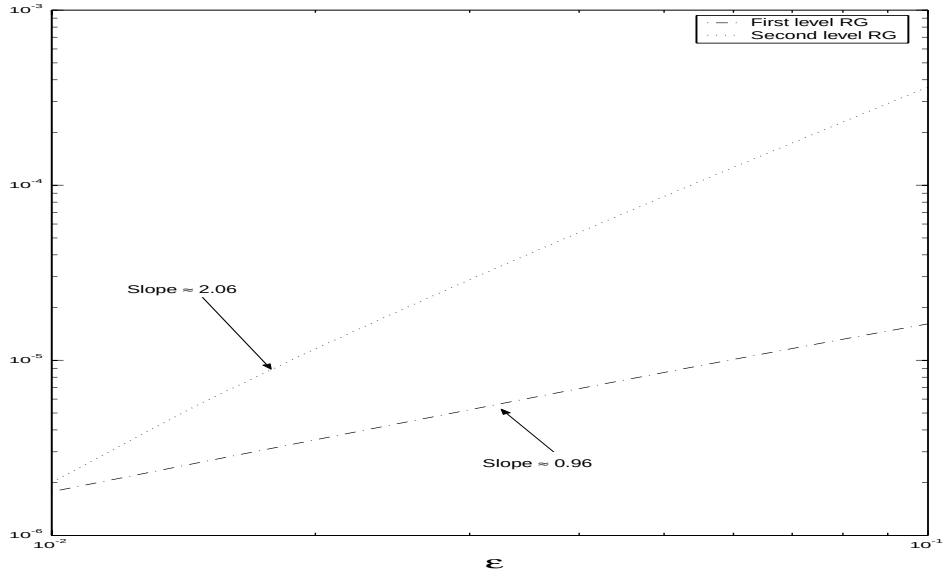

FIG. 5.

on $t \geq 0$, with $y(0)$ and $\dot{y}(0)$ prescribed. Such problems take the form (1) when one introduces

$$x = \begin{pmatrix} y \\ \dot{y} \end{pmatrix}, \qquad M = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}, \quad \text{and } N(x,\epsilon) = \begin{pmatrix} 0 \\ -g(y,\dot{y},\epsilon) \end{pmatrix}, \tag{51}$$

and thus their asymptotic solution on appropriate time intervals is determined by the preceding.

It is more traditional, however, to use the Prüfer transformation

$$y = \rho_\epsilon(t)\cos(t+\psi_\epsilon(t)), \qquad \dot{y} = -\rho_\epsilon(t)\sin(t+\psi_\epsilon(t)) \tag{52}$$

to obtain a system of differential equations for the nonnegative amplitude ρ_ϵ and the phase ψ_ϵ. As in variation of parameters,

$$\dot{y} = \frac{d\rho_\epsilon}{dt}\cos(t+\psi_\epsilon) - \rho_\epsilon \sin(t+\psi_\epsilon)\left(1+\frac{d\psi_\epsilon}{dt}\right)$$

and

$$\ddot{y} = -\frac{d\rho_\epsilon}{dt}\sin(t+\psi_\epsilon) - \rho_\epsilon \cos(t+\psi_\epsilon)\left(1+\frac{d\psi_\epsilon}{dt}\right)$$

imply a linear algebraic system for $\frac{d\rho_\epsilon}{dt}$ and $\frac{d\psi_\epsilon}{dt}$ that yields

$$\begin{cases} \dfrac{d\rho_\epsilon}{dt} = \epsilon \sin(t+\psi_\epsilon) g(\rho_\epsilon\cos(t+\psi_\epsilon), -\rho_\epsilon \sin(t+\psi_\epsilon)), \\ \dfrac{d\psi_\epsilon}{dt} = \dfrac{\epsilon}{\rho_\epsilon}\cos(t+\psi_\epsilon) g(\rho_\epsilon\cos(t+\psi_\epsilon), -\rho_\epsilon \sin(t+\psi_\epsilon)). \end{cases} \tag{53}$$

The needed initial values $\rho_\epsilon(0)$ and $\psi_\epsilon(0)$ for (53) are likewise uniquely specified since

$$y(0) = \rho_\epsilon(0)\cos\psi_\epsilon(0) \text{ and } \dot{y}(0) = -\rho_\epsilon(0)\sin\psi_\epsilon(0). \tag{54}$$

Since ψ_ϵ occurs in the combination $z \equiv t + \psi_\epsilon(t)$, we can rewrite (53) as a 2π-periodic function of z:

$$\begin{cases} \dfrac{d\rho_\epsilon}{dz} = \dfrac{\epsilon\rho_\epsilon \sin z\, g(\rho_\epsilon\cos z, -\rho_\epsilon \sin z)}{\rho_\epsilon + \epsilon\cos z\, g(\rho_\epsilon\cos z, -\rho_\epsilon\sin z)}, \\ \dfrac{d\psi_\epsilon}{dz} = \dfrac{\epsilon\cos z\, g(\rho_\epsilon\cos z, -\rho_\epsilon \sin z)}{\rho_\epsilon + \epsilon\cos z\, g(\rho_\epsilon\cos z, -\rho_\epsilon\sin z)}. \end{cases} \tag{55}$$

Our ansatz (19) suggests seeking an asymptotic solution for (55) in the form

$$\begin{cases} \rho_\epsilon(t) = R_\epsilon(\tau) + \epsilon U(R_\epsilon(\tau), \Psi_\epsilon(\tau), t, \epsilon), \\ \psi_\epsilon(t) = \Psi_\epsilon(\tau) + \epsilon V(R_\epsilon(\tau), \Psi_\epsilon(\tau), t, \epsilon). \end{cases} \tag{56}$$

The advantage obtained is that the first-order renormalized system is triangular, i.e.,

$$\begin{cases} \dfrac{dR_\epsilon}{d\tau} = \alpha(R_\epsilon,\epsilon) = \dfrac{1}{2\pi}\displaystyle\int_0^{2\pi} \sin z\, g(R_\epsilon\cos z, -R_\epsilon\sin z)dz + \mathcal{O}(\epsilon), \\ \dfrac{d\Psi_\epsilon}{d\tau} = \beta(R_\epsilon,\epsilon) = \dfrac{1}{2\pi R_\epsilon}\displaystyle\int_0^{2\pi} \cos z\, g(R_\epsilon\cos z, -R_\epsilon\sin z)dz + \mathcal{O}(\epsilon). \end{cases} \tag{57}$$

Note that $\alpha(R_\epsilon, 0)$ and $\beta(R_\epsilon, 0)$ are half of the corresponding first harmonic coefficients in the Fourier series for $g(R_\epsilon\cos z, -R_\epsilon\sin z)$ on $0 \le z \le 2\pi$. It's an easy system to solve implicitly as

$$\tau = \int_{R_\epsilon(0)}^{R_\epsilon} \frac{du}{\alpha(u,\epsilon)} \quad \text{and} \quad \Psi_\epsilon(\tau) = \psi_\epsilon(0) + \int_0^\tau \beta(R_\epsilon(p),\epsilon)dp, \tag{58}$$

although specifying where $R_\epsilon(\tau)$ is well defined involves all the anticipated complications. By the chain rule, it also follows that

(59)
$$\begin{cases} U_0(R_\epsilon(\tau),\Psi_\epsilon(\tau),t) = \displaystyle\int_0^t [\sin(s+\Psi_\epsilon(\tau))g(R_\epsilon(\tau)\cos(s+\Psi_\epsilon(\tau)) \\ \qquad\qquad - R_\epsilon(\tau)\sin(s+\Psi_\epsilon(\tau))) - \alpha(R_\epsilon(\tau),0)]ds \\ \text{and} \\ V_0(R_\epsilon(\tau),\Psi_\epsilon(\tau),t) = \dfrac{1}{R_\epsilon(\tau)}\displaystyle\int_0^t [\cos(s+\Psi_\epsilon(\tau))g(R_\epsilon(\tau)\cos(s+\Psi_\epsilon(\tau)) \\ \qquad\qquad - R_\epsilon(\tau)\sin(s+\Psi_\epsilon(\tau))) - \beta(R_\epsilon(\tau),0)]ds. \end{cases}$$

Moreover, using the ansatz (56), we get the secular-free approximations

(60)
$$\begin{cases} y = \rho\cos(t+\psi) = R_\epsilon\cos(t+\Psi_\epsilon) + \epsilon(U_0\cos(t+\Psi_\epsilon) - R_\epsilon V_0\sin(t+\Psi_\epsilon)) + \mathcal{O}(\epsilon^2) \\ \text{and} \\ \dot y = -\rho\sin(t+\psi) = -R_\epsilon\sin(t+\Psi_\epsilon) - \epsilon(U_0\sin(t+\Psi_\epsilon) + R_\epsilon V_0\cos(t+\Psi_\epsilon)) + \mathcal{O}(\epsilon^2). \end{cases}$$

Higher-order approximations follow without difficulty, even for many problems where classical methods break down.

(a) As a first concrete example, consider the Duffing–van der Pol equation

$$\ddot y + y + \epsilon y^3 + \epsilon^2(y^2-1)\dot y = 0, \tag{61}$$

introduced by Benney and Newell (1967). Seeking a solution as

$$y = \rho_\epsilon\cos(t+\psi_\epsilon) \quad \text{and} \quad \dot y = -\rho_\epsilon\sin(t+\psi_\epsilon)$$

provides the periodic forcing $g = y^3 + \epsilon(y^2-1)\dot y$ as

$$\begin{aligned} g(y,\dot y,\epsilon) = {} & \frac{1}{4}\rho_\epsilon^3[3\cos(t+\psi_\epsilon) + \cos 3(t+\psi_\epsilon)] \\ & + \epsilon\Big[-\frac{\rho_\epsilon^3}{4}(\sin(t+\psi_\epsilon) + \sin 3(t+\psi_\epsilon)) \\ & \qquad + \rho_\epsilon^2\sin 2(t+\psi_\epsilon) - \rho_\epsilon\sin(t+\psi_\epsilon)\Big]. \end{aligned}$$

Since its leading term has a trivial $\sin z$ coefficient in its Fourier series and $\frac{3}{4}\rho_\epsilon^3$ as the $\cos z$ coefficient, we will have the amplitude and phase equations

$$\frac{d\rho_\epsilon}{d\tau} = \mathcal{O}(\epsilon) \quad \text{and} \quad \frac{d\psi_\epsilon}{d\tau} = \frac{3}{8}\rho_\epsilon^2 + \mathcal{O}(\epsilon).$$

(Note that Cox and Roberts (1995) and Roberts (1997) attain such reductions efficiently by *normal form* transformations implemented using REDUCE. Mudavanhu (2000) obtains the same results and corresponding higher-order terms via a renormalization method automated using MAPLE.) Indeed, our results suggest the more efficient introduction of the slower-time $\kappa = \epsilon^2 t$. Incorporating κ and using the next

terms in (57), we obtain

$$\begin{cases} \dfrac{dR_\epsilon}{d\kappa} = \dfrac{1}{2}R_\epsilon\left(1 - \dfrac{1}{4}R_\epsilon^2\right) + \mathcal{O}(\epsilon) \\ \text{and} \\ \dfrac{d\Psi_\epsilon}{d\tau} = \dfrac{3}{8}R_\epsilon^2 - \dfrac{15\epsilon}{256}R_\epsilon^4 + \mathcal{O}(\epsilon^2). \end{cases} \tag{62}$$

Solving the limiting Bernoulli equation determines an expansion for

$$R_\epsilon(\kappa) = R_0(\kappa) + \epsilon R_1(\kappa) + \epsilon^2(\cdots) \tag{63}$$

as an exponentially decaying amplitude for all $\kappa \geq 0$, with leading term

$$R_0(\kappa) = \frac{2}{\sqrt{1 - (1 - 4/\rho_\epsilon^2(0))e^{-\kappa}}}.$$

The resulting limit cycle behavior follows with the phase

$$\Psi_\epsilon(t) = \psi_\epsilon(0) + \frac{3}{8}\int_0^t R_\epsilon^2(\epsilon^2 s)\left(1 - \frac{5\epsilon}{32}R_\epsilon^2(\epsilon^2 s)\right)ds + \mathcal{O}(\epsilon^2 t). \tag{64}$$

In the integrand, it is clearly preferable to represent $R_\epsilon(\kappa)$ as the sum of its steady-state limit plus an exponentially decaying transient. Higher-order approximations to the solution follow as in (60).

Alternatively, we can use the transformation (51) and the spectral decomposition $M = iV\Lambda V^{-1}$ for a nonsingular modal matrix $V = \left(\begin{smallmatrix} 1 & 1 \\ i & -i \end{smallmatrix}\right)$ and $\Lambda = \left(\begin{smallmatrix} -1 & 0 \\ 0 & 1 \end{smallmatrix}\right)$. Directly applying our basic ansatz,

$$x_\epsilon(t) = Ve^{i\Lambda t}V^{-1}(A_\epsilon + \epsilon U(A_\epsilon(\tau), \epsilon)), \tag{65}$$

where $A_\epsilon = \left(\begin{smallmatrix} a_\epsilon \\ \bar{a}_\epsilon \end{smallmatrix}\right)$, for complex conjugates a_ϵ and $\bar{a}_\epsilon$, involves, to leading order, the amplitude equation

$$\frac{dA_\epsilon}{d\tau} = \langle e^{-i\Lambda t}V^{-1}N(Ve^{i\Lambda t}x, 0)\rangle + \mathcal{O}(\epsilon) = \frac{3}{2}i|a_\epsilon|^2\begin{pmatrix} a_\epsilon \\ -\bar{a}_\epsilon \end{pmatrix} + \mathcal{O}(\epsilon)$$

and the secular-free correction term

$$\begin{aligned} U_0(A_\epsilon, t) &= \int_0^t \{e^{-i\Lambda s}V^{-1}N(Ve^{i\Lambda s}x, 0)\}ds \\ &= \frac{1}{4}\begin{pmatrix} a_\epsilon^3 e^{-2it} - 3\bar{a}_\epsilon|a_\epsilon|^2 e^{2it} + \frac{1}{2}\bar{a}_\epsilon^3 e^{4it} \\ \bar{a}_\epsilon^3 e^{2it} - 3a_\epsilon|a_\epsilon|^2 e^{-2it} + \frac{1}{2}a_\epsilon^3 e^{-4it} \end{pmatrix}. \end{aligned}$$

Letting $a_\epsilon = \frac{R_\epsilon}{2}e^{-i\Psi_\epsilon}$ provides the amplitude and phase equations $\frac{dR_\epsilon}{d\tau} = \mathcal{O}(\epsilon)$, $\frac{d\Psi_\epsilon}{d\tau} = \frac{3}{8}R_\epsilon^2 + \mathcal{O}(\epsilon)$ as before and the corresponding asymptotic approximation

$$y = R_\epsilon\cos(t + \Psi_\epsilon) + \epsilon\frac{R_\epsilon}{16}\left[3\cos(t + \Psi_\epsilon) + \frac{1}{2}\cos 3(t + \Psi_\epsilon)\right] + \epsilon^2(\cdots). \tag{66}$$

Higher-order approximations follow in a straightforward fashion.

(b) We finally seek the RG equations resulting from two weakly coupled van der Pol oscillators

$$\ddot{y} + \Omega y + \epsilon(I - \mathcal{C}^2)\dot{y} = \epsilon\mathcal{B}(\alpha y + \beta\dot{y}), \tag{67}$$

where

$$y = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix}, \qquad \Omega = \begin{pmatrix} 1 & 0 \\ 0 & 1+\Delta \end{pmatrix}, \qquad \mathcal{C} = \begin{pmatrix} y_1 & 0 \\ 0 & y_2 \end{pmatrix}, \qquad \mathcal{B} = \begin{pmatrix} -1 & 1 \\ 1 & -1 \end{pmatrix} \tag{68}$$

and I is an identity matrix (cf. Reinhall and Storti (2000) and Low (2002)). Here α and β are coupling constants, and Δ is a detuning parameter related to the difference in the natural frequencies of the two oscillators. We now seek asymptotic solutions of the form

$$\begin{cases} y_1(t,\epsilon) = R_1(\tau,\epsilon)\cos(t + \Psi_1(\tau,\epsilon)) + \epsilon(\cdots), \\ \\ y_1(t,\epsilon) = R_2(\tau,\epsilon)\cos(t + \Psi_2(\tau,\epsilon)) + \epsilon(\cdots) \end{cases} \tag{69}$$

for the slow time $\tau = \epsilon t$, where R_j and Ψ_j, for $j = 1$ and 2, represent the amplitude and phase modulations. The functions y_j are said to be *phase locked* when the difference

$$\phi_\epsilon = \Psi_{2\epsilon} - \Psi_{1\epsilon} \tag{70}$$

is a constant. When the oscillators are running at unequal frequencies (i.e., $\Delta \neq 0$), ϕ_ϵ will grow unbounded, defining a condition known as a *phase drift*. An intermediate situation exists when ϕ_ϵ varies periodically, a condition known as *phase entrainment*.

Applying our basic ansatz, by first transforming to a four-dimensional system of the form (1), we systematically obtain the RG equations

$$\begin{aligned} 2\frac{dA_{1\epsilon}}{d\tau} &= A_{1\epsilon}(1 - |A_{1\epsilon}|^2) - \beta(A_{1\epsilon} - A_{2\epsilon}) + i\alpha(A_{1\epsilon} - A_{2\epsilon}) + \epsilon(\cdots), \\ 2\frac{dA_{2\epsilon}}{dt} &= A_{2\epsilon}(1 - |A_{2\epsilon}|^2) - \beta(A_{2\epsilon} - A_{1\epsilon}) + i\alpha(A_{2\epsilon} - A_{1\epsilon}) + i\frac{\Delta}{2}A_{1\epsilon} + \epsilon(\cdots). \end{aligned}$$

Letting $A_{j\epsilon} = R_{j\epsilon}e^{-i\Psi_{j\epsilon}}$ for $j = 1$ and 2, we get the system of three slowly varying RG equations

$$\begin{cases} 2\dfrac{dR_{1\epsilon}}{d\tau} = (1 - R_{1\epsilon}^2)R_{1\epsilon} - \beta(R_{1\epsilon} - R_{2\epsilon}\cos\phi_\epsilon) + \alpha R_{2\epsilon}\sin\phi_\epsilon + \epsilon(\cdots), \\ 2\dfrac{dR_{2\epsilon}}{d\tau} = (1 - R_{2\epsilon}^2)R_{2\epsilon} - \beta(R_{2\epsilon} - R_{1\epsilon}\cos\phi_\epsilon) \ - \alpha R_{1\epsilon}\sin\phi_\epsilon + \epsilon(\cdots), \\ 2\dfrac{d\phi_\epsilon}{d\tau} = \Delta - \beta\left(\dfrac{R_{2\epsilon}}{R_{1\epsilon}} - \dfrac{R_{1\epsilon}}{R_{2\epsilon}}\right)\sin\phi_\epsilon - \alpha\left(\dfrac{R_{2\epsilon}}{R_{1\epsilon}} + \dfrac{R_{1\epsilon}}{R_{2\epsilon}}\right)\cos\phi_\epsilon + \epsilon(\cdots). \end{cases} \tag{71}$$

Stability analyses of (67) can be carried out based on these and higher-order amplitude equations (cf. Chakraborty and Rand (1988)).

Relation to two-timing and other classical techniques. The asymptotic solution of the initial value problem (3)

$$\dot{z} = \epsilon f(z, t, \epsilon)$$

(in standard form) could be obtained using the two-time ansatz

$$z = z(t, \tau, \epsilon)$$

for the bounded slow-time $\tau = \epsilon t$. The chain rule implies that

$$\dot{z} = \frac{\partial z}{\partial t} + \epsilon \frac{\partial z}{\partial \tau},$$

and thus substituting a power series expansion

$$z(t, \tau, \epsilon) = z_0(t, \tau) + \epsilon z_1(t, \tau) + \cdots \tag{72}$$

into (3) requires that

$$\frac{\partial z_0}{\partial t} = 0 \tag{73}$$

and

$$\frac{\partial z_j}{\partial t} = g_{j-1}(t, z_0, z_1, \ldots, z_{j-1}) - \frac{\partial z_{j-1}}{\partial \tau} \tag{74}$$

for each $j \geq 1$. Here

$$f(z(t, \tau, \epsilon), t, \epsilon) \sim \sum_{j=0}^{\infty} \epsilon^j g_j(t, z_0, \ldots, z_{j-1}, z_j),$$

where

$$g_j(t, z_0, \ldots, z_{j-1}, z_j) - f_z(z_0(t, \tau), t, 0) z_j$$

is a known function of the earlier coefficients $z_0, z_1, \ldots, z_{j-1}$ and t.

We first obtain the representation

$$z_0(t, \tau) = A_0(\tau) \tag{75}$$

from integrating (73), for some unspecified $A_0(\tau)$. Taking $j = 1$, we then find that

$$\frac{\partial z_1}{\partial t} = f_0(A_0(\tau), t) - \frac{dA_0}{d\tau}. \tag{76}$$

Recall that f_0 is a periodic function of t. To get the boundedness of z_1 as $t \to \infty$ requires the right-hand side to have zero average, i.e., A_0 must be the unique solution of the initial value problem for

$$\frac{dA_0}{d\tau} = \langle f_0(A_0(\tau), t) \rangle. \tag{25}$$

This leaves $\frac{\partial z_1}{\partial t} = \{f_0(A_0(\tau), t)\}$, and so

$$z_1(t, \tau) = A_1(\tau) + U_0(A_0(\tau), t) \tag{77}$$

for an unknown A_1 and the bounded function $U_0 = \int_0^t \{f_0(A_0(\tau), s)\} ds$, already encountered. If we next consider (74) for $j = 2$, the boundedness of z_2 will require the

average of the right-hand side to be zero. This, however, shows that A_1 must satisfy an initial value problem of the form

$$\frac{dA_1}{d\tau} = \left\langle \frac{\partial f_0}{\partial z}(A_0(\tau), t) \right\rangle A_1 + \widetilde{a_1}(A_0(\tau)),$$

with a known inhomogeneity $\widetilde{a}_1$ and the trivial initial value. The unique solution follows as in (26). Continuing, in this manner, to use the Fredholm alternative to get a bounded solution at every stage, we obtain our two-time expansion to any order.

Murdock and Wang (1996) prove that this result is asymptotically valid, to all orders, for finite τ. An attempt to comprehend renormalization has thus provided an opportunity to rethink two-timing. We point out, however, that a less restrictive method of *slowly varying amplitudes* is often used in applications (cf., e.g., the final chapter of Haberman (1998), in addition to the literature already cited). It compares to our ansatz (19),

$$z_\epsilon(t) = A_\epsilon(\tau) + \epsilon U(A_\epsilon(\tau), t, \epsilon),$$

rather than the more general two-timing expansion (72). The idea is to seek an amplitude $A_\epsilon(\tau)$, varying with the slow time τ and ϵ, so that secular terms in the resulting expansion are removed by appropriately selecting successive terms in the power series expansion of the amplitude (or envelope or RG) equation

$$\frac{dA_\epsilon}{d\tau} = a(A_\epsilon, \epsilon).$$

The relationship between *asymptotic matching* or *boundary layer theory* (cf., e.g., Il'in (1992) or O'Malley (1991)) and renormalization can be illustrated by considering the singularly perturbed initial value problem

$$\left\{ \begin{array}{l} \dot{x} = xy + \epsilon a x^3, \\ \epsilon \dot{y} = -y + \epsilon b x^2 \end{array} \right. \tag{78}$$

(introduced in Kuwamura (2001)) on $t \geq 0$ when the constants a and b satisfy $a+b < 0$.

The special case $b = 0$ is of special interest because it is exactly solvable. Because

$$y_\epsilon(t) = e^{-t/\epsilon} y(0),$$

x must be the unique solution

$$x_\epsilon(t) = \frac{e^{\epsilon y(0) e^{-t/\epsilon}} x(0)}{\sqrt{1 - 2a\epsilon x^2(0) \int_0^t e^{\epsilon y(0) e^{-r/\epsilon}} dr}}$$

of the resulting Bernoulli equation. Note that the solution decays algebraically to zero when $a < 0$. It is nearly constant for $a = 0$, and it blows up when

$$\epsilon \int_0^t e^{2\epsilon y(0) e^{-r/\epsilon}} dr = \frac{1}{2ax^2(0)}$$

if $a > 0$.

If we introduce the *fast time*

$$\lambda = \frac{t}{\epsilon}$$

into the corresponding *inner problem*

$$\begin{cases} \dfrac{dx}{d\lambda} = \epsilon xy + \epsilon^2 a x^3, \\ \dfrac{dy}{d\lambda} = -y + \epsilon b x^2, \end{cases}$$

we naturally seek the *inner expansion*

$$\begin{cases} u(\lambda,\epsilon) = u_0(\lambda) + \epsilon u_1(\lambda) + \epsilon^2 u_2(\lambda) + \cdots, \\ v(\lambda,\epsilon) = v_0(\lambda) + \epsilon v_1(\lambda) + \epsilon^2 v_2(\lambda) + \cdots. \end{cases}$$

Proceeding termwise, in the naive manner, we get

$$\begin{aligned} &u_0(\lambda) = x(0), \quad v_0(\lambda) = e^{-\lambda} y(0), \\ &u_1(\lambda) = -(1-e^{-\lambda})x^2(0), \qquad v_1(\lambda) = b(1-e^{-\lambda})x^2(0), \end{aligned}$$

and then, from

$$\frac{du_2}{d\lambda} = u_0 v_1 + u_1 v_0 + a u_0^3$$

and

$$\frac{dv_2}{d\lambda} = -v_2 + 2b u_0 u_1,$$

we get

$$u_2(\lambda) = (a+b)x^3(0)\lambda + bx^3(0)(e^{-\lambda}-1) + \frac{1}{2}(e^{-\lambda}-1)^2 x(0) y^2(0)$$

and

$$v_2(\lambda) = 2bx^2(0)y(0)\left[1 - e^{-\lambda} - \lambda e^{-\lambda}\right].$$

The Tikhonov–Levinson theory applies for t finite and guarantees that the inner expansion can be written as the asymptotic sum

$$\begin{aligned} u(\lambda,\epsilon) &= X(t,\epsilon) + \epsilon\xi(\lambda,\epsilon), \\ v(\lambda,\epsilon) &= \epsilon Y(t,\epsilon) + \eta(\lambda,\epsilon), \end{aligned}$$

where $\binom{X}{\epsilon Y}$ is the *outer expansion* and $\binom{\epsilon\xi}{\eta}$ is the *inner layer correction* that decays to zero exponentially as $\lambda \to \infty$. Replacing λ by t/ϵ defines the surviving outer expansion

$$\begin{aligned} X(t,\epsilon) &= x(0) + \epsilon(x(0)y(0) + (a+b)x^3(0)t) + \epsilon^2(\cdots), \\ \epsilon Y(t,\epsilon) &= \epsilon b x^2(0) + \epsilon^2(\cdots). \end{aligned}$$

Note the secular behavior visible as $\tau = \epsilon t \to \infty$. It is not fixable using Hoppensteadt (1966), because there is no asymptotic stability in t. We can eliminate the secular term, however, by renormalizing. Setting

$$x(0) = A_\epsilon(\tau) + \epsilon P(A_\epsilon(\tau), t, \epsilon) \quad \text{and} \quad y(0) = B_\epsilon(\tau) + \epsilon Q(A_\epsilon(\tau), t, \epsilon)$$

and by picking

$$P_0(A_0,t) = -(a+b)A_0^3 t \quad \text{and} \quad Q_0(A_0,t) = 0,$$

we get a secular-free approximation. Constancy of $x(0)$ and $y(0)$, however, forces A_0 and B_0 to satisfy the limiting amplitude equations

$$\frac{dA_0}{d\tau} = (a+b)A_0^3 \quad \text{and} \quad \frac{dB_0}{d\tau} = 0.$$

This has the algebraically decaying solution

$$A_0(\tau) = \frac{x(0)}{\sqrt{1-2(a+b)x^2(0)\tau}}$$

when $a+b<0$, already observed in the special case $b=0$. Higher-order terms follow, without difficulty. One could, analogously, also directly seek the asymptotic solution as a function of the three times λ, t, and τ.

Acknowledgments. The authors are grateful to a number of colleagues for their encouragement and suggestions. Special thanks go to Bernard Deconinck, Richard Haberman, Jerry Kevorkian, Rachel Kuske, James Murdock, Yoshi Oono, Hong Qian, and Tony Roberts. R. E. O'Malley, Jr., also wishes to thank the Fields Institute for Research in the Mathematical Sciences, Toronto, and the School of Mathematics and the Institute for Mathematics and its Applications at the University of Minnesota for their hospitality and support.

A DYNAMIC PRIORITY QUEUE MODEL FOR SIMULTANEOUS SERVICE OF TWO TRAFFIC TYPES*

CHARLES KNESSL†, DOO IL CHOI‡, AND CHARLES TIER†

Abstract. We consider a priority queue with a dynamic, queue-length-threshold scheduling policy. Customers are classed into two types (type-1 and type-2), and the service order of the two classes depends on the queue length of the type-1 queue. The high priority (type-2) class (e.g., voice) is served until the low priority (e.g., data) queue exceeds the threshold L, at which time service is given to the low priority class until its queue length decreases to L. The arrivals of the two classes follow independent Poisson processes, and the service time of each customer has an exponential distribution with parameter μ. We derive the balance equations in the steady state, and explicitly obtain the joint probability generating function for the queue lengths of the two customer classes. This gives the joint queue length distribution as an integral. We then obtain detailed asymptotic results for the joint distribution. In particular, we study the tail behavior. We also discuss heavy traffic diffusion approximations for this model.

1. Introduction.

1.1. Background. Due to recent applications in ATM (asynchronous transfer mode) networks, there has been renewed interest in priority queues. Here we consider the following model for providing simultaneous service to two classes of customers with different service requirements. There are two classes of customers (called type-1 and type-2 customers) and a single server. The arrivals of type-1 and type-2 customers follow independent Poisson processes with rates λ_1 and λ_2, respectively. The two streams of customers are accommodated into two queues with infinite capacities. Customers in each class are served on a first-come first-served basis. The service order of the two classes is determined by the queue-length-threshold (QLT) scheduling policy. First, we place a threshold L on the queue for type-1 customers. If the number of type-1 customers in the queue is less than or equal to the threshold L, the type-2 customers are served. Otherwise, the type-1 customers are served. If one of the queues is empty, the customers in other queue are served. The service time of a customer of either type has an exponential distribution with parameter μ. This queueing system is called a dynamic (or hybrid) priority queue with QLT scheduling policy (Figure 1.1).

In many modern applications, some classes of customers may have different service requirements than others. A method for supporting the different classes is the use of priority queues. There are static and dynamic priority queues. Examples of static priority queues, including nonpreemptive and preemptive queues, are given in [1], [2], [3], [4]. In such systems, the high priority class (e.g., voice) has much more

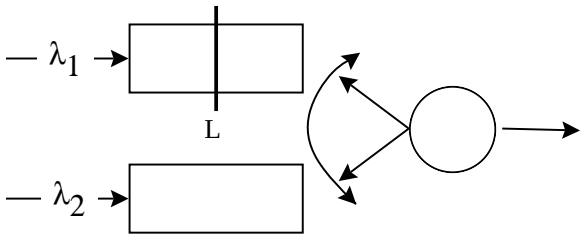

FIG. 1.1. *Model of a dynamic priority queue.*

stringent delay requirements than the low priority class (e.g., data). Therefore, the high priority class may have better performance than its delay requirements, but the low priority class may suffer from unacceptably long delays. In order to overcome this shortcoming, dynamic priority queues have been proposed and studied in [6], [7], [8]. Such models make it possible to improve the performance of the low priority class, while still meeting the service requirement (delay) of the high priority class.

This paper gives exact and asymptotic analyses of a dynamic priority queue with QLT scheduling. The results can be applied to traffic control, and in particular to satisfying the quality of service (QoS) requirements of real-time and nonreal-time traffic in ATM networks [9]. For example, in ATM networks, data is loss-sensitive but delay-insensitive, while voice is delay-sensitive but loss-insensitive. Thus, the high priority class (type-2 customers) may be considered as real-time traffic such as voice and the low priority class (type-1 customers) may be considered as nonreal-time traffic such as data. The value of L is chosen to insure that the type-2 traffic is within its delay requirements, i.e., the more stringent the delay requirement, the larger the value of L. The QLT scheduling policy was shown in [5] to be able to provide higher utilization and more flexible performance, with the proper adjustment of L, than several other scheduling schemes. Also, when $L = \infty$ in our model (or $L = 0$ in reversed priority), this is the well-known nonpreemptive static priority queue.

There has been much previous work on dynamic and static priority queues. Queueing systems with static priority are discussed in [1], [2], [3], [4]. Fratini [6] analyzed a dynamic single server priority queue, with the same scheduling policy as ours. He assumed that the queue for type-1 customers had infinite capacity and that the queue for type-2 customers had a finite capacity (K). The two classes had different general service time distributions. Using a discrete-time Markov chain embedded at service completion epochs, he identified the state transition probability matrix P and numerically analyzed the stationary probability vector x defined by

$$xP = x, \qquad xe = 1.$$

As an application for real-time and nonreal-time traffic in ATM networks, Lee and Sengupta [7] considered a dynamic priority queue. Their model is different from ours in that if the queue length in the buffer of real-time traffic is greater than a threshold, the next packet to be served is from the buffer of real-time traffic. Otherwise, the server checks the type of the packet that it has just served, and serves a packet of the other type. The real-time and nonreal-time traffic follow independent Poisson processes, and the queues have infinite capacities. By using the embedded Markov chain method at the service completion epochs, they obtained the joint probability generating function for queue lengths at these epochs. Then, they derived the marginal probability generating function for each queue length at an arbitrary time

using the obtained generating function and the PASTA (Poisson arrivals see time averages) property.

Recently, Choi and Choi [8] considered the $MMPP, M/G/1$ finite capacity queue with the same scheduling policy as ours. In this paper, the arrivals of type-1 customers follow a Poisson process, and the arrivals of type-2 customers follow a Markov-modulated Poisson process (MMPP) [10]. They applied this model to traffic control for real-time and nonreal-time traffic in ATM networks and assumed that the arrival of type-2 customers (real-time traffic) is MMPP, thus modeling the burstiness of real-time traffic. By using the embedded Markov chain method, they numerically obtained the marginal probability distribution for each queue.

Our model is in some respects simpler than those in [6], [7], [8]. However, we are able to provide more explicit analytic expressions. We also give detailed asymptotic results for the tail behavior of the joint queue length distribution. We first derive the balance equations for our queueing system. In section 2, we consider a simplified model in which the server leaves the type-2 queue only when the type-1 queue exceeds L. We consider the full model in section 3. For both models, we explicitly obtain the joint probability generating function for the queue lengths. By inverting the generating function, we obtain the joint queue length distribution as an integral. From this integral we compute asymptotic approximations for the tail behavior of the joint distribution. This leads to simple formulas that reveal the basic qualitative properties of the distribution. We also discuss heavy traffic diffusion approximations for the models. The main exact results are summarized in Theorems 2.1 and 3.1, the tail probabilities are given in Theorems 2.2–2.4, and the heavy traffic diffusion results are summarized in Theorems 2.5, 2.6, 3.2, and 3.3. The numerical accuracy of our asymptotic results is demonstrated in section 4.

1.2. Formulation of our queueing system. Let $N_1(t)$ and $N_2(t)$ be the queue length of the type-1 and type-2 customers, respectively, at time t. We also let λ_1 and λ_2 be the arrival rates of the type-1 and type-2 customers, and μ is the service rate of both classes. The process $(N_1(t), N_2(t))$ is Markov. We focus on analyzing the stationary probability distribution for the joint queue length, defined by

$$p(m,n) = \lim_{t\to\infty} Pr[N_1(t) = m, N_2(t) = n], \qquad m,\ n \geq 0.$$

We then obtain the following balance equations for the queueing system,

$$m \geq L+1,\ n \geq 1: \tag{1.1}$$
$$(\mu+\lambda_1+\lambda_2)p(m,n) = \lambda_1 p(m-1,n) + \lambda_2 p(m,n-1) + \mu p(m+1,n),$$

$$m = L,\ n \geq 1: \tag{1.2}$$
$$(\mu+\lambda_1+\lambda_2)p(L,n) = \lambda_1 p(L-1,n) + \lambda_2 p(L,n-1) + \mu p(L+1,n) + \mu p(L,n+1),$$

$$1 \leq m \leq L-1,\ n \geq 1: \tag{1.3}$$
$$(\mu+\lambda_1+\lambda_2)p(m,n) = \lambda_1 p(m-1,n) + \lambda_2 p(m,n-1) + \mu p(m,n+1),$$

$$m \geq L+1,\ n = 0: \tag{1.4}$$
$$(\mu+\lambda_1+\lambda_2)p(m,0) = \lambda_1 p(m-1,0) + \mu p(m+1,0),$$

$$m = L,\ n = 0: \tag{1.5}$$
$$(\mu + \lambda_1 + \lambda_2)p(L,0) = \lambda_1 p(L-1,0) + \mu p(L+1,0) + \mu p(L,1),$$

$$1 \le m \le L-1,\ n = 0: \tag{1.6}$$
$$(\mu + \lambda_1 + \lambda_2)p(m,0) = \lambda_1 p(m-1,0) + \mu p(m+1,0) + \mu p(m,1),$$

$$m = 0,\ n \ge 1: \tag{1.7}$$
$$(\mu + \lambda_1 + \lambda_2)p(0,n) = \lambda_2 p(0,n-1) + \mu p(0,n+1),$$

$$m = 0,\ n = 0: \tag{1.8}$$
$$(\lambda_1 + \lambda_2)p(0,0) = \mu p(0,1) + \mu p(1,0),$$

and the normalization

$$\sum_{m,n=0}^{\infty} p(m,n) = 1. \tag{1.9}$$

We assume that the following stability condition holds:

$$\rho_1 + \rho_2 < 1, \tag{1.10}$$

where $\rho_i = \lambda_i/\mu, i = 1, 2$.

2. A simplified model. We start by analyzing a simplified version of our queueing system. We assume that if $N_1(t) \le L$ and $N_2(t) = 0$, then the server becomes idle. Thus the server remains at the high priority (type-2) queue and leaves only when $N_1(t) > L$. This model is reasonable if there is a large overhead associated with switching between the two queues. We shall show that the solution to this simplified model may be used as a "building block" to analyze the more complicated system (1.1)–(1.9). In particular, the results in Theorems 3.1–3.3 in section 3 use the corresponding results in this section.

2.1. Exact solution. For the simplified model, once $N_1(t) \ge L$ for some time t, we have $N_1(t) \ge L$ for all future times. Then, $p(m,n)$ is nonzero only for $m \ge L, n \ge 0$, and we may set $p(L-1,n) = 0$. The boundary condition (1.5) is changed to

$$(\lambda_1 + \lambda_2)p(L,0) = \mu p(L+1,0) + \mu p(L,1), \tag{2.1}$$

and we need consider only (1.1), (1.2), (1.4), and (2.1).

To obtain the joint queue length distribution, we introduce the following generating functions:

$$G(z,w) = \sum_{n=0}^{\infty}\sum_{m=L}^{\infty} p(m,n) z^{m-L} w^n,$$
$$H(w) = \sum_{n=0}^{\infty} p(L,n) w^n.$$

From (1.1), (1.2), (1.4), and (2.1), we obtain the equation

$$\begin{aligned}\left[\lambda_1 z + \lambda_2 w - (\mu + \lambda_1 + \lambda_2) + \frac{\mu}{z}\right] G(z,w) \\ = \mu\left(\frac{1}{w} - 1\right) p(L,0) + \mu\left(\frac{1}{z} - \frac{1}{w}\right) H(w).\end{aligned} \tag{2.2}$$

The left-hand side may be rewritten as

$$\frac{\lambda_1}{z}(z - z_*(w))(z - \tilde{z}(w))G(z,w),$$

where

$$\begin{aligned} z_*(w) &= \frac{1}{2\lambda_1}\left[\mu + \lambda_1 + \lambda_2 - \lambda_2 w - \sqrt{(\mu + \lambda_1 + \lambda_2 - \lambda_2 w)^2 - 4\lambda_1\mu}\right], \\ \tilde{z}(w) &= \frac{1}{2\lambda_1}\left[\mu + \lambda_1 + \lambda_2 - \lambda_2 w + \sqrt{(\mu + \lambda_1 + \lambda_2 - \lambda_2 w)^2 - 4\lambda_1\mu}\right]. \end{aligned}$$

Noting that $|z_*(w)| < 1$ and requiring analyticity of $G(z,w)$ in the complex domain $\{|z| < 1, |w| < 1\}$, we set $z = z_*(w)$ and obtain $H(w)$ as

$$H(w) = \frac{z_*(w)(w-1)}{w - z_*(w)} p(L,0). \tag{2.3}$$

Substituting (2.3) into (2.2), we obtain

$$G(z,w) = \frac{p(L,0)}{\rho_1}\left(\frac{1-w}{w - z_*(w)}\right)\frac{1}{z - \tilde{z}(w)}. \tag{2.4}$$

Using the normalization condition $G(1,1) = 1$, $p(L,0)$ is given by

$$p(L,0) = 1 - \rho_1 - \rho_2.$$

By inverting the generating function $G(z,w)$, we obtain an integral representation for the joint probabilities $p(m,n)$, as given below.

THEOREM 2.1. *The joint queue length distribution for type-*1 *and type-*2 *customers for the simplified model is given by*

$$\begin{aligned} p(L+m,n) = \frac{p(L,0)}{2\pi i}\int_C \frac{1-w}{1-\rho_1 w\tilde{z}(w)}\frac{1}{[\tilde{z}(w)]^m}\frac{1}{w^{n+1}}dw, \\ m,n \geq 0, \end{aligned} \tag{2.5}$$

where $\tilde{z}(w)$ is given below (2.2)*, and*

$$p(L,0) = 1 - \rho_1 - \rho_2. \tag{2.6}$$

The contour C is a small loop about $w = 0$.

Next we investigate the marginal probabilities defined by

$$\begin{aligned} \overline{p}(m) &= \sum_{n=0}^{\infty} p(L+m,n), \\ p(n) &= \sum_{m=0}^{\infty} p(L+m,n). \end{aligned}$$

To obtain $\overline{p}(m)$, we shift the contour C in (2.5) to $C' : |w| = 1+\varepsilon, \varepsilon > 0$. We choose ε sufficiently small so that the only pole inside C' is at $w = 1$. Then we may sum (2.5) over n, yielding

$$\begin{aligned}\overline{p}(m) &= \frac{(1-\rho_1-\rho_2)}{2\pi i}\int_{C'} \frac{1}{\rho_1 w\tilde{z}(w)-1}(\tilde{z}(w))^{-m}dw \\ &= (1-\rho_1-\rho_2)\frac{1}{\rho_1\tilde{z}(1)+\rho_1\tilde{z}'(1)}(\tilde{z}(1))^{-m}.\end{aligned}$$

Recalling that $\tilde{z}(1) = \frac{1}{\rho_1}$ and $\tilde{z}'(1) = \frac{-\rho_2}{\rho_1(1-\rho_1)}$, we obtain

$$\overline{p}(m) = (1-\rho_1)\rho_1^m. \tag{2.7}$$

Noting that $\tilde{z}(w) > 1$ for w small, we obtain the other marginal as

$$p(n) = \frac{(1-\rho_1-\rho_2)}{2\pi i}\int_C \frac{1-w}{1-\rho_1 w\tilde{z}(w)}\left(\frac{\tilde{z}(w)}{\tilde{z}(w)-1}\right)\frac{1}{w^{n+1}}dw. \tag{2.8}$$

2.2. Tail behavior. We compute the probabilities of having large queue lengths by evaluating $p(L+m, n)$ asymptotically, for m and/or n large. For a fixed $\rho_1+\rho_2 < 1$ and m or n large, we shall show that the joint probability is exponentially small. However, having accurate estimates of the tail of the distribution may be important to analyzing system performance, as tail behavior may be used to estimate loss rates, overflow probabilities, etc. In addition, the asymptotic formulas we obtain are much simpler than the exact result (2.5) and thus yield qualitative insights into the structure of the joint distribution.

We estimate (2.5) by using the saddle point and related methods for the asymptotic evaluation of integrals [11]. By writing $\tilde{z}^{-m}w^{-n} = \exp[-m\log\tilde{z} - n\log w]$, the integral in (2.5) has the form $\int_C G(w)e^{mF(w;\alpha)}dw$, where $\alpha = n/m$ and $F = -\log\tilde{z}(w) - \alpha\log w$. This is the standard form for applying the saddle point method, which yields the asymptotic behavior of the integral as $m \to \infty$, with α fixed. However, we will show that different results are obtained for different ranges of $\alpha = n/m$ and also for different ranges of the parameters ρ_1 and ρ_2.

The saddle point equation is

$$\frac{d}{dw}\left[-\log\tilde{z}(w) - \frac{n}{m}\log w\right] = 0$$

or

$$\frac{n}{m} = -\frac{\tilde{z}'(w)w}{\tilde{z}(w)}. \tag{2.9}$$

We recall that $\lambda_1\tilde{z} + \mu/\tilde{z} + \lambda_2 w = \mu + \lambda_1 + \lambda_2$, with which (2.9) simplifies to

$$\sqrt{(\mu+\lambda_1+\lambda_2-\lambda_2 w)^2 - 4\lambda_1\mu} = \frac{m}{n}w\lambda_2,$$

whose solution is

$$w = w_0\left(\frac{m}{n}\right) \equiv \frac{1}{\lambda_2}\frac{(\mu+\lambda_1+\lambda_2)^2 - 4\lambda_1\mu}{\sqrt{(\mu+\lambda_1+\lambda_2)^2\dfrac{m^2}{n^2} - 4\lambda_1\mu\left(\dfrac{m^2}{n^2}-1\right)} + \mu + \lambda_1 + \lambda_2}.$$

We then define

$$z_0\left(\frac{m}{n}\right) = \tilde{z}(w_0) = \frac{1}{2\lambda_1}\left[\left(\frac{m}{n}-1\right)\lambda_2 w_0 + \mu + \lambda_1 + \lambda_2\right].$$

At the saddle point, we have

$$\begin{aligned} m\frac{d^2}{dw^2}\left[-\log\tilde{z}(w) - \frac{n}{m}\log w\right]|_{w=w_0} \\ = \frac{n}{w_0^2} + m\left(\frac{\tilde{z}'(w_0)}{\tilde{z}(w_0)}\right)^2 - m\frac{\tilde{z}''(w_0)}{\tilde{z}(w_0)} \\ = w_0^{-2}n\left[1 + \frac{n}{m} + \frac{2\mu}{\lambda_2}\frac{n^2}{m^2}\frac{1}{z_0 w_0}\right] \equiv w_0^{-2}\mathcal{D}. \end{aligned}$$

Here we have used the quadratic equation satisfied by $\tilde{z}(w)$, and its derivatives. Since $\mathcal{D} > 0$, the steepest decent directions at the saddle are $\arg(w - w_0) = \pm\pi/2$, which correspond to a steepest descent contour that is locally parallel to the imaginary axis in the complex w-plane.

In addition to the saddle point, the asymptotic expansion of (2.5) may depend on the singularities of the integrand. Setting

$$G(w) = \frac{1-\rho_1-\rho_2}{2\pi i}\left(\frac{1-w}{1-\rho_1 w\tilde{z}(w)}\right)\frac{1}{w},$$

we see that $G(w)$ has branch points at

$$w = W_\pm = \frac{1}{\lambda_2}\left[\mu + \lambda_1 + \lambda_2 \pm 2\sqrt{\lambda_1\mu}\right] = 1 + \frac{(\sqrt{\mu} \pm \sqrt{\lambda_1})^2}{\lambda_2}. \tag{2.10}$$

Furthermore, the equation $1 = \rho_1 w\tilde{z}(w)$ has the solution

$$w = w_* \equiv \frac{\mu}{\lambda_1+\lambda_2} = \frac{1}{\rho_1+\rho_2}$$

if $\mu\lambda_1 < (\lambda_1+\lambda_2)^2$, and thus our integrand has a pole at w_* for this parameter range. In Figure 2.1 we sketch the parameter range in the (ρ_1, ρ_2) plane where the queue is stable, which is the triangle $T = \{(\rho_1,\rho_2) :\ \rho_1 \geq 0,\ \rho_2 \geq 0,\ \rho_1+\rho_2 < 1\}$. We divide this into two subregions, according to whether the pole at w_* is present or absent. Hence, we set

$$\begin{aligned} R_A &= \{(\rho_1,\rho_2) :\ 0 \leq \rho_1 < 1,\ 0 \leq \rho_2 < \sqrt{\rho_1}(1-\sqrt{\rho_1})\}, \\ R_B &= \{(\rho_1,\rho_2) :\ 0 \leq \rho_1 < 1,\ \sqrt{\rho_1}(1-\sqrt{\rho_1}) < \rho_2 < 1\} \end{aligned}$$

and note that the curve separating R_A from R_B is precisely $\mu\lambda_1 = (\lambda_1+\lambda_2)^2$ or $\rho_1 = (\rho_1+\rho_2)^2$ (see Figure 2.1).

We first consider region R_A. For $m \to \infty$ and the ratio m/n fixed, we shift the contour into another circle about the origin, which passes through $w = w_0$. Since $w_0 < W_-$ and there is no pole at w_*, such a contour deformation is permissible. Furthermore, the new contour traverses the saddle point in the steepest descent direction, and then the standard estimate (see [11]) yields

$$\begin{aligned} \int_C G(w)e^{mF(w;\alpha)}dw &\sim G(w_0)i\sqrt{\frac{2\pi}{mF''(w_0;\alpha)}}e^{mF(w_0;\alpha)} \\ &= \frac{(1-\rho_1-\rho_2)(1-w_0)}{1-\rho_1 w_0 z_0}\frac{w_0^{-n}z_0^{-m}}{\sqrt{2\pi\mathcal{D}}}. \end{aligned}$$

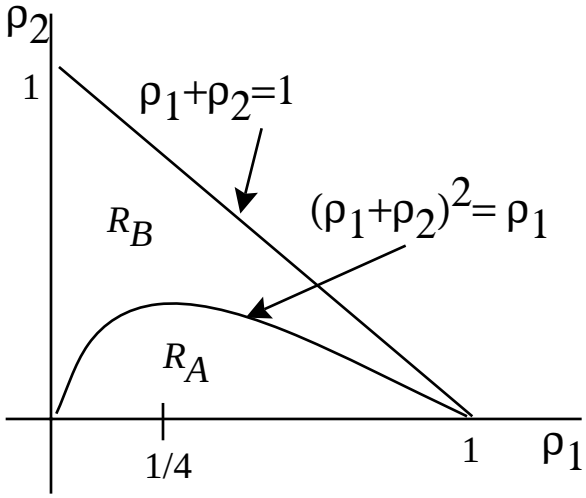

FIG. 2.1. *A sketch of the domains R_A and R_B in the (ρ_1, ρ_2) parameter space.*

This approximation is no longer valid as $m/n \to 0$, for then the saddle point w_0 approaches the branch point at W_-. It also becomes invalid as $m/n \to \infty$, as then $w_0 \to 0$, which is also a singularity of the integrand.

To construct expansions appropriate for m/n large or small, we first consider the limit $m = \mathcal{O}(1)$ as $n \to \infty$. Now the expansion of the integral in (2.5) is determined by the singularity that is closest to the origin in the w-plane, and this is the branch point at $w = W_-$ (cf. (2.10)). We approximate the integrand near W_- using

$$\tilde{z}(w) = \frac{1}{2\lambda_1}\left[2\sqrt{\mu\lambda_1} + \lambda_2\sqrt{W_+ - W_-}\sqrt{W_- - w} + \mathcal{O}(W_- - w)\right],$$

$$[\tilde{z}(w)]^{-m} = \rho_1^{m/2}\left[1 - \sqrt{\frac{\rho_2}{\rho_1}}\rho_1^{1/4}\sqrt{W_- - w}\; m + \mathcal{O}(W_- - w)\right],$$

$$\frac{1-w}{1-\rho_1 w\tilde{z}(w)} = \frac{1-W_-}{1-\sqrt{\rho_1}W_-}\left[1 + \frac{\sqrt{\rho_2}\rho_1^{1/4}W_-}{1-\sqrt{\rho_1}W_-}\sqrt{W_- - w} + \mathcal{O}(W_- - w)\right].$$

Here we have used $W_+ - W_- = 4\sqrt{\lambda_1\mu}/\lambda_2$. Using the above, we obtain the leading order term in the expansion of (2.5) as

$$\frac{1-W_-}{1-\sqrt{\rho_1}W_-}(1-\rho_1-\rho_2)\rho_1^{m/2}\left[\frac{\sqrt{\rho_2}\rho_1^{1/4}W_-}{1-\sqrt{\rho_1}W_-} - m\sqrt{\frac{\rho_2}{\rho_1}}\rho_1^{1/4}\right] I, \tag{2.11}$$

where

$$I = \frac{1}{2\pi i}\int_\Gamma w^{-n-1}\sqrt{W_- - w}\,dw$$

and the contour Γ is sketched in Figure 2.2. Setting $w = W_-(1+\zeta/n)$ and parame-

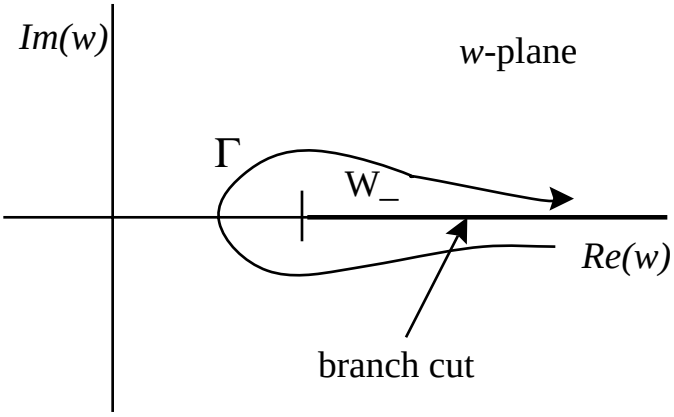

FIG. 2.2. *A sketch of the contour* Γ *in the complex* w*-plane.*

terizing Γ as a real integral, we are led to

$$I \sim -\frac{1}{\pi}\frac{\sqrt{W_-}}{n^{3/2}}W_-^{-n}\int_0^\infty e^{-\zeta}\sqrt{\zeta}d\zeta.$$

The last integral is equal to $\sqrt{\pi}/2$, and hence (2.11) gives the leading term for $n \to \infty$ with m fixed.

Now consider the limit $m \to \infty$ with n fixed. The major contribution comes from small values of w. We scale $w = u/m$ and use

$$[\tilde{z}(w)]^{-m} = [\tilde{z}(0) + \tilde{z}'(0)w + \cdots]^{-m} \sim [\tilde{z}(0)]^{-m}\exp\left[-\frac{\tilde{z}'(0)}{\tilde{z}(0)}mw\right].$$

The integral (2.5) thus becomes (apart from the factor $[\tilde{z}(0)]^{-m}$)

$$\frac{1-\rho_1-\rho_2}{2\pi i}\int_C m^n \exp\left[-\frac{\tilde{z}'(0)}{\tilde{z}(0)}u\right]u^{-n-1}du = \frac{1-\rho_1-\rho_2}{n!}m^n\left(\frac{-\tilde{z}'(0)}{\tilde{z}(0)}\right)^n,$$

where

$$\frac{-\tilde{z}'(0)}{\tilde{z}(0)} = \frac{\lambda_2}{\sqrt{(\mu+\lambda_1+\lambda_2)^2-4\lambda_1\mu}} > 0.$$

We summarize our main results below.

THEOREM 2.2. *For* $(\rho_1,\rho_2) \in R_A$*, the steady state probabilities in* (2.5) *have the asymptotic expansions*

(a) $m,\ n \to \infty$ *with* $0 < m/n < \infty$*:*

$$p(L+m,n) \sim \frac{1-\rho_1-\rho_2}{1-\rho_1 w_0 z_0}\left(\frac{1-w_0}{\sqrt{2\pi\mathcal{D}}}\right)w_0^{-n}z_0^{-m},$$

$$w_0 = w_0\left(\frac{m}{n}\right) = \frac{1}{\lambda_2}\frac{(\mu+\lambda_1+\lambda_2)^2-4\lambda_1\mu}{\sqrt{(\mu+\lambda_1+\lambda_2)^2\dfrac{m^2}{n^2}-4\lambda_1\mu\left(\dfrac{m^2}{n^2}-1\right)}+\mu+\lambda_1+\lambda_2},$$

$$z_0 = z_0\left(\frac{m}{n}\right) = \frac{1}{2\lambda_1}\left[\left(\frac{m}{n} - 1\right)\lambda_2 w_0 + \mu + \lambda_1 + \lambda_2\right],$$

$$\mathcal{D} = n\left[1 + \frac{n}{m} + \frac{2\mu}{\lambda_2}\frac{n^2}{m^2}\frac{1}{z_0 w_0}\right];$$

(b) $n \to \infty$ *with* $m = \mathcal{O}(1)$*:*

$$p(L+m,n) \sim \frac{1-\rho_1-\rho_2}{2\sqrt{\pi}}\left(\frac{W_- - 1}{\sqrt{\rho_1}W_- - 1}\right)\frac{\sqrt{\rho_2}}{\rho_1^{1/4}}\left[m + \frac{\sqrt{\rho_1}W_-}{\sqrt{\rho_1}W_- - 1}\right]\frac{\rho_1^{m/2}}{n^{3/2}}\sqrt{W_-}W_-^{-n},$$

$$W_- = \frac{1}{\lambda_2}\left[\mu + \lambda_1 + \lambda_2 - 2\sqrt{\lambda_1\mu}\right];$$

(c) $m \to \infty$ *with* $n = \mathcal{O}(1)$*:*

$$p(L+m,n) \sim (1-\rho_1-\rho_2)\frac{m^n}{n!}[\tilde{z}(0)]^{-m}\left(\frac{\lambda_2}{\sqrt{S}}\right)^n,$$

$$\tilde{z}(0) = \frac{\mu + \lambda_1 + \lambda_2 + \sqrt{S}}{2\lambda_1}, \qquad S = (\mu + \lambda_1 + \lambda_2)^2 - 4\lambda_1\mu.$$

We note that (a) gives the probability of having simultaneously large queue lengths for both customer classes. Part (b) gives the probability of having many type-2 (e.g., voice) customers, while part (c) gives the probability of having many type-1 (e.g., data) customers above the threshold L. We can easily show that $\sqrt{\rho_1}W_- > 1$ precisely for $(\rho_1, \rho_2) \in R_A$, so that the formula in (b) is positive for all $m \geq 0$, as it must be.

We next consider the region R_B. Now the integrand has a pole at w_* in addition to the saddle at w_0, whose location changes with m/n. As m/n increases from zero to infinity, the saddle moves from W_- to 0 and coalesces with the pole when

$$\frac{m}{n} = \beta \equiv \frac{(\lambda_1+\lambda_2)^2 - \mu\lambda_1}{\mu\lambda_2} = \frac{(\rho_1+\rho_2)^2 - \rho_1}{\rho_2}.$$

Note that $\beta > 0$ precisely when $(\rho_1, \rho_2) \in R_B$. For $m/n < \beta$, we have $w_* < w_0$, while if $m/n > \beta$, we have $w_* > w_0$. For $m \to \infty$ and $n = \mathcal{O}(1)$, we again obtain the result in part (c) of Theorem 2.2. For $m, n \to \infty$ with $m/n \in (\beta, \infty)$, we shift the contour C into the steepest descent contour and obtain the same result as in Theorem 2.2(a). If $m, n \to \infty$ and $m/n \in (0, \beta)$, we must take into account the contribution from the pole at w_* in deforming the contour. The residue at this pole is equal to

$$(1-\rho_1-\rho_2)\frac{(1-w_*)}{-\rho_1(w\tilde{z})'(w_*)}[\tilde{z}(w_*)]^{-m}(\rho_1+\rho_2)^{n+1}. \tag{2.12}$$

From the definition of $\tilde{z}$ we easily obtain

$$\tilde{z}(w_*) = 1 + \frac{\lambda_2}{\lambda_1}, \qquad \tilde{z}'(w_*) = \frac{\lambda_2(1+\lambda_2/\lambda_1)^2}{\mu - \lambda_1(1+\lambda_2/\lambda_1)^2}.$$

By comparing (2.12) to the saddle point contribution, we can show that the contribution from the pole is larger. Thus, for $m/n \in (0, \beta)$ and $m \to \infty$, $p(L+m, n)$ is asymptotically given by the negative of (2.12). The negative sign arises due to the

fact that the saddle point contour ($|w| = w_0$) has a radius larger than the original contour C.

Finally, we consider the limit $m, n \to \infty$ with $m/n \approx \beta$. Note that the saddle point approximation, as given by Theorem 2.2(a) for $m/n > \beta$, becomes singular as $m/n \downarrow \beta$, and $1 - \rho_1 w_0 z_0$ vanishes in this limit. The case of a saddle coalescing with a pole is a standard problem in the asymptotic evaluation of integrals (see [11]). The appropriate expansion for $m/n \approx \beta$ may be obtained by expanding the integrand near $w = w_*$. In this limit we have

$$G(w) \sim \frac{1-\rho_1-\rho_2}{2\pi i}\left(\frac{1-w_*}{-\rho_1(w\tilde{z})'(w_*)}\right)\frac{1}{w-w_*},$$

$$\begin{aligned} n\log w \,+\, m\log[\tilde{z}(w)] &= n\log w_* + m\log[\tilde{z}(w_*)] + \left(\frac{n}{w_*} + m\frac{\tilde{z}'(w_*)}{\tilde{z}(w_*)}\right)(w-w_*) \\ &+\, \frac{1}{2}\left[\frac{-n}{w_*^2} + m\frac{\tilde{z}''(w_*)}{\tilde{z}(w_*)} - m\left(\frac{\tilde{z}'(w_*)}{\tilde{z}(w_*)}\right)^2\right](w-w_*)^2 + \mathcal{O}((w-w_*)^3) \\ &= -n\log(\rho_1+\rho_2) + m\log\left(1+\frac{\rho_2}{\rho_1}\right) + (\rho_1+\rho_2)\left(n - \frac{m}{\beta}\right)(w-w_*) \\ &-\, \frac{1}{2}(\rho_1+\rho_2)^2\left[n + \frac{2m\rho_1}{\rho_2\beta^3} + \frac{m}{\beta^2}\right](w-w_*)^2 + \mathcal{O}((w-w_*)^3). \end{aligned}$$

We set $w - w_* = (\rho_1+\rho_2)^{-1}[n + m/\beta^2 + 2m\rho_1/(\rho_2\beta^3)]^{-1/2}\eta$ and obtain

$$\int_C G(w)e^{mF(w;\alpha)}dw \sim (1-\rho_1-\rho_2)\frac{-\mu\lambda_2\beta}{(\lambda_1+\lambda_2)^2}(\rho_1+\rho_2)^n\left(\frac{\rho_1}{\rho_1+\rho_2}\right)^m J,$$

where J is the integral

$$J = \frac{1}{2\pi i}\int_{C'} e^{\Delta_0\eta}e^{\eta^2/2}\frac{d\eta}{\eta}, \qquad \Delta_0 = \frac{m/\beta - n}{\sqrt{n + m/\beta^2 + 2m\rho_1/(\rho_2\beta^3)}},$$

and we assume that $m/\beta - n = \mathcal{O}(\sqrt{m})$ so that $\Delta_0 = \mathcal{O}(1)$. Here C' is a vertical contour in the η-plane such that $\Re(\eta) < 0$. The last integral is easily evaluated as $J = -(2\pi)^{-1/2}\int_{\Delta_0}^{\infty} e^{-u^2/2}du$, and we thus have the desired expression for $p(L+m,n)$ that is valid for $m, n \to \infty$ with $m/n \approx \beta$. Below we summarize the results.

THEOREM 2.3. *For $(\rho_1, \rho_2) \in R_B$, the steady state probabilities in* (2.5) *have the asymptotic expansions*

(a) *$n \to \infty$ with $0 \le m/n < \beta$, $\beta = [(\rho_1+\rho_2)^2 - \rho_1]/\rho_2$:*

$$p(L+m,n) \sim (1-\rho_1-\rho_2)\frac{(\lambda_1+\lambda_2)^2 - \mu\lambda_1}{(\lambda_1+\lambda_2)^2}\left(\frac{\lambda_1}{\lambda_1+\lambda_2}\right)^m(\rho_1+\rho_2)^n;$$

(b) *$m, n \to \infty$ with $m/n = \beta + \mathcal{O}(m^{-1/2})$:*

$$\begin{aligned} &p(L+m,n) \\ &\sim (1-\rho_1-\rho_2)\frac{(\lambda_1+\lambda_2)^2 - \mu\lambda_1}{(\lambda_1+\lambda_2)^2}\left(\frac{\lambda_1}{\lambda_1+\lambda_2}\right)^m(\rho_1+\rho_2)^n\frac{1}{\sqrt{2\pi}}\int_{\Delta}^{\infty} e^{-u^2/2}du, \end{aligned}$$

$$\Delta = \left(\frac{m-n\beta}{\sqrt{n}}\right)\frac{1}{\sqrt{\beta^2+\beta+2\rho_1/\rho_2}};$$

(c) $m, n \to \infty$ *with* $\beta < m/n < \infty$*: the result is the same as Theorem* 2.2(a)*; for* $m \to \infty$ *with* $n = \mathcal{O}(1)$*, Theorem* 2.2(c) *applies.*

The expression in (a) shows that the solution is asymptotically of "product form" for this range of m, n. We have thus identified two regions in the parameter (ρ_1, ρ_2) space where the structure of the joint distribution is different. Theorems 2.2 and 2.3 furthermore show that the expansion of $p(L + m, n)$ depends on the ratio m/n for both of the regions in Figure 2.1.

We next consider the asymptotic behavior of the marginal distributions $\overline{p}(m)$ and $p(n)$. The former has a simple geometric form, but the latter is complicated, and thus we evaluate it asymptotically for $n \to \infty$. We also note that for either region R_A or R_B, the saddle point approximation (i.e., the formula in Theorem 2.2(a)) can be simplified for $m/n \approx (1 - \rho_1)/\rho_2$. To do so, we first compute the point at which $p(L + m, n)$ is maximal as a function of n, for a fixed large m. We write

$$w_0^{-n} z_0^{-m} = \exp\left(-m \log[z_0(x)] - \frac{m}{x} \log[w_0(x)]\right), \qquad x = \frac{m}{n}.$$

At the maximum we must have

$$\frac{z_0'(x)}{z_0(x)} + \frac{1}{x}\frac{w_0'(x)}{w_0(x)} - \frac{1}{x^2} \log[w_0(x)] = 0,$$

and we can easily show that this is satisfied if

$$x = \beta_* \equiv \frac{1 - \rho_1}{\rho_2}.$$

We then have $w_0(\beta_*) = 1$ and $z_0(\beta_*) = 1/\rho_1$. After a lengthy calculation, we find that

$$\frac{d^2}{dx^2}\left[\log[z_0(x)] + \frac{1}{x}\log[w_0(x)]\right]\Big|_{x=\beta_*} = \frac{\rho_2^3}{1-\rho_1}\frac{1}{(1-\rho_1)^2 + \rho_2(1+\rho_1)}$$

and

$$\frac{1-\rho_1-\rho_2}{1-\rho_1 w_0(x) z_0(x)}\frac{1-w_0(x)}{\sqrt{2\pi\mathcal{D}}}\Big|_{x=\beta_*} = \frac{1-\rho_1}{\sqrt{2\pi m}}\frac{(1-\rho_1)^{3/2}}{\sqrt{\rho_2}\sqrt{(1-\rho_1)^2 + \rho_2(1+\rho_1)}}.$$

Using these expressions in Theorem 2.2(a), we obtain a simple form for $p(L+m, n)$ for $m, n \to \infty$ with $m/n \approx \beta_*$, which we summarize below. We also give the expansions for the marginal $p(n)$ as $n \to \infty$. These are easily obtained from (2.8) by identifying the singularity of the integrand closest to the origin, and this is $w = W_-$ for R_A and $w = w_*$ for R_B.

THEOREM 2.4. *Further asymptotic properties of the distribution are as follows:*

(a) $m, n \to \infty$ *with* $m/n = \beta_* + \mathcal{O}(m^{-1/2})$*,* $\beta_* = (1 - \rho_1)/\rho_2$*:*

$$p(L+m, n) \sim (1-\rho_1)\rho_1^m \frac{1}{\sqrt{2\pi m}} \frac{(1-\rho_1)^{3/2}}{\sqrt{\rho_2}\sqrt{(1-\rho_1)^2 + \rho_2(1+\rho_1)}} \times \exp\left[-\frac{1}{2m}\frac{(1-\rho_1)^3}{\rho_2[(1-\rho_1)^2 + \rho_2(1+\rho_1)]}\left(n - \frac{\rho_2 m}{1-\rho_1}\right)^2\right];$$

(b) $n \to \infty$ *with* $(\rho_1, \rho_2) \in R_A$*:*

$$p(n) \sim \frac{(1-W_-)^2}{(1-\sqrt{\rho_1}W_-)^2}\frac{(1-\rho_1-\rho_2)\sqrt{W_-}}{(1-\sqrt{\rho_1})^2}\frac{\sqrt{\rho_2}\rho_1^{1/4}}{2\sqrt{\pi}}\frac{W_-^{-n}}{n^{3/2}};$$

(c) $n \to \infty$ *with* $(\rho_1, \rho_2) \in R_B$*:*

$$p(n) \sim \frac{1-\rho_1-\rho_2}{\rho_2(\rho_1+\rho_2)}[(\rho_1+\rho_2)^2-\rho_1](\rho_1+\rho_2)^n.$$

We note that $\beta_* > \beta$ for all $\rho_1+\rho_2 < 1$. Thus when $m/n \approx \beta_*$, we are always in the case where the leading term in the expansion of $p(L+m,n)$ comes from the saddle point. Part (a) shows that if the number of type-1 customers above L is large and $= m$, then the number of type-2 customers is also likely to be large and close to $\rho_2 m/(1-\rho_1)$. Furthermore, there is a Gaussian spread about this mean value. From part (a) we also conclude that, for $m \to \infty$, $\sum_{n=0}^{\infty} p(L+m,n) \sim (1-\rho_1)\rho_1^m$. This result is of course not just asymptotic, but exact for all $m \geq 0$. This completes our analysis of the tail behavior of the joint distribution and its marginals.

2.3. Heavy traffic diffusion approximation. We study the system when it becomes close to unstable, i.e., as $\rho_1+\rho_2 \uparrow 1$. If $\rho_1+\rho_2 \uparrow 1$ for a fixed $\rho_2 \in (0,1)$, the probability mass becomes concentrated in the range where n is large but $m = \mathcal{O}(1)$. More precisely, we define $\varepsilon = 1-\rho_1-\rho_2 \to 0^+$ and obtain the limiting distribution from (2.5) as

$$p(L+m,n) \sim \varepsilon(1-\rho_1)\rho_1^m e^{-Y}, \qquad Y = \varepsilon n.$$

Thus, in this limit there tend to be only a few type-1 customers above the threshold L, while the number of type-2 customers tends to be large, of the order $\mathcal{O}(\varepsilon^{-1})$. Since the latter customers may represent voice messages, this situation is clearly not desirable. We next obtain another heavy traffic limit, whose behavior is much less trivial than that above.

We again define the small positive parameter ε by $1 = \rho_1+\rho_2+\varepsilon$, but we now assume that

$$\rho_2 = \varepsilon b = \mathcal{O}(\varepsilon), \qquad 1-\rho_1 = \varepsilon(b+1) = \mathcal{O}(\varepsilon),$$

where $b > 0$. This assumption means that the traffic intensity of type-2 customers is relatively small, while the type-1 customer queue is close to instability. Even though ρ_2 is small, with this scaling both of the queue lengths will tend to be large, so that it seems appropriate to still classify this limit as one of "heavy traffic." Even though the load of type-2 customers is small, large queue lengths tend to develop since the server is devoting a lot of time trying to service the large backlog of type-1 customers. We thus scale m and n to be large, with

$$m = \frac{X}{\varepsilon}, \qquad n = \frac{Y}{\varepsilon}.$$

In (2.5) we scale $w = 1-\varepsilon s$, and for $\varepsilon \to 0^+$ we have

$$\begin{aligned}
\tilde{z}(w) - 1 &\sim \frac{\varepsilon}{2}\left[b+1+\sqrt{(b+1)^2+4bs}\right], \\
w^{-n-1} &\sim e^{sY}, \\
[\tilde{z}(w)]^{-m} &\sim \exp\left\{-\frac{X}{2}\left[b+1+\sqrt{(b+1)^2+4bs}\right]\right\},
\end{aligned}$$

with $p(L,0) = \varepsilon$. We can also approximate the contour C by a vertical Bromwich contour Br in the complex s-plane. We thus obtain the limiting density in the form

$$p(L+m,n) = p\left(L+\frac{X}{\varepsilon}, \frac{Y}{\varepsilon}\right) \sim \varepsilon^2 P(X,Y), \tag{2.13}$$

where

$$P(X,Y)=\frac{1}{2\pi i}\int_{Br}\frac{2se^{sY}\exp\left\{-\frac{X}{2}\left[b+1+\sqrt{(b+1)^2+4bs}\right]\right\}}{b+1+2s-\sqrt{(b+1)^2+4bs}}ds \tag{2.14}$$

and, on Br, $\Re(s)>0$. We refer to P as the heavy traffic diffusion approximation.

An alternate approach to obtaining P is to introduce the heavy traffic scaling into the difference equations. From these we find that P in (2.13) satisfies the parabolic partial differential equation (PDE)

$$P_{XX}+(b+1)P_X-bP_Y=0,\qquad X,Y>0,$$

with boundary conditions (BC)

$$\begin{gathered}P_X(0,Y)+P_Y(0,Y)+(b+1)P(0,Y)=0,\qquad Y>0,\\ P(X,0)=0,\qquad X>0.\end{gathered}$$

Solving this problem using, e.g., Laplace transforms, we regain the expression in (2.14). The approximation (2.13) may be refined to the series $p(L+m,n)=\varepsilon^2[P(X,Y)+\varepsilon P^{(1)}(X,Y)+\varepsilon^2P^{(2)}(X,Y)+\cdots]$, but the calculation of the higher order terms $P^{(j)}$ is tedious. Below we summarize the final results for the diffusion model and its marginals and also give several alternate representations for P.

THEOREM 2.5. *In the heavy traffic limit where $\rho_1+\rho_2=1-\varepsilon$ and $\rho_2=\varepsilon b$, $b>0$, we have for $\varepsilon\to0^+$, $p(L+m,n)\sim\varepsilon^2P(X,Y)$, where*

$$\begin{aligned}P(X,Y)&=\frac{1}{2\pi i}\int_{Br}\frac{2se^{sY}\exp\left\{-\frac{X}{2}\left[b+1+\sqrt{(b+1)^2+4bs}\right]\right\}}{b+1+2s-\sqrt{(b+1)^2+4bs}}ds\\
&=(b-1)e^{-bX}e^{-Y}I\{b>1\}+e^{-(b+1)X/2}\frac{(b+1)^3}{4\pi}i\\
&\quad\times\int_{-\infty}^{\infty}\frac{\sinh\eta}{4b-(b+1)^2\cosh\eta}\left[1-\frac{b+1}{2b}\cosh\eta+i\sqrt{2}\sinh\left(\frac{\eta}{2}\right)\right]\\
&\quad\times\exp\left[-\frac{(b+1)^2}{4b}Y\cosh\eta-\frac{X}{\sqrt{2}}(b+1)i\sinh\left(\frac{\eta}{2}\right)\right]d\eta\\
&=(b-1)e^{-bX}e^{-Y}I\{b>1\}\\
&\quad+\frac{e^{-(b+1)X/2}e^{-Y}}{2\sqrt{\pi b}}\int_Y^{\infty}\frac{A(X,u)}{\sqrt{u}}\exp\left[-\frac{bX^2}{4u}-\frac{(b-1)^2}{4b}u\right]du,\end{aligned}$$

$$A(X,u)=\frac{b}{u}\left(\frac{3X}{2u}+1\right)-\left(\frac{b^2-1}{4}\frac{X}{u}+\frac{b^2X^2}{2u^2}+\frac{b^2X^3}{4u^3}\right).$$

If $b=1$, the above simplifies to

$$P(X,Y)=\frac{1}{\sqrt{\pi Y}}\left(1+\frac{X}{2Y}\right)e^{-X}e^{-Y}\exp\left(-\frac{X^2}{4Y}\right),\qquad b=1.$$

The marginals are given by

$$\overline{P}(X) = \int_0^\infty P(X,Y)dY = (b+1)e^{-(b+1)X},$$
$$P(Y) = \int_0^\infty P(X,Y)dX$$
$$= \left[\frac{b-1}{b}I\{b>1\} + \frac{1}{2\sqrt{\pi b}}\int_Y^\infty u^{-3/2}\exp\left[-\frac{(b-1)^2}{4b}u\right]du\right]e^{-Y},$$

where $I\{\cdot\}$ is the indicator function. When $b = 1$, the Y-marginal is $P(Y) = e^{-Y}/\sqrt{\pi Y}$.

From the result for P, we see that for any $X > 0$ the conditional density $P(Y|X) = P(X,Y)/\overline{P}(X)$ is continuous. However, when $X = 0$, the conditional density carries mass at the origin, and we have

$$P(Y|0) = \frac{1}{b+1}\delta(Y)$$
$$+ \frac{b}{b+1}e^{-Y}\left[\frac{b-1}{b}I\{b>1\} + \frac{1}{2\sqrt{\pi b}}\int_Y^\infty u^{-3/2}\exp\left(-\frac{(b-1)^2}{4b}u\right)du\right].$$

Thus the mass at $Y = 0$ is $1/(b+1)$, and the mass for $Y > 0$ is $b/(b+1)$. We can also study the tail behavior of the diffusion approximation as X and/or $Y \to \infty$. The qualitative structure of $P(X,Y)$ in this limit is similar to that in Theorems 2.2–2.4. Below we summarize the results, omitting the derivations.

THEOREM 2.6. *Asymptotic expansions of $P(X,Y)$ and $P(Y)$ in Theorem* 2.5 *are as follows:*

(a) $Y \to \infty$*:*

$$b>1: \quad P(Y) \sim \frac{b-1}{b}e^{-Y},$$
$$b=1: \quad P(Y) \sim \frac{e^{-Y}}{\sqrt{\pi Y}},$$
$$b>1: \quad P(Y) \sim \frac{2\sqrt{b}}{\sqrt{\pi}(b-1)^2}Y^{-3/2}\exp\left[-\frac{(b+1)^2}{4b}Y\right];$$

(b) $X, Y \to \infty$ *with* $Y - bX/(b+1) = \sqrt{X}U = \mathcal{O}(\sqrt{X})$*:*

$$P\left(\frac{bX}{b+1} + \sqrt{X}U|X\right) \sim \frac{(b+1)^{3/2}}{2\sqrt{\pi X}b}\exp\left[-\frac{(b+1)^3}{4b^2}U^2\right];$$

(c) $Y \to \infty$, $X = \mathcal{O}(1)$, $b < 1$*:*

$$P(X,Y) \sim \frac{\sqrt{b}}{2\sqrt{\pi}}\left(\frac{b+1}{1-b}\right)Y^{-3/2}\left[X + \frac{4b}{1-b^2}\right]\exp\left[-\frac{X}{2}(b+1) - \frac{Y}{4b}(b+1)^2\right];$$

(d) $X, Y \to \infty$ *with* $0 < Y/X < \infty$, $b < 1$*:*

$$P(X,Y) \sim K(X,Y)e^{-\phi(X,Y)},$$
$$\phi(X,Y) = \frac{X}{2}(b+1) + \frac{Y}{4b}(b+1)^2 + \frac{bX^2}{4Y},$$
$$K(X,Y) = \frac{\sqrt{b}X}{2\sqrt{\pi}Y^{3/2}}\left(\frac{bX+(b+1)Y}{bX-(b-1)Y}\right);$$

(e) $X, Y \to \infty$ *with* $0 < Y/X < \infty$, $b > 1$*:*

$$Y/X > \frac{b}{(b-1)}: \quad P(X,Y) \sim (b-1)e^{-bX}e^{-Y},$$

$$Y/X < \frac{b}{(b-1)}: \quad P(X,Y) \sim K(X,Y)e^{-\phi(X,Y)},$$

$$Y/X \approx \frac{b}{(b-1)}: \quad P(X,Y) \sim (b-1)e^{-bX}e^{-Y}\frac{1}{\sqrt{2\pi}}\int_{-\infty}^{\Lambda} e^{-u^2/2}du,$$

$$\Lambda = \frac{(b-1)^{3/2}}{b\sqrt{2X}}\left(Y - \frac{bX}{b-1}\right) = \mathcal{O}(1).$$

Note that these results are closely analogous to the asymptotic results for the discrete probabilities $p(L+m, n)$. Theorems 2.5 and 2.6 show that the structure of the problem is nontrivial in the heavy traffic limit where $\rho_1 + \rho_2 \uparrow 1$ and $\rho_2 \to 0^+$. We also note that this limit corresponds to the vicinity of the "corner" point $(\rho_1, \rho_2) = (1, 0)$ in the parameter space in Figure 2.1. The curve that separates R_A from R_B passes through this point. The equation $(\rho_1+\rho_2)^2 = \rho_1$ is the same as $(1-\varepsilon)^2 = 1-\varepsilon(b+1)$, which as $\varepsilon \to 0^+$ becomes $b = 1 + \mathcal{O}(\varepsilon)$. This further explains the dichotomous behavior of P, according to whether $b > 1$ or $b < 1$.

3. $M_1, M_2/M/1$ priority queue with a dynamic scheduling policy. We now consider the full problem (1.1)–(1.9) in which the server serves type-1 customers when $N_2(t) = 0$. We are able to use the results in section 2 as part of our analysis here. For example, the solution in Theorem 3.1 uses the results in Theorem 2.5, and the asymptotic results in Theorems 3.2(a) and 3.3(a) rely on the asymptotic results in Theorem 2.5 in section 2.

3.1. Exact solution. In this subsection, we derive the joint queue length distribution. We use the same notation as in the previous section and introduce the following probability generating functions:

$$G(z,w) = \sum_{n=0}^{\infty}\sum_{m=L}^{\infty} p(m,n)z^{m-L}w^n,$$

$$H_j(w) = \sum_{n=0}^{\infty} p(j,n)w^n, \qquad 0 \le j \le L.$$

From (1.1), (1.2), (1.4), and (1.5), we obtain

$$\begin{aligned}&\left[\lambda_1 z + \lambda_2 w - (\mu + \lambda_1 + \lambda_2) + \frac{\mu}{z}\right]G(z,w)\\ &\qquad = -\lambda_1 H_{L-1}(w) + \mu\left(\frac{1}{z} - \frac{1}{w}\right)H_L(w) + \frac{\mu}{w}p(L,0).\end{aligned} \tag{3.1}$$

In order to determine $G(z,w)$ in (3.1), we must know $H_{L-1}(w), H_L(w)$, and $p(L,0)$. We first compute $H_{L-1}(w)$ and $p(L,0)$, and then derive $H_L(w)$ by using the analyticity of $G(z,w)$.

From (1.3) and (1.6), we obtain the following equation, which relates $H_{m-1}(w)$ and $H_m(w)$:

$$\begin{aligned}&\left[\lambda_2 w - (\mu + \lambda_1 + \lambda_2) + \frac{\mu}{w}\right]H_m(w) + \lambda_1 H_{m-1}(w)\\ &\qquad = -\mu p(m+1,0) + \frac{\mu}{w}p(m,0), \qquad 1 \le m \le L-1.\end{aligned} \tag{3.2}$$

From (1.7) and (1.8), we obtain an equation for $H_0(w)$,

$$\Big[\lambda_2 w - (\mu+\lambda_1+\lambda_2) + \frac{\mu}{w}\Big] H_0(w) = -\mu p(1,0) + \mu\left(\frac{1}{w}-1\right)p(0,0), \tag{3.3}$$

which can also be written as

$$\frac{\lambda_2}{w}(w-w_-)(w-w_+)H_0(w) = -\mu p(1,0) + \mu\left(\frac{1}{w}-1\right)p(0,0), \tag{3.4}$$

where w_- and w_+ are zeros of $L(w) \equiv w^2 - \frac{\mu+\lambda_1+\lambda_2}{\lambda_2}w + \frac{\mu}{\lambda_2} = 0$ and $|w_-| < 1$; i.e.,

$$w_- = \frac{(\mu+\lambda_1+\lambda_2) - \sqrt{(\mu+\lambda_1+\lambda_2)^2 - 4\mu\lambda_2}}{2\lambda_2},$$
$$w_+ = \frac{(\mu+\lambda_1+\lambda_2) + \sqrt{(\mu+\lambda_1+\lambda_2)^2 - 4\mu\lambda_2}}{2\lambda_2}.$$

Letting $w = w_-$ in (3.4), we obtain

$$p(1,0) = \left(\frac{1}{w_-}-1\right)p(0,0), \tag{3.5}$$

and then (3.4) yields

$$H_0(w) = \frac{1}{(1-w/w_+)}p(0,0). \tag{3.6}$$

Next we will calculate $H_j(w)$ for $1 \le j \le L-1$. We first take $L = \infty$ and show how to use this solution to solve the problem for finite L. If $L = \infty$, we introduce the generating functions

$$H(z,w) = \sum_{m=0}^{\infty} H_m(w) z^m,$$
$$F(z) = \sum_{m=0}^{\infty} p(m,0) z^m.$$

Then, using (3.2) and (3.3) with $L = \infty$, we obtain

$$\Big[\lambda_2 w - (\mu+\lambda_1+\lambda_2) + \lambda_1 z + \frac{\mu}{w}\Big] H(z,w)$$
$$= \mu\Big(\frac{1}{w}-\frac{1}{z}\Big)F(z) + \mu\Big(\frac{1}{z}-1\Big)p(0,0).$$

Upon dividing by w/μ, the above may be rewritten as

$$\rho_2(w-w_-(z))(w-w_+(z))H(z,w)$$
$$= \Big(1-\frac{w}{z}\Big)F(z) + w\Big(\frac{1}{z}-1\Big)p(0,0), \tag{3.7}$$

where $w_-(z)$ and $w_+(z)$ are zeros of the equation $w^2 - \frac{\mu+\lambda_1+\lambda_2-\lambda_1 z}{\lambda_2}w + \frac{\mu}{\lambda_2} = 0$ and $|w_-(z)| < 1$; hence

$$w_-(z) = \frac{(\mu+\lambda_1+\lambda_2-\lambda_1 z) - \sqrt{(\mu+\lambda_1+\lambda_2-\lambda_1 z)^2 - 4\mu\lambda_2}}{2\lambda_2},$$
$$w_+(z) = \frac{(\mu+\lambda_1+\lambda_2-\lambda_1 z) + \sqrt{(\mu+\lambda_1+\lambda_2-\lambda_1 z)^2 - 4\mu\lambda_2}}{2\lambda_2}.$$

Setting $w = w_-(z)$ in (3.7), we obtain $F(z)$ as

$$F(z) = \frac{w_-(z)(1-1/z)}{1-w_-(z)/z} p(0,0). \tag{3.8}$$

Substituting (3.8) into (3.7), we obtain

$$H(z,w) = p(0,0)\frac{1}{\rho_2}\left(\frac{z-1}{z-w_-(z)}\right)\frac{1}{w_+(z)}\left(\frac{1}{1-w/w_+(z)}\right). \tag{3.9}$$

Finally, by comparing the coefficients of (3.9) to those of the probability generating function, we obtain $p(m,n)$ as

$$p(m,n) = \frac{p(0,0)}{2\pi i}\int_C \left(\frac{1-z}{1-\rho_2 z w_+(z)}\right)\frac{1}{[w_+(z)]^n}\frac{1}{z^{m+1}}dz \qquad (L=\infty).$$

Note that the above integral is the same as (2.5) with m and n (and also λ_1 and λ_2) interchanged.

The above expression for $p(m,n)$ satisfies (1.1)–(1.8) for all m,n with $0 \le m \le L-1$. Hence for $L < \infty$ and $0 \le m \le L-1$ we obtain

$$p(m,n) = \frac{p(0,0)}{2\pi i}\int_C \left(\frac{1-z}{1-\rho_2 z w_+(z)}\right)\frac{1}{[w_+(z)]^n}\frac{1}{z^{m+1}}dz \tag{3.10}$$

and

$$H_m(w) = \frac{p(0,0)}{2\pi i}\int_C \frac{1-z}{1-\rho_2 z w_+(z)}\left(\frac{w_+(z)}{w_+(z)-w}\right)\frac{1}{z^{m+1}}dz. \tag{3.11}$$

Using (3.10) and (3.11), we can easily show that (3.2)–(3.6) are satisfied. In (3.2) and (3.3) we let $w=1$, and we sum from $m=0$ to $L-1$ to find that $p(L,0)$ is given by

$$\begin{aligned} p(L,0) &= \rho_1 H_{L-1}(1) \\ &= \rho_1 \frac{p(0,0)}{2\pi i}\int_C \frac{1-z}{1-\rho_2 z w_+(z)}\left(\frac{w_+(z)}{w_+(z)-1}\right)\frac{1}{z^L}dz. \end{aligned} \tag{3.12}$$

We next derive the probability generating function $G(z,w)$. Equation (3.1) can be rewritten as

$$\begin{aligned} &\rho_1(z-z_*(w))(z-\tilde{z}(w))G(z,w) \\ &\quad = -\rho_1 z H_{L-1}(w) + z\left(\frac{1}{z}-\frac{1}{w}\right)H_L(w) + \frac{z}{w}p(L,0), \end{aligned} \tag{3.13}$$

where $H_{L-1}(w)$ and $p(L,0)$ are now known in terms of $p(0,0)$, and $z_*(w)$ and $\tilde{z}(w)$ are the same as in section 2. In (3.13), we set $z = z_*(w)$ and thus obtain $H_L(w)$. Then, after some calculation, we obtain the joint probability generating function as

$$G(z,w) = \frac{p(L,0)-\rho_1 w H_{L-1}(w)}{\rho_1(w-z_*(w))}\left(\frac{1}{z-\tilde{z}(w)}\right), \tag{3.14}$$

where $p(L,0)$ and $H_{L-1}(w)$ are given by (3.12) and (3.11), respectively. Finally, we obtain the joint queue length probabilities $p(m,n)$ by inverting $G(z,w)$:

$$\begin{aligned} p(m,n) = \frac{p(0,0)}{(2\pi i)^2}\rho_1 \int_C\int_C &\left(\frac{1-z}{1-\rho_2 z w_+(z)}\right)\frac{[w_+(z)]^2}{(w_+(z)-1)}\frac{(1-w)}{(w_+(z)-w)}\frac{1}{z^L} \\ &\times \frac{1}{(1-\rho_1 w\tilde{z}(w))}\frac{1}{[\tilde{z}(w)]^{m-L}}\frac{1}{w^{n+1}}dzdw, \qquad m \ge L,\ n \ge 0. \end{aligned} \tag{3.15}$$

The unknown constant $p(0,0)$ can be obtained by the normalization condition

$$G(1,1) + \sum_{m=0}^{L-1} H_m(1) = 1.$$

A routine calculation yields

$$p(0,0) = 1 - \rho_1 - \rho_2. \tag{3.16}$$

We have thus obtained the following result.

THEOREM 3.1. *The joint probabilities $p(m,n)$ for the queue lengths are given by*
(a) *for $0 \le m \le L-1, n \ge 0$,*

$$p(m,n) = \frac{p(0,0)}{2\pi i} \int_C \left(\frac{1-z}{1-\rho_2 z w_+(z)} \right) \frac{1}{[w_+(z)]^n} \frac{1}{z^{m+1}} dz,$$

(b) *for $m \ge L, n \ge 0$,*

$$p(m,n) = \frac{p(0,0)}{(2\pi i)^2} \rho_1 \int_C \int_C \left(\frac{1-z}{1-\rho_2 z w_+(z)} \right) \frac{[w_+(z)]^2}{(w_+(z)-1)} \frac{(1-w)}{(w_+(z)-w)} \frac{1}{z^L} \times \frac{1}{(1-\rho_1 w \tilde{z}(w))} \frac{1}{[\tilde{z}(w)]^{m-L}} \frac{1}{w^{n+1}} dz dw,$$

where

$$p(0,0) = 1 - \rho_1 - \rho_2,$$

and $w_+(z)$ and $\tilde{z}(w)$ are given below (3.7) *and below* (2.2)*, respectively.*

To study the tail probabilities, it is reasonable to assume that $L \to \infty$ and then to scale m and n using L. The expansions for Theorem 3.1(a) as m and/or $n \to \infty$ follow immediately from the results of section 2.2, simply by interchanging $m \leftrightarrow n$ and $\lambda_1 \leftrightarrow \lambda_2$ (or $\rho_1 \leftrightarrow \rho_2$). The expansion of the double integral in part (b) is more complicated, and we have thus far not been able to enumerate all the different cases. However, we were able to obtain detailed results in the heavy traffic case; these we discuss next.

3.2. Heavy traffic behavior. We study $p(m,n)$ in the heavy traffic case, where $N_1(t)$ and $N_2(t)$ are likely to be large. There are now two distinct nontrivial heavy traffic limits. We call these **HTL 1** and **HTL 2**, and the precise scalings are

HTL 1. $\rho_1 + \rho_2 = 1 - \varepsilon$, $\rho_1 = \varepsilon a = \mathcal{O}(\varepsilon)$, $L = A/\varepsilon = \mathcal{O}(\varepsilon^{-1})$,

HTL 2. $\rho_1 + \rho_2 = 1 - \varepsilon$, $\rho_2 = \varepsilon b = \mathcal{O}(\varepsilon)$, $L = A/\varepsilon = \mathcal{O}(\varepsilon^{-1})$.

Note that **HTL 2** has the same scaling of ρ_1 and ρ_2 as we used for the simplified model in section 2. In both these limits we obtain a nontrivial, two-dimensional structure to $p(m,n)$. To achieve this it is also necessary to scale the threshold L to be large.

Below we give only the final results. The calculations are very similar to those presented in section 2.

THEOREM 3.2. *In the heavy traffic limit* **HTL 2**, *we have as $\varepsilon \to 0^+$*
(a) *$m - L = (X - A)/\varepsilon$, $n = Y/\varepsilon$:*

$$p(m,n) \sim \varepsilon^2 e^{-A} P(X - A, Y; b),$$

where P is the density in Theorem 2.5*;*

(b) $m \le L-1$, $n = \mathcal{O}(1)$, $m = X/\varepsilon$, $X > 0$:

$$p(m,n) \sim \varepsilon(\varepsilon b)^n e^{-X};$$

(c) $m, n = \mathcal{O}(1)$:

$$p(m,n) \sim \varepsilon^{n+1} b^n F(m,n), \qquad F(m,n) = \frac{1}{2\pi i}\int_C \frac{1}{(1-z)(2-z)^n z^{m+1}} dz;$$

(d) $m - L = \zeta/\sqrt{\varepsilon} = \mathcal{O}(\varepsilon^{-1/2})$, $m \ge L$, $n = \mathcal{O}(1)$:

$$p(m,n) \sim \varepsilon e^{-A} \frac{1}{2\pi i}\int_C u^{-n-1} e^{-\sqrt{b}\sqrt{1-u}\zeta} du.$$

Here the contours C are small loops about the origin.

We see from Theorem 3.2 that in the limit **HTL 2** the limiting distribution becomes a two-dimensional diffusion in the region $\{X > A,\ Y > 0\}$ coupled to a one-dimensional diffusion along $\{0 < X < A,\ n = 0\}$. The total masses in the respective regions are easily obtained from (a) and (b):

$$\sum_{n=0}^{\infty}\sum_{m=L}^{\infty} p(m,n) \sim e^{-A}\int_0^{\infty}\int_A^{\infty} P(X-A, Y; b)\, dX\, dY = e^{-A},$$

$$\sum_{n=0}^{\infty}\sum_{m=0}^{L-1} p(m,n) \sim \sum_{m=0}^{L-1} p(m,0) \sim \int_0^A e^{-X} dX = 1 - e^{-A}.$$

The masses in regions (c) and (d) are asymptotically $o(1)$ as $\varepsilon \to 0^+$. Theorem 3.2 is easily established from the exact representations in Theorem 3.1.

An alternate approach to the heavy traffic limit would be to analyze the difference equations directly, with the **HTL 2** scaling. Using this approach, it is easy to show that if $p(m,n) \sim \varepsilon^2 Q(X,Y)$, then Q satisfies the PDE and BC:

$$\begin{gathered} Q_{XX} + (b+1)Q_X - bQ_Y = 0, \qquad X > A,\ Y > 0, \\ Q_X(A,Y) + Q_Y(A,Y) + (b+1)Q(A,Y) = 0, \qquad Y > 0, \\ Q(X,0) = 0, \qquad X > A. \end{gathered}$$

Furthermore, by assuming a priori that $p(m,n) \sim \varepsilon^{n+1} R_n(X)$, we find that $R_0(X)$ satisfies

$$R_0''(X) + R_0'(X) = 0, \qquad 0 < X < A.$$

Then by considering separately the scale $m, n = \mathcal{O}(1)$, we derive the BC: $R_0'(0) + R_0(0) = 0$. It follows that $R_0(X) = Ke^{-X}$ and that $Q(X,Y) = K_* P(X-A, Y)$. However, we have the two constants K and K_*, and normalization of $p(m,n)$ will give only one relation between them. Hence a second relation must be obtained; i.e., the two-dimensional diffusion must somehow be coupled to the one-dimensional one. By considering the scale $m - L = \mathcal{O}(\varepsilon^{-1/2})$ and $n = \mathcal{O}(1)$, we obtain another expansion that asymptotically matches to $R_0(X)$ and to $Q(X,Y)$ in the appropriate limits. This yields the additional relation $K_* = R_0(A) = e^{-A}R_0(0) = Ke^{-A}$, and then normalization shows that $K = 1$. The merit of the direct approach sketched

here is that it should be possible to generalize to more complicated models, e.g., ones with general service time distributions.

Next we give the **HTL 1** results.

THEOREM 3.3. *In the heavy traffic limit* **HTL 1**, *we have as* $\varepsilon \to 0^+$

(a) $m = X/\varepsilon < L$, $n = Y/\varepsilon$:

$$p(m,n) \sim \varepsilon^2 P(Y,X;a) = \frac{\varepsilon^2}{2\pi i}\int_{Br} \frac{2\theta e^{\theta X}\exp[-\frac{Y}{2}(a+1+\sqrt{(a+1)^2+4a\theta})]}{a+1+2\theta-\sqrt{(a+1)^2+4a\theta}}d\theta;$$

(b) $m \geq L$, $m-L = \mathcal{O}(1)$, $n = Y/\varepsilon$:

$$p(m,n) \sim (\varepsilon a)^{m+1-L}\frac{1}{2\pi i}\int_{Br}\frac{8\theta e^{\theta A}}{a+1+2\theta-\sqrt{(a+1)^2+4a\theta}} \times \frac{e^{-Y}-e^{-Y(a+1+\sqrt{(a+1)^2+4a\theta})/2}}{[a+1+\sqrt{(a+1)^2+4a\theta}][a-1+\sqrt{(a+1)^2+4a\theta}]}d\theta;$$

(c) $m \geq L$, $m-L = \mathcal{O}(1)$, $n = \mathcal{O}(1)$:

$$p(m,n) \sim \varepsilon(\varepsilon a)^{m+1-L}\frac{1}{2\pi i}\int_C \frac{1}{(1-w)^2(2-w)^{m-L}w^{n+1}}dw \times \frac{1}{2\pi i}\int_{Br}\frac{4\theta e^{\theta A}}{[a+1+2\theta-\sqrt{(a+1)^2+4a\theta}][a+1+\sqrt{(a+1)^2+4a\theta}]}d\theta.$$

Thus, now the limiting distribution behaves as a two-dimensional diffusion in the range $\{0 < X < A, Y > 0\}$, coupled to a one-dimensional diffusion along $\{m = L, Y > 0\}$. The mass in the first region is

$$M_-(A) = \sum_{n=0}^{\infty}\sum_{m=0}^{L-1} p(m,n) \sim \frac{4}{2\pi i}\int_{Br}\frac{e^{\theta A}-1}{[a+1+2\theta-\sqrt{(a+1)^2+4a\theta}][a+1+\sqrt{(a+1)^2+4a\theta}]}d\theta,$$

where we have used part(a) of Theorem 3.3. The remaining mass is, using part (b) with $m = L$,

$$M_+(A) = \sum_{n=0}^{\infty}\sum_{m=L}^{\infty} p(m,n) \sim \sum_{n=0}^{\infty} p(L,n) \sim \frac{a}{2\pi i}\int_{Br}\frac{8\theta e^{\theta A}}{[a+1+2\theta-\sqrt{(a+1)^2+4a\theta}][a+1+\sqrt{(a+1)^2+4a\theta}]^2}d\theta.$$

Using contour integration, it is possible to show that these two expressions indeed sum to one.

Finally, we discuss the direct approach to the diffusion model. In the limit **HTL 1** we find that for $x < A$ ($m < L$) we have $p(m,n) \sim \varepsilon^2\bar{Q}(X,Y)$, where

$$\bar{Q}_{YY} + (a+1)\bar{Q}_Y - a\bar{Q}_X = 0, \qquad 0 < X < A,\ Y > 0,$$
$$\bar{Q}_X(X,0) + \bar{Q}_Y(X,0) + (a+1)\bar{Q}(X,0) = 0, \qquad 0 < X < A,$$
$$\bar{Q}(0,Y) = 0,$$

and thus $\bar{Q}(X,Y) = K_1 P(Y,X;a)$, where P is as in Theorem 2.5. For $Y = \varepsilon n > 0$ and $m = L, L+1, \ldots$ we use $p(m,n) \sim \varepsilon^{l+1} Q_l(Y)$, where $l = m - L$. Then we find that $Q_0(Y)$ satisfies the forced one-dimensional diffusion equation

$$Q_0''(Y) + Q_0'(Y) = -a\bar{Q}(A,Y), \qquad Y > 0.$$

From a careful consideration of the scale $m - L = \mathcal{O}(1)$, $m \geq L$, $n = \mathcal{O}(1)$, we obtain the boundary condition $Q_0(0) = 0$. Then we can easily solve for $Q_0(Y)$ in terms of the previously obtained $\bar{Q}(A,Y)$. Now both diffusions are known up to a common multiplicative constant, which follows from normalization.

4. Discussion and numerical results. We demonstrate the usefulness of both our exact and asymptotic results. The exact results for the two models are given in Theorems 2.1 and 3.1. In both cases, the exact formulas for the stationary probabilities are given in terms of complex contour integrals. These integrals can be evaluated by computing the residue at zero. However, for m and/or n large, the residue calculation is not feasible. The asymptotic results for the tail probabilities (cf. Theorems 2.2–2.4) and the heavy traffic diffusion results (cf. Theorems 2.5, 2.6, 3.2, 3.3) provide good approximations precisely when the computation of the exact solution is difficult.

We consider several examples of the simplified model in section 2. The marginal probability $p(n)$ for the number in the high priority queue is given by the exact formula (2.8), while its asymptotic approximation is given in Theorem 2.4 (b) and (c). For each of the tables, we evaluate the integral in (2.8) by computing the residue at $w = 0$ using the symbolic computation program *Maple*.

In Table 4.1, we consider a system with $\lambda_1 = 1/4$, $\lambda_2 = 1/2$, and $\mu = 1$. Thus, $\rho_1 = 1/4$ and $\rho_2 = 1/2$ so that $(\rho_1, \rho_2) \in R_B$ (cf. Figure 2.1). As we see from Table 4.1, the asymptotic expansion is quite accurate for $n > 5$, where the relative error is less than 5%. In Table 4.2, we consider the same queue as in Table 4.1 except that $\lambda_2 = 2/3$. Again the asymptotic results are extremely accurate.

In Table 4.3, we consider a system with $\lambda_1 = 3/4$, $\lambda_2 = 1/150$, and $\mu = 1$. Thus, $\rho_1 = 3/4$ and $\rho_2 = 1/150$ so that $(\rho_1, \rho_2) \in R_A$. For this case the results are not as accurate as for those in Tables 4.1 and 4.2. As n increases, the accuracy of the asymptotic expansion increases. For $n > 30$ the calculation of the exact formula is difficult, and so we no longer have a basis of comparison. If we choose (ρ_1, ρ_2) closer to the curve separating regions R_A and R_B in Figure 2.1, then the error is larger for each n. However, for sufficiently large n, we expect the asymptotic result to be very accurate. The difference in the size of the errors in these examples is due to the fact that in region R_A the error (in Theorem 2.4(b)) is $\mathcal{O}(1/n)$, while in region R_B the error is exponentially small. In fact, it can be shown that the error term for R_B is the same as the leading term for the region R_A. Neither expansion is valid at or near the transition curve that separates R_A and R_B. There a new expansion must be constructed. This new expansion involves hypergeometric functions, and we do not consider it here.

As a last example, we compare the heavy traffic diffusion approximation for the marginal probability $p(n)$, as given in Theorem 2.5, to the exact expression (2.8). In Figure 4.1, we present graphs of both (2.8) and the heavy traffic approximation in Theorem 2.5 when $\rho_1 = 4/5$ and $\rho_2 = 1/10$, so that $\varepsilon = 1/10$ and $b = 1$. For these parameters, the heavy traffic approximation is $\varepsilon P(Y) = \varepsilon e^{-Y}/\sqrt{\pi Y}$. As we see qualitatively, the heavy traffic result provides an accurate approximation if $n > 4$. In fact, the error is less than 3% for all $n > 4$.

MODELLING THE DYNAMICS OF TURBULENT FLOODS*

Z. MEI†, A. J. ROBERTS‡, AND ZHENQUAN LI‡

Abstract. Consider the dynamics of turbulent flow in rivers, estuaries, and floods. Based on the widely used k-ϵ model for turbulence, we use the techniques of center manifold theory to derive dynamical models for the evolution of the water depth and of vertically averaged flow velocity and turbulent parameters. This new model for the shallow water dynamics of turbulent flow resolves the vertical structure of the flow and the turbulence, includes interaction between turbulence and long waves, and gives a rational alternative to classical models for turbulent environmental flows.

Key words. k-ϵ turbulence, water waves, floods, center manifold

1. Introduction.

Consider the dynamics of a turbulent flow over ground, as occurs in rivers, channels, or floods. In such flows it is the large-scale horizontal variations which are important; the vertical structure of velocity and turbulence may be expected to be determined by the local conditions of the horizontal flow. In this situation we may seek a model of the flow which involves only "coarse" depth-averaged quantities. Such models have been constructed before; for example, Fredsoe and Deigaard [15, pp. 37–39] depth-average the k-equation model of turbulent flow to model the dynamics of breakers on a beach, whereas depth-averaged k-ϵ equations have been used by Rastogi and Rodi [37] to model heat and mass transfer in open channels and by Keller and Rodi [24] to investigate flood plain flows. The need for such sophisticated models was also indicated by Peregrine [35, p. 97], commenting that an empirical friction law derived from channel flow underestimates the turbulence in breakers and surf, and Mei [29, p. 485], observing that eddy viscosities need to be different in and outside of the surf zone.

However, the recent development of center manifold theory and related techniques presages a much deeper understanding of the process of modelling nonlinear dynamics and foresees the systematic reduction of many nonlinear problems to an underlying low-dimensional system. For example, the process of depth-averaging has been shown to be deficient as a modelling paradigm [44]. In the context of turbulent flow, we show in section 3 how the mean motions may be determined by a few critical modes which have a nontrivial structure in the vertical; e.g., as a first approximation the horizontal velocity u and turbulent energy density k are taken to have a cube-root dependence. Moreover, the amplitude of these modes and their evolution may be expressed in terms of depth-averaged quantities. We derive the following coupled nonlinear set of equations to model the turbulent, large-scale flow of water over ground (see (28)):

$$\frac{\partial \eta}{\partial t} \sim -\frac{\partial(\eta \bar{u})}{\partial x}, \tag{1a}$$

$$\frac{\partial \bar{u}}{\partial t} \sim -1.030\frac{\tilde{\nu}\bar{u}}{\eta^2} + (0.0504 - 0.243\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^3}{\eta^2\bar{k}}$$

$$+ 0.961\,g\left(\theta - \frac{\partial \eta}{\partial x}\right) - 1.105,\bar{u}\frac{\partial \bar{u}}{\partial x} + 1.44\frac{\partial}{\partial x}\left(\tilde{\nu}\frac{\partial \bar{u}}{\partial x}\right), \tag{1b}$$

$$\frac{\partial \bar{k}}{\partial t} \sim -0.993\,\bar{\epsilon} - 0.0927\frac{\bar{k}^3}{\eta^2\bar{\epsilon}} + (0.589 + 0.516\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^2}{\eta^2} - 1.106\,\bar{u}\frac{\partial \bar{k}}{\partial x}$$

$$+ 1.31\frac{\partial}{\partial x}\left(\tilde{\nu}\frac{\partial \bar{k}}{\partial x}\right), \tag{1c}$$

$$\frac{\partial \bar{\epsilon}}{\partial t} \sim -2.101\frac{\bar{\epsilon}^2}{\bar{k}} + (1.552 - 3.215\,\tilde{\lambda})\frac{\tilde{\nu}\bar{\epsilon}\bar{u}^2}{\bar{k}\eta^2}$$

$$- 0.173\,\tilde{\lambda}\bar{\epsilon}\frac{\partial \bar{u}}{\partial x} + 0.533\,\tilde{\lambda}\frac{\bar{\epsilon}\bar{u}}{\bar{k}}\frac{\partial \bar{k}}{\partial x} - (1 + 0.735\,\tilde{\lambda})\bar{u}\frac{\partial \bar{\epsilon}}{\partial x}$$

$$+ 0.81\frac{\partial}{\partial x}\left(\tilde{\nu}\frac{\partial \bar{\epsilon}}{\partial x}\right). \tag{1d}$$

Here η is the water depth and $\bar{u}$, $\bar{k}$, and $\bar{\epsilon}$ are depth-averaged flow velocity, turbulent energy, and turbulent dissipation, respectively. The other variables appearing are $\tilde{\nu} = C_\mu \bar{k}^2/\bar{\epsilon}$, measuring the local eddy diffusivity (see (24)), and $\tilde{\lambda} = \eta^2\bar{\epsilon}^2/\bar{k}^3$, being proportional to the ratio of the vertical mixing time to the turbulent eddy time (see (25)). For example, in section 5.3 this model is used to predict the flow after a dam breaks. See in Figure 6 the formation of a turbulent bore rushing downstream from the dam. The turbulence in the bore is generally highest near the front and decays away behind as seen in Figure 7. This gives one example of the variations in spatial structure of the turbulence that underlies shallow water flows.

Modelling turbulent flow is one of the major challenges in fluid dynamics. While large eddies, which can be as large as the flow domain, extract energy from the mean flow and feed it into turbulent motion, the eddies also act as a vortex stretching mechanism and transfer the energy to the smallest scales where viscous dissipation takes place. It is the scale at which the dissipation occurs that determines the rate of energy dissipation. However, the inflow of energy into turbulent motion is a characteristic of only the large-scale motion. In other words, the turbulent but small-scale motion is often dominated and determined by the large-scale motion and can be treated as a perturbation of the mean flow. The coupling of energy transportation and energy dissipation with the mean flow is adequately described by widely used second-order closure models. In particular, the most popular choice is the two equation k-ϵ model; see, for example, Launder, Reece, and Rodi [26], Hanjalić and Launder [19], Rodi [50], and Speziale [52] for reviews.

We base our analysis upon the k-ϵ model (section 2) for the turbulence underlying the free surface of a fluid in a channel or river or over a flood plain. The resultant model (1) is basically a model for the evolution of vertically averaged quantities; the model resolves large-scale, compared to the depth, dynamical structures in the horizontal. It is important to distinguish between models obtained by depth-averaged equations (which are known to be incorrect [44] for other similar long-wave dynamics) and our model, which is, for convenience, written in terms of depth-averaged quantities.

In section 4 we derive the "coarse" low-dimensional model (1) from the "fine" k-ϵ equations. Despite the well-recognized limitations of the k-ϵ equations as a model of turbulence, we anticipate that the information retained in our coarse model is

reasonably insensitive to deficiencies in the k-ϵ dynamics. Further modelling may be done via more sophisticated Reynolds stress models for channel flow, such as that described by Gibson and Rodi [17]. One aspect to note is that the model we derive has *no* adjustable parameters—all constants are determined from values established for the k-ϵ turbulence model and its boundary conditions. Thus the model predictions are definitive. We describe some example solutions in section 5 to illustrate the dynamical predictions of the model.

Penultimately, in Appendix A we comment on the status of the theory of center manifolds in this development of a low-dimensional model of turbulent flow using center manifold techniques. Finally, in Appendix B we list the computer algebra program used to perform the intricate algebra in constructing the model.

2. The k-ϵ model of turbulent flow. Consider the two-dimensional inviscid k-ϵ model of turbulent flow over rough ground. Distance parallel to the ground's slope is measured by x, while we measure distance normal to the slope by y. Molecular dissipation is neglected because we anticipate little direct effect for it in flood waves of a depth $\mathcal{O}$(metre) over ground with roughness which may be many times the length-scale of viscous dissipation. Turbulent eddies are proposed to be the dominant mechanism for dispersion and dissipation. We denote the ensemble mean velocity components and pressure by u, v, and p, respectively; that is, for simplicity, we omit any distinguishing overbars (instead overbars will later be used to denote depth-averaged quantities). Then the incompressible k-ϵ model (with ensemble means) is

$$\text{(2a)} \qquad \begin{bmatrix} 0 \\ \frac{\partial \boldsymbol{u}}{\partial t} \end{bmatrix} = \begin{bmatrix} \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} \\ \boldsymbol{F}(p, \boldsymbol{u}) \end{bmatrix},$$

where the vector $\boldsymbol{u} = (u, v, \eta, k, \epsilon)$[1] is formed from the velocities u and v in the lateral and normal directions, respectively, the height of the free surface $y = \eta(x, t)$, the turbulent energy density k, and its dissipation rate ϵ. The nonlinear model governing the evolution of the unknowns $\boldsymbol{u}$ and p is

$$\text{(2b)} \quad \boldsymbol{F}(p, \boldsymbol{u}) = \begin{bmatrix} -u\frac{\partial u}{\partial x} - v\frac{\partial u}{\partial y} - \frac{\partial p}{\partial x} + g\sin\theta - \frac{2}{3}\frac{\partial k}{\partial x} + 2\frac{\partial}{\partial x}\left(\nu\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left\{\nu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)\right\} \\ -u\frac{\partial v}{\partial x} - v\frac{\partial v}{\partial y} - \frac{\partial p}{\partial y} - g\cos\theta - \frac{2}{3}\frac{\partial k}{\partial y} + 2\frac{\partial}{\partial y}\left(\nu\frac{\partial v}{\partial y}\right) + \frac{\partial}{\partial x}\left\{\nu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)\right\} \\ -u(x, \eta, t)\frac{\partial \eta}{\partial x} + v(x, \eta, t) \\ -u\frac{\partial k}{\partial x} - v\frac{\partial k}{\partial y} + \left\{\frac{\partial}{\partial x}\left(\frac{\nu}{\sigma_k}\frac{\partial k}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{\nu}{\sigma_k}\frac{\partial k}{\partial y}\right)\right\} + P_h - \epsilon \\ -u\frac{\partial \epsilon}{\partial x} - v\frac{\partial \epsilon}{\partial y} + \left\{\frac{\partial}{\partial x}\left(\frac{\nu}{\sigma_\epsilon}\frac{\partial \epsilon}{\partial x}\right) + \frac{\partial}{\partial y}\left(\frac{\nu}{\sigma_\epsilon}\frac{\partial \epsilon}{\partial y}\right)\right\} + \frac{C_{\epsilon 1}}{T}P_h - C_{\epsilon 2}\frac{\epsilon^2}{k} \end{bmatrix}.$$

Here the eddy viscosity

$$\text{(3)} \qquad \nu = C_\mu \frac{k^2}{\epsilon}$$

is a result of the turbulent mixing and varies in space and time. Later we use the approximate values of the constants

$$\text{(4)} \qquad C_\mu = 0.09\,, \quad \sigma_k = 1\,, \quad \sigma_\epsilon = 1.3\,, \quad C_{\epsilon 1} = 1.44\,, \quad C_{\epsilon 2} = 1.92\,,$$

[1] We adopt the notation that a vector in parentheses, such as $(u, v, \eta, k, \epsilon)$, is a shorthand for the corresponding column vector.

in order to form definite models. Also

$$P_h = \nu \left[2 \left(\frac{\partial u}{\partial x} \right)^2 + 2 \left(\frac{\partial v}{\partial y} \right)^2 + \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right)^2 \right]$$

describes the generation of turbulence through instabilities associated with mean-velocity gradients. T is the time-scale of the turbulent eddies and is frequently defined as

$$T = \max \left\{ k/\epsilon, C_T \sqrt{\nu_m/\epsilon} \right\};$$

the cutoff at viscous time-scales $\sqrt{\nu_m/\epsilon}$ is to avoid a singularity in turbulent production at a wall; see [14, p. 470], for example. However, here we eschew the incorporation of direct viscous effects and so avoid this singularity by using $T = \bar{k}/\bar{\epsilon}$ as the typical turbulent time-scale, where the overbars denote depth averages. The downward slope of the bed, θ, is assumed to be small and to have negligible variation.

The boundary conditions on the bottom and the free surface are important in the details of the construction of the low-dimensional model. The following arguments lead to the given boundary conditions:

- The standard condition is that, in view of the extremely low density of air, the pressure of the air on the fluid surface is effectively constant, which we take to be zero without loss of generality. Thus the normal stress of the fluid across the free surface should vanish:

$$p + \frac{2}{3}k - \frac{2\nu}{1+\eta_x^2} \left[\frac{\partial v}{\partial y} + \frac{\partial u}{\partial x} - \eta_x \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \right] = 0 \quad \text{on } y = \eta\,. \tag{5}$$

  This is only approximately true—corrections should exist of the order of $\overline{p'\eta'}$ in terms of fluctuations about the ensemble means and similarly for other equations involving the free surface. However, the time-scale of gravity waves, $\sqrt{\ell/(2\pi g)}$, associated with the turbulent length-scale, $\ell \propto k^{3/2}/\epsilon$, should be typically much shorter than the turbulent eddy turn-over time, $\ell/\sqrt{k}$ (true for the scaling introduced in section 3.2), and, as in [22, section 2.3], we expect there to be little interaction between the turbulent fluctuations and the free surface dynamics.
- In this work we assume that the horizontal extent of the flood waves is small enough so that wind stress is negligible. This is in contrast to large-scale geophysical simulations, such as that by Arnold and Noye [2], where the wind stress is very important. Thus the fluid surface is free of tangential stress:

$$\left(1 - \eta_x^2\right) \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right) + 2\eta_x \left(\frac{\partial v}{\partial y} - \frac{\partial u}{\partial x} \right) = 0 \quad \text{on } y = \eta\,. \tag{6}$$

  A wind stress could be incorporated into the model by appropriately replacing the zero right-hand side.
- Symmetry conditions for turbulent variables k and ϵ on the free surface (see Arnold and Noye [3] or Fredsoe and Deigaard [15, p. 117] for examples) lead to

$$\frac{\partial k}{\partial n} = 0 \quad \text{on } y = \eta\,, \tag{7}$$

$$\text{and} \quad \frac{\partial \epsilon}{\partial n} = 0 \quad \text{on } y = \eta\,. \tag{8}$$

These assert that the energy in turbulent eddies cannot be lost or gained by transport through the free surface, and similarly for the turbulent dissipation. More sophisticated models of the free surface effect upon turbulence by Gibson and Rodi [17, p. 238] use these zero net flux boundary conditions. Spilling breakers on the water surface could perhaps be modelled by a turbulent production term on the right-hand side of these boundary conditions.

- At the ground, $y = 0$, there must be no flow across the flat bottom:

$$v(x, 0, t) = 0\,. \tag{9}$$

- Other boundary conditions on the ground are more arguable (compare our treatment with that of Arnold and Noye [3, 4]). We are interested only in the flow outside of any molecular boundary layer that may exist on the stream bed—we imagine that the structure of any ordered viscous layer will be broken up by the roughness. This is supported by recent experiments by Krogstad and Antonia [25] who show that roughness of a wall, even on a scale 1/100th the thickness of a turbulent boundary layer, tends to *reduce* the overall anisotropy of the turbulence. A major limitation of the k-ϵ model is the high level of anisotropy near a wall, so such a reduction in anisotropy due to roughness will favor the k-ϵ model. Note that we treat the ground as $y = 0$ in the mathematical model even though we imagine it to be rough. In effect, ensemble means are also done over all realizations of a "rough" bed with mean slope θ and hence mean position $y = 0$.
  We suppose that the bottom inhibits the turbulence in its immediate neighborhood so that the turbulent energy falls to zero:

$$k = 0 \quad \text{on } y = 0\,. \tag{10}$$

In using the k-ϵ model for near-wall turbulence, Durbin [12, 13] asserts that $\partial k/\partial y = 0$ on the wall as well. However, Figure 1 by Durbin [12] shows this latter condition is significant only for the viscous boundary layer—a layer we ignore due to the roughness of the ground. Instead of this requirement, we place the fairly weak constraint on the turbulent dissipation:

$$\nu \frac{\partial \epsilon}{\partial y} \to 0 \quad \text{as } y \to 0\,. \tag{11}$$

This is weak because $\nu \propto k^2 \to 0$ as $y \to 0$. In essence, this condition asserts that the bed does not directly act as a source or sink of turbulent dissipation.

- Although $\nu \propto k^2 \to 0$ as $y \to 0$, we suppose that ν approaches zero slowly enough so that turbulence is still an effective mixing mechanism near the bed. Thus, the ensemble mean horizontal velocity should also vanish on the bed (as also used by Lin and Falconer [27, p. 740]):

$$u = 0 \quad \text{on } y = 0\,. \tag{12}$$

These three boundary conditions on the bed are the same as those used by "low Reynolds" k-ϵ turbulent models [33, p. 64]. The difference here is that we do not include the near-wall dependence upon local Reynolds numbers $R_t = k^2/\epsilon\nu_m$ and $R_y = \sqrt{k}y/\nu_m$ because these involve molecular viscosity ν_m.

The boundary conditions are different to those we used in an earlier treatment of this problem [30]. The difference occurs because there we assumed that the stress $\partial u/\partial y$ is small near the bottom and is more appropriate to weakly turbulent flows. Here we seek the dynamics of flows with a strong level of turbulence leading to the boundary condition (12).

3. Basis of the low-dimensional model. In this paper we consider flows that vary "slowly" in the x and t directions. In this context, the meaning of "slow" is that the dynamics are slower relative to the vertical mixing time induced by the turbulence. In particular, the derivatives of the flow variables with respect to x and t are small quantities that can be collected with the "nonlinear" part of the equations and treated as perturbations. Hence we rewrite the equations as

$$\begin{bmatrix} 0 \\ \dot{u} \\ \dot{v} \\ \dot{\eta} \\ \dot{k} \\ \dot{\epsilon} \end{bmatrix} = \begin{bmatrix} 0 & 0 & \frac{\partial}{\partial y} & 0 & 0 & 0 \\ 0 & \frac{\partial}{\partial y}\left(\nu\frac{\partial}{\partial y}\right) & 0 & 0 & 0 & 0 \\ -\frac{\partial}{\partial y} & 0 & 2\frac{\partial}{\partial y}\left(\nu\frac{\partial}{\partial y}\right) & 0 & -\frac{2}{3}\frac{\partial}{\partial y} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{\sigma_k}\frac{\partial}{\partial y}\left(\nu\frac{\partial}{\partial y}\right) & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{\sigma_\epsilon}\frac{\partial}{\partial y}\left(\nu\frac{\partial}{\partial y}\right) \end{bmatrix} \begin{bmatrix} p \\ u \\ v \\ \eta \\ k \\ \epsilon \end{bmatrix}$$

$$+ \begin{bmatrix} \frac{\partial u}{\partial x} \\ -u\frac{\partial u}{\partial x} - v\frac{\partial u}{\partial y} - \frac{\partial p}{\partial x} + g\sin\theta - \frac{2}{3}\frac{\partial k}{\partial x} + 2\frac{\partial}{\partial x}\left(\nu\frac{\partial u}{\partial x}\right) + \frac{\partial}{\partial y}\left(\nu\frac{\partial v}{\partial x}\right) \\ -u\frac{\partial v}{\partial x} - v\frac{\partial v}{\partial y} - g\cos\theta + \frac{\partial}{\partial x}\left[\nu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)\right] \\ -u(x,\eta,t)\frac{\partial \eta}{\partial x} + v(x,\eta,t) \\ -u\frac{\partial k}{\partial x} - v\frac{\partial k}{\partial y} + \frac{\partial}{\partial x}\left(\frac{\nu}{\sigma_k}\frac{\partial k}{\partial x}\right) + P_h - \lambda\epsilon \\ -u\frac{\partial \epsilon}{\partial x} - v\frac{\partial \epsilon}{\partial y} + \frac{\partial}{\partial x}\left(\frac{\nu}{\sigma_\epsilon}\frac{\partial \epsilon}{\partial x}\right) + \frac{C_{\epsilon 1}}{T}P_h - C_{\epsilon 2}\lambda\frac{\epsilon^2}{k} \end{bmatrix}$$

$$= \mathcal{L}(p, \boldsymbol{u}) + \mathcal{F}(p, \boldsymbol{u}, \lambda)\,. \tag{13}$$

Treating the time and lateral variations and the "nonlinear" terms as small, we see that $\mathcal{L}(p, \boldsymbol{u})$ comprises the leading term in the equation.

With a little adaptation, the operator $\mathcal{L}$ has a critical space of equilibrium points parametrized by the water depth η and the mean fields $\bar{u}$, $\bar{k}$, and $\bar{\epsilon}$. To ensure that the turbulent energy and turbulent dissipation are critical modes of $\mathcal{L}$ and thus retained in our model of turbulent floods, we need k and ϵ to be conserved to leading order. The parameter $\lambda \in [0, 1]$ is an artificial parameter which we use to adjust the rate of decay of turbulent energy and its dissipation; by making λ small we initially neglect the natural turbulent decay, but when $\lambda = 1$ we recover the standard k-ϵ model. This is reasonable because the combined effect of $\dot{k} = -\epsilon$ and $\dot{\epsilon} = -C_{\epsilon 2}\epsilon^2/k$ is a *slow* algebraic decay of turbulence [28, p. 277] that is appropriate for the long-term center manifold dynamics.

3.1. Vertical mixing. The operator $\mathcal{L}$ is considered to be the dominant feature of the k-ϵ model (2). It is primarily composed of the differential operator

$$\frac{\partial}{\partial y}\left(\nu\frac{\partial}{\partial y}\right),$$

which represents vertical mixing by turbulent eddies. By identifying this as the dominant term in the equations we are physically supposing that turbulent mixing in the

vertical is stronger than the other processes that redistribute momentum and turbulent energy. For example, Lin and Falconer [27, p. 738] comment that "the shallow regions of tidal embayments are usually well mixed."

The boundary conditions on the bottom, (10) and (11), in conjunction with the k and ϵ components of $\mathcal{L}$ in (13) admit homogeneous solutions $k \propto y^{1/3}$ and ϵ constant. Such a cube-root profile in the vertical fits with arguments that the turbulence should be weaker near the bottom due to its constraining effects. Given such a profile, the turbulent diffusivity $\nu \propto y^{2/3}$ and so the horizontal velocity component of $\mathcal{L}$ also admits homogeneous solutions $u \propto y^{1/3}$. Although our long-wave model will be expressed in terms of depth-averaged quantities, we base the vertical structure that they measure on these cube-root profiles.

Traditionally, many theoretical approaches have assumed constant or near constant vertical profiles (see [15, section 4.3.1] or [36, p. 670] for examples), as indeed we also have in an earlier treatment of this problem [30]. However, as seen in experiments the horizontal velocity profile is typically curved (see [51, Fig. 12], [7], or [54, Fig. 2]) as is the turbulent energy (see [15, Fig. 4.25]). A logarithmic profile is a well-established approximation; here we work with the cube-root profile as it is compatible with the k-ϵ equations, is analytically tractable, and is a rough initial approximation to the logarithmic profile.

These cube-root profiles result in downwards turbulent transport of momentum and turbulent energy with constant flux and eventual removal from the fluid at the bed. In order to maintain flow at leading order (only) we modify the conservative free surface boundary conditions (6)–(7) to supply the requisite flux at leading order and to remove the supply at higher order. We replace (6)–(7) with the boundary conditions that on $y = \eta$

$$(1 - a\gamma)\left[\left(1 - \eta_x^2\right)\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) + 2\eta_x\left(\frac{\partial v}{\partial y} - \frac{\partial u}{\partial x}\right)\right] = \frac{1-\gamma}{3\eta}u, \tag{14}$$

$$(1 - a\gamma)\left[\frac{\partial k}{\partial y} - \frac{\partial \eta}{\partial x}\frac{\partial k}{\partial x}\right] = \frac{1-\gamma}{3\eta}k, \tag{15}$$

where the artificial parameter γ, as for λ introduced earlier, is small in the asymptotic scheme but eventually will be set to 1 to recover the desired boundary conditions (6)–(7). Such manipulation of the governing equations has worked well in developing analogous models of the laminar viscous flow of a thin fluid layer [44, 47]; the resulting model was found to be independent of the two different manipulations. The particular choice (14)–(15) here enables us to develop the necessary asymptotic expansions purely in polynomials of $y^{1/3}$.

The center manifold analysis forms a power series in γ which needs to be summed for $\gamma = 1$. The parameter $a \neq 1$ is free for us to choose. Initially we omitted a, equivalent to choosing $a = 0$, but after two years of exploration we determined that an Euler transformation of the series in γ greatly improves the convergence; e.g., see Hinch [21, Chap. 8]. Introducing $a \neq 0$ is equivalent to such an Euler transformation. Another view of $a \neq 0$ is that of an over-relaxation parameter in an iterative scheme. In this problem it appears that $a \approx 1/2$ is a good compromise between conflicting influences and is used henceforth.

From the special structure of the vertical mixing operator $\mathcal{L}$ with the modified boundary conditions, we deduce that there are four critical modes of interest in the long-term dynamics. These modes correspond to the leading-order conservation, and hence long-life, of fluid mass, momentum, turbulent energy, and turbulent dissipation.

These modes span the space $\mathcal{M}_0$:

$$(p, \boldsymbol{u}) = \left(g(\eta - y),\, U\tfrac{4}{3}\left(\tfrac{y}{\eta}\right)^{1/3},\, 0,\, H,\, K\tfrac{4}{3}\left(\tfrac{y}{\eta}\right)^{1/3},\, E \right), \tag{16}$$

where U, H, K, and E are arbitrary functions of x and t. Note that the turbulent diffusivity, ν, then also varies slowly in x and t; to leading order it is

$$\nu_0 = C_\mu \frac{16K^2}{9E} \left(\frac{y}{\eta}\right)^{2/3}.$$

As proven in Appendix A, the dominant operator $\mathcal{L}$, linearized about the space of equilibrium points, has eigenvalues which are all negative (due to the decaying dynamics of turbulent dispersion), except for the four zero eigenvalues corresponding to the four conserved modes. By continuity in the "nonlinear" perturbation $\mathcal{F}$, the center manifold is also exponentially attractive, at least for small enough nonlinearity. Since all other modes decay exponentially quickly, the long time behavior of the flow is determined by the functions $U(x,t)$, $H(x,t)$, $K(x,t)$, and $E(x,t)$. Respectively, these represent the vertically averaged horizontal velocity, the surface elevation, the vertically averaged turbulent energy, and the vertically averaged turbulent dissipation. In essence, we construct a "vertically averaged" model, but in u and k there is structure in the vertical, roughly proportional to $y^{1/3}$, whose amplitude we measure by the vertical average.

3.2. Approximating the center manifold. Center manifold techniques systematically develop such a model in the vertically averaged quantities. Based on the relatively low-dimensional space of exponentially attractive equilibria $\mathcal{M}_0$, center manifold theory [9] suggests that the nonlinear terms $\mathcal{F}$ "bend" $\mathcal{M}_0$ to a nearby manifold $\mathcal{M}$ of slow evolution. Further, $\mathcal{M}$ will similarly attract exponentially quickly all solutions in its vicinity; in standard formulations $\mathcal{M}$ is called the center manifold. Once on $\mathcal{M}$, solutions evolve slowly according to a low-dimensional system of evolution equations—these evolution equations form the simplified model of the original dynamics. This general approach to forming low-dimensional models of dynamical systems is reviewed by Roberts [45].

We have never found it profitable to decompose dynamics into that on the null space $\mathcal{M}_0$ and its complement. Many do this in order to write the center manifold as a graph. We view the complement space as an artifice of the linearization, whereas we are interested in a physically meaningful parametrization of the center manifold $\mathcal{M}$. Thus the appropriate geometric picture is simply the curving center manifold $\mathcal{M}$ embedded in the original physical state space. Hence we construct the model in terms of easily understandable physical quantities, namely the vertical averages. Nonetheless, the physically relevant complement space at any point on $\mathcal{M}$ is the local direction of projection of initial conditions [41, 11, 48]. Determining this projection is difficult for nonlinear long-wave approximations and is beyond the scope of this paper.

In this problem, the center manifold $\mathcal{M}$ is parametrized by the four "amplitudes," U, H, K, and E, which are functions of x and evolve in time. Due to the difficult nature of the nonlinear terms in the k-ϵ model (2) we have to be very careful about these amplitudes and their derivatives. We introduce two independent small parameters: δ as an amplitude scale and ϑ to scale spatial derivatives. Then we treat the flow fields and derivatives as

$$u, k = \mathcal{O}(\delta^2), \quad \epsilon = \mathcal{O}(\delta^3), \quad \eta = h + \mathcal{O}(\delta^2), \quad \text{and} \quad \frac{\partial}{\partial x} = \mathcal{O}(\delta\vartheta). \tag{17}$$

Note that in this scaling, the turbulent length-scale $\ell \propto k^{3/2}/\epsilon = \mathcal{O}(1)$. This ensures that the turbulent eddies modelled by k and ϵ are not asymptotically larger than the water depth; large-scale horizontal eddies are resolved by variations in the amplitudes of the model. Also from these scalings, the turbulent diffusivity $\nu = \mathcal{O}(k^2/\epsilon) = \mathcal{O}(\delta)$ and thus the time-scale of vertical mixing is $\mathcal{O}(1/\delta)$. Consequently, we must consider horizontal scales larger than $\mathcal{O}(1/\delta)$, which accounts for requiring the product $\delta\vartheta$ in the scaling of horizontal derivatives. In standard applications of center manifold theory, we are free to scale the amplitudes in any reasonable fashion or, indeed, to treat the amplitudes as independent; as discussed in [40] a change in the scaling just reorders the appearance of the same set of terms in the model. In this application of center manifold techniques, physical considerations and the nonstandard nonlinearities place the constraints on the scaling that derivatives $\frac{\partial}{\partial x} = \mathcal{O}(\delta\vartheta)$ and that the slope $\theta = \mathcal{O}(\delta^3\vartheta)$. Nonetheless, we exploit usefully some of the capability of center manifold techniques to treat amplitudes as independent variables by the above introduction of two independent small parameters, δ and ϑ.

Two other independent small parameters in this problem are γ, the artificial forcing at the free surface, and λ, an artificial adjustment of turbulent interaction. We treat all four of these parameters as independently small.

In terms of the field variables, we define the four amplitudes U, H, K, and E in terms of physical quantities such that

$$\bar{u} = \delta^2 U\,, \tag{18a}$$

$$\eta = h + \delta^2 H\,, \tag{18b}$$

$$\bar{k} = \delta^2 K\,, \tag{18c}$$

$$\bar{\epsilon} = \delta^3 E\,, \tag{18d}$$

where the overbar denotes a vertical average over the whole fluid depth at any x and t; for example,

$$\bar{u} = \frac{1}{\eta}\int_0^\eta u\,dy. \tag{19}$$

Denoting the collective amplitudes by $\boldsymbol{s}(x,t) = (U, H, K, E)$, we pose the low-dimensional assumption that the evolution of the physical variables may be expressed in terms of the evolution of the four amplitudes (effectively equivalent to the "slaving" principle of synergetics [18]):

$$(p, \boldsymbol{u}) = \mathcal{V}(y, \boldsymbol{s}) \quad \text{such that} \quad \frac{\partial \boldsymbol{s}}{\partial t} = \mathcal{G}(\boldsymbol{s})\,. \tag{20}$$

In general, we cannot find these functions $\mathcal{V}$ and $\mathcal{G}$ exactly, as this would be tantamount to exactly solving the original equations. Instead we determine asymptotic approximations in the four small parameters.

It would be decidedly awkward to explicitly write out an asymptotic expansion in the four asymptotic parameters. But it is also inappropriate to link their relative magnitudes into one parameter as we need to find relatively high-order in γ but not in the others. Thus we apply an iterative algorithm in computer algebra to find the center manifold and the evolution thereon, which is based directly upon the approximation theorem 3 in [9, 46] and its variants, as explained in detail by Roberts [46]. An outline of the procedure follows.

The aim is to find the functional $\mathcal{V}$ and evolution $\mathcal{G}$ such that the pressure, velocity, and turbulence fields described by (20) form actual solutions of the scaled turbulent equations—this ensures fidelity between our model and the fluid dynamics of the k-ϵ equations. Suppose that at some stage in an iterative scheme we have some approximation, $\tilde{\mathcal{V}}$ and $\tilde{\mathcal{G}}$. We then seek a correction, $\mathcal{V}'$ and $\mathcal{G}'$, to obtain a more accurate solution to the turbulence equations. Substituting

$$(p, \boldsymbol{u}) = \tilde{\mathcal{V}} + \mathcal{V}' \quad \text{such that} \quad \frac{\partial \boldsymbol{s}}{\partial t} = \tilde{\mathcal{G}} + \mathcal{G}'$$

into the scaled turbulence equations, then rearranging, dropping products of corrections, and using a leading-order approximation wherever factors multiply corrections (see [46] for details), we obtain a system of equations for the corrections which is of the form

$$\mathcal{L}\mathcal{V}' = \tilde{\boldsymbol{R}} + \mathcal{E}\mathcal{G}' \,, \tag{21}$$

where $\mathcal{E} = \partial\mathcal{V}/\partial\boldsymbol{s}|_{\boldsymbol{s}=\boldsymbol{0}}$ is the basis for the linear subspace $\mathcal{M}_0$ in (16), and, most importantly, $\tilde{\boldsymbol{R}}$ is the residual of the scaled k-ϵ equations using the current approximation $\tilde{\mathcal{V}}$ and $\tilde{\mathcal{G}}$. This homological equation is solved by choosing corrections $\mathcal{G}'$ to the evolution so that the right-hand side is in the range of $\mathcal{L}$; then the correction to the fields $\mathcal{V}'$ is determined. The solution is made unique by requiring that the amplitudes $\boldsymbol{s}$ have some specific physical meaning, here the vertical averages of the fields as in (18). Then the current approximation $\tilde{\mathcal{V}}$ and $\tilde{\mathcal{G}}$ is updated. The iteration is repeated until the residual of the governing equations, $\tilde{\boldsymbol{R}}$, becomes zero to some order of error, whence the center manifold model will be accurate to the same order of error (by the approximation theorem 3 of Carr [9]).

A computer algebra program was written to perform all the necessary detailed algebra for this physical problem. A listing is given in Appendix B. The very important feature of this iteration scheme is that it is performed until the residuals of the actual governing equations are zero to some order of error. Thus the correctness of the results that we present here is based only upon the correct evaluation of the residuals and upon sufficient iterations to drive these to zero. The key to the correctness of the results produced by the computer program is the proper coding of the k-ϵ turbulence equations. These can be seen in the computed residuals within the iterative loop of the program.

4. Constructing the low-dimensional model. As a first step in constructing a dynamical model we discard any variation in x and any influence of slope θ. Thus we first examine the dynamics of a uniform layer of turbulent fluid, k and ϵ nonzero, slowly decelerating, $u \to 0$, due to turbulent drag on the bed.

4.1. The physical fields to low-order. As discussed in section 3.2 on the vertical mixing operator, the leading-order approximation to the shape of the center manifold is just the solutions to $\mathcal{L}\mathcal{V} = 0$. We deduce that

$$u \approx \delta^2 U(x,t)\tfrac{4}{3}\left(\tfrac{y}{\eta}\right)^{1/3}, \quad v \approx 0, \quad k \approx \delta^2 K(x,t)\tfrac{4}{3}\left(\tfrac{y}{\eta}\right)^{1/3},$$
$$\epsilon \approx \delta^3 E(x,t), \quad \text{and} \quad \nu \approx \delta C_\mu \tfrac{16K^2}{9E}\left(\tfrac{y}{\eta}\right)^{2/3}.$$

At higher orders in the small parameters δ, ϑ, λ, and γ, we construct more refined descriptions of the fluid flow and its dynamics through the evolution of the amplitudes.

However, we leave the influence of spatial variations through nonzero ϑ until the next section.

By iterations of the scheme outlined in the previous section we obtain a basic description of the turbulence production and decay. The nonlinear processes and boundary condition corrections modify the cube-root profile and simultaneously determine the slow evolution of the amplitudes.

It is useful to record the asymptotic expansions directly in terms of physical quantities η, $\bar{u}$, $\bar{k}$, and $\bar{\epsilon}$ rather than the corresponding artificially scaled quantities H, U, K, and E. We find the following expressions for the first significant modifications to the fields within the fluid, written in terms of a scaled vertical coordinate $\zeta = y/\eta$ which ranges from $\zeta = 0$ at the bed to $\zeta = 1$ at the fluid surface:

$$v \approx 0\,, \tag{22a}$$

$$u \approx \upsilon_0(\zeta)\bar{u} + \left[C_{\epsilon 1}\sigma_\epsilon \upsilon_1(\zeta) - \sigma_k \upsilon_2(\zeta)\right] \frac{\bar{u}^3}{\bar{k}} + \left(C_{\epsilon 2}\sigma_\epsilon - \sigma_k\right) \upsilon_3(\zeta) \frac{\lambda\eta^2 \bar{u}\bar{\epsilon}}{\tilde{\nu}\bar{k}}\,, \tag{22b}$$

$$k \approx \upsilon_0(\zeta)\bar{k} + \left[C_{\epsilon 1}\sigma_\epsilon \upsilon_1(\zeta) + \sigma_k \upsilon_2(\zeta)\right] \bar{u}^2 + \left(C_{\epsilon 2}\sigma_\epsilon + \sigma_k\right) \upsilon_3(\zeta) \frac{\lambda\eta^2 \bar{\epsilon}}{\tilde{\nu}}\,, \tag{22c}$$

$$\epsilon \approx \bar{\epsilon} + C_{\epsilon 1}\sigma_\epsilon \epsilon_p(\zeta) \frac{\bar{u}^2\bar{\epsilon}}{\bar{k}} + C_{\epsilon 2}\sigma_\epsilon \epsilon_d(\zeta) \frac{\lambda\eta^2\bar{\epsilon}^2}{\tilde{\nu}\bar{k}}\,, \tag{22d}$$

$$\nu \approx \nu_0(\zeta)\frac{\bar{k}^2}{\bar{\epsilon}} + \left[-C_{\epsilon 1}\sigma_\epsilon \nu_1(\zeta) + \sigma_k \nu_2(\zeta)\right] \frac{\bar{\epsilon}\eta^2}{\bar{k}} + \left[C_{\epsilon 2}\sigma_\epsilon \nu_3(\zeta) - \sigma_k \nu_4(\zeta)\right] \frac{\bar{\epsilon}^3\eta^4}{\bar{k}^4}\,. \tag{22e}$$

These expressions are correct to errors $\mathcal{O}\big(\delta^6 + \lambda^3 + \gamma^3, \vartheta\big)$, where, for example, a multinomial term

$$\delta^a \lambda^b \gamma^c \vartheta^d = \mathcal{O}\big(\delta^A + \lambda^B + \gamma^C, \vartheta^D\big) \quad \text{if} \quad \frac{a}{A} + \frac{b}{B} + \frac{c}{C} \geq 1 \text{ and } d \geq D\,.$$

The vertical structure functions occurring in the expressions on the right-hand side of (22) are as follows:

- For the turbulent dissipation,

$$\epsilon_p(\zeta) = \frac{4}{9}\zeta^{4/3} - \frac{8}{9}\zeta^{2/3} + \frac{12}{35}\,,$$
$$\epsilon_d(\zeta) = -\frac{243}{512}\zeta^{4/3} + \frac{81}{128}\zeta - \frac{405}{3584}\,,$$

  as shown in Figure 1. See the effect of turbulent dissipation production, at a rate proportional to $\bar{u}^2$, through the velocity shear. Since velocity shear is largest near the bed, as seen in the shape of $\epsilon_p(\zeta)$, this enhances turbulent dissipation ϵ near the bed.

  However, the natural turbulent dissipation within the fluid causes a greater decay of turbulent dissipation near the bed, due to the smaller turbulent energy there, and so counters this enhancement. Being proportional to $1/\tilde{\nu}$, this effect on the ϵ-profile is greatest in weakly turbulent flows.

- For the turbulent energy density,

$$\upsilon_0(\zeta) = \frac{4}{3}\zeta^{1/3} + \gamma\left(\frac{1}{12}\zeta^{1/3} - \frac{1}{6}\zeta^{5/3}\right),$$

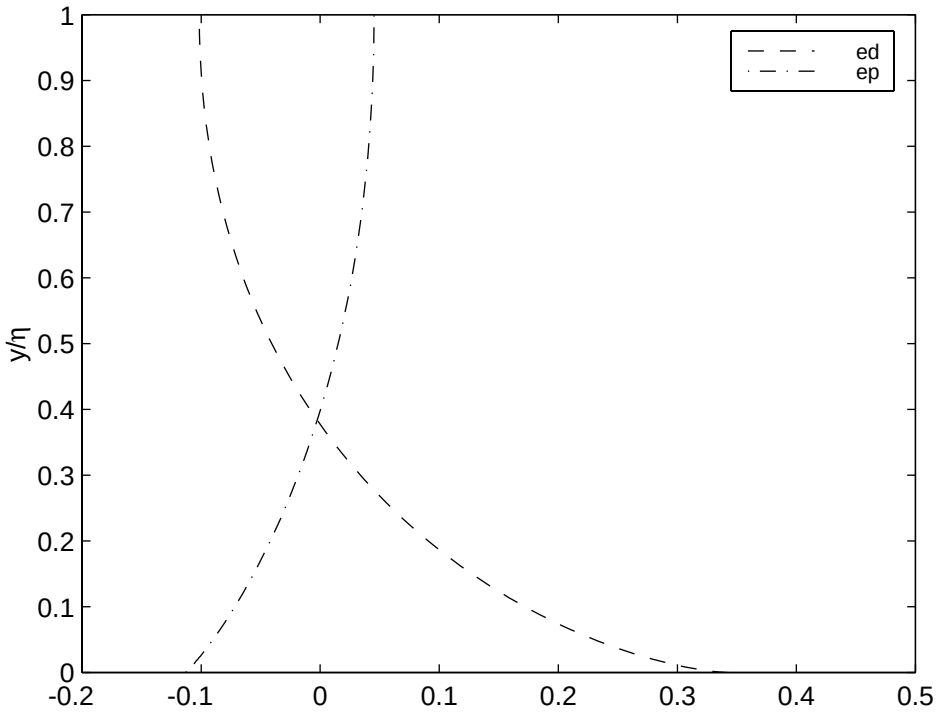

FIG. 1. *The vertical structure of the turbulent dissipation field within the fluid as a function of the scaled vertical coordinate* $\zeta = y/\eta$: $-\cdot-\cdot-\cdot-$, $\epsilon_p(\zeta)$; $- - - -$, $\epsilon_d(\zeta)$.

$$\upsilon_1(\zeta) = \frac{16}{135}\zeta^{5/3} - \frac{32}{135}\zeta + \frac{8}{81}\zeta^{1/3},$$
$$\upsilon_2(\zeta) = \frac{1}{9}\zeta^{5/3} - \frac{4}{9}\zeta^{2/3} + \frac{3}{10}\zeta^{1/3},$$
$$\upsilon_3(\zeta) = -\frac{27}{256}\zeta^{5/3} + \frac{9}{64}\zeta^{4/3} - \frac{99}{3584}\zeta^{1/3},$$

as shown in Figure 2. Observe the cube-root structure in the vertical is modified to $\upsilon_0(\zeta)$. As shown in Figure 2, when γ is set to 1 to recover the original boundary conditions from (15), the cube-root dependence is maintained near the bed but is effectively flattened near the fluid surface to closely approximate the absence of turbulent energy flux through the free surface. This correction is simultaneously determined with a corresponding decay term in the evolution equations, as seen below, due to the removal of the sustaining flux. We look even closer at the effects of modifying the free surface boundary conditions in section 4.2.

Also the effect of turbulent production, proportional to $\bar{u}^2$, through the velocity shear is largest near the bed; as seen in the shape of $\upsilon_1(\zeta)$ and $\upsilon_2(\zeta)$, this enhances turbulent energy k near the bed.

However, the natural turbulent dissipation within the fluid causes a relatively greater decay of turbulent energy near the bed as compared with the body of the fluid, as seen in $\upsilon_3(\zeta)$, and so counters this enhancement. Being proportional to $1/\tilde{\nu}$, this effect on the k-profile is greatest in weakly turbulent

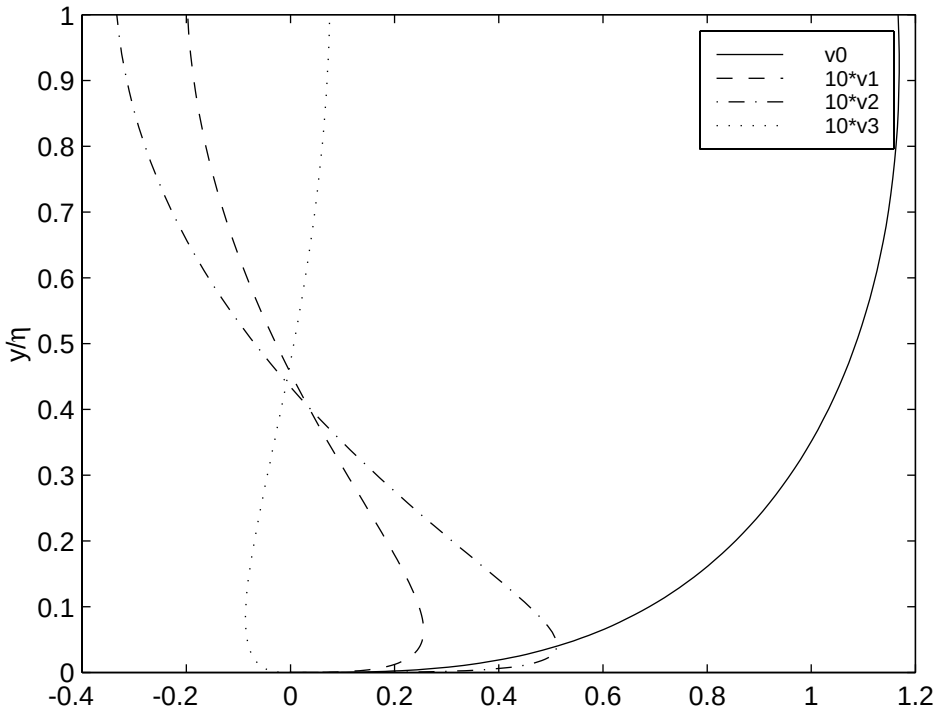

FIG. 2. *The vertical structure functions for the turbulent energy density and horizontal velocity fields within the fluid as a function of the scaled vertical coordinate* $\zeta = y/\eta$: ———, $\upsilon_0(\zeta)$ *(with* $\gamma = 1$*);* – – –, $10 \times \upsilon_1(\zeta)$; –·–·–·–, $10 \times \upsilon_2(\zeta)$; ·····, $10 \times \upsilon_3(\zeta)$.

flows.

- The basic cube-root structure of the horizontal velocity is modified in exactly the same way and for the same reasons as for the basic turbulent energy k-profile.
  Modifications of the velocity profile due to the turbulent production and dissipation occur, but they occur primarily through the indirect effects of modifications to the turbulent diffusivity profile $\nu(\zeta)$. These are weak due to the subtractions in (22b).
- The corresponding vertical structure of the turbulent mixing coefficient ν is shown in Figure 3, where the five components are

$$\begin{aligned}
\nu_0(\zeta) &= \frac{20}{9}\zeta^{2/3} - \frac{8}{9}\zeta^2, \\
\nu_1(\zeta) &= \frac{64}{135}\zeta^2 - \frac{128}{135}\zeta^{4/3} + \frac{2944}{8505}\zeta^{2/3}, \\
\nu_2(\zeta) &= -\frac{32}{27}\zeta + \frac{4}{5}\zeta^{2/3} + \frac{8}{27}\zeta^2, \\
\nu_3(\zeta) &= \frac{57}{448}\zeta^{2/3} - \frac{3}{4}\zeta^{5/3} + \frac{9}{16}\zeta^2, \\
\nu_4(\zeta) &= \frac{33}{224}\zeta^{2/3} + \frac{9}{16}\zeta^2 - \frac{3}{4}\zeta^{5/3}.
\end{aligned}$$

Simultaneously with the determination of the above fields, the solvability con-

dition for the linear equations of the form (21) supplies terms in the asymptotic, low-dimensional evolution equations for the amplitudes of the four critical modes. Writing these in terms of physical variables we find, with errors $\mathcal{O}\big(\delta^6 + \lambda^3 + \gamma^3, \vartheta\big)$, that

$$\frac{\partial \eta}{\partial t} \sim 0, \tag{23a}$$

$$\frac{\partial \bar{u}}{\partial t} \sim -\frac{56\gamma\tilde{\nu}}{81\eta^2}\bar{u} - \frac{\lambda}{16}\left[C_{\epsilon 2}\sigma_\epsilon - \sigma_k\right]\frac{\bar{\epsilon}\bar{u}}{\bar{k}} + \frac{16}{81}\left[\frac{32}{45}C_{\epsilon 1}\sigma_\epsilon - \sigma_k\right]\frac{\tilde{\nu}\bar{u}^3}{\eta^2\bar{k}}, \tag{23b}$$

$$\frac{\partial \bar{k}}{\partial t} \sim -\lambda\left[\frac{7}{8} + \frac{C_{\epsilon 2}\sigma_\epsilon}{16\sigma_k}\right]\bar{\epsilon} - \frac{56\gamma\tilde{\nu}}{81\sigma_k\eta^2}\bar{k} + \frac{16}{243}\left[7 + \frac{32C_{\epsilon 1}\sigma_\epsilon}{15\sigma_k}\right]\frac{\tilde{\nu}}{\eta^2}\bar{u}^2, \tag{23c}$$

$$\frac{\partial \bar{\epsilon}}{\partial t} \sim -\lambda\frac{9}{8}C_{\epsilon 2}\frac{\bar{\epsilon}^2}{\bar{k}} + \frac{256}{243}C_{\epsilon 1}\frac{\tilde{\nu}\bar{\epsilon}}{\eta^2\bar{k}}\bar{u}^2, \tag{23d}$$

where

$$\tilde{\nu}(x,t) = C_\mu\frac{\bar{k}^2}{\bar{\epsilon}} \tag{24}$$

is a measure of the local turbulent diffusivity. These form a crude approximation to the evolution equations for the four amplitudes of the model when there are no horizontal variations.

TABLE 1
Terms in the series expansions in γ of selected coefficients in the model for homogeneous turbulent decay. The last row is the sum of known terms at $\gamma = 1$.

The two fifth-order evolution equations (23c)–(23d) summarize the turbulent production and decay processes. Setting the artificial parameters $\lambda = \gamma = 1$ to approximate the dynamics of the original problem, observe, first, the natural decay of turbulent energy and dissipation in the body of the fluid, second, decay of turbulent energy with coefficient proportional to $\tilde{\nu}/\eta^2$ via turbulent mixing transporting energy to the bed, and third, the generation of turbulence energy and its dissipation through the shear in the vertical, proportional to $\tilde{\nu}\bar{u}^2/\eta^2$.

The horizontal velocity evolution (23b) similarly includes terms $\tilde{\nu}\bar{u}/\eta^2$, which represents the effective drag of the bottom via turbulent mixing to the bed, and weak cubic, proportional to $\tilde{\nu}\bar{u}^3/(\eta^2\bar{k})$, and linear, proportional to $\bar{\epsilon}\bar{u}/\bar{k}$, modification of this drag through changes in the stress tensor in the momentum equations. (Note that the coefficients are the difference of two terms, and that with the usual values for the parameters (4) there is significant cancellation.)

The free surface stays horizontal, (23a), because there are no horizontal gradients until we look at order ϑ effects in a later section.

4.2. Convergence in the artificial parameters. One limitation on the accuracy of the above model is that even within the k-ϵ model of turbulence the coefficients are only approximate. This is due to both the modification of the free surface boundary conditions on u and k to (14)–(15) and the introduction of λ in (13). Although setting $\gamma = 1$ recovers the original boundary conditions (6)–(7) and $\lambda = 1$ recovers the original k-ϵ model, there is no certainty that this will give a model which is a good approximation to the "true" system. In essence the coefficients in the model are multivariable Taylor series in γ and in λ. In this subsection we present evidence that these series converge for $\gamma = \lambda = 1$, and so we can form a reasonable model.

Arbitrarily high-order terms in the center manifold expansion may be computed in principle. Our computer algebra program currently is limited by memory and time constraints to about 8th order in γ and lower orders in other parameters.[2] This is only attainable by the simplification of setting the k-ϵ parameters to the conventional numerical values in (4). By executing the REDUCE program and discarding terms $\mathcal{O}\big(\delta^6, \gamma^8, \lambda^2, \vartheta\big)$, we discover more terms in the series in γ. Listed in Table 1 are the expansions of some of the coefficients appearing later in the models.

Look down the columns in the table and see that the coefficients in each series

[2] In some applications [31, 43, 55] such routine computations can be performed to 30th order and are convincingly used to show the convergence or otherwise of the series expansions.

generally decrease by at least a factor of two. This suggests that the radii of convergence of the series in γ are roughly two or more. Thus simply evaluating the series at $\gamma = 1$ is reasonably good—some are shown in the bottom line of the table.[3]

The convergence in the parameter λ is problematical because it seems to appear always in the combination $\lambda\eta^2\bar{\epsilon}/(\tilde{\nu}\bar{k})$, that is $\lambda\eta^2\bar{\epsilon}^2/\bar{k}^3$. Thus convergence depends upon the properties of the solution which are generally unknown beforehand. We suggest that truncating to linear terms in λ forms an adequate approximation. It seems at least self-consistent to do this as later homogeneous solutions, namely (30)–(33), show a balance for the relatively small value $\eta^2\bar{\epsilon}^2/\bar{k}^3 \approx 0.2$. Thus the nonlinear terms in λ are generally expected to have a negligible influence in most flows of interest.[4]

First, the series are summed for $\gamma = 1$ as discussed in the previous subsection. Then introducing

$$\tilde{\lambda} = \frac{\lambda\eta^2\bar{\epsilon}^2}{\bar{k}^3} = C_\mu\lambda\frac{\eta^2/\tilde{\nu}}{\bar{k}/\bar{\epsilon}} \propto \lambda\frac{\text{vertical mixing time}}{\text{turbulent eddy time}}\,, \tag{25}$$

for brevity we write the model of decay of homogeneous turbulent flow as follows, with errors $\mathcal{O}\big(\delta^6, \lambda^2, \vartheta\big)$,

$$\frac{\partial\eta}{\partial t} = 0\,, \tag{26a}$$

$$\frac{\partial\bar{u}}{\partial t} = -(1.030 + 0.359\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}}{\eta^2} + (0.0504 - 0.243\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^3}{\eta^2\bar{k}}\,, \tag{26b}$$

$$\frac{\partial\bar{k}}{\partial t} = -(0.0927 + 0.993\,\tilde{\lambda})\frac{\bar{k}^3}{\eta^2\bar{\epsilon}} + (0.589 + 0.516\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^2}{\eta^2}\,, \tag{26c}$$

$$\frac{\partial\bar{\epsilon}}{\partial t} = -2.101\,\tilde{\lambda}\frac{\bar{k}^2}{\eta^2} + (1.552 - 3.215\,\tilde{\lambda})\frac{\tilde{\nu}\bar{\epsilon}\bar{u}^2}{\bar{k}\eta^2}\,. \tag{26d}$$

Note that setting $\lambda = 1$ to recover the original problem is just equivalent to using $\tilde{\lambda} = \eta^2\bar{\epsilon}^2/\bar{k}^3$. Observe that the first terms on the right-hand sides of the above equations represent decay terms through, for example, in the $\bar{u}$ and $\bar{k}$ equations, turbulent transport to the stream bed. The last terms in the $\bar{k}$ and $\bar{\epsilon}$ equations represent the production of turbulence through the velocity shear.

One feature of the model derived here is that it has no adjustable coefficients. All constants are derived from well-known physical parameters and accepted constants of the k-ϵ equations. Despite its relative complexity, the model has been systematically derived and the constants which appear are well defined. However, there are adjustable parameters, namely, the order of truncation of the series expansions. The model (26), for example, contains just the low-order terms in expansions in δ and λ.

[3]Actually, the introduction of the parameter a, and the selection of $a = 1/2$, was motivated by our original series in γ exhibiting singularities for $\gamma \approx -1$, as indicated by Domb–Sykes plots [21]. These singularities ruined the convergence at $\gamma = 1$. However, an Euler transform of the series to accelerate convergence is precisely equivalent to choosing nonzero a, and a few numerical experiments lead to $a \approx 1/2$ causing good convergence.

[4]We noticed in simulations that if ever $\eta^2\bar{\epsilon}^2/\bar{k}^3$ happened to become as large as approximately 3 at any point in x and t, then the dynamics became rapidly unstable. It may be that higher-order terms in the parameter λ, perhaps formed into a Padé approximant, could stabilize such a local instability. However, this aspect has not been explored as it is likely to involve infeasible amounts of algebraic computation.

4.3. Dynamics of spatial structure. The leading-order effect of horizontal gradients, such as that due to a sloping free surface, is found by computing terms of order ϑ in the asymptotic expansions. We describe these in this subsection.

Dominantly, horizontal gradients affect the velocity and pressure fields. By computing terms to order $\delta^3\vartheta$ we find that the velocity fields (22a)–(22b) are modified to

$$v = -\zeta^{4/3}\eta\frac{\partial\bar{u}}{\partial x} + \mathcal{O}\big(\delta^6 + \lambda^3 + \gamma^3 + \vartheta^3\big), \tag{27a}$$

$$u = \cdots + 3v_3(\zeta)\frac{g\eta^2}{\tilde{\nu}}\frac{\partial\eta}{\partial x} + \mathcal{O}\big(\delta^6 + \lambda^3 + \gamma^3 + \vartheta^3\big), \tag{27b}$$

where the $\cdots$ indicate the terms on the right-hand side of (22b) and where $v_3(\zeta)$ is drawn in Figure 2. The shape of v is required by the continuity equation. The modification to u asserts reasonably that at low levels of turbulence, large $1/\tilde{\nu}$, horizontal accelerations through decreasing depth, $\eta_x < 0$, cause the fluid to respond with a flatter profile through a subtraction of $v_3(\zeta)$ from $v_0(\zeta)$, as seen in Figure 2.

The structure of the fields within the fluid rapidly become more complicated at higher order. We do not detail the fields any more.

By executing the computer algebra program and discarding generated terms $\mathcal{O}\big(\delta^6, \gamma^6, \lambda^2, \vartheta^2\big)$, we discover first-order effects of horizontal variations with sufficient terms in the series in γ to sum them reliably for $\gamma = 1$. We find the same production and decay terms identified in (26) and, in addition, extra terms in the horizontal gradients. Using the accepted values (4) for the constants of the k-ϵ equations, we obtain the following model with our best estimates of its coefficients:

$$\frac{\partial\eta}{\partial t} \sim -\frac{\partial(\eta\bar{u})}{\partial x}, \tag{28a}$$

$$\begin{aligned}\frac{\partial\bar{u}}{\partial t} \sim{}& -(1.030 + 0.359\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}}{\eta^2} + (0.0504 - 0.243\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^3}{\eta^2\bar{k}} \\ &+ \left[0.961 - 0.019\,\tilde{\lambda} - (0.019 - 0.087\,\tilde{\lambda})\frac{\bar{u}^2}{\bar{k}}\right] g\left(\theta - \frac{\partial\eta}{\partial x}\right) \\ &- (1.105 + 0.104\,\tilde{\lambda})\bar{u}\frac{\partial\bar{u}}{\partial x} - (0.032 - 0.056\,\tilde{\lambda})\frac{\bar{u}^2}{\bar{k}}\frac{\partial\bar{k}}{\partial x} \\ &+ (0.025 - 0.041\,\tilde{\lambda})\frac{\bar{u}^2}{\bar{\epsilon}}\frac{\partial\bar{\epsilon}}{\partial x},\end{aligned} \tag{28b}$$

$$\begin{aligned}\frac{\partial\bar{k}}{\partial t} \sim{}& -0.0927\frac{\bar{k}^3}{\eta^2\bar{\epsilon}} - 0.993\,\bar{\epsilon} + (0.589 + 0.516\,\tilde{\lambda})\frac{\tilde{\nu}\bar{u}^2}{\eta^2} \\ &- (0.025 + 0.011\,\tilde{\lambda})g\bar{u}\left(\theta - \frac{\partial\eta}{\partial x}\right) \\ &- (1.106 - 0.065\,\tilde{\lambda})\bar{u}\frac{\partial\bar{k}}{\partial x} - (0.030 + 0.056\,\tilde{\lambda})\bar{k}\frac{\partial\bar{u}}{\partial x} \\ &+ (0.025 - 0.060\,\tilde{\lambda})\frac{\bar{u}\bar{k}}{\bar{\epsilon}}\frac{\partial\bar{\epsilon}}{\partial x},\end{aligned} \tag{28c}$$

$$\begin{aligned}\frac{\partial\bar{\epsilon}}{\partial t} \sim{}& -2.101\frac{\bar{\epsilon}^2}{\bar{k}} + (1.552 - 3.215\,\tilde{\lambda})\frac{\tilde{\nu}\bar{\epsilon}\bar{u}^2}{\bar{k}\eta^2} \\ &+ \left(-0.006 + 0.562\,\tilde{\lambda}\right) g\frac{\bar{u}\bar{\epsilon}}{\bar{k}}\left(\theta - \frac{\partial\eta}{\partial x}\right)\end{aligned}$$

$$- 0.173\,\tilde{\lambda}\bar{\epsilon}\frac{\partial \bar{u}}{\partial x} + 0.533\,\tilde{\lambda}\frac{\bar{\epsilon}\bar{u}}{\bar{k}}\frac{\partial \bar{k}}{\partial x} - (1 + 0.735\,\tilde{\lambda})\bar{u}\frac{\partial \bar{\epsilon}}{\partial x}. \tag{28d}$$

We expect that the coefficients in the above equations, when considered as a model of the k-ϵ equations given in section 2, are accurate as shown. Except for the surface equation (28a), the first line in each equation is the same as in the horizontally homogeneous model (23); subsequent lines detail the additional terms needed to begin modelling long waves. A simpler version of the above model, obtained by omitting terms with small coefficients, is recorded in the introduction as the model (1).

Equation (28a) is an exact statement of the conservation of water and is not modified by any higher-order effects. To order $\delta^3\vartheta$, it may be written as

$$\frac{\partial \eta}{\partial t} + h\frac{\partial \bar{u}}{\partial x} = 0, \tag{29a}$$

which is a linear description of the conservation of water. Similarly, with $\theta = 0$ and in very low levels of turbulence ($\tilde{\nu} \approx 0$), the horizontal momentum equation (28b) may be written to order $\delta^3\vartheta$ as

$$\frac{\partial \bar{u}}{\partial t} = -0.961\,g\frac{\partial \eta}{\partial x}\,. \tag{29b}$$

This describes the horizontal acceleration due to slope of the fluid surface. These last two coupled equations form a standard description of linear wave dynamics except for one remarkable feature: the effect of gravity is reduced by the factor 0.961. For example, this would predict that even low levels of turbulence reduce the phase speed of waves by about two percent. As in thin films of viscous fluid [44], the phenomenon is due to the response of the fluid, approximately $v_0(\zeta)$ shown in Figure 2, being at an angle to the forcing 1 (either due to gravity or horizontal pressure gradients) when considered in the space of functions on $[0, \eta]$. Consequently, the forcing is less effective. Such a depression in phase speed may be observable in the propagation of long waves on turbulent flow.[5]

Returning to the order δ^5 momentum equation (28b), we note several interesting effects:

- The first line contains the turbulent drag terms identified in the previous subsection.
- The second lines describe the effects of surface and bed slope. Within the square brackets
  - the first term gives the depression of wave speed discussed above;
  - the second term very weakly enhances the phase speed correction in turbulent flow;
  - whereas it is difficult to ascribe one definite cause to the last term, coefficient modifications of the form $\bar{u}^2/\bar{k}$ are common in this model and reflect the relative importance of the turbulence on the mean flow.
- The third and fourth lines are dominated by the nonlinear advection term $\bar{u}\bar{u}_x$, with coefficient approximately 1.1. This coefficient is larger than 1 because of the shear: the maximum $u(y) > \bar{u}$ advects itself faster than $\bar{u}$. This third line also shows small "cross-talk" effects in the advection through the $\bar{u}^2\left(\log\bar{k}\right)_x$ and $\bar{u}^2\left(\log\bar{\epsilon}\right)_x$ terms.

[5]This modelling approach shows that where there is vertical or cross-sectional structure, depth-averaging or cross-sectional integration is generally unsound as a modelling tool. The reason is that it is the size and structure of the dynamical modes which determine the evolution (here approximately cube-root) and not the particular amplitudes used to measure the motion (here depth averages).

The dynamics of k and ϵ averages are given by equations (28c)–(28d).

- The first lines of each equation are the same turbulent production and decay terms identified in the previous subsection.
- The next line in each equation may arise from the modification of the turbulent production through the change of the velocity profile, seen in (27b), due to horizontal acceleration.
- The remaining terms simply represent horizontal advection by the fluid velocity. Note that different properties are advected at different effective speeds[6] as indicated by the different coefficients of the $\bar{u}\partial/\partial x$ terms—1.1 for $\bar{u}$ and $\bar{k}$, and 1 for $\bar{\epsilon}$.

The model, (1), reported in the introduction is a simplified version of (28). The solutions described in the next section show that the terms neglected from (28) in writing (1) are relatively small, contributing at most a few percent in the numerical balance of the terms, and so may be neglected at least for initial exploration.

The model (28) is purely hyperbolic, so a spatial diffusion is incorporated into (1) to help stabilize simulations. It was physically appealing to incorporate the turbulent diffusion $(\tilde{\nu}\bar{u}_x)_x$ into the $\bar{u}$ equation, and similarly for $\bar{k}$ and $\bar{\epsilon}$. The coefficients of these terms were determined by executing the computer algebra program to higher order in spatial derivatives but lower order in the artificial parameter λ. That the coefficients are larger than that of turbulent diffusion in the k-ϵ-model is due to the same process as that giving the enhanced Trouton vicosity in laminar flows, e.g., [38]. Such diffusion made hardly any difference to the simulations as a whole yet usefully avoided the generation of unphysical and ruinous spikes in the numerical solution. Higher-order terms in lateral derivatives may be able to refine the long-wave expansion employed here and controlled by the parameter ϑ. Although the long-wave approximation has been shown to converge in some simple dynamical circumstances [31, 43, 55], such higher-order derivative terms may easily destabilize the model (1), would involve enormous algebra to compute, and probably add little to the structurally stable model (1). An important parameter is the rate of attraction to the center manifold of the model, here locally proportional to $\tilde{\nu}/\eta^2$: when this is large the long-wave approximation is expected to be very good. Fortunately, in this application relatively rapid lateral variations are closely associated with the generation of turbulence; hence the local eddy diffusivity $\tilde{\nu}$ is typically large exactly where needed to resolve the lateral structure. Thus in this work we truncate the model (1) to the lateral effective diffusion terms.

5. Predictions of the new model. In this section we investigate some of the predictions the newly derived model (1) might make. We look at decaying turbulence, uniform flow on slopes, approximation to the St Venant equations, and a dam break simulation.

5.1. Decaying turbulence. Homogeneous turbulence decays algebraically. If there is no slope ($\theta = 0$), no variations in x, no mean flow ($\bar{u} = 0$), and no surface waves ($\eta = \text{const}$), then it is consistent to seek solutions of the model (1) in the form $\bar{k} \propto t^{-2}$ and $\bar{\epsilon} \propto t^{-3}$. Substituting and solving for the constants of proportionality, the model 1, or (28), predicts the turbulence decays according to

$$\bar{k} \sim 8.97\,\eta^2 t^{-2}\,, \quad \bar{\epsilon} \sim 12.8\,\eta^2 t^{-3}\,, \quad \tilde{\nu} \sim 0.565\,\eta^2 t^{-1}\,, \quad \tilde{\lambda} \sim 0.227 \tag{30}$$

[6] Though due to the nonlinear interaction terms we should really report on the speeds associated with the characteristics of the equations.

for large time t. The turbulence ultimately decays with the balance $\bar{\epsilon} \sim 0.48\,\bar{k}^{3/2}/\eta$.

However, the transients before this large time behavior may be long. There are two regimes of interest characterized by large and small $\tilde{\lambda}$ compared to 0.227. (Recall from (25) that $\tilde{\lambda}$ is the ratio of the vertical mixing time to the turbulent eddy mixing time.)

- For small $\tilde{\lambda}$, high turbulence $\bar{k}$, and low dissipation $\bar{\epsilon}$, the dissipation is roughly constant, actually
$$\bar{\epsilon} \approx \frac{1}{\sqrt{\bar{\epsilon}_\infty^{-2} + 15.1/k^3}}\,,$$
as the turbulence decays to (30) on a time-scale of approximately $2(\eta^2/\bar{\epsilon})^{1/3}$.
- For large $\tilde{\lambda}$, the vertical mixing time is relatively rapid and the turbulence decays with a different power law for some time. We find that $\bar{\epsilon} \propto \bar{k}^{2.11}$, which is only a little different from (30). The rate of decay towards (30) is relatively slow,
$$(\bar{k}, \bar{\epsilon}) \approx A\left(t^{-0.90}, 0.90\,t^{-1.90}\right),$$
and forms a long lasting transient.

The above results are for a stationary fluid. Instead, if the fluid is moving with uniform velocity on a horizontal bed, then the characteristics of the decaying bulk motion and turbulence are different in detail. We seek solutions of the model (1) in the form $\bar{k} \propto t^{-2}$ and $\bar{\epsilon} \propto t^{-3}$, as before, but now with $\bar{u} \propto t^{-1}$. Substituting and solving for the constants of proportionality, the model (1) may be rewritten as a generalized eigenvalue problem for $\tilde{\lambda}$. It is then straightforward to determine that the only positive solution is

$$\begin{aligned} &\bar{u} \sim 6.24\,\eta t^{-1}, \quad \bar{k} \sim 23.2\,\eta^2 t^{-2}, \quad \bar{\epsilon} \sim 49.6\,\eta^2 t^{-3}, \\ &\tilde{\nu} \sim 0.98\,\eta^2 t^{-1}, \quad \tilde{\lambda} \sim 0.198. \end{aligned} \tag{31}$$

Numerical solutions show that there are long lasting transients of a similar nature to those mentioned above for a stationary fluid. We do not elaborate further as this class of solutions is less likely to be of interest in applications.

5.2. Roll waves on turbulence flow down a slope. Water flowing down a slope generates turbulence that provides the drag to balance the gravitational forcing. But if we suppose only the turbulent parameters are in quasi equilibrium, but not the speed, then a St Venant approximation is obtained to the flow dynamics. When the flow is fast enough and the turbulence weak enough, we see the spontaneous development of turbulent roll waves. For flow down a slope the turbulent roll waves appear with a finite wavelength (see Figure 4), whereas the St Venant approximation predicts an infinite wavelength [34].

Let the downward bed slope be $\theta \neq 0$, but as in the previous subsection assume there are no variations in x, that is, just a mean flow ($\bar{u} \neq 0$) with no surface waves ($\eta = \text{const}$). Then it is consistent to seek solutions of the model (1) in the form $\bar{u} \propto \eta^{1/2}\theta^{3/2}$, $\bar{k} \propto \eta\theta$, and $\bar{\epsilon} \propto \eta^{1/2}\theta^{3/2}$. Substituting and solving for the constants of proportionality leads to a nonlinearly perturbed eigenvalue problem for $\tilde{\lambda}$ which is solved iteratively to give

$$\begin{aligned} &\bar{u} \approx 3.11\,\eta^{1/2}(g\theta)^{1/2}, \quad \bar{k} \approx 2.16\,\eta g\theta\,, \quad \bar{\epsilon} \approx 1.36\,\eta^{1/2}(g\theta)^{3/2}, \\ &\tilde{\nu} \approx 0.308\,\eta^{3/2}(g\theta)^{1/2}, \quad \tilde{\lambda} \approx 0.184. \end{aligned} \tag{32}$$

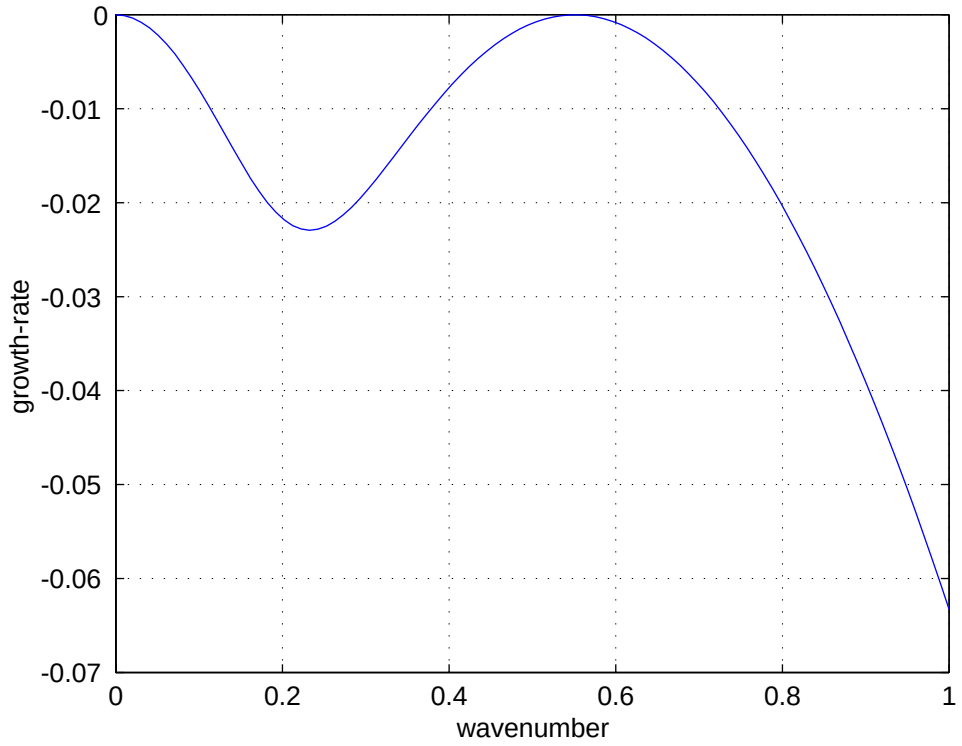

FIG. 4. *The leading growth-rate, the real part of the eigenvalue α, for turbulent roll waves down the critical slope $\theta = 0.602$ showing that an instability will first arise at finite wavenumber l.*

We expect this flow to be established on a time-scale of the vertical mixing, which is

$$T_{\rm mix} = \frac{\eta^2}{\tilde{\nu}} \approx 4\sqrt{\frac{\eta}{g\theta}}.$$

The flow (32) appears to have a high level of turbulence consistent with flow along a very rough channel.

Another interesting balance occurs when we assume that the production of turbulence parameters, $\bar{k}$ and $\bar{\epsilon}$, equals their dissipation through natural dissipation and bed drag. This leads to a reduced model in the form of St Venant's equation used in open channel flow, e.g., [34]. Assume that at all times the production and dissipation of $\bar{k}$ and $\bar{\epsilon}$ are given in the first lines on the right-hand sides of (1c) and (1d). That is, assume that the bed slope is small enough and that the flow is evolving slowly enough that spatial and temporal gradients are negligible. Then seek a balance with $\bar{k} \propto \bar{u}^2$ and $\bar{\epsilon} \propto \bar{u}^3$ to find

$$\bar{k} \approx 0.224\,\bar{u}^2, \quad \bar{\epsilon} \approx 0.0453\,\bar{u}^3/\eta, \quad \tilde{\nu} \approx 0.0992\,\eta\bar{u}, \quad \tilde{\lambda} \approx 0.184. \tag{33}$$

With this balance the momentum equation (1b) becomes

$$\frac{\partial \bar{u}}{\partial t} = -0.100\frac{\bar{u}^2}{\eta} + 0.96\,g\left(\theta - \frac{\partial \eta}{\partial x}\right) - 1.11\,\bar{u}\frac{\partial \bar{u}}{\partial x} + \frac{\partial}{\partial x}\left(0.143\,\bar{u}\eta\frac{\partial \bar{u}}{\partial x}\right), \tag{34}$$

which has exactly the same form as St Venant's equation for open channel flow except for the longitudinal diffusion term $\partial_x(\nu_0\bar{u}_x)$ for coefficient $\nu_0 = 0.143\,\bar{u}\eta$. Such a diffusion term, with previously unknown but assumed constant diffusivity, was included in St Venant's model by Needham and Merkin [34]—that $\nu_0 > \tilde{\nu}$ is due to the same process as that giving the Trouton vicosity in laminar flows, e.g., [38]. The three other coefficients are worthy of comment: the self-advection coefficient of (1.11) accounts for the vertical nonuniformity of the velocity profile with mean $\bar{u}$; the influence of gravity is reduced to $0.96\,g$ because, as explained earlier for (29b), the response of the fluid flow is not constant in the vertical so some of gravitational forcing is not used; and lastly the bed drag $\bar{u}^2/\eta$ has coefficient 0.100 which is larger than typical values. However, note that such drag coefficients have to vary depending upon the roughness of the channel bottom as often expressed by different roughness coefficients in Manning's law, e.g., [6, p. 246] or [23, p. 137]. We surmise that the flows we describe with model (1) have strong mixing in the vertical due to strong turbulence generated by a rough channel bed or other extremely turbulent flows such as breaking waves or dam spillways.

Needham and Merkin [34] analyzed a model close to (34) and deduced that the balanced turbulent flow (33) became unstable if the Froude number $F > 4$. The instability developed into roll waves propagating along the flow; long waves were most unstable. Here the Froude number $F \approx 0.96\,\theta/0.1$ and so we might expect roll waves to develop on flow down very steep slopes, $\theta > 0.42$, because of the effectiveness of turbulent damping on lesser slopes. Analysis of the full model (1), rather than the St Venant approximation (34), shows a slightly different picture. Seeking solutions to the model (1) linearized about the equilibrium flow (32) for nondimensional depth $\eta = 1$ and proportional to $\exp(ilx + \alpha t)$ leads to an eigenproblem for the complex eigenvalue α as a function of wavenumber l and the slope θ. Plotted in Figure 4 is the growth-rate, the real part of the eigenvalue α, as a function of wavenumber l for the critical slope $\theta_c = 0.602$: observe the zero growth-rate at wavenumber $l = 0.551$; for larger slopes θ, $\Re\{\alpha\}$ becomes positive here. In contrast to the St Venant model, the unstable roll waves are here predicted to have a finite wavelength $2\pi/l = 11.4$. The roll waves have similar shapes to that found by Needham and Merkin [34] and for many other roll waves on a fluid: see in Figure 5 the steepening at the front of the roll wave and the relatively longer tail. Here see we predict the turbulent intensity $\bar{k}$ is maximum a little behind the peak of the wave. In contrast to Needham and Merkin's model, we found no evidence for subcritical roll waves in our simulations. One point of interest arose in the eigenvalue computations: over a wide range of slopes and wavenumbers (< 1) we observed that the leading three eigenvalues were generally well separated from the fourth. For example, for slope $\theta = 0.1$, three eigenvalues had $\Re\{\alpha\} \approx -0.2$ whereas the other had $\Re\{\alpha\} \approx -0.9$. This suggests that for many purposes a three mode model of turbulent flow may be sufficient rather than the four mode model (1) derived here. We leave this for further research.

5.3. Simulate a dam breaking. One of the canonical flows of shallow water occurs after a dam breaks. Here we simulate such a flow and resolve the water slumping downstream and becoming extremely turbulent as it does so. For simplicity we use the model (1) reported in the introduction.

Imagine a dam at $x = 0$ initially holding back water of nondimensional depth $\eta = 1$. At time $t = 0$ the dam breaks and releases the water to rush downstream. To avoid overly poor conditioning in the numerics we let the water in front of the dam be of depth $\eta = 0.1$ (all quantities will be nondimensional so that in effect $g = 1$).

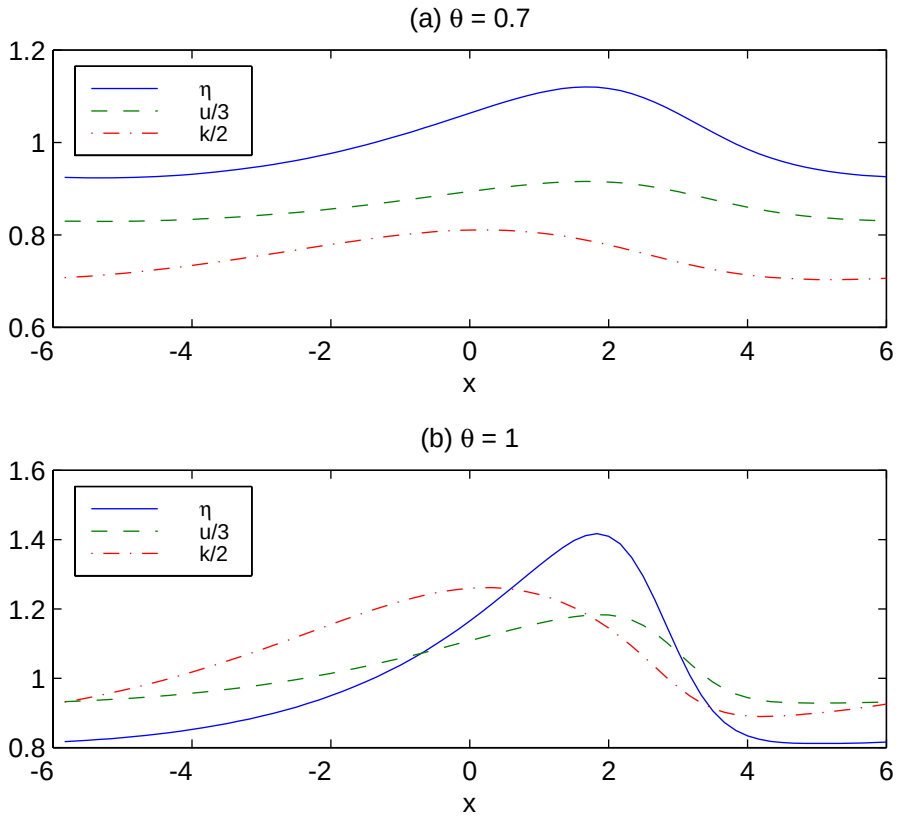

FIG. 5. *Profile of two roll waves on different slopes obtained by numerical simulation of model* (1) *until the solutions settled on a steadily propagating wave: solid, fluid depth* η*; dashed, mean velocity* $\bar{u}/3$*; and dot-dash, mean turbulent intensity* $\bar{k}/2$.

Also, to smooth the initial few time steps, we actually set the initial depth η to a tanh profile that smoothly varies between these extremes such that the water slope was a maximum of 2 (rather large under the slowly varying assumption) at the dam. The water is assumed initially quiescent, $\bar{u} = 0$ throughout, and has a low level of turbulence, somewhat arbitrarily chosen to be $\bar{k} = 0.0001$. Turbulent dissipation is initially set such that $\tilde{\lambda} = 0.227$ so that the balance of decaying turbulence (30) holds throughout.

The model (1) is simply discretized on a regular grid in space-time with a time step of $\Delta t = 1/10$ and space step of $\Delta x = 1/10$. The equations are discretized using a stencil 3 points wide in space using second-order accurate centered differencing in space. The resulting ordinary differential equations together with appropriate boundary conditions are integrated forward in time (with constant time step) as a set of differential algebraic equations using the robust, second-order, backward difference solver of [49]. The domain of simulation extended from six dam heights to the left behind the dam to six dam heights downstream. We integrated over a time $t = 6$, which is long enough for the disturbance to nearly reach the ends of the computational domain (linear waves on the dammed water having nondimensional speed 1).

The results of this simulation are shown in Figures 6 and 7. Observe that when

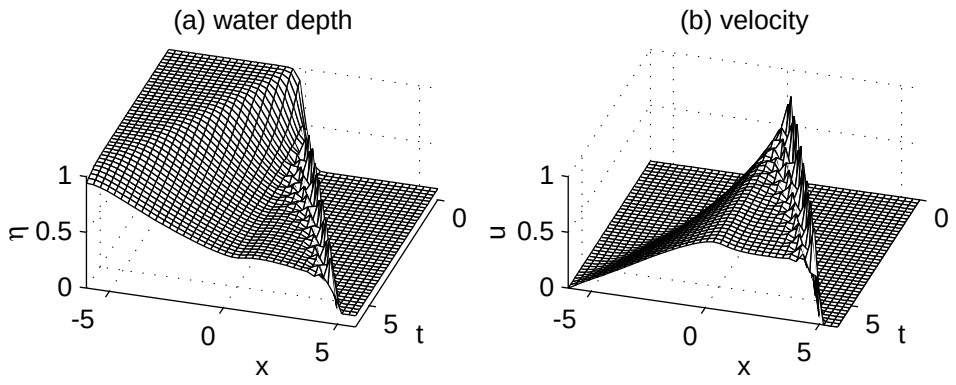

FIG. 6. *Simulation of dam breaking showing* (a) *the water depth* η *and* (b) *the mean downstream velocity* $\bar{u}$. *Observe the formation of a bore with superposed waves.*

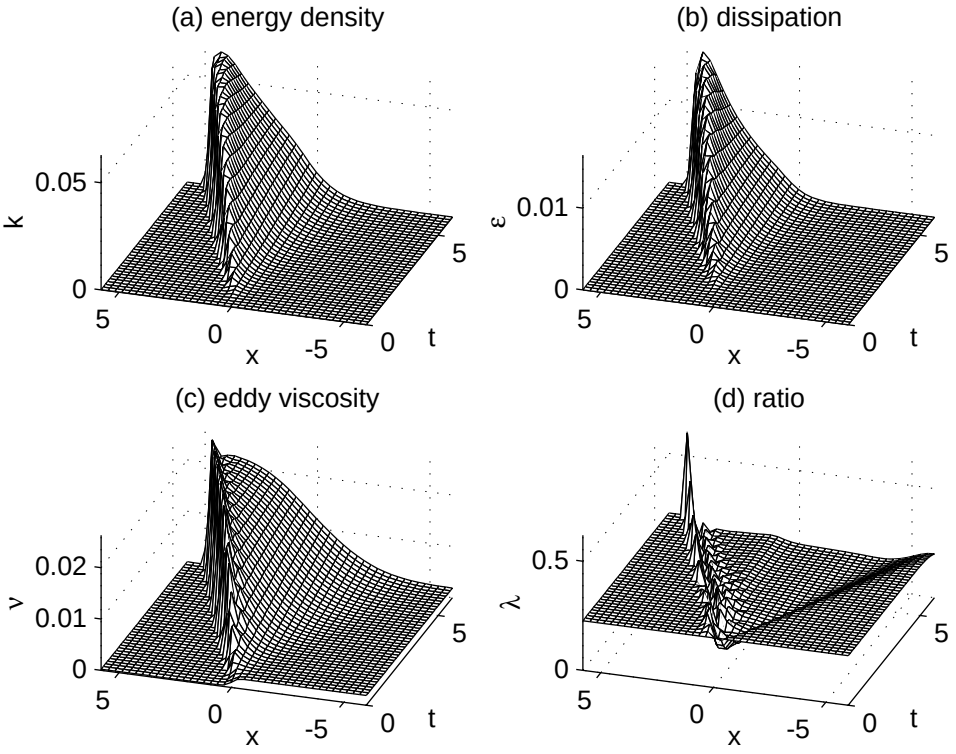

FIG. 7. *Simulation of dam breaking showing the time evolution of the turbulence parameters (note the view point is rotated from Figure* 6*):* (a) *the turbulent energy density* $\bar{k}$ *is highest just a little behind the bore and then tails away;* (b) *the turbulent dissipation* $\bar{\epsilon}$ *behaves similarly;* (c) *the turbulent eddy viscosity* $\tilde{\nu}$ *is greatest at the front of the bore; and* (d) *the parameter* $\tilde{\lambda}$, *apart from a peak at the front of the bore, is generally depressed from the decaying balance value of* 0.227 *in* (30).

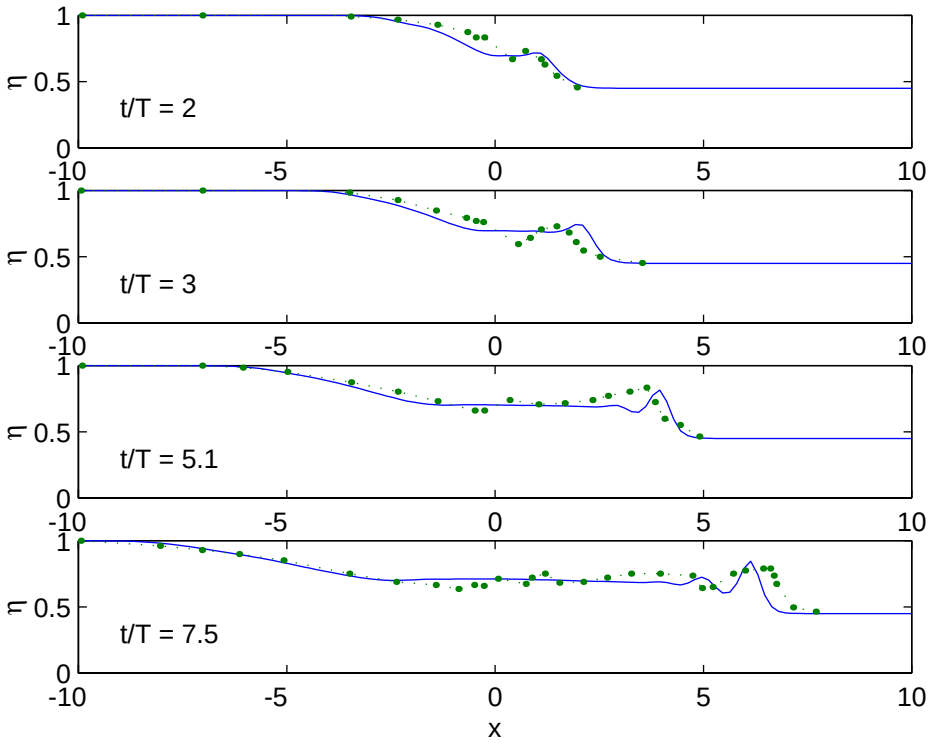

FIG. 8. *Compare model* (1) *(solid lines) with the experiments of Stansby, Chegini, and Barnes* [53, Fig. 8(c), p. 423] *(dots), where water of depth* 10 *cm* ($\eta = 1$) *behind a dam rushes forward over water of depth* 4.5 *cm* ($\eta = 0.45$) *after the dam (at* $x = 0$*) breaks. The time-scale* $T = \sqrt{H/g} =$ 0.1 *secs.*

the dam breaks, the water slumps down and rushes downstream in a turbulent bore. The bore appears undular but may be evolving towards a series of solitary waves—they cannot be differentiated on this time-scale. The turbulent structure shown in Figure 7 has interesting features. Apparently the energy density peaks a little behind the bore, then decays approximately linearly with distance. It appears that up to time $t = 7$ the generation of turbulence is still significantly greater than its decay as the peak is still growing. The turbulent dissipation and eddy viscosity behave similarly, though the eddy viscosity appears to peak much closer to the front of the turbulent bore. The parameter $\tilde{\lambda}$ plotted in Figure 7(d) reaffirms that relatively small values appear relevant to such flows.[7] The peak of $\tilde{\lambda}$ at the front of the bore predicts that there is a lot of vertical mixing at the front, but less so behind the bore where $\tilde{\lambda}$ is smaller. All of the above seem physically reasonable.

A further similar simulation matches the experiments of Stansby, Chegini, and Barnes [53]. In Figure 8 we plot a comparison of the water depth between the model (1) and the experiment reported in Figure 8(c) of Stansby, Chegini, and Barnes.[8] The model (1) was solved with $\Delta x = 1/6$, $\Delta t = 1/10$ and initially η a

[7] We find that our model (1) becomes quickly unstable if ever the parameter $\tilde{\lambda} > 3$ approximately.

[8] Unfortunately it does not seem reasonable to compare with the other two experiments of Stansby, Chegini, and Barnes [53] as in both it appears from our digitization that water is not conserved by

tanh profile, $\bar{u} = 0$, $\tilde{\lambda} = 0.227$, and $\bar{k} = 10^{-4}$, except for a bump in $\bar{k}$ to 0.018 to represent the initial plunging jet seen in the experiments. The location of the turbulent bore is reasonably well predicted. It appears that the height of the undulations in the model's bore is approximately that of the turbulent fluctuations seen in the water level.

This model that we have derived and solved in some cases of interest explicitly accounts for the spatio-temporal variations of the intensity and broad nature of the turbulence underlying the flow of shallow water.

Appendix A. Comments on theory in this application. This appendix addresses the connection to the rigorous theory of center manifolds in this application. We emphasize that throughout this paper we describe the application of center manifold techniques and *not* the application of the rigorous center manifold theory. There are two main reasons for this which we elaborate on below.

First, here we construct an infinite dimensional center manifold. At each point in x there are four degrees of freedom, parametrized by η, $\bar{u}$, $\bar{k}$, and $\bar{\epsilon}$; but there are an infinitude of x positions and so there is an infinite number of degrees of freedom in the mathematical model. However, there is currently very little theory on infinite dimensional center manifolds appearing via slowly varying approximations, e.g., [16] and what there is does not rigorously apply here, nor does it apply directly to many other physically interesting models such as dispersion in pipes [32], laminar long-wave, thin-film flows [44], and the dynamics in flow reactors [5]; the principal reason is that $\partial/\partial x$ is an unbounded operator, because of its small scale characteristics, whereas the slowly varying approximation treats $\partial/\partial x$ as small. Thus we use the formal technique of constructing complete low-dimensional models [10, 39, 40, 41, 42], techniques suggested and developed by standard applications of the theory. We expect that eventually theory will be developed which supports the application of center manifold concepts to slowly varying approximations.

But there is a second obstacle to supporting this model with theory. In standard applications of center manifold theory the nonlinear terms in the original problem are required to be smooth in the neighborhood of the equilibrium under consideration (here the origin, a state of no flow, and no turbulence). However, here many nonlinear terms are definitely not smooth; for example, turbulent dispersion terms such as $\frac{\partial}{\partial x}\left(C_\mu \frac{k^2}{\epsilon}\frac{\partial u}{\partial x}\right)$ and interaction terms such as $C_{\epsilon 2}\frac{\epsilon^2}{k}$ are unbounded as $(u, k, \epsilon) \to \mathbf{0}$. In rigorous applications of center manifold theory, one may choose the various critical modes and parameters to have any set of relative orders of magnitude. The resulting asymptotic expressions are the same [39], it is only the sequence in which the terms appear that changes with a change in relative orders of magnitude. Indeed, this reflects a very desirable property of a modelling procedure, namely, that the results are essentially independent of arbitrary human-made assumptions (such as order of magnitude) in the analysis. However, in this application the highly nonsmooth nature of the original equations means that in order to apply the center manifold techniques we need to choose carefully the various orders of magnitudes of the variables and parameters, via (17). The aim, as in all asymptotic analyses, is to obtain a tractable and physically relevant leading order problem. The techniques of center manifold

up to 6–7%, compared to better than 1% for their Figure 8(c). This is a significant discrepancy which, if associated with the identification of the bore, would correspond to an error in its location of up to $\Delta x \approx 1.5$ (15 cm). The discrepancy is likely to be due to entrained air [53, p. 422] which we have not attempted to model, and which is likely to be insignificant in a real dam break [53, p. 407].

theorems are then applied, it is just that the current center manifold theorems cannot give *rigorous* justification.

Notwithstanding these theoretical limitations we consider that the systematic techniques are applicable because of the attractivity of the manifold of equilibria, $\mathcal{M}_0$, of the linear operator $\mathcal{L}$. In the spirit of center manifold theory, we claim that the "small nonlinear" terms on the right-hand side of (13) just perturb the shape of $\mathcal{M}_0$ to a nearby manifold $\mathcal{M}$ and perturb the evolution thereon. Thus our last task, and the one fulfilled in this appendix, is to prove the exponential decay to $\mathcal{M}_0$ at a nonzero level of turbulence. The "small nonlinear" terms will affect the rate of decay to $\mathcal{M}$, perhaps slowing the attraction in some regimes, but by continuity, since $\mathcal{M}_0$ is exponentially attractive, $\mathcal{M}$ will be attractive for small enough nonlinearity.

Linearizing the k-ϵ equations (13) about $\mathcal{M}_0$,

$$(p_0, \boldsymbol{u}_0) = \left(g(h-y), \tfrac{4}{3}\left(\tfrac{y}{h}\right)^{1/3} U(x,t), 0, H(x,t), \tfrac{4}{3}\left(\tfrac{y}{h}\right)^{1/3} K(x,t), E(x,t) \right), \tag{35}$$

we obtain $(0, \partial \boldsymbol{u}/\partial t) = \mathcal{L}(p, \boldsymbol{u})$, where the linear operator $\mathcal{L}$ is

$$\begin{bmatrix}
0 & 0 & \frac{\partial \cdot}{\partial y} & 0 & 0 & 0 \\
0 & \frac{\partial}{\partial y}\left(\nu_0 \frac{\partial \cdot}{\partial y}\right) & 0 & 0 & C_\mu \frac{\partial}{\partial y}\left(\frac{\partial u_0}{\partial y}\frac{2k_0}{\epsilon_0}\cdot\right) & -C_\mu \frac{\partial}{\partial y}\left(\frac{\partial u_0}{\partial y}\frac{k_0^2}{\epsilon_0^2}\cdot\right) \\
-\frac{\partial \cdot}{\partial y} & 0 & 2\frac{\partial}{\partial y}\left(\nu_0 \frac{\partial \cdot}{\partial y}\right) & 0 & -\frac{2}{3}\frac{\partial \cdot}{\partial y} & 0 \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{C_\mu}{\sigma_k}\frac{\partial}{\partial y}\left(\frac{k_0^2}{\epsilon_0}\frac{\partial \cdot}{\partial y} + \frac{2k_0}{\epsilon_0}\frac{\partial k_0}{\partial y}\cdot\right) & -\frac{C_\mu}{\sigma_k}\frac{\partial}{\partial y}\left(\frac{\partial k_0}{\partial y}\frac{k_0^2}{\epsilon_0^2}\cdot\right) \\
0 & 0 & 0 & 0 & 0 & \frac{C_\mu}{\sigma_\epsilon}\frac{\partial}{\partial y}\left(\frac{k_0^2}{\epsilon_0}\frac{\partial \cdot}{\partial y}\right)
\end{bmatrix},$$

subject to boundary conditions

$$p + \frac{2}{3}k = 0 \quad \text{on } y = h\,, \tag{36}$$

$$u = 0 \quad \text{on } y = 0\,, \tag{37}$$

$$\frac{\partial u}{\partial y} - \frac{u}{3h} = 0 \quad \text{on } y = h\,, \tag{38}$$

$$v = 0 \quad \text{on } y = 0\,, \tag{39}$$

$$k = 0 \quad \text{on } y = 0\,, \tag{40}$$

$$\frac{\partial k}{\partial y} - \frac{k}{3h} = 0 \quad \text{on } y = h\,, \tag{41}$$

$$y^{2/3}\frac{\partial \epsilon}{\partial y} \to 0 \quad \text{as } y \to 0\,, \tag{42}$$

$$\frac{\partial \epsilon}{\partial y} = 0 \quad \text{on } y = h\,. \tag{43}$$

We seek solutions proportional to $\exp(\lambda t)$. The first thing to note is that we address a generalized eigenproblem

$$\mathcal{L}\begin{bmatrix} p_0 \\ \boldsymbol{u} \end{bmatrix} = \begin{bmatrix} 0 \\ \lambda \boldsymbol{u} \end{bmatrix}$$

as the first row of $\mathcal{L}$ comes from the continuity equation.

Thus the first row, with the boundary condition (39), gives $v = 0$ for any eigenvalue λ. Furthermore, the third row, from the vertical momentum equation with the

pressure boundary condition (36), then gives that $p = -\frac{2}{3}k$ for any λ. These considerations give no constraint on the eigenvalue λ. Ignoring the p and v components of the eigenproblem then leads to a standard eigenproblem—one where the operator is in block, upper-triangular form. Thus consider the components in turn, starting from the last, and we show that all eigenvalues must be nonpositive and thus $\mathcal{M}_0$ is attractive.

- For any eigenfunction $\boldsymbol{u}$, if turbulent dissipation $\epsilon \neq 0$, then

$$\frac{h^{4/3}}{T\sigma_\epsilon}\frac{\partial}{\partial y}\left(y^{2/3}\frac{\partial \epsilon}{\partial y}\right) = \lambda\epsilon\,, \tag{44}$$

where

$$T = \frac{9h^2}{16\tilde{\nu}}\,,$$

is the time-scale of cross-depth turbulent diffusion. Multiplying (44) by ϵ, $\int_0^h \cdots dy$, and integrating by parts we deduce

$$\lambda = -\frac{h^{4/3}}{T\sigma_\epsilon}\frac{\int_0^h y^{2/3}\left(\frac{\partial \epsilon}{\partial y}\right)^2 dy}{\int_0^h \epsilon^2 dy} \leq 0\,,$$

provided that the boundary conditions (43) (assuming $\epsilon \not\to \infty$ for $y \to h$) and

$$\epsilon\frac{\partial \epsilon}{\partial y} = o\big(y^{-2/3}\big) \quad \text{as } y \to 0 \tag{45}$$

are satisfied. The equality $\lambda = 0$ holds if and only if $\partial\epsilon/\partial y \equiv 0$, which leads to

$$\epsilon = E(x,t)\,,$$

a function independent of y. Since (44) indicates nontrivial solutions near $y = 0$ are of the form $\epsilon \sim A + By^{1/3}$, then the condition (45) is effectively equivalent to (42).

Further, apply Sturm–Liouville theory to (44) under boundary conditions (43) and (42). Changing the vertical variable from $y = hz^3$ to z, the eigenvalue problem becomes

$$\frac{\partial^2 \epsilon}{\partial z^2} = 9T\sigma_\epsilon\lambda z^2\epsilon\,,$$

(a form of Bessel's equation [1, (9.1.51)]) with the following normal separate boundary conditions:

$$\frac{\partial \epsilon}{\partial z} = 0 \quad \text{on } y = 0 \text{ and } y = h.$$

Applying standard Sturm–Liouville theory, see, for example, Birkhoff and Rota [8, pp. 296] or Hartman [20, pp. 337 and the following ones], we see that the eigenvalues are discrete and must tend to infinity:

$$0 = \lambda_1 > \lambda_2 > \cdots \to -\infty.$$

Thus, linearly, solutions in the neighborhood of the manifold $\mathcal{M}_0$ are attracted exponentially quickly to it (at a rate at least as fast as $\exp(\lambda_2 t)$).
Sturm–Liouville theory may be also applied directly for the u and k components to show that any eigenvalues associated primarily with them are discrete. We do not record the details in the following.

- Similarly, for any eigenfunction $\boldsymbol{u}$, if turbulent dissipation $\epsilon = 0$ but the turbulent energy $k \neq 0$, then

$$\frac{h^{4/3}}{T\sigma_k}\frac{\partial}{\partial y}\left(y^{2/3}\frac{\partial k}{\partial y} + \frac{2k}{3y^{1/3}}\right) = \lambda k. \tag{46}$$

Multiplying this by $y^{2/3}$ we rewrite it as

$$\frac{h^{4/3}}{T\sigma_k} y^{-1/3}\frac{\partial}{\partial y}\left[y^2\frac{\partial}{\partial y}\left(y^{-1/3}k\right)\right] = \lambda y^{2/3}k.$$

Multiplying by k, $\int_0^h \cdots dy$ and integrating by parts we deduce that

$$\lambda = -\frac{h^{4/3}}{T\sigma_k}\frac{\int_0^h y^2\left[\frac{\partial}{\partial y}\left(y^{-1/3}k\right)\right]^2 dy}{\int_0^h y^{2/3}k^2 dy} \leq 0,$$

provided (41) and

$$k = o\left(y^{1/12}\right) \quad \text{as } y \to 0 \tag{47}$$

are satisfied. The equality $\lambda = 0$ holds here if and only if $\frac{\partial}{\partial y}\left(y^{-1/3}k\right) \equiv 0$, which together with boundary condition (40) implies that

$$k = K(x,t)\tfrac{4}{3}\left(\tfrac{y}{h}\right)^{1/3}$$

with a function $K(x,t)$ independent of y. Since the indicial equation of (46) indicates that nontrivial solutions near $y = 0$ are of the form $k \sim Ay^{-2/3} + By^{1/3}$, then the boundary condition (47) is equivalent to (40).

- The only possible eigenvalue associated with nonzero η is 0.
- Last, for any eigenfunction $\boldsymbol{u}$, if $\epsilon = k = \eta = 0$ but the horizontal velocity $u \neq 0$, then

$$\frac{h^{4/3}}{T}\frac{\partial}{\partial y}\left(y^{2/3}\frac{\partial u}{\partial y}\right) = \lambda u, \tag{48}$$

and we rewrite this as

$$\frac{h^{4/3}}{T} y^{-1/3}\frac{\partial}{\partial y}\left[y^{4/3}\frac{\partial}{\partial y}\left(y^{-1/3}u\right)\right] = \lambda u.$$

Multiplying by u, $\int_0^h \cdots dy$ and integrating by parts we deduce that

$$\lambda = -\frac{h^{4/3}}{T}\frac{\int_0^h y^{4/3}\left[\frac{\partial}{\partial y}\left(y^{-1/3}u\right)\right]^2 dy}{\int_0^h u^2 dy} \leq 0,$$

provided (38) and

$$u = o\left(y^{1/6}\right) \quad \text{as } y \to 0 \tag{49}$$

are satisfied. Similarly to the ϵ and k equations, the equality $\lambda = 0$ holds here if and only if $\frac{\partial}{\partial y}\left(y^{-1/3}u\right) \equiv 0$. This and the boundary condition (40) yields a unique solution

$$u = U(x,t)\tfrac{4}{3}\left(\tfrac{y}{h}\right)^{1/3}$$

with $U(x,t)$ independent of y. Since the indicial equation of (48) indicates nontrivial solutions near $y = 0$ are of the form $u \sim A + By^{1/3}$, then the boundary condition (49) is effectively equivalent to (37).

We have proven that *if the boundary conditions* (36)–(43) *are satisfied, then, except for the four-fold eigenvalue zero whose eigenfunctions span* $\mathcal{M}_0$*, the eigenvalues of* $\mathcal{L}$ *are negative and bounded away from* 0. Thus we expect the manifold (35) is locally attractive. Further, the time-scale of this attraction is the cross-depth turbulent diffusion time-scale T.

Appendix B. Computer algebra constructs the model.

Here we list the REDUCE[9] computer algebra program used to derive the long-wave models of turbulent flow.

The algorithm is the iterative algorithm described in [46, 48] adapted to this difficult asymptotic problem. The program refines the description of the center manifold and the evolution thereon until the residual of the governing differential equations are driven to zero, to some asymptotic error. The key to the correctness of the results is then in the correct coding of the residuals—see inside the iterative loop.

Note that because the thickness of the film is continuously varying in space and time, and because of the cube-root structure in the vertical, it is convenient to work with equations in terms of a scaled vertical coordinate $z = \sqrt[3]{y/\eta}$ so that the free surface of the film is always $z = 1$. However, the turbulence equations are not explicitly rewritten in this new coordinate because the computer handles all the necessary details of the transformation.

```
COMMENT Constructs a model of turbulent 2D flow of shallow water flow
on a flat slope based on the k-epsilon turbulence dynamical equations.
Calculates the centre manifold & reduced dynamic system on it for the
k-\epsilon model with the following boundary conditions for u, v, p, k
and \epsilon: u=v=k=deps/dy=0 at y=0, dk/dn=deps/dn=0 on y=eta. Fiddle
the free-surface BC to linearly force u & k at the surface. This gives
roughly cube-root profile in the vertical structure of u & k, whereas
eps is roughly constant.  Write results in terms of z=(y/eta)^(1/3).
Here scale derivatives as ddx*del for better control.

THE MCKEAN'S CARICATURE OF THE FITZHUGH–NAGUMO MODEL I. THE SPACE-CLAMPED SYSTEM*

ARNAUD TONNELIER†

Abstract. Within the context of Liénard equations, we present the FitzHugh–Nagumo model with an idealized nonlinearity. We give an analytical expression (i) for the transient regime corresponding to the emission of a finite number of action potentials (or spikes), and (ii) for the asymptotic regime corresponding to the existence of a limit cycle. We carry out a global analysis to study periodic solutions, the existence of which is linked to the solutions of a system of transcendental equations. The periodic solutions are obtained with the help of the harmonic balance method or as limit behavior of the transient regime. We show how the appearance of periodic solutions corresponds either to a fold limit cycle bifurcation or to a Hopf bifurcation at infinity. The results obtained are in agreement with local analysis methods, i.e., the Melnikov method and the averaging method. The generalization of the model leads us to formulate two conjectures concerning the number of limit cycles for the piecewise linear Liénard equations.

1. Introduction.

We consider the autonomous system

$$\begin{aligned} \frac{dv}{dt} &= p(v) - w, \\ \frac{dw}{dt} &= bv, \end{aligned} \tag{1.1}$$

where $t \in \mathbb{R}$, $b > 0$, $v(t) \in \mathbb{R}$ represents the system status variable at time t, $w(t) \in \mathbb{R}$ represents an additional variable, and $p : \mathbb{R} \to \mathbb{R}$ is a given function. These equations are known as the Liénard system [23], [22]. Special cases of (1.1) provide mathematical models for many applications in science and engineering. We mention here biology [31], [17], electronics (e.g., the van der Pol model [38]), chemistry [19], and mechanics (for instance, damped mass spring systems).

In this paper we consider the case of a cubic-like function for p. System (1.1) then describes the behavior of an isolated excitable cell where v is the membrane potential and w the recovery variable. When p is given by

$$p(v) = v(1-v)(v-a), \qquad \text{where} \quad 0 < a < 1, \tag{1.2}$$

system (1.1) is the polynomial FitzHugh–Nagumo model [8], [32]. It has given rise to many studies and the reader is referred to the references given in [31] and [17]. There are no particular requirements with respect to the choice of p, except to have a graphical representation similar to that given by (1.2). When p is a polynomial function, it is difficult to obtain analytical results since exact solutions cannot be obtained. In order to be able to go further with the study and the understanding of

the model, we will follow the choice originally proposed by McKean [29], considering that

$$p(v) = -v + h(v - a), \qquad \text{where} \quad 0 < a < 1, \tag{1.3}$$

and h is the Heaviside function

$$h(x) = \begin{cases} 0 \text{ if } x < 0, \\ 1 \text{ if } x > 0. \end{cases} \tag{1.4}$$

The study of model (1.1)–(1.3) with a diffusive term on v was initiated by McKean [29] and developed considerably by Rinzel and Keller [34] and Wang [39], [40]. Their analyses covered the existence and the stability of traveling wave solutions.

The use of idealized nonlinearity with the help of the Heaviside function has become a classic procedure in the modeling of threshold effects in excitable media [3], [6], [16]. This approach leads to analytical results concerning properties of the model and provides a qualitative description for a more general class of functions. As far as we know, no specific studies have been carried out on the model isolated in space (1.1)–(1.3). More generally, we are going to study the following system:

$$\begin{aligned} \frac{dv}{dt} &= -\lambda v + \mu h(v - a) - w, \\ \frac{dw}{dt} &= bv, \end{aligned} \tag{1.5}$$

where

$$\lambda > 0,\ \mu > 0,\ a > 0, \text{ and } \mu > \lambda a. \tag{1.6}$$

The latter condition shows the restriction that must be imposed upon p to obtain a shape similar to that obtained with (1.2). We are going to carry out a global analysis of equations (1.5) considering (λ, μ, a, b) as parameters. It should be noted that the change of variables

$$(\tilde{t}, \tilde{w}, \tilde{\lambda}, \tilde{\mu}) \to \frac{1}{\sqrt{b}}(t, w, \lambda, \mu) \tag{1.7}$$

enables us to consider the case $b = 1$. Nevertheless, we will not make this choice given the usefulness of the parameter b in the interpretation of the results. In addition, we are going to consider the case $b \to 0$.

Our study covers the case where a constant input I is injected into the system:

$$\begin{aligned} \frac{dv}{dt} &= p(v) - w + I, \\ \frac{dw}{dt} &= bv. \end{aligned}$$

We obtain (1.5) by putting $\tilde{w} = w - I$, which, in the phase plane, corresponds to a shift of the v-nullcline. The case of a variable current $I(t)$ will be discussed briefly and will be the subject of another paper. It should be noted that the FitzHugh–Nagumo model has an additional term in the recovery variable $\dot{w} = b(v - \gamma w)$, and the simplification $\gamma = 0$ introduces an artifact in the sense that a constant current does not change the behavior. However, since we are not interested in the bistable

regime, this limiting situation allows a qualitative description of the excitable regime and captures the bifurcations of the complete system as $\gamma \to 0$.

This article is organized as follows. In section 2, we present the context into which we put our study and introduce the elements that are useful to our analysis. In section 3, we discuss the so-called *spike solution* that corresponds to the emission of a finite number of action potentials. Particular attention is given to the study of the singular perturbed system obtained as $b \to 0$. Section 4 is devoted to an analytical study of periodic solutions, and a geometric analysis is given in section 5. We determine, in section 6, an approximation of the bigger limit cycle. Section 7 provides a mathematical link between excitability and oscillations. In the final section, we summarize our results and we discuss the problem of the number of limit cycles for the piecewise linear Liénard equations.

2. General. First, let us consider system (1.1) with p having a cubic shape similar to that given by (1.2). For a smooth reaction function, $p \in C^1$, classical results from dynamical systems theory enable us to state the following proposition.

PROPOSITION 2.1. *The single fixed point $E_0 = (0, p(0))$ is locally stable if and only if $p'(0) < 0$. If $p'(0) \geq 0$, a limit cycle, surrounding E_0, appears via a Hopf bifurcation.*

Proof. The single fixed point of (1.1) is $(0, p(0))$. Its local stability is given by the eigenvalues of the Jacobian matrix of (1.1) at $(0, p(0))$:

$$J = \begin{bmatrix} p'(0) & -1 \\ b & 0 \end{bmatrix}.$$

For $p'(0) < 0$, we obtain local stability of the fixed point. The equality $p'(0) = 0$ corresponds to the Hopf bifurcation equation. The second part of the proposition is obtained by constructing an invariant set containing E_0 and using the Poincaré–Bendixson theorem. □

The Hopf bifurcation is a mechanism that is frequently encountered in the appearance of small-amplitude oscillations [13]. It is possible to specify the behavior of the solution in the neighborhood of its Hopf bifurcation and to obtain, locally, an analytical expression for the solution of system (1.1) [20]. However, the case that we are going to look at is the so-called *excitable* one, which corresponds to $p'(0) < 0$. There is no precise mathematical definition of excitability, and we say that a system is excitable if a perturbation from its resting state leads to a large excursion for the solution in the phase plane and a return to its resting state. This phenomenon is characterized by a solution $(v(t), w(t))$ of (1.5) satisfying the following two properties:

$$\begin{aligned} &\text{(P1)} \quad \exists\, 0 < t_1 < t_2, \text{ so that } v \text{ is increasing on } [t_1, t_2], \\ &\text{(P2)} \quad \lim_{t \to +\infty} v(t) = 0. \end{aligned}$$

Such a solution will be called a *spike solution*. It should be noted that (P2) is always satisfied when the domain of attraction of $(0, p(0))$ is the whole phase plane. For our study, property (P1) is sufficient to characterize the excitability of our system. When p is the function involved in (1.5), property (P1) will be satisfied as soon as (v, w) crosses the threshold segment $[-\lambda a, -\lambda a + \mu]$ in the phase plane. These two properties are in agreement with the characterization of excitability given in [1], i.e., the existence, in the phase space of the so-called *amplifying set* and *decaying set*.

We are going to examine the two phenomena associated with the emergence of an action potential. These phenomena will be written according to the concept of *spike*

solution and periodic solution. The *spike solution* is a transient regime characterized by a finite number of action potentials. The periodic solution corresponds to the emission of an infinite number of action potentials. It is an asymptotic regime that shows the presence of a limit cycle. These two regimes represent the basic properties of neuronal excitability [33], [15].

Before proceeding with an analytical study of these regimes, we are going to give a qualitative interpretation of the dynamical behavior of system (1.1). This system can be rewritten in a convenient form usually used within the context of self-excited oscillations [30], [12]:

$$\frac{d^2v}{dt^2} - p'(v)\frac{dv}{dt} + bv = 0.$$

It is then useful to consider the energy derived from the harmonic oscillator (obtained as $p' = 0$) defined by

$$E = \frac{1}{2}\left(\frac{dv}{dt}\right)^2 + \frac{b}{2}v^2.$$

This gives a solution,

$$\frac{dE}{dt} = p'(v)\left(\frac{dv}{dt}\right)^2. \tag{2.1}$$

We find the stability of the fixed point $(0, p(0))$, provided by Proposition 2.1, when $p'(0) < 0$, which corresponds to damped oscillations in the neighborhood of this fixed point. As p' is not negative everywhere on $\mathbb{R}$, it is not possible to obtain a conclusion concerning the global stability of $(0, p(0))$. In particular, it is possible that the added energy, when $p' > 0$, is sufficient to give rise to a limit cycle. Equation (2.1) provides information concerning this cycle to the extent that it must contain at least one root of p'. Note that this result can be found using the Poincaré–Bendixson criterion. When p is the cubic polynomial proposed by FitzHugh–Nagumo (1.2), system (1.1) does not have a limit cycle [24]. Nevertheless, while keeping a similar shape for p, it is possible to obtain a limit cycle. For example, for

$$p(x) = \begin{cases} -x & \text{if } x \leq 0, \\ 10x(x - 0.3)(1 - x) & \text{if not,} \end{cases}$$

and $b = 6$, one observes, numerically, the existence of a stable limit cycle. Thus the constraint on p, said to be of cubic shape, leaves a variability in the dynamical behavior of (1.1). In the case we are going to study, where p is represented in Figure 2.1, we will see that the energy input due to the jump discontinuity of v', $\Delta v' = \mu$ when v crosses the line $v = a$, may be sufficient to give rise to a limit cycle. In this case, the limit cycle coexists with the fixed point $(0, 0)$ and this situation is termed as *hard self-excitation*.

Before beginning this study, it is necessary to specify the meaning given to a solution of (1.5) when p is discontinuous. Geometrically, a solution corresponds to a trajectory in the phase plane (v, w). If this trajectory crosses the line of discontinuity transversally, the solution is easy to define: for t such that $v(t) = a$, $v'(t)$ has a jump discontinuity $(v'(t^+) - v'(t^-) = \pm\mu)$, and elsewhere the solution is C^1 and satisfies (1.5) in the classical sense. In the case where the trajectory tangentially meets the

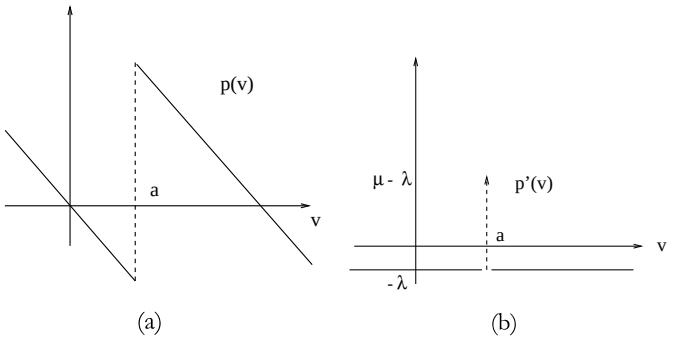

FIG. 2.1. (a) *The nonlinear function* p *and* (b) *its distributional derivative* p'.

line of discontinuity, the solution satisfies $v(t) = a$ on a nonempty set. In this case, we speak of a *generalized solution* and approach the problem from a geometrical point of view. It is not the purpose of this article to give a precise mathematical characterization of this solution, and the reader is referred to [7], [18]. It should be noted that the problem of discontinuous vector fields is covered extensively in control theory, e.g., [5], [14].

Our main results are given in the following summary. In section 3, we demonstrate that the spike solution contains only one spike when $\lambda^2 \geq 4b$ and several spikes can be emitted otherwise (depending on the initial conditions). In the former case, we derive a simple expression for the solution as $b \to 0$ and, in the latter, we give the general expression for the spike solution. The next sections focus on the case $\lambda^2 < 4b$ for which we derive, in section 4, analytical results on the existence and the expression of the periodic solutions. The periodic orbits appear via a double limit cycle bifurcation that we compute in the plane (a, b). Using a geometrical analysis (section 5), we characterize the two periodic solutions, represented in the phase plane by two concentric limit cycles. We show how in the limiting situation $\lambda \to 0$ and $\mu \to 0$ the periodic orbits can be obtained with the use of the Melnikov function. Moreover, we discuss the existence of two different types of unstable limit cycles referred to either as a classical or a generalized solution. The generalized solution is related to the discontinuity of the vector field. In section 6, the study as $\lambda \to 0$ allows us to capture and to describe the bigger limit cycle which is obtained as a Hopf bifurcation at infinity. In section 7, we show how the spike solutions and the periodic solutions are related.

3. Excitability and singular perturbation. The purpose of this section is to study the *spike solution*. In particular, we characterize this solution by the number of spikes that are part of the solution. This number corresponds to the number of times that v crosses the threshold a, where $v'^- > 0$ (where v'^- designates the left-hand derivative of v). This number includes the initial pulse corresponding to the perturbation due to the initial condition, noted as (v_0, w_0). In order to simplify the study we consider the case where $w_0 = 0$. We distinguish between several cases, according to the value of $\lambda^2 - 4b$. We prove the following proposition.

PROPOSITION 3.1. *For* $\lambda^2 \geq 4b$*, there is a spike solution when* $a < v_0 < \frac{\mu}{\lambda}$*. This solution only presents a single spike.*

Proof. First, we look at the case where $\lambda^2 > 4b$. For $v_0 < a$ and as long as $v(t) < a$, we have

$$v''(t) + \lambda v'(t) + bv(t) = 0.$$

The solution is then given by

$$v(t) = \frac{v_0}{r_+ - r_-}\left(-(\lambda - r_-)e^{r_+ t} + (\lambda + r_+)e^{r_- t}\right),$$

where

$$r_\pm = \frac{1}{2}(-\lambda \pm \sqrt{\lambda^2 - 4b}). \tag{3.1}$$

Let $\tilde{t}$ be the time defined by $\tilde{t} = 1/(r_+ - r_-)\ln(1 + \frac{\lambda}{r_+})/(1 + \frac{\lambda}{r_-})$. If $v_0 > 0$, v is decreasing on $[0, \tilde{t}\,]$ and increasing on $[\tilde{t}, +\infty[$. In addition, we have $\lim_{t\to+\infty} v(t) = 0$ and thus $\forall t > 0, v(t) < a$. When $v_0 < 0$, if $\forall t, v(t) < a$, the study is completed; conversely, if there is a time t^* so that $v(t^*) = a$, then the trajectory crosses the line $w = 0$ for a value of v greater than a, and, given a time shift, the study corresponds to the case where $v_0 > a$.

If $v_0 > a$, there is a time t^* so that $v(t^*) = 0$ and $w(t^*) = w_1 > -\lambda a + \mu$. If we put $t^* = 0$, this gives $v(t) = \frac{w_1}{r_+ - r_-}(e^{r_- t} - e^{r_+ t})$ and thus $\forall t > 0$, $v(t) < 0$ and $\lim_{t\to+\infty} v(t) = 0$.

The case where $\lambda^2 = 4b$ is dealt with in a similar way. □

For $\lambda^2 - 4b \geq 0$, the response to an input $I = I_0\delta(t - t_0)$ is a single action potential when $I_0 > a$.

We will now obtain a simple analytical expression for the potential v. The previous study showed the existence of several phases when a spike is emitted. This point can be made more specific by studying the case $b \ll 1$. This situation models the behavior of a system in which two time scales are involved; i.e., v is a fast variable and w is a slow variable. The mathematical description of the excitability is a classical one (see, for example, [17]) and is carried out using the singular perturbation theory. In our case, the relevance is to allow explicit solutions that give a simple expression for v according to the different phases of the *spike solution*.

Let there be (v_0, w_0) so that $a < v_0 < \frac{\mu}{\lambda}$ and $w_0 = 0$. In addition, let us assume that $v_0 - \frac{\mu}{\lambda}$ is of order greater than a $O(b)$. The variations of v can be separated into four phases. The first phase, which is the *excited phase*, is fast and the motion is governed approximatively by the system

$$\begin{aligned} \frac{dv}{dt} &= p(v) - w, \\ \frac{dw}{dt} &= 0, \end{aligned}$$

which gives

$$v(t) = \frac{1}{\lambda}\left(\mu + e^{-\lambda t}(\lambda v_0 - \mu)\right). \tag{3.2}$$

This approximation is valid as long as $v(t)$ is at a greater distance from the v-nullcline than a $O(b)$ value. If not, we enter the second phase where the dynamic is described using a new time scale $\tau = bt$. In this phase, v is adjusted to maintain a pseudoequilibrium at $w = p(v)$, and we have $v(\tau) = \frac{1}{\lambda}(\mu - w)$. We obtain

$$v(t) = \frac{\mu}{\lambda}e^{-\frac{\tau}{\lambda}}. \tag{3.3}$$

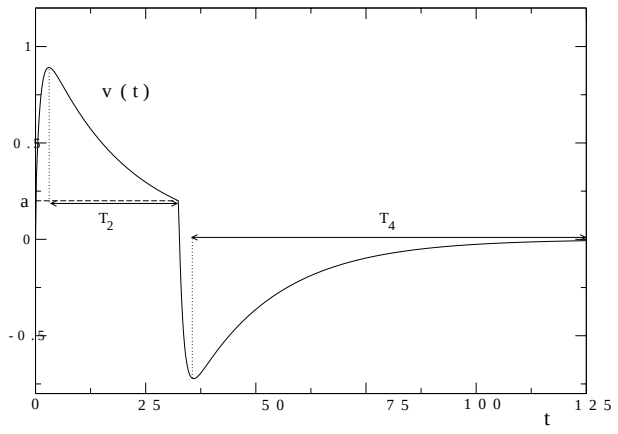

FIG. 3.1. *Solution $v(t)$ of (1.5) for $(v_0, w_0) = (0.25, 0)$, $\lambda = 1$, $a = 0.2$, $b = 0.05$, and $\mu = 1$. Intervals T_2 and T_4 designate the durations of the two slow phases.*

We enter into the third phase as v reaches a. We have a fast motion where v is given by

$$v(t) = \frac{\mu}{\lambda}(e^{-\lambda t} - 1) + a. \tag{3.4}$$

The final phase is characterized by a slow return to the equilibrium state according to

$$v(t) = \left(a - \frac{\mu}{\lambda}\right) e^{-\frac{\tau}{\lambda}}. \tag{3.5}$$

We can easily find these results by observing that the roots r_+ and r_- given by (3.1) are written $r_+ = -\frac{b}{\lambda} + O(b^2)$ and $r_- = -\lambda + O(b)$. The fast dynamic is obtained using the zero order approximation, and the slow motion by using the first order one. The different phases, (3.2)–(3.5), correspond to the charge and discharge of a capacitor, and are graphically shown in Figure 3.1. They allow precise identification of the role of each parameter. In particular, the amplitude of the potential is parameterized by $\frac{\mu}{\lambda}$ and a. In addition, it is possible to obtain an approximation of the duration of a spike T using the durations of the slow dynamics of phases two and four, written T_2 and T_4, respectively. We consider that the duration of phase four is the time for which $v(t) = O(b)$. This gives

$$T = T_2 + T_4,$$

where

$$\begin{aligned} T_2 &= \frac{\lambda}{b} \ln \frac{\mu}{\lambda a} + O\left(\frac{1}{b}\right), \\ T_4 &= O\left(-\frac{\ln b}{b}\right). \end{aligned} \tag{3.6}$$

For $b \ll 1$, it is possible to obtain a simple description of the subthreshold response to a variable input $I(t)$. This response is the one given by an RC filter, where $\lambda = \frac{1}{RC}$ and is written

$$v(t) = e^{-\lambda \cdot} * I(t).$$

If we consider a train of impulses at regular intervals, the system reacts preferentially at a high input frequency in that the higher the input frequency, the earlier a spike is emitted. More precisely, with $I(t) = I_0 \sum_{t_i} \delta(t - t_i)$, where $t_i = iT$ and $i \in \mathbb{N}$, the subthreshold response is given by

$$v(t) = I_0 e^{-\lambda t} \frac{1 - e^{\lambda(n+1)T}}{1 - e^{\lambda T}},$$

where n is the index of the final pulse of $I(t)$ before the system reaches the threshold. Thus, for an input such as $I_0 < a$ with a small frequency

$$\frac{1}{T} < \frac{\lambda}{\ln(\frac{a}{a - I_0})},$$

the system cannot emit an action potential.

Now, and for the rest of this article, unless indicated otherwise, we are going to consider the case in which $\lambda^2 - 4b < 0$. We shall see that the model presents a richer dynamic in the sense that the *spike solution* is able to present several action potentials. In addition, we will show in the following section the existence of periodic solutions. We continue the case of a solution satisfying $\lim_{t \to +\infty} v(t) = 0$ and, therefore, there exists a constant $C > 0$ and a time t^* starting from which we have

$$|v(t)| < Ce^{-\frac{\lambda}{2}t}.$$

We can then define the Laplace transform of v

$$\mathcal{L}(v)(p) = \int_0^\infty v(t) e^{-pt} dt$$

for which the region of convergence is the half plane

$$D = \left\{ p \in \mathbb{C} \mid \mathrm{Re}(p) > -\frac{\lambda}{2} \right\}.$$

We define the finite sequence of times, written $(t_i)_{0 \ldots 2n-1}$, so that $t_0 = 0$, and for $i \neq 0$, $v(t_i) = a$ and $\Delta v'(t_i) = (-1)^i \mu$. This sequence indicates the passage of potential via the line of discontinuity and corresponds to a jump of the derivative of v. An equivalent characterization of t_i is given by $v'(t_{2j}^-) > 0$ and $v'(t_{2j+1}^-) < 0$. We have, on $]t_{2i}, t_{2i+1}[$, $v(t) > a$ with $v(t_0) = v_0 > a$. The number n corresponds to the number of spikes emitted by the system. For $w_0 = 0$, we calculate

$$\mathcal{L}(v)(p) = \frac{\mu}{p^2 + \lambda p + b} \sum_{i=0}^{n-1} (e^{-pt_{2i}} - e^{-pt_{2i+1}}) + \frac{pv_0}{p^2 + \lambda p + b}.$$

We write in the following $r = \sqrt{4b - \lambda^2}$. Using inverse Laplace transforms gives

$$v(t) = v_0 \alpha(t) + \sum_{i=0}^{2n-1} (-1)^i h(t - t_i) \varphi(t - t_i), \tag{3.7}$$

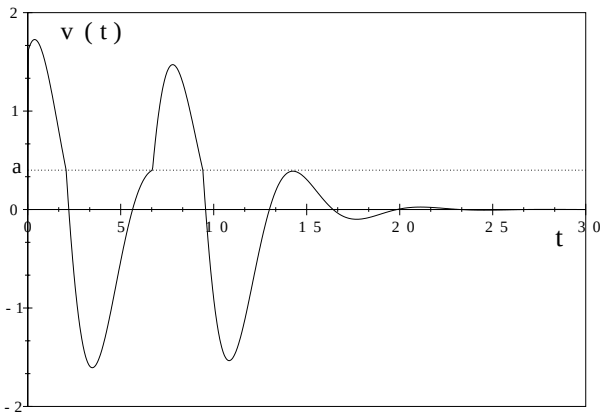

FIG. 3.2. *Solution $v(t)$ of* (1.5) *for* $(v_0, w_0) = (1.6, 0)$, $\lambda = 0.8$, $\mu = 2$, $a = 0.4$, *and* $b = 1$. *This* spike solution *presents two action potentials, or spikes.*

where

$$\varphi(t) = \frac{2\mu}{r} e^{-\frac{\lambda}{2}t} \sin \frac{r}{2} t, \tag{3.8}$$

$$\alpha(t) = e^{-\frac{\lambda}{2}t} \Big(\cos \frac{r}{2} t - \frac{\lambda}{r} \sin \frac{r}{2} t \Big). \tag{3.9}$$

The above expression characterizes the transient regime with (i) a term that depends on the initial excitation, v_0, and corresponds to damped oscillations of period $\frac{4\pi}{\sqrt{4b-\lambda^2}}$, and (ii) a sum of terms with the form $(-1)^i S_{t_i}(h\varphi)$ (where S is the shift operator) reproducing an excitation when $v'^- > 0$ (even i) or an inhibition $v'^- < 0$ (odd i). This sum shows the different crossing $v = a$ and is defined implicitly by the existence of times t_i such as $v(t_i) = a$. It is clear that t_1 exists: it is given by the smallest strictly positive solution of the equation

$$v_0 \alpha(t) + \varphi(t) = a.$$

The sequence of times (t_i) cannot be expressed with known functions and is implicitly defined using expression (3.7). Figure 3.2 illustrates the case in which the system generates two action potentials. The return to the resting state takes place via damped oscillations and induces computational properties which differ from that studied above. If we consider the case of a system that has not emitted a spike, its subthreshold response to an input $I(t)$ is given by

$$v(t) = \alpha * I,$$

corresponding to the response of an RLC filter, with $\lambda = \frac{R}{L}$ and $b = \frac{1}{LC}$, when an input I is applied. In particular, the filter response is more significant for an input signal having a resonant frequency close to $\sqrt{b - \frac{\lambda^2}{4}}$.

4. Periodic solutions. Let us assume that system (1.5) has a periodic solution. According to the expression of the vector field, this solution delimits a domain containing the origin, which is a stable fixed point. In addition, when $\lambda \neq 0$, it is possible

to construct an invariant region large enough to include this limit cycle. Thus, there are at least two limit cycles surrounding the origin, with an alternation of stable and unstable cycles, the largest being stable.

We are looking for a periodic solution $(v(t), w(t)) \in \left(L^2(0,T)\right)^2$, where T is the period of the solution. This solution can be expressed in a Fourier series

$$\begin{aligned} v(t) &= \sum_n v_n e^{2i\pi n \frac{t}{T}}, \\ w(t) &= \sum_n w_n e^{2i\pi n \frac{t}{T}}. \end{aligned} \tag{4.1}$$

The technique used, which is known as the method of the harmonic balance (see [2], for example), involves identifying (v_n, w_n) using the differential equation satisfied by (v, w).

In the phase plane, a periodic solution crosses the line $v = a$ at two points, one of which satisfies $w > 0$ and the other $w < 0$. We set t_1 and t_2 as the two successive times that satisfy $v(t_i) = a,\ i = 1, 2$, so that $\forall t \in]t_1, t_2],\ v(t) > a$. The time-translation invariance of the periodic solution allows us to define the real τ so that $t_1 = -\tau$, $t_2 = \tau$, where $0 < \tau < \frac{T}{2}$. The periodic solution looked for satisfies

$$v(t) = \begin{cases} > a & \text{on }]-\tau, \tau[, \\ < a & \text{on } [-\frac{T}{2}, -\tau[\cup]\tau, \frac{T}{2}]. \end{cases} \tag{4.2}$$

The function $t \to h(v(t) - a)$ is a T-periodic function such as

$$h(v(t) - a) = \begin{cases} 1 & \text{if } \ t \in [-\tau, \tau], \\ 0 & \text{if not,} \end{cases}$$

and we calculate that

$$h(v(t) - a) = \frac{2\tau}{T} + \sum_{n \neq 0} \frac{1}{\pi n} \sin\left(2\pi n \frac{\tau}{T}\right) e^{2i\pi n \frac{t}{T}}.$$

Therefore we obtain

$$v(t) = \sum_n c_n \sin\left(2\pi n \frac{\tau}{T}\right) e^{2i\pi n \frac{t}{T}}, \tag{4.3}$$

where

$$c_n = \frac{2\mu T i}{-4\pi^2 n^2 + bT^2 + i2\pi\lambda T n}.$$

At this stage in the study, we may remark that the mean value of v is zero (which could be seen directly with (1.5)). The mean value of w is $w_0 = \frac{2\mu\tau}{T}$. The amplitude spectrum of v is $O\left(\frac{1}{n^2}\right)$, which ensures the normal convergence of the associated Fourier series.

Let f be the function defined by

$$f(t) = \sum_n i c_n e^{i2\pi n \frac{t}{T}}.$$

With the help of trigonometric transformations, (4.3) is written

$$v(t) = \frac{1}{2}(f(t - \tau) - f(t + \tau)). \tag{4.4}$$

We calculate

$$f(t) = \frac{-2\mu}{r\left(\cosh\frac{\lambda T}{2} - \cos\frac{r}{2}T\right)} e^{\frac{\lambda}{4}(T-2t)} \left(e^{-\frac{\lambda T}{4}} \sin\frac{r}{2}(T-t) + e^{\frac{\lambda T}{4}} \sin\frac{r}{2}t\right) \tag{4.5}$$

for $0 \le t \le T$, where $r = \sqrt{4b - \lambda^2}$ and f is defined on $\mathbb{R}$ by periodicity. Therefore, f is continuous on $\mathbb{R}$ and has a derivative for $t \neq \mathbb{Z}T$. Note that f does not depend on the auxiliary variable τ. A periodic solution exists if and only if there is T and τ such as $0 < \tau < \frac{T}{2}$, solutions of

$$\begin{aligned} f(0) - f(2\tau) &= 2a, \\ f(-2\tau) - f(0) &= 2a, \end{aligned} \tag{4.6}$$

so that v, given by (4.4), satisfies (4.2). We note $x = \frac{T}{2}$ and $y = \tau$. Elementary operations show that (4.6) can be written in the form

$$\begin{aligned} F(x,y) &= 0, \\ F(x,y-x) &= 0, \\ 0 < y &< x, \end{aligned} \tag{4.7}$$

where

$$F(x,y) = \mu \sinh\lambda x \sin ry - \mu \sin rx \sinh\lambda y - ar(\cosh\lambda x - \cos rx)\cosh\lambda y. \tag{4.8}$$

The existence of periodic solutions for the differential system (1.5) is given by the existence of roots for a system of transcendental equations. We have therefore reduced the differential problem to an algebraic one that corresponds to a search for roots in $\mathbb{R}$. In contrast to perturbation methods, it is interesting to note that our analysis is a global one and gives an analytical formula for a periodic solution.

Remark. A similar study can be carried out for $\lambda^2 - 4b > 0$. We then write $r = \sqrt{\lambda^2 - 4b}$. We find that

$$f(t) = \frac{-2\mu}{r\left(\cosh\frac{\lambda T}{2} - \cosh\frac{r}{2}T\right)} e^{\frac{\lambda}{4}(T-2t)} \left(e^{-\frac{\lambda T}{4}} \sinh\frac{r}{2}(T-t) + e^{\frac{\lambda T}{4}} \sinh\frac{r}{2}t\right),$$

where T and τ are given by the resolution of (4.7) with F defined by

$$F(x,y) = \mu \sinh\lambda x \sinh ry - \mu \sinh rx \sinh\lambda y - ar(\cosh\lambda x - \cosh rx)\cosh\lambda y. \tag{4.9}$$

Using $r < \lambda$, it is easy to show that $F(x, y-x) < 0$ when $0 < y < x$, and, therefore, there cannot be solutions of (4.7) with F given by (4.9), which confirms the result of the previous section.

Starting from the study carried out above, it is possible to state several simple properties concerning a periodic solution. First of all, it is easy to see that its existence is controlled by parameters r, λ, and $\frac{a}{\mu}$. In addition, we have the following bound for the periodic solution:

$$\|v\|_{+\infty} < \frac{4\mu}{\sqrt{4b - \lambda^2}} \cdot \frac{e^{\frac{\lambda T}{2}} + 1}{e^{\frac{\lambda T}{2}} - 2},$$

which is valid for $e^{\frac{\lambda T}{2}} > 2$. In particular, we can see that the smaller the period, the larger the bound.

Based on (4.7), in the general case, it is difficult to give conditions for the existence of (T, τ). More precisely, two phenomena appear to make the study tricky: (i) the presence of solutions of (4.7) that do not correspond to a periodic solution, and (ii) the presence of a periodic solution not detected by our analysis. We will look more closely at the second point in the next section. The first point arises from the fact that the existence of exactly two solutions for the equation $v(t) = a$ on $[0, T]$, corresponding to (4.2), is not reported in system (4.7). These two situations can be illustrated by looking at the solutions of (4.7) as $a \to 0$. If we take $a = 0$, the resolution of (4.7) leads to the family of solutions $(T_k, \tau_{p_k})_k$, where $k \in \mathbb{N},\ k > 1$:

$$\begin{aligned} T_k &= \frac{2k\pi}{\sqrt{4b - \lambda^2}}, \\ \tau_{p_k} &= \frac{p_k \pi}{\sqrt{4b - \lambda^2}}, \quad \text{where } p_k = 1 \dots k-1, \end{aligned} \tag{4.10}$$

and the implicit functions theorem leads to the existence of these solutions for a sufficiently small a. In fact, only the solution obtained for $k = 2$ is admissible; other solutions do not satisfy the assumptions of our study (given by (4.2)). Numerically, this solution corresponds to a stable limit cycle. As we have already mentioned, there must be an unstable cycle separating the domain of attraction of the origin from the stable cycle one. Therefore, we are in a situation where a limit cycle has not been detected.

Before clarifying this situation, we carry out a numerical study of the specific case used in [29], [34], and [39], where $\mu = 1$ and $\lambda = 1$. The results are illustrated in Figure 4.1, where we determine in the plane (a, b) the region where a periodic solution exists. It appears that there is a value of a, noted a^*, for which there is no periodic solution for $a \geq a^*$. When $a < a^*$, the existence of a periodic solution is obtained for $b \geq b_f(a)$. The curve $b_f(a)$ is given by the resolution, in $\{(x, y) \in \mathbb{R}^2 / \ 0 < y < x\}$, of

$$\begin{aligned} F(x, y) &= 0, \\ F(x, x - y) &= 0, \\ \det F_{x,y} &= 0, \end{aligned} \tag{4.11}$$

where $F_{x,y}$ is the Jacobian matrix of the system above with respect to (x, y). Geometrically speaking, the latter condition corresponds to a tangential intersection between the two curves defined by the equations $F(x, y) = 0$ and $F(x, x-y) = 0$. For $b = b_f(a)$, there is a single unstable limit cycle. For $b > b_f(a)$, there are two concentric limit cycles. The larger one is stable, and the smaller one is unstable, separating the different domains of attraction. At $b = b_f(a)$ a fold limit cycle bifurcation (or double limit cycle bifurcation) occurs. Several limiting situations can be analytically specified. When $a \to 0$, system (4.7) always has an admissible solution (given by (4.10) with $k = 2$), and the only restriction on b is related to the existence of r. We therefore have $\lim_{a \to 0} b_f(a) = 0.25$.

We determine the value of a^* using an asymptotic expansion of (4.7) as $b \to +\infty$. More exactly, we use an asymptotic expansion as $r \to +\infty$.

We write

$$x = \frac{x_1}{r} + O\left(\frac{1}{r^2}\right)$$

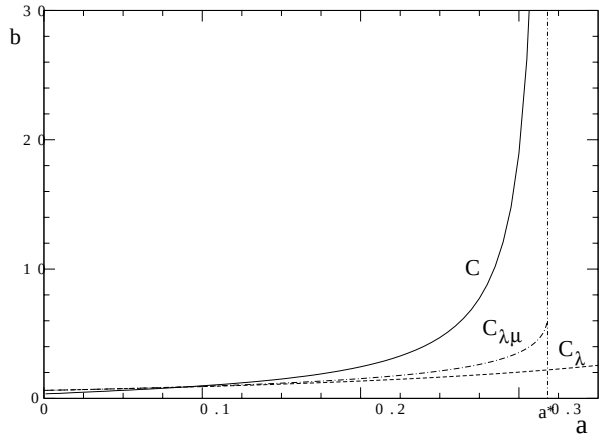

FIG. 4.1. *Curve of the fold limit cycle bifurcation* $C = \{b_f(a),\ 0 \le a < a^*\}$ *so that there are two periodic solutions if and only if* $b > b_f(a)$ *with* $a < a^*$. *Parameters are* $\lambda = 1$, $\mu = 1$. *Curves* C_λ *and* $C_{\lambda\mu}$ *correspond to the two approximations given by* (6.7).

as the expansion of x (it is easy to show that the zero order term is zero). The leading order expansion of $F(x, y)$ is

$$F(x, y) = a(\cos x_1 - 1)r + O(1),$$

which gives us the approximation

$$T = \frac{4\pi}{r} + O\left(\frac{1}{r^2}\right).$$

One notes the similarity with the expression (4.10) obtained above. In the same way, if we write

$$y = \frac{y_1}{r} + O\left(\frac{1}{r^2}\right),$$

the determination of y_1 is carried out by canceling the higher order term of the expansion of $F(x, y)$. We find

$$2\pi \sin(y_1) - \frac{a}{2}x_2^2 - a\pi^2 = 0, \tag{4.12}$$

and it should be noted that the expansion of $F(x, y-x)$ leads to the same expression. We show that $x_2 = 0$ (while remarking that x_2 is the first order term in the expansion of T as $b \to 0$ and using the symmetries of the differential equations (1.5)). We therefore find a solution of (4.12) if and only if

$$a \le \frac{1}{\pi}, \tag{4.13}$$

which enables us to obtain the value $a^* = \frac{1}{\pi}$ (Figure 4.1). When $a < a^*$ and r is large enough, we found two values of τ corresponding to exactly two limit cycles. We remark that, asymptotically, both these cycles have the same period.

We can now predict the behavior of system (1.5) for any (λ, μ). The change of variables

$$(\tilde{b}, \tilde{a}, \tilde{t}, \tilde{v}, \tilde{w}) = \left(\frac{b}{\lambda^2}, \frac{\lambda}{\mu}a, \lambda t, \frac{\lambda}{\mu}v, \frac{w}{\mu}\right)$$

enables us to find the case previously studied. Condition (4.13) is then written as

$$a \leq \frac{\mu}{\lambda\pi}, \tag{4.14}$$

and the bifurcation curve obtained from b_f is given by

$$b = \lambda^2 b_f\Big(\frac{\lambda}{\mu}a\Big). \tag{4.15}$$

Thus, for sufficiently small λ, the system has always a limit cycle. We will discuss this point in more detail in section 6. For μ large enough, the condition for existence of a periodic solution is written as $b \geq \frac{\lambda^2}{4}$.

5. Geometrical study. We are going to specify the dynamical behavior of the system in the phase plane. We also will make use of a geometrical analysis to characterize solutions of the transcendental equations system (4.7) in the sense that the search for periodic solutions should be carried out among the intersection points of the two curves $C_1 = \{(x, y), F(x, y) = 0\}$ and $C_2 = \{(x, y), F(x, y - x) = 0\}$ in the space region $0 < y < x$. Three configurations can then be distinguished.

5.1. No periodic solution. The simplest situation is obtained when the two curves C_1 and C_2 do not present any intersections. In this case, the origin is globally attractive. We already have illustrated such a configuration in Figure 3.2 and have shown that this case still appears when $\lambda^2 > 4b$ (in this case, C_1 and C_2 are defined using F given by (4.9)).

5.2. Pair of admissible solutions. We have seen that when $r \to +\infty$, it is possible to find exactly two pairs of solutions for system (4.7). When these solutions lead to an expression for the limit cycle, given by (4.4), satisfying the hypotheses (4.2), they correspond to solutions that are admissible. From numerical simulations, it appears that this situation occurs when C_1 and C_2 are two closed convex curves (in the region of the plane where $0 < y < x$). In this case, there are exactly two intersection points, which correspond to the two limit cycles (stable and unstable).

This configuration can also be found using perturbation methods. In particular, we will show a mechanism for the birth of these two limit cycles in the phase plane. We consider the following Hamiltonian system:

$$\begin{aligned} \frac{du}{dt} &= -w, \\ \frac{dw}{dt} &= bv \end{aligned} \tag{5.1}$$

for which the Hamiltonian function, written H, is given by

$$H(v, w) = v^2 + \frac{1}{b}w^2. \tag{5.2}$$

System (1.5) can be written as a perturbation of the Hamiltonian system (5.1)

$$\begin{aligned} \frac{dv}{dt} &= -w - \lambda g(v), \\ \frac{dw}{dt} &= bv, \end{aligned} \tag{5.3}$$

where $\lambda \ll 1$ and $g(v) = v - h(v-a)$. We take $\mu = \lambda$, but we have seen that the study can easily be extended to any (λ, μ) of the same order. It is easy to see that for system (5.3) the origin becomes a focus. In order to have a closer look at what becomes of the periodic trajectory of the center, we are going to use the Melnikov method [11]. This method, which arises from the averaging method, enables us to determine the periodic trajectories that are transformed into limit cycles and thus obtain an approximation of these cycles. The Melnikov function, associated with the level curve $H(v,w) = v^2 + \frac{1}{b}w^2 = l^2$, is

$$M(l) = \int_0^{2\pi} dt\ v g(v)|_{v=l\cos t}.$$

We obtain

$$M(l) = \pi l^2 - 2h(l-a)\sqrt{l^2 - a^2}.$$

Level curves of the unperturbed Hamiltonian system which transform into limit cycles are obtained as solutions of $M(l) = 0$. When $l < a$, the only solution is $l = 0$ and we find that the trajectories tend towards the origin. When $l > a$, $M(l) = 0$ is written as

$$l^4 - \frac{4}{\pi^2}l^2 + \frac{4}{\pi^2}a^2 = 0.$$

There are solutions if and only if $a \le \frac{1}{\pi}$. We then have the following result:

– If $a = \frac{1}{\pi}$, there is a single limit cycle which corresponds to the level curve defined by

$$H(v,w) = \frac{2}{\pi^2}. \tag{5.4}$$

– If $a < \frac{1}{\pi}$, there are two limit cycles which correspond to the level curves defined by

$$H(v,w) = \frac{2}{\pi^2}\left(1 \pm \sqrt{1 - \pi^2 a^2}\right). \tag{5.5}$$

These results can be added to by using system (4.7). When $\mu = \lambda \ll 1$, the second order asymptotic expansion of F gives

$$\begin{aligned} F(x,y) = {} & 2a\sqrt{b}(\cos(2\sqrt{b}x) - 1) \\ & + \Big(- a\sqrt{b}(x^2 + y^2) + \frac{a}{4\sqrt{b}}(1 - \cos(2\sqrt{b}x)) \\ & + \Big(\frac{ax}{2} - y\Big)\sin(2\sqrt{b}x) + x\sin(2\sqrt{b}y) + a\sqrt{b}y^2\cos(2\sqrt{b}y)\Big)\lambda^2 + O(\lambda^3). \end{aligned}$$

Canceling the zero order term gives

$$T = \frac{2\pi}{\sqrt{b}} + O(\lambda).$$

To find a zero order approximation of τ, written τ_0, it is necessary to use the second order expansion of F. In this case, the first order term of the expansion of T, written as T_1, is involved and the cancellation of the second order term of F (or of $F(x, y-x)$) is written as

$$-ab^2T_1^2 - a\pi^2 + \pi\sin(2\sqrt{b}\tau_0) = 0.$$

Note that the system obtained by the transformation $\lambda \to -\lambda$ and $t \to -t$ has a phase portrait that is obtained from the original system taking the symmetric with respect to the line $w = 0$. We then have $T(-\lambda) = T(\lambda)$, $\tau(-\lambda) = \tau(\lambda)$ and the expansion of T and τ have the form

$$\begin{aligned} T &= T_0 + T_2\lambda^2 + T_4\lambda^4 + \cdots, \\ \tau &= \tau_0 + \tau_2\lambda^2 + \tau_4\lambda^4 + \cdots. \end{aligned}$$

In particular, we have $T_1 = 0$ and, when $a \leq \frac{1}{\pi}$, we find two possible values for the first term of the expansion of τ corresponding to the two limit cycles obtained above:

$$\begin{aligned} {}^1\tau_0 &= \frac{1}{2\sqrt{b}}\arcsin(a\pi), \\ {}^2\tau_0 &= \frac{1}{2\sqrt{b}}(\pi - \arcsin(a\pi)). \end{aligned}$$

It is possible to obtain more refined approximations by continuing the series expansion of T and τ using (4.7). The approximation of limit cycles is then given from (4.4), (4.5). It is interesting to note the similarity of the expressions obtained here and those obtained for large r. This result is not surprising given the change of variables (1.7). In Figure 5.1 and Figure 5.2, we show a typical configuration under study. The two limit cycles that have just been characterized correspond to solutions in the classical sense in that they satisfy hypothesis (4.2) and can be obtained by our Fourier analysis.

5.3. Only one admissible solution. From numerical simulations, we observe configurations where there is only one admissible solution for system (4.7). This situation does not only appear when there is a single intersection between C_1 and C_2 since, as we have already mentioned as $a \to 0$, there can be several intersections so that only one of which is suitable. Moreover, it is possible to find exactly two intersections between C_1 and C_2 only one of which is suitable. This situation is illustrated in Figure 5.3. We have therefore detected a single limit cycle that appears to be the stable one. Naturally, the unstable cycle still exists and here we talk about a *generalized solution*, insofar as we cannot define it in the classical sense. From numerical simulations, we observe that the appearance of this *generalized solution* corresponds to a bifurcation of curves C_1 or C_2 in that at least one of these two curves no longer corresponds to a single closed curve (see Figure 5.3).

In the phase plane, the study of the vector field enables us to specify the unstable cycle, called a separatrix because it is the boundary between two domains of attraction. We write the coordinate points $(a, -\lambda a)$, (a, y_B) as A and B, respectively,

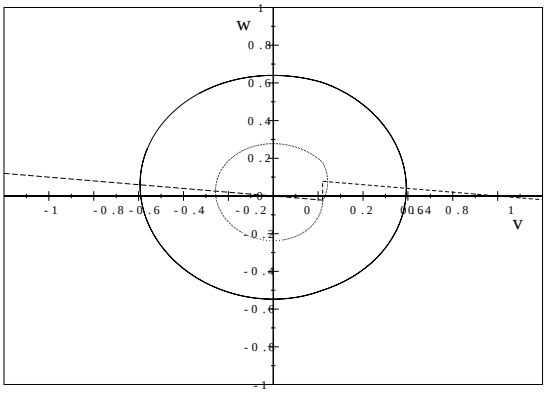

FIG. 5.1. *Unstable (dotted line) and stable (full line) limit cycles of system* (1.5). *The v-nullcline is represented. The parameters are* $\lambda = \mu = 0.1$, $a = 0.22$, $b = 1$.

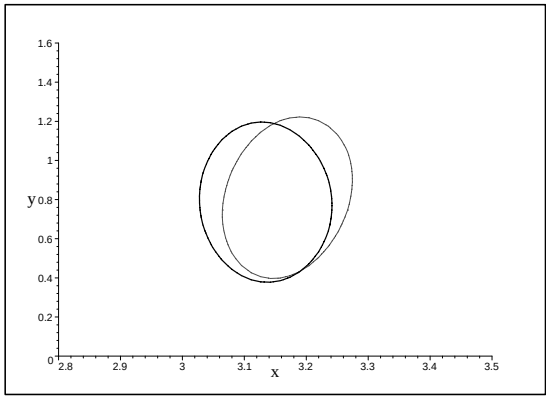

FIG. 5.2. *Curves* C_1 *(thick line) and* C_2 *(thin line). The two intersections correspond to the two limit cycles given in Figure* 5.1 *(the parameters are given in Figure* 5.1*).*

where $y_B \in \mathcal{I}$ and $\mathcal{I}$ designates the interval $[-\lambda a, -\lambda a + \mu]$. Let $\mathcal{P}$ be the parameterized curve obtained when considering the solution of system (1.5) starting from A by reversing the time. The equation for this curve is given by

$$x(t) = a(\cos rt - \tfrac{\lambda}{r} \sin rt) e^{\lambda t},$$
$$y(t) = -a \left(\lambda \cos rt + \tfrac{2}{r}(b - \tfrac{\lambda^2}{2}) \sin rt \right) e^{\lambda t}$$

as long as $x(t) < a$. Let t^* be the smallest real so that $t^* > 0$ and $x(t^*) = a$. If $y(t^*) \leq -\lambda a + \mu$, then we take $y_B = y(t^*)$ and the curve $\Gamma = [A, B] \cup \mathcal{P}$ is the boundary being looked for. This situation is displayed in Figure 5.4. If we now have $y(t^*) > -\lambda a + \mu$, we again consider the solution of system (1.5) by reversing the time but with $(x(t^*), y(t^*))$ as the initial condition. This solution crosses the segment $\mathcal{I}$ at the point B that is looked for. If this solution does not present an intersection with $\mathcal{I}$, we are in the presence of an unstable cycle that can be defined in a classical sense given by the resolution of (4.7). Nevertheless, we have not succeeded in establishing

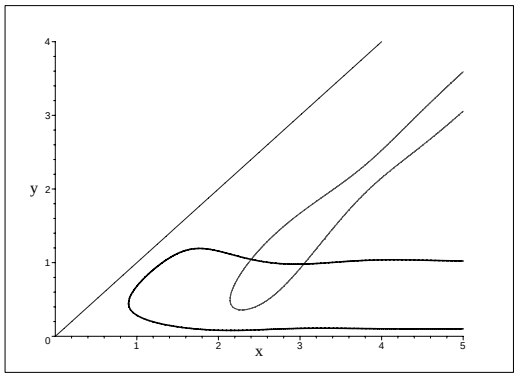

FIG. 5.3. *Curves C_1 (thick line) and C_2 (thin line). The line $y = x$ is represented. The parameters are those of Figure* 5.4.

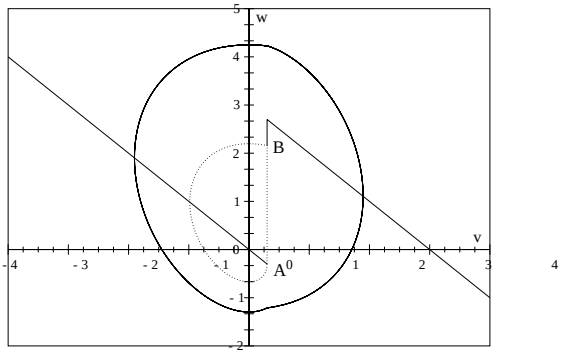

FIG. 5.4. *Stable limit cycle (full line) and unstable limit cycle (dotted line) marking the boundary with the domain of attraction of* $(0,0)$. *The parameters are* $\lambda = 1$, $a = 0.3$, $b = 2$, *and* $\mu = 3$.

precise links between the existence of the point B and the solutions of (4.7).

Another approach is to consider a family of *near* systems, the solutions of those tending towards those of (1.5). From this technique arises the mathematical difficulty of the notion of limit being considered. However, let us define the system

$$\begin{aligned} \frac{dv}{dt} &= p_\delta(v) - w, \\ \frac{dw}{dt} &= bv, \end{aligned} \tag{5.6}$$

where $p_\delta(x) = -\lambda x + \mu h_\delta(x - a)$ and h_δ is the continuous function defined by

$$h_\delta(x) = \begin{cases} 0 & \text{if } x \le 0, \\ \frac{x}{\delta} & \text{if } 0 < x < \delta, \\ 1 & \text{if } x \ge \delta. \end{cases}$$

Numerically speaking, for small values of δ, the orbits of (5.6) are a good approximation of those of system (1.5). This result requires careful study, which we have not undertaken here. The convenience of (5.6) is that they allow the application of classical theorems of existence as well as the usual numerical integration methods like the

Runge–Kutta method. In addition, it seems possible to extend the results obtained for the discontinuous system to these continuous piecewise linear systems as $\delta \to 0$.

6. Large relaxation time. In this section, we study the case of a small λ which corresponds to a system with a large time constant. When $\lambda \ll 1$, the asymptotic expansion of (4.8) is written as

$$F(x,y) = -2a\sqrt{b}(1-\cos(2\sqrt{b}x)) + \lambda\mu(x\sin(2\sqrt{b}y) - y\sin(2\sqrt{b}x)) + O(\lambda^2). \tag{6.1}$$

Therefore we have

$$T = \frac{2\pi}{\sqrt{b}} + O(\lambda),$$
$$\tau = \frac{\pi}{2\sqrt{b}} + O(\lambda).$$

The existence of a periodic solution for small λ has already been noted in section 4. We obtain a single solution for τ which is related to the big cycle. The small cycle cannot be captured by this limiting situation. Using the third order expansion of $F(x,y)$ and $F(x,y-x)$, we find that

$$\begin{aligned} T &= \frac{2\pi}{\sqrt{b}} + \frac{\pi}{4b\sqrt{b}}\lambda^2 + O(\lambda^3), \\ \tau &= \frac{\pi}{2\sqrt{b}} - \frac{a\pi}{2\mu\sqrt{b}}\lambda + \frac{\pi}{16b\sqrt{b}}\lambda^2 + O(\lambda^3). \end{aligned} \tag{6.2}$$

Using the first order expansion of T, we calculate

$$f(t) = -\frac{2\mu}{\lambda\pi}\sin\sqrt{b}t + O(1).$$

Calculation of the approximation of v, using (4.5), (4.4), (6.2), gives

$$v(t) = \frac{2\mu}{\lambda\pi}\cos\sqrt{b}t + O(1). \tag{6.3}$$

The approximation that is obtained coincides with the term carrying the fundamental frequency in the Fourier series of v. Using $w_0 = \frac{\mu}{2}$, the limit cycle approximation is given by

$$v^2 + \frac{1}{b}\left(w - \frac{\mu}{2}\right)^2 = \frac{4\mu^2}{\lambda^2\pi^2} + O(1). \tag{6.4}$$

Numerically speaking, this approximation appears to be a good one, even for large values of λ. It is possible to refine the approximation obtained by using higher order terms in the expansion (6.2). We then find

$$v(t) = \frac{2\mu}{\lambda\pi}\cos\sqrt{b}t + \frac{\mu}{\pi}\left(\frac{\pi}{\sqrt{b}} - t\right)\cos\sqrt{b}t + O(\lambda). \tag{6.5}$$

Remark 1. The terms in the expansion of v have zero mean value.

Remark 2. Approximation (6.5) must be considered for $t \in [0,T]$. This raises the problem of matching at T, a problem that we will not discuss here since we will use

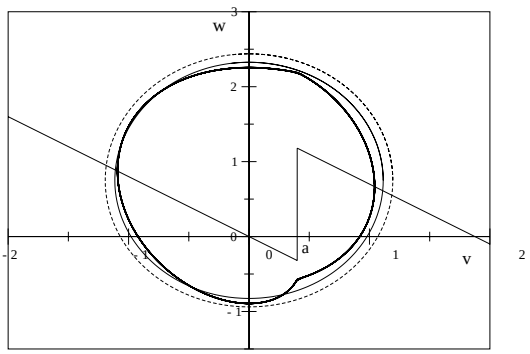

FIG. 6.1. *Stable limit cycle of system* (1.5) *(thick line) and its approximations given by* (6.6) *(thin line) and* (6.4) *(dotted line). The parameters are* $\lambda = 0.8$, $\mu = 1.5$, $a = 0.4$, *and* $b = 2$.

approximation (6.3). From a numerical point of view, this approximation appears to be better for a wide range of values of λ. This is due to the appearance of secular terms in the asymptotic expansion (6.5).

Remark 3. If the expansion of T is continued, there is no term of third order, which leads us to believe that T presents an even power series expansion.

It is interesting to compare the approximation that has just been calculated with the one previously obtained (5.5). The value found for the largest cycle, in the case of small (λ, μ), gives

$$v^2 + \frac{1}{b}\left(w - \frac{\mu}{2}\right)^2 = \frac{2\mu^2}{\lambda^2\pi^2}\left(1 + \sqrt{1 - \frac{\lambda^2\pi^2 a^2}{\mu^2}}\right), \tag{6.6}$$

which, for small values of a, corresponds to the approximation (6.4). Numerically speaking, this approximation is very precise, as shown in Figure 6.1.

Using approximations (6.4) and (6.6), we can formulate an approximate necessary condition for the existence of a periodic solution since the expression of the vector field requires that the interior of the limit cycle contains the point $(a, -\lambda a)$, which yields to

$$b > \frac{(\lambda a + \frac{\mu}{2})^2}{d^2 - a^2} \tag{6.7}$$

with $d \in \{d_\lambda, d_{\lambda\mu}\}$, where d_λ^2 and $d_{\lambda\mu}^2$ are the values of the right-hand term of equations (6.4) and (6.6), respectively. Approximation (6.4) imposes the condition $a < \frac{2\mu}{\lambda\pi}$, which is a requirement greater than that given by (6.6). Even far from its validity domain, approximation (6.7) remains useful. When $\lambda = 1$ and $\mu = 1$, Figure 4.1 shows the approximation (6.7) obtained from the study for small λ (curve C_λ) and for small (λ, μ) (curve $C_{\lambda\mu}$). For small values of a, the requirement appears to be a little too strong, in that it imposes $b > \frac{\pi^2}{16}$ when $b > \frac{1}{4}$ would do.

Let us precisely give the bifurcation giving rise to the stable limit cycle for small λ. In this case, the system under study may be considered as a perturbation of

$$\frac{dv}{dt} = \mu h(v - a) - w,$$

(6.8)
$$\frac{dw}{dt} = bv.$$

System (6.8) was previously considered as a perturbation of the Hamiltonian system obtained for $\mu = 0$. However, in this analysis, μ is not considered as a small parameter. The harmonic balance method leads to the following two cases:

- τ does not exist and we find a family of periodic solutions defined by

  (6.9)
  $$H(v, w) = c^2, \quad \text{where} \quad c < a,$$

  where H is given by (5.2).
- If we assume that τ exists, we find that the Fourier series expansion of v is divergent and therefore there is no periodic solution such as $v > a$.

For an initial condition outside the ellipse obtained with $c = a$ in (6.9), a solution of (6.8) tends towards infinity since the orbits of system (6.8) are given by

$$v^2 + \frac{1}{b}w^2 = \text{const} \quad \text{for} \quad v < a,$$
$$v^2 + \frac{1}{b}(w - \mu)^2 = \text{const} \quad \text{for} \quad v > a,$$

and, if we consider the sequence $(w_n)_{n\in\mathbb{N}}$ associated with the Poincaré section defined by $v = a$, we have

$$w_n = w_{n-1} + 2\mu.$$

Thus, the orbits spiral around the origin and move away from it. The addition of the perturbation $-\lambda v$ leads to (i) the destruction of the family of periodic solutions so that $v < a$ (the origin becomes a stable focus) and (ii) the appearance of a limit cycle towards which the orbits converge while spiraling. We have seen that the birth of the limit cycle takes place at ∞ since the diameter of the ellipse can be made arbitrarily large. We are going to specify this result in bifurcation terms.

We write (r, θ) for the polar coordinates of (v, w) and, because we are interested in the system at ∞, we introduce the variable $u = \frac{1}{r}$. Given a change of variables, we can consider the case $b = 1$. Writing (1.5) using the new variables gives

$$\frac{du}{dt} = \lambda u \cos^2\theta - u^2\mu\cos\theta h\left(\frac{\cos\theta}{u} - a\right),$$
$$\frac{d\theta}{dt} = 1 + \lambda\sin\theta\cos\theta - u\mu\sin\theta h\left(\frac{\cos\theta}{u} - a\right).$$

We are interested in the behavior of the system for $\lambda \ll 1$ and u close to 0. In this case, θ is a fast variable, the dynamic of which can be approximated by $\theta' = 1$. The averaging theorem [11] enables us to consider the approximation given by the averaged system

$$\frac{du}{dt} = \frac{1}{2\pi}\int_0^{2\pi} d\theta \quad \lambda u\cos^2\theta - u^2\mu\cos\theta h(\cos\theta),$$

where we have used the approximation $h(\frac{\cos\theta}{u} - a) \sim h(\cos\theta)$ for small $u > 0$.

We find

$$\frac{du}{dt} = \Big(\frac{\lambda}{2} - \frac{\mu}{\pi}u\Big)u,$$

which shows the appearance of a stable limit cycle. The radius of this cycle is given by $u = \frac{\lambda\pi}{2\mu}$ and is in agreement with the approximation (6.4). This is a supercritical Andronov–Hopf bifurcation which appears at ∞. As far as we know, such a bifurcation was mentioned for the first time in [37].

7. Excitability and oscillations. We may interpret the appearance of oscillations as the limit behavior of a *spike solution* when the number of action potentials becomes large. We are going to give mathematical content to this statement by showing that the periodic solution, written as $v_\gamma(t)$, can be obtained as the limit of the *spike solution*, written as $v_n(t)$, when the number of spikes n tends towards $+\infty$. Most often, the birth of oscillations is shown in terms of bifurcations using equations based on system parameters. Here, the characterization is directly obtained from the system solutions.

We consider (3.7), omitting the transient regime containing v_0, because we are interested in the asymptotic state. Using a time shift, we consider the symmetrical sum obtained from (3.7):

$$v_n(t) = \sum_{k=-n}^{n} \phi(t - t_{2k}) - \phi(t - t_{2k+1}),$$

where

$$\phi(t) = h(t)\varphi(t)$$

and φ is given by (3.8). If we assume that the spikes are produced at periodic time intervals, there exist T and τ so that $t_{2k} = kT - \tau$ and $t_{2k+1} = kT + \tau$. The existence of the pair (T, τ) is studied in section 4. We should also note that the assumption just made is linked to v_0 insofar as not all orbits converge towards a periodic solution.

We have $\phi \in L^1(\mathbb{R})$, and the Poisson formula, in the space of tempered distributions $\mathcal{S}'$, gives us

$$\lim_{n\to+\infty} v_n(t) = \frac{1}{T}\sum_{-\infty}^{+\infty} \widehat{\phi}\left(\frac{k}{T}\right) 2\ i\ \sin\left(2\pi\tau\frac{k}{T}\right) e^{2i\pi k\frac{t}{T}}.$$

As ϕ', the distributional derivative of ϕ, is in $L^1(\mathbb{R})$, equality occurs for every t, and we have the uniform convergence of the series. We calculate that

$$\widehat{\phi}(w) = \frac{2\mu}{2b - 8\pi^2 w^2 + 4i\pi\lambda w},$$

giving

$$\lim_{n\to+\infty} v_n(t) = v_\gamma(t),$$

where $v_\gamma(t)$ is the periodic solution given by (4.3), which establishes the stated result.

8. Discussion. Estimation of the maximal number and relative positions of limit cycles of a two-dimensional autonomous system is an open problem corresponding to the second part of the sixteenth Hilbert problem. Given the difficulty of the general problem, mathematicians have become interested in a particular system class, the Liénard system:

$$\begin{aligned} \frac{dv}{dt} &= p(v) - w, \\ \frac{dw}{dt} &= v. \end{aligned} \tag{8.1}$$

Most results concern the case in which p is a polynomial function. Even in this case, there are no general theoretical results and most approaches are local ones insofar as they determine only the number of limit cycles for certain parameter values. Limit cycles are obtained using perturbation methods via a Hopf bifurcation or a global bifurcation (see [28] and the references therein). Some global approaches make it possible to link the number of limit cycles to the roots of a polynomial [10], [25], but the results remain to be demonstrated.

We have studied the Liénard system where p is a piecewise linear function (linear on $]-\infty, a[$ and on $]a, +\infty[$) allowing a finite jump discontinuity at $a > 0$. We have shown that the limit cycles are characterized by the roots of a system of two transcendental equations. These roots correspond to the period of the oscillations and to an additional parameter. We have obtained an explicit expression of the limit cycles as a function of these two roots. Our results are in agreement with the local methods in that (i) the fold limit cycle bifurcation can be obtained as a perturbation of a center and (ii) the large size limit cycle can be obtained as a Hopf bifurcation at ∞. We might also consider the limit cycle obtained as $a \to 0$ as a kind of *degenerated* Hopf bifurcation. We have shown the existence of at least two limit cycles, and arguments similar to those used in [27] should enable us to demonstrate that at most two limit cycles exist. When p is a polynomial function, such a result can be obtained only for a polynomial of degree at least five [36]. It has already been observed that discontinuous dynamical systems have a richer dynamic than regular dynamical systems [9]. The obtained results, and numerical simulations that we have carried out, lead us to formulate two conjectures concerning the number of limit cycles of a piecewise linear Liénard system.

Conjecture 1. The Liénard system (8.1), with p piecewise linear on $n+1$ intervals and having n finite jump discontinuity, has up to $2n$ limit cycles.

Conjecture 2. The Liénard system (8.1), with p continuous and piecewise linear on $n+1$ intervals, has up to n limit cycles.

Conjecture 2 generalizes the result obtained in [26], [27] in which the authors proposed a continuous, and piecewise linear on $2n+1$ intervals, function p so that Liénard system (8.1) has exactly n limit cycles. The parity and periodicity of p appear to be the two properties that limit the number of limit cycles.

Beyond mathematical interest of the system under study, it is of great importance in mathematical biology where excitable systems are widely used [31], [17]. Our system is a piecewise linear version of the FitzHugh–Nagumo equations with a simplified version of the recovery process which provides an understanding of the behavior in a transparent way. First of all, we have distinguished between two dynamics according to the value of $\lambda^2 - 4b$. When $\lambda^2 - 4b \geq 0$, the system is termed *leaky integrator* and only a single spike can be emitted in response to an excitation given by the input $I = I_0\delta(t - t_0)$. When $\lambda^2 - 4b < 0$, the system is referred as being *resonator*. In this case, the response is obtained as the superposition of

$$v(t) = e^{-\frac{t}{\eta}} \sin \Omega t,$$

where $\eta = \frac{1}{\lambda}$ and $\Omega = \sqrt{b - \frac{\lambda^2}{4}}$ denote, respectively, the time constant and the natural frequency of the system. When this response is a finite sum, we obtain what we call a *spike solution*. In the case of infinite sum, we obtain a periodic solution for which an analytical expression is given by

$$v = \frac{1}{2}(S_{-\tau}f - S_{\tau}f),$$

where S is the shift operator $S_y g(x) = g(x+y)$ and f is a function that depends on the period T. In the general case, it is not possible to have an explicit expression for T and τ. However, we have obtained a set of approximate solutions which shows that the period is well approximated using

$$T = \frac{4\pi}{\sqrt{4b - \lambda^2}}.$$

We have detected two possible mechanisms for the appearance of oscillations: a fold limit cycle bifurcation and a Hopf bifurcation at infinity.

A significant biological interest is the extension of our analysis to the complete system where the recovery process is given by

$$\frac{dw}{dt} = b(v - \gamma w).$$

In this case, a change of variables allows us to rewrite the FitzHugh–Nagumo system as the generalized Liénard equation

$$\begin{aligned} \frac{dv}{dt} &= F(v) - w, \\ \frac{dw}{dt} &= G(v). \end{aligned} \tag{8.2}$$

When p is the polynomial function (1.2), the two functions F and G are third degree polynomial functions and, in contrast to the case $\gamma = 0$, three limit cycles can be obtained. We plan to explore the piecewise linear case for which an analytical study is possible but yields much more complicated expressions than those obtained in this paper. Results on such an extension will be reported elsewhere.

There remains much work to be done on our system. The simplicity of the model allows us to hope for analytical results for bursting [35]. The coexistence of a limit cycle and a stable fixed point favors the existence of such a phenomenon when an additional slow variable is added to the system. Another aspect is the study of coupled equations. In particular, we hope for promising results concerning the dynamics of coupled oscillators using the approximations obtained for the periodic solution. As a first step, we plan to explore the forced system in the context of forced piecewise linear systems [4], [21].

Acknowledgments. The author thanks J. Demongeot and J. L. Martiel for many helpful discussions.

WAVE PROPAGATION IN SPATIALLY DISTRIBUTED EXCITABLE MEDIA*

JIANBO YANG†, SERAFIM KALLIADASIS†, JOHN H. MERKIN‡, AND STEPHEN K. SCOTT§

Abstract. Consider wave propagation through regions of no excitability (gaps) in an otherwise excitable medium. Propagation in the gaps takes place via simple diffusion. We extend the geometric method for a one-gap system developed by Lewis and Keener to the case of two and three gaps, and we obtain conditions for successful wave propagation and failure. We show that, like the one-gap system, steady-state multiplicity for the case of two gaps arises via a limit point bifurcation. We also demonstrate that in some cases the presence of a large number of gaps promotes wavefront propagation.

Key words. spatially heterogeneous excitable media, bistable, successful propagation/failure

1. Introduction.

Wave propagation in spatially distributed media is relevant to a large variety of biological and chemical systems, including nerve signal transmission, population dynamics, and combustion. There are many different ways in which spatial inhomogeneity can be created. In all cases, spatial variation of the parameters in reaction-diffusion equations has been shown to have important consequences for traveling wave propagation and pattern formation. For example, Kay and Sherratt [1, 2] considered the effect of spatial variation of the demographic kinetic parameters on predator-prey systems. They were able to demonstrate that a small amount of noise has no appreciable effect on the die-out of the regular oscillations after the invasion of a front of predators with an irregular wake. However, moderate to large levels of noise could lead to the persistence of regular oscillations, but generally with a spatial frequency different from that which would normally be generated behind the invasion front. For a scalar reaction-diffusion equation with a cubic kinetic term and with a spatially varying diffusion coefficient, Xin [3] showed that, if the variation of the diffusion coefficient from its mean is sufficiently large, traveling waves no longer exist, so that a wavefront will begin to propagate from given initial conditions but will then stop advancing—a phenomenon known as "quenching" or "wave-block." Several other authors have analyzed propagation with spatially varying diffusion coefficients including wave-blocking phenomena in bistable reaction-diffusion systems [4, 5] and the excitable FitzHugh–Nagumo equation [6].

In this paper we study wave propagation through localized regions of no excitability in an otherwise excitable medium. Following Sneyd and Sherratt [7] and Lewis and Keener [8], we will refer to these regions of no excitability as the "gaps." Such a gap model has relevance in several areas. For instance, the role of the gaps is analogous to

that of fire breaks in flame propagation [9]. In the context of Ca^{2+} wave propagation between inositol 1,4,5-trisphosphate (IP_3) receptors [7], the gaps correspond to regions of low IP_3 concentration. The propagation of electrical excitation in cardiac tissue also encounters regions of depressed excitability. For instance, the atrioventricular node, the normal electrical pathway between the atria and ventricular myocardium, is a localized region of low excitability and conductivity [8]. Finally, gaps can be used to model demyelination of nerve fibers [10, 11] resulting from diseases of the central nervous system [12]—in this case, the loss of myelin slows or even stops the transmission of action potentials through the nerve cells.

Our excitable medium model is the bistable reaction-diffusion equation

$$u_t = u_{xx} + g(u,x) \tag{1a}$$

on $-\infty < x < +\infty$, $t > 0$, where the function $g(u,x)$ is defined piecewise as follows:

$$g(u,x) = \begin{cases} f(u), & -\infty < x \le x_1,\ x_2 < x \le x_3,\ \dots,\ x_{2n} < x < +\infty, \\ 0, & \text{otherwise.} \end{cases} \tag{1b}$$

The kinetic term f is taken to be the cubic function

$$f(u) = u(1-u)(u-\alpha), \qquad 0 < \alpha < \frac{1}{2}, \tag{1c}$$

that describes excitation outside the n gaps, $[x_i, x_{i+1}]$ for $i = 1, 3, \dots, 2n-1$. Equation (1a) is subject to the boundary conditions

$$u \to 1, \qquad x \to -\infty,$$

$$u \to 0, \qquad x \to +\infty, \tag{1d}$$

with all the x derivatives tending to zero as $x \to \pm\infty$. The bistable equation is essentially a version of the nonlinear cable equation that has been used to describe the flow of electricity along nerve axons [12]. Within the context of nerve impulse transmission in particular, the bistable equation can be used as a model for myelinated nerve axons. The same equation was also adopted by Lewis and Keener [8] as a model system for the atrioventricular node in the heart. These authors studied the existence, stability, and bifurcation properties of the steady states of the bistable equation (1a) in the presence of a single gap. They developed a phase plane/geometric method that allows the derivation of criteria for wave-block: their analysis indicates that wave-block is associated with a limit point bifurcation; i.e., there exists a minimal gap width above which wave-block occurs. Furthermore, they considered different gap dynamics, including a leaky gap with a linear decay of u in addition to diffusion, and a gap with small but nonzero excitability. A gap with linear decay was also considered by Grindrod and Sleeman [10] and Grindrod [11] to describe leakage of ionic transport from the axoplasm into small pockets of plasma held within the myelin sheath, while a general analysis of the steady states of the bistable equation with a spatially varying reaction term has recently been performed by Salazar and Solà-Morales [13].

The mechanism for successful propagation and failure through an active medium with localized regions of no excitability was studied in detail by Poptsova and Guria [14]. These authors performed initial-value computations of the bistable equation as well as the two-variable excitable FitzHugh–Nagumo model, to demonstrate the

existence of a critical gap width for a single-gap system above which wave-block (referred to by the authors as "locking-up") occurs. They also performed initial-value computations for a periodic sequence of gaps and spacings between the gaps, and they demonstrated the existence of a critical separation distance below which wave-block occurs.

The problem of wave propagation in the presence of several gaps separated by different spacings is considered here. This is a substantially more complex situation than propagation in a heterogeneous medium with a single gap. Our analysis parallels the work by Lewis and Keener [8] and extends their geometric method to a hybrid geometric-algebraic method for the case of multiple gaps. The method allows us to obtain criteria for propagation failure in the bistable equation (1), where gap dynamics is governed purely by diffusion, and to gain insight into the underlying dynamical structure of the problem. Although the geometric method facilitates the visualization of the steady states in the phase plane, setting up the equations governing these steady states and solving for the critical quantities directly does give a systematic way to construct these steady states. For two gaps with lengths less than the critical length for a medium with a single gap, our analysis reveals the existence of a critical spacing between the two gaps, below which the system approaches a steady state and propagation is suppressed. However, if the first gap length is larger than the critical length, with the second gap still being less than the critical length, there are two critical values for the spacing: for values of the spacing less than the smaller critical value and greater than the larger critical value, the system approaches a steady state. The same phenomenon occurs in a medium with three gaps, provided that the final gap length is less than the critical length for a medium with a single gap. For a given value of the spacing between the first two gaps, there are *two* critical values for the second spacing: for values of the second spacing less than the smaller critical value and greater than the larger critical value, the system approaches a steady state. This somewhat surprising result implies that the final spacing has a profound impact on wave propagation and, in fact, promotes propagation across purely diffusive regions only when its value is between the two critical values.

Hence, the bistable equation behaves in a dramatically different fashion than the system we studied previously [15], in which a heterogeneous medium was considered using a cubic autocatalysis model with autocatalyst decay in the gaps, which were defined as the regions where the reactant concentration was zero. In this two-variable model, the autocatalyst was taken to diffuse and react with a reactant loaded at a constant initial concentration throughout a reaction domain except in the gap regions. One of our main findings was that if any gap length is larger than a critical value, wave propagation will be suppressed; unlike the case studied here, for three gaps in the reaction domain there was only one critical value for the second spacing. Finally, our predictions from the hybrid geometric-algebraic method are in excellent agreement with numerical solutions of the system in (1) as an initial-value problem.

2. Wave propagation: Success and failure in a single-gap domain. In the absence of heterogeneities, the bistable equation in (1) admits traveling wave solutions that connect the two stable rest states, $u = 0$ and $u = 1$ (see, for example, Keener and Sneyd [12]). The solution is of the form

$$u(x,t) = u(\xi) = \frac{1}{2}\left[1 - \tanh(\sqrt{2}\xi/4)\right], \qquad c = \frac{1-2\alpha}{\sqrt{2}}, \tag{2}$$

where $\xi = x - ct$. Note that the direction of propagation changes at $\alpha = 1/2$. This traveling wave solution is a heteroclinic trajectory that connects the two saddle-points

$(0,0)$ and $(1,0)$ in the (u, u_ξ) phase plane. In addition, the bistable equation exhibits threshold phenomena (see [16]). Specifically, if the initial data is sufficiently small, the solution of the bistable equation approaches zero uniformly in the limit $t \to \infty$. However, there are initial conditions with compact support lying between 0 and 1 for which the solution approaches 1 uniformly for large times and, as a consequence of the comparison theorem for scalar parabolic operators, any two solutions of the bistable equation that are ordered at some time remain ordered for all subsequent times. Hence, initial conditions larger than the threshold will initiate a solution that approaches 1 for large times. Finally, the traveling wave solution of the bistable equation has been shown to be stable by Fife and McLeod [17], and in fact, starting from any initial data that lies between 0 and α as $x \to +\infty$ and between α and 1 as $x \to -\infty$, the solution will become arbitrarily close to some phase shift of the traveling wave solution (2) for sufficiently large times.

The impact of a single gap, of width $W = x_2 - x_1$, on the propagation of an established permanent-form traveling wave was considered in detail by Poptsova and Guria [14] and Lewis and Keener [8]. For W small but nonzero, the dynamics is similar to the spatially uniform case with $W = 0$. Poptsova and Guria [14] and Lewis and Keener [8] demonstrated that, as the front of the wave approaches the gap, it slows down because there is no excitability within the gap. For W sufficiently small, the front is able to supply sufficient u across the gap to excite the upstream side of the gap. Thus, after a delay, the wavefront can propagate through the gap and, after a sufficiently large distance, the front is able to recover fully and reestablish its permanent waveform. As W is increased, the delay increases, but the wavefront is still able to penetrate across the heterogeneity. Eventually, for W larger than some critical value W_c, the solution approaches a spatially inhomogeneous steady state of system (1), with $u_t = 0$ and without any wave development beyond the gap. A similar wave-block phenomenon was observed in the cubic autocatalytic system with decay studied in [15].

This behavior is confirmed from a full numerical solution of the bistable equation (1) as an initial-value problem in an extended domain, with long intervals before the first gap and after the last gap, to establish domain independence and to ensure that u approaches the two rest states 1 and 0 on the space spanned by the eigenvectors obtained from the linearized version of (1) at the infinities. We utilize a standard Crank–Nicolson-type implicit scheme for solving parabolic equations, with the x-derivatives approximated by central differences. (The advantages of an implicit scheme over an explicit scheme are obvious, as an explicit scheme would require very short time steps for a reasonable spatial accuracy.) The translational invariance of the system in x allows us to take $x = 0$ as the starting point of the computations. We start the integrations with $u = 0$ everywhere except in the first 100 grid points, where we set $u = 1.0$. The time-discretization uses a two-level scheme. In advancing from time t to time $t + \Delta t$, we replace the time derivative terms by first-order differences involving the solution at the old time level and the as-yet-unknown solution at the new time level. We evaluate the other terms using a weighted average of the solution at the two time levels. At each time level, the fully discrete system is a set of nonlinear algebraic equations, which we solve using Newton–Raphson iteration. The accuracy of the numerical simulations was determined by careful convergence tests under mesh refinement and time-step sizing. In all cases, grid sizes and time steps were kept smaller than 10^{-1}, while in some cases grid sizes and time steps as small as 10^{-3} were employed to accurately resolve critical gaps and spacings.

Our results confirm the value $W_c \simeq 6.5$ for $\alpha = 0.3$ obtained by Lewis and

Keener [8]. Figure 2.1 depicts the evolution of the wavefront towards a gap with width $W = 7.0$. The wavefront slows down and eventually stops. The final result of the evolution is a steady-state solution of the bistable equation. Lewis and Keener developed a phase plane method to construct the steady-state solutions and to predict the critical width W_c. Their method is essentially based on piecing together in the phase plane the invariant manifolds that constitute the steady-state solutions. Below we offer an algebraic version of the geometric method of Lewis and Keener.

Figure 2.2 shows the steady state of Figure 2.1 in the (u, u_x) phase plane. Three

curves in the phase portrait are of particular interest: (i) the curve $\mathcal{H}$, which is a portion of the homoclinic orbit emanating from the saddle point at (0,0) and is described by $u_x = -\sqrt{-2\int_0^u f(v)dv}$; (ii) the transfer map of the homoclinic orbit by the flow in the gap which maps points on $\mathcal{H}$ onto a new curve ψ_W defined by $\psi_W : [u, u_x] \mapsto [-u_x W + u, u_x]$; (iii) the stable manifold of the saddle point $(u, u_x) = (1, 0)$ described by $u_x = -\sqrt{2\int_u^1 f(v)dv}$. Hence, the equations describing the steady state are

$$u_x^B = -\sqrt{-2\int_0^{u^B} f(v)dv}, \tag{3a}$$

$$u^C = -u_x^B W + u^B, \tag{3b}$$

$$u_x^C = -\sqrt{2\int_{u^C}^1 f(v)dv}, \tag{3c}$$

$$u_x^B = u_x^C, \tag{3d}$$

where the superscripts B and C refer to points B and C, respectively, in the phase plane and in Figure 2.1. The above are four equations for the five unknowns u_x^B, u^B, u_x^C, u^C, and W. The existence of real solutions to these equations ensures that the transfer map and the stable manifold of (1,0) intersect. However, the intersection can be either tangent or transversal. To ensure a tangent intersection, and hence intersection at only one point, the slopes of the transfer map and the stable manifold must coincide at point C. For this purpose we must express ψ as a function of u. However, it is not possible to obtain an explicit expression for $\psi(u)$, and therefore we resort to the parametric representation

$$u = -W\sqrt{-2\int_0^t f(v)dv} + t,$$

$$\psi \equiv u_x = -\sqrt{-2\int_0^t f(v)dv},$$

where $0 \le t \le t_{\max}$ with $t_{\max} = (2/3)(1+\alpha)+(1/3)\sqrt{4-10\alpha+4\alpha^2}$. Hence, the slope ψ_u can be easily obtained: $\psi_u = (du_x/dt)/(du/dt)$. At point C, u_x evaluated from ψ, $u_x = -\sqrt{-2\int_0^{t^C} f(v)dv}$, must be equal to u_x evaluated from the stable manifold, $u_x = -\sqrt{2\int_{u^C}^1 f(v)dv}$. A comparison of $\sqrt{-2\int_0^{t^C} f(v)dv} = \sqrt{2\int_{u^C}^1 f(v)dv}$ with (3a), (3c), and (3d) indicates that $t^C = u^B$. Hence, the condition of equal slopes at C,

$$\psi_u(t^C) = \frac{f(u^C)}{\sqrt{-2\int_1^{u^C} f(v)dv}},$$

can be expressed in terms of u^B and u^C and, after being combined with (3a)–(3d), gives a system of three nonlinear algebraic equations:

$$\int_0^{u^B} f(\upsilon)d\upsilon = \int_1^{u^C} f(\upsilon)d\upsilon, \tag{4a}$$

$$f(u^B)f(u^C) = 2\frac{f(u^B) - f(u^C)}{u^B - u^C}\int_0^{u^B} f(\upsilon)d\upsilon, \tag{4b}$$

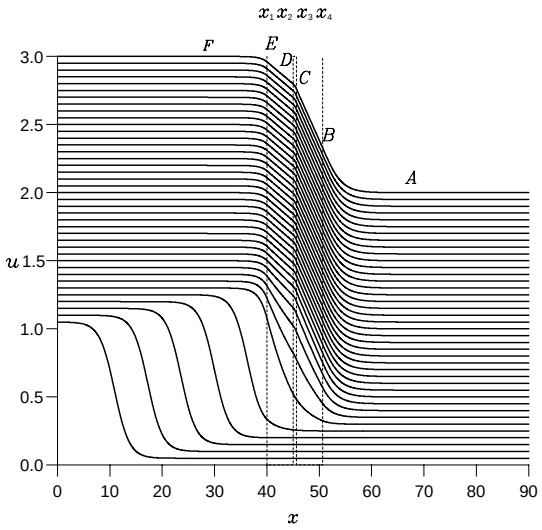
$$W_c = \frac{u^C - u^B}{\sqrt{-2\int_0^{u^B} f(\upsilon)d\upsilon}}. \tag{4c}$$

The first two equations can be solved with a simple trial-and-error procedure to obtain u^B and u^C. The critical gap width W_c can then be obtained explicitly from (4c). For $\alpha = 0.3$, $W_c = 6.402$. An asymptotic analysis of these equations as $\alpha \to 1/2$ shows that $W_c \sim 2\sqrt{2}[(1-2\alpha)/12]^{1/3}$ with $u^{B,C} \sim 1 - [(1-2\alpha)/12]^{1/3}$.

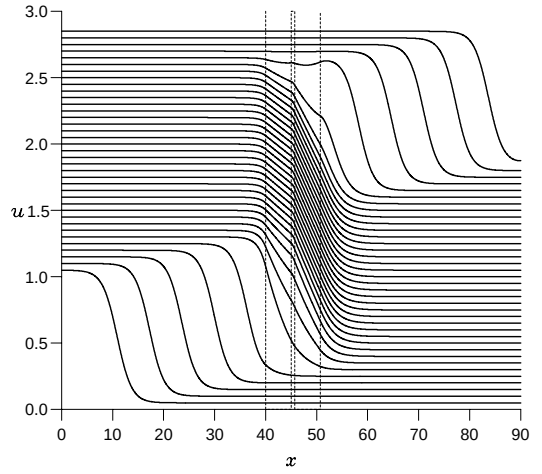
Finally, two points of interest in the phase portrait are u_1, the maximum u value on the homoclinic orbit $\mathcal{H}$ (see Figure 2.2), and u_2, the u value on the stable manifold of (1,0) with a slope the maximum of $-u_x$ on the homoclinic orbit. Lewis and Keener [8] pointed out that different kinetic terms f that are the same on the intervals $0 < u < u_1$ and $u_2 < u < 1$ would give the same W_c and the same steady states for $W > W_c$. This is simply due to that fact that f does not play a role in the purely diffusive gap. The kinetic term f, however, is critical in determining the shape of the homoclinic orbit and the stable manifold. The same argument can be readily extended to the case of two- and three-gap systems studied in the next two sections.

3. Propagation in a domain with two gaps. We consider the propagation of a wavefront in a domain with two gaps of widths W_1 and W_2. The region of excitability of length S between the two gaps will boost any wave passing through the first gap before it encounters the second gap. Hence, we seek to determine the minimum separation distance S_c between the two gaps that allows the wavefront to propagate successfully through the whole domain. Numerical integration of (1) for $\alpha = 0.3$ suggests that $S_c \simeq 0.68$ for $W_1 = W_2 = 5$. Figure 3.1(a) shows wave-block for $W_1 = W_2 = 5.0$ (less than the critical value $W_c = 6.402$ for a domain with a single gap) with a spacing $S = 0.66$. Figure 3.1(b) shows successful propagation of the wavefront for $S = 0.69$ (for the same values of W_1 and W_2).

We now extend the geometric method developed by Lewis and Keener to the case with two gaps. Figure 3.2 shows the phase portrait of the steady state in Figure 3.1(a). As with the one-gap case, we can compute the transfer map $\psi_{W_2} : [u, u_x] \mapsto [-u_x W_2 + u, u_x]$ to obtain the mapped curve ψ and the stable manifold of the saddle-point $(1, 0)$. Notice that the transfer map of the homoclinic orbit is now defined by the last gap W_2, while the first gap W_1 corresponds to curve DE emanating from the stable manifold of (1,0) in the phase plane. Another curve of interest in Figure 3.2 is the phase orbit ϕ tangent to ψ. The monotonicity of ψ_{W_2} in W_2 and the continuity of ψ and any orbit in the phase plane ensures that, for a given W_2, there will be only one orbit tangent to the mapped curve ψ. This phase orbit is given by $u_x = -\sqrt{-2\int_0^u f(\upsilon)d\upsilon + \beta}$, where $\beta = u_x^2$ at $u = 0$ for the phase orbit ϕ. We shall demonstrate that this phase orbit determines the critical spacing for propagation failure.



(a)



(b)

FIG. 3.1. (a) *Failure of wavefront propagation in a domain with two gaps,* $W_1 = W_2 = 5.0 < W_c$ *for a spacing between the two gaps of* $S = 0.66$ *with* $\alpha = 0.3$*;* (b) *successful propagation for* $W_1 = W_2 = 5.0$ *and* $S = 0.69$. *Here* u *is plotted at equal times from time* $t = 22.5$. *The time lapse between successive curves is* 22.5 *time units.*

The condition of equal slopes for ψ and ϕ, along with the fact that u_x^C evaluated from ψ must be equal to u_x^C evaluated from ϕ, gives

$$\frac{f(t^C)}{W_2 f(t^C) + \sqrt{-2\int_0^{t^C} f(v)dv}} = \frac{f(u^C)}{\sqrt{-2\int_0^{t^C} f(v)dv}}, \tag{5a}$$

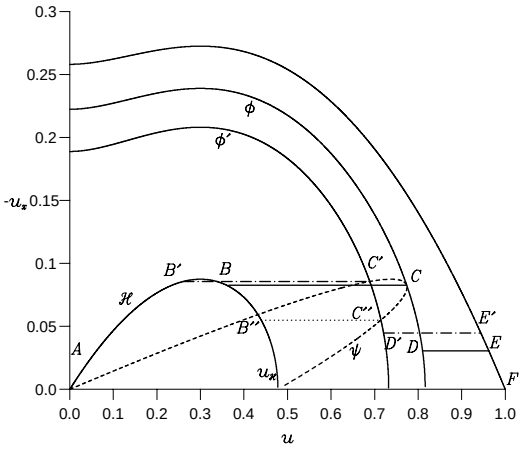


FIG. 3.2. *Phase portrait of $u_{xx} + f(u) = 0$. The phase orbit ϕ determines the critical spacing between the two gaps. The tangent intersection between ϕ and ψ occurring at $\beta = 0.04949$ corresponds to the steady state in Figure* 3.1(a). *The phase orbit through C' and C'' corresponds to $\beta = 0.0357$. The curve $AB'C'D'E'F$ is a stable steady state for $S = 0.49 < S_c$ and $W_1 = W_2 = 5.0$. The curve $AB''C''D'E'F$ is an unstable steady state for $W_1 = W_2 = 5.0$ and $S = 0.13$. Here $u_{\mathcal{H}}$ corresponds to the intersection of the homoclinic orbit with the u-axis.*

where

$$u^C = -W_2\sqrt{-2\int_0^{t^C} f(v)dv} + t^C. \tag{5b}$$

The above form a system of two equations for the two unknowns u^C and t^C, which can be easily solved numerically. The constant β for the phase orbit ϕ can then be obtained from

$$\beta = 2\left\{\int_0^{u^C} f(v)dv - \int_0^{t^C} f(v)dv\right\}, \tag{5c}$$

which fully determines point C and the orbit ϕ. Point B can now be determined from the second gap, which is purely diffusive: $u^C = u^B - u_x^B W_2$, where $u_x^B = u_x^C = -\sqrt{-2\int_0^{t^C} f(v)dv}$, or

$$u^B = u^C - W_2\sqrt{-2\int_0^{t^C} f(v)dv}, \tag{5d}$$

which fully determines point B. We can now locate points D and E from the requirement that u_x^E evaluated from the stable manifold must be equal to u_x^D evaluated from ϕ, which when combined with (5c) yields

$$\int_0^{u^C} f(v)dv - \int_0^{t^C} f(v)dv = \int_0^{u^D} f(v)dv - \int_{u^E}^1 f(v)dv. \tag{6a}$$

TABLE 3.1
Lower critical spacing between two gaps of width W_1 and W_2 obtained from the initial-value problem and the geometric method for $\alpha = 0.3$.

W_1	W_2	Equation (7)
4.0	4.0	0.32
5.0	5.0	0.65
6.0	6.0	1.36

The final equation is then obtained from the first gap: $u^E = u^D - W_1 u_x^E$, with $u_x^E = -\sqrt{2\int_{u^E}^1 f(\upsilon)d\upsilon}$ as obtained from the stable manifold. We therefore have

$$u^E - u^D = W_1\sqrt{2\int_{u^E}^1 f(\upsilon)d\upsilon}. \tag{6b}$$

A comparison of $u_x^B = -\sqrt{-2\int_0^{u^B} f(\upsilon)d\upsilon}$ with $u_x^C = -\sqrt{-2\int_0^{t^C} f(\upsilon)d\upsilon}$ shows that $u^B \equiv t^C$. We then have four equations, (5a), (5d), (6a), and (6b), for the four unknowns u^B, u^C, u^E, and u^D. We can now utilize the phase orbit ϕ to obtain an explicit expression for the critical spacing S_c between the two gaps:

$$S_c = \int_{u^C}^{u^D} \frac{du}{\sqrt{-2\int_0^u f(\upsilon)d\upsilon + \beta}}. \tag{7}$$

For $S < S_c$, wave-block occurs. The dashed-dot line in Figure 3.2 depicts one such steady state for $S = 0.49$; as in the single-gap case, there are actually two steady states, one of which stable (associated with C') as we shall demonstrate later on.

The steady state in Figure 3.1(a) can also be constructed with an alternative method. The phase orbit ϕ in Figure 3.2 can be mapped by the flow in the first gap W_1. The mapped curve, say ψ', can be easily obtained as follows: simple diffusion in the first gap implies $u^E - u^D = -W_1 u_x^D$, which, with u_x^D evaluated from ϕ, gives $u^E - u^D = W_1\sqrt{-2\int_0^{u^D} f(\upsilon)d\upsilon + \beta}$, the equation for ψ'. This curve, not shown in Figure 3.2, will intersect the stable manifold transversally exactly at point E. (It can be shown that the point at which ϕ intersects the $-u_x$ axis will be mapped into the region to the right of the stable manifold of (1,0).) We can then easily locate point D (DE is parallel to the u-axis), and hence a simple integration on ϕ from C to D will give S_c.

Table 3.1 shows the critical spacing obtained from (7) (obviously one must first use (5a), (5c), (5d) and (6a), (6b) to obtain u^B, u^C, u^D, u^E, and β) and the initial-value problem for different values of $W_1 = W_2$. We notice that S_c increases as the gap width increases. The variation of S_c as a function of W_2 for given W_1 ($< W_c$) as obtained from (7) is given in Figure 3.3. Clearly, for a domain with two equal gaps, wave propagation will fail at the final gap if $W_1 = W_2 > W_c$, where W_c is the critical gap width for the single-gap domain. On the other hand, if $W_1 = W_2 = W_c/2$, the wavefront will propagate even if both gaps are brought together, so $S_c \to 0$ in this limit. All curves in Figure 3.3 blow-up to infinity as W_1 approaches W_c from below: from Figure 3.2, as W_2 approaches W_c, point C moves close to the stable manifold of (1,0), while the segment DE moves closer to the u-axis.

For a domain with two unequal gaps, with $W_2 < W_c$ and $W_1 < W_c$, it is clear that, with W_1 fixed, $S_c \to \infty$ as $W_2 \to W_c$. Also if $W_2 < W_c - W_1$, $S_c \to 0$ and

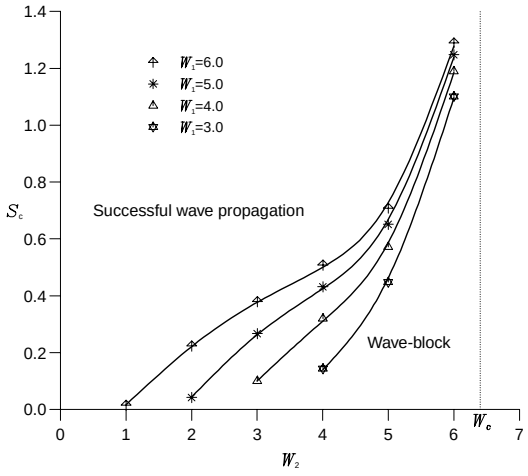

FIG. 3.3. *Critical spacing S_c for a two-gap system as a function of W_2 for different W_1 values with $W_1 < W_c$, obtained from* (7).

the wavefront will propagate successfully in this case even if the two gaps merge. However, for $W_1 > W_c$ the situation can be dramatically different: from Figures 3.4(a) and 3.4(b), where $W_1 = 7.0 > W_c$ and $W_2 = 5.0 < W_c$, we see that there is a critical spacing length between the two gaps for successful propagation. From the initial-value problem, we obtain $S_c \simeq 0.765$ in this case. This phenomenon is quite different from what we found in [15], where we showed that, if any gap length is larger than the critical length for a domain with a single gap, wave propagation is always blocked. Of course, the fundamental differences between the two systems are that the system in [15] is a two-variable model and the dynamics in the gap is characterized by a linear decay of the autocatalytic intermediate species in addition to pure diffusion. Furthermore, we anticipate wave-block when $S \to \infty$ as Figure 2.1 shows. This then implies that there exists a *second* critical length for S above 0.765. From the initial-value problem, we find that this second critical spacing is approximately 5.13; see Figure 3.5 for a numerical experiment with $W_1 = 7.0$, $W_2 = 5.0$, and $S = 5.13$. This is also different from what we met in [15], where a sufficiently large spacing promotes propagation: for the present problem with two gaps, a sufficiently large spacing can inhibit propagation across the purely diffusive region. These observations do not necessarily imply that, whenever there is decay in the gap (as in [15]), facilitation of propagation will not occur. Indeed, we anticipate that facilitation could certainly occur if the decay were sufficiently small with respect to the negative portion of the kinetic term f.

Interestingly, in some circumstances, successful propagation can occur in one direction but not in the other direction; i.e., the assymmetry due to multiple gaps can induce unidirectional block. For instance, consider the case $W_1 = 7$ and $W_2 = 5$. For a spacing S between the two critical spacings, the wave will propagate successfully; however, reversing the direction of propagation, i.e., $W_1 = 5$ and $W_2 = 7$, will block the wavefront for all S as $W_2 > W_c$ for a single-gap system.

Figure 3.6 is a phase plane representation of the steady state in Figure 3.5. ψ_2 is the curve obtained from mapping the homoclinic orbit $\mathcal{H}$ for $W_2 = 5$. However, unlike

the phase portrait in Figure 3.2, where point B is located in the region $u > \alpha$, point B in Figure 3.6 is located to the left of the maximum value of $-u_x$ for the homoclinic orbit. Point B is then mapped into point C, with BC parallel to the u axis. There is a periodic orbit ϕ within $\mathcal{H}$ passing through C, and one can use this periodic orbit to define CD in the spacing between the two gaps. Point D is then connected to point E on the stable manifold of (1,0), with point E defined from the curve ψ_1 resulting from the mapping of the periodic orbit ϕ for $W_1 = 7$. We shall demonstrate that this periodic orbit determines the second critical spacing for a two-gap system.

An algebraic representation of the phase portrait can be obtained as follows: the

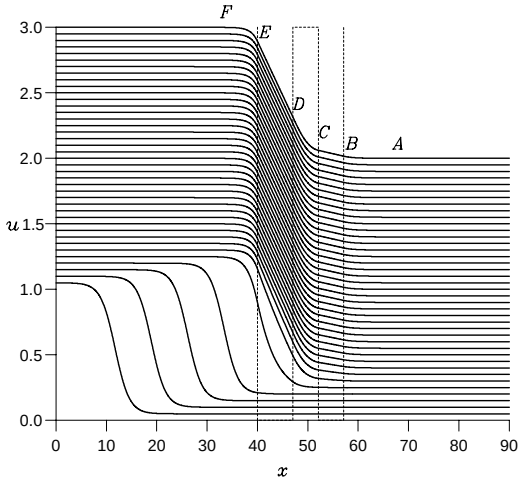

FIG. 3.5. *Wave propagation in a two-gap domain with* $W_1 = 7.0 > W_c$, $W_2 = 5.0 < W_c$, *and* $S = 5.13$, *leading eventually to wave-block. equation of any periodic orbit within $\mathcal{H}$ is given by

$$u_x = -\sqrt{\frac{1}{2}u^4 - \frac{2(\alpha+1)}{3}u^3 + \alpha u^2 - \beta},$$

where $\beta \in [0, \beta_{\max} = -(1/6)\alpha^4 + (1/3)\alpha^3]$, a constant parameterizing the periodic orbits within $\mathcal{H}$, with $\beta = \beta_{\max}$ corresponding to point $(\alpha, 0)$. We now utilize the

parametric representation of ψ_1,

$$u = -W_1\sqrt{\frac{1}{2}t^4 - \frac{2(\alpha+1)}{3}t^3 + \alpha t^2 - \beta} + t \equiv f_1(t,\beta),$$

$$\psi_1 = u_x = -\sqrt{\frac{1}{2}t^4 - \frac{2(\alpha+1)}{3}t^3 + \alpha t^2 - \beta} \equiv f_2(t,\beta),$$

from which the slope of ψ_1 with respect to u can be easily obtained as $du_x/du = (du_x/dt)/(du/dt) = f_1(t,\beta)/f_2(t,\beta)$. To ensure a tangent intersection at E, the slope of ψ_1 with respect to u must be equal to the slope of the stable manifold at E:

$$\frac{f(u^E)}{\sqrt{-2\int_1^{u^E} f(\upsilon)d\upsilon}} = \frac{f_2(t^E,\beta)}{f_1(t^E,\beta)}. \tag{8}$$

The requirement that u_x^E evaluated from ψ_1 equal u_x^E evaluated from the stable manifold gives

$$\sqrt{-2\int_1^{u^E} f(\upsilon)d\upsilon} = \sqrt{\frac{1}{2}(t^E)^4 - \frac{2(\alpha+1)}{3}(t^E)^3 + \alpha(t^E)^2 - \beta}, \tag{9}$$

and, as ED represents a purely diffusive process,

$$u^D = u^E - W_1\sqrt{-2\int_1^{u^E} f(\upsilon)d\upsilon}. \tag{10}$$

With $t^E \equiv u^D$, equations (8), (9), and (10) are a system of three equations for the three unknowns u^E, u^D, and β. With BC now a purely diffusive process and $u_x^B = u_x^C$ with u_x evaluated from the homoclinic orbit, we obtain

$$u^C = u^B + W_2\sqrt{-2\int_0^{u^B} f(\upsilon)d\upsilon}. \tag{11}$$

The final equation originates from the requirement that u_x evaluated from the homoclinic orbit at B equal u_x evaluated from the periodic orbit at C:

$$-\sqrt{\frac{1}{2}(u^C)^4 - \frac{2(\alpha+1)}{3}(u^C)^3 + \alpha(u^C)^2 - \beta} = \sqrt{-2\int_0^{u^B} f(\upsilon)d\upsilon}. \tag{12}$$

Thus (11) and (12) form a system of two equations for the two unknowns u^C and u^B. The periodic orbit ϕ can then be used to obtain an explicit expression for the second critical spacing $S_c^{'}$,

$$S_c^{'} = \int_{u^C}^{u^D} \frac{du}{\sqrt{\frac{1}{2}u^4 - \frac{2(\alpha+1)}{3}u^3 + \alpha u^2 - \beta}}, \tag{13}$$

where $\beta = 9.897 \times 10^{-4}$ for $W_1 = 7$ and $W_2 = 5$. The second critical spacing obtained from (13) is $S_c^{'} \simeq 5.15$, in excellent agreement with the 5.13 value obtained from the initial-value problem in Figure 3.5. The agreement between the expression in (13)

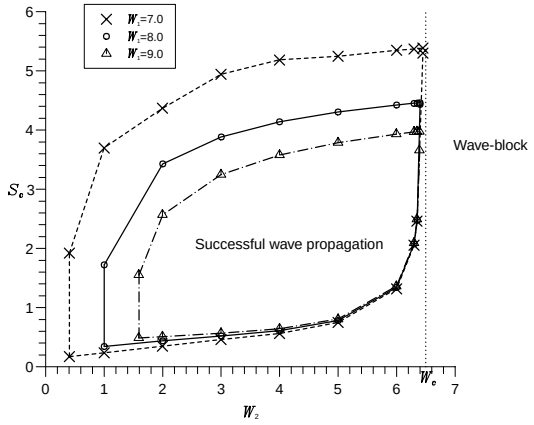

FIG. 3.7. *Critical spacings for a two-gap system as a function of W_2 for different W_1 values with $W_1 > W_c$.*

and the initial-value problem improves as we increase the domain size and decrease the space and time steps in our numerical scheme.

Figure 3.7 shows the variation of S_c with W_2 for given W_1 ($> W_c$). Notice the existence of a closed region in the $S - W_2$ parameter space, outside of which there is block and inside of which there is successful propagation. As W_1 increases, the region for successful propagation shrinks, while as W_1 approaches W_c from above, the turning point close to the line $W_2 = W_c$ moves towards infinity.

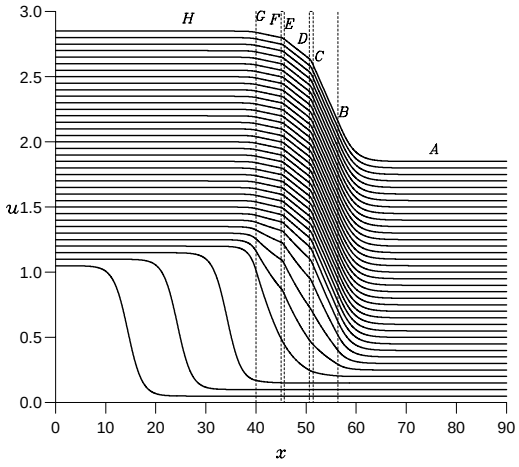
4. Propagation with three gaps. Figure 4.1(a) shows wave-block for $W_1 = W_2 = W_3 = 5 < W_c$ with $\alpha = 0.3$. The first spacing is $S_1 = 0.66$, and the second spacing $S_2 = 0.69$. Figure 4.1(b) depicts the successful propagation of a wavefront for $S_1 = 0.66$, $S_2 = 0.72$. The numerical solution of the bistable equation as an initial-value problem indicates that for $S_1 = 0.66$, $S_{2,c} \simeq 0.71$ for $W_1 = W_2 = W_3 = 5$.

We now construct the steady-state wavefront for a domain with three gaps. Figure 4.2 shows the phase plane portrait of the steady state in Figure 4.1(a). Point C can be found from the solution of (5a), (5b), with W_2 replaced by W_3. Once u^C and t^C are known, β_2 for the phase orbit ϕ_2 can be evaluated from (5c). The remaining equations are

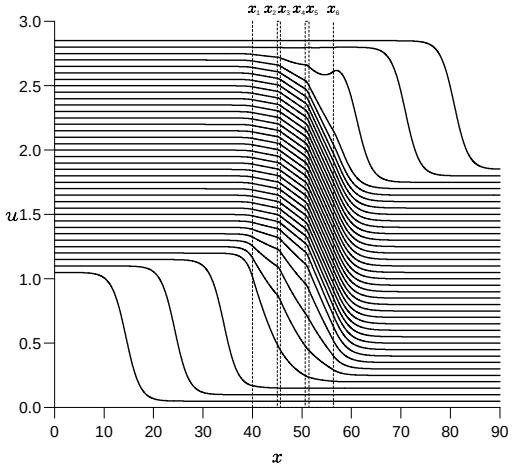
$$u^F = u^G - W_1\sqrt{2\int_{u^G}^{1} f(v)dv}, \tag{14a}$$

$$S_1 = \int_{u^E}^{u^F} \frac{du}{\sqrt{-2\int_0^u f(v)dv + \beta_1}}, \tag{14b}$$

$$W_2\sqrt{-2\int_0^{u^D} f(v)dv + \beta_2} + u^D = u^E, \tag{14c}$$



(a)



(b)

FIG. 4.1. (a) *Propagation failure through a three-gap domain with* $W_1 = W_2 = W_3 = 5.0 < W_c$. *The spacings between the three gaps are* $S_1 = 0.66$ *and* $S_2 = 0.69$*;* (b) *successful propagation with* $W_1 = W_2 = W_3$ *for* $S_1 = 0.66$ *and* $S_2 = 0.72$. *Here* u *is plotted at equal time intervals from time* $t = 35$ *with a time lapse between successive curves of* 35 *time units.*

$$\beta_2 - \beta_1 = 2\left\{\int_0^{u^D} f(v)dv - \int_0^{u^E} f(v)dv\right\}, \tag{14d}$$

$$\beta_1 = 2\left\{\int_0^{u^F} f(v)dv - \int_{u^G}^1 f(v)dv\right\}, \tag{14e}$$

where β_1 is the constant for the phase orbit ϕ_1. Hence, we have a system of five equations with five unknowns, u^G, u^F, u^E, u^D, and β_1, which can be solved numerically to

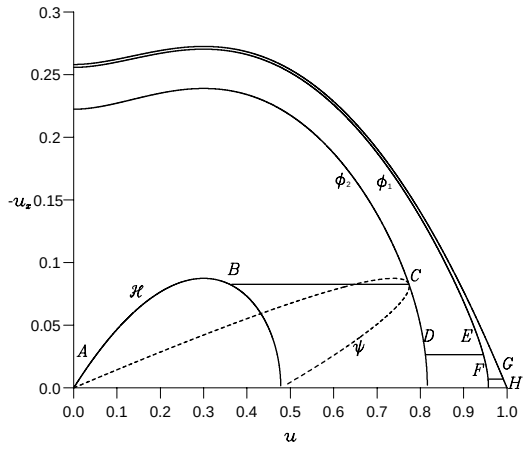


FIG. 4.2. *Phase-portrait of $u_{xx} + f(u) = 0$ for the three-gap steady state in Figure* 4.1(a). *The phase orbits $\phi_{1,2}$ determine the smallest critical size of the second spacing.*

TABLE 4.1
Critical second spacing as a function of the first spacing S_1 for a domain with three gaps $W_1 = W_2 = W_3 = 5.0$ for $\alpha = 0.3$.

S_1	Equation (14)
0.06	0.81
0.21	0.77
0.36	0.74
0.51	0.71
0.66	0.70

determine the points G, F, E, D and the phase orbit ϕ_1. The second critical spacing, $S_{2,c}$, can then be obtained explicitly from

$$S_{2,c} = \int_{u^C}^{u^D} \frac{du}{\sqrt{-2\int_0^u f(v)dv + \beta_2}}. \tag{15}$$

Equations (14a), (14c)–(14e), and (15) form a system of five equations for the five unknowns, u^G, u^F, u^E, u^D, and β_1. Alternatively, for a given S_2, the first critical spacing, $S_{1,c}$, can be obtained from (14b).

Table 4.1 gives the critical length of the second spacing obtained from (15). All gap lengths were taken as equal to 5. Notice the weak dependence of $S_{2,c}$ on S_1. For $S_2 \to \infty$ and $S_1 < S_c$ we anticipate wave-block, as in this case the third gap has no influence on the first two gaps and the system behaves essentially as a two-gap system with the resulting steady state being exactly the same as the steady state associated with a two-gap domain. This then means that there exists a *second* critical length, $S_{2,c}^{'}$, above 0.71 and such that the wave fails to propagate for $S_2 < S_{2,c}$, $S_2 > S_{2,c}^{'}$ and propagates successfully for $S_{2,c} < S_2 < S_{2,c}^{'}$. The analytical construction of $S_{2,c}^{'}$ follows a procedure similar to that for the two-gap system in the previous section. From the initial-value problem, we find $S_{2,c}^{'} \simeq 9.0$—see Figure 4.3 for a numerical experiment with $S_1 = 0.66$ and $S_2 = 9.0$. Hence, like the one-spacing case analyzed

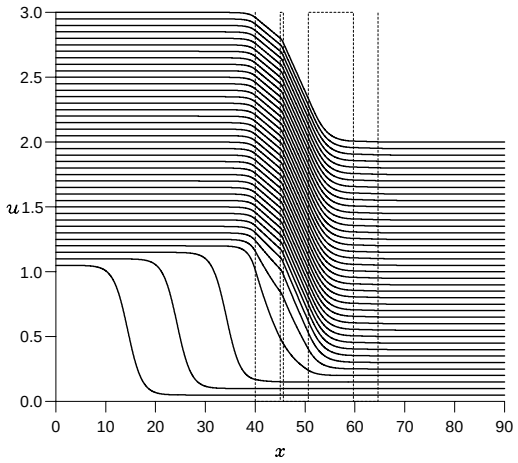

FIG. 4.3. *Wave propagation in a three-gap domain with* $W_1 = W_2 = W_3 = 5.0$ *and* $S_1 = 0.66$, $S_2 = 9.0$, *leading eventually to wave-block. Contrast with Figure* 3.1(b), *where wave propagation is successful. Here* u *is plotted at equal times from time* $t = 35$, *with a time lapse between successive curves of* 35 *time units.*

in section 3, successful propagation is observed for values of S_2 between the two critical values.

It is now useful to summarize the critical conditions for propagation across two or three gaps. From these conditions, a series of "rules" can be established to allow us to predict whether a wave will pass through an array of two or three gaps:

(i) Two-gap system.

1. $W_1 > W_c \simeq 6.5$ and $W_2 < W_c$. There exist two critical spacings S_c, $S_c^{'}$, with $S_c < S_c^{'}$. We have three cases:
   – for $S < S_c$, the wave is blocked.
   – for $S_c < S < S_c^{'}$, wave propagation is successful.
   – for $S > S_c^{'}$, the wave is blocked.
2. $W_1 < W_c$ and $W_2 < W_c$. There exists only one critical spacing, S_c. Here we have two cases:
   – for $S < S_c$, the wave is blocked.
   – for $S > S_c$, wave propagation is successful.
3. $W_2 > W_c$. The wave is blocked independently of W_1.

(ii) Three-gap system. The situation here is much more complicated, and the development of critical conditions for successful wave propagation and failure requires a case-by-case analysis. Here, we focus on the case $W_1 = W_2 = W_3 = 5.0$. S_c is the critical spacing for a two-gap system with $W_1 = W_2 = 5.0$. $S_{1,2}$ are the spacings between the first two and last two gaps, respectively.

1. $S_1 < S_c$. There exist two critical spacings for S_2, $S_{2,c}$, and $S_{2,c}^{'}$, with $S_{2,c} < S_{2,c}^{'}$. Here we have three cases:
   – for $S_2 < S_{2,c}$, the wave is blocked.
   – for $S_{2,c} < S_2 < S_{2,c}^{'}$, wave propagation is successful.
   – for $S_2 > S_{2,c}^{'}$, the wave is blocked.
2. $S_1 > S_c$. There exists only one critical spacing for S_2, $S_{2,c}$. We now have two

cases:
– for $S_2 < S_{2,c}$, the wave is blocked.
– for $S_2 > S_{2,c}$, wave propagation is successful.

5. Propagation with several gaps. The procedure outlined in the previous sections can be generalized to an N-gap domain. In this case we have a system of $3N-3$ equations for the $3N-3$ unknowns, $\beta_i\,(i=1,2,\dots,N-2)$, $u_i\,(i=1,2,\dots,2N-2)$, and one of $S_1, S_2, \dots, S_{N-1}$ (for $W_i\,(i=1,2,\dots,N)$ fixed):

$$u^i = u^{i+1} + W_{\frac{i+1}{2}}\sqrt{-2\int_0^{u^i} f(v)dv + \beta_{i-2}}, \qquad i=3,5,\dots,2N-1,$$

$$\beta_{i+1}-\beta_i = 2\left\{\int_0^{u^{2i+2}} f(v)dv - \int_0^{u^{2i+1}} f(v)dv\right\}, \qquad i=2,3,\dots,N-2,$$

$$S_i = \int_{u^{2i+2}}^{u^{2i+1}} \frac{du}{\sqrt{-2\int_0^u f(v)dv + \beta_i}}, \qquad i=1,2,\dots,N-1,$$

where $u^1 = u^2 + W_1\sqrt{2\int_{u^1}^1 f(v)dv}$ and $\beta_1 = 2\{\int_0^{u^2} f(v)dv - \int_{u^1}^1 f(v)dv\}$.

We must therefore fix $N-2$ of the spacings S_i or, alternatively, fix $2N-2$ spacings and gaps from the total number of $2N-1$ spacings and gaps. Obviously, the spacings have to be chosen such that $-u_x$ always decays as x increases, and hence $u_{x_i}(i=2N-1,2N-2,\dots,1)$ should be a decreasing sequence of $x_i\,(i=2N-1,2N-2,\dots,1)$. In other words, the phase plane of an N-gap system should form a "staircase" from the point where the mapped curve intersects the phase orbit ϕ_{N-1} until the point x_1. We notice that the point u^{2N-1} is always determined from the transfer map of the homoclinic orbit through the *final* gap W_N, and hence only points $u^i\,(i=2N-2,2N-3,\dots,1)$ need to be determined.

The existence of two critical values for S in a two-gap domain, and two critical values for S_2 in a three-gap domain, renders the development of rules for prediction of wave propagation and failure in an N-gap system almost a prohibitive process. Indeed, even for the relatively simple case of four gaps and three spacings, we anticipate, by analogy with the three-gap system, that there will be two critical values for S_1, S_2, and S_3. (Clearly, for a sufficiently large S_2 the four-gap system should approach the steady state of the system $\{W_1, S_1, W_2\}$ in Figure 3.1(a).) We have to emphasize here that we always require the final gap $W_N < W_{cr}$. (W_{cr} is the critical gap length for a medium with a single gap.) At the same time as we increase the number of gaps, the critical values of the spacings between the gaps should decrease: the number of phase orbits, which represent the various invariant manifolds of the steady state, increases, and the "staircase" that links all these orbits gets closer to a continuous curve. (Notice, for example, that the value of S_c in (7) decreases as the distance between u^C and u^D decreases.) Therefore, a large number of spacings/gaps can actually promote wavefront propagation across purely diffusive regions. Figure 5.1 shows successful propagation in an extended domain with a random distribution of gaps occupying 80% of the domain [100, 200]. Notice that the wavefront propagates successfully and without significant slowing through the spacings of length 0.51 and 0.60, which are smaller than 0.68, the smallest critical spacing between a two-gap system with $W_1 = W_2 = 5.0$ considered in section 3.

The question of successful propagation/failure for a large number of gaps (larger than the three considered in section 4) can be addressed by generating a large number

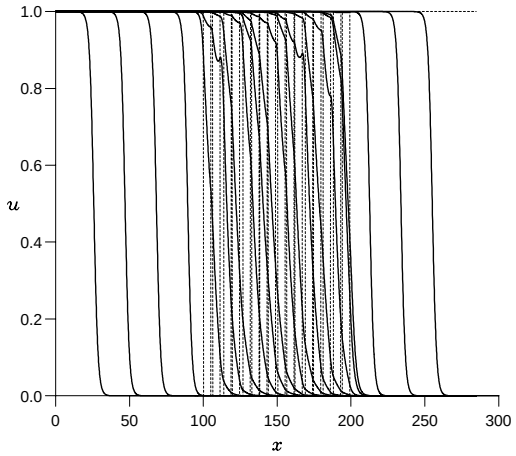

FIG. 5.1. *Successful wave propagation in an extended domain with a random distribution of gaps occupying* 80% *of the domain* $[100, 200]$. *All gaps are taken to be equal to* 5. *The sequence of spacings is the following:* 1.33, 2.58, 0.72, 2.40, 0.99, 0.51, 0.72, 1.48, 1.11, 0.60, 2.18, 0.69, 1.57, 1.94, *and* 1.18. *The time lapse between successive curves is* 75 *time units.*

of random distributions of gaps with a given "void fraction" (fraction of the domain occupied by the gaps). We then have to numerically determine from the initial-value problem the probability (percentage "pass rate") that a wave will successfully propagate along the whole length of the domain. For this purpose, we performed numerical simulations with 20 different random distributions of gaps with length 5 occupying 80% of the domain [100, 200] and a total of 15 spacings in this domain. In all cases, the wave propagated successfully through the medium. However, there might be a particular combination of spacings/gaps which blocks the wavefront. Although an accurate estimate of the probability for successful propagation might require a number of distributions much larger than 20 (which would be computationally a very intensive process), the fact that 20 different random distributions lead to successful propagation indicates a high probability for success.

The above observations depend on the value of the excitability threshold α. In general, as α decreases, the homoclinic orbit that connects to $(0, 0)$ shrinks and, although there is more available space in the phase plane for the phase orbits associated with the steady state, the critical spacings decrease as the intersection between the mapped curve and the phase orbit ϕ_{N-1} gets closer to the u-axis. (At the same time, a more excitable system should require smaller critical spacings for successful propagation.) However, the critical gaps for successful propagation should increase as the distance between the homoclinic orbit and the stable manifold increases.

In addition, we also computed the average speed of the wavefront, defined as the speed of the point at which $u = 1/2$ and based on the time it takes for the front to travel from the first to the last gap. A very interesting conclusion is that, for the system in Figure 5.1 with 16 gaps in the domain [100, 200], the front travels faster than in the cases of 1, 2, or 3 gaps with a void fraction 80% in the same domain. This result along with the main conclusions of the previous sections should have significant implications for a number of areas where the bistable equation in (1) is used as a model system to study wave propagation in heterogeneous media. For example, as Poptsova

and Guria [14] point out, in the context of biophysics, malfunction of the propagation of an impulse in cardiac tissue can cause different cardiac diseases such as ischemia and arrhythmia, which might be explained by the presence of local nonexcitable areas in the cardiac fibre.

6. Multiplicity and stability of solutions. Lewis and Keener [8] proved that, for the one-gap case, if the gap length is larger than the critical length, there exist two steady-state solutions arising via a limit point bifurcation. In this study, we take the two-gap case as an example and show that, if the spacing length is less than (for $W_{1,2} < W_c$ fixed) or the first gap length is larger than (for $W_2 < W_c$ and S fixed) the corresponding critical length, there will also be two steady-state solutions arising via a limit point bifurcation (two such steady states, $AB'C'D'E'F$ and $AB''C''D'E'F$, are depicted in Figure 3.2). From the phase plane analysis in the two-gap case, we have shown that either the spacing length or the gap length is related to the phase orbit constant β, and so we take β as our bifurcation parameter. A bifurcation diagram for this system is shown in Figure 6.1, with $\beta^* = 0.04949$ and $u^*(x_4) = 0.3464$. To acquire further information about the steady solutions, we consider the bifurcation structure of the system $u_{xx} + f(u) = 0$ in more detail.

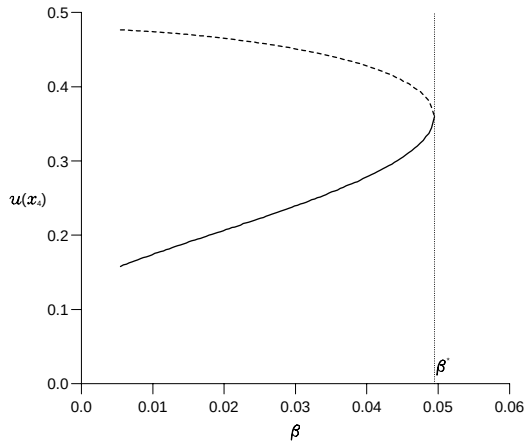

FIG. 6.1. *Bifurcation diagram for $u(x_4)$ of the steady-state solution vs. phase orbit constant β in the two-gap case. The solid line represents stable solutions, and the dashed line represents unstable solutions. The critical β is $\beta^* = 0.04949$. The parameters are $\alpha = 0.3$ and $W_2 = 5.0$.*

Let $v = u_x$ and $v = G_{\mathcal{H}}(u) = \sqrt{-2\int_0^u f(u)du}$ describe the homoclinic orbit $\mathcal{H}$ for $v > 0$ on $u \in (0, u_{\mathcal{H}})$. The function $G_{\mathcal{H}}(u)$ is strictly decreasing for $u \in (\alpha, \overline{u}_{\mathcal{H}})$, with $\overline{u}_{\mathcal{H}}$ the maximum value of $\bar{u}$ on the homoclinic orbit, and thus can be inverted on this region, $u = G_{\mathcal{H}}^{-1}(v) \equiv U_{\mathcal{H}}(v)$. Similarly, $v = G_C(u) = \sqrt{-2\int_0^u f(v)dv + \beta}$ describes the phase orbit through points C' and C'' of Figure 3.2, and therefore we can use $u = G_C^{-1}(v;\beta) = U_C(v;\beta)$ to describe the decreasing portion of the phase orbit with constant β. We can now express the map ψ_{W_2} as

$$\psi_{W_2} : [U_{\mathcal{H}}(v), v] \to [vW_2 + U_{\mathcal{H}}(v), v]$$

and look for a solution to

$$vW_2 + U_{\mathcal{H}}(v) = U_C(v;\beta),$$

where $v \equiv u_x(x_4)$ is a solution of the steady-state equation. Rearranging this equation, we obtain

$$F(v;\beta) = vW_2 + U_{\mathcal{H}}(v) - U_C(v;\beta) = 0.$$

Assume now that we know a solution of the steady-state equation for $\beta = \beta_0$ with $u_x(x_4;\beta_0) = v_0$; then

$$F(v_0;\beta_0) = v_0W_2 + U_{\mathcal{H}}(v_0) - U_C(v_0;\beta_0) = 0. \tag{16a}$$

By expanding F in a Taylor series about (v_0,β_0), we get

$$\begin{aligned} F(v;\beta) \sim\ & [W_2 + U^v_{\mathcal{H}}(v_0) - U^v_C(v_0;\beta_0)](v-v_0) - U^\beta_C(v_0;\beta_0)(\beta-\beta_0) \\ & + \frac{1}{2}[U^{vv}_{\mathcal{H}}(v_0) - U^{vv}_C(v_0;\beta_0)](v-v_0)^2 - \frac{1}{2}U^{\beta\beta}_C(v_0;\beta_0)(\beta-\beta_0)^2 \\ & - U^{v\beta}_C(v-v_0)(\beta-\beta_0) + \{\text{h.o.t.}\}, \end{aligned} \tag{16b}$$

where

$$U^v_{\mathcal{H}}(v_0) = \frac{dU_{\mathcal{H}}}{dv}(v_0), \quad U^v_C(v_0,\beta_0) = \frac{\partial U_C}{\partial v}(v_0,\beta_0), \quad U^\beta_C(v_0,\beta_0) = \frac{\partial U_C}{\partial \beta}(v_0,\beta_0),$$

$$U^{vv}_{\mathcal{H}}(v_0) = \frac{d^2U_{\mathcal{H}}}{dv^2}(v_0), \quad U^{vv}_C(v_0,\beta_0) = \frac{\partial^2 U_C}{\partial v^2}(v_0,\beta_0), \quad U^{\beta\beta}_C(v_0,\beta_0) = \frac{\partial^2 U_C}{\partial \beta^2}(v_0,\beta_0),$$

$$U^{v\beta}_C(v_0,\beta_0) = \frac{\partial^2 U_C}{\partial v \partial \beta}(v_0,\beta_0).$$

Thus, bifurcations can occur when

$$W_2 + U^v_{\mathcal{H}}(v_0) - U^v_C(v_0;\beta_0) = 0. \tag{16c}$$

Note that $U^v_{\mathcal{H}}(v_0) < 0$ is necessary for obtaining solutions to this equation, because W_2 and $-U^v_C(v_0;\beta_0)$ are both > 0. This is always the case for the branch of the homoclinic orbit that we have chosen to work with. However, this is not the case on the $u \in (0,\alpha)$ portion of the homoclinic orbit $\mathcal{H}$, which also means that all bifurcations occur when $u > \alpha$. By solving the two equations (16a) and (16c), we can get v_0 and β_0 as a function of v_0.

We now let

$$\beta \sim \beta_0 + \epsilon\beta_1 + \epsilon^2\beta_2 + \cdots, \qquad v \sim v_0 + \epsilon v_1 + \epsilon^2 v_2 + \cdots,$$

where $0 < \epsilon \ll 1$. When these series are substituted into (16b), one gets the $O(\epsilon)$ term

$$-U^\beta_C(v_0;\beta_0)\beta_1 = 0,$$

which implies $\beta_1 = 0$. At $O(\epsilon^2)$ we find

$$-U^\beta_C(v_0;\beta_0)\beta_2 + \frac{1}{2}[U^{vv}_{\mathcal{H}}(v_0) - U^{vv}_C(v_0;\beta_0)]v_1^2 = 0,$$

and hence β_2 is arbitrary. Choosing $\beta_2 = -1$ yields

$$v_1 = \pm\sqrt{\frac{-2U_C^{\beta}(v_0;\beta_0)}{U_{\mathcal{H}}^{vv}(v_0) - U_C^{vv}(v_0;\beta_0)}},$$

which is real if the quantity in the root is > 0, i.e.,

$$-\frac{U_C^{\beta}(v_0;\beta_0)}{U_{\mathcal{H}}^{vv}(v_0) - U_C^{vv}(v_0;\beta_0)} > 0.$$

We can easily confirm that this always the case, and hence we have two solutions which coalesce at $\beta = \beta_0$ and vanish as β increases above β_0. From the phase portrait in Figure 3.2 and from (5d), (6b), and (7), we can see that the two steady-state solutions correspond to different first gap and spacing lengths. That is, if we fix W_2 and S, there are two solutions with different first gaps. Alternatively, if we fix W_1 and W_2, there two solutions with different spacings. Finally, the solution branch with $v < v_0$ immediately following the bifurcation point has

$$W_2 + U_{\mathcal{H}}^{v}(v) - U_C^{v}(v;\beta) > 0,$$

while the solution with $v > v_0$ has

$$W_2 + U_{\mathcal{H}}^{v}(v) - U_C^{v}(v;\beta) < 0.$$

Whenever there are two solutions, the upper solution (as in Figure 6.1) is unstable and the lower is stable. Lewis and Keener [8] proved the stability of the steady states for the one-gap case by constructing time-independent lower and upper solutions of (1). We follow the same method here to study the stability of the two branches in Figure 6.1. Although our discussion is confined to the two-gap case, it can be extended to any number of gaps.

Following Pauwelussen [18], we call χ a lower solution of the equation $Nu \equiv u_t - u_{xx} - g(u,x) = 0$ if χ satisfies $N\chi \leq 0$ on differentiable segments of χ and $\chi_x(x^+,t) \geq \chi_x(x^-,t)$ on any point x at which χ_x has discontinuities. Similarly, ω is an upper solution when it satisfies the same conditions with all the inequality signs reversed. Using upper and lower solutions, the following lemma from Pauwelussen [18], which is an extension of a theorem by Aronson and Weinberger [16] based on the comparison principle, allows us to examine the asymptotic behavior of the solutions as $t \to \infty$: if $\omega(x)$ is an upper solution of (1), then $u(x,t;\omega)$ is a nonincreasing function of t, with $\lim_{t\to\infty} u(x,t;\omega) = q(x)$, where $q(x)$ the largest stationary solution of (1) satisfying the inequality $q(x) \leq \omega(x)$. Similarly, if $\chi(x)$ is a lower solution of (1), then $u(x,t;\chi)$ is a nondecreasing function of t, and $\lim_{t\to\infty} u(x,t;\chi) = \tau(x)$, where $\tau(x)$ is the smallest possible stationary solution of (1) such that $\tau(x) \geq \chi(x)$.

Therefore, a steady state $\bar{u}(x)$ with $\chi < \bar{u} < \omega$, where χ and ω are lower and upper solutions, respectively, and arbitrarily close to $\bar{u}$, is stable since, as $t \to \infty$, $u(x,t;\chi)$ will tend to the smallest steady state that is greater than or equal to χ, and $u(x,t;\omega)$ will tend to the largest steady state that is smaller than or equal to ω. Because χ and ω are arbitrarily close to $\bar{u}$ (by construction), the smallest steady state and the largest steady state is $\bar{u}$. Hence, $\lim_{t\to\infty} u(x,t;\chi) = \lim_{t\to\infty} u(x,t;\omega) = \bar{u}$, which proves the stability of $\bar{u}$. On the other hand, a steady state $\bar{u}(x)$ with $\omega < \bar{u} < \chi$, where χ and ω are lower and upper solutions, respectively, and arbitrarily close to $\bar{u}$, is unstable since $u(x,t;\omega)$ approaches the largest steady state that is smaller than ω. This solution is the smaller of the two steady states and is associated with the lower branch in Figure

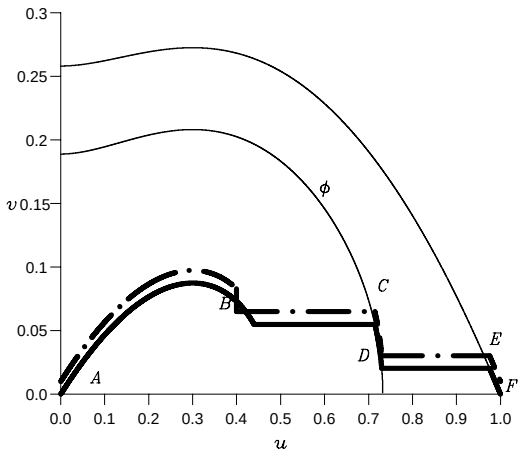

FIG. 6.2. *Steady-state solution (solid line) and time-independent upper solution (dot-dashed line) for a two-gap system.*

6.1, indicating that the smaller solution is stable and the largest solution unstable. At the same time, $u(x,t,\chi)$ will not approach a steady state as there is no steady-state solution larger than χ.

We now construct an upper solution ω, with $\omega < \bar{u}$. From $x = x_D$ to x_C in Figure 6.2, we take ω to closely follow curve χ with $\omega_x(x_C) = \bar{u}_x(x_C) + \epsilon$, with ϵ arbitrarily small. Because curve χ is monotonic with $d\bar{u}/d\bar{u}_x < 0$ in the region of interest, we require that $\epsilon > 0$ such that $\omega < \bar{u}$. For $x_C < x < x_B$, we take ω to be a straight line such that ω and ω_x are continuous at $x = x_C$. The equation for $\omega(x_B)$ is then $\omega(x_B) = -W_2(\bar{u}_x(x_C) + \epsilon) + U_C(\bar{u}_x(x_C) + \epsilon, \beta)$. The remainder of ω is taken to be the homoclinic orbit with ω continuous. Thus, ω is a solution everywhere except $x = x_B$, where ω_x is not continuous for $\epsilon \neq 0$. Finally, for ω to be an upper solution, the jump condition $\omega_x(x_B^+) < \omega_x(x_B^-)$ must be satisfied. We therefore require that $\omega(x_B) < U_{\mathcal{H}}(\bar{u}_x(x_C) + \epsilon)$ for points with $\bar{u} \in (\alpha, \bar{u}_{\mathcal{H}})$, where $U'_{\mathcal{H}} < 0$. This gives the inequality

$$-W_2(\bar{u}_x(x_C) + \epsilon) + U_C(\bar{u}_x(x_C) + \epsilon, \beta) - U_{\mathcal{H}}(\bar{u}_x(x_C) + \epsilon) < 0,$$

which, when expanded in a Taylor series at $\epsilon = 0$, yields

$$\begin{aligned} &-W_2(\bar{u}_x(x_C)) + U_C(\bar{u}_x(x_C), \beta) - U_{\mathcal{H}}(\bar{u}_x(x_C)) \\ &- (W_2 + U'_C(\bar{u}_x(x_C), \beta) - U'_{\mathcal{H}}(\bar{u}_x(x_C)))\epsilon + \cdots < 0. \end{aligned}$$

Because $\bar{u}(x)$ is the steady-state solution, we have that

$$-W_2(\bar{u}_x(x_C)) + U_C(\bar{u}_x(x_C), \beta) - U_{\mathcal{H}}(\bar{u}_x(x_C)) = 0,$$

and since ϵ is positive and arbitrarily small, for ω to exist we require that

$$W_2 + U'_C(\bar{u}_x(x_C), \beta) - U'_{\mathcal{H}}(\bar{u}_x(x_C)) > 0.$$

Similar arguments can be used to construct the lower solutions, as well as lower and upper solutions with $\chi < \bar{u} < \omega$. Notice that in all cases and independently of the number of gaps, the lower and upper solutions require only *one* discontinuity at the downstream edge of the last gap (point B in Figure 6.2 for a two-gap system).

7. Conclusion. We have considered wave propagation in an excitable medium through localized regions of no excitability (the "gaps") by using the bistable equation as a model system. We extended the geometric method of Lewis and Keener for a single gap domain to a hybrid geometric-algebraic method for the case of multiple gaps. The method allowed us to obtain criteria for successful wave propagation and failure ("wave-block") in the bistable equation. For a system with two and three gaps, we found that there are two critical values for the last spacing when all other spacings are fixed: for values of the second spacing that are less than the smaller critical value and greater than the larger critical value, wave-block occurs. Our findings can be readily extended to a larger number of gaps. We also demonstrated that much like the one-gap case, a two-gap system exhibits multiplicity and is such that there are two steady states with different values of the first gap for a fixed second gap and spacing, and two steady states with different spacings for fixed first and second gaps. Finally, in some cases increasing the number of gaps/spacings was found to promote wavefront propagation across purely diffusive regions as the critical gaps for successful propagation increase and the critical spacings decrease.

Acknowledgment. We thank the anonymous referee for useful comments and suggestions.

A THERMOMECHANICAL MODEL FOR ENERGETIC MATERIALS WITH PHASE TRANSFORMATIONS*

GREGORY A. RUDERMAN†, D. SCOTT STEWART‡, AND JACK JAI-ICK YOH‡

Abstract. A model is developed to describe energetic materials with phase transformations from solid to liquid to gas with an exothermic chemical reaction. The model uses a phase variable and a reaction progress variable as thermodynamically independent state variables. A configurational force balance is used to derive an evolution law for the phase variable. The evolution equation for the reaction progress variable is posed as a basic law. In various limits the material is a classical elastic solid, a Newtonian viscous liquid, and a compressible gas. The model is examined in relation to classical equilibrium thermodynamics in a quasi-static limit. The model formulation is specialized to simple motions which are analyzed in a companion paper.

Key words. combustion, phase transformations, energetic materials

1. Introduction.

This paper presents a thermodynamically self-consistent model that can describe a material that undergoes phase transitions from solid to liquid to gas with an exothermic chemical reaction. The model development is quite basic and is likely to have wider applications, but the motivation for the study is to describe the behavior and properties of energetic materials such as those used in pyrotechnic materials such as condensed explosives and solid propellants.

Condensed phase energetic materials (EMs) are most typically room temperature organic solids that bind substantial chemical energy in molecular bonds. Upon initiation of chemical reaction between submolecular constituents within the solid, energy is released that is subsequently available to do work or is converted into heat. The advantage of the condensed phase explosive is that the energy per unit volume is approximately a thousand times higher than its premixed, gaseous counterpart.

For the purposes of illustration and to help us develop a conceptual framework, we will consider the energetic material HMX, $[CH_2 - N(N0_2)]_4$, [1] (a solid explosive compound) to be a base-line energetic material. HMX is solid at room temperature and pressure, and when fully chemically decomposed, its gaseous products are simple gases like water vapor, carbon dioxide, and molecular nitrogen. There are thousands of known energetic (explosive) compounds, so our choice of HMX is both practical (because of its wide use) and representative, in that nearly all of the modeling issues considered here apply to similar materials. Fundamental scientific questions surround the phenomena of ignition and release of energy in these materials (EMs) subsequent to impact with a piston or due to a rapid shearing motion. At high impact speeds, (typically on the order of 1000 m/sec), simple hydrodynamic models give an adequate

description for both ignition and transition to detonation. Hydrodynamic models are expressed in the form of the Euler equations for reactive gas dynamics [2], which balance kinetic energy, elastic potential energy, and the chemical energy released by the reaction. By virtue of the speed of collision and the short duration of the ignition event, one can justify the neglect of other types of energy and their transfer. However, at lower impact speeds (typically below 1000 m/sec) one must fully take into account the solid nature of the material. In contrast, models for lower-speed impact must reflect a large number of types of energy and mechanisms by which energy in the condensed phases can be transformed, localized, and dissipated. A successful model must be able to describe three-dimensional stress distributions, heat conduction, phase transformations, and chemical reaction as the material changes from solid to liquid to gas.

Thus, accounting for the change in phase and chemical reaction are essential parts of modeling the ignition of energetic solids. In order to do this in a continuum modeling framework, one must add additional thermodynamic state variables that reflect the internal degrees of freedom that measure the extent of reaction and phase change in the material. Necessarily, one must posit additional balance laws and provide the required constitutive theory to complete a model formulation. One does this by using physical considerations (that may lie in the proposed model's subscale physics) to pose the required additional balance laws. For example, in the case of classical combustion theory (see Williams [3] for a representative discussion of the derivation of the commonly used equations of combustion theory), the additional state variables that correspond to the internal degrees of freedom are the mass fractions of all the independent chemical species. The additional balance laws are literal statements of molecular mass balance for each independent species. Other constitutive forms required to describe the evolution of the mass fraction variable are based on well-known laws of collisional reaction (in the case of gaseous chemical reaction), Fickean diffusion, and so on. Importantly, the added balance laws themselves have an identifiable, *molecular origin* and are directly related to physically unambiguous statements of mass balance. However, while the physics at the molecular subscale is clear, the continuum-scale formulation embraces the added (partial) mass conservation statements as primitive, physical laws that must be given by ansatz.

When modeling the phase changes from solid to liquid to gas it is also important to have a physical understanding of the molecular origins of state variables and constitutive forms that describe the phase change. On the molecular scale, a typical EM solid like HMX is comprised of nitrated hydrocarbon molecules that reside in a highly ordered crystal lattice. Large quantities of energy are released only if there is a chemical reaction between smaller pieces of the molecule, juxtaposed or dislodged by deformation, which subsequently release their chemical energy through elementary exothermic reactions typical of those for the gas-phase chemistry. For example, the liquid phase of HMX is known to be very reactive and short-lived compared to the solid phase; likewise HMX vapor is extremely reactive [4], [5]. The liquid phase is molecularly less well ordered than the solid, with larger average intermolecular distances than the solid. If correlated to the average intermolecular spacing (say), the gas phase is less ordered than the liquid. Thus a state variable (sometimes called an order parameter or a phase field variable) can be introduced to reflect a continuum measure of molecular order of the condensed phases (solid crystalline and liquid phases) and the gaseous phase. We will call the order parameter, or phase field variable, simply the phase variable ϕ and assume that it is normalized in such a way so that $\phi = 0$

corresponds to a solid, $\phi = 1$ a liquid, and $\phi = 2$ a gas.

In this formulation, the precise relationship of noninteger values of a phase variable like ϕ to the molecular subscale structure of the material is somewhat ambiguous in contrast to the unambiguous meaning of reactant mass fractions in combustion theory. In a more advanced theory it is anticipated that ϕ will be assigned to specific molecular coordinates. Advances in molecular dynamics of condensed phase systems do promise to eventually provide a more substantial basis for physical assignment of the phase variables, possibly based on the average molecular spacing (say) or other molecularly based kinematic variables [6], [7].

Despite possible ambiguity in its precise physical interpretation, if a phase variable is to be used in a model to represent an independent degree of freedom, it should be constrained by standard principles found in the theory of continuum mechanics. In the regions where the phase is pure (i.e., $\phi = 0$, 1, or 2) the material properties and the constitutive relations must describe the pure material with the properties of that phase. We require that the formulation has a sense in which it is thermodynamically and tensorially consistent. This allows further developments in a rational and systematic manner in three dimensions. We consider a simplified model of an EM (HMX, say) which we suppose has three relevant phases: a solid phase, a liquid phase, and a gas phase. We assume that the path from solid to gas goes through the successive phase transformations, solid $\rightarrow$ liquid $\rightarrow$ gas. Phase boundaries are to be represented by (typically thin) regions across which the value of the phase variable changes from one constant to another. Also, we will use a single (lumped chemistry) progress variable λ, to describe the extent of exothermic chemical reaction λ with value $\lambda = 0$ when no reaction has occurred and $\lambda = 1$ when the reaction is completed. The model allows chemical reactions in any phase.

A key aspect of the model is explicit partitioning of the energy associated with specific internal (thermal) energy, chemical reaction energy, elastic potential (deformational) energy, and energies associated with phase change, such as the enthalpies associated with melting of the solid and evaporation of the liquid, and potential energies stored at phase boundaries. The partitioning of the energy is represented by a decomposition of the Helmholtz free energy ψ into the various parts associated with the energies listed above, such that $\psi = \psi_{thermal} + \psi_{elastic} + \psi_{reaction} + \psi_{phase} + \psi_{grad(phase)}$. The constitutive forms used for $\psi_{thermal}$ and $\psi_{elastic}$ are found in discussions of thermo-elastic materials. The constitutive forms for ψ_{phase} and $\psi_{grad(phase)}$ contain the energies of phase change and energies stored near phase change interfaces. The constitutive form for $\psi_{reaction}$ can be found in a discussion of premixed combustible materials. The free energies and other constitutive variables are allowed to depend on both the phase variable ϕ and the reaction progress variable λ as well as the temperature T and the deformation gradient $\boldsymbol{F}$ and the gradient of ϕ, $\vec{\nabla}\phi$. The governing equations are formulated by statements of conservation of mass, momentum, energy, evolution equations for the change in phase, and the progress of the chemical reaction.

The treatment we use to describe the evolution of the phase variable follows classical treatments that arose in the discussion of solidification (for example, see [8]) but specifically follows a consistent formulation pioneered by Gurtin [9]. Gurtin has argued for a separate continuum balance of configurational forces acting near the boundaries separating pure phases in the volumetric bulk. The arguments for including these additional forces may be justified by consideration of short-range van der Waals forces that typically are generated near phase boundaries due to local changes in the intermolecular distances. The arguments for such configurational forces

are similar to those used to explain classical surface tension forces. The hypothesis is that if the configurational forces act in the vicinity of the boundary near the change in phase and in the bulk, they can be in balance, and if so, they must not effect the overall (conventional) momentum balances. Hence the force balance is posited as a basic law. However, with the postulate of a balance of configurational forces comes the consequence that those forces do work. The working rate is accounted for explicitly in the overall energy balance.

The second law of thermodynamics (the Clausius–Duhem inequality) restricts the form of the constitutive theory so that the rate processes are dissipative and entropy is increasing. An important outcome of these arguments is the derivation of an evolution equation for the phase variable ϕ that is essentially a Ginzburg–Landau equation with additional forcing terms. The evolution equation for ϕ is a time-dependent, reaction-diffusion equation which is amply capable of describing the pattern formation associated with phase transformation. The richness of the resulting theory becomes evident in the energy equation. Due to the decomposition of the Helmholtz free energy, the energy equation contains contributions from all the different terms in the partition and reflects the fact that in the energetic material, energy is converted and distributed to many different forms such as elastic, kinetic, internal, and phase gradient energy (stored in interfaces).

In the sections that follow, the development of the model is given, based on the continuum-thermodynamic formulation described above. In section 2 we review the continuum-thermodynamic formulation consistent with conventional combustion theory [3], [10], [11], [12] that specifically includes a reaction progress variable. A (nonstandard) presentation of the Helmholtz energy decomposition is given and the attendant standard arguments for restrictions placed by the second law are given. In section 3 we present a model for a material that changes from solid to liquid to gas and present a Helmholtz free-energy decomposition that is suitable to describe such a material, subject to second law restrictions. In section 4, the combined model for an EM (with both phase change and chemical reaction) is then presented. In section 5 we discuss various limiting cases of the model. We discuss the relationship of the model to classical quasi-static thermodynamics and illustrate examples based on fits to HMX properties to illustrate the dynamics of a phase change that would be calculated in the classical theory. Section 6 presents special formulations of the model equation for three important simple motions. These cases are (i) constant volume evolution (which is a generalization of the classical constant volume explosion formulation found in combustion theory), (ii) one-dimensional, time-dependent longitudinal compression (expansion), and (iii) one-dimensional, time-dependent shear motion. The solution of the equations for these three important cases for an HMX-like material is the subject of the companion paper [13].

In what follows, a "c" subscript denotes a condensed phase, either solid or liquid, an "f" subscript denotes fluid, either liquid or gas, an "s" subscript denotes solid, an "l" subscript denotes liquid, and a "g" subscript denotes gas. The spelled out subscripts "solid," "liquid," and "gas" refer to constant values for that pure phase. The notation is kept as simple as possible in an attempt make the paper easier to read. Bold face quantities can either be vectors or tensors. If obvious, the constant arguments during differentiation are dropped. Our notation is standard, insofar as is possible and follows a well-known text like Bowen [12].

1.1. Kinematics. Let the Eulerian (spatial) coordinates of position in the lab-frame be given by $\boldsymbol{x}$ and the Lagrangian (material) coordinates (or particle coordi-

nates) be given by $\boldsymbol{X}$. For simplicity we will assume that $\boldsymbol{X}$ represent the initial position of material particles. Then the mapping of the deformations that define the particle trajectory paths is given by

$$\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{X}, t)\,. \tag{1.1}$$

The deformation gradient $\boldsymbol{F}$ is defined by the derivative

$$\boldsymbol{F} = \frac{\partial \boldsymbol{x}}{\partial \boldsymbol{X}}\,, \tag{1.2}$$

and the velocity of particles $\boldsymbol{v}$ is defined by the time derivative of the particle trajectories $\boldsymbol{v} = (\partial \boldsymbol{x}/\partial t)_{\boldsymbol{X}}$. The velocity gradient is $\boldsymbol{L} = \vec{\nabla}\boldsymbol{v}$. Let the dot notation, $\dot{()}$, refer to the material derivative. A standard identity that can be verified by the previous definitions and the chain rule gives the material (particle-fixed) time derivative of the deformation gradient as $\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}$. A statement of conservation of mass in the material frame is that the ratio of the instantaneous density, ρ, of the particle to a reference (ambient) density of the solid, ρ_0, is equal to the determinant of the deformation gradient

$$\det(\boldsymbol{F}) = \frac{\rho_0}{\rho}\,. \tag{1.3}$$

2. Review of the thermomechanics for a simple model of a reactive flow. The standard combustion model, for a premixed mixture that can explode or burn, can be derived from a simple mixture theory; see references [3], [10], [11], [12]. The combined model that we introduce later incorporates the features of the standard combustion model, so we review its derivation. Importantly, the reaction progress variable λ represents a product mass flux. Hence λ is treated differently from the phase variable ϕ, which is introduced later to describe the change in phase from solid to liquid to gas.

For the purpose of discussion, one assumes that there are only two distinct species, fuel and product (say). The corresponding chemical reaction is written as $F \rightarrow P + Q_{hc}\,(heat)$. All physical properties of the two species such as the molecular weights, specific heats, conductivities, etc. are assumed to be identical, save the heats of formation, the weighted difference of which is the heat of combustion.

We start with the balance laws for conservation of mass, linear momentum (without body forces), and energy:

$$\dot{\rho} + \rho\,(\vec{\nabla}\cdot\boldsymbol{v}) = 0\,, \tag{2.1}$$

$$\rho\,\dot{\boldsymbol{v}} = \vec{\nabla}\cdot\boldsymbol{\sigma} + \rho\boldsymbol{f}\,, \tag{2.2}$$

$$\rho\dot{e} = \boldsymbol{\sigma} : \vec{\nabla}\boldsymbol{v} - \vec{\nabla}\cdot\boldsymbol{q} + \rho\, r\,. \tag{2.3}$$

In the energy equation, r is a volumetric energy production term that typically represents radiation or volumetric heating (or cooling) in combustion theory. The body force is given by $\boldsymbol{f}$. In addition, we invoke a primitive evolution law for the reaction progress variable λ:

$$\rho\dot{\lambda} = \vec{\nabla}\cdot\boldsymbol{s} + \rho\,\Omega\,. \tag{2.4}$$

The vector $\boldsymbol{s}$ is the flux of mass of reacted species per unit area per unit time and $\rho\,\Omega$ is the instantaneous rate of creation of mass of the reacted species per unit volume.

Then λ is recognized as the mass fraction of the product species. Further, by direct correspondence with the standard combustion equations, one can interpret $\boldsymbol{s} = \rho\lambda\boldsymbol{V}$, where $\boldsymbol{V}$ is the diffusion velocity of the product species (say), and where $\rho\lambda$ is the partial density fraction of the same product.

To these basic laws we add the second law of thermodynamics, the Clausius–Duhem inequality

$$\rho\,\dot{\eta} \geq -\vec{\nabla}\cdot\left(\frac{\boldsymbol{q}}{T}\right) + \vec{\nabla}\cdot\left(\frac{Q_{hc}\boldsymbol{s}}{T}\right) + \frac{\rho r}{T}\,, \tag{2.5}$$

where Q_{hc}, the heat of combustion, is the exothermic energy release per unit mass and the term $\vec{\nabla}\cdot(Q_{hc}\,\boldsymbol{s}/T)$ represents the gradient of the entropy flux associated with the chemical reaction.

2.1. Constitutive forms and restrictions. Next consider the classical forms and assumptions that lead to the combustion equations of premixed materials found in texts like [3] or [10]. The formulation uses the Helmholtz free energy, which is defined in terms of the internal energy and entropy as $\psi = e - T\eta$. We start with the assumption that ψ is specified by

$$\psi = \psi(\boldsymbol{F}, T, \lambda), \tag{2.6}$$

and we assume similar dependencies for e, η, and all other thermodynamic variables. Next we consider the implication of the entropy inequality and deduce various restriction imposed by it on the constitutive formulation.

If we use the definition of the Helmholtz free energy to get an expression for the entropy, as $\eta = (e - \psi)/T$, and take the material derivative, we obtain $\dot{\eta} = (\dot{e} - \dot{\psi} - \eta\dot{T})/T$. In particular the derivative $\dot{\psi}$ appears and, using the form assumed above, it is calculated as

$$\dot{\psi} = \frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} + \frac{\partial\psi}{\partial T}\dot{T} + \frac{\partial\psi}{\partial\lambda}\dot{\lambda}\,. \tag{2.7}$$

Using this expression for $\dot{\psi}$ and using the energy equation to replace $\dot{e}$ in the entropy inequality leads to an intermediate result:

$$\left(\boldsymbol{\sigma} - \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T\right) : \vec{\nabla}\boldsymbol{v} - \rho\left(\eta + \frac{\partial\psi}{\partial T}\right)\dot{T} - (\boldsymbol{q} - Q_{hc}\boldsymbol{s})\cdot\frac{\vec{\nabla}T}{T} - \rho\frac{\partial\psi}{\partial\lambda}\dot{\lambda} - Q_{hc}\vec{\nabla}\cdot\boldsymbol{s} \geq 0\,. \tag{2.8}$$

We restrict our choice in constitutive theory to forms that will automatically satisfy this dissipation inequality as the physical processes in the material range over all admissible deformations and temperature fields. For example, since $\vec{\nabla}\boldsymbol{v}$ can be regarded as an independent field, then in the standard way we restrict the form of the stress tensor such that

$$\boldsymbol{\sigma} = \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T + \boldsymbol{\sigma}^{diss}\,, \tag{2.9}$$

where the dissipative stress $\boldsymbol{\sigma}^{diss}$ satisfies $\boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} \geq 0$. This last requirement is clearly satisfied by the classical choice for a viscous fluid,

$$\boldsymbol{\sigma}^{diss} = \nu_g(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_g\boldsymbol{D}\,, \tag{2.10}$$

where $\boldsymbol{D} = (\vec{\nabla}\boldsymbol{v} + \vec{\nabla}\boldsymbol{v}^T)/2$ and ν_g, μ_g are positive and are identified as the gas-phase bulk and shear viscosities. The assumed form of the stress becomes

$$\boldsymbol{\sigma} = \rho \frac{\partial \psi}{\partial \boldsymbol{F}} \boldsymbol{F}^T + \nu_g (\vec{\nabla} \cdot \boldsymbol{v}) \boldsymbol{I} + 2\mu_g \boldsymbol{D} \,. \tag{2.11}$$

In a similar fashion, since $\dot{T}$ is independent, we require that the Helmholtz free energy must satisfy Gibbs' relation

$$\frac{\partial \psi}{\partial T} = -\eta \,. \tag{2.12}$$

The entropy inequality is now satisfied if the following reduced inequality is satisfied:

$$-(\boldsymbol{q} - Q_{hc}\boldsymbol{s}) \cdot \frac{\vec{\nabla} T}{T} - \rho \frac{\partial \psi}{\partial \lambda} \dot{\lambda} - Q_{hc} \vec{\nabla} \cdot \boldsymbol{s} \geq 0 \,. \tag{2.13}$$

If we assume that the change in the Helmholtz free energy with respect to the progress variable is related to the heat of combustion (which also can be verified and put into direct correspondence with forms derived in mixture theory of reacting gases; see [10], [11], [12]),

$$\frac{\partial \psi}{\partial \lambda} = -Q_{hc} \,, \tag{2.14}$$

and we use the evolution equation for the progress variable $\rho\dot{\lambda} - \vec{\nabla} \cdot \boldsymbol{s} = \rho\Omega$, then the reduced inequality can be recast as

$$-(\boldsymbol{q} - Q_{hc}\boldsymbol{s}) \cdot \frac{\vec{\nabla} T}{T} + \rho \, Q_{hc} \, \Omega \geq 0 \,. \tag{2.15}$$

Finally we make the choice that the energy flux vector is the sum of a Fourier heat conductive flux and an energy flux associated with the diffusion of the product species,

$$\boldsymbol{q} = -k\vec{\nabla} T + Q_{hc} \, \boldsymbol{s} \,, \tag{2.16}$$

and we require that for an exothermic chemical reaction with $Q_{hc} > 0$, the reaction rate must be positive with $\Omega \geq 0$. With these restrictions the second law is automatically satisfied. Recall that $\boldsymbol{s}$ represented the mass flux vector of the product species, $\boldsymbol{s} = \rho\lambda\boldsymbol{V}$, where $\boldsymbol{V}$ is the diffusion velocity of that species. Without further restriction we can make a standard assumption that the diffusion velocity is related to the gradient of the species concentration through a Fick's law relation,

$$\boldsymbol{s} = \rho\lambda\boldsymbol{V} = d \, \vec{\nabla}\lambda \,, \tag{2.17}$$

where $d \geq 0$ is a diffusion coefficient.

2.2. Temperature form of the energy equation. We present the temperature form of the energy equation in terms of a specification of the Helmholtz free energy, in order to set the stage for later discussions. We use the definition of the specific internal energy in terms of the temperature and the entropy, $e = \psi + T\eta$, to obtain $\dot{e} = \dot{\psi} + \eta\dot{T} + T\dot{\eta}$. Next we use the form of the Helmholtz energy $\psi(\boldsymbol{F}, T, \lambda)$ and Gibbs' relation $\eta = -\partial\psi/\partial T$ to generate expressions for $\dot{\psi}$ and $\dot{\eta}$ as

$$\dot{e} = \frac{\partial \psi}{\partial \boldsymbol{F}} \boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} + \frac{\partial \psi}{\partial T} \dot{T} \,, \quad \dot{\eta} = -\frac{\partial^2 \psi}{\partial T \partial \boldsymbol{F}} \boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} - \frac{\partial^2 \psi}{\partial T^2} \dot{T} \,. \tag{2.18}$$

We then insert these expression into (2.3) and make some further simplifications. A collection of terms appears that is associated with the stress-related dissipation

$$\left(\boldsymbol{\sigma} - \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T\right) : \vec{\nabla}\boldsymbol{v} = \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v}\,.$$

Using the classical definition of the specific heat at constant deformation (volume),

$$c_v \equiv T\frac{\partial\eta}{\partial T}\bigg|_{\boldsymbol{F}} = -T\left(\frac{\partial^2\psi}{\partial T^2}\right)\bigg|_{\boldsymbol{F}}, \tag{2.19}$$

the energy equation can be rewritten as follows:

$$\rho c_v\dot{T} = -\vec{\nabla}\cdot\boldsymbol{q} + \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} + \rho T\frac{\partial^2\psi}{\partial T\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v}\,. \tag{2.20}$$

The term $\rho T(\partial^2\psi/\partial T\partial\boldsymbol{F})\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v}$ is a stress work term classically associated with thermal stresses. As we will see below in the case of gaseous combustion for ideal gases, this term is proportional to the pressure work term $-p\,(\vec{\nabla}\cdot\boldsymbol{v})$, where $p = \rho R_g T$ and R_g is the ideal gas constant.

2.2.1. The form of the Helmholtz free energy from classical combustion theory. To complete the classical formulation for premixed combustion, one must specify the form of the Helmholtz free energy. The forms can be extracted from the correct forms found in the binary mixture theory of premixed gases; see [12], [3], [10], [11]. Let $\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T$ be the left Cauchy–Green tensor and let $III_{\boldsymbol{B}} = (\rho_0/\rho)^2$ be the third invariant of $\boldsymbol{B}$. Then the form of the Helmholtz free energy for a thermally ideal material, with the additional term required for the change in enthalpy associated with combustion, is comprised of three parts: a thermal energy density $\psi_1 = c_v[(T - T_0) - T\ln(T/T_0)]$, a strain energy density associated with the temperature (that defines the pressure in terms of the density and temperature) $\psi_2 = -1/2\,R_g T\ln(III_{\boldsymbol{B}})$, and the chemical enthalpy $\psi_3 = -Q_{hc}\lambda$. Thus the total free energy $\psi = \psi_1 + \psi_2 + \psi_3$ is

$$\psi = c_v(T - T_0) - c_v T\ln\left(\frac{T}{T_0}\right) - \frac{1}{2}R_g T\,\ln(III_{\boldsymbol{B}}) - Q_{hc}\lambda\,. \tag{2.21}$$

It follows that the elastic part of the stress can be computed from this form of the free energy and identifies the classical thermodynamic pressure p. In particular, we have that $\rho(\partial\psi/\partial\boldsymbol{F})\boldsymbol{F}^T = 2\rho(\partial\psi/\partial\boldsymbol{B})\boldsymbol{B} = -\rho R_g T\boldsymbol{I} \equiv -p\boldsymbol{I}$, which leads to the identification of the pressure p by the ideal gas law, $p = \rho R_g T$. Also, the thermal stress work term is rewritten $\rho\,(\partial\psi/\partial\boldsymbol{F})\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} = -p\,(\vec{\nabla}\cdot\boldsymbol{v})$. The corresponding form of the entropy and the internal energy (obtained from the definition of the Helmholtz free energy and Gibbs' relation) are given by

$$e = c_v(T - T_0) - Q_{hc}\lambda\,, \qquad \eta = c_v\ln\left(\frac{T}{T_0}\right) + \frac{R}{2}\,\ln(III_{\boldsymbol{B}})\,. \tag{2.22}$$

2.3. Summary of the governing equations for a premixed reactive fluid. Here we summarize the results of the last section that reduce to the classical form of the combustion equations for a premixed combustible fluid. These equations incorporate the various restrictions and constitutive forms that we assumed and are suitable for solving initial value problems ordinarily associated with the theory of premixed

combustion. The entropy (dissipation) inequality is not included in our list since it is automatically satisfied by construction of the model. The equations for $\rho, \boldsymbol{v}, T$, and λ are

$$\dot{\rho} + \rho\vec{\nabla}\cdot\boldsymbol{v} = 0\,, \tag{2.23}$$

$$\rho\,\dot{\boldsymbol{v}} = \vec{\nabla}\cdot\boldsymbol{\sigma} + \rho\boldsymbol{f}\,, \tag{2.24}$$

$$\rho c_v \dot{T} = \vec{\nabla}\cdot(k\vec{\nabla}T) + \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} - p(\vec{\nabla}\cdot\boldsymbol{v}) + \rho\, Q_{hc}\,\Omega\,, \tag{2.25}$$

$$\rho\dot{\lambda} = \vec{\nabla}\cdot(d\,\vec{\nabla}\lambda) + \rho\Omega\,, \tag{2.26}$$

with the constitutive relation for the stress given by $\boldsymbol{\sigma} = -\rho R_g T\boldsymbol{I} + \nu_g\vec{\nabla}\cdot\boldsymbol{v}\boldsymbol{I} + 2\mu_g\boldsymbol{D}$, with $\boldsymbol{\sigma}^{diss} = \nu_g\vec{\nabla}\cdot\boldsymbol{v}\boldsymbol{I} + 2\mu_g\boldsymbol{D}$, and with $\boldsymbol{D} = (\vec{\nabla}\boldsymbol{v} + \vec{\nabla}\boldsymbol{v}^T)/2$.

3. Thermomechanics of a model of a material with phase changes from solid to liquid to gas. Here we develop a model for a material that can undergo a phase change from solid to liquid to gas in preparation for the development of the combined model, which includes chemical reaction and exothermic energy release. The important difference in the development in this section from that in section 2 is the introduction of a phase variable that is used to describe and delineate the separate phases. In order to describe the phase transitions we introduce the (normalized) variable ϕ so that $\phi = 0$ corresponds to the solid phase, $\phi = 1$ to the liquid phase, and $\phi = 2$ to the vapor phase. In its pure phases, solid, liquid, and gas, the material is prescribed by classical models for that pure phase, i.e., a compressible elastic solid and a compressible Newtonian liquid and gas.

A consistent thermodynamic formulation for the model is developed through an extension of a formulation proposed by Gurtin [9]. Energy expended by the system during a phase change is associated with configurational forces of two types—a configurational stress that acts at or near the boundaries between phases which is balanced by a configurational force distributed in the bulk. The power expenditure of these forces must be accounted for in the energy balance. If one assumes that the configurational forces in the material are balanced separately (this is a posited balance), then the evolution of the phase field ϕ is constrained by the entropy inequality to be dissipative and further considerations lead to the derivation of an evolution law for ϕ. This is in contrast to the formulation of the last section, which considered the evolution law for the progress variable λ as posited. Presumably (and we have considered this in some detail that is not presented here), an alternative to deriving the equation for ϕ is to pose an evolution equation as fundamental and then derive the consequence of local balance for the configurational forces. Either way, one comes to similar physical conclusions. The consequences of this choice, in absence of better, physically based arguments, need to be judged against the forms of the equations that result that allow us to solve interesting initial value problems.

The starting point is the form of the general laws. The differential form of the general law for mass, (2.1), and momentum, (2.2), are unchanged from the previous section. We turn to the more unfamiliar considerations of the force balance law associated with the phase change and corresponding changes in the energy balance next.

3.0.1. Force balances associated with the change in phase. Associated with the evolution of the phase variable ϕ, we introduce a balance of configurational stress $\boldsymbol{\xi}$, a configurational internal force density π_ϕ. The integral form of the balance

law for a body in region $\mathcal{B}$ with boundary $\partial\mathcal{B}$ is

$$\int_{\partial\mathcal{B}} \boldsymbol{\xi}\cdot\boldsymbol{n}\, dA + \int_{\mathcal{B}} (\pi_\phi)\, dV = 0, \tag{3.1}$$

and with the use of the divergence theorem, the corresponding differential form of the balance law is

$$\vec{\nabla}\cdot\boldsymbol{\xi} + \pi_\phi = 0\,. \tag{3.2}$$

3.0.2. Rate of work. The rate of work expended on $\mathcal{B}$ is due to the external forces acting on the surface and within the volume of $\mathcal{B}$. Gurtin [9] shows that the correct form for the rate of work due to all stresses is

$$\mathcal{W} \equiv \int_{\partial\mathcal{B}} \big(\boldsymbol{\sigma}\boldsymbol{n}\cdot\boldsymbol{v} + \boldsymbol{\xi}\cdot(\dot{\phi}\boldsymbol{n})\big)\, dA + \int_{\mathcal{B}} \boldsymbol{b}\cdot\boldsymbol{v}\, dV. \tag{3.3}$$

The integral form of the energy balance can be written in the standard way as the material derivative of the total energy (internal and kinetic) equated to the rate of work minus the energy flux out of the body plus the rate of heating by any other source; thus

$$\frac{D}{Dt}\int_{\mathcal{B}} \rho(e + \tfrac{1}{2}|\boldsymbol{v}|^2)\, dV = \mathcal{W} - \int_{\partial\mathcal{B}} \boldsymbol{q}\cdot\boldsymbol{n}\, dA + \int_{\mathcal{B}} \rho r\, dV\,. \tag{3.4}$$

To obtain the differential form we convert the surface integrals into volume integrals and use the divergence theorem. The resulting integral must hold everywhere for all subvolumes, so the resulting integrand is set to zero, which leads to an intermediate differential form (not shown). We then use the momentum equation and take its dot product with the velocity $\boldsymbol{v}$ to get the standard work-energy statement on a material path and subtract that result from the above-mentioned intermediate form to get the following form of the energy equation:

$$\rho\dot{e} = -\vec{\nabla}\cdot\boldsymbol{q} + \boldsymbol{\sigma} : \vec{\nabla}\boldsymbol{v} + \boldsymbol{\xi}\cdot\vec{\nabla}(\dot{\phi}) - \pi_\phi\dot{\phi} + \rho r\,. \tag{3.5}$$

The main difference from the classical form is the appearance of the two work terms $\boldsymbol{\xi}\cdot\vec{\nabla}(\dot{\phi})$ and $-\pi_\phi\dot{\phi}$ that derive from the configurational forces. For upcoming considerations of the entropy inequality, it is useful to use identities (which can be verified easily in Cartesian index notation) to rewrite the term $\boldsymbol{\xi}\cdot\vec{\nabla}(\dot{\phi})$ as

$$\boldsymbol{\xi}\cdot\vec{\nabla}(\dot{\phi}) = \dot{\overline{\vec{\nabla}\phi}}\cdot\boldsymbol{\xi} + \vec{\nabla}\phi\otimes\boldsymbol{\xi} : \boldsymbol{L}\,, \tag{3.6}$$

so that the revised energy equation reads as

$$\rho\dot{e} = -\vec{\nabla}\cdot\boldsymbol{q} + \boldsymbol{\sigma} : \vec{\nabla}\boldsymbol{v} + \dot{\overline{\vec{\nabla}\phi}}\cdot\boldsymbol{\xi} + \vec{\nabla}\phi\otimes\boldsymbol{\xi} : \vec{\nabla}\boldsymbol{v} - \pi_\phi\dot{\phi} + \rho r\,. \tag{3.7}$$

3.0.3. The entropy inequality. Finally, to these basic laws we must add the second law of thermodynamics, the Clausius–Duhem inequality

$$\rho\,\dot{\eta} \geq -\vec{\nabla}\cdot\Big(\frac{\boldsymbol{q}}{T}\Big) + \frac{\rho r}{T}\,. \tag{3.8}$$

Note that since ϕ is not assumed to be related to a partial mass density of material, there is no entropy flux term like $\vec{\nabla}\cdot(Q_{hc}\,\boldsymbol{s}/T)$ that appears in the combustion-based entropy inequality (2.5). Equation (3.8) is the classical (inert) form of the entropy inequality.

3.0.4. Constitutive forms and restrictions from the entropy inequality. We restrict our attention to a general class of constitutive equations and start with a very general assumption that the free energy density ψ, the Cauchy stress $\boldsymbol{\sigma}$, the configurational stresses $\boldsymbol{\xi}$, and the internal configurational force π_ϕ, the entropy density η, and the heat flux $\boldsymbol{q}$ at any point $(\boldsymbol{x}, t)$ are dependent on the deformation gradient $\boldsymbol{F}$, the temperature T, the phase field ϕ, the gradients $\vec{\nabla}T$, $\vec{\nabla}\phi$, and the velocity gradient $\boldsymbol{L}$, such that we can write

$$\psi = \psi(\boldsymbol{F}, T, \phi, \vec{\nabla}T, \vec{\nabla}\phi, \boldsymbol{L}). \tag{3.9}$$

We assume that $\boldsymbol{\sigma}, \boldsymbol{\xi}, \pi_\phi, \eta$, and $\boldsymbol{q}$ all depend on the same argument list, $(\boldsymbol{F}, T, \phi, \vec{\nabla}T, \vec{\nabla}\phi, \boldsymbol{L})$. We use the definition of the Helmholtz free energy to get an expression for the entropy, $\eta = (e - \psi)/T$, take the material derivative, and then use the energy equation to replace $\dot{e}$ and use the chain rule to replace $\dot{\psi}$. These substitutions into the entropy inequality lead to the intermediate result:

$$\left(\boldsymbol{\sigma} - \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T + \vec{\nabla}\phi\otimes\boldsymbol{\xi}\right) : \vec{\nabla}\boldsymbol{v} - \rho\left(\eta + \frac{\partial\psi}{\partial T}\right)\dot{T} - \left(\pi_\phi + \rho\frac{\partial\psi}{\partial\phi}\right)\dot{\phi}$$

$$-\rho\,\frac{\partial\psi}{\partial\vec{\nabla}T}\cdot\dot{\vec{\nabla}T} - \left(\rho\frac{\partial\psi}{\partial\vec{\nabla}\phi} - \boldsymbol{\xi}\right)\cdot\dot{\vec{\nabla}\phi} - \rho\left(\frac{\partial\psi}{\partial\boldsymbol{L}}\right) : \dot{\boldsymbol{L}} - \boldsymbol{q}\cdot\frac{\vec{\nabla}T}{T} \geq 0\,. \tag{3.10}$$

Again we restrict our choice of constitutive forms to those that automatically satisfy this dissipation inequality as the physical process in the material ranges over all admissible deformations and temperature and phase fields. We restrict the form of the stress tensor such that

$$\boldsymbol{\sigma} = \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T - \vec{\nabla}\phi\otimes\boldsymbol{\xi} + \boldsymbol{\sigma}^{diss}\,, \tag{3.11}$$

where again $\boldsymbol{\sigma}^{diss}$ must be chosen to satisfy $\boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} \geq 0$. Later we will take $\boldsymbol{\sigma}^{diss}$ to be given by (2.10), where the shear and bulk viscosities are taken to be functions of the phase field variable ϕ. We require that Gibbs' relation be satisfied and that the configurational force $\boldsymbol{\xi}$ be defined by the derivative of the Helmholtz free energy with respect to the gradient of ϕ such that

$$\eta = -\frac{\partial\psi}{\partial T} \quad \text{and} \quad \boldsymbol{\xi} = \rho\frac{\partial\psi}{\partial\vec{\nabla}\phi}\,. \tag{3.12}$$

We also assume that the Helmholtz free energy is independent of $\boldsymbol{L} = \vec{\nabla}\boldsymbol{v}$ and the temperature gradient $\vec{\nabla}T$ so that

$$\frac{\partial\psi}{\partial\boldsymbol{L}} = 0 \quad \text{and} \quad \frac{\partial\psi}{\partial\vec{\nabla}T} = 0 \tag{3.13}$$

hold. We also suppose that the energy flux vector is described by a Fourier heat conduction law, $\boldsymbol{q} = -k\vec{\nabla}T$, and insist that k is a positive constant that can be a function of the temperature and the order parameter, i.e., $k(\phi, T) \geq 0$. Then the reduced dissipation inequality now has the form

$$-\left(\pi_\phi + \rho\frac{\partial\psi}{\partial\phi}\right)\dot{\phi} \geq 0\,. \tag{3.14}$$

The final form of the reduced dissipation inequality is satisfied if we require that the phase changes be dissipative and if we allow π_ϕ to take the form

$$-\left(\pi_\phi + \rho\frac{\partial\psi}{\partial\phi}\right) = B\dot{\phi}, \tag{3.15}$$

where $B \geq 0$. Equation (3.15) is an evolution equation for the phase variable ϕ. Note that the configurational force balance (3.2) defines $\pi_\phi = -\vec{\nabla}\cdot\boldsymbol{\xi}$ and with the configurational force identified by $\boldsymbol{\xi} = \rho(\partial\psi/\partial\vec{\nabla}\phi)$ leads to $\pi_\phi = -\vec{\nabla}\cdot(\rho\partial\psi/\partial\vec{\nabla}\phi)$. Thus (3.15) can be re-expressed as

$$B\dot{\phi} = \vec{\nabla}\cdot\left(\rho\frac{\partial\psi}{\partial\vec{\nabla}\phi}\right) - \rho\frac{\partial\psi}{\partial\phi}\,. \tag{3.16}$$

Given appropriate forms for ψ (such as quadratic dependence of ψ on $\vec{\nabla}\phi$), (3.16) is recognized as an advection, reaction-diffusion equation, which, given an assumed form for ψ, can generate a Ginzburg–Landau equation. The coefficient B^{-1} is then recognized as a kinetic rate constant for the phase transformation.

3.1. Temperature form of the energy equation. In order to show the coupling between the thermal (temperature) field, the stress field, and the phase field, we present an alternative form of the energy equation. Starting with the energy balance (3.7) we use the definition of the specific internal energy in terms of the temperature and the entropy, $e = \psi + T\eta$, to obtain $\dot{e} = \dot{\psi} + \eta\dot{T} + T\dot{\eta}$. Next we use the form of the Helmholtz energy $\psi(\phi, T, \vec{\nabla}\phi, \boldsymbol{F})$ and Gibbs' relation, $\eta = -\partial\psi/\partial T$, to generate expressions for $\dot{\psi}$ and $\dot{\eta}$:

$$\dot{\psi} = \frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} + \frac{\partial\psi}{\partial T}\dot{T} + \frac{\partial\psi}{\partial\phi}\dot{\phi} + \frac{\partial\psi}{\partial\vec{\nabla}\phi}\cdot\dot{\vec{\nabla}\phi}\,, \tag{3.17}$$

$$\dot{\eta} = -\frac{\partial^2\psi}{\partial T\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} - \frac{\partial^2\psi}{\partial T^2}\dot{T} - \frac{\partial^2\psi}{\partial T\partial\phi}\dot{\phi} - \frac{\partial^2\psi}{\partial T\partial\vec{\nabla}\phi}\cdot\dot{\vec{\nabla}\phi}\,. \tag{3.18}$$

We then insert these expressions into (3.7) and make some further simplifications. In the resulting collection, terms proportional to $\dot{T}$ drop out because of Gibb's relation $\eta = -\partial\psi/\partial T$. Likewise, terms proportional to $\dot{\vec{\nabla}\phi}$ drop out because of the relation for the configurational stress $\boldsymbol{\xi} = \rho(\partial\psi/\partial\vec{\nabla}\phi)$. A collection of terms appear that is associated with the stress-related dissipation

$$\left(\boldsymbol{\sigma} - \rho\frac{\partial\psi}{\partial\boldsymbol{F}}\boldsymbol{F}^T + \vec{\nabla}\phi\otimes\boldsymbol{\xi}\right) : \vec{\nabla}\boldsymbol{v} = \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v},$$

and a collection of terms associated with the dissipation induced by the phase transformation appears,

$$-\left(\rho\frac{\partial\psi}{\partial\phi} + \pi_\phi\right)\dot{\phi} = B\dot{\phi}^2\,.$$

Using the classical definition of the specific heat at constant deformation (volume), $c_v \equiv T(\partial\eta/\partial T)_{\boldsymbol{F}} = -T(\partial^2\psi/\partial T^2)_{\boldsymbol{F}}$, the energy equation can be rewritten as follows:

$$\begin{aligned}\rho c_v\dot{T} = -\vec{\nabla}\cdot\boldsymbol{q} + \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} + B\dot{\phi}^2 + \rho T\frac{\partial^2\psi}{\partial T\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} \\ + \ \rho T\frac{\partial^2\psi}{\partial T\partial\phi}\dot{\phi} + \rho T\frac{\partial^2\psi}{\partial T\partial\vec{\nabla}\phi}\cdot\dot{\vec{\nabla}\phi} + \rho r\,.\end{aligned} \tag{3.19}$$

Some straightforward physical interpretations can be made for the various terms. The term $\boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v}$ is the viscous dissipation associated with the stress. The term $B\dot{\phi}^2$ is a dissipation associated with the phase change. The term $\rho T(\partial^2\psi/\partial T\partial\phi)\,\dot{\phi}$ is an energy source term that is associated with enthalpic changes in phase (similar to those associated with the heat of combustion for reacting flows). The term $\rho T(\partial^2\psi/\partial T\partial\boldsymbol{F})\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v}$ is (again) a stress work term classically associated with thermal stresses. Similarly, the term $\rho T(\partial^2\psi/\partial T\partial\vec{\nabla}\partial\phi)\cdot\dot{\vec{\nabla}}\phi$ is a thermal stress work term associated with the configurational stress of the phase change.

3.1.1. Invariance requirements and isotropy. Most energetic solids are encountered as fine-grained polycrystalline aggregates and are often modeled with conventional isotropic liquid and gaseous forms. We now restrict our attention to isotropic materials, and we ignore possible anisotropic properties in this model. As is conventional we require that the material response is invariant under superposed rigid changes of observer. It can be shown in a standard way that the constitutive dependence on the deformation gradient $\boldsymbol{F}$ can be replaced by the left Cauchy–Green tensor $\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T$ and that the dependence on the velocity gradient is replaced by the symmetric stretching tensor $\boldsymbol{D} = (\boldsymbol{L} + \boldsymbol{L}^T)/2$. Furthermore, isotropy requires that the dependence on $\boldsymbol{B}$ appears through its principal scalar invariants $I_{\boldsymbol{B}} = \text{trace}\boldsymbol{B}$, $II_{\boldsymbol{B}} = \frac{1}{2}\big((\text{trace}\boldsymbol{B})^2 - \text{trace}(\boldsymbol{B}^2)\big)$, and $III_{\boldsymbol{B}} = \det\boldsymbol{B}$.

3.1.2. Constitutive specification of the Helmholtz free energy. Having made arguments that constrain the general form of the constitutive description, we next specialize the forms to extend the phase field constitutive forms and to capture commonly used classical forms for the pure solid, liquid, and gas phases. Without regard to exothermic chemical reaction, we will assume that the Helmholtz free energy is composed of four parts, such that we can write

$$\psi = \psi_1 + \psi_2 + \psi_3 + \psi_4\,. \tag{3.20}$$

The first two, ψ_1, ψ_2, are to be associated with the formulation of the phase transformations—the phase gradient energy density and the enthalpies associated with the phase transition. The latter two, ψ_3, ψ_4, are of classical origins—the thermal energy density and the strain energy density.

We assume that the Helmholtz free energy depends on $\vec{\nabla}\phi$ only through ψ_1 and that the phase gradient energy density is specified with the explicit quadratic dependence by

$$\psi_1 = \tfrac{1}{2}\gamma_\phi|\vec{\nabla}\phi|^2\,. \tag{3.21}$$

It follows from (3.12) that the configurational force $\boldsymbol{\xi}$ is determined by the formula

$$\boldsymbol{\xi} = \rho\frac{\partial\psi}{\partial\vec{\nabla}\phi} = \rho\gamma_\phi\vec{\nabla}\phi\,. \tag{3.22}$$

The physical interpretation of the phase-configurational stress $\boldsymbol{\xi}$ is as a traction that acts near or in the phase transition region in the direction of the gradient of $\vec{\nabla}\phi$, i.e., perpendicular to contours of constant ϕ.

Next we consider the contribution ψ_2, the phase transition energy density which reflects enthalpy changes during phase transition and is specified as

$$\psi_2 = \frac{1}{2}\Psi^{well}\mathcal{F}(\phi) + \beta_m(\phi)Q_m\Big(\frac{T}{T_m} - 1\Big) + \beta_v(\phi)Q_v\Big(\frac{T}{T_v} - 1\Big)\,. \tag{3.23}$$

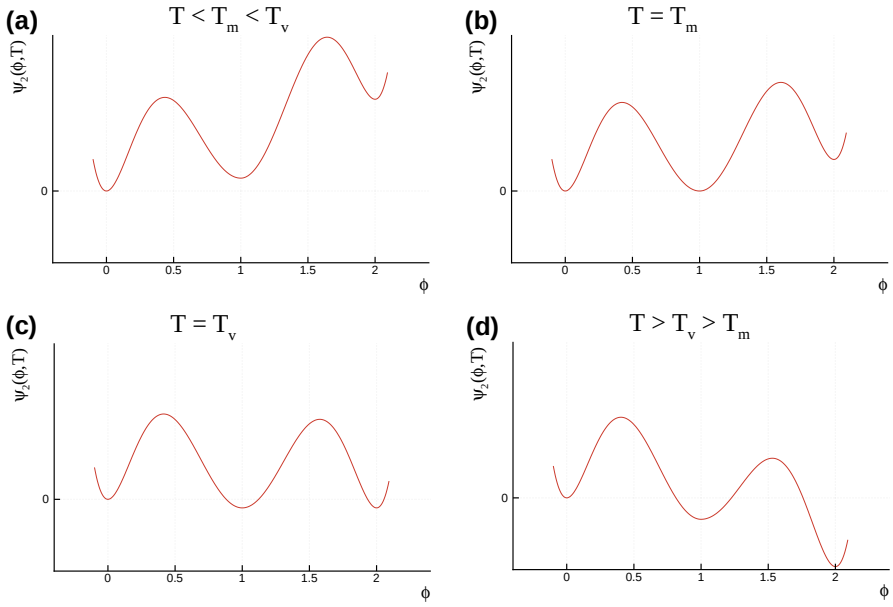

FIG. 1. *Plot of ψ_2 as a function of ϕ with T variation.*

The constants $\Psi^{well} > 0$, $Q_m < 0$, and $Q_v < 0$ represent a potential well depth and the heats of melting and vaporization. The constants $T_m > 0$ and $T_v > 0$ represent temperatures of melting and vaporization. The triple-well potential $\mathcal{F}(\phi)$ can be described by a smooth positive definite function whose isolated zeros are at $\phi = 0, 1$, and 2, representing three local minima. In addition, $\mathcal{F}(\phi)$ is assumed to be locally quadratic near the zeros at $\phi = 0, 1$, and 2, i.e., near $\phi = 0$, $\mathcal{F} \sim \phi^2$, near $\phi = 1$, $\mathcal{F} \sim (\phi - 1)^2$, and near $\phi = 2$, $\mathcal{F} \sim (\phi - 2)^2$. As an illustration, $\mathcal{F} = [\phi(\phi - 1)(\phi - 2)]^2$ has this property. The function $\beta_m(\phi)$ is assumed to be smooth and monotonically increasing and has values from 0 to 1 on the range $0 \le \phi \le 1$ with zero derivative elsewhere. The function $\beta_v(\phi)$ is similarly assumed to be monotonically increasing with values from 0 to 1 on the range $1 \le \phi \le 2$. Note that the derivative of transition energy density $\partial\psi_2/\partial\phi$ generates source terms in both the energy and phase equations represented as

$$\frac{\partial \psi_2}{\partial \phi} = \frac{1}{2}\Psi^{well}\frac{\partial \mathcal{F}}{\partial \phi}(\phi) + \beta_m'(\phi)Q_m\Big(\frac{T}{T_m} - 1\Big) + \beta_v'(\phi)Q_v\Big(\frac{T}{T_v} - 1\Big). \tag{3.24}$$

Figure 1 illustrates the assumed dependence of $\psi(\phi, T)$ on ϕ and T. Starting from (a) through (d), temperature T is raised from below T_m to above T_v, representing a standard melting-evaporation process. The transition energy density in case (a) has its minimum at $\phi = 0$. As T is increased through T_m and then T_v, we see a shift in the global minima from pure solid to solid-liquid and to liquid-vapor. As T eventually exceeds T_v as shown in (d), the energy minimizing well shifts to a vapor state at $\phi = 2$. The coefficients and functions Ψ^{well}, β_m, β_v can be adjusted (if needed) to reflect more accurately the physical properties observed in accordance with the phase transformation. Here we have chosen very simple forms.

We again assume the classical form for the thermal energy density and choose ψ_3

(which has the same form as ψ_1 in section 2) to be

$$\psi_3 = c_v \left[(T - T_0) - T \ln(T/T_0) \right], \tag{3.25}$$

where c_v is the specific heat at constant deformation. This is consistent with simple ideal models for solids, liquids, and gases.

Finally we choose a form for ψ_4, the strain energy density. We assume that it is composed of three subparts. The first part is associated with the thermal expansion stresses commonly identified in the condensed phase:

$$\psi_{4a} = -\frac{\alpha_c(\phi) K}{2\rho_0} (T - T_0) \ln(III_{\boldsymbol{B}}), \tag{3.26}$$

where K is the solid bulk modulus and α_c is the linear coefficient of thermal expansion. We again take $\alpha_c(\phi)$ to be a smooth, nonzero function in the condensed phases, solid and liquid, and zero in the gas phase. For example, $\alpha_c(0) = \alpha_{solid}$, $\alpha_c(1) = \alpha_{liquid}$, and $\alpha_c(2) = 0$. The second part of ψ_4 is associated with the pressure commonly identified in an ideal gas that we encountered in the previous section on gaseous combustion:

$$\psi_{4b} = -\frac{1}{2} R_g(\phi) T \ln(III_{\boldsymbol{B}}). \tag{3.27}$$

Here $R_g(\phi)$ plays the role of the ideal gas constant except that it is assumed to be nonzero in the gas phase and at or near zero in the solid and liquid condensed phase such that $R_g(0) = 0$, $R_g(1) = 0$, $R_g(2) = R_{gas}$.

The third part, ψ_{4c}, is based on properties of a compressible neo-Hookean, Blatz–Ko solid [15] which is given as

$$\psi_{BK} = \frac{\mu}{2\rho_0} (I_{\boldsymbol{B}} - 3) + \frac{\mu(1 - 2\nu)}{2\rho_0 \nu} \left(III_{\boldsymbol{B}}^{-\nu/(1-2\nu)} - 1 \right). \tag{3.28}$$

The constants ν and μ here represent the Poisson ratio of the material and the elastic Lamé parameter, μ. The contribution to the stress associated with this potential is

$$\boldsymbol{\sigma}_{BK} = 2\rho \frac{\partial \psi_{BK}}{\partial \boldsymbol{B}} \boldsymbol{B} = \mu_s \frac{\rho}{\rho_0} \boldsymbol{B} - \mu \frac{\rho}{\rho_0} III_{\boldsymbol{B}}^{-\nu/(1-2\nu)} \boldsymbol{I}. \tag{3.29}$$

We use this to model the elastic deformation of the solid, but for the liquid we pose a slightly altered form of this potential based on purely isotropic deformations. Consider the isotropic (either uniform contraction or expansion) given by $\boldsymbol{x} = s\boldsymbol{X}$, where s is the stretch ratio of material line segments. It follows simply that $\boldsymbol{F} = s\boldsymbol{I}$, $\boldsymbol{B} = s^2 \boldsymbol{I}$, $III_{\boldsymbol{B}} = \det(\boldsymbol{B}) = (\rho_0/\rho)^2 = s^6$, $s = (\rho_0/\rho)^{1/3}$, $\boldsymbol{B} = (\rho_0/\rho)^{1/3} \boldsymbol{I}$, and $(\rho_0/\rho)^{1/3} = III_{\boldsymbol{B}}^{1/6}$. For the Blatz–Ko solid, the isotropic stress is related to the volume ratio by

$$\boldsymbol{\sigma} = -\mu \frac{\rho}{\rho_0} \left[\left(\frac{\rho}{\rho_0} \right)^{-\frac{2\nu}{1-2\nu}} - \left(\frac{\rho}{\rho_0} \right)^{-\frac{1}{3}} \right] \boldsymbol{I}. \tag{3.30}$$

We choose our model for the strain energy of the liquid to have the same functional form for the isotropic stress dependence on the density ratio as that for the solid, and

merely note that we replace the dependence on ρ_0/ρ by $III_{\boldsymbol{B}}^{1/2}$ and work backwards. The corresponding Helmholtz free energy for the liquid would take the form

$$\psi_{BK(liquid)} = \frac{3}{2}\frac{\mu}{\rho_0} III_{\boldsymbol{B}}^{1/3} + \frac{\mu(1-2\nu)}{2\rho_0\nu}\left(III_{\boldsymbol{B}}^{-\nu/(1-2\nu)} - 1\right). \tag{3.31}$$

We can combine the two potentials for the solid and the liquid in the following way. Let $\mu_s(\phi)$ be a coefficient such that $\mu_s(0) = \mu_{solid}$ and it is zero for $\phi \geq 1$. Let $\mu_l(\phi)$ be a smooth function such that $\mu_l(1) = \mu_{liquid}$ with $\mu_l(0) = \mu_l(2) = 0$. One makes similar definitions for ν_s and ν_l. Let μ_c be defined as the sum $\mu_c = \mu_l + \mu_s$, and $\nu_c = \nu_l + \nu_s$. Then the combined solid, liquid, elastic potential can be written as

$$\psi_{4c} = \frac{\mu_s}{2\rho_0}(I_{\boldsymbol{B}} - 3) + \frac{3}{2}\frac{\mu_l}{\rho_0} III_{\boldsymbol{B}}^{1/3} + \frac{\mu_c(1-2\nu_c)}{2\rho_0\nu_c}\left(III_{\boldsymbol{B}}^{-\nu_c/(1-2\nu_c)} - 1\right). \tag{3.32}$$

Note that other functional forms for the strain energy density could have been chosen for ψ_{4c}, but we chose the Blatz–Ko form since it has a simple reduction to compressible linear elasticity in the limit of small strain, which is deemed convenient for our purposes. We anticipate that as the solid become significantly nonlinearly elastic, we expect that a phase transformation will occur so that the specific choice of Blatz–Ko is not a sensitive one for the properties of the model. The deformational portion of stress associated with this strain energy is ψ_{4c},

$$\boldsymbol{\sigma}^{def} \equiv 2\rho\frac{\partial\psi_{4c}}{\partial\boldsymbol{B}}\boldsymbol{B} = \mu_s\frac{\rho}{\rho_o}\boldsymbol{B} - \mu_c\frac{\rho}{\rho_o} III_{\boldsymbol{B}}^{-\nu_s/(1-2\nu_s)}\boldsymbol{I} + \mu_l\frac{\rho}{\rho_o} III_{\boldsymbol{B}}^{1/3}\boldsymbol{I}. \tag{3.33}$$

3.2. Total free-energy density and summary of constitutive forms. The form of $\psi = \psi_1 + \psi_2 + \psi_3 + \psi_{4a} + \psi_{4b} + \psi_{4c}$ is written as

$$\begin{aligned}
\psi = {} & \frac{\mu_s(\phi)}{2\rho_0}(I_{\boldsymbol{B}} - 3) + \frac{\mu_c(\phi)(1-2\nu_s)}{2\rho_0\nu_s}\left(III_{\boldsymbol{B}}^{-\nu_s/(1-2\nu_s)} - 1\right) + \frac{3\mu_l(\phi)}{2\rho_o} III_{\boldsymbol{B}}^{1/3} \\
& - \frac{\alpha_c(\phi)K}{2\rho_0}(T - T_0)\ln(III_{\boldsymbol{B}}) - \frac{1}{2}R_g(\phi)T\ln(III_{\boldsymbol{B}}) && \text{strain energy density} \\
& - c_v(\phi)\left[T\ln\left(\frac{T}{T_0}\right) - (T - T_0)\right] && \text{thermal energy density} \\
& + \frac{1}{2}\Psi^{well}\mathcal{F}(\phi) + \beta_m(\phi)\left(\frac{T}{T_m} - 1\right)Q_m + \beta_v(\phi)\left(\frac{T}{T_v} - 1\right)Q_v && \text{phase transition energy density} \\
& + \frac{1}{2}\gamma_\phi|\vec{\nabla}\phi|^2. && \text{gradient energy density}
\end{aligned} \tag{3.34}$$

The constitutive theory is essentially complete. The stress is given by the general expression

$$\boldsymbol{\sigma} = \rho\frac{\partial\psi}{\partial\boldsymbol{B}}\boldsymbol{B} - \vec{\nabla}\phi\otimes\boldsymbol{\xi} + \boldsymbol{\sigma}^{diss}, \tag{3.35}$$

with $\boldsymbol{\xi}$ given by $\boldsymbol{\xi} = \rho\gamma_\phi\vec{\nabla}\phi$ and $\boldsymbol{\sigma}^{diss}$ given by $\boldsymbol{\sigma}^{diss} = \mu_f(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_f\boldsymbol{D}$. The stress formula becomes

$$\begin{aligned}
\boldsymbol{\sigma} = {} & \mu_s\frac{\rho}{\rho_0}\boldsymbol{B} - \mu_c\frac{\rho}{\rho_0} III_{\boldsymbol{B}}^{-(\nu_s/1-2\nu_s)}\boldsymbol{I} + \mu_l\frac{\rho}{\rho_o} III_{\boldsymbol{B}}^{1/3}\boldsymbol{I} \\
& - \alpha_c(\phi)K\frac{\rho}{\rho_0}(T - T_0)\boldsymbol{I} - \rho R_g(\phi)T\boldsymbol{I} \\
& - \rho\gamma_\phi\vec{\nabla}\phi\otimes\vec{\nabla}\phi + \nu_f(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_f\boldsymbol{D}.
\end{aligned} \tag{3.36}$$

The energy flux vector remains $\boldsymbol{q} = -k\vec{\nabla}T$. The various source terms in the energy and phase equations can be computed from the forms given in (3.34).

We can now summarize the governing equations for the phase change model as

$$\dot{\rho} + \rho\vec{\nabla}\cdot\boldsymbol{v} = 0\,, \tag{3.37}$$

$$\rho\,\dot{\boldsymbol{v}} = \vec{\nabla}\cdot\boldsymbol{\sigma} + \rho\boldsymbol{f}\,, \tag{3.38}$$

$$\begin{aligned}\rho c_v\dot{T} = {}& \vec{\nabla}\cdot(k\vec{\nabla}T) + \boldsymbol{\sigma}^{diss} : \vec{\nabla}\boldsymbol{v} + B\dot{\phi}^2 + \rho T\frac{\partial^2\psi}{\partial T\partial\boldsymbol{F}}\boldsymbol{F}^T : \vec{\nabla}\boldsymbol{v} \\ & + \rho T\frac{\partial^2\psi}{\partial T\partial\phi}\dot{\phi} + \rho T\frac{\partial^2\psi}{\partial T\partial\vec{\nabla}\phi}\cdot\dot{\vec{\nabla}}\phi + \rho r\,,\end{aligned} \tag{3.39}$$

$$B\dot{\phi} = \vec{\nabla}\cdot(\rho\gamma_\phi\vec{\nabla}\phi) - \rho\frac{\partial\psi}{\partial\phi}\,, \tag{3.40}$$

$$\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}, \tag{3.41}$$

where B, c_v, γ_ϕ, k, etc. are constitutive scalars which could be regarded as functions of both ϕ and T. We have added the kinematic identity (3.41) in order to compute the evolution of the displacement gradients.

4. The combined model: Modifications to include chemical reaction. Here we list the modifications required to combine both models into one. First we take the phase change model as the starting point and we retain all the assumptions and assumed forms of the previous section, specifically in regards to the appearance of ϕ. The configurational force balance (3.2) is retained as a fundamental balance law (the consequence of which leads to the derivation of the evolution equation for ϕ, equation (3.40)).

Next we assume that, in addition to ϕ, which measures the molecular order of the phase, the mass fraction λ simultaneously measures the amount of exothermic chemical reaction that has taken place. So λ is added to all the argument lists; in particular, in the expression for ψ we assume the dependence

$$\psi = \psi(\boldsymbol{F}, T, \phi, \lambda, \vec{\nabla}\phi, \boldsymbol{L})\,. \tag{4.1}$$

A statement of conservation of λ is added in the form of (2.4), which reflects a molecularly based conservation of species. The second law must be modified to include the entropy flux associated with the heat of combustion (so it takes the same form as (2.5)),

$$\rho\,\dot{\eta} \geq -\vec{\nabla}\cdot\left(\frac{\boldsymbol{q}}{T}\right) + \vec{\nabla}\cdot\left(\frac{Q_{hc}\boldsymbol{s}}{T}\right) + \frac{\rho r}{T}\,. \tag{4.2}$$

One argues the entropy inequality in exactly the same manner as in the previous section, with the same assumptions and conclusions of section 3, with the additional exception that one uses the evolution equation for λ, (2.4), to reduce the dissipation inequality in the manner explained in section 2. The energy flux vector is identified by the requirement of positivity of the left-hand side of (2.15), which leads to

$$\boldsymbol{q} = -k\vec{\nabla}T + Q_{hc}\boldsymbol{s}\,. \tag{4.3}$$

The vector $\boldsymbol{s}$ can be chosen according to Fick's law such that

$$\boldsymbol{s} = d\,\vec{\nabla}\lambda\,. \tag{4.4}$$

The Helmholtz free energy is designated as $\psi = \psi_1+\psi_2+\psi_3+\psi_{4a}+\psi_{4b}+\psi_{4c}+\psi_5$, where ψ_{1-4c} are defined in the previous section and ψ_5 is the chemical enthalpy $\psi_5 = -Q_{hc}\lambda$. The configurational stress is again of the form $\boldsymbol{\xi} = \rho\gamma_\phi\vec{\nabla}\phi$. The representation of the stress is

$$\begin{aligned}\boldsymbol{\sigma} = {}& \mu_s\frac{\rho}{\rho_0}\boldsymbol{B} - \mu_c\frac{\rho}{\rho_0}III_{\boldsymbol{B}}^{-(\nu_s/(1-2\nu_s)}\boldsymbol{I} + \mu_l\frac{\rho}{\rho_o}III_{\boldsymbol{B}}^{1/3}\boldsymbol{I}\\ & - \alpha_c(\phi)K\frac{\rho}{\rho_0}(T-T_0)\boldsymbol{I} - \rho R_g(\phi)T\boldsymbol{I}\\ & - \rho\gamma_\phi\vec{\nabla}\phi\otimes\vec{\nabla}\phi + \nu_f(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_f\boldsymbol{D}\,.\end{aligned} \tag{4.5}$$

The various scalar material properties identified previously, such as $c_v, \gamma_\phi, \ldots$, now can also have explicit dependence on λ as well as ϕ and T.

A revised list of the governing equations for the combined model with reaction and phase change is

$$\dot{\rho} + \rho\vec{\nabla}\cdot\boldsymbol{v} = 0\,, \tag{4.6}$$

$$\rho\,\dot{\boldsymbol{v}} = \vec{\nabla}\cdot\boldsymbol{\sigma} + \rho\boldsymbol{f}\,, \tag{4.7}$$

$$\begin{aligned}\rho c_v\dot{T} = {}& \vec{\nabla}\cdot(k\vec{\nabla}T) + \boldsymbol{\sigma}^{diss}:\vec{\nabla}\boldsymbol{v} + B\dot{\phi}^2 + \rho T\frac{\partial^2\psi}{\partial T\partial\boldsymbol{F}}\boldsymbol{F}^T:\vec{\nabla}\boldsymbol{v}\\ & + \rho T\frac{\partial^2\psi}{\partial T\partial\phi}\dot{\phi} + \rho T\frac{\partial^2\psi}{\partial T\partial\vec{\nabla}\phi}\cdot\dot{\vec{\nabla}\phi} + \rho\,Q_{hc}\,\Omega + \rho r\,,\end{aligned} \tag{4.8}$$

$$B\dot{\phi} = \vec{\nabla}\cdot(\rho\gamma_\phi\vec{\nabla}\phi) - \rho\frac{\partial\psi}{\partial\phi}\,, \tag{4.9}$$

$$\rho\dot{\lambda} = \vec{\nabla}\cdot(d\vec{\nabla}\lambda) + \rho\,\Omega\,, \tag{4.10}$$

$$\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}\,. \tag{4.11}$$

With the specific constitutive forms chosen for ψ, the energy equation becomes

$$\begin{aligned}\rho c_v\dot{T} = {}& \vec{\nabla}\cdot(k\vec{\nabla}T)+\nu_f(\vec{\nabla}\cdot\boldsymbol{v})^2+2\mu_f\boldsymbol{D}:\boldsymbol{D}+B\dot{\phi}^2-\alpha_c(\phi)K\frac{\rho}{\rho_0}T(\vec{\nabla}\cdot\boldsymbol{v})-\rho R_g(\phi)T(\vec{\nabla}\cdot\boldsymbol{v})\\ & + \left\{-\frac{\alpha_c'(\phi)}{2}K\frac{\rho}{\rho_0}T\ln(III_{\boldsymbol{B}}) - \rho\frac{R_g'(\phi)}{2}T\ln(III_{\boldsymbol{B}}) - \rho c_v'(\phi)T\ln\left(\frac{T}{T_0}\right)\right.\\ & \left. + \rho\left[\beta_m'(\phi)\frac{T}{T_m}Q_m + \beta_v'(\phi)\frac{T}{T_v}Q_v\right]\right\}\dot{\phi} + \rho Q_{hc}\Omega + \rho r,\end{aligned} \tag{4.12}$$

and the evolution law for ϕ becomes

$$\begin{aligned}B\dot{\phi} = {}& \vec{\nabla}\cdot\left(\rho\gamma_\phi\vec{\nabla}\phi\right) + \rho c_v'(\phi)\left[T\ln\left(\frac{T}{T_0}\right) - (T-T_0)\right]\\ & - \frac{\mu_s'(\phi)}{2}\frac{\rho}{\rho_0}(I_{\boldsymbol{B}}-3) - \frac{\mu_c'(\phi)}{2}\frac{\rho}{\rho_0}\frac{(1-2\nu_s)}{\nu_s}\left(III_{\boldsymbol{B}}^{-\nu_s/(1-2\nu_s)}-1\right) + \frac{3\mu_l'(\phi)}{2}\frac{\rho}{\rho_o}III_{\boldsymbol{B}}^{1/3}\\ & + \frac{\alpha_c'(\phi)}{2}K\frac{\rho}{\rho_0}(T-T_0)\ln(III_{\boldsymbol{B}}) + \frac{1}{2}\rho R_g'(\phi)T\ln(III_{\boldsymbol{B}})\\ & - \rho\frac{1}{2}\Psi^{well}\frac{\partial\mathcal{F}}{\partial\phi} - \rho\left[\beta_m'(\phi)\left(\frac{T}{T_m}-1\right)Q_m + \beta_v'(\phi)\left(\frac{T}{T_v}-1\right)Q_v\right].\end{aligned} \tag{4.13}$$

4.1. Material transition functions. An important ingredient of our model is the use of ϕ-dependent material properties or material transition functions. Earlier in section 2.4.2, we encountered $\beta_m(\phi), \beta_v(\phi)$ in the specification of the phase transition energy density, $\mu_c(\phi), \mu_l(\phi), \mu_s(\phi), \alpha_c(\phi), R_g(\phi)$ in the specification of the strain energy density, $c_v(\phi)$ in the specification of the thermal energy density, as well as functions associated with dissipative processes like $\nu_f(\phi)$. The model assumes that these functions have limiting pure phase values when $\phi = 0, 1, 2$. The structure of these functions has an influence on the exact details of the spatial structure of the transition layers and their dynamics when particular problems are solved. However, one makes an implicit assumption that when the transitions occur in thin layers relative to other geometric lengths, the structure within the layer does not strongly influence the information transmitted across the layer. This modeling precept is consistent with the use of viscous dissipation to describe continuum shock structure when the shock is molecularly thin.

For illustration sake, Figures 2 and 3 show typical transition functions that we have used to carry out representative simulations discussed in the companion paper [13]. These functions are constructed from simple polynomials in ϕ and their smooth extensions. The figures clearly show the basic properties that are required. For example, in Figure 2(c), the representation of the thermal expansion parameter $\alpha_c(\phi)$, which has the same (constant) value in the solid and liquid phase, is zero in the gas phase. Another example is that $\beta'_m(\phi)$ is zero for all values of ϕ except for those between 0 and 1, and terms that multiply $\beta'_m(\phi)$ are only involved in the solid to liquid transitions of melting or freezing and are totally absent in the liquid-gas transition of evaporation and condensation.

5. Some limiting cases.

5.1. Pure phases. The results for pure phases can be identified by the constitutive forms for the stress tensor. First we will consider the solid, $\phi = 0$, in the additional limit of small strain. The small strain limit is represented in terms of the displacement gradient $\boldsymbol{H} = \boldsymbol{F} - \boldsymbol{I}$, where $|\boldsymbol{H}| << 1$. Define the small strain tensor $\boldsymbol{E} = (\boldsymbol{H} + \boldsymbol{H}^T)/2$, and the left Cauchy–Green tensor can be written as $\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T = \boldsymbol{I} + 2\boldsymbol{E} + \boldsymbol{H}\boldsymbol{H}^T$. Our limiting form for the stress relation reduces to

$$\boldsymbol{\sigma} = -\alpha_{solid}\,\frac{\rho}{\rho_0} K(T - T_0)\boldsymbol{I} + \frac{2\,\mu_{solid}\;\nu_{solid}}{1 - 2\,\nu_{solid}}\, I_{\boldsymbol{E}}\,\boldsymbol{I} + 2\,\mu_{solid}\,\boldsymbol{E}\,, \tag{5.1}$$

When one considers the limit of a liquid, $\phi = 1$, the expression for the stress becomes

$$\boldsymbol{\sigma} = -\alpha_{liquid}\,K\frac{\rho}{\rho_0}(T - T_0)\,\boldsymbol{I} - \mu_{liquid}\,\frac{\rho}{\rho_0}\left(\left(\frac{\rho}{\rho_0}\right)^{2\,\nu_{liquid}/(1-2\,\nu_{liquid})} - \left(\frac{\rho}{\rho_0}\right)^{-2/3}\right)\boldsymbol{I} + \nu_{liquid}(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_{liquid}\boldsymbol{D}; \tag{5.2}$$

similarly for the limit of the gas, $\phi = 2$, the expression for the stress becomes

$$\boldsymbol{\sigma} = -\rho R_{gas} T\boldsymbol{I} + \nu_{gas}(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_{gas}\boldsymbol{D}\,. \tag{5.3}$$

5.2. Motionless phase transition. In this case we simply assume that the system is nearly motionless with $\boldsymbol{v} \approx 0$ and consider the pure phase change from solid

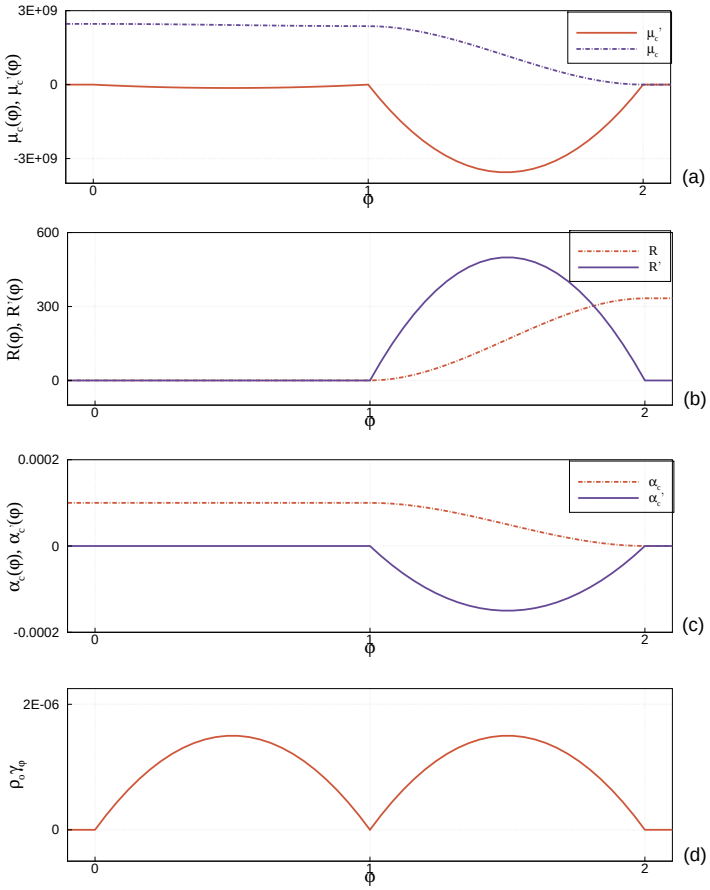

FIG. 2. *Plots of transition functions for HMX simulation and their derivatives with respect to the phase variable. Shear modulus, ideal gas constant, thermal expansion coefficient, and phase diffusion coefficient are shown from top to bottom.*

to liquid with no chemical reaction. In addition, we neglect the thermal expansion configurational forces, consistent with a nearly zero velocity field, and the thermal dissipation associated with the phase transition. Further we assume that ϕ is in the range $0 \leq \phi \leq 1$ and $\mathcal{F}(\phi)$ is effectively a double-well potential. We take the specific heat to be constant and are left with a thermal-diffusional model for the temperature and phase field given by the equations

$$\rho c_v \dot{T} = \vec{\nabla} \cdot (k \vec{\nabla} T) + \rho \beta'_m(\phi) \frac{T}{T_m} Q_m \dot{\phi} \tag{5.4}$$

and

$$B\dot{\phi} = \vec{\nabla} \cdot (\rho \gamma_\phi \vec{\nabla} \phi) - \rho \frac{1}{2} \Psi^{well} \frac{\partial \mathcal{F}}{\partial \phi} - \rho \beta'_m(\phi) \left(\frac{T}{T_m} - 1 \right) Q_m. \tag{5.5}$$

These equations are a generalized form of a thermally dependent Ginzburg–Landau theory of phase transitions often cited in discussions of solidification of binary alloys (see, for example, Wheeler, Boettinger, and McFadden [14].) Simple systems

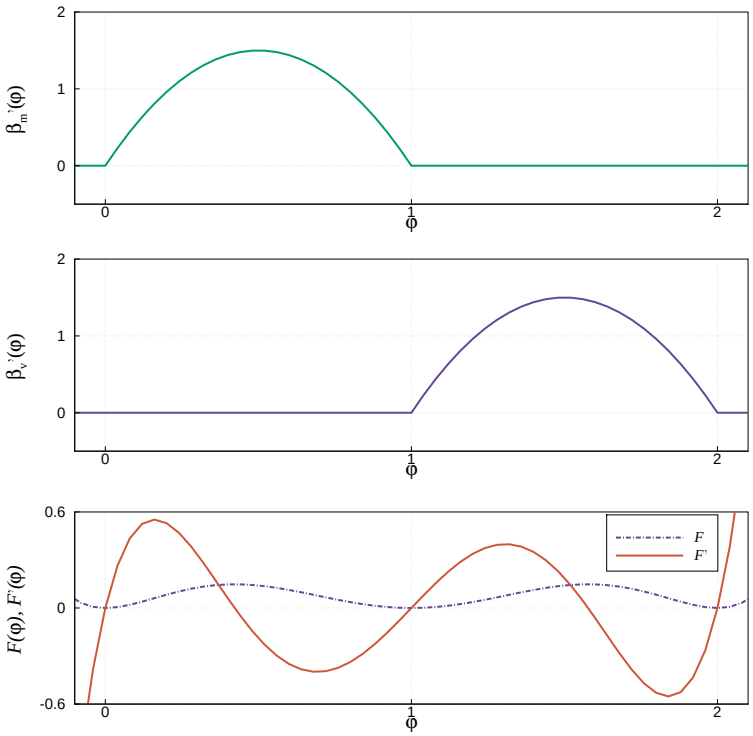

FIG. 3. *φ-dependent transfer functions (derivatives) for heat of phase transformations, β'_m and β'_v. The third figure depicts the triple-well Ginzburg–Landau potential function and its derivative.*

of this form, with a double-well potential and a single latent heat term, that have been analyzed in the literature have been shown to correspond to various forms of the classical (sharp interface) description of phase transitions. Further analysis leads to modified Stefan problems that incorporate surface tension and kinetic undercooling [8].

5.3. Relation to the simpler theory of quasi-static phase transformation. Here we briefly discuss the manner in which our model relates to the theory of quasi-static phase transformations that are a part of classical equilibrium thermodynamics. We assume that the changes in the state in the material happen so slowly that all inertial effects can be neglected and that the material undergoes only isotropic volume changes that are measured by changes in the density. The stress is spherical so that $\boldsymbol{\sigma} = -p\boldsymbol{I}$. The deformation is homogeneous such that $\boldsymbol{x} = s\boldsymbol{X}$, with $\boldsymbol{F} = s\boldsymbol{I}$, $\det(\boldsymbol{F}) = s = (\rho_0/\rho)$, $\boldsymbol{B} = (\rho_0/\rho)^2\boldsymbol{I}$, and strain invariants $III_{\boldsymbol{B}} = (\rho_0/\rho)^2$ and $I_{\boldsymbol{B}} - 3 = 3[(\rho_0/\rho)^2 - 1]$. One neglects all spatial gradients.

Next we consider the volume changes that occur as the temperature rises when the material is subjected to constant volumetric heating (given by constant r), under isobaric (constant pressure) conditions. For simplicity, we will also assume that the specific heat is constant in all phases. Then the change in the thermodynamic states would be controlled by a simplified version of the energy equation (for the

temperature) and the phase evolution equation. These are written as

$$\rho c_v \frac{\partial T}{\partial t} = \rho \left(\beta'_m(\phi) \frac{T}{T_m} Q_m + \beta'_v(\phi) \frac{T}{T_v} Q_v \right) \frac{\partial \phi}{\partial t} + \rho r \,, \tag{5.6}$$

$$B \frac{\partial \phi}{\partial t} = -\rho \frac{1}{2} \Psi^{well} \frac{\partial \mathcal{F}}{\partial \phi} - \rho \left[\beta'_m(\phi) \frac{T - T_m}{T_m} Q_m + \beta'_v(\phi) \frac{T - T_v}{T_v} Q_v \right], \tag{5.7}$$

and for the purpose of illustration, (4.5) is simplified by linearizing ρ about ρ_0 in the solid and liquid phases to obtain the thermal equation of state, a relation between p, ρ, T, and ϕ,

$$p = \frac{6\,\mu_c(\phi)\nu_s}{1 - 2\nu_s} \left(\frac{\rho}{\rho_0} - 1 \right) + \alpha_c K \frac{\rho}{\rho_0} (T - T_0) - \rho R_g T. \tag{5.8}$$

The above equations are solved subject to the initial condition that the material is initially solid and, at the reference temperature, $\phi(0) = 0$ and $T(0) = T_0$. For constant pressure, a specified temperature, and ϕ, (5.8) determines the specific volume, $V = 1/\rho$. The solution of the initial value problem for T and ϕ determines a trajectory in T, V, ϕ-space at fixed p. A typical solution shows that as the temperature rises in the solid, the volume increases along the isobar. A phase transition (change in ϕ) does not take place till the temperature nears the melting temperature, T_m. Above that temperature local analysis shows that a change in stability of the state $\phi = 0$ occurs and then the transition from $\phi = 0$ to $\phi = 1$ occurs. Since the volumetric change is small (4% or less), the deviation in a T, v isobar is not large in some sense. As the temperature continues to rise, the second phase transition occurs near the vaporization temperature, T_v. Since the thermal equation of state is effectively modeled by the ideal gas law, a rather large change in the specific volume occurs. Finally, after the phase transition to vapor is completed and $\phi = 2$ is reached, the temperature continues to climb on the gas phase isobar with increasing volume. Figure 4 show plots of a T, V-trajectory for a isobaric phase transition for the HMX-like material described in [13]. Figure 5 shows the corresponding ϕ, V-trajectory at different pressures. Again, the purpose here is simply to illustrate that conventional notions of quasi-static phase transformations described in classical thermodynamics are embedded in this model.

6. Special forms of the model for three simple motions. In this concluding section we write out special and exact forms of the differential equations for the model when the material undergoes three simple motions: (i) evolution at constant volume, (ii) one-dimensional, time-dependent, longitudinal motion, and (iii) one-dimensional, time-dependent shear motion. All three are very important in the analysis of ignition of EMs. The three cases are the exclusive subject of the companion paper [13], in which numerical simulation and the properties of the model are discussed further.

6.1. Constant volume evolution and thermal explosion. A simple but extremely important subcase that is studied extensively in combustion theory describes the constant volume thermal explosion, where the velocity $\boldsymbol{v}$ and all spatial gradients are exactly zero. The density is constant hence the volume of a material particle is constant. For illustration, we neglect thermal expansion and assume constant specific heat and gas constants. We are left with three ODEs in time for the temperature, phase change, and reaction progress:

$$\rho c_v \frac{\partial T}{\partial t} = \rho \left(\beta'_m(\phi) \frac{T}{T_m} Q_m + \beta'_v(\phi) \frac{T}{T_v} Q_v \right) \frac{\partial \phi}{\partial t} + \rho Q_{hc} \Omega + \rho r \,, \tag{6.1}$$

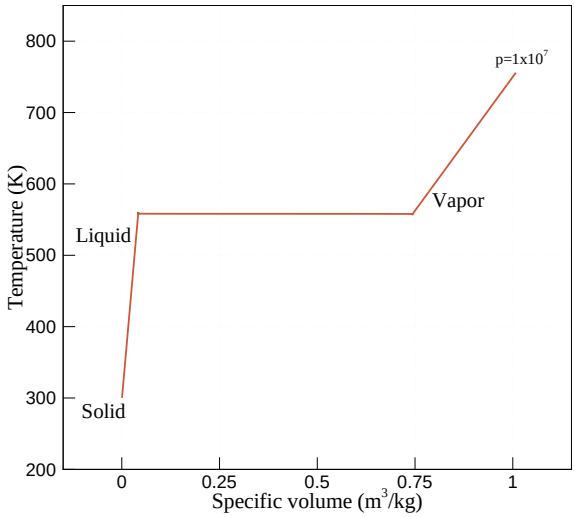

FIG. 4. *T, V-trajectory on an isobar ($p = 10^7$ Pa) under the quasi-static assumptions. The large volume jump from liquid to gas happens at nearly constant temperature T_v.*

$$B\frac{\partial \phi}{\partial t} = -\rho \frac{1}{2}\Psi^{well}\frac{\partial \mathcal{F}}{\partial \phi} - \rho\left[\beta_m'(\phi)\frac{T-T_m}{T_m}Q_m + \beta_v'(\phi)\frac{T-T_v}{T_v}Q_v\right], \tag{6.2}$$

$$\frac{\partial \lambda}{\partial t} = \Omega. \tag{6.3}$$

If one discards phase change, we recover the equations from standard combustion theory for constant volume thermal explosion, $c_v(\partial T/\partial t) = Q_{hc}\,\Omega\,, (\partial\lambda/\partial t) = \Omega$. Of course, the more interesting behavior occurs when phase change is included. The typical dynamics of these ODEs are discussed at length in [13].

6.2. Longitudinal motion. Next we turn to specializations of the equations to simplified motions that lead to PDEs in one space dimension and one time dimension; this is particularly suited to the study of ignition phenomena in EMs (which is one of our main concerns). First we consider longitudinal compression associated with a flyer-plate impact test. In this idealization, an infinite slab experiences a displacement loading normal to its surface. Specifically we consider the following one-dimensional motion:

$$x_1 = X_1 + f_1(X_1, t), \qquad x_2 = X_2, \qquad x_3 = X_3\,, \tag{6.4}$$

where f_1 is the 1-displacement.

For this motion, there is one nonzero velocity component, $v_1 = \partial f_1/\partial t|_{\boldsymbol{X}}(X_1, t)$, $\boldsymbol{F}$ is diagonal with $F_{11} = \partial x_1/\partial X_1 = 1 + f_1'$, and $F_{22} = F_{33} = 1$. The density is related to the single strain gradient by $1 + f_1' = \rho_0/\rho$. Also, $\boldsymbol{B}$ is diagonal with $B_{11} = (1 + f_1')^2$, $B_{22} = 1$, $B_{33} = 1$. The first and third invariants of $\boldsymbol{B}$ are $I_{\boldsymbol{B}} =$

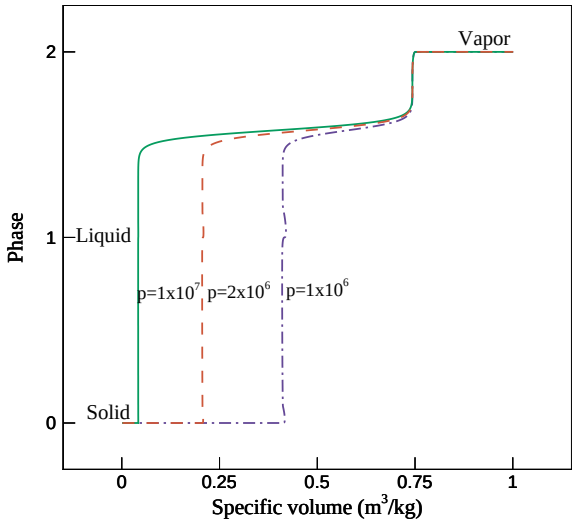

FIG. 5. *Phase-V trajectory of constant pressure under the thermo-quasistatic assumption.*

$2 + (1 + f_1')^2$ and $III_{\boldsymbol{B}} = (1 + f_1')^2$, with $III_{\boldsymbol{B}} = (\rho_0/\rho)^2$ and $I_{\boldsymbol{B}} - 3 = (\rho_0/\rho)^2 - 1$. Hence we use the density as the independent strain measure and replace f_1'. The one nonzero component of the velocity gradient and rate of strain tensor are, respectively, $L_{11} = D_{11} = \partial v_1/\partial x_1$. Also, $(\vec{\nabla}\phi \otimes \vec{\nabla}\phi)_{11} = (\partial\phi/\partial x_1)^2$. It then follows that all the shear stresses are zero, $\sigma_{12} = \sigma_{23} = \sigma_{13} = 0$, and the normal stresses σ_{11} are given by

$$\sigma_{11} = -\mu_c \left(\frac{\rho}{\rho_0}\right)\left[\left(\frac{\rho}{\rho_0}\right)^{\frac{2\nu_s}{1-2\nu_s}} - \left(\frac{\rho}{\rho_0}\right)^{-2}\right] - \alpha_c K \frac{\rho}{\rho_0}(T - T_0) - \rho R_g T - \rho\gamma_\phi \left(\frac{\partial\phi}{\partial x_1}\right)^2 + (\nu_f + 2\mu_f)\frac{\partial v_1}{\partial x_1}\,. \tag{6.5}$$

The other normal stress are the same as the σ_{11} stress, minus the phase stress, i.e., $\sigma_{22} = \sigma_{33} = \sigma_{11} + \rho\gamma_\phi(\partial\phi/\partial x_1)^2$.

The specific governing equations for longitudinal compression are the mass and momemtum equations

$$\frac{\partial\rho}{\partial t} + v_1\frac{\partial\rho}{\partial x_1} + \rho\frac{\partial v_1}{\partial x_1} = 0\,, \tag{6.6}$$

$$\rho\left(\frac{\partial v_1}{\partial t} + v_1\frac{\partial v_1}{\partial x_1}\right) = \frac{\partial}{\partial x_1}\left\{-\mu_c\left(\frac{\rho}{\rho_0}\right)\left[\left(\frac{\rho}{\rho_0}\right)^{\frac{2\nu_s}{1-2\nu_s}} - \left(\frac{\rho}{\rho_0}\right)^{-2}\right] - \alpha_c K\frac{\rho}{\rho_0}(T - T_0) - \rho R_g T - \rho\gamma_\phi\left(\frac{\partial\phi}{\partial x_1}\right)^2 + (\nu_f + 2\mu_f)\frac{\partial v_1}{\partial x_1}\right\} \tag{6.7}$$

and the energy balance, phase evolution, and reaction progress evolution equations that take the specific forms

$$
\begin{aligned}
\rho c_v \left(\frac{\partial T}{\partial t} + v_1 \frac{\partial T}{\partial x_1}\right) &= \frac{\partial}{\partial x_1}\left(k \frac{\partial T}{\partial x_1}\right) + (\nu_f + 2\mu_f)\left(\frac{\partial v_1}{\partial x_1}\right)^2 \\
&+ B\dot{\phi}^2 - \left[\alpha_c K \frac{\rho}{\rho_0} T + \rho R_g(\phi) T\right] \frac{\partial v_1}{\partial x_1} \\
&+ \left\{ -\frac{1}{2}\alpha_c'(\phi) K \frac{\rho}{\rho_0} T \ln(III_{\boldsymbol{B}}) - \frac{1}{2}\rho R_g'(\phi) T \ln(III_{\boldsymbol{B}}) - \rho c_v'(\phi) T \ln(T/T_0) \right. \\
&\left. + \rho \left[\beta_m'(\phi) \frac{T}{T_m} Q_m + \beta_v'(\phi) \frac{T}{T_v} Q_v\right] \right\} \dot{\phi} + \rho\, Q_{hc} \Omega + \rho r,
\end{aligned} \tag{6.8}
$$

$$
\begin{aligned}
&B\left(\frac{\partial \phi}{\partial t} + v_1 \frac{\partial \phi}{\partial x_1}\right) = \frac{\partial}{\partial x_1}\left(\rho \gamma_\phi \frac{\partial \phi}{\partial x_1}\right) + \rho c_v'(\phi)\left[T \ln\left(\frac{T}{T_0}\right) - (T - T_0)\right] \\
&- \frac{\mu_s'(\phi)}{2}\frac{\rho}{\rho_0}(I_{\boldsymbol{B}} - 3) - \frac{\mu_c'(\phi)}{2}\frac{\rho}{\rho_0}\frac{(1-2\nu_s)}{\nu_s}\left(III_{\boldsymbol{B}}^{-\nu_s/(1-2\nu_s)} - 1\right) - \frac{3\,\mu_l'(\phi)}{2}\frac{\rho}{\rho_o} III_{\boldsymbol{B}}^{1/3} \\
&+ \frac{\alpha_c'(\phi)}{2} K \frac{\rho}{\rho_0}(T - T_0)\ln(III_{\boldsymbol{B}}) + \frac{1}{2}\rho R_g'(\phi) T \ln(III_{\boldsymbol{B}}) \\
&- \frac{1}{2}\rho \Psi^{well}\frac{\partial \mathcal{F}}{\partial \phi} - \rho\left[\beta_m'(\phi)\frac{T - T_m}{T_m} Q_m + \beta_v'(\phi)\frac{T - T_v}{T_v} Q_v\right],
\end{aligned} \tag{6.9}
$$

and

$$
\rho\left(\frac{\partial \lambda}{\partial t} + v_1 \frac{\partial \lambda}{\partial x_1}\right) = \frac{\partial}{\partial x_1}\left(d \frac{\partial \lambda}{\partial x_1}\right) + \rho\, \Omega\,. \tag{6.10}
$$

6.3. Shear motion. Now we turn to specialization of the equations to shear motion, which again leads to PDEs in one space dimension, transverse to the motion, and one time dimension. A nominal geometry is a slab of fixed thickness loaded on one surface with constant velocity while the other is fixed. The bottom surface is taken to be fixed (zero displacement) for the entire duration of the test. Specifically, we consider the following one-dimensional motion:

$$
x_1 = X_1 + f_1(X_2, t), \qquad x_2 = X_2 + f_2(X_2, t), \qquad x_3 = X_3\,, \tag{6.11}
$$

where f_1 and f_2 are the in-plane displacements, which can also be regarded as functions of the spatial coordinate and time x_2, t. Corresponding to this motion, one has the velocities with dependencies $v_1(x_2, t), v_2(x_2, t)$, and $v_3 = 0$ and $\partial/\partial x_1 = \partial/\partial x_3 = 0$. The expression of the material time derivative is given by $\dot{()} = \partial/\partial t + v_2\, \partial/\partial x_2$.

The shear deformation is described by

$$
\begin{aligned}
(\boldsymbol{F})_{ij} &= \frac{\partial x_i}{\partial X_j} = \begin{bmatrix} 1 & f_1' & 0 \\ 0 & 1 + f_2' & 0 \\ 0 & 0 & 1 \end{bmatrix}_{ij}, \\
(\boldsymbol{B})_{ij} &= (\boldsymbol{F}\boldsymbol{F}^T)_{ij} = \begin{bmatrix} 1 + {f_1'}^2 & f_1'(1 + f_2') & 0 \\ f_1'(1 + f_2') & (1 + f_2')^2 & 0 \\ 0 & 0 & 1 \end{bmatrix}_{ij},
\end{aligned} \tag{6.12}
$$

$$(\boldsymbol{L})_{ij} = (\vec{\nabla}\boldsymbol{v})_{ij} = \frac{\partial v_i}{\partial x_j} = \begin{bmatrix} 0 & \frac{\partial v_1}{\partial x_2} & 0 \\ 0 & \frac{\partial v_2}{\partial x_2} & 0 \\ 0 & 0 & 0 \end{bmatrix}, \qquad (\boldsymbol{D})_{ij} = \begin{bmatrix} 0 & \frac{1}{2}\frac{\partial v_1}{\partial x_2} & 0 \\ \frac{1}{2}\frac{\partial v_1}{\partial x_2} & \frac{\partial v_2}{\partial x_2} & 0 \\ 0 & 0 & 0 \end{bmatrix}_{ij}. \tag{6.13}$$

The invariants of $\boldsymbol{B}$ are computed as $I_{\boldsymbol{B}} = 1+{f_1'}^2+(1+f_2')^2+1$ and $III_{\boldsymbol{B}} = (1+f_2')^2 = (\rho_0/\rho)^2$ with $1+f_2' = \rho_0/\rho$. Also $I_{\boldsymbol{B}} - 3 = (\rho_0/\rho)^2 - 1 + {f_1'}^2$. In addition, from the kinematic identity, $\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}$, we obtain two nontrivial relations $\dot{f}_1' = (1+f_2')\partial v_1/\partial x_2$ and $\dot{f}_2' = (1+f_2')\partial v_2/\partial x_2$, where the material derivative is $\dot{\overline{()}} = \partial/\partial t + v_2\,\partial/\partial x_2$. The second of the two results just restates mass conservation and is equivalent to replacing $1+f_2'$ with ρ_0/ρ. But the first is an independent expression for the shear strain, which can be recast in terms of the density and transverse velocity gradient as

$$\dot{\overline{(f_1')}} = \left(\frac{\rho_0}{\rho}\right)\frac{\partial v_1}{\partial x_2}. \tag{6.14}$$

Finally, the contribution to the configurational stress has only one nonzero component, $(\vec{\nabla}\phi\otimes\vec{\nabla}\phi)_{22} = (\partial\phi/\partial x_2)^2$.

Using the density ρ and the shear strain f_1' as the two independent kinematic variables, we can now write down expressions for the components of the stress tensor. The cross-plane shear stresses are zero, i.e., $\sigma_{13} = \sigma_{23} = 0$. The in-plane shear stress σ_{12} is given by the expression

$$\sigma_{12} = \mu_s\, f_1' + \mu_f \frac{\partial v_1}{\partial x_2}. \tag{6.15}$$

The in-plane normal stress σ_{22} is given by

$$\sigma_{22} = -\mu_c\left(\frac{\rho}{\rho_0}\right)\left[\left(\frac{\rho}{\rho_0}\right)^{\frac{2\nu_s}{1-2\nu_s}} - \left(\frac{\rho}{\rho_0}\right)^{-2}\right] - \alpha_c K\frac{\rho}{\rho_0}(T-T_0) - \rho R_g T - \rho\gamma_\phi\left(\frac{\partial\phi}{\partial x_2}\right)^2 + (\nu_f + 2\mu_f)\frac{\partial v_2}{\partial x_2}. \tag{6.16}$$

The specific governing equations for the shear motion for the full model are

$$\frac{\partial\rho}{\partial t} + v_2\frac{\partial\rho}{\partial x_2} + \rho\frac{\partial v_2}{\partial x_2} = 0, \tag{6.17}$$

$$\rho\left(\frac{\partial v_1}{\partial t} + v_2\frac{\partial v_1}{\partial x_2}\right) = \frac{\partial}{\partial x_2}\left[\mu_s f_1' + \mu_f\frac{\partial v_1}{\partial x_2}\right], \tag{6.18}$$

$$\rho\left(\frac{\partial v_2}{\partial t} + v_2\frac{\partial v_2}{\partial x_2}\right) = \frac{\partial}{\partial x_2}\left\{-\mu_c\left(\frac{\rho}{\rho_0}\right)\left[\left(\frac{\rho}{\rho_0}\right)^{\frac{2\nu_s}{1-2\nu_s}} - \left(\frac{\rho}{\rho_0}\right)^{-2}\right] - \alpha_c(\phi)K\frac{\rho}{\rho_0}(T-T_0) - \rho R_g(\phi)T - \rho\gamma_\phi\left(\frac{\partial\phi}{\partial x_2}\right)^2 + (\nu_f+2\mu_f)\frac{\partial v_2}{\partial x_2}\right\}, \tag{6.19}$$

$$
\begin{aligned}
(6.20)\quad \rho c_v\left(\frac{\partial T}{\partial t}+v_2\frac{\partial T}{\partial x_2}\right) &= \frac{\partial}{\partial x_2}\left(k\frac{\partial T}{\partial x_2}\right)+\left[\mu_f\left(\frac{\partial v_1}{\partial x_2}\right)^2+(\nu_f+2\mu_f)\left(\frac{\partial v_2}{\partial x_2}\right)^2\right]\\
&\quad + B\dot{\phi}^2-\left[\alpha_c K\frac{\rho}{\rho_0}T+\rho R_g T\right]\frac{\partial v_2}{\partial x_2}\\
&\quad +\left\{-\frac{1}{2}\alpha_c'(\phi)K\frac{\rho}{\rho_0}T\ln(III_{\boldsymbol{B}})-\frac{1}{2}\rho R_g'(\phi)T\ln(III_{\boldsymbol{B}})-\rho c_v'(\phi)T\ln(T/T_0)\right.\\
&\quad \left.+\rho\left[\beta_m'(\phi)\frac{T}{T_m}Q_m+\beta_v'(\phi)\frac{T}{T_v}Q_v\right]\right\}\dot{\phi}+\rho\, Q_{hc}\Omega+\rho r\,,
\end{aligned}
$$

$$
\begin{aligned}
(6.21)\quad B\left(\frac{\partial \phi}{\partial t}+v_2\frac{\partial \phi}{\partial x_2}\right) &= \frac{\partial}{\partial x_2}\left(\rho\gamma_\phi\frac{\partial \phi}{\partial x_2}\right)+\rho c_v'(\phi)\left[T\ln(T/T_0)-(T-T_0)\right]\\
&\quad -\frac{\mu_s'(\phi)}{2}\frac{\rho}{\rho_0}(I_{\boldsymbol{B}}-3)-\frac{\mu_c'(\phi)}{2}\frac{\rho}{\rho_0}\frac{(1-2\nu_s)}{\nu_s}\left(III_{\boldsymbol{B}}^{-\nu_s/(1-2\nu_s)}-1\right)-\frac{3\,\mu_l'(\phi)}{2}\frac{\rho}{\rho_o}III_{\boldsymbol{B}}^{1/3}\\
&\quad +\frac{\alpha_c'(\phi)}{2}K\frac{\rho}{\rho_0}(T-T_0)\ln(III_{\boldsymbol{B}})+\frac{1}{2}\rho R_g'(\phi)T\ln(III_{\boldsymbol{B}})\\
&\quad -\frac{1}{2}\rho\Psi^{well}\frac{\partial \mathcal{F}}{\partial \phi}-\rho\left[\beta_m'(\phi)\frac{T-T_m}{T_m}Q_m+\beta_v'(\phi)\frac{T-T_v}{T_v}Q_v\right]
\end{aligned}
$$

and for chemical reaction are

$$
(6.22)\qquad \rho\left(\frac{\partial \lambda}{\partial t}+v_2\frac{\partial \lambda}{\partial x_2}\right)=\frac{\partial}{\partial x_2}\left(d\,\frac{\partial \lambda}{\partial x_2}\right)+\rho\Omega\,.
$$

Finally, the kinematic relation (6.14) for the shear strain (which must be included) is expressed as

$$
(6.23)\qquad \frac{\rho}{\rho_0}\left(\frac{\partial f_1'}{\partial t}+v_2\frac{\partial f_1'}{\partial x_2}\right)=\frac{\partial v_1}{\partial x_2}\,.
$$

7. Conclusions. We have posed a three-dimensional model for a representative energetic material with two independent state variables that represent the change in phase and the extent of exothermic reaction. The model has a context and formulation in which it is thermodynamically consistent. This is in contrast to other models which may not be self-consistent because the constitutive theory is invoked a posteriori. Gurtin's notion of a fundamental balance of configurational forces leads to evolution laws for the phase variable. Limiting forms of this model are consistent with classical theories, but the model also yields limiting forms that can describe the transition between two phases, if desired. The combined model is very rich in the sense that the coupling between phase evolution and the energy equations is complex, due in part to the necessary partition of the Helmholtz free energy.

In [13] we use experimental data based on the behavior and properties of HMX to study representative dynamics of the three simple motions discussed in section 6. The examples we develop show a variety of behavior observed over many time and length scales. Strain localization and phase transition phenomena are observed, as well as many other complex phenomena.

A THERMOMECHANICAL MODEL FOR ENERGETIC MATERIALS WITH PHASE TRANSFORMATIONS: ANALYSIS OF SIMPLE MOTIONS*

JACK JAI-ICK YOH†, D. SCOTT STEWART†, AND GREGORY A. RUDERMAN‡

Abstract. This paper examines the behavior of a thermomechanical model for energetic materials posed in the companion paper and specifically analyzes three simple motions: (i) constant volume evolution, (ii) one-dimensional, time-dependent longitudinal compression (expansion), and (iii) time-dependent shear. The model describes phase transitions from solid to liquid to gas and exothermic chemical reaction. Thermal and mechanical properties are matched to the explosive HMX in order to illustrate representative dynamics and transitions. Constant volume thermal explosion, shock melting, and shear localization are demonstrated.

Key words. combustion, phase transformations, energetic materials

1. Introduction.

This paper (paper II) is the second of two papers that describe a continuum model for the behavior of a condensed phase energetic material that undergoes phase transformation. Such materials are often used in explosive and pyrotechnic systems and are commonly known as solid explosives. Explosive materials are usually stable solids at room temperature and pressure, and when subjected to sufficiently strong mechanical or thermal stimulus, they undergo transitions to liquid and gas before releasing the bulk of their stored energy by chemical reaction mainly in the gas phase. Paper I [2] presented the continuum formulation that describes phase transitions from solid to liquid to gas. The model also includes energy-release due to chemical reaction. The state of the phase and the progress of the chemical reaction are represented by two thermodynamically independent variables, ϕ and λ. The phase variable ϕ takes on the value 0 for a pure solid, 1 for a pure liquid, and 2 for a pure gas. The progress of the (exothermic) chemical reaction is represented by λ, which ranges from 0 (unreacted) to 1 (completely reacted).

Most of paper I explains the model's formulation and assumptions and the restricted form of the constitutive theory based on standard arguments from the second law of thermodynamics. Following Gurtin's suggestion [1], configurational forces are assumed to be in global and local balance and further arguments lead to the derivation of an evolution law for ϕ, which is of the advection, diffusion, reaction type. Following combustion theory for a reactive mixture, an evolution law for the reaction progress variable λ is posited as a fundamental law.

Hence, our model is fully three-dimensional and is thermodynamically and tensorially consistent. Specialization of the model and limiting forms are examined in

paper I, and the equations for the special cases of constant volume evolution, one-dimensional, time-dependent longitudinal compression motion and time-dependent shear motion are obtained. Solutions to initial boundary-value problems for the equations for these simple motions illustrate the behavior of the model and reveal its properties. The results testify to the model's potential suitability for modeling complex phenomena that involve both phase transformation and chemical reaction in one combined framework. Material constants and properties of the energetic material (solid explosive) HMX are used to determine representative values for the model. These include properties such as (but not limited to) the elastic properties, viscosities, specific heats, gas constant, heats of melting (fusion), vaporization (condensation), and combustion (detonation).

In section 2 the equations for the three-dimensional model are given. In section 3 we discuss how we assigned the material properties of HMX to the model. In section 4 the special forms of the equations for the three simple motions are indicated (and the reader is referred to paper I). We also solve the case for constant volume evolution and discuss the properties of the underlying ODEs and their dynamics. To avoid unnecessary repetition of previously stated equations, we will refer to the equations as follows. For (6.1) of paper I, we will write (I 6.1). In section 5 the numerical methodology is given for longitudinal and shear motions. Section 6 presents representative numerical solutions for mechanically induced phase transformation and includes examples of interesting properties of the model such as shear localization and shock melting.

2. Mathematical formulations.

2.1. Kinematics and some definitions. The coordinates of position in the lab-frame are given by $\boldsymbol{x}$ and the initial position of the material particles is given by $\boldsymbol{X}$. The mapping of the deformations is given by $\boldsymbol{x} = \boldsymbol{x}(\boldsymbol{X}, t)$. The deformation gradient $\boldsymbol{F}$ is defined by the derivative $\boldsymbol{F} = \partial\boldsymbol{x}/\partial\boldsymbol{X}$. The left Cauchy–Green tensor $\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T$ is used to describe finite deformations. The velocity is defined by the time derivative of the particle trajectories $\boldsymbol{v} = (\partial\boldsymbol{x}/\partial t)_{\boldsymbol{X}}$. The velocity gradient is the gradient of the velocity field defined by the tensor $\boldsymbol{L} = \vec{\nabla}\boldsymbol{v}$. Let the dot notation, $\dot{\overline{()}}$, refer to the material derivative. The rate of stretching tensor is given by $\boldsymbol{D} = [\vec{\nabla}\boldsymbol{v} + (\vec{\nabla}\boldsymbol{v})^\top]/2$. The time derivative of the deformation gradient is $\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}$. Consideration of conservation of mass relates the instantaneous density ρ to a reference (ambient) density of the solid, ρ_0, by $\det(\boldsymbol{F}) = \rho_0/\rho$ as well as $\det(\boldsymbol{B}) = (\rho_0/\rho)^2$.

2.2. General formulation. The derivation of the model and its constitutive specification was the principal subject of paper I [2]. The arguments in paper I developed a ϕ-dependent constitutive expression for the stress $\boldsymbol{\sigma}$ as

$$\begin{aligned}\boldsymbol{\sigma} = {} & \mu_s \frac{\rho}{\rho_0}\boldsymbol{B} - \mu_c \frac{\rho}{\rho_0} III_{\mathbf{B}}^{-[\nu_c/(1-2\nu_c)]}\boldsymbol{I} + \mu_l \frac{\rho}{\rho_0} III_{\mathbf{B}}^{1/3}\boldsymbol{I} \\ & - \alpha_c K \frac{\rho}{\rho_0}(T - T_0)\boldsymbol{I} - \rho R_g T \boldsymbol{I} \\ & - \rho\gamma_\phi \vec{\nabla}\phi \otimes \vec{\nabla}\phi + \nu_f(\vec{\nabla}\cdot\boldsymbol{v})\boldsymbol{I} + 2\mu_f \boldsymbol{D}\,. \end{aligned} \tag{2.1}$$

The material properties μ_c, μ_s, μ_l, α_c, R_g, γ_ϕ, ν_f, and μ_f are assumed to be functions of ϕ such that they are nonzero in the appropriate phase and are zero otherwise. The shear modulus μ_s is associated with a Blatz–Ko compressible solid and μ_l is associated with a liquid. The function μ_c represents the shear modulus of the condensed phase

such that $\mu_c = \mu_s + \mu_l$, with the properties that $\mu_c(0) = \mu_s(0) = \mu_{solid}$, $\mu_l(0) = 0$, $\mu_s(1) = 0$, $\mu_c(1) = \mu_l(1) = \mu_{liquid}$, and $\mu_c(2) = \mu_s(2) = \mu_l(2) = 0$. The function α_c is associated with a thermal expansion stress, R_g is associated with the ideal gas constant in a gas, ν_f and μ_f are associated with strain rate generated viscous stress, and γ_ϕ is associated with phase change induced stresses that act in regions with nonzero phase gradients. Derivatives of the ϕ-dependent functions appear as $\alpha'(\phi, T) = \partial\alpha/\partial\phi|_T$. The "$s$" subscript refers to the solid phase, the "l" subscript refers to the liquid phase, and the "c" subscript refers to the condensed phase. Similarly the "f" subscript refers to the fluid properties for both liquid and gas phases. If spelled out, the subscript "solid," "liquid," or "gas" refer to a constant material property. The various scalar material properties, such as c_v, γ_ϕ, could have explicit dependence on λ as well as ϕ and T. The governing equations for the model with reaction and phase change (without body forces) are

$$\dot{\rho} + \rho\vec{\nabla}\cdot\boldsymbol{v} = 0\,, \tag{2.2}$$

$$\rho\,\dot{\boldsymbol{v}} = \vec{\nabla}\cdot\boldsymbol{\sigma}\,, \tag{2.3}$$

$$\begin{aligned}
\rho c_v\dot{T} = {}& \vec{\nabla}\cdot(k\vec{\nabla}T) + \nu_f(\vec{\nabla}\cdot\boldsymbol{v})^2 + 2\mu_f\boldsymbol{D}:\boldsymbol{D} + B\dot{\phi}^2 \\
& - \alpha_c K\frac{\rho}{\rho_0}T(\vec{\nabla}\cdot\boldsymbol{v}) - \rho R_g T(\vec{\nabla}\cdot\boldsymbol{v}) \\
& + \left\{-\frac{\alpha_c'(\phi)}{2}K\frac{\rho}{\rho_0}T\ln(III_{\mathbf{B}}) - \rho\frac{R_g'(\phi)}{2}T\ln(III_{\mathbf{B}}) - \rho c_v'(\phi)T\ln(T/T_0)\right. \\
& \left. + \rho\left[\beta_m'(\phi)\frac{T}{T_m}Q_m + \beta_v'(\phi)\frac{T}{T_v}Q_v\right]\right\}\dot{\phi} + \rho Q_{hc}\,\Omega + \rho r\,,
\end{aligned} \tag{2.4}$$

$$\begin{aligned}
B\dot{\phi} = {}& \vec{\nabla}\cdot\left(\rho\gamma_\phi\vec{\nabla}\phi\right) + \rho c_v'(\phi)\left[T\ln(T/T_0) - (T - T_0)\right] \\
& - \frac{\mu_s'(\phi)}{2}\frac{\rho}{\rho_0}(I_{\mathbf{B}} - 3) - \frac{\mu_c'(\phi)}{2}\frac{\rho}{\rho_0}\frac{(1-2\nu_c)}{\nu_c}\left(III_{\mathbf{B}}^{-\nu_c/(1-2\nu_c)} - 1\right) \\
& + \frac{3\mu_l'(\phi)}{2}\frac{\rho}{\rho_0}III_{\mathbf{B}}^{1/3} \\
& + \frac{\alpha_c'(\phi)}{2}K\frac{\rho}{\rho_0}(T - T_0)\ln(III_{\mathbf{B}}) + \frac{1}{2}\rho R_g'(\phi)T\ln(III_{\mathbf{B}}) \\
& - \rho\frac{1}{2}\Psi^{well}\frac{\partial F}{\partial\phi} - \rho\left[\beta_m'(\phi)\left(\frac{T}{T_m} - 1\right)Q_m + \beta_v'(\phi)\left(\frac{T}{T_v} - 1\right)Q_v\right],
\end{aligned} \tag{2.5}$$

$$\rho\dot{\lambda} = \vec{\nabla}\cdot(d\vec{\nabla}\lambda) + \rho\,\Omega\,, \tag{2.6}$$

$$\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}\,. \tag{2.7}$$

Table 1 gives the values for material properties that appear in (2.1)–(2.7). The values are based upon HMX along with references to the data source or a notation that we have used a model value.

2.3. Material transition functions. An important ingredient of our model is the use of ϕ-dependent material properties, or material transition functions. Their most prominent use is in the definition of the source terms in the ϕ-evolution equation and the energy (temperature) equation. Also, functions such as $\mu_c(\phi)$, $\mu_s(\phi)$, $\mu_l(\phi)$, $\alpha_c(\phi)$, $R_g(\phi)$, $c_v(\phi)$ all change with the phase variable ϕ. The model assumes that these are defined in such a way so that they take on proper values for pure phases when the material has the limiting pure-phase values for ϕ. The ϕ-dependent material

TABLE 1
Material properties typical of HMX.

Material property	Value	Refs.
density of β-HMX (ρ_0)	1.71 g/cm^3	[7]
density of liquid-HMX	1.65 g/cm^3	[13]
specific heat at constant volume (c_v)	1.5×10^3 J/kg K	[7]
isothermal bulk modulus ($K = \rho \left.\frac{\partial p}{\partial \rho}\right\|_T$)	13.5 GPa	[7]
shear modulus (μ_{solid})	2.46 GPa	modeled
shear modulus (μ_{liquid})	2.37 GPa	modeled
Poisson's ratio (ν_c)	0.414	calculated
viscosity coefficient (μ_f)	0.45 N s/m^2	[5]
bulk viscosity coefficient (ν_f)	-2/3 μ_f	Stokes hypothesis
thermal expansion coefficient (α_{solid})	0.000134 1/K [7]	
thermal conductivity (k)	.36 W/m K	[7]
phase diffusion coefficient ($\rho\gamma_\phi$)	1.0×10^{-6} m kg/s^2	modeled
universal gas constant (R_u)	8313 J/kmole K	
molar weight of β-HMX	296.2 kg/kmole	[5]
gas constant per unit mass (R_{gas})	300 J/kg K	modeled
melting temperature (T_m)	558 K	[5]
vaporization temperature (T_v)	588 K	modeled
heat of melting (Q_m)	-200×10^3 J/kg	[5]
heat of vaporization (Q_v)	-100×10^3 J/kg	modeled
heat of combustion (Q_{hc})	5.0×10^6 J/kg	[8]
rate of heat source (ρr)	5000 J/m^{3}s	modeled
frequency of Arrhenius kinetic (A)	9.3×10^{16} 1/s	[8]
activation temperature (E_a/R_u)	24660 K	[8]
depth of phase well (Ψ^{well})	550 J/kg	modeled
multiplication factor of $\dot{\phi}$ (B)	1.5 kg/m s	modeled

transition functions used for this paper are listed in the appendix and are made up of simple, smooth, or piece-wise smooth polynomials in ϕ.

Figure 1 shows the material transition functions $\beta'_m(\phi)$, $\beta'_v(\phi)$ that are used to construct ψ_2, which represents free-energy changes during phase transition and is given by

$$\psi_2 = \frac{1}{2}\Psi^{well}F(\phi) + \beta_m(\phi)Q_m\Big(\frac{T}{T_m} - 1\Big) + \beta_v(\phi)Q_v\Big(\frac{T}{T_v} - 1\Big), \tag{2.8}$$

where $\Psi^{well} > 0$ is a constant that describes the potential and $Q_m < 0$ and $Q_v < 0$ are constants representing the heats of melting and vaporization. The constants $T_m > 0$ and $T_v > 0$ are melting and vaporization temperatures. Here we assume a specific form for $F(\phi)$ (listed in the appendix) that is a smooth positive definite function with isolated zeros at $\phi = 0, 1$, and 2 representing three local minima. In addition, $F(\phi)$ is assumed to be locally quadratic near the zeros at $\phi = 0, 1$ and 2, i.e., near $\phi = 0$, $F \sim \phi^2$, near $\phi = 1$, $F \sim (\phi - 1)^2$, and near $\phi = 2$, $F \sim (\phi - 2)^2$. The function $\beta_m(\phi)$ is assumed to be smooth and monotonically increasing and has values from 0 to 1 on the range $0 \le \phi \le 1$ with zero derivative elsewhere. Similarly, the function $\beta_v(\phi)$ is assumed to be monotonically increasing with values from 0 to 1 on the range $1 \le \phi \le 2$. The derivative of transition energy density $\partial\psi_2/\partial\phi$ generates source terms

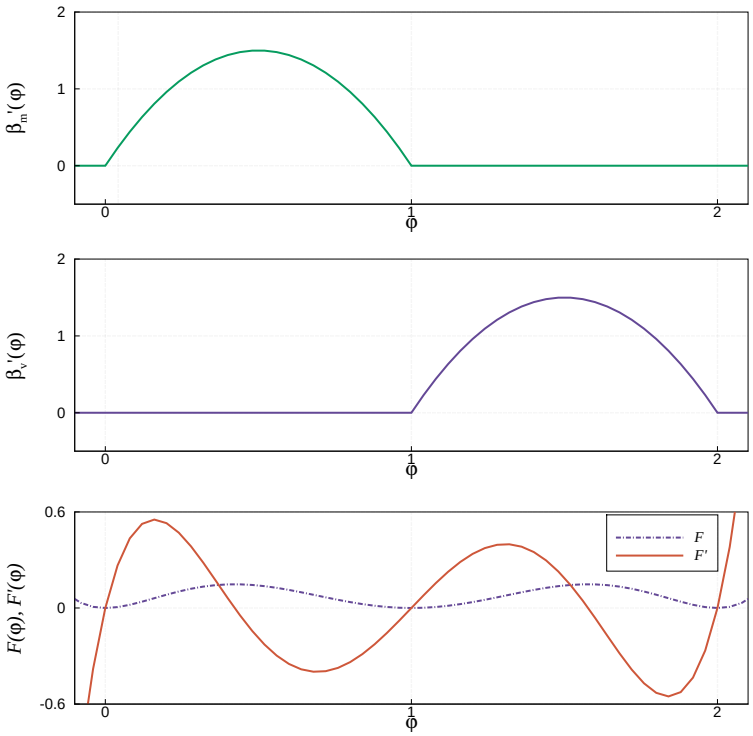

FIG. 1. *Material transition functions β'_m and β'_v and Ginzburg–Landau potential F used to prescribe the phase transition energy density ψ_2.*

in the phase equation represented as

$$\frac{\partial \psi_2}{\partial \phi} = \frac{1}{2}\Psi^{well}\frac{\partial F}{\partial \phi}(\phi) + \beta'_m(\phi)Q_m\Big(\frac{T}{T_m} - 1\Big) + \beta'_v(\phi)Q_v\Big(\frac{T}{T_v} - 1\Big). \tag{2.9}$$

Figure 2 illustrates the assumed dependence of $\psi_2(\phi, T)$ on ϕ and T. Starting from (a) through (d), the temperature T is raised from below T_m to above T_v, representing a standard melting-evaporation process. The transition energy density in (a) has its minimum at $\phi = 0$. As T is increased through T_m and then T_v, we see a shift in the global minima from pure solid to solid-liquid and to liquid-vapor. As T eventually exceeds T_v as shown in (d), the energy minimizing well shifts to a vapor state at $\phi = 2$. Figure 3 shows examples of the other material transition functions and their derivatives.

3. Matching material properties to HMX. Here we discuss our fit of the model's material properties to mimic an energetic material like HMX. Figure 4 shows a pressure-temperature plane that indicates regions where, from classical and experimental considerations, HMX can be considered to be a static solid, liquid, or a gas in thermodynamic equilibrium. Some of the boundaries (specifically the solid/liquid boundary) are known from experiment. Note that solid phases of HMX are not differentiated here, and it is assumed that the β-phase of solid HMX is representative. The solid/liquid boundary is of particular interest and is computed via a Kraut–Kennedy law. It is well known that HMX liquid is quite unstable [3] and once the liquid phase

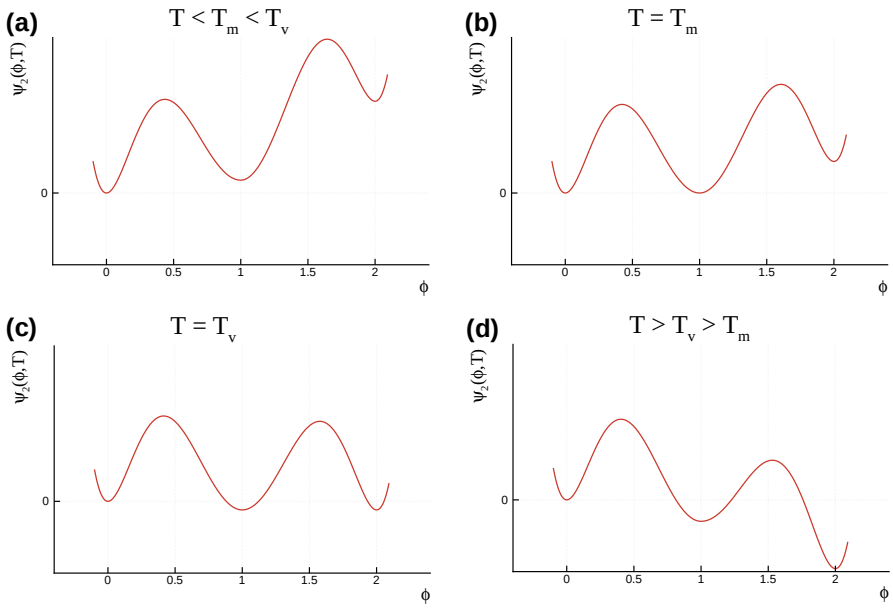

FIG. 2. *Plot of ψ_2 as a function of ϕ with T variation.*

appears it quickly evolves into gas, partly from exothermic energy released by chemical reaction in the condensed phase. For the purpose of our early modeling efforts, we have decided to match the HMX melt temperature to the experimental melt temperature $T = 558$ K and the evaporation temperature at $T = 588$ K. Figure 4 shows a shaded box that represents the range of temperatures and pressures (level of stress) predicted by computation with model.

In our model, p-V isotherms (where $V = 1/\rho$) can be obtained directly from (2.1) by setting all derivatives equal to zero and by assuming a homogeneous deformation such that $\boldsymbol{B} = (\rho_0/\rho)^{2/3}\boldsymbol{I}$ and $\boldsymbol{\sigma} = -p\boldsymbol{I}$ (where p is the pressure) to obtain

$$p = \mu_c \left(\frac{\rho}{\rho_0}\right)\left[\left(\frac{\rho}{\rho_0}\right)^{\frac{2\nu_c}{1-2\nu_c}} - \left(\frac{\rho}{\rho_0}\right)^{-\frac{2}{3}}\right] + \alpha_c K \frac{\rho}{\rho_0}(T - T_0) - \rho R_g T\,. \tag{3.1}$$

HMX liquid is approximately 4% less dense than HMX solid [13]. Figure 5 shows a plot of an isotherm computed from (3.1) with values shown in Table 1. Experimental data points on the solid isotherms obtained by Yoo and Cynn [10] are shown for comparison. Since HMX liquid is so chemically unstable, experimental data for the liquid isotherm is not available. One implication of the lower density for HMX liquid is that the isothermal sound speed (the negative slope of the p-V isotherm) is greater in the solid than in the liquid. Figure 6 shows a plot of an isotherm computed from (3.1) for the ideal gas term that is proportional to R_g. Figure 7 shows a representative isotherm on log-scales at 300 K, for the full range of values for the model when the material is solid, liquid, or gas, as computed from (3.1).

4. Form of the model for three simple motions. Here we consider the differential equations for the model when the material undergoes three simple motions: (i) evolution at constant volume, (ii) time-dependent longitudinal motion, and (iii)

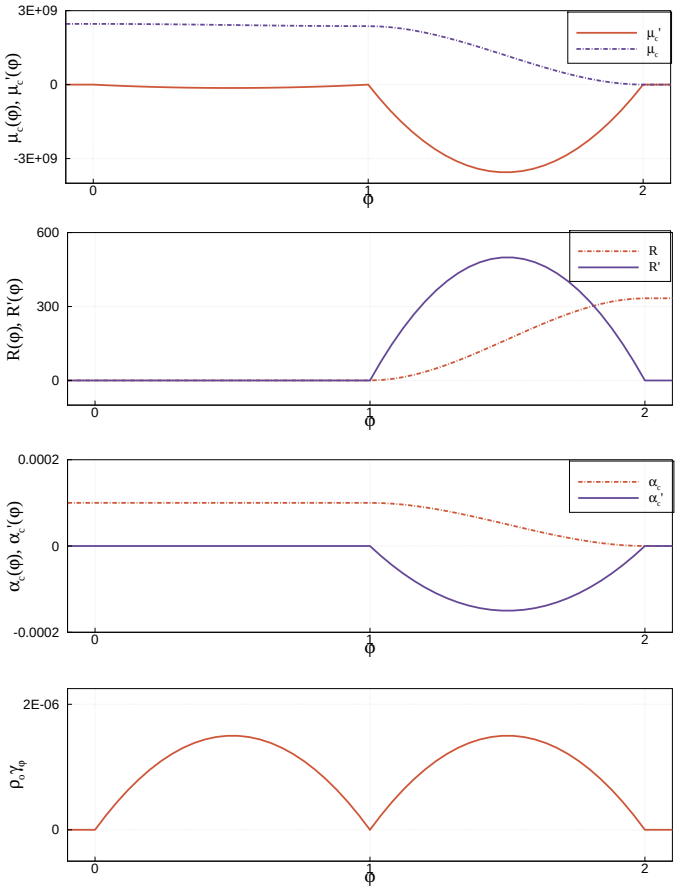

FIG. 3. *Plots of transition functions and their derivatives for the HMX simulant derivatives with respect to the phase variable. Shear modulus, ideal gas constant, thermal expansion coefficient, and phase diffusion coefficient are shown from top to bottom.*

one-dimensional, time-dependent shear motion. All three cases are amenable to extensive computational and theoretical analysis and their discussion reveals the underlying mathematical properties of the model. All three are very important in the traditional analysis of ignition of energetic materials. The reduction for the three special motions follow directly from the general form of equations (2.1)–(2.7) and were derived in the last section of paper I.

4.1. Evolution at constant volume. An important simple case often considered in combustion theory describes constant volume thermal explosion, where the velocity $\boldsymbol{v}$ as well as all spatial gradients are exactly zero and the density is constant. For illustration (in this section only), we neglect thermal expansion and assume a constant specific heat and gas constant. We are left with three ODEs in time for the temperature T, phase variable ϕ, and reaction progress variable λ (see (I 6.1), (I 6.2), and (I 6.3)). If phase change is discarded, we recover the equations from standard combustion theory for constant volume thermal explosion, $c_v(\partial T/\partial t) = Q_{hc}\,\Omega\,, (\partial\lambda/\partial t) = \Omega$. Of course, the more interesting behavior occurs when phase change is included.

Figure 8 shows an example of the time evolution of constant volume heating

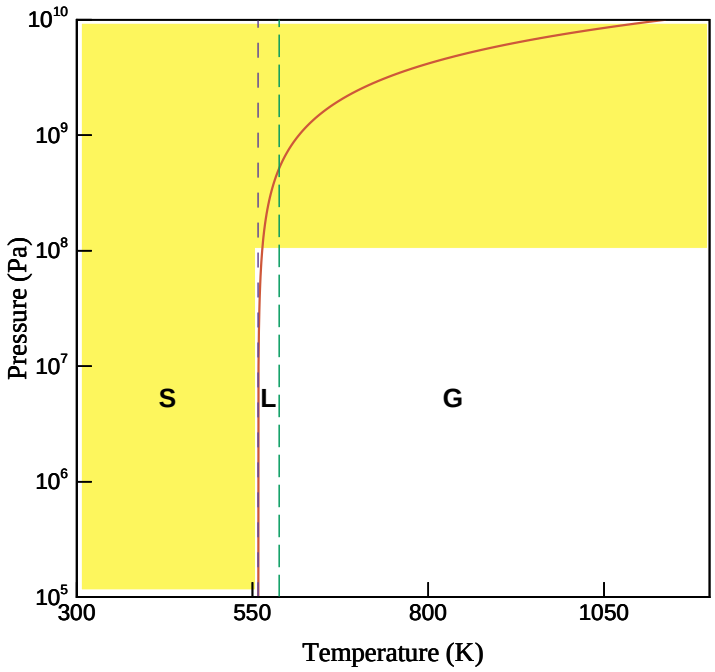

FIG. 4. *The solid curve is the melt temperature-pressure relation for β-HMX given by the semi-empirical Kraut–Kennedy law* [4], [7]. *Dashed line and long-dashed line are constant melt temperature and vapor temperature used in the current numerical simulation, respectively.*

without chemical reaction starting from a solid ($\phi = 0$) at an initial temperature of $T = 300$ K. The heating rate r and the kinetic parameter B control the transformation rates. It is possible to see (at least qualitatively) all of the phase change behaviors expected during constant volume heating. As heat is first applied, the temperature increases linearly. As the temperature increases further, the material begins to melt and the endothermic process absorbs heat from the system. (In Figure 8 the slight temperature decrease is barely visible in the nearly constant temperature interval.) At the completion of the phase transformation to liquid, the temperature rises in the liquid at a constant rate until the vaporization temperature is reached and second phase transition from liquid to gas phase occurs. After that, constant rate heating in the gas occurs.

The sharp transitions that are apparent in Figure 8 (for example, near the times $t = 0.05$ and $t = 0.09$ sec) are the result of a bifurcation and a change of stability in the ODEs near the transition temperatures T_m and T_v. To see this clearly, consider the stability of the solid phase during constant rate heating. The temperature and the phase variable can be represented to leading order as $T = T_0 + r\,t/c_v$ and $\phi = 0$ (with $\lambda = 0$ for all time), so that a stability analysis assumes that T and ϕ take the form

$$T = T_0 + \frac{r}{c_v}t + T'(t) + \cdots, \qquad \phi = \phi'(t) + \cdots, \tag{4.1}$$

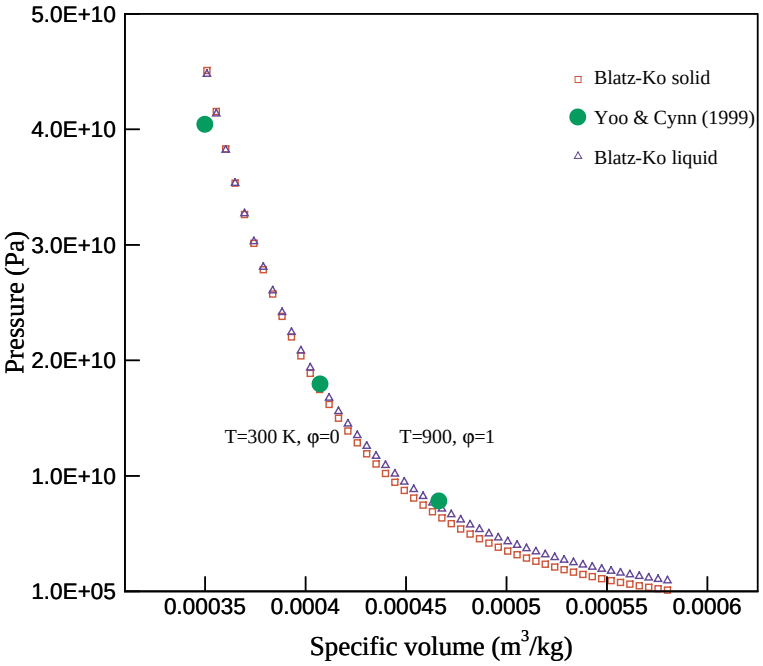

FIG. 5. *P-V isotherms at $T = 300\ K$ and $T = 900\ K$. $\left|\frac{dp}{dV}\right|_{\phi=0} > \left|\frac{dp}{dV}\right|_{\phi=1}$ implies that the speed of sound is greater in solid than in the liquid HMX.*

where T' and ϕ' are assumed to be small. The linearization of (I 6.1), (I 6.2) with $\beta'_m \approx 6\phi'$ and $\partial F/\partial\phi \approx 8\phi'$ is straightforward and leads to equations for T', ϕ':

$$\frac{dT'}{dt} = 0\,, \tag{4.2}$$

$$\frac{d\phi'}{dt} = -\frac{\rho}{B}\left\{4\Psi^{well} - 6Q_m\left(1 - \frac{T^{(0)}}{T_m}\right)\right\}\phi'\,, \tag{4.3}$$

where $T^{(0)}$ is the leading-order temperature found from simple constant rate heating

$$T^{(0)} = T_0 + \frac{r}{c_v}t\,. \tag{4.4}$$

The stability properties of the solution for ϕ' are governed by the sign of $d\phi'/dt$ found on the right-hand side of (4.3). For early times, the argument is always negative, since $T^{(0)} < T_m$ and $Q_m < 0$. Consequently, the solution is exponentially stable. (It is a simple matter to write down the exact solution of (4.3).) As the temperature rises, the stability changes as $d\phi'/dt$ changes sign, and this time it is found by setting the right-hand side of (4.3) exactly equal to zero. In this case the leading-order temperature is

$$T^{(0)} = T_m - \frac{2}{3}\frac{\Psi^{well}}{Q_m}T_m\,. \tag{4.5}$$

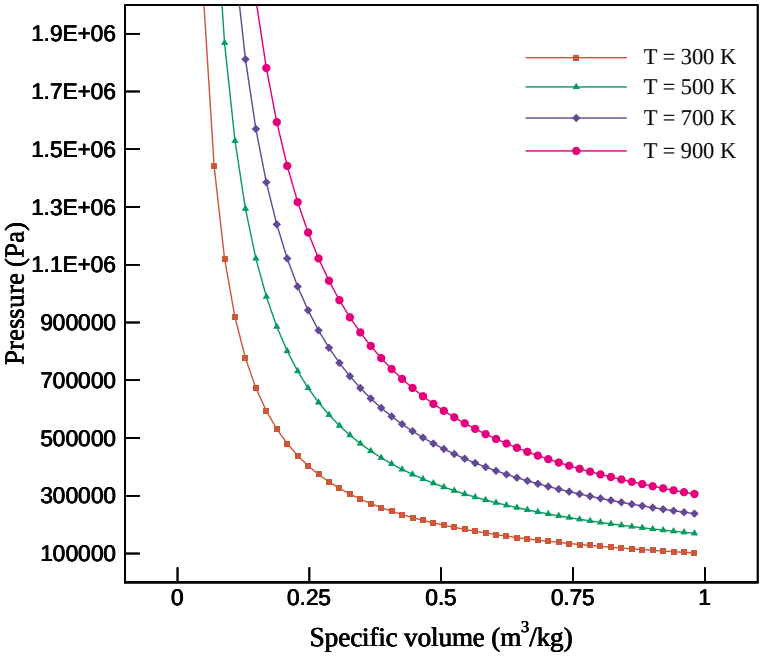

FIG. 6. *P-V isotherms at four different temperatures for HMX vapor ($\phi = 2$).*

For the case where $|\Psi^{well}/Q_m| << 1$, the phase transition temperature associated with this simple change of stability is close to T_m. So we find that below the melt temperature the perturbations are stable, but near the melt temperature the stability changes type and becomes unstable. Any perturbation grows and subsequently an abrupt transition occurs from $\phi = 0$. Another point is that our assumed properties for F strictly require a nonzero perturbation of ϕ to be combined with heating in order to observe a phase transition. In cases other than constant volume evolution, other source terms exist in the ϕ-evolution equation (specifically those related to derivatives of the Helmholtz free energy associated with deformation) and they can be the source of thermomechanical disturbances that can grow when the phase becomes dynamically unstable.

Figure 9 shows a representative solution to (I 6.1)–(I 6.3) with an Arrhenius form assumed for $\Omega = A(\phi)(1-\lambda)\exp[-E_a/(R_u T)]$. The function $A(\phi)$ is chosen to be zero in the solid phase and takes the value listed in Table 1 in the gas phase. Initially the material is solid and cold and heated at a uniform rate. So the phase transformations from solid to liquid to gas occur in the same way as shown in Figure 8. However, for this example, once the gas is in abundance, the chemical reaction starts and the gas undergoes a classically well understood constant volume thermal explosion. If we had chosen to adopt a more complex kinetic form for Ω, reaction could take place first in the liquid phase. In the near future, we plan to use more realistic kinetic scheme for HMX. Clearly there is the flexibility within this formulation to model many aspects of condensed phase energy release.

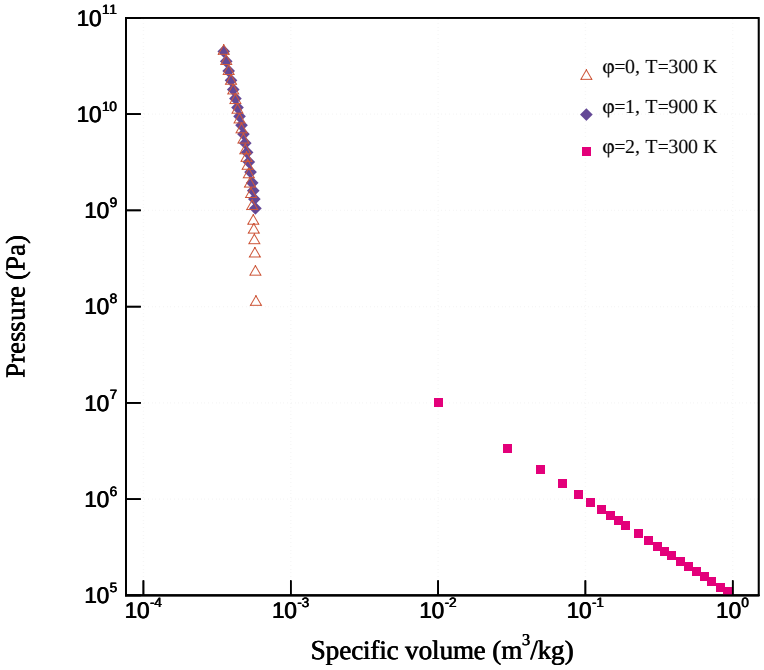

FIG. 7. *P-V isotherms for solid, liquid, and vapor HMX at $T = 300$ K, drawn to a single range of P-V axes.*

4.2. Longitudinal motion. Next we consider simple longitudinal motion. Typically, explosives are tested by subjecting them to impact with a flyer-plate. In an idealization of this experiment, an infinite slab experiences a displacement loading normal to its surface. As a computational matter, the same flow can be modeled as a reverse impact experiment, where the sample is set into uniform motion and suddenly comes to rest at the origin. We must consider following one-dimensional motion:

$$x_1 = X_1 + f_1(X_1, t)\,, \quad x_2 = X_2\,, \quad x_3 = X_3\,, \tag{4.6}$$

where f_1 is the displacement in the 1-direction. There is one nonzero velocity component, $v_1 = \partial f_1/\partial t|_{\boldsymbol{X}}(X_1, t)$, and $\boldsymbol{F}$ and $\boldsymbol{B}$ are both diagonal, and $B_{11} = (1 + f_1')^2$, $B_{22} = 1, B_{33} = 1$. The first and third invariants of $\boldsymbol{B}$ are $I_{\boldsymbol{B}} = 2 + (1 + f_1')^2$ and $III_{\boldsymbol{B}} = (1 + f_1')^2 = (\rho_0/\rho)^2$. Then $I_{\mathbf{B}} - 3 = (\rho_0/\rho)^2 - 1$. Hence we use the density as the independent strain measure and replace f_1'. The one nonzero component of the rate of strain tensor is $D_{11} = \partial v_1/\partial x_1$. Also $(\vec{\nabla}\phi \otimes \vec{\nabla}\phi)_{11} = (\partial\phi/\partial x_1)^2$. It follows that all the shear stresses are zero, $\sigma_{12} = \sigma_{23} = \sigma_{13} = 0$, and the normal stress σ_{11}, is given by (I 6.5).

The governing equations for longitudinal compression are the mass and momentum equations in (I 6.6), (I 6.7), the energy equation (written in temperature form) in (I 6.8), and the phase and reaction progress evolution equations, given by (I 6.9) and (I 6.10). This special formulation is a set of five PDEs for the dependent variables ρ, v_1, T, ϕ, and λ in terms of the independent variables x_1 and t.

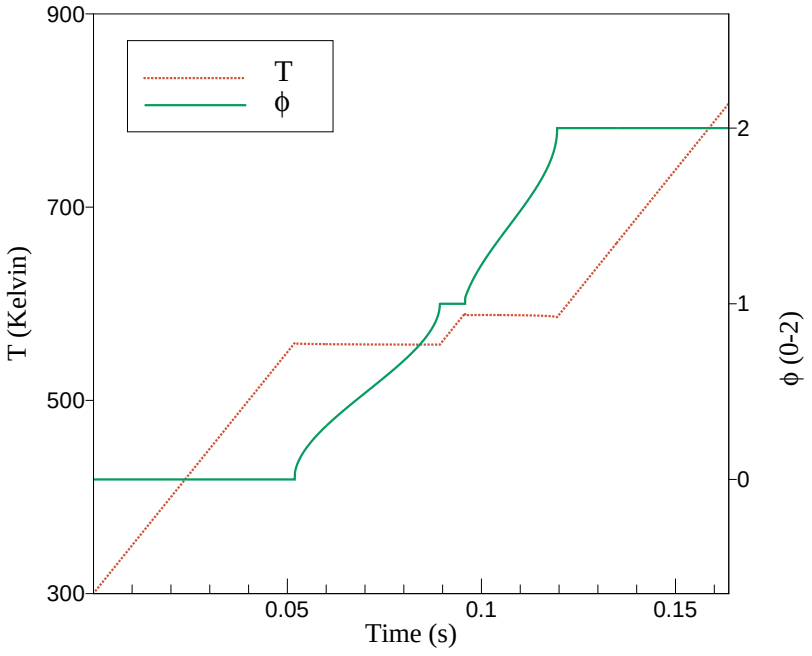

FIG. 8. *Constant volume phase transformation without reaction.*

4.3. Shear motion. The specialization of the equations to shear motion leads to PDEs in one space variable and time. The nominal geometry is a slab of fixed thickness loaded at one surface with constant velocity. The other surface is taken to be fixed (zero displacement) for the entire duration of the test. We consider the following shear motion:

$$x_1 = X_1 + f_1(X_2, t), \qquad x_2 = X_2 + f_2(X_2, t), \qquad x_3 = X_3\,, \tag{4.7}$$

where f_1 and f_2 are the in-plane displacements, which can also be regarded as functions of the spatial coordinate and time x_2, t. Corresponding to this motion one has the velocities with $v_1(x_2,t), v_2(x_2,t)$, $v_3 = 0$, and $\partial/\partial x_1 = \partial/\partial x_3 = 0$. The expression of the material time derivative is given by $\dot{\overline{()}} = \partial/\partial t + v_2\,\partial/\partial x_2$. The shear deformation is described by (I 6.12) and (I 6.13). The invariants of $\boldsymbol{B}$ are computed as $I_{\mathbf{B}} = 1 + {f_1'}^2 + (1+f_2')^2 + 1$ and $III_{\mathbf{B}} = (1+f_2')^2 = (\rho_0/\rho)^2$ with $1 + f_2' = \rho_0/\rho$. Also $I_{\mathbf{B}} - 3 = (\rho_0/\rho)^2 - 1 + {f_1'}^2$. In addition, from the kinematic identity $\dot{\boldsymbol{F}} = \boldsymbol{L}\boldsymbol{F}$, we obtain two nontrivial relations $\dot{f}_1' = (1+f_2')\partial v_1/\partial x_2$ and $\dot{f}_2' = (1+f_2')\partial v_2/\partial x_2$, where the material derivative is $\dot{\overline{()}} = \partial/\partial t + v_2\,\partial/\partial x_2$. The second of the two results is equivalent to replacing $1 + f_2'$ with ρ_0/ρ. The first is an independent expression for the shear strain which can be recast in terms of the density and transverse velocity gradient as in (I 6.14). Finally, $\vec{\nabla}\phi \otimes \vec{\nabla}\phi$ has only one nonzero component, $(\vec{\nabla}\phi \otimes \vec{\nabla}\phi)_{22} = (\partial\phi/\partial x_2)^2$.

We use the density ρ and the shear strain f_1' as the two independent kinematic

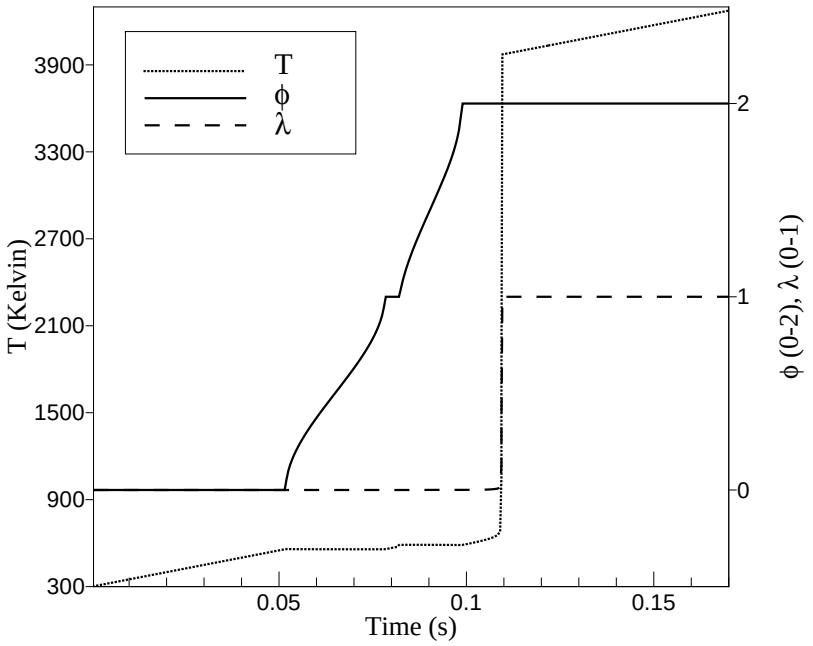

FIG. 9. *Constant volume thermal explosion.*

variables. We can now write down expressions for the components of the stress tensor. The cross-plane shear stresses are zero, i.e., $\sigma_{13} = \sigma_{23} = 0$. The in-plane shear stress σ_{12} is given by the expression (I 6.15). The in-plane normal stress σ_{22} is given by (I 6.16).

The specific governing equations for the shear motion are listed in (I 6.17)–(I 6.22). Finally the kinematic relation (I 6.14) for the shear strain (which must be included) is expressed as in (I 6.23). This special formulation is a set of seven PDEs for the dependent variables $\rho, v_1, v_2, T, \phi, \lambda$, and f_1' in terms of the independent variables x_2 and t.

5. Numerical methodology. We have implemented an efficient high-order temporal scheme for stiff equations based on the method of lines (MOL) to solve for longitudinal and shear motions. The MOL can be implemented for various choices of spatial discretization. For discretization of convective terms we use a fourth-order convex essentially nonoscillatory (ENO) method [6] combined with a third-order, low-storage, semi-implicit Runge–Kutta method [9] for the MOL-ODEs. We do not describe the ENO discretization here. Interested readers are referred to [6].

5.1. Description of low-storage semi-implicit Runge–Kutta solver. A more comprehensive discussion of the temporal scheme can be found in [9], and only a brief description of the method is given below. To solve a system of autonomous ODEs of the form $\boldsymbol{u}' = \boldsymbol{f}(\boldsymbol{u}) + \boldsymbol{g}(\boldsymbol{u})$, we use an explicit scheme for the nonstiff term $\boldsymbol{f}$ and an implicit scheme for the stiff term $\boldsymbol{g}$. We solve the system in an explicit/implicit

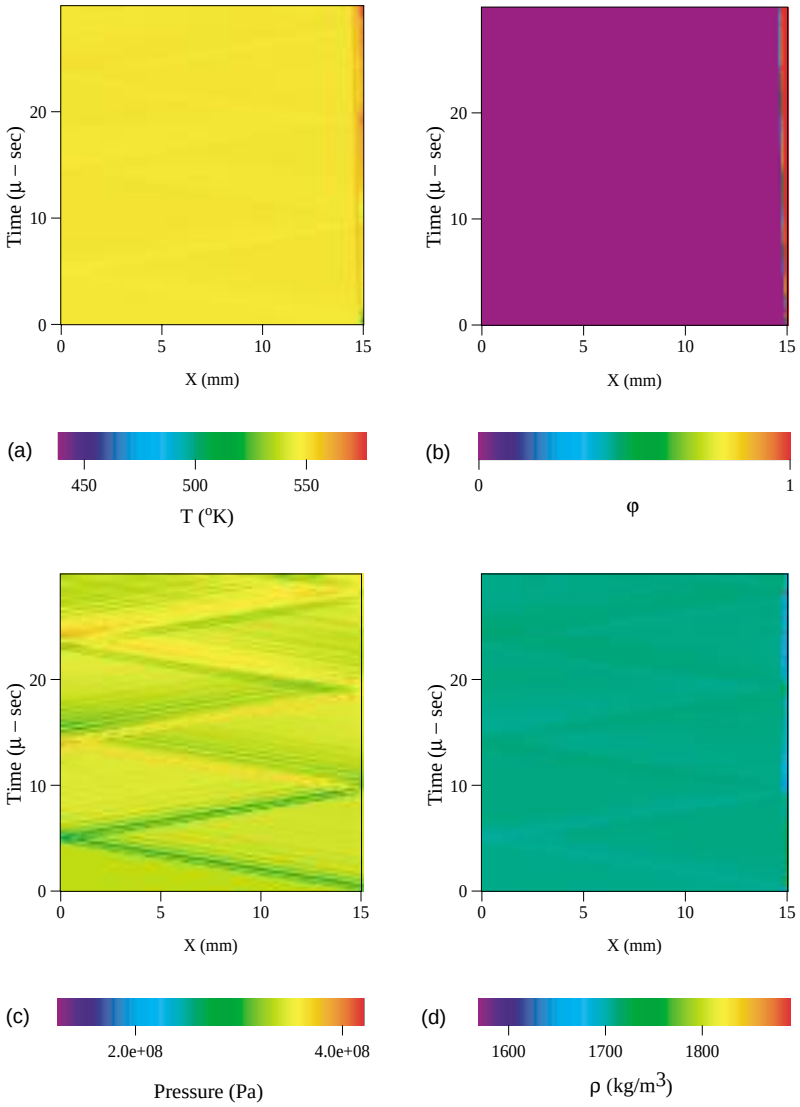

FIG. 10. *Temperature, phase, pressure, and density fields for a representative shear experiment* ($v_{shear} = 600\ m/s$, $T_0 = 550\ K$).

hybrid fashion to achieve high-order accuracy and stiffly stable calculation. A typical third-order method of this kind is given below:

$$\begin{aligned} \boldsymbol{k}_j &= a_j \boldsymbol{k}_{j-1} + h[\boldsymbol{f}(\boldsymbol{u}_{j-1}) + \boldsymbol{g}(\boldsymbol{u}_{j-1} + \bar{c}_j \boldsymbol{k}_{j-1} + c_j \boldsymbol{k}_j)], \\ \boldsymbol{u}_j &= \boldsymbol{u}_{j-1} + b_j \boldsymbol{k}_j \\ &\quad (j = 1, \ldots, 3), \end{aligned} \tag{5.1}$$

where h is the time increment, and the coefficients of the scheme are as follows:

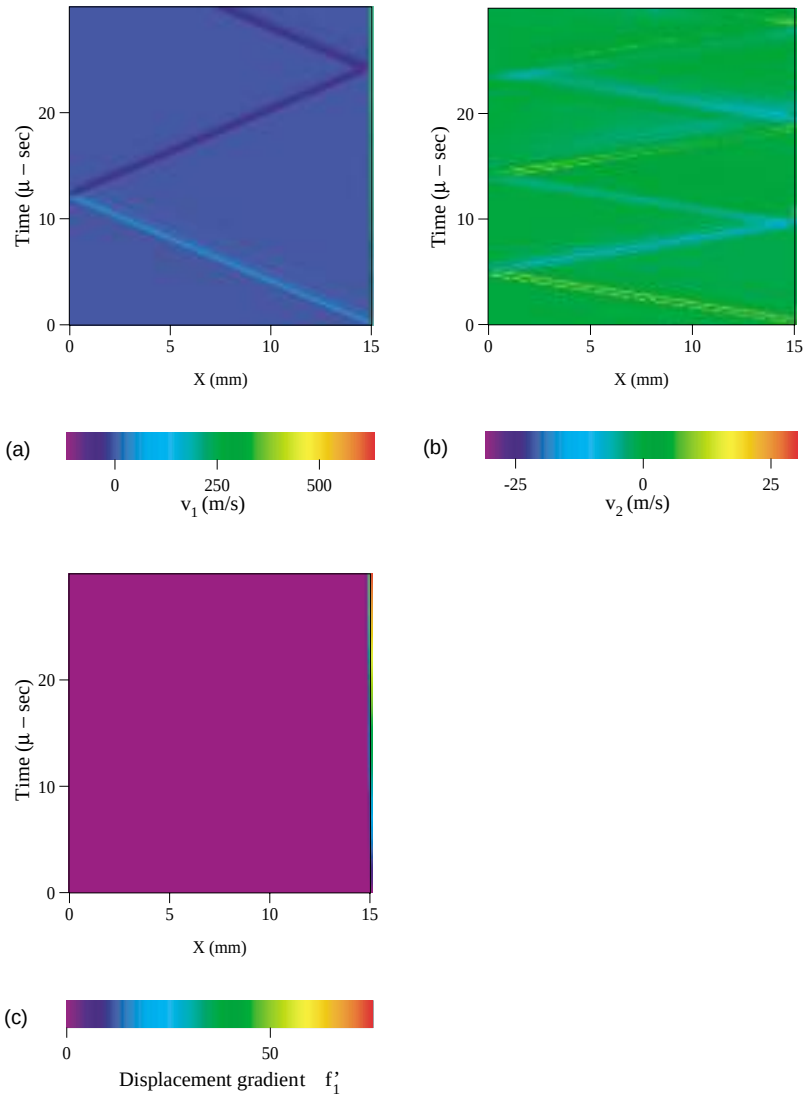

FIG. 11. *Shear velocity (v_1), compression velocity (v_2), and displacement gradient (du_1/dX_2) fields for a representative shear experiment ($v_{shear} = 600$ m/s, $T_0 = 550$ K).*

$$b_1 = \frac{1}{3}, \quad b_2 = \frac{15}{16}, \quad b_3 = \frac{8}{15}, \quad a_2 = -\frac{5}{9}, \quad a_3 = -\frac{153}{128},$$
$$c_1 = \frac{1}{5}, \quad c_2 = \frac{49}{75}, \quad c_3 = \frac{143}{600}, \quad \bar{c}_2 = -\frac{59}{135}, \quad \bar{c}_3 = -\frac{5283}{25600} \tag{5.2}$$

with $a_1 = 0, \bar{c}_1 = 0$.

In many instances where implicit calculation is not required, one can simply assign zero to the stiff vector $\boldsymbol{g}$ and assign the entire source as a nonstiff vector $\boldsymbol{f}$ and the standard explicit Runge–Kutta scheme is recovered.

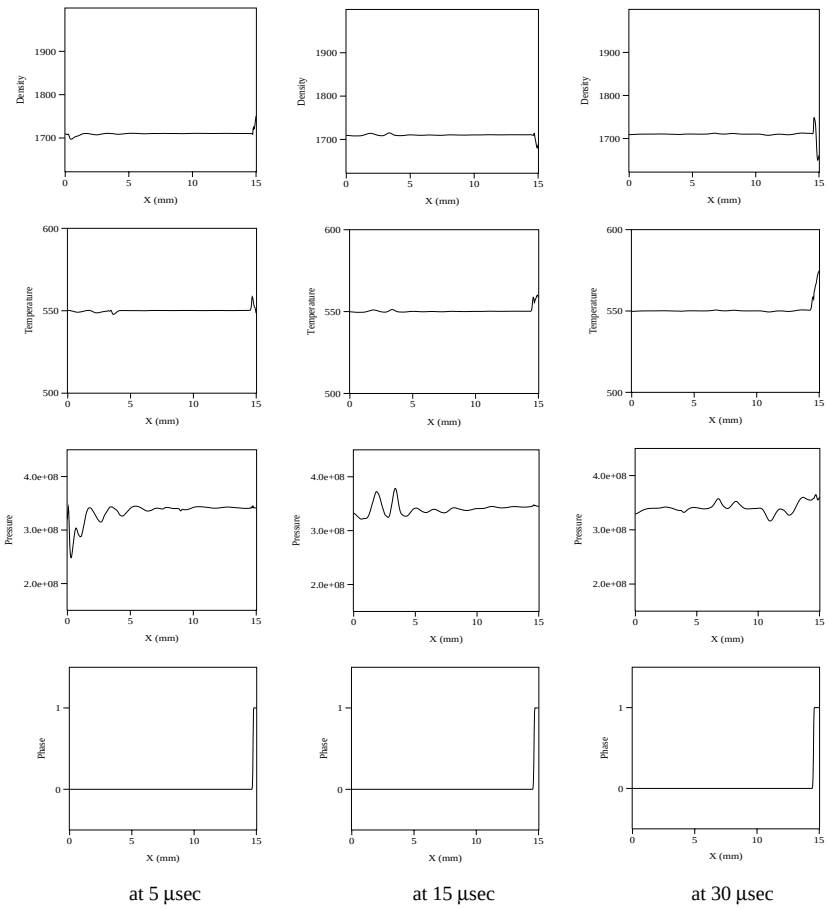

FIG. 12. *Snapshots of density, temperature, pressure, and phase field (from top to bottom) taken at time* $t = 5,\ 15,\ 30\,\mu sec$ *from Figures* 10 *and* 11 *of the plane shearing experiment.*

5.2. Implementation. Before starting the computation one writes the governing PDEs in a conservative form such that limiting forms of the equations admit discontinuous solutions which are also admitted by the numerical approximation. Further, the stiff and nonstiff terms must be intelligently separated. In particular, convective terms, which are a priori discretized in space via a fourth-order convex ENO scheme, are always treated as nonstiff terms. The viscous stress terms of momentum equations are treated as nonstiff and are discretized by a fourth-order central differencing. Only the reaction source term, Ω, is treated as stiff and is subjected to the implicit numerical procedure. Otherwise the explicit method solves all the remaining terms of the equations.

We consider the shear motion to illustrate the numerical implementation. After converting the equations into a conservative form and separating the stiff and nonstiff terms, we can write the conservative variables and the fluxes as follows:

$$\text{(5.3)}\quad \boldsymbol{u} = \begin{bmatrix} \rho \\ \rho v_1 \\ \rho v_2 \\ \rho c_v T \\ \rho\phi \\ \rho f_1' \\ \rho\lambda \end{bmatrix}, \quad \boldsymbol{f} = \begin{bmatrix} -\frac{\partial}{\partial x_2}(\rho v_2) \\ -\frac{\partial}{\partial x_2}(\rho v_1 v_2 + \sigma_{12}) \\ -\frac{\partial}{\partial x_2}(\rho v_2 v_2 + \sigma_{22}) \\ -\frac{\partial}{\partial x_2}(\rho c_v T v_2) + \omega_1 \\ -\frac{\partial}{\partial x_2}(\rho\phi v_2) + \omega_2 \\ -\frac{\partial}{\partial x_2}(\rho f_1' v_2) + \rho_0 \frac{\partial v_1}{\partial x_2} \\ -\frac{\partial}{\partial x_2}(\rho\lambda v_2) \end{bmatrix}, \quad \text{and } \boldsymbol{g} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ \rho\Omega \end{bmatrix},$$

where ω_1 and ω_2 are the right-hand-side source terms of T and ϕ. The convective terms are discretized by the fourth-order convex ENO scheme [6] and the resulting semidiscretized equations $\boldsymbol{u}_t = \boldsymbol{f} + \boldsymbol{g}$ are a system of autonomous ODEs in $\boldsymbol{u}$ and are integrated in time via the third-order Runge–Kutta method as discussed earlier.

6. Simulations of longitudinal and shear motions. We have validated the code written for the full model through a series of graduated tests. Since equations that correspond to classical elastodynamics and classical gas dynamics can be obtained simply by suppressing the appropriate terms, limiting versions of the code can be used to solve problems with exact solutions, like standard Riemann problems or small amplitude linear wave propagation. These tests are fully documented in Yoh's Ph.D. thesis [11]. Similar test cases can be found in Ruderman's thesis [12]. For example, Riemann problems have been computed for a special case of an ideal gas. In the special limiting case of small-displacement elasticity for shear motions, with the assumption of constant material properties, one can show that there are dilatation waves that travel at $\sqrt{(\lambda_s + 2\mu_s)/\rho_0}$ and shear waves that travel at $\sqrt{\mu_s/\rho_0}$, where $\lambda_s = 2\mu_s\nu_c/(1 - 2\nu_c)$.

6.1. One-dimensional shear motions. Here we discuss representative solutions to an initial boundary-value problem that represents numerical experiments for shear motion. The problem set up is as follows: A slab of material 15 mm thick in the x_2-direction is initially at an elevated temperature and suddenly subjected to a constant velocity shearing motion at the edge $x_2 = 15$ mm while the edge at $x_2 = 0$ is held fixed. The material is thermally insulated. For the purpose of these experiments, the gas phase is suppressed and does not appear, hence the transitions documented here occur only between solid and liquid. We show representative results for two different initial conditions. First, we consider the initial temperature at 550 K with the constant shear velocity of 600 m/s, dubbed shear case A. In the second case, the initial temperature is slightly above the melting transition temperature at 560 K with a lower shearing velocity of 200 m/s, dubbed shear case B. Shear case B exhibits more complex dynamics associated with multiple regions of phase change. Both cases show generic elastic wave interactions and reflections within solid-fluid regions. The computational domain has 500 points spread uniformly over 15 mm.

Figures 10 and 11 show x_2-t contour plots of the thermodynamic variables T, ϕ, p, ρ, the velocities v_1 and v_2, and the displacement gradient $f_1'(X_2)$. Initially the hot sample, just below the melting temperature at 550 K, is exposed to the wall shear at 600 m/s. The rapid shearing at $x_2 = 15$ mm produces sufficient heating to cause rapid melting in a thin layer near the moving boundary. This is easily observed in Figure 10(a) and 10(b) for the temperature T and phase variable ϕ, respectively. The shearing motion is then confined mostly to a thin shear layer as seen in Figure 11(a) for velocity v_1 (in the direction of the imposed motion at $x_2 = 15$ mm). Note that the shear wave in the solid associated with v_1 is clearly observed as a wave that initially

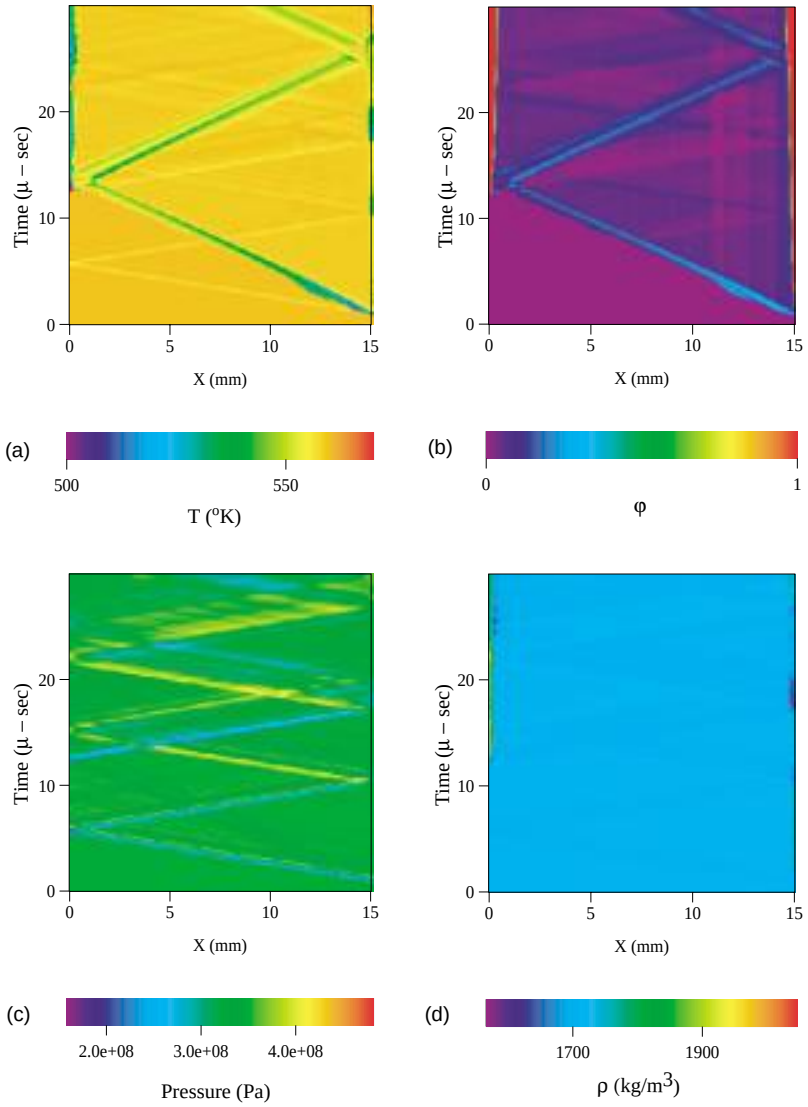

FIG. 13. *Temperature, phase, pressure, and density fields for a representative shear experiment* ($v_{shear} = 200$ *m/s*, $T_0 = 560$ *K*).

enters the domain at $x_2 = 15$ mm and travels toward $x_2 = 0$ mm and subsequently reflects off the stationary wall.

Figure 11(b) for v_2 displays waves that travel at the dilatational wave speed, which is approximately twice the shear wave speed. The dilatational waves are generated by the initial growth of the melted layer and are associated with pressure waves of magnitude of approximately 10^8 Pa = 1 kbar. Note that the initial stress in the system is elevated due to the effect of thermal expansion at the initially raised temperature. Close inspection of the temperature and pressure fields shown in Figure 10(a), (c) shows evidence of high frequency acoustic waves that can be traced to reflections and transmissions of waves through the solid/liquid interface near $x_2 = 15$ mm.

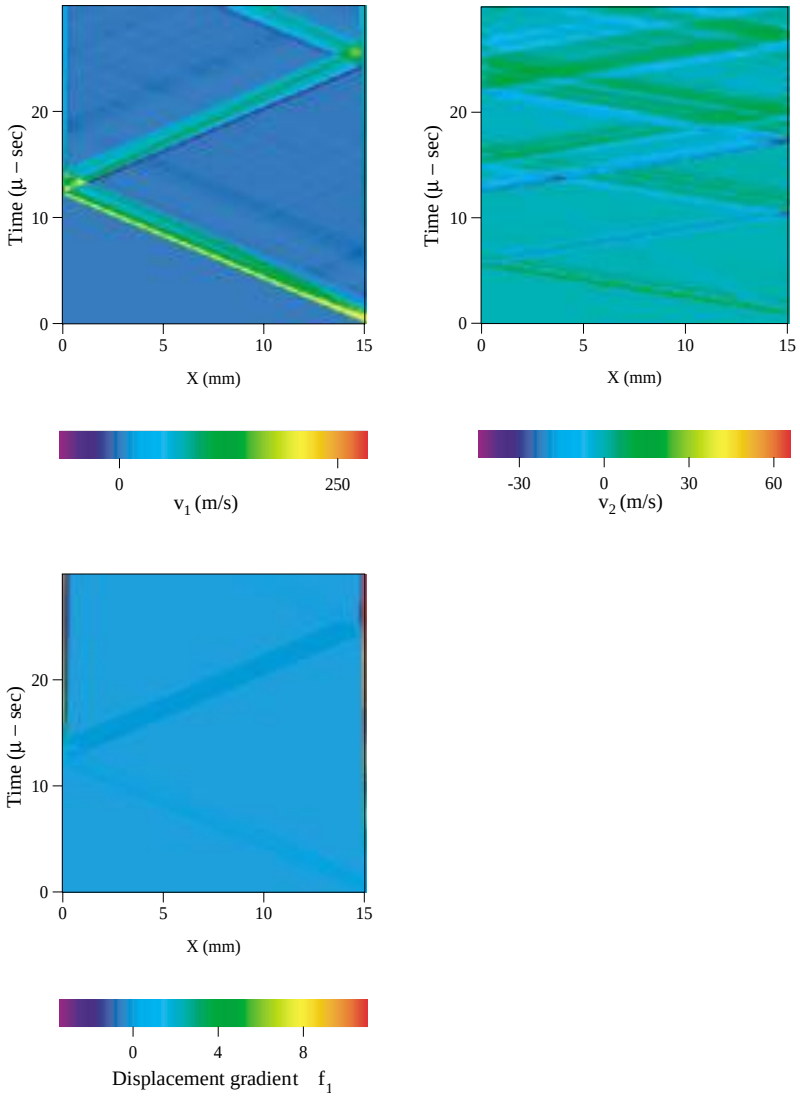

FIG. 14. *Shear velocity (v_1), compression velocity (v_2), and displacement gradient (du_1/dX_2) fields for a representative shear experiment ($v_{shear} = 200$ m/s, $T_0 = 560$ K).*

Figure 12 shows computed profiles for shear case A for ρ, T, p, and ϕ at times 5, 15, and 30 μsec, which represents time cuts across Figure 10(a)–(d). The profiles show elevated temperatures and phase change (melting) confined to the layer near the $x_2 = 15$ mm boundary. The fluctuations in the pressure, density, and temperature profiles are the result of the acoustic disturbances propagating through the solid and across the solid/liquid layer.

Note that the layer of liquid that develops at $x_2 = 15$ mm is a localized shear layer and can be thought of as a shear band. The material in the melt layer has very large v_1-velocities and subsequently undergoes large deformation. The material in the solid phase essentially remains fixed in place as the fluid layer slides across it.

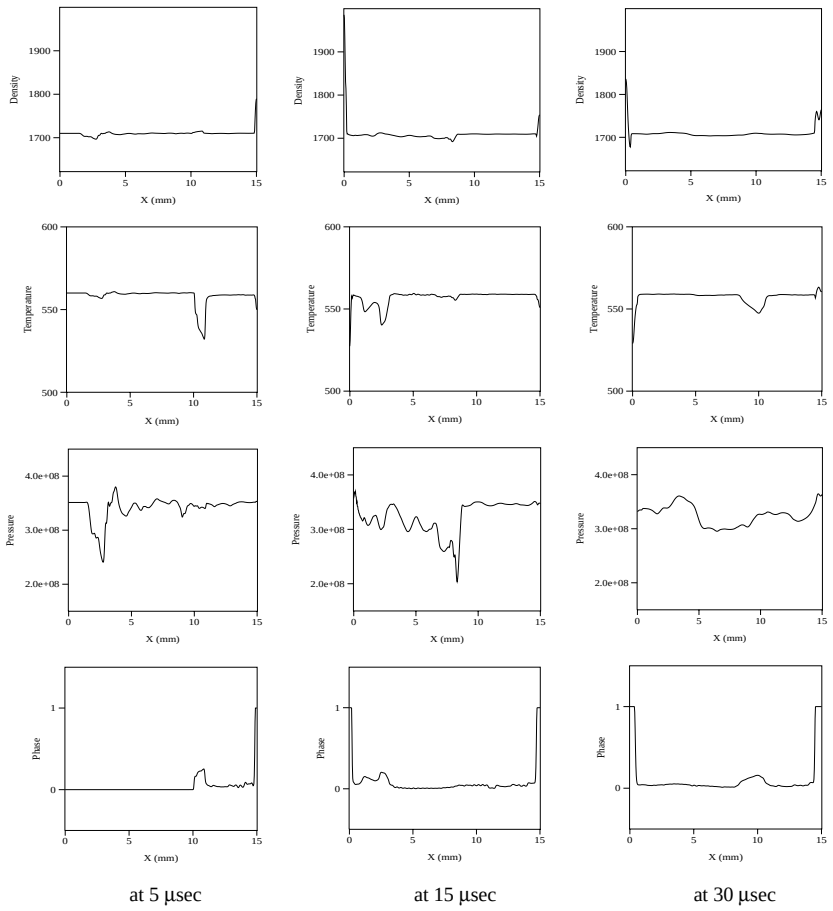

FIG. 15. *Instantaneous profiles of density, temperature, pressure, and phase field (from top to bottom) taken at time* $t = 5,\ 15,\ 30\,\mu$*sec corresponding to Figures* 13 *and* 14 *of the plane shearing experiment.*

Shear case B has the solid with its initial temperature slightly above the melt temperature, suddenly subjected to a (lower) constant shear motion of 200 m/s. As in case A, a melt layer forms near $x_2 = 15$ mm and the dilation wave travels across the slab. After reflection at the fixed wall, a second melt layer develops near $x_2 = 0$ mm. Figures 13, 14, and 15 show the additional complexity in the x_2-t record. The second melt layer causes additional scatter of waves generated near the $x_2 = 15$ mm boundary, and, in turn, the growth of the layer generates additional disturbances which transmit through the regions. One recalls that there are additional terms in the ϕ-evolution equation that are associated with the deformational part of the stress. We clearly see that the stress waves (by themselves) can induce the phase transformation. One sees transient phase generation carried on the subcharacteristics in the phase variable plot Figure 13(b). The next set of experiments for longitudinal motions illustrates shock melting.

6.2. One-dimensional longitudinal motion: Reverse impact. The results discussed next are for two different longitudinal motions where a HMX specimen of thickness 15 mm is initially solid at the melt temperature ($T = 558$ K) and subjected

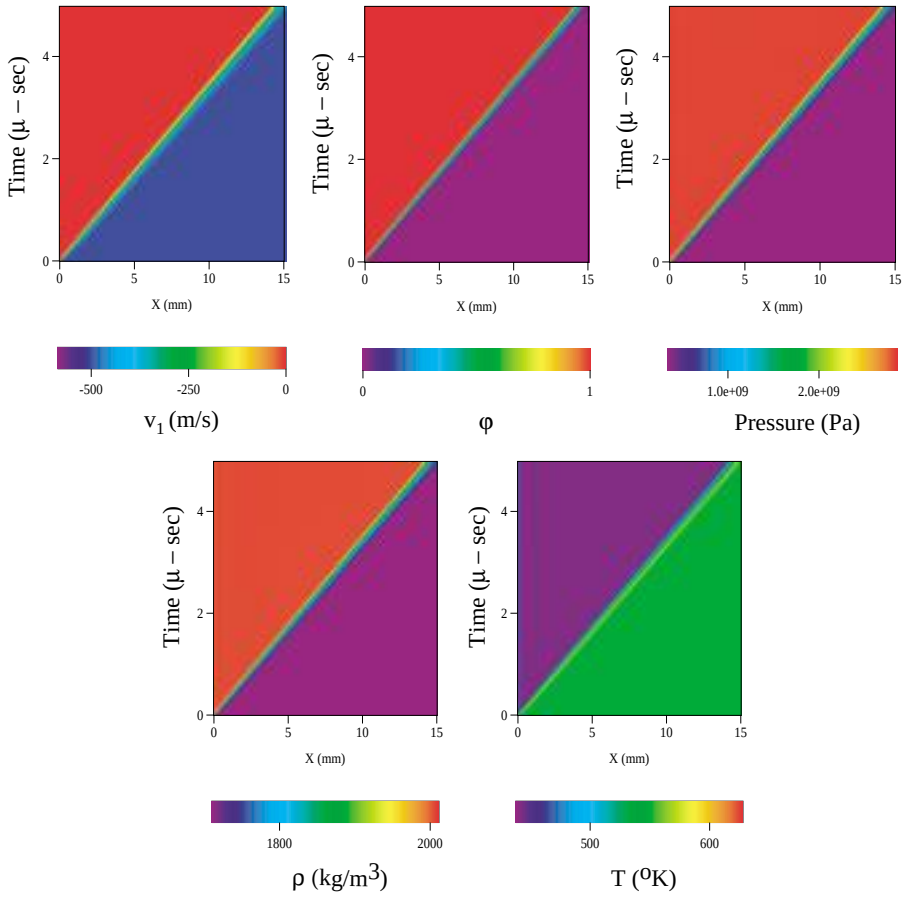

FIG. 16. *Velocity, phase, pressure, density and temperature fields for a representative reverse-impact (longitudinal) experiment ($v_{impact} = -500$ m/s, $T_0 = 550$ K).*

to a reverse impact at speed −500 m/s for longitudinal case A and −200 m/s for longitudinal case B. The computational domain spans the 0.015 m with 500 mesh points.

For longitudinal case A, Figures 16 and 17 illustrate the phenomenon of shock melting as predicted by the model. Figure 16(a)–(e) clearly shows the emergence of a shock wave from the stationary wall into the oncoming stream. Ahead of the shock the material is solid with $\phi = 0$; behind the shock the material is liquid with $\phi = 1$. The model predicts a shock with definite spatial structure as illustrated by the structure profiles taken at $t = 3\,\mu$sec and shown in Figure 17. In the shocked state, where the material has liquefied, there is a significant pressure increase to about 2.8 GPa (28 kbar)—a 20% density increase—and a drop in the temperature due to the endothermic nature of the phase transformation. The pressure and density rise monotonically across the shock structure. The temperature increases slightly, then drops with the onset of the phase transformation from solid to liquid. Throughout the structure, the phase changes monotonically from solid to liquid.

Longitudinal case B corresponds to a reverse-impact experiment where the impact speed is reduced to −200 m/s but the initial temperature is raised slightly to 560 K,

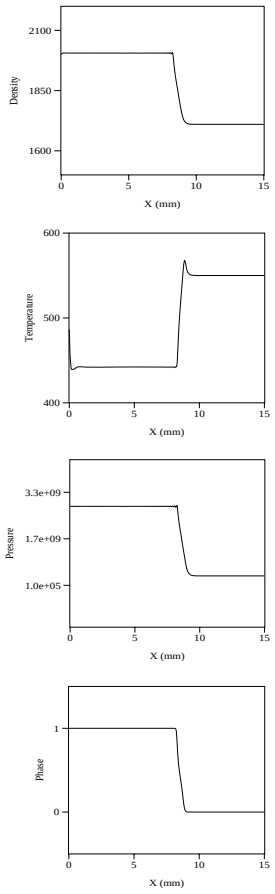

FIG. 17. *Snapshots of density, temperature, pressure, and phase field (from top to bottom) taken at time* $t = 3\,\mu$*sec from Figure* 16 *of the longitudinal exercise.*

just two degrees above the melt temperature. Figure 18 shows the x_1-t contour plots. Figure 19 shows corresponding line cuts taken at time $t = 3\,\mu$sec. Similar to longitudinal case A, shock induced phase transformation occurs; however, a stable intermediate phase is produced behind the shock front with $\phi = 0.33$. Interestingly, the model can be shown to allow these intermediate states in ϕ due to the contributions of the other stress-dependent source terms proportional to $\mu_s'(\phi), \mu_c'(\phi), \alpha_c'(\phi)$, etc. as found in (2.7). A complete analysis of all possible ϕ-states and their stability is beyond the scope of this paper. However, we can illustrate the stability of the intermediate state for longitudinal case B by a numerical evaluation as follows. We take the evolution equation for ϕ, (I 6.9), to be rewritten as $\frac{\partial \phi}{\partial t} = -v_1 \frac{\partial \phi}{\partial x_1} + w_2$, where w_2 is the source term for the material derivative of ϕ. We then take the shock structure as obtained numerically at $t = 3\,\mu$sec for both longitudinal cases A and B and plot $\partial\phi/\partial t$ versus ϕ in Figure 20. Stable equilibria points (in ϕ) are found by the zeros of $\partial\phi/\partial t$. For longitudinal case A, only $\phi = 0$ and $\phi = 1$ are stable with $\partial\phi/\partial t = 0$. But for longitudinal case B, the intermediate state $\phi = 0.33$ is found to be stable. Our numerical experiments suggest that increasing the intensity of the reverse impact causes the intermediate states to disappear with $\phi = 0, 1$ as the only

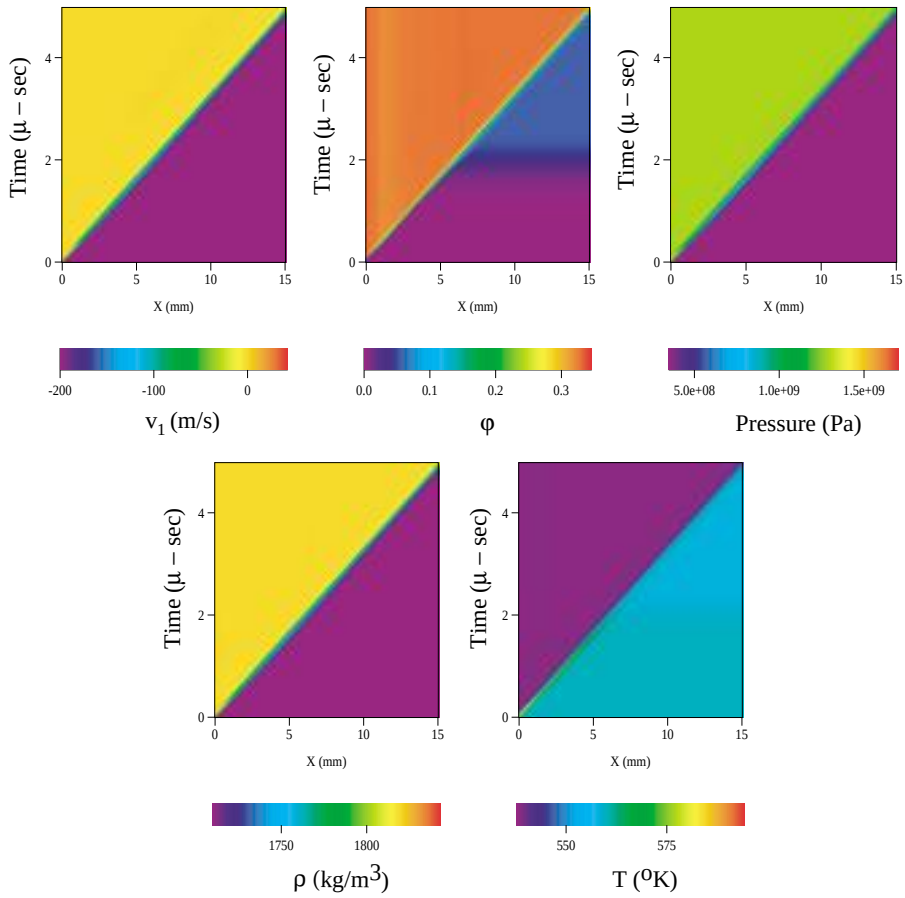

FIG. 18. *Velocity, phase, pressure, density and temperature fields for a representative reverse-impact (longitudinal) experiment ($v_{impact} = -200$ m/s, $T_0 = 560$ K).*

stable equilibria.

7. Conclusions. We have illustrated that our model, fitted to a real material, leads to predictions of simple motions (constant volume evolution, shear motion, and longitudinal motion) that are plausible. The model has the property that the constitutive theory automatically changes with the phase and is consistent with classical properties of that phase. We have shown that it is possible to fit the model to the known behavior of a real material.

Although idealized, the representative numerical experiments exhibit extremely rich behaviors. Strain localization phenomena occurred via melting in thin layers in many of the trials we have conducted. The phase change phenomena is directly coupled to the material loading through the change in material type and changes in properties that are carried with the phase. We are ready to apply this new continuum model to more complex physical problems of interest to us. Of course, extremely interesting and varied mathematical problems, such as steady traveling waves and their multidimensional stability, will arise that can profitably be analyzed by asymptotic means. The models embedded within this larger model may have greater application

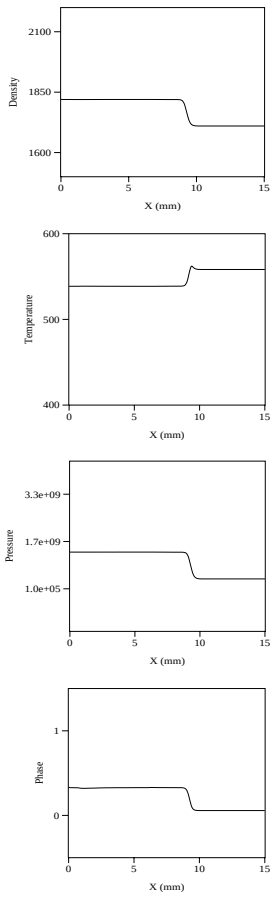

FIG. 19. *Snapshots of density, temperature, pressure, and phase field (from top to bottom) taken at time* $t = 3\,\mu$*sec from Figure* 18 *of the longitudinal experiment.*

to the general theory of phase transformation. Of specific near term interest to us is a detailed study of the mechanically induced ignition of an energetic solid. We also plan to pursue a simplified version of this model to more fully examine the processes of classical melting/freezing and vaporization/condensation in the context of the model. We also anticipate the near term application of the model to problems of vaporizing fuels and condensed phase propellant combustion.

EULER'S ELASTICA AND CURVATURE-BASED INPAINTING*

TONY F. CHAN†, SUNG HA KANG†, AND JIANHONG SHEN‡

Abstract. Image inpainting is a special image restoration problem for which image prior models play a crucial role. Euler's elastica was first introduced to computer vision by Mumford [*Algebraic Geometry and its Applications*, Springer-Verlag, New York, 1994, pp. 491–506] as a curve prior model. By functionalizing the elastica energy, Masnou and Morel [*Proceedings of the 5th IEEE International Conference Image Processing*, 3 (1998), pp. 259–263] proposed an elastica-based variational inpainting model. The current paper is intended to contribute to the development of its mathematical foundation and the study of its properties and connections to the earlier works of Bertalmio, Sapiro, Caselles, and Ballester [*SIGGRAPH* 2000, ACM Press, New York, 2000] and Chan and Shen [*J. Visual Comm. Image Rep.*, 12 (2001), pp. 436–449]. A computational scheme based on numerical PDEs is presented, which allows the automatic handling of topologically complex inpainting domains.

1. Introduction.

Among museum conservators and restoration artists, inpainting refers to the practice of retouching or recovering damaged ancient paintings [14, 40]. The goal is to remove the cracks or recover the missing patches in an undetectable manner.

The term *digital inpainting* was initially introduced into digital image processing by Bertalmio, Sapiro, Caselles, and Ballester in [3], where the authors first made an innovative construction of a third-order PDE inpainting model. Equally important in [3] is that the authors demonstrated the broad applications of digital inpainting in film restoration, text removal, scratch removal, and special effects in movies. The same group of authors has also recently developed a variational inpainting model based on a joint cost functional on the gradient vector field and gray values [1]. An earlier variational inpainting model was studied by Masnou and Morel [27] in the context of disocclusion in computer vision. Recently, Chan and Shen have proposed the *total variation* (TV) inpainting model [8] and a new PDE inpainting model based on *curvature driven diffusions* (CDD) [9]. In [8], Chan and Shen also discovered novel applications in digital zooming and primal-sketch-based [26] image coding schemes.

Inpainting is essentially an interpolation problem, with special focus on situations in which image information is partially missing or inaccessible on certain two-dimensional (2-D) regions. What makes image inpainting highly nontrivial is the complexity of image functions, caused by the richness of geometric structures and a large dynamic range of scales.

A simple but often sufficient mathematical model for generic nontexture images

is the BV (*bounded variation*) space, where the most crucial low-level visual cue—the edge—is permissible (see Rudin and Osher [36], Rudin, Osher, and Fatemi [37], and Chambolle and Lions [7] for examples). Yet, in both the approximation community and that of numerical analysis, as far as we know, there has not been much work on the inpainting of BV functions. A recent related paper by Cohen et al. [12] discusses the nonlinear approximation of BV functions, motivated by the wavelets thresholding technique and the Rudin–Osher–Fatemi denoising model [37]. The nonlinear interpolation studied therein is for the near-optimal approximation and representation of a given *complete* noisy image u_0. But inpainting has a different objective, which is to recover the entire clean image u from a given *incomplete* noisy image u_0 observed only outside a missing domain K.

The inpainting of BV images is generally an ill-posed problem, which can be seen more clearly through a one-dimensional (1-D) example. Imagine that we know the values (or even the derivatives) of a function f at $a-h$ and $a+h$. If f is smooth, then as $h \to 0$ we can apply smooth interpolants such as Lagrange's and Hermite's to infer the values of f on $(a-h, a+h)$ with a certain degree of precision guaranteed. But for a BV function f, all such smooth interpolants fail to work properly no matter how small h is, since a "widthless" jump can always occur in $(a-h, a+h)$. Under the TV Radon measure, a single point in 1-D can have nonzero mass, which makes the corresponding interpolation problem ill-posed generally. (In the high-dimensional case, the BV interpolant performs better than in 1-D, due to its connection to the *minimal surface* problem. See, for example, [8, 18].)

The good news is that images as BV functions are not too intractable. Each image is a 2-D projection of a window of the 3-D world, in which individual objects often have their geometric or surface reflectivity regularities. Such regularities partially diminish the ill-posedness of the inpainting problem.

Given an image, if we partially cover it with a piece of paper of moderate size and ask a person to guess what has been occluded in the original image, most people will come up with a "rational" best guess. For example, if a green apple in a photo is partially occluded by a piece of paper, then one often first estimates the occluded boundary and then inpaints with the green color over the occluded area belonging to the apple. All these decisions are realized by the best guesses or, more scientifically, by Bayesian inference [16, 21, 30]. The two ingredients of Bayesian inference are the *prior* model and *data* model. The data model is simple for most inpainting problems: the available data is simply a part of a complete image that we try to restore. Thus the prior model plays a crucial role in our inference process. For the apple experiment mentioned above, the *a priori* knowledge of the shape and color of an apple is helpful for a person trying to make a meaningful inpainting.

In order to develop a general inpainting model, one should never rely on the *prior* model of a *specific* class of image objects (such as apples). The model must employ generic regularities to better condition the ill-posedness. The Rudin–Osher–Fatemi BV [37] and Mumford–Shah's object-and-edge models [31] are the two most well-known prior models for generic nontexture images. However, as Chan and Shen [8] and Esedoglu and Shen [15] discussed, they become less suitable in some large-scale inpainting problems where they lead to a violation of the *connectivity principle* in vision psychology [20]. As a result, it is clear that a good inpainting model must consider *high-order* geometric information such as the curvature feature of the level sets [9].

In the current paper, we study a variational inpainting model that has arisen

from a second-order plane curve model—Euler's elastica. The gap between a prior model for curves and that for images is formally bridged by the level set concept: generally, a curve prior model can always be "lifted" to an image prior model once being imposed on all the level sets of an image (similar to the *coarea* formula in the theory of BV functions [18]). Indeed, this is how Masnou and Morel first proposed this model for image inpainting in [27]. Our current paper is intended to (a) study the mathematical foundation and properties of the inpainting models based on elasticas and curvatures, (b) explore the connection of this work to the earlier empirical works on PDE-based inpainting models, and (c) construct numerical PDE schemes for the associated nonlinear PDEs. Compared with Masnou and Morel's linear programming algorithm in [27], the numerical PDE approach is more flexible in that it frees one from laboring over edge detection or pixel coupling along the boundaries, and also that it lifts the topological restriction on the inpainting domain K [27].

Euler's elasticas were first introduced and seriously studied in computer vision by Mumford [29] as a prior curve model. They were employed in the visual disocclusion program in [32] to smoothly connect occluded edges and T-junctions. Earlier in approximation theory, elasticas had been introduced as *nonlinear splines* by Birkhoff and De Boor [4].

We are now ready to introduce the layout of the paper. We begin with a brief introduction to the elasticas (section 2). Then, as in classical interpolation theory, in section 3, we first study the generic local models for nontexture images. By the method of moving frames, we are able to inpaint or interpolate the missing T-junctions or corners inside the inpainting domain based on the elastica interpolant. We then explain the approach that leads to Masnou and Morel's algorithm on individually "engineering" isophotes (i.e., level sets) [27]. A level set-type idea [34] formally "lifts" this isophote-based model to an energy functional that acts directly on gray scale images, a process that we shall call "functionalization."

The rest of the paper is devoted to the mathematical analysis and computational implementation of elastica-based inpainting models.

In section 4, by introducing the concept of the *weak curvature* of a general BV function, we legitimize the functionalization of the elastica energy in the BV space. The direct method for elastica inpainting is generally difficult due to the lack of classical fine properties (such as convexity and lower semicontinuities [2]). But for the extreme case of TV inpainting, we are able to rigorously establish the existence theorems based on the theory of BV functions. We also discuss why the nonuniqueness of the solutions to a general inpainting model should be somehow appreciated instead of being cursed. The last part of the section discusses various relaxation schemes for the constraints of the inpainting energy.

In section 5, we derive the formal Euler–Lagrange equation for a general curvature-based inpainting model. The most interesting result is the structure of the associated flux field $\vec{V}$, which provides a formal way to unify the earlier empirical work of Bertalmio et al. [3] on transport-based inpainting, and that of Chan and Shen on CDD-based inpainting [9]. We therefore conjecture that transport and diffusion are the two universal infinitesimal mechanisms for any PDE-based inpainting schemes.

In section 6, we explain our numerical schemes for the associated nonlinear Euler–Lagrange equation and demonstrate several computational examples. The computational schemes have been inspired by various techniques in the classical literature of computational fluid dynamics.

In the last section, we conclude with a brief discussion on the connection between

the elastica inpainting model and a recent model by Ballester et al. [1] on the joint interpolation of both the normal field $\vec{n} = \nabla u/|\nabla u|$ and gray values u.

2. Euler's elastica and its Bayesian rationale. A curve Γ is said to be *Euler's elastica* if it is the equilibrium curve of the elasticity energy

$$E_2[\gamma] = \int_\gamma (a + b\kappa^2) ds, \tag{2.1}$$

where ds denotes the arc length element, $\kappa(s)$ the scalar curvature, and a, b two positive constant weights. Extra constraints may include the positions and normal directions of the two ends. Euler obtained the energy in 1744 in studying the steady shape of a thin and torsion-free rod under external forces (see [23]).

Since both the arc length and curvature are intrinsic geometric features of a curve, the elastica energy naturally extends to the curves on a general Riemannian manifold M. For example, if M is embedded in a Euclidean space R^N, a curve γ on M can be expressed by the embedded coordinates

$$s \to \vec{x}(s) = (x_1(s), \dots, x_N(s)).$$

Then $\vec{t} = d\vec{x}/ds$ is the tangent and $\prod_{\vec{x}} d\vec{t}/ds = \kappa\vec{n}$ defines the curvature, with $\prod_{\vec{x}}$ representing the orthogonal projection from $T_{\vec{x}}R^N$ to $T_{\vec{x}}M$. For a general Riemannian manifold M, the intrinsic derivative $d\vec{t}/ds$ is defined by the Levi–Civita connection or the covariant derivative (see Chern, Chen, and Lam [11], for example). Such extension onto general manifolds is motivated by inpainting problems on arbitrary surfaces in R^3, for example, the inpainting of an incomplete image on the surface of a Coke can in computer graphics.

By the calculus of variations, it can be shown that an elastica must satisfy

$$2\kappa''(s) + \kappa^3(s) = \frac{a}{b}\kappa(s).$$

For example, Mumford gives a detailed derivation in [29]. More generally, if the elastica lives on a Riemannian surface, there will be an extra term due to the curving of the surface:

$$2\kappa''(s) + \kappa^3(s) + 2G(s)\kappa(s) = \frac{a}{b}\kappa(s),$$

with $G(s)$ denoting the Gaussian curvature of the surface. More studies in elasticas on general Riemannian manifolds can be found in Langer and Singer [22].

The elastica was first seriously studied from the computer vision point of view in Mumford's paper [29], the introduction section of which provides a delightful view of its mathematical history. According to [29], the key link between the elastica and computer vision is founded on the interpolation capability of elasticas, as initially proposed by Birkhoff and De Boor [4]. Such "nonlinear splines" [4], like classical polynomial splines, are natural tools for completing the missing or occluded edges [32].

A remarkable feature of elasticas revealed by Mumford [29] is their Bayesian rationale, which enhances the interpolating role of elasticas in image and vision analysis. It also sheds light on the choice of "2" for the curvature power in the energy formula (2.1). Here we present a slightly polished version of Mumford's original argument.

Consider the random walk of a drunk initially staying at the origin of a 2-D ground. Assume that each individual step is straight. For some given fixed integer N, we try to understand the distribution of all possible N-step polygonal walks. The moving characteristics are the following:

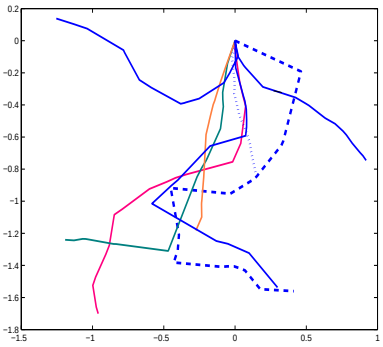

FIG. 2.1. *Some sample paths for the drunk's walking.*

(a) Let h_k denote the step size of the kth step. Then $\{h_k \ : \ k = 1, 2, \dots, N\}$ are independently and identically distributed (i.i.d) of exponential type $\lambda \exp(-\lambda h)$ for some positive mean $1/\lambda$.

(b) Let θ_k denote the orientation of the kth step, measured by the angle between the walking direction and the x-axis, and define $\theta_0 = 0$. Let $\Delta\theta_k = \theta_k - \theta_{k-1}$ $(k = 1, 2, \dots, N)$ denote the turn made at the kth step. The basic assumption is that, at each step k, the larger the step size h_k is, the more uncertain the turn $\Delta\theta_k$ will become. Precisely, $\Delta\theta_k$ is a Gaussian of $N(0, h_k\sigma^2)$. Yet

$$\left\{ n_k = \Delta\theta_k / \sqrt{h_k} \ : \ k = 1, 2, \dots, N \right\}$$

is an independent set and also independent of all the h_k's.

Thus, an N-step polygonal walk γ is completely determined by the data

$$\{h_1, \dots, h_N\} \cup \{\Delta\theta_1, \dots, \Delta\theta_N\},$$

and the likelihood is quantified by

$$\lambda^N \exp(-\lambda(h_1 + \cdots + h_N))\, dh_1 \cdots dh_N \\ \times (\sqrt{2\pi}\sigma)^{-N} \exp\left(-\frac{1}{2\sigma^2} \left[\frac{(\Delta\theta_1)^2}{h_1} + \cdots + \frac{(\Delta\theta_N)^2}{h_N} \right] \right) dn_1 \cdots dn_N.$$

Up to a multiplicative constant, this probability density function is exactly

$$\exp\left(-\lambda L(\gamma) - \frac{1}{2\sigma^2} \|\kappa^2\|_\gamma \right),$$

where L denotes the length and $\|\kappa^2\|_\gamma$ the discrete analogy of $\int_\gamma \kappa^2 ds$. Therefore, the minimization of the elastica energy (2.1), with $a = \lambda$ and $b = 1/(2\sigma^2)$, is equivalent to the maximum likelihood (ML) estimation of such random curves.

Remark 1. Notice that the walking drunk model presented here does not come from the discrete sampling of the Brownian motion, since for the latter (in 2-D), h^2 (not h) is exponential and the turn $\Delta\theta$ is uniform along the unit circle. The dependence of the turns on the step sizes makes the paths smoother than the sampling of Brownian motions, which makes the model a valuable curve model in computer vision, where regularity is important. Figure 2.1 shows a computer simulation of the paths.

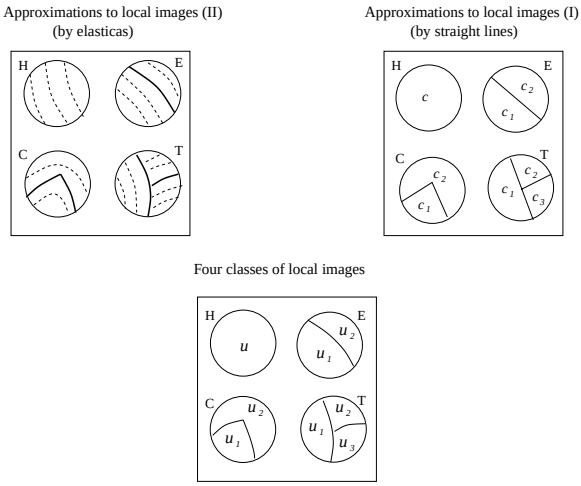

FIG. 3.1. *Local (nontexture) image models and their approximation.*

3. Local (nontexture) image models and elastica isophotes.

3.1. Generic local (nontexture) image models. To model the inpainting of nontexture images, it is important to start with local and small inpainting domains. Focusing on locality is a common practice in numerical mathematics, where from differentiation, integration, and interpolation, to optimization, most well-known numerical schemes (such as the Runge–Kutta schemes, Simpson's integration rule, and the Newton–Raphson searching strategy for zeros or valleys) are inspired by the local models of the target functions, such as the linear model, parabolic model, and so on [19, 39]. Digital inpainting, after all, is the numerical interpolation of 2-D images. Therefore, it is crucial to first understand what an image looks like locally.

Imagine that we have a *small* aperture with a circular shape of radius r, and that we focus on only the part that is captured within when it is moved over a 2-D gray image. Suppose that the image only contains man-made nontexture objects, and that their characteristic scale $l \gg r$. What sorts of local image patches will be observed most frequently?

They can be grouped into four classes, labeled by "H," "E," "C," and "T" (see Figure 3.1), as follows:

(a) Class H. A local image patch belongs to this class if and only if it falls within the *homogeneous* regions. Such a patch has very little intensity variation.

(b) Class E. This occurs when the aperture captures a fraction of the smooth *edge* between two objects or homogeneous regions.

(c) Class C. Like class E, but the aperture captures a recognizable *corner*. Corners are also a universal feature of man-made objects, from tables, windows, and books, to posters.

(d) Class T. This is the case in which the aperture captures a *T-junction*. T-junction is an important cue for occlusion and the perception of orders in the lost dimension of range [32]. A local T-junction patch is characterized by three homogeneous gray values u_1, u_2, and u_3 and two smooth edges—one meets the boundary at its two ends while the other at only one end due to occlusion.

Notice that homogeneous regions are 2-D objects, edges are 1-D objects, and both corners and T-junctions are isolated 0-D objects. Therefore, heuristically, in terms of the probability (or frequency) of being observed through a small aperture, we have the following relation:

$$\text{Prob}(H) \gg \text{Prob}(E) \gg \text{Prob}(C) \text{ or } \text{Prob}(T).$$

Of course, the probabilities do not necessarily represent their perceptual significance in terms of vision inference. In fact, it seems that often the scattered singular features can generate strong response from the vision system (e.g., the wavelets idea [13, 5, 35]).

Notice that class C is indeed very much "man-made" like its ancestors in our 3-D world, in the sense that a local engineering (or small perturbation) of the corner can easily change a class C patch to class E. In this sense class C is unstable and nongeneric.

3.2. Local edge interpolation by elasticas: Moving frames. Suppose an image u_0 has a local patch K missing, and we try to inpaint $u_0\big|_K$ based on the available information surrounding K.

By checking the available data close to K, we can easily determine which class $u_0\big|_K$ belongs to: H, E, or T. (Without a priori knowledge, one can never distinguish the nongeneric class C from the generic class E.) The existence of a corner or the exact configuration of the T-shape inside the inpainting domain will require extra information or additional models and algorithms (especially for the coupling of the three end points in the T-junction case). (For the corner case, for example, see Shah's recent work on elasticas with hinges [38].) In this paper, we shall assume that eventually we do know the exact class that $u_0\big|_K$ belongs to and the precise configurations.

The first level of approximation will be based on the *straight line* curve model (refer to the upper-right panel in Figure 3.1). For a class H type, one can average the available boundary pixel values and inpaint $u_0\big|_K$ by this mean value c. For a class E type, we connect the two edge ends by a straight segment and inpaint the two objects u_1 and u_2 by their boundary mean values c_1 and c_2. For a class C type, we make two straight shoots from the boundary end points into the inpainting domain. The orientations follow their cue left outside K. The two straight lines generate a corner and also segment the patch K into two objects u_1 and u_2. Then u_1 and u_2 are inpainted by their boundary mean values. For the last class T, we connect the two coupled boundary end points by a straight line and shoot from the third one directly toward the interior of K, as for class C. Then the three segmented objects u_1, u_2, and u_3 are inpainted by their boundary mean values c_1, c_2, and c_3.

A second level of approximation is based on the *elastica* curve model (the upper-left panel in Figure 3.1). That is, we shall interpolate the boundary end points by elasticas instead of by straight line segments. We can improve the inpainting accuracy by further approximating each individual (nonedge) isophote by an elastica for the segmented regions, instead of simply making constant approximations. Therefore, we need first to inpaint the missing edges including corners and T-junctions to reduce classes E, C, and T to class H.

Along the boundary, each end point can be represented by $(p, \vec{n})$, with p denoting its position and $\vec{n}$ the normal to the edge, which can be computed from the image available outside the inpainting domain K.

(a) For class E, to inpaint the missing smooth edge, we employ the elastica Γ that satisfies the boundary conditions $(p_1, \vec{n}_1)$ and $(p_2, \vec{n}_2)$.

(b) For class C, to inpaint the corner, we take a *moving frame* approach. The corner is represented by an affine frame $(p; \vec{n}_1', \vec{n}_2')$, with p denoting its unknown position, and $\vec{n}_1'$ and $\vec{n}_2'$ the two unknown unit normals to the smooth edges coming from the boundary end points $(p_1, \vec{n}_1)$ and $(p_2, \vec{n}_2)$. For each i, the energy (2.1) of the elastica that meets the requirement at $(p_i, \vec{n}_i)$ and $(p, \vec{n}_i')$ is denoted by

$$E_2((p_i, \vec{n}_i), (p, \vec{n}_i')).$$

Then the corner is inpainted by a joint optimization:

$$\min_{(p;\vec{n}_1',\vec{n}_2')} E_2((p_1, \vec{n}_1), (p, \vec{n}_1')) + E_2((p_2, \vec{n}_2), (p, \vec{n}_2')). \tag{3.1}$$

For example, if in the elastica energy (2.1) we choose a large ratio b/a (or $a = 0$ for the extremal case), then the solution to (3.1) shall be very close to the straight line shooting method mentioned in the first level of approximation.

(c) For class T, we first inpaint the two coupled end points by an elastica Γ (provided that we have established such coupling from other models or algorithms, as pointed out in the second paragraph). To inpaint the occluded edge from the clue of the third boundary end point $(p_3, \vec{n}_3)$, we again take the *moving frame* approach. Let $(p, \vec{n}_3')$ denote the junction position and the normal direction of the occluded edge. Then the junction inpainting is completed by solving

$$\min_{(p,\vec{n}_3')} E_2((p_3, \vec{n}_3), (p, \vec{n}_3')). \tag{3.2}$$

Here an admissible p must stay on the disoccluded edge Γ.

3.3. Local inpainting by individually engineering the isophotes. After the feature edges have all been interpolated, all four classes of local image inpainting are essentially reduced to the inpainting of class H, the homogeneous patches. In the same fashion as above, such patches can be inpainted by having the broken isophotes interpolated by elasticas *one by one* from the boundary information. This is exactly the idea underlying Masnou and Morel's dynamical programming algorithm [27].

Generically, one can assume that the missing smooth patch $u_0\big|_K$ is *regular* in the sense that it lies close to a regular point where ∇u_0 is nonzero (or by first applying a small step of Gaussian diffusion). Thus the isophotes of u_0 on K are well defined and distinguishable, and each Γ_λ is uniquely labeled by its gray level $u_0 \equiv \lambda$.

The trace of each Γ_λ on the boundary tells the coupling rule of boundary pixels. Suppose that $p_1, p_2 \in \partial K$ share the same gray level λ, and that the normals computed from the available image data outside K are $\vec{n}_1$ and $\vec{n}_2$. Then we inpaint the λ-isophote Γ_λ by an elastica Γ_λ':

$$\Gamma_\lambda' = \operatorname*{argmin}_{\gamma_\lambda \vdash ((p_1,\vec{n}_1),(p_2,\vec{n}_2))} \int_{\gamma_\lambda} (a + b\kappa^2) ds = \operatorname*{argmin}_{\gamma_\lambda \vdash ((p_1,\vec{n}_1),(p_2,\vec{n}_2))} E_2[\gamma_\lambda], \tag{3.3}$$

where $\vdash$ means subject to the boundary conditions: γ_λ goes through p_1 and p_2, and $\dot{\gamma}_\lambda \perp \vec{n}_i$ at the two ends. Notice that generally Γ_λ' does exist but may not be unique (see [22, 29]).

As λ varies according to the available boundary data u_0, (3.3) gives a family of (and theoretically infinitely many) elasticas. On the other hand, if we denote this

bundle of elasticas by

$$\mathcal{F}' = \{\Gamma'_\lambda \ : \ 0 \le \lambda \le 1\},$$

then it is easy to see that $\mathcal{F}'$ is also the minimizer of the following energy for all boundary admissible curve bundles $\mathcal{F} = \{\gamma_\lambda \ : \ 0 \le \gamma \le 1\}$:

$$E[\mathcal{F}] = \int_0^1 E_2[\gamma_\lambda]\, d\lambda \tag{3.4}$$

or, more generally,

$$E_w[\mathcal{F}] = \int_0^1 w(\lambda) E_2[\gamma_\lambda]\, d\lambda, \tag{3.5}$$

with some positive weight function $w(\lambda)$ (whose influence in application will be explained later). However, due to the lack of communication among the elasticas, there exist two potential problems:

(1) two different elastica interpolants Γ'_λ and Γ'_μ with $\lambda \neq \mu$ can meet inside the inpainting domain K, while the original isophotes never met;
(2) even putting problem (1) on hold, generally, it is not guaranteed that the elastica bundle

$$\mathcal{F}' = \{\Gamma'_\lambda \ : \ 0 \le \lambda \le 1\}$$

does "weave" the entire inpainting domain K and leave no "holes." Thus, the inpainting can still be incomplete.

These issues have been taken care in Masnou and Morel's algorithm [27]. Here we propose to resolve these issues by working with the level-set function u_K. (A similar philosophy has now made the *level-set method* of Osher and Sethian [34] a great success in the numerical computation of various interface motion problems.) An admissible curve bundle $\mathcal{F} = \{\gamma_\lambda\}_\lambda$, which not only satisfies the boundary conditions but also avoids the two problems, is uniquely and fully characterized by an inpainting function u_K that is "tangent" to u_0 along ∂K. Conversely, working with u_K instead of the individual isophotes automatically resolves these problems. Thus, first we need to translate the elasticity energies (3.4) or (3.5) into ones that are directly applicable to the inpainting function u_K.

4. The elastica inpainting model.

4.1. The functionalized elastica energy. Let $u = u_K$ be an admissible inpainting, assumed to be smooth enough so that all the conventional differentiations make sense in the following computation. Along any isophote $\gamma_\lambda : u \equiv \lambda$, the curvature of the oriented curve is given by

$$\kappa = \nabla \cdot \vec{n} = \nabla \cdot \left(\frac{\nabla u}{|\nabla u|} \right).$$

On the other hand, let dt denote the length element along the normal direction $\vec{n}$ (or along the steepest ascent integral curve). Then

$$\frac{d\lambda}{dt} = |\nabla u| \qquad \text{or} \qquad d\lambda = |\nabla u|\, dt.$$

Therefore, the integrated elastica energy (3.5) now passes on to u by

$$J[u] = E_w[\mathcal{F}] \tag{4.1}$$

$$= \int_0^1 w(\lambda) \int_{\gamma_\lambda : u=\lambda} (a + b\kappa^2) ds \, d\lambda \tag{4.2}$$

$$= \int_1^0 \int_{\gamma_\lambda : u=\lambda} w(u) \left(a + b \left(\nabla \cdot \frac{\nabla u}{|\nabla u|} \right)^2 \right) |\nabla u| dt \, ds \tag{4.3}$$

$$= \int_K w(u) \left(a + b \left(\nabla \cdot \frac{\nabla u}{|\nabla u|} \right)^2 \right) |\nabla u| \, dx, \tag{4.4}$$

since dt and ds represent a couple of orthogonal length elements. Now the energy is completely expressed in terms of the inpainting u itself. Notice that this formal derivation is much like the coarea formula for BV functions [18].

The weight function $w(\lambda)$ can be set to 1. In applications, it can be defined based on the histogram $h(\lambda)$ of the given image. ($h(\lambda)$ denotes the frequency of pixels with gray value λ.) The histogram of an image typically contains several "humps," each of which corresponds to an object. Since human observers are very sensitive to the regularity of object boundaries, we may assign a high weight to the pixels whose gray values are typically near the "valleys" of the histogram. Therefore we may choose the weight function in the form of

$$w(\lambda) = W(1 - h(\lambda)),$$

with $W(h)$ denoting a suitable positive and increasing function.

4.2. Admissible inpainting and the weak form of curvature. From now on, let us consider the functionalized Euler's elastica energy

$$J_2[u] = \int_K \left(a + b \left(\nabla \cdot \frac{\nabla u}{|\nabla u|} \right)^2 \right) |\nabla u| \, dx, \tag{4.5}$$

with the conditions that

$$u\big|_{\Omega \setminus K} = u_0\big|_{\Omega \setminus K}, \qquad \int_{\partial K} |Du| = 0, \qquad \text{and } |\kappa(p)| < \infty \quad \text{a.e. along } \partial K, \tag{4.6}$$

where a.e. is in the sense of 1-D Hausdorff measure.

We have assumed that the original complete image u_0 (typically on a square domain Ω) belongs to BV(Ω) and has the property that

$$\int_{\partial K} |Du_0| = 0 \tag{4.7}$$

in the sense of the Radon measure $\int |Du_0|$. Under such an assumption, the second boundary condition on u follows naturally. This condition can be made more explicit by the *trace* of BV functions [18]. Let u^- and u^+ denote the interior and exterior traces of u along ∂K with respect to K. Then we have

$$\int_{\partial K} |Du| = \int_{\partial K} |u^+ - u^-| \, d\mathcal{H}_1.$$

Thus the second condition is equivalent to the continuity condition

$$u^- = u^+ = u_0^+ \qquad \text{a.e. along } \partial K \text{ by } d\mathcal{H}_1.$$

We shall call assumption (4.7) on the original complete image the *feasibility condition* for low-level inpainting models, which do not employ global feature recognition or learning. It requires that there be no *essential* overlap between the boundary of the inpainting domain K and the edges of 2-D objects in the image. Imagine, in contrast, the opposite situation, in which an object is completely missing along its boundary. Then no existing image information can possibly bring it back in the absence of high-level intelligence (such as face recognition and symmetry detection). A low-level inpainting model, after all, is expected to interpolate incomplete objects based only on the hints they leave on the exterior of the inpainting domain.

Finally, the last condition in (4.6) demands finite curvatures along the inpainting boundary. Therefore a sudden turn of isophotes is not permitted along ∂K, and the condition is therefore a first-order continuity constraint.

Although the concept of "curvature" for a BV function has been used for both the elastica energy and the boundary conditions, its meaning has very much stayed at a formal level, since an average BV function lacks the necessary regularity for discussing curvatures in the conventional sense.

Therefore we introduce the concept of *weak curvature*, which may not be the only possible generalization but seems to be general enough to serve image analysis.

Suppose $u \in \mathrm{BV}(K)$. Then $|Du|(\cdot) = \int_\cdot |Du|$ is a finite Radon measure on K, and for any open subset $Q \subset K$,

$$\int_Q |Du| = \sup_{\mathbf{g} \in C_0^1(Q, B_1)} \int_Q u \, \nabla \cdot \mathbf{g} \, dx,$$

where B_1 denotes the unit ball centered at the origin in R^2. Let $\mathrm{supp}(|Du|)$ denote the support of the TV measure. Then for any $p \in \mathrm{supp}(|Du|)$ and any of its open neighborhoods N_p,

$$|Du|(N_p) = \int_{N_p} |Du| > 0.$$

Let ρ be a fixed radially symmetric nonnegative mollifier with compact support and unit total integral, and set (for 2-D)

$$\rho_\sigma = \frac{1}{\sigma^2} \rho\left(\frac{x}{\sigma}\right) \qquad \text{and} \qquad u_\sigma = \rho_\sigma * u.$$

Then we define the *weak absolute curvature* $\tilde{\kappa}(p)$ of u at p by

$$\tilde{\kappa}(p) = \limsup_{\sigma \to 0} \left| \nabla \cdot \left(\frac{\nabla u_\sigma}{|\nabla u_\sigma|} \right)(p) \right|, \tag{4.8}$$

where for those σ's that give $|\nabla u_\sigma(p)| = 0$ we define $\nabla \cdot (\nabla u_\sigma / |\nabla u_\sigma|)$ to be ∞. Finally, for any pixel p outside $\mathrm{supp}(|Du|)$, we assign 0 to $\tilde{\kappa}(p)$, since u is a.e. constant near a neighborhood of p. Thus the weak absolute curvature is well defined everywhere for an arbitrary BV function.

There are two important situations in image analysis in which the weak curvature is indeed the ordinary curve curvature for $p \in \mathrm{supp}(|Du|)$. The first situation is presented as follows.

PROPOSITION 4.1. *Suppose that $u \in C^2(K)$ and that $p \in K$ is a regular pixel: $\nabla u(p) \neq \mathbf{0}$. Then $\tilde{\kappa}(p) = |\kappa(p)|$.*

Proof. Assume that the mollifier is supported on the unit ball B_1. From the definition of convolution

$$u_\sigma(q) = \rho_\sigma * u(q) = \int_{B_1} \rho(y) u(q + \sigma y)\, dy,$$

it is easy to see that there is a small neighborhood N_p and some positive number a so that $u_\sigma(q)$ is C^2 over $(\sigma, q) \in (-a, a) \times N_p$. Since ∇u is continuous and nonvanishing at p, we can further refine N_p and a so that all $\nabla u(q + \sigma y)$ (with $(\sigma, q, y) \in (-a, a) \times N_p \times B_1$) are concentrated enough around $\nabla u(p)$. Then, thanks to the averaging property of the mollifier, all $\nabla u_\sigma(q) = (\nabla u)_\sigma(q)$ are nonvanishing, which makes

$$\vec{n}_\sigma(q) = \frac{\nabla u_\sigma(q)}{|\nabla u_\sigma(q)|}$$

C^1 on $(-a, a) \times N_p$. Then $\kappa_\sigma(q) = \nabla \cdot \vec{n}_\sigma(q)$ is well defined on N_p and continuous in σ, especially at p:

$$|\kappa(p)| = \lim_{\sigma \to 0} |\kappa_\sigma(p)| = \tilde{\kappa}(p). \qquad \square$$

The second case occurs when p lies on an intensity edge between two objects.

PROPOSITION 4.2. *Suppose an oriented curve segment γ is a C^2 submanifold in K. Assume that near a given pixel $p \in \gamma$, on one side of γ, $u = c^+$, and on the other, $u = c^-$, two constant gray values. Then $\tilde{\kappa}(p) = |\kappa(p)|$.*

Proof. Since curvature is a second-order local feature, we can replace γ near p by the curvature circle with radius $r = 1/|\kappa(p)|$ and centered at $q = p - r\vec{n}$, where $\vec{n}$ is one of the unit normal vectors at p. Then both the data (c^+, c^-) and the geometry γ are locally rotationally invariant (with respect to the center) in a neighborhood of p. Since the mollifier ρ is radially symmetric and compactly supported, as long as σ is small enough, $u_\sigma = \rho_\sigma * u$ must also be locally rotationally invariant with respect to the center, which means that locally near p, γ is also an isophote of u_σ. Thus under the same orientation of γ, $\kappa_{\sigma \to 0}(p) = \kappa(p)$ and $\tilde{\kappa}(p) = \lim_\sigma |\kappa_\sigma(p)| = |\kappa(p)|$. This completes the proof. $\square$

One useful property of $\tilde{\kappa}$ which can be proven easily is its invariance under the linear scaling of gray values. Let $\tilde{\kappa}_f(p)$ denote the weak curvature of a function f at p.

PROPOSITION 4.3. *Let $u \in BV(K)$ and $v = a + bu$ for some constants a and $b \neq 0$. Then for any $p \in K$, $\tilde{\kappa}_u(p) = \tilde{\kappa}_v(p)$.*

With the help of the concept of weak curvature, the functionalized elastica energy (4.5) can be rigorously defined. A function $u \in \mathrm{BV}(K)$ is said to be *admissible* if

$$\tilde{\kappa} \in L^2(K, |Du|).$$

For all such functions, the generalized elastica energy

$$J_2[u] = \int_K (a + b\tilde{\kappa}^2) |Du| \tag{4.9}$$

is well defined and finite. Together with the boundary conditions (4.6), it defines the so-called *elastica inpainting model*.

The elastica inpainting model is difficult to analyze in terms of existence and uniqueness, due to the nonconvexity of the energy and the involvement of curvature. However, there is indeed a special, simple, yet very useful case for which one can carry out the analysis successfully. This is the TV inpainting model first proposed and implemented in Chan and Shen [8]. In the next subsection, we study the existence and uniqueness of this special case.

4.3. The TV inpainting model of Chan and Shen. The TV inpainting model of Chan and Shen [8] is an extreme case of elastica inpainting in which we weigh highly against the total variation, i.e., $a/b = \infty$. Thus one is led to the minimization of

$$\mathrm{TV}(u) = \int_\Omega |Du|. \tag{4.10}$$

As in the study of minimal surfaces (De Giorgi [17]), the suitable companion condition becomes

$$u\big|_{\Omega\setminus K} = u_0\big|_{\Omega\setminus K}, \tag{4.11}$$

where Ω denotes the entire image domain, generally assumed to be a bounded Lipschitz domain. As in the study of minimal surfaces, Ω can be replaced by any open neighborhood of $\bar{K}$ (see [8]). We call the combination of (4.10) and (4.11) the *noise-free TV inpainting model*.

THEOREM 4.4 (existence of a noise-free TV inpainting). *Suppose that the original complete image u_0 lies in $BV(\Omega)$ and takes gray values between 0 (black) and 1 (white). Then the noise-free TV inpainting model* (4.10) *and* (4.11), *together with the gray value constraint $u \in [0,1]$, has at least one optimal inpainting.*

Proof. Since the original complete image u_0 is admissible, we can find a minimizing sequence of admissible inpaintings $(u_n)_n$. Then both

$$\int_\Omega |Du_n| \qquad \text{and} \qquad \int_\Omega |u_n(x)|dx$$

are bounded because Ω is, and all u_n's take values from $[0,1]$. By the weak compactness of BV functions, there is a subsequence, still denoted by $(u_n)_n$ for convenience, that strongly converges to some $u_{\mathrm{tv}} \in L^1(\Omega)$ in the L^1 norm. Apparently u_{tv} still meets the constraints

$$u_{\mathrm{tv}}\big|_{\Omega\setminus K} = u_0\big|_{\Omega\setminus K} \qquad \text{and} \qquad u_{\mathrm{tv}}(x) \in [0,1].$$

By the lower semicontinuity of the TV measure with respect to the L^1 convergence,

$$\int_\Omega |Du_{\mathrm{tv}}| \le \liminf_{n\to\infty} \int_\Omega |Du_n| = \min_u \int_\Omega |Du|.$$

Thus u_{tv} must be a minimizer. ∎

Another important issue for inpainting is how to deal with noise, since in applications (such as the restoration of degraded photos or films), the available part of the image $u_0\big|_{\Omega\setminus K}$ is often noisy or contains misleading outliers (especially along the damaged boundary of K). Chan and Shen [8] therefore modified the above TV inpainting model by having the constraint (4.11) replaced by the denoising term

$$\frac{1}{\mathrm{Area}(\Omega\setminus K)} \int_{\Omega\setminus K} (u-u_0)^2 dx = \sigma^2, \tag{4.12}$$

where σ^2 is the variance of the homogeneous white noise, which can be estimated from $u_0\big|_{\Omega\setminus K}$ by suitable statistical estimators. By such a constraint, we are assuming that embedded within u_0 is a clean image u_c such that

$$u_0(x) = u_c(x) + n(x),$$

where the white noise $n(x)$ is independent of u_c. Since we pay attention only to its second-order statistics, implicitly we are assuming that $n(x)$ can be well approximated by the Gaussian $N(0, \sigma^2)$.

THEOREM 4.5 (existence of a TV inpainting for a noisy image). *Given an image observation $u_0 : u_0(x) \in [0,1]$ on $\Omega \setminus K$, assume that there exists at least one image $u_c : u_c(x) \in [0,1]$ in $BV(\Omega)$ that meets the denoising constraint* (4.12). *Then there exists at least one optimal TV inpainting in $BV(\Omega)$ that satisfies both the denoising requirement* (4.12) *and the gray scale constraint $u \in [0,1]$.*

Proof. From the assumption on u_c, there exists a minimizing sequence of admissible inpainting $(u_n)_n$ that meets both the denoising constraint and the gray scale constraint. Thanks to the gray scale constraint, $(u_n)_n$ must be bounded in $\mathrm{BV}(\Omega)$. Thus there is subsequence, still denoted by $(u_n)_n$ for convenience, which converges in the L^1 norm to some $u_{\mathrm{tv}} \in L^1(\Omega)$. Then by the lower semicontinuity property [18],

$$\int_\Omega |Du_{\mathrm{tv}}| \le \liminf_{n\to\infty} \int_\Omega |Du_n| = \min_u \int_\Omega |Du|.$$

We can further refine the subsequence so that

$$u_n \to u_{\mathrm{tv}} \qquad \text{a.e. on } \Omega.$$

Thus u_{tv} also meets the gray scale constraint $u_{\mathrm{tv}} \in [0,1]$, and more importantly, by the Lebesgue dominated convergence theorem,

$$\int_{\Omega\setminus K} (u_{\mathrm{tv}} - u_0)^2 dx = \lim_n \int_{\Omega\setminus K} (u_n - u_0)^2 dx.$$

Therefore, u_{tv} is indeed an optimal TV inpainting, subject to the two constraints imposed. ∎

Remark 2. If we drop the assumption that $u_0 \in [0,1]$, and thus remove the gray scale constraint on u, then under the natural assumption (see [7]) that

$$\sigma^2 \le \frac{1}{\mathrm{area}(\Omega \setminus K)} \int_{\Omega\setminus K} (u_0 - \langle u_0 \rangle)^2 dx < \infty,$$

one can still establish the existence theorem by applying Friedrich's trace inequality [24] and Fatou's lemma. (Here $\langle u_0 \rangle$ is the mean value of u_0 over the integration domain.)

The solutions to both TV and elastica inpaintings can be nonunique. In our opinion, such nonuniqueness of the models should not be cursed but appreciated, since it is an important characteristic of the inpainting problem itself. Take, for example, the image in Figure 4.1, whose middle square patch has been encrypted by a random image. We now try to inpaint the square to restore the original complete image.

It seems that we have a black ($u = 0$) bar and a white ($u = 1$) one against a gray background ($u = 1/2$). A perceptually meaningful inpainting would be to fill in either

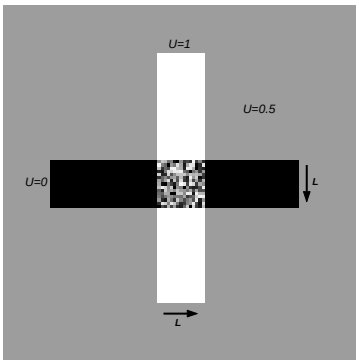

FIG. 4.1. *Nonuniqueness: which is to blame, the model or the problem itself?*

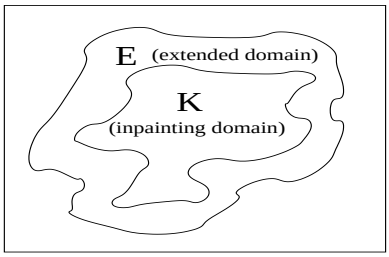

FIG. 4.2. *Inpainting Domain K.*

the black color so that the image shows a black bar occludes a farther white bar, or the white color for the opposite occlusion. Which one is more likely? The available part of the image (both the geometry and colors) is perfectly symmetric. Thus it appears as a half-half situation to human perception. In our opinion, such perceptual uncertainty is the foundation of the nonuniqueness of inpainting models. In terms of the Bayesian decision theory in vision analysis, nonuniqueness corresponds to the situation in which the risk or cost function has many similar valleys which compete with each other.

Fortunately, in many real applications, as Chan and Shen demonstrated in [8, 9], the outputs from the TV inpainting model do always seem to be meaningful to human vision. This is because, in most applications, the location, shape, and size of inpainting domains are often randomly distributed.

4.4. Relaxation of the constraints. As we have seen, the original formulation of the elastica inpainting model (4.5) and (4.6) has mainly been inspired by the image processing point of view. But it is unclear whether the formulation is mathematically feasible. In fact, as well practiced in the theory of BV functions and minimal surfaces [18], it is often more manageable to formulate the problem on a larger domain than the original one. The TV inpainting model for noisy images mentioned above has imparted this idea. The same can be done for general elastica inpaintings.

Let E be a subset contained in $\Omega \setminus K$ such that $E \cup K$ is open and contains the closure of K (see Figure 4.2). For example, depending on the situation, one could

simply take $E = \Omega \setminus K$. Suppose for the original image u_0,

$$J_2[u_0] = \int_{E\cup K} (a + b\tilde{\kappa}^2)\ |Du_0|$$

is finite. We inpaint $u_0\big|_K$ by the minimizer of

$$J_2[u] = \int_{E\cup K} (a + b\tilde{\kappa}^2)\ |Du|, \tag{4.13}$$

with the condition that

$$u\big|_E = u_0\big|_E. \tag{4.14}$$

In this way, the two other original boundary conditions in (4.6) are approximately built into the energy itself.

If the available part of the image in the vicinity of K has been corrupted by homogeneous white noise with variance σ^2, then the condition (4.14) is further replaced by the fitting constraint

$$\frac{1}{\text{area}(E)} \int_E |u - u_0|^2\ dx = \sigma^2. \tag{4.15}$$

PROPOSITION 4.6. *Let $u \in BV(E \cup K)$ be a minimizer of the elastica inpainting* (4.13) *and* (4.15). *Then u automatically satisfies the mean value constraint*

$$\langle u \rangle = \langle u_0 \rangle,$$

where $\langle f \rangle$ denotes the mean value of f over E.

Proof. The technique is similar to that used by Chambolle and Lions [7]. Assume the contrary: $\langle u \rangle \neq \langle u_0 \rangle$. Define $v = u - \langle u - u_0 \rangle$. Then

$$\int_E |v - u_0|^2 dx = \int_E |u - u_0 - \langle u - u_0 \rangle|^2 dx < \int_E |u - u_0|^2 dx = \sigma^2\ \text{area}(E),$$

where the strict inequality is due to the fact that, among all constants, the mean is the best L^2 fitting to a given signal. On the other hand, by the natural assumption of u_0 on E in Remark 2 of section 4.3,

$$\int_E |\langle v \rangle - u_0|^2 dx = \int_E |\langle u_0 \rangle - u_0|^2 dx \geq \sigma^2\ \text{area}(E).$$

Therefore, there must exist some $s \in [0, 1)$ such that

$$\int_E |sv + (1 - s)\langle v \rangle - u_0|^2 dx = \sigma^2\ \text{area}(E).$$

Define $w = sv + (1 - s)\langle v \rangle$. By the invariant property of the weak curvature in Proposition 4.3, we have

$$J_2[w] = \int_{E\cup K} (a + b\tilde{\kappa}^2)|Dw| = s \int_{E\cup K} (a + b\tilde{\kappa}^2)|Du| < \int_{E\cup K} (a + b\tilde{\kappa}^2)|Du| = J_2[u],$$

where the strict inequality is because u cannot be a constant (otherwise the constant must be $\langle u_0 \rangle$ due to the fitting constraint, which is impossible since the whole

argument starts with $\langle u \rangle \neq \langle u_0 \rangle$). This eventually contradicts the fact that u is a minimizer. ∎

Finally, even the fitting constraint (4.15) can be built into the energy functional by minimizing

$$J_2^\lambda[u] = \int_{E \cup K} (a + b\tilde{\kappa}^2)|Du| + \frac{\lambda}{2} \int_E (u - u_0)^2 dx. \tag{4.16}$$

It can also easily be shown that a minimizer of $J_2^\lambda[u]$ automatically satisfies the mean value constraint.

The last formulation bears a formal Bayesian interpretation as Mumford did for various segmentation models [30]. From the probability point of view, the conditional probability

$$P(u_0|u) = \text{const.} \exp\left(-\frac{\lambda}{2} \int_E (u - u_0)^2 dx\right)$$

is the *generative data model*, and the probability

$$P(u) = \text{const.} \exp(-J_2[u])$$

is the *prior model*. Together, the minimization of $J_2^\lambda[u]$ corresponds to the method of MAP, or *maximum a posteriori probability*, in the theory of statistical inference and decision making.

4.5. Local analysis near a generic stationary point: The effect of the curvature power p and $p = 3$. Generally, for any $p \geq 1$, one could consider the p-elastica energy

$$J_p[u] = \int_\Omega (a + b|\kappa|^p)|Du|,$$

and, if necessary, $|\kappa|$ is replaced by the weak absolute curvature $\tilde{\kappa}$. This general form of elasticity energy was also mentioned in Masnou and Morel [27]. So the question arises naturally: is there any essential difference among all the different choices of p's? We claim that, indeed, in some sense $p = 3$ is the threshold.

THEOREM 4.7. *Suppose that u is C^2 near a* generic *stationary pixel z, i.e.,*

$$\nabla u(z) = 0 \quad \textit{but the Hessian } H_u(z) \textit{ is nonsingular.}$$

Then for all $p \geq 3$, $J_p[u] = \infty$.

Therefore, generic stationary points are forbidden by the p-elasticity energy when $p \geq 3$.

Proof. Without loss of generality, assume that $z = (0, 0)$ and $u(z) = 0$. Since curvature is a second-order feature, we can assume that u coincides with its second-order Taylor expansion at z:

$$u(x) = u(x_1, x_2) = (x_1, x_2) A (x_1, x_2)^T,$$

where A is the nonsingular Hessian $H_u(z)$. Thus A must be either elliptic or hyperbolic. Take the elliptic case, for example. Since both $|\nabla u|$ and κ are invariant under Euclidean transforms, we can assume that

$$A = \text{diag}(\sigma_1^2, \sigma_2^2),$$

with $\sigma_1 \geq \sigma_2 > 0$. First we consider the case in which $\sigma_1 = \sigma_2$. For convenience, we can assume that $\sigma_1 = 1$. Then $u = r^2 = x_1^2 + x_2^2$, and by section 4.1,

$$\begin{aligned}\int_{B_1} \kappa^p |\nabla u| dx &= \int_0^1 d\lambda \left(\int_{u=\lambda} \kappa^p ds \right) \\ &= \int_0^1 2r dr \left(2\pi r \left(\frac{1}{r} \right)^p \right) \\ &= 4\pi \int_0^1 \left(\frac{1}{r} \right)^{p-2} dr.\end{aligned}$$

Here, for convenience, we have assumed that the C^2 neighborhood encloses B_1. Thus J_p on B_1 is finite if and only if $p < 3$, and as a result, when $p \geq 3$, J_p on Ω must blow up. The general case follows easily from the fact that along any ellipse isophote

$$\sigma_1^2 x_1^2 + \sigma_2^2 x_2^2 = \lambda = r^2,$$

the curvature is bounded by

$$\frac{\sigma_1}{r} \geq \kappa \geq \frac{\sigma_2}{r}.$$

This completes the proof. □

The $p = 3$ threshold has also appeared in the theoretical work by Bellettini, Dal Maso, and Paolini [2] on boundary elastica energies. It is quite controversial whether we should really encourage generic stationary points for general image interpolation problems. On the one hand, if the p-elastica energy is also imposed outside the inpainting domain K for denoising purposes (as in (4.16) below), then generic stationary pixels should be allowed, and consequently $p < 3$ is required. On the other hand, existing interpolation mechanisms have seemed to generally discourage the emergence of local minima or maxima over the missing domain K. For example, the axiomatic interpolation approach of Caselles, Morel, and Sbert [6] has emphasized the constant gradient condition (i.e., $|\nabla u| = \text{const.}$) along any normal integral line, while the harmonic inpainting model discussed in Chan and Shen [8] is also generically against the existence of a local minimum or maximum, due to the maximum principle of harmonic functions. This issue needs more study.

5. The Euler–Lagrange equation. For the general elastica inpainting model (4.13) or (4.16), the direct method is difficult due to the involvement of the geometric quantity, curvature, which has no linear structure. That is, one cannot say much about the curvature κ_{u+v} of the summation $u + v$, even when precise information on κ_u and κ_v is available. Such an obstacle invalidates the classical linear approach based on Sobolev spaces or the BV space. For example, it is unclear how to prove that the minimizer to (4.16) actually exists.

In this situation, as is well practiced in the PDE method in image processing, one is led to the study of the formal Euler–Lagrange equation. Often the PDEs can handle geometry more explicitly than the variational formulation itself, as in the case of *mean curvature motions* [28].

In this section, we first derive the formal Euler–Lagrange equation for the fitted elastica inpainting model (4.16). We then show that the geometric meaning of the equation unifies the early method of Bertalmio, et al. [3] based on transport PDEs, and that of Chan and Shen [9] based on CDD. We conjecture that transport and CDD are the two universal mechanisms for any low-level nontexture inpainting.

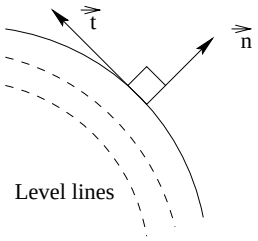

FIG. 5.1. *The normal* $\vec{n} = \nabla u/|\nabla u|$ *and the tangent* $\vec{t}$.

5.1. Derivation of the Euler–Lagrange equation. In the formal derivation, we shall always assume that the image is smooth enough and that the curvature is well defined.

THEOREM 5.1. *Let* $\phi \in C^1(R, (0,\infty))$ *be given and*

$$R[u] = \int_{E\cup K} \phi(\kappa)|\nabla u|\, dx.$$

Then the gradient descent time marching is given by

$$\frac{\partial u(x,t)}{\partial t} = \nabla \cdot \vec{V}(x,t), \qquad x \in E \cup K, \quad t > 0,$$

with the boundary conditions along $\partial(E \cup K)$

$$\frac{\partial u}{\partial \vec{\nu}} = 0 \qquad \textit{and} \qquad \frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial \vec{\nu}} = 0 \tag{5.1}$$

($\vec{\nu}$ *denotes the outer normal of the boundary). The flux field* $\vec{V}$ *is given by*

$$\vec{V} = \phi(\kappa)\, \vec{n} - \frac{\vec{t}}{|\nabla u|} \frac{\partial\, (\phi'(\kappa)|\nabla u|)}{\partial \vec{t}}. \tag{5.2}$$

Here $\vec{n}$ *is the ascending normal field* $\nabla u/|\nabla u|$, *and* $\vec{t}$ *the tangent field (whose exact orientation does not matter due to the parity of* $\vec{t}$ *in the expression) (see Figure* 5.1*).*

Proof. For later convenience, we write $\langle f\rangle = \int_{E\cup K} f dx$, and the boundary integral $\langle f\rangle_\partial = \int_{\partial(E\cup K)} f ds$, with ds denoting the Euclidean arc-length element. Then the variation of $R \to R + \delta R$ is by

$$\begin{aligned}
\delta R &= \langle \delta(\phi(\kappa)|\nabla u|)\rangle \\
&= \langle \phi(\kappa)\ \delta|\nabla u|\rangle + \langle |\nabla u|\ \delta\phi(\kappa)\rangle \\
&= \left\langle \phi(\kappa)\frac{\nabla u}{|\nabla u|}\cdot \delta\nabla u \right\rangle + \langle \phi'(\kappa)|\nabla u|\ \delta\kappa\rangle \\
&= -\langle \nabla\cdot(\phi(\kappa)\vec{n})\ \delta u\rangle + \langle \phi'(\kappa)|\nabla u|\ \delta\kappa\rangle.
\end{aligned}$$

Here in the last line, in order to justify the drop of the boundary integral from the divergence theorem (or integration by parts)

$$\left\langle \frac{\phi(\kappa)}{|\nabla u|}\frac{\partial u}{\partial \vec{\nu}}\ \delta u \right\rangle_\partial,$$

we impose the first boundary condition by noticing that $\phi(\kappa) > 0$:

$$\frac{\partial u}{\partial \vec{\nu}} = 0 \qquad \text{along} \quad \partial(E \cup K). \tag{5.3}$$

Next, we need to work out the variation of the curvature:

$$\begin{aligned}
\delta\kappa = \delta\left(\nabla \cdot \frac{\nabla u}{|\nabla u|}\right) &= \nabla \cdot \left[\frac{1}{|\nabla u|}\,\nabla(\delta u) + \nabla u\;\delta\left(\frac{1}{|\nabla u|}\right)\right] \\
&= \nabla \cdot \left[\frac{1}{|\nabla u|}\nabla(\delta u) - \frac{\nabla u}{|\nabla u|^3}\,(\nabla u \cdot \nabla(\delta u))\right] \\
&= \nabla \cdot \left[\frac{1}{|\nabla u|}\{I - \vec{n} \otimes \vec{n}\}\nabla(\delta u)\right].
\end{aligned}$$

Here I denotes the identity transform, and $P = \vec{n} \otimes \vec{n}$ the orthogonal projection onto the normal direction. Noticing that $I = \vec{n} \otimes \vec{n} + \vec{t} \otimes \vec{t}$, we have

$$\begin{aligned}
\langle \phi'(\kappa)|\nabla u|\;\delta\kappa\rangle &= \left\langle \phi'(\kappa)|\nabla u|\;\nabla \cdot \left[\frac{1}{|\nabla u|}\{\vec{t} \otimes \vec{t}\}\nabla(\delta u)\right]\right\rangle \\
&= \left\langle -\nabla(\phi'(\kappa)|\nabla u|) \cdot \left[\frac{1}{|\nabla u|}\{\vec{t} \otimes \vec{t}\}\nabla(\delta u)\right]\right\rangle.
\end{aligned}$$

We have dropped the boundary integral after applying the divergence theorem:

$$\left\langle \phi'(\kappa)\;\vec{\nu} \cdot \{\vec{t} \otimes \vec{t}\}\nabla(\delta u)\right\rangle_{\partial}.$$

This is well justified under the Neumann boundary condition (5.3) because, from (5.3), $\vec{\nu} \cdot \nabla u = 0$, or equivalently, $\vec{\nu} = \pm\vec{t}$, along $\partial(E \cup K)$. Therefore,

$$\begin{aligned}
\left\langle \phi'(\kappa)\;\vec{\nu} \cdot \{\vec{t} \otimes \vec{t}\}\nabla(\delta u)\;\right\rangle_{\partial} &= \langle \phi'(\kappa)\;\vec{\nu} \cdot \{\vec{\nu} \otimes \vec{\nu}\}\nabla(\delta u)\;\rangle_{\partial} \\
&= \langle \phi'(\kappa)\;\vec{\nu} \cdot \nabla(\delta u)\;\rangle_{\partial} \\
&= \left\langle \phi'(\kappa)\frac{\partial(\delta u)}{\partial \vec{\nu}}\right\rangle_{\partial} = \left\langle \phi'(\kappa)\delta\left(\frac{\partial u}{\partial \vec{\nu}}\right)\right\rangle_{\partial} \\
&= \langle \phi'(\kappa)\;\delta(0)\;\rangle_{\partial} = 0.
\end{aligned}$$

Let us now come back to the calculus of variation. Noticing that $\vec{t} \otimes \vec{t}$ is symmetric, we have

$$\begin{aligned}
\langle \phi'(\kappa)|\nabla u|\delta\kappa\rangle &= \left\langle -\{\vec{t} \otimes \vec{t}\}\left[\frac{1}{|\nabla u|}\nabla(\phi'(\kappa)|\nabla u|)\right] \cdot \nabla(\delta u)\right\rangle \\
&= \left\langle \nabla \cdot \{\vec{t} \otimes \vec{t}\}\left[\frac{1}{|\nabla u|}\nabla(\phi'(\kappa)|\nabla u|)\right]\;\delta u\right\rangle.
\end{aligned}$$

Here, to justify the drop of the boundary integral

$$\left\langle -\vec{\nu} \cdot \{\vec{t} \otimes \vec{t}\}\left[\frac{1}{|\nabla u|}\nabla(\phi'(\kappa)|\nabla u|)\right]\;\delta u\right\rangle_{\partial},$$

we require that, along $\partial(E \cup K)$,

$$\vec{\nu} \cdot \{\vec{t} \otimes \vec{t}\}\left[\frac{1}{|\nabla u|}\nabla(\phi'(\kappa)|\nabla u|)\right] = 0.$$

Since $\vec{\nu} = \pm\vec{t}$ along $\partial(E \cup K)$, we get the second boundary condition:

$$\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial\vec{\nu}} = \vec{\nu}\cdot\nabla(\phi'(\kappa)|\nabla u|) = 0 \qquad \text{along} \quad \partial(E\cup K). \tag{5.4}$$

Eventually, under the boundary conditions (5.3) and (5.4), we have

$$\begin{aligned}\delta R &= \left\langle -\delta u\ \nabla\cdot\left[\phi(\kappa)\ \vec{n} - \frac{1}{|\nabla u|}\{\vec{t}\otimes\vec{t}\}\nabla(\phi'(\kappa)|\nabla u|)\right]\ \right\rangle \\ &= \left\langle -\delta u\ \nabla\cdot\left[\phi(\kappa)\ \vec{n} - \frac{1}{|\nabla u|}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial\vec{t}}\ \vec{t}\right]\ \right\rangle \\ &= \langle -\delta u\ \nabla\cdot\vec{V}\rangle.\end{aligned}$$

This completes the proof. □

Therefore, the gradient of $R[u]$ is in the divergence form. The vector field $\vec{V}$ shall be called the *flux field* in this paper. The theorem shows that the flux field has a natural decomposition in the normal and tangent fields. Moreover, it is *morphologically* invariant.

PROPOSITION 5.2. *The flux field $\vec{V}$ is morphologically invariant.*

Proof. Let g be any smooth morphological transform of gray scales:

$$u \to g(u), \qquad g'(u) > 0.$$

We show that for any image u the fluxes $\vec{V}_u = \vec{V}_{g(u)}$. Notice that κ, $\vec{n}$, and $\vec{t}$ are already morphologically invariant. Furthermore,

$$\begin{aligned}\frac{1}{|\nabla g(u)|}\frac{\partial(\phi'(\kappa)|\nabla g(u)|)}{\partial\vec{t}}\ \vec{t} &= \frac{1}{g'(u)|\nabla u|}\frac{\partial(g'(u)\phi'(\kappa)|\nabla u|)}{\partial\vec{t}}\ \vec{t} \\ &= \frac{g'(u)}{g'(u)|\nabla u|}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial\vec{t}}\ \vec{t} \\ &= \frac{1}{|\nabla u|}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial\vec{t}}\ \vec{t},\end{aligned}$$

where we have applied the fact that u, and therefore $g'(u)$, are both constant in the tangent direction. Thus $\vec{V}_{g(u)} = \vec{V}_u$. □

Masnou and Morel (private communication) have also worked out the Euler–Lagrange equation (5.2), although it is not expressed in the above geometric form.

COROLLARY 5.3. *For the elastica inpainting model* (4.16)*, the gradient descent marching is given by*

$$\frac{\partial u(x,t)}{\partial t} = \nabla\cdot\vec{V}(x,t) - \lambda_E(x)\ (u(x) - u_0(x)), \qquad x\in E\cup K,\ t>0,$$

with the boundary conditions (5.1) *and*

$$\vec{V} = (a + b\kappa^2)\ \vec{n} - \frac{2b}{|\nabla u|}\frac{\partial(\kappa|\nabla u|)}{\partial\vec{t}}\ \vec{t}, \tag{5.5}$$

$$\lambda_E(x) = \lambda\cdot 1_E(x) \qquad (1_E \text{ is the indicator of } E). \tag{5.6}$$

In numerical computation, as Marquina and Osher [25] proposed, the weighted gradient descent method generally converges faster than the original one:

$$\frac{\partial u}{\partial t} = |\nabla u|\ \nabla\cdot\vec{V} - |\nabla u|\ \lambda_E\ (u - u_0). \tag{5.7}$$

By such modification, without the fitting term, the evolution equation is morphologically invariant since the $g'(u)$ factors (associated with a morphological transform g) cancel each other out in $\partial u/\partial t$ and $|\nabla u|$, while the flux field $\vec{V}$ is already morphologically invariant. If $b = 0$, we have the well-known *mean curvature motion* [28].

Our numerical PDE scheme in the coming section is applied to the modified gradient descent equation (5.7).

5.2. The inpainting mechanisms of transport and diffusion. We now show that the flux field $\vec{V}$ beautifully offers a unified viewpoint on the earlier work of Bertalmio et al. on *transport*-based inpainting [3] and on that of Chan and Shen [8] on CDD-based inpainting. In return, these earlier works help reveal the fine structure of elastica inpainting from the PDE point of view.

The first high-order PDE-based inpainting model of Bertalmio et al. [3] is based on the beautiful intuition of smoothness transport along isophotes:

$$\frac{\partial u}{\partial t} = \nabla^{\perp} u \cdot \nabla L(u), \tag{5.8}$$

where $\nabla^{\perp} u = (-u_y, u_x) = |\nabla u|\ \vec{t}$, and $L(u)$ can be any smoothness measure of the image u. For example, in the numerical experiment of [3], L is chosen to be the Laplacian Δu. The model carries the transport nature since, as the evolution approaches its equilibrium state, we have

$$\vec{t} \cdot \nabla L(u) = 0 \qquad \text{and} \qquad \frac{\partial L(u)}{\partial \vec{t}} = 0,$$

which means that the smoothness measure remains constant along any completed isophote. Thus, in terms of the available boundary data, the image evolves as though transporting the boundary smoothness information along the restored isophotes into the inpainting domain.

However, due to the lack of communication among the isophotes, the transport may result in kinks inside the inpainting domain, just as shocks may develop in traffic models. Thus in [3], (5.8) is implemented with the help of intermediate steps of anisotropic diffusions. As we shall see below, such intuition is well supported by the elastica inpainting.

On the other hand, in [9], in order to realize the so-called *connectivity principle* in perceptual disocclusion, Chan and Shen proposed the CDD inpainting model

$$\frac{\partial u}{\partial t} = \nabla \cdot \left(\frac{g(\kappa)}{|\nabla u|} \nabla u \right), \tag{5.9}$$

where $g : R \to [0, +\infty)$ is a continuous function satisfying $g(0) = 0$ and $g(\pm\infty) = +\infty$. If g is replaced by 1, then this is the classical TV anisotropic diffusion. Here $g(\kappa)$ has been introduced to penalize large curvatures and encourage small ones, since physically $D = g(\kappa)/|\nabla u|$ denotes the diffusivity coefficient. With this action, the reconnection of objects which were broken by the inpainting domain is generally encouraged.

It has remained a mystery why we can have two seemingly *orthogonal* inpainting mechanisms: the model in [3] transports information *along* isophotes, while the CDD inpainting model [9] diffuses information *across*. We now explain that the elastica inpainting model makes a unification by incorporating both mechanisms.

We have established in Theorem 5.1 that the flux $\vec{V}$ for the inpainting energy $R[u]$ consists of two components: the normal part $\vec{V}_n = \phi(\kappa)\vec{n}$ and the tangential part

$$\vec{V}_t = -\frac{1}{|\nabla u|}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial \vec{t}}\vec{t}.$$

The normal flux $\vec{V}_n$ precisely corresponds to Chan and Shen's CDD program (5.9) with $g(\kappa) = \phi(\kappa)$.

On the other hand, the tangential component can be written as

$$\vec{V}_t = -\left(\frac{1}{|\nabla u|^2}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial \vec{t}}\right)\nabla^{\perp}u,$$

and its divergence as

$$\nabla \cdot \vec{V}_t = \nabla^{\perp}u \cdot \nabla\left(\frac{-1}{|\nabla u|^2}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial \vec{t}}\right)$$

because $\nabla^{\perp}u$ is divergence-free. It corresponds to the scheme of Bertalmio et al. in the form (5.8), with the smoothness measure

$$L_\phi = \frac{-1}{|\nabla u|^2}\frac{\partial(\phi'(\kappa)|\nabla u|)}{\partial \vec{t}}.$$

We can further work out the expression to

$$L_\phi = \frac{-1}{|\nabla u|^2}\left(|\nabla u|\ \phi''(\kappa)\frac{\partial \kappa}{\partial \vec{t}} + \phi'(\kappa)\ [\nabla \otimes \nabla u](\vec{n}, \vec{t}\,)\right).$$

Here $[\nabla \otimes \nabla u](\bullet, \bullet)$ denotes the Hessian bilinear form. Thus in a simple case such as $\phi(s) = |s|$ and $\kappa \neq 0$, it simplifies to

$$L_\phi = \frac{\pm 1}{|\nabla u|^2}[\nabla \otimes \nabla u](\vec{n}, \vec{t}\,),$$

which more closely resembles the experimental choice in Bertalmio et al. [3] of the Laplacian

$$\Delta u = \text{trace}(\nabla \otimes \nabla u) = [\nabla \otimes \nabla u](\vec{n}, \vec{n}\,) + [\nabla \otimes \nabla u](\vec{t}, \vec{t}\,).$$

In summary, the elastica inpainting scheme combines both the transport mechanism of the Bertalmio group's model and the CDD mechanism of Chan and Shen's model. It thus provides a theoretical foundation for these two earlier empirical works. In return, the earlier works also shed light on the meaning of the flux field $\vec{V}$ and the PDE interpretation of elastica inpainting.

6. Computation and examples.

6.1. Numerical implementation. In this section, we explain the numerical scheme for the evolution equation (5.7):

$$\frac{\partial u}{\partial t} = |\nabla u|\ \nabla \cdot \vec{V} - |\nabla u|\ \lambda_E\ (u - u_0),$$

where the flux $\vec{V}$ and λ_E are as given in Corollary 5.3. We remind our readers that the factor $|\nabla u|$, as suggested by Marquina and Osher in [25], is for accelerating the time marching.

Let (i,j) denote a general pixel, and time be digitized to $n = 0, 1, \ldots$, with a small time step h. Thus $u^n_{(i,j)}$ denotes the value of u at pixel (i,j) at time nh. Then

$$u^{n+1}_{(i,j)} = u^n_{(i,j)} + h\left(|\nabla u^n_{(i,j)}|\, F(u^n_{(i,j)}) - |\nabla u^n_{(i,j)}|\, \lambda_{E,(i,j)}\, (u^n_{(i,j)} - u_{0,(i,j)})\right),$$

where $F(u^n_{(i,j)}) = \nabla \cdot \vec{V}^n_{(i,j)}$ and u_0 is the available image.

We now focus on the spatial digitization of the right-hand side at a fixed time nh. Thus we shall conveniently leave out the superscript n. Following Marquina and Osher [25], the accelerating factor $|\nabla u_{(i,j)}|$ in front of $F(u_{(i,j)})$ is approximated by the central differencing

$$|\nabla u_{(i,j)}| = \frac{1}{2}\sqrt{(u_{(i+1,j} - u_{(i-1,j)})^2 + (u_{(i,j+1)} - u_{(i,j-1)})^2}, \tag{6.1}$$

and the factor $|\nabla u_{(i,j)}|$ in front of $\lambda_{E,(i,j)}\, (u_{(i,j)} - u_{0,(i,j)})$ by the upwind scheme

$$|\nabla u_{(i,j)}| = \sqrt{(\text{upwind } D_x u_{(i,j)})^2 + (\text{upwind } D_y u_{(i,j)})^2},$$

$$\text{upwind } D_x u_{(i,j)} = \begin{cases} u_{(i,j)} - u_{(i-1,j)} & \text{if} \quad (u_{(i+1,j)} - u_{(i-1,j)})(u_{(i,j)} - u_{0,(i,j)}) > 0, \\ u_{(i+1,j)} - u_{(i,j)} & \text{if} \quad (u_{(i+1,j)} - u_{(i-1,j)})(u_{(i,j)} - u_{0,(i,j)}) < 0. \end{cases}$$

The upwinding on y is similar.

Now we focus on the discretization of $F(u_{(i,j)}) = \nabla \cdot \vec{V}_{(i,j)}$. Write $\vec{V} = (V^1, V^2)$ and

$$\vec{n} = (n^1, n^2) = \left(\frac{u_x}{|\nabla u|}, \frac{u_y}{|\nabla u|}\right), \qquad \vec{t} = (t^1, t^2) = \left(-\frac{u_y}{|\nabla u|}, \frac{u_x}{|\nabla u|}\right).$$

Then

$$\begin{aligned} V^1 &= (a + b\kappa^2)\, n^1 - \frac{2b}{|\nabla u|}\left(t^1 D_x(\kappa|\nabla u|) + t^2 D_y(\kappa|\nabla u|)\right) t^1 \\ &= (a + b\kappa^2)\, \frac{D_x u}{|\nabla u|} + \frac{2b}{|\nabla u|^3}\left(-D_y u\, D_x(\kappa|\nabla u|) + D_x u\, D_y(\kappa|\nabla u|)\right)\, D_y u, \end{aligned}$$

where the partial derivative symbols D_x and D_y are introduced to ease the placement of subscripts. The expression of V^2 can be worked out similarly. Based on the half-point central differencing, we have

$$\begin{aligned} F(u_{(i,j)}) = \nabla \cdot \vec{V}_{(i,j)} &= D_x V^1_{(i,j)} + D_y V^2_{(i,j)} \\ &= \left(V^1_{(i+\frac{1}{2},j)} - V^1_{(i-\frac{1}{2},j)}\right) + \left(V^2_{(i,j+\frac{1}{2})} - V^2_{(i,j-\frac{1}{2})}\right). \end{aligned}$$

Thus we need to specify the *half-point* values for all the quantities involved. Take the x-half-point $(i+1/2, j)$, for example. For the curvature, we take the min-mod [33] between the *whole* pixels:

$$\kappa_{(i+\frac{1}{2},j)} = \text{minmod}(\kappa_{(i+1,j)}, \kappa_{(i,j)}), \qquad \text{minmod}(\alpha, \beta) = \frac{\text{sign}(\alpha) + \text{sign}(\beta)}{2} \min(|\alpha|, |\beta|).$$

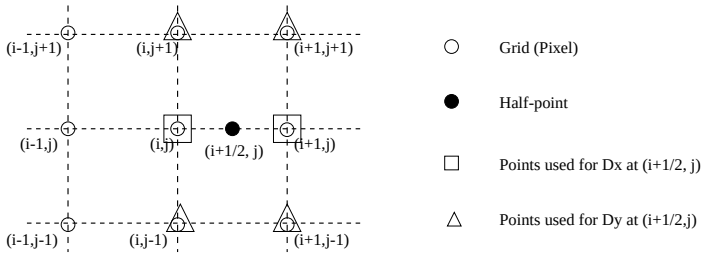

FIG. 6.1. *Grid description for the finite difference schemes.*

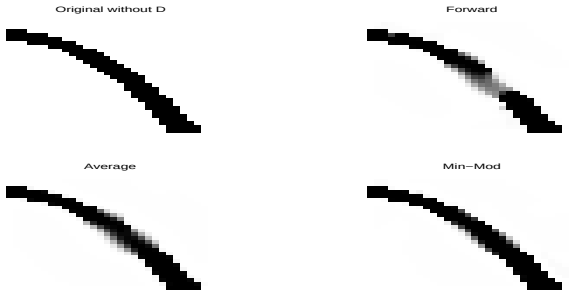

FIG. 6.2. *Experimental results show the advantage of the min-mod discretization in* (6.2). *The upper left panel is the original complete image of a ribbon. The inpainting domain is a square covering the middle part. The other three images are the outputs of the numerical inpainting schemes based on the* forward *substitution, the* average *discretization, and the* min-mod *discretization, separately. (See the text for more details.) The min-mod scheme seems to yield better edge sharpness, as expected from the shock wave computation in computational fluid dynamics.*

D_x's at an x-half-point $(i+1/2, j)$ are approximated by the central differencing of the two adjacent whole pixels $(i+1, j)$ and (i, j). For examples (see Figure 6.1),

$$D_x u_{(i+1/2,j)} = u_{(i+1,j)} - u_{(i,j)},$$
$$D_x(\kappa|\nabla u|)_{(i+1/2,j)} = \kappa_{(i+1,j)}\ |\nabla u|_{(i+1,j)} - \kappa_{(i,j)}\ |\nabla u|_{(i,j)}.$$

Here $|\nabla u|_{(i,j)}$ is as in (6.1). The D_y's at an x-half-point $(i+1/2, j)$ are approximated by the min-mod of the D_y's at the two adjacent whole pixels $(i+1, j)$ and (i, j) (see Figure 6.1). For instance, for $D_y u_{(i+1/2,j)}$,

$$D_y u_{(i+1/2,j)} = \text{minmod}\left(\frac{1}{2}(u_{(i+1,j+1)} - u_{(i+1,j-1)}),\ \ \frac{1}{2}(u_{i,j+1)} - u_{(i,j-1)})\right). \tag{6.2}$$

The same can be done for $D_y(\kappa|\nabla u|)$ at $(i+1/2, j)$. Then $|\nabla u|^2$ at $(i+1/2, j)$ is naturally defined as the sum of squares of $D_x u_{(i+1/2,j)}$ and $D_y u_{(i+1/2,j)}$. Therefore, eventually, all quantities involved are expressed by the gray levels $u_{(i,j)}$ at whole pixels.

Numerical experiments in Figure 6.2 have shown the advantage of the min-mod discretization for D_y at x-half-points, compared with two other competing methods ($w = u$ or $\kappa|\nabla u|$): the *forward* substitution of $D_y w_{(i+1/2,j)}$ by $D_y w_{(i,j)}$, and the *average* substitution by

$$\frac{1}{2}\left(\frac{u_{(i+1,j+1)} - u_{(i+1,j-1)}}{2} + \frac{u_{(i,j+1)} - u_{(i,j-1)}}{2}\right).$$

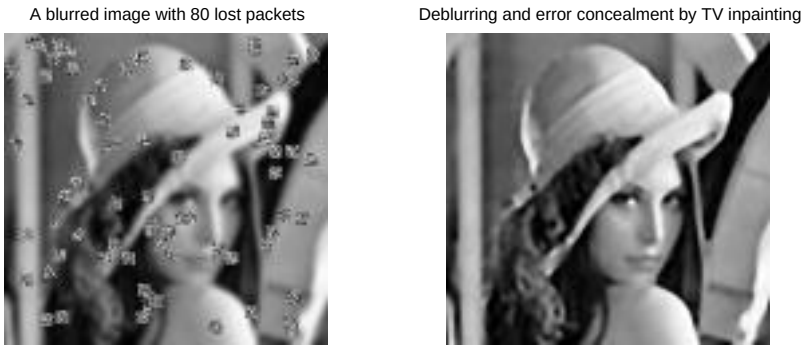

FIG. 6.3. *TV inpainting for the error concealment of a blurry image with packets randomly lost when transmitted through a wireless network* [10].

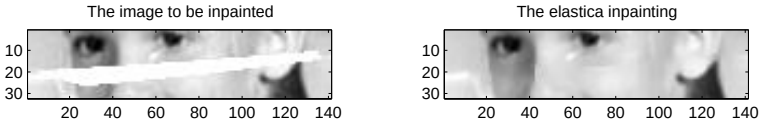

FIG. 6.4. *An example of elastica inpainting for scratch removal.*

As in computational fluid dynamics, the min-mod method seems to catch sharper edges (or *shocks*) more effectively.

6.2. Examples. We provide several numerical examples of elastica inpainting.

Figure 6.3 shows an application of the TV inpainting model (with $b = 0$ in the elastica model (4.16)) for the error concealment of wireless image transmissions where packets are randomly lost. (To be applicable to a blurry image with a linear blurring kernel H, model (4.16) should have the least square data model replaced by (choosing $E = \Omega \setminus K$)

$$\frac{\lambda}{2} \int_{\Omega \setminus K} (Hu - u_0)^2 dx.$$

See the recent paper by Chan and Shen [10] for more detail.) The TV inpainting model works well for most *local* inpainting problems but becomes problematic when applied to the inpainting of incomplete images with large-scale missing domains (see Chan and Shen [8]). For the latter, the curvature term in the elastica model becomes necessary.

Figure 6.4 shows the output of the elastica inpainting model when applied to the digital restoration of an old scratched photograph (image source: [3]). The example shows what an inpainting model must be able to accomplish: consistently reconnecting all the broken isophotes, including broken edges with low contrasts (like the shadow of the nose).

The next two figures demonstrate two universal effects of curvature-based inpainting. The example in Figure 6.5 shows that if more weights are put against the curvature term in the elastica model, the inpainted isophotes and edges become smoother and perceptually better. The second example in Figure 6.6 explains that as more weights are put against the curvature term, the model tends to favor the

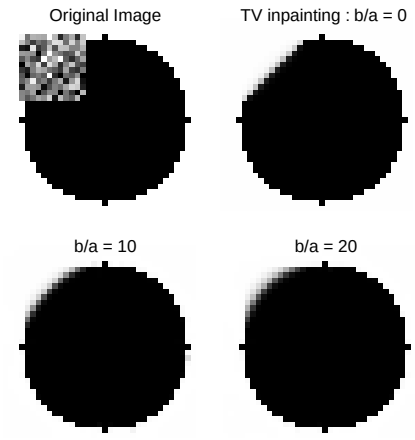

FIG. 6.5. *Effect* I *of elastica inpainting: a larger weight b against the curvature term produces smoother isophotes and edges and better visual results.*

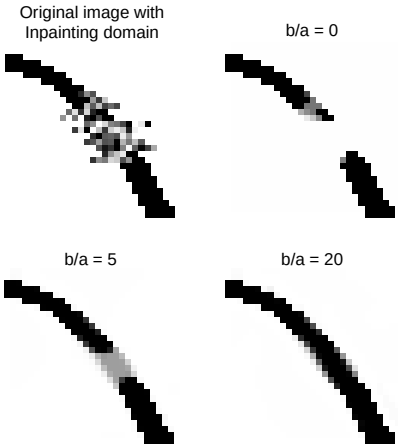

FIG. 6.6. *Effect* II *of elastica inpainting: a large weight b against the curvature term favors the* connectivity principle*: the model encourages the connection of separated parts.*

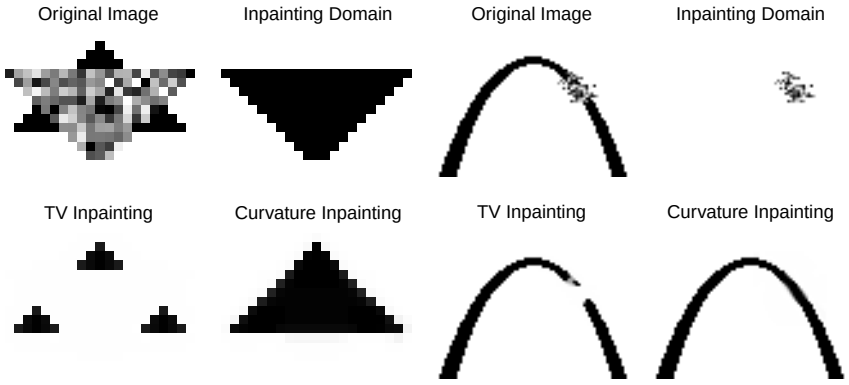

FIG. 6.7. *Two more examples of elastica inpainting.*

connectivity principle in perception [9, 20, 32]. That is, unlike the extreme case of TV inpainting, the model encourages connection.

The last figure (Figure 6.7) shows two more examples of elastica inpainting, where one can further appreciate the power of the elastica inpainting model and the numerical PDE approach. Large scale "communication" among the separated parts is made possible simply because of a good image or curve prior model—Euler's elastica.

7. A remark on the inpainting model of Ballester et al. [1]. Before concluding, we would like to direct our readers to a recent paper by Ballester, Bertalmio, Caselles, Sapiro, and Vergera [1] that is closely connected to our own. We shall conveniently call it the BBCSV model below.

The BBCSV variational inpainting model inpaints both the normal field $\vec{n} = \nabla u/|\nabla u|$ and the gray value image u simultaneously over the extended inpainting domain $K \cup E$, based on the boundary data u_0 and $\vec{n}_0$. (To be consistent and more readable, we have followed our own notations in the current paper.) The BBCSV

model tries to minimize the energy

$$J[u,\vec{n}] = \int_{K\cup E} |\nabla\cdot\vec{n}|^p\ (a+b|\nabla u|)dx + \alpha\int_{K\cup E}(|\nabla u| - \vec{n}\cdot\nabla u)dx \tag{7.1}$$

in a suitably defined admissible space (see [1]).

The second fitting term is used to enforce the ideal meaning of $\vec{n}$: $\vec{n} = \nabla u/|\nabla u|$. Therefore, ideally, the BBCSV energy $J[u,\vec{n}]$ is essentially reduced to

$$\int_{K\cup E}\left|\nabla\cdot\left[\frac{\nabla u}{|\nabla u|}\right]\right|^p\ (a+b|\nabla u|)dx, \tag{7.2}$$

which is different from the p-elastica energy in the current paper:

$$\int_{K\cup E}\left(a+b\left|\nabla\cdot\left[\frac{\nabla u}{|\nabla u|}\right]\right|^p\right)|\nabla u|dx.$$

The major difference between the two is that the elastica model leads to morphologically invariant flows, as shown in Theorem 5.1 and Proposition 5.2.

We refer to [1] for further interesting discussion.

Acknowledgments. We thank the reviewers for all their valuable and constructive comments. We are grateful to Professor Guillermo Sapiro's group for their help on the inpainting topic, and Professors Stanley Osher, Luminita Vese, Li-Tien Cheng, Simon Masnou, Jean-Michel Morel, Peter Olver, Robert Gulliver, Fadil Santosa, Selim Esedoglu, and Rachid Deriche for their helpful interactions and suggestions during this project. Jianhong (Jackie) Shen would also like to thank Professors Gil Strang, Stu Geman, David Mumford, Jayant Shah, and Dan Kersten for their teaching and inspirations on the subject.

THE APEX METHOD IN IMAGE SHARPENING AND THE USE OF LOW EXPONENT LÉVY STABLE LAWS*

ALFRED S. CARASSO†

Abstract. The APEX method is an FFT-based direct blind deconvolution technique that can process complex high resolution imagery in seconds or minutes on current desktop platforms. The method is predicated on a restricted class of shift-invariant blurs that can be expressed as finite convolution products of two-dimensional radially symmetric Lévy stable probability density functions. This class generalizes Gaussian and Lorentzian densities but excludes defocus and motion blurs. Not all images can be enhanced with the APEX method. However, it is shown that the method can be usefully applied to a wide variety of *real blurred images*, including astronomical, Landsat, and aerial images, MRI and PET brain scans, and scanning electron microscope images. APEX processing of these images enhances contrast and sharpens structural detail, leading to noticeable improvements in visual quality. The discussion includes a documented example of nonuniqueness, in which distinct point spread functions produce high-quality restorations of the same blurred image. Significantly, *low exponent* Lévy point spread functions were detected and used in all the above examples. Such low exponents are exceptional in physical applications where symmetric stable laws appear. In the present case, the physical meaning of these Lévy exponents is uncertain.

Key words. image deblurring; blind deconvolution; direct methods; electronic imaging systems; heavy-tailed distributions; low exponent stable laws; APEX method; SECB method; nonuniqueness; astronomical, Landsat, and SEM images; MRI and PET brain scans

1. Introduction.

The APEX method is an FFT-based direct blind deconvolution technique introduced by the author in [9]. The significance of the present paper lies in the successful use of that method in sharpening a wide variety of *real blurred images*, as opposed to the synthetically blurred images discussed in [9]. The reasons behind these successful applications are not fully understood. Not all images can be usefully enhanced with the APEX method. The present paper is essentially self-contained and may be read independently of [9].

Blind deconvolution seeks to deblur an image without knowing the point spread function (psf) describing the blur. Most approaches to that problem are iterative in nature. Because nonuniqueness is compounded with discontinuous dependence on data, such iterative procedures are not always well-behaved. When the iterative process is stable, several thousand iterations may be necessary to achieve useful reconstructions. However, as shown in [9], by limiting the class of blurs, noniterative direct procedures can be devised that accomplish blind deconvolution of 512×512 images in seconds on current desktop platforms.

The APEX method assumes the image $g(x, y)$ to have been blurred by a restricted type of shift-invariant psf $h(x, y)$, one that can be expressed as a finite convolution

*Received by the editors May 11, 2001; accepted for publication (in revised form) June 5, 2002; published electronically December 11, 2002.

†Mathematical and Computational Sciences Division, National Institute of Standards and Technology, Gaithersburg, MD 20899 (alfred.carasso@nist.gov).

product of two-dimensional (2-D) radially symmetric Lévy stable probability density functions. Such so-called class **G** psfs include Gaussians, Lorentzians, and their convolutions. However, the class **G** also excludes defocus and motion blurs and convolutions of such blurs with Gaussians and Lorentzians.

The synthetically blurred images $g(x, y)$ used in [9] were created by numerical convolution of sharp images $f(x, y)$ with class **G** psfs $h(x, y)$. Such blurred images necessarily obey the convolutional model $g(x, y) = h(x, y) \otimes f(x, y) + noise$, on which the APEX method is predicated. In a real image, the blur need not be radially symmetric nor shift-invariant and may otherwise be poorly approximated by an element of **G**. More fundamentally, the blurring operator may not even be linear. Applicability of the APEX method to a given real image is far from obvious. Therefore, useful sharpening of any such image with an APEX-detected psf is always instructive.

Stable distributions are the natural generalization of the Gaussian distribution. Their theory was developed by Paul Lévy in the 1930s in connection with his work on the central limit theorem (see [17]). In the simplest radially symmetric case, these distributions are characterized by an exponent β, $0 < \beta \leq 1$, with $\beta = 1$ corresponding to the Gaussian distribution, and $\beta = 1/2$ corresponding to the Cauchy or Lorentzian distribution. Because stable distributions have infinite variance when $\beta < 1$, their appearance in physical contexts sometimes poses philosophical difficulties. In the present case, use of such heavy-tailed psfs as the framework for the APEX method is motivated by the important role Lévy densities appear to play in numerous imaging systems. This is documented in section 2. When the APEX method is applied to a given image in the manner described below, a Lévy psf with a specific value of β is necessarily detected. That value of β may not be indicative of the actual physical process that created the image. This is true even if deblurring with the detected psf significantly improves the image. As shown in section 4, there are in general infinitely many distinct values of β that can produce useful reconstructions from the same blurred image. In some cases, the usefully enhanced image may not have been blurred by a class **G** psf to begin with. In other cases, APEX processing does not significantly improve the image.

Below, we exhibit ten images where APEX processing provided noticeable improvement. These examples encompass such diverse imaging applications as astronomical, Landsat, and aerial images, MRI and PET brain scans, a scanning electron microscope image, a face image, and other types of interesting images. In some cases, the improvement is due primarily to an increase in contrast. In other cases, there is demonstrable sharpening of structural detail in addition to increased contrast. In all cases, the change in image quality is more than cosmetic, as APEX processing significantly alters the image Fourier transform. It is noteworthy that *low exponent* stable laws, with $\beta \ll 1/2$, were detected and used to deblur all of the images shown below. Such β-values are exceptional in physical contexts where radially symmetric Lévy densities appear. Whether or not these values have a physical origin cannot be ascertained in the present case. Moreover, the APEX detection procedure may not be well founded. Nevertheless, the fact remains that the use of such psfs produced valuable restoration of real imagery from important fields of science and technology. To the author's knowledge, this application of sub-Cauchy stable laws in image processing is new and unanticipated.

In recent years, there has been considerable interest in image processing techniques that can be formulated as initial value problems in nonlinear PDEs. An instructive survey of these developments may be found in [11]. In particular, novel approaches to image deblurring have been devised, based on integrating well-posed

nonlinear anisotropic diffusion equations [33], [38]. In contrast, the APEX method centers around ill-posed continuation in linear fractional diffusion equations. As noted in section 7, for the type of finely textured imagery considered in the present paper, APEX processing compares favorably with what is feasible with nonlinear methods. This indicates that the APEX method can be a useful addition to PDE-based image analysis.

2. Imaging systems, Lévy processes, and the class G. The occurrence and analysis of Lévy processes in the physical sciences are subjects of significant current interest; see [1], [2], [4], [32], [39], [40], [41], [44], and the references therein. An important special case involves 2-D radially symmetric Lévy stable densities $h(x, y)$, implicitly defined in terms of their Fourier transforms by

$$(1) \qquad \hat{h}(\xi,\eta) \equiv \int_{R^2} h(x,y) e^{-2\pi i(\xi x+\eta y)} dxdy = e^{-\alpha(\xi^2+\eta^2)^\beta}, \qquad \alpha > 0, \quad 0 < \beta \leq 1.$$

The cases $\beta = 1$ and $\beta = 1/2$ correspond to Gaussian and Lorentzian (or Cauchy) densities, respectively. For other values of β, $h(x, y)$ in (1) is not known in closed form. When $\beta = 1$, $h(x, y)$ has slim tails and finite variance. For $0 < \beta < 1$, $h(x, y)$ has fat tails and infinite variance. As noted in [44], there are examples in science where the occurrence of a stable law can be deduced from "first principles" in terms of physical mechanisms that do not explicitly involve the parameter β. One such instance is the Holtsmark distribution describing the gravitational field of stars (see [17]). There, mathematical analysis reveals the value $\beta = 3/4$. Such cases must be distinguished from the many other cases in which empirically obtained data with fat tails are *fitted* to a Lévy law, and the exponent β is *inferred* from these data. Given the limitations of physical measurements, such empirically established Lévy processes do not have the degree of scientific legitimacy that attends the Holtsmark distribution. The considerations of the present paper generally lie in this weaker scientific realm. Nevertheless, as will be seen below, techniques derived from such considerations turn out to be effective.

Image intensifiers, charge-coupled devices, and numerous other electronic devices are used in a wide variety of astronomical, industrial, biomedical, military, and surveillance imaging systems; see [3], [14], [15], [18], [31]. Each such device has a psf $h(x, y)$ characterizing that device's imaging properties. The psf is a probability density function since it is nonnegative and integrates to unity. Use of such a device to image an object $f(x, y)$ produces a blurred image $g(x, y) = h(x, y) \otimes f(x, y)$, where $\otimes$ denotes convolution. An ideal device would have $h(x, y) = \delta(x, y)$. The Fourier transform $\hat{h}(\xi, \eta)$ of the psf is generally complex-valued and is called the *optical transfer function* (otf). The absolute value of the otf is the *modulation transfer function* (mtf).

In [42], it is noted that electron optical mtfs are often nearly Gaussian in shape, and that this should be expected from the central limit theorem, since the process of converting incoming signal photons into the final image that is observed on a screen involves many intermediate stages. However, it is also observed in [42] that when such mtfs are fitted with Gaussians, the fitted curves often have *slimmer* tails than is the case for the true mtfs.

A systematic study of electron optical mtf *measurements* is the subject of [22], [24], and [27]. There, the author claims the empirical discovery that a wide variety of electronic imaging devices, including phosphor screens and some types of photographic film, have otfs $\hat{h}(\xi, \eta)$ that are well described by (1) with $1/2 \leq \beta \leq 1$. For any given device, the values of α and β can be determined using specialized graph paper [28].

Other instances of electron optical stable laws are mentioned in [23], [26], and [30]. Analysis of the physical mechanisms responsible for such non-Gaussian behavior is not included in these works. An understanding of such mechanisms may lead to the design of imaging devices with *low* values of β. The latter parameter affects the attenuation of high frequency information in the recorded image. Deconvolution of that image in the presence of noise is generally better behaved at low values of β than it is at high values of β.

The characterization (1) is useful in other areas of optics. The otf for long-exposure imaging through atmospheric turbulence [21] is known to be given by (1), with $\beta = 5/6$ and α determined by atmospheric conditions. Also, as shown in [25], the analytically known diffraction-limited otf for a perfect lens [43, p. 154] can be approximated over a wide frequency range by (1), with $\beta = 3/4$ and α a properly chosen function of the cutoff frequency.

The range of β values discussed above, namely, $1/2 \leq \beta \leq 1$, mirrors that found in most other physical contexts where *symmetric* stable laws appear or are surmised. Values of $\beta \ll 1/2$ seem to be relatively rare in applications. Examples of such β values occur in [29], where mtf data for 56 different kinds of *photographic film* are analyzed. Good agreement is found when these data are fitted with (1) and the pairs (α, β) characterizing each of these 56 mtfs are identified. It is found that 36 types of film have mtfs where $1/2 \leq \beta \leq 1$. The remaining 20 types have mtfs with values of β in the range $0.265 \leq \beta \leq 0.475$.

We now consider imaging systems composed of various elements satisfying (1). Such systems might be used to image objects through a turbulent atmosphere or through other distorting media whose otfs obey (1). The resulting composite otf has the form

$$\hat{h}(\xi, \eta) = e^{-\sum_{i=1}^{J} \alpha_i (\xi^2+\eta^2)^{\beta_i}}, \qquad \alpha_i \geq 0, \quad 0 < \beta_i \leq 1. \tag{2}$$

Such an object corresponds to a *multifractal law* in [4]. We define the class **G** to be the class of all psfs $h(x, y)$ with Fourier transforms satisfying (2). We shall be interested in image deblurring problems

$$Hf \equiv \int_{R^2} h(x-u, y-v) f(u, v) du dv \equiv h(x, y) \otimes f(x, y) = g(x, y), \tag{3}$$

where $g(x, y)$ is the recorded blurred image, $f(x, y)$ is the desired unblurred image, and $h(x, y)$ is a known psf in class **G**. The blurred image $g(x, y)$ includes (possibly multiplicative) noise, which is viewed as a separate additional degradation,

$$g(x, y) = g_e(x, y) + n(x, y). \tag{4}$$

Here, $g_e(x, y)$ is the blurred image that would have been recorded in the absence of any noise, and $n(x, y)$ represents the cumulative effects of all errors affecting final acquisition of the digitized array $g(x, y)$. Neither $g_e(x, y)$ nor $n(x, y)$ are known, only their sum $g(x, y)$. The unique solution of (3) when the right-hand side is $g_e(x, y)$ is the exact sharp image denoted by $f_e(x, y)$. Thus

$$h(x, y) \otimes f_e(x, y) = g_e(x, y). \tag{5}$$

3. Deblurring with the SECB method. The SECB method is a direct FFT-based image deblurring technique designed for equations of the form (3), when $h(x, y)$ is known and belongs to **G**. The method is based on inverse diffusion equations, and

features an important new *slow evolution* regularizing constraint. Such regularization leads to smaller error bounds for the reconstructed image $f(x,y)$, as a function of the noise level ϵ in the blurred image $g(x,y)$, than is mathematically possible with the basic Tikhonov–Miller method. Significantly, the method does not impose smoothness constraints on the unknown image $f(x,y)$, nor does it require knowledge of the noise statistics other than an L^2 upper bound ϵ. Naturally, the method works best when ϵ is small. The above important theoretical advantages, coupled with the practical advantages of fast computation through FFT algorithms, render the SECB method a valuable tool in blind deconvolution. Theoretical analysis of the SECB method, along with error bounds and documented comparisons with the Tikhonov–Miller method, may be found in [5] and [6]. Comparisons with other widely used nonlinear probabilistic algorithms, including the Lucy–Richardson and maximum entropy methods, may be found in [7]. Image deblurring with class **G** psfs is just one example of an extensive class of ill-posed PDE problems [8]. That class includes problems ranging from analytic continuation in the unit disc to the time-reversed Navier–Stokes equations. As shown explicitly in [8], use of the "slow evolution" constraint in that class of problems leads to stronger stability estimates in terms of ϵ than previously known "Hölder-continuity" estimates.

For class **G** psfs, we may define fractional powers H^t, $0 \le t \le 1$, of the convolution integral operator H in (3) as follows:

$$H^t f \equiv \mathcal{F}^{-1}\left\{\hat{h}^t(\xi,\eta)\hat{f}(\xi,\eta)\right\}, \qquad 0 \le t \le 1. \tag{6}$$

Class **G** psfs are intimately related to diffusion processes, and solving (3) is mathematically equivalent to finding the initial value $u(x,y,0) = f(x,y)$ in the *backwards-in-time* problem for the generalized diffusion equation

$$\begin{aligned} &u_t = -\sum_{i=1}^{J} \lambda_i (-\Delta)^{\beta_i} u, \quad \lambda_i = \alpha_i (4\pi^2)^{-\beta_i}, \qquad 0 < t \le 1, \\ &u(x,y,1) \approx g(x,y). \end{aligned} \tag{7}$$

When $f(x,y)$ is known, $u(x,y,t) = H^t f$ is the solution of (7) at time t. The SECB method is a regularization method for solving the ill-posed problem (7) that takes into account the presence of noise in the blurred image data $g(x,y)$ at $t = 1$. With f, g, and n as in (3) and (4), and $u(t)$ the solution of (7), let ϵ, M be known positive constants such that

$$\|u(0)\|_2 = \|f\|_2 \le M, \quad \|u(1) - g\|_2 = \|n\|_2 \le \epsilon, \qquad \epsilon \ll M, \tag{8}$$

where $\|\ \|_2$ denotes the L^2 norm. For any constant $K > 0$ such that $K \ll M/\epsilon$, define $s^*\ (\epsilon, M, K)$ by

$$s^* = \frac{\log\{M/(M - K\epsilon)\}}{\log(M/\epsilon)}. \tag{9}$$

The "slow evolution" constraint applied to the backwards-in-time solution of (7) requires that there exist a known small constant $K > 0$ and a known fixed small $s > 0$, with $s/s^* \gg 1$, such that

$$\|u(s) - u(0)\|_2 \le K\epsilon. \tag{10}$$

Knowledge of the regularization parameters K and s represents a priori information about the solution of (3). As is well known, some form of a priori information is *always* necessary in the solution of ill-posed problems. Given K and s, the SECB solution of the backwards problem for (7) is defined to be that initial value $u^\dagger(0)$ which *minimizes*

$$\|u(1) - g\|_2^2 + K^{-2} \|u(s) - u(0)\|_2^2 \tag{11}$$

over all choices of initial values $u(0)$ in L^2. The SECB deblurred image $f^\dagger(x,y) \equiv u^\dagger(0)$ can be obtained in closed form in Fourier space. With $\overline{z}$ denoting the complex conjugate of z,

$$\hat{f}^\dagger(\xi,\eta) = \frac{\overline{\hat{h}}(\xi,\eta)\hat{g}(\xi,\eta)}{|\hat{h}(\xi,\eta)|^2 + K^{-2}|1 - \hat{h}^s(\xi,\eta)|^2}, \tag{12}$$

leading to $f^\dagger(x,y)$ upon inverse transformation. In practice, FFT algorithms are used to obtain $f^\dagger(x,y)$. This may result in individual pixel values that are negative or that exceed 255, the maximum value in an 8-bit image. Accordingly, all negative values are reset to the value zero, and all values exceeding 255 are reset to the value 255. One way of obtaining initial estimates for K and s in (12) is as follows. With ϵ, M, and the psf $h(x,y)$ known, fix $s > 0$ in the range $0.001 \le s \le 0.01$ and construct the operator H^s as in (6). If $f^\pi(x,y)$ is a prototype image for the class of images under consideration, we can estimate K in (10) by evaluating $\|H^s f^\pi - f^\pi\| / \epsilon$. We may then compute s^* in (9) and verify that $s/s^* \gg 1$. This is usually the case, as s^* is infinitesimally small, provided that $K\epsilon \ll M$. This initial choice of K can be refined interactively when the reconstructed image is a recognizable object. With s fixed as above, increasing K increases resolution until a threshold value is reached. Further increases in K bring out noise. Conversely, if the initial choice of K brings out noise, K must be decreased. Note that for 512×512 images, 20 trial SECB restorations, each with a different value of K, can be obtained simultaneously in about 10 seconds of cpu time on an MIPS R12000 (400MHz) workstation. A visually optimal value of K for fixed small s is usually easily found. We may also form and display

$$u^\dagger(x,y,t) = H^t f^\dagger(x,y) \tag{13}$$

for selected *decreasing* values of t lying between 1 and 0. This simulates *marching backwards in time* in (7) and allows *monitoring* the gradual deblurring of the image. As $t \downarrow 0$, the partial restorations $u^\dagger(x,y,t)$ become sharper. However, noise and other artifacts typically become more noticeable as $t \downarrow 0$. Marching backwards from $t = 0.2$ to $t = 0$, say, may allow detection of features in the image before they become obscured by noise or ringing artifacts.

The above discussion assumed that the psf $h(x,y)$ was known. As shown in sections 5 and 6, such marching backwards in time becomes much more vital in the blind deconvolution problem, where the initial APEX-detected psf may erroneously be *too wide*. Theoretically, use of too wide a psf all the way to $t = 0$ implies sharpening features that may have already become infinitely sharp at some $t_0 > 0$. In practice, this leads to severe ringing and other undesirable artifacts at $t = 0$. Here, it is often advisable to start marching backwards from $t = 1$.

It should be noted that the class **G** is only a small subclass of the class of *infinitely divisible* densities [17]. The latter class includes multimodal nonsymmetric psfs associated with linear diffusion equations more complex than (7). Detection of

such psfs from blurred image data would require considerable extension of the APEX method discussed below.

4. Nonuniqueness in blind deconvolution. Blind deconvolution of images is a mathematical problem that is not fully understood. Well-documented examples of the kinds of behavior that may occur are of particular interest. In this section, we highlight important nonuniqueness aspects of that problem that are helpful in understanding the results of the APEX method. Let $f_e(x,y)$ be a given exact sharp image, let $h(x,y)$ be a Lévy point spread function, and let $g_e(x,y) = h(x,y) \otimes f_e(x,y)$. We shall show that, given the blurred image $g_e(x,y)$, there are in general *many* point spread functions $h_i(x,y) \neq h(x,y)$ that deblur $g_e(x,y)$, producing *high quality* reconstructions $f_i(x,y) \neq f_e(x,y)$, with $h_i(x,y) \otimes f_i(x,y) \approx g_e(x,y)$.

The sharp 512×512 Sydney image $f_e(x,y)$ in Figure 1(a) was synthetically blurred by convolution with a Cauchy density $h(x,y)$ with $\alpha_0 = 0.075$, $\beta_0 = 0.5$. This produced the blurred image $g_e(x,y)$ in Figure 1(b). To avoid distractions caused by noise, the blurred image $g_e(x,y)$ in this experiment was computed and stored in 64-bit precision. Deblurring this noiseless image with the correct psf values $\alpha = 0.075$, $\beta = 0.5$, produces Figure 1(c). This is in excellent visual agreement with $f_e(x,y)$ in Figure 1(a), as expected. However, the visual quality in Figures 1(d)–(f) is generally as good as that in Figure 1(c); the latter three images were deblurred with Lévy densities with values (α,β), where $\alpha > \alpha_0$, $\beta < \beta_0$, and they differ from Figure 1(a) in contrast and brightness. All deblurred images were obtained using the SECB method with $s = 0.001$ and $K = 10000$. One-dimensional (1-D) cross sections of the four distinct psfs used in Figure 1 are displayed in Figure 2. These psfs also exhibit distinct heavy tail behavior not shown in Figure 2.

One can imagine four photographers, simultaneously photographing the identical scene depicted in Figure 1(a), yet producing the four distinct images shown in Figures 1(c)–(f) through use of different lenses, film, filters, exposures, printing, and the like. In practice, given only the blurred image in Figure 1(b), any one of these four restorations would be considered highly successful. Convolution of each reconstruction with its corresponding psf in Figure 2 reproduces the blurred image in Figure 1(b).

For any restoration $f(x,y)$ of the exact image $f_e(x,y)$ in Figure 1(a) and any norm $\|\ \|$, we can evaluate the relative error $\|f - f_e\| / \|f_e\|$. Define the discrete L^1, L^2, and H^m norms as follows:

$$\|f\|_1 = N^{-2} \sum_{x,y=1}^{N} |f(x,y)|,$$

$$\|f\|_2 = \left\{ N^{-2} \sum_{x,y=1}^{N} |f(x,y)|^2 \right\}^{1/2}, \tag{14}$$

$$\|f\|_{H^m} = \left\{ N^{-2} \sum_{\xi,\eta=1}^{N} \left(1 + \xi^2 + \eta^2\right)^m |\hat{f}(\xi,\eta)|^2 \right\}^{1/2}.$$

The relative errors in the L^1, L^2, H^1, and H^5 norms for each of the four restorations in Figure 1 are shown in Table 1. As might be expected, image (c) is the closest to image (a) in each of these norms, since the correct psf values were used to obtain image (c) from image (b). It is also evident from Table 1 that the four restorations are distinct from one another, since they differ from image (a) by different amounts.

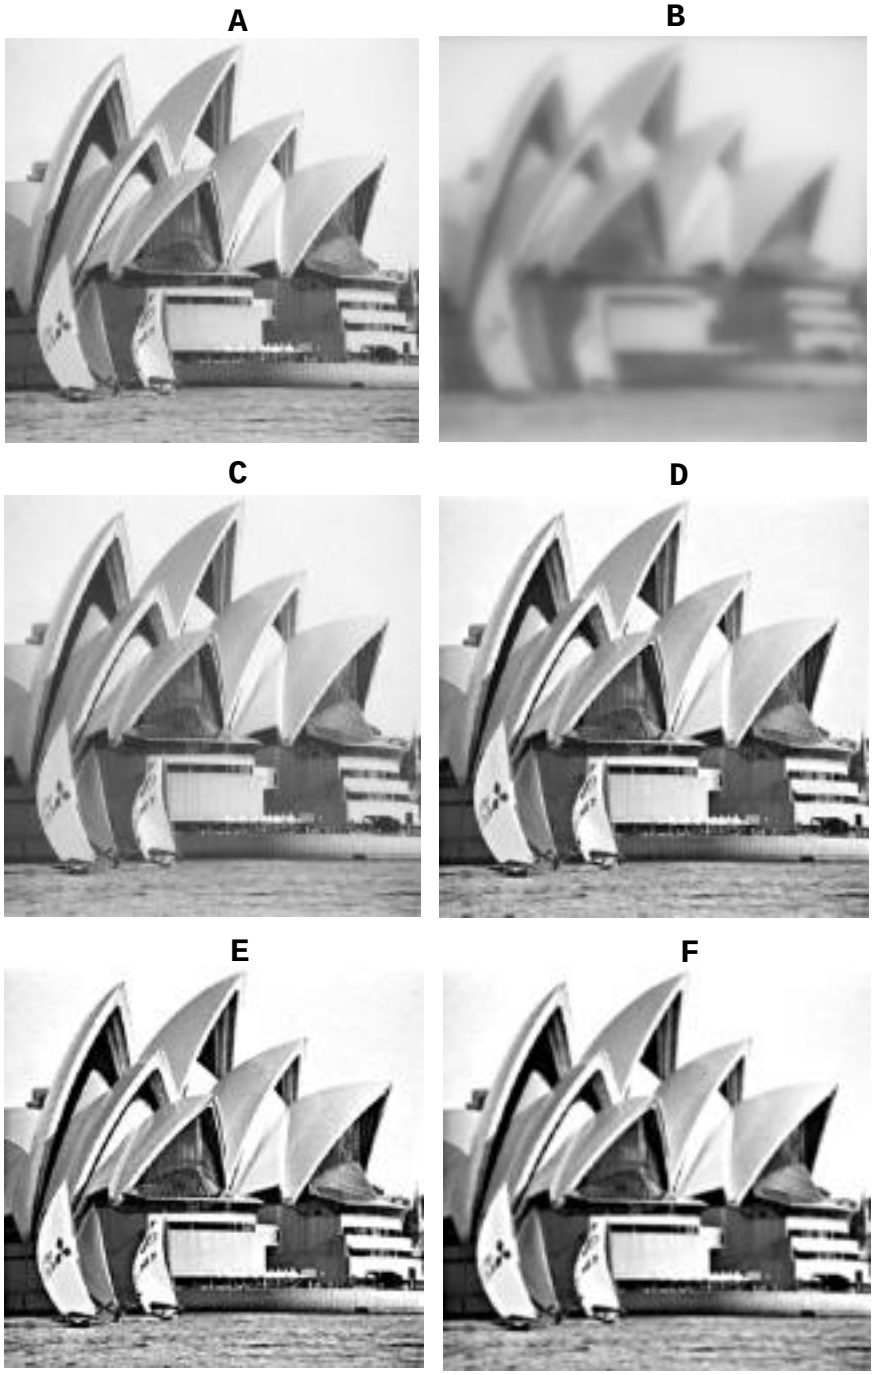

FIG. 1. *Nonuniqueness in blind deconvolution. Distinct psfs exist that produce high quality reconstructions from the same blurred image.* (a) *Original sharp* 512×512 *Sydney image.* (b) *Synthetically blurred Sydney image created by convolution with Lorentzian density with* $\alpha_0 = 0.075$, $\beta_0 = 0.5$. *Blurred image computed and stored in* 64*-bit precision.* (c) *Deblurring of image* (b) *using correct parameters* $\alpha = 0.075$, $\beta = 0.5$. (f) *Deblurring of image* (b) *using* $\alpha = 0.2360994$, $\beta = 0.369666$. *Notice that images* (d), (e), *and* (f) *were found using specific pairs* (α, β), *where* $\alpha > \alpha_0$ *and* $\beta < \beta_0$. *All deblurred images were obtained using the SECB procedure with* $s = 0.001$ *and* $K = 10000$.

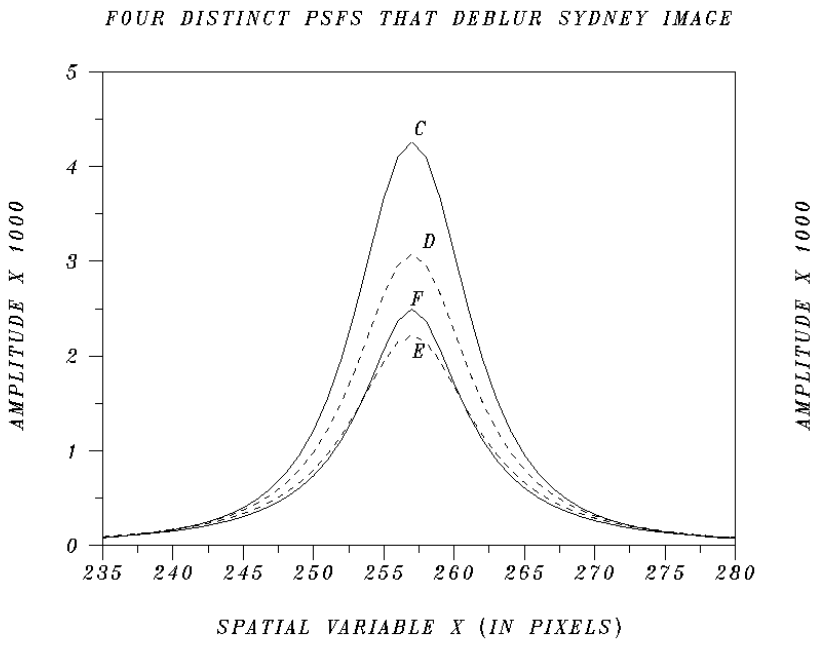

FIG. 2. *Four distinct psfs that deblur image* (b) *in Figure* 1. *Curves C, D, E, and F are* 1-*D cross sections of the* 512×512 *psfs that respectively produced images* (c), (d), (e), *and* (f) *in Figure* 1. *These psfs also exhibit distinct heavy tail behavior.*

TABLE 1
Relative errors in various norms for the four deblurred images in Figure 1.

Restoration	*Parameters* $\alpha,\ \beta$	L^1	L^2	H^1	H^5
Image (c)	$\alpha = 0.075,\ \beta = 0.500$	2.13 %	3.52 %	4.13 %	19.66 %
Image (d)	$\alpha = 0.130,\ \beta = 0.443$	6.63 %	8.37 %	8.67 %	21.11 %
Image (e)	$\alpha = 0.195,\ \beta = 0.404$	12.64 %	15.53 %	15.75 %	25.52 %
Image (f)	$\alpha = 0.236,\ \beta = 0.370$	12.54 %	15.08 %	15.31 %	26.17 %

Most important, the fact that image (e) is a significantly poorer approximation to image (a) in these norms than is image (c) *does not imply* that image (e) is an inaccurate representation of the visual scene depicted in image (a). Notice also that image (f) is not as sharp as image (e), although it is closer to image (a) in three of the four norms.

Iterative algorithms are the most common approach to blind deconvolution. Convergence proofs for such iterative procedures are seldom available. The above example illustrates some of the difficulties underlying any analysis of convergence. Such analysis should allow for the possibility of *infinitely many* useful limit points, while the mathematical characterization of such limit points is not obvious. Moreover, as is evident from Table 1 and has been known for some time, the use of L^p or H^m norms in assessing the visual quality of a reconstruction can be misleading.

5. Marching backwards in time and the APEX method. The APEX method is a blind deconvolution technique based on detecting class **G** psf signatures by appropriate 1-D Fourier analysis of the blurred image $g(x, y)$. The detected

psf parameters are then input into the SECB algorithm to deblur the image. Let $f_e(x,y)$ be an exact sharp image as in (5). Since $f_e(x,y) \geq 0$,

$$|\hat{f}_e(\xi,\eta)| \leq \int_{R^2} f_e(x,y)dxdy = \hat{f}_e(0,0) = \sigma > 0. \tag{15}$$

Also, since $g_e(x,y) = h(x,y) \otimes f_e(x,y)$ and $h(x,y)$ is a probability density,

$$\hat{g_e}(0,0) = \int_{R^2} g_e(x,y)dxdy = \int_{R^2} f_e(x,y)dxdy = \hat{f}_e(0,0) = \sigma > 0. \tag{16}$$

Using σ as a normalizing constant, we may normalize Fourier transform quantities $\hat{q}(\xi,\eta)$ by dividing by σ. Let

$$\hat{q}^*(\xi,\eta) = \frac{\hat{q}(\xi,\eta)}{\sigma} \tag{17}$$

denote the normalized quantity. The function $|\hat{f_e}^*(\xi,\eta)|$ is highly oscillatory, and $0 \leq |\hat{f_e}^*| \leq 1$. Since $f_e(x,y)$ is real, its Fourier transform is conjugate symmetric. Therefore, the function $|\hat{f_e}^*(\xi,\eta)|$ is symmetric about the origin on any line through the origin in the (ξ,η) plane. The same is true for the blurred image data $|\hat{g}^*(\xi,\eta)|$.

All blurred images in this and the next section are of size 512×512 and quantized at 8 bits per pixel. For any blurred image $g(x,y)$, the discrete Fourier transform is a 512×512 array of complex numbers, which we again denote by $\hat{g}(\xi,\eta)$ for simplicity. The "frequencies" ξ,η are now integers lying between -256 and 256, and the zero frequency is at the center of the transform array. This ordering is achieved by premultiplying $g(x,y)$ by $(-1)^{x+y}$. We shall be interested in the values of such transforms along single lines through the origin. The discrete transforms $|\hat{g}^*(\xi,0)|$ and $|\hat{g}^*(0,\eta)|$ are immediately available. Image rotation may be used to obtain discrete transforms along other directions. All 1-D Fourier domain plots shown in this paper are taken along the axis $\eta = 0$ in the (ξ,η) plane. In these plots, the zero frequency is at the center of the horizontal axis, and the graphs are necessarily symmetric about the vertical line $\xi = 0$. Examples of such plots are shown in Figures 3, 5, and 10.

The class of blurred images $g(x,y)$ considered in the present paper can be described in terms of the behavior of $\log|\hat{g}^*(\xi,\eta)|$ along lines through the origin in the (ξ,η) plane. While local behavior is highly oscillatory, global behavior is generally monotone decreasing and *convex*. This is shown in Figure 3 for two typical images along the line $\eta = 0$. In [9], a large class of images with that property was exhibited, the class **W**. The blurred images considered here may be loosely characterized as being in class **W**. Not all blurred images may be so characterized. For example, if the Cindy Crawford image $g(x,y)$ in Figure 3(a) were convolved with a wide Gaussian psf to form a new blurred image $g_1(x,y)$, global behavior in $\log|\hat{g_1}^*(\xi,0)|$, away from the origin, would be monotone decreasing and *concave*. Application of the APEX method to several concave examples is discussed in [9]. Convolution of Figure 3(a) with a defocus psf produces a different kind of blurred image $g_2(x,y)$, and global behavior in $\log|\hat{g_2}^*(\xi,0)|$ is neither concave nor convex. Instead, there is a regular pattern of sharp singularities corresponding to successive zeroes of the defocus otf. Use of the APEX method in the manner to be described below is intended only for blurred images with Fourier behavior analogous to that shown in Figure 3.

The APEX method is based on the following observations. In the basic relation

$$g(x,y) = h(x,y) \otimes f_e(x,y) + n(x,y), \tag{18}$$

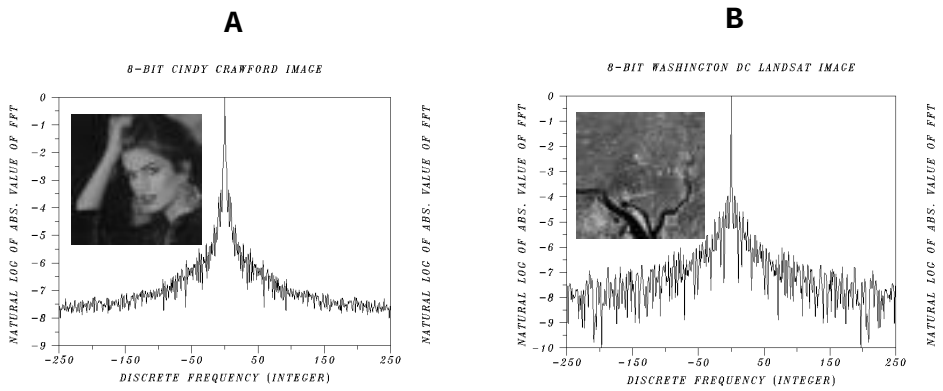

FIG. 3. *Behavior of a normalized Fourier transform in types of blurred images $g(x,y)$ considered in the present paper.* (a) $\log|\hat{g}^*(\xi,0)|$ *in an image of Cindy Crawford.* (b) $\log|\hat{g}^*(\xi,0)|$ *in a Washington, DC Landsat image. While local behavior is highly oscillatory, global behavior is generally monotone decreasing and convex.*

we may safely assume that the noise $n(x,y)$ satisfies

$$\int_{R^2} |n(x,y)|dxdy \ll \int_{R^2} f_e(x,y)dxdy = \sigma > 0, \tag{19}$$

so that

$$|\hat{n}^*(\xi,\eta)| \ll 1. \tag{20}$$

Consider the case in which the otf is a pure Lévy density $\hat{h}(\xi,\eta) = e^{-\alpha(\xi^2+\eta^2)^\beta}$. Since $g = g_e + n$,

$$\log|\hat{g}^*(\xi,\eta)| = \log|e^{-\alpha(\xi^2+\eta^2)^\beta}\hat{f_e}^*(\xi,\eta) + \hat{n}^*(\xi,\eta)|. \tag{21}$$

Let $\Omega = \{(\xi,\eta) \mid \xi^2+\eta^2 \le \omega^2\}$ be a neighborhood of the origin, where

$$e^{-\alpha(\xi^2+\eta^2)^\beta}|\hat{f_e}^*(\xi,\eta)| \gg |\hat{n}^*(\xi,\eta)|. \tag{22}$$

Such an Ω exists since (22) is true for $\xi = \eta = 0$, in view of (20). The radius $\omega > 0$ of Ω decreases as α and n increase. For $(\xi,\eta) \in \Omega$ we have

$$\log|\hat{g}^*(\xi,\eta)| \approx -\alpha(\xi^2+\eta^2)^\beta + \log|\hat{f_e}^*(\xi,\eta)|. \tag{23}$$

Because of the radial symmetry in the psf, it is sufficient to consider (23) along a single line through the origin in the (ξ,η) plane. Choosing the line $\eta = 0$, we have

$$\log|\hat{g}^*(\xi,0)| \approx -\alpha|\xi|^{2\beta} + \log|\hat{f_e}^*(\xi,0)|, \qquad |\xi| \le \omega. \tag{24}$$

Some type of a priori information about $f_e(x,y)$ is necessary for blind deconvolution. In (24), knowledge of $\log|\hat{f_e}^*(\xi,0)|$ on $|\xi| \le \omega$ would immediately yield $\alpha|\xi|^{2\beta}$ on that interval. Moreover, any other line through the origin could have been used in (23). However, such detailed knowledge is unlikely in practice. The APEX method seeks to identify a useful psf from (24) without prior knowledge of $\log|\hat{f_e}^*(\xi,0)|$. The

method assumes instead that $f_e(x,y)$ is a recognizable object, and typically requires several interactive trials before locating a suitable psf. As previously noted, such trial SECB restorations are easily obtained. Here, prior information about $f_e(x,y)$ is disguised in the form of user recognition or rejection of the restored image, and that *constraint* is applied at the end of the reconstruction phase, rather than at the beginning of the detection phase.

In the absence of information about $\log|\hat{f}_e^{\,*}(\xi,0)|$, we replace it by a negative constant $-A$ in (24). For any $A>0$, the approximation

$$\log|\hat{g}^*(\xi,0)| \approx -\alpha|\xi|^{2\beta} - A \tag{25}$$

is not valid near $\xi = 0$, since the curve $u(\xi) = -\alpha|\xi|^{2\beta} - A$ has $-A$ as its apex. Choosing a value of $A>0$, we best fit $\log|\hat{g}^*(\xi,0)|$ with $u(\xi) = -\alpha|\xi|^{2\beta} - A$ on the interval $|\xi| \le \omega$, using nonlinear least squares algorithms. The resulting fit is close only for ξ away from the origin. The returned values for α and β are then used in the SECB deblurring algorithm. Different values of A return different pairs (α,β). Experience indicates that useful values of A generally lie in the interval $2 \le A \le 6$. Increasing the value of A decreases the curvature of $u(\xi)$ at $\xi = 0$, resulting in a larger value of β together with a smaller value of α. A value of $A>0$ that returns $\beta > 1$ is clearly too large, as $\beta > 1$ is impossible for probability density functions [17]. Decreasing A has the opposite effect, producing lower values of β and higher values of α. As a rule, deconvolution is better behaved at lower values of β than it is when $\beta \approx 1$. A significant observation is that *an image blurred with a pair* (α_0,β_0) *can often be successfully deblurred with an appropriate pair* (α,β)*, where* $\alpha > \alpha_0$ *and* $\beta < \beta_0$. Examples of this phenomenon were shown in Figure 1 in connection with the blurred Sydney image. An effective interactive framework for performing the above least squares fitting is the *fit* command in *DATAPLOT* [20]. This is a high-level English-syntax graphics and analysis software package developed at the National Institute of Standards and Technology. This software tool was used throughout this paper.

The following version of the APEX method, using the SECB *marching backwards in time* option (13), has been found useful in a variety of image enhancement problems where the image $g(x,y)$ is such that $\log|\hat{g}^*(\xi,0)|$ is generally globally monotone decreasing and convex, as shown in Figure 3. Choose a value of $A>2$ in (25) such that the least squares fit develops a slight *cusp* at $\xi = 0$. Using the returned pair (α,β) in the SECB method, obtain a sequence $u^\dagger(x,y,t)$ of partial restorations as t decreases from $t=1$, as illustrated in the Cindy Crawford sequence[1] in Figure 4. Often, the initial choice of A results in a psf that is *too wide* in physical space, i.e., wider than the unknown psf that might have blurred the image. Use of that psf all the way to $t=0$ will result in *oversharpening*. Typically, high quality restorations will be found at positive values of t, and these will gradually deteriorate as $t \downarrow 0$. At $t=0$, the restoration may exhibit severe ringing and other undesirable artifacts [9, Figure 13], indicating that continuation backwards in time has proceeded *too far* in (7). Terminating the continuation at some appropriate $t = t_1 > 0$ is equivalent to rescaling the value of α without changing the value of β. If the pair (α,β) produces a high quality restoration at $t = t_1 > 0$, the pair (α_1,β), where $\alpha_1 = (1-t_1)\alpha$, will produce the same quality results at $t=0$. Thus, marching backwards in time is equivalent to simultaneously sampling numerous values of α while keeping β fixed. This process

[1] Given a 512×512 blurred image as input, the APEX procedure computes and displays a time marching sequence of 10 partial restorations in about 10 seconds on an MIPS R12000 (400MHz) workstation.

FIG. 4. *Enhancement of a Cindy Crawford image by marching backwards from $t = 1$ with an APEX-detected psf. Image sequence shows a gradual increase in contrast as t decreases. Undesirable artifacts at $t = 0$ indicate that continuation backwards in time has proceeded too far. Best results are highly subjective in this case, but probably occur at some $t > 0.5$. Note the sharpness of the earrings near $t = 0.5$.*

can be repeated with a different choice of A, resulting in a different value of β. In general, there will be many values of A in (25) returning pairs (α, β) that produce good reconstructions at some $t_{\alpha\beta} > 0$. A large number of distinct pairs (α^*, β^*) can thus be found that produce useful, but distinct, results at $t = 0$. Indeed, this is the process that was used to obtain the four psfs shown in Figure 2.

We have been assuming $\hat{h}(\xi, \eta)$ to be a pure Lévy otf in (18). For more general class **G** otfs (2), we may still use the approximation $\log|\hat{g}^*(\xi, 0)| \approx -\alpha|\xi|^{2\beta} - A$ and apply the same technique to extract a suitable pair (α, β) from the blurred image. Here, the returned APEX values may be considered representative values for the α_i, β_i in (2), producing a single pure Lévy otf approximating the composite otf.

6. Application to real images. The developments in sections 2 through 5 are predicated on two assumptions. The first assumption is that the blurred image $g(x, y)$ obeys the simple convolution equation (3) rather than a more general, possibly nonlinear, integral equation

$$Hf = \int_{R^2} h(x, y, u, v, f(u, v))dudv = g(x, y). \tag{26}$$

In addition to linearity, (3) implies that the blur is isoplanatic. The second assumption is that the point spread function $h(x, y)$ belongs to a restricted class of unimodal, radially symmetric, probability density functions, the class **G** defined in (2). In [9], successful blind deconvolution of *synthetically blurred* images, with added noise, was demonstrated. Such synthetically blurred images necessarily obey (2) and (3).

The applicability of the preceding theory to real blurred images is by no means assured. Deviations from linearity, isoplanatism, unimodality, and radial symmetry

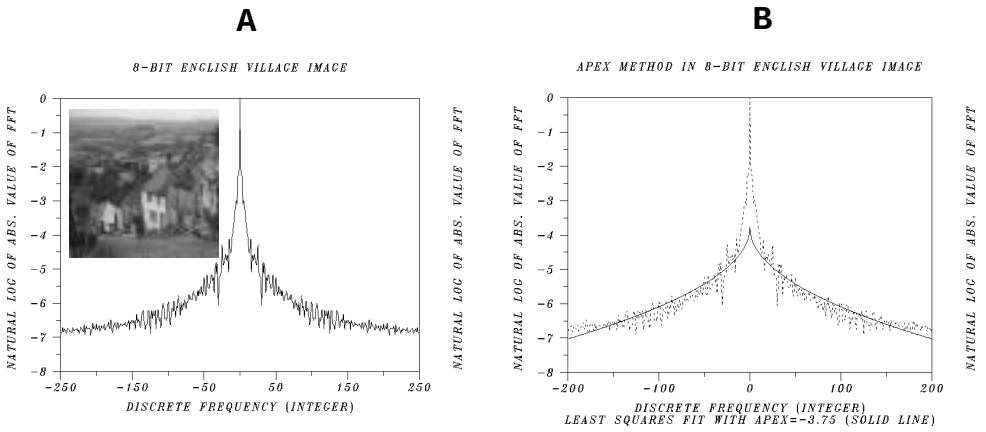

FIG. 5. *The APEX method of psf detection.* (a) $\log|\hat{g}^*(\xi,0)|$ *on* $|\xi| \le 250$ *in the* 8*-bit English village image.* (b) *A least squares fit of* $\log|\hat{g}^*(\xi,0)|$*, with* $u(\xi) = -\alpha\ |\xi|^{2\beta} - 3.75$ *on* $|\xi| \le 200$*, develops a cusp at* $\xi = 0$ *and returns* $\alpha = 0.251274$*,* $\beta = 0.242246$*.*

are possible. Moreover, the class **G** excludes motion and defocus blurs. In addition, the types and intensities of noise processes in real images may differ fundamentally from the noise models typically used in numerical experiments. Therefore, only limited success on a narrow class of images can be expected in real applications.

The examples discussed below involve images obtained from multiple sources using diverse imaging modalities. Some of these images have been used as test images in the literature. In this paper, each of these images is assumed to have been blurred by some unknown process, and we seek to improve visual quality by APEX processing. All images are of size 512×512 and are quantized at 8 bits per pixel.

Our first example is a well-known English village image denoted by $g(x, y)$ and shown in Figure 5(a) together with $\log|\hat{g}^*(\xi,0)|$ on $|\xi| \le 250$. The plot displays globally convex monotone behavior. In Figure 5(b), the APEX fit of $\log|\hat{g}^*(\xi,0)|$ with $u(\xi) = -\alpha|\xi|^{2\beta} - A$ on the interval $|\xi| \le 200$ is shown. With $A = 3.75$, the fit develops a cusp at $\xi = 0$ and returns $\alpha = 0.251274$, $\beta = 0.242246$. With these psf parameters, SECB deblurring using $s = 0.01$, $K = 1300$, and continuation backwards in time terminated at $t = 0.5$ produces Figure 6(b). This is compared with the original in Figure 6(a).

The extent of sharpening in Figure 6(b) becomes evident when zooming in on selected parts of the image. In Figure 7, roof lines on the first three houses are compared before and after APEX processing. There is noticeable enhancement of structural detail in the roof shingles and stone fronts of the three houses in Figure 7(b). In Figure 8(b), Holstein cows grazing in the meadow, not previously identifiable, are clearly visible. So are individual chimney bricks. In Figure 9(b), buildings in the distance, not readily noticed in Figure 9(a), become well defined.

It should be noted that the use of a different value of A, and/or a different neighborhood of the origin Ω in Figure 5(b), may return a different psf pair (α, β). In that case, backwards continuation in the SECB method may need to be terminated at some other value of t to obtain the best image. However, with good choices of A and Ω, the new image would again be a high quality representation of the visual scene in Figure 6(b), while differing from Figure 6(b) at individual pixels. This is

FIG. 6. *Enhancement of the English village image.* (a) *Original* 8*-bit image.* (b) *SECB deblurred image using* $s = 0.01$*,* $K = 1300$*, with APEX-detected values* $\alpha = 0.251274$*,* $\beta = 0.242246$*, and with continuation backwards in time terminated at* $t = 0.5$*.*

the nonuniqueness phenomenon previously discussed in connection with the Sydney image in Figure 1.

Deconvolution of Figure 6(a) with the above APEX-detected psf significantly alters its Fourier transform. As shown in Figure 10(a), the Fourier transform in Figure 6(b) (dashed curve) decays less rapidly as $|\xi|$ increases than was the case in the original Figure 6(a) (solid curve). Evidently, APEX processing amplifies high frequency image components in a stable coherent fashion, resulting in the overall

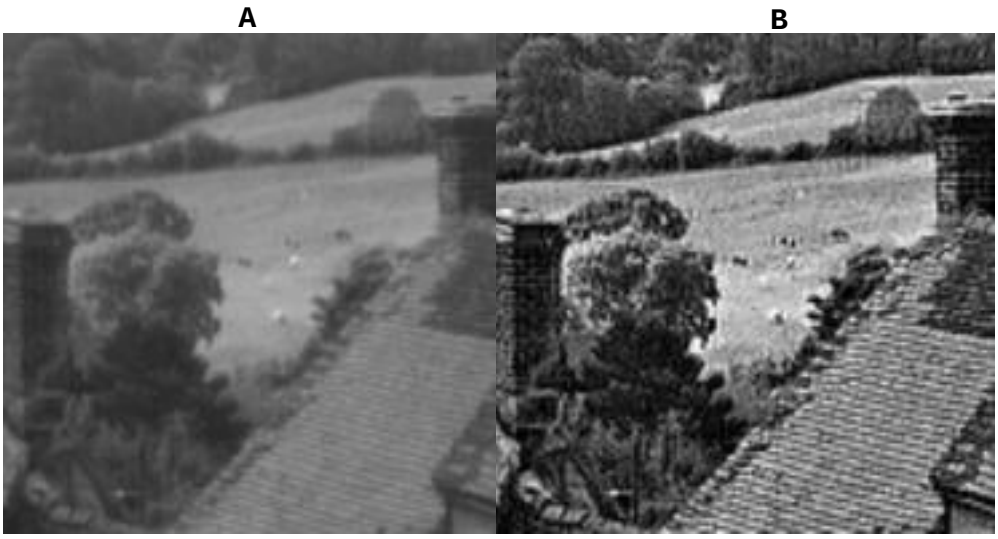

FIG. 8. *Extent of sharpening in the English village scene becomes more evident with zooming. Holstein cows grazing in the meadow in image* (b) *are not readily identifiable in image* (a).

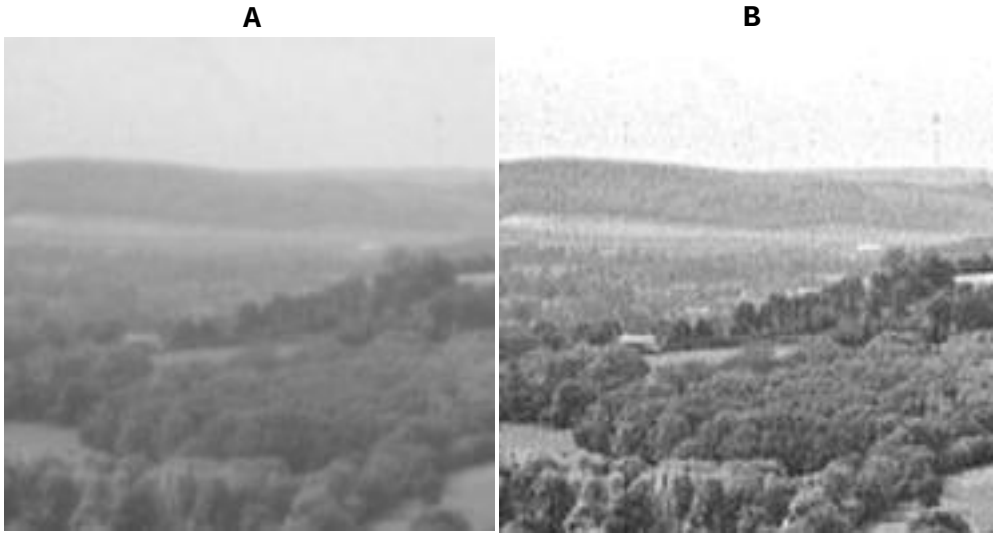

FIG. 9. *Extent of sharpening in the English village image becomes more evident with zooming. The enhanced image* (b) *shows buildings in the distance not immediately apparent in the original image* (a).

improvements visible in Figures 6 through 9. The "before and after" Fourier transform pattern shown in Figure 10(a) occurs in every example discussed in this paper, with the exception of the F15 image in Figure 12; the anomalous behavior in that case is shown in Figure 10(b).

The next example is the boat image in Figure 11(a). With $A = 4.0$, the APEX fit on $|\xi| \leq 250$ returned $\alpha = 0.518155$, $\beta = 0.215083$. Using these values in the SECB method, with $s = 0.01$, $K = 1300$, and continuation terminated at $t = 0.5$, produced

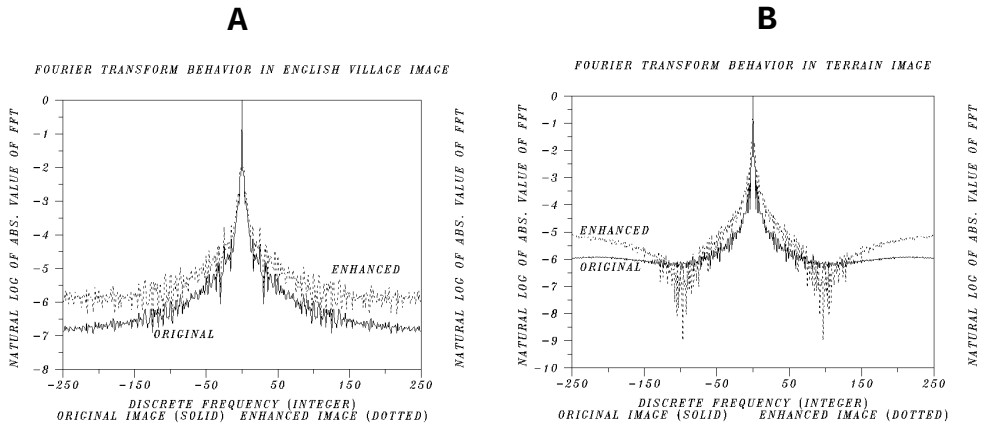

FIG. 10. *APEX processing significantly alters Fourier transform behavior.* (a) *English village image before and after processing.* (b) *F*15 *terrain image in Figure* 12 *before and after processing. The behavior shown in* (b) *is exceptional; all other examples in the present paper conform with the behavior shown in* (a).

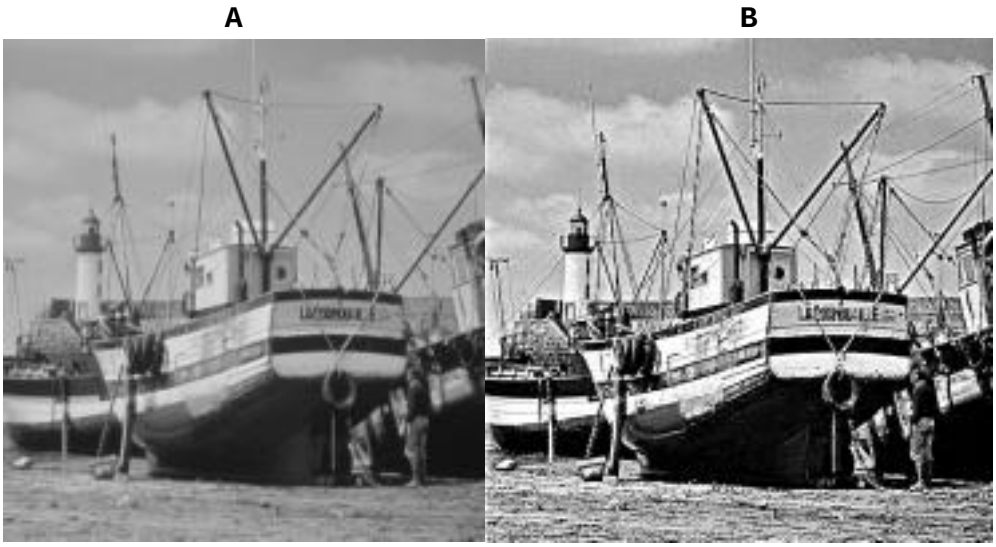

FIG. 11. *Enhancement of the boat image. The APEX method with* $A = 4.0$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.518155$, $\beta = 0.215083$. *Using these parameters, with* $s = 0.01$, $K = 1300$, *and backwards continuation terminated at* $t = 0.5$, *the SECB method applied to image* (a) *produces image* (b). *The number* 7 2 7 *on the side of the boat in image* (b) *was not easily identifiable in image* (a).

Figure 11(b). Enhancement has now rendered visible the number 7 2 7 on the left side of the boat. Other identifiable details include the stripe along the left trouser leg of the man on the ground, the lettering on the sign hanging from the boat to his right, and part of the stone work and stairway to the left of the lighthouse.

The F15 plane image in Figure 12(a) is another interesting example. The aim here is to enhance the background terrain. With $A = 3.5$, the APEX fit on $|\xi| \leq 250$ develops a cusp at $\xi = 0$ and returns $\alpha = 0.856096$, $\beta = 0.107289$. Using these

FIG. 12. *Striking enhancement of terrain features in an F*15 *image. The APEX method with* $A = 3.5$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.856096$, $\beta = 0.107289$. *Using these parameters, with* $s = 0.01$, $K = 1000$, *and backwards continuation terminated at* $t = 0.25$, *the SECB method applied to image* (a) *produced image* (b). *Condensation trails behind the aircraft in image* (b) *were not immediately evident in image* (a).

values in the SECB method, with $s = 0.01$, $K = 1000$, and backwards continuation terminated at $t = 0.25$, produces rather striking enhancement of the ground features in Figure 12(b). This example is noteworthy on two counts: the exceptionally low value of β detected by the APEX method and the previously mentioned unexpected Fourier behavior shown in Figure 10(b).

Beginning with Figure 1, all of the examples discussed so far involve images of familiar objects. This allows for relatively easy evaluation of the results of APEX processing. The next five examples involve less familiar objects. Moreover, fine details visible on a modern high resolution computer screen are sometimes lost in the printing process. Consequently, improvements in image quality in some of the next examples may seem less obvious than in previous examples. At the same time, the performance of the APEX method in reconstructing real details of familiar objects provides a measure of confidence in the results obtained when that method is applied to unfamiliar objects.

Figure 13(a) is a Landsat image of the Washington, DC area. With $A = 4.25$, the APEX fit on $|\xi| \leq 250$ returns $\alpha = 0.540825$, $\beta = 0.182410$. Using these parameters in the SECB method, with $s = 0.01$, $K = 1300$, and continuation terminated at $t = 0.5$, produces Figure 13(b). There is a significant increase in resolution in Figure 13(b), which improves definition of several landmarks and thoroughfares. The Washington Monument, the bridges over the Potomac, Pennsylvania and Maryland Avenues radiating from the Capitol, Massachusetts Avenue to the north, and Virginia Avenue and the Southeast Freeway to the south are some of the features that are more easily identified in the enhanced image.

Figure 14(a) is a scanning electron microscope image of a mosquito's head. A prominent feature is the insect's compound eye. With $A = 4.0$, the APEX fit on $|\xi| \leq 250$ yields $\alpha = 0.734259$, $\beta = 0.156963$. Using these values in the SECB method, with

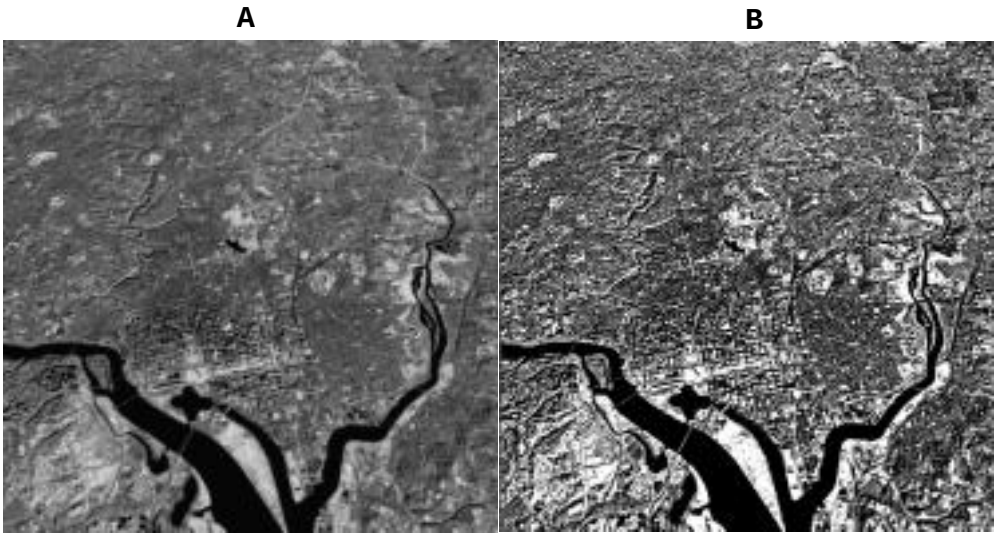

FIG. 13. *Enhancement of a Washington, DC Landsat image. FIG. 14. *Enhancement of a scanning electron microscope image of a mosquito's head showing the compound eye. The APEX method with* $A = 4.0$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.734259$, $\beta = 0.156963$. *Using these parameters, with* $s = 0.001$, $K = 10$, *and backwards continuation terminated at* $t = 0.4$, *the SECB method applied to image* (a) *produced image* (b). *APEX processing enhances contrast and brings the eye into sharper focus. Further applications in electron microscopy are discussed in* [10].

$s = 0.001$, $K = 10.0$, and backwards continuation terminated at $t = 0.4$, produces Figure 14(b). Evidently, APEX processing results in significant overall improvement. In particular, the eye appears in much sharper focus. Further applications to electron

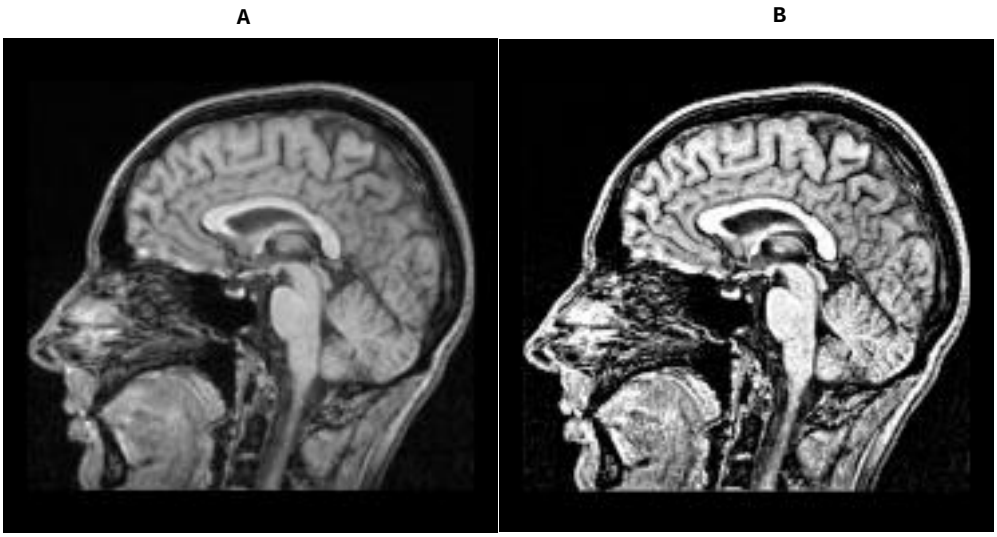

FIG. 15. *Enhancement of a sagittal MRI brain image. The APEX method with* $A = 4.0$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.333267$, $\beta = 0.209416$. *Using these parameters, with* $s = 0.01$, $K = 1300$, *and backwards continuation terminated at* $t = 0.35$, *the SECB procedure applied to image* (a) *produced image* (b). *APEX processing noticeably improves feature definition in areas between two and four o'clock.*

microscopy are discussed in [10].

The sagittal MRI (magnetic resonance imaging) brain image in Figure 15(a) has been used as a test *sharp* image in previous publications. In [5] and [7], synthetically blurred versions of that sharp image were used in a comparative evaluation of restoration algorithms when the psf is *known*. Here, we consider further sharpening the sharp image by blind deconvolution. With $A = 4.0$, the APEX fit on $|\xi| \leq 250$ returns $\alpha = 0.333267$, $\beta = 0.209416$. Using these parameters in the SECB procedure, with $s = 0.01$, $K = 1300$, and continuation terminated at $t = 0.35$, produced the image in Figure 15(b). Substantial improvement is apparent over the whole image. In the sector between two and four o'clock, in particular, sharpening of structural detail significantly improves feature definition.

In PET (positron emission tomography) imaging, a positron emitting radionuclide is injected into the patient and used to tag glucose molecules in their course through the brain. The metabolic rate of glucose is a key parameter that reflects cerebral function and indicates the extent to which regions of the brain are active. Performing specific mental tasks activates various parts of the brain, causing increased glucose uptake and hence increased positron emission. Centers of activity translate into relatively bright spots in the PET image. However, blurring by the scanner psf tends to average out such relative differences, resulting in loss of contrast. Figure 16(a) is a PET image of a transverse (horizontal) slice through the brain. Blind deconvolution is used to enhance that image. With $A = 5.0$, the APEX fit on $|\xi| \leq 250$ returns $\alpha = 0.198931$, $\beta = 0.284449$. Using these parameters in the SECB method, with $s = 0.001$, $K = 5.0$, and backwards continuation terminated at $t = 0.6$, produces Figure 16(b). Note that both images in Figure 16 show identical features, but the contrast has been increased in the APEX-processed image, with some regions becoming darker while others have become lighter. In particular, several bright spots appear

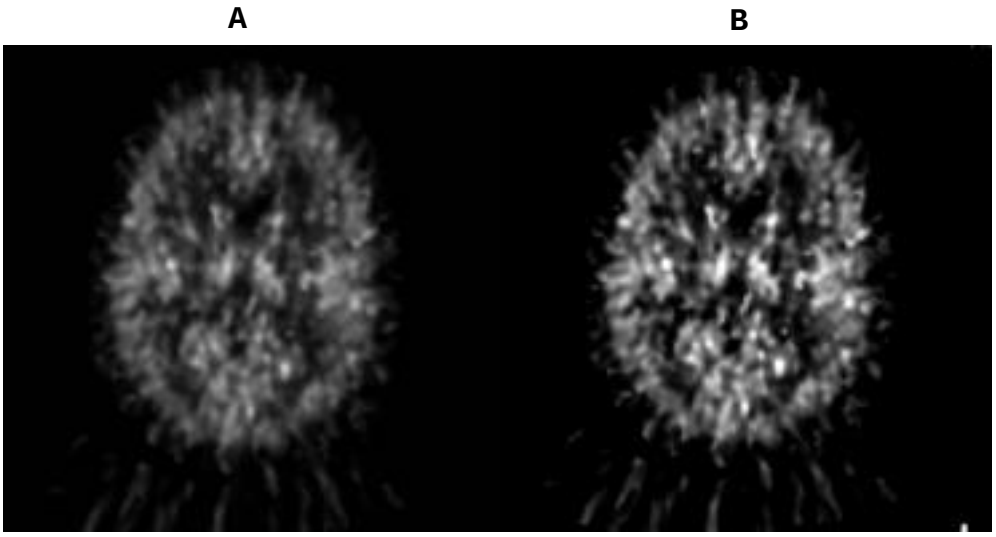

FIG. 16. *Enhancement of a transverse PET brain image. The APEX method with* $A = 5.0$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.198931$, $\beta = 0.284449$. *Using these parameters, with* $s = 0.001$, $K = 5.0$, *and backwards continuation terminated at* $t = 0.6$, *the SECB procedure applied to image* (a) *produced image* (b). *Bright spots in the enhanced image* (b), *indicating areas of the brain responding to applied external stimuli, are more clearly defined than in the original image* (a).

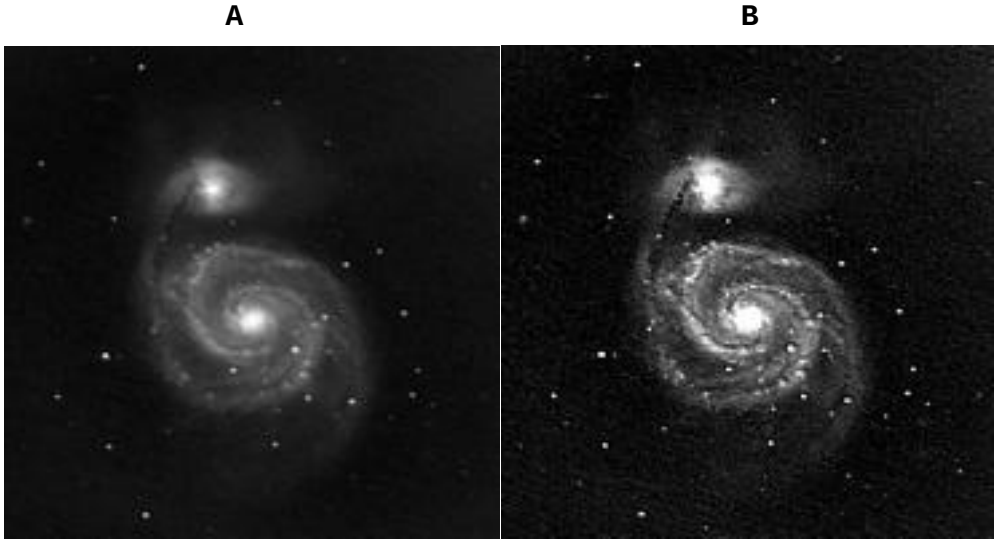

FIG. 17. *Enhancement of the Whirlpool galaxy (M*51*) image. The APEX method with* $A = 4.0$ *on* $|\xi| \leq 250$ *yields* $\alpha = 0.451615$, $\beta = 0.221955$. *Using these parameters, with* $s = 0.001$, $K = 5.0$, *and backwards continuation terminated at* $t = 0.5$, *the SECB applied to image* (a) *produced image* (b). *APEX processing increases resolution and enhances luminosity in the spiral arms and galactic cores.*

in Figure 16(b) that were not as readily apparent in the original image.

Our last example is the Whirlpool galaxy (M51) in Figure 17(a). With $A = 4.0$, the APEX fit on $|\xi| \leq 250$ yields $\alpha = 0.451615$, $\beta = 0.221955$. Using these values in

the SECB method, with $s = 0.001$, $K = 5.0$, and backwards continuation terminated at $t = 0.5$, produced Figure 17(b). In the enhanced image, the spiral arms are more luminous and better defined, and the luminous cores are larger in both the spiral galaxy and its companion. The dark connecting arm between the two galaxies is also more clearly defined. These enhancements are due to a change in Fourier transform behavior brought about by deconvolution with the APEX-detected psf. This change in Fourier behavior is similar to that shown in Figure 10(a), although it is more pronounced. A concomitant effect of deconvolution is amplification of data noise, which now becomes visible against the dark background in Figure 17(b).

Clearly, in this galaxy image as in the preceding PET image, there is no way of knowing whether the enhanced image conforms with reality. Conceivably, the increased luminosity in Figure 17(b) may be exaggerated. However, the bright areas along the galactic arms in Figure 17(b), as well as the bright spots in Figure 16(b), did not materialize spontaneously. These areas must have been just below some brightness threshold in the original image, and APEX processing has served the very useful purpose of revealing their presence. If such areas appear overenhanced, this can be corrected by repeating the SECB procedure and terminating continuation at *higher* values of t.

7. Anisotropic diffusion, total variation deblurring, and the "staircase effect." As is evident from the survey [11], there is considerable interest in the use of anisotropic diffusion equations to perform various tasks in image processing. In pure denoising applications, such methods have been found to be effective at removing high levels of noise while preserving edges in an image. An important related idea is the use of the *total variation* norm for regularizing the image restoration problem [12], [13], [16], [33], [37], [38]. The Euler–Lagrange problem for minimizing the total variation can be written as a nonlinear anisotropic diffusion equation, with a forcing term that describes convolution of the unknown image with the known psf. This is supplemented by homogeneous Neumann boundary conditions together with the blurred image as initial data; see [33]. Deblurring the image is equivalent to stepwise numerical computation of this nonlinear initial value problem until a steady state is reached.

Total variation deblurring is especially useful for recovering "blocky" images, i.e., images that are nearly piecewise constant and have many edges [12], [16]. For this reason, the total variation blind deconvolution approach in [13] aims primarily at recovering blocky images that had been blurred by psfs with *sharp edges*. This is the case with defocus and motion blurs; a defocused satellite image is the example used in [13]. The authors observe that their algorithm is more effective on defocused images than it is on Gaussian blurred images. In a complementary role, the APEX method can also handle blocky images, but it is based on detecting class **G** blurs, a class that includes heavy-tailed psfs but excludes defocus and motion blurs.

A major drawback of the total variation approach is the so-called "staircase effect," whereby the deblurred image can develop spurious piecewise constant regions. This often produces an "oil painting" appearance that does not correspond to the true image and prevents identification of fine detail. For this reason, the authors in [12] and [16] conclude that total variation deblurring is not useful for images that are not nearly piecewise constant. In [34], [35], it is proved that total variation restoration necessarily leads to the staircase effect. In [19], the mathematical premise of minimizing image total variation is questioned, and the authors prove that because of their fine texture, most natural images are *not* of bounded variation. Therefore, in images

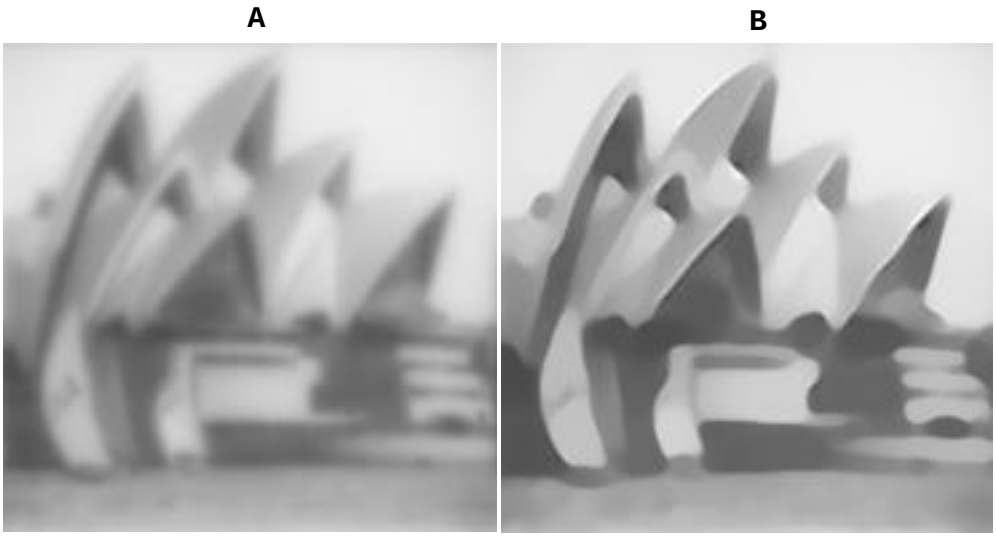

FIG. 18. *Staircase effect in total variation deblurring of the Sydney image.* (a) *Synthetically blurred* 512×512 *Sydney image, previously used in Figure* 1(b)*, was computed in* 64*-bit precision.* (b) *Deblurring of image* (a) *using the known psf and the total variation scheme in* [33]*, with noise variance parameter* $\beta^{\Sigma} = 0.001$*, Lagrange multiplier* $\lambda = 50$*, CFL restriction* $\Delta t = 0.1(\Delta x)^2$*, and stepwise integration to time* $T = 100\Delta t$*. The strong "oil painting" effect in image* (b) *impairs recognition and occurs with other choices of* $\beta^{\Sigma} \leq 0.001$ *and* $\lambda \geq 50$*. Compare with the SECB deblurred image in Figure* 1(c).

with fine texture, total variation deblurring must inevitably smooth out texture.

The following example illustrates why total variation deblurring is typically not useful for the type of textured imagery considered in this paper. The blurred noiseless 512×512 Sydney image, previously used in Figure 1(b), was deblurred using the total variation scheme described in [33, section 5]. This is a pure deblurring problem in which the synthetically blurred input image, Figure 18(a), was computed in 64-bit precision. Moreover, the precisely known psf was used. The aim here is to evaluate the reconstructive ability of the total variation scheme under the most favorable circumstances. As recommended in [33], in this noiseless case the noise variance parameter β^{Σ} should be chosen small, while the Lagrange multiplier λ should be chosen large. Here, several values of β^{Σ} in the range $0.00001 \leq \beta^{\Sigma} \leq 0.01$ were tried, together with several values of λ in the range $1 \leq \lambda \leq 100$. The CFL restriction $\Delta t = 0.1(\Delta x)^2$ was applied with all these choices, and no sign of computational instability was detected. Figure 18(b) is the result of stepwise numerical computation of the nonlinear diffusion problem in [33, section 5] up to time $T = 100\Delta t$, using $\beta^{\Sigma} = 0.001$ and $\lambda = 50$. The "oil painting" effect in Figure 18(b) occurs with other choices of $\beta^{\Sigma} \leq 0.001$ and $\lambda \geq 50$, and the deblurred image does not improve if more time steps are taken. SECB deblurring of the same image is shown in Figure 1(c). In the presence of noise, the SECB deblurred image is less sharp, but maintains its strong qualitative edge over Figure 18(b). It should be noted that the authors in [33] did not intend their scheme to be used for images as seriously blurred as Figure 18(a). However, the staircase effect is still pronounced, even with more mildly blurred images.

8. Concluding remarks. Setting aside all theoretical considerations, APEX processing is a practical enhancement technique that can sharpen significant classes

of images originating from diverse imaging modalities. One important feature of this approach is its fast implementation on desktop platforms. Even with large image sizes, numerous trial restorations can be accomplished in seconds or minutes of cpu time. This makes for easy fine tuning of parameters and a quick determination of whether the APEX method significantly improves a given image. Once improvement is detected, fine tuning must be used to obtain optimal results. Here, another important feature of the APEX method plays a useful role. This is the marching-backwards-in-time option characteristic of class **G** psfs, which allows for deconvolution to be performed in *slow motion*. Robustness is a third important property of the APEX method, allowing detection of multiple psfs capable of significant sharpening. This substantially increases the probability of finding a useful candidate.

On the theoretical side, this paper raises new questions. The first of these is the existence of several useful psfs, as demonstrated for the Sydney image in Figure 1. This phenomenon warrants further investigation. A second question concerns the important role Lévy psfs appear to play in numerous imaging systems. The discussion in section 2 has surveyed *inferences* of stable laws that have been made from mtf measurements. Development of methods of analyzing imaging systems that can rigorously establish such laws, and predict the Lévy exponent β, would be a major advance.

Reconciling the results of section 2 with the behavior of large classes of images raises additional questions. Electronic imaging psfs $h(x,y)$ are found to have Lévy exponents $\beta > 0.5$ in most cases, so that $\log \hat{h}(\xi,0) = -\alpha|\xi|^{2\beta}$ is a monotone decreasing concave function on $\xi > 0$. However, as illustrated in Figure 3, all images $g(x,y)$ used in this paper are such that global behavior in $\log|\hat{g}^*(\xi,0)|$ is generally monotone decreasing and *convex*. Another large class of images with this convexity property, the class **W**, was described in [9]. When such images are APEX-fitted with a Lévy psf in the manner shown in Figure 5(b), a value of $\beta \leq 0.5$ is inevitably detected. An average value of $\beta = 0.23$ was found for the six images in Figures 4, 6, 11, 15, 16, and 17, and significantly lower values were found for the three images in Figures 12, 13, and 14. A possible partial explanation for this discrepancy is provided by the Sydney experiment in Figure 1. There, the APEX method detected several useful psfs with values of β *smaller* than the value that was used to blur the image. The detected β-values in the above nine images may likewise underestimate the true imaging system β-values. An entirely different scenario may be that the APEX method provides generic low exponent Lévy psfs capable of enhancing a wide variety of images, independently of the imaging physics that created them. Other generic enhancement techniques have been used for some time in image processing (see [36, Chapter 10]). More recent approaches based on nonlinear diffusion equations are also intended as generic enhancement methods [11]. However, nonlinear methods generally require large numbers of iterations and may not be well suited for real-time processing of complex high resolution imagery.

Whatever may be the reasons behind it, the effectiveness of the APEX method on many types of images is undeniable, and the method is a useful addition to the image processing toolbox.

PULSE PROPAGATION IN DISCRETE SYSTEMS OF COUPLED EXCITABLE CELLS*

A. CARPIO† AND L. L. BONILLA‡

Abstract. Propagation of pulses in myelinated fibers may be described by appropriate solutions of spatially discrete FitzHugh–Nagumo systems. In these systems, propagation failure may occur if either the coupling between nodes is not strong enough or the recovery is too fast. We give an asymptotic construction of pulses for spatially discrete FitzHugh–Nagumo systems, which agrees well with numerical simulations, and discuss the evolution of initial data into pulses and pulse generation at a boundary. Formulas for the speed and length of pulses are also obtained.

Key words. discrete reaction-diffusion equations, traveling wave pulses, propagation failure, spatially discrete FitzHugh–Nagumo system

1. Introduction.

Effects of spatial discreteness are important in many physical and biological systems comprising interacting smaller components such as atoms, quantum wells, cells, etc. Examples include the motion of dislocations [13], crystal growth and interface motion in crystalline materials [6], the motion of domain walls in semiconductor superlattices [4, 8], sliding of charge density waves [14], and pulse propagation through myelinated nerves [2]. The mathematical study of spatially discrete models is challenging because of special and poorly understood phenomena occurring in them that are absent if the continuum limit of these models is taken. Paramount among these phenomena is the pinning or propagation failure of wave fronts in spatially discrete equations. Physically, the pinning of wave fronts is related to the existence of Peierls stresses in continuum mechanics [17], relocation of electric field domains [1] and self-sustained oscillations of the current in semiconductor superlattices [18, 4], electric current due to the sliding of charge density waves [14], saltatory propagation of impulses in myelinated fibers and its failure [2], etc.

Mathematical understanding of the propagation failure of wave fronts in spatially discrete equations experienced significant progress after a paper by Keener [20]. In [20], Keener used comparison principles to characterize the pinning of wave fronts and their motion for spatially discrete reaction-diffusion equations of the form

$$u_{n,t} = d(u_{n+1} - 2u_n + u_{n-1}) + f(u_n), \tag{1.1}$$

where f is a bistable source term and d measures the strength of the coupling. Models described by (1.1) include the spatially discrete Nagumo equation for nerve conduction

[12, 26] or crystal growth [6], and the Frenkel–Kontorova model for motion of dislocations [13]. More recently, a number of results on the existence of traveling wave fronts $u_n(t) = v(n - ct)$ with smooth profiles v have been established [31, 24, 10]. These papers do not precisely characterize the propagation failure of a wave front for critical values of the control parameters. For a piecewise linear source function, an explicit description has been given by Fáth, extensively using the properties of special functions [11]. In the general case, we have found that propagation failure can be explained as a loss of continuity of the wave front profile in critical values of the control parameter [7]. Furthermore, the smoothness of the wave front profile just before the propagation failure occurs can be exploited to obtain an analytical description of wave fronts and their speed near critical parameter values [7, 9]. This theory has been extended to spatially discrete reaction-diffusion-convection equations describing dynamics of domain walls in semiconductor superlattices [8].

These advances in the mathematical understanding of propagation phenomena have occurred for spatially discrete scalar reaction-diffusion equations. Similar phenomena occur in models of calcium release at discrete sites [22]. The latter consist of scalar reaction-diffusion equations with spatially inhomogeneous source terms that are close to $f(u)$ times a series of delta functions centered at spatially periodic sites. Comparatively little progress has been made in understanding wave propagation and failure in spatially discrete systems. Anderson and Sleeman [2] have extended Keener's techniques to discrete reaction-diffusion systems modelled by the FitzHugh–Nagumo (FHN) dynamics [12, 26]. Hastings and Chen [16] have proved the existence of pulse traveling waves for a myelinated nerve model with a Morris–Lecar type of dynamics. They also comment on the difficulties of extending their results to the FHN system. An attempt to understand the mechanisms of propagation failure in the FHN system has been carried out by Booth and Erneux [5]. They consider slow recovery and very special limiting (small) values of the parameters characterizing the bistable source and the spatial diffusivity in the FHN system. Furthermore, they also impose particular boundary and initial conditions. With these restrictions, they could study how a specific disturbance localized in one cell propagated to neighboring ones until the resulting front failed to propagate. No construction of pulses or formulas for their velocity were given.

In this paper, we asymptotically construct pulse solutions of the spatially discrete FHN system describing nerve conduction through myelinated fibers. We also discuss how the pulses may fail to propagate. Our ideas could be extended to spatially discrete systems whose cell dynamics contain widely separated time scales corresponding to fast excitation and slow recovery variables. Among these systems, let us cite models for bursting behavior in pancreatic β cells [30] or the much more difficult case of front propagation in voltage-biased semiconductor superlattices [4]. In the latter, a separation of time scales exists, but it is not obviously included as a small parameter in the equations. In our presentation, we have chosen the FHN dynamics for its simplicity. This model has been widely used to understand issues that are obscured by technical complications in more realistic models of nerve conduction. We consider the following system of dimensionless equations:

$$\epsilon \frac{du_n}{dt} = d\,(u_{n+1} - 2u_n + u_{n-1}) + Au_n(2 - u_n)(u_n - a) - v_n, \tag{1.2}$$

$$\frac{dv_n}{dt} = u_n - Bv_n, \tag{1.3}$$

$n = 0, \pm 1, \ldots$. Here u_n and v_n are the membrane potential and the recovery variable

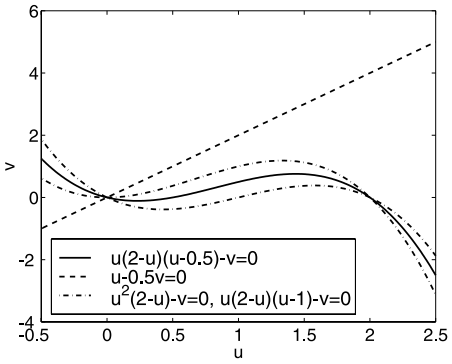

FIG. 1.1. *Nullclines for the space-independent FHN model with different values of a.*

(which acts as an outward ion current) at the nth excitable membrane site (node of Ranvier). The cubic source term is an ionic current, and the discrete diffusive term is proportional to the difference in internodal currents through a given site. The constants A and B are selected so that the source terms in the FHN system are $O(1)$ for u_n and v_n of order 1, that the only stationary uniform solution is $u_n = 0 = v_n$, and that the FHN system has excitable dynamics ($A = 1$, $B = 0.5$ is a good choice; see Figure 1.1). The constant $\epsilon > 0$ is the ratio between the characteristic time scales of both variables. We assume $\epsilon \ll 1$, that is, fast excitation and slow recovery. A dimensional version of (1.2) and (1.3) was derived in the appendix of [3] from an equivalent-circuit model of myelinated nerves. For background on similar models, see [28, 29, 21, 25].

We shall study pulse propagation in the spatially discrete FHN system (1.2) and (1.3) by asymptotic methods. At first sight, such a task is hopeless: asymptotic methods require a degree of smoothness at appropriate time or length scales, and the spatial variable n in these systems is discrete. However, we can use the separation between time scales in the FHN system to show that a pulse is made out of two "sharp" wave fronts separating regions of slow spatial variation. Wave fronts are *smooth* solutions of the *continuous* variable $z = n - ct/\epsilon$, and perturbative arguments apply straightforwardly to them. Thus the theory of wave front propagation for spatially discrete scalar reaction-diffusion equations plays an important role in our construction of pulses.

Let $U_1 < U_2 < U_3$ denote the three zeros of the cubic nonlinearity $f(u)$ in (1.1). U_1 and U_3 are stable solutions for $d = 0$. A wave front is a solution of (1.1) with a smooth profile $u_n(t) = u(n - ct)$ moving at a speed c such that $u(\mp\infty) = U_1$ and $u(\pm\infty) = U_3$. If $f(u)$ is odd about $u = U_2$ and d is sufficiently small, a stationary solution of (1.1) exists and therefore no wave fronts can propagate (see [10]). As the source term departs from this symmetric form, front propagation is made easier. In [7], we selected $d = 1$ and $f(u) = F - Ag(u)$, where $g(u)$ is odd about its middle zero and F is an external force that quantifies departure from symmetry. Notice that we can obtain (1.1) with $d = 1/A$ and $f = (F/A) - g(u)$ after rescaling time. We found that wave fronts propagate for $|F| > F_c$, where $F_c > 0$ depends on A and the specific $g(u)$ that we adopt. Equivalently, we could set $f(u) = -u(u-a)(u-2)$ and use $a - 1$ as a control parameter instead of F. After the "external force" a surpasses a critical value sufficiently far from the symmetry point $a = 1$, stationary fronts may cease to exist and propagating wave fronts may appear. See Figure 1.2(a). Notice that the limiting

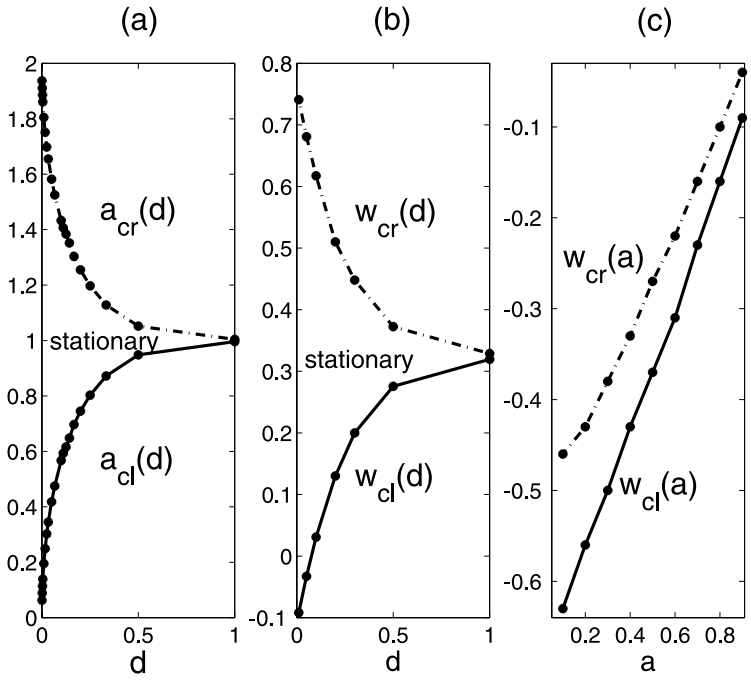

FIG. 1.2. (a) *Critical values* a_{cl} *and* a_{cr} *as functions of* d. (b) *Critical* $w_{cl}(a,d)$ *and* $w_{cr}(a,d)$ *for* $a = 0.5$. (c) *Critical* $w_{cl}(a,d)$ *and* $w_{cr}(a,d)$ *for* $d = 0.5$.

case considered by Booth and Erneux ("slow capture near a limit point"), $d = O(a^2)$, $a \to 0+$, corresponds to the parameter region in the lowest corner in this figure. In this region, propagation failure is the normal situation. We could, alternatively, fix a and set $f(u) = -w - u(u-a)(u-2)$, using w as the control parameter. Then there are critical values $w_{cl}(a,d)$ and $w_{cr}(a,d)$ such that wave fronts fail to propagate if $w_{cl} < w < w_{cr}$; see Figure 1.2(b). How does the parameter a affect the critical values of w? Assume that $a < a_{cl}(d)$ for a fixed value of d, so that wave fronts propagate for $w = 0$. To compensate for this effect, we need a small critical value $w_{cl}(a,d)$ of the parameter w. As a departs more and more from $a_{cl}(d)$, larger and larger critical values $w_{cl}(a,d)$ are needed to return to the situation of propagation failure. A similar situation occurs with $w_{cr}(a,d)$. Thus the critical values of w increase (in absolute value) as $|a - a_c|$ increases; see Figure 1.2(c). The effect of increasing the diffusivity d is to shrink the parameter range in which stationary fronts exist. In fact, as $d \to \infty$ (the continuum limit), the width of the pinning interval is conjectured to decrease exponentially quickly to zero for certain nonlinearities [6, 23]. Propagation failure can be understood as a loss of continuity of the moving front as appropriate critical parameter values are approached. Increasing the discrete diffusivity and deforming the source term sufficiently far from odd symmetry about its middle zero both facilitate the propagation of wave fronts [7, 9]. Reciprocally, weakening the coupling between cells and diminishing the "external force" $a - 1$ helps induce propagation failure.

For the spatially discrete FHN system, the description of wave propagation is more complicated. This also happens for the spatially continuous FHN system ($D\,\partial^2 u/\partial x^2$ instead of discrete diffusion). Depending on the initial condition, stable wave trains or pulses may be approached as time elapses [27, 15, 19]. Pulses cannot be obtained

for ϵ larger than a critical value. For discrete diffusion, we can construct pulses, provided that ϵ is smaller than a critical value $\epsilon_c(a, d)$, a is outside a certain interval (corresponding to propagation failure in the scalar case), and the initial condition is chosen appropriately. Our construction combines the theory of front depinning developed in [7] with Keener's asymptotic ideas [19] developed for the FHN model with spatially continuous diffusion. Our results agree very well with direct numerical solutions of (1.2) and (1.3).

The key ideas of an asymptotic theory for (1.2) and (1.3) in the limit as $\epsilon \to 0$ are simple. First, pulses consist of regions in which $u_n(t)$ vary smoothly with n, separated by moving sharp interfaces (fronts). In the first type of region, we may set $\epsilon = d = 0$ and obtain a description of slow recovery. The sharp interfaces are wave fronts with *smooth profiles*, $u_n(t) = u(z)$, $v_n(t) = v(z)$, with $z = n - ct/\epsilon$. Then v is constant at each side of a front, and the excitation variable u obeys the spatially discrete Nagumo equation, whose fronts we can characterize [7, 9]. A stable pulse is obtained when the velocity of the leading front is equal to that of the trailing front [19]. This condition fixes the pulse width. Its violation or propagation failure of any of the fronts bounding the pulse result in propagation failure thereof. Notice that we use an analytic expression for the wave front velocity of the Nagumo equation, valid as a is near its critical value for propagation failure. For small values of d, the front propagation range is narrow, and the formula for wave front velocity holds for all appropriate values of a; see Figure 1.2(a). For larger values of d, the interval where propagation occurs is wide, and we can use our approximation only for a close to its critical values a_{cl} and a_{cr}. Outside these parameter ranges, the velocity of the Nagumo wave fronts should be calculated numerically.

The rest of the paper is organized as follows. In section 2, we recall certain needed results on wave front propagation and failure for the spatially discrete scalar reaction-diffusion (Nagumo) equation. Section 3 contains the main theoretical ideas of this paper, with the asymptotic construction of pulses for the discrete FHN system. These ideas and our results are tested by numerically solving the FHN system with appropriate boundary conditions in section 4. Comments on propagation failure of pulses in the FHN system are made in section 5. Section 6 briefly discusses how a pulse may be generated by applying a temporary stimulus at one end of a fiber with finitely many nodes. The last section contains our conclusions.

2. The spatially discrete Nagumo equation. We consider the equation

$$\frac{du_n}{ds} = d\,(u_{n+1} - 2u_n + u_{n-1}) + u_n(2 - u_n)(u_n - a) - w \tag{2.1}$$

for some constant w and denote $h(u, w, a) = u(2 - u)(u - a) - w$. As long as $\min h(u, 0, a) < w < \max h(u, a, w)$, this is a "cubic" source having three zeroes $U_i(w, a)$, $i = 1, 2, 3$, $U_1 < U_2 < U_3$. Wave front solutions joining U_1 and U_3 (the two stable zeros) exist. A theory of the pinning and propagation of fronts for this type of equation has been developed in [7, 8]. We sketch its implications for (2.1) below.

First assume $w = 0$, so that the asymmetry of the source is controlled by the parameter a. For d fixed, there are values $a_{cl}(d)$ and $a_{cr}(d)$ such that the following hold:

- The fronts joining $u = 0$ and $u = 2$ are stationary if $a_{cl}(d) \le a \le a_{cr}(d)$. No front propagation is possible.
- Outside this interval, there exist traveling wave fronts $u_n(s) = u(n - cs)$ joining 0 and 2. For $a > a_{cr}(d)$, increasing fronts move to the right and de-

creasing fronts move to the left. For $a < a_{cl}(d)$, fronts move in the opposite way: decreasing fronts move to the right and increasing fronts move to the left. The values $a_{cl}(d)$ and $a_{cr}(d)$ can be approximately calculated as follows. In a large lattice, we decrease or increase a from 1 until we obtain a stationary solution $u_n(a)$ whose linear stability problem has a zero eigenvalue; see Figure 1.2.

Now we fix a and vary w. The asymmetry of the source is controlled by a and w. For fixed d and a, critical values $w_{cl}(a,d)$ and $w_{cr}(a,d)$ are found such that the following hold:

- The fronts joining $U_1(w,a)$ and $U_3(w,a)$ are stationary if $w_{cl}(a,d) \le w \le w_{cr}(a,d)$.
- Outside this interval, there exist traveling wave fronts $u_n(s) = u(n - cs)$ joining $U_1(w,a)$ and $U_3(w,a)$. For $w < w_{cl}$, these fronts move to the left if they increase from U_1 to U_3, and to the right if they decrease from U_3 to U_1. For $w > w_{cr}$, fronts decreasing from U_3 to U_1 move to the left, and increasing fronts move to the right.

To calculate w_{cl} and w_{cr}, we start by fixing a and finding a value $w = w_0$ at which stationary solutions exist for a large lattice. We now decrease or increase w from this value until we obtain a stationary solution $u_n(w)$ whose linear stability problem has a zero eigenvalue; see Figure 1.2.

For w near any of its critical values, we can use the following formula to predict the speed of the fronts for $|w| > |w_c|$:

$$c(a,d,w) \sim \operatorname{sign}(w - w_c)\frac{\sqrt{\alpha\beta(w - w_c)}}{\pi}. \tag{2.2}$$

The parameters α and β, given by $\alpha = \sum \phi_n$, $\beta = \frac{1}{2}\sum[-6u_n(w_c) + 2(2+a)]\phi_n^3$ (see [7, 9]), are functions of a, d, and the critical value of w. In these formulas, ϕ is a positive eigenfunction of the linear stability problem for $u_n(w_c)$ with $\sum \phi_n^2 = 1$, and $u_n(w_c)$ is a stationary solution of (2.1) with $w = w_c$ [9]. If w is not close to its critical values, the speed $c(a,d,w)$ should be calculated numerically.

A peculiarity of the Nagumo equation is the scenario for front propagation failure. As we approach the critical values for a, w, or any other appropriate pinning control parameter, the front profiles become less smooth and a number of steps appear. In the limit as the control parameter tends to its critical value, the transition regions between steps become infinitely steep, the front profile becomes discontinuous, and its velocity vanishes [7, 9].

3. Asymptotic construction of pulses. As we will discuss below, an appropriate initial condition evolves towards a pulse. In particular, we need to fix the parameters $d > 0$, $a < a_{cl}(d)$ (the case $a > a_{cr}(d)$ follows by symmetry), and ϵ smaller than a certain critical value, $\epsilon_c(a,d)$. This last condition also holds for the spatially continuous FHN system, which has two pulse solutions (one stable and one unstable) for $\epsilon < \epsilon_c$. These solutions coalesce at ϵ_c and cease to exist for larger ϵ (see [26, 27]). A pulse consists of regions of smooth variation of u on the time scale t, separated by sharp interfaces in which u varies rapidly on the time scale $T = t/\epsilon$. In the regions where u varies smoothly, we can set $\epsilon = d = 0$, thereby obtaining the reduced problem

$$u_n(2 - u_n)(a - u_n) - v_n = 0, \tag{3.1}$$

$$\frac{dv_n}{dt} = u_n - B\,v_n. \tag{3.2}$$

These regions are separated by sharp interfaces (moving fronts), at which u_n varies rapidly as $u_n(t) = u(z)$, $v_n(t) = v(z)$, with $z = n - ct/\epsilon$. There, to leading order,

$$-c\frac{du}{dz} = d\left[u(z+1) - 2u(z) + u(z-1)\right] + u(z)\left(2 - u(z)\right)\left(a - u(z)\right) - v, \tag{3.3}$$

$$-c\frac{dv}{dz} = 0. \tag{3.4}$$

Thus v is a constant equal to the value $v_n(t)$ at the last point in the region of smooth variation before the front. Equation (3.3) has a wave front solution as discussed in the previous section. We can now discuss different regions in the asymptotic description of a pulse as follows:

1. The region of smooth variation of u in front of the pulse, described by (3.1) and (3.2). In this region, $u_n = U_1(v_n)$, so that
$$\frac{dv_n}{dt} = U_1(v_n) - B\,v_n,$$
and initial data evolve exponentially fast towards equilibrium, $u_n = v_n = 0$.
2. The pulse leading edge. Let $v(t)$ be the value of v_n at the last point of the region in front of the pulse. Eventually, $v \to 0$. At the leading edge, $u_n(t) = u(n - ct/\epsilon)$ is a wave front moving towards the right with speed $C = c(a, d, v)/\epsilon$ measured in points per unit time t. We have the boundary conditions $u(-\infty) = U_3(v)$ and $u(\infty) = U_1(v)$ for the monotone decreasing profile $u(z)$ which satisfies (3.3). It is convenient to call $c_-(v) = c(a, d, v)$. Eventually, $C \sim c_-(0)/\epsilon$, and u_n decreases from $u_n = 2$ to $u_n = 0$ across the leading edge of the pulse.
3. The region between fronts: $u_n = U_3(v_n)$ and
$$\frac{dv_n}{dt} = U_3(v_n) - B\,v_n.$$
There is a finite number of points in this region. On its far right, $v_n = v \to 0$. As we move towards the left, v_n increases until it reaches a certain value $V(t)$ corresponding to that in the trailing wave front.
4. The trailing wave front: $v_n(t) = v(z) = V$, and $u_n(t) = u(z)$ obeys (3.3) with boundary conditions $u(-\infty) = U_1(V)$ and $u(\infty) = U_3(V)$. This front increases monotonically with z, and it moves with speed $C = c(a, d, V)/\epsilon$ measured in points per unit time t. It is convenient to denote $c_+(V) = c(a, d, V)$. We shall indicate how to determine V below. Clearly, if the pulse is to move rigidly, we should have $c_+(V) = c_-(0)$ after a sufficiently long transient period.
5. Pulse tail. Again $u_n = U_1(v_n)$ and $dv_n/dt = U_1(v_n) - Bv_n$. Sufficiently far to the left, $v_n = u_n = 0$.

The number of points between wave fronts of the pulse is not arbitrary: it can be calculated following an argument due to Keener for the spatially continuous case [19]. Let τ be the delay between fronts, i.e., the time elapsed from the instant at which the leading front traverses the point $n = N$ to the instant when the trailing front is at $n = N$. Clearly,

$$\tau = \int_{v(t-\tau)}^{V(t)} \frac{dv}{U_3(v) - Bv}\,. \tag{3.5}$$

The number of points between fronts, $l(t)$, can be calculated as

$$l = \frac{1}{\epsilon} \int_{t-\tau}^{t} c_-(v(t))\, dt. \tag{3.6}$$

On the other hand, the separation between fronts satisfies the equation

$$\frac{dl}{dt} = \frac{c_-(v(t)) - c_+(V(t))}{\epsilon}\,. \tag{3.7}$$

The three equations (3.5), (3.6), and (3.7) can be solved to obtain the three unknowns τ, l, and $V(t)$. (The function $v(t)$ is determined by solving (3.2) with $u_n = U_1(v_n)$ in the region to the left of the leading front.)

After a transient period, $v(t) \to 0$ and $V(t) \to V$ (a constant value), so that we have the simpler expressions

$$\tau = \int_0^V \frac{dv}{U_3(v) - Bv}\,, \tag{3.8}$$

$$\frac{dl}{dt} = \frac{c_-(0) - c_+(V)}{\epsilon}\,, \tag{3.9}$$

instead of (3.5) and (3.7), respectively. The number of points at the pulse top is now

$$l = \frac{c_-(0)\tau}{\epsilon} = \frac{c_-(0)}{\epsilon} \int_0^V \frac{dv}{U_3(v) - Bv}\,. \tag{3.10}$$

This equation yields V as a function of l. Then (3.9) becomes an autonomous differential equation for l that has a stable constant solution at $l = l^*$ such that $c_-(0) = c_+(V(l))$: at $l = l^*$, the right-hand side of (3.9) has a slope $-[U_3(V) - BV]\, c_+'(V)/c_-(0) < 0$.

Recapitulating, for appropriate initial conditions, the leading and trailing fronts of a pulse evolve until l reaches its stable value at which $c_-(0) = c_+(V(l^*))$ and (3.10) holds. To compute l^*, we first determine $V^* = V(l^*)$ by using $c_-(0) = c_+(V(l^*))$. Then we calculate $\tau = \tau^*$ (which does not depend on ϵ!) from (3.8) and $l^* = c_-(0)\tau^*/\epsilon$. Our construction breaks down if the number of points between fronts falls below 1. This yields an upper bound for the critical value of ϵ above which pulse propagation fails: $\epsilon_c \sim c_-(0)\tau^*$.

The asymptotic length of the pulse tail is obtained by first calculating the time needed for v_n to go from 0 to $V(l^*)$ to the left of the trailing front: $T = \int_0^V dv/[U_1(v) - v]$. The tail length is then $L = c_-(0)T/\epsilon$.

4. Numerically calculated pulses. We shall compare numerical solutions for different representative values of d with the approximate pulses provided by our theory. As initial data, we have adopted our approximate pulses. We have also used hump-like profiles with compact support for $u_n(0)$ and $v_n(0)$. It is important that $v_n(0) = 0$ at the leading edge of $u_n(0)$ and to its right, and that $v_n(0) = V \approx w_{cr}(d)$ at the trailing edge, where $v_n(0)$ reaches its maximum. Had we chosen $v_n(0) = 0$ for all n, the u_n profile would have split into two pulses traveling in opposite directions as time elapsed; see Figure 4.1. The region between leading and trailing fronts of the pulse acquires its asymptotic shape quite quickly, but the pulse tail is usually rather long and evolves slowly towards its final form.

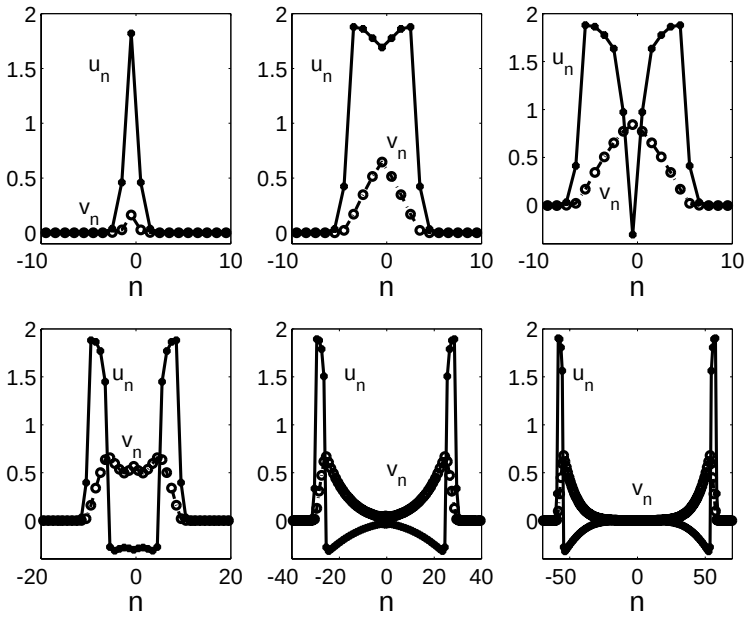

FIG. 4.1. *Splitting of an initial profile into two pulses propagating in opposite directions for* $d = 0.1$, $a = 0.5$, *and* $\epsilon = 0.006$.

- $d = 1$. In this case, $a_{cl} = 0.996$. We choose $a = 0.99 < a_{cl}$ and analyze front propagation for the rescaled Nagumo equation (2.1) first. The front propagation thresholds for these values of d and a are $w_{cl} = 0.0038$ and $w_{cr} = 0.0095$. Figure 4.2(a) shows the speeds of leading and trailing fronts as functions of w, as predicted by (2.2). For $w = 0$, the leading front should move at speed $c_-(0) = 0.0093$. The relation $c_+(V) = c_-(0)$ yields the asymptotic value $V^* = 0.0133$ at the trailing front joining $U_1(V^*) = -0.00665$ to $U_3(V^*) = 1.9933$. The time elapsed between fronts is $\tau^* = 0.00652$, as calculated from (3.8). Then our upper bound for the critical value of ϵ is $\epsilon_c = 0.000064$. Choosing a smaller value, $\epsilon = 0.000005$, we obtain a pulse speed of $C = c_-(0)/\epsilon = 1869$ points per unit time and a pulse width of $l^* = C\tau^* \sim 13$ points. Our numerical solution of the full FHN system (1.2) and (1.3) yields a pulse speed $C = 2000$ and a width of 13 points for $\epsilon = 0.000005$. The trailing front joins -0.006647 and 1.993 with $V^* = -0.0133$; see Figure 4.2(b). Note that the relative error in the predicted speed C is 0.0655. Obviously, rescaling the speed to $C = c_-(0)/\epsilon$ amplifies the error in our predictions. We have not been able to observe pulses for $\epsilon \geq 0.0000076$, which is smaller but not far from our estimation $\epsilon_c = 0.000064$. Let us now choose $a = 0.5$ which is far from a_{cl}. Then $w_{cl} = 0.3194$ and $w_{cr} = 0.3287$. Equation (2.2) predicts $c_-(0) = 0.09983$, whereas the trailing front joins -0.316 to 1.71 at $V^* = 0.6$. If $\epsilon = 0.01$, the speed and width of the pulse are $C = 9.983$ and $l^* = 0.351C \sim 4$, according to our theory. Numerically, we observe $C = 64.7$ and $l^* = 25$. The source of these large errors is the value $c_-(0) = 0.09983$ predicted with formula (2.2). If we replace this value by the numerical front speed calculated directly, $c_-(0) = 0.673$, we obtain $C = 67.3$ and $l^* \sim 24$ points, which better

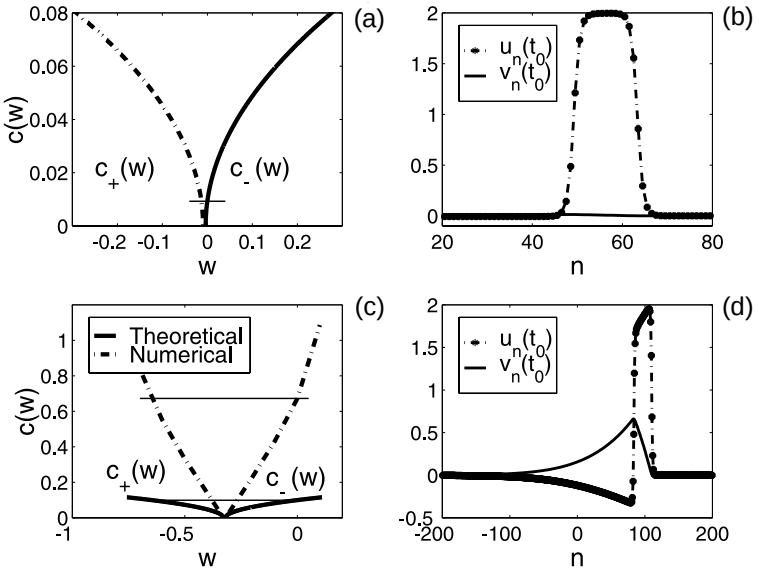

FIG. 4.2. (a) *Predicted speeds for wave fronts of the Nagumo equation* (2.1) *with* $d = 1$, $a = 0.99$. *The horizontal line marks the condition* $c_+(w) = c_-(0)$, *thereby graphically yielding* $w = V^*$. fit the numerically observed values.

- $d = 0.1$. In this case, $a_{cl} = 0.567$, and we shall choose $a = 0.5 < a_{cl}$. Let us first analyze front propagation for the rescaled Nagumo equation (2.1). For these values of d and a, we obtain $w_{cl} = 0.0307$ and $w_{cr} = 0.6175$. Figure 4.3(a) shows the predicted speeds of the leading and trailing fronts as functions of v, as given by formula (2.2). For $w = 0$, the leading front should move with speed $c_-(0) = 0.075662$. At the trailing front, $c_+(V) = c_-(0)$ yields $V^* = 0.648$, $U_1(V^*) = -0.33328$, and $U_3(V^*) = 1.666$. The time elapsed between fronts is $\tau^* = 0.39266$, which gives $l^* = 0.0297/\epsilon$. Our bound for the critical value of ϵ is $\epsilon_c = c_-(0)\tau^* = 0.029$. Selecting $\epsilon = 0.003$, we predict $C = 25.22$ and $l^* \sim 10$ points. Direct numerical calculations yield a pulse speed $C = 26.38$ and a pulse width of about 10 points. The trailing front joins -0.3269 to 1.675 with $V^* = 0.6578$; see Figure 4.3(b). We have not been able to obtain pulses for $\epsilon \geq 0.007$, which is four times smaller than our upper bound of 0.029.
- $d = 0.01$. In this case, $a_{cl} = 0.195$, and we shall choose $a = 0.1 < a_{cl}$. Let us first analyze front propagation for the rescaled Nagumo equation (2.1). The front propagation thresholds for these values of d and a are $w_{cl} = 0.0136$ and $w_{cr} = 1.0784$. Figure 4.4(a) shows the predicted speeds of leading and trailing fronts as functions of w according to (2.2). For $w = 0$, the leading front should move with speed $c_-(0) = 0.052$. Then the trailing front has $V^* = 1.092$ corresponding to $c_+(V) = c_-(0)$, and it joins $U_1(V^*) = -0.6$ to $U_3(V^*) = 1.4$. The time elapsed between fronts is $\tau^* = 0.748$, and the pulse width, $l^* = 0.297/\epsilon$. Our bound for the critical value of ϵ is $\epsilon_c = c_-(0)\tau^* = 0.058$. Selecting $\epsilon = 0.001$, we predict $C = 52$ and $l^* = 39$ points.

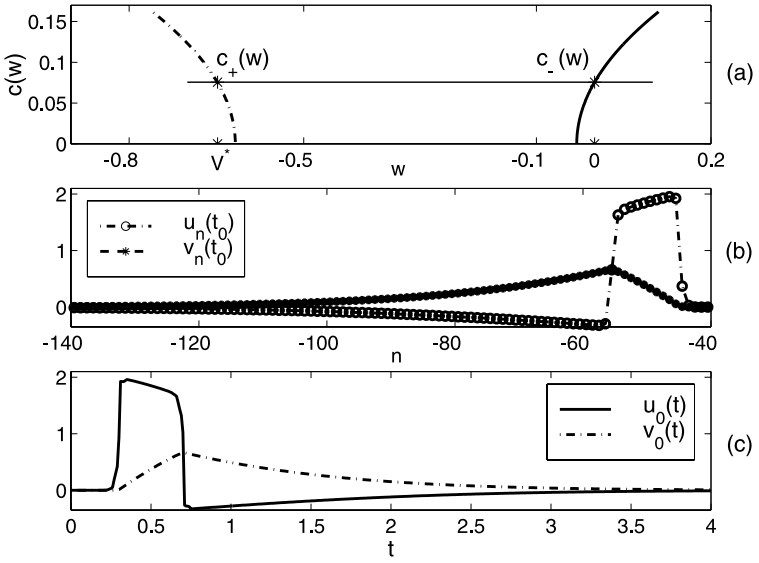

FIG. 4.3. (a) *Predicted speeds for the Nagumo equation* (2.1) *with* $d = 0.1$ *and* $a = 0.5$. *The horizontal line graphically yields* V^* *such that* $c_+(V^*) = c_-(0)$. (b) *Profiles of the FHN pulse for* $\epsilon = 0.003$ (c) *Trajectories of one point,* $u_0(t)$, $v_0(t)$, *as the FHN pulse propagates through it.*

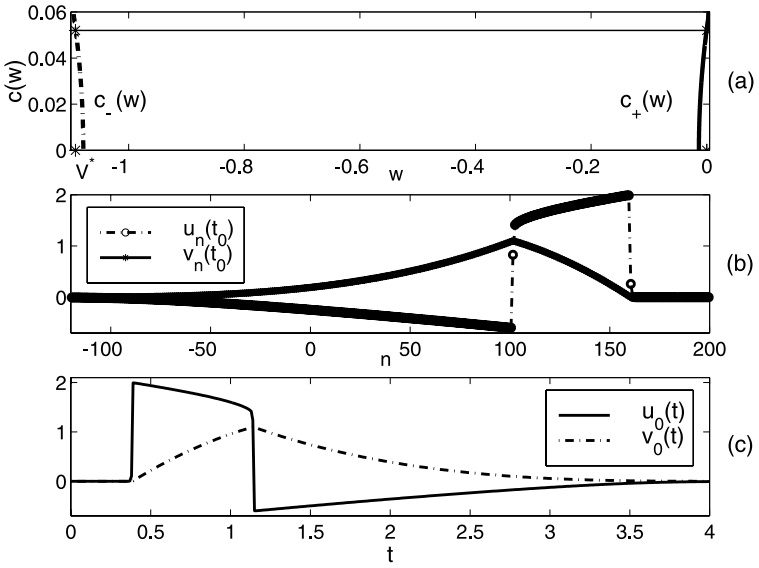

FIG. 4.4. (a) *Predicted speeds for the Nagumo equation* (2.1) *with* $d = 0.01$ *and* $a = 0.1$. (b) *FHN pulse for* $\epsilon = 0.001$. (c) *Trajectory of one point,* $u_0(t)$, *as the FHN pulse propagates through it.*

Numerical observations yield $C = 77.7$ (a relative error of 0.3) and a pulse width of 59 points. Furthermore, the trailing front joins -0.59 to 1.4 with $V^* = 1.095$; see Figure 4.4(b). Again the observed errors in the pulse speed and width are due to errors in the prediction of $c_-(0)$ given by formula (2.2). Replacing this value by the numerically computed front speed $c_+(0) = 0.078$, we obtain $C = 78$ and $l^* \sim 58$, better fit to the real values.

Let us now describe the situation for other values of d. Our asymptotic theory agrees with the numerical results, provided that ϵ is sufficiently small, but the velocity of the Nagumo wave fronts should be either approximated by (2.2) or calculated numerically depending on how close to zero w_{cl} happens to be. For $d < 0.01$, the length of the intervals in which fronts of the Nagumo equation propagate is very small. Then the front speeds are always very small and given by (2.2) with great accuracy. Our asymptotic description of the pulse agrees very well with numerical solutions of the FHN system. If $d > 1$, the spatially discrete FHN system can be approximated by its continuum limit. The length of the pinning intervals for the Nagumo equation is below 0.001, and the wave front velocities are essentially a correction of the wave front velocities for the spatially continuous Nagumo equation (see [21]):

$$c = \sqrt{d}\, c_0 \left(1 - \frac{k_1 c_0^2}{2d} + O\left(\frac{c_0^4}{d^2}\right)\right), \tag{4.1}$$

$$c_0 = \frac{2U_2(w) - U_1(w) - U_3(w)}{\sqrt{2}}, \tag{4.2}$$

$$k_1 = -\frac{\int_{-\infty}^{\infty} e^{-c_0^2 s} V_0'(s) V_0''''(s)\, ds}{12 c_0^4 \int_{-\infty}^{\infty} e^{-c_0^2 s} V_0'(s) V_0''(s)\, ds}. \tag{4.3}$$

Here V_0 is the appropriate wave front solution of the equation

$$c_0^{-2} V_0'' - V_0' + V_0 (2 - V_0)(V_0 - a) - w = 0. \tag{4.4}$$

5. Propagation failure. Two facts may lead to propagation failure: a value of ϵ that is too large or $a \in (a_{cl}(d), a_{cr}(d))$.

Let us consider the first cause of propagation failure now. If ϵ surpasses a certain critical value ϵ_c, recovery is too fast and a stable pulse cannot be sustained. This situation also occurs in spatially continuous FHN systems. In these systems, there exist two pulses (one pulse is stable, the other unstable) for $\epsilon < \epsilon_c$; they coalesce at ϵ_c and cease to exist for larger ϵ. In the discrete FHN system, the phenomenon of wave front propagation failure implies that pulses may propagate only if $a < a_{cl}(d)$ or $a > a_{cr}(d)$. As indicated by (3.10), the number of points between the two fronts of the stable pulse decreases as ϵ increases towards $\epsilon_c(a, d)$. Eventually the two fronts coalesce, and it is not possible to propagate a stable pulse for $\epsilon > \epsilon_c(a, d)$. If we start with an appropriate pulse-like initial condition, we find the scenario of propagation failure depicted in Figures 5.1 and 5.2. For small d ($d = 0.1$), the variable v_n ceases to be almost constant at the leading edge of the pulse, and the distance between the two fronts diminishes. While $v_n \sim 0$ at the rightmost point of the leading front, $v_n \sim w > 0$ at the leftmost point. Thus, u_n in this front decreases from $U_3(w)$ to zero as n increases. The value w increases with ϵ, and $U_3(w)$ decreases. At the same time, the leading front speed diminishes as w increases until w surpasses the propagation threshold and the leading front stops. Since the back front goes on moving, the pulse vanishes; see Figure 5.1. For large d ($d = 1$), a decremental pulse is formed. Its

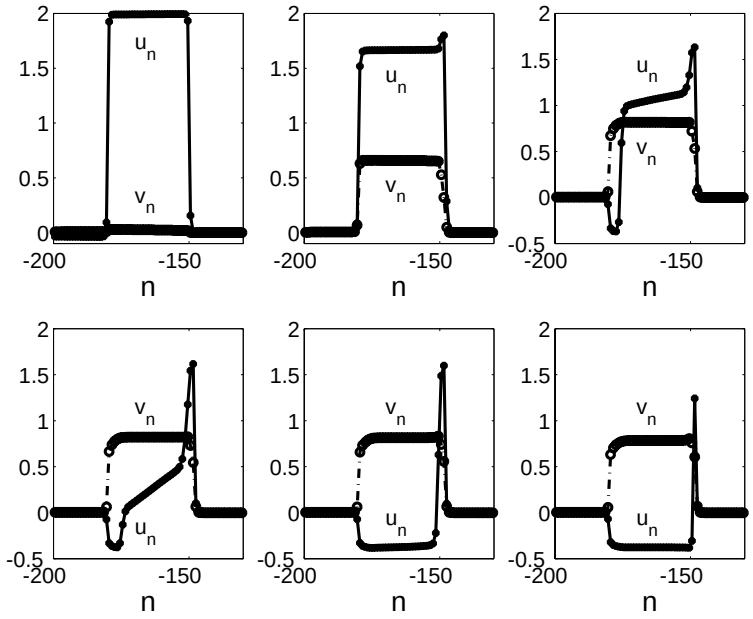

FIG. 5.1. *Snapshots of the excitation and recovery variables for* $d = 0.1$, $a = 0.5$, *and* $\epsilon = 0.007$, *illustrating propagation failure of the pulse for* $\epsilon > \epsilon_c$.

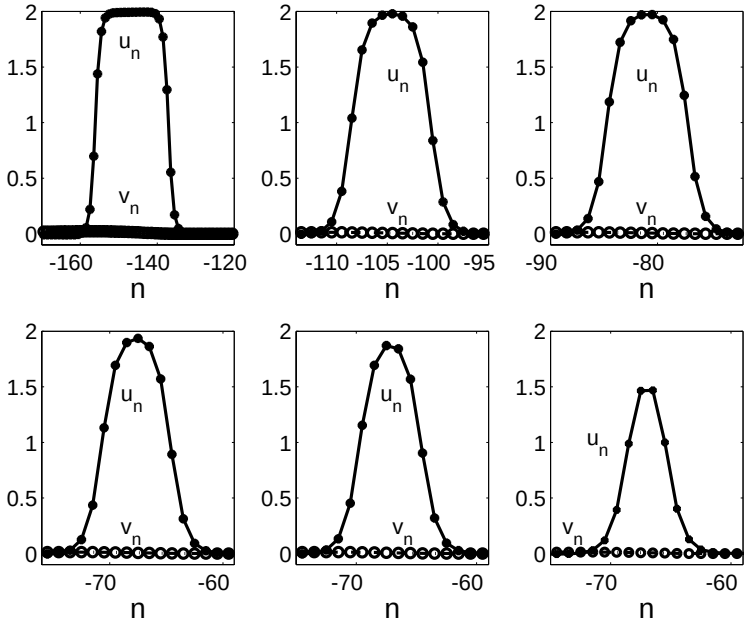

FIG. 5.2. *Same as Figure* 5.1 *for* $d = 1$, $a = 0.99$, *and* $\epsilon = 0.0000076$.

width and height decrease as it moves until it disappears; see Figure 5.2. Numerical simulations of the FHN system show that $\epsilon_c \to 0$ as a tends to either $a_{cl}(d)$ or $a_{cr}(d)$.

Let us assume now that $a \in (a_{cl}(d), a_{cr}(d))$. Then the leading front cannot propagate with $v_n = v = 0$. We need $v_n \sim v < w_{cl}(a,d) < 0$. However, in the region in front of the leading edge, v_n and u_n evolve towards 0, whereas we have $u_n > 0$ at the leading front. Thus $dv_n/dt = u_n - Bv_n \geq 0$ there, and v_n will increase until $v_n > 0$, which contradicts our previous assumption. Thus we cannot have stable propagating pulses. Furthermore, there are no stationary pulses of the type we have discussed for this range of a: if $v_n = u_n/B$, the source $u_n(2-u_n)(a-u_n) - v_n = u_n(2-u_n)(u_n-a) - u_n/B$ has only one zero, not three as in our construction. This does not preclude the existence of other pulses, such as those corresponding to the homoclinic orbit in the phase space of the spatially continuous FHN system. However, we have not observed stable stationary pulses of this type in the spatially discrete FHN system.

6. Pulse generation at a boundary. So far, we have considered the motion of a pulse (or its failure) in a sufficiently large myelinated nerve fiber. We have not discussed how such a pulse might be created in a more realistic situation. Clearly, nerve fibers have finitely many nodes of Ranvier, and pulses are typically generated at the fiber boundary. Thus we are led to consider how a pulse might be generated by an excitation at a boundary and how the pulse propagates or fails in a finite fiber. This problem was tackled by Booth and Erneux [5] using parameter values for which the FHN pulse fails to propagate. We shall now discuss different parameter ranges.

Nerve fibers may have either a few nodes of Ranvier (e.g., 20 for neurons of the central nervous system [25]) or several hundred nodes (in the peripheral nervous system [29]). Thus we shall consider a finite FHN system with N nodes and a Neumann boundary condition at the right end, $u_{N+1} = u_N$. At the left end, we impose $u_0(t) = 2$ for $0 \leq t \leq 0.05$, and $u_0(t) = 0$ for $t > 0.05$. The results corresponding to parameter values $d = 0.1$ and $a = 0.5$ are depicted in Figures 6.1 (for which $\epsilon = 0.006$) and 6.2 (for which $\epsilon = 0.003$). The asymptotic theory predicts that fully developed FHN pulses (corresponding to $N = \infty$) would have widths of $l^* \approx 5$ and $l^* \approx 10$, respectively. The left boundary condition ensures that the membrane potential u_n is excited during sufficient time, so that a wave is generated at the left end of the fiber.

The excitation at the left boundary induces a wave front that propagates with a velocity given approximately by $C = c_-(0)/\epsilon$ along the finite fiber for the parameter values we consider. For example, $C \approx 12.6$ for $\epsilon = 0.006$, which is close to the numerically observed value of 10 in Figure 6.1. Similarly, $C \approx 25.22$ for $\epsilon = 0.003$, which is close to the numerically observed value of 26 in Figure 6.2. If the fiber is long enough, a second wave front follows the first one, and their mutual distance rapidly approaches the asymptotic value l^*. (The number of nodes between fronts is 4 in Figure 6.1, while the asymptotic theory predicts $l^* \approx 5$; in Figure 6.2, numerical observation confirms the asymptotic value $l^* \approx 10$.) The numerical solution of the finite FHN system shows that an eventually truncated FHN pulse comprising the two wave fronts and the region between them is formed, provided that N is at least twice l^*. Otherwise, at best only the first wave front is shed at the boundary, as shown in Figure 6.2(a). Pulses fail to propagate in fibers whose parameters fall in the propagation failure region, as discussed in section 5.

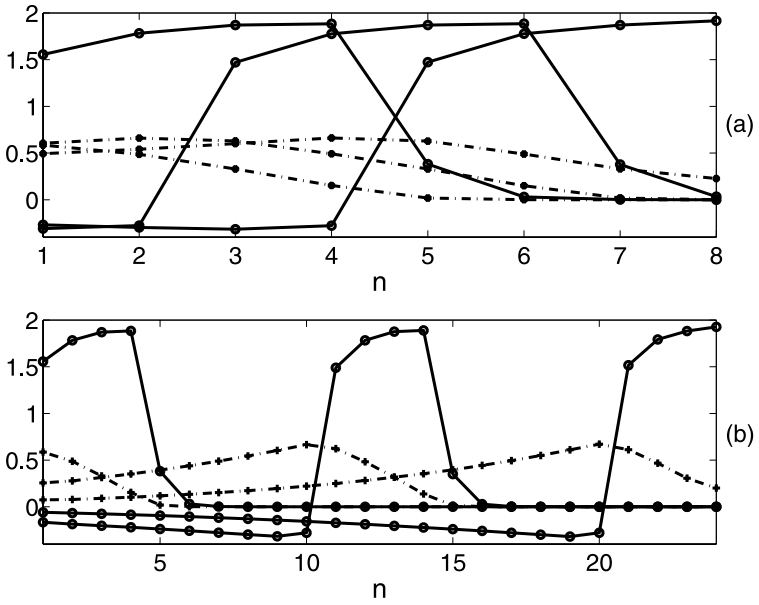

FIG. 6.1. *Snapshots of the excitation (solid line) and recovery (dotted line) variables for an FNH system with N nodes and* $d = 0.1$, $a = 0.5$, *and* $\epsilon = 0.006$. (a) *Profiles at times* 0.4, 0.6, *and* 0.8 *for* $N = 8$. (b) *Profiles at times* 0.4, 1.4, *and* 2.4 *for* $N = 24$.

7. Conclusions. We have constructed stable pulses of the spatially discrete FHN system by asymptotic methods. In a pulse, there are regions where the excitation variable varies smoothly, separated by sharp fronts. These fronts are solutions of the discrete Nagumo equation with a constant value of the recovery variable. Their shape and speed can be approximately calculated near parameter values corresponding to front propagation failure or near the continuum limit. For long times, their width is given by the only stable solution of a one-dimensional autonomous system. We have compared the asymptotic results with numerical solutions of the FHN system and analyzed different scenarios for failure of pulse propagation. Besides the classical scenario of small separation between the time scales of excitation and recovery (large ϵ as in the spatially continuous FHN system), propagation failure of fronts for the spatially discrete Nagumo equation provides a different mechanism of propagation failure of pulses for the discrete FHN system. Wave fronts and pulses can be generated at a boundary and propagate or fail to propagate along a finite FHN system. If the number of nodes is sufficiently large, the two wave fronts comprising an FHN pulse can be shed at the boundary, and their separation rapidly reaches the value given by the asymptotic theory. This is true even if the fiber is too short to accommodate the slowly varying regions at the back of the second wave front of the pulse. In long fibers, a fully developed FNH pulse may be generated by an over-threshold stimulus applied during a short time at one end of the fiber.

BIFURCATION ANALYSIS OF A PREDATOR-PREY SYSTEM WITH NONMONOTONIC FUNCTIONAL RESPONSE*

HUAIPING ZHU†, SUE ANN CAMPBELL‡, AND GAIL S. K. WOLKOWICZ†

Abstract. We consider a predator-prey system with nonmonotonic functional response: $p(x) = \frac{mx}{ax^2+bx+1}$. By allowing b to be negative ($b > -2\sqrt{a}$), $p(x)$ is concave up for small values of $x > 0$ as it is for the sigmoidal functional response. We show that in this case there exists a Bogdanov–Takens bifurcation point of codimension 3, which acts as an organizing center for the system. We study the Hopf and homoclinic bifurcations and saddle-node bifurcation of limit cycles of the system. We also describe the bifurcation sequences in each subregion of parameter space as the death rate of the predator is varied. In contrast with the case $b \geq 0$, we prove that when $-2\sqrt{a} < b < 0$, a limit cycle can coexist with a homoclinic loop. The bifurcation sequences involving Hopf bifurcations, homoclinic bifurcations, as well as the saddle-node bifurcations of limit cycles are determined using information from the complete study of the Bogdanov–Takens bifurcation point of codimension 3 and the geometry of the system. Examples of the predicted bifurcation curves are also generated numerically using XPPAUT. Our work extends the results in [F. Rothe and D. S. Shafer, *Proc. Roy. Soc. Edinburgh Sect. A*, 120 (1992), pp. 313–347] and [S. Ruan and D. Xiao, *SIAM J. Appl. Math.*, 61 (2001), pp. 1445–1472].

Key words. predator-prey system, Hopf bifurcation, homoclinic bifurcation, Bogdanov–Takens bifurcation, saddle-node bifurcation of limit cycles, limit cycle

1. Introduction.

The classical predator prey model with an inhibition response function was introduced in Freedman and Wolkowicz [12] to establish a veritable paradox of enrichment. In this paper we analyze the classical predator-prey model with a specific inhibition response function, the Holling type IV response function. In particular, we study the model

$$\begin{cases} \dot{x} &= rx\left(1-\dfrac{x}{K}\right) - yp(x) = p(x)(F(x)-y), \\ \dot{y} &= y(-d+cp(x)), \\ & x(0) \geq 0, y(0) \geq 0, \end{cases} \tag{1.1}$$

where x and y denote the density of the prey and predator populations, respectively, r, K, d, and c are positive constants, and $F(x) = rx(1-\frac{x}{K})/p(x)$.

The specific growth rate of the prey population in the absence of predator population is assumed to satisfy logistic growth, and so r denotes the intrinsic growth rate of the prey population, and K denotes the carrying capacity. The natural death rate of the predators is denoted by d, and the predator response function is denoted by $p(x)$. It is assumed that the rate of conversion of prey captured to predator is proportional

to the predator response function, where c is the constant of proportionality or yield constant.

The predator-prey system (1.1) has been extensively studied by many authors. (See Ruan and Xiao [28] and Wolkowicz [30] for an extended list of references.) In the literature, different functions have been used to model the predator response. (See Holling [15] and Freedman and Wolkowicz [12] for a description of the general conditions that this function should satisfy.) In Wolkowicz [30], assuming only these general conditions and a technical assumption, a complete one parameter bifurcation analysis of (1.1) was carried out using the carrying capacity K as the bifurcation parameter. It was proved that the model has rich dynamics, including parameters for which there is a homoclinic bifurcation. It was pointed out that both supercritical and subcritical Hopf bifurcations are possible, and that when there is a subcritical Hopf bifurcation, there must be parameters for which there is a saddle-node bifurcation of limit cycles and a range of parameters for which there are at least two limit cycles. To do a more detailed analysis, it is useful to specify the function $p(x)$.

The form most often used (see, for example, Holling [14]), is the Holling type II form, $p(x) = \frac{mx}{b+x}$, also associated with Monod and Michaelis–Menten. This is an increasing function that saturates, i.e., has a finite positive limit as x approaches infinity. For a very nice description of the biological interpretation of each of the parameters, see Rinaldi, Muratori, and Kuznetsov [24], where they also study the effect of periodically forcing each of the parameters individually, and propose a universal bifurcation diagram.

In this paper we consider the Holling type IV functional response, associated with Monod–Haldane (see Andrews [1]):

$$p(x) = \frac{mx}{ax^2 + bx + 1}, \tag{1.2}$$

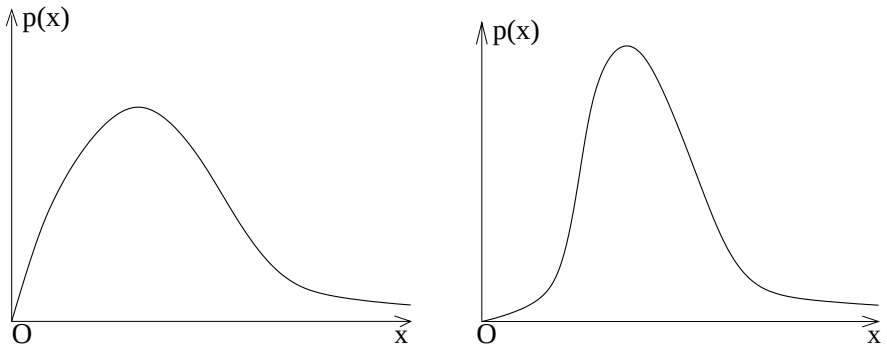
where a and m are positive constants, and $b > -2\sqrt{a}$ (so that $ax^2 + bx + 1 > 0$ for all $x \geq 0$ and hence $p(x) > 0$ for all $x > 0$).

When a is positive, this function increases to a maximum and then decreases, approaching zero as x approaches infinity. Thus, $p(x)$ models the situation where the prey can better defend or disguise themselves when their population becomes large enough, a phenomenon called group defense. See [12] and [28] for more information about this phenomenon and examples of populations that use this strategy.

The response function (1.2) has been primarily considered assuming m positive and a and b nonnegative. In this case, for x sufficiently small, $p(x)$ resembles the Holling type II model while for large x the effect of inhibition is seen (Figure 1.1(a)). If $-2\sqrt{a} < b < 0$ and a is nonnegative, $p(x)$ remains nonnegative, the inhibition effect is still observed for large x, however, for x small $p(x)$ resembles the Holling type III (sigmoidal) function (Figure 1.1(b)). We shall show in section 5 that for model (1.1) with the nonmonotonic response function (1.2), the organizing center of the bifurcation diagram is at

$$b = -\sqrt{a}, \qquad d = \frac{mc}{b + 2\sqrt{a}}, \qquad K = \frac{2}{\sqrt{a}},$$

where there is a Bogdanov–Takens bifurcation of codimension 3. Ignoring the negative, but physically relevant, values of b misses this important fact as well as some rich dynamics of the model.



(a) $b \geq 0$ (b) $-2\sqrt{a} < b < 0$

FIG. 1.1. *Response functions.*

Using the response function (1.2) in (1.1), the model to be considered is

$$\begin{cases} \dot{x} &= rx\left(1-\dfrac{x}{K}\right) - y\dfrac{mx}{ax^2+bx+1} = p(x)(F(x)-y), \\ \dot{y} &= y\left(-d+c\dfrac{mx}{ax^2+bx+1}\right) = y(-d+cp(x)), \\ & x(0)\geq 0, y(0)\geq 0, \end{cases} \tag{1.3}$$

where

$$F(x) = \frac{r}{m}\left(1-\frac{x}{K}\right)(ax^2+bx+1) \tag{1.4}$$

and

$$K,\ r,\ m,\ a,\ c,\ d > 0, \quad \text{and} \quad b > -2\sqrt{a}. \tag{1.5}$$

Rothe and Shafer [25, 26] considered the system

$$\begin{cases} \dfrac{dx}{d\tau} &= rx\left[\left(1-\dfrac{x}{K}\right)\left(\left(\dfrac{x}{\lambda}-1\right)\left(\dfrac{x}{\mu}-1\right)+x\right)-y\right], \\ \dfrac{dy}{d\tau} &= -y\Big(\dfrac{x}{\lambda}-1\Big)\Big(\dfrac{x}{\mu}-1\Big), \end{cases} \tag{1.6}$$

which may be obtained from (1.3) by rescaling time t via

$$\tau = \int_0^t \left[\frac{1}{ax^2(t)+bx(t)+1}\right] dt$$

and by assuming that the system always has two equilibria inside the positive quadrant. Using results for polynomial systems and taking $(\frac{1}{K}, \frac{1}{\lambda}, \frac{1}{\mu})$ as parameters, the authors studied the bifurcations of the model. Rothe and Shafer were the first to consider the case b negative ($-2\sqrt{a} < b$). However, after the transformation and reduction to (1.6), the effect of allowing $b < 0$ was hidden. They proved that there is a set of parameters for which there is a cusp of codimension 2, in a neighborhood of

which the system realizes every phase portrait possible under small smooth perturbation. They also indicated that there is a cusp of codimension at least 3, but did not prove that the codimension is exactly 3. They point out for parameters near this cusp there is a semi-stable limit cycle. The results of [26] are in terms of parameters which are composites of the model parameters and thus are more difficult to interpret for the biological system.

In [28], Ruan and Xiao restricted $b = 0$ in (1.3) and carried out a global analysis. In particular, they proved that a limit cycle cannot coexist with a homoclinic loop. They determined a set of parameters for which the system has a unique limit cycle which is stable and another for which no cycles exist. They also studied the Bogdanov–Takens bifurcation of codimension 2.

Model (1.3) involves 7 parameters (see (1.5)) that all have biological interpretations. By rescaling the state variables and time we could eliminate 3 of them. For example, we could eliminate a, m, and c by using

$$(t,\ x,\ y) \longrightarrow \left(\frac{\sqrt{a}}{mc}t,\ \frac{1}{\sqrt{a}}x,\ \frac{c}{\sqrt{a}}y\right) \tag{1.7}$$

and replacing r by $\frac{\sqrt{a}}{mc}r$, K by $\sqrt{a}K$, d by $\frac{\sqrt{a}}{mc}d$, and b by $\frac{1}{\sqrt{a}}b$. Similarly, using the change of variables

$$(t,\ x,\ y) \longrightarrow \left(\frac{t}{r},\ \frac{r}{mc}x,\ \frac{r}{m}y\right),$$

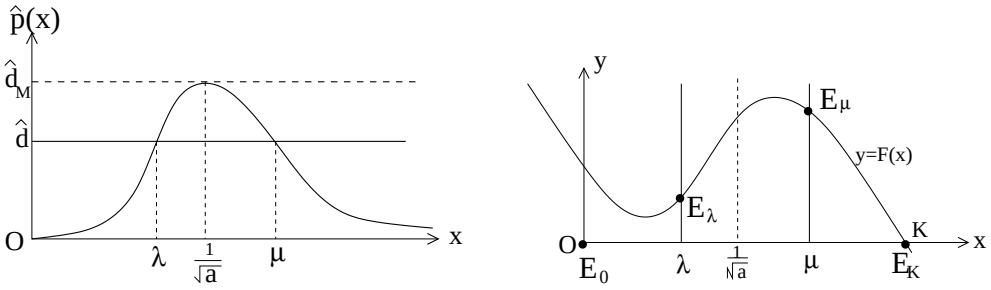
and replacing a by $(\frac{r}{mc})^2 a$, K by $\frac{mc}{r}K$, d by $\frac{1}{r}d$, and b by $\frac{r}{mc}b$ we could eliminate r, m, and c. We choose not to do this so that the effect of all the parameters may be easily seen in our results.

The x and y axes, the nonnegative cone and its interior are all invariant sets with respect to system (1.3). A standard phase plane argument can be used to show that all solutions initiating in the positive cone are bounded (see [30]).

This paper is organized as follows. Section 2 contains the linear analysis of the equilibria, where we emphasize how this depends on the slope of the prey isocline. In section 3 we give the geometric properties of the predator and prey isoclines, and we show how the parameters (1.5) influence the geometry of the isoclines. In section 4, we study the effect of this geometry on the existence, number, and criticality of Hopf bifurcations which occur as $\hat{d} = \frac{d}{mc}$ is varied. We determine that the parameter r plays no role here. In section 5, we continue our analysis, examining the degenerate equilibria, especially the cusp points of codimension 2 and 3. In section 6 we consider the global dynamics. We conclude with section 7 where we summarize our results, compare them with other closely related results, and indicate their biological significance.

2. Linear stability analysis. We consider equilibrium solutions to exist only if they lie in the nonnegative cone. System (1.3) has at most four equilibrium solutions. Two always lie on the boundary of the nonnegative cone: $E_0 = (0, 0)$, representing the extinction of both species, and $E_K = (K, 0)$, representing the extinction of the predator population and the density of the prey population equilibrating at the carrying capacity.

Let $\lambda \le \mu$ denote the two possible solutions of the quadratic equation $cp(x) = d$, and $E_\lambda = (\lambda, F(\lambda))$ and $E_\mu = (\mu, F(\mu))$ denote the corresponding equilibria. Whether zero, one, or both of these other equilibria exist and sit in the nonnegative cone



(a) Parameters λ and μ (b) Isoclines and equilibria

FIG. 2.1. *Typical geometry for system* (1.3).

depends on the relative positions of the prey isocline $y = F(x)$ and the predator isoclines $x = \lambda$ and $x = \mu$. Figure 2.1(b) illustrates one of the possible positions, where both E_λ and E_μ exist.

Define

$$\hat{d} = \frac{d}{mc}, \qquad \hat{p}(x) = \frac{p(x)}{m}. \tag{2.1}$$

Then $cp(x) = d$ or $\hat{p}(x) = \hat{d}$ is equivalent to

$$\hat{g}(x) = a\hat{d}x^2 - (1 - b\hat{d})x + \hat{d} = 0. \tag{2.2}$$

If we define

$$\hat{d}_M = \frac{1}{b + 2\sqrt{a}}, \qquad \Delta_0 = (1 - b\hat{d})^2 - 4a\hat{d}^2, \tag{2.3}$$

then from a simple calculation it follows that for $\hat{d} \in (0, \hat{d}_M]$, (2.2) has two positive roots $\lambda \le \mu$ where

$$\lambda := \frac{1 - b\hat{d} - \sqrt{\Delta_0}}{2a\hat{d}}, \qquad \mu := \frac{1 - b\hat{d} + \sqrt{\Delta_0}}{2a\hat{d}}. \tag{2.4}$$

If $\hat{d} \in (0, \hat{d}_M)$, then $\lambda < \frac{1}{\sqrt{a}} < \mu$. As $\hat{d}$ increases, λ increases and μ decreases. When $\hat{d} = \hat{d}_M$, $\lambda = \mu = \frac{1}{\sqrt{a}}$ (Figure 2.1(a)). When $\hat{d} > \hat{d}_M$, λ and μ are no longer real. Then E_0 and E_K are the only equilibria in the nonnegative cone, and E_K attracts all orbits initiating in the positive cone.

Next we investigate the stability of the equilibrium solutions E_0, E_K, E_λ, and E_μ by linearizing about each one. The variational matrix about any equilibrium $(\bar{x}, \bar{y})$ is

$$V(\bar{x}, \bar{y}) = \begin{bmatrix} p'(\bar{x})(F(\bar{x}) - \bar{y}) + p(\bar{x})F'(\bar{x}) & -p(\bar{x}) \\ cp'(\bar{x})\bar{y} & cp(\bar{x}) - d \end{bmatrix}. \tag{2.5}$$

TABLE 2.1
Linear analysis of the equilibrium solutions.

Fixed point	$K < \lambda < \mu$	$\lambda < K < \mu$	$\lambda < \mu < K$	
E_0	saddle	saddle	saddle	
E_K	attracting node	saddle	attracting node	
E_λ	does not exist	repeller	repeller	$F'(\lambda) > 0$
		attractor	attractor	$F'(\lambda) < 0$
E_μ	does not exist	does not exist	saddle	

An easy calculation indicates that E_0 is always a saddle point. For E_μ, note that the determinant of $V(\mu, F(\mu))$ is

$$\det\Big(V(\mu, F(\mu))\Big) = c\bar{y}p(\mu)p'(\mu) = \frac{c\hat{d}m^2F(\mu)(1 - a\mu^2)}{(a\mu^2 + b\mu + 1)^2}, \tag{2.6}$$

and that for $\hat{d} \in (0, \hat{d}_M)$, $\mu > \frac{1}{\sqrt{a}}$. Hence, if E_μ lies in the positive cone, i.e., when $\mu < K$, $\det(V(\mu, F(\mu))) < 0$, therefore E_μ is a saddle point.

Similarly, when E_λ lies in the positive cone, i.e., if $\lambda < K$, $\det(V(\lambda, F(\lambda))) > 0$. Further, the trace of $V(\lambda, F(\lambda))$ is

$$\text{tr } V(\lambda, F(\lambda)) = p(\lambda)F'(\lambda). \tag{2.7}$$

Hence, E_λ is an attractor (resp., repeller) if $F'(\lambda) < 0$ (resp., $F'(\lambda) > 0$).

From the discussion above, it is clear that there is a saddle-node bifurcation involving E_λ and E_μ when $\hat{d} = \hat{d}_M$.

The two eigenvalues of the variational matrix about E_K are $-r < 0$ and $-d + cp(K) = mc[\hat{p}(K) - \hat{d}]$. Thus E_K is an attracting node if $\hat{d} > \hat{p}(K)$. It is a saddle point if $\hat{d} < \hat{p}(K)$. If $\hat{d} = \hat{p}(K)$, E_K undergoes a transcritical bifurcation. As $\hat{d}$ increases from 0, the steady state bifurcations outlined below occur.

1. If $K < \frac{1}{\sqrt{a}}$, denote $\hat{d}_{\lambda K} = \hat{p}(K)$. A transcritical bifurcation involving E_λ and E_K occurs when $\hat{d} = \hat{d}_{\lambda K}$. E_K changes its stability from a saddle point to an attracting node. When $\hat{d} = \hat{d}_M$, a saddle-node bifurcation involving E_λ and E_μ occurs outside the nonnegative cone.
2. If $K > \frac{1}{\sqrt{a}}$, denote $\hat{d}_{\mu K} = \hat{p}(K)$. A transcritical bifurcation involving E_μ and E_K occurs when $\hat{d} = \hat{d}_{\mu K}$. E_K changes its stability from a saddle point to an attracting node. When $\hat{d} = \hat{d}_M$, a saddle-node bifurcation involving E_λ and E_μ occurs inside the positive cone.
3. If $K = \frac{1}{\sqrt{a}}$, then $\hat{p}(K) = \hat{d}_M$. When $\hat{d} = \hat{d}_M$, E_λ, E_μ, and E_K coalesce at E_K. Phase portrait analysis shows that E_K is an asymptotically stable degenerate node.

The linear analysis for system (1.1) is summarized in Table 2.1.

3. Geometry of the isoclines. The geometry of the prey and predator isoclines plays an important role in the analysis of both the local and global bifurcations. We begin with a useful observation about the intersections of the prey isocline $y = F(x)$ with the predator isoclines, the lines $x = \lambda$ and $x = \mu$.

LEMMA 3.1. *Consider $F(\lambda)$ and $F(\mu)$:*

1. *If* $0 < K < \frac{2}{\sqrt{a}}$ *and* $\hat{d} \in (0, \hat{d}_M)$, *then* $F(\lambda) > F(\mu)$.
2. *If* $K = \frac{2}{\sqrt{a}}$, *then* $F(\lambda) = F(\mu)$ *if and only if* $\hat{d} = \hat{d}_M$. *Otherwise, if* $\hat{d} \in (0, \hat{d}_M)$, *then* $F(\lambda) > F(\mu)$.
3. *If* $K > \frac{2}{\sqrt{a}}$, *then there exists* $\hat{d}_c$,

$$\hat{d}_c = \frac{1}{aK + b}, \tag{3.1}$$

satisfying $\hat{d}_c \in (0, \hat{d}_M)$ *such that*
- *if* $0 < \hat{d} < \hat{d}_c$, *then* $F(\lambda) > F(\mu)$;
- *if* $\hat{d} = \hat{d}_c$, *then* $F(\lambda) = F(\mu)$;
- *if* $\hat{d}_c < \hat{d} < \hat{d}_M$, *then* $F(\lambda) < F(\mu)$;
- *if* $\hat{d} = \hat{d}_M$, *then* $F(\lambda) = F(\mu)$.

Proof. If $\hat{d} \in (0, \hat{d}_M)$, two interior equilibria E_λ and E_μ exist and $\lambda < \mu$. By (2.2), we have

$$\lambda + \mu = \frac{1 - b\hat{d}}{a\hat{d}}, \qquad \lambda\mu = \frac{1}{a}. \tag{3.2}$$

Then

$$\begin{aligned} F(\lambda) - F(\mu) &= \frac{r}{mK}\left[-a(\lambda^3 - \mu^3) + (aK - b)(\lambda^2 - \mu^2) + (bK - 1)(\lambda - \mu)\right] \\ &= \frac{r(\lambda - \mu)}{mK}\left[-a((\lambda + \mu)^2 - \lambda\mu) + (aK - b)(\lambda + \mu) + (bK - 1)\right] \\ &= -\frac{r(\lambda - \mu)}{a\hat{d}^2 mK}\left[(1 - b\hat{d})^2 - a\hat{d}^2 - \hat{d}(aK - b)(1 - b\hat{d}) - a\hat{d}^2(bK - 1)\right] \\ &= -\frac{r(\lambda - \mu)}{a\hat{d}^2 mK}[1 - (aK + b)\hat{d}]. \end{aligned} \tag{3.3}$$

For $0 < K < \frac{2}{\sqrt{a}}$ and $0 < \hat{d} < \hat{d}_M$, $(aK + b)\hat{d} < (b + 2\sqrt{a})\hat{d}_M < 1$. Note that $\lambda < \mu$; therefore, $F(\lambda) > F(\mu)$.

For $K = \frac{2}{\sqrt{a}}$, if $\hat{d} \in (0, \hat{d}_M)$, then $(aK + b)\hat{d} < 1$, hence $F(\lambda) > F(\mu)$. It also follows from (3.3) that $F(\lambda) = F(\mu)$ if and only if $\hat{d} = \hat{d}_M$.

Assume that $K > \frac{2}{\sqrt{a}}$. By $F(\lambda) - F(\mu) = 0$ we obtain either $\lambda = \mu$ or

$$1 - (aK + b)\hat{d} = 0. \tag{3.4}$$

Hence, if $\hat{d} = \hat{d}_M$, $F(\lambda) = F(\mu)$. If $\hat{d} \in (0, \hat{d}_M)$, we can solve (3.4) to obtain $\hat{d} = \hat{d}_c$ such that the rest of the results follow. ∎

The prey isocline $y = F(x)$ is a cubic polynomial with $\lim_{x \to -\infty} F(x) = \infty$ and $\lim_{x \to \infty} F(x) = -\infty$. It is either decreasing or has two humps, a local minimum with x coordinate H_m and a local maximum with x coordinate H_M, where H_m and H_M are the solutions of the quadratic equation $F'(x) = 0$, or, equivalently,

$$3ax^2 - 2(aK - b)x + 1 - bK = 0. \tag{3.5}$$

Let

$$\Delta_1 = a^2K^2 + abK + b^2 - 3a. \tag{3.6}$$

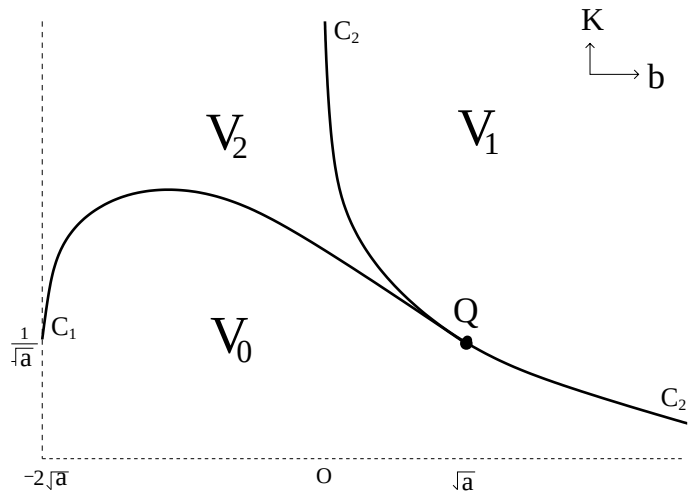


FIG. 3.1. *Three basic regions V_0, V_1, and V_2 in the bK plane, $Q = (\sqrt{a}, \frac{1}{\sqrt{a}})$ (See Proposition 3.2).*

Then when $\Delta_1 \geq 0$, we have

$$H_m := \frac{1}{3a}[aK - b - \sqrt{\Delta_1}\,], \qquad H_M := \frac{1}{3a}[aK - b + \sqrt{\Delta_1}\,]. \tag{3.7}$$

H_m is always to the left of H_M, i.e., $H_m \leq H_M$. The number and the position of the humps of the prey isocline inside the positive cone are determined by the signs of Δ_1 and $1 - bK$. For $K > 0$, the curve defined by $\Delta_1 = 0$ (part of an ellipse) is tangent to $1 - bK = 0$ at the point $Q(\sqrt{a}, \frac{1}{\sqrt{a}})$.

A straightforward analysis of the signs of the quantities Δ_1 and $1 - bK$ gives the following proposition.

PROPOSITION 3.2. *The two curves*

$$\begin{aligned} C_1 &: K = \frac{1}{2a}[\sqrt{3(4a - b^2)} - b], \qquad -2\sqrt{a} \leq b \leq \sqrt{a}, \\ C_2 &: K = \frac{1}{b}, \qquad b > 0, \end{aligned} \tag{3.8}$$

divide the region $K > 0$, $b > -2\sqrt{a}$ into 3 subregions V_0, V_1, and V_2 (see Figure 3.1):

$$\begin{aligned} V_0 &= \left\{ \begin{array}{l} -2\sqrt{a} < b < \sqrt{a} \\ 0 < K < \frac{1}{2a}[\sqrt{3(4a - b^2)} - b] \end{array} \right\} \cup \left\{ \begin{array}{l} \sqrt{a} \leq b \\ 0 < K < \frac{1}{b} \end{array} \right\}, \\ V_1 &= \left\{ 0 < b, \frac{1}{b} \leq K \right\}, \\ V_2 &= \left\{ \begin{array}{l} -2\sqrt{a} < b \leq 0 \\ \frac{1}{2a}[\sqrt{3(4a - b^2)} - b] < K \end{array} \right\} \cup \left\{ \begin{array}{l} 0 < b < \sqrt{a} \\ \frac{1}{2a}[\sqrt{3(4a - b^2)} - b] < K < \frac{1}{b} \end{array} \right\}. \end{aligned} \tag{3.9}$$

In regions V_0, V_1, and V_2, the prey isocline has 0, 1, and 2 humps in the first quadrant, respectively (see Figure 3.2).

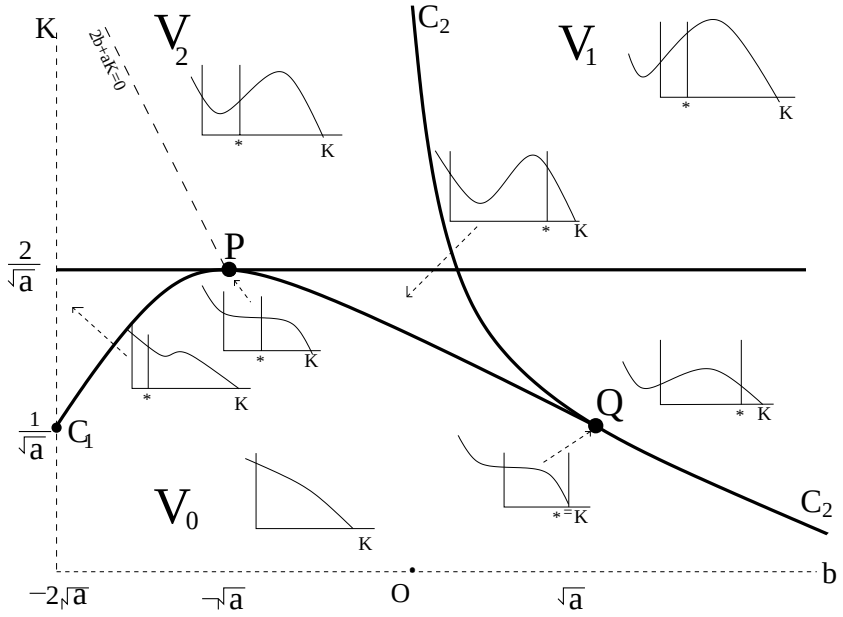

FIG. 3.2. *The positions of the two humps of the prey isocline as a function of K and b. A $*$ indicates the position of the line $x = \frac{1}{\sqrt{a}}$.*

1. *Along C_1, the two humps of the prey isocline coalesce at an inflection point with x coordinate*

$$H_I = \frac{aK - b}{3a} \quad (H_I = H_m = H_M).$$

2. *Along C_2,*
   - *if $K > \frac{1}{\sqrt{a}}$, then $H_m = 0$, i.e., the left hump sits on the y-axis;*
   - *if $0 < K < \frac{1}{\sqrt{a}}$, then $H_M = 0$, i.e., the right hump sits on the y-axis;*
   - *if $K = \frac{1}{\sqrt{a}}$, then $H_m = H_M = H_I = 0$, i.e., the inflection point sits on the y-axis.*
3. *In region V_0, the prey isocline is decreasing and hence there are no humps inside the first quadrant.*
4. *In region V_1, only the right hump H_M sits inside the positive cone and*
   - *if $K = \frac{2}{\sqrt{a}}$, then $H_M = \frac{1}{\sqrt{a}}$,*
   - *if $K > \frac{2}{\sqrt{a}}$, then $H_M > \frac{1}{\sqrt{a}}$,*
   - *if $K < \frac{2}{\sqrt{a}}$, then $H_M < \frac{1}{\sqrt{a}}$.*
5. *In region V_2, both humps sit inside the first quadrant. For $(b, K) \in V_2$,*
   - *if $K = \frac{2}{\sqrt{a}}$ and $b < -\sqrt{a}$, then $H_m = \frac{1}{\sqrt{a}}$,*
   - *if $K = \frac{2}{\sqrt{a}}$ and $b > -\sqrt{a}$, then $H_M = \frac{1}{\sqrt{a}}$,*
   - *if $K = \frac{2}{\sqrt{a}}$ and $b = -\sqrt{a}$, i.e., at the point $P = (-\sqrt{a}, \frac{2}{\sqrt{a}})$, $H_m = H_M = \frac{1}{\sqrt{a}}$,*
   - *if $K > \frac{2}{\sqrt{a}}$, then $H_m < \frac{1}{\sqrt{a}} < H_M$,*
   - *if $K < \frac{2}{\sqrt{a}}$ and $-2\sqrt{a} < b < -\sqrt{a}$, then $\frac{1}{\sqrt{a}} < H_m < H_M$*

- *if* $K < \frac{2}{\sqrt{a}}$ *and* $-\sqrt{a} < b < \sqrt{a}$, *then* $H_m < H_M < \frac{1}{\sqrt{a}}$.

Next we consider how the left and right humps of the prey isocline move as either b or K is varied.

PROPOSITION 3.3.

1. *For any fixed* b *satisfying* $b > -2\sqrt{a}$, *as* K *increases,* H_M *moves to the right and* H_m *moves to the left. Also*

$$\lim_{K\to\infty} H_M = \infty,$$
$$\lim_{K\to\infty} H_m = -\frac{b}{2a}. \quad \textit{(Note that this is positive if and only if } b < 0.\textit{)}$$

2. *For any fixed* $K > 0$,
   - *if* $2b + aK \le 0$ *(and* $-2\sqrt{a} < b < -\sqrt{a}$*), as* b *increases,*
     - H_M *moves left,*
     - *if* $0 < K < \frac{2}{\sqrt{a}}$, *then* H_m *moves right,*
     - *if* $K > \frac{2}{\sqrt{a}}$, *then* H_m *moves left,*
     - *if* $K = \frac{2}{\sqrt{a}}$, *then* $H_m = \frac{1}{\sqrt{a}}$;
3. *if* $2b + aK > 0$, *as* b *increases,*
   - H_m *moves left,*
   - *if* $0 < K < \frac{2}{\sqrt{a}}$, *then* H_M *moves right,*
   - *if* $K > \frac{2}{\sqrt{a}}$, *then* H_M *moves left,*
   - *if* $K = \frac{2}{\sqrt{a}}$, *then* $H_M = \frac{1}{\sqrt{a}}$.

Also

$$\lim_{b\to -2\sqrt{a}} H_m = \frac{2 + \sqrt{a} - |\sqrt{a}K - 1|}{3\sqrt{a}},$$
$$\lim_{b\to -2\sqrt{a}} H_M = \frac{2 + \sqrt{a} + |\sqrt{a}K - 1|}{3\sqrt{a}},$$
$$\lim_{b\to \infty} H_m = -\infty,$$
$$\lim_{b\to \infty} H_M = \frac{K}{2}.$$

Proof. The limits follow from straightforward calculations.

To study the movement of the humps, we need the following derivatives from (3.7):

$$\frac{\partial H_M}{\partial K} = \frac{b + 2aK + 2\sqrt{\Delta_1}}{6a\sqrt{\Delta_1}},$$
$$\frac{\partial H_m}{\partial K} = \frac{-(b + 2aK) + 2\sqrt{\Delta_1}}{6a\sqrt{\Delta_1}}; \tag{3.10}$$

$$\frac{\partial H_M}{\partial b} = \frac{2b + aK - 2\sqrt{\Delta_1}}{6a\sqrt{\Delta_1}},$$
$$\frac{\partial H_m}{\partial b} = -\frac{2b + aK + 2\sqrt{\Delta_1}}{6a\sqrt{\Delta_1}}. \tag{3.11}$$

1. Inside the region $V_1 \cup V_2$, for any fixed $b > -2\sqrt{a}$, we have $b + 2aK > 0$. By (3.10), $\frac{\partial H_M}{\partial K} > 0$, i.e., as we increase K, the right hump moves to the right. For the

left hump, by (3.10) we have

$$\frac{\partial H_m}{\partial K} = \frac{b^2 - 4a}{2a\sqrt{\Delta_1}(b + 2aK + 2\sqrt{\Delta_1})}.$$

For $b \geq 2\sqrt{a}$, the left hump does not lie inside the positive cone. Hence, if it exists, $\frac{\partial H_m}{\partial K} < 0$; i.e., as we increase K, the left hump moves left.

2. Fix K inside the region $V_1 \cup V_2$.

First note that the distance between the two humps has a minimum $\frac{2}{\sqrt{3}a}\sqrt{b^2 - a}$ along the line segment $2b + aK = 0$ when $-2\sqrt{a} \leq b \leq -\sqrt{a}$.

In the subregion where $2b + aK < 0$, by (3.11), $\frac{\partial H_M}{\partial b} < 0$, so as we increase b, the right hump moves left. The sign of

$$\frac{\partial H_m}{\partial b} = \frac{a(\frac{4}{a} - K^2)}{2\sqrt{\Delta_1}(2\sqrt{\Delta_1} - 2b - aK)}$$

indicates the direction that the left hump moves in.

Similarly, in the subregion where $2b + aK > 0$, the results follow from $\frac{\partial H_m}{\partial b} < 0$ and

$$\frac{\partial H_M}{\partial b} = \frac{a(\frac{4}{a} - K^2)}{2\sqrt{\Delta_1}(2b + aK + 2\sqrt{\Delta_1})}. \qquad \square$$

4. Hopf bifurcations. From the analysis in section 2, E_λ is the only candidate for a Hopf bifurcation. It follows from (2.7) that if a Hopf bifurcation occurs, it occurs when λ coincides with a hump of the prey isocline $y = F(x)$, i.e., when λ is such that $F'(\lambda) = 0$ or, equivalently,

$$3a\lambda^2 - 2(Ka - b)\lambda + 1 - Kb = 0. \tag{4.1}$$

Eliminating λ from $\hat{g}(\lambda) = 0$ and $F'(\lambda) = 0$, we obtain

$$(4a - b^2)(aK^2 + bK + 1)\hat{d}^2 + 2(abK^2 + 2(b^2 - 2a)K + b)\hat{d} + 3(1 - bK) = 0. \tag{4.2}$$

For each fixed $a > 0$, (4.2) determines the Hopf bifurcation surface $\hat{d}(b, K)$. This is illustrated in Figure 4.1. The significance of P, Q, and R will be discussed in Proposition 4.3 and Theorem 5.2.

Note that, depending on the values of a and b, there may be one or two values of $\hat{d}$ at which a Hopf bifurcation occurs. These may be found explicitly by solving (4.2) for $\hat{d}$ to obtain

$$\hat{d}_\pm = \frac{-(abK^2 + 2(b^2 - 2a)K + b) \pm (2 + bK)\sqrt{\Delta_1}}{(4a - b^2)(aK^2 + bK + 1)}. \tag{4.3}$$

4.1. Existence of Hopf bifurcations. Our analysis is based on the positions of the humps of the prey isocline relative to the vertical line $x = \frac{1}{\sqrt{a}}$. We study the Hopf bifurcation on the surface (4.2) by fixing (b, K) in each region V_i $(i = 0, 1, 2)$ and using $\hat{d}$ as a bifurcation parameter.

THEOREM 4.1. *Fix all parameters except $\hat{d} > 0$. Provided that $H_m \neq H_M$, a generic Hopf bifurcation occurs*

1. *at $E_\lambda = (H_m, F(H_m))$, when $\hat{d} = \hat{d}_-$, if $0 < H_m < \frac{1}{\sqrt{a}}$ and*

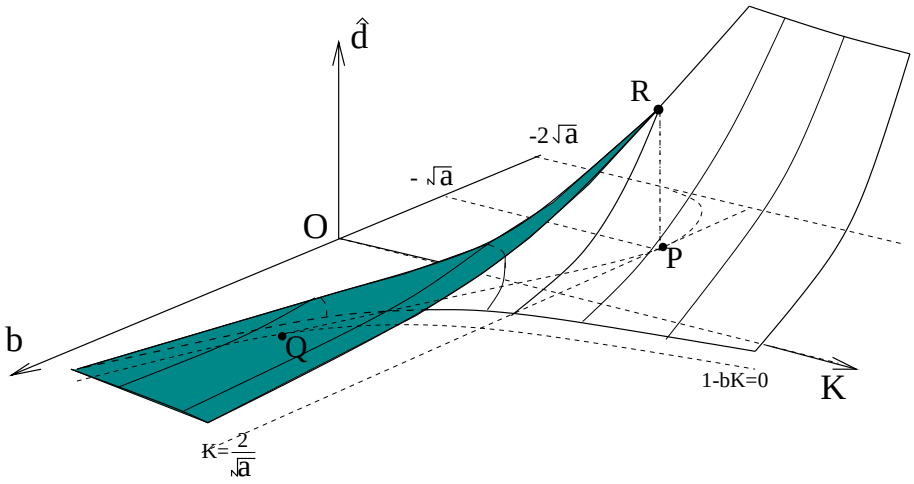

FIG. 4.1. *Hopf bifurcation surface* $\hat{d} = \hat{d}(b, K)$.

2. *at* $E_\lambda = (H_M, F(H_M))$, *when* $\hat{d} = \hat{d}_+$, *if* $0 < H_M < \frac{1}{\sqrt{a}}$.

No other nondegenerate Hopf bifurcations occur in the interior of the positive cone.

Proof. Consider the variational matrix about $E_\lambda = (\lambda, F(\lambda))$ (see (2.5)). It is clear from (2.2), (2.5), and (2.7) that $V(\lambda, F(\lambda))$ has pure imaginary eigenvalues if and only if $0 < \lambda < \frac{1}{\sqrt{a}}$ and $F'(\lambda) = 0$, and hence $\lambda = H_m$ or $\lambda = H_M$.

If $\lambda = H_m$, then $\hat{d} = \hat{p}(H_m)$. Substituting (3.7) in $\hat{p}(H_m)$ yields

$$\hat{d} = \hat{p}(H_m) = \frac{3[aK - b - \sqrt{\Delta_1}]}{2a^2K^2 + 2abK - b^2 + 6a - (2aK + b)\sqrt{\Delta_1}} = \hat{d}_-.$$

Similarly, if $\lambda = H_M$, then $\hat{d} = \hat{p}(H_m)$, and we can show that $\hat{p}(H_M) = \hat{d}_+$.

Next we verify the transversality condition. At E_λ with $\lambda = H_m$ or H_M, let γ be the real part of the eigenvalue. Then a straightforward calculation from (2.5) and (2.7) gives

$$\gamma = \frac{1}{2}p(\lambda)F'(\lambda) = -\left(\frac{rm}{2K}\right)\frac{\lambda(3a\lambda^2 - 2(aK - b)\lambda + 1 - bK)}{a\lambda^2 + b\lambda + 1}. \tag{4.4}$$

Using Maple [29], we obtain

$$\begin{aligned}\frac{\partial\gamma}{\partial\hat{d}} = -\frac{rm\frac{\partial\lambda}{\partial\hat{d}}}{27a^2K}\Big[&3a(bK-1)(2a^2K^2 + 2abK - b^2 + 6a)\\ &-(4a^3K^3 + 3a^2bK^2 + 2b^3 - 9ab + 2)\Big(Ka - b - \sqrt{\Delta_0}\Big)\Big].\end{aligned} \tag{4.5}$$

Note that $\frac{\partial\lambda}{\partial\hat{d}} = -\frac{\lambda}{\hat{d}\sqrt{\Delta_0}} \neq 0$ as long as $\lambda > 0$ and so $\frac{\partial\gamma}{\partial\hat{d}} = 0$ if and only if the term in square brackets in (4.5) equals 0. This occurs only when $H_m = 0$ or $H_M = 0$ or $H_m = H_M = H_I$. Thus the transversality condition is satisfied.

The only other equilibria of (1.3) are E_0, E_μ, and E_K. No nondegenerate Hopf bifurcation can occur at any of these equilibria, since the corresponding variational matrix always has real eigenvalues in each case. ∎

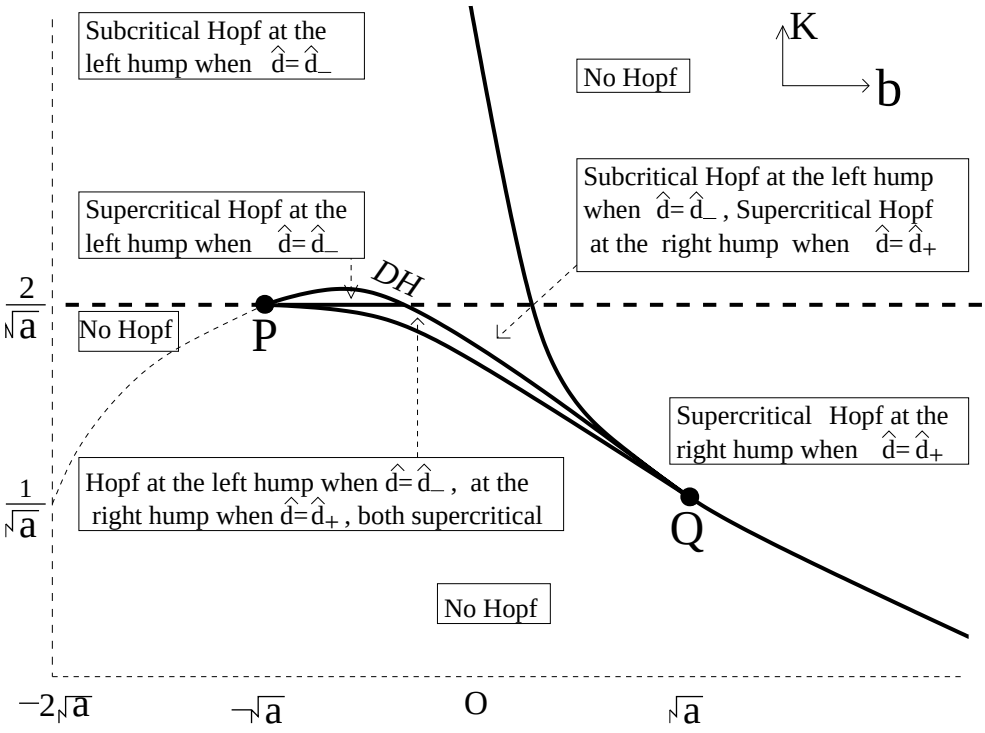

FIG. 4.2. *The existence and criticality of Hopf bifurcations in the bK plane as $\hat{d}$ is varied.*

By the above theorem, if the predator isocline has a hump inside the positive cone, and the hump is to the left of the vertical line $x = \frac{1}{\sqrt{a}}$, there exists a $\hat{d}$ defined by (4.3) such that system (1.3) undergoes a Hopf bifurcation. Hence, if we define

$$V_1^1 = \left\{ (b,K) \in V_1 \middle| K > \tfrac{2}{\sqrt{a}} \right\},$$

$$V_2^0 = \left\{ (b,K) \in V_2 \middle| b < -\sqrt{a},\ K < \tfrac{2}{\sqrt{a}} \right\}$$

from Theorem 4.1 and Proposition 3.2 (as shown in Figure 3.2), we obtain the following corollary as illustrated in Figure 4.1 and Figure 4.2.

COROLLARY 4.2. *Fix all parameters except $\hat{d} > 0$ and allow $\hat{d}$ to vary (see Figure 4.2).*

1. *No Hopf bifurcation occurs if*
   (a) $(b,K) \in V_0 \cup V_1^1 \cup V_2^0$,
   (b) $(b,K) \in C_1$,
   (c) $(b,K) \in C_2$ *and* $K < \frac{1}{\sqrt{a}}$ *or* $K > \frac{2}{\sqrt{a}}$.
2. *There is exactly one Hopf bifurcation and it occurs at $(H_M, F(H_M))$ when $\hat{d} = \hat{d}_+$ if*
   (a) $(b,K) \in C_2$ *and* $\frac{1}{\sqrt{a}} < K < \frac{2}{\sqrt{a}}$ *or*
   (b) $(b,K) \in V_1$, $K < \frac{2}{\sqrt{a}}$.
3. *There is exactly one Hopf bifurcation and it occurs at $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$ if*

- $(b, K) \in V_2$, $K > \frac{2}{\sqrt{a}}$.

4. *There are exactly two Hopf bifurcations: one occurs at* $(H_m, F(H_m))$ *when* $\hat{d} = \hat{d}_-$, *and the other occurs at* $(H_M, F(H_M))$ *when* $\hat{d} = \hat{d}_+$ *if*
   - $(b, K) \in V_2$, $K < \frac{2}{\sqrt{a}}$, *and* $b > -\sqrt{a}$.

Proof. Recall that a Hopf bifurcation occurs when $E_\lambda = (\lambda, F(\lambda))$ coincides with a hump, i.e., when either $H_m = \lambda$ or $H_M = \lambda$ with $0 < \lambda < \frac{1}{\sqrt{a}}$. The results 2(b), 3, and 4 are the consequences of Theorem 4.1 and Proposition 3.2. It remains to prove 1 and 2(a).

Now for $(b, K) \in V_0$, $y = F(x)$ has no humps. For $(b, K) \in V_1^1$, $y = F(x)$ has only one hump, with $H_M > \frac{1}{\sqrt{a}}$. For $(b, K) \in V_2^0$, $y = F(x)$ has two humps, with $\frac{1}{\sqrt{a}} < H_m < H_M$. For $(b, K) \in C_1$, $H_m = H_M = H_I$. For $(b, K) \in C_2$, if $K < \frac{1}{\sqrt{a}}$, $H_M = 0$; if $K > \frac{2}{\sqrt{a}}$, $H_m = 0$ and $H_M < \frac{1}{\sqrt{a}}$. Thus a Hopf bifurcation is precluded in all cases. □

4.2. Criticality of the Hopf bifurcations. In a study [30] of Hopf bifurcation in systems of the form (1.1), the following formula for the Liapunov coefficient, σ, was obtained:

$$\sigma(x) = -\frac{p(x)F''(x)p''(x)}{p'(x)} + p(x)F'''(x) + 2p'(x)F''(x). \tag{4.6}$$

We will use this formula to give a complete description of the criticality of the Hopf bifurcation at $\hat{d} = \hat{d}_+$ and $\hat{d} = \hat{d}_-$.

PROPOSITION 4.3.

1. *When the Hopf bifurcation occurs at* E_λ *with* $\lambda = H_M$, *it is always supercritical.*
2. *Define the curve DH (Figures* 4.1 *and* 4.2*) connecting the two points* $P(-\sqrt{a}, \frac{2}{\sqrt{a}})$ *and* $Q(\sqrt{a}, \frac{1}{\sqrt{a}})$*:*

$$DH: \begin{aligned} &16a^4K^4 + a^2b(8a - 3b^2)K^3 - a^2(144a - 15b^2)K^2 \\ &\qquad - 8ab(9a - b^2)K + 16b^4 - 144ab^2 + 300a^2 = 0. \end{aligned} \tag{4.7}$$

   When the Hopf bifurcation occurs at E_λ *with* $\lambda = H_m$, *it is supercritical if* $(b, K) \in V_2$ *below DH; it is subcritical if* $(b, K) \in V_2$ *and* $-2\sqrt{a} < b < -\sqrt{a}$ *or above DH.*
3. *For* $(b, K) \in DH$, *a degenerate Hopf bifurcation occurs at* E_λ *with* $\lambda = H_m$ *when* $\hat{d} = \hat{d}_-$.

Proof. If the Hopf bifurcation occurs at E_λ with $\lambda = H_M$, it follows from (4.6) that we have

$$\begin{aligned} \sigma(H_M) &= \frac{F''(H_M)}{p'(H_M)}[2p'^2(H_M) - p(H_M)p''(H_M)] + p(H_M)F'''(H_M) \\ &= \frac{2m^2}{(aH_M^2 + bH_M + 1)^3}\frac{F''(H_M)}{p'(H_M)} - \frac{6ra}{mK}p(H_M). \end{aligned} \tag{4.8}$$

Note that $p'(H_M) > 0$ and $F''(H_M) < 0$. It then follows from (4.8) that $\sigma < 0$, i.e., when the Hopf bifurcation occurs at $E_\lambda = (H_M, F(H_M))$ with $\hat{d} = \hat{d}_+$, it is supercritical.

Assume that when $\hat{d} = \hat{d}_-$, a Hopf bifurcation occurs at E_λ with $\lambda = H_m$. By (4.6),

$$\sigma(\lambda) = \frac{2r[3a^2\lambda^3 - 9a\lambda - 2(b - aK)]}{K(1 - a\lambda^2)(a\lambda^2 + b\lambda + 1)}. \tag{4.9}$$

Note that when $\lambda \in (0, \frac{1}{\sqrt{a}})$, the denominator of (4.9) is positive. Consider σ defined by (4.9) as a function of b, K, and λ. Using λ as the parameter with $\lambda \in (0, \frac{1}{\sqrt{a}})$, then $\sigma = 0$ defines a simple curve connecting the two points $P(-\sqrt{a}, \frac{2}{\sqrt{a}})$ and $Q(\sqrt{a}, \frac{1}{\sqrt{a}})$. Now we develop an expression for this curve segment called DH.

If the Hopf bifurcation occurs at $x = \lambda$, then λ satisfies both (2.2) and (4.1). For the Hopf bifurcation to occur at $E_\lambda = (H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$, it follows that

$$\lambda = \frac{(2 + bK)\hat{d}_-}{3 - (b + 2aK)\hat{d}_-}. \tag{4.10}$$

Substituting (4.10) into (4.9) and using (4.3), we obtain an implicit equation $\sigma = 0$ which defines a simple curve in the bK plane, along which the Liapunov coefficient of the Hopf bifurcation vanishes. Using Maple [29], we can solve the equation and obtain $K = \frac{-b \pm \sqrt{b^2 - 4a}}{2a}$, which is not real for $-\sqrt{a} \le b \le \sqrt{a}$, and an implicit equation of b and K, which can be simplified to

$$\begin{aligned} 16a^4K^4 + a^2b(8a - 3b^2)K^3 - a^2(144a - 15b^2)K^2 \\ - 8ab(9a - b^2)K + 16b^4 - 144ab^2 + 300a^2 = 0. \end{aligned} \tag{4.11}$$

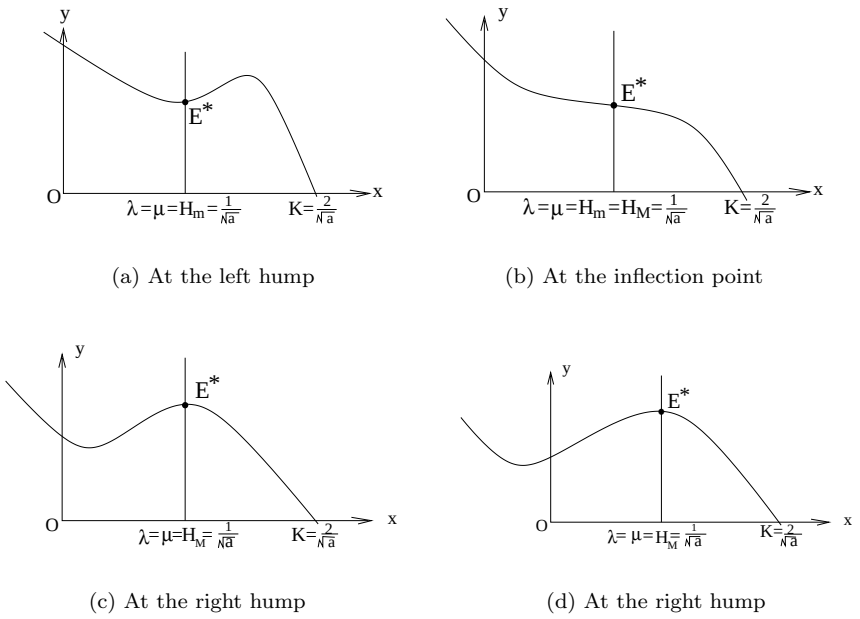
For $K > 0$, (4.11) defines a cusp curve with the cusp point located at P. The upper branch of the cusp curve is above the line $K = \frac{2}{\sqrt{a}}$ and is not relevant because it is an artifact of simplification. The lower branch passes through the point Q where it is tangent to C_2. Only the curve segment DH is relevant since there are no humps for $(b, K) \in V_0$. Along the curve segment DH, the Hopf bifurcation is degenerate. One can verify that for (b, K) above the curve DH, $\sigma > 0$, and so a subcritical Hopf bifurcation occurs at the left hump. Below the curve segment DH, $\sigma < 0$, and so a supercritical Hopf bifurcation occurs at the left hump.

At the two points $P(-\sqrt{a}, \frac{2}{\sqrt{a}})$ and $Q(\sqrt{a}, \frac{1}{\sqrt{a}})$, if the Hopf bifurcation occurs, it occurs at $\lambda = \frac{1}{\sqrt{a}}$, and the associated $\sigma = 0$. The Hopf bifurcation is therefore degenerate. □

The next theorem follows from Theorem 4.1, Corollary 4.2, and Propositions 4.3.

THEOREM 4.4. *Fix all parameters except $\hat{d} > 0$ and allow $\hat{d}$ to vary (see Figures* 3.2*,* 4.1*, and* 4.2*).*

1. *In region $V_1 \setminus V_1^1$, a supercritical Hopf bifurcation occurs at $(H_M, F(H_M))$ when $\hat{d} = \hat{d}_+$.*
2. *In region V_2, for $K > \frac{2}{\sqrt{a}}$, above the curve DH, a subcritical Hopf bifurcation occurs at $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$.*
3. *In region V_2, for $K > \frac{2}{\sqrt{a}}$, below the curve DH, a supercritical Hopf bifurcation occurs at $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$.*
4. *In region V_2, for $b > -\sqrt{a}$, $K < \frac{2}{\sqrt{a}}$, below the curve DH, two Hopf bifurcations occur. When $\hat{d} = \hat{d}_-$, one occurs at $(H_m, F(H_m))$. When $\hat{d} = \hat{d}_+$, one occurs at $(H_M, F(H_M))$. They are both supercritical.*
5. *In region V_2, for $K < \frac{2}{\sqrt{a}}$, above the curve DH, two Hopf bifurcations occur. When $\hat{d} = \hat{d}_-$, one occurs at $(H_m, F(H_m))$ and is subcritical. When $\hat{d} = \hat{d}_+$, one occurs at $(H_M, F(H_M))$ and is supercritical.*



(a) At the left hump (b) At the inflection point

(c) At the right hump (d) At the right hump

FIG. 5.1. *Positions of the isoclines and equilibria at the cusp bifurcation of codimension* 2, (a), (c), (d), *and* 3, (b).

5. The cusp points of codimension 2 and 3. From the analysis in sections 3 and 4, when

$$K = \frac{2}{\sqrt{a}}, \qquad d = \frac{mc}{b+2\sqrt{a}} = mc\hat{d}_M, \tag{5.1}$$

two equilibria E_λ and E_μ coalesce on the vertical line $x = \frac{1}{\sqrt{a}}$. That is,

$$E_\lambda = E_\mu = \left(\frac{1}{\sqrt{a}}, \frac{r(b+2\sqrt{a})}{2m\sqrt{a}}\right) := E^*.$$

Using (2.6) in (2.5) it follows that the equilibrium E^* has two zero eigenvalues.

From Proposition 3.3 and Figure 5.1, the position of E^* is described below. If $b \in (-2\sqrt{a}, -\sqrt{a})$, then E^* is at the left hump (Figure 5.1(a)). As b increases in this range, the right hump moves to the left until $b = -\sqrt{a}$, when the two humps coalesce and E^* is at the inflection point (Figure 5.1(b)). For $b \in (-\sqrt{a}, \infty)$, E^* is at the right hump (Figure 5.1(c)). As b increases, the left hump moves to the left until $b = \frac{\sqrt{a}}{2}$, when the left hump reaches the y-axis and leaves the first quadrant (Figure 5.1(d)).

In this section, we prove that E^* is a cusp singularity of codimension 2 for all $b \in (-2\sqrt{a}, \infty)$ except at $b = -\sqrt{a}$ where it is a cusp singularity of codimension 3. This generalizes the results in [28] and [26]. In [28] they only consider $b = 0$, and hence the cusp singularity of codimension 2. In [26], they proved that there is a set of parameters for which there is a cusp of codimension 2 for (1.6). They also indicated that there is a cusp of codimension at least 3, but did not prove that the codimension is exactly 3.

For any $b \in (-2\sqrt{a}, \infty)$ and K, d satisfying condition (5.1), system (1.3) becomes

$$\begin{cases} \dot{x} = rx\left(1 - \dfrac{\sqrt{a}}{2}x\right) - \dfrac{mxy}{ax^2 + bx + 1}, \\ \dot{y} = y\left[-\dfrac{mc}{b + 2\sqrt{a}} + \dfrac{mcx}{ax^2 + bx + 1}\right], \end{cases} \tag{5.2}$$

which has a unique equilibrium E^* in the positive cone. Using a series of transformations, we shall reduce system (5.2) to normal form.

The translation

$$X = x - \frac{1}{\sqrt{a}}, \qquad Y = y - \frac{r(b + 2\sqrt{a})}{2m\sqrt{a}}, \tag{5.3}$$

brings E^* to the origin. Expanding the right-hand side of the resulting system in a Taylor series about the origin, we obtain

$$\begin{cases} \dot{X} = -\dfrac{m}{b + 2\sqrt{a}}Y - \dfrac{r\sqrt{a}(b + \sqrt{a})}{2(b + 2\sqrt{a})}X^2 + R_{10}(X, Y), \\ \dot{Y} = -\dfrac{acr}{2(b + 2\sqrt{a})}X^2 + R_{20}(X, Y), \end{cases} \tag{5.4}$$

where R_{i0} $(i = 1, 2)$ is C^∞ in (X, Y) and $R_{i0}(X, Y) = O(|(X, Y)|^3)$.

Reversing time and making the transformation

$$X = X, \qquad Z = \frac{m}{b + 2\sqrt{a}}Y,$$

system (5.4) becomes

$$\begin{cases} \dot{X} = Z + \dfrac{r\sqrt{a}(b + \sqrt{a})}{2(b + 2\sqrt{a})}X^2 + R_{11}(X, Z), \\ \dot{Z} = \dfrac{acmr}{2(b + 2\sqrt{a})^2}X^2 + R_{21}(X, Z), \end{cases} \tag{5.5}$$

where R_{i1} $(i = 1, 2)$ is C^∞ in (X, Z) and $R_{i1}(X, Z) = O(|(X, Z)|^3)$.

Making the near-identity transformation

$$u = X, \qquad v = Z + \frac{r\sqrt{a}(b + \sqrt{a})}{2(b + 2\sqrt{a})}X^2 + R_{11}(X, Z), \tag{5.6}$$

we obtain

$$\begin{cases} \dot{u} = v, \\ \dot{v} = \delta_1 u^2 + \delta_2 uv + R_{22}(u, v), \end{cases} \tag{5.7}$$

where R_{22} is C^∞ in (X, Z), $R_{22}(u, v) = O(|(u, v)|^3)$, and

$$\delta_1 = \frac{acmr}{2(b + 2\sqrt{a})^2}, \quad \delta_2 = \frac{r\sqrt{a}(b + \sqrt{a})}{(b + 2\sqrt{a})}. \tag{5.8}$$

Thus we have the following theorem.

THEOREM 5.1. *For any $b > -2\sqrt{a}$, if d and K satisfy (5.1) and $b \neq -\sqrt{a}$, then the equilibrium E^* is a cusp point of codimension 2 (a Bogdanov–Takens bifurcation point).*

If $b = -\sqrt{a}$, the cusp point is at the inflection point of $F(x)$ (Figure 5.1(b)), and by (5.8), $\delta_2 = 0$ in the normal form (5.7). Thus the Bogdanov–Takens bifurcation is degenerate and the codimension of the cusp singularity is at least 3. To show that the codimension is exactly 3, one needs to show that system (5.7) is C^∞ equivalent to the generic normal form of the cusp point of codimension 3. This is the approach taken in the following theorem.

THEOREM 5.2. *If $(b, \hat{d}, K)$ is at the point R (Figure 4.1), i.e.,*

$$b = -\sqrt{a}, \qquad K = \frac{2}{\sqrt{a}}, \qquad d = \frac{mc}{\sqrt{a}}, \tag{5.9}$$

then the equilibrium $E^* = (\frac{1}{\sqrt{a}}, \frac{r}{2m})$ is a cusp point of codimension 3 (a degenerate Bogdanov–Takens bifurcation point).

Proof. It has been shown [8, 18, 21] that any system which has a cusp point of codimension 3 is C^∞ equivalent to the following:

$$\begin{cases} \dot{x} = y, \\ \dot{y} = x^2 + y[\beta x^3 + O(x^4)] + y^2 Q_4(x, y), \end{cases} \tag{5.10}$$

where $\beta \neq 0$. Thus, we will prove this theorem by showing that there exist smooth coordinate changes which take system (1.3) with the parameter values (5.9) into (5.10).

Under condition (5.9), $E^* = (\frac{1}{\sqrt{a}}, \frac{r}{2m})$. As in the case $b \neq -\sqrt{a}$, after translating the equilibrium to the origin and performing a Taylor expansion, we obtain

$$\begin{cases} \dot{X} = -\dfrac{m}{\sqrt{a}} Y + \sqrt{a} m X^2 Y - \dfrac{1}{2} a r X^3 + Q_{10}(X, Y), \\ \dot{Y} = -\dfrac{1}{2}\sqrt{a} c r X^2 - mc\sqrt{a} X^2 Y + \dfrac{1}{2} a r c X^3 + Q_{20}(X, Y), \end{cases} \tag{5.11}$$

where Q_{i0} $(i = 1, 2)$ is C^∞ in (X, Y) and $Q_{i0}(X, Y) = O(|(X, Y)|^4)$.

Reversing time and rescaling

$$X = X, \qquad Z = \frac{m}{\sqrt{a}} Y,$$

system (5.11) becomes

$$\begin{cases} \dot{X} = Z - a X^2 Z + \dfrac{1}{2} a r X^3 + Q_{11}(X, Z), \\ \dot{Z} = \dfrac{crm}{2} X^2 + mc\sqrt{a} X^2 Z - \dfrac{crm\sqrt{a}}{2} X^3 + Q_{21}(X, Z), \end{cases} \tag{5.12}$$

where Q_{i1} $(i = 1, 2)$ is C^∞ in (X, Z) and $Q_{i1}(X, Z) = O(|(X, Z)|^4)$.

Using the near-identity transformation

$$u = X, \qquad v = Z - a X^2 Z + \frac{1}{2} a r X^3 + Q_{11}(X, Z), \tag{5.13}$$

and changing u, v into x, y, we obtain

$$\begin{cases} \dot{x} = y, \\ \dot{y} = g_1(x) + y g_2(x) + y^2 Q_2(x, y), \end{cases} \tag{5.14}$$

where

$$g_1(x) = \frac{cmr}{2}x^2 + O(x^3),$$
$$g_2(x) = \left(mc\sqrt{a} + \frac{3}{2}ra\right)x^2 - mcax^3 + O(x^4),$$

$Q_2(x,y)$ $(i=1,2)$ is C^∞ in (x,y) and $Q_2(x,y) = O(|(X,Z)|^4)$.

Let

$$\omega_0 = ydy - [g_1(x) + yg_2(x) + y^2Q_2(x,y)]dx. \tag{5.15}$$

By using the 1-form (5.15) for system (5.14), we develop the normal form for the cusp singularity.

(1) Reduction of $g_1(x)$ to x^2. Since $g_1''(0) = crm \neq 0$, there exists a local diffeomorphism in x near the origin,

$$X = L(x) = \sqrt[3]{\frac{crm}{2}}x + O(x^2),$$

such that

$$X^2dX = g_1(x)dx. \tag{5.16}$$

By this diffeomorphism, the term $g_1(x)$ is reduced to x^2. Writing x instead of X, ω_0 becomes

$$\omega_0 = ydy - [x^2 + yg_3(x) + y^2Q_3(x,y)]dx, \tag{5.17}$$

where

$$g_3(x) = \alpha x^2 + \beta x^3 + O(x^4)$$

with $\alpha = (mc\sqrt{a} + \frac{3}{2}ar)\frac{\sqrt[3]{4acmr}}{acmr}$ and $\beta = -\frac{2}{r}$.

(2) Elimination of x^2 term from $g_3(x)$. Let $S(x,y) = \frac{1}{2}y^2 - \frac{1}{3}x^3$. Then $dS(x,y) = ydy - x^2dx$. Thus

$$yx^2dx = y^2dy - ydS. \tag{5.18}$$

Substituting (5.18) into (5.17), we obtain

$$\omega_0 = (1+\alpha y)dS(x,y) - \alpha y^2dy - y[\beta x^3 + O(x^4) + yQ_3(x,y)]dx. \tag{5.19}$$

It follows that

$$\begin{aligned}\frac{\omega_0}{1+\alpha y} &= dS(x,y) - \frac{\alpha y^2}{1+\alpha y}dy - \frac{y[\beta x^3 + O(x^4)] + yQ_4(x,y)}{1+\alpha y}dx \\ &= dS(x,y) - \frac{\alpha y^2}{1+\alpha y}dy - y[\beta x^3 + O(x^4) + yQ_4(x,y)]dx,\end{aligned} \tag{5.20}$$

where for $i = 3, 4$, $Q_i(x,y)$ is C^∞ in (x,y) and $Q_i(x,y) = O(|(x,y)|^4)$. Now a near-identity transformation

$$X = x, \quad Y = y + \cdots \tag{5.21}$$

transforms the exact 1-form $dS(x,y) - \frac{\alpha y^2}{1+\alpha y}dy$ into $dS(X,Y)$, where the term YX^3dX remains unchanged. Writing x and y instead of X and Y, system (1.3) in a neighborhood of E^* is thus equivalent to (5.10). Since $\beta = -\frac{2}{r} \neq 0$, E^* is a cusp point of codimension 3. □

By Theorem 5.1, if $K = \frac{2}{\sqrt{a}}$ and $d = \frac{mc}{b+2\sqrt{a}}$ but $b \neq -\sqrt{a}$, the cusp point is of codimension 2. One can find standard analysis for this codimension 2 bifurcation in Dumortier [6], Dumortier and Roussarie [7], Kuznetsov [18], and Mardešić [21]. In [28], the authors study this cusp point in the case $b = 0$ and develop a versal unfolding using K and d as distinguished parameters. The analysis of the cusp point of codimension 2 in the case $b \neq 0$ is similar; thus we will present only the codimension 3 versal unfolding of the cusp singularity. By the analysis in section 3, we have several different choices for the parameters to unfold the codimension 3 singularity: (b,d,K), (b,m,K), (b,c,K), $(a,b,d),\ldots$. In this paper, we take (b,d,K) as the bifurcation parameters and develop a versal unfolding for the codimension 3 cusp singularity when these three parameters are perturbed near the point $(b_0,d_0,K_0) = (-\sqrt{a}, \frac{mc}{\sqrt{a}}, \frac{2}{\sqrt{a}})$. We study the bifurcations of this unfolding by using the results in [8] and [21].

We wish to study system (1.3) for parameters (b,d,K) in a neighborhood of $(-\sqrt{a}, \frac{mc}{\sqrt{a}}, \frac{2}{\sqrt{a}})$. Thus we let

$$\begin{cases} b = -\sqrt{a} + \varepsilon_1, \\ d = \frac{mc}{\sqrt{a}} + \varepsilon_2, \\ K = \frac{2}{\sqrt{a}} + \varepsilon_3 \end{cases} \tag{5.22}$$

in (1.3) and we study the bifurcations of the resulting system

$$\begin{cases} \dot{x} = rx\left[1 - \dfrac{x}{\frac{2}{\sqrt{a}} + \varepsilon_3}\right] - \dfrac{mxy}{ax^2 + (-\sqrt{a} + \varepsilon_1)x + 1}, \\ \dot{y} = y\left[-\left(\dfrac{mc}{\sqrt{a}} + \varepsilon_2\right) + \dfrac{mcxy}{ax^2 + (-\sqrt{a} + \varepsilon_1)x + 1}\right], \end{cases} \tag{5.23}$$

for $\varepsilon = (\varepsilon_1, \varepsilon_2, \varepsilon_3)$ sufficiently small.

THEOREM 5.3. *For parameters $\varepsilon = (\varepsilon_1, \varepsilon_2, \varepsilon_3)$ sufficiently small, system* (5.23) *is a generic unfolding of the cusp singularity of codimension* 3.

Proof. It has been shown in [8] that a generic unfolding, with the parameters (ν_1, ν_2, ν_3), of the codimension 3 cusp singularity is C^∞ equivalent to

$$\begin{cases} \dot{x} &= y, \\ \dot{y} &= \nu_1 + x^2 + y[\nu_2 + \nu_3 x + x^3 + O(x^4)] + y^2 Q(x,y). \end{cases} \tag{5.24}$$

Using the method and results of [8, 10], we will show that system (5.23), with parameters $(\epsilon_1, \epsilon_2, \epsilon_3)$, is also a generic unfolding of the codimension 3 singularity by showing that there exist smooth coordinate changes which take (5.23) into (5.24) with

$$\frac{D(\nu_1, \nu_2, \nu_3)}{D(\varepsilon_1, \varepsilon_2, \varepsilon_3)}\Big|_{\varepsilon=(0,0,0)} \neq 0.$$

System (5.23) has a cusp point at $(\frac{1}{\sqrt{a}}, \frac{r}{2m})$ if $\varepsilon = (0,0,0)$. Applying the translation

$$\bar{x} = x - \frac{1}{\sqrt{a}}, \qquad \bar{y} = y - \frac{r}{2m},$$

and expanding system (5.23) in the power series about the origin, we have

$$\begin{cases} \dot{\bar{x}} = \overline{L}_{11}(\bar{x}) + \bar{y}\overline{L}_{12}(\bar{x}) + \bar{y}^2 Q_{10}(\bar{x},\bar{y}), \\ \dot{\bar{y}} = \overline{L}_{21}(\bar{x}) + \bar{y}\overline{L}_{22}(\bar{x}) + \bar{y}^2 Q_{20}(\bar{x},\bar{y}), \end{cases} \tag{5.25}$$

where $Q_{i0}(0,0) = 0$ $(i = 1, 2)$ and

$$\begin{aligned}
\overline{L}_{11}(\bar{x}) &= \frac{r(a\varepsilon_3 + 2\sqrt{a}\varepsilon_1\varepsilon_3 + 2\varepsilon_1)}{2\sqrt{a}(\sqrt{a}+\varepsilon_1)(2+\sqrt{a}\varepsilon_3)} + \frac{\sqrt{a}r\varepsilon_3}{2+\sqrt{a}\varepsilon_3}\bar{x} \\
&\quad + \frac{\sqrt{a}r(a^{3/2}\varepsilon_3 - 4\sqrt{a}\varepsilon_1 - 2\varepsilon_1^2)}{2(\sqrt{a}+\varepsilon_1)^2(2+\sqrt{a}\varepsilon_3)}\bar{x}^2 - \frac{a^2 r}{2(\sqrt{a}+\varepsilon_1)^2}\bar{x}^3 + O(\bar{x}^4), \\
\overline{L}_{12}(\bar{x}) &= -\frac{m}{\sqrt{a}+\varepsilon_1} + \frac{a^{3/2}m}{(\sqrt{a}+\varepsilon_1)^2}\bar{x}^2 - \frac{a^2 m}{(\sqrt{a}+\varepsilon_1)^2}\bar{x}^3 + O(\bar{x}^4), \\
\overline{L}_{21}(\bar{x}) &= \frac{r}{2m}\left(-\varepsilon_2 - \frac{mc\varepsilon_1}{\sqrt{a}(\sqrt{a}+\varepsilon_1)}\right) - \frac{a^{3/2}cr}{2(\sqrt{a}+\varepsilon_1)^2}\bar{x}^2 + \frac{a^2 cr}{2(\sqrt{a}+\varepsilon_1)^2}\bar{x}^3 + O(\bar{x}^4), \\
\overline{L}_{22}(\bar{x}) &= -\varepsilon_2 - \frac{mc\varepsilon_1}{\sqrt{a}(\sqrt{a}+\varepsilon_1)} - \frac{a^{3/2}cm}{(\sqrt{a}+\varepsilon_1)^2}\bar{x}^2 + \frac{a^2 mc}{(\sqrt{a}+\varepsilon_1)^2}\bar{x}^3 + O(\bar{x}^4).
\end{aligned}$$

By the transformation

$$\tilde{x} = \bar{x}, \qquad \tilde{y} = \overline{L}_{11}(\bar{x}) + \bar{y}\overline{L}_{12}(\bar{x}) + \bar{y}^2 Q_{10}(\bar{x},\bar{y}), \tag{5.26}$$

system (5.25) is C^∞ equivalent to

$$\begin{cases} \dot{\tilde{x}} = \tilde{y}, \\ \dot{\tilde{y}} = L_{21}(\tilde{x}) + \tilde{y}L_{22}(\tilde{x}) + \tilde{y}^2 Q_2(\tilde{x},\tilde{y}), \end{cases} \tag{5.27}$$

where

$$\begin{aligned}
L_{21}(\tilde{x}) &= \frac{r}{2a\sqrt{a}}\left((cm\varepsilon_1 - a\varepsilon_2) + O(|\varepsilon|^2)\right) + \frac{r}{2\sqrt{a}}\left(\varepsilon_3(cm\varepsilon_1 - a\varepsilon_2) + O(|\varepsilon|^3)\right)\tilde{x} \\
&\quad + \left[\frac{1}{2}mcr + O(|\varepsilon|)\right]\tilde{x}^2 - \left[\frac{1}{2}\sqrt{a}cmr + O(|\varepsilon|)\right]\tilde{x}^3 + O(\tilde{x}^4), \\
L_{22}(\tilde{x}) &= \frac{1}{2a}\left(-2mc\varepsilon_1 + 2a\varepsilon_2 + a\sqrt{a}r\varepsilon_3 + O(|\varepsilon|^2)\right) + r\left(-\varepsilon_1 + a\varepsilon_3 + O(|\varepsilon|^2)\right)\tilde{x} \\
&\quad - \frac{\sqrt{a}}{2}\left(3\sqrt{a}r + 2cm + O(|\varepsilon|)\right)\tilde{x}^2 + \left(acm + O(|\varepsilon|)\right)\tilde{x}^3 + O(\tilde{x}^4).
\end{aligned}$$

Note that for ε sufficiently small, $c_{20}(\varepsilon) := \frac{\partial^2 L_{21}}{\partial \tilde{x}^2}(0) = \frac{1}{2}mcr + O(|\varepsilon|) \neq 0$. Thus, in the proof of Theorem 5.3, we can reduce $L_{21}(\tilde{x})$ to a quadratic polynomial without linear terms. First, by rescaling $\tilde{y}$ and time t using

$$\hat{x} = \tilde{x}, \quad \hat{y} = \tilde{y}\sqrt{c_{20}(\varepsilon)}, \quad t = \frac{1}{\sqrt{c_{20}(\varepsilon)}}\tilde{t},$$

the coefficient of $\tilde{x}^2$ in $L_{21}(\tilde{x})$ becomes $1 + O(|\varepsilon|)$, and the coefficient of $\tilde{x}$ becomes

$$c_{10}(\varepsilon) = \frac{1}{\sqrt{a}mc}\left[\varepsilon_3(mc\varepsilon_1 - a\varepsilon_2) + O(|\varepsilon|^3)\right].$$

Then the translation

$$\hat{x} = c_{10}(\varepsilon) + O(|\varepsilon|^3) + \hat{u}, \quad \hat{y} = \hat{v}, \tag{5.28}$$

brings system (5.27) to

$$\begin{cases} \dot{\hat{u}} = \hat{v}, \\ \dot{\hat{v}} = \hat{L}_{21}(\hat{u},\varepsilon) + \hat{v}\hat{L}_{22}(\hat{u},\varepsilon) + \hat{v}^2\hat{Q}_2(\hat{u},\hat{v}), \end{cases} \tag{5.29}$$

where

$$\begin{aligned} &\hat{L}_{21}(\hat{u},\varepsilon) = \hat{\nu}_1(\varepsilon) + \hat{u}^2 + O(\hat{u}^3), \\ &\hat{L}_{22}(\hat{u},\varepsilon) = \hat{\xi}_0(\varepsilon) + \hat{\xi}_1(\varepsilon)\hat{u} + \hat{\xi}_2(\varepsilon)\hat{u}^2 - \hat{\xi}_3(\varepsilon)\hat{u}^3 + O(\hat{u}^4), \end{aligned}$$

and

$$\begin{aligned} \hat{\nu}_1 &= \frac{1}{a\sqrt{a}mc}\left(mc\varepsilon_1 - a\varepsilon_2 + O(|\varepsilon|^2)\right), \\ \hat{\xi}_0 &= \frac{1}{a\sqrt{2rmc}}\left[-2cm\varepsilon_1 + 2a\varepsilon_2 + a\sqrt{a}r\varepsilon_3 + O(|\varepsilon|^2)\right], \\ \hat{\xi}_1 &= \sqrt{\frac{2r}{mc}}\left(-\varepsilon_1 + a\varepsilon_3 + O(|\varepsilon|^2)\right), \\ \hat{\xi}_2 &= \sqrt{\frac{a}{2mcr}}\left(3\sqrt{a}r + 2mc + O(|\varepsilon|)\right), \\ \hat{\xi}_3 &= 3a\sqrt{\frac{ar}{2mc}} + O(|\varepsilon|). \end{aligned}$$

Consider the corresponding 1-form of (5.29):

$$\hat{v}d\hat{v} - \left[\hat{L}_{21}(\hat{u},\varepsilon) + \hat{v}\hat{L}_{22}(\hat{u},\varepsilon) + \hat{v}^2\hat{Q}_2(\hat{u},\hat{v})\right]d\hat{u} = 0. \tag{5.30}$$

Now we reduce $\hat{L}_{21}(\hat{u},\varepsilon)$ to $\tilde{\nu}_1 + \hat{u}^2$. Denote

$$\hat{L}(\hat{u},\varepsilon) = \hat{\nu}_1(\varepsilon)\hat{u} + \frac{1}{3}\hat{u}^3 + O(\hat{u}^4).$$

Using the Malgrange preparation theorem [5], we find a coordinate change of the form

$$\hat{u} = \Phi(\tilde{u},\varepsilon) = \phi(\varepsilon)\tilde{u} + O(\tilde{u}^2), \tag{5.31}$$

where $\phi(0) = 1$ such that

$$\hat{L}(\Phi(\tilde{u},\varepsilon),\varepsilon) = \tilde{\nu}_1(\varepsilon)\tilde{u} + \frac{1}{3}\tilde{u}^3,$$

and $\tilde{\nu}_1(\varepsilon) = \hat{\nu}_1(\varepsilon) + O(|\varepsilon|^2)$. Performing this coordinate change to family (5.30) and writing $\hat{v} = \tilde{v}$, we obtain

$$\tilde{v}d\tilde{v} - \left[\tilde{L}_{21}(\tilde{u},\varepsilon) + \tilde{v}\tilde{L}_{22}(\tilde{u},\varepsilon) + \tilde{v}^2\tilde{Q}_2(\tilde{u},\tilde{v})\right]d\tilde{u} = 0, \tag{5.32}$$

where

$$\tilde{L}_{21}(\tilde{u},\varepsilon) = \hat{\nu}_1(\varepsilon) + \tilde{u}^2,$$
$$\tilde{L}_{22}(\tilde{u},\varepsilon) = \tilde{\xi}_0(\varepsilon) + \tilde{\xi}_1(\varepsilon)\tilde{u} + \tilde{\xi}_2(\varepsilon)\tilde{u}^2 - \tilde{\xi}_3(\varepsilon)\tilde{u}^3 + O(\tilde{u}^4),$$

and $\tilde{\xi}_i(\varepsilon) = \xi_i(\varepsilon) + O(|\varepsilon|^2)$ $(i = 0, 1, 2, 3)$.

Then similar to step (2) in the proof of Theorem 5.2, using $S(\tilde{u},\tilde{v}) = \frac{1}{2}\tilde{v}^2 - \frac{1}{3}\tilde{u}^3$, and a near-identity transformation of the form

$$\begin{aligned} \tilde{u} &= u, \\ \tilde{v} &= v + \tfrac{1}{3}\xi_2(\varepsilon)v^2 + O(v^3), \end{aligned} \tag{5.33}$$

we eliminate the term $\tilde{v}\tilde{u}^2$ in (5.32), and system (5.23) is C^∞ equivalent to

$$\begin{cases} \dot{u} = v, \\ \dot{v} = \tilde{\nu}_1 + u^2 + v[\tilde{\xi}_0 + \tilde{\xi}_2 u - \tilde{\xi}_3 u^3 + O(u^4)] + v^2 Q(u,v). \end{cases} \tag{5.34}$$

For ε sufficiently small, the dominant terms in $\tilde{\nu}_1$ and $\tilde{\xi}_i$ $(i = 0, 2, 3)$ remain unchanged. Hence, we keep the previous notation.

For system (5.34), $\tilde{\xi}_3(0) = 3a\sqrt{\frac{ar}{2mc}} > 0$. Thus the rescaling

$$u = \frac{1}{\tilde{\xi}_3^{\frac{2}{5}}} U, \qquad v = \frac{1}{\tilde{\xi}_3^{\frac{3}{5}}} V, \qquad \tilde{t} = \xi_3^{\frac{1}{5}}\tau$$

shows that system (5.23) is equivalent to

$$\begin{cases} \dot{x} = y, \\ \dot{y} = \tilde{\tilde{\nu}}_1 + x^2 + y[\tilde{\tilde{\xi}}_0 + \tilde{\tilde{\xi}}_1 x - x^3 + O(x^4)] + y^2 Q(x,y), \end{cases} \tag{5.35}$$

where we have replaced (U, V, τ) with (x, y, t).

To apply the results from [8], we change the sign of the term $x^3 y$ in the second equation of (5.36) to positive by the transformation

$$\left(x,\ y,\ t,\ \tilde{\tilde{\nu}}_1,\ \tilde{\tilde{\xi}}_0,\ \tilde{\tilde{\xi}}_1\right) \longrightarrow \left(x,\ -y,\ -t,\ \tilde{\tilde{\nu}}_1,\ -\tilde{\tilde{\xi}}_0,\ -\tilde{\tilde{\xi}}_1\right);$$

then system (5.35) becomes

$$\begin{cases} \dot{x} = y, \\ \dot{y} = \tilde{\tilde{\nu}}_1 + x^2 + y[\tilde{\tilde{\xi}}_0 + \tilde{\tilde{\xi}}_1 x + x^3 + O(x^4)] + y^2 Q(x,y). \end{cases} \tag{5.36}$$

To simplify the expressions for the parameters, we make the rescaling

$$\begin{cases} \nu_1 = \sqrt[5]{\dfrac{81r^2}{4a^4(mc)^{12}}}\,\tilde{\tilde{\nu}}_1, \\ \nu_2 = \sqrt[10]{\dfrac{9}{64a^7r^4(mc)^6}}\,\tilde{\tilde{\xi}}_0, \\ \nu_3 = \sqrt[10]{\dfrac{64r^4}{9a^3(mc)^2}}\,\tilde{\tilde{\xi}}_1. \end{cases} \tag{5.37}$$

This yields (5.24), where using Maple, we obtain

$$
\begin{cases}
\nu_1 = mc\sqrt{a}(mc\varepsilon_1 + a\varepsilon_2) \\
\qquad + 2(mc)^2\varepsilon_1^2 + 4amc\varepsilon_1\varepsilon_2 + a^2\varepsilon_2^2 + O(|(\varepsilon_1,\varepsilon_2)|^3), \\
\nu_2 = -2mc\varepsilon_1 - 2a\varepsilon_2 + a\sqrt{a}r\varepsilon_3 \\
\qquad + \frac{1}{4}\left[-4(mc)^2\varepsilon_1^2 - 3a^2\sqrt{a}mcr\varepsilon_3^2 - 4a^2\varepsilon_2^2 - 16amc\varepsilon_1\varepsilon_2\right. \\
\qquad \left. + 2amc(3\sqrt{a}r + mc)\varepsilon_1\varepsilon_3 + 2a^2(\sqrt{a}r + mc)\varepsilon_2\varepsilon_3\right] + O(|\varepsilon|^3), \\
\nu_3 = -\varepsilon_1 + a\varepsilon_3 + \frac{1}{4}\left[-2rmc\varepsilon_1^2 - 3a^2mcr\varepsilon_3^2 - 2ar\varepsilon_1\varepsilon_2\right. \\
\qquad \left. + \sqrt{a}mc(11\sqrt{a}r + 4mc)\varepsilon_1\varepsilon_3 + 4\sqrt{a}(2\sqrt{a}r + mc)\varepsilon_2\varepsilon_3\right] + O(|\varepsilon|^3),
\end{cases}
\tag{5.38}
$$

and

$$
\frac{D(\nu_1,\nu_2,\nu_3)}{D(\varepsilon_1,\varepsilon_2,\varepsilon_3)}\Big|_{\varepsilon=(0,0,0)} = -a^3rmc \neq 0.
$$

So system (5.23) with parameters $\varepsilon = (\varepsilon_1, \varepsilon_2, \varepsilon_3)$ is a generic family unfolding the codimension 3 cusp singularity. □

By Theorem 5.3, system (5.23) is a generic family unfolding the cusp singularity of codimension 3. So by the main theorem in [8], system (5.23) has the same bifurcation set with respect to ε_3 as (5.24) has with respect to ν, at least up to a homeomorphism in the parameter space. This bifurcation set is a cone with vertex at the origin of the parameter space.

If $\nu_1 > 0$, system (5.24) obviously has no equilibria. In a neighborhood of the origin, $\nu_1 = 0$ is a saddle-node bifurcation plane. Crossing the plane in the direction of decreasing ν_1, two equilibria are created: a saddle and an antisaddle (node or focus). Correspondingly, from (5.38), there is a surface in the parameter space $(\varepsilon_1, \varepsilon_2, \varepsilon_3)$ defined by $\nu_1(\varepsilon_1, \varepsilon_2) = 0$:

$$
\varepsilon_2 = -\frac{mc}{a}\varepsilon_1 + \frac{mc}{a\sqrt{a}}\varepsilon_1^2 + O(\varepsilon_1^3). \tag{5.39}
$$

Along this surface, system (5.23) has a saddle-node bifurcation. Substituting (5.22) into (2.2), it follows that the exact saddle-node bifurcation surface is given by

$$
\Sigma_{SN}: \quad \varepsilon_2 = -\frac{mc}{\sqrt{a}}\frac{\varepsilon_1}{\sqrt{a}+\varepsilon_1}, \tag{5.40}
$$

which is consistent with (5.39). To the right of the surface Σ_{SN}, system (5.23) has no equilibria, thus all the bifurcation surfaces are located to the left of Σ_{SN}. Since up to a homeomorphism in the parameter space, each bifurcation surface is a cone with vertex at the origin; they can best be visualized by drawing their trace on the sphere

$$
S = \left\{(\nu_1,\nu_2,\nu_3)\Big|\nu_1 < 0, \nu_1^2 + \nu_2^2 + \nu_3^2 = \varepsilon_0, \varepsilon_0 > 0 \quad \text{sufficiently small}\right\}
$$

to the left of the surface Σ_{SN}.

As in Figure 5.2, let $\Gamma = S \cap \Sigma_{SN}$ be the intersection of the "half" sphere S with Σ_{SN}. Then along Γ, except for the two points b_1 and b_2, there is a saddle-node bifurcation. The next result follows from the bifurcation diagram given in Figure 3 of [8].

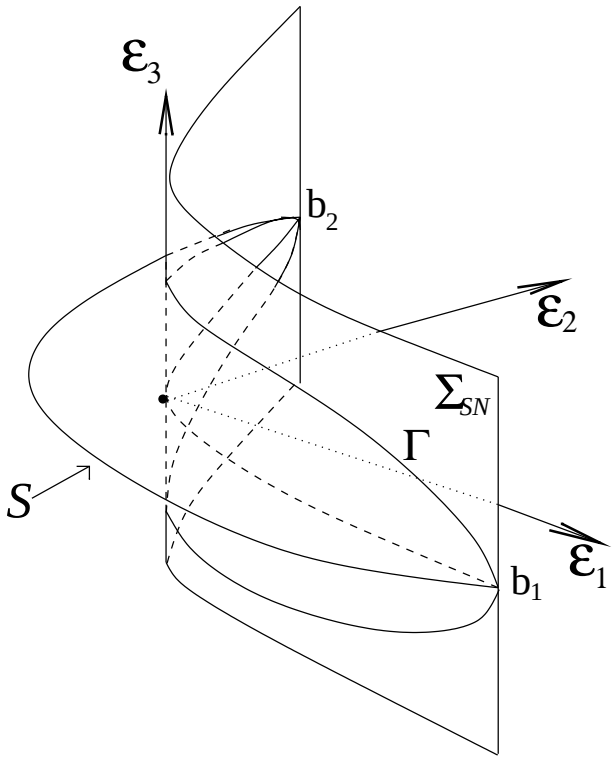


FIG. 5.2. Γ, *the intersection curve of the saddle-node bifurcation surface* Σ_{SN} *with the half sphere* S.

THEOREM 5.4. *For system* (5.24)*, using* $\varepsilon = (\varepsilon_1, \varepsilon_2, \varepsilon_3)$ *as parameters, the bifurcation diagram on* S *is given in Figure* 5.3.

On S, there are three bifurcation curves as shown in Figure 5.3:

- a curve H of Hopf bifurcations,
- a curve H_{om} of homoclinic bifurcations, and
- a curve SN_{lc} of saddle-node bifurcations of limit cycles.

As shown in Figure 5.3, the curve SN_{lc} joins a point h_2 on H to a point c_2 on H_{om}, and SN_{lc} is tangent to H at h_2 and tangent to H_{om} at c_2. The curves H and H_{om} have first order contact with the boundary of S at the points b_1 and b_2. In the neighborhood of b_1 and b_2, system (5.24) is an unfolding of the cusp singularity of codimension 2. This corresponds to the bifurcations along $K = \frac{2}{\sqrt{a}}$ with (d, b) in the neighborhood of $(\frac{mc}{\sqrt{a}}, -\sqrt{a})$. If $b > -\sqrt{a}$, the cusp singularity of codimension 2 is at the right hump, while if $b < -\sqrt{a}$, it is at the left hump.

Along the arc b_1h_2 of the curve H, a supercritical Hopf bifurcation occurs with a stable limit cycle appearing when the arc b_1h_2 is crossed from right to left. Along the arc h_2b_2 of the curve H, a subcritical Hopf bifurcation occurs with an unstable limit cycle appearing when the arc h_2b_2 is crossed from left to right. The point h_2 is a degenerate Hopf bifurcation point, i.e., a Hopf bifurcation point of codimension 2. The point h_2 in Figure 5.3 corresponds to the degenerate Hopf curve DH in Figures 4.2 and 6.1, which represents a three dimensional curve of codimension 2 Hopf bifurcations, projected onto the bK plane.

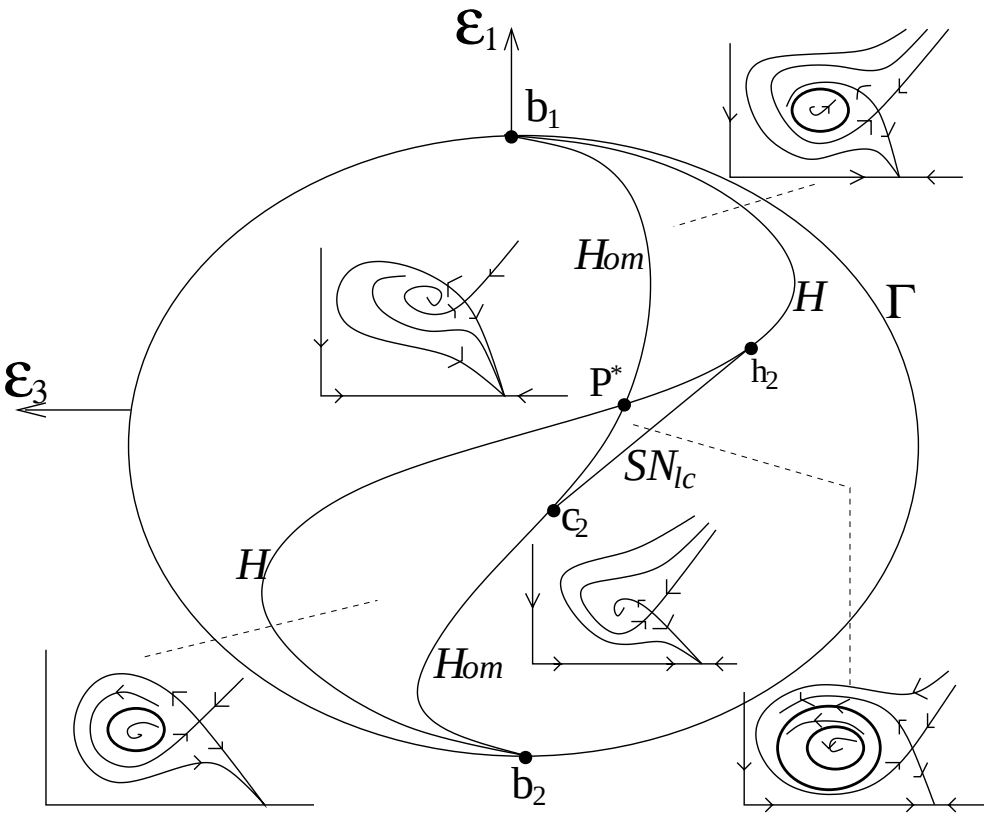

FIG. 5.3. *Bifurcation diagram for system* (5.24) *on* S.

Along the curve H_{om}, except at the point c_2, a homoclinic bifurcation of codimension 1 occurs. When the arc b_1c_2 of H_{om} is crossed from left to right, the two separatrices of the saddle point coincide and a stable limit cycle appears. The same phenomenon gives rise to an unstable limit cycle when the arc c_2b_2 of H_{om} is crossed from right to left. The point c_2 corresponds to a homoclinic bifurcation of codimension 2 (see [2, 23, 27] for references).

The curves H and H_{om} intersect transversally at a unique point P^* representing a parameter value of simultaneous Hopf and homoclinic bifurcation. The point P^* in Figure 5.3 corresponds to the curve HH in Figure 6.1, a projection to the bK plane of the three dimensional curve along which Hopf and homoclinic bifurcations occur simultaneously.

For parameter values in the curved triangle $P^*h_2c_2$, there exist exactly two limit cycles; the inner one is unstable and the outer one is stable. These two limit cycles coalesce in a generic way in a saddle-node bifurcation of limit cycles when the curve SN_{lc} is crossed from left to right. On the arc SN_{lc} itself, there exists a unique semistable limit cycle.

6. Global dynamics. In the previous section we proved that a degenerate Bogdanov–Takens bifurcation of codimension 3 occurs when (5.9) is satisfied. Therefore, when the parameters (1.5) are varied in a neighborhood of (5.9), a degenerate homoclinic bifurcation, degenerate Hopf bifurcation, and saddle-node bifurcation of

limit cycles must occur. In this section, using the information obtained from the analysis of the codimension 3 Bogdanov–Takens bifurcation and the geometry of system (1.3), we study the role of each of the parameters (1.5) in the global bifurcations of system (1.3). In order to do this, we determine when certain phenomena occur simultaneously. We then combine this information with the local dynamics studied in section 4 to determine the sequence of bifurcations in the different regions of parameter space as $\hat{d} = \frac{d}{mc}$ is varied.

6.1. Periodic orbits and homoclinic loops. It was proved in [30] that if system (1.3) has a limit cycle in the positive cone, it has to surround a hump of the prey isocline. In this subsection we prove several theorems which help determine whether system (1.3) has periodic orbits or homoclinic loops. Throughout this section, by periodic orbits we mean nontrivial periodic orbits.

THEOREM 6.1. *For system* (1.3)*, the horizontal line* $y = F(\lambda)$ *can intersect the prey isocline* $y = F(x)$ *at most three points in the first quadrant. If there is a periodic orbit, it lies entirely to the left of* E_K *and* E_μ *(if* E_μ *exists). Furthermore,*

- *if* $\lambda \neq H_m$, H_M*, the periodic orbit must surround* E_λ *and another intersection point* $(x^*, F(x^*))$*, where* $F(x^*) = F(\lambda)$*;*
- *if* $\lambda = H_m$ *or* H_M*, the periodic orbit must surround* E_λ*, the tangent point of* $y = F(\lambda)$ *with* $y = F(x)$*.*

Proof. From (1.4) it is clear that $y = F(x)$ is a cubic polynomial and hence $y = F(\lambda)$ can intersect $y = F(x)$ at at most three points.

If $\hat{d} \geq \hat{d}_M$, then $\dot{y} \leq 0$ along all orbits and hence system (1.3) has no periodic orbits. The only case remaining is $0 < \hat{d} < \hat{d}_M$.

Using standard phase plane arguments, it is clear that any periodic orbit must lie entirely to the left of E_K and E_μ (if E_μ exists). By a consequence of the Poincaré–Bendixson theorem, a periodic orbit in the plane must surround an equilibrium. By phase plane analysis, E_λ is the only candidate.

Consider an auxiliary function of the form $L(x, y) = M(x) + N(y)$, where $M(x)$ and $N(y)$ are continuous and differentiable and satisfy the following equations, respectively:

$$\begin{aligned} &p(x)M'(x) = d - cp(x), \qquad M(\lambda) = 0,\ x > 0, \\ &yN'(y) = F(\lambda) - y, \qquad N(F(\lambda)) = 0,\ y > 0. \end{aligned} \tag{6.1}$$

Solving these equations, we obtain a function $L(x, y)$ defined in the first quadrant. Along the trajectories of system (1.3) we have

$$\frac{d}{dt}L(x, y) = (d - cp(x))[F(x) - F(\lambda)]. \tag{6.2}$$

For $\hat{d} \in (0, \hat{d}_M)$, (6.2) can be rewritten as

$$\dot{L}(t) = \frac{d}{dt}L(x(t), y(t)) = \frac{mca\hat{d}}{ax^2 + bx + 1}(x - \lambda)(x - \mu)[F(x) - F(\lambda)]. \tag{6.3}$$

Denote

$$\bar{\mu} = \min\{\mu, K\}. \tag{6.4}$$

If there is a closed orbit, $\dot{L}$ must undergo a change of sign along this orbit. If $\lambda = H_m$ or H_M, then $\dot{L}$ changes sign when $x = \lambda$, and if $\lambda \neq H_m$ or H_M, $\dot{L}$ can change

sign only when $x = \mu$ or $x = x^* \neq \lambda$, where $F(x^*) = F(\lambda)$. Therefore, $\lambda = H_m$ or H_M, and the periodic orbit surrounds E_λ, or there exists a $x^* \in (0, \lambda) \cup (\lambda, \bar{\mu})$ such that $F(x^*) = F(\lambda)$, and $(x^*, F(x^*))$ sits inside the closed orbit. □

COROLLARY 6.2. *For system* (1.3)*, if E_λ is the only intersection point of the horizontal line $y = F(\lambda)$ with the prey isocline $y = F(x)$, and $\lambda \neq H_M$, then there are neither periodic orbits nor homoclinic loops.*

THEOREM 6.3. *Assume $\hat{d} \in (0, \hat{d}_M)$. Neither periodic orbits nor homoclinic loops exist if either*

1. *$F'(x) \leq 0$ for all $x \in (\lambda, \bar{\mu})$, or*
2. *$F'(\lambda) \geq 0$ and $F'(\mu) \geq 0$.*

Proof. To prove the theorem, we make a change of variables and rescale time by setting

$$u = \ln x, \quad v = \ln y, \quad \tau = \int_0^t \frac{1}{ax^2 + bx + 1} dt \tag{6.5}$$

to obtain

$$\begin{cases} \dot{u} = m[F(e^u) - e^v], \\ \dot{v} = -mc\hat{g}(e^u), \end{cases} \tag{6.6}$$

where $\hat{g}(x)$ is defined in (2.2).

1. We proceed by using the Dulac criterion with the positive auxiliary function $B(v) = e^{m\beta v}$, where β is a nonnegative constant to be determined.

The divergence

$$\begin{aligned} \operatorname{div}(B(v)[\dot{u}, \dot{v}]) &= -me^{m\beta v}[-e^u F'(e^u) + \beta mc\hat{g}(e^u)] \\ &= -me^{m\beta v} R(e^u, \beta), \end{aligned} \tag{6.7}$$

where

$$\begin{aligned} R(x, \beta) &= -xF'(x) + \beta mc\hat{g}(x) \\ &= \frac{3ar}{mK}x^3 + \left(a\hat{d}mc\beta - \frac{2r(aK - b)}{mK}\right)x^2 \\ &\quad + \left[(b\hat{d} - 1)mc\beta - \frac{r(bK - 1)}{mK}\right]x + mc\beta\hat{d}. \end{aligned} \tag{6.8}$$

It follows from Theorem 6.1 that a periodic solution or a homoclinic loop must lie entirely inside the strip

$$\left\{(x, y) \middle| 0 < x < \bar{\mu}, y > 0\right\}.$$

Thus it is enough to show that there exists a $\beta_1 \geq 0$ such that

$$R(x, \beta_1) \geq 0, \quad x \in (0, \bar{\mu}). \tag{6.9}$$

Consider the cubic, $R(x, 0)$. By the hypothesis, $R(x, 0) > 0$ for $\lambda < x < \bar{\mu}$. Therefore (6.9) is satisfied with $\beta_1 = 0$, unless there is either one or two simple roots of $R(x, 0)$ inside the interval $(0, \lambda)$. We now consider this case.

Note that $\lim_{x \to \pm\infty} R(x, \beta) = \pm\infty$ for any $\beta \geq 0$, and $\hat{g}(\lambda) = \hat{g}(\mu) = 0$, $\hat{g}(x) < 0$ if $x \in (\lambda, \mu)$, and $\hat{g}(x) > 0$, otherwise. Therefore for $\beta > 0$, there is always one negative root of $R(x, \beta)$ and for $\beta > 0$ sufficiently small there are two positive roots in $(0, \lambda]$.

Since $R(\lambda,\beta) = -\lambda F'(\lambda) \geq 0$ for all $\beta \geq 0$, and since $\hat{g}(x) > 0$ for $x \in [0,\lambda)$, there exists $\beta_1 > 0$ such that $R(x,\beta_1)$ has a double root in $(0,\lambda]$, and thus $R(x,\beta_1) \geq 0$ for $x \in (0,\bar{\mu})$.

2. The argument is similar. Using the auxiliary function $B(v) = e^{-m\beta v}$, the divergence

$$\operatorname{div}(B(v)[\dot{u},\dot{v}]) = me^{-m\beta v}R(e^u,\beta), \tag{6.10}$$

where $R(x,\beta) = xF'(x) + \beta mc\hat{g}(x)$. Note that $\lim_{x\to\pm\infty} R(x,\beta) = \mp\infty$ for all $\beta \geq 0$, the hypothesis implies that $F'(x) > 0$ for $\lambda < x < \mu$, and there is always a root of $R(x,\beta)$ such that $x \geq \beta$ rather than a negative root. ∎

COROLLARY 6.4.

1. *Assume $K \neq \frac{2}{\sqrt{a}}$. There exists a $\tilde{d} \in (0,\hat{d}_M)$ such that for all $\hat{d} > \tilde{d}$, system* (1.3) *has neither periodic orbits nor homoclinic loops.*
2. *Assume $K > \frac{2}{\sqrt{a}}$. Then for all $\hat{d} > \hat{d}_c$ ($\hat{d}_c$ was defined in* (3.1)*), system* (1.3) *has neither periodic orbits nor homoclinic loops if*
   - *$(b,K) \in V_1^1$, or*
   - *$(b,K) \in V_2$ and $F(0) < F(\lambda)$.*

Proof. 1. As $\hat{d} \in (0,\hat{d}_M)$ increases, λ and μ tend to $\frac{1}{\sqrt{a}}$ monotonically from the left and right side, respectively. Hence if $K \neq \frac{2}{\sqrt{a}}$, neither the left nor the right hump is at $\frac{1}{\sqrt{a}}$, and so there exists a $\tilde{d} \in (0,\hat{d}_M)$ such that for $\hat{d} \in (\tilde{d},\hat{d}_M)$, there are no interior equilibria or both of the interior equilibria satisfy either $F'(\lambda) > 0$ and $F'(\mu) > 0$ or $F'(x) < 0$ for all $x \in (\lambda,\bar{\mu})$. By Theorem 6.3, in either case, system (1.3) has no periodic orbits nor homoclinic loops.

2. This is a direct consequence of part 3 of Lemma 3.1 and Theorem 6.1. ∎

COROLLARY 6.5. *For system* (1.3) *with parameters* (1.5)*, if $(b,K) \in V_0 \cup V_2^0$, then for any $\hat{d} > 0$, system* (1.3) *has neither periodic orbits nor homoclinic loops.*

Proof. For any $(b,K) \in V_0$, $F'(x) < 0$ for all $x > 0$, so the result follows from Theorem 6.3.

Assume $(b,K) \in V_2^0$, and $\hat{d} \in (0,\hat{d}_M)$. In this region, $0 < \frac{1}{\sqrt{a}} < H_m < H_M < K$. By Lemma 3.1, since $K < \frac{2}{\sqrt{a}}$, $F(\lambda) > F(\mu)$. If $\mu \geq H_M$, then $F(\lambda) > F(H_M)$, and there is a unique intersection of $y = F(\lambda)$ and $y = F(x)$. The result follows from Corollary 6.2. If $\frac{1}{\sqrt{a}} < \mu < H_M$, besides $(\lambda, F(\lambda))$, any other intersection of $y = F(\lambda)$ and $y = F(x)$ must have x coordinate great than μ. The result follows from Theorem 6.1. ∎

THEOREM 6.6. *Fix all parameters except $\hat{d} > 0$.*

1. *No homoclinic bifurcation can occur for $\hat{d} \in (0,\hat{d}_{\mu K})$ (where $\hat{d}_{\mu K}$ is the value of $\hat{d}$ at the transcritical bifurcation involving E_μ and E_K).*
2. *When a homoclinic bifurcation occurs,*
   - *if $F'(\mu) < 0$, then it is supercritical,*
   - *if $F'(\mu) > 0$, then it is subcritical.*

Proof. Part 1 is obvious since in this case, if E_μ does not exist, E_λ is the only equilibrium inside the positive cone and it is never a saddle. E_K cannot form a saddle loop as the x-axis is invariant. Part 2 follows from a standard result [2], since $\operatorname{tr}(V(\mu,F(\mu))) = p(\mu)F'(\mu)$ (see (2.5)). ∎

THEOREM 6.7. *Fix all parameters except $\hat{d} > 0$. For $(b,K) \in V_2$ and $K > \frac{2}{\sqrt{a}}$, there exists a $\hat{d}_l \in (\hat{d}_{\mu K},\hat{d}_M)$ such that a homoclinic loop bifurcation involving E_μ occurs when $\hat{d} = \hat{d}_l$.*

Proof. If a homoclinic loop bifurcation occurs, it involves E_μ; hence it occurs for $\hat{d} \in (\hat{d}_{\mu K}, \hat{d}_M)$. For $\hat{d} < \hat{d}_{\mu K} (< \hat{d}_-)$, E_λ is the only equilibrium in the interior of the first quadrant and it is asymptotically stable. Since solutions are bounded, there must either be no limit cycles or an even number, excluding semistable periodic orbits. For $\hat{d} > \hat{d}_M$, system (1.3) has no limit cycles. By Corollary 4.2, there is exactly one Hopf bifurcation which occurs at $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$ and changes the parity of the limit cycles. Therefore, there must exist a $\hat{d}_l \in (\hat{d}_{\mu K}, \hat{d}_M)$ such that a homoclinic loop bifurcation occurs to compensate for this change in the number of limit cycles. ∎

6.2. Simultaneous phenomena. We will subdivide V_0, V_1, and V_2 using the curves defined below along which simultaneous phenomena occur for some $\hat{d} > 0$:

NS:	a Hopf bifurcation at E_λ with $\lambda = H_m$ and a neutral saddle at E_μ when $\mu = H_M$;
$E_{\mu K}$:	a Hopf bifurcation at E_λ with $\lambda = H_m$ or $\lambda = H_M$ and a transcritical bifurcation involving E_μ and E_K;
HH:	a Hopf bifurcation at E_λ with $\lambda = H_m$ and a homoclinic loop involving E_μ;
$Dhom$:	a homoclinic bifurcation involving E_μ when E_μ is a neutral saddle, i.e., $\mu = H_M$ (degenerate homoclinic bifurcation);
ST:	a saddle-node bifurcation of limit cycles and a transcritical bifurcation involving E_μ and E_K.

In the rest of this subsection, we will find analytic expressions for curves $E_{\mu K}$ and NS and prove that curves HH and $Dhom$ must exist in certain regions in parameter space. We will prove the existence of the curve ST in the next subsection. Information about these curves is summarized in Table 6.1 and illustrated in Figure 6.1 and Figure 6.4.

PROPOSITION 6.8. *In the bK plane (Figure* 6.1*), along the curve*

$$NS : K = -\frac{2}{b}, \qquad -\sqrt{a} < b < 0, \tag{6.11}$$

there exists a unique $\hat{d} \in (0, \hat{d}_M)$ such that a Hopf bifurcation at $(H_m, F(H_m))$ and a neutral saddle at $(H_M, F(H_M))$ occur simultaneously. To the left of NS the neutral saddle at $(H_M, F(H_M))$ occurs before the Hopf bifurcation at $(H_m, F(H_m))$. To the right of NS this ordering is reversed.

Proof. Recall from Theorem 4.1 that a Hopf bifurcation occurs at $(H_m, F(H_m))$ where $\hat{d} = \hat{d}_-$ as given in (4.3). In a similar manner to the proof of Theorem 4.1, it can be shown that for $\frac{2}{\sqrt{a}} < K < \frac{1}{b}$, a neutral saddle occurs at $(H_M, F(H_M))$ when $\hat{d} = \hat{d}_+$, as given in (4.3). We thus obtain

$$\hat{d}_+ - \hat{d}_- = \frac{(2 + bK)\sqrt{\Delta_1}}{(4a - b^2)(aK^2 + bK + 1)}. \tag{6.12}$$

Clearly, when $K = -\frac{2}{b}$, $\hat{d}_+ = \hat{d}_- = \frac{3K}{2(aK^2-1)}$, thus the Hopf bifurcation and the neutral saddle occur simultaneously at this value of $\hat{d}$. Note that $b^2 - 4a < 0$. Hence when $-2\sqrt{a} < b < -\frac{2}{K}$, $\hat{d}_+ < \hat{d}_-$, the neutral saddle occurs before the Hopf bifurcation, and when $-\frac{2}{\sqrt{a}} < b < \frac{1}{K}$, the order is reversed. To complete the proof we note that $\Delta_1 = 0$ only when $\lambda = H_m = H_M = H_I = \mu$, which corresponds to the point P. ∎

Recall that a transcritical bifurcation involving E_μ and E_K occurs when $K > \frac{1}{\sqrt{a}}$ and $\hat{d} = \hat{d}_{\mu K} = \hat{p}(K)$ (see (2.1)).

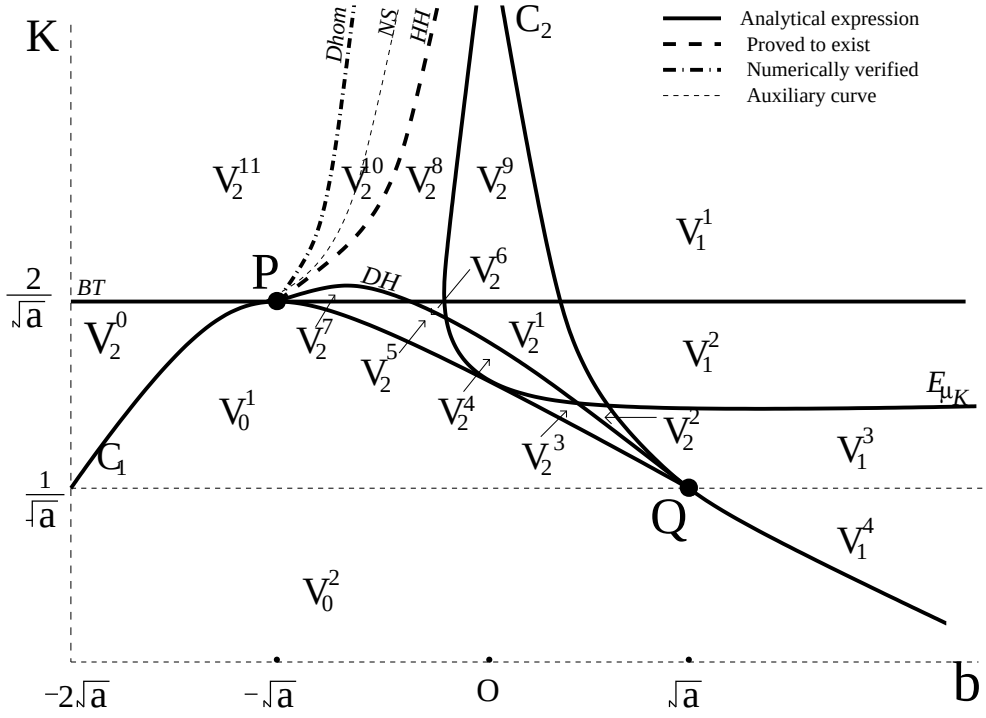

FIG. 6.1. *The subregions of the bK plane determined by the degenerate phenomena of Table* 6.1.

PROPOSITION 6.9. *In the bK plane (Figure* 6.1*), along the curve*

$$E_{\mu K} : b = \frac{3 - aK^2}{K(aK^2 - 2)}, \qquad K > \sqrt{\frac{2}{a}}, \tag{6.13}$$

there exists a unique $\hat{d} \in (0, \hat{d}_M)$ *such that the Hopf bifurcation and the* E_μ *and* E_K *transcritical bifurcation occur simultaneously. The curve* $E_{\mu K}$ *is tangent to* C_1 *at* $(0, \sqrt{3/a})$*. Along this curve, if* $b < 0$*, the Hopf bifurcation occurs at the left hump, and if* $b > 0$*, the Hopf bifurcation occurs at the right hump.*

1. *For* $(b, K) \in V_1 \setminus V_1^1$*,*
   (a) *if* (b, K) *is above* $E_{\mu K}$*, the transcritical bifurcation occurs before the Hopf bifurcation at* E_λ *with* $\lambda = H_M$*;*
   (b) *if* (b, K) *is below* $E_{\mu K}$*, the Hopf bifurcation at* E_λ *with* $\lambda = H_M$ *occurs before the transcritical bifurcation.*
2. *For* $(b, K) \in V_2 \setminus V_2^0$*,*
   (a) *if* (b, K) *is to the left of* $E_{\mu K}$*, the transcritical bifurcation occurs before the Hopf bifurcation at* E_λ *with* $\lambda = H_m$*;*
   (b) *if* (b, K) *is to the right of* $E_{\mu K}$*, the transcritical bifurcation occurs after the Hopf bifurcation at* E_λ *with* $\lambda = H_m$ *and, if* $K < \frac{2}{\sqrt{a}}$*, it occurs before the Hopf bifurcation at* E_λ *with* $\lambda = H_M$*;*
   (c) *if* (b, K) *is below* $E_{\mu K}$*, the Hopf bifurcations at* E_λ *with* $\lambda = H_m$ *and* $\lambda = H_M$ *occur before the transcritical bifurcation.*

Proof. Let $K = \mu$ and set $H_m = \lambda$ (see (2.4) and (3.7)),

$$\begin{cases} K = \dfrac{1 - b\hat{d} + \sqrt{\Delta_0}}{2a\hat{d}}, \\ \dfrac{aK - b - \sqrt{\Delta_1}}{3a} = \dfrac{1 - b\hat{d} - \sqrt{\Delta_0}}{2a\hat{d}}. \end{cases} \tag{6.14}$$

Eliminating $\hat{d}$ from (6.14), we obtain (6.13).

Eliminating $\hat{d}$ from $\mu = K$ and $H_M = \lambda$ yields (6.13).

From Theorem 4.4 it follows that the branch of $E_{\mu K}$ with $b < 0$ corresponds to the Hopf bifurcation at $(H_m, F(H_m))$, whereas the branch with $b > 0$ corresponds to the Hopf bifurcation at $(H_M, F(H_M))$. The ordering of the Hopf bifurcation at $(H_M, F(H_M))$ and the transcritical bifurcation follows from part 1 of Proposition 3.3. As K increases across $E_{\mu K}$ with $b > 0$, the right hump moves to the right. Thus in the region above $E_{\mu K}$, the transcritical bifurcation must occur before the Hopf bifurcation at $(H_M, F(H_M))$, and in the region below, the ordering must be reversed.

To the left of $E_{\mu K}$, it follows from Proposition 6.8 that a Hopf bifurcation can occur at the same time as a neutral saddle. Thus in this region the transcritical bifurcation must occur before the Hopf bifurcation at $(H_m, F(H_m))$. To the right of $E_{\mu K}$, notice that on C_2 above Q, $H_m = 0$. When $\hat{d} = \hat{d}_{\mu K}$, $\lambda > H_m$. Fix $\hat{d}$. For K slightly below C_2, $\lambda > H_m$, but $K < \mu$. Therefore the Hopf bifurcation at $(H_m, F(H_m))$ occurs before the transcritical bifurcation in this region. ∎

For system (1.3), if $b = 0$, it was proved in [28] that the Hopf bifurcation and homoclinic bifurcation cannot occur simultaneously. However, for $b < 0$ they can happen simultaneously along the curve HH. The bifurcation analysis of the codimension 3 cusp singularity in section 5 (Theorem 5.3) indicates that in a neighborhood of the point P, there exist curves DH, HH, and $Dhom$ emanating from P:

$$\begin{aligned} DH &: K = K_{DH}(b), \\ HH &: K = K_{HH}(b), \\ Dhom &: K = K_{Dhom}(b), \end{aligned} \tag{6.15}$$

HH and $Dhom$ are tangent to DH at P, and $Dhom$ is to the left of HH, which is to the left of DH. Recall that an analytic expression for DH was derived (see (4.11)). For any (b, K) along HH in a neighborhood of P, there exists a $\hat{d}_l$ such that when $\hat{d} = \hat{d}_l$, the system undergoes both a Hopf bifurcation and a homoclinic loop bifurcation. For any (b, K) along $Dhom$ in a neighborhood of P, there exists a $\hat{d}_{Dhom} \in (0, \hat{d}_M)$ such that when $\hat{d} = \hat{d}_{Dhom}$, system (1.3) undergoes a degenerate (codimension 2) homoclinic loop bifurcation. Also in a neighborhood of P, for any (b, K) in the region between DH and $Dhom$, there exists a $\hat{d}_{sn} \in (0, \hat{d}_M)$ such that when $\hat{d} = \hat{d}_{sn}$, system (1.3) undergoes a saddle-node bifurcation of limit cycles. In Figure 6.1 and Figure 6.2, we use a dot-dash line to illustrate $Dhom$ and a dashed line to illustrate HH. The global extension of the curve $Dhom$ has been observed numerically using XPPAUT. In the following we prove the position of NS with respect to $Dhom$ and HH.

LEMMA 6.10. *Fix all parameters as in* (1.5) *except* $\hat{d} > 0$. *For* $K < \frac{2}{\sqrt{a}}$ *and* $K > \frac{2}{\sqrt{a}}$ *to the right of* NS, *if a homoclinic bifurcation occurs, it is supercritical.*

Proof. By Proposition 3.2, if $K < \frac{2}{\sqrt{a}}$, $H_M < \frac{1}{\sqrt{a}} \le \mu$. If $K > \frac{2}{\sqrt{a}}$ to the right of NS, then $H_M < \mu$. Hence in both cases, $F'(\mu) < 0$. It follows from part 2 of Theorem 6.6 that if a homoclinic bifurcation occurs in either of these cases, it is supercritical. ∎

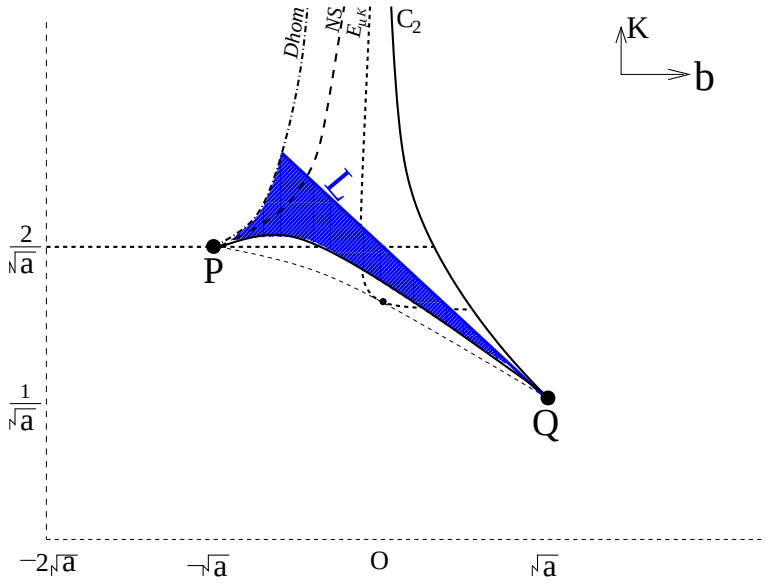

FIG. 6.2. *V^*, subregion of V_2, bounded by Dhom, DH, and C_2. For $(b, K) \in V_{sn}$, the shaded region, there exists a $\hat{d}_{sn} > 0$ such that when $\hat{d} = \hat{d}_{sn}$, system (1.3) undergoes a saddle-node bifurcation of limit cycles.*

COROLLARY 6.11. *Dhom lies to the left of NS.*

Before we establish the relative positions of NS and HH, we need the following results.

LEMMA 6.12.

1. *For $(b, K) \in V_2 \setminus V_2^0$ and to the left of NS, any homoclinic bifurcation that occurs must occur before the Hopf bifurcation.*
2. *For $(b, K) \in V_2$, $K \geq \frac{2}{\sqrt{a}}$ to the right of $E_{\mu K}$, any homoclinic bifurcation that occurs must occur after the Hopf bifurcation.*
3. *For $(b, K) \in V_2 \setminus V_2^0$, $K < \frac{2}{\sqrt{a}}$ to the right of $E_{\mu K}$, any homoclinic bifurcation that occurs must occur after the Hopf bifurcation at $(H_m, F(H_m))$ and before the Hopf bifurcation at $(H_M, F(H_M))$.*
4. *For $(b, K) \in V_2 \setminus V_2^0$, below $E_{\mu K}$ with $b > 0$, both Hopf bifurcations occur before any homoclinic bifurcation.*
5. *For $(b, K) \in V_1 \setminus V_1^1$, any homoclinic bifurcation that occurs must occur before the Hopf bifurcation at $(H_M, f(H_M))$ when $\hat{d} = \hat{d}_+$.*

Proof. 1. For $(b, K) \in V_2 \setminus V_2^0$ and to the left of NS, from Theorem 4.4 and Proposition 6.8, the Hopf bifurcation at $(H_m, F(H_m))$ with $\hat{d} = \hat{d}_-$ occurs after the neutral saddle at $(H_M, F(H_M))$ with $\hat{d} = \hat{d}_+$. This implies that for $\hat{d} \geq \hat{d}_+$ $H_m \leq \lambda \leq \mu < H_M$, and hence $F'(\lambda) \geq 0$ and $F'(\mu) > 0$. By part 2 of Theorem 6.3, there are no periodic orbits or homoclinic loops for $\hat{d} \geq \hat{d}_+$.

2. For $(b, K) \in V_2$ and $K \geq \frac{2}{\sqrt{a}}$, it follows from Theorem 4.4 that the only Hopf bifurcation that occurs is at the $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$, and it is subcritical. By part 2(b) of Proposition 6.9, the Hopf bifurcation occurs before the E_μ and E_K transcritical bifurcation. Hence by part 1 of Theorem 6.6, no homoclinic bifurcation occurs for $\hat{d} \in (0, \hat{d}_-]$.

3. For $(b,K) \in V_2$ and $K < \frac{2}{\sqrt{a}}$, by part 2(b) of Proposition 6.9, the transcritical bifurcation involving E_μ and E_K occurs after the Hopf bifurcation at $(H_m, F(H_m))$ when $\hat{d} = \hat{d}_-$ and before the Hopf bifurcation at $(H_M, F(H_M))$ when $\hat{d} = \hat{d}_+$. A similar argument to that for part 2 shows that no homoclinic bifurcation occurs in $(0, \hat{d}_-]$, and a similar argument to that for part 1 shows that no homoclinic bifurcation occurs for $\hat{d} \geq \hat{d}_+$.

4. For $(b,K) \in V_2 \setminus V_2^0$, below $E_{\mu K}$ ($b > 0$), by Theorem 4.4, Hopf bifurcations occur at E_λ when $\lambda = H_m$ and $\lambda = H_M$. But by part 2(c) of Proposition 6.9, both Hopf bifurcations occur before the transcritical bifurcation involving E_μ and E_K, which implies any homoclinic bifurcation must occur after both Hopf bifurcations.

5. For $(b,K) \in V_1 \setminus V_1^1$, by Theorem 4.4, there is one Hopf bifurcation at $(H_M, F(H_M))$ when $\hat{d} = \hat{d}_+$. If $\hat{d} \geq \hat{d}_+$, then $H_M \leq \lambda < \bar{\mu}$ and $F'(x) \leq 0$ for $x \in (\lambda, \bar{\mu})$. Thus by part 1 of Theorem 6.3, for $\hat{d} \geq \hat{d}_+$ no homoclinic loops can exist. Hence any homoclinic bifurcation that occurs must occur before the Hopf bifurcation. □

PROPOSITION 6.13. *Fix all the parameters in* (1.5) *except* $\hat{d} > 0$. *If* (b,K) *is outside the region bounded by* NS, C_1, *and* $E_{\mu K}$ *(Figure* 6.1*), for all* $\hat{d} \in (0, \hat{d}_M)$, *a Hopf bifurcation and a homoclinic bifurcation cannot occur simultaneously.*

Proof. It follows from Theorem 4.4 that no Hopf bifurcations can occur for (b,K) in the regions V_0, V_2^0, and V_1^1. The proofs for $V_1 \setminus V_1^1$ and $V_2 \setminus V_2^0$ follow from Lemma 6.12. □

Recall that in the neighborhood of P, there exists a curve HH along which the Hopf bifurcation at the left hump and a homoclinic bifurcation occur simultaneously. Let V_{HH} be the region bounded by curves NS, $K = \frac{2}{\sqrt{a}}$, and $E_{\mu K}$ ($b < 0$). Now we prove the following theorem regarding the extension of the curve HH in V_{HH}.

THEOREM 6.14. *Fix all parameters except* $\hat{d} > 0$. *In* V_{HH}, *there exists a curve* HH: $K = K_{HH}(b)$ *with finite end point at* $P(-\sqrt{a}, \frac{2}{\sqrt{a}})$ *(Figure* 6.1*). For any* $(b,K) \in HH$, *there exists a unique* $\hat{d}_{hh} \in (\hat{d}_{\mu K}, \hat{d}_M)$, *such that when* $\hat{d} = \hat{d}_{hh}$, *the subcritical Hopf bifurcation at* $(H_m, F(H_m))$ *and a homoclinic loop bifurcation occur simultaneously.*

Proof. By Theorem 6.7, for $(b,K) \in V_{HH}$ there exists $\hat{d}_l \in (\hat{d}_{\mu K}, \hat{d}_M)$ such that a homoclinic bifurcation occurs at $\hat{d} = \hat{d}_l$. By Proposition 6.13, if the curve $K = K_{HH}(b)$ exists, it lies inside the region V_{HH}.

Now we prove that in V_{HH}, for fixed $K > \frac{2}{\sqrt{a}}$, there exists a $b \in (-\frac{2}{K}, \frac{3-aK^2}{K(aK^2-2)})$ such that the subcritical Hopf bifurcation at the left hump and a homoclinic bifurcation involving E_μ happen simultaneously when $\hat{d} = \hat{d}_- (< \hat{d}_+)$.

(a) First we show that along NS, any homoclinic bifurcation at $\hat{d} = \hat{d}_l$ occurs before the Hopf bifurcation.

From Proposition 6.8, if $b = -\frac{2}{K}$ (i.e., $(b,K) \in NS$), a Hopf bifurcation at $(H_m, F(H_m))$ and a neutral saddle at $(H_M, F(H_M))$ occur simultaneously when $\hat{d} = \frac{3K}{2(ak^2-1)}$. Then for $\hat{d} \in [\frac{3K}{2(aK^2-1)}, \hat{d}_M)$, we have $F'(\lambda) \geq 0$ and $F'(\mu) \geq 0$. By Theorem 6.3 neither periodic orbits nor homoclinic loops can exist. Hence along NS, any homoclinic bifurcation occurs before the Hopf bifurcation.

(b) Next we show that along $E_{\mu K}$, the Hopf bifurcation occurs before any homoclinic bifurcation.

This is obvious since the Hopf bifurcation occurs at $\hat{d} = \hat{d}_{\mu K}$, and any homoclinic bifurcation occurs when $\hat{d} > \hat{d}_{\mu K}$.

TABLE 6.1
Curves in the bK plane corresponding to degenerate phenomena. For the last 7 curves, there exists a $\hat{d}$ such that the indicated bifurcation occur.

Name	Phenomenon	Expression	
C_1	$H_m = H_M$	$K = \frac{\sqrt{3(4a-b^2)}-b}{2a}$, $-2\sqrt{a} < b \leq \sqrt{a}$	(3.8)
C_2	$H_m = 0$ or $H_M = 0$	$K = \frac{1}{b}$, $b > 0$	(3.8)
$E_{\mu K}$	Hopf & $E_\mu - E_K$ transcritical	$b = \frac{3 - aK^2}{K(aK^2 - 2)}$	(6.13)
NS	Hopf & neutral saddle	$K = -\frac{2}{b}$	(6.11)
BT	Bogdanov–Takens	$K = \frac{2}{\sqrt{a}}$	(5.1)
DH	Degenerate Hopf	$\sigma(K, b) = 0$	(4.11)
HH	Hopf & homoclinic	$K = K_{HH}(b)$	Theorem 6.14
$Dhom$	Degenerate homoclinic	$K = K_{Dhom}(b)$	(6.15)

By (a) and (b), for any K with (b, K) in V_{HH} there exists at least one $b^* \in (-\frac{2}{K}, \frac{3-aK^2}{K(aK^2-2)})$ such that at (b^*, K), there exists a unique $\hat{d} \in (\hat{d}_{\mu K}, \hat{d}_M)$ such that a Hopf bifurcation and a homoclinic loop bifurcation occur simultaneously. □

Remark 6.15. Theorem 5.4 proves the local existence of the curve HH emanating from P and lying between the curves NS and DH. Theorem 6.14 shows that this curve may be globally extended into the region V_{HH}. Since both NS and $E_{\mu K}$ tend to $b = 0$ as $K \to \infty$, the global extension of HH should do the same. In Figure 6.1 we have drawn the curve HH as a single branch emanating from P and lying above DH in V_{HH}. This representation of HH is supported by numerical simulations using XPPAUT [11]; however, we have not been able analytically to preclude that HH has multiple branches or crosses the curve DH.

We summarize the relevant curves in the bK plane in Table 6.1. As shown in Figure 6.1, we use these curves to divide V_0, V_1, and V_2 into the following subregions:

$$V_0 = V_0^1 \cup V_0^2,$$
$$V_1 = \bigcup_{k=1}^{4} V_1^k,$$
$$V_2 = \bigcup_{k=0}^{11} V_2^k.$$

6.3. Saddle-node bifurcation of limit cycles. Let V^* be the subregion of V_2 (Figure 6.1) bounded by $Dhom$, DH, and C_2; i.e.,

$$V^* = V_2^1 \cup V_2^2 \cup V_2^6 \cup V_2^8 \cup V_2^9 \cup V_2^{10}. \tag{6.16}$$

To study the saddle-node bifurcation of limit cycles for parameters away from P, we introduce a line segment L in the following proposition (see Figure 6.2).

PROPOSITION 6.16. *In the bK plane, the line*

$$L: \quad K = -\frac{b}{a} + \frac{2}{\sqrt{a}} \tag{6.17}$$

lies between the curves C_2 and DH and is tangent to C_1, DH, and C_2 at Q. In region V_2, below this line, $F(0) > F(H_M)$; above the line, $F(0) < F(H_M)$; and on the line, $F(0) = F(H_M)$.

Proof. The proof follows from direct calculations. □

As shown in Figure 6.2, the line L subdivides the region V^* into two subregions. Denote the shaded subregion below L by

$$V_{sn} = \left\{ (b,K) \in V^* \,\middle|\, K < -\frac{b}{a} + \frac{2}{\sqrt{a}} \right\}.$$

PROPOSITION 6.17. *Fix all the parameters except $\hat{d} > 0$. If $(b,K) \in V_{sn}$, there exists a $\hat{d}_{sn} \in (0, \hat{d}_-)$ such that when $\hat{d} = \hat{d}_{sn}$, system (1.3) undergoes a saddle-node bifurcation of limit cycles.*

Proof. For $(b,K) \in V_{sn}$, it follows from Proposition 6.16 that there exists a $\hat{d}_0 > 0$ such that for $\hat{d} \in (0, \hat{d}_0)$, $F(\lambda) > F(H_M)$. By Corollary 6.2, system (1.3) has neither periodic orbits nor homoclinic loops for $(b,K) \in V_{sn}$ and $\hat{d} \in (0, \hat{d}_0)$. Further, it follows from Theorem 4.4 that there exists a $\hat{d}_- \in [\hat{d}_0, \hat{d}_M)$ such that when $\hat{d} = \hat{d}_-$, system (1.3) undergoes a subcritical Hopf bifurcation at $(H_m, F(H_m))$. Recall that E_λ is asymptotically stable for $0 < \hat{d} < \hat{d}_-$ (see Table 2.1) and so an unstable periodic orbit must be destroyed as $\hat{d}$ increases through $\hat{d}_-$.

(1) In V_{sn} for $K \geq \frac{2}{\sqrt{a}}$ and to the right of the curve NS, from Theorem 4.4, there are no other Hopf bifurcations. From Lemma 6.10 any homoclinic bifurcation that occurs in supercritical. Thus, the only way to create the unstable limit cycle that must be destroyed in the subcritical Hopf bifurcation is to first have a saddle-node bifurcation of limit cycles.

(2) In V_{sn} for $K < \frac{2}{\sqrt{a}}$, by part 5 of Theorem 4.4, in addition to the subcritical Hopf bifurcation at $\hat{d} = \hat{d}_-$, and there is a supercritical Hopf bifurcation at $\hat{d} = \hat{d}_+$. From Lemma 6.10, any homoclinic bifurcation that occurs is supercritical. By a similar argument as for case (1), there must be a saddle-node bifurcation of limit cycles before the two Hopf bifurcations.

(3) In V_{sn} for $K \geq \frac{2}{\sqrt{a}}$, by Theorem 6.7 there exists a $\hat{d}_l$ such that when $\hat{d} = \hat{d}_l$ system (1.3) undergoes a homoclinic bifurcation. By Lemma 6.12, this homoclinic bifurcation must occur before the Hopf bifurcation. By definition, to the right of *Dhom* there must be a supercritical homoclinic bifurcation. Thus, an unstable limit cycle must already surround the asymptotically stable equilibrium. This limit cycle must have been created by a saddle-node bifurcation of limit cycles. □

PROPOSITION 6.18.

1. *In the bK plane (Figure 6.3), the curve*

$$C_{sn}: \quad b = \frac{3 - aK^2}{K}, \quad K \geq \sqrt{\frac{3}{a}} \tag{6.18}$$

lies between the curves C_1 and $E_{\mu K}$ and is tangent to them at $(0, \sqrt{3/a})$. For $(b,K) \in V_{sn}$, below this curve, if $\hat{d} \in (0, \hat{d}_{\mu K})$, system (1.3) has no closed orbits. Therefore the saddle-node bifurcation of limit cycles must occur after the transcritical bifurcation involving E_μ and E_K.

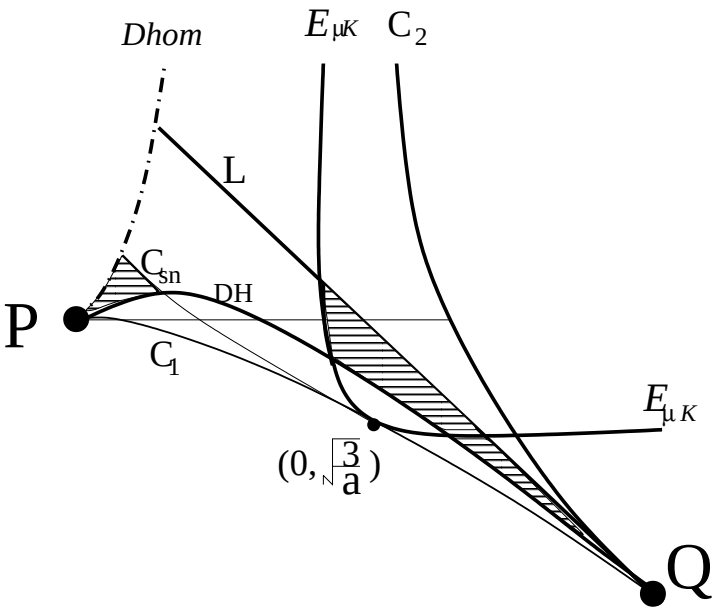

FIG. 6.3. *In the shaded subregion of V_{sn} below C_{sn}, the saddle-node bifurcation of limit cycles occurs after the transcritical bifurcation involving E_μ and E_K. In the shaded subregion of V_{sn} to the right of $E_{\mu K}$, the saddle-node bifurcation of limit cycles occurs before the transcritical bifurcation.*

2. *For $(b, K) \in V_{sn}$ to the right of the branch of $E_{\mu K}$ with $b < 0$, a saddle-node bifurcation of limit cycles occurs before the transcritical bifurcation involving E_μ and E_K.*

Proof. Note that in V_{sn}, $F(0) > F(H_M)$. As $\hat{d}$ increases from 0, there exists a $\hat{d}_0$ such that for $\hat{d} = \hat{d}_0$, $\lambda = \lambda_0$ where $F(\lambda_0) = F(H_M)$ and $\lambda_0 < H_m$. By Corollary 6.2, for $0 < \hat{d} < \hat{d}_0$, there are no periodic orbits or homoclinic loops. Therefore, the saddle-node bifurcation of limit cycles must occur for some $\hat{d} > \hat{d}_0$.

Setting $\mu = K$ and $F(\lambda) = F(H_M)$ in (1.4), (2.4), and (3.7) and eliminating $\hat{d}$, we obtain (6.13) and (6.18). By Proposition 6.9, if (b, K) satisfies (6.13), then when $\hat{d} = \hat{d}_{\mu K}$, we have $\lambda = H_m$. Hence (6.13) is not relevant and (6.18) corresponds to $\hat{d}_{\mu K} = \hat{d}_0$. Straightforward calculations show that curve (6.18) lies between C_1 and $E_{\mu K}$, is tangent to both C_1 and $E_{\mu K}$ at $(0, \sqrt{3/a})$, and lies below L in V_{sn}. Consideration of the sign of $F(\lambda) - F(H_M)$ when $\hat{d} = \hat{d}_{\mu K}$ shows that for $(b, K) \in V_{sn}$ below curve (6.18), $\hat{d}_0 > \hat{d}_{\mu K}$, and above curve (6.18), $\hat{d}_0 < \hat{d}_{\mu K}$. Therefore, the result follows.

On the other hand, for $(b, K) \in V_{sn}$ to the right of the branch of the curve $E_{\mu K}$ with $b < 0$, the Hopf bifurcation at $(H_m, F(H_m))$ occurs at the same time as or before the transcritical bifurcation involving E_μ and E_K. By Proposition 6.17, for $(b, K) \in V_{sn}$, the Hopf bifurcation at $(H_m, F(H_m))$ occurs after the saddle-node bifurcation of limit cycles. Therefore in this region a saddle-node bifurcation of limit cycles must occur before the transcritical bifurcation. □

As shown in Figure 6.4, the segment of C_{sn} between *Dhom* and *DH* and the segment of L between *Dhom* and $E_{\mu K}$ divide the regions V_2^8 and V_2^{10} into subregions V_2^{ia}, V_2^{ib}, and V_2^{ic} $(i = 8, 10)$. For the saddle-node bifurcation of limit cycles and its

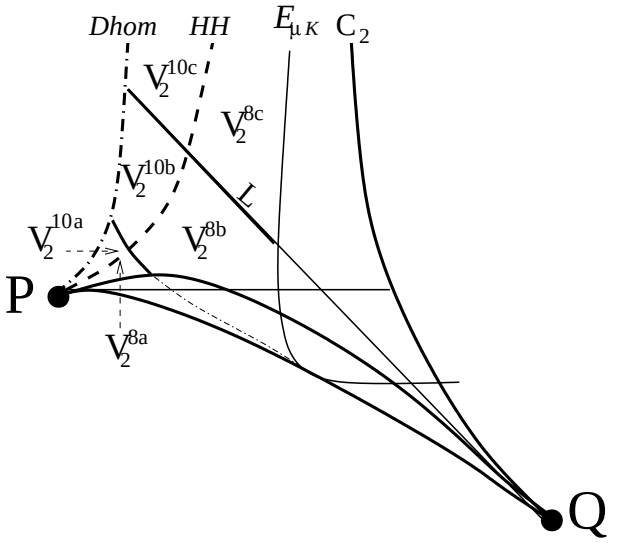

FIG. 6.4. *In V_{sn}, the curve C_{sn} and line L divide the regions V_2^8 and V_2^{10} into subregions V_2^{ia}, V_2^{ib}, and V_2^{ic} $(i = 8, 10)$.*

relative order with respect to the transcritical bifurcation involving E_μ and E_K, we make the following remark.

Remark 6.19.

1. By Proposition 6.18, for (b, K) in V_2^{8a} and V_2^{10a}, the saddle-node bifurcation of limit cycles occurs after the transcritical bifurcation involving E_μ and E_K.
2. When $\hat{d} = 0$, system (1.3) has a degenerate graphic with a line segment of equilibria. The bifurcation analysis of this type of graphic is very complicated (see [9] for reference), and will appear elsewhere.
3. For (b, K) in V_2^{ic} $(i = 8, 10)$ and V_2^9, above the line L, a saddle-node bifurcation of limit cycles may occur or the required limit cycles may come from a bifurcation of the degenerate singularity when $\hat{d} = 0$. Numerical simulations show that for (b, K) in V_2^{ic} $(i = 8, 10)$ and V_2^9, above the line L, system (1.3) has two limit cycles for $\hat{d} > 0$ very small.
4. For (b, K) in V_2^{ib} $(i = 8, 10)$ and V_2^6, it follows from Proposition 6.18 that there exists a curve that lies between C_{sn} and $E_{\mu K}$. For (b, K) on this curve, there exists a $\hat{d}_{sn} > 0$ such that a saddle-node bifurcation of limit cycles and the transcritical bifurcation involving E_μ and E_K occur simultaneously. This curve ST may not be unique.

6.4. Sequences of bifurcations. Although a three dimensional Hopf bifurcation surface is shown in Figure 4.1, it is not convenient to visualize the entire bifurcation diagram for system (1.3) in $(b, \hat{d}, K)$ space. Instead we describe the bifurcation diagram as $\hat{d}$ varies for fixed b and K inside each subregion (see Figure 6.1) of the bK plane. The sequences of bifurcations that occur in the interior of each subregion are given using the "dictionary of phase portraits" in Table 6.2. The sequences on the boundaries of each subregion are not included. These can easily be deduced by reading Tables 6.3–6.5 vertically. On the boundaries various simultaneous or degenerate bifurcations occur.

TABLE 6.2
Dictionary of phase portraits.

THEOREM 6.20. *Fix all parameters except* $\hat{d} > 0$. *For* $(b, K) \in V_0$, *when* $\hat{d} > 0$ *increases, the sequence of phase portraits occurring in the interior of each subregion is given in Table* 6.3. *In the table, moving from left to right as* $\hat{d}$ *increases, the phase portrait changes as a result of one of the following bifurcations:*

- *the transcritical bifurcation involving* E_λ *and* E_K *that occurs at* $\hat{d} = \hat{d}_{\lambda K}$;
- *the transcritical bifurcation involving* E_μ *and* E_K *that occurs at* $\hat{d} = \hat{d}_{\mu K}$;
- *the saddle-node bifurcation involving* E_λ *and* E_μ *that occurs at* $\hat{d} = \hat{d}_M$.

Proof. By Corollary 6.5, system (1.3) has neither periodic orbits nor homoclinic loops for $(b, K) \in V_0$. As $\hat{d} \in (0, \hat{d}_M)$ is varied, if $K > \frac{1}{\sqrt{a}}$, the only bifurcation that can occur is the transcritical bifurcation involving E_μ and E_K that occurs when $\hat{d} = \hat{d}_{\mu K}$ and the saddle-node bifurcation that occurs when $\hat{d} = \hat{d}_M$. If $0 < K < \frac{1}{\sqrt{a}}$, the only bifurcation that can occur is the transcritical bifurcation involving E_λ and E_K that occurs when $\hat{d} = \hat{d}_{\lambda K}$. □

THEOREM 6.21. *Fix all parameters except* $\hat{d} > 0$. *For* $(b, K) \in V_1$, *when* $\hat{d} > 0$ *increases, the sequence of phase portraits occurring in the interior of each subregion is given in Table* 6.4. *In the table, moving from left to right as* $\hat{d}$ *increases, the phase*

portrait changes due to one of the following bifurcations:

- *the transcritical bifurcation involving* E_λ *and* E_K *that occurs at* $\hat{d} = \hat{d}_{\lambda K}$;
- *the transcritical bifurcation involving* E_μ *and* E_K *that occurs at* $\hat{d} = \hat{d}_{\mu K}$;
- *the saddle-node bifurcation involving* E_λ *and* E_μ *that occurs at* $\hat{d} = \hat{d}_M$;
- *the supercritical Hopf bifurcation that occurs when* $\hat{d} = \hat{d}_+$;
- *a supercritical homoclinic bifurcation that occurs when* $\hat{d} = \hat{d}_l$.

For $(b, K) \in V_1^3 \cup V_1^4$, *the sequence is complete up to an even number of saddle-node bifurcations of limit cycles. For* $(b, K) \in V_1^1 \cup V_1^2$, *the sequences are complete up to an even number of saddle-node bifurcations of limit cycles and an even number of extra supercritical homoclinic bifurcations.*

Proof. In V_1 for $\hat{d} > 0$ sufficiently small, E_λ is an unstable node. Since solutions are bounded, a simple phase plane argument shows that there must be a stable limit cycle surrounding E_λ.

If $(b, K) \in V_1^1$, by Theorem 4.4, system (1.3) does not undergo Hopf bifurcations. Thus there must exist $\hat{d}_l$ such that when $\hat{d} = \hat{d}_l$ there is a supercritical homoclinic bifurcation destroying the limit cycle described above. Further, a transcritical bifurcation involving E_μ and E_K occurs when $\hat{d} = \hat{d}_{\mu K}$. By Theorem 6.6, $\hat{d}_{\mu K} < \hat{d}_l$. Thus, for $\hat{d} \in (0, \hat{d}_{\mu K})$, the system has a stable periodic orbit. For $\hat{d} \in (\hat{d}_l, \hat{d}_M)$, the system has no periodic orbit.

If $(b, K) \in V_1^2$, by Theorem 4.4, system (1.3) undergoes a supercritical Hopf bifurcation when $\hat{d} = \hat{d}_+$ ($\lambda = H_M$). It follows from Proposition 6.8 that the Hopf bifurcation occurs after the transcritical bifurcation involving E_μ and E_K at $\hat{d} = \hat{d}_{\mu K}$. For $\hat{d} \in (\hat{d}_+, \hat{d}_M)$, $0 < H_M < \lambda < \frac{1}{\sqrt{a}} < \mu < K$. By part 1 of Theorem 6.3, system (1.3) has neither periodic orbits nor homoclinic loops and hence has the phase portrait D.

If $(b, K) \in V_1^3$, the sequence of bifurcations is the same as in V_1^2 except that the supercritical Hopf bifurcation occurs before the transcritical bifurcation involving E_μ and E_K. Hence by part 1 of Theorem 6.3, no homoclinic bifurcations can occur.

If $(b, K) \in V_1^4$, then $0 < K < \frac{1}{\sqrt{a}}$. For $\hat{d} \in (0, \hat{d}_M)$, $K < \mu$. In this case, the transcritical bifurcation involves E_λ and E_K and occurs when $\hat{d} = \hat{d}_{\lambda K}$. Note that since $\mu > K$, no homoclinic bifurcation can occur by part 1 of Theorem 6.6. ∎

THEOREM 6.22. *Fix all parameters except* $\hat{d} > 0$. *For* $(b, K) \in V_2$, *when* $\hat{d} > 0$ *increases, the sequence of phase portraits occurring in the interior of each subregion is given in Table* 6.5. *In the table, moving from left to right as* $\hat{d}$ *increases, the phase portrait changes as a result of one of the following bifurcations:*

TABLE 6.5

Sequences of phase portraits for $(b, K) \in V_2$. In the three regions indicated by a †, above the line L, instead of a saddle-node bifurcation of limit cycles, there could be a degenerate bifurcation for $\hat{d} = 0$. In this case the sequence of phase portraits would begin with C instead of A. If more than one sequence is shown for a given region, it indicates that all of the sequences given are possible.

For $(b, K) \in V_2^0$, the sequence is complete.

For $(b, K) \in V_2^2 \cup V_2^3$, the sequences are complete up to an even number of extra saddle-node bifurcations of limit cycles.

For $(b, K) \in V_2^1 \cup V_2^4 \cup V_2^5 \cup V_2^6 \cup V_2^7 \cup V_2^9$, the sequences are complete up to an even number of extra supercritical homoclinic bifurcations and an even number of extra saddle-node bifurcations of limit cycles.

For $(b, K) \in V_2^8 \cup V_2^{10} \cup V_2^{11}$, the sequences are complete up to saddle-node bifurcations of limit cycles and an even number of extra homoclinic bifurcations.

Proof. The region V_2 has 12 subregions V_2^i $(i = 0, 1, \ldots, 11)$.

1. For $(b, K) \in V_2^0$, $0 < \frac{1}{\sqrt{a}} < H_m < H_M < K$. It follows from Theorem 4.4 and Corollary 6.5 that system (1.3) does not undergo Hopf bifurcations and has neither periodic orbits nor homoclinic loops. The only bifurcations that can occur are a transcritical bifurcation involving E_μ and E_K at $\hat{d} = \hat{d}_{\mu K}$ and a saddle-node bifurcation involving E_λ and E_μ at $\hat{d} = \hat{d}_M$. The transcritical bifurcation must occur before the saddle-node bifurcation involving E_λ and E_μ.

2. For $(b, K) \in V_2^1 \cup V_2^2 \cup V_2^6$, $0 < H_m < H_M < \frac{1}{\sqrt{a}} < K$. It follows from Theorem 4.4 that there exist $\hat{d}_-$ and $\hat{d}_+$ $(\hat{d}_- < \hat{d}_+)$ such that when $\hat{d} = \hat{d}_-$, a subcritical Hopf bifurcation occurs at $(H_m, F(H_m))$, and when $\hat{d} = \hat{d}_+$, a supercritical Hopf bifurcation occurs at $(H_M, F(H_M))$.

For $(b, K) \in V_2^1$, by Proposition 6.9, the Hopf bifurcation at $(H_m, F(H_m))$ occurs before the transcritical bifurcation involving E_μ and E_K, i.e., $\hat{d}_- < \hat{d}_{\mu K} < \hat{d}_+$. For $\hat{d} \in (\hat{d}_+, \hat{d}_M)$, there are two equilibria, E_λ and E_μ, satisfying $H_M < \lambda < \frac{1}{\sqrt{a}} < \mu < K$. By Theorem 6.3, the system has neither periodic orbits nor homoclinic loops. The two equilibria E_λ and E_μ disappear through a saddle-node bifurcation when $\hat{d} = \hat{d}_M$. If (b, K) is below the line L, by Proposition 6.17, there exists a $\hat{d}_{sn} < \hat{d}_+$ such that the system undergoes a saddle-node bifurcation of limit cycles. If (b, K) is above the line L, by part 3 of Remark 6.19, this saddle node bifurcation of limit cycles may not occur; instead, two limit cycles bifurcate from $\hat{d} = 0$.

For $(b, K) \in V_2^2$, it follows from Proposition 6.9 that the only difference from the case when $(b, K) \in V_2^1$ is that the transcritical bifurcation involving E_μ and E_K occurs after the Hopf bifurcation at $\hat{d} = \hat{d}_+$.

For $(b, K) \in V_2^6$, it follows from Proposition 6.9 that the transcritical bifurcation involving E_μ and E_K occurs before both Hopf bifurcations. Since V_2^6 sits entirely below the line L, by Proposition 6.17, there must exist a $\hat{d}_{sn} \in (0, \hat{d}_-)$ such that system (1.3) undergoes a saddle-node bifurcation of limit cycles. From part 4 of Remark 6.19, it is not clear whether $\hat{d}_{sn} < \hat{d}_{\mu K}$ or $\hat{d}_{\mu K} < \hat{d}_{sn}$.

3. For $(b, K) \in V_2^3 \cup V_2^4 \cup V_2^5$, $0 < H_m < H_M < \frac{1}{\sqrt{a}} < K$. By Theorem 4.4, there are two supercritical Hopf bifurcations, the first at $\hat{d} = \hat{d}_-$ and the second at $\hat{d} = \hat{d}_+$.

It follows from Proposition 6.9 that if $(b, K) \in V_2^3$, $\hat{d}_- < \hat{d}_+ < \hat{d}_{\mu K}$; if $(b, K) \in V_2^4$, $\hat{d}_- < \hat{d}_{\mu K} < \hat{d}_+$; if $(b, K) \in V_2^5$, $\hat{d}_{\mu K} < \hat{d}_- < \hat{d}_+$.

4. For $(b, K) \in V_2^7$, $0 < H_m < \frac{1}{\sqrt{a}} < H_M < K$. By Theorem 4.4, there exists a $\hat{d}_- \in (0, \hat{d}_M)$ such that when $\hat{d} = \hat{d}_-$, system (1.3) undergoes a supercritical Hopf

TABLE 6.6
Additional homoclinic bifurcations observed for $(b, K) \in V_2^1$ as $\hat{d}$ is varied.

F	E	F
$(\hat{d}_{\mu K}, \hat{d}_{l1})$	$(\hat{d}_{l1}, \hat{d}_{l2})$	$(\hat{d}_{l2}, \hat{d}_{+})$

bifurcation. By Proposition 6.9, $\hat{d}_{\mu K} < \hat{d}_{-}$. By Theorem 6.7 and Lemma 6.10, there exists a $\hat{d}_l$ such that when $\hat{d} = \hat{d}_l$, the system undergoes a supercritical homoclinic bifurcation. The homoclinic bifurcation must destroy the periodic orbit created by the Hopf bifurcation, so $\hat{d}_l > \hat{d}_{-}$.

5. For $(b, K) \in V_2^8 \cup V_2^9 \cup V_2^{10} \cup V_2^{11}$, $0 < H_m < \frac{1}{\sqrt{a}} < H_M < K$. By Theorem 4.4, there exists a unique $\hat{d}_{-} \in (0, \hat{d}_M)$ such that when $\hat{d} = \hat{d}_{-}$, system (1.3) undergoes a subcritical Hopf bifurcation. Therefore, an unstable periodic orbit must exist when $\hat{d}_{-} - \epsilon < \hat{d} < \hat{d}_{-}$ for some ϵ. This periodic orbit must be created in either (i) a saddle-node bifurcation of limit cycles for some $\hat{d}_{sn} < \hat{d}_{-}$, or (ii) a degenerate bifurcation at $\hat{d} = 0$ creating an even number of limit cycles, or (iii) a subcritical homoclinic bifurcation. In cases (i) and (ii), the outside, asymptotically stable periodic orbit would have to be destroyed in a supercritical homoclinic bifurcation. Thus, in all three cases, there must exist a $\hat{d}_l$ at which a homoclinic bifurcation occurs.

By definition of *Dhom*, the homoclinic bifurcation changes stability and is subcritical in V_2^{11} and supercritical in $V_2^8 \cup V_2^9 \cup V_2^{10}$. By definition of HH, $\hat{d}_l < \hat{d}_{-}$ to the left of HH and $\hat{d}_l > \hat{d}_{-}$ to the right of HH. By definition of $E_{\mu K}$, $\hat{d}_{-} < \hat{d}_{\mu K}$ to the right of the branch of $E_{\mu K}$ with $b < 0$, and $\hat{d}_{-} > \hat{d}_{\mu K}$ to the left of this branch.

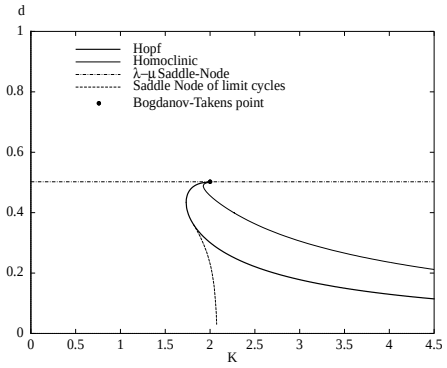
For $(b, K) \in V_2^{11}$, there is a subcritical homoclinic bifurcation at $\hat{d} = \hat{d}_l$ (i.e., case (iii) occurs) and by part 1 of Lemma 6.12, $\hat{d}_l < \hat{d}_{-}$. By part 1 of Theorem 6.6, $\hat{d}_{\mu K} < \hat{d}_l$. Therefore $0 < \hat{d}_{\mu K} < \hat{d}_l < \hat{d}_{-} < \hat{d}_M$.

For $(b, K) \in V_2^{10} \cup V_2^9 \cup V_2^8$, the homoclinic bifurcation is supercritical. In $V_2^{10a} \cup V_2^{10b} \cup V_2^{8a} \cup V_2^{8b}$ and V_2^9 below the line L case (i) occurs. In $V_2^{10c} \cup V_2^{8c}$ and V_2^9 above the line L, case (i) or (ii) occurs.

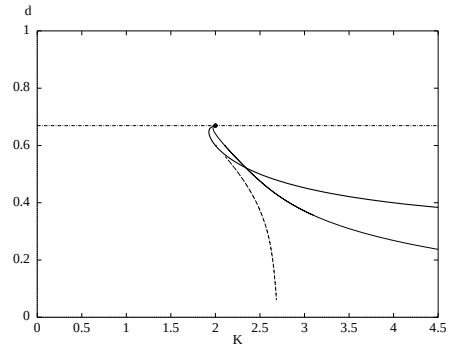
6. By part 1 of Theorem 6.6 and part 1 of Theorem 6.3, there is no homoclinic bifurcation for $(b, K) \in V_2^2 \cup V_2^3$. Solutions are bounded. There are either an even number or zero limit cycles for $\hat{d} > 0$ sufficiently small, and there are no limit cycles for $\hat{d} > \hat{d}_M$. We have considered all the other possible local and necessary global bifurcations. Hence, the sequences are complete as described in Table 6.5 up to saddle-node bifurcations of limit cycles and homoclinic bifurcations as indicated in the statement of the theorem. □

Remark 6.23. The sequence of phase portraits in Table 6.5 is complete up to saddle-node bifurcations of limit cycles and homoclinic loop bifurcations. For $(b, K) \in V_2^1$ and $\hat{d} \in (\hat{d}_{\mu K}, \hat{d}_{+})$, numerical simulations using XPPAUT [11] suggest that in addition to the critical values shown in the table, there could exist $\hat{d}_{l1}, \hat{d}_{l2} \in (\hat{d}_{\mu K}, \hat{d}_{+})$ such that when $\hat{d} = \hat{d}_{l1}$ and $\hat{d} = \hat{d}_{l2}$, system (1.3) undergoes homoclinic bifurcations and includes the subsequence of phase portraits listed in Table 6.6.

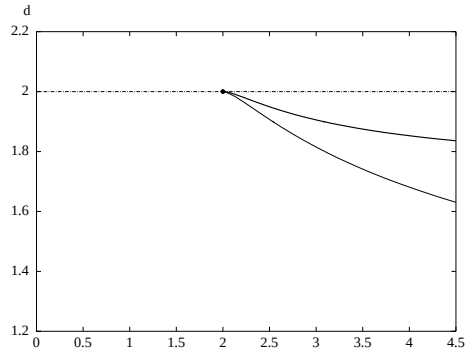
Numerical continuation of bifurcation curves carried out with the software Auto (through the XPPAUT [11] interface), supports our analysis. Fixing $a = m = c = r = 1$, which is consistent with the rescaling (1.7), we calculated the two parameter bifurcation sets in dK space, for $b = 0, -0.5, -1.5$ (Figure 6.5). Fixing K in Figure 6.5 and allowing d to vary vertically, we obtain sequences of bifurcations indicated by our analysis.



(a) $b = 0$



(b) $b = -0.5$



(c) $b = -1.5$

FIG. 6.5. *Two dimensional bifurcation diagram from XPPAUT* [11]*:* $a = m = c = r = 1$.

7. Discussion. This study was stimulated by a series of papers [13, 19, 24]. In [24], six mechanisms for periodically forcing the classical predator-prey model with Holling type II response functions were shown, surprisingly, to have topologically equivalent 2-parameter bifurcation diagrams for the associated first return map with respect to fold, flip, and Neimark–Sacker bifurcation curves of the first and second iterates and period doubling cascades. Even more unexpectedly, in [13] it was shown that the eight mechanisms for periodically forcing the analogous predator-prey model in a chemostat not only produced topologically equivalent diagrams, but these diagrams were topologically equivalent to the ones for the classical model. They conjectured a "universal diagram" for forced predator-prey systems. In [24] the authors state explicitly that it would be of interest to extend their analysis to a predator-prey model that has saddle-node bifurcations of limit cycles and homoclinic bifurcations for the unforced system. System (1.3) seemed like an ideal choice, since we were aware from previous studies [12, 30, 25, 26, 28] that it had the indicated bifurcations as the carrying capacity was varied. We felt certain that it should be possible to obtain 2-parameter bifurcation diagrams of the periodically forced version of system (1.3) that were not topologically equivalent to the ones in [13] and [24].

To our surprise, when the carrying capacity was forced, the 2-parameter bifurcation diagram was not significantly different [32]. In order to find parameters that would produce different diagrams, it was necessary to perform a more detailed bifurcation analysis on the unforced system, i.e., system (1.3), in order to understand the role of all of the parameters, and this was the motivation for this paper.

In fact, based on the results in this paper, in [32], we are able to show that for the Holling type IV response functions, different mechanisms for periodic forcing result in topologically distinct 2-parameter bifurcation diagrams and hence can be different than the postulated universal diagram.

Our work in this paper, analyzing local and global bifurcations of system (1.3), extends and complements the work in [12, 30, 25, 26, 28]. We now understand the role of perturbing each of the parameters on the dynamics. We described, for any fixed $a > 0$, $-2\sqrt{a} < b$, and $K > 0$, the sequence of bifurcations and associated phase portraits which occur as $\frac{d}{cm} > 0$ is varied. These results are summarized in Figure 6.1 and Tables 6.1–6.5 and include both local and global bifurcations. In particular, explicit regions in parameter space are provided for all of the phase portraits illustrated in Table 6.2, including regions where there are at least two limit cycles. We showed that for any $a, r > 0$ and $-2\sqrt{a} < b$ there is a Bogdanov–Takens bifurcation of codimension 2 when $d = \frac{cm}{b+2\sqrt{a}}$ and $K = \frac{2}{\sqrt{a}}$ with $b \neq -\sqrt{a}$ and a Bogdanov–Takens bifurcation of codimension 3 when $b = -\sqrt{a}$, $d = \frac{cm}{\sqrt{a}}$, and $K = \frac{2}{\sqrt{a}}$. We proved that the parameters $b,\ d,\ K$ give a versal unfolding of the codimension 3 bifurcation.

Although the model (1.3) contains seven parameters, our analysis shows that the parameter r has no effect on the existence and stability of equilibria, or of limit cycles created by Hopf bifurcations. Further, as seen in the results above, the parameters $c,\ d$, and m always occur in the ratio $\frac{d}{cm}$, and the parameter a acts as a scaling factor for b and K. These latter relations are not surprising given that $a,\ c$, and m could be removed via the rescaling (1.7), but these relations seem to indicate that this is the most "natural" way to reduce the seven parameters to four.

As discussed above, variation of the parameter d, the death rate of the predator, results in many different bifurcation sequences depending on the values of the other parameters. However, there is a common theme to all the sequences. For $d > 0$ small enough, any system starting with positive initial conditions will lead to coexistence of

the predator and the prey. For d large enough (i.e., $d > \frac{mc}{b+2\sqrt{a}}$), all initial conditions will result in extinction of the predator. In between there exists a range of values of d for which either coexistence or extinction of the predator can occur depending on the initial conditions. Most notably, if the initial prey population is large enough, then extinction of the predator will result regardless of the initial size of the predator population.

Our analysis allows us to describe the tremendous variation in the bifurcation sequences. In particular, we have shown that the coexistence of the predator and the prey can be in the form of a steady state or periodic solution, or, for some sets of parameters, both. We have not been able to exclude the possibility of further variation due to limit cycles appearing and disappearing in global bifurcations. Such variations can lead to biologically interesting sequences of bifurcations. One example, which we have observed numerically, discussed and listed in Table 6.6, involves two homoclinic bifurcations that occur in succession as d is increased. The result is that the system goes from a state where coexistence is possible to one where it is not and then back again. This gives rise to the surprising result that, for this set of parameters, *increasing* the per capita death rate of the predator actually *increases* the predator population's chance of survival (or analogously, *reducing* the per capita death rate of the predator *reduces* the predator population's chances of survival).

ON A DOUBLY NONLINEAR PARABOLIC OBSTACLE PROBLEM MODELLING ICE SHEET DYNAMICS*

N. CALVO†, J. I. DÍAZ‡, J. DURANY†, E. SCHIAVI§, AND C. VÁZQUEZ¶

Abstract. This paper deals with the weak formulation of a free (moving) boundary problem arising in theoretical glaciology. Considering shallow ice sheet flow, we present the mathematical analysis and the numerical solution of the second order nonlinear degenerate parabolic equation modelling, in the isothermal case, the ice sheet non-Newtonian dynamics. An obstacle problem is then deduced and analyzed. The existence of a free boundary generated by the support of the solution is proved and its location and evolution are qualitatively described by using a comparison principle and an energy method. Then the solutions are numerically computed with a method of characteristics and a duality algorithm to deal with the resulting variational inequalities. The weak framework we introduce and its analysis (both qualitative and numerical) are not restricted to the simple physics of the ice sheet model we consider nor to the model dimension; they can be successfully applied to more realistic and sophisticated models related to other geophysical settings.

Key words. ice sheet models, nonlinear degenerate equations, free boundaries, weak solutions, finite elements, duality methods

1. Introduction.

Modelling ice sheet dynamics has been a challenging problem since the beginning of the century, but nowadays the scientific community is showing a renewed, growing interest towards this problem. In fact, our understanding of climate system dynamics depends on the comprehension and predictability of the ice sheet dynamics. Large ice sheets influence and are influenced by climate, and their oscillations may be responsible for sudden shifts in climate in the recent geological past (Fowler [30]). The study of ice sheet models (ISM) is fundamental to the construction and comprehension of global energy balance models (EBM) and general circulation models (GCM) (see, for instance, Tarasov and Peltier [38] for a coupled ISM/EBM model). Various physically based theories have appeared during the last decades in order to explain the flow of these large ice masses, but a proper mathematical treatment is not available yet. This introduces the main aim of this paper, which is to present the mathematical and numerical analysis of an obstacle problem formulation for the study of the slow, isothermal, one-dimensional flow of ice along a rigid impermeable bed. This paper is organized as follows: after a brief description of the model equation and its strong formulation (section 2), we introduce in section 3 some weak formulations that we shall use later. The well-posedness of the model is then considered. Section 4 is devoted to the (qualitative) study of the free (moving)

boundary defined by the model. The quantitative analysis is done in section 5, where we numerically solve the problem by using, among other techniques, the algorithm proposed in Bermúdez and Moreno [8]. Some numerical tests are then performed, and additional information is provided by the consideration of specific real data. Finally, in section 6, we discuss our results and their scope.

2. Model equation and strong formulation. The model equation is the one proposed in Fowler [29], describing the evolution of the thickness $h(t,x)$ for a two-dimensional plane ice sheet. ($z = h(t,x)$ is the top surface of the ice sheet.) Ice is taken to be incompressible, and the flow is very slow. It flows as a viscous medium under its own weight, owing to gravity. A number of additional simplifying assumptions are used in the derivation of the model we consider (isothermal flow, shallow ice approximation, a flat, rigid, and impermeable bed, etc.). We refer to [29] for details on the modelling; for a more general introduction to glaciology, see, for instance, Hutter [32], Paterson [36], and Lliboutry [33]. According Fowler [29], the local thickness of the ice sheet satisfies the following nonlinear diffusion equation:

$$h_t = \left(\frac{h^{n+2}}{n+2} |h_x|^{n-1} h_x - u_b h \right)_x + a \quad \text{on } I(t), \tag{2.1}$$

where $a = a(t,x)$ is a given scaled fixed accumulation-ablation rate function ($a < 0$ signifies ablation) and u_b is a (given) function representing the basal velocity. For each fixed t the domain $I(t)$ represents the (unknown) bounded real interval where $h(t,x) > 0$ (i.e., $I(t) := \{x \,/\, h(x,t) > 0\}$). Notice that the physically relevant rate functions $a(t,x)$ are changing sign functions, which are positive in the central (accumulation) region of the ice sheet and negative near the margins (the boundaries of $I(t)$, i.e., in the ablation region); see Fowler [30, p. 95]. The exponent n that appears in (2.1) represents the so-called Glen's exponent, and it is usually assumed that $n \approx 3$ (see Fowler [29]). We shall assume $n = 3$, but the qualitative analysis remains unchanged for any $n > 1$ (non-Newtonian case). As regards the appropriate (mechanical) boundary condition, it depends on the thermal regime which we consider at the base. There are two possible geophysical situations corresponding to slip or no slip conditions. We shall consider both of them, generalizing in this way Fowler's approach.

When basal ice reaches the melting point, there is a net heat flux arriving at the bed of the ice sheet, and consequently basal melt water is produced: the ice begins to slide. Sliding is expected only where the basal ice is at the melting point. When u_b (the sliding velocity) is a prescribed function of (t,x) (i.e., $u_b = u_b(t,x)$), this equation is a nonlinear diffusion-convection equation for h. It corresponds to slip conditions along an assumed temperate bed (warm-based ice sheet). Once the base reaches the melting point, we assume that the ice above remains cold. Our aim is to show how it is possible to solve this model for a general, prescribed velocity field. For a slow shallow flow over a flat cold base, there is no sliding (i.e., $u_b \equiv 0$), and the isothermal ice sheet equation (2.1) becomes just

$$h_t = \left(\frac{h^{n+2}}{n+2} |h_x|^{n-1} h_x \right)_x + a \quad \text{on } I(t). \tag{2.2}$$

We shall refer to (2.2) as the pure diffusive case. As discussed in Fowler [29], when a cold-based flow regime is considered and the no slip condition is prescribed (due to infinite slope), singularities appear at the margins during the advance of fronts of

a land-based ice sheet (such as the one which covered North America in the last ice age). Classical (finite-differences) numerical methods can fail. A further complication arises due to the fact that the domain where the equation holds is unknown. In fact it has to be determined as part of the solution.

The original *strong* formulation can be stated in the following terms: let $T > 0$, $L > 0$ be positive fixed real numbers, and let $\Omega = (-L, L)$ be an open bounded interval of $\mathbb{R}$ (a sufficiently large, fixed spatial domain). Given an accumulation-ablation rate function $a = a(t, x)$, an eventually zero sliding velocity function $u_b = u(t, x)$ defined on a large fixed parabolic domain $Q = (0, T) \times (-L, L)$, and an initial thickness $h_0 = h_0(x) \geq 0$ (bounded and compactly supported) on Ω, find two curves $S_+, S_- \in C^0([0, T])$, with $S_-(t) \leq S_+(t)$, a set $I(t) := (S_-(t), S_+(t)) \subset \Omega$ for any $t \in [0, T]$, and a sufficiently smooth function $h(t, x)$ defined on the set $Q_T := \bigcup_{t\in(0,T)} I(t)$ such that

$$(2.3) \qquad (\mathrm{SF}) := \begin{cases} h_t = \left[\dfrac{h^{n+2}}{n+2}|h_x|^{n-1}h_x - u_b h\right]_x + a & \text{in} \quad Q_T, \\ h = 0 \quad \text{on} \quad \{S_-(t)\} \cup \{S_+(t)\}, & t \in (0, T), \\ h = h_0 & \text{on} \quad I(0), \end{cases}$$

and $h(t, x) > 0$ on Q_T. Notice that, for each fixed $t \in (0, T)$, $I(t) = (S_-(t), S_+(t)) = \{x \in \Omega : h(t, x) > 0\}$ denotes the ice-covered region. The curves $S_\pm(t)$ are called the interface curves or free boundaries associated with the problem and are defined by

$$S_-(t) = \mathrm{Inf}\{x \in \Omega : h(t, x) > 0\}, \qquad S_+(t) = \mathrm{Sup}\{x \in \Omega : h(t, x) > 0\}.$$

These curves define the interface separating the regions in which $h(t, x) > 0$ (i.e, ice regions) from those in which $h(t, x) = 0$ (i.e., ice-free regions). In the physical context they represent the propagation fronts of the ice sheet. The above formulation needs two different refinements. First, we have to prescribe some additional information on the spatial derivative of h at the free boundary. (We shall assume that the ice flux is zero there; see (3.2).) To introduce the other refinement it is useful to recall that many other examples of degenerate equations are typical of slow phenomena and satisfy the finite speed of propagation property (see, e.g., Díaz [17]).

Assuming $a \equiv 0$, for instance, if h_0 has a compact support, then $h(t, .)$ also has a compact support in $\mathbb{R}$ for any $t \in [0, T]$. So, if $a \equiv 0$, the domain Q_T can be found through the support of the solution $h(t, x)$ of the doubly nonlinear parabolic equation over the whole space $(0, T) \times \mathbb{R}$ and satisfying the initial condition $h(0, x) = h_0(x)$, $x \in \mathbb{R}$. Unfortunately, the physically relevant case, $a \not\equiv 0$, is much more complicated. Indeed, the finite speed of propagation still holds if $a(t, .)$ has compact support in $\mathbb{R}$ (for fixed $t \in (0, T)$). Moreover, in that case it can be shown that $\mathrm{supp}(h(t, .)) \subset \mathrm{supp}(a(t, .))$, and therefore $a(t, .)$ vanishes on the free boundary. Nevertheless, in glaciology models it is well known (see Fowler [30, p. 95]) that $a(t, .) < 0$ near the free boundaries (i.e., the margins of the ice sheet), and so there must exist another reason (other than the degenerate character of the equation) justifying the occurrence of the free boundaries $S_-(t), S_+(t)$. This is a mathematical modelling problem. We must make sure that the mathematical solutions are nonnegative compactly supported solutions (i.e., physically admissible). In short, for a sufficiently large fixed spatial domain, the physically admissible solutions are compactly supported nonnegative bounded functions such that $a < 0$, where $h = 0$ (in

particular, in the free boundary), and this is not predicted by the solutions of the diffusion equation (despite its degenerate character). Mathematically it is then possible (for special choices of the accumulation/ablation rate function) to have negative (no physically admissible) solutions corresponding to negative thickness! A practical way to overcome these inconsistencies is proposed in the following section.

3. Weak formulations. In this section we show that proper mathematical modelling in terms of weak formulations of the physical problem must be considered if the assumed physics have to be respected (i.e., if just physically admissible solutions have to be computed).

Let T, L, and Ω be as before and set $Q := (0,T) \times \Omega \subset \mathbb{R}^2$. The new model we present is based upon the fact that we can extend the function $h(t,x)$ outside of Q_T (the ice-covered regions) by zero on $Q \setminus Q_T = [(0,T) \times \Omega] \setminus Q_T$ (the complementary ice-free region). This extension still satisfies a nonlinear equation (this time of multivalued type) having the great advantage of being defined on an a priori known domain $Q = (0,T) \times \Omega$ (whose parabolic boundary is $\Sigma = \partial Q = (0,T) \times \partial\Omega$). This type of problem is known in the literature as an *obstacle problem*. In our case the obstacle function is $\psi \equiv 0$, the null function. Obstacle problems arise in many contexts related to friction, elasticity, thermodynamics, and so on (see, e.g., Duvaut and Lions [27] for further details). The multivalued formulation we propose appeared first in Díaz and Schiavi [21] (where the no slip condition was considered) to describe the slow, isothermal, one-dimensional flow of *cold* ice (i.e., all the ice is below melting point and the melting point is reached only at the bed) along a *hard* (i.e., rigid, impermeable) bed. Our results can be generalized to deal with the two-dimensional case that describes the evolution of a three-dimensional ice sheet. Here we extend that model to consider (prescribed) sliding along a temperate base. This introduces a nonlinear convective term into the multivalued equation which describes the movement of the ice masses. In order to properly characterize the behavior of h near the free boundary, we assume that the ice flux is not singular in the sense that

$$\frac{h^{n+2}}{n+2}|h_x|^{n-1}h_x - u_b h \in L^1(Q). \tag{3.1}$$

Notice that, formally, this implies

$$(h^m)_x = 0 \qquad \text{on} \quad \{S_-(t)\} \cup \{S_+(t)\}, \quad t \in (0,T), \tag{3.2}$$

where $m = 2(n+1)/n$. Introducing the maximal monotone graph of $\mathbb{R}^2$, β, defined by

$$\beta(r) = \emptyset \text{ (the empty set) if } \quad r < 0, \qquad \beta(0) = (-\infty, 0], \qquad \beta(r) = 0 \text{ if } \quad r > 0, \tag{3.3}$$

the *obstacle formulation* (written in terms of a multivalued equation) is the following: given a bounded, sufficiently large interval $\Omega = (-L, L) \subset \mathbb{R}$, a rate function $a \in L^\infty(Q)$, a sliding velocity $u_b \in L^\infty(Q)$, and a compactly supported initial data $h_0 \in L^\infty(\Omega)$, find a sufficiently smooth function $h(t,x)$ which is a solution of

$$(\mathrm{MF}) := \begin{cases} h_t - \left(\dfrac{h^{n+2}}{n+2}|h_x|^{n-1}h_x - u_b h\right)_x + \beta(h) \ni a(t,x) & \text{in} \quad Q, \\ h(t,x) = 0 & \text{on} \quad \Sigma, \\ h(0,x) = h_0(x) & \text{on} \quad \Omega. \end{cases} \tag{3.4}$$

Notice that β is multivalued just where h is zero, i.e., at the free boundaries. Moreover, by definition (3.3), we have that $0 \in \beta(0)$. Now, let h be a solution (in a weak sense to be specified later) of (3.4), for almost every $x \in \Omega$ and $\forall\, t \in (0,T)$. It is clear that in the null set $Q \setminus Q_T$ we must have $\beta(0) \ni a(t,x)$. This condition shows that, if β is multivalued at the origin, then it is possible to have solutions with a nonempty null set (i.e., $Q \setminus Q_T \neq \emptyset$) corresponding to equations in which $a \neq 0$ on $Q \setminus Q_T$, and thus new results are possible with respect to the single valued case ($\beta \equiv 0$).

Details on this kind of (multivalued) formulations, (MF), and maximal monotone graphs can be found in Brezis [11]. It is well known that the multivalued equation (3.4) can be written in terms of the so-called *complementarity formulation* for obstacle problems, which states: given Ω, a, u_b, and h_0 as before, find a sufficiently smooth function h such that

$$
\text{(CF)} := \begin{cases}
h_t - \left(\dfrac{h^{n+2}}{n+2} |h_x|^{n-1} h_x - u_b h \right)_x - a \geq 0 & \text{in} \quad Q, \\
\left[h_t - \left(\dfrac{h^{n+2}}{n+2} |h_x|^{n-1} h_x - u_b h \right)_x - a \right] h = 0 & \text{in} \quad Q, \\
h \geq 0 & \text{in} \quad Q, \\
h = 0 & \text{on} \quad \Sigma, \\
h = h_0(x) & \text{on} \quad \Omega.
\end{cases} \tag{3.5}
$$

It is obvious that if a regular function h verifies the strong formulation, then its extension by zero over $Q \setminus Q_T$ (which we will denote again by h) satisfies trivially the complementarity formulation, assuming that $a(t,x)$ satisfies the condition

$$
a(t,x) \leq 0 \qquad \text{on} \quad Q \setminus Q_T.
$$

A more general framework is obtained if we define $\phi(r) = |r|^{n-1} r$, $r \in \mathbb{R}$, $n > 1$, and $\psi(s) = s^m$, with $s \geq 0$ and $m = 2(n+1)/n > 1$. (In fact, the existence and the uniqueness of solutions and some qualitative properties remain true if we replace ϕ by any real continuous strictly increasing convex function such that $\phi(0) = 0$, and β as before; see (3.3).) Introducing the new variable $u = u(t,x)$ and the real function $b(s)$ in form

$$
u := h^m = \psi(h) \qquad \Longrightarrow \qquad u^{1/m} = h = \psi^{-1}(u) := b(u), \tag{3.6}
$$

we have $\phi(\psi(h)_x) = \phi(u_x) = |u_x|^{p-2} u_x$, where $p = n+1$. The previous *multivalued formulation* is the following: given Ω, a, u_b, and $u_0 = \psi(h_0)$ as before and a constant $\mu = n^n/[2^n (n+1)^n (n+2)]$, determine a function $u(t,x) = \psi(h(t,x))$ which is the solution of

$$
\text{(GF)} := \begin{cases}
b(u)_t - [\mu \phi(u_x) - u_b b(u)]_x + \beta(u) \ni a(t,x) & \text{in} \quad Q, \\
u(t,x) = 0 & \text{on} \quad \Sigma, \\
b(u(0,x)) = b(u_0(x)) & \text{on} \quad \Omega.
\end{cases} \tag{3.7}
$$

This *general formulation*, (GF), is the one that we shall use to deal with the well-posedness of the model problem (3.4). Notice that we can write $\beta(u)$ instead of $\beta(b(u))$ because $\beta(u) \equiv \beta(h) := \beta(b(u))$ in Q. The equivalence is readily understood, observing that h (i.e., the original variable) and u have exactly the same support. The same remark applies to the boundary condition on Σ.

3.1. On the existence and uniqueness of weak solutions. Problem (3.7) admits various notions of solutions according to the required spatial and time regularity. In any case we must start by assuming some regularity on the data $a(t,x)$, $u_b(t,x)$, and $u_0(x)$. In our case it will be enough to assume that

$$a \in L^\infty(Q), \qquad u_b \in L^\infty(0,T : W^{1,\infty}(\Omega)), \qquad \text{and} \quad u_0 \in L^\infty(\Omega). \tag{3.8}$$

Motivated by (3.1), a natural notion of weak solution is the following.

DEFINITION 3.1. *A function $u \in L^1(Q)$ is a weak solution of* (3.7) *if $u \in L^p(0,T : W_0^{1,p}(\Omega))$, $b(u) \in L^1(Q)$, $u(t,x) \geq 0$ a.e. $(t,x) \in Q$, and there exists a function $j \in L^1(Q)$ such that $j(x,t) \in \beta(u(t,x))$ a.e. $(t,x) \in Q$ and*

$$\int_Q (\zeta_t b(u) - \zeta j + \zeta a) dxdt + \int_\Omega \zeta(0,\cdot) b(u_0) dx = \int_Q \zeta_x [\mu \phi(u_x) - u_b b(u)] dxdt$$

for any $\zeta \in L^p(0,T : W_0^{1,p}(\Omega)) \cap L^\infty(Q)$, $\zeta_t \in L^\infty(Q)$, and $\zeta(T,\cdot) = 0$.

Assuming (3.8) and that b, ϕ are the power functions indicated above, the existence of a weak solution can be obtained by different methods, for instance, by an easy modification of Theorem 2.3 and Proposition 3.2 of Benilan and Wittbold [4]. In fact, in order to check assumption (H1) of [4] it is useful to replace function b by its truncation

$$b_M(r) := \begin{cases} b(r) & \text{if } r \in [0,M], \\ b(M) & \text{if } r \in [M,+\infty), \end{cases}$$

with $M > 0$ an upper bound of any weak solution. (We shall come back to this point later; see Proposition 3.3.) Proving the uniqueness of (and the comparison principle for) weak solutions is a more delicate task due to the presence of the nonlinear term $b(u)$. This type of result is well known (see, for instance, Díaz and de Thelin [18]) in the case in which we additionally know that the weak solution is differentiable with respect to time in the sense that $b(u)_t \in L^1(Q)$. (We recall that from the definition of weak solutions we know merely that $b(u)_t \in L^{p'}(0,T : W^{-1,p'}(\Omega)) + L^1(Q)$ with $p' := p/(p-1)$.) In order to get such results, a weaker notion was introduced in previous works by different authors (see Boccardo et al. [10] for the case of $b(u) = u$, and Carrillo and Wittbold [15] for a general nondecreasing function $b(u)$): the notion of a *renormalized solution*, coming originally from a different context (Di Perna and Lions [24]). In fact both notions coincide in the class of bounded functions $u \in L^\infty(Q)$, which is our case, as we shall prove in this section.

For the sake of simplicity in the exposition we assume that

$$u_b(t,\cdot) \quad \text{is spatially constant.} \tag{3.9}$$

So, by some trivial modifications of the results of Carrillo and Wittbold [15] we arrive at the following result.

THEOREM 3.2. *Assume a_i, u_b, and $u_{0,i}$ satisfying* (3.8) *and* (3.9) *for $i = 1,2$. Let u_i be weak solutions of problem* (3.7) *associated with the data a_i and $u_{0,i}$, respectively. Then for any $t \in [0,T]$*

$$\int_\Omega [b(u_1(t,\cdot)) - b(u_2(t,\cdot))]_+ dx \leq \int_\Omega [b(u_{0,1}) - b(u_{0,2})]_+ dx + \int_0^t \int_\Omega [a_1(s,x) - a_2(s,x)]_+ dxds,$$

where $[f]_+ = \max(f,0)$. In particular, $b(u_{0,1}) \leq b(u_{0,2})$ and $a_1(t,x) \leq a_2(t,x)$, on their respective domains of definition, implies that $b(u_1(t,x)) \leq b(u_2(t,x))$ for any

$t \in [0,T]$ *and a.e.* $x \in \Omega$. *Consequently, there is at most one weak solution of problem* (3.7).

We point out that the above comparison remains true even if the functions u_i are not homogeneous at the boundary but satisfy $u_1(t,x) \le u_2(t,x)$ for any $t \in [0,T]$ and a.e. $x \in \partial\Omega$. This is again a trivial modification of the result by Carrillo and Wittbold [15], which will be used in the following section.

The boundedness of the associated weak solutions can be deduced from the above comparison principle as follows.

PROPOSITION 3.3. *Let* u *be any weak solution of problem* (3.7)*; then*

$$\|u\|_{L^\infty(Q)} \le M_0, \tag{3.10}$$

with

$$M_0 := b^{-1}\left(\max\{\|b(u_0)\|_{L^\infty(\Omega)}, 1\} \exp T\left\{\left[\frac{\|a\|_{L^\infty(Q)}}{\max\{\|b(u_0)\|_{L^\infty(\Omega)}, 1\}} + \|(u_b)_x\|_{L^\infty(\Omega)}\right]\right\}\right).$$

Proof. We take as a candidate *supersolution* a spatially constant function of the form $u_2(t,x) := b^{-1}(Ce^{\lambda t})$ for some $C > 0$ and $\lambda \in \mathbb{R}$ to be determined. Then $u_1(t,x) \le u_2(t,x)$ for any $t \in [0,T]$ and a.e. $x \in \partial\Omega$ and $b(u_{0,1}) \le b(u_{0,2})$ holds if

$$C = \max\{\|b(u_0)\|_{L^\infty(\Omega)}, 1\}.$$

Finally, by substituting u by u_2 in (3.7), it is easy to check that

$$a_2(t,x) := \lambda C e^{\lambda t} + (u_b)_x(x) C e^{\lambda t},$$

and so condition $a_1(t,x) \le a_2(t,x)$ is satisfied if, for instance,

$$\lambda = C^{-1}\|a\|_{L^\infty(Q)} + \|(u_b)_x\|_{L^\infty(\Omega)},$$

which implies the result. □

We point out that although the application of the present version of the comparison principle given in the above theorem requires condition (3.9), the a priori estimate (3.10) can be obtained without using a comparison principle (see, for instance formula (13) of Benilan and Wittbold [4]), and so the boundedness of u remains true also when $(u_b)_x \ne 0$, as we shall consider later.

4. On the free boundary. In this section we shall study both thermal regimes at the base. In the first case the bed is assumed to be cold (below melting point). No sliding is prescribed (i.e., $u_b \equiv 0$), and the pure diffusive case is analyzed. Next, we assume the ice sheet to be warm-based; the bed is then temperate, and sliding is prescribed (i.e., $u_b = u_b(t,x)$). Here we are not concerned with the switching mechanism between cold-temperate dynamics. (Results in that direction can be found in Fowler and Schiavi [31] and Díaz and Schiavi [22].) Our aim is to qualitatively describe the behavior of the free boundaries by means of a priori estimates on the support of the solution.

4.1. The no slip condition (pure diffusive case): Existence of the free boundary and the waiting time property. In this section we shall prove the existence of a nonempty null set

$$N(h(t,\cdot)) := \left\{(t,x) \in \{t\} \times \frac{\Omega}{h(t,x)} = 0\right\}$$

for the (unique) solution $h(t,x)$ of the problem

$$\text{(4.1)}\qquad \begin{cases} h_t - \mu\phi(\psi(h)_x)_x + \beta(h) \ni a(t,x) & \text{in} \quad Q, \\ h(t,x) = 0 & \text{on} \quad \Sigma, \\ h(0,x) = h_0(x) & \text{on} \quad \Omega, \end{cases}$$

which can be deduced from the general formulation (GF) written in terms of the original variable h and of the functions ϕ and ψ introduced before. Assuming extra regularity of the solution (i.e, $h \in C(\bar{Q})$), we are able to analyze a great number of geophysical phenomena related to location and evolution of the free boundary and associated with the behavior of the function $a(t,x)$.

We shall now deal with the existence and location of the free boundary defined by problem (4.1). To show the existence of a free boundary as well as to locally estimate its location, we will use a technique based on the comparison result of section (3.1), which consists of the construction of appropriate local super-sub solutions having compact support. Thus, for all $\epsilon > 0$, we define the set

$$\text{(4.2)}\qquad N_\epsilon(a(t,\cdot)) := \left\{ (t,x) \in \{t\} \times \frac{\Omega}{a(t,x)} \leq -\epsilon \right\}$$

and the set $S_\epsilon(a(t,.)) = Q \setminus N_\epsilon(a(t,\cdot)$. Then we have the following result.

THEOREM 4.1. *Let $h \in C(\bar{Q})$, $h \geq 0$, be a solution of* (4.1)*, and let ϵ be a small real positive number such that the set $N_\epsilon(a(t,.))$ is not empty. Then there exist $R > 0$ and $T_0 \geq 0$ such that $\forall t \geq T_0$ we have*

$$N(h(t,\cdot)) \supset \{(t_0,x_0) \in N_\epsilon(a(t_0,.)) : d(x_0, S_\epsilon(a(t,.))) \geq R\}.$$

Proof. The proof is based on an original idea of Evans and Knerr [28], which applies when $n = 1$ and $a(t,x) \equiv 0$. See also Díaz and Hernández [20] for its adaptation to the case $n > 1$. In our multivalued case, with $n > 1$ but $a(t,x) \not\equiv 0$, we argue as follows. We consider the set $N_\epsilon(a(t,.))$ and define the function

$$\tilde{h}(t,x) = \psi^{-1}\left(\eta(|x - x_0|) + \psi(U(t))\right),$$

where

$$\text{(4.3)}\qquad \eta(r) = c\, r^{\frac{p}{p-1}}, \qquad c = \frac{p-1}{p}\left(\frac{\epsilon}{2}\right)^{\frac{1}{p-1}},$$

and $U(t)$ is the (unique) solution of the initial value problem

$$\text{(4.4)}\qquad \begin{cases} U' + \frac{1}{2}\beta(U) & \ni & -\frac{\epsilon}{2}, \\ U(0) & = & ||h_0||_{L^\infty(\Omega)}. \end{cases}$$

It is easy to state that $U(t) = [-\frac{\epsilon}{2}t + ||h_0||_{L^\infty}]^+$, whence

$$U(t) \equiv 0 \qquad \forall t \geq T_0 = \frac{2}{\epsilon}||h_0||_{L^\infty(\Omega)}.$$

On the other hand, as by construction $\phi(\psi(\tilde{h})_x)_x = \phi(\eta_x)_x = \epsilon/2$, we have (in $N_\epsilon(a(t,.))$)

$$\tilde{h}_t - \mu\phi(\psi(\tilde{h})_x)_x + \beta(\tilde{h})$$

$$\equiv \frac{d}{dt}\left[\psi^{-1}\left(\eta(|x-x_0|)+\psi(U(t))\right)\right]-\mu\phi(\eta_x(|x-x_0|))_x+\beta\left(\psi^{-1}\left(\eta(|x-x_0|)+\psi(U(t))\right)\right)$$

$$\supseteq \frac{\psi'(U)}{\psi'\left(\psi^{-1}\left(\eta(|x-x_0|)+\psi(U(t))\right)\right)}U'-\mu\phi(\eta_x(|x-x_0|))_x+\frac{1}{2}\beta(\psi^{-1}(\eta(|x-x_0|)))+\frac{1}{2}\beta(U)$$

$$\supseteq U'+\frac{1}{2}\beta(U)-\mu\phi(\eta_x(|x-x_0|))_x+\frac{1}{2}\beta\left(\psi^{-1}(\eta(|x-x_0|))\right)\ni-\epsilon\geq a(t,x).$$

Using the comparison principle written in terms of the original variable h, the following estimate holds (see Benilan and Wittbold [4]):

$$||h||_{L^\infty(Q)}\leq||h_0||_{L^\infty(\Omega)}+\int_0^t||a||_{L^\infty(\Omega)}=M(t).$$

Then

$$||h||_{L^\infty(Q)}\leq M(t)\leq\tilde{h}(t,\cdot)\qquad\text{on } N_\epsilon(a(t,\cdot))$$

iff $\psi^{-1}\left(\eta((|x-x_0|))+\psi(U(t))\right)\geq M(t)$; i.e., $\eta(|x-x_0|)+\psi(U(t))\geq\psi(M(t))$. In particular, this is true if $c\,|x-x_0|^{\frac{p}{p-1}}\geq\psi(M(t))$; by (4.3) the above reads

$$|x-x_0|\geq\frac{\psi(M(T))^{\frac{p-1}{p}}}{(\frac{p-1}{p})^{\frac{p-1}{p}}(\frac{\epsilon}{2})^{\frac{1}{p}}}=R,\tag{4.5}$$

and (4.5) implies that $\tilde{h}\geq h$ on $\partial N_\epsilon(a(t,.))$. At $t=0$ we use the monotonicity of ψ^{-1}:

$$\tilde{h}(0,x)=\psi^{-1}\left(\eta(|x-x_0|)+\psi(U(0))\right)=\psi^{-1}\left(\eta(|x-x_0|)+\psi(||h_0||_{L^\infty})\right)$$

$$\geq\psi^{-1}\left(\psi(||h_0||_{L^\infty})\right)=||h_0||_{L^\infty}\geq h_0(x)\geq 0.$$

Summarizing, if $(t,x)\in N_\epsilon(a(t,\cdot))$ is such that $|x-x_0|\geq R$, then

$$h_t-\mu\phi(\psi(h)_x)_x+\beta(h)\ni a\leq\inf\left(\tilde{h}_t-\mu\phi(\psi(\tilde{h})_x)_x+\beta(\tilde{h})\right)\qquad\text{in}\quad N_\epsilon(a(t,\cdot)),$$

$$h(t,x)\leq\tilde{h}(t,x)\qquad\text{on}\quad\partial N_\epsilon(a(t,\cdot)),$$

$$h_0(x)\leq\tilde{h}(0,x)\qquad\text{on}\quad N_\epsilon(a(0,\cdot)).$$

Next, from the comparison result (Theorem 3.2) it follows that

$$0\leq h(t,x)\leq\tilde{h}(t,x)\qquad\text{in}\quad N_\epsilon(a(t,.)),$$

and we end up observing that $h(t,x_0)=0\ \forall t\geq T_0=\frac{2}{\epsilon}||h_0||_{L^\infty}$ and x_0 satisfies inequality (4.5), i.e., $(t,x_0)\in\{N_\epsilon(a(t,.))/|x-x_0|\geq R\}$. □

We shall now analyze the so-called waiting time property. As discussed in Fowler [30, p. 95], the slope of the surface is singular in advance but finite in retreat. This distinction causes the degenerate diffusion equation above to have waiting-time behavior, because following a retreat, the margin slope must rebuild itself before another advance it possible. The following property applies if the initial data is sufficiently *flat* in the *ablation region.*

THEOREM 4.2. *Let $h \in C(\bar{Q})$, $h \geq 0$, be a solution of problem (4.1). Let $\delta = \eta^{-1}(\psi(M))$ and $B_\delta^+(x_0) = \{x \in \Omega / \ x \in [x_0, x_0 + \delta)\}$, with $M = ||h||_{L^\infty(Q)}$, $x_0 = S_+(0)$, $\tilde{c} = (\frac{p-1}{p})\epsilon^{\frac{1}{p-1}}$, and $\eta(|x - x_0|) = \tilde{c}\,|x - x_0|^{\frac{p}{p-1}}$. Assume that there exists $T^* > 0$ such that $a(t,x) \leq -\epsilon$ a.e. $x \in B_\delta^+(x_0)$ and $t \in (0, T^*)$. If $x_0 \in \Omega$ satisfies $0 \leq h_0(x_0) \leq \psi^{-1}(\eta(|x - x_0|))$, then*

$$\exists\, t^*, \quad 0 < t^* \leq T^*, \quad \textit{such that} \quad S_+(0) = S_+(t) \quad \forall t \in (0, t^*).$$

Proof. We define the function

$$\tilde{h}(x) := \psi^{-1}(\eta(|x - x_0|)) \qquad \text{in} \quad B_\delta^+(x_0) \times (0, T^*).$$

Then

$$h_t - \mu\phi(\psi(h)_x)_x + \beta(h) \ni a \leq -\epsilon \leq \inf\big(\tilde{h}_t - \mu\phi(\psi(\tilde{h})_x\big)_x + \beta(\tilde{h})) \quad \text{in } B_\delta^+(x_0) \times (0, T^*).$$

On $\partial B_\delta^+(x_0) \times [0, t^*]$ we have to verify that $h \leq M \leq \tilde{h} = \psi^{-1}(\eta)$, and this is iff $\psi(M) \leq \eta = \tilde{c}|x - x_0|^{\frac{p}{p-1}}$. On ∂B_δ^+ this reads as $\psi(M) \leq \tilde{c}\delta^{\frac{p}{p-1}}$. Using that $\delta = \eta^{-1}(\psi(M))$,

$$h \leq M \leq \tilde{h} \quad \Longleftrightarrow \quad \psi(M) \leq \tilde{c}[\eta^{-1}(\psi(M))]^{\frac{p}{p-1}}$$

$$\Longleftrightarrow \quad \left[\frac{\psi(M)}{\tilde{c}}\right]^{\frac{p-1}{p}} \leq \eta^{-1}(\psi(M)) \quad \Longleftrightarrow \quad \eta\left(\left[\frac{\psi(M)}{\tilde{c}}\right]^{\frac{p-1}{p}}\right) \leq \psi(M),$$

and this is always verified as can be deduced by applying the definition of the function η. Then we have

$$h_t - \mu\phi(\psi(h)_x)_x + \beta(h) \ni a \leq \inf(\tilde{h}_t - \mu\phi(\psi(\tilde{h})_x)_x + \beta(\tilde{h})) \text{ in } B_\delta^+(x_0) \times (0, t^*),$$

$$h(x_0, 0) = h_0(x_0) \leq \tilde{h}(x) = \psi^{-1}(\eta(|x - x_0|)) \quad \text{on } B_\delta^+(x_0),$$

$$h(t,x) \leq M \leq \tilde{h}(x) \quad \text{on } \partial B_\delta^+(x_0) \times (0, t^*).$$

Finally, the comparison result shows that $0 \leq h(t,x) \leq \tilde{h}(x)$, and so $h(t, x_0) \equiv 0$ $\forall t \in (0, t^*)$. ∎

4.2. The slip condition (diffusive-convective case): Existence of the free boundary and the waiting time property. In this section we shall consider the general formulation (GF), assuming that $u_b \not\equiv 0$ and without assuming (3.9). Even if Theorem 3.2 can be extended to cover cases in which (3.9) is not satisfied, the presence of the convection term makes the method of super- and subsolutions very hard to apply. Thus, in order to prove the existence of the free boundary, we shall use a different technique called the *energy method*. It has been developed by different authors in the last twenty years for the study of nonlinear problems for which the maximum principle fails (see, for instance, the monograph of Antontsev, Díaz, and Shmarev [2]). In fact, although this energy method can be applied in different ways, we shall follows the ideas introduced in Díaz and Galiano [19] in order to apply the method to some fluid dynamics problems. We start by pointing out that the equation of problem (3.7) can be written in terms of a nonconservative transport multivalued equation in the form

$$b(u)_t + u_b b(u)_x - \mu\phi(u_x)_x + (u_b)_x b(u) + \beta(u) \ni a(t,x) \qquad \text{in} \quad Q. \tag{4.6}$$

In this way, the equation involves the material derivative $b(u)_t + u_b b(u)_x$, which can be associate to a *virtual non-Newtonian fluid with a reactive term* $(u_b)_x b(u)+\beta(u)$. We shall prove the existence of the free boundary in terms of the so-called *finite speed of propagation* near a given point x_0.

In the next results we shall assume that u_b is a globally Lipschitz continuous function. Thus, we can define the characteristics of the associate flow by

$$\left\{ \begin{array}{rcll} \dfrac{d}{dt}X(t,x) & = & u_b(t,X(t,x)) & \text{on} \quad (0,T), \\ X(0,x) & = & x. & \end{array} \right. \tag{4.7}$$

As usual in continuum mechanics, given a ball $B_\rho(x_0) = \{x \in \mathbb{R} : |x - x_0| \le \rho\}$, we denote the transformed set by

$$B_\rho(x_0)_t = \{\, y \in \mathbb{R} : y = X(t,x) \quad \text{for some} \quad x \in B_\rho(x_0)\}.$$

THEOREM 4.3. *Let b, ϕ, β, a, and u_0 be as in section 3. Let u_b be a globally Lipschitz continuous function on Q. For $\epsilon \ge 0$ let $N_\epsilon(a(t,\cdot)) := \{(t,x) \in \{t\} \times \Omega / \, a(t,x) \le -\epsilon\}$. Assume also that $\epsilon = 0$ if $m(p-1) > 1$, and $\epsilon > 0$ if $m(p-1) \le 1$. Let $u_0 = 0$ on a ball $B_{\rho_0}(x_0)$ for some x_0 such that $(t, B_{\rho_T}(x_0)) \subset N_\epsilon(a(t,\cdot))$ for any $t \in [0,T]$ and some $L \ge \rho_0$. Then there exists a $T_\epsilon \in (0,T]$ and a function $\rho : [0,T_\epsilon] \to [0,\rho_0]$ such that $u(t,x) = 0$ a.e. $x \in B_{\rho(t)}(x_0)$ for any $t \in [0,T_\epsilon]$.*

Proof. We introduce the change of variable $b(w(t,x)) = b(u(t,x))e^{\lambda t}$. Then, it is easy to prove that w satisfies the equation

$$\begin{array}{ll} b(w)_t + u_b b(w)_x - \mu e^{\lambda t(1-(p-1)m)}\phi(w_x)_x + [(u_b)_x + \lambda]b(w) + \beta(w) & \\ \ni a(t,x)e^{\lambda t} \qquad \text{in} \quad Q. & \end{array} \tag{4.8}$$

Thus, by taking $\lambda > 2C$ with $C = \|(u_b)_x\|_{L^\infty(Q)}$ (which is finite, since u_b is a globally Lipschitz continuous function), we have that $[(u_b)_x + \lambda] \ge C > 0$. By multiplying, formally, by w (i.e., by some arguments of regularization, localization, and passing to the limit, as in Díaz and Veron [23]), we get that if $\rho \le L$, then

$$\int_{B_\rho(x_0)_t} \frac{\partial}{\partial t}\Psi(w)dx + \int_{B_\rho(x_0)_t} u_b \Psi(w)_x dx + \mu e^{\lambda t(1-(p-1)m)} \int_{B_\rho(x_0)_t} |w_x|^p \, dx$$

$$\le \mu e^{\lambda t(1-(p-1)m)} w(t,\cdot)\, |w_x(t,\cdot)|^{p-1}\, w_x(t,\cdot)\, \big|_{\partial B_\rho(x_0)_t} - \epsilon \int_{B_\rho(x_0)_t} w dx,$$

where

$$\Psi(w) := wb(w) - \int_0^w b(s)ds \tag{4.9}$$

and we used that $w \ge 0$ and that $\beta(w)w = \{0\}$. Now, by using the Reynolds transport lemma,

$$\int_{B_\rho(x_0)_t} \frac{\partial}{\partial t}\Psi(w) + \int_{B_\rho(x_0)_t} u_b \Psi(w)_x = \frac{d}{dt}\int_{B_\rho(x_0)_t} \Psi(w(t,y))dy.$$

Thus, integrating in $(0,t)$ and using the information on u_0, we get that

$$\int_{B_\rho(x_0)_t} \Psi(w(t,y))dy + C_1 \int_0^t \int_{B_\rho(x_0)_t} |w_x|^p \, dyds$$

$$\leq C_2 \int_0^t w(s,\cdot) \left| |w_x(s,\cdot)|^{p-1} w_x(s,\cdot) \big|_{\partial B_\rho(x_0)_t} \right| ds - \epsilon \int_0^t \int_{B_\rho(x_0)_t} w dx ds, \tag{4.10}$$

with

$$C_1 = \mu \min_{t\in[0,T]} e^{\lambda t(1-(p-1)m)}, \qquad C_2 = \mu \max_{t\in[0,T]} e^{\lambda t(1-(p-1)m)}.$$

Assume now, for the moment, that $1 < (p-1)m$ and $\epsilon = 0$. Then we define the energies

$$B(t,\rho) = \sup_{0\leq s\leq t} \int_{B_\rho(x_0)s} \Psi(w(s,y))dy, \qquad E(t,\rho) = \int_0^t \int_{B_\rho(x_0)_t} |w_x|^p \, dyds. \tag{4.11}$$

Using Hölder inequality and the interpolation-trace inequality of Díaz and Veron [23], we get that

$$B + E \leq K \left(\frac{\partial E}{\partial \rho} \right)^\omega \tag{4.12}$$

for some positive constant K and some $\omega > 1$, and the result follows in a standard way (see, e.g., Díaz and Veron [23], or Antontsev, Díaz, and Shmarev [2]). In the case $1 \geq (p-1)m$ and $\epsilon > 0$ we pass the term $\epsilon \int_0^t \int_{B_\rho(x_0)_t} w dx ds$ to the left-hand side of the inequality (4.10), and we introduce the additional energy function defined as

$$C(t,\rho) = \int_0^t \int_{B_\rho(x_0)_t} |w| \, dyds.$$

(Remember that $|w| = w$.) Then, we can apply Theorem 1 of Antontsev, Díaz, and Shmarev [1], with $\lambda = 0$ since the interpolation-trace inequality (2.6) of that paper applies also to the limit case $\lambda = 0$. Thus, we arrive at the inequality

$$E + C \leq K \left(\frac{\partial (E+C)}{\partial \rho} \right)^\omega \tag{4.13}$$

for some positive constant K and some $\omega > 1$, and the theorem holds. □

Remark 4.1. We point out that, due to the presence of the convective term and the specific exponents involved in (4.6), the statement of the parabolic part of Díaz and Veron [23] is not directly applicable, and this is the reason for using the characteristic transformation argument. Notice, also, that in contrast with the case $u_b = 0$, now it may occur that $T_\epsilon < T$ for any $\epsilon \geq 0$, and notice too that the energy method allows the consideration of the case $\epsilon = 0$ when $m(p-1) > 1$. Moreover, any estimate of the function $\rho(t)$ automatically gives an estimate on the location of the free boundary. Finally, we indicate that it is possible to get global consequences of the above result by estimating (globally) the energies introduced in (4.11). (For some related arguments, see, e.g., Díaz and Veron [23] or Antontsev, Díaz, and Shmarev [2].) Unfortunately the above information on the free boundary is quite implicit and difficult to manage. This also justifies the use of numerical methods.

The waiting time property can also be studied by energy methods once it is reformulated in terms of the characteristics associated with u_b. Notice that if $u_b \equiv 0$, then the characteristics are vertical lines.

THEOREM 4.4. *Let b, ϕ, β, a, u_b, ϵ, $N_\epsilon(a(t,\cdot))$, and x_0 be as in the previous theorem but now with $L > \rho_0$. Let $u_0(x) = 0$ on a ball $B_{\rho_0}(x_0)$ for some x_0 and satisfying that*

$$\int_{B_\rho(x_0)_t} \Psi(u_0(y))dy \le \theta[(\rho-\rho_0)^+]^{\omega/(\omega-1)} \qquad \text{for any} \quad \rho_0 \le \rho \le L \tag{4.14}$$

for some small enough $\theta > 0$ and some $L > \rho_0$, where Ψ is defined by (4.9) *and $\omega > 1$ is the exponent given in* (4.12) *or* (4.13). *Then, there exists $T_0 \in (0,T]$ such that $u(t,x) = 0$ a.e. $x \in B_{\rho_0}(x_0)_t$ for any $t \in [0,T_0]$, where $B_{\rho_0}(x_0)_t = \{y \in \mathbb{R} : y = X(t,x)$ for some $x \in B_{\rho_0}(x_0)\}$, with $X(t,x)$ the characteristics defined by* (4.7).

Proof. The proof follows from the same arguments as those used by Antontsev, Díaz, and Shmarev [1], but adapted to our framework. Thus, the integration by parts formula (4.10) must be replaced by

$$\begin{aligned} &\int_{B_\rho(x_0)_t} \Psi\,(w(t,y))dy + C_1 \int_0^t \int_{B_\rho(x_0)_t} |w_x|^p\, dyds \\ &\qquad \le \int_0^t w(s,\cdot) \left| |w_x(s,\cdot)|^{p-1}\, w_x(s,\cdot)\,\big|_{\partial B_\rho(x_0)_t} \right| ds \\ &\qquad\quad - \epsilon \int_{B_\rho(x_0)_t} w dx + \int_{B_\rho(x_0)_t} \Psi(u_0(y))dy. \end{aligned} \tag{4.15}$$

In particular, inequality (4.12) becomes the nonhomogeneous one,

$$B + E \le K \left(\frac{\partial E}{\partial \rho}\right)^\omega + \theta(\rho-\rho_0)_+^{\omega/(\omega-1)},$$

and the conclusion holds thanks to a technical lemma (see, e.g., Lemma 1 of Antontsev, Díaz, and Shmarev [1]). ∎

5. Numerical solution. This section is devoted to the numerical solution of the ice sheet moving boundary problem whose multivalued formulation (MF) is stated in (3.4). We first introduce the total derivative notation in conservative form,

$$\frac{Dh}{Dt} = \frac{\partial h}{\partial t} + \frac{\partial}{\partial x}(u_b h),$$

so that the complementarity formulation (CF) given by (3.5) can be posed as

$$\begin{cases} \dfrac{Dh}{Dt} - \left(\dfrac{h^{n+2}}{n+2}|h_x|^{n-1}h_x\right)_x - a \ge 0 & \text{in} \quad Q, \\ \left[\dfrac{Dh}{Dt} - \left(\dfrac{h^{n+2}}{n+2}|h_x|^{n-1}h_x\right)_x - a\right] h = 0 & \text{in} \quad Q, \\ h \ge 0 & \text{in} \quad Q, \\ h = 0 & \text{on} \quad \Sigma, \\ h = h_0(x) & \text{on} \quad \Omega. \end{cases} \tag{5.1}$$

An overview of different numerical strategies for solving free boundary problems (fixed domain methods, front-tracking, and front-fixing methods, adaptative algorithms, and others) can be found in [34]. Our approach is based on fixed domain

methods, upwinding time discretization, and duality methods for nonlinearities. More precisely, in the recent paper [13] a first attempt was made to solve (5.1) by combining this approach with a fixed point method for the nonlinear diffusive term. Indeed, the linearization process was based on freezing the nonlinear diffusive term at each step of the algorithm.

In the subsequent paper [14], in order to solve a temperature-profile coupled problem, this method was combined with the algorithm proposed in [12] to approximate ice sheet temperature distribution. However, this profile approximation procedure requires extremely small time steps and, consequently, it leads to very high computing times to obtain an accurate stationary solution.

In the present work, to overcome the drawbacks of the previously described numerical approach, we express the nonlinear diffusive term by means of a monotone operator. As usual in glaciology (see section 2), let $n = 3$. Hence, $m = 2(n+1)/n = 8/3 > 1$ and $p = n + 1 = 4$. Then, by using (3.6), we introduce the following new variable u,

$$u(t,x) = h^{8/3}(t,x), \tag{5.2}$$

so that problem (5.1) can be written in terms of u as

$$\begin{cases} \dfrac{D}{Dt}(u^{3/8}) - \mu\left(|u_x|^2 u_x\right)_x - a \geq 0 & \text{in} \quad Q, \\ \left[\dfrac{D}{Dt}(u^{3/8}) - \mu\left(|u_x|^2 u_x\right)_x - a\right] u = 0 & \text{in} \quad Q, \\ u \geq 0 & \text{in} \quad Q, \\ u = 0 & \text{on} \quad \Sigma, \\ u = u_0(x) = h_0^{8/3}(x) & \text{on} \quad \Omega, \end{cases} \tag{5.3}$$

where the constant μ takes the value $\mu = \frac{(3/8)^3}{5}$. Notice that formulation (5.3) allows us to introduce a maximal monotone operator to express the nonlinear diffusive term and implicitly contains a convective term.

In view of the particular nonlinear diffusive term in (5.3), the classical method analyzed in the framework of linear diffusion problems ($p = 2$) by Nochetto and Verdi [35] cannot be applied. In the same manner, the nonlinear diffusive terms treated in the recent paper [16] do not cover the case of (5.3).

In fact, the nonlinear p-Laplacian term has been numerically studied in [6] and the references therein, but without including either convection or free boundary aspects.

The combination of characteristic methods with duality algorithms for solving (5.3) is justified by its previous validation in analogous free boundary problems in other topics (lubrication [3, 25, 26], phase change [9], and gas flow [7], for example).

One goal of this work is to propose a numerical solution method for approximating the ice sheet profile for prescribed accumulation-ablation rates and the sliding velocity of ice. A further goal is to illustrate the qualitative properties that were analyzed in section 4.

5.1. Time semidiscretization. As in previous works in the glaciology setting [13, 14], problem (5.3) is discretized in time using the scheme of characteristics. For this, let T and M be fixed positive real numbers, and let Δt be the time step so that $T = M\Delta t$. In short, this upwinded time scheme is based on the approximation

of the total derivative; see Pironneau [37] for linear convection-diffusion equations. Thus, in our particular nonlinear convection case, for $m = 0, 1, \ldots, M(M = T/\Delta t)$, we consider the approximation

$$\frac{D}{Dt}(u^{3/8})((m+1)\Delta t, x) \approx \frac{(u^{m+1})^{3/8}(x) - J^m(x)\,(u^m)^{3/8}(\chi^m(x))}{\Delta t}, \tag{5.4}$$

where

$$u^{m+1}(x) = u((m+1)\Delta t, x) \qquad \text{in} \quad \Omega \tag{5.5}$$

and $J^m(x)$ is obtained by numerical quadrature techniques in the expression

$$J^m(x) = J(t^{m+1}, x; t^m) = 1 - \int_{t^m}^{t^{m+1}} (u_b(\tau, \chi(x, t^{m+1}; \tau)))_x \, d\tau,$$

where J is the Jacobian associated with the change of variable mapping $x \to \chi(t, x; \tau)$. Notice that the presence of J arises from the application of the characteristics method when the convection is written in conservative form (see Bercovier, Pironneau, and Sastri [5] for details).

The value $\chi^m(x)$ is given by $\chi^m(x) = \chi((m+1)\Delta t, x; m\Delta t)$, χ being the solution of the final value problem

$$\left\{ \begin{array}{rcl} \dfrac{d\chi(t, x; s)}{ds} & = & u_b(s, \chi(x, t; s)), \\ \chi(t, x; t) & = & x. \end{array} \right. \tag{5.6}$$

The next step consists of the substitution of the approximation (5.4) into (5.3) to obtain the following sequence of nonlinear elliptic complementarity problems.

For $m = 0, 1, 2, \ldots, M$, *find* u^{m+1} *such that*

$$\left\{ \begin{array}{l} \dfrac{(u^{m+1})^{3/8} - J^m((u^m)^{3/8} \circ \chi^m)}{\Delta t} - \mu \dfrac{\partial}{\partial x}\left(|u_x^{m+1}|^2 u_x^{m+1}\right) - a^{m+1} \geq 0 \quad \text{in } \Omega, \\ \qquad\qquad u^{m+1} \geq 0 \quad \text{in } \Omega, \\ \left[\dfrac{(u^{m+1})^{3/8} - J^m((u^m)^{3/8} \circ \chi^m)}{\Delta t} - \mu \dfrac{\partial}{\partial x}\left(|u_x^{m+1}|^2 u_x^{m+1}\right) - a^{m+1}\right] u^{m+1} = 0 \quad \text{in } \Omega, \\ \qquad\qquad u^{m+1} = 0 \quad \text{in } \partial\Omega, \\ \qquad\qquad u^0(x) = h_0 = (h_0)^{8/3} \quad \text{in } \Omega, \end{array} \right. \tag{5.7}$$

where $a^{m+1}(x) = a((m+1)\Delta t, x)$ *and "*$\circ$*" denotes the composition symbol.*

5.2. Spatial discretization. First, in order to solve the nonlinear complementarity problem (5.7) to obtain u^{m+1}, we pose the following equivalent variational inequality formulation.

Find $u^{m+1} \in K$ *such that*

$$\begin{array}{l} \dfrac{1}{\Delta t}\displaystyle\int_\Omega (u^{m+1,})^{3/8}\,(\varphi - u^{m+1})\,dx + \mu \int_\Omega |\, u_x^{m+1}\,|^2\, u_x^{m+1}(\varphi - u^{m+1})_x dx \\ \geq \dfrac{1}{\Delta t}\displaystyle\int_\Omega J^m\,((u^m)^{3/8} \circ \chi^m)(\varphi - u^{m+1})\,dx + \int_\Omega a^{m+1}\,(\varphi - u^{m+1})dx \\ \forall \varphi \in K, \end{array} \tag{5.8}$$

where $K = \{\varphi \in W_0^{1,4}(\Omega) \,/\, \varphi \geq 0 \; a.e. \; in \; \Omega\}$.

Next, the duality algorithm proposed in Bermúdez and Moreno [8] is applied to the variational inequality (5.8). For this, (5.8) is expressed in terms of the indicatrix function I_K of the convex K in the following form.

Find $u^{m+1} \in W_0^{1,4}(\Omega)$ *such that*

$$\frac{1}{\Delta t}\int_\Omega (u^{m+1})^{3/8}(\varphi - u^{m+1})dx + \mu\int_\Omega \mid u_x^{m+1} \mid^2 u_x^{m+1}(\varphi - u^{m+1})_x dx + I_K(\varphi) - I_K(u^{m+1})$$
$$\geq \frac{1}{\Delta t}\int_\Omega J^m\left((u^m)^{3/8} \circ \chi^m\right)(\varphi - u^{m+1})dx + \int_\Omega a^{m+1}(\varphi - u^{m+1})dx \qquad \forall \varphi \in W_0^{1,4}(\Omega). \tag{5.9}$$

Moreover, the use of subdifferential calculus leads to the equivalent formulation

$$\xi_1^{m+1} = -(\mathcal{A}(u^{m+1}) - f^m) \in \partial I_K(u^{m+1}), \tag{5.10}$$

where $\partial I_K(u)$ denotes the subdifferential of the convex function I_K at the point u; see Brezis [11] for more details. Moreover, the operator $\mathcal{A} : W_0^{1,4}(\Omega) \to W^{-1,4/3}(\Omega)$ is defined by

$$\langle \mathcal{A}(\varphi), \psi\rangle = \frac{1}{\Delta t}\int_\Omega \varphi^{3/8}\psi dx + \mu\int_\Omega \mid \varphi_x \mid^2 \varphi_x\psi_x dx,$$

and the element $f^m \in W^{-1,4/3}(\Omega)$ is defined by

$$\langle f^m, \psi\rangle = \int_\Omega a^{m+1}\psi dx + \frac{1}{\Delta t}\int_\Omega J^m((u^m)^{3/8} \circ \chi^m)\psi dx.$$

Therefore, (5.10) is equivalent to the following problem.

Find $u^{m+1} \in W_0^{1,4}(\Omega)$ *such that*

$$\frac{1}{\Delta t}\int_\Omega (u^{m+1})^{3/8}\; \psi \; dx + \int_\Omega \xi_1^{m+1}\; \psi \; dx + \mu\int_\Omega \xi_2^{m+1}\psi_x dx$$
$$-\frac{1}{\Delta t}\int_\Omega J^m((u^m)^{3/8} \circ \chi^m)\psi dx = \int_\Omega a^{m+1}\; \psi \; dx \qquad \forall \psi \in W_0^{1,4}(\Omega), \tag{5.11}$$

$$\xi_1^{m+1} \in \partial I_K\left[u^{m+1}\right], \tag{5.12}$$

$$\xi_2^{m+1} = \Lambda\left(\frac{\partial u^{m+1}}{\partial x}\right), \tag{5.13}$$

where $\Lambda(v) = \mid v \mid^2 v = v^3$.

The application of the Bermúdez–Moreno algorithm [8] to solving the nonlinear problem (5.11)–(5.13) introduces the following new unknowns (multipliers) q_1^{m+1} and q_2^{m+1},

$$q_1^{m+1} \in \partial I_K\left[u^{m+1}\right] - \omega_1 u^{m+1}, \tag{5.14}$$

$$q_2^{m+1} = \Lambda\left(\frac{\partial u^{m+1}}{\partial x}\right) - \omega_2\frac{\partial u^{m+1}}{\partial x}, \tag{5.15}$$

defined in terms of the positive parameters ω_1 and ω_2. So, (5.11) is equivalent to

$$\frac{1}{\Delta t}\int_\Omega (u^{m+1})^{3/8}\psi dx + \int_\Omega (q_1^{m+1}+\omega_1 u^{m+1})\psi\, dx + \mu\int_\Omega \left(q_2^{m+1}+\omega_2\frac{\partial u^{m+1}}{\partial x}\right)\frac{\partial \psi}{\partial x}\, dx$$
$$= \int_\Omega a^{m+1}\psi\, dx + \frac{1}{\Delta t}\int_\Omega J^m\left((u^m)^{3/8}\circ\chi^m\right)\psi dx \qquad \forall \psi \in W_0^{1,4}(\Omega). \tag{5.16}$$

Now, since ∂I_K and Λ are maximal monotone operators, the definitions given by (5.14) and (5.15) can be characterized by their respective identities (see [8]):

$$q_1^{m+1} = (\partial I_K)_{\lambda_1}^{\omega_1}\left[u^{m+1}+\lambda_1 q_1^{m+1}\right], \tag{5.17}$$

$$q_2^{m+1} = \Lambda_{\lambda_2}^{\omega_2}\left[\frac{\partial u^{m+1}}{\partial x}+\lambda_2 q_2^{m+1}\right]. \tag{5.18}$$

In (5.17) and (5.18), the functions $(\partial I_K)_{\lambda_1}^{\omega_1}$ and $\Lambda_{\lambda_2}^{\omega_2}$ denote the Yosida approximations for the operators $(\partial I_K - \omega_1 I)$ and $(\Lambda - \omega_2 I)$ with positive parameters λ_1 and λ_2, respectively (see Brezis [11], for example). Next, to discretize (5.16)–(5.18) in space, we consider piecewise linear Lagrange finite elements. More precisely, for a given positive parameter h we build a uniform finite element mesh τ_h for Ω. Thus, let $x_i = (i-1)h$, $i = 1, \ldots, N+1$, be the mesh nodes. Now, we introduce the classical finite elements spaces and sets:

$$\begin{aligned} V_h &= \{\varphi_h \in C^0(\Omega) \,/\, \varphi_h\,|_E \in P_1 \quad \forall E \in \tau_h\},\\ V_{0h} &= \{\varphi_h \in V_h \,/\, \varphi_h\,|_{\partial\Omega} = 0\},\\ K_h &= \{\varphi_h \in V_{0h} \,/\, \varphi_h(x_i) \geq 0, \quad i = 1, \ldots, N+1\}, \end{aligned} \tag{5.19}$$

where E denotes a standard finite element interval.

Then, the fully discretized problem can be posed as follows.

Find $u_h^{m+1} \in K_h$ such that

$$\begin{aligned} &\frac{1}{\Delta t}\int_\Omega (u_h^{m+1})^{3/8}\psi_h\, dx + \omega_1\int_\Omega u_h^{m+1}\psi_h\, dx + \mu\omega_2\int_\Omega \frac{\partial u_h^{m+1}}{\partial x}\frac{\partial \psi_h}{\partial x}\, dx\\ &= \int_\Omega a_h^{m+1}\,\psi_h\, dx + \frac{1}{\Delta t}\int_\Omega J^m((u_h^m)^{3/8}\circ\chi^m)\psi_h\, dx - \int_\Omega q_{1,h}^{m+1}\psi_h\, dx\\ &- \mu\int_\Omega q_{2,h}^{m+1}\frac{\partial \psi_h}{\partial x}\, dx \quad \forall \psi_h \in V_{0h}. \end{aligned} \tag{5.20}$$

Thus, by treating the first term in (5.20) in explicit form at each step of the inner multipliers loop, the numerical algorithm for solving the fully discretized problem (5.20), (5.18), and (5.17) can be sketched as follows.

Step 0 : Initialize $(u_h^{m+1})_0$ (equal to u_h^m, for example)

Step j : For a given$(u_h^{m+1})_j$, compute $(u_h^{m+1})_{j+1} \in V_{0h}$ by solving the linear problem

$$\begin{aligned}
&\omega_1 \int_\Omega (u_h^{m+1})_{j+1}\psi_h \, dx + \mu\omega_2 \int_\Omega \frac{\partial (u_h^{m+1})_{j+1}}{\partial x}\frac{\partial \psi_h}{\partial x} \, dx \\
&= -\frac{1}{\Delta t}\int_\Omega (u_h^{m+1})_j^{3/8} \, \psi_h \, dx \, - \int_\Omega (q_{1,h}^{m+1})_j \, \psi_h \, dx - \mu \int_\Omega (q_{2,h}^{m+1})_j \frac{\partial \psi_h}{\partial x} dx \\
&+ \int_\Omega a_h^{m+1}\psi_h \, dx + \frac{1}{\Delta t}\int_\Omega J^m \left(((u_h^m)_j)^{3/8} \circ \chi^m\right) \psi_h \, dx \qquad \forall \psi \in V_{0h}.
\end{aligned} \tag{5.21}$$

The multipliers updating (indexed by j) is provided by the following expressions:

$$(q_{1,h}^{m+1})_{j+1} = (\partial I_K)_{\lambda_1}^{\omega_1}[(u_h^{m+1})_{j+1} + \lambda_1 (q_{1,h}^{m+1})_j], \tag{5.22}$$

$$(q_{2,h}^{m+1})_{j+1} = \Lambda_{\lambda_2}^{\omega_2}\left[\frac{\partial}{\partial x}(u_h^{m+1})_{j+1} + \lambda_2 (q_{2,h}^{m+1})_j\right]. \tag{5.23}$$

The convergence of the duality method is established in Bermúdez and Moreno [8] and Bermúdez [7] under the technical constraint $\lambda_i \omega_i = 0.5$ for $i = 1, 2$. For this particular choice of the parameters, the Yosida approximations can easily be computed and are given by

$$(\partial I_K)_{\frac{1}{2\omega_1}}^{\omega_1}(r) = -2\omega_1 \mid r \mid,$$

$$\Lambda_{\frac{1}{2\omega_2}}^{\omega_2}(r) = 2\,\Lambda_{\frac{1}{\omega_2}}(2r) - 2\,\omega_2\, r\,,$$

where $\Lambda_\lambda(r) = (r - s)/\lambda$, the value s being the real solution of the nonlinear equation $\lambda s^3 + s = r$, which has been solved for each r by using Cardano's formulae.

5.3. Numerical results: Comparison tests. In order to validate the correct performance of our numerical approach, we have considered a first test (Test 1), which presents a closed form stationary solution. It corresponds to a no sliding case (i.e., $u_b = 0$) and is adapted from Paterson [36]. More precisely, in Test 1, for a sufficiently large time interval $(0, T)$, we consider the open set $\Omega = (-L, L)$ and the following piecewise constant accumulation-ablation function:

$$a(x) = \begin{cases} a_1 & \text{if } 0 \le |x| < R, \\ -a_2 & \text{if } R \le |x| \le L, \end{cases} \tag{5.24}$$

where $L > 1$, $a_1 > 0$, $a_2 > 0$, and $R \in (0, 1)$. Moreover, we assume that

$$a_1 R = a_2(1 - R) \tag{5.25}$$

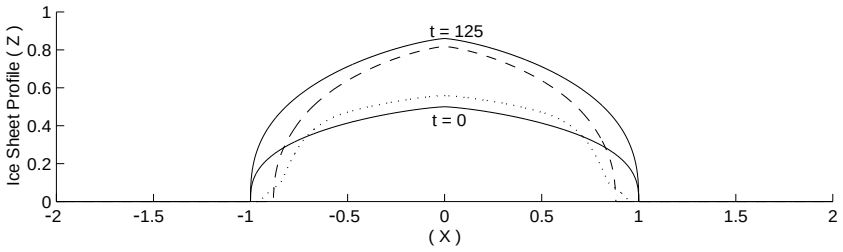

FIG. 5.1. *Computed numerical solution of Test* 1*;* $t = 0(-), t = 5(\cdots), t = 75(--)$, *stationary* $(-)$.

holds. Thus, for the particular values $a_1 = 0.01$ and $a_2 = 0.03$, we have the steady state solution

$$\overline{\eta}(x) = \begin{cases} H\left[1 - \left(1 + \dfrac{a_1}{a_2}\right)^{1/3} \left(\dfrac{|x|}{L}\right)^{4/3}\right]^{3/8} & \text{if } |x| \le R, \\ H\left(1 + \dfrac{a_2}{a_1}\right)^{1/8} \left(1 - \dfrac{|x|}{L}\right)^{1/2} & \text{if } R \le |x| \le 1, \\ 0 & \text{if } 1 \le |x| \le L, \end{cases} \tag{5.26}$$

where $H = (40\, a_1\, R\,)^{1/8}$ represents the thickness at $x = 0$ (the *ice divide*).

Moreover, in Test 1 the values $L = 2$ and $R = 0.75$ have been chosen so that $H = 0.86$. As initial conditions for the evolutive problem, we have considered

$$\eta_0(x) = \begin{cases} c\,(1 - |x|^{4/3})^{3/8} & \text{if } \ |x| \le 1, \\ 0 & \text{if } \ 1 \le |x| \le 2, \end{cases} \tag{5.27}$$

with $c = 0.5$.

For the numerical solution a uniform finite element mesh with $N = 4001$ nodes and a time step $\Delta t = 1$ have been taken.

In Figure 5.1 we present the initial profile ($t = 0$), the computed solutions for $t = 5$ and $t = 75$, and the stationary exact solution (which matches the numerical approximation for $t = 125$) for Test 1. Figure 5.1 is obtained with the described Bermúdez–Moreno method with $\omega_1 = 15$ and $\omega_2 = 30$. The computed results agree with the same test example solved with another numerical approach in Calvo, Durany, and Vázquez [13], but computing time is highly reduced (by about 99 per cent). Notice that in Figure 5.1 for $t = 5$ the ice sheet is retreating. The ice mass shrinks until $t = 25$, and then it expands with time until reaching the stationary solution given by expression (5.26). The initial contraction is mainly due to the fact that accumulation taking place at the center cannot balance the initial effect of ablation near the margins.

Test 2 is proposed to simulate the behavior of the concave profile when increasing the sliding velocity. In this case, we take $L = 2$ and $R = 1$ in (5.24), so that (5.25) is not verified. Thus, in Figures 5.2 and 5.3 several examples are presented by considering the velocity field

$$u_b(t,x) = \begin{cases} C\,x^2 & \text{if } \ x \ge 0, \\ -C\,x^2 & \text{if } \ x < 0 \end{cases} \tag{5.28}$$

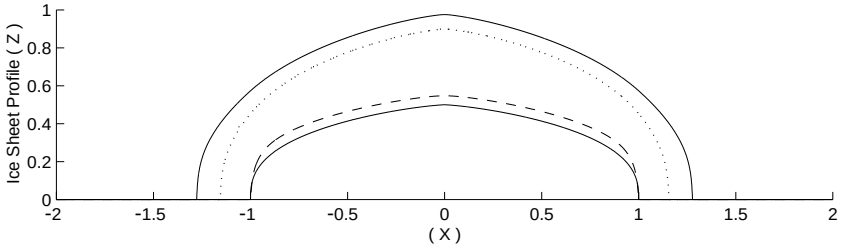

FIG. 5.2. *Numerical solution of Test* 2 *in the case* $C = 0.005$*;* $t = 0(-), t = 5(--)$, $t = 50(\cdots), t = 90(-)$.

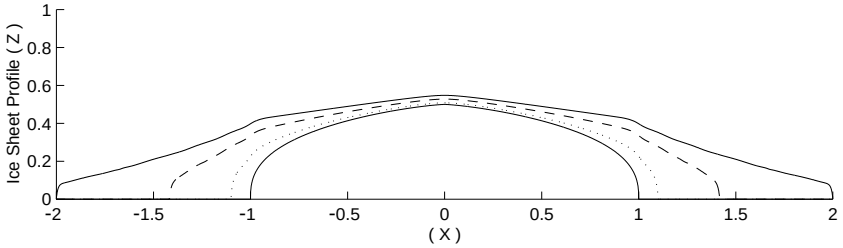

FIG. 5.3. *Numerical solution of Test* 2 *in the case* $C = 0.1$*;* $t = 0(-), t = 1(\cdots), t = 3(--), t = 5(-)$.

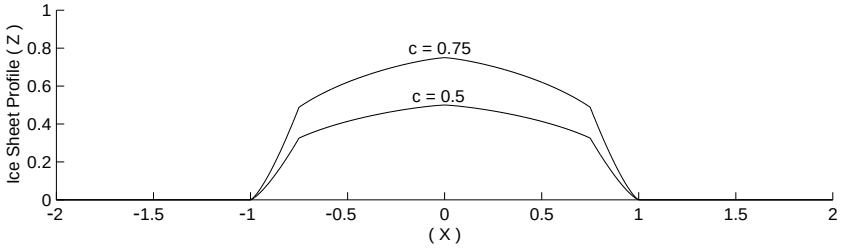

FIG. 5.4. *Convex-concave initial condition* $\overline{\eta}_0$ *for* $c = 0.5$ *and* $c = 0.75$.

and the initial condition (5.27). More precisely, Figure 5.2 shows the results obtained for $t = 5$, $t = 50$, and $t = 90$ in the case $C = 0.005$, and Figure 5.3 presents the computed profiles for $t = 1$, $t = 3$, and $t = 5$ when $C = 0.1$. These figures illustrate how concave profiles disappear in the presence of enough convection ($C = 0.1$). The values of time have been chosen to present the profiles that most emphasize this realistic phenomenon. The time step, the number of nodes, and the parameters in the Bermúdez–Moreno algorithm are the same as those used in Test 1.

Test 3 has been designed to illustrate the *waiting time property* discussed in section 4. The idea is to show how when the initial condition of the problem has a sufficiently flat convex-concave shape (see Figure 5.4), then the displacement of the initial free boundary ($S_+(t_0)$, for example) starts after a certain time (the *waiting time*). Nevertheless, an instantaneous displacement occurs for a concave initial condition (as (5.27), for example).

More precisely, in order to illustrate this so-called *waiting time property*, the numerical solutions obtained from the initial condition (5.27) and the following alter-

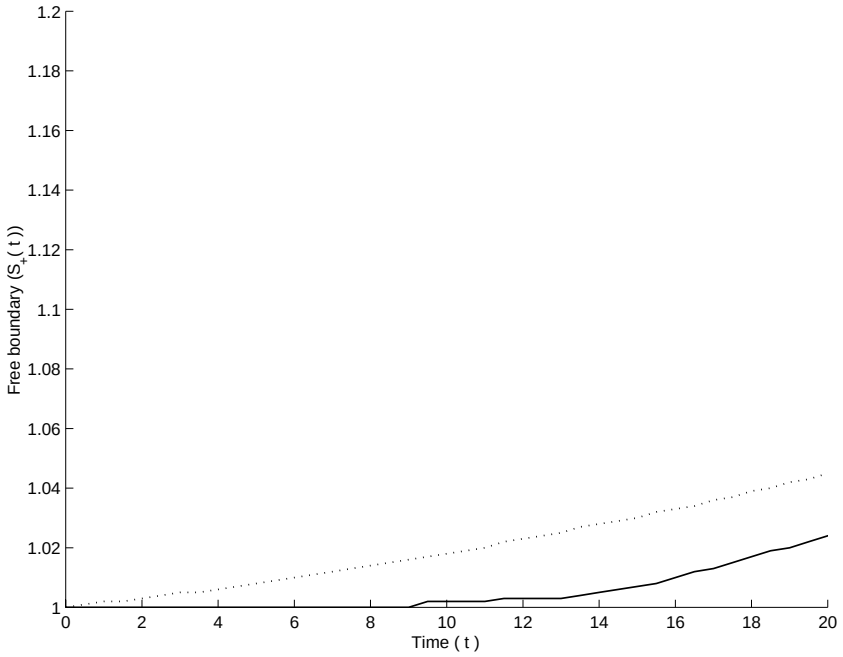

FIG. 5.5. *Moving boundary $S_+(t)$ in Test 3, with convex-concave $\overline{\eta}_0$ $(-)$ and purely concave η_0 $(\cdots)$ initial conditions for $c = 0.5$.*

native one,

$$\overline{\eta}_0(x) = \begin{cases} c\,(1-|x|^{4/3})^{3/8} & \text{if} \quad -0.75 \le x \le 0.75, \\ 16.77\,c\left(\dfrac{a_2}{2}\right)^{1/3} |x-1|^{4/3} & \text{if} \quad 0.75 \le x \le 1, \\ 16.77\,c\left(\dfrac{a_2}{2}\right)^{1/3} |x+1|^{4/3} & \text{if} \quad -1 \le x \le -0.75, \\ 0 & \text{otherwise,} \end{cases} \tag{5.29}$$

are compared for different values of c. Thus, in Figures 5.5 and 5.6 the moving boundaries are compared for the initial conditions (5.27) and (5.29) for $c = 0.5$ and $c = 0.75$, respectively. Notice that the theoretical result stated in section 4 about the *waiting time* property is a local one, while numerical observations yield a global *waiting time*. To our knowledge the proof of global *waiting time* properties is an open and difficult question.

Next we illustrate the relation between the *waiting time* and the initial ice mass stated in the theoretical analysis. As the ice mass associated with an initial condition such as (5.29) depends linearly on the parameter c, in Figure 5.7 we compare the moving boundary evolution for different values of c in the absence of convection. Notice how the *waiting time* decreases when the initial ice mass increases.

Finally, in Figure 5.8 the influence of convection for a fixed initial ice mass associated with $c = 0.75$ is illustrated. Thus, an increasing basal sliding reduces the *waiting time* as expected in real situations.

6. Discussion. In this paper we have used different but equivalent weak formulations, expressed in terms of either multivalued equations or variational inequalities when the complementarity formulation is considered for numerical purposes. This approach makes more precise the original doubly nonlinear formulation of Fowler [29], converting it into an obstacle problem for the associated operator. Assuming some extra regularity properties of the solution, we have given sufficient conditions (in terms of a, the accumulation rate, and h_0, the initial thickness) for the existence of the free moving boundary and its spatial location. For this, we employed two different methods: a comparison principle, combined with the construction of suitable barrier functions in the case $u_b \equiv 0$, and a local energy method if $u_b \neq 0$. In both cases, we prove rigorously the possible existence of a waiting time in the dynamics of the free boundary, whose location and evolution can be qualitatively described as long as suitable and physically admissible hypotheses on the data of the problem hold. From the numerical point of view, the main advantage of the proposed new approach follows from the introduction of a maximal monotone operator for the nonlinear diffusive term that had already been treated in explicit form [13]. Thus, a duality method can also be applied to greatly improve the speed of convergence with respect to the previous work. In order to verify the good performance of the new algorithm as well as the computational cost reduction, a problem with a closed form solution has been tested. Moreover, to complete the theoretical results and reflect some realistic situations, several test examples illustrate some qualitative properties of the ice profile and the associated free boundary.

HYPERBOLIC PHASE TRANSITIONS IN TRAFFIC FLOW*

RINALDO M. COLOMBO†

Abstract. This paper provides a mathematical model of the phenomenon of phase transitions in traffic flow. The model consists of a scalar conservation law coupled with a 2×2 system of conservation laws. The coupling is achieved via a free boundary, where the phase transition takes place. For this model, the Riemann problem is stated and globally solved. The Cauchy problem is proved to admit a solution defined globally in time without any assumption about the smallness of the initial data or the number of phase boundaries. Qualitative properties of real traffic flow are shown to agree with properties of the solutions of the model.

Key words. hyperbolic conservation laws, phase transitions, macroscopic vehicular traffic model, hyperbolic systems, partial differential equations

1. Introduction.

We are concerned with phase transitions in hyperbolic systems of conservation laws. By *phase transition* we mean a discontinuity separating states belonging to different *phases*, i.e., having deep qualitative differences. Equivalently, a phase boundary can be seen as a *free boundary* separating two different models and whose evolution is determined by the solution on both of its sides. In fact, besides the usual phase transitions in fluids that motivate the term, other phenomena are described within this framework. Examples include those from nonlinear elastodynamics [1] and from combustion theory [9, 20].

The present work deals with phase transitions in traffic flow. In the specialized literature (see [15] and the many references therein), it has been shown that traffic flow admits two distinct behaviors, depending on whether it is *free* or *congested*. In this context, "mathematical models and theories ... still cannot explain and predict the experimental features of the phase transitions in real traffic flow which have been found out ..." [15, p. 257]. The model presented below gives such an explanation, showing that "real traffic flow" can be described within the mathematical framework provided here, based on hyperbolic conservation laws that develop phase transitions.

From the analytical point of view, we study a scalar conservation law coupled with a 2×2 system of conservation laws. The coupling is achieved via the phase boundary, i.e., a free boundary whose evolution is regulated by the Rankine–Hugoniot conditions. The whole model admits a bounded variation (**BV**) weak solution defined globally in time. Note that the total variation of the initial data is required merely to be bounded.

The presence of phase transitions usually leads to a lack of uniqueness in the solution to Riemann problems. A standard way out of this dilemma is the introduction of suitable admissibility conditions [1, 20]. Here, we do not need this provision and, assigning the *structure* of the solution, select a unique solution to any Riemann problem.

*Received by the editors July 30, 2001; accepted for publication (in revised form) July 18, 2002; published electronically December 19, 2002.

From the point of view of traffic flow theory, the present model satisfies the requirements stated in [2, 11] and is able to describe various phenomena reported in Kerner's review [15]. Indeed, Kerner's work inspired the present paper, and we shall often refer to it. More precisely, here we present a PDE-based model that can be rigorously stated and studied. The qualitative properties of its solutions fully agree with the qualitative "three phase theory" given by Kerner [14] and supported by him [13] with empirical studies. Furthermore, the mathematical techniques here adopted are those typical of several phase transition models of continuum dynamics, providing a mathematical justification of Kerner's choice of the term "phase transitions" referring to traffic flow.

The present work, while being in full agreement with Kerner's observations, suggests a different choice of terms in the distinction between *synchronized flow* and *wide moving jams*, called by Kerner distinct *phases*. Here, both these configurations are present and have the same properties underlined in [15]. But they essentially correspond to *waves* of two different characteristic families, rather than to different *phases*; see section 4 for a more detailed discussion.

A further example of qualitative agreement between the present model and the observed phenomena is shown in Figure 1.1. Here, the *fundamental diagram*, i.e., the "curve in the flow-density plane which gives a correspondence of the vehicle density to the flow rate in traffic flow" [15, p. 254] is compared with the domain in which the present model is defined and studied. Note that while the former picture consists of measured data, the second is determined uniquely as an invariant domain for a set of PDEs; indeed it displays the sets Ω_f and Ω_c defined in (2.5). These sets are characterized as being *invariant* for the system of PDEs (2.3) introduced below; for a characterization of invariant domains in systems of conservation laws, see [12].

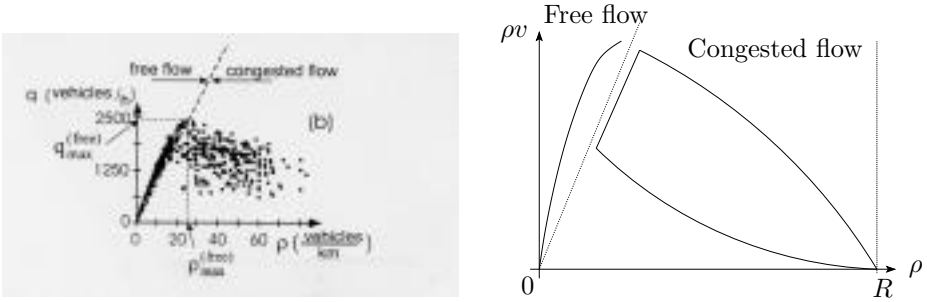

FIG. 1.1. *Left, an experimental fundamental diagram (from* [15]; used with permission) *and, right, the one obtained from the model presented here as an invariant set for* (2.3)*; see* (2.5).

In section 4, further relations between this model and features of real traffic flow will be considered. In particular, the classical Lighthill–Whitham [17] and Richards [18] (LWR) model (2.1) gives a good solution of the *traffic light problem* (see [21, p. 71]. In section 4 we shall consider the solution of the same problem, as provided by the model presented here, obtaining some reasonable improvements. Quantitative tests on the present model are under investigation.

This paper is organized as follows. The next section deals with the statement of the model. Then, section 3 is devoted to the Riemann problem, while the Cauchy problem is left to section 5. The final section 6 contains the technical details.

Throughout, we focus on analytically tractable realistic situations rather than aiming at maximal generality.

2. The model. The two phases we shall be concerned with are *free flow* and *congested flow*. In the case of free flow the classical LWR model

$$\partial_t \rho + \partial_x (\rho \cdot v) = 0, \qquad v = v_f(\rho), \tag{2.1}$$

is applicable. Here, ρ is the car density, while $v = v_f(\rho)$ is a suitable smooth decreasing function giving the car speed v at traffic density ρ.

As the car density ρ increases, the assumption that the speed v is a function of only ρ is no longer acceptable, as clearly shown by several observations (see [15], the references therein, and Figure 1.1, left). As soon as v crosses a certain threshold, the density-flow points are scattered in a cloud rather than along a line. This is *congested flow*. Here, the standard LWR model (2.1) is inadequate. We propose to complete it by means of the 2×2 system (see [8])

$$\begin{cases} \partial_t \rho + \partial_x(\rho \cdot v) = 0, \\ \partial_t q + \partial_x((q - q_*) \cdot v) = 0, \end{cases} \qquad v = v_c(\rho, q), \tag{2.2}$$

where ρ and v appear as *independent* variables. The weighted flow q is a variable originally motivated by the linear momentum in gas dynamics; v_c is given by the speed law (2.4). The threshold parameter q_* distinguishes between possible behaviors of the flow; see [8]. The well-posedness of (2.2) in the sense of the theory of standard Riemann semigroups [5, 6] follows from [3].

Thus, we propose the following model:

$$\begin{array}{ll} \text{Free flow: } (\rho, q) \in \Omega_f, & \text{Congested flow: } (\rho, q) \in \Omega_c, \\ \partial_t \rho + \partial_x [\rho \cdot v] = 0, & \begin{cases} \partial_t \rho + \partial_x [\rho \cdot v] = 0, \\ \partial_t q + \partial_x \left[(q - q_*) \cdot v\right] = 0, \end{cases} \\ v = v_f(\rho), & v = v_c(\rho, q), \end{array} \tag{2.3}$$

where Ω_f and Ω_c denote the *free* and the *congested* phases, respectively. In Ω_f the only variable is the car density ρ. Here, the car speed v is assumed to be a known function v_f of the car density: $v = v_f(\rho)$. In Ω_c the variables are the car density ρ and the car speed v or, equivalently, ρ and the weighted flow q; see [8]. Thus, at a fixed density, different speeds are admissible, as raw data observations require. Note that there may well be car densities at which the flow may be either free or congested.

In what follows we assume that the speed laws in the two phases are

$$v_f(\rho) = \left(1 - \frac{\rho}{R}\right) \cdot V \quad \text{and} \quad v_c(\rho, q) = \left(1 - \frac{\rho}{R}\right) \cdot \frac{q}{\rho}\,. \tag{2.4}$$

The former relation is the simplest standard linear choice (see, for instance, [22]), while the latter was introduced in [8]. Here, R is the maximal possible car density and V is the maximal possible speed. More general expressions can be considered, but we limit ourselves to the expressions above in order to keep the formal analytical difficulties at a minimum while maintaining all the more interesting qualitative features.

In the present model, the road is translation invariant both spatially and temporally, since none of the various functions appearing in (2.3)–(2.4) explicitly depends on x or t. As a consequence, the model may not foresee where and when new queues might form. To this aim, either time/space dependent terms should be introduced, or nondeterministic disturbances should be added. Both possibilities are far from the scope of the present paper. As a consequence, we impose the condition that if (2.3)

is assigned an initial datum contained in a single phase, then the solution will be contained in the same phase for all times. In other words, if the traffic flow is free (or congested) on all the real line, it will remain free (or congested) for all times. This leads us to require that Ω_f be invariant with respect to (2.1) and, similarly, that Ω_c be invariant with respect to (2.2). We are thus lead to define (see Figure 2.1)

$$\begin{aligned} \Omega_f &= \{(\rho, q) \in [0, R] \times [0, +\infty[: v_f(\rho) \geq \hat{V}_f,\ q = \rho \cdot V\}, \\ \Omega_c &= \left\{(\rho, q) \in [0, R] \times [0, +\infty[: v_c(\rho.q) \leq \hat{V}_c,\ \frac{q - q_*}{\rho} \in \left[\frac{Q_1 - q_*}{R}, \frac{Q_2 - q_*}{R}\right]\right\}. \end{aligned} \tag{2.5}$$

Here, $\hat{V}_f$ and $\hat{V}_c$ are the threshold speeds; i.e., above $\hat{V}_f$ the flow is free, while below $\hat{V}_c$ the flow is congested. We impose that the two phases do not intersect and hence that $\hat{V}_f > \hat{V}_c$; see Remark 2 in section 6. Moreover, $\hat{V}_f \leq V$ since $\frac{d}{d\rho}(\rho v(\rho)) \geq 0$ in the free phase. $Q_1 \in]0, q_*[$ and $Q_2 \in]q_*, +\infty[$ depend on the various environmental conditions and determine the width of the "cloud" in the congested phase. The case in which one of the equalities $Q_1 = q_*$ or $Q_2 = q_*$ holds is simpler (see Remark 1 in section 6). Finally, we let $(\check{Q}_f - q_*)/\check{R}_f = (Q_2 - q_*)/R$, as is suggested from the experimental data (see Figure 1.1) and is consistent with the "capacity drop" [15, p. 254] that takes place when passing from the free phase to the congested one.

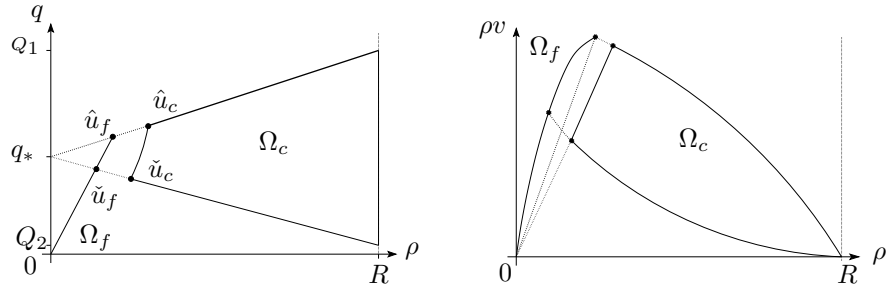

FIG. 2.1. *Left, the fundamental diagram in the (ρ, q)-plane and, right, in the $(\rho, \rho v)$-plane.*

Note that $\max_{\Omega_f} \rho v \geq \max_{\Omega_c} \rho v$, according to the phenomenon of *capacity drop*. The fundamental diagram $\Omega_f \cup \Omega_c$ depends on the specific road to which the model is applied and plays a central role, for the Riemann solver itself depends on its choice.

Note that (2.3) can be formally restated as a 2×2 system of conservation laws, for instance by introducing the map

$$f(\rho, q) = \begin{cases} (\rho \cdot v_f(\rho), q \cdot v_f(q)) & \text{if } (\rho, q) \in \Omega_f, \\ (\rho \cdot v_c(\rho, q), (q - q_*) \cdot v_c(\rho, q)) & \text{if } (\rho, q) \in \Omega_c, \end{cases} \tag{2.6}$$

and writing $\partial_t(\rho, q) + \partial_x[f(\rho, q)] = 0$. However, the solutions to (2.1)–(2.2) defined below are *not* standard Lax solutions [6, 10, 16] to any 2×2 systems of hyperbolic conservation laws. This fact will clearly follow from the next section.

We conclude this section with a remark on the parameters defining the model. The maximal density R, the maximal speed V, and the threshold densities $\hat{V}_f$ and $\hat{V}_c$ have a clear physical meaning and can be estimated as in other traffic models. Q_1 and Q_2 depend on the various environmental conditions. A possible way to determine them consists of imposing the requirement that all measured data fall inside the domain

$\Omega_f \cup \Omega_c$. The situation with q_* is more delicate. A posteriori, in section 4, we shall see a property of the line $q = q_*$ that, indirectly, leads to a possible way to determine q_*. A theory of the inverse problem for systems of hyperbolic conservation laws would give better tools but is at present not available.

3. The Riemann problem. In the free phase the characteristic speed is $\lambda(\rho) = V \cdot (1 - 2\frac{\rho}{R})$, while in the congested phase, from [8] we obtain the characteristic speeds λ_1, λ_2, the eigenvectors r_1, r_2, the i-Lax curve $q = q_i(\rho; \rho_o, q_o)$ exiting (ρ_o, q_o), and the Riemann invariants w_1, w_2. The following display summarizes this information:

$$
\begin{array}{ll}
r_1(\rho, q) = \begin{bmatrix} \rho \\ q - q_* \end{bmatrix}, & r_2(\rho, q) = \begin{bmatrix} R - \rho \\ \frac{R}{\rho} q \end{bmatrix}, \\
\lambda_1(\rho, q) = \left(\dfrac{2}{R} - \dfrac{1}{\rho} \right) \cdot (q_* - q) - \dfrac{q_*}{R}, & \lambda_2(\rho, q) = v_c(\rho, q), \\
\nabla \lambda_1 \cdot r_1 = 2 \dfrac{q_* - q}{R}, & \nabla \lambda_2 \cdot r_2 = 0, \\
q_1(\rho; \rho_o, q_o) = q_* + \dfrac{q_o - q_*}{\rho_o} \rho, & q_2(\rho; \rho_o, q_o) = \dfrac{\rho}{\rho_o} \dfrac{R - \rho_o}{R - \rho} q_o, \\
w_1 = v_c(\rho, q), & w_2 = \dfrac{q - q_*}{\rho}.
\end{array}
\tag{3.1}
$$

In the (ρ, q)-plane the 1-Lax curves are the straight half-lines exiting $(0, q_*)$, while the 2-Lax curves are convex, exit $(0, 0)$, increase monotonically, and $\lim_{\rho \to R} q_2(\rho, \rho_o, q_o) = +\infty$ for all (ρ_o, q_o). Shock and rarefaction curves coincide, but the 2-Lax curves are *not* straight lines. Hence, (2.2) is *not* a Temple system in the sense defined in [19]. The first family is not genuinely nonlinear, for $\nabla \lambda_1 \cdot r_1$ vanishes along the characteristic line $q = q_*$.

By the Riemann problem we mean (2.3) together with the initial datum

$$
(\rho, q)(0, x) = \begin{cases} (\rho^l, q^l) & \text{if } x < 0, \\ (\rho^r, q^r) & \text{if } x > 0. \end{cases}
\tag{3.2}
$$

If (ρ^l, q^l) and (ρ^r, q^r) are in the same phase, then the usual Lax solution to (2.1) or to (2.2) will be used. Note that this solution attains values in the same phase of the initial data, and no phase transition may arise.

If $(\rho^l, q^l) \in \Omega_f$ and $(\rho^r, q^r) \in \Omega_c$, then an *admissible solution* to (2.3), (3.2) is a self-similar function $u \colon [0, +\infty[\times \mathbf{R} \mapsto \Omega_f \cup \Omega_c$ such that there exists a $\Lambda \in \mathbf{R}$ with

1. $u(t,]-\infty, \Lambda t[) \subseteq \Omega_f$ and $u(t,]\Lambda t, +\infty[) \subseteq \Omega_c$;
2. the functions u^l and u^r, respectively defined by

$$
u^l(t, x) = \begin{cases} u(t, x) & \text{if } x < \Lambda \cdot t, \\ u(t, \Lambda t-) & \text{if } x > \Lambda \cdot t, \end{cases}
$$

$$
u^r(t, x) = \begin{cases} u(t, \Lambda t+) & \text{if } x < \Lambda \cdot t, \\ u(t, x) & \text{if } x > \Lambda \cdot t, \end{cases}
$$

   are restrictions of Lax solutions to Riemann problems for (2.1) and (2.2), respectively;
3. the Rankine–Hugoniot conditions

$$
\Lambda \cdot (\rho(t, \Lambda t+) - \rho(t, \Lambda t-)) = \rho(t, \Lambda t+) \cdot v_c(t, \Lambda t+) - \rho(t, \Lambda t-) \cdot v_f(t, \Lambda t-)
$$

   are satisfied for all positive t.

In the other case $(\rho^l, q^l) \in \Omega_c$ and $(\rho^r, q^r) \in \Omega_f$, conditions entirely analogous to the ones above are required.

Statement 3 above ensures that the total number of cars is conserved.

Note that *nucleation* is not possible, since no phase boundary may arise in a Riemann problem with data in a single phase. On the other hand, in the case of the Cauchy problem, zones of free (resp., congested) traffic may well disappear and turn into zones of congested (resp., free) traffic; see Figure 4.3.

We show below that it is possible to define a global Riemann solver for (2.3), (3.2). Furthermore, this solver enjoys properties underlined in the literature [2, 11] as *not* satisfied in several common models. Recall that a *Riemann solver* is a map assigning to any pair of states u^l, u^r an admissible **BV** self-similar solution to (2.3), (3.2).

The main tool in the construction of the Riemann solver is its consistency. Namely, let $\mathcal{R}\colon (u^l, u^r) \mapsto \mathcal{R}(u^l, u^r)$ denote a Riemann solver; i.e., $x \mapsto \mathcal{R}(u^l, u^r)(x)$ is the solution computed at time 1 of the Riemann problem with data u^l, u^r. $\mathcal{R}$ is *consistent* if the following two conditions hold for all u^l, u^m, u^r, and $\bar{x}$:

$$\textbf{I.} \qquad \mathcal{R}(u^l, u^r)(\bar{x}) = \bar{u} \qquad \Rightarrow \qquad \begin{array}{l} \mathcal{R}(u^l, \bar{u}) = \left\{ \begin{array}{ll} \mathcal{R}(u^l, u^r) & \text{if } x \le \bar{x}, \\ \bar{u} & \text{if } x > \bar{x}, \end{array} \right. \\ \mathcal{R}(\bar{u}, u^r) = \left\{ \begin{array}{ll} \bar{u} & \text{if } x < \bar{x}, \\ \mathcal{R}(u^l, u^r) & \text{if } x \ge \bar{x}, \end{array} \right. \end{array}$$

$$\textbf{II.} \quad \left. \begin{array}{l} \mathcal{R}(u^l, u^m)(\bar{x}) = u^m \\ \mathcal{R}(u^m, u^r)(\bar{x}) = u^m \end{array} \right\} \quad \Rightarrow \quad \mathcal{R}(u^l, u^r) = \left\{ \begin{array}{ll} \mathcal{R}(u^l, u^m) & \text{if } x < \bar{x}, \\ \mathcal{R}(u^m, u^r) & \text{if } x \ge \bar{x}. \end{array} \right.$$

This property is enjoyed by the standard Lax solver [16] and is a necessary condition for the well-posedness of the Cauchy problem.

PROPOSITION 3.1. *Assume that the fundamental diagram is as in Figure* 1.1*, with* $\hat{V}_f \ge \hat{V}_c$*. Then, there exists a Riemann solver assigning a unique self-similar admissible solution to any Riemann problem* (2.3), (3.2) *for all pairs of initial states in* $\Omega_f \cup \Omega_c$*. Moreover,*

(0) *the Riemann solver is consistent;*
(1) *no wave travels faster than the cars;*
(2) *any solution attains values in* $\Omega_f \cup \Omega_c$*, i.e., in a compact set where both car density and car speed are bounded and nonnegative;*
(3) *if the initial data are in the same phase, the solution also attains values in that phase;*
(4) *no* 2×2 *system of conservation laws may have as its Lax solutions those defined by this Riemann solver.*

Note that the *vacuum* state $\rho = 0$ is treated as any other state and does not lead to any instability, unlike what happens in [2].

Aiming at the later use of this proposition for the Cauchy problem, we proceed by first generalizing the usual Lax curves of the first and second families exiting a fixed $u^l \in \Omega_f \cup \Omega_c$. Furthermore, if u^r is on the generalized curve exiting u^l, we will suitably define the *size* $\Sigma_i(u^l, u^r)$ of the wave connecting u^l to u^r so that

$$c \cdot \|u^r - u^l\| \le |\Sigma_i(u^l, u^r)| \le C \cdot \|u^r - u^l\|, \tag{3.3}$$

C and c being suitable positive constants independent from u^l, u^r, and i. The role of Σ_i will be essential in the study of the Cauchy problem.

Proof of Proposition 3.1. The proof is achieved through three steps.

A. Generalized Riemann coordinates. Let $\check{u} = (\check{R}, \check{Q})$ be the point in Ω_f defined by $\check{Q} = \check{R} \cdot V$ and $\frac{\check{Q}-q_*}{\check{R}} = \frac{Q_1-q_*}{R}$; see Figure 2.1, left. For $(\rho, q) \in \Omega_f \cup \Omega_c$, define the generalized Riemann coordinates (w_1, w_2) as

$$w_1 = \begin{cases} v_c(\rho, q) & \text{if } (\rho, q) \in \Omega_c, \\ \hat{V}_f & \text{if } (\rho, q) \in \Omega_f, \end{cases}$$

(3.4)

$$w_2 = \begin{cases} \frac{q-q_*}{\rho} & \text{if } (\rho, q) \in \Omega_c, \\ \frac{q-q_*}{\rho} & \text{if } (\rho, q) \in \Omega_f, \rho \geq \check{R}, \\ v_f(\rho) - v_f(\check{R}) + \frac{\check{Q}-q_*}{\check{R}} & \text{if } (\rho, q) \in \Omega_f, \rho \leq \check{R}. \end{cases}$$

The construction of the solution to the Riemann problem (2.3), (3.2) will be carried out in the w coordinates. Define $W_i = \frac{Q_i - q_*}{R}$; see Figure 3.1, right.

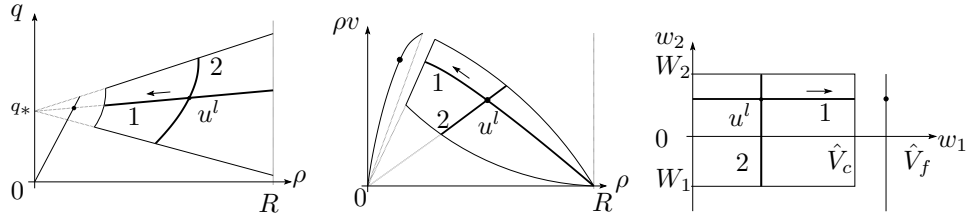

FIG. 3.1. *Generalized Lax curves exiting u^l, with $u^l \in \Omega_c$.*

B. Generalized Lax curves and simple waves. First let $w^l \in \Omega_c$. Then the generalized 1-curve exiting w^l is the segment $w_2 = w_2^l$, $w_1 \in [0, \hat{V}_c]$, to which we add the point $(w_1^l, \hat{V}_f)$; see Figure 3.1. Assume now that w^r is on this generalized 1-curve; i.e., $w_2^r = w_2^l$. Then the solution to (2.3), (3.2) is the standard Lax solution as long as $w^r \in \Omega_c$. If $w^r \in \Omega_f$, the solution to (2.3), (3.2) is as follows:

- if $w_2^l > 0$, a rarefaction followed by a phase transition;
- if $w_2^l = 0$, a single phase transition acting as a contact discontinuity;
- if $w_2^l < 0$, a single shock-like phase transition.

In all cases, the speed of the phase boundary is assigned by the Rankine–Hugoniot conditions. The size of this wave is $\Sigma_1(w^r, w^l) = w_1^r - w_1^l$.

The generalized 2-curve through w^l, for $w^l \in \Omega_c$, coincides with the standard Lax curve; see (3.1). Hence, if w^r lies on the 2-curve exiting w^l, the solution to (2.3), (3.2) is the standard Lax solution, and to the wave connecting w^l to w^r we assign size $\Sigma_2(w^r, w^l) = w_2^r - w_2^l$.

Now let $w^l \in \Omega_f$. We formally assign the standard Lax curves of the scalar equation (2.1) to the second family, defining the wave size as $\Sigma_2(w^r, w^l) = w_2^r - w_2^l$.

Concerning the generalized 1-curve through w^l, with $w^l \in \Omega_f$, the following cases are all the possibilities:

1. If $w_2^l \geq \check{w}_2$, the generalized 1-curve consists of w^l and of the segment $w_2 = w_2^l$ in Ω_c. If w^r belongs to it, the wave size is measured by $\Sigma_1(w^r, w^l) = w_2^r - w_2^l$, and the solution to (2.3), (3.2) is
   - if $w_2^l \in [0, \check{w}_1]$, a shock-like phase transition;
   - if $w_2^l = 0$, a single phase boundary acting as a contact discontinuity;
   - if $w_2^l < 0$, a phase boundary followed by a rarefaction wave.
2. If $w_2^l < \check{w}_2$, then the generalized 1-curve is the lower side of Ω_c, i.e., the segment $w_2 = \frac{Q_1 - q_*}{R}$, $w_1 \in [0, \hat{V}_c]$. Let $q_m(\rho) = q_* + \frac{\rho}{R}(Q_1 - q_*)$ be the equation

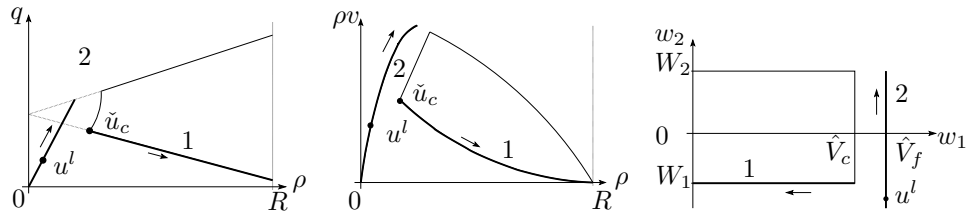

FIG. 3.2. *Generalized Lax curves exiting u^l, with $u^l \in \Omega_f$.*

of this segment in the (ρ, q) coordinates, and consider the two functions

$$\bar{\Lambda}(\rho) = \frac{\rho^l v^l - \rho v_c(\rho, q_m(\rho))}{\rho^l - \rho} \quad \text{and} \quad \bar{\lambda}_1(\rho) = \lambda_1(\rho, q_m(\rho)).$$

The former is the speed of the phase boundary joining $u^l \in \Omega_f$ to $(\rho, q_m(\rho)) \in \Omega_c$, while the latter is the first characteristic speed of $(\rho, q_m(\rho)) \in \Omega_c$. Consider the following three subcases:

- $\bar{\Lambda}(\check{R}_c) \le \bar{\lambda}_1(\check{R}_c)$. Here the solution to (2.3), (3.2) is a phase transition from u^l to $\check{u}_c$, followed by a 1-Lax rarefaction from $\check{u}_c$ to u^r.
- $\bar{\Lambda}(\rho) > \bar{\lambda}_1(\rho)$ for all ρ with $\check{R}_c \le \rho \le \rho^r$. In this case the solution consists of a shock-like phase transition.
- Otherwise, let ρ_m be the smallest car density such that $(\rho_m, q_m(\rho_m)) \in \Omega_c$ with $\bar{\Lambda}(\rho_m) = \bar{\lambda}_1(\rho_m)$. The solution to (2.3), (3.2) is a compound wave composed first by a phase transition and, attached to it, by a 1-Lax rarefaction in Ω_c.

This 1-wave (see Figure 3.2) is assigned the total size

$$\Sigma_1(w^r, w^l) = w_2^r - w_2^l + w_1^l - w_1^r. \tag{3.5}$$

C. The Riemann solver. From the above construction it follows that, given any two points w^l, w^r in $(\Omega_f \cup \Omega_c)^2$, the generalized curves defined above intersect in a single point $w^m \in \Omega_f \cup \Omega_c$, proving (2). The invariance of Ω_f (resp., Ω_c) with respect to (2.1) (resp., (2.2)) ensures (3). Furthermore, the wave speeds are well ordered, in the sense that any 1-generalized wave (eventually containing the phase boundary) propagates more slowly than the generalized 2-wave that follows, since in Ω_c

$$\lambda_2(\rho, q) - \lambda_1(\rho, q) = \frac{q}{R} + \left(\frac{1}{\rho} - \frac{1}{R}\right) q_* > 0, \tag{3.6}$$

which implies (0). Moreover, in the $(\rho, \rho v)$-plane, the Rankine–Hugoniot speed of the phase boundary connecting u^l to u^r is the slope of the segment joining $(\rho^l, \rho^l v^l)$ to $(\rho^r, \rho^r v^r)$. This shows that also, in the case of phase boundaries, any 1-wave reaching u_m is slower than any 2-wave exiting from w^m.

Note that the fastest wave in the solution to (2.3), (3.2) has maximal speed bounded above by the characteristic speed of the state on the right, i.e., by the traffic speed, which shows (1).

Finally, (4) follows immediately from the above construction—for example, from the presence of 3 waves in the solutions to some Riemann problems; see Figure 3.3. ∎

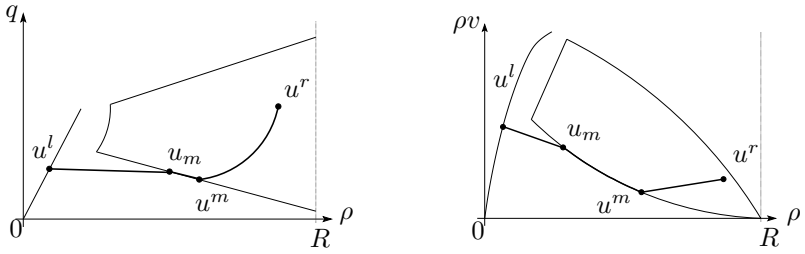

FIG. 3.3. *The solution to a sample Riemann problem.*

4. Qualitative properties of the solutions. In [21] a traffic light at $x = 0$ that turns red is simulated through the restriction to the quadrant $t \geq 0$, $x \leq 0$ of the solution to the Riemann problem for (2.1) with initial data

$$\rho(0,x) = \begin{cases} \rho_i & \text{if } x < 0, \\ R & \text{if } x > 0. \end{cases}$$

The solution is a shock with negative propagation speed. The location of this shock is the end of the queue of cars; each driver, as soon as he reaches it, brakes and immediately stops the car. See Figure 4.1, left.

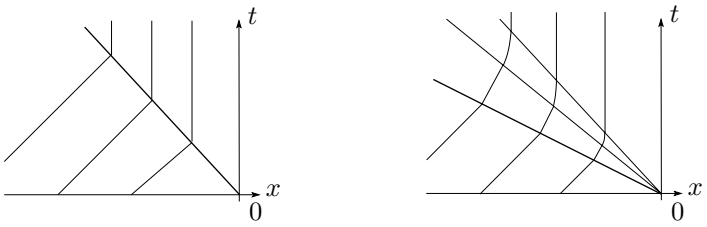

FIG. 4.1. *Car paths when the traffic light turns red.*

We now follow the same scheme but in the framework of (2.3). Assume $Q_1 < q_*$ and assign the initial data

$$(\rho, q)(0,x) = \begin{cases} (\rho_i, q_i) & \text{if } x < 0, \\ (R, q) & \text{if } x > 0, \end{cases}$$

with $(\rho_i, q_i) \in \Omega_f$ and $q \in [Q_1, Q_2]$. Computations based on the solution to Riemann problems defined above show that there exist two threshold parameters ρ_i^- and ρ_i^+ such that

- if $\rho_i \leq \rho_i^-$ or $\rho_i \geq \rho_i^+$, the same behavior as in (2.1) is obtained (see Figure 4.1, left);
- if $\rho_i^- < \rho_i < \rho_i^+$, the solution consists of a phase transition followed by a rarefaction possibly attached to it (see Figure 4.1, right).

Reasonably enough, the LWR description of drivers braking suddenly to zero speed works when there are either many slow cars or few fast cars. In the middle situation, drivers brake and the traffic flow enters the congested region. Here, the car speed continues to diminish, but smoothly.

It is remarkable to note that the description above holds *independently* from the value of $q \in [Q_1, Q_2]$ assigned to the state on the right.

In the case of the traffic light turning green, the present model gives a description similar to that provided by the LWR model.

In Kerner's paper [15] there is a further distinction within the congested phase, namely "synchronized traffic flow" and "wide moving traffic jams." However, he also claims, "On the flow density plane measured points related to fronts of wide moving jams usually cannot be separated from points related to synchronized traffic flow" [15, p. 265]. Usually, in the hyperbolic phase transition models common in continuum dynamics, the term *phase* characterizes suitable subsets of the space where the conserved quantities (or equivalent coordinates) may vary, with *different* phases corresponding to *disjoint* sets.

On the other hand, the observations by Kerner do show the existence of two qualitatively deeply distinct behaviors. This distinction is present also in (2.3): it corresponds to the distinction between waves of the first and second families.

More precisely, "homogeneous-in-speed-states" [15, p. 260], i.e., a type of synchronized flow, are described by states separated by a 2-contact discontinuity in the congested phase. In fact, recall that the traffic speed does not change across a 2-contact discontinuity; see (3.1).

Furthermore, the solid line J shown in Figure 4.2, left, which represents in [15] the "wide moving traffic jam," is here replaced by the 1-Lax curves near the line $q = q_*$, shown in Figure 4.2, right. In fact, along $q = q_*$ we have $\nabla\lambda_1 \cdot r_1 \equiv 0$ (see (3.1)), and the first characteristic family is linearly degenerate. Hence, near to that line, where $\nabla\lambda_1 \cdot r_1$ is small, a sharp increase in the density may persist for a long time.

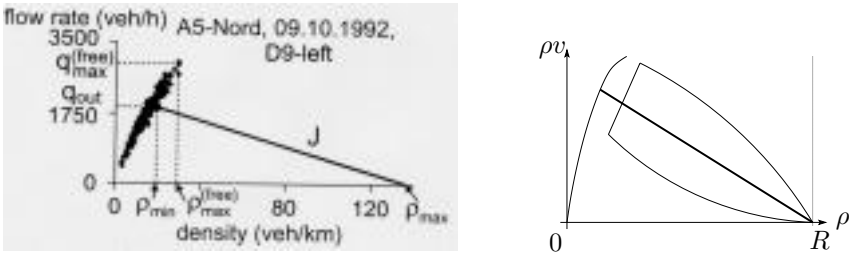

FIG. 4.2. *The transition from free to wide jam. Left, measured data from* [15] *(used with permission) and, right, the line where* $\nabla\lambda_1 \cdot r_1 = 0$ *in the model described here.*

Finally, let us remark that the present model (2.3) describes how a congested zone disappears into a free one due to the interaction of two phase boundaries. This may happen only if behind the congested zone the density is very low, i.e., $\rho^l < \check{R}_f$; see Figure 4.3. Analogously, an interaction between two phase boundaries where $\rho > \check{R}_f$ may lead to a free zone disappearing.

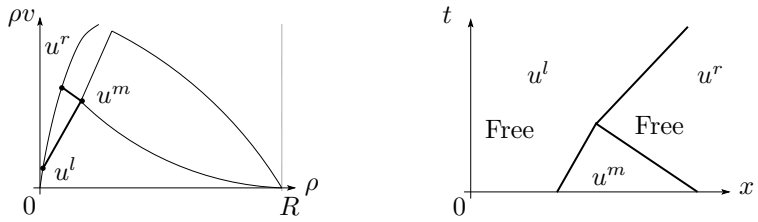

FIG. 4.3. *An interaction between phase boundaries.*

5. The Cauchy problem. Consider the set $\mathcal{U}$ of $\mathbf{BV} \cap \mathbf{L^1}$ functions $u \colon \mathbf{R} \mapsto \Omega_f \cup \Omega_c$ such that there exists a partition of $\mathbf{R}$ into a finite number of disjoint intervals $I_1, \dots, I_n$, with $u(I_i) \subseteq \Omega_f$ and $u(I_{i+1}) \subseteq \Omega_c$ for all i. The more general case in which $(u - u_{-\infty}) \in \mathbf{L^1}$ and $(u - u_{+\infty}) \in \mathbf{L^1}$ for some fixed states $u_{-\infty}$, $u_{+\infty}$ is a straightforward extension involving only formal complications.

Given a function $u \in \mathcal{U}$, we say that there is a *change of phase* at all points $\xi \in \mathbf{R}$ where $u(\xi-)$ and $u(\xi+)$ belong to different phases.

Let $u_o \in \mathcal{U}$. Generalizing the corresponding definition in [6], we call an *admissible solution* of the Cauchy problem for (2.3) on the time interval $[0, T]$, with $0 < T \leq +\infty$, any function $u \colon [0, T] \mapsto \mathcal{U}$ such that

1. u is continuous with respect to the $\mathbf{L^1}$-norm;
2. for all test functions $\phi \in \mathbf{C^1}(\mathbf{R} \mapsto \mathbf{R})$ with compact support contained in $u^{-1}(\Omega_f)$

$$\int_0^T \int_{\mathbf{R}} \left(\rho \cdot \partial_t \phi + \rho \cdot v_f(\rho) \cdot \partial_x \phi \right) \, dx \, dt + \int_{\mathbf{R}} \rho_o(x) \cdot \phi(0, x) \, dx = 0;$$

3. for all test functions $\phi \in \mathbf{C^1}(\mathbf{R} \mapsto \mathbf{R}^2)$ with compact support contained in $u^{-1}(\Omega_c)$

$$\int_0^T \int_{\mathbf{R}} \left(\begin{bmatrix} \rho \\ q \end{bmatrix} \partial_t \phi + \begin{bmatrix} \rho \cdot v_c(\rho, q) \\ (q - q_*) \cdot v_c(\rho, q) \end{bmatrix} \partial_x \phi \right) dx \, dt + \int_{\mathbf{R}} \begin{bmatrix} \rho_o(x) \\ q_o(x) \end{bmatrix} \phi(0, x) \, dx = 0;$$

4. the set of points at which there is a change of phase is the union of a finite number of Lipschitz curves $p_i \colon [0, T] \mapsto \mathbf{R}$ such that if $p_i(\tau) = p_j(\tau)$, then $p_i(t) = p_j(t)$ for all $t \in [\tau, T]$;
5. at all points $(\bar t, \bar x)$ where there is a change of phase, i.e., $\bar x = p_i(\bar t)$, let $\Lambda = \dot p_i(t+)$ and introduce the left and right flows at $(\bar t, \bar x)$ as

$$F^l = \begin{cases} \rho(\bar t, \bar x-) \cdot v_f(\rho(\bar t, \bar x-)) & \text{if } \rho(\bar t, \bar x-) \in \Omega_f, \\ \rho(\bar t, \bar x-) \cdot v_c(\rho(\bar t, \bar x-), q(\bar t, \bar x-)) & \text{if } \rho(\bar t, \bar x-) \in \Omega_c, \end{cases}$$

$$F^r = \begin{cases} \rho(\bar t, \bar x+) \cdot v_f(\rho(\bar t, \bar x+)) & \text{if } \rho(\bar t, \bar x+) \in \Omega_f, \\ \rho(\bar t, \bar x-) \cdot v_c(\rho(\bar t, \bar x+), q(\bar t, \bar x+)) & \text{if } \rho(\bar t, \bar x+) \in \Omega_c. \end{cases}$$

We require that

$$\Lambda \cdot (\rho(\bar t, \bar x+) - \rho(\bar t, \bar x-)) = F^r - F^l.$$

We prove below that (2.3) admits a solution for all initial data in $\mathbf{BV}$.

THEOREM 5.1. *For all $u_o \in \mathbf{BV}$, the problem* (2.3) *admits a solution $u \colon [0, +\infty[\times \mathbf{R} \mapsto \Omega_f \cup \Omega_c$ such that $u(0, x) = u_o(x)$.*

The proof follows the currently standard wave-front tracking machinery already used in various works; see [4, 7] and the references in [6]. We briefly recall below the general construction, underlining only those details specific to the present construction.

For all $u_o \in \Omega_f \cup \Omega_c$, let $\Psi_i(u_o, \sigma)$ denote the point u on the generalized i-curve exiting u_o as defined in section 3 such that the wave from u_o to u has size $\sigma = \Sigma_i(u, u_o)$.

Fix a large $n \in \mathbf{N}$ and introduce the mesh sizes

$$\delta_1^n = \frac{1}{2^n} \cdot \hat{V}_c, \qquad \delta_2^n = \frac{1}{2^n} \cdot \frac{Q_2 - Q_1}{R}, \qquad \bar{\delta}_2^n = \frac{1}{2^n} \cdot \left(v_f(0) - \check{w}_2\right).$$

Let

$$\begin{aligned}
\Omega_f^n &= \left\{u \in \Omega_f \colon w_1 = V \text{ and } w_2 = W_1 + k\delta_2^n \text{ or } w_2 = v_f(\check{\rho}) + k\bar{\delta}_2^n \,;\, k \in \mathbf{N}\right\},\\
\Omega_c^n &= \left\{u \in \Omega_f \colon w_1 = h\delta_1^n \text{ and } w_2 = W_1 + k\delta_2^n \,;\, h, k \in \mathbf{N}\right\},\\
\Omega^n &= \Omega_f^n \cup \Omega_c^n.
\end{aligned}$$

Approximate the initial data u_o by means of a piecewise constant initial datum u_o^n attaining values in Ω^n and such that $\|u_o^n - u_o\|_{\mathbf{L^1}} \leq 2^{-n}$. At every point of jump of u_o^n we approximately solve the Riemann problem within the class of piecewise constant functions. To this aim, we define an approximate solver as follows. Shocks, contact discontinuities, and phase boundaries are solved exactly, i.e., they are given the exact Rankine–Hugoniot speed. Centered rarefaction waves are approximated through rarefaction fans. Let $u^l \in \Omega_n$ and $u^r \in \Omega_n$ be connected by a 1-rarefaction, i.e., $u^r = \Psi_1(u^l, k2^{-n})$, with $\lambda_1(u^l) < \lambda_1(u^r)$; then the approximate solution to the Riemann problem with data u^l, u^r is a fan of rarefaction shock attaining values in Ω^n. Differently from the usual wave-front tracking algorithms, to each of these "shocklets" we assign the Rankine–Hugoniot speed $\lambda = \frac{[\rho v]}{[\rho]}$. The approximation of compound waves is obtained by gluing the solutions above. We thus obtain an approximate solution

$$u^n(t) = \sum_\alpha u_\alpha \cdot \chi_{]x_{\alpha-1}(t), x_\alpha(t)]} \quad \text{with} \quad u_{\alpha+1} = \Psi_2(\Psi_1\left(u_\alpha, \sigma_{1,\alpha}\right), \sigma_{2,\alpha}), \tag{5.1}$$

where $u_\alpha \in \Omega^n$, $x_{\alpha-1}(t) < x_\alpha(t)$ for all α and t. $\sigma_{i,\alpha}$ is the size of the i-wave in the solution of the Riemann problem (2.3) with data u_α, $u_{\alpha-1}$.

A global approximate solution is obtained as soon as suitable bounds on the total variation and on the number of discontinuities are provided. To this aim we introduce the following Glimm functional defined on all functions of the type (5.1):

$$\mathcal{V}(u) = \sum_\alpha \sum_{i=1}^{2} \left|\sigma_{i,\alpha}\right|. \tag{5.2}$$

The interaction estimates provided in section 6 lead to the following result.

PROPOSITION 5.2. *Fix $n \in \mathbf{N}$. Then for all piecewise constant initial data u_o attaining values in Ω_n such that $\mathrm{TV}(u_o) < +\infty$ there exists an approximate solution $u^n \colon [0, +\infty[\times \mathbf{R} \mapsto \Omega_n$ with the following properties:*

(1) *the function $t \mapsto \mathcal{V}(u^n(t))$ is nonincreasing;*

(2) *any strip of the form $[0, T] \times \mathbf{R}$ contains finitely many interaction points.*

The proof follows from Lemmas 6.1 and 6.2 below.

A standard [5, 6, 7, 10] limiting procedure based on Helly's compactness theorem leads to the existence of a global weak solution to (2.3).

6. Technical details. We collect here technical results useful in the preceding sections.

LEMMA 6.1. *Assume that the approximate solution u^n is defined up to time T. Then the map $t \mapsto \mathcal{V}(u^n(t))$ is nonincreasing on the interval $[0, T]$.*

Proof. Assume that only two waves interact. Consider the following cases:

1. The interacting waves σ', σ'' both belong to the second family. Then there is a single outgoing wave σ^+, and $\sigma^+ = \sigma' + \sigma''$.
2. The interacting waves σ', σ'' both belong to the first family, and no 2-wave exits the interaction. Then, again, the resulting 1-wave satisfies $\sigma^+ = \sigma' + \sigma''$.
3. The interacting waves σ', σ'' both belong to the first family, and the resulting wave σ^+ is a 2-wave. Then the choice (3.5) again implies that $\sigma^+ = \sigma' + \sigma''$.
4. The interacting waves σ_1^- and σ_2^- belong to different families. Then the resulting waves σ_1^+, σ_2^+ satisfy $\sigma_i^+ = \sigma_i^-$.

In all the cases above, $\mathcal{V}$ does not increase at the interaction time.

The general case of an interaction in which several waves take part follows by standard arguments. □

The presence of the line $q = q_*$, where $\nabla\lambda_1 \cdot r_1$ vanishes, makes the control of the number of discontinuities more delicate. Indeed, the interaction of two waves, a 1-contact discontinuity, and a 2-shock may produce a new 1-contact and $\mathcal{O}(2^n)$ rarefaction wavelets of the first family.

LEMMA 6.2. *Given an approximate solution defined up to time T, any strip of the form $[0,T] \times \mathbf{R}$ contains finitely many interaction points.*

Proof. The proof follows from Lemma 6.1, since the number of waves in u^n at time t is bounded by $\mathcal{O}(1) \cdot 2^n \cdot \mathcal{V}(u^n(t))$. □

Remark 1. In the case $Q_1 \geq q_*$, the solution to the Riemann problem (2.3), (3.2) is simpler. In fact, all the phase transitions along the lower border of Ω_c behave like shocks if $Q_1 > q_*$, and like contact discontinuities if $Q_1 = q_*$. Furthermore, the number of discontinuities may not increase at any interaction.

Remark 2. Allowing $\hat{V}_f = \hat{V}_c$ leads to the non–well-posedness of the Riemann problem. Let the left state be $\check{u}_c$ and the right state be $\hat{u}_f = \hat{u}_c$; see Figure 2.1. Then, a first solution to (2.3), (3.2) consists of a single Lax 2-wave in the congested phase. Another solution consists of a phase transition from $\check{u}_c$ to $\check{u}_f$ followed by a Lax 2-wave in the free phase.

THIN FILM TRAVELING WAVES AND THE NAVIER SLIP CONDITION*

ROBERT BUCKINGHAM†, MICHAEL SHEARER‡, AND ANDREA BERTOZZI§

Abstract. We consider the lubrication model for a thin film driven by competing gravitational forces and thermal gradients on an inclined plane. We are interested in the general traveling wave problem when the Navier slip boundary condition is used. We contrast (1) gravity dominated flow, (2) Marangoni dominated flow, and (3) flow in which the two driving effects balance. For a "singular slip" model we show that when Marangoni forces are present the resulting traveling wave ODE reduces locally near the contact line to a case not considered previously in the literature. We compute an asymptotic expansion of the solution near the contact line and compare with numerical simulations of the full problem. Using numerical simulations and phase space analysis involving Poincaré sections, we show that for all three problems there is a finite range of admissible contact angles for which traveling wave solutions exist. Even in the well-studied case (1), this is a new observation that has ramifications for the use of constitutive laws at the contact line in the case of singular slip. For case (3) multiple traveling wave solutions are observed with the same contact angle.

Key words. thin liquid films, contact lines, traveling waves, nonlinear partial differential equations

Introduction. Dynamic contact lines occur at the leading edge of a layer of fluid coating a dry solid surface. Understanding how contact lines move has been the subject of intense interest for several decades. In particular, it was shown by Dussan and Davis [13] that motion necessarily implies a singularity of stress at the contact line if the usual no-slip boundary condition is imposed between the fluid and the solid surface. Two approaches to removing this singularity emerged early on, namely (i) the precursor layer model and (ii) the Navier slip condition.

In 1964, Bascom, Cottington, and Singleterry [1] reported experimental observations of contact lines for thin liquid films. A very thin film was observed spreading ahead of the thicker film, beyond the apparent location of the contact line. Based on these and similar observations, one reasonable model is to assume that there is a very thin layer of fluid ahead of the contact line. The contact line itself is then replaced by a rapid transition from the thicker layer to the very thin layer. This is the basis for the so-called *precursor model* studied in various contexts over a number of years. While this is an attractive and tractable way to remove the singularity associated with the film thickness going all the way to zero, modeling the very thin precursor layer using hydrodynamics can be questionable since its thickness is only a
