ASYMPTOTIC SHAPE OF THE ERLANG CAPACITY REGION OF A CRITICALLY LOADED MULTISERVICE SHARED RESOURCE*

JOHN A. MORRISON†

Abstract. We consider a loss model of an unbuffered resource having C channels, which are shared by several different types of service connections. Connections of each type arrive in a Poisson stream and request a number of channels, which depends on the type. An arriving connection is blocked and lost if there are not enough free channels. Otherwise, the channels are held for the duration of the connection, and the holding period is generally distributed. It is assumed that C and the traffic intensities are proportionately large, and that the resource is critically loaded. The admission control problem is considered for specified upper bounds on the blocking probabilities, and the boundary of the admissible set is investigated asymptotically. It is shown that the boundary of the admissible set is not convex, although only very slightly so. This completes the investigation of a critically loaded resource, initiated in [J. A. Morrison and D. Mitra, *SIAM J. Appl. Math.*, to appear], which also investigated overloaded and underloaded resources.

1. Introduction.

We consider an unbuffered resource having C channels, which are shared by J different types of connections. Connections of type j arrive in a Poisson stream with mean rate λ_j, and they require d_j channels. An arriving connection is blocked and lost if there are fewer than d_j free channels. Otherwise, d_j channels are held for the duration of the connection, and the holding period is generally distributed with mean $1/\mu_j$ and is independent of earlier arrival and holding times. The traffic intensity of type j connections is $\rho_j = \lambda_j/\mu_j$, and the product form and the insensitivity property hold [3], [4], [6]; i.e., the joint stationary distribution of the number of active connections of each type depends on the distributions only through ρ_i, $i = 1, \ldots, J$. The blocking probabilities L_j for type j connections satisfy $L_j > 0$ for $\rho_j > 0$ and, assuming that $C \geq \max_i d_i$, $L_j \to 0+$ only if $\rho_i \to 0+$, $i = 1, \ldots, J$. The admissible set in $\mathbb{R}^J$ contains all combinations of ρ_j, $j = 1, \ldots, J$, such that the blocking probability for each connection type satisfies specified bounds, i.e., $L_j \leq \ell_j$, $j = 1, \ldots, J$, where ℓ_j is a prescribed function of C.

Characterization of the admissible set is extremely useful, not only for connection-level admission control, which is the context in which this topic has typically been considered in the past, but also for higher level objectives, such as network economics and network design and operations. The asymptotic view of the admissible set is particularly appropriate for the latter, where the fine details are not as important as the qualitative properties of the shape of the set and tractability of the numerical calculations for large systems.

Special importance is attached to admissible regions with linear boundaries; the solution space is determined by its vertices, which are relatively easy to compute. Optimizations within such spaces are also much easier computationally. Network economics applications are given in [5]. In one such example, the objective function is the

†Bell Laboratories, Lucent Technologies, 600 Mountain Avenue, Murray Hill, NJ 07974 (johnmorrison@lucent.com).

profit of a service provider giving several quality of service (QoS) levels at prices that are the solution to the corresponding optimization problem. The admissible region of solutions is defined by a collection of inequalities imposed by available capacity, one for each QoS level. For further details see [5], and for other such applications see [2], [7], [17], and references therein. See [1], [10] for applications to routing and control. For recent work on loss models of optical networking see [15] and [16].

Convexity is also important, since the tangent hyperplane at points on the boundary of the admissible set intersects the positive axes. Hence, if the boundary of the admissible set is convex, then the region in the positive orthant bounded by the tangent hyperplane at a point on the boundary is admissible and may be used in an approximate optimization.

Mitra and Morrison [9] considered our model here (as well as the finite-sources version), and they investigated the case where C and the traffic intensities $\rho_j = \alpha_j C$, $j = 1, \ldots, J$, are proportionately large, so that $\alpha_j = O(1)$ is bounded away from zero. They derived uniform asymptotic approximations to the blocking probabilities L_j, $j = 1, \ldots, J$, for type j connections. The results for Poisson arrivals are obtained from the finite-sources version as a limiting case. They presented numerical results for $J = 2$ and $J = 3$ types for the finite-sources model. These results constitute a numerical procedure but do not provide a characterization of the admissible set, nor do they resolve specific questions on the linearity and convexity of the boundary.

Consequently, Morrison and Mitra [12] investigated the boundary of the admissible set in the case of Poisson arrivals. The uniform asymptotic approximations to the blocking probabilities are specialized [9] to three regimes in which their behavior is markedly different, namely, the overloaded, the critically loaded, and the underloaded regimes, corresponding to $\sum_{j=1}^{J} d_j \alpha_j > 1$, $\sum_{j=1}^{J} d_j \alpha_j - 1 = O(1/\sqrt{C})$, and $\sum_{j=1}^{J} d_j \alpha_j < 1$, respectively. The corresponding blocking probabilities L_j are $O(1)$, $O(1/\sqrt{C})$, and exponentially small in C, respectively, so that the critically loaded regime is of greatest interest. In [12], the shape of the admissible set is investigated separately for each of the three regimes.

In the asymptotic limit $C \to \infty$, with $\rho_j = \alpha_j C$, $j = 1, \ldots, J$, the boundary of the admissible set lies in a hyperplane if the resource is critically loaded or overloaded. If the resource is underloaded, the boundary of the admissible set, in the limit $C \to \infty$, is convex, but not strictly so, except when $J = 2$.

Refined results, which pertain to $C \gg 1$, are derived in [12]. The correction terms are $O(1/C)$ if the resource is overloaded or underloaded and $O(1/\sqrt{C})$ if the resource is critically loaded. In general, the boundary of the admissible set is not convex. If $J = 2$, then the boundary is slightly convex if the resource is critically loaded, but slightly concave if the resource is overloaded. For $J = 2$, the convexity is maintained from the $C \to \infty$ limit for an underloaded resource. Unfortunately, for $J \geq 3$, the boundary of the admissible set is *not* convex, although only slightly so, whether the resource is overloaded or underloaded. The case of a critically loaded resource requires further investigation, which is carried out in this paper.

In section 2 we first state the refined result obtained in [12] for the critically loaded regime, which is based on refined asymptotic approximations [13] to the blocking probabilities. This illustrates why a further refinement is required. We then state the further refined result, which is based on the refined uniform asymptotic approximations [14] to the blocking probabilities. The result establishes that the boundary of the admissible set is *not* convex, although only very slightly so. In spite of this negative result, it is important that the practitioner be aware of it. Moreover, since

the boundary is only slightly nonconvex, a slightly smaller admissible region with a convex boundary may be used by the practitioner.

In section 3, we derive a refined asymptotic approximation to the boundary of the admissible set, based on the refined uniform asymptotic approximations [14] to the blocking probabilities. In section 4, we express the boundary of the admissible set in appropriate coordinates with respect to the tangent hyperplane at a point on the boundary. In section 5, we show that the discriminant of the quadratic form which arises is negative, and hence that the boundary of the admissible set is *not* convex.

2. Refined results. Throughout the paper, we assume that

$$C \gg 1;\ \rho_j = \alpha_j C, \quad j = 1, \ldots, J, \tag{2.1}$$

where C is an integer and $\alpha_j > 0$ is $O(1)$ and bounded away from zero. We also assume that d_j, $j = 1, \ldots, J$, are distinct positive integers, not large relative to C, and that the greatest common divisor of $d_1, \ldots, d_J$ is 1. The admissible set corresponds to

$$L_j\left(\alpha_1, \ldots, \alpha_J;\ C\right) \le \ell_j, \quad j = 1, \ldots, J, \tag{2.2}$$

where the function L_j gives the blocking probability for type j connections. It is shown [12], in all three regimes, that asymptotically

$$\frac{\partial L_j}{\partial \alpha_k} > 0, \quad j, k = 1, \ldots, J, \tag{2.3}$$

and the boundary of the admissible set is expressed in the form

$$\alpha_J = \alpha_J(\boldsymbol{\alpha}; C), \quad \boldsymbol{\alpha} = \left(\alpha_1, \ldots, \alpha_{J-1}\right). \tag{2.4}$$

If

$$\sqrt{C} \min_j \ell_j = O\left(1\right) \tag{2.5}$$

is bounded below by a positive constant, then on the boundary of the admissible set the resource is critically loaded. The boundary satisfies

$$\sum_{j=1}^{J} d_j \alpha_j = 1 + O\left(1/\sqrt{C}\right), \tag{2.6}$$

which in the asymptotic limit $C \to \infty$ lies in a hyperplane.

We have the following refined approximation [12] to the boundary of the admissible set.

PROPOSITION 2.1. *If* (2.5) *holds, then*

(i) *if* $J = 2$, *then* $0 > d\alpha_2/d\alpha_1 = O(1)$ *and* $0 < d^2\alpha_2/d\alpha_1^2 = O(1/\sqrt{C})$, *so that the boundary of the admissible set is convex, although only slightly so;*

(ii) *we consider the case when*

$$\frac{d_J}{\sqrt{C}\,\ell_J} - \frac{d_i}{\sqrt{C}\,\ell_i} \gg \frac{1}{\sqrt{C}}, \quad i = 1, \ldots, J-1. \tag{2.7}$$

With this assumption the boundary of the admissible set is given by $L_J = l_J$. *Let* $(\boldsymbol{\alpha}^{(0)}, \alpha_J^{(0)})$, *where corresponding to* (2.4) $\alpha_J^{(0)} = \alpha_J(\boldsymbol{\alpha}^{(0)}; C)$, *be a point on the boundary of the admissible set. If* $J \ge 3$, *the linear transformation of variables*

$$\zeta_J = d_J \left[\alpha_J - \alpha_J^{(0)} - \sum_{i=1}^{J-1} \frac{\partial \alpha_J}{\partial \alpha_i}\left(\boldsymbol{\alpha}^{(0)}\right)\left(\alpha_i - \alpha_i^{(0)}\right)\right], \tag{2.8}$$

$$\zeta_{J-1} = \sum_{i=1}^{J-1} d_i(d_i - d_J)\left(\alpha_i - \alpha_i^{(0)}\right), \tag{2.9}$$

$$\zeta_{J-2} = \sum_{i=1}^{J-1} d_i\left(d_i^2 - d_J^2\right)\left(\alpha_i - \alpha_i^{(0)}\right), \tag{2.10}$$

and

$$\zeta_i = \alpha_i - \alpha_i^{(0)}, \quad i = 1, \ldots, J-3 \ (J \geq 4), \tag{2.11}$$

is nonsingular, and $\zeta_J = 0$ *corresponds to the tangent hyperplane to the boundary of the admissible set at* $\boldsymbol{\alpha} = \boldsymbol{\alpha}^{(0)}$. *From* (2.6) *and* (2.8) *we have*

$$\zeta_J = \sum_{j=1}^{J} d_j\left(\alpha_j - \alpha_j^{(0)}\right) + O\left(\frac{1}{\sqrt{C}}\right). \tag{2.12}$$

Let

$$\sigma_0^2 = 2\sum_{j=1}^{J} d_j^2 \alpha_j^{(0)}, \quad \sigma_0 > 0\,. \tag{2.13}$$

If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, *then*

$$\begin{aligned}\zeta_J = {} & \frac{\zeta_{J-1}^2}{2\sqrt{C}}\left[P_2(\sigma_0) + O\left(\frac{1}{\sqrt{C}}\right) + O\left(\zeta_{J-1}\right)\right] \\ & + \frac{\zeta_{J-1}\zeta_{J-2}}{C}\left[R_2(\sigma_0) + O(\zeta_{J-1})\right] + O\left(\frac{\epsilon^2}{C\sqrt{C}}\right)\end{aligned} \tag{2.14}$$

and $P_2(\sigma_0) > 0$. □

If $\zeta_{J-1} = O(\epsilon/\sqrt{C})$, then the leading terms in (2.14) are all $O(\epsilon^2/C\sqrt{C})$. Hence, the next order term in the asymptotic expansion in powers of $1/\sqrt{C}$ is needed to investigate whether or not the boundary of the admissible set is convex. In this paper we establish the following.

PROPOSITION 2.2. *Assume that* (2.5) *and* (2.7) *hold. If in* (2.9)

$$\zeta_{J-1} = Z_{J-1}/\sqrt{C}, \tag{2.15}$$

where $Z_{J-1} = O(1)$, *then*

$$\zeta_J = \frac{1}{2C^{3/2}}\left[P_2(\sigma_0)Z_{J-1}^2 + 2R_2(\sigma_0)Z_{J-1}\zeta_{J-2} + T_2(\sigma_0)\zeta_{J-2}^2\right] + O\left(\frac{1}{C^2}\right). \tag{2.16}$$

Moreover, the discriminant of the quadratic form in (2.16) *is negative. Hence, asymptotically, the boundary of the admissible set is* not *convex, although only very slightly so.* □

We note that in this result we do not need $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$.

3. Boundary of the admissible set. To derive the appropriate refinement of (2.14), we make use of the refined uniform asymptotic approximations [14] to the blocking probabilities, which we now summarize. Let

$$f(z) = \sum_{j=1}^{J} \alpha_j (z^{d_j} - 1) - \log z, \tag{3.1}$$

and let z^* be the unique positive solution of $f'(z) = 0$, so that

$$\sum_{j=1}^{J} \alpha_j d_j (z^*)^{d_j} = 1, \qquad z^* > 0. \tag{3.2}$$

Since $f'(z^*) = 0$,

$$v \triangleq (z^*)^2 f''(z^*) = \sum_{j=1}^{J} \alpha_j d_j^2 (z^*)^{d_j}, \tag{3.3}$$

$$\tau \triangleq (z^*)^3 f^{(3)}(z^*) = \sum_{j=1}^{J} \alpha_j d_j^2 (d_j - 3)(z^*)^{d_j}, \tag{3.4}$$

and

$$y \triangleq (z^*)^4 f^{(4)}(z^*) = \sum_{j=1}^{J} \alpha_j d_j^2 (d_j^2 - 6d_j + 11)(z^*)^{d_j}. \tag{3.5}$$

Next, let

$$K = \frac{1}{(1 - z^*)} - \frac{\sqrt{v}\ \mathrm{sgn}(1 - z^*)}{\sqrt{-2f(z^*)}}, \quad z^* \neq 1, \tag{3.6}$$

$$h_j(z) = \frac{(z^{d_j} - 1)}{z(z - 1)}, \quad z \neq 1, \quad h_j(1) = d_j, \tag{3.7}$$

and

$$N_j = \frac{z^*}{8v} \left(\frac{y}{v} - \frac{5\tau^2}{3v^2} \right) h_j(z^*) + \frac{\tau (z^*)^2}{2v^2} h_j'(z^*) - \frac{(z^*)^3}{2v} h_j''(z^*). \tag{3.8}$$

Since $f(1) = 0$, $f'(z^*) = 0$, and $(z^*)^2 f''(z^*) = v$, the expression for K in (3.6) remains finite as $z^* \to 1$. We define

$$\Omega = \sqrt{\frac{\pi v}{2}} e^{-Cf(z^*)}\ \mathrm{Erfc}\ \left[\mathrm{sgn}(1 - z^*) \sqrt{-Cf(z^*)} \right], \tag{3.9}$$

where the complementary error function is given by

$$\mathrm{Erfc}\,(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-\xi^2} d\xi. \tag{3.10}$$

Then [14], the blocking probabilities are asymptotically given by

$$L_j = \frac{[z^* h_j(z^*) + N_j/C + O(1/C^2)]}{[\Omega\sqrt{C} + K + O(1/C)]}. \tag{3.11}$$

We consider the case where

$$\frac{d_J}{\sqrt{C}\ell_J} - \frac{d_i}{\sqrt{C}\ell_i} \gg \frac{1}{\sqrt{C}}, \quad i = 1, \ldots, J-1, \tag{3.12}$$

and let

$$\kappa = \frac{d_J}{\sqrt{C}\ell_J}. \tag{3.13}$$

We assume that (2.5) holds, so that $\kappa = O(1)$. Since $z^* - 1 = O(1/\sqrt{C})$ in the critically loaded regime, L_j is asymptotically proportional to d_j, to lowest order, and [12] the boundary of the admissible set is given by $L_J = \ell_J$. Hence, from (3.11) and (3.13),

$$\Omega = \frac{\kappa}{d_J}\left[z^* h_J(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}} + O\left(\frac{1}{C^{3/2}}\right). \tag{3.14}$$

We define

$$\phi(w) = \frac{\sqrt{\pi}}{2} e^{w^2}\ \mathrm{Erfc}\,(-w)\ . \tag{3.15}$$

Then, from (3.9) and (3.14),

$$\phi\left[\mathrm{sgn}(z^* - 1)\sqrt{-Cf(z^*)}\right] = \frac{1}{\sqrt{2v}}\left\{\frac{\kappa}{d_J}\left[z^* h_j(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}} + O\left(\frac{1}{C^{3/2}}\right)\right\}. \tag{3.16}$$

But, from (3.10) and (3.15),

$$\phi(w) = e^{w^2}\int_{-w}^{\infty} e^{-\xi^2} d\xi = \int_0^{\infty} e^{2wu} e^{-u^2} du\,. \tag{3.17}$$

Hence $\phi'(w) > 0$, $-\infty < w < \infty$, so that $\phi(w)$ has a unique inverse

$$w(y) = \phi^{-1}(y), \quad y > 0. \tag{3.18}$$

It follows from (3.16) that

$$\mathrm{sgn}(z^* - 1)\sqrt{-Cf(z^*)} = w\left[\frac{1}{\sqrt{2v}}\left\{\frac{\kappa}{d_J}\left[z^* h_J(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}} + O\left(\frac{1}{C^{3/2}}\right)\right\}\right]. \tag{3.19}$$

We let

$$1 - \sum_{j=1}^{J} \alpha_j d_j = \frac{\delta}{\sqrt{C}}, \tag{3.20}$$

where $\delta = O(1)$ from (2.6), and we define

$$\sigma^2 = 2\sum_{j=1}^{J} \alpha_j d_j^2, \qquad \sigma > 0, \tag{3.21}$$

and

$$\eta = \sum_{j=1}^{J} \alpha_j d_j^3, \qquad \rho = \sum_{j=1}^{J} \alpha_j d_j^4. \tag{3.22}$$

It is shown in Appendix A that

$$\operatorname{sgn}(z^*-1)\sqrt{-Cf(z^*)} = \frac{\delta}{\sigma} - \frac{2\delta^2\eta}{3\sigma^5\sqrt{C}} + \frac{\delta^3}{9\sigma^9 C}(16\eta^2 - 3\sigma^2\rho) + O\left(\frac{1}{C^{3/2}}\right), \tag{3.23}$$

and

$$\begin{aligned}
&\frac{1}{\sqrt{2v}}\left\{\frac{\kappa}{d_J}\left[z^* h_J(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}}\right\} \\
&= \frac{\kappa}{\sigma} + \frac{\kappa\delta}{\sigma^5\sqrt{C}}[(d_J-1)\sigma^2 - 2\eta] - \frac{1}{6\sigma^3\sqrt{C}}(2\eta + 3\sigma^2) \\
&\quad + \frac{\kappa\delta^2}{\sigma^9 C}\left[\frac{1}{3}(d_J-1)(2d_J-1)\sigma^4 - 4(d_J-1)\sigma^2\eta + 2(5\eta^2 - \sigma^2\rho)\right] \\
&\quad + \frac{\kappa}{\sigma^7 C}\left(\frac{1}{2}\sigma^2\rho + 2\sigma^2\eta - \sigma^4 - \frac{5}{3}\eta^2\right) \\
&\quad + \frac{\kappa h_J'(1)}{d_J\sigma^5 C}(2\eta - 3\sigma^2) - \frac{\kappa h_J''(1)}{d_J\sigma^3 C} \\
&\quad + \frac{\delta}{6\sigma^7 C}(\sigma^4 - 3\sigma^2\rho + 6\sigma^2\eta + 10\eta^2) + O\left(\frac{1}{C^{3/2}}\right).
\end{aligned} \tag{3.24}$$

The boundary of the admissible set is asymptotically given in terms of $\alpha_1, \ldots, \alpha_J$ by substituting (3.23) and (3.24) into (3.19) and using (3.20)–(3.22).

4. Behavior of the boundary. We now scale by $\zeta_{J-1} = Z_{J-1}/\sqrt{C}$, where $Z_{J-1} = O(1)$. The goal is to express the boundary of the admissible set in the form (2.4). From (2.9) and (2.15) we have

$$\sum_{i=1}^{J-1} d_i(d_i - d_J)(\alpha_i - \alpha_i^{(0)}) = \frac{Z_{J-1}}{\sqrt{C}}\,. \tag{4.1}$$

But, from (2.6),

$$\sum_{j=1}^{J} d_j(\alpha_j - \alpha_j^{(0)}) = O\left(\frac{1}{\sqrt{C}}\right), \tag{4.2}$$

and, from (2.13) and (3.21),

$$\sigma^2 - \sigma_0^2 = 2\sum_{j=1}^{J} d_j^2(\alpha_j - \alpha_j^{(0)}). \tag{4.3}$$

If we use (4.2) to eliminate $\alpha_J - \alpha_J^{(0)}$ to lowest order, it follows from (4.1) that $\sigma^2 - \sigma_0^2 = O(1/\sqrt{C})$, and hence $\sigma = \sigma_0 + O(1/\sqrt{C})$.

From (3.19), (3.23), and (3.24),

$$\delta = \sigma w(\kappa/\sigma) + O\left(\frac{1}{\sqrt{C}}\right). \tag{4.4}$$

Hence,

$$\delta = \delta_0 + O\left(\frac{1}{\sqrt{C}}\right), \quad \delta_0 = \sigma_0 w(\kappa/\sigma_0), \tag{4.5}$$

and, from (3.20),

$$\sum_{j=1}^{J} d_j(\alpha_j - \alpha_j^{(0)}) = O\left(\frac{1}{C}\right). \tag{4.6}$$

If we use (4.6) to eliminate $\alpha_J - \alpha_J^{(0)}$, it follows from (4.1) and (4.3) that

$$\sigma = \sigma_0 + \frac{Z_{J-1}}{\sigma_0\sqrt{C}} + O\left(\frac{1}{C}\right). \tag{4.7}$$

Also, from (2.10) and (3.22), we obtain

$$\eta - \eta_0 = \sum_{j=1}^{J} d_j^3(\alpha_j - \alpha_j^{(0)}) = \zeta_{J-2} + O\left(\frac{1}{C}\right) \tag{4.8}$$

and

$$\rho - \rho_0 = \sum_{j=1}^{J-1} d_j(d_j^3 - d_J^3)(\alpha_j - \alpha_J^{(0)}) + O\left(\frac{1}{\sqrt{C}}\right). \tag{4.9}$$

Now, from (3.19), (3.23), and (3.24),

$$\begin{aligned}\delta = \sigma w\left(\frac{\kappa}{\sigma}\right) + \frac{2\delta^2\eta}{3\sigma^4\sqrt{C}} \\ + \frac{w'(\kappa/\sigma)}{\sqrt{C}}\left[\frac{\kappa\delta}{\sigma^2}\left(d_J - 1 - \frac{2\eta}{\sigma^2}\right) - \left(\frac{1}{2} + \frac{\eta}{3\sigma^2}\right)\right] + O\left(\frac{1}{C}\right).\end{aligned} \tag{4.10}$$

We define

$$\delta_1 = \frac{2\delta_0^2\eta_0}{3\sigma_0^4} + w'\left(\frac{\kappa}{\sigma_0}\right)\left[\frac{\kappa\delta_0}{\sigma_0^2}\left(d_J - 1 - \frac{2\eta_0}{\sigma_0^2}\right) - \left(\frac{1}{2} + \frac{\eta_0}{3\sigma_0^2}\right)\right], \tag{4.11}$$

$$a = \left\{\frac{1}{\sigma}\frac{d}{d\sigma}\left[\sigma w\left(\frac{\kappa}{\sigma}\right)\right]\right\}_{\sigma=\sigma_0} = \frac{1}{\sigma_0}\left[w\left(\frac{\kappa}{\sigma_0}\right) - \frac{\kappa}{\sigma_0}w'\left(\frac{\kappa}{\sigma_0}\right)\right], \tag{4.12}$$

and

$$b = \frac{2\delta_0^2}{3\sigma_0^4} - \frac{1}{\sigma_0^2}w'\left(\frac{\kappa}{\sigma_0}\right)\left(\frac{2\kappa\delta_0}{\sigma_0^2} + \frac{1}{3}\right). \tag{4.13}$$

Then, from (4.5), (4.7), (4.8), and (4.10), we obtain

$$\delta = \delta_0 + \frac{1}{\sqrt{C}}(\delta_1 + aZ_{J-1} + b\zeta_{J-2}) + O\left(\frac{1}{C}\right). \tag{4.14}$$

Next, from (3.20) and (4.14),

$$\sum_{j=1}^{J} d_j(\alpha_j - \alpha_j^{(0)}) = -\frac{1}{C}(aZ_{J-1} + b\zeta_{J-2}) + O\left(\frac{1}{C^{3/2}}\right). \tag{4.15}$$

If we use (4.15) to eliminate $\alpha_J - \alpha_J^{(0)}$, it follows from (4.1) and (4.3) that

$$\frac{1}{2}(\sigma^2 - \sigma_0^2) = \frac{Z_{J-1}}{\sqrt{C}} - \frac{d_J}{C}(aZ_{J-1} + b\zeta_{J-2}) + O\left(\frac{1}{C^{3/2}}\right). \tag{4.16}$$

Hence,

$$\sigma = \sigma_0 + \frac{Z_{J-1}}{\sigma_0\sqrt{C}} - \frac{1}{\sigma_0 C}\left[d_J(aZ_{J-1} + b\zeta_{J-2}) + \frac{Z_{J-1}^2}{2\sigma_0^2}\right] + O\left(\frac{1}{C^{3/2}}\right). \tag{4.17}$$

We are now in a position to obtain a further refinement of the expression for δ, from (3.19), (3.23), and (3.24), with the help of (4.8), (4.9), and (4.17). Some of the details are given in Appendix B. Since we are interested only in the quadratic terms, we do not give the linear terms explicitly. After considerable algebra, it is found that

$$\begin{aligned}
\delta = {} & (\text{linear terms}) - \frac{w(\kappa/\sigma_0)}{2\sigma_0^3 C} Z_{J-1}^2 \\
& + \frac{w''(\kappa/\sigma_0)}{2\sigma_0^5 C}\left[\kappa Z_{J-1} + \left(\frac{2\kappa\delta_0}{\sigma_0^2} + \frac{1}{3}\right)\zeta_{J-2}\right]^2 \\
& + \frac{w'(\kappa/\sigma_0)}{\sigma_0^5 C}\left\{\frac{1}{2}\kappa\sigma_0 Z_{J-1}^2 + 2\sigma_0 Z_{J-1}\zeta_{J-2}\left(\frac{1}{3} - \kappa a + \frac{4\kappa\delta_0}{\sigma_0^2}\right)\right. \\
& \qquad \left. + \zeta_{J-2}^2\left[5\left(\frac{2\kappa\delta_0^2}{\sigma_0^3} - \frac{\kappa}{3\sigma_0} + \frac{\delta}{3\sigma_0}\right) - 2\kappa\sigma_0 b\right]\right\} \\
& + \frac{4\delta_0}{3\sigma_0^4 C}\zeta_{J-2}\left[\left(a - \frac{2\delta_0}{\sigma_0^2}\right)Z_{J-1} + \left(b - \frac{4\delta_0^2}{3\sigma_0^4}\right)\zeta_{J-2}\right] + O\left(\frac{1}{C^{3/2}}\right).
\end{aligned} \tag{4.18}$$

The linear terms include δ_0 in (4.14).

We define

$$P = w\left(\frac{\kappa}{\sigma_0}\right) - \frac{\kappa}{\sigma_0}w'\left(\frac{\kappa}{\sigma_0}\right) - \left(\frac{\kappa}{\sigma_0}\right)^2 w''\left(\frac{\kappa}{\sigma_0}\right), \tag{4.19}$$

$$\begin{aligned}
Q = {} & \frac{4\delta_0}{3\sigma_0}\left(\frac{2\delta_0}{\sigma_0} - \sigma_0 a\right) - \frac{\kappa}{\sigma_0}w''\left(\frac{\kappa}{\sigma_0}\right)\left(\frac{2\kappa\delta_0}{\sigma_0^2} + \frac{1}{3}\right) \\
& - 2w'\left(\frac{\kappa}{\sigma_0}\right)\left(\frac{1}{3} - \kappa a + \frac{4\kappa\delta_0}{\sigma_0^2}\right),
\end{aligned} \tag{4.20}$$

and

$$\begin{aligned}
R = {} & \frac{8\delta_0}{3\sigma_0}\left(\frac{4\delta_0^2}{3\sigma_0^2} - \sigma_0^2 b\right) - w''\left(\frac{\kappa}{\sigma_0}\right)\left(\frac{2\kappa\delta_0}{\sigma_0^2} + \frac{1}{3}\right)^2 \\
& + 2w'\left(\frac{\kappa}{\sigma_0}\right)\left[2\kappa\sigma_0 b - 5\left(\frac{2\kappa\delta_0^2}{\sigma_0^3} - \frac{\kappa}{3\sigma_0} + \frac{\delta_0}{3\sigma_0}\right)\right].
\end{aligned} \tag{4.21}$$

Then, from (2.8) and (3.20), it follows that

$$\zeta_J = \frac{1}{2\sigma_0^5 C^{3/2}}\left(P\sigma_0^2 Z_{J-1}^2 + 2Q\sigma_0 Z_{J-1}\zeta_{J-2} + R\zeta_{J-2}^2\right) + O\left(\frac{1}{C^2}\right). \tag{4.22}$$

If we let

$$P = \sigma_0^3 P_2(\sigma_0), \quad Q = \sigma_0^4 R_2(\sigma_0), \quad R = \sigma_0^5 T_2(\sigma_0), \tag{4.23}$$

then we obtain (2.16). In Appendix C we show that the expressions for $P_2(\sigma_0)$ and $R_2(\sigma_0)$ are consistent with those obtained in [12].

In the next section we consider

$$D = PR - Q^2\,, \tag{4.24}$$

which is proportional to the discriminant of the quadratic form in (4.22).

5. Nonconvexity of the boundary. We first express P, Q, and R as functions of $w(\kappa/\sigma_0)$. From (3.18), we have

$$\phi[w(y)] = y. \tag{5.1}$$

It follows that

$$w' = \frac{1}{\phi'(w)}, \quad w'' = -\frac{\phi''(w)}{[\phi'(w)]^3}\,. \tag{5.2}$$

But, from (4.5), (4.12), and (4.13), with $w = w(\kappa/\sigma_0)$ and the argument w of ϕ suppressed,

$$\frac{\delta_0}{\sigma_0} = w, \quad \sigma_0 a = w - \frac{\phi}{\phi'} \tag{5.3}$$

and

$$\sigma_0^2 b = \frac{2}{3}w^2 - \frac{1}{\phi'}\left(2w\phi + \frac{1}{3}\right). \tag{5.4}$$

Then, from (4.19)–(4.21), we obtain

$$P = w - \frac{\phi}{\phi'} + \frac{\phi^2\phi''}{(\phi')^3}, \tag{5.5}$$

$$Q = \frac{4}{3}w^2 - \frac{2}{3\phi'}(1 + 7w\phi) - 2\left(\frac{\phi}{\phi'}\right)^2 + \frac{\phi\phi''}{(\phi')^3}\left(\frac{1}{3} + 2w\phi\right), \tag{5.6}$$

and

$$\begin{aligned} R = {} & \frac{16}{9}w^3 + \frac{\phi''}{(\phi')^3}\left(\frac{1}{3} + 2w\phi\right)^2 - \frac{4\phi}{(\phi')^2}\left(\frac{1}{3} + 2w\phi\right) \\ & + \frac{2}{\phi'}\left(\frac{5\phi}{3} - \frac{11w}{9} - 6w^2\phi\right). \end{aligned} \tag{5.7}$$

We now consider the behavior of P, Q, and R for $-w \gg 1$. From (3.15) and [8],

$$\phi(w) = -\frac{1}{2w} + \frac{1}{4w^3} - \frac{3}{8w^5} + O\left(\frac{1}{w^7}\right), \quad -w \gg 1. \tag{5.8}$$

Hence,

$$\phi'(w) = \frac{1}{2w^2} - \frac{3}{4w^4} + \frac{15}{8w^6} + O\left(\frac{1}{w^8}\right), \quad -w \gg 1, \tag{5.9}$$

and

$$\phi''(w) = -\frac{1}{w^3} + \frac{3}{w^5} - \frac{45}{4w^7} + O\left(\frac{1}{w^9}\right), \quad -w \gg 1. \tag{5.10}$$

After some straightforward algebra, which we omit, it is found that

$$\begin{aligned} P &= -\frac{2}{w^3} + O\left(\frac{1}{w^5}\right), \quad Q = -2 + O\left(\frac{1}{w^2}\right), \\ R &= -8w + O\left(\frac{1}{w}\right), \quad -w \gg 1. \end{aligned} \tag{5.11}$$

It follows from (4.24) that

$$D = -4 + O\left(\frac{1}{w^2}\right), \quad -w \gg 1. \tag{5.12}$$

Next, we consider the behavior of P, Q, and R for $w \gg 1$. From (3.15) and [8],

$$\phi(w) = \sqrt{\pi} e^{w^2} \left[1 - \frac{1}{2}\,\mathrm{Erfc}\,(w)\right] = \sqrt{\pi} e^{w^2} + O\left(\frac{1}{w}\right), \quad w \gg 1. \tag{5.13}$$

Hence,

$$\phi'(w) = 2\sqrt{\pi} w e^{w^2} + O\left(\frac{1}{w^2}\right), \quad w \gg 1, \tag{5.14}$$

and

$$\phi''(w) = 2\sqrt{\pi}(1 + 2w^2) e^{w^2} + O\left(\frac{1}{w^3}\right), \quad w \gg 1. \tag{5.15}$$

It follows from (5.5)–(5.7) that

$$\begin{aligned} P &= w + O\left(\frac{1}{w^3}\right), \quad Q = \frac{4}{3}(w^2 - 1) + O\left(\frac{1}{w^2}\right), \\ R &= \frac{16}{9} w^3 - 4w + O\left(\frac{1}{w}\right), \quad w \gg 1. \end{aligned} \tag{5.16}$$

Hence, from (4.24), we obtain

$$D = -\frac{4}{9} w^2 + O(1), \quad w \gg 1. \tag{5.17}$$

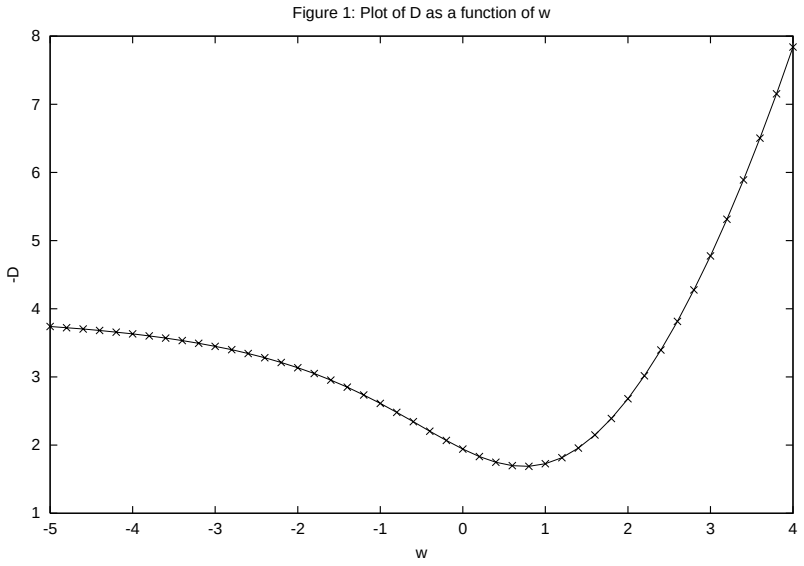

FIG. 1. *Plot of D as a function of w.*

If we differentiate (3.17) with respect to w and integrate by parts, we find that

$$\phi' = 1 + 2w\phi, \quad \phi'' = 2(\phi + w\phi'). \tag{5.18}$$

The quantities ϕ, ϕ', and ϕ'' can be evaluated numerically from (3.15) and (5.18). Then, P, Q, R, and D can be obtained numerically from (5.5)–(5.7) and (4.24). Figure 1 depicts $-D$ as a function of w for $-5 \leq w \leq 4$, and it is seen that $-D > 0$ in that range. Since, from (5.12) and (5.17), $D < 0$ for $-w \gg 1$ and for $w \gg 1$, we conclude that $D < 0$ for $-\infty < w < \infty$. This completes the proof of Proposition 2.2.

We note, as is evident from (5.11) and (5.16), that Q must change sign for some real value of w. If $D < 0$, then (4.24) implies that $PR < 0$ when $Q = 0$. However, we know that $P > 0$ for $-\infty < w < \infty$. Hence, $R < 0$ when $Q = 0$. Figure 2 depicts Q and R for $0 \leq w \leq 2$, and it is seen that $R < 0$ in a range of w which includes the value for which $Q = 0$.

Appendix A. We derive here the expressions in (3.23) and (3.24). If we substitute

$$z^* = 1 + \frac{c_1}{\sqrt{C}} + \frac{c_2}{C} + \frac{c_3}{C\sqrt{C}} + O\left(\frac{1}{C^2}\right) \tag{A.1}$$

in (3.2) and use (3.20)–(3.22), we obtain, after some algebra,

$$c_1 = \frac{2\delta}{\sigma^2}, \quad c_2 = \frac{2\delta^2}{\sigma^6}(\sigma^2 - 2\eta), \quad c_3 = \frac{4\delta^3}{3\sigma^{10}}\left[\sigma^4 - 2\sigma^2(\rho + 3\eta) + 12\eta^2\right]. \tag{A.2}$$

Since $f(1) = 0$ and $f'(z^*) = 0$,

$$\begin{aligned} 0 = f(z^*) + \frac{1}{2}(1 - z^*)^2 f''(z^*) + \frac{1}{6}(1 - z^*)^3 f^{(3)}(z^*) \\ + \frac{1}{24}(1 - z^*)^4 f^{(4)}(z^*) + O[(1 - z^*)^5]. \end{aligned} \tag{A.3}$$

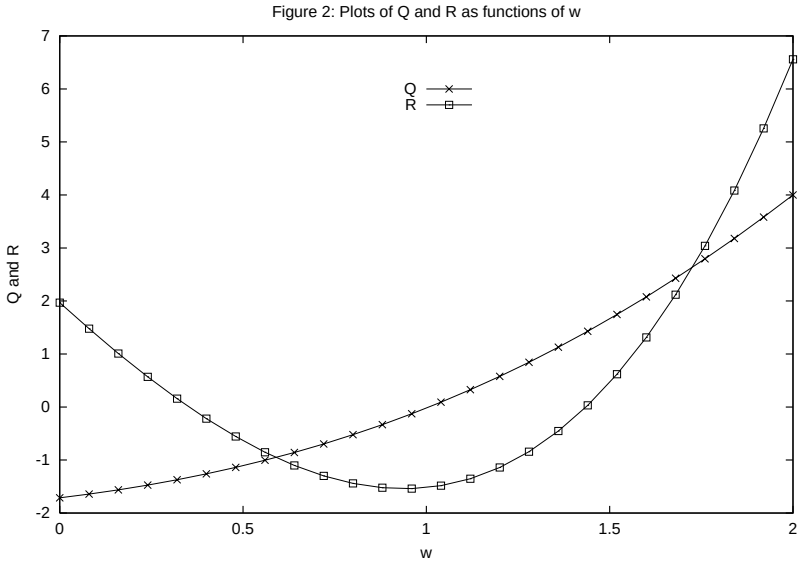

FIG. 2. *Plots of Q and R as functions of w.*

If we expand the expressions for the derivatives of $f(z)$ at $z = z^*$, given by (3.3)–(3.5), in powers of $z^* - 1$ and use (A.1) and (A.2), we obtain, after considerable algebra,

$$-Cf(z^*) = \frac{\delta^2}{\sigma^2}\left[1 - \frac{4\delta\eta}{3\sigma^4\sqrt{C}} + \frac{2\delta^2}{3\sigma^8 C}(6\eta^2 - \sigma^2\rho) + O\left(\frac{1}{C^{3/2}}\right)\right]. \tag{A.4}$$

This result was checked by using the Taylor series expansion of $f(z^*)$ about $z^* = 1$ and calculating the derivatives of $f(z)$ at $z = 1$ from (3.1). It follows from (A.1) and (A.2) that

$$\operatorname{sgn}(z^* - 1) = \operatorname{sgn}\delta. \tag{A.5}$$

Hence, from (A.4), since $\sigma > 0$, we obtain (3.23).

Next, from (3.3), (A.1), and (A.2), we find that

$$2v = \sigma^2\left[1 + \frac{4\delta\eta}{\sigma^4\sqrt{C}} + \frac{4\delta^2}{\sigma^8 C}(\sigma^2\rho - 2\eta^2) + O\left(\frac{1}{C^{3/2}}\right)\right], \tag{A.6}$$

and hence

$$\frac{1}{\sqrt{2v}} = \frac{1}{\sigma}\left[1 - \frac{2\delta\eta}{\sigma^4\sqrt{C}} + \frac{2\delta^2}{\sigma^8 C}(5\eta^2 - \sigma^2\rho) + O\left(\frac{1}{C^{3/2}}\right)\right]. \tag{A.7}$$

Also,

$$\frac{[(z^*)^{d_J} - 1]}{(z^* - 1)} = d_J + \frac{\delta}{\sigma^2\sqrt{C}} d_J(d_J - 1) + \frac{\delta^2}{3\sigma^6 C} d_J(d_J - 1)\left[(2d_J - 1)\sigma^2 - 6\eta\right] + O\left(\frac{1}{C^{3/2}}\right). \tag{A.8}$$

From (3.7), (A.7), and (A.8), we obtain

$$\begin{aligned}(\text{A.9})\ &\frac{z^*h_J(z^*)}{d_J\sqrt{2v}}\\ &=\frac{1}{\sigma}+\frac{\delta}{\sigma^5\sqrt{C}}\left[(d_J-1)\sigma^2-2\eta\right]\\ &+\frac{\delta^2}{\sigma^9C}\left[\frac{1}{3}(d_J-1)(2d_J-1)\sigma^4-4(d_J-1)\sigma^2\eta+2(5\eta^2-\sigma^2\rho)\right]+O\left(\frac{1}{C^{3/2}}\right).\end{aligned}$$

Next, from (3.4), (3.5), (3.21), and (3.22), we have

$$(\text{A.10})\qquad \tau=\eta-\frac{3}{2}\sigma^2+O\left(\frac{1}{\sqrt{C}}\right),\qquad y=\rho-6\eta+\frac{11}{2}\sigma^2+O\left(\frac{1}{\sqrt{C}}\right).$$

Hence, from (3.8), since $2v=\sigma^2+O(1/\sqrt{C})$, we obtain

$$\begin{aligned}(\text{A.11})\qquad \frac{N_J}{\sqrt{2v}}&=\frac{d_J}{\sigma^7}\left(\frac{1}{2}\sigma^2\rho+2\sigma^2\eta-\sigma^4-\frac{5}{3}\eta^2\right)\\ &\quad+\frac{h_J'(1)}{\sigma^5}(2\eta-3\sigma^2)-\frac{h_J''(1)}{\sigma^3}+O\left(\frac{1}{\sqrt{C}}\right).\end{aligned}$$

From (3.23),

$$\begin{aligned}(\text{A.12})\qquad &\frac{\operatorname{sgn}(z^*-1)}{\sqrt{-Cf(z^*)}}\\ &=\frac{\sigma}{\delta}+\frac{2\eta}{3\sigma^3\sqrt{C}}+\frac{\delta}{3\sigma^7C}(\sigma^2\rho-4\eta^2)+O\left(\frac{1}{C^{3/2}}\right),\end{aligned}$$

and, from (A.1) and (A.2),

$$\begin{aligned}(\text{A.13})\qquad \frac{1}{\sqrt{C}(z^*-1)}&=\frac{\sigma^2}{2\delta}-\frac{1}{2\sigma^2\sqrt{C}}(\sigma^2-2\eta)\\ &\quad+\frac{\delta}{6\sigma^6C}(\sigma^4+4\sigma^2\rho-12\eta^2)+O\left(\frac{1}{C^{3/2}}\right).\end{aligned}$$

Hence, from (A.7), we obtain

$$(\text{A.14})\qquad \frac{1}{\sqrt{2Cv}(z^*-1)}=\frac{\sigma}{2\delta}-\frac{1}{2\sigma\sqrt{C}}+\frac{\delta}{6\sigma^7C}(\sigma^4-2\sigma^2\rho+6\sigma^2\eta+6\eta^2)+O\left(\frac{1}{C^{3/2}}\right).$$

Finally, from (3.6), (A.12), and (A.14), we have

$$\begin{aligned}(\text{A.15})\qquad \frac{K}{\sqrt{2Cv}}&=\frac{1}{6\sigma^3\sqrt{C}}(2\eta+3\sigma^2)\\ &\quad-\frac{\delta}{6\sigma^7C}(\sigma^4-3\sigma^2\rho+6\sigma^2\eta+10\eta^2)+O\left(\frac{1}{C^{3/2}}\right).\end{aligned}$$

Now (3.24) follows from (A.9), (A.11), and (A.15).

Appendix B. We here give some of the details of the derivation of the expression for δ given in (4.18). From (4.14) and (4.17), it follows that

$$\frac{1}{\sigma} = \frac{1}{\sigma_0}\left\{1 - \frac{Z_{J-1}}{\sigma_0^2\sqrt{C}} + \frac{1}{\sigma_0^2 C}\left[d_J(aZ_{J-1} + b\zeta_{J-2}) + \frac{3Z_{J-1}^2}{2\sigma_0^2}\right]\right\} + O\left(\frac{1}{C^{3/2}}\right), \tag{B.1}$$

$$\frac{\delta}{\sigma^3\sqrt{C}} = \frac{\delta_0}{\sigma_0^3\sqrt{C}} + \frac{1}{\sigma_0^3 C}\left(\delta_1 + aZ_{J-1} + b\zeta_{J-2} - \frac{3\delta_0}{\sigma_0^2}Z_{J-1}\right) + O\left(\frac{1}{C^{3/2}}\right), \tag{B.2}$$

and, from (4.8),

$$\frac{\delta\eta}{\sigma^5\sqrt{C}} = \left[\frac{\delta_0}{\sigma_0^5\sqrt{C}} + \frac{1}{\sigma_0^5 C}\left(\delta_1 + aZ_{J-1} + b\zeta_{J-2} - \frac{5\delta_0}{\sigma_0^2}Z_{J-1}\right)\right](\eta_0+\zeta_{J-2}) + O\left(\frac{1}{C^{3/2}}\right) \tag{B.3}$$

and

$$\frac{\eta}{\sigma^3\sqrt{C}} = \frac{1}{\sigma_0^3\sqrt{C}}\left(1 - \frac{3Z_{J-1}}{\sigma_0^2\sqrt{C}}\right)(\eta_0 + \zeta_{J-2}) + O\left(\frac{1}{C^{3/2}}\right). \tag{B.4}$$

Hence, from (3.24), (4.9), and (B.1)–(B.4), we obtain

$$\begin{aligned}
&\frac{1}{\sqrt{2v}}\left\{\frac{\kappa}{d_J}\left[z^* h_J(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}}\right\} \\
&= \frac{\kappa}{\sigma_0} - \frac{\kappa Z_{J-1}}{\sigma_0^3\sqrt{C}} + \frac{3\kappa Z_{J-1}^2}{2\sigma_0^5 C} + O\left(\frac{1}{C}\right) \times (\text{linear terms}) \\
&+ \frac{\kappa\delta_0}{\sigma_0^3\sqrt{C}}(d_J - 1) - \frac{2\kappa\delta_0}{\sigma_0^5\sqrt{C}}(\eta_0 + \zeta_{J-2}) \\
&\quad - \frac{2\kappa}{\sigma_0^5 C}\zeta_{J-2}\left(aZ_{J-1} + b\zeta_{J-2} - \frac{5\delta_0}{\sigma_0^2}Z_{J-1}\right) \\
&\quad - \frac{1}{3\sigma_0^3\sqrt{C}}(\eta_0 + \zeta_{J-2}) + \frac{Z_{J-1}\zeta_{J-2}}{\sigma_0^5 C} - \frac{1}{2\sigma_0\sqrt{C}} \\
&\quad + \frac{10\kappa\delta_0^2}{\sigma_0^9 C}\zeta_{J-2}^2 - \frac{5\kappa}{3\sigma_0^7 C}\zeta_{J-2}^2 + \frac{5\delta_0}{3\sigma_0^7 C}\zeta_{J-2}^2 + O\left(\frac{1}{C^{3/2}}\right).
\end{aligned} \tag{B.5}$$

Next, from (4.17) and (B.5), it follows that

$$\begin{aligned}
&\sigma w\left(\frac{1}{\sqrt{2v}}\left\{\frac{\kappa}{d_J}\left[z^* h_J(z^*) + \frac{N_J}{C}\right] - \frac{K}{\sqrt{C}}\right\}\right) \\
&= (\text{linear terms}) - \frac{w(\kappa/\sigma_0)}{2\sigma_0^3 C}Z_{J-1}^2 \\
&\quad + \frac{w'(\kappa/\sigma_0)}{\sigma_0^5 C}\left\{\frac{1}{2}\kappa\sigma_0 Z_{J-1}^2 + 2\sigma_0 Z_{J-1}\zeta_{J-2}\left(\frac{1}{3} - \kappa a + \frac{4\kappa\delta_0}{\sigma_0^2}\right)\right. \\
&\qquad\qquad \left. + \zeta_{J-2}^2\left[5\left(\frac{2\kappa\delta_0^2}{\sigma_0^3} - \frac{\kappa}{3\sigma_0} + \frac{\delta_0}{3\sigma_0}\right) - 2\kappa\sigma_0 b\right]\right\} \\
&\quad + \frac{w''(\kappa/\sigma_0)}{2\sigma_0^5 C}\left[\kappa Z_{J-1} + \left(\frac{2\kappa\delta_0}{\sigma_0^2} + \frac{1}{3}\right)\zeta_{J-2}\right]^2 + O\left(\frac{1}{C^{3/2}}\right).
\end{aligned} \tag{B.6}$$

Also, from (4.8), (4.14), and (4.17), we obtain

$$\frac{\delta^2\eta}{\sigma^4\sqrt{C}} = (\text{linear terms}) + \frac{2\delta_0}{\sigma_0^4 C}\zeta_{J-2}\left(aZ_{J-1} + b\zeta_{J-2} - \frac{2\delta_0}{\sigma_0^2}Z_{J-1}\right) + O\left(\frac{1}{C^{3/2}}\right) \tag{B.7}$$

and, from (4.9),

$$\frac{\delta^3}{\sigma^8 C}(16\eta^2 - 3\sigma^2\rho) = (\text{linear terms}) + \frac{16\delta_0^3}{\sigma_0^8 C}\zeta_{J-2}^2 + O\left(\frac{1}{C^{3/2}}\right). \tag{B.8}$$

The expression for δ in (4.18) now follows from (3.19), (3.23), (3.24), and (B.6)–(B.8).

Appendix C. We here reconcile the expressions for $P_2(\sigma_0)$ and $R_2(\sigma_0)$, given by (4.19), (4.20), and (4.23), with those obtained in [12]. Corresponding to [12], we let

$$w(\kappa/\sigma) = \chi(\sigma), \tag{C.1}$$

where $w(y)$ is given by (3.18). Then,

$$-\frac{\kappa}{\sigma^2}w'\left(\frac{\kappa}{\sigma}\right) = \chi'(\sigma), \qquad \frac{\kappa^2}{\sigma^4}w''\left(\frac{\kappa}{\sigma}\right) = \frac{2}{\sigma}\chi'(\sigma) + \chi''(\sigma). \tag{C.2}$$

Hence, from (4.19) and (4.23), we obtain

$$\sigma_0^3 P_2(\sigma_0) = \chi(\sigma_0) - \sigma_0\chi'(\sigma_0) - \sigma_0^2\chi''(\sigma_0), \tag{C.3}$$

which is consistent with the definition in [12].

Next, from (4.5), (4.12), (4.13), and (4.20), we find that

$$Q = \frac{4}{3}w^2 - \frac{2}{3}\left(1 + \frac{7\kappa}{\sigma_0}w\right)w' - 2\left(\frac{\kappa}{\sigma_0}w'\right)^2 - \frac{\kappa}{\sigma_0}\left(\frac{1}{3} + \frac{2\kappa}{\sigma_0}w\right)w'', \tag{C.4}$$

where we have suppressed the argument κ/σ_0 of w. As in [12], we let

$$G(\sigma) = \chi'(\sigma)\left[\frac{2\chi(\sigma)}{\sigma}\left\{1 - \frac{2}{3}[\chi(\sigma)]^2\right\} + \frac{1}{3\kappa}\{1 - 2[\chi(\sigma)]^2\}\right]. \tag{C.5}$$

Hence, from (C.1) and (C.2),

$$G(\sigma) = \frac{1}{\sigma^2}w'\left(\frac{\kappa}{\sigma}\right)\left[\frac{2\kappa}{\sigma}w\left(\frac{\kappa}{\sigma}\right)\left\{\frac{2}{3}\left[w\left(\frac{\kappa}{\sigma}\right)\right]^2 - 1\right\} + \frac{1}{3}\left\{2\left[w\left(\frac{\kappa}{\sigma}\right)\right]^2 - 1\right\}\right]. \tag{C.6}$$

But, from (5.1), (5.2), and (5.18), we have

$$w'\left(\frac{\kappa}{\sigma}\right)\left[1 + \frac{2\kappa}{\sigma}w\left(\frac{\kappa}{\sigma}\right)\right] = 1. \tag{C.7}$$

It follows from (C.6) that

$$G(\sigma) = \frac{2}{3\sigma^2}\left[w\left(\frac{\kappa}{\sigma}\right)\right]^2 - \frac{1}{\sigma^2}\left[\frac{1}{3} + \frac{2\kappa}{\sigma}w\left(\frac{\kappa}{\sigma}\right)\right]w'\left(\frac{\kappa}{\sigma}\right). \tag{C.8}$$

If we differentiate (C.8) and set $\sigma = \sigma_0$, we find from (4.23) and (C.4) that

$$\sigma_0 R_2(\sigma_0) = -G'(\sigma_0), \tag{C.9}$$

which is consistent with the definition in [12].

Acknowledgments. The author is indebted to Judy Seery for writing the programs for the numerical calculations and for obtaining the figures. He is also grateful to the referees for their helpful suggestions for improving the presentation. The main results of this paper have been stated, without proof, in [11].

STEADY MOTION OF A DROP ALONG A LIQUID INTERFACE*

JAMES J. KRIEGSMANN† AND MICHAEL J. MIKSIS†

Abstract. We investigate the motion of a liquid drop as it flows along the interface of a liquid film. Steady, two-dimensional solutions are found in the lubrication limit for a horizontal and inclined plane. The effects of the physical parameters on the interface shapes are studied. When the plane is inclined, solutions are found only for a special set of parameter values.

Key words. thin films, triple junctions, free boundaries

AMS subject classifications. 76Dxx, 76Txx

DOI. 10.1137/S0036139901400215

1. Introduction.

Spreading of one liquid over another occurs in many interesting and important physical processes, with applications in various fields. Specific examples include liquid waste spills on bodies of water (e.g., oil spreading on the sea or chemical waste spills on ponds), spills into partially saturated porous materials, polymer-polymer coextrusion, and aerosol delivery of bronchial medicated mists. In each of these situations, the spreading process is strongly influenced by the surface tension of the liquid interfaces and the physics of the triple junction, where the three phases intersect. In order to obtain a better understanding of the effect of the triple junction on the dynamics of the flow, we consider here a model problem of the spreading of a liquid droplet along a thin liquid film flowing down an inclined plane. We assume that the fluids are immiscible and that the motion is two-dimensional, and we obtain steady solutions in the lubrication limit. These steady solutions are found only for a limited set of parameter values when the plane is inclined. The effects of the physical parameters on the steady solutions are investigated.

If a drop of one liquid is placed on top of a second immiscible liquid, a three-phase point can exist at the gas/liquid/liquid intersection. We refer to this point as the triple junction. Clearly, for a droplet resting on a liquid interface in two dimensions, there are two triple junctions. The boundary conditions imposed at the triple junction have a major influence on how one liquid spreads over another. For example, if the spreading coefficient is positive, an equilibrium solution is impossible without additional assumptions [14]. If a droplet is spreading over a base liquid bounded above by air, a positive spreading coefficient, $S > 0$, indicates that the surface tension of the base liquid with air, Σ^F, is larger than the sum of the surface tension of the droplet with air, Σ^D, and the surface tension between the liquid and the droplet, Σ^{DF}; i.e., $S = \Sigma^F - \Sigma^D - \Sigma^{DF} > 0$. Because of the relative strength of the surface tension Σ^F, the droplet will completely wet the second liquid in such a case. Such a situation has been investigated by DiPietro, Huh, and Cox [3], DiPietro and Cox [4], and Foda and Cox [5], who developed a theory for the spreading of a droplet in the completely wetting case. Their model included the additional effect of a leading precursor (monolayer) film. The addition of the precursor film to the model allowed

them to obtain steady and similarity solutions. The positive spreading coefficient case has also been investigated by Joanny [8] in the lubrication limit. By adding van der Waals forces into his model, he was able to make statements concerning steady state solutions and spreading rates. In particular, he showed that the radius of a wetting droplet will increase like $t^{1/7}$, where t is time. These results were confirmed experimentally by Fraaije and Cazabat [6]. Also recently, Brochard-Wyart, Debregeas, and de Gennes [2] have examined the spreading of a viscous droplet on a nonviscous liquid and determined that the droplet radius should increase like $t^{1/4}$.

Less work has been done for negative spreading coefficients, $S < 0$. In this case an equilibrium situation is possible without the additional assumption of a monolayer precursor film. An example of such a situation would be seen in a water droplet on top of a pool of carbon tetrachloride or nearly any other organic liquid. Equilibrium solutions of droplets resting on a liquid interface were computed by Pujado and Scriven [13]. Recently, a lubrication model was used by Wilson and Williams [17] to study the problem of a dragged film emerging through the free surface of a second liquid. They determined the final thickness of the coating film as a function of the density ratio and the surface tension of the interfaces. Also recently, a similarity solution for the dynamics of a triple junction was investigated by Miksis and Vanden-Broeck [11]. They were able to determine the location of the triple junction and the resulting capillary waves along the interface as a function of the physical parameters. The models used in these investigations forced equilibrium boundary conditions, i.e., zero net force, at the triple junction. The zero-net-force condition will also be assumed here.

2. Physical description. We consider the two-dimensional flow of a two-phase system consisting of a liquid drop floating on a liquid substrate which completely coats a flat solid surface, as illustrated in Figure 1. The fluids are Newtonian, incompressible, and immiscible, forming a well defined interface between the drop and film. We assume that the gas above the drop and film is passive, with sufficiently small viscosity and density so as to impose no effect upon the system.

Our primary concern is to study the behavior of the interfaces: $\bar{H}(\bar{X},\bar{T})$, the surface of the film; $\bar{A}(\bar{X},\bar{T})$, the upper surface of the drop; and $\bar{B}(\bar{X},\bar{T})$, the interface between the drop and film. Here, $\bar{X}$ is the spatial coordinate parallel to the solid surface, and $\bar{T}$ is time. The surface tensions associated with the interfaces are Σ^F

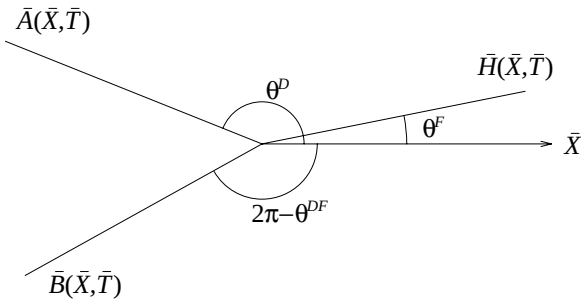

FIG. 2. *Region near the right contact point.*

for the film, Σ^D for the drop, and Σ^{DF} for the interface between the drop and film. These surface tensions are such that

$$\frac{1}{\Sigma^F}\left[\Sigma^F - \Sigma^D - \Sigma^{DF}\right] = S < 0. \tag{1}$$

Here, S is the dimensionless spreading parameter. We assume that Σ^F, Σ^D, Σ^{DF}, and S are well defined for our two liquids, and that they remain constant for all time. The validity of these assumptions is discussed in [7].

Consider the two triple junctions, or contact points, $\bar{X} = \bar{X}_{L,R}(\bar{T})$. We assume that the three interfaces meet here at a well defined massless point. The point bears no mass, and so the surface tension forces must sum to zero, in accordance with Newton's laws. Using the notation shown in Figure 2, this fact is written as

$$\begin{aligned} \Sigma^F \sin\theta^F + \Sigma^D \sin\theta^D + \Sigma^{DF} \sin\theta^{DF} &= 0, \\ \Sigma^F \cos\theta^F + \Sigma^D \cos\theta^D + \Sigma^{DF} \cos\theta^{DF} &= 0. \end{aligned} \tag{2}$$

This force balance is sometimes illustrated through the use of the Neumann triangle, a discussion of which can be found in [14].

Our task is now to determine the dynamics of the droplet illustrated in Figure 1. The liquids are assumed to be viscous, incompressible, and to obey the Navier–Stokes equations. The boundary conditions are no-slip along the solid walls, the continuity of tangential stress at the liquid interfaces, plus the condition that the jump in normal stress is given by the surface tension times the curvature of the interface. Finally, the boundary conditions (2) are assumed to hold at each of the triple junctions. This is a difficult free boundary problem. To simplify matters, we will assume that the liquids are thin, so that the lubrication approximation may be applied. The resulting simplified system of equations for the interface shapes can then be more readily solved.

3. Lubrication approximation. Beyond considering our spreading parameter to be negative, we further assume that it is very small in magnitude,

$$-S = \epsilon^2 \ll 1.$$

If the spreading parameter were identically zero, then (2) would indicate that $\theta^D = \theta^{DF} = \theta^F + \pi$. That is, in the neighborhood of the contact point, the three interfaces would fall upon one shared line. Because S does not vanish, but is very close to zero, we expect that $\left(\theta^D - \theta^F - \pi\right)$ and $\left(\theta^{DF} - \theta^F - \pi\right)$ should not vanish, but they should be very small. If we assume that θ^F is small in magnitude, then θ^D

and θ^{DF} must be very near π, and so all the interface slopes are very small at the contact points.

Since $\bar{H}(\bar{X},\bar{T})$, $\bar{A}(\bar{X},\bar{T})$, and $B(\bar{X},\bar{T})$ all vary slowly in $\bar{X}$ near the triple junctions, we seek solutions for $\bar{H}$, $\bar{A}$, and $\bar{B}$ that vary slowly in $\bar{X}$ everywhere. This suggests that we use a long-wave theory, or, equivalently, that we use the lubrication equations. In order to formally derive the lubrication equations, we introduce two distinct length scales. If the thickness of the film or drop can be characterized by a distance d, we seek solutions that vary over a distance of L, which might characterize the length of the drop, and we seek solutions for which $d/L = \epsilon \ll 1$. Choosing this lubrication ratio equal to $\sqrt{-S}$ leads to a consistent, simplified system. The details of this derivation for our problem can be found in [9]. Here we give only an outline of the derivation and the resulting nonlinear system of evolution equations for the film interfaces.

In order to obtain the leading order lubrication equations in the small parameter ϵ, the Navier–Stokes equation along with the boundary conditions are made dimensionless by the change of variables

$$\begin{aligned} X &= \frac{\bar{X}}{L}, \qquad y = \frac{\bar{Y}}{d}, \qquad T = \frac{\epsilon\rho^F g d\bar{T}}{3\mu^F}, \\ h &= \frac{\bar{H}}{d}, \qquad b = \frac{\bar{B}}{d}, \qquad a = \frac{\bar{A}}{d}, \\ X_L &= \frac{\bar{X}_L}{L}, \quad X_R = \frac{\bar{X}_R}{L}. \end{aligned}$$

Here μ^i and ρ^i are the viscosity and density of the film ($i = F$) and drop ($i = D$), and g is the gravitational acceleration. Following the standard lubrication assumptions [1], [9], the velocity in the direction normal to the plane is assumed to be one order higher in ϵ than the velocity tangent to the plane. In addition, we need to introduce the dimensionless density ratio, viscosity ratio, and Reynolds number,

$$\beta = \frac{\rho^D}{\rho^F}, \quad \lambda = \frac{\mu^D}{\mu^F}, \quad Re = \frac{\epsilon^2(\rho^F)^2 g L^3}{3(\mu^F)^2}.$$

We assume that this Reynolds number is $o(1)$. The dimensionless parameter

$$C = \frac{\epsilon\Sigma^F}{\rho^F g L^2}$$

measures the importance of surface tension. We assume that this parameter, which is the reciprocal of a Bond number, is $O(1)$. Finally, we introduce dimensionless surface tension ratios

$$\begin{aligned} \frac{\Sigma^D}{\Sigma^F} &= \sigma^D, \\ \frac{\Sigma^{DF}}{\Sigma^F} &= \sigma^{DF} + \epsilon^2. \end{aligned}$$

We seek solutions of the dependent variables in the dimensionless equations of motion as regular perturbation expansions in ϵ. To order $O(\epsilon)$, the resulting partial differential equations that describe the evolution of the interfaces are (see [9])

$$
\begin{aligned}
h_T &= \frac{\partial}{\partial X}\left\{h^3\left[\epsilon\cos\alpha\, h_X - C h_{XXX} - \sin\alpha\right]\right\},\\
b_T &= \frac{\partial}{\partial X}\Bigg\{b^3\left[\epsilon(1-\beta)\cos\alpha\, b_X - C\sigma^{DF} b_{XXX}\right]\\
&\qquad + \frac{1}{2}b^2(3a-b)\left[\epsilon\beta\cos\alpha\, a_X - C\sigma^{D} a_{XXX}\right]\\
&\qquad + \sin\alpha\left[\left(\frac{3\beta}{2}-1\right)b^3 - \frac{3\beta}{2}ab^2\right]\Bigg\},\\
a_T &= \frac{\partial}{\partial X}\Bigg\{\frac{1}{2}b^2(3a-b)\left[\epsilon(1-\beta)\cos\alpha\, b_X - C\sigma^{DF} b_{XXX}\right]\\
&\qquad + \left[\left(\frac{1-\lambda}{\lambda}\right)(a-b)^3 + a^3\right]\left[\epsilon\beta\cos\alpha\, a_X - C\sigma^{D} a_{XXX}\right]\\
&\qquad + \sin\alpha\left[-\frac{\beta}{\lambda}a^3 + 3\beta\left(\frac{1-\lambda}{\lambda}\right)a^2 b + \left(\frac{3\beta}{2}-\frac{1}{2}-\frac{\beta}{\lambda}\right)b^2(3a-b)\right]\Bigg\}.
\end{aligned}
\tag{3}
$$

Note that the derivation of these equations parallels the calculation for a single liquid thin film along a substrate; see, e.g., Oron, Davis, and Bankoff [12]. The difference in the calculation occurs in the region where there are two liquid interfaces. The leading order equations from the Navier–Stokes equations are similar to the single-phase case, but when the boundary conditions across the drop/fluid interface are applied, the fluid motion in both liquid regions becomes coupled, resulting in the second two equations in (3).

In order to solve the evolution equations (3), we must supply boundary conditions at the contact points (triple junctions), far-field information, and initial conditions. It is important to keep in mind that the leading order equations we derive have an associated length scale. The equations are therefore really valid only away from the triple junctions, and care also needs to be taken when discussing the far-field. Hence, a proper matched asymptotic analysis needs to be done that accounts for the behavior of the solutions in these different regions. The leading order contact and balance of force conditions at the triple junction follow from a straightforward matched asymptotic analysis, while the derivation of the other conditions local to the triple junction can be found in [9].

The first condition imposed at the triple junctions is continuity of the interfaces. To leading order at $X = X_{R,L}$ these are

$$
\begin{aligned}
h &= b,\\
h &= a.
\end{aligned}
\tag{4}
$$

The balance of surface tension forces (2) must also be imposed at the triple junctions. At $O(1)$, the force balance at the contact line (2) implies

$$
1 - \sigma^{D} - \sigma^{DF} = 0,
\tag{5}
$$

while by pursuing the same equations to $O(\epsilon)$ and $O(\epsilon^2)$, we obtain the boundary conditions at $X = X_{R,L}$,

$$
\begin{aligned}
h_X - \sigma^{D} a_X - \sigma^{DF} b_X &= 0,\\
h_X^2 - \sigma^{D} a_X^2 - \sigma^{DF} b_X^2 &= -2.
\end{aligned}
$$

These conditions affect our leading order system and may be rephrased as

$$
\begin{aligned}
b_X &= h_X - \sqrt{2\frac{\sigma^D}{\sigma^{DF}}} \quad \text{at } X = X_L, \\
a_X &= h_X + \sqrt{2\frac{\sigma^{DF}}{\sigma^D}} \quad \text{at } X = X_L, \\
b_X &= h_X + \sqrt{2\frac{\sigma^D}{\sigma^{DF}}} \quad \text{at } X = X_R, \\
a_X &= h_X - \sqrt{2\frac{\sigma^{DF}}{\sigma^D}} \quad \text{at } X = X_R.
\end{aligned} \tag{6}
$$

The final conditions at the contact points are determined by imposing continuity of pressure and horizontal velocity through the triple junction. To $O(\epsilon^2)$, these conditions imply

$$
\begin{aligned}
h_{XX} - \sigma^D a_{XX} - \sigma^{DF} b_{XX} &= 0, \\
C\left[h_{XXX} - \sigma^D a_{XXX} - \sigma^{DF} b_{XXX}\right] &= \epsilon \cos\alpha \left[h_X - \beta a_X - (1-\beta) b_X\right].
\end{aligned} \tag{7}
$$

We must also supply some information about $h(X,T)$ far upstream and downstream. We will seek solutions for which $h(X,T)$ tends to a constant height, h_{up}, far upstream. Initial conditions for the problem consist of the interface shapes themselves at $T = 0$. A final piece of information that proves to be useful is the speed of the contact points, $\frac{\mathrm{d}}{\mathrm{d}T} X_{L,R}$. It is clear that these speeds must be equivalent to the horizontal component of the velocity of the fluid in the drop at these points. It can be shown that

$$
\frac{\mathrm{d}}{\mathrm{d}T} X_{L,R} = \frac{3}{2}\left[h^2\left(C h_{XXX} + \sin\alpha - \epsilon\cos\alpha\, h_X\right)\right]\Big|_{X=X_{L,R}}. \tag{8}
$$

4. Steady equations and rescaling.

4.1. Equations of motion. The system (3)–(8) has been derived in part by introducing two different length scales, L and d. We have used as our dimensionless horizontal coordinate $X = \bar{X}/L$, and $T = \epsilon\rho^F g d\bar{T}/3\mu^F$ as our dimensionless measure of time. If, instead, we use d as our only length scale, and if we employ

$$
x = \frac{\bar{X}}{d}, \qquad t = \frac{\rho^F g d \bar{T}}{3\mu^F}
$$

as our dimensionless variables, then (3)–(8) are somewhat transformed. Introducing

$$
Bo = \frac{\epsilon^3}{C} = \frac{\rho^F g d^2}{\Sigma^F}
$$

as the Bond number and

$$
x_{r,l}(t) = \frac{\bar{X}_{R,L}}{d}
$$

as the dimensionless locations of the contact points, the transformed system of the partial differential equations can be obtained.

We wish to investigate here only the possibility of steady solutions. Such a solution represents a drop of constant shape moving at a constant speed over the substrate.

The conditions under which such a solution is possible must be determined, as must the speed of the drop and the shape of all interfaces.

The system resulting from the above rescaling may be posed in a moving frame by substituting $x_{\rm new} = x_{\rm old} + Ut$, where U is the speed of either contact point. For steady solutions, the shape of each interface does not vary in time, and so all time derivatives vanish. Upon integrating the resulting equations, we find that

$$h^3\left[Bo^{-1}h''' - \cos\alpha\, h' + \sin\alpha\right] - Uh = -M,$$

$$\begin{aligned} &b^3\left[\frac{\sigma^{DF}}{Bo}b''' - (1-\beta)\cos\alpha\, b'\right] + \frac{1}{2}b^2(3a-b)\left[\frac{\sigma^{D}}{Bo}a''' - \beta\cos\alpha\, a'\right] \\ &\qquad + \sin\alpha\left[\left(1-\frac{3\beta}{2}\right)b^3 + \frac{3\beta}{2}ab^2\right] - Ub = -M, \end{aligned} \tag{9}$$

$$\begin{aligned} &\frac{1}{2}b^2(3a-b)\left[\frac{\sigma^{DF}}{Bo}b''' - (1-\beta)\cos\alpha\, b'\right] \\ &+\left[\left(\frac{1-\lambda}{\lambda}\right)(a-b)^3 + a^3\right]\left[\frac{\sigma^{D}}{Bo}a''' - \beta\cos\alpha\, a'\right] \\ &+\sin\alpha\left[\frac{\beta}{\lambda}a^3 - 3\beta\left(\frac{1-\lambda}{\lambda}\right)a^2b + \left(\frac{3\beta}{2} - \frac{1}{2} - \frac{\beta}{\lambda}\right)b^2(b-3a)\right] - Ua = -M, \end{aligned}$$

where primes denote differentiation with respect to x. The boundary conditions (4) and (7) have been used in the integration of the differential equations (3) to evaluate the constant of integration $M = Uh_{up} - h_{up}^3\sin\alpha$, which is the flux of the lower film. The fact that the film thickness approaches the constant h_{up} far upstream has also been used. The boundary conditions needed to supplement (9) at the contact points are

$$\begin{aligned} h - a &= 0, \\ h - b &= 0, \\ b' &= h' \mp \sqrt{-2S\frac{\sigma^{D}}{\sigma^{DF}}}\,, \\ a' &= h' \pm \sqrt{-2S\frac{\sigma^{DF}}{\sigma^{D}}}\,, \\ h'' - \sigma^{D}a'' - \sigma^{DF}b'' &= 0. \end{aligned} \tag{10}$$

It should be noted that, by evaluating the first of the equations (9) at the contact points and using the expressions (8), the frame speed U can be simply written as

$$U = \frac{3h_{up}^3\sin\alpha}{3h_{up} - h(x_l)} = \frac{3h_{up}^3\sin\alpha}{3h_{up} - h(x_r)}, \tag{11}$$

which implies

$$h(x_l) = h(x_r) \tag{12}$$

so long as $\alpha \neq 0$. We see that, for a solution to be steady, the height of both contact points must be the same.

In seeking steady solutions, we need not concern ourselves with the initial conditions of the system. We must, however, specify the volume of the drop, V:

$$\int_{x_l}^{x_r} (a-b)\mathrm{d}x = V. \tag{13}$$

More properly, of course, this volume is actually an area.

A few points should be kept in mind as we solve the system (9)–(13). First, we have assumed that S is very small in deriving our system, and so a small value should be used if the results are to be meaningful. Second, we should expect that our solutions will vary slowly in x. For example, the slopes of our solutions such as h_x should be $O(\sqrt{|S|})$, since we have assumed that the slopes written as h_X would be $O(1)$. Third, because our solutions should be slowly varying in space, we expect surface tension effects to be important when Bo is small, namely, $O(|S|^{3/2})$. Finally, in deriving our system, we have retained terms to $O(\epsilon)$. The $O(\epsilon)$ quantities have manifested themselves in the $\cos\alpha$ terms. Later, the importance of these presumably small terms is investigated.

4.2. Far-field conditions. In order to solve (9), we must provide some far-field information. Far upstream away from the drop, we have assumed that $h(x)$ approaches the value h_{up}. Far downstream, we expect $h(x)$ to tend to a limiting value h_{dn}. From the first of the equations (9), we see that h_{dn} must satisfy the algebraic equation

$$\sin\alpha\, h_{dn}^3 - U h_{dn} + U h_{up} - \sin\alpha\, h_{up}^3 = 0,$$

which has solutions

$$h_{dn} = h_{up}, \qquad -\frac{h_{up}}{2} \pm \frac{\sqrt{3}}{2} h_{up} \sqrt{\frac{h_{up} + h(x_l)}{3h_{up} - h(x_l)}}\,. \tag{14}$$

We observe that at most two of these solutions are positive and physically significant. If $h(x)$ does tend to a limiting value far downstream, it must asymptote to one of these two allowable values if there is to be a steady solution. A discussion of third order ODEs similar to these can be found in Tuck and Schwartz [15].

In an effort to understand the behavior of $h(x)$ for large values of $|x|$, we seek solutions of the form $h(x) \sim h_\infty + \zeta(x)$, where h_∞ is one of the two values h_{up} or h_{dn} and $\zeta \ll 1$. We substitute this form into the steady equation (9) and retain only linear terms in ζ. The equation admits solutions $\zeta = e^{rx}$, where r satisfies the characteristic equation

$$r^3 - Bo\cos\alpha\, r + \frac{3Bo\sin\alpha[2h_\infty - h(x_l)]}{h_\infty[3h_\infty - h(x_l)]} = 0,$$

which has solutions $r = r_1,\ r_2,\ r_3$. This fact is written as $(r-r_1)(r-r_2)(r-r_3) = 0$, or, by expanding,

$$r^3 - (r_1 + r_2 + r_3)r^2 + (r_1 r_2 + r_1 r_3 + r_2 r_3)r - r_1 r_2 r_3 = 0.$$

By comparing this cubic equation with the characteristic equation, we first can note that $r_1 + r_2 + r_3 = 0$. Also, we see that the sign of $r_1 r_2 r_3$ is determined by the sign of the quotient

$$Q = \frac{\sin\alpha[h(x_l) - 2h_\infty]}{3h_\infty - h(x_l)}. \tag{15}$$

If $Q \neq 0$, then we can be sure that none of the roots are zero. Because we are solving a cubic equation with real coefficients, we are certain that at least one of the roots is real. The fact that the sum of the roots vanishes suggests that one of the roots, r_1, has a negative real part, while another of the roots, r_2, has a positive real part.

If $Q < 0$, then the product of the roots is negative. For the product of the roots to be negative, r_1 must be real, and r_3 must be either the complex conjugate of r_2 or a positive real number, provided that r_2 is real. In summary, r_1 is a negative real number, while the other roots are either positive real numbers or complex conjugates with positive real parts.

If, for the time being, we assume that our steady solution has a contact point height such that $h(x_l) < 2h_{up}$, we see that $Q < 0$. By the preceding analysis, we see in this case that there is one growing mode as $x \to -\infty$. Far downstream, $h(x)$ can approach one of two values, h_{dn}. If, for the time being, we assume that our steady solution has a contact point height such that $h(x_l) < 2h_{dn}$ as well, we see that $Q < 0$. By the preceding analysis, we see in this case that there are two growing modes as $x \to \infty$. Additional discussion of the roots for nonnegative values of Q can be found in Kriegsmann [9].

We will apply the conclusions of the linear analysis to our nonlinear problem and assume that $Q < 0$. To suppress the growth mode far upstream, we require only that

$$\lim_{x \to -\infty} h'(x) = 0, \tag{16}$$

while far downstream we require that

$$\begin{aligned} \lim_{x \to \infty} h'(x) &= 0, \\ \lim_{x \to \infty} h(x) &= h_{dn}, \end{aligned} \tag{17}$$

to eliminate both growth modes. It should be understood that these boundary conditions are to be imposed numerically on a finite computational domain. Note that we have assumed that the upstream height h_{up} and the downstream height h_{dn} both take on values such that $Q < 0$. This fact must be checked in all calculated solutions. Later, the possibility for solutions where this constraint is not met is discussed.

Our steady problem is now fully stated. The differential equations (9) must be solved with boundary conditions (10), extra conditions (11)–(13), and numerical boundary conditions (16)–(17). It should be noted that there are eight free parameters, α, Bo, σ^D, S, β, λ, h_{up}, and V, while $\sigma^{DF} = 1 - \sigma^D$, as given by (5).

Finally, we should remark about the behavior of the interfaces near the contact point. For the steady problem, Kriegsmann [9] has shown that the interfaces have finite first, second, and third derivatives at the triple junction, but in the time dependent case only the second derivative is known to be finite. He also showed that this model implies integrable stresses in the neighborhood of the triple junction.

5. Zero-tilt-angle solutions.

5.1. Equations. We now consider steady solutions when $\alpha = 0$. These are presented to illustrate the effects of the physical parameters in our model. Pujado and Scriven [13] calculated such steady solutions for a more general drop-film system. They permited the interfaces to vary on a length scale similar to the thickness, and they also found both two-dimensional and three-dimensional solutions. We consider only two-dimensional solutions that vary on a length scale much larger than the thickness.

For any such solution, the frame speed U and the flux M must vanish. The steady equations (9) simplify considerably. In order to solve the system, an origin must be selected. This is done by selecting the midpoint of the drop so that the contact points are located at $x = \pm x_c$. In addition to the conditions at the contact points and the volume constraint we must also impose the constraint $\lim_{x\to-\infty} h_0 = h_{up}$. Note that we will denote the zero-tilt-angle solutions with a zero subscript. The resulting system is linear in h_0, b_0, and a_0, but it is nonlinear in x_c. This can be seen by rescaling x so that the contact points would be located at $x = \pm 1$. The differential equations would then have factors of x_c^2 present.

The zero-tilt-angle version of (9) can be integrated, yielding

$$
\begin{aligned}
h_0 &= C_h + C_{hh} e^{-\sqrt{Bo}\,x} \quad \text{for } x > x_c, \\
h_0 &= C_h + C_{hh} e^{\sqrt{Bo}\,x} \quad \text{for } x < -x_c, \\
b_0 &= \begin{cases} C_b + C_{bb} \cosh \sqrt{\frac{(1-\beta)Bo}{\sigma^{DF}}}\, x & \text{if } \beta < 1, \\ C_b + C_{bb} \cos \sqrt{\frac{(\beta-1)Bo}{\sigma^{DF}}}\, x & \text{if } \beta > 1, \\ C_b + C_{bb} x^2 & \text{if } \beta = 1, \end{cases} \\
a_0 &= C_a + C_{aa} \cosh \sqrt{\frac{\beta Bo}{\sigma^D}}\, x,
\end{aligned}
\tag{18}
$$

where we have retained only symmetric terms. Enforcing the boundary conditions at only one contact point and also the condition for $x \to -\infty$, we are left with seven algebraic equations to solve for the seven unknown variables C_h, C_{hh}, C_b, C_{bb}, C_a, C_{aa}, and x_c. This algebraic system is linear in all the variables except x_c and is solved numerically (see Kriegsmann [9] for details).

One should note that, of our eight free parameters for the steady problem, α, Bo, σ^D, S, β, λ, h_{up}, and V, we set α to zero, but the rest are free. For some values of the parameters, the solutions might not be realizable. For example, the drop might dip below the solid surface. In general, however, we may choose the parameters as we please. One should also note that the zero-tilt-angle solutions do not depend upon our choice of λ in any way. This could be anticipated. Since there is no fluid motion, viscosity should not come into play, and λ is a measure of viscosity.

5.2. Solutions. Some zero-tilt-angle solutions are shown in Figure 3. The film height monotonically approaches the value h_{up} both upstream and downstream, though this is not obvious in every graph. The views of the drop and film are chosen as such so that the drop can be seen in greater detail. Also, the labeling conventions shown in the first graph hold for all of the solutions shown in this paper.

In an effort to understand the importance of the density ratio, β is varied while the other dimensionless parameters are held constant. As we consider drops which are progressively more dense, the drops sink progressively lower into the liquid substrate. In the case when $\beta = 0.7$, we see that the film has a constant height $h(x) = h_{up}$ for $|x| > x_c$. This is true in any situation when $\beta = \sigma^D$ (see [9]). If $\beta \neq \sigma^D$, the film height $h(x)$ is not constant but is an exponential function, as stated earlier. If $\beta > \sigma^D$, we see that the contact points dip below h_{up}, and if $\beta < \sigma^D$, the contact points rest above h_{up}.

Next, we investigate the importance of the relative surface tensions by varying σ^D. Figure 4 shows such solutions. Recalling the relationship (5) between σ^D and

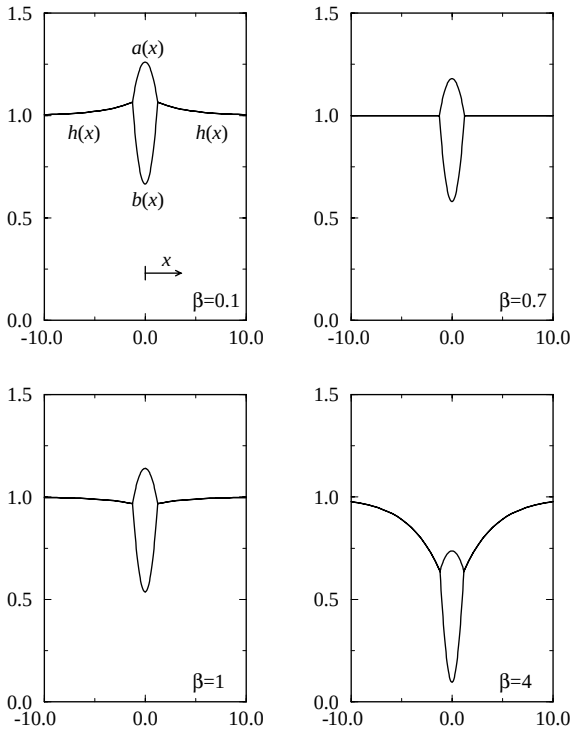

FIG. 3. *Zero-tilt-angle solutions for* $Bo = 0.1$, $\sigma^D = 0.7$, $S = -0.1$, $h_{up} = 1$, *and* $V = 1$. *The density ratio* β *is varied as shown.*

σ^{DF}, $\sigma^D + \sigma^{DF} = 1$, as the tension of the upper surface of the drop is increased, the tension of the lower surface of the drop is necessarily decreased. This is not to say that the surface tensions are dependent on one another; rather a limitation of our model demands that we consider only interactions between liquids for which our assumption (5) is met, i.e., interactions with small spreading coefficients.

That having been said, it can be seen from the solutions that when the tension on the upper surface of the drop is relatively low, the upper surface deforms more dramatically than the lower surface, as expected. On the other hand, if the tension on the upper surface of the drop is relatively high, the upper surface deforms less dramatically than the lower surface.

Figure 5 illustrates the dependence of solutions on the spreading parameter S. It should be remembered that S is the basis of our lubrication approximation. We have agreed to study cases in which S is very small, and we have argued that because of the small magnitude, solutions should vary slowly in x. Because we have derived our equations in this limit, it is pushing the limits of reason to consider a solution to our equations if $S = -1$. Nevertheless, the solutions depicted in Figure 5 show that as the magnitude of S is increased, the width of the drops becomes shorter. This is to be expected, as we have assumed that the ratio of the film thickness to the width of the drop is $O(\sqrt{-S})$.

Finally, we investigate the importance of overall surface tension by varying the Bond number. As the value of Bo is decreased, the surface tension associated with each interface becomes greater and the deformation of each interface is lessened, as shown in Figure 6.

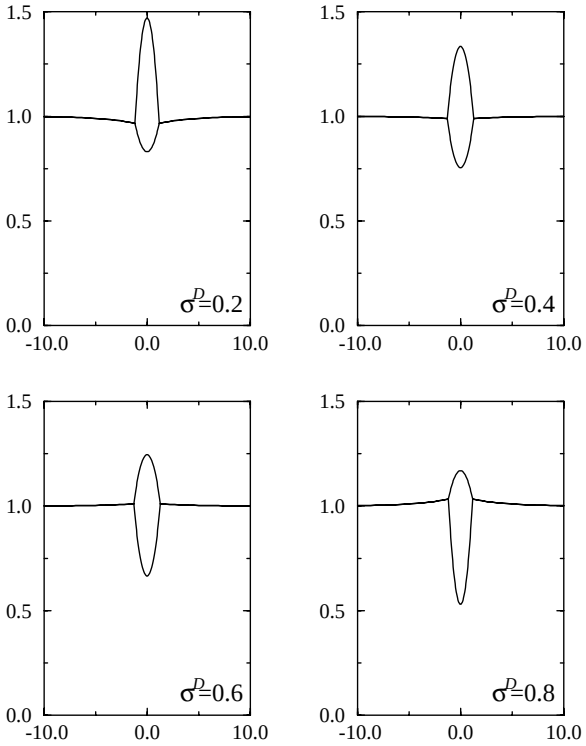

FIG. 4. *Zero-tilt-angle solutions for* $Bo = 0.1$, $S = -0.1$, $\beta = 0.5$, $h_{up} = 1$, *and* $V = 1$. *The surface tension ratio* σ^D *is varied as shown.*

The solutions shown thus far are all accurate solutions of the mathematical system (9)–(13), though they do not all necessarily reflect accurate physical solutions. In the extreme case shown in Figure 3, with $\beta = 4$, we have found a mathematical solution for which the slopes are not small. Nevertheless, by pressing the domains of validity to the extreme, we are easily able to see trends in the solutions.

6. Finite-tilt-angle solutions. We now seek steady solutions when α is greater than zero. The zero-tilt-angle solutions we have found thus far all share the trait that the film height far downstream tends to the upstream height, i.e., $h_{dn} = h_{up}$. Although we will not impose this far-field condition, the solutions we have found for nonzero tilt-angle all share this trait. Hence in this section we will use h_{up} when referring to both the downstream and upstream heights. Here we will assume that the height of the contact point is less than $2h_{up}$, and so it is necessary to apply the boundary conditions (16), (17).

6.1. Numerical method. In order to numerically approximate solutions, we follow a multiple-step procedure. Since we are free to select an origin, we pick it halfway between the contact points so that $x_r = -x_l = x_c$. Next, we guess at the values of $h(x_c)$, $h'(-x_c)$, $b'(x_c)$, $a'(x_c)$, and x_c that are to be held by the steady solution. We further recall that $b(x_c)$, $a(x_c)$, $b(-x_c)$, $a(-x_c)$, $h(-x_c)$, and $h(x_c)$ are all equal by the boundary conditions (10), (12).

We now solve for the interface shapes individually. Here we only briefly outline the numerical method; details are given in Kriegsmann [9]. To begin, we solve the first

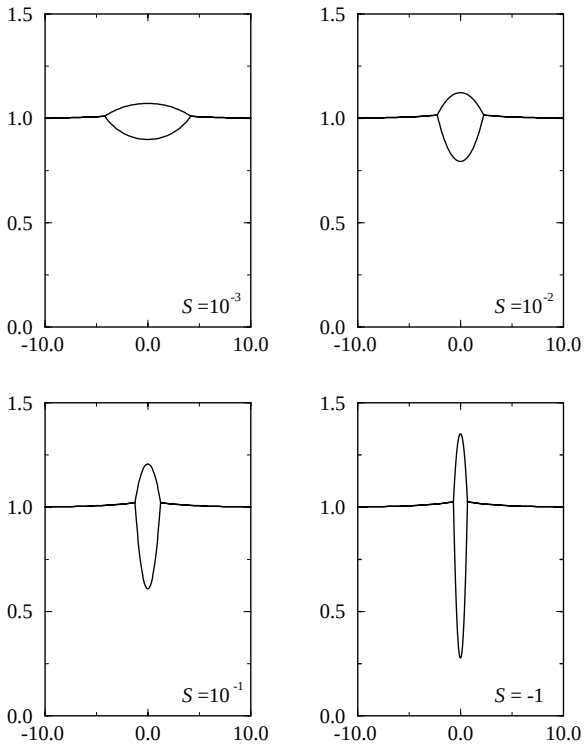

FIG. 5. *Zero-tilt-angle solutions for* $Bo = 0.1$, $\sigma^D = 0.7$, $\beta = 0.5$, $h_{up} = 1$, *and* $V = 1$. *The spreading parameter* S *is varied as shown.*

of the differential equations (9) for $x < -x_c$, given the facts that $h'(x)$ approaches zero for large $|x|$ and that $h(-x_c)$ and $h'(-x_c)$ take on their guessed values. As mentioned earlier, for the film to the left of the drop we impose two boundary conditions at the contact point and one at the end of the computational domain. Next, we solve the same differential equation for $x > x_c$, given the facts that $h(x)$ tends to h_{up} for large x, its slope similarly tends to zero, and that $h(x_c)$ takes on its assumed value. Again as previously mentioned, for the film to the right of the drop, we impose one boundary condition at the contact point and two conditions at the end of the computational domain. Finally, we solve the two coupled differential equations for a and b in (9), with the conditions that $b(-x_c)$, $a(-x_c)$, $b(x_c)$, and $a(x_c)$ take on their guessed height, while $b'(x_c)$ and $a'(x_c)$ are equal to their assumed values.

Given these tentative interface solutions, we check to see whether they satisfy all of the conditions (10), (13). By our construction, the first two conditions of (10) are satisfied at each contact point, leaving us with three conditions at each contact point in addition to the volume constraint. We have made a guess for five different scalars, and we see that seven equations (constraints) must be satisfied. We suspect that there is not always a solution for a given set of physical parameters. In this case, we expect that we may freely select six of the eight physical parameters, for example, α, Bo, σ^D, S, h_{up}, and V, and that there exists a solution only for certain values of λ and β. The viscosity ratio λ and the density ratio β are selected arbitrarily as the two auxiliary dependent variables. The values of the seven scalars, λ, β, $h(x_c)$, $h'(-x_c)$, $b'(x_c)$, $a'(x_c)$, and x_c, are then systematically adjusted by a multidimensional Newton's method to satisfy the seven constraints.

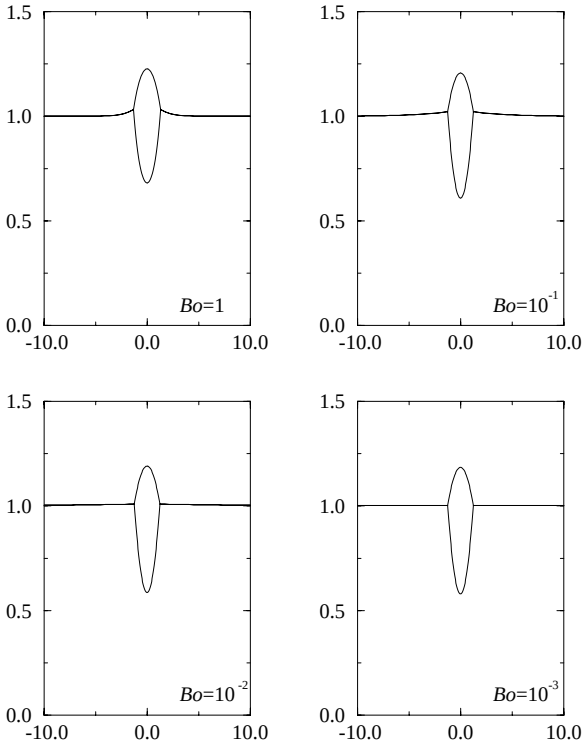

FIG. 6. *Zero-tilt-angle solutions for* $\sigma^D = 0.7$, $S = -0.1$, $\beta = 0.5$, $h_{up} = 1$, *and* $V = 1$. *The Bond number Bo is varied as shown.*

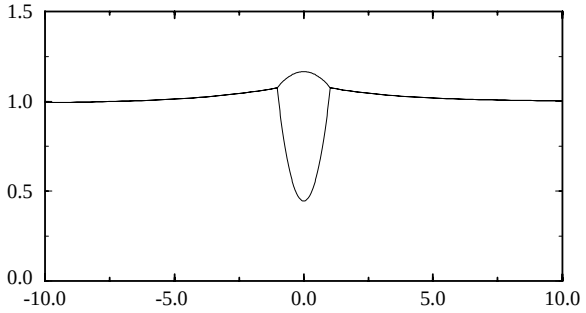

FIG. 7. *Steady solution for* $\alpha = 0.05$, $Bo = 0.1$, $\sigma^D = 0.9$, $S = -0.1$, $h_{up} = 1$, $V = 1$, $\beta = 0.172$, *and* $\lambda = 0.148$.

6.2. Numerical results.

6.2.1. Small-angle solutions. We begin by considering a steady solution for a very small tilt-angle. Figure 7 shows a steady solution for $\alpha = 0.05$, $Bo = 0.1$, $\sigma^D = 0.9$, $S = -0.1$, $h_{up} = 1$, $V = 1$, $\beta = 0.172$, and $\lambda = 0.148$. In this graph, as in most of the graphs to follow in this paper, the computational domain is not shown in its entirety, so that the details near the drop may be observed. Figure 8 illustrates an even closer view of the same solution compared with a solution to the linearized problem, as found by Kriegsmann [9], and a solution to the zero-tilt-angle problem.

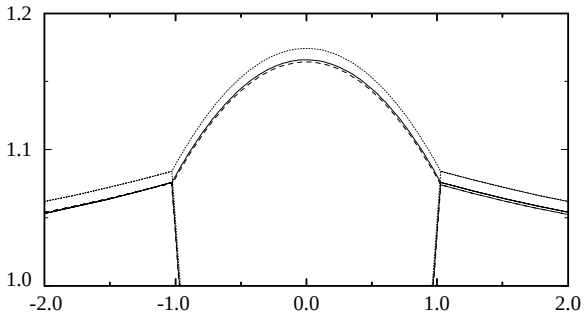

FIG. 8. *Comparison between the zero-tilt-angle solution (dotted), solution to the linearized problem (dashed), and solution to the nonlinear problem (solid).*

By linearized, we imply solutions close to the zero-tilt-angle results, valid in the limit of a small tilt-angle. For the zero-tilt-angle problem, all the same parameters are used, with the exception of $\alpha = 0$. For the linearized problem, the same parameter values are used except for the viscosity ratio, for which the required value is slightly altered, $\lambda = 0.150$. We can see that the solution to the linearized problem is, as expected, a small perturbation away from the zero-tilt-angle solution. The solution to the fully nonlinear problem is reasonably close to the linear solution in this case, for $\alpha = 0.05$. This is to be expected, as solutions to the linearized problem should be accurate in the limit $\alpha \ll 1$.

6.2.2. Large-tilt-angle solutions I. Several nonlinear solutions are shown in Figure 9. The surface tension ratio σ^D is varied, and so the required values of β and λ change as well. In varying σ^D, we see in the steady solutions the same trend present in the zero-tilt-angle solutions. That is, when the surface tension on the upper surface of the drop is relatively low, the upper surface deforms more dramatically than the lower surface. Conversely, when the surface tension on the upper surface of the drop is relatively high, the upper surface deforms less dramatically than the lower surface of the drop.

In fact, the other trends discussed earlier in reference to the zero-tilt-angle solutions are present in the nonlinear finite-tilt-angle solutions as well. As the value of S is raised, the width of the drops becomes shorter. As the Bond number is decreased, the deformation of each interface is lessened. Although these trends are shared by the zero-tilt-angle and finite-tilt-angle solutions, and in truth the solutions even look quite similar, there are quantitative differences. Also, although it is not obvious to the naked eye, the finite-tilt-angle solutions, unlike the zero-tilt-angle solutions, are asymmetric.

As repeatedly mentioned, we have been able to find steady translating solutions only for select sets of physical parameters. In the eight-dimensional parameter space described by α, Bo, σ^D, S, h_{up}, V, β, and λ, we have found steady solutions only on a six-dimensional manifold. To gain an understanding of this manifold, Figures 10–13 reveal numerous cross sections. Each point on the β vs. σ^D and λ vs. σ^D curves represents a steady solution. The final graph in each figure shows the speed of the drop.

Several features can be seen in Figures 10–13. For example, solutions have been found only for $\beta < \sigma^D$. This may be related to the behavior of zero-tilt-angle solutions. The concavity of the zero-tilt-angle steady film interfaces, $h_0(x)$, depends only upon

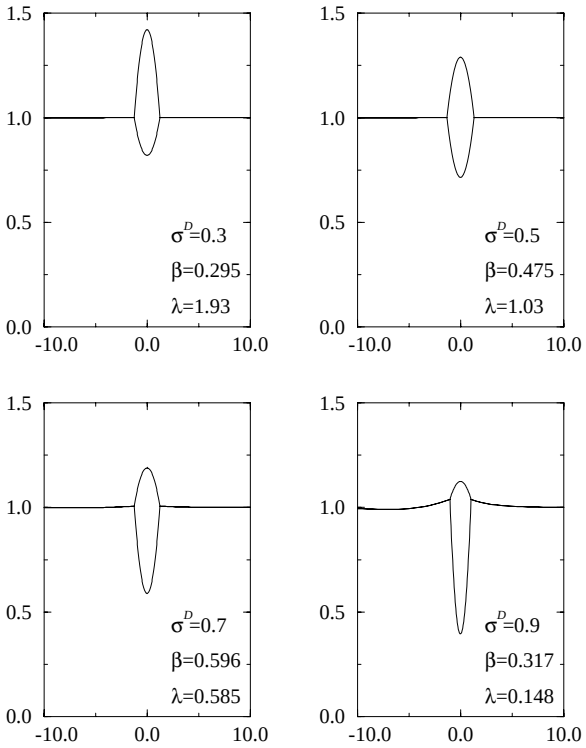

FIG. 9. *Steady solutions for* $\alpha = 0.5$, $Bo = 0.1$, $S = -0.1$, $h_{up} = 1$, *and* $V = 1$. *The values of* σ^D, β, *and* λ *are varied as shown.*

the sign of $(\beta - \sigma^D)$. Furthermore, for reasonably small values of σ^D, we find solutions only if β is very near σ^D and if λ approaches a value which depends almost entirely on σ^D. In this limit, we also observe that the steady solutions found for $\alpha \neq 0$ are almost identical to the zero-tilt-angle solutions found for the same set of parameters, but with $\alpha = 0$. We see from Figure 14 that, for relatively large σ^D, the value of β is far from σ^D, and the steady solution differs somewhat from the zero-tilt-angle solution. Figure 15 shows that, for relatively small σ^D, the value of β is close to σ^D, and the steady solution is almost identical to the zero-tilt-angle solution.

Figures 10–13 further reveal that the necessary value of β depends strongly upon the values of σ^D and h_{up} but only weakly upon the value of the Bond number. Also, we may note that the required value of λ depends weakly upon all parameters except σ^D and β. Finally, we can see that the speed of the drop depends almost exclusively upon α and h_{up}.

Given that the steady solutions never stray too far from the zero-tilt-angle solutions, this final fact is somewhat intuitive. The speed of the drop has been written as

$$U = \frac{3h_{up}^3 \sin\alpha}{3h_{up} - h\left(x_c\right)}.$$

For the zero-tilt-angle solutions, the contact point height $h\left(x_c\right)$ is seen to depend most strongly on the relation between β and σ^D (see Figures 3–6). The steady solutions, which are similar to the corresponding zero-tilt-angle solutions, all include as part

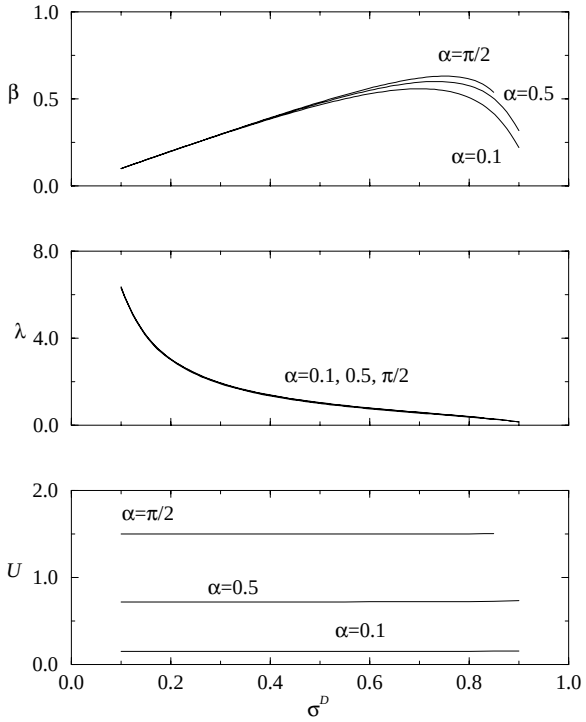

FIG. 10. *Given $Bo = 0.1$, $S = -0.1$, $h_{up} = 1$, $V = 1$, and α, σ^D having values as shown, steady solutions are found only for the special values of β, λ shown. Also, the speed of the drop is displayed.*

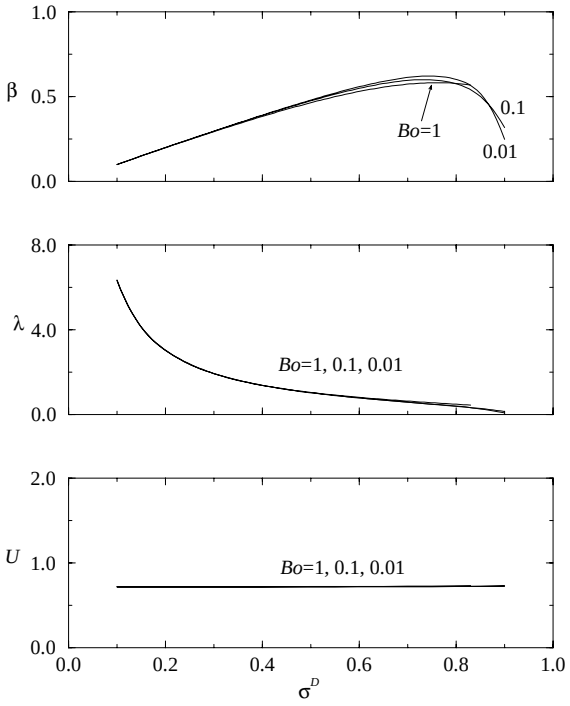

FIG. 11. *Given $\alpha = 0.5$, $S = -0.1$, $h_{up} = 1$, $V = 1$, and Bo, σ^D having values as shown, steady solutions are found only for the special values of β, λ shown. Also, the speed of the drop is displayed.*

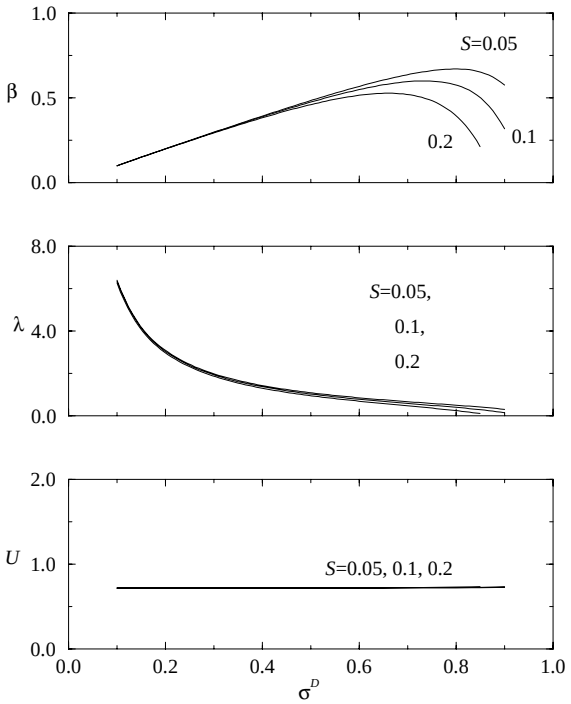

FIG. 12. *Given $\alpha = 0.5$, $Bo = 0.1$, $h_{up} = 1$, $V = 1$, and S, σ^D having values as shown, steady solutions are found only for the special values of β, λ shown. Also, the speed of the drop is displayed.*

of the solution a value of β such that the contact point height $h(x_c)$ is on the same order as the upstream film thickness h_{up}. Since this is true, the drop speed can be approximated:

$$U \approx \frac{3}{2} h_{up}^2 \sin\alpha.$$

This value is the same as the speed of a fluid element on the surface of a perfectly flat film of thickness h_{up}, and it matches the speeds shown in Figures 10–13 almost exactly.

6.2.3. Large-tilt-angle solutions II. The steady finite-tilt-angle solutions found thus far have been to some degree tame. The solutions exist only for a restricted choice of parameters, which conspire to keep the interfaces near those of the corresponding zero-tilt-angle solutions. In some cases, the steady finite-tilt-angle solutions are indistinguishable from the zero-tilt-angle solutions, and in all cases, the drop moves down the plane almost exactly with the surface speed of the undisturbed film.

In order to locate each of these steady solutions, we have considered λ and β as dependent variables. We can also seek solutions by designating different parameters as dependent variables. By choosing h_{up} and λ as such, we are now free to specify the value of β. Many of the solutions described by Figures 10–13 require that β be very near σ^D, and these solutions are somewhat uninteresting, in that they very closely resemble zero-tilt-angle solutions. We may now dictate that β be far from σ^D and hope for more interesting solutions.

Figure 16 shows a family of steady solutions, which are calculated by specifying all the parameters except h_{up} and λ. By comparing the steady solutions for $\alpha = 0.5$

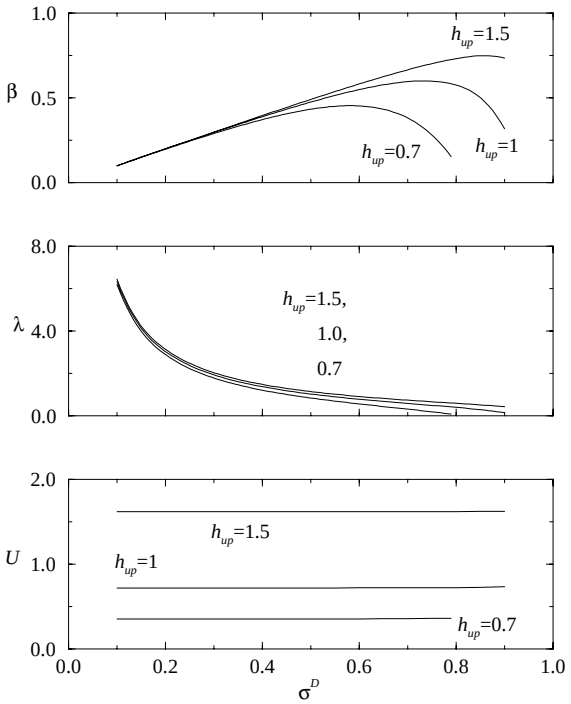

FIG. 13. *Given $\alpha = 0.5$, $Bo = 0.1$, $S = -0.1$, $V = 1$, and h_{up}, σ^D having values as shown, steady solutions are found only for the special values of β, λ shown. Also, the speed of the drop is displayed.*

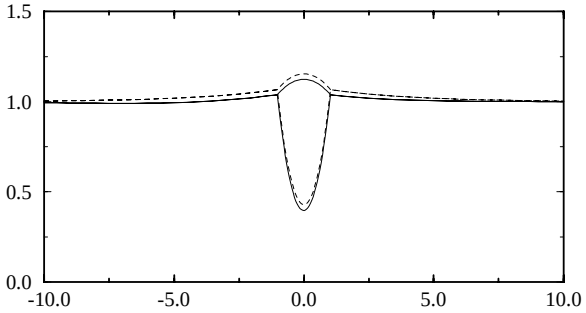

FIG. 14. *Steady solutions for $Bo = 0.1$, $\sigma^D = 0.9$, $S = -0.1$, $h_{up} = 1$, $V = 1$, $\beta = 0.317$, and $\lambda = 0.148$. The tilt-angle is set to $\alpha = 0.5$ (solid) and $\alpha = 0$ (dashed).*

with the zero-tilt-angle solutions for $\alpha = 0$, it is clear once again that, if the value of β is near that of σ^D, the steady solution and zero-tilt-angle solution are nearly identical. By reducing β far below σ^D, we see that the steady solution does differ somewhat from the zero-tilt-angle solution, though the two configurations are quite similar in character.

It is interesting to note that for the solutions shown in Figure 16, the required value of h_{up} increases with β. On the other hand, the solutions themselves are still unexciting, in that they closely resemble zero-tilt-angle solutions. Also, steady solutions still have not been found for $\beta > \sigma^D$.

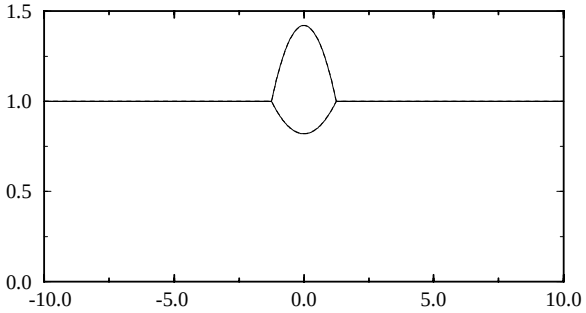

FIG. 15. *Steady solutions for* $Bo = 0.1$, $\sigma^D = 0.3$, $S = -0.1$, $h_{up} = 1$, $V = 1$, $\beta = 0.295$, *and* $\lambda = 1.93$. *The tilt-angle is set to* $\alpha = 0.5$ *(solid) and* $\alpha = 0$ *(dashed). The two solutions are nearly indistinguishable.*

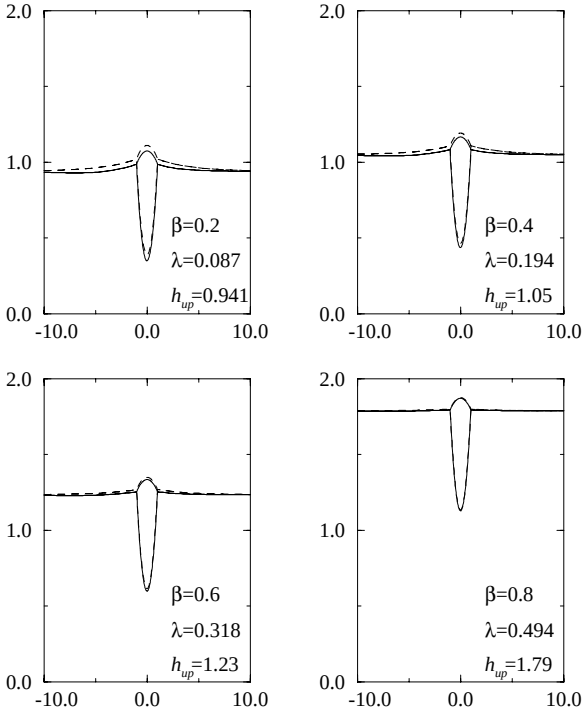

FIG. 16. *Steady solutions for* $Bo = 0.1$, $\sigma^D = 0.9$, $S = -0.1$, *and* $V = 1$. *The values of* β, λ, *and* h_{up} *are varied as shown. Solutions for* $\alpha = 0.5$ *(solid) are compared to the zero-tilt-angle solutions with* $\alpha = 0$ *(dashed).*

6.2.4. Importance of $O(\epsilon)$ terms. In section 4 it is observed that, in deriving our system, we retained terms to $O(\epsilon)$, and that these $O(\epsilon)$ effects are felt in the $\cos\alpha$ terms. Very little difference is noticed in the solutions obtained with and without the $O(\epsilon)$ term, except for α near zero; this is illustrated in Figure 17, where we plot the values that β and λ must assume for the existence of a steady solution if the $O(\epsilon)$ terms are retained or discarded. We see that for $\alpha = \pi/2$ the $\cos\alpha$ terms obviously have no effect. For α very near zero, we see that the removal of the $\cos\alpha$ terms changes the results noticeably. In such a limit, we could not have been justified in neglecting these terms in the formulation of our lubrication equations (seeAcheson

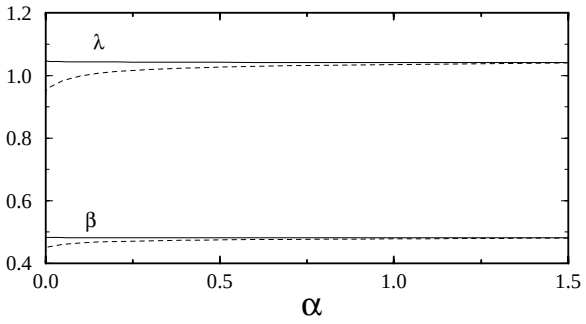

FIG. 17. *Required values of β and λ for existence of solution. The angle α is varied, while $Bo = 0.1$, $\sigma^D = 0.5$, $S = -0.1$, $h_{up} = 1$, and $V = 1$. The $O(\epsilon)$ terms are discarded (solid) and retained (dashed).*

[1]). For intermediate values of α, the inclusion of the $O(\epsilon)$ terms only perturbs our results. It seems proper to have included the $\cos\alpha$ terms in our formulation. The terms are necessary for very small α, and for larger values of α the $O(\epsilon)$ terms simply provide small corrections.

6.2.5. A singular limit. At this point, it seems as though we have reached another unexpected result. We have found that, although it is possible to realize a steady zero-tilt-angle solution for any given values of Bo, σ^D, S, h_{up}, V, β, and λ, if α is increased slightly, then we can find a steady solution only if the parameters take on special values. Figure 17 shows that, although we can find a zero-tilt-angle solution for any values of β and λ, this limit is singular, since β and λ take on single limiting values as $\alpha \to 0$.

To view this result from another angle, consider the case when $Bo = 0.1$, $\sigma^D = 0.5$, $S = -0.1$, $h_{up} = 1$, $V = 1$, $\beta = 0.465$, and $\lambda = 0.999$. If $\alpha = 0$, a steady solution can be found. If α is increased slightly, our claim thus far is that there is no steady solution. If α is further increased to 0.1, then we find that there is a steady solution. Our computations show that the profiles of these two solutions are nearly identical, yet if we perturb α slightly away from 0.1, there is no steady solution. Alternatively, if we perturb any other parameter, there is no steady solution for $\alpha = 0.1$. It would seem reasonable to expect a steady solution if α were between 0 and 0.1, yet we have not found this to be the case.

7. Discussion. In finding all of the preceding finite-tilt-angle solutions, we have found that the downstream film height tends to h_{up}, the upstream film height, and we have assumed that the value of h_{up} is such that the quotient Q is negative (see (15)). These two conditions are not violated by any of the preceding solutions, and so our solution process has been self-consistent.

Previous research (e.g., [10], [16]) has shown that when an external pressure acts on a thin film, in general the downstream height tends to a different value than the upstream height. The case we have considered, where $h_{dn} = h_{up}$, is more the exception than the rule, according to these sources. It is true that our problem is different than one involving a simplified external forcing; in our problem, the drop shape and speed are unknowns coupled with the film dynamics, while in [10], the external forcing is prescribed. Nevertheless, there exists the distinct possibility that we have found solutions that are exceptions to the general rule, and we must consider cases when $h_{dn} \neq h_{up}$.

It seems possible that a steady solution might exist for which $2h_{dn} < h(x_l) < 2h_{up}$. In this case, we see from (15) that Q is negative upstream and positive downstream. The arguments presented in section 4.2 suggest that there is now only one growth mode both upstream and downstream, and that we need only impose reduced far-field conditions, $\lim_{x\to-\infty} h'(x) = 0$ and $\lim_{x\to\infty} h'(x) = 0$, numerically at the ends of the finite computational domain. Hence, it may now be possible to find solutions with $h_{dn} \neq h_{up}$. Although neither h_{up} nor h_{dn}, the value of which is given by (14), is specified directly through boundary conditions, the values are felt through the flux and speed quantities in the differential equations.

In this situation, following the discussion of our numerical method, we now may guess at six scalars to satisfy seven equations, and so solutions might presumably be found as a one-parameter family. For example, β could now be chosen arbitrarily, while λ alone would be a dependent function of the other parameters. Such a result was found in the linearized case by Kriegsmann [9]. If h_{up} is instead chosen as the auxiliary dependent variable, it seems possible that steady solutions could be found for relatively arbitrary choices of the other physical parameters. The time dependent solutions in [10] show, for a simpler problem, the possibility of a film's evolving towards a steady state with adjusted heights upstream and downstream. These heights are determined as part of the steady solution.

In summary, we note that here we have found steady solutions only for certain select parameter sets. The effects of surface tension, spreading coefficient, and viscosity on the solutions have been studied. We speculate that, in the cases for which the parameter sets are chosen differently, there may be steady solutions for which $h_{dn} \neq h_{up}$.

STRONGLY DEGENERATE PARABOLIC-HYPERBOLIC SYSTEMS MODELING POLYDISPERSE SEDIMENTATION WITH COMPRESSION*

STEFAN BERRES†, RAIMUND BÜRGER†, KENNETH H. KARLSEN‡, AND ELMER M. TORY§

Abstract. We show how existing models for the sedimentation of monodisperse flocculated suspensions and of polydisperse suspensions of rigid spheres differing in size can be combined to yield a new theory of the sedimentation processes of polydisperse suspensions forming compressible sediments ("sedimentation with compression" or "sedimentation-consolidation process"). For N solid particle species, this theory reduces in one space dimension to an $N \times N$ coupled system of quasi-linear degenerate convection-diffusion equations. Analyses of the characteristic polynomials of the Jacobian of the convective flux vector and of the diffusion matrix show that this system is of strongly degenerate parabolic-hyperbolic type for arbitrary N and particle size distributions. Bounds for the eigenvalues of both matrices are derived. The mathematical model for $N = 3$ is illustrated by a numerical simulation obtained by the Kurganov–Tadmor central difference scheme for convection-diffusion problems. The numerical scheme exploits the derived bounds on the eigenvalues to keep the numerical diffusion to a minimum.

1. Introduction.

Mathematical models for the (controlled) sedimentation of polydisperse suspensions of small particles, which belong to a finite number of species differing in size or density and are suspended in a viscous fluid, are important to many applications such as the chemical engineering, ceramic, pulp and paper, and food industries, mineral processing, wastewater treatment, and medicine [3, 50, 88, 89, 101, 122]. The characteristic behavior of such mixtures is differential sedimentation, which leads to areas of different composition if an initially homogeneous suspension is allowed to settle. In this paper, we consider the additional property that the solid particles possibly form a compressible sediment layer. A mathematical model for polydisperse suspensions forming compressible sediments is developed, analyzed, and simulated, focusing on three different aspects.

First, we show how two existing sedimentation models—one for monodisperse flocculated suspensions, which are described by *scalar* strongly degenerate parabolic-hyperbolic equations, and one for polydisperse suspensions of rigid spheres differing

in size, which lead to *first-order systems* of conservation laws—can be combined into a model of sedimentation of polydisperse suspensions of particles (or flocs) forming compressible sediments.

Secondly, we prove that this model gives rise to strongly degenerate parabolic-hyperbolic systems of PDEs. (A precise definition of that type property is given below.) This type characterization is valid for arbitrary numbers N of sizes of equal-density particles. The application considered thus provides provably strongly degenerate parabolic-hyperbolic systems of arbitrary size. The well-posedness analysis and design of numerical schemes for such equations has received considerable interest in recent years, but, especially in the system (nonscalar) case, only a few applications are known. The present paper provides such an application.

Finally, for $N = 3$ we illustrate the model by numerical examples using the high-resolution Kurganov–Tadmor central difference scheme [64]. Its exposition in [64] is biased towards systems of conservation laws but also suggests an extension to parabolic-hyperbolic systems. This paper presents the first (to our knowledge) application of that extension to a realistic model.

In what follows, we outline the paper and put it in perspective relative to the existing literature. In section 2, we derive a set of spatially multidimensional model equations for the sedimentation of polydisperse suspensions forming compressible sediments (also called a sedimentation-consolidation process). The modeling starts from the usual mass and linear momentum balance equations for the N solids species (each regarded as one phase) and the fluid. The generic material properties of the suspension are introduced by constitutive assumptions concerning the solid and fluid stress tensors and the solid-fluid interaction forces. In particular, the solid phase pressures and the fluid pressure are replaced by the effective solid stress σ_e and the pore pressure. Here we assume that σ_e is a function of the total solids concentration $\phi := \phi_1 + \cdots + \phi_N$ only, where ϕ_i is the concentration of species i having diameter d_i and density ϱ_i. The way in which σ_e depends on ϕ_1 to ϕ_N determines the resulting diffusion matrix of the above-mentioned degenerate system. Specifying the solid-fluid interaction force for each species and finally performing a dimensional analysis, which permits our neglecting several terms of the linear momentum balance equations, we obtain explicit expressions for the solid-fluid relative velocity (or slip velocity) of each species as a function of $\Phi := (\phi_1, \ldots, \phi_N)^{\mathrm{T}}$ and $\nabla\Phi$, which in turn yield the fluxes of the continuity equations. The final (spatially multidimensional) model equations form a strongly degenerate system of N convection-diffusion equations for $\phi_1, \ldots, \phi_N$ coupled to the divergence-free condition of the volume-average mixture velocity and a three-component equation for the motion of the mixture. These last two equations account for viscous effects and reduce for $\Phi \equiv 0$ to the Stokes system for an incompressible fluid. Finally, we check that for $N = 1$ the strongly degenerate system reduces to the known scalar equation for monodisperse suspensions [26]. An overview of the analysis, numerics, and applications of strongly degenerate parabolic equations is given in section 5. For incompressible sediments, i.e., when $\sigma_e \equiv 0$, the model reduces to the Masliyah–Lockett–Bassoon (MLB) model [71, 73] for polydisperse suspensions of rigid spheres.

The effect of compressible sediment in polydisperse sedimentation has been studied only infrequently [98, 102]. Unfortunately, these treatments are incomplete in that they are not embedded in the appropriate mathematical PDE framework or are limited to $N = 2$. We assume that the mixture forms a compressible sediment layer whenever the cumulative solids concentration ϕ exceeds a critical value (or "gel

point") ϕ_c, and is in hindered settling for $\phi \le \phi_c$. In [102], however, the transition between the hindered settling zone (where $\phi \le \phi_c$) and the compression region (where $\phi > \phi_c$) is introduced by an artificial moving boundary condition, which we avoid by the concept of a degenerate diffusion equation. Our model also describes the relative movement of the solids species against each other within the sediment under the influence of the effective solid stress. This is unlike any previous treatment. Thus, our model is new and therefore derived completely in section 2. On the other hand, we essentially combine arguments that have been discussed extensively in previous works that focus on modeling either flocculated monodisperse [26, 27, 35] or nonflocculated polydisperse suspensions [14, 19, 22]. Thus the presentation in section 2 is fairly concise, and we refer to the cited papers for additional details and justification.

To continue the discussion, we need a precise definition of strongly degenerate parabolic-hyperbolic systems. In fact, in recent years we have seen an increased interest in quasi-linear systems of PDEs that in one space dimension can be written as

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial \boldsymbol{\varphi}(\mathbf{u})}{\partial x} = \frac{\partial}{\partial x}\left(\mathbf{D}(\mathbf{u})\frac{\partial \mathbf{u}}{\partial x}\right), \quad x \in \mathbb{R},\ t > 0, \tag{1.1}$$

where $\mathbf{u} : \mathbb{R} \times \mathbb{R}^+ \to \mathcal{D} \subset \mathbb{R}^N$ is the sought solution vector, $\boldsymbol{\varphi} : \mathcal{D} \to \mathbb{R}^N$ is a flux vector, and $\mathbf{D} : \mathcal{D} \to \mathbb{R}^{N\times N}$ is a diffusion matrix. We allow the system to be degenerate in the sense that $\mathbf{D}(\mathbf{u}) = 0$ for $\mathbf{u} \in \mathcal{D}' \subset \mathcal{D}$; i.e., the system reduces to first order on $\mathcal{D}'$. The system is called *strongly degenerate* if $\mathcal{D}'$ is of nonzero N-dimensional measure. Moreover, we recall that the system (1.1) is *strictly parabolic* at a point $\mathbf{u}_0 \in \mathcal{D}$ if $\mathbf{D}(\mathbf{u}_0) > 0$; i.e., the matrix $\mathbf{D}(\mathbf{u}_0)$ has only positive eigenvalues. On the other hand, if $\mathbf{u}_0$ is chosen such that $\mathbf{D}(\mathbf{u}_0) = 0$, then, according to the usual terminology for conservation laws, the system (1.1) is called *hyperbolic* if the Jacobian $\boldsymbol{\mathcal{J}}_{\boldsymbol{\varphi}}(\mathbf{u}_0)$ has N real eigenvalues, and *strictly hyperbolic* if these eigenvalues are moreover pairwise distinct. Finally, we shall call (1.1) a *strongly degenerate parabolic-hyperbolic system* if, at any point $\mathbf{u}_0$ belonging to the interior $\mathcal{D}^0$ of $\mathcal{D}$, the system (1.1) is either strictly parabolic or strictly hyperbolic in the sense given above and the set $\mathcal{D}^0 \cap \mathcal{D}'$ on which the system is strictly hyperbolic is of nonzero N-dimensional measure. We emphasize here that points $\mathbf{u} \in \mathcal{D}\backslash\mathcal{D}^0$, which are on the boundary of the physically relevant region $\mathcal{D}$, do not enter the type characterization [59]. Note that a strictly hyperbolic first-order system of conservation laws, for which the right-hand side of (1.1) vanishes identically, is included as a special case. Of course, solutions of (1.1) are in general discontinuous, even for smooth initial data. Further properties are discussed in section 5.

If the multidimensional sedimentation equations developed in section 2 are restricted to one space dimension, the motion of the mixture is determined by the velocity at one end of the computational domain. For a closed vessel, this velocity is zero, and only the degenerate system for $\phi_1, \ldots, \phi_N$ needs to be solved. This system of second-order PDEs can then be written as

$$\frac{\partial \Phi}{\partial t} + \frac{\partial \mathbf{f}(\Phi)}{\partial z} = \frac{\partial}{\partial z}\left(\mathbf{A}(\Phi)\frac{\partial \Phi}{\partial z}\right), \tag{1.2}$$

where t is time and z is height. In section 2, we assume that $\sigma_e = 0$ for $\phi \le \phi_c$. This assumption implies $\mathbf{A}(\Phi) = 0$ for $\phi \le \phi_c$. In this case, the system (1.2) is reduced to the first-order system

$$\frac{\partial \Phi}{\partial t} + \frac{\partial \mathbf{f}(\Phi)}{\partial z} = 0. \tag{1.3}$$

We consider the system (1.2) for vectors $\Phi \in \mathcal{D}_{\phi_{\max}}$, where $0 < \phi_{\max} \leq 1$ denotes the maximum admissible cumulative solids concentration, and we define for $0 < \phi_{\mathrm{M}} \leq 1$

$$\mathcal{D}_{\phi_{\mathrm{M}}} := \big\{\Phi = (\phi_1, \ldots, \phi_N) \in \mathbb{R}^N : \phi_1 \geq 0, \ldots, \phi_N \geq 0;\ \phi_1 + \cdots + \phi_N \leq \phi_{\mathrm{M}}\big\}.$$

Moreover, we denote by $\mathcal{D}^0_{\phi_{\mathrm{M}}}$ the interior of $\mathcal{D}_{\phi_{\mathrm{M}}}$, that is,

$$\mathcal{D}^0_{\phi_{\mathrm{M}}} := \big\{\Phi = (\phi_1, \ldots, \phi_N) \in \mathbb{R}^N : \phi_1 > 0, \ldots, \phi_N > 0;\ \phi_1 + \cdots + \phi_N < \phi_{\mathrm{M}}\big\}.$$

Obviously, the type of (1.2) is determined by the properties of $\mathbf{A}(\Phi)$ for $\phi_{\mathrm{c}} < \phi < \phi_{\max}$ and by those of the vector $\mathbf{f}(\Phi)$ (more precisely, of its Jacobian $\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)$) for $0 < \phi \leq \phi_{\mathrm{c}}$ and $\phi = \phi_{\max}$. Since every component of $\mathbf{f}(\Phi) = (f_1(\Phi), \ldots, f_N(\Phi))^{\mathrm{T}}$ depends nonlinearly on every component of Φ, and since $\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)$ is unsymmetric, it is by no means obvious that the system (1.3) is strictly hyperbolic. Since all entries of $\mathbf{A}(\Phi)$ are nonzero on $\mathcal{D}^0_{\phi_{\max}} \backslash \mathcal{D}_{\phi_{\mathrm{c}}}$, it is not apparent either that the system (1.2) is strictly parabolic for $\phi \in \mathcal{D}^0_{\phi_{\max}} \backslash \mathcal{D}_{\phi_{\mathrm{c}}}$. The core of this paper is formed by sections 3 and 4, where these properties are established by analyzing the characteristic polynomials of $\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)$ and $\mathbf{A}(\Phi)$, respectively, where the vector $\mathbf{f}(\Phi)$ and the matrix $\mathbf{A}(\Phi)$ are chosen according to the model developed in section 2. Moreover, for the analysis of section 3, we assume that the particles all have the same density and that the species differ in size only. Our treatment has in part been inspired by Rosso and Sona's recent analysis of equations modeling the separation of oil-water dispersions [87]. In section 3, we discuss the properties of the system (1.3) with $\mathbf{f}(\Phi) = \mathbf{f}^{\mathrm{M}}(\Phi)$,

$$\frac{\partial \phi_i}{\partial t} + \frac{\partial f_i^{\mathrm{M}}(\Phi)}{\partial z} = 0, \quad i = 1, \ldots, N, \tag{1.4}$$

which arises from the model derived in section 2 by considering one space dimension and a closed settling vessel and assuming that the effective solid stress vanishes ($\sigma_{\mathrm{e}} \equiv 0$). The "M" indicates that the constitutive assumptions in section 2 have been chosen according to the MLB approach [22, 71, 73] (see [14, 22] for alternate equations for $\mathbf{f}(\Phi)$). The analysis of section 3 leads to the type of the system (1.2) for $\phi \leq \phi_{\mathrm{c}}$ and fully determines its type for $\sigma_{\mathrm{e}} \equiv 0$, that is, for a suspension of rigid particles [14, 19, 22]. The main result is that in the equal-density case, the system (1.4) is indeed strictly hyperbolic for all $\Phi \in \mathcal{D}^0_{\phi_{\max}}$ for $0 < \phi_{\max} \leq 1$. Strict hyperbolicity holds for all N and arbitrary particle sizes $d_1 > d_2 > \cdots > d_N > 0$.

To outline the significance of the analysis of section 3 in nontechnical terms, let us first say that hyperbolicity of a first-order system of conservation laws like (1.3) is in general a desirable property. In fact, the existence of a complete set of pairwise-distinct eigenvalues at each relevant point Φ of the state space ensures that the solution of (1.3) involves (simple) waves, i.e., solutions which essentially involve one eigenvalue of the Jacobian $\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)$ and a corresponding eigenvector; see [51] for details. The important point is that each eigenvalue represents a finite propagation speed of solution information. For a mixture of flowing phases (in our case, the N "particulate" phases and the fluid), we should expect not only that a good model predicts finite speeds of propagation, but that moreover no solution information travels faster than any of the physical phases. We shall show later (Lemma 6.1 in section 6.3) that the MLB model for equal-density spheres and dilute to moderately concentrated suspensions indeed satisfies this requirement.

To put the hyperbolicity result in the proper perspective, let us now look at the opposite situation. Loss of hyperbolicity for a given vector $\Phi \in \mathbb{R}^N$ means that system

(1.4) has at least one pair of complex-conjugate eigenvalues. For $N = 2$, we then say that the system is *elliptic*. In most cases, for vectors Φ chosen from some subregion of the relevant state space, the system (1.4) is nonhyperbolic or elliptic and is hyperbolic elsewhere. Such systems are called *mixed systems*; see [47] for a survey of applications. In some applications, such as multiphase flow in porous media, the significance of mixed systems is essentially unclear, and loss of hyperbolicity is sometimes related to a model error. For polydisperse sedimentation, however, it is shown in [22] that for arbitrary N the degeneracy into nonhyperbolic type is a criterion for the possible occurrence of horizontal structures like fingers, columns, or blobs during sedimentation. This interpretation of nonhyperbolicity generalizes a criterion formulated in [4] for $N = 2$. Such instabilities have been observed in experiments [4, 117] at certain initial concentrations and are particularly likely to occur in suspensions including one species that is heavier and one that is lighter than the fluid. On the other hand, instabilities have never been observed with equal-density particles.

For a given polydisperse sedimentation model, expressed by the specific algebraic form of the flux vector $\mathbf{f}(\Phi)$, the ellipticity region (which usually has to be determined numerically [22]) for given particle densities and sizes should agree with those concentration regions for which instabilities have been observed experimentally. On the other hand, the model equations should be strictly hyperbolic for arbitrary N and equal-density particles. In [22] we show that the MLB model satisfies the first of these properties and is, in particular, not hyperbolic in general for suspensions in which two or more species have different densities. However, in [22] we were able to prove strict hyperbolicity for the system (1.4) with equal-density particles in the case $N = 2$ only. We indicated in [22] that numerical tests with $N = 3$ never produced an instability region, and we conjectured that the MLB equations were hyperbolic for arbitrary N, which is now proved in the present paper.

The properties of the MLB model contrast with those of several other models. For example, the model proposed by Davis and Gecol [38] again leads to a system of the form (1.4), but which for equal-density particles is hyperbolic only for small values of d_1/d_2 (for example, for $N = 2$ the restriction is $d_1/d_2 < 5$; see [22]), and for which the size of the ellipticity region drastically increases when d_1/d_2 is increased. Since no instabilities have been observed experimentally with equal-density suspensions, these ellipticity regions are unphysical and limit the use of the Davis and Gecol model to small values of d_1/d_2. We refer to [22] for a thorough discussion of mixed systems modeling polydisperse sedimentation and the consequences for the mathematical analysis.

In section 4, we consider the right-hand side of (1.2) using the diffusion matrix $\mathbf{A}(\Phi)$ derived in section 2. While it is obvious that $\mathbf{A}(\Phi) = 0$ on $\mathcal{D}_{\phi_c}$, it is not apparent that $\mathbf{A}(\Phi)$ is positive definite on $\mathcal{D}^0_{\phi_{\max}} \backslash \mathcal{D}_{\phi_c}$. The hyperbolicity and parabolicity properties of (1.2) associated with the matrices $\boldsymbol{\mathcal{J}}_{\mathbf{f}^M}(\Phi)$ and $\mathbf{A}(\Phi)$ are controlled by the independent model functions $V(\phi)$ and $\sigma_e(\phi)$, but their entries are analogous. Thus, the formula for the characteristic polynomial of $\boldsymbol{\mathcal{J}}_{\mathbf{f}^M}(\Phi)$ derived in section 3 also provides (after substitutions) a formula for that of $\mathbf{A}(\Phi)$. It is then straightforward to prove that $\mathbf{A}(\Phi)$ has N distinct nonnegative eigenvalues, which are positive if $\phi_c < \phi < \phi_{\max}$. Thus, (1.2) is strictly parabolic for $\phi_c < \phi < \phi_{\max}$, which is the main result of section 4.

In contrast to the hyperbolicity of the first-order system (1.4), the parabolicity property established in section 4 does not admit a direct physical interpretation. Rather, parabolicity is a condition ensuring the well-posedness (existence, uniqueness,

and stability) of systems of PDEs of the form (1.2). It should, however, be pointed out that mathematically rigorous well-posedness results are available for certain special cases of (1.2) only. These include, on one hand, *scalar* strongly degenerate parabolic-hyperbolic equations [6, 7, 8, 17, 25, 31, 61, 62, 72, 118], and, on the other hand, certain *uniformly parabolic* systems, that is, systems that do not degenerate into first-order type [42, 49, 63, 66]. A closed mathematical theory for the strongly degenerate systems considered in this paper is not available despite the increased interest this kind of equation has attained in recent years. Section 5 provides a short overview of the existing literature on mathematical and numerical theory for strongly degenerate parabolic problems.

In section 6, we first describe the central difference scheme due to Kurganov and Tadmor [64], which is used in this paper. The system (1.2) is discretized by a high-resolution central difference (Riemann solver free) scheme for the convection part (corresponding to the first-order equation (1.4)) combined with a central difference discretization of the parabolic parts (the right-hand side of (1.2)). Then we illustrate the (new) model of polydisperse sedimentation with compression by numerical examples with $N = 3$ and compare the results with simulations of the two (conventional) models of settling of monodisperse flocculated and polydisperse rigid-sphere suspensions (where $\sigma_{\mathrm{e}} \equiv 0$). We refer to [14, 19] for the application of similar numerical schemes to first-order systems like (1.4) describing sedimentation of polydisperse suspensions without compression effects.

The closing section 7 discusses various aspects of the paper. We first show that the type analysis of sections 3 and 4 is also valid in several space dimensions. Next, we briefly comment on the possible extension of the model to polydisperse suspensions with particles of different densities, and we furthermore provide a physical interpretation of one of the eigenvalue bounds derived in section 3. One frequent topic in the sedimentation literature is hydrodynamic diffusion, which is associated with particle velocity fluctuations. We give a brief survey of the literature on hydrodynamic diffusion and provide justification for not including this effect in our model. An important new property of the model is the prediction of diffusive relative movement of the different solids species within the sediment. This effect is clearly visible in the numerical simulations, which correspond to a hypothetical material, and may be less pronounced for real materials. We therefore discuss several alternative gradual and structural modifications of the present model that could reduce sediment diffusivity. Finally, some applications in which the sediment compressibility is important are discussed.

2. Derivation of the model of polydisperse sedimentation with compression.

2.1. Mass and linear momentum balance equations. A suspension may be represented as a superposition of continuous media, each following its own movement with the only restrictions imposed by the interaction between components. Each component obeys the laws of conservation of mass and momentum, incorporating terms to account for the interchange between components [27]. We assume that there is no mass transfer between species.

The local mass balance equations of the solid species and of the fluid can be written as

$$\frac{\partial \phi_i}{\partial t} + \nabla \cdot \big(\phi_i \mathbf{v}_i\big) = 0, \quad i = 1, \ldots, N, \qquad -\frac{\partial \phi}{\partial t} + \nabla \cdot \big((1-\phi)\mathbf{v}_{\mathrm{f}}\big) = 0, \tag{2.1}$$

where $\mathbf{v}_i$ is the phase velocity of solids species i, $i = 1, \dots, N$, and $\mathbf{v}_\mathrm{f}$ is the fluid phase velocity. Defining the volume-average velocity of the mixture $\mathbf{q} := (1-\phi)\mathbf{v}_\mathrm{f} + \phi_1\mathbf{v}_1 + \cdots + \phi_N\mathbf{v}_N$ and the relative velocities or slip velocities $\mathbf{u}_i := \mathbf{v}_i - \mathbf{v}_\mathrm{f}$ for $i = 1, \dots, N$, we derive easily that

$$\phi_i\mathbf{v}_i = \phi_i\big(\mathbf{u}_i + \mathbf{q} - (\phi_1\mathbf{u}_1 + \cdots + \phi_N\mathbf{u}_N)\big), \quad i = 1, \dots, N; \tag{2.2}$$

hence the solids mass balance equations can be rewritten in terms of $\mathbf{q}$ and $\mathbf{u}_1, \dots, \mathbf{u}_N$ as

$$\frac{\partial\phi_i}{\partial t} + \nabla\cdot\big(\phi_i\mathbf{u}_i + \phi_i\mathbf{q} - \phi_i(\phi_1\mathbf{u}_1 + \cdots + \phi_N\mathbf{u}_N)\big) = 0, \quad i = 1, \dots, N. \tag{2.3}$$

The sum of all equations in (2.1) produces the simple mass balance of the mixture, $\nabla\cdot\mathbf{q} = 0$. The momentum balance equations for the N solid species and the fluid are

$$\varrho_i\phi_i\frac{\mathrm{D}\mathbf{v}_i}{\mathrm{D}t} = \nabla\cdot\mathbf{T}_i + \varrho_i\phi_i\mathbf{b} + \mathbf{m}_i^\mathrm{f} + \mathbf{m}_i^\mathrm{s}, \quad i = 1, \dots, N, \tag{2.4}$$

$$\varrho_\mathrm{f}(1-\phi)\frac{\mathrm{D}\mathbf{v}_\mathrm{f}}{\mathrm{D}t} = \nabla\cdot\mathbf{T}_\mathrm{f} + \varrho_\mathrm{f}(1-\phi)\mathbf{b} - (\mathbf{m}_1^\mathrm{f} + \cdots + \mathbf{m}_N^\mathrm{f}). \tag{2.5}$$

Here ϱ_f is the mass density of the fluid, $\mathbf{T}_i$ denotes the stress tensor of particle species i, $i = 1, \dots, N$, $\mathbf{T}_\mathrm{f}$ that of the fluid, $\mathbf{b}$ is the body force, $\mathbf{m}_i^\mathrm{f}$ and $\mathbf{m}_{ij}^\mathrm{s}$ are the interaction forces per unit volume between solid species i and the fluid and between the solid species i and j, respectively, $\mathbf{m}_i^\mathrm{s} := \mathbf{m}_{i1}^\mathrm{s} + \cdots + \mathbf{m}_{iN}^\mathrm{s}$ is the particle-particle interaction term of species i, and we use the standard notation $\mathrm{D}\mathbf{v}/\mathrm{D}t := \partial\mathbf{v}/\partial t + (\mathbf{v}\cdot\nabla)\mathbf{v}$.

2.2. Solid and fluid stress tensors. We assume that the stress tensors of the solid and fluid phases can be written as $\mathbf{T}_i = -p_i\mathbf{I} + \mathbf{T}_i^\mathrm{E}$ for $i = 1, \dots, N$ and $\mathbf{T}_\mathrm{f} = -p_\mathrm{f}\mathbf{I} + \mathbf{T}_\mathrm{f}^\mathrm{E}$, respectively, where p_i denotes the phase pressure of particle species i, p_f that of the fluid, $\mathbf{I}$ denotes the identity tensor, and $\mathbf{T}_i^\mathrm{E}$ and $\mathbf{T}_\mathrm{f}^\mathrm{E}$ are the corresponding extra (or viscous) stress tensors, all of which could be given by expressions that correspond, for example, to a viscous-linear fluid. Since the focus here is on the continuity equations for the solids and we assume that viscous effects due to the motion of the mixture are not dominant, all viscous effects are assigned to the fluid extra-stress tensor. To make this simplification visible in the dimensional analysis, we assume that ν_0^f and $\nu_0^\mathrm{s} < \nu_0^\mathrm{f}$ are characteristic viscosities associated with the fluid and the solid species, respectively.

2.3. Partial pressures, pore pressure, and effective solid stress. The phase pressures $p_1, \dots, p_N$ and p_f are theoretical variables (arising from the averaging procedure [27]), which cannot be measured experimentally. As in [26], they are replaced by the pore pressure p and the effective solid stress σ_e, which are measurable. We assume that σ_e is given by a constitutive equation $\sigma_\mathrm{e} = \sigma_\mathrm{e}(\Phi)$, that is, as a function of the local composition of the sediment. To our knowledge (see also [102]), no suitable function $\sigma_\mathrm{e} = \sigma_\mathrm{e}(\Phi)$ for the polydisperse case has been derived either theoretically or empirically so far. However, most researchers utilize formulas that relate σ_e to the sediment porosity or, equivalently, to the total volumetric solids concentration ϕ [74, 98].

In stating the generic assumptions on σ_e, we follow [81, 92] and consider that during sedimentation, when $\phi \le \phi_\mathrm{c}$, there is no permanent contact between the particles (or aggregates of them), and the momentum transfer between the particles occurs entirely through the fluid or through collisions (although in a moment we shall

show that the latter effect is negligible here). This means that the total stress of the mixture, p_t, which can be decomposed in two different ways as

$$p_\mathrm{t} = p_\mathrm{f} + p_1 + \cdots + p_N = p + \sigma_\mathrm{e}(\phi), \tag{2.6}$$

equals the pore pressure, and therefore $\sigma_\mathrm{e}(\phi) = 0$ for $\phi \le \phi_\mathrm{c}$. (The second equality in (2.6) reflects the well-known effective-stress principle [39].) During consolidation, when $\phi > \phi_\mathrm{c}$, permanent contact is established between the solid particles, and the contact forces are transmitted through solid-solid contacts. Moreover, it can be assumed that the part of the total stress supported by the skeleton of networked solid particles is an increasing function of their concentration ϕ, i.e., $\sigma_\mathrm{e}'(\phi) := d\sigma_\mathrm{e}(\phi)/d\phi > 0$ for $\phi > \phi_\mathrm{c}$. These generic assumptions on $\sigma_\mathrm{e}(\phi)$ can be summarized as

$$\sigma_\mathrm{e}(\phi) \begin{cases} = 0 & \text{for } \phi \le \phi_\mathrm{c}, \\ > 0 & \text{for } \phi > \phi_\mathrm{c}, \end{cases} \qquad \sigma_\mathrm{e}'(\phi) \begin{cases} = 0 & \text{for } \phi \le \phi_\mathrm{c}, \\ > 0 & \text{for } \phi > \phi_\mathrm{c}; \end{cases} \tag{2.7}$$

a specific example is given in section 6. Our concept of effective solid stress has been adopted from soil consolidation theory [81, 92] but is consistent with and in some cases mathematically equivalent to the concepts of compressive yield stress [52, 67], effective pressure [40], or yield pressure [54] utilized by research workers with a focus on solid-liquid separation. All these papers have in common that it is assumed that the effective stress takes positive values if and only if the particles are networked, and that this occurs when $\phi > \phi_\mathrm{c}$, where ϕ_c is a distinct critical concentration, also called the "threshold value" or "gel point."

We now relate the fluid and solid phase pressures p_f and $p_1, \ldots, p_N$ to the effective solid stress σ_e and the pore pressure p. While p is defined within the fluid filling the interstices between the solids, the partial fluid pressure p_f is defined in the fluid component occupying the whole volume of the mixture. Let S be the cross-section of a settling column and $S_\mathrm{f} \subset S$ be its part that is filled out by the fluid in the porous medium, and let ϵ denote the surface porosity $\epsilon := |S_\mathrm{f}|/|S|$, i.e., $dS_\mathrm{f} = \epsilon dS$. Then the surface forces exerted on the fluid in a cross section of the sediment are

$$\int_S p_\mathrm{f}\, dS = \int_{S_\mathrm{f}} p\, dS_\mathrm{f} = \int_S p(\epsilon dS). \tag{2.8}$$

Since we may assume that the surface porosity equals the volume porosity [22], we may replace ϵ by $1 - \phi$, and as a consequence of the localization theorem [53], we obtain $p_\mathrm{f} = (1 - \phi)p$ from (2.8).

The effective solid stress σ_e is that part of the total stress p_t which acts on the porous network formed by the solid particles. Assuming that the cross-sectional surface area fraction of each solids species equals its volume fraction [22], we may conclude that $(\phi_i/\phi)\sigma_\mathrm{e}(\phi)$ is that part of σ_e which acts on species i. In view of $p_\mathrm{f} = (1 - \phi)p$, (2.6) may be rewritten as

$$p_1 + \cdots + p_N = \phi p + \frac{\phi_1 + \cdots + \phi_N}{\phi} \sigma_\mathrm{e}(\phi).$$

Thus, the phase pressure p_i is related to p and σ_e by $p_i = (\phi_i/\phi)(\phi p + \sigma_\mathrm{e}(\phi))$ for $i = 1, \ldots, N$.

2.4. Body force, solid-fluid, and particle-particle interaction forces. We assume that the only body force is gravity, $\mathbf{b} = -g\mathbf{k}$, where g is the acceleration of

gravity and $\mathbf{k}$ is the upwards-pointing unit vector. Furthermore, for a monodisperse suspension [26, 27, 34, 35], the interaction force $\mathbf{m}$ between the fluid and the unique solid phase can be modeled by

$$\mathbf{m} = \alpha(\phi)\mathbf{u} + \beta(\phi)\nabla\phi, \tag{2.9}$$

where α is the resistance coefficient and $\mathbf{u} := \mathbf{v}_\mathrm{s} - \mathbf{v}_\mathrm{f}$ is the solid-fluid relative or slip velocity. Equation (2.9) follows from the theorem of representation of isotropic functions [70, 99, 115, 115A, 115B] if we require that $\mathbf{m}$ be given as the most general linear function of $\mathbf{u}$, ϕ, and $\nabla\phi$. A similar result is obtained in [41], and (2.9) is also presented in [82] within a discussion of general principles for the formulation of constitutive equations. The function $\beta(\phi)$ can be shown to coincide with the pore pressure p (see [26]). In the present case, we analogously assume that the solid-fluid interaction term related to species i is given by $\mathbf{m}_i^\mathrm{f} = \alpha_i(\Phi)\mathbf{u}_i + \beta_i(\Phi)\nabla\phi_i$, where α_i is the resistance coefficient for the transfer of momentum between the fluid and solid phase species i, $i = 1, \dots, N$.

The interaction force between the different solid particle species could be specified by the Nakamura and Capes formula [1, 76, 98]:

$$\mathbf{m}_{ij}^\mathrm{s} = \frac{3}{2}\varphi_\mathrm{e}\frac{\varrho_i\varrho_j\phi_i\phi_j(d_i+d_j)^2}{\varrho_i d_i^3 + \varrho_j d_j^3}\,\|\mathbf{v}_i - \mathbf{v}_j\|\,(\mathbf{v}_i - \mathbf{v}_j), \quad i,j = 1,\dots,N, \quad i \neq j,$$

where the parameter φ_e accounts for non–head-on collisions [98] and its value depends on whether these are plastic or elastic. Typical values of φ_e vary between 0 and 5 [1, 76], and numerical simulations have not turned out to be sensitive to φ_e (see [1]). Nevertheless, the elimination of the term $\mathbf{m}_i^\mathrm{s} = \mathbf{m}_{i1}^\mathrm{s} + \cdots + \mathbf{m}_{iN}^\mathrm{s}$ due to the dimensional analysis (see section 2.5) is not dependent on any particular formula, since there is considerable experimental and theoretical evidence (summarized in [22]) that $\mathbf{m}_{ij}^\mathrm{s}$ can be neglected at the very low Reynolds numbers considered here.

To determine $\beta_1(\Phi), \dots, \beta_N(\Phi)$, we insert the constitutive assumptions into (2.4) and (2.5) and consider the mixture at equilibrium ($t \to \infty$) in a settling column. This state is characterized by $\mathbf{v}_\mathrm{f} = 0$, $\mathbf{u}_1 = \cdots = \mathbf{u}_N = 0$, and $\nabla p = -\varrho_\mathrm{f} g\mathbf{k}$, and we obtain $\beta_1(\Phi) = \cdots = \beta_N(\Phi) = p$; i.e., the functions β_i are all constant with respect to Φ [22, 26]. The linear momentum balances now read

$$\varrho_i\phi_i\frac{\mathrm{D}\mathbf{v}_i}{\mathrm{D}t} = -\varrho_i\phi_i g\mathbf{k} + \nabla\cdot\mathbf{T}_i^\mathrm{E} - \phi_i\nabla p + \alpha_i(\Phi)\mathbf{u}_i + \mathbf{m}_i^\mathrm{s} - \nabla\left(\frac{\phi_i}{\phi}\sigma_\mathrm{e}(\phi)\right), \quad i = 1,\dots,N, \tag{2.10}$$

$$\nabla p = -\varrho_\mathrm{f} g\mathbf{k} - \frac{1}{1-\phi}\big(\alpha_1(\Phi)\mathbf{u}_1 + \cdots + \alpha_N(\Phi)\mathbf{u}_N\big) - \varrho_\mathrm{f}\frac{\mathrm{D}\mathbf{v}_\mathrm{f}}{\mathrm{D}t} + \frac{1}{1-\phi}\nabla\cdot\mathbf{T}_\mathrm{f}^\mathrm{E}. \tag{2.11}$$

2.5. Dimensional analysis. We introduce dimensionless (starred) variables by referring all densities to ϱ_f, all velocities to the velocity U, all lengths to a typical length L, all solid and fluid viscosities to ν_0^s and ν_0^f, respectively, and all pressures to the hydrostatic pressure $\varrho_\mathrm{f} gL$. Here, we assume that U is the settling velocity of a single particle of the fastest settling species in an unbounded medium, and L is the depth of the settling vessel. A characteristic time is then given by $T = L/U$. A dimensionless gradient of a variable u is defined by $\nabla^* u = L\nabla u$, and a dimensionless time derivative by $\partial u/\partial t^* = T\partial u/\partial t = (L/U)\partial u/\partial t$. Using the Froude number of the flow $\mathrm{Fr} := U^2/(gL)$ and the sedimentation Reynolds number $\mathrm{Re} := dU/\nu_0^\mathrm{f}$, where d

is the size of the largest particles, we obtain from (2.4) and (2.11) the dimensionless equations

$$\begin{aligned}\varrho_i^*\phi_i\mathrm{Fr}\frac{\mathrm{D}\mathbf{v}_i^*}{\mathrm{D}t^*} =& -\varrho_i^*\phi_i\mathbf{k}+\frac{d}{L}\frac{\nu_0^{\mathrm{s}}}{\nu_0^{\mathrm{f}}}\frac{\mathrm{Fr}}{\mathrm{Re}}\nabla^*\cdot\left(\mathbf{T}_i^{\mathrm{E}}\right)^*-\phi_i\nabla^*p^*+\alpha_i^*(\Phi)\mathbf{u}_i^*\\ &+\frac{L}{d}\mathrm{Fr}(\mathbf{m}_i^{\mathrm{s}})^*-\nabla^*\left(\frac{\phi_i}{\phi}\sigma_{\mathrm{e}}^*(\phi)\right),\quad i=1,\ldots,N,\end{aligned}\tag{2.12}$$

$$\nabla^*p^*=-\mathbf{k}-\frac{1}{1-\phi}\left(\alpha_1^*(\Phi)\mathbf{u}_1^*+\cdots+\alpha_N^*(\Phi)\mathbf{u}_N^*\right)-\mathrm{Fr}\frac{\mathrm{D}\mathbf{v}_{\mathrm{f}}^*}{\mathrm{D}t^*}+\frac{1}{1-\phi}\frac{d}{L}\frac{\mathrm{Fr}}{\mathrm{Re}}\nabla^*\cdot\left(\mathbf{T}_{\mathrm{f}}^{\mathrm{E}}\right)^*.\tag{2.13}$$

The values $d=10^{-4}\,\mathrm{m}$, $g=10\,\mathrm{m/s^2}$, $L=1\,\mathrm{m}$ (height of a settling vessel), $U=10^{-4}\,\mathrm{m/s}$ (settling velocity of a particle of the fastest species in an unbounded fluid), and $\nu_0^{\mathrm{f}}=10^{-6}\,\mathrm{m^2/s}$ (kinematic viscosity of water) are typical for the particulate systems considered here and imply $\mathrm{Fr}=10^{-9}$, $\mathrm{Re}=10^{-2}$, and $d/L=10^{-4}$. Since all viscous effects have been moved onto the fluid extra-stress tensor, we can assume $\nu_0^{\mathrm{s}}/\nu_0^{\mathrm{f}}\ll 1$. We assume that all dimensionless variables are of the order of magnitude $\mathcal{O}(1)$. Then we obtain, by discarding from (2.12) all terms that have a coefficient that is 10^{-5} or smaller, and discarding the advective acceleration term from (2.13) but retaining the viscous term, the following simplified linear momentum balances:

$$\alpha_i(\Phi)\mathbf{u}_i=\varrho_i\phi_i g\mathbf{k}+\phi_i\nabla p+\nabla\left(\frac{\phi_i}{\phi}\sigma_{\mathrm{e}}(\phi)\right),\quad i=1,\ldots,N,\tag{2.14}$$

$$\nabla p=-\varrho_{\mathrm{f}}g\mathbf{k}-\frac{1}{1-\phi}\left(\alpha_1(\Phi)\mathbf{u}_1+\cdots+\alpha_N(\Phi)\mathbf{u}_N\right)+\frac{1}{1-\phi}\nabla\cdot\mathbf{T}_{\mathrm{f}}^{\mathrm{E}},\tag{2.15}$$

which are written again in their dimensional forms. The small viscous term $\nabla\cdot\mathbf{T}_{\mathrm{f}}^{\mathrm{E}}$ is retained in (2.15) when this equation acts as an equation for the motion of the mixture. We shall comment on the necessity of viscous terms in the multidimensional case in section 2.7.

The term $\nabla\cdot\mathbf{T}_{\mathrm{f}}^{\mathrm{E}}$ is, however, deleted when (2.15) is inserted into (2.14), in order to produce a solvable linear system for the slip velocities $\mathbf{u}_1,\ldots,\mathbf{u}_N$. Thus, this system can be written as

$$\begin{aligned}&\frac{\alpha_i(\Phi)(1-\phi)}{\phi_i}\mathbf{u}_i+\sum_{j=1}^{N}\alpha_j(\Phi)\mathbf{u}_j\\ &=(1-\phi)\left[\left(\varrho_i-\varrho_{\mathrm{f}}\right)g\mathbf{k}+\frac{1}{\phi_i}\nabla\left(\frac{\phi_i}{\phi}\sigma_{\mathrm{e}}(\phi)\right)\right],\quad i=1,\ldots,N.\end{aligned}\tag{2.16}$$

2.6. Explicit formula for the slip velocities $\mathbf{u}_i$. Let $\varrho(\Phi):=(1-\phi)\varrho_{\mathrm{f}}+\phi_1\varrho_1+\cdots+\phi_N\varrho_N$ denote the local density of the mixture, and note that $\phi_1(\varrho_1-\varrho_{\mathrm{f}})+\cdots+\phi_N(\varrho_N-\varrho_{\mathrm{f}})=\varrho(\Phi)-\varrho_{\mathrm{f}}$. Then the following explicit equation for the slip velocities $\mathbf{u}_i$ as functions of Φ is obtained as the solution of the system (2.16), which follows from the Sherman–Morrison formula [22]:

$$\mathbf{u}_i=\frac{\phi_i}{\alpha_i(\Phi)}\left[\left(\varrho_i-\varrho(\Phi)\right)g\mathbf{k}+\frac{\sigma_{\mathrm{e}}(\phi)}{\phi_i}\nabla\left(\frac{\phi_i}{\phi}\right)+\frac{1-\phi}{\phi}\nabla\sigma_{\mathrm{e}}(\phi)\right],\quad i=1,\ldots,N.\tag{2.17}$$

Following [22] and being consistent with Masliyah [73] and Lockett and Bassoon [71], we choose $\phi_i/\alpha_i(\Phi)=-d_i^2V(\Phi)/(18\mu_{\mathrm{f}})$, where μ_{f} is the viscosity of the pure fluid, and

the hindered settling factor $V(\Phi)$ can, for example, be chosen as $V(\Phi) = (1-\phi)^{n(\Phi)-2}$ [86]. Since the dependence of n on Φ is through wall effects, which are small when d is very small compared to the diameter of the settling vessel, we may limit the analysis to formulas of the type $V(\Phi) = V(\phi)$ and obtain

$$\mathbf{u}_i = -\frac{d_i^2}{18\mu_{\mathrm{f}}} V(\phi)\left[\big(\varrho_i - \varrho(\Phi)\big) g\mathbf{k} + \frac{\sigma_{\mathrm{e}}(\phi)}{\phi_i}\nabla\Big(\frac{\phi_i}{\phi}\Big) + \frac{1-\phi}{\phi}\nabla\sigma_{\mathrm{e}}(\phi)\right], \quad i = 1, \dots, N. \tag{2.18}$$

The generic assumption to ensure hyperbolicity, which is satisfied by $V(\phi) = (1-\phi)^{n-2}$, $n > 2$, is

$$V(\phi) > 0, \quad V'(\phi) < 0 \quad \text{for } 0 < \phi < \phi_{\max}. \tag{2.19}$$

2.7. Final form of the model equations. The final model equations are the continuity equations of the solids species and of the mixture ($\nabla \cdot \mathbf{q} = 0$), the linear momentum balance of the fluid (2.15), and the equations (2.18) for the slip velocities $\mathbf{u}_i$ derived from the linear momentum balances of the solid species. To derive explicit expressions for the fluxes $\phi_1\mathbf{v}_1, \dots, \phi_N\mathbf{v}_N$ appearing in these equations, we introduce the reduced densities $\bar{\varrho}_{\mathrm{s}} := \varrho_{\mathrm{s}} - \varrho_{\mathrm{f}}$, where ϱ_{s} is the density of the solid particles if they differ only in size, $\bar{\varrho}_i := \varrho_i - \varrho_{\mathrm{f}}$, $i = 1, \dots, N$, the vector $\bar{\boldsymbol{\varrho}} := (\bar{\varrho}_1, \dots, \bar{\varrho}_N)^{\mathrm{T}}$, and the parameters $\mu := -gd_1^2/(18\mu_{\mathrm{f}})$ and $\delta_i := d_i^2/d_1^2$, $i = 1, \dots, N$, such that (2.18) reads

$$\mathbf{u}_i = \mu\delta_i V(\phi)\left[(\bar{\varrho}_i - \bar{\boldsymbol{\varrho}}^{\mathrm{T}}\Phi)\mathbf{k} + \frac{\sigma_{\mathrm{e}}(\phi)}{g\phi_i}\nabla\Big(\frac{\phi_i}{\phi}\Big) + \frac{1-\phi}{g\phi}\nabla\sigma_{\mathrm{e}}(\phi)\right], \quad i = 1, \dots, N. \tag{2.20}$$

From (2.2), we get $\phi_i\mathbf{v}_i = f_i^{\mathrm{M}}(\Phi)\mathbf{k} + \phi_i\mathbf{q} - \mathbf{a}_i(\Phi, \nabla\Phi)$ for $i = 1, \dots, N$, where the components of $\mathbf{f}^{\mathrm{M}}(\Phi)$ (corresponding to the MLB model for suspensions of rigid spheres) are given by

$$f_i(\Phi) = f_i^{\mathrm{M}}(\Phi) = \mu V(\phi)\phi_i\left[\delta_i(\bar{\varrho}_i - \bar{\boldsymbol{\varrho}}^{\mathrm{T}}\Phi) - \sum_{k=1}^{N}\delta_k\phi_k(\bar{\varrho}_k - \bar{\boldsymbol{\varrho}}^{\mathrm{T}}\Phi)\right], \quad i = 1, \dots, N. \tag{2.21}$$

If we let $\boldsymbol{\delta} := (\delta_1, \dots, \delta_N)^{\mathrm{T}}$, then the vectors $\mathbf{a}_i(\Phi, \nabla\Phi)$ are given by

$$\begin{aligned}\mathbf{a}_i(\Phi, \nabla\Phi) = -\frac{\mu V(\phi)}{g}\Bigg\{&\frac{(1-\phi)\phi_i}{\phi}(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\nabla\sigma_{\mathrm{e}}(\phi) \\ &+ \sigma_{\mathrm{e}}(\phi)\left[\delta_i\nabla\Big(\frac{\phi_i}{\phi}\Big) - \phi_i\left(\delta_1\nabla\Big(\frac{\phi_1}{\phi}\Big) + \cdots + \delta_N\nabla\Big(\frac{\phi_N}{\phi}\Big)\right)\right]\Bigg\}, \quad i = 1, \dots, N.\end{aligned} \tag{2.22}$$

The continuity equations for the solids, i.e., for the N unknowns ϕ_1 to ϕ_N, can then be written as

$$\frac{\partial\phi_i}{\partial t} + \nabla\cdot\big(\phi_i\mathbf{q} + f_i^{\mathrm{M}}(\Phi)\mathbf{k}\big) = \nabla\cdot\mathbf{a}_i(\Phi, \nabla\Phi), \quad i = 1, \dots, N. \tag{2.23}$$

Due to the property (2.7), $\mathbf{a}_i(\Phi, \nabla\Phi) = 0$ wherever $\phi \le \phi_{\mathrm{c}}$. At these concentrations, the system (2.23) turns into the first-order system of N scalar equations analyzed in

[22]. The final coupled set of model equations, valid in several space dimensions, is given by (2.23) and the equations

$$\nabla \cdot \mathbf{q} = 0, \tag{2.24}$$

$$\begin{aligned} \nabla p =& -\nabla \sigma_{\mathrm{e}}(\phi) - (\varrho_{\mathrm{f}} + \bar{\boldsymbol{\varrho}} \cdot \Phi) g \mathbf{k} + \frac{1}{1-\phi} \nabla \cdot \mathbf{T}_{\mathrm{f}}^{\mathrm{E}} \\ \equiv& -\nabla \sigma_{\mathrm{e}}(\phi) - \varrho(\Phi) g \mathbf{k} + \frac{1}{1-\phi} \nabla \cdot \mathbf{T}_{\mathrm{f}}^{\mathrm{E}}. \end{aligned} \tag{2.25}$$

Before discussing the role of (2.25), we set $N = 1$ to check consistency with the model of sedimentation of monodisperse flocculated suspensions [26]. With

$$f^{\mathrm{M}}(\phi) = -\frac{g d^2 \bar{\varrho}_{\mathrm{s}}}{18 \mu_{\mathrm{f}}} V(\phi) \phi (1-\phi)^2, \quad \mathbf{a}(\phi, \nabla\phi) = a(\phi) \nabla \phi = -\frac{f^{\mathrm{M}}(\phi)}{\bar{\varrho}_{\mathrm{s}} g \phi} \nabla \sigma_{\mathrm{e}}(\phi),$$

$$a(\phi) = -\frac{f^{\mathrm{M}}(\phi) \sigma_{\mathrm{e}}'(\phi)}{\bar{\varrho}_{\mathrm{s}} g \phi},$$

we see that (2.23) indeed reduces to the scalar equation

$$\frac{\partial \phi}{\partial t} + \nabla \cdot \big(\phi \mathbf{q} + f^{\mathrm{M}}(\phi) \mathbf{k} \big) = \nabla \cdot \big(a(\phi) \nabla \phi \big) \tag{2.26}$$

derived in [26]. It is easy to see that (2.26) is first-order hyperbolic for $\phi \le \phi_{\mathrm{c}}$ and $\phi = 1$, and second-order parabolic for $\phi_{\mathrm{c}} < \phi < 1$, and therefore a strongly degenerate parabolic equation.

Noting that $\mathbf{v}_{\mathrm{f}} = \mathbf{q} - (\phi_1 \mathbf{u}_1 + \cdots + \phi_N \mathbf{u}_N)$, we can rewrite $\mathbf{T}_{\mathrm{f}}^{\mathrm{E}}$ in terms of the mixture velocity $\mathbf{q}$ and the slip velocities $\mathbf{u}_i$, which are now given functions of Φ. For example, if we use the expression $\mathbf{T}_{\mathrm{f}}^{\mathrm{E}} = \mu(\phi)[\nabla \mathbf{v}_{\mathrm{f}} + (\nabla \mathbf{v}_{\mathrm{f}})^{\mathrm{T}} - (2/3)(\nabla \cdot \mathbf{v}_{\mathrm{f}})\mathbf{I}]$ as for a standard viscous-linear fluid but with a concentration-dependent viscosity function, then (2.25) can be rewritten in the form

$$\nabla p = -\varrho(\Phi) g \mathbf{k} + \frac{1}{1-\phi} \Big[\big(\nabla \mu(\phi) \big)^{\mathrm{T}} \big(\nabla \mathbf{q} + (\nabla \mathbf{q})^{\mathrm{T}} \big) + \mu(\phi) \Delta \mathbf{q} \Big] + \mathbf{g}(\Phi, \nabla\Phi, \nabla^2\Phi), \tag{2.27}$$

where $\mathbf{g}$ is a function depending on Φ and the derivatives of its components of up to second order. For pure fluid, i.e., when $\Phi \equiv 0$ (and thus $\mathbf{q} \equiv \mathbf{v}_{\mathrm{f}}$), (2.24) and (2.25) form the Stokes system for an incompressible fluid for the velocity $\mathbf{q}$ and the pressure p.

We now comment on the necessity of retaining a viscosity term, such as $\mu(\phi)\Delta\mathbf{q}$ in (2.25) or (2.27). In fact, deleting *all* terms which are expected to be small according to the dimensional analysis would require that we consider the following equation instead of (2.25):

$$\nabla p = -\nabla \sigma_{\mathrm{e}}(\phi) - \varrho(\Phi) g \mathbf{k}. \tag{2.28}$$

To elucidate the consequences of (2.28), we take the curl of (2.28), which leads to $\partial \varrho(\Phi)/\partial x = \partial \varrho(\Phi)/\partial y = 0$, such that the local density of the mixture depends on height only [93]. For $N = 1$, the implications of this observation are well known [23, 93]. Although the concentration waves (kinematic waves) are one-dimensional, they are embedded in the three-dimensional mixture flow field $\mathbf{q}$. Since $\mathbf{q}$ does not appear in the field equation (2.28), the coupling between the flow field and the kinematic waves

has to be modeled by boundary conditions, which requires introducing boundary layers of sediment or streaming liquid. The resulting kinematic-wave theory has been useful in explaining the behavior of relatively dilute suspensions in vessels with inclined walls [93] or in centrifuges [90, 91]. In [23], this approach is extended to monodisperse suspensions with compressible sediments, for which numerical solutions can be readily obtained. However, it is also shown in [23] that the kinematic-wave theory does not lead to a mathematically well-posed problem, and that this shortcoming is due to the absence of the aforementioned coupling between kinematic waves and the flow field in (2.28). On the other hand, in [24], energy estimates for slight variants of the coupled system (2.23)–(2.25) with $N = 1$ are obtained. These estimates lead to existence and stability results, and follow from the viscosity term in (2.25).

We now consider one space dimension, for which we get $\partial q/\partial z = 0$, and only (2.23) needs to be solved, since q is given by boundary conditions and (2.25) turns into an equation for the pore pressure p, which permits us to calculate this quantity a posteriori from $\phi_1, \dots, \phi_N$.

2.8. Initial and boundary conditions in one space dimension. In a closed one-dimensional vessel, the mixture velocity at the bottom vanishes; hence $q \equiv 0$, and the remaining equations that actually have to be solved are the system of convection-diffusion equations

$$\frac{\partial \phi_i}{\partial t} + \frac{\partial f_i^{\mathrm{M}}(\Phi)}{\partial z} = \frac{\partial}{\partial z}\left[a_i\left(\Phi, \frac{\partial \Phi}{\partial z}\right)\right], \quad i = 1, \dots, N, \tag{2.29}$$

together with an initial concentration distribution and zero flux boundary conditions, i.e.,

$$\Phi(z, 0) = \Phi^0(z) \in \mathcal{D}_{\phi_{\max}}, \ \ 0 \le z \le L, \tag{2.30}$$

$$\phi_i v_i = f_i^{\mathrm{M}}(\Phi) - a_i\left(\Phi, \frac{\partial \Phi}{\partial z}\right) = 0 \quad \text{for } z = 0 \text{ and } z = L,\ i = 1, \dots, N. \tag{2.31}$$

3. Hyperbolicity of the first-order system. We now assume $\varrho_1 = \cdots = \varrho_N = \varrho_{\mathrm{s}}$, so that the components of $\mathbf{f}^{\mathrm{M}}(\Phi)$ are

$$f_i^{\mathrm{M}}(\Phi) = \mu \bar{\varrho}_{\mathrm{s}} V(\phi)(1 - \phi)(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\phi_i, \quad i = 1, \dots, N, \tag{3.1}$$

and we denote by $P(\lambda)$ the characteristic polynomial of $\mathbf{J} := (\mu\bar{\varrho}_{\mathrm{s}})^{-1}\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$, where $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi) = (\partial f_i^{\mathrm{M}}(\Phi)/\partial\phi_j)_{i,j=1,\dots,N}$ is the Jacobian of $\mathbf{f}^{\mathrm{M}}(\Phi)$. We now derive a closed algebraic expression for $P(\lambda)$. We can write $(\mu\bar{\varrho}_{\mathrm{s}})^{-1}\partial f_i^{\mathrm{M}}(\Phi)/\partial\phi_j = \gamma_j^i(\Phi)\phi_i + \gamma^i(\Phi)\delta_{ij}$ for $i, j = 1, \dots, N$, where

$$\gamma^i(\Phi) := V(\phi)(1 - \phi)(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi), \quad i = 1, \dots, N, \tag{3.2}$$

$$\gamma_j^i(\Phi) := \big(V(\phi)(1 - \phi)\big)'(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi) - V(\phi)(1 - \phi)\delta_j, \quad i, j = 1, \dots, N. \tag{3.3}$$

The characteristic polynomial can be written as

$$P(\lambda) := \det(\mathbf{J} - \lambda\mathbf{I}) = \begin{vmatrix} \gamma_1^1\phi_1 + \gamma^1 - \lambda & \gamma_2^1\phi_1 & \cdots & \gamma_N^1\phi_1 \\ \gamma_1^2\phi_2 & \gamma_2^2\phi_2 + \gamma^2 - \lambda & \cdots & \gamma_N^2\phi_2 \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_1^N\phi_N & \gamma_2^N\phi_N & \cdots & \gamma_N^N\phi_N + \gamma^N - \lambda \end{vmatrix}. \tag{3.4}$$

In what follows, we omit the argument Φ and, for later use, note that $\gamma^i - \gamma^l = V(\phi)(1-\phi)(\delta_i - \delta_l)$, which due to $\delta_1 > \delta_2 > \cdots > \delta_N$ implies $\gamma^N < \gamma^{N-1} < \cdots < \gamma^1$. Moreover, we observe that

$$\gamma_j^1 - \gamma_k^1 = \cdots = \gamma_j^N - \gamma_k^N = -V(\phi)(1-\phi)(\delta_j - \delta_k), \quad j,k = 1,\ldots,N,$$
$$\gamma_1^j - \gamma_1^k = \cdots = \gamma_N^j - \gamma_N^k = \big(V(\phi)(1-\phi)\big)'(\delta_j - \delta_k), \quad j,k = 1,\ldots,N.$$

The common values of $\gamma_j^i - \gamma_k^i$ and $\gamma_i^j - \gamma_i^k$ for all $i = 1,\ldots,N$, $j,k = 1,\ldots,N$, will be denoted by $\gamma_{j,k}$ and $\gamma^{j,k}$, respectively. Since $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ and $\mathbf{A}(\Phi)$ have similar structure and therefore similar characteristic polynomials, it is convenient for later use to prove the following lemma separately.

LEMMA 3.1. *The polynomial $P(\lambda)$ defined in* (3.4) *satisfies*

$$P(\lambda) = \left\{1 + \sum_{m=1}^{N} \frac{\phi_m \gamma_m^m}{\gamma^m - \lambda} - \sum_{m=1}^{N} \frac{\phi_m}{\gamma^m - \lambda} \sum_{l=1}^{N} \frac{\phi_l \gamma_{l,N} \gamma^{l,m}}{\gamma^l - \lambda}\right\} \prod_{k=1}^{N} (\gamma^k - \lambda). \tag{3.5}$$

Proof. In this proof we merely use the definitions of $\gamma_{j,k}$ and $\gamma^{j,k}$ in terms of the γ_j^i's and γ_j's. Subtracting column N from columns 1 to $N-1$ in (3.4) yields

$$P(\lambda) = \begin{vmatrix} \gamma_{1,N}\phi_1 + \gamma^1 - \lambda & \cdots & \gamma_{N-1,N}\phi_1 & \gamma_N^1 \phi_1 \\ \vdots & \ddots & \vdots & \vdots \\ \gamma_{1,N}\phi_{N-1} & \cdots & \gamma_{N-1,N}\phi_{N-1} + \gamma^{N-1} - \lambda & \gamma_N^{N-1}\phi_{N-1} \\ \gamma_{1,N}\phi_N - \gamma^N + \lambda & \cdots & \gamma_{N-1,N}\phi_N - \gamma^N + \lambda & \gamma_N^N \phi_N + \gamma^N - \lambda \end{vmatrix}. \tag{3.6}$$

Expanding this determinant on the last row, we get

$$P(\lambda) = X + (\gamma^N - \lambda)(-1)^N \big(Y_1 - Y_2 + Y_3 - \cdots + (-1)^N Y_{N-1}\big), \tag{3.7}$$

where X and Y_m are the determinants obtained from the determinant in (3.6) by replacing the last row by $(\gamma_{1,N}\phi_N, \ldots, \gamma_{N-1,N}\phi_N, \gamma_N^N\phi_N + \gamma^N - \lambda)$ and by deleting the last row and the mth column, $m = 1,\ldots,N-1$, respectively. Multiplying the last row in X with $(-\phi_i/\phi_N)$ and adding the result to the ith row, $i = 1,\ldots,N-1$, leads to

$$X = \begin{vmatrix} \gamma^1 - \lambda & \cdots & 0 & \phi_1\big(\gamma^{1,N} - (\gamma^N - \lambda)/\phi_N\big) \\ \vdots & \ddots & \vdots & \vdots \\ 0 & \cdots & \gamma^{N-1} - \lambda & \phi_{N-1}\big(\gamma^{N-1,N} - (\gamma^N - \lambda)/\phi_N\big) \\ \gamma_{1,N}\phi_N & \cdots & \gamma_{N-1,N}\phi_N & \gamma_N^N\phi_N + \gamma^N - \lambda \end{vmatrix}.$$

Expanding X on the last row yields

$$X = \left(\gamma_N^N\phi_N + \gamma^N - \lambda - \phi_N \sum_{m=1}^{N-1} \frac{\phi_m \gamma_{m,N}}{\gamma^m - \lambda}\left(\gamma^{m,N} - \frac{\gamma^N - \lambda}{\phi_N}\right)\right) \prod_{k=1}^{N-1} (\gamma^k - \lambda). \tag{3.8}$$

Furthermore, we have $Y_m = (-1)^{N-1-m}\tilde{Y}_m$, where

$$\tilde{Y}_m = \begin{vmatrix} \gamma_{1,N}\phi_1 + \gamma^1 - \lambda & \cdots & \gamma_{m-1,N}\phi_1 & \gamma_{m+1,N}\phi_1 & \cdots & \gamma_{N-1,N}\phi_1 & \gamma_N^1\phi_1 \\ \vdots & \ddots & \vdots & \vdots & & \vdots & \vdots \\ \gamma_{1,N}\phi_{m-1} & \cdots & \gamma_{m-1,N}\phi_{m-1} + \gamma^{m-1} - \lambda & \gamma_{m+1,N}\phi_{m-1} & \cdots & \gamma_{N-1,N}\phi_{m-1} & \gamma_N^{m-1}\phi_{m-1} \\ \gamma_{1,N}\phi_{m+1} & \cdots & \gamma_{m-1,N}\phi_{m+1} & \gamma_{m+1,N}\phi_{m+1} + \gamma^{m+1} - \lambda & \cdots & \gamma_{N-1,N}\phi_{m+1} & \gamma_N^{m+1}\phi_{m+1} \\ \vdots & & \vdots & \vdots & \ddots & \vdots & \vdots \\ \gamma_{1,N}\phi_{N-1} & \cdots & \gamma_{m-1,N}\phi_{N-1} & \gamma_{m+1,N}\phi_{N-1} & \cdots & \gamma_{N-1,N}\phi_{N-1} + \gamma^{N-1} - \lambda & \gamma_N^{N-1}\phi_{N-1} \\ \gamma_{1,N}\phi_m & \cdots & \gamma_{m-1,N}\phi_m & \gamma_{m+1,N}\phi_m & \cdots & \gamma_{N-1,N}\phi_m & \gamma_N^m\phi_m \end{vmatrix},$$

which implies

$$Y_m = (-1)^{N-1-m}\frac{\phi_m}{\gamma^m - \lambda}\left(\gamma_N^m - \sum_{l=1}^{N-1}\frac{\gamma_{l,N}\gamma^{l,m}\phi_l}{\gamma^l - \lambda}\right)\prod_{k=1}^{N-1}(\gamma^k - \lambda),$$

$$m = 1, \dots, N-1. \tag{3.9}$$

Inserting (3.8) and (3.9) into (3.7), we get

$$\begin{aligned} P(\lambda) =& \left\{\gamma_N^N\phi_N + \gamma^N - \lambda - \phi_N\sum_{m=1}^{N-1}\frac{\phi_m}{\gamma^m - \lambda}\gamma_{m,N}\left(\gamma^{m,N} - \frac{\gamma^N - \lambda}{\phi_N}\right)\right. \\ &\left. + (\gamma^N - \lambda)\sum_{m=1}^{N-1}\frac{\phi_m}{\gamma^m - \lambda}\left(\gamma_N^m - \sum_{l=1}^{N-1}\phi_l\frac{\gamma_{l,N}\gamma^{l,m}}{\gamma^l - \lambda}\right)\right\}\prod_{k=1}^{N-1}(\gamma^k - \lambda) \\ =& \left\{1 - \frac{\phi_N}{\gamma^N - \lambda}\sum_{m=1}^{N-1}\frac{\phi_m\gamma_{m,N}\gamma^{m,N}}{\gamma^m - \lambda} + \sum_{m=1}^{N-1}\frac{\phi_m\gamma_{m,N}}{\gamma^m - \lambda}\right. \\ &\left. + \sum_{m=1}^{N}\frac{\phi_m\gamma_N^m}{\gamma^m - \lambda} - \sum_{m=1}^{N-1}\frac{\phi_m}{\gamma^m - \lambda}\sum_{l=1}^{N-1}\frac{\phi_l\gamma_{l,N}\gamma^{l,m}}{\gamma^l - \lambda}\right\}\prod_{l=1}^{N}(\gamma^l - \lambda). \end{aligned} \tag{3.10}$$

The upper index of summation in the second sum in the second equation of (3.10) can be changed to N since $\gamma_{N,N} = 0$, and the second and third sum can be combined into one using $\gamma_{m,N} + \gamma_N^m = \gamma_m^m$. Furthermore, the first and the fourth sums can be combined into one by changing the upper index of summation for m in the fourth sum from $N-1$ to N, from which we obtain (3.5). ∎

We can now prove the following lemma.

LEMMA 3.2. *Let $\lambda \in \mathbb{R}$ and $\delta(\lambda) := (V(\phi)(1-\phi))^{-1}\lambda + \boldsymbol{\delta}^{\mathrm{T}}\Phi$. Then $P(\lambda)$ is given by*

$$\begin{aligned} P(\lambda) =& \left\{V(\phi)(1-\phi) + \sum_{m=1}^{N}\frac{\phi_m}{\delta_m - \delta(\lambda)}\left[-\delta_m V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'\right.\right. \\ &\left.\left. \times\left(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi + \sum_{l=1}^{N}\frac{\delta_l\phi_l(\delta_l - \delta_m)}{\delta_l - \delta(\lambda)}\right)\right]\right\}\big(V(\phi)(1-\phi)\big)^{N-1}\prod_{k=1}^{N}\big(\delta_k - \delta(\lambda)\big). \end{aligned} \tag{3.11}$$

This expression is also well defined for $\lambda \in \{\gamma^1, \dots, \gamma^N\}$ and reads for $k = 1, \dots, N$ as

$$P(\gamma^k) = \phi_k\delta_k\Big\{\big(V(\phi)(1-\phi)\big)' - V(\phi)\Big\}\big(V(\phi)\big)^{N-1}(1-\phi)^N\prod_{\substack{l=1 \\ l\neq k}}^{N}(\delta_l - \delta_k). \tag{3.12}$$

Proof. Using $\gamma^m - \lambda = (\delta_m - \delta(\lambda))V(\phi)(1-\phi)$ and the definitions of $\gamma_{l,N}$ and $\gamma^{l,m}$, we get

(3.13)

$$\begin{aligned}
P(\lambda) =& \Bigg\{ 1 + \sum_{m=1}^{N} \frac{\phi_m[(V(\phi)(1-\phi))'(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi) - V(\phi)(1-\phi)\delta_m]}{V(\phi)(1-\phi)(\delta_m - \delta(\lambda))} + \frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)} \\
&\times \sum_{m=1}^{N}\sum_{l=1}^{N} \frac{\phi_m\phi_l(\delta_l^2 - \delta_l\delta_m - \delta_l\delta_N + \delta_m\delta_N)}{(\delta_m - \delta(\lambda))(\delta_l - \delta(\lambda))} \Bigg\} \big(V(\phi)(1-\phi)\big)^N \prod_{k=1}^{N} \big(\delta_k - \delta(\lambda)\big) \\
=& \Bigg\{ V(\phi)(1-\phi) + \sum_{m=1}^{N} \frac{\phi_m}{\delta_m - \delta(\lambda)} \Bigg[-V(\phi)(1-\phi)\delta_m + \big(V(\phi)(1-\phi)\big)' \\
&\times \left(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi + \sum_{l=1}^{N} \frac{\delta_l\phi_l(\delta_l - \delta_m)}{\delta_l - \delta(\lambda)} \right) \Bigg] \Bigg\} \big(V(\phi)(1-\phi)\big)^{N-1} \prod_{k=1}^{N} \big(\delta_k - \delta(\lambda)\big),
\end{aligned}$$

which is (3.11). This expression can be rewritten as

$$\begin{aligned}
P(\lambda) =& \prod_{l=1}^{N} (\gamma^l - \lambda) \\
&+ \Bigg\{ \sum_{m=1}^{N} \phi_m \Big[-\delta_m V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi) \Big] \prod_{\substack{l=1 \\ l\neq m}}^{N} \big(\delta_l - \delta(\lambda)\big) \\
&+ \big(V(\phi)(1-\phi)\big)' \sum_{m=1}^{N}\sum_{l=1}^{N} \phi_m\phi_l\delta_l(\delta_l - \delta_m) \prod_{\substack{n=1 \\ n\neq m,l}}^{N} \big(\delta_n - \delta(\lambda)\big) \Bigg\} V(\phi)(1-\phi)^{N-1}.
\end{aligned}$$

For $\lambda = \gamma^k$ the first product vanishes, and in the first sum only the summand with $m = k$ and in the second sum only the summands with $m = k$ or $l = k$ do not vanish. This implies

$$\begin{aligned}
P(\gamma^k) =& \Bigg\{ \phi_k \Big[-\delta_k V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'(\delta_k - \boldsymbol{\delta}^{\mathrm{T}}\Phi) \Big] \prod_{\substack{l=1 \\ l\neq k}}^{N} (\delta_l - \delta_k) \\
&+ \big(V(\phi)(1-\phi)\big)' \Bigg[\phi_k \sum_{l=1}^{N} \Bigg(\delta_l\phi_l(\delta_l - \delta_k) \prod_{\substack{n=1 \\ n\neq k,l}}^{N} (\delta_n - \delta_k) \Bigg) \\
&+ \sum_{m=1}^{N} \Bigg(\phi_m\delta_k\phi_k(\delta_k - \delta_m) \prod_{\substack{n=1 \\ n\neq k,m}}^{N} (\delta_n - \delta_k) \Bigg) \Bigg] \Bigg\} \big(V(\phi)(1-\phi)\big)^{N-1} \\
=& \Big\{ -\delta_k\phi_k V(\phi)(1-\phi) + \delta_k\phi_k\big(V(\phi)(1-\phi)\big)' - \phi_k\boldsymbol{\delta}^{\mathrm{T}}\Phi\big(V(\phi)(1-\phi)\big)' \\
&+ \phi_k\boldsymbol{\delta}^{\mathrm{T}}\Phi\big(V(\phi)(1-\phi)\big)' - \delta_k\phi_k\phi\big(V(\phi)(1-\phi)\big)' \Big\} \\
&\times \big(V(\phi)(1-\phi)\big)^{N-1} \prod_{\substack{l=1 \\ l\neq k}}^{N} (\delta_l - \delta_k),
\end{aligned}$$

from which (3.12) can be read off immediately. ∎

THEOREM 3.3. *If* $\varrho_1 = \cdots = \varrho_N = \varrho_s$, $\delta_1 > \delta_2 > \cdots > \delta_N$, *and* $\Phi \in \mathcal{D}^0_{\phi_{\max}}$, *then the system* (1.4) *is strictly hyperbolic; i.e., the Jacobian* $\boldsymbol{\mathcal{J}}_{\mathbf{f}^M}(\Phi)$ *has* N *distinct real eigenvalues.*

Proof. From (3.12) we see that

$$P(\gamma^k) = C_k\big(V(\phi)\big)^{N-1}(1-\phi)^N \prod_{\substack{m=1\\ m\neq k}}^{N} (\delta_m - \delta_k), \quad k = 1, \dots, N,$$

with $C_k := \delta_k\phi_k(V'(\phi)(1-\phi) - 2V(\phi))$. Since $C_1, \dots, C_N < 0$ on $\mathcal{D}^0_{\phi_{\max}}$ due to (2.19), we have

$$\operatorname{sgn}\big(P(\gamma^k)\big) = -\operatorname{sgn}\left(\prod_{\substack{m=1\\ m\neq k}}^{N} (\delta_m - \delta_k)\right) = -\operatorname{sgn}\left(\prod_{m=k+1}^{N} (\delta_m - \delta_k)\right) = (-1)^{N-k+1}.$$

Consequently, we have shown that $\operatorname{sgn}(P(\gamma^i)) = (-1)^{N+1-i}$ for $i = 1, \dots, N$. Whether N is even or odd, we have $P(\lambda) \to \infty$ as $\lambda \to -\infty$ and $P(\gamma^N) < 0$. In view of $\gamma^N < \gamma^{N-1} < \cdots < \gamma^1$ and since $P(\gamma^N) < 0$, there exists a number $\lambda_N < \gamma^N$ with $P(\lambda_N) = 0$. Furthermore, $\operatorname{sgn}(P(\gamma^i)) = (-1)^{N+1-i}$ implies that there exist $N-1$ numbers $\lambda_i \in (\gamma^{i+1}, \gamma^i)$, $i = 1, \dots, N-1$, with $P(\lambda_i) = 0$. This shows that $P(\lambda) = \det(\mathbf{J} - \lambda\mathbf{I})$ has N roots $\lambda_1, \dots, \lambda_N$ satisfying

$$\lambda_N < \gamma^N < \lambda_{N-1} < \gamma^{N-1} < \cdots < \lambda_2 < \gamma^2 < \lambda_1 < \gamma^1. \tag{3.14}$$

Thus the system (1.4) is strictly hyperbolic for all $\Phi \in \mathcal{D}^0_{\phi_{\max}}$, and Theorem 3.3 is proved. ∎

The statement of Theorem 3.3 can still be improved. In fact, it is desirable to have lower and upper bounds for all eigenvalues of $\boldsymbol{\mathcal{J}}_{\mathbf{f}^M}(\Phi)$. However, in (3.14) a lower bound for the eigenvalue λ_N of $\mathbf{J}$ is still lacking. The following theorem shows that by evaluating $P(\lambda)$ at a suitable number $\gamma^\infty < \gamma^1$ it is indeed possible to provide that bound.

THEOREM 3.4. *Define* $\gamma^\infty := -2\boldsymbol{\delta}^{\mathrm{T}}\Phi V(\phi)(1-\phi) + (V(\phi)(1-\phi))'(\boldsymbol{\delta}^{\mathrm{T}}\Phi + \phi)$. *Then, under the conditions of Theorem* 3.3, *the eigenvalues* $\nu_1(\Phi), \dots, \nu_N(\Phi)$ *of* $\boldsymbol{\mathcal{J}}_{\mathbf{f}^M}(\Phi)$ *satisfy*

$$\nu_i(\Phi) \in \big(\mu\bar{\varrho}_s V(\phi)(1-\phi)(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi), \mu\bar{\varrho}_s V(\phi)(1-\phi)(\delta_{i+1} - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\big), \quad i = 1, \dots, N-1, \tag{3.15}$$

$$\nu_N(\Phi) \in \big(\mu\bar{\varrho}_s V(\phi)(1-\phi)(\delta_N - \boldsymbol{\delta}^{\mathrm{T}}\Phi), \mu\bar{\varrho}_s\gamma^\infty\big). \tag{3.16}$$

Proof. We first evaluate $P(\lambda)$ assuming that $\delta(\lambda) < 0$. Moreover, to estimate the factor in curled brackets in the second equation of (3.13), we use $(V(\phi)(1-\phi))'/V(\phi)(1-\phi) < 0$ to justify deleting $-\delta_m$ and replacing δ_l^2 by δ_l in the last sum. Furthermore, we use $1/(\delta_m - \delta(\gamma^\infty)) < -1/\delta(\gamma^\infty)$ in several instances, which leads to

$$\begin{aligned}
&1 + \sum_{m=1}^{N} \frac{\phi_m}{\delta_m - \delta(\lambda)}\left[-\delta_m + \frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)}\left(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi + \sum_{l=1}^{N} \frac{\delta_l\phi_l(\delta_l - \delta_m)}{\delta_l - \delta(\lambda)}\right)\right] \\
&\geq 1 - \frac{\boldsymbol{\delta}^{\mathrm{T}}\Phi}{\delta(\lambda)}\left(\frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)} - 1\right) \\
&\quad + \frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)}\left(\frac{\phi}{\delta(\lambda)^2}\sum_{l=1}^{N}\delta_l\phi_l - \boldsymbol{\delta}^{\mathrm{T}}\Phi\sum_{m=1}^{N}\frac{\phi_m}{\delta_m - \delta(\lambda)}\right).
\end{aligned}$$

If we delete the last sum, the left-hand part of this inequality will remain positive whenever

$$\delta^2(\lambda) + \delta(\lambda)\boldsymbol{\delta}^{\mathrm{T}}\Phi\left[1 - \frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)}\right] + \boldsymbol{\delta}^{\mathrm{T}}\Phi\phi\frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)} > 0.$$

This can be achieved by letting $\lambda = \gamma^\infty$ such that

$$\delta(\gamma^\infty) = \boldsymbol{\delta}^{\mathrm{T}}\Phi\left[\frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)} - 1\right] + \frac{(V(\phi)(1-\phi))'}{V(\phi)(1-\phi)}\phi.$$

In fact, making obvious simplifications, we then obtain $\phi(\phi + \boldsymbol{\delta}^{\mathrm{T}}\Phi) > 0$, and the inequality is proved. Since $\gamma^\infty < \gamma^N$, $P(\gamma^N) < 0$, and $P(\gamma^\infty) > 0$, the smallest eigenvalue λ_N of $\mathbf{J}$ satisfies $\gamma^\infty < \lambda_N < \gamma^N$. Combining this with (3.14) and recalling that the eigenvalues ν_i of $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ are given by $\nu_i = \mu\bar{\varrho}_{\mathrm{s}}\lambda_i$, $i = 1, \ldots, N$, we obtain the statement of Theorem 3.4. ∎

4. Properties of the diffusion matrix. Using

$$\frac{\partial}{\partial z}\left(\frac{\phi_i}{\phi}\right) = \frac{1}{\phi}\frac{\partial\phi_i}{\partial z} - \frac{\phi_i}{\phi^2}\left(\frac{\partial\phi_1}{\partial z} + \cdots + \frac{\partial\phi_N}{\partial z}\right) = \frac{1}{\phi}\left\{\frac{\partial\phi_i}{\partial z} - \frac{\phi_i}{\phi}\left(\frac{\partial\phi_1}{\partial z} + \cdots + \frac{\partial\phi_N}{\partial z}\right)\right\}$$

for $i = 1, \ldots, N$ and defining $W(\phi) := -\mu V(\phi)/(g\phi)$ and

(4.1)
$$\eta_{ij}(\Phi) := W(\phi)\left\{(1-\phi)\phi_i(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\sigma_{\mathrm{e}}'(\phi) + \left[\delta_i\delta_{ij} - \delta_j\phi_i - \frac{\phi_i}{\phi}(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\right]\sigma_{\mathrm{e}}(\phi)\right\}$$

for $i, j = 1, \ldots, N$, where $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ otherwise, we get from (2.22)

$$a_i\left(\Phi, \frac{\partial\Phi}{\partial z}\right) = \eta_{i1}(\Phi)\frac{\partial\phi_1}{\partial z} + \cdots + \eta_{iN}(\Phi)\frac{\partial\phi_N}{\partial z}, \quad i = 1, \ldots, N. \tag{4.2}$$

Defining the matrix $\mathbf{A}(\Phi) := (\eta_{ij}(\Phi))_{1\le i,j\le N}$ and taking $\mathbf{f} = \mathbf{f}^{\mathrm{M}}$, we can rewrite (2.29) in the form (1.2). We show that the eigenvalues of $\mathbf{A}(\Phi)$ are positive and pairwise distinct on $\mathcal{D}^0_{\phi_{\max}}\backslash\mathcal{D}_{\phi_{\mathrm{c}}}$ by evaluating the characteristic polynomial in a fashion similar to section 3. To this end, we first provide an explicit expression for $S(\lambda) := \det(W(\phi)^{-1}\mathbf{A}(\Phi) - \lambda\mathbf{I})$.

LEMMA 4.1. *Let $\delta^*(\lambda) := \lambda/\sigma_{\mathrm{e}}(\phi)$. Then the polynomial $S(\lambda)$ is given by*

$$\begin{aligned} S(\lambda) = &\left\{\sigma_{\mathrm{e}}(\phi) + \sum_{m=1}^{N}\frac{\phi_m}{\delta_m - \delta^*(\lambda)}\left[-\delta_m\sigma_{\mathrm{e}}(\phi) + \left((1-\phi)\sigma_{\mathrm{e}}'(\phi) - \frac{\sigma_{\mathrm{e}}(\phi)}{\phi}\right)\right.\right. \\ &\left.\left.\times\left(\delta_m - \boldsymbol{\delta}^{\mathrm{T}}\Phi + \sum_{l=1}^{N}\frac{\phi_l\delta_l(\delta_l - \delta_m)}{\delta_l - \delta^*(\lambda)}\right)\right]\right\}\big(\sigma_{\mathrm{e}}(\phi)\big)^{N-1}\prod_{k=1}^{N}\big(\delta_k - \delta^*(\lambda)\big). \end{aligned} \tag{4.3}$$

Proof. We write $\eta_{ij}(\Phi)/W(\phi) = s^i_j\phi_i + s^i\delta_{ij}$ for $1 \le i, j \le N$, where we define

$$s^i := \sigma_{\mathrm{e}}(\phi)\delta_i, \quad s^i_j := (1-\phi)(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\sigma_{\mathrm{e}}'(\phi) - \left(\delta_j + \frac{1}{\phi}(\delta_i - \boldsymbol{\delta}^{\mathrm{T}}\Phi)\right)\sigma_{\mathrm{e}}(\phi)$$

for $i,j=1,\dots,N$. Consequently, $S(\lambda)$ can be written as

$$S(\lambda)=\begin{vmatrix} s_1^1\phi_1+s^1-\lambda & s_2^1\phi_1 & \dots & s_N^1\phi_1 \\ s_1^2\phi_2 & s_2^2\phi_2+s^2-\lambda & \dots & s_N^2\phi_2 \\ \vdots & \vdots & \ddots & \vdots \\ s_1^N\phi_N & s_2^N\phi_N & \dots & s_N^N\phi_N+s^N-\lambda \end{vmatrix}.$$

Observe that the numbers s_j^i satisfy

$$s_j^i-s_k^i=-\sigma_{\rm e}(\phi)(\delta_j-\delta_k),\qquad s_i^j-s_i^k=(\delta_j-\delta_k)\left[(1-\phi)\sigma_{\rm e}'(\phi)-\frac{\sigma_{\rm e}(\phi)}{\phi}\right],\qquad i=1,\dots,N; \tag{4.4}$$

i.e., the right-hand parts of (4.4) do not depend on i. Therefore, we may introduce

$$s_{j,k}:=s_j^1-s_k^1=\cdots=s_j^N-s_k^N,\quad s^{j,k}:=s_1^j-s_1^k=\cdots=s_N^j-s_N^k,\quad j,k=1,\dots,N.$$

We can now easily provide an explicit expression for $S(\lambda)$ in terms of the s's, since the rules for the s's correspond to those for the γ's. Thus, replacing $V(\phi)(1-\phi)$ by $\sigma_{\rm e}(\phi)$, $(V(\phi)(1-\phi))'$ by $(1-\phi)\sigma_{\rm e}'(\phi)-\sigma_{\rm e}(\phi)/\phi$, $\delta(\lambda)$ by $\delta^*(\lambda)=\lambda/\sigma_{\rm e}(\phi)$, we obtain (4.3) by closely following the proofs of Lemma 3.1 and of (3.11) in Lemma 3.2. ∎

To localize the eigenvalues of $\mathbf{A}(\Phi)$, we need to evaluate $S(\lambda)$ at $\lambda=0$ and $\lambda=s^1,\dots,s^N$. Using the analogy between $P(\lambda)$ and $S(\lambda)$, we can easily prove the following lemma.

LEMMA 4.2. *The determinant of* $\mathbf{A}(\Phi)$ *is given by* $\det(\mathbf{A}(\Phi))=(W(\phi))^N S(0)$, *where*

$$S(0)=\delta_1\cdots\delta_N\big(\sigma_{\rm e}(\phi)\big)^{N-1}\sigma_{\rm e}'(\phi)\phi(1-\phi)^2\quad \text{for } 0\le\phi\le\phi_{\max} \text{ and } N\ge 2. \tag{4.5}$$

Moreover, for $k=1,\dots,N$ *we have*

$$S(s^k)=\phi_k\delta_k\left\{(1-\phi)\left[(1-\phi)\sigma_{\rm e}'(\phi)-\frac{\sigma_{\rm e}(\phi)}{\phi}\right]-\sigma_{\rm e}(\phi)\right\}\big(\sigma_{\rm e}(\phi)\big)^{N-1}\prod_{\substack{m=1\\ m\ne k}}^{N}(\delta_m-\delta_k). \tag{4.6}$$

Proof. We set $\lambda=\delta^*(\lambda)=0$ in (4.3). Then (4.5) follows from

$$\begin{aligned} S(0)=&\left\{\sigma_{\rm e}(\phi)+\sum_{m=1}^{N}\frac{\phi_m}{\delta_m}\left[-\delta_m\sigma_{\rm e}(\phi)+\left((1-\phi)\sigma_{\rm e}'(\phi)-\frac{\sigma_{\rm e}(\phi)}{\phi}\right)\right.\right.\\ &\left.\left.\times(\delta_m-\boldsymbol{\delta}^{\rm T}\Phi+\boldsymbol{\delta}^{\rm T}\Phi-\delta_m\phi)\right]\right\}\big(\sigma_{\rm e}(\phi)\big)^{N-1}\delta_1\cdots\delta_N\\ =&\left\{\sigma_{\rm e}(\phi)-\phi\sigma_{\rm e}(\phi)+(1-\phi)\phi\left((1-\phi)\sigma_{\rm e}'(\phi)-\frac{\sigma_{\rm e}(\phi)}{\phi}\right)\right\}\big(\sigma_{\rm e}(\phi)\big)^{N-1}\delta_1\cdots\delta_N. \end{aligned} \tag{4.7}$$

Equation (4.6) can then be derived by closely following the proof of (3.12) in Lemma 3.2. ∎

THEOREM 4.3. *Let* $G(\phi):=\phi(1-\phi)^2\sigma_{\rm e}'(\phi)-\sigma_{\rm e}(\phi)$, *and assume that* $V(\phi)\ne 0$ *for* $\phi<\phi_{\max}$ *and* $V(\phi)=0$ *otherwise. Then, for all* $\Phi\in\mathcal{D}^0_{\phi_{\max}}\backslash\mathcal{D}_{\phi_{\rm c}}$, *the matrix* $\mathbf{A}(\Phi)$ *has* N *distinct positive eigenvalues* $\Lambda_1,\dots,\Lambda_N$; *i.e., the system* (1.2) *is strictly parabolic on* $\mathcal{D}^0_{\phi_{\max}}\backslash\mathcal{D}_{\phi_{\rm c}}$. *Moreover, we have the following:*

(a) *If Φ is chosen such that $G(\phi) > 0$, then these eigenvalues satisfy*

$$\begin{aligned} 0 < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_N < \Lambda_N < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_{N-1} < \Lambda_{N-1} \\ < \cdots < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_1 < \Lambda_1 < W(\phi)\delta_1\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi). \end{aligned} \tag{4.8}$$

(b) *At those points Φ where $G(\phi) < 0$, we have*

$$\begin{aligned} 0 < W(\phi)\delta_N\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi) < \Lambda_N < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_N < \Lambda_{N-1} \\ < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_{N-1} < \cdots < \Lambda_1 < W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_1. \end{aligned} \tag{4.9}$$

(c) *If $G(\phi) = 0$, then the eigenvalues are given by $\Lambda_i = W(\phi)\sigma_{\mathrm{e}}(\phi)\delta_i$ for $i = 1, \ldots, N$.*

Proof. Using the function $G(\phi)$, we can rewrite (4.6) as

$$S(s^k) = \frac{\phi_k}{\phi}\delta_k G(\phi)\big(\sigma_{\mathrm{e}}(\phi)\big)^{N-1} \prod_{\substack{m=1 \\ m\neq k}}^{N} (\delta_m - \delta_k), \quad k = 1, \ldots, N. \tag{4.10}$$

This implies

$$\begin{aligned} \operatorname{sgn}\big(S(s^k)\big) &= \operatorname{sgn}\big(G(\phi)\big) \cdot \operatorname{sgn}\left(\prod_{\substack{m=1 \\ m\neq k}}^{N} (\delta_m - \delta_k) \right) \\ &= (-1)^{N-k} \operatorname{sgn}\big(G(\phi)\big), \quad k = 1, \ldots, N. \end{aligned} \tag{4.11}$$

Recall first that, for $\phi > \phi_{\mathrm{c}}$ and due to $\delta_1 > \delta_2 > \cdots > \delta_N$, we have $0 < s^N < s^{N-1} < \cdots < s^1$. If $\operatorname{sgn}(G(\phi)) = 1$, then $S(s^N) > 0$, $S(s^{N-1}) < 0$, and so on, until we obtain $S(s^2) > 0$ and $S(s^1) < 0$ if N is even and $S(s^2) < 0$ and $S(s^1) > 0$ if N is odd. Thus there exist $N - 1$ values

$$0 < s^N < \lambda_N < s^{N-1} < \lambda_{N-1} < s^{N-2} < \cdots < \lambda_3 < s^2 < \lambda_2 < s^1 < \lambda_1 \tag{4.12}$$

with $S(\lambda_2) = \cdots = S(\lambda_N) = 0$. Moreover, $S(\lambda) \to \infty$ for $\lambda \to \infty$ if N is even and $S(\lambda) \to -\infty$ if N is odd. Thus there exists an Nth number $\lambda_1 > s^1$ with $S(\lambda_1) = 0$. Since the determinant of a matrix is the product of its eigenvalues, which are all positive here, (4.7) implies

$$\begin{aligned} \lambda_1 = \frac{S(0)}{\lambda_2 \cdots \lambda_N} < \frac{S(0)}{s^2 \cdots s^N} &= \frac{\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi)(\sigma_{\mathrm{e}}(\phi))^{N-1}\delta_1 \cdots \delta_N}{\delta_2 \cdots \delta_N (\sigma_{\mathrm{e}}(\phi))^{N-1}} \\ &= \delta_1\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi). \end{aligned} \tag{4.13}$$

If $\operatorname{sgn}(G(\phi)) = -1$, then $S(s^N) < 0$, $S(s^{N-1}) > 0$, and so on, and $S(s^2) < 0$, $S(s^1) > 0$ if N is even, and $S(s^2) > 0$, $S(s^1) < 0$ if N is odd. This means that we have $N - 1$ values

$$s^N < \lambda_{N-1} < s^{N-1} < \lambda_{N-2} < s^{N-2} < \cdots < \lambda_1 < s^1 \tag{4.14}$$

with $S(\lambda_1) = \cdots = S(\lambda_{N-1}) = 0$. Since $S(s^N) < 0$ but $S(0) > 0$ due to Lemma 4.2, there exists an Nth value $\lambda_N \in (0, s^N)$ satisfying $S(\lambda_N) = 0$, and we have

$$\begin{aligned} \lambda_N = \frac{S(0)}{\lambda_1 \cdots \lambda_{N-1}} > \frac{S(0)}{s^1 \cdots s^{N-1}} &= \frac{\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi)(\sigma_{\mathrm{e}}(\phi))^{N-1}\delta_1 \cdots \delta_N}{\delta_1 \cdots \delta_{N-1} (\sigma_{\mathrm{e}}(\phi))^{N-1}} \\ &= \delta_N\phi(1-\phi)^2\sigma_{\mathrm{e}}'(\phi). \end{aligned} \tag{4.15}$$

The eigenvalues of $\mathbf{A}(\Phi)$ are given by $\Lambda_i = W(\phi)\lambda_i$, $i = 1, \ldots, N$. Thus, parts (a) and (b) of Theorem 4.3 follow from (4.12)–(4.15). Part (c) is the common limit for $G(\phi) \uparrow 0$ and $G(\phi) \downarrow 0$. □

Since the eigenvalues $\Lambda_1, \ldots, \Lambda_N$ are positive independent of the sign of $G(\phi)$, we see that the system (1.2) is strictly parabolic for all Φ satisfying $\phi_c < \phi < 1$, although, due to the properties of σ_e and W, at least $N - 1$ of these eigenvalues approach zero as $\phi \downarrow \phi_c$ or $\phi \uparrow \phi_{max}$.

5. Strongly degenerate parabolic problems. We have demonstrated that polydisperse sedimentation models taking into account compression effects give rise to strongly degenerate parabolic (also known as mixed hyperbolic-parabolic) systems of PDEs. The general theory of *uniformly parabolic* systems is an old subject and is by now well developed; see [42, 63, 104]. One can consult [100] for some special uniformly parabolic systems, as well as [36, 58, 85] for some results on parabolic systems with weaker parabolicity conditions. The general mathematical theory of *hyperbolic* systems is also fairly well developed (at least in one spatial dimension); see, for example, [32] and the references therein. On the other hand, to date there exists no general theory for *strongly degenerate parabolic* systems. However, the mathematical theory for *scalar* strongly degenerate parabolic equations has advanced significantly in the last few years. It is well known that nonlinear degenerate parabolic equations exhibit "hyperbolic phenomena" like finite speed of propagation or the appearance of interfaces. These effects are consequences of the partial loss of parabolicity. *Strongly* degenerate parabolic equations (e.g., those arising in the theory of sedimentation-consolidation processes) exhibit even more novel hyperbolic features such as the appearance of shock waves, loss of uniqueness, and the need for entropy conditions. Recall that a simple example of a strongly degenerate equation is a hyperbolic equation. Hence, strongly degenerate parabolic equations will in general possess discontinuous (weak) solutions. Moreover, discontinuous solutions are not uniquely determined by their initial (and boundary) data. In fact, an additional condition—the entropy condition—is needed to single out the physically relevant weak solution of the problem.

An entropy condition for strongly degenerate parabolic equations was first proposed in [118], which also established existence of an entropy solution by passing to the limit in a parabolic regularization. In the one-dimensional case, uniqueness of the entropy solution was proved in [119, 120]; see also [6, 7, 8]. Uniqueness of entropy solutions for multidimensional equations was obtained in the recent work [28] for a particular homogeneous boundary value problem. Extensions of this uniqueness result to the initial value problem can be found in [61, 62] for bounded entropy solutions (of more general equations). Uniqueness for unbounded entropy solutions and kinetic solutions is studied in [30] and [31], respectively. The inhomogeneous Dirichlet boundary value problem is treated in [72]. Some other boundary value problems arising in the theory of sedimentation-consolidation processes are studied in [17, 21, 25]. Weakly coupled systems of (strongly) degenerate parabolic equations are treated in [57].

Following up the recent development of a well-posedness theory for scalar strongly degenerate parabolic equations, there has also been a lot of activity on the design and analysis of numerical methods for such equations. Most of this activity can be seen as natural extensions of ideas and techniques from the hyperbolic numerical literature. Let us here mention the studies on monotone finite difference schemes [45], operator splitting methods (see [44] for an overview), finite volume schemes [46, 80], central finite difference schemes [64], the local discontinuous Galerkin method [33], and BGK

schemes [2, 12]. Numerical methods for parabolic systems (with weak degeneracy) are studied and analyzed in [60, 68]. Applications of operator splitting methods and finite difference schemes to scalar sedimentation-consolidation models can be found in [18] and [20], respectively.

In the next section, we will present and apply certain numerical schemes for systems of strongly degenerate parabolic equations. Except for [2], the available numerical literature has so far dealt with *scalar* strongly degenerate parabolic equations. Let us add that the generality in [2] is such that it does not include systems of the form considered in the present paper.

6. Numerical results. The Kurganov–Tadmor (KT) scheme [64] can be regarded as a refinement of the essentially nonoscillatory Nessyahu–Tadmor scheme [77], where the improvement is based on local estimates of the propagation velocities of the Riemann fan emerging from the cell boundaries during each time step. Thus, the accuracy of the resulting scheme depends on how accurately the eigenvalues of the Jacobian of the flux vector are determined. Since only for small systems can these eigenvalues be determined exactly, it is important for large N that sharp estimates can be obtained with low computational effort. The analysis of section 3 indeed provides sharp estimates for the first-order system of equations. Given the importance of these analytical results for the KT scheme, we give in what follows a rather compressed but complete description of this scheme. A general introduction to central schemes for systems of conservation laws is given in [103].

6.1. General difference scheme. Consider the computational domain $Q_T := [0,1] \times [0,T]$ and a rectangular grid defined by $z_j := j\Delta z$, $j = 0, \dots, J$, where J is an even integer and $\Delta z := 1/J$ is the width of a half-cell, and $t_n := n\Delta t$, $n = 0, \dots, \mathcal{N}$, where $\Delta t := T/\mathcal{N}$, $\mathcal{N} \in \mathbb{N}$, and $\lambda := \Delta t/(2\Delta z)$ is the fixed mesh-size ratio. (Thus, all grid-point indices are integers.) The (approximate) cell average of ϕ_i, $i = 1, \dots, N$, with respect to the cell $[z_j, z_{j+2}]$ at time t_n is denoted by $\bar\phi^n_{i,j}$, and we define $\bar\Phi^n_j := (\bar\phi^n_{1,j}, \dots, \bar\phi^n_{N,j})^{\mathrm{T}}$, $j = 1, 3, \dots, J-1$, $n = 0, 1, \dots, \mathcal{N}$. We assume that at time $t = t_n$, $n = 0, 1, \dots, \mathcal{N}-1$, the vector $\bar\Phi^n_j$ either has been calculated from the previous time step (for $n \ge 1$) or is given by the discretization of the initial condition,

$$\bar\phi^0_{i,j} := \frac{1}{2\Delta z} \int_{z_{j-1}}^{z_{j+1}} \phi^0_i(\zeta)\, d\zeta, \quad j = 1, 3, \dots, J-1, \quad i = 1, \dots, N.$$

For the interior cells, the general scheme ("interior scheme") is of the type

$$\bar\Phi^{n+1}_j = \bar\Phi^n_j - \lambda(\mathbf{h}^n_{j+1} - \mathbf{h}^n_{j-1}) + \lambda(\mathbf{p}^n_{j+1} - \mathbf{p}^n_{j-1}), \qquad \begin{matrix} j = 3, 5, \dots, J-3, \\ n = 0, \dots, \mathcal{N}-1, \end{matrix} \tag{6.1}$$

where $\mathbf{h}^n_{j\pm1}$ and $\mathbf{p}^n_{j\pm1}$ are approximations of the "hyperbolic" and "parabolic" fluxes $\mathbf{f}^{\mathrm{M}}$ and $\mathbf{a}$, respectively, through the boundaries of cell $I_j := [z_{j-1}, z_{j+1}]$ at time t_n. The detailed computation of these fluxes from the solution values at time t_n is described in section 6.2.

While the interior scheme (6.1) approximates the field equation (1.2), the boundary conditions (2.31) are discretized by setting $\mathbf{h}^n_0 - \mathbf{p}^n_0 = 0$ and $\mathbf{h}^n_J - \mathbf{p}^n_J = 0$ for $n = 0, \dots, \mathcal{N}-1$. Inserting this into (6.1), where we set $j = 1$ and $j = J-1$, we obtain the following "boundary scheme":

$$\begin{gathered} \bar\Phi^{n+1}_1 = \bar\Phi^n_1 - \lambda\mathbf{h}^n_2 + \lambda\mathbf{p}^n_2, \qquad \bar\Phi^{n+1}_{J-1} = \bar\Phi^n_{J-1} + \lambda\mathbf{h}^n_{J-2} - \lambda\mathbf{p}^n_{J-2}, \\ n = 0, \dots, \mathcal{N}-1. \end{gathered} \tag{6.2}$$

The extension of the CFL stability condition for the explicit KT scheme stated in [64] for scalar equations to the present case of a strongly degenerate parabolic-hyperbolic problem reads

$$\frac{\Delta t}{\Delta z}\max_{\mathcal{D}_{\phi_{\max}}}\rho\big(\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)\big)+\frac{\Delta t}{2\Delta z^2}\max_{\mathcal{D}_{\phi_{\max}}}\rho\big(\mathbf{A}(\Phi)\big)\le\frac{1}{4}, \tag{6.3}$$

where $\rho(\cdot)$ denotes the spectral radius. We view (6.3) as a *necessary* condition for the present explicit KT scheme to produce a physically relevant numerical result, and we emphasize that no rigorous convergence result is associated with (6.3). For that matter, an existence and uniqueness theory for the system (1.1) is still lacking.

6.2. Computation of the numerical fluxes. Given the vectors $\bar\Phi_j^n$, $j=1,3,\dots,J-1$, we calculate a piecewise linear reconstruction of the solution values at time t_n by determining the slope vector $\Phi_j'=(\phi_{1,j}',\dots,\phi_{N,j}')^{\mathrm{T}}$, $j=1,3,\dots,J-1$, whose components are defined by

$$\phi_{i,j}':=\begin{cases}0 & \text{for } j=1 \text{ and } j=J-1,\\ \mathrm{MM}\big(\theta(\bar\phi_{i,j}^n-\bar\phi_{i,j-2}^n),(\bar\phi_{i,j+2}^n-\bar\phi_{i,j-2}^n)/2,\\ \qquad\qquad \theta(\bar\phi_{i,j+2}^n-\bar\phi_{i,j}^n)\big) & \text{for } j=3,5,\dots,J-3\end{cases}$$

for $i=1,\dots,N$. Here $\mathrm{MM}(\cdot,\cdot,\cdot)$ is the minmod function given by $\mathrm{MM}(a,b,c)=\min(a,b,c)$ if $a,b,c>0$, $\mathrm{MM}(a,b,c)=\max(a,b,c)$ if $a,b,c<0$, and $\mathrm{MM}(a,b,c)=0$ otherwise. The extrapolated values of Φ at the cell boundaries z_j, $j=2,4,\dots,J-2$, are then given by

$$\Phi_j^{\mp}:=\bar\Phi_{j\mp1}^n\pm\frac{1}{2}\Phi_{j\mp1}',\qquad j=2,4,\dots,J-2,$$

and are used to calculate the local speeds of propagation

$$a_j^n:=\max\left\{\rho\left(\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi_j^-)\right),\rho\left(\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi_j^+)\right)\right\},\quad j=2,4,\dots,J-2. \tag{6.4}$$

Of course, it is feasible only for small N to use exact eigenvalues here. However, the analysis of section 3 provides estimates of the eigenvalues that can be used here (see section 6.3). Observe that, for each cell I_j, the solution of (1.4) with the piecewise linear initial data defined by $\bar\Phi_j^n$ and the slope vectors Φ_j' remains smooth for $t_n\le t\le t_{n+1}$ in the subinterval $[z_{j-1}+a_{j-1}^n\Delta t,z_{j+1}-a_{j+1}^n\Delta t]$ for $j=1,\dots,J$. Equipped with the numbers a_j^n and the vectors Φ_j', we next calculate the following vectors, which represent the parts of the cell averages pertaining to the left and right half-cells adjacent to $z=z_j$ that are mapped onto a smooth solution:

$$\Phi_{j,\mathrm{L}}^n:=\bar\Phi_{j-1}^n+\left(\frac{1}{2}-\lambda a_j^n\right)\Phi_{j-1}',\qquad \Phi_{j,\mathrm{R}}^n:=\bar\Phi_{j+1}^n-\left(\frac{1}{2}-\lambda a_j^n\right)\Phi_{j+1}'$$

for $j=2,4,\dots,J-2$. The vectors $\Phi_{j,\mathrm{L}}^n$ and $\Phi_{j,\mathrm{R}}^n$ are used to calculate the flux slope vectors

$$\mathbf{f}'(\Phi_{j,c}^n)=\big(f_1'(\Phi_{j,c}^n),\dots,f_N'(\Phi_{j,c}^n)\big)^{\mathrm{T}},\quad c=\mathrm{L},\mathrm{R},\quad j=2,4,\dots,J-2,$$

whose components are defined by

$$f_i'(\Phi_{2,\mathrm{L}}^n)=f_i'(\Phi_{J-2,\mathrm{L}}^n)=0,\qquad f_i'(\Phi_{2,\mathrm{R}}^n)=f_i'(\Phi_{J-2,\mathrm{R}}^n)=0,$$

and

$$f_i'(\Phi_{j,c}^n) := \mathrm{MM}\Big(\theta\big(f_i(\Phi_{j,c}^n) - f_i(\Phi_{j-2,c}^n)\big), \big(f_i(\Phi_{j+2,c}^n) - f_i(\Phi_{j-2,c}^n)\big)/2, \theta\big(f_i(\Phi_{j+2,c}^n) - f_i(\Phi_{j,c}^n)\big)\Big)$$

for $c = \mathrm{L}, \mathrm{R}$, $i = 1, \ldots, N$, and $j = 4, 6, \ldots, J-4$. We then calculate the predictor solution values

$$\Phi_{j,c}^{n+1/2} := \Phi_{j,c}^n - \frac{\lambda}{2}\mathbf{f}'(\Phi_{j,c}^n), \quad c = \mathrm{L}, \mathrm{R}, \quad j = 2, 4, \ldots, J-2,$$

at which the flux vector $\mathbf{f}$ is evaluated in order to calculate the new approximate values $\bar{\Psi}_j^{n+1}$, $j = 2, 3, \ldots, J-1, J$, of the solution at time t_{n+1}, which are referred to a nonuniform grid as follows. For $j = 2, 4, \ldots, J-2$, approximate cell averages $\bar{\Psi}_j^{n+1}$ referring to the intervals $[z_j - a_j^n \Delta t, z_j + a_j^n \Delta t]$, $j = 2, 4, \ldots, J-2$, are calculated by

$$\bar{\Psi}_j^{n+1} = \frac{1}{2}\big(\bar{\Phi}_{j-1}^n + \bar{\Phi}_{j+1}^n\big) + \frac{1 - \lambda a_j^n}{4}\big(\Phi_{j-1}' - \Phi_{j+1}'\big) - \frac{1}{2a_j^n}\Big[\mathbf{f}\big(\Phi_{j,\mathrm{R}}^{n+1/2}\big) - \mathbf{f}\big(\Phi_{j,\mathrm{L}}^{n+1/2}\big)\Big],$$

while the second family of approximate cell averages $\bar{\Psi}_j^{n+1}$ refers to the nonuniform cells $[z_{j-1} + a_{j-1}^n \Delta, z_{j+1} - a_{j+1}^n \Delta t] \subset I_j$, $j = 3, 5, \ldots, J-3$, and is calculated by

$$\bar{\Psi}_j^{n+1} = \bar{\Phi}_j^n - \frac{\lambda}{2}\big(a_{j+1}^n - a_{j-1}^n\big)\Phi_j' - \frac{\lambda}{1 - \lambda(a_{j-1}^n + a_{j+1}^n)}\Big[\mathbf{f}\big(\Phi_{j+1,\mathrm{L}}^{n+1/2}\big) - \mathbf{f}\big(\Phi_{j-1,\mathrm{R}}^{n+1/2}\big)\Big].$$

Using both families of nonuniform approximate cell averages, we determine the vector of discrete derivatives $\Psi_j' = (\Psi_{1,j}', \ldots, \Psi_{N,j}')^{\mathrm{T}}$ for $j = 2, 4, \ldots, J-2$, setting $\Psi_2' = \Psi_{J-2}' = 0$ and

$$\Psi_{i,j}' = \frac{1}{\Delta z}\mathrm{MM}\left(\theta\frac{\bar{\Psi}_{i,j}^{n+1} - \bar{\Psi}_{i,j-1}^{n+1}}{1 + \lambda(a_j^n - a_{j-2}^n)}, \frac{\bar{\Psi}_{i,j+1}^{n+1} - \bar{\Psi}_{i,j-1}^{n+1}}{2 + \lambda(2a_j^n - a_{j-2}^n - a_{j+2}^n)}, \theta\frac{\bar{\Psi}_{i,j+1}^{n+1} - \bar{\Psi}_{i,j}^{n+1}}{1 + \lambda(a_j^n - a_{j+2}^n)}\right)$$

for $i = 1, \ldots, N$ and $j = 4, 6, \ldots, J-4$, where $\theta \in [0, 2]$ is a parameter. Finally, we can calculate the desired numerical flux vectors

$$\mathbf{h}_j^n = \frac{1}{2}\Big[\mathbf{f}\big(\Phi_{j,\mathrm{R}}^{n+1/2}\big) + \mathbf{f}\big(\Phi_{j,\mathrm{L}}^{n+1/2}\big)\Big] - \frac{a_j^n}{2}\big(\bar{\Phi}_{j+1}^n - \bar{\Phi}_{j-1}^n\big) + \frac{a_j^n(1 - \lambda a_j^n)}{4}\big(\Phi_{j-1}' + \Phi_{j+1}'\big) + \lambda\Delta z\big(a_j^n\big)^2\Psi_j', \quad j = 2, 4, \ldots, J-2.$$

For the diffusion part, we approximate $\partial\Phi/\partial z(z_j, t_n)$ by the slope vector

$$\widetilde{\Phi}_j' = (\tilde{\phi}_{1,j}', \ldots, \tilde{\phi}_{N,j}')^{\mathrm{T}}$$

defined by $(\bar{\phi}_{i,j+1}^n - \bar{\phi}_{i,j-1}^n)/(2\Delta z)$ for $j = 2, 4, \ldots, J-2$ and $i = 1, \ldots, N$. Using the diffusion vector $\mathbf{a}(\Phi, \partial\Phi/\partial z)$ given by (4.2), we can calculate the numerical diffusion vectors by

$$\mathbf{p}_j^n = \frac{1}{2}\Big[\mathbf{a}\big(\bar{\Phi}_{j-1}, \widetilde{\Phi}_j'\big) + \mathbf{a}\big(\bar{\Phi}_{j+1}, \widetilde{\Phi}_j'\big)\Big], \quad j = 2, 4, \ldots, J-2. \tag{6.5}$$

6.3. Application to the model of polydisperse sedimentation with compression. In the numerical examples, we consider the standard Richardson and Zaki [86] hindered settling factor

$$V(\phi) = \begin{cases} 0 & \text{for } \phi \le 0 \text{ and } \phi \ge \phi_{\max}, \\ (1-\phi)^{n-2},\ n > 2, & \text{otherwise} \end{cases} \tag{6.6}$$

and the widely used power-law effective solid-stress formula

$$\sigma_{\mathrm{e}}(\phi) = \begin{cases} 0 & \text{for } \phi \le \phi_{\mathrm{c}}, \\ \sigma_0\big((\phi/\phi_{\mathrm{c}})^k - 1\big) & \text{for } \phi > \phi_{\mathrm{c}}, \end{cases} \quad \text{i.e.,} \quad \sigma_{\mathrm{e}}'(\phi) = \begin{cases} 0 & \text{for } \phi < \phi_{\mathrm{c}}, \\ (\sigma_0/\phi_{\mathrm{c}}^k) k \phi^{k-1} & \text{for } \phi > \phi_{\mathrm{c}}, \end{cases} \tag{6.7}$$

with parameters $\sigma_0 > 0$ and $k \ge 1$. Values of σ_0, ϕ_{c}, and k for real materials are given in [16, 105].

For our choice of $V(\phi)$ and under the mild assumption $\phi_{\max} > 1/n$, we may significantly sharpen the upper bound for the eigenvalues of $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ compared with the bound given by Theorem 3.4.

LEMMA 6.1. *For the hindered settling function* (6.6) *and* $\Phi \in \mathcal{D}^0_{1/n}$, *i.e.,* $\phi < 1/n < \phi_{\max}$, *the eigenvalues* $\nu_1(\Phi)$ *to* $\nu_N(\Phi)$ *of* $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ *satisfy* (3.15) *and*

$$\nu_N(\Phi) \in \big(\mu\bar{\varrho}_{\mathrm{s}} V(\phi)(1-\phi)(\delta_N - \boldsymbol{\delta}^{\mathrm{T}}\Phi), -\mu\bar{\varrho}_{\mathrm{s}} V(\phi)(1-\phi)\boldsymbol{\delta}^{\mathrm{T}}\Phi\big). \tag{6.8}$$

Proof. We set $\widetilde{\gamma}^{\infty} := -V(\phi)(1-\phi)\boldsymbol{\delta}^{\mathrm{T}}\Phi$ such that $\delta(\widetilde{\gamma}^{\infty}) = 0$. Using (3.11), we get

$$\begin{aligned} P(\widetilde{\gamma}^{\infty}) &= \left\{ V(\phi)(1-\phi) + \sum_{m=1}^{N} \frac{\phi_m}{\delta_m} \Big[-\delta_m V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'(1-\phi)\delta_m \Big] \right\} \\ &\qquad \times \big(V(\phi)(1-\phi)\big)^{N-1} \delta_1 \cdots \delta_N \\ &= \Big\{ V(\phi)(1-\phi) - \phi V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'\phi(1-\phi) \Big\} \\ &\qquad \times \big(V(\phi)(1-\phi)\big)^{N-1} \delta_1 \cdots \delta_N \\ &= \Big\{ V(\phi)(1-\phi) + \big(V(\phi)(1-\phi)\big)'\phi \Big\} (1-\phi)^N \big(V(\phi)\big)^{N-1} \delta_1 \cdots \delta_N. \end{aligned}$$

For $V(\phi) = (1-\phi)^{n-2}$, the expression in curled brackets is given by

$$\begin{aligned} (1-\phi)^{n-1} - (n-1)(1-\phi)^{n-2}\phi &= (1-\phi)^{n-2}\big((1-\phi) - (n-1)\phi\big) \\ &= (1-\phi)^{n-2}(1-n\phi), \end{aligned}$$

which is positive if and only if $\phi < 1/n$. In this case we thus have $P(\widetilde{\gamma}^{\infty}) > 0$. Since $\widetilde{\gamma}^{\infty} < \gamma^N$, $P(\gamma^N) < 0$, and we have now shown that $P(\widetilde{\gamma}^{\infty}) > 0$, the smallest eigenvalue λ_N of $\mathbf{J}$ satisfies $\widetilde{\gamma}^{\infty} < \lambda_N < \gamma^N$, which implies the statement of the lemma. ∎

Wherever $\phi < 1/n$, Lemma 6.1 can be used to estimate the local speeds of propagation (6.4) in the numerical method since, for our choice of $V(\phi)$, we then have that $\rho(\boldsymbol{\mathcal{J}}_{\mathbf{f}}(\Phi)) \le \mu\bar{\varrho}_{\mathrm{s}}(1-\phi)^{n-1} \max\{\boldsymbol{\delta}^{\mathrm{T}}\Phi, 1 - \boldsymbol{\delta}^{\mathrm{T}}\Phi\}$. Similarly, the eigenvalue bounds of Theorem 4.3 can be utilized to estimate the term $\max \rho(\boldsymbol{\mathcal{J}}_{\mathbf{f}})$ required in the CFL condition (6.3), which limits the step size ratio.

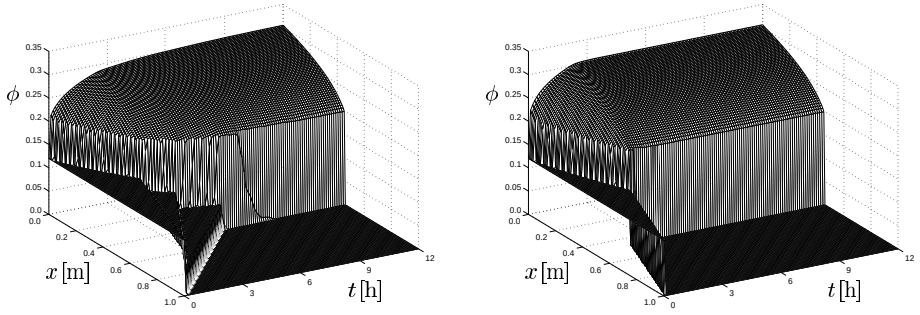

FIG. 1. *Simulations of the sedimentation-consolidation process of a tridisperse suspension (left) and a monodisperse suspension (right) using the same model functions $V(\phi)$ and $\sigma_e(\phi)$: plots of the (total) solids concentration ϕ.*

6.4. Numerical results. The numerical scheme is now employed to simulate settling processes of a tridisperse ($N = 3$) suspension forming compressible sediment. We consider here a (hypothetical) mixture described by the model functions (6.6) with $\phi_{\max} = 0.66$ and $n = 4.7$ (see [94]) and (6.7) with $\sigma_0 = 180\,\mathrm{Pa}$, $\phi_c = 0.2$, and $k = 6$. The remaining parameters are $\mu_f = 10^{-3}\mathrm{Pa{\cdot}s}$ (the dynamic viscosity of water), $d_1 = 1.19 \times 10^{-5}\,\mathrm{m}$, $\bar{\varrho}_s = 1800\,\mathrm{kg/m^3}$, and $g = 9.81\,\mathrm{m/s^2}$.

6.4.1. Settling of a tridisperse suspension. We consider an initially homogeneous suspension with $d_2/d_1 = \sqrt{0.5}$ and $d_3/d_1 = 0.5$, such that $\boldsymbol{\delta} = (1, 0.5, 0.25)^{\mathrm{T}}$, and $\Phi^0 = (0.04, 0.04, 0.04)^{\mathrm{T}}$ in a vessel of height $L = 1\,\mathrm{m}$. For the simulation, we chose $J = 1000$ and $\lambda = 0.0008\,\mathrm{h/m}$. The left diagram of Figure 1 shows the total volumetric solids concentration $\phi = \phi_1 + \phi_2 + \phi_3$ as a function of z and t, while Figure 2 displays the corresponding concentrations of the individual species.

To make the numerical results comparable to those obtained from the two existing models for monodisperse flocculated suspensions and for polydisperse suspensions of rigid spheres, we show in the right diagram of Figure 1 a simulation of the settling of a monodisperse suspension with $\phi_0 = 0.12$, and in Figure 3 the simulation of a tridisperse suspension of rigid particles (forming a sediment without compressibility effects) having the same parameters as the previously discussed case but with $\sigma_0 = 0$. The simulation shown in Figure 3 was made with $\lambda = 0.35\,\mathrm{h/m}$ and $J = 8000$. Note that the visual grid used in all diagrams is much coarser than the computational grid.

6.4.2. Effect of a third particle species on the settling of a bidisperse suspension. To study the effect of the size of a third species on the separation of two other species, we first consider a bidisperse suspension having the parameters given above and $\boldsymbol{\delta}^{\mathrm{T}} = (1.0, 0.5)$. The initial concentration is $\Phi^0 = (0.06, 0.06)^{\mathrm{T}}$. Other parameters for this simulation (and that of Figure 5) are $\lambda = 0.0008\,\mathrm{s/m}$, $J = 600$, and $L = 1\,\mathrm{m}$. Figure 4 shows a simulation of the settling of this suspension.

Next, we add a third species to this bidisperse mixture. The corresponding numerical results are shown in Figure 5. The left and right columns correspond to the size parameters $\delta_3 = 0.25$ and $\delta_3 = 0.1$, respectively. The initial concentrations of the tridisperse mixture are $\Phi^0 = (0.06, 0.06, 0.015)^{\mathrm{T}}$.

6.5. Discussion of the numerical results. In the left plot of Figure 1, three distinct zones are formed by the downwards-propagating concentration discontinuities, and, as expected, the concentration ϕ in the sediment bed increases more slowly than

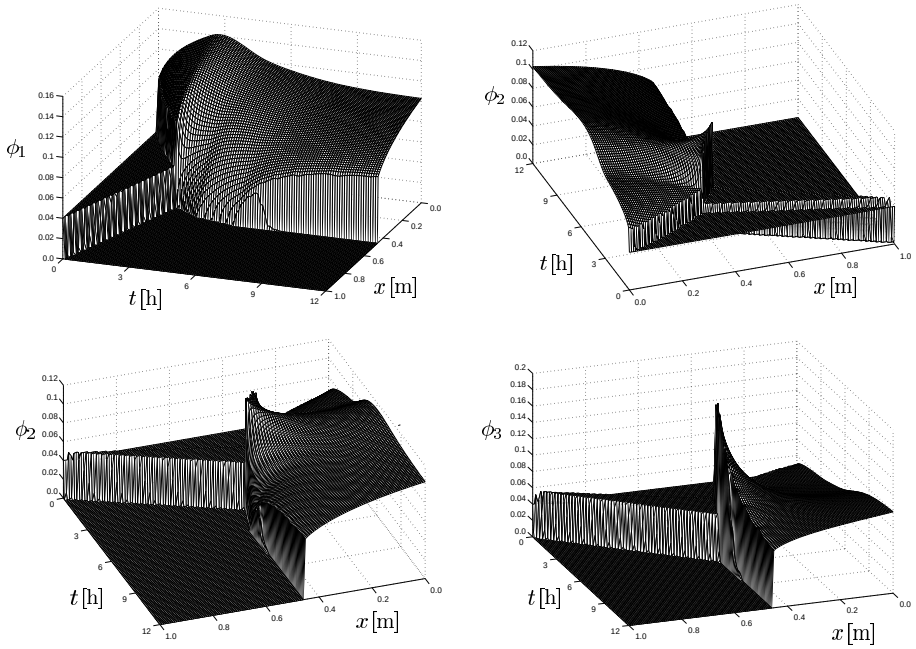

FIG. 2. *Simulation of the sedimentation-consolidation process of a tridisperse suspension: plots of the concentrations ϕ_1 of the largest (top left), ϕ_2 of the second-largest (top right and bottom left; two different views), and ϕ_3 of the smallest species (bottom right).*

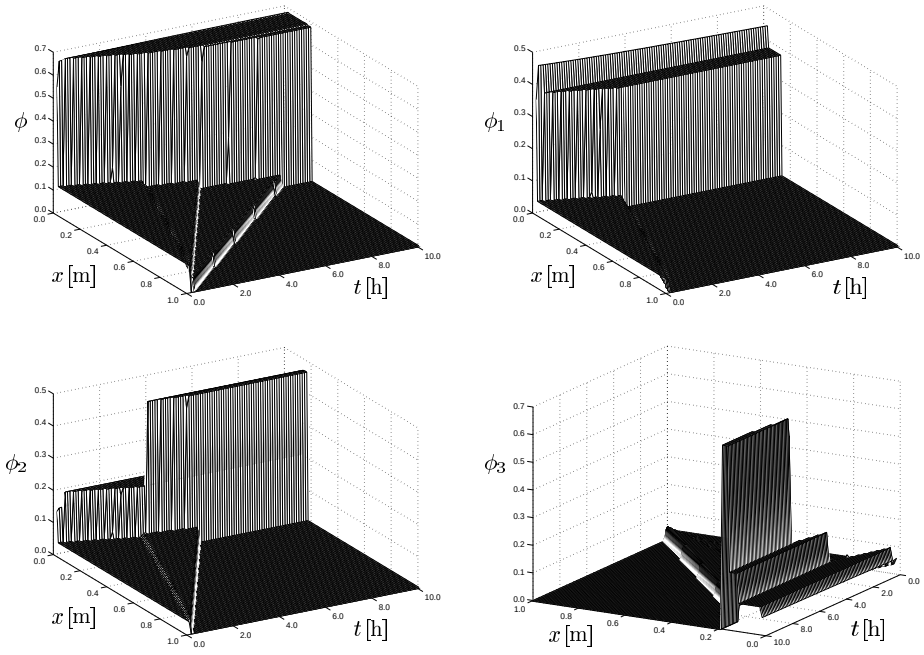

FIG. 3. *Simulation of the sedimentation of a tridisperse suspension of rigid particles (without compression, $\sigma_e \equiv 0$): plots of the cumulative concentration ϕ (top left) and the concentrations ϕ_1, ϕ_2, and ϕ_3 of the largest (top right), the second-largest (bottom left), and smallest species (bottom right).*

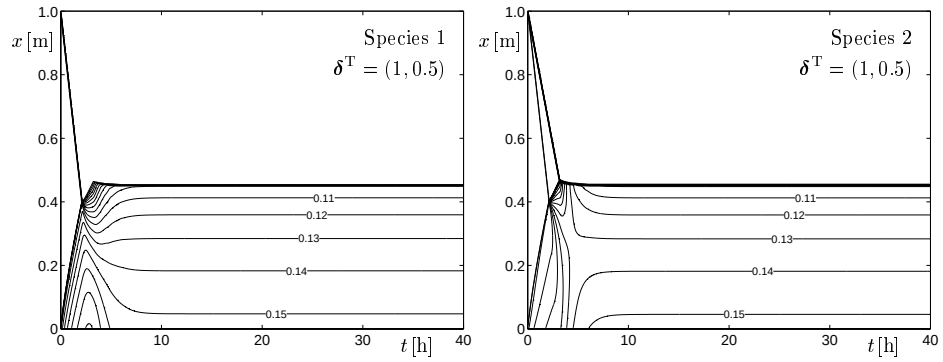

FIG. 4. *Simulation of the settling of an initially homogenous bidisperse suspension: iso-line of the concentrations ϕ_1 of the larger (left) and ϕ_2 of the smaller (right) species, corresponding to $\phi_{1,2} = 0, 0.01, 0.02, 0.03, \ldots$.*

in the monodisperse case. Comparing ϕ in the two tridisperse cases, we see that the zones formed in the first stages of sedimentation are still visible in the upper left plot of Figure 3, but have been entirely smoothed out in the left plot of Figure 1.

The two bottom plots of Figure 3 show the expected layering caused by differential sedimentation and the consequent enhancement of ϕ_2 and ϕ_3 above the lowest zone. Additional numerical examples illustrating the conventional model of sedimentation of suspensions of rigid spheres (when $\sigma_e = 0$) are given in [14, 19] (see also [48]). Figure 2 shows that the additional terms in the equation for suspensions forming compressible sediments result in the upward diffusion of the largest spheres and the downward diffusion of the smallest. Though these terms were expected to smooth the sharp boundaries found in suspensions of incompressible particles, the extent of the migration was unexpected.

The simulations described in (6.4.2) elucidate this phenomenon. We first simulated the sedimentation of an initially homogeneous bidisperse suspension and plotted the isolines of concentration. Figure 4 shows that these isolines ultimately have the same value for both species. This is a consequence of the assumption that $(\phi_i/\phi)\sigma_e(\phi)$ is the part of σ_e that acts on species i. For particles of equal density, and if we assume $V(\phi) > 0$, then the one-dimensional equilibrium form of (2.20) is

$$\bar{\varrho}_s(1-\phi) + \frac{\sigma_e(\phi)}{g\phi_i}\frac{d}{dz}\left(\frac{\phi_i}{\phi}\right) + \frac{1-\phi}{g\phi}\frac{d\sigma_e(\phi)}{dz} = 0, \quad i = 1, \ldots, N, \tag{6.9}$$

which can be rearranged to

$$\frac{d}{dz}\ln\left(\frac{\phi_i}{\phi}\right) = -\frac{1-\phi}{\sigma_e(\phi)}\left(\bar{\varrho}_s g\phi + \frac{d\sigma_e(\phi)}{dz}\right), \quad i = 1, \ldots, N. \tag{6.10}$$

From (3.53) of [27] with $u = 0$, or by setting $\phi_i = \phi$ in (6.9), we see that the expression in large parentheses is zero. Thus, ϕ_i/ϕ is constant and we have

$$\lim_{t\to\infty}\frac{\phi_i(z,t)}{\phi(z,t)} = \frac{\phi_i^0}{\phi_1^0 + \cdots + \phi_N^0}, \quad i = 1, \ldots, N. \tag{6.11}$$

The same phenomenon is also clear in Figure 5. Here the isolines of species 1 and 2 have the same ultimate values, while those of species 3 are proportional to its initial concentration.

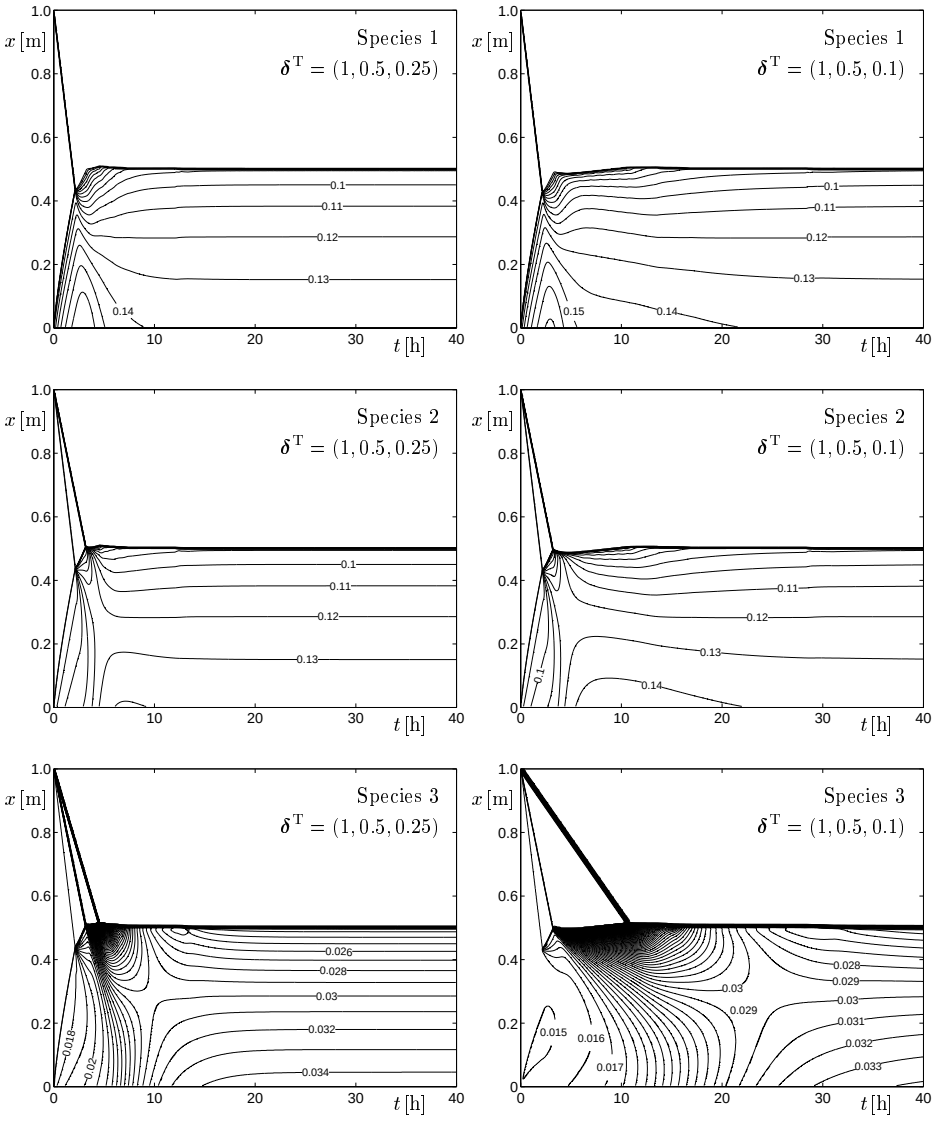

FIG. 5. *Simulations of the settling of tridisperse suspensions with different sizes of species* 3 *($d_3 = 0.5d_1$ in the left and $d_3 = 0.0.316d_1$ in the right column): iso-lines of the concentrations ϕ_1 of the larger (top) and ϕ_2 of the medium-sized (middle) species, corresponding to $\phi_{1,2} = 0, 0.01, 0.02, 0.03, \ldots$, and ϕ_3 of the smallest species (bottom) for $\phi_3 = 0, 0.001, 0.002, \ldots$.*

The complicated structures of the isolines at lower values of t arise from the resolution of the disparity between the segregation that occurs early in the sedimentation process and the ultimate uniformity with respect to species. The details of the process depend sensitively on the values of the terms in a_i. However, certain features are common.

We first consider a bidisperse suspension. When $\phi < \phi_{\mathrm{c}}$, the largest species settles most quickly and predominates in the lower region. In the consolidation phase ($\phi > \phi_{\mathrm{c}}$), the increase in ϕ tends to increase the concentration of both species in

the lower region. Figure 4 shows that species 1 reaches a concentration of 0.18 at the bottom while species 2 is still settling into the top (monodisperse) layer of the solids in compression. However, the larger particles diffuse into this layer, and the smaller particles diffuse out of it. This diffusion continues until the equilibrium state is reached.

In the tridisperse case shown in Figure 5, species 1 diffuses upward while species 2 diffuses both upward into the initially monodisperse upper layer of small particles and downward into the lower layer where large particles initially predominate. Species 3 diffuses downward from the top layer. In addition to reducing the final concentrations of the two larger species, the introduction of the smallest particles delays the evolution to the equilibrium state by introducing a segregated layer at the top of the suspension. In the example on the left, species 3 settles fairly quickly, and the change from segregated to uniform state occurs much earlier than in the example on the right, where species 3 settles very slowly. Further discussion of the phenomenon of sediment diffusivity seen in our simulations is provided in section 7.5.

7. Discussion.

7.1. Type analysis in several space dimensions. The type analysis confirms that the model is well-posed in that the one-dimensional system (1.2) is not of "general" type but has desirable algebraic properties. The analysis in sections 3 and 4 has been limited to one space dimension for notational convenience and since only in that case does the system (2.29), supplemented by the initial and boundary conditions (2.30) and (2.31), completely describe the sedimentation-consolidation process. In $D > 1$ space dimensions, not only system (2.23) for the concentrations of the solids species but also (2.24) and (2.25) for the motion of the mixture have to be solved. These equations are strongly coupled and probably will have to be solved alternately. Although, for $D > 1$, (2.23) no longer completely describes the sedimentation-consolidation process, this multidimensional system still is strongly degenerate parabolic-hyperbolic. To see this, consider first the case $\phi \le \phi_c$, for which the right-hand side of (2.23) vanishes. On the other hand, we recall that a D-dimensional $N \times N$ system of conservation laws

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial \boldsymbol{\varphi}_1(\mathbf{u})}{\partial x_1} + \cdots + \frac{\partial \boldsymbol{\varphi}_D(\mathbf{u})}{\partial x_D} = 0,$$

with $\mathbf{u} \in \mathcal{D} \subset \mathbb{R}^N$ and flux vectors $\boldsymbol{\varphi}_1, \ldots, \boldsymbol{\varphi}_D : \mathcal{D} \to \mathbb{R}^N$, is called hyperbolic if any linear combination $\boldsymbol{\mathcal{J}}(\boldsymbol{\beta}, \mathbf{u}) := \beta_1 \boldsymbol{\mathcal{J}}_{\boldsymbol{\varphi}_1}(\mathbf{u}) + \cdots + \beta_D \boldsymbol{\mathcal{J}}_{\boldsymbol{\varphi}_D}(\mathbf{u})$ of the Jacobians of the flux vectors is diagonalizable with real eigenvalues. The nonlinear fluxes $f_1^{\mathrm{M}}(\Phi), \ldots, f_N^{\mathrm{M}}(\Phi)$ in (2.23) are effective in the vertical direction of the z coordinate only. Considering $D = 3$ (the case $D = 2$ is analogous) and $\mathbf{q} = (q_x, q_y, q_z)^{\mathrm{T}}$, we obtain from (2.23) $\boldsymbol{\varphi}_1(\Phi) = q_x \Phi$, $\boldsymbol{\varphi}_2(\Phi) = q_y \Phi$, and $\boldsymbol{\varphi}_3(\Phi) = q_z \Phi + \mathbf{f}^{\mathrm{M}}(\Phi)$. Thus, the relevant linear combinations are $\boldsymbol{\mathcal{J}}(\boldsymbol{\beta}; \Phi) := (\beta_1 q_x + \beta_2 q_y + \beta_3 q_z)\mathbf{I} + \beta_3 \boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$, where $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ is the Jacobian considered in section 3. Since $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ has N pairwise-distinct eigenvalues and is thus diagonalizable, $\boldsymbol{\mathcal{J}}(\boldsymbol{\beta}; \Phi)$ is also diagonalizable with real eigenvalues, and (2.23) is therefore hyperbolic for $\phi \le \phi_c$. Of course, this statement is true under the same conditions as in the one-dimensional case, that is, for equal-density spheres and vectors $\Phi \in \mathcal{D}^0_{\phi_{\max}}$.

Next, we show that the system (2.23) is parabolic for $\phi > \phi_c$. More precisely, we show that it satisfies the classical definition of parabolicity in the sense of Petrovsky

[42, 49, 66, 104]. We do not state this condition in its most general form but limit the discussion to equations of the form

$$\frac{\partial u_i}{\partial t} + F_i(\mathbf{x}, t, \mathbf{u}, \nabla \mathbf{u}) = \sum_{m,n=1}^{D} \sum_{j=1}^{N} A_{ij}^{mn}(\mathbf{x}, t, \mathbf{u}) \frac{\partial^2 u_j}{\partial x_m \partial x_n}, \quad i = 1, \ldots, N. \tag{7.1}$$

Consider the matrix $\boldsymbol{\mathcal{A}}(\mathbf{x}, t, \mathbf{u})^{mn} := (A_{ij}^{mn})_{1 \le i,j \le N}$. Then (7.1) is called *parabolic in the sense of Petrovsky* (or simply *parabolic*) at a point $(\mathbf{x}, t, \mathbf{u}) \in Q_T \times \mathcal{D} \subset \mathbb{R}^D \times \mathbb{R}^+ \times \mathbb{R}^N$ if, for all vectors $\boldsymbol{\xi} = (\xi_1, \ldots, \xi_D)^{\mathrm{T}}$ with $|\boldsymbol{\xi}| = 1$, the roots $\lambda = \lambda(\mathbf{x}, t, \mathbf{u}, \boldsymbol{\xi})$ of $\det(\boldsymbol{\mathcal{A}}(\mathbf{x}, t, \mathbf{u}, \boldsymbol{\xi}) - \lambda \mathbf{I}) = 0$, where

$$\boldsymbol{\mathcal{A}}(\mathbf{x}, t, \mathbf{u}, \boldsymbol{\xi}) := \sum_{m,n=1}^{D} -\boldsymbol{\mathcal{A}}^{mn}(\mathbf{x}, t, \mathbf{u}) \xi_n \xi_m,$$

satisfy $\mathrm{Re}\,(\lambda(\mathbf{x}, t, \mathbf{u}, \boldsymbol{\xi})) < -\delta(\mathbf{x}, t, \mathbf{u})$ for a constant $\delta > 0$. We now consider the right-hand part of (2.25). From (4.1) and (4.2) we get $\mathbf{a}_i(\Phi, \nabla\Phi) = \eta_{i1}(\Phi)\nabla\phi_1 + \cdots + \eta_{iN}(\Phi)\nabla\phi_N$ and therefore

$$\begin{aligned} \nabla \cdot \mathbf{a}_i(\Phi, \nabla\Phi) &= \sum_{m=1}^{D} \sum_{j=1}^{N} \frac{\partial}{\partial x_m} \left(\eta_{ij}(\Phi) \frac{\partial \phi_j}{\partial x_m} \right) \\ &= \sum_{m=1}^{D} \sum_{j=1}^{N} \eta_{ij}(\Phi) \frac{\partial^2 \phi_j}{\partial x_m^2} + \sum_{m=1}^{D} \sum_{j=1}^{N} \frac{\partial \eta_{ij}(\Phi)}{\partial \phi_j} \left(\frac{\partial \phi_j}{\partial x_m} \right)^2. \end{aligned}$$

Defining

$$F_i(\mathbf{x}, t, \Phi, \nabla\Phi) := \nabla \cdot \left(\phi_i \mathbf{q} + f_i^{\mathrm{M}}(\Phi) \right) - \sum_{m=1}^{D} \sum_{j=1}^{N} \frac{\partial \eta_{ij}(\Phi)}{\partial \phi_j} \left(\frac{\partial\ \phi_j}{\partial x_m} \right)^2, \quad i = 1, \ldots, N,$$

we can rewrite (2.23) in the form (7.1). We then obtain $\boldsymbol{\mathcal{A}}^{mn}(\mathbf{x}, t, \Phi) = \mathbf{A}(\Phi)$ for all $1 \le m, n \le D$ if $m = n$, and $\boldsymbol{\mathcal{A}}^{mn}(\mathbf{x}, t, \Phi) = 0$ otherwise, where $\mathbf{A}(\Phi)$ was introduced in section 4. This implies $\boldsymbol{\mathcal{A}}(\mathbf{x}, t, \Phi, \boldsymbol{\xi}) = -\mathbf{A}(\Phi)$ for all $\boldsymbol{\xi} \in \mathbb{R}^D$ with $|\boldsymbol{\xi}| = 1$. From Theorem 4.3 we see that $\boldsymbol{\mathcal{A}}(\mathbf{x}, t, \Phi, \boldsymbol{\xi})$ has N distinct real eigenvalues $-\Lambda_1, \ldots, -\Lambda_N$ for $\Phi \in \mathcal{D}^0_{\phi_{\max}} \backslash \mathcal{D}_{\phi_c}$. This implies that the parabolicity condition $\mathrm{Re}\,(\lambda(\Phi, \boldsymbol{\xi})) < -\delta(\Phi)$ holds with $\delta(\Phi) = W(\phi)\delta_N \min\{\sigma_e(\phi), \phi(1-\phi)^2\sigma_e'(\phi)\}$. Thus, system (2.23) is parabolic on $\mathcal{D}^0_{\phi_{\max}} \backslash \mathcal{D}_{\phi_c}$, and we conclude that the hyperbolicity and parabolicity properties obtained in sections 3 and 4 remain valid in an arbitrary number of space dimensions.

7.2. Extension to particles with different densities. The model equations established in section 2 admit that the solids species differ in both size and density. The analysis of section 3 is valid for the case of equal-density particles only, while the matrix $\mathbf{A}(\Phi)$ is independent of the particle densities. In [22] it was demonstrated that different densities lead to hyperbolic-elliptic or (for $N \ge 3$) nonhyperbolic systems. Thus, it is tempting to conclude that the model framework of section 2 leads to systems having even more interesting properties (like a second-order parabolic system for $N = 2$ degenerating into a first-order hyperbolic-elliptic one). However, since particles of different densities consist of different materials, the assumption $\sigma_e(\Phi) = \sigma_e(\phi)$, stating that the effective stress depends only on the sediment porosity $1 - \phi$, is very unlikely to remain valid.

7.3. Physical explanation of Lemma 6.1. Recall that $f_i^{\mathrm{M}}(\Phi) = \phi_i v_i$, where v_i is the phase velocity of species i, that is, the settling velocity of a particle of species i. In view of (3.1), Theorem 3.4 states that the eigenvalues ν_1 to ν_{N-1} of $\boldsymbol{\mathcal{J}}_{\mathbf{f}^{\mathrm{M}}}(\Phi)$ satisfy $v_i \le \nu_i \le v_{i+1}$; i.e., the propagation of the characteristic information associated with the eigenvalue ν_i is bounded by the physical velocities of particles of species i and $i+1$ for $i = 1, \dots, N-1$. The upper bound on ν_N given by the parameter γ^∞ of Theorem 3.4, which is valid for any admissible hindered settling function $V(\phi)$, has no obvious physical interpretation, but Theorem 3.4 already provides further support for the MLB model wherever $\sigma_{\mathrm{e}} = 0$ since all waves should travel at bounded finite speeds and, for a given particle size distribution, γ^∞ is uniformly bounded with respect to Φ. However, the upper bound of ν_N in (6.8) also has a physical meaning. From (3.1), the total solids flux is

(7.2)

$$f^{\mathrm{M}}(\Phi) := \phi_1 v_1 + \cdots + \phi_N v_N = f_1^{\mathrm{M}}(\Phi) + \cdots + f_N^{\mathrm{M}}(\Phi) = \mu V(\phi)(1-\phi)^2 \bar{\varrho}_{\mathrm{s}} \boldsymbol{\delta}^{\mathrm{T}} \Phi.$$

On the other hand, we recall from the definition of $\mathbf{q}$ that

$$v_{\mathrm{f}} = \frac{1}{1-\phi}\big(q - (\phi_1 v_1 + \cdots + \phi_N v_N)\big) = \frac{q - f^{\mathrm{M}}(\Phi)}{1-\phi},$$

where v_{f} is the fluid phase velocity. Since we consider $q = 0$, we obtain $-\mu\bar{\varrho}_{\mathrm{s}} V(\phi)(1-\phi)\boldsymbol{\delta}^{\mathrm{T}}\Phi = v_{\mathrm{f}}$. Thus Lemma 6.1 states that, for relatively dilute suspensions (when $\phi < 1/n$), all eigenvalues (and therefore wave velocities) are bounded by the local velocities of the solid and fluid "particles." In the examples in section 6, we chose $1/n = 0.2128 > \phi_{\mathrm{c}} = 0.2$, such that the model equations are either hyperbolic with the sharp estimates of Lemma 6.1 holding or parabolic.

7.4. Hydrodynamic diffusion. The MLB model (like all other equations for polydisperse suspensions) assumes that $\mathbf{v}_i(\Phi)$ is the velocity of every particle of the ith species at that concentration. Of course, it has long been recognized that identical spheres at the same concentration can have very different velocities. See [111] and [114] for references to early work on this topic. More recently, Segrè, Herbolzheimer, and Chaikin [95] and Guazzelli and colleagues [78, 79, 83] used advanced technology to follow the paths of individual spheres and thereby determine their velocities.

There are essentially three methods of introducing this variability into a model. Historically, the first was the three-parameter Markov model [107, 112], which used the variance and autocorrelation of velocity as additional parameters. A decade later, a model was developed [55] (see also [37]) that combined the variance and autocorrelation in a coefficient of self-induced hydrodynamic diffusion. Thus, the two models are related, but not identical [106]. In both, the parameters must be determined experimentally or computationally. Velocity fluctuations appear to depend on wall effects [111, 114] and density stratification [75, 111] as well as on both the distant [110, 111] and local values of Φ. Theoretical [111], computational [65], and some experimental studies [111] indicate that the variance increases with the size of the container, while other experimental studies [78] show no increase. Recent work by Segrè, Herbolzheimer, and Chaikin [95] and Mucha et al. [75] has gone some way towards resolving this contradiction.

The variability of the velocities of the smaller spheres is considerably increased by the presence of larger or denser spheres [56, 83]. Since the hydrodynamic diffusion

coefficient varies with Φ and $\nabla\Phi$, the diffusion model becomes very complicated [109] for polydisperse suspensions. The Markov model is more tractable [109], but both models require data that are currently lacking. The final method of introducing variability is to use one of several numerical techniques [19, 56, 65]; these solve a specific case and demand considerable computational effort.

Fortunately, the overall behavior of suspensions is usually determined primarily by the mean velocity [84, 113] and does not require the determination of the trajectories of individual spheres [107]. Simulations show that the principal effect of hydrodynamic diffusion is a blurring of the interfaces [19, 108]. In many cases, however, these remain fairly sharp. Experimentally, interfaces are readily detected and, owing to self-sharpening [37, 69], closely approximate discontinuities. Thus, the omission of hydrodynamic diffusion terms at this stage is justified by practical limitations, theoretical considerations, computational comparisons, and experimental results.

7.5. Sediment diffusivity. In the examples discussed in section 6.5, ϕ increases fairly quickly during the consolidation phase, and hence the diffusion of species is highlighted. We recall that the material parameters chosen for the simulations do not correspond to a real suspension; rather, the parameters of the function $\sigma_e(\phi)$ have been chosen such that the numerical simulation produces some clearly visible, distinct effects within a relatively thick sediment layer. The latter point requires that the suspension be highly compressible and therefore that σ_0 and k be relatively large. Thus, strength and rapidity of the diffusion processes are to some extent a consequence of our deliberate choice of parameters, and these effects may be less pronounced for real materials. In fact, it is not clear whether the predicted behavior actually occurs in real suspensions. The assumption that $(\phi_i/\phi)\sigma_e(\phi)$ is that part of σ_e that acts on species i appears to be the obvious choice. Also, (1.2) describes nonlinear diffusion with drift, so it is not surprising that species diffuse to regions of lower concentration.

We mention that nonlinear diffusion in polydisperse suspensions has been considered by Esipov [43] and is postulated as part of a general "competition" mechanism for multispecies granular mixtures by Braun [13]. However, the terms considered in [43] account for hydrodynamic diffusion, and the consequences of the nonlinearity do not appear, since (apparently, for simplicity) these diffusivities are replaced by constants, and cross-diffusivities (e.g., the dependence of the flux of particle species 1 on the flux of species 2) are ignored, while in [13] the nonlinearity is retained, but cross-diffusivities are equally neglected, and no physical interpretation of the origin of nonlinear diffusion is given. In our case, it is difficult to imagine a physical process that leads to the predicted results discussed in section 6.5. In compression, the particles touch each other and support those above. This would appear to make relative movement difficult.

One way out of this dilemma is restricting the movement of particles at very high concentrations. In fact, it has long been held that, at very high concentrations, the particles are locked in place and all species move at the same velocity. This should certainly be true in compressible suspensions. The problem may be not that the diffusion coefficient is much too high in general (which could be fixed, for example, by an appropriate choice of the model functions $V(\phi)$ and $\sigma_e(\phi)$), but that differential diffusion, driven by the gradient $\nabla(\phi_i/\phi)$ in (2.20), becomes dominant when sedimentation is very slow. This is quite unphysical. The first part of the simulations appears reasonable. It is the differential movement at the end that is not.

One way to amend this would be to adopt an idea of Shih, Gidaspow, and Wasan [98], who utilize an expression for the portion of the effective solid stress *gradient*

for each species [98, eq. (10)] that is equivalent to leaving out the term involving $\nabla(\phi_i/\phi)$ in our approach. Unfortunately, the presentation of their numerical solution of a bidisperse system with $\bar{\varrho}_1 = \bar{\varrho}_2$ and $\delta_2 = 0.1766$ is limited to just one profile [98, Figs. 4–6] taken at a time at which the uppermost particles of neither species have reached the sediment layer, a situation that roughly corresponds to $t = 1.5\,\mathrm{h}$ in our Figure 4. However, their solution is similar to ours at that stage, since Figure 4 of [98] shows a concentrated sediment formed by the larger particles with a small portion (actually, only slightly different from the initial concentration) of the smaller. It should be pointed out, of course, that no steady-state prediction of the relative volume fractions ϕ_i/ϕ such as (6.10), (6.11) exists when there are no terms involving that same quantity.

Another way to solve our dilemma, which would go even a step further, would be to change to a common rate of sedimentation at some concentration ϕ^* with $\phi_\mathrm{c} < \phi^* < \phi_\mathrm{max}$. For values of ϕ with $\phi^* < \phi < \phi_\mathrm{max}$, we could eliminate the term in ϕ_i/ϕ in (2.20) and treat the suspension as if all particles were the same size, probably using the average value of δ_i. The best guess for ϕ^* could be found from the simulations by noting the concentrations at which the differential sedimentation dominates. (A possibly more realistic alternative would be to introduce a collective movement gradually, but this would be much more complicated.) Though this solution may seem arbitrary, it does have empirical support. For compressible suspensions, differential sedimentation occurs at medium concentrations. When the concentration is sufficiently high, even dense particles settle at the same speed as the particles of lower density. Thus, the final sediment shows no evidence of segregation; see Been and Sills [5]. When all flocs have the same density, there is a concentration at which initial floc size is unimportant. Essentially, we have a connected structure that is being compressed.

Some more treatments that less closely refer to a particular mathematical model support the similar idea of "en masse" sedimentation of multispecies suspensions at high concentrations [5, 29, 121]. Zeng and Lowe [121] consider rigid-sphere suspensions (not forming compressible sediments) but postulate the existence of a "critical concentration," in the sense of the quantity ϕ^* (*not* ϕ_c) introduced above, at which change in sedimentation behavior from differential settling (size fractionation) to "en-masse settling of the entire suspension" occurs [121], and they indicate that values of ϕ^* ranging from 0.3 to 0.55 are suitable, depending on the material. Related experimental findings were reported much earlier by Shannon and coworkers [96, 97], who observed that for equal-density spheres (normally distributed in diameters plus a tail of fines), the rise of the packed bed showed that the solids flux remained constant throughout (in contrast to sedimentation of dilute suspensions, in which the flux decreases after the larger particles have settled out).

The previous discussion shows that there is no obvious unique way to reduce the sediment diffusivity seen in our numerical examples. Published experimental information to which the numerical predictions could be compared is scarce (see the references cited in this section and [9, 116]), and a definite solution of the problems discussed here cannot be suggested. Basically, there seem to exist three alternatives.

Our approach is based on a rigorous derivation and establishes a polydisperse sedimentation model that is "well-posed" in the sense that strict parabolicity is about the best property we can expect system (1.2) to have whenever the right-hand part is different from zero (i.e., for $\phi_\mathrm{c} < \phi < \phi_\mathrm{max}$). This property, combined with the hyperbolicity of the first-order system, makes the model amenable to numerical so-

lution and is conserved when we vary the model functions $V(\phi)$ and $\sigma_e(\phi)$ to reduce sediment diffusivity. In the monodisperse case, it turned out that using the expression $V(\phi) = (1-\phi)^{n-2}$ for all ranges of concentration values (as, for simplicity, done here) leads to an overestimation of particle diffusivity in the sediment, and better agreement was obtained by using piecewise definition of $V(\phi)$ or of the resulting flux density function $f^M(\phi)$; see [15, 16]. The emphasis here is on a *gradual* variation of the parameters, which leaves the nature of the model unaltered.

The next step of modification would be "switching off" the term $\nabla(\phi_i/\phi)$ in (2.20) on the interval $[\phi^*, \phi_{\max}]$, where we admit the limiting case $\phi^* = \phi_c$. The mathematical consequences of such a reduction can be derived easily, since in the derivation of section 4, $\sigma_e(\phi)$ and its derivative $\sigma_e'(\phi)$ are formally treated as independent functions. Thus for the parabolicity analysis, deleting $\nabla(\phi_i/\phi)$ in (2.20) corresponds to sending σ_e to zero and leaving the occurrences of $\sigma_e'(\phi)$ unchanged. From (4.1) we see that then $\mathbf{A}(\Phi)$ is a rank-one matrix having $N-1$ eigenvalues that vanish. The system is then no longer strictly parabolic for $\phi \in [\phi^*, \phi_{\max}]$. This case is explicitly excluded in the analysis of certain schemes [68] but is admitted in others [60] and still has the advantage that explicit tracking of the sediment-suspension interface is unnecessary.

The most radical modification would be to change to an "en masse" sedimentation model for $\phi \in [\phi^*, \phi_{\max}]$. In particular, this would imply that $\phi = \phi^*$ denotes an interface across which we change from the system of N convection-diffusion equations (1.2) to one scalar equation, i.e., between two different models. This idea is viable when we a priori do not wish to differentiate between size classes in the sediment. In fact, this is the main idea of the model advanced by Stamatakis and Tien [102]. There is an advantage in computation time when there is a region in which a scalar equation instead of an $N \times N$ system has to be solved, but formulating transition conditions across the model change interface and tracking it during computation may become complicated.

7.6. Applications. Been and Sills [5] measured local changes in particle size distribution due to the relative movement of particles of different sizes under the influence of effective solid stress and at different initial concentrations. Their experiments were performed with estuarine mud, a natural mixture composed of many different materials for which the constitutive model equations are difficult to determine. More precise knowledge of these functions can be expected in chemical engineering applications, where the settling solids are usually formed by a product having more homogeneous material properties. The model outlined herein should thus be useful for simulations in any of the industrial applications cited in section 1. In particular, the model can also be applied to centrifugal configurations and pressure filtration (see [15, 21] for the monodisperse cases) and thereby be employed to simulate the manufacturing and final composition of ceramic materials with functionally graded material properties (see [9, 10, 11]). Comparing our Figures 2 and 3 illustrates that the effective stress is a decisive factor when the variation of sediment composition should be continuous.

Acknowledgments. We thank the referees for valuable comments and suggestions.

DIVERGENCE CRITERION FOR GENERIC PLANAR SYSTEMS*

SERGEI S. PILYUGIN† AND PAUL WALTMAN‡

Abstract. The divergence criterion has been shown to be helpful in distinguishing between sub- and supercritical Hopf bifurcations, but its applicability is limited to systems whose divergence is sign definite. A step-by-step computational procedure which allows one to extend the applicability of the divergence criterion is derived by altering the system to an equivalent one with sign definite divergence. The procedure is based on multiplying the original vector field by a positive quadratic function in a neighborhood of the bifurcating rest point. This procedure is then applied to several examples of planar systems that exhibit the Hopf bifurcation. Specifically, it is demonstrated that only supercritical bifurcations occur in a system modeling specific immune responses with handling time. It is also shown that the FitzHugh–Nagumo equations and the chemostat equations with substrate inhibition and linear yield coefficient may exhibit both sub- and supercritical Hopf bifurcations. In both cases, simple analytic criteria for determining the criticality of the bifurcation are presented.

1. Introduction.

The bifurcation of a rest point for a system of ordinary differential equations to a periodic solution has been an intriguing area of research for the past half-century. The early work of Hopf [10] is usually referenced as the beginning point of research in this area, and this type of bifurcation bears his name.[1] The theory has been developed very extensively since. Several textbooks cover the subject, including those of Marsden and McCracken [14], Hassard, Kazarinoff, and Wan [8], Chow and Hale [4], and Kuznetsov [13]. The general subject of bifurcations has been developed to a sophisticated level, and it is now a proper part of nonlinear functional analysis.

Bifurcations are important in physical and biological systems because they represent the points at which the dynamics of the system undergoes a qualitative change. In terms of the parameters of the model system, the bifurcation points can frequently be expressed as thresholds. In many instances, experiments can be designed to detect such thresholds to test a particular model and/or theory. We refer the reader to [11] for an expository article on bifurcations in mathematical biology.

Many population models are described by planar dynamical systems, and simply detecting the existence of a Hopf bifurcation is not difficult. However, determining the direction of bifurcation, whether the bifurcation is subcritical or supercritical (i.e., determining the *criticality* of the bifurcation), is a more delicate problem, as the calculations in the above cited textbooks show. The subcritical bifurcations are especially important in biological systems because they show the existence of (often

[1]Depending on the source, the Hopf bifurcation may be also referred to as the Andronov–Hopf bifurcation.

unexpected) periodic solutions and multiple periodic solutions in dissipative systems [19, 9, 16].

In previous work [16], a planar bifurcation theorem which determined the criticality of bifurcation was established using the divergence criterion. In particular, it was shown that a subcritical Hopf bifurcation produces at least two limit cycles in a planar, dissipative system. The applicability of the theorem was restricted to systems whose divergence was of one sign (except for a set of measure zero) in a neighborhood of the bifurcation point. In this work, we develop a general approach for determining the criticality of Hopf bifurcations in planar dynamical systems. We show that, for a generic system, one can multiply the vector field by a positive quadratic function and obtain a system whose divergence is sign definite near the bifurcating rest point. Since the resulting system has the same set of trajectories as the original system, the divergence criterion will determine the criticality of the bifurcation. This approach makes Theorem 2.1 in [16] applicable to a wide class of problems.

The divergence criterion is a generalization of the Dulac criterion. This criterion was used by Hofbauer and So [9] to determine the criticality of the Hopf bifurcation for a class of predator-prey equations, and was later generalized by Pilyugin and Waltman [16]. See also [17] for an earlier planar bifurcation theorem in this direction, and see Wolkowicz [19] and Zhu, Campbell, and Wolkowicz [20] for bifurcation analysis of predator-prey systems using the Lyapunov coefficient method. The change in the vector field simplifies the calculations and often renders them amenable to direct computation or to symbolic algebraic processors such as Mathematica [18] or Maple [7]. Sometimes, the simplification can be truly significant. In [16], the use of the divergence criterion resulted in the correction of mistakes found in a series of papers [1, 5, 6] that used the Lyapunov coefficient criterion.

This paper is organized as follows. We describe the construction of the quadratic function in section 2 and formulate the criterion for determining the criticality of the Hopf bifurcation. In section 3, we illustrate the procedure using two important biological problems. In section 4, we introduce a nonlinear rescaling of the vector field, which further simplifies the divergence criterion for a specific set of planar systems including the chemostat (also known as a bio-reactor or a CSTR), and study the Hopf bifurcation in the chemostat with variable yield and substrate inhibition. We conclude with a discussion section.

2. Divergence criterion for generic systems. Consider a planar dynamical system

$$x' = f(x, y), \qquad y' = g(x, y), \tag{1}$$

where f and g are sufficiently smooth, and assume that $(0, 0)$ is a center, that is, $f^0 = g^0 = 0$, $f^0_x + g^0_y = 0$, and $f^0_x g^0_y - f^0_y g^0_x > 0$, where we adopt the notation $F^0 = F(0, 0)$. Necessarily, $f^0_y g^0_x < 0$. We remark that all of the subsequent calculations and conclusions will remain valid if $(0, 0)$ is replaced by (x^0, y^0) and all derivatives are computed at (x^0, y^0).

The *divergence criterion* states that if the divergence of the vector field of (1) is negative (positive) almost everywhere in some neighborhood of $(0, 0)$, then $(0, 0)$ is a stable (unstable) spiral point. In our earlier work [16], we showed that the Hopf bifurcation is supercritical (subcritical) if the bifurcating rest point is a stable (unstable) spiral point. Therefore, we demonstrated that the criticality of the bifurcation can be determined from the stability of the bifurcating rest point. In this paper, we use

the divergence criterion to distinguish between stable and unstable spiral points or, equivalently, between super- and subcritical Hopf bifurcations.

The divergence criterion may not apply directly to the original system (1), because the divergence of its vector field may not be sign definite near the origin. In this section, we show that for a generic vector field (1), one can choose a quadratic function $a(x, y)$ so that $a(0, 0) = 1$ and the divergence of (af, ag) given by

$$\phi(x, y) = (af)_x + (ag)_y = a(f_x + g_y) + a_x f + a_y g \tag{2}$$

is sign definite in some neighborhood of $(0, 0)$. Since $a(x, y)$ is necessarily positive in some neighborhood of $(0, 0)$, the trajectories of (1) coincide with the trajectories of

$$x' = a(x, y)f(x, y), \qquad y' = a(x, y)g(x, y) \tag{3}$$

near $(0, 0)$. Consequently, systems (1) and (3) have the same orbital structure in a neighborhood of $(0, 0)$.

We begin by formally expanding ϕ, using the Taylor polynomial of second order

$$\phi = \phi^0 + \phi^0_x x + \phi^0_y y + \frac{1}{2}\left(\phi^0_{xx}x^2 + 2\phi^0_{xy}xy + \phi^0_{yy}y^2\right) + H.O.T., \tag{4}$$

where $H.O.T.$ denotes higher order terms. Evaluating (2) at $(0, 0)$, we find that $\phi^0 = 0$. Differentiating (2) yields

$$\phi_x = a(f_{xx} + g_{yx}) + a_x(f_x + g_y) + a_{xx}f + a_x f_x + a_{yx}g + a_y g_x, \tag{5}$$

$$\phi_y = a(f_{xy} + g_{yy}) + a_y(f_x + g_y) + a_{xy}f + a_x f_y + a_{yy}g + a_y g_y. \tag{6}$$

Setting $a(0, 0) = 1$, it follows that

$$\phi^0_x = (f^0_{xx} + g^0_{yx}) + a^0_x f^0_x + a^0_y g^0_x, \quad \phi^0_y = (f^0_{xy} + g^0_{yy}) + a^0_x f^0_y + a^0_y g^0_y. \tag{7}$$

Since $f^0_x g^0_y - f^0_y g^0_x > 0$, equations (7) uniquely define a^0_x and a^0_y. Our primary interest is, of course, to eliminate the first order terms in (4). Thus we set $\phi^0_x = \phi^0_y = 0$ in (7) and solve for a^0_x and a^0_y to obtain

$$a^0_x = \frac{(f^0_{xx} + g^0_{yx})g^0_y - (f^0_{xy} + g^0_{yy})g^0_x}{f^0_y g^0_x - f^0_x g^0_y}, \tag{8}$$

$$a^0_y = \frac{-(f^0_{xx} + g^0_{yx})f^0_y + (f^0_{xy} + g^0_{yy})f^0_x}{f^0_y g^0_x - f^0_x g^0_y}. \tag{9}$$

Subsequent differentiation of (5) and (6) yields

$$\begin{aligned}\phi_{xx} = {} & a_x(f_{xx} + g_{yx}) + a(f_{xxx} + g_{yxx}) + a_{xx}(2f_x + g_y) + a_x(2f_{xx} + g_{yx}) \\ & + a_{yx}g_x + a_y g_{xx} + a_{xxx}f + a_{xx}f_x + a_{yxx}g + a_{yx}g_x,\end{aligned}$$

$$\begin{aligned}\phi_{xy} = {} & a_y(f_{xx} + g_{yx}) + a(f_{xxy} + g_{yxy}) + a_{xy}(2f_x + g_y) + a_x(2f_{xy} + g_{yy}) \\ & + a_{yy}g_x + a_y g_{xy} + a_{xxy}f + a_{xx}f_y + a_{yxy}g + a_{yx}g_y,\end{aligned}$$

$$\begin{aligned}\phi_{yy} = {} & a_y(f_{xy} + g_{yy}) + a(f_{xyy} + g_{yyy}) + a_{yy}(f_x + 2g_y) + a_y(f_{xy} + 2g_{yy}) \\ & + a_{xy}f_y + a_x f_{yy} + a_{xyy}f + a_{xy}f_y + a_{yyy}g + a_{yy}g_y.\end{aligned}$$

Assuming that the functions f and g are sufficiently smooth, the mixed derivatives are independent of the order of differentiation. Therefore, evaluating the above expression at the center $(0,0)$ yields

$$\phi^0_{xx} = Q^{xx} + 2f^0_x a^0_{xx} + 2g^0_x a^0_{xy}, \tag{10}$$

$$\phi^0_{xy} = Q^{xy} + f^0_y a^0_{xx} + g^0_x a^0_{yy}, \tag{11}$$

$$\phi^0_{yy} = Q^{yy} + 2f^0_y a^0_{xy} + 2g^0_y a^0_{yy}, \tag{12}$$

where

$$Q^{xx} = (f^0_{xxx} + g^0_{yxx}) + a^0_x(3f^0_{xx} + 2g^0_{xy}) + a^0_y g^0_{xx},$$

$$Q^{xy} = (f^0_{xxy} + g^0_{yxy}) + a^0_x(2f^0_{xy} + g^0_{yy}) + a^0_y(f^0_{xx} + 2g^0_{xy}),$$

$$Q^{yy} = (f^0_{xyy} + g^0_{yyy}) + a^0_x f^0_{yy} + a^0_y(2f^0_{xy} + 3g^0_{yy}).$$

Thus far, the linear terms in (4) have been eliminated by choosing appropriate values for a^0_x and a^0_y. In what follows, we seek to choose the values a^0_{xx}, a^0_{xy}, and a^0_{yy} so as to make the second order terms in (4) sign definite. The second order terms in (4) are sign definite whenever the discriminant

$$\mathcal{D} = \phi^0_{xx}\phi^0_{yy} - (\phi^0_{xy})^2$$

is positive. We set

$$a^0_{xx} = -\frac{1}{2}\frac{Q^{xy}}{f^0_y}, \qquad a^0_{yy} = -\frac{1}{2}\frac{Q^{xy}}{g^0_x}, \tag{13}$$

because such a choice yields $\phi^0_{xy} = 0$. The discriminant then can be written as

$$\mathcal{D} = \left(Q^{xx} - \frac{Q^{xy}f^0_x}{f^0_y} + 2g^0_x a^0_{xy}\right)\left(Q^{yy} - \frac{Q^{xy}g^0_y}{g^0_x} + 2f^0_y a^0_{xy}\right) = (\beta_1 + \alpha_1 z)(\beta_2 + \alpha_2 z), \tag{14}$$

where $z = a^0_{xy}$, $\beta_1 = Q^{xx} - (Q^{xy}f^0_x/f^0_y)$, $\beta_2 = Q^{yy} - (Q^{xy}g^0_y/g^0_x)$, $\alpha_1 = 2g^0_x$, and $\alpha_2 = 2f^0_y$. Since the product $\alpha_1\alpha_2 = 4g^0_x f^0_y < 0$, the discriminant $\mathcal{D}$ is positive for any z located strictly between the roots $z_1 = -\beta_1/\alpha_1$ and $z_2 = -\beta_2/\alpha_2$. For generic functions f and g, $z_1 \neq z_2$. Thus we choose

$$z^* = -\frac{1}{2}\left(\frac{\beta_1}{\alpha_1} + \frac{\beta_2}{\alpha_2}\right) = -\frac{1}{2}\frac{Q^{xx}f^0_y + Q^{yy}g^0_x}{2g^0_x f^0_y} \tag{15}$$

and set $a^0_{xy} = z^*$.

At this point, we have determined all coefficients of the quadratic function

$$a(x,y) = 1 + a^0_x x + a^0_y y + \frac{1}{2}(a^0_{xx}x^2 + 2a^0_{xy}xy + a^0_{yy}y^2). \tag{16}$$

Finally, we transform the original vector field (f, g) into a vector field (af, ag) with sign definite divergence ϕ near the origin. The divergence ϕ is positive (negative) if ϕ^0_{xx} is positive (negative). Substituting (13) and (15) into (10), we find that

$$\phi^0_{xx} = \frac{1}{2}\left(Q^{xx} - Q^{yy}\frac{g^0_x}{f^0_y}\right) - Q^{xy}\frac{f^0_x}{f^0_y}. \tag{17}$$

For a given planar system that undergoes a Hopf bifurcation, we evaluate appropriate partial derivatives of its vector field at the bifurcation point and compute the quantity (17). The Hopf bifurcation is supercritical (subcritical) if (17) is negative (positive).

Unfortunately, for a generic system, expression (17) may become too complicated for symbolic applications. In this case, our method will have no advantage over the standard normal form computation. However, our approach can, sometimes, have a clear advantage over the standard method. To illustrate this, we treat several examples in subsequent sections. Expression (17) will be greatly simplified if the divergence of the vector field essentially involves only one of the state space variables x or y. It is therefore helpful to introduce a preliminary change of variables to achieve this, whenever possible. A specific change of variables that applies to chemostats is discussed in section 4.

3. Applications. In this section, we apply the change of vector fields to two examples in biological literature and determine the criticality of bifurcation. Before beginning, we note two changes from the usual presentation of bifurcation results.

- It is possible, and the theory is usually presented this way, to change variables so that the bifurcating rest point is always at the origin. Such a change, however, complicates the calculations for a specific problem, and we do not make it. The reader should be cautioned that, as parameters vary, the coordinates of the rest point vary.
- The traditional approach is to fix all of the parameters except one (usually designated as the bifurcation parameter) and let that parameter determine the bifurcation. We choose instead to present a *bifurcation locus*, which is defined as a hypersurface in the parameter space on which the bifurcation occurs. We have two reasons for doing this. First of all, biological problems frequently have many parameters, and it would be artificial to select a single one unless there is a specific experiment which can vary it. Secondly, our technique for determining the criticality of bifurcation depends only on the stability of the rest point at the critical parameter value(s). This implies that any parametric path crossing the bifurcation locus will produce a bifurcation whose criticality is determined exclusively by its crossing point on the bifurcation locus. In particular, any two parametric paths crossing the bifurcation locus via the same point will produce Hopf bifurcations of the same criticality. Of course, one has to ascertain that a bifurcation does indeed occur, that is, that the rest point does change its stability along the parametric path. On the other hand, our result does not require that the parametric path be strictly transverse to the bifurcation locus or, equivalently, that the pair of complex eigenvalues cross the imaginary axis with nonzero velocity. For more details, we refer the reader to the proof of the original Theorem 2.1 in [16].

For any crossing point on the bifurcation locus, the linearization of a planar system has purely imaginary eigenvalues. Such a rest point for the nonlinear system can be a stable or an unstable spiral, or a center, the choice being determined by the

nonlinear terms. Our quadratic factor determines whether the rest point is a stable spiral or an unstable spiral, depending on the sign of the (sign specific) divergence. It is also possible that the quadratic terms in (4) vanish, in which case our technique does not apply. If this is the case, then the rest point could still be a center or a spiral determined by nonlinear terms of higher order (and hence such a case would be nongeneric).

In the next two subsections, we study the criticality of Hopf bifurcations in two biological problems, where we can add to results already in the literature. These examples also illustrate the ease with which the technique can be applied to biological problems.

3.1. Specific immune responses with handling time. In this section, we apply the general divergence criterion to the model of specific immunity studied by Pilyugin and Antia in [15]. The authors reported the existence of Hopf bifurcation in the system

$$x' = rx - \frac{hx}{k+x}y, \tag{18}$$

$$y' = a + \left(\frac{\rho x}{k+x} - d\right) y, \tag{19}$$

where $r,\ h,\ k,\ a,\ \rho,\ d$ are positive parameters. Here x and y are dimensionless variables that represent the abundance of parasite (i.e., the number of infected cells) and the magnitude of the specific (cytotoxic) immune response, respectively. In this model, both the proliferation rate of immune cells $\frac{\rho x}{k+x}$ and the killing rate of infected cells $\frac{hx}{k+x}$ saturate as the number of infected cells x becomes large. The quantities r, a, and d represent the (per capita) rate of parasite replication, the input of immune cells from an external source, and the (per capita) death rate of immune cells, respectively. We restrict the bifurcation analysis to the biologically relevant case $x, y > 0$.

To simplify computations, we multiply the vector field of (18)–(19) by a positive function $k + x$ and consider the new system of the form

$$x' = rx(k+x) - hxy = f(x,y), \quad x(0) > 0, \tag{20}$$

$$y' = a(k+x) + (\rho x - d(k+x))y = g(x,y), \quad y(0) > 0. \tag{21}$$

Since $k + x > 0$, the phase portraits of (18)–(19) and (20)–(21) are identical.

The bifurcating rest point of (20)–(21) has coordinates

$$x^0 = \frac{rdk - ah}{r(\rho - d)} > 0, \quad y^0 = \frac{kr\rho - ah}{h(\rho - d)} > 0. \tag{22}$$

We compute the partial derivatives of f and g to find

$$f_x = rk + 2rx - hy, \quad f_y = -hx, \quad f_{xx} = 2r, \quad f_{xy} = -h, \quad f_{yy} = 0,$$

$$g_x = a + (\rho - d)y, \quad g_y = (\rho - d)x - dk, \quad g_{xy} = \rho - d, \quad g_{xx} = g_{yy} = 0.$$

Consequently,

$$f_x^0 = rx^0, \quad f_y^0 = -hx^0, \quad f_{xx}^0 = 2r, \quad f_{xy}^0 = -h, \quad f_{yy}^0 = 0,$$

$$g_x^0 = \frac{kr\rho}{h}, \quad g_y^0 = -\frac{ah}{r}, \quad g_{xy}^0 = \rho - d, \quad g_{xx}^0 = g_{yy}^0 = 0.$$

The bifurcating rest point must necessarily satisfy $0 = f_x^0 + g_y^0 = rx^0 - \frac{ah}{r}$, and thus

$$x^0 = \frac{ah}{r^2}.$$

Equating this value with that of (22), we find that the bifurcation locus is a subset of the hypersurface

$$d(r^2k + ah) = ah(\rho + r). \tag{23}$$

The determinant of the variational matrix is given by

$$\det(J) = -rx^0\frac{ah}{r} + hx^0\frac{kr\rho}{h} = x^0(kr\rho - ah).$$

A necessary condition for the Hopf bifurcation is that $\det(J) > 0$. Since $x^0 > 0$, it follows that $kr\rho - ah > 0$, and inequalities (22) further imply that $\rho - d > 0$ and $rdk - ah > 0$. Since $\rho - d > 0$ and $rdk - ah > 0$ together imply $kr\rho - ah > 0$, the bifurcation locus can be described as the subset of (23) restricted by two inequalities

$$rdk - ah > 0, \quad \rho - d > 0. \tag{24}$$

Using (8)–(9), we compute

$$a_x^0 = \frac{kr\rho - \frac{ah}{r}(2r + (\rho - d))}{\frac{ah}{r^2}(ah - kr\rho)}, \quad a_y^0 = \frac{(r + (\rho - d))h}{ah - kr\rho}. \tag{25}$$

The quantities Q^{**} are

$$Q^{xx} = a_x^0(6r + 2(\rho - d)), \quad Q^{xy} = -2ha_x^0 + a_y^0(2r + 2(\rho - d)), \quad Q^{yy} = -2ha_y^0.$$

Therefore,

$$\phi_{xx}^0 = a_x^0(r + (\rho - d)) + a_y^0\left(h + \frac{2r}{h}(r + (\rho - d))\right),$$

which can be simplified to

$$\phi_{xx}^0 = -\frac{(r + (\rho - d))^2}{k(r + \rho)}. \tag{26}$$

Clearly, $\phi_{xx}^0 < 0$. Since the divergence of the rescaled vector field is negative definite at any point on the bifurcation locus, the bifurcation is always supercritical.

3.2. Diffusionless FitzHugh–Nagumo equations. Several numerical examples of supercritical and subcritical Hopf bifurcations were presented by Kostova, Ravindran, and Schonbek [12] in the context of the classical FitzHugh–Nagumo equations. They derived a complicated expression to determine the criticality of the Hopf bifurcation using the normal form calculation. In this section, we use the divergence criterion to derive a simple analytic criterion to determine the criticality of the Hopf bifurcation.

The FitzHugh–Nagumo equations for a single neuron are

$$x' = F(x) - y + I = f(x, y), \tag{27}$$

$$y' = \quad x - wy \quad = g(x, y), \tag{28}$$

where $F(x) = \varepsilon x(1-x)(x-\lambda)$ and $\varepsilon > 0,\ 0 < \lambda < 1,\ w > 0$, and I are parameters. The variable x represents the membrane potential, y is the recovery variable that represents a negative feedback, and I is the membrane current.

Computing the partial derivatives of f and g, we find that

$$f_x = F'(x), \quad f_y = -1, \quad f_{xx} = F''(x), \quad f_{xy} = f_{yy} = 0,$$

$$g_x = 1, \quad g_y = -w, \quad g_{xy} = g_{xx} = g_{yy} = 0.$$

Consequently, at any rest point (x^0, y^0), we have

$$f^0_x = F'(x^0), \quad f^0_y = -1, \quad f^0_{xx} = F''(x^0), \quad f^0_{xy} = f^0_{yy} = 0,$$

$$g^0_x = 1, \quad g^0_y = -w, \quad g^0_{xy} = g^0_{xx} = g^0_{yy} = 0.$$

The bifurcation locus consists of rest points (x^0, y^0) such that $f^0_x + g^0_y = 0$ and $f^0_x g^0_y - f^0_y g^0_x > 0$. The former condition implies that $F'(x^0) = w$. The latter condition then implies that $1 - w^2 > 0$. Hence the bifurcation locus is the set of rest points (x^0, y^0) such that

$$f^0 = g^0 = 0, \quad F'(x^0) = w, \quad w^2 < 1. \tag{29}$$

Since $F'(x) = \varepsilon(-3x^2 + 2(1+\lambda)x - \lambda)$, the second condition in (29) implies that x^0 must satisfy the quadratic equation

$$3(x^0)^2 - 2(1+\lambda)x^0 + \lambda + \frac{w}{\varepsilon} = 0$$

or, equivalently,

$$x^0_{1,2} = \frac{(1+\lambda) \pm \sqrt{(1+\lambda)^2 - 3(\lambda + \frac{w}{\varepsilon})}}{3}. \tag{30}$$

Using (8)–(9), we compute

$$a^0_x = \frac{wF''(x^0)}{1-w^2}, \quad a^0_y = -\frac{F''(x^0)}{1-w^2}. \tag{31}$$

The quantities Q^{**} are

$$Q^{xx} = F'''(x^0) + \frac{3w(F''(x^0))^2}{1-w^2} = -6\varepsilon + \frac{3w(F''(x^0))^2}{1-w^2},$$

$$Q^{xy} = -\frac{(F''(x^0))^2}{1-w^2}, \quad Q^{yy} = 0.$$

Therefore,

$$\phi^0_{xx} = \frac{1}{2}\left(-6\varepsilon + \frac{3w(F''(x^0))^2}{1-w^2}\right) + \frac{(F''(x^0))^2}{1-w^2}\frac{F'(x^0)}{-1},$$

which can be further simplified to

$$\phi^0_{xx} = \frac{1}{2}\left(-6\varepsilon + \frac{w(F''(x^0))^2}{1-w^2}\right). \tag{32}$$

Substituting $F''(x^0) = 2\varepsilon(1+\lambda-3x^0)$ into (32), we rewrite the quantity ϕ^0_{xx} as

$$\phi^0_{xx} = \varepsilon\left(-3 + \frac{2\varepsilon w(1+\lambda-3x^0)^2}{1-w^2}\right). \tag{33}$$

Using (30), we can rewrite the quantity $(1+\lambda-3x^0)^2$ as

$$(1+\lambda-3x^0)^2 = (1+\lambda)^2 - 3\left(\lambda + \frac{w}{\varepsilon}\right).$$

Substituting this expression into (33), we finally obtain

$$\phi^0_{xx} = \frac{\varepsilon}{1-w^2}\left(2\varepsilon w(1-\lambda+\lambda^2) - 3(1+w^2)\right). \tag{34}$$

The multiplier $\frac{\varepsilon}{1-w^2}$ is positive due to (29). Consequently, ϕ^0_{xx} has the same sign as the quantity $2\varepsilon w(1-\lambda+\lambda^2) - 3(1+w^2)$. The Hopf bifurcation in the FitzHugh–Nagumo equations is subcritical if $\phi^0_{xx} > 0$, that is, if it occurs on the part of the bifurcation locus where

$$\varepsilon > \frac{3(1+w^2)}{2w(1-\lambda+\lambda^2)},$$

and supercritical if it occurs on the part of the bifurcation locus where the reversed strict inequality holds.

In [12], two numerical examples were presented: a Figure 2 with $\varepsilon = 14.0,\ w = 0.38,\ \lambda = 0.1$ and a Figure 3 with $\varepsilon = 14.0,\ w = 0.06,\ \lambda = 0.5$. In the former case,

$$\varepsilon = 14.0 > \frac{3(1+0.38^2)}{2\cdot 0.38(1-0.1+0.1^2)} = 4.964,$$

and the bifurcation is subcritical. In the latter case,

$$\varepsilon = 14.0 < \frac{3(1+0.06^2)}{2\cdot 0.06(1-0.5+0.5^2)} = 33.453,$$

and the bifurcation(s) are supercritical.

4. Rescaling for chemostat equations. The method presented in this section for rescaling the vector field is a generalization of the technique used by Hofbauer and So [9]. Specifically, we consider the system

$$x' = f(x) - q_1(y)g(x), \quad y' = q_2(y)h(x), \tag{35}$$

where f, g, h, q_i are sufficiently smooth and such that positive solutions of (35) remain positive. Also, suppose that $g(x) > 0$ and $q_2(y) > 0$ for $x, y > 0$. We multiply the vector field (35) by a positive function $Q(y)/g(x)$ to obtain a new system

$$x' = Q(y)f(x)/g(x) - q_1(y)Q(y) = Q(y)G(x) - q_1(y)Q(y), \tag{36}$$

$$y' = Q(y)q_2(y)h(x)/g(x) = Q(y)q_2(y)H(x), \tag{37}$$

where $(Qq_2)' = \beta Q$ and β is a real number to be determined later. The explicit expression for $Q(y)$ is

$$Q(y) = \frac{\exp\left(\beta\int \frac{dy}{q_2(y)}\right)}{q_2(y)} > 0.$$

Any positive rest point (x^0, y^0) of (36)–(37) must satisfy $H(x^0) = 0$. The divergence of the new vector field (36)–(37) is given by

$$D(x,y) = Q(y)G'(x) + (Q(y)q_2(y))'H(x) = Q(y)\big(G'(x) + \beta H(x)\big). \tag{38}$$

Now suppose that (x^0, y^0) is the bifurcating rest point, that is, that $D(x^0, y^0) = 0$. Since $Q(y^0) > 0$ and $H(x^0) = 0$, we necessarily have that

$$G'(x^0) + \beta H(x^0) = G'(x^0) = 0.$$

We choose $\beta = -G''(x^0)/H'(x^0)$, so that in a small neighborhood of (x^0, y^0),

$$G'(x) + \beta H(x) = \frac{\delta}{2}(x - x^0)^2 + H.O.T.,$$

where

$$\delta = G'''(x^0) - \frac{G''(x^0)}{H'(x^0)}H''(x^0) = H'(x^0)\left(\frac{G''}{H'}\right)'(x^0). \tag{39}$$

Since $Q(y) > 0$, the sign of $D(x,y)$ near (x^0, y^0) is the same as the sign of δ. Consequently, the application of the divergence criterion to systems of type (35) can be greatly simplified. For example, the predator-prey models analyzed in [2, 9, 19, 20] fall into this category. The criteria for the criticality of Hopf bifurcations obtained in these works can be directly compared to the expression (39). Various models of the chemostat are also of type (35). In the following subsection, we illustrate this simplified approach by treating a special case of the chemostat with substrate inhibition and a linear yield coefficient.

4.1. Chemostats with substrate inhibition and linear yields. In this section, we study the Hopf bifurcation in the model of a chemostat with linear yield coefficient which also features substrate inhibition of growth at higher substrate levels. For a general study of the chemostat with inhibition, constant yield, and several competitors, see Butler and Wolkowicz [3]. The original model presented in Agrawal et al. [1], takes the following form:

$$x' = 1 - x - y\frac{\mu(x)}{1 + cx}, \tag{40}$$

$$y' = y(\mu(x) - 1), \tag{41}$$

where x and y denote the dimensionless substrate and biomass concentrations, and $\mu(x) = mx\exp(-x/K)$ is the microbial growth rate. The function $1 + cx$ represents the yield coefficient,[2] which is assumed to increase linearly with substrate concentration; thus $c > 0$.

Equations (40)–(41) are of the form (35) with

$$f(x) = 1 - x, \qquad g(x) = \frac{mx\exp(-x/K)}{1 + cx},$$

$$h(x) = mx\exp(-x/K) - 1, \qquad q_1(y) = q_2(y) = y.$$

[2]The yield coefficient is defined as the ratio of the amount of substrate consumed to the amount of biomass produced at a steady state. There is strong biological evidence that the yield may increase with substrate concentration. For details, see [16] and the references therein.

Equations (40)–(41) admit up to two positive rest points. The x-coordinate of a positive rest point must satisfy $\mu(x) = 1$ with $0 < x < 1$. The function $\mu(x)$ has a maximum at $x = K$, and its maximal value is given by $\mu_{\max} = mKe^{-1}$. Consequently, if $mK > e$, then there exist two positive solutions of $\mu(x) = 1$, $x_1^0 < K < x_2^0$. It is easy to verify that the rest point with $x = x_2^0$ (if it is feasible, that is, if $x_2^0 < 1$) is always a saddle. Consequently, the Hopf bifurcation can occur only at the rest point (x_1^0, y_1^0) with $0 < x_1^0 < \min(1, K)$ and $y_1^0 = (1 - x_1^0)(1 + cx_1^0)$. The bifurcation occurs when the trace of the variational matrix of (40)–(41) at (x_1^0, y_1^0) equals zero:

$$-1 - y_1^0 \frac{d}{dx}\Big(\frac{\mu(x)}{1+cx}\Big)(x_1^0) = 0.$$

Consequently, on the bifurcation locus, the value of c is given by

$$c = \frac{K - x_1^0 + (x_1^0)^2}{(x_1^0)^2(1 - K - x_1^0)}. \tag{42}$$

The bifurcation occurs in the feasible region if the value of c given by (42) is positive, that is, if $x_1^0 < 1 - K$ and $0 < K < 1$.

To determine the criticality of the Hopf bifurcation, we computed the functions $G(x)$ and $H(x)$ as defined in (36)–(37) and found that

$$G(x) = \frac{(1-x)(1+cx)\exp(x/K)}{mx}, \tag{43}$$

$$H(x) = \frac{(1+cx)(mx - \exp(x/K))}{mx}. \tag{44}$$

Then we created a Mathematica [18] notebook to compute the quantity δ defined in (39), and found that

$$\delta(x(m,K),K) = \frac{P_0(x) + KP_1(x) + K^2P_2(x) + K^3P_3(x) + K^4P_4(x)}{K^2(K-x)(1-x)(1-K-x)x^3}, \tag{45}$$

where $P_0(x) = 3(1-x)^3x^3$, $P_1(x) = 2x^2(1-x)^2(x-6)$, $P_2(x) = 2x(x-1)(x^2 + x - 8)$, $P_3(x) = 2(5x^2 - 4x - 3)$, $P_4(x) = 2(3-x)$, and $x_1^0 = x(m,K)$. The Hopf bifurcation in (40)–(41) is subcritical if $\delta > 0$ and supercritical if $\delta < 0$.

The existence of both sub- and supercritical Hopf bifurcations in (40)–(41) is illustrated in Figure 1. For $(K,m) \in A$, no rest point with $0 < x < 1$ exists. The curve between A and B is given by $m = e/K$. Region B ($\delta > 0$) corresponds to subcritical bifurcations. The curve between B and C is the implicit plot of $\delta(x(m,K),K) = 0$. Region C ($\delta < 0$) corresponds to supercritical bifurcations. The curve between C and D is the implicit plot of $x(m,K) = 1 - K$. For $(K,m) \in D$, no bifurcations with $c > 0$ occur. The region B terminates at $K = 0.413$, and the region C terminates at $K = 0.5$.

5. Discussion. We have developed a unifying approach for studying the Hopf bifurcation for generic planar systems, which stems from the divergence criterion. Specifically, we presented a step-by-step computational procedure which can be used to distinguish between sub- and supercritical bifurcations. This procedure can be easily programmed in any standard computer algebra system such as Maple [7] or Mathematica [18] so that all of the necessary computations can be automated. This work may serve as a good example of the analytic approach that involves computerized

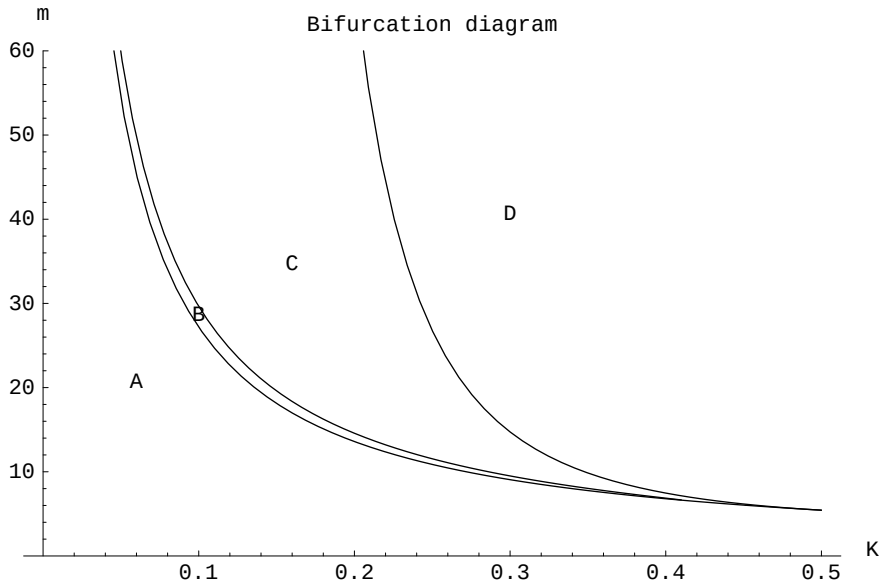

FIG. 1. *Existence and criticality of Hopf bifurcations in the* (K, m) *plane.*

symbolic calculations. The technique is generic in the sense that it can be applied to a generic planar vector field.

We applied our procedure to several important biological systems and obtained new results on the criticality of Hopf bifurcation. Interestingly, we found that in several instances—for example, with diffusionless FitzHugh–Nagumo equations—we were able to perform all calculations by hand in a reasonable amount of time, which illustrated that our method may have an advantage over the calculation of the third Lyapunov coefficient and/or normal form calculation for the Hopf bifurcation. In particular, our method does not require such computational steps as

- changing coordinates to place the bifurcating rest point at the origin,
- finding eigenvalues and eigenvectors of the variational matrix,
- transforming the linear part of the vector field to the canonical form.

In certain examples, our method produces analytic expressions that are easier to simplify.

We have also presented a specific change of variables that works well with a whole class of planar systems including the equations of the chemostat. Performing this change of variables essentially eliminates one of the phase variables from the expression for divergence and thus greatly simplifies the analysis of Hopf bifurcation.

Acknowledgments. The authors are grateful to the anonymous referees and the handling editor for their valuable comments and suggestions.

A METHOD FOR SOLVING DYNAMICALLY ACCELERATING CRACK PROBLEMS IN LINEAR VISCOELASTICITY*

TANYA L. LEISE† AND JAY R. WALTON‡

Abstract. We develop a general solution technique for a dynamically accelerating crack in a linear viscoelastic material, based on a transform method developed by Slepyan (see [*Models and Phenomena in Fracture Mechanics*, Springer-Verlag, New York, 2002]) for solution of dynamic elastic fracture problems. We review the elastic fracture solution method and then treat the viscoelastic mode III fracture problem for crack tip speeds less than the short-time shear wave speed. The analysis includes an exact, closed-form expression for the stress intensity factor for an arbitrary time dependent crack face traction. As examples, we apply this solution method to the Achenbach–Chao and standard linear solid viscoelastic models.

Key words. dynamic fracture, viscoelastic material

DOI. 10.1137/S003613990241953X

1. Introduction.

While dynamic elastic fracture is a well-studied and fairly mature subject (see [4], for example), the literature devoted to dynamic fracture in viscoelastic material is limited. The first exact, closed-form solution for a dynamically accelerating crack in a viscoelastic material was derived by Bourne and Walton [2], who assumed a semi-infinite, antiplane shear crack in an Achenbach–Chao linear viscoelastic solid in the limiting case of a vanishing equilibrium shear modulus. (Also see [13] for an exposition of this viscoelastic solution, and [14] for the inclusion of a Dugdale zone.) With the exception of an approximate analysis by Goleniewski [5], the authors know of no other solutions to date for dynamically accelerating cracks in viscoelastic material.

The first major contributions to the solution of dynamically accelerating cracks in an elastic material were due to Kostrov [6], whose work motivated others in the field such as Eshelby [3]. However, the approach taken by this paper most closely follows the techniques for an elastic material developed by Slepyan [11], which are related to but distinct from the methods developed by Kostrov or Eshelby. We also make use of the ideas developed by Bourne and Walton [2] for a crack in a linear viscoelastic material in the special case of a vanishing equilibrium shear modulus. Our goal is to generalize Bourne and Walton's exact, closed-form solution for this special case to the general case of a linear viscoelastic material. In addition, we derive an explicit expression for the mode III stress intensity factor for a dynamically accelerating crack in a general linear viscoelastic material. One could also use the equations derived in this paper to numerically compute the displacement and stress along the entire boundary (the crack line), facilitating the inclusion of a cohesive zone.

In the following section, we briefly outline the solution method for an accelerating semi-infinite crack in an elastic material for comparison to that for the viscoelastic

problem, to highlight both what is analogous and what is very different. We then extend this solution method to the general case of a dynamically accelerating semi-infinite crack in a linear viscoelastic material in sections 3 and 4. In sections 5 and 6 we apply the solution method to the Achenbach–Chao and standard linear solid viscoelastic models and then make some concluding remarks in section 7.

2. Review of the dynamic elastic problem. The following integral transform method for a dynamically accelerating semi-infinite crack in an elastic material was first developed by Slepyan (see [11]) for all fracture modes. (In fact, in both [11] and [9], a more general problem is considered, where the displacement in front of the crack need not vanish.) It is closely related to the method developed in [15] by Walton and Herrmann, and we extended the method to the cases of finite length and multiple cracks in an elastic material in [8] and [7]. We will review the method as applied to a semi-infinite mode III crack in an elastic material for comparison with the viscoelastic equations that we will derive in sections 3 and 4.

Consider a dynamically accelerating, semi-infinite, antiplane shear crack for a general infinite homogeneous and isotropic linearly elastic body. The governing equations for this elastic fracture problem are

$$\rho\ddot{u}(t) = \mu\triangle u \quad \text{and} \quad \sigma(x,y,t) = \mu\frac{\partial}{\partial y}u(x,y,t), \tag{2.1}$$

where μ is the elastic shear modulus, $u(x,y,t)$ is the out-of-plane displacement $u_3(x,y,t)$, and $\sigma(x,y,t)$ is the shear stress $\sigma_{23}(x,y,t)$. Let $a(t)$ be the crack tip position at time t, as in Figure 2.1. The initial and boundary conditions for this problem are

$$u(x,y,0) = 0 = \dot{u}(x,y,0), \tag{2.2}$$

$$u(x,0,t) = 0 \quad \text{for } x > a(t), \tag{2.3}$$

$$\sigma(x,0,t) = \Lambda(x,t) \quad \text{for } x < a(t), \tag{2.4}$$

$$u(x,y,t) \to 0 \quad \text{as } |y| \to \infty, \tag{2.5}$$

where $a(t)$ is the position of the crack tip as it propagates to the right and $\Lambda(x,t)$ is assumed to be a known loading of the crack face. Furthermore we assume that the crack speed remains subsonic, $0 \le \dot{a}(t) < c$, where $c = \sqrt{\mu/\rho}$ is the shear wave speed.

The key to the solution method is the observation that, after applying Laplace and Fourier transforms and taking the limit as $y \to 0^+$, the governing equations

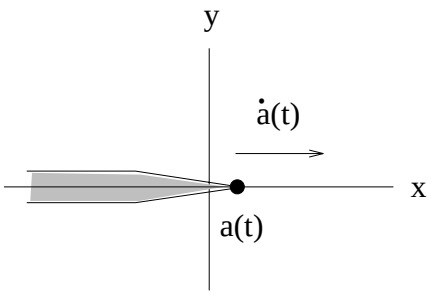

FIG. 2.1. *A semi-infinite dynamically accelerating crack. We consider the antiplane shear case, and thus the crack face displacement is actually perpendicular to the page.*

reduce to a simple transfer map (see [13] for the details of this derivation for both the elastic and viscoelastic cases):

$$\hat{\bar{\sigma}}(p,s) = \hat{\bar{T}}(p,s)\hat{\bar{u}}(p,s), \tag{2.6}$$

where the transfer function is

$$\hat{\bar{T}}(p,s) = -\mu\sqrt{p^2 + s^2/c_s^2}. \tag{2.7}$$

We use Fourier and Laplace transforms defined as follows:

$$\hat{f}(p) = \int_{-\infty}^{\infty} e^{ipx} f(x)dx, \tag{2.8}$$

$$\bar{g}(s) = \int_{0}^{\infty} e^{-st} g(t)dt. \tag{2.9}$$

Decompose the transfer function $T(x,t)$ as $\hat{\bar{T}}(p,s) = \hat{\bar{T}}_+(p,s)\hat{\bar{T}}_-(p,s)$ in such a manner that the functions $T_\pm(x,t)$ and $S_\pm(x,t)$, where $\hat{\bar{S}}_\pm = 1/\hat{\bar{T}}_\pm$, satisfy the following conditions:

$$T_+(x,t) = S_+(x,t) = 0 \quad \text{for } x < ct, \tag{2.10}$$

$$T_-(x,t) = S_-(x,t) = 0 \quad \text{for } x > -ct. \tag{2.11}$$

We also decompose the stress and displacement into parts with support either in front of the crack tip or on the crack face:

$$\sigma_+(x,t) = \begin{cases} \sigma(x,t) & \text{if } x > a(t), \\ 0 & \text{otherwise,} \end{cases} \tag{2.12}$$

$$\sigma_-(x,t) = \begin{cases} \sigma(x,t) & \text{if } x < a(t), \\ 0 & \text{otherwise,} \end{cases} \tag{2.13}$$

and similarly for the displacement $u(x,t)$. Expand (2.6) using these decompositions, and multiply by $\hat{\bar{S}}_+$:

$$\hat{\bar{S}}_+\hat{\bar{\sigma}}_+ + \hat{\bar{S}}_+\hat{\bar{\sigma}}_- = \hat{\bar{T}}_-\hat{\bar{u}}_+ + \hat{\bar{T}}_-\hat{\bar{u}}_-. \tag{2.14}$$

Assuming the properties (2.10) and (2.11), the convolution $T_- * *u_-$ vanishes for $x > a(t)$:

$$T_- * *u_-(x,t) \tag{2.15}$$

$$= \int_{-\infty}^{\infty} dr \int_0^t T_-(r,\tau)u_-(x-r,t-\tau)d\tau \tag{2.16}$$

$$= \int_0^t d\tau \int_{-c\tau}^{x-a(t-\tau)} T_-(r,\tau)u_-(x-r,t-\tau)dr. \tag{2.17}$$

For $x > a(t)$, the two functions in this double integral have no region of support in common, so that the integral vanishes. Similarly, the convolution $S_+ * *\sigma_+$ vanishes for $x < a(t)$. Apply Fourier and Laplace transformations again to the relations

$$T_- * *u_-(x,t) = H(a(t)-x)(S + * * \sigma_- - T_- * *u_+), \tag{2.18}$$

$$S_+ * *\sigma_+(x,t) = -H(x-a(t))(S + * * \sigma_- - T_- * *u_+), \tag{2.19}$$

multiply by $\hat{\tilde{S}}_-$ and $\hat{\tilde{T}}_+$, respectively, and invert the transformations to obtain

$$u_- = S_- * *[H(a(t)-x)(S_+ * *\sigma_- - T_- * *u_+)], \tag{2.20}$$

$$\sigma_+ = -T_+ * *[H(x-a(t))(S_+ * *\sigma_- - T_- * *u_+)]. \tag{2.21}$$

Note that these relations give the unknown quantities in terms of the known quantities (from the boundary conditions) for a semi-infinite crack. These formulas first appeared in [10] (and hold for all three fracture modes).

Let's look more closely at these maps for an antiplane shear crack in elastic material. For this case we decompose the transfer map into two square root functions in the complex plane:

$$\hat{\tilde{T}}_+(p,s) = \sqrt{-ip + s/c}, \tag{2.22}$$

$$\hat{\tilde{T}}_-(p,s) = -\mu\sqrt{ip + s/c}, \tag{2.23}$$

where the branch cuts for the square roots are taken along the negative imaginary axis for (2.22) and along the positive imaginary axis for (2.23). The functions $S_\pm$ are straightforward to find and have the desired support properties:

$$S_+(x,t) = \delta\left(t - \frac{x}{c}\right)\frac{H(x)}{\sqrt{\pi x}}, \tag{2.24}$$

$$S_-(x,t) = -\mu\delta\left(t + \frac{x}{c}\right)\frac{H(-x)}{\sqrt{-\pi x}}, \tag{2.25}$$

where $\delta(\tau)$ denotes the Dirac delta function and $H(x)$ denotes the Heaviside function. Also note that

$$\mathcal{F}^{-1}\circ\mathcal{L}^{-1}\left[\left(-ip + \frac{s}{c}\right)\hat{\tilde{u}}(p,s)\right](x,t) = \frac{1}{c}\frac{\partial u}{\partial t} + \frac{\partial u}{\partial x}, \tag{2.26}$$

$$\mathcal{F}^{-1}\circ\mathcal{L}^{-1}\left[\left(ip + \frac{s}{c}\right)\hat{\tilde{u}}(p,s)\right](x,t) = \frac{1}{c}\frac{\partial u}{\partial t} - \frac{\partial u}{\partial x}. \tag{2.27}$$

Substituting these functions and the boundary conditions into the relations (2.20) and (2.21) leads to expressions for the crack face displacement and stress in front of the crack that depend only on the crack face load $\Lambda(x,t)$ and the crack tip path $a(t)$:

$$u_-(\eta,\xi) = -\frac{1}{2\pi}\int_{\max\{-\eta, b_0\circ b_1^{-1}(\eta)\}}^{\xi}\frac{dq}{\sqrt{\xi - q}}\int_{\max\{-q,0\}}^{\eta}\Lambda(r,q)\frac{dr}{\sqrt{\eta - r}}, \tag{2.28}$$

$$\sigma_+(\eta,\xi) = \frac{1}{\pi}\frac{\partial}{\partial\eta}\int_{-\xi}^{b_1\circ b_0^{-1}(\xi)}\frac{dr}{\sqrt{\eta - r}}\int_{-\xi}^{r}\Lambda(s,\xi)\frac{ds}{\sqrt{r - s}}. \tag{2.29}$$

Here we have used characteristic coordinates $\eta = t + x/c$ and $\xi = t - x/c$ in place of the original (x,t) coordinates, and retarded and advanced time scales $b_0(t)$ and $b_1(t)$, respectively, defined via

$$b_0(t) = t - a(t)/c, \qquad b_1(t) = t + a(t)/c. \tag{2.30}$$

(Since we impose subsonic crack propagation, $0 \leq \dot{a}(t) < c$, the functions $b_0(t)$ and $b_1(t)$ will be strictly increasing and hence invertible.) Taking the limit $x \to a(t)^+$ of (2.29) after reversing the order of integration and then performing a change of variables leads to the usual mode III stress intensity factor:

$$K_{III}(t) = -\frac{1}{\pi}\sqrt{c - \dot{a}(t)} \int_0^t \Lambda(c(r - b_0(t)), r) \frac{dr}{\sqrt{t-r}}. \tag{2.31}$$

See [15], [13], [8], and [7] for more details on this solution method for antiplane shear cracks in elastic material.

3. General framework for viscoelastic case. We will consider a dynamically accelerating, semi-infinite, antiplane shear crack for a general infinite homogeneous and isotropic linearly viscoelastic body. The governing equations for this viscoelastic fracture problem are

$$\rho\ddot{u}(x,y,t) = \mu * \triangle u \quad \text{and} \quad \sigma(x,y,t) = \frac{\partial}{\partial y}(\mu * du), \tag{3.1}$$

where $\mu(t)$ is the shear relaxation function, $u(x,y,t)$ is the out-of-plane displacement u_3, $\sigma(x,y,t)$ is the shear stress σ_{23}, and the convolutions are with respect to t. Let $a(t)$ be the crack tip position at time t, as in Figure 2.1. The initial and boundary conditions for this problem are

$$u(x,y,0) = 0 = \dot{u}(x,y,0), \tag{3.2}$$

$$u(x,0,t) = 0 \quad \text{for } x > a(t), \tag{3.3}$$

$$\sigma(x,0,t) = \Lambda(x,t) \quad \text{for } x < a(t), \tag{3.4}$$

$$u(x,y,t) \to 0 \quad \text{as } |y| \to \infty. \tag{3.5}$$

See [13] for the details of the derivation of the transfer map corresponding to this problem.

Finding a solution method for a crack in a viscoelastic material is, of course, complicated by the dependence on time histories of the displacement and stress. The decomposition of the transfer function must be carefully chosen to result in useful support properties. In general, we will assume that the transfer function has form

$$\hat{\tilde{T}}(p,s) = -\sqrt{p^2 + s^2/\tilde{c}(s)^2} \tag{3.6}$$

for the transfer map

$$\hat{\tilde{\sigma}}(p,s) = \hat{\tilde{T}}(p,s)\hat{\tilde{D}}(p,s), \tag{3.7}$$

where

$$\hat{\tilde{D}}(p,s) = \tilde{\mu}(s)\hat{\tilde{u}}(p,s), \tag{3.8}$$

and $\tilde{\mu}(s) = \mu_0 + \int_0^\infty e^{-ts}\dot{\mu}(t)dt$ is the s-multiplied Laplace transform of the shear relaxation function. A natural choice for a decomposition $\hat{\tilde{T}}(p,s) = \hat{\tilde{T}}_+(p,s)\hat{\tilde{T}}_-(p,s)$ (with $\hat{\tilde{S}}_\pm = 1/\hat{\tilde{T}}_\pm$ as before) is

$$\hat{\tilde{T}}_+(p,s) = \sqrt{-ip + s/\tilde{c}(s)}, \tag{3.9}$$

$$\hat{\tilde{T}}_-(p,s) = -\sqrt{ip + s/\tilde{c}(s)}, \tag{3.10}$$

with the branch cut for the square roots taken along the negative real axis. The complication in finding the inverse Laplace transform lies in the nonconstant transverse wave speed function $\tilde{c}(s) = \sqrt{\tilde{\mu}(s)/\rho}$.

The key to analyzing the transfer function is to examine the inverse Laplace transform of $\exp[-|x|s/\tilde{c}(s)]$, a crucial component of the Dirichlet-to-Neumann map. Observe that since

$$\hat{\tilde{S}}_{\pm}(p,s) = \frac{\pm 1}{\sqrt{\mp ip + s/\tilde{c}(s)}}, \tag{3.11}$$

the functions $S_{\pm}(x,t)$ will be found via

$$S_{+}(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} e^{-ipx}dp \frac{1}{2\pi i}\int_{\Gamma} e^{st}\frac{ds}{\sqrt{-ip + s/\tilde{c}(s)}} \tag{3.12}$$

$$= \frac{1}{2\pi i}\int_{\Gamma} e^{s(t-x/\tilde{c}(s))}ds \frac{1}{2\pi}\int_{-\infty+is/\tilde{c}(s)}^{\infty+is/\tilde{c}(s)} e^{-ipx}\frac{dp}{\sqrt{-ip}} \tag{3.13}$$

$$= \frac{H(x)}{\sqrt{\pi x}}\mathcal{L}^{-1}\big[e^{-xs/\tilde{c}(s)}\big], \tag{3.14}$$

with $S_{-}(x,t) = -S_{+}(-x,t)$. By definition of the inverse Laplace transform, the contour Γ is a vertical line placed to the right of any singularities. Hence this decomposition will place any poles and branch cuts in the left half of the complex plane (relative to Γ), and the inverse transform will have support $t - |x|/c > 0$.

Define $\breve{c}(s)$ via $\tilde{c}(s) = c\breve{c}(s)$, where $c = \sqrt{\mu_0/\rho}$ is the glassy (short-time) shear wave speed and $c_\infty = \sqrt{\mu_\infty/\rho}$ is the equilibrium (long-time) shear wave speed. The properties of $\breve{c}(s)$ are assumed to be as follows:

1. $\breve{c}(s) \to 1$ as $s \to \infty$.
2. $\breve{c}(s) \to \delta$ as $s \to 0$, where $\delta = c_\infty/c \le 1$.
3. $1/\breve{c}(s) = 1 + \gamma(s)$, with $s\gamma(s) = O(1)$ as $|s| \to \infty$.

(For example, the Achenbach–Chao and standard linear solid models both satisfy these conditions.) These conditions should ensure that the inverse Laplace transform in (3.14) is well defined. To see this, decompose the exponential function into two pieces:

$$e^{-\frac{|x|s}{\tilde{c}(s)}} = e^{-\frac{|x|\tilde{\gamma}}{c}}e^{-\frac{|x|s}{c}} + e^{-\frac{|x|\tilde{\gamma}}{c}}e^{-\frac{|x|s}{c}}\big(e^{-\frac{|x|}{c}(s\gamma(s)-\tilde{\gamma})} - 1\big), \tag{3.15}$$

where $\tilde{\gamma} = \lim_{|s|\to\infty} s\gamma(s)$. In terms of the shear relaxation function $\mu(t) = \mu_0 m(t/\tau)$, where $m(t)$ is nondimensional, we have $\tilde{\gamma} = |m'(0)|/2$, which equals $(1-\delta)/\tau$ for the Achenbach–Chao model and $(1-\delta^2)/2\tau$ for standard linear solid model.

The first term on the right-hand side of (3.15) will be similar to the elastic case, while the second term will lead to a dependence on the time history.

$$\mathcal{L}^{-1}\left[e^{-\frac{|x|\tilde{\gamma}}{c}}e^{-\frac{|x|s}{c}}\right] = e^{-\frac{|x|\tilde{\gamma}}{c}}\delta(t-|x|/c), \tag{3.16}$$

while the function $F(x,t)$ is defined via

$$\mathcal{L}^{-1}\left[e^{-\frac{|x|s}{c}}\big(e^{-\frac{|x|}{c}(s\gamma(s)-\tilde{\gamma})} - 1\big)\right](t) = \mathcal{L}^{-1}\big[e^{-\frac{|x|}{c}(s\gamma(s)-\tilde{\gamma})} - 1\big]\left(t - \frac{|x|}{c}\right) \tag{3.17}$$

$$= H\left(t - \frac{|x|}{c}\right)F\left(|x|, t - \frac{|x|}{c}\right). \tag{3.18}$$

Under the given assumptions, the transfer functions for the viscoelastic case will take the form

$$S_+(x,t) = \frac{H(x)}{\sqrt{\pi x}} e^{-\frac{x\tilde{\gamma}}{c}} \left(\delta\left(t - \frac{x}{c}\right) + H\left(t - \frac{x}{c}\right) F\left(x, t - \frac{x}{c}\right)\right), \tag{3.19}$$

$$S_-(x,t) = -\frac{H(-x)}{\sqrt{-\pi x}} e^{\frac{x\tilde{\gamma}}{c}} \left(\delta\left(t + \frac{x}{c}\right) + H\left(t + \frac{x}{c}\right) F\left(-x, t + \frac{x}{c}\right)\right). \tag{3.20}$$

Compare these to the functions $S_\pm$ given in (2.24) and (2.25) found for the elastic case. These transfer functions result (when convolved) in operators that are the sum of an elastic-like operator plus one involving the time history. With this in mind, define the elastic-like part as

$$S_{E\pm} = \pm \frac{H(\pm x)}{\sqrt{\pm \pi x}} e^{\mp \frac{x\tilde{\gamma}}{c}} \delta(t \mp x/c) \tag{3.21}$$

(noting that this elastic-like part involves only instantaneous moduli), while the component involving the time history is

$$S_{H\pm} = \pm \frac{H(\pm x)}{\sqrt{\pm \pi x}} e^{\mp \frac{x\tilde{\gamma}}{c}} H\left(t \mp \frac{x}{c}\right) F\left(\pm x, t \mp \frac{x}{c}\right). \tag{3.22}$$

Since

$$e^{-\frac{|x|}{c}(s\gamma(s) - \tilde{\gamma})} - 1 = \sum_{n=1}^{\infty} \frac{(-|x|)^n (s\gamma(s) - \tilde{\gamma})^n}{c^n n!}, \tag{3.23}$$

we have that $F(|x|, t - |x|/c) = O(|x|)$ as $|x| \to 0$. Convolutions with these functions have the following form in characteristic coordinates $\eta = t + x/c$ and $\xi = t - x/c$:

$$S_{E+} * * f = \sqrt{\frac{c}{2\pi}} \int_{-\xi}^{\eta} e^{-\frac{\tilde{\gamma}}{2}(\eta - r)} \tilde{f}(r, \xi) \frac{dr}{\sqrt{\eta - r}}, \tag{3.24}$$

(3.25)

$$S_{H+} * * f = \sqrt{\frac{c}{2\pi}} \int_{\frac{\xi - \eta}{2}}^{\xi} dq \int_{\xi - 2q}^{\eta} F\left(\frac{c}{2}(\eta - r), \xi - q\right) \tilde{f}(r - \xi + q, q) \frac{e^{-\frac{\tilde{\gamma}}{2}(\eta - r)} dr}{\sqrt{\eta - r}}.$$

Convolutions with S_- are similar but with roles of η and ξ exchanged and with a minus sign in front.

To find $T_\pm(x,t)$, rewrite the square roots as

$$\hat{\tilde{T}}_\pm(x,t) = \pm \frac{\mp ip + s/\tilde{c}(s)}{\sqrt{\mp ip + s/\tilde{c}(s)}} \tag{3.26}$$

and observe that

$$\mp ip + \frac{s}{\tilde{c}(s)} = \mp ip + \frac{s}{c} + \frac{\tilde{\gamma}}{c} + \frac{s\gamma(s) - \tilde{\gamma}}{c}, \tag{3.27}$$

whose inverse transform is the sum of derivatives, an identity operator, and a smoothing operator, as compared to the elastic case, which involves only derivatives (2.26)

and (2.27). The expression for these functions can be simplified into the sum of an elastic-like part $T_{E\pm}$ and a time history part $T_{H\pm}$:

$$T_{E+} * * f = \sqrt{\frac{2}{c\pi}} e^{-\frac{\tilde{\gamma}}{2}\eta} \frac{\partial}{\partial \eta} \int_{-\xi}^{\eta} e^{\frac{\tilde{\gamma}}{2} r} \tilde{f}(r, \xi) \frac{dr}{\sqrt{\eta - r}}, \tag{3.28}$$

(3.29)

$$T_{H+} * * f = -\frac{1}{c} \sqrt{\frac{2}{c\pi}} \int_{\frac{\xi-\eta}{2}}^{\xi} dq \int_{\xi-2q}^{\eta} F\left(\frac{c}{2}(\eta - r), \xi - q\right) \tilde{f}(r - \xi + q, q) \frac{e^{-\frac{\tilde{\gamma}}{2}(\eta - r)} dr}{(\eta - r)^{3/2}}.$$

Observe that T_{E+} and S_{E+} are inverse Abel operators.

Convolution with T_- leads to similar expressions, with the roles of η and ξ reversed and a change of sign.

4. Construction of the maps for the viscoelastic case. Due to the dependence on time history, the supports of $S_\pm$ will be $0 \le x \le ct$ and $-ct \le x \le 0$, as seen in the previous section, so that conditions (2.10) and (2.11) from the elastic case are not satisfied. This fact leads us to decompose the displacement $u(x,t)$ into three parts, with supports separated in the xt-plane by the crack tip path $x = a(t)$ and the line $x = a_0$:

$$u_+(x,t) = \begin{cases} u(x,t) & \text{if } x > a(t), \\ 0 & \text{otherwise,} \end{cases} \tag{4.1}$$

$$u_c(x,t) = \begin{cases} u(x,t) & \text{if } a_0 < x < a(t), \\ 0 & \text{otherwise,} \end{cases} \tag{4.2}$$

$$u_-(x,t) = \begin{cases} u(x,t) & \text{if } x < a_0, \\ 0 & \text{otherwise.} \end{cases} \tag{4.3}$$

The corresponding functions $D_c(x,t)$ and $D_-(x,t)$ as defined by (3.8) will have the same supports as $u_c(x,t)$ and $u_-(x,t)$, respectively, and $D_+(x,t)$ will be identically zero since we assume that $u_+(x,t) \equiv 0$. The stress $\sigma(x,t)$ will be split as in (2.12) and (2.13), with $\sigma_+(x,t)$ having support in the region $x > a(t)$, and $\sigma_-(x,t) = \Lambda(x,t)$, the known crack face loading, for $x < a(t)$. See Figure 4.1.

Expand (3.7) using these decompositions and multiply by $\hat{\tilde{S}}_+$:

$$\hat{\tilde{S}}_+ \hat{\tilde{\sigma}}_+ + \hat{\tilde{S}}_+ \hat{\tilde{\sigma}}_- = \hat{\tilde{T}}_- \hat{\tilde{D}}_c + \hat{\tilde{T}}_- \hat{\tilde{D}}_-. \tag{4.4}$$

The convolution $S_+ * * \sigma_+$ has support $x > a_0$, while the convolution $S_+ * * \sigma_-$ has support $x < a_0 + ct$. The convolution $T_- * * D_c$ has support $a_0 - ct < x < a(t)$, while the convolution $T_- * * D_-$ has support $x < a_0$.

Apply Fourier and Laplace transformations again to the following three equations, where Heaviside functions have been included to indicate intervals of support:

$$S_+ * * \sigma_+(x,t) = H(x - a_0)(-S_+ * * \sigma_- + T_- * * D_c), \tag{4.5}$$

$$T_- * * D_c(x,t) = H(a(t) - x)(S_+ * * \sigma_+ + S_+ * * \sigma_- - T_- * * D_-), \tag{4.6}$$

$$T_- * * D_-(x,t) = H(a_0 - x)(S_+ * * \sigma_- - T_- * * D_c). \tag{4.7}$$

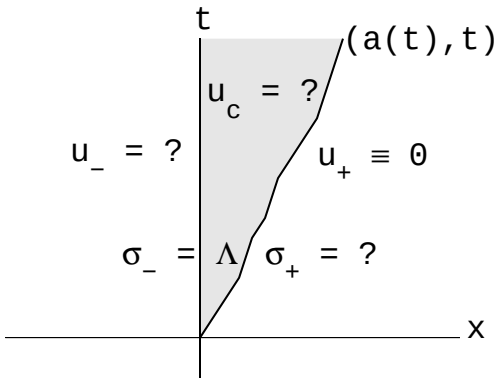

FIG. 4.1. *Division of the upper half of the xt-plane into three regions, separated by the crack tip path $x = a(t)$ and the line $x = a_0$ (the t-axis), for a semi-infinite, dynamically accelerating crack.*

Multiply the transform of (4.5) by $\hat{\tilde{T}}_+$, and the transforms of (4.6) and (4.7) by $\hat{\tilde{S}}_-$, then invert the transformations to obtain

$$\sigma_+(x,t) = T_+ * * \Big[H(x-a_0)\big[H(a(t)-x)(T_- * * D_c) - H(a_0+ct-x)(S_+ * * \Lambda)\big]\Big], \tag{4.8}$$

$$D_c(x,t) = S_- * * \Big[H(a(t)-x)H(x-a_0+ct)\big[H(x-a_0)(S_+ * * \sigma_+) + H(a_0+ct-x)(S_+ * * \Lambda) - H(a_0-x)(T_- * * D_-)\big]\Big], \tag{4.9}$$

$$D_-(x,t) = S_- * * \Big[H(a_0-x)\big[H(a_0+ct-x)(S_+ * * \Lambda) - H(a(t)-x)H(x-a_0+ct)(T_- * * D_c)\big]\Big]. \tag{4.10}$$

Unfortunately, D_c is unknown and cannot directly be solved using the above maps. However, if we can derive a formula for D_c that involves only the known loading $\Lambda(x,t)$, then we can use these maps to find the remaining crack face displacement D_- and the stress σ_+ in front of the crack tip.

The function $\sigma_+(x,t)$ vanishes for $x < a(t)$, so the right-hand side of (4.8) equals zero if $x < a(t)$. Define a new (completely known) function $t_0(x,t)$ with support $a_0 < x < a(t)$ as follows (analogous to what is done in [2]),

$$t_0(x,t) = H(a(t)-x)H(x-a_0)\left[T_+ * * \big[H(x-a_0)(S_+ * * \Lambda)\big]\right], \tag{4.11}$$

and then use (4.8) to form a new equation:

$$H(a(t)-x)\left[T_+ * * \big[H(x-a_0)H(a(t)-x)(T_- * * D_c)\big]\right] = t_0(x,t). \tag{4.12}$$

We could solve this new differo-integral equation for D_c using numerical methods, leading to a complete numerical solution for all boundary data by combining with (4.8) and (4.10). We will instead calculate asymptotic behavior near the crack tip; in particular, we wish to determine the stress intensity factor (SIF) $K(t)$, defined via $K(t) = \lim_{x\to a(t)^+}[\sqrt{x-a(t)}\sigma_+(x,t)]$.

We will consider two cases: a stationary crack $a(t) \equiv a_0$ and a moving crack $a(t) > a_0$. Start by assuming that the crack tip has not yet begun to move: $a(t) = a_0$. Since D_c has no support in this case, (4.8) reduces to (the dots refer to bounded terms not contributing to the SIF)

$$\sigma_+(x,t) = -T_+ * *\big[H(x-a_0)H(a_0+ct-x)(S_+ * *\Lambda)\big] \tag{4.13}$$

$$= -\left(\frac{\partial}{\partial\eta} + \frac{\tilde{\gamma}}{c}\right)[S_{E+} * *[H(x-a_0)H(a_0+ct-x)(S_+ * *\Lambda)]] + \cdots . \tag{4.14}$$

Multiplying by $\sqrt{x-a_0}$ and taking the limit as $x \to a_0^+$ yields the SIF corresponding to a stationary crack tip $a(t) \equiv a_0$:

$$K_{\text{stationary}}(t) = -\frac{\sqrt{c}}{\pi}\int_0^t \Lambda\left(c\left(r-t+\frac{a_0}{c}\right),r\right)\frac{e^{-\tilde{\gamma}(t-r)}dr}{\sqrt{t-r}} - \frac{\sqrt{c}}{\pi}\int_0^t du\int_0^u \Lambda\left(c\left(r-u+\frac{a_0}{c}\right),r\right)F(c(u-r),t-u)\frac{e^{-\tilde{\gamma}(u-r)}dr}{\sqrt{u-r}}. \tag{4.15}$$

Now consider the case where the crack has progressed beyond its initial position: $a(t) > a_0$. The term directly involving $\Lambda(x,t)$ in (4.8) will have the form of a bounded integral divided by $\sqrt{x-a_0}$, so that this term has no contribution to the SIF if $a(t) > a_0$. We need consider only the term involving $D_c(x,t)$ in (4.8) to derive the SIF for this case. Therefore, in order to determine the SIF for a moving crack tip, we will first derive an expression for the SIF in terms of the displacement $D_c(x,t)$.

Using (4.8) and observing that for a moving crack tip there is no singularity in the term involving $\Lambda(x,t)$ or the term involving T_{H+}, we obtain

$$K(t) = \lim_{x\to a(t)^+}\big[\sigma_+(x,t)\sqrt{x-a(t)}\big] \tag{4.16}$$

$$= \lim_{x\to a(t)^+}\sqrt{x-a(t)}\big[T_+ * *[H(x-a_0)H(a(t)-x)(T_- * *D_c)]\big] \tag{4.17}$$

$$= \sqrt{\frac{c-\dot{a}(t)}{c\pi}}\lim_{x\to a(t)^+} e^{-\frac{\tilde{\gamma}}{2}\eta}\sqrt{\eta - b_1\circ b_0^{-1}(\xi)} \cdot \frac{\partial}{\partial\eta}\int_{\xi+\frac{2a_0}{2}}^{b_1\circ b_0^{-1}(\xi)} e^{\frac{\tilde{\gamma}}{2}r}(T_- * *D_c)(r,\xi)\frac{dr}{\sqrt{\eta-r}} \tag{4.18}$$

$$= -\sqrt{\frac{c-\dot{a}(t)}{c\pi}}\lim_{x\to a(t)^-}(T_- * *D_c)(x,t). \tag{4.19}$$

In the above limit we have used the fact that

$$\lim_{x\to a(t)^+}\frac{x-a(t)}{\eta - b_1\circ b_0^{-1}(\xi)} = \frac{1}{2}(c-\dot{a}(t)). \tag{4.20}$$

Next we will make use of the supports of the various convolutions and (4.5)–(4.6) to construct an expression for $T_- * *D_c$. Using (4.6) and the facts that $T_- * *D_-$

vanishes for $x > a_0$ and $S_{E+} * *\sigma_+$ vanishes for $x < a(t)$, we have that

$$\lim_{x\to a(t)^-}(T_- * *D_c)(x,t) = \lim_{x\to a(t)^-}(S_+ * *\sigma_+ + S_+ * *\Lambda)(x,t) \tag{4.21}$$

$$= \lim_{x\to a(t)^-}(S_{H+} * *\sigma_+ + S_+ * *\Lambda)(x,t) \tag{4.22}$$

$$= (S_{H+} * *\sigma_+)(a(t),t) + (S_+ * *\Lambda)(a(t),t), \tag{4.23}$$

where

$$(S_+ * *\Lambda)(a(t),t) = \sqrt{\frac{c}{\pi}}\int_0^t e^{-\tilde{\gamma}(t-r)}\Lambda(c(r-b_0(t)),r)\frac{dr}{\sqrt{t-r}} \tag{4.24}$$
$$+\sqrt{\frac{c}{\pi}}\int_0^t dr\int_{b_0(r)}^{b_0(t)}\Lambda(c(r-q),r)F(c(q-r)+a(t),b_0(t)-q)\frac{e^{-\tilde{\gamma}(q-r+a(t)/c)}dq}{\sqrt{q-r+a(t)/c}}.$$

Now apply (4.8) to derive a new expression for $S_{H+} * *\sigma_+$ on the region $a_0 < x < a(t)$:

$$S_{H+} * *\sigma_+ = S_{H+} * *T_+ * *\big[H(x-a_0)H(a(t)-x)(T_- * *D_c) \tag{4.25}$$
$$- H(x-a_0)H(a_0+ct-x)(S_+ * *\Lambda)\big],$$

and then apply (4.6) as well as the fact that the support of $T_- * *D_-$ is $x < a_0$:

$$S_{H+} * *\sigma_+ = S_{H+} * *T_+ * *\big[H(x-a_0)H(a(t)-x)(S_+ * *\sigma_+ + S_+ * *\Lambda) \tag{4.26}$$
$$- H(x-a_0)H(a_0+ct-x)(S_+ * *\Lambda)\big].$$

After simplifying, we now have an operator equation for $S_{H+} * *\sigma_+$ for $a_0 < x < a(t)$:

$$S_{H+} * *\sigma_+ = S_{H+} * *T_+ * *\big[H(x-a_0)H(a(t)-x)(S_{H+} * *\sigma_+) \tag{4.27}$$
$$- H(x-a(t))H(a_0+ct-x)(S_+ * *\Lambda)\big].$$

To simplify calculations, the operator in (4.27) can be reduced to a much simpler form, using the facts that S_+ and T_+ are inverse operators when convolved, as are S_{E+} and T_{E+}:

$$S_{H+} * *T_+ * *f = f - S_{E+} * *T_+ * *f \tag{4.28}$$

$$= f - (S_{E+} * *T_{E+} * *f + S_{E+} * *T_{H+} * *f) \tag{4.29}$$

$$= -S_{E+} * *T_{H+} * *f. \tag{4.30}$$

Observe that this new expression involves no derivatives and fewer integrations than the original form.

Putting together (4.19), (4.23), (4.27), and (4.30), we can derive a closed-form expression for the SIF for a moving crack tip that involves only the known crack face loading $\Lambda(x,t)$:

$$K(t) = -\sqrt{\frac{c-\dot{a}(t)}{c\pi}}G(a(t)^+,t) \tag{4.31}$$
$$-\sqrt{\frac{c-\dot{a}(t)}{c\pi}}\sum_{n=0}^{\infty}\big[S_{E+} * *T_{H+} * *\big[H(x-a_0)H(a(t)-x)(-S_{E+} * *T_{H+} * *)\big]^n G\big](a(t),t),$$

where we have defined $G(x,t)$ to be

$$G(x,t) = H(x-a(t))H(a_0+ct-x)(S_+ **\Lambda)(x,t). \tag{4.32}$$

From (4.30), we observe that the operator in (4.27) is second kind Volterra, which implies that the Neumann expansion in (4.31) will converge. Alternatively, we could solve the second kind Volterra integral equation

$$J(x,t) + (S_{E+} **T_{H+} **J)(x,t) = (S_{E+} **T_{H+} **G)(x,t) \tag{4.33}$$

for the function $J(x,t) = H(x-a_0)H(a(t)-x)(S_{H+}**\sigma_+)$ and then use the following expression for the SIF:

$$K(t) = -\sqrt{\frac{c-\dot a(t)}{c\pi}}G(a(t)^+,t) - \sqrt{\frac{c-\dot a(t)}{c\pi}}J(a(t)^-,t). \tag{4.34}$$

Also note that the expression in (4.31) agrees with (4.15) in the case that $\dot a(t) = 0$ and hence is the general expression for the viscoelastic SIF; compare to the elastic SIF given by (2.31).

In the next two sections we will apply this solution method to two common models of linear viscoelasticity and, in particular, state the time history function for each. Numerical simulations and comparison to the steady-state solution will be done in a forthcoming paper.

5. The Achenbach–Chao model. The Achenbach–Chao viscoelastic model (introduced by Achenbach and Chao [1] as an approximation to the standard linear solid) is particularly convenient to work with, as it avoids the need to integrate around branch cuts when finding $S_\pm(x,t)$ (as must be done for the standard linear solid, for example). The s-multiplied Laplace transforms of the relaxation function $\mu(t)$ and wave speed $c(t)$ for an Achenbach–Chao viscoelastic material are defined to be

$$\tilde\mu(s) = \mu_0\left[\frac{\delta+\tau s}{1+\tau s}\right]^2, \tag{5.1}$$

$$\tilde c(s) = c\frac{\delta+\tau s}{1+\tau s}. \tag{5.2}$$

The modified displacement function $D(x,t)$ has the following form for the Achenbach–Chao model:

$$D(x,t) = \mu_0 u(x,t) + \mu_0\int_0^t u(x,t-u)\left[\delta^2 + (1-\delta^2)\left(1-\frac{1-\delta}{1+\delta}\frac{u}{\tau}\right)e^{-u/\tau}\right]du. \tag{5.3}$$

The time history function for the Achenbach–Chao model is

$$F(x,\xi) = e^{-\delta\xi/\tau}\sum_{k=0}^{\infty}\frac{\xi^k\big((1-\delta)\delta x/(c\tau^2)\big)^{k+1}}{k!(k+1)!} \tag{5.4}$$

$$= e^{-\delta\xi/\tau}\sqrt{\frac{\delta(1-\delta)x/c}{\xi\tau^2}}I_1\left(2\sqrt{\frac{\delta(1-\delta)}{\tau^2}\frac{x}{c}\xi}\right). \tag{5.5}$$

Here $I_1(z)$ is the modified Bessel function of the first kind. (Note that $\lim_{t\to|x|/c}F(|x|,t-|x|/c) = \delta(1-\delta)|x|/c\tau^2$, and thus $F(|x|,t-|x|/c)/\sqrt{|x|}$ is not singular.)

The SIF for the Achenbach–Chao model reduces in the case $\delta = 1$ to the elastic SIF given in (2.31), and in the case $\delta = 0$ to the expression found in [2] for the SIF of the Achenbach–Chao approximation to a Maxwell fluid.

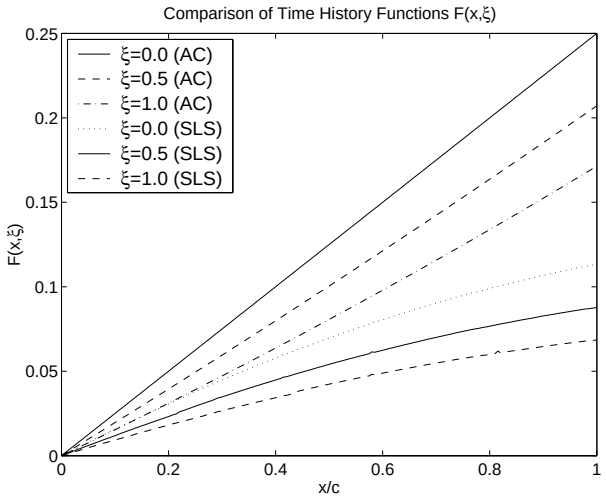

FIG. 6.1. *Comparison of time history functions $F(x,\xi)$ for the Achenbach–Chao (AC) and standard linear solid (SLS) models, for parameter values $\delta = 0.5$ and $\tau = 1$.*

6. Standard linear solid. As another example, we consider the standard linear solid viscoelastic model. The s-multiplied Laplace transforms of the relaxation function $\mu(t)$ and wave speed $c(t)$ are defined to be

$$\tilde{\mu}(s) = \mu_0 \left[\frac{\delta^2 + s}{1 + s} \right], \tag{6.1}$$

$$\tilde{c}(s) = c \sqrt{\frac{\delta^2 + s}{1 + s}}. \tag{6.2}$$

The time history function for the standard linear solid model is

$$F(x,\xi) = \frac{1}{\pi} e^{\frac{1-\delta^2}{2}\frac{|x|}{c}} \int_{\delta^2}^{1} e^{-s\xi} e^{-\frac{s|x|}{c}} \sin\left(\frac{|x|}{c} s \sqrt{\frac{1-s}{s-\delta^2}} \right) ds. \tag{6.3}$$

The time history functions for the two models are compared in Figure 6.1.

7. Concluding remarks. The key to this solution method is the observation that, after applying Laplace and Fourier transforms and taking the limit as $y \to 0^+$, the governing equations to the dynamic fracture problem reduce to a simple transfer map. In this paper we have focused on the mode III (antiplane shear) case, but the transfer maps corresponding to the mode I and II elastic and viscoelastic fracture problems share the same structure:

$$\hat{\tilde{\sigma}}(p,s) = \hat{\tilde{T}}(p,s) \hat{\tilde{u}}(p,s), \tag{7.1}$$

where $\sigma(x,t)$ is the appropriate component of the stress tensor and $u(x,t)$ is the appropriate displacement along the boundary $y = 0^+$. The elastic mode III transfer function $T(p,s)$ is quite simple,

$$\hat{\tilde{T}}_{III}(p,s) = -\mu \sqrt{p^2 + s^2/c_s^2}, \tag{7.2}$$

while that for the elastic mode I case is more complicated, requiring a more complicated decomposition:

$$\hat{\tilde{T}}_I(p,s) = \frac{\mu^2 R(p,s)}{\rho s^2 \sqrt{p^2 + s^2/c_L^2}}, \tag{7.3}$$

where $R(p,s)$ is the Rayleigh wave function. (The mode II transfer function is similar.) See [9] for the details of the mode I elastic case of subsonic fracture. For faster fracture speeds, this method could still be carried out by choosing appropriate decompositions as described in [12], although the problem of how to jump across speed barriers remains unaddressed.

The difficulty in applying this method to a crack in a viscoelastic material is due to the dependence on the time history. Based on the analysis of section 3, for any fracture mode the viscoelastic transfer function should lead to expressions for the stress and displacement that involve an elastic-like part T_E plus a time history part T_H, which greatly increases the computational difficulty in obtaining, for example, the crack face displacement, as compared to in the elastic case. In principle, however, one can carry out an analysis similar to the one given in this paper for an opening mode crack in a linear viscoelastic material, though the details will be considerably more complicated.

FAST OPTIMAL DESIGN OF SEMICONDUCTOR DEVICES*

MARTIN BURGER† AND RENÉ PINNAU‡

Abstract. This paper presents a new approach to the design of semiconductor devices, which leads to fast optimization methods whose numerical effort is of the same order as a single forward simulation of the underlying model, the *stationary drift-diffusion system*. The design goal we investigate is to increase the outflow current on a contact for fixed applied voltage; the natural design variable is the doping profile.

By reinterpreting the doping profile as a state variable and the electrostatic potential as the new design variable, we obtain a simpler optimization problem, whose Karush–Kuhn–Tucker conditions partially decouple. This property allows us to construct efficient iterative optimization algorithms, which avoid solving the fully coupled drift-diffusion system, and need only solves of the continuity equations and their adjoints. The efficiency and success of the new approach is demonstrated in several numerical examples.

Key words. semiconductor design, drift-diffusion, optimal control, dopant profiling

1. Introduction.

Optimal design and characterization of semiconductor devices is a field of growing interest in recent years, in engineering (cf., e.g., [5, 6, 13, 14, 18, 21, 22, 23]) as well as in the applied mathematics community (cf., e.g., [2, 3, 7, 8, 9, 10, 11]). A major objective in the optimal design of devices is to improve the current flow over some contact by modifying the device doping profile, which enters as a source term in the mathematical model used for semiconductor devices, the so-called *drift-diffusion system*.

The stationary drift-diffusion system in physical variables (cf. [15, 24]) consists of nonlinear elliptic equations for the electrostatic potential V, the electron density n, and the hole density p, in a bounded domain $\Omega \subset \mathbb{R}^N$, $N \leq 3$:

$$\begin{aligned} \operatorname{div}(\epsilon_s \nabla V) &= q(n - p - C) && \text{in } \Omega, \\ \operatorname{div}(D_n \nabla n - \mu_n n \nabla V) &= 0 && \text{in } \Omega, \\ \operatorname{div}(D_p \nabla p + \mu_p p \nabla V) &= 0 && \text{in } \Omega, \end{aligned}$$

where ϵ_s denotes the semiconductor permittivity, q the elementary charge, μ_n and μ_p are the electron and hole mobilities, and D_n and D_p are the electron and hole diffusion coefficients, respectively. This system is supplemented by homogeneous Neumann boundary conditions on a part $\partial\Omega_N$ of the boundary, modelling the insulating parts of the boundary, and Dirichlet conditions on the remaining part, which models the

Ohmic contacts of the device:

$$V(x) = V_D(x) = U(x) + V_{bi}(x) = U(x) + U_T \ln\left(\frac{n_D(x)}{n_i}\right) \qquad \text{on } \partial\Omega_D,$$

$$n(x) = n_D(x) = \frac{1}{2}\left(C(x) + \sqrt{C(x)^2 + 4n_i^2}\right) \qquad \text{on } \partial\Omega_D,$$

$$p(x) = p_D(x) = \frac{1}{2}\left(-C(x) + \sqrt{C(x)^2 + 4n_i^2}\right) \qquad \text{on } \partial\Omega_D.$$

Here n_i is the intrinsic density, U_T the thermal voltage, and U the applied biasing voltage.

Under usual conditions, the mobilities and diffusion coefficients are related by Einstein's relation, i.e., $D_{n/p} = \mu_{n/p} U_T$, which enables the transformation into the so-called *Slotboom variables* [19] defined by

$$n = n_i e^{V/U_T} u, \qquad p = n_i e^{V/U_T} v. \tag{1.1}$$

The assumption that ϵ_s and q are constant allows for the choice of an appropriate scaling, yielding the system

$$\lambda^2 \Delta V = (e^V u - e^{-V} v) - C \qquad \text{in } \Omega, \tag{1.2}$$

$$\operatorname{div}\left(\mu_n e^V \nabla u\right) = 0 \qquad \text{in } \Omega, \tag{1.3}$$

$$\operatorname{div}\left(\mu_p e^{-V} \nabla v\right) = 0 \qquad \text{in } \Omega, \tag{1.4}$$

where $\lambda^2 = (\epsilon_s U_T)/(q\, C_{max}\, L^2)$ is the scaled Debye length of the device (for details, see, e.g., [16]). The Dirichlet boundary conditions can be written as

$$V = V_D = U + V_{bi} \qquad \text{on } \partial\Omega_D, \tag{1.5}$$

$$u = u_D \qquad \text{on } \partial\Omega_D, \tag{1.6}$$

$$v = v_D \qquad \text{on } \partial\Omega_D, \tag{1.7}$$

where u_D and v_D are the transformations of n_D and v_D under (1.1). On the remaining part $\partial\Omega_N = \partial\Omega \setminus \partial\Omega_D$, the homogeneous Neumann conditions can be formulated on J_n and J_p, where J_n and J_p are the electron and hole current densities, which are related to the Slotboom variables by

$$J_n = \mu_n e^v \nabla u, \qquad J_p = -\mu_p e^{-V} \nabla v. \tag{1.8}$$

Hence, we have

$$\frac{\partial V}{\partial \nu} = 0 \qquad \text{on } \partial\Omega_N, \tag{1.9}$$

$$\frac{\partial u}{\partial \nu} = 0 \qquad \text{on } \partial\Omega_N, \tag{1.10}$$

$$\frac{\partial v}{\partial \nu} = 0 \qquad \text{on } \partial\Omega_N. \tag{1.11}$$

Throughout the whole paper, we shall assume that all Dirichlet boundary values V_D, u_D, and v_D are bounded in $H^{\frac{1}{2}}(\Omega) \cap L^\infty(\Omega)$, which is the basis for an existence proof of the drift-diffusion system in $(H^1(\Omega) \cap L^\infty(\Omega))^3$ (see [16]).

The objective of the optimization, the current flow over a contact Γ, is given by

$$I = \int_\Gamma J \cdot \nu = \int_\Gamma (J_n + J_p) \cdot d\nu. \tag{1.12}$$

An optimal control approach to the optimization of a functional related to the current density J or the current flow I was investigated in [10, 11], where the drift-diffusion system (1.2)–(1.11) was interpreted as an equation constraint determining the state (V, u, v). Consequently, a penalty term related to the control variable C was added to the objective in order to stabilize the system. To the penalizing problem, an iterative algorithm was applied, which as usual needed solutions of the drift-diffusion system and some adjoint system in each iteration. In this paper we investigate a completely different approach; namely, we reinterpret the potential V as the design variable, and the doping profile C as a state variable. For a given V satisfying appropriate boundary conditions, it is easy to show that the drift-diffusion system has a unique solution (u, v, C) and, moreover, that the partial differential equations (1.2)–(1.4) have a simple triangular structure in the new state variables. Corresponding to our interpretation of state and design variables we add to the objective functional a penalty term corresponding to V in order to stabilize the problem. As we shall see below, this yields a reasonably simple optimality system, from which a fast optimization algorithm can be constructed.

For the sake of simplicity and shortness of presentation, we assume that $\mu_n = \mu_p = 1$, but analogous reasoning is possible for general mobilities, even for energy dependent ones. Moreover, we ignore recombination-generation terms [19], noting that they could be incorporated into our analysis with only few modifications.

The paper is organized as follows: in section 2 we review the current state of semiconductor design and introduce our new optimization approach. Some basic analysis of the optimization problem under investigation (such as the existence of solutions and first-order optimality) is provided in section 3. Section 4 is devoted to the iterative solution of the optimal design problem, and in particular an efficient method based on a lower diagonal approximation of the Karush–Kuhn–Tucker system is introduced. Numerical results for some diodes and a metal-semiconductor field effect transistor (MESFET) are presented in section 5, and finally we give some conclusions in section 6.

2. Optimal design of semiconductor devices. In the following we discuss some basic problems in optimal semiconductor design and present a new approach for optimization problems at a single applied voltage.

Although the optimal design of semiconductor devices is of major importance in practical applications, the first systematic approaches to such optimization problems have been carried out only in the last few years (cf. [10, 11, 18, 21, 22, 23]). One of the main reasons for this late development is the computational difficulties and the complexity of such optimization problems. Even the numerical solution of the drift-diffusion system itself is not a simple task, and an optimization based on the drift-diffusion model therefore becomes quite involved. In the first optimization approaches to this problem, gradient-type methods were used, with gradient evaluations either by finite differencing (cf. [18, 21, 22, 23]) or by an adjoint method (cf. [10, 11]). Both approaches resulted in a very high numerical effort due to a large number of iterations needed. E.g., by finite differencing, around 4000 direct solutions of the drift-diffusion system were needed for the optimization of a metal-oxide-semiconductor field effect transistor (MOSFET), at a rather coarse discretization of the doping profile with 62

design parameters (cf. [18]). The adjoint approach, used in [11] for the minimization of a functional of the form

$$Q_\beta(C) := Q(n(C), p(C), V(C)) + \frac{\beta}{2}\|C - C^*\|^2 \to \min_C, \tag{2.1}$$

reduces the number of nonlinear solves, and adds few solves of an adjoint linear system. This reduces the numerical effort, but causes the need for an accurate discretization and numerical solution of the adjoint system, which is not well investigated so far.

We use a different approach, based on exchanging the interpretations of control and state between C and V. We interpret the potential V as the design variable and interpret the Poisson equation (1.2) as a state equation for the doping profile C. Consequently, we introduce a penalty dependent on $V - V^*$ rather than on $C - C^*$. As the initial guess V^* we use the one obtained from the solution of the drift-diffusion system with doping profile C^*. Since the Laplacian of $V - V^*$ is needed for the evaluation of $C - C^*$, it seems natural to use a penalty term dependent on

$$W := \Delta(V - V^*), \tag{2.2}$$

i.e., we minimize the functional

$$Q_\epsilon(u, u, V, W) := Q(u, v, V) + \frac{\epsilon}{2}\int_\Omega |W(x)|^2 \, dx, \tag{2.3}$$

subject to (2.2) and the drift-diffusion system. In order to ensure that C does not change its boundary values, W must satisfy homogeneous boundary conditions on $\partial\Omega_D$; on the remaining boundary we may use any homogeneous boundary condition. For simplicity we will carry out our analysis for

$$W = 0 \qquad \text{on } \partial\Omega. \tag{2.4}$$

In a numerical test (cf. section 5.3) we will use the boundary condition $W = 0$ on $\partial\Omega_D$, and $\frac{\partial W}{\partial \nu} = 0$ on $\partial\Omega_N$, which permits a similar analysis.

Of particular importance are functionals Q, which depend only on the values of the outflow current density on some contact Γ, i.e.,

$$Q(u, v, V) = R(J \cdot \nu|_\Gamma) = R\left(\left(e^V \frac{\partial u}{\partial \nu} - e^{-V}\frac{\partial u}{\partial \nu}\right)\Big|_\Gamma\right). \tag{2.5}$$

In [11], the functional under investigation was

$$R(J \cdot \nu|_\Gamma) = \frac{1}{2}\|(J - J^*) \cdot \nu\|^2_{H^{-\frac{1}{2}}(\Gamma)}, \tag{2.6}$$

corresponding to the objective of finding an outflow current density $J \cdot \nu$ close to a desired density $J^* \cdot \nu$. Since in most practical applications, one is rather interested in the total current flow on a contact, we rather consider the functional

$$R(J. \cdot \nu|_\Gamma) = \frac{1}{2}\left|\int_\Gamma J \cdot d\nu - I^*\right|^2 \tag{2.7}$$

(for some desired current flow I^*) as the motivation for the analysis in this paper, and we also use it for our numerical tests. We note that for one-dimensional diodes, which have been investigated in [11] and will be used for some of our numerical tests too, the above two functionals are equivalent, since the geometry of a contact corresponds to a boundary point of an interval.

3. Analysis of the optimization problem. In the following we provide some analysis of the optimization problem

$$Q_\epsilon(u,v,V,W) \to \min_{(n,p,V,W)\in\mathcal{D}_{ad}}, \tag{3.1}$$

with the admissible domain

$$\mathcal{D}_{ad} := \{(u,v,V,W) \in H^1(\Omega)^2 \times (H^1(\Omega)\cap L^\infty(\Omega)) \times L^2(\Omega) \\ \text{satisfying (1.3)–(1.11), (2.2)}\}.$$

We shall investigate the existence of minima as well as a derivation of the Karush–Kuhn–Tucker conditions, which allow us to deduce further regularity of minimizers.

3.1. Existence of a minimum. We start our analysis with a basic result on the existence of minima, for which we need two fundamental properties, namely, the weak lower semicontinuity of the objective functional and the weak closedness of the admissible domain. The weak lower semicontinuity of Q_ϵ is obviously obtained in $H^1(\Omega)^3 \times L^2(\Omega)$; the weak closedness of $\mathcal{D}_{ad}$ is obtained if $\Delta(V-V^*)$ remains in $L^2(\Omega)$. This leads us to the following result.

THEOREM 3.1 (existence). *Let $\epsilon > 0$. Then there exists a minimum*

$$(\overline{u},\overline{v},\overline{V},\overline{W}) \in H^1(\Omega)^2 \times (H^1(\Omega)\cap L^\infty(\Omega)) \times L^2(\Omega) \tag{3.2}$$

of (3.1).

Proof. Suppose that $(u^k,v^k,V^k,W^k)_{k\in\mathbb{N}}$ is a minimizing sequence; then we immediately conclude that W^k is bounded in $L^2(\Omega)$, and thus, by standard elliptic regularity, $V^k - V^*$ is uniformly bounded in $H^2(\Omega) \hookrightarrow C(\overline{\Omega})$. Since the a priori guess V^* is in $L^\infty(\Omega)$, we obtain uniform boundedness of V^k in $L^\infty(\Omega)$. Standard energy arguments for the elliptic equations (1.3) and (1.4) consequently yield the boundedness of u^k and v^k in $H^1(\Omega)\cap L^\infty(\Omega)$. Thus, we may extract a weakly converging subsequence $(u_{k_\ell},v_{k_\ell},V_{k_\ell},W_{k_\ell})_{k_\ell\in\mathbb{N}} \in H^1(\Omega)^2 \times H^1(\Omega) \times L^2(\Omega)$, which also preserves the L^∞ bound (and such that $\Delta(V_{k_\ell}-V^*)$ converges weakly in $L^2(\Omega)$). The weak closedness of the admissible domain and the weak lower semicontinuity of the objective functional imply that the weak limit of this subsequence is a minimizer of (3.1). ∎

A direct consequence of the representation

$$C = C^* - \lambda^2 W + n - n^* - p + p^*$$

is the existence of a doping profile $C \in L^2(\Omega)$ such that (u,v,V) is a solution of the corresponding drift-diffusion system.

COROLLARY 3.2. *Let $\epsilon > 0$. Then there exists a minimum*

$$(\overline{u},\overline{v},\overline{V},\overline{W}) \in H^1(\Omega)^2 \times (H^1(\Omega)\cap L^\infty(\Omega)) \times L^2(\Omega) \tag{3.3}$$

of (3.1) *and a doping profile $\overline{C} \in L^2(\Omega)$ such that $(\overline{u},\overline{v},\overline{V})$ is a weak solution of the drift-diffusion system* (1.2)–(1.11) *with $C = \overline{C}$.*

3.2. First-order optimality. In order to derive the first-order optimality conditions, we define the Lagrangian given by

$$\mathcal{L}(u,v,V,W;\mu_1,\mu_2,\mu_3) = Q_\epsilon(u,v,V,W) + \int_\Omega \left(e^V\nabla u\cdot\nabla\mu_1 - e^{-V}\nabla v\nabla\mu_2\right)\,dx \\ + \int_\Omega \left(\nabla(V-V^*)\cdot\nabla\mu_3 + W\mu_3\right)\,dx. \tag{3.4}$$

One observes that the only nonlinear terms in the equation constraints (1.3)–(1.11), (2.2) are of the form $e^V \nabla u$ and $e^{-V}\nabla v$, and these are continuously Fréchet-differentiable in $\mathcal{D}_{ad}$ since $V \in H^1(\Omega) \cap L^\infty(\Omega)$ and $(u, v) \in H^1(\Omega)^2$. Hence, with little effort we obtain the following result.

PROPOSITION 3.3. *The Lagrangian $\mathcal{L}$ is continuously Fréchet-differentiable on $\mathcal{D}_{ad} \times H^1(\Omega)^3$.*

Each solution of the optimization problem is a saddle point of the Lagrangian, i.e., a solution of

$$\inf_{(u,v,V,W)} \sup_{(\mu_1,\mu_2,\mu_3)} \mathcal{L}(u, v, V, W; \mu_1, \mu_2, \mu_3). \tag{3.5}$$

For such saddle points we can derive the Karush–Kuhn–Tucker conditions by computing the variations of the Lagrangian $\mathcal{L}$ with respect to all primal and dual variables, which all must vanish. The variations with respect to the dual variables yield just the equality constraints, while from the variation with respect to the primal variables we deduce that

$$0 = \frac{\partial}{\partial u} Q_\epsilon(u, v, V, W)\hat{u} + \int_\Omega \left(e^V \nabla \hat{u} \cdot \nabla \mu_1\right) dx, \tag{3.6}$$

$$0 = \frac{\partial}{\partial v} Q_\epsilon(u, v, V, W)\hat{v} - \int_\Omega \left(e^V \nabla \hat{v} \cdot \nabla \mu_2\right) dx, \tag{3.7}$$

$$\begin{aligned} 0 = {} & \frac{\partial}{\partial V} Q_\epsilon(u, v, V, W)\hat{V} \\ & + \int_\Omega \left(\hat{V}\left(e^V \nabla u \cdot \nabla \mu_1 + e^{-V}\nabla v \nabla \mu_2\right) + \nabla \hat{V} \cdot \nabla \mu_3\right) dx, \end{aligned} \tag{3.8}$$

$$0 = \int_\Omega \hat{W}(\epsilon W - \mu_3) dx \tag{3.9}$$

holds for all variations $(\hat{u}, \hat{v}, \hat{V}, \hat{W}) \in H^1(\Omega)^3 \times L^2(\Omega)$.

One observes that the so-called *adjoint equations* (3.6)–(3.8) have a simple triangular structure with respect to the Lagrangian variables. Thus, the problem of proving existence and uniqueness of the Lagrangian variables $(\mu_1, \mu_2, \mu_3) \in H^1_{0,D}(\Omega)^3$ solving (3.6)–(3.8) for given primal variables (u, v, V) simplifies to analyzing subsequently three different variational problems, which turn out to be coercive in $H^1_{0,D}(\Omega)$, with

$$H^1_{0,D}(\Omega) := \{\varphi \in H^1(\Omega) \mid \varphi|_{\partial\Omega_D} = 0\}.$$

This yields another advantage of our approach with respect to the direct optimal control approach, where analyzing the adjoint problem is a difficult task, which is possible only close to thermal equilibrium (cf. [11]).

THEOREM 3.4. *Let $(u, v, V, W) \in \mathcal{D}_{ad}$ be given; then there exists a unique solution $(\mu_1, \mu_2, \mu_3) \in H^1_{0,D}(\Omega)^3$ of the variational problem* (3.6)–(3.8).

Proof. The variational problem (3.6) is of the form

$$A(\mu_3, \hat{u}) = \langle F, \hat{u}\rangle \qquad \forall\ \hat{u} \in H^1_{0,D}(\Omega),$$

with a continuous linear functional F on $H^1_{0,D}(\Omega)$ and a coercive, continuous bilinear form

$$A(u, v) = \int_\Omega e^V \nabla u \cdot \nabla v\ dx \quad \text{ on } H^1_{0,D}(\Omega)^2.$$

Thus, existence and uniqueness of μ_1 follow from the Lax–Milgram theorem. Since we can apply analogous reasoning to (3.7), we also obtain the existence and uniqueness of μ_2. Since μ_1 and μ_2 are determined by (3.6), (3.7), we may consider them as a given right-hand side in (3.8). The latter is now a scalar problem for μ_3, whose well-posedness can again be shown by a straightforward application of the Lax–Milgram theorem. Note that $L^2(\Omega) \hookrightarrow H^{-1}(\Omega)$. ∎

Our subsequent analysis will be carried out for the important case of Q being the outflow current functional (2.5). In this case, the derivative of the functional Q is given by

$$Q'(u,v,V)(\hat{u},\hat{v},\hat{V}) = R'(J\cdot\nu|_\Gamma)\left(e^V\frac{\partial\hat{u}}{\partial\nu} - e^{-V}\frac{\partial\hat{v}}{\partial\nu} + \left(e^V\frac{\partial u}{\partial\nu} + e^{-V}\frac{\partial v}{\partial\nu}\right)\hat{V}\right), \tag{3.10}$$

and, noticing that $\hat{V} \in H^1_{0,D}(\Omega)$, we observe that the last term on the right-hand side vanishes. In the particular case of (2.7) the derivative simplifies to

$$Q'(u,v,V)(\hat{u},\hat{v},\hat{V}) = \left(\int_\Gamma J\cdot d\nu - I^*\right)\int_\Gamma\left(e^V\frac{\partial\hat{u}}{\partial\nu} - e^{-V}\frac{\partial\hat{v}}{\partial\nu}\right)ds. \tag{3.11}$$

Due to the simple form of (3.9), it seems obvious that we need to eliminate the Lagrangian variable $\mu_3 = \epsilon W$ and rewrite (3.8) as

$$0 = \int_\Omega\left(\hat{V}\left(e^V\nabla u\cdot\nabla\mu_1 + e^{-V}\nabla v\nabla\mu_2\right) + \epsilon\nabla\hat{V}\cdot\nabla W\right)dx. \tag{3.12}$$

This suggests the interpretation of W as the design variable and (3.12) as the optimality condition corresponding to the minimization of the functional Q, subject to the equality constraints (1.3), (1.4) for the state variables (u,v,V).

If we choose the Lagrangian variables μ_i, $i = 1,2$, such that $\mu_i = 0$ only on $\partial\Omega_D \setminus \Gamma$ and $\mu_1 = \mu_2 = \eta$ on Γ for some real constant η, then we can derive a simple form of the optimality system. With this choice, the Lagrangian becomes

$$\begin{aligned}\mathcal{L}(u,v,V,W;\mu_1,\mu_2,\mu_3) = Q_\epsilon(u,v,V,W) &+ \int_\Omega\left(e^V\nabla u\cdot\nabla\mu_1 - e^{-V}\nabla v\nabla\mu_2\right)\,dx\\ &+ \int_\Omega\left(\nabla(V-V^*)\cdot\nabla\mu_3 + W\mu_3\right)\,dx - \eta\int_\Gamma J\cdot d\nu,\end{aligned} \tag{3.13}$$

and the optimality with respect to u yields

$$\left(\int_\Gamma J\cdot d\nu - I^* - \eta\right)\int_\Gamma\left(e^V\frac{\partial\hat{u}}{\partial\nu}\right)ds + \int_\Omega\left(e^V\nabla\hat{u}\cdot\nabla\mu_1\right)dx = 0. \tag{3.14}$$

With the choice $\eta = \int_\Gamma J\cdot d\nu - I^*$, this reduces to the weak form corresponding to the elliptic partial differential equation

$$\text{div}\,\left(e^V\nabla\mu_1\right) = 0 \qquad \text{in } \Omega, \tag{3.15}$$

subject to the boundary conditions

$$\mu_1 - \int_\Gamma J\cdot d\nu + I^* = 0 \qquad \text{on } \Gamma, \tag{3.16}$$

$$\mu_1 = 0 \qquad \text{on } \partial\Omega_D\setminus\Gamma, \tag{3.17}$$

$$\frac{\partial\mu_1}{\partial\nu} = 0 \qquad \text{on } \partial\Omega_N. \tag{3.18}$$

Analogous reasoning yields the equation

$$\text{div } \left(e^{-V}\nabla\mu_2\right) = 0 \qquad \text{in } \Omega, \tag{3.19}$$

subject to the same boundary conditions as for μ_1, determining the Lagrangian variable μ_2. Finally, we determine the optimality condition with respect to W, which can be rewritten as the equation

$$\epsilon\Delta W = e^{V}\nabla u\cdot\nabla\mu_1 + e^{-V}\nabla v\nabla\mu_2 \qquad \text{in } \Omega, \tag{3.20}$$

subject to homogeneous Dirichlet conditions on $\partial\Omega_D$ and homogeneous Neumann conditions on $\partial\Omega_N$.

3.3. Regularity. In the following we use the Karush–Kuhn–Tucker system derived above, which must be fulfilled by any solution of the optimal design problem, to prove additional regularity of minimizers. First, since W satisfies the Poisson equation (3.20) with right-hand side in $L^1(\Omega)$ and subject to the homogeneous boundary conditions (2.4), we may conclude that $W \in W^{1,\rho}(\Omega)$, $\rho < \frac{N}{N-1}$ (cf. [20]).

For the primal variables u and v, which satisfy the homogeneous elliptic equations (1.3) and (1.4), respectively, we can apply a standard maximum principle as in [16], which implies $u \in L^\infty(\Omega)$ and $v \in L^\infty(\Omega)$. Analogous reasoning can be applied to the dual variables μ_1 and μ_2, which solve the same elliptic equations as u and v, and whose Dirichlet boundary data are uniformly bounded too (since μ_i is piecewise constant on $\partial\Omega_D$). Hence, we may conclude that $\mu_i \in L^\infty(\Omega)$, $i = 1, 2$. As a consequence of this type of regularity, we obtain that

$$\begin{aligned}\nabla(C - C^*) = -\lambda^2\nabla W + e^{V}(u\nabla V + \nabla u) + e^{-V}(v\nabla V - \nabla v)\\ - e^{V^*}(u^*\nabla V^* + \nabla u^*) - e^{-V^*}(v^*\nabla V^* - \nabla v^*)\end{aligned} \tag{3.21}$$

is bounded in $L^\rho(\Omega)$ (with ρ as above and $\rho \le 2$ for $N = 1$), since all the gradient terms on the right-hand side are in $L^\rho(\Omega)$ and the zero-order terms are in $L^\infty(\Omega)$. Thus, we have deduced the following type of regularity for minimizers.

THEOREM 3.5. *Let $(\overline{u}, \overline{v}, \overline{V}, \overline{W}) \in \mathcal{D}_{ad}$ be a minimizer of* (3.1). *Then,*

$$\overline{u} \in L^\infty(\Omega), \qquad \overline{v} \in L^\infty(\Omega), \qquad \overline{W} \in H^1(\Omega). \tag{3.22}$$

The Lagrangian variables $\overline{\mu}_i \in H^1(\Omega)$ associated with (1.3) *and* (1.4) *satisfy*

$$\overline{\mu}_1 \in L^\infty(\Omega), \qquad \overline{\mu}_2 \in L^\infty(\Omega). \tag{3.23}$$

Moreover, if $C^* \in W^{1,\rho}(\Omega)$, then the associated doping profile $\overline{C}$ (via (1.2)*) satisfies $\overline{C} \in W^{1,\rho}(\Omega)$ for $\rho < \frac{N}{N-1}$ ($\rho \le 2$ for $N = 1$).*

We finally give an interpretation of the optimality system with respect to the local regularity of the doping profile. If the initial doping profile C^* has a discontinuity (occurring typically at a pn (positive-negative) junction), then the corresponding solution V^* is locally not C^2 across the junction, but (via standard regularity) on every open set not containing the junction. Since, for a solution of the optimality system, $V - V^*$ satisfies a Poisson equation with homogeneous boundary data and a right-hand side W that we may expect to be smooth (W solves a Poisson equation itself), the solution $V - V^*$ should have higher regularity even across the discontinuity of the doping profile. Hence, the only source of lower regularity is contained in V^*, and thus its location must be the same for $V = (V - V^*) + V^*$.

4. A fast optimization method. In the following we discuss a simple optimization method, which allows the design of semiconductor devices by solving decoupled elliptic partial differential equations only. For simplicity we consider the case of (2.5), (2.7) in the following, but an analogous approach is possible for different objective functionals, too.

We start by discussing the Lagrange–Newton iteration for the primal variables (u^k, v^k, V^k, W^k) and the dual variables (μ_1^k, μ_2^k) given by

$$\Delta V^k = \Delta V^* + W^k, \tag{4.1}$$

$$\text{div } (e^{V^{k-1}}\nabla u^k) = -\text{div } (e^{V^{k-1}}(V^k - V_{k-1})\nabla u^{k-1}), \tag{4.2}$$

$$\text{div } (e^{-V^{k-1}}\nabla v^k) = \text{div } (e^{-V^{k-1}}(V^k - V_{k-1})\nabla u^{k-1}), \tag{4.3}$$

$$\text{div } (e^{V^{k-1}}\nabla \mu_1^k) = -\text{div } (e^{V^{k-1}}(V^k - V_{k-1})\nabla \mu_1^{k-1}), \tag{4.4}$$

$$\text{div } (e^{-V^{k-1}}\nabla \mu_2^k) = \text{div } (e^{-V^{k-1}}(V^k - V_{k-1})\nabla \mu_2^{k-1}), \tag{4.5}$$

$$\begin{aligned} -\epsilon W^k = &-e^{V^{k-1}}\left((V^k\nabla u^{k-1} + \nabla u^k)\cdot\nabla\mu_1^{k-1} + \nabla u^{k-1}\cdot\nabla\mu_1^k\right) \\ &+ e^{-V^{k-1}}\left((-V^k\nabla v^{k-1} + \nabla v^k)\cdot\nabla\mu_2^{k-1} + \nabla v^{k-1}\cdot\nabla\mu_2^k\right), \end{aligned} \tag{4.6}$$

subject to the boundary conditions (1.5)–(1.11). As for the solution of the drift-diffusion system, the full Lagrange–Newton method yields a sequence of systems of partial differential equations, which is in general convection-dominated due to the strong influence of first-order terms. As for the drift-diffusion system, we may expect the numerical solution of this system to be a difficult task, particularly for large applied voltages. Moreover, the advantage of our optimization approach, namely, the partial decoupling into scalar elliptic partial differential equations, is lost by using this Newton-type approach.

Therefore it seems favorable to use a different iterative method for the solution of the optimality system. Using a lower triangular approximation of the optimality system, we first solve (2.2) with given W for the potential V, and subsequently the continuity equations (1.3), (1.4) with given potential V for u and v. With given potential and given u and v, we solve the adjoint equations (3.15), (3.19) to obtain the Lagrangian variables μ_1 and μ_2. Finally, we can perform a gradient step with respect to the design variable W using the optimality equation (3.20). Due to the simple structure of this equation, it seems reasonable to discretize the Laplace term in an implicit way and thus to solve

$$-\epsilon\Delta W + \tau W = \tau W^* - e^V\nabla u\cdot\nabla\mu_1 + e^{-V}\nabla v\nabla\mu_2 \tag{4.7}$$

for an appropriately chosen damping parameter τ, where W^* is the old value of W. Putting this all together, we can write this iteration as

$$\Delta V^k = \Delta V^* + W^{k-1}, \tag{4.8}$$

$$\text{div } (e^{V^k}\nabla u^k) = 0, \tag{4.9}$$

$$\text{div } (e^{-V^k}\nabla v^k) = 0, \tag{4.10}$$

$$\text{div } (e^{V^k}\nabla \mu_1^k) = 0, \tag{4.11}$$

$$\text{div } (e^{-V^k}\nabla \mu_2^k) = 0, \tag{4.12}$$

$$-\epsilon W^k + \tau W^k = \tau W^{k-1} - e^{V^k}\nabla u^k\cdot\nabla\mu_1^k + e^{-V^k}\nabla v^k\nabla\mu_2^k, \tag{4.13}$$

subject to the above boundary conditions. The only coupling in the boundary conditions occurs in the condition $\mu_i = \int_\Gamma J^k\cdot d\nu$, but there also we can use the previously

computed values for u^k and v^k to obtain J^k. The corresponding value of the doping profile can be computed independently by

$$C^k - C^* = -\lambda^2 W^k + n^k - n^* - p^k + p^*, \tag{4.14}$$

where $n^k = e^{V^k} u^k$ and $p^k = e^{-V^k} v^k$.

5. Numerical examples. In the following we report numerical results for three different examples, two bipolar diodes and a unipolar MESFET device. For all the numerical experiments we use the physical parameters for silicon as given in Table 5.1, with a standard forward-bias scaling of the variables (cf. [16]). Moreover, we use the mobilities $\mu_n = \mu_p = \mu_0$. The objective functional is given by (2.5), (2.7), with the aim of increasing the current flow over a contact. This aim can in general be achieved for ϵ sufficiently small, but for some cases only with a doping profile deviating far from the original, so that one may rather use the result for a larger value of ϵ. All the numerical examples have been implemented within the software system MATLAB.

TABLE 5.1
Physical parameters for silicon.

Parameter	Physical meaning	Numerical value
q	elementary charge	$1.6 \cdot 10^{-19}$ As
n_i	intrinsic density	10^{10} cm^{-3}
ϵ_S	permittivity constant	10^{-12} As V^{-1}s^{-1}
μ_0	low field mobility	$1.5 \cdot 10^3$ cm^{2}V^{-1}s^{-1}
U_T	thermal voltage at $T = 300$K	0.0259 V

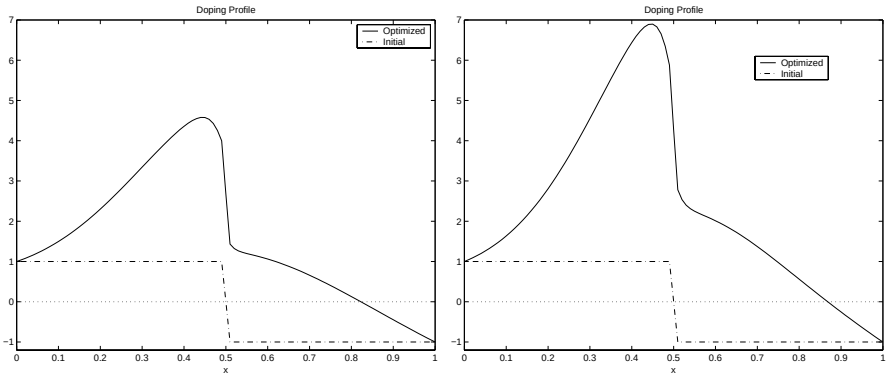

FIG. 5.1. *Initial (dash-dotted) and optimized (solid) doping profile in the example of section* 5.1, *for* $\epsilon = 10^{-2}$ *(left) and* $\epsilon = 10^{-3}$ *(right), with dimensionless units in the* x*- and* y*-axes according to the forward-bias scaling.*

5.1. A pn-diode. Our first example is a pn-diode, with the domain Ω scaled to the unit interval $(0, 1)$. The pn-diode is characterized by a doping profile that has exactly one positive and one negative region; we choose one of the simplest possibilities for the (scaled) initial doping profile, namely, a function jumping almost abruptly from the value 1 to -1 at the junction. This initial profile is shown as the dash-dotted function in Figure 5.1. The Debye length in this experiment is given by $\lambda^2 = 10^{-3}$, and the value of the applied voltage is $U = 10U_T = 0.259$. The optimization objective

is to increase the current flow (i.e., the current flow density, which is constant in the domain since $J_x = 0$) by 50%, and consequently we chose

$$I^* = 1.5 \cdot \int_\Gamma J_0 \cdot d\nu, \tag{5.1}$$

where $\Gamma = \{0\}$ and J_0 is the current flow density obtained with the initial doping.

For the numerical solution of the drift-diffusion system and the linear elliptic equations arising during the iterative solution of the optimization problem in this example (as well as the following one) we use an exponentially fitted scheme of Scharfetter–Gummel type (cf. [1, 4]); the fineness of the uniform spatial grid is given by $h = 10^{-2}$. For the discretization of all variables involved $(C, V, W, n, p, \mu_1, \mu_2)$ we use piecewise linear finite elements. The drift-diffusion system with given initial doping profile is solved using Newton's method and voltage continuation to obtain the initial value of the potential (cf. [17]).

The numerical experiments were performed for several values of ϵ, with the result that most changes appeared for ϵ between 10^{-3} and 10^{-2}, and thus we plot the results for these two values in Figure 5.1. (Note that for large values of ϵ the penalty does not allow enough change to the initial configuration, while for small values the observation tends to be almost zero in our case, so that further change in the solution is negligible.) Figure 5.1 shows the optimized doping profiles (solid) in both cases compared to the initial one (dash-dotted). The dashed line is the coordinate axis for x; its cut with the doping profile marks the pn-junction. One observes that the optimized doping profiles have similar shapes for both values of ϵ, but the magnitude of the doping in the n-region grows with decreasing ϵ. In both cases the n-region grows at the expense of the p-region; i.e., the pn-junction moves right, and the value of C is larger than the initial one in the whole domain. Moreover, the doping profile remains steep around the center point $x = 0.5$, which numerically confirms the result obtained from the analysis of the optimality system.

An analogous effect happens with the potential V, which is the actual design variable in our approach, and with the electron and hole densities, i.e., the shape changes strongly compared to the initial one for $\epsilon = 10^{-2}$, and if we decrease the value of ϵ, the resulting current flow can be forced to be closer to the desired flow only by a change in magnitude. The resulting potentials for both values compared to the initial ones are shown in Figure 5.2. The electron and hole densities are shown in Figure 5.3 for the value of $\epsilon = 10^{-3}$.

Finally, we illustrate the behavior of the objective functional, observation, and penalizing energy term in the left-hand plot of Figure 5.4, and the change in the current-voltage characteristic in the right-hand plot (both for $\epsilon = 10^{-3}$). Not surprisingly, the objective functional and observation are reduced in a few iterations, while the energy initially increases since the doping is pulled away from the initial one. In the later stage of the iteration, the observation part remains almost constant, and a decrease in the objective functional is obtained only due to a (slow) decrease in the energy. An inspection of the current-voltage plot shows that the optimized doping profile also yields a characteristic whose absolute value increases exponentially for positive applied voltages, but which lies above the initial one for all applied voltages.

5.2. An npn-diode. Our second numerical example is an npn-diode, with the same parameter settings as in the example of section 5.1, and with the same choice of objective. The initial doping profile is a piecewise constant function taking the values

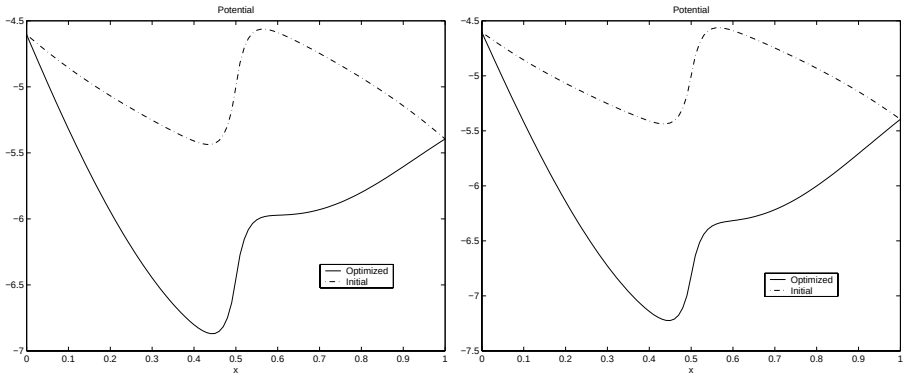

FIG. 5.2. *Initial (dash-dotted) and optimized (solid) potential in the example of section* 5.1*, for* $\epsilon = 10^{-2}$ *(left) and* $\epsilon = 10^{-3}$ *(right).*

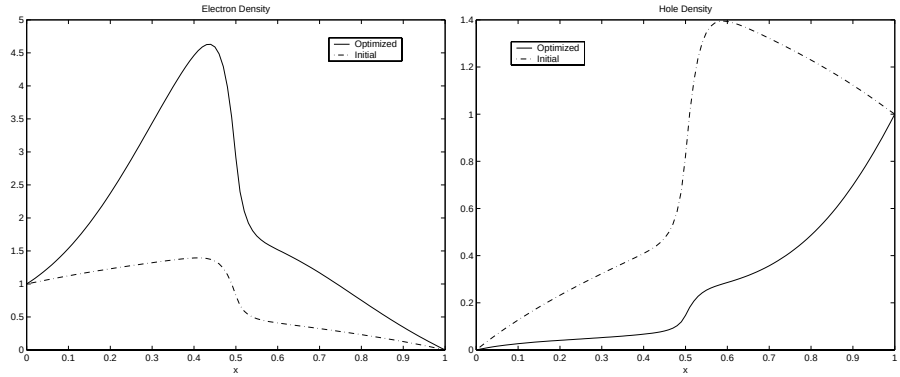

FIG. 5.3. *Initial (dash-dotted) and optimized (solid) electron (left) and hole density (right) in the example of section* 5.1*, for* $\epsilon = 10^{-3}$*.*

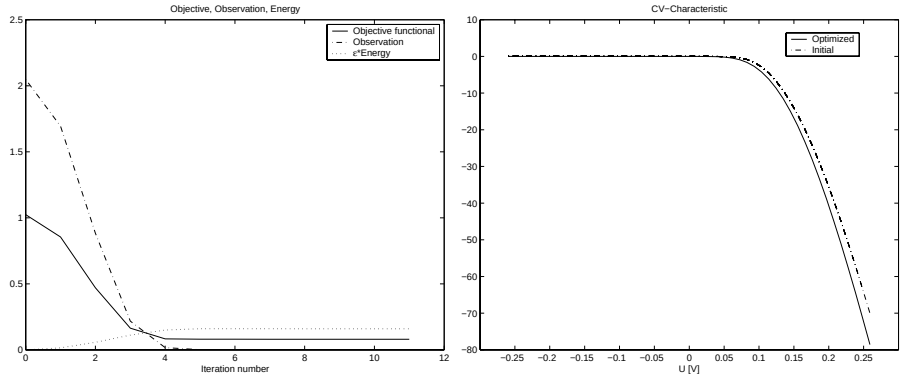

FIG. 5.4. *Evolution of the objective functional (solid), observation (dash-dotted), and energy (dotted) in the example of section* 5.1 *(left), and the current-voltage characteristic for* $\epsilon = 10^{-3}$ *(right, scaled current plotted vs. U[V]).*

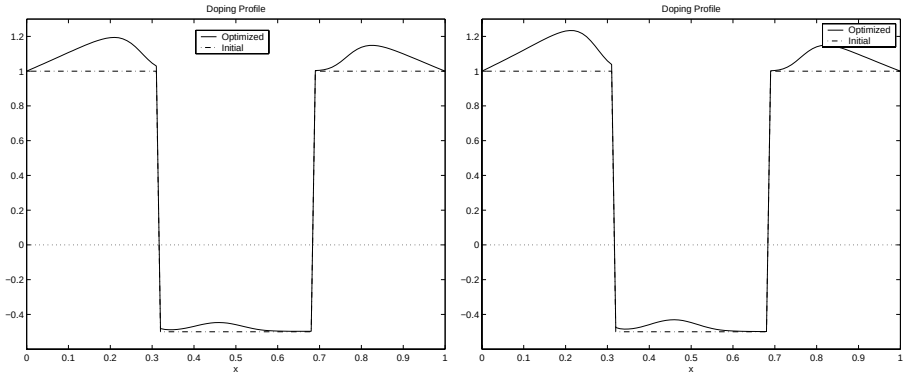

FIG. 5.5. *Initial (dash-dotted) and optimized (solid) doping profile in the example of section* 5.2, *for* $\epsilon = 10^{-6}$ *(left) and* $\epsilon = 10^{-8}$ *(right).*

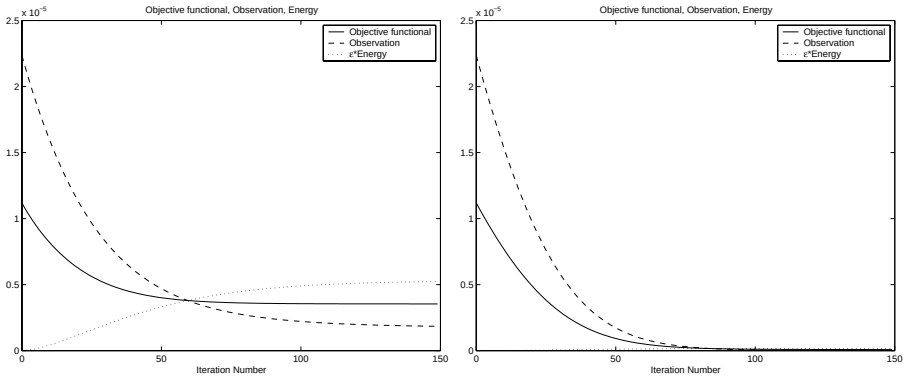

FIG. 5.6. *Evolution of the objective functional (solid), observation (dashed), and energy (dotted) in the example of section* 5.2, *for* $\epsilon = 10^{-6}$ *(left) and* $\epsilon = 10^{-8}$ *(right).*

one and $-\frac{1}{2}$; it is shown as the dash-dotted function in Figure 5.5. The values of the parameter ϵ that lead to useful results are now between 10^{-6} and 10^{-8}, which is due to the lower absolute values of the current obtained in this example. The objective value obtained in the first case is around 0.4, while the objective is reduced almost to zero for the the second. The evolution of the objective functional, the observation, and the energy term is plotted in Figure 5.6, showing a similar behavior as in the example of section 5.1. For $\epsilon = 10^{-8}$, the energy term is already negligible, and the iteration is driven by the reduction of the observation error.

The optimized and initial values for the doping profile are plotted in Figure 5.5 and for the potential in Figure 5.7. In this case, the change in the potential is quite small, and the doping profile is increased slightly both in the n- and p-regions. A more significant change happens in the electron density, shown for the case of $\epsilon = 10^{-8}$ in Figure 5.8. As one might expect, the electron density is changed mainly in the n-regions, while the hole density is changed in the p-region.

Finally, we plot the negative CV-characteristics (i.e., the map $U \mapsto J$) of the initial and optimized devices for both values of ϵ in Figure 5.9. The shape of these current-voltage curves remains similar for all values of ϵ, but obviously changes in magnitude as ϵ tends to zero.

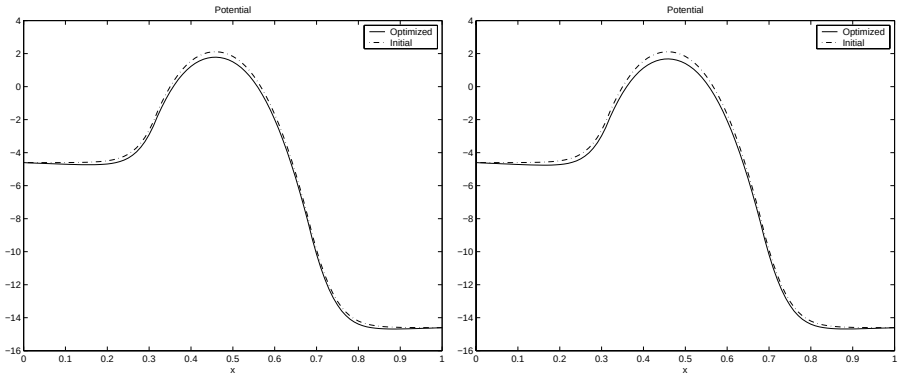

FIG. 5.7. *Initial (dash-dotted) and optimized (solid) potential in the example of section* 5.2, *for* $\epsilon = 10^{-6}$ *(left) and* $\epsilon = 10^{-8}$ *(right).*

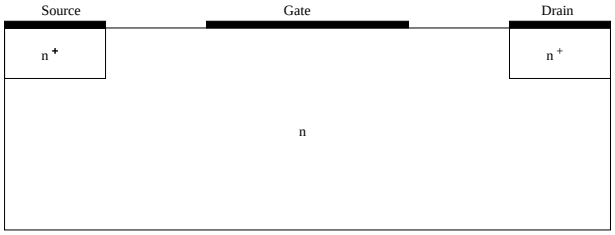

FIG. 5.10. *Device geometry in the example of section* 5.3.

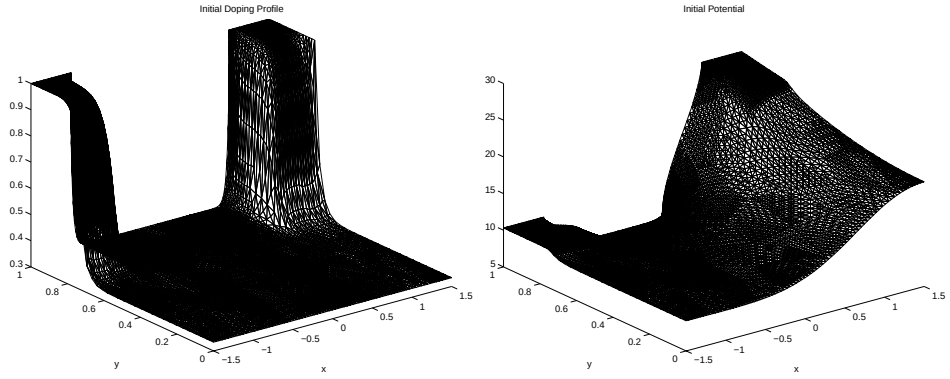

FIG. 5.11. *Initial value of the doping profile and the potential in the example of section* 5.3.

5.3. A MESFET device. As our final example, we consider the optimal design of a MESFET in two spatial dimensions. We use a device geometry and initial doping profile as in an example considered in [12], with a length of 6μm and a width of 2μm. The geometry and the position of the contacts is shown in Figure 5.10. The scaled initial doping profile (by the value $C_s = 10^{14}\text{cm}^{-3}$) is shown in Figure 5.11; in order to improve the visibility, we plot the initial values and subsequently the results with different scaling of the x- and the y-axes. A MESFET can be modeled as a unipolar device, which is also reflected by the positivity of the doping profile in the whole device region. Thus, we have $p = v = 0$ in Ω, and the equation for v as well as the adjoint equation determining the Lagrangian variable $\mu_2 \equiv 0$ can be eliminated, which reduces the computational effort. The boundary data are specified by $n = 0.5(C + \sqrt{C^2 + 4\delta^2})$, a temperature of $T = 300^\circ$ on each contact, and

- at the source, $V = V_{bi} - 0.1[V] = 0.1670[V]$;
- at the drain, $V = V_{bi} + 0.4[V] = 0.6670[V]$;
- at the gate, $V = V_{bi} = 0.2385[V]$.

Our objective is to increase the current flow over the drain by 50%, and consequently we choose

$$I^* = 1.5 \cdot \int_\Gamma J_0 \cdot d\nu, \tag{5.2}$$

where Γ is the drain contact and J_0 is the current flow density obtained with the initial doping.

For the finite element discretization of the original problem we used an adaptive solver (with a standard error estimate for the Poisson equation), with a resulting mesh

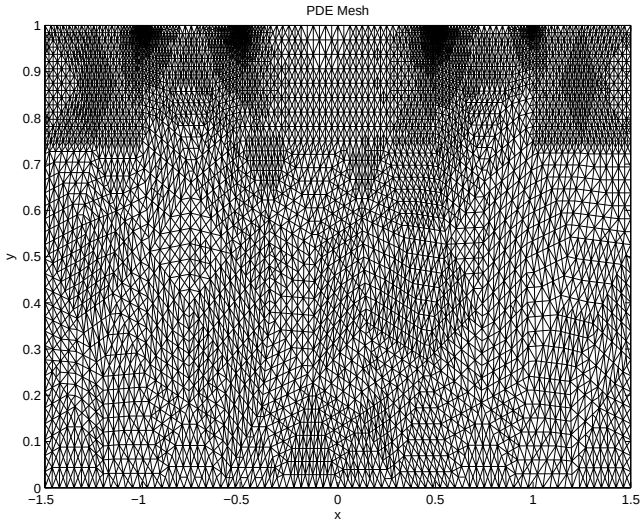

FIG. 5.12. *Mesh used for the optimization in the example of section* 5.3.

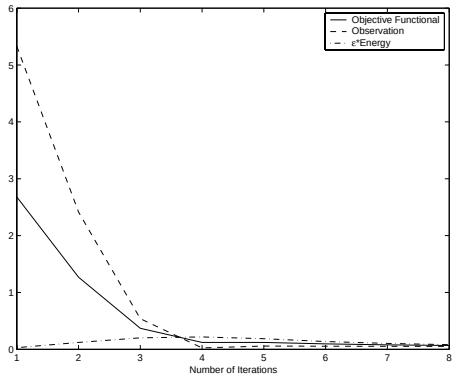

FIG. 5.13. *Evolution of the objective functional (solid), observation error (dashed), and energy term (dash-dotted) in the example of section* 5.3.

(shown in Figure 5.12) consisting of $n_t = 15434$ triangular elements. This mesh is used subsequently also for the optimization algorithm. The refinement was started from a relatively fine mesh in the bulk. Probably one could use a coarser mesh for all computations, but due to the efficiency of our optimization algorithm we are able to solve the optimal design problem with reasonable effort even for this fine triangulation. This strategy of using grid adaption only for the initial problem is motivated by the above observation that steep junctions will remain at the same location during the optimization process.

In this case, it turns out that a suitable choice of ϵ is 10^{-3}, and here we show the results for this value. Changes of ϵ lead to a behavior similar to that in the previous examples. The resulting increase in the current flow over the drain is around 45% for this parameter value. The evolution of the objective function, the observer error, and the energy term are shown in Figure 5.13. The optimized doping profile and the optimized potential are shown in Figure 5.14. A comparison with the initial value

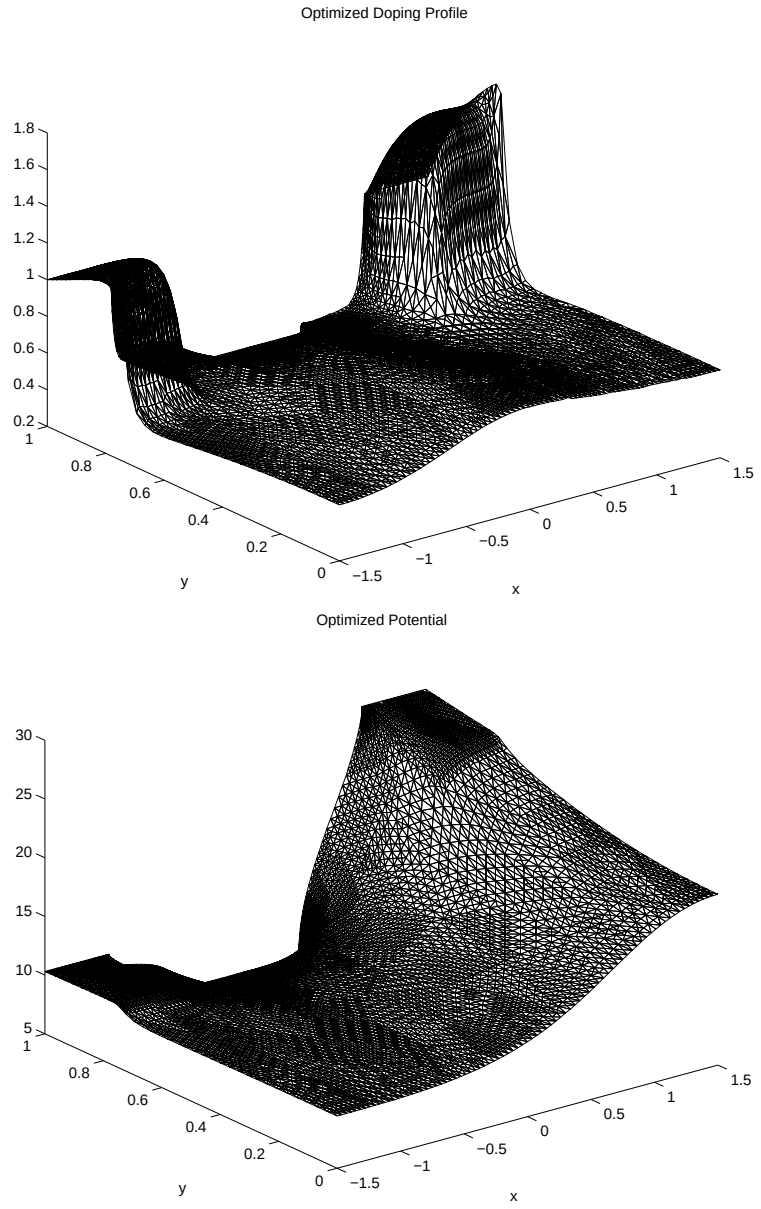

FIG. 5.14. *Optimized doping profile and potential in the example of section* 5.3, $\epsilon = 10^{-3}$.

shows that the doping profile is increased mainly close to the drain, while it is slightly decreased close to the device corner opposite to the drain. The change in the potential is less significant, due to the fact that the main shape of the potential is determined by the rather high difference in the boundary values. Changes in the doping profile (and in the electron density $n = e^V u$) are mainly caused by the Laplacian of $V - V^*$, which is still of considerable magnitude.

An inspection of the evolution of the objective demonstrates again the efficiency of our approach, since a minimum is obtained with only a few iterations. Since, in

each iteration, we have to solve only four scalar elliptic partial differential equations, the numerical effort per iteration is similar to two Gummel-type iteration steps for the (unipolar) drift-diffusion system. Since in general the number of iterations in a Gummel-type method for the drift-diffusion system is of similar size to the number of iterations needed for the optimal design problem, the overall numerical effort for optimization is around the effort for two forward solves of the nonlinear drift-diffusion system, which is a surprising result.

6. Conclusions. We have presented a new, fast approach to the optimal design of semiconductor devices, which can be applied if a performance optimization of the device at a single fixed applied voltage is desired. The numerical experiments illustrate reasonable convergence properties of the simple algorithm we have proposed to solve the optimal design problem, and clearly demonstrate its efficiency. In particular, we have obtained an optimization procedure with a numerical effort of similar magnitude to one with few forward solves.

We finally would also like to mention the natural limitations or possible generalizations of the approach presented in this paper. These limitations arise if the optimization goal involves current flows for several applied voltages and consequently several different potentials, since we can interpret only one of the potentials as the design variable in this case. This statement applies, in particular, in the context of identifying unknown doping profiles, which is usually done by minimizing a least-squares functional involving a large number of different voltages (cf. [2]). In many typical optimal design situations, however, the aim is to control at most the currents for two different voltages, namely, for an *on-state voltage* and an *off-state voltage* (close to equilibrium). The usual aim in such a situation is to maximize the on-state current flow on a contact by keeping the off-state current flow below some threshold value (cf. [21, 23]). In optimal design problems of this type it seems natural to eliminate the Poisson equation for the on-state potential and keep that for the off-state potential, since solutions of the drift-diffusion system close to equilibrium are rather cheap. A numerical investigation of such optimal design situations shall be left to future research.

Acknowledgments. The authors thank Prof. Peter Markowich (University of Vienna) for interesting discussions and, in particular, for stimulating this collaboration.

ASYMPTOTIC SHAPE OF THE ERLANG CAPACITY REGION OF A MULTISERVICE SHARED RESOURCE*

JOHN A. MORRISON† AND DEBASIS MITRA†

Abstract. We consider a loss model of an unbuffered resource having C channels, which are shared by several different types of service connections. Connections of each type arrive in a Poisson stream and request a number of channels, which depends on the type. An arriving connection is blocked and lost if there are not enough free channels. Otherwise, the channels are held for the duration of the connection, and the holding period is generally distributed. It is assumed that C and the traffic intensities are proportionately large. The admission control problem is considered for specified upper bounds on the blocking probabilities, and the boundary of the admissible set is investigated asymptotically. The results are derived by investigating the local behavior with respect to the tangent hyperplane at a point on the boundary of the admissible set. The lowest order results that hold in the asymptotic limit $C \to \infty$ are given first. Importantly, the boundary is linear for the critically loaded and overloaded regimes and weakly convex for the underloaded regime. Next, refined results that hold for $C \gg 1$ are given, which indicate that the boundary is nonconvex, although only slightly so, for the overloaded and underloaded regimes. The critically loaded regime requires further investigation, which is carried out in [J. A. Morrison, *SIAM J. Appl. Math.*, 64 (2003), pp. 1–17].

1. Introduction.

We consider an unbuffered resource having C channels, which are shared by J different types of connections. Connections of type j arrive in a Poisson stream with mean rate λ_j, and they require d_j channels. An arriving connection is blocked and lost if there are fewer than d_j free channels. Otherwise, d_j channels are held for the duration of the connection, and the holding period is generally distributed with mean $1/\mu_j$ and is independent of earlier arrival and holding times. The traffic intensity of type j connections is $\rho_j = \lambda_j/\mu_j$, and the product form and the insensitivity property hold [4], [5], [7]; i.e., the joint stationary distribution of the number of active connections of each type depends on the distributions only through ρ_i, $i = 1, \ldots, J$. The blocking probabilities L_j for type j connections satisfy $L_j > 0$ for $\rho_j > 0$ and, assuming that $C \geq \max_i d_i$, $L_j \to 0+$ only if $\rho_i \to 0+$, $i = 1, \ldots, J$. The admissible set in $\mathbb{R}^J$ contains all combinations of ρ_j, $j = 1, \ldots, J$, such that the blocking probability for each connection type satisfies specified bounds, i.e., $L_j \leq \ell_j$, $j = 1, \ldots, J$, where ℓ_j is a prescribed function of C.

Characterization of the admissible set is extremely useful, not only for connection-level admission control, which is the context in which this topic has typically been considered in the past, but also for higher level objectives, such as network economics and network design and operations. The asymptotic view of the admissible set is particularly appropriate for the latter, where the fine details are not as important as the qualitative properties of the shape of the set and tractability of the numerical calculations for large systems.

Special importance is attached to admissible regions with linear boundaries; the solution space is determined by its vertices, which are relatively easy to compute. Optimizations within such spaces are also much easier computationally. Network economics applications are given in [6]. In one such example, the objective function is the profit of a service provider giving several quality of service (QoS) levels at prices that are the solution to the corresponding optimization problem. The admissible region of solutions is defined by a collection of inequalities imposed by available capacity, one for each QoS level. For further details see [6], and for other such applications see [2], [8], [19] and references therein. See [1], [11] for applications to routing and control. For recent work on loss models of optical networking see [17] and [18].

Convexity is also important, since the tangent hyperplane at points on the boundary of the admissible set intersects the positive axes. Hence, if the boundary of the admissible set is convex, then the region in the positive orthant bounded by the tangent hyperplane at a point on the boundary is admissible and may be used in an approximate optimization.

Mitra and Morrison [10] considered our model here (as well as the finite-sources version), and they investigated the case when C and the traffic intensities $\rho_j = \alpha_j C$, $j = 1, \ldots, J$, are proportionately large, so that $\alpha_j = O(1)$ is bounded away from zero. They derived uniform asymptotic approximations to the blocking probabilities L_j, $j = 1, \ldots, J$, for type j connections. The results for Poisson arrivals are obtained from the finite-sources version as a limiting case. They presented numerical results for $J = 2$ and $J = 3$ types for the finite-sources model. These results constitute a numerical procedure but do not provide a characterization of the admissible set, nor do they resolve specific questions on the linearity and convexity of the boundary.

In this paper we investigate the boundary of the admissible set in the case of Poisson arrivals. The admissible set $\mathcal{A}$ is given by

$$\mathcal{A} = \{\alpha_1, \ldots, \alpha_J | L_j(\alpha_1, \ldots, \alpha_J; C) \leq \ell_j(C),\ j = 1, \ldots, J\}. \tag{1.1}$$

The uniform asymptotic approximations to the blocking probabilities are specialized [10] to three regimes in which their behavior is markedly different, namely, the overloaded, the critically loaded, and the underloaded regimes, corresponding to $\sum_{j=1}^{J} d_j \alpha_j > 1$, $\sum_{j=1}^{J} d_j \alpha_j - 1 = O(1/\sqrt{C})$, and $\sum_{j=1}^{J} d_j \alpha_j < 1$, respectively. The corresponding blocking probabilities L_j are $O(1)$, $O(1/\sqrt{C})$, and exponentially small in C, respectively. The shape of the admissible set is investigated separately for each of the three regimes, and it is assumed that $\min_j \ell_j$ is $O(1)$, $O(1/\sqrt{C})$, and exponentially small in C, respectively.

The lowest order results are stated in section 2. In the asymptotic limit $C \to \infty$, with $\rho_j = \alpha_j C$, $j = 1, \ldots, J$, the boundary of the admissible set lies in a hyperplane if the resource is critically loaded, which is the regime of greatest interest, or if it is overloaded. If the resource is underloaded, the boundary of the admissible set, in the limit $C \to \infty$, is convex, but not strictly so, except when $J = 2$.

The refined results, which pertain to $C \gg 1$, are stated in section 3. In general, the boundary of the admissible set is not convex. If $J = 2$, then the boundary is slightly convex if the resource is critically loaded, but slightly concave if the resource is overloaded. For $J = 2$, the convexity is maintained for an underloaded resource. Unfortunately, for $J \geq 3$, the boundary of the admissible set is *not* convex, although only slightly so, whether the resource is overloaded or underloaded. The case of a critically loaded resource requires further investigation, which is to appear in a forthcoming paper [12], and shows that the boundary of the admissible set is *not* convex, although only very slightly so.

The above results follow from consideration of the local behavior with respect to the tangent hyperplane at a point on the boundary of the admissible set. For instance, in the underloaded regime, the tangent hyperplane is given by $\xi_J = 0$. Locally, for $J \geq 3$, the boundary has the asymptotic form

$$\xi_J \sim A\xi_{J-1}^2 - \frac{B}{C}\xi_{J-2}^2 \,, \tag{1.2}$$

where ξ_{J-1} and ξ_{J-2} are linear in α_i, $i = 1, \ldots, J-1$, and A and B are $O(1)$ and positive. To this order, for $J > 3$, quadratic terms involving ξ_i, $i = 1, \ldots J-3$, are absent. Since A and B are positive, the boundary is nonconvex, but only slightly so because of the $O(1/C)$ negative coefficient of ξ_{J-2}^2. In the limit $C \to \infty$ the boundary is not strictly convex, because of the degeneracy in the quadratic form.

Although our results are negative, in that they show that the boundary of the admissible set is not convex in general, it is important that the practitioner be aware of this. Moreover, since the boundary is only slightly nonconvex, a slightly smaller admissible region with a convex boundary may be used by the practitioner.

The lowest order analysis of the boundary of the admissible set for an underloaded resource is given in section 4. Both the lowest order and refined approximations for an overloaded resource are derived in section 5. A critically loaded resource is analyzed in section 6, and a refined approximation to the boundary of the admissible set is derived in section 7. A refined approximation for an underloaded resource is derived in section 8, and a check on a negative coefficient, which gives rise to the nonconvexity of the boundary of the admissible set, is carried out in section 9.

2. Lowest order results. Throughout the paper, we assume that

$$C \gg 1; \ \rho_j = \alpha_j C, \quad j = 1, \ldots, J, \tag{2.1}$$

where C is an integer and $\alpha_j > 0$ is $O(1)$ and bounded away from zero. We also assume that d_j, $j = 1, \ldots, J$, are distinct positive integers, not large relative to C, and that the greatest common divisor of $d_1, \ldots, d_J$ is 1. The admissible set corresponds to

$$L_j\left(\alpha_1, \ldots, \alpha_J; \ C\right) \leq \ell_j, \quad j = 1, \ldots, J, \tag{2.2}$$

where the function L_j gives the blocking probability for type j connections. It is shown, in all three regimes, that asymptotically

$$\frac{\partial L_j}{\partial \alpha_k} > 0, \quad j, k = 1, \ldots, J, \tag{2.3}$$

and the boundary of the admissible set is expressed in the form

$$\alpha_J = \alpha_J(\boldsymbol{\alpha}; C), \quad \boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_{J-1}) \,. \tag{2.4}$$

We first give the lowest order asymptotic results, which are obtained from the finite-sources version [10] as a limiting case. We have the following proposition.

PROPOSITION 2.1. (A) *If ℓ_j, $j = 1, \ldots, J$, is asymptotically bounded away from zero, then on the boundary of the admissible set the resource is overloaded. Let*

$$a_j = (1 - \ell_j)^{1/d_j} \,, \quad j = 1, \ldots, J, \tag{2.5}$$

and, by choice of notation,

$$a_J = \max_j a_j. \tag{2.6}$$

Then the boundary of the admissible set satisfies

$$\sum_{j=1}^{J} d_j a_J^{d_j} \alpha_j = 1 + O\left(\frac{1}{C}\right), \tag{2.7}$$

which in the asymptotic limit $C \to \infty$ lies in a hyperplane.

(B) *If*

$$\sqrt{C} \min_j \ell_j = O(1) \tag{2.8}$$

is bounded below by a positive constant, then on the boundary of the admissible set the resource is critically loaded. The boundary satisfies

$$\sum_{j=1}^{J} d_j \alpha_j = 1 + O\left(1/\sqrt{C}\right), \tag{2.9}$$

which in the asymptotic limit $C \to \infty$ lies in a hyperplane. Note, by comparison with (2.7)*, that for a common $C \gg 1$ the admissible set here is smaller and the order of magnitude of the error is larger. An asymptotic approximation to the error term in* (2.9) *is derived in section 6.*

(C) *If at least one ℓ_j is exponentially small, the resource is underloaded. Let*

$$\ell_j = \frac{e^{-C\omega}}{\sqrt{2\pi C}} \beta_j, \quad j = 1, \ldots, J; \quad \min_j \beta_j = 1, \quad \omega > 0. \tag{2.10}$$

Note that some of the ℓ_j may not be exponentially small. Also, let $\tau > 1$ be the unique solution of

$$\sum_{j=1}^{J} \alpha_j \left(d_j \tau^{d_j} \log \tau + 1 - \tau^{d_j}\right) = \omega. \tag{2.11}$$

Then the boundary of the admissible set satisfies

$$\sum_{j=1}^{J} d_j \alpha_j \tau^{d_j} = 1 + O\left(\frac{1}{C}\right), \tag{2.12}$$

which is nonlinear in view of (2.11)*.* ∎

We investigate further the nature of the boundary of the admissible set given by (2.11) and (2.12). We have the following proposition.

PROPOSITION 2.2. *Suppose that* (2.10) *holds so that the resource is underloaded. Let $(\boldsymbol{\alpha}^{(0)}, \alpha_J^{(0)})$, where, corresponding to* (2.4)*, $\alpha_J^{(0)} = \alpha_J(\boldsymbol{\alpha}^{(0)}; C)$, be a point on the boundary of the admissible set. Define*

$$a_i(\tau) = d_J \tau^{d_J} \left(\tau^{d_i} - 1\right) - d_i \tau^{d_i} \left(\tau^{d_J} - 1\right), \tag{2.13}$$

and let $\tau_0 > 1$ be the solution of (2.11) *corresponding to $\alpha_j = \alpha_j^{(0)}$, $j = 1, \ldots, J$. Also, let*

$$\xi_J = \left(\tau_0^{d_J} - 1\right) \left[\alpha_J - \alpha_J^{(0)} - \sum_{i=1}^{J-1} \frac{\partial \alpha_J}{\partial \alpha_i} \left(\boldsymbol{\alpha}^{(0)}\right) \left(\alpha_i - \alpha_i^{(0)}\right)\right] \tag{2.14}$$

and

$$\xi_{J-1} = \sum_{i=1}^{J-1} a_i(\tau_0)\left(\alpha_i - \alpha_i^{(0)}\right). \tag{2.15}$$

The tangent hyperplane to the boundary of the admissible set at $\boldsymbol{\alpha} = \boldsymbol{\alpha}^{(0)}$ *is given by* $\xi_J = 0$. *From* (2.11) *and* (2.12), *it follows that*

$$\left(\tau^{d_J} - 1\right)\frac{\partial \alpha_J}{\partial \alpha_i} = -\left(\tau^{d_i} - 1\right) + O\left(\frac{1}{C}\right), \quad i = 1, \ldots, J-1, \tag{2.16}$$

and hence, from (2.14), *that*

$$\xi_J = \sum_{j=1}^{J}\left(\tau_0^{d_j} - 1\right)\left(\alpha_j - \alpha_j^{(0)}\right) + O\left(\frac{1}{C}\right). \tag{2.17}$$

Let

$$v_0 = \sum_{j=1}^{J} d_j^2 \alpha_j^{(0)} \tau_0^{d_j}. \tag{2.18}$$

If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, *so that* $\xi_{J-1} = O(\epsilon)$, *then*

$$\xi_J = \xi_{J-1}^2 \left[\frac{1}{2v_0\left(\tau_0^{d_J} - 1\right)^2} + O(\epsilon)\right] + O\left(\frac{\epsilon^2}{C}\right). \tag{2.19}$$

Hence in the asymptotic limit $C \to \infty$, *the boundary of the admissible set is convex, but not strictly so, except when* $J = 2$. □

We remark that, in the limit $C \to \infty$, from (2.11) and (2.12), $\tau \equiv \tau_0$ corresponds to the intersection of two hyperplanes of dimension $J-1$, i.e., to a hyperplane of dimension $J-2$. In particular, if $J = 3$, $\tau \equiv \tau_0$ corresponds to a straight line, and the boundary of the admissible set is a ruled surface.

Proposition 2.2 is established in section 4. Results for the overloaded regime, the subject of Proposition 2.1(A), are derived in section 5. The results for the critically loaded regime in (B) are proven in section 6.

3. Refined results. We now consider refined approximations to the boundary of the admissible set. Corresponding to Proposition 2.1(A), which is for the overloaded regime, we have the following proposition.

PROPOSITION 3.1. *If* ℓ_j, $j = 1, \ldots, J$, *is asymptotically bounded away from zero, we consider the case when*

$$C(a_J - a_i) \gg 1, \quad i = 1, \ldots, J-1, \tag{3.1}$$

where a_j *is given by* (2.5). *With this assumption the boundary of the admissible set is given by* $L_J = \ell_J$. *Then, we have the following.*

(i) *If $J = 2$, then $0 > d\alpha_2/d\alpha_1 = O(1)$ and $0 > d^2\alpha_2/d\alpha_1^2 = O(1/C)$, so that the boundary of the admissible set is* concave*, although only slightly.*

(ii) *If $J \geq 3$, the linear transformation of variables*

$$\eta_J = d_J a_J^{d_J} \left[\alpha_J - \alpha_J^{(0)} - \sum_{i=1}^{J-1} \frac{\partial \alpha_J}{\partial \alpha_i} \left(\boldsymbol{\alpha}^{(0)} \right) \left(\alpha_i - \alpha_i^{(0)} \right) \right], \tag{3.2}$$

$$\eta_{J-1} = \sum_{i=1}^{J-1} d_i (d_i - d_J) a_J^{d_i} \left(\alpha_i - \alpha_i^{(0)} \right), \tag{3.3}$$

$$\eta_{J-2} = \sum_{i=1}^{J-1} d_i \left(d_i^2 - d_J^2 \right) a_J^{d_i} \left(\alpha_i - \alpha_i^{(0)} \right), \tag{3.4}$$

and

$$\eta_i = \alpha_i - \alpha_i^{(0)}, \quad i = 1, \ldots, J-3 \ (J \geq 4), \tag{3.5}$$

is nonsingular, and $\eta_J = 0$ corresponds to the tangent hyperplane to the boundary of the admissible set at $\boldsymbol{\alpha} = \boldsymbol{\alpha}^{(0)}$. From (2.7) *and* (3.2) *we have*

$$\eta_J = \sum_{j=1}^{J} d_j a_J^{d_j} \left(\alpha_j - \alpha_j^{(0)} \right) + O\left(\frac{1}{C} \right). \tag{3.6}$$

If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then

$$\eta_J = \frac{1}{2C \left(\displaystyle\sum_{j=1}^{J} \alpha_j^{(0)} d_j^2 a_J^{d_j} \right)^2} \left[\frac{\displaystyle\sum_{j=1}^{J} \alpha_j^{(0)} d_j^3 a_J^{d_j}}{\displaystyle\sum_{j=1}^{J} \alpha_j^{(0)} d_j^2 a_J^{d_j}} \eta_{J-2}^2 - \eta_{J-1} \eta_{J-2} \right] + O\left(\frac{\epsilon^2}{C^2} \right) + O\left(\frac{\epsilon^3}{C} \right). \tag{3.7}$$

Hence, asymptotically, the boundary of the admissible set is non*convex, although only slightly so.* ∎

Next, corresponding to Proposition 2.1(B), we have the following proposition.

PROPOSITION 3.2. *If* (2.8) *holds, then we have the following:*

(i) *If $J = 2$, then $0 > d\alpha_2/d\alpha_1 = O(1)$ and $0 < d^2\alpha_2/d\alpha_1^2 = O(1/\sqrt{C})$, so that the boundary of the admissible set is convex, although only slightly so.*

(ii) *We consider the case when*

$$\frac{d_J}{\sqrt{C}\,\ell_J} - \frac{d_i}{\sqrt{C}\,\ell_i} \gg \frac{1}{\sqrt{C}}, \quad i = 1, \ldots, J-1. \tag{3.8}$$

If $J \geq 3$, the linear transformation of variables

$$\zeta_J = d_J \left[\alpha_J - \alpha_J^{(0)} - \sum_{i=1}^{J-1} \frac{\partial \alpha_J}{\partial \alpha_i} \left(\boldsymbol{\alpha}^{(0)} \right) \left(\alpha_i - \alpha_i^{(0)} \right) \right], \tag{3.9}$$

$$\zeta_{J-1} = \sum_{i=1}^{J-1} d_i (d_i - d_J) \left(\alpha_i - \alpha_i^{(0)} \right), \tag{3.10}$$

$$\zeta_{J-2} = \sum_{i=1}^{J-1} d_i \left(d_i^2 - d_J^2 \right) \left(\alpha_i - \alpha_i^{(0)} \right), \tag{3.11}$$

and

$$\zeta_i = \alpha_i - \alpha_i^{(0)}, \quad i = 1, \ldots, J-3 \ (J \geq 4), \tag{3.12}$$

is nonsingular, and $\zeta_J = 0$ corresponds to the tangent hyperplane to the boundary of the admissible set at $\boldsymbol{\alpha} = \boldsymbol{\alpha}^{(0)}$. From (2.9) *and* (3.9) *we have*

$$\zeta_J = \sum_{j=1}^{J} d_j \left(\alpha_j - \alpha_j^{(0)} \right) + O\left(\frac{1}{\sqrt{C}} \right). \tag{3.13}$$

Let

$$\sigma_0^2 = 2 \sum_{j=1}^{J} d_j^2 \alpha_j^{(0)}, \quad \sigma_0 > 0. \tag{3.14}$$

If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then

$$\begin{aligned} \zeta_J = {} & \frac{\zeta_{J-1}^2}{2\sqrt{C}} \left[P_2(\sigma_0) + O\left(\frac{1}{\sqrt{C}} \right) + O\left(\zeta_{J-1} \right) \right] \\ & + \frac{\zeta_{J-1} \zeta_{J-2}}{C} \left[R_2(\sigma_0) + O(\zeta_{J-1}) \right] + O\left(\frac{\epsilon^2}{C\sqrt{C}} \right), \end{aligned} \tag{3.15}$$

and $P_2(\sigma_0) > 0$. □

If $\zeta_{J-1} = O(\epsilon/\sqrt{C})$, then the leading terms in (3.15) are all $O(\epsilon^2/C\sqrt{C})$, and the term involving $\zeta_{J-2}^2/C\sqrt{C}$, in particular, is needed to ascertain whether or not the boundary of the admissible set is convex. Hence, the next order term in the asymptotic expansion in powers of $1/\sqrt{C}$ is required, and this is derived in [12].

Finally, corresponding to Proposition 2.1(C), we have the following proposition.

PROPOSITION 3.3. *If* (2.10) *holds, we let $\tau_0 > 1$ be the solution of* (2.11) *corresponding to $\alpha_j = \alpha_j^{(0)}$, $j = 1, \ldots, J$, and define*

$$B(\tau) = \min_j \left[\frac{\beta_j (\tau - 1)}{(\tau^{d_j} - 1)} \right], \quad \tau > 1. \tag{3.16}$$

In general, $B(\tau)$ is only piecewise differentiable. We consider the case when $B(\tau)$ is differentiable at $\tau = \tau_0$. For $J \geq 3$, with $a_i(\tau)$ given by (2.13)*, the linear transformation of variables* (2.14), (2.15),

$$\xi_{J-2} = \sum_{i=1}^{J-1} a_i'(\tau_0) \left(\alpha_i - \alpha_i^{(0)}\right), \tag{3.17}$$

where the prime denotes derivative, and

$$\xi_i = \alpha_i - \alpha_i^{(0)}, \quad i = 1, \ldots, J-3 \ (J \geq 4), \tag{3.18}$$

is nonsingular. If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then

$$\begin{aligned} \xi_J = \xi_{J-1}^2 &\left[\frac{1}{2v_0\left(\tau_0^{d_J} - 1\right)^2} + O(\epsilon) + O\left(\frac{1}{C}\right)\right] \\ &- \frac{\tau_0^2 \xi_{J-2}^2}{4Cv_0^2\left(\tau_0^{d_J} - 1\right)^2} + O\left(\frac{\epsilon}{C}\xi_{J-1}\right) + O\left(\frac{\epsilon^2}{C^2}\right). \end{aligned} \tag{3.19}$$

Hence, asymptotically, the boundary of the admissible set is non*convex, although only slightly so.* ∎

4. Underloaded regime. We establish Proposition 2.2. We consider an underloaded resource, so that

$$\sum_{j=1}^{J} d_j \alpha_j < 1. \tag{4.1}$$

Let z^* be the unique positive solution of

$$\sum_{j=1}^{J} d_j \alpha_j (z^*)^{d_j} = 1. \tag{4.2}$$

Then, from (4.1), $z^* > 1$. We define

$$f(z) = \sum_{j=1}^{J} \alpha_j (z^{d_j} - 1) - \log z \tag{4.3}$$

and

$$v(z^*) = \sum_{j=1}^{J} \alpha_j d_j^2 (z^*)^{d_j}. \tag{4.4}$$

Then (see [10]), the blocking probabilities satisfy

$$L_j = \frac{e^{Cf(z^*)}}{\sqrt{2\pi C v(z^*)}} \left\{\frac{[(z^*)^{d_j} - 1]}{(z^* - 1)} + O\left(\frac{1}{C}\right)\right\}. \tag{4.5}$$

Since, from (4.2) and (4.3), $f'(z^*) = 0$, it follows that

$$\frac{\partial f(z^*)}{\partial \alpha_k} = (z^*)^{d_k} - 1 > 0, \tag{4.6}$$

and (4.5) implies (2.3).

Let

$$\psi(z) = \sum_{j=1}^{J} \alpha_j \left(d_j z^{d_j} \log z + 1 - z^{d_j} \right). \tag{4.7}$$

Then, from (4.2) and (4.3), $\psi(z^*) = -f(z^*)$, and

$$\psi'(z) = \log z \sum_{j=1}^{J} \alpha_j d_j^2 z^{d_j - 1} > 0, \quad z > 1. \tag{4.8}$$

From (2.2), (2.10), and (4.5), it follows that $\psi(z^*) \geq \omega + O(1/C)$. Hence $z^* \geq \tau + O(1/C)$, where $\psi(\tau) = \omega$, so that (2.11) holds, and the boundary of the admissible set satisfies (2.12). We consider α_J, and hence τ, as functions of $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_{J-1})$ and C. From (2.11) and (2.12) we obtain

$$\sum_{j=1}^{J} \alpha_j \left(1 - \tau^{d_j}\right) + \log \tau = \omega + O\left(\frac{1}{C}\right), \tag{4.9}$$

and hence (2.16).

Now, from (2.12), for $k = 1, \ldots, J-1$,

$$d_k \tau^{d_k} + d_J \tau^{d_J} \frac{\partial \alpha_J}{\partial \alpha_k} + \sum_{j=1}^{J} \alpha_j d_j^2 \tau^{d_j - 1} \frac{\partial \tau}{\partial \alpha_k} = O\left(\frac{1}{C}\right). \tag{4.10}$$

We let

$$v = \sum_{j=1}^{J} \alpha_j d_j^2 \tau^{d_j}. \tag{4.11}$$

Then, from (2.13), (2.16), and (4.10), we have

$$\frac{\partial \tau}{\partial \alpha_k} = \frac{\tau a_k(\tau)}{v(\tau^{d_J} - 1)} + O\left(\frac{1}{C}\right), \quad k = 1, \ldots, J-1. \tag{4.12}$$

Also, from (2.13),

$$\tau \frac{d}{d\tau} \left[\frac{(\tau^{d_i} - 1)}{(\tau^{d_J} - 1)} \right] = -\frac{a_i(\tau)}{(\tau^{d_J} - 1)^2}. \tag{4.13}$$

Hence, from (2.16), (4.12), and (4.13), we obtain

$$\frac{\partial^2 \alpha_J}{\partial \alpha_i \partial \alpha_k} = \frac{a_i(\tau) a_k(\tau)}{v(\tau^{d_J} - 1)^3} + O\left(\frac{1}{C}\right), \quad i, k = 1, \ldots, J-1. \tag{4.14}$$

From (2.13), we have

$$\frac{d}{dt}\left[\frac{a_i(t)}{t^{d_J+d_i}}\right] = \frac{d_i d_J}{t}\left(\frac{1}{t^{d_i}} - \frac{1}{t^{d_J}}\right), \tag{4.15}$$

which is nonzero for $t > 1$ and $i = 1, \ldots, J-1$, since d_j, $j = 1, \ldots, J$, are distinct. Hence $a_i(\tau) \neq 0$, since $\tau > 1$ and $a_i(1) = 0$. With ξ_{J-1} defined by (2.15), it follows, by induction, from (4.12) and (4.14), that, for $n \geq 2$, the leading term in

$$\sum_{i_1=1}^{J-1} \cdots \sum_{i_n=1}^{J-1} \frac{\partial^n \alpha_J}{\partial\alpha_{i_1} \ldots \partial\alpha_{i_n}}(\alpha_1^{(0)}, \ldots, \alpha_{J-1}^{(0)}) \prod_{m=1}^{n} \left(\alpha_{i_m} - \alpha_{i_m}^{(0)}\right) \tag{4.16}$$

contains the factor ξ_{J-1}^2. If we use the Taylor series expansion

$$\begin{aligned} \alpha_J = \alpha_J^{(0)} &+ \sum_{i=1}^{J-1} \frac{\partial \alpha_J}{\partial \alpha_i}\left(\boldsymbol{\alpha}^{(0)}\right)\left(\alpha_i - \alpha_i^{(0)}\right) \\ &+ \frac{1}{2}\sum_{i=1}^{J-1}\sum_{k=1}^{J-1} \frac{\partial^2 \alpha_J}{\partial\alpha_i \partial\alpha_k}\left(\boldsymbol{\alpha}^{(0)}\right)\left(\alpha_i - \alpha_i^{(0)}\right)\left(\alpha_k - \alpha_k^{(0)}\right) + \cdots \end{aligned} \tag{4.17}$$

and let $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then, from (2.14), (2.18), and (4.14), we obtain (2.19), where $\tau_0 > 1$ is the solution of (2.11) corresponding to $\alpha_j = \alpha_j^{(0)}$, $j = 1, \ldots, J$. This establishes Proposition 2.2.

5. Overloaded regime. We now consider an overloaded resource, so that

$$\sum_{j=1}^{J} d_j \alpha_j > 1. \tag{5.1}$$

Then, from (4.2), $0 < z^* < 1$, and [10], the blocking probabilities satisfy

$$L_j = 1 - (z^*)^{d_j} + O(1/C). \tag{5.2}$$

However, from (4.2), $\partial z^*/\partial\alpha_k < 0$, $k = 1, \ldots, J$. It follows, from (5.2), that (2.3) holds. Moreover, from (2.2), (2.5), and (2.6), the boundary of the admissible set satisfies $z^* = a_J + O(1/C)$, and (4.2) implies (2.7). Consequently, $\partial^2\alpha_J/\partial\alpha_i\partial\alpha_k = O(1/C)$, and it is necessary to consider the first order correction term in (5.2).

In Appendix A we establish the following proposition.

PROPOSITION 5.1. *Let*

$$t(z^*) = \sum_{j=1}^{J} \alpha_j d_j^2 (d_j - 3)(z^*)^{d_j}. \tag{5.3}$$

Then, with $v(z^*)$ given by (4.4),

$$L_j = 1 - (z^*)^{d_j} + \frac{d_j (z^*)^{d_j}}{2Cv(z^*)}\left[d_j - 5 + \frac{2}{(1-z^*)} - \frac{t(z^*)}{v(z^*)}\right] + O\left(\frac{1}{C^2}\right). \tag{5.4}$$

∎

It follows from (2.2), (2.5), and (5.4) that

$$z^* \geq a_j \left\{ 1 + \frac{1}{2Cv(a_j)} \left[d_j - 5 + \frac{2}{(1-a_j)} - \frac{t(a_j)}{v(a_j)} \right] + O\left(\frac{1}{C^2}\right) \right\}, \tag{5.5}$$

$j = 1, \ldots, J$. Under the assumption (3.1), the maximum in (5.5) is obtained for $j = J$ and, from (4.2), the boundary of the admissible set satisfies

$$\sum_{j=1}^{J} \alpha_j d_j a_J^{d_j} \left\{ 1 + \frac{d_j}{2Cv(a_J)} \left[d_J - 5 + \frac{2}{(1-a_J)} - \frac{t(a_J)}{v(a_J)} \right] + O\left(\frac{1}{C^2}\right) \right\} = 1. \tag{5.6}$$

In view of (4.4), this may be written in the form

$$\sum_{j=1}^{J} \alpha_j d_j a_J^{d_j} + \frac{1}{2C} \left[d_J - 5 + \frac{2}{(1-a_J)} - \frac{t(a_J)}{v(a_J)} \right] + O\left(\frac{1}{C^2}\right) = 1. \tag{5.7}$$

We consider α_J as a function of $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_{J-1})$ and C, as in (2.4). Then, from (4.4), for $i = 1, \ldots, J-1$,

$$\frac{\partial v(a_J)}{\partial \alpha_i} = d_i^2 a_J^{d_i} + d_J^2 a_J^{d_J} \frac{\partial \alpha_J}{\partial \alpha_i}, \tag{5.8}$$

and, from (5.3),

$$\frac{\partial t(a_J)}{\partial \alpha_i} = d_i^2 (d_i - 3) a_J^{d_i} + d_J^2 (d_J - 3) a_J^{d_J} \frac{\partial \alpha_J}{\partial \alpha_i}. \tag{5.9}$$

Hence, from (2.7),

$$\frac{\partial v(a_J)}{\partial \alpha_i} = d_i (d_i - d_J) a_J^{d_i} + O\left(\frac{1}{C}\right), \tag{5.10}$$

and

$$\frac{\partial t(a_J)}{\partial \alpha_i} = d_i (d_i - d_J)(d_i + d_J - 3) a_J^{d_i} + O\left(\frac{1}{C}\right). \tag{5.11}$$

It follows from (5.7) that

$$\begin{aligned} & d_i a_J^{d_i} + d_J a_J^{d_J} \frac{\partial \alpha_J}{\partial \alpha_i} \\ & \quad = \frac{d_i (d_i - d_J)}{2Cv(a_J)} a_J^{d_i} \left[(d_i + d_J - 3) - \frac{t(a_J)}{v(a_J)} \right] + O\left(\frac{1}{C^2}\right). \end{aligned} \tag{5.12}$$

Finally, from (5.10)–(5.12), for $i, k = 1, \ldots, J-1$, we obtain

$$\begin{aligned} d_J a_J^{d_J} \frac{\partial^2 \alpha_J}{\partial \alpha_i \partial \alpha_k} = {} & \frac{d_i d_k (d_i - d_J)(d_k - d_J)}{2C[v(a_J)]^3} a_J^{d_i + d_k} \\ & \cdot \left[2t(a_J) + (6 - d_i - d_k - 2d_J) v(a_J) \right] + O\left(\frac{1}{C^2}\right). \end{aligned} \tag{5.13}$$

If $J = 2$, then

$$t(a_2) + (3 - d_1 - d_2)v(a_2) = -d_1 d_2 \left(\alpha_1 d_1 a_2^{d_1} + \alpha_2 d_2 a_2^{d_2} \right) < 0, \tag{5.14}$$

and Proposition 3.1(i) follows from (2.7) and (5.13). If $J \geq 3$, we use the Taylor series expansion (4.17). We note, from (4.4) and (5.3), that

$$t(a_J) + 3v(a_J) = \sum_{j=1}^{J} \alpha_j d_j^3 a_J^{d_j}. \tag{5.15}$$

From (5.13), (5.15), and the transformation of variables (3.2)–(3.5), which is nonsingular since $d_1, \ldots, d_J$ are distinct, we obtain (3.7) and hence Proposition 3.1(ii).

6. Critically loaded regime. We now consider a critically loaded resource, so that

$$\sum_{j=1}^{J} d_j \alpha_j = 1 - \frac{\delta}{\sqrt{C}}, \tag{6.1}$$

where $\delta = O(1)$ may have either sign. Let

$$\sigma^2 = 2 \sum_{j=1}^{J} d_j^2 \alpha_j, \quad \sigma > 0, \tag{6.2}$$

and

$$\beta = \frac{2e^{-(\delta/\sigma)^2}}{\sigma \sqrt{\pi}\ \mathrm{Erfc}\,(-\delta/\sigma)}, \tag{6.3}$$

where the complementary error function is given by

$$\mathrm{Erfc}\,(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-\xi^2} d_\xi. \tag{6.4}$$

Then (see [3], [10], [16]), the blocking probabilities satisfy

$$L_j = \frac{d_j \beta}{\sqrt{C}} \left[1 + O\left(\frac{1}{\sqrt{C}} \right) \right]. \tag{6.5}$$

It follows, from (6.1)–(6.5), that

$$\frac{\partial L_j}{\partial \alpha_k} = \frac{4 d_j d_k e^{-(\delta/\sigma)^2}}{\sigma^2 \sqrt{\pi}\ \mathrm{Erfc}\,(-\delta/\sigma)} \left[\frac{\delta}{\sigma} + \frac{e^{-(\delta/\sigma)^2}}{\sqrt{\pi}\ \mathrm{Erfc}\,(-\delta/\sigma)} \right] + O\left(\frac{1}{\sqrt{C}} \right). \tag{6.6}$$

The quantity in square brackets in (6.6) was shown [14] to be positive, and hence (2.3) holds.

As in [10], we define

$$\kappa = \max_j \frac{d_j}{\sqrt{C} \ell_j}, \tag{6.7}$$

which is $O(1)$, in view of (2.8), and

$$\phi(y) = \frac{\sqrt{\pi}}{2} e^{y^2} \text{ Erfc}\,(-y). \tag{6.8}$$

Then the admissible set satisfies

$$\sigma\phi(\delta/\sigma) \geq \kappa + O(1/\sqrt{C}). \tag{6.9}$$

However, from (6.4) and (6.8),

$$\phi(y) = e^{y^2} \int_{-y}^{\infty} e^{-\xi^2} d\xi = \int_0^{\infty} e^{2yu} e^{-u^2} du. \tag{6.10}$$

Hence $\phi'(y) > 0$, $-\infty < y < \infty$, so that $\phi(y)$ has a unique inverse, and (6.9) may be written, as in [10], in the form $\delta \geq \sigma\phi^{-1}(\kappa/\sigma) + O(1/\sqrt{C})$. We define

$$\chi(\sigma) = \phi^{-1}(\kappa/\sigma). \tag{6.11}$$

Then, from (6.1), the boundary of the admissible set satisfies

$$\sum_{j=1}^{J} d_j \alpha_j = 1 - \frac{\sigma}{\sqrt{C}}\, \chi(\sigma) + O\left(\frac{1}{C}\right). \tag{6.12}$$

This establishes Proposition 2.1(B) and provides an asymptotic approximation to the error term in (2.9).

We now consider α_J as a function of $\boldsymbol{\alpha} = (\alpha_1, \ldots, \alpha_{J-1})$ and C, as in (2.4). We define

$$\theta^2 = 2\left[d_J + \sum_{i=1}^{J-1} d_i(d_i - d_J)\alpha_i\right], \quad \theta > 0. \tag{6.13}$$

Then, from (6.2) and (6.12), $\sigma = \theta + O(1/\sqrt{C})$, and

$$d_J \alpha_J = 1 - \sum_{i=1}^{J-1} d_i \alpha_i - \frac{\theta}{\sqrt{C}}\, \chi(\theta) + O\left(\frac{1}{C}\right). \tag{6.14}$$

It follows, from (6.13) and (6.14), that

$$\theta \frac{\partial \theta}{\partial \alpha_i} = d_i(d_i - d_J), \quad i = 1, \ldots, J-1, \tag{6.15}$$

and

$$\frac{\partial \alpha_J}{\partial \alpha_i} = -\frac{d_i}{d_J}\left\{1 + \frac{(d_i - d_J)}{\sqrt{C}}\left[\chi'(\theta) + \frac{\chi(\theta)}{\theta}\right]\right\} + O\left(\frac{1}{C}\right) < 0, \tag{6.16}$$

where the prime denotes derivative. Also, for $i = 1, \ldots, J-1$ and $k = 1, \ldots, J-1$,

$$d_J \frac{\partial^2 \alpha_J}{\partial \alpha_i \partial \alpha_k} = d_i d_k (d_i - d_J)(d_k - d_J)\frac{P_2(\theta)}{\sqrt{C}} + O\left(\frac{1}{C}\right), \tag{6.17}$$

where

$$P_2(\theta) = \frac{1}{\theta^3}\left[\chi(\theta) - \theta\chi'(\theta) - \theta^2\chi''(\theta)\right]. \tag{6.18}$$

It is shown in Appendix B that $P_2(\theta) > 0$ for $\theta > 0$. Hence, if $J = 2$, we obtain Proposition 3.2(i).

From (6.15) and (6.17) it follows, by induction, that the higher order partial derivatives have the form

$$d_J \frac{\partial^n \alpha_J}{\partial\alpha_{i_1}\cdots\partial\alpha_{i_n}} = \frac{1}{\sqrt{C}}\prod_{m=1}^{n} d_{i_m}(d_{i_m} - d_J)P_n(\theta) + O\left(\frac{1}{C}\right) \tag{6.19}$$

for $n \geq 2$, where $P_{n+1}(\theta) = P_n'(\theta)/\theta$. If $J \geq 3$, we use the Taylor series expansion (4.17) and introduce the linear transformation of variables (3.9)–(3.12). The transformation is nonsingular, since $d_1, \ldots, d_J$ are distinct. If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then, from (6.19), we obtain

$$\zeta_J = \frac{\zeta_{J-1}^2}{2\sqrt{C}}\left[P_2(\theta_0) + O(\zeta_{J-1})\right] + O\left(\frac{\epsilon^2}{C}\right), \tag{6.20}$$

where $\theta_0 = \theta(\boldsymbol{\alpha}^{(0)})$, and we note that $\theta_0 = \sigma_0 + O(1/\sqrt{C})$, where $\sigma_0 = \sigma(\boldsymbol{\alpha}^{(0)})$ is given by (3.14). Hence, it is necessary to consider a refined asymptotic approximation to ascertain the nature of the boundary of the admissible set when ζ_{J-1} is close to zero.

7. Refined critically loaded approximation. Let

$$\eta = \sum_{j=1}^{J} d_j^3 \alpha_j. \tag{7.1}$$

Then, a refined asymptotic approximation to the blocking probabilities in the critically loaded regime is (see [14])

$$L_j = \frac{d_j\beta}{\sqrt{C}}\left\{1 + \frac{\delta}{\sigma^2\sqrt{C}}\left[\frac{2\eta}{\sigma^2}\left(\frac{2\delta^2}{3\sigma^2} - 1\right) + d_j - 1\right]\right. \tag{7.2}$$
$$\left. - \frac{\beta}{2\sqrt{C}}\left[1 + \frac{2\eta}{3\sigma^2}\left(1 - \frac{2\delta^2}{\sigma^2}\right)\right] + O\left(\frac{1}{C}\right)\right\}.$$

We consider the case when (3.8) holds, so that, from (6.7),

$$\kappa = \frac{d_J}{\sqrt{C}\ell_J}, \tag{7.3}$$

which is $O(1)$. Then, asymptotically, the boundary of the admissible set satisfies

$$1 = \kappa\beta\left\{1 + \frac{\delta}{\sigma^2\sqrt{C}}\left[\frac{2\eta}{\sigma^2}\left(\frac{2\delta^2}{3\sigma^2} - 1\right) + d_J - 1\right]\right. \tag{7.4}$$
$$\left. - \frac{\beta}{2\sqrt{C}}\left[1 + \frac{2\eta}{3\sigma^2}\left(1 - \frac{2\delta^2}{\sigma^2}\right)\right] + O\left(\frac{1}{C}\right)\right\}.$$

Now, from (6.1), (6.2), (6.13), and (6.14),

$$\sigma = \theta + O(1/\sqrt{C}) \tag{7.5}$$

and

$$\delta = \theta\chi(\theta) + O(1/\sqrt{C}). \tag{7.6}$$

We define

$$\psi = d_J^2 + \sum_{i=1}^{J-1} d_i \left(d_i^2 - d_J^2\right) \alpha_i. \tag{7.7}$$

Then, from (6.1) and (7.1),

$$\eta = \psi + O(1/\sqrt{C}). \tag{7.8}$$

From (6.3) and (6.8), we have

$$\frac{1}{\beta} = \sigma\phi\left(\frac{\delta}{\sigma}\right). \tag{7.9}$$

Hence, from (7.4)–(7.6), (7.8), and (7.9), it follows that $\beta = 1/\kappa + O(1/\sqrt{C})$, and

$$\begin{aligned}\sigma\phi\left(\frac{\delta}{\sigma}\right) = \kappa\Bigg\{1 + \frac{\chi(\theta)}{\theta\sqrt{C}}\left[\frac{2\psi}{\theta^2}\left\{\frac{2}{3}[\chi(\theta)]^2 - 1\right\} + d_J - 1\right] \\ - \frac{1}{2\kappa\sqrt{C}}\left[1 + \frac{2\psi}{3\theta^2}\left\{1 - 2[\chi(\theta)]^2\right\}\right] + O\left(\frac{1}{C}\right)\Bigg\}.\end{aligned} \tag{7.10}$$

From (6.2) and (6.14), it follows that

$$\sigma^2 = \theta^2 - \frac{2}{\sqrt{C}} d_J \theta\chi(\theta) + O\left(\frac{1}{C}\right), \tag{7.11}$$

so that

$$\sigma = \theta - \frac{d_J}{\sqrt{C}}\chi(\theta) + O\left(\frac{1}{C}\right) \tag{7.12}$$

and

$$\sigma\chi(\sigma) = \theta\chi(\theta) - \frac{d_J}{\sqrt{C}}\chi(\theta)\left[\chi(\theta) + \theta\chi'(\theta)\right] + O\left(\frac{1}{C}\right). \tag{7.13}$$

Hence, from (6.11) and (7.10), it is found that

$$\begin{aligned}\delta = \theta\chi(\theta) - \frac{d_J}{\sqrt{C}}\chi(\theta)\left[\chi(\theta) + \theta\chi'(\theta)\right] \\ + \frac{\chi'(\theta)}{\sqrt{C}}\left\{\frac{1}{2\kappa}\left[\theta^2 + \frac{2}{3}\psi\left\{1 - 2\left[\chi(\theta)\right]^2\right\}\right]\right. \\ \left. - \theta\chi(\theta)\left[\frac{2\psi}{\theta^2}\left\{\frac{2}{3}[\chi(\theta)]^2 - 1\right\} + d_J - 1\right]\right\} + O\left(\frac{1}{C}\right).\end{aligned} \tag{7.14}$$

We define

$$F(\theta) = \theta\chi(\theta)\chi'(\theta) + \frac{\theta^2}{2\kappa}\chi'(\theta) - d_J\chi(\theta)[\chi(\theta) + 2\theta\chi'(\theta)] \tag{7.15}$$

and

$$G(\theta) = \chi'(\theta)\left[\frac{2\chi(\theta)}{\theta}\left\{1 - \frac{2}{3}[\chi(\theta)]^2\right\} + \frac{1}{3\kappa}\{1 - 2[\chi(\theta)]^2\}\right]. \tag{7.16}$$

Then, from (6.1) and (7.14)–(7.16), we obtain

$$d_J\alpha_J = 1 - \sum_{i=1}^{J-1} d_i\alpha_i - \frac{\theta}{\sqrt{C}}\chi(\theta) - \frac{1}{C}[F(\theta) + \psi G(\theta)] + O\left(\frac{1}{C^{3/2}}\right). \tag{7.17}$$

However, from (7.7),

$$\frac{\partial\psi}{\partial\alpha_i} = d_i\left(d_i^2 - d_J^2\right), \quad i = 1, \ldots, J-1. \tag{7.18}$$

Hence, from (6.15), (7.17), and (7.18),

$$\begin{aligned}\frac{\partial\alpha_J}{\partial\alpha_i} = &-\frac{d_i}{d_J}\left\{1 + \frac{(d_i - d_J)}{\sqrt{C}}\left[\chi'(\theta) + \frac{\chi(\theta)}{\theta}\right]\right.\\ &\left. + \ \frac{(d_i - d_J)}{C\theta}[F'(\theta) + \psi G'(\theta)] + \left(d_i^2 - d_J^2\right)\frac{G(\theta)}{C}\right\} + O\left(\frac{1}{C^{3/2}}\right).\end{aligned} \tag{7.19}$$

We now define

$$Q_2(\theta) = \frac{F'(\theta)}{\theta^3} - \frac{F''(\theta)}{\theta^2}, \qquad R_2(\theta) = -\frac{G'(\theta)}{\theta}. \tag{7.20}$$

Then, with $P_2(\theta)$ as in (6.18), for $i = 1, \ldots, J-1$ and $k = 1, \ldots, J-1$, we obtain

$$\begin{aligned}d_J\frac{\partial^2\alpha_J}{\partial\alpha_i\partial\alpha_k} = &\ d_id_k(d_i - d_J)(d_k - d_J)\left\{\frac{P_2(\theta)}{\sqrt{C}} + \frac{1}{C}\left[Q_2(\theta) + \frac{\psi}{\theta}R_2'(\theta)\right]\right\}\\ &+ \ d_id_k[(d_i - d_J)(d_k^2 - d_J^2) + (d_k - d_J)(d_i^2 - d_J^2)]\frac{R_2(\theta)}{C} + O\left(\frac{1}{C^{3/2}}\right).\end{aligned} \tag{7.21}$$

From (6.15), (7.18), and (7.21) it follows, by induction, that the higher order partial derivatives have the form

$$\begin{aligned}d_J\frac{\partial^n\alpha_J}{\partial\alpha_{i_1}\cdots\partial\alpha_{i_n}} = &\prod_{m=1}^{n} d_{i_m}(d_{i_m} - d_J)\left\{\frac{P_n(\theta)}{\sqrt{C}} + \frac{1}{C}\left[Q_n(\theta) + \frac{\psi}{\theta}R_n'(\theta)\right]\right\}\\ &+ \ \sum_{r=1}^{n}\prod_{\substack{m=1\\ m\neq r}}^{n} d_{i_m}(d_{i_m} - d_J)d_{i_r}(d_{i_r}^2 - d_J^2)\frac{R_n(\theta)}{C} + O\left(\frac{1}{C^{3/2}}\right)\end{aligned} \tag{7.22}$$

for $n \geq 2$, where

$$P_{n+1}(\theta) = P_n'(\theta)/\theta, \quad Q_{n+1}(\theta) = Q_n'(\theta)/\theta, \quad R_{n+1}(\theta) = R_n'(\theta)/\theta. \tag{7.23}$$

Hence, from (3.10) and (3.11), for $n \geq 2$,

$$d_J \sum_{i_1=1}^{J-1} \cdots \sum_{i_n=1}^{J-1} \frac{\partial^n \alpha_J}{\partial \alpha_{i_1} \cdots \partial \alpha_{i_n}}(\boldsymbol{\alpha}^{(0)}) \prod_{m=1}^{n} (\alpha_{i_m} - \alpha_{i_m}^{(0)}) \tag{7.24}$$

$$= \left\{ \frac{P_n(\theta_0)}{\sqrt{C}} + \frac{1}{C}\left[Q_n(\theta_0) + \frac{\psi_0}{\theta_0} R_n'(\theta_0) \right] \right\} \zeta_{J-1}^n + \frac{n}{C} R_n(\theta_0) \zeta_{J-1}^{n-1} \zeta_{J-2} + O\left(\frac{1}{C^{3/2}} \right),$$

where $\theta_0 = \theta(\boldsymbol{\alpha}^{(0)})$ and $\psi_0 = \psi(\boldsymbol{\alpha}^{(0)})$.

For $J \geq 3$, we use the Taylor series expansion (4.17) and introduce the linear transformation of variables (3.9)–(3.12). If $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, then it follows from (7.24) that

$$\zeta_J = \frac{\zeta_{J-1}^2}{2\sqrt{C}} \left[P_2(\theta_0) + O\left(\frac{1}{\sqrt{C}} \right) + O(\zeta_{J-1}) \right] \tag{7.25}$$

$$+ \frac{1}{C} \zeta_{J-1} \zeta_{J-2} \left[R_2(\theta_0) + O(\zeta_{J-1}) \right] + O\left(\frac{\epsilon^2}{C\sqrt{C}} \right).$$

Since $\theta_0 = \sigma_0 + O(1/\sqrt{C})$, where $\sigma_0 = \sigma(\boldsymbol{\alpha}^{(0)})$ is given by (3.14), we obtain (3.15) and hence Proposition 3.2(ii).

8. Refined underloaded approximation. We now return to an underloaded resource. From (2.2), (2.10), and (4.5), since $\psi(z^*) = -f(z^*)$, it follows that

$$\psi(z^*) \geq \omega - \frac{1}{C} \log \left\{ \frac{\beta_j (z^* - 1)}{[(z^*)^{d_j} - 1]} \right\} - \frac{\log v(z^*)}{2C} + O\left(\frac{1}{C^2} \right), \tag{8.1}$$

$j = 1, \ldots, J$. Hence, $z^* \geq \tau + \rho/C + O(1/C^2)$, where, as in [10],

$$\rho \psi'(\tau) = -\log B(\tau) - \frac{1}{2} \log v, \tag{8.2}$$

where $B(\tau)$ and v are given by (3.16) and (4.11). However, from (4.8),

$$\sum_{j=1}^{J} \alpha_j d_j \left[\tau + \frac{\rho}{C} + O\left(\frac{1}{C^2} \right) \right]^{d_j} = \sum_{j=1}^{J} \alpha_j d_j \tau^{d_j} + \frac{\rho \psi'(\tau)}{C \log \tau} + O\left(\frac{1}{C^2} \right). \tag{8.3}$$

Hence, the boundary of the admissible set satisfies

$$\sum_{j=1}^{J} \alpha_j d_j \tau^{d_j} - \frac{1}{C \log \tau} \left[\log B(\tau) + \frac{1}{2} \log v \right] + O\left(\frac{1}{C^2} \right) = 1. \tag{8.4}$$

From (2.11) and (8.4), we obtain

$$\sum_{j=1}^{J} \alpha_j (1 - \tau^{d_j}) + \log \tau + \frac{1}{C} \left[\log B(\tau) + \frac{1}{2} \log v \right] + O\left(\frac{1}{C^2} \right) = \omega. \tag{8.5}$$

Hence, for $i = 1, \ldots, J-1$,

$$1 - \tau^{d_i} + (1 - \tau^{d_J})\frac{\partial \alpha_J}{\partial \alpha_i} + \frac{1}{2Cv}\,\frac{\partial v}{\partial \alpha_i} + \frac{1}{\tau}\,\frac{\partial \tau}{\partial \alpha_i}\left[1 - \sum_{j=1}^{J} \alpha_j d_j \tau^{d_j} + \frac{\tau B'(\tau)}{CB(\tau)}\right] = O\left(\frac{1}{C^2}\right). \tag{8.6}$$

However, from (4.11),

$$\frac{\partial v}{\partial \alpha_i} = d_i^2 \tau^{d_i} + d_J^2 \tau^{d_J}\frac{\partial \alpha_J}{\partial \alpha_i} + \sum_{j=1}^{J} \alpha_j d_j^3 \tau^{d_j - 1}\frac{\partial \tau}{\partial \alpha_i}. \tag{8.7}$$

Also, from (2.13),

$$\tau a_i'(\tau) = d_J^2 \tau^{d_J}(\tau^{d_i} - 1) - d_i^2 \tau^{d_i}(\tau^{d_J} - 1). \tag{8.8}$$

Hence, from (2.16) and (4.12),

$$\frac{\partial v}{\partial \alpha_i} = \frac{a_i(\tau)}{v(\tau^{d_J} - 1)} \sum_{j=1}^{J} \alpha_j d_j^3 \tau^{d_j} - \frac{\tau a_i'(\tau)}{(\tau^{d_J} - 1)} + O\left(\frac{1}{C}\right). \tag{8.9}$$

We let

$$A = \frac{1}{v(\tau^{d_J} - 1)^2}\left\{\frac{[\log B(\tau) + \frac{1}{2}\log v]}{\log \tau} - \frac{\tau B'(\tau)}{B(\tau)}\right\} \tag{8.10}$$

and

$$D = \frac{\tau}{2v(\tau^{d_J} - 1)^2}, \qquad E = -\frac{1}{2v^2(\tau^{d_J} - 1)^2}. \tag{8.11}$$

Then, from (4.12), (8.4), (8.6), and (8.9), we obtain

$$\frac{\partial \alpha_J}{\partial \alpha_i} = -\frac{(\tau^{d_i} - 1)}{(\tau^{d_J} - 1)} - \frac{1}{C}\left[\left(A + E\sum_{j=1}^{J} \alpha_j d_j^3 \tau^{d_j}\right) a_i(\tau) + D a_i'(\tau)\right] + O\left(\frac{1}{C^2}\right) \tag{8.12}$$

for $i = 1, \ldots, J-1$. However, from (2.11),

$$d_i \tau^{d_i}\log \tau + 1 - \tau^{d_i} + \frac{\partial \alpha_J}{\partial \alpha_i}\left(d_J \tau^{d_J}\log \tau + 1 - \tau^{d_J}\right) + \sum_{j=1}^{J} \alpha_j d_j^2 \tau^{d_j - 1}\log \tau \frac{\partial \tau}{\partial \alpha_i} = 0, \quad i = 1, \ldots, J-1. \tag{8.13}$$

It follows, from (2.13), (4.11), (8.12), and (8.13), that

$$\frac{v}{\tau}\,\frac{\partial \tau}{\partial \alpha_i} = \frac{a_i(\tau)}{(\tau^{d_J - 1})} + \frac{\left(d_J \tau^{d_J}\log \tau + 1 - \tau^{d_J}\right)}{C\log \tau} \cdot \left[\left(A + E\sum_{j=1}^{J} \alpha_j d_j^3 \tau^{d_j}\right) a_i(\tau) + D a_i'(\tau)\right] + O\left(\frac{1}{C^2}\right) \tag{8.14}$$

for $i = 1, \ldots, J-1$.

From (2.16) and (4.12), we have

$$(\tau^{d_J}-1)\frac{\partial}{\partial\alpha_k}\left(\sum_{j=1}^{J}\alpha_j d_j^3\tau^{d_j}\right) \tag{8.15}$$

$$= d_k^3\tau^{d_k}(\tau^{d_J}-1) - d_J^3\tau^{d_J}(\tau^{d_k}-1) + \frac{a_k(\tau)}{v}\sum_{j=1}^{J}\alpha_j d_j^4\tau^{d_j} + O\left(\frac{1}{C}\right).$$

However, from (8.8), it follows that

$$\tau[\tau a_k'(\tau)]' = d_J^3\tau^{d_J}(\tau^{d_k}-1) - d_k^3\tau^{d_k}(\tau^{d_J}-1) + d_k d_J(d_J-d_k)\tau^{d_J+d_k}. \tag{8.16}$$

Hence, from (2.13) and (8.8), we obtain

$$d_J^3\tau^{d_J}(\tau^{d_k}-1) - d_k^3\tau^{d_k}(\tau^{d_J}-1) \tag{8.17}$$

$$= \tau^2 a_k''(\tau) + \tau a_k'(\tau) - \frac{d_J\tau^{d_J}}{(\tau^{d_J}-1)}[\tau a_k'(\tau) - d_J a_k(\tau)].$$

We define

$$H = \frac{1}{v(\tau^{d_J}-1)^2}\left[\frac{d_J\tau^{d_J}}{(\tau^{d_J}-1)} - \frac{1}{2} - \frac{\log v}{2\log\tau} + \frac{\tau B'(\tau)}{B(\tau)} - \frac{\log B(\tau)}{\log\tau} + \frac{\tau}{v}\,\frac{\partial v}{\partial\tau}\right]. \tag{8.18}$$

Then, from (4.11), (8.10), and (8.11), it is found that

$$A + E\sum_{j=1}^{J}\alpha_j d_j^3\tau^{d_j} + \frac{\partial D}{\partial\tau} + \frac{\partial D}{\partial v}\sum_{j=1}^{J}\alpha_j d_j^3\tau^{d_j-1} = -H \tag{8.19}$$

and

$$\frac{D(d_J\tau^{d_J}\log\tau + 1 - \tau^{d_J})}{\tau(\tau^{d_J}-1)\log\tau} \tag{8.20}$$

$$+ v\left\{\frac{\partial A}{\partial v} + \frac{\partial E}{\partial v}\sum_{j=1}^{J}\alpha_j d_j^3\tau^{d_j} + E\left[1 - \frac{d_J\tau^{d_J}}{(\tau^{d_J}-1)}\right]\right\} = H.$$

Finally, from (4.13), (8.9), (8.11), (8.12), (8.14), (8.15), (8.17), (8.19), and (8.20), for $i,k = 1,\ldots,J-1$, we obtain

$$\frac{\partial^2\alpha_J}{\partial\alpha_i\partial\alpha_k} = \left[\frac{1}{v(\tau^{d_J}-1)^3} + O\left(\frac{1}{C}\right)\right]a_i(\tau)a_k(\tau) \tag{8.21}$$

$$- \frac{\tau^2[a_i''(\tau)a_k(\tau) + a_i'(\tau)a_k'(\tau) + a_i(\tau)a_k''(\tau)]}{2Cv^2(\tau^{d_J}-1)^3}$$

$$+ \frac{\tau H}{Cv(\tau^{d_J}-1)}[a_i'(\tau)a_k(\tau) + a_i(\tau)a_k'(\tau)] + O\left(\frac{1}{C^2}\right).$$

We assume now that $J \geq 3$. From (2.13) and (8.8), it is found that

$$\tau[a_i'(\tau)a_k(\tau) - a_i(\tau)a_k'(\tau)] = \tau^{d_J+d_i+d_k}(\tau^{d_J}-1)m_{ik}(\tau), \tag{8.22}$$

where

$$m_{ik}(t) = d_i d_k (d_i - d_k)\left(1 - \frac{1}{t^{d_J}}\right) + d_J d_i (d_J - d_i)\left(1 - \frac{1}{t^{d_k}}\right) - d_J d_k (d_J - d_k)\left(1 - \frac{1}{t^{d_i}}\right). \tag{8.23}$$

Hence,

$$t^{d_J+1} m'_{ik}(t) = d_J d_i d_k n_{ik}(t), \tag{8.24}$$

where

$$n_{ik}(t) = d_i - d_k + (d_J - d_i)t^{d_J - d_k} + (d_k - d_J)t^{d_J - d_i}. \tag{8.25}$$

Thus,

$$t n'_{ik}(t) = (d_J - d_i)(d_J - d_k)t^{d_J}\left(\frac{1}{t^{d_k}} - \frac{1}{t^{d_i}}\right). \tag{8.26}$$

Since d_j, $j = 1, \ldots, J$, are distinct, it follows, for $i \neq k$, $i, k = 1, \ldots, J-1$, and for $t > 1$, that $n'_{ik}(t) \neq 0$, which implies $n_{ik}(t) \neq 0$, since $n_{ik}(1) = 0$, i.e., $m'_{ik}(t) \neq 0$, which implies $m_{ik}(t) \neq 0$, since $m_{ik}(1) = 0$.

In particular, since $\tau > 1$, $m_{J-2,J-1}(\tau) \neq 0$. It follows from (8.22) that the linear transformation of variables (2.14), (2.15), (3.17), and (3.18) is nonsingular. We recall that, for $n \geq 2$, the leading term in (4.16) contains the factor ξ_{J-1}^2. Then, if we use the Taylor series expansion (4.17), and let $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$, we obtain (3.19) from (8.21), where v_0 is given by (2.18) and $\tau_0 > 1$ is the solution of (2.11) corresponding to $\alpha_j = \alpha_j^{(0)}$, $j = 1, \ldots, J$. This establishes Proposition 3.3.

9. Check on negative coefficient. As a check on the negative coefficient in (3.19), which pertains to $J \geq 3$, we now consider points on the boundary of the admissible set corresponding to $\tau(\boldsymbol{\alpha}) \equiv \tau(\boldsymbol{\alpha}^{(0)}) = \tau_0$, where $\boldsymbol{\alpha}$ is given by (2.4). From (2.11) and (2.12), in the limit $C \to \infty$, this corresponds to the intersection of two hyperplanes of dimension $J-1$, i.e., to a hyperplane of dimension $J-2$, and hence $\xi_J = 0$. For $C \gg 1$, from (2.11)–(2.13), with $\tau = \tau_0$, if we eliminate α_J to lowest order, we obtain

$$\sum_{i=1}^{J-1} a_i(\tau_0)\alpha_i = d_J \tau_0^{d_J} \log \tau_0 + 1 - \tau_0^{d_J} - \omega d_J \tau_0^{d_J} + O\left(\frac{1}{C}\right). \tag{9.1}$$

Also, from (8.8), we have

$$\left(\tau_0^{d_J} - 1\right)\sum_{j=1}^{J} d_j^2 \tau_0^{d_j}\alpha_j + \tau_0 \sum_{i=1}^{J-1} a'_i(\tau_0)\alpha_i = d_J^2 \tau_0^{d_J}\sum_{j=1}^{J}(\tau_0^{d_j} - 1)\alpha_j. \tag{9.2}$$

We now let $\alpha_i - \alpha_i^{(0)} = O(\epsilon)$, $0 < \epsilon \ll 1$, $i = 1, \ldots, J-1$. Then, from (2.4), $\alpha_J - \alpha_J^{(0)} = O(\epsilon)$. Hence, from (8.5), with $\tau = \tau_0$,

$$\sum_{j=1}^{J}(\tau_0^{d_j} - 1)(\alpha_j - \alpha_j^{(0)}) = \frac{1}{2C}\log\left(\frac{v}{v_0}\right) + O\left(\frac{\epsilon}{C^2}\right), \tag{9.3}$$

where, from (4.11),

$$v = \sum_{j=1}^{J} d_j^2 \tau_0^{d_j} \alpha_j \tag{9.4}$$

and v_0 is given by (2.18). It follows, from (3.17) and (9.2)–(9.4), that

$$v - v_0 = -\frac{\tau_0 \xi_{J-2}}{(\tau_0^{d_J} - 1)} + O\left(\frac{\epsilon}{C}\right). \tag{9.5}$$

From (2.14), (2.15), (3.17), (8.12), and (9.3), we obtain

$$\xi_J = \frac{1}{2C} \log\left(\frac{v}{v_0}\right) + \frac{(\tau_0^{d_J} - 1)}{C} \left[\left(A_0 + E_0 \sum_{j=1}^{J} d_j^3 \tau_0^{d_j} \alpha_j^{(0)}\right) \xi_{J-1} + D_0 \xi_{J-2}\right] + O\left(\frac{\epsilon}{C^2}\right). \tag{9.6}$$

However, from (9.5),

$$\log\left(\frac{v}{v_0}\right) = -\frac{\tau_0 \xi_{J-2}}{v_0(\tau_0^{d_J} - 1)} - \frac{\tau_0^2 \xi_{J-2}^2}{2v_0^2(\tau_0^{d_J} - 1)^2} + O\left(\frac{\epsilon}{C}\right). \tag{9.7}$$

Also, from (2.15) and (9.1), $\xi_{J-1} = O(\epsilon/C)$. Hence, from (8.11), (9.6), and (9.7),

$$\xi_J = -\frac{\tau_0^2 \xi_{J-2}^2}{4Cv_0^2(\tau_0^{d_J} - 1)^2} + O\left(\frac{\epsilon^2}{C^2}\right), \tag{9.8}$$

since, from (2.14) and (4.17), the error term contains the factor ϵ^2. This establishes the correctness of the negative coefficient in (3.19).

Appendix A. It was shown [15] that the blocking probabilities are given by

$$L_j = 1 - \frac{G(C - d_j)}{G(C)}, \tag{A.1}$$

where, for integer values of n,

$$G(C - n) = \frac{1}{2\pi i} \int_{|z|<1} k_n(z) e^{Cf(z)} dz, \tag{A.2}$$

with $f(z)$ as in (4.3),

$$k_n(z) = \frac{z^{n-1}}{(1 - z)}, \tag{A.3}$$

and the integral is taken in a counterclockwise direction around a circle of radius less than 1. Moreover, asymptotically, since $0 < z^* < 1$ in the case under consideration,

$$G(C - n) = \frac{e^{Cf(z^*)}}{2\sqrt{\pi C}} \cdot \left\{\beta_1 k_n(z^*) + \frac{1}{2C}\left[3\beta_3 k_n(z^*) + 3\beta_1\beta_2 k_n'(z^*) - \frac{1}{2}\beta_1^3 k_n''(z^*)\right] + O\left(\frac{1}{C^2}\right)\right\}, \tag{A.4}$$

where

$$\frac{\beta_1}{z^*} = \frac{\sqrt{2}}{\sqrt{v(z^*)}}, \qquad \frac{\beta_2}{z^*} = \frac{t(z^*)}{3[v(z^*)]^2}, \tag{A.5}$$

and z^*, $v(z^*)$, and $t(z^*)$ are given by (4.2), (4.4), and (5.3).

The definition of β_3 is not needed here since, from (A.3) and (A.4),

$$\frac{G(C-n)}{G(C)} = (z^*)^n \left\{1 + \frac{1}{2C}\left(3\beta_2\left[\frac{k_n'(z^*)}{k_n(z^*)} - \frac{k_0'(z^*)}{k_0(z^*)}\right] - \frac{1}{2}\beta_1^2\left[\frac{k_n''(z^*)}{k_n(z^*)} - \frac{k_0''(z^*)}{k_0(z^*)}\right]\right) + O\left(\frac{1}{C^2}\right)\right\}. \tag{A.6}$$

However, from (A.3),

$$\log k_n(z) = (n-1)\log z - \log(1-z), \tag{A.7}$$

and it follows that

$$\begin{aligned} \frac{k_n'(z)}{k_n(z)} &= \frac{1}{(1-z)} + \frac{(n-1)}{z}, \\ \frac{k_n''(z)}{k_n(z)} &= \frac{2}{(1-z)^2} + \frac{2(n-1)}{z(1-z)} + \frac{(n-1)(n-2)}{z^2}. \end{aligned} \tag{A.8}$$

Hence,

$$\frac{k_n'(z)}{k_n(z)} - \frac{k_0'(z)}{k_0(z)} = \frac{n}{z}, \qquad \frac{k_n''(z)}{k_n(z)} - \frac{k_0''(z)}{k_0(z)} = \frac{2n}{z(1-z)} + \frac{n(n-3)}{z^2}. \tag{A.9}$$

Then, from (A.5) and (A.6), we obtain

$$\frac{G(C-n)}{G(C)} = (z^*)^n \left\{1 - \frac{n}{2Cv(z^*)}\left[n - 5 + \frac{2}{(1-z^*)} - \frac{t(z^*)}{v(z^*)}\right] + O\left(\frac{1}{C^2}\right)\right\}. \tag{A.10}$$

The expression for L_j in (5.4) follows from (A.1).

Appendix B. We show here that $P_2(\theta) > 0$ for $\theta > 0$, where $P_2(\theta)$ is given by (6.18). From (6.11), we have

$$\theta\phi[\chi(\theta)] = \kappa, \tag{B.1}$$

where $\phi(y)$ is given by (6.10). We recall that $\phi'(y) > 0$ for $-\infty < y < \infty$, so that $\phi(y)$ has a unique inverse. Since $\phi(-\infty) = 0$ and $\phi(\infty) = \infty$, it follows that $-\infty < \chi < \infty$ for $\theta > 0$. From (B.1), we obtain

$$\theta\chi'(\theta) = -\frac{\phi(\chi)}{\phi'(\chi)}, \qquad \theta\chi'(\theta) + \theta^2\chi''(\theta) = \frac{\phi(\chi)}{\phi'(\chi)}\left\{1 - \frac{\phi(\chi)\phi''(\chi)}{[\phi'(\chi)]^2}\right\}. \tag{B.2}$$

Hence,

$$\chi(\theta) - \theta\chi'(\theta) - \theta^2\chi''(\theta) = \frac{K(\chi)}{[\phi'(\chi)]^3}, \tag{B.3}$$

where

$$K(\chi) = \chi[\phi'(\chi)]^3 - \phi(\chi)[\phi'(\chi)]^2 + [\phi(\chi)]^2\phi''(\chi). \tag{B.4}$$

From (6.18), since $\phi'(\chi) > 0$, it suffices to show that $K(\chi) > 0$ for $-\infty < \chi < \infty$.

Now,

$$K'(\chi) = 3\chi[\phi'(\chi)]^2\phi''(\chi) + [\phi(\chi)]^2\phi'''(\chi). \tag{B.5}$$

However, from (6.10),

$$\phi'(\chi) = 2\int_0^\infty ue^{2\chi u}e^{-u^2}du > 0, \tag{B.6}$$

$$\phi''(\chi) = 4\int_0^\infty u^2e^{2\chi u}e^{-u^2}du > 0, \tag{B.7}$$

and

$$\phi'''(\chi) = 8\int_0^\infty u^3e^{2\chi u}e^{-u^2}du > 0. \tag{B.8}$$

Hence, $K'(\chi) > 0$ for $0 \le \chi < \infty$. However (see [9]), from (6.10), $\phi(0) = \sqrt{\pi}/2$, $\phi'(0) = 1$, and $\phi''(0) = \sqrt{\pi}$, so that $K(0) > 0$. It follows that $K(\chi) > 0$ for $0 \le \chi < \infty$.

We now consider $-\infty < \chi < 0$. If we integrate by parts in (B.6), we obtain

$$\phi'(\chi) = 1 + 2\chi\phi(\chi). \tag{B.9}$$

Hence,

$$\phi''(\chi) = 2[\phi(\chi) + \chi\phi'(\chi)] = 2[\chi + (2\chi^2 + 1)\phi(\chi)]. \tag{B.10}$$

However, from (6.10),

$$\phi(\chi) = e^{\chi^2}I(\chi), \qquad I(\chi) = \int_{-\chi}^\infty e^{-\xi^2}d\xi. \tag{B.11}$$

It follows, from (B.4) and (B.9)–(B.11), that

$$H(\chi) \triangleq e^{-3\chi^2}K(\chi) \tag{B.12}$$

$$= (8\chi^4 + 2)I^3 + (12\chi^3 - 2\chi)e^{-\chi^2}I^2 + (6\chi^2 - 1)e^{-2\chi^2}I + \chi e^{-3\chi^2}.$$

Since $I'(\chi) = \exp(-\chi^2)$, we obtain

$$H'(\chi) = -4\chi^3 I\, M(\chi), \tag{B.13}$$

where

$$M(\chi) = -8I^2 - \left(\frac{10}{\chi} + \frac{1}{\chi^3}\right)e^{-\chi^2}I - \frac{3}{\chi^2}e^{-2\chi^2}. \tag{B.14}$$

Next, we find that

$$M'(\chi) = \left(4 + \frac{12}{\chi^2} + \frac{3}{\chi^4}\right)e^{-\chi^2}N(\chi), \tag{B.15}$$

where

$$N(\chi) = I + \frac{(5\chi + 2\chi^3)}{(3 + 12\chi^2 + 4\chi^4)} e^{-\chi^2}. \tag{B.16}$$

Hence,

$$e^{\chi^2} N'(\chi) = 1 + \frac{(5 - 4\chi^2 - 4\chi^4)}{(3 + 12\chi^2 + 4\chi^4)} - \frac{8\chi^2(3 + 2\chi^2)(5 + 2\chi^2)}{(3 + 12\chi^2 + 4\chi^4)^2}. \tag{B.17}$$

After some algebraic simplification, we obtain

$$N'(\chi) = \frac{24 e^{-\chi^2}}{(3 + 12\chi^2 + 4\chi^4)^2} > 0. \tag{B.18}$$

Now, from (B.11), $I(-\infty) = 0$ and hence, from (B.16), $N(-\infty) = 0$. It follows, from (B.18), that $N(\chi) > 0$ for $\chi > -\infty$. Hence, from (B.15), $M'(\chi) > 0$ for $-\infty < \chi < 0$. Since $M(-\infty) = 0$, from (B.14), it follows that $M(\chi) > 0$ for $-\infty < \chi < 0$, and hence, from (B.13), that $H'(\chi) > 0$ for $-\infty < \chi < 0$. However, from (B.11), $I(\chi)$ is exponentially small for $-\chi \gg 1$. It follows, from (B.12), that $H(\chi) > 0$, and hence $K(\chi) > 0$ for $-\infty < \chi < 0$. This completes the proof.

Acknowledgments. The authors are grateful to the referees for their helpful suggestions for improving the presentation.

A MEMBRANE IN ADHESIVE CONTACT*

KEVIN T. ANDREWS†, L. CHAPMAN†, J. R. FERNÁNDEZ‡, M. FISACKERLY†, M. SHILLOR†, L. VANERIAN†, AND T. VANHOUTEN†

Abstract. A model for the process of quasi-static evolution of an elastic membrane in adhesive contact with a rigid obstacle is developed, analyzed, and numerically simulated. The model consists of an elliptic variational inequality for the membrane displacements and a nonlinear ordinary differential equation for the evolution of the adhesion field. By using regularity results from the theory of elliptic variational inequalities and a fixed point argument, the system is shown to have a unique weak solution. A fully discrete algorithm is described and shown to converge, and its error estimates are derived. In this process we make critical use of the regularity properties of the solution. Finally, the results of numerical simulations, based on the fully discrete algorithm, are presented.

Key words. contact, obstacle, membrane, free boundary, adhesion, existence and uniqueness, subdifferential, elliptic variational inequality, error estimates, numerical solutions

1. Introduction.

This work deals with a new version of the classical contact problem between a stretched membrane and a rigid obstacle which lies beneath it. The novelty consists of allowing for adhesion between the membrane and the obstacle. Indeed, we assume that the obstacle, or a part of it, is covered with an adhesive which binds the membrane. As a result of the forces acting in the system, its state evolves in time; in particular, the bonds may break and consequently the bonding may deteriorate. The adhesion process is modeled by the introduction of the bonding field which measures the fractional density of the active bonds. Assuming a quasi-static process, the model consists of an elliptic variational inequality for the displacements coupled with a nonlinear ordinary differential equation for the bonding field. The problem is a free boundary problem, since the contact zone is unknown, and its determination is a part of the solution.

Adhesion processes are of considerable interest in industry because nonmetallic parts and components cannot be joined by welding and an adhesive needs to be utilized. The modeling and simulation of an adhesive contact problem applied to laminate materials, as well as further examples of industrial applications, can be found in [18].

Existence, uniqueness, and other results related to the classical contact problem for the membrane can be found in [6, 16, 19, 21] and references therein. Models for adhesive contact problems are very recent and can be found in [8, 5, 7, 9, 10, 12, 13, 15, 17, 18, 20] and references therein. The existence of a weak solution for the problem of dynamic contact of a membrane has been established in [1].

Following this introduction the rest of the paper is organized as follows. The model is described in section 2 and involves, in addition to the displacement field, the bonding field β, which measures the fractional density of the adhesive. In section 3 the

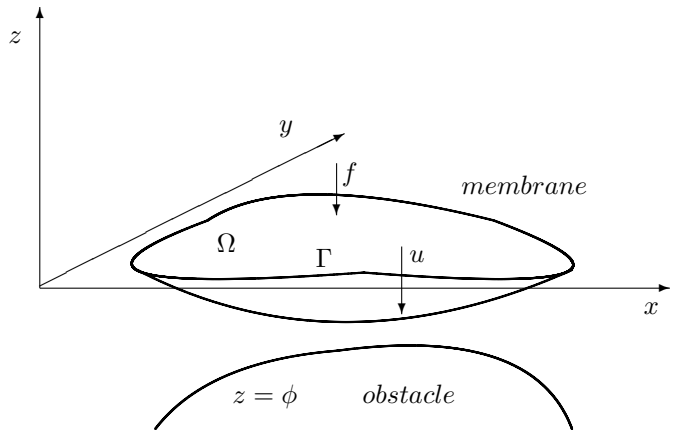

FIG. 1. *The membrane above the obstacle.*

model is set as an elliptic variational inequality for the displacements coupled with an ordinary differential equation for the bonding field β. Using regularity results from the theory of elliptic variational inequalities and a fixed point argument, we prove the existence of a unique weak solution for the problem in section 4. A fully discrete scheme for numerical simulations of the problem is developed in section 5, where it is shown to converge. This work uses the regularity properties of the solution. Also, an error estimate on the approximate numerical solutions is obtained. Then, in section 6, we present numerical simulations obtained by using a computer code based on the fully explicit scheme. We conclude the paper in section 7.

2. The model. We construct a model for the quasi-static process of adhesive contact between a membrane and a rigid obstacle which lies below it. The membrane is attached to a rigid rim, its displacements are restricted to lying on or above the rigid obstacle, and the membrane is in adhesive contact with the obstacle.

Let Ω denote the projection of the membrane on the xy plane, let $\Gamma = \partial\Omega$ be its boundary, let $z = \phi(x, y)$ represent the location of the rigid obstacle, and let $\Omega_T = \Omega \times (0, T)$. We assume that the membrane is being acted upon by an external vertical force f and that contact between the membrane and the obstacle involves adhesion. The setting is depicted in Figure 1.

We let $u = u(x, y, t)$ represent the vertical displacement of the membrane at location (x, y) and time t and take the upward direction as positive. We denote by $\xi(x, y, t)$ the reaction force of the obstacle, which is also positive when directed upward, and let $\eta(x, y, t)$ represent the tensile adhesive force, which will be described shortly.

The process is assumed to be quasi-static, so we neglect the inertial term in the equation of motion. Thus, the evolution of the state of the membrane is governed by

$$-\alpha\Delta u = f + \xi + \eta \quad \text{in } \Omega_T. \tag{2.1}$$

Here $\alpha = \hat{T}/\rho$, where $\hat{T}$ is the tension in the membrane and ρ is its surface density, both assumed to be positive constants.

Since the membrane is restricted to always lie above the obstacle ϕ, we have

$$u \geq \phi \quad \text{in } \Omega_T. \tag{2.2}$$

When contact between the membrane and the obstacle takes place, the obstacle's reaction force ξ is directed upward and exactly cancels the applied force, and so

$$u = \phi \quad \text{implies} \quad \xi \geq 0 \quad \text{in } \Omega_T. \tag{2.3}$$

When there is no contact the reaction force vanishes; thus $u > \phi$ implies $\xi = 0$. We may combine these three statements into the following linear complementarity condition:

$$\phi \leq u, \quad 0 \leq \xi, \quad \xi(u - \phi) = 0. \tag{2.4}$$

The last condition prevents both inequalities from being strict at the same time, since when contact takes place $\phi = u$ and in the absence of contact $\xi = 0$.

We now describe the adhesion process, which in this work is assumed to be irreversible, i.e., once a bond is severed there is no rebonding (see [9, 10, 18]). Models which allow for rebonding can be found in the recent articles [5, 4, 7, 15]. Let $\beta = \beta(x, y, t)$ denote the *bonding field*, which measures the fractional density of active bonds between the membrane and the obstacle. When $\beta = 1$ the bonding is complete at a point; when $\beta = 0$ there is no bonding, since all the bonds have been broken. Partial bonding at a point occurs when $0 < \beta < 1$. Thus, the bonding field has to satisfy

$$0 \leq \beta \leq 1 \quad \text{in } \Omega_T. \tag{2.5}$$

We assume that the adhesive is spread over the whole of the obstacle. The modifications needed when the adhesive is spread only on a part of the obstacle are straightforward, and we comment on them at the end of section 4.

The adhesive restoring force $\eta = \eta(x, y, t)$ is directed downward, as it acts to prevent the separation of the membrane from the obstacle. It is assumed to be jointly proportional to the distance from the obstacle and to β^2 (cf. [4]); thus,

$$\eta = -\kappa(u - \phi)\beta^2 \quad \text{in } \Omega_T, \tag{2.6}$$

where $\kappa > 0$ is the bonding coefficient or interface stiffness and $\kappa\beta^2$ is the system's "spring constant." We note that (2.2) implies that $\eta \leq 0$ and that when the membrane is in contact with the obstacle there is no adhesive restoring force, i.e., $\eta = 0$.

Following [5, 9, 10], we assume that the process is irreversible and the evolution of the adhesion field is given by

$$\beta' = -\gamma\kappa(u - \phi)^2\beta \quad \text{in } \Omega_T. \tag{2.7}$$

Here $1/\gamma > 0$ is the adhesion rate constant, and here and below we use a prime to denote a partial time derivative. To accompany this equation we must prescribe an initial condition $\beta(x, y, 0) = \beta_0(x, y)$, where β_0 is a given adhesive intensity distribution. We note that both $-\eta$ and $\kappa(u - \phi)^2\beta$ are related to partial derivatives of the free energy; see, e.g., [9, 10]. Indeed, if the surface free energy $\Psi(u, \beta)$ is defined as

$$\Psi(u, \beta) = w(1 - \beta) + \frac{1}{2}\kappa\beta^2(u - \phi)^2$$

[10, p. 154], where w is the Dupré adhesion energy, then (2.6) is obtained as $-\eta = \partial\Psi/\partial u$, where the minus sign reflects the downward direction of the adhesive force. Equation (2.7) follows from $-(1/\gamma)\beta' = \partial\Psi/\partial\beta$, where we omit the constant w for

the sake of simplicity. We turn next to describing the obstacle reaction force ξ. To that end we introduce the indicator function of the interval $(-\infty, 0]$,

$$\chi_{(-\infty,0]}(r) = \begin{cases} 0, & r \le 0, \\ \infty, & r > 0, \end{cases}$$

and its subdifferential,

$$\partial\chi_{(-\infty,0]}(r) = \begin{cases} 0, & r < 0, \\ [0,\infty), & r = 0, \\ \emptyset, & r > 0. \end{cases} \tag{2.8}$$

Using (2.8), we may rewrite the impenetrability condition (2.3) in the form

$$\xi \in \partial\chi_{(-\infty,0]}(\phi - u).$$

Then, using (2.6), equation (2.1) can be written as

$$-\alpha\Delta u - f + \kappa(u-\phi)\beta^2 \in \partial\chi_{(-\infty,0]}(\phi - u). \tag{2.9}$$

To complete the model we specify the displacements $u = g$ on the boundary Γ for $0 \le t \le T$.

Collecting the equations and conditions above, we can give the following formulation of the problem of quasi-static adhesive contact between a membrane and a rigid obstacle.

Problem P. Find a pair of functions $\{u, \beta\}$ such that

$$-\alpha\Delta u - f + \kappa(u-\phi)\beta^2 \in \partial\chi_{(-\infty,0]}(\phi - u) \quad \text{in } \Omega_T, \tag{2.10}$$

$$u \ge \phi \quad \text{in } \Omega_T, \tag{2.11}$$

$$u = g \quad \text{on } \Gamma \times (0,T), \tag{2.12}$$

$$\beta' = -\gamma\kappa(u-\phi)^2\beta \quad \text{in } \Omega_T, \tag{2.13}$$

$$\beta(0) = \beta_0 \quad \text{in } \Omega. \tag{2.14}$$

The classical obstacle problem for the membrane is obtained when $\beta \equiv 0$. Clearly, taking adhesion into account adds an interesting new twist to the problem.

We remark that it is possible to relate the two conditions (2.5) and (2.7) on β to the single inclusion

$$\frac{1}{\gamma}\beta' + \kappa(u-\phi)^2\beta + \partial\chi_{(-\infty,0]}(\beta') + \partial\chi_{[0,1]}(\beta) \ni 0.$$

Here the first subdifferential $\partial\chi_{(-\infty,0]}$ enforces the condition $\beta' \le 0$, and the second $\partial\chi_{[0,1]}$ enforces $0 \le \beta \le 1$. However, the way the problem is set, $\beta' \le 0$ follows anyway, and we do not need to enforce $0 \le \beta \le 1$ separately for the following reasons. When the initial condition for the bonding field satisfies $\beta_0 \le 1$, then it follows from (2.7) that $\beta' \le 0$ and so $\beta \le 1$ in Ω_T. If $\beta = 0$ at a point, then (2.7) implies $\beta' = 0$ there and thus $\beta = 0$ for all subsequent times. Consequently, if we begin with $0 \le \beta_0 \le 1$, then we have $0 \le \beta \le 1$ at all subsequent times. The fact that the adhesion process is irreversible is reflected in (2.7) and thus is responsible for obtaining $0 \le \beta \le 1$ in Ω_T. If we allow for the possibility of rebonding, then we no longer have this implication, and the condition $0 \le \beta \le 1$ has to be enforced separately, as has been done in [1].

The problem, as has been mentioned above, is a free boundary problem. Indeed, if

$$\Lambda(t) = \{(x, y) \in \Omega : u(x, y, t) = \phi(x, y)\}$$

is the contact set, then its boundary $\Gamma^* = \Gamma^*(t) = \partial\Lambda(t)$ is the *free boundary* which separates the contact set from the set where the membrane is above the obstacle. The evolution of this free boundary is an aspect of the problem that is of independent interest and will be addressed in the future.

The steady states of the problem can be obtained by assuming that the forces and the dependent variables are time independent. Let $\overline{f} = \overline{f}(x, y)$, $\overline{u} = \overline{u}(x, y)$, and $\overline{\beta} = \overline{\beta}(x, y)$ be the steady forces, displacements, and bonding field, respectively. It follows from (2.13) that either $\overline{u} = \phi$ or $\overline{\beta} = 0$. We conclude that $\{\overline{u}, \overline{\beta}\}$ satisfies the problem

$$\begin{aligned} -\alpha\Delta\overline{u} - \overline{f} &\in \partial\chi_{(-\infty,0]}(\phi - \overline{u}) \quad \text{in } \Omega, \\ \overline{u} &\geq \phi \quad \text{in } \Omega, \\ \overline{u} &= g \quad \text{on } \Gamma. \end{aligned}$$

This is the classical contact problem for the membrane and it has a unique weak solution $\overline{u}$; see, e.g., [16, 19]. On the other hand, if $\Lambda = \{\overline{u} = \phi\}$ is the contact set, then $\overline{\beta} = 0$ outside of Λ, and on Λ we have $\overline{\beta} = \beta^*$, where β^* is an arbitrary function in $L^\infty(\Lambda)$ such that $0 \leq \beta^* \leq 1$.

It may be of interest to identify those steady state functions $\overline{\beta}$ which are limits, as $t \to \infty$, of solutions of the evolution problem (2.10)–(2.14). This topic is currently open.

Finally, for technical reasons, it is convenient to formulate the problem so that the boundary condition on Γ is homogeneous. For this purpose we assume that $g(t)$ is the restriction to Γ of some function in $H^2(\Omega)$, which we also denote by $g(t)$. Let $w = u - g$, and denote $\tilde{f} = f + \Delta g$. Then the above problem may be formulated as follows.

Problem P. Find a pair of functions $\{w, \beta\}$ such that

$$-\alpha\Delta w - \tilde{f} + \kappa(w + g - \phi)\beta^2 \in \partial\chi_{(-\infty,0]}(\phi - g - w) \quad \text{in } \Omega_T, \tag{2.15}$$

$$w \geq \phi - g \quad \text{in } \Omega_T, \tag{2.16}$$

$$w = 0 \quad \text{on } \Gamma \times (0, T), \tag{2.17}$$

$$\beta' = -\gamma\kappa(w + g - \phi)^2\beta \quad \text{in } \Omega_T, \tag{2.18}$$

$$\beta(0) = \beta_0 \quad \text{in } \Omega. \tag{2.19}$$

In the next section we derive a variational or weak formulation of this problem.

3. Variational formulation. We proceed to obtain a variational formulation of the conditions (2.15)–(2.17). Let

$$V = \{v \in H^1(\Omega) : v = 0 \text{ on } \Gamma\},$$

and let the set of admissible functions be given by

$$K = \{v \in V : v \geq \phi - g(t) \quad \text{in } \Omega\}.$$

We assume that $\phi \leq g(t)$ on Ω, so that $0 \in K \neq \emptyset$. We note that K is a closed convex subset of V.

Next, let $t \in [0,T]$ be fixed, and for the sake of simplicity we write $w(t)$ instead of $w(x,y,t)$. We multiply both sides of (2.15) by $(v - w(t))$, where $v \in K$ is a test function, and integrate over Ω. Using the divergence theorem and the boundary condition (2.17), we have that the left-hand side can be written as

$$\alpha \int_\Omega \nabla w(t) \cdot \nabla (v - w(t))\,\mathrm{d}x + \kappa \int_\Omega (w(t) + g(t) - \phi)\beta^2(t)(v - w(t))\,\mathrm{d}x \\ - \int_\Omega \tilde{f}(v - w(t))\,\mathrm{d}x,$$

where $\tilde{f} = f + \Delta g$. Note that the boundary term vanishes since $v = w = 0$ on Γ. For the right-hand side we have, for any $\xi(t) \in \partial\chi_{(-\infty,0]}(\phi - g(t) - w)$, that

$$\int_\Omega \xi(t)(v - w(t))\,\mathrm{d}x = \int_\Omega \xi(t)(v + g(t) - \phi)\,\mathrm{d}x + \int_\Omega \xi(t)(\phi - g(t) - w(t))\,\mathrm{d}x.$$

The second integral on the right-hand side vanishes by (2.4). In the first integral on the right-hand side we have that $0 \le \xi$ and, since $v \in K$, $0 \le v + g(t) - \phi$; thus the first integral is nonnegative. We conclude that

$$\alpha \int_\Omega \nabla w(t) \cdot \nabla (v - w(t))\,\mathrm{d}x + \kappa \int_\Omega (w(t) + g(t) - \phi)\beta^2(t)(v - w(t))\,\mathrm{d}x \\ \ge \int_\Omega \tilde{f}(v - w(t))\,\mathrm{d}x.$$

This is a variational inequality for $w = w(t)$ for each $0 \le t \le T$.

Finally, we collect all the conditions and obtain the following variational formulation of problem (2.15)–(2.19).

Problem P_V. Find a pair of functions $\{w, \beta\}$ such that

$$w \in L^2(0,T;V), \quad w(t) \in K \ \text{ a.e. in } (0,T), \quad \beta \in W^{1,\infty}(0,T;L^\infty(\Omega)), \tag{3.1}$$

and, for a.e. $t \in (0,T)$ and each $v \in K$,

$$\alpha \int_\Omega \nabla w(t) \cdot \nabla (v - w(t))\,\mathrm{d}x + \kappa \int_\Omega (w(t) + g - \phi)\beta^2(t)(v - w(t))\,\mathrm{d}x \\ \ge \int_\Omega \tilde{f}(v - w(t))\,\mathrm{d}x \tag{3.2}$$

and

$$\beta'(t) = -\gamma\kappa(w(t) + g - \phi)^2\beta(t) \quad \text{a.e. in } \Omega_T, \tag{3.3}$$

$$\beta(0) = \beta_0 \quad \text{a.e. in } \Omega, \ \ t = 0. \tag{3.4}$$

We reformulate (3.2) in operator form by first defining, for each $\beta \in L^\infty(\Omega)$, the bilinear form $a : V \times V \to \mathbb{R}$ given by

$$a(\beta; v, w) = \int_\Omega (\alpha \nabla v \cdot \nabla w + \kappa\beta^2 vw)\,\mathrm{d}x, \qquad v, w \in V,$$

and the force function $F_\beta \in V'$ given by

$$(F_\beta, v) = \int_\Omega (\kappa(\phi - g)\beta^2 + \tilde{f})v\,\mathrm{d}x.$$

Then, Problem P_V can be written as follows: For almost every $t \in [0,T]$, find $w(t) \in K$ such that

$$a(\beta(t); w(t), v - w(t)) \geq (F_\beta(t), v - w(t)) \tag{3.5}$$

for all $v \in K$, together with (3.3) and initial conditions (3.4).

We use this formulation in the next section and in the numerical discretization of the problem.

4. Existence and uniqueness. In this section we establish the solvability of the variational problem (3.1)–(3.4). We assume that the domain Ω is of type $C^{1,1}$ [19, 21] so as to be able to obtain increased regularity of the solution. We make the following specific assumptions on the problem data:

$$g \in W^{1,\infty}(0,T; H^2(\Omega)), \tag{4.1}$$

$$f \in W^{1,\infty}(0,T; L^2(\Omega)), \tag{4.2}$$

$$\gamma = \text{const} > 0, \tag{4.3}$$

$$\phi \in H^2(\overline{\Omega}), \qquad \phi \leq g \text{ on } \overline{\Omega}, \tag{4.4}$$

$$\kappa = \text{const} > 0, \tag{4.5}$$

$$\beta_0 \in L^\infty(\Omega), \qquad 0 \leq \beta_0 \leq 1 \quad \text{a.e. on } \Omega. \tag{4.6}$$

We remark that it is possible to obtain solutions under weaker regularity conditions than those listed above; however, such solutions need not possess the regularity needed for the convergence analysis of section 5. Also, for the sake of simplicity we have chosen γ and κ to be positive constants, but our results hold more generally for the case when $\gamma \in L^\infty(\Omega)$, $\gamma > 0$ a.e. on Ω, $\kappa \in L^\infty(\Omega)$, and $\kappa \geq 0$ a.e. on Ω. We note that (4.4) implies that $0 \in K$.

We have the following existence and uniqueness result.

THEOREM 4.1. *Under the assumptions* (4.1)–(4.6), *there exists a unique weak solution* $\{w, \beta\}$ *of* (3.1)–(3.4) *such that*

$$w \in W^{1,\infty}(0,T; V) \cap L^\infty(0,T; H^2(\Omega)), \quad \beta \in W^{1,\infty}(0,T; L^\infty(\Omega)). \tag{4.7}$$

We note that the free energies associated with adhesion contact problems are nonconvex and consequently the usual convexity arguments that lead to uniqueness of the solution cannot be applied here. The uniqueness here follows from the fixed point argument used in the proof of the theorem.

The proof of the theorem uses a fixed point argument and is divided into several parts. Throughout this section, C will represent a positive generic constant which is independent of t and β but whose value may change from line to line.

We start by defining a convenient inner product on the space V. To this end we observe that there exists a $C > 0$ such that

$$C|v|_{H^1(\Omega)} \leq |\nabla v|_H \qquad \forall v \in V. \tag{4.8}$$

We consider now the inner product on V given by

$$(u, v)_V = (\nabla u, \nabla v)_H \tag{4.9}$$

and let $|\cdot|_V$ be the associated norm. Here and throughout the rest of the paper $H = L^2(\Omega)$. By using (4.8) we find that $|\cdot|_{H^1(\Omega)}$ and $|\cdot|_V$ are equivalent norms on V and, therefore, $(V, (\cdot,\cdot)_V)$ is a real Hilbert space.

We now establish an existence result for fixed β.

LEMMA 4.2. *Let* (4.1)–(4.5) *hold. Given any* $\beta \in C(0,T;H)$ *with* $\beta(x,t) \in [0,1]$, *a.e.* $x \in \Omega$, *for all* $t \in [0,T]$, *there exists a unique* $w = w_\beta \in C(0,T;V)$ *which satisfies* $w(t) \in K$ *and which solves* (3.5) *for all* $t \in [0,T]$. *Moreover,*

$$|w(t)|_{H^2(\Omega)} \le C, \tag{4.10}$$

where C *is independent of* β *and* t. *If, additionally, we have* $\beta \in W^{1,\infty}(0,T;L^\infty(\Omega))$, *then* $w \in W^{1,\infty}(0,T;V)$.

Proof. Using (4.5) and (4.9), we find that the bilinear symmetric form a satisfies

$$|a(u,v)| \le C|u|_V|v|_V \qquad \forall u,v \in V, \tag{4.11}$$

$$a(v,v) \ge C|v|_V^2 \qquad \forall v \in V, \tag{4.12}$$

and hence a is a continuous and coercive form on V.

Since K is a nonempty closed convex set of V, it follows from the projection theorem (see, e.g., [16, 19, 21]) that, for each $t \in [0,T]$, there exists a unique element $w(t) \in K$ which solves (3.5). Choosing $v = 0$ in (3.5) and using (4.12), we obtain that $|w(t)|_V \le C$. Now let $A_\beta : V \to V'$ be defined by $(A_\beta(w), v) = a(\beta; v, w)$. Since the hypotheses on the data imply that $F_\beta \in W^{1,\infty}(0,T;H)$, we have by Proposition 5.2.2 of [19] that

$$|A_\beta(w(t))|_H \le C(|F_\beta(t)|_H + |A_\beta(\phi)|_H) \le C. \tag{4.13}$$

Consequently, standard regularity results [19, 21] in the linear elliptic theory give that $w(t) \in H^2(\Omega)$. More specifically, by Theorem 2.24 of [21] and (4.13) we have that

$$|w(t)|_{H^2(\Omega)} \le C(|A_\beta(w(t))|_H + |w(t)|_V) \le C, \tag{4.14}$$

which gives (4.10). We next show that the function $t \to w(t)$ is continuous. To that end let t_1, $t_2 \in [0,T]$ and, for the sake of simplicity, we let $w(t_i) = w_i$, $\beta(t_i) = \beta_i$, $F_{\beta_i}(t_i) = F_i$ and let a_i denote the bilinear form $a(\beta_i; \cdot, \cdot)$. Using (3.5) twice and algebraic manipulations, we obtain

$$a_1(w_1 - w_2, w_1 - w_2) + \kappa((\beta_1^2 - \beta_2^2)w_2, w_1 - w_2)_H \le (F_1 - F_2, w_1 - w_2)_H. \tag{4.15}$$

Now, from (4.10), (4.12), (4.15), and Cauchy's inequality with ϵ, we find

$$|w_1 - w_2|_V^2 \le C(|F_1 - F_2|_H^2 + |\beta_1 - \beta_2|_H^2). \tag{4.16}$$

Since $\beta \in C(0,T;H)$, we obtain from (4.1), (4.2), (4.4), and (4.16) that $w \in C(0,T;V)$, which concludes the proof of the main statement of the lemma. To obtain the additional regularity result, we introduce, for any nonzero real number h, the difference quotient in t,

$$\delta_h w(t) = (w(t+h) - w(t))/h, \tag{4.17}$$

and then note that (4.16) implies that, for all t satisfying $|h| \le t \le T - |h|$,

$$|\delta_h w(t)|_V^2 \le C(|\delta_h F_\beta(t)|_H^2 + |\delta_h \beta(t)|_H^2). \tag{4.18}$$

Since $\beta' \in L^\infty(0,T;H)$ and $F'_\beta \in L^\infty(0,T;H)$, this implies that $w' \in L^\infty(0,T;V)$, which completes the proof of the lemma. ∎

Let w_β denote the solution in Lemma 4.2 corresponding to β, and consider the initial-value problem

$$\theta' + \gamma\kappa(w_\beta + g - \phi)^2\theta = 0 \quad \text{in} \quad \Omega_T, \tag{4.19}$$

$$\theta(0) = \beta_0 \quad \text{a.e. on } \Omega. \tag{4.20}$$

Under the assumptions on the data given in (4.1)–(4.6), there exists a unique function $\theta = \theta(\beta) \in W^{1,\infty}(0,T;L^\infty(\Omega))$ which solves (4.19)–(4.20). Let Z denote the closed convex subset of $C(0,T;H)$ which is defined by

$$Z = \{\ \beta \in C(0,T;H) :\ \beta(x,t) \in [0,1], \quad \text{a.e. } x \in \Omega, \quad \text{for all } \ t \in [0,T]\ \}. \tag{4.21}$$

We have the following containment result.

LEMMA 4.3. *If $\beta \in Z$, then $\theta(\beta) \in Z$.*

Proof. The result follows from (4.19) and the assumption that $\beta_0(x) \in [0,1]$ for almost every $x \in \Omega$. Indeed, (4.19) implies that for almost every $x \in \Omega$, the function $t \longmapsto \theta(\beta)(x,t)$ is decreasing and hence $\theta(\beta)(x,t) \le 1$ a.e. on Ω_T. Moreover, $\theta'(x,t)$ vanishes when $\theta(\beta)(x,t) = 0$, implying that $\theta(\beta)(x,t) = 0$ a.e. on Ω_T. This completes the proof of the lemma. ∎

To complete the proof of Theorem 4.1, we need only show that the map $\beta \to \theta^n(\beta)$ is a contraction on Z for some n. To that end, suppose that $\beta_i,\ i = 1,2$, are two functions in Z and let $t \in [0,T]$. We need to compare the functions $w_1 = w_{\beta_1}$ and $w_2 = w_{\beta_2}$.

Since $\beta_1,\ \beta_2 \in Z$, we find, by using arguments similar to those used in the proof of (4.16), that

$$|w_1(t) - w_2(t)|_V \le C|\beta_1(t) - \beta_2(t)|_H.$$

This implies, by the continuity of the embedding of V into H, that

$$|w_1(t) - w_2(t)|_H \le C|\beta_1(t) - \beta_2(t)|_H. \tag{4.22}$$

Now (4.19), (4.20), (4.10), and the continuity of the embedding of V into H yield

$$\begin{aligned}
&|\theta(\beta_1)(t) - \theta(\beta_2)(t)|_H \\
&\qquad \le \int_0^t |\gamma\kappa(w_1 + g - \phi)^2(s)\theta(\beta_1)(s) - \gamma\kappa(w_2 + g - \phi)^2(s)\theta(\beta_2)(s)|_H ds \\
&\qquad \le C\int_0^t |w_1(s) - w_2(s)|_H ds + C\int_0^t |\theta(\beta_1)(s) - \theta(\beta_2)(s)|_H ds.
\end{aligned}$$

Using a Gronwall-type inequality, we obtain

$$|\theta(\beta_1)(t) - \theta(\beta_2)(t)|_H \le C\int_0^t |w_1(s) - w_2(s)|_H ds. \tag{4.23}$$

Thus, (4.22) and (4.23) yield

$$|\theta(\beta_1)(t) - \theta(\beta_2)(t)|_H \le C\int_0^t |\beta_1(s) - \beta_2(s)|_H ds. \tag{4.24}$$

Iterating this inequality n times, we deduce

$$|\theta^n(\beta_1) - \theta^n(\beta_2)|_{C(0,T;H)} \le \frac{C^n T^n}{n!} |\beta_1 - \beta_2|_{C(0,T;H)}.$$

Therefore, θ^n is a contraction mapping on Z for any n sufficiently large, and hence θ has a unique fixed point in Z which is the unique solution of Theorem 4.1.

Remark. In the problem above, the adhesive is assumed to cover the whole of the obstacle so that the adhesion field β is defined over all of Ω. If the adhesive does not cover the entire obstacle, but only the portion corresponding to a subset $\Omega^* \subset\subset \Omega$, then we need to introduce the following minor modifications. Equations (2.13) and (2.14) hold in Ω_T^*. On the left-hand side of (2.10) we have to replace the term $\kappa(u-\phi)\beta^2$ with $\kappa(u-\phi)\tilde{\beta}^2$, where $\tilde{\beta}^2$ is equal to β^2 on Ω_T^* and is zero otherwise. In the variational formulation (3.2) the second integral on the left-hand side is over Ω^* instead of Ω, and (3.3) and (3.4) hold in Ω^*. If Ω^* is of class $C^{1,1}$, all the results above hold true for this problem too.

5. Numerical approximations. In this section we consider a fully discrete approximation of Problem P_V. For the sake of simplicity we assume that $g = 0$ and thus $\tilde{f} = f$ and $\phi \leq 0$; otherwise, we need to use $\tilde{f}$ and shift the dependent variable to $w = u - g$, as above. We assume that the membrane $\Omega \subset \mathbb{R}^2$ is a polygonal domain and we define a regular triangulation $\{\mathcal{T}^h\}_{h>0}$ composed of triangles on it, where h is the maximal diameter of these triangles. We define the element spaces

$$V^h = \{v^h \in C(\bar{\Omega});\, v^h_{|\tau} \in P_1(\tau), \quad \tau \in \mathcal{T}^h,\, v^h = 0 \quad \text{on} \quad \Gamma\},$$
$$B^h = \{\gamma^h \in L^\infty(\Omega)\,;\, \gamma^h_{|\tau} \in P_0(\tau), \quad \tau \in \mathcal{T}^h\},$$

where $P_1(\tau)$ denotes the polynomial space in two variables of degree at most one. We will use $V^h \subset V$ and $B^h \subset L^\infty(\Omega)$ to approximate the spaces V and $L^\infty(\Omega)$, respectively.

Next, we define the piecewise averaging operator $P^h : L^1(\Omega) \to B^h$ (see [13]) by

$$P^h u_{|\tau} = \frac{1}{\text{meas}(\tau)} \int_\tau u dx, \qquad \tau \in \mathcal{T}^h, \quad u \in L^1(\Omega).$$

We next select an approximation $U^h \subset V^h$ of the convex set U of admissible displacements, as follows. We denote by ϕ^h the Lagrange interpolation function of the obstacle shape function ϕ, and we assume that $\phi^h \geq \phi$ in Ω. Therefore, one choice of U^h is

$$U^h = \{v^h \in V^h;\, v^h \geq \phi^h \ \text{ in } \ \Omega\},$$

and, thus, the following conformity condition holds true:

$$U^h \subset U. \tag{5.1}$$

We suppose below that (5.1) is satisfied. Finally, to simplify the manipulations and some of the expressions, but without loss of generality, we assume that $\phi = 0$.

To simplify the presentation we redefine the form a as

$$a(v, w) = \alpha \int_\Omega \nabla v \cdot \nabla w \, \mathrm{d}x$$

and the functional j as

$$j(\beta; v, w) = \int_\Omega \kappa \beta^2 v w \, \mathrm{d}x.$$

To discretize the time derivatives, we consider a nonuniform partition of the time interval $[0,T]$, denoted by $0 = t_0 < t_1 < \cdots < t_N = T$. We define $k_n = t_n - t_{n-1}$, $n = 1, \ldots, N$, and let $k = \max_n k_n$ be the largest time step. For a continuous function $w(t)$ we let $w(t_n) = w_n$ and define $\rho = \kappa\gamma$.

A fully discrete approximation of Problem P_V is the following.

Problem PV^{hk}. Find the discrete displacement field $u^{hk} = \{u_n^{hk}\}_{n=0}^N \subset U^h$ and the discrete adhesion field $\beta^{hk} = \{\beta_n^{hk}\}_{n=0}^N \subset B^h$ such that

$$\beta_0^{hk} = \beta_0^h, \tag{5.2}$$

$$a(u_n^{hk}, v^h - u_n^{hk}) + j(\beta_n^{hk}; u_n^{hk}, v^h - u_n^{hk}) \geq (f_n, v^h - u_n^{hk})_H, \quad n = 0, 1, \ldots, N, \tag{5.3}$$

$$\beta_n^{hk} = \beta_{n-1}^{hk} - \rho k_n P^h[(u_{n-1}^{hk})^2](\beta_{n-1}^{hk})_+ \text{ in } \Omega, \quad n = 1, \ldots, N, \tag{5.4}$$

where β_0^h is an approximation of the initial condition β_0.

Here we have used $(\beta_{n-1}^{hk})_+ = \max\{0, \beta_{n-1}^{hk}\}$, which is the positive part of β_{n-1}^{hk}, to ensure that numerically $0 \leq \beta_{n-1}^{hk}$. The inequality $\beta_{n-1}^{hk} \leq 1$ is guaranteed since $\beta_0 \leq 1$, and the second term on the right-hand side is nonpositive.

By using classical results on variational inequalities (see, e. g., [11]), we find that Problem PV^{hk} has a unique solution $(u^{hk}, \beta^{hk}) \subset U^h \times B^h$.

In what follows we denote by c a generic constant that may vary from line to line but in any case depends only on the data and is independent of h or k. Our aim now is to obtain an error estimate for the differences $u_n - u_n^{hk}$ and $\beta_n - \beta_n^{hk}$. To that end we integrate (3.3) between 0 and t_n and obtain

$$\beta_n = \beta_0 - \rho \int_0^{t_n} (u(s))^2 \beta(s)_+ ds, \tag{5.5}$$

and we rewrite (5.4) in the form

$$\beta_n^{hk} = \beta_0^h - \rho \sum_{j=1}^n k_j P^h[(u_{j-1}^{hk})^2](\beta_{j-1}^{hk})_+. \tag{5.6}$$

Subtracting (5.6) from (5.5) and performing some algebraic manipulations, we get

(5.7)

$$|\beta_n - \beta_n^{hk}|_H \leq |\beta_0 - \beta_0^h|_H + c \left(I_n + \sum_{j=1}^n k_j |(I - P^h)[(u_{j-1})^2]|_H + \sum_{j=1}^n k_j |(u_{j-1})^2(\beta_{j-1})_+ - (u_{j-1}^{hk})^2(\beta_{j-1}^{hk})_+|_H \right),$$

where

$$I_n = \left| -\rho \int_0^{t_n} (u(s))^2 \beta_+(s) ds + \rho \sum_{j=1}^n k_j (u_{j-1})^2 (\beta_j)_+ \right|_H$$

is the integration error. Now, since $0 \leq \beta \leq 1$ we obtain

$$\begin{aligned} |(u_{j-1})^2(\beta_{j-1})_+ - (u_{j-1})^2(\beta_{j-1}^{hk})_+|_H & \\ &\leq c(|(u_{j-1})^2 - (u_{j-1}^{hk})^2|_H + |\beta_{j-1} - \beta_{j-1}^{hk}|_H) \\ &\leq c(|u_{j-1} - u_{j-1}^{hk}|_V + |\beta_{j-1} - \beta_{j-1}^{hk}|_H), \end{aligned}$$

and so we obtain

$$|\beta_n - \beta_n^{hk}|_H \le |\beta_0 - \beta_0^h|_H + c\left(I_n + \sum_{j=1}^{n} |(I-P^h)[(u_{j-1}^{hk})^2]|_H + \sum_{j=1}^{n} k_j e_{j-1}\right),$$

where $e_n = |u_n - u_n^{hk}|_V + |\beta_n - \beta_n^{hk}|_H$. Next, we put $v = v^h$ at time $t = t_n$ in (3.2) and subtract (5.3) to obtain

$$\begin{aligned} a(u_n - u_n^{hk}, u_n - u_n^{hk}) + j(\beta_n; u_n, u_n - u_n^{hk}) - j(\beta_n^{hk}; u_n^{hk}, u_n - u_n^{hk}) \\ \le a(u_n, u_n - v^h) + a(u_n - u_n^{hk}, u_n - v^h) + j(\beta_n; u_n, u_n - v^h) \\ - j(\beta_n^{hk}; u_n^{hk}, u_n - v^h) + (f_n, u_n - v^h)_H \quad \forall v^h \in V. \end{aligned}$$

Since

$$\begin{aligned} & j(\beta_n; u_n, u_n - u_n^{hk}) - j(\beta_n^{hk}; u_n^{hk}, u_n - u_n^{hk}) \\ = {} & j(\beta_n; u_n, u_n - u_n^{hk}) - j(\beta_n^{hk}; u_n, u_n - u_n^{hk}) + j(\beta_n^{hk}; u_n - u_n^{hk}, u_n - u_n^{hk}), \end{aligned}$$

after some calculations we obtain

$$|u_n - u_n^{hk}|_V^2 \le c\left(|u_n - v^h|_V + |u_n - u_n^{hk}|_V |u_n - v^h|_V + |\beta_n - \beta_n^{hk}|_H |u_n - u_n^{hk}|_V\right).$$

Using the Cauchy inequality $ab \le \epsilon a^2 + (1/4\epsilon)b^2$ for $a, b, \epsilon \in \mathbb{R},\ \epsilon > 0$, we find that

$$|u_n - u_n^{hk}|_V \le c\left(|u_n - v^h|_V^{1/2} + |u_n - v^h|_V + |\beta_n - \beta_n^{hk}|_H\right). \tag{5.8}$$

Taking into account (5.7) and (5.8), we obtain the error estimate

(5.9)

$$\begin{aligned} |u_n - u_n^{hk}|_V + |\beta_n - \beta_n^{hk}|_H \le c \Bigg(& |u_n - v^h|_V^{1/2} + |u_n - v^h|_V \\ & + I_n + \sum_{j=1}^{n} k_j |(I-P^h)[(u_{j-1})^2]|_H + \sum_{j=1}^{n} k_j e_{j-1} \Bigg). \end{aligned}$$

Proceeding as in [14], we obtain

$$I_n \le ck\left(|u'|_{L^\infty(0,T;H)} + |\beta'|_{L^\infty(0,T;H)}\right). \tag{5.10}$$

Applying a discrete version of the Gronwall inequality, we derive from (5.9) and (5.10) the following result.

THEOREM 5.1. *Let the assumptions of Theorem* 4.1 *hold. Then we have the error estimate*

(5.11)

$$\begin{aligned} \max_{1\le n\le N}\{|u_n - u_n^{hk}|_V + |\beta_n - \beta_n^{hk}|_H\} \le c \Bigg(& \inf_{v^h \in U^h} [|u_n - v^h|_V^{1/2} + |u_n - v^h|_V] \\ & + k\left(|u'|_{L^\infty(0,T;H)} + |\beta'|_{L^\infty(0,T;H)}\right) + \sum_{j=1}^{n} k_j |(I-P^h)[(u_{j-1})^2]|_H \Bigg). \end{aligned}$$

Estimate (5.11) is a basis for the convergence order analysis. Indeed, we have the following result.

COROLLARY 5.2. *Let the assumptions of Theorem* 4.1 *hold. If we assume, in addition, that the initial condition* β_0^h *is chosen so that* $|\beta_0 - \beta_0^h|_H \le ch$ *and that the operator* P^h *satisfies*

$$|(I - P^h)v|_H \le ch \quad \text{for } v \in H^2(\Omega),$$

then

(5.12)

$$\max_{1\le n\le N}\{|u_n - u_n^{hk}|_V + |\beta_n - \beta_n^{hk}|_H\} \le c\Big(h^{1/2}|u|_{L^\infty(0,T;H^2(\Omega))} + k(|u'|_{L^\infty(0,T;H)} + |\beta'|_{L^\infty(0,T;H)})\Big).$$

We remark that it is likely that the error estimate (5.12) holds for solutions of weaker regularity. However, in the present setting we have, as a consequence of (2.1) and the regularity of our solutions, that the reaction force satisfies

$$\xi \in L^\infty(0,T;H). \tag{5.13}$$

Consequently, it follows that

$$|a(u_n, v^h - u_n) + j(\beta_n; , u_n, v^h - u_n) - (f_n, v^h - u_n)_H| \le |\xi|_{L^\infty(0,T;H)}|u_n - v^h|_H.$$

Thus we obtain the following improved error estimate.

THEOREM 5.3. *Let the hypotheses of Corollary* 5.2 *hold. Then*

(5.14)

$$\max_{1\le n\le N}\{|u_n - u_n^{hk}|_V + |\beta_n - \beta_n^{hk}|_H\} \le c\Big(h(|\xi|_{L^\infty(0,T;H)} + |u|_{L^\infty(0,T;H^2(\Omega))}) + k(|u'|_{L^\infty(0,T;H)} + |\beta'|_{L^\infty(0,T;H)})\Big).$$

6. Numerical simulations. In order to verify the performance of the numerical algorithm described in the previous section and to gain insight into the behavior of the solutions, we performed several numerical experiments. In this section, we present three of the results obtained in these numerical simulations. Our main purpose is to show that the algorithm performed well. But also there is some interest in the results, which depict the evolution of the bonding field.

6.1. The numerical scheme. In the numerical simulations presented below, we use the fully discretized scheme PV^{hk} analyzed in the previous section. In all cases, we assume that V^h is composed of continuous and piecewise affine functions and B^h consists of piecewise constant functions. Therefore, Problem PV^{hk} is solved as follows.

Given $\beta_0^{hk} \in B^h$, *find* u_0^{hk} *satisfying*

$$a(u_0^{hk}, v^h - u_0^{hk}) + j(\beta_0^{hk}; u_0^{hk}, v^h - u_0^{hk}) \ge (f_0, v^h - u_0^{hk})_H \quad \forall v^h \in U^h. \tag{6.1}$$

Then, for $n = 1, \dots, N$, *find* (β_n^{hk}, u_n^{hk}) *satisfying*

$$\beta_n^{hk} = \beta_{n-1}^{hk} - \rho k_n P^h[(u_{n-1}^{hk})^2](\beta_{n-1}^{hk})_+ \text{ in } \Omega, \tag{6.2}$$

$$a(u_n^{hk}, v^h - u_n^{hk}) + j(\beta_n^{hk}; u_n^{hk}, v^h - u_n^{hk}) \ge (f_n, v^h - u_n^{hk})_H \quad \forall v^h \in U^h. \tag{6.3}$$

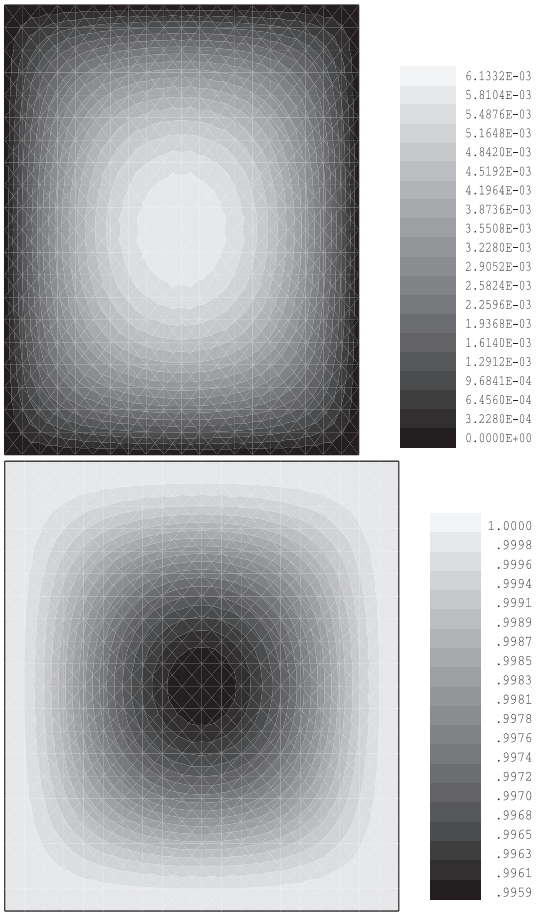

FIG. 2. *Test Problem* 1. *The displacement and adhesion fields at final time.*

The variational inequalities (6.1) and (6.3) have been solved by using a penalty-duality algorithm (see, e.g., [2, 3]). The numerical method was implemented on a IBM RISC6000 computer, and a typical run took about 15 seconds of CPU time.

6.2. Numerical solutions. We present now three test problems for the algorithm. In all examples, we choose $\Omega = (0,1) \times (0,1)$ as the membrane domain and we assume that the displacement field vanishes on $\Gamma = \partial\Omega$. Moreover, in the first two we assume that the obstacle shape function $\phi = 0$, while in the third example it is piecewise linear. We study the evolution of the displacement and adhesion fields during the time period of one second (i.e., $T = 1$ sec).

In the first example, we used the following data:

$$\kappa = 1\,N/m^3, \quad \gamma = 1\,m/N\,sec, \quad \alpha = 1\,N/m,$$
$$f(x,y,t) = 100\,N/m^2, \quad \phi = 0\,m,$$
$$\beta_0 = 1 \quad \text{in} \quad \Omega.$$

In Figure 2 we plot the displacement and the adhesion fields at the final time. The discretization parameter $k = 0.01$ was used.

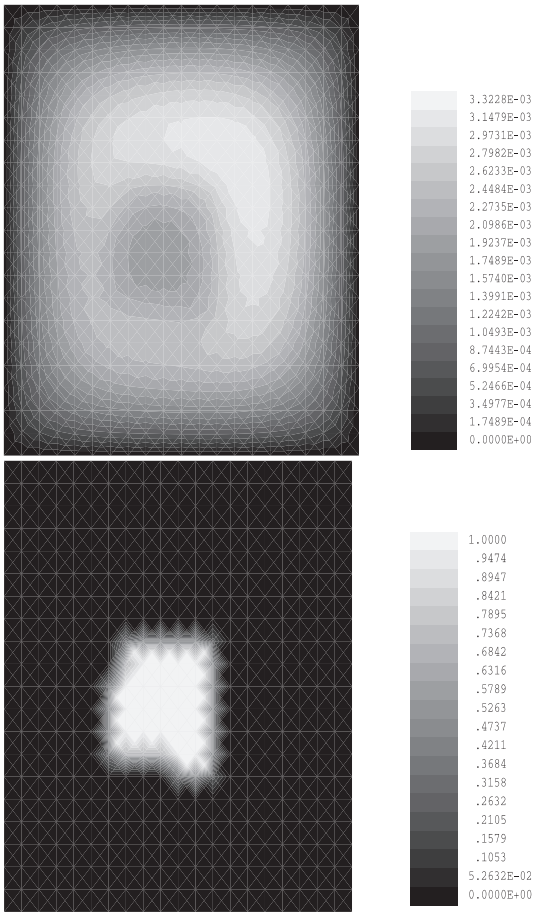

FIG. 3. *Test Problem* 2. *The displacement and adhesion fields at final time.*

In the second example, we used the following numerical data:

$$\kappa = 10^4\, N/m^3, \quad \gamma = 10^{-2}\, m/N\, sec, \quad \alpha = 1\, N/m,$$
$$f(x,y,t) = 100\, N/m^2, \quad \phi = 0\, m,$$
$$\beta_0(x,y,) = \begin{cases} 1 & \text{if} \quad 0.3 \le x \le 0.6,\ 0.3 \le y \le 0.6, \\ 0 & \text{elsewhere.} \end{cases}$$

We note that initially there is glue only on a part of the obstacle, and since the process is irreversible, the rest of the obstacle remains clear of glue.

Figure 3 depicts the displacement and adhesion fields at the final time for the value $k = 0.001$.

Finally, in the third example we used a nonflat obstacle of the form

$$\phi = \phi(x,y) = \begin{cases} 4x - 2 & \text{if } \ 0 \le x \le 0.25, \\ -1 & \text{if } \ 0.25 \le x \le 0.75, \\ 4x - 4 & \text{if } \ 0.75 \le x \le 1. \end{cases}$$

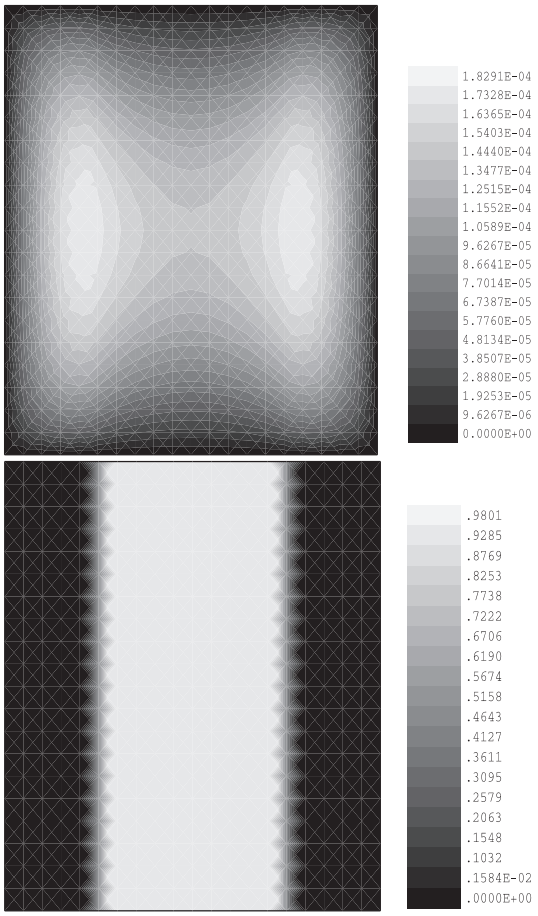

FIG. 4. *Test Problem* 3. *The displacement and adhesion fields for* $f = 10$.

We used the same values of the constants as in the two examples above, but with four different forces $f = 1, 10, 50, 100$ and initial adhesive

$$\beta_0(x, y) = \begin{cases} 1 & \text{if } 0.25 \le x \le 0.75, \\ 0 & \text{elsewhere.} \end{cases}$$

In Figure 4 we show the displacement and adhesion fields at $t = 1$ for $f = 10$.

In Figure 5 we show the displacement and adhesion fields at final time for the four different forces.

The algorithm was found to behave well, and the results are close to what one would expect. These simulations depict the behavior of the solutions. The settings and the conditions were chosen so that the evolution of the bonding field would be clear, and since the model is irreversible, the debonding is monotone.

The algorithm and the code could and will be used for thorough investigations, in conjunction with experimental results in real adhesion problems, for the purpose of parameter identification and model validation. In this way, they can be used to predict the behavior of real systems.

7. Conclusion. A model for the adhesive contact between a membrane and a rigid obstacle has been derived, its variational form obtained, and the existence of the

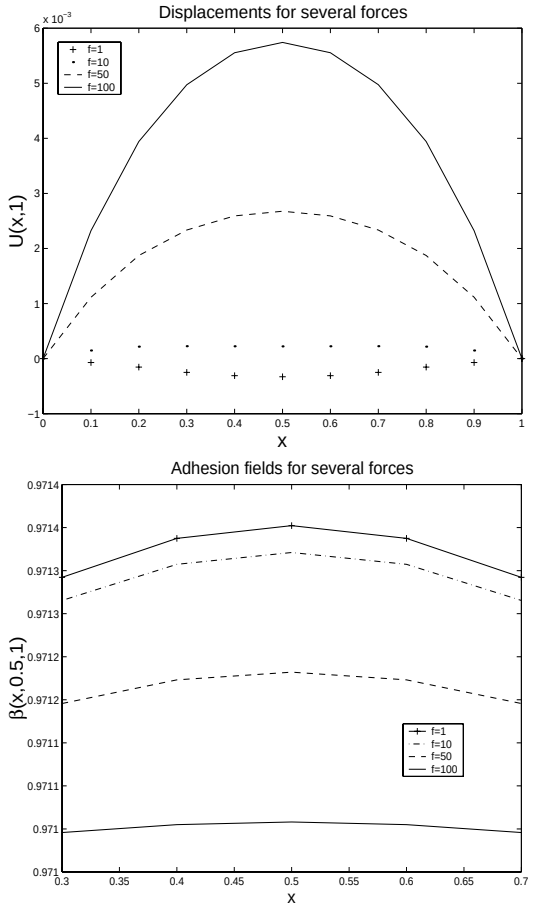

FIG. 5. *Test Problem* 3. *The displacement and adhesion fields for four forces.*

unique weak solution established. The model is in the form of an elliptic variational inequality for the membrane displacements coupled with an ordinary differential equation for the bonding field. The problem is a new and interesting version of the classical contact problem for the membrane and is a free boundary problem as well.

The existence and uniqueness of the weak solution have been proven by using regularity results in the theory of elliptic variational inequalities and a fixed point argument. A fully discrete algorithm for the problem has been derived and its convergence established. Error estimates were obtained together with the convergence order. The algorithm has been implemented and numerical simulations presented.

An open problem warranting further investigation is the evolution of the free boundary. It would be of interest to estimate and simulate the evolution of the contact set and the free boundary Γ^*. Another open question of interest deals with the asymptotic behavior of the solutions. In particular, it would be interesting to characterize the subset of functions in $L^\infty(\Omega)$ that are limits, as $t \to \infty$, of bonding fields β that are solutions to membrane problems.

Finally, the validation of the model by comparison to experimental results, including the recovery of parameters from experimental observations, are obvious applied next steps.

HOMOGENIZATION OF THE MAXWELL EQUATIONS AT FIXED FREQUENCY*

NIKLAS WELLANDER† AND GERHARD KRISTENSSON‡

Abstract. The homogenization of the Maxwell equations at fixed frequency is addressed in this paper. The bulk (homogenized) electric and magnetic properties of a material with a periodic microstructure are found from the solution of a local problem on the unit cell by suitable averages. The material can be anisotropic and satisfies a coercivity condition. The exciting field is generated by an incident field from sources outside the material under investigation. A suitable sesquilinear form is defined for the interior problem, and the exterior Calderón operator is used to solve the exterior radiating fields. The concept of two-scale convergence is employed to solve the homogenization problem. A new a priori estimate is proved as well as a new result on the correctors.

Key words. Maxwell equations, homogenization, heterogeneous materials, periodic microstructure, effective properties, two-scale convergence, corrector results

DOI. 10.1137/S0036139902403366

1. Introduction.

The concept of two-scale convergence is a well-established tool in the theory of homogenization of elliptic equations with rapidly oscillating coefficients; see, e.g., [2, 3, 7, 10, 12, 14, 17, 19, 21, 26, 27, 28]. The results apply to several types of partial differential equations that are used in the engineering sciences, such as heat conduction, elastic deformation, porous media, and acoustics. The situation is, however, different with the Maxwell equations, and the few results that exist adopt boundary conditions that are of less importance in applications. Specifically, the boundary conditions employed in the literature (see, e.g., [4, 6, 15, 18, 20, 26, 27, 28]) are those of perfectly conducting walls. This situation applies to the case of a resonator filled with a heterogeneous material, but for other situations these boundary conditions are less applicable. Moreover, there is a need for a better understanding of how a microscopic structure alters the macroscopic electric and magnetic behavior of the material if the sources of the electromagnetic fields are located outside the heterogeneous material. In fact, most applications in the engineering sciences use external excitations, and to find the homogenized parameters of a heterogeneous material, other boundary conditions, such as the penetrable boundary conditions, must be used.

The engineering literature is dominated by the simple mixture formulae, which are derived using physical arguments. For an excellent overview and history of the mixture formulae, see [22].

The object of this paper is to analyze thoroughly the homogenization of the Maxwell equations for a bounded object with penetrable boundary conditions. This homogenization problem seems not to have been published before in the literature. Moreover, the boundary condition implies that the excitation must be due to external sources. This situation is very important in many engineering applications, such as antenna applications. The two-scale convergence of the Maxwell equations depends on an a priori estimate of the fields. The external sources alter the traditional way of homogenization with two-scale convergence. In fact, in addition to the interior homogenization problem, there is an exterior scattering problem that couples via the boundary conditions to the interior problem. We solve this problem by introducing the Calderón operators, which map the tangential electric field to the tangential magnetic field on the bounding surface. In order to apply the boundary conditions and the Calderón operators, a new a priori estimate has been derived. The paper also includes new results on the correctors.

The paper is organized in the following way. Section 2 contains the prerequisites of the paper. The existence of solutions is proved in section 3, and the homogenization of the Maxwell equations is derived in section 4. We illustrate the exterior Calderón operator with two examples in section 5. The paper is concluded with a series of appendices that contain definitions of function spaces (Appendix A), and some important theorems (Appendix B). In Appendix C, the vector spherical waves used in section 5 are defined.

2. Formulation of the problem.

2.1. Domain and incident fields. Assume Ω is a bounded, open, simply connected set in $\mathbb{R}^3$ with $C^{1,1}$ boundary, $\partial\Omega$. The outward-pointing unit normal is $\hat{\boldsymbol{\nu}}$. The exterior of the volume Ω is denoted $\Omega_e = \mathbb{R}^3 \backslash \overline{\Omega}$, which is assumed vacuous. See Figure 2.1 for a typical geometry.

The incident fields, $\boldsymbol{E}_i$ and $\boldsymbol{H}_i$, are assumed to have their sources outside Ω in a bounded region Ω_i, i.e., $\Omega \cap \Omega_i = \emptyset$. It is assumed to be a fixed field throughout this paper. Outside this region the fields satisfy the time-harmonic Maxwell equations in vacuum time convention $e^{-i\omega t}$, i.e., they satisfy[1]

$$\begin{cases} \nabla \times \boldsymbol{E}_i(\boldsymbol{x}) = ik_0 \boldsymbol{H}_i(\boldsymbol{x}), \\ \nabla \times \boldsymbol{H}_i(\boldsymbol{x}) = -ik_0 \boldsymbol{E}_i(\boldsymbol{x}), \end{cases} \qquad \boldsymbol{x} \in \mathbb{R}^3.$$

The wave number in a vacuum is $k_0 = \omega/c_0$, where ω is the angular frequency of the fields, and c_0 is the speed of light in a vacuum. The incident fields $\boldsymbol{E}_i$ and $\boldsymbol{H}_i$ are assumed to have traces on $\partial\Omega$ belonging to $H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$, i.e., $(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i, \hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i) \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega) \times H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$; see Appendix A for definitions of the function spaces. Otherwise, the incident fields are arbitrary.

2.2. Interior problem. In Ω we assume there is a material modeled by the permittivity dyadic $\epsilon(\boldsymbol{x})$ and the permeability dyadic $\mu(\boldsymbol{x})$. The permittivity dyadic

[1] We use scaled electric and magnetic fields in this paper; i.e., the SI-unit fields $\boldsymbol{E}_{\mathrm{SI}}$ and $\boldsymbol{H}_{\mathrm{SI}}$ are related to the fields $\boldsymbol{E}$ and $\boldsymbol{H}$ used in this paper by

$$\boldsymbol{E}_{\mathrm{SI}}(\boldsymbol{x}) = \frac{\boldsymbol{E}(\boldsymbol{x})}{\sqrt{\epsilon_0}}, \qquad \boldsymbol{H}_{\mathrm{SI}}(\boldsymbol{x}) = \frac{\boldsymbol{H}(\boldsymbol{x})}{\sqrt{\mu_0}},$$

where the permittivity and permeability of vacuum are denoted ϵ_0 and μ_0, respectively.

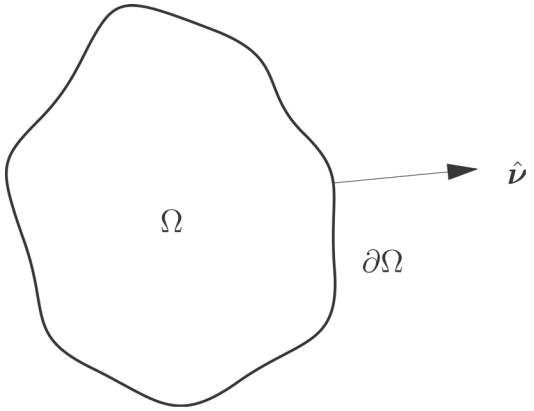

FIG. 2.1. *Typical geometry of the scattering problem in this paper.*

is assumed to satisfy

$$-ik_0\boldsymbol{\xi}\cdot\left(\epsilon(\boldsymbol{x})-\epsilon(\boldsymbol{x})^\dagger\right)\cdot\boldsymbol{\xi}^*\geq C_1|\boldsymbol{\xi}|^2 \qquad \text{for all } \boldsymbol{\xi}\in\mathbb{C}^3 \text{ and a.e. } \boldsymbol{x}\in\Omega \tag{2.1}$$

and

$$|\epsilon(\boldsymbol{x})\cdot\boldsymbol{\xi}|\leq C_2|\boldsymbol{\xi}| \qquad \text{for all } \boldsymbol{\xi}\in\mathbb{C}^3 \text{ and a.e. } \boldsymbol{x}\in\Omega, \tag{2.2}$$

where † denotes the Hermitian of the dyadic ϵ and $C_i>0$, $i=1,2$. The condition in (2.1) corresponds physically to a passive material, i.e., a material that show dissipation. The entries of $\epsilon(\boldsymbol{x})$ are assumed to belong to $L^\infty(\Omega)$, which implies (2.2). Similar assumptions hold for the permeability μ. We note that it follows that ϵ and μ are invertible and that the inverses have the same kind of properties [9, p. 22].

In Ω the electric field $\boldsymbol{E}$ and the magnetic field $\boldsymbol{H}$ satisfy the Maxwell equations

$$\begin{cases}\nabla\times\boldsymbol{E}(\boldsymbol{x})=ik_0\mu(\boldsymbol{x})\cdot\boldsymbol{H}(\boldsymbol{x}),\\ \nabla\times\boldsymbol{H}(\boldsymbol{x})=-ik_0\epsilon(\boldsymbol{x})\cdot\boldsymbol{E}(\boldsymbol{x}),\end{cases} \qquad \boldsymbol{x}\in\Omega. \tag{2.3}$$

We are looking for solutions $\boldsymbol{E}$ and $\boldsymbol{H}$ of these equations in the space $H(\mathrm{rot},\Omega)$. A weak formulation of the solution to this problem is found in section 3.2.1.

2.3. Exterior problem. The presence of the material in the domain Ω distorts the incident fields $\boldsymbol{E}_i$ and $\boldsymbol{H}_i$. This distortion is denoted by the scattered fields, $\boldsymbol{E}_s$ and $\boldsymbol{H}_s$. They belong to $H_{\mathrm{loc}}(\mathrm{rot},\overline{\Omega}_e)$ and satisfy

$$\begin{cases}\nabla\times\boldsymbol{E}_s(\boldsymbol{x})=ik_0\boldsymbol{H}_s(\boldsymbol{x}),\\ \nabla\times\boldsymbol{H}_s(\boldsymbol{x})=-ik_0\boldsymbol{E}_s(\boldsymbol{x}),\end{cases} \qquad \boldsymbol{x}\in\Omega_e. \tag{2.4}$$

Moreover, the scattered fields satisfy the Silver–Müller radiation condition at infinity, i.e., one of the following conditions (see [11]):

$$\begin{cases}\hat{\boldsymbol{x}}\times\boldsymbol{E}_s(\boldsymbol{x})-\boldsymbol{H}_s(\boldsymbol{x})=o(1/x),\\ \hat{\boldsymbol{x}}\times\boldsymbol{H}_s(\boldsymbol{x})+\boldsymbol{E}_s(\boldsymbol{x})=o(1/x)\end{cases} \qquad \text{as } x\to\infty \tag{2.5}$$

uniformly in all directions $\hat{\boldsymbol{x}}$.

In Ω_e the sum of the incident and the scattered fields is defined as the total field, i.e.,

$$\begin{cases} \boldsymbol{E}_t(\boldsymbol{x}) = \boldsymbol{E}_i(\boldsymbol{x}) + \boldsymbol{E}_s(\boldsymbol{x}), \\ \boldsymbol{H}_t(\boldsymbol{x}) = \boldsymbol{H}_i(\boldsymbol{x}) + \boldsymbol{H}_s(\boldsymbol{x}), \end{cases} \qquad \boldsymbol{x} \in \Omega_e.$$

The boundary conditions on $\partial\Omega$ are

$$\begin{cases} \hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i|_{\partial\Omega} + \hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s|_{\partial\Omega} = \hat{\boldsymbol{\nu}} \times \boldsymbol{E}|_{\partial\Omega}\,, \\ \hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i|_{\partial\Omega} + \hat{\boldsymbol{\nu}} \times \boldsymbol{H}_s|_{\partial\Omega} = \hat{\boldsymbol{\nu}} \times \boldsymbol{H}|_{\partial\Omega}\,, \end{cases} \tag{2.6}$$

where the traces of the fields are taken from the outside (inside) in the left-hand (right-hand) side of the equations and belong to $H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$.

2.4. Calderón operators. The Calderón operator C^e utilizes the solution of a specific exterior problem. In fact, the following exterior problem, based upon (2.4) and (2.5) and given $\boldsymbol{m} \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$, is fundamental:

$$\begin{cases} (1) \quad (\boldsymbol{E}_s, \boldsymbol{H}_s) \in H_{\mathrm{loc}}(\mathrm{rot}, \overline{\Omega}_e) \times H_{\mathrm{loc}}(\mathrm{rot}, \overline{\Omega}_e), \\ (2) \quad \begin{cases} \nabla \times \boldsymbol{E}_s(\boldsymbol{x}) = ik_0 \boldsymbol{H}_s(\boldsymbol{x}), \\ \nabla \times \boldsymbol{H}_s(\boldsymbol{x}) = -ik_0 \boldsymbol{E}_s(\boldsymbol{x}), \end{cases} \quad \boldsymbol{x} \in \Omega_e, \\ (3) \quad \begin{cases} \hat{\boldsymbol{x}} \times \boldsymbol{E}_s(\boldsymbol{x}) - \boldsymbol{H}_s(\boldsymbol{x}) = o(1/x) \\ \text{or} \\ \hat{\boldsymbol{x}} \times \boldsymbol{H}_s(\boldsymbol{x}) + \boldsymbol{E}_s(\boldsymbol{x}) = o(1/x) \end{cases} \quad \text{as } x \to \infty, \\ (4) \quad \hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s|_{\partial\Omega} = \boldsymbol{m} \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega). \end{cases} \tag{2.7}$$

(Problem (R))

This problem has a unique solution [4, 9]; see also section 3.1.

We have the following results proved in [9, p. 35].

THEOREM 2.1. *With the boundary $\partial\Omega$ of regularity $C^{1,1}$, the mapping*

$$\boldsymbol{\gamma}_\tau : \boldsymbol{u} \to \hat{\boldsymbol{\nu}} \times \boldsymbol{u}|_{\partial\Omega}$$

is a continuous mapping from $H_{loc}(\mathrm{rot}, \overline{\Omega}_e)$ onto $H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$.

The trace theorem is a local property of the field at the boundary, and the theorem shows that the field loses regularity on the boundary. We note that a similar result holds when the trace is taken from the inside of the boundary; see section 3.2.

The linear mapping of the electric field to the corresponding magnetic field on the boundary for a solution of the exterior problem is called the exterior Calderón operator. The following makes this definition precise.

DEFINITION 2.2. *The exterior Calderón operator C^e is defined as*

$$C^e : \boldsymbol{m} \to \hat{\boldsymbol{\nu}} \times \boldsymbol{H}_s|_{\partial\Omega}\,, \qquad H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega) \to H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega),$$

where $\boldsymbol{m} = \hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s|_{\partial\Omega}$ and the fields $\boldsymbol{E}_s$ and $\boldsymbol{H}_s$ satisfy Problem (R) *in* (2.7).

Notice that the exterior Calderón operator C^e is uniquely defined for all $\boldsymbol{m} \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$, since Problem (R) has a unique solution. Two explicit examples of the exterior Calderón operator are given in section 5.

THEOREM 2.3. *The exterior Calderón operator defined in Definition* 2.2 *has the following properties:*

1. *The exterior Calderón operator satisfies the positivity condition*

$$\Re \iint_{\partial\Omega} C^e(\boldsymbol{m}) \cdot (\hat{\boldsymbol{\nu}} \times \boldsymbol{m}^*)\, dS \geq 0 \qquad \text{for all } \boldsymbol{m} \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega). \tag{2.8}$$

2. *The exterior Calderón operator satisfies*

$$(C^e)^2 = -\mathbf{I} \text{ on } H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega),$$

which implies that C^e is bounded on $H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$.

3. *The exterior Calderón operator is independent of the material properties inside Ω.*

Here dS denotes the surface measure of $\partial\Omega$.

Proof of Theorem 2.3. Property 1 is a simple consequence of the radiation condition and proved in, e.g., [9]. Specifically, the radiation conditions, (2.5), imply

$$\Re \iint_{\partial\Omega} \hat{\boldsymbol{\nu}} \cdot (\boldsymbol{E}_s \times \boldsymbol{H}_s^*)\, dS = \Re \iint_{|\boldsymbol{x}|=R} \hat{\boldsymbol{x}} \cdot (\boldsymbol{E}_s \times \boldsymbol{H}_s^*)\, dS = \iint_{|\boldsymbol{x}|=R} |\boldsymbol{E}_s|^2\, dS + o(1)$$

as $R \to \infty$, which implies (2.8), since $\hat{\boldsymbol{\nu}} \cdot (\boldsymbol{E}_s^* \times \boldsymbol{H}_s) = -C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s) \cdot \boldsymbol{E}_s^*$.

Moreover, to prove property 2 we utilize the symmetry $\{\boldsymbol{E}_s, \boldsymbol{H}_s\} \to \{\boldsymbol{H}_s, -\boldsymbol{E}_s\}$ in (2.4) and the uniqueness of the exterior problem.

Property 3 is a consequence of the uniqueness of the exterior problem. ∎

An immediate consequence of the positivity property of C^e is that

$$-\Re \iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s) \cdot \boldsymbol{E}_s^*\, dS \geq 0 \qquad \text{for all } \hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega). \tag{2.9}$$

3. Existence of solutions. The existence of exterior and interior solutions is addressed in this section.

3.1. Exterior problem. The system (2.4) with the radiation condition (2.5) supplied with the boundary condition

$$\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s|_{\partial\Omega} = \boldsymbol{m} \quad \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega),$$

i.e., Problem (R) in (2.7), has a unique solution in $(\boldsymbol{E}_s, \boldsymbol{H}_s) \in H_{\mathrm{loc}}(\mathrm{rot}, \overline{\Omega}_e) \times H_{\mathrm{loc}}(\mathrm{rot}, \overline{\Omega}_e)$ for any $\boldsymbol{m} \in H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$ [9, p. 107].

3.2. Interior problem. We have the interior trace result, similar to Theorem 2.1.

THEOREM 3.1. *With the boundary $\partial\Omega$ of regularity $C^{1,1}$, the mapping*

$$\boldsymbol{\gamma}_\tau : \boldsymbol{u} \to \hat{\boldsymbol{\nu}} \times \boldsymbol{u}|_{\partial\Omega}$$

is a continuous mapping from $H(\mathrm{rot}, \Omega)$ onto $H^{-\frac{1}{2}}(\mathrm{div}, \partial\Omega)$.

3.2.1. Sesquilinear form and weak solutions. Using Theorem 3.1, we can now define the sesquilinear form (see [9])

$$\begin{aligned} a(\boldsymbol{u}, \boldsymbol{v}) = &- \iiint_\Omega \left\{ \frac{1}{ik_0} (\nabla \times \boldsymbol{v}^*) \cdot \mu^{-1} \cdot (\nabla \times \boldsymbol{u}) + ik_0 \boldsymbol{v}^* \cdot \epsilon \cdot \boldsymbol{u} \right\} dv \\ &- \iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{u}) \cdot \boldsymbol{v}^*\, dS \end{aligned}$$

for $\boldsymbol{u}$ and $\boldsymbol{v}$ in $H(\mathrm{rot}, \Omega)$. We denote the volume measure in $\mathbb{R}^3$ by dv in this paper.

A weak formulation of the original problem is then to find $\boldsymbol{E} \in H(\mathrm{rot}, \Omega)$ such that

$$a(\boldsymbol{E}, \boldsymbol{v}) = \iint_{\partial\Omega} (\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i - C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)) \cdot \boldsymbol{v}^* \, dS \quad \text{for all } \boldsymbol{v} \in H(\mathrm{rot}, \Omega). \tag{3.1}$$

This solution satisfies the boundary conditions, (2.6), and couples to the exterior solution in (2.4)–(2.5). The corresponding magnetic field $\boldsymbol{H}$ is then constructed as[2]

$$\begin{cases} \boldsymbol{H}(\boldsymbol{x}) = -\frac{i}{k_0}\mu^{-1}(\boldsymbol{x}) \cdot (\nabla \times \boldsymbol{E}(\boldsymbol{x})), \\ \nabla \times \boldsymbol{H}(\boldsymbol{x}) = -ik_0\epsilon(\boldsymbol{x}) \cdot \boldsymbol{E}(\boldsymbol{x}), \end{cases} \qquad \boldsymbol{x} \in \Omega.$$

To see this, let $\boldsymbol{E}$ be a sufficiently regular solution to the Maxwell equations, (2.3). Then (3.1) is equivalent to the Maxwell equations with a coupling to an exterior solution since

$$\begin{aligned} a(\boldsymbol{E}, \boldsymbol{v}) &= -\iiint_{\Omega} \{(\nabla \times \boldsymbol{v}^*) \cdot \boldsymbol{H} - \boldsymbol{v}^* \cdot (\nabla \times \boldsymbol{H})\} \, dv - \iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}) \cdot \boldsymbol{v}^* \, dS \\ &= \iint_{\partial\Omega} \{(\hat{\boldsymbol{\nu}} \times \boldsymbol{H}) \cdot \boldsymbol{v}^* - C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}) \cdot \boldsymbol{v}^*\} \, dS, \end{aligned}$$

which is identical to (3.1) by the use of the boundary conditions on $\partial\Omega$ and by the definition

$$\iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_s) \cdot \boldsymbol{v}^* \, dS = \iint_{\partial\Omega} (\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_s) \cdot \boldsymbol{v}^* \, dS.$$

Moreover, the sesquilinear form a is coercive, i.e.,

$$\begin{aligned} \Re a(\boldsymbol{u}, \boldsymbol{u}) = &- \iiint_{\Omega} \frac{1}{ik_0} (\nabla \times \boldsymbol{u}^*) \cdot \left(\mu^{-1} - \mu^{-1^\dagger}\right) \cdot (\nabla \times \boldsymbol{u}) \, dv \\ &- \iiint_{\Omega} ik_0 \boldsymbol{u}^* \cdot \left(\epsilon - \epsilon^\dagger\right) \cdot \boldsymbol{u} \, dv \\ &- \Re \iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{u}) \cdot \boldsymbol{u}^* \, dS \geq C\|\boldsymbol{u}\|^2_{H(\mathrm{rot},\Omega)}, \end{aligned} \tag{3.2}$$

since from (2.1) we get[3]

$$\begin{cases} -ik_0\boldsymbol{\xi} \cdot \left(\epsilon(\boldsymbol{x}) - \epsilon(\boldsymbol{x})^\dagger\right) \cdot \boldsymbol{\xi}^* \geq C_1|\boldsymbol{\xi}|^2, \\ \frac{i}{k_0}\boldsymbol{\xi} \cdot \left(\mu^{-1}(\boldsymbol{x}) - \mu^{-1^\dagger}(\boldsymbol{x})\right) \cdot \boldsymbol{\xi}^* \geq C_2|\boldsymbol{\xi}|^2 \end{cases} \qquad \text{for all } \boldsymbol{\xi} \in \mathbb{C}^3 \text{ and a.e. } \boldsymbol{x} \in \Omega,$$

and we have also used (2.9).

---

[2]This construction is consistent since $-ik_0\epsilon(\boldsymbol{x}) \cdot \boldsymbol{E}(\boldsymbol{x})$ is the weak curl of $\boldsymbol{H}(\boldsymbol{x}) = -\frac{i}{k_0}\mu^{-1}(\boldsymbol{x}) \cdot (\nabla \times \boldsymbol{E}(\boldsymbol{x}))$. In fact, we have

$$(\boldsymbol{H}, \nabla \times \boldsymbol{\phi}) + ik_0 \, (\epsilon \cdot \boldsymbol{E}, \boldsymbol{\phi}) = 0 \qquad \text{for all } \boldsymbol{\phi} \in D(\Omega; \mathbb{C}^3)$$

since $a(\boldsymbol{E}, \boldsymbol{\phi}) = 0$ for all $\boldsymbol{\phi} \in D(\Omega; \mathbb{C}^3)$.

[3]With (2.1) we get

$$\frac{i}{k_0} \, (\mu^t \cdot \boldsymbol{\zeta}) \cdot \left(\mu^{-1} - \mu^{-1^\dagger}\right) \cdot (\mu^t \cdot \boldsymbol{\zeta})^* = \frac{i}{k_0}\boldsymbol{\zeta} \cdot \left(\mu^\dagger - \mu\right) \cdot \boldsymbol{\zeta}^* \geq \frac{C_2}{k_0^2}|\boldsymbol{\zeta}|^2.$$

Applying this result with $\boldsymbol{\zeta} = \mu^{t^{-1}} \cdot \boldsymbol{\xi}$, we get

$$\frac{i}{k_0}\boldsymbol{\xi} \cdot \left(\mu^{-1} - \mu^{-1^\dagger}\right) \cdot \boldsymbol{\xi}^* \geq \frac{C_2}{k_0^2}|\mu^{t^{-1}} \cdot \boldsymbol{\xi}|^2 \geq C|\boldsymbol{\xi}|^2$$

since μ is invertible.

3.2.2. Existence of a unique solution. Equation (3.1) has a unique solution in $H(\mathrm{rot},\Omega)$ due to the Lax–Milgram theorem (see Theorem A.1), since the sesquilinear form $a(\boldsymbol{u},\boldsymbol{v})$ is continuous, bounded, and coercive, and the right-hand side of (3.1) is continuous on $H(\mathrm{rot},\Omega)$. In fact,

$$\begin{aligned}
&\left| \iint_{\partial\Omega} (\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i - C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)) \cdot \boldsymbol{v}^* \, dS \right| \\
&\quad \leq \left(\|\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} + \|C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} \right) \|\boldsymbol{v}\|_{H^{-\frac{1}{2}}(\mathrm{rot},\partial\Omega)} \\
&\quad \leq C' \left(\|\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} + \|(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} \right) \|\boldsymbol{v}\|_{H(\mathrm{rot},\Omega)}
\end{aligned}$$

by Minkowski's inequality, duality [9, p. 38], and the continuous dependence of the trace norm on the norm of the corresponding function space.

4. Homogenization. So far we have considered a general heterogeneous scattering problem with a unique solution in $H(\mathrm{rot},\Omega)$ for a given incident electromagnetic field. But if the heterogeneous material in Ω has a typical spatial scale which is much smaller than the size of the domain, then one runs into severe numerical problems if one tries to apply some standard numerical code, e.g., a finite element method (FEM). The principal obstacle is that the fine scale requires a very fine numerical mesh which generates a far too large linear system of equations for any computer to solve. However, if the wavelength of the incident field is much larger than the fine scale, then the field cannot resolve the fine scale and the solution of the Maxwell equations can be approximated by the solution of a scattering problem with constant coefficients; i.e., the heterogeneous material in Ω has been replaced by a homogeneous material with the same effective material properties. The procedure for finding these effective properties of the heterogeneous material is called homogenization.

4.1. Heterogeneous problem. Let us begin with the definition of a Y-cell which is the open unit cube in $\mathbb{R}^3$, i.e., $Y =]0,1[^3$. Further, from now on we assume that ϵ and μ are Y-periodic, which is defined as $\epsilon(\boldsymbol{x}+\hat{\boldsymbol{e}}_k) = \epsilon(\boldsymbol{x})$ for every $k = 1,2,3$, where $\hat{\boldsymbol{e}}_k$, $k = 1,2,3$, is the canonical basis in $\mathbb{R}^3$.

In the following, we assume that the material in the domain Ω is periodic with period ε in the three Cartesian coordinate directions, i.e., it is the union of a collection of disjoint, open identical cubes[4] with side length ε (Y^ε-cells); see Figure 4.1. It is easily verified that the scaled permeability and permittivity, $\epsilon(\boldsymbol{x}/\varepsilon)$ and $\mu(\boldsymbol{x}/\varepsilon)$, are periodic with period ε.

In Ω the fields satisfy the source-free Maxwell equations[5]

$$\begin{cases}
\nabla \times \boldsymbol{E}^\varepsilon(\boldsymbol{x}) = ik_0 \boldsymbol{B}^\varepsilon(\boldsymbol{x}), \\
\nabla \times \boldsymbol{H}^\varepsilon(\boldsymbol{x}) = -ik_0 \boldsymbol{D}^\varepsilon(\boldsymbol{x}), \\
\nabla \cdot \boldsymbol{B}^\varepsilon(\boldsymbol{x}) = 0, \\
\nabla \cdot \boldsymbol{D}^\varepsilon(\boldsymbol{x}) = 0,
\end{cases} \qquad \boldsymbol{x} \in \Omega,$$

[4]More generally, $Y = (0,a_1) \times (0,a_2) \times (0,a_3)$, where $a_i > 0$, $i = 1,2,3$, and $\epsilon(\boldsymbol{x} + a_k \hat{\boldsymbol{e}}_k) = \epsilon(\boldsymbol{x})$ for every $\boldsymbol{x} \in \mathbb{R}^3$ and for every $k = 1,2,3$. A similar result holds for the permeability μ.

[5]The electric and magnetic fields are scaled as above (see footnote 1), and the SI-unit flux densities $\boldsymbol{D}_{\mathrm{SI}}$ and $\boldsymbol{B}_{\mathrm{SI}}$ are related to the fields $\boldsymbol{D}$ and $\boldsymbol{B}$ used in this paper by

$$\boldsymbol{D}_{\mathrm{SI}}(\boldsymbol{x}) = \sqrt{\epsilon_0}\boldsymbol{D}(\boldsymbol{x}), \qquad \boldsymbol{B}_{\mathrm{SI}}(\boldsymbol{x}) = \sqrt{\mu_0}\boldsymbol{B}(\boldsymbol{x}).$$

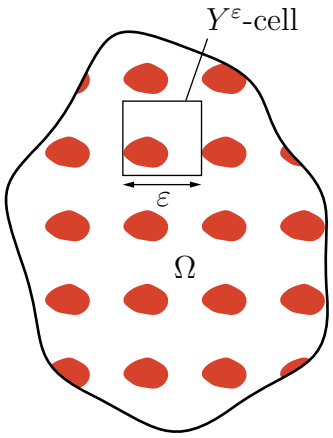

FIG. 4.1. *Typical periodic geometry of the material parameters.*

almost everywhere, with boundary conditions given by (2.6). By using the constitutive relations for the periodic material,

$$\begin{cases} \boldsymbol{D}^\varepsilon(\boldsymbol{x}) = \epsilon(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{E}^\varepsilon(\boldsymbol{x}), \\ \boldsymbol{B}^\varepsilon(\boldsymbol{x}) = \mu(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{H}^\varepsilon(\boldsymbol{x}), \end{cases} \qquad \boldsymbol{x}\in\Omega,$$

we eliminate $\boldsymbol{D}^\varepsilon$, $\boldsymbol{B}^\varepsilon$ and obtain

$$\begin{cases} \nabla\times\boldsymbol{E}^\varepsilon(\boldsymbol{x}) = ik_0\mu(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{H}^\varepsilon(\boldsymbol{x}), \\ \nabla\times\boldsymbol{H}^\varepsilon(\boldsymbol{x}) = -ik_0\epsilon(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{E}^\varepsilon(\boldsymbol{x}), \\ \nabla\cdot\{\epsilon(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{E}^\varepsilon(\boldsymbol{x})\} = 0, \\ \nabla\cdot\{\mu(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{H}^\varepsilon(\boldsymbol{x})\} = 0, \end{cases} \qquad \boldsymbol{x}\in\Omega, \tag{4.1}$$

where the solution $(\boldsymbol{E}^\varepsilon, \boldsymbol{H}^\varepsilon)$ is in $H(\mathrm{rot},\Omega)\times H(\mathrm{rot},\Omega)$ and belongs to a family of solutions, one for each ε. In the homogenization procedure we identify the limit of the fields $\boldsymbol{E}^\varepsilon, \boldsymbol{H}^\varepsilon$ when $\varepsilon\to 0$. This limit satisfies the homogenized system with constant coefficients, which is a model of a homogeneous material.

4.1.1. A priori estimate. We note that the heterogeneous system in (4.1) is of the same form as (2.3) and that the constitutive relations satisfy the same assumptions as in section 2.2. A weak formulation of the two first equations in (4.1) supplied with boundary conditions (2.6) reads

$$a^\varepsilon(\boldsymbol{E}^\varepsilon,\boldsymbol{v}) = \iint_{\partial\Omega} (\hat{\boldsymbol{\nu}}\times\boldsymbol{H}_i - C^e(\hat{\boldsymbol{\nu}}\times\boldsymbol{E}_i))\cdot\boldsymbol{v}^*\,dS \quad \text{for all } \boldsymbol{v}\in H(\mathrm{rot},\Omega), \tag{4.2}$$

where

$$\begin{aligned} a^\varepsilon(\boldsymbol{u},\boldsymbol{v}) = -\iiint_\Omega \Big\{ &\frac{1}{ik_0}(\nabla\times\boldsymbol{v}^*)\cdot\mu^{-1}(\boldsymbol{x}/\varepsilon)\cdot(\nabla\times\boldsymbol{u}) \\ &+ ik_0\boldsymbol{v}^*\cdot\epsilon(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{u}\Big\}\,dv - \iint_{\partial\Omega} C^e(\hat{\boldsymbol{\nu}}\times\boldsymbol{u})\cdot\boldsymbol{v}^*\,dS. \end{aligned} \tag{4.3}$$

We have the following a priori estimate.

THEOREM 4.1. *Let $\boldsymbol{E}^\varepsilon, \boldsymbol{H}^\varepsilon$ be a solution of (4.2); then*

$$\|\boldsymbol{E}^\varepsilon\|_{H(\mathrm{rot},\Omega)} + \|\boldsymbol{H}^\varepsilon\|_{H(\mathrm{rot},\Omega)} \leq C,$$

where the constant C depends only on the domain Ω, the material parameters in Ω, and the strength of the incident field.

Proof of Theorem 4.1. The sesquilinear form $a^\varepsilon(\boldsymbol{u},\boldsymbol{v})$ is coercive (cf. (3.2)), and the weak formulation (4.2) gives

$$\begin{aligned}
C\|\boldsymbol{E}^\varepsilon\|^2_{H(\mathrm{rot},\Omega)} &\leq \Re a^\varepsilon(\boldsymbol{E}^\varepsilon,\boldsymbol{E}^\varepsilon) \leq |a^\varepsilon(\boldsymbol{E}^\varepsilon,\boldsymbol{E}^\varepsilon)| \\
&= \left| \iint_{\partial\Omega} (\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i - C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)) \cdot (\boldsymbol{E}^\varepsilon)^* \, dS \right| \\
&\leq \left(\|\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} + \|C^e(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} \right) \|\boldsymbol{E}^\varepsilon\|_{H^{-\frac{1}{2}}(\mathrm{rot},\partial\Omega)} \\
&\leq C' \left(\|\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} + \|(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} \right) \|\boldsymbol{E}^\varepsilon\|_{H(\mathrm{rot},\Omega)}
\end{aligned}$$

by Minkowski's inequality, duality [9, p. 38], and the continuous dependence of the trace norm on the norm of the corresponding function space. It follows now that

$$\|\boldsymbol{E}^\varepsilon\|_{H(\mathrm{rot},\Omega)} \leq C' \left(\|\hat{\boldsymbol{\nu}} \times \boldsymbol{H}_i\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} + \|(\hat{\boldsymbol{\nu}} \times \boldsymbol{E}_i)\|_{H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)} \right) \leq C$$

by the assumption of the incident field. The bound of $\boldsymbol{E}^\varepsilon$ can now be used in (4.1) to get the estimate of $\boldsymbol{H}^\varepsilon$. ∎

4.2. Homogenized problem.

THEOREM 4.2. *The sequence of solutions $(\boldsymbol{E}^\varepsilon, \boldsymbol{H}^\varepsilon)$ of (4.1) converges weakly in $H(\mathrm{rot},\Omega) \times H(\mathrm{rot},\Omega)$ to $(\boldsymbol{E},\boldsymbol{H}) \in H(\mathrm{rot},\Omega) \times H(\mathrm{rot},\Omega)$, the unique solution of the homogenized Maxwell equations*

$$\begin{cases}
\nabla \times \boldsymbol{E}(\boldsymbol{x}) = ik_0\mu^h \cdot \boldsymbol{H}(\boldsymbol{x}), \\
\nabla \times \boldsymbol{H}(\boldsymbol{x}) = -ik_0\epsilon^h \cdot \boldsymbol{E}(\boldsymbol{x}), \\
\nabla \cdot \boldsymbol{B}(\boldsymbol{x}) = 0, \\
\nabla \cdot \boldsymbol{D}(\boldsymbol{x}) = 0,
\end{cases} \tag{4.4}$$

which is coupled to the exterior problem (2.4)–(2.5) via the boundary conditions (2.6). The homogenized permeability and permittivity ϵ^h and μ^h are defined by

$$\begin{cases}
\epsilon^h = \iiint_Y \epsilon(\boldsymbol{y}) \cdot (\mathbf{I}_3 - \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y})) \, dv_{\boldsymbol{y}}, \\
\mu^h = \iiint_Y \mu(\boldsymbol{y}) \cdot (\mathbf{I}_3 - \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_h(\boldsymbol{y})) \, dv_{\boldsymbol{y}},
\end{cases}$$

$$\boldsymbol{\chi}_e(\boldsymbol{y}) = \sum_{i=1}^3 \chi_e^i(\boldsymbol{y})\hat{\boldsymbol{e}}_i, \qquad \boldsymbol{\chi}_h(\boldsymbol{y}) = \sum_{i=1}^3 \chi_h^i(\boldsymbol{y})\hat{\boldsymbol{e}}_i, \tag{4.5}$$

where $\chi_e^i(\boldsymbol{y})$ and $\chi_h^i(\boldsymbol{y})$, $i = 1,2,3$, in $H^1_\#(Y)/\mathbb{C}$ solve the local elliptic problems

$$\begin{cases}
\iiint_Y \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \left(\hat{\boldsymbol{e}}_i - \nabla_{\boldsymbol{y}} \chi_e^i(\boldsymbol{y}) \right) dv_{\boldsymbol{y}} = 0, \\
\iiint_Y \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \mu(\boldsymbol{y}) \cdot \left(\hat{\boldsymbol{e}}_i - \nabla_{\boldsymbol{y}} \chi_h^i(\boldsymbol{y}) \right) dv_{\boldsymbol{y}} = 0
\end{cases} \tag{4.6}$$

for all $w \in H^1_\#(Y)$.

We note that the weak convergence is sharp in the sense that it never converges strongly in $H(\mathrm{rot},\Omega)$ except in the electrostatic case (see the note after Theorem B.3). However, we can get strong convergence by the use of corrector functions; see section 4.2.2. These functions contain the fine-scale information in the problem and yield strong convergence when scaled and added to the homogenized solution.

Proof of Theorem 4.2. We use the concept of two-scale convergence; see Appendix B. Due to the a priori estimates there exists a subsequence which converges in the two-scale sense. We will keep the index ε for this subsequence. In the end we conclude that the whole original sequence converges due to the fact that the homogenized system has a unique solution. Let $\boldsymbol{\phi}(\boldsymbol{x}) = \varepsilon w(\boldsymbol{x}/\varepsilon)\boldsymbol{v}(\boldsymbol{x})$, where $w \in H^1_{\#}(Y)$ and $\boldsymbol{v} \in C_0^\infty(\Omega;\mathbb{C}^3)$. Then $\boldsymbol{\phi} \in H(\mathrm{rot},\Omega)$ and is an admissible test function. We get in (4.1)

$$\begin{cases} \displaystyle\iiint_\Omega \boldsymbol{E}^\varepsilon(\boldsymbol{x})\cdot\{\varepsilon w(\boldsymbol{x}/\varepsilon)\nabla_{\boldsymbol{x}}\times\boldsymbol{v}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}} w(\boldsymbol{x}/\varepsilon)\times\boldsymbol{v}(\boldsymbol{x})\}\,dv \\ \qquad\qquad - ik_0\displaystyle\iiint_\Omega \varepsilon w(\boldsymbol{x}/\varepsilon)\boldsymbol{v}(\boldsymbol{x})\cdot\{\mu(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{H}^\varepsilon(\boldsymbol{x})\}\,dv = 0, \\ \displaystyle\iiint_\Omega \boldsymbol{H}^\varepsilon(\boldsymbol{x})\cdot\{\varepsilon w(\boldsymbol{x}/\varepsilon)\nabla_{\boldsymbol{x}}\times\boldsymbol{v}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}} w(\boldsymbol{x}/\varepsilon)\times\boldsymbol{v}(\boldsymbol{x})\}\,dv \\ \qquad\qquad + ik_0\displaystyle\iiint_\Omega \varepsilon w(\boldsymbol{x}/\varepsilon)\boldsymbol{v}(\boldsymbol{x})\cdot\{\epsilon(\boldsymbol{x}/\varepsilon)\cdot\boldsymbol{E}^\varepsilon(\boldsymbol{x})\}\,dv = 0. \end{cases}$$

In the limit $\varepsilon \searrow 0$ we get

$$\begin{cases} \displaystyle\iiint_\Omega \boldsymbol{E}^\varepsilon(\boldsymbol{x})\cdot(\nabla_{\boldsymbol{y}} w(\boldsymbol{x}/\varepsilon)\times\boldsymbol{v}(\boldsymbol{x}))\,dv \to 0, \\ \displaystyle\iiint_\Omega \boldsymbol{H}^\varepsilon(\boldsymbol{x})\cdot(\nabla_{\boldsymbol{y}} w(\boldsymbol{x}/\varepsilon)\times\boldsymbol{v}(\boldsymbol{x}))\,dv \to 0, \end{cases}$$

since $\boldsymbol{E}^\varepsilon$ and $\boldsymbol{H}^\varepsilon$ are uniformly bounded in ε in the $L^2(\Omega;\mathbb{C}^3)$-norm. By the use of Theorem B.6, we get

$$\begin{cases} \displaystyle\iiint_\Omega\iiint_Y \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})\cdot(\nabla_{\boldsymbol{y}} w(\boldsymbol{y})\times\boldsymbol{v}(\boldsymbol{x}))\,dv_{\boldsymbol{y}}\,dv_{\boldsymbol{x}} = 0, \\ \displaystyle\iiint_\Omega\iiint_Y \boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y})\cdot(\nabla_{\boldsymbol{y}} w(\boldsymbol{y})\times\boldsymbol{v}(\boldsymbol{x}))\,dv_{\boldsymbol{y}}\,dv_{\boldsymbol{x}} = 0, \end{cases}$$

which implies after cyclic permutation that

$$\begin{cases} \displaystyle\iiint_Y \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})\times\nabla_{\boldsymbol{y}} w(\boldsymbol{y})\,dv_{\boldsymbol{y}} = \boldsymbol{0}, \\ \displaystyle\iiint_Y \boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y})\times\nabla_{\boldsymbol{y}} w(\boldsymbol{y})\,dv_{\boldsymbol{y}} = \boldsymbol{0}, \end{cases} \qquad \boldsymbol{x}\in\Omega \text{ a.e.}$$

for all $w \in H^1_{\#}(Y)$. The functions $\boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})$ and $\boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y})$ both belong to the space $L^2(\Omega;L^2_{\#}(Y;\mathbb{C}^3))$. From Lemma B.5 we conclude that the fields $\boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})$ and $\boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y})$ can be decomposed as

$$\begin{cases} \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{E}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y}), \\ \boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{H}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Psi_1(\boldsymbol{x},\boldsymbol{y}), \end{cases}$$

where

$$\boldsymbol{E}(\boldsymbol{x}) = \langle \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})\rangle = \iiint_Y \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y})\,dv_{\boldsymbol{y}}$$

and similarly for the field $\boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y})$. In summary,

$$\begin{cases} \boldsymbol{E}^\varepsilon(\boldsymbol{x}) \overset{2\text{-s}}{\rightharpoonup} \boldsymbol{E}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y}), \\ \boldsymbol{H}^\varepsilon(\boldsymbol{x}) \overset{2\text{-s}}{\rightharpoonup} \boldsymbol{H}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Psi_1(\boldsymbol{x},\boldsymbol{y}). \end{cases}$$

Multiplication of (4.1) by the admissible test functions $\boldsymbol{\phi} \in C_0^\infty(\Omega;\mathbb{C}^3)$ gives

$$\begin{cases} \iiint_\Omega \nabla_{\boldsymbol{x}} \times \boldsymbol{E}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\phi}(\boldsymbol{x})\, dv - ik_0 \iiint_\Omega \boldsymbol{\phi}(\boldsymbol{x}) \cdot \{\mu(\boldsymbol{x}/\varepsilon) \cdot \boldsymbol{H}^\varepsilon(\boldsymbol{x})\}\, dv = 0, \\ \iiint_\Omega \nabla_{\boldsymbol{x}} \times \boldsymbol{H}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\phi}(\boldsymbol{x})\, dv + ik_0 \iiint_\Omega \boldsymbol{\phi}(\boldsymbol{x}) \cdot \{\epsilon(\boldsymbol{x}/\varepsilon) \cdot \boldsymbol{E}^\varepsilon(\boldsymbol{x})\}\, dv = 0. \end{cases}$$

In the limit $\varepsilon \searrow 0$ we get

(4.7)
$$\begin{cases} \iiint_\Omega \nabla_{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x}) \cdot \boldsymbol{\phi}(\boldsymbol{x})\, dv_{\boldsymbol{x}} \\ \qquad - ik_0 \iiint_\Omega \iiint_Y \boldsymbol{\phi}(\boldsymbol{x}) \cdot \mu(\boldsymbol{y}) \cdot (\boldsymbol{H}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Psi_1(\boldsymbol{x},\boldsymbol{y}))\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}} = 0, \\ \iiint_\Omega \nabla_{\boldsymbol{x}} \times \boldsymbol{H}(\boldsymbol{x}) \cdot \boldsymbol{\phi}(\boldsymbol{x})\, dv_{\boldsymbol{x}} \\ \qquad + ik_0 \iiint_\Omega \iiint_Y \boldsymbol{\phi}(\boldsymbol{x}) \cdot \epsilon(\boldsymbol{y}) \cdot (\boldsymbol{E}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y}))\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}} = 0. \end{cases}$$

Here we have used Theorem B.8, which states that

$$\nabla \times \boldsymbol{E}^\varepsilon \overset{2\text{-s}}{\rightharpoonup} \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x},\boldsymbol{y}),$$

which gives the weak limit $\nabla_{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})$ since the admissible test function $\boldsymbol{\phi}$ does not depend on $\boldsymbol{y}$.

The divergence equations are multiplied by $v(\boldsymbol{x}) = \varepsilon\psi(\boldsymbol{x})\phi(\boldsymbol{x}/\varepsilon)$, where $\psi \in C_0^\infty(\Omega)$, $\phi \in H^1_\#(Y)$. We note that $w_\epsilon(\boldsymbol{y}) = \hat{\boldsymbol{e}}_i \cdot \epsilon(\boldsymbol{y}) \cdot \hat{\boldsymbol{e}}_j \in L^\infty_\#(Y)$ and $w_\mu(\boldsymbol{y}) = \hat{\boldsymbol{e}}_i \cdot \mu(\boldsymbol{y}) \cdot \hat{\boldsymbol{e}}_j \in L^\infty_\#(Y)$, which implies that $w_\epsilon(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi$ and $w_\mu(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi \in L^2_\#(Y;\mathbb{C}^3)$. Theorem B.3 and an integration by parts give

$$\begin{aligned} &\lim_{\varepsilon\searrow 0} \iiint_\Omega \nabla \cdot \{\epsilon(\boldsymbol{x}/\varepsilon) \cdot \boldsymbol{E}^\varepsilon(\boldsymbol{x})\}\, \varepsilon\psi(\boldsymbol{x})\phi(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \\ &\quad = -\lim_{\varepsilon\searrow 0} \iiint_\Omega \{\varepsilon\nabla\psi(\boldsymbol{x})\phi(\boldsymbol{x}/\varepsilon) + \psi(\boldsymbol{x})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{x}/\varepsilon)\} \cdot \{\epsilon(\boldsymbol{x}/\varepsilon) \cdot \boldsymbol{E}^\varepsilon(\boldsymbol{x})\}\, dv_{\boldsymbol{x}} \\ &\quad = -\iiint_\Omega \iiint_Y \psi(\boldsymbol{x})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \{\boldsymbol{E}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y})\}\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}} = 0 \end{aligned}$$

for all $\phi \in H^1_\#(Y)$ and all $\psi \in H^1_0(\Omega)$. Using similar arguments for the magnetic field, we get the local equations

(4.8)
$$\begin{cases} \iiint_Y \nabla_{\boldsymbol{y}}\phi(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \{\boldsymbol{E}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y})\}\, dv_{\boldsymbol{y}} = 0, \\ \iiint_Y \nabla_{\boldsymbol{y}}\phi(\boldsymbol{y}) \cdot \mu(\boldsymbol{y}) \cdot \{\boldsymbol{H}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\Psi_1(\boldsymbol{x},\boldsymbol{y})\}\, dv_{\boldsymbol{y}} = 0, \end{cases} \qquad \boldsymbol{x} \in \Omega \text{ a.e.}$$

Define the vector fields

$$\boldsymbol{\chi}_e(\boldsymbol{y}) = \sum_{i=1}^3 \chi_e^i(\boldsymbol{y})\hat{\boldsymbol{e}}_i, \qquad \boldsymbol{\chi}_h(\boldsymbol{y}) = \sum_{i=1}^3 \chi_h^i(\boldsymbol{y})\hat{\boldsymbol{e}}_i.$$

The variables can be separated by using the ansatz

$$\begin{cases} \nabla_{\boldsymbol{y}}\Phi_1(\boldsymbol{x},\boldsymbol{y}) = -\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_e(\boldsymbol{y})\cdot\boldsymbol{E}(\boldsymbol{x}), \\ \nabla_{\boldsymbol{y}}\Psi_1(\boldsymbol{x},\boldsymbol{y}) = -\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_h(\boldsymbol{y})\cdot\boldsymbol{H}(\boldsymbol{x}) \end{cases}$$

inserted into (4.8), which gives

$$\begin{cases} \langle\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot(\epsilon(\boldsymbol{y}) - \epsilon(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_e(\boldsymbol{y}))\rangle\cdot\boldsymbol{E}(\boldsymbol{x}) = 0, \\ \langle\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot(\mu(\boldsymbol{y}) - \mu(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_h(\boldsymbol{y}))\rangle\cdot\boldsymbol{H}(\boldsymbol{x}) = 0 \end{cases}$$

for all $\phi \in H^1_{\#}(Y)$, i.e.,

$$\begin{cases} \nabla_{\boldsymbol{y}}\cdot(\epsilon(\boldsymbol{y}) - \epsilon(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_e(\boldsymbol{y})) = 0, \\ \nabla_{\boldsymbol{y}}\cdot(\mu(\boldsymbol{y}) - \mu(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_h(\boldsymbol{y})) = 0 \end{cases}$$

a.e. in $\Omega \times Y$. Inserting the solutions of the local equations into (4.7) yields the macroscopic homogenized equations

$$\begin{cases} \displaystyle\iiint_\Omega \nabla_{\boldsymbol{x}}\times\boldsymbol{E}(\boldsymbol{x})\cdot\boldsymbol{\phi}(\boldsymbol{x})\,dv_{\boldsymbol{x}} \\ \quad \displaystyle - ik_0\iiint_\Omega\iiint_Y \boldsymbol{\phi}(\boldsymbol{x})\cdot(\mu(\boldsymbol{y}) - \mu(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_h(\boldsymbol{y}))\,dv_{\boldsymbol{y}}\cdot\boldsymbol{H}(\boldsymbol{x})\,dv_{\boldsymbol{x}} = 0, \\ \displaystyle\iiint_\Omega \nabla_{\boldsymbol{x}}\times\boldsymbol{H}(\boldsymbol{x})\cdot\boldsymbol{\phi}(\boldsymbol{x})\,dv_{\boldsymbol{x}} \\ \quad \displaystyle + ik_0\iiint_\Omega\iiint_Y \boldsymbol{\phi}(\boldsymbol{x})\cdot(\epsilon(\boldsymbol{y}) - \epsilon(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\boldsymbol{\chi}_e(\boldsymbol{y}))\,dv_{\boldsymbol{y}}\cdot\boldsymbol{E}(\boldsymbol{x})\,dv_{\boldsymbol{x}} = 0 \end{cases}$$

and

$$\begin{cases} \nabla\cdot\boldsymbol{B}(\boldsymbol{x}) = 0, \\ \nabla\cdot\boldsymbol{D}(\boldsymbol{x}) = 0, \end{cases}$$

which defines the homogenized permeability and permittivity as

$$\begin{cases} \epsilon^h = \displaystyle\iiint_Y \epsilon(\boldsymbol{y})\cdot(\mathbf{I}_3 - \nabla_{\boldsymbol{y}}\boldsymbol{\chi}_e(\boldsymbol{y}))\,dv_{\boldsymbol{y}}, \\ \mu^h = \displaystyle\iiint_Y \mu(\boldsymbol{y})\cdot(\mathbf{I}_3 - \nabla_{\boldsymbol{y}}\boldsymbol{\chi}_h(\boldsymbol{y}))\,dv_{\boldsymbol{y}}, \end{cases}$$

i.e., $\boldsymbol{B} = \mu^h\cdot\boldsymbol{H}$ and $\boldsymbol{D} = \epsilon^h\cdot\boldsymbol{E}$. The existence of a unique solution of the homogenized system follows from the properties of the homogenized permeability and permittivity, μ^h and ϵ^h, respectively (see section 4.2.1), which satisfies the same assumptions as the material properties for the heterogeneous system. □

4.2.1. The properties of the homogenized parameters. An immediate consequence of Theorem 4.2 is that the homogenized parameters are independent of the properties of the domain Ω and of the properties of the incident field. Moreover, the homogenized material properties satisfy the same assumptions as the heterogeneous parameters do, i.e., they are coercive and bounded. Coercivity and boundedness follow from the fact that the homogenized parameters are bounded from below and above by the harmonic and arithmetic averages of the heterogeneous parameters; hence the

homogenized parameters are bounded from below and above (e.g., see [5] or [24]). If the heterogeneous material parameters are symmetric (reciprocal material), then the homogenized parameters are also symmetric as proved below.

PROPOSITION 4.3. *The homogenized permeability and permittivity are symmetric, provided the heterogeneous parameters are symmetric.*

Proof of Proposition 4.3. We restrict ourselves to the electric parameters since the arguments for the permeability are the same. By assumption the material parameters are symmetrical, i.e., $\epsilon(\boldsymbol{y}) = \epsilon^t(\boldsymbol{y})$ and $\mu(\boldsymbol{y}) = \mu^t(\boldsymbol{y})$.

We define the average over the Y-cell by

$$\langle f \rangle = \iiint_Y f(\boldsymbol{y})\, dv_{\boldsymbol{y}}.$$

The local problem, (4.6), can be written as ($i = 1, 2, 3$)

$$\langle \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \hat{\boldsymbol{e}}_i \rangle = \left\langle \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \chi_e^i(\boldsymbol{y}) \right\rangle$$

for all $w \in H^1_{\#}(Y)$. We rewrite these equations in one set of equations (see (4.5))

$$\langle \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \rangle = \langle \nabla_{\boldsymbol{y}} w(\boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}) \rangle$$

for all $w \in H^1_{\#}(Y)$. Due to the symmetry in ϵ we get

$$\langle \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \boldsymbol{\chi}(\boldsymbol{y}) \rangle = \left\langle (\nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}))^t \cdot \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}) \right\rangle$$

if we choose $w = \chi_e^i$.

The homogenized parameters in (4.4) are

$$\begin{aligned} \epsilon^h &= \langle \epsilon(\boldsymbol{y}) \rangle - \langle \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}) \rangle \\ &= \langle \epsilon(\boldsymbol{y}) \rangle - \left\langle (\nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}))^t \cdot \epsilon(\boldsymbol{y}) \cdot \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}) \right\rangle, \end{aligned}$$

which proves that ϵ^h is symmetric. ∎

4.2.2. Correctors. This section is concluded by the proof of a new result on correctors.

We begin with the two-scale limit of the heterogeneous system (4.1), which is given by

$$\text{(4.9)} \quad \begin{cases} \displaystyle\iiint_\Omega \iiint_Y (\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{y})) \cdot \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} dv_{\boldsymbol{x}} \\ \displaystyle = ik_0 \iiint_\Omega \iiint_Y \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y}) \cdot \mu(\boldsymbol{y}) \cdot \boldsymbol{H}_0(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} dv_{\boldsymbol{x}}, \\ \displaystyle\iiint_\Omega \iiint_Y (\nabla_{\boldsymbol{x}} \times \boldsymbol{H}_0(\boldsymbol{x}, \boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{H}_1(\boldsymbol{x}, \boldsymbol{y})) \cdot \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} dv_{\boldsymbol{x}} \\ \displaystyle = -ik_0 \iiint_\Omega \iiint_Y \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{y}) \cdot \epsilon(\boldsymbol{y}) \cdot \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} dv_{\boldsymbol{x}} \end{cases}$$

for all $\boldsymbol{\phi} \in D(\Omega; C^\infty_{\#}(Y; \mathbb{C}^3))$. These equations follow from the fact that (see Appendix B)

$$\boldsymbol{E}^\varepsilon(\boldsymbol{x}) \overset{\text{2-s}}{\rightharpoonup} \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y})$$

and

$$\nabla \times \boldsymbol{E}^\varepsilon(\boldsymbol{x}) \overset{\text{2-s}}{\rightharpoonup} \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x},\boldsymbol{y}),$$

where

$$\begin{cases} \boldsymbol{E}_0 \in L^2(\Omega; L^2_{\#}(Y;\mathbb{C}^3)), \\ \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0 \in L^2(\Omega; L^2_{\#}(Y;\mathbb{C}^3)), \\ \boldsymbol{E}_1 \in L^2(\Omega; H_{\#}(\mathrm{rot}, Y)/\mathbb{C}). \end{cases}$$

The system (4.9) contains macroscopic and microscopic information which gives the homogenized system when averaged over the local scale. The local equations and the two-scale limit system (4.9) provide us with the following correctors in the case when the solution of the homogenized system is smooth enough.

THEOREM 4.4. *Let $\boldsymbol{E}^\varepsilon, \boldsymbol{H}^\varepsilon$ be the solution of* (4.1)*, let $\boldsymbol{E}, \boldsymbol{H}$ be the solution of the homogenized Maxwell equations* (4.4)*, and let $\boldsymbol{E}_1, \boldsymbol{H}_1$ solve the two-scale limit system* (4.9)*. If $\boldsymbol{E}_0$, $\boldsymbol{H}_0$, $\boldsymbol{E}_1$, $\boldsymbol{H}_1$, $\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0$, $\nabla_{\boldsymbol{x}} \times \boldsymbol{H}_0$, $\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_1$, $\nabla_{\boldsymbol{x}} \times \boldsymbol{H}_1$, $\nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1$, and $\nabla_{\boldsymbol{y}} \times \boldsymbol{H}_1$ are admissible test functions, then*

$$\begin{cases} \lim_{\varepsilon\to 0} \|\boldsymbol{E}^\varepsilon(\boldsymbol{x}) - \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{x}/\varepsilon) - \varepsilon \boldsymbol{E}_1(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\|_{H(\mathrm{rot},\Omega)} = 0, \\ \lim_{\varepsilon\to 0} \|\boldsymbol{H}^\varepsilon(\boldsymbol{x}) - \boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{x}/\varepsilon) - \varepsilon \boldsymbol{H}_1(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\|_{H(\mathrm{rot},\Omega)} = 0, \end{cases}$$

where

$$\begin{cases} \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{E}(\boldsymbol{x}) - \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_e(\boldsymbol{y}) \cdot \boldsymbol{E}(\boldsymbol{x}), \\ \boldsymbol{H}_0(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{H}(\boldsymbol{x}) - \nabla_{\boldsymbol{y}} \boldsymbol{\chi}_h(\boldsymbol{y}) \cdot \boldsymbol{H}(\boldsymbol{x}), \end{cases}$$

$$\boldsymbol{\chi}_e(\boldsymbol{y}) = \sum_{i=1}^{3} \chi_e^i(\boldsymbol{y}) \hat{\boldsymbol{e}}_i, \qquad \boldsymbol{\chi}_h(\boldsymbol{y}) = \sum_{i=1}^{3} \chi_h^i(\boldsymbol{y}) \hat{\boldsymbol{e}}_i,$$

and where $\chi_e^i(\boldsymbol{y})$ and $\chi_h^i(\boldsymbol{y})$, $i = 1,2,3$, in $H^1_{\#}(Y)$ solve the local problems (4.6)*.*

Proof. The assumptions imply that (see Theorem B.8)

$$\begin{cases} \boldsymbol{E}^\varepsilon \overset{\text{2-s}}{\rightharpoonup} \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}), \\ \nabla \times \boldsymbol{E}^\varepsilon \overset{\text{2-s}}{\rightharpoonup} \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x},\boldsymbol{y}) \end{cases}$$

and $\nabla_{\boldsymbol{y}} \times \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{0}$.

The proof is carried out using the sesquilinear form

$$Q^\varepsilon(\boldsymbol{u},\boldsymbol{v}) = -\iiint_\Omega \left\{ \frac{1}{ik_0} (\nabla \times \boldsymbol{v}^*) \cdot \mu^{-1}(\boldsymbol{x}/\varepsilon) \cdot (\nabla \times \boldsymbol{u}) + ik_0 \boldsymbol{v}^* \cdot \epsilon(\boldsymbol{x}/\varepsilon) \cdot \boldsymbol{u} \right\} dv,$$

which is identical to (4.3) but without the surface integral term.

The coercivity assumption, (2.1), implies

$$C\|\boldsymbol{u}(\boldsymbol{x})\|^2_{H(\mathrm{rot},\Omega)} \le \Re Q^\varepsilon(\boldsymbol{u},\boldsymbol{u}).$$

We get

$$C\|\boldsymbol{E}^\varepsilon(\boldsymbol{x}) - \boldsymbol{E}_0(\boldsymbol{x},\boldsymbol{x}/\varepsilon) - \varepsilon \boldsymbol{E}_1(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\|^2_{H(\mathrm{rot},\Omega)} \le I_1^\varepsilon + I_2^\varepsilon,$$

where

$$\begin{cases} I_1^\varepsilon = \Re Q^\varepsilon \left(\boldsymbol{E}^\varepsilon(\boldsymbol{x}), \boldsymbol{A}_\varepsilon(\boldsymbol{x}) \right), \\ I_2^\varepsilon = -\Re Q^\varepsilon \left(\boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \varepsilon \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon), \boldsymbol{A}_\varepsilon(\boldsymbol{x}) \right), \end{cases}$$

where, for short, we denote $\boldsymbol{A}_\varepsilon(\boldsymbol{x}) = \boldsymbol{E}^\varepsilon(\boldsymbol{x}) - \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) - \varepsilon \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)$. Due to the assumptions of the fields in $\boldsymbol{A}_\varepsilon(\boldsymbol{x})$, we have

$$\begin{cases} \boldsymbol{A}_\varepsilon \overset{\text{2-s}}{\rightharpoonup} \boldsymbol{0}, \\ \nabla \times \boldsymbol{A}_\varepsilon \overset{\text{2-s}}{\rightharpoonup} \boldsymbol{0}, \end{cases}$$

since

$$\begin{cases} \boldsymbol{E}^\varepsilon \overset{\text{2-s}}{\rightharpoonup} \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y}), \\ \nabla \times \boldsymbol{E}^\varepsilon \overset{\text{2-s}}{\rightharpoonup} \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{y}) \end{cases}$$

and $\nabla_{\boldsymbol{y}} \times \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{0}$.

We start by analyzing the first integral I_1^ε. Since $\boldsymbol{E}^\varepsilon$ satisfies the Maxwell equations, (4.1), we get

$$I_1^\varepsilon = \Re \iiint_\Omega (\nabla \times \boldsymbol{H}^\varepsilon(\boldsymbol{x})) \cdot \boldsymbol{A}_\varepsilon(\boldsymbol{x})^* \, dv - \Re \iiint_\Omega \boldsymbol{H}^\varepsilon(\boldsymbol{x}) \cdot (\nabla \times \boldsymbol{A}_\varepsilon(\boldsymbol{x}))^* \, dv.$$

We now use $\nabla \cdot (\nabla \times \boldsymbol{H}^\varepsilon) = 0$ and $\nabla \cdot (\nabla \times \boldsymbol{A}_\varepsilon) = 0$ and, moreover, the fact that $\nabla \times \boldsymbol{H}^\varepsilon \in L^2(\Omega; \mathbb{C}^3)$ and $\nabla \times \boldsymbol{A}_\varepsilon \in L^2(\Omega; \mathbb{C}^3)$. The div-curl lemma (see [24, 25]) can be used and the limit is zero, since

$$\boldsymbol{A}_\varepsilon(\boldsymbol{x}) \rightharpoonup \boldsymbol{0} \text{ and } \nabla \times \boldsymbol{A}_\varepsilon(\boldsymbol{x}) \rightharpoonup \boldsymbol{0}$$

weakly in $L^2(\Omega; \mathbb{C}^3)$.

The second integral is now analyzed:

$$\begin{aligned} I_2^\varepsilon = -\Re \iiint_\Omega \Big\{ & \frac{1}{ik_0} \left(\nabla \times \boldsymbol{A}_\varepsilon(\boldsymbol{x}) \right)^* \cdot \mu^{-1}(\boldsymbol{x}/\varepsilon) \\ & \cdot \left(\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \varepsilon \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) \right) \\ & + ik_0 \boldsymbol{A}_\varepsilon(\boldsymbol{x})^* \cdot \epsilon(\boldsymbol{x}/\varepsilon) \cdot \left(\boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \varepsilon \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) \right) \Big\} \, dv_{\boldsymbol{x}}. \end{aligned}$$

We pass to the limit, $\varepsilon \searrow 0$, and use that $\mu^{-1}(\boldsymbol{x}/\varepsilon) \cdot (\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \varepsilon \nabla_{\boldsymbol{x}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon))$ and $\epsilon(\boldsymbol{x}/\varepsilon) \cdot (\boldsymbol{E}_0(\boldsymbol{x}, \boldsymbol{x}/\varepsilon) + \varepsilon \boldsymbol{E}_1(\boldsymbol{x}, \boldsymbol{x}/\varepsilon))$ are admissible test functions and obtain

$$\lim_{\varepsilon \searrow 0} I_2^\varepsilon = 0;$$

the theorem is proved. ∎

Remark 4.1. It is still an open question how irregular a function can be and still be an admissible test function. However, if the homogenized solution $\boldsymbol{E} \in C(\overline{\Omega}; \mathbb{C}^3)$, then $\boldsymbol{E}_0 \in L^2_{\#}(Y; C(\overline{\Omega}; \mathbb{C}^3))$ is admissible (see Appendix B). Further, if $\boldsymbol{E} \in C(\overline{\Omega}; \mathbb{C}^3)$, then $\boldsymbol{H} \in C(\overline{\Omega}; \mathbb{C}^3)$ by symmetry, and via (4.9) we find that $\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_0 + \nabla_{\boldsymbol{y}} \times \boldsymbol{E}_1$ is smooth in x, and for sufficient smoothness $\nabla_{\boldsymbol{x}} \times \boldsymbol{E}_1$ is also an admissible test function. To the knowledge of the authors there exist no results about regularity of the solutions of the Maxwell equations in the anisotropic, constant coefficient case. However, we believe that for sufficient regular boundary and incident fields, the solutions are admissible test functions.

5. Examples. In this section, we give two explicit examples of the exterior Calderón operator.

5.1. Plane boundary. The general representation of the solution to Problem (R) in (2.7) in a region $x_3 > c$ (plane interface Ω, $x_3 = c$) is found by a Fourier transform in the lateral coordinates x_1 and x_2.

The Fourier transform $\boldsymbol{E}(\boldsymbol{\xi}, x_3)$ of the electric field $\boldsymbol{E}(\boldsymbol{x})$, $\boldsymbol{x} = \hat{\boldsymbol{e}}_1 x_1 + \hat{\boldsymbol{e}}_2 x_2 + \hat{\boldsymbol{e}}_3 x_3$, with respect to the lateral position vector $\boldsymbol{\rho} = \hat{\boldsymbol{e}}_1 x_1 + \hat{\boldsymbol{e}}_2 x_2$ is defined by

$$\boldsymbol{E}(\boldsymbol{\xi}, x_3) = \iint_{\mathbb{R}^2} \boldsymbol{E}(\boldsymbol{x}) e^{-i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\rho},$$

where the Fourier variable $\boldsymbol{\xi}$ is

$$\boldsymbol{\xi} = \hat{\boldsymbol{e}}_1 \xi_1 + \hat{\boldsymbol{e}}_2 \xi_2$$

and $d\boldsymbol{\rho} = dx_1\, dx_2$. The modulus of this vector is denoted ξ, i.e.,

$$\xi = \sqrt{\xi_1^2 + \xi_2^2}.$$

By the Fourier inversion formula,

$$\boldsymbol{E}(\boldsymbol{x}) = \frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \boldsymbol{E}(\boldsymbol{\xi}, x_3) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\xi},$$

where $d\boldsymbol{\xi} = d\xi_1\, d\xi_2$. Specifically, the tangential electric field on the surface $\partial\Omega$ is

$$-\,\hat{\boldsymbol{e}}_3 \times (\hat{\boldsymbol{e}}_3 \times \boldsymbol{E}(\boldsymbol{x}))|_{\partial\Omega} = \frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\xi},$$

where $\boldsymbol{A}(\boldsymbol{\xi})$ is the Fourier transform of the trace of the tangential electric field.

The general form of the solution to Problem (R) in (2.7) in a region $x_3 > c$ is (see [16])

$$\begin{cases} \boldsymbol{E}(\boldsymbol{x}) = \frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \left(\mathbf{I}_2 - \dfrac{\xi}{\xi_3} \hat{\boldsymbol{e}}_3 \hat{\boldsymbol{e}}_\parallel \right) \cdot \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho} + i\xi_3(x_3 - c)}\, d\boldsymbol{\xi}, \\ \boldsymbol{H}(\boldsymbol{x}) = \frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \left(\dfrac{\boldsymbol{\xi}}{k_0} + \dfrac{\xi_3}{k_0} \hat{\boldsymbol{e}}_3 \right) \times \left(\mathbf{I}_2 - \dfrac{\xi}{\xi_3} \hat{\boldsymbol{e}}_3 \hat{\boldsymbol{e}}_\parallel \right) \cdot \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho} + i\xi_3(x_3 - c)}\, d\boldsymbol{\xi}, \end{cases}$$

where $\mathbf{I}_2$ is the identity dyadic in $\mathbb{R}^2$, and a pertinent orthogonal basis in $\mathbb{R}^2$ is $\{\hat{\boldsymbol{e}}_\parallel, \hat{\boldsymbol{e}}_\perp\}$, defined by

$$\hat{\boldsymbol{e}}_\parallel = \boldsymbol{\xi}/\xi, \qquad \hat{\boldsymbol{e}}_\perp = \hat{\boldsymbol{e}}_3 \times \hat{\boldsymbol{e}}_\parallel$$

and where

$$\xi_3 = \left(k_0^2 - \xi^2\right)^{1/2} = \begin{cases} \sqrt{k_0^2 - \xi^2} & \text{for } \xi < k_0, \\ i\sqrt{\xi^2 - k_0^2} & \text{for } \xi > k_0 \end{cases}$$

and the standard convention of the square root of a nonnegative argument is intended.

The representation of the fields can be simplified using dyadic calculus:

$$\begin{cases} \boldsymbol{E}(\boldsymbol{x}) = \dfrac{1}{4\pi^2} \iint_{\mathbb{R}^2} \left(\mathbf{I}_2 - \dfrac{\xi}{\xi_3} \hat{\boldsymbol{e}}_3 \hat{\boldsymbol{e}}_\parallel \right) \cdot \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho} + i\xi_3(x_3 - c)}\, d\boldsymbol{\xi}, \\ \boldsymbol{H}(\boldsymbol{x}) = \dfrac{1}{4\pi^2} \iint_{\mathbb{R}^2} \left(\dfrac{\xi}{k_0} \hat{\boldsymbol{e}}_3 \hat{\boldsymbol{e}}_\perp + \dfrac{k_0}{\xi_3} \hat{\boldsymbol{e}}_\perp \hat{\boldsymbol{e}}_\parallel - \dfrac{\xi_3}{k_0} \hat{\boldsymbol{e}}_\parallel \hat{\boldsymbol{e}}_\perp \right) \cdot \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho} + i\xi_3(x_3 - c)}\, d\boldsymbol{\xi}. \end{cases}$$

From these relations the exterior Calderón operator is the transformation from

$$\hat{\boldsymbol{e}}_3 \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega} = \frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \hat{\boldsymbol{e}}_3 \times \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\xi}$$

to

$$\hat{\boldsymbol{e}}_3 \times \boldsymbol{H}(\boldsymbol{x})|_{\partial\Omega} = -\frac{1}{4\pi^2} \iint_{\mathbb{R}^2} \left(\frac{k_0}{\xi_3} \hat{\boldsymbol{e}}_\parallel \hat{\boldsymbol{e}}_\parallel - \frac{\xi_3}{k_0} \hat{\boldsymbol{e}}_\perp \hat{\boldsymbol{e}}_\perp \right) \cdot \boldsymbol{A}(\boldsymbol{\xi}) e^{i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\xi},$$

where the vector field $\boldsymbol{A}(\boldsymbol{\xi})$ is determined from $\hat{\boldsymbol{e}}_3 \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega}$ by

$$\boldsymbol{A}(\boldsymbol{\xi}) = -\iint_{\mathbb{R}^2} \hat{\boldsymbol{e}}_3 \times (\hat{\boldsymbol{e}}_3 \times \boldsymbol{E}(\boldsymbol{x}))|_{\partial\Omega}\, e^{-i\boldsymbol{\xi}\cdot\boldsymbol{\rho}}\, d\boldsymbol{\rho}.$$

We note that in this example the domain and the boundary are unbounded, which yields other function spaces for the traces. We refer to [9] for the details.

5.2. Spherical boundary. For a spherical boundary, $x = a$, the exterior Calderón operator can be represented in a series of vector spherical waves; see Appendix C.

The general form of the solution to Problem (R) in (2.7) in a region $x > a$ is (see (C.2) and (C.3))

$$\begin{cases} \boldsymbol{E}(\boldsymbol{x}) = \displaystyle\sum_{\tau n} a_{\tau n} \boldsymbol{u}_{\tau n}(k_0 \boldsymbol{x}), \\ \boldsymbol{H}(\boldsymbol{x}) = -i \displaystyle\sum_{\tau n} a_{\tau n} \boldsymbol{u}_{\bar{\tau} n}(k_0 \boldsymbol{x}), \end{cases}$$

where the index $\bar{\tau}$ is the dual index of τ, defined by $\bar{1} = 2$ and $\bar{2} = 1$.

The traces of the electric and the magnetic fields are ($\kappa = k_0 a$)

$$\begin{cases} \hat{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega} = \displaystyle\sum_n \left(a_{1n} h_l^{(1)}(\kappa) \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) - a_{2n} \frac{(\kappa h_l^{(1)}(\kappa))'}{\kappa} \boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) \right), \\ \hat{\boldsymbol{x}} \times \boldsymbol{H}(\boldsymbol{x})|_{\partial\Omega} = -i \displaystyle\sum_n \left(a_{2n} h_l^{(1)}(\kappa) \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) - a_{1n} \frac{(\kappa h_l^{(1)}(\kappa))'}{\kappa} \boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) \right). \end{cases}$$

For a given tangential field $\hat{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega}$, the expansion coefficients $a_{\tau n}$ are found by the orthogonality relation (see (C.1))

$$\begin{cases} a_{1n} = \dfrac{1}{h_l^{(1)}(\kappa)} \displaystyle\iint_\gamma \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) \cdot (\hat{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega}), \\ a_{2n} = -\dfrac{\kappa}{(\kappa h_l^{(1)}(\kappa))'} \displaystyle\iint_\gamma \boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) \cdot (\hat{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega}). \end{cases}$$

The exterior Calderón mapping is the mapping from $\hat{\boldsymbol{x}} \times \boldsymbol{E}(\boldsymbol{x})|_{\partial\Omega}$ (which determines the expansion coefficients $a_{\tau n}$ uniquely) to $\hat{\boldsymbol{x}} \times \boldsymbol{H}(\boldsymbol{x})|_{\partial\Omega}$.

6. Conclusions. This paper analyzes the homogenization of the Maxwell equations for a material with periodic microscale. The material can be anisotropic and satisfies a coercivity condition (passive material), and the sources of the excitation are located in the region outside the heterogeneous material in Ω. We utilize the concept of two-scale convergence. A new a priori estimate is established, and a proof of strong convergence of the corrector fields is presented. The homogenized parameters are shown to be independent of the properties of the domain Ω and of the properties of the incident field.

Appendix A. Function spaces. In this appendix, we list the various function spaces used in this paper. Let Ω be a bounded, open, simply connected set in $\mathbb{R}^3$ with Lipschitz boundary $\partial\Omega$. A Y-periodic function, f, is defined as $f(\boldsymbol{x}+\hat{\boldsymbol{e}}_k)=f(\boldsymbol{x})$ for every $k=1,2,3$, where $\hat{\boldsymbol{e}}_k$, $k=1,2,3$, is the canonical basis in $\mathbb{R}^3$.

The space $C(\Omega)$ is the space of continuous functions in Ω. We also use $C_0(\overline{\Omega})$, which consists of all uniformly continuous functions which are zero at the boundary. The space $C^\infty(\Omega)$ is the space of infinitely continuously differentiable functions in Ω, and $C_0^\infty(\Omega)$ are the functions in this space with compact support in Ω, which we also denote $D(\Omega)$. Moreover,

$$C_\#^\infty(Y)=\left\{\phi\in C^\infty(\mathbb{R}^3),\phi\ Y\text{-periodic}\right\}.$$

Several function spaces with square integrable functions are used in this paper. The basic space is

$$L^2(\Omega)\stackrel{\text{def}}{=}\left\{u(\boldsymbol{x}):u\text{ Lebesgue integrable},\iiint_\Omega|u(\boldsymbol{x})|^2\,dv_{\boldsymbol{x}}<\infty\right\}$$

with norm

$$\|u\|_{L^2(\Omega)}=\left\{\iiint_\Omega|u(\boldsymbol{x})|^2\,dv_{\boldsymbol{x}}\right\}^{1/2}.$$

Similarly for vector-valued spaces we have the norm

$$\|\boldsymbol{u}\|_{L^2(\Omega;\mathbb{C}^3)}=\left\{\iiint_\Omega|\boldsymbol{u}(\boldsymbol{x})|^2\,dv_{\boldsymbol{x}}\right\}^{1/2}.$$

We also define two function spaces of periodic functions:

$$L_\#^2(Y)\stackrel{\text{def}}{=}\left\{\text{the completion of }C_\#^\infty(Y)\text{ in the }L^2(Y)\text{-norm}\right\}$$

and

$$L_\#^\infty(Y)\stackrel{\text{def}}{=}\left\{\phi\in L^\infty(\mathbb{R}^3),\phi\ Y\text{-periodic}\right\},$$

$$\begin{cases}H(\mathrm{div},\Omega)\stackrel{\text{def}}{=}\left\{\boldsymbol{u}\in L^2(\Omega;\mathbb{C}^3):\nabla\cdot\boldsymbol{u}\in L^2(\Omega)\right\},\\ H(\mathrm{rot},\Omega)\stackrel{\text{def}}{=}\left\{\boldsymbol{u}\in L^2(\Omega;\mathbb{C}^3):\nabla\times\boldsymbol{u}\in L^2(\Omega;\mathbb{C}^3)\right\},\end{cases}$$

which are Hilbert spaces with norms

$$\begin{cases}\|\boldsymbol{u}\|_{H(\mathrm{div},\Omega)}=\left(\|\boldsymbol{u}\|^2_{L^2(\Omega;\mathbb{C}^3)}+\|\nabla\cdot\boldsymbol{u}\|^2_{L^2(\Omega)}\right)^{1/2},\\ \|\boldsymbol{u}\|_{H(\mathrm{rot},\Omega)}=\left(\|\boldsymbol{u}\|^2_{L^2(\Omega;\mathbb{C}^3)}+\|\nabla\times\boldsymbol{u}\|^2_{L^2(\Omega;\mathbb{C}^3)}\right)^{1/2}.\end{cases}$$

The curl and the divergence are defined in the weak sense as

$$\begin{cases}(\nabla\times\boldsymbol{u},\boldsymbol{\phi})=(\boldsymbol{u},\nabla\times\boldsymbol{\phi})\qquad\text{for all }\boldsymbol{\phi}\in D(\Omega;\mathbb{C}^3),\\ (\nabla\cdot\boldsymbol{u},\phi)=-(\boldsymbol{u},\nabla\phi)\qquad\text{for all }\phi\in D(\Omega).\end{cases}$$

In the exterior region, we define spaces of locally integrable functions as

$$\begin{cases} H_{\rm loc}(\mathrm{div},\overline{\Omega}_e) \stackrel{\rm def}{=} \left\{\boldsymbol{u}\in D'(\Omega_e;\mathbb{C}^3) : \xi\boldsymbol{u}\in H(\mathrm{div},\Omega_e) \text{ for all } \xi\in D(\mathbb{R}^3)\right\}, \\ H_{\rm loc}(\mathrm{rot},\overline{\Omega}_e) \stackrel{\rm def}{=} \left\{\boldsymbol{u}\in D'(\Omega_e;\mathbb{C}^3) : \xi\nabla\times\boldsymbol{u}\in H(\mathrm{rot},\Omega_e) \text{ for all } \xi\in D(\mathbb{R}^3)\right\}, \end{cases}$$

where $\Omega_e = \mathbb{R}^3\setminus\overline{\Omega}$ and $D'(\Omega_e)$ is the space of distributions. The appropriate trace spaces used in this paper are $H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega)$ and $H^{-\frac{1}{2}}(\mathrm{rot},\partial\Omega)$ defined by

$$\begin{cases} H^{-\frac{1}{2}}(\mathrm{div},\partial\Omega) \stackrel{\rm def}{=} \left\{\boldsymbol{u}\in H^{-\frac{1}{2}}(\partial\Omega;\mathbb{C}^3),\ \hat{\boldsymbol{\nu}}\cdot\boldsymbol{u}=0,\ \mathrm{div}_{\partial\Omega}\boldsymbol{u}\in H^{-\frac{1}{2}}(\partial\Omega)\right\}, \\ H^{-\frac{1}{2}}(\mathrm{rot},\partial\Omega) \stackrel{\rm def}{=} \left\{\boldsymbol{u}\in H^{-\frac{1}{2}}(\partial\Omega;\mathbb{C}^3),\ \hat{\boldsymbol{\nu}}\cdot\boldsymbol{u}=0,\ \mathrm{rot}_{\partial\Omega}\boldsymbol{u}\in H^{-\frac{1}{2}}(\partial\Omega)\right\}, \end{cases}$$

where the surface divergence, $\mathrm{div}_{\partial\Omega}$, and the surface rotation, $\mathrm{rot}_{\partial\Omega}$, are defined by duality and restriction,

$$\begin{cases} (\mathrm{div}_{\partial\Omega}\boldsymbol{u},\phi) = -(\boldsymbol{u},\mathrm{grad}_{\partial\Omega}\phi) \qquad \text{for all } \phi\in D(\partial\Omega), \\ \mathrm{rot}_{\partial\Omega}\boldsymbol{u} = \hat{\boldsymbol{\nu}}\cdot(\nabla\times\boldsymbol{u})|_{\partial\Omega}, \end{cases}$$

and the surface gradient, $\mathrm{grad}_{\partial\Omega}$, is defined by the orthogonal projection of ∇ on the surface $\partial\Omega$.

We also define the function spaces

$$\begin{cases} H_{\#}(\mathrm{div},Y) \stackrel{\rm def}{=} \{\boldsymbol{u}\in H(\mathrm{div},Y), \boldsymbol{u}\ Y\text{-periodic}\}, \\ H_{\#}(\mathrm{rot},Y) \stackrel{\rm def}{=} \{\boldsymbol{u}\in H(\mathrm{rot},Y), \boldsymbol{u}\ Y\text{-periodic}\} \end{cases}$$

and

$$\begin{cases} H^1_{\#}(Y) \stackrel{\rm def}{=} \left\{\text{the completion of } C^\infty_{\#}(Y) \text{ in the } H^1(Y)\text{-norm}\right\}, \\ H^1_{\#}(Y)/\mathbb{C} \stackrel{\rm def}{=} \left\{\phi\in H^1_{\#}(Y),\ \text{equivalent up to a complex constant}\right\}. \end{cases}$$

If γ denotes the unit sphere in $\mathbb{R}^3$, the following norms are used in the paper:

$$\begin{cases} \|\boldsymbol{u}\|_\gamma = \left\{\iint_\gamma |\boldsymbol{u}(\hat{\boldsymbol{x}})|^2\ d\gamma\right\}^{1/2}, \\ \|\boldsymbol{u}\|_\infty = \sup_{|\hat{\boldsymbol{x}}|=1}|\boldsymbol{u}(\hat{\boldsymbol{x}})|, \end{cases}$$

and $d\gamma$ denotes the surface measure on the unit sphere in $\mathbb{R}^3$.

We conclude this appendix by stating the Lax–Milgram theorem [13].

THEOREM A.1 (Lax–Milgram). *Assume that H is a Hilbert space with norm $\|\cdot\|$. Moreover, assume that*

$$B : H\times H\to\mathbb{C}$$

is a sesquilinear functional on H, for which there exists constants $a,b>0$ such that

$$|B[u,v]|\le a\|u\|\|v\| \qquad \textit{for all } u,v\in H$$

and

$$b\|u\|^2\le|B[u,u]| \qquad \textit{for all } u\in H.$$

Finally, let $f : H\to\mathbb{C}$ be a bounded linear functional on H.

Then there exists a unique $u \in H$ such that

$$B[u,v] = f(v) \quad \textit{for all } v \in H.$$

Appendix B. Two-scale convergence.

DEFINITION B.1. *A sequence $\{\boldsymbol{u}^\varepsilon\}$ in $L^2(\Omega;\mathbb{C}^3)$ two-scale converges to $\boldsymbol{u}_0 \in L^2(\Omega \times Y;\mathbb{C}^3)$ if*

$$\lim_{\varepsilon \searrow 0} \iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} = \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}) \cdot \boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for every $\boldsymbol{\phi} \in D(\Omega; C^\infty_\#(Y;\mathbb{C}^3))$. We denote this by $\boldsymbol{u}^\varepsilon \overset{2\text{-}s}{\rightharpoonup} \boldsymbol{u}_0$.

The class of test functions can be enlarged to all admissible test functions defined below [2].

DEFINITION B.2. *We say that $\boldsymbol{\phi} \in L^2(\Omega; L^2_\#(Y;\mathbb{C}^3))$ is an admissible test function if $\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)$ is measurable and*

$$\lim_{\varepsilon \searrow 0} \|\boldsymbol{\phi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\|_{L^2(\Omega;\mathbb{C}^3)} = \|\boldsymbol{\phi}(\boldsymbol{x},\boldsymbol{y})\|_{L^2(\Omega \times Y;\mathbb{C}^3)}.$$

Remark B.1. Some examples of admissible test functions are $L^2(\Omega; C_\#(Y;\mathbb{C}^3))$ and for Ω bounded $L^2_\#(Y; C(\overline{\Omega};\mathbb{C}^3))$.

We cite two important theorems by Nguetseng [19].

THEOREM B.3 (Nguetseng [19]). *Let $u^\varepsilon \in L^2(\Omega)$. Suppose that there exists a constant $C > 0$ such that*

$$\|u^\varepsilon\|_{L^2(\Omega)} \le C \textit{ for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$\iiint_\Omega u^\varepsilon(\boldsymbol{x}) \Psi(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y u_0(\boldsymbol{x},\boldsymbol{y}) \Psi(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $\Psi \in C_0(\overline{\Omega}; C_\#(Y))$, where $u_0 \in L^2(\Omega; L^2_\#(Y))$. Moreover,

$$\iiint_\Omega u^\varepsilon(\boldsymbol{x}) v(\boldsymbol{x}) w(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y u_0(\boldsymbol{x},\boldsymbol{y}) v(\boldsymbol{x}) w(\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $v \in C_0(\overline{\Omega})$ and all $w \in L^2_\#(Y)$.

We note that if u^ε is a sequence in $L^2(\Omega)$, which two-scale converges to the limit $u_0 \in L^2(\Omega \times Y)$, then u^ε also converges to $u(\boldsymbol{x}) = \iiint_Y u_0(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}$ in $L^2(\Omega)$ weakly [2]. Moreover, if u^ε converges strongly to $u(\boldsymbol{x})$ in $L^2(\Omega)$, then u^ε two-scale converges to the same limit $u(\boldsymbol{x})$. The second theorem is the following.

THEOREM B.4 (Nguetseng). *Let $u^\varepsilon \in H^1(\Omega)$. Suppose that there exists a constant $C > 0$ such that*

$$\|u^\varepsilon\|_{H^1(\Omega)} \le C \textit{ for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$u^\varepsilon \to u \textit{ in } H^1(\Omega)\textit{-weak}$$

and

$$\iiint_\Omega \frac{\partial u^\varepsilon(\boldsymbol{x})}{\partial x_j} v(\boldsymbol{x}) w(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \\ \to \iiint_\Omega \iiint_Y \left\{ \frac{\partial u(\boldsymbol{x})}{\partial x_j} + \frac{\partial u_1(\boldsymbol{x},\boldsymbol{y})}{\partial y_j} \right\} v(\boldsymbol{x}) w(\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}},$$

$j = 1, 2, 3$, *for all* $v \in C_0(\overline{\Omega})$ *and all* $w \in L^2_\#(Y)$, *where* $u_1 \in L^2(\Omega; H^1_\#(Y)/\mathbb{C})$.

In addition to these two theorems, we observe that, taking $w = 1$, we get from Theorem B.3

$$\iiint_\Omega u^\varepsilon(\boldsymbol{x}) v(\boldsymbol{x})\, dv_{\boldsymbol{x}} \to \iiint_\Omega u(\boldsymbol{x}) v(\boldsymbol{x})\, dv_{\boldsymbol{x}}$$

for all $v \in C_0(\overline{\Omega})$, where

$$u(\boldsymbol{x}) = \iiint_Y u_0(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}}$$

is the usual weak $L^2(\Omega)$-limit of $u^\varepsilon(\boldsymbol{x})$. It follows that u_0 is uniquely expressed in the form

$$u_0(\boldsymbol{x}, \boldsymbol{y}) = u(\boldsymbol{x}) + \tilde{u}_0(\boldsymbol{x}, \boldsymbol{y}),$$

where

$$\iiint_Y \tilde{u}_0(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} = 0.$$

LEMMA B.5. *Let* $\boldsymbol{f} \in H^1_\#(Y; \mathbb{C}^3)$ *and assume that* $\nabla_{\boldsymbol{y}} \times \boldsymbol{f}(\boldsymbol{y}) = \boldsymbol{0}$. *Moreover, assume that* $\langle \boldsymbol{f} \rangle = 0$. *Then there exists a unique function* $q \in H^1_\#(Y)/\mathbb{C}$ *such that*

$$\boldsymbol{f}(\boldsymbol{y}) = \nabla_{\boldsymbol{y}} q(\boldsymbol{y}).$$

Proof of Lemma B.5. The periodicity of the function $\boldsymbol{f} \in H^1_\#(Y; \mathbb{C}^3)$ implies that $\boldsymbol{f}$ has a Fourier expansion

$$\boldsymbol{f}(\boldsymbol{y}) = \sum_n \boldsymbol{f}_n e^{i\boldsymbol{k}_n \cdot \boldsymbol{y}},$$

where the vector $\boldsymbol{k}_n$ is defined as

$$\boldsymbol{k}_n = 2\pi n_1 \hat{\boldsymbol{e}}_1 + 2\pi n_2 \hat{\boldsymbol{e}}_2 + 2\pi n_3 \hat{\boldsymbol{e}}_3$$

and where n_1, n_2, n_3 are integers and $n = (n_1, n_2, n_3)$. The sequence $\boldsymbol{f}_n$ belongs to $\left(\ell^2_1\right)^3$. The assumption that $\langle \boldsymbol{f} \rangle = 0$ implies that $\boldsymbol{f}_{(0,0,0)} = 0$. Moreover, the coefficients $\boldsymbol{f}_n$ satisfy

$$\boldsymbol{k}_n \times \boldsymbol{f}_n = \boldsymbol{0} \quad \text{for all } n.$$

Therefore $\boldsymbol{f}_n$ has the form

$$\boldsymbol{f}_n = \hat{\boldsymbol{k}}_n \left(\hat{\boldsymbol{k}}_n \cdot \boldsymbol{f}_n \right).$$

Define q_n as

$$\begin{cases} q_n = -i(\hat{\boldsymbol{k}}_n \cdot \boldsymbol{f}_n)/k_n \text{ for } n \neq (0,0,0), \\ q_{(0,0,0)} \text{ arbitrary}, \end{cases}$$

where $k_n = |\boldsymbol{k}_n|$. The coefficients $q_n \in \left(\ell_1^2\right)^3$,

$$\boldsymbol{f}_n = i\boldsymbol{k}_n q_n \quad \text{for all } n,$$

and

$$\boldsymbol{f}(\boldsymbol{y}) = \sum_n i\boldsymbol{k}_n q_n e^{i\boldsymbol{k}_n \cdot \boldsymbol{y}} = \nabla_{\boldsymbol{y}} q(\boldsymbol{y}),$$

where

$$q(\boldsymbol{y}) = \sum_n q_n e^{i\boldsymbol{k}_n \cdot \boldsymbol{y}} \in H^1_{\#}(Y)/\mathbb{C},$$

since $q_{(0,0,0)}$ is arbitrary and the lemma is proved. ∎

The obvious vector analogous theorems follow.

THEOREM B.6. *Let $\boldsymbol{u}^\varepsilon \in L^2(\Omega;\mathbb{C}^3)$. Suppose that there exists a constant $C > 0$ such that*

$$\|\boldsymbol{u}^\varepsilon\|_{L^2(\Omega;\mathbb{C}^3)} \leq C \text{ for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$\iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $\boldsymbol{\Psi} \in C_0(\overline{\Omega}; C_{\#}(Y;\mathbb{C}^3))$, where $\boldsymbol{u}_0 \in L^2(\Omega; L^2_{\#}(Y;\mathbb{C}^3))$. Moreover,

$$\iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{v}(\boldsymbol{x}) w(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{v}(\boldsymbol{x}) w(\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $\boldsymbol{v} \in C_0(\overline{\Omega};\mathbb{C}^3)$ and all $w \in L^2_{\#}(Y)$.

The field $\boldsymbol{u}_0$ is uniquely expressed in the form

$$\boldsymbol{u}_0(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{u}(\boldsymbol{x}) + \tilde{\boldsymbol{u}}_0(\boldsymbol{x}, \boldsymbol{y}),$$

where

$$\iiint_Y \tilde{\boldsymbol{u}}_0(\boldsymbol{x}, \boldsymbol{y})\, dv_{\boldsymbol{y}} = \boldsymbol{0}.$$

We have the following results proved in [23].

THEOREM B.7. *Let $\boldsymbol{u}^\varepsilon \in H(\mathrm{div}, \Omega)$. Suppose that there exists a constant $C > 0$ such that*

$$\|\boldsymbol{u}^\varepsilon\|_{H(\mathrm{div},\Omega)} \leq C \quad \text{for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$\boldsymbol{u}^\varepsilon \to \boldsymbol{u} \text{ in } L^2(\Omega;\mathbb{C}^3)\text{-weak}$$

and

$$\iiint_\Omega \nabla_{\boldsymbol{x}} \cdot \boldsymbol{u}^\varepsilon(\boldsymbol{x}) v(\boldsymbol{x}) w(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}$$
$$\to \iiint_\Omega \iiint_Y \left\{\nabla_{\boldsymbol{x}} \cdot \boldsymbol{u}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}} \cdot \boldsymbol{u}_1(\boldsymbol{x},\boldsymbol{y})\right\} v(\boldsymbol{x}) w(\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $v \in C_0(\overline{\Omega})$ *and all* $w \in L^2_\#(Y)$, *where* $\boldsymbol{u}(\boldsymbol{x}) = \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}$, $\boldsymbol{u}_0$ *is the two-scale limit of* $\boldsymbol{u}^\varepsilon$, *and* $\boldsymbol{u}_1 \in L^2(\Omega; H_\#(\mathrm{div}, Y))$.

THEOREM B.8. *Let* $\boldsymbol{u}^\varepsilon \in H(\mathrm{rot}, \Omega)$. *Suppose that there exists a constant* $C > 0$ *such that*

$$\|\boldsymbol{u}^\varepsilon\|_{H(\mathrm{rot},\Omega)} \le C \quad \textit{for all } \varepsilon.$$

Then a subsequence (still denoted by ε*) can be extracted from* ε *such that, letting* $\varepsilon \searrow 0$,

$$\boldsymbol{u}^\varepsilon \to \boldsymbol{u}_0 \textit{ in } L^2(\Omega;\mathbb{C}^3)\textit{-weak}$$

and

$$\iiint_\Omega \nabla \times \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot v(\boldsymbol{x}) \boldsymbol{w}(\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}$$
$$\to \iiint_\Omega \iiint_Y \left\{\nabla_{\boldsymbol{x}} \times \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}) + \nabla_{\boldsymbol{y}} \times \boldsymbol{u}_1(\boldsymbol{x},\boldsymbol{y})\right\} \cdot v(\boldsymbol{x}) \boldsymbol{w}(\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $v \in C_0(\overline{\Omega})$ *and all* $\boldsymbol{w} \in L^2_\#(Y;\mathbb{C}^3)$, *where* $\boldsymbol{u}_1 \in L^2(\Omega; H_\#(\mathrm{rot}, Y))$.

Proof of Theorem B.8. From Theorem B.6 we get

$$\iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}) \cdot \boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

and

$$\iiint_\Omega \nabla \times \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \boldsymbol{\chi}_0(\boldsymbol{x},\boldsymbol{y}) \cdot \boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $\boldsymbol{\Psi} \in C_0(\overline{\Omega}; C_\#(Y;\mathbb{C}^3))$, where $\boldsymbol{u}_0, \boldsymbol{\chi}_0 \in L^2(\Omega; L^2_\#(Y;\mathbb{C}^3))$. Choose test functions $\boldsymbol{\Psi} \in C_0(\overline{\Omega}; C_\#(Y;\mathbb{C}^3))$ such that $\nabla_{\boldsymbol{y}} \times \boldsymbol{\Psi} = 0$. We get by integration by parts

$$\iiint_\Omega \nabla \times \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} = \iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \nabla \times \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}$$
$$= \iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x}) \cdot \nabla_{\boldsymbol{x}} \times \boldsymbol{\Psi}(\boldsymbol{x}, \boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}$$
$$\to \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}) \cdot \nabla_{\boldsymbol{x}} \times \boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$
$$= \iiint_\Omega \iiint_Y \nabla_{\boldsymbol{x}} \times \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}) \cdot \boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}.$$

This means that

$$\iiint_\Omega \iiint_Y (\boldsymbol{\chi}_0(\boldsymbol{x},\boldsymbol{y}) - \nabla_{\boldsymbol{x}} \times \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})) \cdot \boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}} = 0$$

for all $\boldsymbol{\Psi} \in C_0(\overline{\Omega}; C_{\#}(Y;\mathbb{C}^3))$ such that $\nabla_{\boldsymbol{y}} \times \boldsymbol{\Psi} = 0$. By the decomposition of $L^2(\Omega;\mathbb{C}^3)$ (e.g., see [9]) there exists a function $\boldsymbol{u}_1 \in L^2(\Omega; H_{\#}(\mathrm{rot}, Y))$ such that

$$\nabla_{\boldsymbol{y}} \times \boldsymbol{u}_1 = \boldsymbol{\chi}_0(\boldsymbol{x},\boldsymbol{y}) - \nabla_{\boldsymbol{x}} \times \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}). \qquad \square$$

THEOREM B.9 (see Wellander [26] or [27]). *Let $\boldsymbol{u}^\varepsilon \in H(\mathrm{rot},\Omega)$. Suppose that there exists a constant $C > 0$ such that*

$$\|\boldsymbol{u}^\varepsilon\|_{H(\mathrm{rot},\Omega)} \le C \quad \text{for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$\boldsymbol{u}^\varepsilon \overset{2\text{-}s}{\rightharpoonup} \boldsymbol{u}(\boldsymbol{x}) + \nabla_{\boldsymbol{y}}\phi(\boldsymbol{x},\boldsymbol{y}),$$

where $\phi \in L^2(\Omega; H^1_{\#}(Y))$ is a scalar-valued function satisfying

$$\iiint_Y \nabla_{\boldsymbol{y}}\phi(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}} = \boldsymbol{0}.$$

Moreover,

$$\nabla \times \boldsymbol{u}^\varepsilon \rightharpoonup \nabla \times \boldsymbol{u}(\boldsymbol{x}) \text{ in } L^2(\Omega;\mathbb{C}^3).$$

THEOREM B.10 (see Wellander [26] or [27]). *Let $\boldsymbol{u}^\varepsilon \in H(\mathrm{div},\Omega)$. Suppose that there exists a constant $C > 0$ such that*

$$\|\boldsymbol{u}^\varepsilon\|_{H(\mathrm{div},\Omega)} \le C \quad \text{for all } \varepsilon.$$

Then a subsequence (still denoted by ε) can be extracted from ε such that, letting $\varepsilon \searrow 0$,

$$\boldsymbol{u}^\varepsilon \overset{2\text{-}s}{\rightharpoonup} \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})$$

and

$$\varepsilon\nabla\cdot\boldsymbol{u}^\varepsilon \overset{2\text{-}s}{\rightharpoonup} \nabla_{\boldsymbol{y}}\cdot\boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y}).$$

Proof of Theorem B.10. From Theorem B.6 we get

$$\iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x})\cdot\boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})\cdot\boldsymbol{\Psi}(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

and

$$\iiint_\Omega \nabla\cdot\boldsymbol{u}^\varepsilon(\boldsymbol{x})\Psi(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} \to \iiint_\Omega \iiint_Y \chi_0(\boldsymbol{x},\boldsymbol{y})\Psi(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}$$

for all $\boldsymbol{\Psi} \in C_0(\overline{\Omega}; C_{\#}(Y;\mathbb{C}^3))$ and $\Psi \in C_0(\overline{\Omega}; C_{\#}(Y))$, where $\boldsymbol{u}_0 \in L^2(\Omega; L^2_{\#}(Y;\mathbb{C}^3))$ and $\chi_0 \in L^2(\Omega; L^2_{\#}(Y))$.

We get by integration by parts

$$\begin{aligned}
&\iiint_\Omega \varepsilon\nabla\cdot\boldsymbol{u}^\varepsilon(\boldsymbol{x})\Psi(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} = -\iiint_\Omega \varepsilon\boldsymbol{u}^\varepsilon(\boldsymbol{x})\cdot\nabla\Psi(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}\\
&\quad = -\iiint_\Omega \varepsilon\boldsymbol{u}^\varepsilon(\boldsymbol{x})\cdot\nabla_{\boldsymbol{x}}\Psi(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}} - \iiint_\Omega \boldsymbol{u}^\varepsilon(\boldsymbol{x})\cdot\nabla_{\boldsymbol{y}}\Psi(\boldsymbol{x},\boldsymbol{x}/\varepsilon)\, dv_{\boldsymbol{x}}\\
&\quad \to -\iiint_\Omega \iiint_Y \boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}\Psi(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}\\
&\quad = \iiint_\Omega \iiint_Y \nabla_{\boldsymbol{y}}\cdot\boldsymbol{u}_0(\boldsymbol{x},\boldsymbol{y})\Psi(\boldsymbol{x},\boldsymbol{y})\, dv_{\boldsymbol{y}}\, dv_{\boldsymbol{x}}. \qquad \square
\end{aligned}$$

Appendix C. Vector spherical harmonics. The vector spherical harmonics are defined as (see [8])

$$\begin{cases} \boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) = \frac{1}{\sqrt{l(l+1)}}\nabla \times (\boldsymbol{x} Y_n(\hat{\boldsymbol{x}})) = \frac{1}{\sqrt{l(l+1)}}\nabla Y_n(\hat{\boldsymbol{x}}) \times \boldsymbol{x}, \\ \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) = \frac{1}{\sqrt{l(l+1)}} x \nabla Y_n(\hat{\boldsymbol{x}}), \\ \boldsymbol{A}_{3n}(\hat{\boldsymbol{x}}) = \hat{\boldsymbol{x}} Y_n(\hat{\boldsymbol{x}}), \end{cases}$$

where the spherical harmonics are denoted $Y_n(\hat{\boldsymbol{x}})$. The index n is a multi-index for the integer indices $l = 0, 1, 2, 3, \ldots$, $m = 0, 1, \ldots, l$, and $\sigma =$ e,o (even and odd in the azimuthal angle). From these definitions we see that the first two vector spherical harmonics, $\boldsymbol{A}_{1n}(\hat{\boldsymbol{x}})$ and $\boldsymbol{A}_{2n}(\hat{\boldsymbol{x}})$, are tangential to the unit sphere γ in $\mathbb{R}^3$ and they are related by

$$\begin{cases} \hat{\boldsymbol{x}} \times \boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) = \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}), \\ \hat{\boldsymbol{x}} \times \boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) = -\boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}). \end{cases}$$

The vector spherical harmonics form an orthonormal set over the unit sphere γ in $\mathbb{R}^3$, i.e.,

$$\iint_\gamma \boldsymbol{A}_{\tau n}(\hat{\boldsymbol{x}}) \cdot \boldsymbol{A}_{\tau' n'}(\hat{\boldsymbol{x}})\, d\gamma = \delta_{nn'}\delta_{\tau\tau'}. \tag{C.1}$$

The radiating solutions to the Maxwell equations in a vacuum are defined as

$$\begin{cases} \boldsymbol{u}_{1n}(k_0\boldsymbol{x}) = h_l^{(1)}(k_0 x)\boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}), \\ \boldsymbol{u}_{2n}(k_0\boldsymbol{x}) = \frac{1}{k_0}\nabla \times \left(h_l^{(1)}(k_0 x)\boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}) \right), \end{cases}$$

where $h_l^{(1)}(k_0 x)$ is the spherical Hankel function of the first kind [1]. These vector waves satisfy

$$\nabla \times (\nabla \times \boldsymbol{u}_{\tau n}(k_0\boldsymbol{x})) - k_0^2 \boldsymbol{u}_{\tau n}(k_0\boldsymbol{x}) = \boldsymbol{0}, \qquad \tau = 1, 2, \tag{C.2}$$

and they also satisfy the radiation condition in (2.5). Another representation of the definition of the vector waves is

$$\begin{cases} \boldsymbol{u}_{1n}(k_0\boldsymbol{x}) = h_l^{(1)}(k_0 x)\boldsymbol{A}_{1n}(\hat{\boldsymbol{x}}), \\ \boldsymbol{u}_{2n}(k_0\boldsymbol{x}) = \frac{(k_0 x h_l^{(1)}(k_0 x))'}{k_0 x}\boldsymbol{A}_{2n}(\hat{\boldsymbol{x}}) + \sqrt{l(l+1)}\frac{h_l^{(1)}(k_0 x)}{k_0 x}\boldsymbol{A}_{3n}(\hat{\boldsymbol{x}}), \end{cases}$$

where $'$ denotes differentiation with respect to the argument of the spherical Hankel function. A simple consequence of these definitions is

$$\begin{cases} \boldsymbol{u}_{1n}(k_0\boldsymbol{x}) = \frac{1}{k_0}\nabla \times \boldsymbol{u}_{2n}(k_0\boldsymbol{x}), \\ \boldsymbol{u}_{2n}(k_0\boldsymbol{x}) = \frac{1}{k_0}\nabla \times \boldsymbol{u}_{1n}(k_0\boldsymbol{x}). \end{cases} \tag{C.3}$$

A HOMOGENIZATION TECHNIQUE FOR THE BOLTZMANN EQUATION FOR LOW PRESSURE CHEMICAL VAPOR DEPOSITION*

MATTHIAS K. GOBBERT† AND CHRISTIAN RINGHOFER‡

Abstract. We present a homogenization technique for rarefied gas flow over a microstructured surface consisting of patterns of periodic features. The length scale of the model domain is comparable to the mean free path of the molecules, while the scale of the surface patterns is much smaller. The flow is modeled by a system of linear Boltzmann equations with a diffusive boundary condition at the patterned surface. The resulting homogenized boundary condition holds at a virtual flat surface and incorporates the microscopic geometry information about the surface structure on the macroscopic level. Numerical results validate the approach. The setup models low pressure chemical vapor deposition processes in the manufacturing of integrated circuits.

Key words. Boltzmann equation, rarefied gas dynamics, boundary homogenization, microstructured surface, chemical vapor deposition

1. Introduction.

Low pressure chemical vapor deposition is used in the manufacturing of integrated circuits to deposit a thin layer of material onto the surface of a silicon wafer. The deposition surface necessarily involves a microstructure given by the electrical components of the future microchip. Classical models for this process include reactor scale models [17] with a typical length scale of over 10 cm, which model the gas flow throughout the chemical reactor, and feature scale models [3] with a typical length scale of under 1 μm, which focus on the evolution of the film profile inside an individual feature.

In more detail, the process works as follows. Molecules of the species to be deposited are carried inside the chemical reactor by an inert carrier gas to a microstructured surface, where they are partially absorbed and partially reflected at a certain rate. The length scale of the surface structure is several orders of magnitude smaller than that of the reactor and therefore cannot be reasonably resolved on the reactor scale. On the other hand, this structure will influence the gas flow through the boundary conditions; i.e., adsorption on the microstructured surface will result in a different behavior of the gas flow than adsorption on a flat surface, even on the macroscopic reactor scale. We therefore have to solve a homogenization problem at the boundary by deriving a boundary condition for the flow problem which incorporates the microscopic geometric information about the surface structure into the macroscopic flow picture.

Based on analytic work in [2, 5, 6, 8, 11], the authors and coworkers have previously introduced [7, 12] a mesoscopic scale model on a length scale intermediate to those of the classical reactor scale and feature scale models, which was designed to provide information on the effects of feature clustering on a length scale of about 1.0 cm at comparably high pressures of at least 1 torr (where 760 torr = 1 atm). In that regime, the mean free path of the gas molecules was well inside the domain size, and the gas flow could be modeled as diffusion-dominated [8, 9, 11, 12, 18]. While [8, 11] derive the homogenized model formally for the concrete problem of interest, [2, 5, 6] handle the analysis rigorously for a more general class of models.

However, as individual feature sizes decrease below 1 μm, the length scale of interest for clustering effects also decreases. Therefore, this work considers a mesoscopic scale model with a domain with typical length scale on the order of 0.01 cm. Using this together with typical values for the total pressure of 1 torr or less, the mean free path of the gas molecules is of length comparable to the typical length scale. The Knudsen number Kn, which is defined as the ratio of the mean free path and the typical length scale, is on the order of unity, and the process lies in the transition regime for gaseous flow modeling [15].

The proper mathematical model for a gas flow in the transition regime is given by the Boltzmann equation of gas dynamics for the (scaled) probability density $f(x, v, t)$ that there is a molecule in the region $[x_1, x_1 + dx_1] \times [x_2, x_2 + dx_2] \times [x_3, x_3 + dx_3]$ with velocity in $[v_1, v_1 + dv_1] \times [v_2, v_2 + dv_2] \times [v_3, v_3 + dv_3]$ during time $[t, t + dt]$,

$$\frac{\partial f}{\partial t} + v \cdot \nabla f = Q(f, f), \tag{1.1}$$

with the collision operator

$$Q(f,f)(x,v,t) = \iiint \big[f(x,v',t)f(x,v'_*,t) - f(x,v,t)f(x,v_*,t)\big] B(\vartheta, |V|)\, d\vartheta\, d\varepsilon\, dv_*, \tag{1.2}$$

where $v' = v - n(n \cdot V)$ and $v'_* = v_* + n(n \cdot V)$ denote the precollision velocities, with $V = v - v_*$ and $n = (\sin\vartheta\cos\varepsilon, \sin\vartheta\sin\varepsilon, \cos\vartheta)^T$ (see [4, 15]).

A complete model for chemical vapor deposition will consist of one Boltzmann equation for each gaseous species $f_i(x, v, t)$, $i = 0, 1, \ldots, n_s$, to form the system

$$\frac{\partial f_i}{\partial t} + v \cdot \nabla_x f_i = \sum_{j=0}^{n_s} Q_{ij}(f_i, f_j), \quad i = 0, 1, \ldots, n_s, \tag{1.3}$$

where the collision operators $Q_{ij}(f_i, f_j)$ model the collisions between molecules of species i and species j for $0 \le i, j \le n_s$. This model includes the inert background gas $f_0(x, v, t)$ of the manufacturing process, which is a rarefied gas itself but still much denser than the reacting species. Under these assumptions, the collisions of a reacting species with the background gas will be much more frequent than collisions *among* the reacting species, and it is legitimate to neglect all collisions except the ones with the background species $j = 0$ on the right-hand side of (1.3); this also decouples the equation for the background species f_0 from the other equations, which can hence be solved for independently from the other solutions f_i, $i = 1, \ldots, n_s$.

In the classical derivation [4, Chapter IV], it is additionally assumed that the background gas is in equilibrium and spatially homogeneously distributed. Then its

distribution function $f_0(x, v, t)$ is given by a Maxwellian distribution of the form

$$f_0(x, v, t) = M(v) := \frac{1}{(2\pi)^{d/2}} \exp\left(-\frac{|v|^2}{2}\right), \tag{1.4}$$

where $d \in \{1, 2, 3\}$ denotes the dimension of the velocity space under consideration. Then, the time-evolution of the probability distribution of a typical reacting species is given by the system of linear Boltzmann equations

$$\frac{\partial f_i}{\partial t} + v \cdot \nabla f_i = Q_i(f_i), \quad i = 1, \ldots, n_s, \tag{1.5}$$

with the linear collision operators

$$Q_i(f_i)(x, v, t) = \int S_i(v, v') \left[\frac{f_i(x, v', t)}{M(v')} - \frac{f_i(x, v, t)}{M(v)}\right] dv'; \tag{1.6}$$

see [4, Chapter IV] for a detailed derivation. Here, $S_i(v, v') = S_i(v', v)$ denotes the scattering cross section, which describes the probability that a molecule with velocity v' before a collision scatters to a velocity v after the collision. A generalization to spatially varying background gases is possible. We will assume that the reacting species are introduced into the reactor chamber starting at the beginning of the processing step, i.e., that $f_i = 0$, $i = 1, \ldots, n_s$, at $t = 0$.

For the analysis, we therefore consider the representative equation for $f(x, y, v, t)$:

$$\frac{\partial f}{\partial t} + v_1 \frac{\partial f}{\partial x_1} + v_2 \frac{\partial f}{\partial x_2} + v_3 \frac{\partial f}{\partial y} = Q(f). \tag{1.7}$$

Here, $x \equiv (x_1, x_2)^T$ counts across the reacting surface, and $y \equiv x_3$ points into the gaseous domain perpendicular to the surface. That is, molecules with velocities $v = (v_1, v_2, v_3)^T$ travel towards the mean wafer surface when $v_3 < 0$. More precisely, the microstructured surface Γ_ε is for this paper assumed to be given by a function

$$y = \tilde{h}(x) = \varepsilon\, h(x, \tfrac{x}{\varepsilon}), \tag{1.8}$$

with the small parameter $0 < \varepsilon \ll 1$. This parameter represents the ratio of the typical feature mouth (or, more precisely, the so-called pitch, i.e., the distance from the center of one feature to the next one), e.g., 1 μm, to the typical length scale of the mesoscopic scale model, e.g., 100 μm.

In this dimensionless form, $h(x, \xi)$ is periodic in $\xi \equiv (\xi_1, \xi_2)^T$ with period 1 in each component; that is,

$$h(x, \xi) = h(x, \xi + e_1) = h(x, \xi + e_2) \quad \text{for all } (x, \xi), \tag{1.9}$$

where $e_1 = (1, 0)^T$ and $e_2 = (0, 1)^T$ denote the unit vectors in two dimensions. Physically, this reflects the fact that the microscopic features on a computer chip are not random but arranged in clusters of hundreds or thousands of (by design) identical features, periodic with the feature pitch as period. However, this periodic structure will be different in different regions of the chip, and therefore we allow the function h to depend on the slow spatial variable x as well. Realistic values for ε include the range from 10^{-4} to 10^{-3}.

The model is complemented by a boundary condition on the reacting surface for all molecules that flow into the gaseous domain, i.e., that satisfy $n \cdot v \leq 0$, where $n =$

$n(x,y)$ denotes the unit outward normal vector at position $(x,y)^T \in \Gamma_\varepsilon$. Specifically, we assume that the reinsertion occurs with Maxwellian distributed velocities and set

(1.10)
$$f(x,y,v,t) = M(v) \int_{n\cdot w>0} a(x,\tfrac{x}{\varepsilon},w)\, f(x,y,w,t)\, dw \quad \text{for } n\cdot v \le 0 \text{ and } (x,y)^T \in \Gamma_\varepsilon,$$

where $a(x,\frac{x}{\varepsilon},w) \ge 0$ denotes a given function, and n is the unit outward normal vector on the surface Γ_ε. This boundary condition reflects a pseudo–steady-state assumption, that is, the deposition of molecules on the surface progresses several orders of magnitude more slowly than the flow of the rarefied gas; therefore neither the functions $a(x,\frac{x}{\varepsilon},w)$ nor the geometry of the surface $y=\tilde{h}(x)$ depends on the time t of the gas flow under consideration. However, they are certainly allowed to depend on x; that is, different regions of the surface can see different deposition conditions; this is important in actual applications.

The model in its present form with a microstructured surface is not numerically tractable because of the high cost of resolving the domain close to the rough surface Γ_ε. The goal of this work is to obtain a model with a reduced boundary condition on a flat surface Γ_0 given by $y=0$ that gives equivalent results for $f(x,y,v,t)$ in the bulk of the gaseous domain away from the surface in an asymptotic sense using the expansion parameter ε.

To this end, we make the ansatz

$$f(x,y,v,t) = \tilde{f}(x,y,v,t) + \hat{f}(\tfrac{x}{\varepsilon},\tfrac{y}{\varepsilon},\tfrac{t}{\varepsilon},x,v,t) + o(1), \tag{1.11}$$

where $\tilde{f}$ denotes the bulk variable, for which we wish to derive a numerically tractable model, and $\hat{f}$ is the small-scale correction, which is assumed to be periodic in $\xi = \frac{x}{\varepsilon}$ in the same way as the surface function $h(x,\xi)$. There is only one scale for the velocity v of the molecules; hence there have to be pairs of corresponding length and time scales on both the long (x and t) and the short scales ($\xi = \frac{x}{\varepsilon}$ and $\tau = \frac{t}{\varepsilon}$). Note that we have assumed the Knudsen number to be of order $O(1)$ in the bulk of the mesoscopic scale model, whose solution is $f(x,y,v,t)$. This means that on the $O(\varepsilon)$ spatial scale, the feature scale, collisions will be negligible, and we obtain free transport inside the features of the surface. Therefore, due to the hyperbolic nature of the Boltzmann equation, we can assume only that $\hat{f}$ decays weakly with ε at any fixed distance from the surface; that is, we assume that small-scale fluctuations in the inner solution $\hat{f}$ average out to zero at any fixed finite distance above the surface as $\varepsilon \to 0$. That is, we require that

$$\lim_{\varepsilon\to 0} \iint \hat{f}(\tfrac{x}{\varepsilon},\tfrac{y}{\varepsilon},\tfrac{t}{\varepsilon},x,v,t)\, \psi(x,t)\, dx\, dt = 0 \tag{1.12}$$

for all test functions $\psi(x,t)$.

Based on these assumptions, we will derive the appropriate reduced boundary condition for the bulk term $\tilde{f}(x,y,v,t)$ on the *flat* surface $y=0$

$$\tilde{f}(x,y,v,t) = M(v) \int \tilde{a}(x,v,w)\, \tilde{f}(x,y,w,t)\, dw \quad \text{for } v_3 > 0 \text{ and } y = 0, \tag{1.13}$$

where the integral kernel $\tilde{a}(x,v,w)$ incorporates the information about the microscopic surface geometry into the flow equations. This problem is tractable numerically, since it is posed on a domain with a flat reacting surface, and the values of $\tilde{a}(x,v,w)$ can be

precomputed for all times, since $\tilde{a}$ does not depend on the macroscopic time t. This effective boundary condition still reflects the assumption of a pseudo–steady state in the original model, because $\tilde{a}$ does not depend on the time t that is the relevant time scale for the gas flow on the mesoscopic scale.

We remark that in the previous work [2, 5, 6, 8, 11], where the flow was assumed to be Maxwellian inside the features as well, the only information needed about the surface geometry was the ratio of surface areas between the microstructured surface and the flat surface. This ratio is now replaced by the integral kernel $\tilde{a}$, which contains much more information about the actual shape of the surface and is necessary for the non-Maxwellian picture. This approach has to be viewed as an alternative to the work presented in [1], which deals with specular reflections on a random surface, as opposed to random reflections on a deterministic surface. The result is, however, quite different for the obvious reason that we allow for absorption into the surface; i.e., in our resulting homogenized problem the total mass inside the gas phase domain will not be conserved.

Section 2 details the analytical derivation of the reduced boundary condition, where we will restrict ourselves to the two-dimensional case for notational simplicity. The generalization to three dimensions is straightforward. Section 3 provides a numerical demonstration of the result for a setup that closely resembles the structure of the application problem under consideration by using a periodic boundary geometry.

2. Analysis. This section considers the two-dimensional linear Boltzmann equation

$$\frac{\partial f}{\partial t} + v_1 \frac{\partial f}{\partial x} + v_2 \frac{\partial f}{\partial y} = Q(f) \tag{2.1}$$

with boundary condition (1.10) at the reacting wafer surface. Note that we have changed the notation slightly in going to a two-dimensional problem: The gas phase domain is now given by $y > \varepsilon\, h(x, \frac{x}{\varepsilon})$, and molecules travel towards the surface for velocities $v = (v_1, v_2)^T$ with $v_2 < 0$. We introduce the surface density ρ as

$$\rho(\tfrac{x}{\varepsilon}, \tfrac{t}{\varepsilon}, x, t) = \int_{n\cdot w \geq 0} a(x, \tfrac{x}{\varepsilon}, w) \left(\tilde{f}(x, 0, w, t) + \hat{f}(\tfrac{x}{\varepsilon}, h(x, \tfrac{x}{\varepsilon}), \tfrac{t}{\varepsilon}, x, w, t) \right) dw + o(1) \tag{2.2}$$

for the integral on the right-hand side of (1.10). Using the ansatz $f = \tilde{f} + \hat{f} + o(1)$, the boundary condition (1.10) then reads

$$\tilde{f}(x, 0, v, t) + \hat{f}(\xi, h(x, \xi), \tau, x, v, t) = M(v)\, \rho(\xi, \tau, x, t) + o(1) \quad \text{for } \sigma \leq 0, \tag{2.3}$$

using also the shorthand notation $\sigma(x, \xi, v) = n \cdot v = v_1 \partial_\xi h(x, \xi) - v_2 + \mathcal{O}(\varepsilon)$. Here we have already replaced the argument $y = \varepsilon\, h(x, \xi)$ by 0 in the evaluation of $\tilde{f}$ at the boundary. The homogenized boundary condition (1.13) on the limiting flat surface $y = 0$ will be as derived follows.

Tracing back the characteristics, we will first solve the boundary layer problem for the inner solution $\hat{f}$ in terms of boundary data consisting of the outer solution $\tilde{f}$ and the boundary density ρ defined in (2.2). This result is given in Theorem 2.2 in subsection 2.1. The surface density ρ involves both the inner and the outer solutions and forms the connection between them. Its behavior in the limit of the fast time variables $\tau \to \infty$ is analyzed in Theorem 2.4.

In subsection 2.2, using the weak decay condition (1.12), we derive the homogenized boundary condition for $\tilde{f}$ on the flat surface $y = 0$ in terms of the surface density ρ and finally in terms of $\tilde{a}$ as in (1.13). This quantity will contain only information about the microscopic and quasi-periodic geometry of the surface and can be solved beforehand for a given surface structure.

2.1. Solution to the inner equation. The asymptotic ansatz applied to (2.1) leads to the inner problem for the layer correction term $\hat{f}(\xi, \eta, \tau, x, v, t)$ as a function of the layer variables ξ, η, τ:

$$\frac{\partial \hat{f}}{\partial \tau} + v_1 \frac{\partial \hat{f}}{\partial \xi} + v_2 \frac{\partial \hat{f}}{\partial \eta} = 0 \tag{2.4}$$

for any fixed x, v, t. Using the method of characteristics with $\xi' = v_1$ and $\eta' = v_2$ yields

$$\hat{f}(\xi, \eta, \tau, x, v, t) = \hat{f}(\xi - sv_1, \eta - sv_2, \tau - s, x, v, t)$$

for all parameters s sufficiently small. We can then follow the characteristics back to the boundary or back to the initial condition $\hat{f} = 0$ at $\tau = 0$ to obtain

$$\begin{aligned} &\hat{f}(\xi, \eta, \tau, x, v, t) \\ &\quad = \hat{f}(\xi - v_1 s, \eta - v_2 s, \tau - s, x, v, t) \\ &\quad = \begin{cases} \hat{f}(\xi - v_1\phi_0, \eta - v_2\phi_0, \tau - \phi_0, x, v, t) & \text{if } \phi_0 < \tau, \\ 0 & \text{if } \phi_0 \geq \tau \end{cases} \\ &\quad = H(\tau - \phi_0)\, \hat{f}(\xi - v_1\phi_0, \eta - v_2\phi_0, \tau - \phi_0, x, v, t), \end{aligned} \tag{2.5}$$

with

$$\phi_0(\xi, \eta, x, v) = \begin{cases} \min\{s > 0 \,:\, \eta - v_2 s = h(x, \xi - v_1 s)\}, \\ \infty \quad \text{if } \eta - v_2 s \neq h(x, \xi - v_1 s) \text{ for all } s > 0, \end{cases} \tag{2.6}$$

and using the Heaviside function

$$H(z) = \begin{cases} 0 & \text{for } z < 0, \\ 1 & \text{for } z \geq 0. \end{cases}$$

The function ϕ_0 denotes the intersection time, i.e., the time it takes for a molecule emitted from the surface with velocity v to reach the point (ξ, η). The boundary condition for the inner equation then reads

$$\hat{f}(\xi, h(x, \xi), \tau, x, v, t) = M(v)\, \rho(\xi, \tau, x, t) - \tilde{f}(x, 0, v, t) \quad \text{for } \sigma(x, \xi, v) \leq 0. \tag{2.7}$$

In order to apply the boundary condition to the solution in (2.5), we need to guarantee that $\sigma(x, \xi - v_1\phi_0, v) \leq 0$ in the case when the characteristic traces back to the boundary, i.e., ϕ_0 is finite.

LEMMA 2.1. *If $\phi_0(\xi, \eta, x, v)$ is finite and* either (i) $\eta = h(x, \xi)$ *and* $\sigma(x, \xi, v) > 0$ or (ii) $\eta > h(x, \xi)$, *then it holds that* $\sigma(x, \xi - v_1\phi_0, v) \leq 0$.

Proof. Define

$$g(s) = \eta - sv_2 - h(x, \xi - sv_1).$$

By definition of ϕ_0, the first positive root of $g(s)$ is given by $s = \phi_0$. Then

$$g'(s) = -v_2 + v_1 \partial_\xi h(x, \xi - s v_1) = \sigma(x, \xi - s v_1, v),$$

and we have to show that $g'(\phi_0) = \sigma(x, \xi - v_1 \phi_0, v) \leq 0$.

Case (i). If $\eta = h(x, \xi)$ and $\sigma(x, \xi, v) > 0$, then

$$g(0) = 0, \quad g'(0) > 0 \quad \Rightarrow \quad g(s) > 0 \quad \text{for } 0 < s < \phi_0(\xi, \eta, x, v) \quad \Rightarrow \quad g'(\phi_0) \leq 0.$$

Case (ii). If $\eta > h(x, \xi)$, then

$$g(0) > 0 \quad \Rightarrow \quad g(s) > 0 \quad \text{for } s < \phi_0(\xi, \eta, x, v), \quad g(\phi_0) = 0 \quad \Rightarrow \quad g'(\phi_0) \leq 0. \qquad \square$$

THEOREM 2.2. *The solution $\hat{f}(\xi, \eta, \tau, x, v, t)$ to the inner problem* (2.4) *with boundary condition* (2.7) *and initial condition $\hat{f} = 0$ at $\tau = 0$ is given by*

$$\hat{f}(\xi, \eta, \tau, x, v, t) = \begin{cases} M(v)\rho(\xi, \tau, x, t) - \tilde{f}(x, y = 0, v, t) \\ \qquad \textit{if } \eta = h(x, \xi) \textit{ and } \sigma(x, \xi, v) \leq 0, \\ H(\tau - \phi_0)(M(v)\rho(\xi - v_1\phi_0, \tau - \phi_0, x, t) - \tilde{f}(x, y = 0, v, t)) \\ \qquad \textit{if (i) } \eta = h(x, \xi) \textit{ and } \sigma(x, \xi, v) > 0 \text{ or (ii) } \eta > h(x, \xi), \end{cases}$$

with the intersection time ϕ_0 given by (2.6).

Proof. Define the characteristics

$$g(s, \xi, \eta, \tau, x, v, t) := \hat{f}(\xi - s v_1, \eta - s v_2, \tau - s, x, v, t);$$

then $dg/ds = 0$. Follow the characteristics in four possible cases, as follows.

Case 1. If $\eta > h(x, \xi)$ and the line $(\xi - s v_1, \eta - s v_2, \tau - s)$ intersects $\tau = 0$ first $(\tau < \phi_0(\xi, \eta, x, v))$, then

$$\hat{f}(\xi, \eta, \tau, x, v, t) = \hat{f}(\xi - \tau v_1, \eta - \tau v_2, \tau = 0, x, v, t) = 0.$$

Case 2. If $\eta > h(x, \xi)$ and the line $(\xi - s v_1, \eta - s v_2, \tau - s)$ intersects $\eta = h(x, \xi)$ first $(\tau > \phi_0(\xi, \eta, x, v))$, then

$$\hat{f}(\xi, \eta, \tau, x, v, t) = \hat{f}(\xi - v_1\phi_0, \eta - v_2\phi_0, \tau - \phi_0, x, v, t), \quad \phi_0 = \phi_0(\xi, \eta, x, v).$$

Then $\eta - v_2\phi_0(\xi, \eta, x, v) = h(x, \xi - v_1\phi_0(\xi, \eta, x, v))$, and hence

$$\hat{f}(\xi, \eta, \tau, x, v, t) = M(v)\rho(\xi - v_1\phi_0, \tau - \phi_0, x, t) - \tilde{f}(x, 0, v, t),$$

because $\sigma(x, \xi - \phi_0 v_1, v) \leq 0$ by Lemma 2.1.

Case 3. If $\eta = h(x, \xi)$ and $\sigma(x, \xi, v) \leq 0$ (boundary condition), then

$$\hat{f}(\xi, h(x, \xi), \tau, x, v, t) = M(v)\rho(\xi, \tau, x, t) - \tilde{f}(x, 0, v, t).$$

Case 4. If $\eta = h(x, \xi)$ and $\sigma(x, \xi, v) > 0$, then follow the ray $(\xi - s v_1, \eta - s v_2, \tau - s)$ back until either $\tau - s = 0$ or $\eta - s v_2 = h(x, \xi - s v_1)$. We distinguish the following two subcases.

(a) If $\eta = h(x, \xi)$ and $\sigma(x, \xi, v) > 0$ and $\tau < \phi_0(\xi, \eta, x, v)$ (that is, $\tau = 0$ is intersected first), then

$$\hat{f}(\xi, \eta, \tau, x, v, t) = \hat{f}(\xi - \tau v_1, h - \tau v_2, \tau = 0, x, v, t) = 0.$$

(b) If $\eta = h(x,\xi)$ and $\sigma(x,\xi,v) > 0$ and $\tau > \phi_0(\xi,\eta,x,v)$ (that is, $\eta = h(x,\xi)$ is intersected first), then

$$\hat{f}(\xi,\eta,\tau,x,v,t) = \hat{f}(\xi - v_1\phi_0, h - v_2\phi_0, \tau - \phi_0, x, v, t),$$
$$\phi_0 = \phi_0(\xi, h(x,\xi), x, v),$$

and

$$\hat{f}(\xi,\eta,\tau,x,v,t) = M(v)\rho(\xi - v_1\phi_0, \tau - \phi_0, x, t) - \tilde{f}(x,0,v,t),$$

because $\sigma(x, \xi - \phi_0 v_1, v) \le 0$ by Lemma 2.1. □

We now turn to the evolution of the surface density ρ defined in (2.2). On the one hand, according to (2.2), ρ is defined in terms of $\tilde{f}$ and $\hat{f}$ evaluated at the surface $y = \varepsilon\, h(x, \frac{x}{\varepsilon})$. On the other hand, according to Theorem 2.2, the inner solution $\hat{f}$ at the surface is given in terms of ρ and $\tilde{f}$. Combining these two formulas, we are able to write an evolution equation for ρ in terms of the outer solution $\tilde{f}$ alone. In other words, we are able to write $\rho = F[\tilde{f}]$ with some integral operator to be defined. Moreover, for the computation of the reduced boundary condition (1.13), we will need to make a statement about the behavior of $\rho(\xi,\tau,x,t)$ for the fast time variable $\tau \to \infty$. To this end, it is convenient to make the following definitions. First we introduce for convenience a new symbol for the function ϕ_0 in Theorem 2.2 evaluated at the boundary by defining $\phi_1(\xi,x,v) := \phi_0(\xi, h(x,\xi), x, v)$, that is,

$$\phi_1(\xi,x,v) = \begin{cases} \min\{s > 0 \,:\, h(x,\xi) - v_2 s = h(x, \xi - v_1 s)\}, \\ \infty \quad \text{if } h(x,\xi) - v_2 s \neq h(x,\xi - v_1 s) \text{ for all } s > 0. \end{cases} \tag{2.8}$$

The function ϕ_1 denotes the time taken by molecules emitted from the boundary to reach another point at the boundary, and is formally set to ∞ if they never do. Furthermore, we define the indicator function on the set of all ξ, x, v for which, formally, ϕ_1 is infinite:

$$\chi(\xi,x,v) = \begin{cases} 0 & \text{if } \phi_1(\xi,x,v) < \infty, \\ 1 & \text{if } \phi_1(\xi,x,v) = \infty. \end{cases} \tag{2.9}$$

To analyze the limiting behavior of the surface density ρ as $\tau \to \infty$ we will need that the corresponding limiting problem actually has a solution. This is the statement of the following lemma.

LEMMA 2.3. *The integral equation*

$$Z(\xi,x) = g(\xi,x) + \int H(\sigma(x,\xi,w))a(x,\xi,w)\,(1 - \chi(\xi,x,w))\,M(w)\,Z(\xi - w_1\phi_1(\xi,x,w), x)\,dw$$

has a solution $Z(\xi,x)$ for any function $g(\xi,x)$, provided that

$$\int H(\sigma(x,\xi,w))a(x,\xi,w)\,(1 - \chi(\xi,x,w))\,M(w)\,dw \le C \tag{2.10}$$

for some constant $0 \le C < 1$.

Proof. Introduce the notation

$$A(x,\xi,w) := H(\sigma(x,\xi,w))a(x,\xi,w)\,(1 - \chi(\xi,x,w))\,M(w),$$

which satisfies $A(x,\xi) \geq 0$ since $a(x,\xi,w)$ and all other terms are nonnegative. Then we consider the integral equation

$$Z(\xi,x) = \int A(x,\xi,w)\, Z(\xi - w_1\phi_1(\xi,x,w),x)\, dw + g(\xi,x).$$

To compute the solution iteratively, introduce the fixed-point iteration for $\{Z_n(\xi,x)\}$ by

$$Z_{n+1}(\xi,x) = \int A(x,\xi,w)\, Z_n(\xi - w_1\phi_1(\xi,x,w),x)\, dw + g(\xi,x) \quad \text{for } n = 0,1,2,\ldots,$$

with initial iterate $Z_0(\xi,x) = 0$. Hence, the difference between successive iterates satisfies

$$(Z_{n+1} - Z_n)(\xi,x) = \int A(x,\xi,w)\ (Z_n - Z_{n-1})(\xi - w_1\phi_1(\xi,x,w),x)\, dw,$$

and we can bound it as

$$\|Z_{n+1} - Z_n\|_\infty \leq \int A(x,\xi,w)\, dw\, \|Z_n - Z_{n-1}\|_\infty.$$

The convergence of this sequence is guaranteed if condition (2.10) is satisfied. ∎

Remark 2.1. Condition (2.10) constitutes a restriction on the function $a(x,\xi,w)$ in the boundary condition chosen in the application. It will be verified in section 3 for our choice of $a(x,\xi,w)$.

THEOREM 2.4. *If $a(x,\xi,w)$ satisfies* (2.10)*, then the boundary density ρ is of the form*

$$\rho(\xi,\tau,x,t) = F_\infty[\tilde{f}](\xi,x,t) + \rho_1(\xi,\tau,x,t),$$

where $F_\infty[\tilde{f}] = \rho_\infty$ is given implicitly by the integral equation

$$\begin{aligned}\rho_\infty(\xi,x,t) = &\int H(\sigma(x,\xi,w))a(x,\xi,w)\chi(\xi,x,w)\, \tilde{f}(x,0,w,t)\, dw \\ &+ \int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))M(w)\, \rho_\infty(\xi - w_1\phi_1,x,t)\, dw,\end{aligned} \tag{2.11}$$

and the remainder term ρ_1 satisfies $\int_0^\infty \rho_1(\xi,\tau,x,t)\, d\tau < \infty$.

Proof. Inserting the expression for $\hat{f}(\xi,h(x,\xi),\tau,x,v,t)$ for $\sigma(x,\xi,v) > 0$ from Theorem 2.2 into the definition (2.2) for ρ gives

(2.12)

$$\begin{aligned}\rho(\xi,\tau,x,t) = &\int H(\sigma(x,\xi,w))a(x,\xi,w)\,[1 - H(\tau - \phi_1(\xi,x,w))]\ \tilde{f}(x,0,w,t)\, dw \\ &+ \int H(\sigma(x,\xi,w))a(x,\xi,w)H(\tau - \phi_1(\xi,x,w))M(w)\, \rho(\xi - w_1\phi_1,\tau - \phi_1,x,t)\, dw.\end{aligned}$$

We are interested in the limiting behavior for $\tau \to \infty$. To this end, we have to distinguish the cases when $\phi_1 < \infty$ holds, which means that the Heaviside function in (2.12) will become equal to unity for τ sufficiently large, and the case $\phi_1 = \infty$ for

which the Heaviside function will always be zero. Therefore we write

$$
\begin{aligned}
&\rho(\xi,\tau,x,t)\\
&\quad=\int H(\sigma(x,\xi,w))a(x,\xi,w)\left[1-(1-\chi(\xi,x,w))H(\tau-\phi_1(\xi,x,w))\right]\,\tilde{f}(x,0,w,t)\,dw\\
&\quad+\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))H(\tau-\phi_1(\xi,x,w))M(w)\\
&\qquad\qquad\times\rho(\xi-w_1\phi_1,\tau-\phi_1,x,t)\,dw,
\end{aligned}
\tag{2.13}
$$

with χ defined as in (2.9). Letting, formally, τ tend to infinity gives $\rho=\rho_\infty+\rho_1$ with (2.11) for $\rho_\infty(\xi,x,t)$. The solution ρ_∞ exists due to Lemma 2.3. This is, of course, only a formal definition for ρ_∞; the key is to estimate the remainder term ρ_1. The remainder term ρ_1 satisfies the integral equation

$$
\begin{aligned}
&\rho_1(\xi,\tau,x,t)\\
&\quad=\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))H(\tau-\phi_1(\xi,x,w))M(w)\\
&\qquad\qquad\times\rho_1(\xi-w_1\phi_1,\tau-\phi_1,x,t)\,dw\\
&\quad+\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))(1-H(\tau-\phi_1(\xi,x,w)))\\
&\qquad\qquad\times(\tilde{f}(x,0,w,t)-M(w)\rho_\infty(\xi-w_1\phi_1,x,t))\,dw.
\end{aligned}
\tag{2.14}
$$

Let $\mathcal{L}[\rho_1](\xi,s,x,t):=\int_0^\infty \rho_1(\xi,\tau,x,t)\,e^{-s\tau}\,d\tau$, with $0\le s<\infty$, denote the Laplace transform of ρ_1. The transform of (2.14) is then given by

$$
\begin{aligned}
&\mathcal{L}[\rho_1](\xi,s,x,t)\\
&\quad=\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))M(w)e^{-s\phi_1(x,\xi,w)}\\
&\qquad\qquad\times\mathcal{L}[\rho_1](\xi-w_1\phi_1,s,x,t)\,dw\\
&\quad+\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))\,\frac{1}{s}\,\left[1-e^{-s\phi_1(x,\xi,w)}\right]\\
&\qquad\qquad\times(\tilde{f}(x,0,w,t)-M(w)\rho_\infty(\xi-w_1\phi_1,x,t))\,dw.
\end{aligned}
$$

The variable s appears as a parameter only in the integral equation, so in order to find $\mathcal{L}[\rho_1](\xi,0,x,t)$, we can solve directly

$$
\begin{aligned}
&\mathcal{L}[\rho_1](\xi,0,x,t)\\
&\quad=\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))M(w)\,\mathcal{L}[\rho_1](\xi-w_1\phi_1,0,x,t)\,dw\\
&\quad+\int H(\sigma(x,\xi,w))a(x,\xi,w)(1-\chi(\xi,x,w))\,\frac{1}{\phi_1}\\
&\qquad\qquad\times(\tilde{f}(x,0,w,t)-M(w)\rho_\infty(\xi-w_1\phi_1,x,t))\,dw.
\end{aligned}
\tag{2.15}
$$

By Lemma 2.3, the solution $\mathcal{L}[\rho_1](\xi,0,x,t)$ exists, and we therefore have

$$
\int_0^\infty \rho_1(\xi,\tau,x,t)\,d\tau=\mathcal{L}[\rho_1](\xi,0,x,t)<\infty
$$

by definition of the transform. □

Remark 2.2. Theorem 2.4 establishes the limiting behavior of ρ for $\tau \to \infty$ in a weak sense, namely, that $\rho_1(\xi, \frac{t}{\varepsilon}, x, t)$ will go to zero when integrated with respect to t against a test function. This is precisely the property that will be needed for the derivation of the boundary condition.

2.2. Boundary condition for the outer solution. This subsection will use the weak convergence property for the inner solution to derive the boundary condition for the outer solution. Because the layer equation (2.4) does not have any damping, $\hat{f}$ will give a contribution throughout the half-space $y > 0$. However, this contribution will result in high frequency oscillations only for $y > 0$. Therefore, we formulate the Boltzmann equation in the weak sense and require that $\hat{f}$ tend to zero weakly for fixed $y > 0$ and $\varepsilon \to 0$. Thus, we require in a weak sense for y, v fixed that

$$\lim_{\varepsilon \to 0} \int_0^\infty \int_{-\infty}^{+\infty} \hat{f}\left(\tfrac{x}{\varepsilon}, \tfrac{y}{\varepsilon}, \tfrac{t}{\varepsilon}, x, v, t\right) \psi(x,t)\, dx\, dt = 0 \tag{2.16}$$

for all test functions $\psi(x,t)$.

THEOREM 2.5. *The integral in* (2.16) *goes to zero for* $\varepsilon \to 0$ *and all fixed* $y > 0$, v *if and only if*

$$\tilde{f}(x,0,v,t) = M(v) \int_0^1 F_\infty[\tilde{f}](\xi - v_1\phi_3, x, t)\, d\xi \quad \textit{for all } v_2 > 0$$

holds with

$$\phi_3(\xi, x, v) = \min\{s \in \mathbb{R} : -v_2 s = h(x, \xi - v_1 s)\}$$

and the operator $F_\infty[\tilde{f}]$ *defined as in Theorem* 2.4.

Proof. Let $I_\varepsilon := \iint \hat{f}(\frac{x}{\varepsilon}, \frac{y}{\varepsilon}, \frac{t}{\varepsilon}, x, v, t)\, \psi(x,t)\, dx\, dt$ denote the integral in (2.16). We need to estimate I_ε for velocities v with $v_2 > \kappa(\varepsilon)$, where κ is some function with $\kappa(\varepsilon) > 0$ and $\kappa(\varepsilon) \to 0$ as well as $\varepsilon/\kappa(\varepsilon) \to 0$ as $\varepsilon \to 0$. Since we are interested in the bulk solution $\tilde{f}(x, y, v, t)$, we need to consider only $\eta = \frac{y}{\varepsilon} > h(x, \frac{x}{\varepsilon})$.

We have from Theorem 2.2 for $\frac{y}{\varepsilon} > h(x, \frac{x}{\varepsilon})$ and $v_2 > \kappa(\varepsilon) > 0$

$$\hat{f}(\tfrac{x}{\varepsilon}, \tfrac{y}{\varepsilon}, \tfrac{t}{\varepsilon}, x, v, t) = H(\tfrac{t}{\varepsilon} - \phi_0)\Big(M(v)\rho(\tfrac{x}{\varepsilon} - v_1\phi_0, \tfrac{t}{\varepsilon} - \phi_0, x, t) - \tilde{f}(x, 0, v, t)\Big),$$

with $\phi_0(\frac{x}{\varepsilon}, \frac{y}{\varepsilon}, x, v) = \min\big\{s > 0 : \frac{y}{\varepsilon} - v_2 s = h(x, \frac{x}{\varepsilon} - v_1 s)\big\}$, where this simplified (compared to (2.6)) definition for ϕ_0 is possible because the existence of the minimum is guaranteed for $v_2 > \kappa(\varepsilon) > 0$. To transform

$$\phi_0(\tfrac{x}{\varepsilon}, \tfrac{y}{\varepsilon}, x, v) = \frac{y}{v_2\varepsilon} + \phi_2(\tfrac{x}{\varepsilon} - \tfrac{v_1 y}{v_2 \varepsilon}, \tfrac{y}{\varepsilon}, x, v),$$

define

$$\phi_2(\tfrac{x}{\varepsilon} - \tfrac{v_1 y}{v_2\varepsilon}, \tfrac{y}{\varepsilon}, x, v) = \min\left\{s > -\frac{y}{v_2\varepsilon} \,:\, -v_2 s = h(x, \tfrac{x}{\varepsilon} - \tfrac{v_1 y}{v_2\varepsilon} - v_1 s)\right\}. \tag{2.17}$$

This gives

$$\begin{aligned}&\hat{f}(\tfrac{x}{\varepsilon}, \tfrac{y}{\varepsilon}, \tfrac{t}{\varepsilon}, x, v, t)\\ &= H(\tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2)\left(M(v)\rho(\tfrac{x}{\varepsilon} - \tfrac{v_1 y}{v_2\varepsilon} - v_1\phi_2, \tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2, x, t) - \tilde{f}(x, 0, v, t)\right),\end{aligned}$$

with $\phi_2 \equiv \phi_2(\frac{x}{\varepsilon} - \frac{v_1 y}{v_2 \varepsilon}, \frac{y}{\varepsilon}, x, v)$ for $v_2 > \kappa(\varepsilon)$.

We introduce the transformation

$$x = x_{j\xi} := \frac{v_1}{v_2} y + \varepsilon j + \varepsilon \xi, \quad j \in \mathbb{Z}, \quad \xi \in [0,1],$$

to rewrite I_ε into

$$I_\varepsilon = \varepsilon \sum_{j=-\infty}^{+\infty} \int_0^\infty \int_0^1 H(\tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2)\Big(M(v)\rho(j + \xi - v_1\phi_2, \tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2, x_{j\xi}, t) - \tilde{f}(x_{j\xi}, 0, v, t)\Big)\, \psi(x_{j\xi}, t)\, d\xi\, dt,$$

with $\phi_2 \equiv \phi_2(j + \xi, \frac{y}{\varepsilon}, x_{j\xi}, v) = \min\{s > -\frac{y}{v_2\varepsilon} \,:\, -v_2 s = h(x_{j\xi}, j + \xi - v_1 s)\}$. Because $h(x,\xi)$ and hence also ρ and ϕ_2 are 1-periodic in ξ, we can drop the j from their first arguments. Since ρ, $\tilde{f}$, and ψ vary only slowly in x and since ξ varies only in $[0,1]$, we make an $\mathcal{O}(\varepsilon)$ perturbation by replacing $x_{j\xi}$ by $x_j := \frac{v_1}{v_2} y + \varepsilon j$. Together this gives

$$I_\varepsilon = \varepsilon \sum_{j=-\infty}^{+\infty} \int_0^\infty \int_0^1 H(\tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2)\Big(M(v)\rho(\xi - v_1\phi_2, \tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2, x_j, t) - \tilde{f}(x_j, 0, v, t)\Big)\, \psi(x_j, t)\, d\xi\, dt + \mathcal{O}(\varepsilon),$$

with $\phi_2 \equiv \phi_2(\xi, \frac{y}{\varepsilon}, x_j, v) = \min\{s > -\frac{y}{v_2\varepsilon} \,:\, -v_2 s = h(x_j, \xi - v_1 s)\}$. The sum over the j forms a Riemann sum for an integral with approximation error $\mathcal{O}(\varepsilon)$. Thus, we obtain

(2.18)
$$I_\varepsilon = \int_0^\infty \int_{-\infty}^{+\infty} \int_0^1 H(\tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2)\Big(M(v)\rho(\xi - v_1\phi_2, \tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2, z, t) - \tilde{f}(z, 0, v, t)\Big)\, \psi(z, t)\, d\xi\, dz\, dt + \mathcal{O}(\varepsilon),$$

with $\phi_2 \equiv \phi_2(\xi, \frac{y}{\varepsilon}, z, v) = \min\{s > -\frac{y}{v_2\varepsilon} \,:\, -v_2 s = h(z, \xi - v_1 s)\}$.

Now we replace $\rho = \rho_\infty + \rho_1$ with $F_\infty[\tilde{f}] = \rho_\infty$, as defined in Theorem 2.4. For the remainder term involving ρ_1 this gives

$$E_\varepsilon := \int_0^\infty \int_{-\infty}^{+\infty} \int_0^1 H(\tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2) M(v) \rho_1(\xi - v_1\phi_2, \tfrac{t}{\varepsilon} - \tfrac{y}{v_2\varepsilon} - \phi_2, z, t) \times \psi(z, t)\, d\xi\, dz\, dt.$$

We transform again to a fast variable $\tau := \frac{t}{\varepsilon} - \frac{y}{v_2\varepsilon} - \phi_2$ and obtain

$$E_\varepsilon = \varepsilon M(v) \int_0^\infty \int_{-\infty}^{+\infty} \int_0^1 \rho_1(\xi - v_1\phi_2, \tau, z, \tfrac{y}{v_2} + \varepsilon\tau + \varepsilon\phi_2) \times \psi(z, \tfrac{y}{v_2} + \varepsilon\tau + \varepsilon\phi_2)\, d\xi\, dz\, d\tau.$$

Since the test function ψ is smooth and has compact support, and since Theorem 2.4 guarantees that $\int_0^\infty \rho_1(\xi - v_1\phi_2, \tau, z, t)\, d\tau$ is bounded, the integrals in E_ε remain bounded, and $E_\varepsilon \to 0$, as $\varepsilon \to 0$.

In the remaining parts of (2.18), we use the fact that the Heaviside function is scaling-invariant to get $H(\frac{t}{\varepsilon} - \frac{y}{v_2\varepsilon} - \phi_2) = H(t - \frac{y}{v_2} - \varepsilon\phi_2)$. From the definition (2.17) of ϕ_2 it follows that, for $v_2 > \kappa(\varepsilon) > 0$, $|\phi_2| \leq \max\{h\}/\kappa(\varepsilon)$ holds. Therefore, the dependence of the Heaviside function on $\varepsilon\phi_2$ is negligible, and it can be taken out of the ξ-integral, introducing only another $\mathcal{O}(\frac{\varepsilon}{\kappa})$ error. Also, the integrand involving $\tilde{f}$ does not depend on the fast variable ξ any more, and so the integration over the interval $[0,1]$ yields just unity. This gives after $\varepsilon \to 0$

(2.19)
$$0 = \int_0^\infty \int_{-\infty}^{+\infty} H(t - \tfrac{y}{v_2}) \left(M(v) \int_0^1 \rho_\infty(\xi - v_1\phi_2, z, t)\, d\xi - \tilde{f}(z, 0, v, t) \right) \psi(z, t)\, dz\, dt$$

for any fixed $v_2 > 0$. Taking the limit $\varepsilon \to 0$ in $\phi_2 \equiv \phi_2(\xi, \frac{y}{\varepsilon}, z, v) = \min\{s > -\frac{y}{v_2\varepsilon} : -v_2 s = h(z, \xi - v_1 s)\}$ results in the minimum being taken over the entire real line, since $y > 0$ and $v_2 > 0$. It also makes ϕ_2 independent of ε and y, and we introduce the notation

$$\phi_3 \equiv \phi_3(\xi, z, v) = \min\{s \in \mathbb{R} : -v_2 s = h(z, \xi - v_1 s)\}.$$

Therefore, (2.19) is satisfied in a weak sense if and only if

$$\tilde{f}(z, 0, v, t) = M(v) \int_0^1 \rho_\infty(\xi - v_1\phi_3, z, t)\, d\xi$$

holds for all z, v, t with $v_2 > 0$. ∎

Remark 2.3. For any fixed velocity v with $v_2 > 0$, the function ϕ_3 is guaranteed to exist with $-\max\{h(x,\xi)\}/v_2 \leq \phi_3(\xi, x, v) \leq -\min\{h(x,\xi)\}/v_2$, since the surface function $h(x, \xi)$ is smooth.

Theorem 2.5 essentially yields the reduced boundary condition. In practice, one will not solve the integral equation (2.11) to compute $F_\infty[\tilde{f}]$ at every time step. It is preferable to write the term $F_\infty[\tilde{f}]$ as an integral operator with a time independent integral kernel. A direct calculation leads from (2.11) to

$$F_\infty[\tilde{f}](\xi, x, t) = \int K_\infty(\xi, x, v)\, \tilde{f}(x, 0, v, t)\, dv,$$

where the integral kernel K_∞ satisfies

(2.20)
$$\begin{aligned} K_\infty(\xi, x, v) &= H(\sigma(x, \xi, v)) a(x, \xi, v) \chi(\xi, x, v) \\ &\quad + \int H(\sigma(x, \xi, w)) a(x, \xi, w)\, (1 - \chi(\xi, x, w))\, M(w)\, K_\infty(\xi - w_1\phi_1(\xi, x, w), x, v)\, dw, \end{aligned}$$

and $K_\infty(\xi, x, v)$ again exists because of Lemma 2.3. Note that K_∞ will be non-negative, provided that $a(x, \xi, w)$ is not too large.

In summary, we have obtained the following numerical problem for the bulk solution $\tilde{f}(x, y, v, t)$:

$$\frac{\partial \tilde{f}}{\partial t} + v_1 \frac{\partial \tilde{f}}{\partial x} + v_2 \frac{\partial \tilde{f}}{\partial y} = Q(\tilde{f}), \tag{2.21}$$

with boundary condition for inflowing molecules on the *flat* surface $y = 0$

$$\tilde{f}(x,0,v,t) = M(v) \int \tilde{a}(x,v,w)\tilde{f}(x,0,w,t)dw \quad \text{for } v_2 > 0, \tag{2.22}$$

with

$$\tilde{a}(x,v,w) := \int_0^1 K_\infty(\xi - v_1\phi_3(\xi,x,v),x,w)\, d\xi \tag{2.23}$$

and

$$\phi_3(\xi,x,v) = \min\{s \in \mathbb{R} : -v_2 s = h(x,\xi - v_1 s)\}. \tag{2.24}$$

This problem is tractable numerically, since it is posed on a domain with a flat reacting surface; the effect of the microscopic surface has been integrated into the boundary condition. The numerical approach in practice will be as follows.

Step 1. Given a surface function $h(x,\xi)$, compute the intersection times ϕ_1 in (2.8) and ϕ_3 in (2.24).

Step 2. Solve the integral equation (2.20) for K_∞.

Step 3. Compute the boundary kernel $\tilde{a}(x,v,w)$ in (2.23).

The function $\tilde{a}(x,v,w)$ provides the information about the microscopic surface geometry on the macroscopic level. These steps have to be performed only once for a given surface function $h(x,\xi)$. Following these preprocessing steps, the Boltzmann equation (2.21) with the homogenized boundary condition (2.22) is solved for the bulk solution $\tilde{f}(x,y,v,t)$.

3. Numerical validation. As a validation problem, we consider the linear Boltzmann equation for a single species

$$\frac{\partial f}{\partial t} + v_1 \frac{\partial f}{\partial x} + v_2 \frac{\partial f}{\partial y} = Q(f). \tag{3.1}$$

We use a relaxation time approximation $S(v,v') = (1/\tau)M(v)M(v')$ in the linear collision operator (1.6) to obtain the simple form

$$Q(f)(x,y,v,t) = -\frac{1}{\tau}\,[f(x,y,v,t) - N(x,y,t)\,M(v)]$$

with the constant relaxation time $\tau > 0$. Here and in the following, N denotes the number density given by $N(x,y,t) = \int f(x,y,v,t)\,dv$. The numerical domain is chosen as

$$\Omega_\varepsilon = \{(x,y) \in \mathbb{R}^2 : \tilde{h}(x) < y < 1, \quad 0 < x < 1\}, \tag{3.2}$$

with a microstructured surface Γ_ε at the bottom given by

$$y = \tilde{h}(x) = \frac{\varepsilon}{8}\left(1 + \cos\left(2\pi\frac{x}{\varepsilon}\right)\right)$$

with homogenization parameter $0 < \varepsilon \ll 1$. This model is designed to closely resemble the salient features of the application problem that motivated the model and to support the above analysis; this motivates also the choice of the simple form of the collision operator. Other types of boundary models, e.g., using random reflections [1], could be used but would not be appropriate examples for our application.

The following model is chosen as the boundary condition describing the reactions of the gaseous species at the wafer surface that result in the deposition of the solid film. If $0 \le R \le 1$ denotes the sticking factor (the probability that a molecule sticks to the surface), then the inflow into the gaseous domain is equal to $(1-R)$ times the outflow from the gaseous domain, namely (see [4]),

$$\int_{n\cdot v<0} |n\cdot v|\, f(x,y,v,t)\, dv = (1-R) \int_{n\cdot v>0} |n\cdot v|\, f(x,y,v,t)\, dv, \tag{3.3}$$

where $n = n(x,y)$ denotes the unit outward normal vector at position $(x,y) \in \Gamma_\varepsilon$. To obtain the boundary condition in the form (1.10), assume reinjection with random velocities, that is, $f(x,y,v,t) = b(x,t)M(v)$ for $n\cdot v < 0$; then

$$f(x,y,v,t) = M(v) \int_{n\cdot w>0} a\left(x, \frac{x}{\varepsilon}, w\right) f(x,w,t)\, dw,$$

with

$$a\left(x, \frac{x}{\varepsilon}, w\right) = \frac{1-R}{c} |n\cdot w|, \quad c = \int_{n\cdot v<0} |n\cdot v|\, M(v)\, dv.$$

The problem is completed by choosing Maxwellian inflow at the top and periodic boundary conditions at both sides. This chosen setup of the problem is representative of the application under consideration. We choose $\tau = 1$ and $R = 0.5$ as values.

To check condition (2.10) for this choice of $a(x, \frac{x}{\varepsilon}, w)$, we compute

$$\begin{aligned} I(x, \tfrac{x}{\varepsilon}) &:= \int H(\sigma(x, \tfrac{x}{\varepsilon}, w)) a(x, \tfrac{x}{\varepsilon}, w) \left(1 - \chi(\tfrac{x}{\varepsilon}, x, w)\right) M(w)\, dw \\ &= (1-R)\, \frac{\int_{n\cdot w>0} |n\cdot w| \left(1 - \chi(\frac{x}{\varepsilon}, x, w)\right) M(w)\, dw}{\int_{n\cdot v<0} |n\cdot v|\, M(v)\, dv}. \end{aligned}$$

Since $0 \le \chi \le 1$, the fraction is always bounded by 1, which is seen by using the transformation $w = -v$ in the denominator and using the symmetry of the Maxwellian in (1.4). In the case that $0 < R \le 1$, we have $1-R < 1$ and $I < 1$. In the limiting case $R = 0$, we can still conclude that $I < 1$, because χ does not vanish almost everywhere in reasonable situations in the application, and hence the fraction will be less than 1 except in pathological cases.

The problem was solved numerically by choosing an expansion in velocity space of the form following [14, 16, 19, 20, 21, 22] and the references therein,

$$f(x,y,v,t) = \sum_{k=1}^{K} f_k(x,y,t)\varphi_k(v),$$

where the $\{\varphi_k(v), k = 1,\dots,K\}$ form an orthogonal set of basis functions with respect to the inner product

$$\langle \varphi_k, \varphi_\ell \rangle = \int \varphi_k(v)\varphi_\ell(v)\omega(v)\, dv = \delta_{k\ell},$$

with weight function $\omega(v) = 1/M(v)$. The basis functions are chosen as Maxwellians multiplied by (properly transformed) Hermite polynomials. To arrive at a Gaussian quadrature for the integrals, the discretization points in velocity space are roots of appropriate Hermite polynomials.

A Galerkin discretization by inserting the expansion for f and forming inner products with all basis functions then leads to the system of hyperbolic equations for the expansion coefficients $F = (f_k)$

$$\frac{\partial F}{\partial t} + A^{(1)} \frac{\partial F}{\partial x} + A^{(2)} \frac{\partial F}{\partial y} = CF,$$

with the $K \times K$ matrices $A^{(1)}$, $A^{(2)}$, and C with components

$$A^{(1)}_{k,\ell} = \langle v_1 \varphi_\ell, \varphi_k \rangle , \quad A^{(2)}_{k,\ell} = \langle v_2 \varphi_\ell, \varphi_k \rangle , \quad C_{k,\ell} = \langle Q(\varphi_\ell), \varphi_k \rangle .$$

We actually use an equivalent collocation basis for the Hermite polynomials, which results in the matrices $A^{(1)}$ and $A^{(2)}$ being diagonal; see [10, 13, 23] for more details. This system is solved by a finite-difference method using first-order upwinding and explicit time-stepping. The solution on the homogenized domain

$$\Omega_0 = (0,1) \times (0,1) \tag{3.4}$$

is straightforward (that was the point of the homogenization). The comparison solution on the microstructured domain Ω_ε is obtained by transforming the domain to the unit square. The transformation is designed such that it is an identity in the upper half of the domain, i.e., for $y \geq 0.5$; this is done in order to facilitate the comparison of both numerical solutions there without incurring additional interpolation error from a mesh transformation.

We discretize the velocity space by six basis functions in both x- and y-directions, resulting in a hyperbolic system of 36 equations. The maximum velocity is bounded by 4 in each direction. Using $\Delta x = 1/128$ and $\Delta y = 1/64$, the CFL condition requires a time step of $\Delta t = 1/1024$, accounting for an additional factor of about 4 from the transformation of the domain. Solutions are computed until the final time $t_{fin} = 2$. We compute solutions $f(x, y, v, t)$ with number densities denoted by $N(x, y, t)$ on domains Ω_ε in (3.2), $\varepsilon = 1/4$, $1/8$, $1/16$, and $1/32$. The solution to the homogenized problem is computed on Ω_0 in (3.4) and denoted by $\tilde{f}(x, y, v, t)$, with number density $\tilde{N}(x, y, t)$. Smaller values do not yield reliable solutions for the grid spacing used in the x-direction.

Figures 3.1, 3.2, 3.3, and 3.4 show comparisons of the number density $\tilde{N}(x, y, t)$ at $T = t_{fin} = 2$ on the homogenized domain to the number density $N(x, y, t)$ on the microstructured domain with the indicated values of ε. The plots show the physical behavior of the flow: The reacting chemical is supplied at the top of the domain at $y = 1$, then moves towards the wafer surface at $y = \tilde{h}(x)$, where it gets partially consumed in the surface reaction. Notice that the oscillations of the solution are limited to a boundary layer close to the microstructured surface; this effect is attributable to the smoothing property of the collision operator; that is, the solution is smoother than could be theoretically expected.

Table 3.1 shows the errors between the densities $\tilde{N}(x, y, t)$ and $N(x, y, t)$ of the homogenized and the original problems for various values of ε. They are compared only across the upper half of the domain, i.e., for $y \geq 0.5$, by choosing the subdomain $\tilde{\Omega} = (0,1) \times (0.5, 1)$ in the norms

$$\|N\|_{L^1(\tilde{\Omega})} := \iint_{\tilde{\Omega}} |N(x, y, t)| \, dx \, dy$$

and

$$\|N\|_{L^\infty(\tilde{\Omega})} := \max_{(x,y) \in \tilde{\Omega}} |N(x, y, t)|$$

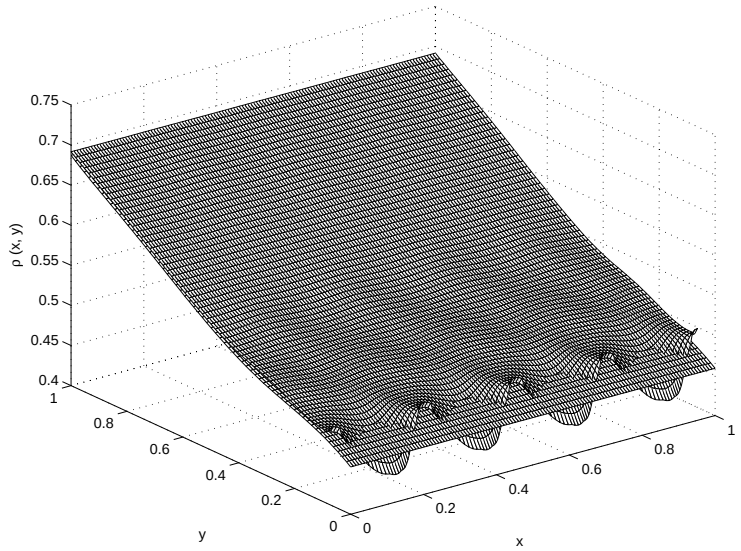

FIG. 3.1. *Comparison of the number densities on the homogenized and the microstructured domains with* $\varepsilon = 1/4$.

$\varepsilon=1/32$	9.0618e-06	1.5652e-05	4.4112e-05	2.1743e-03	8.8528e-03	8.8848e-03

in velocity space given by $v_1=-0.6167$ and v_2 as listed in the table. This quantity mimics the behavior of $\iint \tilde{f}\,\psi\,dx\,dt$ with $\psi\equiv 1$. Table 3.3 shows the corresponding relative quantity $I(\tilde{f}-f)(y,v,T)\,/\,I(f)(y,v,T)$ at the same values of T, y, and v. The convergence rate is not uniform for all velocities. For those components f_k that correspond to velocities pointing towards the wafer surface, i.e., with $v_2<0$, the main portion of the information travels from the given inflow condition, and convergence is good. For the other components corresponding to information traveling back up from the wafer surface, i.e., with $v_2>0$, both absolute and relative errors deteriorate somewhat.

NONLINEAR STABILITY OF A LATITUDINAL RING OF POINT-VORTICES ON A NONROTATING SPHERE*

STEFANELLA BOATTO† AND HILDEBERTO E. CABRAL‡

Abstract. We study the nonlinear stability of relative equilibria of configurations of identical point-vortices on the surface of a sphere. In particular, we study how the stability changes as a function of the colatitude θ and of the number of vortices N. By using the integrals of motion, we view the system in a suitable corotating frame where the polygonal vortex configuration is at rest. Then after a sufficient criterion due to Dirichlet, the stability ranges are the θ-intervals for which the Hessian of the Hamiltonian—evaluated at the equilibrium configuration—is positive or negative definite. We find that the stability intervals coincide with those for linear stability determined by Polvani and Dritschel [*J. Fluid Mech.*, 255 (1993), pp. 35–64]. For $N = 3$ we recover the result previously established by Pekarsky and Marsden [*J. Math. Phys.*, 39 (1998), pp. 5894–5907].

1. Introduction.

In this article, by using a very clear and simple method, we complete a stability analysis started by Thomson over a century ago [35, 36]. In 1883, while studying and modeling the atomic structure, Thomson investigated the *linear* stability of corotating point-vortices in the plane. In particular, his interest was in configurations of identical vortices equally spaced along the circumference of a circle, i.e., located at the vertices of a regular polygon. He proved that for six or fewer vortices the polygonal configurations are stable, while for seven vortices—the Thomson heptagon—he erroneously concluded that the configuration is slightly unstable [26]. It took more than a century to make some progress on this problem. In his Ph.D. thesis, Dritschel succeeded in solving the aspect of the heptagon mystery concerned with its linear stability analysis, leaving open the nonlinear stability question: he proved that the Thomson heptagon is neutrally stable and that for eight or more vortices the corresponding polygonal configurations are linearly unstable [13]. In 1993, Polvani and Dritschel generalized the techniques used in [13] to study the linear stability of a "latitudinal" ring of point vortices (see Figure 1) on the sphere [31], a more relevant problem from the atmospheric modeling point of view. They proved that polygonal configurations are more unstable on the sphere than in the plane. In particular, they showed that at the pole, for $N < 7$ the configuration is stable, for $N = 7$ it is neutrally stable, and for $N > 7$ it is unstable. The ranges of linear stability in the colatitude θ, as a function of N, are summarized in Table 1.

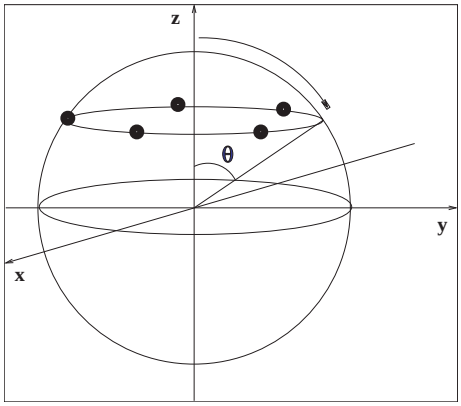

FIG. 1. *Latitudinal ring of point-vortices.*

TABLE 1
Regular polygonal configurations of N vortices. Stability ranges as a function of the colatitude θ and of the number of vortices N.

Number of vortices (N)	Colatitude (θ)
3	$0° \leq \theta \leq 90°$
4	$0° \leq \theta \leq 55°$
5	$0° \leq \theta \leq 45°$
6	$0° \leq \theta \leq 27°$
7	$\theta = 0°$

In 1998, Kidambi and Newton fully studied the motion of three vortices on the sphere and gave a geometrical interpretation of the conserved quantities [18]. By means of the energy momentum method (the Marsden–Meyer–Weistein reduction), Pekarsky and Marsden studied the nonlinear stability analysis for the integrable case of polygonal configurations of three vortices of arbitrary vorticities (k_1, k_2, and k_3) on the sphere, leaving open the stability analysis for nonintegrable vortex systems ($N > 3$) [30]. More recently Cabral and Schmidt completed the linear and nonlinear stability analysis at once for polygonal configurations in the plane [10], leaving untouched the analogous analysis on the sphere. They proved that for seven or fewer vortices the polygonal configurations are *nonlinearly* stable in the plane and, beyond that, they studied the stability of polygonal configurations of identical vortices of strength $k = 1$ and with a central vortex of arbitrary strength K (see Figure 2). They determined the range of stability as a function of K (see Table 2 and [10, Theorems 5.1 and 7.1]) to be

$$\begin{cases} (N^2 - 8N + 8)/16 < K < (N-1)^2/4 & \text{when } N \text{ is even,} \\ (N^2 - 8N + 7)/16 < K < (N-1)^2/4 & \text{when } N \text{ is odd.} \end{cases} \tag{1}$$

The stability of the heptagon, being still a special case, had to be studied by us-

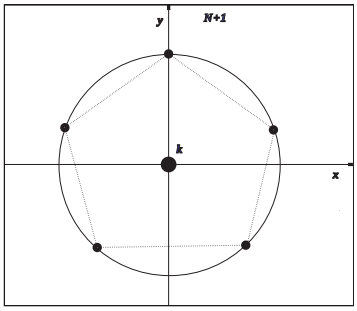

FIG. 2. *Centered pentagonal configuration.*

TABLE 2

Vortex configurations with N identical vortices at the vertices of a regular polygon plus a central vortex of strength K. As a function of N, intervals of vortex strength K assure nonlinear stability of the centered polygonal configurations.

Number of vortices (N)	Stability range for K (the strength of the central vortex)
3	$-0.5 < K < 1.00$
4	$-0.5 < K < 2.25$
5	$-0.5 < K < 4.00$
6	$-0.25 < K < 6.25$
7	$0 = K < 9$

ing normal form reduction and considering higher order terms in the Hamiltonian (see [10]).

In 2001, by means of group theory techniques, Lim, Montaldi, and Roberts exhaustively classified the relative equilibria of a system of identical point-vortices on a sphere [23]. In 2002, Laurent-Polz [21] studied the system formed by $2N$ point-vortices with N vortices of strength $+1$ and N vortices of strength -1. He proved the existence of some fixed and relative equilibria and studied their stability by means of the energy momentum method, as in [30]. Soulière and Tokieda extended the study of periodic vortex motion to various manifolds with symmetry [34], and Montaldi, Soulière, and Tokieda fully determined fixed and relative equilibrium configurations for vortices on the cylinder [25]. We would like to point out that many people are working in this area, both for its mathematical beauty and open questions, and for its great interest as a modeling problem for the vortex dynamics of the earth's atmosphere [26, 31, 11, 14]. We refer the reader to the nice book by Newton for a review on N-vortex dynamics [27] and to the article by H. Aref et al. for a quite complete and updated review on relative vortex configurations [3].

In this article we accomplish the stability analysis for integrable ($N = 3$) and nonintegrable ($3 < N \leq 7$) polygonal configurations of identical point-vortices on the sphere. We introduce a much simpler method than in [10, 30, 21] that at one stroke furnishes a complete linear and nonlinear analysis for the spherical case and that,

moreover, can easily be generalized to an analogous stability analysis for polygonal vortex configurations in other geometries [5, 8], including the planar case previously studied by Cabral and Schmidt [10]. More specifically, by using a *sufficient* criterion due to Dirichlet, we derive the stability ranges as θ-intervals for which the Hessian of the Hamiltonian—evaluated at the equilibrium configuration—is positive or negative definite. At this point we would like to remind the reader that, in general, linear and nonlinear stability ranges may not coincide. As is well known, a system can be linearly stable or unstable and nonlinearly stable or unstable; all four possibilities occur in practice [24, 33, 9]. As a result of our analysis we find that the nonlinear stability ranges (with the exception of the equator where other techniques need to be used to infer stability) coincide with the ranges of linear stability previously determined by Polvani and Dritschel (see Table 2).

Before ending this introduction we would like to make the following remarks:

(a) Relative equilibrium configurations are so called because the motion vanishes in an appropriate rotating frame. The study of such configurations was termed "vortex statics" by Kelvin in 1910 [17], who, with Thomson [35, pp. 94–108], found the relative equilibria of identical vortices. If all circulations have the same sign, relative equilibria are the only stationary configurations possible. Palmore [29] investigated this case and found that many relative equilibria must occur (for more details, see [28, 3]).

(b) When dealing with a system with integrable vortex dynamics (such as three-vortex systems) we can simply make a canonical reduction to a system of one degree of freedom. Therefore relative equilibrium configurations and their stability can be simply inferred by determining the maxima and the minima of the reduced vortex Hamiltonian. For a complete analysis, including the general case of vortices with different vorticities, and for further details about the global dynamics of integrable vortex systems, see Boatto and Laskar [6].

(c) By analogy with the planar case (see Figure 2 and Table 2), in a follow-up article [5] we are generalizing this nonlinear stability analysis to the case of latitudinal polygonal vortex configurations with vortices of strengths k_1 and k_2 at the poles. From the atmospheric dynamics point of view, the central vortex is a model for a polar vortex (southern or northern polar vortex), and "latitudinal" chains of point-vortices are models for planetary waves. Therefore this kind of analysis could help answer questions of the type: Does the presence of a Polar vortex (in the southern or in the northern hemisphere) favor the presence of waves (jets) at a given latitude? To show how the presence of a central polar vortex of strength K dramatically changes the stability ranges, at the end of section 3 we report the results of the stability analysis for the case $N = 3$, for which we obtain fully analytical expressions.

The article is organized as follows. In section 2 we derive the equations of motion, in particular the vortex Hamiltonian, and show the differences between the planar and the spherical cases. In section 3 we summarize the main results and the main tools for proving stability—the Dirichlet theorem on stability and a theorem on positive (negative) quadratic forms (see Gel´fand [15, Theorem 1, p. 49]). In section 4 we derive the stability ranges explicitly.

2. Equations of motion. The starting hypothesis for our derivation is that the fluid can be modeled as a *two-dimensional incompressible* fluid with constant density, i.e., a fluid whose velocity field verifies

$$\nabla \cdot \mathbf{u} = 0, \tag{2}$$

with $\mathbf{u} = (u_x, u_y, u_z) = (\dot{x}, \dot{y}, \dot{z})$. In atmospheric dynamics, a fluid verifying (2) represents the simplest fluid model, called the barotropic model [11]. We are particularly interested in characterizing the fluid dynamics for a given vorticity field, ω:

$$\omega = \nabla \times \mathbf{u}. \tag{3}$$

Regarding this, we notice that in two dimensions our task is simplified since we can recast the fluid equations into a Hamiltonian formalism. In fact, notice that on the plane $\mathbf{u} = (\dot{x}, \dot{y})$, and (2) is still verified if we represent the velocity components (see [19]) as

$$\dot{x} = \frac{\partial \Psi}{\partial y}, \qquad \dot{y} = -\frac{\partial \Psi}{\partial x}, \tag{4}$$

i.e., by means of Ψ, called the *stream function*. Formally Ψ plays the role of a Hamiltonian for the pair of conjugate variables (x, y). By substituting (4) into (3), we obtain

$$\Delta \Psi(\mathbf{r}) = \omega(\mathbf{r}), \tag{5}$$

i.e., a Poisson equation with ω as a source term. Then, once we specify the vorticity field, by inverting (5) we obtain the stream function Ψ as

$$\Psi(\mathbf{r}) = \iint G(\mathbf{r}, \mathbf{r}')\omega(\mathbf{r}) dA', \tag{6}$$

where $G(\mathbf{r}, \mathbf{r}')$ is the Green function. The Green function, both for the plane and for the sphere, is (see [11, 19])

$$G(\mathbf{r}, \mathbf{r}') = -\frac{1}{4\pi} \log \parallel \mathbf{r} - \mathbf{r}' \parallel^2 .$$

Then by (6), once we specify the vorticity field $\omega(\mathbf{r})$, we can compute Ψ, and by (4) we know the velocity field everywhere.

2.1. Point-vortices on the plane. In our specific case we are interested in the simplest of all vorticity fields: a system of point-vortices. A point-vortex can be thought of as an entity in which the vorticity is concentrated into a point. Therefore in the *plane* the vorticity for a system of N point-vortices is

$$\omega(\mathbf{r}) = \sum_{\alpha=1}^{N} k_\alpha \delta(\mathbf{r} - \mathbf{r}_\alpha), \tag{7}$$

where k_α, $\alpha = 1, \ldots, N$, is constant and corresponds to the vorticity of the αth vortex. Therefore by applying the inversion formula (6), the stream function is

$$\Psi(\mathbf{r}) = -\frac{1}{4\pi} \sum_{\alpha=1}^{N} k_\alpha \log \parallel \mathbf{r} - \mathbf{r}_\alpha \parallel^2 . \tag{8}$$

This equation describes, together with (4), the dynamics of a test particle at a point (x, y) in the plane. Analogously, it can be shown that the dynamics of a system of point-vortices in the plane is given by the equations

$$k_\alpha \frac{dX_\alpha}{dt} = \frac{\partial H_p}{\partial Y_\alpha}, \qquad k_\alpha \frac{dY_\alpha}{dt} = -\frac{\partial H_p}{\partial X_\alpha}, \tag{9}$$

where $(q_\alpha, p_\alpha) = (X_\alpha, k_\alpha Y_\alpha)$, $\alpha = 1, \ldots, N$, is a pair of conjugate variables and H_p is the generalization of the stream-function Ψ (8) for the vortex system,

$$H_p = -\frac{1}{4\pi} \sum_{\alpha<\beta} k_\alpha k_\beta \log \parallel \mathbf{r}_\alpha - \mathbf{r}_\beta \parallel^2 . \tag{10}$$

Notice that in addition to the Hamiltonian H_p, a system of point-vortices in the plane has the integrals of motion

$$L = \sum_{\alpha=1}^{N} k_\alpha \parallel \mathbf{r}_\alpha \parallel^2, \quad P_x = \sum_{\alpha=1}^{N} k_\alpha X_\alpha, \quad P_y = \sum_{\alpha=1}^{N} k_\alpha Y_\alpha,$$

expressing, respectively, the conservation of angular momentum and linear momentum in space. Furthermore, by introducing the Poisson bracket

$$[f, g] = \sum_{\alpha=1}^{N} \left(\frac{\partial f}{\partial q_\alpha} \frac{\partial g}{\partial p_\alpha} - \frac{\partial f}{\partial p_\alpha} \frac{\partial g}{\partial q_\alpha} \right) = \sum_{\alpha=1}^{N} \frac{1}{k_\alpha} \left(\frac{\partial f}{\partial X_\alpha} \frac{\partial g}{\partial Y_\alpha} - \frac{\partial f}{\partial Y_\alpha} \frac{\partial g}{\partial X_\alpha} \right),$$

we can show that we can construct three integrals in involution out of the four conserved quantities H_p, L, P_y, and P_y. These are H_p, $P_x^2 + P_y^2$, and L; in fact,

$$[H_p, P_x^2 + P_y^2] = 0, \quad [H_p, L] = 0, \quad [P_x^2 + P_y^2, L] = 0.$$

It is then possible to reduce the system of equations from N to $N - 2$ degrees of freedom. It follows that a system with $N \leq 3$ is integrable, whereas the system of equations of four vortices has been shown by Ziglin to be nonintegrable in the sense that there are no other first integrals analytically dependent on the coordinates and circulations, and functionally independent of L, H_v, P_x, P_y (see [16]). It has been shown, however, that a system of four identical vortices (i.e., $k_\alpha = k$ for $\alpha = 1, \ldots, 4$) can undergo periodic or quasi-periodic motion for special initial conditions. More specifically, the motion of a system of four identical vortices can be periodic, quasi-periodic, or chaotic, depending on the symmetry of the initial configuration [2, 4, 7].

The simplest relative equilibrium is given by a system of two vortices with vorticity of the same sign. For such a system the vortex motion is always periodic, and the orbits are always circles. We do not have the option, as in the Kepler problem, where the two masses can describe elliptical orbits. For further comments comparing vortex dynamics with celestial mechanics, see [1, 27, 6].

2.2. Point-vortices on a sphere. When considering point-vortices on the surface of the sphere, an additional constraint is given by the sphere topology. In fact, the sphere being a compact manifold and, more specifically, a manifold with no boundaries, the Green theorem gives us a constraint on the distribution of vorticity,

$$\iint_S \omega(\mathbf{r}') dA' = \iint_S \nabla \cdot \nabla \Psi(\mathbf{r}') dA' = 0;$$

i.e., the vorticity distribution must have a zero average on the sphere [11]. To fulfill this requirement, it is sufficient to include, in addition to the N point-vortices delta-distributed, an evenly spread constant vorticity Γ, whose magnitude is equal to minus the average of the point-vortices over the sphere, i.e.,

$$\omega(\mathbf{r}) = \sum_{\alpha}^{N} k_\alpha \delta(\mathbf{r} - \mathbf{r}_\alpha) + \Gamma, \tag{11}$$

with $\Gamma = -\sum_{\alpha=1}^{N} k_\alpha/4\pi R^2$, R being the radius of the sphere, $\mathbf{r}$ and $\mathbf{r}_\alpha$ designating, respectively, a generic point and the location of the αth vortex on the sphere. Then, for this case, the vortex Hamiltonian is found to be

$$H_s = \frac{1}{4\pi R^2} \sum_{\alpha<\beta} k_\alpha k_\beta \log \parallel \mathbf{r}_\alpha - \mathbf{r}_\beta \parallel^2, \tag{12}$$

and the corresponding conjugate variables are $p_j = k_j \cos(\theta_j)$ and $q_j = \varphi_j$, $j = 1, \ldots, N$, where φ_j and θ_j are the usual angles of spherical coordinates, respectively the longitude and the colatitude, and k_j is the vortex strength of the jth vortex. Then the dynamics of N point-vortices on the surface of a sphere is given by the equations (see [18, 31])

$$k_j \dot{p}_j = \frac{\partial H_s}{\partial q_j}, \qquad k_j \dot{q}_j = -\frac{\partial H_s}{\partial p_j}.$$

As for the planar case [7], in addition to the Hamiltonian H_s, a system of point-vortices on a sphere has the integrals of motion

$$L = \sum_{\alpha=1}^{N} k_\alpha \parallel \mathbf{r}_\alpha \parallel^2, \quad P_x = \frac{1}{R} \sum_{\alpha=1}^{N} k_\alpha x_\alpha, \quad P_y = \frac{1}{R} \sum_{\alpha=1}^{N} k_\alpha y_\alpha, \quad P_z = \frac{1}{R} \sum_{\alpha=1}^{N} k_\alpha z_\alpha,$$

expressing, respectively, the conservation of angular momentum and linear momentum in the space. Notice that, in the case of vortices on a sphere, the integral of motion L simplifies to $L = R^2 \sum_{\alpha=1}^{N} k_\alpha$ and is therefore redundant. Furthermore, as in section 2.1, by introducing the Poisson bracket $[f, g] = \sum_{\alpha=1}^{N} (\frac{\partial f}{\partial q_\alpha} \frac{\partial g}{\partial p_\alpha} - \frac{\partial f}{\partial p_\alpha} \frac{\partial g}{\partial q_\alpha})$, it can easily be shown that we can construct three integrals in involution out of the four conserved quantities H_s, P_x, P_y, and P_z. These are H_s, $P_x^2 + P_y^2$, and P_z; in fact,

$$[H_s, P_x^2 + P_y^2] = 0, \quad [H_s, P_z] = 0, \quad [P_x^2 + P_y^2, P_z] = 0.$$

It is then possible to reduce the system of equations from N to $N - 2$ degrees of freedom. It follows that a system with $N \leq 3$ is integrable. Notice that while in the planar case [7] we had the freedom of choosing a reference frame within which the origin coincides with the center of vorticity, so that $P_x = P_y = 0$, in the spherical case there is a privileged point in space, i.e., the center of the sphere. In this case, the momentum vector $\mathbf{M} = (P_x, P_y, P_z)$ plays a special role in characterizing the dynamics of the vortex system. We then use the freedom in the axis orientations to select a reference system with the z-axis in the direction of $\mathbf{M}$ (see [18]). This choice still gives $P_x = P_y = 0$, as for the planar case. In what follows there is no loss of generality in considering a sphere of radius one ($R = 1$), and since we consider the case of identical vortices—$k_\alpha = k$, $\alpha = 1, \ldots, N$—we choose $k = 1$. Then the Hamiltonian becomes

$$H_s = \frac{1}{4\pi} \sum_{\alpha<\beta} \log \parallel \mathbf{r}_\alpha - \mathbf{r}_\beta \parallel^2 . \tag{13}$$

We then use the rotational symmetry of the Hamiltonian (12) to view the vortex dynamics in an appropriate corotating frame. In fact, by considering the canonical

transformation

$$\text{(14)}\qquad \begin{cases} \phi_1 = \varphi_1 - \varphi_N & J_1 = p_1 \\ \phi_2 = \varphi_2 - \varphi_N & J_2 = p_2 \\ \vdots & \vdots \\ \phi_{N-1} = \varphi_{N-1} - \varphi_N & J_{N-1} = p_{N-1} \\ \phi_N = \varphi_N & J_N = \sum_{k=1}^{N} p_k, \end{cases}$$

we reduce the problem by one degree of freedom: ϕ_N is a cyclic coordinate, and J_N is the momentum vector $\mathbf{M}$.

3. Main results. To determine the nonlinear stability regions for a system of N identical point-vortices, we use a sufficient condition for stability which may be traced back to Lagrange for potential systems and was later proved by Dirichlet [12] for systems with integrals; this was subsequently generalized by Lyapunov in his direct method (section 3.1). To apply the Dirichlet criterion we need to establish whether the Hessian of the Hamiltonian is positive or negative definite. For this purpose we use the Jacobi method described in section 3.2.

As result of our analysis, we find that the nonlinear stability ranges coincide—apart from the equatorial plane—with the linear stability ranges previously found by Polvani and Dritschel [31], as shown in Table 2. Detailed calculations are done in section 4.

3.1. Nonlinear stability: The Dirichlet criterion. Let x^* be an equilibrium of an autonomous system of ordinary differential equations,

$$\text{(15)}\qquad \frac{dx}{dt} = f(x), \quad x \in \Omega \subset \mathbb{R}^n,$$

that is, $f(x^*) = 0$. Denote by $\phi(t, x)$ the solution of (15) such that $\phi(0, x) = x$. For $r > 0$, denote by $B_r(x)$ the open ball in $\mathbb{R}^n$ with center x and radius r.

Let us recall that a function Ψ is said to be positive definite (resp., negative definite) at a point x^* if $f(x^*) = 0$ and if there exists a neighborhood V of x^* such that $f(x) > 0$ (resp., $f(x) < 0$) for all $x \neq x^*$ in V.

THEOREM 1 (Dirichlet; see [32]). *If there exists a positive (or negative) definite integral Ψ of the system* (15) *in a neighborhood of the equilibrium x^*, then x^* is stable.*

For an autonomous Hamiltonian system, Theorem 1 translates into the following. Let $z^* = 0$ be an equilibrium of the system with an analytic Hamiltonian

$$H(z) = H_2(z) + H_3(z) + \cdots,$$

where $H_k(z)$ is a homogeneous polynomial of degree k in z.

Since H is a first integral of the system, Dirichlet's theorem implies that if, at the equilibrium the quadratic form $H_2(z)$ is positive (or negative) definite, then the equilibrium is stable.

3.2. A theorem on positive (negative) quadratic forms: The method of Jacobi. To determine whether the Hessian of the Hamiltonian is positive or negative definite, we make use of the Jacobi method illustrated in the following theorem (see Gel´fand [15, Theorem 1, p. 49]).

THEOREM 2. *Let $A(x;x)$ be a quadratic form defined relative to some basis $\mathbf{f}_1, \mathbf{f}_2, \ldots, \mathbf{f}_n$ by the equation*

$$A(x;x) = \sum_{i,k=1}^{n} a_{ik}\eta_i\eta_k, \qquad a_{ik} = A(\mathbf{f}_i;\mathbf{f}_k),$$

where $\eta_1, \ldots, \eta_n$ are coordinates of x in this basis. Further, let the determinants

$$\Delta_1 = a_{11}, \qquad \Delta_2 = \begin{vmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{vmatrix}, \qquad \ldots,$$

$$\Delta_n = \begin{vmatrix} a_{11} & a_{12} & \ldots & a_{1n} \\ a_{11} & a_{12} & \ldots & a_{1n} \\ \ldots & \ldots & \ldots & \ldots \\ a_{n1} & a_{n2} & \ldots & a_{nn} \end{vmatrix}$$

all be different from zero. Then there exists a basis $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n$ relative to which $A(x;x)$ is expressed as a sum of squares,

$$A(x;x) = \frac{\Delta_o}{\Delta_1}\zeta_1^2 + \frac{\Delta_1}{\Delta_2}\zeta_2^2 + \cdots + \frac{\Delta_{n-1}}{\Delta_n}\zeta_n^2.$$

Here $\Delta_0 = 1$ and $\zeta_1, \zeta_2, \ldots, \zeta_n$ are the coordinates of x in the basis $\mathbf{e}_1, \mathbf{e}_2, \ldots, \mathbf{e}_n$.

4. The Hessian of the Hamiltonian and its principal minors. In this section we simply illustrate the calculations to determine, as a function of N, the region for which the Hamiltonian is negative or positive definite when evaluated at the equilibrium configuration. We remind the reader that, after having performed the canonical transformation (14), we evaluate the principal minor determinants of the Hessian matrix of the Hamiltonian at the relative equilibrium configurations. As announced in section 2, the Hamiltonian is the reduced Hamiltonian for which the vortex dynamics is viewed in the reference system rotating with the relative equilibrium configuration (i.e., with a frequency $\dot{\varphi}_N$).

In the reduced system the Hessian of the Hamiltonian takes the form

$$\mathcal{H}(H_s) = \left(\begin{array}{c|c} \frac{\partial^2 H_s}{\partial\phi_\alpha\partial\phi_\beta} & \frac{\partial^2 H_s}{\partial J_\alpha\partial\phi_\beta} \\ \hline \frac{\partial^2 H_s}{\partial\phi_\alpha\partial J_\beta} & \frac{\partial^2 H_s}{\partial J_\alpha\partial J_\beta} \end{array}\right), \qquad \alpha,\beta = 1,\ldots,N-1,$$

which, evaluated at the equilibrium configuration—$J_{o\alpha} = z_o = \cos\theta_o$ and $\phi_{o\alpha} = 2\pi\,\alpha/N$ for $\alpha = 1,\ldots,N-1$—becomes

$$\mathcal{H}(H_s)_{eq} = b\left(\begin{array}{c|c} \tilde{S}_o - S_o\mathbb{I} & 0 \\ \hline 0 & \frac{\partial^2 H_s}{\partial J_\alpha\partial J_\beta} \end{array}\right), \tag{16}$$

where $b = 1/2\pi$, $\mathbb{I}$, and 0 are, respectively, the $((N-1)\times(N-1))$ identity and the zero matrices,

$$S_o = \sum_{\alpha=1}^{N-1} \frac{1}{1-\cos(\phi_{o\alpha})} = \frac{1}{6}(N^2-1), \qquad \text{with} \quad \phi_{o\alpha} = \frac{2\pi}{N}\alpha,$$

and $\tilde{S}_o$ is a symmetric matrix with zero-diagonal elements and with off-diagonal elements

$$(\tilde{S}_o)_{\alpha\beta} = \frac{1}{1-\cos(\phi_{o\alpha}-\phi_{o\beta})}, \qquad \text{with} \quad \phi_{o\alpha} = \frac{2\pi}{N}\alpha, \quad \phi_{o\beta} = \frac{2\pi}{N}\beta.$$

Then for the determinants of principal minors of (16) we obtain the following:

Case 1. $N = 2$:

$$\Delta_1 = -\frac{1}{2}, \qquad \Delta_2 = +\frac{z_o^2}{2r_o^4}.$$

Then clearly, $\Delta_1 < 0$, $\Delta_2 > 0$ for all $z_o \neq \{0, 1\}$, i.e., for all colatitudes but the equatorial one, and at the poles since $z_o = \cos\theta$. By Theorem 2 (section 3), we can conclude that the Hessian (16) is negative definite at all colatitudes θ, with the exception of the values $\theta = 90^\circ$ (i.e., at the equator) and $\theta = 0^\circ$ (i.e., at the poles). Then by Theorem 1 we can infer that "colatitudinal" relative equilibrium configurations of two vortices are always nonlinearly stable, with the exception of the values $\theta = 90^\circ$ and $\theta = 0^\circ$.

Case 2. $N = 3$:

$$\Delta_1 = -\frac{4}{3}, \qquad \Delta_2 = \frac{4}{3}, \qquad \Delta_3 = -\frac{16z_o^2}{r_o^4}, \qquad \Delta_4 = \frac{16\, z_o^4}{r_o^8}.$$

Then, $\Delta_1 < 0$, $\Delta_2 > 0$, $\Delta_3 < 0$, and $\Delta_4 > 0$ for all $z_o \neq \{0, 1\}$, i.e., for all colatitudes but the equatorial one and at the poles. Then by the same argument as for Case 1 ($N = 2$), we conclude that "colatitudinal" relative equilibrium configurations of three vortices are always nonlinearly stable. The case $\theta = 90^\circ$ needs further analysis; for more details, see Pekarsky and Marsden [30].

Case 3. $N = 4$:

$$\Delta_1 = -5, \qquad \Delta_2 = \frac{21}{4}, \qquad \Delta_3 = -9, \qquad \Delta_4 = 9\frac{6z_o^2-1}{r_o^4},$$

$$\Delta_5 = -27\frac{z_o^2(9z_o^2-2)}{r_o^8}, \quad \text{and} \quad \Delta_6 = 324\frac{z_o^4(3z_o^2-1)}{r_o^{12}}.$$

Then by symmetry restricting the analysis to the domain $0^\circ \le \theta \le 90^\circ$, we find the following:

$$\Delta_4 > 0 \quad \text{if} \quad 0^\circ < \theta \le \arccos\left(\frac{1}{\sqrt{6}}\right) \approx 66^\circ,$$

$$\Delta_5 < 0 \quad \text{if} \quad 0^\circ < \theta \le \arccos\left(\frac{\sqrt{2}}{3}\right) \approx 62^\circ,$$

$$\Delta_6 > 0 \quad \text{if} \quad 0^\circ < \theta \le \arccos\left(\frac{1}{\sqrt{3}}\right) \approx 55^\circ.$$

Then, by the same argument as for the case $N = 2$, we conclude that the Hessian is negative definite if $0° < \theta \leq \arccos(1/\sqrt{3})$; i.e., nonlinear stability holds in the region extending from the pole down to a latitude of about 35°.

Case 4. $N = 5$:

$$\Delta_1 = -4, \quad \Delta_2 = 0.4(37 - \sqrt{5}) > 0, \quad \Delta_3 = -1.92(25 - \sqrt{5}) < 0, \quad \Delta_4 = 115.2,$$

$$\Delta_5 = -46.08\frac{20z_o^2 - 5 - \sqrt{5}}{r_o^4}, \quad \Delta_6 = \frac{1}{5}\frac{(20z_o^2 - 5 + \sqrt{5})(12z_o^2 - \sqrt{5} - 3)}{r_o^8},$$

$$\Delta_7 = -32\,\Delta_4\frac{z_o^2}{r_o^{12}}(2z_o - 1)^2, \quad \text{and} \quad \Delta_8 = \Delta_4\,320\frac{(2z_o^2 - 1)^2 z_o^4}{r_o^{16}}.$$

Then we find the following:

$$\Delta_5 < 0 \quad \text{if} \quad 0° \leq \theta \leq \arccos\left(\frac{\sqrt{25 + 5\sqrt{5}}}{10}\right) \approx 53°,$$

$$\Delta_6 > 0 \quad \text{if} \quad 0° \leq \theta \leq \arccos\left(\sqrt{\frac{3 + \sqrt{5}}{12}}\right) \approx 48°,$$

$$\Delta_7 < 0 \quad \text{if} \quad \theta \neq \arccos\left(\frac{1}{\sqrt{2}}\right) = 45°,$$

$$\Delta_8 > 0 \quad \text{if} \quad \theta \neq \arccos\left(\frac{1}{\sqrt{2}}\right) = 45°,$$

and therefore the Hessian is negative definite if $0° < \theta < 45°$; i.e., nonlinear stability holds in the region extending from the pole down to a latitude of 45°.

Case 5. $N = 6$:

$$\Delta_1 = -\frac{35}{6}, \quad \Delta_2 = \frac{1081}{36}, \quad \Delta_3 = -\frac{10361}{72}, \quad \Delta_4 = \frac{5740}{9}, \quad \Delta_5 = -2400,$$

$$\Delta_6 = -\frac{\Delta_5}{3}\frac{30z_o^2 - 17}{r_o^4}, \quad \Delta_7 = \frac{\Delta_5}{12}\frac{(10z_o^2 - 3)(90z_o^2 - 59)}{r_o^8},$$

$$\Delta_8 = -\frac{\Delta_5}{6}\frac{(20z_o^2 - 9)(150z_o^4 - 125z_o^2 + 12)}{r_o^{12}},$$

$$\Delta_9 = 5\,\Delta_5\frac{z_o^2(5z_o^2 - 3)(125z_o^4 - 125z_o^2 + 24)}{r_o^{16}},$$

$$\Delta_{10} = -150\,\Delta_5\,\frac{z_o^4(5z_o^2 - 4)(5z_o^2 - 3)^2}{r_o^{20}}.$$

Then,

$$\Delta_6 > 0 \quad \text{if} \quad 0° \leq \theta \leq \arccos\left(\sqrt{\frac{17}{30}}\right) \approx 41°,$$

$$\Delta_7 < 0 \quad \text{if} \quad \theta \neq \arccos\left(\sqrt{\frac{3}{10}}\right) \approx 36°,$$

$$\Delta_8 > 0 \quad \text{if} \quad \theta \neq \arccos\left(\sqrt{\frac{9}{20}}\right) \approx 48^\circ,$$

$$\Delta_9 < 0 \quad \text{if} \quad 0 \leq \theta \neq \arccos\left(\sqrt{\frac{1}{2} + \frac{\sqrt{145}}{50}}\right) \approx 30.6^\circ,$$

$$\Delta_{10} > 0 \quad \text{if} \quad \theta \neq \arccos\left(\sqrt{\frac{4}{5}}\right) \approx 27^\circ,$$

so that the Hessian is negative definite for $0^\circ \leq \theta \leq \arccos(\sqrt{4/5})$; i.e., nonlinear stability holds in the region from the pole down to a latitude of approximately 63°.

For the case $N = 7$ we obtain that for all $z_0 \neq \pm 1$ the principal minors have different signs and are not alternating. As for the planar case [10, 5], we can therefore conclude that the Hessian is not definite and further analysis is necessary.

It is shown in Boatto, Cabral, and Simó [5] that a polygonal ring of N identical vortices is stable if

$$r_o^2 < \tfrac{7-N}{4} \qquad \text{for N odd,}$$

$$r_o^2 < -\tfrac{N^2-8N+8}{4(N-1)} \qquad \text{for N even,}$$

where $r_o^2 = 1 - z_o^2$. Therefore a polygonal configuration with $N \geq 7$ is not stable on a sphere.

Before ending this section we would like to make the following remarks:

(a) We remind the reader that for three vortices (Case 2, $N = 3$) the dynamics is integrable (see section 2.2); therefore stability can be simply inferred by reducing the Hamiltonian to that of a system of one degree of freedom,

$$H = B_1 \log\left\{\frac{1}{64}(3 - M^2 + 2\,MJ_1)^2(3 - M^2 + 2\,MJ_2)^2(3 + M^2 - 2\,MJ_2 - 2\,MJ_1)^2\right\}, \tag{17}$$

where $J_1 = z_1$, $J_2 = z_2$, and $M = z_1 + z_2 + z_3$ is the momentum [6]. It can immediately be shown that $(J_1, J_2) = (M/3, M/3)$ is a critical point of (17) and corresponds to a latitudinal equilateral triangle configuration. Furthermore, the Hessian of (17) at the equilibrium ($J_1 = J_2 = z_o = M/3$) takes the form

$$\mathcal{H}(H)\left(J_1 = \frac{M}{3}, J_2 = \frac{M}{3}\right) = -B_1 \frac{72\,M^2}{(M^2-9)^2}\begin{pmatrix} 2 & 1 \\ 1 & 2 \end{pmatrix},$$

and therefore we can simply deduce that the equilateral triangle configuration is stable everywhere on the sphere except at the poles ($M = 3$) and at the equator ($M = 0$). Such an analysis can be easily generalized to the case of nonidentical vortices; for details, see [6].

(b) The presence of a polar vortex greatly modifies the stability analysis of the polygonal ring. We have already discussed in the introduction that for the planar case Cabral and Schmidt [10] showed that a central vortex of vortex strength K could stabilize a polygonal configuration of identical vortices, and they provided analytical expressions for the K-intervals which assure stability

for a given N (see (1) and [5]). Similarly, for the spherical case—for a polar vortex of vorticity K and a latitudinal polygonal ring of N identical point-vortices—Boatto and Cabral have found explicit analytical expressions for the θ- and K-intervals which assure stability (for details, see [5]). They have found the following stability ranges for $N = 3$.
For $z \neq \frac{1}{3}$, let $\kappa_1(z)$ and $\kappa_2(z)$ be the minimum and the maximum of the two functions

$$g_2(z) = -\frac{2z}{1+z} \quad \text{and} \quad g_3(z) = \frac{2z(3z^2-4z-3)}{(1+z)^2(1-3z)}.$$

We notice that

$$\kappa_1 = g_3 \quad \text{and} \quad \kappa_2 = g_2 \quad \text{for} \quad -1 < z \leq \frac{1}{3} \quad \text{and} \quad 0 \leq z < \frac{1}{3}$$

and

$$\kappa_1 = g_2 \quad \text{and} \quad \kappa_2 = g_3 \quad \text{for} \quad -\frac{1}{3} \leq z \leq 0 \quad \text{and} \quad \frac{1}{3} < z < 1.$$

Then, according to z ($z = \cos\theta$, θ being the colatitude), we have stability in the following situations:

$$\begin{array}{cccc}
-1 < z < z', & \kappa_1(z) < \kappa < 0 & \text{or} & \kappa > \kappa_2(z) > 0, \\
z = z', & & & \kappa > \kappa_2(z) > 0, \\
z' < z < 0, & 0 < \kappa < \kappa_1(z) & \text{or} & \kappa > \kappa_2(z) > 0, \\
0 \leq z \leq \frac{1}{3}, & & & \kappa > 0, \\
\frac{1}{3} < z < 1, & & & 0 < \kappa < \kappa_2(z),
\end{array}$$

where $z' = -\frac{\sqrt{13}-2}{3}$ is the negative root of the equation $3z^2 - 4z - 3 = 0$.

5. Conclusions. Our nonlinear stability ranges coincide with those computed by Polvani and Dritschel for linear stability [31].

There are many other interesting stability problems concerning relative equilibria, and we refer the reader to the book by Newton [27] and the article by Aref et al. [3] for a review. We would like to stress that our stability approach is rather simple: it consists of viewing the dynamics in a good reference frame and using a Lyapunov-like criterion (the Dirichlet criterion).

Furthermore, our study also has relevance for its modeling aspect. In 1998, a subtropical hexagonal jet was observed in the southern hemisphere [22]. This structure proved to be stable for quite a few days, and the question arises of understanding its persistence. The simplest model of a hexagonal jet is a regular polygonal configuration of point-vortices.

The addition of one or two polar vortices strongly modifies the stability ranges (θ-intervals) for the latitudinal ring. More details will be given in a forthcoming paper [5].

Acknowledgments. We express our thanks to A. Chenciner, N. Lebovitz, and D. S. Schmidt for helpful discussions.

GEOCHEMICAL PHASE DIAGRAMS AND GALE DIAGRAMS*

P. H. EDELMAN†, S. W. PETERSON‡, V. REINER§, AND J. H. STOUT¶

Abstract. The problem of predicting the possible topologies of a geochemical phase diagram, based on the chemical formula of the phases involved, is shown to be intimately connected with and aided by well-studied notions in discrete geometry: Gale diagrams, triangulations, secondary fans, and oriented matroids.

Key words. Gale diagram, Gale transform, phase diagram, triangulation, secondary polytope, secondary fan, geochemistry, heterogeneous equilibrium, closed net, Euler sphere

AMS subject classifications. 52B35, 52C40, 86A99

DOI. 10.1137/S003613990241182X

1. Introduction.

A central problem in geochemistry has been to understand how the equilibrium state of a chemical system varies with temperature and pressure, and to predict the form of its temperature-pressure phase diagram (hereafter called just the *phase diagram*). The purpose of this paper is to explain how some recently developed tools from discrete geometry (the theory of oriented matroids, triangulations, Gale diagrams, and secondary fans) can be used to elucidate this problem. Our goal is to be comprehensible to both discrete geometers and workers in geochemistry.

Figure 1 illustrates the familiar phase diagram for a simple chemical system that involves three phases (ice, water, steam) of the same chemical compound, H_2O. The topological structure of this diagram is fairly simple: there is a unique point, called a triple point, where all three phases can be present in equilibrium. The triple point lies at the junction of three curves. Along each of these curves, exactly two of the phases are present in equilibrium (either ice + water, or ice + steam, or water + steam), and these three curves separate two-dimensional regions where only one phase (pure ice, pure water, or pure steam) can be present in equilibrium.

This example of a phase diagram is quite an elementary one, in that all the phases have the same underlying chemistry, that of H_2O. Geochemists are interested in phase diagrams as the principal tool in reconstructing the temperature and pressure conditions from rock formations once deep within the Earth but which now reside at its surface. Thus it is important to have accurate phase diagrams involving much more complex systems, in which the phases have different chemistry as well as different states.

To be more precise, a *phase* means a physically homogeneous substance, having its own chemical formula, although different phases within the system can have the same

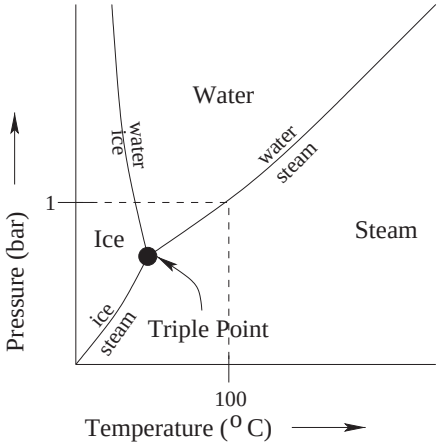

FIG. 1. *The phase diagram for the simple chemical system with phases ice, water, and steam.*

formula (as in the ice-water-steam example). At a particular temperature and pressure, the equilibrium state consists of groups of one or more phases that are referred to as *phase assemblages*. Within a closed system at fixed temperature and pressure, only certain phase assemblages will be stable, namely, those having the lowest possible *Gibbs free energy* under the given conditions. Other assemblages with higher energy than the minimum under those conditions are referred to as *metastable*—these assemblages react spontaneously to produce a stable assemblage and a net decrease in energy. For example, pure water placed in the stability field of ice will spontaneously freeze because a lower Gibbs energy assemblage (ice) is available under those conditions. When there are different chemical formulae present among the phases, more exotic reactions than simple phase changes are possible. The regions of simultaneous stability for various collections of phase assemblages and the chemical reactions that relate them can be conveniently summarized in the phase diagram.

The locus of temperatures and pressures within which a particular phase assemblage is stable is called its *stability field*. The stability field is called *invariant*, *univariant*, or *divariant* depending upon its dimension, that is, the number of degrees of freedom one can vary while staying within that stability field. In the example above, the triple point (ice-water-steam) is an invariant point, there are three univariant curves (ice-water, ice-steam, water-steam), and three divariant stability fields (pure ice, pure water, pure steam). The univariant fields correspond to simple chemical reactions that transform one phase assemblage to another, and hence are sometimes referred to as *reaction lines*. In producing these phase diagrams, a prediction of the possible topologies (i.e., number of invariant points, number of univariant curves joining them, etc.) is indispensable, as the thermodynamic data needed to resolve such topological features can sometimes be difficult to obtain.

It turns out that much of the complexity of the phase diagram for a chemical system is governed by two parameters:

- the number of phases, m, and
- the number of components, n (defined below).

We will see in section 3 that these two parameters correspond to the *size of the ground set* and the *rank* of a related vector configuration (or affine point configuration or oriented matroid) associated with the chemical system. It is well known, in

both geochemistry and discrete geometry, that what matters most in predicting the complexity of the phase diagram is not the sizes of n and m, but rather the sizes of n and $m - n$ (the rank and the *corank*).

The *number of components* n for a chemical system is defined as follows. Think of the chemical formulae of the various phases of the system as vectors in a vector space of all possible such formulae (the *chemical composition space*—see section 3), whose coordinate axes correspond to the elements present on earth. Then the number n of components of the chemical system is simply the dimension of the subspace spanned by the chemical formulae of the phases present in the system.[1] For example, the system of ice, water, and steam from Figure 1 has $m = 3$ and $n = 1$, while the system depicted in Figure 2 (in section 3) has $m = 4$ and $n = 2$.

Phase diagram topologies for chemical systems with $m \leq n + 2$ are fairly well understood, even as m grows large. For $m \leq n+1$ they are essentially trivial, and for $m = n + 2$, they look roughly like Figure 1, having an invariant point surrounded by several univariant reaction curves. The schematic picture of such an invariant point surrounded by reaction curves is referred to as an *invariant point map* [17]. We will explain in section 8 why invariant point maps look roughly like a *two-dimensional Gale diagram*, in concordance with rules for the phase diagram's construction first delineated by Schreinemakers [25] nearly 100 years ago.

However, by $m = n + 3$ (a situation common for chemical systems applicable to the earth) the topology of the phase diagram can become quite complex as m grows large. For example, under certain genericity assumptions about the chemical formulae of the phases, the diagram will contain exactly $n+3$ invariant points located at various temperature and pressure coordinates. These invariant points are connected to one another by various reaction lines to a form a network of points and lines referred to by geochemists as a *petrogenetic grid*. For example, a typical grid for $n = 4$ and $m = 7$ will have seven invariant points connected by 21 different reaction lines.

The phase diagram topology of this (as well as higher order systems) has been represented schematically by geochemists via a *straight line net*, made up of a set of invariant point maps linked together by common reaction lines. In section 9 we will explain how straight line nets for systems with $m = n + 3$ can be constructed using *three-dimensional Gale diagrams* and *secondary fans*, and hence why their phase diagrams strongly resemble the encoding of a three-dimensional Gale diagram as a two-dimensional *affine Gale diagram*.

Within the geochemical literature, there are two general approaches to reconstructing the topology of the phase diagram. The first approach was pioneered by Schreinemakers [25], who reasoned about the relative Gibbs energies of phases to deduce invariant point maps for $m = n + 2$. This method has been extended by various authors (see [29], [31], [32]; [6]; [16], and references therein) to produce viable straight line nets for systems with $m = n + 3$. All feasible topologies are enumerated by this method, and then empirical data is used to eliminate those diagrams which are physically impossible. This approach can be made much more efficient by the methods described in this paper.

The alternative approach is to compute the variation in Gibbs energy directly for every phase of interest. Modern thermodynamic databases (e.g., [13] and references therein) now make these computations possible. The method fails in some cases be-

[1] It will be convenient in section 3 to choose a basis for this space, that is, a minimal set of phases such that all the formulae of the phases can be expressed as linear combinations of these basic components; hence the term *number of components* of the system.

cause the data either lacks the accuracy to distinguish between topologically different diagrams or is simply not available for some phases. The latter situation is becoming more common as new phases are discovered by laboratory synthesis under high pressure conditions. The quantities of these phases are so small that the necessary thermodynamic data will not be available in the foreseeable future. Thus geochemists must rely on the topological approach developed earlier.

We should point out that there have been a few authors [12], [27] who have given a somewhat similar mathematical formulation of this problem, but without taking advantage of the language, techniques, and highly developed theory provided by Gale diagrams and oriented matroids. The applications derived in section 10 of this paper are, as far as we know, new. Furthermore, the theory described in this paper is the basis for JAVA applets written by the second author and available on the web [18], which give practical tools for use in geochemistry for predicting phase diagram topology.

2. A geochemistry-discrete geometry glossary. For the convenience of the reader, and as a guide to what lies in store, we present a (very rough) glossary of corresponding terms.

Geochemistry	Discrete geometry
chemical formula for a phase	vector in composition space
chemical system	acyclic vector configuration $\mathcal{V}$
chemography	affine point configuration $\mathcal{A}$
number of phases m	number of vectors/points
number of components n	rank of vector/point configuration
reactions among phases	linear/affine dependences of $\mathcal{V}/\mathcal{A}$
minimal reactions	circuits
stable assemblage of phases	simplex in a triangulation of $\mathcal{A}$
phase diagram	affine plane slice of secondary fan
phase diagram when $m = n + 2$	2-dimensional (2-D) Gale diagram $\mathcal{A}^*$
reaction half-line for $m = n + 2$	vector in 2-D Gale diagram $\mathcal{A}^*$
phase diagram when $m = n + 3$	2-D affine Gale diagram for $\mathcal{A}^*$
invariant point when $m = n + 3$	vector in 3-D Gale diagram $\mathcal{A}^*$
closed net when $m = n + 3$	spherical representation of $\mathcal{A}^*$
Euler sphere for $m = n + 3$	great circles normal to $\mathcal{A}^*$

3. Chemical composition space. In this section, we introduce the chemical composition space that allows one to associate to each chemical system a configuration of vectors, an affine point configuration, and their oriented matroid. For terminology on vector configurations, point configurations, and oriented matroids, we refer the reader to two excellent references: the bible of the subject, [2] (in particular, its section 1.2), and Ziegler's book, [33, Lecture 6].

DEFINITION 3.1. *The formulae of chemical compounds may be represented in a natural way by vectors in a* chemical composition space *whose axes are indexed by the elements in the periodic table. For example, H_2O has coordinates which are two units on the hydrogen axis, one unit on the oxygen axis, and zero on all other axes. The m phases of a chemical system in this way give rise to a collection $\mathcal{V} = \{v_1, \ldots, v_m\}$ of vectors spanning a subspace of some dimension n, which is called the* number of components *of the system. By picking a basis for this subspace, we can identify it with*

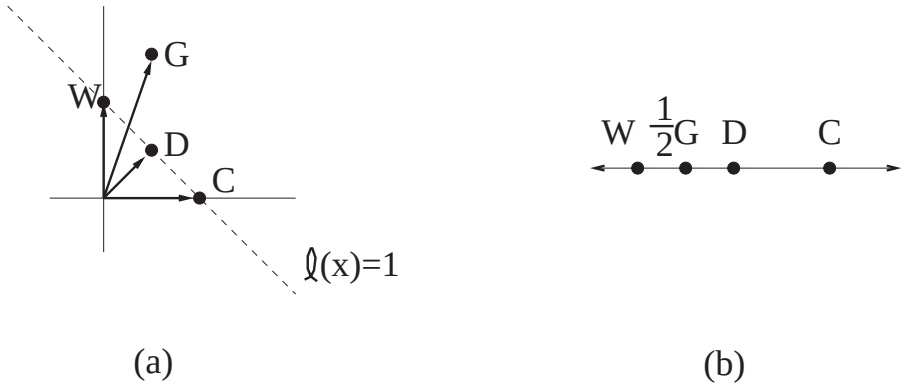

FIG. 2. (a) *Vector configuration* $\mathcal{V}$ *and* (b) *affine point configuration* $\mathcal{A}$ *for the chemical system with phases corundum (C), diaspore (D), gibbsite (G), and water (W).*

$\mathbb{R}^n$ *and specify each* v_i *by a column vector in* $\mathbb{R}^n$*. This allows us to identify* $\mathcal{V}$ *with an* $n \times m$ *matrix having full rank* n*, which we also call* $\mathcal{V}$ *by an abuse of notation.*

Example 3.2. Consider a chemical system of relevance to geology having $m = 4$ phases, which we denote by descriptive initials rather than by v_1, v_2, v_3, v_4:

$$\begin{array}{lll} C = & \text{corundum} & \mathrm{Al_2O_3}, \\ D = & \text{diaspore} & \mathrm{AlO(OH)}, \\ G = & \text{gibbsite} & \mathrm{Al(OH)_3}, \\ W = & \text{water} & \mathrm{H_2O}. \end{array} \tag{1}$$

Since the compounds in this system involve only the elements Al, O, H, this system can have n at most 3. However, one can check that these chemical formulae span a space of dimension $n = 2$. Choosing C and W to be the standard basis vectors in this space (that is, the *components* for this system), one can represent the configuration $\mathcal{V}$ as the columns of the matrix

$$\mathcal{V} = \begin{array}{c} \begin{matrix} C & D & G & W \end{matrix} \\ \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & 0 \\ 0 & \frac{1}{2} & \frac{3}{2} & 1 \end{bmatrix} \end{array}, \tag{2}$$

and the associated vector configuration is depicted in Figure 2(a).

Notice that, by choosing a basis that identifies this n-dimensional subspace with $\mathbb{R}^n$, we are already abstracting away from the actual chemical formulae of the phases and paying attention only to properties that are invariant under a simultaneous change-of-basis acting on the vectors, that is, properties invariant under $GL_n(\mathbb{R})$. One such set of properties is the oriented matroid associated to the vector configuration $\mathcal{V}$.

DEFINITION 3.3. *The* oriented matroid $\mathcal{M}$ *associated to* $\mathcal{V}$ *is a combinatorial abstraction of the vectors* $\mathcal{V}$*, which forgets their actual coordinates but retains data specifying the signs involved in linear dependences among the* v_i*. The way in which we choose to record this data is to list the* signed circuits *of* $\mathcal{M}$ *coming from each minimal (nontrivial) linear dependence* $\sum_i \lambda_i v_i = 0$*, that is, the* signed set (X^+, X^-)*, where*

$$X^{\pm} := \{i \in \{1, \ldots, m\} : \operatorname{sign}(\lambda_i) = \pm\}.$$

Here minimality for signed sets is interpreted with respect to the ordering of their support sets:

$$(X^+, X^-) < (Y^+, Y^-) \quad \textit{means} \quad X^+ \cup X^- \subseteq Y^+ \cup Y^-.$$

It is sometimes convenient to represent a signed set (X^+, X^-) *instead by its* sign vector *in* $\{+, 0, -\}^m$*, which has* $\pm$ *in the coordinates indexed by* $X^\pm$*, and* 0 *in all other coordinates. For example, a minimal dependence of the form* $+5v_1 - 3v_2 + \frac{7}{8}v_4$ *among* $m = 4$ *phases would be recorded by the circuit whose signed set is* $(\{1, 4\}, \{2\})$ *or by its sign vector* $(+ - 0 +)$.

It is possible to write down a small set of *circuit axioms* satisfied by the set $\mathcal{C}$ of signed circuits coming from any vector configuration, in such a way that collections of signed sets satisfying these axioms (*oriented matroids*) mimic many features of sets of vectors in a real vector space; see [2, p. 4]. Note that, since the negation of a linear dependence gives another linear dependence, one of these circuit axioms for an oriented matroid says that the set of sign vectors of circuits is closed under negation.

The linear dependences among the v_i have an obvious chemical interpretation: they are the coefficients in the mass-preserving chemical reactions possible among the phases.

Example 3.4. Continuing the previous example, there are three minimal linear dependences/reactions, giving rise to the following signed circuits (represented by two opposite sign vectors below):

Minimal reaction/dependence	Circuits as sign vectors
$G \rightleftharpoons 1D + 1W$	$0 + - +, \quad 0 - + -$
$2D \rightleftharpoons 1C + 1W$	$+ - 0 +, \quad - + 0 -$
$3D \rightleftharpoons 1C + 1G$	$+ - + 0, \quad - + - 0$

Note that another possible reaction among these phases is

$$1C + 2W \rightleftharpoons 1D + 1G,$$

which would give rise to dependences with sign vectors

$$+ - - +, \quad - + + -,$$

but these are not signed circuits because their support sets are not minimal under inclusion.

The fact that every chemical compound contains a nonnegative amount of each element implies that the vector configuration $\mathcal{V}$ will be *acyclic*, that is, there will be no signed circuits with $X^- = \{\varnothing\}$. Equivalently, there exists a linear functional $\ell(x)$ in $(\mathbb{R}^n)^*$ such that $\ell(v_i) > 0$ for all i. This allows one to replace each v_i by a rescaled vector a_i satisfying $\ell(a_i) = 1$, so that the a_i lie in the affine hyperplane $\ell(x) = 1$ inside $\mathbb{R}^n$, giving rise to an *affine point configuration*[2] $\mathcal{A}$ in $(n-1)$-dimensional affine space $\mathbb{R}^{n-1}$. In chemical terms, this replacement corresponds to simply changing conventions for writing down basic quantities of each phase: instead of considering one mole to be the basic unit of quantity for some phase, one can consider a half a mole or some other fraction to be its basic unit of quantity.[3]

[2] In [17], this affine point configuration $\mathcal{A}$ is called the *chemography* of the system.

[3] We have already pointed out that two phases can have the same chemical formula, giving rise to two copies of the same vector $v_i = v_j$ in $\mathcal{V}$; these give rise to what are called *parallel elements* of the oriented matroid $\mathcal{M}$. We should note, however, that parallel elements can also arise after doing the rescaling from $\mathcal{V}$ to $\mathcal{A}$ if two phases have chemical formulae which differ by a scalar multiple, e.g., if both oxygen O_2 and ozone O_3 were present as phases.

The effect of this rescaling is to turn linear dependences $\sum_i \lambda_i v_i = 0$ of the original vector configuration $\mathcal{V}$ into *affine dependences* of $\mathcal{A}$, that is, relations $\sum_i \bar{\lambda}_i a_i = 0$ with $\sum_i \bar{\lambda}_i = 0$. In terms of chemical reactions, this means that the reactions will not only achieve mass-balance for each atom, but also "coefficient balance," as in the following example.

Example 3.5. Continuing the previous example, we can choose the linear function $\ell(x) = x_1 + x_2$ in $\mathbb{R}^2$ and rescale the coordinates of C, D, G, W so that they have $\ell(x) = 1$, giving the new matrix

$$\mathcal{A} = \begin{array}{c} \begin{matrix} C & D & \frac{1}{2}G & W \end{matrix} \\ \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{4} & 0 \\ 0 & \frac{1}{2} & \frac{3}{4} & 1 \end{bmatrix} \end{array}. \tag{3}$$

The affine point configuration in $\mathbb{R}^1$ represented by $\mathcal{A}$ is depicted in Figure 2(b).

The rescaling in this case required only replacing G by $\frac{1}{2}G$, so that, for example, the previous reaction/linear dependence

$$\begin{aligned} 1G &\rightleftharpoons 1D + 1W, \\ 1\mathrm{Al(OH)_3} &\rightleftharpoons 1\mathrm{AlO(OH)} + 1\mathrm{H_2O}, \end{aligned}$$

which achieves mass-balance for each atom but not coefficient balance ($1 \neq 1 + 1$), now gives rise to the affine dependence

$$2 \cdot \left(\frac{1}{2}G\right) \rightleftharpoons 1D + 1W,$$

achieving coefficient balance: $2 = 1 + 1$.

Switching from the vector configuration $\mathcal{V}$ to the affine point configuration has psychological advantages, in that it allows one to reduce the dimension by one for visualization purposes, and it makes it easier to think about our next topic: triangulations[4] of $\mathcal{A}$.

4. Triangulations and subdivisions. Our goal in this section is to explain a phenomenon well known to geochemists: by performing reactions that minimize the Gibbs free energy resulting in stable phase assemblages at a particular temperature and pressure, nature (generically) "computes" a triangulation of the point set $\mathcal{A}$.

Having fixed a temperature and pressure (T, P), each of the phases $a_1, \ldots, a_m$ of the chemical system will have a certain *Gibbs free energy* $g_i(T, P)$ per molar quantity (or per whatever basic quantity is being used after rescaling v_i to a_i).

DEFINITION 4.1. *These values $g_i(T, P)$ can be used as* heights *to "lift" the points a_i in $\mathbb{R}^{n-1}$ to points*

$$\hat{a}_i := \begin{bmatrix} a_i \\ g_i(T, P) \end{bmatrix} \in \mathbb{R}^n,$$

giving a new lifted *configuration of points $\hat{\mathcal{A}}$. In other words, we plot the points a_i together with their height along an extra* Gibbs energy axis*; see Figure* 3 *for two examples having $n = 2$.*

[4]We should point out that there is a well-defined notion of triangulations for general vector configurations (even when they are not acyclically oriented), as well as for oriented matroids that do not come from configurations of vectors. See [24] and the references contained therein.

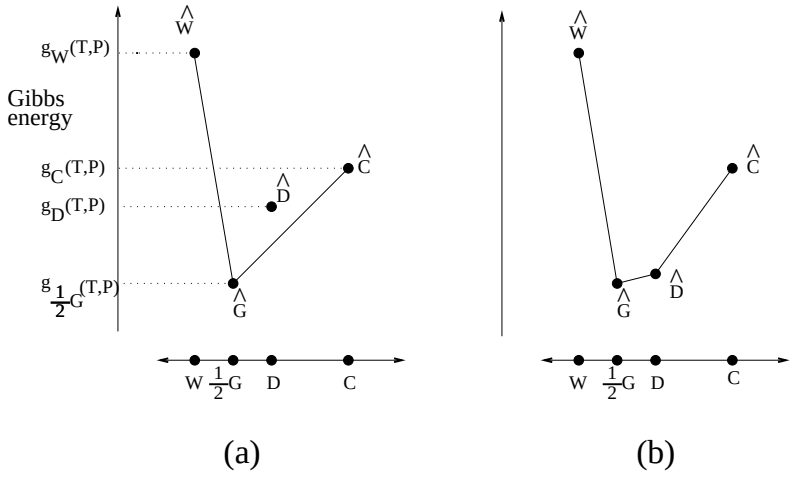

FIG. 3. *The chemography $\mathcal{A}$ from Figure 2, "lifted" to $\hat{\mathcal{A}}$ by the Gibbs energy values at two different values of temperature and pressure.*

The *convex hull*, that is, the set of all convex combinations, of this set $\hat{\mathcal{A}}$ of lifted points has the following physical interpretation. Suppose that we have an assemblage consisting of x_i units of the basic quantity of phase a_i for each $i = 1, \ldots, m$, and assume (without loss of generality) that $\sum_i x_i = 1$. Then this assemblage will have total Gibbs energy $\sum_i x_i g_i(T, P)$, which is the same as the height on the Gibbs energy axis of the point $\sum_i x_i \hat{a}_i$, which is a weighted average of the lifted points $\hat{\mathcal{A}}$ and therefore lies somewhere in their convex hull. If this point does not lie on the *lower convex hull* of these lifted points, then this is not a stable assemblage of phases: there exist some reaction(s) available which would alter the fractions of each phase a_i in a way that lowers the total Gibbs energy.

Example 4.2. We continue our previous example and assume that the Gibbs energies of the phases are as depicted in Figure 3(a). Consider the assemblage consisting of $\frac{1}{2}$ mole of C together with $\frac{1}{2}$ mole of D. It lifts to the point $\frac{1}{2}\hat{C} + \frac{1}{2}\hat{D}$ at the midpoint of the line segment $\hat{C}\hat{D}$ in Figure 3(a), whose height $\frac{1}{2}g_C(T_0, P_0) + \frac{1}{2}g_D(T_0, P_0)$ represents the total Gibbs energy of this assemblage. It is not stable because one can run the reaction

$$3D \rightleftharpoons 1C + 1G$$

in the forward direction to convert the $\frac{1}{2}$ mole of D into $\frac{1}{6}$ mole each of C and G. This creates an assemblage with lower total Gibbs energy consisting of $\frac{2}{3}$ mole of C together with $\frac{1}{6}$ mole of G (or, equivalently, $\frac{1}{3}$ mole of $\frac{1}{2}G$). The latter assemblage, however, is stable, as it lifts to a point on the segment $\hat{C}\hat{G}$ lying in the lower convex hull of $\hat{\mathcal{A}}$.

On the other hand, if the Gibbs energies of the phases look as they do in Figure 3(b), then the initial assemblage of $\frac{1}{2}$ mole of C together with $\frac{1}{2}$ mole of D would be stable, and no reactions would occur.

Note that even after the temperature and pressure (T, P) have been fixed, there can be more than one possible stable assemblage, and which stable assemblages appear depends upon the initial quantities of each phase present. In petrology, when one takes

various samples from different locations inside a stratum of rock formed under the same temperature and pressure conditions, one has a chance of sampling from all the different stable assemblages.

From the previous discussion, we conclude that the sets of phases which can form stable assemblages correspond to the sets of vertices that lie on a face of the lower convex hull of $\hat{\mathcal{A}}$. Note that projecting these faces of the lower hull in $\mathbb{R}^n$ down into $\mathbb{R}^{n-1}$ produces a set of convex polytopes that disjointly cover the convex hull of $\mathcal{A}$, forming what is usually called a *polytopal subdivision* of $\mathcal{A}$. If the vector

$$g = (g_1(T,P), \ldots, g_m(T,P)) \in \mathbb{R}^m$$

is sufficiently generic, then each of the faces of the lower convex hull will be an $(n-1)$-dimensional *simplex* (that is, the convex hull of n affinely independent points), and this polytopal subdivision is called a *triangulation* of $\mathcal{A}$; see [10, Chapter 7] for formal definitions.

DEFINITION 4.3. *Triangulations and polytopal subdivisions of $\mathcal{A}$ which are induced in this fashion from a vector of heights $g = (g_1, \ldots, g_m)$ in $\mathbb{R}^m$ are called* coherent *or* regular*, and we call $\Delta(g)$ the subdivision induced by g.*

We summarize here some of the conclusions of the preceding discussion.

PROPOSITION 4.4. *For each fixed temperature and pressure (T,P), the vector*

$$g = g(T,P) := (g_1(T,P), \ldots, g_m(T,P)) \in \mathbb{R}^m$$

of Gibbs energies for the phases $\mathcal{A} = \{a_1, \ldots, a_m\}$ induces a coherent polytopal subdivision $\Delta(g)$ of $\mathcal{A}$. The polytopes participating in this subdivision have vertex sets corresponding exactly to the stable assemblages of phases at that temperature and pressure (T,P).

It is perhaps surprising that in general not all triangulations of a point configuration $\mathcal{A}$ need be coherent. In Figure 4 we show an affine configuration with six points in $\mathbb{R}^2$ with two incoherent triangulations. This example is well known in the discrete geometry literature (see, e.g., [10, Chapter 7, Figure 27]), and is the "smallest" example due to the following result.

THEOREM 4.5 (see [15]). *When either $n \leq 2$ or $m - n \leq 2$, every triangulation of an affine point configuration of m points in $\mathbb{R}^{n-1}$ is coherent.*

Bearing in mind Proposition 4.4, in order to understand the topology of the phase diagram for a chemical system, one needs to understand how the coherent subdivision $\Delta(g)$ of a point configuration $\mathcal{A}$ varies with the height vector g in $\mathbb{R}^m$. This is our next goal.

5. Secondary fans. The goal of this section is to introduce the secondary fan $\mathcal{F}(\mathcal{A})$ and its close relative, the pointed secondary fan $\mathcal{F}'(\mathcal{A})$, which govern how the coherent subdivisions $\Delta(g)$ of $\mathcal{A}$ change as one varies the height vector g in $\mathbb{R}^m$. Some references for this material are [3, section 4] and [10, Chapter 7].

Having fixed a particular affine point configuration $\mathcal{A}$ of m points in $\mathbb{R}^{n-1}$, one can ask when two height vectors g and g' in $\mathbb{R}^m$ give rise to the same subdivision Δ. It should come as no surprise that the set of vectors g which give rise to a particular subdivision Δ forms a polyhedral cone $\mathcal{C}(\mathcal{A},\Delta) \subset \mathbb{R}^m$; that is, it is defined by a finite set of linear inequalities (which depend on the coordinates of the points $\mathcal{A}$ and on Δ). As one varies the subdivision Δ, these cones $\mathcal{C}(\mathcal{A},\Delta)$ fit together to disjointly cover $\mathbb{R}^m$.

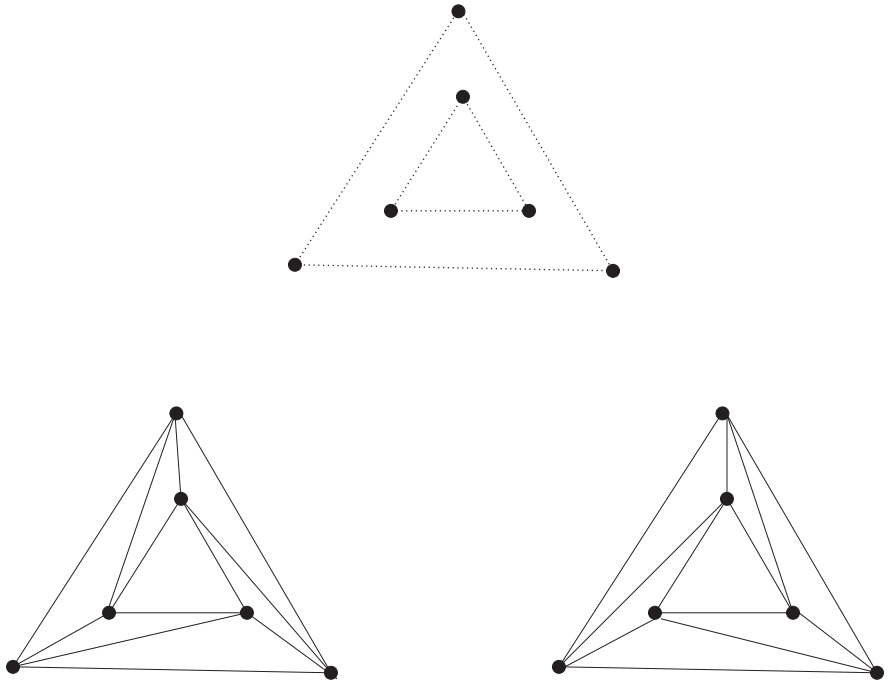

FIG. 4. *Incoherent triangulations of an affine point configuration $\mathcal{A}$: the standard, smallest example, along with its two incoherent triangulations.*

DEFINITION 5.1. *In the terminology of discrete geometry, these cones form a* (complete) fan *called the* secondary fan $\mathcal{F}(\mathcal{A})$*; see Figure* 5(a) *for the example of ice-water-steam from the Introduction.*[5]

We can now rephrase precisely what the phase diagram means in these terms.

DEFINITION 5.2. *Consider the (T, P)-plane in which the phase diagram is drawn as a copy of $\mathbb{R}^2$. Then the Gibbs energy functions $g_i(T, P)$ for the m phases can be viewed as specifying a* Gibbs energy map

$$\begin{array}{rccl} \gamma: & \mathbb{R}^2 & \to & \mathbb{R}^m, \\ & (T,P) & \mapsto & g(T,P) \quad = (g_1(T,P), \ldots, g_m(T,P)). \end{array}$$

The image $\gamma(\mathbb{R}^2)$ of this map will be some two-dimensional surface in $\mathbb{R}^m$. The decomposition of $\mathbb{R}^m$ into the cones of the secondary fan $\mathcal{F}(\mathcal{A})$ will restrict to a decomposition of this surface $\gamma(\mathbb{R}^2)$; see Figure 5(b) for the example of ice-water-steam. This decomposition of the surface then *pulls back* to induce a decomposition of the (T, P)-plane $\mathbb{R}^2$ into regions, which are the regions of simultaneous stability for various collections of phase assemblages (i.e., two pairs $(T, P), (T', P')$ lie in the same region of the phase diagram if and only if their images under γ lie in the same cone of $\mathcal{F}(\mathcal{A})$). In other words, we have the following statement, illustrated in Figure 5(b).

[5]Although we are not aware of a geochemical interpretation, we should point out a beautiful result of Gelfand, Kapranov, and Zelevinsky asserting that the secondary fan $\mathcal{F}(\mathcal{A})$ is actually the *normal fan* of a convex polytope, which they called the *secondary polytope* $\Sigma(\mathcal{A})$; see [10, Chapter 7]. One should also be aware of a slight difference in focus when referring to their results, which they mainly prove for $\Sigma(\mathcal{A})$, but which can then be translated into results about $\mathcal{F}(\mathcal{A})$.

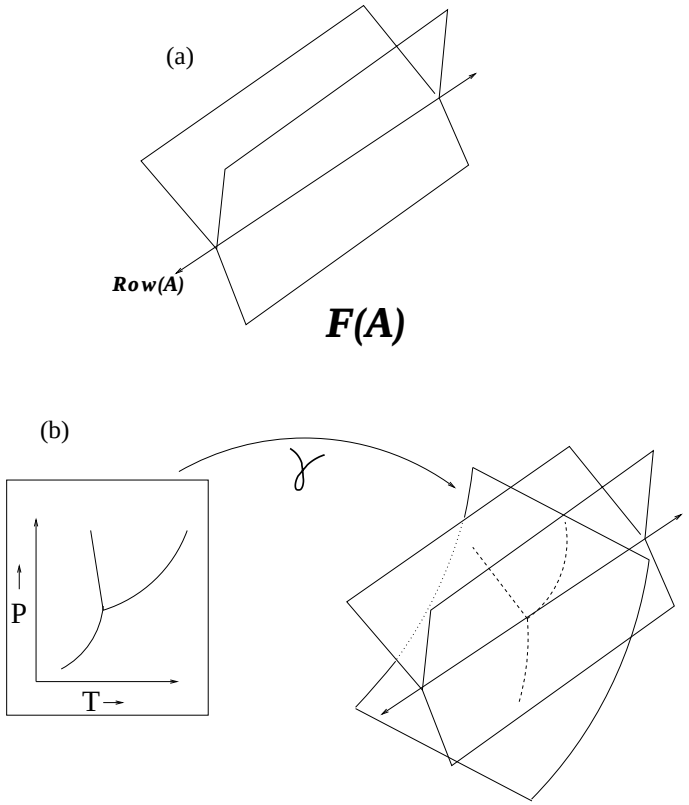

FIG. 5. *For the chemical system of ice, water, and steam with $n = 1$ and $m = 3$, we have* (a) *the secondary fan $\mathcal{F}(\mathcal{A})$,* (b) *the image surface $\gamma(\mathbb{R}^2)$ decomposed by $\mathcal{F}(\mathcal{A})$, and the phase diagram as the pull-back of this decomposition.*

PROPOSITION 5.3. *The phase diagram for a chemical system having chemography $\mathcal{A}$ is exactly the decomposition of the (T, P)-plane $\mathbb{R}^2$, which is the pull-back under γ^{-1} of the decomposition of the image surface $\gamma(\mathbb{R}^2)$ induced by the cones of the secondary fan $\mathcal{F}(\mathcal{A})$.*

Thus understanding possible phase diagram topologies amounts to understanding the structure of the secondary fan $\mathcal{F}(\mathcal{A})$ and the Gibbs energy map γ well enough to predict how the fan $\mathcal{F}(\mathcal{A})$ can decompose two-dimensional surfaces $\gamma(\mathbb{R}^2)$ in $\mathbb{R}^m$.

It turns out that there is a natural way to cut down the dimension of $\mathcal{F}(\mathcal{A})$ by the number of components n, without losing any information. Recall that $\mathcal{A}$ also denotes the $n \times m$ matrix whose columns are the n-vectors a_i (with each of these column vectors lying in the affine hyperplane $\ell(x) = 1$). It is not hard to see that two height vectors g and g', which differ by a vector lying in the row space $\mathrm{Row}(\mathcal{A})$ of this matrix $\mathcal{A}$, will induce the same coherent subdivision Δ: one can show that the two configurations of lifted points they produce will differ by an affine transformation of $\mathbb{R}^n$, and consequently their convex hulls will differ only by a "tilt" that does not affect the structure of their lower hulls. As a consequence, each of the cones $\mathcal{C}(\mathcal{A}, \Delta)$ in the secondary fan $\mathcal{F}(\mathcal{A})$ extends trivially in the n directions defined by $\mathrm{Row}(\mathcal{A})$; it is a Cartesian product

$$\mathcal{C}(\mathcal{A}, \Delta) = \mathcal{C}'(\mathcal{A}, \Delta) \times \mathrm{Row}(\mathcal{A}),$$

where $\mathcal{C}'(\mathcal{A}, \Delta)$ is a cone in an $(m-n)$-dimensional subspace of $\mathbb{R}^m$ complementary[6] to $\mathrm{Row}(\mathcal{A})$. As Δ varies over all coherent subdivisions, these cones $\mathcal{C}'(\mathcal{A}, \Delta)$ disjointly cover this complementary $(m-n)$-dimensional subspace, producing what is called the *pointed secondary fan* $\mathcal{F}'(\mathcal{A})$.

We next make explicit the simplifying assumption which is implicit in the geochemical literature on this subject.

Assumption 5.4 (geochemical assumption). Over the ranges of temperature and pressure $(T, P) \in \mathbb{R}^2$ relevant to most phase diagrams, the Gibbs energy map $\gamma : \mathbb{R}^2 \to \mathbb{R}^m$ is sufficiently close to linear that the image surface $\gamma(\mathbb{R}^2)$ behaves nearly like a two-dimensional affine plane in $\mathbb{R}^m$.

Furthermore, this two-dimensional affine plane is located generically with respect to the cones of the secondary fan $\mathcal{F}(\mathcal{A})$ in the following sense: it has transverse intersection with every cone $\mathcal{C}$ in the secondary fan (including the smallest face which is the row space $\mathrm{Row}(\mathcal{A})$). This means that the intersection is empty if the dimension of the cone $\mathcal{C}$ is less than $m-2$, and otherwise when $\mathcal{C}$ has dimension $m-2, m-1, m$, respectively, the intersection is either empty or it is of dimension $0, 1, 2$, respectively.

With these assumptions, and in particular the transversality assumption, the problem of enumerating the possible phase diagram topologies reduces to understanding the ways in which the pointed secondary fan $\mathcal{F}'(\mathcal{A})$ can decompose an affine two-dimensional plane inside the $(m-n)$-dimensional space where it lives. It turns out that Gale diagrams hold the key to this problem.

6. Gale diagrams and duality. In this section we introduce Gale diagrams of a vector configuration or affine point configuration, and explain their relationship to (pointed) secondary fans and oriented matroid duality.

DEFINITION 6.1. *Given the $n \times m$ matrix $\mathcal{A}$ of rank n whose columns give an affine point configuration, choose a* dual matrix $\mathcal{A}^*$ *to be any $(m-n) \times m$ matrix whose row space* $\mathrm{Row}(\mathcal{A}^*)$ *coincides with the nullspace (or kernel)* $\mathrm{Ker}(\mathcal{A})$. *By an abuse of notation similar to that in Definition* 3.1, *the configuration of column vectors $\{a_1^*, \ldots, a_m^*\}$ of this matrix will also be denoted $\mathcal{A}^*$ and is called a* Gale diagram *or* Gale transform [9] *for $\mathcal{A}$. Similarly, we could have started with any $n \times m$ matrix $\mathcal{V}$ of rank n corresponding to a vector configuration and defined a Gale diagram $\mathcal{V}^*$ for it in the same fashion.*

Example 6.2. Recall our running example with

$$\mathcal{A} = \begin{array}{c} \begin{matrix} C & D & \frac{1}{2}G & W \end{matrix} \\ \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{4} & 0 \\ 0 & \frac{1}{2} & \frac{3}{4} & 1 \end{bmatrix} \end{array}. \tag{4}$$

An example of a valid Gale diagram for this is

$$\mathcal{A}^* = \begin{array}{c} \begin{matrix} C^* & D^* & G^* & W^* \end{matrix} \\ \begin{bmatrix} 1 & -3 & 2 & 0 \\ 2 & -4 & 0 & 2 \end{bmatrix} \end{array}, \tag{5}$$

pictured as a vector configuration in Figure 6.

[6] It would be more natural to think of the cones $\mathcal{C}'(\mathcal{A}, \Delta)$ as living in the *quotient space* $\mathbb{R}^m/\mathrm{Row}(\mathcal{A})$, but we won't quibble here.

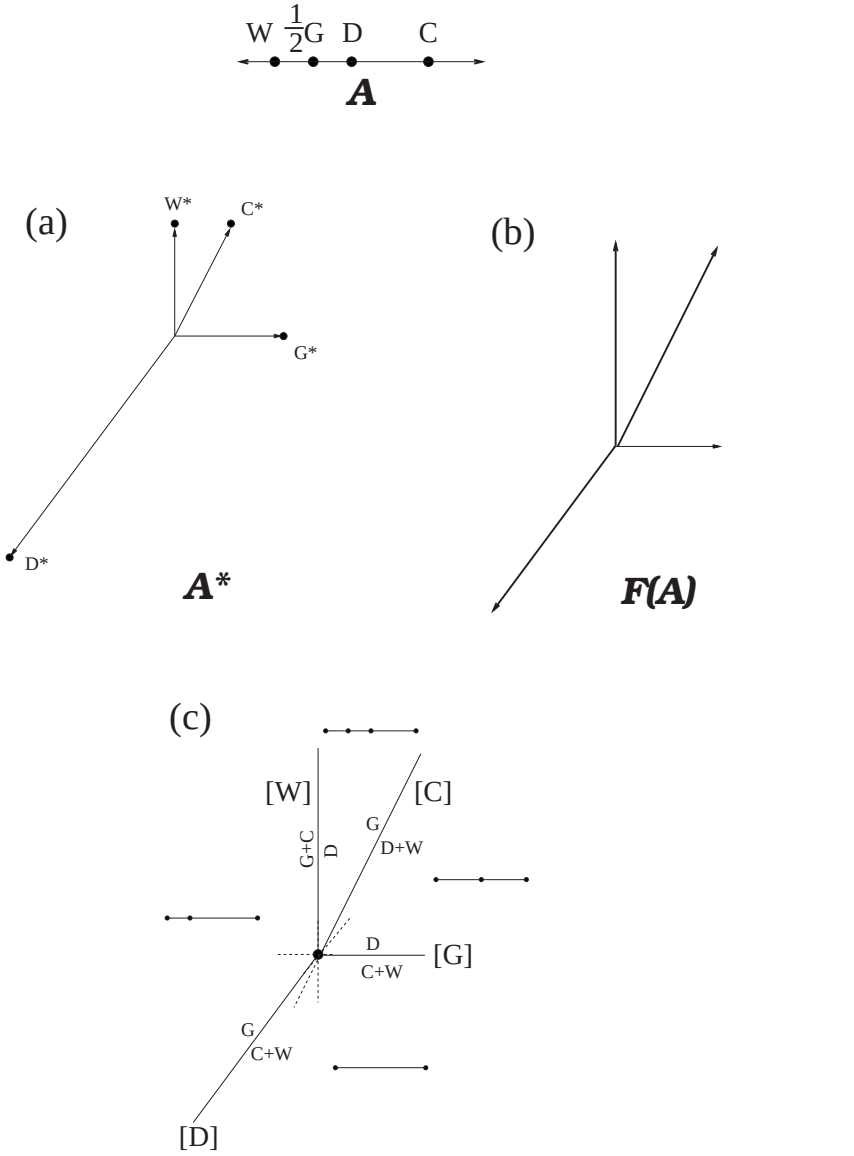

FIG. 6. (a) *Gale diagram* $\mathcal{A}^*$, (b) *secondary fan* $\mathcal{F}(\mathcal{A})$, *and* (c) *invariant point map, for the chemical system corundum-diaspore-gibbsite-water.*

Note the use of the term "a" Gale diagram, instead of "the" Gale diagram. This is because the rows of $\mathcal{A}^*$ are not uniquely defined: they can be altered by row operations, that is, by the action of $GL_{m-n}(\mathbb{R})$ on the left. This means that the Gale diagram vectors $\mathcal{A}^*$ are also well defined only up to the same $GL_{m-n}(\mathbb{R})$-action.[7]

However, the oriented matroid $\mathcal{M}^*$ associated to the Gale vectors $\mathcal{A}^*$ *is* uniquely defined by the oriented matroid $\mathcal{M}$ associated to $\mathcal{A}$: it is the *dual oriented matroid*

[7]Recall from section 3 that there was a similar ambiguity in the definition of the columns of $\mathcal{A}$ or $\mathcal{V}$, stemming from a choice of basis for the space that they span.

[2, section 3.4] of $\mathcal{M}$. One manifestation of this duality is that the circuits $\mathcal{C}$ for $\mathcal{A}$ (or $\mathcal{M}$) correspond to sets in $\mathcal{A}^*$ (or $\mathcal{M}^*$) with their own interesting geometric characterization. These sets in $\mathcal{A}^*$ are called cocircuits.

DEFINITION 6.3. *Given a configuration of vectors $\mathcal{V} = \{v_1, \ldots, v_m\}$ in $\mathbb{R}^n$, its* covectors *are all possible sign vectors in $\{+, 0, -\}^m$ that can be achieved by evaluating some nonzero linear functional $f \in (\mathbb{R}^n)^*$ on the vectors in $\mathcal{V}$:*

$$c = c(f) = (\text{sign}(f(v_1)), \ldots, \text{sign}(f(v_m))).$$

A covector c for $\mathcal{V}$ which is maximal with respect to its set of zeroes is called a cocircuit *of $\mathcal{V}$. Equivalently, a covector is a cocircuit if its corresponding signed subset has minimal support or, equivalently, if the subset of $\mathcal{V}$ on which it is 0 contains at least $n-1$ linearly independent vectors. Denote by $\mathcal{C}^*$ the set of cocircuits of $\mathcal{V}$.*

As with the circuits $\mathcal{C}$, it is possible to write down a list of *cocircuit axioms* that will be satisfied by the cocircuits $\mathcal{C}^*$ coming from any vector configuration $\mathcal{V}$, and in this way to axiomatize the definition of an oriented matroid $\mathcal{M}$ in terms of cocircuits. The observation from above that the circuits C of $\mathcal{A}, \mathcal{V}, \mathcal{M}$ are exactly the cocircuits $\mathcal{C}^*$ of $\mathcal{A}^*, \mathcal{V}^*, \mathcal{M}^*$ means that these cocircuit axioms will look exactly like the circuit axioms.

Example 6.4. In our previous example of $\mathcal{A}$, the first circuit of $\mathcal{A}$ as listed in Example 3.4 was $(0 + - +)$, coming from the reaction $1G \leftrightharpoons 1D + 1W$. In $\mathcal{A}^*$ this is a cocircuit representing the fact that the line spanned by C^* has G^* on one side and D^*, W^* on the opposite side; i.e., there exists a linear functional f for which

$$f(C^*) = 0, \quad f(D^*) > 0, \quad f(W^*) > 0, \quad \text{and } f(G^*) < 0.$$

How does the Gale diagram $\mathcal{A}^*$ relate to the pointed secondary fan $\mathcal{F}'(\mathcal{A})$? The relationship comes from looking at the positive cones spanned by the vectors of $\mathcal{A}^*$.

DEFINITION 6.5. *Given any set $W = \{w_1, \ldots, w_k\}$ of vectors in $\mathbb{R}^N$, define the* positive cone *spanned by W to be*

$$\text{pos}(W) := \left\{ \sum_{i=1}^{k} c_i w_i \in \mathbb{R}^N : c_i > 0 \quad \textit{for all } i \right\}.$$

If the set of vectors W happen to be linearly independent, then $\text{pos}(W)$ *is called a* (relatively open) simplicial cone.

Recall that the affine point configuration $\mathcal{A}$ corresponds to an acyclic vector configuration. It is a consequence of oriented matroid duality [2, Proposition 4.8.9] that $\mathcal{A}^*$ will be *totally cyclic*; that is, the origin 0 lies in the cone $\text{pos}(\mathcal{A}^*)$. As a consequence, the collection of positive cones spanned by subsets of $\mathcal{A}^*$ will cover the column space $\text{Col}(\mathcal{A}^*)$, and this covering is closely related to the pointed secondary fan $\mathcal{F}'(\mathcal{A})$, as shown in the following.

THEOREM 6.6 (see [3, section 4]). *The column space* $\text{Col}(\mathcal{A}^*)$ *has a natural identification with the $(m-n)$-dimensional subspace complementary to* $\text{Row}(\mathcal{A})$ *within $\mathbb{R}^m$ covered by the pointed secondary fan $\mathcal{F}'(\mathcal{A})$.*

Furthermore, under this identification, the cones of $\mathcal{F}'(\mathcal{A})$ are exactly the common refinement of all the open simplicial cones $\text{pos}(W)$ *spanned by linearly independent subsets W of the Gale (column) vectors $\mathcal{A}^*$.*

One can be more precise about this relationship, as follows.

THEOREM 6.7 (see [3, Lemma 4.3]). *Given a coherent triangulation Δ of $\mathcal{A}$, the corresponding $(m-n)$-dimensional cone in the secondary fan $\mathcal{F}'(\mathcal{A})$ is the intersection*

$$\bigcap_{\sigma \in \Delta} \operatorname{pos}(\mathcal{A}^* - \sigma^*),$$

where σ runs through the vertex sets of the $(n-1)$-dimensional simplices in the triangulation Δ and

$$\sigma^* := \{a_i^* : a_i \in \sigma\}.$$

Example 6.8. Because the corundum-diaspore-gibbsite-water example of $\mathcal{A}$ has $m = 4$ and $n = 2$, so that $m = n + 2$, the pointed secondary fan $\mathcal{F}'(\mathcal{A})$ is two-dimensional. Therefore its top-dimensional cones are simply the sectors between cyclically adjacent Gale vectors in $\mathcal{A}^*$. These cones are depicted in Figure 6(b). In (c) of the same figure, these regions are labelled (as part of the geochemists' invariant point map; see section 8 below) by their corresponding coherent triangulations.

For example, the sector lying between the Gale vectors W^* and D^* corresponds to a triangulation Δ having two segments $\{GW, CG\}$. This agrees with Theorem 6.7: the complementary sets $\{C^*D^*, D^*W^*\}$ are exactly the ones whose positive cones contain this sector. On the other hand, the sector between D^*, G^* lies in the positive cone of no other pairs of Gale vectors and hence corresponds to the triangulation having only one segment, namely, the one with vertices $\mathcal{A} - \{D, G\} = \{C, W\}$.

Sections 8 and 9 will closely explore the consequences of the geometry of the Gale diagram for phase diagrams when m is at most $n + 3$. But first we must further explore more general geometric questions.

7. Geometry of the phase diagram in general. In this section we will explain the relationship between Gibbs' phase rule (e.g., [21]) and the secondary fan, and how the phase rule predicts the dimension of various stability fields. We then look closely at the meaning of two-, one-, and zero-dimensional regions in the phase diagram, relating them to m-, $(m-1)$-, and $(m-2)$-dimensional cones in the secondary fan.

When one fixes particular molar fractions x_i of each of the (rescaled) phases a_i in $\mathcal{A}$ initially contained in a particular sample, the discussion of section 5 shows how to predict the stable assemblage of phases which will result after allowing the system to find chemical equilibrium. The initial molar fractions give a point $\sum_i x_i a_i = 1$ with $\sum_i x_i = 1$, which lies in the convex hull of $\mathcal{A}$ and lifts to a point $\sum_i x_i \hat{a}_i$, which lies in the convex hull of $\hat{\mathcal{A}}$ but may or may not lie in the *lower* convex hull. After performing reactions which affect the fractions x_i (but preserve the condition $\sum_i x_i = 1$ due to our rescaling) to reach chemical equilibrium, the lifted point $\sum_i x_i \hat{a}_i$ will eventually lie in a unique face $\hat{F}$ of the lower hull of $\hat{\mathcal{A}}$. The lifted points $\hat{\mathcal{A}}' \subset \mathcal{A}$ which happen to lie on this face $\hat{F}$ lie above a subset $\mathcal{A}' \subset \mathcal{A}$ of the original phases; that is, $\mathcal{A}'$ are those phases which appear with nonzero fraction in this chemical equilibrium, and $\mathcal{A}'$ labels a polytope F which is part of the corresponding coherent subdivision of $\mathcal{A}$.

Gibbs' phase rule relates three quantities relevant to this situation:

- the number of phases $m' = |\mathcal{A}'| (\leq m = |\mathcal{A}|)$ participating in this chemical equilibrium,
- the number of components $n' (\leq n)$ of the subsystem $\mathcal{A}'$, that is, the dimension of the subspace of chemical composition space spanned by $\mathcal{A}'$, and

- the number of degrees of freedom f in (T, P), which one can vary while maintaining these same phases in equilibrium, or in other words, the dimension of the *union* of all regions in the phase diagram which have $\mathcal{A}'$ labelling one of the polytopes F in their corresponding subdivision of $\mathcal{A}$.

PROPOSITION 7.1 (Gibbs' phase rule). *With the above notation,*

$$f = n' + 2 - m'.$$

In particular, one can have at most $n' + 2$ phases that involve n' components in chemical equilibrium.

Note that, in the geochemical literature, the phase rule is often stated as

$$f \leq n + 2 - m',$$

which is consistent with the fact that $n' \leq n$.

Example 7.2. In Figure 1, the triple point has an assemblage of $m' = 3$ phases in equilibria (ice, water, steam), with $n' = 1$ and $f = 0$, while the assemblage consisting of pure ice has $m' = n' = 1$ and $f = 2$.

In Figure 6(c), the line segment DW corresponds to a stable assemblage $\{D, W\}$ in two different divariant regions and the curve that separates them (all in the upper right), so $f = 2$, and it has $m' = n' = 2$. The assemblage $\{D, G, W\}$ is stable only along the univariant curve lying between the two aforementioned divariant regions, so $f = 1$, and it has $m' = 3, n' = 2$. The quadruple point in the middle ($f = 0$) of the diagram has all four phases in equilibrium; that is, $m'(= m) = 4$ and $n'(= n) = 2$.

We give here a proof of Gibbs' phase rule in terms of the secondary fan $\mathcal{F}(\mathcal{A})$ in $\mathbb{R}^m$.

Proof. There is a cone $\mathcal{C}$ in the secondary fan consisting of those vectors $g \in \mathbb{R}^m$ for which the lifted points $\hat{\mathcal{A}}$ have $\hat{\mathcal{A}}'$ lying on a face $\hat{F}$ of the lower hull: this cone is the intersection of the vector space V on which the lifted points $\hat{\mathcal{A}}'$ all lie on a single n'-dimensional affine subspace, with the half-spaces given by various inequalities that assert that all the other lifted points $\hat{a}_i$ in $\mathcal{A} - \mathcal{A}'$ lift *above* this affine subspace. The subspace V is defined by $m' - n'$ linear conditions: after choosing the height coordinates of g to lift n' of the elements $\mathcal{A}'$ which are affinely independent, the remaining $m' - n'$ coordinates must be lifted to heights which are linear functions of those first n' heights. Thus V has dimension $m - (m' - n')$. The fact that lifting all the points $\mathcal{A} - \mathcal{A}'$ to any sufficiently large heights will force $\hat{F}$ to be in the lower hull shows that the cone $\mathcal{C}$ obtained by intersecting V with the various half-space inequalities will have the same dimension as V, namely, $m - (m' - n')$.

By Proposition 5.3 and Assumption 5.4, the union of all regions in the phase diagram which have $\mathcal{A}'$ labelling one of the polytopes F in their corresponding subdivision of $\mathcal{A}$ comes from the transverse intersection of an affine 2-plane with the cone $\mathcal{C}$. If $m' - n' > 2$, there would be no intersection, due to Assumption 5.4. If $m' - n' \leq 2$, then, since we assumed that these phases $\mathcal{A}'$ could exist in stable equilibrium, there would be a nonempty intersection. Depending upon whether $m' - n' = 0, 1$, or 2, this transverse intersection of $\mathcal{C}$ with an affine 2-plane would have dimension $f = 2, 1$, or 0, respectively; i.e., $f = 2 - (m' - n') = n' + 2 - m'$. ∎

Understanding the two-, one-, and zero-dimensional regions in the phase diagram amounts to understanding the cones of dimensions $m, m-1$, and $m-2$ in the secondary fan $\mathcal{F}(\mathcal{A})$ or, equivalently, the cones of dimensions $m - n, m - n - 1, m - n - 2$ in the pointed secondary fan $\mathcal{F}'(\mathcal{A})$. The two-dimensional regions in the phase diagram correspond to the top-dimensional cones in $\mathcal{F}(\mathcal{A})$ (or $\mathcal{F}'(\mathcal{A})$), which are labelled by

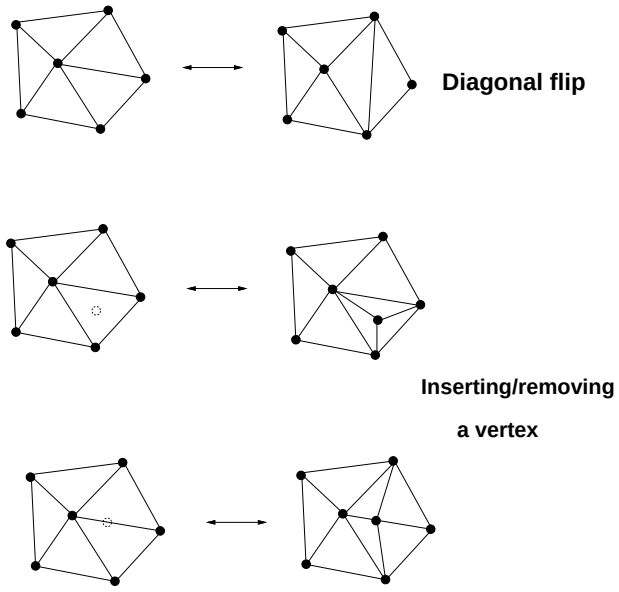

FIG. 7. *Three examples of pairs of bistellar operations for triangulations of affine point configurations $\mathcal{A}$ in $\mathbb{R}^2$.*

the coherent triangulations of $\mathcal{A}$ in the manner described in Theorem 6.7, and there is little to add to that description. The more interesting cases are those of the one- and zero-dimensional stability fields.

7.1. Bistellar operations and one-dimensional stability fields. The one-dimensional curves separating the regions in the phase diagrams correspond to natural transformations on triangulations of $\mathcal{A}$ called *bistellar operations*, which are closely related to the circuits of $\mathcal{A}$. We discuss these now somewhat informally; for a more formal treatment, see [10, Chapter 7, section 2C].

Figure 7 illustrates three examples of a pair of triangulations of affine point configurations $\mathcal{A}$ in $\mathbb{R}^2$ that are related by a bistellar operation. For each bistellar operation between two triangulations, there is a distinguished subset $C \subset \mathcal{A}$, which is the support set $C = X^+ \cup X^-$ of some signed circuit (X^+, X^-) of $\mathcal{A}$ and such that the convex hull of C is triangulated (differently!) in the two triangulations. In this case, we say that the bistellar operation is *supported on the circuit* C. Note that in the first two examples in Figure 7 this circuit C has a full two-dimensional convex hull, but as the third example illustrates, C can have a convex hull of lower dimension.

Recall that a circuit $C = X^+ \cup X^-$ of $\mathcal{A}$ corresponds to a cocircuit of $\mathcal{A}^*$, that is, there is an $(m-n-1)$-dimensional hyperplane H_C spanned by the Gale vectors indexed by $\mathcal{A} - C$, which separates the Gale vectors indexed by X^+ from those indexed by X^-. When C is the circuit supporting a bistellar operation between two triangulations, this reflects the following geometry of pointed secondary fans.

PROPOSITION 7.3 (see [10, section 7.2.C]). *Two triangulations Δ, Δ' differ by a bistellar operation supported on a signed circuit C if and only if their corresponding top-dimensional cones in $\mathcal{F}'(\mathcal{A})$ are adjacent along a wall whose linear span is the hyperplane H_C.*

This has an interpretation for the temperature-pressure phase diagram that is well known to geochemists: the segments of curves separating regions in the phase

diagram are always portions of a larger curve corresponding to some minimal reaction possible among the phases in the chemical system. Two regions will be adjacent and separated by such a curved segment if and only if their corresponding triangulations differ by retriangulating the convex hull of the phases involved in that reaction.

It is also useful to think of a bistellar operation as represented by the coherent polytopal subdivision that labels the wall between the two top-dimensional cones guaranteed by the previous proposition. In the language of Gibbs' phase rule, this subdivision contains a special polytopal face F labelled by a subset $\mathcal{A}' \subset \mathcal{A}$ having $m' = n' + 1$; namely, $\mathcal{A}'$ is the support set of the circuit C. Note that if $n' = n$, then F is a full $(n-1)$-dimensional polytope in the subdivision, and all the other full-dimensional polytopes in the subdivision are $(n-1)$-dimensional simplices.

A reasonable question at this point is, How well do the bistellar operations tie together the set of all triangulations of $\mathcal{A}$—is it possible to connect any two triangulations of a point set $\mathcal{A}$ by a sequence of bistellar operations? The answer has important consequences for calculating the set of triangulations of $\mathcal{A}$: the algorithms (e.g., [20]) that start with one triangulation and find the rest bistellarly connected to it by performing all possible bistellar operations are much faster than algorithms that find *all* triangulations by the currently available techniques [7], [20].

Unfortunately, the answer to the above question is in general no: Santos [22], [23] has recently produced examples of triangulations of affine point configurations that are connected to *no* other triangulations (!) by bistellar operations. Fortunately, however, there are positive results relevant for the geochemical applications:

- all triangulations are connected by bistellar operations when $n \leq 3$ (see [14]),
- the same holds when $m - n \leq 3$ (see [1]), and
- the subset of *coherent* triangulations are always connected by bistellar operations (see [10]).

In particular, this last result allows one to rely on the very fast bistellar flip algorithms of [20] (utilized in [18]) to find all of the coherent triangulations.

7.2. Invariant points and indifferent crossings. We conclude this section with an informal discussion of zero-dimensional regions in the phase diagram. These will correspond to cones of dimension $m-2$ in $\mathcal{F}(\mathcal{A})$ or cones of dimension $m-n-2$ in $\mathcal{F}'(\mathcal{A})$. These correspond to coherent polytopal subdivisions of $\mathcal{A}$ of two possible types, and therefore give rise to two distinct types of points in the phase diagram: invariant points and indifferent crossings.

DEFINITION 7.4. *If a coherent polytopal subdivision of $\mathcal{A}$ corresponds to a cone of dimension $m-2$ in $\mathcal{F}(\mathcal{A})$, then one of the polytopes F' in the subdivision might correspond to a stable assemblage $\mathcal{A}'$ having $m' = n'+2$ phases. When this occurs, the same holds for every polytope in the subdivision which contains F' as a face. However, the remaining polytopes which do not contain F' will all be simplices.*

It is in this situation that geochemists reserve the term invariant point *for the corresponding zero-dimensional region in the phase diagram. In this situation it is possible for all of the phases in $\mathcal{A}'$ to coexist in chemical equilibrium, but one cannot vary (T, P) at all while maintaining this. For example, the central points in Figures* 1 *and* 6(c) *are invariant points, as are the points labelled $[B], [C], [D], [G], [W]$ within the diagrammed regions of Figure* 12 *(below).*

Geochemists usually label the invariant point by the phases $\mathcal{B} := \mathcal{A} - \mathcal{A}'$ *not* involved in the invariant equilibrium. It is also well known to geochemists that the local structure of the phase diagram around an invariant point is similar to the corresponding phase diagram with $m' = n'+2$ for the chemical subsystem $\mathcal{A}'$. This corresponds to

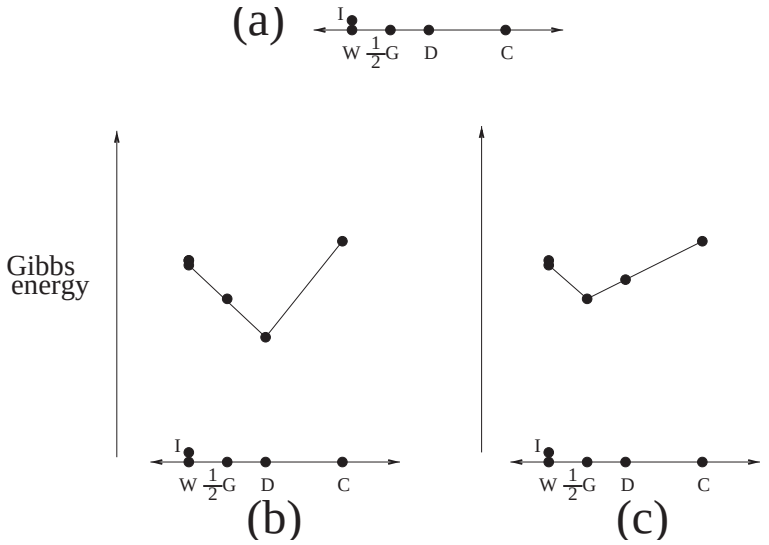

FIG. 8. *An $m = n+3$ system illustrating the distinction between invariant points and indifferent crossings.*

the known fact (see [4]) that the local structure of the pointed secondary fan $\mathcal{F}'(\mathcal{A})$ about the cone $\text{pos}(\mathcal{B})$ and the structure of the fan $\mathcal{F}'(\mathcal{A}') = \mathcal{F}'(\mathcal{A} - \mathcal{B})$ coincide, reflecting the fundamental duality between *deletion* and *contraction* in (oriented) matroid theory: the dual point configuration $(\mathcal{A}-\mathcal{B})^*$ to the deletion $\mathcal{A}-\mathcal{B}$ is isomorphic to the contraction $\mathcal{A}^*/\mathcal{B}^*$.

DEFINITION 7.5. *On the other hand, when a cone in $\mathcal{F}(\mathcal{A})$ has dimension $m-2$, there can also be two polytopes F' and F'' in the corresponding polytopal subdivision, neither contained as a face of the other, corresponding to stable assemblages $\mathcal{A}'$ and $\mathcal{A}''$ with $m' = n' + 1, m'' = n'' + 1$. The polytopes in the subdivision containing neither of F' or F'' will all be simplices. For each of $\mathcal{A}'$ or $\mathcal{A}''$ individually, the union of regions in the phase diagram where they occur as a stable assemblage corresponds to a cone of dimension $m-1$ in $\mathcal{F}(\mathcal{A})$ and a curve in the phase diagram coming from a minimal reaction possible in $\mathcal{A}$. These two curves intersect at what is called an* indifferent crossing*, where either $\mathcal{A}'$ or $\mathcal{A}''$ might exist in equilibrium (as might assemblages corresponding to other simplices in the subdivision), but the union $\mathcal{A}' \cup \mathcal{A}''$ cannot stably coexist: the faces F', F'' lift to two different faces in the lower hull of $\hat{\mathcal{A}}$, lying above disjoint possibilities for the molar fractions of the phases.*

Example 7.6. To illustrate the distinction between the two kinds of cones of dimension $m-2$ in $\mathcal{F}(\mathcal{A})$ that give rise to invariant points versus indifferent crossings, we augment our previous chemical system of corundum, diaspore, gibbsite, and water with a fifth phase: ice, abbreviated I, having chemical formula H_2O, the same as water. Rescaling this to a chemography as before gives a new chemography $\mathcal{A}$ with $n = 2$ as before, but now with $m = 5 = n+3$, depicted in Figure 8(a). Figure 8(b) and (c) depict lifted configurations $\hat{\mathcal{A}}$ that would correspond to cones of dimension $(m-2)$ in $\mathcal{F}(\mathcal{A})$, corresponding to an invariant point and indifferent crossing, respectively.

In (b), the interesting stable assemblage is $\mathcal{A}' = \{D, G, W, I\}$, having $m' = 4, n'(= n) = 2$, so $m' = n' + 2$, and the corresponding lifted points $\hat{\mathcal{A}}'$ lie on a single face F' in the lower hull of $\hat{\mathcal{A}}$. If the phase diagram were to contain a point corresponding to

this cone of $\mathcal{F}(\mathcal{A})$, it would be an invariant point, labelled $[C]$ for the missing phase corundum not present in $\mathcal{A}'$.

In (c), there are at least two interesting stable assemblages: $\mathcal{A}' = \{W, I\}$, with $m' = 2, n' = 1$, and $\mathcal{A}'' = \{C, D, G\}$, with $m'' = 3, n' = 2$, so that $m' = n' + 1, m'' = n'' + 1$, and their corresponding lifted points $\hat{\mathcal{A}}', \hat{\mathcal{A}}''$ span different faces F', F'' of the lower hull of $\hat{\mathcal{A}}$. If the phase diagram were to contain a point corresponding to this cone of $\mathcal{F}(\mathcal{A})$, it would be an indifferent crossing, lying at the intersection of two curves corresponding to the two circuits (reactions) involving the phases $\mathcal{A}'$ and $\mathcal{A}''$.

8. The case $m = n+2$: Phase diagram = Gale diagram. After dispensing quickly with the cases $m = n$ and $m = n + 1$, in this section we examine in detail the structure of the Gale diagram $\mathcal{A}^*$, the pointed secondary fan $\mathcal{F}'(\mathcal{A})$, and the phase diagram when $m = n + 2$. The conclusion is that they all look roughly the same in this case.

When $m = n$, the m phases cannot perform any reactions that preserve mass-balance, and so are mutually inert and nothing can happen.

When $m = n + 1$, not much interesting happens. There is exactly one reaction possible, corresponding to the unique signed circuit $C = (X^+, X^-)$ of $\mathcal{A}$. The Gale diagram $\mathcal{A}^*$ is a set of vectors lying on the real line $\mathbb{R}^1$ with their tails at the origin 0. Those a_i^* having $i \in X^+$ will point in the positive direction, those with $i \in X^-$ will point in the negative direction, and those $i \in \{1, \ldots, m\} - (X^+ \cup X^-)$ will be zero vectors pointing nowhere. The secondary fan $\mathcal{F}'(\mathcal{A})$ decomposes the $\mathbb{R}^1$ into two cones: the two rays emanating from the origin in the positive and negative directions. These rays correspond to the two triangulations of $\mathcal{A}$ which differ by a bistellar operation supported on C. At a particular temperature and pressure, the Gibbs energy of the ensemble of products/reactants, whichever is lower, will force the reaction to run in one direction or another, so that the stable assemblages will correspond to the simplices of one or the other triangulation. In this case, the phase diagram consists of two divariant regions separated by the univariant curve corresponding to the single reaction.

When $m = n+2$, things start to become interesting. First, we can assume without loss of generality that there are no *indifferent phases*,[8] that is, every phase participates in some possible reaction or phase change. By excluding indifferent phases, we know that the Gale diagram $\mathcal{A}^*$ has m nonzero Gale vectors $a_1^*, \ldots, a_m^*$, although it is possible that some differ by positive scalar multiples and hence point in the same direction.[9] The pointed secondary fan $\mathcal{F}'(\mathcal{A})$ will look very similar to the Gale diagram, having at most m rays emanating from the origin, pointing in the directions of the Gale vectors, and two-dimensional cones lying between cyclically adjacent Gale vectors. According to Proposition 5.3, the phase diagram should look roughly like a two-dimensional slice of this two-dimensional pointed secondary fan $\mathcal{F}'(\mathcal{A})$, that is, like $\mathcal{F}'(\mathcal{A})$ itself. Hence the phase diagram will closely resemble the Gale diagram $\mathcal{A}^*$.

Roughly speaking, geochemists have known some version of this, in the guise of a method for constructing their *invariant point maps* as schematic representations of the local picture around an invariant point, based on knowledge of the minimal reactions possible among the phases. Their method uses Schreinemakers' *fundamental axiom*

[8] An indifferent phase would give rise to an element a_i of the oriented matroid for $\mathcal{A}$, known as an *isthmus* or *coloop*, and also to a zero Gale vector $a_i^* = 0$.

[9] This will happen whenever there are affine hyperplanes in $\mathbb{R}^{n-1}$ that contain all but two of the points of $\mathcal{A}$.

[25], [30], which is a reformulation of the oriented matroid duality assertion that the circuits of $\mathcal{A}$ coincide with the cocircuits of $\mathcal{A}^*$. The axioms assert that

- each phase a_i should label some univariant reaction half-line emanating from the invariant point, corresponding to a minimal reaction among the remaining phases other than a_i, and
- the extension of this half-line to a line through the origin should separate the other univariant reaction half-lines into those corresponding to the two sides of the reaction in question.

In other words, each Gale vector a_i^* lies on a line through the origin corresponding to a cocircuit of $\mathcal{A}^*$, which corresponds to a circuit of $\mathcal{A}$.

Using this rule, one can sketch the invariant point map by proceeding through the list of minimal reactions among the phases and using the axiom to place the half-lines around each other in cyclic order. There is an initial choice of orientation one must make for the diagram using the first reaction (should the reactant/products/missing-phase-half-line go in *clockwise* or *counterclockwise* order around the invariant point?), but after that the picture is determined. To decide which orientation is consistent with the actual geochemical phase diagram (i.e., to determine the actual placement of the image surface $\gamma(\mathbb{R}^2)$ within the secondary fan $\mathcal{F}(\mathcal{A})$), some thermodynamic data is required.

Example 8.1. Figure 6(c) shows the invariant point map constructed for the corundum-diaspore-gibbsite-water example. Note that we have used the geochemical conventions of labelling the univariant reaction half-lines emanating from the invariant point by the phase(s) missing from the reaction, putting the product/reactants on either side of the line, and indicating with dashes the *metastable* extensions of these half-lines.

9. The case $m = n + 3$: Phase diagram = affine Gale diagram. We next examine in detail the structure of the Gale diagram $\mathcal{A}^*$, the pointed secondary fan $\mathcal{F}'(\mathcal{A})$, and the phase diagram when $m = n + 3$. The conclusion is that two methods used by geochemists to reduce an essentially three-dimensional picture to two dimensions have parallel constructions in discrete geometry, and the phase diagram bears a close resemblance to a two-dimensional affine Gale diagram.

When $m = n + 3$, we can again assume without loss of generality that there are no indifferent phases, and hence no zero Gale vectors a_i^*. However, we make no other genericity assumptions for the moment. The Gale diagram $\mathcal{A}^*$ is a vector configuration in $\mathbb{R}^3$. As before, some Gale vectors may differ by a positive scalar multiple and hence give rise to the same ray in the secondary fan $\mathcal{F}'(\mathcal{A})$, so we know there will be at most m such rays. Note that, unlike the case $m = n+2$, here the cones of the pointed secondary fan $\mathcal{F}'(\mathcal{A})$ can be more exotic in shape: they are intersections of the three-dimensional simplicial cones spanned by linearly independent subsets of $\mathcal{A}^*$, and hence can have arbitrary polygonal cross sections.

The one-dimensional cones (rays) in $\mathcal{F}'(\mathcal{A})$ will correspond to zero-dimensional (point) regions in the phase diagram when they intersect the image surface $\gamma(\mathbb{R}^2)$ of the Gibbs energy map. As discussed in subsection 7.2, these points will either be indifferent crossings or invariant points. Since the invariant points correspond to chemical subsystems $\mathcal{A}' \subset \mathcal{A}$ which have $m' = n' + 2$ if we have $n' = n$ (as happens generically), then $|\mathcal{A}'| = |\mathcal{A}| - 1$; that is, there is exactly one phase a_i missing from $\mathcal{A}'$, and the corresponding ray in $\mathcal{F}'(\mathcal{A})$ is spanned by the Gale vector a_i^*. This is the reason that invariant points in phase diagrams with $m = n + 3$ are generically labelled by the single phase missing from the invariant equilibrium at that point. As

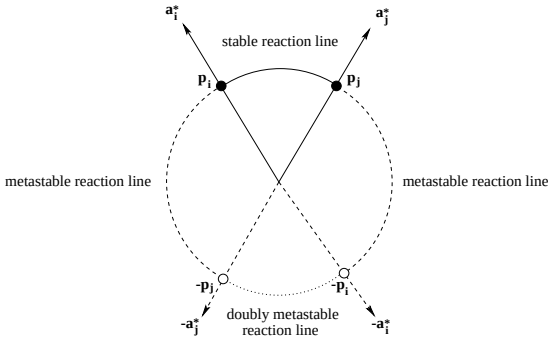

FIG. 9. *A typical reaction loop defined by two Gale vectors* $\mathbf{a}_i^*$ *and* $\mathbf{a}_j^*$.

also discussed in subsection 7.2, the local structure about the invariant point will look like the invariant point map for the $m' = n' + 2$ subsystem $\mathcal{A}'$.

Vector configurations in $\mathbb{R}^3$ (like $\mathcal{A}^*$) can be difficult to visualize. We discuss two methods that have been commonly used to cut down the dimension by one (and produce a picture closer in spirit to the phase diagram): the *spherical representation* and *affine Gale diagrams*.

9.1. The spherical representation: Closed nets. Intersecting the pointed secondary fan $\mathcal{F}'(\mathcal{A})$ in $\mathbb{R}^3$ with a unit sphere centered about the origin gives a useful spherical representation, similar to what has been called a *closed net* in [29]. In the conventions for the closed net, one includes not only the point of intersection with the sphere $p_i := a_i^*/|a_i^*|$ for each ray spanned by a Gale vector a_i^* (represented by a black dot labelled by the corresponding phase a_i), but also its negation $-p_i$ (represented by a white dot labelled similarly).[10] Furthermore, the arc representing the intersection curve on the sphere of a two-dimensional cone in $\mathcal{F}'(\mathcal{A})$ is augmented to be part of a great circle called a *reaction loop*, corresponding to the unique minimal reaction (circuit of $\mathcal{A}$, cocircuit of $\mathcal{A}^*$) to which it is associated. Typically such a reaction will involve all but two phases a_i, a_j (although this will not always be the case when $\mathcal{A}$ is not generic and therefore has some circuits of smaller support). As one traverses such a typical reaction loop, one passes through four arcs, as depicted in Figure 9.

The point of the closed net representation is that a hemispherical or planar projection of it from some angle should give a schematic picture of the actual phase diagram. Which projection occurs in nature will depend upon the location and orientation of the image surface $\gamma(\mathbb{R}^2)$ of the Gibbs energy map from section 5 inside the secondary fan $\mathcal{F}(\mathcal{A})$. Under our Assumption 5.4, one of each pair $\{p_i, -p_i\}$ will appear in the projection, and there are four possibilities for the portion of a typical reaction loop that will appear in the projection, depicted in Figure 10.

Example 9.1. We add a fifth phase (different from the ice added in Example 7.6) to our original example of corundum, diaspore, gibbsite, and water: the mineral *boehmite* (B), which is a *polymorph* of diaspore, that is, has the same chemical formula AlO(OH) but a different crystal structure. Thus B, D become parallel elements in the oriented matroid $\mathcal{M}$ for this new point configuration $\mathcal{A}$, having $m = 5$ and $n = 2$, so that $m = n + 3$.

[10] This supplementation of the Gale diagram $\mathcal{A}^*$ by adding in negations of all its vectors is reminiscent of the *Lawrence construction* [2, section 9.3] in oriented matroid theory.

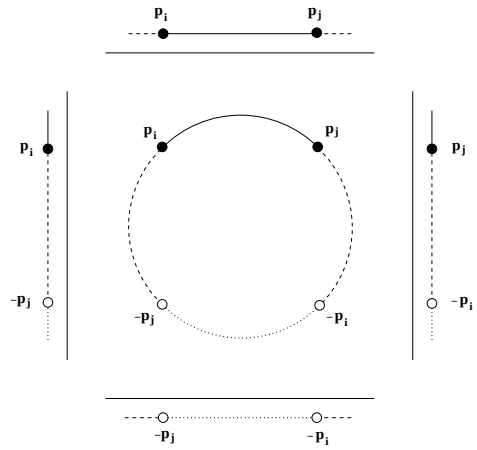

FIG. 10. *The four possible projections of a reaction loop onto an affine* 2*-plane.*

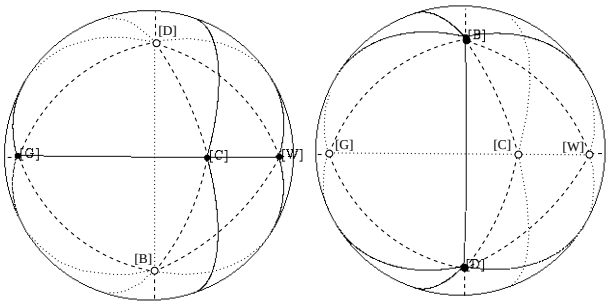

FIG. 11. *Two opposing hemispheric views of the closed net for the system with phases corundum, boehmite, diaspore, gibbsite, and water.*

We have

$$\mathcal{A} = \begin{array}{c} \begin{matrix} C & D & B & \frac{1}{2}G & W \end{matrix} \\ \begin{bmatrix} 1 & \frac{1}{2} & \frac{1}{2} & \frac{1}{4} & 0 \\ 0 & \frac{1}{2} & \frac{1}{2} & \frac{3}{4} & 1 \end{bmatrix} \end{array}, \tag{6}$$

and a valid Gale transform is

$$\mathcal{A}^* = \begin{array}{c} \begin{matrix} C^* & D^* & B^* & G^* & W^* \end{matrix} \\ \begin{bmatrix} 1 & 0 & 0 & -4 & 3 \\ 0 & 1 & 0 & -2 & 1 \\ 0 & 0 & 1 & -2 & 1 \end{bmatrix} \end{array}. \tag{7}$$

Two opposite hemispheric views of the closed net for this example are depicted in Figure 11. Note that the parallel elements B, D in $\mathcal{A}$ give rise to a circuit

$$\begin{matrix} C & D & B & G & W \\ 0 & + & - & 0 & 0 \end{matrix}$$

that corresponds to a cocircuit of $\mathcal{A}^*$: the Gale vectors C^*, G^*, W^* are coplanar, and

their corresponding points on the closed net lie on a great circle which separates D^* from B^*.

9.2. Two-dimensional affine Gale diagrams. The affine Gale diagram is simply an affine point configuration in $\mathbb{R}^2$ used to encode the three-dimensional vector configuration $\mathcal{A}^*$; see [33, Definition 6.17], [2, section 9.1]. Arbitrarily choose a two-dimensional affine plane Γ in $\mathbb{R}^3$ to "slice" the Gale vectors: if this plane Γ is defined by the equation $f(x) = c$ for some generic linear functional $f \in (\mathbb{R}^3)^*$ and some positive value c, then we replace each Gale vector a_i^* by the unique point $ca_i^*/f(a_i^*)$ in its span that lies in this plane Γ. Color these rescaled Gale points in Γ black or white, depending upon whether $f(a_i^*) > 0$ or $f(a_i^*) < 0$. Since $\mathcal{A}$ was an affine point configuration and hence $\mathcal{A}^*$ is a totally cyclic vector configuration, there will always be both black and white points in the affine Gale diagram, regardless of how the functional f is chosen.

We can further annotate the affine Gale diagram by drawing in line segments that correspond to the intersections of two-dimensional cones from $\mathcal{F}'(\mathcal{A})$ with the plane Γ that happen to connect the black points in the diagram. Bearing in mind Assumption 5.4, the choice of the functional f (equivalently, the choice of the plane Γ) corresponds to the choice of the location of the image surface $\gamma(\mathbb{R}^2)$ of the Gibbs energy map. It follows from Proposition 5.3 that this "decorated affine Gale diagram" is a schematic picture for one possible toplogy of the phase diagram. Such schematic pictures, when annotated further with more arcs of reaction loops using conventions similar to the closed nets discussed in subsection 9.1 above, have appeared in [17] and are called *potential solutions* for the phase diagram topology.

When are two such affine Gale diagrams/potential solutions considered "equivalent"? Fortunately, discrete geometers and geochemists agree on this answer: when the assignment of either a black or a white dot to each phase is the same. Equivalently, this means they have the same sign vector $(\text{sign}(f(a_1^*)), \ldots, \text{sign}(f(a_m^*))) \in \{+,-\}^m$ or, in oriented matroid terminology, that f achieves the same *acyclic (re)orientation* (or *tope*) of the vector configuration $\mathcal{A}^*$ (see [2, section 3.8]). This turns out to have the following geometric reinterpretation: if we regard the functional $f(x) = f_1x_1 + f_2x_2 + f_3x_3$ as its vector of coefficients (f_1, f_2, f_3), then the acyclic orientation achieved by f is determined by which side of each of the hyperplanes $(a_i^*)^\perp$ normal to the Gale vectors it lies on. Therefore intersecting this arrangement of hyperplanes $(a_i^*)^\perp$ with the unit sphere in $\mathbb{R}^3$ gives an arrangement of great circles on the sphere (called the *Euler sphere* in [16]), whose two-dimensional regions parametrize the different acyclic orientations/affine Gale diagrams/potential solutions.

The method developed in [16] of constructing potential solutions for systems with $m = n+3$ systems involved looking at each phase, using the method of Schreinemakers from section 8 to infer the local structure/invariant point map about the invariant point at which that phase is missing from the assemblage, and then "fitting together" these various invariant point maps to produce the straight line net.

Example 9.2. Figure 12 shows a view of the Euler sphere for the previous example with $m = n + 3$, along with two of its regions labelled by their corresponding affine Gale diagrams/potential solutions.

There is a good bit of theory to help one enumerate these acyclic reorientations (see [2, Theorem 4.6.1] and subsection 10.2 below) or to produce a list of them all algorithmically using a straightforward application of Farkas' lemma [26, section 7.3]. In the Java applet CHEMOGALE [18], such an algorithm is part of the implementation. For systems input by the user with $m = n+2$ or $n+3$, the program computes $\mathcal{A}^*$

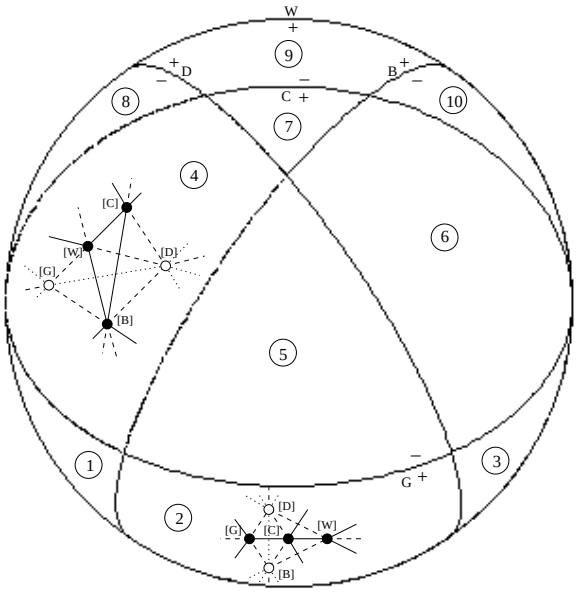

FIG. 12. *The hemisphere of the Euler sphere lying in one side of* $(W^*)^\perp$ *for the* $m = n + 3$ *system with phases corundum, boehmite, diaspore, gibbsite, and water. Two regions are shown labelled by the corresponding affine Gale diagrams/potential solutions to phase diagram topology.*

and uses data generated by [20] to obtain $\mathcal{F}'(\mathcal{A})$. When $m = n + 3$, the intersection of $\mathcal{F}'(\mathcal{A})$ with the unit sphere is depicted, allowing the user to select two-dimensional cones of $\mathcal{F}'(\mathcal{A})$ and receive the corresponding triangulation. For $m = n + 3$ systems, the user may also view the Euler sphere and see the potential solution to the phase diagram topology associated with each region. This work was fully described in [19, Chapter 3].

10. Further implications/applications. We collect here a few further implications/applications of some of the theory developed.

10.1. Slopes around invariant points. Let p be an invariant point in the phase diagram, and let $\{a_1, \ldots, a_k\}$ be the union of all sets of phases that can form stable assemblages at p. There will be at most k univariant reaction curves emanating from p corresponding to reactions that omit each of the phases a_i, and each has a limiting slope μ_i as it enters p. Doing the experiments to determine these slopes accurately is expensive and time-consuming, so it is helpful to be able to determine the slopes from as little data as possible.

PROPOSITION 10.1. *Knowing the formulae* $\{a_1, \ldots, a_k\}$ *of the phases and knowing three different limiting slopes* $\mu_{i_1}, \mu_{i_2}, \mu_{i_3}$ *determines all of the slopes* $\mu_1, \ldots, \mu_k$.

Proof. As discussed in section 7.2, the local structure of the phase diagram about p coincides with the phase diagram for only the subsystem of phases in $\mathcal{A}' := \{a_1, \ldots, a_k\}$, and this must be a system with $k = n+2$ phases. Let its Gale transform be $\mathcal{A}'^* := \{a_1^*, \ldots, a_k^*\}$, so that, up to an invertible linear change-of-basis in $\mathbb{R}^2$, these give the slopes of the rays emanating from the origin in the pointed secondary fan $\mathcal{F}'(\mathcal{A}')$. By Assumption 5.4, the slopes $\{\mu_1, \ldots, \mu_k\}$ are also related to the slopes of these rays in the pointed secondary fan by an invertible linear change-of-basis (namely,

the Jacobian matrix of the Gibbs energy map $\gamma : \mathbb{R}^2 \to \mathbb{R}^m$ evaluated at the point $p \in \mathbb{R}^2$, composed with the linear projection map from $\mathbb{R}^m \to \mathbb{R}^{m-n}$ that sends the secondary fan to the pointed secondary fan). Hence the (known) slopes of the Gale vectors in $\mathcal{A}'^*$ are related to the limiting slopes about p by an invertible linear change-of-basis. Therefore knowledge of three distinct slopes $\mu_{i_1}, \mu_{i_2}, \mu_{i_3}$ will determine any other slope μ_{i_r}, e.g., by invariance under invertible linear transformations of the *cross-ratio*

$$(\mu_{i_1}, \mu_{i_2} \mid \mu_{i_3}, \mu_{i_r}) := \frac{(\mu_{i_r} - \mu_{i_1})(\mu_{i_3} - \mu_{i_2})}{(\mu_{i_r} - \mu_{i_2})(\mu_{i_3} - \mu_{i_1})}. \qquad \square$$

Example 10.2. In the example of corundum, diaspore, gibbsite, and water, which had Gale diagram

$$\mathcal{A}^* = \begin{array}{c} \begin{matrix} C^* & D^* & G^* & W^* \end{matrix} \\ \begin{bmatrix} 1 & -3 & 2 & 0 \\ 2 & -4 & 0 & 2 \end{bmatrix} \end{array}, \tag{8}$$

we see that the slopes of C^*, D^*, G^*, W^* are $2, \frac{4}{3}, 0, \infty$, giving the cross-ratio

$$(\mu_{C^*}, \mu_{G^*} \mid \mu_{W^*}, \mu_{D^*}) = \frac{(\frac{4}{3} - 2)(\infty - 0)}{(\frac{4}{3} - 0)(\infty - 2)} = -\frac{1}{2}.$$

Thus if we have already determined (say, from thermodynamic data) that the phase diagram has limiting slopes $\mu_{[C]}, \mu_{[G]}, \mu_{[W]}$ for the three reaction curves labelled $[C], [G], [W]$ entering the invariant point, then the limiting slope $\mu_{[D]}$ of the fourth reaction curve labelled $[D]$ will satisfy

$$-\frac{1}{2} = (\mu_{[C]}, \mu_{[G]} \mid \mu_{[W]}, \mu_{[D]}) = \frac{(\mu_{[D]} - \mu_{[C]})(\mu_{[W]} - \mu_{[G]})}{(\mu_{[D]} - \mu_{[G]})(\mu_{[W]} - \mu_{[C]})},$$

which can be solved for $\mu_{[D]}$, giving the formula

$$\mu_{[D]} = \frac{3\mu_{[C]}\mu_{[G]} - 2\mu_{[C]}\mu_{[W]} - \mu_{[G]}\mu_{[W]}}{2\mu_{[G]} - 3\mu_{[W]} + \mu_{[C]}}.$$

10.2. Counting potential solutions. As mentioned in section 9.2, there is theory available for counting the acyclic orientations of a vector configuration (or oriented matroid) such as the Gale diagram $\mathcal{A}^*$. Here we elaborate on this and explain how to easily count potential solutions to phase diagram topology when $m = n + 3$.

As we saw in section 9.2, counting the potential solutions to phase diagram topology amounts to counting the three-dimensional cones cut out by an arrangement of planes through the origin in $\mathbb{R}^3$, or the two-dimensional regions cut out by an arrangement of great circles on a sphere, or the acyclic orientations of the oriented matroid $\mathcal{M}^*$ associated to the Gale diagram $\mathcal{A}^*$. The problem of counting the n-dimensional regions cut out by an arrangement of $(n-1)$-dimensional hyperplanes through the origin in $\mathbb{R}^n$ was treated first by Winder in 1966, and then later independently by both Las Vergnas and Zaslavsky around 1975. The basic idea is that even though the combinatorial structure of the regions cut out (e.g., how many faces of each dimension they have) depends on the associated *oriented* matroid, the number of regions only

depends on the coarser information recorded in the *matroid*. We review some of this material here; see [2, section 4.6] for a fuller treatment.

For example, one way to record the matroid data associated to $\mathcal{A}^*$ is to list all of its (unsigned) *circuits*, which are the support sets of minimal linear dependences (with no record of the signs of the coefficients in the dependence). A more useful way to encode the data for counting the regions (but equivalent data to specifying the circuits) is to write down the *lattice of flats* $L(\mathcal{A}^*)$, which is the partial ordering by inclusion of all subspaces spanned by subsets of $\mathcal{A}^*$. The bottom element of this partially ordered set, called $\hat{0}$, corresponds to the zero subspace (spanned by the empty set of Gale vectors).

The *Möbius function* $\mu(x, y)$ is an integer associated to each pair of elements $x \leq y$ which are related in the partial order L, defined recursively by these properties:

$$\mu(x, x) = +1,$$
$$\mu(x, y) = -\sum_{x \leq z < y} \mu(x, z) \quad \text{if } x < y.$$

One can use this to count regions via the following result.

THEOREM 10.3 (see [2, Theorem 4.6.1]). *The number of regions cut out by the hyperplanes normal to a collection of vectors with lattice of flats L is*

$$\sum_{x \in L} |\mu(\hat{0}, x)|.$$

Since we wish to apply this to geochemical systems with $m = n + 3$, we detail here explicitly (in more concrete terms) what happens in this case.

PROPOSITION 10.4. *Let $\mathcal{A}$ be a chemography with $m = n + 3$, so that its Gale diagram $\mathcal{A}^*$ is a configuration of vectors in $\mathbb{R}^3$. Then the number of potential solutions to phase diagram topology is*

$$2\left(1 + \sum_{P} (m_P - 1)\right),$$

where P runs through all two-dimensional planes spanned by pairs of the Gale vectors $\mathcal{A}^*$, and m_P is the number of distinct lines spanned by Gale vectors lying in the plane P (or, equivalently, the number of parallelism classes of Gale vectors within the plane P).

In particular, if $\mathcal{A}$ is in a general position (in the sense that every subset of n elements in $\mathcal{A}$ is affinely independent or, equivalently, every minimal reaction among the phases involves at least $n+1$ phases), the number of potential solutions is (cf. [17]*)*

$$2\left(1 + \binom{n}{2}\right).$$

Proof. Since $\mathcal{A}^*$ lives in $\mathbb{R}^3$, there are four kinds of elements x in the lattice of flats:

- $x = \hat{0}$, having $\mu(\hat{0}, \hat{0}) = +1$,
- $x = \ell$, a line spanned by a Gale vector a_i^*, having $\mu(\hat{0}, \ell) = -1$,
- $x = P$, a two-dimensional plane spanned by Gale vectors, having

$$\mu(\hat{0}, P) = -\left(\mu(\hat{0}, \hat{0}) + \sum_{\ell \subset P} \mu(\hat{0}, \ell)\right) = m_P - 1, \qquad \text{and}$$

- $x = \mathbb{R}^3$, having

$$\begin{aligned}\mu(\hat{0}, \mathbb{R}^3) &= -\left(\mu(\hat{0}, \hat{0}) + \sum_{\ell} \mu(\hat{0}, \ell) + \sum_{P} \mu(\hat{0}, P)\right) \\ &= -1 + \#\{\text{lines } \ell \text{ spanned by Gale vectors}\} \\ &\quad + \sum_{P} (m_P - 1).\end{aligned}$$

Adding the absolute values of all of these gives the result stated in the proposition.

In the generic case, since $\mathcal{A}$ has n points, there will be n distinct Gale vectors $\mathcal{A}^*$, no two of which span the same line ℓ, and there will be $\binom{n}{2}$ different planes P spanned by them. ($\mathcal{A}$ is generic if and only if $\mathcal{A}^*$ is generic by matroid duality.) Also, each of these planes will contain exactly two lines ℓ, so $m_P - 1 = 1$. The second assertion follows from plugging these values into the first equation. □

Example 10.5. In Figure 12, the Euler sphere shown has 20 regions total (10 visible on the hemisphere shown and 10 more on the "underside"). One can compare this with the formula predicted in Proposition 10.4, which can be evaluated with the aid of the closed net picture of Gale vectors in Figure 11. This figure shows (the intersection with the sphere of) eight planes P spanned by pairs of Gale vectors, namely,

$$BC, BG, BW, DG, DC, DW, BD, BGW,$$

of which the first seven have $m_P = 2$, and the last has $m_P = 3$. Thus the proposition would predict

$$2(1 + 7 \cdot (2 - 1) + 1 \cdot (3 - 1)) = 20$$

regions, as expected.

GLOBAL RESULTS FOR AN EPIDEMIC MODEL WITH VACCINATION THAT EXHIBITS BACKWARD BIFURCATION*

JULIEN ARINO†, C. CONNELL MCCLUSKEY†, AND P. VAN DEN DRIESSCHE†

Abstract. Vaccination of both newborns and susceptibles is included in a transmission model for a disease that confers immunity. The interplay of the vaccination strategy together with the vaccine efficacy and waning is studied. In particular, it is shown that a backward bifurcation leading to bistability can occur. Under mild parameter constraints, compound matrices are used to show that each orbit limits to an equilibrium. In the case of bistability, this global result requires a novel approach since there is no compact absorbing set.

Key words. epidemic model, vaccination, backward bifurcation, compound matrices, global dynamics

1. Introduction.

Vaccination is a commonly used method for controlling diseases, e.g., pertussis, measles, or influenza. Mathematical models including vaccination aid in deciding on a vaccination strategy and in determining changes in qualitative behavior that could result from such a control measure (see, e.g., [5, 6]). If the vaccine is not totally effective, then recent models show that a backward bifurcation is possible for some parameter values [9, 10]. In such a case, the basic reproduction number as modified by vaccination must be reduced below a certain threshold (that is less than one) in order to ensure that the disease dies out. Backward bifurcation has been observed in other disease transmission models, for example the HIV/AIDS models discussed in [2, 8] and the bovine respiratory syncytial virus model in [4].

Our model is a generalization of that of [10], allowing individuals recovering from the disease to go into a temporarily immune class rather than directly back into the susceptible class. A recent model [9] allows for a recovered class and considers vaccination for a disease that has acute and chronic infective stages as well as variable infectivity.

In section 2, we develop our model with general parameters, and illustrate its behavior in section 3 by using vaccination-related values appropriate for pertussis [1, 5]. In particular, we focus on the vaccination parameters and how changes in these may alter the qualitative behavior of the model by leading to subthreshold endemic states via backward bifurcation. Some local stability results are proved.

Previous investigations of the stability of subthreshold endemic states associated with backward bifurcations rely mainly on local results. We use compound matrices and geometric ideas to develop global results under mild parameter restrictions. These tools have been used for analyzing other models of disease transmission in which there is a unique endemic equilibrium; see, e.g., [11, 14, 16, 18]. In section 4, we present a brief summary of this geometric approach for studying the global dynamics of our model, concentrating on the novel features. This method is then used in section 5 to

prove global results for the model. (Some technical details are placed in Appendices A and B.) Concluding remarks are given in section 6.

2. Formulation of an *SIRS* model with vaccination. Following [10], but with newborn vaccination and a recovered class, the model has the flow diagram given in Figure 2.1 with the following assumptions. Each of the N individuals can be in one of four states: susceptible, infective, recovered, and vaccinated; the numbers in these states are denoted by S, I, R, and V, respectively. Thus, $N = S + I + R + V$. Birth occurs in the system with rate constant $d > 0$. Of these newborns, a fraction $\alpha \in [0, 1]$ are vaccinated at birth. Death occurs with the same rate constant d as birth; thus the total population N is constant. The transmission coefficient β is the number of contacts made by one infective per unit time multiplied by the probability that a contact with a susceptible leads to infection. The disease is transmitted horizontally, with the transmission modeled using a standard incidence function; thus the rate at which susceptibles become infective is $\beta SI/N$. For contacts between infectives and vaccinated individuals this coefficient is multiplied by a factor $\sigma \in [0, 1]$. Thus $1 - \sigma$ is the vaccine efficacy. Susceptible individuals are vaccinated with rate constant ϕ, and the vaccine protection wanes with rate constant $\theta > 0$. Infective individuals recover with rate constant $\gamma > 0$ and then have temporary immunity. They leave the recovered state with rate constant ν. We assume $\alpha d + \phi > 0$ to ensure that there is a nonzero flow of individuals into class V.

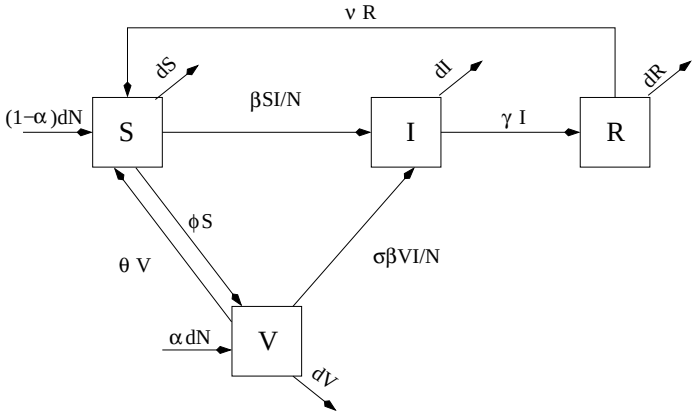

FIG. 2.1. *The flow diagram of the SIRV model.*

The model is formulated as the following system of ordinary differential equations:

$$\frac{dS}{dt} = (1-\alpha)dN - dS - \beta\frac{SI}{N} - \phi S + \theta V + \nu R, \tag{2.1a}$$

$$\frac{dI}{dt} = \beta\frac{SI}{N} + \sigma\beta\frac{VI}{N} - (d+\gamma)I, \tag{2.1b}$$

$$\frac{dR}{dt} = \gamma I - (d+\nu)R, \tag{2.1c}$$

$$\frac{dV}{dt} = \alpha dN + \phi S - (d+\theta)V - \sigma\beta\frac{VI}{N}, \tag{2.1d}$$

with nonnegative initial conditions and $N(0) > 0$.

System (2.1) is well posed: solutions remain nonnegative for nonnegative initial conditions. As the total population is constant, the system can be rewritten in terms

of proportions as

$$\frac{dS}{dt} = (1-\alpha)d - dS - \beta SI - \phi S + \theta(1-S-I-R) + \nu R, \tag{2.2a}$$

$$\frac{dI}{dt} = \beta SI + \sigma\beta(1-S-I-R)I - (d+\gamma)I, \tag{2.2b}$$

$$\frac{dR}{dt} = \gamma I - (d+\nu)R, \tag{2.2c}$$

$$V = 1-(S+I+R), \tag{2.2d}$$

where here S, I, R, V denote the proportions in the susceptible, infective, recovered, and vaccinated states, respectively. Conclusions about system (2.1) can be easily recovered from system (2.2), and we employ system (2.2) from now on. System (2.2a)–(2.2c) can be written as $dx/dt = f(x)$ with $x = (S, I, R)^T$.

In the case $\sigma = 1$, the vaccine is totally useless, and (2.2) reduces to an SIRS model without vaccination. The behavior is then determined by $\mathcal{R}_0 = \beta/(d+\gamma)$. This is the classical basic reproduction number in the SIRS model, namely, the average number of new infections caused by one infective (in a completely susceptible population) during the infective period. From now on we assume that $\sigma < 1$.

3. Equilibria and bifurcations. For system (2.2), there is always the disease-free equilibrium (DFE)

$$X_0 = (S_{DFE}, 0, 0, V_{DFE}) = \left(\frac{\theta + d(1-\alpha)}{d+\theta+\phi}, 0, 0, \frac{\phi + d\alpha}{d+\theta+\phi}\right). \tag{3.1}$$

Now consider endemic equilibria with $I = I^* > 0$. From (2.2b) at an endemic equilibrium, $\beta(S+\sigma V) = d+\gamma$. Since $S + \sigma V < 1$, this can be true only for $\beta > d+\gamma$; hence, for $\mathcal{R}_0 \le 1$ there exists no endemic equilibrium. For $\mathcal{R}_0 > 1$, the existence of endemic equilibria is determined by the presence in $(0, 1]$ of positive real solutions of the quadratic

$$P(I) = AI^2 + BI + C = 0,$$

with

$$A = -\sigma\beta^2\frac{d+\nu+\gamma}{d+\nu},$$

$$B = \sigma\beta^2 - \beta(d+\theta+\sigma(d+\gamma+\phi)) - \frac{\beta\gamma}{d+\nu}(d+\theta+\sigma\phi),$$

$$C = (d+\theta+\sigma\phi - d\alpha(1-\sigma))\beta - (d+\gamma)(d+\theta+\phi).$$

Thus, depending on parameter values, the number of endemic equilibria is zero, one, or two. For $\sigma = 0$ (the vaccine is totally effective), at most one endemic equilibrium is possible. From now on we make the realistic assumption that the vaccine is not totally effective, and thus $0 < \sigma < 1$. From (2.2a)–(2.2d), it can be shown that if I^* is a positive solution of $P(I) = 0$, then S^*, R^*, and V^* are positive; thus the equilibrium is biologically relevant. For a positive real solution I^* to $P(I) = 0$, the endemic equilibrium point (EEP) in system (2.2) is given by

$$(S^*, I^*, R^*, V^*) = \left(\frac{(1-\alpha)d + \frac{(\nu-\theta)\gamma I^*}{d+\nu} + (1-I^*)\theta}{d+\beta I^*+\phi+\theta}, I^*, \frac{\gamma I^*}{d+\nu}, 1-S^*-I^*-R^*\right).$$

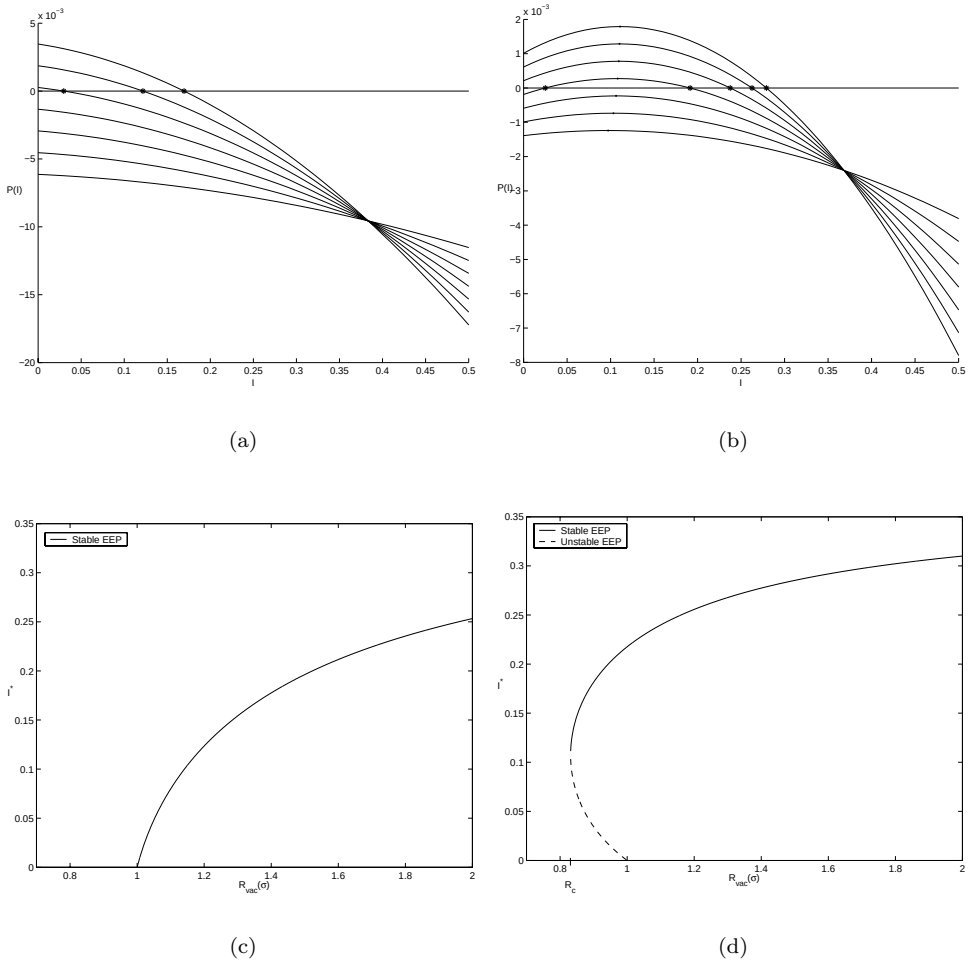

FIG. 3.1. (a) *Plot of the quadratic $P(I)$, with increasing values of σ (at left, from bottom to top, $\sigma = 0.04, 0.06, \ldots, 0.16$) in the forward bifurcation case, $\phi = 0.2$.* (b) *As* (a) *but in the backward bifurcation case, $\phi = 0.05$.* (c) *Bifurcation in the $(\mathcal{R}_{vac}(\sigma), I^*)$-plane, $\phi = 0.2$.* (d) *Bifurcation in the $(\mathcal{R}_{vac}(\sigma), I^*)$-plane, $\phi = 0.05$.*

In Figure 3.1, $P(I)$ is plotted versus I for increasing values of σ and $\phi = 0.2$ or 0.05 (all other parameters being fixed at the values indicated in Table 3.1). The values of γ, d and the vaccination parameters of Table 3.1 are appropriate for pertussis [1, 5], whereas β and ν are estimated to illustrate our bifurcation results. Figure 3.1(a) shows the situation that prevails when the bifurcation is a classical forward one. In this case, an increase in σ through some critical value σ_c (which depends on the other parameter values) leads through a transcritical bifurcation to a unique endemic equilibrium. Figure 3.1(b) shows the occurrence of the backward bifurcation. In this case, an increase of σ leads to the curve $P(I)$ becoming tangent to the horizontal axis defining a critical value σ_c at a saddle-node bifurcation. As σ becomes larger than σ_c, two equilibria exist. We expect bistability with the DFE and the equilibrium with the larger I value being stable. As σ increases further, the equilibrium with the smaller

TABLE 3.1
Parameter values used in simulations.

Parameter	Typical value or range	Meaning
β	0.4 /day	Transmission coefficient
γ	1/(21 days)	Average infectious period 21 days
d	1/(75 years)	Average lifespan 75 years
ν	1/(31 days)	Average period of immunity 31 days
α	0.9	Proportion of vaccinated newborns
ϕ	0.05 to 0.2/day	Vaccination rate constant
σ	0.04 to 0.2	Vaccine is between 80% and 96% effective
θ	1/(5 years)	Average vaccine waning time 5 years

I value moves to the left. When this equilibrium leaves the positive orthant through a transcritical bifurcation with the DFE, there is only one endemic equilibrium.

Since the concavity of the quadratic $P(I)$ is fixed (as $A < 0$), observation of Figure 3.1(b) gives necessary conditions for the existence of two equilibria: $P'(0) = B > 0$ and $P(0) = C < 0$. Together with the fact that the roots of $P(I)$ are real, this gives the bistability region $B > 0$, $C < 0$ and $\Delta = B^2 - 4AC > 0$. Figure 3.2 shows this region as a function of σ and ϕ, with all other parameters fixed as in Table 3.1.

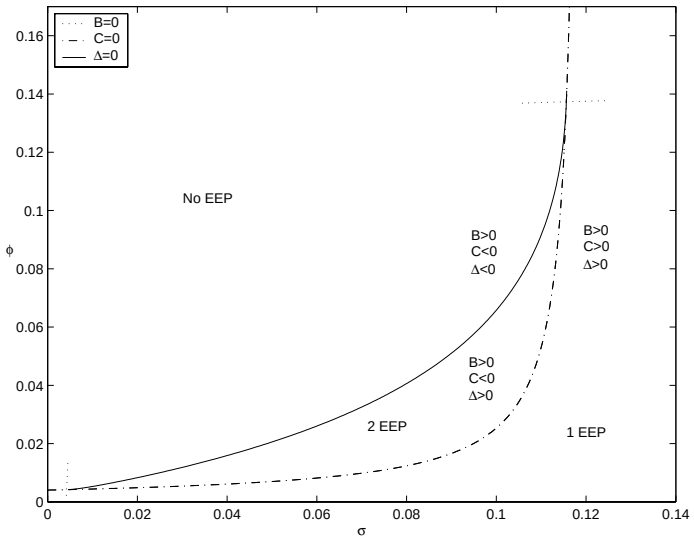

FIG. 3.2. *Bifurcation diagram in the (σ, ϕ)-plane.*

Using for example the method of [20], the basic reproduction number as modified by vaccination is

$$\mathcal{R}_{vac} = \frac{\beta}{d+\gamma}\left(S_{DFE} + \sigma V_{DFE}\right),$$

which from (3.1) gives

$$\mathcal{R}_{vac} = \mathcal{R}_0 \frac{d+\theta+\sigma\phi-d\alpha(1-\sigma)}{d+\theta+\phi}. \tag{3.2}$$

We write $\mathcal{R}_{vac}(\sigma)$ to indicate σ as the bifurcation parameter when all other parameters are fixed. Note that $\mathcal{R}_0(d(1-\alpha)+\theta)/(d+\theta+\phi) < \mathcal{R}_{vac}(\sigma) < \mathcal{R}_0$ (equalities are achieved at $\sigma = 0$ and $\sigma = 1$, respectively). The constant term C in the polynomial $P(I)$ can be written as $(d+\gamma)(d+\theta+\phi)(\mathcal{R}_{vac}-1)$; thus $P(0)$ has the same sign as $\mathcal{R}_{vac}-1$. Define $\mathcal{R}_c = \mathcal{R}_{vac}(\sigma_c)$. For a forward bifurcation, this gives $\mathcal{R}_c = 1$; see Figure 3.1(c). For a backward bifurcation, $\mathcal{R}_c < 1$; see Figure 3.1(d). The existence of endemic equilibria is summarized as follows.

PROPOSITION 3.1. *For model* (2.2)*, if* $\mathcal{R}_{vac} < \mathcal{R}_c$ *or* $\mathcal{R}_{vac} = \mathcal{R}_c = 1$*, there is no endemic equilibrium; if* $\mathcal{R}_c < \mathcal{R}_{vac} < 1$*, then there are two distinct endemic equilibria; if* $\mathcal{R}_c = \mathcal{R}_{vac} < 1$*,* $\mathcal{R}_c < \mathcal{R}_{vac} = 1$*, or* $\mathcal{R}_{vac} > 1$*, there is a unique endemic equilibrium.*

When two endemic equilibria are present, let X^* and X_* be the endemic equilibria with the larger and smaller value of I^*, respectively; when $\mathcal{R}_{vac} \neq \mathcal{R}_c$ and a unique endemic equilibrium exists, it is denoted by X^*; when $\mathcal{R}_{vac} = \mathcal{R}_c$ and a unique endemic equilibrium exists, it is denoted by X_c. A global result (for $\mathcal{R}_0 < 1$) and local stability of the equilibria are summarized in the following theorem, which justifies the stability of equilibria as shown in Figures 3.1(c) and 3.1(d).

THEOREM 3.2. *If* $\mathcal{R}_0 < 1$*, then the DFE* X_0 *is the only equilibrium for system* (2.2a)–(2.2c)*, and it is globally asymptotically stable;* X_0 *is locally asymptotically stable for* $\mathcal{R}_{vac} < 1$ *and unstable for* $\mathcal{R}_{vac} > 1$*. When present, the endemic equilibrium* X_* *is unstable, and if* $\theta \le \nu$*, then* X^* *is locally asymptotically stable.*

Proof. As remarked earlier, for $\mathcal{R}_0 \le 1$ there exists no endemic equilibrium. Further, if $\mathcal{R}_0 < 1$, then I can be used as a Lyapunov function to show that the DFE is globally asymptotically stable.

From [20, Theorem 2], $\mathcal{R}_{vac}$ is a threshold value, with X_0 being locally asymptotically stable if $\mathcal{R}_{vac} < 1$ and unstable if $\mathcal{R}_{vac} > 1$. Linearizing (2.2a)–(2.2c) about an endemic equilibrium gives the Jacobian matrix

$$\frac{\partial f}{\partial x}(S^*, I^*, R^*) = \begin{bmatrix} -d-\beta I^*-\phi-\theta & -\beta S^*-\theta & \nu-\theta \\ (1-\sigma)\beta I^* & -\sigma\beta I^* & -\sigma\beta I^* \\ 0 & \gamma & -(d+\nu) \end{bmatrix}.$$

In the case in which two endemic equilibria exist, $\det\big(\frac{\partial f}{\partial x}(X_*)\big) > 0$ and $\operatorname{tr}\big(\frac{\partial f}{\partial x}(X_*)\big) < 0$. Thus $\frac{\partial f}{\partial x}(X_*)$ has a positive eigenvalue and two eigenvalues with negative real part, making X_* unstable hyperbolic.

Let λ_j, $j = 1, 2, 3$, be the eigenvalues of $\frac{\partial f}{\partial x}(X^*)$ with $\Re(\lambda_1) \le \Re(\lambda_2) \le \Re(\lambda_3)$. It can be shown that $\det\big(\frac{\partial f}{\partial x}(X^*)\big) < 0$ and so $\lambda_1\lambda_2\lambda_3 < 0$. This means that either $\Re(\lambda_j) < 0$ for $j = 1, 2, 3$ or $\Re(\lambda_1) < 0 \le \Re(\lambda_2) \le \Re(\lambda_3)$. Since $\operatorname{tr}\big(\frac{\partial f}{\partial x}(X^*)\big) < 0$, it follows that $\lambda_1+\lambda_2+\lambda_3 < 0$, which implies that $\Re(\lambda_1+\lambda_2) < 0$ and $\Re(\lambda_1+\lambda_3) < 0$.

Assume now that $\theta \le \nu$, and consider the second additive compound [12] of the Jacobian matrix

$$\frac{\partial f}{\partial x}^{[2]}(X^*) = \begin{bmatrix} -\begin{pmatrix}(1+\sigma)\beta I^* \\ +d+\phi+\theta\end{pmatrix} & -\sigma\beta I^* & \theta-\nu \\ \gamma & -\begin{pmatrix}\beta I^*+2d \\ +\phi+\theta+\nu\end{pmatrix} & -\beta S^*-\theta \\ 0 & (1-\sigma)\beta I^* & -\big(\sigma\beta I^*+d+\nu\big) \end{bmatrix}.$$

Using the signs of the matrix elements, it is easily shown that $\det\big(\frac{\partial f}{\partial x}^{[2]}(X^*)\big) < 0$.

The eigenvalues of $\frac{\partial f}{\partial x}^{[2]}(X^*)$ are $\lambda_i + \lambda_j$, $1 \le i < j \le 3$, and so

$$\begin{aligned} -1 &= \operatorname{sgn}\left(\det\left(\frac{\partial f}{\partial x}^{[2]}(X^*)\right)\right) \\ &= \operatorname{sgn}\left(\Re(\lambda_1+\lambda_2)\,\Re(\lambda_1+\lambda_3)\Re(\lambda_2+\lambda_3)\right) \\ &= \operatorname{sgn}\left(\Re(\lambda_2+\lambda_3)\right). \end{aligned}$$

Thus, $\Re(\lambda_j) < 0$ for $j = 1, 2, 3$, and therefore X^* is locally asymptotically stable. ∎

Remark 3.3. For all of the numerical simulations performed here, the parameters satisfy $\theta \le \nu$; i.e., the average period of immunity is no longer than the average vaccine waning time. If $\theta \ge \nu$, then there is no endemic equilibrium for $\mathcal{R}_{vac} \le 1$, since each of the coefficients in $P(I)$ is nonpositive; thus there can be no bistability.

More general techniques are needed to determine the global dynamics for the case $\mathcal{R}_0 > 1$.

4. A geometric approach to global dynamics. In this section, a brief outline of a general mathematical framework for studying global dynamics is given. This approach to global dynamics is developed in the papers of Smith [17] and Li and Muldowney [12, 13, 15]. While this method is usually applied to demonstrate the global stability of a unique equilibrium [11, 14], here it is used to demonstrate bistability for a system that exhibits a backward bifurcation. In [11, 14], compound matrix techniques together with the existence of a compact absorbing set are used to prove global asymptotic stability of the endemic equilibrium point. For cases in which our model exhibits bistability, no such compact absorbing set exists; thus, a sequence of surfaces that exists for time $\epsilon > 0$ and minimizes the functional measuring surface area must be considered.

Let B be the Euclidean ball in $\mathbb{R}^2$, and let $\bar{B}$ and ∂B be its closure and boundary, respectively. Letting $\operatorname{Lip}(X \to Y)$ denote the set of Lipschitzian functions from X to Y, a function $\varphi \in \operatorname{Lip}(\bar{B} \to \mathcal{D})$ is a (simply connected rectifiable) surface in $\mathcal{D}$. A function $\psi \in \operatorname{Lip}(\partial B \to \mathcal{D})$ is a closed rectifiable curve in $\mathcal{D}$ and is called simple if it is one-to-one. Let $\Sigma(\psi, \mathcal{D}) = \{\varphi \in \operatorname{Lip}(\bar{B} \to \mathcal{D}) : \varphi|_{\partial B} = \psi\}$. In [15], it is shown that if ψ is contained in a simply connected open subset of $\mathcal{D}$, then $\Sigma(\psi, \mathcal{D})$ is nonempty.

Let $\|\cdot\|$ be a norm on $\mathbb{R}^{\binom{n}{2}}$. Consider a functional $\mathcal{S}$ on surfaces in $\mathcal{D}$ defined by

$$\mathcal{S}\varphi = \int_{\bar{B}} \left\| P \cdot \left(\frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2} \right) \right\| du, \tag{4.1}$$

where $u = (u_1, u_2)$, $u \mapsto \varphi(u)$ is Lipschitzian on $\bar{B}$, the wedge product $\frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2}$ is a vector in $\mathbb{R}^{\binom{n}{2}}$ (see [19]), and P is an $\binom{n}{2} \times \binom{n}{2}$ matrix such that $\|P^{-1}\|$ is bounded on $\varphi(\bar{B})$. The following result follows from the development in [12] and [15].

PROPOSITION 4.1. *Suppose that ψ is a simple closed rectifiable curve in $\mathbb{R}^n$. Then there exists $\delta > 0$ such that*

$$\mathcal{S}\varphi \ge \delta$$

for all $\varphi \in \Sigma(\psi, \mathbb{R}^n)$.

Functionals of the form (4.1) give a measure of the surface area of the surface φ. In this context, Proposition 4.1 can be interpreted as stating that, given a curve $\psi \subset \mathbb{R}^n$ and a measure of surface area, all surfaces with boundary ψ have surface area uniformly bounded away from zero.

Let $x \mapsto f(x) \in \mathbb{R}^n$ be a C^1 function for x in a set $\mathcal{D} \subset \mathbb{R}^n$. Consider the differential equation

$$\frac{dx}{dt} = f(x). \tag{4.2}$$

(This is used in section 5 with $x = (S, I, R)^T$ for the system (2.2a)–(2.2c).) For any surface φ, the new surface φ_t is defined by $\varphi_t(u) = x(t, \varphi(u))$. Note that when viewed as a function of t, $\varphi_t(u)$ gives the solution to (4.2) that passes through the point $\varphi(u)$ at $t = 0$.

It is shown in [15] that $D_+\mathcal{S}\varphi_t$, the right-hand derivative of $\mathcal{S}\varphi_t$, is given by

$$D_+\mathcal{S}\varphi_t = \int_{\bar{B}} \lim_{h\to 0^+} \frac{1}{h}\Big[\big\|z + hQ\big(\varphi_t(u)\big)z\big\| - \|z\|\Big]\, du, \tag{4.3}$$

where the matrix $Q = P_f P^{-1} + P\frac{\partial f}{\partial x}^{[2]} P^{-1}$. Here P_f is the directional derivative of P in the direction of the vector field f, $\frac{\partial f}{\partial x}^{[2]}$ is the second additive compound [12] of $\frac{\partial f}{\partial x}$, and $z = P \cdot (\frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2})$ is a solution to the differential equation

$$\frac{dz}{dt} = Q\big(\varphi_t(u)\big)z. \tag{4.4}$$

Thus, (4.3) can be rewritten as

$$D_+\mathcal{S}\varphi_t = \int_{\bar{B}} D_+\big\|z\big\|\, du.$$

If there exists $\eta > 0$ such that $D_+\|z\| \le -\eta\|z\|$ for all $z \in \mathbb{R}^{\binom{n}{2}}$ and all $x \in \mathcal{D}$, then $D_+\mathcal{S}\varphi_t \le \int_{\bar{B}} -\eta\|z\|\, du = -\eta\mathcal{S}\varphi_t$, and so $\mathcal{S}\varphi_t \le \mathcal{S}\varphi\, \mathrm{e}^{-\eta t}$ as long as φ_t remains in $\mathcal{D}$. If $\varphi_t \subset \mathcal{D}$ for all t, then $\lim_{t\to\infty} \mathcal{S}\varphi_t = 0$.

Suppose that ψ is the trace of a periodic solution of (4.2). Then ψ is invariant under the flow described by (4.2). Let $\varphi \in \Sigma(\psi, \mathcal{D})$. Then $\varphi_t(\partial B) = x(t, \varphi(\partial B)) = x(t, \psi(\partial B)) = \psi(\partial B)$. Thus, $\varphi_t \in \Sigma(\psi, \mathcal{D})$ as long as $\varphi_t \subset \mathcal{D}$. If $\mathcal{D}$ is positively invariant, then $\varphi_t \in \Sigma(\psi, \mathcal{D})$ for all $t \ge 0$, and therefore, by Proposition 4.1, $\mathcal{S}\varphi_t \ge \delta$ for all $t \ge 0$. Thus, by the remarks of the previous paragraph, the condition that $D_+\|z\| \le -\eta\|z\|$ for all z and x precludes the existence of periodic solutions to (4.2).

In the absence of a compact absorbing set, a surface may not remain in $\mathcal{D}$ for all time. Thus, we consider a sequence of surfaces $\{\varphi^k\}$ in $\Sigma(\psi, \mathcal{D})$ such that $\lim_{k\to\infty} \mathcal{S}\varphi^k = \delta$, where $\delta = \inf\{\mathcal{S}\varphi : \varphi \in \Sigma(\psi, \mathcal{D})\}$ and for which there exists $\epsilon > 0$ such that $\varphi^k_t(\bar{B}) \subset \mathcal{D}$ for $t \in [0, \epsilon]$ and $k = 1, 2, \ldots$. If $D_+\|z\| \le -\eta\|z\|$ for all $z \in \mathbb{R}^{\binom{n}{2}}$ and all $x \in \mathcal{D}$, then $\mathcal{S}\varphi^k_\epsilon \le \mathcal{S}\varphi^k \mathrm{e}^{-\eta\epsilon}$, and therefore there exists l such that $\mathcal{S}\varphi^l_\epsilon < \delta$. This implies that the boundary of φ^l_ϵ is not ψ, and therefore ψ is not invariant under (4.2). Thus, if for every simple closed curve ψ in $\mathcal{D}$ there is a sequence of surfaces $\{\varphi^k\}$ in $\Sigma(\psi, \mathcal{D})$ that all remain in $\mathcal{D}$ for some time $\epsilon > 0$, and there is a surface functional $\mathcal{S}$ of the form given in (4.1), then the condition $D_+\|z\| \le -\eta\|z\|$ precludes the existence of invariant closed curves, including periodic orbits, homoclinic orbits, and heteroclinic cycles.

The above conditions are robust under local C^1 perturbations to the original differential equation (4.2). Thus, if (4.2) satisfies the above hypotheses, then so do all systems that are sufficiently C^1-close to (4.2). Therefore, Pugh's closing lemma [7] leads to the following result in the spirit of Criterion 3.1 in [15], giving conditions that preclude the existence of nonconstant nonwandering points.

THEOREM 4.2. *Suppose there exists a norm $\|\cdot\|$ on $\mathbb{R}^{\binom{n}{2}}$ and $\eta > 0$ such that $D_+\|z\| \le -\eta\|z\|$ for all $z \in \mathbb{R}^{\binom{n}{2}}$ satisfying (4.4) and all $x \in \mathcal{D}$ for $\mathcal{D}$ simply connected. Further, suppose that for any simple closed curve ψ in $\mathcal{D}$ there exists a sequence of surfaces $\{\varphi^k\}$ that minimizes $\mathcal{S}$ relative to $\Sigma(\psi, \mathcal{D})$ and there exists $\epsilon > 0$ such that $\varphi_t^k \subset \mathcal{D}$ for $t \in [0, \epsilon]$ and $k = 1, 2, \ldots$. Then any omega limit point of (4.2) in the interior of $\mathcal{D}$ is an equilibrium.*

In order to apply the theorem to a particular system, it is necessary to find a norm $\|\cdot\|$ and a matrix P (which then determines the matrix Q) such that $D_+\|z\| \le -\eta\|z\|$ and to show that an appropriate sequence of surfaces exists.

5. Global analysis of the *SIRS* model with vaccination. Recalling that for $\mathcal{R}_0 < 1$ the DFE is globally asymptotically stable (Theorem 3.2), we now apply the theory outlined in the previous section to system (2.2a)–(2.2c) for $\mathcal{R}_0 > 1$. Let $\mathcal{D} = \{(S, I, R) : S, R \ge 0, I > 0, S + I + R \le 1\}$. The Jacobian matrix at a general point $x = (S, I, R)^T$ is given by

$$\frac{\partial f}{\partial x} = \begin{bmatrix} -d - \beta I - \phi - \theta & -\beta S - \theta & \nu - \theta \\ (1-\sigma)\beta I & \beta(S + \sigma V - \sigma I) - (d + \gamma) & -\sigma\beta I \\ 0 & \gamma & -(d + \nu) \end{bmatrix}, \tag{5.1}$$

where $V = 1 - S - I - R$ from (2.2d). The second additive compound [12] of the Jacobian matrix is the 3×3 matrix given by

$$\frac{\partial f}{\partial x}^{[2]} = \begin{bmatrix} \begin{pmatrix} \beta(S + \sigma V - (1+\sigma)I) \\ -[2d + \phi + \theta + \gamma] \end{pmatrix} & -\sigma\beta I & \theta - \nu \\ \gamma & -(\beta I + 2d + \phi + \theta + \nu) & -(\beta S + \theta) \\ 0 & (1-\sigma)\beta I & \begin{pmatrix} \beta(S + \sigma V - \sigma I) \\ -[2d + \gamma + \nu] \end{pmatrix} \end{bmatrix}.$$

Let $P = \frac{1}{I} I_3$, where I_3 is the 3×3 identity matrix. Then $P_f P^{-1} = -\frac{1}{I}\frac{dI}{dt} I_3$ with $\frac{dI}{dt}$ given by (2.2b), and

$$\begin{aligned} Q &= P_f P^{-1} + P \frac{\partial f}{\partial x}^{[2]} P^{-1} \\ &= \begin{bmatrix} -[(1+\sigma)\beta I + d + \phi + \theta] & -\sigma\beta I & \theta - \nu \\ \gamma & \begin{pmatrix} \gamma - [\beta(S + \sigma V + I) \\ + d + \phi + \theta + \nu] \end{pmatrix} & -(\beta S + \theta) \\ 0 & (1-\sigma)\beta I & -(\sigma\beta I + d + \nu) \end{bmatrix}. \end{aligned} \tag{5.2}$$

For $z = (z_1, z_2, z_3)^T$, let $\|z\|$ be given by

$$\|z\| = \begin{cases} \max\{|z_1| + |z_3|, |z_2| + |z_3|\} & \text{if} \quad 0 \le z_2 z_3, \\ \max\{|z_1| + |z_3|, |z_2|\} & \text{if} \quad z_2 z_3 \le 0. \end{cases} \tag{5.3}$$

This norm is used as a Lyapunov function for system (4.4). The following two propositions, with proofs given in the appendices, lead to our main result.

PROPOSITION 5.1. *Assume that in system* (2.2a)–(2.2c) *the parameters satisfy the following inequalities:*

$$\begin{aligned} \theta &< d + 2\nu, \\ 2\gamma &< d + \phi + \theta + \nu, \\ \gamma &< d + \phi + \nu. \end{aligned} \tag{5.4}$$

Then there exists $\eta > 0$ *such that* $D_+\|z\| \le -\eta\|z\|$ *for all* $z \in \mathbb{R}^3$ *and all* $S, I, R, V \ge 0$, $I \ne 0$, *where* z *is a solution of* (4.4) *with* Q *and* $\|\cdot\|$ *given by* (5.2) *and* (5.3), *respectively.*

Note that inequalities (5.4) are independent of the transmission coefficient β, the proportion of newborns vaccinated α, and the vaccine efficacy σ but depend on the other model parameters.

PROPOSITION 5.2. *Let* ψ *be a simple closed curve in* $\mathcal{D}$. *There exist* $\epsilon > 0$ *and a sequence of surfaces* $\{\varphi^k\}$ *that minimizes* $\mathcal{S}$ *given by* (4.1) *relative to* $\Sigma(\psi, \mathcal{D})$ *such that* $\varphi_t^k \subset \mathcal{D}$ *for all* $k = 1, 2, \ldots$ *and all* $t \in [0, \epsilon]$.

THEOREM 5.3. *If inequalities* (5.4) *hold, then each positive semitrajectory of* (2.2a)–(2.2c) *in* $\bar{\mathcal{D}}$ *limits to a single equilibrium.*

Proof. Let Γ be a positive semitrajectory in $\bar{\mathcal{D}}$ with omega limit set Ω. Suppose that Ω intersects the interior of $\mathcal{D}$. Propositions 5.1 and 5.2 ensure that Theorem 4.2 can be applied to system (2.2a)–(2.2c). Theorem 4.2 implies that every omega limit point of (2.2a)–(2.2c) in the interior of $\mathcal{D}$ is an equilibrium. Since the system has a finite number of equilibria, there are only a finite number of points in the interior of $\mathcal{D}$ which can be in Ω. As Γ is bounded, Ω must be connected. Thus, Ω must consist of a single equilibrium.

Suppose, on the other hand, that Ω is contained in the boundary $\partial\mathcal{D}$ of $\mathcal{D}$. Since omega limit sets are invariant, Ω must be contained in the largest invariant subset of $\partial\mathcal{D}$. By considering (2.2a)–(2.2c) with the assumption that θ, γ, and $\alpha d + \phi$ are positive, it is easily shown that $\{X_0\}$ is the only invariant subset of $\partial\mathcal{D}$ and therefore $\Omega = \{X_0\}$. □

For the parameters given in Table 3.1 and used in Figure 3.2, inequalities (5.4) are satisfied for $\phi > 0.063$, which contains part of the bistability region. With $\theta = 1/(1$ year) and $\nu = 1/(14$ days), and all other parameters fixed as in Table 3.1, Figure 5.1 shows a two-dimensional bifurcation diagram in the (σ, ϕ)-plane. Inequalities (5.4) are satisfied for $\phi > 0.021$, including the entire region for which bistability occurs.

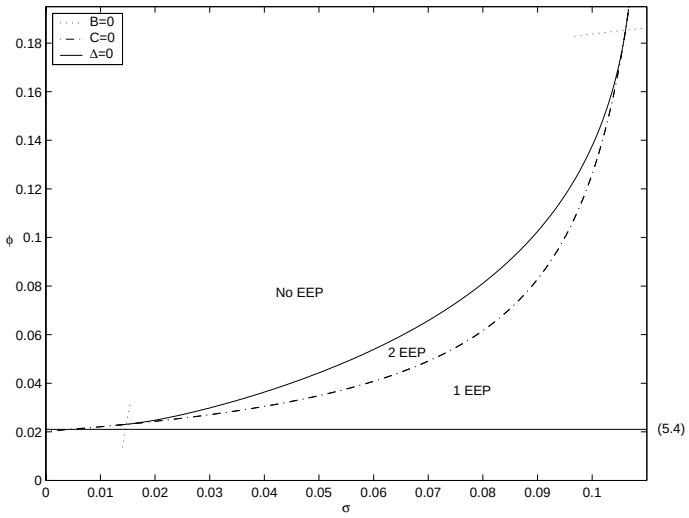

FIG. 5.1. *Bifurcation diagram in the* (σ, ϕ)*-plane, for* $1/\theta$ *equal to one year and* $1/\nu$ *equal to two weeks. The second inequality of* (5.4) *holds for* ϕ *above the horizontal line labeled* (5.4). *The other two inequalities of* (5.4) *hold in the whole region.*

COROLLARY 5.4. *Assume that inequalities* (5.4) *hold for system* (2.2a)–(2.2c).

(i) *If there is no endemic equilibrium, then all solutions limit to the DFE* X_0.

(ii) *If* $\mathcal{R}_{vac} > 1$, *then* (S, I, R) *tends to the unique endemic equilibrium* X^*, *provided that* $I(0) > 0$.

(iii) *If there are two endemic equilibria, or if* X_c *is the only endemic equilibrium, then depending on the initial values, the disease dies out or limits to a constant endemic value.*

Proof. Statements (i) and (iii) follow directly from Theorem 5.3. For (ii), $\mathcal{R}_{vac} > 1$, and so the DFE is unstable with a two-dimensional stable manifold (see (5.1)), which is $\{I = 0\}$. Since from Theorem 5.3 every solution limits to an equilibrium, and since solutions with $I(0) > 0$ do not go to the DFE, they must limit to X^*. □

COROLLARY 5.5. *Suppose that* $\theta \leq \nu$ *and* $2\gamma < d+\phi+\theta+\nu$. *Then the conclusions of Corollary* 5.4 *hold. Furthermore, if system* (2.2a)–(2.2c) *has two endemic equilibria, then the basins of attraction of* X^* *and* X_0 *have positive measure and the basin of attraction of* X_* *has zero measure.*

Proof. If $\theta \leq \nu$ and $2\gamma < d + \phi + \theta + \nu$, then the inequalities (5.4) are satisfied and so the conclusions of Corollary 5.4 follow. From Theorem 3.2, X^* is locally asymptotically stable. Thus it has a basin of attraction with positive measure. It is shown in section 3 that X_* is unstable hyperbolic. Thus, the set of points which limit to X_* has Lebesgue measure zero. When there are two endemic equilibria, $\mathcal{R}_{vac} < 1$, and thus X_0 is locally asymptotically stable and has a basin of attraction with positive measure. □

Remark 5.6. For ν sufficiently large (i.e., a sufficiently short period of immunity), inequalities (5.4) hold and the conclusion of Corollary 5.5 holds. In the limiting case as ν tends to infinity, upon recovery infective individuals progress directly to the susceptible class; thus the model reduces to an SIS model with vaccination, similar to that considered in [10].

Remark 5.7. By using norms other than the norm given by (5.3), inequalities (5.4) can be replaced with other conditions which lead to the same conclusions. For example, if $\|z\|$ is given by

$$\|z\| = \max_{j=1,2,3} |z_j|,$$

then (5.4) can be replaced with

$$2\gamma \leq d + \nu + \theta. \tag{5.5}$$

Similarly, if $\|z\|$ is given by

$$\|z\| = \begin{cases} |z_1| + |z_2| + |z_3| & \text{if} \quad \operatorname{sgn}(z_1) = \operatorname{sgn}(z_2) = \operatorname{sgn}(z_3), \\ \max\{|z_1| + |z_2|, |z_1| + |z_3|\} & \text{if} \quad \operatorname{sgn}(z_1) = \operatorname{sgn}(z_2) = -\operatorname{sgn}(z_3), \\ \max\{|z_1| + |z_3|, |z_2|\} & \text{if} \quad \operatorname{sgn}(z_1) = -\operatorname{sgn}(z_2) = \operatorname{sgn}(z_3), \\ \max\{|z_1| + |z_3|, |z_2| + |z_3|\} & \text{if} \quad -\operatorname{sgn}(z_1) = \operatorname{sgn}(z_2) = \operatorname{sgn}(z_3), \end{cases}$$

then (5.4) can be replaced with

$$\begin{aligned} &\theta < d + 2\nu, \\ &\gamma < d + \phi + \min\{\theta, \nu\}. \end{aligned} \tag{5.6}$$

For parameter values given in Table 3.1, the inequalities found in (5.4) are less restrictive than those given in (5.5) or (5.6).

6. Concluding remarks. The model formulated in section 2 incorporates vaccination for a disease in a simple manner, with vaccinated individuals in a class distinct from that of the individuals who have recovered from the disease. By contrast, in some models (e.g., [3]) these two classes are combined. The basic reproduction number as modified by vaccination, namely $\mathcal{R}_{vac}$ as given by (3.2), is a key parameter in our model. To eradicate the disease, it may not be sufficient to reduce $\mathcal{R}_{vac}$ below one. In the case of bistability, $\mathcal{R}_{vac}$ must be further reduced; see Figure 3.1(d). Increasing vaccination of either newborns or the population at risk has the effect of reducing $\mathcal{R}_{vac}$. An important parameter in $\mathcal{R}_{vac}$ is the efficacy of the vaccine, namely, $1-\sigma$. Bistability may occur for a range of σ values. This range depends on the values of the other parameters in the model. The occurrence of a backward bifurcation is illustrated for some parameter values in Figures 3.1(b), 3.1(d), 3.2, 5.1. In the case of bistability, the asymptotic behavior of the proportion of infectives depends on the initial conditions. In such a situation, global analysis is more complicated than in a situation with a unique endemic equilibrium and a compact absorbing set. An appropriate sequence of surfaces that minimizes the functional measuring surface area must be considered. This novel approach is outlined in section 4 and then applied to our model in section 5. Global results are proved under mild parameter restrictions, and it is indicated that alternative restrictions arise from alternative choices of norms. The rate of vaccination of susceptibles and the vaccine waning rate play a role in these restrictions, whereas the vaccine efficacy and the proportion of newborns vaccinated do not. Theorem 5.3 rules out any complicated behavior (e.g., limit cycles) under mild parameter restrictions, and numerical simulations have found no such behavior for any parameter values. A more realistic model including vaccination should incorporate age structure and demographics (see, e.g., [5]). However, global results are then not available, and simulations must be performed to gain some insight into the model behavior and to determine vaccination strategy.

The analysis of our model can be regarded as the first application of using a minimizing sequence of surfaces in this context. This method may also be useful in other models for which there exist solutions that limit to boundary equilibria.

Appendix A. Proof of Proposition 5.1.

Proof. We demonstrate the existence of some $\eta > 0$ such that $D_+\|z\| \le -\eta\|z\|$, where z is a solution of (4.4). By linearity, if this inequality is true for some z, then it is also true for $-z$. The proof is subdivided into eight cases based on the octant and the definition of the norm in (5.3).

Case 1. If $0 < z_1, z_2, z_3$ and $|z_1| + |z_3| > |z_2| + |z_3|$, then $\|z\| = |z_1| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_1| + |z_3|) \\ &= D_+(z_1 + z_3) \\ &= \frac{dz_1}{dt} + \frac{dz_3}{dt} \\ &= -\big((1+\sigma)\beta I + d + \phi + \theta\big)z_1 + (1-2\sigma)\beta I z_2 + \big(\theta - (\sigma\beta I + d + 2\nu)\big)z_3. \end{aligned}$$

Noting that $(1-2\sigma)\beta I z_2 \le (1-\sigma)\beta I z_2 \le (1-\sigma)\beta I z_1$,

$$\begin{aligned} D_+\|z\| &< -(2\sigma\beta I + d + \phi + \theta)z_1 + (\theta - (\sigma\beta I + d + 2\nu))z_3 \\ &\le \max\{-(2\sigma\beta I + d + \phi + \theta),\ \theta - (\sigma\beta I + d + 2\nu)\}\,\|z\|. \end{aligned}$$

Thus, in order that $D_+\|z\|$ be bounded away from zero on the negative side for all z

and all $I > 0$, we require that

$$\theta < d + 2\nu. \tag{A.1}$$

Case 2. If $0 < z_1, z_2, z_3$ and $|z_1| + |z_3| < |z_2| + |z_3|$, then $\|z\| = |z_2| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_2| + |z_3|) \\ &= \frac{dz_2}{dt} + \frac{dz_3}{dt} \\ &= \gamma z_1 + \big(\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big)\big) z_2 - \big(\beta(S + \sigma I) + d + \theta + \nu\big) z_3. \end{aligned}$$

Since $z_1 < z_2$, this becomes

$$D_+\|z\| < \big(2\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big)\big) z_2 - \big(\beta(S + \sigma I) + d + \theta + \nu\big) z_3.$$

In order that $D_+\|z\|$ be bounded away from zero on the negative side for all $S, I, V > 0$, we require that

$$2\gamma < d + \phi + \theta + \nu. \tag{A.2}$$

Case 3. If $z_1 < 0 < z_2, z_3$ and $|z_1| + |z_3| > |z_2| + |z_3|$, then $\|z\| = |z_1| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_1| + |z_3|) \\ &= D_+(-z_1 + z_3) \\ &= -\frac{dz_1}{dt} + \frac{dz_3}{dt} \\ &= \big((1 + \sigma)\beta I + d + \phi + \theta\big) z_1 + \beta I z_2 - (\sigma\beta I + d + \theta) z_3 \\ &= -\big((1 + \sigma)\beta I + d + \phi + \theta\big)|z_1| + \beta I |z_2| - (\sigma\beta I + d + \theta)|z_3|. \end{aligned}$$

Since $|z_2| < |z_1|$,

$$\begin{aligned} D_+\|z\| &< -(\sigma\beta I + d + \phi + \theta)|z_1| - (\sigma\beta I + d + \theta)|z_3| \\ &\le -(d + \theta)\|z\|. \end{aligned}$$

Thus, in this case, $D_+\|z\|$ is automatically bounded away from zero on the negative side.

Case 4. If $z_1 < 0 < z_2, z_3$ and $|z_1| + |z_3| < |z_2| + |z_3|$, then $\|z\| = |z_2| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_2| + |z_3|) \\ &= \frac{dz_2}{dt} + \frac{dz_3}{dt} \\ &= \gamma z_1 + \big(\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big)\big) z_2 - \big(\beta(S + \sigma I) + d + \theta + \nu\big) z_3 \\ &= -\gamma|z_1| + \big(\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big)\big)|z_2| \\ &\qquad - \big(\beta(S + \sigma I) + d + \theta + \nu\big)|z_3| \\ &< \big(\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big)\big)|z_2| - \big(\beta(S + \sigma I) + d + \theta + \nu\big)|z_3| \\ &\le \max\big\{\gamma - \big(\beta(S + \sigma V + \sigma I) + d + \phi + \theta + \nu\big), -\big(\beta(S + \sigma I) + d + \theta + \nu\big)\big\}\,\|z\|. \end{aligned}$$

Thus we require that

$$\gamma < d + \phi + \theta + \nu. \tag{A.3}$$

Case 5. If $z_2 < 0 < z_1, z_3$ and $|z_1| + |z_3| > |z_2|$, then $\|z\| = |z_1| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_1| + |z_3|) \\ &= \frac{dz_1}{dt} + \frac{dz_3}{dt} \\ &= -\big((1+\sigma)\beta I + d + \phi + \theta\big)z_1 + (1-2\sigma)\beta I z_2 + \big(\theta - (\sigma\beta I + d + 2\nu)\big)z_3 \\ &= -\big((1+\sigma)\beta I + d + \phi + \theta\big)|z_1| + (2\sigma-1)\beta I|z_2| + \big(\theta - (\sigma\beta I + d + 2\nu)\big)|z_3|. \end{aligned}$$

Since $(2\sigma - 1)\beta I|z_2| \le \sigma\beta I|z_2| < \sigma\beta I(|z_1| + |z_3|)$,

$$\begin{aligned} D_+\|z\| &< -(\beta I + d + \phi + \theta)|z_1| + \big(\theta - (d + 2\nu)\big)|z_3| \\ &\le \max\{-(\beta I + d + \phi + \theta),\ \theta - (d + 2\nu)\}\|z\|. \end{aligned}$$

Thus, we require that (A.1) hold.

Case 6. If $z_2 < 0 < z_1, z_3$ and $|z_1| + |z_3| < |z_2|$, then $\|z\| = |z_2|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_2|) \\ &= -\frac{dz_2}{dt} \\ &= -\gamma z_1 - \big(\gamma - \big(\beta(S + \sigma V + I) + d + \phi + \theta + \nu\big)\big)z_2 + (\beta S + \theta)z_3 \\ &= -\gamma|z_1| + \big(\gamma - \big(\beta(S + \sigma V + I) + d + \phi + \theta + \nu\big)\big)|z_2| + (\beta S + \theta)|z_3|. \end{aligned}$$

Since $-\gamma|z_1| < 0$ and $|z_3| < |z_2|$,

$$D_+\|z\| < \big(\gamma - \big(\beta(\sigma V + I) + d + \phi + \nu\big)\big)|z_2|.$$

Thus, we require that

$$\gamma < d + \phi + \nu. \tag{A.4}$$

Case 7. If $z_3 < 0 < z_1, z_2$ and $|z_1| + |z_3| > |z_2|$, then $\|z\| = |z_1| + |z_3|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_1| + |z_3|) \\ &= \frac{dz_1}{dt} - \frac{dz_3}{dt} \\ &= -\big((1+\sigma)\beta I + d + \phi + \theta\big)z_1 - \beta I z_2 + (\theta + \sigma\beta I + d)z_3 \\ &= -\big((1+\sigma)\beta I + d + \phi + \theta\big)|z_1| - \beta I|z_2| - (\theta + \sigma\beta I + d)|z_3| \\ &\le -(d + \theta)\|z\|. \end{aligned}$$

Thus, in this case, $D_+\|z\|$ is automatically bounded away from zero on the negative side.

Case 8. If $z_3 < 0 < z_1, z_2$ and $|z_1| + |z_3| < |z_2|$, then $\|z\| = |z_2|$ and

$$\begin{aligned} D_+\|z\| &= D_+(|z_2|) \\ &= \frac{dz_2}{dt} \\ &= \gamma z_1 + \big(\gamma - \big(\beta(S + \sigma V + I) + d + \phi + \theta + \nu\big)\big)z_2 - (\beta S + \theta)z_3 \\ &= \gamma|z_1| + \big(\gamma - \big(\beta(S + \sigma V + I) + d + \phi + \theta + \nu\big)\big)|z_2| + (\beta S + \theta)|z_3|. \end{aligned}$$

Noting that $|z_1| + |z_3| < |z_2|$,

$$D_+\|z\| < \big(\gamma - \big(\beta(S + \sigma V + I) + d + \phi + \theta + \nu\big) + \max\{\gamma, \beta S + \theta\}\big)\|z\|.$$

Thus, we require that (A.2) and (A.4) hold.

Note that (A.2) and (A.4) each imply (A.3). Thus, if inequalities (A.1), (A.2), and (A.4) hold, then there exists $\eta > 0$ such that $D_+\|z\| \le -\eta\|z\|$ for almost every $z \in \mathbb{R}^3$ and all nonnegative S, I, R, and V. The boundary between the different cases, including, for example, $z_j = 0$ for some j, is resolved by continuity. Thus, (A.1), (A.2), and (A.4) (equivalently (5.4)) imply that $D_+\|z\| \le -\eta\|z\|$ for all $z \in \mathbb{R}^3$. □

Appendix B. Proof of Proposition 5.2.

Proof. Let $\xi = \frac{1}{2}\min\{I : (S, I, R) \in \psi\}$ and let $\epsilon > 0$. Note that the model is well posed so solutions remain in the nonnegative orthant. In $\mathcal{D}$, $\frac{dI}{dt} \ge -(d + \nu)I$. Thus, if a solution satisfies $I(0) \ge \xi$, then the solution remains in $\mathcal{D}$ for time ϵ.

Therefore, it suffices to show that there exists a sequence of surfaces $\{\varphi^k\}$ that minimizes $\mathcal{S}$ relative to $\Sigma(\psi, \tilde{\mathcal{D}})$, where $\tilde{\mathcal{D}} = \{(S, I, R) \in \mathcal{D} : I \ge \xi\}$. Let $\varphi = (S(u), I(u), R(u)) \in \Sigma(\psi, \mathcal{D})$. Define a new surface $\tilde{\varphi} = (\tilde{S}, \tilde{I}, \tilde{R})$ by

(B.1)

$$\tilde{\varphi}(u) = \begin{cases} \varphi(u) & \text{if } I(u) \ge \xi, \\ (S, \xi, R) & \text{if } I(u) < \xi \text{ and } S(u) + \xi + R(u) \le 1, \\ \big(\frac{S}{S+R}(1-\xi),\ \xi,\ \frac{R}{S+R}(1-\xi)\big) & \text{if } I(u) < \xi \text{ and } S(u) + \xi + R(u) > 1. \end{cases}$$

Note that $\tilde{\varphi} \in \Sigma(\psi, \tilde{\mathcal{D}})$. We now demonstrate that $\mathcal{S}\tilde{\varphi} \le \mathcal{S}\varphi$.

Since φ is Lipschitzian, the partial derivatives $\frac{\partial \varphi}{\partial u_j}$, $j = 1, 2$, exist almost everywhere. Thus,

$$\frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2} = \begin{bmatrix} \frac{\partial S}{\partial u_1} \\ \frac{\partial I}{\partial u_1} \\ \frac{\partial R}{\partial u_1} \end{bmatrix} \wedge \begin{bmatrix} \frac{\partial S}{\partial u_2} \\ \frac{\partial I}{\partial u_2} \\ \frac{\partial R}{\partial u_2} \end{bmatrix} = \begin{bmatrix} \det \begin{pmatrix} \frac{\partial S}{\partial u_1} & \frac{\partial S}{\partial u_2} \\ \frac{\partial I}{\partial u_1} & \frac{\partial I}{\partial u_2} \end{pmatrix} \\ \det \begin{pmatrix} \frac{\partial S}{\partial u_1} & \frac{\partial S}{\partial u_2} \\ \frac{\partial R}{\partial u_1} & \frac{\partial R}{\partial u_2} \end{pmatrix} \\ \det \begin{pmatrix} \frac{\partial I}{\partial u_1} & \frac{\partial I}{\partial u_2} \\ \frac{\partial R}{\partial u_1} & \frac{\partial R}{\partial u_2} \end{pmatrix} \end{bmatrix}$$

is a vector in $\mathbb{R}^3$ for almost every $u \in B$. To examine $\big\|\frac{\partial \tilde{\varphi}}{\partial u_1} \wedge \frac{\partial \tilde{\varphi}}{\partial u_2}\big\|$, we do a case analysis based on the definition of $\tilde{\varphi}$ given in (B.1).

Case 1. If $I(u) \ge \xi$, then $\tilde{\varphi} = \varphi$ and therefore $\big\|\frac{\partial \tilde{\varphi}}{\partial u_1} \wedge \frac{\partial \tilde{\varphi}}{\partial u_2}\big\| = \big\|\frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2}\big\|$ when all of the relevant partial derivatives exist.

Case 2. If $I(u) < \xi$ and $S(u) + \xi + R(u) \le 1$, then $\tilde{\varphi}(v) = (S(v), \xi, R(v))$. Therefore

$$\frac{\partial \tilde{\varphi}}{\partial u_1} \wedge \frac{\partial \tilde{\varphi}}{\partial u_2} = \begin{bmatrix} \det \begin{pmatrix} \frac{\partial S}{\partial u_1} & \frac{\partial S}{\partial u_2} \\ 0 & 0 \end{pmatrix} \\ \det \begin{pmatrix} \frac{\partial S}{\partial u_1} & \frac{\partial S}{\partial u_2} \\ \frac{\partial R}{\partial u_1} & \frac{\partial R}{\partial u_2} \end{pmatrix} \\ \det \begin{pmatrix} 0 & 0 \\ \frac{\partial R}{\partial u_1} & \frac{\partial R}{\partial u_2} \end{pmatrix} \end{bmatrix} = \begin{bmatrix} 0 \\ \det \begin{pmatrix} \frac{\partial S}{\partial u_1} & \frac{\partial S}{\partial u_2} \\ \frac{\partial R}{\partial u_1} & \frac{\partial R}{\partial u_2} \end{pmatrix} \\ 0 \end{bmatrix}$$

almost everywhere. If y_j is equal to either z_j or zero for $j=1,2,3$, then $\|(y_1,y_2,y_3)^T\| \le \|(z_1,z_2,z_3)^T\|$ for the given norm. It follows that $\left\|\frac{\partial\tilde{\varphi}}{\partial u_1}\wedge\frac{\partial\tilde{\varphi}}{\partial u_2}\right\| \le \left\|\frac{\partial\varphi}{\partial u_1}\wedge\frac{\partial\varphi}{\partial u_2}\right\|$.

Case 3. If $I(u)<\xi$ and $S(u)+\xi+R(u)>1$, then $\tilde{\varphi}(v)=\left(\frac{S}{S+R}(1-\xi),\ \xi,\ \frac{R}{S+R}(1-\xi)\right)$. Therefore

$$\frac{\partial\tilde{\varphi}}{\partial u_j}=(1-\xi)\frac{R\frac{\partial S}{\partial u_j}-S\frac{\partial R}{\partial u_j}}{(S+R)^2}\begin{bmatrix}1\\0\\-1\end{bmatrix}$$

for $j=1,2$. Thus, $\frac{\partial\tilde{\varphi}}{\partial u_1}$ and $\frac{\partial\tilde{\varphi}}{\partial u_2}$ are linearly dependent, and so their wedge product is zero [19]. Therefore $\left\|\frac{\partial\tilde{\varphi}}{\partial u_1}\wedge\frac{\partial\tilde{\varphi}}{\partial u_2}\right\|=0\le\left\|\frac{\partial\varphi}{\partial u_1}\wedge\frac{\partial\varphi}{\partial u_2}\right\|$.

The above three cases show that $\left\|\frac{\partial\tilde{\varphi}}{\partial u_1}\wedge\frac{\partial\tilde{\varphi}}{\partial u_2}\right\| \le \left\|\frac{\partial\varphi}{\partial u_1}\wedge\frac{\partial\varphi}{\partial u_2}\right\|$ for almost all $u\in\bar{B}$. We also note that $\tilde{I}(u)=\max\{I(u),\xi\}$ and thus $1/\tilde{I}\le 1/I$. Therefore from (4.1),

$$\begin{aligned}\mathcal{S}\tilde{\varphi}&=\int_{\bar{B}}\frac{1}{\tilde{I}}\left\|\frac{\partial\tilde{\varphi}}{\partial u_1}\wedge\frac{\partial\tilde{\varphi}}{\partial u_2}\right\|du\\&\le\int_{\bar{B}}\frac{1}{I}\left\|\frac{\partial\varphi}{\partial u_1}\wedge\frac{\partial\varphi}{\partial u_2}\right\|du\\&=\mathcal{S}\varphi.\end{aligned}$$

Let $\{\varphi^k\}$ be a sequence of surfaces that minimizes $\mathcal{S}$ relative to $\Sigma(\psi,\mathcal{D})$. Let $\{\tilde{\varphi}^k\}$ be a sequence of surfaces in $\Sigma(\psi,\tilde{\mathcal{D}})$ defined by the above construction. Since $\mathcal{S}\tilde{\varphi}^k\le\mathcal{S}\varphi^k$ for each k, and $\Sigma(\psi,\tilde{\mathcal{D}})$ is a subset of $\Sigma(\psi,\mathcal{D})$, it follows that $\{\tilde{\varphi}^k\}$ minimizes $\mathcal{S}$ relative to $\Sigma(\psi,\tilde{\mathcal{D}})$. □

ANALYSIS OF A VARIATIONAL APPROACH TO PROGRESSIVE LENS DESIGN*

JING WANG†, ROBERT GULLIVER‡, AND FADIL SANTOSA‡

Abstract. We consider a variational approach to the progressive lens design problem. The corresponding Euler–Lagrange equation is a fourth-order nonlinear elliptic partial differential equation. We analyze two linearizations of the equation and show the existence and uniqueness as well as the regularity of the solutions for various boundary conditions. We end with an example of a progressive lens designed by solving the elliptic partial differential equation.

Key words. progressive lens, fourth-order boundary value problems, well-posedness

1. Introduction. *Presbyopia* is very common in people over age forty, and is caused by the loss of the accommodative power of the human eye. Single-vision reading glasses can be used to correct this problem; however, they enable good vision only for nearby objects and have to be taken off for distance vision. To avoid this inconvenience, more complicated lenses such as the bifocal lens, which consists of two single-vision lenses with different powers, and the trifocal lens, which adds one more lens for intermediate vision, have been designed. A major drawback of these kinds of lenses is the jump in the image as the eye moves from seeing far-distance to near-distance objects.

One of the best solutions to presbyopia is the progressive addition lens (PAL, for short). A PAL comprises a large distance-view zone with low power on the upper part of the lens and a small near-view zone with higher power on the lower part; between these two zones, the power increases progressively and smoothly.

In progressive lenses, the progression of the power arises from a local variation in the curvatures of the surface. In ophthalmic optics, the power at each point is given by the formula

$$Pow = (1-n)P^b + \frac{(n-1)P^f}{1 - d(1-\frac{1}{n})P^f},$$

where n is the refractive index of the material, d is the thickness of the lens, and P^f and P^b are the mean curvatures of the front and back surfaces, respectively. For a thin lens ($d \ll 1$), the formula simplifies to

$$Pow = (n-1)(P^f - P^b).$$

In typical progressive lenses, the back surface is usually a surface of constant mean curvature. Thus P^f is the only factor determining the progressive power of the lens. To simplify notation, we write it as P.

‡School of Mathematics, University of Minnesota-Twin Cities, 127 Vincent Hall, 206 Church Street S.E., Minneapolis, MN 55455 (gulliver@math.umn.edu, santosa@math.umn.edu).

Suppose that k_1, k_2 are the two local principal curvatures of the front surface; then $P = (k_1 + k_2)/2$. The quantity

$$A = (n-1)|k_1 - k_2|$$

is called the local cylinder (or astigmatism).

An ideal progressive surface is one with the prescribed smooth progressive power and with zero astigmatism everywhere. But in order for the astigmatism to be zero everywhere, the surface has to be either a sphere or a plane, which will not provide progressive power. Alternatively, one would wish the surface to have smooth progressive power and as small an astigmatism as possible. In fact, in design of ophthalmic lenses, certain regions on the surface are required to have very small astigmatism; for the rest of the surface, the astigmatism should be smooth and as small as possible. The regions of very small astigmatism are areas of the lenses critical to the eyes for far, intermediate, and near vision.

There have been some direct methods for designing progressive lenses, e.g., those of Winthrop [12] and Baudart, Ahsbahs, and Miege [4]. In a direct method, power is assigned along a curve on the lens. Elsewhere on the lens, power is distributed smoothly away from this curve. The construction is done in such a way that the cylinder is as small as possible in the critical areas of the lens. However, the performance of such lenses are often less than satisfactory because there is no real control over the distribution of the cylinder. Indirect methods based on optimization have been proposed by other lens designers. In such a method, a cost function that attempts to balance the power distribution with the unavoidable cylinder is created. The goal is to minimize the cost function. An example of such a cost function, and one which we will analyze in this work, is that proposed by Loos, Greiner, and Seidel [9]. In their approach, the desired power function over the whole surface is specified. The task then is to construct the surface with power close to this function and with a weighted total cylinder as small as possible.

The current paper addresses theoretical issues arising in lens design by the variational approach. In section 2, we give a brief review of principal curvatures and the compatibility conditions for the existence of surfaces. Section 3 introduces the variational approach for the lens design problem. The Euler–Lagrange equation, which is a fourth-order nonlinear elliptic equation, is also derived there.

A similar variational problem arises in the study of surfaces governed by free energy functionals. In [10], Nitsche analyzed such a problem with constant weight functions and power function. He showed that if the constants satisfy the so-called structural conditions, then for both Dirichlet boundary conditions and natural boundary conditions the solution to the problem exists, is unique, and is in the regular class $C^{4,\lambda}(\overline{\Omega})$, where the Hölder exponent λ is a number in the interval $0 < \lambda < 1$.

For progressive lenses, the power varies among different areas. Also, due to the fact that there is importance associated with critical areas of the lens, the weight functions will not be constants. Thus the Euler–Lagrange equation is more complicated. To simplify the analysis of the partial differential equation, we consider two linearizations.

In section 4, we linearize the equation about a flat surface. The linearized PDE is very similar to the equation of elastic plate theory (see Ciarlet [7]). We will solve the problem on a square region. Three types of boundary conditions are considered: (1) a clamped boundary condition, (2) a partially clamped boundary condition, (3) a natural boundary condition. For all three boundary conditions, we prove the existence

and uniqueness of the solutions with reasonable choices of weight functions α and β. For the third boundary condition, a solution that is unique up to a linear ambiguity exists. Regularity of the solutions follows from Friedrichs's work [8]. In section 5, we consider a linearization near a spherical surface. Similar to the linearization from a plane, we consider the same boundary conditions as the above linearization about the flat surface. We show that, with the first boundary condition, the equation has a unique solution when the size of the square region over which the problem is solved is less than the radius of the base spherical surface. With the second and the third boundary conditions, the solution is unique when the size of the square region is less than 1.15 times the radius of the base spherical surface. Again, for the natural boundary condition case, the solution is unique up to an addition of a linear function.

A numerical approach for this problem is addressed in a separate work [11], where we propose a finite element method to solve the resulting PDEs.

2. Compatibility conditions. It is clear that the power and the cylinder of the front surface are determined only by the principal curvatures. Thus, if we could control the distribution of the principal curvatures, then we could control the quality of the lens. Unfortunately, there are complicated relations governing the two principal curvatures, as shown below.

Given a surface $z = u(x, y)$, we can write it in a parametric form as $U(x_1, x_2) = (u_1(x_1, x_2), u_2(x_1, x_2), u_3(x_1, x_2))$ with $u_1(x_1, x_2) = x_1 = x$, $u_2(x_1, x_2) = x_2 = y$, and $u_3(x_1, x_2) = u(x, y)$. Let $g_{ij} = \langle \frac{\partial U}{\partial x_i}, \frac{\partial U}{\partial x_j} \rangle$. Then the *first fundamental form* is defined as

$$\mathrm{I} = g_{11}dx_1^2 + 2g_{12}dx_1dx_2 + g_{22}dx_2^2.$$

Let $n = \frac{\partial U}{\partial x_1} \times \frac{\partial U}{\partial x_2} / |\frac{\partial U}{\partial x_1} \times \frac{\partial U}{\partial x_2}|$ be the unit outer normal vector to the surface, and let $L_{ij} = \langle \frac{\partial^2 U}{\partial x_i \partial x_j}, n \rangle$. The *second fundamental form* is defined as

$$\mathrm{II} = L_{11}dx_1^2 + 2L_{12}dx_1dx_2 + L_{22}dx_2^2.$$

Suppose that the principal curvatures are k_1 and k_2; then the *Gauss curvature* K and the *mean curvature* H are

$$K = k_1 \cdot k_2 = \frac{L_{11}L_{22} - L_{12}^2}{g_{11}g_{22} - g_{12}^2}, \quad H = \frac{k_1 + k_2}{2} = \frac{L_{11}g_{22} - 2L_{12}g_{12} + L_{22}g_{11}}{2(g_{11}g_{22} - g_{12}^2)^{3/2}}.$$

In terms of the original surface $z = u(x, y)$, H and K can be written explicitly as

$$H = \frac{(1 + u_x^2)u_{yy} - 2u_xu_yu_{xy} + (1 + u_y^2)u_{xx}}{2(1 + u_x^2 + u_y^2)^{3/2}}, \quad K = \frac{u_{xx}u_{yy} - u_{xy}^2}{(1 + u_x^2 + u_y^2)^2}.$$

In general, for any arbitrary specified principal curvatures, the surface may not exist. Certain conditions must be satisfied for the existence of the surface. These conditions are called the *Gauss equations* and *Codazzi equations* and are given by

$$\frac{\partial \Gamma_{jk}^l}{\partial x_i} - \frac{\partial \Gamma_{ik}^l}{\partial x_j} + \Gamma_{jk}^s\Gamma_{is}^l - \Gamma_{ik}^s\Gamma_{js}^l = L_{jk}g^{lm}L_{mi} - L_{ik}g^{lm}L_{mj}, \tag{2.1}$$

$$\Gamma_{ij}^l L_{lk} + \frac{\partial L_{ij}}{\partial x_k} = \Gamma_{kj}^l L_{li} + \frac{\partial L_{kj}}{\partial x_i}, \tag{2.2}$$

where $\Gamma_{ij}^k = \frac{1}{2}g^{lk}(\frac{\partial g_{jl}}{\partial x_i} + \frac{\partial g_{li}}{\partial x_j} - \frac{\partial g_{ij}}{\partial x_l})$ are the *Christoffel symbols* and (g^{ij}) is the inverse matrix of (g_{ij}).

These two conditions are exactly the compatibility conditions for the existence of the surface, as shown in the next theorem (see [3]).

THEOREM 2.1 (fundamental theorem of surface theory). *Let Ω be an open, simply connected subset of $\mathbb{R}^2$. Assume*

$$\mathrm{I} = g_{11}dx_1^2 + 2g_{12}dx_1dx_2 + g_{22}dx_2^2, \quad \mathrm{II} = L_{11}dx_1^2 + 2L_{12}dx_1dx_2 + L_{22}dx_2^2,$$

where g_{ij} and L_{ij} are differentiable functions of x for all $x \in \Omega$. If I *is positive definite and the Gauss equations* (2.1) *and Codazzi equations* (2.2) *are satisfied, then*

(i) *there exists a surface $U : \Omega \to \mathbb{R}^3$ whose first and second fundamental forms are* I *and* II*;*

(ii) *any two surfaces U and V defined on Ω, which have the same first and second fundamental forms, differ by an isometry of $\mathbb{R}^3$.*

3. Variational approach to progressive surface design. As we see from the previous section, certain relationships for the principal curvatures must be met in order that they correspond to a surface. Unfortunately, the relationships are too complicated to be of direct use in lens design. An indirect method, in which the lens design problem is posed as a variational problem of attempting to fit the prescribed power on the surface while minimizing the total weighted cylinder, has been proposed by Loos, Greiner, and Seidel [9]. We will describe such an approach next.

3.1. Design of an objective functional. Let us consider a surface given by $z = u(x, y) : \Omega \to \mathbb{R}$, where the domain $\Omega \in \mathbb{R}^2$. Suppose that the desired distribution of the mean curvature on the graph is specified by a function $P(x, y) : \Omega \to \mathbb{R}$. Then the quality of the surface could be measured by

$$\mathrm{I}(u) = \int_\Omega \left\{ \alpha(x,y) \left(\frac{k_1 - k_2}{2} \right)^2 + \beta(x,y) \left(\frac{k_1 + k_2}{2} - P(x,y) \right)^2 \right\} dx\, dy, \tag{3.1}$$

where $\alpha(x, y), \beta(x, y) : \Omega \to \mathbb{R}$ are two positive weight functions for the surface astigmatism and power, respectively. The weight α will be large in areas where the lens is to have minimum astigmatism, while the weight β will be large in areas where the lens is to have the correct prescribed power. In typical designs, these areas overlap.

In terms of the Gauss curvature $K = k_1 \cdot k_2$ and the mean curvature $H = (k_1 + k_2)/2$, the above functional can be rewritten as

$$\mathrm{I}(u) = \int_\Omega \left\{ \alpha \left(H(x,y)^2 - K(x,y) \right) + \beta \left(H(x,y) - P(x,y) \right)^2 \right\} dx\, dy. \tag{3.2}$$

The task of this approach is to minimize $\mathrm{I}(u)$. At a minimum, we would have constructed a lens with nearly correct powers in the appropriate regions and minimized the astigmatism in these regions.

Numerical optimization methods could be used to minimize the functional. In [9], Loos, Greiner, and Seidel first approximated the functional by a quadratic functional, and then Newton's method was used to locate a minimum. For the weight functions α and β, piecewise constant functions were used. Allione, Ahsbahs, and Saux [2] discussed other types of numerical methods for lens optimization problems.

3.2. Euler–Lagrange equations. For the surface $z = u(x, y)$, H and K can be expressed explicitly as

$$H = \frac{(1+u_x^2)u_{yy} - 2u_x u_y u_{xy} + (1+u_y^2)u_{xx}}{2(1+u_x^2+u_y^2)^{3/2}} \quad \text{and} \quad K = \frac{u_{xx}u_{yy} - u_{xy}^2}{(1+u_x^2+u_y^2)^2}. \tag{3.3}$$

Thus

$$\begin{aligned}
\mathrm{I}(u) &= \mathrm{I}(u_x, u_y, u_{xx}, u_{xy}, u_{yy}) \\
&= \int_\Omega \Big\{ \alpha(x,y) \left(H(u_x, u_y, u_{xx}, u_{xy}, u_{yy})^2 - K(u_x, u_y, u_{xx}, u_{xy}, u_{yy}) \right) \\
&\qquad + \beta(x,y) \left(H(u_x, u_y, u_{xx}, u_{xy}, u_{yy}) - P(x,y) \right)^2 \Big\} \, dxdy.
\end{aligned}$$

The necessary condition for $\mathrm{I}(u)$ to be the minimum is

$$\left. \frac{d}{dt} \right|_{t=0} \mathrm{I}(u + t\delta) = 0 \quad \forall \delta \in C_0^\infty(\Omega),$$

i.e.,

$$\begin{aligned}
0 &= \left. \frac{d}{dt} \right|_{t=0} \mathrm{I}(u + t\delta) \\
&= \int_\Omega \Big\{ 2 \left((\alpha+\beta)H - \beta P \right) \left(H_{u_x}\delta_x + H_{u_y}\delta_y + H_{u_{xx}}\delta_{xx} + H_{u_{xy}}\delta_{xy} + H_{u_{yy}}\delta_{yy} \right) \\
&\qquad - \alpha \left(K_{u_x}\delta_x + K_{u_y}\delta_y + K_{u_{xx}}\delta_{xx} + K_{u_{xy}}\delta_{xy} + K_{u_{yy}}\delta_{yy} \right) \Big\} \, dxdy.
\end{aligned} \tag{3.4}$$

Suppose that α, β, and P are at least twice differentiable; then integration by parts twice yields the following fourth-order PDE:

$$\begin{aligned}
&(\alpha K_{u_x})_x + (\alpha K_{u_y})_y - (\alpha K_{u_{xx}})_{xx} - (\alpha K_{u_{xy}})_{xy} - (\alpha K_{u_{yy}})_{yy} \\
&\quad - 2\left((\alpha H + \beta H - \beta P) H_{u_x} \right)_x - 2\left((\alpha H + \beta H - \beta P) H_{u_y} \right)_y \\
&\quad + 2\left((\alpha H + \beta H - \beta P) H_{u_{xx}} \right)_{xx} + 2\left((\alpha H + \beta H - \beta P) H_{u_{xy}} \right)_{xy} \\
&\quad + 2\left((\alpha H + \beta H - \beta P) H_{u_{yy}} \right)_{yy} = 0.
\end{aligned} \tag{3.5}$$

This is the *Euler–Lagrange equation* of the problem.

For the nonlinear fourth-order PDE (3.5), it is easy to check that the fourth-order terms contributed by K are zero, and thus all the fourth-order terms are from H. The fourth-order leading terms are

$$\begin{aligned}
P_4(D)u = \frac{(\alpha+\beta)}{(1+u_x^2+u_y^2)^3} \Big\{ &(1+u_y^2)[(1+u_x^2)u_{yyxx} - 2u_x\, u_y\, u_{xyxx} + (1+u_y^2)u_{xxxx}] \\
&- 2u_x\, u_y[(1+u_x^2)u_{yyxy} - 2u_x\, u_y\, u_{xyxy} + (1+u_y^2)u_{xxxy}] \\
&+ (1+u_x^2)[(1+u_x^2)u_{yyyy} - 2u_x\, u_y\, u_{xyyy} + (1+u_y^2)u_{xxyy}] \Big\}.
\end{aligned}$$

Since

$$P_4(\xi,\eta) = \frac{(\alpha+\beta)}{(1+u_x^2+u_y^2)^3}[(1+u_x^2)\eta^2 - 2u_x\,u_y\xi\,\eta + (1+u_y^2)\xi^2]^2$$

$$= \frac{(\alpha+\beta)}{(1+u_x^2+u_y^2)^3}[\xi^2+\eta^2+(u_x\eta - u_y\xi)^2]^2$$

$$\geq \frac{(\alpha+\beta)}{(1+u_x^2+u_y^2)^3}[\xi^2+\eta^2]^2,$$

we can conclude that the PDE (3.5) is elliptic if $\alpha+\beta > 0$.

To simplify the analysis of (3.5), we are going to linearize it. Two types of linearizations will be considered. The first linearization is about a plane, under the assumption that $|\nabla u| \ll 1$. The second linearization is about a sphere; namely, we will assume that the surface is a slight perturbation from a spherical surface and suppose that the gradient of the perturbation is small. Due to the fact that a lens is closer to a sphere than to a plane, the second linearization is of more practical value for lens design. The techniques used in the analysis of the linearized equation about a plane will be useful in studying the case of linearization about a sphere.

4. Linearization about the flat surface. If $|\nabla u| \ll 1$, then approximately $H \approx \frac{1}{2}\Delta u$ and $K \approx u_{xx}u_{yy} - u_{xy}^2$. In this case, the variational equation will be

$$\int_\Omega \{(\alpha+\beta)\Delta u\Delta v - 2\alpha(u_{xx}v_{yy} + u_{yy}v_{xx} - 2u_{xy}v_{xy})\}\,dx\,dy = \int_\Omega 2\beta P\Delta v\,dx\,dy \tag{4.1}$$

for all $v \in C_0^\infty(\Omega)$. The corresponding PDE is (again, if all the coefficients are at least twice differentiable)

$$\Delta((\alpha+\beta)\Delta u) - 2[(\alpha u_{yy})_{xx} + (\alpha u_{xx})_{yy} - 2(\alpha u_{xy})_{xy}] = \Delta(2\beta P). \tag{4.2}$$

Equation (4.1) is very similar to the equation of Kirchoff plate theory [7]. Borrowing terms used in plate theory, the boundary condition (BC) can be one of the following types:

(i) clamped,
(ii) partially clamped,
(iii) natural.

Define the bilinear functional

$$B(u,v) = \int_\Omega (\alpha+\beta)\Delta u\Delta v - 2\alpha(u_{xx}v_{yy} + u_{yy}v_{xx} - 2u_{xy}v_{xy})dx\,dy \tag{4.3}$$

and the linear functional

$$L(v) = \int_\Omega 2\beta P\Delta v\,dx\,dy. \tag{4.4}$$

Then the problem is to solve

$$B(u,v) = L(v) \quad \forall v \in C_0^\infty(\Omega). \tag{4.5}$$

The basic tool we use to establish the results in the subsequent analysis is the Lax–Milgram lemma [7], which we restate here for completeness.

LEMMA 4.1 (Lax–Milgram lemma). *Let V be a Banach space with norm $\|\cdot\|$. Let $L : V \to \mathbb{R}$ be a continuous linear form, and let $B : V \times V \to \mathbb{R}$ be a symmetric and continuous bilinear form that is V-elliptic, in the sense that there exists a constant $c > 0$ such that*

$$B(v, v) \geq c\|v\|^2 \quad \forall v \in V.$$

Then the problem: Find $u \in V$ such that

$$B(u, v) = L(v) \quad \forall v \in V$$

has a unique solution.

The space we will use for establishing the results is $H^2(\Omega)$, for which the norm is defined as (see [1])

$$\|v\|_{2,\Omega} = \left\{ |v|_{0,\Omega}^2 + \sum_{i=1}^{2} |\partial_i v|_{0,\Omega}^2 + \sum_{i,j=1}^{2} |\partial_{ij} v|_{0,\Omega}^2 \right\}^{1/2},$$

where $|v|_{0,\Omega} = \left\{ \int_\Omega |v|^2 dx\, dy \right\}^{1/2}$, $\partial_1 = \partial/\partial x$, $\partial_2 = \partial/\partial y$, and $\partial_{ij} = \partial_i \partial_j$. Define the seminorm $|\cdot|_{2,\Omega}$ by

$$|v|_{2,\Omega} = \left\{ \sum_{i,j=1}^{2} |\partial_{ij} v|_{0,\Omega}^2 \right\}^{1/2}.$$

4.1. BC (i): Clamped boundary condition. We suppose that u is clamped on the boundary, i.e., $u = 0, \nabla u = 0$ on $\partial\Omega$.

An ingredient critical for this boundary condition is the Poincaré–Friedrichs inequality [5].

LEMMA 4.2 (Poincaré–Friedrichs inequality). *Let Ω be a domain in $\mathbb{R}^2$; then there exists a constant $c > 0$ such that*

$$c^{-1}\|v\|_{2,\Omega} \leq |v|_{2,\Omega} \quad \forall v \in H_0^2(\Omega). \tag{4.6}$$

THEOREM 4.3. *Let Ω be a domain in $\mathbb{R}^2$. Assume that $P(x, y), \alpha(x, y), \beta(x, y) \leq M$ in Ω, where $M > 0$ is a constant; also $\alpha(x, y) \geq 0$ and there exists a constant $\beta_0 > 0$ such that $\beta(x, y) \geq \beta_0$ for all $(x, y) \in \Omega$. Then the variational equation (4.1) has a unique solution in $H_0^2(\Omega)$. In addition, if $\alpha(x, y), \beta(x, y) \in C^k(\Omega)$ and $P(x, y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

Proof. For all $v \in C_0^\infty(\Omega)$, by Green's formula,

$$\int_\Omega \partial_{ij} v\, \partial_{ij} v\, dx\, dy = \int_\Omega \partial_{iij} v\, \partial_j v\, dx\, dy = \int_\Omega \partial_{ii} v\, \partial_{jj} v\, dx\, dy.$$

Since $C_0^\infty(\Omega)$ is dense in $H_0^2(\Omega)$, the above relation remains true for all $v \in H_0^2(\Omega)$; i.e., for all $v \in H_0^2(\Omega)$, $|v|_{2,\Omega} = |\Delta v|_{0,\Omega}$. Thus by the Poincaré–Friedrichs inequality (Lemma 4.2),

$$|\Delta v|_{0,\Omega} = |v|_{2,\Omega} \geq c^{-1}\|v\|_{2,\Omega}.$$

Since $\alpha((\Delta v)^2 - 4v_{xx}v_{yy} + 4v_{xy}^2)) = \alpha((v_{xx} - v_{yy})^2 + 4v_{xy}^2) \geq 0$, this implies

$$B(v, v) \geq \beta|\Delta v|_{0,\Omega}^2 \geq c^{-2}\beta_0\|v\|_{2,\Omega}^2,$$

and thus $B(v, v)$ is $H_0^2(\Omega)$-elliptic. Thus, by the Lax–Milgram lemma, the variational problem has a unique solution in $H_0^2(\Omega)$.

The regularity of the solution follows from the result in Friedrichs [8]. ∎

Remark. Note that the conditions here for α and β resemble the so-called structural conditions in Nitsche [10].

4.2. BC (ii): Partially clamped boundary conditions. Let $H^2_\Gamma(\Omega)$ be the subspace of $H^2(\Omega)$ such that $f|_\Gamma = 0$, $\frac{\partial f}{\partial \nu}|_\Gamma = 0$, where Γ is part of the boundary of Ω with positive measure. A Poincaré-type inequality is still valid, as shown in [7].

LEMMA 4.4. *Let Ω be a domain in $\mathbb{R}^2$, and let Γ be a measurable subset of $\partial\Omega$ with length $(\Gamma) > 0$. Then there exists a constant $c > 0$ such that*

$$c^{-1}\|v\|_{2,\Omega} \le |v|_{2,\Omega} \quad \forall v \in H^2_\Gamma(\Omega).$$

THEOREM 4.5. *Let Ω be a domain in $\mathbb{R}^2$; assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω, and that $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$ for all $(x,y) \in \Omega$, where $\alpha_0 > 0$ is a constant. Then the variational equation (4.1) has a unique solution in $H^2_\Gamma(\Omega)$. In addition, if $\alpha(x,y), \beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

Proof. When $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$, we have $(\alpha+\beta)\Delta u \Delta u \ge 2\alpha(\Delta u)^2$, and so

$$\begin{aligned} B(u,u) &\ge \int_\Omega 2\alpha((\Delta u)^2 - 2u_{xx}u_{yy} + 2u_{xy}^2)\,dx\,dy \\ &= \int_\Omega 2\alpha(|u_{xx}|^2 + |u_{yy}|^2 + 2|u_{xy}|^2)\,dx\,dy \\ &\ge 2\alpha_0 |u|^2_{2,\Omega}. \end{aligned}$$

By Lemma 4.4,

$$B(u,u) \ge 2\alpha_0 c^{-2}\|u\|^2_{2,\Omega}.$$

Then the Lax–Milgram lemma implies that the problem has a unique solution in $H^2_\Gamma(\Omega)$. The regularity of the solution follows from the result in Friedrichs [8]. ∎

This means that if the solution is fixed on a part of the boundary and free on the rest of the boundary, then the PDE has a unique solution.

4.3. BC (iii): Natural boundary conditions. To derive the natural boundary condition, we return to the variational equation (4.5). For the first term of $B(u,v)$ in (4.3), by Green's formula, we have

$$\begin{aligned} \int_\Omega (\alpha+\beta)\Delta u\,\Delta v\,dx\,dy &= \int_\Omega v\Delta((\alpha+\beta)\Delta u)\,dx\,dy \\ &\quad + \int_{\partial\Omega}\left[(\alpha+\beta)\Delta u\frac{\partial v}{\partial \nu} - \frac{\partial((\alpha+\beta)\Delta u)}{\partial \nu}v\right] dS. \end{aligned}$$

For the second term of $B(u,v)$ in (4.3), notice that (with Einstein's convention)

$$u_{xx}v_{yy} + u_{yy}v_{xx} - 2u_{xy}v_{xy} = u_{ii}v_{jj} - u_{ij}v_{ij}.$$

Using Green's formula again, we arrive at

$$\int_\Omega \alpha u_{ii}\,v_{jj}\,dx\,dy = \int_\Omega (\alpha u_{ii})_{jj}\,v\,dx\,dy + \int_{\partial\Omega}\alpha u_{ii}\,v_j\,\nu_j\,dS - \int_{\partial\Omega}(\alpha u_{ii})_j\,v\,\nu_j\,dS,$$

$$\int_\Omega \alpha u_{ij}\,v_{ij}\,dx\,dy = \int_\Omega (\alpha u_{ij})_{ij}\,v\,dx\,dy + \int_{\partial\Omega}\alpha u_{ij}\,v_j\,\nu_i\,dS - \int_{\partial\Omega}(\alpha u_{ij})_i\,v\,\nu_j\,dS.$$

Thus the second term of $B(u,v)$ becomes

$$\begin{aligned}
&\int_\Omega \alpha(u_{xx}v_{yy}+u_{yy}v_{xx}-2u_{xy}v_{xy})\,dx\,dy\\
&\quad=\int_\Omega[(\alpha u_{ii})_{jj}-(\alpha u_{ij})_{ij}]\,v\,dx\,dy\\
&\qquad+\int_{\partial\Omega}[(\alpha_i u_{ij}\,\nu_j-\alpha_j u_{ii}\,\nu_j)\,v+\alpha u_{ii}\,v_j\,\nu_j-\alpha u_{ij}\,v_j\,\nu_i]\,dS.
\end{aligned}$$

To simplify this further, let τ be the unit tangent vector along $\partial\Omega$ and ν be the unit outward normal vector to $\partial\Omega$; then we have

$$\begin{cases} v_\nu = v_x\nu_x + v_y\nu_y,\\ v_\tau = -v_x\nu_y + v_y\nu_x \end{cases}$$

and

$$\begin{cases} v_x = v_\nu\nu_x - v_\tau\nu_y,\\ v_y = v_\nu\nu_y + v_\tau\nu_x. \end{cases}$$

Using these, we obtain that

$$\int_{\partial\Omega}(\alpha_i u_{ij}\nu_j-\alpha_j u_{ii}\nu_j)\,v\,dS=\int_{\partial\Omega}(-\alpha_x u_{y\tau}+\alpha_y u_{x\tau})\,v\,dS.$$

Moreover,

$$\begin{aligned}
&\int_{\partial\Omega}(\alpha u_{ii}v_j\nu_j-\alpha u_{ij}v_j\nu_i)\,dS\\
&\quad=-\int_{\partial\Omega}\alpha(u_{yx}\nu_y-u_{yy}\nu_x)v_x+\alpha(u_{xy}\nu_x-u_{xx}\nu_y)v_y\,dS\\
&\quad=\int_{\partial\Omega}(\alpha u_{y\tau}v_x-\alpha u_{x\tau}v_y)\,dS\\
&\quad=\int_{\partial\Omega}-\alpha(u_{x\tau}\nu_x+u_{y\tau}\nu_y)v_\tau+\alpha(u_{y\tau}\nu_x-u_{x\tau}\nu_y)v_\nu\,dS\\
&\quad=\int_{\partial\Omega}(\alpha(u_{x\tau}\nu_x+u_{y\tau}\nu_y))_\tau v+\alpha(u_{y\tau}\nu_x-u_{x\tau}\nu_y)v_\nu\,dS.
\end{aligned}$$

The last equality is obtained by integration by parts along the boundary.

Also

$$\int_\Omega \beta P\Delta v\,dx\,dy=\int_\Omega\Delta(\beta P)v\,dx\,dy+\int_{\partial\Omega}\left[\beta P\frac{\partial v}{\partial\nu}-\frac{\partial(\beta P)}{\partial\nu}v\right]dS.$$

Thus the natural boundary conditions are

(4.7)
$$\begin{cases} 2(\alpha_x u_{y\tau}-\alpha_y u_{x\tau})-\dfrac{\partial((\alpha+\beta)\Delta u)}{\partial\nu}-2(\alpha(u_{x\tau}\nu_x+u_{y\tau}\nu_y))_\tau+2\dfrac{\partial(\beta P)}{\partial\nu}=0,\\ (\alpha+\beta)\Delta u-2\alpha(u_{y\tau}\nu_x-u_{x\tau}\nu_y)-2\beta P=0. \end{cases}$$

Notice that the differential equation (4.5) and the natural boundary conditions (4.7) involve only the second and higher derivatives of u. Therefore if $u(x, y)$ is a solution of the problem, then for any linear function $l(x, y)$ in $\mathbb{R}^2$, $u(x, y)+l(x, y)$ will also be a solution of the problem. That is, the solution is not unique. We will show that the kernel is exactly the space of all the linear functions. We can then apply Fredholm's alternative after eliminating the finite dimensional kernel and establish the well-posedness of the problem.

4.3.1. Kernel of the equation. To show that the kernel is exactly the three dimensional space of linear functions, we first impose some constraints on u.

Since $C^2(\Omega)$ is dense in $H^2(\Omega)$, we first assume $u \in C^2(\Omega)$ with the following constraints:

$$\int_\Omega u \, dx\, dy = 0, \quad \int_\Omega u_x \, dx\, dy = 0, \quad \int_\Omega u_y \, dx\, dy = 0. \tag{4.8}$$

As we mentioned above, with the natural boundary condition, the PDE is equivalent to the variational equation

$$B(u, v) = L(v), \quad u, v \in H^2(\Omega).$$

Here, we will need a more general version of the Poincaré inequality [6].

LEMMA 4.6 (generalized Poincaré inequality). *Let Ω be a domain in $\mathbb{R}^2$, and let $1 \le p < \infty$; then there exists a constant c_0 such that*

$$\int_\Omega |v|^p dx\, dy \le c_0 \left\{ \int_\Omega |\nabla v|^p dx\, dy + \left| \int_\Omega v \, dx\, dy \right|^p \right\} \tag{4.9}$$

for all $v \in W^{1,p}(\Omega)$, where $c_0 = c_0(\Omega)$.

COROLLARY 4.7. *Let Ω be a domain in $\mathbb{R}^2$ and $u(x, y) \in H^2(\Omega)$ with the constraints* (4.8)*; then there exists a constant c such that*

$$\|u\|_{2,\Omega} \le c|u|_{2,\Omega}.$$

Proof. First assume $u \in C^2(\Omega)$; then, since $\int_\Omega u \, dx\, dy = 0$, we have immediately from (4.9)

$$\int_\Omega |u|^2 dx\, dy \le c_0 \int_\Omega (|u_x|^2 + |u_y|^2) dx\, dy.$$

Similarly, due to the constraints that $\int_\Omega u_x \, dx\, dy = 0$ and $\int_\Omega u_y \, dx\, dy = 0$, we have

$$\int_\Omega |u_x|^2 dx\, dy \le c_0 \int_\Omega (|u_{xx}|^2 + |u_{xy}|^2) dx\, dy,$$

$$\int_\Omega |u_y|^2 dx\, dy \le c_0 \int_\Omega (|u_{xy}|^2 + |u_{yy}|^2) dx\, dy.$$

Combining the results, we get

$$\int_\Omega |u|^2 dx\, dy \le c_0^2 \int_\Omega (|u_{xx}|^2 + 2|u_{xy}|^2 + |u_{yy}|^2) dx\, dy,$$

$$\int_\Omega (|u_x|^2 + |u_y|^2) dx\, dy \le c_0 \int_\Omega (|u_{xx}|^2 + 2|u_{xy}|^2 + |u_{yy}|^2) dx\, dy,$$

which implies

$$\|u\|_{2,\Omega} \le \sqrt{1 + c_0 + c_0^2}\ |u|_{2,\Omega}.$$

Because $C^2(\Omega)$ is dense in $H^2(\Omega)$, the above inequality is also true for all $u \in H^2(\Omega)$. □

With Corollary 4.7, the result for the partially clamped boundary condition can be applied to the natural boundary condition.

THEOREM 4.8. *Let Ω be a domain in $\mathbb{R}^2$; assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω; and take $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$ for all $(x,y) \in \Omega$, where $\alpha_0 > 0$ is a constant. Then, with the constraints* (4.8)*, the variational equation* (4.5) *has a unique solution in $H^2(\Omega)$. In addition, if $\alpha(x,y), \beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

We denote the solution to (4.5) with natural boundary condition (4.7) and constraints (4.8) by u_0. Now let u be an arbitrary solution of the variational equation without the constraints, and let

$$b = \frac{1}{|\Omega|}\int_\Omega u_x\,dx\,dy, \quad c = \frac{1}{|\Omega|}\int_\Omega u_y\,dx\,dy,$$

and

$$a = \frac{1}{|\Omega|}\int_\Omega (u - bx - cy)dx\,dy.$$

Define $\tilde{u} = u - (a + bx + cy)$; then $\tilde{u}$ is also a solution of the variational equation and

$$\int_\Omega \tilde{u}\,dx\,dy = 0, \quad \int_\Omega \tilde{u}_x\,dx\,dy = 0, \quad \int_\Omega \tilde{u}_y\,dx\,dy = 0.$$

By Theorem 4.8, $\tilde{u} \equiv u_0$ in $H^2(\Omega)$. This means that any solution to the variational equation must differ from u_0 by a linear function. We summarize the result in the following.

THEOREM 4.9. *Let Ω be a domain in $\mathbb{R}^2$; assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω; and assume $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$ for all $(x,y) \in \Omega$, where $\alpha_0 > 0$ is a constant. Then the solution to the variational equation* (4.1) *is unique in $H^2(\Omega)$ up to the addition of a linear function. In addition, if $\alpha(x,y)$, $\beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

5. Linearization about spherical surfaces. Since a progressive surface is in practice a slight perturbation from a spherical surface, it is certainly reasonable to suppose

$$u = u_0 + v,$$

where u_0 is a prescribed spherical surface of radius R and v is the deviation from it. Then a straightforward calculation from (3.3) leads to

$$H(u) = \frac{1}{R} + \frac{(1 + u_{0x}^2)v_{yy} - 2u_{0x}u_{0y}v_{xy} + (1 + u_{0y}^2)v_{xx}}{2g^3} + E_1$$

and

$$K(u) = \frac{(u_{0xx} + v_{xx})(u_{0yy} + v_{yy}) - (u_{0xy} + v_{xy})^2}{g^4} + E_2,$$

where $g = \sqrt{1 + u_{0x}^2 + u_{0y}^2}$ and E_1, E_2 are the error terms which satisfy

$$|E_i| \le C_i |\nabla v|, \quad i = 1, 2.$$

Here $C_i, i = 1, 2$, are two constants which depend only on $|\nabla v|$, $|D^2(v)|$, $|\nabla u_0|$, and $|D^2(u_0)|$.

Suppose that the domain satisfies $x^2 + y^2 \le cR^2$ with constant $c < 1$. In addition, suppose $|\nabla v| \ll 1$ and that $|D^2(v)|$ is bounded above in the domain. Then, $|E_i| \ll 1, i = 1, 2$, and thus

$$H(u) \approx \frac{1}{R} + \frac{(1 + u_{0x}^2)v_{yy} - 2u_{0x}u_{0y}v_{xy} + (1 + u_{0y}^2)v_{xx}}{2g^3},$$

$$K(u) \approx \frac{(u_{0xx} + v_{xx})(u_{0yy} + v_{yy}) - (u_{0xy} + v_{xy})^2}{g^4}.$$

Let

$$H_{u_0}(v) = \frac{(1 + u_{0x}^2)v_{yy} - 2u_{0x}u_{0y}v_{xy} + (1 + u_{0y}^2)v_{xx}}{2g^3}, \tag{5.1}$$

$$K_{u_0}(w, v) = \frac{w_{xx}v_{yy} + w_{yy}v_{xx} - 2w_{xy}v_{xy}}{g^4}. \tag{5.2}$$

Then $H_{u_0}(v)$ is linear and $K_{u_0}(w, v)$ is bilinear and symmetric. Consider again the functional (3.2):

$$\mathrm{I}(u) = \int_\Omega [\alpha(x, y)(H(u)^2 - K(u)) + \beta(x, y)(H(u) - P(x, y))^2] dx\, dy.$$

Assume that u minimizes the above functional, and let $\delta \in C_0^\infty(\Omega)$ be the test function. By computing the first variation of $\mathrm{I}(u)$ at u and using the notation (5.1) and (5.2), we will get

$$\int_\Omega [2(\alpha + \beta)H_{u_0}(v)H_{u_0}(\delta) - \alpha K_{u_0}(\delta, v)]\, dx\, dy$$

$$= \int_\Omega \left[\alpha K_{u_0}(\delta, u_0) + 2\left(\beta P - \frac{\alpha + \beta}{R}\right) H_{u_0}(\delta)\right] dx\, dy.$$

Let

$$B(w, v) = \int_\Omega [2(\alpha + \beta)H_{u_0}(w)H_{u_0}(v) - \alpha K_{u_0}(w, v)]\, dx\, dy \tag{5.3}$$

and

$$L(w) = \int_\Omega \left[\alpha K_{u_0}(w, u_0) + 2\left(\beta P - \frac{\alpha + \beta}{R}\right) H_{u_0}(w)\right] dx\, dy. \tag{5.4}$$

Then, it is clear that $B(w, v)$ is bilinear and $L(w)$ is linear. Thus the problem is to find $v \in V$ such that

$$B(w, v) = L(w) \quad \forall w \in V, \tag{5.5}$$

where V is a subspace of $H^2(\Omega)$.

Similar to the linearization about the flat surface, three types of BCs will be considered:

(i) clamped,
(ii) partially clamped,
(iii) natural.

5.1. BC (i): Clamped boundary condition.

THEOREM 5.1. *Let Ω be a subdomain of a square region of size d centered at $(0,0)$ in $\mathbb{R}^2$, and assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω. Assume further that $\alpha(x,y) \geq 0$ and that there exists a constant $\beta_0 > 0$ such that $\beta(x,y) \geq \beta_0$ for all $(x,y) \in \Omega$. If $d < 0.8165\,R$, then the variational equation (5.5) has a unique solution in $H_0^2(\Omega)$. In addition, if $\alpha(x,y), \beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

Proof. Since $u_0(x,y)$ is a spherical surface, then $u_0(x,y)$ could be expressed as $u_0(x,y) = -\sqrt{R^2 - x^2 - y^2}$. By direct calculation, we will have

$$H_{u_0}(v) = \frac{\sqrt{R^2 - x^2 - y^2}[(R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}]}{2R^3}, \tag{5.6}$$

$$K_{u_0}(v,v) = \frac{(R^2 - x^2 - y^2)^2(2v_{xx}v_{yy} - 2v_{xy}^2)}{R^4}. \tag{5.7}$$

We can rewrite (5.3) as

$$\begin{aligned} B(v,v) &= \int_\Omega \left\{2(\alpha+\beta)H_{u_0}^2(v) - \alpha K_{u_0}(v,v)\right\} dx\,dy \\ &= \int_\Omega \alpha\left(2H_{u_0}^2(v) - K_{u_0}(v,v)\right) dx\,dy + 2\int_\Omega \beta H_{u_0}^2(v) dx\,dy. \end{aligned} \tag{5.8}$$

The first integrand of $B(v,v)$ is

$$\begin{aligned} &\alpha\left(2H_{u_0}^2(v) - K_{u_0}(v,v)\right) \\ &\quad = \frac{\alpha(R^2 - x^2 - y^2)}{2R^6}\Big[\left((R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}\right)^2 \\ &\qquad\qquad - 2\,R^2(R^2 - x^2 - y^2)(2v_{xx}v_{yy} - 2v_{xy}^2)\Big]. \end{aligned}$$

Now, consider the matrix

$$A = \begin{pmatrix} R^2 - x^2 & -xy \\ -xy & R^2 - y^2 \end{pmatrix}\begin{pmatrix} v_{xx} & v_{xy} \\ v_{xy} & v_{yy} \end{pmatrix}.$$

The trace of A is

$$\mathrm{tr}(A) = \left[(R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}\right],$$

and the determinant of A is

$$\det(A) = R^2(R^2 - x^2 - y^2)(v_{xx}v_{yy} - v_{xy}^2).$$

By the fact that $\mathrm{tr}(A)^2 - 4\det(A) \geq 0$ for any 2×2 matrix A, we have

$$\alpha\,(2H_{u_0}(v)H_{u_0}(v) - K_{u_0}(v,v)) \geq 0.$$

It remains to analyze the second part of $B(v,v)$ in (5.8):

$$\begin{aligned}
&[(R^2-y^2)v_{yy} - 2xyv_{xy} + (R^2-x^2)v_{xx}]^2 \\
&\quad = [R^2\Delta v - (y^2v_{yy} + x^2v_{xx} + 2xyv_{xy})]^2 \\
&\quad = R^4(\Delta v)^2 - 2R^2\Delta v(y^2v_{yy} + x^2v_{xx} + 2xyv_{xy}) \\
&\quad + (y^2v_{yy} + x^2v_{xx} + 2xyv_{xy})^2.
\end{aligned}$$

Assume $|x|, |y| \leq r = \delta R$, where $\delta \in [0,1]$ is to be chosen later. Then

$$|y^2v_{yy} + x^2v_{xx} + 2xyv_{xy}| \leq \delta^2R^2(|v_{xx}| + |v_{yy}| + 2|v_{xy}|).$$

By the Schwarz inequality,

$$\begin{aligned}
&|2R^2\Delta v(y^2v_{yy} + x^2v_{xx} + 2xyv_{xy})| \\
&\qquad \leq 2R^4\delta^2(|v_{xx}| + |v_{yy}|)(|v_{xx}| + |v_{yy}| + 2|v_{xy}|) \\
&\qquad \leq 2R^4\delta^2(3|v_{xx}|^2 + 3|v_{yy}|^2 + 2|v_{xy}|^2);
\end{aligned}$$

thus, we have

$$\begin{aligned}
&[(R^2-y^2)v_{yy} - 2xyv_{xy} + (R^2-x^2)v_{xx}]^2 \\
&\qquad \geq R^4[(\Delta v)^2 - 2\delta^2(3|v_{xx}|^2 + 3|v_{yy}|^2 + 2|v_{xy}|^2)] \\
&\qquad \geq R^4[(\Delta v)^2 - 6\delta^2(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)].
\end{aligned}$$

If $1 - 6\delta^2 = \eta > 0$, i.e., if $\delta < 1/\sqrt{6} \approx 0.4082$, then the above inequality implies

$$\begin{aligned}
&[(R^2-y^2)v_{yy} - 2xyv_{xy} + (R^2-x^2)v_{xx}]^2 \\
&\qquad \geq R^4[(\Delta v)^2 - (1-\eta)(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)]
\end{aligned}$$

and

$$\begin{aligned}
&2\int_\Omega \beta H_{u_0}(v)H_{u_0}(v)dx\,dy \\
&\qquad \geq \beta_0\frac{1-2\delta^2}{2}\int_\Omega \{(\Delta v)^2 - (1-\eta)(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)\}dx\,dy \\
&\qquad = \beta_0\frac{1-2\delta^2}{2}\eta|v|^2_{2,\Omega} \\
&\qquad = c_0|v|^2_{2,\Omega},
\end{aligned}$$

where $c_0 = \beta_0\frac{1-2\delta^2}{2}\eta > 0$. Here, we have used the fact that in $H_0^2(\Omega)$, $|\Delta v|_{0,\Omega} = |v|_{2,\Omega}$. Finally, by the Poincaré–Friedrichs inequality (4.6) and the Lax–Milgram lemma (Lemma 4.1), equation (5.5) has a unique solution in $H_0^2(\Omega)$.

That is, if the size of the square region is less than $0.8165\,R$, then the problem could be uniquely solved. The regularity of the solution follows from the result in Friedrichs [8]. ∎

Remarks.

1. If we use the Cauchy ϵ-inequality ($ab \le \epsilon a^2 + \frac{b^2}{4\epsilon}$) instead of the Schwarz inequality, we will have

$$\begin{aligned}
&|2R^2\Delta v(y^2 v_{yy} + x^2 v_{xx} + 2xyv_{xy})| \\
&\qquad \le 2R^4\delta^2(|v_{xx}| + |v_{yy}|)(|v_{xx}| + |v_{yy}| + 2|v_{xy}|) \\
&\qquad \le 2R^4\delta^2\left((2+2\epsilon)(|v_{xx}|^2 + |v_{yy}|^2) + 2\frac{1}{2\epsilon}|v_{xy}|^2\right).
\end{aligned}$$

   By choosing $\epsilon = (\sqrt{2}-1)/2$, $2 + 2\epsilon = 1/(2\epsilon)$, we have

$$\begin{aligned}
&[(R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}]^2 \\
&\qquad \ge R^4[(\Delta v)^2 - 2(\sqrt{2}+1)\delta^2(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)].
\end{aligned}$$

   Thus if $1 - 2(\sqrt{2}+1)\delta^2 > 0$, i.e., if $\delta < \sqrt{1/(2(\sqrt{2}+1))} \approx 0.4551$, then the conclusion is still true.

2. If we solve the equation on a circular region $x^2 + y^2 \le r^2$ instead of a square region and assume $r = \delta R$, then with the Schwarz inequality, we will have

$$\begin{aligned}
&[(R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}]^2 \\
&\qquad \ge R^4[(\Delta v)^2 - 5\delta^2(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)].
\end{aligned}$$

   This means that if $\delta < 1/\sqrt{5} \approx 0.4472$, then the equation has a unique solution in the circular region.
   If we use the Cauchy ϵ-inequality, we will have

$$\begin{aligned}
&[(R^2 - y^2)v_{yy} - 2xyv_{xy} + (R^2 - x^2)v_{xx}]^2 \\
&\qquad \ge R^4[(\Delta v)^2 - (\sqrt{5}+2)\delta^2(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2)].
\end{aligned}$$

   Thus if $\delta < \sqrt{1/(\sqrt{5}+2)} \approx 0.4859$, the above conclusion is still true.

5.2. BC (ii): Partially clamped boundary condition. Let $H^2_\Gamma(\Omega)$ be the subspace of $H^2(\Omega)$ such that $f(x,y)|_\Gamma = 0$, $\frac{\partial f}{\partial \nu}|_\Gamma = 0$. Here Γ is part of the boundary of Ω with positive measure.

THEOREM 5.2. *Let Ω be a subdomain of a square region of size d centered at $(0,0)$ in $\mathbb{R}^2$, and assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω. If $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$ for all $(x,y) \in \Omega$, where $\alpha_0 > 0$ is a constant, then if $d \le R$, the variational equation (5.5) has a unique solution in $H^2_\Gamma(\Omega)$. In addition, if $\alpha(x,y), \beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

Proof. If $\beta(x,y) \ge \alpha(x,y) \ge \alpha_0$, we have

$$B(u,u) \ge \int_\Omega \left[4\alpha H^2_{u_0}(v) - \alpha K_{u_0}(v,v)\right] dx\, dy,$$

where $H_{u_0}(v)$ and $K_{u_0}(v,v)$ are given by (5.6) and (5.7).

Since $R^2(R^2-x^2-y^2) = (R^2-x^2)(R^2-y^2) - x^2y^2$, $K_{u_0}(v,v)$ can be rewritten as

$$\begin{aligned} K_{u_0}(v,v) &= \frac{(R^2-x^2-y^2)^2(2v_{xx}v_{yy}-2v_{xy}^2)}{R^4} \\ &= \frac{2(R^2-x^2-y^2)}{R^6}\left[((R^2-x^2)(R^2-y^2)-x^2y^2)(v_{xx}v_{yy}-v_{xy}^2)\right]. \end{aligned}$$

Thus

$$B(v,v) \geq \int_\Omega \alpha \frac{(R^2-x^2-y^2)}{R^6}(\mathrm{I}+2x^2y^2v_{xy}^2-\mathrm{II})dx\,dy,$$

where

$$\begin{aligned} \mathrm{I} &= (R^2-x^2)^2v_{xx}^2 + (R^2-y^2)^2v_{yy}^2 + 2(R^2-x^2)(R^2-y^2)v_{xy}^2, \\ \mathrm{II} &= 4xy(R^2-y^2)v_{xy}v_{yy} + 4xy(R^2-x^2)v_{xy}v_{xx} - 2x^2y^2v_{xx}v_{yy}. \end{aligned}$$

Assume $|x|, |y| \leq r = \delta R$, where $\delta \in [0,1]$ is to be chosen later. Then

$$\begin{aligned} \mathrm{I} &= (R^2-x^2)^2v_{xx}^2 + (R^2-y^2)^2v_{yy}^2 + 2(R^2-x^2)(R^2-y^2)v_{xy}^2 \\ &\geq (1-\delta^2)^2R^4(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2), \end{aligned}$$

and

$$\begin{aligned} \mathrm{II} &= 4xy(R^2-y^2)v_{xy}v_{yy} + 4xy(R^2-x^2)v_{xy}v_{xx} - 2x^2y^2v_{xx}v_{yy} \\ &\leq 2\delta^2R^4(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2) + \delta^4R^4(|v_{xx}|^2 + |v_{yy}|^2) \\ &\leq (2\delta^2+\delta^4)R^4(|v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2). \end{aligned}$$

Thus, if $(1-\delta^2)^2 > 2\delta^2+\delta^4$, i.e., if $1-4\delta^2 > 0$, which implies $\delta < 1/2$, then $R^2-x^2-y^2 \geq R^2/2$ and

$$\begin{aligned} B(v,v) &\geq \int_\Omega \alpha \frac{(R^2-x^2-y^2)}{R^2}\left((1-\delta^2)^2 - (2\delta^2+\delta^4)\right)|D^2v|dx\,dy \\ &\geq \int_\Omega \alpha_0 \frac{(1-\delta^2)^2-(2\delta^2+\delta^4)}{2}|D^2v|dx\,dy \\ &= c_0|v|_{2,\Omega}^2, \end{aligned}$$

where $|D^2v|^2 = |v_{xx}|^2 + |v_{yy}|^2 + 2|v_{xy}|^2$ and $c_0 = \alpha_0\frac{(1-\delta^2)^2-(2\delta^2+\delta^4)}{2} > 0$.

By Lemma 4.4,

$$B(u,u) \geq c_1\|v\|_{2,\Omega}^2.$$

Then the Lax–Milgram lemma (Lemma 4.1) implies that the problem has a unique solution. The regularity of the solution follows from the result in Friedrichs [8]. ∎

This means that if the solution is fixed on a part of the boundary and free on the rest of the boundary, then the PDE has a unique solution in $H_\Gamma^2(\Omega)$.

From the above proof, it is clear that, to have a unique solution, δ cannot be arbitrarily large. It is desirable to find δ as large as possible for practical purposes.

Remarks.

1. If we use the Cauchy ϵ-inequality ($ab \le \epsilon a^2 + \frac{b^2}{4\epsilon}$) instead of the Schwarz inequality, we will have

$$\begin{aligned}\mathrm{II} &= 4xy(R^2-y^2)v_{xy}v_{yy} + 4xy(R^2-x^2)v_{xy}v_{xx} - 2x^2y^2v_{xx}v_{yy}\\ &\le \delta^2R^4\left(4\epsilon(|v_{xx}|^2+|v_{yy}|^2) + \frac{2}{\epsilon}|v_{xy}|^2\right) + \delta^4R^4(|v_{xx}|^2+|v_{yy}|^2)\\ &\le \delta^2R^4\left((4\epsilon+\delta^2)(|v_{xx}|^2+|v_{yy}|^2) + \frac{2}{\epsilon}|v_{xy}|^2\right).\end{aligned}$$

Solving $4\epsilon + \delta^2 = 1/\epsilon$, we get $\epsilon = \frac{\sqrt{\delta^4+16}-\delta^2}{8}$. With this choice of ϵ, we have

$$B(v,v) \ge \int_\Omega \alpha(1-2\delta^2)\left((1-\delta^2)^2 - \frac{8\delta^2}{\sqrt{\delta^4+16}-\delta^2}\right)|D^2v|dx\,dy.$$

By solving $(1-\delta^2)^2 = 8\delta^2/(\sqrt{\delta^4+16}-\delta^2)$, we derive $1-4\delta^2+\delta^4-2\delta^6 = 0$, and with the help of Mathematica we get

$$\delta = \sqrt{\frac{1}{6} - \frac{23}{6(19+12\sqrt{23})^{1/3}} + \frac{1}{6}(19+12\sqrt{23})^{1/3}} \approx 0.507992.$$

Thus if $r < 0.50799\,R$, then the conclusion of the above theorem is still true.

2. If we solve the equation on a circular region $x^2+y^2 \le r^2$ instead of a square region and assume $r = \delta\,R$, then with the Schwarz inequality, we will have

$$\begin{aligned}\mathrm{II} &= 4xy(R^2-y^2)v_{xy}v_{yy} + 4xy(R^2-x^2)v_{xy}v_{xx} - 2x^2y^2v_{xx}v_{yy}\\ &\le \delta^2R^4(|v_{xx}|^2+|v_{yy}|^2+2|v_{xy}|^2) + \frac{\delta^4}{4}R^4(|v_{xx}|^2+|v_{yy}|^2)\\ &\le \delta^2\left(1+\frac{\delta^4}{4}\right)R^4(|v_{xx}|^2+|v_{yy}|^2+2|v_{xy}|^2).\end{aligned}$$

Solving $(1-\delta^2)^2 > \delta^2(1+\frac{\delta^4}{4})$ gives $\delta < \sqrt{\frac{3-\sqrt{6}}{2}} \approx 0.5246$.
If we use the Cauchy ϵ-inequality, we will have

$$\begin{aligned}\mathrm{II} &= 4xy(R^2-y^2)v_{xy}v_{yy} + 4xy(R^2-x^2)v_{xy}v_{xx} - 2x^2y^2v_{xx}v_{yy}\\ &\le 2\delta^2R^4(|v_{xx}||v_{xy}| + |v_{yy}||v_{xy}|) + \frac{\delta^4R^4}{4}(|v_{xx}|^2+|v_{yy}|^2)\\ &\le 2\delta^2R^4\left(\epsilon(|v_{xx}|^2+|v_{yy}|^2) + 2\frac{|v_{xy}|^2}{4\epsilon}\right) + \frac{\delta^4R^4}{4}(|v_{xx}|^2+|v_{yy}|^2)\\ &= R^4\delta^2\left[\left(2\epsilon+\frac{\delta^2}{4}\right)(|v_{xx}|^2+|v_{yy}|^2) + 2\frac{|v_{xy}|^2}{2\epsilon}\right].\end{aligned}$$

Let $2\epsilon + \frac{\delta^2}{4} = \frac{1}{2\epsilon}$; we have $\epsilon = (-\delta^2 + \sqrt{\delta^4+64})/8$. Solving $(1-\delta^2)^2 > \delta^2(\delta^2+\sqrt{\delta^4+64})/8$ via Mathematica, we get $\delta^2 \approx 0.37399$, which gives $\delta \approx 0.611549$.

5.3. BC (iii): Natural boundary condition. For the same reason that the variational equations involve only the second derivatives of u, the analysis of the solution for the natural boundary condition is almost the same as for the linearization about a flat surface. Therefore, we state the following theorem but omit its proof.

THEOREM 5.3. *Let Ω be a subdomain of a square region of size d centered at $(0,0)$ in $\mathbb{R}^2$, and assume that $P(x,y)$, $\alpha(x,y)$, and $\beta(x,y)$ are bounded above in Ω. If $\beta(x,y) \geq \alpha(x,y) \geq \alpha_0$ for all $(x,y) \in \Omega$, where $\alpha_0 > 0$ is a constant, then if $d \leq R$, the solution to the variational equation (5.5) exists in $H^2(\Omega)$ and is unique up to an addition of a linear function. In addition, if $\alpha(x,y), \beta(x,y) \in C^k(\Omega)$ and $P(x,y) \in H^k(\Omega)$, then for every compact subdomain Ω_1 of Ω, the solution $u \in H^{k+2}(\Omega_1)$.*

6. Numerical results. In practice, lenses are designed on a circular region of diameter 80mm. For computational simplicity, we solve the design problem in the square domain $[-40,40] \otimes [-40,40]$.

We considered both of the linearizations analyzed above and solved the problems for all three types of boundary conditions by finite element methods. We found that linearization about a spherical surface with natural boundary conditions produces the best lens. We will describe the findings below. Detailed analysis of the numerical methods and description of the setting of the weight functions as well as the prescribed power functions which produced the result shown can be found in [11].

Figure 6.1 shows the results where the radius of the spherical surface $R = 107$mm, the index of the material $n = 1.53$, and the add-power (power addition from the base power) is 2 diopters (diopter $= (n-1)/($focal length$)$) for the near-vision area. The progressive lens surface is shown in Figure 6.1(a), while Figure 6.1(b) shows the difference between the progressive lens surface and the initial spherical surface.

To optically analyze the surface, we need to calculate the power and the cylinder of the surface. However, since the surface produced by the method is piecewise quadratic, the second derivatives at the grid points are not well defined. Thus it is not possible to calculate the cylinder and the power of the surface directly. An efficient and popular method in the lens industry for analyzing lenses is to fit a lens by tensor product B-splines of degree 3 to 5 and compute the cylinder and the power of the interpolated surface. This gives a very good approximation of the cylinder and the power of the true surface. We used the same method with tensor product B-splines of degree 5 for analyzing our lenses.

Figure 6.2 shows the power and cylinder contours of the surface given in Figure 6.1(a).

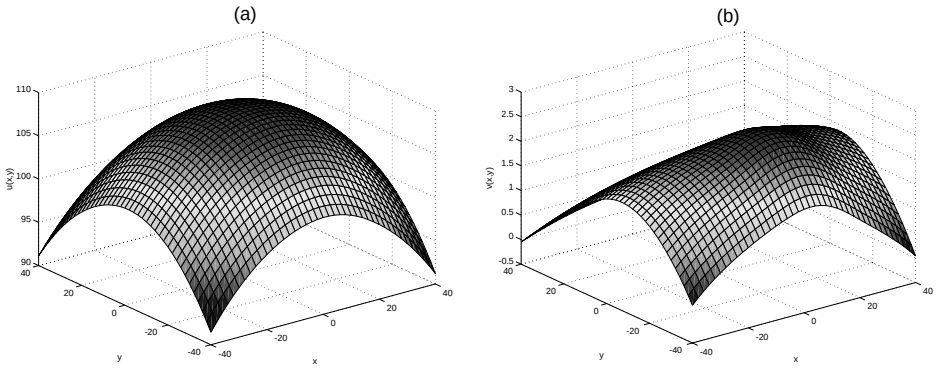

FIG. 6.1. *Numerical results:* (a) *progressive surface,* (b) *addition to the spherical surface.*

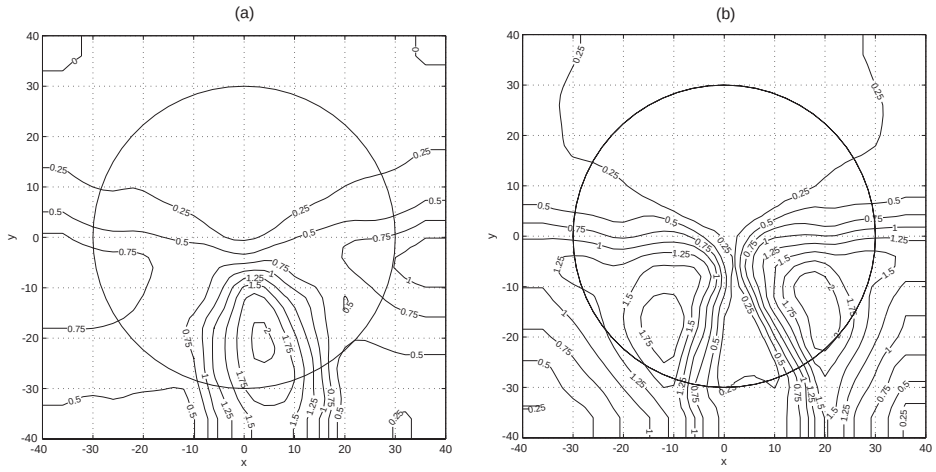

FIG. 6.2. *Numerical results with the natural boundary condition.* (a) *power contour,* (b) *cylinder contour.*

The circles in Figures 6.2(a)–(b) indicate the area of radius < 30mm that is actually used in making prescription lenses. We can see that the add-power of 2 diopters is achieved and that both the power and the cylinder change smoothly through out the lens. Moreover, there is a clear corridor connecting the far and near regions in the cylinder. Note also that the maximum cylinder is about the same as the add-power, which is typical in progressive lenses.

7. Discussions. In this first of a two-part paper, we have analyzed the variational problem of progressive lens design. The design problem consists of finding a surface whose power distribution over a lens is close to a desired distribution, while minimizing the astigmatism over a specific region. This is a nonlinear optimization problem. We considered linearizations about a plane and a sphere. The resulting equations in each case are fourth-order PDEs similar to those that describe deformations of plates. We considered the existence and uniqueness of solutions under various boundary conditions. For completeness, a numerical example is included, which demonstrates the effectiveness of the methods.

In the second part of our work [11], we will address in detail the computational issues arising in this design problem. The results from the present work will serve to guide the design of accurate and convergent numerical methods for solving the progressive lens design problem.

Acknowledgments. The authors express their gratitude to Dr. Jianping Wei for helpful discussions on this work. We are grateful to the anonymous referees for their careful reading of the manuscript and for pointing out references and patents relevant to this work.

ACOUSTIC SCATTERING BY INHOMOGENEOUS OBSTACLES*

P. A. MARTIN†

Abstract. Acoustic scattering problems are considered when the material parameters (density and speed of sound) are functions of position within a bounded region. An integro-differential equation for the pressure in this region is obtained. It is proved that solving this equation is equivalent to solving the scattering problem. Problems of this kind are often solved by regarding the effects of the inhomogeneity as an unknown source term driving a Helmholtz equation, leading to an equation of Lippmann–Schwinger type. It is shown that this approach is incomplete when the density is discontinuous. Analogous scattering problems for elastic waves and for electromagnetic waves are also discussed briefly.

Key words. Bergmann's equation, Lippmann–Schwinger equation

AMS subject classifications. 76Q05, 35J05, 35J25, 45B05

DOI. 10.1137/S0036139902414379

1. Introduction.

Time-harmonic acoustic waves in an inhomogeneous compressible fluid can be modelled using Bergmann's equation (see (2.3) below). If the waves are generated by a point source located at $\boldsymbol{r}'$, the pressure at $\boldsymbol{r}$, $\mathcal{G}(\boldsymbol{r};\boldsymbol{r}')$, satisfies

$$\nabla^2\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') - \rho^{-1}(\operatorname{grad}\rho)\cdot\operatorname{grad}\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') + k^2(\boldsymbol{r})\,\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') = \delta(\boldsymbol{r}-\boldsymbol{r}'), \tag{1.1}$$

where $k^2(\boldsymbol{r}) = [\omega/c(\boldsymbol{r})]^2$, ω is the frequency, $c(\boldsymbol{r})$ is the speed of sound, and $\rho(\boldsymbol{r})$ is the density. ($\mathcal{G}$ is an exact Green's function for the problem.) Equation (1.1) is supposed to hold everywhere in space, and it is to be solved subject to a radiation condition at infinity.

How does one solve (1.1)? According to a recent review article by Tourin, Fink, and Derode [39], "the solution of (1.1) can be written as"

$$\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') = G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}') + \int G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}_1)\,V(\boldsymbol{r}_1)\mathcal{G}(\boldsymbol{r}_1;\boldsymbol{r}')\,d\boldsymbol{r}_1, \tag{1.2}$$

where the integration is over all of space, V is a "potential operator", defined by

$$V(\boldsymbol{r}) = k_{\mathrm{e}}^2 - k^2(\boldsymbol{r}) + \rho^{-1}(\operatorname{grad}\rho(\boldsymbol{r}))\cdot\operatorname{grad}, \tag{1.3}$$

k_{e} is the wavenumber for a related homogeneous medium, and G_{e} is the (known) solution of the problem for that medium: G_{e} satisfies

$$\nabla^2 G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}_1) + k_{\mathrm{e}}^2 G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}_1) = \delta(\boldsymbol{r}-\boldsymbol{r}_1) \tag{1.4}$$

and the radiation condition and is given explicitly by (3.1) below. Equation (1.2) is not derived in [39] and no indication of its range of validity is given. In fact, as we shall see, (1.2) is not valid when $\rho(\boldsymbol{r})$ is discontinuous. (This is unfortunate, because most of the applications in [39] are to arrays of discrete scatterers, such as steel rods in water.)

1.1. A formal derivation. Equations such as (1.1) are often treated by moving all the complicated terms to the right-hand side where they are regarded as a forcing term. Thus, write (1.1) as

$$\nabla^2\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') + k_{\mathrm{e}}^2\,\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') = V(\boldsymbol{r})\mathcal{G}(\boldsymbol{r};\boldsymbol{r}') + \delta(\boldsymbol{r}-\boldsymbol{r}').$$

Equation (1.2) then follows by noting that

$$u(\boldsymbol{r}) = \int G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}')\,f(\boldsymbol{r}')\,d\boldsymbol{r}' \quad \text{solves} \quad (\nabla^2 + k_{\mathrm{e}}^2)u = f. \tag{1.5}$$

Formal derivations of this kind are often found in textbooks; see, for example, [9, sect. 8.9.1] or [18, eqn. (21.37)]. The result (1.5) can be justified readily if one assumes that f is (Hölder) continuous. However, for discrete scatterers, there will be interfaces across which $k(\boldsymbol{r})$ and the normal derivative of $\mathcal{G}$, $\partial\mathcal{G}/\partial n$, will be discontinuous (although $\mathcal{G}$ and $\rho^{-1}\partial\mathcal{G}/\partial n$ are both continuous across such interfaces).

1.2. The present paper. The formal derivation in section 1.1 is incomplete. It can be repaired so as to give the correct result. Thus, when considered as a distribution, we have

$$V\mathcal{G} = \{V\mathcal{G}\} + [\rho]\,\delta(S)\,(\rho^{-1}\partial\mathcal{G}/\partial n),$$

where $\{V\mathcal{G}\}$ denotes the value of $V\mathcal{G}$ anywhere but on the interfaces S and $[\rho]$ denotes the discontinuity in ρ across S [41, sect. 1.13]. Then, (1.5) suggests an additional term on the right-hand side of (1.2), namely

$$\int_S G_{\mathrm{e}}(\boldsymbol{r};\boldsymbol{r}_s)\,[\rho](\boldsymbol{r}_s)\left(\frac{1}{\rho}\frac{\partial\mathcal{G}}{\partial n}\right)(\boldsymbol{r}_s;\boldsymbol{r}')\,ds(\boldsymbol{r}_s). \tag{1.6}$$

In this paper, we shall derive an equation, similar to (1.2), that respects the proper transmission conditions across interfaces: we do not use distribution theory. We prove that solving this equation is equivalent to solving the transmission problem for the acoustic pressure (Theorem 3.1).

We are mainly concerned with the following problem: acoustic scattering by a bounded inhomogeneity embedded in an unbounded homogeneous medium. The density and sound-speed are assumed to be functions of position within the inhomogeneity, and they can be discontinuous across the interface between the inhomogeneity and the surrounding fluid. Problems in which the inhomogeneity is *spherically symmetric*, so that ρ and c are assumed to be given functions of the spherical polar coordinate r (only), have been studied by several authors; see [28] for references.

The new equation is derived in section 3. It reduces to the well-known Lippmann–Schwinger equation when the density in the inhomogeneity is constant and equal to the density of the surrounding homogeneous fluid. It also reduces to the equation derived formally above, namely (1.2), *but only when there is no discontinuity in the density across the boundary of the inhomogeneity.* If there is such a discontinuity (as is typical in applications), an extra term is needed; see (1.6) and (4.4) below. Analogous scattering problems for electromagnetic waves and for elastic waves are discussed briefly in sections 4.4 and 4.5, respectively.

2. Formulation. Consider the scattering of time-harmonic sound waves in a homogeneous compressible fluid by an inhomogeneous obstacle. In the exterior fluid, B_{e}, we can write

$$p_{\mathrm{e}} = p_{\mathrm{inc}} + p_{\mathrm{sc}}, \tag{2.1}$$

where p_e is the (total) acoustic pressure, p_{inc} is the given incident field, and p_{sc} is the scattered field. The governing equation for p_{sc} is

$$(\nabla^2 + k_e^2)p_{sc} = 0 \quad \text{in } B_e, \tag{2.2}$$

where $k_e = \omega/c_e$ is the wave number (assumed to be real and positive), ω is the frequency, and c_e is the constant speed of sound. We assume that the incident field p_{inc} satisfies (2.2) everywhere, except possibly at some places in B_e (so that p_{inc} could correspond to a point source in B_e, for example). We require that p_{sc} satisfies the Sommerfeld radiation condition at infinity.

Within the obstacle, B, the governing equation is Bergmann's equation ([3, 28] and [29, p. 408])

$$\rho_i \operatorname{div}\left(\rho_i^{-1} \operatorname{grad} p_i\right) + k_i^2 p_i = 0 \quad \text{in } B, \tag{2.3}$$

where p_i is the pressure and $k_i = \omega/c_i$. The interior density ρ_i and speed of sound c_i can vary with position in B. At the interface S between B and B_e, we have a pair of transmission conditions, expressing continuity of pressure and normal velocity. These are

$$p_e = p_i \quad \text{and} \quad \frac{1}{\rho_e}\frac{\partial p_e}{\partial n} = \frac{1}{\rho_i}\frac{\partial p_i}{\partial n} \quad \text{on } S, \tag{2.4}$$

where ρ_e is the (constant) density of the fluid in B_e.

Summarizing, we have the following problem to solve.

Scattering Problem. Let p_{inc} be a given incident field. Find a pair of functions, $\{p_e, p_i\}$, where $p_{sc} = p_e - p_{inc}$ satisfies (2.2) and the Sommerfeld radiation condition, p_i satisfies (2.3), and p_e and p_i satisfy the transmission conditions (2.4) across the interface S.

Werner wrote an important paper on the Scattering Problem in 1963 [43]. He reduced the problem to a system of coupled integral equations, using single-layer, double-layer, and volume potentials; see Appendix A. Werner's approach is an example of an *indirect method*, meaning that the unknown quantities do not have any physical relevance. He proved that the Scattering Problem has exactly one solution; his uniqueness result is in [42]. However, as far as we know, his system of integral equations has not been used in computations.

We shall use a *direct method*, meaning that the unknown quantity is recognized as a physical variable, namely p_i. Moreover, we shall use only volume potentials; this is convenient from a computational point of view, because one does not have to approximate a mixture of surface and volume contributions.

In solving the Scattering Problem, we seek classical solutions. We shall appeal to Werner's existence result, so we suppose that $p_{sc} \in C^2(B_e) \cap C^1(\overline{B_e})$ and $p_i \in C^2(B) \cap C^1(\overline{B})$. We assume that $\rho_i \in C^2(\overline{B})$ and $c_i \in C^1(\overline{B})$ are both positive. Finally, we assume that S is smooth (C^2). It is likely that these conditions can be weakened; for example, Werner's uniqueness theorem [42] requires that ρ_i and c_i be in Hölder spaces, with $\rho_i \in C^{1,\alpha}(\overline{B})$ and $c_i \in C^{0,\alpha}(\overline{B})$.

Bergmann's equation (2.3) can be written in other ways. One alternative is

$$\nabla^2 p_i + \rho_i \left(\operatorname{grad} \rho_i^{-1}\right) \cdot \operatorname{grad} p_i + k_e^2 N p_i = 0 \quad \text{in } B, \tag{2.5}$$

where $N = (k_i/k_e)^2 = (c_e/c_i)^2$ is the (square of the) *refractive index*. Another is

$$\nabla^2 p_i + k_e^2 p_i = V p_i \quad \text{in } B,$$

where (see (1.3))

$$Vu = k_{\mathrm{e}}^2(1-N)u + \rho_{\mathrm{i}}^{-1}(\operatorname{grad}\rho_{\mathrm{i}})\cdot\operatorname{grad} u. \tag{2.6}$$

Bergmann's equation can also be reduced to an equation without first derivatives by introducing a new dependent variable [3], $u = p_{\mathrm{i}}\rho_{\mathrm{i}}^{-1/2}$: u is found to satisfy

$$\nabla^2 u + (k_{\mathrm{i}}^2 + K)u = 0, \tag{2.7}$$

where

$$K = \tfrac{1}{2}\rho_{\mathrm{i}}^{-1}\nabla^2\rho_{\mathrm{i}} - \tfrac{3}{4}\rho_{\mathrm{i}}^{-2}\left|\operatorname{grad}\rho_{\mathrm{i}}\right|^2 \tag{2.8}$$

$$= -\rho_{\mathrm{i}}^{1/2}\nabla^2\left(\rho_{\mathrm{i}}^{-1/2}\right). \tag{2.9}$$

Equations (2.7) and (2.8) (but not (2.9)) can be found in [4, p. 171]. Equation (2.7) can also be written as *Schrödinger's equation* [32, eqn. (10.59)].

Much has been written on the case where ρ_{i} is constant, so that the second term on the left-hand side of (2.5) can be deleted [12, Chap. 8]; see [23] for a review of available point-source solutions (Green's functions) for various functional forms of N. Here, we do not make this assumption: we allow both ρ_{i} and N to vary with position. Note that if the material in B is actually homogeneous, so that ρ_{i} and k_{i} are both constants, boundary integral equations over S can be used; see [20] for a review.

Kriegsmann and Reiss [22] have given long-wave approximations to the solution of the Scattering Problem, assuming that $\rho_{\mathrm{i}}/\rho_{\mathrm{e}} \simeq 1$. Specifically, they take $\rho_{\mathrm{i}}/\rho_{\mathrm{e}} = 1 + O(\varepsilon^2)$ and $k_{\mathrm{e}}a = O(\varepsilon)$, where a is the diameter of B and $0 < \varepsilon \ll 1$.

Colton and Monk [13] have reviewed progress with inverse problems for (2.3), which they write as $\operatorname{div}\left(\rho_{\mathrm{i}}^{-1}\operatorname{grad} p_{\mathrm{i}}\right) + k_{\mathrm{e}}^2\tilde{N}p_{\mathrm{i}} = 0$, where $\tilde{N} = N/\rho_{\mathrm{i}}$. They also assume that ρ_{i} is constant near S so that the ratio $\rho_{\mathrm{e}}/\rho_{\mathrm{i}}$ occurring in $(2.4)_2$ is constant; in general, this need not be true.

2.1. Uniqueness. The Scattering Problem has at most one solution [42]. This uniqueness theorem can be proved as follows. Set $p_{\mathrm{inc}} \equiv 0$ and then apply Green's theorem to p_{e} and its complex conjugate, $\overline{p_{\mathrm{e}}}$, in the exterior, giving

$$2ik_{\mathrm{e}}\lim_{R\to\infty}\int_{S_R}|p_{\mathrm{e}}|^2\,ds + \int_S\left(p_{\mathrm{e}}\,\frac{\partial\overline{p_{\mathrm{e}}}}{\partial n} - \overline{p_{\mathrm{e}}}\,\frac{\partial p_{\mathrm{e}}}{\partial n}\right)ds = 0. \tag{2.10}$$

Here, the unit normal to S, $\boldsymbol{n}$, points out of B, S_R is a large sphere of radius R that encloses S, we have used the radiation condition, and we have assumed that k_{e} is real. Next, apply the divergence theorem in B to the vector field $(\overline{p_{\mathrm{i}}}/\rho_{\mathrm{i}})\operatorname{grad} p_{\mathrm{i}}$, giving

$$\int_B\left(|\operatorname{grad} p_{\mathrm{i}}|^2 - k_{\mathrm{i}}^2|p_{\mathrm{i}}|^2\right)\frac{dV}{\rho_{\mathrm{i}}} = \int_S\frac{\overline{p_{\mathrm{i}}}}{\rho_{\mathrm{i}}}\,\frac{\partial p_{\mathrm{i}}}{\partial n}\,ds,$$

where we have used (2.3). The imaginary part of this equation gives

$$\int_S\left(p_{\mathrm{i}}\,\frac{\partial\overline{p_{\mathrm{i}}}}{\partial n} - \overline{p_{\mathrm{i}}}\,\frac{\partial p_{\mathrm{i}}}{\partial n}\right)\frac{ds}{\rho_{\mathrm{i}}} = \int_B\left(k_{\mathrm{i}}^2 - \overline{k_{\mathrm{i}}^2}\right)|p_{\mathrm{i}}|^2\,\frac{dV}{\rho_{\mathrm{i}}}.$$

Then, making use of the transmission conditions (2.4), (2.10) gives

$$k_{\mathrm{e}}\lim_{R\to\infty}\int_{S_R}|p_{\mathrm{e}}|^2\,ds + 2\int_B\operatorname{Re}(k_{\mathrm{i}})\operatorname{Im}(k_{\mathrm{i}})\,|p_{\mathrm{i}}|^2\,\frac{\rho_{\mathrm{e}}}{\rho_{\mathrm{i}}}\,dV = 0.$$

Rellich's lemma [11, Lem. 3.11] then implies that $p_\mathrm{e} \equiv 0$ in B_e, provided that

$$\mathrm{Re}\,(k_\mathrm{i})\,\mathrm{Im}\,(k_\mathrm{i}) \geq 0.$$

The transmission conditions then imply that $p_\mathrm{i} = 0$ and $\partial p_\mathrm{i}/\partial n = 0$ on S. Thus, p_i solves the Cauchy problem for the elliptic partial differential equation (2.3), in which the (positive) coefficients ρ_i^{-1} and $k_\mathrm{i}^2/\rho_\mathrm{i}$ are C^2 and C^1, respectively. It follows that $p_\mathrm{i} \equiv 0$ in B, as required. Here, we have used a unique continuation result due to Müller [30] and Aronszajn [2]; see [21] for a brief review.

3. An integral representation and an integro-differential equation. We shall consider integral representations obtained using the free-space Green's function for the exterior fluid,

$$G_\mathrm{e}(P,Q) = -\exp(ik_\mathrm{e}R)/(4\pi R), \tag{3.1}$$

where P and Q are typical points in three-dimensional space and $R = |\boldsymbol{r}_P - \boldsymbol{r}_Q|$ is the distance between P and Q.

An application of Green's second theorem in B_e to p_sc and G_e gives

$$\int_S \left\{ G_\mathrm{e}(P,q)\,\frac{\partial p_\mathrm{sc}}{\partial n_q} - p_\mathrm{sc}(q)\,\frac{\partial}{\partial n_q} G_\mathrm{e}(P,q) \right\} ds_q = \begin{cases} p_\mathrm{sc}(P), & P \in B_\mathrm{e}, \\ 0, & P \in B. \end{cases}$$

A similar application in B to p_inc and G_e gives

$$\int_S \left\{ G_\mathrm{e}(P,q)\,\frac{\partial p_\mathrm{inc}}{\partial n_q} - p_\mathrm{inc}(q)\,\frac{\partial}{\partial n_q} G_\mathrm{e}(P,q) \right\} ds_q = \begin{cases} 0, & P \in B_\mathrm{e}, \\ -p_\mathrm{inc}(P), & P \in B. \end{cases}$$

Adding these gives

$$\int_S \left\{ G_\mathrm{e}(P,q)\,\frac{\rho_\mathrm{e}}{\rho_\mathrm{i}}\frac{\partial p_\mathrm{i}}{\partial n_q} - p_\mathrm{i}(q)\,\frac{\partial}{\partial n_q} G_\mathrm{e}(P,q) \right\} ds_q = \begin{cases} p_\mathrm{sc}(P), & P \in B_\mathrm{e}, \\ -p_\mathrm{inc}(P), & P \in B, \end{cases} \tag{3.2}$$

where we have used (2.1) and the transmission conditions (2.4). The first of these gives an integral representation for $p_\mathrm{sc}(P)$ in terms of a distribution of sources and dipoles over S. Such representations are common in scattering theory. However, it is not very convenient here because we do not know p_i or $\partial p_\mathrm{i}/\partial n$ on S.

To make progress, recall Green's first theorem,

$$\int_B \left\{ \phi\,\nabla^2\psi + (\mathrm{grad}\,\phi)\cdot(\mathrm{grad}\,\psi) \right\} dV = \int_S \phi\,\frac{\partial\psi}{\partial n}\,ds,$$

where ϕ and ψ are sufficiently smooth in B. Choose $\phi(Q) = p_\mathrm{i}(Q)$ and $\psi(Q) = G_\mathrm{e}(P,Q)$ with $P \in B_\mathrm{e}$, whence

$$\begin{aligned} &\int_S p_\mathrm{i}(q)\,\frac{\partial}{\partial n_q} G_\mathrm{e}(P,q)\,ds_q \\ &\qquad = \int_B \left\{ (\mathrm{grad}\,p_\mathrm{i})\cdot(\mathrm{grad}_Q\,G_\mathrm{e}) - k_\mathrm{e}^2 p_\mathrm{i}(Q)\,G_\mathrm{e}(P,Q) \right\} dV_Q, \end{aligned} \tag{3.3}$$

where we have used $(\nabla^2 + k_\mathrm{e}^2)G_\mathrm{e}(P,Q) = 0$ for $P \neq Q$. Similarly, if we choose $\psi(Q) = p_\mathrm{i}(Q)$ and $\phi(Q) = (\rho_\mathrm{e}/\rho_\mathrm{i})G_\mathrm{e}(P,Q)$ with $P \in B_\mathrm{e}$, we obtain

$$\begin{aligned} &\int_S \frac{\rho_\mathrm{e}}{\rho_\mathrm{i}}\,\frac{\partial p_\mathrm{i}}{\partial n_q}\,G_\mathrm{e}(P,q)\,ds_q \\ &\qquad = \int_B \frac{\rho_\mathrm{e}}{\rho_\mathrm{i}} \left\{ (\mathrm{grad}\,p_\mathrm{i})\cdot(\mathrm{grad}_Q\,G_\mathrm{e}) - k_\mathrm{e}^2\,N(Q)\,p_\mathrm{i}(Q)\,G_\mathrm{e}(P,Q) \right\} dV_Q, \end{aligned} \tag{3.4}$$

where we have used (2.5). Subtracting (3.3) from (3.4) gives the left-hand side of (3.2) for $P \in B_{\rm e}$, whence $p_{\rm sc}(P) = (\mathcal{L}p_{\rm i})(P)$ for $P \in B_{\rm e}$, where

$$(\mathcal{L}v)(P) = \int_B \big\{(\alpha(Q)-1)\,(\operatorname{grad} v)\cdot(\operatorname{grad}_Q G_{\rm e}(P,Q)) + (1-N\alpha)\,k_{\rm e}^2\,v(Q)\,G_{\rm e}(P,Q)\big\}\,dV_Q \tag{3.5}$$

and

$$\alpha(P) = \rho_{\rm e}/\rho_{\rm i}(P).$$

We repeat the calculations for $P \in B$, having excised a small sphere centered at P. The singularity at $P = Q$ has no effect on (3.4) but it causes $-p_{\rm i}(P)$ to be added to the left-hand side of (3.3). Then, (3.2) for $P \in B$ becomes

$$-p_{\rm inc}(P) = -p_{\rm i}(P) + (\mathcal{L}p_{\rm i})(P), \quad P \in B.$$

At this stage, we have proved one half of the following theorem.

THEOREM 3.1. *Let the pair $\{p_{\rm e}, p_{\rm i}\}$ solve the Scattering Problem. Then $v(P) \equiv p_{\rm i}(P) \in C^2(B)$ solves*

$$v(P) - (\mathcal{L}v)(P) = p_{\rm inc}(P), \quad P \in B, \tag{3.6}$$

where $\mathcal{L}v$ is defined by (3.5). *Conversely, let v solve* (3.6). *Then the pair $\{p_{\rm e}, p_{\rm i}\}$, defined by*

$$p_{\rm e}(P) = p_{\rm inc}(P) + (\mathcal{L}v)(P) \quad \textit{for } P \in B_{\rm e} \tag{3.7}$$

and $p_{\rm i}(P) = v(P)$ for $P \in B$ solves the Scattering Problem.

Proof. We have to prove the second half of the theorem. From (3.7), we define $p_{\rm sc}$ using

$$p_{\rm sc}(P) = (\mathcal{L}v)(P), \quad P \in B_{\rm e}; \tag{3.8}$$

evidently, $p_{\rm sc}$ satisfies (2.2) and the Sommerfeld radiation condition, as it inherits these properties from $G_{\rm e}$.

Next, let us show that $p_{\rm i} \equiv v$ satisfies (2.3). As $p_{\rm inc}$ satisfies (2.2) in B, (3.6) gives

$$(\nabla^2 + k_{\rm e}^2)(v - \mathcal{L}v) = 0 \quad \text{in } B. \tag{3.9}$$

Now, from the definition (3.5), we have

$$(\mathcal{L}v)(P) = -\frac{\partial}{\partial x_j^P}\int_B (\alpha-1)\,\frac{\partial v}{\partial x_j^Q}\,G_{\rm e}(P,Q)\,dV_Q + k_{\rm e}^2\int_B (1-N\alpha)\,v(Q)\,G_{\rm e}(P,Q)\,dV_Q, \tag{3.10}$$

where $P \equiv (x_1^P, x_2^P, x_3^P)$, $Q \equiv (x_1^Q, x_2^Q, x_3^Q)$, and summation over j is implied. The second integral in (3.10) is an acoustic volume potential, and the first term is the sum of three first derivatives of volume potentials. The properties of volume potentials are

summarized in Appendix B. In particular, the result of applying $(\nabla^2 + k_e^2)$ is given by (B.1), so that we obtain

$$(\nabla^2 + k_e^2)(\mathcal{L}v) = -\frac{\partial}{\partial x_j^P}\left\{(\alpha - 1)\,\frac{\partial v}{\partial x_j^P}\right\} + k_e^2\,(1 - N\alpha)\,v(P)$$
$$= (\nabla^2 + k_e^2)v - \rho_e \operatorname{div}\left(\rho_i^{-1}\operatorname{grad} v\right) - k_i^2(\rho_e/\rho_i)v, \quad P \in B,$$

whence (3.9) gives the desired result.

To verify the transmission conditions, observe that (3.6) gives

$$p_i(P) - p_{inc}(P) = (\mathcal{L}v)(P), \quad P \in B. \tag{3.11}$$

However, as $\mathcal{L}v$ comprises a volume potential and first derivatives of volume potentials, it follows that $(\mathcal{L}v)(P)$ is continuous as P crosses S (see Appendix B). Thus, (3.8) and (3.11) show that the first transmission condition, $(2.4)_1$, is satisfied.

For the second transmission condition, we take the normal derivative of (3.8) and (3.11) to give

$$\frac{\partial}{\partial n}\left\{p_{sc} - (p_i - p_{inc})\right\} = \left[\frac{\partial}{\partial n}\,\mathcal{L}v\right] \quad \text{on } S, \tag{3.12}$$

where $[f]$ is the discontinuity in f across S, defined by

$$[f(p)] = \lim_{P_e \to p} f(P_e) - \lim_{P \to p} f(P), \quad P_e \in B_e, \quad P \in B, \quad p \in S. \tag{3.13}$$

It is shown in Appendix B that

$$\left[\frac{\partial}{\partial n}\,\mathcal{L}v\right] = \left(\frac{\rho_e}{\rho_i} - 1\right)\frac{\partial v}{\partial n}, \tag{3.14}$$

and then (3.12) and $v \equiv p_i$ imply that $(2.4)_2$ is satisfied. This completes the proof of Theorem 3.1. □

4. Discussion of the integro-differential equation (3.6).

4.1. Solvability. We have seen that solving the Scattering Problem is equivalent to solving (3.6), which is an integro-differential equation for $v(P)$, $P \in B$. This equation is uniquely solvable. To see this, we appeal to Werner's existence result [43]: the solution $\{p_e, p_i\}$ of the Scattering Problem exists and, by the first half of Theorem 3.1, p_i solves (3.6). For uniqueness, suppose that $v_0(P)$ solves (3.6) with $p_{inc} \equiv 0$. Construct $p_e = (\mathcal{L}v_0)(P)$ for $P \in B_e$ and $p_i = v_0(P)$ for $P \in B$. By the second half of Theorem 3.1, these fields solve the homogeneous Scattering Problem; they must vanish identically by the uniqueness theorem for the Scattering Problem (section 2.1). In particular, $v_0(P) \equiv 0$ for $P \in B$, as required.

We note that an integro-differential equation equivalent to (3.6) was derived by Gerjuoy and Saxon [15] in 1954. In fact, they derived a coupled system, involving the pressure and the velocity, which they regarded as preferable to a single equation for the pressure as they were motivated by a desire to obtain variational principles.

4.2. The Lippmann–Schwinger equation. As a special case of the Scattering Problem, suppose that $\rho_i(Q) = \rho_e$ for all $Q \in B$, so that the density of the scatterer is

the same as that of the surrounding homogeneous fluid. Then, the integro-differential equation (3.6) reduces to the integral equation

$$v(P) - k_{\mathrm{e}}^2 \int_B \{1 - N(Q)\} v(Q)\, G_{\mathrm{e}}(P,Q)\, dV_Q = p_{\mathrm{inc}}(P), \quad P \in B, \tag{4.1}$$

where $N(Q) = (k_{\mathrm{i}}/k_{\mathrm{e}})^2 = \{c_{\mathrm{e}}/c_{\mathrm{i}}(Q)\}^2$. This integral equation and its numerical treatment have been discussed in [10, 5, 46, 8] and [9, sect. 8.9.1]

Let us define $N(P) = 1$ for $P \in B_{\mathrm{e}}$ and

$$w(P) = \begin{cases} p_{\mathrm{e}}(P), & P \in B_{\mathrm{e}}, \\ p_{\mathrm{i}}(P), & P \in B. \end{cases}$$

Then, we can combine (4.1) with the representation (3.7) to obtain

$$w(P) - k_{\mathrm{e}}^2 \int \{1 - N(Q)\} w(Q)\, G_{\mathrm{e}}(P,Q)\, dV_Q = p_{\mathrm{inc}}(P) \tag{4.2}$$

for all $P \in B \cup B_{\mathrm{e}}$, where the integration is over all Q. We recognize this equation as the *Lippmann–Schwinger equation* [24]; see, for example, [1], [12, sect. 8.2] [32, sect. 10.3], and [35, Thm. 9.4]. Notice that our derivation shows that the Lippmann–Schwinger equation is valid even when $N(Q)$ is discontinuous as Q crosses S. This fact is implicit in [34] and explicit in [44].

4.3. An alternative equation. As we know that $v \equiv p_{\mathrm{i}}$ solves (2.5) in B, we can use this fact to rewrite the expression for $\mathcal{L}v$. Thus

$$(\alpha - 1)\, (\operatorname{grad} v) \cdot (\operatorname{grad}_Q G_{\mathrm{e}}) = \operatorname{div}\{(\alpha - 1)\, G_{\mathrm{e}} \operatorname{grad} v\} - G_{\mathrm{e}} \operatorname{div}\{(\alpha - 1) \operatorname{grad} v\}$$

and

$$\begin{aligned} \operatorname{div}\{(\alpha - 1) \operatorname{grad} v\} &= (\alpha - 1)\, \nabla^2 v + \rho_{\mathrm{e}} \left(\operatorname{grad} \rho_{\mathrm{i}}^{-1}\right) \cdot \operatorname{grad} v \\ &= (\alpha - 1) \left\{\nabla^2 v + \rho_{\mathrm{i}} \left(\operatorname{grad} \rho_{\mathrm{i}}^{-1}\right) \cdot \operatorname{grad} v\right\} + \rho_{\mathrm{i}} \left(\operatorname{grad} \rho_{\mathrm{i}}^{-1}\right) \cdot \operatorname{grad} v \\ &= (1 - \alpha)\, k_{\mathrm{e}}^2 N v - \rho_{\mathrm{i}}^{-1} (\operatorname{grad} \rho_{\mathrm{i}}) \cdot \operatorname{grad} v. \end{aligned}$$

Hence, substituting in (3.5), we obtain

$$(\mathcal{L}v)(P) = \int_B G_{\mathrm{e}}(P,Q)\, (Vv)(Q)\, dV_Q + (\mathcal{L}_E v)(P),$$

where Vv is defined by (2.6) and

$$\begin{aligned} (\mathcal{L}_E v)(P) &= \int_B \operatorname{div}\{(\alpha(Q) - 1)\, G_{\mathrm{e}} \operatorname{grad} v\}\, dV_Q \\ &= \int_S \{\alpha(q) - 1\}\; G_{\mathrm{e}}(P,q)\, \frac{\partial v}{\partial n}\, ds_q, \end{aligned} \tag{4.3}$$

by the divergence theorem. Thus, the Scattering Problem can be reduced to solving

$$p_{\mathrm{i}}(P) = p_{\mathrm{inc}}(P) + \int_B G_{\mathrm{e}}(P,Q)\, (Vp_{\mathrm{i}})(Q)\, dV_Q + p_E(P), \quad P \in B, \tag{4.4}$$

where

$$p_E(P) = (\mathcal{L}_E p_{\mathrm{i}})\,(P) = \int_S \left(\frac{\partial p_{\mathrm{e}}}{\partial n} - \frac{\partial p_{\mathrm{i}}}{\partial n}\right) G_{\mathrm{e}}(P,q)\, ds_q$$

and we have used $(2.4)_2$ in (4.3).

When both $\rho_{\rm i}$ and N are constants, (4.4) reduces to an equation obtained previously by Ramm [37]. However, in this situation, the scatterer is homogeneous and the problem can be reduced to boundary integral equations over S; see [20].

If we had attempted to solve the Scattering Problem using the formal method described in section 1.1, we would have obtained precisely (4.4) but with $p_E(P) \equiv 0$. In general, this extra term is not zero, and its magnitude is difficult to estimate. Observe that, from (4.3), p_E does vanish if $\rho_{\rm i}(q) = \rho_{\rm e}$ for all $q \in S$, which means that the density is continuous across S. Otherwise, the single-layer potential $p_E(P)$ should be retained.

4.4. Electromagnetic waves. For Maxwell's equations, we can encounter exactly the same difficulty as in acoustics. Thus, in an inhomogeneous medium, the electric field $\boldsymbol{E}$ satisfies

$$\mu \operatorname{curl} \left\{\mu^{-1} \operatorname{curl} \boldsymbol{E}\right\} - k^2 \boldsymbol{E} = \boldsymbol{0},$$

where $\mu(\boldsymbol{r})$ is the magnetic permeability, $k(\boldsymbol{r}) = \omega\sqrt{\mu\varepsilon}$, and $\varepsilon(\boldsymbol{r})$ is the electric permittivity. Moreover, the transmission conditions across an interface S are that $\boldsymbol{n} \times \boldsymbol{E}$ and $\boldsymbol{n} \times (\mu^{-1} \operatorname{curl} \boldsymbol{E})$ should both be continuous. (See, for example, [9, sect. 8.9.2]; for existence and uniqueness theorems, see [31].) We can then mimic the derivations in section 3 to show that discontinuities in μ across S will lead to an extra term similar to p_E in (4.4).

Specifically, we find the following electromagnetic analogue of (3.6):

$$\left\{1 - \frac{1}{3}\left(1 - \frac{\varepsilon_{\rm i}(P)}{\varepsilon_{\rm e}}\right)\right\} \boldsymbol{E}_{\rm i}(P) - \int_B \boldsymbol{W}(P,Q)\, dV_Q = \boldsymbol{E}_{\rm inc}(P), \quad P \in B. \tag{4.5}$$

Here, $\boldsymbol{E}_{\rm i}$ is the field in B, $\boldsymbol{E}_{\rm inc}$ is the incident field, $\varepsilon_{\rm e}$ is the (constant) electric permittivity in $B_{\rm e}$, and $\varepsilon_{\rm i}$ is the electric permittivity in B. The field $\boldsymbol{W}$ is defined by

$$\begin{aligned}\boldsymbol{W}(P,Q) = {} & \left(1 - \frac{\mu_{\rm e}}{\mu_{\rm i}}\right) (\operatorname{grad}_Q G_{\rm e}) \times \operatorname{curl} \boldsymbol{E}_{\rm i}(Q) \\ & + \left(1 - \frac{\varepsilon_{\rm i}}{\varepsilon_{\rm e}}\right) \left\{k_{\rm e}^2 G_{\rm e} \boldsymbol{E}_{\rm i} - \operatorname{grad}_P \left(\boldsymbol{E}_{\rm i} \cdot \operatorname{grad}_Q G_{\rm e}\right)\right\},\end{aligned}$$

where $\mu_{\rm e}$ is the (constant) magnetic permeability in $B_{\rm e}$, $\mu_{\rm i}$ is the magnetic permeability in B, and $k_{\rm e} = \omega\sqrt{\mu_{\rm e}\varepsilon_{\rm e}}$. The integral in (4.5) is to be interpreted in the Cauchy principal-value sense with a spherical exclusion volume. In the special case that $\mu_{\rm i}(Q) \equiv \mu_{\rm e}$, (4.5) reduces to eqn. (2.1.41) in [40].

The electromagnetic analogue of (4.4) is

$$\boldsymbol{E}_{\rm i}(P) = \boldsymbol{E}_{\rm inc}(P) + \int_B G_{\rm e}(P,Q)\, \boldsymbol{V}(Q)\, dV_Q + \int_S \boldsymbol{F}(P,q)\, ds_q, \tag{4.6}$$

where

$$\begin{aligned}\boldsymbol{V} &= (k_{\rm e}^2 - k_{\rm i}^2)\boldsymbol{E}_{\rm i} - (\mu_{\rm i}^{-1} \operatorname{grad} \mu_{\rm i}) \times \operatorname{curl} \boldsymbol{E}_{\rm i} + \operatorname{grad} \operatorname{div} \boldsymbol{E}_{\rm i}, \\ \boldsymbol{F} &= \left(1 - \frac{\varepsilon_{\rm i}}{\varepsilon_{\rm e}}\right) (\boldsymbol{n} \cdot \boldsymbol{E}_{\rm i}) \operatorname{grad}_q G_{\rm e} \\ &\quad + \left\{\left(1 - \frac{\mu_{\rm e}}{\mu_{\rm i}}\right) (\boldsymbol{n} \times \operatorname{curl} \boldsymbol{E}_{\rm i}) + \boldsymbol{n}(\varepsilon_{\rm i}^{-1} \operatorname{grad} \varepsilon_{\rm i}) \cdot \boldsymbol{E}_{\rm i}\right\} G_{\rm e},\end{aligned}$$

and $k_{\rm i} = \omega\sqrt{\mu_{\rm i}\varepsilon_{\rm i}}$. Notice that $\boldsymbol{F}$ vanishes if $\varepsilon_{\rm i}(q) = \varepsilon_{\rm e}$, $\mu_{\rm i}(q) = \mu_{\rm e}$ and $\varepsilon_{\rm i}(P)$ is constant near S. Also, in the special case that $\mu_{\rm i}(Q) \equiv \mu_{\rm e}$, (4.6) reduces to eqn. (4.18) in [36].

4.5. Elastic waves. We can also consider analogous problems for elastic waves: scattering of elastic waves in a homogeneous solid by an inhomogeneous (and anisotropic) inclusion. It turns out that the formal method of section 1.1 (described in detail in [33, 17]) and the method of section 3 yield exactly the same equation for the displacement within the inclusion, $\boldsymbol{u}$. This is because the "extra term" analogous to p_E involves the discontinuity in the traction vector across the interface: this is zero for a perfect (welded) interface. (For imperfect interfaces [27], a nonzero contribution is obtained.) Some applications of the volume equation for $\boldsymbol{u}$ can be found in [38, 6, 7]. A polarization approach (leading to a coupled system) has been developed by Willis [45]. Long-wave approximations can be found in [45, 38].

Appendix A. Werner's solution. Werner [43] proved an existence theorem for a problem that is very similar to our Scattering Problem: he considered inhomogeneous forms of (2.2) and (2.3) but supposed that $p_{\rm inc} \equiv 0$. His method leads to the following integral representations:

$$p_{\rm sc}(P) = -\int_S \left\{ \alpha(q)\,\mu(q)\,G_{\rm e}(P,q) - \nu(q)\,\frac{\partial}{\partial n_q} G_{\rm e}(P,q) \right\} ds_q, \quad P \in B_{\rm e},$$

$$p_{\rm i}(P) = \int_S \left\{ \mu\,G_{\rm e}(P,q) - \nu\,\frac{\partial}{\partial n_q} G_{\rm e}(P,q) \right\} ds_q + \int_B \varphi(Q)\,G_{\rm e}(P,Q)\,dV_Q, \quad P \in B.$$

The two surface densities, $\mu(q)$ and $\nu(q)$, and the volume density, $\varphi(Q)$, satisfy the following system of integral equations:

$$\nu(p) + \int_S \mu(q)\,\{1-\alpha(q)\}\,G_{\rm e}(p,q)\,ds_q + \int_B \varphi(Q)\,G_{\rm e}(p,Q)\,dV_Q = -p_{\rm inc}, \tag{A.1}$$

$$\frac{1+\alpha}{2}\mu + \int_S \mu(1-\alpha)\frac{\partial}{\partial n_p} G_{\rm e}(p,q)\,ds_q + \int_B \varphi \frac{\partial}{\partial n_p} G_{\rm e}(p,Q)\,dV_Q = -\frac{\partial p_{\rm inc}}{\partial n_p}, \tag{A.2}$$

$$\varphi + \int_S V_P \left\{ \mu\,G_{\rm e}(P,q) - \nu\,\frac{\partial G_{\rm e}}{\partial n_q} \right\} ds_q - \int_B \varphi\,(V_P G_{\rm e}(P,Q))\,dV_Q = 0. \tag{A.3}$$

Equations (A.1) and (A.2) hold for $p \in S$, whereas (A.3) holds for $P \in B$. V_P denotes the operator V (defined by (2.6)) applied with respect to P.

Werner's proof [43] can be adapted to show that the system (A.1)–(A.3) is uniquely solvable.

Appendix B. Volume potentials. Define a *volume potential* $W(P)$ by

$$W(P) = \int_B \varphi(Q)\,G_{\rm e}(P,Q)\,dV_Q,$$

where $G_{\rm e}(P,Q) = -\exp(ik_{\rm e}R)/(4\pi R)$. The properties of such potentials are similar to those of *Newtonian potentials* for which $k_{\rm e} = 0$: thus, define

$$W_0(P) = -\frac{1}{4\pi}\int_B \frac{\varphi(Q)}{R}\,dV_Q.$$

From [12, sect. 8.2], we have

$$(\nabla^2 + k_{\rm e}^2)W = \begin{cases} 0, & P \in B_{\rm e}, \\ \varphi(P), & P \in B, \end{cases} \tag{B.1}$$

where $B_{\rm e}$ is the region exterior to B. Also, if φ is piecewise continuous, then $W(P)$ and its first partial derivatives are continuous everywhere in three-dimensional space;

see, for example, [19, Chapter VI, sect. 3], [14, Chapter IV, sect. 1.2], [41, sect. 3.9], [12, Thm. 8.1], and [16, sect. 4.2].

We also require the behavior of the second derivatives of W near the boundary of B, S. As Kellogg remarks [19, p. 156], "in general, the derivatives of second order will not exist. It is clear that they cannot all be continuous, for as we pass from an exterior to an interior point through the boundary where φ is not 0, $\nabla^2 W_0$ experiences a break of φ." This discontinuous behavior is described in [25, p. 175] and [26, p. 125]:

$$\left[\frac{\partial^2}{\partial n\, \partial x_i^P} W_0(P)\right] = -\varphi(p)\, n_i(p), \quad p \in S.$$

The same formula holds for W because the difference, $W - W_0$, is less singular. Finally, the result (3.14) is obtained from (3.10), using $\varphi(Q) = (1-\alpha)\partial v/\partial x_i^Q$. Note that the second term in (3.10) is a volume potential: it does not contribute as its first derivatives are continuous across S.

Acknowledgments. I am grateful for the constructive comments provided by two anonymous referees. I also thank Prof. D. Tataru for his help with the unique continuation aspect of section 2.1.

ON LOCAL ISOTROPY IN STRATIFIED HOMOGENEOUS TURBULENCE*

B. A. PETTERSSON REIF† AND Ø. ANDREASSEN†

Abstract. This paper examines the postulate of local isotropy in stratified homogeneous turbulence from a theoretical point of view. The study is based on a priori analysis of the evolution equations governing single-point turbulence statistics that are formally consistent with the Navier–Stokes equations. The Boussinesq approximation has been utilized to account for the effect of buoyancy—a simplifying assumption which constitutes an excellent approximation for the case considered here. The study concludes that the hypothesis of local isotropy is formally inconsistent with the Navier–Stokes equations in homogeneous stratified turbulence. An estimate is provided that suggests that local isotropy may constitute only a physically justifiable approximation in the limit of a clear-cut separation between the time scales associated with the imposed buoyancy and the turbulent eddy turnover time scale. This is unlikely to happen in most flows, at least those not too far from equilibrium. The results also suggest that the dynamical dependence of the small-scale turbulence on large-scale anisotropies associated with imposed density stratification is significantly stronger than that caused by an imposed mean straining.

Key words. local isotropy, homogeneous turbulence, single-point correlation, density stratification, shear turbulence

DOI. 10.1137/S0036139903421559

1. Introduction.

It is well established that the imposition of density stratification and mean straining significantly promotes anisotropy on the energetic large-scale turbulence motion. It is frequently also argued that the small-scale motion would remain virtually unaffected by the large-scale anisotropy at sufficiently high Reynolds number (Re). This view inherently assumes that any direct effects of the large-scale motion on the smallest scales would be negligible at high enough Re and that large-scale anisotropies would not mediate across the spectral gap fast enough to overcome the nonlinear scrambling of the cascade process. Small-scale turbulence is therefore expected to be statistically independent of the large-scale motion at sufficiently high Re. This is essentially the postulate of local isotropy put forward by Kolmogorov [6] more than 70 years ago, a postulate that has been enormously influential in turbulence research.

The conjecture of locally isotropic turbulence is sometimes also based on the notion of a clear-cut separation of characteristic time scales; since the limiting behavior of the small-to-large-scale time scale ratio asymptotes to $\tau/T \sim Re^{-1/2} \to 0$ as $Re \to \infty$, it is believed that small-scale turbulence would have sufficiently long time to interact with itself and to establish a state of directional independence, or local isotropy.

The terminology "local isotropy" alludes to statistical isotropy of the smallest, dissipative scales of motion, i.e., scales much smaller than the energetic large-scale motion. Mathematically, "isotropy" implies that any statistical measure must display invariance to arbitrary reflections and rotations. Local isotropy is, however, not only

*Received by the editors January 21, 2003; accepted for publication (in revised form) April 29, 2003; published electronically November 19, 2003.

†Norwegian Defence Research Establishment (FFI), NO-2027 Kjeller, Norway (bre@ffi.no, oya@ffi.no).

a concept of theoretical interest. It is in fact widely used, for instance, by experimentalists to infer the rate of viscous dissipation of turbulent kinetic energy (formally defined as $\varepsilon \equiv 2\nu s'_{ij}s'_{ij}$) by only conducting measurements of one of the six independent components of the fluctuating rate-of-strain tensor s'_{ij} (defined in (2.8)). In particular, by imposing the assumption of local isotropy, the number of derivative correlations that must be determined can be reduced from twelve to just a single one, e.g., $\varepsilon \sim \overline{(\partial_1 u_1)^2}$; see, e.g., [5].

There exist several hundred articles and papers on the concept of locally isotropic turbulence. Among the pioneering ones are those due to Kolmogorov [6] and Obukhov [10], to mention only a few. Monin and Yaglom [8] provide an extensive review on the early developments of the topic, whereas more recent reviews are provided by Nelkin [9], Frisch [3], Sreenivasan and Antonia [14], and Warhaft [20]. Among the many studies there are a growing number of theoretical, experimental, and numerical investigations that suggest that the concept of local isotropy is somewhat dubious. Townsend [17] and Uberoi [18] were probably among the first to suggest that there exists a direct effect of large-scale anisotropy on the dissipative scales of motion, in addition to the indirect influence through the cascading process. This view was supported by, e.g., Durbin and Speziale [2] who demonstrated that, as a formally consistent consequence of the Navier–Stokes equations, there must indeed exist a direct effect of mean straining on the dissipative scales. They concluded that local isotropy is a physically implausible argument in turbulence affected by mean straining.

Brasseur and Wei [1] and Yeung, Brasseur, and Wang [22] conducted numerical studies of the triadic interactions in forced turbulence. These studies demonstrated that triadic interactions between widely disparate scales directly modified the structure of the smallest scales in accordance with the structure of the large energetic ones. Experimental results in uniform turbulent shear flow [12] also imply a direct coupling between the large- and small-scales in strained turbulence. They further concluded, fully in line with Durbin and Speziale [2], that the hypothesis of local isotropy in isothermal turbulent shear flows seems untenable even in the limit of infinite Re.

Sreenivasan [13] reviewed experimental work on local isotropy of passive scalar fields and suggested that local isotropy is not a natural concept for scalar fields in shear flows, except perhaps for such extreme Re that are of no practical use on earth. Van Atta [19] analyzed experimental data in stably stratified turbulence and noted that the effects are surprisingly rapid, destroying the directional independence of the smallest scales as soon as buoyancy forces become dynamically important. This was essentially confirmed by the enormous numerical simulations of Werne and Fritts [21] who studied a stratified shear layer. They found that turbulence affected by mean straining tends to develop a state of local streamwise axisymmetry, as opposed to local isotropy. The concept of locally axisymmetric turbulence in strained homogeneous flows has been theoretically and experimentally considered by George and Hussain [5] who concluded that a theory of local axisymmetry provides more credibility to the numerous measurements that have failed to confirm local isotropy. These findings, along with many more not mentioned here, add to the body of literature that sheds new light on the concept of locally isotropic turbulence.

The present study examines local isotropy from a theoretical point of view. It extends the approach suggested in [2] to homogeneous flows affected by both density stratification and mean straining. The methodology is based on an examination of the dynamical equations governing single-point turbulence correlations that are characteristic of small-scale turbulence; these equations are formally consistent with the

Navier–Stokes equations. The objective of the study is to provide insight into whether or not the hypothesis of local isotropy is a formally consistent concept in stratified flows, and if not, to provide also an estimate of under what circumstances it would constitute a physically plausible approximation. The practical implications are related to the development of semiempirical models intended to describe the statistical coupling between large- and small-scale turbulence; a development which is crucial for improved turbulence model formulations.

2. The evolution of single-point turbulence statistics. The present analysis is based on the incompressible Navier–Stokes equations in the limit of homogeneous turbulence and to cases where the Boussinesq approximation constitutes a reasonable assumption. The latter assumption is not believed to be a severe limitation in the present context; the Boussinesq approximation represents a first-order perturbation of the fluid density. In cases where this approximation fails, an even stronger effect of buoyancy is expected.

Single-point turbulence statistics allude to correlations of fluctuating quantities evaluated at the same position in space and time. Dynamical equations governing these statistics can be rigorously derived from the conservation equations for mass, momentum (Navier–Stokes), and energy:

$$\partial_i \tilde{u}_i = 0, \tag{2.1}$$

$$\partial_t \tilde{u}_i + \tilde{u}_k \partial_k \tilde{u}_i = -\partial_i \tilde{p} + \nu \nabla^2 \tilde{u}_i + \frac{\rho}{\rho_0} g_i, \tag{2.2}$$

$$\partial_t \tilde{\theta} + \tilde{u}_k \partial_k \tilde{\theta} = \kappa \nabla^2 \tilde{\theta} + 2 \frac{\nu}{c_v} \tilde{s}_{ij} \tilde{s}_{ij}. \tag{2.3}$$

Repeated indices imply summation, e.g., $\tilde{u}_k \partial_k \tilde{\theta} = \tilde{u}_1 \partial_1 \tilde{\theta} + \tilde{u}_2 \partial_2 \tilde{\theta} + \tilde{u}_3 \partial_3 \tilde{\theta}$. The superscript $\tilde{}$ denotes instantaneous quantities, the subscript $_0$ denotes a constant reference state, and $\tilde{s}_{ij} \equiv \frac{1}{2}(\partial_i \tilde{u}_j + \partial_j \tilde{u}_i)$ is the instantaneous rate-of-strain tensor. Spatial and temporal differentiation are denoted $\partial_m \equiv \partial/\partial x_m$ and $\partial_t \equiv \partial/\partial t$, respectively, and $\nabla^2 = \partial^2_{mm} \equiv \partial^2/(\partial x_m \partial x_m)$. Here, $\nu = \mu/\rho_0$ is the kinematic viscosity and $\kappa = \alpha/(\rho_0 c_v)$ the thermal diffusivity, where μ, α, and c_v denote the dynamic viscosity, thermal conductivity, and specific heat, respectively. $\mathbf{g}$ is the gravitational acceleration. According to the Boussinesq approximation, the density ratio ρ/ρ_0 in (2.2) varies according to

$$\frac{\rho}{\rho_0} = 1 - \beta(\tilde{\theta} - \Theta_0), \tag{2.4}$$

where $\beta \equiv [-\partial \log(\rho)/\partial\theta]_\Theta$ defines the thermal expansion coefficient at fixed mean temperature $\Theta(\mathbf{x}, t)$.

Equations governing fluctuating quantities can systematically be derived using the following procedure:

1. Decompose the instantaneous velocity, pressure, and temperature fields into mean and fluctuating parts, i.e., $\tilde{a}(\mathbf{x}, t) = A(\mathbf{x}, t) + a(\mathbf{x}, t)$.

2. Average to obtain the dynamical equation for the mean field; $A(\mathbf{x}, t) \equiv \overline{\tilde{a}(\mathbf{x}, t)}$, since $\overline{a(\mathbf{x}, t)} \equiv 0$ by definition.

3. Obtain the evolution equations for the fluctuating fields $a(\mathbf{x}, t)$ by subtracting 2 from 1.

Using this procedure, the evolution of the ith component of the fluctuating velocity $u_i(\mathbf{x},t)$ for an incompressible fluid can then be written as

$$\partial_t u_i + U_k\partial_k u_i + u_k\partial_k U_i + u_k\partial_k u_i + \overline{u_k\partial_k u_i} = -\frac{1}{\rho_0}\partial_i p + \nu\nabla^2 u_i - \beta g_i\theta, \tag{2.5}$$

$$\partial_i u_i = 0. \tag{2.6}$$

Here, $\mathbf{U}(\mathbf{x},t)$ denotes the mean velocity field and $\theta(\mathbf{x},t)$ is the fluctuating temperature field. The corresponding dynamical equation governing the evolution of the fluctuating temperature field $\theta(\mathbf{x},t)$ reads as follows:

$$\begin{aligned}\partial_t\theta + U_m\partial_m\theta = &-u_m\partial_m\Theta - u_m\partial_m\theta + \kappa\nabla^2\theta + 4\frac{\nu}{c_v}S_{ij}s'_{ij}\\ &+ 2\frac{\nu}{c_v}\left(s'_{ij}s'_{ij} - \overline{s'_{ij}s'_{ij}}\right).\end{aligned} \tag{2.7}$$

Here,

$$s'_{ij} = \frac{1}{2}(\partial_i u_j + \partial_j u_i) \tag{2.8}$$

and

$$S_{ij} = \frac{1}{2}(\partial_i U_j + \partial_j U_i) \tag{2.9}$$

denote the fluctuating and mean rate-of-strain tensor, respectively.

Transport equations governing suitable turbulence correlation can now be constructed from (2.5)–(2.7), and the results are formally consistent with the incompressible Navier–Stokes equations in the limit of the Boussinesq approximation. The assumption of homogeneity constitutes the only additional simplification and it implies that statistical measures of the flow must be translational invariant, i.e., single-point correlations are spatially constant.

The fluctuating pressure field $p(\mathbf{x},t)$ in (2.5) is the solution to a Poisson equation which can be obtained by taking the divergence of (2.5). Invoking the incompressibility and homogeneity constraints then gives

$$\nabla^2 p = -\rho_0\partial_i u_k\partial_k u_i - 2\rho_0\partial_k u_i\partial_i U_k - \rho_0\beta g_i\partial_i\theta, \tag{2.10}$$

which represents nonlocal effects on single-point statistics.[1] The fluctuating momentum and temperature equations, (2.5) and (2.7), can symbolically be written in operator form as $\mathcal{R}u_i = 0$ and $\mathcal{R}\theta = 0$, respectively. The transport equation governing the second-order moments, $\tau_{ij} = \overline{\tau'_{ij}} \equiv \overline{u_i u_j}$, is readily obtained by multiplying (2.5) by u_j, adding the result to itself with i and j interchanged, and finally averaging. This can symbolically be written as $\overline{u_j\mathcal{R}u_i + u_i\mathcal{R}u_j} = 0$. The result for homogeneous turbulence reads

$$\begin{aligned}d_t\tau_{ij} = &-\frac{1}{\rho_0}\left(\overline{u_j\partial_i p} + \overline{u_i\partial_j p}\right) - (\tau_{ik}\partial_k U_j + \tau_{jk}\partial_k U_i)\\ &- \varepsilon_{ij} - \beta\left(g_i\overline{u_j\theta} + g_j\overline{u_i\theta}\right),\end{aligned} \tag{2.11}$$

[1] It is interesting to note that the solution of (2.10) shows that the evolution of single-point moments implicitly depends on two-point correlations, i.e., correlations of velocity components evaluated at different position in space; see, e.g., Rotta [11] for more details.

where $d_t \equiv d/dt$ is the local time derivative. Recall that all spatial derivatives of turbulence correlations are zero in homogeneous turbulence. The second-order viscous dissipation rate tensor is given by

$$\varepsilon_{ij} = 2\nu\overline{\varepsilon'_{ij}} \equiv 2\nu\overline{\partial_m u_i \partial_m u_j}. \tag{2.12}$$

The evolution equation governing the turbulent kinetic energy, $k \equiv \frac{1}{2}\tau_{ii}$, is obtained by taking the trace of (2.11) and multiplying by $\frac{1}{2}$:

$$d_t k = -\tau_{ik}\partial_k U_i - \varepsilon - \frac{1}{2}\beta g_i \overline{u_i\theta}, \tag{2.13}$$

where $\varepsilon \equiv \frac{1}{2}\varepsilon_{ii}$ is the rate of turbulent energy dissipation.

By first writing (2.11) as $\overline{\mathcal{R}\tau'_{ij}} = 0$, the corresponding transport equation for the third-order moments, $\tau_{ijk} \equiv \overline{\tau'_{ijk}} \equiv \overline{u_i u_j u_k}$, can then be derived as $\overline{u_k \mathcal{R}\tau'_{ij} + \tau'_{ij}\mathcal{R}u_k} = 0$. The result can be written as

$$\begin{aligned} d_t\tau_{ijk} = &-\frac{1}{\rho_0}\left(\overline{\tau'_{ij}\partial_k p} + \overline{\tau'_{ik}\partial_j p} + \overline{\tau'_{jk}\partial_i p}\right) \\ &- \left(\tau_{mij}\partial_m U_k + \tau_{mik}\partial_m U_j + \tau_{mjk}\partial_m U_i\right) \\ &- \varepsilon_{ijk} - \beta\left(g_k\overline{\tau'_{ij}\theta} + g_j\overline{\tau'_{ik}\theta} + g_i\overline{\tau'_{jk}\theta}\right), \end{aligned} \tag{2.14}$$

where

$$\varepsilon_{ijk} \equiv 2\nu\left(\overline{u_i\varepsilon'_{jk}} + \overline{u_j\varepsilon'_{ik}} + \overline{u_k\varepsilon'_{ij}}\right) \tag{2.15}$$

denotes the third-order viscous dissipation rate tensor.

The equation governing the transport of turbulent heat flux ($\overline{u_i\theta}$) can readily be derived as $\overline{\theta\mathcal{R}u_i + u_i\mathcal{R}\theta} = 0$:

$$d_t\overline{u_i\theta} = -\frac{1}{\rho_0}\overline{\theta\partial_i p} + \mathcal{P}_{i\theta} - \varepsilon_{i\theta} - \beta g_i\overline{\theta^2} + 4\frac{\nu}{c_v}S_{kj}\overline{u_i s'_{kj}} + 2\frac{\nu}{c_v}\overline{u_i s'_{kj}s'_{kj}}, \tag{2.16}$$

where

$$\varepsilon_{i\theta} \equiv (\kappa + \nu)\,\overline{\partial_m\theta\partial_m u_i} \tag{2.17}$$

and

$$\mathcal{P}_{i\theta} = -\left(\overline{u_m\theta}\partial_m U_i + \tau_{mi}\partial_m\Theta\right) \tag{2.18}$$

represent the rate of dissipation and production of turbulent heat flux, respectively.

To this end the dynamical equations governing the turbulent heat flux ($\overline{u_i\theta}$) and second- and third-order velocity-moments (τ_{ij} and τ_{ijk}) have been derived. This rather limited choice of basic single-point correlations suffices to assess the validity of the local isotropy postulate in stratified turbulence and to provide an estimate of when this hypothesis may constitute a physically plausible approximation. It should be noted, however, that the above-mentioned correlations are characteristic for the large-scale energetic part of the turbulence spectrum. In order to study the dynamics

of the dissipative scales, on the other hand, correlations characteristic for these scales must be considered. In particular, the dynamical equations governing the dissipation rate tensors ε_{ij}, ε_{ijk}, and $\varepsilon_{i\theta}$ appear in (2.11), (2.14), and (2.16), respectively. These tensors comprise correlations between fluctuating gradients and characterize therefore the high wave-number part in spectral space or the small scales in physical space.

The transport equation for dissipation rate $\varepsilon_{i\theta}$ of turbulent heat flux can be derived as $(\kappa+\nu)\overline{\partial_m\theta\partial_m(\mathcal{R}u_i)}+(\kappa+\nu)\overline{\partial_m u_i\partial_m(\mathcal{R}\theta)}=0$, and the result can be written as

$$d_t\varepsilon_{i\theta} = -\varepsilon_{k\theta}\partial_k U_i - 2\mathcal{E}_{mk\theta i}\partial_m U_k + 4\frac{\nu}{c_v}S_{kj}\mathcal{J}_{ikj}$$

$$-\frac{1}{2}\left(1+Pr^{-1}\right)\varepsilon_{ik}\partial_k\Theta - \frac{1}{2}\beta\left(1+Pr\right)g_i\varepsilon_\theta + \mathcal{F}_{i\theta} \tag{2.19}$$

for homogeneous turbulence, where $Pr\equiv\nu/\kappa$ is the Prandtl number, $\mathcal{E}_{mk\theta i}=\overline{\partial_m\theta\partial_k u_i}$, and $\mathcal{J}_{ikj}=\overline{\partial_m u_i\partial_m s'_{kj}}$. The dissipation rate of temperature variance $\overline{\theta^2}$ is defined as

$$\varepsilon_\theta \equiv 2\kappa\overline{\partial_m\theta\partial_m\theta}, \tag{2.20}$$

whereas the last term in (2.19) is

$$\mathcal{F}_{i\theta} = -\frac{\kappa+\nu}{\rho_0}\overline{\partial_i\theta\nabla^2 p} + (\kappa+\nu)\left(\overline{u_n\partial_n u_i\nabla^2\theta}+\overline{u_n\partial_n\theta\nabla^2 u_i}\right)$$

$$+(\kappa+\nu)^2\,\overline{\nabla^2\theta\nabla^2 u_i} + 2\frac{\nu}{c_v}\overline{\partial_m u_i\partial_m(s'_{kj}s'_{kj})}. \tag{2.21}$$

The evolution equation for ε_{ij} is derived as $\mathcal{R}\varepsilon_{ij}=2\nu[\overline{u_i\partial_m(\mathcal{R}u_j)}+\overline{u_j\partial_m(\mathcal{R}u_i)}]=0$ and the result reads

$$d_t\varepsilon_{ij} = \mathcal{H}_{ij} - 2\mathcal{E}_{mkij}\partial_m U_k - (\varepsilon_{jk}\partial_k U_i + \varepsilon_{ik}\partial_k U_j) - \beta\left(g_i\overline{\varepsilon'_{j\theta}}+g_j\overline{\varepsilon'_{i\theta}}\right), \tag{2.22}$$

where $\mathcal{E}_{ijkm}\equiv 2\nu\overline{\partial_i u_k\partial_j u_m}$ and

$$\mathcal{H}_{ij} = -4\nu^2\overline{\partial^2_{mk}u_i\partial^2_{mk}u_j} - 2\nu\left(\overline{\varepsilon'_{jk}\partial_k u_i}+\overline{\varepsilon'_{ik}\partial_k u_j}\right)$$

$$-\frac{2\nu}{\rho_0}\overline{(\partial_j u_i+\partial_i u_j)\,\nabla^2 p}. \tag{2.23}$$

The corresponding evolution equation for third-order dissipation rate tensor ε_{ijk}, (2.15), is obtained as $\mathcal{R}\varepsilon_{ijk}=2\nu(\mathcal{L}_{kij}+\mathcal{L}_{jik}+\mathcal{L}_{ijk})=0$, where $\mathcal{L}_{kij}=\overline{(u_k\mathcal{R}\varepsilon'_{ij}+\varepsilon'_{ij}\mathcal{R}u_k)}$. After some algebra, the final result can be symbolically written as

$$d_t\varepsilon_{ijk} = \mathcal{P}_{ijk}+\mathcal{U}_{ijk}+\mathcal{G}_{ijk}+\mathcal{N}_{ijk}, \tag{2.24}$$

where

$$\mathcal{P}_{ijk} = P_{ijk}+P_{jik}+P_{kij}, \tag{2.25}$$

$$\mathcal{U}_{ijk} = U_{ijk}+U_{jik}+U_{kij}, \tag{2.26}$$

$$\mathcal{G}_{ijk} = G_{ijk}+G_{jik}+G_{kij}, \tag{2.27}$$

$$\mathcal{N}_{ijk} = N_{ijk}+N_{jik}+N_{kij} \tag{2.28}$$

and

$$\begin{aligned} P_{kij} = &-\frac{2\nu}{\rho_0}\left(\overline{(u_i\nabla^2 u_j + u_j\nabla^2 u_i)\partial_k p}\right) \\ &-\frac{2\nu}{\rho_0}\left(\overline{(u_i\nabla^2 u_k + u_k\nabla^2 u_i)\partial_j p}\right) \\ &-\frac{2\nu}{\rho_0}\left(\overline{(u_k\nabla^2 u_j + u_j\nabla^2 u_k)\partial_i p}\right) \\ &-\frac{4\nu}{\rho_0}\overline{(\partial_i(u_j u_k) + \partial_j(u_i u_k) + \partial_k(u_i u_j))\nabla^2 p}, \end{aligned} \tag{2.29}$$

$$\begin{aligned} U_{kij} = &-2\nu\left(\overline{u_k\left(\partial_m u_i \partial_n u_j + \partial_m u_i \partial_n u_j\right)}\right)\partial_m U_n \\ &-\varepsilon_{nij}\partial_n U_k - \varepsilon_{knj}\partial_n U_i - \varepsilon_{kin}\partial_n U_j, \end{aligned} \tag{2.30}$$

$$G_{kij} = -2\nu\beta\left(g_i\overline{u_k\varepsilon'_{j\theta}} + \overline{u_k\varepsilon'_{i\theta}} + \overline{u_i\varepsilon'_{j\theta}}\right), \tag{2.31}$$

$$\begin{aligned} N_{kij} = &\ 2\nu\left(\overline{u_k\partial_m u_n\left(\partial_n u_i\partial_m u_j + \partial_n u_j\partial_m u_i\right)} - \overline{u_n\partial_n u_k\partial_m u_i\partial_m u_j}\right) \\ &-2\nu^2\left(\overline{\partial_m u_i\partial_m u_j\nabla^2 u_k} + \overline{\partial_m u_k\left(\partial_m u_j\nabla^2 u_i + \partial_m u_i\nabla^2 u_j\right)}\right) \\ &-4\nu^2\overline{u_k\nabla^2 u_i\nabla^2 u_j}. \end{aligned} \tag{2.32}$$

It follows directly from (2.29)–(2.32) that $P_{kij} = P_{kji}$, $U_{kij} = U_{kji}$, $G_{kij} = G_{kji}$, and $N_{kij} = N_{kji}$. Consequently, $\mathcal{P}_{ijk}$, $\mathcal{U}_{ijk}$, $\mathcal{G}_{ijk}$, and $\mathcal{N}_{ijk}$ are symmetric for any permutation of indices; see (2.28). This property is obviously required by the definition of ε_{ijk} (2.15).

3. Imposing local isotropy a priori. The theory of isotropic turbulence is essentially based on the fact that all statistical measures of the flow must display invariance to arbitrary reflections and rotations. The properties of isotropic tensors can here be put to good use in order to establish whether the postulate is formally consistent with the Navier–Stokes equations. This methodology was first used by Durbin and Speziale [2], where it was applied to the second-order dissipation rate equations (2.12) to investigate the impact of mean straining on the small scales. The objective here is not only to elucidate the impact of density stratification on small-scale turbulence, but also to relate it to the impact of mean straining.

It is well known that, at any given order, a general isotropic tensor can be written as a linear combination of a set of linearly independent isotropic tensors. The number of independent isotropic tensors depends on the order of the tensor itself. Here, we will consider tensors up to fourth rank. The most general isotropic forms of *any* first-, second-, third-, and fourth-order isotropic tensor[2] can be written as

$$\mathcal{X}_i = 0, \tag{3.1}$$

$$\mathcal{X}_{ij} = \alpha_0\delta_{ij}, \tag{3.2}$$

$$\mathcal{X}_{ijk} = \alpha_1\epsilon_{ijk} = 0, \tag{3.3}$$

$$\mathcal{X}_{ijkl} = \alpha_2\delta_{ij}\delta_{kl} + \alpha_3\delta_{ik}\delta_{jl} + \alpha_4\delta_{il}\delta_{jk}, \tag{3.4}$$

[2]These are not specific to turbulence correlation tensors, but generally valid for first- through fourth-order tensors.

where the fundamental isotropic tensor of rank 2 is the Kronecker delta,

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j, \\ 0 & \text{otherwise,} \end{cases} \tag{3.5}$$

and of rank 3 is the Levi–Civita alternating tensor,

$$\epsilon_{ijk} = \begin{cases} 1 & \text{if } ijk \text{ is from the sequence 12312,} \\ -1 & \text{if } ijk \text{ is from the sequence 32132,} \\ 0 & \text{otherwise.} \end{cases} \tag{3.6}$$

As already alluded to, the implications of the small-scale isotropy postulate can be elucidated by writing the evolution equations (2.12), (2.15), and (2.19) in their most general isotropic forms using (3.1)–(3.4).

3.1. First-order velocity-temperature correlations. Let us first consider the equation governing the dissipation rate of turbulent heat flux. The isotropic form of (2.19) is obtained by substituting

$$\varepsilon_{i\theta}^{ISO} = 0, \tag{3.7}$$

$$\mathcal{F}_{i\theta}^{ISO} = 0, \tag{3.8}$$

$$\varepsilon_{ik}^{ISO} = \frac{1}{3}\varepsilon_{mm}\delta_{ik}, \tag{3.9}$$

$$\mathcal{E}_{km\theta i}^{ISO} \sim \epsilon_{kmi} = 0, \tag{3.10}$$

$$\mathcal{J}_{ikj}^{ISO} \sim \epsilon_{ikj} = 0, \tag{3.11}$$

which follows from (3.1)–(3.4). The last two results follow from the symmetry properties $\mathcal{E}_{km\theta i} = \mathcal{E}_{mk\theta i}$ and $\mathcal{J}_{ikj} = \mathcal{J}_{ijk}$, where the former only applies to homogeneous turbulence. The isotropic form of (2.19) then becomes

$$0 = -\frac{2}{3}\varepsilon\partial_i\Theta - \varepsilon_\theta g_i \beta Pr, \tag{3.12}$$

where $\varepsilon \equiv \frac{1}{2}\varepsilon_{mm}$ is the dissipation rate of turbulent kinetic energy. According to (3.12), isotropy would first require that the gravitation (g_i) must act in the direction of the mean temperature gradient $\partial_i\Theta$, which obviously not is generally true. Second, *if* the direction of the gravitational acceleration happens to coincide with the mean temperature gradient, e.g., $i = 2$, the resulting relationship $2\varepsilon\partial_2\Theta = -3\varepsilon_\theta\beta g_2 Pr$ seems far too stringent to be generally true. The implication of local isotropy, i.e., that $\varepsilon_{i\theta} = 0$, is therefore formally inconsistent with the Navier–Stokes equations. In fact, a closer examination of the evolution equation governing the third-order "generalized" dissipation tensor $\mathcal{E}_{km\theta i}$ yields the following additional constraints: $\varepsilon\partial_i\Theta = 0$ if $m \neq k = i$. For $m = k \neq i$, (3.12) is recovered. The terminology "generalized" alludes to the relation $(\kappa + \nu)\mathcal{E}_{mm\theta i} \equiv \varepsilon_{i\theta}$. Another interesting observation that can be made from (2.19) is that mean straining does not formally conflict with the assumption of local isotropy on this particular level of velocity-temperature correlation.

3.2. Second-order velocity-moments. Local isotropy on the second-order moment level requires (2.22) to balance in the isotropic limit (3.4). The terms in (2.22)

are replaced by their most general isotropic counterparts, and the result is

$$\varepsilon_{i\theta}^{ISO} = 0, \tag{3.13}$$

$$\varepsilon_{ij}^{ISO} = \frac{2}{3}\varepsilon\delta_{ij}, \tag{3.14}$$

$$\mathcal{H}_{ij}^{ISO} = \frac{1}{3}\mathcal{H}_{mm}\delta_{ij} = \frac{2}{3}\mathcal{H}\delta_{ij}, \tag{3.15}$$

$$\mathcal{E}_{mkij}^{ISO} = \varepsilon\left(\alpha_2\delta_{ij}\delta_{kl} + \alpha_3\delta_{ik}\delta_{jl} + \alpha_4\delta_{il}\delta_{jk}\right), \tag{3.16}$$

where the coefficients $\alpha_2 - \alpha_4$ are determined by imposing (i) homogeneity ($\mathcal{E}_{mkij} = \mathcal{E}_{kmij}$), (ii) continuity ($\mathcal{E}_{mkmj} = 0$), and (iii) the definition $\mathcal{E}_{mmij} = 2\varepsilon$. These constraints yield $\alpha_1 = 4/15$, $\alpha_2 = -1/15 = \alpha_3$. The resulting isotropic form of (2.12) can then be written as

$$d_t\varepsilon\delta_{ij} = \mathcal{H}\delta_{ij} - \frac{2}{5}\varepsilon S_{ij}, \tag{3.17}$$

where $\mathcal{H} \equiv \frac{1}{2}\mathcal{H}_{mm}$. This is the equation derived by Durbin and Speziale [2] which proves that the assumption of local isotropy is formally inconsistent with the Navier–Stokes equation on the second-order moment level when mean straining is imposed, i.e., when $i \neq j$. Clearly, the imposition of buoyancy does not render the local isotropy assumption formally invalid on the second-order velocity-moment level. It should further be noted that the implicit dependence on the stratification contained in the fluctuating pressure term in (2.23) does not contribute to the scalar $\mathcal{H}$ in incompressible flows.

Based on the theoretical arguments in the previous section, $\varepsilon_{i\theta}^{ISO} \neq 0$ in general. If we retain $\varepsilon_{i\theta}^{ISO} \neq 0$ and the assumption of local isotropy for rank 2 tensors, however, (3.17) becomes

$$d_t\varepsilon\delta_{ij} = \mathcal{H}\delta_{ij} - \frac{2}{5}\varepsilon S_{ij} - \underbrace{\frac{3}{2}\beta\left(g_i\varepsilon_{j\theta} + g_j\varepsilon_{i\theta}\right)}_{\mathcal{B}_{ij}}. \tag{3.18}$$

Equation (3.18) then provides us with another fact that strongly supports our assumption that $\varepsilon_{i\theta}^{ISO} \neq 0$ should be true; it implies that the rate of decay of ε, in the absence of mean shear ($S_{ij} = 0$), *should be unaffected by any imposed density stratification if the small-scale turbulence were truly isotropic*. However, there is no numerical or experimental evidence that this should be the case! On the contrary, it has been observed that even the slightest effect of buoyancy significantly alters the evolution of ε ($d_t\varepsilon$); see, e.g., Thoroddsen and Van Atta [16].

In order to provide an estimate of the nonlinear term $\mathcal{H}$ in (3.18), let us consider decaying grid turbulence unaffected by mean straining and stratification. The evolution equation for the turbulent time scale k/ε is readily obtained by combining (2.13) and (3.17). The results reads

$$d_t\left(\frac{k}{\varepsilon}\right) = -\left(1 + \frac{k}{\varepsilon^2}\mathcal{H}\right). \tag{3.19}$$

There exists experimental evidence that grid-generated turbulent kinetic energy exhibits a power-law decay, i.e., $k \sim t^{-n}$, where the decay exponent is $n \approx 1.3$ in a large number of measurements reported in the literature; cf., e.g., [7]. The value

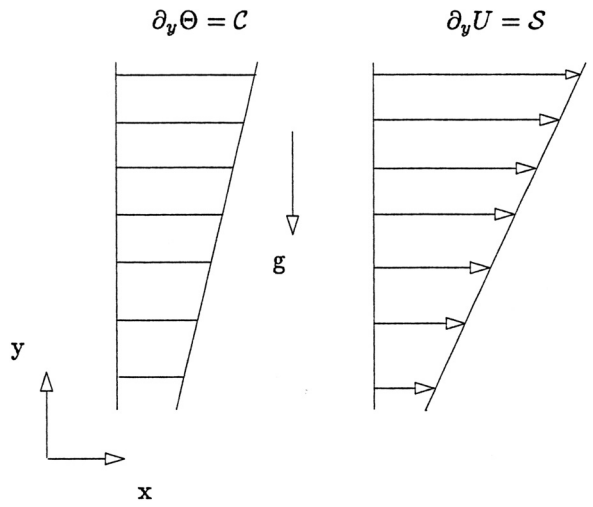

FIG. 3.1. *Homogeneous shear flow.*

of the decay exponent is reported to increase to $n \approx 5/2$ in the final period of decay. The power-law behavior of k requires $\varepsilon \sim t^{-(n+1)}$, and henceforth $k/\varepsilon \sim t$ and $d_t(k/\varepsilon) \sim O(1)$. With this, equation (3.19) provides the estimate

$$\mathcal{H} = \mathcal{O}\left(\frac{\varepsilon^2}{k}\right), \tag{3.20}$$

which is widely used, almost without exception, by turbulence modelers.

Let us now consider homogeneous shear flow with $\partial_y U = \mathcal{S} > 0$, $\partial_y \Theta = \mathcal{C} > 0$, and $\mathbf{g} = [0, -g, 0]$; see Figure 3.1. The assumption of local isotropy, in terms of an imposed density stratification, would then be a formally justified approximation if we can neglect $\mathcal{B}$ as compared to $\mathcal{H}$ in (3.18), i.e., if $||\mathcal{B}|| \ll ||\mathcal{H}||$ or equivalently if

$$k\mathcal{C} \gg |Ri_g \varepsilon_{2\theta}| \left(\frac{\mathcal{S}k}{\varepsilon}\right)^2 \tag{3.21}$$

by using the estimate (3.20). The gradient Richardson number $Ri_g \equiv \mathcal{N}^2/\mathcal{S}^2$, and $\mathcal{N}^2 \equiv \beta g \mathcal{C}$ is the Brunt–Väisala frequency. If we consider a flow close to equilibrium, it is reasonable to assume that $\mathcal{P}_{2\theta}/\varepsilon_{2\theta} = \mathcal{O}(1)$ in (2.16), where $\mathcal{P}_{2\theta} \equiv -\tau_{22}\mathcal{C} = -\frac{2}{3}k\mathcal{C}$. The last equality is obtained by substituting the isotropic value $\tau_{22} = \frac{2}{3}k$. Equation (3.21) can then be written as

$$|Ri_g| = \left|\frac{\mathcal{N}^2}{\mathcal{S}^2}\right| \ll \left(\frac{\varepsilon}{\mathcal{S}k}\right)^2 = \mathcal{O}(0.1). \tag{3.22}$$

The right-hand side of (3.22) has been evaluated using $\mathcal{S}k/\varepsilon \sim 6$, which typically is reached in physical and numerical experiments of homogeneous shear flows near equilibrium [15]. The constraint (3.22) thus implies that local isotropy constitutes a justifiable approximation only at very small Richardson numbers, in fact, so small that buoyancy effect cannot essentially be present in practice. The inequality also suggests that the imposition of density stratification exerts a significantly stronger effect on the dissipative scales than an imposed mean straining.

Durbin and Speziale [2] further demonstrated, in the absence of density stratification, that

$$\frac{\mathcal{S}k}{\varepsilon} \ll \mathcal{O}(1) \tag{3.23}$$

is a necessary condition for local isotropy to constitute a formally justified approximation in the absence of density stratification. This relation is readily obtained by requiring $||\mathcal{H}|| \gg ||\varepsilon\mathcal{S}||$ in (3.17). Using this and (3.22) yields the combined constraint

$$\left|\frac{\mathcal{N}^2k^2}{\varepsilon^2}\right| \ll \frac{\mathcal{S}^2k^2}{\varepsilon^2} \ll \mathcal{O}(1). \tag{3.24}$$

This result implies that the time scales associated with buoyancy and mean shear must be much larger than the integral turbulent time scale in order for the local isotropy hypothesis to constitute a formally justified approximation. In the absence of mean straining, the magnitude of the Brunt–Väisala frequency is thus required to be much smaller than that of the integral scale turbulent frequency in order for the hypothesis to constitute a physically plausible approximation. This is not feasible in homogeneous flows, at least for flows relatively close to equilibrium.

We can also recast (3.22) in terms of the buoyancy and shear Reynolds numbers frequently used in the literature,

$$Re_B = \left|\frac{\varepsilon}{\nu N^2}\right| = \frac{\varepsilon}{\nu|\beta g\mathcal{C}|} \qquad \text{and} \qquad Re_S = \frac{\varepsilon}{\nu\mathcal{S}^2}, \tag{3.25}$$

by noting that $Ri_g = Re_S/Re_B$. The result (3.24) can then be written as

$$\frac{1}{Re_B} \ll \frac{1}{Re_S} \ll \frac{1}{Re}, \tag{3.26}$$

where $Re \equiv k^2/(\varepsilon\nu)$ is the integral scale turbulent Re.

3.3. Third-order velocity-moments. Let us finally focus our attention on the evolution of the third-order dissipation rate tensor (ε_{ijk}). If small-scale turbulence on the third-order velocity-moment level were truly isotropic, the evolution equation (2.15) must be fully consistent with the mathematical properties (3.4). The terms $\mathcal{P}_{ijk}$, $\mathcal{U}_{ijk}$, and $\mathcal{N}_{ijk}$ are all third-rank tensors of the fluctuating velocity field. Since these terms must be symmetric for any permutation of indices, it follows from (3.6) that

$$\varepsilon_{ijk}^{ISO} = \mathcal{P}_{ijk}^{ISO} = \mathcal{U}_{ijk}^{ISO} = \mathcal{N}_{ijk}^{ISO} = 0 \qquad \forall \;\; i,j,k. \tag{3.27}$$

The term $\mathcal{G}_{ijk} \sim g_i d_{j\theta k}$ differs from the other terms in (2.24) in that it only compromises a second-rank tensor of fluctuating quantities, i.e., $d_{j\theta k}$. The most general isotropic form of $d_{j\theta k}$ can then be written as

$$d_{j\theta k}^{ISO} = \frac{1}{3}\overline{u_m\varepsilon'_{m\theta}}\delta_{jk} \neq 0, \tag{3.28}$$

according to (3.2). The result on the third-order velocity-moment level shows that the assumption of local isotropy is formally consistent with Navier–Stokes equations on the third-moment level if and only if $\overline{u_m\varepsilon'_{m\theta}} \equiv 0$. This requirement is, on the other hand, generally not fulfilled.

4. Concluding remarks. The present study has demonstrated that the hypothesis of local isotropy is formally inconsistent with the Navier–Stokes equations in homogeneous stratified turbulence, irrespective of whether the stratification is stable or not. The imposition of a mean temperature gradient is shown to essentially affect the small-scale turbulence in the same manner as an imposed mean shear, but with a significantly stronger impact.

George [4] has suggested, based on experimental findings, that the small-scale motion remains closely linked to the large-scale coherent motion. Anisotropies of the large scales would thus be reflected over the entire spectral range. These findings are consistent with the results presented herein.

The outcome of the present analysis is also very similar to the findings of Yeung, Brasseur, and Wang [22], although their approach is rather different. They considered the effect of anisotropic large-scale turbulence on the small-scale anisotropy, whereas the present study focuses on the imposition mean-flow anisotropy. Despite this difference, both cases reach the same conclusion, namely, that the imposition of large-scale anisotropy, be it related to turbulence or the mean flow, does not show up on all levels of small-scale velocity-moments.

In particular, density stratification does not formally conflict with the local isotropy hypothesis on the second-order level, whereas it shows up for the first- and third-order correlations examined here. Similarly, mean shear does not formally conflict with the isotropy assumption on the first- and third-order levels, whereas it is formally inconsistent on the second-order level. It is, however, sufficient to show anisotropy on *any* small-scale statistics in order for the local isotropy hypothesis to be violated. This was pointed out by Yeung, Brasseur, and Wang [22], who also argued that the converse is not true; a single statistical measure that displays a state of local isotropy is a necessary but not a sufficient condition to guarantee small-scale isotropy.

A qualitative analysis of the second-order dissipation rate transport equation has indicated that local isotropy constitutes a physically justifiable approximation, at this particular level of single-point moments, only if the imposed time scale associated with buoyancy, or mean straining, is much larger than the integral turbulent time scale. It can therefore be concluded that local isotropy does not seem to be a physically plausible argument in flows relatively close to equilibrium, since the imposed and the eddy turnover time scales usually are of the same order. A successful continuation in the development of predictive methods for turbulent flows relies heavily upon the ability to characterize small-scale turbulence in terms of the large scales. The theoretical outcome of this study has shown that it seems necessary to include information of the *mean* flow field in models for the small-scale turbulence in order to retain some consistency with the Navier–Stokes equations.

Acknowledgments. The authors wish to thank Prof. P. A. Durbin (Stanford University) and Dr. J. Werne (Colorado Research Associates, Div Boulder) for commenting on the draft.

RESONANCE AND BOUND STATES IN PHOTONIC CRYSTAL SLABS*

STEPHEN P. SHIPMAN† AND STEPHANOS VENAKIDES‡

Abstract. Using boundary-integral projections for time-harmonic electromagnetic (EM) fields, and their numerical implementation, we analyze EM resonance in slabs of two-phase dielectric photonic crystal materials. We characterize *resonant frequencies* by a complex Floquet–Bloch dispersion relation $\omega = W(\beta)$ defined by the existence of a nontrivial nullspace of a pair of boundary-integral projections parameterized by the wave number β and the time-frequency ω. At resonant frequencies, the crystal slab supports a source-free EM field. We link *complex* resonant frequencies, where the imaginary part is small, to resonant scattering behavior of incident source fields at nearby real frequencies and anomalous transmission of energy through the slab. At a *real* resonant frequency, the source-free field supported by the slab is a *bound state*. We present numerical examples which demonstrate the effects of structural defects on the resonant properties of a crystal slab and surface waves supported by a dielectric defect.

1. Overview.

Photonic crystals are material structures with spatially periodic electromagnetic (EM) properties. A two-dimensional (2D) dielectric *photonic crystal slab* (Figure 1.1) has dielectric permittivity that does not vary in the z direction, is constant beyond some finite value of $|x|$, and is periodic in y. The photonic crystal slabs in our study consist of an array of circular homogeneous rods embedded in a matrix of a contrasting dielectric permittivity.

It is well known that photonic crystals may act as resonators. In previous work [1], [2], we investigated resonant behavior in photonic crystal slabs. In particular, a periodic channel defect in a slab whose period cell is shown in Figure 7.3(3b) below resulted in the appearance of narrow ranges of frequency values over which the steady-state field in the crystal exhibited amplitudes that were many times greater than the amplitude of the polarized, time and space harmonic incident EM source field [2]. The dielectric materials that we consider have no losses or gains; thus the phenomenon is due solely to resonant behavior in the scattering by the crystal. Over these narrow frequency ranges, the transmission of energy through the slab is either enhanced or inhibited, producing "spikes" in the transmission coefficient (as in Figures 7.1(5) and 7.3(3a) below). The exploitation of photonic crystal resonances in the engineering of photonic devices has received much attention in the literature in recent years. See, for example, [3] and [4] for applications to filters and transmission enhancement. The connection between the structure of transmission dips and properties of quasi-guided eigenmodes is investigated in [5] for square-patterned slabs on a substrate.

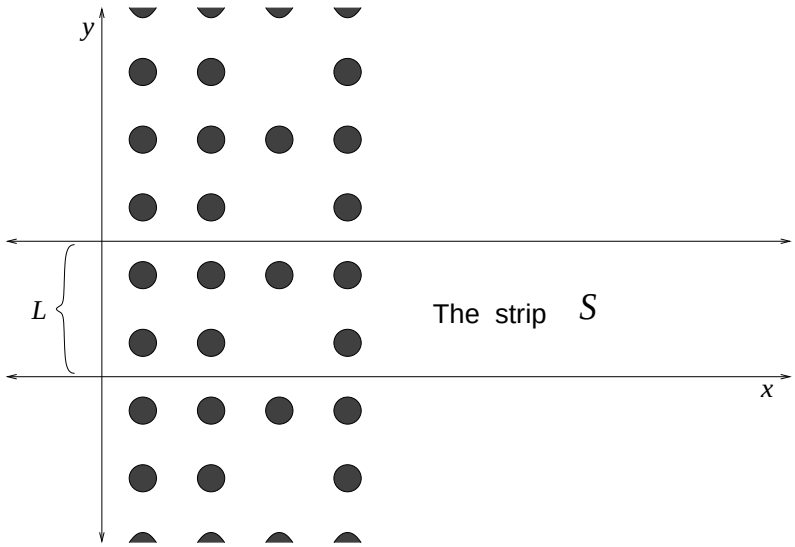

FIG. 1.1. *A cross section of a photonic crystal slab consisting of an array of homogeneous dielectric rods standing perpendicular to the xy-plane. The rod structure is periodic in the y-direction, with period L, and extends indefinitely as* $y \to \pm\infty$. *The rod structure is finite in the x-direction. Exterior to the rods is a homogeneous material of contrasting dielectric permittivity extending to infinity to the right and left. Pseudoperiodic fields in the plane can be analyzed in the strip* $\mathcal{S} = \{(x, y) : -\infty < x < \infty,\ 0 \le y \le L\}$ *consisting of a single period of the dielectric permittivity function.*

A connection between resonant frequencies and proper eigenvalues is known for Helmholtz resonators. Beale [6] shows that the (complex) resonant frequencies of a cavity in $\mathbb{R}^3$ with an opening converge to the eigenvalues (bound state frequencies) of the closed cavity as the opening disappears.

In the present study, we link resonant scattering behavior in dielectric photonic crystal slabs to certain complex frequencies with a small imaginary part at which the structure supports a source-free field (the term "source" is defined precisely in section 4). These are Bloch fields $\psi(x, y) = \tilde{\psi}(x, y)e^{i(\beta y - \omega t)}$, with $\tilde{\psi}(x, y)$ periodic in y and real wave number β. If a source-free field exists for a real value of ω, the structure sustains a traveling or standing wave along the slab that decays exponentially as $|x| \to \infty$ so that the slab acts as a waveguide. We call such a field a *localized field* or a *bound state*, localization being in the strip $\mathcal{S} = \{(x, y) : -\infty < x < \infty,\ 0 \le y \le L\}$, consisting of one period of the dielectric permittivity function (Figure 1.1). Frequencies at which the crystal slab supports a source-free field are called *resonant frequencies*, and they are described by a *dispersion relation* $\omega = W(\beta)$. We take $\Re(\omega) > 0$ and prove that $\Im(W(\beta)) \le 0$ with equality if and only if the corresponding source-free field is a bound state. If $\Im(W(\beta)) < 0$, then the field grows exponentially as $|x| \to \infty$, but decays in time.

In numerical experiments with several structures, we find isolated values of the wave number β for which the frequency $\omega = W(\beta)$ appears to be real, giving rise to an isolated bound state. At nearby values of β, $W(\beta)$ attains an imaginary part, and sources at real frequencies near $\Re(W(\beta))$ produce resonant scattering behavior. At these frequencies, the transmission coefficient exhibits anomalous behavior (see Figure 7.1). We also find a wave number range over which we show that the imaginary part

of the frequency is exactly zero (see Figure 7.2). Indeed, a slab nine rods thick yields a real branch of the dispersion relation; all but the first rod have equal radii, and the radius of the first rod is larger. The wave modes sustained by this structure are mainly supported on the larger rod, demonstrating that waves can exist on a defective surface of an otherwise perfect crystal.

Following the Floquet–Bloch theory, our mathematical investigation restricts the analysis to a single period of the dielectric permittivity considered as a function of x and y. Thus the problem is posed on the strip $\mathcal{S} = \{(x, y) : -\infty < x < \infty,\ 0 \le y \le L\}$, where L is the period in the y direction, as illustrated in Figure 1.1. Pseudoperiodic boundary conditions then apply to the fields: $\psi(x, L) = e^{i\beta L}\psi(x, 0)$ and $\partial_y\psi(x, L) = e^{i\beta L}\partial_y\psi(x, 0)$ for all values of x.

We use boundary-integral projections of Calderón's type with pseudoperiodic Green's functions and Green's identities on the strip $\mathcal{S}$. In sections 3 and 4 we show how these projections give rise to a system of two coupled integral equations that relate the trace of the steady-state field and its normal derivative on the boundaries of the rods to the trace of the source field and its normal derivative. The latter fields constitute the forcing. The system is Fredholm of the second kind in the former fields; that is, the integral operator involved is a compact perturbation of the identity.

The existence of a resonant frequency requires the existence of a nullspace of the boundary-integral operator; the latter depends parametrically on the dielectric structure and the parameters β (which we always assume to be real) and ω. To locate resonant frequencies in section 7, we discretize the integral operator and search for (β, ω) pairs for which it has an eigenvalue equal to zero. In this way, we calculate numerically the dispersion relations $\omega = W(\beta)$. In some cases, ω is a real function of β, so that the relation describes how the frequency of an x-localized wave traveling along the slab depends on its Bloch wave number. In other cases, ω is a complex function of β. We prove that, in this case, the corresponding fields become unbounded as $|x| \to \infty$ (they decay as $t \to \infty$), and therefore do not represent bound states. They do, however, force nearby real frequencies to exhibit resonant behavior. This phenomenon is examined also in [5] using a scattering matrix for square-patterned slabs.

2. Free pseudoperiodic Green's functions. We consider a lossless photonic crystal that consists of an array of dielectric rods, each with the same constant dielectric coefficient $\epsilon_1 > 0$, embedded in a matrix of a material with some other constant dielectric coefficient $\epsilon_0 > 0$. The rods stand perpendicular to the xy-plane and do not vary with z. The array is truncated to a finite width in the x-direction and extends periodically in the y-direction, with period 2π. Its planar cross section consists of a finite union D of planar domains D_j (the cross sections of the rods) with C^2 boundaries in the strip $\mathcal{S} = \{(x, y) : 0 < y < 2\pi\}$ that repeats periodically in the y-direction. We let $\partial\mathcal{S}$ have an inward-pointing normal vector, and we let $n(\mathbf{r})$ denote the outward-directed normal vector to the boundary ∂D of D.

Let $\psi(x, y)e^{-i\omega t}$ be the out-of-plane component (electric or magnetic) of a polarized time-harmonic electromagnetic field with nondimensionalized frequency[1] ω in the photonic crystal structure (it is constant in the z-direction). The Maxwell equations then reduce to the Helmholtz equation

$$\nabla^2\psi + \epsilon_1\omega^2\psi = 0 \quad (\text{in } D), \qquad \nabla^2\psi + \epsilon_0\omega^2\psi = 0 \quad (\text{in } \mathcal{S} \setminus \bar{D})$$

[1] We use ω for the reduced time-frequency in this paper; it is equal to our k in [1] and [2]. It relates to the physical frequency Ω (cycles per time) and period L by $\omega = \Omega L/c$, where c is the speed of light.

and the matching conditions

$$\lim_{h\to 0}\left(\psi(\mathbf{r}-hn(\mathbf{r}))-\psi(\mathbf{r}+hn(\mathbf{r}))\right)=0, \tag{2.1a}$$

$$\lim_{h\to 0}\left(\frac{\partial\psi(\mathbf{r}-hn(\mathbf{r}))}{\partial n(\mathbf{r})}-\nu\frac{\partial\psi(\mathbf{r}+hn(\mathbf{r}))}{\partial n(\mathbf{r})}\right)=0, \tag{2.1b}$$

on the boundary ($\mathbf{r}\in\partial D$). In these equations, $\nabla^2=\partial^2/\partial x^2+\partial^2/\partial y^2$, $\nu=1$ in the electric polarization case, and $\nu=\epsilon_1/\epsilon_0$ in the magnetic polarization case.

We will consider Helmholtz fields ψ that are pseudoperiodic in y. This means that, for some real number β, $\psi=e^{i\beta y}\tilde{\psi}$, where $\tilde{\psi}$ is periodic in y with the same period (2π) as the crystal.

First, we present the fundamental pseudoperiodic solutions of the Helmholtz equation.

THEOREM 2.1. *Let ϵ and β be real numbers and ω a complex number such that, for all integers m, $\epsilon\omega^2-(m+\beta)^2\neq 0$. For each integer m, let μ_m be defined by*

$$\mu_m^2-(m+\beta)^2+\epsilon\omega^2=0,$$

with $\Re(\mu_m)<0$ for all but a finite number of values of m. Then the series

$$G(\mathbf{r})=-\frac{1}{4\pi}\sum_{m=-\infty}^{\infty}\frac{1}{\mu_m}\exp\left(\mu_m|x|+i(m+\beta)y\right)$$

converges and is of class C^∞ for all $\mathbf{r}=(x,y)\in\mathbb{R}^2\setminus\{(0,2\pi n):n\in\mathbb{Z}\}$ and

$$\nabla^2G+\epsilon\omega^2G=-\sum_{n=-\infty}^{\infty}\delta(x,y-2\pi n)e^{2\pi ni\beta},$$

where δ is the Dirac delta-function in $\mathbb{R}^2$ with unit impulse at the origin.

Proof. We first consider the case in which $\Re(\mu_m)\leq 0$ for all $m\in\mathbb{Z}$. Then the series defining $G(\mathbf{r})$ converges to a tempered distribution on $\mathbb{R}^2$. This is seen as follows: Let $\phi(x,y)$ be a function of Schwartz class. Then, for m large enough so that $\Re(\mu_m)<0$, we have

$$\left|\iint\frac{1}{\mu_m}\exp(\mu_m|x|+i(m+\beta)y)\phi(x,y)\,dx\,dy\right| \leq\frac{1}{|\mu_m|}\int e^{\Re(\mu_m)|x|}\int|\phi(x,y)|\,dy\,dx\leq\frac{-2A}{|\mu_m|\Re(\mu_m)}, \tag{2.2}$$

where A is such that

$$\sup_{(x,y)\in\mathbb{R}^2}(1+y^2)|\phi(x,y)|<A\left(\int(1+z^2)^{-1}dz\right)^{-1}.$$

Since $\Re(\mu_m)/m=\mathcal{O}(1)$ as $m\to\infty$, the series for $G(\mathbf{r})$ converges to a tempered distribution.

Let $\widehat{G}(\mathbf{s})$, where $\mathbf{s}=(s_1,s_2)$, be the Fourier transform of $G(\mathbf{r})$:

$$\widehat{G}(\mathbf{s})=-\frac{1}{4\pi}\sum_{m=-\infty}^{\infty}\frac{-2}{s_1^2+\mu_m^2}\delta(s_2-(m+\beta));$$

$$[(\nabla^2+\epsilon\omega^2)G]\hat{}(\mathbf{s}) = \frac{1}{2\pi}\sum_{m=-\infty}^{\infty}\frac{-s_1^2-(m+\beta)^2+\epsilon\omega^2}{s_1^2+\mu_m^2}\delta(s_2-(m+\beta)) \tag{2.3}$$
$$= -\frac{1}{2\pi}\sum_{m=-\infty}^{\infty}\delta(s_2-(m+\beta))$$

$$\implies \quad (\nabla^2+\epsilon\omega^2)G = -\frac{1}{2\pi}\delta(x)\sum_{m=-\infty}^{\infty}e^{i(m+\beta)y}$$
$$= -\frac{1}{2\pi}\delta(x)e^{i\beta y}\sum_{m=-\infty}^{\infty}e^{imy} = -\delta(x)e^{i\beta y}\sum_{n=-\infty}^{\infty}\delta(y-2\pi n) \tag{2.4}$$
$$= -\sum_{n=-\infty}^{\infty}e^{2\pi n i\beta}\delta(x,y-2\pi n).$$

The result holds if we replace $1/\mu_m \exp(\mu_m|x| + i(m+\beta)y)$ in $G(\mathbf{r})$ with $-1/\mu_m \exp(-\mu_m|x| + i(m+\beta)y)$ for a finite number of integers m, because this amounts to adding a finite number of functions

$$\psi_m = \frac{1}{\mu_m}(e^{-\mu_m|x|}+e^{\mu_m|x|})e^{i(m+\beta)y} = \frac{1}{\mu_m}(e^{-\mu_m x}+e^{\mu_m x})e^{i(m+\beta)y},$$

which satisfy $(\nabla^2+\epsilon\omega^2)\psi_m = 0$.

Finally, we note that the ellipticity of $\nabla^2+\epsilon\omega^2$ implies that any distribution solution on a domain must be a function of class C^∞. Thus $G(\mathbf{r})$ is of class C^∞ on $\mathbb{R}^2 \setminus \{(0,2\pi n) : n \in \mathbb{Z}\}$. □

For our purposes, we make the following choices of the sign of μ_m. For real values of ω (such that $(m+\beta)^2 - \epsilon\omega^2 \neq 0$ for all integers m), we choose μ_m such that $G(\hat{\mathbf{r}})$ is a *radiating* Green's function. Thus, for the finite number of consecutive integers m such that $(m+\beta)^2 - \epsilon\omega^2 < 0$ (it is possible that there are no such values of m), we take μ_m to lie on the positive imaginary axis; these values of m give the finite number of outwardly *propagating* modes. For all other values of m, we take $\mu_m < 0$; these give the *decaying* modes.

In our investigations, we will consider continuous perturbations of ω into the lower-half complex plane, and we allow the values of μ_m to vary analytically with ω. As ω attains a negative imaginary part, the finite number of values of μ_m that gave the propagating modes now attain a positive real part and therefore grow as $|x| \to \infty$. For all other values of m, μ_m attains a negative imaginary part.

Figure 2.1 shows the number of propagating modes for real values of β and ω. Pairs (β,ω) for which there are no propagating modes and perturbations of these in the imaginary ω direction admit no scattering (extended) EM fields in the strip $\mathcal{S}$.

We will make use of the set of Helmholtz fields which, to the right and left of the scatterer, are equal to a superposition of modes that build the Green's functions G that we defined in Theorem 2.1.

DEFINITION 2.2. *We say that a function ψ is in the class $\mathcal{E}(\beta,\omega,\epsilon)$ if its domain contains $\{(x,y) : |x| > x_*\}$ for some $x_* > 0$ and*

$$\psi(x,y) = \sum_{m=-\infty}^{\infty} A_m^{\pm}\exp\left(\mu_m|x| + i(m+\beta)y\right) \quad \textit{for} \quad \pm x > x_*$$

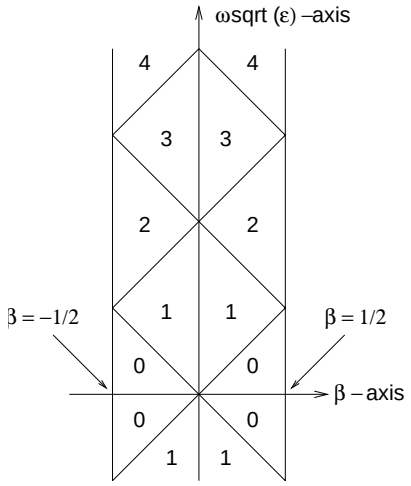

FIG. 2.1. *The number of propagating modes for real values of β and ω. The pattern is repeated periodically in β, with period 1. For fixed β and ω, there is a propagating mode for each m such that $|\sqrt{\epsilon}\omega| > |m + \beta|$.*

for some complex numbers $A_m^{\pm}$, where $\mu_m = \left((m+\beta)^2 - \epsilon\omega^2\right)^{1/2}$ with the sign determination described above.

Remark. The role of the class $\mathcal{E}(\beta, \omega, \epsilon)$ is to continue analytically into the complex ω-plane as $|x| \to \infty$ the standard outgoing radiation condition that applies when ω is real: $\mathcal{E}(\beta, \omega, \epsilon)$ contains the radiating fields when ω is real and their analytic continuations into the complex ω-plane.

3. The boundary-integral projections. Let $\xi \in H^1(\partial D)$ and $\eta \in L^2(\partial D)$ be given (H^1 is the linear space of functions on ∂D with square-integrable arclength derivatives), and denote $\boldsymbol{\xi} = (\xi, \eta)^t$. For any point $\hat{\mathbf{r}}$ in the strip $\mathcal{S}$ exterior to D, define

$$\psi(\hat{\mathbf{r}}) = \int_{\partial D} \left(\frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \xi(\mathbf{r}) - G(\hat{\mathbf{r}} - \mathbf{r}) \eta(\mathbf{r}) \right) ds(\mathbf{r}) \qquad (\hat{\mathbf{r}} \text{ exterior to } D). \tag{3.1}$$

This field is an element of $\mathcal{E}(\beta, \omega, \epsilon)$. For $\hat{\mathbf{r}} \in D$, define

$$\psi(\hat{\mathbf{r}}) = \int_{\partial D} \left(-\frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \xi(\mathbf{r}) + G(\hat{\mathbf{r}} - \mathbf{r}) \eta(\mathbf{r}) \right) ds(\mathbf{r}) \qquad (\hat{\mathbf{r}} \in D). \tag{3.2}$$

Both fields satisfy the Helmholtz equation (in the variable $\hat{\mathbf{r}}$) in their respective domains.

Let $\hat{\mathbf{r}}$ now be a point on ∂D, and consider the limits to $\hat{\mathbf{r}}$ of these exterior and interior fields and their normal derivatives:

$$\boldsymbol{\psi}_e(\hat{\mathbf{r}}) = \begin{bmatrix} \psi_e(\hat{\mathbf{r}}) \\ \\ \partial_n \psi_e(\hat{\mathbf{r}}) \end{bmatrix} := \begin{bmatrix} \lim\limits_{h \to 0^+} \psi(\hat{\mathbf{r}} + hn(\hat{\mathbf{r}})) \\ \\ \lim\limits_{h \to 0^+} \dfrac{\partial \psi}{\partial n(\hat{\mathbf{r}})}(\hat{\mathbf{r}} + hn(\hat{\mathbf{r}})) \end{bmatrix},$$

$$\boldsymbol{\psi}_i(\hat{\mathbf{r}}) = \begin{bmatrix} \psi_i(\hat{\mathbf{r}}) \\ \\ \partial_n \psi_i(\hat{\mathbf{r}}) \end{bmatrix} := \begin{bmatrix} \lim\limits_{h \to 0^+} \psi(\hat{\mathbf{r}} - hn(\hat{\mathbf{r}})) \\ \\ \lim\limits_{h \to 0^+} \dfrac{\partial \psi}{\partial n(\hat{\mathbf{r}})}(\hat{\mathbf{r}} - hn(\hat{\mathbf{r}})) \end{bmatrix}.$$

These limits are again in $H^1(\partial D) \times L^2(\partial D)$. See the appendix for a more detailed discussion of these limits.

The limit of the first-order normal derivatives of the Green's function produces singular contributions according to the Plemelj formula, and we obtain

$$\boldsymbol{\psi}_e = \tfrac{1}{2}(I + H)\boldsymbol{\xi},$$
$$\boldsymbol{\psi}_i = \tfrac{1}{2}(I - H)\boldsymbol{\xi},$$

in which H is an integral operator from $H^1(\partial D) \times L^2(\partial D)$ to itself defined by

(3.3)
$$(H\boldsymbol{\xi})(\hat{\mathbf{r}}) = 2 \begin{bmatrix} \displaystyle\int_{\partial D} \left(\frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \xi(\mathbf{r}) - G(\hat{\mathbf{r}} - \mathbf{r}) \eta(\mathbf{r}) \right) ds(\mathbf{r}) \\ \displaystyle\lim_{h \to 0} \int_{\partial D} \frac{\partial G(\hat{\mathbf{r}} + h\, n(\hat{\mathbf{r}}) - \mathbf{r})}{\partial n(\hat{\mathbf{r}}) \partial n(\mathbf{r})} \xi(\mathbf{r}) ds(\mathbf{r}) - \displaystyle\int_{\partial D} \frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\hat{\mathbf{r}})} \eta(\mathbf{r}) ds(\mathbf{r}) \end{bmatrix}.$$

H has the form

$$H \begin{bmatrix} \xi \\ \eta \end{bmatrix} = 2 \begin{bmatrix} K & -J \\ L & -K' \end{bmatrix} \begin{bmatrix} \xi \\ \eta \end{bmatrix},$$

in which the entries of the matrix are integral operators on ∂D. The integral kernels of J, K, and K' are $G(\hat{\mathbf{r}} - \mathbf{r})$, $\partial G(\hat{\mathbf{r}} - \mathbf{r})/\partial n(\mathbf{r})$, and $\partial G(\hat{\mathbf{r}} - \mathbf{r})/\partial n(\hat{\mathbf{r}})$, respectively. By integration by parts and using the identity

$$\frac{\partial^2 G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\hat{\mathbf{r}}) \partial n(\mathbf{r})} + \frac{\partial^2 G(\hat{\mathbf{r}} - \mathbf{r})}{\partial s(\hat{\mathbf{r}}) \partial s(\mathbf{r})} = -n(\hat{\mathbf{r}}) \cdot n(\mathbf{r}) (\partial_x^2 + \partial_y^2) G(\hat{\mathbf{r}} - \mathbf{r}),$$

one can show that the integral kernel of L is

$$n(\hat{\mathbf{r}}) \cdot n(\mathbf{r}) \epsilon \omega^2 G(\hat{\mathbf{r}} - \mathbf{r}) + \frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial s(\hat{\mathbf{r}})} \frac{d}{ds},$$

where s is the arclength parameter and $\partial G/\partial s$ is a principal-value kernel (see the proof of Theorem 2.1 in [2]).

THEOREM 3.1. *H is a bounded linear operator from $H^1(\partial D) \times L^2(\partial D)$ into itself, the operators*

$$P_e = \tfrac{1}{2}(I + H),$$

$$P_i = \tfrac{1}{2}(I - H)$$

are complementary projections, and

$$H^2 = I.$$

Proof. Let us consider a solution ψ of $\nabla^2 \psi + \epsilon \omega^2 \psi = 0$ defined in D that has a continuous extension to $\overline{D}$ whose restriction to ∂D is in $H^1(\partial D)$ and such that $\lim_{h \to 0^-} \partial \psi / dn(\mathbf{r})(\mathbf{r} + hn(\mathbf{r}))$ exists and belongs to $L^2(\partial D)$. Then Green's identity holds: For $\hat{\mathbf{r}} \in D$,

$$\psi(\hat{\mathbf{r}}) = \int_{\partial D} \left(-\frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \psi(\mathbf{r}) + G(\hat{\mathbf{r}} - \mathbf{r}) \frac{\partial \psi(\mathbf{r})}{\partial n(\mathbf{r})} \right) ds(\mathbf{r}). \tag{3.4}$$

Green's identity says that (3.2) holds if we put ψ and $\partial_n\psi$ in place of ξ and η, and therefore

$$P_i^2(\boldsymbol{\xi}) = P_i(\boldsymbol{\psi_i}) = \boldsymbol{\psi_i} = P_i(\boldsymbol{\xi}),$$

and thus $P_i^2 = P_i$.

Now let a solution ψ of $\nabla^2\psi + \epsilon\omega^2\psi = 0$ such that $\psi \in \mathcal{E}(\beta, \omega, \epsilon)$ be defined in $\mathcal{S} \setminus \overline{D}$, and suppose that ψ has a continuous extension to $\overline{D}$ whose restriction to ∂D is in $H^1(\partial D)$ and such that $\lim_{h\to 0-} \partial\psi/dn(\mathbf{r})(\mathbf{r}+hn(\mathbf{r}))$ exists and belongs to $L^2(\partial D)$. Again, Green's identity holds: For $\hat{\mathbf{r}} \in \mathcal{S} \setminus \overline{D}$,

$$\psi(\hat{\mathbf{r}}) = \int_{\partial D} \left(\frac{\partial G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \psi(\mathbf{r}) - G(\hat{\mathbf{r}} - \mathbf{r}) \frac{\partial \psi(\mathbf{r})}{\partial n(\mathbf{r})} \right) ds(\mathbf{r}). \tag{3.5}$$

The contribution from the upper and lower sides of the strip $\mathcal{S}$ cancel because of the pseudoperiodicity of ψ and G^ϵ. Straightforward calculation shows that the contributions from vertical line segments truncating the strip on the left and right vanish identically as the points of truncation tend to infinity, because both G and ψ are in $\mathcal{E}(\beta, \omega, \epsilon)$. Again, we find that $P_e^2 = P_e$ by putting ψ and $\partial_n\psi$ in place of ξ and η in (3.1).

It is straightforward to calculate that $H^2 = I$. □

The operators in Theorem 3.1 are *boundary-integral projections of Calderón's type*. See Calderón [7], Seeley [8], and Ryaben'kii [9]. Nédélec [10] derives the Calderón's projections for the full harmonic Maxwell equations for a bounded domain in $\mathbb{R}^3$.

4. The Fredholm system of boundary-integral equations. We describe the EM scattering by a photonic crystal slab in terms of the decomposition given by the boundary-integral projections. We have seen that any pair of functions $(\xi, \eta)^t = \boldsymbol{\xi}$ in $H^1(\partial D) \times L^2(\partial D)$ can be expressed uniquely as the sum of the limiting values to ∂D of an interior Helmholtz field and its normal derivative and an exterior Helmholtz field in $\mathcal{E}(\beta, \omega, \epsilon)$ and its normal derivative.

DEFINITION 4.1. *An exterior-source field $\boldsymbol{\xi} = \boldsymbol{\phi}_i^{\epsilon_0}$ has zero exterior component in the above decomposition over the exterior medium ($\epsilon = \epsilon_0$); that is,*

$$P_e^{\epsilon_0}\boldsymbol{\phi}_i^{\epsilon_0} = 0, \quad P_i^{\epsilon_0}\boldsymbol{\phi}_i^{\epsilon_0} = \boldsymbol{\phi}_i^{\epsilon_0}.$$

An interior-source field $\boldsymbol{\xi} = \boldsymbol{\phi}_e^{\epsilon_1}$ has zero interior component in the above decomposition over the interior medium ($\epsilon = \epsilon_1$); that is,

$$P_i^{\epsilon_1}\boldsymbol{\phi}_e^{\epsilon_1} = 0, \quad P_e^{\epsilon_1}\boldsymbol{\phi}_e^{\epsilon_1} = \boldsymbol{\phi}_e^{\epsilon_1}.$$

In other words, when the sources are in the exterior, the source field extends from ∂D to a Helmholtz field over the medium ϵ_0 in the interior. Similarly, when the sources are in the interior, the source field extends from ∂D to a Helmholtz field of class $\mathcal{E}(\beta, \omega, \epsilon_1)$ over the medium ϵ_1 in the exterior.

Remark. In our numerical calculations of transmission in section 7, we use plane-wave source fields from the left at real frequencies ω; that is,

$$\psi_i^{\epsilon_0} = \exp\left(i\sqrt{\epsilon_0\omega^2 - (m+\beta)^2}\, x + i(m+\beta)y \right), \qquad \psi_e^{\epsilon_1} = 0.$$

A solution to the scattering problem has total exterior and interior fields ψ_{ext} and ψ_{int}, with traces (field and normal derivative) on ∂D given by

$$\boldsymbol{\psi}_{\text{ext}} = \boldsymbol{\psi}_e^{\epsilon_0} + \boldsymbol{\phi}_i^{\epsilon_0}, \qquad \boldsymbol{\psi}_{\text{int}} = \boldsymbol{\psi}_i^{\epsilon_1} + \boldsymbol{\phi}_e^{\epsilon_1}, \tag{4.1}$$

where $\boldsymbol{\psi}_i^{\epsilon_1}$ and $\boldsymbol{\psi}_e^{\epsilon_0}$ are the traces of the interior and exterior scattered fields. The field $\boldsymbol{\psi}_i^{\epsilon_1}$ extends to a Helmholtz field in the interior, and $\boldsymbol{\psi}_e^{\epsilon_0}$ extends to a Helmholtz field of class $\mathcal{E}(\beta,\omega,\epsilon_0)$ in the exterior. When ω is real, the exterior extension of $\boldsymbol{\psi}_e^{\epsilon_0}$ either decays or satisfies the outward radiation condition as $|x|\to\infty$.

The matching conditions at the interface of the two media are given by

$$\begin{bmatrix} \psi_{\rm int}(\hat{\mathbf{r}}) \\ \partial_n\psi_{\rm int}(\hat{\mathbf{r}}) \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 0 & \nu \end{bmatrix} \begin{bmatrix} \psi_{\rm ext}(\hat{\mathbf{r}}) \\ \partial_n\psi_{\rm ext}(\hat{\mathbf{r}}) \end{bmatrix}. \tag{4.2}$$

We write the matching conditions in short form by defining $\Gamma = \left[\begin{smallmatrix} 1 & 0 \\ 0 & \nu \end{smallmatrix}\right]$ and $\boldsymbol{\psi} = \left[\begin{smallmatrix} \psi_{\rm ext}(\hat{\mathbf{r}}) \\ \partial_n\psi_{\rm ext}(\hat{\mathbf{r}}) \end{smallmatrix}\right]$ on ∂D and inserting them into (4.1) to obtain

$$\boldsymbol{\psi} = \boldsymbol{\psi}_e^{\epsilon_0} + \boldsymbol{\phi}_i^{\epsilon_0}, \qquad \Gamma\boldsymbol{\psi} = \boldsymbol{\psi}_i^{\epsilon_1} + \boldsymbol{\phi}_e^{\epsilon_1}. \tag{4.3}$$

We apply the projections $P_i^{\epsilon_0}$ and $P_e^{\epsilon_1}$ to the two equations, respectively,

$$P_i^{\epsilon_0}\boldsymbol{\psi} = \boldsymbol{\phi}_i^{\epsilon_0} \quad \text{and} \quad P_e^{\epsilon_1}\Gamma\boldsymbol{\psi} = \boldsymbol{\phi}_e^{\epsilon_1}. \tag{4.4}$$

DEFINITION 4.2. *By the* scattering problem *at* (β,ω)*, we mean the system of equations* (4.4) *with the source fields (see Definition* 4.1*) in the right-hand sides belonging to the space* $H^1(\partial D)\times L^2(\partial D)$*. A* scattering state *or* scattering field *is a Helmholtz field whose trace on* ∂D *is a solution of the system with a nonzero source. If there exists a nontrivial solution* $\boldsymbol{\psi}$ *in the absence of sources (zero right-hand sides), we call the frequency* ω *a* resonant frequency *(for the wave number* β*). The corresponding Helmholtz field is necessarily in* $\mathcal{E}(\beta,\omega,\epsilon_0)$*. If the field decays as* $|x|\to\infty$*, we call it a* bound state*.*

Remarks. 1. Our definition of scattering state analytically continues the traditional scattering states at real frequencies into the complex ω-plane. This is possible by our analytic continuation of the condition that defines the notion of an outgoing radiating field (see the Remark after Definition 2.2). A scattering state is an analytic function of ω, and a resonant frequency is a singularity of this function.

2. We say that a scattering field at a nonresonant real frequency near a resonant frequency exhibits *resonant behavior* if it exhibits amplitudes in the crystal structure that are large compared to the source amplitude.

3. We will need to consider only frequencies ω such that $\Re(\omega)>0$. We will prove in Theorems 5.1 and 5.2 that, in this case, a dielectric photonic crystal slab supports only Helmholtz fields with $\Im(\omega)\le 0$ and that such a field decays as $|x|\to\infty$ if $\Im(\omega)=0$, and is unbounded if $\Im(\omega)<0$.

We add the two equations (4.4) to obtain

$$(P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma)\boldsymbol{\psi} = \boldsymbol{\phi}_i^{\epsilon_0} + \boldsymbol{\phi}_e^{\epsilon_1}. \tag{4.5}$$

Inserting the expressions

$$P_i^{\epsilon_0} = \tfrac{1}{2}(I + H^{\epsilon_0}), \qquad P_e^{\epsilon_1} = \tfrac{1}{2}(I - H^{\epsilon_1})$$

from Theorem 3.1, and letting $\boldsymbol{\phi} = \boldsymbol{\phi}_i^{\epsilon_0} + \boldsymbol{\phi}_e^{\epsilon_1}$ represent the total source field, we rewrite (4.5) as

$$\left[\frac{1}{2}\,(I+\Gamma) + \frac{1}{2}\,(H^{\epsilon_0} - H^{\epsilon_1}\Gamma)\right]\boldsymbol{\psi} = \boldsymbol{\phi}.$$

Finally, we insert the expression (3.3) for H^{ϵ_0} and H^{ϵ_1} to obtain the following expanded version of (4.5) (recall $\boldsymbol{\psi} = \boldsymbol{\psi}_{ext}$):

$$\psi_{\rm ext}(\hat{\mathbf{r}}) + \int_{\partial D} \left[\frac{\partial \left(G^{\epsilon_1} - G^{\epsilon_0}\right)(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\mathbf{r})} \psi_{\rm ext}(\mathbf{r}) \right.$$
$$\left. - (\nu G^{\epsilon_1} - G^{\epsilon_0})(\hat{\mathbf{r}} - \mathbf{r}) \frac{\partial \psi_{\rm ext}}{\partial n(\mathbf{r})}(\mathbf{r}) \right] ds(\mathbf{r}) \;=\; \phi(\hat{\mathbf{r}}), \tag{4.6a}$$

$$\frac{1+\nu}{2} \frac{\partial \psi_{\rm ext}}{\partial n(\hat{\mathbf{r}})}(\hat{\mathbf{r}}) + \int_{\partial D} \left[\frac{\partial^2 \left(G^{\epsilon_1} - G^{\epsilon_0}\right)(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\hat{\mathbf{r}}) \partial n(\mathbf{r})} \psi_{\rm ext}(\mathbf{r}) \right.$$
$$\left. - \frac{\partial \left(\nu G^{\epsilon_1} - G^{\epsilon_0}\right)(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\hat{\mathbf{r}})} \frac{\partial \psi_{\rm ext}}{\partial n(\mathbf{r})}(\mathbf{r}) \right] ds(\mathbf{r}) \;=\; \frac{\partial \phi}{\partial n(\hat{\mathbf{r}})}(\hat{\mathbf{r}}). \tag{4.6b}$$

This is a Fredholm equation of the second kind; cancellation in the difference of the Green's functions reduces the leading singularities of all the kernels to at most logarithmic, making the corresponding operators of Hilbert–Schmidt class in $L^2(\partial D) \times L^2(\partial D)$. Equation (4.6) can thus be solved for $\boldsymbol{\psi}$ in $L^2(\partial D) \times L^2(\partial D)$ whenever the nullspace is trivial. The solution $\boldsymbol{\psi}$ necessarily belongs to $H^1(\partial D) \times L^2(\partial D)$; indeed, (4.6) can be written as $\boldsymbol{\psi} = M\boldsymbol{\psi} + 2(I + \Gamma)^{-1}\boldsymbol{\phi}$, where M consists of kernels with at most logarithmic singularities, and is thus bounded from $L^2(\partial D) \times L^2(\partial D)$ to $H^1(\partial D) \times H^1(\partial D)$. In fact, M is bounded from $H^s(\partial D) \times H^s(\partial D)$ to $H^{s+1}(\partial D) \times H^{s+1}(\partial D)$, and so $\boldsymbol{\psi}$ is C^∞ if $\boldsymbol{\phi} = 0$, i.e., if $\boldsymbol{\psi}$ is a nullfield. In summary, if the source field $\boldsymbol{\phi}$ belongs to $H^1(\partial D) \times L^2(\partial D)$, then so does the field $\boldsymbol{\psi}$.

Boundary integral equations of the second kind for EM fields have also been derived by Müller [11], Colton and Kress [12], [13], and Nédélec [10].

THEOREM 4.3. *If the system*

$$P_e^{\epsilon_0} \boldsymbol{f} = 0, \qquad P_i^{\epsilon_1} \boldsymbol{f} = 0$$

has only the trivial solution, then the scattering problem (4.4) *is equivalent to the Fredholm system* (4.5) *(equivalently,* (4.6)*).*

Proof. Given (4.5), we may write

$$P_i^{\epsilon_0} \boldsymbol{\psi} = \boldsymbol{\phi}_i^{\epsilon_0} + \boldsymbol{f}, \qquad P_e^{\epsilon_1} \Gamma \boldsymbol{\psi} = \boldsymbol{\phi}_e^{\epsilon_1} - \boldsymbol{f}.$$

Applying $P_e^{\epsilon_0}$ to the first relation and $P_i^{\epsilon_1}$ to the second relation, we obtain

$$P_e^{\epsilon_0} \boldsymbol{f} = 0, \qquad P_i^{\epsilon_1} \boldsymbol{f} = 0.$$

These equations imply $\boldsymbol{f} = 0$ by the hypothesis of the theorem. ∎

A comparison of the conditions of the theorem with (4.4) allows us to reformulate the theorem in a more physical way, as follows.

THEOREM 4.4 (reformulated Theorem (4.3)). *If the inverse dielectric structure (physics terminology meaning the original geometry with the two dielectric materials interchanged) does not support an electrically polarized field, then our scattering problem* (4.4) *is equivalent to the Fredholm system* (4.5) *(equivalently,* (4.6)*).*

5. Resonant frequencies and bound states. We have seen that the dielectric structure supports a nonzero source-free electromagnetic field ψ at (β,ω) if and only if the field satisfies

$$P_i^{\epsilon_0} \boldsymbol{\psi} = 0 \quad \text{and} \quad P_e^{\epsilon_1} \Gamma \boldsymbol{\psi} = 0, \tag{5.1}$$

where $\boldsymbol{\psi}(\mathbf{r}) = \left(\lim_{h\to 0}\psi(\mathbf{r}+hn(\mathbf{r})), \lim_{h\to 0}\partial_n\psi(\mathbf{r}+hn(\mathbf{r}))\right)^t$ on ∂D. This implies that

$$(P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma)\boldsymbol{\psi} = 0, \tag{5.2}$$

so that $(P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma)$ has a nontrivial nullspace at the resonant frequency ω for wave number β.

We now present a theorem that provides conditions for the existence of resonance frequencies.

THEOREM 5.1. *Let the frequency ω and a real value of β be given, and assume that $(m+\beta)^2 - \epsilon\omega^2 \neq 0$ for all integers m. If $P_i^{\epsilon_0}+P_e^{\epsilon_1}\Gamma$ has a nontrivial nullspace, then at least one of the following holds:*

1. *ω is a resonant frequency for the structure, with interior dielectric coefficient ϵ_1 and exterior coefficient ϵ_0 for the wave number β, according to whether $\nu = 1$ or $\nu = \epsilon_1/\epsilon_0$ in Γ, or*
2. *ω is a resonant frequency for the inverse structure, with ϵ_1 and ϵ_0 switched, for the wave number β.*

If ω^2 is real, then the corresponding source-free Helmholtz field ψ in $\mathcal{E}(\beta,\omega,\epsilon_0)$ or $\mathcal{E}(\beta,\omega,\epsilon_1)$ decays to zero as $|x|\to\infty$ and is therefore an x-localized field (a bound state in the strip $\mathcal{S}$). Otherwise, $\Im(\omega^2) < 0$ and ψ becomes unbounded as $|x|\to\infty$.

Remarks. 1. In our numerical studies, we will be interested only in the case in which $\Re(\omega) > 0$ and $\Im(\omega)$ is small and negative. Assuming $\Re(\omega) > 0$, the condition $\Im(\omega^2) < 0$ is equivalent to $\Im(\omega) < 0$.

2. Suppose that the pair (β_0,ω_0) with $\omega_0 > 0$ admits a bound state and that the Green's function has no propagating modes (see Figure 2.1). Then, for (β,ω) in a neighborhood of (β_0,ω_0), the Green's function has only decaying modes, so that all functions in $\mathcal{E}(\beta,\omega,\epsilon_0)$ are decaying. This implies that, in a vicinity of β_0 (we always assume β is real), a relation $\omega = W(\beta)$ describing resonant frequencies must be real-valued and must therefore be a dispersion relation for bound states.

Proof. We assume that (5.2) holds for some nonzero $\boldsymbol{\psi}$. Theorem 4.3, with both source fields in (4.4) taken to be zero, implies that equations (5.1) hold (giving statement (1) in Theorem 5.1) *or* that there exists a nonzero $\boldsymbol{f}$ such that $P_e^{\epsilon_0}\boldsymbol{f} = 0$ and $P_i^{\epsilon_1}\boldsymbol{f} = 0$ (giving statement (2) in Theorem 5.1).

We defer the proof of the condition on ω^2 and the behavior of the fields as $|x|\to\infty$ to the proof of Theorem 5.2. ∎

THEOREM 5.2. *Suppose that $\psi \in \mathcal{E}(\beta,\omega,\epsilon_0)$ is pseudoperiodic in y, is not identically zero, and satisfies $\nabla^2\psi + \epsilon\omega^2\psi = 0$ in $\mathcal{S}\setminus\partial D$ (where $\epsilon = \epsilon_1$ in D and ϵ_0 otherwise) and the matching conditions (4.2) on ∂D. Then $\Im(\omega^2) \le 0$. In addition, $|\psi|\to 0$ as $|x|\to\infty$ if and only if ω^2 is real-valued.*

Proof. Let T denote the finite strip $\{(x,y) : -x_0 \le x \le x_0, 0 \le y \le 2\pi\}$, where $x_0 > x_* > 0$ and x_* is given in Definition 2.2, and let ∂T be its boundary with outward-pointing normal vector n. We also take n pointing outward on ∂D. The divergence theorem gives

$$\int_{\partial T}\overline{\psi}\partial_n\psi ds + \int_{\partial D}\left(\overline{\psi}_{\rm int}\partial_n\psi_{\rm int} - \overline{\psi}_{\rm ext}\partial_n\psi_{\rm ext}\right)ds = \iint_T\left(\nabla\overline{\psi}\cdot\nabla\psi + \overline{\psi}\nabla^2\psi\right)dA.$$

Using the relation $\overline{\psi}\partial_n\psi = \overline{\tilde{\psi}}\partial_n\tilde{\psi} + i\beta n_y|\tilde{\psi}|^2$ (n_y is the y-component of the normal vector n), we see that the integrals over the top and bottom parts of ∂T cancel, and the integral over ∂T becomes an integral over $\Gamma_L\cup\Gamma_R$, where Γ_L and Γ_R are the left

and right sides of ∂T. On the right-hand side, we use the Helmholtz equation. We now have

(5.3)
$$\int_{\Gamma_L\cup\Gamma_R} \overline{\psi}\partial_n\psi ds + \int_{\partial D}\left(\overline{\psi}_{\rm int}\partial_n\psi_{\rm int} - \overline{\psi}_{\rm ext}\partial_n\psi_{\rm ext}\right) ds = \iint_T \left(|\nabla\psi|^2 - \epsilon\omega^2|\psi|^2\right) dA.$$

Using the conjugate equation for the interior of D, $\nabla^2\overline{\psi}_{\rm int}+\epsilon_1\overline{\omega}^2\overline{\psi}_{\rm int}=0$, we compute

$$\begin{aligned} -\iint_D |\psi_{\rm int}|^2(\epsilon_1\omega^2-\epsilon_1\overline{\omega}^2)dA &= -\iint_D \left(\overline{\psi}_{\rm int}\epsilon_1\omega^2\psi_{\rm int} - \psi_{\rm int}\epsilon_1\overline{\omega}^2\overline{\psi}_{\rm int}\right) dA \\ &= \iint_D \left(\overline{\psi}_{\rm int}\nabla^2\psi_{\rm int} - \psi_{\rm int}\nabla^2\overline{\psi}_{\rm int}\right) dA = \int_{\partial D}\left(\overline{\psi}_{\rm int}\partial_n\psi_{\rm int} - \psi_{\rm int}\partial_n\overline{\psi}_{\rm int}\right) ds. \end{aligned}$$

Therefore,

$$\Im\int_{\partial D}\overline{\psi}_{\rm int}\partial_n\psi_{\rm int}ds = -\epsilon_1\Im(\omega^2)\iint_D|\psi_{\rm int}|^2dA.$$

Using this and the matching conditions $\psi_{\rm int}=\psi_{\rm ext}$ and $\partial_n\psi_{\rm int}=\nu\partial_n\psi_{\rm ext}$ on ∂D, we can write the imaginary part of (5.3):

$$\Im\int_{\Gamma_L\cup\Gamma_R}\overline{\psi}\partial_n\psi ds \;-\; \epsilon_1(1-\nu^{-1})\Im(\omega^2)\iint_D|\psi|^2dA \;=\; -\Im(\omega^2)\iint_T\epsilon|\psi|^2dA. \tag{5.4}$$

By Definition 2.2, since $\psi\in\mathcal{E}(\beta,\omega,\epsilon_0)$, there exist complex numbers $A_m^{\pm}$ such that

$$\psi(x,y) = \sum_{m=-\infty}^{\infty} A_m^{\pm}\exp\left(\mu_m|x| + i(m+\beta)y\right) \quad \text{for} \quad \pm x > x_0.$$

Straightforward computation yields

$$\int_{\Gamma_L\cup\Gamma_R}\overline{\psi}\partial_n\psi ds \;=\; 2\pi\sum_{m=-\infty}^{\infty}\mu_m\left(|A_m^-|^2+|A_m^+|^2\right)e^{2\Re(\mu_m)|x_0|},$$

and, after splitting the right-hand side of (5.4) into an interior and an exterior integral, we obtain

$$\begin{aligned} &2\pi\sum_{m=-\infty}^{\infty}\Im(\mu_m)\left(|A_m^-|^2+|A_m^+|^2\right)e^{2\Re(\mu_m)|x_0|} \\ &\qquad = -\Im(\omega^2)\left(\epsilon_1\nu^{-1}\iint_D|\psi|^2dA + \epsilon_0\iint_{T\setminus D}|\psi|^2dA\right). \end{aligned} \tag{5.5}$$

If $\Im(\omega^2)>0$, all modes are decaying in x ($\Re(\mu_m)<0$ for all m), and we obtain a contradiction by letting x_0 tend to ∞; therefore, $\Im(\omega^2)\le 0$. If $\Im(\omega^2)=0$, then $\Im(\mu_m)>0$ for all propagating modes and $\Im(\mu_m)=0$ for all decaying modes; therefore, $A_m^{\pm}=0$ for all propagating modes, so that $|\psi|\to 0$ as $|x|\to\infty$. Conversely, if $|\psi|\to 0$ as $|x|\to\infty$, then $A_m^{\pm}=0$ for all nondecaying modes (those for which $\Re(\mu_m)\ge 0$), and thus the left-hand side of 5.5 decays exponentially as $x_0\to\infty$. Letting x_0 tend to ∞ shows that $\Im(\omega^2)=0$. ∎

Remarks. 1. The quantity $\Im\int_\Gamma\overline{\psi}\partial_n\psi\,ds$ appearing in the proof of Theorem 5.2 is the time-averaged energy flow carried by ψ through Γ.

2. If $\Im(\omega^2)<0$, then ψ does not decay as $|x|\to\infty$, and thus by the definition of $\mathcal{E}(\beta,\omega,\epsilon)$, ψ becomes unbounded as $|x|\to\infty$, and this completes the proof of Theorem 5.1.

6. Dispersion relations. We define a *dispersion relation* for a photonic crystal slab to be a multivalued function $\omega = W(\beta)$ describing pairs (β, ω) for which ω is a resonant frequency for wave number β. This means that the pair (5.1) is satisfied for a nonzero field $\boldsymbol{\psi}(\mathbf{r}) = \left(\lim_{h\to 0} \psi(\mathbf{r} + hn(\mathbf{r})), \lim_{h\to 0} \partial_n \psi(\mathbf{r} + hn(\mathbf{r}))\right)^t$ on ∂D, where ψ is a pseudoperiodic source-free Helmholtz field in the class $\mathcal{E}(\beta, \omega, \epsilon_0)$. If we are able to eliminate the second alternative in Theorem 5.1, then the single equation (5.2) is sufficient for defining a dispersion relation, as it would then imply the pair (5.1). In the numerical examples below, we are able computationally to eliminate the second alternative.

Because our operator is of the Hilbert–Schmidt class from $L^2(\partial D) \times L^2(\partial D)$, its determinant is defined, and it depends analytically on β and ω. Thus, a *necessary* condition for the pair (β, ω) to support a source-free field in the given crystal is

$$D(\beta, \omega) := \det(P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma) = 0. \tag{6.1}$$

The dispersion relation is therefore given by branches of $D(\beta, \omega) = 0$. Whether this condition is also *sufficient* depends on the inverse dielectric structure. Indeed, we know from Theorem 5.1 that if the inverse structure does not support an electrically polarized source-free field, then (6.1) does define a dispersion relation for fields in the original structure.

In practice, we obtain dispersion relations by computing the curves $\lambda(\beta, \omega) = 0$ numerically, where λ is an eigenvalue of $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$. Suppose that zero is a simple eigenvalue at the pair (β_0, ω_0). Then the smallest eigenvalue λ is an analytic function of β and ω in a neighborhood of (β_0, ω_0), say $\lambda = \lambda(\beta, \omega)$. Suppose also that $\lambda(\beta_0, \omega) \not\equiv 0$ near ω_0. By the Weierstraß preparation theorem, there exists an integer $n \geq 1$ such that

$$\lambda(\beta, \omega) = h(\beta, \omega)(\omega^n + W_{n-1}(\beta)\omega^{n-1} + \cdots + W_1(\beta)\omega + W_0(\beta)) \tag{6.2}$$

near (β_0, ω_0), where h and W_i $(i = 0, \ldots, n-1)$ are analytic functions and $h \neq 0$ near (β_0, ω_0). Thus, $\lambda = 0$ is equivalent to $\omega^n + W_{n-1}(\beta)\omega^{n-1} + \cdots + W_1(\beta)\omega + W_0(\beta) = 0$. Let us consider the case in which $n = 1$ (this is when $\partial\lambda/\partial\omega \neq 0$ near (β_0, ω_0)). Then we have a relation

$$\omega = W(\beta)$$

that describes the locus of (β, ω)-pairs for which $\lambda = 0$. For real values of β near β_0, the curve $\omega = W(\beta)$ in the complex ω-plane gives a dispersion relation; it is periodic in β with period 1.

We made two assumptions in the preceding paragraph: that zero is a *simple* eigenvalue at (β_0, ω_0), and that $\partial\lambda/\partial\omega \neq 0$ there. Numerical calculations show that both assumptions are true generically, giving rise to dispersion relations for simple eigenvalues. When two branches cross, as in Figure 7.3(1a) and (2a) below, we see an eigenvalue of multiplicity 2. We have not encountered a situation in which there is a simple eigenvalue at some point (β_0, ω_0) and $\partial\lambda/\partial\omega = 0$ there, that is, $\partial^k\lambda/\partial\omega^k = 0$ for $k < n$ and $\partial^n\lambda/\partial\omega^n \neq 0$ for some $n > 1$ in (6.2). In this situation, (6.2) shows that there would exist a dispersion relation defined by an equation that is algebraic in ω and may have several branches emanating from (β_0, ω_0).

If $\omega = W(\beta)$ lies on the real ω-axis over a range of β-values, then we have a dispersion relation for x-localized Helmholtz fields ψ in the crystal (bound states in the strip $\mathcal{S}$). The complex time-dependent electric or magnetic fields associated with

ψ are $\psi(x,y)e^{-i\omega t} = \tilde{\psi}(x,y)e^{i(\beta y-\omega t)}$ (with $\tilde{\psi}$ periodic in y), which are Bloch waves traveling along the photonic crystal slab. If $\omega_0 = W(\beta_0)$ is real but the dispersion relation goes into the lower-half ω-plane for $\beta \neq \beta_0$, then there exists a bound state just for the isolated pair (β_0, ω_0), and nearby pairs $(\beta, W(\beta))$ are complex resonant frequencies. We demonstrate numerically below that both situations do occur.

One of the main phenomena observed in this study is that *complex resonant frequencies are linked to resonant scattering behavior and transmission anomalies at nearby* real *frequencies.* See also [5].

7. Numerical studies: Bound states, surface waves, and resonances. In this section we present three examples that illustrate the connections between complex dispersion relations, bound states and resonant frequencies, transmission anomalies, and resonant behavior of real frequencies. In particular, we calculate a dispersion relation for surface waves at bandgap frequencies on a thick structure approximating a semi-infinite crystal, and we provide a mathematical context for understanding resonant phenomena produced by a channel defect in a crystal slab.

We calculate the dispersion relations numerically as follows. We first search for a pair (β_0, ω_0) at which $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$ has an eigenvalue that is practically zero: $\lambda(\beta_0, \omega_0) \approx 0$. Then we increment β to β_1 and search in a complex vicinity of ω_0 for a value ω_1 such that $\lambda(\beta_1, \omega_1) \approx 0$. We continue to increment β, and in this way trace out a curve $\omega(\beta)$ represented by the computed points (β_n, ω_n) such that $\lambda(\beta_n, \omega_n) \approx 0$. To find the value ω_n, we simply compute the minimum of the smallest eigenvalue $\lambda(\beta, \omega)$ of $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$ as ω varies over a grid about ω_{n-1}, keeping β fixed at β_n, and then refine the search if necessary. We intend to develop a more efficient gradient search method for future investigations. In the examples in subsections 7.1 and 7.2, we find the initial pair (β_0, ω_0) by taking $\beta_0 = 0$ and computing the minimum eigenvalue of $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$, using MATLAB, on a grid of real values of ω in the interval $(0, 1)$. An initial bound state was easy to find. In the example of subsection 7.3, we knew to search in the vicinity of a spike in the transmission graph that we had computed in [2].

To show that $\lambda(\beta, \omega)$ actually achieves a value of zero, it suffices to fix β and compute (numerically) a positive winding number of λ as an analytic function of ω about some small closed curve in the complex ω-plane. We perform this verification at selected points on the dispersion relations. We also check numerically that the alternative (part (2)) in Theorem 5.1 does not hold.

To compute the eigenvalues of the boundary-integral operator $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$, we discretize the integral system using quadratic basis elements for the fields and point-sampling of the equations. Complete details of these calculations are presented in [2]. Once we have obtained a numerical solution to $(P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma)\boldsymbol{\psi} = \boldsymbol{\phi}$, we compute the scattering and bound ($\phi = 0$) states using Green's identities (3.4) and (3.5).

In all three examples, we study electrically polarized fields with $\epsilon_0 = 1$ and $\epsilon_1 = 12$.

In the figures, the fields in the crystals are represented by contour plots of their magnitudes. White represents the maximal amplitude, and black represents an amplitude of zero. One y-period is shown, with the x-direction truncated outside the support of the crystal slab.

7.1. A single string of rods. (Figure 7.1.) Our first example is a good illustration of the connection between dispersion relations, bound states, and resonant scattering phenomena. The period of our dielectric structure consists of a single rod in air, so that the crystal slab degenerates into a string of rods running in the y-direction.

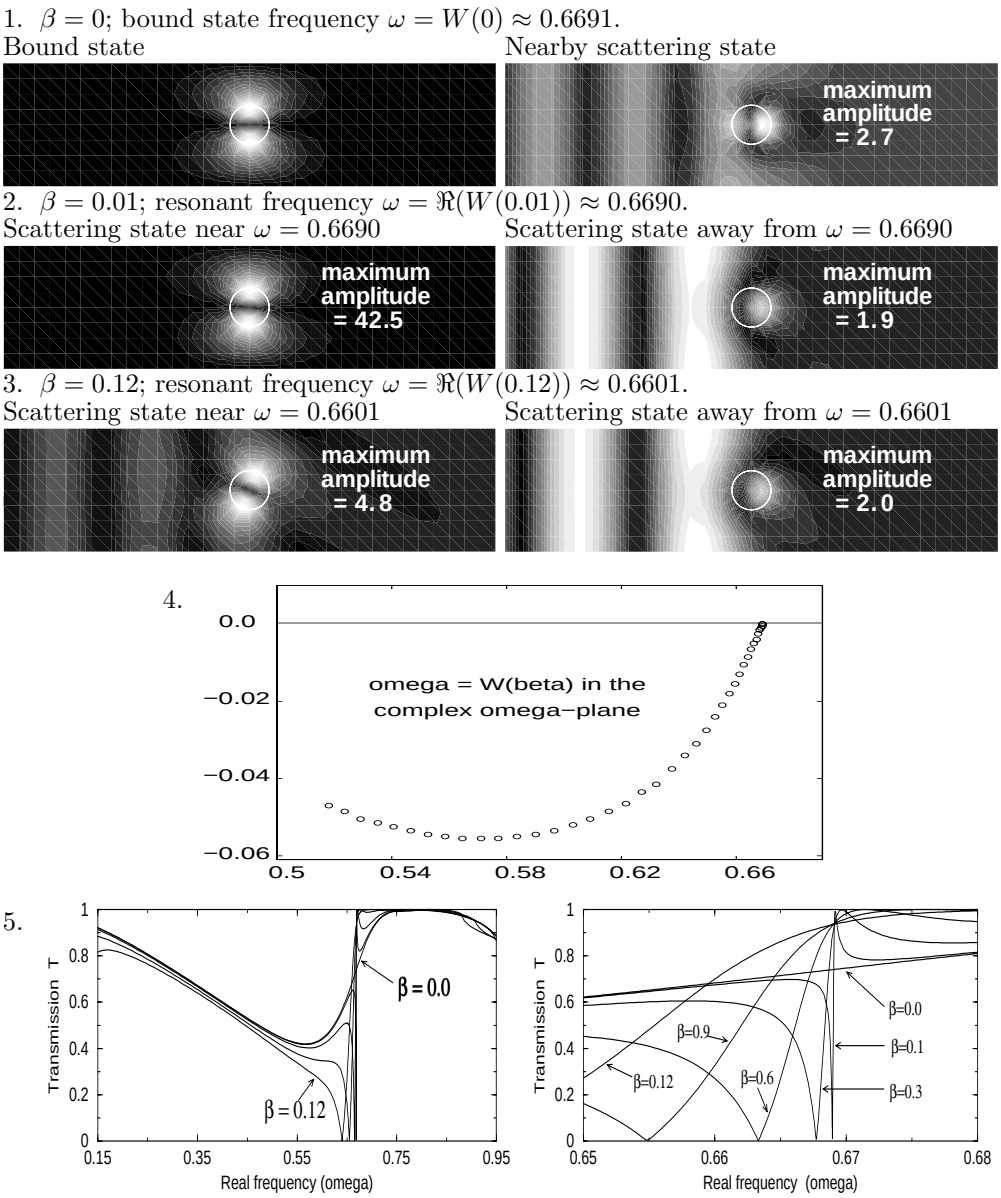

FIG. 7.1. *In the contour plots, one period in y of the crystal is shown, with the magnitude of the electrically polarized fields plotted.* 1. *There is a bound state at* $(\beta = 0, \omega = W(0) \approx 0.6691)$. *There is no unusually high amplification of an incident plane-wave source (of amplitude* 1*) for* $\beta = 0$ *at frequencies* ω *near the bound-state frequency.* 2,3. *When* $\Im(W(\beta)) < 0$, *incident plane-wave sources are amplified in the rod at frequencies near the real part of* $W(\beta)$. *A smaller imaginary part corresponds to greater amplification. The field structure at resonant frequencies is similar to that of the bound state.* 4. *The dispersion relation* $W(\beta)$ *plotted in the complex* ω *plane for real values of beta from* $\beta = 0$ *to* $\beta = 0.38$. 5. *Spikes in the transmission coefficient near* $\omega = \Re(W(\beta))$ *for* $\beta > 0$, *where* $\Im(W(\beta)) < 0$.

We find numerically a y-periodic (this means $\beta = 0$) bound state at $\omega \approx 0.6691$. This is a standing wave that exists in the absence of any sources. However, as β moves away from zero, the bound state disappears and the dispersion relation $\omega = W(\beta)$ enters the lower-half complex ω-plane (Figure 7.1(4)). In place of a bound state, we find instead resonant scattering states at *real* frequencies near the real part $\Re(W(\beta))$ of the complex resonant frequency on the dispersion relation. These states are sustained by plane-wave source fields that are amplified as they experience resonant scattering within the dielectric structure. Coinciding with these large fields are anomalies (spikes) in the transmission coefficient[2] $T(\beta, \omega)$ for real values of ω near $\Re(W(\beta))$, for a fixed value of β (see Figure 7.1(5)). These spikes consist of a drop to 0% transmission ($T=0$) to the left of the frequency of the periodic bound state that exists at $\beta = 0$, followed by a sharp increase to 100% transmission ($T = 1$) to the right. As $|\beta|$ decreases to zero, the width of the spike decreases and the resonant amplification of the scattering fields increases. The phenomena become more and more localized about the bound-state frequency. At $\beta = 0$, the transmission anomaly and resonant behavior disappear, and we have in their place the bound state.

We find that, for $\omega_0 \approx 0.6691$, $T(\beta, \omega_0) \approx 0.935$ for values of β near but not equal to zero (see Figure 7.1(5)). However, continuing our calculation of the curve $T(0, \omega)$ through $\omega = \omega_0$ gives $T(0, \omega_0) \approx 0.739$. Thus we demonstrate numerically that $\lim_{\beta \to 0} T(\beta, \omega_0) \neq \lim_{\omega \to \omega_0} T(0, \omega)$, so that we cannot define the transmission coefficient continuously at $(0, \omega_0)$. This observation strengthens our belief that there is a bound state at $(0, \omega_0)$, that is, that $\Im(W(0))$ is indeed *exactly* zero.

From Figure 7.1(4), the dispersion relation evidently has the form

$$\omega = \omega_0 + a(\beta)\beta^2,$$

where a is analytic and $a(0) \neq 0$. ($W(\beta)$ is symmetric about $\beta = 0$, as the Green's functions at $\pm\beta$ have the same set of modes, and the structure is symmetric in y.)

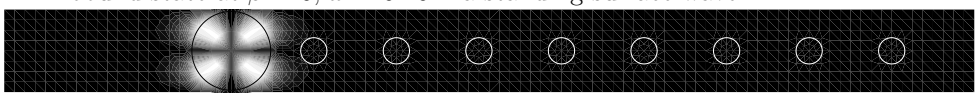
7.2. Surface waves. (Figure 7.2.) We investigate waves on the surface of a semi-infinite photonic crystal. We seek waves at the interface between the left half-plane containing air and the right half-plane filled with a square lattice of circular rods. If we consider frequencies that cannot propagate through the infinite crystal, or bandgap frequencies, it is reasonable to approximate the semi-infinite crystal by a finite slab several rods thick (truncated in the x-direction but still periodic in y). To capture surface waves at bandgap frequencies, we place a defect on the left surface of the slab by making the first rod much larger than the others.

There appears to be a periodic ($\beta = 0$) bound state at $\omega \approx 0.401$, as the smallest eigenvalue of $P_i^{\epsilon_0} + P_e^{\epsilon_1}\Gamma$ is practically zero there. The field is localized at the defective surface of the slab (see Figure 7.2(1))—it is a standing surface wave.

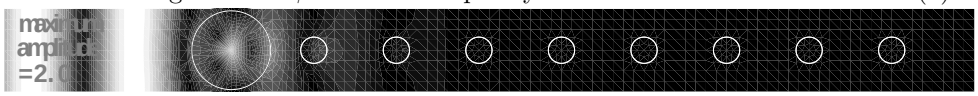
As β moves away from zero, the surface wave disappears, and we obtain a dispersion relation $\omega = W(\beta)$ with a very small negative imaginary part. At about $\beta \approx 0.345$, however, the relation enters a regime in which $|W(\beta)| < \min_{m \in \mathbb{Z}}(|\beta + m|)$, which is the scenario in which *all* modes of the Green's function decay in $|x|$ and the exterior medium admits no traveling waves. We deduce from Theorem 5.1 (or Theorem 5.2) that this part of the dispersion relation is necessarily real and is therefore a

[2]Our transmission coefficient is the square root of the ratio of the energy transmitted through the slab on the right to the energy of a plane-wave source field $\exp(i\sqrt{\epsilon_0\omega^2 - (m+\beta)^2}\,x + i(m+\beta)y)$ incident upon the slab from the left. Details of how we calculate the transmission coefficient are given in [2].

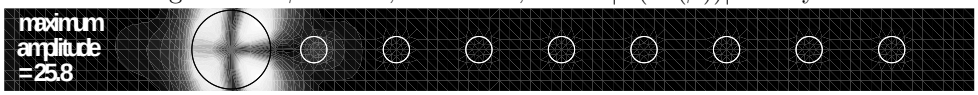
1. A bound state at $\beta = 0$, $\omega \approx 0.401$: a standing surface wave.



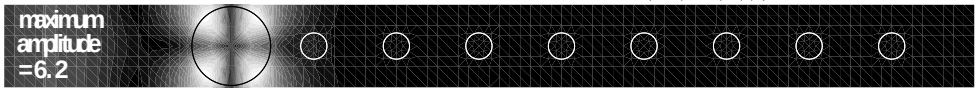
2. A scattering state for $\beta = 0$ at a frequency near that of the bound state in (1).



3. A scattering state at $\beta = 0.23$, $\omega \approx 0.368$, where $|\Im(W(\beta))|$ is very small.



4. A scattering state at $\beta = 0.28$, $\omega \approx 0.358$, near $\max |\Im(W(\beta))|$.



5. A bound state at $\beta = 0.40$, $\omega \approx 0.335$: a traveling surface wave.

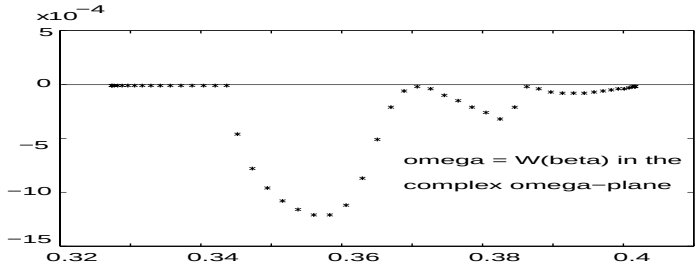

FIG. 7.2. *A crystal slab with a defect on the left surface, where one rod is bigger than the rest. In the contour plots, one period in y of the crystal is shown, with the magnitude of the electrically polarized fields plotted.* 1,2. *There is a periodic ($\beta = 0$) bound state, which is a standing surface wave localized in the large rod at the surface of the crystal slab. At frequencies near that of the surface wave, incident plane-wave sources are not amplified in the rod.* 3,4. *When $\Im(W(\beta)) < 0$, incident plane-wave sources (with amplitude 1) at frequencies near $\Re(W(\beta))$ resonate in the first rod.* 5. *A bound state at parameter values on the dispersion relation, where $\omega = W(\beta)$ is necessarily real and the strip admits no scattering (extended) states.* 6. *$\Re(W(\beta))$ plotted against β. $\Im(W(\beta)) = 0$ when $\Re(W(\beta)) < |\beta|$ ($0.345 < |\beta| < 0.5$).* 7. *$\omega = W(\beta)$ plotted in the complex ω-plane.*

dispersion relation for x-localized fields. In fact, in this regime, there are no scattering (extended) states in the strip (see Remark 2 following Theorem 5.1).

We therefore demonstrate the existence of a dispersion relation for waves traveling along the surface of a photonic crystal slab. Our choice of eight rods to approximate the semi-infinite crystal appears to be sufficient: Increasing the number of rods results in no appreciable difference in the calculated curve. Thus, we are led to believe that the dispersion relation for the semi-infinite crystal exists and that the dispersion relation for the slab is a good approximation.

As in the case of the single string of rods in the previous example, we see again how the complex part of the dispersion relation, which is very close to the real axis, affects the scattering states at nearby real frequencies. We do not find anomalies in the transmission as we did in that example; however, we believe that they are there but are too sharp to be detected numerically because of the small size of the imaginary part of the dispersion relation and the thickness of the slab.

7.3. A channel defect. (Figure 7.3.) In [2], we studied the effect that a periodic channel through a photonic crystal slab has on the transmission coefficient and the structure of the scattering states. Our intention was to study resonant behavior at bandgap frequencies and modes propagating through the channel; however, we also found intriguing sharp transmission spikes and resonant scattering fields in near–full-transmission frequency regions. The phenomena are similar in behavior to those in our previous two examples, and a similar analysis provides us with a better mathematical understanding of them.

The (β,ω) pairs at which resonant behavior and transmission anomalies occur for the crystal with a periodic channel are described by a dispersion relation $\omega = W(\beta)$, which we calculate numerically.[3] We demonstrate in [2] that both phenomena disappear as the width of the channel decreases and the slab returns to its perfect structure. In the present study, we find that, in place of resonant scattering states, the perfect slab admits bound states, also described by a dispersion relation.

Our numerical calculations give us dispersion relations that lie practically on the real ω-axis. However, they may have a small negative imaginary part that we cannot resolve numerically. Based on our findings in the previous two examples, we conjecture that the relation is identically real for the perfect slab (there is no resonant amplification, and there are no transmission spikes) and that it has a very small negative imaginary part for the slab with a periodic channel (there are high-amplitude resonances and very sharp transmission spikes).

The structure of the resonant fields near $\omega = \Re(W(\beta))$ when $\Im(W(\beta))$ is small resembles the field of a nearby bound state, if such a bound state exists. See Figure 7.3(1) and (3), which shows the y-directional structure of a bound state and a resonant scattering state. A typical scattering state at small values of β exhibits the structure of an x-directional interference pattern, a point we discuss in [2].

In summary, we have a plausible explanation for the channel-induced resonant behavior that we observed in [2]: There is a dispersion relation $\omega = W(\beta)$ for bound states traveling along the perfect crystal slab. When a periodic channel is introduced, the new (perturbed) relation $\omega = W(\beta)$ gives resonant frequencies with a small imaginary part. These are responsible for the observed buildup of large fields in the slab and for the transmission anomaly near $\omega = \Re(W(\beta))$. In the limit of zero imaginary

[3] In [2], we scaled the frequency in this example by 1/6 to compare with the scale of the finer period of one rod. We did not make that scaling here.

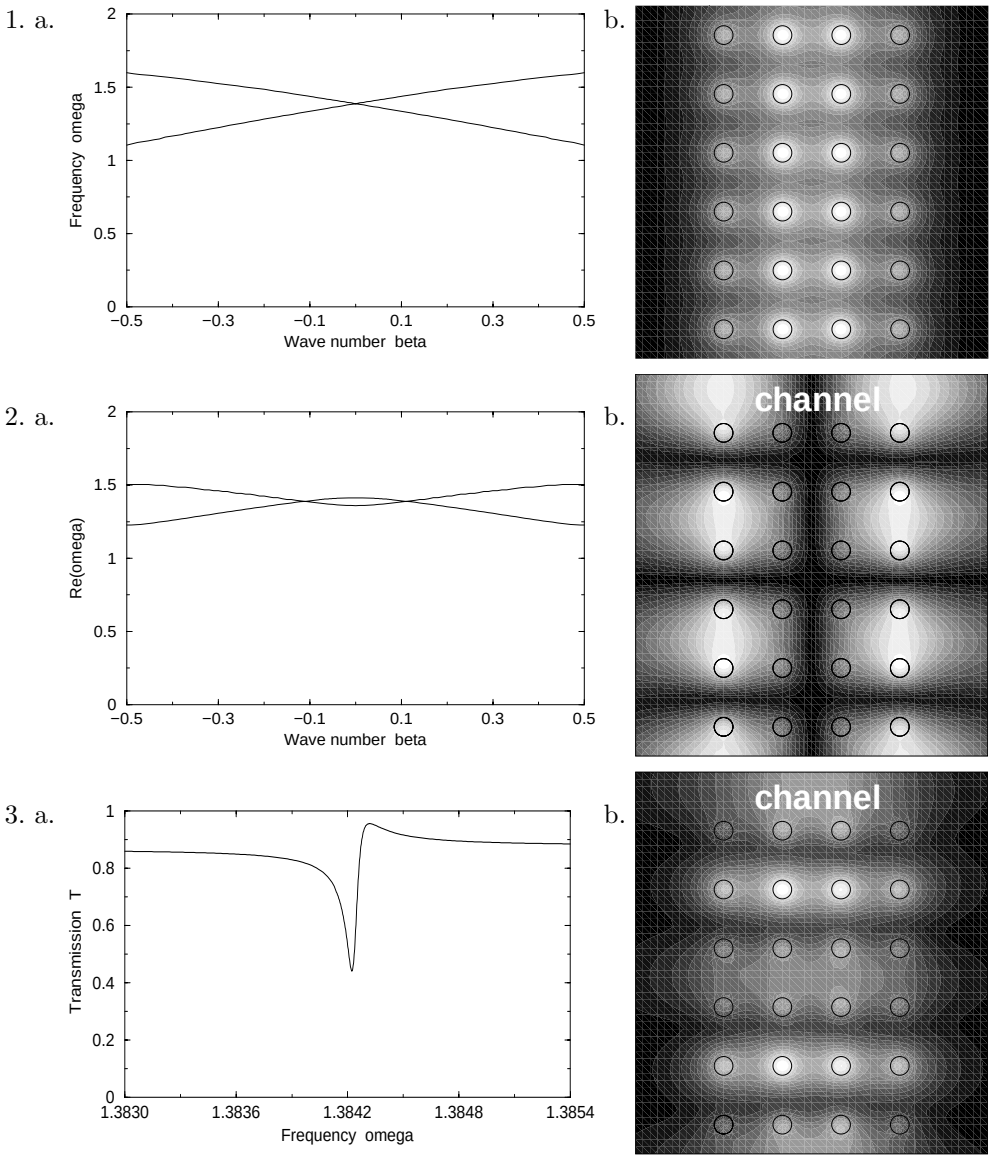

FIG. 7.3. *In the contour plots, a period in y of the crystal is shown, and the strip is truncated in the x-direction. The magnitude of the electrically polarized fields is plotted.* 1.a. *Branches of the dispersion relation for a perfect square-lattice crystal four rods thick.* 1.b. *The bound state at* $\beta = 0.1$ *and* $\omega \approx 1.434$. 2.a. *Branches of the real part of the dispersion relation for the crystal with a periodic channel containing an extra half-period of space after every six rows of rods.* 2.b. *A resonant scattering state at* $\beta = 0.5$ *and* $\omega \approx 1.224$. 3.a. *An anomaly in the transmission coefficient for* $\beta = 0.1$. 3.b. *A resonant scattering state at* $\beta = 0.1$ *and* $\omega \approx 1.3842$ *(slightly to the left of where the two branches of the dispersion relation cross, on the lower branch). The amplitude of the field in the crystal reaches about* 49 *times the amplitude of the incident field.*

part, the anomaly occurs at a single point (the point of the bound state) and is not observed through the numerical scattering experiment.

The numerical evidence indicates that the slab with a periodic channel supports resonant frequencies that converge to bound state frequencies as the channel closes up. A similar phenomenon is known for Helmholtz resonators, in which resonant frequencies of a cavity with an opening converge to the bound state frequencies of the closed cavity as the opening disappears (Beale [6]).

8. Appendix. Let D be a domain whose boundary $C = \partial D$ is a closed curve of class C^2 with arclength parameterization $\gamma(t)$, $t \in [a, b]$, and outward-pointing normal vector $n(t)$ at $\gamma(t)$. For sufficiently small values of $\rho > 0$, the function $\gamma_\rho(t) = \gamma(t) - \rho n(t)$ parameterizes a C^1 closed curve C_ρ contained in the interior of D.

The Green's kernel $G(\mathbf{r})$ (or its derivatives) takes a function ϕ on C to a function ψ_ρ on C_ρ by

$$\psi_\rho(\mathbf{r}) = \int_C G(\hat{\mathbf{r}} - \mathbf{r})\phi(\mathbf{r}) ds(\mathbf{r}),$$

where $\hat{\mathbf{r}} \in C_\rho$. This map can be realized as a map taking a function on $[a, b]$ to another by recycling notation and writing

$$\psi_\rho(t) = \int_a^b G(\gamma_\rho(t) - \gamma(s))\phi(s)\, ds.$$

We make the identifications $H^1(C) \equiv H^1([a, b])$ and $L^2(C) \equiv L^2([a, b])$.

1. The singular part of the integral kernel $G(\gamma(t) - \gamma(s))$ is $\log|t - s|$, and the singular part of its derivative, $d/dt \log|t-s|$, which has the Hilbert-transform singularity, is a principal-value integral. Both are bounded operators from L^2 to L^2, so $G(\gamma(t) - \gamma(s))$ is a bounded operator from L^2 to H^1. $G(\gamma_\rho(t) - \gamma(s))$ and $d/dt\, G(\gamma_\rho(t) - \gamma(s))$ are regularizations of these singular kernels, so $G(\gamma_\rho(t) - \gamma(s))$ converges to $G(\gamma(t) - \gamma(s))$ as $\rho \to 0$ as bounded operators from L^2 to H^1.
2. By the theory of the double-layer potential and the Plemelj formula, the integral kernels

$$\frac{\partial G(\gamma_\rho(t) - \gamma(s))}{\partial n(\gamma(s))}, \qquad -\frac{\partial G(\gamma_\rho(t) - \gamma(s))}{\partial n(\gamma(t))},$$

as applied to L^2, are a regularization of their limiting form as $\rho \to 0$, which is $1/2$ the identity operator plus a weakly singular integral kernel.
3. Using the identity

$$\frac{\partial^2 G(\hat{\mathbf{r}} - \mathbf{r})}{\partial n(\hat{\mathbf{r}})\partial n(\mathbf{r})} + \frac{\partial^2 G(\hat{\mathbf{r}} - \mathbf{r})}{\partial t(\hat{\mathbf{r}})\partial t(\mathbf{r})} = -n(\hat{\mathbf{r}}) \cdot n(\mathbf{r})(\partial_x^2 + \partial_y^2) G(\hat{\mathbf{r}} - \mathbf{r})$$

and the Helmholtz equation

$$(\partial_x^2 + \partial_y^2) G(\hat{\mathbf{r}} - \mathbf{r}) + \epsilon\omega^2 G(\hat{\mathbf{r}} - \mathbf{r}) = 0 \quad \text{for} \quad \hat{\mathbf{r}} \neq \mathbf{r},$$

we can rewrite the kernel $\partial^2 G(\hat{\mathbf{r}} - \mathbf{r})/\partial n(\hat{\mathbf{r}})\partial n(\mathbf{r})$ for $\hat{\mathbf{r}} \notin \partial D$, applied to a

function $\xi \in H^1$:

$$\int_{\partial D} \frac{\partial^2 G(\hat{\mathbf{r}}-\mathbf{r})}{\partial n(\hat{\mathbf{r}})\partial n(\mathbf{r})}\xi(\mathbf{r})\,ds(\mathbf{r}) = \int_{\partial D}\left(n(\hat{\mathbf{r}})\cdot n(\mathbf{r})\epsilon\omega^2 G(\hat{\mathbf{r}}-\mathbf{r})\xi(\mathbf{r}) + \frac{\partial G(\hat{\mathbf{r}}-\mathbf{r})}{\partial t(\hat{\mathbf{r}})}\frac{d\xi}{dt(\mathbf{r})}(\mathbf{r})\right) ds(\mathbf{r}). \tag{8.1}$$

The kernel $\partial G/\partial t$ converges to a principal-value kernel as $\hat{\mathbf{r}} \to \partial D$, and, since $d\xi/dt(\mathbf{r}) \in L^2$, we see that the operator with kernel $\partial^2 G(\hat{\mathbf{r}}-\mathbf{r})/\partial n(\hat{\mathbf{r}})\partial n(\mathbf{r})$ converges to a bounded operator from H^1 to L^2 as $\hat{\mathbf{r}} \to \partial D$.

HOPF BIFURCATION IN QUASI-GEOSTROPHIC CHANNEL FLOW*

ZHI-MIN CHEN†, MICHAEL GHIL‡, ERIC SIMONNET§, AND SHOUHONG WANG¶

This paper is dedicated to the memory of Jacques-Louis Lions

Abstract. In this article, we conduct a rigorous stability and bifurcation analysis for a highly idealized model of planetary-scale atmospheric and oceanic flows. The model is governed by the two-dimensional, quasi-geostrophic equation for the conservation of vorticity in an east-west oriented, periodic channel. The main result is the existence of Hopf bifurcation of the flow as the Reynolds number crosses a critical value.

The key idea in proving this result is translating the eigenvalue problem into a difference equation and treating the latter by continued-fraction methods. Numerical results are obtained by using a finite-difference scheme with high spatial resolution and these results agree closely with the theoretical predictions. The spatio-temporal structure of the limit cycle corresponds to a wave that propagates slowly westward and is symmetric about the midaxis of the channel. For plausible paramater values that correspond to midlatitude atmospheric flows, the period of this wave is 20–25 days.

Key words. quasi-geostrophic channel flow, Hopf bifurcation, atmospheric and oceanic waves

1. Introduction.

A key problem in the study of climate dynamics is to understand and predict the periodic, quasi-periodic, aperiodic, and fully turbulent characteristics of large-scale atmospheric and oceanic flows. Bifurcation theory enables one to determine how qualitatively different flow regimes appear and disappear as control parameters vary; it provides us, therefore, with an important method to explore the theoretical limits of predicting these flow regimes. In the present paper, we study bifurcations of the original partial differential equations (PDEs) that govern geophysical flows, whereas most studies so far have only considered systems of ordinary differential equations (ODEs) that are obtained by projecting the PDEs onto a finite-dimensional solution space, either by finite differencing or by truncating a Fourier expansion (see Ghil and Childress [10] and further references there). The present approach should allow us to overcome some of the inherent limitations of the numerical bifurcation results that dominate the climate dynamics literature up to this point, and to capture the essential dynamics of the governing PDE systems.

The basic equations of large-scale atmospheric and oceanic circulation are the primitive equations. These equations can be derived from the full Navier–Stokes equations *with gravity, rotation, and variable density* by neglecting vertical accelerations (the so-called hydrostatic approximation) and compressibility effects (i.e., sound waves); see Ghil and Childress [10], Kalnay [21], Lions, Temam, and Wang [24, 25], and Pedlosky [36]. One philosophy in the geosciences is to study in great detail simplified models that approximate well the dominant balance of forces on the planetary-scale atmospheric and oceanic flows before addressing the more complete PDE systems that govern these flows in all their complexity. By starting with models that incorporate only the most important effects, and by gradually bringing in others, one is able to proceed inductively and thereby avoid the pitfalls inevitably encountered when a great many poorly understood factors are introduced all at once.

The ideas of dynamical systems theory and nonlinear functional analysis have been applied so far to climate dynamics mainly by careful numerical studies. These were pioneered by Lorenz [26, 27], Stommel [43], and Veronis [44, 45] among others, who explored the bifurcation structure of low-order models of atmospheric and oceanic flows. More recently, pseudoarclength continuation methods have been applied to atmospheric (Legras and Ghil [23]) and oceanic (Speich, Dijkstra, and Ghil [42] and Dijkstra [9]) models with increasing horizontal resolution. These numerical bifurcation studies have so far produced fairly reliable results for two classes of geophysical flows: (i) atmospheric flows in a periodic midlatitude channel, in the presence of bottom topography and a forcing jet; and (ii) oceanic flows in a rectangular midlatitude basin, subject to wind stress on its upper surface. In both cases, the symmetry properties of the forcing have a decisive effect on the bifurcations that arise—saddle-node (Charney and DeVore [6] and Pedlosky [35]) or Hopf (Legras and Ghil [23] and Jin and Ghil [19]) in the atmospheric channel and saddle-node, pitchfork, or Hopf [2, 4, 14, 16, 18, 32, 37, 38, 42] in the oceanic basin.

More recently, the role of global bifurcations, via homoclinic and heteroclinic orbits, has been demonstrated numerically in the wind-driven ocean circulation problem, for both shallow-water (Chang et al. [5], Simonnet et al. [40, 41]) and quasi-geostrophic (QG) (Meacham [31] and Nadiga and Luce [34]) models. Both of these models represent further simplifications of the primitive equations [10, 36]. Still, the only mathematically rigorous proof of a bifurcation in either the atmospheric or the oceanic problem outlined here appears, as far as we know, in the work of Wolansky [47, 48], and it extends solely to the existence of asymmetric stationary solutions.

The present paper addresses the somewhat more difficult problem of proving the existence of Hopf bifurcation in a QG flow in two dimensions. The main difficulty in solving this problem is in estimating the crucial information on the spectrum of the problem linearized around the basic flow. The main objective of this article is to overcome this difficulty and bring a new set of tools to the rigorous study of successive bifurcations in geophysical fluid dynamics problems.

More precisely, we conduct a bifurcation analysis of the following idealized two-dimensional (2-D) QG flow problem. The governing equation dictates the conservation of vorticity, as modified by forcing and dissipation:

$$\partial_t \Delta\psi + \varepsilon J(\psi, \Delta\psi) + \partial_x \psi = E\Delta^2\psi - \tau_0 \sin \pi y, \tag{1.1}$$

where $\psi = \psi(x, y, t)$ is a streamfunction and $J(\psi, \phi) = \partial_x\psi\partial_y\phi - \partial_y\psi\partial_x\phi$ is the advection operator. The x-axis is directed to the east and the y-axis to the north. The zonal

and meridional velocity components u and v are obtained from the streamfunction by

$$u = -\psi_y, \qquad v = \psi_x.$$

The relative vorticity ξ and the streamfunction ψ are related by the Poisson equation

$$\Delta\psi = \xi.$$

Equation (1.1) is derived from either the shallow-water equations with rotation or the primitive equations by the so-called QG approximation, which assumes that the balance between the Coriolis force and the pressure gradient dominates the flow. This approximation corresponds to a singular perturbation that filters out the Poincaré waves, also called inertia-gravity waves (i.e., gravity waves modified by the presence of rotation). The QG equation (1.1) only supports Rossby waves, whose phase velocity—in the absence of forcing and dissipation, i.e., with a zero right-hand side—is comparable to the characteristic particle velocity; see Ghil and Childress [10] and Pedlosky [36]. Wolansky [48] studied the so-called barotropic, 2-D version of the QG model (1.1), while Wang [46] obtained results on existence, uniqueness, and long-time dynamics of the so-called baroclinic, three-dimensional (3-D) version.

The flow domain is a rectangular region $\Omega = \{(x, y);\ 0 \le x \le 2/a;\ 0 \le y \le 2\}$. For simplicity, we use here only the zonal component of the forcing. In an atmospheric model, this forcing represents—in the QG vorticity equation (1.1), in which there are no explicit thermodynamic effects—the transfer of angular momentum into midlatitudes due to the tropical Hadley cell (Lorenz [28]). Alternatively, one can think about a zonal forcing jet that would be in perfect geostrophic equilibrium with the pole-to-equator temperature gradient (Lorenz [27] and Ghil and Childress [10]).

In an oceanic model, the time-and-longitude independent forcing on the right-hand side of (1.1) is the curl of the wind stress

$$\nabla \times \tau = -\tau_0 \sin \pi y;$$

a wind stress of the form $\tau = -\tau_0(\cos \pi y, 0)$ mimics the annually averaged zonal wind distribution over the North Atlantic or North Pacific, with westerly (i.e., eastward) winds over the midlatitudes and easterlies in the tropics and polar latitudes.

The parameters ε and E are positive constants, called the Rossby and Ekman numbers, respectively. They measure the relative importance of nonlinearity and lateral diffusion. The effect of the bottom friction is neglected in this article. The Reynolds number is defined here as

$$R = \frac{\varepsilon}{E}.$$

The unknown streamfunction ψ satisfies periodic boundary conditions at $x = 0, 2/a$ and free-slip boundary conditions at $y = 0, 2$:

$$\begin{cases} \psi(t, 2/a, y) = \psi(t, 0, y), \\ \psi(t, x, 0) = \psi(t, x, 2) = 0;\ \partial_y^2\psi(t, x, 0) = \partial_y^2\psi(t, x, 2) = 0. \end{cases} \tag{1.2}$$

Along the meridional boundaries $y = 0, 2$, $\Delta\psi = \partial_y^2\psi = -\partial_y u$, and $u_y = 0$ corresponds to free slip along these boundaries. More general, "partial-slip" boundary conditions—intermediate between free slip and no slip ($u = -\psi_y = 0$)—are discussed in Appendix A of [18] for the 2-D shallow-water equations and in [14] for a 3-D version of the QG equations.

It is readily seen that (1.1) with (1.2) admits the steady-state solution $\psi_0 = \psi_0(y)$, where

$$\psi_0 = \frac{\tau_0}{\pi^4 E} \sin \pi y. \tag{1.3}$$

We shall take $\tau_0 = 1$ below for simplicity.

This midlatitude channel with zonal periodicity is a better model for the atmospheric problem that we outlined above than for the oceanic one. Still, the methods we apply might eventually be extended to the latter. As mentioned already, Wolansky [47] studied existence, uniqueness, and stability of stationary solutions of (1.1) in the presence of topography and free-surface effects, which are omitted here. Wolansky [48] showed, for a domain bounded by a closed streamline and nondivergent forcing, that sufficient conditions exist under which a branch of asymmetric stationary solutions bifurcates from the symmetric branch obtained when the domain, as well as the forcing, admits a symmetry group. His results were shown to apply in an infinite channel with the symmetry group of zonal translations.

The main objective of this article is to prove the following theorem.

THEOREM 1.1.

(i) *Let $a \geq \sqrt{3}/2$ and $E > 0$. Then* (1.1) *and* (1.2) *are linearly stable around ψ_0 for any Reynolds number $R > 0$, where $\psi_0 = \psi_0(y)$ is given by* (1.3).

(ii) *Let $\sqrt{3}/4 \leq a \leq \alpha_0$ and $E > 0$. Then there exists a critical Reynolds number $R_0 > 0$ for* (1.1) *and* (1.2). *Moreover* (1.1) *and* (1.2) *admit a nontrivial, time-periodic, classical solution ψ_R branching off ψ_0 as the Reynolds number R crosses R_0, provided that $E > c_0$ for some constant $c_0 > 0$.*

This theorem is based essentially on the eigenvalue analysis of the spectral problem with respect to the linearization of (1.1) and (1.2) around ψ_0, by using the continued-fraction method first introduced by Meshalkin and Sinai [33]. For the 2-D Navier–Stokes equations, without the Coriolis term and with periodic boundary conditions in both the x and y directions, stability and bifurcation were studied in [7, 17, 33]. For the 3-D Navier–Stokes equations, without the Coriolis term and with periodic boundary conditions in three directions, pitchfork bifurcation was studied by Chen and Wang [8]. They showed that the bifurcated branches exist for all Reynolds number values past the critical one and that the stationary solutions on these branches stay bounded as $R \to \infty$.

For 2-D incompressible viscous flows with periodic boundary conditions, Meshalkin and Sinai [33] deduced the linear stability of the steady state (1.3) when $a = 1$ with respect to all Reynolds numbers, Iudovich [17] proved the existence of steady-state bifurcation when $0 < a < 1$, and Chen and Price [7] obtained the existence of Hopf bifurcation for some a with $0 < a < \sqrt{3}/2$. Steady-state bifurcation, however, no longer occurs for any a under the free-slip boundary conditions described by (1.2).

In the present paper, the constant a is bounded from below by $\sqrt{3}/4$ for Hopf bifurcation to occur. In fact, for $0 < a < \sqrt{3}/4$ multiple pairs of eigenvalues crossing the imaginary line do occur, and by applying our approach here in a more sophisticated manner, the existence of time-periodic solutions can also be proven rigorously in this case; this will be reported elsewhere. Numerically, the multiple periodic solutions are found in section 6 here (Figures 6.2 and 6.3).

To prove assertion (ii) of Theorem 1.1 requires verifying a transversal crossing condition; see (1.7) below. This verification is rendered more difficult by the presence of the so-called β-term $\partial_x \psi$ in (1.1), which arises due to the meridional gradient of

the planetary vorticity [10, 36]. In order to prove the validity of this condition, we have to assume that $E > c_0$ for some constant c_0, although numerical experiments reveal the occurrence of Hopf bifurcation for large τ_0 but small E [14, 18, 40, 41, 42]. Technical difficulties prevent us from covering in Theorem 1.1 the range of x-periods given by $\alpha_0 < a < \sqrt{3}/2$, with $3/4 < \alpha_0 \simeq 0.8$. The overall situation for our QG channel flow, governed by (1.1), (1.2), is illustrated in Figure 1.1.

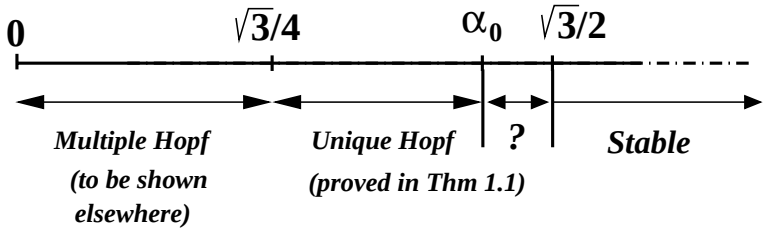

FIG. 1.1. *Range of values of the channel aspect ratio a for which various assertions hold. The equivalence between the spectral problem* (1.5) *with boundary conditions* (1.2) *and the difference equation of* (2.5)–(2.10) *holds for* $\sqrt{3}/4 \le a \le \sqrt{3}/2$ *(see Lemma* 2.2 *below). The numerical results in Figure* 6.2 *indicate that Hopf bifurcation also occurs for* $\alpha_0 \le a < \sqrt{3}/2$.

To prove Theorem 1.1, we decompose the streamfunction into a stationary part $\psi_0(x, y)$ given by (1.3) and a perturbation with exponential time dependence

$$\psi(x, y, t) = e^{\rho t}\phi(x, y), \tag{1.4}$$

where ϕ satisfies the boundary conditions (1.2). Introducing this solution into the governing equation and linearizing the latter with respect to the amplitude of the perturbation, we obtain the spectral problem

$$\rho\Delta\phi + \varepsilon\left(\partial_x\phi\,\partial_y\Delta\psi_0 - \partial_y\psi_0\,\partial_x\Delta\phi\right) + \partial_x\phi = E\Delta^2\phi.$$

Substituting the basic solution ψ_0 from (1.3) yields

$$L(\rho)\phi \doteq \left(E\Delta^2 - \partial_x + \frac{R}{\pi^3}\cos\pi y(\pi^2 + \Delta)\partial_x - \rho\Delta\right)\phi = 0. \tag{1.5}$$

The stability assertion (i) in the main theorem, i.e., the nonexistence of an eigenvalue ρ with $\operatorname{Re}\rho \ge 0$ for all $R > 0$, will be obtained by using the argument that Meshalkin and Sinai [33] first applied to the linear stability analysis of the 2-D Navier–Stokes equations.

The main effort is devoted to the proof of the bifurcation assertion (ii) of Theorem 1.1. Using the functional analysis framework of the Hopf bifurcation theorem in an infinite-dimensional setting (Joseph and Sattinger [20], Marsden and McCracken [30]), assertion (ii) of this theorem will follow if the following assertions can be shown to hold:

(a) There exists a critical Reynolds number $R_0 > 0$ and an eigenvalue $\rho = \rho(R_0)$ of (1.2) and (1.5) such that $\operatorname{Re}\rho(R_0) = 0$ and $\operatorname{Im}\rho(R_0) \ne 0$;

(b) this eigenvalue is simple, i.e.,

$$1 = \dim \bigcup_{n\ge 1} \left\{\phi \in H^4; L^n(\rho)\phi = 0\right\}; \tag{1.6}$$

(c) the transversal crossing condition

$$\text{Re}\,\frac{d\rho(R_0)}{dR} > 0. \tag{1.7}$$

Here H^4 denotes the complex space

$$H^4 = \{\phi \in L_2(\Omega);\ \Delta^2\phi \in L_2(\Omega),\ \phi \text{ satisfies (1.2)}\},$$

which contains the solution space of (1.1) and (1.2). This is a Hilbert space in the norm

$$\|\phi\|_{H^4} = \|\Delta^2\phi\|_{L_2(\Omega)}.$$

It is readily seen from the definition of H^4 that the bifurcating solution can be represented in the form of the Fourier expansion

$$\psi(x,y,t) = \sum_{m=-\infty}^{\infty}\sum_{n\geq 1-k}\sum_{k=0}^{1}(X_{m,n,k}(t)\cos ma\pi x + Y_{m,n,k}(t)\sin ma\pi x)\sin(n+k/2)\pi y. \tag{1.8}$$

This paper is organized as follows. The rigorous stability and bifurcation analysis of the problem is carried out in sections 2–5. Section 2 contains the proof of assertion (i) and a basic lemma on formulating the spectral problem. The proof of assertion (ii) is completed by combining section 3 on the existence of R_0 and $\rho(R_0)$, section 4 on the simplicity of the eigenvalue $\rho = \rho(R_0)$, and section 5 on the transversal crossing condition (1.7).

These analytical results are verified and complemented by numerical results in section 6. This section also contains comments on the geophysical significance of the periodic solutions. Brief remarks on the role of symmetry breaking in the bifurcation of time-periodic vs. stationary solutions follow in section 7.

2. Stability and equivalent formulation of the spectral problem. To prove the linear stability result of Theorem 1.1 and to obtain an equivalent formulation of the spectral problem, we follow the argument of Meshalkin and Sinai [33] by transforming the spectral problem into a difference equation, which is solved by continued-fraction methods.

As stated already in section 1, the free-slip boundary condition in (1.2) is equivalent to the condition $\phi = \Delta\phi = 0$ at $y = 0$ and $y = 2$. An application of this condition to (1.5) yields the generalized boundary condition

$$\Delta^n\phi = 0 \text{ at } y = 0 \text{ and } y = 2 \quad (n = 0, 1, 2, \ldots).$$

Thus the general expansion of the unknown function $\phi \in H^4$ for the spectral problem represented by (1.2) and (1.5) takes the form

$$\phi(x,y) = \sum_{m=-\infty}^{\infty}\sum_{n\geq 1-k}\sum_{k=0}^{1} e^{ima\pi x} i^n \phi_{n,m,k}\sin(n+k/2)\pi y, \quad i = \sqrt{-1}\ . \tag{2.1}$$

The fact that i^n appears explicitly in the coefficients of this expansion is only for convenience of notation in the derivation.

Note that no bifurcation can occur for Reynolds number R for which the corresponding eigenvalue ρ lies in the complex half-plane $\mathrm{Re}\rho < 0$. In order to obtain our stated bifurcation result, it is necessary to specify all of the eigenvalues ρ with $\mathrm{Re}\rho \geq 0$ and their corresponding eigenfunctions. However, the general expression of the eigenfunction in (2.1) is too complicated for this purpose. Fortunately, the eigenfunctions can be expressed in a simpler form, as given by the following lemma.

LEMMA 2.1. *Let $a \geq \sqrt{3}/4$ and let ρ be an eigenvalue of* (1.2) *and* (1.5) *such that $\mathrm{Re}\rho > -E\pi^2(a^2 + 1/4)$. Then $a < \sqrt{3}/2$ and the corresponding eigenfunction has the form*

$$\phi(x,y) = e^{\pm ia\pi x} \sum_{n=0}^{\infty} i^n \phi_n \sin(n+1/2)\pi y. \tag{2.2}$$

Proof. To begin with, we show that for given integers m and $k = 0, 1$, the subspace of H^4

$$\left\{ \phi \in H^4;\ \phi = \sum_{n \geq 1-k} e^{ima\pi x} i^n \phi_n \sin(n+k/2)\pi y \right\} \tag{2.3}$$

is invariant with respect to the spectral operator $\Delta^{-2}L(\rho)$, L being defined by (1.5).

For ϕ in the previous subspace, we see that

$$\begin{aligned}
&e^{-ima\pi x} L\phi \\
&= \sum_{n\geq 1-k} \{\pi^2[m^2a^2 + (n+k/2)^2]\rho - ima\pi\} i^n \phi_n \sin(n+k/2)\pi y \\
&\quad + \sum_{n\geq 1-k} E\pi^4[m^2a^2 + (n+k/2)^2]^2 i^n \phi_n \sin(n+k/2)\pi y \\
&\quad - R \sum_{n\geq 1-k} a[a^2 + (n+k/2)^2 - 1] i^{n+1} \phi_n \cos\pi y \sin(n+k/2)\pi y \\
&= \sum_{n\geq 1-k} \{\pi^2[m^2a^2 + (n+k/2)^2]\rho - ima\pi\} i^n \phi_n \sin(n+k/2)\pi y \\
&\quad + \sum_{n\geq 1-k} E\pi^4[m^2a^2 + (n+k/2)^2]^2 i^n \phi_n \sin(n+k/2)\pi y \\
&\quad - \frac{R}{2} \sum_{n\geq 2-k} ma[m^2a^2 + (n-1+k/2)^2 - 1] i^n \phi_{n-1} \sin(n+k/2)\pi y \\
&\quad + \frac{R}{2} \sum_{n\geq 0} ma[m^2a^2 + (n+1+k/2)^2 - 1] i^n \phi_{n+1} \sin(n+k/2)\pi y \\
&\quad + \frac{R}{2} ma(m^2a^2 - 3/4) i\phi_0 \sin(k/2)\pi y.
\end{aligned}$$

We thus have

$$L \sum_{n\geq 1-k} e^{ima\pi x} i^n \phi_n \sin(n+k/2)\pi y = \sum_{n\geq 1-k} e^{ima\pi x} i^n \psi_n \sin(n+k/2)\pi y, \tag{2.4}$$

where ψ_n is a linear combination of ϕ_{n-1}, ϕ_n, and ϕ_{n+1}. More precisely, for $n > 1-k$,

$$\begin{aligned}
\psi_n &= \{\pi^2[m^2a^2 + (n+k/2)^2]\rho - ima\pi + E\pi^4[m^2a^2 + (n+k/2)^2]^2\}\phi_n \\
&\quad - \frac{R}{2} ma[m^2a^2 + (n-1+k/2)^2 - 1]\phi_{n-1} + \frac{R}{2} ma[m^2a^2 + (n+1+k/2)^2 - 1]\phi_{n+1},
\end{aligned}$$

while

$$\begin{aligned}\psi_{1-k} = &\{\pi^2[m^2a^2 + (1-k/2)^2]\rho - ima\pi + E\pi^4[m^2a^2 + (1-k/2)^2]^2\}\phi_{1-k}\\ &+ \frac{R}{2}kma[m^2a^2 + (1+k/2)^2 - 1]\phi_1 + \frac{R}{2}kma(m^2a^2 - 3/4)i\phi_0\\ &+ \frac{R}{2}(1-k)ma(m^2a^2+3)\phi_2.\end{aligned}$$

This gives the invariance of the subspace (2.3), and thus we may assume that any eigenfunction ϕ is in this subspace for some integer m and some $k = 0, 1$.

We can now prove the desired assertion. Indeed, suppose that (ρ, ϕ) solves the spectral problem $L(\rho)\phi = 0$ and thus, by (2.4),

$$\psi_n = 0, \quad n \geq 1 - k. \tag{2.5}$$

If $m = 0$, this implies immediately $\phi_n = 0$ for $n \geq 1 - k$. If $m \neq 0$, the spectral problem yields

$$\sum_{n\geq 1-k} [m^2a^2 + (n + k/2)^2 - 1]\psi_n\bar{\phi}_n = 0,$$

where $\bar{\phi}_n$ is the complex conjugate of ϕ_n, and so its real part satisfies

$$\sum_{n\geq 1-k} [m^2a^2+(n+k/2)^2]\{\mathrm{Re}\rho+E\pi^2[m^2a^2+(n+k/2)^2]\}[m^2a^2+(n+k/2)^2-1]|\phi_n|^2 = 0. \tag{2.6}$$

This result, together with the condition $\mathrm{Re}\rho + E\pi^2(a^2 + 1/4) > 0$ and (2.5), implies

$$\begin{cases} \phi_n \equiv 0 & \text{when } k = 0, a > 0, -\infty < m < \infty,\\ \phi_n \equiv 0 & \text{when } k = 1, a > \sqrt{3}/2, -\infty < m < \infty,\\ \phi_n \equiv 0 & \text{when } k = 1, \sqrt{3}/4 \leq a \leq \sqrt{3}/2, |m| \geq 2,\end{cases}$$

since $m^2a^2 + (n + k/2)^2 - 1 \geq 0$.

The proof is thus complete. □

This lemma immediately gives the stability result contained in assertion (i) of Theorem 1.1.

As we shall see, it is important to realize that $k = 0$ corresponds to a function $\phi(x, y)$ that is antisymmetric about the axis $y = 1$ of the channel, while $\phi(x, y)$ is symmetric about this axis for $k = 1$. It follows from Lemma 2.1 that no bifurcation can arise in the problem governed by (1.1) and (1.2) from an antisymmetric instability.

To address the bifurcation problem, we thus consider the spectral equation (1.5)

$$\mathrm{Re}\ \rho > -E\pi^2(a^2 + 1/4), \quad \phi = \sum_{n=0}^{\infty} e^{\pm ia\pi x} i^n \phi_n \sin(n + 1/2)\pi y \in H^4$$

in the case $\sqrt{3}/4 \leq a < \sqrt{3}/2$. For simplicity, let

$$d_n = \frac{2\pi^2[a^2 + (n+1/2)^2]\rho - 2a\pi i + 2E\pi^4[a^2 + (n+1/2)^2]^2}{Ra[a^2 + (n+1/2)^2 - 1]}; \tag{2.7}$$

it follows, in particular, that $\mathrm{Re}\ d_0 < 0$ and $\mathrm{Re}\ d_n > 0$ with $n \geq 1$.

For the eigenfunction

$$\phi = \sum_{n=0}^{\infty} e^{ia\pi x} i^n \phi_n \sin(n+1/2)\pi y \in H^4, \tag{2.8}$$

let

$$\xi_n = a[a^2 + (n+k/2)^2 - 1]\phi_n. \tag{2.9}$$

The spectral problem $L(\rho)\phi = 0$ is, by (2.4), equivalent to $\psi_n = 0$; see (2.5). With definitions (2.7) and (2.9), the latter formulation becomes

$$\begin{cases} d_0\xi_0 + i\xi_0 + \xi_1 = 0, & n = 0, \\ d_n\xi_n - \xi_{n-1} + \xi_{n+1} = 0, & n \geq 1, \end{cases} \tag{2.10}$$

and (2.6) can be rewritten as

$$\sum_{n\geq 0} \operatorname{Re} d_n |\xi_n|^2 = 0. \tag{2.11}$$

It is readily seen that (2.10) implies that $\xi_n = 0$ for all $n \geq 0$ whenever there exists an $n_0 \geq 0$ for which $\xi_{n_0} = 0$.

Thus we may assume that $\xi_n \neq 0$ for $n \geq 0$. Hence, we obtain from (2.10) that

$$\frac{\xi_1}{\xi_0} = -d_0 - i, \quad \frac{\xi_n}{\xi_{n-1}} = \frac{1}{d_n + \dfrac{\xi_{n+1}}{\xi_n}}, \quad n \geq 1.$$

It follows therewith from (2.8) that $\rho = \rho(R)$ solves the following continued-fraction equation:

$$-d_0 - i = \cfrac{1}{d_1 + \cfrac{1}{d_2 + \cfrac{1}{\ddots}}}. \tag{2.12}$$

Moreover, we see that the spectral problem $L(\rho)\phi = 0$ is equivalent to the complex conjugate spectral problem $L(\bar{\rho})\bar{\phi} = 0$, with

$$\bar{\phi} = \sum_{n=0}^{\infty} e^{-ia\pi x} i^n (-1)^n \bar{\phi}_n \sin(n+1/2)\pi y \in H^4,$$

and thus $(\bar{\rho}, \bar{\phi})$ satisfies the complex conjugate of the three-term recursions (2.10), namely,

$$\begin{cases} \bar{d}_0\bar{\xi}_0 - i\bar{\xi}_0 + \bar{\xi}_1 = 0, & n = 0, \\ \bar{d}_n\bar{\xi}_n - \bar{\xi}_{n-1} + \bar{\xi}_{n+1} = 0, & n \geq 1. \end{cases} \tag{2.13}$$

Note that (2.10) and (2.13) are two distinct difference equations.

The above argument implies the following fundamental lemma.

LEMMA 2.2. *For* $\sqrt{3}/4 \le a < \sqrt{3}/2$, *the spectral problem described by* (1.5) *and* (1.2) *with unknown spectral solution* (ρ, ϕ) *such that*

$$\mathrm{Re}\rho > -E\pi^2(a^2+1/4), \quad \phi(x,y) = \sum_{n=0}^{\infty} e^{ia\pi x} i^n \phi_n \sin(n+1/2)\pi y \in H^4$$

is equivalent to the difference equation (2.10) *with* (d_n, ξ_n) *satisfying the constraints* (2.7), (2.9), (2.11), *and* (2.12). *Moreover, for a nontrivial eigenfunction* ϕ, *the corresponding sequence* $\{\xi_n\}$ *may be represented in the product form*

$$\begin{aligned} \xi_n &= c\gamma_1 \cdots \gamma_n, \quad n \ge 1, \\ \xi_0 &= c, \end{aligned}$$

where c *is an arbitrary complex constant and the factors* γ_n *are given by the infinite continued fractions*

$$\gamma_n = \cfrac{1}{d_n + \cfrac{1}{d_{n+1} + \cfrac{1}{\ddots}}}.$$

Furthermore, the spectral problem described by (1.5) *and* (1.2) *with another unknown solution* $(\bar{\rho}, \bar{\phi})$, *the complex conjugate of* (ρ, ϕ), *is equivalent to the difference equation* (2.13).

3. Existence of a critical Reynolds number. In this section, we show the existence of a critical Reynolds number R_0 and the existence of an eigenvalue $\rho(R)$ such that $\mathrm{Re}\,\rho(R_0) = 0$ and $\mathrm{Im}\,\rho(R_0) > 0$. We begin with the existence of the eigenvalue ρ, which may reach, and eventually cross, the imaginary axis of the complex plane.

LEMMA 3.1. *The spectral problem expressed by* (1.5) *and* (1.2) *admits a unique pair of complex conjugate eigenvalues* $\rho = \rho(R)$ *and* $\bar{\rho} = \bar{\rho}(R)$ *for any* $R > 0$ *and* $\sqrt{3}/4 \le a \le \alpha_0$, *such that* $\mathrm{Re}\,\rho > -E\pi^2(a^2+1/4)$.

Proof. From Lemma 2.2, we see readily that it suffices to show the existence and uniqueness of a function $\rho = \rho(R)$ that satisfies (2.7)–(2.12). Combining (2.7) and (2.12), we may write $\rho(R)$ as

$$\rho = -E\pi^2(a^2+1/4) + \frac{i2a\pi + iRa(3/4-a^2)}{2\pi^2(a^2+1/4)} + \cfrac{\dfrac{Ra(3/4-a^2)}{2\pi^2(a^2+1/4)}}{d_1 + \cfrac{1}{d_2 + \cfrac{1}{\ddots}}}. \tag{3.1}$$

To derive the existence of the unique pair of eigenvalues that satisfies the required strong inequality, we denote by $\Phi_R(\rho)$ the right-hand side of (3.1). It suffices then to show the existence of a fixed point of Φ_R in the complex plane $\mathbb{C}$. Indeed, since $\mathrm{Re}\rho \ge -E\pi^2(a^2+1/4)$, $R > 0$, and $a^2 < 3/4$, we have

$$\mathrm{Re}\Phi_R(\rho) > -E\pi^2(a^2+1/4)$$

and

$$|\Phi_R(\rho)| \le E\pi^2(a^2+1/4) + \frac{2a\pi + Ra(3/4-a^2)}{2\pi^2(a^2+1/4)} + \frac{Ra(3/4-a^2)}{2\pi^2(a^2+1/4)}\frac{1}{\mathrm{Re}\, d_1}$$
$$\le E\pi^2(a^2+1/4) + \frac{2a\pi + Ra(3/4-a^2)}{2\pi^2(a^2+1/4)} + \frac{R^2a^2(3/4-a^2)(a^2+5/4)}{8\pi^4(a^2+1/4)(a^2+9/4)E}. \tag{3.2}$$

Denoting this bound by K_R, we see that Φ_R maps the closed convex set

$$C_R = \{z \in \mathbb{C}; -E\pi^2(a^2+1/4) \le \mathrm{Re} z,\ |z| \le K_R\} \tag{3.3}$$

into itself. It follows from Brouwer's fixed point theorem that there exists a value $\rho(R)$ in this compact set such that $\Phi_R(\rho(R)) = \rho(R)$. This gives the existence of the desired pair of eigenvalues.

By Lemmas 2.1 and 2.2, we see that there is a one-to-one correspondence between each pair of complex conjugate eigenvalues of the spectral problem $L(\rho)\phi = 0$ and a solution ρ to the difference equation (2.10). In order to show that the pair of eigenvalues is unique, we suppose the existence of two pairs of complex conjugate solutions $\rho_j = \rho_j(R)$ and $\bar\rho_j = \bar\rho_j(R)$, with $\mathrm{Re}\rho_j > -E\pi^2(a^2+1/4)$ for $j = 1, 2$ and $R > 0$. This is equivalent to (2.10) admitting two solutions ρ_j for $j = 1, 2$ such that

$$\gamma_n(\rho_j) = \frac{1}{d_n + \gamma_{n+1}(\rho_j)} = \lim_{m\to\infty} \cfrac{1}{d_n + \cfrac{1}{d_{n+1} + \cfrac{1}{\ddots \cfrac{1}{d_{n+m}}}}}$$

for $d_n = d_n(\rho_j)$ defined by (2.7) and $\mathrm{Re}\rho_j > -E\pi^2(a^2+1/4)$. We have

$$\gamma_n(\rho_1) - \gamma_n(\rho_2) = -\gamma_n(\rho_1)\gamma_n(\rho_2)[d_n(\rho_1) - d_n(\rho_2) + \gamma_{n+1}(\rho_1) - \gamma_{n+1}(\rho_2)],$$

and so, by induction,

$$\gamma_1(\rho_1) - \gamma_1(\rho_2) = \sum_{n\ge1}(-1)^n[d_n(\rho_1) - d_n(\rho_2)]\eta_n(\rho_1)\eta_n(\rho_2)$$
$$= \sum_{n\ge1}(-1)^n \frac{2\pi[a^2 + (n+1/2)^2]}{Ra[a^2 + (n+1/2)^2 - 1]}\eta_n(\rho_1)\eta_n(\rho_2)(\rho_1 - \rho_2); \tag{3.4}$$

here $\{\eta_n(\rho_j)\}$ is now the solution specified by Lemma 2.2 such that $\eta_n = \xi_n$ and $\eta_0 = c = 1$. This yields, for $\rho_1 \ne \rho_2$,

$$|\rho_1 - \rho_2|$$
$$= \frac{Ra(3/4-a^2)}{2\pi^2(a^2+1/4)}|\gamma_1(\rho_1) - \gamma_1(\rho_2)|$$
$$\le \frac{3/4-a^2}{2(a^2+1/4)}\sum_{n\ge1}\frac{a^2+(n+1/2)^2}{[a^2+(n+1/2)^2-1]}(|\eta_n(\rho_1)|^2 + |\eta_n(\rho_2)|^2)|\rho_1 - \rho_2|$$
$$< \frac{3/4-a^2}{2a^2+1/2}\sum_{i=1}^{2}\sum_{n\ge1}\frac{[a^2+(n+1/2)^2]\{\mathrm{Re}\rho_i + E\pi^2[a^2+(n+1/2)^2]\}}{[\mathrm{Re}\rho_i + E\pi^2(a^2+1/4)][a^2+(n+1/2)^2-1]}|\eta_n(\rho_i)|^2|\rho_1 - \rho_2|$$
$$= |\rho_1 - \rho_2|,$$

where we have used (2.11). The strong inequality implies $\rho_1 = \rho_2$, which completes the proof of Lemma 3.1. ∎

LEMMA 3.2. *Let $\rho = \rho(R)$ with $R > 0$ be one of the two complex conjugate eigenvalues obtained in Lemma* 3.1. *Then we have* $\mathrm{Im}\rho(R) \neq 0$.

Proof. Assuming otherwise, i.e., $\mathrm{Im}\,\rho = 0$, we derive a contradiction. To this end, notice that

$$\begin{aligned}\left|\frac{\mathrm{Im}\,d_n}{\mathrm{Re}\,d_n}\right| &= \frac{\left|(a^2+(n+1/2)^2)\mathrm{Im}\,\rho\pi^2 - a\pi\right|}{\pi^2(a^2+(n+1/2)^2)\left\{E[a^2+(n+1/2)^2]\pi^2+\mathrm{Re}\,\rho\right\}} \\ &> \frac{\left|(a^2+(n+1+1/2)^2)\pi^2\mathrm{Im}\,\rho - a\pi\right|}{\pi^2(a^2+(n+1+1/2)^2)\left\{E[a^2+(n+1+1/2)^2]\pi^2+\mathrm{Re}\,\rho\right\}} \\ &= \left|\frac{\mathrm{Im}\,d_{n+1}}{\mathrm{Re}\,d_{n+1}}\right|.\end{aligned}$$

This, together with induction on n, implies that

$$\frac{|\mathrm{Im}\,\gamma_1|}{\mathrm{Re}\,\gamma_1} < \left|\frac{\mathrm{Im}\,d_1}{\mathrm{Re}\,d_1}\right|.$$

Thus we have

$$\left|\frac{\mathrm{Im}\,(-d_0 - i)}{-\mathrm{Re}\,d_0}\right| < \left|\frac{\mathrm{Im}\,d_1}{\mathrm{Re}\,d_1}\right|,$$

and so

$$\frac{|2(a^2+1/4)\pi^2\mathrm{Im}\,\rho - 2a\pi - Ra(3/4-a^2)|}{(a^2+1/4)\mathrm{Re}\,\rho + E(a^2+1/4)^2\pi^2} < \frac{2|(a^2+9/4)\pi^2\mathrm{Im}\,\rho - a\pi|}{(a^2+9/4)\mathrm{Re}\,\rho + E(a^2+9/4)^2\pi^2}.$$

Therefore,

$$\begin{aligned}\frac{|2(a^2+1/4)\pi^2\mathrm{Im}\,\rho - 2a\pi - Ra(3/4-a^2)|}{2|(a^2+9/4)\pi^2\mathrm{Im}\,\rho - a\pi|} &< \frac{(a^2+1/4)[\mathrm{Re}\,\rho + E(a^2+1/4)\pi^2]}{(a^2+9/4)[\mathrm{Re}\,\rho + E(a^2+9/4)\pi^2]} \\ &\leq \frac{a^2+1/4}{a^2+9/4},\end{aligned}$$

where we have used the condition $\mathrm{Re}\,\rho + E(a^2+1/4)\pi^2 > 0$. This implies

$$1 + \frac{Ra(3/4-a^2)}{2|(a^2+9/4)\pi^2\mathrm{Im}\,\rho - a\pi|} < \frac{a^2+1/4}{a^2+9/4} + \frac{2\pi^2|\mathrm{Im}\,\rho|}{|(a^2+9/4)\pi^2\mathrm{Im}\,\rho - a\pi|} < 1,$$

which leads to a contradiction and hence $\mathrm{Im}\,\rho > 0$. The proof of Lemma 3.2 is thus complete. ∎

LEMMA 3.3. *For one of the two eigenvalues obtained in Lemma* 3.1, *we have*

$$-\frac{1}{10} < \frac{2\pi^2}{a}\limsup_{R\to\infty}\frac{\mathrm{Im}\rho(R)}{R} < 2. \tag{3.5}$$

Proof. By (2.11), (2.12), and Lemma 2.2, we have

$$-\mathrm{Re}\,d_0|\xi_0|^2 > \mathrm{Re}\,d_1|\xi_1|^2,$$

or

$$-\mathrm{Re}\,d_0 > \mathrm{Re}\,d_1|d_0+i|^2.$$

Together with (2.7), this implies

$$\frac{(a^2+1/4)^2}{3/4-a^2} > \frac{(a^2+9/4)^2}{a^2+5/4}\left[\frac{2\pi^2(a^2+1/4)\mathrm{Im}\,\rho - 2a\pi}{Ra(3/4-a^2)} - 1\right]^2,$$

and so

$$\frac{(a^2+1/4)^2(a^2+5/4)}{(3/4-a^2)(a^2+9/4)^2} > \left[\frac{2\pi^2(a^2+1/4)}{a(3/4-a^2)}\limsup_{R\to\infty}\frac{\mathrm{Im}\,\rho}{R} - 1\right]^2.$$

Therefore, the double inequality (3.5) holds for $\sqrt{3}/4 \le a < \sqrt{3}/2$ and the proof of Lemma 3.3 is thus complete. □

Now we prove the main result of this section.

THEOREM 3.4. *Let $\rho(R)$ be either one of the two complex conjugate eigenvalues obtained in Lemma* 3.1. *Then there exists a critical Reynolds number R_0 such that* $\mathrm{Re}\rho(R_0) = 0$ *and* $\mathrm{Im}\rho(R_0) \neq 0$.

Proof. First, we prove the smoothness of $\rho(R)$ by using the implicit function theorem. Define the function

$$F(\rho, R) = i + d_0 + \cfrac{1}{d_1 + \cfrac{1}{d_2 + \cfrac{1}{\ddots}}} \tag{3.6}$$

with $d_n = d_n(\rho, R)$ given by (2.7). We see immediately that $F(\rho(R), R) = 0$, due to (2.12) and Lemma 3.1. It follows from (3.4) that

$$\frac{\partial F(\rho,R)}{\partial\rho} = \sum_{n\ge 0}(-1)^n\frac{\partial d_n}{\partial\rho}\eta_n^2 = \sum_{n\neq 0}(-1)^n\frac{2\pi[a^2+(n+1/2)^2]}{Ra[(a^2+(n+1/2)^2-1]}\eta_n^2, \tag{3.7}$$

where $\{\eta_n\}$ is the solution specified by Lemma 2.2 such that $\eta_0 = 1$. Hence we have, by (2.11), that

$$\begin{aligned}\left|\frac{\partial F(\rho,R)}{\partial\rho}\right| &\ge \frac{2\pi^2(a^2+1/4)}{Ra(3/4-a^2)}|\eta_0|^2 - \sum_{n\ge 1}\frac{2\pi^2[a^2+(n+1/2)^2]}{Ra[a^2+(n+1/2)^2-1]}|\eta_n|^2 \\ &= \frac{2\pi^2}{Ra}\sum_{n\ge 1}\frac{[a^2+(n+1/2)^2][\mathrm{Re}\rho + E\pi^2(a^2+(n+1/2)^2)]}{[\mathrm{Re}\rho + E\pi^2(a^2+1/4)][a^2+(n+1/2)^2-1]}|\eta_n|^2 \\ &\quad - \sum_{n\ge 1}\frac{2\pi^2[a^2+(n+1/2)^2]}{Ra[a^2+(n+1/2)^2-1]}|\eta_n|^2 \\ &= \frac{2\pi^4 E}{\mathrm{Re}\rho + E\pi^2(a^2+1/4)}\sum_{n\ge 1}\frac{[a^2+(n+1/2)^2](n+1)n}{Ra[a^2+(n+1/2)^2-1]}|\eta_n|^2 > 0.\end{aligned} \tag{3.8}$$

Thus, by the implicit function theorem, $\rho = \rho(R)$ is continuously differentiable.

Next, letting $R \to 0$ in (2.7) and (2.12), we see that

$$\lim_{R\to 0}\mathrm{Re}\,\rho(R) = -E\pi^2(a^2+1/4).$$

Finally, by Lemma 3.2 and the smoothness of $\rho(R)$, it suffices to show that

$$\limsup_{R\to\infty}\mathrm{Re}\,\rho(R) > 0.$$

To do so, we suppose that $\limsup_{R\to\infty} \mathrm{Re}\,\rho(R) \le 0$, which will lead to a contradiction.

Without loss of generality, by Lemma 3.3, we may suppose that

$$\lim_{R\to\infty} \mathrm{Re}\,\rho(R) = \mu, \quad \lim_{R\to\infty} \frac{2\pi^2 \mathrm{Im}\,\rho(R)}{Ra} = \nu \tag{3.9}$$

for some constants μ and ν. Otherwise, we may consider instead a subsequence $\{R_n\}$ that converges to these values.

Applying (2.12) and Lemma 2.2 yields

$$-d_0 - i = \frac{1}{d_1 + \dfrac{1}{d_2 + \gamma_3}}. \tag{3.10}$$

Hence

$$\begin{aligned} \lim_{R\to\infty} \gamma_3 &= \frac{1}{-\dfrac{1}{\lim\limits_{R\to\infty} i\mathrm{Im}\,d_0 + i} - \lim\limits_{R\to\infty} i\mathrm{Im}\,d_1} - \lim_{R\to\infty} i\mathrm{Im}\,d_2 \\ &= i\frac{\lim\limits_{R\to\infty} \mathrm{Im}\,d_0 + 1}{\lim\limits_{R\to\infty} \mathrm{Im}\,d_1(\lim\limits_{R\to\infty} \mathrm{Im}\,d_0 + 1) - 1} - \lim_{R\to\infty} i\mathrm{Im}\,d_2, \end{aligned} \tag{3.11}$$

or

$$\lim_{R\to\infty} (\mathrm{Im}\,\gamma_3 + \mathrm{Im}\,d_2) = \frac{\lim\limits_{R\to\infty} \mathrm{Im}\,d_0 + 1}{\lim\limits_{R\to\infty} \mathrm{Im}\,d_1(\mathrm{Im}\,d_0 + 1) - 1}. \tag{3.12}$$

Furthermore, it follows from (3.10) that

$$-d_0 - i = \frac{d_2 + \gamma_3}{d_1(d_2 + \gamma_3) + 1} = \frac{(d_2 + \gamma_3)(\overline{d_1(d_2 + \gamma_3)} + 1)}{|d_1(d_2 + \gamma_3) + 1|^2},$$

and thus

$$\begin{aligned} &-\mathrm{Re}\,d_0 |d_1(d_2 + \gamma_3) + 1|^2 \\ &= \mathrm{Re}\,(d_2 + \gamma_3)\mathrm{Re}\,(d_1(d_2 + \gamma_3) + 1) - \mathrm{Im}\,(d_2 + \gamma_3)\mathrm{Im}\,\overline{d_1(d_2 + \gamma_3)} \\ &= \mathrm{Re}\,(d_2 + \gamma_3)(\mathrm{Re}\,d_1 \mathrm{Re}\,(d_2 + \gamma_3) + 1) + \mathrm{Re}\,d_1(\mathrm{Im}\,d_2 + \mathrm{Im}\,\gamma_3)^2. \end{aligned} \tag{3.13}$$

Multiplying the last equation by R and passing to the limit $R \to \infty$, we obtain, after using (3.9), (3.11), (3.12), and the positivity of $\mathrm{Re}\,\gamma_3$,

$$\begin{aligned} \lim_{R\to\infty} R|\mathrm{Re}\,d_0| &= \frac{\lim\limits_{R\to\infty} R\mathrm{Re}\,(d_2 + \gamma_3) + \lim\limits_{R\to\infty} R\mathrm{Re}\,d_1 \lim\limits_{R\to\infty} (\mathrm{Im}\,d_2 + \mathrm{Im}\,\gamma_3)^2}{|\lim\limits_{R\to\infty} \mathrm{Im}\,d_1 \lim\limits_{R\to\infty} (\mathrm{Im}\,d_2 + \mathrm{Im}\,\gamma_3) - 1|^2} \\ &\ge \frac{\lim\limits_{R\to\infty} R\mathrm{Re}\,d_2 + \lim\limits_{R\to\infty} R\mathrm{Re}\,d_1 \lim\limits_{R\to\infty} (\mathrm{Im}\,d_2 + \mathrm{Im}\,\gamma_3)^2}{|\lim\limits_{R\to\infty} \mathrm{Im}\,d_1 \lim\limits_{R\to\infty} (\mathrm{Im}\,d_2 + \mathrm{Im}\,\gamma_3) - 1|^2} \\ &= \lim_{R\to\infty} R\mathrm{Re}\,d_1(\lim_{R\to\infty} \mathrm{Im}\,d_0 + 1)^2 \\ &\quad + \lim_{R\to\infty} R\mathrm{Re}\,d_2(1 - \lim_{R\to\infty} \mathrm{Im}\,d_1(\mathrm{Im}\,d_0 + 1))^2. \end{aligned}$$

That is,

$$\begin{aligned}
&\frac{a^2+1/4}{3/4-a^2}\left[\mu+E(a^2+1/4)\pi^2\right]\\
&\geq \frac{a^2+9/4}{a^2+5/4}\left[\mu+E(a^2+9/4)\pi^2\right]\left(1-\frac{a^2+1/4}{3/4-a^2}\nu\right)^2\\
&\quad+\frac{a^2+25/4}{a^2+21/4}\left[\mu+E(a^2+25/4)\pi^2\right]\left[\frac{a^2+9/4}{a^2+5/4}\left(1-\frac{a^2+1/4}{3/4-a^2}\nu\right)\nu-1\right]^2.
\end{aligned}$$

This, together with the condition $-E(a^2+1/4)\pi^2 \leq \mu \leq 0$, implies

$$\begin{aligned}
\frac{(a^2+1/4)^2}{3/4-a^2} &\geq \frac{(a^2+9/4)^2}{a^2+5/4}\left(1-\frac{a^2+1/4}{3/4-a^2}\nu\right)^2\\
&\quad+\frac{(a^2+25/4)^2}{a^2+21/4}\left[1-\frac{a^2+9/4}{a^2+5/4}\left(1-\frac{a^2+1/4}{3/4-a^2}\nu\right)\nu\right]^2\\
&> \frac{(a^2+1/4)^2}{3/4-a^2}
\end{aligned} \tag{3.14}$$

for $\sqrt{3}/4 \leq a \leq \alpha_0$, with $\alpha_0 \simeq 0.80$. This leads to a contradiction and hence $\lim_{R\to\infty} \operatorname{Re}\rho > 0$. The proof of Theorem 3.4 is thus complete. ∎

4. Spectral simplicity condition. This section is devoted to the simplicity of each of the two complex conjugate eigenvalues that cross the imaginary axis. We prove the following theorem.

THEOREM 4.1. *Let the critical Reynolds number R_0 and the eigenvalue $\rho = \rho(R_0)$ with $\operatorname{Im}\rho > 0$ be as shown to exist in Theorem* 3.4. *Then this eigenvalue is simple, i.e.,*

$$\dim \bigcup_{n\geq 1} \left\{\phi \in H^4;\ L^n\phi = 0\right\} = 1, \tag{4.1}$$

where $L = L(\rho)$ is the linear operator defined in (1.5).

Proof. We introduce the invariant subspaces of the spectral problem (1.5) for any integer m:

$$E_{m,k} = \left\{ \phi \in H^4;\ \psi(x,y) = \sum_{n\geq 1-k} i^n \phi_n e^{ima\pi x} \sin(n+k/2)\pi y \right\},\ \ k = 0, 1.$$

Hence the simplicity condition holds true provided that the following assertions are valid:

$$\dim \bigcup_{n\geq 1} \{\phi \in E_{m,k};\ L^n\phi = 0\} = 0 \tag{4.2}$$

for $(m,k) \neq (1,1)$, and

$$\dim \bigcup_{n\geq 1} \{\phi \in E_{1,1};\ L^n\phi = 0\} = 1. \tag{4.3}$$

Equation (4.2) follows immediately from Lemmas 2.1 and 2.2. Thus it remains to prove (4.3). We first note from Lemma 2.2 and Theorem 3.4 that

$$\dim\{\phi \in E_{1,1};\ L\phi = 0\} = 1.$$

By induction, it suffices to show

$$\dim\left\{\phi \in E_{1,1}\,;\ L^2\phi = 0\right\} = 1. \tag{4.4}$$

Indeed, rewrite the equation $L^2\phi = 0$ as

$$L\chi = 0, \tag{4.5}$$

after setting

$$L\phi = \chi \tag{4.6}$$

for some $\phi \in E_{1,1}$. It remains to show that $\phi \equiv 0$. Following the derivation of (2.10), we obtain the equivalent formulation of (4.5) and (4.6) in terms of two coupled difference equations:

$$\begin{cases} d_n\xi_n' - \xi_{n-1}' + \xi_{n+1}' = \xi_n, & n \geq 1, \\ d_n\xi_n - \xi_{n-1} + \xi_{n+1} = 0, & n \geq 1, \\ d_0\xi_0' + i\xi_0' + \xi_1' = \xi_0, & n = 0, \\ d_0\xi_0 + i\xi_0 + \xi_1 = 0, & n = 0; \end{cases} \tag{4.7}$$

here d_n is defined by (2.7) and $\{\xi_n/d_n\}$, $\{\xi_n'\} \in l_2^2$, while l_2^2 denotes the Hilbert space

$$l_2^2 = \left\{ \{\xi_n\};\ \|\{\xi_n\}\|_{l_2^2}^2 = \sum_{n\geq 0} n^2|\xi_n|^2 < \infty \right\}.$$

Define an operator $M : l_2^2 \mapsto l_2^2$ such that $M\{\xi_n\} = \{\eta_n\}$ with

$$\eta_n = \frac{1}{d_n}(\xi_{n+1} - \xi_{n-1}),\ \ \eta_0 = \frac{1}{d_0}(i\xi_0 + \xi_1),\ \ n \geq 1.$$

Equation (4.7) becomes

$$\begin{cases} (1+M)\{\xi_n'\} = \left\{\dfrac{\xi_n}{d_n}\right\}, \\ (1+M)\{\xi_n\} = 0. \end{cases} \tag{4.8}$$

We see that M is compact in l_2^2. It follows from Riesz–Schauder theory (also called the Fredholm alternative principle; see Theorem 5.3 in [15]) that (4.8) is solvable if and only if

$$\sum_{n\geq 0} \frac{\xi_n\bar{\zeta}_n}{d_n} = 0 \tag{4.9}$$

whenever $\{\zeta_n\} \in l_2^2$ is a nontrivial solution of the dual equation

$$(1 + M^*)\{\zeta_n\} = 0, \tag{4.10}$$

where M^* is the dual operator of M.

Such a nontrivial solution of (4.10) is given by

$$\zeta_n + \frac{\zeta_{n-1}}{\bar{d}_{n-1}} - \frac{\zeta_{n+1}}{\bar{d}_{n+1}} = 0, \quad n \geq 1,$$
$$\zeta_0 - \frac{i\zeta_0}{\bar{d}_0} - \frac{\zeta_1}{\bar{d}_1} = 0, \quad n = 0.$$

This becomes, by setting $\hat{\zeta}_n = (-1)^n \bar{\zeta}_n / d_n$,

$$d_n\hat{\zeta}_n - \hat{\zeta}_{n-1} + \hat{\zeta}_{n+1} = 0, \quad n \geq 1,$$
$$d_0\hat{\zeta}_0 + i\hat{\zeta}_0 + \hat{\zeta}_1 = 0, \quad n = 0.$$

By Lemma 2.2 and Theorem 3.4, we have

$$\hat{\zeta}_n = (-1)^n \frac{\bar{\zeta}_n}{d_n} = c\xi_n, \quad n \geq 0,$$

for some constant $c \neq 0$. Thus (4.9) becomes

$$\sum_{n\geq 0} \frac{\xi_n \bar{\zeta}_n}{d_n} = c \sum_{n\geq 0} (-1)^n \xi_n^2 = 0.$$

Hence, it follows from (2.11) that

$$\begin{aligned} 0 &= \left| \sum_{n\geq 0} (-1)^n \xi_n^2 \right| \\ &\geq |\xi_0|^2 - \sum_{n\geq 1} |\xi_n|^2 \\ &= \frac{1}{|\operatorname{Re} d_0|} \sum_{n\geq 1} (\operatorname{Re} d_n - |\operatorname{Re} d_0|)|\xi_n|^2. \end{aligned}$$

Since $\operatorname{Re} d_n - |\operatorname{Re} d_0| > 0$ for $\sqrt{3}/4 \leq a < \sqrt{3}/2$, we thus have $\{\xi_n\} = 0$ and hence (4.4). The proof of Theorem 4.1 is complete. □

5. Transversal crossing condition. The objective of this section is to show that the pair of eigenvalues $\{\rho(R), \bar{\rho}(R)\}$ crosses the imaginary axis transversally and away from the origin. This result reads as follows.

THEOREM 5.1. *Let $\rho = \rho(R_0)$ and R_0 be as characterized in Lemma* 2.2 *and Theorems* 3.4 *and* 4.1. *Then the transversal crossing condition* (1.7) *holds, provided that $E > c_0$ for some constant $c_0 > 0$.*

Proof. Recalling the definition of the function $F = F(\rho, R)$ in (3.6), we see that the eigenvalue $\rho = \rho(R)$ satisfies the equation $F(\rho(R), R) = 0$, and so

$$\frac{\partial F}{\partial \rho} \frac{\mathrm{d}\rho(R)}{dR} + \frac{\partial F}{\partial R} = 0.$$

It follows from the derivation of (3.7) that

$$\frac{\partial F}{\partial R} = -\frac{1}{R} \sum_{n\geq 0} (-1)^n d_n \eta_n^2.$$

Thus, by (2.7) with $R = R_0$, (3.7), and (3.8), we have

$$\pi R_0 \mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R} = \pi \mathrm{Re}\,\frac{\displaystyle\sum_{n\geq 0}(-1)^n d_n \eta_n^2}{\displaystyle\sum_{n\geq 0}(-1)^n \frac{\partial d_n}{\partial \rho}\eta_n^2}$$
$$= \mathrm{Re}\,\frac{\displaystyle\sum_{n\geq 0}(-1)^n \frac{\pi^3 E[a^2+(n+1/2)^2]^2 - ia}{a^2+(n+1/2)^2-1}\eta_n^2}{\displaystyle\sum_{n\geq 0}(-1)^n \frac{a^2+(n+1/2)^2}{a^2+(n+1/2)^2-1}\eta_n^2}.$$

This equals, after setting $a^2 + (n+1/2)^2 = \beta_n$,

$$\mathrm{Re}\,\frac{\displaystyle\sum_{n\geq 0}(-1)^n \frac{\pi^3 E\beta_n^2 - ia}{\beta_n - 1}\eta_n^2}{\displaystyle\sum_{n\geq 0}(-1)^n \frac{\beta_n}{\beta_n - 1}\eta_n^2}$$
$$= \pi^3 E\beta_0 + \sum_{n\geq 1}(-1)^n \frac{\pi^3 E\beta_n(\beta_n-\beta_0)}{\beta_n - 1}\mathrm{Re}\,(\xi_n^2) - \frac{a}{\beta_0}\sum_{n\geq 1}(-1)^n \frac{\beta_n-\beta_0}{\beta_n-1}\mathrm{Im}\,(\xi_n^2),$$

where the solution $\{\xi_n\}$ is chosen such that

$$\xi_0^2 = \frac{1}{\displaystyle\sum_{n\geq 0}(-1)^n \frac{\beta_n}{\beta_n-1}\eta_n^2}. \tag{5.1}$$

We thus have

$$\pi R_0 \mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R}$$
$$= \pi^3 E\beta_0 \left[1 - \frac{1}{\beta_0}\sum_{n\geq 1}\frac{\beta_n(\beta_n-\beta_0)}{\beta_n-1}|\xi_n|^2\right] - \frac{a}{\beta_0}\sum_{n\geq 1}(-1)^n\frac{\beta_n-\beta_0}{\beta_n-1}\mathrm{Im}\,(\xi_n^2)$$
$$+ \pi^3 E\sum_{n\geq 1}\frac{\beta_n(\beta_n-\beta_0)}{\beta_n-1}[|\xi_n|^2 + (-1)^n\mathrm{Re}\,(\xi_n^2)].$$

Furthermore, by (2.11) and (5.1), we have

$$1 - \frac{1}{\beta_0}\sum_{n\geq 1}\frac{\beta_n(\beta_n-\beta_0)}{\beta_n-1}|\xi_n|^2$$
$$= 1 - \frac{1}{\beta_0}\sum_{n\geq 1}\frac{\beta_n^2}{\beta_n-1}|\xi_n|^2 + \sum_{n\geq 1}\frac{\beta_n}{\beta_n-1}|\xi_n|^2$$

$$
\begin{aligned}
&= |\xi_0|^2 \left[\left| \sum_{n\geq 0} (-1)^n \frac{\beta_n}{\beta_n - 1} \eta_n^2 \right| + \sum_{n\geq 1} \frac{\beta_n}{\beta_n - 1} |\eta_n|^2 + \frac{\beta_0}{\beta_0 - 1} \right] \\
&\geq |\xi_0|^2 \left[\left| \sum_{n\geq 0} (-1)^n \frac{\beta_n}{\beta_n - 1} \mathrm{Re}\,(\eta_n^2) \right| + \sum_{n\geq 1} \frac{\beta_n}{\beta_n - 1} |\eta_n|^2 + \frac{\beta_0}{\beta_0 - 1} \right] \\
&\geq |\xi_0|^2 \sum_{n\geq 1} \frac{\beta_n}{\beta_n - 1} |\eta_n|^2 - |\xi_0|^2 \left| \sum_{n\geq 1} (-1)^n \frac{\beta_n}{\beta_n - 1} \mathrm{Re}\,(\eta_n^2) \right| \\
&\geq |\xi_0|^2 \frac{\beta_1}{\beta_1 - 1} (|\eta_1|^2 - |\mathrm{Re}\,(\eta_1^2)|)
\end{aligned}
$$

and

$$
\begin{aligned}
\left| \sum_{n\geq 1} (-1)^n \frac{\beta_n - \beta_0}{\beta_n - 1} \mathrm{Im}\,(\xi_n^2) \right| &\leq \sum_{n\geq 1} \frac{\beta_n - \beta_0}{\beta_n - 1} |\mathrm{Im}\,(\xi_n^2)| \\
&\leq \frac{1}{\beta_1} \sum_{n\geq 1} \frac{\beta_n^2}{\beta_n - 1} |\xi_n|^2 = \frac{\beta_0^2}{\beta_1(1-\beta_0)} |\xi_0|^2.
\end{aligned}
$$

Collecting terms while using (2.12) and Lemma 2.2, we have

$$
\begin{aligned}
&\frac{R_0}{\pi^2 |\xi_0|^2} \mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R} \\
&\geq E\beta_0 (|\eta_1|^2 - |\mathrm{Re}\,\eta_1^2|) + E(\beta_1 - \beta_0) \left(|\eta_1|^2 - \frac{\mathrm{Re}\,\xi_1^2}{|\xi_0|^2} \right) - \frac{a\beta_0}{\pi^3 \beta_1 (1-\beta_0)} \\
&= E\beta_0 (|d_0 + i|^2 - |\mathrm{Re}\,(d_0 + i)^2|) \\
&\quad + 2E \left(|d + i|^2 - \frac{\mathrm{Re}\,[(d_0 + i)^2 \xi_0^2]}{|\xi_0|^2} \right) - \frac{a\beta_0}{\pi^3 \beta_1 (1-\beta_0)}.
\end{aligned}
$$

Let us now apply the following lemma, whose proof will be given at the end of this section.

LEMMA 5.2. *One of the following two estimates,*

$$
\liminf_{E\to\infty} \frac{E}{R_0} > 0 \tag{5.2}
$$

or

$$
\liminf_{E\to\infty} |\mathrm{Re}\ d_0| > 0, \tag{5.3}
$$

holds true.

If $|1 + \mathrm{Im}\, d_0| > |\mathrm{Re}\, d_0|$, we have

$$
\begin{aligned}
\frac{R_0}{\pi^2 |\xi_0|^2} \mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R} &\geq E\beta_0 (|d_0 + i|^2 - |\mathrm{Re}\,(d_0 + i)^2|) - \frac{a\beta_0}{\pi^3 \beta_1 (1-\beta_0)} \\
&= 2E\beta_0 (\mathrm{Re}\, d_0)^2 - \frac{a\beta_0}{\pi^3 \beta_1 (1-\beta_0)};
\end{aligned}
$$

the latter is positive due to Lemma 5.2, after letting $E > c_0$ for some constant $c_0 > 0$.

If $|\mathrm{Re}\, d_0| \geq |1 + \mathrm{Im}\, d_0| > |\mathrm{Re}\, d_0|/4$, we see that

$$\begin{aligned}\frac{R_0}{\pi^2|\xi_0|^2}\mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R} &\geq E\beta_0(|d_0+i|^2 - |\mathrm{Re}\,(d_0+i)^2|) - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)}\\ &= 2E\beta_0(1+\mathrm{Im}\, d_0)^2 - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)}\\ &\geq \frac{1}{2}E\beta_0(\mathrm{Re}\, d_0)^2 - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)} > 0,\end{aligned}$$

which is positive as well for E large enough.

For the remaining case $|\mathrm{Re}\, d_0|/4 \geq |1 + \mathrm{Im}\, d_0| \geq 0$, we see that $-\mathrm{Re}\,(\xi_0^2) > 0$ due to (2.11) and (5.1). Hence we have

$$\begin{aligned}&\frac{R_0}{\pi^2|\xi_0|^2}\mathrm{Re}\,\frac{\mathrm{d}\rho(R_0)}{\mathrm{d}R}\\ &\geq 2E\left\{|d+i|^2 - \frac{\mathrm{Re}\,[(d_0+i)^2\xi_0^2]}{|\xi_0|^2}\right\} - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)}\\ &\geq 2E\left[|d+i|^2 + \frac{2(\mathrm{Re}\, d_0)(1+\mathrm{Im}\, d_0)\mathrm{Im}\,(\xi_0^2)}{|\xi_0|^2}\right] - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)}\\ &\geq E(\mathrm{Re}\, d_0)^2 - \frac{a\beta_0}{\pi^3\beta_1(1-\beta_0)}.\end{aligned}$$

This also implies the desired assertion by letting E be large enough. The proof of Theorem 5.1 is complete, subject to proving Lemma 5.2. □

Proof of Lemma 5.2. Let us first note, from (2.11) and Lemma 2.2, that

$$\mathrm{Re}\, d_1|\eta_1|^2 < -\mathrm{Re}\, d_0,$$

or, by (2.12),

$$\frac{\beta_0^2(\beta_1-1)}{\beta_1^2(1-\beta_0)} > |d_0+i|^2 = \left[\frac{2\pi^2\beta_0\mathrm{Im}\,\rho - a\pi}{R_0 a(1-\beta_0)} - 1\right]^2 + \left[\frac{2\pi^4 E\beta_0^2}{R_0 a(1-\beta_0)}\right]^2. \tag{5.4}$$

This implies

$$|d_1| + |d_2| < c_1, \tag{5.5}$$

and $R_0 > c_2 E$ for some positive constants c_1 and c_2, independent of E and R_0. Thus $E \to \infty$ implies $R_0 \to \infty$.

On the contrary, we suppose that

$$\liminf_{E\to\infty} \frac{E}{R_0} = 0, \tag{5.6}$$

which will lead to a contradiction. Indeed, by following the final step in the proof of Theorem 3.4, we use (2.12) or (3.10) to obtain

$$\begin{aligned}\lim_{E\to\infty}\gamma_3 &= \frac{1}{-\dfrac{1}{\lim\limits_{E\to\infty} i\mathrm{Im}\, d_0 + i} - \lim\limits_{E\to\infty} i\mathrm{Im}\, d_1} - \lim_{E\to\infty} i\mathrm{Im}\, d_2\\ &= i\frac{\lim\limits_{E\to\infty}\mathrm{Im}\, d_0 + 1}{\lim\limits_{E\to\infty}\mathrm{Im}\, d_1(\lim\limits_{E\to\infty}\mathrm{Im}\, d_0 + 1) - 1} - \lim_{E\to\infty} i\mathrm{Im}\, d_2\end{aligned} \tag{5.7}$$

and

$$\lim_{E\to\infty}(\operatorname{Im}\gamma_3+\operatorname{Im}d_2)=\frac{\lim\limits_{E\to\infty}\operatorname{Im}d_0+1}{\lim\limits_{E\to\infty}\operatorname{Im}d_1(\operatorname{Im}d_0+1)-1}, \tag{5.8}$$

where, for simplicity of notation, we have supposed the existence of the limit.

Furthermore, multiplying (3.13) by R_0/E and passing to the limit $E\to\infty$, we obtain, after applying (5.4), (5.5), (5.6), (5.7), (5.8), and the positivity of $\operatorname{Re}\gamma_3$,

$$\begin{aligned}\frac{R_0}{E}|\operatorname{Re}d_0| &= \frac{\lim\limits_{E\to\infty}\dfrac{R_0}{E}\operatorname{Re}(d_2+\gamma_3)+\dfrac{R_0}{E}\operatorname{Re}d_1\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)^2}{|\lim\limits_{E\to\infty}\operatorname{Im}d_1\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)-1|^2}\\ &\geq \frac{\dfrac{R_0}{E}\operatorname{Re}d_2+\dfrac{R_0}{E}\operatorname{Re}d_1\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)^2}{|\lim\limits_{E\to\infty}\operatorname{Im}d_1\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)-1|^2};\end{aligned}$$

that is,

$$\begin{aligned}\frac{\beta_0^2}{1-\beta_0} &\geq \frac{\dfrac{\beta_2^2}{\beta_2-1}+\dfrac{\beta_1^2}{\beta_1-1}\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)^2}{|\lim\limits_{E\to\infty}\operatorname{Im}d_1\lim\limits_{E\to\infty}(\operatorname{Im}d_2+\operatorname{Im}\gamma_3)-1|^2}\\ &\geq \frac{\beta_2^2}{\beta_2-1}[1-\lim_{E\to\infty}\operatorname{Im}d_1(\operatorname{Im}d_0+1)]^2\\ &\geq \frac{\beta_2^2}{\beta_2-1}\left[1-\frac{\beta_1(1-\beta_0)}{4\beta_0(\beta_1-1)}\right]^2.\end{aligned}$$

We thus have

$$\frac{(a^2+1/4)^2}{3/4-a^2}\geq\frac{(a^2+25/4)^2}{a^2+21/4}\left[1-\frac{(a^2+9/4)(3/4-a^2)}{4(a^2+1/4)(a^2+5/4)}\right]^2>\frac{(a^2+1/4)^2}{3/4-a^2}.$$

This leads to a contradiction for $\sqrt{3}/4\leq a\leq\alpha_0$, and hence (5.2) is valid. The proof of Lemma 5.2, and hence that of Theorem 5.1, is complete. □

As stated in section 1, assertion (i) of Theorem 1.1 was proven in section 2, while assertion (ii) follows by combining the results of Theorems 3.4, 4.1, and 5.1.

6. Numerical experiments. In this section, we compute numerically the Hopf bifurcation of the zonally periodic problem (1.1) with boundary conditions given by (1.2) and for various values of the aspect ratio a. We discretize a steady-state version of (1.1), as well as the spectral problem (1.5), both using the free-slip boundary conditions (1.2). The finite-difference discretization uses the Arakawa scheme, which conserves energy and enstrophy for 2-D incompressible flows [1]. The spatial resolution is $\Delta x=\Delta y=0.0249$; i.e., there are $N=80$ points in the y direction, $N\Delta y=2$; this resolution is kept the same for all values of a tested ($0.2\leq a\leq 0.86$).

The basic solution $\psi_0=\psi_0(x_i,y_i)$ is found by a pseudoarclength continuation algorithm [9, 23, 39, 42] that solves the discretized steady-state version of (1.1) instead of using (1.3). In order to solve the spectral problem (1.5) we compute the first 10 leading eigenvalues of its discretized version, i.e., those that are closest to the imaginary axis, since it is prohibitive to compute the whole spectrum for our resolution

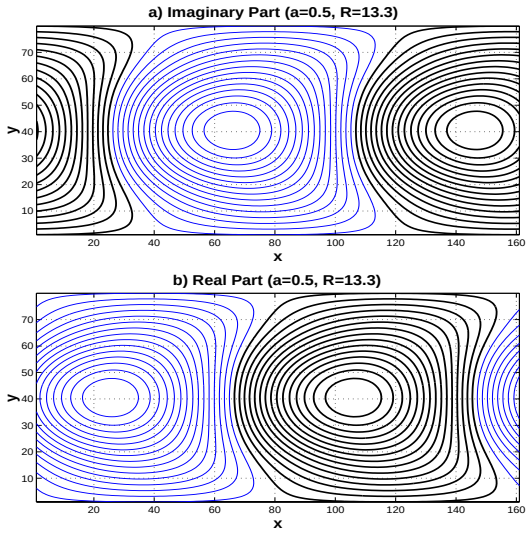

FIG. 6.1. *Unstable oscillatory mode for* $a = 0.5$ *and* $R = 13.3$*:* (a) *Imaginary part* ($t = -T/4$)*; and* (b) *real part* ($t = 0$)*. Light contour lines correspond to negative values and heavy contours to positive ones.*

of $N \times N/a = O(10^4)$ variables. This is achieved using a spectral transformation of the problem combined with a simultaneous iteration technique algorithm (see [39, 40, 42]). An oscillatory eigenfunction $\mathbf{\Phi_r} + i\mathbf{\Phi_i}$ and the corresponding pair of complex conjugate eigenvalues $\kappa_r \pm i\kappa_i$ provide the time-periodic disturbance structure $\mathbf{\Phi}(t)$ with angular frequency κ_i and growth rate κ_r, i.e.,

$$\mathbf{\Phi}(t) = \mathrm{e}^{\kappa_r t} \left[\mathbf{\Phi_r} \cos \kappa_i t - \mathbf{\Phi_i} \sin \kappa_i t \right]. \tag{6.1}$$

Figure 6.1 shows the spatial patterns of the leading eigenvector that loses its stability as R is increased. According to (6.1) this instability propagates westward and it does so for all aspect ratios a we used. The dipolar east-west structure of the destabilizing perturbation is also independent of a. The time-periodic solution is thus characterized by a westward propagation of alternating positive and negative vortices. When a nonlinearly saturated, finite-amplitude version of this oscillatory mode is added to the basic zonal flow Ψ_0, it results in a meandering of the eastward jet (not shown).

The numerically obtained spatial patterns also confirm the theoretical result that this instability is symmetric with respect to the midaxis of the channel. Moreover, numerical results tend to show that there is no other 2-D instability but this one: for fairly large values of $R >> R_0$, there is no other eigenvalue that crosses the imaginary axis.

We now investigate the value of the critical Reynolds number R_0 at the Hopf bifurcation, as a function of the aspect ratio a. We also compute the period $T = 2\pi/\kappa_i$ of the instability at R_0. Both the curves $R_0 = R_0(a)$ and $T = T(a)$ are shown in Figures 6.2(a) and 6.2(b), respectively. The vertical asymptote in both panels strongly suggests that for $a \geq \sqrt{3}/2$ the flow is linearly stable around Ψ_0, in excellent agreement with Theorem 1.1.

Both curves are continuous and monotonic across the entire interval $\sqrt{3}/4 \leq a < \sqrt{3}/2$. This indicates that the difficulties in proving Hopf bifurcation for $\alpha_0 \leq a <$

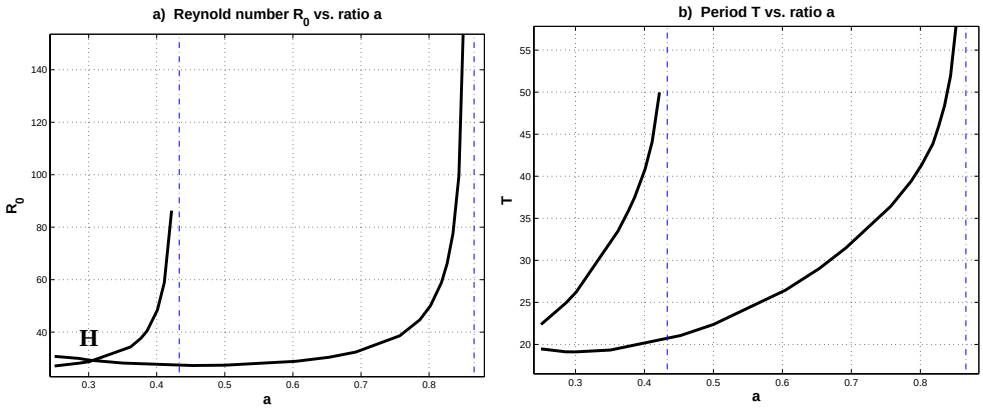

FIG. 6.2. *Dependence of the model's oscillatory instabilities on the aspect ratio a:* (a) *Critical Reynolds number* R_0*; and* (b) *period* T *of the limit cycle at Hopf bifurcation.* T *has been nondimensionalized by* L/U *with* $L = 4000$ km *and* $U = 15$ ms^{-1}*. The vertical dash-dotted straight lines correspond to* $a = \sqrt{3}/4$ *and* $a = \sqrt{3}/2$*, respectively.* H *refers to the simultaneous crossing of the imaginary axis by two distinct eigenmodes, with wavenumbers* $m = 1$ *and* $m = 2$*, respectively.*

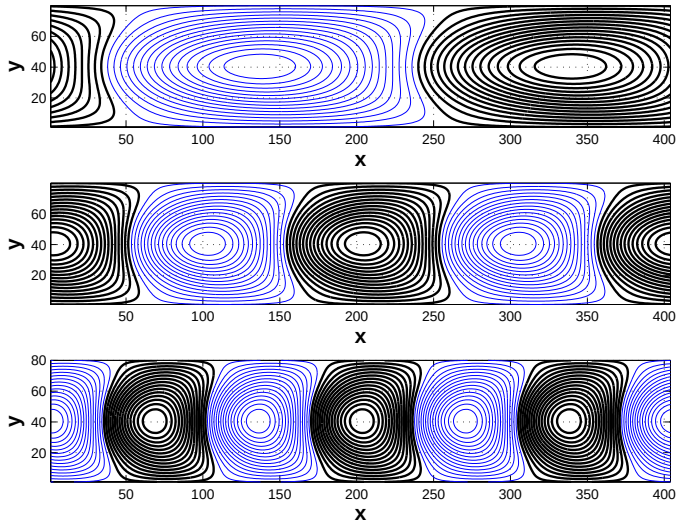

FIG. 6.3. *Real parts of the three unstable modes for* $a = 0.2$ *and* $R = 26.6$.

$\sqrt{3}/2$ are purely technical. In this interval, the flow becomes unstable as well, with a spatial pattern that resembles Figure 6.1 (not shown). The period of the instability increases as the zonal length of the channel decreases and it tends to infinity as a tends to the critical value $\sqrt{3}/2$. Numerical experiments also confirm that only a single instability with wavenumber one is found in the interval $\sqrt{3}/4 \le a < \sqrt{3}/2$.

For $a < \sqrt{3}/4$, interesting phenomena occur that are not captured by our Theorem 1.1. Numerical experiments indicate the existence of additional oscillatory instabilities, characterized by higher spatial harmonics, as shown in Figures 6.2 and 6.3. The competition between these instabilities is expected to generate chaotic dynamics as a is decreased. Codimension-2 Hopf–Hopf bifurcations, with complex global

dynamics nearby, are likely to play a key role in this process. The first of these bifurcations is denoted in Figure 6.2(a) by H and it occurs at $a \simeq 0.31$. At $a = 0.2$ and $R = 26.6$ (not shown in Figure 6.2), three unstable modes, with $m = 1, 2, 3$, coexist. These modes are shown in Figure 6.3 and are all symmetric about the channel's midaxis.

To gain some geophysical insight into the nature of the fundamental instability, we select characteristic dimensional magnitudes for the width $2L$ of the channel and the maximum $\tau_0 U/\pi^3 E$ of the zonal velocity in the midlatitude atmospheric jet. The value of $L = 4000$ km thus yields a meridional extent of the channel of 8000 km. The choice of $U = 15$ ms^{-1} and E between 50 and 100 corresponds to maximum zonal jet velocities between 25 and 50 ms^{-1} that agree well with those observed. Taking the midaxis of the β-channel at 45° N, as is often done in theoretical studies of large-scale atmospheric flow, and $a \simeq 0.26$ yields a channel length of $2L/a$ that corresponds to about 360° in longitude.

With these choices of L, U, and a, the numerical results shown in Figures 6.2(b) and 6.3 yield periods of 20–25 days for the instabilities obtained. Of these, the second one, with zonal wavenumber $m = 2$, has about the correct dimensional wavelength to match the westward-traveling Branstator–Kushnir [3, 22] wave. This wave has been shown to have, indeed, an equivalent-barotropic, i.e., essentially 2-D, structure and a period of about 25 days [11, 12, 13].

7. Symmetry considerations. As discussed in section 1, the symmetry properties of the domain and the forcing, on the one hand, and of the perturbation that gives rise to the bifurcation, on the other, have a decisive effect on whether the bifurcation leads to a branch of stationary or oscillatory solutions. Legras and Ghil [23] and Jin and Ghil [19] pointed out that, in the atmospheric channel problem with bottom topography, back-to-back saddle-node bifurcations resulted when the zonal forcing jet had a flat or unimodal velocity profile; see also Charney and DeVore [6] and Pedlosky [35]. To the contrary, when a higher-order component, which exhibited an inflection point, was present in the forcing jet, an oscillatory instability with so-called intraseasonal periods of 30–60 days could set in by resonance with this higher-order component and lead to a stable limit cycle.

Traveling Rossby waves are the unique type of solutions of (1.1) in the same periodic-channel geometry and in the absence of forcing, topography, and dissipation. The longest known period of this type of so-called free Rossby wave is about 16 days (Madden [29]). The periods of the oscillatory instabilities obtained previously, with bottom topography [6, 19, 23, 35], and here without it, are considerably longer: 25–50 days. Our rigorous result in Theorem 1.1 shows that Hopf bifurcation occurs even for a flat bottom of the channel, in agreement with the numerical results of section 6. The separate effects of forcing and dissipation, on the one hand, and topography, on the other, on the period of oscillatory solutions will be studied further elsewhere.

In the oceanic rectangular-basin problem, on the other hand, given the antisymmetric wind-stress forcing profile of (1.1) here, a steady double-gyre circulation resulted that is antisymmetric with respect to the basin's zonal symmetry axis [4, 18, 42]. This circulation is first destabilized by a pitchfork bifurcation—perfect in QG models [4, 5, 14] and perturbed in shallow-water models [18, 40, 41]—that arises from a purely exponential instability, which is symmetric with respect to the symmetry axis defined here as $y = 1$. Oscillatory instabilities documented numerically in either type of model, QG or shallow-water, also included some that have an asymmetric spatial pattern. The periods of these asymmetric instabilities are also much longer

than those of the oceanic problem's free modes (i.e., the Rossby basin modes arising in the absence of forcing and dissipation); see Simonnet and Dijkstra [39] and Simonnet et al. [41].

The symmetry properties of the Hopf bifurcation here are thus in agreement with those obtained numerically for the atmospheric channel flow. The situation for the oceanic double-gyre problem is more complex and requires further investigation. It might be possible, using some of these symmetry ideas, to adapt the approach and methods used here to this oceanic problem, in spite of the fact that analytic stationary solutions are harder to find for it [18, 44].

Acknowledgments. The first draft of this paper was prepared for presentation at the mathematical congress honoring the memory of Jacques-Louis Lions held in July 2002 at the Collège de France, Paris. It is a pleasure to thank the organizers and the participants of this congress for the impetus to complete the paper in its present form. Constructive comments by Gershon Wolansky and an anonymous reviewer helped improve the presentation and stimulated us to add section 6.

STOCHASTIC MODE REDUCTION FOR THE IMMERSED BOUNDARY METHOD*

PETER R. KRAMER† AND ANDREW J. MAJDA‡

Abstract. We apply the formulation of a stochastic mode reduction method developed in a recent paper of Majda, Timofeyev, and Vanden-Eijnden [*Comm. Pure Appl. Math.*, 54 (2001), pp. 891–974] (MTV) to obtain simplified equations for the dynamics of structures immersed in a thermally fluctuating fluid at low Reynolds (or Kubo) number, as simulated by a recent extension of the immersed boundary (IB) method by Kramer and Peskin [*Proceedings of the Second MIT Conference on Computational Fluid and Solid Mechanics*, Elsevier Science, Oxford, UK, 2003, pp. 1755–1758]. The effective dynamics of the immersed structures are not obvious in the primitive equations, which involve both fluid and structure dynamics, but the procedure of MTV allows the rigorous derivation of a reduced stochastic system for the immersed structures alone. We find, in the limit of small Reynolds (or Kubo) number, that the Lagrangian particle constituents of the immersed structures undergo a drift-diffusive motion with several physically correct features, including the coupling between dynamics of different particles. The MTV procedure is also applied to the spatially discretized form of the IB equations with thermal fluctuations to assist in the design and assessment of numerical algorithms.

Key words. stochastic mode reduction, immersed boundary method, Brownian motion

1. Introduction.

In several applications of modern interest, the governing equations can be written as a complex system of stochastic differential equations, with the variables (modes) evolving over a wide range of characteristic time scales. Sometimes, the variables can be grouped into a "fast" class of modes and a "slow" class of modes, with a wide separation between the time scales of the two classes. In such a situation, one can exploit singular perturbation techniques using the ratio of the fast to slow time scales as a small parameter to reduce the system by averaging the effects of the fast modes on the system. A rigorous procedure for averaging over fast fluctuations in a stochastic system was first provided by Khas'minskii [24, 23] and then later developed into more widely applicable theorems by Kurtz [30] (see also [9]), Ellis and Pinsky [7], and Papanicolaou [39]. (See the textbook [17] for an applied exposition.) Recently, Majda, Timofeyev, and Vanden-Eijnden [34, 35, 36] ([36] hereafter referred to as MTV) have developed these mathematical techniques into a methodological framework for climate modeling, where the governing equations are often essentially quadratically nonlinear and contain both slowly varying climate and "mean flow" modes and more rapidly fluctuating modes. In this work and the companion paper [26], we demonstrate how the MTV framework can be applied productively to a quite different class of applications, namely the simulation of microscale fluid systems with immersed structures and thermal fluctuations, such as microphysiological

systems, colloid suspensions, and polymer suspensions. In the present paper, we focus on the immersed boundary (IB) method [42] for simulating biological systems, as extended recently by Kramer and Peskin [28] to include thermal fluctuations and thereby extend its applicability to small scales (microns).

The IB method emphasizes the dynamics of the fluid environment in which the biological structures, such as polymers, membranes, and particles, are immersed. The forces generated by the biological structures as they are deformed or interact with external fields are communicated locally as forces on the fluid. The fluid then responds dynamically to these forces in a way represented by the Navier–Stokes equations. The structures are then advected (and strained) by their local fluid velocity. Thermal fluctuations are introduced through forces on the fluid. The immersed structures are not directly thermally forced, but rather undergo thermal fluctuations through advection by the thermally fluctuating fluid [28].

The IB method, then, is described by a coupled system of differential equations with the fluid modes stochastically forced. The details of this dynamical system will be presented in section 2. In the microscopic systems for which the method is designed, viscosity plays a strong role. More precisely, one can define a thermal Reynolds number (product of particle size and thermal velocity divided by kinematic viscosity) which will often be small in typical systems of interest. In such instances, the MTV stochastic mode reduction framework can be applied based on this small parameter to deduce a simplified system governing the immersed particles and structures, with the fluid variables eliminated (see section 3). To unify the discussion with the other simulation methods in [26], it is useful to note that the thermal Reynolds number in the IB method can be identified with a "thermal Kubo number," defined as the ratio of the rate of decorrelation of a particle's (Lagrangian) thermal velocity due to its advection into different fluid regions relative to its rate of decorrelation due to viscous damping.

The main motivation for this work is to obtain a rigorous characterization of the effective dynamics of immersed structures in the IB method at low thermal Reynolds (or Kubo) number. These results can then be used to assess the physical fidelity of the simulation method, to point out possible areas for improvement in the simulation scheme, and to calibrate the numerical parameters in applications. As discussed in [27] and section 2 below, thermal fluctuations are incorporated into the IB simulation equations in a rational manner based on statistical mechanics, but because of a basic approximation in the IB method, it is not a priori clear that the simulated Brownian motion of particles displays physically appropriate behavior. In [27], an approximate semianalytical calculation shows that in fact the IB equations do generate correct physical scaling behavior for various statistical features of multiparticle Brownian motion. Several of these results are corroborated and extended in the present work by the rigorous application of the MTV stochastic mode reduction procedure. In particular, a reduced set of stochastic differential equations describing the dynamics of the immersed structures is derived, with the role of the weak advective nonlinearity operating over long time scales and the nonlinear interaction between the immersed structures rigorously assessed. Such nonlinear effects are neglected in [27].

The immersed structures in the IB method are shown, through the stochastic mode reduction procedure, to obey effective drift-diffusive dynamics at long times, with both the drift coefficient and diffusion coefficient explicitly presented in section 4. Through a study of how the drift of the structures is related to the forces they feel, the structure of the self-diffusion coefficient, and the correlations between the diffusive motion of different particles, we explore to what extent the IB method, in ideal form

without numerical discretization issues, can capture various statistical physical aspects of thermally fluctuating systems. We find that many statistical physical features are properly described by the IB method, but identify a discrepancy between how the correlation in the diffusion of two closely separated particles is simulated by the IB method and its physically proper form for rigid particles. The source of the difference appears to be the lack of a sense of rigidity of particles in the IB method, rather than an artifact arising from the discretization of the fluid.

A cruder physical derivation of the same results is presented in section 5 as an aid to intuitive interpretation. Next, in section 6, we show how the effective dynamics are modified under spatial discretization. We do not consider temporal discretization, since the MTV procedure is not formulated for discrete-time systems, though it would seem that the conclusions concerning the effective dynamics would not be altered substantially [14]. Here we give explicit formulas that indicate how the discrete and continuous long-time dynamics are related. This allows us to calibrate parameters in the discrete numerical simulation as a design principle. A detailed analysis and comparison with numerical simulations will be presented in [27].

We close the introduction by describing some connections of the present work with some other stochastic analytical techniques. Our main technical tool is a singular perturbation analysis of the Kolmogorov backward equation (adjoint to the Fokker–Planck equation), a deterministic second-order parabolic partial differential equation associated with the stochastic dynamics of the full system [9, 30, 39]. The solution of this equation, in the limit of small thermal Reynolds (or Kubo) number, can be shown through a theorem of Kurtz [9, 30] to approach the solution of another second-order parabolic partial differential equation in which the variables corresponding to the fluid modes have been eliminated. The effective stochastic dynamics of the immersed structures, including their drift and diffusion coefficients, can be read off from this limiting equation.

This approach allows the treatment of a system with slow and fast modes, both of which are influenced by each other, as is the case for the IB method in general when the immersed structures do exert force. If, however, the immersed structures are simply force-free particles, then the evolution of the fluid is independent of the particle dynamics. The effective particle dynamics under the IB method can then be analyzed by a variety of other techniques. For example, the dynamics of the particles can be viewed as a random evolution problem [20, 21, 40], where the fluid variables play the role of the auxiliary Markov process parametrizing the advection operator. The long-time limiting effective dynamics, averaging out the influence of the fluid variables, can then be calculated through other fast-averaging formulas [2, 20, 21, 40]. Another approach is to view the motion of the particles as tracers in a turbulent diffusion problem, with the fluid velocity field treated as a prescribed Markovian random, time-dependent field and zero "bare" molecular diffusivity [10, 33]. The long-time behavior of the immersed particles can then be treated through homogenization techniques [1, 11]. If the nonlinear advection term can be safely ignored (due to the low Reynolds number), then the fluid velocity field is nothing more than a superposition of Ornstein–Uhlenbeck processes, for which a simpler analysis is possible [4, 11, 27]. We remark though that the standard turbulent diffusion assumption of point particles must be revised to account for the finite effective size of particles in the IB method.

The derivation of effective dynamics for interacting particle systems on large scales and long times can also be approached through "hydrodynamic limit" techniques [15, 18, 38, 50]. Here, one seeks to pass rigorously from a detailed description of the individual particle dynamics to continuum field equations describing the evolution

of the density and momentum of the collective medium formed by the particles. To our knowledge, such work is primarily focused on Hamiltonian systems with small or zero noise, or on random lattice dynamics with conservation laws. We are not aware of any such applications to systems of particles with strong damping and stochastic driving from the environment, which is the mathematical context of our present study. Moreover, hydrodynamic limit techniques seem most suited for systems in which the constituent particles interact with all other particles according to a universal law governed by their separation distance. It is not clear how to adapt these methods to polymer systems with a variety of bonded interactions. And if hydrodynamic limit techniques could be applied in certain circumstances to the IB method at low thermal Reynolds (or Kubo) number, the results would be complementary. Rather than preserving the Lagrangian framework which accounts for arbitrary N-particle interactions, the hydrodynamic limit would generally be expressed in an Eulerian framework in terms of number densities and correlation functions of the immersed particles.

2. Variables and equations for the IB method. In the IB method [42], the entire system of the fluid with immersed structures is treated as a constant density fluid. We moreover assume that the fluid domain Ω is a cube of side length L with periodic boundary conditions. This is typical for applications of the IB method, because it permits the use of a fast Fourier transform [42]. For the moment, though, we will still consider the space-time domain as continuous.

The evolution of the fluid is given by the incompressible Navier–Stokes equations

$$\rho\left(\frac{\partial \mathbf{u}(\mathbf{x},t)}{\partial t}+\mathbf{u}(\mathbf{x},t)\cdot\nabla\mathbf{u}(\mathbf{x},t)\right)=\mu\nabla^2\mathbf{u}(\mathbf{x},t)-\nabla p(\mathbf{x},t)+\mathbf{f}(\mathbf{x},t),\tag{2.1}$$

$$\nabla\cdot\mathbf{u}(\mathbf{x},t)=0,$$

where $\mathbf{u}(\mathbf{x},t)$ is the fluid velocity, ρ is the density, μ is the dynamic viscosity, p is the pressure, and $\mathbf{f}(\mathbf{x},t)$ is a force density. We decompose the force density into a sum,

$$\mathbf{f}(\mathbf{x},t)=\mathbf{f}_{\mathrm{IS}}(\mathbf{x},t)+\mathbf{f}_T(\mathbf{x},t),$$

with $\mathbf{f}_{\mathrm{IS}}(\mathbf{x},t)$ representing the contribution arising from the immersed structures and $\mathbf{f}_T(\mathbf{x},t)$ representing thermally fluctuating forces from microscopic processes. We next describe how these contributions to the force density are expressed concretely.

The collection of immersed structures will be modelled as a finite collection of Lagrangian particles, located at positions $\mathbf{X}=\{\mathbf{X}_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathcal{A}}$, where $\boldsymbol{\alpha}$ is a Lagrangian labelling index taking values from some finite set $\mathcal{A}$. The various stresses exerted by the immersed structures in response to deformations will be modelled in general through gradients of some interparticle potential $\Phi(\mathbf{X})$. Note that stresses such as those arising from bending resistance can be modelled by n-body interactions with $n>2$, and still fall within our scope. We assume that there are no external forces, so that the total momentum of the system is conserved ($\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X})=0$, where $\nabla_{\boldsymbol{\alpha}}$ denotes a gradient with respect to the position of the Lagrangian particle $\mathbf{X}_{\boldsymbol{\alpha}}$). By choosing an appropriate inertial frame, we can then assume that the total system momentum is always zero. (We briefly discuss in section 4.3 how the results would be modified if external forces were allowed to be present.)

With the potential prescribed, we can then describe the force density exerted on the fluid by applying the force exerted on each Lagrangian particle at its current position $\mathbf{X}_{\boldsymbol{\alpha}}(t)$, spread out via a smoothed delta function $\delta_a(\mathbf{x})$ with length scale a.

The choice of smoothing is dictated by numerical considerations, such as compact support and the minimization of oscillations in the fluid-particle interaction as the particles move with respect to the fluid grid [42]. We therefore write

$$\mathbf{f}_{\mathrm{IS}}(\mathbf{x},t) = -\sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X}(t))\delta_a(\mathbf{x}-\mathbf{X}_{\boldsymbol{\alpha}}(t)). \tag{2.2}$$

The parameter a acts as an effective particle size.

The thermal force density is obtained using a fluctuation-dissipation theorem from statistical hydrodynamics [27, 31] and is most clearly expressed in terms of its Fourier series expansion:

$$\begin{aligned} \mathbf{f}_T(\mathbf{x},t) &= \sum_{\mathbf{k}\in S} \mathbf{f}_{T,\mathbf{k}}(t) e^{2\pi i \mathbf{k}\cdot\mathbf{x}/L}, \\ \mathbf{f}_{T,\mathbf{k}}(t) &= \sqrt{\frac{8\pi^2 k^2 \mu k_B T}{L^5}}\, \frac{d\tilde{\mathbf{W}}_{\mathbf{k}}(t)}{dt}, \end{aligned} \tag{2.3}$$

where k_B is Boltzmann's constant, T is the absolute temperature, and $\{\tilde{\mathbf{W}}_{\mathbf{k}}(t)\}_{\mathbf{k}\in S}$ are a collection of standard complex Brownian processes, which are mutually independent except for the complex conjugacy relation

$$\tilde{\mathbf{W}}_{-\mathbf{k}}(t) = \overline{\tilde{\mathbf{W}}_{\mathbf{k}}(t)}, \tag{2.4}$$

which arises from the need to keep $\mathbf{f}_T(\mathbf{x},t)$ real-valued. By a "standard complex Brownian motion," we refer to a mean-zero Gaussian process with stationary increments satisfying

$$\langle d\tilde{\mathbf{W}}(t) \otimes d\tilde{\mathbf{W}}(t')\rangle = 0, \qquad \langle d\tilde{\mathbf{W}}(t) \otimes \overline{d\tilde{\mathbf{W}}(t')}\rangle = \mathcal{I}\delta(t-t')\,dt\,dt', \tag{2.5}$$

where $\mathcal{I}$ is the identity matrix. Please note that the definition of complex Brownian motion processes used in MTV [36] differs by a factor of two in normalization of the variance. In (2.3) and elsewhere in the paper, for simplicity in exposition, we occasionally use the formal notation $d\tilde{\mathbf{W}}(t)/dt$ for the white noise derivative of Brownian motion. Of course, the equations can be given a rigorous interpretation through use of the more proper Itô stochastic differential notation [37]. The set of wavenumbers is just the lattice of integers in three dimensions, with the zero mode excluded since it will always vanish: $S = \mathbb{Z}^3 \setminus \{\mathbf{0}\}$.

We note that the continuum formulation in which all these modes are retained requires care in a serious interpretation, because the velocity field induced by the thermal forcing in (2.3) exhibits an ultraviolet catastrophe due to singular small scale structure. We will not concern ourselves with such subtleties here, because in any numerical implementation the number of modes simulated is finite. Therefore, we will proceed just as if S were a finite collection of modes corresponding to some symmetric Galerkin truncation. However, in our actual discretized implementation, the IB equations are not simply crudely cut off in this way, and we show in section 6 how the results and arguments should be modified to apply to the actual numerical discretization.

With the Navier–Stokes equations (2.1) and the equations (2.2) and (2.3) for the force density, we have defined how the fluid evolves. The particle positions are updated by simple advection by the fluid at a locally interpolated fluid velocity:

$$\frac{d\mathbf{X}_{\boldsymbol{\alpha}}(t)}{dt} = \mathbf{u}_a(\mathbf{X}_{\boldsymbol{\alpha}}(t),t).$$

The same smoothed delta function that was used to spread force is used to interpolate velocity:

$$\mathbf{u}_a(\mathbf{x},t) = \int_\Omega \mathbf{u}(\mathbf{x}',t)\delta_a(\mathbf{x}-\mathbf{x}')\,d\mathbf{x}'; \tag{2.6}$$

this choice (along with the enforced reflection symmetry $\delta_a(\mathbf{x}) = \delta_a(-\mathbf{x})$) conserves energy in the particle-fluid interactions [42]. Note that, particularly in this integration, the delta function δ_a should be viewed as periodic (with its spikes centered at every point of the form (n_1L, n_2L, n_3L) with n_1, n_2, and n_3 integers). Equivalently, the convolution in (2.6) should be viewed as convolution on a torus [25].

2.1. Summary of IB equations in dimensional form. Summarizing, we have the following system of equations for the IB method:

$$\begin{aligned}
\rho\left(\frac{\partial \mathbf{u}(\mathbf{x},t)}{\partial t} + \mathbf{u}(\mathbf{x},t)\cdot\nabla\mathbf{u}(\mathbf{x},t)\right) &= \mu\nabla^2\mathbf{u}(\mathbf{x},t) - \nabla p(\mathbf{x},t) + \mathbf{f}_T(\mathbf{x},t) \\
&\quad - \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X}(t))\delta_a(\mathbf{x}-\mathbf{X}_{\boldsymbol{\alpha}}(t)), \\
\nabla\cdot\mathbf{u}(\mathbf{x},t) &= 0, \\
\frac{d\mathbf{X}_{\boldsymbol{\alpha}}(t)}{dt} &= \mathbf{u}_a(\mathbf{X}_{\boldsymbol{\alpha}}(t),t), \\
\mathbf{u}_a(\mathbf{x},t) &= \int_\Omega \mathbf{u}(\mathbf{x}',t)\delta_a(\mathbf{x}-\mathbf{x}')\,d\mathbf{x}',
\end{aligned} \tag{2.7a}$$

with the thermal forcing given by the following random process:

$$\mathbf{f}_T(\mathbf{x},t) = \sum_{\mathbf{k}\in S} \sqrt{\frac{8\pi^2k^2\mu k_BT}{L^5}}\, e^{2\pi i\mathbf{k}\cdot\mathbf{x}/L}\frac{d\tilde{\mathbf{W}}_{\mathbf{k}}(t)}{dt}. \tag{2.7b}$$

These equations are supplemented with initial conditions

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \mathbf{X}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{u}(\mathbf{x},t=0) = \mathbf{u}^0(\mathbf{x}).$$

2.2. Nondimensionalization. To prepare for the asymptotic results and calculations in subsequent sections, we nondimensionalize the IB equations. This will make manifest the role of the relevant Kubo number as a small parameter. We choose to nondimensionalize with respect to a length and time scale associated with the thermal forcing.

2.2.1. Parameters of externally specified functions. To facilitate the parametrization of the contributions from the initial data and the prescribed force law of the immersed structures, we express each in terms of dimensionless functions.

The initial velocity field will be described by a magnitude U_0 and length scale ℓ_v, and we write

$$\mathbf{u}^0(\mathbf{x}) = U_0\tilde{\mathbf{u}}^0(\mathbf{x}/\ell_v),$$

where $\tilde{\mathbf{u}}^0$ is a dimensionless function.

We identify ψ as a *force density* induced by the immersed structures, and ℓ_f as a length scale on which the immersed structure forces vary. More explicitly, we assume

$$\Phi(\mathbf{X}) = \psi\ell_f a^3\tilde{\Phi}(\mathbf{X}/\ell_f)$$

for some nondimensional function $\tilde{\Phi}$ with order unity amplitude and order unity gradients of its argument. Then an elementary constituent particle (with volume a^3) will experience a force of magnitude ψa^3.

Envisioning that the immersed structures will be modelled as a collection of elementary constituent particles with effective size a and spacing on the order of a, we will nondimensionalize $\mathbf{X}_{0,\boldsymbol{\alpha}}$ with respect to a:

$$\mathbf{X}_{0,\boldsymbol{\alpha}} = a\tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}.$$

Of course, the functions described above could have various amplitudes and length scales, depending on the model, but such complications do not bear on the central point of this work.

2.2.2. Reference units. We choose the following units to normalize the equations with respect to the thermal dynamics of the particles:

(i) length scale $\ell_T = a$,
(ii) time scale $\tau_T = \sqrt{\rho a^5/k_B T}$,
(iii) mass $m_T = \rho a^3$.

For example, the mass reference unit is just the mass associated with an elementary particle in the IB formulation (a single delta function), and length and time units are chosen so that the reference velocity

$$V_T \equiv \frac{\ell_T}{\tau_T} = \sqrt{\frac{k_B T}{\rho a^3}}$$

has the order of magnitude of the thermalized velocity of an elementary particle (since the IB system with thermal forcing respects the equipartition law [27]). Note that, after nondimensionalization, the fluid density, the width of the delta function (as well as the grid spacing), and the root-mean-square of the fluid velocity averaged over an elementary particle region are all order unity.

2.2.3. Nondimensional groups. With the above nondimensionalization, the IB dynamics are governed by the following nondimensional groups:

(i) Kubo number based on thermal forcing

$$\mathrm{Ku_T} = \frac{\ell_T^2}{\nu \tau_T} = \sqrt{\frac{k_B T}{\rho \nu^2 a}}, \tag{2.8}$$

where $\nu = \mu/\rho$ is the kinematic viscosity of the fluid;

(ii) nondimensionalized measures of the effects of structural forces and initial velocity

$$\phi = \frac{\psi a^4}{k_B T}, \qquad \Upsilon = \sqrt{\frac{U_0^2 \rho a^3}{k_B T}} = \frac{U_0}{V_T};$$

(iii) length scale ratios

$$\tilde{K} = \frac{L}{a}, \qquad \tilde{\ell}_f = \frac{\ell_f}{a}, \qquad \tilde{\ell}_v = \frac{\ell_v}{a}.$$

We pause to clarify why the nondimensional group $\mathrm{Ku_T}$ is identified as a Kubo number and can also be viewed here as a thermal particle Reynolds number. A

Kubo number is generally defined as the ratio of the time scales of decorrelation of a particle's motion due to intrinsic (Eulerian) processes to that due to advection across variable spatial structure [29, 52]. In the present context, $\tau_T = \ell_T/V_T$ is the time scale on which one of the Lagrangian particles would change its velocity due to its motion (at typical speed V_T) because of its sampling of a new environment after it moves a distance equal to its size $\ell_T = a$. The time scale $\ell_T^2/\nu = a^2/\nu$, on the other hand, describes the intrinsic (Eulerian) decorrelation rate of the fluid velocity averaged over the region occupied by a particle of size a.

Alternatively, the group (2.8) can be viewed as a thermal particle Reynolds number $\mathrm{Re_T}$, since it is the product of a characteristic particle length scale ($\ell_T = a$) and the thermal velocity of the fluid $V_T = \ell_T/\tau_T$ divided by the kinematic viscosity [51]. (Note that the notion of the thermal velocity of a fluid makes sense only if it is discretized or smoothed over some finite region (here taken to be of width a).) The fact that the thermal particle Reynolds number $\mathrm{Re_T} = \mathrm{Ku_T}$ decreases with the length scale a may be surprising; the reason is that the root-mean-square velocity sampled over a region a scales as $a^{-3/2}$ because of its short-range correlations. Therefore, while $\mathrm{Re_T}$ is small, it is not as minuscule as one might expect based on macroscopic intuition. For typical parameter values $k_B = 1.4 \times 10^{-16}$erg/K, $T = 300$ K, $\nu = 0.01$ cm/s, we have

$$\mathrm{Re_T} \approx \sqrt{\frac{5 \times 10^{-4}\mu\mathrm{m}}{a}}.$$

The elementary constituent size in a numerical simulation will be of the order $a \sim 0.01 - 0.1\mu$m, and thus we see that the Reynolds number based on the thermal forcing can be expected to be on the order of 10^{-2}–10^{-1}. We emphasize the thermal Kubo number interpretation because it allows the most parallel handling of the three simulation methods discussed in the companion paper [26].

2.2.4. Nondimensionalized IB equations. We now nondimensionalize the independent and dependent variables with respect to the reference units described in section 2.2.2, but denote their nondimensional versions by the same symbols. We retain special symbols for the nondimensionalized externally prescribed functions, as defined in section 2.2.3,

$$\begin{aligned}
\left(\frac{\partial \mathbf{u}(\mathbf{x},t)}{\partial t} + \mathbf{u}(\mathbf{x},t)\cdot\nabla\mathbf{u}(\mathbf{x},t)\right) &= \mathrm{Ku_T^{-1}}\nabla^2\mathbf{u}(\mathbf{x},t) - \nabla p(\mathbf{x},t) + \mathbf{f}_T(\mathbf{x},t) \\
&\quad - \phi\sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}(t)}{\tilde{\ell}_f}\right)\delta_1(\mathbf{x}-\mathbf{X}_{\boldsymbol{\alpha}}(t)), \\
\nabla\cdot\mathbf{u}(\mathbf{x},t) &= 0, \\
\frac{d\mathbf{X}_{\boldsymbol{\alpha}}(t)}{dt} &= \mathbf{u}_1(\mathbf{X}_{\boldsymbol{\alpha}}(t),t), \\
\mathbf{u}_1(\mathbf{x},t) &= \int_\Omega \mathbf{u}(\mathbf{x}',t)\delta_1(\mathbf{x}-\mathbf{x}')\,d\mathbf{x}',
\end{aligned} \tag{2.9a}$$

with the thermal forcing given by the following random process

$$\mathbf{f}_T(\mathbf{x},t) = \mathrm{Ku_T^{-1/2}}\tilde{K}^{-3/2}\sum_{\mathbf{k}\in S}\sqrt{2\left(4\pi^2\left(\frac{k}{\tilde{K}}\right)^2\right)}e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}\frac{d\tilde{\mathbf{W}}_{\mathbf{k}}(t)}{dt} \tag{2.9b}$$

and initial data

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{u}(\mathbf{x}, t=0) = \Upsilon \tilde{\mathbf{u}}^0 \left(\frac{\mathbf{x}}{\tilde{\ell}_v} \right). \tag{2.9c}$$

(We note that $\nabla_{\boldsymbol{\alpha}} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f)$ is to be interpreted as the gradient with respect to the $\boldsymbol{\alpha}$ coordinate of $\tilde{\Phi}$, evaluated at $\mathbf{X}/\tilde{\ell}_f$.)

3. Stochastic mode reduction procedure. For the microscopic applications for which the IB method with thermal fluctuations has been designed, the systems are at low thermal Kubo number, so the fluid motion is strongly damped by viscosity. The positions of the immersed structures, however, have no such damping terms in their equations of motion, and should therefore evolve on a slower time scale than the fluid variables. To make these notions quantitative, we consider the Kubo number based on the thermal forcing, $\mathrm{Ku_T}$, as a small parameter. Then we see from (2.9) that, at least formally, the (nondimensionalized) fluid variables evolve on the fast time scale $\mathrm{Ku_T^{-1}}$, while the immersed structure positions evolve on a slower time scale of $O(1)$ or longer. The IB equations are therefore well suited for the stochastic mode reduction framework developed in MTV. That is, we can systematically eliminate the fluid variables from consideration for small $\mathrm{Ku_T}$ and obtain a closed stochastic equation for the immersed structure positions $\{\mathbf{X}_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ alone. We now sketch this stochastic mode reduction procedure for the IB system. The detailed calculations can be found in the appendix. The result will be presented at the beginning of section 4.

3.1. Fourier expansion of IB equations. We prepare by expanding the velocity field (which is assumed periodic) in a Fourier series:

$$\mathbf{u}(\mathbf{x}, t) = \sum_{\mathbf{k}\in S} e^{2\pi i \mathbf{k}\cdot\mathbf{x}/\tilde{K}} \hat{\mathbf{u}}_{\mathbf{k}}(t). \tag{3.1}$$

The Navier–Stokes equations now become a coupled collection of stochastic ordinary differential equations. The nondimensionalized IB system (2.9), expressed in terms of the Fourier coefficients of the velocity field, reads

$$\begin{aligned} d\hat{\mathbf{u}}_{\mathbf{k}}(t) &= -\mathcal{B}_{\mathbf{k}}(\mathbf{U}(t), \mathbf{U}(t))\, dt - 4\pi^2 (k/\tilde{K})^2 \mathrm{Ku_T^{-1}} \hat{\mathbf{u}}_{\mathbf{k}}(t)\, dt \\ &\quad - \phi \mathcal{P}_{\mathbf{k}} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f) \hat{\delta}_{1,\mathbf{k}} e^{-2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(t)/\tilde{K}}\, dt \\ &\quad + \mathrm{Ku_T^{-1/2}} \tilde{K}^{-3/2} \sqrt{2(4\pi^2(k/\tilde{K})^2)}\, \mathcal{P}_{\mathbf{k}} d\tilde{\mathbf{W}}_{\mathbf{k}}(t), \\ d\mathbf{X}_{\boldsymbol{\alpha}}(t) &= \tilde{K}^3 \sum_{\mathbf{k}\in S} e^{2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(t)/\tilde{K}} \hat{\mathbf{u}}_{\mathbf{k}}(t) \hat{\delta}_{1,\mathbf{k}}\, dt, \end{aligned} \tag{3.2a}$$

with initial data

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \qquad \hat{\mathbf{u}}_{\mathbf{k}}(\mathbf{x}, t=0) = \Upsilon \hat{\tilde{\mathbf{u}}}^0_{\mathbf{k},\tilde{\ell}_v}. \tag{3.2b}$$

The Fourier expansion coefficients of the nonlinear advection term are

$$\mathcal{B}_{\mathbf{k}}(\mathbf{U}, \mathbf{U}) = 2\pi i \tilde{K}^{-1} \mathcal{P}_{\mathbf{k}} \sum_{\mathbf{k}'\in S} (\mathbf{u}_{\mathbf{k}'} \cdot \mathbf{k}) \mathbf{u}_{\mathbf{k}-\mathbf{k}'}. \tag{3.2c}$$

The effect of the pressure has been replaced in the standard way [32] through the introduction of a projection tensor which enforces incompressibility of each Fourier velocity mode:

$$\mathcal{P}_{\mathbf{k}} = \mathcal{I} - \frac{\mathbf{k} \otimes \mathbf{k}}{k^2}.$$

In our notation, variables with $\mathbf{k}$ subscripts indicate Fourier coefficients, as defined through the nondimensionalized Fourier transform (3.1). Note that $\{\hat{\tilde{\mathbf{u}}}^0_{\mathbf{k},\tilde{\ell}_v}\}_{\mathbf{k}\in S}$ are the Fourier coefficients of $\tilde{\mathbf{u}}^0(\mathbf{x}/\tilde{\ell}_v)$ and not of $\tilde{\mathbf{u}}^0(\mathbf{x})$. Finally, $\mathbf{U}$ is a shorthand for the collection of all Fourier velocity modes $\{\hat{\mathbf{u}}_{\mathbf{k}}\}_{\mathbf{k}\in S}$, though we recall that the zero mode $\mathbf{u}_0 \equiv \mathbf{0}$ because of our assumption that the global system momentum is conserved. To avoid excessive proliferation of $\mathcal{P}_{\mathbf{k}}$ symbols, we will consider the variables $\hat{\mathbf{u}}_{\mathbf{k}}$ to always be constrained to satisfy the incompressibility condition $\mathbf{k} \cdot \hat{\mathbf{u}}_{\mathbf{k}} = 0$. We will not concern ourselves unduly with the infinite number of modes in S, an ideal continuum fluid system. Indeed, all results converge, and our main interest is really in a discretized finite version of these equations (section 6).

For the sake of integration and differentiation, it will be convenient to follow a convention in complex analysis of treating $\hat{\mathbf{u}}_{\mathbf{k}}$ and $\hat{\mathbf{u}}^*_{\mathbf{k}}$ as independent variables, each with two degrees of freedom (due to the transversality condition $\mathbf{k} \cdot \hat{\mathbf{u}}_{\mathbf{k}} = \mathbf{k} \cdot \hat{\mathbf{u}}^*_{\mathbf{k}} = \mathbf{0}$). Note, however, that because $\mathbf{u}(\mathbf{x}, t)$ is a real-valued vector field, its Fourier coefficients must satisfy the complex conjugacy relations

$$\hat{\mathbf{u}}_{-\mathbf{k}}(t) = \hat{\mathbf{u}}^*_{\mathbf{k}}(t).$$

Therefore, we can consider $\{\hat{\mathbf{u}}_{\mathbf{k}}\}_{\mathbf{k}\in S}$ as a complete set of independent fluid coordinates.

3.2. Kolmogorov backward equation formulation. The calculation is performed on the Kolmogorov backward equation associated with the nondimensionalized IB equations (3.2):

$$\begin{aligned}
-\frac{\partial \rho(s, \mathbf{X}, \mathbf{U}|t)}{\partial s} = \sum_{\mathbf{k}\in S} \Bigg[& -\mathcal{B}_{\mathbf{k}}(\mathbf{U}, \mathbf{U}) - \phi \mathcal{P}_{\mathbf{k}} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right) \hat{\delta}_{1,\mathbf{k}} e^{-2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}} \\
& - \mathrm{Ku}_{\mathrm{T}}^{-1} \left(4\pi^2 \left(\frac{k}{\tilde{K}}\right)^2\right) \hat{\mathbf{u}}_{\mathbf{k}} \Bigg] \cdot \frac{\partial \rho}{\partial \hat{\mathbf{u}}_{\mathbf{k}}} \\
& + \mathrm{Ku}_{\mathrm{T}}^{-1} \sum_{\mathbf{k}\in S} \tilde{K}^{-3} \left(4\pi^2 \left(\frac{k}{\tilde{K}}\right)^2\right) \frac{\partial}{\partial \hat{\mathbf{u}}^*_{\mathbf{k}}} \cdot \frac{\partial \rho}{\partial \hat{\mathbf{u}}_{\mathbf{k}}} \\
& + \tilde{K}^3 \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \sum_{\mathbf{k}\in S} e^{2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}} \hat{\delta}_{1,\mathbf{k}} \hat{\mathbf{u}}_{\mathbf{k}} \cdot \frac{\partial \rho}{\partial \mathbf{X}_{\boldsymbol{\alpha}}},
\end{aligned} \tag{3.3}$$

$$\rho(s = t, \mathbf{X}, \mathbf{U}|t) = f(\mathbf{X}, \mathbf{U}).$$

The solution $\rho(s, \mathbf{X}, \mathbf{U}|t)$ to this Kolmogorov backward equation has the mathematical interpretation as the following conditional expectation:

$$\rho(s, \mathbf{X}, \mathbf{U}|t) = \mathbb{E}\left[f(\mathbf{X}(t), \mathbf{U}(t))|\mathbf{X}(s) = \mathbf{X}, \mathbf{U}(s) = \mathbf{U}\right], \tag{3.4}$$

where $\mathbf{X}(t)$ and $\mathbf{U}(t)$ evolve according to the IB equations (3.2) forward in time, conditioned on their starting at time $s < t$ from values $\mathbf{X}(s) = \mathbf{X}$ and $\mathbf{U}(s) = \mathbf{U}$,

and $\mathbb{E}$ denotes an average over the stochastic noise terms in the evolution equations. Because of the slight complication of using complex coordinates, we provide a formal derivation of the Kolmogorov backward equation in the appendix.

Some notational remarks are in order. We hope the reader will not be confused by our previous use of ρ as a symbol for fluid density; with the nondimensionalization in section 2.2, the fluid density has been removed from the problem and we have reallocated its symbol. To avoid straining the reader's eyes with numerous subscripts upon subscripts, we have used partial derivative notation to represent gradients with respect to vectorial modes when they apply to functions of both $\mathbf{U}$ and $\mathbf{X}$:

$$\frac{\partial}{\partial \hat{\mathbf{u}}_{\mathbf{k}}} = \nabla_{\hat{\mathbf{u}}_{\mathbf{k}}}, \qquad \frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}} = \nabla_{\mathbf{X}_{\boldsymbol{\alpha}}}.$$

We still use the abbreviation $\nabla_{\boldsymbol{\alpha}}$ for $\nabla_{\mathbf{X}_{\boldsymbol{\alpha}}}$ when applied to a function only of $\mathbf{X}$. Following the usual practice in complex analysis, $\hat{\mathbf{u}}_{\mathbf{k}}$ and $\hat{\mathbf{u}}^*_{\mathbf{k}}$ are considered to be independent variables in differentiation, so that, for example, $\partial g(\hat{\mathbf{u}}^*_{\mathbf{k}})/\partial \hat{\mathbf{u}}_{\mathbf{k}} = 0$. Finally, we have suppressed the time arguments of most terms in the Kolmogorov backward equation; they are all understood to be evaluated at the running time argument s.

The Kolmogorov backward equation is not being used here to actually solve for the evolution of some expectation of some function of the system variables, but merely as a tool to cast the stochastic dynamics in terms of a deterministic PDE. Perhaps the Kolmogorov forward (or Fokker–Planck) equation, which describes the evolution of the probability density of the system variables, may be a more intuitive formulation, but rigorous theorems are generally easier to prove for the backward equation (see MTV section 4.4 and references therein).

3.3. Identification of small parameter and rescaling of time. We identify $\varepsilon = \mathrm{Ku_T}$ as the small parameter and rescale to a longer time $t \to t/\varepsilon$. This temporal rescaling is necessary to see nontrivial dynamics in the $\varepsilon \downarrow 0$ limit, as we shall discuss in section 5. The Kolmogorov backward equation for the rescaled function

$$\rho^{\varepsilon}(s, \mathbf{X}, \mathbf{U}|t) = \rho(s/\varepsilon, \mathbf{X}, \mathbf{U}|t/\varepsilon)$$

may then be written as

$$\begin{aligned} -\frac{\partial \rho^{\varepsilon}(s, \mathbf{X}, \mathbf{U}|t)}{\partial s} &= \varepsilon^{-2}\mathcal{L}_1\rho^{\varepsilon} + \varepsilon^{-1}\mathcal{L}_2\rho^{\varepsilon}, \\ \rho^{\varepsilon}(s = t, \mathbf{X}, \mathbf{U}|t) &= f(\mathbf{X}, \mathbf{U}), \end{aligned} \tag{3.5a}$$

with differential operators

$$\begin{aligned} \mathcal{L}_1 &= \sum_{\mathbf{k}\in S}\left[-\left(4\pi^2\left(\frac{k}{\tilde{K}}\right)^2\right)\hat{\mathbf{u}}_{\mathbf{k}}\right]\cdot\frac{\partial}{\partial \hat{\mathbf{u}}_{\mathbf{k}}} + \left(4\pi^2\left(\frac{k}{\tilde{K}}\right)^2\right)\tilde{K}^{-3}\frac{\partial}{\partial \hat{\mathbf{u}}^*_{\mathbf{k}}}\cdot\frac{\partial}{\partial \hat{\mathbf{u}}_{\mathbf{k}}}, \\ \mathcal{L}_2 &= \sum_{\mathbf{k}\in S}\left[-\mathcal{B}_{\mathbf{k}}(\mathbf{U},\mathbf{U}) - \phi\mathcal{P}_{\mathbf{k}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\hat{\delta}_{1,\mathbf{k}}e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\right]\cdot\frac{\partial}{\partial \hat{\mathbf{u}}_{\mathbf{k}}} \\ &\quad + \tilde{K}^3\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\sum_{\mathbf{k}\in S}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\hat{\delta}_{1,\mathbf{k}}\hat{\mathbf{u}}_{\mathbf{k}}\cdot\frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}}. \end{aligned} \tag{3.5b}$$

3.4. Computation of limiting equation. We now apply singular perturbation techniques to this problem to find the equation satisfied by $\rho_0 \equiv \lim_{\varepsilon \downarrow 0} \rho^\varepsilon$. This calculation is presented in the appendix. We find that

$$\begin{aligned} -\frac{\partial \rho_0}{\partial s} &= \bar{\mathcal{L}} \rho_0, \\ \rho_0(s = t, \mathbf{X}|t) &= f(\mathbf{X}), \end{aligned} \tag{3.6a}$$

where the limiting differential operator is given by

$$\begin{aligned} \bar{\mathcal{L}} g(\mathbf{X}) = &-\phi \tilde{K}^3 \sum_{\mathbf{k} \in S} \frac{\hat{\delta}_{1,\mathbf{k}}^2}{4\pi^2 (k/\tilde{K})^2} \mathcal{P}_{\mathbf{k}} \sum_{\boldsymbol{\alpha}, \boldsymbol{\alpha}' \in \mathcal{A}} \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right) e^{2\pi i \mathbf{k} \cdot (\mathbf{X}_{\boldsymbol{\alpha}} - \mathbf{X}_{\boldsymbol{\alpha}'})/\tilde{K}} \cdot \frac{\partial g(\mathbf{X})}{\partial \mathbf{X}_{\boldsymbol{\alpha}}} \\ &+ \tilde{K}^3 \sum_{\boldsymbol{\alpha}, \boldsymbol{\alpha}' \in \mathcal{A}} \sum_{\mathbf{k} \in S} \frac{|\hat{\delta}_{1,\mathbf{k}}|^2}{4\pi^2 (k/\tilde{K})^2} e^{2\pi i \mathbf{k} \cdot (\mathbf{X}_{\boldsymbol{\alpha}} - \mathbf{X}_{\boldsymbol{\alpha}'})} \frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}} \cdot \mathcal{P}_{\mathbf{k}} \cdot \frac{\partial g(\mathbf{X})}{\partial \mathbf{X}_{\boldsymbol{\alpha}'}}. \end{aligned} \tag{3.6b}$$

3.4.1. Passage to reduced stochastic representation. We realize now that the PDE for ρ_0 is again a Kolmogorov backward equation for a Markov process, which we present in the next proposition. This relation can be checked through a stochastic Taylor expansion [22], as in the appendix. We use the fact that $\hat{\delta}_{1,\mathbf{k}} = \hat{\delta}_{1,\mathbf{k}}^*$ due to the assumed even symmetry $\delta_1(\mathbf{x}) = \delta_1(-\mathbf{x})$.

4. Effective dynamics for immersed structures at low thermal Kubo number. The outcome of the stochastic mode reduction procedure is summarized in the following proposition.

PROPOSITION 4.1 (IB dynamics at small Kubo number). *Suppose the IB system* (2.9) *conserves total momentum* ($\sum_{\boldsymbol{\alpha} \in \mathcal{A}} \nabla_{\boldsymbol{\alpha}} \Phi(\mathbf{X}) = 0$). *Then, in the limit* $\mathrm{Ku_T} \to 0$, *with all other nondimensional quantities held fixed, the solution for the immersed structure dynamics* $\{\mathbf{X}_{\boldsymbol{\alpha}}(t)\}_{\boldsymbol{\alpha} \in \mathcal{A}}$, *obtained from the complete coupled fluid-structure system and rescaled in time as*

$$\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) = \lim_{\mathrm{Ku_T} \to 0} \mathbf{X}_{\boldsymbol{\alpha}}(t/\mathrm{Ku_T}),$$

converges in law to the solution of the following simplified stochastic differential system involving only the structure variables $\{\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t)\}$:

$$\begin{aligned} d\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) &= \bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\bar{\mathbf{X}}(t))\, dt + \sum_{\mathbf{k} \in S} \mathcal{S}_{\mathbf{k}}(\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t))\, d\tilde{\mathbf{W}}_{\mathbf{k}}(t), \\ \bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t = 0) &= \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \end{aligned} \tag{4.1}$$

where the stochastic complex white noise terms $d\tilde{\mathbf{W}}_{\mathbf{k}}(t)$ *are defined below* (2.3) *and are given the Itô interpretation. The explicit expression for the drift term is*

$$\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X}) = -\phi \sum_{\boldsymbol{\alpha}'} \bar{\mathcal{M}}(\mathbf{X}_{\boldsymbol{\alpha}} - \mathbf{X}_{\boldsymbol{\alpha}'}) \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f), \tag{4.2}$$

and the matrix coefficients of the stochastic terms are

$$\mathcal{S}_{\mathbf{k}}(\mathbf{x}) = \sqrt{2\hat{\bar{\mathcal{M}}}_{\mathbf{k}}}\, e^{2\pi i \mathbf{k} \cdot \mathbf{x}/\tilde{K}}. \tag{4.3}$$

We have defined the mobility matrix function

$$\bar{\mathcal{M}}(\mathbf{r}) = \sum_{\mathbf{k}\in S} \hat{\bar{\mathcal{M}}}_{\mathbf{k}} e^{2\pi i \mathbf{k}\cdot\mathbf{r}/\tilde{K}} \tag{4.4}$$

and its Fourier coefficients

$$\hat{\bar{\mathcal{M}}}_{\mathbf{k}} \equiv \tilde{K}^3 \frac{\mathcal{P}_{\mathbf{k}} |\hat{\delta}_{1,\mathbf{k}}|^2}{4\pi^2 (k/\tilde{K})^2}.$$

The $\{\hat{\delta}_{1,\mathbf{k}}\}_{\mathbf{k}\in S}$ *are the Fourier coefficients of the delta function* $\delta_1(\mathbf{x})$ *(which we recall is to be viewed as a periodic smoothed delta function on the lattice generated by the fundamental cubic fluid domain),*

$$\hat{\delta}_{1,\mathbf{k}} = \frac{1}{\tilde{K}^3} \int_\Omega e^{-2\pi i \mathbf{k}\cdot\mathbf{x}/\tilde{K}} \delta_1(\mathbf{x})\, d\mathbf{x},$$

and we have introduced the projection tensor which enforces incompressibility of each Fourier velocity mode:

$$\mathcal{P}_{\mathbf{k}} = \mathcal{I} - \frac{\mathbf{k}\otimes\mathbf{k}}{k^2}.$$

The asymptotic statement in the proposition can be justified rigorously (see MTV section 4.4), provided that only a finite number of Fourier modes are retained. Later, in section 6, we modify these results to describe finite truncations which are better suited for numerical simulations. The asymptotics reported in the proposition are uniformly valid if the parameters ϕ and Υ are order unity or become small. Large values of ϕ might be of interest in structural models with some vibrational modes that may have time scales comparable to those of the fluid (or at least much faster than other translational and rotational modes of the structures). In this case, it may be desirable to apply the stochastic mode reduction procedure to eliminate some of the fast vibrational modes as well as the fluid modes. This falls outside the scope of our present results, and we leave its study for future work.

We will defer a discussion of the physical origin of the dynamics for $\bar{\mathbf{X}}(t)$ until section 5. There we will also develop the somewhat complicated formulas for the effective drift and diffusion coefficients into some more transparent consequents for one- and two-particle motion.

Here, we make only some brief remarks about the mathematical structure (section 4.1) and physical fidelity (section 4.2) of the effective dynamics, and comment on how the situation would be changed in a system which did not conserve momentum (section 4.3).

4.1. Mathematical remarks.

1. Perhaps somewhat surprisingly, in the low thermal Kubo number limit, the nonlinear advection term in the Navier–Stokes equation has no influence on the effective equation for $\bar{\mathbf{X}}(t)$. This fact is a consequence of the nonlinear advection term's having zero mean when averaged against the invariant measure (see (A.5)) for the velocity modes:

$$\langle \mathbf{u}\cdot\nabla\mathbf{u}\rangle = \langle \nabla\cdot(\mathbf{u}\otimes\mathbf{u})\rangle = \mathbf{0}.$$

A fundamental reason for the vanishing of the nonlinear advection term is the symmetry of the velocity field statistics under parity inversion:

$$\mathbf{x}\to -\mathbf{x}, \qquad \mathbf{u}\to -\mathbf{u}. \tag{4.5}$$

2. The factors of $\tilde{K}^3$ and $\tilde{K}^{3/2}$ in the drift and noise coefficients do not indicate a divergence with the size of the period cell, since $\hat{\delta}_{1,\mathbf{k}}$ scales as $O(\tilde{K}^{-3})$ and decays rapidly for $|k| \geq \tilde{K}$. Therefore, the $\tilde{K} \to \infty$ limits of the drift and noise contributions are in fact finite.

4.2. Physical fidelity of effective dynamics.

1. The drift term $\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X})$ is in accord with what one would expect on physical grounds, based on a low Reynolds number approximation in which the Navier–Stokes approximations are governed by a quasi-steady balance between the viscous and forcing terms (see section 5.1 below). The IB dynamics, however, do not produce a divergence-drift term, which, strictly speaking, should be present on physical grounds. We discuss this term in more detail in [26], where we can see its explicit form in the coarse-graining of particle-based dynamics. This term is small except when the elementary particles are close together (compared to their sizes); see [12, pp. 232–233].

2. The mobility matrix $\bar{\mathcal{M}}(\mathbf{r})$ describing the particle velocities in response to forces is a symmetric, nonnegative definite matrix function by Khinchin's theorem [53]. This implies that for any configuration of N particles the $3N \times 3N$ matrix relating the effective hydrodynamic velocity of each particle to the force on each particle is a symmetric, nonnegative definite matrix in the ordinary sense. This is also in accord with what one expects from physical arguments [19].

3. The random component of the IB dynamics can be shown to generate a physically appropriate absolute diffusion and relative diffusion of Lagrangian particles, provided that the particles are not too close together (relative to their sizes) [28]. In the IB dynamics, however, the motion of one particle is completely unaffected by the presence of other particles which do not generate force. In physical reality, though, the diffusion of a particle is hindered over the long run by the presence of other particles because they affect the fluid motion through a change of boundary conditions induced by rigidity of the particle, even if the particle does not induce any net force or torque [44, 45]. This correction to the motion of the particles is naturally proportional to the volume density occupied by the immersed particles.

4. The reduced system for the effective dynamics of the immersed structures obeys the Einstein relation [6, 16, 46]. The mobility matrix $\bar{\mathcal{M}}(\mathbf{r})$ in (4.4) is exactly the same as the matrix of relative diffusivities between different particles, as we show explicitly in section 5.2. The IB system should, on first principles, satisfy this Einstein relation because it is founded on statistical mechanical principles, but this fact is not at all transparent in the primitive formulation (2.9).

In summary, the IB method appears to generate physically correct dynamics of immersed structures in the presence of thermal fluctuations, provided that the particles constituting the structures are not too closely situated relative to their effective sizes. On the other hand, our analysis in the present work indicates that there is some quantitative difference between the statistical behavior of particles in the IB method and the physical behavior of rigid particles when the separation distance is comparable to the particle sizes. In practice, the structures (polymers, membranes, etc.) in the IB method are generally constructed with the elementary particles separated by a distance on the order of their effective size, so this regime is worth some scrutiny. One reason for the difference in behavior is surely that the Lagrangian particles in the IB method do not act on the fluid as rigid particles with a definite surface do. In particular, the fluid does not respond to the presence of an IB elementary particle unless that particle experiences a force, whereas a force-free rigid particle does exert

stress on the fluid to move it out of the way and to satisfy the no-slip condition on the surface. For physiological applications for which the IB method is primarily designed [42], the immersed structures are often elastic, so it may well be desirable to simulate it numerically using elementary particles that are not fully rigid. Moreover, the closely spaced IB particles will, often in applications, be modelled with some direct force interaction whose effects may dominate those of the rigidity of the particles. If some partial rigidity (or solidity) effects are still desired, however, they could perhaps be incorporated through a modification [41] of the IB approach described in [28]. A detailed exploration of theses issues is beyond the scope of this work and will be explored elsewhere.

We remark that the possible need for special handling of closely spaced particles in a fluid would not be unique to the IB method. Straightforward implementations of the particle-based method of simulations (to be described in [26]) based on Oseen (see [8]) or Rotne and Prager [47] hydrodynamic interaction approximations, which cause the divergence-drift term to cancel out, simulate rigid particle motion accurately only when their separation distance is large compared to their sizes. Only through a more elaborate introduction of lubrication forces as in Stokesian dynamics [3, 48] could the hydrodynamic interaction between closely spaced rigid particles be simulated accurately.

4.3. Changes in presence of nontrivial global system momentum. The simplified stochastic equations would require changes if the global system momentum were not a conserved quantity, such as if the system were subject to some fixed external potential. First of all, we would need to include the zero Fourier mode of the velocity,

$$\mathbf{u}_0(t) = \tilde{K}^{-3} \int_\Omega \mathbf{u}(\mathbf{x}, t)\, d\mathbf{x},$$

as a slow mode along with the immersed structure positions. The extent to which the effective dynamics are changed by the inclusion of this slow mode depends on its amplitude.

4.3.1. Weak zero velocity mode. If the slow mode $\mathbf{u}_0(t)$ has a small amplitude ($O(\mathrm{Ku_T})$ or less), then the stochastic mode reduction procedure can be carried through with simple changes, and the resulting effective equations would be changed in the following way:

1. The stochastic differential equations (4.1) for $d\mathbf{X}_{\boldsymbol{\alpha}}(t)$ would include a drift term $\mathbf{u}_0^\sharp(t)\, dt$, where $\mathbf{u}_0^\sharp = \mathrm{Ku_T^{-1}}\mathbf{u}_0(t)$.

2. The following evolution equation for $\mathbf{u}_0^\sharp(t)$ would be included in the effective dynamics:

$$d\mathbf{u}_0^\sharp(t) = -\phi^\sharp \sum_{\boldsymbol{\alpha}'} \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f)\, dt,$$

where $\phi^\sharp = \phi \mathrm{Ku_T^{-1}}$.

Two situations in which the global system momentum can be expected to be weak are when

1. the forcing by the immersed structures is weak ($\phi \sim O(\mathrm{Ku_T})$), or

2. the external force couples to the system in such a way that the total force experienced self-averages to a small quantity when there are many immersed structures.

4.3.2. Strong zero velocity mode. If, on the other hand, the zero velocity mode has stronger amplitude, then more significant changes need to be made. For example, if the zero velocity mode has amplitude comparable with the (order unity) amplitudes of the other Fourier modes, then the hierarchy of significant dynamical variation is altered in the following way:

1. As before, the fluid velocity modes (other than the zero mode) vary on a fast time scale $O(\mathrm{Ku_T})$ (in the original nondimensional time coordinate).

2. The presence of a global system momentum would induce immersed structure motion on an $O(1)$ time scale and would itself vary on an $O(1)$ time scale as the structures were moved through the external potential.

3. The drift and diffusive motion due to internal forces and thermal fluctuations evolve on a slow time scale $O(\mathrm{Ku_T^{-1}})$.

Now, the fast velocity mode dynamics are unchanged by the presence of the global momentum. The evolution of the zero velocity Fourier mode and immersed structure positions on the $O(1)$ time scale is, to leading order, independent of the fast velocity modes. It is hard, however, to provide a general closed-form description for these $O(1)$ time scale dynamics for general nonlinear external potentials. Of course, the equations are easily solved for linear external potentials (such as gravity), but the resulting dynamics will be unphysical at long time scales (global system momentum growing unboundedly) unless the effects of backflow are somehow introduced. Of central interest in this paper is the effective drift-diffusive motion of the immersed structures on time scales $\mathrm{Ku_T^{-1}}$. The stochastic mode reduction procedure can be carried through to do this only if we can find an appropriate change of variables which removes the $O(1)$ time-scale motion of the particles. The formal procedure for doing so is presented in MTV section 5.3, but an explicit result requires a closed-form solution of the $O(1)$ time-scale dynamics, which is not generally available for the IB equations in the presence of a nonlinear external potential.

For simplicity, we hereafter consider only systems which conserve global system momentum, which we can arrange to be zero.

5. Physical discussion of effective dynamics. We wish here to provide some simple physical derivations of the drift and diffusion terms for the immersed structures as reported in Proposition 4.1, to provide an intuitive picture to complement the systematic mathematical derivation of section 3.

5.1. Drift term. At low Kubo number, the viscous dissipation term in the fluid momentum evolution equation in (2.9a) formally dominates the inertial terms. As the thermal forcing has mean zero, we can then suppose that the fluid motion inducing the deterministic part of the evolution of the immersed structures is given by the following simplified balance of viscous and pressure forces against the forces induced by the straining of the immersed structures:

$$\mathrm{Ku_T^{-1}}\nabla^2\mathbf{u}(\mathbf{x},t) - \nabla p(\mathbf{x},t) - \phi\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f)\delta_1(\mathbf{x}-\mathbf{X}_{\boldsymbol{\alpha}}(t)) = 0,$$

$$\nabla\cdot\mathbf{u}(\mathbf{x},t) = 0.$$

Solving this linear system by a Fourier transform, we obtain

$$\mathbf{u}(\mathbf{x},t) = \sum_{\mathbf{k}\in S} e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}\hat{\mathbf{u}}_{\mathbf{k}}(t),$$

$$\hat{\mathbf{u}}_{\mathbf{k}}(t) = -\mathrm{Ku_T}\phi\sum_{\boldsymbol{\alpha}'\in\mathcal{A}}\frac{\mathcal{P}_{\mathbf{k}}\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f)\hat{\delta}_{1,\mathbf{k}}e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}'}(t)/\tilde{K}}}{4\pi^2(k/\tilde{K})^2},$$

with the Fourier symbols defined in section 3.1. Substituting this into the evolution equation in (3.2a) for $\mathbf{X}_{\boldsymbol{\alpha}}(t)$, we obtain the following expression for the deterministic component of the motion for the immersed structures at low Kubo number:

$$\left(\frac{d\mathbf{X}_{\boldsymbol{\alpha}}(t)}{dt}\right)_{\text{det}} = -\text{Ku}_{\text{T}}\phi\tilde{K}^3 \sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \frac{\mathcal{P}_{\mathbf{k}}\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f)\hat{\delta}^2_{1,\mathbf{k}}e^{2\pi i\mathbf{k}\cdot(\mathbf{X}_{\boldsymbol{\alpha}}(t)-\mathbf{X}_{\boldsymbol{\alpha}'}(t))/\tilde{K}}}{4\pi^2(k/\tilde{K})^2}.$$

Note how the velocity induced by the immersed structure is $O(\text{Ku}_{\text{T}})$, and so will only produce a significant displacement over a $O(\text{Ku}_{\text{T}}^{-1})$ time scale. Upon rescaling time in this way, we recover the systematically computed drift coefficient (4.2).

5.2. Diffusion term. The stochastic dynamics of the immersed structures are in response to the stochastic fluctuations of the fluid, which are in turn due to the thermal forcing. We ignore structural forces here since they contribute, to leading order, to the deterministic rather than the random component of the particle motion. The motion of the structures is then purely random (with zero mean drift) and is described at a basic level by the evolution of the second-order moments of the coordinates. One such measure of the random motion, which can be cleanly computed, is the diffusion correlation tensor

$$\mathcal{D}(\mathbf{r}) \equiv \frac{1}{2}\frac{d}{dt}\left\langle (\mathbf{X}_{\boldsymbol{\alpha}}(t)-\mathbf{X}_{\boldsymbol{\alpha}}(t'))\otimes(\mathbf{X}_{\boldsymbol{\alpha}'}(t)-\mathbf{X}_{\boldsymbol{\alpha}'}(t'))\,|\mathbf{X}_{\boldsymbol{\alpha}}(t')=\mathbf{x}+\mathbf{r},\mathbf{X}_{\boldsymbol{\alpha}'}(t')=\mathbf{x}\right\rangle_{t=t'}, \tag{5.1}$$

which describes the correlation in the random motion of two particles during the moment at which they are situated with relative separation $\mathbf{r}$. Note that this diffusion correlation tensor does not depend on $\mathbf{x}$ nor t', provided that the fluid is in thermal equilibrium so that the system is statistically invariant under space and time translations. The single-particle diffusivity is just given by the diagonal entries $\mathcal{D}(\mathbf{0})$ because two coincident particles will move as a single particle due to the common random flow environment.

We now provide a direct but approximate calculation for the diffusion correlation tensor and then show that it agrees with the results of Proposition 4.1. To do this, we will ignore the nonlinear advection term in the fluid equation, on the grounds that the Reynolds number is small. We have the following approximation for the evolution of the random component of the Fourier modes of the fluid velocity field:

$$d\hat{\mathbf{u}}_{\mathbf{k}}(t) = -4\pi^2(k/\tilde{K})^2\text{Ku}_{\text{T}}^{-1}\hat{\mathbf{u}}_{\mathbf{k}}(t)\,dt + \text{Ku}_{\text{T}}^{-1/2}\tilde{K}^{-3/2}\sqrt{2(4\pi^2(k/\tilde{K})^2)}\,\mathcal{P}_{\mathbf{k}}d\tilde{\mathbf{W}}_{\mathbf{k}}(t).$$

These linear stochastic differential equations can be solved explicitly when the fluid is in thermal equilibrium. We find that each Fourier mode of the velocity field is independent of the others and evolves as a mean-zero Gaussian Markov process with correlation function

$$\begin{aligned}\langle\hat{\mathbf{u}}_{\mathbf{k}}(t)\otimes\hat{\mathbf{u}}_{\mathbf{k}}(t')\rangle &= 0,\\ \langle\hat{\mathbf{u}}_{\mathbf{k}}(t)\otimes\hat{\mathbf{u}}^*_{\mathbf{k}}(t')\rangle &= \tilde{K}^{-3}e^{-\text{Ku}_{\text{T}}^{-1}4\pi^2(k/\tilde{K})^2|t-t'|}\mathcal{P}_{\mathbf{k}}.\end{aligned}$$

The fluctuating component of the smoothed version of the velocity field, $\mathbf{u}_1$, which advects the immersed structures, also has independent Fourier coefficients which evolve

according to mean-zero Gaussian random processes with correlation structure

$$\begin{aligned}&\langle \hat{\mathbf{u}}_{1,\mathbf{k}}(t) \otimes \hat{\mathbf{u}}_{1,\mathbf{k}}(t')\rangle = 0,\\ &\langle \hat{\mathbf{u}}_{1,\mathbf{k}}(t) \otimes \hat{\mathbf{u}}^*_{1,\mathbf{k}}(t')\rangle = \tilde{K}^3 e^{-\mathrm{Ku}_\mathrm{T}^{-1} 4\pi^2 (k/\tilde{K})^2 |t-t'|} |\hat{\delta}_{1,\mathbf{k}}|^2 \mathcal{P}_{\mathbf{k}}.\end{aligned} \tag{5.2}$$

It will be convenient in the following development to define the increment in the Lagrangian particle positions:

$$\Delta \mathbf{X}_{\boldsymbol{\alpha}}(t) = \mathbf{X}_{\boldsymbol{\alpha}}(t+\Delta t) - \mathbf{X}_{\boldsymbol{\alpha}}(t).$$

Suppose that at time t we have two elementary particles situated at $\mathbf{X}_{\boldsymbol{\alpha}}(t) = \mathbf{x}+\mathbf{r}$ and $\mathbf{X}_{\boldsymbol{\alpha}'}(t) = \mathbf{x}$. The second-order moments of the changes in position of these particles due to the random thermal fluctuations in the fluid are given by

$$\begin{aligned}&\langle \Delta \mathbf{X}_{\boldsymbol{\alpha}}(t) \otimes \Delta \mathbf{X}_{\boldsymbol{\alpha}'}(t)\rangle\\ &\quad = \int_t^{t+\Delta t} ds \int_t^{t+\Delta t} ds' \, \langle \mathbf{u}_1(\mathbf{X}_{\boldsymbol{\alpha}}(s), s) \otimes \mathbf{u}_1(\mathbf{X}_{\boldsymbol{\alpha}'}(s'), s')\rangle\\ &\quad = \sum_{\mathbf{k}\in S} \sum_{\mathbf{k}'\in S} \int_t^{t+\Delta t} ds \int_t^{t+\Delta t} ds' \, \langle \hat{\mathbf{u}}_{1,\mathbf{k}}(s) \otimes \hat{\mathbf{u}}_{1,\mathbf{k}'}(s') e^{2\pi i (\mathbf{k}\cdot \mathbf{X}_{\boldsymbol{\alpha}}(s) + \mathbf{k}'\cdot \mathbf{X}_{\boldsymbol{\alpha}'}(s'))/\tilde{K}}\rangle.\end{aligned} \tag{5.3}$$

Suppose now that we consider $\mathrm{Ku}_\mathrm{T} \ll \Delta t \ll 1$. The velocity field decorrelates on the short time scale Ku_T (see (5.2)), but the particle positions, which integrate this fluid velocity, will change very little over the time interval Δt. Therefore, if we condition on the position of the particles at time t, as in the definition of the diffusion correlation tensor (5.1), we can reasonably approximate $\mathbf{X}_{\boldsymbol{\alpha}}(s)$ and $\mathbf{X}_{\boldsymbol{\alpha}'}(s')$ to be frozen within the last integrand in (5.3):

$$\begin{aligned}\mathcal{D}(\mathbf{r}) &\approx \frac{1}{2\Delta t} \sum_{\mathbf{k}\in S} \sum_{\mathbf{k}'\in S} \int_t^{t+\Delta t} ds \int_t^{t+\Delta t} ds' \, \langle \hat{\mathbf{u}}_{1,\mathbf{k}}(s) \otimes \hat{\mathbf{u}}_{1,\mathbf{k}'}(s')\rangle e^{2\pi i (\mathbf{k}\cdot(\mathbf{x}+\mathbf{r}) + \mathbf{k}'\cdot\mathbf{x})/\tilde{K}}\\ &= \frac{\tilde{K}^3}{2\Delta t} \sum_{\mathbf{k}\in S} |\hat{\delta}_{1,\mathbf{k}}|^2 \mathcal{P}_{\mathbf{k}} \int_t^{t+\Delta t} ds \int_t^{t+\Delta t} ds' \, e^{-\mathrm{Ku}_\mathrm{T}^{-1} 4\pi^2 (k/\tilde{K})^2 |s-s'|} e^{2\pi i \mathbf{k}\cdot\mathbf{r}/\tilde{K}}\\ &\approx \frac{\tilde{K}^3}{\Delta t} \mathrm{Ku}_\mathrm{T} \sum_{\mathbf{k}\in S} |\hat{\delta}_{1,\mathbf{k}}|^2 \frac{\mathcal{P}_{\mathbf{k}}}{4\pi^2 (k/\tilde{K})^2} e^{2\pi i \mathbf{k}\cdot\mathbf{r}/\tilde{K}} \Delta t \quad \text{for } \mathrm{Ku}_\mathrm{T} \ll \Delta t \ll 1.\end{aligned}$$

Therefore, the diffusion correlation tensor in the low Kubo number limit is given by the above approximate calculation as

$$\mathcal{D}(\mathbf{r}) = \tilde{K}^3 \mathrm{Ku}_\mathrm{T} \sum_{\mathbf{k}\in S} |\hat{\delta}_{1,\mathbf{k}}|^2 \frac{\mathcal{P}_{\mathbf{k}}}{4\pi^2 (k/\tilde{K})^2} e^{2\pi i \mathbf{k}\cdot\mathbf{r}/\tilde{K}}. \tag{5.4}$$

Notice again that this diffusion is $O(\mathrm{Ku}_\mathrm{T})$, so the random motion is significant only on $O(\mathrm{Ku}_\mathrm{T}^{-1})$ time scales.

After this rescaling, this heuristically deduced law of coupled diffusion of the immersed structures agrees with what the noise terms of the effective dynamics in Proposition 4.1 would produce in the absence of drift. Indeed, if we have $\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) = \mathbf{x}+\mathbf{r}$ and $\bar{\mathbf{X}}_{\boldsymbol{\alpha}'}(t) = \mathbf{x}$, then applying the rules of (Itô) stochastic calculus [37], we have over

a short time interval of duration Δt

$$\begin{aligned}\langle \Delta\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) \otimes \Delta\bar{\mathbf{X}}_{\boldsymbol{\alpha}'}(t)\rangle &= \left\langle \left(\sum_{\mathbf{k}\in S} \mathcal{S}_{\mathbf{k}}(\mathbf{x}+\mathbf{r})\,\Delta\tilde{\mathbf{W}}_{\mathbf{k}}(t)\right) \otimes \left(\sum_{\mathbf{k}'\in S} \mathcal{S}_{\mathbf{k}'}(\mathbf{x})\,\Delta\tilde{\mathbf{W}}_{\mathbf{k}'}(t)\right)\right\rangle \\ &\quad + o(\Delta t) \\ &= \sum_{\mathbf{k},\mathbf{k}'\in S} \langle \mathcal{S}_{\mathbf{k}}(\mathbf{x}+\mathbf{r}) \langle \Delta\tilde{\mathbf{W}}_{\mathbf{k}}(t) \otimes \Delta\tilde{\mathbf{W}}_{\mathbf{k}'}(t)\rangle \cdot \mathcal{S}^{\dagger}_{\mathbf{k}'}(\mathbf{x})\rangle,\end{aligned}$$

with the noise increment

$$\Delta\tilde{\mathbf{W}}_{\mathbf{k}}(t) \equiv \int_t^{t+\Delta t} d\tilde{\mathbf{W}}_{\mathbf{k}}(t).$$

Now using the statistical properties of the complex white noise processes (see (2.5) and surrounding discussion), we have

$$\begin{aligned}\langle \Delta\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) \otimes \Delta\bar{\mathbf{X}}_{\boldsymbol{\alpha}'}(t)\rangle &= \sum_{\mathbf{k},\mathbf{k}'\in S} \langle \mathcal{S}_{\mathbf{k}}(\mathbf{x}+\mathbf{r}) \cdot \mathcal{I}\Delta t \delta_{\mathbf{k},-\mathbf{k}'} \cdot \mathcal{S}^{\dagger}_{\mathbf{k}'}(\mathbf{x})\rangle + o(\Delta t) \\ &= \sum_{\mathbf{k}\in S} \langle \mathcal{S}_{\mathbf{k}}(\mathbf{x}+\mathbf{r}) \cdot \mathcal{S}^{\dagger}_{-\mathbf{k}}(\mathbf{x})\rangle\,\Delta t + o(\Delta t).\end{aligned}$$

Substituting the expression (4.3) for $\mathcal{S}_{\mathbf{k}}(\mathbf{x})$, dividing by $2\Delta t$, and taking $\Delta t \to 0$, we obtain agreement with the heuristically deduced expression (5.4). The difference of the factor $\mathrm{Ku_T}$ is due to the fact that $\bar{\mathbf{X}}_{\boldsymbol{\alpha}}$ is defined with respect to the rescaled time $t/\mathrm{Ku_T}$.

We now directly observe the Einstein relation, which in our nondimensionalization reads $\mathcal{D}(\mathbf{r}) = \mathcal{M}(\mathbf{r}) = \mathrm{Ku_T}\bar{\mathcal{M}}(\mathbf{r})$, where $\mathcal{M}(\mathbf{r})$ is the mobility matrix (4.4) expressed in terms of the original time scale.

5.3. Discussion. The physical derivations of the drift and diffusion at low Kubo number are intended to provide some intuition for the results stated in Proposition 4.1. These formal arguments, however, involve assumptions which have varying degrees of plausibility and confidence, so the systematic and rigorous approach developed in section 3 is valuable. In particular, the systematic calculation allows precise assessment of the influence of the nonlinear advection term. Though indeed it is $O(\mathrm{Ku_T})$ weak relative to the viscous diffusion term, we are considering motion on $O(\mathrm{Ku_T^{-1}})$ time scales, so the nonlinearity could in principle have an $O(1)$ integrated influence on the particle motion. We found though, in section 3 that the nonlinear advection term does not in fact have an $O(1)$ effect due to cancellation caused by a parity symmetry (4.5) which it possesses.

6. Coarse-graining of the discretized IB method. In a numerical implementation, the velocity field can be represented by only a finite number of parameters. For a spectral code which retains the Fourier representation of the derivatives applied to the linear terms in the Navier–Stokes equations, the results of the continuum formulation would carry over by a simple Galerkin truncation. But such an abrupt spectral cutoff is usually not desirable in numerical simulations.

The version of the IB method implemented by Kramer and Peskin in [28] defines the fluid on a discrete, periodic, cubic mesh with (dimensional) spacing $h = L/K$, where K is an integer. The traditional IB method [42] has $h = a$, but there is no

difficulty in extending the numerical simulation approach for $h = ma$, where m is a nonnegative integer. An equivalent representation of the velocity field is through a finite set of Fourier coefficients $\{\hat{\mathbf{u}}_{\mathbf{k}}\}$ sufficient to resolve the velocity field on this mesh. The spatial derivatives appearing in the Navier–Stokes equations in (2.9a) must be replaced by operators with domain and range consistent with the finite-dimensional function space supported by the numerical resolution. The usual implementation is through finite-difference operators. We work out now how the effective dynamics of the particles are altered due to the discretization. These results are important for providing a benchmark against which numerical simulations can be compared more precisely. Temporal discretization lends itself less readily to the MTV framework, so we keep time continuous here.

6.1. Spatial discretization. We write the dynamical equations in the spatially discretized IB system (2.9) as

$$\begin{aligned}
&\frac{\partial \mathbf{u}(\mathbf{x},t)}{\partial t} + \mathcal{B}^{(d)}_{\mathbf{k}}(\mathbf{u},\mathbf{u})(\mathbf{x},t) = \mathrm{Ku}_{\mathrm{T}}^{-1}(\Delta^{(d)}_{\tilde{h}}\mathbf{u})(\mathbf{x},t) - (\nabla^{(d)}_{\tilde{h}}p)(\mathbf{x},t) + \mathbf{f}_T(t) \\
&\qquad\qquad - \phi \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}\left(\frac{\mathbf{X}(t)}{\tilde{\ell}_f}\right) \delta_1(\mathbf{x} - \mathbf{X}_{\boldsymbol{\alpha}}(t)), \\
&(\tilde{\nabla}^{(d)}_{\tilde{h}} \cdot \mathbf{u})(\mathbf{x},t) = 0, \\
&\frac{d\mathbf{X}_{\boldsymbol{\alpha}}(t)}{dt} = \mathbf{u}_1(\mathbf{X}_{\boldsymbol{\alpha}}(t),t), \\
&\mathbf{u}_1(\mathbf{x},t) = \tilde{h}^3 \sum_{\mathbf{x}'\in\tilde{h}\mathbb{Z}^3_K} \mathbf{u}(\mathbf{x}',t)\delta_1(\mathbf{x}-\mathbf{x}').
\end{aligned} \tag{6.1}$$

In these equations, $\mathbf{x}$ is restricted to taking values on the periodic cubic lattice $\tilde{h}\times\mathbb{Z}^3_K$, where

$$\mathbb{Z}^3_K \equiv [1,2,\ldots,K]^3,$$

and $\tilde{h}$ is a nondimensional length scale ratio:

$$\tilde{h} \equiv \frac{h}{a} = \frac{\tilde{K}}{K}.$$

$\mathcal{B}^{(d)}_{\mathbf{k}}$ is some finite-difference approximation for the nonlinear advection operator, $\Delta^{(d)}_{\tilde{h}}$ is a discrete Laplacian, $\nabla^{(d)}_{\tilde{h}}$ is a discrete gradient, and $\tilde{\nabla}^{(d)}_{\tilde{h}}$ is another discrete gradient used in defining a divergence operator. The current implementation of the IB method [42] takes the usual centered-difference approximations for the linear differential operators, namely,

$$\begin{aligned}
\nabla^{(d)}_{\tilde{h}} &= \sum_{m=1}^{3} \hat{e}_m D^0_{\tilde{h},m}, \\
\Delta^{(d)}_{\tilde{h}} &= \sum_{m=1}^{3} D^+_{\tilde{h},m} D^-_{\tilde{h},m}, \\
\tilde{\nabla}^{(d)}_{\tilde{h}} &= \nabla^{(d)}_{\tilde{h}},
\end{aligned} \tag{6.2}$$

where

$$(D^+_{\tilde{h},m}g)(\mathbf{x}) = \frac{g(\mathbf{x}+\tilde{h}\hat{e}_m) - g(\mathbf{x})}{\tilde{h}},$$

$$(D^-_{\tilde{h},m}g)(\mathbf{x}) = \frac{g(\mathbf{x}) - g(\mathbf{x}-\tilde{h}\hat{e}_m)}{\tilde{h}},$$

$$(D^0_{\tilde{h},m}g)(\mathbf{x}) = \frac{g(\mathbf{x}+\tilde{h}\hat{e}_m) - g(\mathbf{x}-\tilde{h}\hat{e}_m)}{2\tilde{h}},$$

and $\hat{e}_m$ denotes a unit vector in the mth coordinate direction. The nonlinear term in the Navier–Stokes equation is discretized by a skew-symmetric central differencing scheme which conserves energy exactly (see [42]):

$$\mathcal{B}^{(d)}_{\mathbf{k}}(\mathbf{u},\mathbf{u})(\mathbf{x},t) \equiv \frac{1}{2}\left(\mathbf{u}(\mathbf{x},t)\cdot\nabla^{(d)}_{\tilde{h}}\mathbf{u}(\mathbf{x},t) + \nabla^{(d)}_{\tilde{h}}\cdot(\mathbf{u}(\mathbf{x},t)\otimes\mathbf{u}(\mathbf{x},t))\right).$$

Other discretizations can also be contemplated. For example, an upwind differencing scheme for the nonlinear term has often been used for numerical simulations at higher Reynolds number to provide numerical stability [43]. A purely divergence-form discretization would conserve total momentum exactly. Finally, Cowen [5] is investigating other discretizations for the divergence operator, adapted to the choice of the interpolation/spreading delta function, which improve volume conservation properties. For this reason, we will express the formulas for the effective drift and diffusion coefficients in terms of the general abstract differential operators $\nabla^{(d)}_{\tilde{h}}$, $\tilde{\nabla}^{(d)}_{\tilde{h}}$, and $\Delta^{(d)}_{\tilde{h}}$, without assuming that they take the specific form of (6.2). It is important to note, however, that the pressure term will conserve energy only if $\tilde{\nabla}^{(d)}_{\tilde{h}} = \nabla^{(d)}_{\tilde{h}}$.

Because the finite-difference derivative operators remain invariant under translations by a grid spacing $\tilde{h}$, they act diagonally as multiplication operators on Fourier modes. In this way we can define their action on Fourier modes $\mathbf{k}$ through the symbols $\mathcal{F}_{\mathbf{k}}(\cdot)$, defined in general for an operator $\mathcal{O}$ with translation invariance on the basic lattice, by

$$\mathcal{O}\mathbf{g}(\mathbf{x},t) = \sum_{\mathbf{k}\in\mathbb{Z}^3_K} e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}\mathcal{F}_{\mathbf{k}}(\mathcal{O})\hat{\mathbf{g}}(\mathbf{k},t),$$

where

$$\mathbf{g}(\mathbf{x},t) = \sum_{\mathbf{k}\in\mathbb{Z}^3_K} e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}\hat{\mathbf{g}}(\mathbf{k},t).$$

For the implemented version described in (6.2), the Fourier representation of the finite-difference operators would be

$$\mathcal{F}_{\mathbf{k}}(\Delta^{(d)}_{\tilde{h}}) = -\frac{4}{\tilde{h}^2}\sum_{m=1}^{3}\sin^2\frac{\pi k_m}{K},$$

$$\mathcal{F}_{\mathbf{k}}(\nabla^{(d)}_{\tilde{h}}) = \mathcal{F}_{\mathbf{k}}(\tilde{\nabla}^{(d)}_{\tilde{h}}) = \frac{i}{\tilde{h}}\sum_{m=1}^{3}\hat{e}_m\sin\frac{2\pi k_m}{K}.$$

Note that these Fourier representations of the discretized operators converge to the Fourier representation of the corresponding continuum operators as $K\to\infty$ (with the period cell length $\tilde{K} = K\tilde{h}$ held fixed).

The thermal forcing must be changed as follows (see [28]) in order to maintain the correct statistical mechanics for the spatially discretized system (6.1):

$$\mathbf{f}_T(\mathbf{x},t) = \mathrm{Ku}_\mathrm{T}^{-1/2}\tilde{K}^{-3/2}\sum_{\mathbf{k}\in S_K}\sqrt{2\mathcal{F}_\mathbf{k}(-\Delta_{\tilde{h}}^{(d)})}e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}\mathcal{P}_\mathbf{k}^{(dI)}\frac{d\tilde{\mathbf{W}}_\mathbf{k}(t)}{dt}, \tag{6.3}$$

where

$$S_K = \mathbb{Z}_K^3 \setminus (K,K,K) \tag{6.4}$$

and the projection tensor

$$\mathcal{P}_\mathbf{k}^{(dI)} = \mathcal{I} - \frac{\mathcal{F}_\mathbf{k}(\tilde{\nabla}_{\tilde{h}}^{(d)})\otimes\mathcal{F}_\mathbf{k}(\tilde{\nabla}_{\tilde{h}}^{(d)})}{\mathcal{F}_\mathbf{k}(\tilde{\nabla}_{\tilde{h}}^{(d)}\cdot\tilde{\nabla}_{\tilde{h}}^{(d)})} \tag{6.5}$$

must be included when $\tilde{\nabla}_{\tilde{h}}^{(d)} \neq \nabla_{\tilde{h}}^{(d)}$ for proper results. When $\tilde{\nabla}_{\tilde{h}}^{(d)} = \nabla_{\tilde{h}}^{(d)}$, the inclusion or omission of the factor $\mathcal{P}_\mathbf{k}^{(dI)}$ in (6.3) has no effect on the system dynamics.

6.2. Changes in drift and diffusion due to discretization. Whatever the precise forms of the discretized derivatives, the resulting drift and noise terms in the effective dynamics (4.1) have the form

$$\begin{aligned}\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X}) &= -\phi\sum_{\boldsymbol{\alpha}'\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}\left(\frac{\mathbf{X}}{\bar{\ell}_f}\right)\bar{\mathcal{M}}^{(d)}(\mathbf{X}_{\boldsymbol{\alpha}'},\mathbf{X}_{\boldsymbol{\alpha}}-\mathbf{X}_{\boldsymbol{\alpha}'}),\\ \mathcal{S}_\mathbf{k}(\mathbf{x}) &= \sqrt{2}\tilde{K}^{3/2}\frac{\mathcal{P}_\mathbf{k}^{(dI)}e^{2\pi i\mathbf{k}\cdot\mathbf{x}/\tilde{K}}}{\sqrt{\mathcal{F}_\mathbf{k}(-\Delta_{\tilde{h}}^{(d)})}}\sum_{\mathbf{p}\in\mathbb{Z}^3}\hat{\delta}_{1,K\mathbf{p}+\mathbf{k}}e^{2\pi i\mathbf{p}\cdot\mathbf{x}/\tilde{h}},\end{aligned} \tag{6.6a}$$

with the mobility matrix function given by

$$\begin{aligned}\bar{\mathcal{M}}^{(d)}(\mathbf{x}',\mathbf{r}) &= \sum_{\mathbf{q}\in S}\sum_{\mathbf{p}\in\mathbb{Z}^3}\hat{\bar{\mathcal{M}}}_{\mathbf{p},\mathbf{q}}^{(d)}e^{2\pi i\mathbf{q}\cdot\mathbf{r}/\tilde{K}}e^{2\pi i\mathbf{p}\cdot\mathbf{x}/\tilde{h}},\\ \hat{\bar{\mathcal{M}}}_{\mathbf{p},\mathbf{q}}^{(d)} &= \tilde{K}^3\frac{\mathcal{P}_\mathbf{q}^{(dII)}\hat{\delta}_{1,K\mathbf{p}+\mathbf{q}}\hat{\delta}_{1,\mathbf{q}}^*}{\mathcal{F}_\mathbf{q}(-\Delta_{\tilde{h}}^{(d)})}.\end{aligned} \tag{6.6b}$$

Note that in general we must distinguish two versions of the projection tensor $\mathcal{P}_\mathbf{k}$ in the discretized formalism:

$$\mathcal{P}_\mathbf{k}^{(dII)} = \mathcal{I} - \frac{\mathcal{F}_\mathbf{k}(\nabla_{\tilde{h}}^{(d)})\otimes\mathcal{F}_\mathbf{k}(\tilde{\nabla}_{\tilde{h}}^{(d)})}{\mathcal{F}_\mathbf{k}(\nabla_{\tilde{h}}^{(d)}\cdot\tilde{\nabla}_{\tilde{h}}^{(d)})},$$

and $\mathcal{P}_\mathbf{k}^{(dI)}$ as given in (6.5). In the discretized formalism, the projection tensors $\mathcal{P}_\mathbf{k}$ appearing in the dynamical equation for the velocity modes in (3.2a), except in front of the noise term, are to be replaced by $\mathcal{P}_\mathbf{k}^{(dII)}$. On the other hand, the projection tensor $\mathcal{P}_\mathbf{k}$ appearing in front of the noise term and in (A.11) should be replaced by $\mathcal{P}_\mathbf{k}^{(dI)}$.

The effective drift and random terms for the discretized IB formalism have the same form as those appearing in the continuum IB formalism (Proposition 4.1), with the following key differences:

1. The mobility matrix function depends not only on the relative separation of the location of applied force and the responding particle, but also on the absolute location of the applied force relative to the fluid grid. Indeed, the mobility matrix function is readily seen to be periodic in the force location $\mathbf{x}'$ along the grid axes with period equal to the grid spacing $\tilde{h}$. This implies that the dynamics of the particles will depend somewhat on their position relative to the fluid grid. The grid-induced oscillations of the mobility matrix function are quantified by the $\mathbf{p} \neq \mathbf{0}$ terms in (6.6b) and will be studied quantitatively in [27].

2. The formulas involve a clear aliasing of wavenumbers separated by integer vector multiples of K, the number of grid points in each direction.

3. The mobility matrix function $\bar{\mathcal{M}}^{(d)}(\mathbf{r})$ is a symmetric, nonnegative definite matrix function if and only if the discretized derivatives obey $\nabla_{\tilde{h}}^{(d)} = \tilde{\nabla}_{\tilde{h}}^{(d)}$. In this case, the effective dynamics still obey the Einstein relation between the mobility matrix and the relative diffusivities of particles, though we no longer have a simple relation between the Fourier coefficients of the noise and the mobility matrix as in (4.3). The violation of the Einstein relation when $\nabla_{\tilde{h}}^{(d)} \neq \tilde{\nabla}_{\tilde{h}}^{(d)}$ occurs because the discretized pressure term does not conserve energy in this case.

4. The dissipation factor for each mode is naturally changed from the continuum value $4\pi^2(k/\tilde{K})^2$ to the value $\mathcal{F}_{\mathbf{k}}(-\Delta_{\tilde{h}}^{(d)})$ appropriate to the discretized viscous diffusion operator.

5. The sum is taken over a finite set of modes S_K (6.4), and there is no issue of ultraviolet divergence.

As we emphasize in section A.6, the nonlinear advection term in the continuum formulation makes no contribution to the effective structure dynamics in the low $\mathrm{Ku_T}$ limit due to a parity symmetry (4.5). This symmetry is also preserved under the implemented discretization (6.2) or if the nonlinear advection term is alternatively discretized by upwind differencing. In general, provided the discretization scheme respects the parity symmetry (4.5), the presence of the discretized weak nonlinear advection term does not change the effective dynamics of the particles on nondimensional time scales $O(\mathrm{Ku_T^{-1}})$ to leading order. If, however, the discretization violates this symmetry, there may be spurious contamination from the discretized nonlinearity.

The effective immersed structure dynamics derived for the immersed structures evolving according to the discretized IB method can be used as a design criterion for a numerical procedure. For example, the single-particle diffusivity (which is the same as $\mathcal{D}(\mathbf{0})$ given by a discretized modification of the formula (5.4) following the above discussion) may be used as a means to identify the effective size of the simulated particle. Of course this size will be order unity in our nondimensionalized units, but since the elementary particles are represented as smoothed delta functions rather than objects with rigid boundaries, it is not a priori clear how to associate a definite size value to the particles. The general Stokes–Einstein formula [16, 46] relating the diffusivity of a particle to its size, along with the explicit formulas for the effective diffusion of the IB particles, gives us a quantitative way to associate the simulation parameters with the effective particle sizes which are desired in a simulation. The above formulas for the coarse-grained discretized IB dynamics are used extensively in [28, 27] to explore how well the IB method replicates the correct statistical physics of immersed structure motion and to provide a benchmark for the results of numerical simulations.

7. Conclusions. We have demonstrated how the stochastic mode reduction framework developed by Majda, Timofeyev, and Vanden-Eijnden (MTV) can be ap-

plied to obtain coarse-grained approximations for the equations underlying the IB method for the simulation of microfluid systems with thermal fluctuations. In this way we were able to characterize rigorously the effective drift and diffusion behavior of immersed structures in the IB method. In particular, with full rigor, the equations governing the coarse-grained spatially continuous and discrete IB methods have been compared with each other and also with the desired physical behavior. Provided that the pressure gradient is discretized in an energy-conserving way and the nonlinear advection term is discretized in a manner (such as a central difference approximation) which respects the parity symmetry (4.5), the continuous and spatially discretized IB methods have structurally similar coarse-grained dynamics with explicit formulas identifying the drift and diffusion coefficients. The main difference between the structural form of the coarse-grained dynamics of the elementary particles in the IB method and those of physically proper rigid particles (as well as the particle-based simulation methods discussed in [26]) is the absence of the "divergence-drift" term for the IB method, which is significant only for Lagrangian particles spaced closely compared to their effective sizes. As discussed in section 4.2, one source of this discrepancy is lack of rigidity of the Lagrangian particles in the IB method, which may be desirable for physiological systems with flexible and elastic structures. Incorporation of rigidity into the IB method [41] might bring its effective dynamics into closer agreement with those of rigid particle-based methods [3, 8, 26, 48] at small separation distances. Finally, the explicit formulas for the effective diffusion of the Lagrangian particles under spatial discretization provide a means for choosing the size parameter precisely in applications so as to match desired diffusion coefficients.

Appendix. Details of computations for stochastic mode reduction. The details of the calculation from section 3 are presented here.

A.1. Derivation of Kolmogorov backward equation. We provide here a formal derivation of the Kolmogorov backward equation (3.3) based on a stochastic Taylor expansion [22, 37]. Consider the change of $\rho(s, \mathbf{X}, \mathbf{U}|t)$ over a small time interval Δs, using its definition (3.4) and the law of total expectation (see [49]):

$$\begin{aligned}
&\rho(s+\Delta s, \mathbf{X}, \mathbf{U}|t) - \rho(s, \mathbf{X}, \mathbf{U}|t) \\
&\quad = \rho(s+\Delta s, \mathbf{X}, \mathbf{U}|t) \\
&\qquad\qquad - \mathbb{E}\left[f(\mathbf{X}(t), \mathbf{U}(t))|\mathbf{X}(s) = \mathbf{X}, \mathbf{U}(s) = \mathbf{U}\right] \\
&\quad = \rho(s+\Delta s, \mathbf{X}, \mathbf{U}|t) \\
&\qquad\qquad - \mathbb{E}\left[\mathbb{E}\left(f(\mathbf{X}(t), \mathbf{U}(t))|\mathbf{X}(s+\Delta s), \mathbf{U}(s+\Delta s)\right)\big|\mathbf{X}(s) = \mathbf{X}, \mathbf{U}(s) = \mathbf{U}\right] \\
&\quad = \rho(s+\Delta s, \mathbf{X}, \mathbf{U}|t) \\
&\qquad\qquad - \mathbb{E}\left[\rho(s+\Delta s, \mathbf{X}(s+\Delta s), \mathbf{U}(s+\Delta s)|t)|\mathbf{X}(s) = \mathbf{X}, \mathbf{U}(s) = \mathbf{U}\right] \\
&\quad = \mathbb{E}\left[\rho(s+\Delta s, \mathbf{X}, \mathbf{U}|t) - \rho(s+\Delta s, \mathbf{X}(s+\Delta s), \mathbf{U}(s+\Delta s)|t)\right. \\
&\qquad\qquad\qquad\qquad \left.\big|\mathbf{X}(s) = \mathbf{X}, \mathbf{U}(s) = \mathbf{U}\right].
\end{aligned}$$

Now we will want to perform a stochastic Taylor expansion of the second term, using the following expressions for the increments in the system variables during the small time step Δs:

$$\mathbf{X}_{\boldsymbol{\alpha}}(s+\Delta s) - \mathbf{X}_{\boldsymbol{\alpha}}(s) = \tilde{K}^3 \sum_{\mathbf{k}\in S} e^{2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(s)} \hat{\mathbf{u}}_{\mathbf{k}}(s)\hat{\delta}_{1,\mathbf{k}}\Delta s + O((\Delta s)^2),$$

$$\begin{aligned}\Delta\hat{\mathbf{u}}_{\mathbf{k}}(s) \equiv \hat{\mathbf{u}}_{\mathbf{k}}(s+\Delta s) - \hat{\mathbf{u}}_{\mathbf{k}}(s) &= -\mathcal{B}_{\mathbf{k}}(\mathbf{U}(s),\mathbf{U}(s))\Delta s - 4\pi^2(k/\tilde{K})^2 \mathrm{Ku}_{\mathrm{T}}^{-1}\hat{\mathbf{u}}_{\mathbf{k}}(s)\Delta s \\ &\quad - \phi\mathcal{P}_{\mathbf{k}} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}}\tilde{\Phi}(\mathbf{X}_{\boldsymbol{\alpha}}(s)/\tilde{\ell}_f)\hat{\delta}_{1,\mathbf{k}} e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(s)}\Delta s \\ &\quad + \mathrm{Ku}_{\mathrm{T}}^{-1/2}\tilde{K}^{-3/2}\sqrt{2(4\pi^2(k/\tilde{K})^2)}\,\mathcal{P}_{\mathbf{k}}\Delta\tilde{\mathbf{W}}_{\mathbf{k}}(s) + o(\Delta s),\end{aligned}$$

which arise upon integrating the equations of motion (3.2) over the short time interval Δs and using the Itô property of the noise [37]. The noise increments $\Delta\tilde{\mathbf{W}}_{\mathbf{k}}(s) = \int_s^{s+\Delta s} d\tilde{\mathbf{W}}_{\mathbf{k}}(s)$ are Gaussian, mean-zero complex random variables, which are independent except for the complex conjugacy property

$$\Delta\tilde{\mathbf{W}}_{-\mathbf{k}} = \overline{\Delta\tilde{\mathbf{W}}_{\mathbf{k}}}. \tag{A.1}$$

Their covariances are given by integration of (2.5):

$$\langle \Delta\tilde{\mathbf{W}}_{\mathbf{k}} \otimes \Delta\tilde{\mathbf{W}}_{\mathbf{k}}\rangle = 0, \qquad \langle \Delta\tilde{\mathbf{W}}_{\mathbf{k}} \otimes \overline{\Delta\tilde{\mathbf{W}}_{\mathbf{k}}}\rangle = \Delta s\mathcal{I}. \tag{A.2}$$

Now we can compute

$$\begin{aligned}&\rho(s+\Delta s,\mathbf{X},\mathbf{U}|t) - \rho(s,\mathbf{X},\mathbf{U}|t) \\ &\quad = \mathbb{E}\left[\rho(s+\Delta s,\mathbf{X},\mathbf{U}|t) - \left(\rho(s+\Delta s,\mathbf{X},\mathbf{U}|t) + \sum_{\boldsymbol{\alpha}\in\mathcal{A}}(\Delta\mathbf{X}_{\boldsymbol{\alpha}})\cdot\frac{\partial\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\right.\right. \\ &\qquad\quad + \sum_{\mathbf{k}\in S}(\Delta\hat{\mathbf{u}}_{\mathbf{k}})\cdot\frac{\partial\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\hat{\mathbf{u}}_{\mathbf{k}}} \\ &\qquad\quad \left.\left. + \frac{1}{2}\sum_{\mathbf{k},\mathbf{k}'\in S}(\Delta\hat{\mathbf{u}}_{\mathbf{k}})\cdot\frac{\partial^2\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\hat{\mathbf{u}}_{\mathbf{k}}\partial\hat{\mathbf{u}}_{\mathbf{k}'}}\cdot(\Delta\hat{\mathbf{u}}_{\mathbf{k}'})\right)\,\middle|\,\mathbf{X}(s)=\mathbf{X},\mathbf{U}(s)=\mathbf{U}\right] \\ &\qquad + o(\Delta s) \\ &\quad = -\tilde{K}^3\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\sum_{\mathbf{k}\in S} e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(s)}\hat{\delta}_{1,\mathbf{k}}\hat{\mathbf{u}}_{\mathbf{k}}(s)\cdot\frac{\partial\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\Delta s \\ &\qquad + \sum_{\mathbf{k}\in S}\left[\mathcal{B}_{\mathbf{k}}(\mathbf{U}(s),\mathbf{U}(s)) + 4\pi^2\left(\frac{k}{\tilde{K}}\right)^2\mathrm{Ku}_{\mathrm{T}}^{-1}\hat{\mathbf{u}}_{\mathbf{k}}(s)\right. \\ &\qquad\qquad \left. + \phi\mathcal{P}_{\mathbf{k}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}_{\boldsymbol{\alpha}}(s)}{\tilde{\ell}_f}\right)\hat{\delta}_{1,\mathbf{k}}e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}(s)}\right]\cdot\frac{\partial\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\hat{\mathbf{u}}_{\mathbf{k}}}\Delta s \\ &\qquad - \sum_{\mathbf{k}\in S}\mathrm{Ku}_{\mathrm{T}}^{-1}\tilde{K}^{-3}\left(4\pi^2\left(\frac{k}{\tilde{K}}\right)^2\right)\mathcal{P}_{\mathbf{k}} : \frac{\partial^2\rho(s,\mathbf{X},\mathbf{U}|t)}{\partial\hat{\mathbf{u}}_{\mathbf{k}}\partial\hat{\mathbf{u}}_{\mathbf{k}}^*}\Delta s + o(\Delta s).\end{aligned} \tag{A.3}$$

We used (A.1) and (A.2) to collapse the sum over $\mathbf{k}$ and $\mathbf{k}'$ in the last term to a single sum (with $\mathbf{k}' = -\mathbf{k}$). Dividing the final relation by Δs, then sending $\Delta s \to 0$, leads to the Kolmogorov backward equation (3.3). The $\mathcal{P}_{\mathbf{k}}$ can be dropped from the term involving second derivatives of $\hat{\mathbf{u}}_{\mathbf{k}}$ because $\mathbf{k}\cdot\partial/(\partial\hat{\mathbf{u}}_{\mathbf{k}}) = 0$ follows automatically from the fact that $\hat{\mathbf{u}}_{\mathbf{k}}$ is understood to always be restricted so that $\mathbf{k}\cdot\hat{\mathbf{u}}_{\mathbf{k}} = 0$.

A.2. Asymptotic expansion of solution. We show now how to derive the limiting equation (3.6) from the original Kolmogorov backward equation (3.5) with the small parameter ε. We expand the solution in powers of ε:

$$\rho^\varepsilon = \rho_0 + \varepsilon\rho_1 + \varepsilon^2\rho_2 + \cdots.$$

Then, writing out the first three equations of the asymptotic hierarchy, we have

$$\begin{aligned} &\mathcal{L}_1\rho_0 = 0, \\ &\mathcal{L}_1\rho_1 = -\mathcal{L}_2\rho_0, \\ &\mathcal{L}_1\rho_2 = -\frac{\partial\rho_0}{\partial s} - \mathcal{L}_2\rho_1. \end{aligned} \tag{A.4}$$

We will now solve these in succession; all three must be considered to obtain a full description of the evolution of ρ_0. Our presentation will take the form of a formal calculation, but the results find rigorous support from the theorem of Kurtz [9, 30] for any finite truncation of the set of modes S.

Since we are interested in deriving effective equations for only the (slow) particle coordinates $\mathbf{X}$, we can restrict attention to initial data which depends only on $\mathbf{X}$:

$$f = f(\mathbf{X}).$$

In the solvability conditions that will follow after consideration of the second- and higher-order equations of the hierarchy, it will be helpful to explicitly identify some analytical properties of $\mathcal{L}_1$. Since $\mathcal{L}_1$ is the generator of the Ornstein–Uhlenbeck process, the projection $\mathcal{P}_N$ onto its null space can be identified with the operation of averaging against its invariant measure (MTV):

$$\begin{aligned} (\mathcal{P}_N g)(\mathbf{X}) = (\mathbb{E}_{OU} g)(\mathbf{X}) &\equiv \int_{\mathbb{C}^S} d\mathbf{U}\, \pi_{OU}(\mathbf{U}) g(\mathbf{X}, \mathbf{U}), \\ \pi_{OU}(\mathbf{U}) &= \left(\prod_{\mathbf{k}\in S} \frac{\tilde{K}^3}{4\pi} \right) \exp\left(-\frac{1}{2}\tilde{K}^3 \sum_{\mathbf{k}\in S} |\hat{\mathbf{u}}_{\mathbf{k}}|^2 \right). \end{aligned} \tag{A.5}$$

Also, the null space of $\mathcal{L}_1^*$ is exactly spanned by π_{OU}, so in applying the solvability conditions, it is helpful to note that (see [13])

$$g \in \operatorname{Ran}\mathcal{L}_1 \Leftrightarrow g \in (\operatorname{Ker}\mathcal{L}_1^*)^\perp \Leftrightarrow \mathbb{E}_{OU} g = 0. \tag{A.6}$$

A.3. First equation in asymptotic hierarchy. The leading-order equation in (A.4) implies simply that ρ_0 does not depend on the fast variables $\mathbf{U}$:

$$\rho_0 = \rho_0(s, \mathbf{X}|t).$$

Another way of expressing this is

$$\mathbb{E}_{OU}\rho_0 = \rho_0.$$

A.4. Second equation in asymptotic hierarchy. The solvability condition for the second equation in (A.4) is

$$\mathbb{E}_{OU}\mathcal{L}_2\rho_0 = \mathbb{E}_{OU}\mathcal{L}_2\mathbb{E}_{OU}\rho_0 = 0,$$

which is trivially satisfied because $\mathbb{E}_{OU}\mathcal{L}_2\mathbb{E}_{OU} = 0$.

Therefore, the equation may be solved directly by writing

$$\rho_1 = -\mathcal{L}_1^{-1}\mathcal{L}_2\mathbb{E}_{OU}\rho_0 + \tilde{\rho}_1. \tag{A.7}$$

Since $\mathcal{L}_1$ has a one-dimensional null-space, the inverse operator $\mathcal{L}_1^{-1}$ should be thought of as a particular continuous choice of an inverse image associated with each function in the range of $\mathcal{L}_1$. We make a specific choice in section A.6. The function $\tilde{\rho}_1 = \tilde{\rho}_1(\mathbf{X}, s|t)$ is a function in the null space of $\mathcal{L}_1$; its presence reflects the one-dimensional indeterminacy of the inversion of $\mathcal{L}_1$.

A.5. Third equation in asymptotic hierarchy. Substituting the solution (A.7) into the third equation in (A.4) and applying the solvability condition, we obtain the desired evolution equation for ρ_0 in operator-theoretic form:

$$\begin{aligned} -\frac{\partial \rho_0}{\partial s} &= -\mathbb{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbb{E}_{OU}\rho_0, \\ \rho_0(s = t, \mathbf{X}|t) &= f(\mathbf{X}). \end{aligned} \tag{A.8}$$

The arbitrary function $\tilde{\rho}_1 \in \operatorname{Ker}\mathcal{L}_1$ has now disappeared because $\mathbb{E}_{OU}\mathcal{L}_2\tilde{\rho}_1 = 0$. Therefore, we see that the evolution equation for ρ_0 will not depend on the particular way in which we choose to invert $\mathcal{L}_1$.

A.6. Explicit computation of limiting PDE. To express the differential operator

$$\bar{\mathcal{L}} \equiv -\mathbb{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbb{E}_{OU},$$

appearing on the right-hand side of (A.8), in a concrete form, we follow the development in Appendix B of MTV. To map the formulas appearing there to the present problem, we write

$$\mathcal{L}_1 = \sum_{\mathbf{k}\in S}\left(-\gamma_{\mathbf{k}}\hat{\mathbf{u}}_{\mathbf{k}}\cdot\frac{\partial}{\partial\hat{\mathbf{u}}_{\mathbf{k}}} + \frac{\sigma_{\mathbf{k}}^2}{2}\frac{\partial}{\partial\hat{\mathbf{u}}_{\mathbf{k}}}\cdot\frac{\partial}{\partial\hat{\mathbf{u}}_{\mathbf{k}}^*}\right),$$

with

$$\gamma_{\mathbf{k}} \equiv 4\pi^2(k/\tilde{K})^2, \qquad \sigma_{\mathbf{k}} \equiv \sqrt{2\tilde{K}^{-3}(4\pi^2(k/\tilde{K})^2)}. \tag{A.9}$$

We pass to the representation of $\mathcal{L}_2$ acting on Fourier transformed functions of the fast variables $\mathbf{U}$. We must be careful in defining this Fourier transform, however, because the variables constituting $\mathbf{U}$ are complex and are constrained by the complex conjugacy relations $\hat{\mathbf{u}}_{-\mathbf{k}} = \hat{\mathbf{u}}_{\mathbf{k}}^*$. Therefore, we define the Fourier transform of functions $g(\mathbf{U})$ by

$$\hat{g}(\mathbf{P}) = \int_{\mathbb{C}^S}\exp\left[\frac{1}{4}i\sum_{\mathbf{k}\in S}\left(\hat{\mathbf{u}}_{\mathbf{k}}\cdot(\mathbf{p}_{\mathbf{k}} + \mathbf{p}_{-\mathbf{k}}^*) + \hat{\mathbf{u}}_{\mathbf{k}}^*\cdot(\mathbf{p}_{-\mathbf{k}} + \mathbf{p}_{\mathbf{k}}^*)\right)\right] g(\mathbf{U})\, d\mathbf{U},$$

where $\mathbf{P} = \{\mathbf{p}_{\mathbf{k}}\}_{\mathbf{k}\in S}$. This artifice first ensures that the exponent is purely imaginary (so that the Fourier integration is at least well defined in each mode), and second allows us to identify $\mathbf{p}_{-\mathbf{k}}$ with $\mathbf{p}_{\mathbf{k}}^*$ just as we have been identifying $\hat{\mathbf{u}}_{-\mathbf{k}}$ with $\hat{\mathbf{u}}_{\mathbf{k}}^*$. Indeed, $\hat{g}$ must perforce depend on $\mathbf{p}_{\mathbf{k}}$ and $\mathbf{p}_{-\mathbf{k}}^*$ in the same way, and thus these

variables can be identified with each other. Also, we can and will restrict the domain of definition of the variables $\mathbf{p_k}$ to the hyperplane $\mathbf{p_k} \cdot \mathbf{k} = 0$; the component of $\mathbf{p_k}$ parallel to $\mathbf{k}$ is irrelevant because of the restriction $\hat{\mathbf{u}}_\mathbf{k} \cdot \mathbf{k} = 0$. Finally, it can be readily checked that the Fourier transform rules for derivatives carry over to our present definition of the Fourier transform in a straightforward way:

$$\hat{\mathbf{u}}_\mathbf{k} \to -i \frac{\partial}{\partial \mathbf{p_k}}, \qquad \frac{\partial}{\partial \hat{\mathbf{u}}_\mathbf{k}} \to -i \mathbf{p_k}.$$

Proceeding, then, we write down the Fourier transform of the operator $\mathcal{L}_2$ as

$$\begin{aligned}\hat{\mathcal{L}}_2 = \sum_{\mathbf{k}\in S} \Bigg[& -2\pi \tilde{K}^{-1} \mathcal{P}_\mathbf{k} \sum_{\mathbf{k}'\in S} \mathbf{k} \cdot \frac{\partial}{\partial \mathbf{p}_{\mathbf{k}'}} \frac{\partial}{\partial \mathbf{p}_{\mathbf{k}-\mathbf{k}'}} \\ & + i\phi \mathcal{P}_\mathbf{k} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right) \hat{\delta}_{1,\mathbf{k}} e^{-2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}} \Bigg] \cdot \mathbf{p_k} \\ & - i\tilde{K}^3 \sum_{\mathbf{k}\in S} \hat{\delta}_{1,\mathbf{k}} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} e^{2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}} \frac{\partial}{\partial \mathbf{p_k}} \cdot \frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}}.\end{aligned}$$

We can now adapt relation (B.4) of MTV to our present case with complex-valued variables:

$$\begin{aligned}& -\mathbb{E}_{OU} \mathcal{L}_2 \mathcal{L}_1^{-1} \mathcal{L}_2 \mathbb{E}_{OU} g(\mathbf{X}) \\ & \quad = \int_{\mathbb{C}^S} d\mathbf{P}\, \hat{\bar{P}}_{OU}(\mathbf{P}) \hat{\mathcal{L}}_2 \int_0^\infty dt \\ & \quad \exp\left(\sum_{\mathbf{k}\in S} \gamma_\mathbf{k} t - \frac{1}{4} \sum_{\mathbf{k}\in S} \frac{\sigma_\mathbf{k}^2 |\mathbf{p_k}|^2}{\gamma_\mathbf{k}} (e^{2\gamma_\mathbf{k} t} - 1) \right) \left[\hat{\mathcal{L}}_2 (g(\mathbf{X}) \delta(\mathbf{P}')) \right]_{\mathbf{P}' = \boldsymbol{\beta}(\mathbf{P},t)},\end{aligned}$$

where $\mathbf{P}$ is shorthand notation for the collection $\{\mathbf{p_k}\}_{\mathbf{k}\in S}$ (similarly for $\mathbf{P}'$),

$$\hat{\bar{P}}_{OU}(\mathbf{P}) = \exp\left(-\frac{1}{4} \sum_{\mathbf{k}\in S} \frac{\sigma_\mathbf{k}^2 |\mathbf{p_k}|^2}{\gamma_\mathbf{k}} \right)$$

is the Fourier transform of the invariant measure $\pi_{OU}(\mathbf{U})$ in (A.5), and

$$\boldsymbol{\beta}(\mathbf{P}, t) = \{ e^{\gamma_\mathbf{k} t} \mathbf{p_k} \}_{\mathbf{k}\in S}.$$

We have here chosen to define $\mathcal{L}_1^{-1}$ in terms of its Fourier transform:

$$(\hat{\mathcal{L}}_1^{-1} b)(\mathbf{P}) = -\int_0^\infty \exp\left(-\frac{1}{4} \sum_{\mathbf{k}\in S} \frac{\sigma_\mathbf{k}^2 |\mathbf{p_k}|^2}{\gamma_\mathbf{k}} (e^{2\gamma_\mathbf{k} t} - 1) \right) \exp\left(\sum_{\mathbf{k}\in S} \gamma_\mathbf{k} t \right) \hat{b}(\boldsymbol{\beta}(\mathbf{P}, t))\, dt.$$

Computing now the action of the rightmost $\hat{\mathcal{L}}_2$, we obtain

$$\begin{aligned}& \exp\left(\sum_{\mathbf{k}\in S} \gamma_\mathbf{k} t \right) \left(\left[\hat{\mathcal{L}}_2 (g(\mathbf{X}) \delta(\mathbf{P}')) \right]_{\mathbf{P}' = \boldsymbol{\beta}(\mathbf{P},t)} \right) \\ & \qquad = -i\tilde{K}^3 \sum_{\mathbf{k}\in S} \hat{\delta}_{1,\mathbf{k}} e^{-\gamma_\mathbf{k} t} \sum_{\boldsymbol{\alpha}\in\mathcal{A}} e^{2\pi i \mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}} \frac{\partial g}{\partial \mathbf{X}_{\boldsymbol{\alpha}}} \cdot \frac{\partial \delta(\mathbf{P})}{\partial \mathbf{p_k}}.\end{aligned}$$

Continuing,

$$\begin{aligned}
&\hat{\mathcal{L}}_1^{-1}\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}))\\
&\quad= -\int_0^\infty dt\, \exp\left(-\frac{1}{4}\sum_{\mathbf{k}\in S}\frac{\sigma_{\mathbf{k}}^2|\mathbf{p}_{\mathbf{k}}|^2}{\gamma_{\mathbf{k}}}(e^{2\gamma_{\mathbf{k}}t}-1)\right)\\
&\qquad\qquad\times\left[-i\tilde{K}^3\sum_{\mathbf{k}\in S}\hat{\delta}_{1,\mathbf{k}}e^{-\gamma_{\mathbf{k}}t}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{p}_{\mathbf{k}}}\right]\\
&\quad= i\tilde{K}^3\sum_{\mathbf{k}\in S}\hat{\delta}_{1,\mathbf{k}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{p}_{\mathbf{k}}}\int_0^\infty e^{-\gamma_{\mathbf{k}}t}\,dt\\
&\quad= i\tilde{K}^3\sum_{\mathbf{k}\in S}\frac{\hat{\delta}_{1,\mathbf{k}}}{\gamma_{\mathbf{k}}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{p}_{\mathbf{k}}}.
\end{aligned}$$

Next, using the distribution identity $\mathbf{p}_{\mathbf{k}}\otimes\frac{\partial\delta(\mathbf{p}_{\mathbf{k}})}{\partial\mathbf{p}_{\mathbf{k}}}=-\mathcal{I}\delta(\mathbf{p}_{\mathbf{k}})$, we have

$$\begin{aligned}
&\hat{\mathcal{L}}_2\hat{\mathcal{L}}_1^{-1}\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}))\\
&\quad= -i\tilde{K}^3\sum_{\mathbf{k}\in S}\left[-2\pi\tilde{K}^{-1}\mathcal{P}_{\mathbf{k}}\sum_{\mathbf{k}'\in S}\mathbf{k}\cdot\frac{\partial}{\partial\mathbf{p}_{\mathbf{k}'}}\frac{\partial}{\partial\mathbf{p}_{\mathbf{k}-\mathbf{k}'}}\right.\\
&\qquad\qquad\left.+\,i\phi\mathcal{P}_{\mathbf{k}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\hat{\delta}_{1,\mathbf{k}}e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\right]\\
&\qquad\qquad\cdot\left[\frac{\hat{\delta}_{1,\mathbf{k}}}{\gamma_{\mathbf{k}}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\frac{\partial g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\delta(\mathbf{P})\right]\\
&\qquad+\tilde{K}^6\sum_{\mathbf{k},\mathbf{k}'\in S}\frac{\hat{\delta}_{1,\mathbf{k}}\hat{\delta}_{1,\mathbf{k}'}}{\gamma_{\mathbf{k}}}\sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}}e^{2\pi i(\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}+\mathbf{k}'\cdot\mathbf{X}_{\boldsymbol{\alpha}'})/\tilde{K}}\frac{\partial^2 g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}}\partial\mathbf{X}_{\boldsymbol{\alpha}'}}:\frac{\partial^2\delta(\mathbf{P})}{\partial\mathbf{p}_{\mathbf{k}}\partial\mathbf{p}_{\mathbf{k}'}}\\
&\qquad+\tilde{K}^6\sum_{\mathbf{k},\mathbf{k}'\in S}\frac{\hat{\delta}_{1,\mathbf{k}}\hat{\delta}_{1,\mathbf{k}'}}{\gamma_{\mathbf{k}}}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i(\mathbf{k}+\mathbf{k}')\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\frac{\partial g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\frac{\partial^2\delta(\mathbf{P})}{\partial\mathbf{p}_{\mathbf{k}}\partial\mathbf{p}_{\mathbf{k}'}}\cdot(2\pi i\mathbf{k}).
\end{aligned}\tag{A.10}$$

Finally, taking the leftmost expectation defining $\bar{\mathcal{L}}$, we have

$$\begin{aligned}
\bar{\mathcal{L}}g(\mathbf{X}) &= -\int_{\mathbb{C}^S}\hat{\bar{P}}_{OU}(\mathbf{P})\hat{\mathcal{L}}_2\hat{\mathcal{L}}_1^{-1}\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}))\\
&= -\tilde{K}^3\sum_{\mathbf{k}\in S}\phi\mathcal{P}_{\mathbf{k}}\sum_{\boldsymbol{\alpha}'\in\mathcal{A}}\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\hat{\delta}_{1,\mathbf{k}}e^{-2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}'}/\tilde{K}}\hat{\delta}_{1,\mathbf{k}}\gamma_{\mathbf{k}}^{-1}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot\mathbf{X}_{\boldsymbol{\alpha}}/\tilde{K}}\cdot\frac{\partial g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\\
&\quad+\tilde{K}^6\sum_{\mathbf{k}\in S}\frac{|\hat{\delta}_{1,\mathbf{k}}|^2\sigma_{\mathbf{k}}^2}{2\gamma_{\mathbf{k}}^2}\sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}}e^{2\pi i\mathbf{k}\cdot(\mathbf{X}_{\boldsymbol{\alpha}}-\mathbf{X}_{\boldsymbol{\alpha}'})/\tilde{K}}\frac{\partial}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\mathcal{P}_{\mathbf{k}}\cdot\frac{\partial g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}'}}\\
&\quad+\tilde{K}^6\sum_{\mathbf{k},\mathbf{k}'\in S}\frac{\hat{\delta}_{1,\mathbf{k}}\hat{\delta}_{1,\mathbf{k}'}\sigma_{\mathbf{k}}^2}{2\gamma_{\mathbf{k}}^2}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\frac{\partial g(\mathbf{X})}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\mathcal{P}_{\mathbf{k}}\cdot(2\pi i\mathbf{k})
\end{aligned}$$

$$= -\phi\tilde{K}^3 \sum_{\mathbf{k}\in S} \frac{\hat{\delta}_{1,\mathbf{k}}^2}{\gamma_{\mathbf{k}}} \mathcal{P}_{\mathbf{k}} \sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right) e^{2\pi i\mathbf{k}\cdot(\mathbf{X}_{\boldsymbol{\alpha}}-\mathbf{X}_{\boldsymbol{\alpha}'})/\tilde{K}} \cdot \frac{\partial g(\mathbf{X})}{\partial \mathbf{X}_{\boldsymbol{\alpha}}}$$

$$+ \tilde{K}^6 \sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}} \sum_{\mathbf{k}\in S} \frac{|\hat{\delta}_{1,\mathbf{k}}|^2\sigma_{\mathbf{k}}^2}{2\gamma_{\mathbf{k}}^2} e^{2\pi i\mathbf{k}\cdot(\mathbf{X}_{\boldsymbol{\alpha}}-\mathbf{X}_{\boldsymbol{\alpha}'})/\tilde{K}} \frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}} \cdot \mathcal{P}_{\mathbf{k}} \cdot \frac{\partial g(\mathbf{X})}{\partial \mathbf{X}_{\boldsymbol{\alpha}'}}.$$

We have used the fact that

$$\mathbb{E}_{OU} \frac{\partial^2 \delta(\mathbf{P})}{\partial \mathbf{p}_{\mathbf{k}} \partial \mathbf{p}_{\mathbf{k}'}} = \begin{cases} -\frac{\sigma_{\mathbf{k}}^2}{2\gamma_{\mathbf{k}}} \mathcal{P}_{\mathbf{k}} & \text{if } \mathbf{k}+\mathbf{k}'=0, \\ 0 & \text{otherwise.} \end{cases} \tag{A.11}$$

We show in more detail how the contribution from the first term in brackets in (A.10), arising from the nonlinear advection term in the Navier–Stokes equations, vanishes upon averaging. From (A.11) we have

$$\mathbb{E}_{OU} \sum_{\mathbf{k}'} \frac{\partial}{\partial \mathbf{p}_{\mathbf{k}'}} \frac{\partial \delta(\mathbf{P})}{\partial \mathbf{p}_{\mathbf{k}-\mathbf{k}'}} = 0 \quad \text{unless } \mathbf{k} = \mathbf{0}.$$

However, since this expression appears in an inner product with $\mathbf{k}$ in (A.10), the term arising from nonlinear advection in the Navier–Stokes equations makes no contribution at all upon averaging.

We finally complete the calculation of $\bar{\mathcal{L}}$ by converting back to our original problem parameters, using the expressions (A.9) for $\gamma_{\mathbf{k}}$ and $\sigma_{\mathbf{k}}$. We thereby arrive at (3.6).

Acknowledgments. The authors thank Eric Vanden-Eijnden for helpful discussions and suggestions, and the referees for constructive comments which improved the presentation.

STOCHASTIC MODE REDUCTION FOR PARTICLE-BASED SIMULATION METHODS FOR COMPLEX MICROFLUID SYSTEMS*

PETER R. KRAMER† AND ANDREW J. MAJDA‡

Abstract. We illustrate the stochastic mode reduction procedure as formulated recently by Majda, Timofeyev, and Vanden-Eijnden [*Comm. Pure Appl. Math.*, 54 (2001), pp. 891–974] (MTV) on the equations of motion underlying various particle-based simulation approaches (such as Stokesian dynamics and Brownian dynamics) and the conceptually distinct dissipative particle dynamics (DPD) simulation approaches for complex microfluid systems. The resulting coarse-grained dynamics are compared and contrasted with each other. We show that the stochastic mode reduction procedure provides a way to recover the Smoluchowski dynamics for a standard model of multiple interacting particles in a fluid. The DPD, however, has some subtle aspects which obstruct the application of the stochastic mode reduction procedure. We discuss the mathematical and physical properties of the DPD method that underlie this difficulty.

Key words. Brownian dynamics, Brownian motion, dissipative particle dynamics, Smoluchowski reduction

1. Introduction.

In [24], we showed how the stochastic mode reduction framework of Majda, Timofeyev, and Vanden-Eijnden [31, 32, 33] (with MTV hereafter referring to [33]) could be used to assist in the design and analysis of the immersed boundary (IB) method [26, 25, 40] for numerically simulating microphysiological systems consisting of various elastic structures and particles immersed in a fluid with thermal fluctuations. The procedure exploited the smallness of the thermal Reynolds number, which implied a separation of time scales for the dynamics of the fluid and the immersed structures, and derived a simplified stochastic system for the immersed structures with the fluid variables eliminated using rigorous singular perturbation techniques [14, 18, 29, 39]. It is natural to explore how this approach works on other numerical simulation techniques for complex fluid systems consisting of immersed structures and thermal fluctuations. We study here the application of the stochastic mode reduction framework of MTV to the equations underlying particle-based (PB) dynamics schemes such as Brownian dynamics [10], Stokesian dynamics [6, 46], and the conceptually distinct dissipative particle dynamics [1, 11, 13, 23, 35, 38]. These numerical approaches differ fundamentally from the IB method in that they do not treat the fluid dynamically, but rather immediately model its effective influence on the particles. The detailed equations of motion for each of the simulation methods involve some nontrivial approximations or assumptions, even before any numerical discretization is contemplated.

As we shall discuss briefly in the relevant sections, even though the equations

and variables underlying these simulation approaches are rather different from each other and the IB method, they each can be treated within the MTV framework to deduce a simplified system governing the immersed particles and structures when the viscous friction with the fluid is sufficiently strong. The notion of Reynolds number is a bit obscure for the methods discussed in the present paper, since viscosity does not enter as a governing parameter. Instead, we take the small parameter in the asymptotic analysis as a certain "thermal Kubo number," which is defined as the ratio of the rate of decorrelation of a particle's (Lagrangian) thermal velocity due to its advection into different fluid regions relative to its rate of decorrelation due to viscous damping. The limit of small thermal Kubo number seems appropriate for many microfluid applications and plays a universal role in preparing for a stochastic mode reduction procedure for the methods described in the present paper as well as the IB method discussed in [24].

For the IB method, a small thermal Kubo number implies a separation between the fast time scales of the fluid and the slow time scales of the immersed structures. For the methods treated in the present paper, the fluid is not treated dynamically. Instead, the system variables consist of the positions and momenta of the elementary components of the immersed structures. Stochastic forcing modeling thermal fluctuations is naturally applied to the momenta of the particles. A low thermal Kubo number implies that the time scale for the momentum variables is much faster than that of the position variables. The stochastic mode reduction procedure of MTV then suggests a simplification of the system through elimination of the momentum variables and the development of a new set of effective "coarse-grained" equations for the position variables. By coarse-grained dynamics for the particles in these simulation schemes we mean a simplified description involving only the particle positions and not the rapidly fluctuating velocities. The derivations of the simplified coarse-grained dynamics can be accomplished rigorously for the classical equations underlying PB methods such as Brownian dynamics and Stokesian dynamics, but the dissipative particle dynamics (DPD) scheme has some aspects which can obstruct the deduction of simplified effective dynamics.

The application of the MTV procedure to eliminate the fast momentum variables from the classical PB equations (section 2) yields the standard Smoluchowski (or Brownian dynamics) limit for the positions of the immersed structures, which have been computed previously with several other approaches [10, 37, 47, 49, 50]. The variation of the Chapman–Enskog procedure used in [47] has some foundational similarities to the method of derivation we present, but the present approach is based on a rigorous theorem [29], whereas the validity of the Chapman–Enskog expansion is less certain [45, 47]. Moreover, we calculate the differential operators associated with the simplified dynamics in a different way, involving a slight extension of the framework developed in MTV to a context in which the noise driving the fast modes is not diagonal.

A similar calculation can be made to derive effective equations for the elementary particles in a DPD system (section 3). These resulting equations look formally very similar to those arising from the classical PB equations. Due to the finite-ranged nature of the frictional interactions, however, degeneracies emerge which can spoil the MTV stochastic mode reduction procedure. The formal calculation appears to apply only for some fraction of realizations of the dynamics which increases with increasing density. We cannot yet, however, make this into a rigorous statement. It would be interesting to extend the rigorous aspect of the MTV framework to cover systems with degeneracies such as DPD, but we will not attempt this here.

2. Application of stochastic mode reduction for PB simulation methods. Many scientists and engineers wishing to simulate microscopic fluid-particle systems with thermal fluctuations adopt a PB perspective in contrast to the fluid-based perspective of the IB method. In the PB setup, one appeals to the low Reynolds number of the system to eliminate the fluid degrees of freedom by assuming that the fluid is always in a quasi-steady state determined by the time-independent Stokes equations responding to whatever forces the particles happen to be exerting at that moment [6, 10, 20]. The fluid then ceases to be an independent dynamical quantity. The state of the system can be completely described by the positions $\mathbf{X} = \{\mathbf{X}_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ and velocities $\mathbf{V} = \{\mathbf{V}_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ of each immersed particle. These variables are updated according to Newton's laws, incorporating three kinds of forces:

(i) interparticle forces governed by some general potential of the particle configuration $\Phi(\mathbf{X})$,

(ii) hydrodynamic drag forces which are determined by the momentary positions and velocities of the particles, and

(iii) thermally fluctuating forces.

We provide details in section 2.1. Note that the approximation that the fluid evolves according to the quasi-steady Stokes equations requires stronger assumptions than simply noting that the Reynolds number is small [8], and these stronger assumptions are not necessarily met in practice [25].

While the PB simulation approaches are founded on these Newton law evolution equations for $\mathbf{X}$ and $\mathbf{V}$, these equations are not suitable for numerical simulation in many situations where the particle velocities decorrelate on a much faster time scale than the time over which the particle position variables change significantly. The equations of motion in this case are very stiff, but the disparity in time scales also permits a simplification of the system to one involving only the slow variables (particle positions). For the present example, this is known as the reduction of the full Fokker–Planck equation (involving position and momentum variables) to the Smoluchowski equation (involving only position variables). This procedure has been undertaken in various ways (formal asymptotic arguments [27], multiple time scale expansions [3], Chapman–Enskog expansion [47], projection operators [37, 49], asymptotic moment equation expansions [50], and asymptotic integration of stochastic differential equations [10, 22]). We show here how this reduction can be performed within the MTV stochastic mode reduction framework. While the ideas behind the calculations are related to those in the earlier works (particularly the adaptation of the Chapman–Enskog expansion approach in [47] and the multiple time scale derivations for the case of a single particle in [3, 49]), the MTV framework has a distinct organizational and computational structure which is systematic, fairly transparent, and founded on a rigorous theorem [29].

2.1. Formulation. We now write the equations on which the PB methods are based, with particle position and momentum resolved. For simplicity in exposition, we assume that all particles have the same mass m, though similar procedures can be applied to the more general case, as we shall discuss in section 2.5.

$$
\begin{aligned}
d\mathbf{X}_{\boldsymbol{\alpha}}(t) &= \mathbf{V}_{\boldsymbol{\alpha}}(t)\,dt,\\
m\,d\mathbf{V}_{\boldsymbol{\alpha}}(t) &= -\sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \mathcal{R}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t))\mathbf{V}_{\boldsymbol{\alpha}'}(t)\,dt - \nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X}(t))\,dt\\
&\quad + \sqrt{2k_BT}\sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \mathcal{S}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t))\,d\mathbf{W}_{\boldsymbol{\alpha}'}.
\end{aligned}
\tag{2.1}
$$

These equations, as previously stated, are nothing more than Newton's second law, with the right-hand side of the second equation in (2.1) describing the three kinds of forces that are assumed to act on the particles. The first term is the model for the force felt by the particles due to the fluid, under the governing assumption that the fluid is always in a quasi-steady state responding to the currently applied forces and positions of the particles. The tensor $\mathcal{R}$ is the hydrodynamic resistance matrix [6, 20], which is symmetric, positive definite, and depends on the momentary particle configuration $\mathbf{X}$. Its entries $\mathcal{R}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}$ indicate how the motion of particle $\boldsymbol{\alpha}'$ induces a hydrodynamic drag force on particle $\boldsymbol{\alpha}$. The second term in the second equation in (2.1) is just the force felt by a particle due to its direct interaction with other particles via the generalized potential Φ, just as in the IB method, but it is now permissible for Φ to include external forces which do not conserve total momentum. The third term describes the random thermal fluctuations, with strength specified by the matrix $\mathcal{S}(t)$, which is (any) square root of the symmetric, positive definite matrix $\mathcal{R}(t)$:

$$\mathcal{R}(\mathbf{X}) = \mathcal{S}(\mathbf{X})\mathcal{S}^{\dagger}(\mathbf{X}).$$

The $\{\mathbf{W}_{\boldsymbol{\alpha}}\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ are a collection of independent standard real-valued Brownian motions, which are mean zero Gaussian processes with stationary increments satisfying

$$\langle d\mathbf{W}(t) \otimes d\mathbf{W}(t')\rangle = \mathcal{I}\delta(t-t')\,dt\,dt'. \tag{2.2}$$

Note that the Brownian motion $\mathbf{W}_{\boldsymbol{\alpha}}$ does not describe the Brownian motion of the particle with label $\boldsymbol{\alpha}$. Indeed, the Brownian motions of the particles are actually coupled, while $\{\mathbf{W}_{\boldsymbol{\alpha}}(t)\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ are independent. One may think of the $\{\mathbf{W}_{\boldsymbol{\alpha}}(t)\}_{\boldsymbol{\alpha}\in\mathcal{A}}$ as a diagonalization of the thermal noise driving the particles. If the particles are well separated, then $\mathbf{W}_{\boldsymbol{\alpha}}(t)$ gives a leading order *approximation* to the thermal Brownian motion of particle $\boldsymbol{\alpha}$.

The equations of motion are supplemented by the initial conditions

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \mathbf{X}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{V}_{\boldsymbol{\alpha}}(t=0) = \mathbf{V}_{0,\boldsymbol{\alpha}}.$$

In Stokesian dynamics [6, 46], an imposed background spatially linear flow $\mathbf{u}^{\infty}(\mathbf{x})$ is admitted, and can be incorporated into our framework by generalizing the resistance force term in (2.1) to

$$-\sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \mathcal{R}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t)) \cdot (\mathbf{V}_{\boldsymbol{\alpha}'}(t) - \mathbf{u}^{\infty}(\mathbf{X}_{\boldsymbol{\alpha}'}(t))) + (\mathcal{R}^{E}(\mathbf{X}(t)){:}\mathcal{E}^{\infty})_{\boldsymbol{\alpha}}.$$

Here $\mathcal{R}^{E}(\mathbf{X})$ is another resistance tensor (with one particle and two spatial indices) relating to the imposed (constant) strain $\mathcal{E}^{\infty} = \frac{1}{2}(\nabla\mathbf{u}^{\infty} + (\nabla\mathbf{u}^{\infty})^{\dagger})$. We see that this generalization is mathematically equivalent to adding a (nonconservative) force

$$-\sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \mathcal{R}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t)) \cdot \mathbf{u}^{\infty}(\mathbf{X}_{\boldsymbol{\alpha}'}(t)) + (\mathcal{R}^{E}(\mathbf{X}(t))\mathcal{E}^{\infty})_{\boldsymbol{\alpha}},$$

which can be handled in the same way as the interparticle force term. To avoid extra burden in the calculations and nondimensionalization, we therefore proceed with no imposed flow $\mathbf{u}^{\infty} \equiv 0$ but comment in subsection 2.3 on how it could be incorporated.

2.2. Nondimensionalization.

2.2.1. Parameters of externally specified functions. We nondimensionalize the potential for the interacting particles by

$$\Phi(\mathbf{X}) = F\ell_f\tilde{\Phi}(\mathbf{X}/\ell_f),$$

where F is a typical force amplitude and ℓ_f is a length scale characterizing the range of the interparticle forces. Note that we are now using a force magnitude rather than a force density magnitude as we did for the IB method in [24]; this is due to the shift from a fluid-based to PB perspective. We let ℓ_0 be a length scale characterizing the typical initial separation between particles, and V_0 a typical magnitude of the initial particle velocities, and write

$$\mathbf{X}_{0,\boldsymbol{\alpha}} = \ell_0 \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{V}_{0,\boldsymbol{\alpha}} = V_0 \tilde{\mathbf{V}}_{0,\boldsymbol{\alpha}},$$

where $\tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}$ and $\tilde{\mathbf{V}}_{0,\boldsymbol{\alpha}}$ are nondimensionalized initial data which are to be thought of (at least formally) as order unity.

The resistance tensor $\mathcal{R}$ depends both on the current configuration $\mathbf{X}(t)$ of the particles and on their sizes and shapes. For now, we will assume that all particles are identical, with maximal diameter a and hydrodynamic drag friction γ. In the dilute limit (where the particle separation scale is much larger than the particle size a), we would have $\mathcal{R} = \gamma\mathcal{I}$, where $\mathcal{I}$ is the identity matrix, but the resistance tensor in a nondilute solution will have both diagonal and off-diagonal modifications due to hydrodynamic coupling between different particles. We can express the resistance tensor in terms of a nondimensional function $\tilde{\mathcal{R}}$ (depending on the shape of the particles) [20] which has order unity variations (i.e., is properly normalized):

$$\mathcal{R}(\mathbf{X}) = \gamma\tilde{\mathcal{R}}(\mathbf{X}/a).$$

The amplitude of the thermal forces is similarly expressed in terms of a nondimensional normalized function:

$$\mathcal{S}(\mathbf{X}) = \sqrt{\gamma}\tilde{\mathcal{S}}(\mathbf{X}/a),$$

with $\tilde{\mathcal{S}}\tilde{\mathcal{S}}^\dagger = \tilde{\mathcal{R}}$. We will assume that $\mathcal{R}$ is appropriately mollified to avoid singularities as two or more particles coalesce, as must be done in any numerical implementation.

2.2.2. Reference units. We use the following:

(i) length scale $\ell_T = a$,
(ii) time scale $\tau_T = \sqrt{ma^2/k_BT}$,
(iii) mass scale $m_T = m$.

These units are chosen with motivation similar to those used to nondimensionalize the IB equations in [24]. We have simply chosen $\ell_T = a$, both because physiological systems are typically composed of extended structures such as polymers and membranes which will be modeled by stringing together particles separated by distances comparable to their sizes and because it matches most closely the nondimensionalization choices made for other simulation methods discussed in this paper. The characteristic velocity is again the order of magnitude of the thermal velocity of a particle:

$$V_T = \frac{\ell_T}{\tau_T} = \sqrt{\frac{k_BT}{m}}.$$

2.2.3. Nondimensional groups.

(i) The thermal Kubo number

$$\mathrm{Ku_T} = \frac{\sqrt{mk_BT}}{\gamma a},$$

which describes the ratio of the time scale of frictional decorrelation m/γ to the time scale ℓ_T/V_T over which the particles would move across a spatial structural length $\ell_T = a$. Note that if the fluid density ρ is comparable to the particle mass density m/a^3, we can also think of the thermal Kubo number as a thermal particle Reynolds number $\ell_T V_T/\nu$, because the self-friction constant scales as $\gamma \sim \rho\nu a$. We note, though, that the equations for PB dynamics are most accurate in the limit in which the particle mass density is much greater than that of the fluid [8, 21, 30, 36, 44, 48].

(ii) Nondimensionalized measures of the effects of structural forces and initial velocity,

$$\phi = \frac{Fa}{k_B T}, \qquad \Upsilon = \frac{V_0}{V_T}.$$

(iii) The length scale ratios

$$\tilde{\ell}_f = \frac{\ell_f}{a}, \qquad \tilde{\ell}_0 = \frac{\ell_0}{a}.$$

2.2.4. Nondimensionalized PB dynamics. Nondimensionalizing with respect to the reference units described in section 2.2.2 and denoting nondimensional variables (but not externally prescribed functions) by the same notation as for their dimensional form, we obtain

$$\begin{aligned} d\mathbf{X}_{\boldsymbol{\alpha}}(t) &= \mathbf{V}_{\boldsymbol{\alpha}}(t)\, dt, \\ d\mathbf{V}_{\boldsymbol{\alpha}}(t) &= -\phi \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f)\, dt - \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} \mathrm{Ku}_{\mathrm{T}}^{-1} \tilde{\mathcal{R}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t)) \mathbf{V}_{\boldsymbol{\alpha}'}(t)\, dt \\ &\quad + \sqrt{2} \mathrm{Ku}_{\mathrm{T}}^{-1/2} \tilde{\mathcal{S}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t))\, d\mathbf{W}_{\boldsymbol{\alpha}'}. \end{aligned}$$

The nondimensionalized initial conditions are

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \tilde{\ell}_0 \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{V}_{\boldsymbol{\alpha}}(t=0) = \Upsilon \tilde{\mathbf{V}}_{0,\boldsymbol{\alpha}}.$$

2.3. Effective dynamics for PB dynamics at low thermal Kubo number. Elimination of the fast momentum modes yields the following description of the evolution of the positions of the particles.

PROPOSITION 2.1 (PB dynamics at small Kubo number). *In the limit* $\mathrm{Ku_T} \to 0$ *with all other nondimensional quantities held fixed, the solution for the particle positions* $\{\mathbf{X}_{\boldsymbol{\alpha}}(t)\}_{\boldsymbol{\alpha}}$ *obtained from the complete system* (2.1) *and rescaled in time as*

$$\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) = \lim_{\mathrm{Ku_T} \to 0} \mathbf{X}_{\boldsymbol{\alpha}}(t/\mathrm{Ku_T})$$

converges in law to the solution of the following simplified closed stochastic differential system involving only the particle positions $\{\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t)\}$:

$$\begin{aligned} d\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) &= \bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\bar{\mathbf{X}}(t))\, dt + \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} \mathcal{S}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(\bar{\mathbf{X}}(t))\, d\mathbf{W}_{\boldsymbol{\alpha}'}(t), \\ \bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t=0) &= \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \end{aligned} \tag{2.3}$$

where the stochastic real white noise terms $d\mathbf{W}_{\boldsymbol{\alpha}}(t)$ *are defined near* (2.2) *and are given the Itô interpretation. The explicit expression for the drift term is*

$$\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X}) = \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} \left[-((\tilde{\mathcal{R}}(\mathbf{X}))^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'} \cdot \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f) + \nabla_{\boldsymbol{\alpha}'} \cdot (\tilde{\mathcal{R}}^{-1}(\mathbf{X}))_{\boldsymbol{\alpha}',\boldsymbol{\alpha}} \right], \tag{2.4}$$

and the matrix coefficients of the stochastic terms are

$$\mathcal{S}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(\mathbf{X}) = \sqrt{2}(\tilde{\mathcal{R}}^{-1/2}(\mathbf{X}))_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}.$$

The drift term here includes not only the motion of the particles responding to the interparticle forces under the quasi-steady assumption for the fluid state, but a "divergence-drift" term, which appears due to the spatial dependence of $\tilde{\mathcal{R}}$ and is present even in the absence of forces on the particles [10, 19, 41]. The clearest way to understand the divergence-drift is by noting that the diffusion correlation tensor

$$\mathcal{D}(\mathbf{r}) \equiv \frac{1}{2}\frac{d}{dt}\left\langle (\mathbf{X}_{\boldsymbol{\alpha}}(t) - \mathbf{X}_{\boldsymbol{\alpha}}(t')) \otimes (\mathbf{X}_{\boldsymbol{\alpha}'}(t) - \mathbf{X}_{\boldsymbol{\alpha}'}(t')) \,|\mathbf{X}_{\boldsymbol{\alpha}}(t') = \mathbf{x} + \mathbf{r}, \mathbf{X}_{\boldsymbol{\alpha}'}(t') = \mathbf{x}\right\rangle_{t=t'} \tag{2.5}$$

is, for the nondimensionalized PB system, exactly $\mathcal{D}(\mathbf{X}) = (\tilde{\mathcal{R}}(\mathbf{X}))^{-1}$, so that the divergence-drift term is $\nabla \cdot \mathcal{D}$. Roughly speaking, the divergence-drift arises because variable diffusivity induces a bias to the mean particle motion due to the asymmetric strength of fluctuations in opposite directions. This term is important only when two particles happen to be close together relative to their sizes [15, pp. 232–233], and is omitted in simulations based only on Oseen or Rotne–Prager approximations to the resistance tensor [2, 9, 10, 17, 28, 43].

The coarse-grained PB dynamics respect the Einstein relation between mobility and diffusion correlations. Unlike the IB method, it is permissible for the potential in the PB dynamics to include external forces (so that total momentum need not be conserved), and the conclusions of Proposition 2.1 are unchanged.

If a steady background flow $\mathbf{u}^\infty(\mathbf{x})$ is imposed which is not too strong relative to the thermal fluctuations, the only change in the effective dynamics is the addition of the nondimensionalized form of the terms $\mathbf{u}^\infty(\mathbf{X}_{\boldsymbol{\alpha}}(t)) + (\mathcal{R}^{-1} \cdot \mathcal{R}^E{:}\mathcal{E}^\infty)_{\boldsymbol{\alpha}}$ to the right-hand side of the expression (2.4) for the effective drift, in agreement with how these effects are handled within Stokesian dynamics [6].

2.4. Stochastic mode reduction for PB dynamics. We now derive Proposition 2.1, following the general prescription from MTV, which we presented in some detail in [24]. We focus here only on those aspects of the calculation that are particular to the PB equations; the basic notation and formalism are the same as in [24].

2.4.1. Kolmogorov backward equation formalism. We identify $\varepsilon = \mathrm{Ku_T}$ as the small parameter and rescale to a longer time $t \to t/\varepsilon$. We denote the system variables in terms of the collection of particle positions $\mathbf{X}$ and velocities $\mathbf{V}$. Then the Kolmogorov backward equation under this time rescaling can be written as

$$\begin{aligned} -\frac{\partial \rho^\varepsilon(s, \mathbf{X}, \mathbf{V}|t)}{\partial s} &= \varepsilon^{-2}\mathcal{L}_1\rho^\varepsilon + \varepsilon^{-1}\mathcal{L}_2\rho^\varepsilon, \\ \rho^\varepsilon(s = t, \mathbf{X}, \mathbf{V}|t) &= f(\mathbf{X}, \mathbf{V}), \end{aligned}$$

with differential operators

$$\begin{aligned} \mathcal{L}_1 &= \sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}' \in \mathcal{A}} -\mathbf{V}_{\boldsymbol{\alpha}} \cdot \tilde{\mathcal{R}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}) \cdot \frac{\partial}{\partial \mathbf{V}_{\boldsymbol{\alpha}'}} + \frac{\partial}{\partial \mathbf{V}_{\boldsymbol{\alpha}}} \cdot \tilde{\mathcal{R}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}) \cdot \frac{\partial}{\partial \mathbf{V}_{\boldsymbol{\alpha}'}}, \\ \mathcal{L}_2 &= -\sum_{\boldsymbol{\alpha} \in \mathcal{A}} \phi \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}\left(\frac{\mathbf{X}(t)}{\tilde{\ell}_f}\right) \cdot \frac{\partial}{\partial \mathbf{V}_{\boldsymbol{\alpha}}} + \mathbf{V}_{\boldsymbol{\alpha}} \cdot \frac{\partial}{\partial \mathbf{X}_{\boldsymbol{\alpha}}}. \end{aligned}$$

2.4.2. Asymptotic expansion of solution. We assume that f depends only on the slow variables $f = f(\mathbf{X})$ to avoid consideration of irrelevant initial transients. The solvability conditions for the equations in the asymptotic hierarchy are obtained by integrating against the invariant measure π_{OU} associated with the operator $\mathcal{L}_1$, which here is

$$\pi_{OU}(\mathbf{V}) = \left(\prod_{\boldsymbol{\alpha}\in\mathcal{A}} \frac{1}{2\pi}\right) \exp\left(-\frac{1}{2}\sum_{\boldsymbol{\alpha}\in\mathcal{A}} |\mathbf{V}_{\boldsymbol{\alpha}}|^2\right).$$

The first two equations in the asymptotic hierarchy are solved in the same way as in [24], and the solvability condition resulting from the third equation is again

$$\begin{aligned} -\frac{\partial \rho_0}{\partial s} &= -\mathbf{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbf{E}_{OU}\rho_0, \\ \rho_0(s=t,\mathbf{X}|t) &= f(\mathbf{X}); \end{aligned} \tag{2.6}$$

thus the main task is to compute explicitly

$$\bar{\mathcal{L}} \equiv -\mathbf{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbf{E}_{OU}.$$

2.4.3. Explicit computation of limiting PDE. Thus far, our derivation largely coincides with the expansion procedure in [47]. However, instead of diagonalizing $\mathcal{L}_1$ in terms of Hermite polynomials, we follow in the spirit of the procedure developed in Appendix B of MTV. We show how this approach can be modified to directly treat a case such as the present one, where $\mathcal{L}_1$ is not diagonal in the fast variables $\mathbf{V}$.

We pass again to fast Fourier variables $\mathbf{P} = \{\mathbf{p}_{\boldsymbol{\alpha}}\}$ defined through

$$\hat{g}(\mathbf{P}) = \int_{\mathbb{R}^N} \exp\left[i\sum_{\boldsymbol{\alpha}\in\mathcal{A}} \mathbf{p}_{\boldsymbol{\alpha}}\cdot\mathbf{V}_{\boldsymbol{\alpha}}\right] g(\mathbf{V})\, d\mathbf{V}.$$

The differential operators act on functions of $\mathbf{P}$ and $\mathbf{X}$ as follows:

$$\begin{aligned} \hat{\mathcal{L}}_1 &= \frac{\partial}{\partial \mathbf{P}}\cdot\tilde{\mathcal{R}}(\mathbf{X})\cdot\mathbf{P} - \mathbf{P}\cdot\tilde{\mathcal{R}}(\mathbf{X})\cdot\mathbf{P}, \\ \hat{\mathcal{L}}_2 &= i\phi\mathbf{P}\cdot\nabla_{\mathbf{X}}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right) - i\frac{\partial}{\partial\mathbf{P}}\cdot\frac{\partial}{\partial\mathbf{X}}. \end{aligned}$$

We have written these operators in a "grand matrix" form, which will facilitate later computations. We just think of quantities like $\mathbf{X}$ and $\mathbf{P}$ as vectors with $3N$ components, and matrices like $\tilde{\mathcal{R}}$ as $3N\times 3N$ matrices. Scalar products between vectors (and vector operators) then involve summing over particle labels in addition to the Cartesian dimensions.

We now need to compute $\hat{\mathcal{L}}_1^{-1}$ and will have to generalize Lemma A.2 in MTV to allow for the nondiagonal structure of $\hat{\mathcal{L}}_1$. Since a similar result will be needed for the DPD calculation below, we present here a lemma sufficient for both calculations.

LEMMA 2.2. *Suppose we are given a first order differential operator of the form*

$$\hat{\mathcal{L}}_1 = \frac{\partial}{\partial\mathbf{P}}\cdot\mathcal{A}\cdot\mathbf{P} - \mathbf{P}\cdot\mathcal{A}\cdot\mathbf{P},$$

where $\mathcal{A}$ is a positive definite symmetric matrix. Then, given any function $\hat{g}(\mathbf{P})$ satisfying $\hat{\mathcal{L}}_1^\dagger \hat{g} = 0$, $\hat{g}$ has an inverse image of $\hat{\mathcal{L}}_1$ of the following form:

$$(\hat{\mathcal{L}}_1^{-1}\hat{g})(\mathbf{P}) = -\int_0^\infty \exp\left(\operatorname{Tr}\mathcal{A}t - \frac{1}{2}\mathbf{P}\cdot(\exp(\mathcal{A}t)\cdot\exp(\mathcal{A}t) - \mathcal{I})\cdot\mathbf{P}\right)\hat{g}(\boldsymbol{\beta}(t))\,dt,$$

where

$$\boldsymbol{\beta}(t) = \exp(\mathcal{A}t)\cdot\mathbf{P}.$$

Note that $\hat{\mathcal{L}}_1$ has a one-dimensional kernel (consisting of constant functions), and thus the inverse of $\hat{\mathcal{L}}_1$ is not uniquely defined. However, all choices of inverse images under $\hat{\mathcal{L}}_1$ differ only by functions of $\mathbf{X}$, which are annihilated in the computation of $\bar{\mathcal{L}}$. Therefore, any choice of inverse image will suffice. Note also that Lemma 2.2 is indeed a generalization of Lemma A.2 in MTV, even though an extra constant parameter appears in the latter; this can always be removed by suitable rescaling of the variables $\mathbf{P}$. We will prove Lemma 2.2 below in section 2.6.

We are now ready to write down the form for the differential operator $\bar{\mathcal{L}}$ describing the effective particle dynamics on time scales $O(\mathrm{Ku}_\mathrm{T}^{-1})$ in the limit $\mathrm{Ku}_\mathrm{T} \to 0$. Modifying the development in Appendix B of MTV in the manner indicated by Lemma 2.2, we have

$$\begin{aligned}\bar{\mathcal{L}}g(\mathbf{X}) &= -\mathbf{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbf{E}_{OU}g(\mathbf{X})\\ &= \int_{\mathbb{R}^N} d\mathbf{P}\,\hat{\tilde{P}}_{OU}(\mathbf{P})\hat{\mathcal{L}}_2\int_0^\infty dt\,\left[\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}'))\right]_{\mathbf{P}'=\boldsymbol{\beta}(\mathbf{P},t)}\\ &\qquad\times\exp\left((\operatorname{Tr}\tilde{\mathcal{R}})t - \frac{1}{2}\mathbf{P}\cdot(\exp(\tilde{\mathcal{R}}t)\cdot\exp(\tilde{\mathcal{R}}t) - \mathcal{I})\cdot\mathbf{P}\right),\end{aligned} \tag{2.7}$$

where

$$\boldsymbol{\beta}(\mathbf{P},t) = \exp(\tilde{\mathcal{R}}t)\cdot\mathbf{P},$$

and

$$\hat{\tilde{P}}_{OU}(\mathbf{P}) = \exp\left(-\frac{1}{2}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}|\mathbf{p}_{\boldsymbol{\alpha}}|^2\right) \tag{2.8}$$

is the invariant measure for the particle velocities, expressed in terms of the Fourier coordinates $\mathbf{P}$. We compute this expression in pieces:

$$\begin{aligned}\left[\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}'))\right]_{\mathbf{P}'=\boldsymbol{\beta}(\mathbf{P},t)} &= -i\left[\frac{\partial g}{\partial\mathbf{X}}\cdot\frac{\partial\delta(\mathbf{P}')}{\partial\mathbf{P}'}\right]_{\mathbf{P}'=\boldsymbol{\beta}(\mathbf{P},t)}\\ &= -i(\operatorname{Det}(\exp(\tilde{\mathcal{R}}t)))^{-1}\frac{\partial g}{\partial\mathbf{X}}\cdot\exp\big(-\tilde{\mathcal{R}}t\big)\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{P}}.\end{aligned}$$

Thanks to the delta function of $\mathbf{P}$ and the relation $\operatorname{Det}(\exp(\tilde{\mathcal{R}}t)) = \exp(\operatorname{Tr}\tilde{\mathcal{R}}t)$, the integral over t can be evaluated to give

$$\hat{\mathcal{L}}_1^{-1}\hat{\mathcal{L}}_2\mathbf{E}_{OU}g(\mathbf{X}) = i\frac{\partial g}{\partial\mathbf{X}}\cdot\exp\big(-\tilde{\mathcal{R}}t\big)\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{P}} = i\frac{\partial g}{\partial\mathbf{X}}\cdot\tilde{\mathcal{R}}^{-1}\cdot\frac{\partial\delta(\mathbf{P})}{\partial\mathbf{P}},$$

since $\tilde{\mathcal{R}}$ is a positive definite matrix [6]. Continuing,

$$\hat{\mathcal{L}}_2\hat{\mathcal{L}}_1^{-1}\hat{\mathcal{L}}_2\mathbf{E}_{OU}g(\mathbf{X}) = \operatorname{Tr}\frac{\partial}{\partial\mathbf{X}}\left(\frac{\partial g}{\partial\mathbf{X}}\cdot\tilde{\mathcal{R}}^{-1}\cdot\frac{\partial^2\delta(\mathbf{P})}{\partial\mathbf{P}^{\otimes 2}}\right) + \phi\frac{\partial g}{\partial\mathbf{X}}\cdot\tilde{\mathcal{R}}^{-1}\cdot\nabla_{\mathbf{X}}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\delta(\mathbf{P}).$$

Finally, integrating against the invariant measure (2.8) for $\mathbf{P}$ and using the symmetry of $\tilde{\mathcal{R}}$, we obtain

$$\bar{\mathcal{L}}g(\mathbf{X}) = \frac{\partial}{\partial\mathbf{X}}\cdot\left(\tilde{\mathcal{R}}^{-1}\cdot\frac{\partial g}{\partial\mathbf{X}}\right) - \phi\left((\tilde{\mathcal{R}})^{-1}\cdot\nabla_{\mathbf{X}}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\right)\cdot\frac{\partial g}{\partial\mathbf{X}}.$$

Returning to our more concrete notation, this reduced operator has exactly the (nondimensionalized) Smoluchowski form

$$\bar{\mathcal{L}}g(\mathbf{X}) = \sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}}\left[\frac{\partial}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\left((\tilde{\mathcal{R}}^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}\cdot\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}'}}\right) - \phi\left((\tilde{\mathcal{R}}^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}\cdot\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}\left(\frac{\mathbf{X}}{\tilde{\ell}_f}\right)\right)\cdot\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\right].$$

The drift and diffusion coefficients stated in Proposition 2.1 are read off this effective Kolmogorov backward operator in the standard way.

2.5. Generalized mass matrix. The above calculation can be directly generalized to systems of particles with unequal masses or even systems involving nondiagonal mass matrices (as in the case where some coordinates may correspond to rotational degrees of freedom) [4, 5, 6]. The nondimensionalization requires some modification, but this is straightforward for any particular system under consideration. (For example, the reference mass might be chosen as the average mass or mass of the largest particle, etc.) We assume that this nondimensionalization has been done. There will be some other nondimensional parameters characterizing the system (e.g., mass and particle size ratios), but all these will be considered to be held fixed in the low thermal Kubo number limit, and so we do not need to account for them specifically. We restrict attention to the case in which the system variables $\mathbf{X}$ and $\mathbf{V}$ involve only rigid motions of bodies so that the mass matrix is constant.

We start with the nondimensional form of the particle dynamics equations with general nondimensionalized mass matrix $\tilde{\mathcal{M}}$:

$$\begin{aligned} &d\mathbf{X}_{\boldsymbol{\alpha}}(t) = \mathbf{V}_{\boldsymbol{\alpha}}(t)\,dt,\\ &\sum_{\boldsymbol{\alpha}'\in\mathcal{A}}\tilde{\mathcal{M}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}\cdot d\mathbf{V}_{\boldsymbol{\alpha}'}(t) = -\phi\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f)\,dt\\ &\quad+\sum_{\boldsymbol{\alpha}'\in\mathcal{A}}\left[-\mathrm{Ku}_{\mathrm{T}}^{-1}\tilde{\mathcal{R}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t))\mathbf{V}_{\boldsymbol{\alpha}'}(t)\,dt + \sqrt{2}\mathrm{Ku}_{\mathrm{T}}^{-1/2}\mathcal{S}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}(\mathbf{X}(t))\,d\mathbf{W}_{\boldsymbol{\alpha}'}(t)\right], \end{aligned} \tag{2.9}$$

with $\tilde{\mathcal{S}}\tilde{\mathcal{S}}^{\dagger} = \tilde{\mathcal{R}}$ (see [6]).

We can transform this system with generalized nondimensional mass matrix to the simplified case considered above (i.e., (2.1)), where the nondimensional mass matrix is the identity matrix, as follows,

$$\mathbf{V}^{(\tilde{\mathcal{M}})} = \tilde{\mathcal{M}}^{1/2} \cdot \mathbf{V}, \qquad \mathbf{X}^{(\tilde{\mathcal{M}})} = \tilde{\mathcal{M}}^{1/2} \cdot \mathbf{X},$$

noting that the mass matrix $\tilde{\mathcal{M}}$ is symmetric and positive definite. Multiplying the first equation in (2.9) by $\tilde{\mathcal{M}}^{1/2}$ and the second equation in (2.9) by $\tilde{\mathcal{M}}^{-1/2}$ and making this change of variables, we find that

$$\begin{aligned}
&d\mathbf{X}_{\boldsymbol{\alpha}}^{(\tilde{\mathcal{M}})}(t) = \mathbf{V}_{\boldsymbol{\alpha}}^{(\tilde{\mathcal{M}})}(t)\, dt,\\
&d\mathbf{V}_{\boldsymbol{\alpha}}^{(\tilde{\mathcal{M}})}(t) = -\phi \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} (\tilde{\mathcal{M}}^{-1/2})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'} \cdot \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}(\mathbf{X}^{(\tilde{\mathcal{M}})}(t)/\tilde{\ell}_f)\, dt\\
&+ \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} \left[-\mathrm{Ku}_{\mathrm{T}}^{-1} \tilde{\mathcal{R}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}^{(\tilde{\mathcal{M}})}(\mathbf{X}^{(\tilde{\mathcal{M}})}(t)) \mathbf{V}_{\boldsymbol{\alpha}'}^{(\tilde{\mathcal{M}})}(t)\, dt + \sqrt{2}\mathrm{Ku}_{\mathrm{T}}^{-1/2} \mathcal{S}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}^{(\mathcal{M})}(\mathbf{X}^{(\tilde{\mathcal{M}})}(t))\, d\mathbf{W}_{\boldsymbol{\alpha}'}(t) \right],
\end{aligned}$$

where

$$\begin{aligned}
\tilde{\mathcal{R}}^{(\tilde{\mathcal{M}})} &= \tilde{\mathcal{M}}^{-1/2} \cdot \tilde{\mathcal{R}} \cdot \tilde{\mathcal{M}}^{-1/2},\\
\mathcal{S}^{(\mathcal{M})} \cdot \mathcal{S}^{(\mathcal{M})\dagger} &= \tilde{\mathcal{R}}^{(\tilde{\mathcal{M}})}.
\end{aligned}$$

Consequently, the effective coarse-grained dynamics for a system of particles governed by a general nondimensional mass matrix can be obtained by making the following replacements in Proposition 2.1:

$$\begin{aligned}
\bar{\mathbf{X}} &\longrightarrow \tilde{\mathcal{M}}^{1/2} \cdot \bar{\mathbf{X}},\\
\tilde{\mathcal{R}} &\longrightarrow \tilde{\mathcal{M}}^{-1/2} \cdot \tilde{\mathcal{R}} \tilde{\mathcal{M}}^{-1/2},\\
\nabla_{\mathbf{X}} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f) &\longrightarrow \tilde{\mathcal{M}}^{-1/2} \cdot \nabla_{\mathbf{X}} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f).
\end{aligned}$$

We find in this way that the effective drift and diffusion coefficients for the particle coordinates $\mathbf{X}$ are to be replaced by

$$\begin{aligned}
\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X}) &= \sum_{\boldsymbol{\alpha}' \in \mathcal{A}} -((\tilde{\mathcal{R}}(\mathbf{X}))^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'} \cdot \nabla_{\boldsymbol{\alpha}'} \tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f)\\
&\qquad + \sum_{\boldsymbol{\alpha}',\boldsymbol{\alpha}'' \in \mathcal{A}} \nabla_{\boldsymbol{\alpha}'} \cdot (\tilde{\mathcal{R}}^{-1}(\mathbf{X}))_{\boldsymbol{\alpha}',\boldsymbol{\alpha}''} (\tilde{\mathcal{M}}^{1/2})_{\boldsymbol{\alpha}'',\boldsymbol{\alpha}},\\
\mathcal{S}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(\mathbf{X}) &= \sqrt{2}(\tilde{\mathcal{R}}^{-1/2}(\mathbf{X}))_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}.
\end{aligned}$$

In other words, only the divergence-drift term needs modification by the generalized mass matrix.

2.6. Proof of Lemma 2.2. Following Appendix B of MTV, we write

$$\hat{\mathcal{L}}_1^{-1} = -\int_0^\infty e^{\hat{\mathcal{L}}_1 t}\, dt. \tag{2.10}$$

Since $\hat{\mathcal{L}}_1$ is still a first order differential operator, we can compute $\mathcal{T}(t) \equiv e^{\hat{\mathcal{L}}_1 t}$ using the method of characteristics. The characteristic equation is

$$\frac{d\boldsymbol{\Pi}(\boldsymbol{\beta},t)}{dt} = -\mathcal{A}\boldsymbol{\Pi}(\boldsymbol{\beta},t), \qquad \boldsymbol{\Pi}(\boldsymbol{\beta},t=0) = \boldsymbol{\beta},$$

which has solution $\mathbf{\Pi}(\boldsymbol{\beta},t) = \exp(-\mathcal{A}t)\boldsymbol{\beta}$. The transformation to the characteristic coordinate $\boldsymbol{\beta}$ is therefore given by

$$\boldsymbol{\beta}(\mathbf{P},t) = \exp(\mathcal{A}t)\mathbf{P}. \tag{2.11}$$

Along the characteristics, the evolution operator obeys the ODE

$$\frac{\partial}{\partial t}\left(\mathcal{T}(t)\hat{g}|_{\mathbf{P}=\mathbf{\Pi}(\boldsymbol{\beta},t)}\right) = \left(\operatorname{Tr}\mathcal{A} - \mathbf{\Pi}(\boldsymbol{\beta},t)\cdot\mathcal{A}\cdot\mathbf{\Pi}(\boldsymbol{\beta},t)\right)\mathcal{T}(t)\hat{g}|_{\mathbf{P}=\mathbf{\Pi}(\boldsymbol{\beta},t)},$$

which has solution

$$\mathcal{T}(t)\hat{g}|_{\mathbf{P}=\mathbf{\Pi}(\boldsymbol{\beta},t)} = \exp\left(\operatorname{Tr}\mathcal{A}t - \int_0^t \mathbf{\Pi}(\boldsymbol{\beta},s)\cdot\mathcal{A}\cdot\mathbf{\Pi}(\boldsymbol{\beta},s)\,ds\right)\hat{g}\Big|_{\mathbf{P}=\boldsymbol{\beta}}.$$

The integral can be evaluated exactly, using the given fact that $\mathcal{A}$ is a symmetric matrix:

$$\begin{aligned}\int_0^t \mathbf{\Pi}(\boldsymbol{\beta},s)\cdot\mathcal{A}\cdot\mathbf{\Pi}(\boldsymbol{\beta},s)\,ds &= \int_0^t \boldsymbol{\beta}\cdot\exp(-\mathcal{A}s)\mathcal{A}\exp(-\mathcal{A}s)\cdot\boldsymbol{\beta}\\ &= \frac{1}{2}\boldsymbol{\beta}\cdot(\mathcal{I}-\exp(-\mathcal{A}t)\exp(-\mathcal{A}t))\cdot\boldsymbol{\beta}.\end{aligned}$$

Reverting from the characteristic coordinate $\boldsymbol{\beta}$ to the original coordinate $\mathbf{P}$ via (2.11), we have

$$\mathcal{T}(t)\hat{g} = \exp\left(\operatorname{Tr}\mathcal{A}t - \frac{1}{2}\mathbf{P}\cdot(\exp(\mathcal{A}t)\exp(\mathcal{A}t)-\mathcal{I})\cdot\mathbf{P}\right)\hat{g}(\boldsymbol{\beta}(\mathbf{P},t)).$$

Upon substitution into (2.10), we obtain the statement in Lemma 2.2. ∎

3. Application of stochastic mode reduction for DPD. The final simulation method which we will treat with the stochastic mode reduction procedure is DPD [1, 7, 11, 13, 23, 35, 38]. This simulation scheme has several formal similarities to the PB methods mentioned in section 2, but differs fundamentally in interpretation. DPD is intended to be used for "complex fluid" systems such as suspensions of polymers, colloids, or other macromolecules. Rather than attempting to resolve the coordinates and configurations of the macromolecules, DPD instead coarse-grains the system in terms of fluid particles which represent some parcel of the fluid suspension. These fluid particles are mesoscopic in size and interact with each other through some force laws that endeavor to capture constitutively the properties of the multiphase mixture. These forces include both conservative and dissipative components. More precisely, under DPD the equations of motion for the fluid particles can be written in the following form [13, 35]:

$$\begin{aligned} m d\mathbf{V}_{\boldsymbol{\alpha}}(t) &= \left[-\nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X}(t)) - \sum_{\boldsymbol{\alpha}'\neq\boldsymbol{\alpha}} \gamma\omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)/\ell_\gamma)(\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)\cdot\mathbf{V}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t))\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)\right] dt\\ &\quad + \sum_{\boldsymbol{\alpha}'\neq\boldsymbol{\alpha}} \sigma\tilde{\omega}(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)/\ell_\gamma)\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)\,dW_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t),\end{aligned} \tag{3.1a}$$

$$d\mathbf{X}_{\boldsymbol{\alpha}}(t) = \mathbf{V}_{\boldsymbol{\alpha}}(t)\,dt,$$

with initial conditions

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0)=\mathbf{X}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{V}_{\boldsymbol{\alpha}}(t=0)=\mathbf{V}_{0,\boldsymbol{\alpha}}. \tag{3.1b}$$

We use the same notation as in other simulation approaches to describe analogous structures and concepts in the DPD framework. The new notation is the following:

(i) $r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)=|\mathbf{X}_{\boldsymbol{\alpha}}(t)-\mathbf{X}_{\boldsymbol{\alpha}'}(t)|$ is the distance between two DPD particles;

(ii) $\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)=(\mathbf{X}_{\boldsymbol{\alpha}}(t)-\mathbf{X}_{\boldsymbol{\alpha}'}(t))/r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)$ is the unit vector directed from particle $\boldsymbol{\alpha}'$ to $\boldsymbol{\alpha}$;

(iii) $\mathbf{V}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)=\mathbf{V}_{\boldsymbol{\alpha}}(t)-\mathbf{V}_{\boldsymbol{\alpha}'}(t)$ is the relative velocity between two DPD particles;

(iv) γ describes the frictional coupling constant between two DPD particles;

(v) σ denotes a normalization factor for the thermal forces;

(vi) ℓ_γ denotes a length scale over which the fluid particles exert thermal and frictional forces on each other (this may loosely be viewed as an effective size of the fluid particles);

(vii) ω and $\tilde{\omega}$ are dimensionless functions which describe the strength of the frictional and thermal coupling between particles when they are separated by various distances; these functions typically vanish beyond some particle separation distance;

(viii) $\{W_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)\}_{\boldsymbol{\alpha}\neq\boldsymbol{\alpha}'}$ is a collection of independent standard real-valued one-dimensional Brownian motions (see the discussion near (2.2)) whose differentials describe random thermal force exchanges between particles $\boldsymbol{\alpha}$ and $\boldsymbol{\alpha}'$.

The fluctuation-dissipation theorem, or consistency with Gibbs–Boltzmann statistics for a thermal equilibrium state, implies the following relationships between the above parameters:

$$\gamma=\frac{m\sigma^2}{2k_BT}, \qquad \omega=\tilde{\omega}^2.$$

Equations (3.1) have a discontinuity when two or more particles coalesce, unless $\omega(r)$ and $\tilde{\omega}(r)$ are chosen to vanish at small r. This is physically reasonable, since if the soft fluid particles overlap significantly, the forces they exert on each other should begin to cancel out because of the integration of their interaction over wide angles. The published numerical implementations appear to leave the discontinuity in their simulated equations, which does not matter much because coalescence is a rare event (in three dimensions). For mathematical purposes, it will be convenient to assume that $\omega(r)$ (and therefore also $\tilde{\omega}(r)$) vanishes smoothly at $r=0$.

Note that the thermal forces in DPD conserve momentum because the DPD particles alone compose the complex fluid system, in contrast to the rigid particles in the standard PB simulation method, which can exchange momentum with the fluid medium. Also, note that the friction term in DPD is different from that in the rigid PB formalism (2.1). We have restricted our attention to isothermal systems so that a common temperature T characterizes all of the DPD fluid particles. The generalizations of DPD to systems with thermal gradients [1, 11] involve an extra equation for the dynamics of the internal energy of the fluid particles which does not fit well within the stochastic modeling framework of MTV.

We will obtain here, using the MTV stochastic modeling framework, a simplified formal description of the dynamics of the DPD particles at low thermal Kubo number. This procedure may be viewed as an analogue of the Smoluchowski reduction for the conventional dynamic model of particles in a fluid (section 2), and indeed the results and calculations are rather similar after certain identifications are made. The results

from the stochastic mode reduction procedure will determine the effective drift and diffusivity of the DPD particles. As these are fictitious particles, it is not so important that these quantities correspond to fundamental physical laws (in contrast to the IB method [26, 25]).

We must stress that, unlike in the previous sections where the results had a rigorous foundation, the stochastic mode reduction procedure has only a limited formal validity for the DPD system. The reason is that the finite range of the frictional interactions allows the dynamical and uncontrolled appearance of slow modes of particle motion which do not feel frictional damping. The simplified dynamics can be expected to be relevant only for sufficiently dense systems, as we shall explain in section 3.3.4. However, we are not yet able to make this into a rigorous statement.

The coarse-grained dynamics of the DPD particles have previously been characterized in a different way in [12, 34] through the calculation of kinetic coefficients such as viscosities of the DPD fluid via Chapman–Enskog expansions. Our framework for calculation provides more detail than these kinetic coefficients in one sense because it incorporates the spatial correlation structure of the DPD fluid particle motion. On the other hand, the stochastic mode elimination framework does not seem well suited to computing quantities such as effective viscosity or pressure of the DPD fluid, since the velocities of the DPD particles, which are needed for these calculations, are fast modes which are eliminated.

3.1. Nondimensionalization.

3.1.1. Parameters of externally specified functions. The thermal and frictional coupling has already been expressed in terms of nondimensional functions ω and $\tilde{\omega}$. We nondimensionalize the potential and initial velocities as we did for PB dynamics,

$$\Phi(\mathbf{X}) = F\ell_f \tilde{\Phi}(\mathbf{X}/\ell_f), \qquad \mathbf{V}_{0,\boldsymbol{\alpha}} = V_0 \tilde{\mathbf{V}}_{0,\boldsymbol{\alpha}},$$

and the initial particle locations as in the IB method,

$$\mathbf{X}_{0,\boldsymbol{\alpha}} = \ell_\gamma \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}};$$

this latter nondimensionalization is naturally suggested by the notion that ℓ_γ is a typical fluid particle size and the fluid particles should be space-filling.

3.1.2. Reference units. Here we will use the following:

(i) length scale $\ell_T = \ell_\gamma$,

(ii) time scale $\tau_T = \sqrt{m\ell_\gamma^2/k_BT}$,

(iii) mass scale $m_T = m$.

We have chosen these reference units based on thermal (and frictional properties) of the particles, as we did for the other methods. Note that the reference velocity scale,

$$v_T \equiv \frac{\ell_T}{\tau_T} = \sqrt{\frac{k_BT}{m}},$$

is the order of magnitude which the velocity of the fluid particles would have in thermal equilibrium in the absence of applied forces.

3.1.3. Nondimensional groups.

(i) The thermal Kubo number

$$\mathrm{Ku_T} = \sqrt{\frac{mk_BT}{\gamma^2\ell_\gamma^2}}.$$

If we were to assume that the frictional constant for the DPD particles scales with respect to physical parameters in the same way as rigid particles in viscously overdamped flows ($\gamma \propto (m/\ell_\gamma^3)\nu\ell_\gamma$), then we can also think of $\mathrm{Ku_T}$ as a thermal particle Reynolds number.

(ii) Nondimensionalized measures of the effects of structural forces and initial velocity

$$\phi = \frac{F\ell_\gamma}{k_B T}, \qquad \Upsilon = \frac{V_0}{v_T}.$$

(iii) The length scale ratio

$$\tilde{\ell}_f = \frac{\ell_f}{\ell_\gamma}.$$

3.1.4. Nondimensionalized DPD equations. Nondimensionalizing with respect to the reference units described in section 3.1.2 and denoting nondimensional variables (but not externally prescribed functions) by the same notation as their dimensional form, we obtain

$$\begin{aligned} d\mathbf{X}_{\boldsymbol{\alpha}}(t) &= \mathbf{V}_{\boldsymbol{\alpha}}(t)\,dt, \\ d\mathbf{V}_{\boldsymbol{\alpha}}(t) &= \Bigg[-\phi \sum_{\boldsymbol{\alpha}' \neq \boldsymbol{\alpha}} \nabla_{\boldsymbol{\alpha}} \tilde{\Phi}(\mathbf{X}(t)/\tilde{\ell}_f) \\ &\qquad - \sum_{\boldsymbol{\alpha}' \neq \boldsymbol{\alpha}} \mathrm{Ku_T}^{-1} \omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t))(\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t) \cdot \mathbf{V}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t))\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t) \Bigg]\, dt \\ &\quad + \sum_{\boldsymbol{\alpha}' \neq \boldsymbol{\alpha}} \sqrt{2}\mathrm{Ku_T}^{-1/2} \omega^{1/2}(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t))\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t)\, dW_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(t), \end{aligned}$$

with initial conditions

$$\mathbf{X}_{\boldsymbol{\alpha}}(t=0) = \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \qquad \mathbf{V}_{\boldsymbol{\alpha}}(t=0) = \Upsilon\tilde{\mathbf{V}}_{0,\boldsymbol{\alpha}}.$$

3.2. Effective dynamics for DPD particles at low Kubo number. As we shall discuss in section 3.3.4, there is a degeneracy in the DPD equations which does not appear to allow a direct, rigorous application of the theorem by Kurtz [29] to obtain the simplified small Kubo number dynamics. However, it appears that the degeneracy plays only a small role in sufficiently dense systems, and that the formal procedure should be meaningful in these situations. We therefore state the results of stochastic mode reduction on the DPD equations in terms of a formal, nonrigorous proposition.

PROPOSITION 3.1 (DPD at small Kubo number (only formal)). *Consider the DPD system* (3.1) *under the restriction that* $\sum_{\boldsymbol{\alpha}\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}}\Phi(\mathbf{X}) = 0$ *and the system is sufficiently dense. Then in the limit* $\mathrm{Ku_T} \to 0$ *with all other nondimensional quantities held fixed, the solution for the particle positions* $\{\mathbf{X}_{\boldsymbol{\alpha}}(t)\}_{\boldsymbol{\alpha}}$*, obtained from the complete DPD system* (3.1) *and rescaled in time as*

$$\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) = \lim_{\mathrm{Ku_T}\to 0} \mathbf{X}_{\boldsymbol{\alpha}}(t/\mathrm{Ku_T}),$$

can be approximated in some weak sense by the solution of the following simplified stochastic differential system involving only the particle positions $\{\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t)\}$:

$$\begin{aligned} d\bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t) &= \bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\bar{\mathbf{X}}(t))\,dt + \sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \mathcal{S}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(\bar{\mathbf{X}}(t))\,d\mathbf{W}_{\boldsymbol{\alpha}'}(t), \\ \bar{\mathbf{X}}_{\boldsymbol{\alpha}}(t=0) &= \tilde{\mathbf{X}}_{0,\boldsymbol{\alpha}}, \end{aligned} \tag{3.2}$$

where the stochastic real white noise terms $d\mathbf{W}_{\boldsymbol{\alpha}}(t)$ *are defined near* (2.2) *and are given the Itô interpretation. The explicit expression for the drift term is*

$$\bar{\mathbf{V}}_{\boldsymbol{\alpha}}(\mathbf{X}) = -\sum_{\boldsymbol{\alpha}'\in\mathcal{A}} ((\tilde{\mathcal{Q}}(\mathbf{X}))^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'} \cdot \nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}(\mathbf{X}/\tilde{\ell}_f) + \sum_{\boldsymbol{\alpha}'\in\mathcal{A}} \nabla_{\boldsymbol{\alpha}'}(\tilde{\mathcal{Q}}^{-1}(\mathbf{X}))_{\boldsymbol{\alpha}',\boldsymbol{\alpha}}, \tag{3.3}$$

and the matrix coefficients of the stochastic terms are

$$\mathcal{S}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}(\mathbf{X}) = \sqrt{2}(\tilde{\mathcal{Q}}^{-1/2}(\mathbf{X}))_{\boldsymbol{\alpha},\boldsymbol{\alpha}'},$$

where

$$\tilde{\mathcal{Q}}_{\boldsymbol{\alpha},\boldsymbol{\alpha}'} \equiv= \begin{cases} \sum_{\boldsymbol{\alpha}''\neq\boldsymbol{\alpha}} \omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}''})\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}''}\otimes\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}''} & \text{for } \boldsymbol{\alpha}'=\boldsymbol{\alpha}. \\ -\omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'})\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\otimes\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'} & \text{for } \boldsymbol{\alpha}''\neq\boldsymbol{\alpha}. \end{cases} \tag{3.4}$$

The inverse of $\tilde{\mathcal{Q}}$ *is to be understood as having domain orthogonal to the null-space of* $\tilde{\mathcal{Q}}$.

On a formal level, the coarse-grained DPD is quite similar to that of the coarse-grained PB dynamics described in Proposition 2.1; the resistance tensor $\tilde{\mathcal{R}}$ is simply replaced by an effective DPD resistance tensor $\tilde{\mathcal{Q}}$ defined in (3.4). However, the restrictions for the validity of the effective coarse-grained DPD stated in Proposition 3.1 are substantial.

First, the total momentum of the system must be conserved, as for IB dynamics. This rules out consideration of external potentials, which would induce $O(1)$ motion of the center of mass of the DPD particle system over $O(1)$ time scales. This center of mass motion would influence the relative motion of the DPD particles because of the forces applied by the external potential. As with the IB method discussed in [24], we do not know how to generalize our simplified stochastic dynamics to incorporate these changes.

Secondly, the system must be sufficiently dense so that, with large probability, the collection of particles does not (or rarely does) break up into two or more clusters which feel no frictional or thermal coupling with each other. Indeed, in such a configuration, the relative position of the centers of mass of these two clusters would be a degree of freedom that would not feel the strong damping at all and cannot be described within the stochastic mode reduction framework. (It acts as a slow mode, but we cannot identify it a priori!) We discuss this issue below in the context of the actual stochastic mode elimination procedure.

3.3. Stochastic mode reduction for DPD. We now derive Proposition 3.1 following the general prescription from MTV, which we presented in some detail in [24]. We focus here only on those aspects of the calculation that are particular to the DPD equations; the basic notation and formalism are the same as for PB dynamics in section 2.4. We will encounter a technical gap, so the calculations here should only be viewed as formal.

3.3.1. Kolmogorov backward equation formalism. We identify $\varepsilon = \mathrm{Ku_T}$ as the small parameter and rescale to a longer time $t \to t/\varepsilon$. We denote the system variables in terms of the collection of particle positions $\mathbf{X}$ and velocities $\mathbf{V}$, as in section 2. Then the Kolmogorov backward equation under this time rescaling can be written as

$$-\frac{\partial \rho^\varepsilon(s,\mathbf{X},\mathbf{V}|t)}{\partial s} = \varepsilon^{-2}\mathcal{L}_1\rho^\varepsilon + \varepsilon^{-1}\mathcal{L}_2\rho^\varepsilon,$$
$$\rho^\varepsilon(s=t,\mathbf{X},\mathbf{V}|t) = f(\mathbf{X},\mathbf{V}),$$

with differential operators

$$\mathcal{L}_1 = \sum_{\boldsymbol{\alpha}\neq\boldsymbol{\alpha}'} \omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}) \left[\frac{1}{2}\left(\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot\left(\frac{\partial}{\partial\mathbf{V}_{\boldsymbol{\alpha}}} - \frac{\partial}{\partial\mathbf{V}_{\boldsymbol{\alpha}'}}\right)\right)^2 - \hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot(\mathbf{V}_{\boldsymbol{\alpha}}-\mathbf{V}_{\boldsymbol{\alpha}'})\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot\frac{\partial}{\partial\mathbf{V}_{\boldsymbol{\alpha}}}\right],$$

$$\mathcal{L}_2 = \sum_{\boldsymbol{\alpha}\in\mathcal{A}} -\phi\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}(t)}{\tilde{\ell}_f}\right)\frac{\partial}{\partial\mathbf{V}_{\boldsymbol{\alpha}}} + \mathbf{V}_{\boldsymbol{\alpha}}\cdot\frac{\partial}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}.$$

3.3.2. Asymptotic expansion of solution. We follow the same formalism as in [24], again assuming f depends only on the slow variables $f = f(\mathbf{X})$ to avoid consideration of initial transients. The solvability conditions for the equations in the asymptotic hierarchy are obtained by integrating against the invariant measure π_{OU} associated with the operator $\mathcal{L}_1$, which here is

$$\pi_{OU}(\mathbf{V}) = \left(\prod_{\boldsymbol{\alpha}\in\mathcal{A}}\frac{1}{2\pi}\right)\exp\left(-\frac{1}{2}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}|\mathbf{V}_{\boldsymbol{\alpha}}|^2\right).$$

The first two equations in the asymptotic hierarchy are solved in the same way as in [24], and the solvability condition resulting from the third equation is again (2.6), so the main task is to compute explicitly

$$\bar{\mathcal{L}} \equiv -\mathbf{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbf{E}_{OU}.$$

3.3.3. Explicit computation of limiting PDE. We again follow the spirit of the calculation in Appendix B of MTV but, as in section 2.4.3, need to make some modifications because $\mathcal{L}_1$ is not diagonal in the fast variables $\mathbf{V}$.

We pass again to fast Fourier variables $\mathbf{P} = \{\mathbf{p}_{\boldsymbol{\alpha}}\}$ defined through

$$\hat{g}(\mathbf{P}) = \int_{\mathbb{R}^N}\exp\left[i\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\mathbf{p}_{\boldsymbol{\alpha}}\cdot\mathbf{V}_{\boldsymbol{\alpha}}\right]g(\mathbf{V})\,d\mathbf{V}.$$

The differential operators act on functions of $\mathbf{P}$ and $\mathbf{X}$ as follows:

$$\hat{\mathcal{L}}_1 = \sum_{\boldsymbol{\alpha}\neq\boldsymbol{\alpha}'}\omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'})\left[-\frac{1}{2}\left(\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot(\mathbf{p}_{\boldsymbol{\alpha}}-\mathbf{p}_{\boldsymbol{\alpha}'})\right)^2 + \hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot\left(\frac{\partial}{\partial\mathbf{p}_{\boldsymbol{\alpha}}} - \frac{\partial}{\partial\mathbf{p}_{\boldsymbol{\alpha}'}}\right)\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot\mathbf{p}_{\boldsymbol{\alpha}}\right]$$
$$= \sum_{\boldsymbol{\alpha}\neq\boldsymbol{\alpha}'}\omega(r_{\boldsymbol{\alpha}\boldsymbol{\alpha}'})\left[-\frac{1}{2}\left(\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot(\mathbf{p}_{\boldsymbol{\alpha}}-\mathbf{p}_{\boldsymbol{\alpha}'})\right)^2 + \hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot\frac{\partial}{\partial\mathbf{p}_{\boldsymbol{\alpha}}}\hat{e}_{\boldsymbol{\alpha}\boldsymbol{\alpha}'}\cdot(\mathbf{p}_{\boldsymbol{\alpha}}-\mathbf{p}_{\boldsymbol{\alpha}'})\right],$$

$$\hat{\mathcal{L}}_2 = i\sum_{\boldsymbol{\alpha}\in\mathcal{A}}\phi\mathbf{p}_{\boldsymbol{\alpha}}\cdot\nabla_{\boldsymbol{\alpha}}\tilde{\Phi}\left(\frac{\mathbf{X}(t)}{\tilde{\ell}_f}\right) - i\frac{\partial}{\partial\mathbf{p}_{\boldsymbol{\alpha}}}\cdot\frac{\partial}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}.$$

We proceed again as in section 2.4.3 but need to pay special attention to the structure of $\hat{\mathcal{L}}_1$. Note that $\hat{\mathcal{L}}_1$ has a form satisfying the hypotheses of Lemma 2.2 with the symmetric matrix $\mathcal{A} = \tilde{\mathcal{Q}}$ defined in (3.4), except that we need to take care about positive definiteness. As we discuss in section 3.3.4, we can readily show that $\tilde{\mathcal{Q}}$ is nonnegative definite, but it may possess several nontrivial zero eigenvalues. $\tilde{\mathcal{Q}}$ will always have one zero eigenvalue corresponding to an eigenvector with all entries equal; this simply reflects the fact that the momentum of the center of mass feels no damping. If there are no external forces, this momentum remains constant and can be projected away without difficulty. Of greater concern is the possible presence of additional zero eigenvalues, with eigenvectors depending on the particle configuration. These would imply that certain combinations of the velocities acted as slow rather than fast modes. Since these combinations are configuration-dependent, we cannot simply project them away or reclassify them a priori as slow modes. Zero eigenvalues of $\tilde{\mathcal{Q}}$ beyond the one corresponding to center of mass motion, therefore, would obstruct our ability to obtain simplified dynamics for DPD in the small Kubo number limit. We will refer to particle configurations $\mathbf{X}$ that give rise to multiple zero eigenvalues of $\tilde{\mathcal{Q}}$ as "degenerate configurations." As we shall discuss in section 3.3.4, we cannot exclude the possibility of these degenerate configurations, but the probability that any given realization of the dynamics will pass through a degenerate configuration over some finite time interval should become small as the density of the system increases. (In fact, this probability would appear to remain uniformly small over a fixed interval in the rescaled time $t \to t/\mathrm{Ku_T}$ as $\mathrm{Ku_T} \to 0$.) A larger class of realizations may go through degenerate configurations for sufficiently brief periods of time that the coarse-grained dynamics are unaltered. Therefore, we expect that the simplified stochastic dynamical description should apply in some sense to a large fraction of realizations if the density of the system is sufficiently large. To make such a statement have true mathematical sense would require a more proper formulation. Indeed, over any finite time interval, some nonzero fraction of realizations of the *simplified* dynamics described in Proposition 3.1 will pass through degenerate configurations for which the equations are not well defined; thus it is not appropriate to speak of convergence in law to the formal coarse-grained DPD equations.

We defer further discussion of these important technical matters until section 3.3.4. For now, let us suppose that we are restricting attention to the subset of systems which do not pass through a degenerate configuration, so that $\tilde{\mathcal{Q}}$ has, over the (rescaled) time interval of interest, exactly three zero eigenvalues corresponding to motion of the center of mass. We can project these degrees of freedom away from consideration by working in a frame comoving with the (constant) center of mass velocity, and then, by analogy to (2.7), we compute

$$\begin{aligned}\bar{\mathcal{L}}g(\mathbf{X}) &= -\mathbf{E}_{OU}\mathcal{L}_2\mathcal{L}_1^{-1}\mathcal{L}_2\mathbf{E}_{OU}g(\mathbf{X}) \\ &= \int_{\mathbb{R}^N} d\mathbf{P}\,\hat{\tilde{P}}_{OU}(\mathbf{P})\hat{\mathcal{L}}_2\int_0^\infty dt\,\left[\hat{\mathcal{L}}_2(g(\mathbf{X})\delta(\mathbf{P}'))\right]_{\mathbf{P}'=\boldsymbol{\beta}(\mathbf{P},t)} \\ &\qquad \times \exp\left((\,\mathrm{Tr}\,\tilde{\mathcal{Q}})t - \frac{1}{2}\mathbf{P}\cdot(\exp(\tilde{\mathcal{Q}}t)\cdot\exp(\tilde{\mathcal{Q}}t) - \mathcal{I})\cdot\mathbf{P}\right),\end{aligned}$$

where

$$\boldsymbol{\beta}(\mathbf{P},t) = \exp(\tilde{\mathcal{Q}}t)\cdot\mathbf{P}$$

and

$$\hat{\tilde{P}}_{OU}(\mathbf{P}) = \exp\left(-\frac{1}{2}\sum_{\boldsymbol{\alpha}\in\mathcal{A}}|\mathbf{p}_{\boldsymbol{\alpha}}|^2\right).$$

Then by making the same kind of calculations as we did for the PB dynamics in section 2.4.3, we obtain

$$\bar{\mathcal{L}}g(\mathbf{X}) = \sum_{\boldsymbol{\alpha},\boldsymbol{\alpha}'\in\mathcal{A}}\left[\frac{\partial}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\cdot\left((\tilde{\mathcal{Q}}^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}\cdot\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}'}}\right)\right.$$
$$\left. - \phi\left((\tilde{\mathcal{Q}}^{-1})_{\boldsymbol{\alpha},\boldsymbol{\alpha}'}\cdot\nabla_{\boldsymbol{\alpha}'}\tilde{\Phi}\left(\frac{\mathbf{X}}{\bar{\ell}_f}\right)\right)\cdot\frac{\partial g}{\partial\mathbf{X}_{\boldsymbol{\alpha}}}\right].$$

This is exactly the Kolmogorov backward differential operator corresponding to the stochastic dynamics recorded in Proposition 3.1.

3.3.4. Positive definiteness of $\tilde{\mathcal{Q}}$. We now discuss in more detail the positive definiteness of $\tilde{\mathcal{Q}}$ in (3.4).

DEFINITION 3.2. *Given a frictional coupling function $\omega(r)$, a particle configuration $\mathbf{X}$ will be said to be* frictionally connected *if for each pair of particles $\boldsymbol{\alpha}$ and $\boldsymbol{\alpha}'$ and each pair of unit vectors $\hat{e},\hat{e}'\in\mathbb{R}^3$ there exists a finite chain of particles $\{\boldsymbol{\alpha}^{(i)}\}_{i=1}^n$ with $\boldsymbol{\alpha}^{(1)}=\boldsymbol{\alpha}$ and $\boldsymbol{\alpha}^{(n)}=\boldsymbol{\alpha}'$ obeying the following conditions:*

(i) $\omega(|\mathbf{X}_{\boldsymbol{\alpha}^{(i+1)}}-\mathbf{X}_{\boldsymbol{\alpha}^{(i)}}|)>0$ *for* $1\le i\le n-1$,

(ii) $(\mathbf{X}_{\boldsymbol{\alpha}^{(i+1)}}-\mathbf{X}_{\boldsymbol{\alpha}^{(i)}})\cdot(\mathbf{X}_{\boldsymbol{\alpha}^{(i)}}-\mathbf{X}_{\boldsymbol{\alpha}^{(i-1)}})\neq 0$ *for* $2\le i\le n-1$,

(iii) $\hat{e}\cdot(\mathbf{X}_{\boldsymbol{\alpha}^{(2)}}-\mathbf{X}_{\boldsymbol{\alpha}^{(1)}})\neq 0$ *and* $\hat{e}'\cdot(\mathbf{X}_{\boldsymbol{\alpha}^{(n)}}-\mathbf{X}_{\boldsymbol{\alpha}^{(n-1)}})\neq 0$.

Otherwise, the configuration is said to be frictionally disconnected.

Colloquially, a frictionally connected configuration is one for which any relative motion of any pair of particles induces some sort of frictional damping. This need not be a direct frictional coupling. Imagine, for example, a large but dense cluster of particles with cluster diameter larger than the distance over which frictional coupling acts. Choose two particles at opposite edges of the cluster, and pick arbitrary directions $\hat{e}$ and $\hat{e}'$ associated with the respective particles. Suppose that a chain of particles can be found between these two particles such that each pair of successive particles has a nonzero frictional interaction, no two successive pairs have orthogonal separation vectors, and the separation vectors of the pairs at the ends are not orthogonal to $\hat{e}$ and $\hat{e}'$. Then any motion of the first particle along $\hat{e}$ and the second particle along $\hat{e}'$ will create some frictional damping within the chain, no matter how the other particles are chosen to move along with the two given particles. If no such chain can be found between the two particles, then that implies that they lie in frictionally decoupled subclusters, so that there is an extra degree of freedom (rigid motion of each subcluster) beyond center of mass motion which is not frictionally damped. To understand the nonorthogonality restrictions in the definition of frictional connectedness, note that, for any pair of frictionally interacting particles, the motion of one particle along a line normal to their separation vector incurs frictional damping only at second order in its displacement (and so is vanishing to first order).

Direct calculations establish the following result.

PROPOSITION 3.3. *The matrix $\tilde{\mathcal{Q}}$ in* (3.4) *is always nonnegative definite: $\mathbf{V}\cdot\tilde{\mathcal{Q}}\cdot\mathbf{V}\ge 0$ for any vector $\mathbf{V}$. Let K be the null-space of $\tilde{\mathcal{Q}}$: $\mathbf{V}\in K\leftrightarrow\tilde{\mathcal{Q}}\cdot\mathbf{V}=\mathbf{0}$. This null-space always contains a three-dimensional subspace of vectors characterized*

by $\mathbf{V}_{\boldsymbol{\alpha}} = \mathbf{V}_{\boldsymbol{\alpha}'}$ *for all* $\boldsymbol{\alpha}, \boldsymbol{\alpha}' \in \mathcal{A}$. *The null-space is strictly larger than this three-dimensional subspace whenever the configuration* $\mathbf{X}$ *is frictionally disconnected.*

The general three-dimensional subspace of null vectors corresponds to the center of mass motion, and we can easily eliminate them from our system by a simple linear projection if there is no external potential. The additional vectors in the null-space from frictionally disconnected configurations represent additional undamped modes in the system involving relative motion. For example, if there exists a cluster $\{\boldsymbol{\alpha} \in \mathcal{A}_c\}$ of particles which are not in frictional contact with any particles not in this cluster, then the null-space of $\tilde{\mathcal{Q}}$ contains all vectors $\mathbf{V}$ with the property $\mathbf{V}_{\boldsymbol{\alpha}} = \mathbf{V}_{\boldsymbol{\alpha}'}$ for all $\boldsymbol{\alpha}, \boldsymbol{\alpha}' \in \mathcal{A}_c$, and $\mathbf{V}_{\boldsymbol{\alpha}} = 0$ for all $\boldsymbol{\alpha} \notin \mathcal{A}_c$.

CONJECTURE 3.4. *For frictionally connected configurations* $\mathbf{X}$*, the null-space of the matrix* $\tilde{\mathcal{Q}}$ *is precisely the three-dimensional space described in Proposition* 3.3. *There are no additional null eigenvectors.*

The reason for the conjecture is that, from a physical standpoint, the system has no undamped relative degrees of freedom other than center of mass motion. We have not been able to provide a mathematical proof, however. The matrix $\tilde{\mathcal{Q}}$ has the form of an infinitesimal generator of a continuous time Markov chain [42], except that the off-diagonal components consist of nonnegative dyadic matrices rather than nonnegative scalars. The usual arguments for characterizing the null-space of an infinitesimal generator, however, suffered algebraic defects when we tried to apply them to the case at hand.

If we grant the conjecture, then a sufficiently dense system should remain frictionally connected with high probability, and one could imagine applying Kurtz's theorem [29] only on such realizations. A proper technical framework, however, would need to be constructed to make such a statement mathematically meaningful, and this is beyond the scope of the present work.

4. Conclusion. The MTV stochastic mode reduction procedure provides a way to recover rigorously the Smoluchowski equation for PB models at low thermal Kubo number. In contrast, the governing equations for DPD have an algebraic structure amenable to the MTV procedure, but they incur analytical obstacles due to the finite range of the frictional interaction. This feature introduces a mobile degeneracy which prevents the a priori identification of the fast and slow modes in the system; slow modes can, rather, emerge dynamically. It would be interesting to formulate a mathematically sound way to obtain and describe the simplified dynamics of such a system, particularly when the degeneracies occur rarely.

Acknowledgments. The authors thank Eric Vanden-Eijnden for helpful discussions and suggestions, and the referees for constructive comments which improved the presentation.

THE ELECTROPHORETIC MOBILITY OF A CLOSELY FITTING SPHERE IN A CYLINDRICAL PORE*

EHUD YARIV† AND HOWARD BRENNER†

Abstract. We analyze the electrophoretic motion of a freely suspended closely fitting sphere, eccentrically positioned within an infinitely long cylindrical pore, when subjected to a uniform electric field acting parallel to the pore. The thin Debye-layer approximation is employed. Using singular perturbation expansions, the fluid domain is separated into an "inner" gap region around the sphere's equator, wherein electric field and velocity gradients are large, and an "outer" region, consisting of the remaining fluid domain, wherein field variations are moderate. Laplace's equation is solved within the gap region using stretched coordinates, whereby matching with the outer solution is facilitated by use of an integral conservation equation for the electric field flux. Using a reciprocal theorem, the electrokinetic contributions to the force (torque) on the sphere are represented as quadratures of the electric field over the sphere surface, with the respective stress fields pertaining to purely translational (rotational) motions appearing as Green's functions. The translational velocity of a concentrically positioned sphere is found to be half that for a sphere in an unbounded fluid. Both the translational and rotational sphere mobilities increase in magnitude with increasing eccentricity.

Key words. singular perturbations, Stokes flow, reciprocal theorem

1. Introduction.

The effects of boundaries upon the electrophoretic motion of colloidal particles have been the subject of many studies, as these effects are inevitable in any practical system. The complete system of electrokinetic equations is strongly coupled and nonlinear, making analytic treatment difficult even for the simplest geometries [17]. This has led to extensive use of the "thin Debye layer" approximation, which results in linear equations in the outer "bulk" region, lying outside of the Debye double layers surrounding the various surfaces, say $\mathcal{S}$, in contact with the electrolytic fluid (i.e., particle and wall surfaces). Indeed, in many practical cases the Debye-layer thickness, say λ_D, is of the order of nanometers [20], which allows use of this asymptotic approximation, even for micron-size particles. Within the framework of this approximation [9], the flow in the bulk region is governed by the conventional Stokes equations (without any electrical body force), albeit satisfying a slip condition on $\mathcal{S}$. This condition reflects the finite velocity jump across the layer, which is proportional to the electric field existing at its outer edge (in the bulk domain). This field is derived from an electric potential, which satisfies a Neumann-type boundary-value problem in the bulk region.

The simplicity of the former model allows the solution of electrophoretic problems posed for geometric configurations that involve both a particle and a wall. It is common to use a sphere as a simple geometric model for particle shape in various applications.[1] In cases where the sphere is remote from the wall compared with its radius, the electrostatic and flow problems can be solved using reflection techniques.

[1]Even long molecules, such as DNA, tend to coil into spherical equilibrium shapes.

This has been done for the cases of a sphere moving far from a planar wall [9], as well as for a relatively small sphere moving within an infinitely long circular cylinder [9, 21]. First-order electrophoretic wall effects are found in such circumstances to be proportional to $(a/b)^3$, where a is the sphere's radius and b is a typical sphere-wall distance. As such, these effects are rather weak compared with the $O(a/b)$ hydrodynamic interactions (in the absence of electrophoretic effects) occurring during sedimentation of a sphere which interacts with a distant boundary [8].

Exact sphere-boundary solutions, valid for $a/b \sim O(1)$, may be obtained using eigenfunction expansions. Such solutions are difficult to derive, except for rather simple configurations involving elementary geometrical symmetries. Roughly speaking, these types of solutions are classified into two categories. The first consists of two-sphere interactions [16, 11], as well as sphere motion in proximity to a plane [10, 13]. The second involves sphere motion in bounded regions, as in the case of a concentrically positioned sphere translating within an infinitely long circular cylinder [12]. More complex geometries necessitate the use of strictly numerical methods, such as collocation [14] or boundary integrals [18].

While these exact solutions are valid in principle for all $O(1)$ sphere-sphere or sphere-boundary separations, numerical convergence of the pertinent series solutions becomes poor for small separations. It is exactly in such circumstances that electrophoretic flows exhibit a unique behavior, qualitatively different from that occurring during conventional, electrolyte-free Stokes flows. In the latter case, particle drag becomes unbounded (and, consequently, particle mobility goes to zero) as the sphere-wall gap thickness shrinks to zero, reflecting the increasingly large viscous stresses existing within the narrow gap. However, this is not the general rule in electrophoretic motions. The most notable difference occurs during the movement of a sphere parallel to a wall, wherein the results of [10] predict increasingly *large* magnitudes of sphere velocities as the sphere-wall separation vanishes. In the case of sphere motion within a cylindrical pore, the results of [12] predict sphere velocities *comparable* with those for an unbounded domain.

It is important to emphasize that all previously mentioned results were obtained under the thin-Debye-layer approximation, and thus do not represent interactions between the respective particle and wall double layers. As such, this singular behavior has to do with gap separations that are small compared with particle size but still large relative to the Debye-layer thickness, λ_D. Mobility models for such thin gap geometries are important in the analysis of colloidal dispersion phenomena, especially in the formation of electrophoretic aggregates. Furthermore, the continuous progress achieved to date in microfabrication techniques has resulted in microfluidic devices whose channel depth is comparable to colloidal particle size [7]. The importance of the availability of accurate mobility models covering the entire range of separations has led to the development of improved numerical series solution schemes [24], as well as to the proposal of empirical formulae.

Analytic, closed-form analyses of near-contact geometries may be affected by using singular perturbation schemes. Usually, the range of validity of such asymptotic solutions overlaps those of the "exact" solutions. Thus, the combination of asymptotic approximation together with exact solutions provides uniformly valid hybrid mobility models. Several asymptotic solutions have already been obtained for geometries of the first category. In this context, analysis of the motion of a sphere parallel to a plane wall was presented in [22]. This study clearly demonstrates the strong effect upon particle mobility arising from the intense electric field existing within the narrow gap region.

The present investigation deals with a singular case associated with the second category, namely the motion of a closely fitting sphere in a direction parallel to the wall of an infinitely long circular cylinder. We consider the general case of an eccentrically positioned sphere. This geometry, which is extremely difficult to analyze in the case of arbitrary sphere-to-channel radius ratios (for which only the concentric case has been solved; see [12]), lends itself to analytic treatment within an appropriate asymptotic framework. The conventional, electrolyte-free, Stokes motion of a closely fitting sphere has already been analyzed in [4]. The same geometry was also used in the analysis of van der Waals and double-layer sphere-channel interactions [1]. During the course of the subsequent analysis, we solve the electrostatic problem for this geometry in order to obtain the electric field distribution. It is convenient to separately solve Laplace's equation in the narrow gap region between the sphere and wall using scaled variables. The matching procedure is based upon the balance of net electric flux along the channel, thereby avoiding the difficult solution of Laplace's equation in the "outer" region. With the electrostatic solution in hand, the linear Stokes flow problem is well defined. This problem is decomposed into four distinct parts, labeled (a)–(d), reflecting different boundary condition contributions. The first two parts constitute "simple" Stokes flows, with no electrokinetic effects, already available in [4]. The remaining problems, (c) and (d), reflect the electrokinetically driven portion of the flow.

In principle, the Stokes equations governing the latter problems need to be solved in analytic detail, subject to the pertinent slip conditions imposed by the electric field at the respective channel wall and sphere surfaces. However, by virtue of the existence of a reciprocal theorem [2], such detailed solutions become unnecessary, since the theorem allows the force and torque acting on the sphere to be expressed directly in terms of appropriate quadratures of the electric field over its surface, wherein the purely hydrodynamic translational and rotational stress fields available from [4] appear as Green's functions.

The present paper furnishes leading-order asymptotic solutions of the electrostatic and Stokes flow problems. These solutions rationalize the $O(1)$ velocities obtained in [12] for closely fitting geometries. While the present asymptotic scheme may be utilized to systematically derive higher-order corrections, such corrections would have but small practical significance, as the basic channel-sphere geometry itself already constitutes a rather simplified model of the actual systems encountered in practice.

This paper is organized as follows: In the next section we formulate the mathematical problem governing the electric potential and flow fields. The flow problem is then decomposed into the above-mentioned parts, (a)–(d). Geometrical descriptions of the pertinent equations and boundary conditions appropriate to small gap widths are outlined. The electrostatic problem, governing the electrical potential, is solved in section 3. Following that, a reciprocal theorem is used in section 4 to compute the "electrokinetic" flow contribution, part (c). In section 5 we demonstrate that the "potential" part, (d), does not contribute to the force and torque acting on the sphere. Finally, the separate force and torque contributions of the preceding sections are combined in section 6, and the linear and angular velocities of a freely suspended sphere are derived therefrom.

2. Problem formulation. Consider a spherical particle (radius a) eccentrically positioned within an infinitely long circular cylinder [radius $(1+\varepsilon)a$; $\varepsilon > 0$] filled with an electrolyte solution. The cylinder wall, $\mathcal{W}$, as well as the sphere surface, $\mathcal{P}$, are assumed to possess uniform surface charge densities, with respective zeta potentials

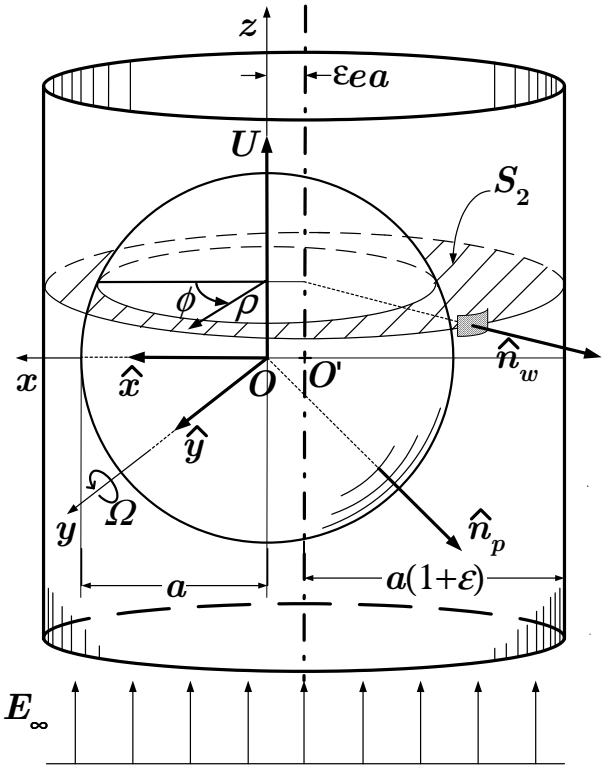

FIG. 2.1. *Schematic of the sphere-cylinder geometry.*

ζ_w and ζ_p. A uniform electric field, E_∞, is applied parallel to the cylinder walls (see Figure 2.1), causing translation and rotation of the sphere relative to $\mathcal{W}$ with respective velocities $\boldsymbol{U}$ and $\boldsymbol{\Omega}$.

We focus on the case of thin Debye layers [9] around both $\mathcal{W}$ and $\mathcal{P}$. As the gap separation, εa, constitutes the smallest bulk scale, the usual limit, namely $\lambda_D/a \to 0$, is here modified to $\lambda_D/\varepsilon a \to 0$. Thus, the electric potential φ is governed by Laplace's equation in the bulk region and satisfies a "no-flux" boundary condition on $\mathcal{W} \cup \mathcal{P}$, namely $\hat{\boldsymbol{n}} \cdot \nabla\varphi = 0$ ($\hat{\boldsymbol{n}}$ being a generic vector normal to $\mathcal{W} \cup \mathcal{P}$). Since the fluid in the bulk region is electrically neutral, no electrical body forces appear in the pertinent Stokes equations. The electric field affects the bulk flow only through the finite velocity slip, $\epsilon_{\rm el}\zeta_\alpha \nabla\varphi/\mu$ (with μ and $\epsilon_{\rm el}$, respectively, denoting the presumably uniform fluid viscosity and dielectric permittivity coefficients), experienced by the fluid on the respective wall ($\alpha = w$) and particle ($\alpha = p$) surfaces. This slip embodies Smoluchowski's result governing the velocity jump across the Debye layer.

In nondimensionalizing the pertinent equations, we normalize length variables with a, the electric potential with $E_\infty a$, linear velocities with the characteristic electrophoretic velocity $U_0 = \epsilon_{\rm el} E_\infty \zeta_p/\mu$, angular velocities with U_0/a, stresses (and pressure) with $\mu U_0/a$, forces with $\mu U_0 a$, and torques with $\mu U_0 a^2$. Thus, the dimensionless electric potential satisfies (i) Laplace's equation in the fluid domain,

$$\nabla^2\varphi = 0; \tag{2.1}$$

(ii) Neumann-type boundary conditions on the solid boundaries,

$$\hat{\boldsymbol{n}}_w \cdot \nabla\varphi = 0 \quad \text{on} \quad \mathcal{W}, \tag{2.2}$$

$$\hat{\boldsymbol{n}}_p \cdot \nabla\varphi = 0 \quad \text{on} \quad \mathcal{P} \tag{2.3}$$

(with unit normal vectors $\hat{\boldsymbol{n}}_w$ and $\hat{\boldsymbol{n}}_p$ on $\mathcal{W}$ and $\mathcal{P}$ pointing in the respective directions depicted in Figure 2.1); and (iii) the far-field condition

$$\nabla\varphi \to -\hat{\boldsymbol{z}} \quad \text{as} \quad |z| \to \infty, \tag{2.4}$$

wherein $\hat{\boldsymbol{z}}$ is a unit vector pointing in the direction of the applied electric field.

The fluid velocity and pressure fields in the bulk region, $(\boldsymbol{v}, p)$, satisfy the incompressible Stokes equations, namely

$$\nabla \cdot \boldsymbol{v} = 0, \quad \nabla p = \nabla^2 \boldsymbol{v}, \tag{2.5}$$

as well as the boundary conditions

$$\boldsymbol{v} = \gamma \nabla\varphi \quad \text{on} \quad \mathcal{W}, \tag{2.6}$$

$$\boldsymbol{v} = \nabla\varphi + \boldsymbol{U} + \boldsymbol{\Omega} \times \boldsymbol{r} \quad \text{on} \quad \mathcal{P}. \tag{2.7}$$

In the above, $\gamma = \zeta_w/\zeta_p$, and $\boldsymbol{r}$ is a position vector measured relative to the sphere center O. These conditions incorporate both rigid-body motion (on $\mathcal{P}$) and electrokinetic slip on both surfaces. Far from the sphere, the velocity field approaches an electroosmotic "plug flow,"

$$\boldsymbol{v} \to -\gamma\hat{\boldsymbol{z}} \quad \text{as} \quad |z| \to \infty, \tag{2.8}$$

with z a rectilinear coordinate measuring distance parallel to the cylinder walls (see Figure 2.1). This condition isolates the present motion from effects giving rise to *mechanically* driven motion of the fluid (and sphere), thus rendering the fluid motion purely "electrophoretic." (In circumstances where the motion is driven by both mechanical and electrical agencies, the force and torque associated with the pressure- or net-flow-driven motions [4] may be superimposed upon the present results.)

Once the velocity and pressure fields are obtained, the hydrodynamic stress field in the bulk region may be calculated by the Newtonian expression

$$\boldsymbol{\pi} = -p\mathbf{I} + \left[(\nabla\boldsymbol{v}) + (\nabla\boldsymbol{v})^\dagger\right]. \tag{2.9}$$

The force and torque acting upon the particles are then given by the respective expressions

$$\boldsymbol{F} = \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}, \tag{2.10a}$$

$$\boldsymbol{T} = \oint_{\mathcal{P}} dA\, \boldsymbol{r} \times (\hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}). \tag{2.10b}$$

The mathematical problem governing the flow on the bulk scale, namely (2.5)–(2.10), retains the conventional form of a Stokes problem, albeit with electrokinetic slip conditions on $\mathcal{P}$ and $\mathcal{W}$. This allows for the use of general creeping-flow theorems (cf.

section 4). Moreover, given the linearity of the flow problem, it proves convenient to decompose the flow field $(\boldsymbol{v}, p)$ into four distinct parts, labeled (a)–(d), each satisfying the linear Stokes equations (cf. [22]). The linear boundary conditions (2.6)–(2.7) and the up- or downstream velocity profile (far from the sphere) are separated as follows:

	(a)	(b)	(c)	(d)
on $\mathcal{P}$:	$\boldsymbol{v} = \boldsymbol{U}$	$\boldsymbol{v} = \boldsymbol{\Omega} \times \boldsymbol{r}$	$\boldsymbol{v} = (1-\gamma)\nabla\varphi$	$\boldsymbol{v} = \gamma\nabla\varphi$
on $\mathcal{W}$:	$\boldsymbol{v} = \boldsymbol{0}$	$\boldsymbol{v} = \boldsymbol{0}$	$\boldsymbol{v} = \boldsymbol{0}$	$\boldsymbol{v} = \gamma\nabla\varphi$
as $\lvert z\rvert \to \infty$:	$\boldsymbol{v} \to \boldsymbol{0}$	$\boldsymbol{v} \to \boldsymbol{0}$	$\boldsymbol{v} \to \boldsymbol{0}$	$\boldsymbol{v} \to -\gamma\hat{\boldsymbol{z}}$

The total hydrodynamic force (and torque) on the sphere is obtained by superposing the comparable contributions resulting from flow fields (a)–(d). Flow field (a) is identical to that resulting from translation (sans rotation) of the sphere with linear velocity $\boldsymbol{U}$ within the cylinder and with no slip on the walls. Similarly, flow field (b) arises from the rotation (sans translation) of the sphere with angular velocity $\boldsymbol{\Omega}$ within the cylinder and with no slip on the walls. Parts (c) and (d) constitute the "electrokinetic" portions of the overall flow. Each individual flow field contributes, in general, to the force and torque acting on the sphere. Imposition of the requirement of zero net force and torque serves to determine $\boldsymbol{U}$ and $\boldsymbol{\Omega}$.

2.1. Sphere-cylinder geometry; closely fitting sphere. In dimensionless form, the cylinder possesses a radius $1+\varepsilon$. The sphere center O is positioned at a distance εe from the cylinder axis (see Figure 2.1). Clearly, $0 < e < 1$, the respective lower and upper bounds corresponding to concentric and fully eccentric positions. The cylinder-sphere configuration possesses two symmetry planes, both passing through O: a cross-sectional plane, say π_1, normal to the cylinder axis, and a meridian plane, say π_2. It is convenient to employ particle-fixed Cartesian (x, y, z) and circular cylindrical (ρ, ϕ, z) coordinate systems, centered about O. The z axis lies parallel to the cylinder's symmetry axis, the x axis lies along the line of intersection formed from π_1 and π_2 (with the unit vector $\hat{\boldsymbol{x}}$ pointing from the cylinder axis towards O), and the direction of the unit vector $\hat{\boldsymbol{y}}$ is taken such that the (x, y, z) axes constitute a right-handed orthogonal system. The azimuthal angle ϕ is measured from π_2. Thus, π_1 coincides with the plane $z = 0$, whereas π_2 is given by $\phi = (0, \pi)$. The cylinder wall surface $\mathcal{W}$ and sphere surface $\mathcal{P}$ are described in these coordinates by the respective relations (see Figure 2.2(a))

$$\rho_w(\phi) = \left[(1+\varepsilon)^2 - \varepsilon^2 e^2 \sin^2\phi\right]^{1/2} - \varepsilon e \cos\phi, \tag{2.11}$$

$$\rho_p(z) = (1-z^2)^{1/2}. \tag{2.12}$$

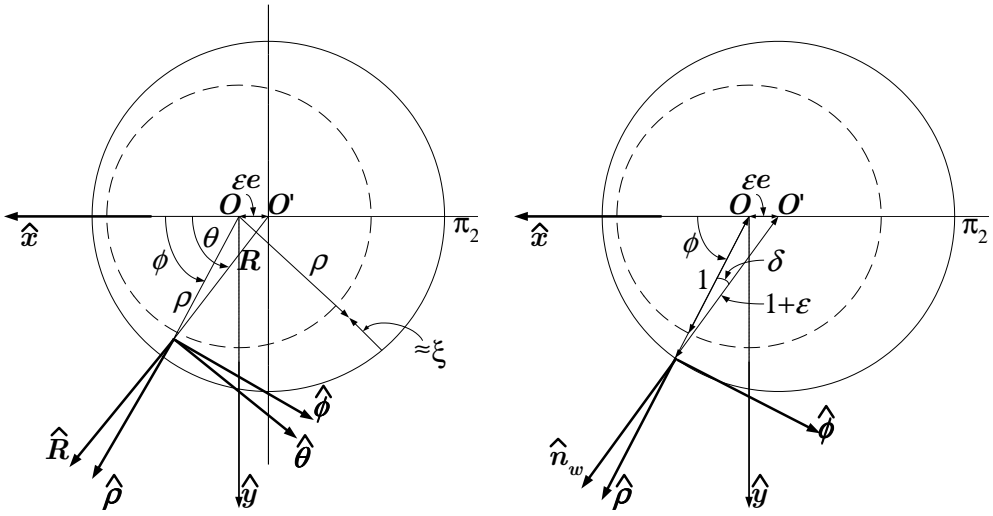
In terms of the system of circular cylindrical coordinates, the electric potential satisfies the following relations:

$$\frac{\partial^2\varphi}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial\varphi}{\partial\rho} + \frac{1}{\rho^2}\frac{\partial^2\varphi}{\partial\phi^2} + \frac{\partial^2\varphi}{\partial z^2} = 0 \quad \text{for} \quad \rho_p(z) < \rho < \rho_w(\phi), \tag{2.13}$$

$$\hat{\boldsymbol{n}}_p \cdot \left(\hat{\boldsymbol{\rho}}\frac{\partial\varphi}{\partial\rho} + \hat{\boldsymbol{z}}\frac{\partial\varphi}{\partial z}\right) = 0 \quad \text{at} \quad \rho = \rho_p(z), \tag{2.14}$$

$$\hat{\boldsymbol{n}}_w \cdot \left(\hat{\boldsymbol{\rho}}\frac{\partial\varphi}{\partial\rho} + \hat{\boldsymbol{\phi}}\frac{1}{\rho}\frac{\partial\varphi}{\partial\phi}\right) = 0 \quad \text{at} \quad \rho = \rho_w(\phi), \tag{2.15}$$

$$\frac{\partial\varphi}{\partial z} \to -1 \quad \text{as} \quad \lvert z\rvert \to \infty. \tag{2.16}$$



(a) (b)

FIG. 2.2. *The cross-sectional plane* $z = 0$: (a) *particle- and wall-fixed coordinate systems.* (b) *geometrical relations between the unit vectors* $\hat{\boldsymbol{\rho}}$, $\hat{\boldsymbol{\phi}}$, *and* $\hat{\mathbf{n}}_w$.

Owing to the cylinder-sphere configurational symmetry, it is obvious (and, indeed, consistent with (2.11)–(2.16)) that φ is an odd function of z and, moreover, that it possesses symmetry with respect to reflection in the plane π_2; that is, it is invariant under the transformation $\phi \mapsto 2\pi - \phi$. A dynamical consequence of the underlying geometric symmetry is that the sphere translates parallel to the wall and rotates in a direction normal to π_2; that is, $\boldsymbol{U} = \hat{\boldsymbol{z}}U$ and $\boldsymbol{\Omega} = \hat{\boldsymbol{y}}\Omega$.[2]

In what follows, we focus upon the case of a closely fitting sphere, $\varepsilon \ll 1$. The purely hydrodynamic, potential-independent flows, (a) and (b), respectively corresponding to a translating and rotating sphere, have already been obtained [4] for that limiting case. These "mechanical" flows are highly singular, with large velocity and pressure variations occurring in the gap region, $|z| \ll 1$. The same will be seen to be true for the "electrokinetic" flows, (c) and (d). Indeed, consider the flux of electric field through the following pair of cross-sectional planes, the first passing through the sphere ($-1 < z < 1$), the second being remote ($|z| \gg 1$). As the electric vector field is solenoidal, as well as tangent to both $\mathcal{P}$ and $\mathcal{W}$ (see (2.1)–(2.3)), the uniform flux in the remote plane has to pass through the accessible part of the first plane, say S_2 (see Figure 2.1), requiring that

$$\int_0^{2\pi} d\phi \int_{\rho_p(z)}^{\rho_w(\phi)} d\rho\, \rho\, \frac{\partial \varphi}{\partial z} = -\pi\,(1+\varepsilon)^2\,. \tag{2.17}$$

[2]This rectilinear motion is consistent with the linear structure of the problem formulation. It is expected that both nonlinear electrokinetic effects, as well as Brownian diffusion, may result in a lateral migration of the particle. As such, the incorporation of both mechanisms is essential for either stability or averaging analysis of the present problem.

For $|z| \ll 1$, the annular integration domain becomes small, leading to a large electric field magnitude. As the electric field is the driver of the fluid motion (cf. (2.6)–(2.7)), it is expected that the concomitant flow fields, (c) and (d), will be singular as well. It is therefore convenient to analyze the electric field (and, subsequently, the flow) problems in the gap "inner" region independently of the more distant behavior of the pertinent fields.

For $\varepsilon \ll 1$, the cylinder wall is described by the relation

$$\rho_w(\phi) \sim 1 + \varepsilon(1 - e\cos\phi) - \varepsilon^2 \frac{1}{2}\left(e\sin\phi\right)^2 + \varepsilon^3 \frac{1}{2}\left(e\sin\phi\right)^2 + O\left(\varepsilon^4\right). \tag{2.18}$$

Define a new radial coordinate ξ as

$$\xi = 1 + \varepsilon(1 - e\cos\phi) - \rho. \tag{2.19}$$

Since $\xi \sim O(\varepsilon^2)$ on $\mathcal{W}$, this variable approximates the distance measured from the wall (along a line normal to the z axis; see Figure 2.2(a)). In terms of this new variable, and for $|z| \ll 1$, the equation describing $\mathcal{P}$ (cf. (2.11)) adopts the form

$$\xi = \varepsilon(1 - e\cos\phi) + \frac{1}{2}z^2 + \frac{1}{8}z^4 + \frac{1}{16}z^6 + \cdots. \tag{2.20}$$

In what follows, we rescale the coordinates in accordance with the scheme of [4]: Defining the "stretched" variables,

$$X = \xi/\varepsilon, \quad Z = z/\varepsilon^{1/2}, \tag{2.21}$$

leads to the following representation of the surface $\mathcal{P}$:

$$X = H(\phi, Z) + \frac{1}{8}\varepsilon Z^4 + \frac{1}{16}\varepsilon^2 Z^6 + \cdots \equiv X_p(\phi, Z; \varepsilon). \tag{2.22}$$

Here,

$$H(\phi, Z) = \left[\tau(\phi)\right]^2 + \frac{1}{2}Z^2 \tag{2.23}$$

constitutes the leading-order scaled gap separation width, with $\tau(\phi) = (1 - e\cos\phi)^{1/2}$. The comparable expansion of $\mathcal{W}$ is

$$X = \varepsilon\frac{1}{2}\left(e\sin\phi\right)^2 - \varepsilon^2\frac{1}{2}\left(e\sin\phi\right)^2 + \cdots \equiv X_w(\phi, Z; \varepsilon). \tag{2.24}$$

For future reference, we note that the gradient operator is given in terms of the stretched coordinates by the expression

$$\nabla = -\varepsilon^{-1}\hat{\boldsymbol{\rho}}\frac{\partial}{\partial X} + \varepsilon^{-1/2}\hat{\boldsymbol{z}}\frac{\partial}{\partial Z} + \hat{\boldsymbol{\phi}}\left(\frac{\partial}{\partial\phi} + e\sin\phi\frac{\partial}{\partial X}\right), \tag{2.25}$$

wherein $(\hat{\boldsymbol{\rho}}, \hat{\boldsymbol{\phi}}, \hat{\boldsymbol{z}})$ denote the respective unit vectors in the circular cylindrical coordinate system (see Figure 2.2(a)).

3. The electric potential within the gap. The potential $\varphi(X,\phi,Z;\varepsilon)$ in the gap region is governed by (i) Laplace's equation in the fluid domain, $X_w(\phi,Z;\varepsilon) < X < X_p(\phi,Z;\varepsilon)$,

$$\frac{\partial^2\varphi}{\partial X^2}+\varepsilon\left[\frac{\partial^2\varphi}{\partial Z^2}-\frac{1}{1+\varepsilon\,(1-\varepsilon\cos\phi-X)}\frac{\partial\varphi}{\partial X}\right] + \varepsilon^2\frac{1}{[1+\varepsilon\,(1-\varepsilon\cos\phi-X)]^2}\left(\frac{\partial^2\varphi}{\partial\phi^2}+e^2\sin\phi\frac{\partial^2\varphi}{\partial X^2}+2e\sin\phi\frac{\partial^2\varphi}{\partial X\partial\phi}+e\cos\phi\frac{\partial\varphi}{\partial X}\right)=0; \tag{3.1}$$

(ii) the boundary condition on $\mathcal{P}$,

$$\frac{\partial\varphi}{\partial X}+\varepsilon\left[(1-e\cos\phi-X)\,\frac{\partial\varphi}{\partial X}-Z\frac{\partial\varphi}{\partial Z}\right]=0 \quad \text{at} \quad X=X_p(\phi,Z;\varepsilon); \tag{3.2}$$

and (iii) the boundary condition on $\mathcal{W}$,

$$\hat{\boldsymbol{n}}_w\cdot\left[\hat{\boldsymbol{\rho}}\frac{\partial\varphi}{\partial X}-\varepsilon\hat{\boldsymbol{\phi}}\frac{1}{1+\varepsilon\,(1-e\cos\phi-X)}\left(\frac{\partial\varphi}{\partial\phi}+e\sin\phi\frac{\partial\varphi}{\partial X}\right)\right] = 0 \quad \text{at} \quad X=X_w(\phi,Z;\varepsilon). \tag{3.3}$$

From (2.24) and (2.25) we obtain the following expression for the direction of a vector normal to $\mathcal{W}$:

$$\hat{\boldsymbol{\rho}}-\varepsilon\hat{\boldsymbol{\phi}}\,e\sin\phi\,[1+O(\varepsilon)]\,. \tag{3.4}$$

Thus, to first order in ε, the corresponding unit vector $\hat{\boldsymbol{n}}_w$ is given by $\hat{\boldsymbol{\rho}}-\varepsilon\hat{\boldsymbol{\phi}}e\sin\phi$. This result could have been anticipated from Figure 2.2(b), wherein to leading order the small angle δ is given by $\varepsilon e\sin\phi$.

The inner electric field may be related to the uniform field (at the "infinity" of the *outer* problem) via the global flux condition (2.17), written in terms of the stretched coordinates[3] as

$$\varepsilon^{1/2}\int_0^{2\pi}d\phi\int_{X_w(\phi,Z;\varepsilon)}^{X_p(\phi,Z;\varepsilon)}dX\;\;[1+\varepsilon\,(1-e\cos\phi-X)]\,\frac{\partial\varphi}{\partial Z}=-\pi\,(1+\varepsilon)^2\,. \tag{3.5}$$

This condition, serving to illustrate the singular nature of the electric field, suggests the trial expansion

$$\varphi(X,\phi,Z;\varepsilon)\sim\varepsilon^{-1/2}\left[\varphi^{(0)}(X,\phi,Z)+\varepsilon\varphi^{(1)}(X,\phi,Z)+\cdots\right]. \tag{3.6}$$

The sequence of boundary-value problems governing the respective fields $\{\varphi^{(i)}\}$ $(i\geq 0)$ are obtained from (3.1)–(3.4), with the boundary conditions transferred from the actual boundaries, $X_w(\phi,Z;\varepsilon)$ and $X_p(\phi,Z;\varepsilon)$, to the corresponding virtual boundaries, $X=0$ and $X=H(\phi,Z)$, using standard techniques. The leading-order term, $\varphi^{(0)}(X,\phi,Z)$, satisfies the following equations:

$$\frac{\partial^2\varphi^{(0)}}{\partial X^2}=0 \quad \text{for} \quad 0<X<H(\phi,Z), \tag{3.7}$$

$$\frac{\partial\varphi^{(0)}}{\partial X}=0 \quad \text{at} \quad X=0,H(\phi,Z). \tag{3.8}$$

[3]Obviously, if the exact problem governing φ were to be solved, this condition would prove redundant.

The comparable $O(\varepsilon)$ balance yields

$$\frac{\partial^2 \varphi^{(1)}}{\partial X^2} = -\frac{\partial^2 \varphi^{(0)}}{\partial Z^2} \quad \text{for} \quad 0 < X < H(\phi, Z), \tag{3.9}$$

$$\frac{\partial \varphi^{(1)}}{\partial X} = 0 \quad \text{at} \quad X = 0, \tag{3.10}$$

$$\frac{\partial \varphi^{(1)}}{\partial X} = Z \frac{\partial \varphi^{(0)}}{\partial Z} \quad \text{at} \quad X = H(\phi, Z). \tag{3.11}$$

As noted above, the electric field in the gap region is related to that in the outer region through the integral flux balance (3.5), which, to leading order, yields

$$\int_0^{2\pi} d\phi \int_0^{H(\phi,Z)} dX \; \frac{\partial \varphi^{(0)}}{\partial Z} = -\pi. \tag{3.12}$$

It is obvious from (3.7)–(3.8) that $\varphi^{(0)} = \varphi^{(0)}(\phi, Z)$. This function is to be obtained from the solvability conditions (cf. [19]) governing the first-order problem (3.9)–(3.11), namely

$$\frac{\partial^2 \varphi^{(0)}}{\partial Z^2} + \frac{Z}{H(\phi, Z)} \frac{\partial \varphi^{(0)}}{\partial Z} = 0. \tag{3.13}$$

This second-order differential equation possesses the solution

$$\frac{\partial \varphi^{(0)}}{\partial Z} = \frac{C(\phi)}{H(\phi, Z)}, \quad \varphi^{(0)} = \frac{\sqrt{2} C(\phi)}{\tau(\phi)} \arctan \frac{Z}{\tau(\phi)\sqrt{2}} + D(\phi). \tag{3.14}$$

The functions of integration, $C(\phi)$ and $D(\phi)$, cannot be determined from the formulation of the gap problem alone. (Indeed, as the far-field condition (2.16) is inapplicable within the gap region, the boundary-value problem posed by (3.1)–(3.3) does not possess a unique solution.) In standard asymptotic approaches, such functions are determined by matching of the inner gap solution with an appropriate outer one. To leading order, the outer problem consists of a sphere positioned within a circular cylinder of an equal radius. Since these two geometric surfaces do not belong to a common orthogonal family of coordinates, the solution of this problem would appear to be extremely difficult to obtain.

In what follows we present an alternative matching procedure to obtain $\varphi^{(0)}$, invoking a line of reasoning similar to that of [4]. The *ansatz* lies in the existence of the limit

$$\Delta \varphi^{(0)}(\phi) = \lim_{Z \to -\infty} \varphi^{(0)}(\phi, Z) - \lim_{Z \to \infty} \varphi^{(0)}(\phi, Z) = -\frac{\sqrt{2}\pi C(\phi)}{\tau(\phi)}. \tag{3.15}$$

Since the electric field is $O(1)$ in the outer region, it is obvious that this limit constitutes the leading-order term in the expression for the outer potential difference (namely between the values in the region just below the sphere equator, $z < 0$, and that immediately above, $z > 0$). But this term cannot depend upon ϕ, for otherwise it would produce $O(\varepsilon^{-1/2})$ electric fields in the outer region. We therefore conclude that

$$C(\phi) = -\frac{\Delta \varphi^{(0)}}{\pi\sqrt{2}} \tau(\phi), \tag{3.16}$$

wherein the potential difference $\Delta\varphi^{(0)}$ is a constant which depends only upon the position of the sphere within the cylinder cross section. (As another consequence, we find that $D(\phi)$ cannot depend upon ϕ and may thus be taken to be zero.) This constant is obtained from (3.12), yielding

$$\Delta\varphi^{(0)} = \frac{\pi\mu_0}{\sqrt{2}}, \tag{3.17}$$

wherein the parameter

$$\mu_0 = \frac{2\pi}{\int_0^{2\pi} \tau(\phi)\, d\phi} \tag{3.18}$$

is a function of e. Back substitution into (3.16) yields

$$C(\phi) = -\frac{\mu_0 \tau(\phi)}{2}, \tag{3.19}$$

which completes the calculation of the leading-order electric potential in the gap region. With this latter field available, we now turn to analyze the flow fields derived by this field, namely parts (c) and (d).

4. Flow field (c). The boundary-value problem governing the flow field (c) consists of (i) Stokes equations in the fluid domain,

$$\nabla \cdot \boldsymbol{v} = 0, \quad \nabla^2 \boldsymbol{v} = \nabla p; \tag{4.1}$$

(ii) the nonhomogeneous boundary condition on the sphere,

$$\boldsymbol{v} = (1-\gamma)\,\nabla\varphi \quad \text{on} \quad \mathcal{P}; \tag{4.2}$$

and (iii) the homogeneous boundary conditions on the wall and at infinity,

$$\boldsymbol{v} = \boldsymbol{0} \quad \text{on} \quad \mathcal{W}, \tag{4.3}$$

$$\boldsymbol{v} \to \boldsymbol{0} \quad \text{as} \quad |z| \to \infty. \tag{4.4}$$

In principle, once this problem is solved, the accompanying force and torque may be obtained via integration (2.10) of the resulting stress field, obtained from (2.9). However, this detailed calculation can be avoided by utilizing a result, obtained [2] for the case of a particle positioned in an arbitrary Stokes flow which vanishes at infinity. Specifically, the hydrodynamic force and torque acting on the particle are expressed as linear functionals of the prescribed velocity field at its surface, say $\widetilde{\boldsymbol{v}}$. This result, in the present dimensionless notation, is formulated in the following relations:

$$\boldsymbol{F}_k = \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\Pi}^{\dagger}_{\mathrm{tr}} \cdot \widetilde{\boldsymbol{v}}, \qquad \boldsymbol{T} = \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\Pi}^{\dagger}_{\mathrm{rot}} \cdot \widetilde{\boldsymbol{v}}, \tag{4.5}$$

wherein $\boldsymbol{\Pi}_{\mathrm{tr}}$ and $\boldsymbol{\Pi}_{\mathrm{rot}}$ denote the respective translational and rotational triadic "stress" fields [8]. Explicitly, the dyadic stress field arising from translational motion of the particle with an arbitrary velocity $\boldsymbol{U}$ is given by $\boldsymbol{\Pi}_{\mathrm{tr}} \cdot \boldsymbol{U}$; similarly, the dyadic stress field arising from rotational motion of the particle with an arbitrary angular velocity $\boldsymbol{\Omega}$ is given by $\boldsymbol{\Pi}_{\mathrm{rot}} \cdot \boldsymbol{\Omega}$.

The original derivation [2] of this result was given for a particle in an unbounded fluid. However, equations (4.5) are equally applicable to bounded systems so long

as the velocity field vanishes on the walls (cf. [5, 22]). As such, it directly applies to flow field (c) (which is actually the reason for the separation of the electrokinetic contribution into the two distinct parts, (c) and (d)). It is readily verified that the respective nonvanishing components of the force (in the z direction) and torque (about the y direction) acting on the sphere are, respectively, given by

$$F = \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}_{\rm tr} \cdot \widetilde{\boldsymbol{v}}, \quad T = \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}_{\rm rot} \cdot \widetilde{\boldsymbol{v}}, \tag{4.6}$$

wherein $\boldsymbol{\pi}_{\rm tr}$ ($\boldsymbol{\pi}_{\rm rot}$) denotes the stress field associated with pure translation (rotation) of the sphere with a unit linear (angular) velocity in the z (y) direction. The translational and rotational stress fields, $\boldsymbol{\pi}_{\rm tr}$ and $\boldsymbol{\pi}_{\rm rot}$, may be obtained by substitution of the respective velocity fields into (2.9). In the present context, the outward unit vector $\hat{\boldsymbol{n}}_p$ is simply given by $\rho\hat{\boldsymbol{\rho}}+z\hat{\boldsymbol{z}}$, whereas the velocity field on $\mathcal{P}$ is $\widetilde{\boldsymbol{v}} = (1-\gamma)\nabla\varphi$.

Consider first the force acting on the sphere. The translational velocity field, say $\boldsymbol{v}_{\rm tr}$, for the case of a closely fitting sphere, was evaluated by [4]. The corresponding tractions on $\mathcal{P}$ are symmetric with respect to z, as too is the electric field (cf. (3.14)). We thus obtain

$$F = 2(1-\gamma)\int_0^{2\pi} d\phi \int_0^1 dz\, \hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}_{\rm tr} \cdot \nabla\varphi. \tag{4.7}$$

Introduction of an intermediate parameter χ ($\varepsilon^{1/2} \ll \chi \ll 1$) enables the decomposition of this integral into respective "inner" (i.e., gap) and "outer" contributions

$$F_{\rm inner} = 2(1-\gamma)\int_0^{2\pi} d\phi \int_0^{\chi} dz\, \hat{\boldsymbol{n}}_p \cdot \pi_{\rm tr} \cdot \nabla\varphi, \tag{4.8}$$

$$F_{\rm outer} = 2(1-\gamma)\int_0^{2\pi} d\phi \int_{\chi}^1 dz\, \hat{\boldsymbol{n}}_p \cdot \pi_{\rm tr} \cdot \nabla\varphi. \tag{4.9}$$

Within the gap region, the translational velocity and pressure fields were shown [4] to possess the following expansions:

$$u \sim \varepsilon^{-1/2}\left[u^{(0)}(X,\phi,Z) + \varepsilon u^{(1)}(X,\phi,Z) + \cdots\right], \tag{4.10}$$

$$v \sim \varepsilon^{-1/2}\left[v^{(0)}(X,\phi,Z) + \varepsilon v^{(1)}(X,\phi,Z) + \cdots\right], \tag{4.11}$$

$$w \sim \varepsilon^{-1}\left[w^{(0)}(X,\phi,Z) + \varepsilon w^{(1)}(X,\phi,Z) + \cdots\right], \tag{4.12}$$

$$p \sim \varepsilon^{-5/2}\left[p^{(0)}(X,\phi,Z) + \varepsilon p^{(1)}(X,\phi,Z) + \cdots\right]. \tag{4.13}$$

In the above, (u,v,w) denote the respective velocity components relative to the circular cylindrical system. The corresponding tractions within the gap region are obtained via substitution of the above expansions into (2.9), yielding

$$\hat{\boldsymbol{n}}_p \cdot \boldsymbol{\pi}_{\rm tr} \sim -\left\{\varepsilon^{-5/2}\hat{\boldsymbol{\rho}}\, p^{(0)} - \varepsilon^{-3/2}\hat{\boldsymbol{\phi}}\frac{\partial v^{(0)}}{\partial X} - \varepsilon^{-2}\hat{\boldsymbol{z}}\left[Zp^{(0)} + \frac{\partial w^{(0)}}{\partial X}\right]\right\}\left[1 + O(\varepsilon)\right]. \tag{4.14}$$

The leading-order expression for $\nabla\varphi$ is obtained using (2.25) and (3.6) (note that $\varphi^{(0)}$ is independent of X):

$$\nabla\varphi \sim \left[-\varepsilon^{-1/2}\hat{\boldsymbol{\rho}}\frac{\partial\varphi^{(1)}}{\partial X} + \varepsilon^{-1/2}\hat{\boldsymbol{\phi}}\frac{\partial\varphi^{(0)}}{\partial\phi} + \varepsilon^{-1}\hat{\boldsymbol{z}}\frac{\partial\varphi^{(0)}}{\partial Z}\right]\left[1 + O(\varepsilon)\right]. \tag{4.15}$$

Thus, the leading-order inner contribution to the force is

$$F_{\text{inner}} \sim 2\varepsilon^{-5/2}(1-\gamma)\int_0^{2\pi} d\phi \int_0^{\chi/\varepsilon^{1/2}} dZ \left[p^{(0)} \frac{\partial \varphi^{(1)}}{\partial X} - Z p^{(0)} \frac{\partial \varphi^{(0)}}{\partial Z} - \frac{\partial w^{(0)}}{\partial X} \frac{\partial \varphi^{(0)}}{\partial Z} \right]_{X=H}. \tag{4.16}$$

Use of (3.11) reveals that the first two terms in the brackets cancel one another at $X = H$. The expressions of [4] give $\left[\partial w^{(0)}/\partial X\right]_{X=H} = 3\tau^5 \eta_0 / H^2$, wherein the parameter

$$\eta_0 = \frac{2\pi}{\int_0^{2\pi} \left[\tau(\phi)\right]^5 \, d\phi} \tag{4.17}$$

is a function of e. Since the bracketed expression in (4.16) is integrable over $0 < Z < \infty$ (cf. (3.14)), and since χ is an arbitrary parameter, the upper range of the integral over Z may be set equal to ∞:

$$F_{\text{inner}} \sim 3(1-\gamma)\mu_0 \eta_0 \varepsilon^{-5/2} \int_0^{2\pi} d\phi \, \left[\tau(\phi)\right]^6 \int_0^{\infty} \frac{dZ}{\left[H(\phi, Z)\right]^3}. \tag{4.18}$$

Performing the integration [6] yields

$$F_{\text{inner}} \sim (1-\gamma)\varepsilon^{-5/2} f_{\text{el}}^{(0)}(e), \tag{4.19}$$

wherein

$$f_{\text{el}}^{(0)}(e) = \frac{9\sqrt{2}\pi^2 \eta_0(e)}{8}. \tag{4.20}$$

It is obvious that the leading-order outer region contribution is asymptotically smaller, since to leading order the outer region geometry is independent of ε (cf. [22]). The total force resulting from the "electric" flow field (c) thus possesses the expansion

$$F = (1-\gamma) f_{\text{el}}(e; \varepsilon), \tag{4.21}$$

wherein

$$f_{\text{el}}(e) \sim \varepsilon^{-5/2} f_{\text{el}}^{(0)}(e) \left[1 + O(\varepsilon)\right]. \tag{4.22}$$

Next, consider the torque acting on the sphere. The rotational flow field, associated with rotation of the sphere at unit angular velocity, possesses the same structure as the translational one, namely (4.10)–(4.13), except that all leading-order fields vanish identically. (This is equivalent to the pertinent expansions beginning at one higher-order exponent in ε.) Thus, the counterpart of (4.16) is

$$T_{\text{inner}} \sim 2\varepsilon^{-3/2}(1-\gamma)\int_0^{2\pi} d\phi \int_0^{\chi/\varepsilon^{1/2}} dZ \left[p^{(1)} \frac{\partial \varphi^{(1)}}{\partial X} - Z p^{(1)} \frac{\partial \varphi^{(0)}}{\partial Z} - \frac{\partial w^{(1)}}{\partial X} \frac{\partial \varphi^{(0)}}{\partial Z} \right]_{X=H}, \tag{4.23}$$

with $p^{(1)}$ and $w^{(1)}$ now denoting flow variables of the rotational problem. As with the comparable expression (4.16), the first two terms in the brackets cancel one another.

The detailed solution of the rotational problem appears in [3], from which it is found that

$$\left[\frac{\partial w^{(1)}}{\partial X}\right]_{X=H} = \frac{2e\eta_0\left[\tau\left(\phi\right)\right]^5}{\left[H\left(\phi,Z\right)\right]^2} + \frac{4\left[\tau\left(\phi\right)\right]^2\cos\phi}{\left[H\left(\phi,Z\right)\right]^2} - \frac{4\cos\phi}{H\left(\phi,Z\right)}.$$

Substitution into (4.23) of this expression, in conjunction with (3.14), yields

$$T_{\text{inner}} \sim 2(1-\gamma)\mu_0\varepsilon^{-3/2}\int_0^{2\pi}d\phi\int_0^{\infty}dZ\left\{\frac{e\eta_0\left[\tau\left(\phi\right)\right]^6}{\left[H\left(\phi,Z\right)\right]^3} + \frac{2\left[\tau\left(\phi\right)\right]^3\cos\phi}{\left[H\left(\phi,Z\right)\right]^3} - \frac{2\left[\tau\left(\phi\right)\right]\cos\phi}{\left[H\left(\phi,Z\right)\right]^2}\right\}. \tag{4.24}$$

Effecting the integration [6] gives

$$T_{\text{inner}} \sim \varepsilon^{-3/2}\, g_{\text{el}}^{(0)}(e), \tag{4.25}$$

wherein

$$g_{\text{el}}^{(0)}(e) = \frac{3\sqrt{2}\pi^2}{4}e\,\eta_0(e) + \frac{\left(1-e^2\right)^{1/2}-1}{e\left(1-e^2\right)^{1/2}}\frac{\sqrt{2}\pi^2\mu_0(e)}{2}. \tag{4.26}$$

Again, as with the comparable expression governing the force, the contribution of the outer region to the torque is asymptotically smaller than that given by the preceding expression. The total torque resulting from flow field (c) is thus

$$T = (1-\gamma)g_{\text{el}}(e), \tag{4.27}$$

wherein

$$g_{\text{el}}(e;\varepsilon) \sim \varepsilon^{-3/2} g_{\text{el}}^{(0)}(e)\left[1+O\left(\varepsilon\right)\right]. \tag{4.28}$$

5. Flow field (d). Here, the flow field satisfies the following boundary conditions:

$$\boldsymbol{v} = \gamma\nabla\varphi \quad \text{on} \quad \mathcal{P}, \tag{5.1}$$

$$\boldsymbol{v} = \gamma\nabla\varphi \quad \text{on} \quad \mathcal{W}, \tag{5.2}$$

$$\boldsymbol{v} \to \gamma\nabla\varphi = -\gamma\hat{\boldsymbol{z}} \quad \text{as} \quad |z| \to \infty. \tag{5.3}$$

As any irrotational flow field satisfies the Stokes equations identically, it is obvious that $\boldsymbol{v} \equiv \gamma\nabla\varphi$ (cf. [22]). Moreover, following (2.1), no pressure variations are associated with this flow field. The corresponding stress field (see (2.9)) is

$$\boldsymbol{\pi} = 2\gamma\nabla\nabla\varphi. \tag{5.4}$$

Consider the resulting force on the sphere, given by (see (2.10a))

$$\boldsymbol{F} = 2\gamma\oint_{\mathcal{P}} dA\,\hat{\boldsymbol{n}}_p\cdot\nabla\nabla\varphi. \tag{5.5}$$

As the stress field is divergence free, the surface of integration may be deformed into any conveniently configured surface within the fluid domain, say $\mathcal{P}'$, that completely encloses the sphere; that is,

$$\boldsymbol{F} = 2\gamma \oint_{\mathcal{P}'} dA\, \hat{\boldsymbol{n}} \cdot \nabla\nabla\varphi, \tag{5.6}$$

wherein $\hat{\boldsymbol{n}}$ denotes a generic unit vector pointing out of $\mathcal{P}'$. Thus, we choose a finite cylinder, say of height $2h$, whose envelope, which coincides laterally with $\mathcal{W}$, possesses two flat ends, $z = \pm h$. In effecting the requisite integration, it is convenient to employ a second circular cylindrical coordinate system, (R, θ, z), centered about the intersection O' of the cylinder axis with π_1 (see Figure 2.2). The gradient operator in this system is

$$\nabla = \hat{\boldsymbol{R}}\frac{\partial}{\partial R} + \hat{\boldsymbol{\theta}}\frac{1}{R}\frac{\partial}{\partial \theta} + \hat{\boldsymbol{z}}\frac{\partial}{\partial z}, \tag{5.7}$$

wherein $\hat{\boldsymbol{R}}$ and $\hat{\boldsymbol{\theta}}$ denote the respective radial and azimuthal unit vectors. Note that the unit vectors $(\hat{\boldsymbol{R}}, \hat{\boldsymbol{\theta}}, \hat{\boldsymbol{z}})$ are independent of both R and Z. In terms of the new coordinates, the boundary condition (2.2) on the cylinder wall, $R = 1 + \varepsilon$, adopts the simple form

$$\frac{\partial \varphi}{\partial R} = 0. \tag{5.8}$$

Now, consider the force tractions acting on this wall, wherein $\hat{\boldsymbol{n}} = \hat{\boldsymbol{R}}$. The integrand of (5.5) possesses the form

$$\hat{\boldsymbol{n}} \cdot \nabla\nabla\varphi = \hat{\boldsymbol{R}}\frac{\partial^2 \varphi}{\partial R^2} + \hat{\boldsymbol{\theta}}\left(\frac{1}{R}\frac{\partial^2 \varphi}{\partial \theta \partial R} - \frac{1}{R^2}\frac{\partial \varphi}{\partial \theta}\right) + \hat{\boldsymbol{z}}\frac{\partial^2 \varphi}{\partial Z \partial R}. \tag{5.9}$$

In light of the boundary condition (5.8), both terms involving mixed derivatives vanish identically. The other two terms are antisymmetric in z, which results in the respective tractions for the regions $z > 0$ and $z < 0$ cancelling one another. Thus, the wall portion of $\mathcal{P}'$ does not contribute to the force. On the two ends of $\mathcal{P}'$, whereon $z = \pm h$ and $\hat{\boldsymbol{n}} = \pm\hat{\boldsymbol{z}}$, the integrand possesses the form

$$\hat{\boldsymbol{n}} \cdot \nabla\nabla\varphi = \pm\left(\hat{\boldsymbol{R}}\frac{\partial^2 \varphi}{\partial Z \partial R} + \hat{\boldsymbol{\theta}}\frac{1}{R}\frac{\partial^2 \varphi}{\partial \theta \partial Z} + \hat{\boldsymbol{z}}\frac{\partial^2 \varphi}{\partial Z^2}\right). \tag{5.10}$$

As h becomes large, all the derivatives in this expression become small (see (2.16)), while the area of the integration domain, namely $(1 + \varepsilon)^2$, remains constant. As the force is independent of h, it is clear that the contributions from the two ends also vanish.

The torque acting on the sphere is given by

$$\boldsymbol{T} = 2\gamma \oint_{\mathcal{P}} dA\, \boldsymbol{r} \times (\hat{\boldsymbol{n}}_p \cdot \nabla\nabla\varphi). \tag{5.11}$$

To evaluate this integral, we use the spherical form of the gradient operator,

$$\nabla = \hat{\boldsymbol{r}}\frac{\partial}{\partial r} + \frac{1}{r}\nabla_{\boldsymbol{e}}, \tag{5.12}$$

wherein $r = |\boldsymbol{r}|$, with $\hat{\boldsymbol{r}}$ a radial unit vector pointing away from O (that is, $\boldsymbol{r} = r\hat{\boldsymbol{r}}$) and the operator $\nabla_{\boldsymbol{e}} = r(\mathbf{I} - \hat{\boldsymbol{r}}\hat{\boldsymbol{r}}) \cdot \nabla$ representing differentiation on the surface of the unit sphere $\mathcal{P}$. (In principle, this operator may be expressed in terms of any two polar angles about O.) Note that $\boldsymbol{r} = \hat{\boldsymbol{r}} = \hat{\boldsymbol{n}}_p$ on $\mathcal{P}$ and that $\hat{\boldsymbol{r}}$ is independent of r. Hence,

$$\begin{aligned} \boldsymbol{T}/2\gamma &= \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{r}} \times \frac{\partial}{\partial r} (\nabla\varphi) \\ &= \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{r}} \times \left[\hat{\boldsymbol{r}} \frac{\partial^2 \varphi}{\partial r^2} + \frac{1}{r} \nabla_{\boldsymbol{e}} \left(\frac{\partial \varphi}{\partial r} \right) - \frac{1}{r^2} \nabla_{\boldsymbol{e}} \varphi \right] \\ &= \oint_{\mathcal{P}} dA\, \hat{\boldsymbol{r}} \times \left[\nabla_{\boldsymbol{e}} \left(\frac{\partial \varphi}{\partial r} \right) - \nabla_{\boldsymbol{e}} \varphi \right]. \end{aligned} \tag{5.13}$$

In terms of the spherical coordinate r, the potential φ satisfies the following condition on $\mathcal{P}$ (see (2.3)):

$$\left(\frac{\partial \varphi}{\partial r} \right)_{r=1} = 0. \tag{5.14}$$

As the operator $\nabla_{\boldsymbol{e}}$ is r-independent, it commutes with evaluation at $r = 1$. Thus, the first term in the brackets of (5.13) vanishes; explicitly,

$$\begin{aligned} \boldsymbol{T}/2\gamma &= -\oint_{\mathcal{P}} dA\, \hat{\boldsymbol{r}} \times \nabla_{\boldsymbol{e}} \varphi \\ &= -\oint_{\mathcal{P}} dA\, \hat{\boldsymbol{r}} \times \nabla\varphi = -\oint_{\mathcal{P}} dA\, \hat{\boldsymbol{n}}_p \times \nabla\varphi. \end{aligned} \tag{5.15}$$

Since $\nabla\varphi$ is a curl-free field, the last integral may be evaluated over any surface within the fluid domain for which we again employ the finite cylinder $\mathcal{P}'$. On the wall portion of $\mathcal{P}'$, wherein $\hat{\boldsymbol{n}} = \hat{\boldsymbol{R}}$, we obtain the contribution

$$\int_0^{2\pi} d\theta \int_{-h}^{h} dz \left(\hat{\boldsymbol{\theta}} \frac{\partial \varphi}{\partial z} - \hat{\boldsymbol{z}} \frac{1}{R} \frac{\partial \varphi}{\partial \theta} \right). \tag{5.16}$$

In view of the antisymmetric dependence of φ upon z, the second term does not contribute to this integral. Performing the inner integration furnishes the intermediate expression

$$\int_0^{2\pi} [\varphi(R = 1 + \varepsilon, \theta, h) - \varphi(R = 1 + \varepsilon, \theta, -h)]\, \hat{\boldsymbol{\theta}}(\theta)\, d\theta. \tag{5.17}$$

As h becomes large, the dependence of the bracketed terms upon θ becomes exponentially weak. Since $\int_0^{2\pi} \hat{\boldsymbol{\theta}}(\theta)\, d\theta = \mathbf{0}$, the above integral must vanish. Finally, on the two ends of the cylinder, wherein $\hat{\boldsymbol{n}} = \pm\hat{\boldsymbol{z}}$, $\nabla\varphi$ tends to $-\hat{\boldsymbol{z}}$ as h becomes large; hence, $\hat{\boldsymbol{n}} \times \nabla\varphi$ approaches zero there. We thus conclude that the surface integral of $\hat{\boldsymbol{n}} \times \nabla\varphi$ over $\mathcal{P}'$ must vanish, and, consequently, that flow field (d) does not generate a torque on the sphere.

6. Sphere mobility. With the contributions of flows (c) and (d) evaluated, the various terms in the expressions for the force and torque on the sphere may be assembled. The force and torque resulting from the translational flow field (a) have already been calculated [4] for $\varepsilon \ll 1$ and are represented in the respective forms

$$F = U f_{\mathrm{tr}}(e; \varepsilon), \quad T = U g_{\mathrm{tr}}(e; \varepsilon). \tag{6.1}$$

Similarly, the force and torque resulting from the rotational flow field (b) are represented as

$$F = \Omega f_{\rm rot}(e;\varepsilon), \quad T = \Omega g_{\rm rot}(e;\varepsilon). \tag{6.2}$$

The respective force and torque coefficients appearing above have been shown [4] to possess the following asymptotic expansions:

$$f_{\rm tr}(e;\varepsilon) \sim \varepsilon^{-5/2} f_{\rm tr}^{(0)}(e)\left[1+O(\varepsilon)\right], \quad g_{\rm tr}(e;\varepsilon) \sim \varepsilon^{-3/2} g_{\rm tr}^{(0)}(e)\left[1+O(\varepsilon)\right], \tag{6.3}$$

$$f_{\rm rot}(e;\varepsilon) \sim \varepsilon^{-3/2} f_{\rm rot}^{(0)}(e)\left[1+O(\varepsilon)\right], \quad g_{\rm rot}(e;\varepsilon) \sim \varepsilon^{-1/2} g_{\rm rot}^{(0)}(e)\left[1+O(\varepsilon)\right]. \tag{6.4}$$

The force and torque resulting from the "electric" portion (c) were obtained in section 4 (see (4.21)–(4.22), (4.27)–(4.28)). Also, as was demonstrated in section 5, part (d) does not contribute to either the force or the torque.

The total force and torque exerted on the sphere, resulting from superposition of contributions (a)–(d), are thus, respectively, given by

$$\sum F = U f_{\rm tr} + \Omega f_{\rm rot} + (1-\gamma) f_{\rm el}, \tag{6.5}$$

$$\sum T = U g_{\rm tr} + \Omega g_{\rm rot} + (1-\gamma) g_{\rm el}. \tag{6.6}$$

Hence, the respective particle velocities of a freely suspended sphere are

$$U = (1-\gamma)\,\frac{f_{\rm rot}\, g_{\rm el} - g_{\rm rot}\, f_{\rm el}}{f_{\rm tr}\, g_{\rm rot} - f_{\rm rot}\, g_{\rm tr}}, \quad \Omega = (1-\gamma)\,\frac{g_{\rm tr}\, f_{\rm el} - f_{\rm tr}\, g_{\rm el}}{f_{\rm tr}\, g_{\rm rot} - f_{\rm rot}\, g_{\rm tr}}, \tag{6.7}$$

which, to leading order, yield

$$U \sim (1-\gamma)\, U^{(0)}(e)\left[1+O(\varepsilon)\right], \quad \Omega \sim (1-\gamma)\,\Omega^{(0)}(e)\left[1+O(\varepsilon)\right], \tag{6.8}$$

wherein

$$U^{(0)}(e) = \frac{f_{\rm rot}^{(0)}\, g_{\rm el}^{(0)} - g_{\rm rot}^{(0)} f_{\rm el}^{(0)}}{f_{\rm tr}^{(0)} g_{\rm rot}^{(0)} - f_{\rm rot}^{(0)}\, g_{\rm tr}^{(0)}}, \quad \Omega^{(0)}(e) = \frac{g_{\rm tr}^{(0)}\, f_{\rm el}^{(0)} - f_{\rm tr}^{(0)} g_{\rm el}^{(0)}}{f_{\rm tr}^{(0)} g_{\rm rot}^{(0)} - f_{\rm rot}^{(0)}\, g_{\rm tr}^{(0)}}. \tag{6.9}$$

These velocities reflect a balance between the electrical driving forces[4] and the retarding hydrodynamic forces arising from the fluid viscosity. It may appear surprising that despite the large $O(\varepsilon^{-5/2})$ drag acting on the sphere, the latter still moves with an $O(1)$ speed. This result obviously arises from the large $O(\varepsilon^{-1/2})$ potential drop across the gap, which has to be supplied by the external voltage supply.[5] Both sphere velocities are proportional to the potential difference $1-\gamma$, a result common to other types of sphere-wall geometries [9, 10, 23, 22, 21]. Indeed, were the zeta potentials of the sphere and wall equal (corresponding to the case $\gamma = 1$), the boundary-value problem (2.5)–(2.7) would possess the trivial irrotational solution, $\boldsymbol{v} = \nabla\varphi$, which results in neither a force nor a torque acting on the sphere.

Consider the dependence of $U^{(0)}$ upon e. Explicit expressions for $f_{\rm el}^{(0)}$ and $g_{\rm el}^{(0)}$ are given in (4.20) and (4.26), whereas those for the comparable translational and rotational coefficients are provided in [4] as

$$f_{\rm tr}^{(0)} = -\frac{9}{4}\pi^2\sqrt{2}\eta_0, \quad g_{\rm tr}^{(0)} = -\frac{3}{2}\pi^2\sqrt{2}e\eta_0, \quad g_{\rm rot}^{(0)} = -\pi^2\sqrt{2}e^2\eta_0 - 2\sqrt{2}\eta_3, \tag{6.10}$$

[4]The electric field acts directly on the electrically nonneutral fluid elements within the Debye layer. On the bulk scale, this action is manifested by the slip condition (2.6)–(2.7).

[5]This added potential drop constitutes, however, only a small portion of the applied voltage, the latter also maintaining an electric field along the "infinite" channel length.

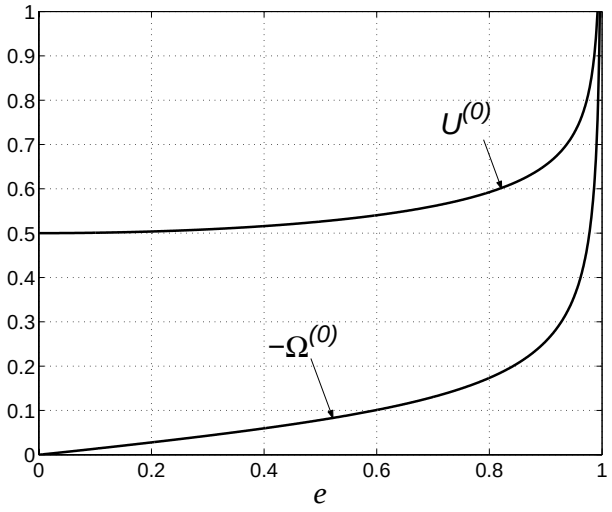


FIG. 6.1. *Variation with e of leading-order linear and angular velocities.*

and, obviously, $f_{\rm rot}^{(0)} = g_{\rm tr}^{(0)}$. In the above, the e-dependent parameter η_3 is defined as

$$\eta_3 = \frac{1}{\pi}\int_0^{2\pi} \frac{\cos^2\phi}{\tau(\phi)} d\phi, \tag{6.11}$$

whereas η_0 was defined in (4.17). These parameters are easily expressed in terms of complete elliptic functions [4]. Using similar means, it readily follows that

$$\mu_0(e) = \frac{\pi(1-m/2)^{1/2}}{2E\left(m^{1/2}\right)}, \tag{6.12}$$

wherein $m = 2e/(1+e)$, with E the complete elliptic integral of the second kind [6]. Note that $\mu_0(0) = 0$, whereas $\mu_0(1) = \pi/2\sqrt{2}$.

Using the limiting values of the functions η_0 and η_3 [4], one finds that $U^{(0)}(0) = 1/2$, corresponding to exactly half of the value of the electrophoretic sphere velocity in the absence of wall effects. This result is in agreement with the numerical trend observed by Keh and Chiou [12], who provide the value 0.50177 for the largest ratio of sphere-to-channel radius studied by them, namely $(1+\varepsilon)^{-1} = 0.999$. For a highly eccentric sphere, $1 - e \ll 1$, we find that

$$U^{(0)}(e) \sim \frac{\pi^2}{24\,(1-e^2)^{1/2}\left(\ln\frac{32}{1-e} - \frac{8}{3}\right)}, \tag{6.13}$$

representing only a very moderate divergence. (Recall, however, that the present calculation breaks down as the minimum separation distance within the gap becomes comparable with the Debye length.)

The variation of $U^{(0)}$ with e is presented in Figure 6.1. Also presented is the variation of the angular velocity $\Omega^{(0)}$: in the axisymmetric case $e = 0$ this velocity vanishes, whereas for $1 - e \ll 1$ it becomes increasingly large in magnitude, with $\Omega^{(0)}/U^{(0)} \to -3/2$. (The cross-over of the $U^{(0)}$ and $\Omega^{(0)}$ curves occurs for e very close to unity, and is not shown in the figure.)

Acknowledgments. We thank Dr. Sangtae Kim of Eli Lilly and Company for his encouragement of this work.

A SECOND ORDER SHAPE OPTIMIZATION APPROACH FOR IMAGE SEGMENTATION*

MICHAEL HINTERMÜLLER† AND WOLFGANG RING†

Abstract. The problem of segmentation of a given image using the active contour technique is considered. An abstract calculus to find appropriate speed functions for active contour models in image segmentation or related problems based on variational principles is presented. The speed method from shape sensitivity analysis is used to derive speed functions which correspond to gradient or Newton-type directions for the underlying optimization problem. The Newton-type speed function is found by solving an elliptic problem on the current active contour in every time step. Numerical experiments comparing the classical gradient method with Newton's method are presented.

1. Introduction.

Identifying curve-like objects in images is one of the fundamental tasks in image analysis. In image segmentation we are interested in finding boundary curves for regions with approximately constant color or gray values. These curves usually represent boundaries of objects in the image. Image segmentation is therefore often the starting point for the treatment of other, more involved problems in image analysis such as automatic object recognition or image registration.

In recent years, image segmentation has been greatly influenced by two different ideas. On the one hand, global energy principles which should be satisfied for the optimal contour have been introduced and successfully applied. On the other hand, deformable (active) contours, which are represented as zero level sets of a time-dependent function $u : \mathbb{R}^2 \times [0,T] \to \mathbb{R}$, have been used to describe the geometric variable. Kass, Witkin, and Terzopoulos [22] introduced parametrized curves (now referred to as classical snakes) which evolve in such a way that the sum of an internal energy, comprising an elasticity and a rigidity term, and an external energy, indicating the presence of edges in the image, is minimized. Caselles, et al. [6] introduced a geometrically intrinsic (parametrization-independent) formulation of active contours, treating the propagating curve as the zero level set of a function $u : \mathbb{R}^2 \times [0,T] \to \mathbb{R}$. The propagation of the level set function u is driven by an appropriate speed function $F : \mathbb{R}^2 \to \mathbb{R}$, which occurs in the level set equation

$$u_t + F\,|\nabla u| = 0 \text{ on } \mathbb{R}^2. \tag{1.1}$$

The speed function F proposed in [6] is given by

$$F = g\left(\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) + \nu\right), \tag{1.2}$$

where $g : \mathbb{R}^2 \to \mathbb{R}$ is an edge detector and ν is a constant. The edge detector is chosen in such a way that $g = 0$ at ideal edges of the image and $g > 0$ otherwise. The construction of the speed function F is such that the active contour propagates according to a curve-shortening mean curvature flow (see, e.g., [19]) with an additional constant deflation velocity ν. The motion of the curve is stopped at points which are located on (strong enough) edges where $g \sim 0$. Thus, g functions as a stopping criterion.

Several authors (see, e.g., [8, 26, 27, 37, 30]) have observed that a similar speed function, given by

$$F = \operatorname{div}\left(g\frac{\nabla u}{|\nabla u|}\right) = g \operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) + \frac{1}{|\nabla u|}\langle \nabla g, \nabla u\rangle, \tag{1.3}$$

can be interpreted as the gradient direction for the cost functional

$$J(\Gamma) = \int_\Gamma g\, dS \tag{1.4}$$

with respect to the contour Γ, where S denotes the arclength measure on Γ. The flow in the negative gradient direction with respect to the cost functional (1.4) can therefore be considered as a geodesic flow with respect to the Riemannian metric $g : \mathbb{R}^2 \to \mathbb{R}$. Thus, the intrinsic curve propagation (1.1) with speed function (1.3) can also be derived from variational principles. In fact, it can be proved (see [8, 4]) that minimizing the classical snake model and the geodesic model (1.4) are (in some sense) equivalent.

It has turned out to be useful to add a domain integral term to the cost functional (1.4) to speed up the propagation. A corresponding cost functional has the form

$$J(\Gamma) = \int_\Gamma g\, dS + \nu \int_\Omega g\, d\mathbf{x}. \tag{1.5}$$

Many variants of the speed functions (1.2) and (1.3) or their corresponding variational principle have been considered in the literature, including affine invariant geodesic flow [30, 29], generalizations to three-dimensional situations [25, 9], region-based active contours [31, 20, 21], segmentation of moving objects [7], and active contour models based on the Mumford–Shah functional [13, 11, 12, 10]. We also refer to the recent monographs [5, 32], which treat the image segmentation problem extensively and provide numerous references to further literature on the subject.

Usually, in the image processing literature, parametrized contours and methods from classical calculus of variations (see [8, 37, 4]) are used to derive the Euler–Lagrange equation for a cost functional of type (1.4), even if the propagation of the contour is treated in the intrinsic level set formulation. We propose (and advertise) the use of an alternative technique with which we can calculate sensitivities with respect to geometric variables on a purely intrinsic basis. We shall use the speed method, which is commonly applied for the sensitivity analysis of shape optimization problems but, as it seems, is not very well known in the image processing community. The speed method has several advantages over the use of parametrized curves (or surfaces). It is intrinsic, i.e., independent of the chosen parametrization, it can treat the case where the current contour consists of several disjoint closed curves in a unified way, and it has (via the Hadamard–Zolésio structure theorem [15, sect. 3.3, p. 348]) a very natural link to the level set formulation of curve propagation. We also stress

the fact that the Euler–Lagrange equations for many of the cost functionals discussed in the references, which we listed in the previous paragraph, can be easily derived using the speed method. Application of Lemmas 1 and 3 will do the job for most cases. Most of the results related to shape sensitivity calculus (with the exception of the usage of the shape derivative of the signed distance function) can be found in the book by Sokołowski and Zolésio [36] and in the new book by Delfour and Zolésio [15]. The advantage of utilizing shape sensitivity analysis in combination with the level set method as motivated above was previously observed in [24] in the context of inverse problems.

We also want to stress the nature of the segmentation problem as a (nonlinear) optimization problem. It is our goal to find the optimal contour in the least possible number of time steps and to achieve maximal descent in each individual step. This objective is quite different from aiming for a smooth propagation of a contour, which is often the focus of attention for level set–based propagating interface problems. For this reason, we propose applying and adapting ideas from nonlinear programming to active contour propagation. In the following we shall employ line search methods and preconditioning of the gradient direction. To realize the latter idea, we calculate a Newton-type speed function for the level set formulation of the variational problem (1.4). It turns out that the calculation of the Newton-type speed function involves the solution of an elliptic equation on the active contour Γ. That is, we have to track the zero level set at every step of the propagation, and we have to assemble appropriate (geometry-dependent) stiffness and mass matrices. This implementational and computational effort is repaid by a significant reduction of the number of iterations.

The structure of the paper is the following. In section 2, we recall basic facts and formulas from shape sensitivity analysis. Section 3 deals with the calculation of certain useful identities concerning the shape derivative of the signed distance function of a smooth open domain. These identities will prove to be very helpful in section 5. In section 4, we explain how the gradient of a shape functional of the form (1.4) can be interpreted as a normal vector field to the boundary of the current shape via the Hadamard–Zolésio structure theorem and how a connection to the level set formulation can be drawn. In this section, we also introduce the concept of second order (Newton-type) preconditioning of the shape gradient. Section 5 deals with the calculation of the Newton direction for a shape functional of type (1.4). In this context it turns out that, if we restrict our consideration to a certain class of possible speed functions, we get a symmetric shape Hessian, which depends only on intrinsic properties of the current contour. Moreover, this restricted class of speed functions has desirable properties for the stable propagation of the level set function according to the level set equation (1.1). In section 6, we derive the elliptic equation on the actual contour which defines the Newton-type speed function. This equation involves the Laplace–Beltrami operator. The Newton-type algorithm and its numerical realization are the subject of section 7. Also, a numerical technique for relaxing the CFL-condition for the time step size in the level set equation is considered. Finally, in section 8, a report on numerical test runs of the new algorithm and a comparison with the method based on the negative gradient as the speed function are given.

2. Shape sensitivity analysis via the speed method. We briefly recall the speed method from shape optimization, which can be used to calculate sensitivities of a functional with respect to a geometric variable such as a domain or the boundary of an open domain. Our main references for this section are the books [15, 36]. This

section also contains basic facts from tangential calculus on smooth boundaries of open sets.

In image analysis, sensitivities with respect to geometric objects such as contours are usually calculated using parametrized curves and techniques from classical calculus of variations as, e.g., in [8, 37]. We now present a technique for sensitivity analysis which works on boundaries of open sets instead of parametrized curves.

Let $\Gamma = \partial\Omega$ be the boundary of an open set $\Omega \subset \mathbb{R}^2$. We call such a boundary Γ a *contour* in $\mathbb{R}^2$. Suppose $V : \mathbb{R}^2 \to \mathbb{R}^2$ is a given smooth vector field with compact support in $\mathbb{R}^2$. We consider the initial value problem

$$\begin{cases} \mathbf{X}'(t) = V\big(\mathbf{X}(t)\big), \\ \mathbf{X}(0) = \mathbf{x}, \end{cases} \tag{2.1}$$

with $\mathbf{x} \in \mathbb{R}^2$ given. The flow (or time-t map) with respect to V is defined as the mapping $T_t : \mathbb{R}^2 \to \mathbb{R}^2$, with

$$T_t(\mathbf{x}) = \mathbf{X}(t), \tag{2.2}$$

where $\mathbf{X}(t)$ is the solution to (2.1) at time t. If Γ is a contour, we define

$$\Gamma_t = \{T_t(\mathbf{x}) \,:\, \mathbf{x} \in \Gamma\} = T_t(\Gamma). \tag{2.3}$$

In an analogous way, we define $\Omega_t = T_t(\Omega)$ for an arbitrary open set Ω. Note that, if $V \in \mathcal{C}_0^k(\mathbb{R}^2, \mathbb{R}^2)$, then $T_t \in \mathcal{C}^k(\mathbb{R}^2, \mathbb{R}^2)$; thus, smoothness properties of Γ are inherited by Γ_t, provided that the vector field V is smooth enough.

Suppose we are given a functional $J : G \to \mathbb{R}$, where G is an appropriate set of contours. We define the *Eulerian derivative* of J at a contour Γ in the direction of a perturbation vector field V by

$$dJ(\Gamma; V) = \lim_{t \downarrow 0} \frac{1}{t}\Big(J(\Gamma_t) - J(\Gamma)\Big). \tag{2.4}$$

Let B be a Banach space of perturbation vector fields. We say that the functional J is shape differentiable at Γ in B if $dJ(\Gamma; V)$ exists for all $V \in B$ and the mapping $V \mapsto dJ(\Gamma; V)$ is linear and continuous on B. We use the analogous definition for functionals $J(\Omega)$ which depend on an open set Ω as an independent variable instead of on a contour Γ.

We now present a series of lemmas which cover some results from shape calculus which will become useful later on. We start with the Eulerian derivative of a domain integral.

LEMMA 1. *Suppose $\phi \in W^{1,1}_{\mathrm{loc}}(\mathbb{R}^2)$ and $\Omega \subset \mathbb{R}^2$ is open and bounded. Then, the functional*

$$J(\Omega) = \int_\Omega \phi \, d\mathbf{x}$$

is shape differentiable for perturbation vector fields $V \in \mathcal{C}_0^1(\mathbb{R}^2; \mathbb{R}^2)$. The Eulerian derivative of J is given by

$$dJ(\Omega; V) = \int_\Omega \operatorname{div}(\phi\, V)\, d\mathbf{x}. \tag{2.5a}$$

If $\Gamma = \partial\Omega$ is of class $\mathcal{C}^1$, then

$$dJ(\Omega; V) = \int_\Gamma \phi \, \langle V, \mathbf{n} \rangle \, dS, \tag{2.5b}$$

where $\mathbf{n}$ denotes the exterior unit normal vector to Ω, $\langle \cdot, \cdot \rangle$ the inner product on $\mathbb{R}^2$, and dS the arclength measure on Γ.

Proof. See Propositions 2.45 and 2.46 in [36, p. 77]. ∎

For a vector field $V \in \mathcal{C}_0^1(\mathbb{R}^2; \mathbb{R}^2)$ and an open set of class $\mathcal{C}^2$ with boundary Γ, we define the tangential divergence of V by

$$\operatorname{div}_\Gamma V = (\operatorname{div} V - \langle DV \cdot \mathbf{n}, \mathbf{n} \rangle)\big|_\Gamma, \tag{2.6}$$

where DV denotes the Jacobian matrix of V. If the vector field V is defined only on Γ, we can still define the tangential divergence of V as the tangential divergence of an arbitrary extension of V. It can be shown (cf. [36, Prop. 2.51, p. 82]) that the definition does not depend on the particular choice of the extension. With this, we are able to state the following result on boundary integrals.

LEMMA 2. *Suppose $\phi \in W^{2,1}_{\mathrm{loc}}(\mathbb{R}^2)$ and Γ is a contour of class $\mathcal{C}^1$. Then, the functional*

$$J(\Gamma) = \int_\Gamma \phi \, dS \tag{2.7}$$

is shape differentiable for perturbation vector fields $V \in \mathcal{C}_0^1(\mathbb{R}^2; \mathbb{R}^2)$ with

$$dJ(\Gamma; V) = \int_\Gamma \big(\langle \nabla \phi, V \rangle + \phi \operatorname{div}_\Gamma V \big) \, dS. \tag{2.8}$$

Proof. See sections 2.18 and 2.19 in [36]. ∎

Using tangential calculus (see sections 2.19 and 2.20 in [36] or the results in [16]), we can simplify the expression (2.8). We define the tangential gradient of a function $h \in \mathcal{C}^2(\Gamma)$ as

$$\nabla_\Gamma h = \nabla \tilde{h}\big|_\Gamma - \frac{\partial \tilde{h}}{\partial n} \mathbf{n} \tag{2.9}$$

on Γ, where $\tilde{h}$ denotes an arbitrary smooth extension of h. It can be shown that the definition (2.9) does not depend on the specific choice of the extension. We have the following Green's formula on Γ.

PROPOSITION 1 (Green's theorem on Γ). *Suppose Γ is a contour of class $\mathcal{C}^2$, $h \in \mathcal{C}^2(\Gamma)$, and $V \in \mathcal{C}_0^1(\mathbb{R}^2; \mathbb{R}^2)$ with $\langle V, \mathbf{n} \rangle = 0$ for every point $\mathbf{x} \in \Gamma$. Then, we have*

$$\int_\Gamma \langle \nabla_\Gamma h, V \rangle \, dS = - \int_\Gamma h \operatorname{div}_\Gamma V \, dS. \tag{2.10}$$

Remark 1. Green's formula also holds for functions h in the Sobolev space $H^1(\Gamma)$. In this case, (2.10) acts as a definition for the tangential gradient $\nabla_\Gamma h$.

Suppose we are given a smooth vector field V. We set $V_\tau = V - \langle V, \mathcal{N} \rangle \mathcal{N}$ as the tangential component of V with respect to Γ. Here $\mathcal{N}$ denotes an extension of the normal vector field $\mathbf{n}$ on Γ. We have

$$\begin{aligned}
\operatorname{div}_\Gamma V &= \operatorname{div}_\Gamma V_\tau + \operatorname{div}_\Gamma \big(\langle V, \mathcal{N} \rangle \mathcal{N} \big) \\
&= \operatorname{div}_\Gamma V_\tau + \big(\operatorname{div} \big(\langle V, \mathcal{N} \rangle \mathcal{N} \big) - \big\langle D\big(\langle V, \mathcal{N} \rangle \mathcal{N} \big) \cdot \mathcal{N}, \mathcal{N} \big\rangle \big)\big|_\Gamma \\
&= \operatorname{div}_\Gamma V_\tau + \big(\langle V, \mathcal{N} \rangle \big(\operatorname{div} \mathcal{N} - \langle D\mathcal{N} \cdot \mathcal{N}, \mathcal{N} \rangle \big) \big)\big|_\Gamma \\
&= \operatorname{div}_\Gamma V_\tau + \langle V, \mathcal{N} \rangle \operatorname{div}_\Gamma \mathcal{N}\big|_\Gamma.
\end{aligned}$$

The term $\operatorname{div}_\Gamma \mathcal{N}|_\Gamma$ is usually denoted by κ and is called the *curvature* of Γ. Thus, we find

$$\operatorname{div}_\Gamma V = \operatorname{div}_\Gamma V_\tau + \kappa \langle V, \mathbf{n} \rangle$$

on Γ. We thus obtain an equivalent expression for the Eulerian derivative of the cost functional (2.7). We have

$$\begin{aligned} dJ(\Gamma; V) &= \int_\Gamma \big(\langle \nabla \phi, V \rangle + \phi \operatorname{div}_\Gamma V \big)\, dS \\ &= \int_\Gamma \left(\left\langle \nabla_\Gamma \phi + \frac{\partial \phi}{\partial n}\, \mathbf{n}, V \right\rangle + \phi \operatorname{div}_\Gamma (V_\tau) + \phi\, \kappa\, \langle V, \mathbf{n} \rangle \right) dS \\ &= \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \phi\, \kappa \Big) \langle V, \mathbf{n} \rangle\, dS + \int_\Gamma \Big(\langle \nabla_\Gamma \phi, V_\tau \rangle + \phi \operatorname{div}_\Gamma (V_\tau) \Big)\, dS. \end{aligned}$$

The last integral is zero due to Proposition 1. We therefore obtain the following lemma.

LEMMA 3. *Under the assumptions of Lemma* 2 *the Eulerian derivative of the cost functional* (2.7) *is equivalently given by*

$$dJ(\Gamma; V) = \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \phi\, \kappa \Big) \langle V, \mathbf{n} \rangle\, dS. \tag{2.11}$$

It is also useful to be able to calculate sensitivities for more general functionals of the form

$$J(\Omega) = \int_\Omega \phi(\Omega, \mathbf{x})\, d\mathbf{x} \tag{2.12}$$

or

$$J(\Gamma) = \int_\Gamma \psi(\Gamma, \mathbf{x})\, dS(\mathbf{x}), \tag{2.13}$$

where the functions $\phi(\Omega) : \Omega \to \mathbb{R}$ and $\psi(\Gamma) : \Gamma \to \mathbb{R}$ themselves depend on the geometric variables Ω and Γ, respectively. In this case, formulas (2.5) and (2.11) have to be corrected by terms which take care of the derivatives of ϕ and ψ with respect to Ω or Γ. We define the following two variants of derivatives of a geometry-dependent function with respect to the geometry.

DEFINITION 1. *Suppose $\psi(\Gamma) \in B(\Gamma)$ for all $\Gamma \in G$, where $B(\Gamma)$ is some appropriate Banach space of functions on Γ, and let $V \in \mathcal{C}_0^1(\mathbb{R}^2, \mathbb{R}^2)$. We set $\psi^t = \psi(\Gamma_t) \circ T_t(V)$ and $\psi^0 = \psi(\Gamma)$, and we assume that $\psi^t \in B(\Gamma_t)$ for all $0 < t < T$ with some $T > 0$. If the limit*

$$\dot{\psi}(\Gamma; V) = \lim_{t \downarrow 0} \frac{1}{t} \big(\psi^t - \psi^0 \big) \tag{2.14}$$

exists in the strong (weak) topology on $B(\Gamma)$, then $\dot{\psi}(\Gamma; V)$ is called the strong (weak) material derivative *of ψ at Γ in direction V.*

The analogous definition holds for functions $\phi(\Omega)$ which are defined on open sets and not on contours.

The material derivative is the derivative of ϕ (or ψ) with respect to the geometry for a moving (Lagrangian) coordinate system. Let us first consider the case of a

domain function $\phi : \Omega \to \mathbb{R}$. It is easily seen that, for the special case where ϕ is independent of Ω, we find

$$\dot{\phi}(\Omega; V) = \dot{\phi}(V) = \langle \nabla\phi, V\rangle.$$

For a function which does not depend on Ω, any reasonable derivative with respect to Ω in a fixed (Eulerian) coordinate system must be 0. It is therefore natural to subtract the term $\langle \nabla\phi, V\rangle$ from $\dot{\phi}$ to define a derivative of ϕ with respect to Ω in a stationary coordinate system. This is the idea of the following definition.

DEFINITION 2. *Suppose that the weak material derivative $\dot{\phi}(\Omega; V)$ and the expression $\langle \nabla\phi(\Omega), V\rangle$ exist in $B(\Omega)$. Then, we set*

$$\phi'(\Omega; V) = \dot{\phi}(\Omega; V) - \langle \nabla\phi, V\rangle \tag{2.15}$$

and we call $\phi'(\Omega; V)$ the shape derivative *of ϕ at Ω in direction V.*

Note that

$$\phi'(\Omega; V) = \phi'(V) = 0$$

for any function ϕ which does not depend on Ω.

For boundary functions $\psi(\Gamma) : \Gamma \to \mathbb{R}$, the expression $\langle \nabla\psi, V\rangle$ does not make sense. In this case, we define the shape derivative as

$$\psi'(\Gamma; V) = \dot{\psi}(\Gamma; V) - \langle \nabla_\Gamma \psi, V\rangle\big|_\Gamma. \tag{2.16}$$

With these definitions we are able to calculate the Eulerian derivatives for the shape functionals (2.12) and (2.13).

PROPOSITION 2. *Suppose $\phi = \phi(\Omega)$ is given such that the weak L^1-material derivative $\dot{\phi}(\Omega; V)$ and the shape derivative $\phi'(\Omega; V) \in L^1(\Omega)$ exist. Then, the cost functional* (2.12) *is shape differentiable and we have*

$$dJ(\Omega; V) = \int_\Omega \phi'(\Omega; V)\, d\mathbf{x} + \int_\Gamma \phi\, \langle V, \mathbf{n}\rangle\, dS. \tag{2.17}$$

For boundary functions $\psi(\Gamma)$ we get, under the same technical assumptions for the cost functional (2.13)*,*

$$dJ(\Gamma; V) = \int_\Gamma \psi'(\Gamma; V)\, dS + \int_\Gamma \kappa\, \psi\, \langle V, \mathbf{n}\rangle\, dS. \tag{2.18}$$

If $\psi(\Gamma) = \phi(\Omega)\big|_\Gamma$, then we have

$$dJ(\Gamma; V) = \int_\Gamma \phi'(\Omega; V)\big|_\Gamma\, dS + \int_\Gamma \Big(\frac{\partial\phi}{\partial n} + \kappa\,\phi\Big)\, \langle V, \mathbf{n}\rangle\, dS. \tag{2.19}$$

Suppose that $\phi(\Omega)$ satisfies $\phi(\Omega)|_\Gamma = 0$ for all (admissible) domains Ω, and let $\vartheta \in \mathcal{D}(\mathbb{R}^2)$ be given. We define the cost functional

$$J_0(\Gamma) = \int_\Gamma \vartheta\, \phi(\Omega)\, dS = 0$$

for arbitrary Γ. Thus,

$$0 = dJ_0(\Gamma; V) = \int_\Gamma \vartheta\, \phi'(\Omega, V)\, dS + \int_\Gamma \frac{\partial}{\partial n}\Big(\vartheta\, \phi(\Omega)\Big)\, \langle V, \mathbf{n}\rangle\, dS.$$

If we choose ϑ such that

$$\frac{\partial \vartheta}{\partial n} = 0 \quad \text{on } \Gamma \tag{2.20}$$

and if we use the fact that the set of test functions which satisfy (2.20) is dense in $L^2(\Gamma)$, we get

$$\phi'(\Omega; V)\big|_\Gamma = -\frac{\partial \phi}{\partial n} \langle V, \mathbf{n}\rangle\big|_\Gamma$$

on Γ. We have therefore proved the following lemma.

LEMMA 4. *Suppose that $\phi(\Omega) \in H^{\frac{3}{2}+\epsilon}(\Omega)$ satisfies $\phi(\Omega)|_\Gamma = 0$ for all (admissible) domains Ω and that the shape derivative $\phi'(\Omega; V)$ exists in $H^{\frac{1}{2}+\epsilon}(\Omega)$ for some $\epsilon > 0$. Then, we have*

$$\phi'(\Omega; V)\big|_\Gamma = -\frac{\partial \phi}{\partial n} \langle V, \mathbf{n}\rangle\big|_\Gamma. \tag{2.21}$$

Remark 2. The Hadamard–Zolésio structure theorem [15, Thm. 3.6 and Cor. 1, p. 348f] states that the Eulerian derivative of a domain or boundary functional always has a representation of the form

$$dJ(\Omega; V) = \big\langle G, \langle V, \mathbf{n}\rangle \big\rangle_{\mathcal{C}^{-k}(\Gamma), \mathcal{C}^k(\Gamma)} = \big\langle G\,\mathbf{n}, V \big\rangle_{\mathcal{C}_2^{-k}(\Gamma), \mathcal{C}_2^k(\Gamma)}; \tag{2.22}$$

that is, the Eulerian derivative is concentrated on Γ and can be identified with the *normal vector field* $G\,\mathbf{n}$ on Γ. We set

$$D_\Gamma J(\Omega) = G\,\mathbf{n}, \tag{2.23}$$

and we call this expression the *shape gradient* of J at Ω.

3. Shape derivative of the signed distance function. The signed (or oriented) distance function is a useful tool in shape analysis. Many differential geometric quantities such as the normal vector field of a contour Γ or its curvature can be easily expressed in terms of the signed distance function b_Γ of Γ. We shall now apply the techniques introduced in the previous section to calculate the shape derivative of the signed distance function of a given (open, bounded) set Ω. This will be helpful later on when we have to calculate Eulerian derivatives of functionals which depend also on geometric properties of Γ such as normal direction or curvature. The following definitions and facts are taken from [15, Chap. 5]. The *distance function* d_A of a subset $A \subset \mathbb{R}^2$ is defined as

$$d_A(\mathbf{x}) = \inf_{\mathbf{y}\in A} |\mathbf{y} - \mathbf{x}|. \tag{3.1}$$

The *signed distance function* b_Ω of a bounded open set $\Omega \subset \mathbb{R}^2$ is defined as

$$b_\Omega(\mathbf{x}) = d_\Omega(\mathbf{x}) - d_{\mathbb{R}^2\setminus\Omega}(\mathbf{x}). \tag{3.2}$$

If we set $\Gamma = \partial\Omega$, we can express d_Ω in terms of Γ. We have

$$b_\Omega(\mathbf{x}) = \begin{cases} d_\Gamma(\mathbf{x}) & \text{for } \mathbf{x} \in \operatorname{int}(\mathbb{R}^2 \setminus \Omega), \\ 0 & \text{for } \mathbf{x} \in \Gamma, \\ -d_\Gamma(\mathbf{x}) & \text{for } \mathbf{x} \in \Omega. \end{cases} \tag{3.3}$$

We shall use the notation $b_\Gamma = b_\Omega$. Note in particular that

$$b_\Gamma\big|_\Gamma = 0. \tag{3.4}$$

It can be shown that b_Γ is uniformly Lipschitz continuous on $\mathbb{R}^2$ and hence, by Rademacher's theorem, differentiable a.e. on $\mathbb{R}^2$ with $|\nabla b_\Gamma| = 1$ a.e. on $\mathbb{R}^2 \setminus \Gamma$. If $\mathrm{meas}(\Gamma) = 0$, then we have

$$|\nabla b_\Gamma|^2 = 1 \quad \text{a.e. on } \mathbb{R}^2. \tag{3.5}$$

If Γ is smooth and compact ($C^{1,1}$ is enough), then ∇b_Γ is Lipschitz continuous, and we have $\nabla b_\Gamma(\mathbf{x}) = \mathbf{n}(p_\Gamma(\mathbf{x}))$ for all $\mathbf{x}$ in some neighborhood of Γ, where p_Γ denotes the projection onto Γ. Thus, ∇b_Γ can be considered as an extension of the unit normal vector field $\mathbf{n}$ onto a neighborhood of Γ, and we have

$$\nabla b_\Gamma\big|_\Gamma = \mathbf{n}. \tag{3.6}$$

Moreover, the second fundamental form of Γ can be expressed in terms of b_Γ. For a C^2-submanifold $\Gamma \subset \mathbb{R}^2$ we have

$$\Delta b_\Gamma\big|_\Gamma = \kappa. \tag{3.7}$$

See [15, p. 369] for the last relation. Taking the gradient on both sides of the Eikonal equation (3.5) yields

$$D^2 b_\Gamma \cdot \nabla b_\Gamma = 0 \quad \text{on } \Gamma. \tag{3.8}$$

Let $W \in \mathcal{C}_0^1(\mathbb{R}^2, \mathbb{R}^2)$ be a given perturbation vector field. We shall derive certain properties of the shape derivative $b'_\Gamma = b'_\Gamma(\Gamma; W)$ of the signed distance function. The signed distance function satisfies the Eikonal equation (3.5) together with the boundary condition (3.4). The weak form of (3.5) is given by

$$\int_{\mathbb{R}^2} |\nabla b_\Gamma|^2 \, \psi \, d\mathbf{x} = \int_{\mathbb{R}^2} \psi \, d\mathbf{x} \tag{3.9}$$

for all test functions $\psi \in \mathcal{D}(\mathbb{R}^2)$. Taking the Eulerian derivative on both sides of (3.9) and using (2.17), we get

$$2 \int_{\mathbb{R}^2} \langle \nabla b'_\Gamma, \nabla b_\Gamma \rangle \, \psi \, d\mathbf{x} = 0 \tag{3.10}$$

for all $\psi \in \mathcal{D}(\mathbb{R}^2)$. Note that, since the functional (3.9) is defined on a fixed domain and depends on Γ only via b_Γ in the integral, the boundary term in (2.17) vanishes. This can be see by writing

$$\int_{\mathbb{R}^2} |\nabla b_\Gamma|^2 \, \psi \, d\mathbf{x} = \int_\Omega |\nabla b_\Gamma|^2 \, \psi \, d\mathbf{x} + \int_{\mathbb{R}^2 \setminus \Omega} |\nabla b_\Gamma|^2 \, \psi \, d\mathbf{x}$$

and applying (2.17) to both terms on the right-hand side. The boundary integrals from both contributions sum up to zero. Equation (3.10) implies that

$$\langle \nabla b'_\Gamma, \nabla b_\Gamma \rangle = 0. \tag{3.11}$$

Equation (3.11) holds at least on some neighborhood of Γ on which b_Γ is smooth enough to guarantee the existence of a (weak) material derivative and hence the applicability of (2.17).

If we apply Lemma 4 to b_Γ and use (3.5), we get $b'_\Gamma|_\Gamma = -\frac{\partial b_\Gamma}{\partial n}\langle V, \mathbf{n}\rangle|_\Gamma = -\langle \nabla b_\Gamma, \nabla b_\Gamma\rangle \cdot \langle V, \mathbf{n}\rangle = -\langle V, \mathbf{n}\rangle$ by (3.5). With $v_n = \langle V, \mathbf{n}\rangle$, we obtain

$$b'_\Gamma\big|_\Gamma = -v_n. \tag{3.12}$$

Since $\nabla b'_\Gamma$ is orthogonal to $\mathbf{n}$ by (3.11), we have

$$\nabla b'_\Gamma = \nabla_\Gamma b'_\Gamma = -\nabla_\Gamma v_n \text{ on } \Gamma. \tag{3.13}$$

Moreover, we have $\Delta b'_\Gamma\big|_\Gamma = \operatorname{div}(\nabla b'_\Gamma)\big|_\Gamma = \operatorname{div}_\Gamma(\nabla_\Gamma b'_\Gamma) + \langle D^2 b'_\Gamma \cdot \nabla b_\Gamma, \nabla b_\Gamma\rangle\big|_\Gamma$. Because $0 = \nabla\langle \nabla b'_\Gamma, \nabla b_\Gamma\rangle = D^2 b'_\Gamma \cdot \nabla b_\Gamma + D^2 b_\Gamma \cdot \nabla b'_\Gamma$ and since $D^2 b_\Gamma$ is symmetric, we can conclude that $\langle D^2 b'_\Gamma \cdot \nabla b_\Gamma, \nabla b_\Gamma\rangle = -\langle D^2 b_\Gamma \cdot \nabla b'_\Gamma, \nabla b_\Gamma\rangle = \langle \nabla b'_\Gamma, D^2 b_\Gamma \cdot \nabla b_\Gamma\rangle = 0$ due to (3.8). Therefore, we obtain

$$\Delta b'_\Gamma\big|_\Gamma = -\Delta_\Gamma v_n. \tag{3.14}$$

4. Gradient and Newton-type level set flow for a shape optimization problem. For the numerical solution of a shape optimization problem one can use shape sensitivity information to move the geometric variable step by step in the direction of the negative gradient. Alternatively, one can use some other descent direction, which can be obtained from the gradient by applying a Newton-type preconditioner to the negative gradient. Like the shape gradient, the descent direction should have the form of a normal vector field on Γ (see Remark 2). Suppose $F\,\mathbf{n}$ is such a descent direction, where $F : \Gamma \to \mathbb{R}$ is a scalar function which depends on Γ. If we embed the discrete iterative optimization procedure in a continuous flow $\Gamma(t)$ which propagates in direction $F\,\mathbf{n}$, we get the following propagating front formulation for $\Gamma(t)$:

$$\dot{\mathbf{x}}(t) = F\big(\mathbf{x}(t), \Gamma(t)\big)\,\mathbf{n}(\mathbf{x}(t)) \quad \text{for } \mathbf{x}(t) \in \Gamma(t). \tag{4.1}$$

An equivalent formulation is given by the level set equation

$$u_t + \tilde{F}|\nabla u| = 0 \quad \text{on } \mathbb{R}^2 \times (0, T), \tag{4.2}$$

where the propagating front is the zero level set of the function u, i.e.,

$$\Gamma(t) = \{\mathbf{x} \in \mathbb{R}^2 \,:\, u(\mathbf{x}, t) = 0\}. \tag{4.3}$$

In (4.2), the scalar function $\tilde{F} : \mathbb{R}^2 \times [0, T) \to \mathbb{R}$ is chosen such that $\tilde{F}|_{\Gamma(t)} = F(\Gamma(t))$. See [35] for an extensive exposition of propagating front problems and their analytical and numerical treatment in the level set context. Note that by the Hadamard–Zolésio structure theorem (see Remark 2), the shape gradient $D_\Gamma J$ can always be interpreted as a scalar speed function G on Γ, which can be used in the level set formulation. Thus, shape sensitivity analysis and the level set method can be combined in a very natural way.

We want to use a speed function $F : \Gamma \to \mathbf{R}$, which represents a Newton-type descent direction for the shape optimization problem (1.4). This function is determined in the following way. Let $F : \Gamma \to \mathbb{R}$ and $G : \Gamma \to \mathbb{R}$ be given functions. We now establish a one-to-one correspondence between scalar speed functions and a

certain class of perturbation vector fields. Let $\tilde{F}$ and $\tilde{G}$ denote extensions of F and G, respectively, which are constructed as solutions to the transport equations

$$\langle \nabla \tilde{F}, \nabla b_\Gamma \rangle = 0 \quad \text{on } \mathbb{R}^2, \quad \tilde{F}\big|_\Gamma = F, \tag{4.4}$$

and

$$\langle \nabla \tilde{G}, \nabla b_\Gamma \rangle = 0 \quad \text{on } \mathbb{R}^2, \quad \tilde{G}\big|_\Gamma = G. \tag{4.5}$$

Note that Γ is noncharacteristic with respect to the transport equation; thus, (4.4) and (4.5) have unique solutions, at least locally in some neighborhood of Γ, which is small enough such that the characteristics of (4.4) (which are straight lines) do not intersect. With these solutions, we define the vector fields

$$V_F = \tilde{F}\,\nabla b_\Gamma \quad \text{and} \quad V_G = \tilde{G}\,\nabla b_\Gamma \tag{4.6}$$

on some neighborhood of Γ on which $\tilde{F}$, $\tilde{G}$, and ∇b_Γ are smooth. Outside this neighborhood we assume that V_F and V_G are extended in some smooth way. Note that the construction of V_F and V_G is such that

$$\langle V_F, \mathbf{n} \rangle = F \text{ and } \langle V_G, \mathbf{n} \rangle = G \quad \text{on } \Gamma. \tag{4.7}$$

Now we consider a cost functional of type (1.4). Let $d^2J(\Gamma;V;W) = d(dJ(\Omega;V))(\Omega;W)$ be the second Eulerian derivative of the cost functional (1.4). In general, the second Eulerian derivative is not symmetric in the two arguments V and W and does not depend only on $V|_\Gamma$ and $W|_\Gamma$. From the subsequent computation we shall see, however, that for perturbation vector fields of the form (4.6), the second Eulerian derivative is symmetric in (V_F, V_G) and depends only on F and G.

We propose the following optimization algorithm. We define a Newton-type speed function $F : \Gamma \to \mathbf{R}$ as the solution to

$$d^2J(\Gamma; V_F; V_G) = -dJ(\Gamma; V_G) \quad \text{for all } G : \Gamma \to \mathbb{R}. \tag{4.8}$$

We then find the extension $\tilde{F}$ of F onto some neighborhood of Γ by solving the transport equation (4.4). Finally, we use $\tilde{F}$ as speed function for one time step in the level set equation

$$u_t + \tilde{F}|\nabla u| = 0. \tag{4.9}$$

The step size is chosen such that some line search criterion is satisfied. With the updated geometry, we start the procedure over again until some stopping criterion is reached.

5. Calculation of the Newton-type speed function. In this section, we calculate the second Eulerian derivative for shape functionals of the form

$$J_1(\Gamma) = \int_\Gamma \phi \, dS \tag{5.1}$$

and

$$J_2(\Omega) = \int_\Omega \phi \, d\mathbf{x} \tag{5.2}$$

for some fixed $\phi \in W^{2,1}_{loc}(\mathbb{R}^2)$. For the following calculations we assume that Γ is of class $\mathcal{C}^2$, which implies that $b_\Gamma \in \mathcal{C}^2$ on some neighborhood of Γ (see [15, Thm. 4.3, p. 219]).

When it is clear from the context, we omit "$|_\Gamma$." We start with the calculation for J_1. Using (2.11), (3.6), and (3.7), we obtain

$$\begin{aligned} dJ_1(\Gamma, V_F) &= \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \phi\, \kappa \Big) \, \langle V_F, \mathbf{n} \rangle \, dS \\ &= \int_\Gamma \big(\langle \nabla \phi, \nabla b_\Gamma \rangle + \phi\, \Delta b_\Gamma \big) \, \langle V_F, \nabla b_\Gamma \rangle \, dS. \end{aligned} \tag{5.3}$$

In this section, we consider only perturbation vector fields V_F, which satisfy (4.6). Note that $dJ_1(\Gamma; V_F)$ (for fixed V_F) is a shape functional of type (2.13). Therefore, the second Eulerian derivative can be calculated by applying formula (2.19) to $dJ_1(\Gamma; V_F)$. With $b'_\Gamma = b'_\Gamma(\Gamma; V_G)$ we get

$$\begin{aligned} d^2 J_1(\Gamma; V_F; V_G) &= \int_\Gamma \frac{\partial}{\partial n} \Big[\big(\langle \nabla \phi, \nabla b_\Gamma \rangle + \phi\, \Delta b_\Gamma \big) \, \langle V_F, \nabla b_\Gamma \rangle \Big] \, \langle V_G, \mathbf{n} \rangle \, dS \\ &\quad + \int_\Gamma \kappa \Big(\frac{\partial \phi}{\partial n} + \phi\, \kappa \Big) \, \langle V_F, \mathbf{n} \rangle \, \langle V_G, \mathbf{n} \rangle \, dS \\ &\quad + \int_\Gamma \big(\langle \nabla \phi, \nabla b'_\Gamma \rangle + \phi\, \Delta b'_\Gamma \big) \, \langle V_F, \mathbf{n} \rangle \, dS \\ &\quad + \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \phi\, \kappa \Big) \, \langle V_F, \nabla b'_\Gamma \rangle \, dS \\ &= I_1 + I_2 + I_3 + I_4. \end{aligned}$$

Using (4.7), (3.13), (3.14), and Green's formula (2.10), the integral I_3 simplifies to

$$\begin{aligned} I_3 &= - \int_\Gamma \big(\langle \nabla \phi, \nabla_\Gamma G \rangle + \phi \Delta_\Gamma G \big) \, F \, dS \\ &= - \int_\Gamma \big(\langle \nabla \phi, \nabla_\Gamma G \rangle \, F - \langle \nabla_\Gamma (\phi\, F), \nabla_\Gamma G \rangle \big) \, dS \\ &= \int_\Gamma \phi \, \langle \nabla_\Gamma F, \nabla_\Gamma G \rangle \, dS. \end{aligned} \tag{5.4}$$

Now let us consider I_1. We have

$$\begin{aligned} I_1 &= \int_\Gamma \Big(\frac{\partial^2 \phi}{\partial n^2} + \frac{\partial \phi}{\partial n}\, \kappa + \phi \langle \nabla (\Delta b_\Gamma), \nabla b_\Gamma \rangle \Big) \, F \, G \, dS \\ &\quad + \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \kappa\, \phi \Big) \, \frac{\partial}{\partial n} \langle V_F, \nabla b_\Gamma \rangle \, G \, dS \\ &= K_1 + K_2. \end{aligned}$$

From (3.5), we conclude

$$0 = \Delta \langle \nabla b_\Gamma, \nabla b_\Gamma \rangle = 2 \langle \nabla (\Delta b_\Gamma), \nabla b_\Gamma \rangle + 2 D^2 b_\Gamma : D^2 b_\Gamma,$$

where $A : B = \sum_{i,j} a_{i,j}\, b_{i,j}$ denotes the tensor product of matrices $A = (a_{i,j})$ and $B = (b_{i,j})$. Thus,

$$\langle \nabla (\Delta b_\Gamma), \nabla b_\Gamma \rangle = - \| D^2 b_\Gamma \|_F^2,$$

where $\| \cdot \|_F$ denotes the Frobenius norm of a matrix.

In I_2 we find a term of the form $\phi\,\kappa^2\,F\,G$. We have $\kappa^2 = (\mathrm{trace}(D^2 b_\Gamma))^2$. In two dimensions, the relation

$$(\mathrm{trace} D^2 b_\Gamma)^2 - \|D^2 b_\Gamma\|_F^2 = 2(b_\Gamma)_{x_1,x_1}(b_\Gamma)_{x_2,x_2} - 2(b_\Gamma)_{x_1,x_2}^2 = 2\det(D^2 b_\Gamma) = 0$$

holds due to (3.8). With this, we obtain

$$I_2 + K_1 = \int_\Gamma \Big(\frac{\partial^2\phi}{\partial n^2} + 2\frac{\partial\phi}{\partial n}\,\kappa\Big)\,F\,G\,dS. \tag{5.5}$$

The remaining term is $K_2 + I_4$. We find

$$\begin{aligned} K_2 + I_4 &= \int_\Gamma \Big(\frac{\partial\phi}{\partial n} + \kappa\,\phi\Big)\,\Big(\frac{\partial}{\partial n}\langle V_F, \nabla b_\Gamma\rangle\,G - \langle V_F, \nabla_\Gamma G\rangle\Big)\,dS \\ &= \int_\Gamma \Big(\frac{\partial\phi}{\partial n} + \kappa\,\phi\Big)\,\Big(\frac{\partial}{\partial n}\langle V_F, \nabla b_\Gamma\rangle\,G - \langle V_F, \nabla_\Gamma G\rangle\Big)\,dS. \end{aligned}$$

For the second expression in the above integral, we obtain, using (4.7) and definition (2.9),

$$\langle V_F, \nabla_\Gamma G\rangle = \Big\langle V_F, \nabla\langle V_G, \nabla b_\Gamma\rangle - \frac{\partial}{\partial n}\langle V_G, \nabla b_\Gamma\rangle\,\mathbf{n}\Big\rangle.$$

Thus, we get

$$\begin{aligned} &K_2 + I_4 \\ &\quad = \int_\Gamma \Big(\frac{\partial\phi}{\partial n} + \kappa\,\phi\Big)\,\Big(\frac{\partial}{\partial n}\langle V_F, \nabla b_\Gamma\rangle\,G + \frac{\partial}{\partial n}\langle V_G, \nabla b_\Gamma\rangle\,F - \big\langle \nabla\langle V_G, \nabla b_\Gamma\rangle, V_F\big\rangle\Big)\,dS. \end{aligned} \tag{5.6}$$

Note that the first two terms $\frac{\partial}{\partial n}\langle V_F, \nabla b_\Gamma\rangle\,G + \frac{\partial}{\partial n}\langle V_G, \nabla b_\Gamma\rangle\,F$ in (5.6) are symmetric in V_F and V_G, but they cannot be determined just from the restrictions $F = \langle V_F, \mathbf{n}\rangle|_\Gamma$ and $G = \langle V_G, \mathbf{n}\rangle|_\Gamma$. The term $\langle \nabla\langle V_G, \nabla b_\Gamma\rangle, V_F\rangle$ has the same nonintrinsic behavior and is not even symmetric in V_F and V_G. Now let us assume that V_F and V_G satisfy (4.6) on some neighborhood of Γ. Using this assumption, together with (3.8), we get

$$\begin{aligned} \nabla\langle V_F, \nabla b_\Gamma\rangle &= DV_F\cdot\nabla b_\Gamma + D^2 b_\Gamma\cdot V_F = D(\tilde F\,\nabla b_\Gamma)\cdot\nabla b_\Gamma + \tilde F D^2 b_\Gamma\cdot\nabla b_\Gamma \\ &= \langle\nabla\tilde F, \nabla b_\Gamma\rangle\cdot\nabla b_\Gamma + 2\langle V_F, D^2\nabla b_\Gamma\cdot\nabla b_\Gamma\rangle = 0, \end{aligned}$$

hence

$$\frac{\partial}{\partial n}\langle V_F, \nabla b_\Gamma\rangle = \big\langle\nabla\langle V_F, \nabla b_\Gamma\rangle, \nabla b_\Gamma\big\rangle = 0,$$

and, with the same reasoning,

$$\frac{\partial}{\partial n}\langle V_G, \nabla b_\Gamma\rangle = 0.$$

Thus, if we restrict our attention to perturbation vector fields of the form (4.4)–(4.6), the nonintrinsic and asymmetric terms in $d^2 J_1(\Gamma; V_F, V_G)$ vanish.

Taking all intermediate results together, we obtain the following expression for the second Eulerian derivative of J_1:

$$d^2 J_1(\Gamma; V_F; V_G) = \int_\Gamma \Big[\Big(\frac{\partial^2\phi}{\partial n^2} + 2\frac{\partial\phi}{\partial n}\,\kappa\Big)\,F\,G + \phi\langle\nabla_\Gamma F, \nabla_\Gamma G\rangle\Big]\,dS. \tag{5.7}$$

For J_2 we obtain, using Lemma 1,

$$dJ_2(\Omega; V_F) = \int_\Gamma \phi \, \langle V_F, \nabla b_\Gamma \rangle \, dS. \tag{5.8}$$

If we apply (2.19) in Proposition 2 and Lemma 4, we get

$$\begin{aligned} d^2 J_2(\Omega; V_F, V_G) = &\int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \kappa \phi \Big) \, \langle V_F, \mathbf{n} \rangle \, \langle V_G, \mathbf{n} \rangle \, dS \\ &+ \int_\Gamma \phi \, \Big(\frac{\partial}{\partial n} \langle V_F, \mathbf{n} \rangle \, G - \langle V_F, \nabla_\Gamma G \rangle \Big) \, dS. \end{aligned}$$

As in the discussion of expression (5.6), we find that the second integral is zero if V_F and V_G satisfy (4.6). We therefore get

$$d^2 J_2(\Omega; V_F; V_G) = \int_\Gamma \Big(\frac{\partial \phi}{\partial n} + \kappa \phi \Big) \, F \, G \, dS. \tag{5.9}$$

6. Gradient and Newton-type flow for variational image segmentation. In this section, we apply the results of sections 2 and 4 to cost functionals of the form (1.5). We consider a grayscale image given by its intensity map $I : \mathbb{R}^2 \to \mathbb{R}$, which assigns each point $\mathbf{x}$ its gray value $I(\mathbf{x}) \in \mathbb{R}$. For simplicity (to avoid special treatment of the boundary), we assume that the image is defined on all of $\mathbb{R}^2$. Let $\tilde{g} : [0, \infty) \to (0, \infty)$ be a given decreasing function which satisfies $\tilde{g}(r) \to 0$ as $r \to \infty$. The function $g_I(\mathbf{x}) = \tilde{g}(|\nabla I|(\mathbf{x}))$ acts as an edge detector in the sense that $g_I(\mathbf{x}) = 0$ if $\mathbf{x}$ lies on an ideal edge of I. In this paper, we use

$$g_I(\mathbf{x}) = \frac{1}{1 + \big(|\nabla I|(\mathbf{x})\big)^k} \text{ with } k = 1, 2. \tag{6.1}$$

To suppress the influence of noise, we replace ∇I in the above expression by a smoothed version $\nabla \hat{I}$. For the sake of simplicity, we use Gaussian smoothing, but other, more effective geometric smoothers (see, e.g., [3]) can be used as well. The method we propose also works for other edge detectors of the form $g_I : \mathbb{R}^2 \to \mathbb{R}$ for which $g_I \sim 0$ on edges and $g \sim c$ with $c > 0$ otherwise, provided that they satisfy the necessary smoothness requirements for performing shape sensitivity analysis of a functional of type (6.2) as exposed in sections 2–5.

Segmentation of an image is the task of partitioning a given image into disjoint parts of approximately constant gray value. Let Γ be the union of the boundaries of these homogeneous regions. Since homogeneous regions with different gray values are separated by edges, it is likely that the boundary Γ is located at points where the edge detector g_I has small values. In Figure 1 it is seen that the edges of the image coincide with the deep valley in the edge detector. This motivates the following variational approach. We seek the final segmenting contour Γ as the minimizer of the functional

$$J(\Gamma) = \int_\Gamma g_I \, dS + \nu \int_\Omega g_I \, d\mathbf{x}, \tag{6.2}$$

where $\Gamma = \partial\Omega$ and $\nu > 0$. We find the minimizer of (6.2) as the steady state of a family of propagating contours $\Gamma(t)$ which approach the minimal contour from the outside. Note that a contour of length zero (a point) is a global minimizer for (6.2). This,

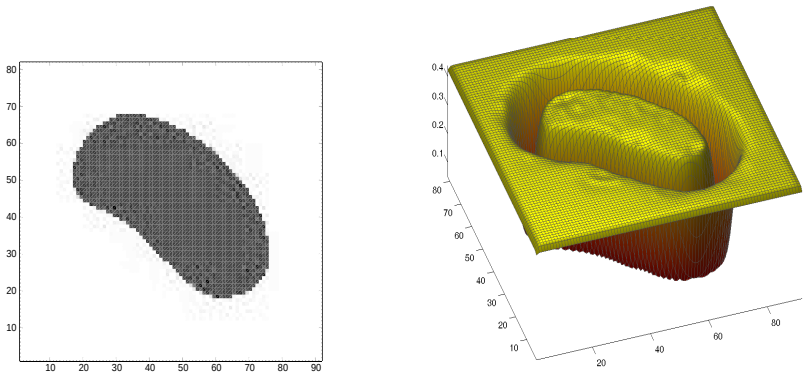

FIG. 1. *Grayscale image I and corresponding edge-map g.*

however, is not the desired segmenting contour. Rather, we want the propagation of the active contour to get stuck at the bottom of the valley of the edge detector, which is a *local minimizer* for (6.2). The second term in (6.2) is a regularization term, which helps shrink the active contour in the homogeneous regions where the influence of the edges is not very strong. The parameter ν must not be chosen too large, because otherwise the algorithm might overshoot the edge and end up at the global minimizer.

The Euler–Lagrange equation for the cost functional (6.2) with respect to the geometrical variable Γ was derived, e.g., in [8, 37] using parametrized curves $\Gamma = \Gamma(s,t)$, where s denotes the curve parameter and t is a time variable describing the movement of the curve. We derive the same result applying the speed method described in section 2. Applying Lemma 3 and (2.5b) in Lemma 1 immediately yields

$$dJ(\Gamma;V) = \langle D_\Gamma J, V\rangle = \int_\Gamma \left\langle \Big(\frac{\partial g_I}{\partial n} + g_I\,(\kappa+\nu)\Big)\,\mathbf{n}, V\right\rangle dS.$$

Thus, the flow for a contour $\Gamma(t)$ which propagates in the direction of the negative gradient with respect to the functional (6.2) is given by

$$\Gamma_t = -\big(g_I\,(\kappa+\nu) + \langle \nabla g_I, \mathbf{n}\rangle\big)\,\mathbf{n}. \tag{6.3}$$

Note that in our case $\mathbf{n}$ denotes the *exterior* normal vector to the region enclosed by Γ, so we have different signs in the expression (6.3) as, e.g., in [8, 37]. The level set formulation corresponding to (6.3) (see [35]) is given by

$$u_t = g_I\left(\operatorname{div}\left(\frac{\nabla u}{|\nabla u|}\right) + \nu|\nabla u|\right) + \langle \nabla g_I, \nabla u\rangle = \left(\operatorname{div}\left(g_I\,\frac{\nabla u}{|\nabla u|}\right) + \nu\right)|\nabla u|. \tag{6.4}$$

For $\nu = 0$, (6.3) or (6.4) can be interpreted as geodesic curve-shortening flow with respect to an image-dependent metric g_I (cf. [8, 30]).

We now use the results from section 5 for the setup of a Newton-type algorithm as described in section 4, specifically in (4.8), (4.6), (4.5), and (4.4) for variational image segmentation. Using (5.7) and (5.9), we find that (4.8) for the Newton-type

speed function F has the form of an elliptic equation on Γ: Find $F : \Gamma \to \mathbb{R}$ such that

$$\int_\Gamma \Big[\Big(\frac{\partial^2 g_I}{\partial n^2} + (2\kappa+\nu)\,\frac{\partial g_I}{\partial n} + \nu\,\kappa\,g_I\Big)\,F\,G + g_I\langle\nabla_\Gamma F, \nabla_\Gamma G\rangle\Big]\,dS = -\int_\Gamma \Big(\frac{\partial g_I}{\partial n} + (\kappa+\nu)\,g_I\Big)\,G\,dS \tag{6.5}$$

for all test functions $G : \Gamma \to \mathbb{R}$.

The elliptic problem (6.5) has a unique solution, and the solution to (6.5) is a descent direction with respect to (6.2) if the bilinear form on the left-hand side is coercive on $H^1(\Gamma)$. Since $g_I > 0$ on $\mathbb{R}^2$, this is the case if

$$\Big(\frac{\partial^2 g_I}{\partial n^2} + (2\kappa+\nu)\,\frac{\partial g_I}{\partial n} + \nu\,\kappa\,g_I\Big) > 0 \quad \text{on } \Gamma. \tag{6.6}$$

See [36, section 2.21] for a comprehensive treatment of elliptic problems on contours. We give some heuristic arguments why condition (6.6) is likely to be satisfied in a neighborhood of the optimal contour. Let us consider the case $\nu = 0$. If the optimal contour is located at the bottom of a valley for the edge detector g_I and if the contour is approximately aligned with the direction of the valley, we have $\frac{\partial g_I}{\partial n} \sim 0$ and g_I is convex in the direction normal to the contour, i.e., $\frac{\partial^2 g_I}{\partial n^2} > 0$. Thus, (6.6) is satisfied for such a contour.

The positive definiteness of (6.5) is an important computational issue. For the actual computations, the Hessian has to be modified such that positive definiteness is maintained also for contours outside the (possibly very small) neighborhood of the optimal contour, where the convexity of g_I in the normal direction is strong enough to guarantee coercivity. This topic (among others) is addressed in the next section.

7. Implementation of an active contour algorithm for image segmentation based on the Newton-type speed function. It is often said that the speed function

$$F = -\big(g_I\,\kappa + \langle\nabla g_I, \mathbf{n}\rangle\big)$$

corresponds to the negative gradient direction with respect to the cost functional (6.2) with $\nu = 0$ and, therefore, propagation with this speed function decreases the cost functional as fast as possible. On the other hand, it is observed that the decrease of J along the propagation of the level set function u is not very fast and that the time steps in the numerical implementation of the level set algorithm must be chosen relatively small. Otherwise, zig-zagging trajectories for the points on the contour are observed. In the worst case, the time-stepping procedure can even become unstable. In other words, the numerical realization of the front-propagation problem (6.4) suffers from many drawbacks which are well known for gradient-based algorithms in nonlinear programming. Usually, the constant (expanding or shrinking) term, i.e., $\nu > 0$ in (6.2), is added to the speed function F to speed up the propagation. This procedure has the disadvantage that an additional parameter (the constant deflation or inflation speed) is introduced into the algorithm. It is a difficult task to choose this parameter in a reasonable way. If it is too large, it is possible that weak edges in the image are not recognized and the propagation of the contour does not stop at the edge. If it is chosen too small, the desired speed-up cannot be achieved (see Table 2).

We propose a speed-up method for the propagating interface problem which—in ideal cases—is even parameter free, i.e., $\nu = 0$ is set in all iterations. The method

can be considered as a preconditioned gradient method or, alternatively, as a Newton-type technique. As speed function F in the level set equation (1.1), we choose the Newton-type direction with respect to the cost functional (6.2) as calculated in section 5. Additionally, we use a line search technique in order to relax the restriction on the time step size in the discretization of the level set equation given by the CFL-condition. We consider the following algorithm.

ALGORITHM 1.

(1) **Initialization.** *Choose an initial (closed) contour* Γ_0. *Initialize the level set function* u^0 *such that* Γ_0 *is the zero level set of* u^0*; set* $k = 0$. *Choose a bandwidth* $w \in \mathbb{N}$ *and* $\nu \in \mathbb{R}$.

(2) **Newton direction.** *Find the zero level set* Γ_k *of the actual level set function* u^k. *Solve* (6.5) *to obtain the Newton-type direction* F^k.

(3) **Extension.** *Extend* F^k *to a band around the actual zero level set* Γ_k *with bandwidth* w *yielding* F^k_{ext}.

(4) **Update.** *Perform a time step in the level set equation with speed function* F^k_{ext} *to update* u^k *on the band. Let* $\hat{u}^{k+1}$ *denote this update.*

(5) **Reinitialization.** *Reinitialize* $\hat{u}^{k+1}$ *in order to obtain a signed distance function* u^{k+1} *with zero level set given by the zero level set of* $\hat{u}^{k+1}$. *Set* $k = k+1$ *and go to* (2).

Before we discuss steps (1)–(5) of Algorithm 1 in detail, we note that the algorithm operates only on a band around the actual zero level set (or contour) Γ_k. This so-called narrow band approach was introduced by Chopp [14]. The key aspect is the fact that typically only knowledge around the actual contour is of importance in the propagation of the contour through the level set equation (which, then, is also considered only on the band). Clearly, in our situation the shape gradient and the shape Hessian used in (6.5) are both defined only on Γ_k. Thus, the narrow band approach is appropriate. In the discrete setting, the restriction to a band around the actual zero level set reduces the computational time and the memory requirement. In [1] a fixed band is chosen with respect to the contour and then, as soon as the propagated contour approaches the boundary of the band, the band is reinitialized with respect to the actual contour. In contrast to this technique, we allow a continuously moving band, i.e., the band is moved together with the contour. This enables us to take larger time steps while preserving a low computational cost. For more details on the narrow band approach in level set methods we refer to [14, 1, 35].

Now let us discuss the steps of Algorithm 1 and the respective numerical realization.

Initialization. In the literature there exist different characteristic choices with respect to ν in the cost functional (6.2). In the following discussion, we decide to consider deflation, i.e., we choose $\nu \geq 0$ and Γ_0 such that the objects which should be segmented are within the area enclosed by Γ_0. Depending on Γ_0, a signed distance function u^0 is computed with Γ_0 as zero level set. This is done by utilizing the fast marching technique [33, 34] on the band around Γ_0 for solving the Eikonal equation

$$|\nabla u^0| = 1 \quad \text{with} \quad u^0 = 0 \text{ on } \Gamma_0.$$

Unless it is chosen too small, the algorithm is not sensitive (except for computational time) with respect to the bandwidth w.

Newton direction. This step is the core part of the new algorithm. As already mentioned in the previous section, the coercivity in $H^1(\Gamma)$ of the bilinear form in (6.5) is essential for having a well-defined Newton-type descent direction. Typically, in the

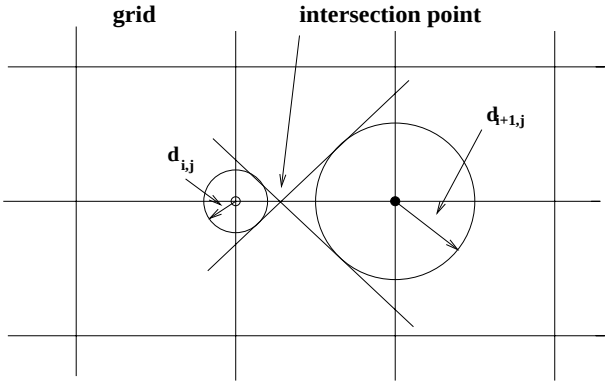

FIG. 2. *Computation of additional intersection points (on the discrete contour).*

course of the iteration it happens that

$$\frac{\partial^2 g_I}{\partial n} + (2\kappa + \nu)\frac{\partial g_I}{\partial n} + \nu\kappa g_I \leq 0 \quad \text{on some parts of } \Gamma_k.$$

Thus, the coercivity of the corresponding bilinear form is lost. To circumvent these difficulties, we incorporate the following modification of (6.5). Find $F : \Gamma \to \mathbb{R}$ such that

$$\int_\Gamma \Big[\Big(\frac{\partial^2 g_I}{\partial n^2} + (2\kappa+\nu)\,\frac{\partial g_I}{\partial n} + \nu\,\kappa\,g_I\Big)_+ F\,G + g_I\langle\nabla_\Gamma F, \nabla_\Gamma G\rangle\Big]\,dS = -\int_\Gamma \Big(\frac{\partial g_I}{\partial n} + (\kappa+\nu)\,g_I\Big)\,G\,dS \tag{7.1}$$

for all test functions $G : \Gamma \to \mathbb{R}$. Above we use $(\cdot)_+ = \max(\cdot, \epsilon)$ for $0 < \epsilon \ll 1$. In our numerical tests it turns out that frequently $\epsilon = 0$ can be set, i.e., we basically cut off the nonconvex part of the shape Hessian. For $\epsilon > 0$, equation (7.1) realizes a small correction of the Newton direction towards the steepest descent direction, i.e., the negative shape gradient.

The discretization of (7.1) is a rather delicate issue. This is due to the fact that $\langle\nabla_\Gamma F, \nabla_\Gamma G\rangle$ corresponds to the Laplace–Beltrami operator on $\Gamma = \Gamma_k$. We first need a discrete model Γ_k^h of Γ_k. For this purpose, we recall that one of the advantages of the level set method is the fact that it operates on a fixed (Cartesian) grid. In our case, the nodes are given by the pixels of the image. The information on the contour Γ_k is included in u^k, i.e., it is the zero level set of u^k. In order to get Γ_k^h we compute additional points on the grid lines (which are the lines joining the pixels of the given image) representing the discrete contour. Let us assume that $x_{i,j}$, $i = 1, \ldots, M$ and $j = 1, \ldots, N$, denote the grid points (nodes) and u_h^k is the signed distance function defined on the nodes. Whenever it is observed that $u_h^k(x_{i,j})$ and $u_h^k(x_{i+1,j})$ change sign, then the interface obviously passes through the grid line connecting $x_{i,j}$ and $x_{i+1,j}$. An analogous observation is true for $x_{i,j}$ and $x_{i,j+1}$. Since $d_{i,j} = |u_h^k(x_{i,j})|$ and $d_{i+1,j} = |u_h^k(x_{i+1,j})|$ give the distances to the contour, we compute an additional intersection point z_l^k as outlined in the graphic in Figure 2. The black node and the white node indicated different signs of u_h^k at these points. The discrete contour is given by the piecewise linear approximation joining the intersection points. For

simplicity, we temporarily assume that $\partial\Gamma_k^h = 0$ for all k and that $N_{\Gamma_k^h}$ represents the number of intersection points. Thus, Γ_k^h is a polygon. Let n_h^k denote the normal to Γ_h^k, and let $[z_l^k, z_{l+1}^k]$ represent a linear piece of Γ_k^h. For the discretization of F^k we use the ansatz

$$F_h^k(z) = \sum_{l=1}^{N_{\Gamma_k^h}} F_l^k \phi_{h,l}(z)$$

with $\phi_{h,l}$ the linear functions on Γ_k^h, which are globally continuous and satisfy $\phi_{h,l}(z_j^k) = \delta_{lj}$ for $l, j = 1, \dots, N_{\Gamma_k^h}$. We define the discretized tangential gradient $\nabla_{\Gamma_k^h}$ by

$$\nabla_{\Gamma_k^h} F_h^k(z) = \sum_{l=1}^{N_{\Gamma_k^h}} F_l^k \nabla_{\Gamma_k^h} \phi_{h,l}(z)$$

with

$$\nabla_{\Gamma_k^h} \phi_{h,l}(z) = \begin{cases} h_l^{-1} & \text{if} \quad z \in [z_{l-1}^k, z_l^k], \\ h_{l+1}^{-1} & \text{if} \quad z \in [z_l^k, z_{l+1}^k], \\ 0 & \text{else.} \end{cases}$$

Here h_l is the length of $[z_{l-1}^k, z_l^k]$; this is analogous for h_{l+1}. Note that $\nabla_{\Gamma_k^h} F_h^k$ is constant on each linear piece of Γ_k^h.

Let a_h^k denote the piecewise constant approximation of

$$a(z) = \left(\left(\frac{\partial^2 g_I}{\partial n^2} \right) + (2\kappa + \nu) \left(\frac{\partial g_I}{\partial n} \right) + \nu\, \kappa\, g_I \right)_+ (z) \quad \text{for } z \in \Gamma_k$$

with

$$a_h^k(z_l^k) = \left(\left(\frac{\partial^2 g_I}{\partial n^2} \right)_h + (2\kappa_h + \nu) \left(\frac{\partial g_I}{\partial n} \right)_h + \nu\, \kappa_h\, g_I \right)_+ (z_l^k) \quad \text{for } z_l^k \in \Gamma_k^h.$$

The approximation of the normal derivatives and the mean curvature in z_l^h, $l = 1, \dots, N_{\Gamma_k^h}$, are discussed below. Let b_h^k denote the piecewise constant approximations of g_I, which are defined as

$$b_h^k(z) = \frac{1}{2}(g_{I,h}(z_l^k) + g_{I,h}(z_{l+1}^k)) \quad \text{for } z \in [z_l^k, z_{l+1}^k].$$

For the discretization of the first term under the integral in (7.1), we use a mass lumping technique which yields a positive definite diagonal matrix. The right-hand side is approximated by utilizing the trapezoidal rule on each linear piece of Γ_k^h. The discretization of (7.1) is then given by

$$\sum_{l=1}^{N_{\Gamma_k^h}} F_l \left(a_h^k(z_l^k) h_l + \int_{\Gamma_k^h} b_h^k \langle \nabla_{\Gamma_k^h} \phi_{h,l} \nabla_{\Gamma_k^h} \phi_{h,j} \rangle \right) = \sum_{l=1}^{N_{\Gamma_k^h}} c_h^k(z_l^k) \hat{h}_l \tag{7.2}$$

for $j = 1, \dots, N_{\Gamma_k^h}$. Above, $\hat{h}_l$ is given by $\hat{h}_l = \frac{1}{2}(h_l + h_{l+1})$. In the case where Γ_k^h contains nonclosed components, $\hat{h}_l$ has to be modified on terminal linear pieces of these components.

When assembling the system matrix in (7.2) one has to be careful in order to produce a tridiagonal band matrix. In order to obtain this structure we employ the following technique. We compute a list containing all intersection points. First, we check whether one of the intersection points in the list is located on the grid lines joining the boundary pixels of the image. If this is the case, then we start with an intersection point on the boundary. In any case, we take z_l with the minimal l and follow the corresponding piece of the contour, compute the respective entries in the stiffness matrix corresponding to the actual intersection point, and delete this point from the list. If we have finished the piece of the discrete contour and the list is not empty, we repeat this procedure by checking intersection points on the boundary. If it turns out that there are no intersection points located on a boundary grid line, then we take z_l with minimal l. The final stiffness matrix is tridiagonal allowing efficient solutions of the discretization of (7.2).

For details concerning asymptotic error estimates for the finite element discretization of the elliptic equation (7.1) as described above, we refer to [17, 18].

The discretization of κ on the (fixed) grid points is based on finite differences like those in [35]. To obtain an approximation of $\frac{\partial g_I}{\partial n}$, we evaluate g_I in the grid points, compute $\nabla_h g_I$ by central differences, and compute $n_h = \frac{\nabla_h u_h^k}{|\nabla_h u_h^k|}$ as an approximation to the normal derivative in all grid points. Then

$$\left(\frac{\partial g_I}{\partial n}\right)_h (x_{i,j}) = \nabla_h g_I(x_{i,j})^T n_h(x_{i,j}).$$

Values for κ_h and $(\frac{\partial g_I}{\partial n})_h$ at intersection points are obtained as weighted averages of the respective quantity at neighboring grid points.

Extension. Since $dJ(\Gamma_k; V_G)$, $d^2J(\Gamma_k; V_F; V_G)$, and, thus, the Newton-type direction F^k are defined only on Γ_k, but the level set equation is defined on Ω (or at least on a band around Γ_k), an extension of F^k to Ω (or the band) must be computed. There exist many possible ways to extend F^k. According to (4.4), F^k_{ext} in step 3 of Algorithm 1 must satisfy

$$\langle \nabla F^k_{ext}, \nabla u^k \rangle = 0, \quad F^k_{ext}|_{\Gamma_k} = F^k. \tag{7.3}$$

On the discrete level, we realize (7.3) by employing the technique of [2]. Again, the fast marching method is used on the narrow band only. For more details we refer to [2].

Update. The discretization of the level set equation follows the standard suggestions in, e.g., [35]; i.e., the time stepping is done by using an explicit Euler scheme combined with an ENO-scheme for the term involving the spatial derivatives. Usually, the CFL-condition gives a link between the step size of the time and the spatial discretization such that the difference scheme is stable [23]. In our situation, the CFL-condition yields

$$\|F^k_{ext,h}\|_\infty \Delta t^k \leq \Delta x,$$

where Δt^k denotes the time step size in iteration k and Δx is the mesh size of the spatial discretization. Obviously, this might lead to very small time step sizes. This is especially true at early stages of the iteration process where the shape gradient is still large. Close to the discrete solution the CFL-condition becomes less stringent since $F^k_{ext,h}$ becomes "smaller."

In contrast to the requirement induced by the CFL-condition, we determine Δt^k based on considerations coming from optimization concepts. First, we relax Δt^k_{CFL}, the time step size required by the CFL-condition, by choosing a threshold $T^k := \ell \Delta t^k_{CFL}$ with $\ell > 1$. Due to our modification of the shape Hessian (its discretization induces a positive definite matrix), we expect that F^k is a local descent direction; i.e., for sufficiently small time step sizes the cost functional J is reduced by propagating Γ_k through the level set equation. A so-called sufficient decrease condition, well known from nonlinear programming [28], is given by the Armijo-condition. In our context this condition becomes

$$J(\Gamma_{k+1}) - J(\Gamma_k) \leq \mu \Delta t^k \langle F^k, dJ(\Gamma_k; F^k)\rangle < 0$$

with a fixed parameter $\mu \in (0,1)$. Numerically we realize the Armijo-condition in the following way: Let $\Gamma^h_k(\Delta t)$ denote the zero level of $u^k_h(\Delta t)$, the result of a time step with Δt in the discretized level set equation with speed function given by $F^k_{ext,h}$. At every iteration level k, we utilize the following algorithm.

ALGORITHM 2.

(1) *Set* $a_0 = \Delta t^k_{CFL}$, $b_0 = T^k$, $r_0 = b_0 - a_0$, $0 < \xi \ll \frac{1}{2}$. *Choose* $\Delta t_0 \in (a_0 + \xi r_0, b_0 - \xi r_0)$ *and* $0 < \mu_1 < \mu_2 < 1$*; set* $l = 0$. *Choose the maximal number of cycles* $L \in \mathbb{N}$.

(2) *Perform a time step in the level set equation with time step size* Δt_l *and speed function* $F^k_{ext,h}$, *and compute* $u^k_h(\Delta t_l)$.

(3) *Compute the zero level set* $\Gamma^h_k(\Delta t_l)$ *of* $u^k_h(\Delta t_l)$. *If* $l = L$, *then* $\Delta t^k = \Delta t_l$, $\hat{u}^{k+1}_h := u^k_h(\Delta t^k)$ *and RETURN to Algorithm* 1. *If* $\Gamma^h_k(\Delta t_l)$ *satisfies*

$$J_h(\Gamma^h_k(\Delta t_l)) - J_h(\Gamma^h_k) \leq \mu_2 \Delta t_l \langle F^k_h, dJ(\Gamma_k; F^k)_h\rangle < 0, \tag{7.4}$$

then $a_{l+1} = \Delta t_l$, $b_{l+1} = b_l$, $r_{l+1} = b_{l+1} - a_{l+1}$, *and compute* $\Delta t_{l+1} \in (a_{l+1} + \xi r_{l+1}, b_{l+1} - \xi r_{l+1})$. *If* (7.4) *is satisfied with* μ_2 *replaced by* μ_1 *and*

$$J_h(\Gamma^h_k(\Delta t_l)) - J_h(\Gamma^h_k) > \mu_2 \Delta t_l \langle F^k_h, dJ(\Gamma_k; F^k)_h\rangle,$$

then $\Delta t^k = \Delta t_l$, $\hat{u}^{k+1}_h := u^k_h(\Delta t^k)$ *and RETURN to Algorithm* 1. *If*

$$J_h(\Gamma^h_k(\Delta t_l)) - J_h(\Gamma^h_k) > \mu_1 \Delta t_l \langle F^k_h, dJ(\Gamma_k; F^k)_h\rangle, \tag{7.5}$$

then $b_{l+1} = \Delta t_l$, $a_{l+1} = a_l$, $r_{l+1} = b_{l+1} - a_{l+1}$, *and compute* $\Delta t_{l+1} \in (a_{l+1} + \xi r_{l+1}, b_{l+1} - \xi r_{l+1})$. *Set* $l = l + 1$ *and go to step* (2).

This step size strategy takes place in step 4 of the discrete analogue of Algorithm 1. The output (of Algorithm 2) is $\hat{u}^{k+1}_h = u^k_h(\Delta t^k)$.

Relaxing the CFL-condition significantly and computing time steps by Algorithm 2 is substantiated by the fact that we are not as interested in tracking an interface as we are in finding—as quickly as possible—a contour which locally minimizes the cost functional.

Reinitialization. Since we allow larger time steps compared to the typical choices for level set–based front propagation, the reinitialization is of importance. Like in the initialization phase, we use a fast marching technique for solving the Eikonal equation

$$|\nabla u| = 1 \quad \text{with} \quad u = 0 \quad \text{on} \quad \Gamma^{k+1}$$

numerically. Here, Γ^{k+1} is the zero level set of $\hat{u}^{k+1}$.

8. Numerical results. In this section we report on numerical tests attained by Algorithm 1 for the discretization described in the previous section. With respect to the grayscales contained in the image data, the first two examples represent the ideal situation. We use these examples to demonstrate the advantages of the Newton-type direction compared to the gradient direction with deflation or inflation. Also comparisons with a method based on the negative gradient are given. The third example is related to the task of segmenting a contrast agent–based image of a kidney. Here we show that the new algorithm can handle inflation, i.e., $\nu < 0$, efficiently.

Let us start by reporting on the results for the image in Figure 3. Table 1 displays the time step sizes Δt^k accepted by Algorithm 2, the corresponding CFL-based time step Δt^k_{CFL}, the cost value J^k_h prior to the reinitialization, and $J^k_{h,r}$ after the reinitialization for Algorithm 1. Moreover, $\nu = 0$ is chosen. From Table 1 we can see that the Newton-type method stops after 9 iterations. The time step sizes Δt^k and Δt^k_{CFL} are increasing, which is expected since F^k_h should ideally vanish at a local solution. Also, our step size rule (Algorithm 2) yields significantly larger time steps than obtained from the CFL-condition. The cost functional is monotonically decreasing, and the reinitialization has only a slight influence on the cost functional value. If the speed function is changed from the Newton-type direction to the gradient direction with $\nu = 0$, then the algorithm (with step size strategy) needs 327 iterations (instead of 9 iterations for the Newton-type direction) to reduce the objective value from $J^1_h = 66.8179$ to $J^{327}_h = 3.6318$. If we allow a constant deflation by choosing

$\nu = 1$ in the gradient-based method, then 13 iterations are needed. The fact that ν has to be chosen appropriately in order to avoid overshooting the desired contour or a slowly converging algorithm is a clear disadvantage. We also ran the algorithm with the gradient-based speed function with $\nu = 1$ and no step size strategy; i.e., $\Delta t^k = \Delta t^k_{CFL}$ was chosen. Then 31 iterations are needed for finding the local minimum numerically. In our test runs we also observe that the Newton-type direction acts more globally than the gradient direction. In fact, in the right graph of Figure 3 we can observe that the gradient direction detects certain parts of the contour rather quickly, while it takes some time to correctly detect the nonconvex part of the contour. The Newton-type direction yields a rather global propagation of the zero level set towards the desired contour; i.e., in the detection process (evolution of the zero level set of u_h^k) the zero level sets approach the desired contour more uniformly; see the left graph of Figure 3. Also, the contours based on the gradient-type propagation are less regular than the contours obtained from the Newton-type propagation. This behavior does not depend on our preference for employing Algorithm 2. It merely reflects our theoretical findings, i.e., computing F^k as the solution of the elliptic equation (7.1) induces additional smoothness properties of F^k. In Table 2 we summarize the convergence behavior.

Our second example is concerned with the segmentation of the letters "O" and "K" as displayed in Figure 4. Besides the aspect that our initial contour has to split into two disjoint contours, it is interesting to investigate how the Newton direction copes with the contours of "K" which involve, e.g., rather acute angles and specific nonconvexities. We shall also see that the appropriate choice of ν is a delicate issue for the gradient method. This is due to the fact that we have to balance the two objectives of fast progress and accurate segmentation. For the Newton method, on the other hand, a rather small value for ν already gives good progress without degrading the

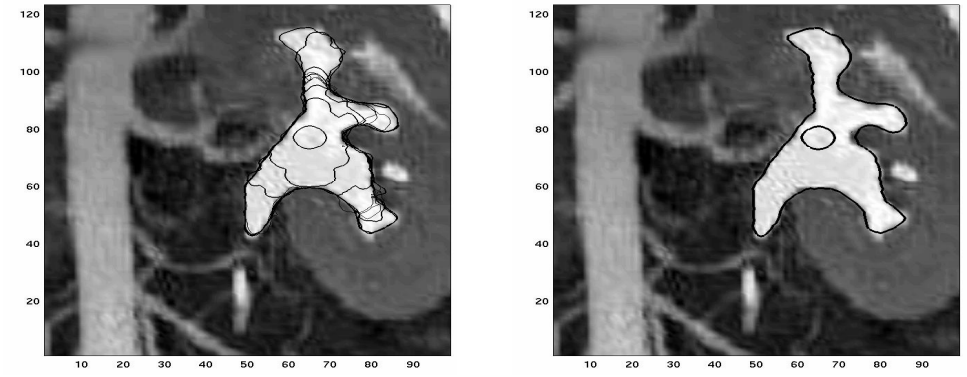

FIG. 5. *Image with zero level sets of u_h^k based on the Newton-type direction with $\nu = -0.3$ (left) and the corresponding initial and final contours (right).*

segmentation behavior.

The gradient-based direction with constant deflation ($\nu = 1$) with or without Algorithm 2 typically overshoots the right uppermost and lowermost corners. As a consequence, the segmentation misses the "K." For smaller values for ν the convergence speed of the gradient-based algorithm is significantly reduced, and too small ν eventually prevents the algorithm from convergence. From the right graph in Figure 4 we can observe that, like in the previous example, the contours for the gradient-based speed function are quite irregular. This prevents the algorithm from taking larger time step sizes.

For the Newton-type speed function, we choose $\nu = 0.01$ and still get reasonable progress in every iteration (successful termination after 33 iterations) but avoid the overshooting of the corners of "K." The evolution of the contours is displayed in the left graph of Figure 4. We initialize the algorithm with the outermost ellipse which shrinks towards the convex hull of the two letters and finally collapses onto two separate contours. With the same value for ν, the gradient-based algorithm with a step size strategy needs more then 100 iterations.

The final example is concerned with the task of segmenting a contrast agent–based image of a kidney. We initialize the algorithm by choosing a small circle inside the part of the image which we aim to segment. Thus, ν has to be assigned a negative value in order to allow inflation of the initial contour. In the left graph of Figure 5 we display some of the iterates of the Newton-type method with $\nu = -0.3$. The algorithm detects the correct contour after 47 iterations. The right graph shows the initial and the final contours for the Newton-type method.

MULTIVALUED FUNDAMENTAL DIAGRAMS AND STOP AND GO WAVES FOR CONTINUUM TRAFFIC FLOW EQUATIONS*

MARCO GÜNTHER†, AXEL KLAR‡, THORSTEN MATERNE‡, AND RAIMUND WEGENER†

Abstract. In the present paper a kinetic model for vehicular traffic leading to multivalued fundamental diagrams is developed and investigated in detail. For this model phase transitions can appear depending on the local density and velocity of the flow. A derivation of associated macroscopic traffic flow equations from the kinetic equation is given. Moreover, numerical experiments show the appearance of stop and go waves for highway traffic with a bottleneck.

Key words. traffic flow, macroscopic equations, kinetic derivation, multivalued fundamental diagram, stop and go waves, phase transitions

1. Introduction.

Classical models for vehicular traffic consider the continuity equation for the density ρ closing the equation by an equilibrium assumption on the mean velocity u, which means approximating u by a uniquely determined equilibrium value $U^e(\rho)$ (see [21]). The function $Q^e(\rho) = \rho U^e(\rho)$ is the so-called fundamental diagram. An additional momentum equation for u has been introduced by Payne [19] and Whitham [21] in analogy to fluid dynamics. Daganzo [3] has pointed out inconsistencies, like wrong-way traffic, of models such as the Payne–Whitham model in certain situations. The inconsistencies are resolved by the introduction of a new macroscopic model by Aw and Rascle [2]. For a mathematical discussion, see [1] or Greenberg [4]. Another basic problem of macroscopic traffic-flow equations has been described by Kerner [10, 11, 12]. The observations there suggest a more complicated dependence of the homogeneous steady speed states on density: the states are not given by a uniquely defined function $u = U^e(\rho)$, as used in the above models, but cover a whole range in the density-flow diagram.

Kinetic equations for vehicular traffic can be found, for example, in [20, 18, 16, 13]. Procedures for deriving macroscopic traffic equations, including the Aw–Rascle model, from underlying kinetic models have been performed in different ways by several authors; see, for example, [6] and [15]. These procedures are developed by analogy to the transition from the kinetic theory of gases to continuum gas dynamics. In the present paper a kinetic model is developed allowing for multiple stationary solutions. This leads to multivalued fundamental diagrams. Different steady speed states can appear for fixed density. They may be interpreted as traffic jams or free flow/synchronized traffic; compare [12]. An overview on these issues is given in [7]. Moreover, we refer to Nelson and Sopasakis [17] for investigations on this point for the Prigogine model, and to [5] for investigations on a simplified macroscopic model. Finally, the macroscopic

equations derived from the kinetic model exhibit the desired features such as stop and go behavior.

The paper is arranged in the following way. In section 2 the kinetic model is presented, reduced to a cumulative description of the highway. In section 3 the stationary distributions of the kinetic model are investigated, and the multivalued fundamental diagrams are determined. Section 4 contains the derivation of macroscopic models. Each section concludes with the discussion of an example. Finally, in section 5, numerical results are given showing the density-velocity relation and the different homogeneous stationary states which appear in the model. Moreover, a nonhomogeneous traffic flow situation with a bottleneck is investigated, showing the appearance of stop and go waves.

2. The kinetic model. The kinetic model developed here is based on the work in [14] and describes highway traffic in a cumulative way, averaging over all lanes.

2.1. Preliminaries. The basic quantity in a kinetic approach is the single-car distribution $f(x, v)$ describing the density of cars at x with velocity v. Here and in the following we do not write the time dependence explicitly. The total density ρ on the highway is defined by

$$\rho(x) = \int_0^w f(x, v)dv,$$

where w denotes the maximal velocity. Let $F(x, v)$ denote the probability distribution in v of cars at x, i.e., $f(x, v) = \rho(x)F(x, v)$. The mean velocity is

$$u(x) = \int_0^w vF(x, v)dv.$$

An important role is played by the distribution $f^{(2)}(x, v, h, v_+)$ of pairs of cars at the spatial point x with velocity v and leading cars at $x + h$ with velocity v_+. This distribution function has to be approximated by the one-vehicle distribution function $f(x, v)$. We use the chaos assumption

$$f^{(2)}(x, v, h, v_+) = q(h, v; \rho, u)\, f(x, v)\, F(x + h, v_+);$$

compare Nelson [16]. For a vehicle with velocity v the function $q(h, v; \rho, u)$ denotes the distribution of leading vehicles with distance h under the assumption that the velocities of the vehicles are distributed according to the distribution function f.

Moreover, we introduce the following thresholds for braking (H_B) and acceleration (H_A):

$$H_X(v) = H_0 + vT_X, \quad X = B, A.$$

$T_B = T_B(\rho, u)$ and $T_A = T_A(\rho, u)$ with $T_B < T_A$ are reaction times which may depend on ρ and u. H_0 denotes the minimal distance between the vehicles. We write $H_X = H_X(v) = H_X(v; \rho, u)$. From a microscopic point of view, drivers will brake once the distance between the driver and its leading car becomes smaller than a threshold H_B, and will accelerate once this distance becomes larger than H_A. Otherwise the cars will not change velocities. Velocities are changed instantaneously once acceleration or braking lines are reached. Models including acceleration of the cars can be developed as well; see [8] for an example.

The basic additional feature here compared to previous models (see [15]) is the fact that the reaction times may depend on ρ and u. This will be sufficient to obtain multivalued fundamental diagrams. Using different values for the reaction times, we assume that, according to their local situation, drivers react with different behavior. Having different T_B, they allow for different distances to their leading cars. Free flow of cars will be related to smaller distances and thus smaller T_B between cars driving at a given speed. So-called synchronized traffic is associated with slightly larger T_B and thus slightly larger distances between cars for a given speed. Traffic which is not synchronized is associated with even larger T_B and thus with lower speeds at the above fixed density. A special choice of $T_B = T_B(u)$ is given and discussed in detail in section 5.

The distribution of leading vehicles $q(h, v; \rho, u)$ is prescribed a priori. The main properties that $q(h, v; \rho, u)$ has to fulfill are positivity,

$$\int_0^\infty q(h, v; \rho, u)dh = 1,$$

and

$$\int_0^w \int_0^\infty hq(h, v; \rho, u)dh\, F(v)dv = \frac{1}{\rho}. \tag{1}$$

Equation (1) means that the average headway of the cars is $1/\rho$. The leading vehicles are assumed to be distributed in an uncorrelated way with a minimal distance H_B from the car under consideration (see Nelson [16]):

$$q(h, v; \rho, u) = \tilde{\rho}\, e^{-\tilde{\rho}(h - H_B(v))}\, \chi_{[H_B(v),\infty)}(h).$$

The reduced density $\tilde{\rho}$ has to be defined in such a way that (1) is fulfilled. One obtains

$$\tilde{\rho} = \frac{\rho}{1 - \rho \int_0^w H_B(v)F(v)dv} = \frac{\rho}{1 - \rho\, H_B(u; \rho, u)}. \tag{2}$$

REMARK 2.1. *The reduced density $\tilde{\rho}$ must be positive, i.e.,*

$$1 - \rho\, H_B(u; \rho, u) = 1 - \rho\,(H_0 + uT_B(\rho, u)) > 0.$$

This defines a range of admissible values in the (ρ, u)-plane.

The probability P_{ov} for overtaking or lane changing and the corresponding probability $P_B = 1 - P_{ov}$ for braking are determined from microscopic considerations. A car overtakes if there is sufficent space in the new lane, i.e., if the cars in the new lane have at least a distance $H_B(v)$ from the changing car. Averaging over the distribution function yields

$$P_{ov}(v; \rho, u) = \rho \int_0^w \int_0^w \int_{H_B(v)+H_B(v')}^\infty \int_h^\infty q(h', \tilde{v}; \rho, u)dh'dhF(\tilde{v})d\tilde{v}F(v')dv'. \tag{3}$$

REMARK 2.2. *The main mechanism for obtaining features like multivalued fundamental diagrams and stop and go behavior is the choice of T_B, i.e., the assumption that there are different states of drivers. We note that the exact choice of T_B is not important. Such an assumption is directly related to the assumption that drivers have different behavior concerning the accepted headway to their leading cars H_B. This, in*

turn, is related to the probability of overtaking. We note that the probability of overtaking is most important in the theory of Kerner [12] *for explaining multivalued fundamental diagrams. Thus, the present approach can be compared—and justified—by comparing the results for the probability of overtaking obtained here to the qualitative results of Kerner* [12]. *For such a comparison, see the figures in* [12] *and Figure* 7 *below.*

REMARK 2.3. *In the following we present a kinetic model. Note that the results like multivalued fundamental diagrams and stop and go behavior of the derived macroscopic equations do not depend on the exact choice of the microscopic interactions that we have chosen here. The model developed in the next section is only chosen due to the fact that explicit stationary solutions are available.*

2.2. The evolution equation. The kinetic model is given by the following evolution equation for the distribution function f:

$$\begin{aligned}\partial_t f + v\partial_x f &= \hat{C}^+(f)\\ &= (\hat{G}_B^+ - \hat{L}_B^+)(f) + (\hat{G}_A^+ - \hat{L}_A^+)(f) + (\hat{G}_S - \hat{L}_S)(f).\end{aligned} \tag{4}$$

$\hat{G}_B^+, \hat{L}_B^+$ denote the gain and loss terms due to braking, and $\hat{G}_A^+, \hat{L}_A^+$ those due to acceleration interactions. $\hat{G}_S$ and $\hat{L}_S$ are terms describing a random behavior of the drivers. They are explained in the following.

For the *braking interaction* one obtains the gain term

$$\hat{G}_B^+(f) = \int\int_{\hat{v}>\hat{v}_+} |\hat{v}-\hat{v}_+| q(H_B(\hat{v}),\hat{v};\rho,u) P_B(\hat{v};\rho,u) \sigma_B(v;\hat{v},\hat{v}_+) f(x,\hat{v}) F(x+H_B(\hat{v}),\hat{v}_+) d\hat{v} d\hat{v}_+$$

with the distribution σ_B of new velocities v after the interaction. The loss term is given by

$$\hat{L}_B^+(f) = \int_{\hat{v}_+<v} |v-\hat{v}_+| q(H_B(v),v;\rho,u) P_B(v;\rho,u) f(x,v) F(x+H_B(v),\hat{v}_+) d\hat{v}_+.$$

In other words, the driver is braking if he is not changing to the left lane for overtaking. Reaching the braking line, the vehicle brakes such that the new velocity v is distributed with a distribution function σ_B, depending on the old velocities $\hat{v}, \hat{v}_+$.

For the *acceleration interaction* the gain term is given by

$$\hat{G}_A^+(f) = \int\int_{\hat{v}<\hat{v}_+} |\hat{v}-\hat{v}_+| q(H_A(\hat{v}),\hat{v};\rho,u) \sigma_A(v;\hat{v},\hat{v}_+) f(x,\hat{v}) F(x+H_A(\hat{v}),\hat{v}_+) d\hat{v} d\hat{v}_+.$$

The loss term is

$$\hat{L}_A^+(f) = \int_{\hat{v}_+>v} |v-\hat{v}_+| q(H_A(v),\hat{v}_+;\rho,u) f(x,v) F(x+H_A(v),\hat{v}_+) d\hat{v}_+.$$

Thus, the new velocity is again distributed according to σ_A depending on the old velocities. Finally, a relaxation term is introduced, describing a random behavior of the drivers. It is given by

$$\hat{G}_S(f) = \nu(\rho,u) \int_0^w \sigma_S(v,\hat{v}) f(x,\hat{v}) d\hat{v},$$

where ν denotes an interaction frequency and $\int_0^\infty \sigma_S(v,\hat{v})dv = 1$. The loss term is

$$\hat{L}_S(f) = \nu(\rho,u)\int_0^w \sigma_S(\hat{v},v)f(x,v)d\hat{v} = \nu(\rho,u)\, f(v).$$

REMARK 2.4. *For remarks on this Boltzmann–Enskog approach to traffic flow modelling, see* [13].

In the following, (4) is simplified by using appropriate averages. We consider the functions $q(H_X(v),v;\rho,u)$, $X = A,B$ appearing in the above integrals and replace the velocity v in these expressions with the mean velocity u. This means that we approximate

$$q(H_A(v),v;\rho,u) \;\sim\; q(H_A(u),u;\rho,u) := q_A(\rho,u) \;=\; \tilde{\rho}\, e^{-\tilde{\rho}(T_A-T_B)u}$$

and

$$q(H_B(v),v;\rho,u) \;\sim\; q(H_B(u),u;\rho,u) := q_B(\rho,u) = \tilde{\rho}.$$

The probability for braking is approximated using formula (3) and substituting $H_B(v)$ and $q(h,v)$ by $H_B(u)$ and $q(h,u)$, respectively. We obtain

$$P_{ov}(\rho,u) = (1-\rho H_B(u))e^{-\frac{\rho H_B(u)}{1-\rho H_B(u)}}. \tag{5}$$

With $P_B = 1 - P_{ov}$ this gives

$$P_B(\rho,u) = 1-(1-\rho H_B(u))e^{-\frac{\rho H_B(u)}{1-\rho H_B(u)}}. \tag{6}$$

To rewrite the equations in a simpler form, we use

$$k = k(\rho,u) = \frac{P_B\, q_B}{q_A + P_B q_B}$$

and

$$\gamma = \gamma(\rho,u) = \frac{q_A}{1-k} = q_A + P_B q_B.$$

Finally, we define c by

$$\gamma\, c \;=\; \nu$$

and assume for simplicity that c depends on ρ, u through k, which means

$$c \;=\; c(k).$$

Using these approximations, (4) is rewritten as

$$\begin{aligned}\partial_t f + v\partial_x f &= C^+(f)\\ &= \gamma\left[k(G_B^+ - L_B^+)(f) + (1-k)(G_A^+ - L_A^+)(f) + c(G_S - L_S)(f)\right],\end{aligned} \tag{7}$$

with

$$G_B^+(f) = \int\int_{\hat{v}>\hat{v}_+} |\hat{v}-\hat{v}_+|\sigma_B(v;\hat{v},\hat{v}_+)f(x,\hat{v})F(x+H_B(\hat{v}),\hat{v}_+)d\hat{v}d\hat{v}_+,$$

$$L_B^+(f) = \int_{\hat{v}_+<v} |v-\hat{v}_+|f(x,v)F(x+H_B(v),\hat{v}_+)d\hat{v}_+,$$

$$G_A^+(f) = \int\int_{\hat{v}<\hat{v}_+} |\hat{v}-\hat{v}_+|\sigma_A(v;\hat{v},\hat{v}_+)f(x,\hat{v})F(x+H_A(\hat{v}),\hat{v}_+)d\hat{v}d\hat{v}_+,$$

$$L_A^+(f) = \int_{\hat{v}_+>v} |v-\hat{v}_+|f(x,v)F(x+H_A(v),\hat{v}_+)d\hat{v}_+,$$

$$G_S(f) = \int_0^w \sigma_S(v,\hat{v})f(x,\hat{v})d\hat{v},$$

$$L_S(f) = f(v).$$

2.3. An example. For the probability distributions σ_A, σ_B we choose the following simple expressions:

$$\sigma_B(v,\hat{v},\hat{v}_+) = \frac{1}{\hat{v}-\hat{v}_+}\,\chi_{[\hat{v}_+,\hat{v}]}(v) \tag{8}$$

and

$$\sigma_A(v,\hat{v},\hat{v}_+) = \frac{1}{\hat{v}_+-\hat{v}}\,\chi_{[\hat{v},\hat{v}_+]}(v). \tag{9}$$

This means that we have an equidistribution of the new velocities between the velocity of the car and the velocity of its leading car. Finally,

$$\sigma_S(v,\hat{v}) = \frac{1}{w}. \tag{10}$$

A special choice of c is given in the last section.

3. Stationary distributions and multivalued fundamental diagrams. In this section we investigate the stationary homogeneous equations and determine the multivalued fundamental diagrams.

3.1. The general case. We consider the local interaction operator

$$C(f) = \gamma\,[k(G_B - L_B)(f) + (1-k)(G_A - L_A)(f) + c(G_S - L_S)(f)]$$

with $f = \rho F$. The gain and loss terms G_B, L_B, etc., are defined in the same way as G_B^+, L_B^+, etc.; however, $x + H_X(v)$, $X = A, B$ is substituted by x wherever it appears. The homogeneous stationary equation is

$$C(f) = 0.$$

We assume that for fixed ρ and k there is a unique solution

$$f = f^e = \rho F^e(k,v)$$

of this equation. This is true for the example stated above. The exact form of the distribution functions is given in detail below.

Thus, for fixed k the mean value of F^e is then

$$u^e(k) := \int_0^w v F^e(k,v) dv.$$

The function u^e is uniquely determined due to the above assumption as a function of k. However, this does not immediately yield the fundamental diagram, i.e., an equilibrium relation between flux and density.

Instead, the fundamental diagram is determined from the following considerations. Let u be the (possibly multivalued) solution of the equation

$$u \;=\; u^e(k(\rho,u))$$

for fixed ρ. We denote this (possibly multivalued) solution by $u = U^e(\rho)$. If there is a unique solution, we obtain a well-defined relation for equilibrium velocity and density and the usual fundamental diagram $Q^e(\rho) = \rho U^e(\rho)$. However, in general this equation will have a multitude of different solutions u, even infinitely many. Plotting a dependence of this solution on the density, one obtains in the general case a two-dimensional region in the density-velocity plane, where the solutions are located. The fundamental diagram is then a multivalued function $Q^e(\rho) = \rho U^e(\rho)$.

3.2. The example. First we determine the stationary solutions $F^e(k)$ for a fixed value of the parameter k. Substituting the explicit expressions (8)–(10) for σ_X, $X = A, B, S$, one obtains

$$\begin{aligned}
G_B(f) &= G_A(f) = \rho \int_0^v F(\hat v)\, d\hat v \int_v^w F(\hat v)\, d\hat v,\\
L_B(f) &= \rho F(v) \left[v \int_0^v F(\hat v)\, d\hat v - \int_0^v \hat v F(\hat v)\, d\hat v \right],\\
L_A(f) &= \rho F(v) \left[\int_v^w \hat v F(\hat v)\, d\hat v - v \int_v^w F(\hat v)\, d\hat v \right],\\
G_S(f) &= \frac{\rho}{w},\\
L_S(f) &= f.
\end{aligned}$$

Defining $\mathcal{F} : [0,w] \to [0,1]$ by $\mathcal{F}(v) = \int_0^v F(\hat v)\, d\hat v$ and denoting the inverse function with $v(p)$, a straightforward computation shows that the integral equation $C(f) = 0$ is equivalent to the following boundary value problem for $v(p)$:

$$v'' = v' \, \frac{3p + k - 2}{p(1-p) + \frac{c}{w}}, \qquad v(0) = 0, \quad v(1) = w. \tag{11}$$

Using

$$h(p) = \frac{k-p}{\left(q - \left(p - \frac12\right)\right)^{\frac12 + r} \left(q + \left(p - \frac12\right)\right)^{\frac12 - r}}$$

with

$$q = \sqrt{\frac{c}{w} + \frac14}\,, \qquad r = \frac{2k-1}{4q},$$

the solution of (11) is explicitly given as

$$v(p) = w\frac{h(p) - h(0)}{h(1) - h(0)}.$$

A parameter representation of the unique stationary solutions $F = F^e(k, v)$ for fixed k is given as

$$F^e(k, v(p)) = \frac{1}{v'(p)}.$$

The mean velocity $u^e(k)$ of $F^e(k)$ is given by

$$u^e(k) = \int_0^w vF^e(k, v)\, dv = \int_0^1 v(\tilde{p})\, d\tilde{p} = w\frac{H(1) - H(0) - h(0)}{h(1) - h(0)}$$

with

$$H(p) = \int_0^p h(\tilde{p})d\tilde{p} = \left(q - \left(p - \frac{1}{2}\right)\right)^{\frac{1}{2}-r} \left(q + \left(p - \frac{1}{2}\right)\right)^{\frac{1}{2}+r}.$$

The multivalued fundamental diagrams are then obtained as the solutions of the equation $u = u^e(k(\rho, u))$ for fixed ρ. A numerical investigation of this nonlinear equation is given in the last section. (Plots of $u^e(k)$ and of the fundamental diagram are shown in Figures 4 and 5, 6, respectively.)

4. Derivation of macroscopic models. In this section macroscopic equations for density and mean velocity are derived following the procedure in [15].

4.1. Balance equations. Multiplying the inhomogeneous kinetic equation (7) with 1 and v and integrating it with respect to v, one obtains the following set of balance equations:

$$\begin{aligned} \partial_t\rho + \partial_x(\rho u) &= 0, \\ \partial_t(\rho u) + \partial_x(P + \rho u^2) + E &= S, \end{aligned} \tag{12}$$

with the "traffic pressure"

$$P = \int_0^w (v - u)^2 f dv, \tag{13}$$

the Enskog flux term

$$E = \int_0^w v[C(f)(x, v, t) - C^+(f)(x, v, t)]dv, \tag{14}$$

and the source term

$$S = \int_0^w vC(f)(x, v, t)dv. \tag{15}$$

To obtain closed equations for ρ and u one has to specify the dependence of P, E, and S on ρ and u.

4.2. Closure relations. We use the ansatz $f^{ex} = f^{ex}(\rho, u) = f^{ex}(\rho, u; v)$ for the distribution function to approximate the true distribution f and to close the equations. Let the function F^{ex} be defined by

$$f^{ex} = \rho F^{ex}.$$

We require that $F^{ex}(u)$ fulfill two properties, namely, having density

$$1 = \int_0^w F^{ex}(u, v)dv \tag{16}$$

and mean value

$$u = \int_0^w vF^{ex}(u, v)dv. \tag{17}$$

Note that the equilibrium distribution $F^e(k(\rho, u), v)$ has a mean value $u^e(k(\rho, u))$ and does not necessarily fulfill the above requirement. We construct F^{ex} using the one parameter family $F^e(k, v)$ and choosing a suitable value for k. The following simple ansatz for F^{ex} fulfills conditions (16), (17):

$$F^{ex}(u, v) = F^e(k^e(u), v),$$

where $F^e = F^e(k, v)$ is the uniquely defined function from section 3 and $k^e = k^e(u)$ is the inverse function to u^e, i.e.,

$$u^e(k^e(u)) = u.$$

Here k^e is well defined if we assume that $u^e(k)$ is strictly monotone decreasing in k. This is true for our example; see Figure 4. We note that for this definition of $f^{ex}(\rho, u)$ one obtains a positive function f^{ex} for all values of v.

Equation (12) is now closed by approximating the traffic pressure P in (13) by

$$P = \int_0^w (v - u)^2 f dv \ \sim \ \int_0^w (v - u)^2 f^{ex}(\rho, u; v)dv =: P^{ex}(\rho, u) = \rho\Theta^{ex}(u),$$

where the definition of the variance Θ^{ex} is given by the last equality sign. Further approximation of the variance gives

$$P \sim \rho\Theta^{ex}(u) \sim \rho\Theta^{ex}(u^e(k)) =: \rho\theta^e(k).$$

Moreover, the Enskog term E is approximated by linearizing expression (14) for E in H and substituting $f^{ex}(\rho, u)$ for f. One obtains

$$E \ \sim \ \rho A^{ex}(u)\partial_x u,$$

where $A^{ex}(u)$ is defined by

$$A^{ex} = -I(F^{ex}, \partial_u F^{ex}),$$

with

$$I(f, g) = I_B(f, g) + I_A(f, g),$$

$$I_B(f, g) = \gamma k \int \int_{\hat{v} > \hat{v}_+} |\hat{v} - \hat{v}_+| H_B(\hat{v}) f(\hat{v}) g(\hat{v}_+) \left[\int_0^w v\sigma_B(v, \hat{v}, \hat{v}_+)dv - \hat{v} \right] d\hat{v}_+ d\hat{v},$$

and

$$I_A(f,g) = \gamma(1-k)\int\int_{\hat{v}<\hat{v}_+} |\hat{v}-\hat{v}_+| H_A(\hat{v}) f(\hat{v}) g(\hat{v}_+) \left[\int_0^w v\sigma_A(v,\hat{v},\hat{v}_+)dv - \hat{v}\right] d\hat{v}_+ d\hat{v}.$$

To compute A^{ex} we use

$$\partial_u F^{ex}(u) = \frac{\partial_k F^e(k^e(u))}{\partial_k u^e(k^e(u))}.$$

Further approximation gives

$$A^{ex}(u) \sim A^{ex}(u^e(k)) =: a^e(k)$$

and

$$E \ \sim \ \rho a^e(k(\rho,u))\partial_x u.$$

Finally, the source term S has to be approximated:

$$S \ \sim \ S^{ex}(\rho,u) = \int_0^w vC(f^{ex})dv.$$

Further approximations are discussed in the next subsection.

One obtains macroscopic equations of the form

$$\begin{aligned} \partial_t \rho + \partial_x(\rho u) &= 0, \\ \partial_t(\rho u) + \partial_x(\rho\theta^e(k) + \rho u^2) + \rho a^e(k)\partial_x u &= S^{ex}(\rho,u), \end{aligned} \tag{18}$$

with $k = k(\rho,u)$ given above.

4.3. The example. In the case of our example the above expressions can be simplified. A short computation shows that for any distribution function f we have the following relation between $P = P(f)$ and $S = S(f)$:

$$S = \gamma\left(\left(\frac{1}{2}-k\right)P + c\rho\left(\frac{w}{2}-u\right)\right). \tag{19}$$

Computation of P^{ex} and θ^e. Using the distribution function $f = F^e(k)$, the above expression is equal to 0 for arbitrary k, since $S(F^e(k))$ is equal to zero by definition of F^e. Choosing $k = k^e = k^e(u)$, we get

$$P^{ex}(\rho,u) \ = \ \rho c(k^e(u))\frac{\frac{w}{2}-u}{k^e(u)-\frac{1}{2}}.$$

Further approximation as before gives

$$P^{ex}(\rho,u) \ \sim \ \rho\theta^e(k(\rho,u))$$

with

$$\theta^e(k) = c(k)\frac{\frac{w}{2}-u}{k-\frac{1}{2}}.$$

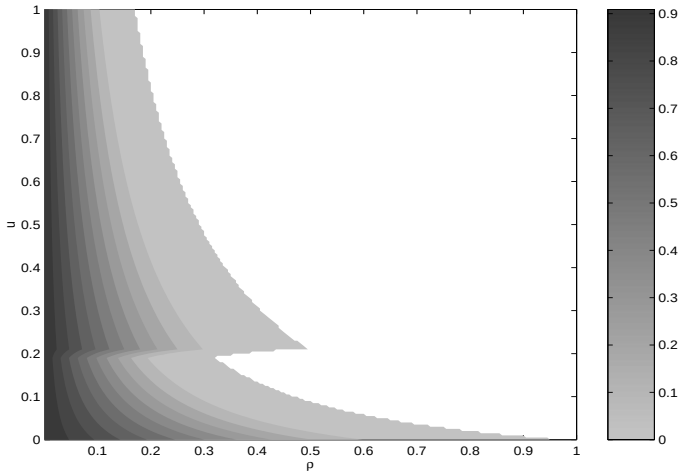

FIG. 1. *Probability* $P_{ov}(\rho, u)$.

Computation and approximation of S^{ex}. To compute S^{ex} we use (19) and substitute P^{ex} found above. We obtain

$$S^{ex}(\rho,u) \;=\; \gamma\rho\left(\frac{w}{2}-u\right)\left(c(k)-c(k^e(u))\frac{\frac{1}{2}-k}{\frac{1}{2}-k^e(u)}\right).$$

A simplification is given by substituting $\rho\theta^e(k)$ instead of P^{ex} into (19):

$$S^{ex}(\rho,u) \;\sim\; \rho\gamma c(k)\,(u^e(k)-u)\,;$$

i.e., the right-hand side has relaxation form.

Computation of A^{ex}. A^{ex} and a^e are computed as described above using the special form of F^e.

REMARK 4.1. *The macroscopic equations are then given by* (18) *with the explicit formulas derived above. As can be observed numerically (see* [15]*), the term containing* $\rho\theta^e(k)$ *in* (18) *is small compared to the other terms. Eventually, we obtain*

$$\partial_t\rho+\partial_x(\rho u)=0, \tag{20}$$
$$\partial_t(\rho u)+\partial_x(\rho u^2)+\rho a^e(k)\partial_x u=\rho\nu\,(u^e(k)-u)\,.$$

Thus, one obtains a multimodal variant of the Aw–Rascle equations with a multimodal relaxation term on the right-hand side. This is exactly what has been used and further investigated in [5].

5. Numerical investigations. In this section we investigate the example described in the text. The stationary homogeneous kinetic equation is discussed together with the resulting macroscopic equations.

5.1. Choice and further discussion of free parameters. For the numerical simulations, we normalize and choose $w=1$ and $H_0=1$. As described above, we use different reaction times to describe the drivers' behavior in different flow situations. Smaller reaction times are associated with higher velocities. To put things as simply as possible, we choose

$$T_B=\begin{cases}10, & u<0.2,\\ 5, & u\geq 0.2.\end{cases}$$

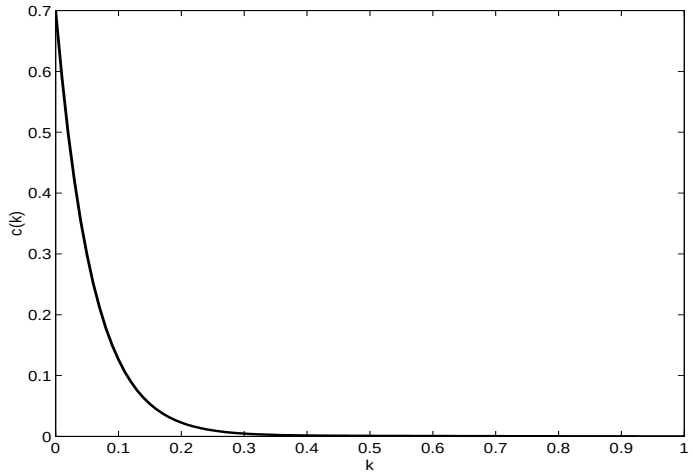

FIG. 2. *Frequency of random events* $c(k)$.

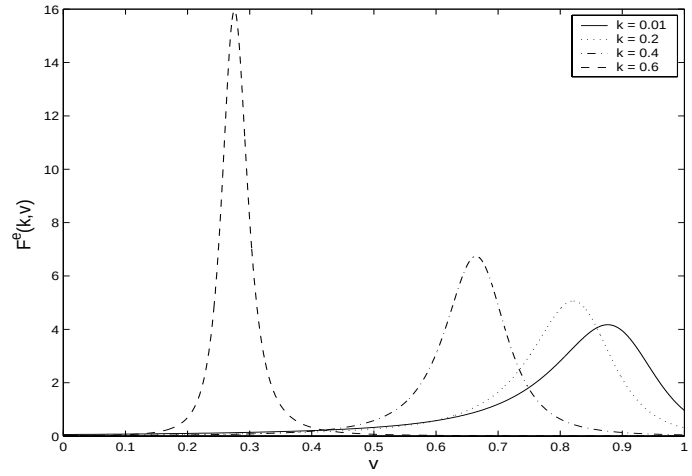

FIG. 3. *Stationary distribution functions* $F^e(k, v)$ *for different* k.

Thus, in terms of the accepted distance H_B to the leading car, drivers behave in the following way: once their velocity falls below a certain speed, relatively larger distances are required as before. Here, we do not distinguish between three traffic states like free flow, synchronized traffic, and jam, but rather between two states. For numerical reasons the step function has been smoothed.

As mentioned before, different choices of T_B would yield similar results as long as T_B was not constant. Choosing a constant reaction time T_B results in a uniquely determined and not a multivalued fundamental diagram.

The resulting probability of overtaking $P_{ov}(\rho, u)$, according to (5), is plotted in Figure 1 in the range of admissible values (ρ, u), according to (2).

Either T_B or P_{ov} should be viewed as the basic quantity of the multivalued approach presented here. In particular, as shown in Figure 7 below, considering P_{ov} for the equilibrium velocity gives good qualitative coincidence with the corresponding

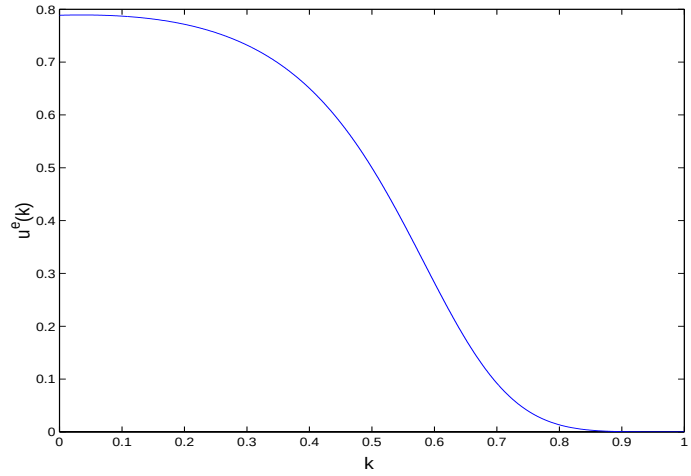

FIG. 4. *Function* $u^e(k)$.

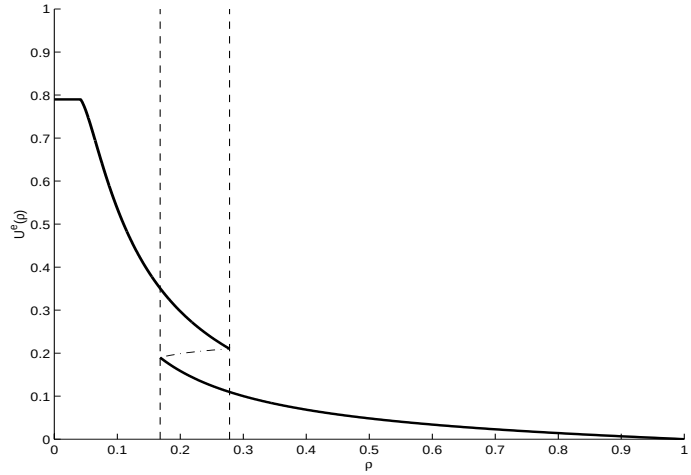

FIG. 5. *Density-velocity dependence* $U^e(\rho)$.

figures in [12], justifying the choice of T_B.

Moreover, we set $T_A = 2T_B$ and choose c as in Figure 2. A reasonable function c should be zero for maximal density ($k = 1$). In this case there is no more random behavior of the drivers; all drivers have velocity 0. For the case $k = 0$ we have chosen c as a finite quantity. If these two features are fulfilled, the qualitative behavior of the model, in particular the multimodal behavior, does not depend on the exact form of c. Moreover, changing the interaction rules for braking and acceleration, results similar to those below can be obtained with models as in [15] with $c = 0$.

5.2. The spatially homogeneous case (stationary, homogeneous kinetic equation). Using the values described above, we compute the stationary solution of the homogeneous kinetic equation following section 3.

The stationary distribution functions are shown in Figure 3.

For maximal density ($k = 1$) the stationary distribution function $f(v)$ is a δ function at $v = 0$. For the low density case the distribution function is a function

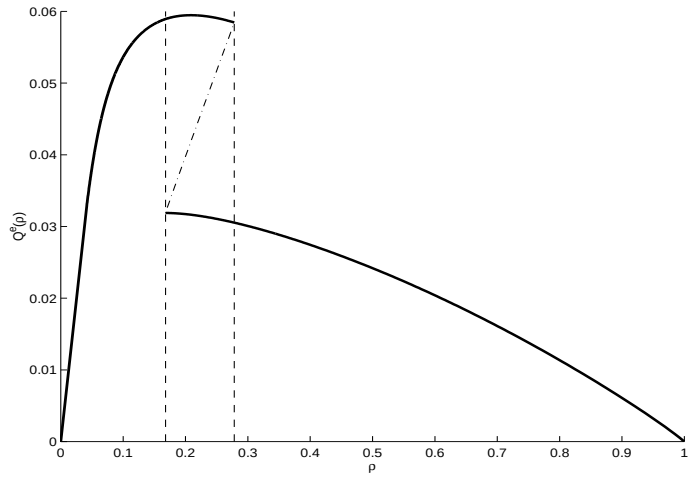

FIG. 6. *Fundamental diagram* $Q^e(\rho)$.

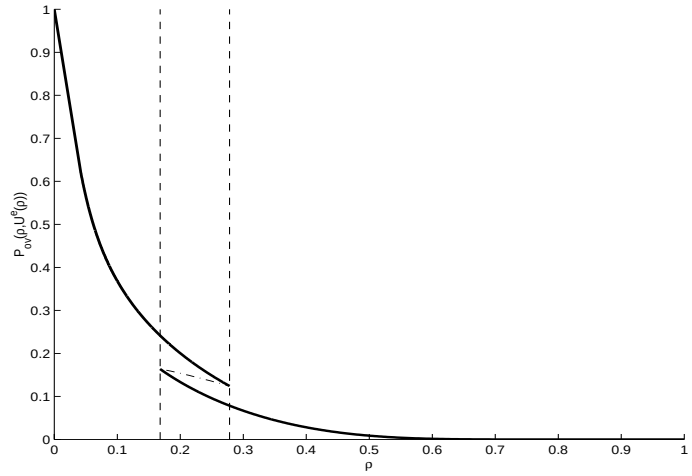

FIG. 7. *Probability* $P_{ov}(\rho, U^e(\rho))$.

with a certain positive variance, depending on the value of c at $k = 1$.

According to section 3, we can compute the function $u^e(k)$ from these stationary distributions in a straightforward way. The dependence of the function u^e on k is plotted in Figure 4.

Moreover, the results found for the nonlinear equation $u = u^e(k(\rho, u))$ are as follows. There are values ρ_1 and ρ_2 such that for $\rho < \rho_1$ we have only one solution, $U_e^1(\rho)$. For $\rho_1 < \rho < \rho_2$ three solutions $U_e^1(\rho)$, $U_e^2(\rho)$, and $\bar{U}(\rho)$ exist. For the region $\rho > \rho_2$ again only one solution $U_e^2(\rho)$ exists. Figure 5 shows the speed-density relation. We note that these values are contained in the admissible range of values (ρ, u) defined by (2). Figure 6 shows the associated multivalued fundamental diagram (flux-density relation).

The resulting multivalued probability of overtaking for equilibrium values of the velocity $P_{ov}(\rho, U^e(\rho))$ is plotted in Figure 7.

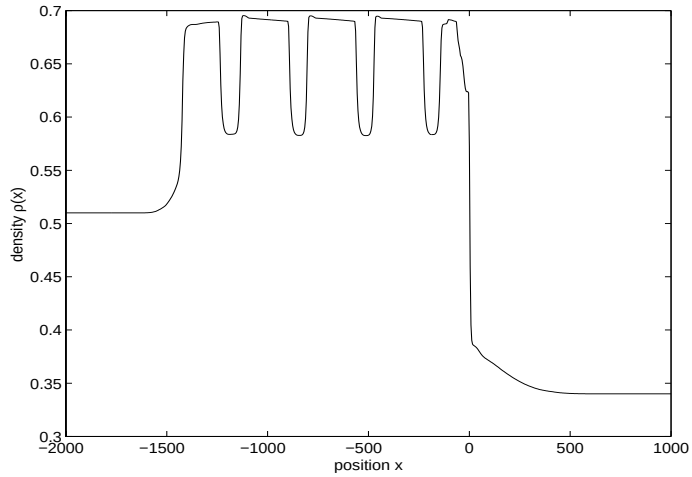

FIG. 8. *Stop and go waves, density* ρ.

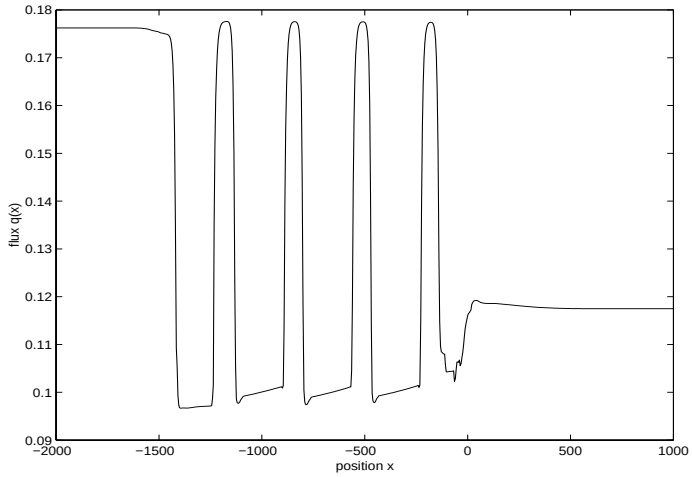

FIG. 9. *Stop and go waves, flux* $q = \rho u$.

As mentioned, $P_{ov}(\rho, U^e(\rho))$ can be compared to the corresponding figures in [12]. Good qualitative coincidence is observed here.

5.3. The spatially inhomogeneous case (macroscopic equations). Finally, the macroscopic equations are investigated for a bottleneck situation. For the computations we choose a second-order shock-capturing method as in [9]. Figures 8 and 9 show the density and flux for a three lane highway with a reduction of lanes from three to two at $x = 0$. One clearly observes large changes in density ρ and flux $q = \rho u$ in the backwards travelling traffic jam, which might be interpreted as stop and go behavior. As one can check numerically, the outgoing flux in Figure 9 is approximately equal to (correctly) averaged flux in the stop and go region.

Summary.

- Multivalued fundamental diagrams are obtained from kinetic equations which match—at least qualitatively—experimental observations in [11, 12]. In par-

ticular, the fundamental quantity, the probability of overtaking P_{ov}, shows good qualitative coincidence with the corresponding results here.

- Macroscopic traffic flow models are derived from the kinetic equation. These models are able to show stop and go patterns for highway traffic with a bottleneck.

RADIATION INDUCED INSTABILITY*

PATRICK HAGERTY†, ANTHONY M. BLOCH†, AND MICHAEL I. WEINSTEIN‡

Abstract. In this paper we discuss the stability and instability properties of two classes of conservative dynamical systems which are comprised of a finite dimensional and an infinite dimensional subsystem. The finite dimensional component is a linear mechanical system with gyroscopic terms. The mechanical system is coupled to a wave equation defined on an infinite spatial domain via two different types of coupling which we denote by Lamb coupling and wave field coupling. We also investigate the effect of dispersion on the coupled system. In particular, we analyze the conditions under which coupling to a wave system induces instability in the finite dimensional system. Analytic results are compared to computer simulations.

Key words. conservative systems, dissipation, stability

1. Introduction. Energy transfer within interconnected mechanical systems is important in many real world settings. When a finite dimensional system is coupled to an infinite dimensional system, energy can be radiated from the finite dimensional system and absorbed by the infinite dimensional system. We call this process *radiation damping*. For example, satellites and space stations have a central rigid body which can radiate energy through flexible components such as solar panels and antennae. Radiation damping can also describe dissipation (e.g., friction, viscosity) in a conservative context, where energy dissipates from one form (such as motion of a mechanical system) into another form (such as heat) of a larger conservative system. In general relativity, energy may be radiated from a system of masses via gravitational waves (see [23] for details). The Lagrangian or Hamiltonian structure of such systems is also of interest (see [21] or [4], for example).

An early physical model of radiation damping was introduced by Lamb [18]. In the Lamb model, an oscillator coupled to a string describes the free vibrations of a nucleus in an extended medium. The oscillator transfers energy to the string by generating waves as it moves; see also [12]. A model of a particle coupled to a wave field is studied in [15].

In many linear and nonlinear partial differential equations, it is fruitful to view the dynamics in terms of "particle-like" and "field-like" components. A decomposition into these types of modes leads to an equivalent description in terms of two coupled subsystems: the first is finite dimensional and governs the "particle-like" or bound state part of the solution, while the second is infinite dimensional and dispersive. Coupling terms are responsible for how the dynamics of "particles" influence the field and how the dispersive wave field influences the particle dynamics. An approxi-

mate closed equation for the particle dynamics can, in some cases, be derived, where the effect of the dispersive radiation field appears in the form of radiation damping corrections to the finite dimensional dynamics. This approach has been used in the context of the theory of quantum resonances [28], [22], ionization and parametric resonance problems [14], [13], and in the context of the decay of "breather-like" states of nonlinear wave equations [29]. In this paper we explore how, in manner analogous to the mechanism by which dissipation can induce instability [5], radiation damping can induce instability in mechanical systems.

In section 2, we present the stability properties and Hamiltonian formalism of gyroscopic systems, also referred to as Chetaev systems. We also describe the Chetaev system as a normal form of the linearized equations of motion about a relative equilibrium of a simple mechanical system acted on by an abelian group. As we increase the gyroscopic forces in a Chetaev system, it is possible to stabilize (or specifically *gyroscopically* stabilize) an equilibrium of the system. For example, a charged, inverted spherical pendulum can be gyroscopically stabilized by increasing the strength of the ambient magnetic field.

In section 3, we describe a gyroscopic version of the Lamb model coupled to a standard nondispersive wave equation and to a dispersive wave equation, expanding on the results in [10]. We show that instabilities will arise in certain mechanical systems. However, dispersive wave coupling restricts the oscillator access to low frequency wave modes and allows for a band of stability to exist.

In the dispersionless case, the system is of the form

$$\begin{aligned} \frac{\partial^2 \mathbf{w}}{\partial t^2}(z,t) &= c^2 \frac{\partial^2 \mathbf{w}}{\partial z^2}(z,t), \quad z \in \mathbb{R} - \{0\}, t \in \mathbb{R}, \\ M\ddot{\mathbf{q}}(t) + S\dot{\mathbf{q}}(t) + V\mathbf{q}(t) &= T\Big[\frac{\partial \mathbf{w}}{\partial z}\Big]_{z=0}, \\ \mathbf{w}(0,t) &= \mathbf{q}(t), \end{aligned} \tag{1.1}$$

where c is the speed of transverse waves in the string, T is the tension of the string, $\mathbf{w} = \big[w_1(z,t) \dots w_n(z,t)\big]^T$ is the displacement of the string in the first n dimensions, and $[\frac{\partial \mathbf{w}}{\partial z}]_{z=0}$ is the jump discontinuity in the slope of the string.

In section 4, we introduce a nonlocal field coupling of a gyroscopic system to a dispersive or a nondispersive infinite dimensional system. Dispersive waves still allow for a band of stability, but the instabilities produced by the nondispersive wave coupling have a broader destabilizing effect on mechanical systems. In contrast to the analogous dissipation induced instability, field radiation induces instability in stable, as well as gyroscopically stable, mechanical systems. In this setting, the coupled wave equation and the gyroscopic system take the form

$$\begin{aligned} M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} &= \kappa \int_{\mathbb{R}} \chi(z) w(z,t) dz \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}, \\ \ddot{w} - c^2 \frac{\partial^2 w}{\partial z^2} &= \kappa \chi(z) \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}, \end{aligned} \tag{1.2}$$

where κ is a coupling parameter and $\chi(\xi)$ is a suitable distribution.

In section 5 we consider an example of a more complicated finite dimensional mechanical system: a rigid body with rotors coupled to a wave field. In this case the configuration space of the system includes a nonabelian group, $SO(3)$.

Finally, we include an appendix which discusses some of details of the physical models used in this paper and the numerical techniques used in simulations.

2. Gyroscopic systems. We recall some general properties of linear systems with gyroscopic forces. The general form of a gyroscopic system is

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = 0, \tag{2.1}$$

where $\mathbf{q} \in \mathbb{R}^n$, M is a positive definite symmetric $n \times n$ matrix, S is skew, and V is symmetric. As in [5], we shall call this the *Chetaev system* (see [8]). An important property of this system is that it is the normal form for a simple mechanical system about a *relative equilibrium* which is given modulo an abelian group; see [20] and section 5.

We say the system is *gyroscopically stable* if for $S = 0$ the origin is an unstable equilibrium, but for $S \neq 0$, the origin is a spectrally stable equilibrium (i.e., the eigenvalues of the linearized system have nonpositive real part). The matrix S is sometimes referred to as a magnetic term as it can arise from charged oscillators in a magnetic field.

If we include the magnetic terms in the symplectic form, then the Hamiltonian, $H : T^*Q \to \mathbb{R}$, of a gyroscopic system is the sum of the kinetic energy and potential energy,

$$H = \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T V\mathbf{q}. \tag{2.2}$$

The symplectic form, Ω, is defined by the Poisson bracket on the cotangent bundle T^*Q,

$$\Omega(X_F, X_K) = \{F, K\}_{magnetic} = \frac{\partial F}{\partial q^i}\frac{\partial K}{\partial p_i} - \frac{\partial K}{\partial q^i}\frac{\partial F}{\partial p_i} - S^{ij}\frac{\partial F}{\partial p_i}\frac{\partial K}{\partial p_j}, \tag{2.3}$$

where X_G denotes the Hamiltonian vector field with Hamiltonian G.

PROPOSITION 2.1. *The Hamiltonian vector field X_H on the symplectic vector space $(\mathbb{R}^{2n}, \Omega)$ has an equivalent representation $X_{\tilde{H}}$ on the symplectic vector space $(\mathbb{R}^{2n}, \tilde{\Omega})$, where*

$$\begin{aligned} \tilde{H} &= \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T (V + W)\mathbf{q} + \mathbf{p}^T X\mathbf{q}, \\ \tilde{\Omega}(X_F, X_K) = \{F, G\}_{canonical} &= \frac{\partial F}{\partial q^i}\frac{\partial K}{\partial p_i} - \frac{\partial K}{\partial q^i}\frac{\partial F}{\partial p_i} \end{aligned} \tag{2.4}$$

for a skew matrix X and a symmetric matrix W defined implicitly by

$$XM + MX = -S, \qquad W = -XMX. \tag{2.5}$$

Furthermore, the Lyapunov equation (2.5) *can be solved using the Fredholm alternative.*

Proof. We obtain the implicit definitions of X and W by matching equations of motion on each manifold. Using the Fredholm alternative, we show that (2.5) has a

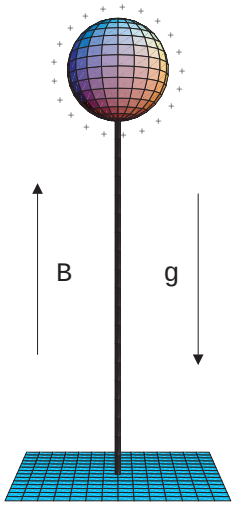

FIG. 1. *Inverted spherical pendulum.*

solution for X. Let us define the linear operator on skew matrices $L(X) = XM + MX$ and show that S is orthogonal to the kernel of L^T with the inner product on skew matrices being the trace $\langle A, B\rangle = \text{Trace}(AB)$. Computing L^T, we have $\langle A, L(B)\rangle = \langle L(A), B\rangle = \text{Trace}((MA + AM)B)$. Hence L is self-adjoint with respect to this inner product.

Suppose that Y is in the kernel of L^T; then we have

$$MY + YM = 0, \qquad Y = -M^{-1}YM\,. \tag{2.6}$$

We also have that $MY + (MY)^T = -2YM$, and hence YM is symmetric. Using the commuting property of the trace, we compute that S is orthogonal to Y, $\langle S, Y\rangle = 0$. The Fredholm alternative is satisfied and we can solve (2.5) for X. This completes the proof. □

Classically, the two representations of the Chetaev systems are equally useful. However, the classical symplectic form, $\tilde{\Omega}$, is preferable when quantizing the mechanical system. (See [5], [2], [8] for further physical discussions.)

2.1. Examples of Chetaev systems. Two physical models of Chetaev systems which can be gyroscopically stabilized are (i) an oscillator in a magnetic field and (ii) an oscillator on a rotating disk. We derive the dynamics from a Lagrangian and a Hamiltonian perspective.

2.1.1. Planar oscillator in a constant magnetic field. The linearized equations of motion of a charged spherical pendulum in a magnetic field are those of a charged planar oscillator in a magnetic field (see Figure 1). The equations of motion form a Chetaev mechanical system. (For derivation of the full equations see Appendix A.) We describe here the motion of a planar charged oscillator in a magnetic field. Let $\mathbf{B}$ be a divergence-free vector field. Let $\mathbf{A}$ be the vector potential $\mathbf{B} = \nabla \times \mathbf{A}$. Note that if we choose $\mathbf{B}$ to be the constant magnetic field in the direction normal to the plane of oscillation, the vector potential can be chosen as $\mathbf{A} = \frac{1}{2}\mathbf{B} \times \mathbf{q}$, where $\mathbf{q} = (x, y, 0)^T$ is the position of the oscillator.

Assume the oscillator has unit mass and unit charge and that the speed of light is unity. The Lagrangian, $L : T\mathbb{R}^2 \to \mathbb{R}$, is defined mechanically by the kinetic energy minus the potential energy:

$$\begin{aligned} L(\mathbf{q}, \dot{\mathbf{q}}) &= \frac{1}{2}\|\dot{\mathbf{q}}\|^2 + \mathbf{A} \cdot \dot{\mathbf{q}} - U(\mathbf{q}) \\ &= \frac{1}{2}(\dot{x}^2 + \dot{y}^2) + \mathbf{A} \cdot (x, y, 0)^T - \frac{1}{2}(\alpha x^2 + \beta y^2). \end{aligned} \tag{2.7}$$

Choosing $\mathbf{B}$ to be of constant strength B normal to the plane of oscillation, we have

$$L = \frac{1}{2}(\dot{x}^2 + \dot{y}^2) - \frac{1}{2}(\alpha x^2 + \beta y^2) + \frac{1}{2}B(x\dot{y} - y\dot{x}), \tag{2.8}$$

where the last term is the velocity dependent magnetic term.

The associated Hamiltonian, $H : T^*\mathbb{R}^2 \to \mathbb{R}$, is

$$H = p_x\dot{x} + p_y\dot{y} - L = \frac{1}{2}(p_x^2 + p_y^2) + \frac{1}{2}(\alpha x^2 + \beta y^2) + H_B, \tag{2.9}$$

where

$$H_B = \frac{1}{2}B(p_x y - p_y x) + \frac{1}{8}B^2(x^2 + y^2), \tag{2.10}$$

and the associated momenta are given by

$$p_x = \frac{\partial L}{\partial \dot{x}} = \dot{x} - \frac{1}{2}By, \qquad p_y = \frac{\partial L}{\partial \dot{y}} = \dot{y} + \frac{1}{2}Bx\,. \tag{2.11}$$

In the above notation, H_B is the contribution of a magnetic field. Since we include the magnetic terms in the Hamiltonian, we use the canonical symplectic form, $\tilde{\Omega}$, to obtain the equations of motion:

$$\begin{aligned} -\dot{p}_x = \frac{\partial H}{\partial x} = \left(\alpha + \frac{1}{4}B^2\right)x - \frac{1}{2}Bp_y, \qquad -\dot{p}_y = \frac{\partial H}{\partial y} = \left(\beta + \frac{1}{4}B^2\right)y + \frac{1}{2}Bp_x, \\ \dot{x} = \frac{\partial H}{\partial p_x} = p_x + \frac{1}{2}By, \qquad \dot{y} = \frac{\partial H}{\partial p_y} = p_y - \frac{1}{2}Bx\,. \end{aligned} \tag{2.12}$$

We thus have the dynamics

$$\begin{aligned} \ddot{x} - B\dot{y} + \alpha x = 0, \\ \ddot{y} + B\dot{x} + \beta y = 0\,. \end{aligned} \tag{2.13}$$

If α and β are both negative, the oscillator is gyroscopically stabilized (i.e., the eigenvalues are purely imaginary) if $B^2 + \alpha + \beta > 2\sqrt{\alpha\beta}$. Hence we can increase the strength of the magnetic field to stabilize the oscillator.

2.1.2. Planar oscillator on a rotating plate. Another physical model of a Chetaev system is a planar oscillator on a plate rotating with angular velocity ω (see Figure 2). We write the Lagrangian as the kinetic energy minus the potential energy,

$$L = \frac{1}{2}((\dot{x} - \omega y)^2 + (\dot{y} + \omega x)^2) - \frac{1}{2}(\alpha x^2 + \beta y^2)\,. \tag{2.14}$$

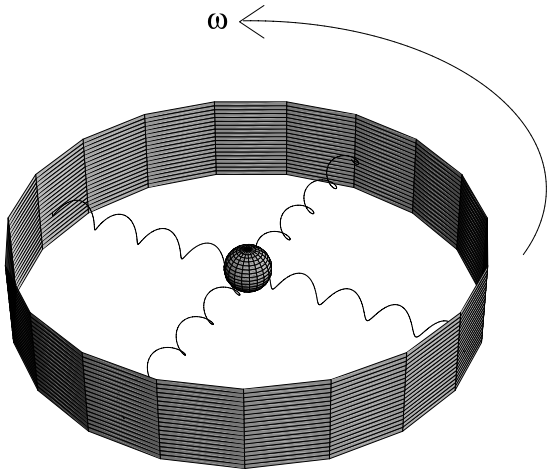

FIG. 2. *Rotating plate with springs.*

In the Hamiltonian setting we have

$$H = \frac{1}{2}(p_x^2 + p_y^2) + \frac{1}{2}(\alpha x^2 + \beta y^2) + H_\omega, \tag{2.15}$$

$$H_\omega = \omega(p_x y - p_y x), \tag{2.16}$$

and the associated momenta are given by

$$p_x = \frac{\partial L}{\partial \dot{x}} = \dot{x} - \omega y, \qquad p_y = \frac{\partial L}{\partial \dot{y}} = \dot{y} + \omega x. \tag{2.17}$$

We obtain the equations of motion:

$$\begin{aligned} -\dot{p}_x = \frac{\partial H}{\partial x} = \alpha x - \omega p_y, \qquad -\dot{p}_y = \frac{\partial H}{\partial y} = \beta y + \omega p_x, \\ \dot{x} = \frac{\partial H}{\partial p_x} = p_x + \omega y, \qquad \dot{y} = \frac{\partial H}{\partial p_y} = p_y - \omega x. \end{aligned} \tag{2.18}$$

This gives the dynamics

$$\begin{aligned} \ddot{x} - 2\omega\dot{y} + (\alpha - \omega^2)x = 0, \\ \ddot{y} + 2\omega\dot{x} + (\beta - \omega^2)y = 0. \end{aligned} \tag{2.19}$$

Remark 1. The rotating disc affects the oscillator differently from a magnetic field—compare (2.19) and (2.13). While the magnetic field only adds $\dot{\mathbf{q}}$ terms, the rotating disc also adds additional $\mathbf{q}$ terms to the dynamics. For the equations (2.13), we can see that in the case of a physically stable oscillator with $\alpha, \beta > 0$ for rotation rate ω sufficiently large, the system becomes only gyroscopically stable, i.e., the coefficients $\alpha - \omega^2$ and $\beta - \omega^2$ are negative but the eigenvalues are on the imaginary axis due to the presence of gyroscopic terms.

Remark 2. In either case above, if the system is gyroscopically stable, it can be shown that adding a small amount of dissipation to the system renders it unstable (i.e., there are unstable eigenvalues). For a more precise statement and generalization, see section 2.2.

2.2. Stability of Chetaev systems. In this section we first summarize the stability properties of Chetaev systems and then discuss their dissipative perturbations. The stability of the Chetaev system depends both on the signature of the bilinear form associated with a quadratic Hamiltonian and also on the magnetic terms in the symplectic form. In particular, the magnetic terms can stabilize gyroscopic systems with negative eigenvalues of V.

As for gyroscopic stability, the number of negative eigenvalues of the quadratic form plays a crucial part as discussed in [8]. We summarize this in the following proposition.

PROPOSITION 2.2. *Consider the canonical gyroscopic system $M\ddot{\mathbf{q}}+S\dot{\mathbf{q}}+V\mathbf{q}=0$, where M is a symmetric positive definite matrix, S is a skew-symmetric matrix, and V is a symmetric matrix:*

- *If V has an odd number of negative eigenvalues (counting multiplicity), then the origin is an unstable equilibrium.*
- *If V has an even number of negative eigenvalues (counting multiplicity), we can choose S so that the origin is a spectrally stable equilibrium.*

Proof. By standard reduction to a first order system for $(\mathbf{q}, \dot{\mathbf{q}})$, it suffices to consider the first order linear operator L,

$$L = \begin{bmatrix} 0 & I \\ -M^{-1}V & -M^{-1}S \end{bmatrix}. \tag{2.20}$$

Let $p(\lambda)$ be the characteristic polynomial of the matrix L, and let $\lambda_1, \ldots, \lambda_n$ be the eigenvalues of the matrix V.

$$p(0) = \det L = (-1)^n \det(-M^{-1}V) = \det(M^{-1}) \prod_{i=1}^{n} \lambda_i \,. \tag{2.21}$$

Suppose that V has an odd number of negative eigenvalues. Due to the positive-definiteness of M, we have $p(0) < 0$. Since

$$\lim_{\lambda\to\infty} p(\lambda) = \lim_{\lambda\to\infty} \det\Big(L - \lambda I\Big) = \lim_{\lambda\to\infty} (-1)^{2n}\lambda^{2n} + O(\lambda^{2n-1}) = \infty, \tag{2.22}$$

$p(\lambda)$ must change sign and by continuity has a positive root, corresponding to a real and positive eigenvalue of L, an instability.

Hence, if V has an odd number of negative eigenvalues (counting multiplicity), then the characteristic polynomial of L has a positive real root and the origin cannot be gyroscopically stabilized.

Now to prove the second item, suppose that V has an even number of negative eigenvalues (counting multiplicity). By choosing a basis in which V is diagonal, we can introduce a skew matrix S to stabilize each pair of negative eigendirections, as in the gyroscopic stabilization for $n = 2$ shown in introductory examples. This completes the proof. ∎

Gyroscopically stable systems exhibit interesting instability when perturbed by dissipative forces. Suppose now that V has at least one negative eigenvalue. A key result of [5] is that adding small dissipation always yields instability. More precisely, we show the following.

THEOREM 2.3. *Under the above conditions, if we modify the general Chetaev system by adding a small Rayleigh dissipation term,*

$$M\ddot{\mathbf{q}} + (S + \epsilon R)\dot{\mathbf{q}} + V\mathbf{q} = 0 \tag{2.23}$$

for small $\epsilon > 0$, where R is symmetric and positive definite, then the perturbed linearized equations

$$\dot{z} = L_\epsilon z,$$

where $z = (q, p)$, are spectrally unstable, i.e., at least one pair of eigenvalues of L_ϵ is in the right half plane.

This result builds on basic work of [30], [8], and [11]. We refer to this as *dissipation induced instability*. Some of the radiation induced instabilities that arise in the gyroscopic Lamb model are analogous to the dissipation induced instability. Using the Hamiltonian representation with canonical symplectic form, $\tilde{\Omega}$, we see that the Hamiltonian of a gyroscopically stabilized Chetaev system is indefinite. In this case, with the addition of Rayleigh dissipation, the Hamiltonian does not bound the motion of the Chetaev system. In particular, the displacement and velocities may grow exponentially.

As in section 5.1.2, we present the Chetaev system as a normal form of the linearized equations of motion about the relative equilibrium of an abelian group action. [5] also proves a similar stability result for the nonabelian case, but the abelian result is sufficient for our purposes.

3. Lamb coupling. In the original Lamb model [18], an oscillator is physically coupled to a string (see Figure 3). The vibrations of the oscillator transmit waves into the string and are carried off to infinity. Hence, the oscillator loses energy and is effectively damped by the string.

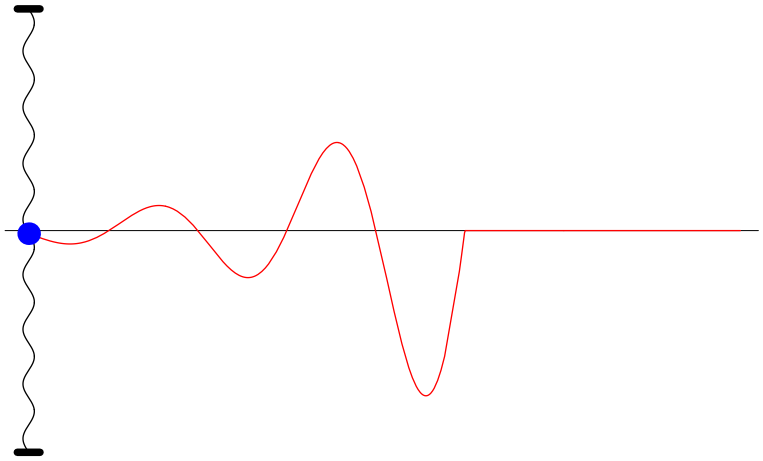

FIG. 3. *Lamb model of an oscillator coupled to a string.*

Let $w(x, t)$ be the displacement of the string at position $x \in \mathbb{R}$ at time t. Let ρ be the mass density of the string, and let T be the tension. We can compute the wave speed of transverse oscillations of the free string to be $c = \frac{T}{\rho}$. Assuming a singular mass density at $x = 0$, we can couple the dynamics of an oscillator, q, of mass M, to the otherwise free wave to resolve the singularity:

$$\begin{aligned} \frac{\partial^2 w}{\partial t^2} &= c^2 \frac{\partial^2 w}{\partial x^2}, \\ M\ddot{q} + Vq &= T[w_x]_{x=0}, \\ q(t) &= w(0, t), \end{aligned} \tag{3.1}$$

where $\sqrt{V/M}$ is the frequency of the uncoupled oscillating mass M and $[w_x]_{x=0} = w_x(0+,t) - w_x(0-,t)$ is the jump discontinuity of the slope of the string. Note that (3.1) is a Hamiltonian system, as demonstrated for a more complex system in section 3.1.

Perturbing the oscillator at time $t = 0$ from its equilibrium position, we can use the d'Alembert solution to the wave equation to solve for w,

$$w = \begin{cases} Ce^{(ct-|x|)\omega} & \text{for } |x| < ct, \\ 0 & \text{for } |x| > ct, \end{cases} \tag{3.2}$$

where $\omega = -\frac{T}{Mc} + i\sqrt{\frac{V^2}{M^2} - (\frac{T}{Mc})^2}$ and C is the size of the initial displacement. For small tension we have damping and oscillator motion, while for large tension, we have pure damping. From the solution of the wave equation, we can compute the jump condition of the oscillator,

$$[w_x]_{x=0} = -2C\omega e^{\omega ct} = -\frac{2}{c}\dot{q}. \tag{3.3}$$

We obtain a reduced form of the dynamics describing the explicit motion of the oscillator subsystem,

$$M\ddot{q} + \frac{2T}{c}\dot{q} + Vq = 0. \tag{3.4}$$

The coupling term arises explicitly as a Rayleigh dissipation term $\frac{2T}{c}\dot{q}$ in the dynamics of the oscillator. For the gyroscopic Lamb coupling, the dissipation term will induce instabilities in gyroscopically stabilized Chetaev systems.

3.1. Gyroscopic Lamb model. In this section, we investigate a variant of the Lamb model, a Chetaev system which includes gyroscopic terms coupled to the standard wave equation (see, e.g., Figure 4). We have the boundary constraint that the displacement of the gyroscopic oscillator fixes a point of the string. We show that this local coupling perturbation destabilizes gyroscopically stabilized Chetaev systems.

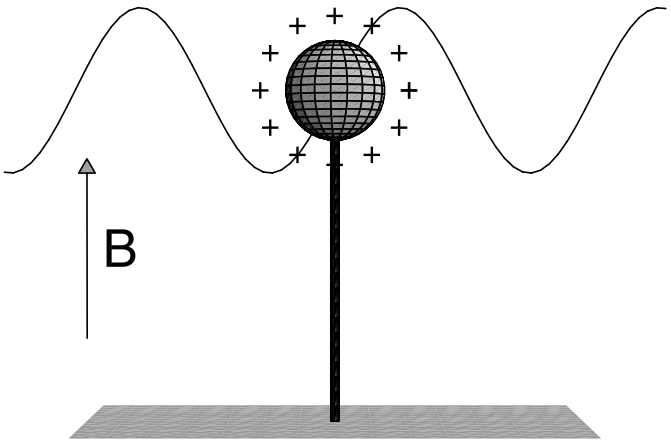

FIG. 4. *Gyroscopic Lamb coupling to a spherical pendulum.*

We begin with a model of a string in $\mathbb{R}^{n+1}$, whose transverse vibrations are independent. Suppose the string lies initially along the x_{n+1}-axis. For simplicity, we denote the x_{n+1} dimension as the z dimension. Coupling the transverse motion to an n dimensional gyroscopic system, we use the method described in [16] to solve the following:

$$\begin{aligned} \frac{\partial^2 \mathbf{w}}{\partial t^2}(z,t) &= c^2 \frac{\partial^2 \mathbf{w}}{\partial z^2}(z,t), \quad z \in \mathbb{R} - \{0\}, t \in \mathbb{R}, \\ M\ddot{\mathbf{q}}(t) + S\dot{\mathbf{q}}(t) + V\mathbf{q}(t) &= T\Big[\frac{\partial \mathbf{w}}{\partial z}\Big]_{z=0}, \\ \mathbf{w}(0,t) &= \mathbf{q}(t), \end{aligned}$$

where c is the speed of transverse waves in the string, T is the tension of the string, $\mathbf{w} = \big[w_1(z,t) \dots w_n(z,t)\big]^T$ is the displacement of the string in the first n dimensions, and $[\frac{\partial \mathbf{w}}{\partial z}]_{z=0}$ is the jump discontinuity in the slope of the string. Let us define the initial conditions on the string by $\mathbf{w}_1(z) = \frac{\partial \mathbf{w}}{\partial t}(z,0)$ and $\mathbf{w}_0(z) = \mathbf{w}(z,0)$.

By direct computation we obtain an exact reduced dynamical system for $\mathbf{q}$. This reduction contains explicit dissipation terms reflecting the oscillator/field coupling. The results on reduction and stability are summarized in the following two results. The proofs are given in section 3.1.2.

PROPOSITION 3.1. *If the initial data* $\mathbf{w}_0$ *and* $\mathbf{w}_1$ *have compact support, then for* $\pm ct \notin \operatorname{supp}(\mathbf{w}_0) \cup \operatorname{supp}(\mathbf{w}_1)$ *the oscillator dynamics of the gyroscopic Lamb model reduces to*

$$M\ddot{\mathbf{q}}(t) + \left(S + \frac{2T}{c}\right)\dot{\mathbf{q}}(t) + V\mathbf{q}(t) = 0. \tag{3.5}$$

In [5], small dissipation is shown to induce instability in gyroscopically stable systems (see Theorem 2.3). In the gyroscopic Lamb model, radiation (energy transfer into an infinite dimensional system) produces a Rayleigh dissipation term which depends on the tension of the string. Since dissipation induces instability in these systems for small dissipation, small tension coupling yields radiation induced instability via an analogous mechanism. We summarize the main result of *radiation induced* instability in gyroscopically stabilized Chetaev systems with a theorem.

THEOREM 3.2. *If a gyroscopic mechanical system is gyroscopically stable (i.e., V has a negative eigendirection), then local coupling via the Lamb model induces instability for small coupling parameter T.*

The ability to describe the coupled system in a conservative manner is one of the key differences between radiation induced instability and dissipation induced instability. We delay the proofs of the above theorems to demonstrate the conservative nature of the gyroscopic Lamb model. While we can obtain the equations of motion from a force calculation, we emphasize the conservative nature of the gyroscopic Lamb model by representing the system as the flow of a Hamiltonian vector field.

3.1.1. Hamilton's equations of motion. For an uncoupled wave equation, the kinetic energy, T_{string}, depends on the velocity of the string, while the potential energy, U_{string}, depends on the shape of the string,

$$T_{string} = \sum_{i=1}^{n} \int_{\mathbb{R}} \left\| \frac{\partial w_i}{\partial t} \right\|^2 dz, \quad U_{string} = \sum_{i=1}^{n} \int_{\mathbb{R}} c^2 \left\| \frac{\partial w_i}{\partial z} \right\|^2 dz. \tag{3.6}$$

Let $Z = \mathcal{H}^1(\mathbb{R}) \times L^2(\mathbb{R})$, where $\mathcal{H}^1(\mathbb{R})$ is the space of square integrable functions whose first derivatives are also square integrable and $L^2(\mathbb{R})$ is the space of square integrable densities. Hence $(w_i, \pi_i) \in Z$ if w_i and $\frac{\partial w_i}{\partial z}$ are each square integrable and $\pi_i = \pi_i' dz$, where π' is a square integrable function on $\mathbb{R}$. We define the canonical symplectic form, Ω_Z, on the vector space Z as

$$\Omega_Z((w_1, \pi_1), (w_2, \pi_2)) = \int_{\mathbb{R}} w_1 \pi_2 - w_2 \pi_1. \tag{3.7}$$

PROPOSITION 3.3. *The gyroscopic Lamb model* (3.1) *has a Hamiltonian representation with Hamiltonian* $(H, (Z, \Omega_Z)^n)$, *with*

$$\begin{aligned} H(\mathbf{w}, \pi) &= \int \sum_{i=1}^{n} \frac{1}{2}(\pi_i')^2 + \frac{1}{2}c^2 \left\| \frac{\partial w_i}{\partial z} \right\|^2 + \delta(z) H_{osc.}(\mathbf{w}, \pi') dz, \\ H_{osc.}(\mathbf{w}, \pi') &= \frac{1}{2}\pi'^T M^{-1} \pi' + \frac{1}{2}\mathbf{w}^T (V + W)\mathbf{w} + \pi'^T X \mathbf{w} - T\mathbf{w}^T [\mathbf{w}_z]_{z=0}. \end{aligned} \tag{3.8}$$

Proof. The symplectic form induces Hamilton's equations for field theory,

$$\Omega(X_H, \cdot) = dH, \tag{3.9}$$

$$\frac{\partial w_i}{\partial t} = \frac{\delta H}{\delta \pi_i}, \quad \frac{\partial \pi_i}{\partial t} = -\frac{\delta H}{\delta w_i}. \tag{3.10}$$

Computing the variations, we have

$$\begin{aligned} \int \frac{\delta H}{\delta \pi_i} \cdot \delta \pi_i dz &= \lim_{\epsilon \to 0} \epsilon^{-1} (H(\mathbf{w}, \pi + \epsilon \delta \pi_i) - H(\mathbf{w}, \pi)) \\ &= \int \left(\pi_i' + \delta(z) \frac{\partial H_{osc.}}{\partial \pi_i} \right) \cdot \delta \pi_i dz \end{aligned} \tag{3.11}$$

and

$$\begin{aligned} \int \frac{\delta H}{\delta w_i} \cdot \delta w_i dz &= \lim_{\epsilon \to 0} \epsilon^{-1} (H(\mathbf{w} + \epsilon \delta w_i, \pi) - H(\mathbf{w}, \pi)) \\ &= \int \left(-c^2 \frac{\partial^2 w_i}{dz^2} + \delta(z) \frac{\partial H_{osc.}}{\partial w_i} \right) \cdot \delta w_i dz. \end{aligned} \tag{3.12}$$

For $z \neq 0$, we have

$$\frac{\partial w_i}{\partial t} = \pi_i', \quad \frac{\partial \pi_i'}{\partial t} = c^2 \frac{\partial^2 w_i}{\partial z^2}, \tag{3.13}$$

or equivalently

$$\frac{\partial^2 \mathbf{w}}{\partial t^2}(z, t) = c^2 \frac{\partial^2 \mathbf{w}}{\partial z^2}(z, t), \quad z \in \mathbb{R} - \{0\}, t \in \mathbb{R}. \tag{3.14}$$

For the singular part of the Hamiltonian at $z = 0$, we define $\mathbf{q}(t) = \mathbf{w}(0,t)$ and $\mathbf{p}(t) = \pi'(0,t)$. Notice that $[\mathbf{w}_z]_{z=0}$ is independent of variations $\delta\mathbf{w}(0)$. We use the induced canonical symplectic form, $\tilde{\Omega}$, on $T^*\mathbb{R}^n$ to obtain the Hamilton's equations of motion:

$$\begin{aligned}\dot{\mathbf{q}} &= \frac{\partial H_{osc.}}{\partial \mathbf{p}} = M^{-1}\mathbf{p} + X\mathbf{q},\\ \dot{\mathbf{p}} &= \frac{\partial H_{osc.}}{\partial \mathbf{q}} = (V+W)\mathbf{q} - X\mathbf{p} - T[\mathbf{w}_z]_{z=0}.\end{aligned} \tag{3.15}$$

Differentiating and writing the above first order system as a second order system, we obtain

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = T[\mathbf{w}_z]_{z=0}. \tag{3.16}$$

This completes the proof. □

3.1.2. Radiation induced instability in the Lamb model. To prove radiation induced instability, we obtain a reduced form of the Chetaev subsystem. We can use the d'Alembert method of solving the wave equation or find the solution via Laplace transforms. We save the latter technique for the more general dispersive case.

Proof of Proposition 3.1. [16] explicitly develops the d'Alembert solution of the wave equation coupled to a simple harmonic oscillator. We use the same method applied to a Chetaev system coupled to a higher dimensional wave equation. The method is to use the d'Alembert method of solving the wave equation on the domain unaffected by the coupling. Inside the domain affected by the coupling, we use continuity and coupling dynamics to solve for the wave equation.

Our model decomposes into n independent one dimensional wave equations; we can use the d'Alembert decomposition to two traveling waves:

$$\mathbf{u}(z,t) = \mathbf{f}_\pm(z - ct) + \mathbf{g}_\pm(z + ct), \qquad \pm z > 0, \tag{3.17}$$

where $\mathbf{f}_\pm, \mathbf{g}_\pm$ are functions on $\mathbb{R}^n$. In components, we have

$$\mathbf{f}_\pm = \left[f_{\pm 1} \dots f_{\pm 2n}\right]^T, \quad \mathbf{g}_\pm = \left[g_{\pm 1} \dots g_{\pm 2n}\right]^T, \tag{3.18}$$

where $f_i, g_i, i = \pm 1, \dots, \pm n$ are real-valued functions on $\mathbb{R}$. By the d'Alembert method of solving the wave equation, we have the formulas

$$\mathbf{f}_\pm(z) = \frac{1}{2}\mathbf{w}_0(z) - \frac{1}{2c}\int_0^z \mathbf{w}_1(v)dv, \qquad \pm z > 0, \tag{3.19}$$

$$\mathbf{g}_\pm(z) = \frac{1}{2}\mathbf{w}_0(z) + \frac{1}{2c}\int_0^z \mathbf{w}_1(v)dv, \qquad \pm z > 0. \tag{3.20}$$

Since the d'Alembert formula for $|z| \geq c|t|$ is defined in terms of known functions, the method remains valid and we have

$$\mathbf{w}(z,t) = \frac{\mathbf{w}_0(z-ct) + \mathbf{w}_0(z+ct)}{2} + \frac{1}{2c}\int_{z-ct}^{z+ct} \mathbf{w}_1(v)dv. \tag{3.21}$$

To use the d'Alembert formula for $|z| < c|t|$, we need to define $\mathbf{f}_+(z)$ for $z < 0$ and to define $\mathbf{g}_-(z)$ for $z > 0$. From the boundary condition and from continuity of the string, we have

$$\mathbf{f}_\pm(-ct) + \mathbf{g}_\pm(ct) = \mathbf{q}(t), \qquad t > 0, \tag{3.22}$$

$$M\ddot{\mathbf{q}}(t) = -S\dot{\mathbf{q}}(t) - V\mathbf{q}(t) + T\left[\frac{\partial \mathbf{f}_+}{\partial z}(-ct) + \frac{\partial \mathbf{g}_+}{\partial z}(ct) - \frac{\partial \mathbf{f}_-}{\partial z}(-ct) - \frac{\partial \mathbf{g}_-}{\partial z}(ct)\right]. \tag{3.23}$$

Differentiating and solving for $\mathbf{f}'_+$ and $\mathbf{g}'_-$, where the $'$ denotes $\frac{\partial}{\partial z}$, we have

$$\begin{aligned} -c\mathbf{f}'_+(-ct) &= \dot{\mathbf{q}}(t) - c\mathbf{g}'_+(ct), \\ c\mathbf{g}'_-(ct) &= \dot{\mathbf{q}}(t) + c\mathbf{f}'_-(-ct), \qquad t > 0. \end{aligned} \tag{3.24}$$

Substituting, we arrive at a differential equation for $\mathbf{q}$ in terms of known functions

$$\begin{aligned} M\ddot{\mathbf{q}}(t) + S\dot{\mathbf{q}}(t) + V\mathbf{q}(t) &= 2T\left[\mathbf{g}'_+(ct) - \mathbf{f}'_-(-ct) - \frac{1}{c}\dot{\mathbf{q}}(t)\right], \quad t > 0. \\ &= -\frac{2T}{c}\dot{\mathbf{q}}(t) + T\left[\mathbf{w}'_0(ct) - \mathbf{w}'_0(-ct) + \frac{1}{c}(\mathbf{w}_1(ct) + \mathbf{w}_1(-ct))\right]. \end{aligned} \tag{3.25}$$

The effect of coupling to a wave equation (3.25) is manifested by the presence of an explicit dissipative term. If we assume that the initial conditions of the string are such that $\mathbf{w_1}$ and $\mathbf{w_0}$ both have compact support, then for large t we have $\pm ct$ outside the support of $|\mathbf{w_0}| + |\mathbf{w_1}|$, reducing (3.25) to

$$\begin{aligned} M\ddot{\mathbf{q}}(t) + S\dot{\mathbf{q}}(t) + V\mathbf{q}(t) &= -\frac{2T}{c}\dot{\mathbf{q}}(t), \\ \pm ct &\notin \operatorname{supp}(|\mathbf{w_0}| + |\mathbf{w_1}|). \end{aligned} \tag{3.26}$$

This completes the proof the of proposition. ∎

Proof of Theorem 3.2. Assuming that the initial string has a finite energy, we have that $\mathbf{w}$ and $\mathbf{w_1}$ decay as $|z| \to \infty$. Hence, there are initial conditions of the string which have compact support in an H^1 Sobolev neighborhood of $\mathbf{w}$. Hence we can use the result from Proposition 3.1. We construct a Lyapunov function W as the sum of the energy of the system and a magnetic term,

$$W(\mathbf{q}) = \frac{1}{2}\dot{\mathbf{q}}^T M\dot{\mathbf{q}} + \frac{1}{2}\mathbf{q}^T V\mathbf{q} + \delta\mathbf{q}^T VM\dot{\mathbf{q}}. \tag{3.27}$$

In [5], W is shown to have a negative eigendirection for δ sufficiently small if V has a negative eigendirection, and that $\dot{W}$ is negative definite. Invoking the Lyapunov instability theorem, the gyroscopic Lamb model is spectrally unstable if V has a negative eigendirection. ∎

The results from Theorem 3.2 are consistent with Kreĭn signature results on instability (see [1] and [5]), in contrast to the broader instability one sees in the nonlocal coupling case (see section 4).

3.2. Dispersive gyroscopic Lamb model. In this section, we develop an explicit solution to a dispersive gyroscopic Lamb model, i.e., a gyroscopically stable Chetaev system coupled to a dispersive wave equation. As the dispersive wave equation we choose the Klein–Gordon equation with "mass" m:

$$\begin{aligned} \frac{\partial^2 \mathbf{w}}{\partial t^2}(z,t) &= c^2 \frac{\partial^2 \mathbf{w}}{\partial z^2}(z,t) - m^2 \mathbf{w}(z,t), \quad z \in \mathbb{R} - \{0\}, t \in \mathbb{R}, \\ M\ddot{\mathbf{q}}(t) + S\dot{\mathbf{q}}(t) + V\mathbf{q}(t) &= T\Big[\frac{\partial \mathbf{w}}{\partial z}\Big]_{z=0}, \\ \mathbf{w}(0,t) &= \mathbf{q}(t). \end{aligned} \tag{3.28}$$

The coupled system has a Hamiltonian, H, given by

$$H(\mathbf{w},\pi) = \int \sum_{i=1}^{n} \frac{1}{2}(\pi_i')^2 + \frac{1}{2}c^2 \left\| \frac{\partial w_i}{\partial z} \right\|^2 + \frac{1}{2}m^2 \|w\|^2 + \delta(z) H_{osc.}(\mathbf{w},\pi') dz, \tag{3.29}$$

$$H_{osc.}(\mathbf{w},\pi') = \frac{1}{2}\pi'^T M^{-1} \pi' + \frac{1}{2}\mathbf{w}^T (V+W)\mathbf{w} + \pi'^T X \mathbf{w} - T\mathbf{w}\Big[\mathbf{w}_z\Big]_{z=0}$$

on the same symplectic vector space $((Z,\Omega_Z)^n)$ as the gyroscopic Lamb model.

Equation (3.28) is linear translation invariant in time, so the initial value problem can be solved by a Laplace transform, which we denote by

$$\mathcal{L}[f](s) = \int_0^\infty f(t) e^{st} dt.$$

In the transformed space, we have

$$\begin{aligned} (s^2 M + sS + V)\mathcal{L}[\mathbf{q}] &= M(\dot{\mathbf{q}}(0) + s\mathbf{q}(0)) + s\mathbf{q}(0) + T\Big[\mathcal{L}[\mathbf{w}_z]\Big]_{z=0}, \\ (s^2 + m^2)\mathcal{L}[\mathbf{w}] - c^2 \mathcal{L}[\mathbf{w}_{zz}] &= \mathbf{w}_t(z,0) + s\mathbf{w}(z,0), \quad z \neq 0, \\ \mathcal{L}[\mathbf{w}](0,s) &= \mathcal{L}[\mathbf{q}](s). \end{aligned} \tag{3.30}$$

For simplicity of the calculation, we assume that $\mathbf{q}(0) = \mathbf{w}_t(z,0) = \mathbf{w}(z,0) = 0$ and that the perturbation comes from a nontrivial velocity of the oscillator at the origin. We can integrate the homogeneous dispersive wave equation on each interval to obtain

$$\mathcal{L}[\mathbf{w}](z,s) = \begin{cases} \mathbf{a} e^{\frac{\sqrt{s^2+m^2}\, z}{c}} & \text{for } z < 0, \\ \mathbf{a} e^{-\frac{\sqrt{s^2+m^2}\, z}{c}} & \text{for } z > 0. \end{cases} \tag{3.31}$$

From the boundary constraints, we have $\mathcal{L}[\mathbf{q}] = \mathbf{a}$.

Solving for $\mathcal{L}[\mathbf{w}]$ as a function of $\mathcal{L}[\mathbf{q}]$ and computing the jump condition of the string at $z = 0$, we have

$$\begin{aligned} \mathcal{L}[\mathbf{w}_z](z,s) &= -\operatorname{sign}(z) \frac{\sqrt{s^2+m^2}}{c} e^{-\operatorname{sign}(z)\frac{\sqrt{s^2+m^2}\, z}{c}} \mathcal{L}[\mathbf{q}], \\ \Big[\mathcal{L}[\mathbf{w}_z]\Big]_{z=0} &= -2\frac{\sqrt{s^2+m^2}}{c} \mathcal{L}[\mathbf{q}]. \end{aligned} \tag{3.32}$$

The equations of motion for the coupled Chetaev system decouple from the dispersive wave equation,

$$\left(s^2 M + sS + V + 2T\frac{\sqrt{s^2+m^2}}{c} I \right) \mathcal{L}[\mathbf{q}] = M\dot{\mathbf{q}}(0). \tag{3.33}$$

Taking the inverse Laplace transform and using the identity

$$\mathcal{L}\left[\frac{J_1(t)}{t}\right] = \sqrt{s^2+1} - s, \tag{3.34}$$

we obtain

$$M\ddot{\mathbf{q}} + \left(S + \frac{2T}{c}I\right)\dot{\mathbf{q}} + V\mathbf{q} = -\frac{2Tm}{c}\int_0^t \frac{1}{t-s}J_1(m(t-s))\mathbf{q}(s)ds, \tag{3.35}$$

where J_1 is the Bessel function of the first kind. We can define the approximate identity $J^\epsilon = \frac{J_1(\frac{t}{\epsilon})}{t}$. Since J_1 is an $L^1(\mathbb{R})$ function such that $\int_0^\infty J_1(t)dt = 1$, we can use the approximate identity nature of the convolution to have a necessary condition on stability summarized in a lemma.

LEMMA 3.4. *If* $\mathbf{q}$ *is continuous and bounded for all time, then*

$$\lim_{\epsilon\to 0} J^\epsilon * \mathbf{q}(t) = \mathbf{q}(t). \tag{3.36}$$

By the above lemma, we obtain an asymptotic expansion for the perturbed dynamics of the coupled oscillator.

PROPOSITION 3.5. *Consider the dynamical system*

$$M\ddot{\mathbf{q}} + \left(S + \frac{2T}{c}I\right)\dot{\mathbf{q}} + \left(V + \frac{Tm}{c}I\right)\mathbf{q} = 0. \tag{3.37}$$

As m *tends to infinity, the zero equilibrium of the dispersive Lamb model becomes unstable if the zero equilibrium of system* (3.37) *is unstable.*

Proof. In order to produce a contradiction, assume that the dispersive Lamb model is stable as $m \to \infty$. By applying Lemma 3.4 to the reduced dynamics (3.35), we have

$$M\ddot{\mathbf{q}} + \left(S + \frac{2T}{c}I\right)\dot{\mathbf{q}} + \left(V + \frac{Tm}{c}I\right)\mathbf{q} = O\left(\frac{1}{\sqrt{m}}\right). \tag{3.38}$$

Hence, the associated dynamical system (3.37) must also have a stable zero equilibrium. This contradicts the assumption that the system (3.37) is unstable. Our assumption that the dispersive Lamb model is stable as $m \to \infty$ must be false. This completes the proof. ∎

For large values of m, the asymptotic analysis suggests that a gyroscopically stabilized Chetaev system will maintain its stability after dispersive Lamb coupling. The dispersive nature of the wave equation restricts the access of the oscillator from interacting with low frequencies of the wave. This restriction effectively shifts the potential of the oscillator. The potential shift can even stabilize previously unstable oscillators.

The evolution of a Chetaev subsystem mirrors that of stable Chetaev system with dissipation. In the limit as m tends to zero, the asymptotic behavior of the system retains the explicit damping contribution as in the nondispersive coupling.

4. Nonlocal field coupling to gyroscopic Chetaev systems. While the Lamb model imposes the boundary constraint that the oscillator is physically attached to the wave field, we now investigate the effect of an ambient field on a Chetaev system without such a constraint. Energy is transmitted between the ambient field and the Chetaev system not through boundary constraints, but rather through coupling in the Hamiltonian. We analyze the contribution of a nonlocal distribution on the wave field acting as a force on the oscillator. Mathematically the field acts through a coupling distribution which for simplicity we take for computations to be a Dirac-δ function.

4.1. Nondispersive, nonlocal wave field coupling to a Chetaev system. Here we investigate a field coupling of the mechanical gyroscopic system to the wave equation. As before, we have the standard nondispersive wave equation

$$\frac{\partial^2 w}{\partial t^2} - c^2 \frac{\partial^2 w}{\partial z^2} = 0. \tag{4.1}$$

We model force of the wave field on the Chetaev system by the magnitude of the wave field. In the spirit of conservation, the coupled system remains Hamiltonian, while each perturbed subsystem may not. Coupling of this type is important in various physical models; see [28], [27], [29] and references therein. The interaction between the wave equation and the Chetaev system is modeled with a coupling parameter κ and with a coupling distribution $\chi(\xi)$; the equations of motion are

$$\begin{aligned} M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} &= \kappa \int_{\mathbb{R}} \chi(z) w(z,t) dz \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}, \\ \frac{\partial^2 w}{\partial t^2} - c^2 \frac{\partial^2 w}{\partial z^2} &= \kappa \chi(z) \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}. \end{aligned} \tag{4.2}$$

For simplicity, we choose $\chi(z)$ to be the Dirac-δ distribution. (So in fact, even though we will continue to use the terminology "nonlocal coupling" for the type of system discussed in this section, the special case we consider here is also a type of focused, local with respect to the ambient field, coupling without boundary constraints.)

The above coupled system remains Hamiltonian with H defined as

$$H = \frac{1}{2}\left(\int_{\mathbb{R}} w_t^2 + c^2 w_z^2 dz + \dot{\mathbf{q}}^T M \dot{\mathbf{q}} + \mathbf{q}^T V \mathbf{q} \right) - \kappa \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q} \int_{\mathbb{R}} \chi(z) w(z,t) dz. \tag{4.3}$$

Notice that the Hamiltonian is indefinite; hence the energy of the system does not uniformly bound the motion of the Chetaev system nor the motion of the wave field. Furthermore, the magnetic terms are present in the mechanical symplectic form defined by the Chetaev symplectic form, Ω, defined in (2.3).

4.1.1. Reduction of nondispersive system to a finite dimensional system. Even though the Chetaev system and the wave equation seem intimately coupled, we can decouple the wave motion from that of the Chetaev system as follows.

Taking the Fourier transform with respect to z in the wave equation yields

$$\begin{aligned}
&\hat{w}(k,t) = \int_{\mathbb{R}} e^{-ikz} w(z)dz,\\
&\hat{w}_{tt}(k,t) + c^2k^2\hat{w}(k,t) = \kappa \left[1 \dots 1\right] \mathbf{q}(t),\\
&\hat{w}(k,t) = \kappa \int_0^t \frac{\sin(ck(t-s))}{ck} \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}(s)ds + \hat{w}_{free}(k,t).
\end{aligned} \tag{4.4}$$

The above equation is the retarded Green's function for the wave equation, and w_{free} is the homogeneous solution satisfying initial conditions. Computing $w(0,t)$, we have

$$\begin{aligned}
w(0,t) &= \frac{1}{2\pi}\int_{\mathbb{R}} \hat{w}(k,t)dk\\
&= w_{free}(0,t) + \frac{\kappa}{4\pi c}\int_0^t \int_{\mathbb{R}} \frac{2\sin(ck(t-s))}{ck} d(ck) \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}(s)ds\\
&= w_{free}(0,t) + \frac{\kappa}{2c}\int_0^t \operatorname{sgn}(t-s) \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}(s)ds\\
&= w_{free}(0,t) + \frac{\kappa}{2c}\int_0^t \left[1 \dots 1\right] \mathbf{q}(s)ds.
\end{aligned} \tag{4.5}$$

Thus the Chetaev system reduces to

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \kappa w_{free}(0,t)\left[1 \dots 1\right]^T + \frac{\kappa^2}{2c} Ones(n) \int_0^t \mathbf{q}(s)ds, \tag{4.6}$$

where $Ones(n)$ is an $n \times n$ matrix with each matrix element equal to one.

4.1.2. Differentiated system. We can interpret (4.6) as an integral feedback on the Chetaev system. To analyze the stability, we investigate the stability of the differentiated system.

Suppose that initially the coupling field is identically zero, and hence $w_{free}(0,t) = 0$ for all time $t > 0$. Since our system decouples, we consider the related system of ordinary differential equations. Let us write the system as a first order system with the variable Q:

$$Q = \begin{bmatrix} \mathbf{q}^T & \dot{\mathbf{q}}^T & \ddot{\mathbf{q}}^T \end{bmatrix}^T. \tag{4.7}$$

Differentiating the reduced system yields

$$\dot{Q} = AQ, \tag{4.8}$$

where

$$A = \begin{bmatrix} 0 & I & 0 \\ 0 & 0 & I \\ \frac{\kappa^2}{2c}M^{-1}Ones(n) & -M^{-1}V & -M^{-1}S \end{bmatrix}. \tag{4.9}$$

PROPOSITION 4.1. *If $\kappa \neq 0$, then the system* (4.8) *is unstable.*

Proof. Since $\mathrm{Trace}(M^{-1}S) = -\mathrm{Trace}(SM^{-1}) = -\mathrm{Trace}(M^{-1}S)$, $M^{-1}S$ is traceless. For nonzero κ, we compute the rank of A as $\mathrm{rank}(A) = 2n+1$. The matrix A has an odd number $(2n+1)$ of nonzero eigenvalues which sum to zero. Since the nonzero eigenvalues satisfy an odd degree polynomial with real coefficients, A has at least one nonzero real eigenvalue. Hence, A has an eigenvalue with positive real part; thus the system is unstable. ∎

Example. Assume $n = 2$, $M = I$, $S = \left[\begin{smallmatrix} 0 & -B \\ B & 0 \end{smallmatrix}\right]$, and $V = \left[\begin{smallmatrix} \alpha & 0 \\ 0 & \beta \end{smallmatrix}\right]$. Computing the characteristic equation of the matrix A, we have

$$p(\mu) = \mu\left(\mu^5 + (B^2+\alpha+\beta)\mu^3 - 2\frac{\kappa^2}{2c}\mu^2 + \alpha\beta\mu - \frac{\kappa^2}{2c}(\alpha+\beta)\right). \tag{4.10}$$

Let $\mu_1, \ldots, \mu_5$ be the nonzero eigenvalues of A. Then we have

$$\prod_{i=1}^{5} \mu_i = \frac{\kappa^2}{2c}(\alpha+\beta). \tag{4.11}$$

Note the system is gyroscopically stabilized when $B^2 + \alpha + \beta \geq 2\sqrt{\alpha\beta}$. Also, $\mathrm{Trace}(A) = 0$. Hence if $\gamma(\alpha+\beta) \neq 0$, then A has an eigenvalue with positive real part. In particular, if $\alpha, \beta < 0$ and $\kappa \neq 0$, then there are real negative eigenvalues. Thus, there exists a conjugate pair of eigenvalues with positive real part. Hence the differentiated system is unstable.

We can quantify the rate at which the coupled system becomes unstable. If we additionally have $\alpha \neq \beta$, we use first order perturbation theory to compute the speed at which the eigenvalues leave the imaginary axis,

$$\mu' = \frac{d\mu}{d\gamma}\Big|_{\gamma=0}. \tag{4.12}$$

Computing μ', we have

$$\mu' = \frac{2\mu^2 + (\alpha+\beta)}{5\mu^4 + 3(w_0^2+w_1^2)\mu^2 + w_0^2 w_1^2}, \tag{4.13}$$

where the eigenvalues of the unperturbed system are $\pm iw_0, \pm iw_1$. Simplifying in terms of w_0 and w_1, we have

$$(\pm iw_j)' = \frac{-2w_j^2 + (\alpha+\beta)}{2w_j^2(w_j^2 - w_{1-j}^2)}. \tag{4.14}$$

We compare μ' with the μ' from a purely dissipative perturbation (see the analogous calculation in [19], [5] and references therein); we have

$$(\pm iw_j)' = \frac{(\pm iw_j)'_{dissipative}}{w_j^2}. \tag{4.15}$$

Since we use the differentiated systems, we require the existence of higher derivatives. In particular, a C^3 solution to the reduced system (4.6) is a solution to the differentiated system (4.8). Conversely, a solution to the differentiated system (4.8) is a solution to the reduced system (4.6) if initial conditions are satisfied. Satisfying

the initial conditions imposes a mild linear constraint on the system that is easily satisfied. We summarize the result with a theorem.

THEOREM 4.2. *The Chetaev system coupled to the standard, nondispersive wave equation via nonlocal coupling* (4.2)*, where* $\chi(z)$ *is the Dirac-*δ *distribution, yields the reduced finite dimensional system* (4.6)*. All* C^2 *solutions of this system are unstable.*

Proof. Let us write the solution to the differentiated problem as

$$\mathbf{q}(t) = \sum_i \lambda_i \mathbf{A}_i e^{\mu_i t}, \tag{4.16}$$

where $\mu_i, \mathbf{A_i}$ are eigenvalues and position components of the eigenvectors for the linear system and λ_i is a scaling chosen to satisfy initial conditions. Evaluation of (4.6) at $t = 0$ with $w_{free} = 0$ yields

$$M\ddot{\mathbf{q}}(0) + S\dot{\mathbf{q}}(0) + V\mathbf{q}(0) = \mathbf{0}. \tag{4.17}$$

We have

$$\ddot{\mathbf{q}}(0) = \sum_i \mu_i^2 \mathbf{A}_i, \qquad \dot{\mathbf{q}}(0) = \sum_i \mu_i \mathbf{A}_i, \qquad \mathbf{q}(0) = \sum_i \mathbf{A}_i. \tag{4.18}$$

Using the fact that μ_i is an eigenvalue of the differentiated system, we have

$$(\mu_i^3 M + \mu_i^2 S + \mu_i V - \gamma Ones(n))\mathbf{A}_i = \mathbf{0}. \tag{4.19}$$

Substituting, the initial condition is satisfied if

$$\gamma Ones(n) \sum_{i,\mu_i \neq 0} \frac{\lambda_i}{\mu_i} \mathbf{A}_i = \mathbf{0}. \tag{4.20}$$

This is just a linear constraint on the initial conditions, which can be satisfied while exhibiting a negative eigendirection. ∎

This instability is unlike the effect of Rayleigh dissipation of the type in gyroscopic Lamb coupling (3.5), i.e., dissipation arising from a term consisting of a positive definite symmetric matrix multiplying velocities. For small coupling, Rayleigh dissipation induces instability only if the Chetaev system is gyroscopically stable (i.e., it is unstable for $B = 0$ but stable for suitably large B). In the nonlocal field coupling model, instability is always induced. (See Chetaev [8] and [5] for a discussion of Rayleigh dissipation induced instability).

Example 1. For $n = 2$, $\alpha = -1$, $\beta = -2$, $c = 1$, and $B = 3$, the origin of the uncoupled system is gyroscopically stabilized. Increasing the coupling parameter, we show that the weaker eigenvalues destabilize as κ increases from 0 to 1 in Figure 5.

Example 2. As discussed above, we have shown that nonlocal coupling has a broader destabilizing effect than dissipation. In particular, the integral coupling can destabilize a system regardless of whether or not it is gyroscopically stabilized, while Rayleigh dissipative perturbations destabilize a Chetaev system only if it is initially gyroscopically stabilized. For $\alpha = 1$, $\beta = 2$, $c = 1$, and $B = 3$, we show numerically how increasing the coupling parameter destabilizes the system; see Figure 6.

4.2. Dispersive, nonlocal wave field coupling to a Chetaev system. In this section, we demonstrate that the nature of the wave field, to which the Chetaev system is coupled, has a significant impact on the stability of the overall system. We

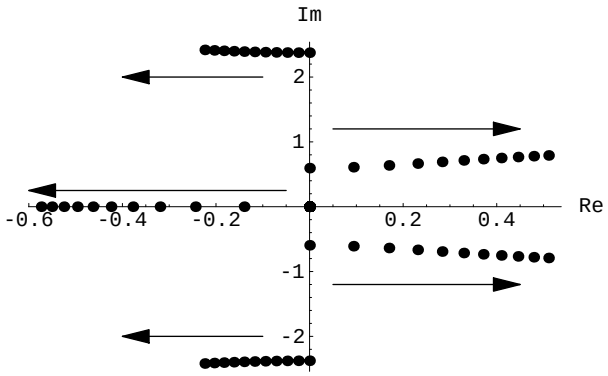

FIG. 5. *Destabilization of a gyroscopically stabilized system.*

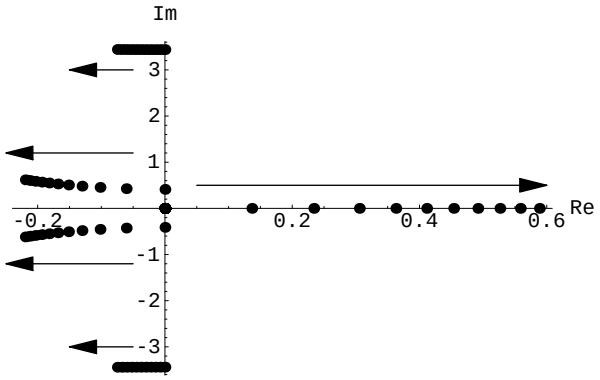

FIG. 6. *Destabilization of stabilized system ($\alpha = 1, \beta = 2, B = 3, c = 1$). κ increases from* 0 *to* 1. *A lone eigenvalue escapes from the origin, while the eigenvalues of the original system move into the left half plane.*

now consider the case of a gyroscopic system coupled to the linear Klein–Gordon equation, a standard dispersive wave equation,

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \kappa \int_{\mathbb{R}} \chi(z) w(z,t) d\xi \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}, \tag{4.21}$$

$$\frac{\partial^2 w}{\partial t^2} - c^2 \frac{\partial^2 w}{\partial z^2} + m^2 w = \kappa \chi(z) \begin{bmatrix} 1 \dots 1 \end{bmatrix} \mathbf{q}.$$

In this case, we show that a region of stability is possible for small coupling.

4.2.1. Energy bounds. For some potentials, we can explicitly show that the Hamiltonian is positive definite and hence can be used to bound the motion of the system. In the case that the Hamiltonian is indefinite, our system may or may not be stable. The main stability results of this section we present in the following theorem.

THEOREM 4.3. *If $|\kappa| < \min(m^2, c^2)$, then the nonlocal dispersive wave coupling to a mechanical gyroscopic system* (4.21)*, with $\chi(z) = \delta(z)$, is stable if $V - |\kappa| Ones(n)$*

is positive definite, where Ones(n) is an $n \times n$ matrix with each entry equal to unity. Explicitly, we have a uniform bound of $\|w\|_{H^1}$, $\|w_t\|$, $|\mathbf{q}|$, and $|\dot{\mathbf{q}}|$ in terms of initial energy.

Proof of Theorem 4.3. We will use energy estimates to give a uniform bound in phase space of the gyroscopic system coupled to the Klein–Gordon equation.

We use the form of the Chetaev system with the magnetic terms in the symplectic form, Ω. In this case, the Hamiltonian of the coupled system becomes

$$H = \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T V\mathbf{q} + \frac{1}{2}\int_{\mathbb{R}} w_t^2 + c^2 w_z^2 + m^2 w^2 dz - \kappa w(0,t)\mathbf{q}_\Sigma, \tag{4.22}$$

where $\mathbf{q}_\Sigma = \begin{bmatrix}1 \dots 1\end{bmatrix}\mathbf{q}$. Using the Cauchy–Schwarz inequality, we have the following energy estimate:

$$\begin{aligned} H &\geq \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T V\mathbf{q} \\ &\quad + \frac{1}{2}(\|w_t\|_{L_2}^2 + \min(c^2, m^2)\|w\|_{H^1}^2) - \frac{1}{2}|\kappa|(w(0,t)^2 + (\mathbf{q}_\Sigma)^2) \\ &= \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T (V - |\kappa| Ones(n))\mathbf{q} \\ &\quad + \frac{1}{2}(\|w_t\|_{L_2}^2 + \min(c^2, m^2)\|w\|_{H^1}^2) - \frac{1}{2}|\kappa| w(0,t)^2, \end{aligned} \tag{4.23}$$

where $Ones(n)$ is an $n \times n$ matrix with all entries equal to unity. From a standard Sobolev inequality, we have the result that if $w \in C_0^1(\mathbb{R}^2)$, then $w(0,t)^2 \leq \|w\|_{H^1}^2$. Using the Sobolev inequality, we have another bound on the energy:

$$\begin{aligned} H &\geq \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T \Big(V - |\kappa| Ones(n)\Big)\mathbf{q} \\ &\quad + \frac{1}{2}\Big(\|w_t\|_{L_2}^2 + (\min(c^2, m^2) - |\kappa|)\|w\|_{H^1}^2\Big). \end{aligned} \tag{4.24}$$

Our Hamiltonian is positive definite if $|\kappa| < \min(c^2, m^2)$ and the matrix $\tilde{H}$ is positive definite, where

$$\tilde{H} = \begin{bmatrix} V - |\kappa| Ones(n) & 0 \\ 0 & M^{-1} \end{bmatrix}. \tag{4.25}$$

Equivalently, H is positive definite if $|\kappa| < \min(c^2, m^2)$ and $V - |\kappa| Ones(n)$ is positive definite. ∎

By the same argument we obtain the following theorem.

THEOREM 4.4. *Suppose $|\kappa| < \frac{1}{n}\min(m^2, c^2)$, and let $\lambda_1, \dots, \lambda_n$ be eigenvalues of V. Let $\alpha = \min_{i=1,\dots,n}(|\lambda_i|)$. If $|\kappa| < \alpha$, then the nonlocal dispersive wave field coupling to the Chetaev system* (4.21)*, with $\chi(z) = \delta(z)$, is stable. Explicitly, we have a uniform bound of $\|w\|_{H^1}$, $\|w_t\|$, $|\mathbf{q}|$, and $|\dot{\mathbf{q}}|$ in terms of initial energy.*

Proof. Using the Cauchy–Schwarz inequality in each component of $\mathbf{q}$ in equation (4.23), we have

$$\begin{aligned} H &\geq \frac{1}{2}\mathbf{p}^T M^{-1}\mathbf{p} + \frac{1}{2}\mathbf{q}^T (V - |\kappa| I)\mathbf{q} \\ &\quad + \frac{1}{2}\Big(\|w_t\|_{L_2}^2 + (\min(c^2, m^2) - n|\kappa|)\|w\|_{H^1}^2\Big). \end{aligned} \tag{4.26}$$

∎

4.2.2. Linear algebra and stability of Chetaev systems. By energy estimates, stability is guaranteed if either the matrix $V - |\kappa| Ones(n)$ or the matrix $V - |\kappa| I$ is positive definite. Dispersion enables purely stable Chetaev systems (stable if $S = 0$) to remain stable for small coupling parameters. In this subsection, we prove some spectral results for these perturbed matrices to see how large the perturbation can be and guarantee stability. Even though positive definiteness of the Hamiltonian is a sufficient condition for stability, it is not a necessary condition as seen in gyroscopically stabilized Chetaev systems.

PROPOSITION 4.5. *Let $\lambda_1, \ldots, \lambda_n$ be eigenvalues of a symmetric $n \times n$ matrix V. Let $\alpha = \min_{i=1,\ldots,n}(|\lambda_i|)$. If $|\kappa| < \frac{\alpha}{n}$, then $W = V - \kappa Ones(n)$ has the same signature as V.*

Proof. Since V is symmetric and $Ones(n)$ is symmetric, W is symmetric and hence has real eigenvalues. Since a change of signature requires a zero eigenvalue of the perturbed matrix, we equivalently show

$$\det\Big(V - \kappa Ones(n)\Big) \neq 0 \quad \forall \kappa \in \Big(0, \frac{\alpha}{n}\Big). \tag{4.27}$$

If V and $Ones(n)$ commute, we can find a change of basis which simultaneously diagonalizes both V and $Ones(n)$. Working in this basis, we have that

$$\begin{aligned} \det\Big(V - \kappa Ones(n)\Big) &= \det\Big(\mathrm{diag}(\lambda_1, \ldots, \lambda_n) - \kappa \mathrm{diag}(\sigma(0, \ldots, 0, n))\Big) \\ &\neq 0 \qquad \forall \kappa \in \Big(0, \frac{\alpha}{n}\Big), \end{aligned} \tag{4.28}$$

where σ is a permutation of n elements. The eigenvalues of W are the eigenvalues of V with the exception that one of the eigenvalues is moved to the left by κn units. Hence if $0 < \kappa < \frac{\alpha}{n}$, then V and W have the same signature, as desired.

In the general case, we define a function f of κ as follows:

$$f(\kappa) = \det\Big(V - \kappa Ones(n)\Big). \tag{4.29}$$

Changing bases so that $Ones(n)$ is diagonal, we have

$$f(\kappa) = \det(\tilde{V} - \kappa \mathrm{diag}(n, 0, 0, \ldots, 0)), \tag{4.30}$$

where $\tilde{V}$ does not depend on κ. Hence f is linear in κ.

We now find a bound on the slope of $f(\kappa)$.

$$\begin{aligned} f'(\kappa) = f'(0) &= \lim_{\epsilon \to 0} \frac{1}{\epsilon}(f(\epsilon) - f(0)) = \lim_{\epsilon \to 0} \frac{1}{\epsilon}\Big(\det\Big(V - \epsilon Ones(n)\Big) - \det(V)\Big) \\ &= \lim_{\epsilon \to 0} \frac{1}{\epsilon}\Big(f(0)\det\Big(I - \epsilon(V^{-1} Ones(n))\Big) - f(0)\Big) \\ &= \lim_{\epsilon \to 0} \frac{1}{\epsilon}\Big(f(0)\left(1 - \epsilon \mathrm{Trace}\Big(V^{-1} Ones(n)\Big) + O(\epsilon^2)\right) - f(0)\Big) \\ &= -\det(V)\mathrm{Trace}\Big(V^{-1} Ones(n)\Big). \end{aligned} \tag{4.31}$$

Let C be an orthogonal matrix that diagonalizes $Ones(n)$ to $D = \mathrm{diag}(n, 0, 0, \ldots, 0)$.

$$\begin{aligned} \mathrm{Trace}\Big(V^{-1} Ones(n)\Big) &= \mathrm{Trace}\Big(C V^{-1} C^{-1} C Ones(n) C^{-1}\Big) \\ &= \mathrm{Trace}\Big(C V^{-1} C^{-1} D\Big). \end{aligned} \tag{4.32}$$

A well-known result of [25] states that the diagonal elements of $CV^{-1}C^{-1}$ lie in the convex hull of the permutations of $\{\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_n}\}$. Minimizing over permutations yields

$$\left|\text{Trace}\Big(CV^{-1}C^{-1}D\Big)\right| \leq \max_{d=(d_1,\ldots,d_n)} \left(\frac{nd_1}{|\lambda_{\sigma(1)}|} + \sum_{i=2}^{n} \frac{d_2}{|\lambda_{\sigma(i)}|}\right), \tag{4.33}$$

where σ is a permutation of n elements and $d_i \geq 0$ with $\sum_{i=1}^{n} d_i = 1$. The right-hand side of the above equation is a linear function on a convex set and hence attains its maximum at an extreme point,

$$\left|\text{Trace}\Big(CV^{-1}C^{-1}D\Big)\right| \leq \max_{i\in\{1,\ldots,n\}} \Big(\frac{n}{|\lambda_i|}\Big) \leq \frac{n}{\alpha}. \tag{4.34}$$

Let $\beta = \max_{i=1,\ldots,n}(|\lambda_i|)$. Finally, we have a bound on the slope of $f(\kappa)$,

$$\frac{|f(0)|}{\beta/n} \leq |f'(\kappa)| \leq \frac{|f(0)|}{\alpha/n}. \tag{4.35}$$

Thus for $|\kappa| < \frac{\alpha}{n}$ we have $f(\kappa) \neq 0$; hence the signatures of V and of $V - \kappa Ones(n)$ are the same, as desired. ∎

COROLLARY 4.6. *Let $\lambda_1, \ldots, \lambda_n$ be eigenvalues of a symmetric, positive definite $n \times n$ matrix V. Suppose $\kappa > \max_{i=1,\ldots,n}(\lambda_i)$. Then $V - \kappa Ones(n)$ has a different signature from the signature of V. In particular, $V - \kappa Ones(n)$ has at least one negative eigenvalue.*

Proof. For $\kappa > \max_{i=1,\ldots,n}(\lambda_i)$, we have $\text{Trace}(V - \kappa Ones(n)) < 0$. A symmetric matrix with negative trace has at least one negative eigenvalue. ∎

COROLLARY 4.7. *Let $\lambda_1, \ldots, \lambda_n$ be eigenvalues of a symmetric $n \times n$ matrix V. Suppose $|\lambda_i| > 0$ for $i = 1, \ldots, n$. Let $\alpha = \min_{i=1,\ldots,n}(|\lambda_i|)$ and $\beta = \max_{i=1,\ldots,n}(|\lambda_i|)$. We have the following results:*

- *As $|\kappa|$ increases, the matrix $V - |\kappa|Ones(n)$ changes signature at most once.*
- *If $V - |\kappa|Ones(n)$ changes signature, it does so for $|\kappa| \leq \frac{\beta}{n}$.*
- *If $V - |\kappa|Ones(n)$ changes signature, then an odd number of eigenvalues change sign.*

Proof. Linearity of $f(\kappa) = \det(V - \frac{\kappa}{n}Ones(n))$ in κ proves the first and third claims. Bounds in the $f'(\kappa)$ prove the second claim. ∎

4.2.3. Reduction of dispersive system to a finite dimensional system. Analogously to the computation in section 4.1.1, we eliminate the dynamics of the wave field to obtain reduced dynamics of a perturbed Chetaev system. Taking the Fourier transform of the field equation, we have

$$\ddot{\hat{w}} + \omega^2(k)\hat{w} = \kappa\hat{\chi}\mathbf{q}_\Sigma(t), \tag{4.36}$$

where $\omega = \sqrt{c^2k^2 + m^2}$ and

$$\mathbf{q}_\Sigma(s) = \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}^T \mathbf{q}(s).$$

Let $\hat{g}$ be the Green's function for the above equation,

$$\ddot{\hat{g}} + \omega^2\hat{g} = \delta(t), \qquad \hat{g} = H(t)\frac{\sin\omega t}{\omega}, \tag{4.37}$$

where $H(t)$ is the Heaviside function. Computing $w(0,t)$ from the Green's function, we have

$$\begin{aligned} w(0,t) &= w_{free}(0,t) + \frac{1}{2\pi}\int_{\mathbb{R}} \hat{w}\ dk \\ &= w_{free}(0,t) + \frac{1}{2\pi}\int_{\mathbb{R}} (\kappa\hat{\chi}\mathbf{q}_\Sigma) * \hat{g}\ dk \\ &= w_{free}(0,t) + \frac{\kappa}{2\pi}\int_{\mathbb{R}}\int_{\mathbb{R}} \hat{\chi}\mathbf{q}_\Sigma(s)\hat{g}(t-s)\ ds\ dk, \end{aligned} \tag{4.38}$$

where w_{free} is a homogeneous solution to the dispersive wave equation. Assuming that the coupling starts at $t = 0$, we have $\mathbf{q}_\Sigma(t) = 0$ for $t < 0$. We can interchange the order of integration,

$$w(0,t) = w_{free}(0,t) + \frac{\kappa}{2\pi}\int_0^t \int_{\mathbb{R}} \hat{\chi}\mathbf{q}_\Sigma(s)\frac{\sin\omega(t-s)}{\omega}\ dk\ ds. \tag{4.39}$$

Choosing χ to be the Dirac-δ distribution and zero initial conditions in the wave field, the reduced dynamics becomes

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \frac{\kappa^2}{2\pi}\int_0^t \int_{\mathbb{R}} \mathbf{q}_\Sigma(s)\frac{\sin\omega(t-s)}{\omega}\ dk\ ds \begin{bmatrix} 1 \\ \vdots \\ 1 \end{bmatrix}. \tag{4.40}$$

Explicitly using the form of the Klein–Gordon coupling, we can integrate the interior integral,

$$\int_{\mathbb{R}} \frac{\sin\omega s}{\omega} dk = 2\int_m^\infty \frac{\sin\omega s}{c\sqrt{\omega^2 - m^2}} d\omega = \frac{\pi}{c} J_0(ms), \tag{4.41}$$

where J_0 is the Bessel function of the first kind. We obtain an integrodifferential equation for the reduced dynamics,

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \frac{\kappa^2}{2c} Ones(n) \int_0^t J_0(m(t-s))\mathbf{q}(s)\ ds. \tag{4.42}$$

From the reduced dynamics (4.42), we can investigate the stability.

4.3. Asymptotic analysis and numerical simulations. For small coupling, we have shown that strongly stable Chetaev systems remain stable for $m \neq 0$ by Theorems 4.3 and 4.4. However, the energy bound results yield no information for gyroscopically stabilized Chetaev systems. Using the compact reduced form (4.42), asymptotic analysis suggests that gyroscopic systems maintain their stability under dispersive wave field perturbations. Moreover, the asymptotic analysis also suggests that an unstable system may be stabilized for a band of coupling parameters. In this section, we develop asymptotic expansions for the reduced dynamics (4.42) and compare the results with numerical simulations.

For large values of m, the wave field's effect on the Chetaev system appears to be a convolution with an approximate identity, $mJ_0(mt)$. Since $J_0(t)$ is not in $L^1(\mathbb{R})$, showing the approximate identity nature of the convolution becomes nontrivial, but nonetheless true, which is summarized in a theorem.

THEOREM 4.8. *Consider the integrodifferential equation* (4.42) *with the nonresonant hypothesis* H1 *and the stability hypothesis* H2*:*

H1. $M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = O(\kappa^2)$,

H2. $\mathbf{q}$ *and* $\dot{\mathbf{q}}$ *are bounded.*

As the dispersion parameter, m, tends to infinity, we have an asymptotic expansion for the dynamics,

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + \Big(V - \frac{\kappa^2}{2mc} Ones(n)\Big)\mathbf{q} = O(\kappa^2 m^{\frac{-3}{2}}). \tag{4.43}$$

Since the error of the asymptotic expansion is $O(\kappa^2 m^{\frac{-3}{2}})$, the expansion will remain valid even for large coupling parameter κ, provided m is sufficiently large. The hypotheses H1 and H2 guarantee the validity of the expansion, but numerical simulations suggest that the expansion is accurate even when the system becomes unstable. In either case, the stability of the dynamical system (4.43) is a necessary condition for the stability of the coupled Chetaev system. If we relax the H2 hypothesis, the asymptotic expansion holds over any finite time interval.

We also note that the asymptotic expansion is consistent with the results from energy bounds. In particular, we can use the results from section 4.2.2 to investigate the stability of the Chetaev system

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + \Big(V - \frac{\kappa^2}{2mc} Ones(n)\Big)\mathbf{q} = 0. \tag{4.44}$$

For small values of m, we retain the nondispersive wave field dynamics.

THEOREM 4.9. *An asymptotic expansion of the reduced wave field dynamics* (4.42)*, as m tends to zero, is given by*

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \frac{\kappa^2}{2c} Ones(n) \int_0^t \mathbf{q}(s)ds + O(m). \tag{4.45}$$

We now begin the proofs of the theorems.

Proof of Theorem 4.8. The strategy used in this proof is to reduce the coupling term to a convolution with an approximate identity though integration by parts and substitution of H1. To simplify notation, we define the following integrals for Bessel function parameters $\nu \in \{0, 1\}$ and $n \in \{0, 1, 2\}$ derivatives of $\mathbf{q}$:

$$I_{n,\nu} = \int_0^t \frac{J_\nu(m(t-s))}{(t-s)^\nu} \frac{d^n\ \mathbf{q}(s)}{ds^n} ds. \tag{4.46}$$

In the new notation, our reduced system becomes

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} = \frac{\kappa^2}{2c} Ones(n) I_{0,0}. \tag{4.47}$$

Integrating $I_{0,0}$ by parts and using the fact that $sJ_0(s) = d/ds(sJ_1(s))$, we have

$$\begin{aligned}
I_{0,0} &= \int_0^t J_0(m(t-s))\mathbf{q}(s)ds \\
&= \int_0^t J_0(m(t-s))(t-s)\frac{\mathbf{q}(s)}{t-s} ds \\
&= -\frac{1}{m} J_1(m(t-s))\mathbf{q}(s)\Big|_0^t + \frac{1}{m}\int_0^t J_1(m(t-s))\left(\dot{\mathbf{q}}(s) + \frac{\mathbf{q}(s)}{t-s}\right) ds \\
&= \frac{J_1(mt)}{m}\mathbf{q}(0) + \frac{1}{m} I_{0,1} + \frac{1}{m^2} J_0(m(t-s))\dot{\mathbf{q}}(s)\Big|_0^t - \frac{1}{m^2} I_{2,0} \\
&= \frac{J_1(mt)}{m}\mathbf{q}(0) + \frac{1}{m^2}(\dot{\mathbf{q}}(t) - J_0(mt)\dot{\mathbf{q}}(0)) + \frac{1}{m} I_{0,1} - \frac{1}{m^2} I_{2,0}.
\end{aligned} \tag{4.48}$$

Similarly to the dispersive Lamb model, we recognize $I_{n,1}$ as an approximate identity convolution with $\frac{d^n\mathbf{q}}{dt^n}$ as m tends to infinity.

With the H1 nonresonant hypothesis, we solve $I_{0,0}$ to order κ^2 in terms of approximate identity convolutions, $I_{n,1}$, and nonintegral terms. In particular, we have

$$\ddot{\mathbf{q}} = -M^{-1}S\dot{\mathbf{q}} - M^{-1}V\mathbf{q} + O(\kappa^2). \tag{4.49}$$

We also integrate by parts to simplify $I_{1,0}$:

$$\begin{aligned} I_{1,0} &= \int_0^t J_0(m(t-s))(t-s)\frac{\dot{\mathbf{q}}(s)}{t-s}ds \\ &= -\frac{1}{m}J_1(m(t-s))\dot{\mathbf{q}}(s)\Big|_0^t + \frac{1}{m}\int_0^t J_1(m(t-s))\Big(\ddot{\mathbf{q}}(s) + \frac{\dot{\mathbf{q}}(s)}{t-s}\Big)ds \\ &= \frac{J_1(mt)}{m}\dot{\mathbf{q}}(0) + \frac{1}{m}I_{1,1} + \frac{1}{m}\int_0^t J_1(m(t-s))\ddot{\mathbf{q}}(s)ds. \end{aligned} \tag{4.50}$$

Employing the H1 hypothesis, we have

$$\begin{aligned} I_{1,0} &= \frac{J_1(mt)}{m}\dot{\mathbf{q}}(0) + \frac{1}{m}I_{1,1} \\ &\quad - \frac{1}{m}\int_0^t J_1(m(t-s))\Big(M^{-1}S\dot{\mathbf{q}}(s) + M^{-1}V\mathbf{q}(s)\Big)ds + O(\kappa^2) \\ &= \frac{J_1(mt)}{m}\dot{\mathbf{q}}(0) + \frac{1}{m}I_{1,1} - \frac{1}{m^2}J_0(m(t-s))M^{-1}S\dot{\mathbf{q}}(s)\Big|_0^t + \frac{1}{m^2}M^{-1}SI_{2,0} \\ &\quad - \frac{1}{m}\int_0^t J_1(m(t-s))M^{-1}V\mathbf{q}(s)ds + O(\kappa^2) \\ &= \Big(\frac{J_1(mt)}{m} + \frac{J_0(mt)}{m^2}M^{-1}S\Big)\dot{\mathbf{q}}(0) - \frac{1}{m^2}M^{-1}S\dot{\mathbf{q}}(t) + \frac{1}{m}I_{1,1} + \frac{1}{m^2}M^{-1}SI_{2,0} \\ &\quad - \frac{1}{m}\int_0^t J_1(m(t-s))M^{-1}V\mathbf{q}(s)ds + O(\kappa^2) \\ &= \Big(\frac{J_1(mt)}{m} + \frac{J_0(mt)}{m^2}M^{-1}S\Big)\dot{\mathbf{q}}(0) - \frac{1}{m^2}M^{-1}S\dot{\mathbf{q}}(t) + \frac{1}{m}I_{1,1} + \frac{1}{m^2}M^{-1}SI_{2,0} \\ &\quad + \frac{1}{m^2}M^{-1}V\Big(J_0(mt)\mathbf{q}(0) - \mathbf{q}(t)\Big) + \frac{1}{m^2}M^{-1}VI_{1,0} + O(\kappa^2). \end{aligned} \tag{4.51}$$

Integrating the nonresonant hypothesis H1, we have

$$I_{2,0} = -M^{-1}SI_{1,0} - M^{-1}VI_{0,0} + O(\kappa^2). \tag{4.52}$$

Taking linear combinations of (4.48), (4.51), and (4.52), we have an approximation for $I_{0,0}$ in terms of approximate identity convolutions of the form $I_{n,1}$ and nonintegral terms. Using H2 and invoking the convolution Lemma 3.4, we have

$$\lim_{m\to\infty} I_{n,1} = \frac{d^n}{dt^n}\mathbf{q}(t). \tag{4.53}$$

In particular, the error in the limit is $O(m^{\frac{-1}{2}})$. Collecting highest order terms in m of the linear combination, we have

$$I_{0,0} = \frac{1}{m}I_{0,1} + O(m^{\frac{-3}{2}}) = \frac{1}{m}\mathbf{q}(t) + O(m^{\frac{-3}{2}}). \tag{4.54}$$

Hence we have an asymptotic expansion of the perturbed dynamics,

$$M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + \Big(V - \frac{\kappa^2}{2mc} Ones(n)\Big)\mathbf{q} = O(\kappa^2 m^{\frac{-3}{2}}), \tag{4.55}$$

as desired. ∎

Proof of Theorem 4.9. Since $\mathbf{q}$ analytically depends on the parameter, m, we have

$$\begin{aligned} M\ddot{\mathbf{q}} + S\dot{\mathbf{q}} + V\mathbf{q} &= \frac{\kappa^2}{2c} Ones(n) \int_0^t J_0(m(t-s))\mathbf{q}(s)ds\Big|_{m=0} + O(m) \\ &= \frac{\kappa^2}{2c} Ones(n) \int_0^t \mathbf{q}(s)ds + O(m) \end{aligned} \tag{4.56}$$

as m tends to zero. ∎

We have already shown the instability of the nondispersive wave field coupling, and the asymptotic analysis suggests that the nondispersive limit has a similar instability.

4.3.1. One dimensional example: Simple harmonic oscillator coupled to the Klein–Gordon equation. We illustrate the asymptotic behavior first in the case of a one dimensional Chetaev system coupled to a dispersive wave equation. Consider a simple harmonic oscillator coupled to the Klein–Gordon equation with the following Hamiltonian system:

$$\begin{aligned} H &= H_0 + \kappa^2 H_1, \\ H_0 &= \frac{1}{2}(\dot{x}^2 + \alpha x^2) + \frac{1}{2}\int_{\mathbb{R}} w_t^2 + c^2 w_z^2 + m^2 q^2 dz, \\ H_1 &= -\frac{1}{\kappa} w(0,t)x. \end{aligned} \tag{4.57}$$

The Hamiltonian equations of motion are

$$\begin{aligned} \ddot{x} + \alpha^2 x &= \kappa w(0,t), \\ \ddot{w} - c^2 \frac{\partial^2 w}{\partial z^2} + m^2 w &= \kappa \delta(z) x. \end{aligned} \tag{4.58}$$

We can reduce the coupled system to an integral equation for a perturbed oscillator by solving for $w(0,t)$:

$$\begin{aligned} w(0,t) &= \frac{1}{2\pi}\int_{\mathbb{R}} \hat{w}(k,t)dk \\ &= \frac{\kappa}{2\pi}\int_0^t x(s)\int_{\mathbb{R}} \frac{\sin(\omega(t-s))}{\omega} dk ds \\ &= \frac{\kappa}{2c}\int_0^t J_0(m(t-s))x(s)ds, \end{aligned} \tag{4.59}$$

where $\omega = \sqrt{c^2k^2 + m^2}$ and J_0 is the Bessel function of the first kind. The perturbed oscillator remains Hamiltonian with the following dynamics:

$$\ddot{x} + \alpha^2 x = \frac{\kappa^2}{2c}\int_0^t J_0(m(t-s))x(s)ds. \tag{4.60}$$

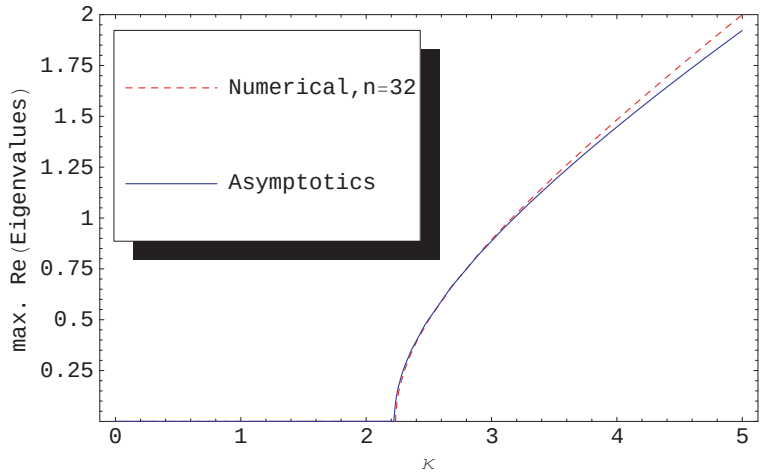

FIG. 7. *Bifurcation of eigenvalues. One dimensional dispersive wave field coupling:* $\Omega = 1$, $n = 32$, $m = 5$, $c = 1$, *and* $\alpha = 1$.

For the large m limit, we have

$$\ddot{x} + \left(\alpha^2 - \frac{\kappa^2}{2mc}\right) x \simeq 0. \tag{4.61}$$

Figure 7 shows a bifurcation diagram of the asymptotic results compared to a numerical solution to the full system. The maximum real part of the spectrum is plotted as a function of κ. The full coupled system is discretized with lattice size Ω and n lattice points for the wave system.

4.3.2. Two dimensional gyroscopic system coupled to a dispersive wave equation. The interesting gyroscopic behavior of a Chetaev system is captured in the two dimensional model. We see from section 4.2.2 the large m coupling can effectively move an eigenvalue of V to the left. The continuous nature of the movement allows for bands of stability for small coupling parameter κ and instability for larger coupling. We demonstrate, with numerical results, that stability is maintained for small coupling parameter. See Figures 8 and 9.

The effective movement of an eigenvalue of V allows for an interesting gyroscopic stabilization of an unstable Chetaev system for an interval of positive coupling parameters κ. We realize this dispersive wave field stabilization numerically and asymptotically in Figure 10.

5. The nonabelian setting. In this section we present an example of wave field coupling to a more complicated mechanical system—a rigid body with rotors. The configuration space is this case is the cross product of a nonabelian group, $SO(3)$, and two copies of the circle. This system models a controlled satellite. To analyze this system we need a little more geometry.

5.1. Normal form of principle bundles. Here we present a geometric development of the Chetaev system as a normal form of a group action on a mechanical system. For a more complete development of the normal forms and reduction theory of nonabelian group actions, see [5] and [26], from which we highlight some results.

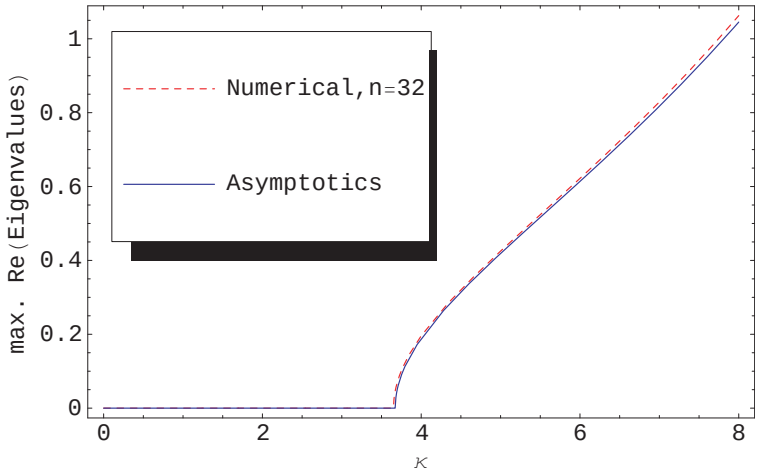

FIG. 8. *Bifurcation of eigenvalues. Two dimensional dispersive wave field coupling to stable Chetaev system:* $\Omega = 1$, $n = 32$, $m = 10$, $c = 1$, $\alpha = 1$, $\beta = 2$, *and* $B = 3$.

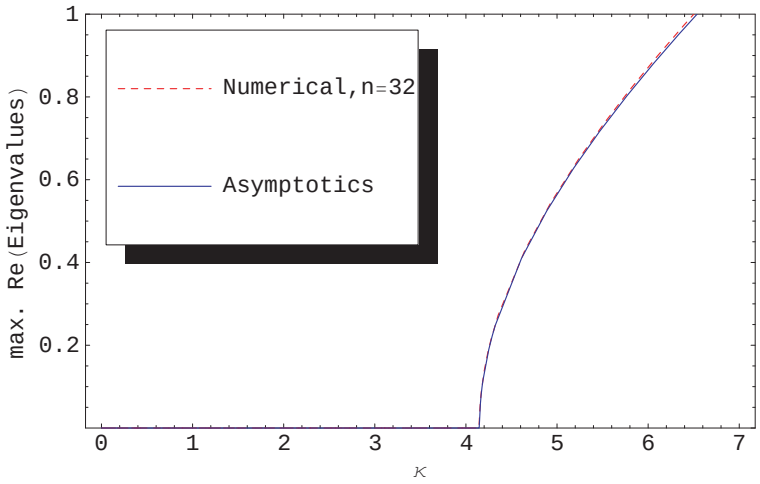

FIG. 9. *Bifurcation of eigenvalues. Two dimensional dispersive wave field coupling to gyroscopically stabilized Chetaev system:* $\Omega = 1$, $n = 32$, $m = 10$, $c = 1$, $\alpha = -1$, $\beta = -2$, *and* $B = 3$.

We show that the Chetaev system is the normal form of the linearized motion about a relative equilibrium of an abelian group action.

We consider the configuration space, Q, to be a Riemannian manifold with metric $\langle\langle\ ,\ \rangle\rangle$. Let G be a Lie group which acts freely on Q by isometries. By lifting the group action to the tangent bundle, TQ, or to the cotangent bundle, T^*Q, we have that G acts symplectically. For a mechanical system, the Lagrangian is of the form

$$L(q,v) = \frac{1}{2}\|v\|_q^2 - V(q), \tag{5.1}$$

and the Hamiltonian is of the form

$$H(q,p) = \frac{1}{2}\|p\|_q^2 + V(q), \tag{5.2}$$

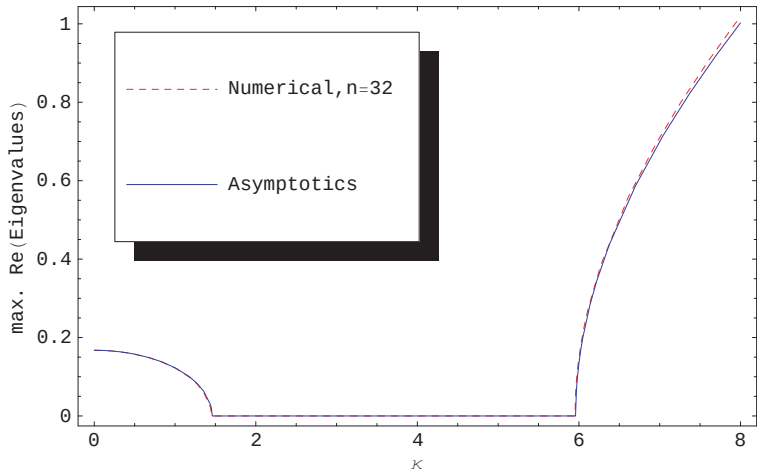

FIG. 10. *Bifurcation of eigenvalues. Two dimensional dispersive wave field coupling to unstable Chetaev system:* $\Omega = 1$, $n = 32$, $m = 10$, $c = 1$, $\alpha = \frac{1}{10}$, $\beta = -2$, *and* $B = 3$.

where $\|\cdot\|_q$ is the norm on T_qQ or the norm induced on T_q^*Q, and where V is a G-invariant potential. Since G acts freely on Q, the projection $\pi : Q \to Q/G$ defines a principle G-bundle.

Recall that the infinitesimal generator of $\xi \in \mathfrak{g}$ on Q is denoted ξ_Q and defined

$$\xi_Q(q) = \frac{d}{dt}\Big|_{t=0} \exp(\xi t) \cdot q. \tag{5.3}$$

For each $q \in Q$, we can define the *locked inertia tensor* to be the map $\mathbb{I} : \mathfrak{g} \to \mathfrak{g}^*$ defined by $\langle \mathbb{I}\eta, \xi \rangle = \langle\langle \eta_Q(q), \xi_Q(q) \rangle\rangle$. For coupled rigid bodies, $\mathbb{I}(q)$ is the classical moment of inertia tensor. We can now define a mechanical connection A.

DEFINITION 5.1. *We define the* mechanical connection *on the principle bundle* $Q \to Q/G$ *to be the map* $A : TQ \to \mathfrak{g}$ *given by* $A(q, v) = \mathbb{I}(q)^{-1}(\mathbf{J}(q, v))$, *where* $\mathbf{J} : TQ \to \mathfrak{g}^*$ *is the* momentum map *defined by* $\langle \mathbf{J}(q, v), \xi \rangle = \langle\langle v, \xi_Q(q) \rangle\rangle$. *In other words,* A *is the map that assigns to each* (q, v) *the corresponding angular velocity of the locked system.*

For $\mu \in \mathfrak{g}^*$, we let G_μ be the isotropy subgroup for the co-adjoint action of G on $\mathfrak{g}^*$,

$$G_\mu = \{g \in G \mid Ad^*_{g^{-1}}\mu = \mu\}. \tag{5.4}$$

The mechanical connection provides a natural decomposition into a horizontal space, hor_q, and a vertical space, ver_q,

$$\text{hor}_q = \{(q, v) \mid \mathbf{J}(q, v) = 0\} \subset T_qQ \tag{5.5}$$

$$\text{ver}_q = \{\xi_Q(q) \mid \xi \in \mathfrak{g}\} = \mathfrak{g} \cdot q \subset T_qQ. \tag{5.6}$$

The horizontal space is the space horizontal to G-orbits. The vertical space is the kernel of the projection map π.

We obtain the Chetaev system from the reduced dynamics of a Hamiltonian system about a *relative equilibrium*, $z_e = (q_e, v_e)$, defined by the Hamiltonian vector field at z_e pointing in the direction of the group orbit through z_e,

$$X_H(z_e) \in T_{z_e}(G \cdot z_e). \tag{5.7}$$

From the relative equilibrium theorem, there exists a $\xi \in \mathfrak{g}$ such that z_e is a critical point of the augmented Hamiltonian, H_ξ,

$$H_\xi(z) = H(z) - \langle \mathbf{J}(z) - \mathbf{J}(z_e), \xi \rangle. \tag{5.8}$$

To investigate the stability of the relative equilibrium modulo $G_{\mathbf{J}(z_e)}$, we analyze the second variation of $\delta^2 H_\xi(z_e)$ (the first variation vanishes at z_e) and the corresponding symplectic form Ω. Assuming that z_e is a regular point and $\mathbf{J}(z_e)$ is a generic point of $\mathfrak{g}^*$, we can define a rigid-internal splitting such that $\delta^2 H_\xi(z_e)$ block diagonalizes. The rigid component has a co-adjoint orbit representation, while the internal component, or shape-space, consists of $T^*(Q/G)$.

The rigid component is a subset of the vertical space, ver_{z_e}, orthogonal to the isotropy Lie algebra, $\mathfrak{g}_\mu$, for the momentum of the relative equilibrium $\mu = \mathbf{J}(z_e)$. Explicitly, we have

$$\mathcal{V}_{RIG} = \{\xi_Q(z_e) \in T_{z_e}Q \mid \langle \mathbb{I}\xi, \eta \rangle = 0 \ \forall \eta \in \mathfrak{g}_{\mathbf{J}(z_e)}\}. \tag{5.9}$$

The internal coordinates or shape-space represents the part of the system which is unaffected by the group action, Q/M. Due to the linearization of the system about the relative equilibrium, the internal variables live in $T_{[z_e]}Q/G$:

$$\mathcal{V}_{INT} = \{\delta q \in T_{z_e}Q \mid [\delta q] \in T_{[z_e]}Q/G\}. \tag{5.10}$$

In this splitting ($(r, q, p) \in \mathcal{V}_{RIG} \times \mathcal{V}_{INT} \times \mathcal{V}^*_{INT}$; see [26], [5] and references therein) $\delta^2 H_\xi$ block diagonalizes

$$\delta^2 H_\xi = \begin{bmatrix} A_\mu & 0 & 0 \\ 0 & V & 0 \\ 0 & 0 & M^{-1} \end{bmatrix}, \tag{5.11}$$

with symplectic form, Ω,

$$\Omega = \begin{bmatrix} L_\mu & C & 0 \\ -C^T & S & I \\ 0 & -I & 0 \end{bmatrix}, \tag{5.12}$$

where A_μ is the energy from the co-adjoint orbit block and V is the amended potential.

The linearized Hamiltonian vector field is defined from $\Omega(X_H, \cdot) = dH\cdot$,

$$X_H(r, q, p) = \begin{bmatrix} -L_\mu^{-1}A_\mu & 0 & -L_\mu^{-1}CM^{-1} \\ 0 & 0 & M^{-1} \\ -C^T L_\mu^{-1} A_\mu & -V & -\tilde{S}M^{-1} \end{bmatrix} \begin{bmatrix} r \\ q \\ p \end{bmatrix}, \tag{5.13}$$

where $S = \tilde{S} - C^T L_\mu C$.

5.1.1. Nonabelian example: Rigid body with two internal rotors. We consider a rigid body with two symmetric internal rotors; see Figure 11. For more detail on the stability of the rigid body, see [6] and [5]. The configuration space is $SO(3) \times S^1 \times S^1$, where each of the rotors has a configuration space of S^1. The Lagrangian is a function on the tangent bundle, $T(SO(3) \times S^1 \times S^1)$. Let $\mathbb{I}_{body}$ be the inertia tensor of the rigid body, $\mathbb{I}_{rotor} = \mathrm{diag}(J_1^1, J_2^2, 0)$ the diagonal matrix of rotor inertia about the principle axes, and $\mathbb{I}'_{rotor}$ be the remaining rotor inertia about the other axes. We define the locked inertia tensor, $\mathbb{I}_{lock}$, of the full system as

$$\mathbb{I}_{lock} = \mathbb{I}_{body} + \mathbb{I}_{rotor} + \mathbb{I}'_{rotor} = \mathrm{diag}(B_1, B_2, B_3). \tag{5.14}$$

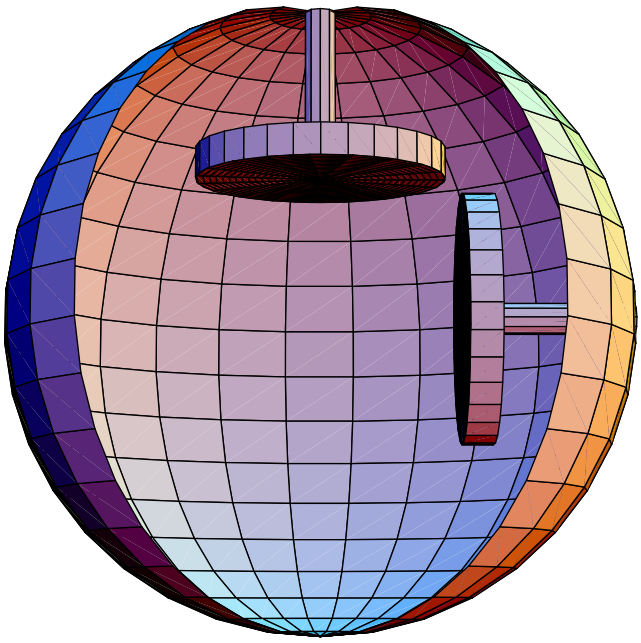

FIG. 11. *Rigid body with two internal rotors.*

Let $\mathbb{I}_{lock} - \mathbb{I}_{rotor} = \mathrm{diag}(A_1, A_2, A_3)$. Assume $B_1 > B_2 > B_3$.

As a simple mechanical system, the Lagrangian is the kinetic energy of the system, i.e., the total kinetic energy of the body plus the total kinetic energy of the rotor.

(5.15)
$$\begin{aligned} L((R,\theta_r),(\Omega,\Omega_r)) &= \frac{1}{2}\Omega\cdot\mathbb{I}_{body}\Omega + \frac{1}{2}\Omega\cdot\mathbb{I}'_{rotor}\Omega + \frac{1}{2}(\Omega+\Omega_r)\cdot\mathbb{I}_{rotor}(\Omega+\Omega_r) \\ &= \frac{1}{2}\Omega\cdot(\mathbb{I}_{lock}-\mathbb{I}_{rotor})\Omega + \frac{1}{2}(\Omega+\Omega_r)\cdot\mathbb{I}_{rotor}(\Omega+\Omega_r), \end{aligned}$$

where $R \in SO(3)$ is the attitude of the rigid body relative to an inertial frame, $\theta_r \in S^1 \times S^1 \times \{0\}$ is the angular configuration of the rotors, $\Omega \in \mathbb{R}^3 \cong \mathfrak{so}(3)$ is the vector of body angular velocities, and $\Omega_r \in \mathbb{R}^2 \times \{0\} \cong T_{\theta_r}(S^1 \times S^1) \times \{0\}$ is the vector of rotor angular velocities about the principle axes with respect to a body fixed frame.

The Euler–Lagrange equations of motion are

(5.16)
$$\begin{aligned} (\mathbb{I}_{lock}-\mathbb{I}_{rotor})\dot{\Omega} &= (\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r)\times\Omega, \\ (\mathbb{I}_{lock}-\mathbb{I}_{rotor})\dot{\Omega}_r &= \Omega\times(\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r), \\ \dot{R} &= R\Omega, \\ \dot{\theta}_r &= \Omega_r. \end{aligned}$$

We consider the normal form of the linearized equations of motion about the relative equilibrium $z_e = (q_e, v_e)$ with $q_e = (R, 0, 0)$ and $v_e = (\Omega^e, \Omega^e_r)$ with $\Omega^e = (0, 0, \omega)^T$

and $\Omega_r^e = (0,0,0)^T$. The relative equilibrium, z_e, is a member of an equivalence class of TQ/G, where the action of $G = SO(3)$ can be lifted from acting on Q by rotations of the rigid body to acting on the tangent bundle isometrically. Notice that the associated Hamiltonian vector field X_H on T^*Q evaluated at z_e points in the direction of the group orbit through z_e,

$$X_H(z_e) = (R\Omega^e, 0, 0, 0) \in T_{z_e}(G \cdot z_e). \tag{5.17}$$

We will use the mechanical connection to split the configuration variables into rigid and internal components. After the reduction of the phase space, TQ/G, the rigid component of the splitting is the subset of the rigid tangent space, $\mathfrak{so}(3)$, orthogonal to the isotropy subgroup $G_\mu = S^1$. The internal component is the part of phase space which is not affected by the group action.

First, we define the rigid component of the principle bundle:

$$\begin{aligned}
\mathcal{V}_{RIG} &= \{\xi_Q(q_e) \in T_{q_e}Q \mid \langle \mathbb{I}(q)\xi, \eta\rangle = 0 \ \forall \eta \in \mathfrak{s}^1 \subset \mathfrak{so}(3)\} \\
&= \{\xi_Q(q_e) \in T_{q_e}Q \mid d\Omega_3 \cdot \xi_Q(q_e) = 0\} \\
&= \{((\delta\Omega_1, \delta\Omega_2, 0) \times R, 0, 0, 0) \in T_{q_e}Q \mid (\delta\Omega_1, \delta\Omega_2, 0) \in \mathfrak{so}(3) \cong \mathbb{R}^3\} \\
&= \{(\delta\Omega_1, \delta\Omega_2) \in \mathbb{R}^2\}.
\end{aligned} \tag{5.18}$$

We can realize $\mathfrak{s}^1$ as the Lie algebra to the isotropy subgroup for $\mathbf{J}(z_e) \in \mathfrak{so}(3)^*$ for the co-adjoint action of $SO(3)$ on $\mathfrak{so}(3)^*$. Thus, the rigid variables, $r = (\delta\Omega_1, \delta\Omega_2)$, are even dimensional and represent the co-adjoint orbit block.

In this case, the internal component is the $T(\mathbb{T}^2)$. We can choose the natural configuration for the shape-space, $q = M^{-1}\delta\theta_r$, with associated reduced momenta, $p = \delta\Omega_r$. From the linearized equations of motions, we have

$$\frac{d}{dt}\begin{bmatrix} r \\ q \\ p \end{bmatrix} = \begin{bmatrix} -L_\mu^{-1}A_\mu & 0 & -L_\mu^{-1}CM^{-1} \\ 0 & 0 & M^{-1} \\ -C^T L_\mu^{-1}A_\mu & -V & -\tilde{S}M^{-1} \end{bmatrix} \begin{bmatrix} r \\ q \\ p \end{bmatrix}, \tag{5.19}$$

where

$$\begin{aligned}
L_\mu &= \begin{bmatrix} 0 & -\frac{1}{\omega} \\ \frac{1}{\omega} & 0 \end{bmatrix}, \quad A_\mu = \begin{bmatrix} \frac{B_3 - B_1}{A_2} & 0 \\ 0 & \frac{B_3 - B_2}{A_1} \end{bmatrix}, \\
M^{-1} &= \begin{bmatrix} \frac{J_1^1}{A_2} & 0 \\ 0 & \frac{J_2^2}{A_1} \end{bmatrix}, \quad \tilde{S} = \begin{bmatrix} 0 & \omega \\ -\omega & 0 \end{bmatrix}, \\
C &= -I, \quad V = 0.
\end{aligned} \tag{5.20}$$

5.1.2. Abelian group action. If the group G is an abelian group, the co-adjoint orbit block becomes trivial. The isotropy subgroup, G_μ, of the co-adjoint action is all of G. Hence the linearized system about a relative equilibrium contains only the internal components,

$$H_{linear} = \begin{bmatrix} V & 0 \\ 0 & M^{-1} \end{bmatrix}, \tag{5.21}$$

with symplectic form

$$\Omega = \begin{bmatrix} S & I \\ -I & 0 \end{bmatrix}. \tag{5.22}$$

The corresponding second order equations are precisely the Chetaev system

$$M\ddot{q} + S\dot{q} + Vq = 0. \tag{5.23}$$

The abelian case is a classical result dating back to [24].

5.2. Nonabelian example of a wave field coupling: Rigid body with internal rotors. In the previous sections, we have coupled a wave equation to the Chetaev system and investigated the stability of the trivial equilibrium. In this section, we demonstrate a similar destabilizing effect for a wave field coupling to the relative equilibrium of a nonabelian group action. In particular, we couple the standard wave equation to a rigid body with internal rotors. We use the same notation as introduced in section 5.1.1. We model internal radiation, that is, the field coupling to the internal rotors:

$$\begin{aligned}
(\mathbb{I}_{lock} - \mathbb{I}_{rotor})\dot{\Omega} &= (\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r) \times \Omega, \\
(\mathbb{I}_{lock} - \mathbb{I}_{rotor})\dot{\Omega}_r &= \Omega \times (\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r) + \kappa \int_{\mathbb{R}} \chi(\xi) u(\xi,t) d\xi \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix}, \\
\dot{\theta}_r &= \Omega_r, \\
\ddot{u} - c^2 u_{\xi\xi} &= \kappa \chi(\xi) Ones(3) \theta_r.
\end{aligned} \tag{5.24}$$

Assuming the distribution χ is the Dirac-δ distribution, the wave equation decouples in precisely the same way as in the abelian case, yielding the following equations of motion for the rigid body:

$$\begin{aligned}
(\mathbb{I}_{lock} - \mathbb{I}_{rotor})\dot{\Omega} &= (\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r) \times \Omega, \\
(\mathbb{I}_{lock} - \mathbb{I}_{rotor})\dot{\Omega}_r &= \Omega \times (\mathbb{I}_{lock}\Omega + \mathbb{I}_{rotor}\Omega_r) + \frac{\kappa^2}{2c} Ones(3) \int_0^t \Omega_r(s) ds, \\
\dot{\theta}_r &= \Omega_r,
\end{aligned} \tag{5.25}$$

ignoring the free wave homogeneous contribution.

We linearize the system about the relative equilibrium $z_e \in \mathfrak{so}(3) \times T(\mathbb{T}^2)$, where $z_e = ((0,0,\omega),(0,0),(0,0))$. We have the following integral equation in terms of $Q = \begin{bmatrix} r & q & p \end{bmatrix}^T$, with $r = \delta\Omega$, $q = M^{-1}\delta\theta_r$, and $p = \delta\Omega_r$:

$$\dot{Q} = \begin{bmatrix} -L_\mu^{-1} A_\mu & 0 & -L_\mu^{-1} C M^{-1} \\ 0 & 0 & M^{-1} \\ -C^T L_\mu^{-1} A_\mu & -V + \frac{\kappa^2}{2mc} (\mathbb{I}_{lock} - \mathbb{I}_{rotor})^{-1} Ones(3) \int_0^t M \cdot ds & -\tilde{S} M^{-1} \end{bmatrix} Q, \tag{5.26}$$

where

$$\begin{aligned}
L_\mu &= \begin{bmatrix} 0 & -\frac{1}{\omega} \\ \frac{1}{\omega} & 0 \end{bmatrix}, \quad A_\mu = \begin{bmatrix} \frac{B_3 - B_1}{A_2} & 0 \\ 0 & \frac{B_3 - B_2}{A_1} \end{bmatrix}, \\
M^{-1} &= \begin{bmatrix} \frac{J_1^1}{A_2} & 0 \\ 0 & \frac{J_2^2}{A_1} \end{bmatrix}, \quad \tilde{S} = \begin{bmatrix} 0 & \omega \\ -\omega & 0 \end{bmatrix}, \\
C &= -I, \quad V = 0.
\end{aligned} \tag{5.27}$$

Differentiating the system, we reduce the integrodifferential equation into a standard ordinary differential equation,

(5.28)
$$\frac{d}{dt}\begin{bmatrix}\dot{r}\\ q\\ \dot{q}\\ \dot{p}\end{bmatrix} = \begin{bmatrix} -L_\mu^{-1}A_\mu & 0 & 0 & -L_\mu^{-1}CM^{-1}\\ 0 & 0 & I & 0\\ 0 & 0 & 0 & M^{-1}\\ -C^TL_\mu^{-1}A_\mu & \frac{\kappa^2}{2mc}(\mathbb{I}_{lock}-\mathbb{I}_{rotor})^{-1}Ones(3)M & -V & -\tilde{S}M^{-1}\end{bmatrix}\begin{bmatrix}\dot{r}\\ q\\ \dot{q}\\ \dot{p}\end{bmatrix}.$$

Implicitly, we define the matrix W as

(5.29)
$$\frac{d}{dt}\begin{bmatrix}r\\ q\\ \dot{q}\\ \dot{p}\end{bmatrix} = W\begin{bmatrix}r\\ q\\ \dot{q}\\ \dot{p}\end{bmatrix}.$$

We can clearly see that the diagonal in W is zero; thus the sum of the eigenvalues is zero. To show instability we need only show that there exists an eigenvalue with nonzero real part. We can also see that the matrix W is rank 5 under the generic condition

$$\omega^2\kappa^2\Big(A_1(B_2-B_3)(B_3-B_2+J_1^1)+A+2(B_1-B_3)(B_3-B_2+J_2^2)\Big)\neq 0. \tag{5.30}$$

Generically, W has an odd number of nonzero eigenvalues. The matrix W has real entries, so the complex eigenvalues come in conjugate pairs. There must exist a real nonzero eigenvalue. Thus, our system becomes unstable.

We have presented only one example of the nonabelian coupling, but the instability is completely analogous to the abelian or Chetaev case. We plan to address the general instability of the nonabelian case in future research.

6. Conclusion. We have presented several mechanisms through which internal energy transfer may destabilize a system. One such mechanism models radiation damping, or energy transfer from a finite dimensional subsystem to an infinite dimensional subsystem.

We have generalized the Lamb model of an oscillator coupled to a wave equation to include coupling of Chetaev systems. For gyroscopic Lamb coupling, energy is transferred from the oscillator into the wave field, inducing instability. The radiation induced instability is analogous to dissipation induced instability studied in [5]. When we include dispersion in the gyroscopic Lamb model, there is effectively a stabilizing shift in the potential of the oscillator to balance the damping term.

Similarly to the gyroscopic Lamb model, the wave field coupling can exhibit radiation induced instability. In contrast to the Lamb model, the wave field coupling to an oscillator does not rely on boundary constraints as a mechanism for energy transfer. We investigate a local coupling whose interaction with an oscillator depends on the strength of the field at a point. While the gyroscopic Lamb model induces instability in gyroscopically stabilized oscillators, the wave field coupling induces instability in all oscillators. For large dispersion, the mechanical system has restricted access to low frequency wave modes, allowing a band of stable coupling parameters to exist. Furthermore, largely dispersive wave field coupling also shifts the potential to allow even unstable oscillators to be stabilized.

In addition to dispersive and nondispersive wave equations, future research plans include investigating the stability of the beam equation coupled to a rigid body. This is of particular interest in modeling antennae on satellites.

Another avenue of research includes coupling multiple oscillators through a wave equation or a beam equation. It might be possible to tune the system so as to trap energy between the oscillators. We can further extend the model to describe a lattice of nonlinear, coupled oscillators, such as the Toda lattice, via an infinite dimensional system.

Appendix A. Spherical pendulum. In this section, we derive the linearized equations of motion for the whirling spherical pendulum about the inverted equilibrium.

Consider a rigid spherical pendulum moving in a constant gravitational field. Let θ, ϕ, and r be the standard spherical coordinates for the pendulum.

We compute the equations of motion in a rotating frame. Since our pendulum is rigid, r is constant. The Lagrangian is

$$L(\mathbf{q}, \dot{\mathbf{q}}) = \frac{1}{2} m \|\dot{\mathbf{q}}\|^2 - U(\mathbf{q}) = \frac{\mathbf{1}}{\mathbf{2}} \mathbf{m}(\mathbf{r^2}\dot{\theta}^{\mathbf{2}} + \mathbf{r^2}\sin^{\mathbf{2}}\theta\dot{\phi}^{\mathbf{2}}) - \mathbf{mg}\cos\theta. \tag{A.1}$$

The Euler–Lagrange equation of motion are

$$mr^2\ddot{\theta} - mr^2\dot{\phi}^2 \sin\theta\cos\theta - mg\sin\theta = 0, \tag{A.2}$$

$$mr^2(\sin^2\theta\ddot{\phi} + 2\sin\theta\cos\theta\dot{\phi}\dot{\theta}) = 0. \tag{A.3}$$

Expanding the Lagrangian about $\theta = \pi$, the stable equilibrium, and keeping terms to second order in θ yields the following Lagrangian:

$$L(\theta, \phi, \dot{\theta}, \dot{\phi}) = \frac{1}{2} m(r^2\dot{\theta}^2 + r^2\theta^2\dot{\phi}^2) + mg\left(1 - \frac{1}{2}\theta^2\right), \tag{A.4}$$

with Euler–Lagrange equations of motion

$$mr^2\ddot{\theta} - mr^2\dot{\phi}^2\theta + mg\theta = 0, \tag{A.5}$$

$$mr^2(\theta^2\ddot{\phi} + 2\theta\dot{\phi}\dot{\theta}) = 0. \tag{A.6}$$

In a rotating coordinate system, we make the change of variables $x = r\theta\cos(\phi - \psi)$, $y = r\theta\sin(\phi - \psi)$, where ψ is the angle of rotation. Let the angular velocity $\omega = \dot{\psi}$ be constant. In the new coordinates the Lagrangian becomes

$$L(x, y, \dot{x}, \dot{y}) = \frac{1}{2} m((\dot{x} - \omega y)^2 + (\dot{y} + \omega x)^2) + mg\left(1 - \frac{x^2 + y^2}{2}\right). \tag{A.7}$$

Our linearized equations of motion are

$$\ddot{x} - 2\omega\dot{y} + (g - \omega^2)x = 0, \tag{A.8}$$

$$\ddot{y} + 2\omega\dot{x} + (g - \omega^2)y = 0. \tag{A.9}$$

We now physically motivate the rotating frame by modeling a rotor, with moment of inertia I, which rotates the pendulum. The Lagrangian is as follows:

$$L(\theta, \phi, \dot{\theta}, \dot{\phi}) = \frac{1}{2} m(r^2\dot{\theta}^2 + r^2\sin^2\theta\dot{\phi}^2) - mg\cos\theta + \frac{1}{2} I\omega^2. \tag{A.10}$$

The Euler–Lagrange equations of motion remain unchanged with an additional equation:

$$mr^2\ddot{\theta} - mr^2\dot{\phi}^2\sin\theta\cos\theta - mg\sin\theta = 0, \tag{A.11}$$

$$mr^2(\sin^2\theta\ddot{\phi} + 2\sin\theta\cos\theta\dot{\phi}\dot{\theta}) = 0, \tag{A.12}$$

$$\dot{\omega} = 0. \tag{A.13}$$

Without a coupling term, a rotating frame is indistinguishable from the inertial frame. The linearization remains identical.

We now wish to stabilize the inverted equilibrium by creating a restoring potential that breaks the symmetry of the motion of the pendulum. Imagine the pendulum with the pivot at the origin. Assume there is an asymmetric potential within the sphere. In particular, we have a potential V dependent on θ and $\phi-\psi$, where ψ is the angle of equatorial rotation of the spherical shell and ϕ is the standard angle of the pendulum.

Assuming that the rotor that is spinning the spherical shell is rotating with a constant angular velocity ω, we compute the Lagrangian

$$L(\theta,\phi,\dot\theta,\dot\phi)=\frac{1}{2}m(r^2\dot\theta^2+r^2\sin^2\theta\dot\phi^2)-mg\cos\theta-V(\theta,\phi-\omega t). \tag{A.14}$$

The Euler–Lagrange equations of motion are

$$\begin{aligned} mr^2\ddot\theta-mr^2\dot\phi^2\sin\theta\cos\theta-mg\sin\theta+\frac{\partial V(\theta,\phi-\omega t)}{\partial\theta}=0,\\ mr^2(\sin^2\theta\ddot\phi+2\sin\theta\cos\theta\dot\phi\dot\theta)+\frac{\partial V(\theta,\phi-\omega t)}{\partial\phi}=0. \end{aligned} \tag{A.15}$$

We work out the equations of motion for an explicit asymmetric potential V:

$$V(\theta,\phi-\psi)=-\frac{mr^2\sin^2\theta}{2}(\alpha\cos^2(\phi-\psi)+\beta\sin^2(\phi-\psi)). \tag{A.16}$$

Expanding the Lagrangian about the inverted equilibrium $\theta=\pi$, and in the rotating coordinate system, we have $x=r\theta\cos(\phi-\psi)$, $y=r\theta\sin(\phi-\psi)$, and

$$L=\frac{1}{2}m((\dot x-\omega y)^2+(\dot y+\omega x)^2)+mg\left(1-\frac{x^2+y^2}{2}\right)+\frac{m}{2}(\alpha x^2+\beta y^2). \tag{A.17}$$

Our linearized equations of motion are

$$\ddot x-2\omega\dot y+(g-\omega^2-\alpha)x=0, \tag{A.18}$$

$$\ddot y+2\omega\dot x+(g-\omega^2-\beta)y=0. \tag{A.19}$$

We would like to perturb the motion of the spherical pendulum by coupling it to a magnetic field.

Let $\mathbf{B}$ be a divergence-free vector field. Let $\mathbf{A}$ be the vector potential, $\mathbf{B}=\nabla\times\mathbf{A}$. Note if $\mathbf{B}$ is a constant magnetic field, we can choose $\mathbf{A}=\frac{1}{2}\mathbf{B}\times\mathbf{q}$.

Assume the bob on a spherical pendulum has a charge e and mass m. The Lagrangian, as a function from TS^2 to $\mathbb{R}$, is

$$L(\mathbf{q},\dot{\mathbf{q}})=\frac{1}{2}m\|\dot{\mathbf{q}}\|^2+\frac{e}{c}\mathbf{A}\cdot\dot{\mathbf{q}}-U(\mathbf{q}) \tag{A.20}$$

$$=\frac{1}{2}m(r^2\dot\theta^2+r^2\sin^2\theta\dot\phi^2)-mg\cos\theta+\frac{e}{c}\mathbf{A}\cdot\dot{\mathbf{q}}. \tag{A.21}$$

We now assume that the magnetic field $\mathbf{B}$ is constant, parallel to the gravitational field. The Lagrangian becomes

$$L(\theta,\phi,\dot\theta,\dot\phi)=\frac{1}{2}m(r^2\dot\theta^2+r^2\sin^2\theta\dot\phi^2)-mg\cos\theta+\frac{e}{2c}B\dot\phi r^2\sin^2\theta. \tag{A.22}$$

The Euler–Lagrange equations are

$$mr^2\ddot{\theta} - mr^2 \sin\theta\cos\theta\dot{\phi}^2 - mg\sin\theta - \frac{e}{c}B\dot{\phi}r^2\sin\theta\cos\theta = 0, \tag{A.23}$$

$$mr^2\sin^2\theta\ddot{\phi} + mr^2\dot{\theta}\sin\theta\cos\theta\left(\dot{\phi} + \frac{eB}{2mc}\right) = 0. \tag{A.24}$$

We expand the Lagrangian about $\theta = \pi$ and keep terms to second order in θ. In the coordinates $x = r\theta\cos(\phi - \psi)$, $y = r\theta\sin(\phi - \psi)$, we have the Lagrangian

$$L = \frac{1}{2}m((\dot{x} - \omega y)^2 + (\dot{y} + \omega x)^2) + mg - \frac{mg + \frac{eB\omega}{c}}{2}(x^2 + y^2) + \frac{eB}{2c}(x\dot{y} - y\dot{x}). \tag{A.25}$$

The angular velocity of rotation ω is constant; hence the Euler–Lagrange equations follow

$$\ddot{x} - \left(2\omega + \frac{eB}{mc}\right)\dot{y} + \left(g - \frac{eB\omega}{mc} - \omega^2\right)x = 0, \tag{A.26}$$

$$\ddot{y} + \left(2\omega + \frac{eB}{mc}\right)\dot{x} + \left(g - \frac{eB\omega}{mc} - \omega^2\right)y = 0. \tag{A.27}$$

Similarly, linearization about the inverted equilibrium yields the following equations of motion:

$$\ddot{x} - \left(2\omega + \frac{eB}{mc}\right)\dot{y} - \left(g + \frac{eB\omega}{mc} + \omega^2\right)x = 0, \tag{A.28}$$

$$\ddot{y} + \left(2\omega + \frac{eB}{mc}\right)\dot{x} - \left(g + \frac{eB\omega}{mc} + \omega^2\right)y = 0. \tag{A.29}$$

We can increase the magnetic field to *gyroscopically* stabilize the inverted equilibrium. Explicitly, for $B^2 \geq \frac{4gm^2c^2}{e^2}$, the inverted equilibrium is gyroscopically stabilized.

Appendix B. Network theory. It is also of interest to discuss the linked Chetaev system and the wave equation from the point of view of network theory and linear systems theory. As have seen, the wave coupling induces instability. It is of interest (see [3]) to analyze infinite dimensional systems from the point of view of systems theory and, in particular, to understand asymptotic stability or instability. One problem of interest is the Darlington synthesis problem (see, e.g., [7], [17] and references therein), where one shows that one can realize any positive real transfer functions by terminating a lossless two port by a 1-ohm resistor. One can then extend this to the infinite dimensional Hamiltonian setting by terminating by an infinite transmission line.

The situation here is somewhat different but related: In particular, we view the Chetaev system as a two port connected to a wave system with integral coupling. The previous calculations show that this system can be reduced to a two port with integral feedback.

Consider the two-degree-of-freedom Chetaev system with inputs:

$$\begin{aligned} \ddot{x} - B\dot{y} + \alpha x &= u_x, \\ \ddot{y} + B\dot{x} + \beta y &= u_y. \end{aligned} \tag{B.1}$$

Without coupling, we can think of this system as a linear four dimensional first order system with two inputs u_x and u_y (to be determined) and two outputs x and y. This makes the Chetaev system a classical two port.

We can also think of the wave field as a first order system:

$$\frac{\partial}{\partial t}\mathbf{w} = A\mathbf{w}, \tag{B.2}$$

where $\mathbf{w} = [w, \dot{w}]^T$ and

$$A = \begin{bmatrix} 0 & 1 \\ m^2 + c^2 \frac{\partial^2}{\partial \xi^2} & 0 \end{bmatrix}.$$

We think of the input as the second variable $\dot{w}$.

With the integral coupling, we connect the finite and the infinite systems through their inputs. Equivalently, the Chetaev system is given dynamical feedback through the wave equation. In this context, the reduced system in each type of coupling (3.35 and 4.42) becomes a first order system with integral feedback. Moreover, the integral feedback affects the Chetaev system in a not-necessarily-Hamiltonian fashion: as we have seen we may have only one unstable eigenvalue.

We remark also that instead of the mechanical systems discussed here we can physically realize the Chetaev system via coupled LC-circuits. The discussion also extends essentially without change to the n port case.

Appendix C. Bessel functions. In this appendix, we explicitly derive the integral formula

$$2\int_m^\infty \frac{\sin \omega s}{c\sqrt{\omega^2 - m^2}} d\omega = \frac{\pi}{c} J_0(ms), \tag{C.1}$$

where J_0 is the Bessel function of the first kind.

Let us begin by taking the Laplace transform, denoted $\mathcal{L}[\cdot]$, with respect to s of the right-hand side of equation (C.1),

$$\mathcal{L}\Big[2\int_m^\infty \frac{\sin \omega s}{c\sqrt{\omega^2 - m^2}} d\omega\Big] = 2\int_0^\infty \int_m^\infty \frac{\sin \omega s}{c\sqrt{\omega^2 - m^2}} e^{-sz} d\omega ds, \tag{C.2}$$

provided $\mathrm{R}e(z) > 0$. Integrating with respect to s, we have

$$\int e^{-sz} \sin \omega s \; ds = -e^{sz} \frac{\omega \cos \omega z + z \sin \omega s}{\omega^2 + z^2} \tag{C.3}$$

and

$$\mathcal{L}\Big[2\int_m^\infty \frac{\sin \omega s}{c\sqrt{\omega^2 - m^2}} d\omega\Big] = 2\int_m^\infty \frac{w}{c\sqrt{\omega^2 - m^2}(\omega^2 + z^2)} d\omega. \tag{C.4}$$

With an appropriate substitution, we use the integral

$$\int \frac{w}{\sqrt{\omega^2 - m^2}(\omega^2 + z^2)} d\omega = \frac{\arctan\Big(\frac{\sqrt{\omega^2 - m^2}}{\sqrt{m^2 + z^2}}\Big)}{\sqrt{m^2 + z^2}} \tag{C.5}$$

to finish computing the Laplace transform:

$$\mathcal{L}\Big[2\int_m^\infty \frac{\sin \omega s}{c\sqrt{\omega^2 - m^2}} d\omega\Big] = \frac{\pi}{c\sqrt{m^2 + z^2}}. \tag{C.6}$$

To finish deriving (C.1), we need only compute the Laplace transform of $J_0(s)$. This computation can be done explicitly with contour integration (see [9]); however, we present a more dynamic approach. From the Bessel differential equation, of which $J_0(s)$ is a solution, we have

$$sJ_0''(s) + J_0'(s) + sJ_0(s) = 0, \qquad J_0(0) = 1, \qquad J_0'(0) = 0, \qquad \int_0^\infty J_0(s)ds = 1. \tag{C.7}$$

Taking the Laplace transform of the differential equation, we obtain

$$-\frac{d}{dz}\Big(z^2\mathcal{L}\Big[J_0\Big] - J_0'(0) - zJ_0(0)\Big) + z\mathcal{L}\Big[J_0\Big] - J_0(0) - \frac{d}{dz}\mathcal{L}\Big[J_0\Big] = 0. \tag{C.8}$$

We solve the above differential equation, with the initial condition $\mathcal{L}[J_0](0) = \int_0^\infty J_0(s)ds = 1$, to get

$$\mathcal{L}\Big[J_0\Big] = \frac{1}{\sqrt{1 + z^2}}. \tag{C.9}$$

A change of variables produces the desired result,

$$\mathcal{L}\Big[\frac{\pi}{c}J_0(ms)\Big] = \frac{\pi}{c\sqrt{m^2 + z^2}}. \tag{C.10}$$

GRATING PROFILE RECONSTRUCTION BASED ON FINITE ELEMENTS AND OPTIMIZATION TECHNIQUES*

J. ELSCHNER†, G. C. HSIAO‡, AND A. RATHSFELD†

Abstract. We consider the inverse diffraction problem to recover a two-dimensional periodic structure from scattered waves measured above and beneath the structure. The task is reformulated in the form of an optimization problem including special regularization terms. The solvability and the dependence on the parameter of regularization is analyzed. Numerical results for synthetic data demonstrate the practicability of the inversion algorithm.

Key words. diffraction grating, profile reconstruction, optimization method, conjugate gradient algorithm

1. Introduction.

The scattering theory in periodic structures has many applications in micro-optics, where periodic structures are often called diffraction gratings (cf. [21] for an introduction to the direct problem). The treatment of the inverse problem, recovering the periodic structure or the shape of the grating profile from the scattered field, is useful, e.g., in quality control and design of diffractive elements with prescribed far field patterns (see [5], [22]).

Various methods for the computation of the grating profile curve of perfectly conducting gratings have been proposed by Ito and Reitich [14], Arens and Kirsch [3], Hettlich [18], Bruckner, Elschner, and Yamamoto [8], and Bruckner and Elschner [7]. Chandezon, Poyedinchuk, and Yashina [9] propose an algorithm for the determination of the interface separating dielectric substrate and superstrate materials. We follow the technique of [8] (cf. [11, section 5.4] for the original algorithms applied to obstacle scattering). However, we consider reflection by and transition through gratings described by general material dependent wave number functions and replace the boundary integral approach of [8] by a finite element algorithm (cf. [1] for a similar finite element optimization of a different functional over a set of transition curves). A related nonperiodic inverse scattering problem has been studied by Angell, Hsiao, and Wen [2] using a similar optimization procedure based upon a domain integral representation.

To be more precise, we start with a short introduction to the direct problem of diffraction by gratings in section 2. The (transverse electric) TE component of the electric field of the time-harmonic light wave is the solution of a two-dimensional Helmholtz equation over the cross section of the grating device. We recall the variational formulation corresponding to the coupling of differential and boundary integral representations and define the Rayleigh coefficients of the Helmholtz solution. These correspond to the portion of light and the phase shift of the reflected and transmitted

modes. In section 3 we introduce the inverse problem. From measured Rayleigh coefficients for several incidence directions, we wish to reconstruct the grating, i.e., the wave number distribution over the grating cross section. The solution is obtained as the minimizer of an optimization problem, where the objective function consists of three terms. The first is the residual of the Helmholtz equation, the second the deviation of the computed Rayleigh coefficients from the measured data, and the third is a regularization term to cope with the ill-posedness of the inverse problem. We show the existence of minimizers and prove the convergence of these minimizers to the true solution if the regularization parameter tends to zero. Section 4 is devoted to the finite element discretization of the Helmholtz equation, and section 5 to the discretization of the optimization problem. For the solution of the finite-dimensional optimization problem we propose the conjugate gradient algorithm of Fletcher, Reeves, Polak, and Ribière (cf., e.g., [20]). In the last section we present numerical experiments. In particular, we compare the conjugate gradient algorithm with an SQP method.

Finally, we remark that the proposed treatment of the inverse problem is a first theoretical approach. Due to the severe ill-posedness of the problem, the accuracy of the reconstruction cannot be satisfactory for realistic applications. For better approximations the class of admissible gratings must be restricted in accordance with the technical requirements.

2. The direct problem. Consider an ideal optical grating (cf. the cross section in Figure 2.1). This is an ideal infinite plate in three-dimensional space covering a half space filled by a substrate material. The plate consists of different materials. Moreover, the materials are disposed in such a manner that the material does not change in one of the two directions parallel to the plane of the plate. With respect to the other direction parallel to the plane, the material distribution is supposed to be periodic with period d. The materials are nonmagnetic with the permeability μ_0 and have the dielectric constants ε. The coordinate system is chosen such that the x_2 axis is perpendicular to the plane of the grating, such that the material distribution together with the resulting diffraction solution is invariant in the x_3 direction, and such

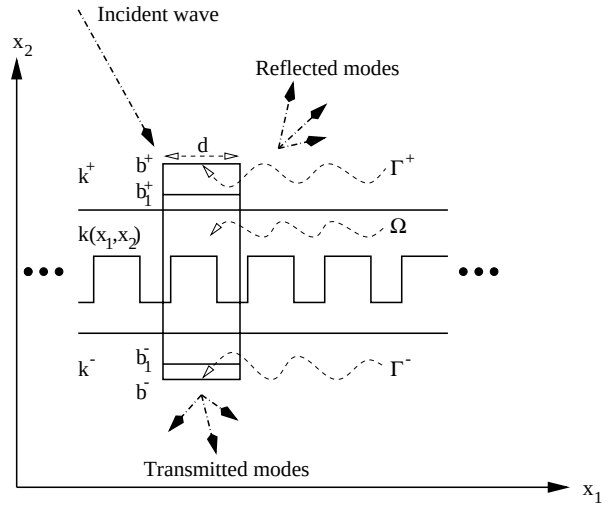

FIG. 2.1. *Cross section of grating.*

that the x_1 axis is parallel to the plane of the grating. Thus the materials of the problem are determined by the function $\varepsilon(x_1, x_2)$, which is d-periodic in x_1. Due to the invariance with respect to x_3, it is sufficient to consider the electromagnetic fields restricted to the plane spanned by the x_1 and x_2 axes. More precisely, we introduce two artificial boundaries $\Gamma^{\pm} := \{(x_1, x_2) : x_2 = b^{\pm}\}$ forming the upper and lower bounds of the cross section of the grating structure, respectively, and denote by Ω the rectangle $(0, d) \times (b^-, b^+)$, which covers one period of the cross section. We assume that the material above Γ^+ and below Γ^- is homogeneous with $\varepsilon = \varepsilon^+ > 0$ and $\varepsilon = \varepsilon^-$, respectively. Between Γ^+ and Γ^- the material may be inhomogeneous, and we assume that the function ε is piecewise continuous. Further, we introduce the wave number function $k = k(x_1, x_2) := \omega\sqrt{\mu_0\varepsilon}$ and $k^{\pm} := \omega\sqrt{\mu_0\varepsilon^{\pm}}$ with ω the angular frequency of the incident light wave. Thus the wave can be described by a time independent factor times $\exp(-\mathbf{i}\omega t)$. We suppose that

$$k^+ > 0, \quad \Re\mathrm{e}\, k^- > 0, \quad \Im\mathrm{m}\, k^- \geq 0, \quad \Re\mathrm{e}\, k(x_1, x_2) > 0, \quad \Im\mathrm{m}\, k(x_1, x_2) \geq 0. \tag{2.1}$$

Moreover, we suppose that there exists $b_1^{\pm}$ with $b^- < b_1^- < b_1^+ < b^+$ such that $k|_{\Omega^{\pm}} \equiv k^{\pm}$ for $\Omega^- := (0, d) \times (b^-, b_1^-)$ and $\Omega^+ := (0, d) \times (b_1^+, b^+)$.

Assume that an incoming plane wave is incident in the (x_1, x_2)-plane upon the grating from the top with the angle of incidence $\theta \in (-\pi/2, \pi/2)$. Then the electromagnetic field does not depend on x_3. For simplicity, we restrict ourselves to the case of TE polarization, i.e., the electric field $\mathbf{E}$ is supposed to remain parallel to the x_3 axis (to the grooves) and is therefore determined by a single scalar quantity $v = v(x_1, x_2)$ (the transverse component of $\mathbf{E}$). Due to our special geometry, Maxwell's equations for the electric and magnetic field reduce to a single equation for v. The function v satisfies the two-dimensional Helmholtz equation

$$\Delta v + k^2 v = 0 \tag{2.2}$$

in the regions with continuous permittivity ε. In the infinite regions the usual outgoing wave conditions are required. At the material interfaces the solutions are subjected to the transmission conditions, i.e., the solution v and its normal derivative $\partial_n v$ have to cross the interface continuously.

The diffraction problems admit variational formulations in the bounded periodic cell Ω which were introduced in [23, 6, 5, 15]. The incoming wave has the form $v^i(x_1, x_2) = \exp(\mathbf{i}\alpha x_1 - \mathbf{i}\beta x_2)$, where $\alpha = k^+ \sin\theta$, $\beta = k^+ \cos\theta$. If we define the function $u(x_1, x_2) := v(x_1, x_2)\exp(-\mathbf{i}\alpha x_1)$, then u can be shown to be d-periodic, and the diffraction problem for TE polarization can be transformed to a variational problem for u in the rectangle Ω. In fact, multiplying the differential equation (2.2) by some smooth function, applying Green's formula, and taking into account the transmission conditions at the material interfaces and the outgoing wave condition on $\Gamma^{\pm}$, it can be shown (cf. [23, 5, 12]) that the diffraction problem for TE polarization is equivalent to the variational equation

$$\begin{aligned} \mathcal{B}_{TE}(u, \varphi) &:= \int_\Omega \nabla_\alpha u \cdot \overline{\nabla_\alpha \varphi} - \int_\Omega k^2\, u\, \bar{\varphi} + \int_{\Gamma^+} (T_\alpha^+ u)\, \bar{\varphi} + \int_{\Gamma^-} (T_\alpha^- u)\, \bar{\varphi} \\ &= -\int_{\Gamma^+} 2\mathbf{i}\beta \exp(-\mathbf{i}\beta b^+)\, \bar{\varphi} \end{aligned} \tag{2.3}$$

for all φ, where $\nabla_\alpha = (\partial_{x_1,\alpha}, \partial_{x_2}) := \nabla + \mathbf{i}(\alpha, 0)$ and $T_\alpha^{\pm}$ are the usual hypersingular Dirichlet-to-Neumann maps for the solution in the outer domain. In particular, the

functions $T_\alpha^\pm u$ are defined on $\Gamma^\pm$ as

$$(T_\alpha^\pm u)(x_1, b^\pm) := -\sum_{n=-\infty}^{\infty} \mathbf{i}\beta_n^\pm \hat{u}_n^\pm \exp(\mathbf{i}nKx_1), \tag{2.4}$$

where $K := 2\pi/d$, and $\hat{u}_n^\pm$ denote the Fourier coefficients of $u(x_1, b^\pm)$:

$$\hat{u}_n^\pm := \frac{1}{d}\int_0^d u(x_1, b^\pm)\exp(-\mathbf{i}nKx_1)\,\mathrm{d}x_1.$$

The numbers $\beta_n^\pm$ are defined as

$$\beta_n^\pm = \beta_n^\pm(\alpha) := \sqrt{(k^\pm)^2 - \alpha_n^2}, \qquad 0 \le \arg\beta_n^\pm < \pi,$$

where as usual $\alpha_n := \alpha + nK$ and $k^\pm = k^\pm(x_1, b^\pm)$. Note that any solution of (2.3) satisfies on $\Gamma^\pm$ the nonlocal boundary conditions

$$\partial_n u|_{\Gamma^+} + T_\alpha^+ u|_{\Gamma^+} = -2\mathbf{i}\beta\exp(-\mathbf{i}\beta b^+), \quad \partial_n u|_{\Gamma^-} + T_\alpha^- u|_{\Gamma^-} = 0. \tag{2.5}$$

The variational equation (2.3) should be satisfied for all test functions $\varphi \in H^1_{per}(\Omega)$, that is, the function space of all complex-valued functions φ which are d-periodic in x_1 and which together with their first-order partial derivatives are square integrable in Ω (cf. [10] for the variational approach to classical elliptic boundary value problems).

The variational formulation (2.3) is very useful, because the transmission and outgoing wave conditions are enforced implicitly, and it allows us to seek the solution in the function space $H^1_{per}(\Omega)$, which is natural for second-order partial differential equations on nonsmooth domains. Here one can apply well-established methods for the analysis and numerical solution of the diffraction problems.

THEOREM 2.1 (cf., e.g., [12]). *Suppose that k satisfies condition* (2.1). *Then the sesquilinear form $\mathcal{B}_{TE}$ is strongly elliptic over $H^1_{per}(\Omega)$.*

We recall that a bounded sesquilinear form $\mathcal{B}_{TE}(\cdot,\cdot)$ given on the Hilbert space $H^1_{per}(\Omega)$ is called strongly elliptic if there exist a complex number ϕ, $|\phi| = 1$, a constant $c > 0$, and a compact form $\mathcal{Q}(\cdot,\cdot)$ such that

$$\Re\mathrm{e}\,\mathcal{B}_{TE}(\phi\,u, u) \ge c\|u\|_X^2 - \mathcal{Q}(u,u) \quad \forall\, u \in H^1_{per}(\Omega).$$

As usual, the sesquilinear form $\mathcal{B}_{TE}$ corresponds to a bounded linear operator B mapping $H^1_{per}(\Omega)$ into its dual $H^1_{per}(\Omega)'$ via $\mathcal{B}_{TE}(u,v) = \langle Bu, v\rangle$, $u, v \in H^1_{per}(\Omega)$. According to the proof of the last theorem (cf. [12]), the bilinear form $\mathcal{B}_{TE}$ splits into the compact form $\mathcal{C}_k(u,v) := -k^2\int_\Omega uv$, a strongly elliptic form $\mathcal{P}$ with $\mathcal{P}(u,u) \ge c\|u\|^2_{H^1_{per}(\Omega)}$ and constant $c > 0$, and a finite-dimensional form $\mathcal{T}$. Correspondingly, we get $B = P + T + C_k$ with $\langle Pu, u\rangle \ge c\|u\|^2_{H^1_{per}(\Omega)}$, with finite range operator T, and with compact C_k. From this splitting we infer that B is a Fredholm operator of index zero. Thus the strong ellipticity is the basis for proving the invertibility of operator B under additional conditions.

We write $B = B(k,\theta)$ to indicate the dependence of B on the wave number function k and on the incidence angle θ. The variational equation (2.3) is equivalent to the operator equation $B(k,\theta)u = w$ with $w \in H^1_{per}(\Omega)'$. Here $\langle w, \varphi\rangle$, i.e., the functional w applied to $\varphi \in H^1_{per}(\Omega)$ is defined by the right-hand side of (2.3). The operator $B(k,\theta)$ is a second-order differential operator. To get an equation with a

well-conditioned operator acting in the single space $H^1_{per}(\Omega)$, we multiply the equation by the inverse of $\widetilde{B}(\theta) := B(\tilde{k}, \theta)$ with a fixed simple wave number function $\tilde{k}$. Thus (2.3) is equivalent to $[\widetilde{B}(\theta)^{-1}B(k,\theta)]u = \widetilde{B}(\theta)^{-1}w$.

The invertibility of the operators $\widetilde{B}(\theta)$ and $B(k,\theta)$ will be supposed in the following. Partial results on this are reported, e.g., in [23, 5, 12]. Here we give only a stability result with respect to the wave number function.

THEOREM 2.2. *Suppose that the squared wave number functions k_n^2 form a weakly convergent sequence in the space $L^2(\Omega)$. (Note that the squared wave number function enters linearly into the scene.) If $B(k_0,\theta)$ is the operator defined with k_0 such that k_0^2 is the weak limit of the k_n^2 and if this $B(k_0,\theta)$ is invertible, then there exist an integer $n_0 > 0$ and a real $c > 0$ such that $\|B(k_n,\theta)u\|_{H^1_{per}(\Omega)'} \geq c\|u\|_{H^1_{per}(\Omega)}$ for any $u \in H^1_{per}(\Omega)$ and $n \geq n_0$. Since the $B(k_n,\theta)$ are Fredholm operators with index zero, the last estimate implies the invertibility of $B(k_n,\theta)$ if $n \geq n_0$.*

Proof. If the theorem were not true, then there is a sequence $\{u_n\} \subset H^1_{per}(\Omega)$ such that $\|u_n\|_{H^1_{per}(\Omega)} = 1$ and $\|B(k_n,\theta)u_n\|_{H^1_{per}(\Omega)'} \to 0$. Then, without loss of generality, we may suppose that u_n tends weakly to u_0 in $H^1_{per}(\Omega)$. Hence, $\|u_n - u_0\|_{L^p(\Omega)} \to 0$ for any p with $1 \leq p < \infty$. From the weak convergence of u_n we infer the weak convergence in $H^1_{per}(\Omega)'$ of $[P+T]u_n \rightharpoonup [P+T]u_0$. Indeed, $Tu_n \to Tu_0$ and $\langle Pu_n, \varphi\rangle = \langle u_n, P'\varphi\rangle \to \langle u_0, P'\varphi\rangle = \langle Pu_0, \varphi\rangle$ for all $\varphi \in H^1_{per}(\Omega)$.

Furthermore, since $\|u_n - u_0\|_{L^p(\Omega)} \to 0$ for any $p < \infty$, we obtain the relation $\|u_n\overline{\varphi} - u_0\overline{\varphi}\|_{L^2(\Omega)} \to 0$ for any $\varphi \in H^1_{per}(\Omega)$. Hence, $\mathcal{C}_k(u_n,\varphi) = -\int_\Omega k_n^2 u_n\overline{\varphi} \to -\int_\Omega k_0^2 u_0\overline{\varphi}$. Together with the weak convergence $[P+T]u_n \rightharpoonup [P+T]u_0$, we have $B(k_n,\theta)u_n \rightharpoonup B(k_0,\theta)u_0$. This implies $B(k_0,\theta)u_0 = 0$ and $u_0 = 0$. Consequently, $C_{k_n}u_n \to 0$ and $Tu_n \to 0$ together with $\|B(k_n,\theta)u_n\|_{H^1_{per}(\Omega)'} \to 0$ yield $Pu_n \to 0$, which contradicts $\langle Pu_n, u_n\rangle \geq c\|u_n\|^2_{H^1_{per}(\Omega)} = 1$. ∎

Note that any periodic solution of (2.3) can be represented as a Fourier series on $\Gamma^\pm$, i.e.,

$$
\begin{aligned}
u(x_1,b^+) &= \sum_{n=-\infty}^{\infty} A_n^+ \exp(\mathbf{i}\beta_n^+ b^+)\, \exp(\mathbf{i}nKx_1) + \exp(-\mathbf{i}\beta b^+),\\
u(x_1,b^-) &= \sum_{n=-\infty}^{\infty} A_n^- \exp(-\mathbf{i}\beta_n^- b^-)\, \exp(\mathbf{i}nKx_1)
\end{aligned}
\tag{2.6}
$$

for suitable coefficients $A_n^\pm$. It is not hard to see that the extensions of these series multiplied by the factor $\exp(\mathbf{i}\alpha x_1)$ (recall that $v(x_1,x_2) = u(x_1,x_2)\exp(\mathbf{i}\alpha x_1)$),

$$
\sum_{n=-\infty}^{\infty} A_n^\pm \exp(\pm\mathbf{i}\beta_n^\pm x_2)\, \exp(\mathbf{i}[\alpha+n]Kx_1), \quad x_2 \gtrless b^\pm,
\tag{2.7}
$$

define solutions of the Helmholtz equation satisfying the outgoing wave condition. The coefficients $A_n^\pm$ in the expansion (2.7) are called Rayleigh coefficients. The most interesting are those with $n \in \mathcal{U}^\pm$,

$$
\mathcal{U}^\pm := \begin{cases} \{n \in \mathbb{Z} : |n+\alpha| < k^\pm\} & \text{if } \Im\mathrm{m}\, k^\pm = 0,\\ \emptyset & \text{if } \Im\mathrm{m}\, k^\pm > 0. \end{cases}
$$

Indeed, these coefficients $A_n^\pm$ describe the magnitude and the phase shift of those

terms $A_n^{\pm}\exp(\mathbf{i}[\alpha+n]Kx_1)\exp(\pm\mathbf{i}\beta_n^{\pm}x_2)$ in the representation of $u(x_1,x_2)\exp(\mathbf{i}\alpha x_1)$ for $x_2 \gtrless b^{\pm}$, which correspond to propagating plane waves. The terms with $n \notin \mathcal{U}^{\pm}$ lead to evanescent waves only. Hence, the $A_n^{\pm}$ with $n \in \mathcal{U}^{\pm}$ can be considered to be the far field data of the diffraction problems at optical gratings. The optical efficiencies of the grating are defined by

$$e_n^{\pm} := (\beta_n^{\pm}/\beta)|A_n^{\pm}|^2,\ (n,\pm) \in \mathcal{U}^* := \left\{(n,+):\ n \in \mathcal{U}^+\right\} \cup \left\{(n,-):\ n \in \mathcal{U}^-\right\}, \tag{2.8}$$

which is the ratio of the energy of the nth propagating mode to the energy of the incident wave.

Restricting the solution $\Omega \ni (x_1,x_2) \mapsto u(k,\theta)(x_1,x_2)$ to $\Gamma^{\pm}$, we get the Rayleigh coefficients $A_n^{\pm}$ by computing the Fourier coefficients according to (2.6). The linear operator of restricting u to $\Gamma^{\pm}$ and of computing the Rayleigh coefficients $A_n^{\pm}$ will be denoted by $F(\theta)$, i.e.,

$$\begin{aligned} A &:= \left(A_n^{\pm}\right)_{(n,\pm)\in\mathcal{U}^*} \ = \ F(\theta)\ u + A^i, \\ A^i &:= \left(-\exp(-\mathbf{i}\beta b^+)\delta_{(n,\pm),(0,+)}\right)_{(n,\pm)\in\mathcal{U}^*}. \end{aligned}$$

If the refractive indices of the cover material above the grating and the substrate material beneath the grating are fixed, then the operator $F(\theta)$ is independent of the function k inside the grating.

3. The inverse problem. For the inverse problem, we suppose that the distribution of the material in the grating between the lines $\{(x_1,b_1^+):\ 0<x_1<d\}$ and $\{(x_1,b_1^-):\ 0<x_1<d\}$ is unknown. In other words, our task is to determine the unknown function $k(x_1,x_2)$ for $b_1^- < x_2 < b_1^+$. To get this, we illuminate the grating by plane waves $v^i(x_1,x_2) = \exp(\mathbf{i}k^+\sin\theta\, x_1 - ik^+\cos\theta\, x_2)$ under the incident angles $\theta = \theta_l,\ l = 1,\dots,L$, and measure the Rayleigh coefficients $A_{meas,n}^{\pm}(\theta_l)$ for $(n,\pm) \in \mathcal{U}^* = \mathcal{U}^*(\theta_l)$ and for each angle $\theta_l,\ l = 1,\dots,L$. We seek a material distribution and the corresponding wave number function $k(x_1,x_2)$ such that the Rayleigh coefficients $A_n^{\pm} = A_n^{\pm}(k,\theta_l)$, obtained by solving the variational equation (2.3) with respect to $u(x_1,x_2) = u(k,\theta_l)(x_1,x_2)$ and by computing the Fourier coefficients $A_n^{\pm}(k,\theta_l)$ of $u|_{\Gamma^{\pm}}$ according to (2.6), coincide with the measured data $A_{meas,n}^{\pm}(\theta_l)$ for $(n,\pm) \in \mathcal{U}^*(\theta_l)$ and $l = 1,\dots,L$. In other words, we seek an unknown squared wave number function k^2 and the corresponding solutions $u(k,\theta_l)$ from $[\widetilde{B}(\theta_1)^{-1}B(k,\theta_l)]u(k,\theta_l) = \widetilde{B}(\theta_1)^{-1}w(\theta_l)$ such that the computed Rayleigh coefficients $A(\theta_l) = F(\theta_l)u(k,\theta_l) + A^i(\theta_l)$ coincide with the measured $A_{meas}(\theta_l) := (A_{meas,n}^{\pm}(\theta_l))_{(n,\pm)\in\mathcal{U}^*(\theta_l)}$. Expressing our objective in formulae, we seek k^2 and $u_l = u(k,\theta_l)$ such that

$$\begin{aligned} &\sum_{l=1}^{L} \left\| \left[\widetilde{B}(\theta_1)^{-1}B(k,\theta_l)\right] u_l - \widetilde{B}(\theta_1)^{-1}w_l \right\|^2_{L^2(\Omega)} \ = 0, \\ &\sum_{l=1}^{L} \left\| \left[F(\theta_l)\ u_l + A^i(\theta_l)\right] - A_{meas}(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))} = 0. \end{aligned}$$

Here $w_l = w(\theta_l)$ stands for the right-hand-side functional in (2.3) with θ replaced by θ_l. The symbol $\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))$ denotes the complex Euclidean space of vectors over the index set $\mathcal{U}^*(\theta_l)$.

The operator $F(\theta_l)$ is smoothing and the equation $F(\theta_l)u_l = A(\theta_l) - A^i(\theta_l)$ is severely ill-posed. To cope with measurement errors in the values of $A_{meas}(\theta_l)$ we need a regularization, i.e., we try to find solutions k^2 and u_l such that the left-hand sides of the last two equations are small and that, simultaneously, the solution is relatively smooth. Relatively smooth means that the H^1_{per} Sobolev norms of u_l and the $H^{1/2}_{per}$ Sobolev norm of k^2 do not blow up. This will be helpful also if the solution should not be unique. Finally, we define the nonlinear objective functional

$$\begin{aligned}\mathcal{F}\left(k^2, u_1, \dots, u_L; \gamma\right) := & \frac{\sum_{l=1}^{L} \left\| \widetilde{B}(\theta_1)^{-1} B(k,\theta_l) u_l - \widetilde{B}(\theta_1)^{-1} w_l \right\|^2_{L^2(\Omega)}}{\sum_{l=1}^{L} \left\| \widetilde{B}(\theta_1)^{-1} w_l \right\|^2_{L^2(\Omega)}} \\ & + c_d \frac{\sum_{l=1}^{L} \left\| \left[F(\theta_l)\, u_l + A^i(\theta_l)\right] - A_{meas}(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}}{\sum_{l=1}^{L} \|A_{meas}(\theta_l)\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}} \\ & + c_v \gamma \left\|k^2\right\|^2_{H^{1/2}_{per}(\Omega)} + c_s \gamma \sum_{l=1}^{L} \|u_l\|^2_{H^1_{per}(\Omega)}. \end{aligned} \tag{3.1}$$

Here c_d, c_v, and c_s denote appropriate equilibration constants which are to be determined by numerical experiments. At first glance, one might think that the last regularization term in (3.1) is unnecessary. Indeed, the first term containing the constraint condition forces u_l to have a bounded L^2 norm. Unfortunately, our proof heavily relies on the boundedness of the stronger H^1 norm. In our numerical experiments (cf. section 6), we have tested various choices of c_s. We have found that a certain small $c_s\gamma$ leads to better results than $c_s = 0$. The number γ is a small positive regularization parameter which is to be chosen in dependence on the measurement error. Using the functional F, we finally arrive at the optimization problem

$$\begin{aligned} & \mathcal{F}\left(k^2, u_1, \dots, u_L; \gamma\right) \quad \longrightarrow \min, \\ & \text{with } k^2 \in H^{1/2}_{per}(\Omega), \\ & u_l \in H^1_{per}(\Omega),\ l = 1, \dots, L. \end{aligned} \tag{3.2}$$

This optimization problem will be discretized and solved numerically in the subsequent sections. For its solvability and its connection to the exact inverse problem, we get the following two theorems.

THEOREM 3.1. *For any fixed positive regularization parameter γ, there exists a minimizer $\{k_0^2,\ u_{l,0},\ l = 1, \dots, L\}$ of the optimization problem* (3.2).

Proof. Suppose $\{k_n^2,\ u_{l,n},\ l = 1, \dots, L\}_{n\in\mathbb{N}}$ is a minimizing sequence. Without loss of generality we may suppose $k_n^2 \rightharpoonup k_0^2$ in $H^{1/2}_{per}(\Omega)$, $k_n^2 \to k_0^2$ in $L^2(\Omega)$, and $u_{l,n} \rightharpoonup u_{l,0}$ weakly in $H^1_{per}(\Omega)$ since $\|k_n^2\|_{H^{1/2}_{per}(\Omega)}$ and $\|u_{l,n}\|_{H^1_{per}(\Omega)}$ are trivially bounded. Similarly to the proof of Theorem 2.2, we conclude $B(k_n,\theta_l)u_{l,n} \rightharpoonup B(k_0,\theta_l)u_{l,0}$ weakly in $H^1_{per}(\Omega)'$, and thus $\widetilde{B}(\theta_1)^{-1}B(k_n,\theta_l)u_{l,n} \rightharpoonup \widetilde{B}(\theta_1)^{-1}B(k_0,\theta_l)u_{l,0}$ weakly in $H^1_{per}(\Omega)$. Hence, $\widetilde{B}(\theta_1)^{-1}B(k_n,\theta_l)u_{l,n} \to \widetilde{B}(\theta_1)^{-1}B(k_0,\theta_l)u_{l,0}$ strongly in $L^2(\Omega)$. Moreover, $u_{l,n} \rightharpoonup u_{l,0}$ implies that $u_{l,n}|_{\Gamma^\pm} \to u_{l,0}|_{\Gamma^\pm}$ strongly in $L^2(\Gamma^\pm)$ and the

strong convergence $F(\theta_l)u_{l,n} \to F(\theta_l)u_{l,0}$. In other words, the first two terms in the objective functionals converge, and the limit relations for weakly convergent sequences $\|u_{l,n}\|_{H^1_{per}(\Omega)} \le \liminf \|u_{l,n}\|_{H^1_{per}(\Omega)}$ and $\|k_0^2\|_{H^{1/2}_{per}(\Omega)} \le \liminf \|k_n^2\|_{H^{1/2}_{per}(\Omega)}$ lead us to the upper estimate $\mathcal{F}(k_0^2, u_{1,0}, \dots, u_{L,0}; \gamma) \le \liminf \mathcal{F}(k_n^2, u_{1,n}, \dots, u_{L,n}; \gamma)$. Since $\{k_n^2,\ u_{l,n},\ l = 1, \dots, L\}_{n\in\mathbb{N}}$ is a minimizing sequence, we conclude that the value $\mathcal{F}(k_0^2, u_{1,0}, \dots, u_{L,0}; \gamma)$ is the attained minimum. ∎

THEOREM 3.2. *Suppose that, for the given data $A_{meas}(\theta_1), \dots, A_{meas}(\theta_L)$, there exists a wave number function $k_*^2 \in H^{1/2}_{per}(\Omega)$ such that the Rayleigh coefficients corresponding to k_* exactly match the values $A_{meas}(\theta_1), \dots, A_{meas}(\theta_L)$, i.e., $F(\theta_l)u(k_*, \theta_l) + A^i(\theta_l) = A_{meas}(\theta_l)$ for the solutions $u(k_*, \theta_l)$ of $B(k_*, \theta_l)u(k_*, \theta_l) = w_l$. Further suppose $0 < \gamma_m \to 0$ and that $\{k_m^2,\ u_{l,m},\ l = 1, \dots, L\}$ is a minimizer of the functional $\mathcal{F}(\dots; \gamma_m)$. Then there exists a $k_0^2 \in H^{1/2}_{per}(\Omega)$ and a subsequence of $\{k_m^2\}_{m\in\mathbb{N}}$ converging to k_0^2 weakly in $H^{1/2}_{per}(\Omega)$ and strongly in $L^2(\Omega)$. The corresponding solutions $u(k_0, \theta_l)$ of the variational equations (cf. (2.3)) or equivalently of $B(k_0, \theta_l)u(k_0, \theta_l) = w_l$ satisfy $F(\theta_l)u(k_0, \theta_l) + A^i(\theta_l) = A_{meas}(\theta_l)$; i.e., their Rayleigh coefficients coincide with the measured data $A_{meas}(\theta_l)$ for $l = 1, \dots, L$.*

Proof. From our assumption on the existence of k_* and from

$$
\begin{aligned}
c_v\gamma_m \left\|k_m^2\right\|^2_{H^{1/2}_{per}(\Omega)} + c_s\gamma_m \sum_{l=1}^{L} \|u_{l,m}\|^2_{H^1_{per}(\Omega)} &\le \mathcal{F}\left(k_m^2, u_{1,m}, \dots, u_{L,m}; \gamma_m\right) \\
&\le \mathcal{F}\left(k_*^2, u(k_*, \theta_1), \dots, u(k_*, \theta_L); \gamma_m\right) \\
&= c_v\gamma_m \left\|k_*^2\right\|^2_{H^{1/2}_{per}(\Omega)} \\
&\quad + c_s\gamma_m \sum_{l=1}^{L} \|u(k_*, \theta_1)\|^2_{H^1_{per}(\Omega)} \longrightarrow 0,
\end{aligned}
\tag{3.3}
$$

we obtain the uniform boundedness of $\|k_m^2\|_{H^{1/2}_{per}(\Omega)}$ and $\|u_{l,m}\|_{H^1_{per}(\Omega)}$. Therefore, we can switch to weakly convergent subsequences. Without loss of generality suppose that k_m^2 and $u_{l,m}$ converge weakly in the corresponding Sobolev spaces. Repeating the arguments of the proof to Theorem 3.1 and using (3.3) leads to

$$
\begin{aligned}
\mathcal{F}\left(k_m^2, u_{1,m}, \dots, u_{L,m}; \gamma_m\right) \longrightarrow\ & \frac{\displaystyle\sum_{l=1}^{L} \left\| \widetilde{B}(\theta_1)^{-1} B(k_0, \theta_l) u_{l,0} - \widetilde{B}(\theta_1)^{-1} w_l \right\|^2_{L^2(\Omega)}}{\displaystyle\sum_{l=1}^{L} \left\| \widetilde{B}(\theta_1)^{-1} w_l \right\|^2_{L^2(\Omega)}} \\
& + c_d\, \frac{\displaystyle\sum_{l=1}^{L} \left\| \left[F(\theta_l)\ u_{l,0} + A^i(\theta_l)\right] - A_{meas}(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}}{\displaystyle\sum_{l=1}^{L} \|A_{meas}(\theta_l)\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}} \\
=\ & 0.
\end{aligned}
$$

The assertions of the theorem follow. ∎

COROLLARY 3.3. *Suppose the assumptions of the last theorem and, additionally, that the wave number function k_* is the unique solution of the inverse problem, i.e., that the relations $F(\theta_l)u(k, \theta_l) + A^i(\theta_l) = A_{meas}(\theta_l)$ and $B(k, \theta_l)u(k, \theta_l) = w_l$ for*

$k = 1, \dots, L$ imply $k_* = k$. Then the whole sequence $\{k_m^2\}_{m\in\mathbb{N}}$ converges to k_*^2 weakly in $H^{1/2}_{per}(\Omega)$ and strongly in $L^2(\Omega)$.

Proof. The proof is straightforward since a sequence is convergent if all subsequences have subsequences with a fixed limit. ∎

Remark 3.1. In general, the uniqueness assumption is hard to verify. For perfectly conducting gratings bounded by a curve of small oscillation represented as a finite Fourier series, uniqueness is proved in [16]. In [15] it has been shown that the knowledge of a finite number of Rayleigh coefficients even for all incident angles is not sufficient to determine the grating. The situation improves slightly if the measurement of Rayleigh coefficients is replaced by the measurement of the field u restricted to the lines $\{(x_1, b_2^+) : \ 0 < x_1 < d\}$ and $\{(x_1, b_2^-) : \ 0 < x_1 < d\}$ with $b_2^- < b^- < b^+ < b_2^+$. Note that the differences between the two data types are not so essential if the second data type is discretized. Moreover, the theoretical results of this section remain valid for the new kind of measurements. The case of smooth wave number functions depending only on the x_1 variable is treated in [15]. For grating structures corresponding to perfectly conducting gratings bounded by C^2 curves and for the reflected data measured in any direction of incidence, uniqueness is shown in [16]. A fixed incidence direction together with measured data corresponding to a finite number of wave lengths λ is treated in [19]. Gratings consisting of two materials (corresponding to the wave numbers $k^\pm$) separated by a Lipschitz curve and absorbing substrate materials are considered in the subsequent Theorem 3.5. If only local uniqueness in the inverse problem is known, then the optimization problem and the numerical methods in section 5 with suitable initial guess can be used to recover the grating. For local uniqueness, we refer to the local stability results and the papers quoted in [13].

COROLLARY 3.4. *Suppose the assumptions of Theorem* 3.2 *are satisfied. However, consider noisy data $A^{noisy}_{meas}(m, \theta_l) \in \ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))$ such that the error to the exactly measured data $A_{meas}(\theta_l)$ satisfies $\|A^{noisy}_{meas}(m, \theta_l) - A_{meas}(\theta_l)\|_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))} \le \gamma_m$. Suppose the minimizers are determined for the functional $\mathcal{F}(\dots; \gamma_m)$ with $A_{meas}(\theta_l)$ replaced by $A^{noisy}_{meas}(m, \theta_l)$. Then the assertions of Theorem* 3.2 *remains valid. If, additionally, k_* is the unique solution of the inverse problem, then the assertions of Corollary* 3.3 *stay in force.*

Proof. The proof is a straightforward modification of that to Theorem 3.2. ∎

THEOREM 3.5. *Assume that the graphs $\{(x_1, f_j(x_1)) : \ 0 < x_1 < d\}$ of two different Lipschitz continuous functions f_j $(j = 1, 2)$ cut Ω into an upper region $\{(x_1, x_2) : \ f_j(x_1) < x_2 < b^+\}$ with constant wave number $k^+ > 0$ and a lower region $\{(x_1, x_2) : \ b^- < x_2 < f_j(x_1)\}$ with constant wave number k^- such that $\Re\mathrm{e}\, k^- > 0$ and $\Im\mathrm{m}\, k^- > 0$. For these two gratings and for one planar incident wave $(L = 1)$, we assume that u_1 and u_2 are the solutions of the TE problem. (That is, $\triangle u_j - [k^+]^2 u_j = 0$ holds on $\{(x_1, x_2) : \ f_j(x_1) < x_2 < b^+\}$ and $\triangle u_j - [k^-]^2 u_j = 0$ holds on $\{(x_1, x_2) : \ b^- < x_2 < f_j(x_1)\}$, and the functions u_j and their normal derivatives are continuous across the surfaces $\{(x_1, f_j(x_1)) : \ 0 < x_1 < d\}$.) Then coincidence of the data $u_1|_{\Gamma^+} = u_2|_{\Gamma^+}$ and $u_1|_{\Gamma^-} = u_2|_{\Gamma^-}$ implies $f_1 = f_2$.*

Remark 3.2. This generalizes the uniqueness result by Bao [4] for a perfectly reflecting substrate material below the interface.

Proof. Setting $f(x_1) := \max\{f_1(x_1), f_2(x_1)\}$ and $g(x_1) := \min\{f_1(x_1), f_2(x_1)\}$, we consider the function $u := u_1 - u_2$. Then $u|_{\Gamma^+} = 0$, $u|_{\Gamma^-} = 0$, $\partial_\nu u|_{\Gamma^+} = 0$, and $\partial_\nu u|_{\Gamma^-} = 0$ (cf. (2.5)), which together with the unique continuation theorem implies $u = 0$ in the regions $\{(x_1, x_2) : \ f(x_1) < x_2 < b^+\}$ and $\{(x_1, x_2) : \ b^- < x_2 < g(x_1)\}$.

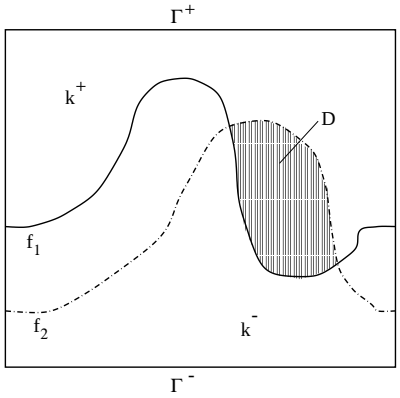

FIG. 3.1. *Gratings defined by two graphs.*

If D (cf. Figure 3.1) is a simply connected region bounded by the graphs of f and g (and possibly by the vertical lines $\{(x_1, x_2) : x_2 = 0\}$ and $\{(x_1, x_2) : x_2 = d\}$), then we have $\Delta u_1 + [k^+]^2 u_1 = 0$ and $\Delta u_2 + [k^-]^2 u_2 = 0$ in D, or vice versa. Additionally, we get $u_1 = u_2$ and $\partial_\nu u_1 = \partial_\nu u_2$ on the boundary ∂D of D, where ∂_ν stands for the normal derivative at the boundary points of ∂D. Applying Green's formula, which is justified for $u_j \in H^2(\Omega)$, $j = 1, 2$, we arrive at

$$0 = \int_D \{u_1 \Delta \overline{u}_1 - \overline{u}_1 \Delta u_1\} = \int_{\partial D} \{u_1 \partial_\nu \overline{u}_1 - \overline{u}_1 \partial_\nu u_1\} = \int_{\partial D} \{u_2 \partial_\nu \overline{u}_2 - \overline{u}_2 \partial_\nu u_2\}$$
$$= \int_D \{u_2 \Delta \overline{u}_2 - \overline{u}_2 \Delta u_2\} = 2\mathbf{i} \Im\mathrm{m}\, [k^-]^2 \int_D |u_2|^2 = 0.$$

Note that for the third equality we have used the quasi-periodicity of the solutions u_j leading to $\{u_j \partial_\nu \overline{u}_j - \overline{u}_j \partial_\nu u_j\} = 0$ over the vertical boundary parts of D. Therefore, $u_2 = 0$ in D. Consequently, $u_2 = 0$ in Ω, which is a contradiction to the fact that u_2 is the scattered wave component corresponding to a nonzero incident wave. ∎

4. The finite element solution. To define the finite element method, we split domain Ω into the union of triangles such that the diameter of each triangle is less than a prescribed mesh size h and that the triangles have no interior points in common. Moreover, we assume that any two triangles of the partition are either disjoint or their intersection is a common edge or a common corner point (no hanging nodes). By S_h^1 we denote the set of all piecewise linear functions subordinate to the partition. Then, the finite element solution u_h of the Helmholtz equation (2.2) in its variational form (2.3) is the unique solution $u_h \in S_h^1$ satisfying

$$\mathcal{B}_{TE}(u_h, \varphi_h) = \int_\Omega \nabla_\alpha u_h \cdot \overline{\nabla_\alpha \varphi_h} - \int_\Omega k^2\, u_h\, \overline{\varphi_h} + \int_{\Gamma^+} (T_\alpha^+ u_h)\, \overline{\varphi_h} + \int_{\Gamma^-} (T_\alpha^- u_h)\, \overline{\varphi_h}$$
$$= -\int_{\Gamma^+} 2\mathbf{i}\beta \exp(-\mathbf{i}\beta b^+)\, \overline{\varphi_h} \quad \forall \varphi_h \in S_h^1. \tag{4.1}$$

Clearly, choosing the usual hat function basis $\{\varphi_{h,j} : j = 1, \ldots, N\}$ of S_h^1, the last discrete variational equation is equivalent to an equation in the N-dimensional complex Euclidean space $\ell^2_{\mathbb{C}}(N)$, i.e., to the matrix equation $B_h \xi = \eta$ for the unknown

coefficients ξ_j of the function u_h, where

$$B_h := (\mathcal{B}_{TE}(\varphi_{h,j}, \varphi_{h,j'}))_{j',j=1,\dots,N},$$
$$\xi := (\xi_j)_{j=1,\dots,N}, \quad u_h(x_1,x_2) \;=\; \sum_{j=1}^{N} \xi_j\, \varphi_{h,j}(x_1,x_2),$$
$$\eta := (\eta_j)_{j=1,\dots,N}, \quad \eta_j := -\int_{\Gamma^+} 2\mathbf{i}\beta \exp(-\mathbf{i}\beta b^+)\, \overline{\varphi_{h,j}}\,.$$

In other words, if the function $k = k(x_1, x_2)$ is given, then we can determine an approximate solution u_h by solving $B_h\xi = \eta$. Clearly, the matrix, the right-hand side, and the solution depend on the angle of incidence θ and on the wave number function $k = k(x_1, x_2)$. To indicate this dependence, we write $u_h = u_h(k, \theta)$ and the matrix equation as $B_h(k, \theta)\xi(k, \theta) = \eta(\theta)$.

Restricting the solution $\Omega \ni (x_1, x_2) \mapsto u_h(k, \theta)(x_1, x_2)$ to $\Gamma^\pm$, we get the Rayleigh coefficients $A_n^\pm$ by computing the Fourier coefficients according to (2.6). We denote the so-obtained approximate values of $A_n^\pm$ by $A_{h,n}^\pm$ and get the approximate efficiencies by setting $e_{h,n}^\pm := (\beta_n^\pm/\beta)|A_{h,n}^\pm|^2$. The linear operator of restricting u_h to $\Gamma^\pm$ and of computing the Rayleigh coefficients $A_{h,n}^\pm$ will be denoted by $F_h(\theta)$, i.e.,

$$A_h := \left(A_{h,n}^\pm\right)_{(n,\pm)\in\mathcal{U}^*} \;=\; F_h(\theta)\,\xi + A^i(\theta).$$

If the refractive indices of the cover material above the grating and the substrate material beneath the grating are fixed, then the operator $F_h(\theta)$ is independent of the function k inside of the grating.

Finally, we remark that the linear system of equations $B_h(k, \theta)\xi(k, \theta) = \eta(\theta)$ is the discretization of a second-order differential equations. Consequently, the condition number of the finite element matrix $B_h(k, \theta)$ behaves like $\mathcal{O}(h^{-2})$ for h tending to zero. Therefore, a preconditioner is used for the iterative solution of $B_h(k, \theta)\xi(k, \theta) = \eta(\theta)$, i.e., we solve $[\widetilde{B}_h(\theta)^{-1}B_h(k, \theta)]\xi(k, \theta) = \widetilde{B}_h(\theta)^{-1}\eta(\theta)$ instead of $B_h(k, \theta)\xi(k, \theta) = \eta(\theta)$ with a matrix $\widetilde{B}_h(\theta)$ easy to invert and close to $B_h(k, \theta)$. Several preconditioning techniques are possible. In our special case, we can choose $\widetilde{B}_h(\theta)$, e.g., as the finite element matrix $\widetilde{B}_h(\theta) := B_h(\tilde{k}, \theta)$, where the wave number function $\tilde{k}(x_1, x_2)$ is equal to k^+ for $x_2 > (b^- + b^+)/2$ and equal to k^- for $x_2 < (b^- + b^+)/2$. If the partition of the finite element method is obtained by dividing the rectangles of a uniform rectangular partition of the rectangle Ω along the diagonals, then $B_h(\tilde{k}, \theta)$ is easy to invert. Indeed, if we group the degrees of freedom in clusters according to their x_2 coordinates, then $B_h(\tilde{k}, \theta)$ is a triangular block matrix with circular blocks.

5. The discretized inverse problem. For a numerical solution of the inverse problem of section 3, we switch to the discrete level, i.e., we seek the coefficient vectors $\xi(l)$ of the finite element solutions $u_h(k, \theta_l) = \sum \xi(l)_j \varphi_{h,j}$ from $\widetilde{B}_h(\theta_1)^{-1}B_h(k, \theta_l)\xi(l) \approx \widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l)$ such that the computed Rayleigh coefficients $A_h(\theta_l) = F_h(\theta_l)\xi(l) + A^i(\theta_l)$ differ only slightly from the measured $A_{meas}(\theta_l) := (A_{meas,n}^\pm(\theta_l))_{(n,\pm)\in\mathcal{U}^*(\theta_l)}$. The unknown squared wave number function k^2 is to be approximated by a function from a discrete space. We fix a partition coarser than that of the finite element method and choose the space S_h^0 as the set of all functions which are piecewise constant subordinate to the fixed partition and which fulfil $k^2(x_1, x_2) = [k^+]^2$ for $0 < x_1 < d$ and $b_1^+ < x_2 < b^+$ as well as $k^2 = [k^-]^2$ for $0 < x_1 < d$ and $b^- < x_2 < b_1^-$. As usual, the corresponding basis of functions equal

to one over one triangle of the grid and to zero over the others will be denoted by $\{\chi_{h,j} : j = 1, \dots, M\}$. We can identify the functions $k^2 \in S_h^0$ with the vectors of coefficients $\kappa = (\kappa_j)_{j=1,\dots,M}$ satisfying $k(x_1, x_2)^2 = \sum_j \kappa_j \chi_{h,j}(x_1, x_2)$. In particular, we write $B_h(\kappa, \theta_l)$ for $B_h(\sum_j \sqrt{\kappa_j}\chi_{h,j}, \theta_l)$. Using the discretized and reduced $H^{1/2}_{per}(\Omega)$ norm

$$\|\kappa\|^2_{V(\Omega)} := \sum_j |\kappa_j|^2 w_j + \sum_{\substack{j,j': \\ \text{indices of} \\ \text{neighbors}}} |\kappa_j - \kappa_{j'}|^2 \sqrt{w_j}$$

with w_j the measure of the jth triangle, we define the discrete nonlinear objective functional by

$$\begin{aligned}\mathcal{F}_h(\kappa, \xi(1), \dots, \xi(L); \gamma) := {} & \frac{\sum_{l=1}^{L} \left\| \widetilde{B}_h(\theta_1)^{-1} B_h(\kappa, \theta_l)\xi(l) - \widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(N)}}{\sum_{l=1}^{L} \left\| \widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(N)}} \\ & + c_d \frac{\sum_{l=1}^{L} \left\| \left[F_h(\theta_l)\, \xi(l) + A^i(\theta_l)\right] - A_{meas}(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}}{\sum_{l=1}^{L} \|A_{meas}(\theta_l)\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}} \\ & + c_v\gamma \|\kappa\|^2_{V(\Omega)} + c_s\gamma \sum_{l=1}^{L} \left\| \sum_{j=1}^{N} \xi(l)_j \varphi_{h,j} \right\|^2_{H^1_{per}(\Omega)}. \end{aligned} \tag{5.1}$$

Here c_d, c_v, and c_s denote appropriate equilibration constants which are to be determined by numerical experiments, and γ is the regularization parameter. Using the functional $\mathcal{F}_h$, we finally arrive at the discrete optimization problem

$$\begin{aligned} & \mathcal{F}_h(\kappa, \xi(1), \dots, \xi(L); \gamma) \quad \longrightarrow \min, \\ & \quad \text{with } \kappa \in \ell^2_{\mathbb{C}}(M), \\ & \xi(l) \in \ell^2_{\mathbb{C}}(N),\ l = 1, \dots, L. \end{aligned} \tag{5.2}$$

This will be solved using the following nonlinear conjugate gradient algorithm, which we prepare by giving formulae for the gradients. Note that the complex variables are treated as couples of real variables.

First we observe that the matrix-valued mapping $k^2 \mapsto [B_h(k, \theta_l) - B_h(0, \theta_l)] = (-\int_\Omega k^2 \varphi_{h,j}\overline{\varphi_{h,j'}})_{j',j}$ is linear and independent of θ_l. We easily get that

$$\nabla_\kappa B_h(\kappa, \theta_l) = \nabla_\kappa B_h = \left([\nabla_\kappa B_h]_j \right)_{j=1,\dots,M},$$

$$[\nabla_\kappa B_h]_j := \left(-\int_\Omega \varphi_{h,i}\overline{\varphi_{h,i'}}\chi_{h,j} \right)_{i',i=1,\dots,N},$$

$$\nabla_\kappa B_h\, \kappa' = \sum_{j=1}^{M} [\nabla_\kappa B_h]_j\, \kappa'_j.$$

If $\langle\cdot,\cdot\rangle_{\ell^2_{\mathbb{C}}(N)}$ stands for the scalar product in the N-dimensional Euclidean space, then the gradient of $\mathcal{F}_h$ is given by

$$\begin{aligned}
&\nabla\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\left(\kappa',\xi(1)',\ldots,\xi(L)'\right)\\
&=\big(\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\,\kappa',\nabla_{\xi(1)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\,\xi(1)',\\
&\quad\nabla_{\xi(2)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\xi(2)',\ldots,\nabla_{\xi(L)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\xi(L)'\big),
\end{aligned}$$

$$\begin{aligned}
&\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\kappa'\\
&=\Re\mathrm{e}\Big\langle 2\rho_1\sum_{l=1}^{L}\Big\langle\widetilde{B}_h(\theta_1)^{-1}\left[B_h(\kappa,\theta_l)\xi(l)-\eta(\theta_l)\right],\widetilde{B}_h(\theta_1)^{-1}\nabla_\kappa B_h\,\xi(l)\Big\rangle_{\ell^2_{\mathbb{C}}(N)},\kappa'\Big\rangle_{\ell^2_{\mathbb{C}}(M)}\\
&+2c_v\gamma\sum_j\Re\mathrm{e}\left[\kappa_j\overline{\kappa'_j}\right]\omega_j+2c_v\gamma\sum_{j,j^*}\Re\mathrm{e}\left[(\kappa_j-\kappa_{j^*})(\overline{\kappa'_j}-\overline{\kappa'_{j^*}})\right]\sqrt{\omega_j}\,,\\
&\quad\nabla_{\xi(l)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\xi(l)'\\
&=\Re\mathrm{e}\big\langle 2\rho_1\Big[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)\Big]^*\Big[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)\xi(l)-\widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l)\Big],\xi(l)'\big\rangle_{\ell^2_{\mathbb{C}}(N)}\\
&+\Re\mathrm{e}\big\langle 2\rho_2\,F_h(\theta_l)^*\left[\left[F_h(\theta_l)\,\xi(l)+A^i(\theta_l)\right]-A_{meas}(\theta_l)\right],\xi(l)'\big\rangle_{\ell^2_{\mathbb{C}}(N)}\\
&+\Re\mathrm{e}\left\langle 2\,c_s\gamma\left[\sum_{j=1}^{N}\xi(l)_j\varphi_{h,j}\right],\left[\sum_{j'=1}^{N}\xi(l)'_{j'}\varphi_{h,j'}\right]\right\rangle_{H^1_{per}(\Omega)},
\end{aligned}$$

$$\rho_1:=\frac{1}{\displaystyle\sum_{l=1}^{L}\left\|\widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l)\right\|^2_{\ell^2_{\mathbb{C}}(N)}},\quad \rho_2:=\frac{c_d}{\displaystyle\sum_{l=1}^{L}\|A_{meas}(\theta_l)\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}}\,.$$

Here $[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)]^*$ is the adjoint (transposed and complex conjugate) of matrix $[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)]$, and $F_h(\theta_l)^*$ that of $F_h(\theta_l)$. Treating the gradients as vectors, we arrive at

$$\begin{aligned}
&\nabla\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\\
&\quad=\big(\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right),\nabla_{\xi(1)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right),\\
&\qquad\nabla_{\xi(2)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right),\ldots,\nabla_{\xi(L)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)\big),\\
&\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)=\Big(\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)_j\Big)_{j=1,\ldots,M}\in\ell^2_{\mathbb{C}}(M),
\end{aligned}$$

$$\begin{aligned}
&\nabla_\kappa\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)_j:=2\rho_1\\
&\quad\times\sum_{l=1}^{L}\Big\langle\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)\xi(l)-\widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l),\widetilde{B}_h(\theta_1)^{-1}\left[\nabla_\kappa B_h\right]_j\xi(l)\Big\rangle_{\ell^2_{\mathbb{C}}(N)}\\
&\qquad+2\,c_v\gamma\left\{w_j\kappa_j+\sqrt{w_j}\sum_{\substack{j':j,j'\text{ are}\\ \text{indices of}\\ \text{neighbors}}}\left[\kappa_j-\kappa_{j'}\right]-\sum_{\substack{j':j,j'\text{ are}\\ \text{indices of}\\ \text{neighbors}}}\sqrt{w_{j'}}\left[\kappa_j-\kappa_{j'}\right]\right\},
\end{aligned}$$

$$\nabla_{\xi(l)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)=\left(\nabla_{\xi(l)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)_j\right)_{j=1,\ldots,N}\in\ell^2_{\mathbb{C}}(N),$$

$$\begin{aligned}\nabla_{\xi(l)}\mathcal{F}_h\left(\kappa,\xi(1),\ldots,\xi(L);\gamma\right)_j:=\;&2\rho_1\\ &\times\left[\left[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)\right]^*\left[\widetilde{B}_h(\theta_1)^{-1}B_h(\kappa,\theta_l)\xi(l)-\widetilde{B}_h(\theta_1)^{-1}\eta(\theta_l)\right]\right]_j\\ &+2\rho_2\left[F_h(\theta_l)^*\left[\left[F_h(\theta_l)\,\xi(l)+A^i(\theta_l)\right]-A_{meas}(\theta_l)\right]\right]_j\\ &+2\,c_s\gamma\left\langle\left[\sum_{j'=1}^{N}\xi(l)_{j'}\varphi_{h,j'}\right],\varphi_{h,j}\right\rangle_{H^1_{per}(\Omega)}.\end{aligned}$$

Now the nonlinear conjugate gradient algorithm of Fletcher–Reeves modified by Polak–Ribière (cf., e.g., [20]) takes the following form.

Conjugate Gradient Algorithm.

Given the constant $0<c_1=10^{-3}$*;*

Given the initial guess $(\kappa_0,\xi_0(1),\ldots,\xi_0(L))$*;*

Evaluate $\mathcal{F}_{h,0}:=\mathcal{F}_h\left(\kappa_0,\xi_0(1),\ldots,\xi_0(L);\gamma\right)$ *and the gradient* $\nabla\mathcal{F}_{h,0}:=\nabla\mathcal{F}_h\left(\kappa_0,\xi_0(1),\ldots,\xi_0(L);\gamma\right)$*;*

Set the first search direction $p_0:=\left(\kappa_0^d,\xi_0^d(1),\ldots,\xi_0^d(L)\right)=-\nabla\mathcal{F}_{h,0}$ *and set* $j=0$*;*

while $\nabla\mathcal{F}_{h,j}=\nabla\mathcal{F}_h\left(\kappa_j,\xi_j(1),\ldots,\xi_j(L);\gamma\right)\neq 0$

Compute step size α_j *of the correction* $\left(\alpha_j\kappa_j^d,\alpha_j\xi_j^d(1),\ldots,\alpha_j\xi_j^d(L)\right)$ *such that* α_j *is the largest number in* $\{256,128,64,32,16,\ldots\}$ *with*

$$\begin{aligned}&\mathcal{F}_h\left(\kappa_j+\alpha_j\kappa_j^d,\xi_j(1)+\alpha_j\xi_j^d(1),\ldots,\xi_j(L)+\alpha_j\xi_j^d(L);\gamma\right)\\ &\leq\mathcal{F}_h\left(\kappa_j,\xi_j(1),\ldots,\xi_j(L);\gamma\right)+c_1\alpha_j\nabla\mathcal{F}_{h,j}^T\left(\kappa_j^d,\xi_j^d(1),\ldots,\xi_j^d(L);\gamma\right);\end{aligned}$$

Set the new iterate solution $(\kappa_{j+1},\xi_{j+1}(1),\ldots,\xi_{j+1}(L))$ *to*

$$\left(\kappa_j+\alpha_j\kappa_j^d,\xi_j(1)+\alpha_j\xi_j^d(1),\ldots,\xi_j(L)+\alpha_j\xi_j^d(L)\right);$$

Evaluate gradient $\nabla\mathcal{F}_{h,j+1}:=\nabla\mathcal{F}_h\left(\kappa_{j+1},\xi_{j+1}(1),\ldots,\xi_{j+1}(L);\gamma\right)$*;*

Set $\beta_{j+1}=\max\left\{\dfrac{\nabla\mathcal{F}_{h,j+1}^T(\nabla\mathcal{F}_{h,j+1}-\nabla\mathcal{F}_{h,j})}{\|\nabla\mathcal{F}_{h,j}\|^2},0\right\}$*;*

Set new search direction $p_{j+1}=\left(\kappa_{j+1}^d,\xi_{j+1}^d(1),\ldots,\xi_{j+1}^d(L)\right)$ *to*

$$p_{j+1}:=-\nabla\mathcal{F}_{h,j+1}+\beta_{j+1}\left(\kappa_j^d,\xi_j^d(1),\ldots,\xi_j^d(L)\right);$$

Set $j=j+1$

end(while)

The line search part, i.e., the determination of α_j, can be improved. In fact, instead of changing α_j to half its value, we can take the argument of the minimum of a quadratic interpolation to $\alpha_j\mapsto\mathcal{F}_h(\kappa_j+\alpha_j\kappa_j^d,\xi_j(1)+\alpha_j\xi_j^d(1),\ldots,\xi_j(L)+\alpha_j\xi_j^d(L);\gamma)$ as the next value for α_j.

Usually, this conjugate gradient method converges to a local minimum of the objective function $\mathcal{F}_h$. The determination of the global minimum for high-dimensional optimization is a difficult and expensive problem. Note that a high number of degrees of freedom is required for the finite element method in order to resolve the oscillations of the Helmholtz equation. Even if a fast method for the computation of the global minimum were available, we would have to be careful. Indeed, the global solution of the optimization problem with regularization parameter γ set to zero might be

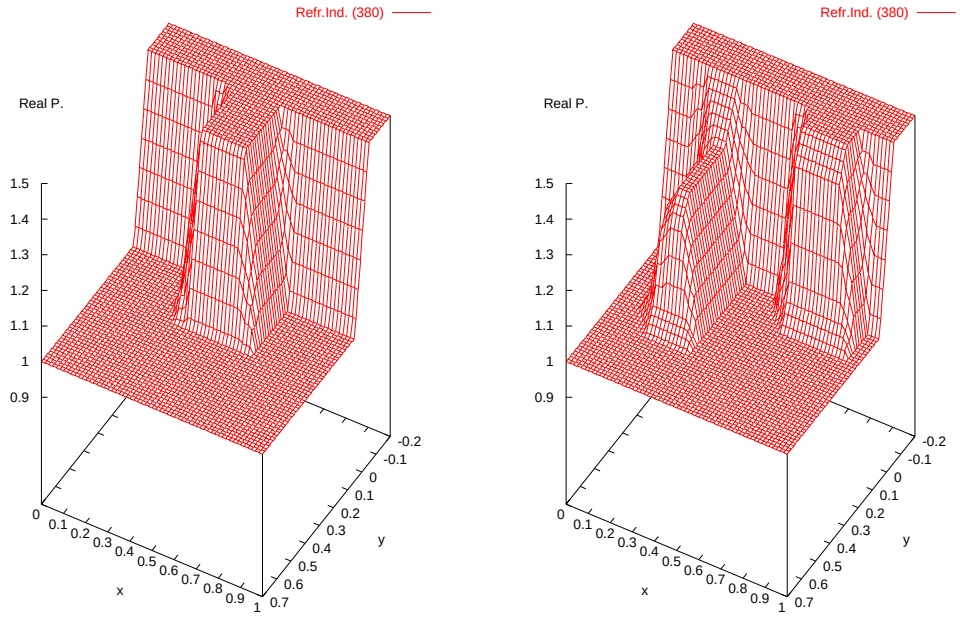

FIG. 6.1. *The two gratings: Rectangular and two towers.*

close to a local minimum of the regularized problem ($\gamma > 0$) different from the global minimum. In any case, due to the locality of the conjugate gradient solution, the choice of the initial solution is very important. Fortunately, for our numerical experiments, the choice of the initial guess as the mean value wave number function and the corresponding solutions of the Helmholtz solutions, i.e.,

$$\kappa_{0,j} := k_0^2,\ j = 1, \dots, M, \quad k_0 := \frac{k^- + k^+}{2},$$
$$\xi_0(l) := [B_h(k_0, \theta_l)]^{-1} \eta(\theta_l),\ l = 1, \dots, L,$$

was satisfactory.

6. The numerical experiment. The conjugate gradient approach. For our numerical tests we consider two gratings. Both are chosen with $b^- = -0.2\,\mu$m, $b_1^- = 0\,\mu$m, $b_1^+ = 0.5\,\mu$m, and $b^+ = 0.7\,\mu$m. The period is $d = 1\,\mu$m. The grating materials are characterized by the refractive index ν, which determines the value of the wave number function by the formula $k = \nu d/\lambda$. The wave length of light is $\lambda = 635\,$nm. The cover material over the grating (for $x_2 > b_1^+$) is air with $\nu = 1$. The index of the substrate material (for $x_2 < b_1^-$) is $\nu = 1.5$. The first grating is rectangular (cf. Figure 6.1, where a continuous linear interpolation of the piecewise constant function is plotted), i.e., the refractive index is

$$\nu = \nu(x_1, x_2) := \begin{cases} 1.5 & \text{for } \left|x_1 - \frac{1}{2}\right| \le \frac{1}{6} \text{ and } x_2 \le \frac{1}{4}, \\ 1.0 & \text{for } \left|x_1 - \frac{1}{2}\right| > \frac{1}{6} \text{ or } x_2 > \frac{1}{4}\,. \end{cases}$$

The second (cf. Figure 6.1) is a two tower grating with

$$\nu = \nu(x_1, x_2) := \begin{cases} 1.5 & \text{for } \left|x_1 - \frac{3}{4}\right| \le \frac{1}{6} \text{ and } x_2 \le \frac{1}{8}, \\ 1.35 & \text{for } \left|x_1 - \frac{1}{4}\right| \le \frac{1}{6} \text{ and } x_2 \le \frac{3}{8}, \\ 1.5 & \text{for } x_2 < 0, \\ 1.0 & \text{else.} \end{cases}$$

For the two gratings, we have computed the Rayleigh coefficients corresponding to nonevanescent modes under the angles of incidence θ_l, $l = 1, \dots L$.

$$\{\theta_l : \ l = 1, \dots L\} := \begin{cases} \{0\} & \text{if } L = 1, \\ \{-60, 0, 60\} & \text{if } L = 3, \\ \{-60, -40, -20, 0, 20, 40, 60\} & \text{if } L = 7, \\ \{-60, -55, -50, -45, \dots, 45, 50, 55, 60\} & \text{if } L = 25. \end{cases}$$

Depending on the angle of incidence, these Rayleigh coefficients are three numbers of the A_n^+, $n = -2, -1, 0, 1, 2$, and five numbers of the A_n^-, $n = -3, -2, -1, 0, 1, 2, 3$. From these numbers we have to recover the grating by the inverse algorithm described in section 5.

Since our simulated measurement data should be obtained by a method different from that involved in the inverse algorithm, we have computed the $A_n^\pm$ by a finite element method over a high level nonuniform triangulation. Actually we have employed a standard grid generator and more than 200 000 unknown finite elements. The finite element operator $B_h(k, \theta)$ used for the algorithm of section 5 is based on a coarse uniform triangulation. More precisely, we split the domain $\Omega = (0, 1) \times (-0.2, 0.7)$ into 40×36 equal squares and divide each square into two triangles by a cut along the diagonal. Taking into account the periodicity, the resulting number of finite elements is 1600. The unknown wave number function is sought as a function piecewise continuous over the triangulation resulting from halving the squares of a 20×18 uniform rectangular partition. This means there are 720 triangles in Ω and exactly 400 unknowns for the wave number function corresponding to the triangles falling into the strip $(0, d) \times (b_1^-, b_1^+) = (0, 1) \times (0, 0.5)$.

The constants c_s, c_d, c_v, and γ have to be adapted to the special case at hand. So one should take a typical example with known wave number solution and determine the constants such that the resulting approximation of the wave number function is the closest to the known exact solution. Then the unknown gratings should be recovered using the just obtained constants. Note that, in general, the determination of the regularization parameter is a hard problem. It is probably easiest to adjust it for a simple case with known solution and to reuse it for the general case.

Following this philosophy, we have determined the "optimal" constants for the first rectangular grating. We have set $c_d = 0.005$, and the other numbers, including the number of necessary conjugate gradient iterations, are given in Table 6.1. More precisely, we have chosen the equilibration parameter c_d such that the first term in the functional (5.1) is about the same size as the second (cf. the choice of the analogous parameter γ following (5.56) in [11]). The equilibrium parameters c_v and c_d have been optimized together with the regularization parameter γ. In a series of calculations we have doubled and halved, independently, the values $c_v\gamma$ and $c_s\gamma$ and found the "optimal" values presented in Table 6.1. Here "optimality" means that the approximate values of the refractive index at the points (0.0083,0.1417), (0.5167,0.1583), and (0.8167,0.2583) are closest to the exact values 1., 1.5, and 1.,

TABLE 6.1
Constants for the objective functional.

L	$c_v\gamma$	$c_s\gamma$	Iterations
1	0.000 000 9	0.000 001 5	2 000
3	0.000 000 5	0.000 000 25	8 000
7	0.000 000 03	0.000 000 005	25 000
25	0.000 000 2	0.000 000 000 05	50 000

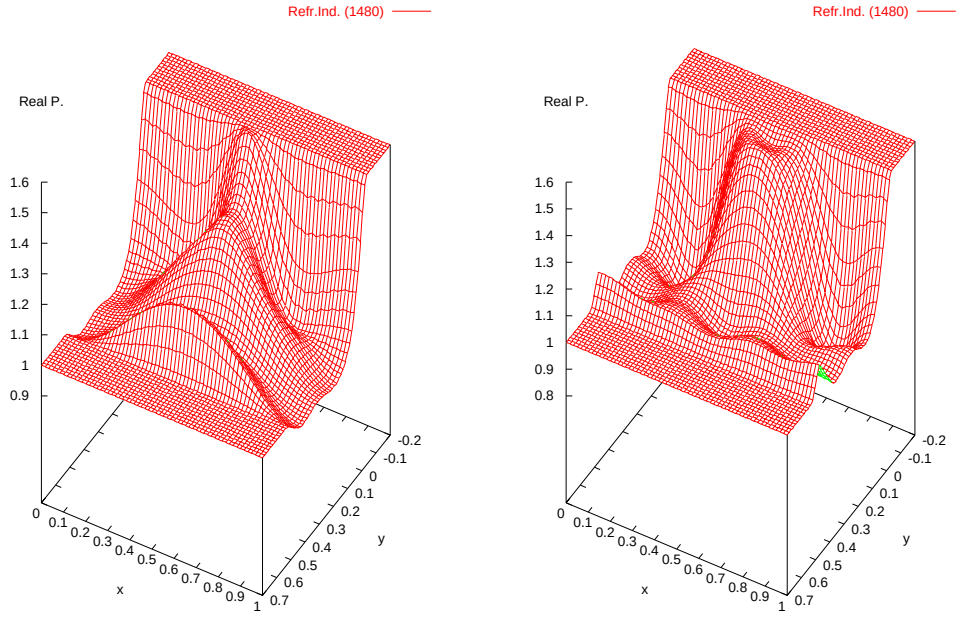

FIG. 6.2. *Reconstructed rectangular grating.* $L = 1$ *and* $L = 3$. *Conjugate gradient method.*

respectively. The plots of the resulting reconstructed wave number functions are shown in Figures 6.2 and 6.3. With larger L, i.e., with more measurement data, the recovered wave number improves slightly.

Next we have taken the optimal parameters of the rectangular grating and employed them in the algorithm for the two towers grating. Figures 6.4 and 6.5 show the results of the reconstruction which are close to the exact function (cf. Figure 6.1).

The SQP approach. Clearly, the conjugate gradient algorithm for the optimization problem (5.2) can be replaced by different optimization methods. For example, we consider the implementation SNOPT 5.3-4 of the SQP method [17]. Since this method is capable of dealing with constraints, we define

$$\mathcal{F}_h^{sqp}(\kappa, \xi(1), \dots, \xi(L); \gamma) := c_d \frac{\displaystyle\sum_{l=1}^{L} \left\| \left[F_h(\theta_l)\, \xi(l) + A^i(\theta_l) \right] - A_{meas}(\theta_l) \right\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}}{\displaystyle\sum_{l=1}^{L} \|A_{meas}(\theta_l)\|^2_{\ell^2_{\mathbb{C}}(\mathcal{U}^*(\theta_l))}} + c_v\gamma \|\kappa\|^2_{V(\Omega)} + c_s\gamma \sum_{l=1}^{L} \left\| \sum_{j=1}^{N} \xi(l)_j \varphi_{h,j} \right\|^2_{H^1_{per}(\Omega)} \tag{6.1}$$

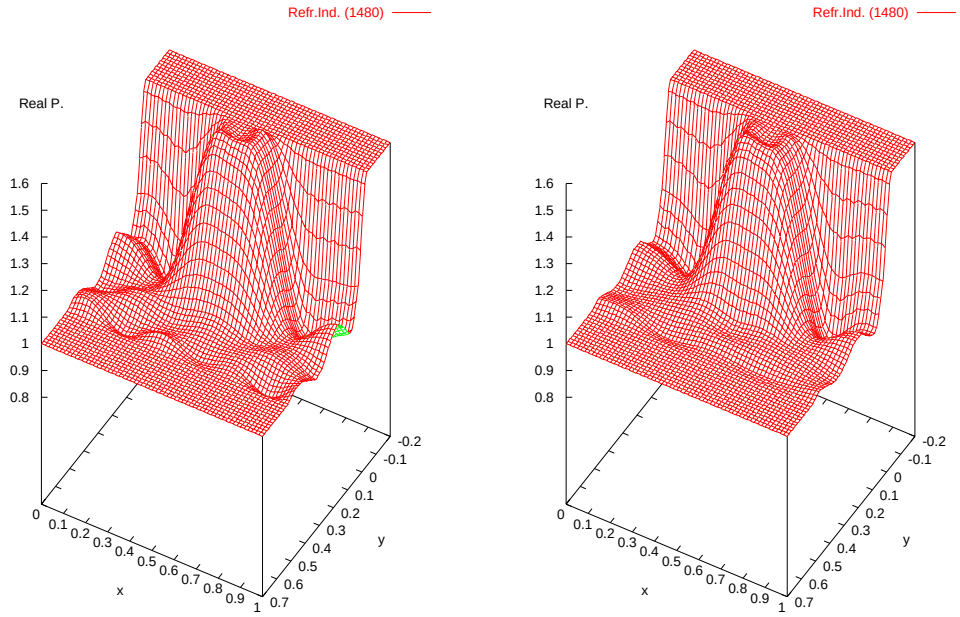

FIG. 6.3. *Reconstructed rectangular grating.* $L = 7$ *and* $L = 25$. *Conjugate gradient method.*

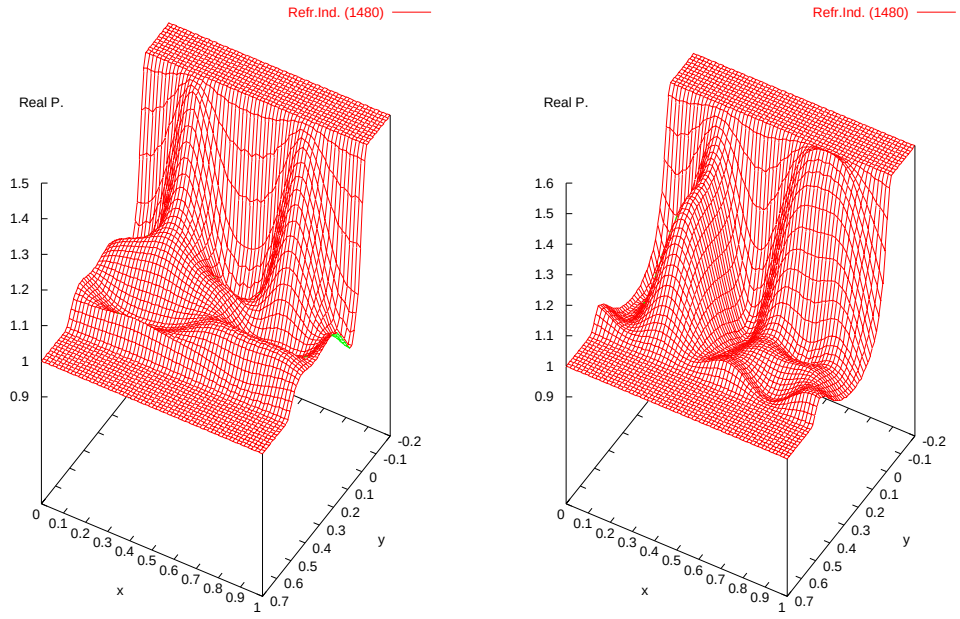

FIG. 6.4. *Reconstructed two towers.* $L = 1$ *and* $L = 3$. *Conjugate gradient method.*

and solve the optimization problem with constraints

$$\begin{aligned} \mathcal{F}_h^{sqp}(\kappa, \xi(1), \dots, \xi(L); \gamma) \quad &\longrightarrow \min, \\ \text{with } \kappa \in \ell^2_{\mathbb{C}}(M), & \\ \xi(l) \in \ell^2_{\mathbb{C}}(N),\ l = 1, \dots, L, & \\ B_h(\kappa, \theta_l)\xi(l) = \eta(\theta_l). & \end{aligned} \tag{6.2}$$

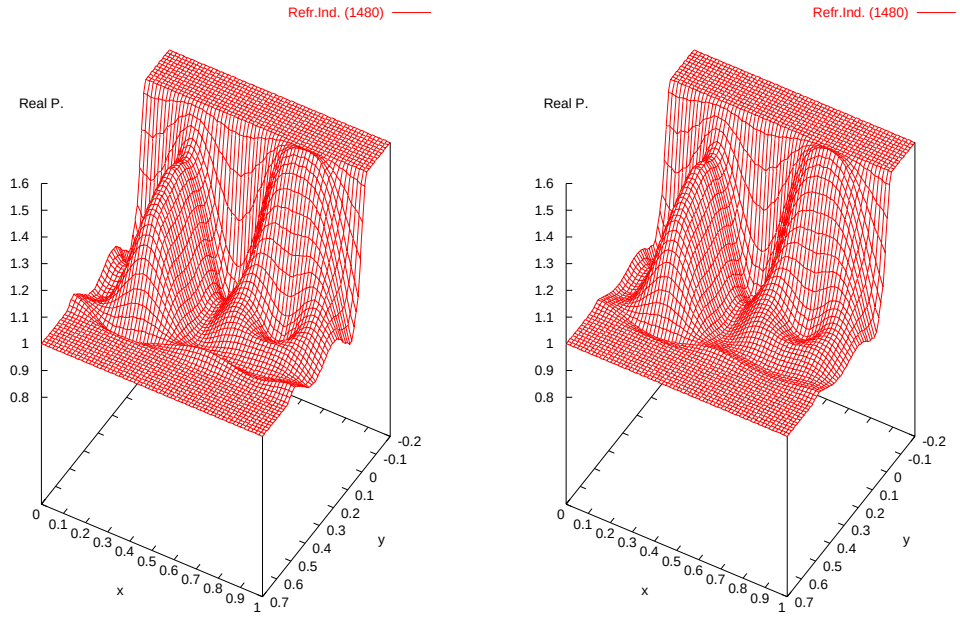

FIG. 6.5. *Reconstructed two towers.* $L = 7$ *and* $L = 25$. *Conjugate gradient method.*

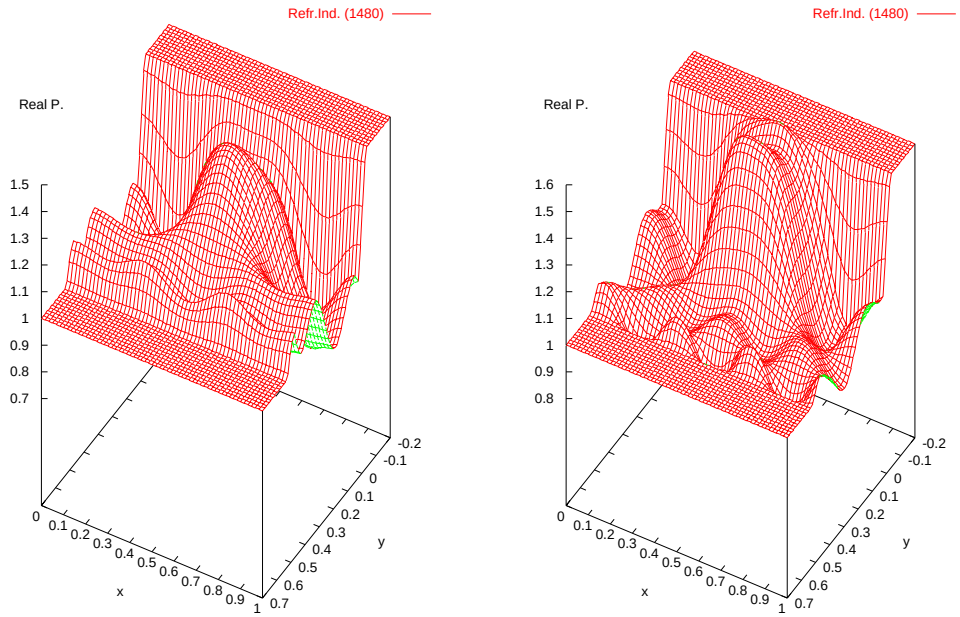

FIG. 6.6. *Reconstructed rectangular grating.* $L = 3$ *and* $L = 7$. *SQP method.*

Taking $c_d = 0.005$ and the parameters from Table 6.1, we arrive at visually the same pictures of reconstructed gratings (cf. Figures 6.6 and 6.7 and compare with Figures 6.1–6.5). Due to the extra effort for solving the constraint equations $B_h(\kappa, \theta_l)\xi(l) = \eta(\theta_l)$ exactly, the SQP method is much slower. Moreover, the SQP algorithm requires more storage capacity. However, to be fair, we have to admit that our simple test

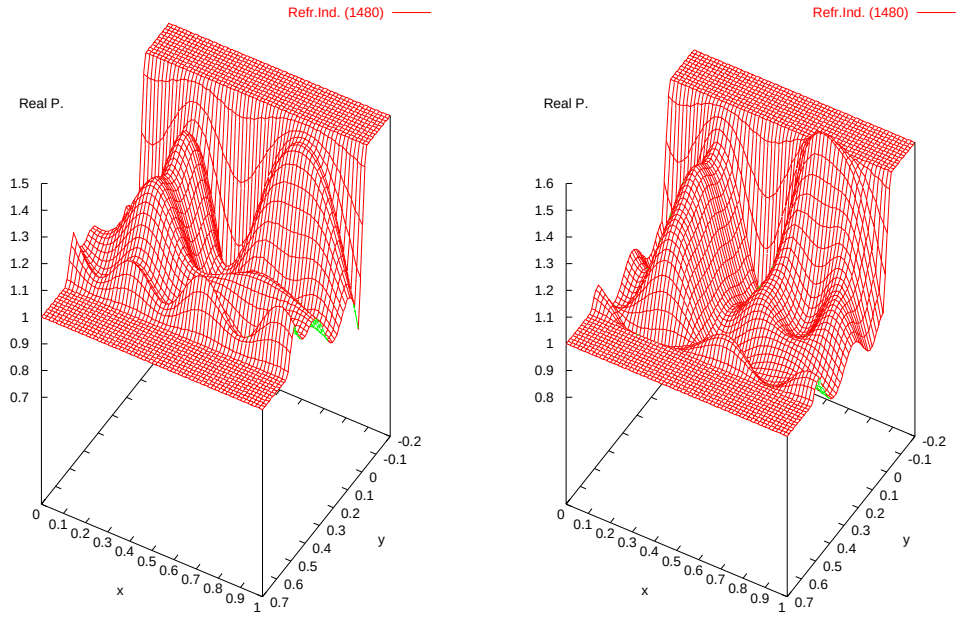

FIG. 6.7. *Reconstructed two towers. $L = 3$ and $L = 7$. SQP method.*

is performed employing a general code and default parameters. Changing the SQP parameters and including preconditioners might improve the performance.

Acknowledgments. The authors thank A. Möller and R. Henrion for many helpful consultations concerning the implementation of the optimization algorithms.

ON THE NATURE OF INITIAL-BOUNDARY VALUE SOLUTIONS FOR DISPERSIVE EQUATIONS*

NATASHA FLYER† AND BENGT FORNBERG‡

Abstract. If the initial and boundary data for a partial differential equation (PDE) do not obey an infinite set of compatibility conditions, singularities will arise in its solutions. For dissipative equations, these singularities are well localized in both time and space, and an effective numerical remedy is available for accurate computation of initial transients. This study analyzes the nature of similar corner discrepancies for dispersive equations, such as $u_t - u_{xxx} = 0$ and $iu_t - u_{xx} = 0$.

Key words. time-space corner singularities, dispersive equations, initial-boundary value problems

DOI. 10.1137/S0036139902415853

1. Introduction.

Solutions to initial-boundary value problems (IBVPs) will feature "corner singularities" in the space-time domain where initial and boundary data meet, unless these two data sets are connected by an infinite number of compatibility conditions [2]. Since the two data sets usually arise from different considerations, these singularities are almost always present. Although the issue has been analyzed at least since the 1950s (as surveyed in [2] and [3]), the focus has mostly been theoretical rather than numerical. For dissipative equations, the irregularities that are caused by these corner singularities are short-lived in time and remain local in space. These features allowed for the development of a highly effective strategy for restoring full numerical accuracy with little extra computational cost, as described in [4]. For dispersive PDEs, the irregularities do not stay local in space, and it depends on the equation whether or not they will be short-lived in time. Methods for effective numerical treatment will likely vary from equation to equation. The goal of the present paper is to give illustrating examples of dispersive corner singularities, largely by means of finding corner basis functions, which illuminate the mixing of temporal and/or spatial scales that occurs initially. If the boundaries are introduced to the problem only for the purpose of truncating what otherwise would have been an infinite domain, the preferred strategy would quite certainly be to create artificial boundary conditions in such a way that these space-time domain corner singularities do not arise.

Section 2 introduces the concept of corner basis functions, first for the well-known model equations $u_t + u_x = 0$ and $u_t - u_{xx} = 0$. It is shown how corner basis functions describe the nature of the corner singularities for these equations. Since the general character of solutions to dispersive equations may be less familiar, section 3 starts with some illustrative solutions for the linearized KdV equation, $u_t - u_{xxx} = 0$, and then proceeds with establishing its corner basis functions. Section 4 contains a similar discussion for the linear Schrödinger equation, $iu_t - u_{xx} = 0$. Based on these corner basis functions, we discuss in section 5 the character of IBV solutions for the two

dispersive equations just mentioned. The final section offers some concluding remarks, summarizing the nature of corner singularities for PDEs of the type $u_t \pm u_{nx} = 0$, $n = 1, 2, 3, \ldots$, in terms of corner basis functions.

2. Corner basis functions for $u_t + u_x = 0$ and $u_t - u_{xx} = 0$. The quarter plane problem ($x > 0,\ t > 0$)

$$\begin{aligned} &\text{PDE:} && u_t + u_x = 0, \\ &\text{IC:} && u(x,0) = f(x), \\ &\text{BC:} && u(0,t) = g(t) \end{aligned} \tag{2.1}$$

has the analytic solution

$$u(x,t) = \begin{cases} f(x-t), & x > t, \\ g(t-x), & x < t. \end{cases} \tag{2.2}$$

Assuming that $f(x)$ and $g(t)$ are smooth functions, the solution (2.2) is smooth for all times if and only if an infinite sequence of compatibility conditions holds in the corner at $x = 0$, $t = 0$ [2], [3]:

$$\begin{aligned} &g(0) - f(0) && = 0, && \text{continuity} \\ &g_t(0) + f_x(0) && = 0, && \text{PDE} \\ &g_{tt}(0) - f_{xx}(0) && = 0, && \text{differentiated versions of the PDE} \\ &g_{ttt}(0) + f_{xxx}(0) && = 0, && \quad\downarrow \\ &\vdots \\ &g_{nt}(0) + (-1)^{n+1} f_{nt}(0) && = 0. \end{aligned} \tag{2.3}$$

If we are given a problem (2.1) for which any of the equalities in (2.3) fail to hold, one strategy for transforming the problem to one with a smooth solution (better suited for most numerical methods) is to create an explicitly known function $s(x,t)$ which also satisfies the PDE and which possesses an identical corner singularity. To construct $s(x,t)$, we introduce the concept of corner basis functions $u_n(x,t)$ with the properties

(2.4) (i) $u_n(x,t)$ satisfies the PDE away from the corner,

(ii) $u_n(x,0) \equiv 0$,

(iii) $$\frac{1}{n!}\frac{\partial^j u_n(0,t)}{\partial t^j} = \begin{cases} 1 & \text{for } j = k, \\ 0 & \text{for } j \neq k. \end{cases}$$

The corner basis functions are derived by Taylor expanding the boundary condition (BC) in time and then for each term in the expansion solving the PDE with zero initial condition (IC), as shown below in the case of (2.1).

$$\begin{aligned} u_0(x,t) &= \begin{cases} 0, & x > t, \\ 1, & x < t, \end{cases} \\ u_1(x,t) &= \begin{cases} 0, & x > t, \\ t - x, & x < t, \end{cases} \\ u_2(x,t) &= \begin{cases} 0, & x > t, \\ (t-x)^2, & x < t, \end{cases} \\ &\cdots, \end{aligned} \tag{2.5}$$

i.e.,

$$u_n(x,t) = \begin{cases} 0, & x > t, \\ (t-x)^n, & x < t, \end{cases} \quad n = 0, 1, 2, \dots .$$

If the right-hand sides of (2.3) were not equal to 0, 0, 0, 0, ... but instead equal to $r_0,\ r_1,\ r_2,\ r_3,\ \dots$, the function

$$s(x,t) = r_0\, u_0(x,t) + \frac{r_1}{1!}\, u_1(x,t) + \frac{r_2}{2!}\, u_2(x,t) + \frac{r_3}{3!}\, u_3(x,t) + \cdots \tag{2.6}$$

would have exactly the same corner singularity as the solution $u(x,t)$. Standard numerical methods can then be applied to the difference function

$$v(x,t) = u(x,t) - s(x,t), \tag{2.7}$$

which is infinitely smooth and well suited for numerics (satisfying the same PDE and IC, and having known BCs). However, in practice, we are limited to machine precision and thus need to use only a finite number p of compatibility conditions, corresponding to a truncated version of (2.6). The difference in (2.7) will be of size $O(t^p)$, the first neglected term in the expansion $s(x,t)$. For small t, we can make this difference arbitrarily small by choosing p sufficiently large.

This idea of creating corner singularity functions $u_n(x,t),\ n = 0, 1, 2, \dots$, and then subtracting a combination of them is of no particular utility for (2.1) since the analytic solution (2.2) is almost as simple algebraically as are the corner functions (2.5). Furthermore, the corner irregularity will persist for all times. If (2.1) is generalized to variable coefficients, the singularity will travel along a curved characteristic path, and cancellation based solely on corner information is not feasible.

Turning to the heat equation, it may at first appear that corner corrections are not needed. Figures 2.1(a), (b) show the analytic solution to the IBVP

$$\begin{aligned} &\text{PDE:} \quad u_t - u_{xx} = 0, \\ &\text{IC:} \quad\ u(x,0) \quad = 0, && 0 \le x \le 1, \\ &\text{BCs:} \begin{cases} u(0,t) & = \sin 2\pi t, \\ u_x(1,t) & = 0, \end{cases} && t > 0, \end{aligned} \tag{2.8}$$

over $0 \le x \le 1,\ 0 \le t \le 1$ and $0 \le x \le 10^{-3},\ 0 \le t \le 10^{-3}$, respectively. No matter how much we zoom in on the area near the origin, the solution surface will graphically look indistinguishable from the one shown to the right (Figure 2.1(b)).

However, this apparent regularity of the solution near the origin is severely misleading. The seemingly smooth solution in fact features a sharp irregularity, as the plot over $0 \le x \le 1,\ 0 \le t \le 10^{-3}$ in Figure 2.2(a) reveals.

A 21-node numerical Chebyshev solution (implemented without grid clustering at the right boundary, cf. [6, section 5.1, Example 3], and using a fourth-order Runge–Kutta method in time) will feature errors of the order 10^{-4} near the origin during the first moments, due to the fact that the PDE is not satisfied in the corner $(0,0)$ by the solution. This numerical observation is theoretically proven in [3]. At later times, the error decreases to around 10^{-12}. In Figure 2.2(b), the numerical corner error has already decayed to around 10^{-6} by the first displayed time level.

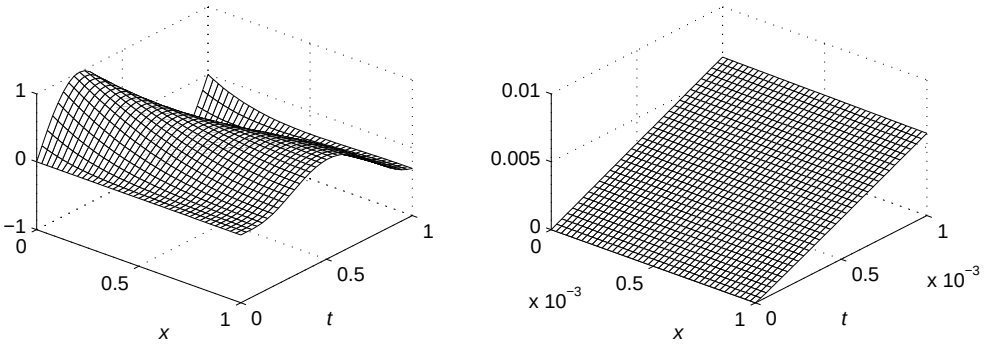

FIG. 2.1. *Analytic solution to the IBV problem* (2.8) *shown over* (a) $0 \le x \le 1,\ 0 \le t \le 1$ *and* (b) $0 \le x \le 10^{-3},\ 0 \le t \le 10^{-3}$.

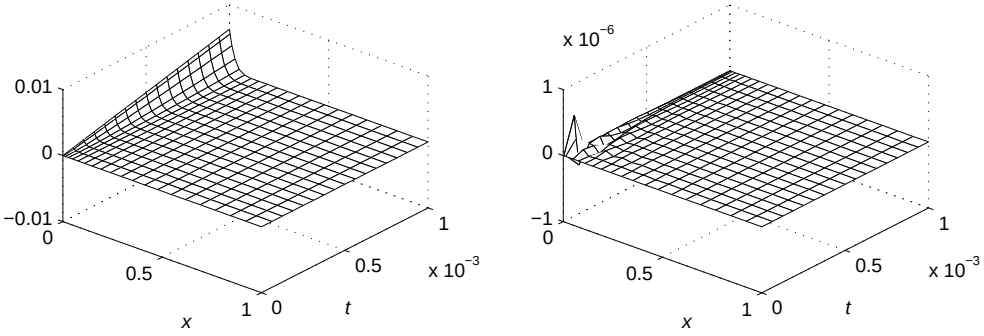

FIG. 2.2. (a) *Analytic solution to IBV problem* (2.8). (b) *Error in Chebyshev numerical solution. Both are shown over* $0 \le x \le 1,\ 0 \le t \le 10^{-3}$ *and displayed on a grid that is quadratically refined at the left edge.*

Although corner irregularities for the heat equation persist only a very short time, corrections for them are needed in order to obtain an accurate solution of initial transients. For the constant coefficient case

$$\begin{aligned} &\text{PDE:} && u_t - u_{xx} = 0, && \\ &\text{IC:} && u(x,0) = f(x), && x > 0, \\ &\text{BC:} && u(0,t) = g(t), && t > 0, \end{aligned} \tag{2.9}$$

we need to replace the compatibility conditions (2.3) by

$$\begin{aligned} g(0) - f(0) &= 0, && \text{continuity} \\ g_t(0) - f_{xx}(0) &= 0, && \text{PDE} \\ g_{tt}(0) - f_{xxxx}(0) &= 0, && \text{differentiated versions of the PDE} \\ \dots, & && \downarrow \\ g_{nt}(0) - f_{(2n)x}(0) &= 0, && \end{aligned}$$

and the corner functions (2.5) by

$$
\begin{aligned}
u_0(x,t) &= \operatorname{Erfc}\left(\tfrac{x}{2\sqrt{t}}\right),\\
u_1(x,t) &= -\sqrt{\tfrac{t}{\pi}}\; x\; e^{-x^2/(4t)} + \left(t+\tfrac{x^2}{2}\right)\operatorname{Erfc}\left(\tfrac{x}{2\sqrt{t}}\right),\\
u_2(x,t) &= -\tfrac{1}{6}\sqrt{\tfrac{t}{\pi}}\; x\; (10\,t+x^2)\; e^{-x^2/(4t)} + \left(t^2+t\,x^2+\tfrac{x^4}{12}\right)\operatorname{Erfc}\left(\tfrac{x}{2\sqrt{t}}\right),\\
u_3(x,t) &= -\tfrac{1}{60}\sqrt{\tfrac{t}{\pi}}\; x\; (132\,t^2+28\,t\,x^2+x^4)\; e^{-x^2/(4t)}\\
&\quad + \left(t^3+\tfrac{3}{2}t^2x^2+\tfrac{1}{4}t\,x^4+\tfrac{x^6}{120}\right)\operatorname{Erfc}\left(\tfrac{x}{2\sqrt{t}}\right),\\
&\ldots .
\end{aligned}
\tag{2.10}
$$

These functions all satisfy the PDE with the IC and BC $u_n(x,0)=0,\ u_n(0,t)=t^n,\ n=0,1,2,\ldots$.

One way to derive (2.10) is to note that the change of variables $\xi=\frac{x}{\sqrt{t}},\ \tau=\log t$ transforms $u_t-u_{xx}=0$ into $u_\tau=u_{\xi\xi}+\frac{\xi}{2}u_\xi$. The $u_0(x,t)$ solution corresponds to an equilibrium solution of the transformed PDE. With the BCs $u(0)=1,\ u(\infty)=0$ we find $u(\xi)=\operatorname{Erfc}(\frac{\xi}{2})$ $(=1-\frac{2}{\sqrt{\pi}}\int_0^{\xi/2}e^{-\varsigma^2}d\varsigma)$, and consequently $u_0(x,t)=\operatorname{Erfc}(\frac{x}{2\sqrt{t}})$. The subsequent corner functions can then (like for all other PDEs) be generated recursively:

$$
u_n(x,t) = n\int_0^t u_{n-1}(x,t)\,dt, \quad n=1,2,\ldots . \tag{2.11}
$$

Alternatively, we can obtain a general expression for all the $u_n(x,t)$ functions in terms of Kummer's confluent ${}_1F_1$ hypergeometric functions:

$$
u_n(x,t) = t^n\left\{{}_1F_1(-n,\tfrac{1}{2},-\tfrac{x^2}{4t}) - \tfrac{x\,\Gamma(n+1)}{\sqrt{t}\,\Gamma(n+\frac{1}{2})}\;{}_1F_1(\tfrac{1}{2}-n,\tfrac{3}{2},-\tfrac{x^2}{4t})\right\},\ n=0,1,2,\ldots . \tag{2.12}
$$

To arrive at (2.12), we generalize the observation above regarding the $u_0(x,t)$ corner function by noting that $\frac{u_n(x,t)}{t^n}$ becomes a function of one variable $\xi=\frac{x}{\sqrt{t}}$ only, which we write as $u_n(\xi)$. From its definition and the governing PDE, this function will need to satisfy

$$
(u_n)_{\xi\xi}+\frac{\xi}{2}(u_n)_\xi - n\,u_n = 0 \quad \text{with} \quad \begin{cases} u_n(0) &= 1,\\ u_n(\infty) &= 0. \end{cases}
$$

The general solution to the ODE can be written

$$
u_n(\xi) = c_1\;\; {}_1F_1(-n,\tfrac{1}{2},-\tfrac{\xi^2}{4}) + c_2\;\xi\;\; {}_1F_1(\tfrac{1}{2}-n,\tfrac{3}{2},-\tfrac{\xi^2}{4}).
$$

The condition $u_n(0)=1$ says that $c_1=1$, and leading order asymptotics of the ${}_1F_1$ functions (see [1]) demonstrate that cancellation of growths as $\xi\to\infty$ requires $\frac{c_2}{c_1}=-\frac{\Gamma(n+1)}{\Gamma(n+\frac{1}{2})}$.

Figure 2.3 shows $u_0(x,t),\ u_1(x,t)$, and $u_2(x,t)$ displayed over two different time intervals. The irregularity remains local in both time and space. For dissipative equations like (2.9), corner functions form a very effective means of improving the accuracy of numerical calculations since, as is shown in [4],

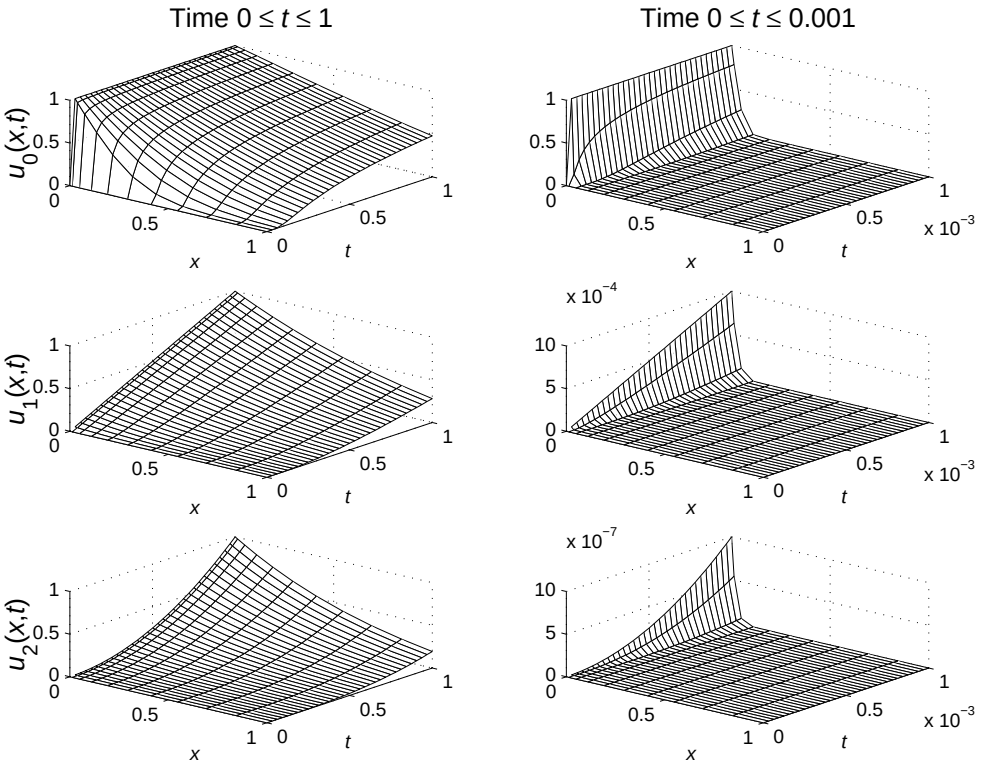

FIG. 2.3. *The corner functions* $u_0(x,t)$, $u_1(x,t)$, *and* $u_2(x,t)$ *for the heat equation* $u_t - u_{xx} = 0$, *shown over* $0 \le x \le 1$ *and (left column)* $0 \le t \le 1$, *(right column)* $0 \le t \le 0.001$. *The grid is again quadratically refined towards the left edge.*

1. only 3–4 correction functions typically suffice for correction to machine precision, and
2. generalizations to variable coefficients are straightforward.

3. Illustrative solutions and corner functions for $u_t - u_{xxx} = 0$. Similar to the heat equation, IBV solutions to the linearized KdV equation

$$u_t - u_{xxx} = 0 \tag{3.1}$$

will typically feature two scales: (1) a slow, long-term part and (2) a high-frequency part emanating from the corners and described by corner basis functions. Initially, the high-frequency part of the solution is of infinitesimal size but then expands to cover the whole domain. To illustrate the first part and to provide a background for discussing the latter part, we first consider different half-plane problems containing only slow long-term scales.

3.1. Traveling wave solutions in different half-planes.

3.1.1. The upper half-plane ($t > 0$). With the IC

$$\text{IC:} \quad u(x,0) = \cos(kx), \tag{3.2}$$

the solution of (3.1) becomes

$$\text{solution:} \quad u(x,t) = \cos(kx - k^3 t). \tag{3.3}$$

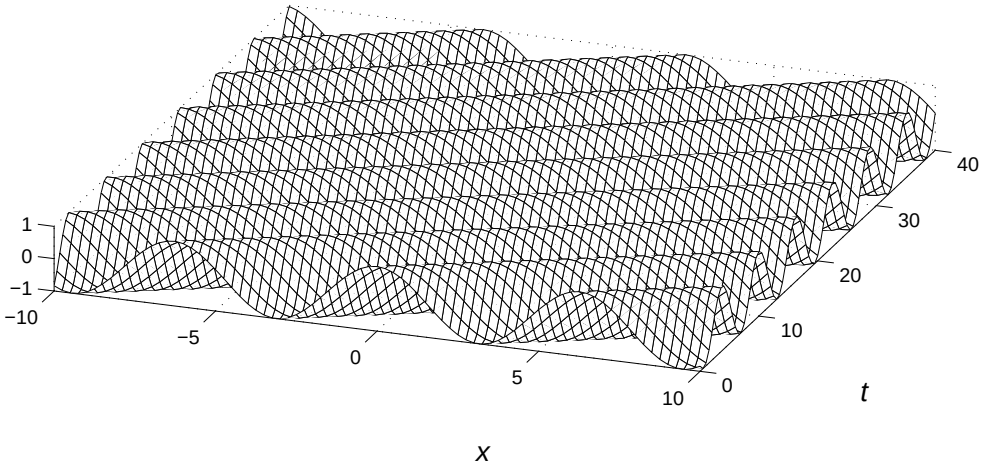

FIG. 3.1. *Upper half-plane solution to* $u_t - u_{xxx} = 0$ *with IC* $u(x,0) = \cos(x)$.

This is a single Fourier mode whose phase speed increases with the wave number k as $c = k^2$. We can note that *all* waves travel to the right, as shown in Figure 3.1 for $k = 1$.

3.1.2. The right half-plane ($x > 0$). For the equation (3.1) we need to impose two BCs on the left side (taken to be $x = 0$). Two cases can be noted. The first case has a sinusoidal forcing on the boundary, with the first derivative $u_x(0,t) = 0$.

Case 1.

$$\text{BCs:} \quad \begin{cases} u(0,t) = \sin(k^3 t), \\ u_x(0,t) = 0, \end{cases}$$

$$\text{solution:} \quad u(x,t) = \tfrac{1}{\sqrt{3}} \left[\cos(kx - k^3 t + \tfrac{\pi}{3}) - e^{-\frac{\sqrt{3}}{2}kx} \cos(\tfrac{1}{2}kx + k^3 t + \tfrac{\pi}{3}) \right].$$

In the second case, the solution is zero and it is the first derivative that has a sinusoidal forcing:

Case 2.

$$\text{BCs:} \quad \begin{cases} u(0,t) = 0, \\ u_x(0,t) = \sin(k^3 t), \end{cases}$$

$$\text{solution:} \quad u(x,t) = \tfrac{1}{\sqrt{3}\,k} \left[\cos(kx - k^3 t + \tfrac{\pi}{6}) - e^{-\frac{\sqrt{3}}{2}kx} \cos(\tfrac{1}{2}kx + k^3 t - \tfrac{\pi}{6}) \right].$$

Figures 3.2 and 3.3 show Cases 1 and 2, respectively. We notice in Figure 3.2 how the crests of the waves emerge perpendicularly to the left boundary in order to accommodate the zero first derivative BC. Similarly, Figure 3.3 shows how the waves again are deformed near the boundary, this time to accommodate the condition $u(0,t) = 0$. As these two cases demonstrate, forcing the left boundary with a Fourier mode will produce outgoing waves with the same wave number, differing between the two cases only in amplitude and phase shift. It is therefore possible to create a

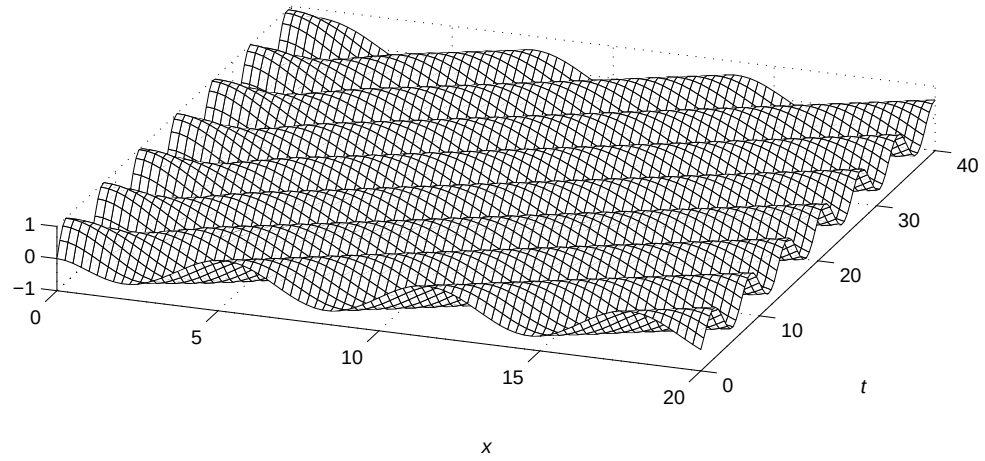

FIG. 3.2. *Solution to the right half-plane problem for* $u_t - u_{xxx} = 0$ *with the left BCs* $u(0,t) = \sin t,\ u_x(0,t) = 0$.

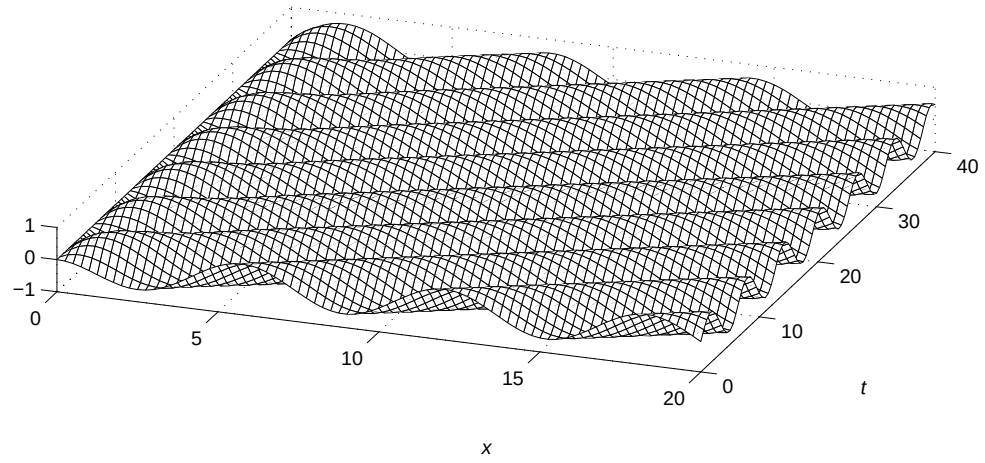

FIG. 3.3. *Solution to the right half-plane problem for* $u_t - u_{xxx} = 0$ *with left BCs* $u(0,t) = 0,\ u_x(0,t) = \sin t$.

BC so that the outgoing waves cancel, and only the exponential decay to the right remains. However, this is a very special case; sinusoidal forcing will in general produce sinusoidal waves traveling to the right.

3.1.3. The left half-plane ($x < 0$). For the right half-plane problems, we considered forcing on the left side. We now consider forcing on the right side, requiring only one BC for the PDE:

$$\begin{aligned} &\text{BC:} && u(0,t) = \sin(k^3 t), \\ &\text{solution:} && u(x,t) = e^{\frac{\sqrt{3}}{2}kx} \sin(\tfrac{1}{2}kx + k^3 t). \end{aligned}$$

There can be no waves traveling to the left for (3.1), and the solution therefore decays exponentially away from the boundary, as is seen in Figure 3.4. This also implies that

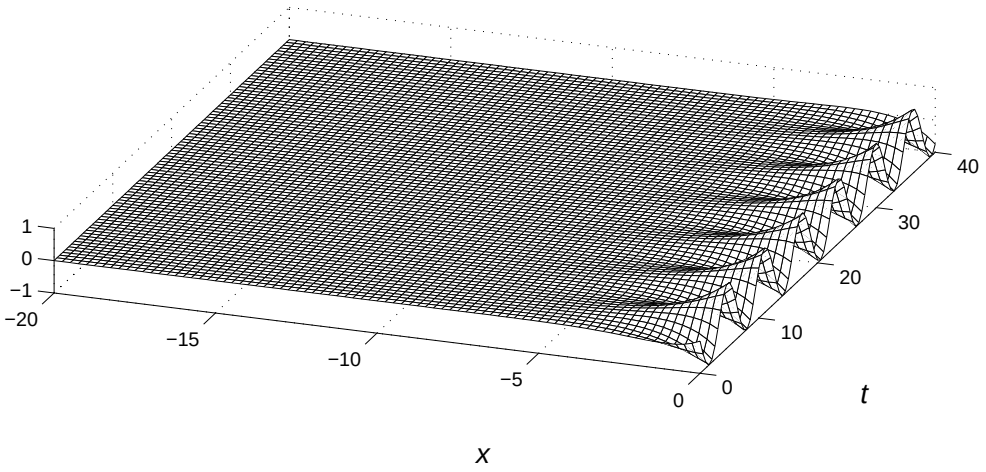

FIG. 3.4. *Solution to the left half-plane problem for* $u_t - u_{xxx} = 0$ *with forcing* $u(0,t) = \sin t$ *on the right boundary.*

when waves arrive from the left to a right boundary, there can be no reflection, but only decay. With incoming waves of the form $u(x,t) = \cos(kx - k^3 t)$, closed form solutions for the cases with Neumann and Dirichlet right BCs become as follows.

Case 1.

$$\begin{aligned} &\text{BC:} && u_x(0,t) = 0, \\ &\text{solution:} && u(x,t) = \cos(kx - k^3 t) + e^{\frac{\sqrt{3}}{2}kx} \cos(\tfrac{1}{2}kx + k^3 t + \tfrac{\pi}{3}). \end{aligned}$$

Case 2.

$$\begin{aligned} &\text{BC:} && u(0,t) = 0, \\ &\text{solution:} && u(x,t) = \cos(kx - k^3 t) - e^{\frac{\sqrt{3}}{2}kx} \cos(\tfrac{1}{2}kx + k^3 t). \end{aligned}$$

These solutions are shown in Figures 3.5 and 3.6.

In both cases, the incoming wave from the left undergoes a transition near the right boundary in order to accommodate the BCs at the right edge. The half-plane solutions for (3.1) can be summed up as waves traveling *solely* to the right, with at most a thin transition region at a right-hand boundary. The character of these half-plane solutions set the stage for solving the quarter-plane problem, leading us to sets of left and right corner basis functions.

3.2. Left corner functions. Since (3.1) needs two BCs to the left, we need to obtain two independent sets of corner functions $u_n(x,t)$ and $v_n(x,t)$. These functions should all obey the PDE, the IC $u_n(x,0) = v_n(x,0) = 0$, and the BCs

$$\begin{cases} u_n(0,t) = t^n, & \frac{\partial}{\partial x} u_n(0,t) = 0, \\ v_n(0,t) = 0, & \frac{\partial}{\partial x} v_n(0,t) = t^n, \end{cases} \qquad n = 0,\ 1,\ 2,\ \ldots .$$

Following the approach which led us to the corner functions (2.12) for the heat

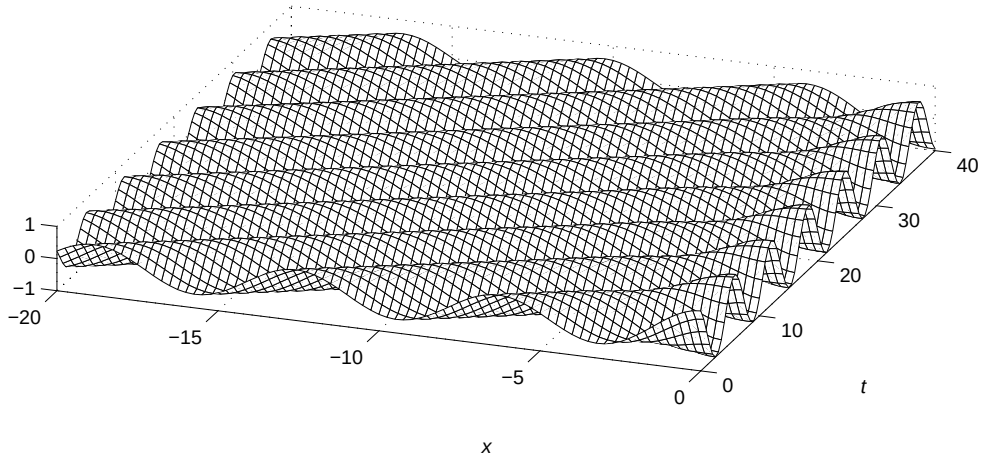

FIG. 3.5. *Solution to the left half-plane problem for* $u_t - u_{xxx} = 0$ *with incoming sinusoidal wave and right BC* $u_x(0,t) = 0$.

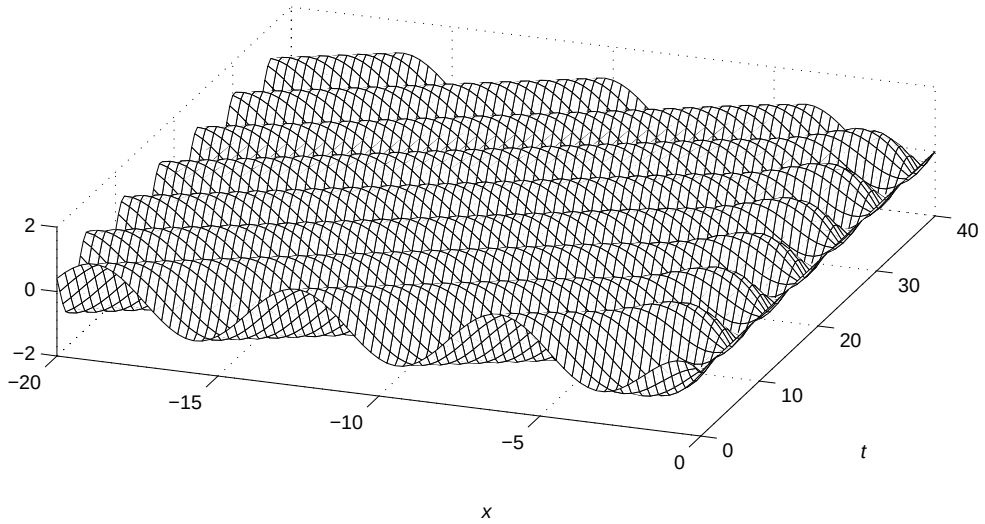

FIG. 3.6. *Solution to the left half-plane problem for* $u_t - u_{xxx} = 0$ *with incoming sinusoidal wave and right BC* $u(0,t) = 0$.

equation, we note that $\frac{u_n(x,t)}{t^n} = u_n(\xi)$ and $\frac{v_n(x,t)}{t^{n+1/3}} = v_n(\xi)$ both are functions of $\xi = \frac{x}{\sqrt[3]{t}}$ only, satisfying

$$(u_n)_{\xi\xi\xi} + \frac{\xi}{3}(u_n)_\xi - n\, u_n = 0, \;\; \{u_n(0) = 1,\ (u_n)_\xi(0) = 0,\ u_n(\infty) = 0\}$$

and

$$(v_n)_{\xi\xi\xi} + \frac{\xi}{3}(v_n)_\xi - (n + \tfrac{1}{3})\, v_n = 0, \;\; \{v_n(0) = 0,\ (v_n)_\xi(0) = 1,\ v_n(\infty) = 0\},$$

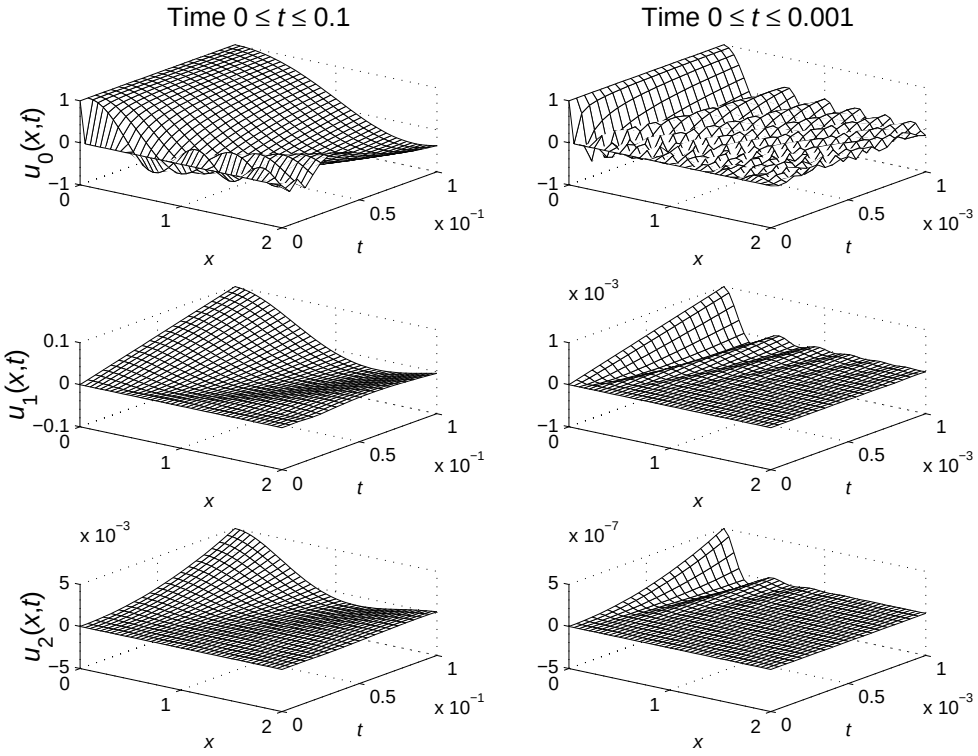

FIG. 3.7. *First three corner functions* $u_n(x,t)$ *for* $u_t - u_{xxx} = 0$, *displayed over* $0 \le t \le 0.1$ *and* $0 \le t \le 0.001$ *(left and right column, respectively).*

respectively, leading to the general expressions for the corner functions:

$$u_n(x,t) = t^n \left\{ {}_1F_2(-n, \{\tfrac{1}{3}, \tfrac{2}{3}\}, -\tfrac{x^3}{27t}) - \tfrac{x^2}{2t^{2/3}} \tfrac{\Gamma(n+1)}{\Gamma(n+\frac{1}{3})}\ {}_1F_2(\tfrac{2}{3} - n, \{\tfrac{4}{3}, \tfrac{5}{3}\}, -\tfrac{x^3}{27t}) \right\}, \quad n = 0, 1, 2, \dots,$$

and

$$v_n(x,t) = t^{n+\frac{1}{3}} \left\{ {}_1F_2(-n, \{\tfrac{2}{3}, \tfrac{4}{3}\}, -\tfrac{x^3}{27t}) - \tfrac{x^2}{2t^{2/3}} \tfrac{\Gamma(n+1)}{\Gamma(n+\frac{2}{3})}\ {}_1F_2(\tfrac{1}{3} - n, \{\tfrac{4}{3}, \tfrac{5}{3}\}, -\tfrac{x^3}{27t}) \right\}, \quad n = 0, 1, 2, \dots.$$

Figures 3.7 and 3.8 display the first three corner functions of each of the two types.

3.3. Right corner functions. Since the PDE is incapable of transporting any waves to the left, waves reaching a right side boundary will get absorbed no matter what BC is used there. As a consequence, the right corner functions on the domain $x < 0$, $t > 0$ will be nonoscillatory and reminiscent of the ones for the heat equation. Denoting these by $w_n(x,t)$, $n = 0, 1, 2, \dots$, we find by the same means as in the previous section

$$w_n(x,t) = t^n \left\{ {}_1F_2(-n, \{\tfrac{1}{3}, \tfrac{2}{3}\}, -\tfrac{x^3}{27t}) + \tfrac{x}{t^{1/3}} \tfrac{\Gamma(n+1)}{\Gamma(n+\frac{2}{3})}\ {}_1F_2(\tfrac{1}{3} - n, \{\tfrac{2}{3}, \tfrac{4}{3}\}, -\tfrac{x^3}{27t}) \right.$$
$$\left. + \tfrac{(-1)^n\sqrt{3}}{4\pi} \tfrac{x^2}{t^{2/3}} \Gamma(n+1)\ \Gamma(\tfrac{2}{3} - n)\ {}_1F_2(\tfrac{2}{3} - n, \{\tfrac{4}{3}, \tfrac{5}{3}\}, -\tfrac{x^3}{27t}) \right\},\ n = 0, 1, 2, \dots.$$

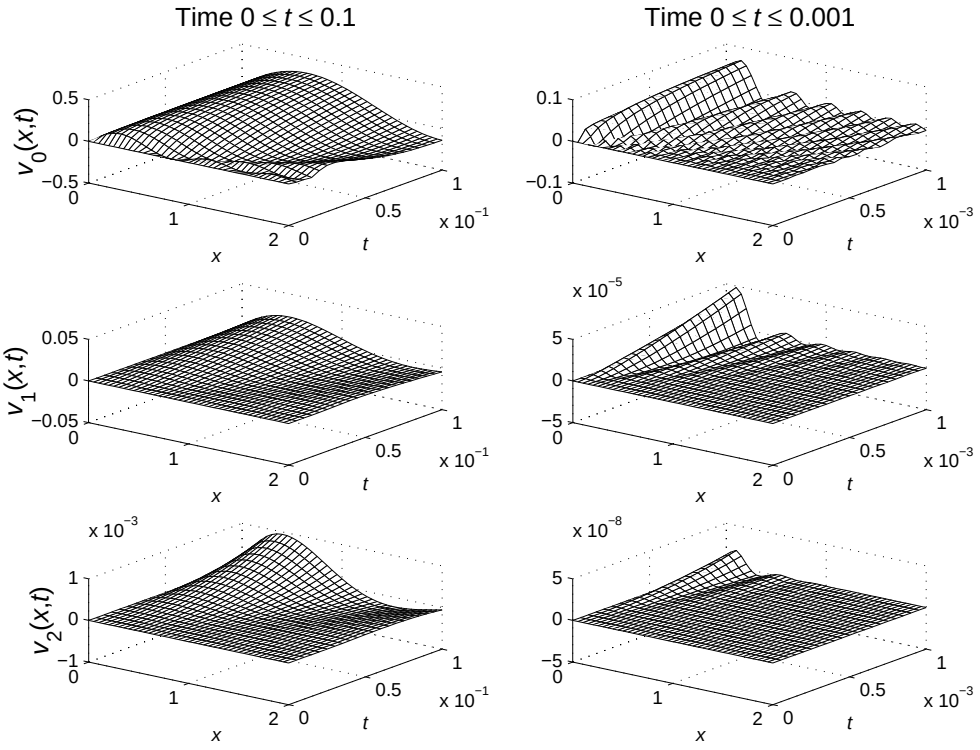

FIG. 3.8. *First three corner functions* $v_n(x,t)$ *for* $u_t - u_{xxx} = 0$, *displayed over* $0 \le t \le 0.1$ *and* $0 \le t \le 0.001$ *(left and right column, respectively).*

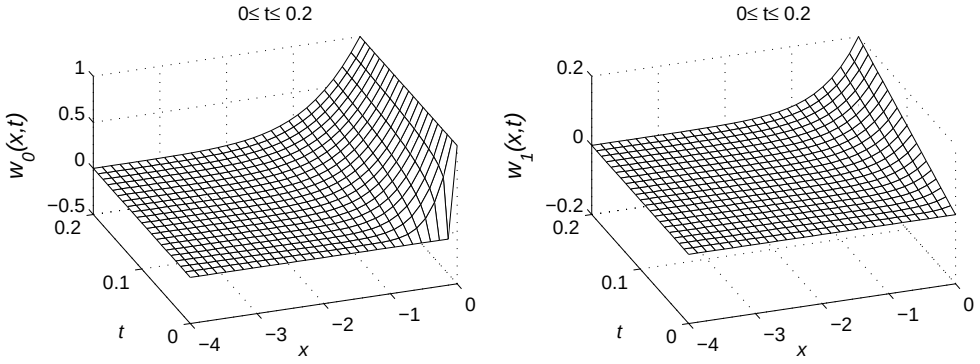

FIG. 3.9. *The right corner functions* $w_0(x,t)$ *and* $w_1(x,t)$ *to* $u_t - u_{xxx} = 0$.

Figure 3.9 displays the first two $w_n(x,t)$-functions.

For all the corner functions we have derived ($u_n(x,t)$ for the heat equation and $u_n(x,t)$, $v_n(x,t)$, $w_n(x,t)$ for the linearized KdV equation), the first hypergeometric function has $-n$ as its first parameter. This implies that, for $n = 0, 1, 2, \dots$, its usually infinite Taylor series truncates to become a finite degree polynomial.

To conclude this discussion of right corner functions, we note that a general

solution to (3.1) with

$$\begin{aligned} &\text{IC:} \quad u(x,0) = f(x), \quad x < 0, \\ &\text{BC:} \quad u(0,t) = g(t), \quad t > 0, \end{aligned}$$

can be expressed in terms of coupled contour principal value integrals [5].

4. Corner analysis for $iu_t - u_{xx} = 0$. The next example we consider is the linear Schrödinger equation

$$iu_t - u_{xx} = 0. \tag{4.1}$$

Although this also is a dispersive PDE, it will be shown that the character of IBV solutions for this equation is fundamentally different than for the linear KdV equation (3.1). Like the diffusion equation $u_t - u_{xx} = 0$, equation (4.1) requires only one BC on each side. Also, since the analysis is similar to that for the diffusion equation, we will here not consider any introductory half-plane problems.

4.1. Corner functions. Since $iu_t - u_{xx} = 0$ differs from the heat equation only by a factor of i, the same similarity transformation $\xi = \frac{x}{\sqrt{t}}$ and $\tau = \log t$ will again lead us to the corner functions. Substituting these transformations into $iu_t - u_{xx} = 0$ yields

$$iu_\tau - \frac{i\xi}{2} u_\xi - u_{\xi\xi} = 0. \tag{4.2}$$

The equilibrium solution satisfies

$$u_{\xi\xi} + \frac{i\xi}{2} u_\xi = 0,$$

leading to

$$u_0(x,t) = \operatorname{Erfc}\left(\sqrt{i}\frac{x}{2\sqrt{t}}\right) = \frac{1+i}{\sqrt{2\pi}} \int_{\frac{x}{\sqrt{t}}}^{\infty} e^{-i\frac{\eta^2}{4}} d\eta. \tag{4.3}$$

Separating (4.3) into real and imaginary parts results in

$$u_0(x,t) = 1 - S\left(\frac{x}{\sqrt{2\pi t}}\right) - C\left(\frac{x}{\sqrt{2\pi t}}\right) + i\left[S\left(\frac{x}{\sqrt{2\pi t}}\right) - C\left(\frac{x}{\sqrt{2\pi t}}\right)\right],$$

where S and C are the Fresnel sine, $\int_0^z \sin(\pi t^2/2)dt$, and cosine, $\int_0^z \cos(\pi t^2/2)dt$, functions. Higher-order corner functions are again most easily expressed in terms of hypergeometric functions. In analogy to (2.12), we obtain

$$u_n(x,t) = t^n \left\{ {}_1F_1(-n, \tfrac{1}{2}, \tfrac{-ix^2}{4t}) - \tfrac{x\sqrt{i}}{\sqrt{t}} \tfrac{\Gamma(n+1)}{\Gamma(n+\frac{1}{2})} {}_1F_1(\tfrac{1}{2} - n, \tfrac{3}{2}, \tfrac{-ix^2}{4t}) \right\}, \; n = 0, 1, \ldots,$$

which satisfies (4.1) with IC $u(x,0) = 0$ and the BCs $u(0,t) = t^n$, $u(\infty,t) = 0$.

The real and imaginary parts of the corner functions $u_0(x,t)$ and $u_1(x,t)$ are plotted in Figure 4.1.

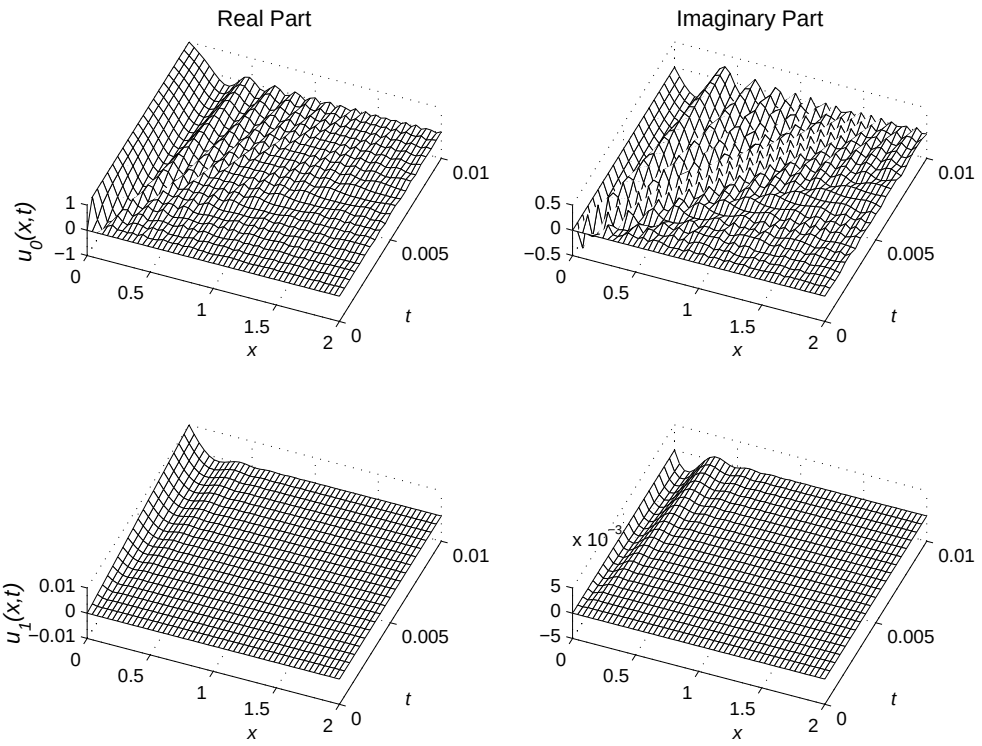

FIG. 4.1. *Real and imaginary part of the first two corner functions u_0 and u_1 to $iu_t - u_{xx} = 0$.*

5. Qualitative solution features in the case of two boundaries. In this section, the properties of $u_t - u_{xxx} = 0$ are contrasted with those of $iu_t - u_{xx} = 0$. In the former case ($u_t - u_{xxx} = 0$), high-frequency waves race across the interval and become absorbed at the opposite boundary. Like for the heat equation, the solutions are infinitely differentiable for all $t > 0$. In the latter case ($iu_t - u_{xx} = 0$), the waves are reflected off the boundaries for all times, resulting in a solution that is several times differentiable only for rare values of $t > 0$ (when recurrences to the IC happen to occur). This lack of smoothness has severe impact on the accuracy of straightforward numerical calculations.

5.1. Features of the solution to $u_t - u_{xxx} = 0$ in the case of two boundaries. Although the IBV problem

$$\begin{aligned} &\text{PDE:} && u_t - u_{xxx} = 0, && \\ &\text{IC:} && u(x,0) = 0, && 0 < x \le 1, \\ &\text{BCs:} && u(0,t) = f(t),\ u_x(0,t) = g(t),\ u(1,t) = 0, && t > 0, \end{aligned} \tag{5.1}$$

does not appear to admit a simple closed form solution for general functions $f(t)$ and $g(t)$, it can be verified that the function

$$u(x,t) = \frac{3}{2\pi} \int_0^\infty \frac{e^{\frac{1}{2}rx - r^3 t}}{r} \sin\left(\frac{\sqrt{3}}{2} r(x-1)\right) \left(e^{-3r/2} + 2\cos\left(\frac{\sqrt{3}}{2} r\right)\right) dr \tag{5.2}$$

satisfies it for some particular choice of $f(t)$ and $g(t)$. We note the following:

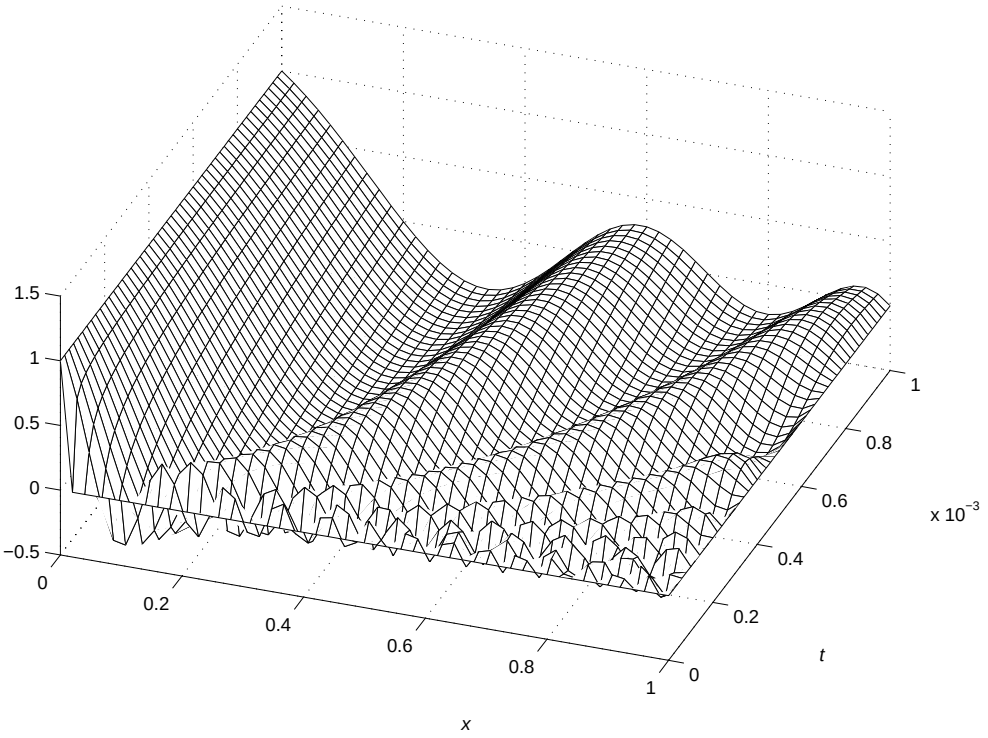

FIG. 5.1. *Solution* $u(x,t)$ (5.2) *to the IBV problem for* $u_t - u_{xxx} = 0$, *displayed for time* $0 \le t \le 10^{-3}$.

- $\lim_{t\to 0+} u(x,t) = 0$ for $0 < x \le 1$ (although the integral for $u(x,t)$ diverges if $t = 0$ is substituted directly into it).
- The function $f(t)$ (as obtained from (5.2)) is not identically equal to one although it satisfies $f(0) = 1$ and $f^k(0) = 0,\ k = 1, 2, \ldots$.

Figure 5.1 shows $u(x,t)$ for $0 \le t \le 10^{-3}$, illustrating how high-frequency waves emerge out of the singular corner and then get absorbed (with no reflections) at the right edge.

5.2. Features of the solution to $iu_t - u_{xx} = 0$ in the case of two boundaries. Consider the IBV problem

$$\begin{aligned} &\text{PDE:} && iu_t - u_{xx} = 0, && \\ &\text{IC:} && u(x,0) = 0, && 0 \le x \le 1, \\ &\text{BCs:} && u(0,t) = \sin t,\ u(1,t) = 0, && t > 0. \end{aligned} \tag{5.3}$$

The long-term solution

$$u_L(x,t) = \frac{i}{2}\left(e^{it}\frac{\sin(1-x)}{\sin 1} - e^{-it}\frac{\sinh(1-x)}{\sinh 1}\right)$$

satisfies the PDE and the BCs. The fast scale solution, emanating from the corner, is

$$u_T(x,t) = u(x,t) - u_L\,(x,t)$$

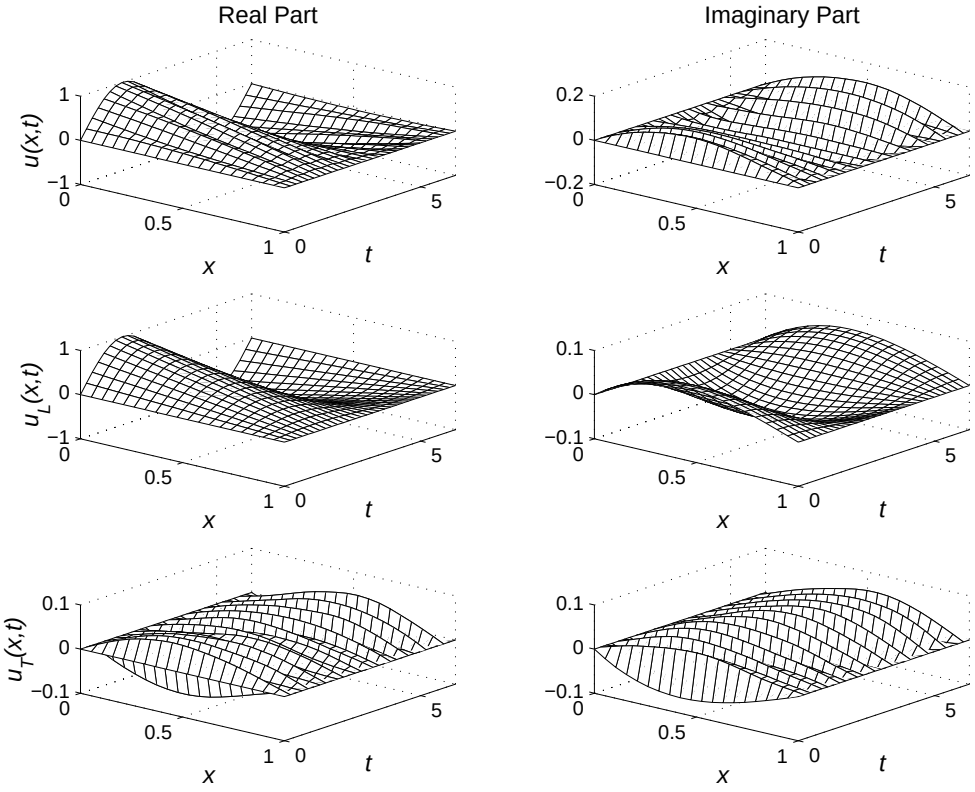

FIG. 5.2. *Full solution $u(x,t)$, long-term solution $u_L(x,t)$, and transient solution $u_T(x,t)$ for* (5.3).

and will again need to satisfy the PDE but with different IC and BC:

$$\begin{aligned} &\text{IC:} \quad u_T(x,0) = -\tfrac{i}{2}\left(\tfrac{\sin(1-x)}{\sin 1} - \tfrac{\sinh(1-x)}{\sinh 1}\right), && 0 \le x \le 1, \\ &\text{BC:} \ u_T(0,t) = u_T(1,t) = 0, && t > 0. \end{aligned}$$

It can be written as a simple sine series expansion:

$$u_T(x,t) = 2\pi i \sum_{k=1}^{\infty} \frac{k}{1-(k\pi)^4} e^{i(k\pi)^2 t} \sin k\pi x. \tag{5.4}$$

Figure 5.2 shows the real and imaginary parts of the $u(x,t)$, $u_L(x,t)$, and $u_T(x,t)$. Figure 5.3 shows the full solution over a short time interval, revealing

1. emanating waves from the corner, as described by the $u_n(x,t)$ corner functions (cf. Figure 4.1) and
2. the reflection of all waves at the boundaries.

The latter fact means that, in contrast to the heat equation, $u_t - u_{xx} = 0$, or the linear KdV equation, $u_t - u_{xxx} = 0$, the solution will not become smoother with time. Indeed, (5.4) shows that $\frac{\partial^4 u}{\partial x^4}$ and $\frac{\partial^2 u}{\partial t^2}$ will fail to exist at almost all x and t. Unless (5.3) is modified to contain some form of dissipation (interior or at the boundaries), accurate numerical solutions would appear to be quite difficult to obtain.

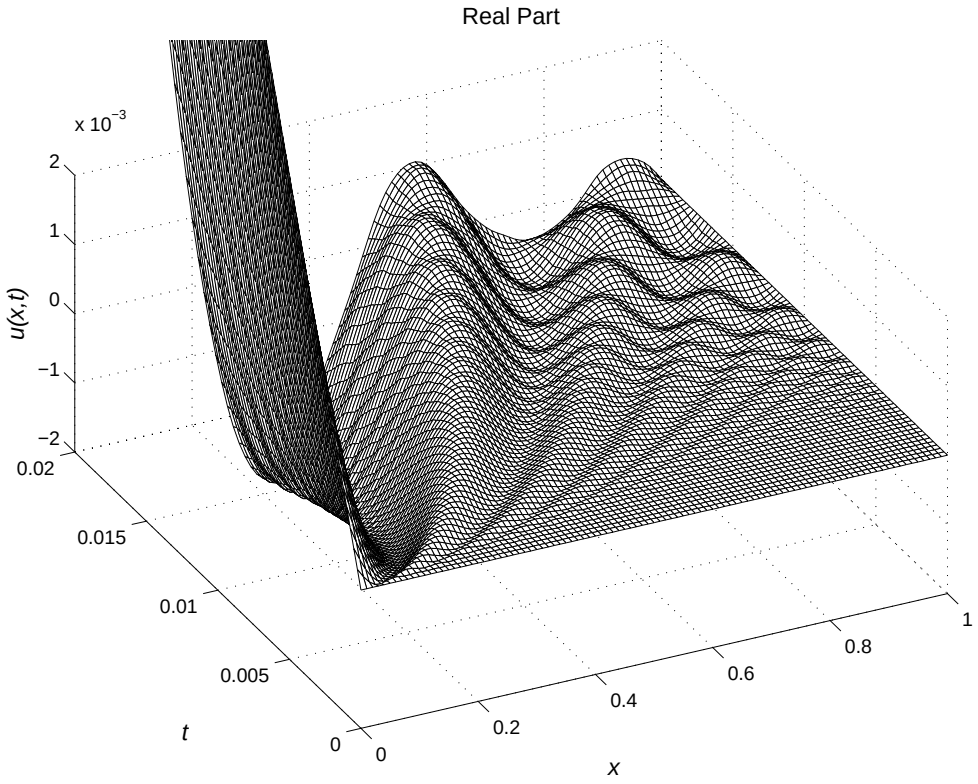

FIG. 5.3. *Real part of the solution $u(x,t)$ to the IBVP test problem for $iu_t - u_{xx} = 0$, shown for $0 \le t \le 0.02$.*

6. Concluding remarks. Since the initial data and the boundary data for PDEs typically arise from different considerations, discrepancies will almost always occur in the corners of the time-space domain. Unless infinitely many compatibility conditions hold in the corners, the solutions will feature singularities which may or may not remain local in time and space. With modern high-order or spectral methods, these discrepancies are often the dominant source of numerical error. It is thus essential to

1. identify and understand the nature of the corner singularities for the IBV problem being solved, and
2. devise numerical remedies to restore expected levels of accuracy.

Both issues have been addressed for second-order convective-diffusive equations in [4]. This study has focused on the first point above for dispersive equations, showing that the concept of corner basis functions, introduced in [4], is critical in understanding the nature of the singularities.

To summarize the different characters of the corner singularities for the PDEs considered, analytic expressions for the first corner basis function, $u_0(x,t)$, are given in Table 6.1 and are graphically contrasted over two different time intervals in Figure 6.1. The analytical form of the corner basis functions for the general PDE $u_t \pm u_{nx} = 0$, $n = 1, 2, 3, \ldots$, has also been included in the table. The constants c_k are determined by the BC $u_0(0,t) = 1$ and all higher derivative BCs equal to zero. The dissipative case $u_t - u_{4x} = 0$ is also illustrated.

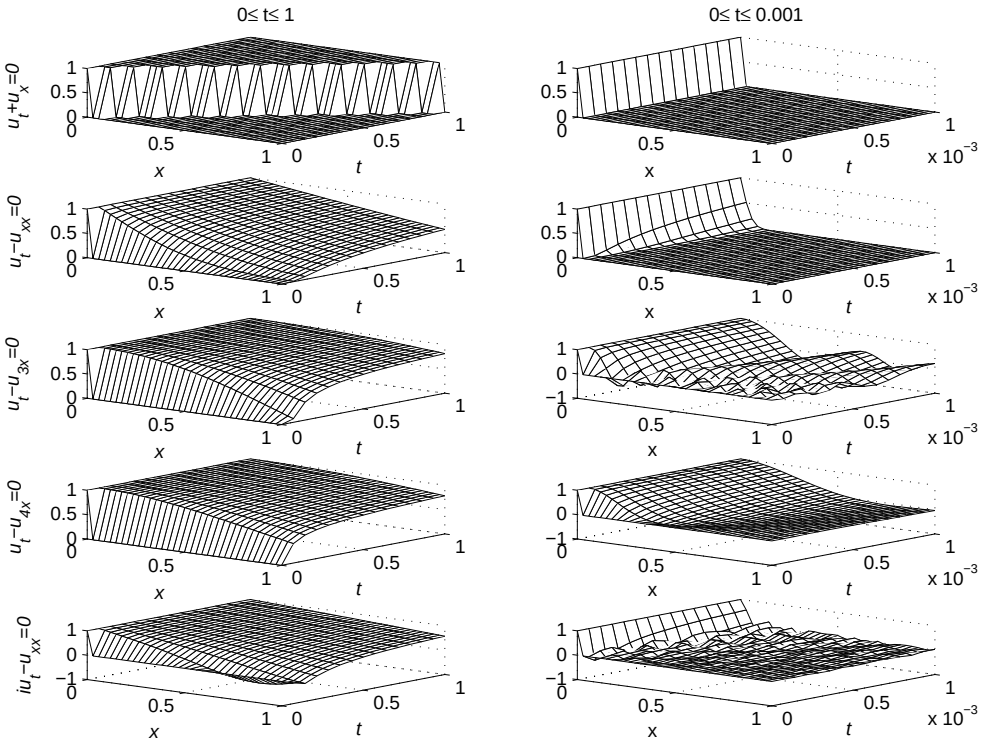

FIG. 6.1. *The $u_0(x,t)$ corner functions for the equations, $u_t \pm u_{nx} = 0$, $n = 1, \dots, 4$, and $iu_t - u_{xx} = 0$ (real part).*

The nature of the corner singularities for each PDE is different, including propagation of the discontinuity throughout the domain, dissipation of it locally, and high-frequency oscillations which either get absorbed or reflected at boundaries. In subsequent studies, numerical techniques for restoring accuracy of high-order and spectral methods for dispersive IBV problems will be explored.

NEW FREQUENCY-AVERAGED APPROXIMATIONS TO THE EQUATIONS OF RADIATIVE HEAT TRANSFER*

EDWARD W. LARSEN†, GUIDO THÖMMES‡, AND AXEL KLAR‡

Abstract. We develop new direction- and frequency-averaged approximations to the equations of radiative heat transfer in glass for optically thick, diffusive regimes. These approximations, which are based on the SP_N approach given in [E. Larsen, G. Thömmes, A. Klar, M. Seaïd, and T. Götz, *J. Comput. Phys.*, 183 (2002), pp. 652–675], represent asymptotic corrections to the familiar Rosseland, or equilibrium diffusion, approximation. Numerical results for realistic problems in the simulation of radiative heat transfer in glass cooling confirm the accuracy and efficiency of the new approximations.

Key words. radiative transfer equations, simplified P_N (SP_N) approximations, frequency averages, asymptotic analysis

1. Introduction.

We consider industrial radiative heat transfer (RHT) processes, such as those that occur in gas turbines, or in the cooling of hot glass molds. These phenomena are governed by the radiative transfer equations [7], which in scaled form contain the dimensionless parameter

$$\varepsilon = \frac{1}{\kappa_{ref} x_{ref}}, \tag{1.1}$$

where κ_{ref} and x_{ref} are reference absorption and length scales. Physically, ε is the ratio of a typical photon mean free path to a typical length scale of the problem. For a spatial point x in a domain $V \subset \mathbb{R}^3$ consisting of glass, the following radiative transfer equations hold for all $\varepsilon > 0$:

$$\varepsilon^2 \frac{\partial T}{\partial t} = \varepsilon^2 \nabla \cdot k \nabla T - \int_{\nu_1}^{\infty} \int_{S^2} \kappa (B - I)\, d\Omega d\nu, \tag{1.2a}$$

$$\Omega \in S^2 : \quad \varepsilon \Omega \cdot \nabla I = \kappa (B - I). \tag{1.2b}$$

Here, B denotes Planck's function for black body radiation in glass:

$$B(\nu, T) = n_1^2 \frac{2 h_P \nu^3}{c^2} \left(e^{h_P \nu / k_B T} - 1 \right)^{-1},$$

which contains Planck's constant h_P, Boltzmann's constant k_B, the index of refraction in glass n_1, the speed of light c, and the material temperature T. On the system boundary ($x \in \partial V$), the incident radiation intensity I is prescribed by semitransparent, i.e., partly reflective, boundary conditions

$$\forall n \cdot \Omega < 0 : \quad I(\Omega) = \rho(n \cdot \Omega) I(\Omega') + \left[1 - \rho(n \cdot \Omega) \right] B^{(a)}(\nu, T_b), \tag{1.2c}$$

where the direction Ω' of the exiting ray in (1.2c), which specularly reflects into the incident ray Ω, is given by

$$\Omega' = \Omega - 2(n \cdot \Omega)n.$$

Note that we have to use Planck's function $B^{(a)}$ for air,

$$B^{(a)}(\nu, T) = n_2^2 \frac{2h_P \nu^3}{c^2} \Big(e^{h_P \nu / k_B T} - 1 \Big)^{-1},$$

in the boundary conditions. The temperature at the boundary obeys

$$\varepsilon k \, n \cdot \nabla T = h(T_b - T) + \alpha\pi \int_0^{\nu_1} \Big[B^{(a)}(\nu, T_b) - B^{(a)}(\nu, T) \Big] \, d\nu. \tag{1.2d}$$

At the initial time $t = 0$, T is prescribed for all $x \in V$ by

$$T(x, 0) = T_0(x). \tag{1.2e}$$

In (1.2), $I(x, t, \Omega, \nu)$ denotes the *specific radiation* intensity at point $x \in V$ traveling in direction $\Omega \in S^2$ with frequency $\nu > 0$ at time $t \geq 0$. $T(x, t)$ denotes the *material temperature* at point $x \in V$ at time $t \geq 0$.

The outside radiation is assumed to be a Planckian for air, $B^{(a)}(\nu, T_b)$, at specified temperature T_b for incident directions on the boundary (satisfying $n \cdot \Omega < 0$, where n denotes the outward normal on ∂V). Equations (1.2) contain the known opacity $\kappa(\nu)$, heat conductivity k, and convective heat transfer coefficient h. The integration in the second term of the temperature boundary condition (1.2d) is performed on the opaque interval of the spectrum $[0, \nu_1]$, where radiation is completely absorbed. The refractive indices at the boundary are n_1 (glass) $> n_2$ (exterior air).

The reflectivity $\rho \in [0, 1]$ is, from (1.2c), the fraction of exiting radiation that is reflected back into V. This is defined by

$$\rho(\mu) = \begin{cases} 1, & \sin\theta_1 \geq n_2/n_1, \\ \frac{1}{2}\Big(\frac{\tan^2(\theta_1 - \theta_2)}{\tan^2(\theta_1 + \theta_2)} + \frac{\sin^2(\theta_1 - \theta_2)}{\sin^2(\theta_1 + \theta_2)} \Big), & \sin\theta_1 < n_2/n_1, \end{cases} \tag{1.3}$$

where the refraction angles θ_1 and θ_2 are given by $\cos\theta_1 = |n \cdot \Omega| = \mu$ and

$$n_1 \sin\theta_1 = n_2 \sin\theta_2.$$

Finally, the hemispheric emissivity α is defined in terms of the reflectivity ρ by

$$\alpha = 2n_1 \int_0^1 [1 - \rho(\mu)] \, d\mu.$$

In astrophysical problems, an extra term $\partial I / c\partial t$ is often included in the left-hand side of (1.2b). However, for the problems of glass annealing considered in this paper, this term is negligibly small, so we ignore it. For a full discussion of the above equations and their applications we refer, for example, to [6], [10], [5] and the monographs [3] and [8].

In the optically thick regime, where the opacity κ is large and the radiation is conveyed in a diffusion-like manner, it is appropriate to consider the above equations for $\varepsilon \ll 1$. In this "diffusive regime, the solution of the transport equation asymptotically limits to the solution of the *equilibrium diffusion equation* (see [6])

$$\frac{\partial T}{\partial t} = \nabla \cdot k \nabla T + \nabla \cdot \Big(\frac{4\pi}{3} \int_{\nu_1}^{\infty} \frac{1}{\kappa} \frac{\partial B}{\partial T} \, d\nu \Big) \nabla T, \tag{1.4}$$

which is independent of the direction and frequency variables.

Considering numerical solutions of the above equations, the solution of the radiative transfer equations is much more complex and costly than the solution of the equilibrium diffusion equation. However, in many situations, the equilibrium diffusion solution is not sufficiently accurate. For example, in the annealing (cooling) of glass, the radiative transfer process produces boundary layers in T at the outer glass surface. These give rise to mechanical stresses—due to the thermal contraction of the glass upon cooling—which can cause defects or breaking. The equilibrium diffusion approximation does not accurately describe these important boundary layer regions.

Therefore, approximations to the full radiative transfer model that are computationally less time consuming, yet sufficiently more accurate than equilibrium diffusion theory, have been sought. In [7], *simplified P_N* ($\mathrm{SP_N}$) approximations are developed as alternatives to the full radiative transfer equations and the usual $\mathrm{P_N}$ (spherical harmonic) approximations. The $\mathrm{SP_N}$ approximations are derived by asymptotic and variational analyses and employ frequency-dependent diffusion equations, or coupled systems of frequency-dependent diffusion equations. Approximate models of this type contain boundary layer effects and can be remarkably accurate—much more accurate than equilibrium diffusion theory; see [7].

A drawback of the $\mathrm{SP_N}$ approximations, from the point of view of efficient simulations, is the large number of frequency bands often encountered in applications. For the RHT equations and their $\mathrm{P_N}$ and $\mathrm{SP_N}$ approximations, this leads to a coupled system of equations, since each frequency band is treated in a separate equation. In the present paper, we develop a new *grey simplified P_N* ($\mathrm{GSP_N}$) approximation that eliminates the frequency variable. (More precisely, the new grey approximation compresses all the frequency bands into one. The term "grey," borrowed from the astrophysical literature, means "frequency-independent.") We also develop "partially averaged" approximations, in which the number of frequency bands is reduced, but not to one. (A "fully averaged" approximation would have only one band, and would be "grey.") The elimination or reduction of frequency significantly reduces computation time. Yet, our numerical results show that this process yields solutions that are much more accurate than the equilibrium diffusion solution and are often nearly as accurate as the $\mathrm{SP_N}$ solution, even in the important boundary layers. We believe that the resulting approximations will provide practical industrial tools for simulating the annealing of glass.

The remainder of this paper is organized as follows: In section 2, the *outer* asymptotic expansion to derive the frequency-dependent $\mathrm{SP_N}$ approximations to (1.2a) and (1.2b) are reviewed. In sections 3 and 4, the GSPN procedure—in which the frequency is eliminated as an independent variable—is presented. This procedure has the practical advantage that it leads to equations that are much less expensive to compute. However, it represents a significant step beyond standard $\mathrm{SP_N}$ theory. In section 5, numerical comparisons of the $\mathrm{SP_N}$, $\mathrm{GSP_N}$, and equilibrium diffusion approximations are presented. We conclude with a discussion in section 6.

2. The SP_1 and SP_2 approximations. To solve (1.2a) in the domain V, we write the transport equation as

$$\Big(1+\frac{\varepsilon}{\kappa}\Omega\cdot\nabla\Big)I(x,t,\Omega,\nu)=B(\nu,T)$$

and use a Neumann series to formally solve for I. Assuming a homogeneous medium, one obtains

$$\begin{aligned} I &= \Big(1+\frac{\varepsilon}{\kappa}\Omega\cdot\nabla\Big)^{-1}B \\ &\widetilde{=} \Big[1-\frac{\varepsilon}{\kappa}\Omega\cdot\nabla+\frac{\varepsilon^2}{\kappa^2}(\Omega\cdot\nabla)^2-\frac{\varepsilon^3}{\kappa^3}(\Omega\cdot\nabla)^3+\frac{\varepsilon^4}{\kappa^4}(\Omega\cdot\nabla)^4\cdots\Big]B. \end{aligned} \tag{2.1}$$

Integrating with respect to Ω and using

$$\int_{S^2}(\Omega\cdot\nabla)^n f\ d\Omega=[1+(-1)^n]\,\frac{2\pi}{n+1}\nabla^n f,$$

where $\nabla^2=\nabla\cdot\nabla$ is the spatial Laplacian and f is sufficiently smooth, we obtain

$$\begin{aligned} \phi(x,t,\nu) &= \int_{S^2} I(x,t,\Omega,\nu)\ d\Omega \\ &= 4\pi\Big[1+\frac{\varepsilon^2}{3\kappa^2}\nabla^2+\frac{\varepsilon^4}{5\kappa^4}\nabla^4+\frac{\varepsilon^6}{7\kappa^6}\nabla^6\cdots\Big]B+\mathcal{O}(\varepsilon^8). \end{aligned}$$

Hence

$$\begin{aligned} 4\pi B &= \Big[1+\frac{\varepsilon^2}{3\kappa^2}\nabla^2+\frac{\varepsilon^4}{5\kappa^4}\nabla^4+\frac{\varepsilon^6}{7\kappa^6}\nabla^6\Big]^{-1}\phi+\mathcal{O}(\varepsilon^8) \\ &= \Bigg\{1-\Big[\frac{\varepsilon^2}{3\kappa^2}\nabla^2+\frac{\varepsilon^4}{5\kappa^4}\nabla^4+\frac{\varepsilon^6}{7\kappa^6}\nabla^6\Big] \\ &\quad+\Big[\frac{\varepsilon^2}{3\kappa^2}\nabla^2+\frac{\varepsilon^4}{5\kappa^4}\nabla^4+\frac{\varepsilon^6}{7\kappa^6}\nabla^6\Big]^2 \\ &\quad-\Big[\frac{\varepsilon^2}{3\kappa^2}\nabla^2+\frac{\varepsilon^4}{5\kappa^4}\nabla^4+\frac{\varepsilon^6}{7\kappa^6}\nabla^6\Big]^3\cdots\Bigg\}\phi+\mathcal{O}(\varepsilon^8), \\ &= \Big[1-\frac{\varepsilon^2}{3\kappa^2}\nabla^2-\frac{4\varepsilon^4}{45\kappa^4}\nabla^4-\frac{44\varepsilon^6}{945\kappa^6}\nabla^6\Big]\phi+\mathcal{O}(\varepsilon^8). \end{aligned} \tag{2.2}$$

If we discard terms of $\mathcal{O}(\varepsilon^4)$ or $\mathcal{O}(\varepsilon^6)$—and rearrange asymptotically, if necessary, to obtain robust second-order partial differential equations—we obtain the SP_1 and SP_2 approximations, respectively, for $\phi(x,t,\nu)$. We now summarize these different approximate equations and boundary conditions, derived in [7] (see also [9], [2]).

The SP_1 approximation, which is equivalent to the P_1 spherical harmonic approximation, is

$$-\varepsilon^2\nabla\cdot\Big(\frac{1}{3\kappa}\nabla\phi\Big)+\kappa\phi=\kappa(4\pi B)+\mathcal{O}(\varepsilon^4),\quad x\in V, \tag{2.3}$$

$$\frac{\partial T}{\partial t}=\nabla\cdot(k\nabla T)+\int_{\nu_1}^{\infty}\nabla\cdot\Big(\frac{1}{3\kappa}\nabla\phi\Big)d\nu+\mathcal{O}(\varepsilon^2), \tag{2.4}$$

$$\phi(x,\nu,t)+\Big(\frac{1+3r_2}{1-2r_1}\Big)\Big(\frac{2\varepsilon}{3\kappa}\Big)n\cdot\nabla\phi(x,\nu,t)=4\pi B^{(a)}(\nu,T_b),\quad x\in\partial V. \tag{2.5}$$

The SP_2 approximation is

$$-\varepsilon^2\nabla\cdot\left(\frac{3}{5\kappa}\nabla\phi\right)+\kappa\phi=\kappa(4\pi B)+\mathcal{O}(\varepsilon^6),\quad x\in V, \tag{2.6}$$

$$\frac{\partial T}{\partial t}=\nabla\cdot(k\nabla T)+\int_{\nu_1}^{\infty}\nabla\cdot\left(\frac{1}{3\kappa}\ \nabla\phi\right)d\nu+\mathcal{O}(\varepsilon^4), \tag{2.7}$$

$$\begin{aligned}\phi(x,\nu,t)+\left(\frac{1+3r_2}{1-4r_3}\right)\left(\frac{4\varepsilon}{5\kappa}\right)n\cdot\nabla\phi(x,\nu,t)\\ =4\pi B^{(a)}(\nu,T)+\left(\frac{1-2r_1}{1-4r_3}\right)\left(\frac{24\pi}{5}\right)[B^{(a)}(\nu,T_b)-B^{(a)}(\nu,T)],\quad x\in\partial V.\end{aligned} \tag{2.8}$$

The constants r_1, r_2, and r_3 in (2.5) and (2.8) are moments of $\rho(\mu)$:

$$r_n=\int_0^1\ \mu^n\rho(-\mu)\ d\mu,\quad n=1,2,3.$$

The boundary and initial conditions for T in both the SP_1 and SP_2 approximations are given by (1.2d) and (1.2e).

The SP_1 approximation (2.3)–(2.5) and the SP_2 approximation (2.6)–(2.8) do not contain the direction variable Ω, but they do contain the frequency variable ν. Our goal in this paper is to develop accurate frequency-independent (grey) and partially frequency-averaged approximations to these frequency-dependent SP_N approximations.

In [7], the differential equations (2.3), (2.4), (2.6), and (2.7) are derived by an asymptotic analysis based on (2.2). The formal asymptotic order of error is indicated in each of these above equations. However, the boundary conditions (2.5) and (2.8) were derived by an approximate variational analysis, not by an asymptotic analysis, and it is not known if a rigorous asymptotic order of error can be assigned to them. In spite of this lack of strict asymptotic "pedigree," the SP_1 and SP_2 approximations have been shown to be accurate approximations to the full radiative transfer equations for small and even intermediate values of ε (see [7]).

In this paper, we treat the SP_1 and SP_2 approximations as fundamental equations and derive formal asymptotic approximations to them. Specifically, we derive (i) the GSP_1 *approximation*, a grey (frequency-independent) approximation to the SP_1 equations with $\mathcal{O}(\varepsilon^2)$ error, and (ii) the GSP_2 *approximation*, a grey approximation to the SP_2 equations with $\mathcal{O}(\varepsilon^3)$ error. The GSP_1 approximation is equivalent to the well-known *Rosseland*, or *equilibrium diffusion* approximation, while the GSP_2 approximation is new and represents an asymptotic correction to the Rosseland approximation. We also derive "partially averaged" approximations, in which frequency is not eliminated from the problem, but the number of frequency bands is significantly reduced.

If the SP_1 equations are an $\mathcal{O}(\varepsilon^2)$ approximation to the full radiative transfer model (this assumption amounts to asserting that (2.5) has $\mathcal{O}(\varepsilon^2)$ error), then the GSP_1 equations approximate the radiative transfer model with $\mathcal{O}(\varepsilon^2)$ error. Likewise, if the SP_2 equations are an $\mathcal{O}(\varepsilon^3)$ approximation to the full radiative transfer model (this assumption amounts to asserting that (2.8) has $\mathcal{O}(\varepsilon^3)$ error), then the GSP_2 equations approximate the radiative transfer model with $\mathcal{O}(\varepsilon^3)$ error.

We do not attempt to calculate a grey approximation to the SP_1 equations with error $\mathcal{O}(\varepsilon^3)$ or smaller, because the resulting grey approximation can have no better

than $\mathcal{O}(\varepsilon^2)$ error relative to the full radiative transfer equations. It does make sense to attempt to calculate a grey approximation to the SP_2 equations with error $\mathcal{O}(\varepsilon^4)$, because the resulting grey approximation *could* then have $\mathcal{O}(\varepsilon^4)$ error relative to the full radiative transfer equations. However, the best that we could manage is the $\mathcal{O}(\varepsilon^3)$ approximation presented in this paper.

Regardless of these asymptotic subtleties, numerical simulations presented in section 5 demonstrate that the GSP_2 approximation is significantly more accurate than the GSP_1 (Rosseland) approximation, yet is only slightly more expensive to compute. For very difficult problems, the partially averaged equations are shown to be even more accurate than the grey equations, typically almost as accurate as the original SP_N equations on which the approximations developed in this paper are directly based. As might be expected, the cost of the partially averaged simulations is greater than the cost of the grey calculations but less than the cost of the full SP_N calculations.

3. The GSP_1 approximation. The starting point for deriving the GSP_1 approximation is the system of SP_1 equations (2.3)–(2.5) stated above.

In (2.3) and (2.4), we have indicated that the formal errors are $\mathcal{O}(\varepsilon^4)$ and $\mathcal{O}(\varepsilon^2)$, respectively (see [7] for details). Overall, the error in the SP_1 equations is expected to be $\mathcal{O}(\varepsilon^2)$. If we delete the $\mathcal{O}(\varepsilon^2)$ diffusion term in (2.3) and also the boundary condition (2.5)—since these are not strictly needed—(2.3) yields, with $\mathcal{O}(\varepsilon^2)$ error,

$$\phi = 4\pi B. \tag{3.1}$$

Then (2.4) becomes, also with $\mathcal{O}(\varepsilon^2)$ error,

$$\begin{aligned}\frac{\partial T}{\partial t} - \nabla\cdot(k\nabla T) &= \int_{\nu_1}^{\infty} \nabla\cdot\frac{4\pi}{3\kappa}\,\nabla\, B(\nu,T)d\nu \\ &= \nabla\cdot\int_{\nu_1}^{\infty}\frac{4\pi}{3\kappa}\,\frac{\partial B}{\partial T}(\nu,T)\,\nabla T d\nu \\ &= \nabla\cdot\Big(\frac{4\pi}{3}\int_{\nu_1}^{\infty}\frac{1}{\kappa}\frac{\partial B}{\partial T}(\nu,T)d\nu\Big)\nabla T.\end{aligned}$$

Equivalently,

$$\frac{\partial T}{\partial t} = \nabla\cdot[k + k_R(T)]\,\nabla T, \tag{3.2}$$

with

$$k_R(T) = \frac{4\pi}{3}\int_{\nu_1}^{\infty}\frac{1}{\kappa(\nu)}\frac{\partial B}{\partial T}(\nu,T)d\nu. \tag{3.3}$$

Equations (3.2), (3.3), (1.2d), and (1.2e) constitute the familiar *Rosseland*, or *equilibrium diffusion*, approximation. In our lexicon, we also call this the *grey simplified* P_1 (GSP_1) approximation, because it is a frequency-independent (grey) approximation to the frequency-dependent SP_1 equations. The formal error in this approximation is $\mathcal{O}(\varepsilon^2)$, which is the same as the formal error in the SP_1 approximation.

However, in discarding the $\varepsilon^2\nabla\cdot\frac{1}{3\kappa}\nabla\phi$ term in (2.3) and the boundary condition (2.5) on ϕ, we thereby discarded the boundary layers in the SP_1 solution. The frequency-dependent SP_1 solution contains boundary layers, but the frequency-independent GSP_1 (Rosseland) solution does not.

4. The $\mathbf{GSP_2}$ approximation.

4.1. $\mathbf{GSP_2}$ equations. The starting point now is the system of SP_2 (2.6)–(2.8). Equation (2.6) for a homogeneous medium gives

$$\left(1 - \frac{3\varepsilon^2}{5\kappa^2}\nabla^2\right)\phi = 4\pi B + \mathcal{O}(\varepsilon^6),$$

so

$$\phi = \left(1 + \frac{3\varepsilon^2}{5\kappa^2}\nabla^2\right)4\pi B + \mathcal{O}(\varepsilon^4). \tag{4.1}$$

Then,

$$\frac{\phi}{3\kappa} = \frac{4\pi}{3}\frac{B}{\kappa} + \varepsilon^2\nabla^2\frac{4\pi}{5}\frac{B}{\kappa^3} + \mathcal{O}(\varepsilon^4) \tag{4.2}$$

and

$$\frac{1}{3}\int_{\nu_1}^{\infty}\frac{\phi}{\kappa}\,d\nu = \frac{4\pi}{3}\int_{\nu_1}^{\infty}\frac{B}{\kappa}\,d\nu + \varepsilon^2\nabla^2\frac{4\pi}{5}\int_{\nu_1}^{\infty}\frac{B}{\kappa^3}\,d\nu + \mathcal{O}(\varepsilon^4). \tag{4.3}$$

Thus, if we define

$$W(x,t) = \frac{1}{3}\int_{\nu_1}^{\infty}\frac{\phi(x,\nu,t)}{\kappa(\nu)}\,d\nu \tag{4.4}$$

and

$$f_n(T) = \frac{4\pi}{n+2}\int_{\nu_1}^{\infty}\frac{B(\nu,T)}{\kappa^n(\nu)}\,d\nu \qquad (n = 1, 3), \tag{4.5}$$

which satisfy $f_n'(T) > 0$, then (2.7) and (4.3) become, with $\mathcal{O}(\varepsilon^4)$ error,

$$\frac{\partial T}{\partial t} = \nabla\cdot(k\nabla T) + \nabla^2 W, \tag{4.6}$$

$$W = f_1(T) + \varepsilon^2\nabla^2 f_3(T). \tag{4.7}$$

It is now trivial to use (4.7) to eliminate W from (4.6), producing a nonlinear fourth-order (in space) differential equation for T:

$$\frac{\partial T}{\partial t} = \nabla\cdot(k\nabla T) + \nabla^2 f_1(T) + \varepsilon^2(\nabla^2)^2 f_3(T), \tag{4.8}$$

which has formal error $\mathcal{O}(\varepsilon^4)$. However, this equation is ill-conditioned, so we do not propose to attempt to solve it for T. Instead we convert (4.7) into a well-conditioned second-order differential equation for W, with formal $\mathcal{O}(\varepsilon^4)$ asymptotic error.

To do this, we first write (4.7) as

$$W = f_1(T) + \mathcal{O}(\varepsilon^2),$$

so

$$\nabla W = f_1'(T)\nabla T + \mathcal{O}(\varepsilon^2),$$

and hence

$$\nabla T = \frac{1}{f_1'(T)}\nabla W + \mathcal{O}(\varepsilon^2). \tag{4.9}$$

Equations (4.7) and (4.9) now give, with $\mathcal{O}(\varepsilon^4)$ error,

$$\begin{aligned} W &= f_1(T) + \varepsilon^2 \nabla^2 f_3(T) \\ &= f_1(T) + \varepsilon^2 \nabla \cdot f_3'(T) \nabla T \\ &= f_1(T) + \varepsilon^2 \nabla \cdot \frac{f_3'(T)}{f_1'(T)} \nabla W, \end{aligned}$$

or

$$-\varepsilon^2 \nabla \cdot \left(\frac{f_3'(T)}{f_1'(T)} \nabla W \right) + W = f_1(T). \tag{4.10}$$

In (4.10), the positive function

$$\frac{f_3'(T)}{f_1'(T)} \equiv D(T)$$

has the role of a space-dependent diffusion coefficient. This is physically appropriate, as W is an intensity-like quantity, and the diffusion coefficient for W should intuitively depend on T.

The GSP_2 equations, which are defined throughout the physical system V, consist of the two coupled (4.6) and (4.10) for T and W. The formal error in these equations is $\mathcal{O}(\varepsilon^4)$. Next, we derive initial and boundary conditions for these equations. Unfortunately, the error in the boundary condition for W is $\mathcal{O}(\varepsilon^3)$, not $\mathcal{O}(\varepsilon^4)$. Still, this is more accurate than the $\mathcal{O}(\varepsilon^2)$ error in the Rosseland approximation.

4.2. $\mathbf{GSP_2}$ initial and boundary conditions. As before, the initial and boundary conditions for (4.6) are (1.2e) and (1.2d), respectively. Using the boundary condition (2.8), we shall derive a boundary condition for

$$W(x,t) = \frac{1}{3} \int_{\nu_1}^{\infty} \frac{\phi(x,\nu,t)}{\kappa(\nu)} d\nu,$$

i.e., for (4.10), with $\mathcal{O}(\varepsilon^3)$ error.

When we introduce the constants

$$\begin{aligned} \alpha_1 &\equiv \frac{4}{5} \left(\frac{1+3r_2}{1-4r_3} \right), \\ \alpha_2 &\equiv \frac{6}{5} \left(\frac{1-2r_1}{1-4r_3} \right), \end{aligned}$$

then (2.8) may be written

$$\phi + \frac{\varepsilon \alpha_1}{\kappa} n \cdot \nabla \phi = 4\pi \left[B^{(a)} + \alpha_2 (B_b^{(a)} - B^{(a)}) \right], \quad x \in \partial V. \tag{4.11}$$

Dividing by 3κ and integrating over $\nu_1 \le \nu < \infty$, we obtain, using (4.4) and (4.5),

$$W + \frac{\varepsilon \alpha_1}{3} n \cdot \nabla \int_{\nu_1}^{\infty} \frac{\phi}{\kappa^2} \, d\nu = f_1^{(a)}(T) + \alpha_2 [f_1^{(a)}(T_b) - f_1^{(a)}(T)]. \tag{4.12}$$

However, (4.1) gives

$$\phi = 4\pi B + \mathcal{O}(\varepsilon^2).$$

Dividing by κ^2 and integrating over $\nu_1 \le \nu < \infty$, we obtain

$$\int_{\nu_1}^{\infty} \frac{\phi}{\kappa^2}\, d\nu = 4\pi \int_{\nu_1}^{\infty} \frac{B}{\kappa^2}\, d\nu + \mathcal{O}(\varepsilon^2) = 4f_2(T) + \mathcal{O}(\varepsilon^2).$$

Hence (4.12) becomes, with $\mathcal{O}(\varepsilon^3)$ error,

$$W + \frac{4\alpha_1\varepsilon}{3} n \cdot \nabla f_2(T) = f_1^{(a)}(T) + \alpha_2[f_1^{(a)}(T_b) - f_1^{(a)}(T)], \quad x \in \partial V. \tag{4.13}$$

We also have from (4.10)

$$W = f_1(T) + \mathcal{O}(\varepsilon^2), \quad x \in V. \tag{4.14}$$

The previous two equations imply

$$W + \frac{4\alpha_1\varepsilon}{3}(f_2)'(T)\; n \cdot \nabla T = f_1^{(a)}(T) + \alpha_2[f_1^{(a)}(T_b) - f_1^{(a)}(T)],$$
$$n \cdot \nabla W = (f_1)'(T)\; n \cdot \nabla T + \mathcal{O}(\varepsilon^2).$$

Eliminating $n \cdot \nabla T$, we obtain, with $\mathcal{O}(\varepsilon^3)$ error,

$$W + \left(\frac{4\alpha_1\varepsilon}{3}\, \frac{(f_2)'(T)}{(f_1)'(T)}\right) n \cdot \nabla W = f_1^{(a)}(T) + \alpha_2[f_1^{(a)}(T_b) - f_1^{(a)}(T)], \quad x \in \partial V. \tag{4.15}$$

This boundary condition for W can be used with (4.10). The positive quantity

$$\frac{4\alpha_1\varepsilon}{3}\, \frac{(f_2)'(T)}{(f_1)'(T)}$$

in (4.15) plays the role of an *extrapolation distance*, which is familiar from neutron transport.

4.3. GSP$_2$ approximation: Summary. To summarize, we propose the following GSP$_2$ equations for $T(x,t)$ and $W(x,t)$, which hold for all $x \in V$ and $t > 0$:

$$\frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + \nabla^2 W, \tag{4.16}$$

$$-\varepsilon^2 \nabla \cdot \left(\frac{f_3'(T)}{f_1'(T)} \nabla W\right) + W = f_1(T). \tag{4.17}$$

The following boundary conditions for T and W hold for $x \in \partial V$ and $t > 0$:

$$\varepsilon k\, n \cdot \nabla T = h(T_b - T) + \alpha\pi \int_0^{\nu_1} \left[B^{(a)}(\nu, T_b) - B^{(a)}(\nu, T)\right]\, d\nu, \tag{4.18}$$

$$W + \left(\frac{4\alpha_1\varepsilon}{3}\, \frac{(f_2)'(T)}{(f_1)'(T)}\right) n \cdot \nabla W = f_1^{(a)}(T) + \alpha_2[f_1^{(a)}(T_b) - f_1^{(a)}(T)]. \tag{4.19}$$

The following initial condition for T holds for $x \in V$:

$$T(x,0) = T_0(x). \tag{4.20}$$

The GSP_2 equations formally approximate the SP_2 equations with $\mathcal{O}(\varepsilon^3)$ error. If the SP_2 equations themselves approximate the radiative transfer equations with $\mathcal{O}(\varepsilon^3)$ error—this is tantamount to an assumption on the accuracy of the SP_2 boundary condition—then the GSP_2 equations also approximate the radiative transfer equations with $\mathcal{O}(\varepsilon^3)$ error.

If one chooses to approximate the GSP_2 equations by allowing $\mathcal{O}(\varepsilon^2)$ errors, then the derivative term on the left side of (4.17) can be dropped, and the boundary condition (4.19) for W can then be dropped because it is not needed. The resulting equations reduce to the GSP_1, or Rosseland equations. Hence the above GSP_2 equations are an $\mathcal{O}(\varepsilon^3)$ correction to the $\mathcal{O}(\varepsilon^2)$ Rosseland equation.

In our derivation of the GSP_2 equations and boundary conditions, we assumed that all quantities involved in the manipulations (i.e., the solution and its derivatives) are $\mathcal{O}(1)$. The goal of our asymptotic manipulations has been to obtain a set of equations and boundary conditions that

(a) is well-conditioned,
(b) is asymptotically accurate if the solution and all its derivations are $\mathcal{O}(1)$, and
(c) is robust if derivatives of the solution are large (possibly, in boundary layer regions).

Thus there is no guarantee that the above GSP_2 equations are accurate for problems with boundary layers. Indeed, no boundary layer scaling or analysis has been used in the derivation of these equations! Nevertheless, we show next that numerical solutions of the GSP_2 equations are (i) much more accurate than the Rosseland solution, even in boundary layer regions, and (ii) often of comparable accuracy to the SP_2 equations, even in boundary layer regions. Thus, even though our derivation of the GSP_2 equations does not explicitly account for boundary layers, it seems to accomplish this in some implicit manner.

5. Partial averaging. To obtain more accurate results the averaging procedure may be slightly modified. We proceed in the same way as described above; however, we integrate only over certain intervals in frequency space instead of integrating the respective terms over the whole frequency interval $[\nu_1, \infty)$. This procedure does not lead to a single-band or grey approximation but to a multiband approximation.

Starting with a multiband model (i.e., a piecewise constant absorption coefficient) with N bands, the number of bands can be strongly reduced with such a procedure. We denote the number of frequency bands after the averaging procedure with M.

The procedure leads to the following partially averaged SP_2 equations for $T(x,t)$ and $W_i(x,t)$, $i = 1, \ldots, M$, which hold for all $x \in V$ and $t > 0$:

$$\frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T) + \nabla^2 \sum_{i=1}^{M} W_i, \tag{5.1}$$

$$-\varepsilon^2 \nabla \cdot \left(\frac{(f_3^{(i)})'(T)}{(f_1^{(i)})'(T)} \nabla W_i \right) + W_i = f_1^{(i)}(T), \tag{5.2}$$

with

$$f_n^{(i)}(T) = \frac{4\pi}{n+2} \int_{\nu_i}^{\nu_{i+1}} \frac{B(\nu, T)}{\kappa^n(\nu)} \, d\nu \qquad (n = 1, 3, \;\; i = 1, \ldots, M), \tag{5.3}$$

where $\nu_{M+1} = \infty$.

The following boundary conditions for T and W_i hold for $x \in \partial V$ and $t > 0$:

$$\varepsilon k\, n \cdot \nabla T = h(T_b - T) + \alpha\pi \int_0^{\nu_1} \left[B^{(a)}(\nu, T_b) - B^{(a)}(\nu, T) \right] \, d\nu, \tag{5.4}$$

$$W_i + \left(\frac{4\alpha_1 \varepsilon}{3} \, \frac{(f_2^{(i)})'(T)}{(f_1^{(i)})'(T)} \right) n \cdot \nabla W_i = f_1^{(a,i)}(T) + \alpha_2 [f_1^{(a,i)}(T_b) - f_1^{(a,i)}(T)]. \tag{5.5}$$

The following initial condition for T holds for $x \in V$:

$$T(x, 0) = T_0(x). \tag{5.6}$$

As can be seen in section 6, choosing suitable intervals in frequency space and averaging in the way described above leads to strongly improved results.

6. Numerical comparisons. We now compare solutions of the full radiative transfer equations with solutions of the approximate SP_2 equations, GSP_2 equations, and Rosseland (GSP_1) equation. We investigate problems in one-dimensional slab geometry, in which the temperature and radiation depend spatially on the x-coordinate but not on the y- or z-coordinates. The direction-dependent radiation is assumed to be rotationally symmetric around the x-axis.

The problems considered correspond to the cooling of a uniform slab of glass surrounded by air at room temperature $T_b = 300K$. Initially, the temperature inside the glass is taken to be $T_0(x) = 1000K$. The radiation outside the glass is assumed to be a Planckian, i.e., isotropic with $I_b(\Omega, \nu) = B^{(a)}(\nu, T_b,)$. For $t > 0$, the glass cools down by the processes considered in this paper: regular heat conduction (linear diffusion) and thermal RHT.

We used standard finite difference techniques to discretize the diffusion equations, with uniform space and time grids. We chose $\Delta x = 0.02$ in the scaled interval $[0, 1]$ and 100 equal time steps $\Delta t = 10^{-5}$ to reach the final time $t = 10^{-3}$.

We assumed the scaled physical parameters k and h to have the values $k = 1$ and $h = 1$. The refractive coefficients were chosen to be $n_1 = 1.46$ (glass) and $n_2 = 1$ (air). The corresponding hemispheric emissivity is $\alpha = 0.92$.

We approximated the opacity $\kappa(\nu)$ by a piecewise constant step function defined on the frequency bands $[\nu_i, \nu_{i+1}]$, $i = 1, \ldots, N$ ($\nu_{N+1} = \infty$), and with associated absorption rates $\kappa(\nu) = \kappa_i$ for $\nu \in [\nu_i, \nu_{i+1}]$.

We first considered several problems with only two frequency bands. For $\nu_1 = 4.28 \cdot 10^{14} Hz$ and $\nu_2 = 9.99 \cdot 10^{14} Hz$ (corresponding to $\lambda_1 = 3\mu m$ and $\lambda_2 = 7\mu m$, respectively), we considered the following cases: $\kappa_1 = 1$ and $\kappa_2 = 2$, $\kappa_1 = 10$ and $\kappa_2 = 20$, $\kappa_1 = 50$ and $\kappa_2 = 100$, $\kappa_1 = 1$ and $\kappa_2 = 10$, $\kappa_1 = 1$ and $\kappa_2 = 100$ (see Figures 6.1–6.5.) In all these problems, the SP_2 solution agrees very well with the full radiative transfer solution, and the GSP_2 solution is significantly closer to these than is the Rosseland solution.

We also studied a more realistic problem with eight frequency bands. The absorption coefficients were chosen according to Table 6.1; these data have been used for practical simulations of annealing in glass. The edge of the opaque part of the spectrum is located at the wavelength $\lambda = 7\mu m$, thus giving $\nu_1 = c/\lambda_1 = 4.28 \cdot 10^{13} s^{-1}$.

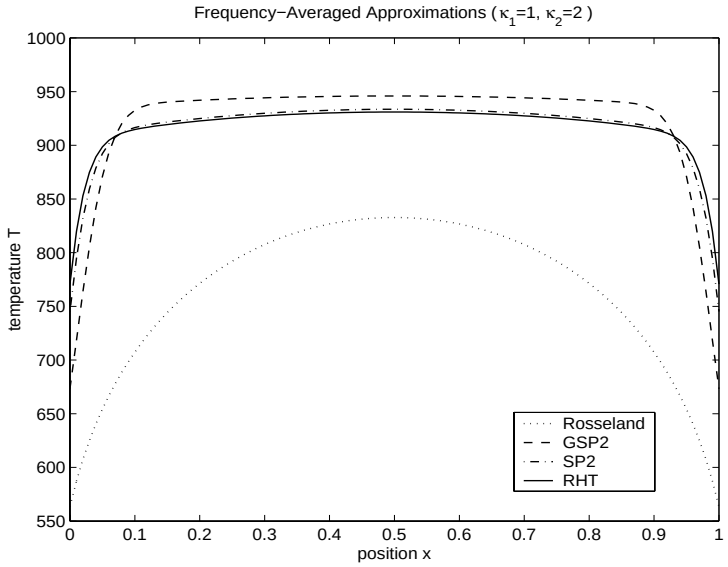

FIG. 6.1. *Comparison of the different approximations for* $\kappa_1 = 1$ *and* $\kappa_2 = 2$.

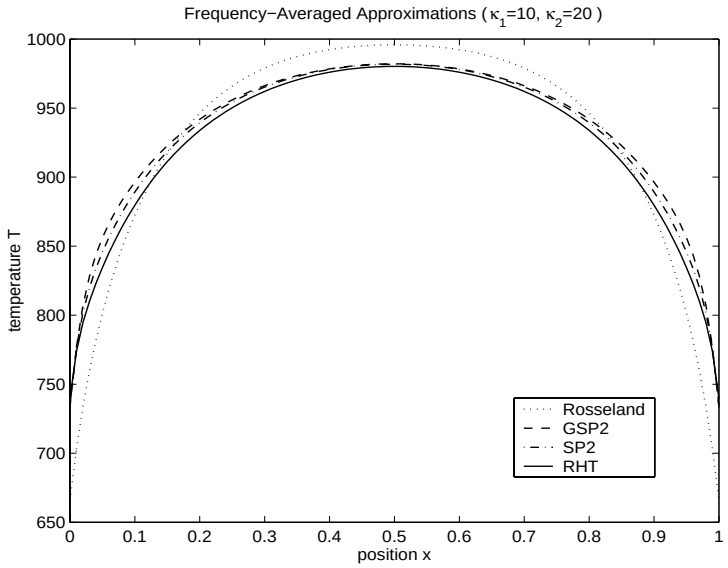

FIG. 6.2. *Comparison of the different approximations for* $\kappa_1 = 10$ *and* $\kappa_2 = 20$.

Figure 6.6 shows the frequency-averaged GSP_2 solution in comparison with the full RHT solution, the (grey) Rosseland solution, and the (frequency-dependent) SP_2 solution. Again, the GSP_2 solutions are in much closer agreement with the full radiative transfer solution and the SP_2 solution than is the Rosseland solution.

In additional to the GSP_2 solution in Figure 6.6, averaging was also done partially with respect to certain frequency bands as explained above. In the following two figures the results of partial averaging are plotted. Figure 6.7 shows results where averaging is done over the first two and the last six of the frequency bands, thus

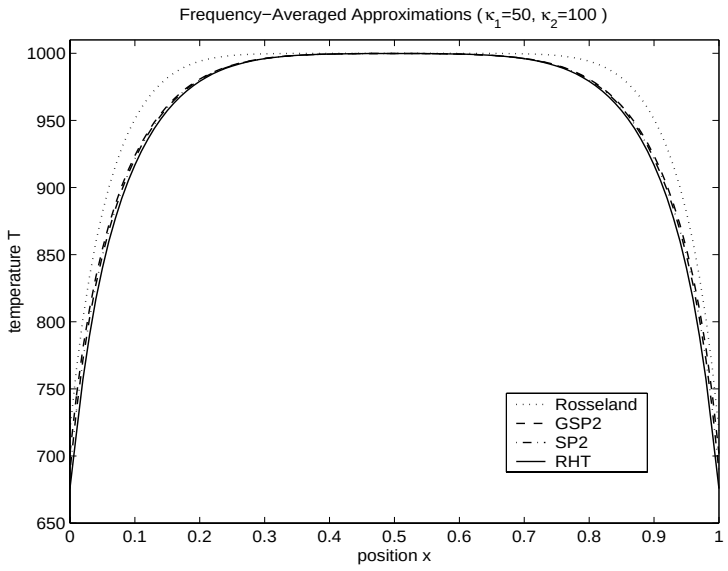

FIG. 6.3. *Comparison of the different approximations for* $\kappa_1 = 50$ *and* $\kappa_2 = 100$.

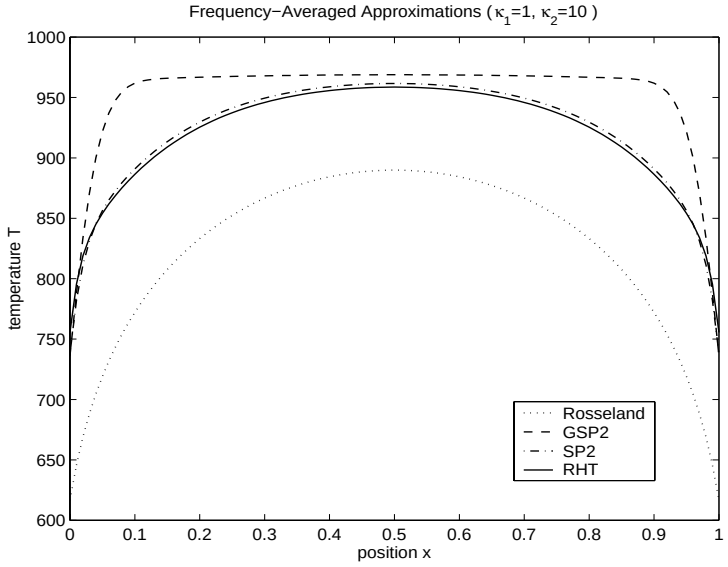

FIG. 6.4. *Comparison of the different approximations for* $\kappa_1 = 1$ *and* $\kappa_2 = 10$.

resulting in a 2-band model. Figure 6.8 shows results with averaging over bands 1 and 2, bands 3 and 4, and bands 5 to 8, resulting in a 3-band model. In both cases very good agreement of the averaged solutions with the radiative heat transfer solution can be observed. Research on how to choose the frequency bands for partial averaging in an optimal way is referred to future work.

However, we do observe, for each of the above problems, that when the GSP_2 solution disagrees with the full radiative transfer solution, the main region of disagreement is in the outer boundary layers; in these cases, the GSP_2 boundary layers

are steeper than the those in the exact radiative transfer solution. The Rosseland solution, on the other hand, tends to underpredict the steepness of the boundary layers. The more expensive partially averaged solutions generally provide much more accurate estimates of the temperature in the outer boundary layers. At this time we are not certain whether these trends apply consistently in all problems.

Finally, Table 6.2 below displays a run-time comparison of the different models for the 8-band problem, with data measured on a PC with the AMD-K6 200 processor, running MATLAB 5 under Linux 2.2. The Rosseland solution is (as expected) the least expensive, the GSP_2 solution is only slightly more expensive, the frequency-dependent SP_2 calculation is significantly more expensive, and the frequency-and-angle-dependent radiative transfer calculation is by far the most expensive of these simulations. The computation time for the partially averaged models is proportional to the number of equations (number of frequency bands plus temperature equation) used in the models. It ranges from the computation time needed for GSP_2 up to the time needed for SP_2.

7. Conclusions. Summarizing our numerical results, we conclude that the GSP_2 approximation yields significantly more accurate temperatures in the interior of the physical system than does the Rosseland approximation. In the important outer boundary layers, where thermal stresses can cause cracking of glass, the GSP_2 solution is often extremely accurate, and when not, it seems to overpredict the steepness of the boundary layers. Thus, annealing schedules based on the GSP_2 solution should generally overpredict the time required for the glass to cool. On the other hand, annealing schedules based on the Rosseland model should generally underpredict the cooling time which may lead to cracking. The partially averaged solutions provide very accurate estimates of the temperature in the boundary layers. Of course, the optimal cooling schedule will be obtained using the full radiative transfer solution, but solving this equation is significantly more expensive than solving the grey or frequency-averaged SP_N equations.

We now wish to discuss more thoroughly a point that has already been mentioned in this paper and previously in [7]. Specifically, the asymptotic analysis in this paper and in [7] contains no boundary layer analysis and no expansion of the solution of the underlying radiative transfer problem. Instead, we perform in this paper asymptotic manipulations on the frequency-dependent SP_N equations to obtain simpler equations and boundary conditions. In all cases, we seek (systems of) second-order equations in space that are well conditioned and that behave robustly in the presence of boundary layers. Our formal manipulations (i) assume that spatial derivatives are $\mathcal{O}(1)$ and (ii) do not explicitly account for boundary layers. Also, the underlying SP_N boundary conditions are obtained not by an asymptotic analysis—which seems to be forbiddingly complex—but rather by a variational analysis. In spite of these limitations, the SP_N approximations are remarkably accurate in boundary layers [2], [7], [9]. For the problems considered in this paper, the SP_2 solutions are nearly identical to the radiative transfer solutions. Moreover, the less accurate GSP_2 and the partially averaged SP_2 approximations also perform well in the boundary layers—certainly, they

are much more accurate than the Rosseland approximation. Overall, it is unclear why this favorable result should hold. There may be processes at work, not fully understood by the authors, that allow the approach taken in this paper to yield accurate results in boundary layers, even though the underlying asymptotic scaling never explicitly takes these layers into account.

Because the GSP_2 and the partially averaged SP_2 equations capture boundary layer effects, extra care must be taken in selecting spatial grids for them. In particular, spatial grids used for GSP_2 and partially averaged SP_2 must be finer in the boundary layer region than the grids used Rosseland's approximation in order to resolve the boundary layers that are not present in the Rosseland solution.

This discussion of boundary layers leads an interesting question: if the main deficiency of the Rosseland approximation occurs in boundary layer regions, then would it be preferable to develop an approximate theory employing the Rosseland equation in the interior of the system, coupled to one-dimensional boundary layer solutions that are valid at the outer boundary (or interface) parts of the system? (For example, see [1] or [4] and the references cited therein.) The conceptual advantages of this approach are that the underlying Rosseland equation is simpler to solve than the coupled GSP_2 equations, and the one-dimensional boundary layer solutions will probably contain more accurate transport physics than the GSP_2 equations.

The methodology adopted in the present paper is to explore the gains of accuracy that are attainable from the SP_2 and GSP_2 approximation to the RHT equations. A significant advantage of this approach is that differential (diffusion) equations are obtained having a structure that is very similar to equations already implemented in industrial (diffusion) codes. Thus the implementation of the (G)SP_2 equations in these codes is relatively straightforward. (This advantage of SP_N approximations is widely recognized in the nuclear engineering community.) A second advantage is that the GSP_2 equations are only slightly more expensive to solve than the Rosseland equation (see Table 6.2), while the GSP_2 solutions are significantly more accurate than the classic Rosseland solution. A third advantage is that the treatment of boundary layers in the GSP_2 equations is "natural"; the boundary layers exist directly within the GSP_2 equations and do not have to be "matched" to the solution of a (Rosseland) diffusion problem. (This is particularly important because the underlying problem is nonlinear.)

However, we must nonetheless acknowledge the fact that when the GSP_2 solutions disagree with the exact solution, the disagreement occurs mainly in the boundary layer regions. More precisely, the GSP_2 approximation is not generally capable of the accuracy of the SP_2 equations—which are accurate in the boundary layers. It is possible that some of the physics and accuracy that are lost in collapsing the SP_2 equations down to the GSP_2 equations could be regained by including boundary layer solutions into the approximate GSP_2 solution, similar to the procedure in [1]. This would add to the complexity of the method, and to the difficulty of implementation, but it could well raise the accuracy of the overall solution. This is a significant possibility for future research on this problem.

Finally, in developing a grey approximation to the SP_N equations, we also developed (i) an alternative grey $\mathcal{O}(\varepsilon^3)$ approximation to the SP_2 equations and (ii) a grey $\mathcal{O}(\varepsilon^3)$ approximation to the SP_3 equations. However, numerical simulations showed that these approximations are less accurate than the GSP_2 approximation, so it did not seem appropriate to discuss them in detail here. As discussed in the previous paragraphs, there is room for improvement in the GSP_2 approximation developed in this paper, particularly in the boundary layer regions. For example, an approxima-

tion that is more accurate (formally $\mathcal{O}(\varepsilon^4)$ rather than $\mathcal{O}(\varepsilon^3)$) in the boundary layers would certainly be desirable. However, this advance must await fresh insights and future work.

SECONDARY CIRCULATION IN GRANULAR FLOW THROUGH NONAXISYMMETRIC HOPPERS*

PIERRE A. GREMAUD†, JOHN V. MATTHEWS‡, AND DAVID G. SCHAEFFER§

Abstract. Jenike's radial solution, widely used in the design of materials-handling equipment, is a similarity solution of steady-state continuum equations for the flow under gravity of granular material through an infinite, right-circular cone. In this paper we study how the geometry of the hopper influences this solution. Using perturbation theory, we compute a first-order correction to the (steady-state) velocity resulting from a small change in hopper geometry, either distortion of the cross section or tilting away from vertical. Unlike for the Jenike solution, all three components of the correction velocity are nonzero; i.e., there is secondary circulation in the perturbed flow.

Key words. granular, similarity solution, perturbation theory

1. Introduction.

In manufacturing industries, raw materials are stored in granular form in a silo, and when needed, they are expected to flow out of the silo under gravity through a hopper. Problems in the discharge process are frequent and expensive; see, e.g., [8]. As demonstrated by a Rand Corporation study [9], these problems are symptomatic of our poor understanding of the behavior of granular materials.[1]

Jenike's radial solution is a central component of silo design. Despite its importance, this solution is subject to many severe restrictions:

1. Granular material is modeled as a continuum, with an ad hoc constitutive law.
2. The flow is assumed to be steady.
3. The flow domain, a mathematical idealization, is an infinite cone, given in spherical polar coordinates by the formula

$$\{(r, \theta, \phi) : 0 < r < \infty,\ 0 \le \theta < \theta_w\} \qquad (\theta_w = \text{constant}).$$

4. Only similarity solutions are considered.

[1]The study compared the design output and the actual output of a total of 60 manufacturing plants in various industries, 22 that were based primarily on liquids-processing technology and 38 on solids-processing technology. On average, the liquids-processing plants produced at 84% of design capacity while the solids-processing plants produced at only 63% of design capacity. To quote Merrow [9], "In economic terms, the difference between 63% of design and 84% is very large. It implies a capital cost per unit of output about one-third higher for the solids-processing plants, on the basis of poor performance alone. In addition, poor performance is inevitably associated with higher operating and maintenance costs per unit of product." Moreover, the standard deviation of the solids-processing data set was much greater, indicative of our difficulties in predicting the behavior of granular solids.

In this paper we relax restrictions 3 and 4 partly. Specifically, we generalize the domain to an infinite *pyramidal* hopper described by the inequality

$$0 \le \theta < \theta_w + \epsilon \cos m\phi, \tag{1.1}$$

where ϵ is a small parameter and m is a positive integer. Assuming a perturbation series

$$v^{(0)} + \epsilon v^{(1)} + \cdots$$

for the flow velocity in the domain (1.1), where $v^{(0)}$ is Jenike's solution, we derive a linear PDE for the first-order correction $v^{(1)}$. The r-dependence of $v^{(1)}$ still has similarity form, and the ϕ-dependence may be handled by separation of variables. In this way we reduce solving the PDE for $v^{(1)}$ to solving a two-point boundary problem on the interval $0 < \theta < \theta_w$.

In Jenike's solution, only the radial component $v_r^{(0)}$ of the velocity is nonzero. By contrast, all three components of the correction velocity $v^{(1)}$ are nonzero. In other words, *distortion of the conical domain leads to secondary circulation.* For example, in Figure 5.1 below, the flow in the θ, ϕ-directions is shown for a circular hopper that is tilted slightly to the right, and in Figure 5.2, for a slightly distorted vertical hopper.

Circulation was previously observed by Williams and Rege in discrete element simulations of granular systems [11], [13]. While a connection between such time-dependent, discrete simulations and the steady-state continuum theory below is unclear, the similarities are uncanny. Both find a secondary circulation in essentially two-dimensional granular systems undergoing a uniform compression.

The outline of the paper is as follows. In section 2, the governing equations are recalled together with Jenike's construction of similarity solutions in conical domains. For nonaxisymmetric domains of the type (1.1), the problem is then linearized about Jenike's solution in section 3. The resulting system is discretized in section 4. Numerical results and discussion are offered in section 5.

2. The model.

2.1. Governing equations and boundary conditions. The unknowns are the 3-component velocity vector v, the 3×3 symmetric stress tensor T, and a scalar plasticity coefficient λ. (The density ρ is a constant.) In total, there are $3 + 6 + 1 = 10$ unknown functions. In writing the equations for these variables, we need the strain rate tensor $V = -1/2(\nabla v + \nabla v^T)$ and the deviatoric part of the stress tensor $\operatorname{dev} T = T - \frac{1}{3} (\operatorname{tr} T)\, \mathrm{I}$. Note the sign convention: V measures the *compression* rate of the material; analogously, positive eigenvalues of T correspond to *compressive* stresses. This sign convention reflects the fact that granular materials disintegrate under tensile stresses.

Following [12], we require that these variables satisfy

$$\nabla \cdot T = \rho\, g, \tag{2.1}$$

$$V = \lambda \operatorname{dev} T, \tag{2.2}$$

$$|\operatorname{dev} T|^2 = 2s^2 (\operatorname{tr} T/3)^2, \tag{2.3}$$

where g is the (vector) acceleration of gravity, $|\cdot|$ denotes the Frobenius norm

$$|T|^2 = \sum_{i,j=1}^{3} T_{ij}^2 = \operatorname{tr} T^2$$

(the latter equality only for symmetric tensors), and $s = \sin\delta$, with δ being the angle of internal friction of the material under consideration (see [10]). Equation (2.1) expresses force balance; i.e., Newton's second law with inertia neglected because the flow is assumed slow; it is equivalent to three scalar equations. Equations (2.2) and (2.3) are constitutive laws, the alignment condition and the von Mises yield condition, respectively; they are equivalent to six and to one scalar equations, respectively. Thus (2.1)–(2.3) is a determined system, ten equations for ten unknowns. Since (2.3) contains no derivatives, this system has a differential-algebraic character. Taking the trace of (2.2), we see that $\operatorname{div} v = -\operatorname{tr} V = 0$; thus, incompressibility is part of the constitutive assumptions. Incidentally, for a solution to be physical, the function λ in (2.2) must satisfy $\lambda \geq 0$ everywhere; otherwise, friction would be adding energy to the system rather than dissipating it. In fact, we want λ to be strictly positive since one of the assumptions underlying the derivation of (2.1)–(2.3) is that material is actually deforming.

We seek solutions of (2.1)–(2.3) in a pyramidal domain, expressed in spherical polar coordinates as

$$\Omega = \{(r, \theta, \phi) : 0 \leq \theta < \mathcal{C}(\phi)\}, \tag{2.4}$$

where $\mathcal{C}$ is a given smooth 2π-periodic function. Such a domain represents a mathematical idealization of a converging hopper, in general, a nonaxisymmetric one.

On the boundary $\partial\Omega = \{(r, \mathcal{C}(\phi), \phi)\}$, wall impenetrability imposes one boundary condition on the velocity; i.e.,

$$v_N = 0, \tag{2.5}$$

where v_N is the normal velocity. Two additional boundary conditions come from Coulomb's law of sliding friction. The surface traction τ—i.e., the force exerted by the wall on the material—is given by

$$\tau_i = \sum_{j=1}^{3} T_{ij} N_j,$$

where N is the unit interior normal to $\partial\Omega$. If the vector τ has normal component τ_N and tangential component $\tau_T = \tau - \tau_N N$, then we require that

$$\tau_T = -\mu_w \, \tau_N (v/|v|), \tag{2.6}$$

where μ_w is the coefficient of friction between the wall and the material. Note the following: (i) If T is positive definite (i.e., if all stresses are compressive), then $\tau_N > 0$. (ii) While τ_N is a scalar, τ_T is effectively a two-component vector; thus, (2.6) is equivalent to two scalar equations. (iii) Because of (2.5), the velocity v is tangential to $\partial\Omega$; we are assuming that $v \neq 0$ at the boundary.

2.2. Jenike's similarity solution. Suppose that the domain (2.4) is axisymmetric; i.e., suppose

$$\Omega = \{(r, \theta, \phi) : 0 \leq \theta < \theta_w\}, \tag{2.7}$$

where θ_w is a constant. In this case Jenike [7] found that (2.1)–(2.3) have solutions that are independent of ϕ and have a similarity dependence on r,

$$v^{(0)}(r, \theta) = r^{-2} \, \hat{v}^{(0)}(\theta), \qquad T^{(0)}(r, \theta) = r \, \hat{T}^{(0)}(\theta). \tag{2.8}$$

(Here and below, a hat above a variable indicates a function that depends on θ alone.) Moreover, only the radial component of velocity is nonzero; i.e., $v_\theta^{(0)} = v_\phi^{(0)} = 0$. Similarly, $T_{r\phi}^{(0)} = T_{\theta\phi}^{(0)} = 0$. Indeed, all components of T can be expressed in terms of two scalar variables, the so-called Sokolovskii variables [10]: the mean stress $p^{(0)} = \operatorname{tr} T^{(0)}/3$ and an angle ψ; specifically,

$$\operatorname{dev} T^{(0)} = s\, p^{(0)} \begin{bmatrix} -\frac{2}{\sqrt{3}}\cos 2\psi & -\sin 2\psi & 0 \\ -\sin 2\psi & \frac{1}{\sqrt{3}}\cos 2\psi & 0 \\ 0 & 0 & \frac{1}{\sqrt{3}}\cos 2\psi \end{bmatrix}, \tag{2.9}$$

where $p^{(0)} = r\hat{p}^{(0)}$ and the function ψ, like $\hat{p}^{(0)}$, depends only on θ.

The boundary conditions (2.5), (2.6) may be written more explicitly when Ω is axisymmetric. Equation (2.5) reduces to

$$v_\theta = 0. \tag{2.10}$$

Let us decompose the vector equation (2.6) into a direction and a magnitude. Regarding the direction, the vectors τ_T and v are parallel if

$$T_{r\theta} v_\phi - T_{\theta\phi} v_r = 0. \tag{2.11}$$

Jenike's solution satisfies both (2.10) and (2.11) trivially. The two sides of (2.6) have equal magnitude if

$$T_{r\theta} + \mu_w T_{\theta\theta} = 0. \tag{2.12}$$

We briefly summarize the construction of Jenike's solution, referring to [12] for more details. The ansatz (2.9) arranges that (2.3) holds automatically. On substitution into (2.1), we obtain a first-order 2×2 system of ODEs for $\hat{p}^{(0)}$ and ψ. This system has a regular singular point at $\theta = 0$, and one boundary condition comes from requiring that the solution be regular there; the other boundary condition comes from (2.12). Thus the stresses are determined as the solution of a two-point boundary-value problem. (In axial symmetry, the stress equations decouple from the velocity.) Once the stresses are known, (2.2) reduces to a linear first-order ODE for $\hat{v}_r^{(0)}$. The velocity is determined only up to a multiplicative constant, but the normalization of the velocity will scale out of the calculations below.

Incidentally, for Jenike's solution the plasticity coefficient λ in (2.2), which cancels out in the derivation of the equation for $\hat{v}_r^{(0)}$, has the form

$$\lambda^{(0)}(r, \theta) = r^{-4} \hat{\lambda}^{(0)}(\theta).$$

Using (2.2), the function $\hat{\lambda}^{(0)}$ may be determined from $\hat{v}_r^{(0)}$.

3. Linearized analysis for a nearly axisymmetric domain.

3.1. Derivation of linearized differential equations. Equations (2.1)–(2.3), a 10×10 nonlinear DAE system that is elliptic in the sense of Agmon, Douglis, and Nirenberg [1], present formidable mathematical and numerical challenges. In this paper, we consider a simplified problem that prepares the way for computations with the full problem on a general domain.

Suppose the function $\mathcal{C}$ specifying the boundary of Ω in (2.4) has the expansion

$$\mathcal{C}(\phi) = \theta_w + \epsilon \cos(m\,\phi) + \mathcal{O}(\epsilon^2), \tag{3.1}$$

where m is a positive integer. For example, a slightly tilted (circular) cone admits such a representation with $m = 1$, where ϵ measures the angle of tilt; likewise for a (vertical) pyramidal hopper having a slightly elliptical cross section, with $m = 2$.

An expansion of the solution

$$v = v^{(0)} + \epsilon v^{(1)} + \mathcal{O}(\epsilon^2), \qquad T = T^{(0)} + \epsilon T^{(1)} + \mathcal{O}(\epsilon^2) \tag{3.2}$$

is sought, where $v^{(0)}, T^{(0)}$ are equal to Jenike's radial solution; see (2.8). Substituting (3.2) into (2.1)–(2.3), we derive the equations for the first-order perturbation

$$\nabla \cdot T^{(1)} = 0, \tag{3.3}$$

$$V^{(1)} = \lambda^{(1)}\,\mathrm{dev}T^{(0)} + \lambda^{(0)}\mathrm{dev}T^{(1)}, \tag{3.4}$$

$$\mathrm{tr}(\mathrm{dev}T^{(0)}\,\mathrm{dev}T^{(1)}) = 2\,s^2\,p^{(0)}p^{(1)}, \tag{3.5}$$

where $p^{(i)} = \mathrm{tr}\,T^{(i)}/3,\ i = 0, 1$, are the mean stresses.

The correction velocity $v^{(1)}$ has the same r-dependence as the Jenike solution (although all three components of $v^{(1)}$ may be nonzero), and its ϕ-dependence can be obtained through separation of variables. Indeed, suppose each component of $v^{(1)}$ has the form

$$v_j^{(1)} = r^{-2}\,\hat{v}_j^{(1)}(\theta)\,\mathrm{trig}\,m\phi, \tag{3.6}$$

where $\mathrm{trig}\,m\phi$ denotes either $\cos m\phi$ or $\sin m\phi$. In order to satisfy the appropriately modified version of the boundary condition (2.10) on the perturbed domain, $v_\theta^{(1)}$ will have to be in phase with (3.1); i.e., we need

$$v_\theta^{(1)} = r^{-2}\,\hat{v}_\theta^{(1)}(\theta)\cos m\phi.$$

It is readily seen that if

$$v_r^{(1)} = r^{-2}\,\hat{v}_r^{(1)}(\theta)\cos m\phi \qquad \text{and} \qquad v_\phi^{(1)} = r^{-2}\,\hat{v}_\phi^{(1)}(\theta)\sin m\phi,$$

then all terms in

$$\nabla \cdot v^{(1)} = \partial_r v_r^{(1)} + 2r^{-1}v_r^{(1)} + r^{-1}\partial_\theta v_\theta^{(1)} + r^{-1}\cot\theta v_\theta^{(1)} + r^{-1}\csc\theta\partial_\phi v_\phi^{(1)} \tag{3.7}$$

are proportional to $r^{-3}\cos m\phi$; i.e., variables separate in the equation $\nabla \cdot v = 0$.

Tables 3.1–3.3 help systematize the elimination of ϕ-dependence in (3.3)–(3.5) with separation of variables. The appropriate r- and ϕ-dependencies for the scalar $p^{(1)}$, for the vector $v^{(1)}$, and for the tensor $T^{(1)}$ are indicated in Table 3.1. (Note that symmetric 3×3 tensors are represented as vectors in $\mathbf{R}^6$, the components being enumerated in the order shown.) In Table 3.2 we record, for the reader's convenience, the expressions in spherical coordinates for four differential operators that occur in these equations.

The main point, which makes separation of variables work in this problem, is that the θ-dependent part of each of these linear operators is given by

$$\widehat{\nabla p} = (g_1\partial_\theta + g_0)\hat{p}, \tag{3.8a}$$

$$\widehat{\nabla \cdot v} = (d_1^T\partial_\theta + d_0^T)\hat{v}, \tag{3.8b}$$

$$\hat{V} = -(G_1\partial_\theta + G_0)\hat{v}, \tag{3.8c}$$

$$\widehat{\nabla \cdot T} = (D_1\partial_\theta + D_0)\hat{T}, \tag{3.8d}$$

TABLE 3.1
The r- and ϕ-dependence of scalars, vectors, and tensors in separation of variables.

Scalars :	$p = r\,\hat{p}(\theta)\cos m\phi$		
Vectors :	$v = \frac{1}{r^2}\begin{bmatrix} \hat{v}_r(\theta)\cos m\phi \\ \hat{v}_\theta(\theta)\cos m\phi \\ \hat{v}_\phi(\theta)\sin m\phi \end{bmatrix}$	*Tensors* :	$T = r\begin{bmatrix} \hat{T}_{rr}(\theta)\cos m\phi \\ \hat{T}_{r\theta}(\theta)\cos m\phi \\ \hat{T}_{\theta\theta}(\theta)\cos m\phi \\ \hat{T}_{r\phi}(\theta)\sin m\phi \\ \hat{T}_{\theta\phi}(\theta)\sin m\phi \\ \hat{T}_{\phi\phi}(\theta)\cos m\phi \end{bmatrix}$

TABLE 3.2
Differential operators in spherical coordinates.

$$\nabla p = [\,\partial_r p,\ r^{-1}\partial_\theta p,\ r^{-1}\csc\theta\partial_\phi p\,]^T$$

$$\nabla\cdot v = \partial_r v_r + 2r^{-1}v_r + r^{-1}\partial_\theta v_\theta + r^{-1}\cot\theta v_\theta + r^{-1}\csc\theta\partial_\phi v_\phi$$

$$V = \begin{bmatrix} V_{rr} \\ V_{r\theta} \\ V_{\theta\theta} \\ V_{r\phi} \\ V_{\theta\phi} \\ V_{\phi\phi} \end{bmatrix} = -\begin{bmatrix} \partial_r v_r \\ \frac{1}{2}\left(r^{-1}\partial_\theta v_r - r^{-1}v_\theta + \partial_r v_\theta\right) \\ r^{-1}\left(v_r + \partial_\theta v_\theta\right) \\ \frac{1}{2}\left(r^{-1}\csc\theta\,\partial_\phi v_r - r^{-1}v_\phi + \partial_r v_\phi\right) \\ \frac{1}{2}r^{-1}\left(\partial_\theta v_\phi - \cot\theta\, v_\phi + \csc\theta\partial_\phi v_\theta\right) \\ r^{-1}\left(v_r + \cot\theta\, v_\theta + \csc\theta\,\partial_\phi v_\phi\right) \end{bmatrix}$$

$$\nabla\cdot T = \begin{bmatrix} \partial_r T_{rr} + r^{-1}\csc\theta\,\partial_\phi T_{r\phi} + r^{-1}\partial_\theta T_{r\theta} + r^{-1}(2T_{rr} - T_{\phi\phi} - T_{\theta\theta} + T_{r\theta}\cot\theta) \\ \partial_r T_{r\theta} + r^{-1}\csc\theta\,\partial_\phi T_{\theta\phi} + r^{-1}\partial_\theta T_{\theta\theta} + r^{-1}\left(3T_{r\theta} + (T_{\theta\theta} - T_{\phi\phi})\cot\theta\right) \\ \partial_r T_{r\phi} + r^{-1}\csc\theta\,\partial_\phi T_{\phi\phi} + r^{-1}\partial_\theta T_{\theta\phi} + r^{-1}(3T_{r\phi} + 2T_{\theta\phi}\cot\theta) \end{bmatrix}$$

where $g_1, g_0, \ldots, D_0$ are the matrices given in Table 3.3.

The calculation needed to verify (3.8b) was described above; the other equations may be verified similarly. Incidentally, (3.8a) may be derived by substituting $T = pI$ in (3.8d), and (3.8b) may be derived by taking the trace of (3.8c).

With this notation, (3.3)–(3.5) reduces to a system of ODEs in θ,

$$(D_1\partial_\theta + D_0)\hat{T}^{(1)} = 0, \tag{3.9}$$

$$-(G_1\partial_\theta + G_0)\hat{v}^{(1)} = \hat{\lambda}^{(1)}\,\mathrm{dev}\hat{T}^{(0)} + \hat{\lambda}^{(0)}\mathrm{dev}\hat{T}^{(1)}, \tag{3.10}$$

$$\mathrm{tr}(\mathrm{dev}\hat{T}^{(0)}\,\mathrm{dev}\hat{T}^{(1)}) = 2\,s^2\,\hat{p}^{(0)}\hat{p}^{(1)}. \tag{3.11}$$

Recalling the representation of symmetric tensors as 6-component vectors, we observe that the left-hand side of (3.11) may be rewritten as an inner product

$$\mathrm{tr}\left(\mathrm{dev}\hat{T}^{(0)}\,\mathrm{dev}\hat{T}^{(1)}\right) = \mathrm{dev}\hat{T}^{(0)T}\mathcal{M}\,\mathrm{dev}\hat{T}^{(1)},$$

where $\mathcal{M}$ is the 6×6 matrix

$$\mathcal{M} = \mathrm{diag}(1,2,1,2,2,1);$$

thus we may rewrite (3.11) as

$$\mathrm{dev}\hat{T}^{(0)T}\mathcal{M}\,\mathrm{dev}\hat{T}^{(1)} = 2\,s^2\,\hat{p}^{(0)}\hat{p}^{(1)}. \tag{3.12}$$

TABLE 3.3
Matrices in (3.8).

$$g_1 = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}^T \qquad g_0 = \begin{bmatrix} 1 & 0 & \frac{m}{\sin\theta} \end{bmatrix}^T$$

$$d_1 = \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}^T \qquad d_0 = \begin{bmatrix} 0 & \cot\theta & \frac{m}{\sin\theta} \end{bmatrix}^T$$

$$G_1 = \begin{bmatrix} 0 & 0 & 0 \\ 1/2 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1/2 \\ 0 & 0 & 0 \end{bmatrix} \qquad G_0 = \begin{bmatrix} -2 & 0 & 0 \\ 0 & -3/2 & 0 \\ 1 & 0 & 0 \\ -\frac{m}{2\sin\theta} & 0 & -3/2 \\ 0 & -\frac{m}{2\sin\theta} & -\frac{\cot\theta}{2} \\ 1 & \cot\theta & \frac{m}{\sin\theta} \end{bmatrix}$$

$$D_1 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \end{bmatrix} \qquad D_0 = \begin{bmatrix} 3 & \cot\theta & -1 & \frac{m}{\sin\theta} & 0 & -1 \\ 0 & 4 & \cot\theta & 0 & \frac{m}{\sin\theta} & -\cot\theta \\ 0 & 0 & 0 & 4 & 2\cot\theta & -\frac{m}{\sin\theta} \end{bmatrix}$$

Let us show that the deviatoric stresses in (3.9), (3.10), (3.12) can be eliminated from these equations to obtain

$$(D_1\partial_\theta + D_0)\left(-\frac{1}{\hat\lambda^{(0)}}(G_1\partial_\theta + G_0)\hat v^{(1)} - \frac{\hat\lambda^{(1)}}{(\hat\lambda^{(0)})^2}\hat V^{(0)}\right) + (g_1\partial_\theta + g_0)\hat p^{(1)} = 0, \tag{3.13}$$

$$(d_1^T\partial_\theta + d_0^T)\hat v^{(1)} = 0, \tag{3.14}$$

where in (3.13)

$$\hat\lambda^{(1)} = -\frac{1}{2s^2}\frac{1}{(\hat p^{(0)})^2\hat\lambda^{(0)}}\,\hat V^{(0)T}\mathcal{M}(G_1\partial_\theta + G_0)\hat v^{(1)} - \frac{\hat\lambda^{(0)}}{\hat p^{(0)}}\,\hat p^{(1)}. \tag{3.15}$$

Equation (3.14) follows on taking the trace of (3.10). Next, we rewrite (3.10) as

$$\mathrm{dev}\hat T^{(1)} = -\frac{1}{\hat\lambda^{(0)}}(G_1\partial_\theta + G_0)\hat v^{(1)} - \frac{\hat\lambda^{(1)}}{(\hat\lambda^{(0)})^2}\hat V^{(0)}, \tag{3.16}$$

where we have eliminated $\mathrm{dev}\hat T^{(0)}$ using the relation $\hat V^{(0)} = \hat\lambda^{(0)}\mathrm{dev}\hat T^{(0)}$—effectively, (2.2) for Jenike's solution. Recalling that $\hat T^{(1)} = \mathrm{dev}\hat T^{(1)} + \hat p^{(1)}I$, we substitute (3.16) into (3.9) to derive (3.13). Similarly, (3.15) follows on substituting (3.16) into (3.12) and rearranging.

As a final simplification, we substitute (3.15) into (3.13), obtaining the linear, homogeneous system of ODEs

$$-(A_2\partial_{\theta\theta} + A_1\partial_\theta + A_0)\hat v^{(1)} + (b_1\partial_\theta + b_0)\hat p^{(1)} = 0, \tag{3.17}$$

$$(d_1^T\partial_\theta + d_0^T)\hat v^{(1)} = 0, \tag{3.18}$$

where, with the definition

$$P = I - \frac{1}{2s^2(\hat p^{(0)})^2(\hat\lambda^{(0)})^2}\hat V^{(0)}\hat V^{(0)T}\mathcal{M},$$

the coefficient matrices are given by

$$
\begin{aligned}
A_2 &= \frac{1}{\hat{\lambda}^{(0)}} D_1 P G_1, \\
A_1 &= \frac{1}{\hat{\lambda}^{(0)}} (D_0 P G_1 + D_1 P G_0) + D_1 \partial_\theta \left(\frac{1}{\hat{\lambda}^{(0)}} P G_1 \right), \\
A_0 &= \frac{1}{\hat{\lambda}^{(0)}} D_0 P G_0 + D_1 \partial_\theta \left(\frac{1}{\hat{\lambda}^{(0)}} P G_0 \right), \\
b_1 &= g_1 + D_1 \frac{\hat{V}^{(0)}}{\hat{p}^{(0)} \hat{\lambda}^{(0)}}, \\
b_0 &= g_0 + (D_1 \partial_\theta + D_0) \frac{\hat{V}^{(0)}}{\hat{p}^{(0)} \hat{\lambda}^{(0)}}.
\end{aligned}
$$

These matrices depend on θ and in fact several are singular as $\theta \to 0$. In Corollary 4.2 below, we show that this system has a six-dimensional solution space.

The combination $\hat{V}^{(0)}/(\hat{p}^{(0)}\hat{\lambda}^{(0)})$, which occurs in various places in the above formulas, admits a convenient representation; i.e., combining (2.2) and (2.9), we deduce that

$$
\frac{1}{\hat{p}^{(0)} \hat{\lambda}^{(0)}} \hat{V}^{(0)} = s \begin{bmatrix} -\frac{2}{\sqrt{3}} \cos 2\psi \\ -\sin 2\psi \\ \frac{1}{\sqrt{3}} \cos 2\psi \\ 0 \\ 0 \\ \frac{1}{\sqrt{3}} \cos 2\psi \end{bmatrix}. \tag{3.19}
$$

The following supplementary information will be needed in section 4.

LEMMA 3.1. *Under the reflection $\theta \mapsto -\theta$, the functions in separation of variables have the parities*

$$\hat{p}(-\theta) = (-1)^m \hat{p}(\theta), \tag{3.20a}$$

$$\hat{v}_r^{(1)}(-\theta) = (-1)^m \hat{v}_r^{(1)}(\theta), \tag{3.20b}$$

$$\hat{v}_\theta^{(1)}(-\theta) = (-1)^{m+1} \hat{v}_\theta^{(1)}(\theta), \tag{3.20c}$$

$$\hat{v}_\phi^{(1)}(-\theta) = (-1)^{m+1} \hat{v}_\phi^{(1)}(\theta). \tag{3.20d}$$

Proof. The reflection $\theta \mapsto -\theta$ and the rotation $\phi \mapsto \phi + \pi$ are different representations of the same mapping. Therefore, since p is a scalar,

$$\hat{p}(-\theta) \cos m\phi = \hat{p}(\theta) \cos m(\phi + \pi) = (-1)^m \hat{p}(\theta) \cos m\phi,$$

which proves (3.20a). Equation (3.20b) follows from the same argument since v_r transforms as a scalar under changes in the angular coordinates. Rather than analyze the parities of v_θ and v_ϕ, we prefer an indirect argument. Since $\nabla \cdot v^{(1)}$ is a scalar, $\nabla \cdot v^{(1)}$ has parity $(-1)^m$ under the reflection $\theta \mapsto -\theta$, and on inspecting (3.7), we deduce (3.20c), (3.20d). ∎

Incidentally, although we shall not need that information below, we remark that under this reflection $\hat{T}_{rr}$, $\hat{T}_{\theta\theta}$, $\hat{T}_{\theta\phi}$, and $\hat{T}_{\phi\phi}$ have parity $(-1)^m$, while $\hat{T}_{r\theta}$ and $\hat{T}_{\phi r}$ have parity $(-1)^{m+1}$.

TABLE 3.4
Leading orders in the expansions at $\theta = 0$ of the coefficient matrices of (3.17)–(3.18).

$$
\begin{array}{lcl}
A_2(\theta) & = & \begin{bmatrix} \frac{1}{2} & 0 & 0 \\ 0 & \frac{5}{6} & 0 \\ 0 & 0 & \frac{1}{2} \end{bmatrix} + \mathcal{O}(\theta) \\
A_1(\theta) & = & \theta^{-1} \begin{bmatrix} \frac{1}{2} & 0 & 0 \\ 0 & \frac{5}{6} & \frac{m}{3} \\ 0 & -\frac{m}{3} & \frac{1}{2} \end{bmatrix} + \mathcal{O}(1) \\
A_0(\theta) & = & \theta^{-2} \begin{bmatrix} -\frac{m^2}{2} & 0 & 0 \\ 0 & -\frac{m^2}{2} - \frac{5}{6} & -\frac{4m}{3} \\ 0 & -\frac{4m}{3} & -\frac{5m^2}{6} - \frac{1}{2} \end{bmatrix} + \mathcal{O}(\theta^{-1}) \\
b_1(\theta) & = & (1 + s/\sqrt{3}) \begin{bmatrix} 0 & 1 & 0 \end{bmatrix}^T + \mathcal{O}(\theta) \\

d_0(\theta) & = & \theta^{-1} \begin{bmatrix} 0 & 1 & m \end{bmatrix}^T + \mathcal{O}(1)
\end{array}
$$

3.2. Boundary conditions at the centerline. Equations (3.17), (3.18) have a regular singular point at $\theta = 0$. The leading orders of the coefficient matrices in these equations are given in Table 3.4. This information may be determined *without knowing the Jenike solution explicitly* since, using the fact that $\psi(0) = 0$, we deduce from (3.19) that

$$\frac{\hat{V}^{(0)}}{\hat{p}^{(0)}\hat{\lambda}^{(0)}}(0) = \frac{s}{\sqrt{3}} \begin{bmatrix} -2 & 0 & 1 & 0 & 0 & 1 \end{bmatrix}^T.$$

According to the method of Frobenius [3], equations (3.17), (3.18) admit solutions of the form

$$\hat{v}^{(1)}(\theta) = \theta^{\nu} F(\theta), \qquad \hat{p}^{(1)}(\theta) = \theta^{\nu-1} f(\theta), \tag{3.21}$$

where $F(\theta)$ and $f(\theta)$ are analytic near $\theta = 0$. Suppose the exponent ν is real; if $1 \le \nu$, such a solution is continuous; if $\nu < 0$, it is singular; and if $0 \le \nu < 1$, it is continuous, *provided* $f(0) = 0$.

PROPOSITION 3.2. *There are exactly three linearly independent solutions of* (3.17), (3.18) *of the form* (3.21) *that are continuous at* $\theta = 0$.

Proof. Substitution of (3.21) into (3.17), (3.18) gives an indicial equation with roots

$$\nu = \pm(m+1), \pm m, \pm(m-1). \tag{3.22}$$

If $m \ge 2$, three of the roots of (3.22) are negative and three are positive. The three solutions associated with the positive indices are linearly independent and continuous. (We remark that since the positive roots differ by integers, in principle these solutions

might contain log terms. This would not affect their continuity. Moreover, using Maple we have verified that no such log terms arise. See section 5.2 for more details about the Maple code.)

If $m = 1$, there are four nonnegative roots of (3.22), including zero which is a double root. Because of a log term, the double root zero contributes at most one continuous solution. Again using Maple we have eliminated the various alternative possibilities to show that zero and the two positive roots (3.22) contribute exactly three linearly independent continuous solutions and these do not contain any log terms. □

Incidentally, since the roots of the indicial equation are integers and since no log terms arise, the continuous solutions of the lemma are actually *analytic* near $\theta = 0$.

Note that there are six roots (3.22) of the indicial equation. Therefore (3.17), (3.18) has a six-dimensional solution space. (We also prove this by a different argument in Corollary 4.2.) Thus, according to the proposition, the condition that solutions be regular at $\theta = 0$ is equivalent to three boundary conditions. Therefore, regularity at $\theta = 0$ plus the three boundary conditions (2.5), (2.6) will provide a complete set of boundary conditions.

3.3. Boundary conditions at the hopper wall. We derive the perturbed version of (2.5) in some detail; similar issues arise for (2.6), and we treat the latter equation more succinctly. The calculations are greatly simplified by the fact that we may neglect any quantity that is $\mathcal{O}(\epsilon^2)$. To exploit this simplification efficiently, we temporarily use the notation $F \sim G$ to mean that $F = G + \mathcal{O}(\epsilon^2)$.

Including a prefactor of r^2 to remove all r-dependence from the equation, we may rewrite (2.5) as

$$r^2 v(r, \theta_w + \epsilon \cos m\phi, \phi) \cdot N = 0. \tag{3.23}$$

Because of the perturbation, (3.23) differs from (2.10) in three respects:

- the velocity v contains an additional term, $v \sim v^{(0)} + \epsilon v^{(1)}$;
- the velocity is evaluated at a location shifted by $\epsilon \cos m\phi$;
- the direction of the normal N is changed.

Regarding the first two points, we observe that

$$r^2 v(r, \theta_w + \epsilon \cos m\phi, \phi) \sim \hat{v}^{(0)}(\theta_w) + \epsilon \cos m\phi \, \partial_\theta \hat{v}^{(0)}(\theta_w) + \epsilon \operatorname{trig} m\phi \, \hat{v}^{(1)}(\theta_w),$$

where $\operatorname{trig} m\phi$ equals $\cos m\phi$ or $\sin m\phi$, depending on the component of $\hat{v}^{(1)}$. Regarding the third point, $\partial\Omega$ is the zero set of the function $\theta - \theta_w - \epsilon \cos m\phi$. Taking the gradient of this function, we conclude that the (inward) normal is

$$N \sim \begin{bmatrix} 0 & -1 & -\epsilon \frac{\sin m\phi}{\sin \theta_w} \end{bmatrix}^T.$$

Modulo an $\mathcal{O}(\epsilon^2)$-error, N has unit length. Substituting the previous two equations into (3.23), we deduce that

$$-r^2 v(r, \theta_w + \epsilon \cos m\phi, \phi) \cdot N \sim \hat{v}_\theta^{(0)}(\theta_w) + \epsilon \cos m\phi \left(\partial_\theta \hat{v}_\theta^{(0)}(\theta_w) + \hat{v}_\theta^{(1)}(\theta_w) \right) + \epsilon \frac{\sin m\phi}{\sin \theta_w} \hat{v}_\phi^{(0)}(\theta_w).$$

However, since $v_\theta^{(0)}$ and $v_\phi^{(0)}$ vanish identically for Jenike's solution, the velocity boundary condition for the perturbed problem reduces to

$$\hat{v}_\theta^{(1)}(\theta_w) = 0. \tag{3.24}$$

We turn to the stress boundary condition (2.6). As regards the scalar τ_N in (2.6), we observe that, since $T^{(0)}_{r\phi}$ and $T^{(0)}_{\theta\phi}$ vanish for Jenike's solution,

$$\tau_N = \sum_{i,j=1}^{3} T_{ij} N_i N_j \sim T^{(0)}_{\theta\theta} + \epsilon T^{(1)}_{\theta\theta}. \tag{3.25}$$

The vectors τ_T and v_T in (2.6) lie in a two-dimensional subspace tangent to $\partial\Omega$. Note that the unperturbed tangent space is spanned by the r and ϕ coordinate directions. Even allowing for the perturbation, the two sides of (2.6) will be equal iff their r- and ϕ-components are equal; in symbols, iff

$$\begin{bmatrix} \tau_{Tr} \\ \tau_{T\phi} \end{bmatrix} = -\frac{\mu_w \tau_N}{|v|} \begin{bmatrix} v_r \\ v_\phi \end{bmatrix}.$$

This equality will hold iff (i) the two sides of the equation are parallel vectors and (ii) the first components of the two sides are equal; again, in symbols, iff

$$\tau_{Tr} v_\phi - \tau_{T\phi} v_r = 0 \qquad \text{and} \tag{3.26}$$

$$\tau_{Tr} + \mu_w \tau_N (v_r/|v|) = 0. \tag{3.27}$$

Regarding v, it is clear that

$$\begin{bmatrix} v_r \\ v_\phi \end{bmatrix} \sim \begin{bmatrix} v^{(0)}_r \\ 0 \end{bmatrix} + \epsilon \begin{bmatrix} v^{(1)}_r \\ v^{(1)}_\phi \end{bmatrix}. \tag{3.28}$$

Regarding $\tau_T = \tau - \tau_N N$, we claim that

$$\begin{bmatrix} \tau_{Tr} \\ \tau_{T\phi} \end{bmatrix} \sim -\begin{bmatrix} T^{(0)}_{r\theta} \\ 0 \end{bmatrix} - \epsilon \begin{bmatrix} T^{(1)}_{r\theta} \\ T^{(1)}_{\theta\phi} \end{bmatrix}. \tag{3.29}$$

Verifying this claim is straightforward except that, in analyzing the second component, one must invoke the fact that Jenike's solution satisfies $T^{(0)}_{\theta\theta} = T^{(0)}_{\phi\phi}$. On substituting (3.28) and (3.29) into (3.26), we obtain the equation

$$\epsilon \left(T^{(0)}_{r\theta} v^{(1)}_\phi - v^{(0)}_r T^{(1)}_{\theta\phi} \right) = 0 \qquad \text{at } \theta = \theta_w + \epsilon \cos m\phi.$$

The difference between evaluating this expression at $\theta = \theta_w$ and at the perturbed location is $\mathcal{O}(\epsilon^2)$. Removing the r-dependence (proportional to r) and the ϕ-dependence (proportional to $\sin m\phi$) from this equation, we obtain the first stress boundary condition for the perturbed problem:

$$\left(\hat{T}^{(0)}_{r\theta} \hat{v}^{(1)}_\phi - \hat{v}^{(0)}_r \hat{T}^{(1)}_{\theta\phi} \right) = 0 \qquad \text{at } \theta = \theta_w. \tag{3.30}$$

Regarding (3.27), we claim that

$$|v| = \sqrt{v_r^2 + v_\theta^2 + v_\phi^2} \sim |v_r|.$$

Indeed, it is clear from (3.28) that the contribution of v_ϕ to $|v|$ is $\mathcal{O}(\epsilon^2)$, and by (3.24) the contribution of v_θ to $|v|$ is $\mathcal{O}(\epsilon^4)$. Thus, $v_r/|v| \sim -1$. Substituting (3.25) and (3.29) into (3.27), we obtain the condition

$$(T^{(0)}_{r\theta} + \epsilon T^{(1)}_{r\theta}) + \mu_w (T^{(0)}_{\theta\theta} + \epsilon T^{(1)}_{\theta\theta}) \sim 0 \qquad \text{at } \theta = \theta_w + \epsilon \cos m\phi.$$

By (2.12), $T^{(0)}_{r\theta} + \mu_w T^{(0)}_{\theta\theta}$ vanishes at $\theta = \theta_w$, but at the perturbed location these terms make an $\mathcal{O}(\epsilon)$-contribution. Allowing for this contribution and eliminating the r- and ϕ-dependence, we derive the second stress boundary condition for the perturbed problem:

$$\hat{T}^{(1)}_{r\theta} + \mu_w \hat{T}^{(1)}_{\theta\theta} = -\partial_\theta \left(\hat{T}^{(0)}_{r\theta} + \mu_w \hat{T}^{(0)}_{\theta\theta} \right) \qquad \text{at } \theta = \theta_w. \tag{3.31}$$

We have put the inhomogeneous term, which does not involve the perturbation $T^{(1)}$, on the right side of the equation. (By contrast, (3.30) and (3.24) are homogeneous.)

It is noteworthy that the perturbed boundary conditions (3.24), (3.30), (3.31) resemble (2.10), (2.11), (2.12) rather closely.

4. Numerical approximation of the two-point boundary-value problem. The coefficients in (3.17), (3.18) depend on the zeroth-order solution discussed in section 2.2. This solution can be found numerically without difficulty; see, e.g., [6], where a shooting method is used, or [10]. We will consider the zeroth-order solution as given, and we will focus on the corrections $\hat{v}^{(1)}$ and $\hat{p}^{(1)}$.

To simplify the notation before discretization, we set

$$w = \hat{v}^{(1)}, \quad z = \frac{d}{d\theta}\hat{v}^{(1)}, \quad \text{and} \quad q = p^{(1)}$$

and rewrite equations (3.17), (3.18) as a first-order system

$$\begin{bmatrix} \mathrm{I} & 0 & 0 \\ 0 & -A_2 & b_1 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} w' \\ z' \\ q' \end{bmatrix} + \begin{bmatrix} 0 & -\mathrm{I} & 0 \\ -A_0 & -A_1 & b_0 \\ d_0^T & d_1^T & 0 \end{bmatrix} \begin{bmatrix} w \\ z \\ q \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}, \tag{4.1}$$

where the coefficient matrices are the same as above. System (4.1) is completed by the three boundary conditions (3.24), (3.30), (3.31).

The above system (4.1) is differential-algebraic; in the next lemma, we show it has index one. (The meaning of this term is defined in the proof, or see [4].) The approximation of solutions of the initial-value problem for such low-index DAEs is relatively well understood; see, for instance, [4] for convergence results. Moreover, some results for the initial-value problem may be extended to boundary-value problems; see [5]. These considerations provide a theoretical justification for our using the midpoint rule to solve (4.1) numerically.

LEMMA 4.1. *Assuming downward flow, i.e., $v_r(\theta) < 0$ for any θ, the first-order system is differential-algebraic of index one.*

Proof. We need to show that by differentiating some of the components of (4.1) at most once, the algebraic character of the system can be eliminated, leaving a purely differential equation. Let us differentiate only the last component of (4.1),

$$d_0^T w + d_1^T z = 0. \tag{4.2}$$

The resulting system may be written as

$$\begin{bmatrix} I & 0 & 0 \\ 0 & -A_2 & b_1 \\ 0 & d_1^T & 0 \end{bmatrix} \begin{bmatrix} w' \\ z' \\ q' \end{bmatrix} + \begin{bmatrix} \text{linear} \\ \text{zeroth-order} \\ \text{terms} \end{bmatrix} = 0. \tag{4.3}$$

We claim the coefficient matrix in (4.3) is nonsingular. Then, multiplying (4.3) by the inverse of this matrix, we obtain a purely differential equation.

To prove the claim, it suffices to show that

$$B = \begin{bmatrix} +\hat{\lambda}^{(0)} A_2 & b_1 \\ d_1^T & 0 \end{bmatrix} \tag{4.4}$$

is nonsingular, where, without changing invertibility, we have inserted a factor of $-\hat{\lambda}^{(0)}$ in the upper left, which simplifies the calculation. Let us introduce the notation W for the column vector on the right-hand side of (3.19), so that $\hat{V}^{(0)}/(\hat{p}^{(0)}\hat{\lambda}^{(0)}) = s\,W$. Then from the definitions following (3.17), (3.18), we have $b_1 = g_1 + sD_1W$. Similarly, regarding A_2, since $\mathcal{M}G_1 = D_1^T$, we have $\hat{\lambda}^{(0)}A_2 = D_1G_1 - \frac{1}{2}(D_1W)(D_1W)^T$. But

$$D_1W = \begin{bmatrix} -\sin 2\psi & \frac{1}{\sqrt{3}}\cos 2\psi & 0 \end{bmatrix}^T.$$

Hence matrix (4.4) equals

$$B = \begin{bmatrix} \frac{1}{2} - \frac{1}{2}\sin^2 2\psi & * & * & -s\sin 2\psi \\ \frac{1}{2\sqrt{3}}\cos 2\psi \sin 2\psi & * & * & 1 + \frac{s}{\sqrt{3}}\cos 2\psi \\ 0 & 0 & \frac{1}{2} & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix},$$

where $*$ indicates elements that do not affect the invertibility of B. It is readily calculated that

$$\det B = -\frac{1}{4}\left(\cos^2 2\psi + \frac{s}{\sqrt{3}}\cos 2\psi\right).$$

As shown on p. 43 of [12], the assumption that $v_r^{(0)} < 0$ implies that $|\psi(\theta)| < \pi/4$, and the claim follows. ∎

COROLLARY 4.2. *The solution space of* (4.1) *has dimension six.*

Proof. The solution space of (4.3), which is seven-dimensional, may be parameterized by initial values $\begin{bmatrix} w(\theta_0) & z(\theta_0) & q(\theta_0) \end{bmatrix}^T$. Since (4.3) was obtained from (4.1) by differentiating (4.2), we conclude that for a solution of (4.3),

$$d_0^T w(\theta) + d_1^T z(\theta) \equiv 0 \quad \text{iff} \quad d_0^T w(\theta_0) + d_1^T z(\theta_0) = 0.$$

Thus the solution space of (4.1) may be identified with the set of solutions of (4.3) whose initial conditions satisfy the scalar equation (4.2). ∎

The boundary-value problem (4.1), (3.24), (3.30), (3.31) is discretized using a symmetric implicit Runge–Kutta method [2], [4]. Since the solutions are expected to behave smoothly with respect to θ, the simplest of those methods, namely the midpoint rule, is chosen. In spite of being only second-order accurate, this choice is shown to be adequate below. The interval $(0, \theta_w)$ is divided into N subintervals of size $\Delta\theta = \theta_w/N$, defining a uniform mesh with nodes $\theta_i = i\,\Delta\theta$, $i = 0, 1, \ldots, N$. At each grid point θ_i there are seven unknowns,

$$U^i = [w_1^i \;\; w_2^i \;\; w_3^i \;\; z_1^i \;\; z_2^i \;\; z_3^i \;\; q^i]^T.$$

Since there are $N+1$ grid points, there are $7(N+1)$ unknowns in total. The midpoint

TABLE 4.1
Numerical boundary conditions at $\theta = 0$.

$m = 1$	$w_1^0 = 0$	$w_2^0 + w_3^0 = 0$	$z_3^0 = 0$	$q^0 = 0$
$m \geq 2$	$w_1^0 = 0$	$w_2^0 = 0$	$w_3^0 = 0$	$q^0 = 0$

rule for the ODE (4.1) is applied on each interval $[\theta_{i-1}, \theta_i]$, $i = 1, \ldots, N$, leading to $7N$ equations for the $7(N+1)$ unknowns.

Seven additional equations are needed to close the system, and these are provided by the boundary conditions. At $\theta = \theta_w$, the three conditions (3.24), (3.30), (3.31) are imposed, and at $\theta = 0$, the four numerical boundary conditions listed in Table 4.1 are imposed. The latter boundary conditions may be justified as follows. According to (3.21), (3.22), as $\theta \to 0$,

$$w \sim \theta^\nu, \qquad q \sim \theta^{\nu-1},$$

where $\nu \geq m - 1$. Thus $w(0) = 0$ if $m \geq 2$, and $q(0) = 0$ if $m \geq 3$. In fact, if $m = 2$, direct calculation of the Frobenius solution (3.21) shows that $q(0) = 0$ remains true in this case, too. If $m = 1$, we refer to Lemma 3.1: by parity, w_1, q, and $z_3 = dw_3/d\theta$ all vanish at $\theta = 0$. The fourth boundary condition in Table 4.1 follows from the last equation in (4.1) in the limit $\theta \to 0$.

The resulting $7(N+1) \times 7(N+1)$ system has the following structure:

$$\begin{bmatrix} S_1 & R_1 & & & & \\ & S_2 & R_2 & & & \\ & & \ddots & \ddots & & \\ & & & S_N & R_N & \\ B_0 & & & & B_w \end{bmatrix} \begin{bmatrix} U^0 \\ U^1 \\ \vdots \\ U^{N-1} \\ U^N \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ Q \end{bmatrix}. \tag{4.5}$$

The last row of the above system corresponds to the implementation of the boundary conditions; the 7×7 matrices B_0 and B_w contain the coefficients entering in the formula from Table 4.1 and (3.24), (3.30), (3.31), respectively, while Q corresponds to the nonhomogeneous part of the boundary condition (3.31).

5. Numerical results.

5.1. Secondary circulation. We claim that, for solutions of (4.1), secondary circulation—i.e., flow tangential to the spherical cap $\{r = \text{const}\}$—may be described in terms of the stream function

$$\Psi = \frac{1}{mr} \sin\theta \sin m\phi \, w_2(\theta).$$

In other words, we must show that

$$v_\theta^{(1)} = \frac{1}{r \sin\theta} \partial_\phi \Psi, \tag{5.1a}$$

$$v_\phi^{(1)} = -\frac{1}{r} \partial_\theta \Psi. \tag{5.1b}$$

Since $v_\theta^{(1)} = r^{-2} w_2(\theta) \cos m\phi$, equation (5.1a) follows by direct differentiation. On

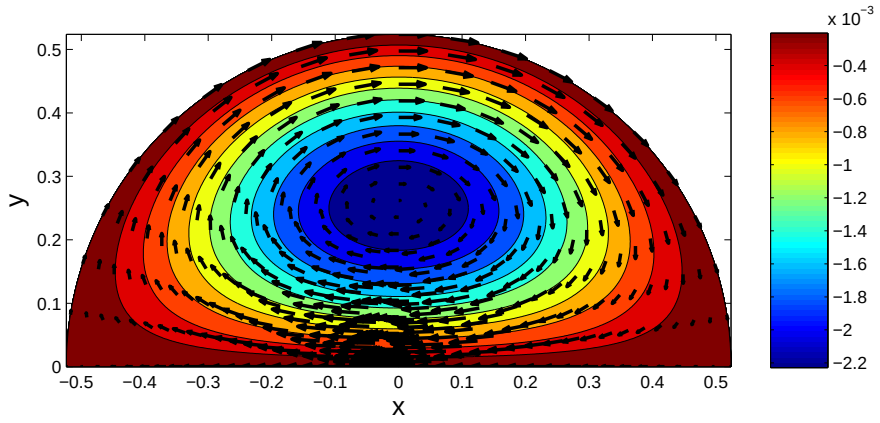

FIG. 5.1. *Stream function showing secondary flow in a tilted hopper ($m = 1$, $\theta_w = 30°$, $\delta = 30°$, angle of wall friction $= 14°$), i.e., $\mu_w = \tan 14°$. By symmetry, only half of the hopper is represented.*

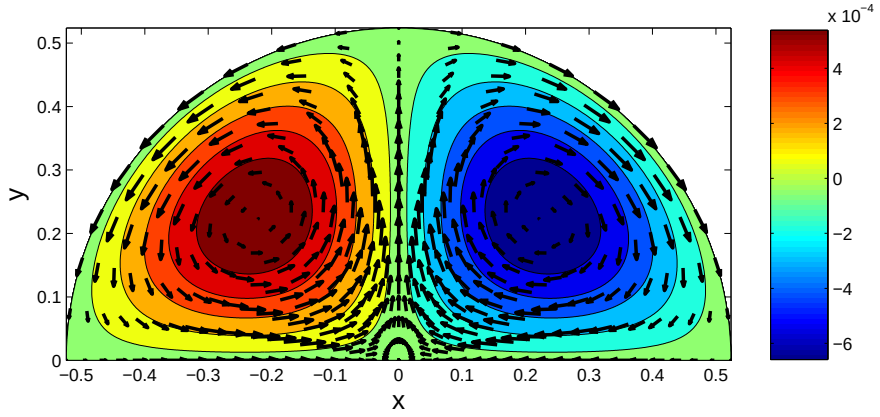

FIG. 5.2. *Stream function showing secondary flow in an "elliptical" hopper ($m = 2$, $\theta_w = 30°$, $\delta = 30°$, angle of wall friction $= 14°$).*

the other hand, since $v_r^{(1)} = r^{-2} w_1(\theta) \cos m\phi$, we have $(\partial_r + 2r^{-1}) v_r = 0$, so by (3.7)

$$(\partial_\theta + \cot\theta) w_2(\theta) \cos m\phi + \csc\theta \, w_3(\theta) \, \partial_\phi(\sin m\phi) = 0,$$

from which (5.1b) follows. Figures 5.1 and 5.2 show plots of the level lines of Ψ, which equal the projection of the streamlines onto a spherical cap $\{r = \text{const}\}$. Figure 5.1 corresponds to a tilted hopper ($m = 1$), while Figure 5.2 corresponds to an "elliptical" hopper ($m = 2$). The grains do not move along radial lines but follow more complicated and fully three-dimensional trajectories.

The sign of the main circulation changes when μ_w increases. The corresponding transition is independent of the value of m, but is a property of the radial solution itself. Specifically, the circulation vanishes when the boundary condition for the correction terms (3.31) is homogeneous, i.e., $\partial_\theta \hat{T}_{r\theta}^{(0)} + \mu_w \partial_\theta \hat{T}_{\theta\theta}^{(0)} = 0$ at $\theta = \theta_w$. The range of θ_w in Figure 5.3 is limited by the mass-flow limit—exceeding this limit leads to flows with rigid regions, to which the present model does not apply. The range of μ_w

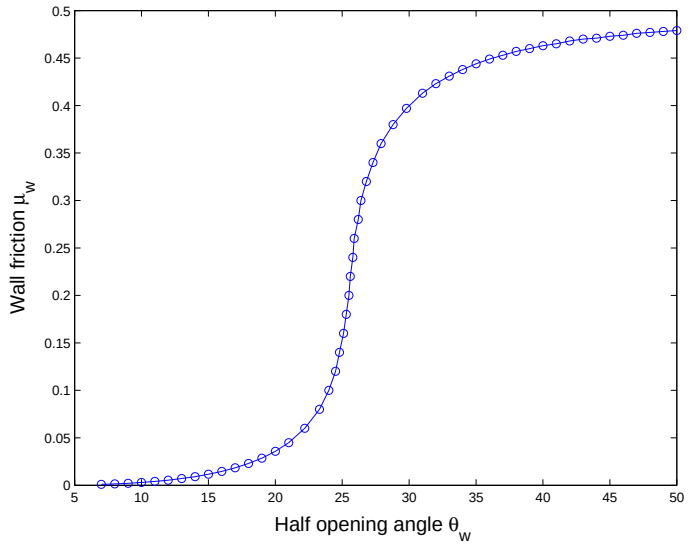

FIG. 5.3. *Critical values leading to sign changes of the circulation (internal friction $\delta = 30°$).*

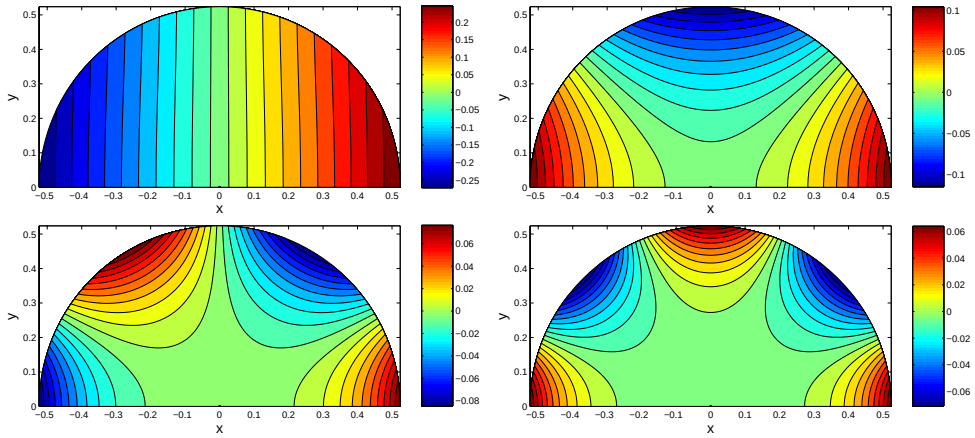

FIG. 5.4. *Influence of the geometry on the mean stress corrections ($\theta_w = 30°$, $\delta = 30°$, angle of wall friction $= 14°$); upper left: $m = 1$, upper right: $m = 2$, lower left: $m = 3$, lower right: $m = 4$.*

is limited by the condition that $\mu_w < \sin\delta = 1/2$; here the upper bound corresponds to a fully rough wall [7].

The effects of the geometry on the mean stress corrections are illustrated in Figure 5.4.

5.2. Checks on the computation. For comparison with the above numerical solution, the method of Frobenius was applied directly to the system (3.17), (3.18) using Maple. Given Jenike's radial field, a linear system for the coefficients of the series solution is readily formed and solved, yielding a solution with three free parameters, corresponding to the three linearly independent solutions in Proposition 3.2. Subsequently, the three boundary conditions (3.24), (3.30), (3.31) provide the needed relations to determine the solution to the full boundary-value problem.

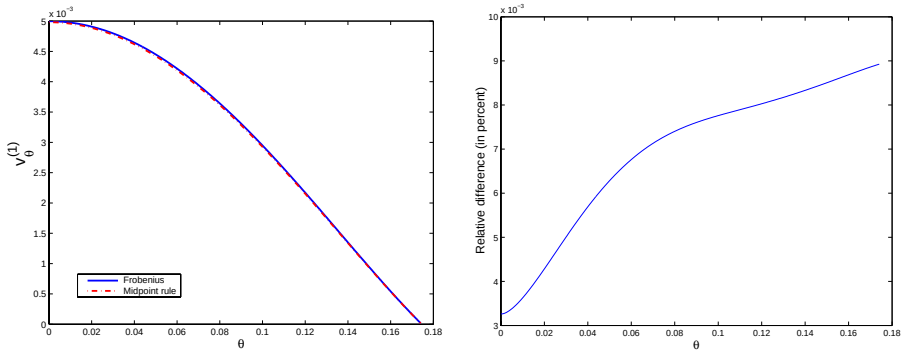

FIG. 5.5. *Comparison of* $v_\theta^{(1)}$ *from the purely numerical method of section* 4 *and from the Frobenius method of section* 5.2. *(Using* $m = 1$, $\theta_w = 10°$, $\delta = 30°$, *and* $\mu_w = 0.3$.*)*

Two methods of obtaining the radial field were employed. Under the assumption that θ_w^2 and μ_w/θ_w are both small and of the same order, a series representation of the Jenike field was computed within Maple itself. Under the less restrictive assumption that only θ_w be small (say 10°), numerical solutions were computed in MATLAB, fitted to polynomials, and then imported into Maple. In both cases, the resulting polynomials were then used to compute the first-order correction. The corrections to the stress and velocity obtained through this symbolic approach agree extremely well with the results of the purely numerical method of sections 4 and 5: for the representative values $m = 1$, $\theta_w = 10°$, $\delta = 30°$, and $\mu_w = 0.3$, the corrections obtained by the two different methods have a relative difference of less than 1%; see Figure 5.5.

Acknowledgments. The authors thank Bob Behringer, Steve Campbell, Tim Kelley, Tony Royal, and Michael Shearer for many helpful discussions.

RESONANCES FOR MICROSTRIP TRANSMISSION LINES*

HABIB AMMARI† AND FAOUZI TRIKI†

Abstract. In this paper we rigorously derive asymptotic formulae for resonances associated with a microstrip transmission line mounted on a planar waveguide with variable electromagnetic characteristics when the width of the line goes to zero.

Key words. microstrip transmission lines, waveguides, resonances, characteristic numbers, generalized Rouché theorem, integral operators, asymptotic expansions

DOI. 10.1137/S0036139902418390

1. Introduction.

In this paper we discuss resonance problems inherent in microstrip transmission lines mounted on planar open waveguides. Microstrip transmission lines are widely used in printed-circuit technology, microwave integrated circuits, and the antenna industry [7], [15], [6], [11]. Since microstrip transmission lines are highly resonant structures, an accurate determination of their resonances is of great importance [4], [7], [15], [6], [11]. Our aim in this work is to rigorously derive asymptotic formulae for resonances associated with the full Maxwell's equations in a microstrip transmission line mounted on a planar open waveguide when the width of the microstrip transmission line goes to zero. The waveguide is half space ($y > 0$) with the Dirichlet boundary condition on $y = 0$. The region $0 < y < h$ is considered the core of the fiber, while the remainder is considered the cladding. The electric permittivity of the waveguide is y-dependent in the core and is constant in the cladding. The magnetic permeability is constant in each part. The electromagnetic characteristics of the waveguide are then given by

$$\varepsilon(y) = \begin{cases} \varepsilon_1(y) & \text{in }]0, h[, \\ \varepsilon_2 & \text{in }]h, +\infty[\end{cases}$$

and

$$\mu(y) = \begin{cases} \mu_1 & \text{in }]0, h[, \\ \mu_2 & \text{in }]h, +\infty[, \end{cases}$$

where $\varepsilon_1(y)\mu_1 \geq \varepsilon_2\mu_2$ and $\mu_1 \neq \mu_2$.

This resonant problem is a spectral problem nonlinear in the spectral variable, that is, the frequency. By integral equations, we reduce this problem to the existence and the distribution of the characteristic values of two families of self-adjoint integral operators in the complex plane. Powerful techniques from the theory of meromorphic operator-valued functions and careful asymptotic analysis of integral kernels are combined for solving this problem. Our results are expected to lead to sophisticated

numerical tools for working engineers and scientists in the design and analysis of microstrip structures and circuits to be installed on waveguides. It is also hoped that this work will provide some insight into correct analysis of both the resonant and the radiation problems for microstrip transmission lines.

The paper is organized as follows. In section 2, we model the search of the resonances of the microstrip transmission line as two nonlinear spectral problems (2.6) and (2.7). Then, in section 3, we reformulate (2.6) and (2.7) as two systems of integral equations depending on the small parameter 2α which is the width of the transmission line. We transform these systems into the determination of the characteristic values of two integral operator-valued functions $\mathcal{A}_\alpha$ and $\mathcal{B}_\alpha$ in the complex plane. The main ingredient for doing this is an inverse transform formula stated in Lemma 3.1. A similar formula was first derived by Magnanini and Santosa [8]. A generalization of the Rouché theorem to operator-valued functions shows the existence of resonances close to the resonant frequencies of the waveguide, considered as a reference structure. The idea of reducing the resonant problem to the study of characteristic values of some integral operators has been introduced by Russian authors; see [12] and the references listed there. Section 4 is devoted to the rigorous derivation of asymptotic expansions of the resonances as α goes to zero. In Appendix A, we give a proof of Lemma 3.1. Appendix B contains statements of the main results from the work of Gohberg and Sigal [2] that are used here.

Our asymptotic formulae can be interpreted as follows. As will be shown in this paper, the introduction of the microstrip transmission line perturbs the guided frequencies and transforms the guided modes into radiative modes with a complex z-wave number γ ($\Im(\gamma) > 0$). In other words, the complex part of the perturbations in γ that are due to the transmission line corresponds to losses in the guided modes by the planar waveguide. The main problem in applications then is to reduce these losses.

It should also be remarked that the leading order resonances perturbations resulting from the presence of the microstrip transmission line are of order $O(\frac{1}{\ln \alpha})$. This finding is closely connected with the work of Ozawa [10] (see also [5]). Ozawa derives an asymptotic expression of the eigenvalues of the Laplacian in a bounded domain in $\mathbb{R}^2$ in the presence of an interior small perfectly conducting ball (with the Dirichlet boundary condition on its boundary). Ozawa's asymptotic expression bears some resemblance to ours. We finally note that our approach can be used to correctly solve the radiation problem for microstrip transmission lines. The resonant problem for microstrip gratings that are planar periodic structures can also be solved by a similar method.

2. Position of the problem. Let (e_x, e_y, e_z) be an orthonormal basis of $\mathbb{R}^3$. The microstrip structure extends in the domain $\mathbb{R}^3_+ = \mathbb{R} \times \mathbb{R}_+ \times \mathbb{R}$ and is invariant under any translation in the z-direction. It consists of a perfectly conducting ground plane $G \times \mathbb{R} = \mathbb{R} \times \{y = 0\} \times \mathbb{R}$ coated with a dielectric layer of constant thickness h. A single infinite strip line $P \times \mathbb{R} =]-\alpha, \alpha[\times \{y = h\} \times \mathbb{R}$ of width 2α is posed on the upper plane $\{y = h\}$. The exterior medium, characterized by a positive constant electric permittivity ε_2 and a positive constant magnetic permeability μ_2, fills the upper domain $\mathcal{O}_2 \times \mathbb{R} = \mathbb{R} \times]h, +\infty[\times \mathbb{R}$. The dielectric layer fills the lower domain $\mathcal{O}_1 \times \mathbb{R} = \mathbb{R} \times]0, h[\times \mathbb{R}$. We assume that the electric permittivity ε_1 of the dielectric layer is a variable function in the y-direction and its magnetic permittivity is a positive constant μ_1. Throughout this paper, we adopt the following notation: $f^\pm$ is the limit of $f(y)$ when $y \to h^\pm$; $[f] = f^+ - f^-$ on P denotes the jump between the boundary

values of f on the two sides of P.

The microstrip transmission line is illuminated by a harmonic incident plane wave, $\mathcal{E}^{inc}(x,y,z,t)$ and $\mathcal{H}^{inc}(x,y,z,t)$. We denote by ω its frequency, by $\vec{k} = k_x e_x + k_y e_y + k_z e_z$ its wave vector, and by $\vec{X} = (x,y,z)$ the space vector. The frequency $\omega = |\vec{k}|$ is a fixed positive real. Thus we have

$$\mathcal{E}^{inc}(\vec{X},t) = E_0^{inc}(\vec{X}) e^{-i\omega t + \vec{k}.\vec{X}},$$
$$\mathcal{H}^{inc}(\vec{X},t) = H_0^{inc}(\vec{X}) e^{-i\omega t + \vec{k}.\vec{X}}.$$

Let $(\mathcal{E},\mathcal{H})$ be the total electric and magnetic fields in the waveguide structure. Hence

$$\mathcal{E}(\vec{X},t) = \mathcal{E}^{inc}(\vec{X},t) + \mathcal{E}^{sca}(\vec{X},t),$$
$$\mathcal{H}(\vec{X},t) = \mathcal{H}^{inc}(\vec{X},t) + \mathcal{H}^{sca}(\vec{X},t),$$

where $\mathcal{E}^{sca}$ and $\mathcal{H}^{sca}$ are the scattered electric and magnetic fields, respectively. The vector fields $\mathcal{E}$ and $\mathcal{H}$ are the solutions of the following linear Maxwell system:

$$\begin{cases} \operatorname{curl} \mathcal{E}(\vec{X},t) = \mu(y)\, \partial_t \mathcal{H}(\vec{X},t), \\ \operatorname{curl} \mathcal{H}(\vec{X},t) = -\varepsilon(y)\, \partial_t \mathcal{E}(\vec{X},t). \end{cases}$$

Guided modes of the waveguide structure are particular solutions such that

$$\begin{cases} \mathcal{E}(x,y,z,t) = \Re\left(\mathbb{E}(x,y,z)\exp(-i\omega t)\right), \\ \mathcal{H}(x,y,z,t) = \Re\left(\mathbb{H}(x,y,z)\exp(-i\omega t)\right), \end{cases}$$

which gives that the electric field $\mathbb{E}(x,y,z)$ satisfies

$$\begin{cases} \operatorname{curl}\left(\dfrac{1}{\mu(y)}\operatorname{curl}\mathbb{E}\right) + \omega^2 \varepsilon(y)\mathbb{E} = 0 \quad \text{in } \mathbb{R}^3_+ \setminus P \times \mathbb{R}, \\ \operatorname{div}(\varepsilon(y)\mathbb{E}) = 0 \quad \text{in } \mathbb{R}^3_+ \setminus P \times \mathbb{R}, \\ \mathbb{E} \wedge e_y = 0 \quad \text{on } (G \cup P) \times \mathbb{R}. \end{cases} \tag{2.1}$$

The z-invariance of the microstrip line structure yields to a z-dependency of the form $e^{i\gamma z}$ for the field $\mathbb{E}(x,y,z)$, where γ is real, called the z-wave number:

$$\mathbb{E}(x,y,z) = e^{i\gamma z} E(x,y). \tag{2.2}$$

Hence, if $\varepsilon_1(y)$ is assumed to be constant, then the problem (2.1) may be reduced to a system of three two-dimensional Helmholtz scalar equations. We refer the reader to [1] for a proof.

LEMMA 2.1. *The components E_x, E_y, and E_z of the electric field $E(x,y)$ defined by* (2.2)*, where $\mathbb{E}$ is a solution to* (2.1)*, solve the following transmission boundary-value problems:*

$$\begin{cases} \Delta E_y + (\omega^2 \varepsilon(y)\mu(y) - \gamma^2) E_y = 0 & \text{in} \quad \mathcal{O}_1 \cup \mathcal{O}_2, \\ [\partial_y E_y] = 0 & \text{on} \quad L, \\ [\varepsilon E_y] = 0 & \text{on} \quad L \setminus P, \\ \partial_y E_y = 0 & \text{on} \quad G \cup P, \end{cases} \tag{2.3}$$

$$\begin{cases} \Delta E_x + (\omega^2\varepsilon(y)\mu(y) - \gamma^2)E_x = 0 & \text{in} \quad \mathcal{O}_1 \cup \mathcal{O}_2, \\ [E_x] = 0 & \text{on} \quad L, \\ \left[\dfrac{1}{\mu}\partial_y E_x\right] = \dfrac{1}{\mu_2}\left(1 - \dfrac{\varepsilon_2\mu_2}{\varepsilon_1(h)\mu_1}\right)\partial_x E_y^+ & \text{on} \quad L \setminus P, \\ E_x = 0 & \text{on} \quad G \cup P, \end{cases} \tag{2.4}$$

and

$$\begin{cases} \Delta E_z + (\omega^2\varepsilon(y)\mu(y) - \gamma^2)E_z = 0 & \text{in} \quad \mathcal{O}_1 \cup \mathcal{O}_2, \\ [E_z] = 0 & \text{on} \quad L, \\ \left[\dfrac{1}{\mu}\partial_y E_z\right] = \dfrac{i\gamma}{\mu_2}\left(1 - \dfrac{\varepsilon_2\mu_2}{\varepsilon_1(h)\mu_1}\right)E_y^+ & \text{on} \quad L \setminus P, \\ E_z = 0 & \text{on} \quad G \cup P. \end{cases} \tag{2.5}$$

Our aim in this work is to investigate the problem of finding $\gamma^2(\omega)$ such that at least one of the scalar Helmholtz equations (2.3)–(2.5) has a nontrivial solution subject to a radiation condition at infinity. This behavior at infinity will be made clear after (3.6).

We will consider a slightly more general problem. Throughout this paper, we assume that $\varepsilon_1(y)$ is a variable function in $]0, h[$. This would allow us to solve as well the general resonant problem in the acoustic case. We denote by Σ the set of these numbers. We remark that since (2.3) is independent of the two other Helmholtz equations, the set Σ is then the union of two families:

Family (a): the electric field $E(x, y) = (E_x, 0, E_z)$. This solution is called a longitudinal section electric mode. One of the components E_x or E_z is nontrivial and satisfies

$$\begin{cases} \Delta u + (\omega^2\varepsilon\mu - \gamma^2)u = 0 & \text{in} \quad \mathcal{O}_1 \cup \mathcal{O}_2, \\ [u] = 0 & \text{on} \quad L, \\ \left[\dfrac{1}{\mu}\partial_y u\right] = 0 & \text{on} \quad L \setminus P, \\ u = 0 & \text{on} \quad G \cup P. \end{cases} \tag{2.6}$$

Family (b): the electric field $E(x, y) = (E_x, E_y, E_z)$. This solution is called a longitudinal section magnetic mode. The component E_y is nontrivial and satisfies

$$\begin{cases} \Delta v + (\omega^2\varepsilon\mu - \gamma^2)v = 0 & \text{in} \quad \mathcal{O}_1 \cup \mathcal{O}_2, \\ [\partial_y v] = 0 & \text{on} \quad L, \\ [\varepsilon v] = 0 & \text{on} \quad L \setminus P, \\ \partial_y v = 0 & \text{on} \quad G \cup P. \end{cases} \tag{2.7}$$

Let $\Sigma_{\mathbf{a}}$ and $\Sigma_{\mathbf{b}}$ be the set of values of γ for fixed ω (or equivalently ω for fixed γ) such that (2.6), respectively (2.7), has a nontrivial solution. Then, we have $\Sigma = \Sigma_{\mathbf{a}} \cup \Sigma_{\mathbf{b}}$. The eigenfunctions associated with γ in Σ are called degenerate modes. If $\Sigma_{\mathbf{a}} \cap \Sigma_{\mathbf{b}} = \varnothing$, then E_x and E_z are uniquely determined for any $\gamma \in \Sigma_b$. Note that because the treatments of families (a) and (b) are quite different, we consider both of them in

detail. We recall the following definitions. We refer the reader to Appendix B for more details.

DEFINITION 2.2. *A complex number γ is called a resonance if and only if the system of Helmholtz equations* (2.3)–(2.5) *has a nontrivial solution.*

DEFINITION 2.3. *Let X and Y be two Banach spaces and $\mathcal{L}(X,Y)$ be the space of bounded linear operators acting from X to Y. We denote by 0_X (respectively, 0_Y) the null element of X (respectively, Y). Let $A:\mathbb{C}\to\mathcal{L}(X,Y)$ be an operator-valued function. The complex number Γ^* is a characteristic value of A if and only if the function $A(\Gamma)$ is holomorphic in a punctured neighborhood of Γ^*; there exists a function $x:\mathbb{C}\to X$ such that $x(\Gamma^*)\neq 0_X, \Gamma\mapsto x(\Gamma)$, and $\Gamma\mapsto A(\Gamma)x(\Gamma)$ are holomorphic in $\Gamma=\Gamma^*$, and $A(\Gamma^*)x(\Gamma^*)=0_Y$. The order of Γ^*, as a zero of $\Gamma\mapsto A(\Gamma)x(\Gamma)$, is called its multiplicity. The function $\Gamma\mapsto x(\Gamma)$ is a root function associated with Γ^*.*

DEFINITION 2.4. *Let D be an open connected domain in $\mathbb{C}$. The full multiplicity of the operator-valued function $\Gamma\mapsto A(\Gamma)$ in D, denoted by $\mathcal{M}(A,\partial D)$, is defined by*

$$\mathcal{M}(A,\partial D)=N(A,\partial D)-P(A,\partial D),$$

where $P(A,\partial D)$ (respectively, $N(A,\partial D)$) is the number of poles (respectively, characteristic values) of A in D, counted according to their multiplicity.

3. Integral representation formulae. We assume that $y\to\varepsilon_1(y)$ is a decreasing, positive, and piecewise $\mathcal{C}^1$ function. We introduce the following notation:

$$\begin{aligned}
&q(y)=\omega^2(\varepsilon_1(0)\mu_1-\varepsilon(y)\mu(y)),\\
&d^2(\omega)=\omega^2(\varepsilon_1(0)\mu_1-\varepsilon_2\mu_2)\geq 0,\\
&\widetilde{\varepsilon}(y)=\begin{cases}\varepsilon_1(h) & \text{in }]0,h[,\\ \varepsilon_2 & \text{in }]h,+\infty[.\end{cases}
\end{aligned}$$

Note that the function $q(y)$ is positive since $y\to\varepsilon_1(y)$ is a decreasing function and $d^2(\omega)$ is its minimum.

3.1. Family (a). In this subsection, we study the completeness of an associated one-dimensional eigenvalue problem. We derive an integral representation formula of solutions $u(x,y)$ to (2.6). Then we prove that the jump between the boundary value of $\frac{1}{\mu(y)}\partial_y u(x,y)$ on the two sides of the transmission line P is a characteristic function of an integral operator-valued function.

Let $g_a(y,\lambda)$ be defined by

$$\begin{cases}
\partial_{yy}g_a(y,\lambda)+(\lambda-q(y))g_a(y,\lambda)=0 \quad \text{in }]0,h[\cup]h,+\infty[,\\
[g_a(.,\lambda)]=0 \quad \text{on } y=h,\\
\left[\dfrac{1}{\mu}\partial_y g_a(.,\lambda)\right]=0 \quad \text{on } y=h,\\
g_a(0,\lambda)=0 \quad \text{and } \partial_y g_a(0,\lambda)=\sqrt{\lambda}.
\end{cases}\tag{3.1}$$

Setting $\phi_a(y,\lambda)$ the solution of the ODE,

$$\begin{cases}
\partial_{yy}\phi_a(y,\lambda)+(\lambda-q(y))\phi_a(y,\lambda)=0 \quad \text{in }]0,h[,\\
\phi_a(0,\lambda)=0 \quad \text{and } \partial_y\phi_a(0,\lambda)=\sqrt{\lambda},
\end{cases}\tag{3.2}$$

we then write

$$g_a(y,\lambda)=\begin{cases}\phi_a(y,\lambda) & \text{if } y\in]0,h[,\\ \phi_a(h,\lambda)\cos\Big[\sqrt{\lambda-d^2}(y-h)\Big]+\dfrac{\mu_2}{\mu_1}\dfrac{\partial_y\phi_a(h,\lambda)}{\sqrt{\lambda-d^2}}\sin\Big[\sqrt{\lambda-d^2}(y-h)\Big] & \\ \text{if } y\in]h,+\infty[.\end{cases}$$

For $\lambda\geq d^2$, $g_a(y,\lambda)$ is bounded. For $\lambda<d^2$, in view of the above expression of g_a, we impose the dispersion relation

$$\phi_a(h,\lambda)+\frac{\mu_2}{\mu_1}\frac{\partial_y\phi_a(h,\lambda)}{\sqrt{\lambda-d^2}}=0 \tag{3.3}$$

to make $g_a(y,\lambda)$ bounded in $\mathbb{R}^+$. According to [8], there will be a finite number of roots $\lambda_l^a(\omega)$ to (3.3) with associated solutions: $g_a(y,\lambda_l^a)$ for $l=1,2,\dots,m_a$. Moreover, the set of eigenfunctions $g_a(y,\lambda),\lambda\in]0,+\infty[$ is complete in $L^2(\mathbb{R}_+)$. When the magnetic permeabilities μ_1 and μ_2 are equal ($\mu_1=\mu_2$), Magnanini and Santosa [8] proved the completeness of the associated eigenvalue problem and rigorously derived an inverse transform formula. See also the work of Wilcox [13], [14], where the spectrum of the Pekeris operator is investigated. Here the following more general inverse transform formula will prove essential. We refer the reader to Appendix A for a proof.

LEMMA 3.1. *Let $f\in L^2(\mathbb{R}_+,\frac{dy}{\mu(y)})$. We have the inverse transform formula:*

$$\begin{aligned}f(x)=&\sum_{l=1}^{m_a}\frac{2\mu_1\sqrt{d^2-\lambda_l^a}\int_0^{+\infty}g_a(y,\lambda_l^a)f(y)\frac{dy}{\mu(y)}}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2+2\sqrt{d^2-\lambda_l^a}\int_0^h\phi_a(y,\lambda_l^a)^2dy}g_a(x,\lambda_l^a)\\ &+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}\int_0^{+\infty}g_a(y,\lambda)f(y)\frac{dy}{\mu(y)}}{(\lambda-d^2)\phi_a(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}g_a(x,\lambda)d\lambda.\end{aligned} \tag{3.4}$$

We now return to the Helmholtz equation (2.6). Let

$$U(x,\lambda)=\int_0^{+\infty}u(x,y)g_a(y,\lambda)\,\frac{dy}{\mu(y)}.$$

Multiplying (2.6) by $\frac{1}{\mu(y)}g_a(y,\lambda)$ and integrating with respect to the variable y over the interval $]0,+\infty[$, we obtain after some straightforward manipulations for $x\in\mathbb{R}$

$$\partial_{xx}U(x,\lambda)+(\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2)U(x,\lambda)=\phi_a(h,\lambda)\left[\frac{1}{\mu}\partial_y u\right](x,h)\chi(]-\alpha,\alpha[), \tag{3.5}$$

where $\chi(]-\alpha,\alpha[)$ denotes the characteristic function of the interval $]-\alpha,\alpha[$. The solution of (3.5), which is outgoing for $0\leq\lambda+\gamma^2<\omega^2\varepsilon_1(0)\mu_1$ and decays exponentially for $\lambda+\gamma^2>\omega^2\varepsilon_1(0)\mu_1$ as $|x|\to+\infty$, is readily given for $x\in\mathbb{R}$ by the following expression:

$$U(x,\lambda)=\phi_a(h,\lambda)\int_{-\alpha}^{\alpha}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}\left[\frac{1}{\mu}\partial_y u\right](\zeta,h)d\zeta. \tag{3.6}$$

By the inversion formula in Lemma 3.1, we have

$$\begin{aligned}u(x,y)=&\sum_{l=1}^{m_a}\frac{2\mu_1\sqrt{d^2-\lambda_l^a}U(x,\lambda_l^a)}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2+2\sqrt{d^2-\lambda_l^a}\int_0^h\phi_a(y,\lambda_l^a)^2dy}g_a(y,\lambda_l^a)\\ &+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}U(x,\lambda)}{(\lambda-d^2)\phi_a(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}g_a(y,\lambda)d\lambda\quad\forall\,(x,y)\in\mathbb{R}^2_+;\end{aligned}$$

hence, by (3.6) and by interchanging the order of integration, we obtain that the jump between the boundary values of $\frac{1}{\mu(y)}\partial_y u(x,y)$ on the two sides of the transmission line P solves the integral equation:

$$\begin{aligned}
&\int_{-\alpha}^{\alpha}\left[\sum_{l=1}^{m_a}\frac{\mu_1\sqrt{d^2-\lambda_l^a}\phi_a(h,\lambda_l^a)^2}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2+2\sqrt{d^2-\lambda_l^a}\int_0^h\phi_a(y,\lambda_l^a)^2dy}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^a-\gamma^2}}}{i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^a-\gamma^2}}\right.\\
&\left.+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\lambda-d^2)\phi_a(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}d\lambda\right]\\
&\times\left[\frac{1}{\mu}\partial_y u\right](\zeta,h)d\zeta\\
&=0
\end{aligned}$$

for all $x\in]-\alpha,\alpha[$. By the change of variables $X=\frac{x}{\alpha}$ and $X'=\frac{\zeta}{\alpha}$ we immediately obtain

$$\begin{aligned}
&\alpha\int_{-1}^{1}\left[\sum_{l=1}^{m_a}\frac{\mu_1\sqrt{d^2-\lambda_l^a}\phi_a(h,\lambda_l^a)^2}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2+2\sqrt{d^2-\lambda_l}\int_0^h\phi_a(y,\lambda_l^a)^2dy}\frac{e^{i\alpha|X'-X|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^a-\gamma^2}}}{i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^a-\gamma^2}}\right.\\
&\left.+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\lambda-d^2)\phi_a(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}\frac{e^{i\alpha|X'-X|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}d\lambda\right]\\
&\times\left[\frac{1}{\mu}\partial_y u\right](\alpha X',h)dX'\\
&=0
\end{aligned}\tag{3.7}$$

for all $X\in]-1,1[$.

Let ω be a nonnegative real, $0\le l_0\le m$, and $\Gamma=\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_{l_0}^a-\gamma^2}$ a complex value, where $\lambda_{l_0}^a(\omega)$ is a fixed root of the dispersion relation (3.3). We introduce the kernel

$$\begin{aligned}
a_\alpha(\Gamma;X,X')&=\frac{\frac{1}{\ln\alpha}\mu_1\sqrt{d^2-\lambda_{l_0}^a}\phi_a(h,\lambda_{l_0}^a)^2}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_{l_0}^a)^2+2\sqrt{d^2-\lambda_{l_0}^a}\int_0^h\phi(y,\lambda_{l_0}^a)^2dy}\frac{e^{i\alpha|X'-X|\Gamma}}{i\Gamma}\\
&+\sum_{l=1,l\neq l_0}^{m_a}\frac{\frac{1}{\ln\alpha}\mu_1\sqrt{d^2-\lambda_l^a}\phi_a(h,\lambda_l^a)^2}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2+2\sqrt{d^2-\lambda_l^a}\int_0^h\phi_a(y,\lambda_l^a)^2dy}\frac{e^{i\alpha|X'-X|\sqrt{\lambda_{l_0}-\lambda_l^a+\Gamma^2}}}{i\sqrt{\lambda_{l_0}^a-\lambda_l^a+\Gamma^2}}\\
&+\frac{1}{\pi\ln\alpha}\int_{d^2}^{+\infty}\frac{\mu_2\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\lambda-d^2)\phi_a(h,\lambda)^2+(\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}\frac{e^{i\alpha|X'-X|\sqrt{\lambda_{l_0}^a-\lambda+\Gamma^2}}}{2i\sqrt{\lambda_{l_0}^a-\lambda+\Gamma^2}}d\lambda
\end{aligned}$$

and $\mathcal{A}_\alpha(\Gamma)$ to be the integral operator defined by

$$\begin{aligned}
\mathcal{A}_\alpha(\Gamma):\quad &(H^{1/2})'(-1,1)\longrightarrow\widetilde{H}^{1/2}(-1,1),\\
&\psi(X)\longrightarrow\mathcal{A}_\alpha(\Gamma)\psi(X)=\int_{-1}^{1}a_\alpha(\Gamma;X,X')\psi(X')\,dX',
\end{aligned}$$

where $(H^{1/2})'(-1,1)$ is the L^2-dual of $H^{1/2}(-1,1)$ and $\widetilde{H}^{1/2}(-1,1)$ denotes the space of functions in $H^{1/2}(-1,1)$ such that their extensions by 0 on $]-\infty,-1[\cup]1,+\infty[$ are in $H^{1/2}(\mathbb{R})$. Identity (3.7) may alternatively be written in the form

$$\mathcal{A}_\alpha(\Gamma)\left[\frac{1}{\mu}\partial_y u\right](\alpha X) = 0 \quad \forall\, X \in\,]-1,1[.$$

It is therefore obvious that the function $X' \to [\frac{1}{\mu}\partial_y u](\alpha X', h)$ is then a characteristic function of the integral operator-valued function $\mathcal{A}_\alpha$. We will give a rigorous study of the integral operator-valued function $\Gamma \to \mathcal{A}_\alpha(\Gamma)$, when Γ is in a small complex neighborhood of 0.

3.2. Family (b). In this subsection we derive an integral representation formula for the solution $v(x,y)$ to the Helmholtz equation (2.7). We prove that the jump of $\varepsilon(y)v(x,y)$ across the transmission line P is a characteristic function of an integral operator-valued function. Let $g_b(y,\lambda)$ denote the solution to

$$\begin{cases} \partial_{yy} g_b(y,\lambda) + (\lambda - q(y)) g_b(y,\lambda) = 0 \quad \text{in }]0,h[\cup]h,+\infty[, \\ [\widetilde{\varepsilon}(.) g_b(.,\lambda)] = 0 \quad \text{on } y = h, \\ [\partial_y g_b(.,\lambda)] = 0 \quad \text{on } y = h, \\ g_b(0,\lambda) = 1 \text{ and } \partial_y g_b(0,\lambda) = 0. \end{cases} \tag{3.8}$$

We introduce $\phi_b(y,\lambda)$ as the solution of

$$\begin{cases} \partial_{yy}\phi_b(y,\lambda) + (\lambda - q(y))\phi_b(y,\lambda) = 0 \quad \text{in }]0,h[, \\ \phi_b(0,\lambda) = 1 \text{ and } \partial_y \phi_b(0,\lambda) = 0 \end{cases} \tag{3.9}$$

to get

$$g_b(y,\lambda) = \begin{cases} \phi_b(y,\lambda) \quad \text{if } y \in\,]0,h[, \\ \dfrac{\varepsilon_1(h)}{\varepsilon_2}\phi_b(h,\lambda)\cos\Big[\sqrt{\lambda - d^2}(y-h)\Big] + \dfrac{\partial_y\phi_b(h,\lambda)}{\sqrt{\lambda-d^2}}\sin\Big[\sqrt{\lambda-d^2}(y-h)\Big] \\ \quad \text{if } y \in\,]h,+\infty[. \end{cases}$$

For $\lambda \geq d^2$, $g_b(y,\lambda)$ is bounded. For $\lambda < d^2$, we should impose as before the condition

$$\phi_b(h,\lambda) + \frac{\varepsilon_2}{\varepsilon_1(h)}\frac{\partial_y\phi_b(h,\lambda)}{\sqrt{\lambda-d^2}} = 0 \tag{3.10}$$

to make ϕ_b bounded in $\mathbb{R}^+$. We now know that there is a finite number of roots $\lambda_l^b(\omega)$ to the dispersion relation (3.10) with associated solutions $g_b(y,\lambda_l^b)$ for $l = 1,2,\ldots,m_b$. Furthermore, the associated system of eigenfunctions $g_b(y,\lambda)$ for $\lambda \in]0,+\infty[$ is complete in $L^2(\mathbb{R}_+)$. We will need the following inverse transform.

LEMMA 3.2. *Let $f \in L^2(\mathbb{R}_+, \widetilde{\varepsilon}(y)dy)$. We have the inverse transform formula*

$$\begin{aligned} f(x) = \frac{1}{\varepsilon_2}\sum_{l=1}^{m_b} & \frac{2\sqrt{d^2-\lambda_l^b}\int_0^{+\infty} g_b(y,\lambda_l^b) f(y)\,\widetilde{\varepsilon}(y)dy}{\frac{\varepsilon_2}{\varepsilon_1(h)}\phi_b(h,\lambda_l^a)^2 + 2\sqrt{d^2-\lambda_l^b}\int_0^h \phi_b(y,\lambda_l^b)^2 dy} g_b(x,\lambda_l^b) \\ & + \frac{1}{\pi}\frac{\varepsilon_2}{\varepsilon_1^2(h)}\int_{d^2}^{+\infty} \frac{\sqrt{\lambda-d^2}\int_0^{+\infty} g_b(y,\lambda) f(y)\,\widetilde{\varepsilon}(y)dy}{(\lambda-d^2)\phi_b(h,\lambda)^2 + (\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b(h,\lambda)^2} g_b(x,\lambda)d\lambda. \end{aligned} \tag{3.11}$$

Let us introduce

$$V(x,\lambda)=\int_0^{+\infty} v(x,y)g_b(y,\lambda)\,\widetilde{\varepsilon}(y)dy.$$

As for establishing identity (3.5), multiplying (2.7) by $\widetilde{\varepsilon}(y)g_b(y,\lambda)$ and integrating in the variable y over the interval $]0,+\infty[$, we arrive at

$$\partial_{xx}V(x,\lambda)+(\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2)V(x,\lambda)=\partial_y\phi_b(h,\lambda)[\varepsilon v](x,h)\chi(]-\alpha,\alpha[) \tag{3.12}$$

for $x\in\mathbb{R}$. The solution of the ODE (3.12), which is outgoing for $0\le\lambda+\gamma^2<\omega^2\varepsilon_1(0)\mu_1$ and decays exponentially for $\lambda+\gamma^2>\omega^2\varepsilon_1(0)\mu_1$ as $|x|\to+\infty$, is given by

$$V(x,\lambda)=\partial_y\phi_b(h,\lambda)\int_{-\alpha}^{\alpha}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}[\varepsilon v](\zeta,h)d\zeta\quad\forall\,x\in\mathbb{R}.$$

Hence, by Lemma 3.2 and by interchanging the order of integration, we obtain from the Neumann boundary condition that is imposed on the transmission line P, $\partial_y v(x,h)=0$, for any $x\in\,]-\alpha,\alpha[$, that the following integral equation on P holds:

$$\int_{-\alpha}^{\alpha}\left[\sum_{l=1}^{m_b}\frac{\frac{1}{\varepsilon_2}\sqrt{d^2-\lambda_l^b}\partial_y\phi_b(h,\lambda_l^b)^2}{\frac{\varepsilon_2}{\varepsilon_1(h)}\phi_b(h,\lambda_l^b)^2+\sqrt{d^2-\lambda_l^b}\int_0^h\phi_b(y,\lambda_l^b)^2dy}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^b-\gamma^2}}}{i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_l^b-\gamma^2}}\right.$$
$$\left.+\frac{1}{\pi}\int_{d^2}^{+\infty}\frac{\frac{\varepsilon_2}{\varepsilon_1^2(h)}\sqrt{\lambda-d^2}\partial_y\phi_b(h,\lambda)^2}{(\lambda-d^2)\phi_b(h,\lambda)^2+(\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b(h,\lambda)^2}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}d\lambda\right]$$
$$\times[\varepsilon v](\zeta,h)d\zeta=0$$

for all $x\in\,]-\alpha,\alpha[$. By the change of variables $X=\frac{x}{\alpha}$ and $X'=\frac{\zeta}{\alpha}$ the last integral equation becomes

$$\mathcal{B}_\alpha(\Gamma)\left([\varepsilon v](\alpha.,h)\right)(X)=0\quad\forall\,X\in\,]-1,1[,$$

where the integral operator-valued function $\mathcal{B}_\alpha(\Gamma)$ is defined by

$$\mathcal{B}_\alpha(\Gamma):\widetilde{H}^{1/2}(-1,1)\longrightarrow H^{-1/2}(-1,1),$$
$$\psi(X)\longrightarrow\mathcal{B}_\alpha(\Gamma)\psi(X)=\int_{-1}^{1}b_\alpha(\Gamma;X,X')\psi(X')dX'.$$

Here $\Gamma=\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda_{l_0}^b-\gamma^2}$, where ω is a positive real, $0\le l_0\le m$, $\lambda_{l_0}^b(\omega)$ is a fixed root of (3.10), and the the kernel b_α is given by

$$b_\alpha(\Gamma;X,X')=\frac{\frac{\alpha^2}{\varepsilon_2}\sqrt{d^2-\lambda_{l_0}^b}\partial_y\phi_b(h,\lambda_{l_0}^b)^2}{\frac{\varepsilon_2}{\varepsilon_1(h)}\phi_b(h,\lambda_{l_0}^b)^2+\sqrt{d^2-\lambda_{l_0}^b}\int_0^h\phi_b(y,\lambda_{l_0}^b)^2dy}\frac{e^{i\alpha|X'-X|\Gamma}}{i\Gamma}$$
$$+\sum_{l=1,l\neq l_0}^{m_b}\frac{\frac{\alpha^2}{\varepsilon_2}\sqrt{d^2-\lambda_l^b}\partial_y\phi_b(h,\lambda_l^b)^2}{\frac{\varepsilon_2}{\varepsilon_1(h)}\phi_b(h,\lambda_l^b)^2+\sqrt{d^2-\lambda_l^b}\int_0^h\phi_b(y,\lambda_l^b)^2dy}\frac{e^{i\alpha|X'-X|\sqrt{\lambda_{l_0}^b-\lambda_l^b+\Gamma^2}}}{i\sqrt{\lambda_{l_0}^b-\lambda_l^b+\Gamma^2}}$$
$$+\frac{\alpha^2}{\pi}\int_{d^2}^{+\infty}\frac{\frac{\varepsilon_2}{\varepsilon_1^2(h)}\sqrt{\lambda-d^2}\partial_y\phi_b(h,\lambda)^2}{(\lambda-d^2)\phi_b(h,\lambda)^2+(\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b(h,\lambda)^2}\frac{e^{i|x-\zeta|\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}}{2i\sqrt{\omega^2\varepsilon_1(0)\mu_1-\lambda-\gamma^2}}d\lambda$$

for all $X,X'\in]-1,1[$.

4. Characteristic problem and asymptotic expansions. In this section, we first prove that the resonances are exactly the characteristic values of the operator-valued functions $\mathcal{A}_\alpha(\Gamma)$ and $\mathcal{B}_\alpha(\Gamma)$. Next, we derive an asymptotic formula for these functions. By the generalized Rouché theorem [2] (see Theorem B.4 in Appendix B for a precise statement of this theorem), we derive the leading order terms in the asymptotic expansions of the resonances and their associated guided modes.

4.1. The operator-valued function $\mathcal{A}_\alpha(\Gamma)$. Let ω be a fixed positive real, $0 \leq l_0 \leq m_a$, and $\Gamma = \sqrt{\omega^2\varepsilon_1(0)\mu_1 - \lambda_{l_0}^a - \gamma^2}$ a complex variable, where $\lambda_{l_0}^a(\omega)$ is a root of the dispersion relation (3.3) that is supposed to be different from $d^2(\omega)$. Then 0 is a resonance of the reference waveguide. In this section, we prove that in a fixed neighborhood of 0 lying in the set

$$\mathcal{V}_0 = \left\{ \Gamma \in \mathbb{C}, |\Gamma| < \min_{\lambda \in \{(\lambda_l^a)_{0\leq l\leq m_a, l\neq l_0}, d^2\}} |\lambda_{l_0}^a - \lambda| \right\},$$

there exists a unique resonance of the microstrip line for small values of α, defined as the unique characteristic value of the operator-valued function $\Gamma \mapsto \mathcal{A}_\alpha(\Gamma)$ in $\mathcal{V}_0$. The following results hold.

THEOREM 4.1. *Let $D_{\delta_0}(0) = \{\Gamma \in \mathbb{C}, |\Gamma| < \delta_0\}$, for $\delta_0 > 0$, be a complex neighborhood around 0 in $\mathcal{V}_0$. δ_0 is chosen such that 0 is the unique pole of $\mathcal{A}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$. Then there exists a constant $\alpha_0 > 0$ such that, for $|\alpha| \leq \alpha_0$, we have the following:*

(a) *The operator-valued function $\mathcal{A}_\alpha(\Gamma)$ is finitely meromorphic and of Fredholm type at every point of the domain $D_{\delta_0}(0)$.*

(b) *The following asymptotic formula holds:*

$$\mathcal{A}_\alpha(\Gamma) = A_0^\alpha + \frac{1}{\ln\alpha}\Big(A_1(\Gamma) + \frac{A_{-1}}{\Gamma}\Big) + O(\alpha), \tag{4.1}$$

where $O(\alpha)$ is uniform in the set $\big\{\phi \in (H^{1/2})'(-1,1), ||\phi||_{(H^{1/2})'(-1,1)} \leq 1\big\}$ and for $\Gamma \in \partial D_{\delta_0}(0) = \{\Gamma \in \mathbb{C}, |\Gamma| = \delta_0\}$. The operators $A_0^\alpha, A_1(\Gamma)$, and A_{-1} are defined by

$$\begin{aligned}
A_0^\alpha &: (H^{1/2})'(-1,1) \longrightarrow \widetilde{H}^{1/2}(-1,1),\\
A_0^\alpha\phi(X) &= -\frac{a_0\mu_2}{\pi\ln\alpha}\left(\frac{\mu_1}{\mu_2}\right)^2 \int_{-1}^{1} \ln(\alpha|X'-X|)\phi(X')dX',\\
A_1(\Gamma) &: (H^{1/2})'(-1,1) \longrightarrow \widetilde{H}^{1/2}(-1,1),\\
A_1(\Gamma)\phi(X) &= C(\Gamma)\int_{-1}^{1}\phi(X')dX',\\
A_{-1} &: (H^{1/2})'(-1,1) \longrightarrow \widetilde{H}^{1/2}(-1,1),\\
A_{-1}\phi(X) &= 2\mu_1 c_{l_0}^a \int_{-1}^{1}\phi(X')dX',
\end{aligned}$$

where $\Gamma \to C(\Gamma)$ is a holomorphic function in the disc $D_{\delta_0}(0)$,

$$c_l^a = \frac{1}{i}\frac{\sqrt{d^2-\lambda_l^a}\,\phi_a(h,\lambda_l^a)^2}{\frac{\mu_1}{\mu_2}\phi_a(h,\lambda_l^a)^2 + 2\sqrt{d^2-\lambda_l^a}\int_0^h \phi(y,\lambda_l^a)^2 dy}, \quad 1 \leq l \leq m_a, \tag{4.2}$$

and

(4.3)

$$a_0 = a_0(\eta) = (1-\eta)\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k} C_k^p(-2)^p \frac{C_{2(p+1)}^{(p+1)}}{2^{2(p+1)}}\right)\eta^k \text{ for } \eta = \frac{(\frac{\mu_1}{\mu_2})^2 - 1}{(\frac{\mu_1}{\mu_2})^2 + 1}.$$

In order to prove this theorem it is convenient to first establish two technical auxiliary results. These results are stated in the following lemmas.

LEMMA 4.2. *For every $y \in [0,h]$ we have*

$$\phi_a(y,\lambda) = \sin(\sqrt{\lambda}y) - \frac{\cos(\sqrt{\lambda}y)}{2\sqrt{\lambda}}\int_0^y q(\tau)d\tau + O\left(\frac{1}{\lambda}\right), \tag{4.4}$$

$$\partial_y\phi_a(y,\lambda) = \sqrt{\lambda}\cos(\sqrt{\lambda}y) + \frac{1}{2}\sin(\sqrt{\lambda}y)\int_0^y q(\tau)d\tau + O\left(\frac{1}{\sqrt{\lambda}}\right), \tag{4.5}$$

where $O(\frac{1}{\lambda})$ and $O(\frac{1}{\sqrt{\lambda}})$ are uniform in $y \in [0,h]$.

Proof. Let $y \in]0,h]$. Multiplying the ODE (3.2) by $\sin\sqrt{\lambda}(y-\tau)$ and integrating by parts over $]0,y[$ with respect to the variable τ, we obtain that

$$\int_0^y q(\tau)\sin(\sqrt{\lambda}(y-\tau))\phi_a(\tau,\lambda)d\tau + \sqrt{\lambda}(\sin(\sqrt{\lambda}y) - \phi_a(y,\lambda)) = 0.$$

Therefore

$$\phi_a(y,\lambda) = \sin(\sqrt{\lambda}y) + \frac{1}{\sqrt{\lambda}}\int_0^y q(\tau)\sin(\sqrt{\lambda}(y-\tau))\phi_a(\tau,\lambda)d\tau. \tag{4.6}$$

Let $\theta(\lambda) = \max 0 \le y \le h|\phi_a(y,\lambda)|$. Since $q(\tau) \ge 0$, for $\tau \in (0,h)$, it immediately follows from the last equation that

$$\theta(\lambda) \le 1 + \frac{\theta(\lambda)}{\sqrt{\lambda}}\int_0^h q(\tau)d\tau,$$

which gives that

$$\theta(\lambda) \le \frac{1}{1 - \frac{1}{\sqrt{\lambda}}\int_0^h q(\tau)d\tau} \le \frac{1}{2} \quad \text{as } \lambda \to +\infty,$$

and so

$$\phi_a(y,\lambda) = \sin(\sqrt{\lambda}y) + O\left(\frac{1}{\sqrt{\lambda}}\right),$$

where $O(\frac{1}{\sqrt{\lambda}})$ is uniform in $y \in [0,h]$. Substituting now the last expansion into (4.6) and using the piecewise differentiability of the function $\varepsilon_1(\tau)$, we get

$$\phi_a(y,\lambda) = \sin(\sqrt{\lambda}y) - \frac{\cos(\sqrt{\lambda}y)}{2\sqrt{\lambda}}\int_0^y q(\tau)d\tau + O\left(\frac{1}{\lambda}\right).$$

Multiplying the ODE (3.2) by $\cos(\sqrt{\lambda}(y-\tau))$ and integrating by parts over $]0,h[$, we find that

$$\partial_y\phi_a(y,\lambda) = \sqrt{\lambda}\cos\sqrt{\lambda}y + \frac{1}{\sqrt{\lambda}}\int_0^y q(\tau)\cos(\sqrt{\lambda}(y-\tau))\phi_a(\tau,\lambda)d\tau. \tag{4.7}$$

Therefore, substituting (4.4) into (4.7) and using one more time the piecewise differentiability of $\varepsilon_1(\tau)$ leads to the promised result. □

Now, multiplying (3.2) by $\partial_y\phi_a(y,\lambda)$ and integrating by parts over $]0,h[$, we obtain that

$$\partial_y\phi_a^2(h,\lambda)+\lambda\phi_a^2(h,\lambda)=\lambda+2\int_0^h q(y)\phi_a(y,\lambda)\partial_y\phi_a(y,\lambda)dy.$$

As a consequence, we calculate

$$\begin{aligned}\partial_y\phi_a^2(h,\lambda)+\left(\frac{\mu_1}{\mu_2}\right)^2(\lambda-d^2)\phi_a^2(h,\lambda)&=\lambda\left[1+\left(\left(\frac{\mu_1}{\mu_2}\right)^2-1\right)\phi_a^2(h,\lambda)\right]\\&\quad+2\int_0^h q(y)\phi_a(y,\lambda)\partial_y\phi_a(y,\lambda)dy-\left(\frac{\mu_1}{\mu_2}\right)^2d^2\phi_a^2(h,\lambda).\end{aligned}$$

Since $y\to q(y)$ is $\mathcal{C}^1$-piecewise, the function of λ given by $\displaystyle\int_0^h q(y)\phi_a(y,\lambda)\partial_y\phi_a(y,\lambda)dy$ is $O(1)$ as $\lambda\to+\infty$. A direct application of Lemma 4.2 yields

$$\frac{\phi_a^2(h,\lambda)}{(\frac{\mu_1}{\mu_2})^2(\lambda-d^2)\phi_a(h,\lambda)^2+\partial_y\phi_a(h,\lambda)^2}=\frac{\phi_a^2(h,\lambda)}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\phi_a^2(h,\lambda)]}+R_{2,a}(\lambda),$$

where

(4.8)

$$\begin{aligned}R_{2,a}(\lambda)&=\phi_a^2(h,\lambda)\frac{-2\int_0^h q(y)\phi_a(y,\lambda)\partial_y\phi_a(y,\lambda)dy+(\frac{\mu_1}{\mu_2})^2d^2\phi_a^2(h,\lambda)}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\phi_a^2(h,\lambda)](({\frac{\mu_1}{\mu_2}})^2(\lambda-d^2)\phi_a(h,\lambda)^2+\partial_y\phi_a(h,\lambda)^2)}\\&=O\left(\frac{1}{\lambda^2}\right)\quad\text{as }\lambda\to+\infty.\end{aligned}$$

From Lemma 4.2 it also follows that

$$\frac{\phi_a^2(h,\lambda)}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\phi_a^2(h,\lambda)]}=\frac{\sin^2(h\sqrt{\lambda})}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})]}+R_{3,a}(\lambda),$$

where

(4.9)

$$\begin{aligned}R_{3,a}(\lambda)&=\frac{(1-(\frac{\mu_1}{\mu_2})^2)\phi_a^2(h,\lambda)(\phi_a^2(h,\lambda)-\sin^2(h\sqrt{\lambda}))}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})][1+((\frac{\mu_1}{\mu_2})^2-1)\phi_a^2(h,\lambda)]}\\&\quad+\frac{\phi_a^2(h,\lambda)-\sin^2(h\sqrt{\lambda})}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})]}\\&=O\left(\frac{1}{\lambda^{3/2}}\right)\quad\text{as }\lambda\to+\infty.\end{aligned}$$

Combining identities (4.8) and (4.9), we conclude that

$$\begin{aligned}&\frac{\sqrt{\lambda-d^2}\phi_a^2(h,\lambda)}{(\frac{\mu_1}{\mu_2})^2(\lambda-d^2)\phi_a(h,\lambda)^2+\partial_y\phi_a(h,\lambda)^2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}\\&=\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}\frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\lambda}+R_a^\alpha(\lambda,\Gamma,X'-X),\end{aligned}$$

where

$$R_a^\alpha(\lambda,\Gamma,X'-X)=R_{1,a}^\alpha(\lambda,\Gamma,X'-X)\frac{\sin^2(h\sqrt{\lambda})}{\lambda[1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})]}$$
$$+\left(R_{2,a}(\lambda)+R_{3,a}(\lambda)\right)e^{-\alpha|X'-X|\sqrt{\lambda}}+R_{1,a}^\alpha(\lambda,\Gamma,X'-X)\left(R_{2,a}(\lambda)+R_{3,a}(\lambda)\right).$$

Here the remainder $R_{1,a}^\alpha$ is given by

$$\begin{aligned}R_{1,a}^\alpha(\lambda,\Gamma,X'-X) &= \frac{(\lambda_{l_0}^a+\Gamma^2-d^2)e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}\Big(\sqrt{\lambda-d^2}+\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}\Big)}\\ &+ e^{-\alpha|X'-X|\sqrt{\lambda}}\Big(e^{\alpha|X'-X|\frac{\lambda_{l_0}^a+\Gamma^2}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}+\sqrt{\lambda}}}-1\Big).\end{aligned}\tag{4.10}$$

Moreover, $R_a^\alpha(\lambda,\Gamma,X'-X)=O(\frac{1}{\lambda^{3/2}})$ as $\lambda\to+\infty$, where $O(\frac{1}{\lambda^{3/2}})$ is uniform in $\alpha\in D_{\alpha_0}(0)$, $\Gamma\in D_{\delta_0}(0)$, and $(X-X')\in[-2,2]$. On the other hand, we have $R_a^0(\lambda,X'-X)=R_a^0(\lambda,\Gamma)$ and $R_a^\alpha(\lambda,\Gamma,X'-X)-R_a^0(\lambda,\Gamma)=O(\frac{1}{\lambda})$. Consequently, the following estimate holds:

$$\int_{d^2}^{+\infty}\frac{\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\frac{\mu_1}{\mu_2})^2(\lambda-d^2)\phi_a(h,\lambda)^2+\partial_y\phi_a(h,\lambda)^2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}d\lambda\tag{4.11}$$
$$=\int_{d^2}^{+\infty}\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}\frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\lambda}d\lambda+\int_{d^2}^{+\infty}R_a^0(\lambda,\Gamma)d\lambda+O(\alpha\ln\alpha),$$

where the remainder $O(\alpha\ln\alpha)$ is holomorphic in the disc $D_{\delta_0}(0)$ and uniform in $(X'-X)\in[-2,2]$.

Remark 4.1. Following the lines of the work of Magnanini and Santosa [8] that is based on the Levitan–Levinson method as described in [3], it is possible to derive an expression for the Green function $H(X,X',Y,Y')$ of the following transmission problem:

$$\begin{cases}\Delta_{X,Y}H(X,X',Y,Y')=\delta(X-X')\delta(Y-Y') & \text{in } O_1\cup O_2,\\ [\mu H]=0 \quad \text{on } L,\\ [\partial_y H]=0 \quad \text{on } L,\\ H=0 \quad \text{on } G.\end{cases}$$

It is quite easy to see from the previous calculations that $H(\alpha X,\alpha X',h^-,h^-)$ is in fact given by

$$H(\alpha X,\alpha X',h^-,h^-)=-\frac{1}{2\pi}\int_0^{+\infty}\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}\frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\lambda}d\lambda.$$

We should now rigorously derive an asymptotic expansion of $H(\alpha X,\alpha X',h^-,h^-)$ as α approaches 0. To do so, we introduce the parameter

$$\eta=\frac{(\frac{\mu_1}{\mu_2})^2-1}{(\frac{\mu_1}{\mu_2})^2+1}$$

to write

$$\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}=\frac{(1-\eta)\sin^2(h\sqrt{\lambda})}{1+\eta\cos(2h\sqrt{\lambda})}$$

and use the following result.

LEMMA 4.3. *Let the function F_η be defined by*

$$F_\eta(X)=\frac{1}{2\pi}\int_0^{+\infty}\frac{\sin^2(h\sqrt{\lambda})}{\cos^2 h\sqrt{\lambda}+\frac{1+\eta}{1-\eta}\sin^2(h\sqrt{\lambda})}\frac{e^{-\alpha X\sqrt{\lambda}}}{\lambda}d\lambda \quad \textit{for } X>0.$$

Under the assumption that $|\eta|<1$ we have

$$F_\eta(X)=-\frac{a_0}{2\pi}\ln\left(\frac{X^2}{X^2+4h^2}\right)+\frac{1}{\pi(1-\eta)}\sum_{k=1}^{+\infty}\left(\sum_{p=1}^{k}C_k^p(-2)^p\sum_{q=1}^{p+1}w_q^{p+1}\ln\left(\frac{X^2}{h^2}+4q^2\right)\right)\eta^k.$$

Furthermore, when X approaches 0^+, we have

$$F_\eta(X)=-\frac{a_0}{\pi}\ln X+a_1+\sum_{n=1}^{+\infty}a_{2n}X^{2n},$$

where

$$\begin{cases}
a_0(\eta)=(1-\eta)\displaystyle\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k}C_k^p(-2)^p w_0^{p+1}\right)\eta^k,\\
a_1(\eta)=\dfrac{\ln h(1-\eta)}{\pi}\displaystyle\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k}C_k^p(-2)^p w_0^{p+1}\right)\eta^k\\
\qquad+\dfrac{1-\eta}{\pi}\displaystyle\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k}C_k^p(-2)^p\left(\sum_{q=1}^{p+1}w_q^{p+1}\ln 4q^2\right)-d_p\right)\eta^k,\\
a_{2n}(\eta)=\dfrac{1-\eta}{\pi}\displaystyle\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k}C_k^p(-2)^p\sum_{q=1}^{p+1}\frac{w_q^{p+1}}{(2qh)^{2n}}\right)\eta^k, \quad 1\le n,\\
w_0^k=\dfrac{C_{2k}^k}{2^{2k}}, \quad 1\le k,\\
w_p^k=\dfrac{C_{2k}^{k+p}}{2^{2k}p}, \quad 1\le p\le k.
\end{cases}$$

Proof. Since $|\eta|<1$, by using the trigonometric identity $\cos(2h\sqrt{\lambda})=-2\sin^2(h\sqrt{\lambda})+1$, and after some easy manipulations, we obtain the expansion

$$F_\eta(X)=\frac{1-\eta}{\pi}\sum_{k=0}^{+\infty}\left(\sum_{p=0}^{k}C_k^p(-2)^p D_p(X)\right)\eta^k,$$

where

$$D_p(X)=\frac{1}{2}\int_0^{+\infty}\sin^{2(p+1)}(h\sqrt{\lambda})e^{-X\sqrt{\lambda}}\frac{d\lambda}{\lambda}.$$

By applying the substitution $h^2\lambda = \nu^2$ we readily get

$$D_p(X) = \int_0^{+\infty} \sin^{2(p+1)}(\nu) e^{-\nu \frac{X}{h}} \frac{d\nu}{\nu}$$

for $X > 0$, and so

$$\partial_X D_p(X) = -\frac{1}{h} \int_0^{+\infty} \sin^{2(p+1)}(\nu) e^{-\nu \frac{X}{h}} d\nu \quad \forall\, X > 0.$$

Let us now introduce

$$H_p(X) = \int_0^{+\infty} \sin^{2p}(\nu) e^{-\nu X} d\nu.$$

Straightforward integrations by parts yield

$$H_p(X) = \frac{2p(2p-1)}{X^2 + 4p^2} H_{p-1}(X), \quad p \geq 1, \quad H_0(X) = \frac{1}{X},$$

and consequently

$$H_p(X) = \frac{2p!}{X \prod_{q=1}^{p} (X^2 + 4q^2)}, \quad p \geq 1,$$

from which it immediately follows that

$$\partial_X D_p(X) = -\frac{1}{h} H_{p+1}\left(\frac{X}{h}\right), \quad p \geq 0.$$

Thus

$$D_p(X) = -w_0^{p+1} \ln\left(\frac{X}{h}\right) + \sum_{q=1}^{p+1} w_q^{p+1} \ln\left(\frac{X^2}{h^2} + 4q^2\right) + d_p, \quad p \geq 0,$$

where

$$d_p = \int_0^{+\infty} \sin^{2(p+1)}(\nu) e^{-\nu} \frac{d\nu}{\nu} - \sum_{q=1}^{p+1} w_q^{p+1} \ln(1 + 4q^2).$$

Based on the first identity stated at the beginning of the proof it is now quite easy to obtain the desired result. □

Remark 4.2. By Remark 4.1 and the latter lemma, we easily verify that in the particular case $\mu_1 = \mu_2$ (i.e., $\eta = 0$) we have

$$\begin{aligned} H(X, 0, h^-, h^-) = -\frac{1}{2\pi} \int_0^{+\infty} \sin^2(h\sqrt{\lambda}) \frac{e^{-X\sqrt{\lambda}}}{\lambda} d\lambda = -F_0(X) \\ = \frac{1}{4\pi} \ln\left(\frac{X^2}{X^2 + 4h^2}\right), \end{aligned}$$

which is in accordance with the following well-known expression of H,

$$H(X, X', Y, Y') = \frac{1}{4\pi} \ln\left(\frac{(X - X')^2 + (Y - Y')^2}{(X - X')^2 + (Y + Y')^2}\right).$$

We are now ready to proceed with the following proof.

Proof of Theorem 4.1. We start with deriving an asymptotic formula for $a_\alpha(\Gamma; X, X')$ when α approaches 0. With the definition of c_l^a we rewrite

$$a_\alpha(\Gamma; X, X') = \frac{2\mu_1 c_{l_0}^a}{\ln\alpha}\frac{e^{i\alpha|X'-X|\Gamma}}{\Gamma} + \frac{2\mu_1}{\ln\alpha}\sum_{l=1,l\neq l_0}^{m_a} c_l^a \frac{e^{i\alpha|X'-X|\sqrt{\lambda_{l_0}^a-\lambda_l^a+\Gamma^2}}}{\sqrt{\lambda_{l_0}^a-\lambda_l^a+\Gamma^2}}$$
$$- \frac{\mu_2}{2\pi\ln\alpha}\int_{d^2}^{+\infty} \frac{\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\lambda-d^2)\phi_a(h,\lambda)^2 + (\frac{\mu_2}{\mu_1})^2\partial_y\phi_a(h,\lambda)^2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}d\lambda.$$

Note that the first term in the expression of $a_\alpha(\Gamma; X, X')$ is holomorphic in $\alpha \in D_{\alpha_0}(0)$. Therefore, we only need to handle the last two terms. For the estimation of the second term we use that

$$\frac{\sqrt{\lambda-d^2}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}} = e^{-\alpha|X'-X|\sqrt{\lambda}} + R_{1,a}^\alpha(\lambda,\Gamma,X'-X),$$

where $R_{1,a}^\alpha(\lambda,\Gamma,X'-X)$ is defined by (4.10) and satisfies the estimate

$$R_{1,a}^\alpha(\lambda,\Gamma,X'-X) = O\left(\frac{1}{\sqrt{\lambda}}\right) \tag{4.12}$$

as $\lambda \to +\infty$. The remainder $O(\frac{1}{\sqrt{\lambda}})$ is uniform in $\alpha \in D_{\alpha_0}(0)$, $\Gamma \in D_{\delta_0}(0)$, and $(X-X') \in [-2,2]$. The third term is now easy to estimate. From Lemmas 4.2 and 4.3 we know that

(4.13)
$$-\frac{\mu_2}{2\pi\ln\alpha}\int_{d^2}^{+\infty} \frac{\sqrt{\lambda-d^2}\phi_a(h,\lambda)^2}{(\frac{\mu_1}{\mu_2})^2(\lambda-d^2)\phi_a(h,\lambda)^2 + \partial_y\phi_a(h,\lambda)^2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^a-\Gamma^2}}d\lambda$$
$$= -\frac{a_0\mu_2}{\pi\ln\alpha}\ln(\alpha|X'-X|)$$
$$+ \frac{1}{\ln\alpha}\left(-\mu_2 a_1 + \frac{\mu_2}{2\pi}\int_0^{d^2}\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}\frac{d\lambda}{\lambda} - \frac{\mu_2}{2\pi}\int_{d^2}^{+\infty} R_a^0(\lambda,\Gamma)d\lambda\right)$$
$$+ O(\alpha),$$

where $O(\alpha)$ is holomorphic in $D_{\delta_0}(0)$ and uniform in $(X'-X) \in [-2,2]$. Upon insertion of the last expansion into the expression of $a_\alpha(\Gamma; X, X')$ we finally obtain the asymptotic formula

$$a_\alpha(\Gamma; X, X') = -\frac{a_0\mu_2}{\pi\ln\alpha}\left(\frac{\mu_1}{\mu_2}\right)^2\ln(\alpha|X'-X|) + \frac{1}{\ln\alpha}\left(\frac{2\mu_1 c_{l_0}^a}{\Gamma} + C(\Gamma)\right) + O(\alpha),$$

where

$$C(\Gamma) = \left(\frac{\mu_1}{\mu_2}\right)^2\left[-\mu_2 a_1 + \frac{\mu_2}{2\pi}\int_0^{d^2}\frac{\sin^2(h\sqrt{\lambda})}{1+((\frac{\mu_1}{\mu_2})^2-1)\sin^2(h\sqrt{\lambda})}\frac{d\lambda}{\lambda}\right.$$
$$\left. - \frac{\mu_2}{2\pi}\int_{d^2}^{+\infty} R_a^0(\lambda,\Gamma)d\lambda\right] + \sum_{l=1,l\neq l_0}^{m_a}\frac{2\mu_1 c_l^a}{\sqrt{\lambda_{l_0}^a-\lambda_l^a+\Gamma^2}},$$

and $O(\alpha)$ is holomorphic in $\Gamma \in D_{\delta_0}(0)$ and uniform in $(X' - X) \in [-2, 2]$. This completes the proof of the second part of Theorem 4.1.

By construction, we know that $\Gamma \to \mathcal{A}_\alpha(\Gamma)$ is a meromorphic operator-valued function in $D_{\delta_0}(0)$ and has 0 as a unique pole. Moreover, for every $\Gamma \in \overline{D_{\delta_0}(0)}/\{0\}$, $\mathcal{A}_\alpha(\Gamma)$ is an invertible operator. From the asymptotic expansion (4.1), it immediately follows that $\mathcal{A}_\alpha(\Gamma)$ is a finitely meromorphic operator that is of Fredholm type at $\Gamma = 0$ for small values of α. Then, it is in all the domain $D_{\delta_0}(0)$. □

We now study the existence and the distribution of the characteristic values of the operator-valued function $\mathcal{A}_\alpha(\Gamma)$.

The following theorem asserts that there exits a unique resonance Γ_α lying in a small neighborhood of 0.

THEOREM 4.4. *There exists a constant $\alpha_0 > 0$ such that for $|\alpha| < \alpha_0$ we have*

$$\mathcal{M}(\mathcal{A}_\alpha(\Gamma), \partial D_{\delta_0}(0)) = 0.$$

Furthermore, there exists a unique characteristic value Γ_α of the operator-valued function $\Gamma \mapsto \mathcal{A}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$.

Proof. We begin the proof by establishing an explicit formula for $(A_0^\alpha)^{-1}$. Let $\phi \in (H^{1/2})'(]-1,1[)$ and $\psi \in \widetilde{H}^{1/2}(]-1,1[)$ be such that $A_0^\alpha \phi = \psi$, or equivalently

$$\big(1/\phi\big) + \frac{1}{\ln \alpha} \mathcal{L}_0 \phi(X) = -\frac{\pi}{\mu_2 a_0} \left(\frac{\mu_2}{\mu_1}\right)^2 \psi(X), \tag{4.14}$$

where

$$\big(1/\phi\big) = \int_{-1}^{1} \phi(x') dX',$$

and

$$\mathcal{L}_0 \phi(X) = \int_{-1}^{1} \ln|X' - X| \phi(X') dX'.$$

Since the operator $\mathcal{L}_0 : (H^{1/2})'(]-1,1[) \to \widetilde{H}^{1/2}(]-1,1[)$ is invertible, we have

$$\big(1/\phi\big) \mathcal{L}_0^{-1} 1(X) + \frac{1}{\ln \alpha} \phi(X) = \frac{\pi}{\mu_1 a_0} \mathcal{L}_0^{-1} \psi(X).$$

A simple integration over $]-1,1[$ gives

$$\big(1/\phi\big) = -\frac{\pi}{\mu_2 a_0} \left(\frac{\mu_2}{\mu_1}\right)^2 \frac{\big(\mathcal{L}_0^{-1}\psi(X)/1\big)}{\big(\mathcal{L}_0^{-1}1(x)/1\big) + \frac{1}{\ln \alpha}}.$$

By inserting this into (4.14) we immediately obtain

$$\phi(X) = (A_0^\alpha)^{-1}\psi(X) = -\frac{\pi \ln \alpha}{\mu_2 a_0} \left(\frac{\mu_2}{\mu_1}\right)^2 \left[\mathcal{L}_0^{-1}\psi(X) - \frac{\big(\mathcal{L}_0^{-1}\psi(X)/1\big)}{\big(\mathcal{L}_0^{-1}1(x)/1\big) + \frac{1}{\ln \alpha}} \mathcal{L}_0^{-1} 1(X)\right].$$

By the Hilbert inversion formula [9] we may calculate $\big(\mathcal{L}_0^{-1}1(x)/1\big) = \frac{2}{\ln 2}$. We remark that $(A_0^\alpha)^{-1} A_1(\Gamma) = O(1)$ and $(A_0^\alpha)^{-1} A_{-1} = O(1)$. Thus, the following estimate

$$(A_0^\alpha)^{-1}(\mathcal{A}_\alpha(\Gamma) - A_0^\alpha) = O\left(\frac{1}{\ln \alpha}\right)$$

holds uniformly in $\Gamma \in \partial D_{\delta_0}(0)$. From this we deduce that there exists a constant α_0 such that for $|\alpha| \leq \alpha_0$ we have

$$|(A_0^\alpha)^{-1}(\mathcal{A}_\alpha(\Gamma) - A_0^\alpha)|_{\mathcal{L}((H^{1/2})'(]-1,1[),(H^{1/2})'(]-1,1[))} < 1 \quad \forall\, \Gamma \in \partial D_{\delta_0}(0).$$

Due to the generalized Rouché theorem [2] (see Theorem B.2 in Appendix B) we now obtain the following assertion for all $|\alpha| \leq \alpha_0$:

$$\mathcal{M}(\mathcal{A}_\alpha(\Gamma), \partial D_{\delta_0}(0)) = \mathcal{M}(\mathcal{A}_0^\alpha, \partial D_{\delta_0}(0)) = 0.$$

Since 0 is the unique pole of $\mathcal{A}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$, it immediately follows from the latter assertion that there exists a unique characteristic value Γ_α in $D_{\delta_0}(0)$. ∎

We now want to derive an asymptotic expression for Γ_α. Let the operators $\widetilde{A}_k$ be defined by

$$A_1(\Gamma)\Gamma + A_{-1} = \sum_{k=-1}^{+\infty} \widetilde{A}_k \Gamma^{k+1}.$$

In the following theorems we summarize our main findings in this section.

THEOREM 4.5. *There exists a positive constant α_0 such that for $|\alpha| \leq \alpha_0$ the following holds:*

$$\Gamma_\alpha = \sum_{p=1}^{+\infty} \frac{1}{(-\ln \alpha)^p} \operatorname{tr}\left[(\mathcal{A}_0^\alpha)^{-p} \sum_{j=1}^{+\infty} \sum_{\substack{k_1+\cdots+k_j=p-1-j \\ k_s \geq -1}} \widetilde{A}_{k_1} \ldots \widetilde{A}_{k_j}\right] + O(\alpha). \tag{4.15}$$

Furthermore, the leading order term in the asymptotic expansion of Γ_α is given by

$$\Gamma_\alpha = \frac{2\pi c_{l_0}^a \mu_2}{a_0 \mu_1} (\ln \alpha)^{-1} + O((\ln \alpha)^{-2}), \tag{4.16}$$

where $c_{l_0}^a$ and a_0 are defined by (4.2) *and* (4.3)*, respectively.*

Proof. From the generalized Rouché theorem [2] (see Theorem B.4 in Appendix B) we immediately obtain the asymptotic expansion (4.15) for the resonance Γ_α. The leading order term in this expression, given by (4.16), can be easily derived from the asymptotic expansion of $\mathcal{A}_\alpha(\Gamma)$ stated in Theorem 4.1. ∎

The following theorem holds.

THEOREM 4.6. *There exists a constant $\alpha_0 > 0$ such that for $|\alpha| \leq \alpha_0$ we have*

$$\Gamma_\alpha = \frac{1}{2i\pi} \sum_{p=1}^{+\infty} \frac{1}{p} \operatorname{tr}\left[(\mathcal{A}_0^\alpha)^{-p} \int_{\partial D_{\delta_0}} (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^p d\Gamma\right].$$

Proof. Recalling that $\mathcal{A}_\alpha(\Gamma)$ is a finitely meromorphic operator-valued function that is of Fredholm type in $D_{\delta_0}(0)$, 0 is the unique pole of $\mathcal{A}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$, and Γ_α is the unique characteristic value of $\mathcal{A}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$, the generalized Rouché theorem implies

$$\Gamma_\alpha = \frac{1}{2i\pi} \operatorname{tr} \int_{\partial D_{\delta_0}} \Gamma(\mathcal{A}_\alpha(\Gamma))^{-1} \frac{\partial}{\partial \Gamma} \mathcal{A}_\alpha(\Gamma) d\Gamma.$$

Since, for $|\alpha| \leq \alpha_0$, we have

$$(\mathcal{A}_\alpha(\Gamma))^{-1} = \sum_{p=0}^{+\infty} (\mathcal{A}_0^\alpha)^{-p} \Big[(\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))(\mathcal{A}_0^\alpha)^{-1}\Big]^p,$$

the expression of Γ_α can alternatively be written as follows:

$$\Gamma_\alpha = \frac{1}{2i\pi} \sum_{p=0}^{+\infty} \text{ tr } \left[(\mathcal{A}_0^\alpha)^{-(p+1)} \int_{\partial D_{\delta_0}} \Gamma (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^p \frac{\partial}{\partial \Gamma} \mathcal{A}_\alpha(\Gamma) d\Gamma \right].$$

By noticing that

$$\frac{1}{p+1} \sum_{s=0}^{p} (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^s \frac{\partial}{\partial \Gamma} \mathcal{A}_\alpha(\Gamma) (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^{p-s} = -\frac{1}{p+1} \frac{\partial}{\partial \Gamma} (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^{p+1}$$

and by integrating by parts, we arrive at the desired result. □

It immediately follows from Theorem 4.5 that

$$\frac{1}{2i\pi} \text{ tr } \left[(\mathcal{A}_0^\alpha)^{-(p+1)} \int_{\partial D_{\delta_0}} (\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))^p d\Gamma \right]$$
$$= \left(\frac{-1}{\ln \alpha} \right)^p \text{ tr } \left[(\mathcal{A}_0^\alpha)^{-p} \sum_{j=1}^{+\infty} \sum_{\substack{k_1 + \cdots + k_j = p-1-j \\ k_s \geq -1}} \widetilde{A}_{k_1} \ldots \widetilde{A}_{k_j} \right] + O(\alpha). \quad \square$$

We now construct an asymptotic expansion for the characteristic function corresponding to the characteristic value Γ_α. Let ϕ_α^a be the normalized characteristic function corresponding to the characteristic value Γ_α in $L^2(]-1,1[)$:

$$\phi_\alpha^a(X) = \frac{[\frac{1}{\mu} \partial_y u_\alpha](\alpha X)}{|[\frac{1}{\mu} \partial_y u_\alpha](\alpha X)|_{L^2(]-1,1[)}}.$$

Here we have used the extra-regularity of the characteristic function ϕ_α^a. A combination of the fact that the integral operator with kernel $\ln|X - X'|$ is invertible from the Hölder space

$$\left\{ \varphi \in \mathcal{C}^0(]-1,1[), \sqrt{1-X^2}\varphi(X) \in \mathcal{C}^{0,\delta}([-1,1]) \right\}$$

onto the Hölder space

$$\Big\{ \psi \in \mathcal{C}^{0,\delta}([-1,1]) \cap \mathcal{C}^1(]-1,1[), \sqrt{1-X^2}\psi'(X) \in \mathcal{C}^{0,\delta}(]-1,1[) \cap \mathcal{C}^{0,\nu}([-1,1]),$$
$$\sqrt{1-X^2}\psi'(X)|_{X=\pm 1} = 0 \Big\},$$

where $\mathcal{C}^{0,\delta}$ and $\mathcal{C}^{0,\nu}$ are the Hölder spaces with indices $0 < \nu < \delta < \frac{1}{2}$ (see [1] for a proof), together with the classical Sobolev imbedding theorems, ensures that the characteristic function ϕ_α^a lies in fact in $L^2(]-1,1[)$.

Let P_α^a denote the orthogonal projection on $\text{Ker}(\mathcal{A}_\alpha(\Gamma_\alpha))$:

$$P_\alpha^a = \big(./\phi_\alpha^a(X)\big)_{L^2(]-1,1[)} \phi_\alpha^a(X).$$

The following theorem holds.

THEOREM 4.7. *There exists a positive constant α_0 such that for $|\alpha| \leq \alpha_0$,*

$$P_\alpha^a = P_0^a + O(\alpha),$$

where $P_0^a = \frac{1}{2}\big(./1\big)_{L^2(]-1,1[)}$ *and the remainder* $O(\alpha)$ *is the operator norm.*

Proof. The generalized Rouché theorem implies that

$$P_\alpha^a - P_0^a = \frac{1}{2i\pi}\int_{\partial D_{\delta_0}} (\mathcal{A}_\alpha(\Gamma))^{-1}\frac{\partial}{\partial\Gamma}\mathcal{A}_\alpha(\Gamma)d\Gamma.$$

On the other hand, we have for $|\alpha| \leq \alpha_0$

$$(\mathcal{A}_\alpha(\Gamma))^{-1} = \sum_{p=0}^{+\infty}(\mathcal{A}_0^\alpha)^{-p}[(\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))(\mathcal{A}_0^\alpha)^{-1}]^p,$$

and therefore

$$P_\alpha^a - P_0^a = \sum_{p=0}^{+\infty}(\mathcal{A}_0^\alpha)^{-1}\frac{1}{2i\pi}\int_{\partial D_{\delta_0}}\Big((\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma))(\mathcal{A}_0^\alpha)^{-1}\Big)^p\frac{\partial}{\partial\Gamma}\mathcal{A}_\alpha(\Gamma)d\Gamma.$$

Recalling from Theorem 4.5 that

$$\mathcal{A}_0^\alpha - \mathcal{A}_\alpha(\Gamma) = -\frac{1}{\ln\alpha}\Big(A_1(\Gamma) + \frac{A_{-1}}{\Gamma}\Big) + O(\alpha),$$

insertion of the above identity into the expression of P_α^a immediately gives

$$\begin{aligned}
&P_\alpha^a - P_0^a\\
&= \sum_{p=0}^{+\infty}\left(\frac{1}{\ln\alpha}\right)^{p+1}(\mathcal{A}_0^\alpha)^{-1}\frac{1}{2i\pi}\\
&\times\int_{\partial D_{\delta_0}}\left(-\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)(\mathcal{A}_0^\alpha)^{-1}\right)^p\frac{\partial}{\partial\Gamma}\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)d\Gamma\\
&+ O(\alpha).
\end{aligned}$$

Note that $\mathcal{A}_0^\alpha A_1(\Gamma) = A_1(\Gamma)\mathcal{A}_0^\alpha$ and $\mathcal{A}_0^\alpha A_{-1} = A_{-1}\mathcal{A}_0^\alpha$. By writing now that

$$\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)^p\frac{\partial}{\partial\Gamma}\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right) = \frac{1}{p+1}\frac{\partial}{\partial\Gamma}\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)^{p+1},$$

and by integrating by parts, we finally obtain

$$\frac{1}{2i\pi}\int_{\partial D_{\delta_0}}\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)^p\frac{\partial}{\partial\Gamma}\left(A_1(\Gamma)+\frac{A_{-1}}{\Gamma}\right)d\Gamma = 0,$$

which is the desired result. □

Direct application of Theorem 4.7 yields

$$\big(1/\phi_\alpha^a(X)\big)^2_{L^2(]-1,1[)} = 2 + O(\alpha).$$

Corollary 4.8. *There exists a constant* α_0 *such that for* $|\alpha| \leq \alpha_0$ *we have*

$$\phi_\alpha^a(X) = \frac{1}{\sqrt{2}} + O(\alpha),$$

where the remainder $O(\alpha)$ *is uniform in* $X \in [-1,1]$.

4.2. The operator-valued function $\mathcal{B}_\alpha(\Gamma)$. Let ω be a fixed positive real, $0 \le l_0 \le m_b$, and $\Gamma = \sqrt{\omega^2\varepsilon_1(0)\mu_1 - \lambda_{l_0}^b - \gamma^2}$ a complex variable, where $\lambda_{l_0}^b(\omega)$ is a root of (3.3) different from $d^2(\omega)$. Then 0 is a resonance of the reference waveguide. In this section, we prove that in a fixed complex neighborhood of 0 lying in the set

$$\mathcal{V}_0 = \left\{ \Gamma \in \mathbb{C}, |\Gamma| < \min_{\lambda \in \{(\lambda_l^b)_{0\le l\le m_b, l\ne l_0}, d^2\}} |\lambda_{l_0}^b - \lambda| \right\},$$

there exists a unique resonance of the microstrip transmission line for small values of α, defined as the unique characteristic value of the function $\mathcal{B}_\alpha(\Gamma)$ in that neighborhood.

Our main results in this section are summarized in the following theorem.

THEOREM 4.9. *Let $D_{\delta_0}(0) = \{\Gamma \in \mathbb{C}, |\Gamma| < \delta_0\}$, $\delta_0 > 0$, a neighborhood of 0 lying in $\mathcal{V}_0$. There exists a positive constant α_0 such that, for $|\alpha| \le \alpha_0$, we have the following:*

(a) *The operator-valued function $\mathcal{B}_\alpha(\Gamma)$ is finitely meromorphic and of Fredolm type at every point of the domain $D_{\delta_0}(0)$.*

(b) *The following asymptotic formula holds:*

$$\mathcal{B}_\alpha(\Gamma) = B_0 + B_1\alpha^2 \ln\alpha + \Big(B_2(\Gamma) + \frac{B_{-1}}{\Gamma}\Big)\alpha^2 + O(\alpha^3 \ln\alpha),$$

where the remainder $O(\alpha^3 \ln\alpha)$ is uniform in $\{\phi \in \widetilde{H}^{1/2}(-1,1), |\phi|_{\widetilde{H}^{1/2}(-1,1)} \le 1\}$ and in $\Gamma \in \partial D_{\delta_0}(0) = \{\Gamma \in \mathbb{C}, |\Gamma| = \delta_0\}$. The operators $B_0^\alpha, B_1(\Gamma)$, and B_{-1} are defined by

$$\begin{aligned}
B_0^\alpha &: \widetilde{H}^{1/2}(-1,1) \longrightarrow H^{-1/2}(-1,1),\\
B_0^\alpha\phi(X) &= -\frac{a_0\varepsilon_2}{\pi\varepsilon_1^2(h)} \int_{-1}^{1} \frac{1}{(X'-X)^2}\phi(X')dX',\\
b_1(\Gamma) &: \widetilde{H}^{1/2}(-1,1) \longrightarrow H^{-1/2}(-1,1),\\
B_1(\Gamma)\phi(X) &= b_1 \int_{-1}^{1} \phi(X')dX',\\
B_2(\Gamma) &: \widetilde{H}^{1/2}(-1,1) \longrightarrow H^{-1/2}(-1,1),\\
B_2(\Gamma)\phi(X) &= \int_{-1}^{1} b_2(\Gamma; X', X)\phi(X')dX',\\
B_{-1} &: \widetilde{H}^{1/2}(-1,1) \longrightarrow H^{-1/2}(-1,1),\\
B_{-1}\phi(X) &= \frac{2c_{l_0}^b}{\varepsilon_2} \int_{-1}^{1} \phi(X')dX'.
\end{aligned}$$

Here $\Gamma \to B_2(\Gamma)$ is an holomorphic operator-valued function in the disc $D_{\delta_0}(0)$.

In order to prove this theorem we will need two technical results. By the same arguments as we went through earlier in the proof of Lemma 4.2, the following result that will prove useful later holds.

LEMMA 4.10. *For every $y \in [0,h]$ we have*

$$\phi_b(y,\lambda) = \cos(\sqrt{\lambda}y) + \frac{\int_0^y q(\tau)d\tau}{2}\frac{\sin(\sqrt{\lambda}y)}{\sqrt{\lambda}} + O\left(\frac{1}{\lambda}\right),$$

$$\partial_y\phi_b(y,\lambda) = -\sqrt{\lambda}\sin(\sqrt{\lambda}y) + \frac{\int_0^y q(\tau)d\tau}{2}\cos(\sqrt{\lambda}y) + \left(\frac{3q(y) - \int_0^y q(\tau)\int_0^\tau q(s)dsd\tau}{4}\right)\frac{\sin(\sqrt{\lambda}y)}{\sqrt{\lambda}} - q(y)\frac{\sin^3(\sqrt{\lambda}y)}{\sqrt{\lambda}} + O\left(\frac{1}{\lambda}\right).$$

Here $O(\frac{1}{\lambda})$ and $O(\frac{1}{\sqrt{\lambda}})$ are uniform in $y \in [0,h]$.

Next, multiplying (3.10) by $\partial_y\phi_b(y,\lambda)$ and integrating over $]0,h[$ yields

$$\partial_y\phi_b^2(h,\lambda) + \phi_b^2(h,\lambda) = \lambda + 2\int_0^h q(y)\phi_b(y,\lambda)\partial_y\phi_b(y,\lambda)dy.$$

Hence

$$(\lambda - d^2)\phi_b^2(h,\lambda) + \left(\frac{\varepsilon_2}{\varepsilon_1(h)}\right)^2\partial_y\phi_b^2(h,\lambda) = \lambda\left[1 + \left(\left(\frac{\varepsilon_2}{\varepsilon_1(h)}\right)^2 - 1\right)\frac{\partial_y\phi_b^2(h,\lambda)}{\lambda}\right] + 2\int_0^h q(y)\phi_b(y,\lambda)\partial_y\phi_b(y,\lambda)dy - d^2\phi_b^2(h,\lambda).$$

Since $y \to (\varepsilon_1(0)\mu_1 - \varepsilon_1(y)\mu_1)$ is $\mathcal{C}^1$-piecewise, the λ-function

$$\omega^2\int_0^h(\varepsilon_1(0)\mu_1 - \varepsilon_1(y)\mu_1(y))\phi_b(y,\lambda)\partial_y\phi_b(y,\lambda)dy$$

is $O(1)$ as $\lambda \to +\infty$. Lemma 4.10 yields

$$\frac{\partial_y\phi_b^2(h,\lambda)}{(\lambda - d^2)\phi_b^2(h,\lambda) + (\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b^2(h,\lambda)} = \frac{\partial_y\phi_b^2(h,\lambda)}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\frac{\partial_y\phi_b^2(h,\lambda)}{\lambda}\right]} + R_{3,b}(\lambda),$$

where

$$R_{3,b}(\lambda) = \partial_y\phi_b^2(h,\lambda)\frac{2\omega^2\int_0^h(\varepsilon_1(0)\mu_1 - \varepsilon_1(y)\mu_1(y))\phi_b(y,\lambda)\partial_y\phi_b(y,\lambda)dy - d^2\phi_b^2(h,\lambda)}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\frac{\partial_y\phi_b^2(h,\lambda)}{\lambda}\right]((\lambda - d^2)\phi_b^2(h,\lambda) + (\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b^2(h,\lambda))},$$

and $R_{3,b}(\lambda) = O(\frac{1}{\lambda^2})$ as $\lambda \to +\infty$. We also have

$$\frac{\partial_y\phi_b^2(h,\lambda)}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\frac{\partial_y\phi_b^2(h,\lambda)}{\lambda}\right]} = \frac{\sin^2\sqrt{\lambda}h}{1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\sin^2\sqrt{\lambda}h} + \beta_1\frac{\sin\sqrt{\lambda}h\cos\sqrt{\lambda}h}{\sqrt{\lambda}\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\sin^2\sqrt{\lambda}h\right]} + \beta_2\frac{1}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\sin^2\sqrt{\lambda}h\right]} + \beta_3\frac{\sin^2\sqrt{\lambda}h}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\sin^2\sqrt{\lambda}h\right]} + \beta_4\frac{\sin^4\sqrt{\lambda}h}{\lambda\left[1 + ((\frac{\varepsilon_2}{\varepsilon_1(h)})^2 - 1)\sin^2\sqrt{\lambda}h\right]} + R_{4,b}(\lambda),$$

where

$$\begin{cases} \beta_1 = -\displaystyle\int_0^h q(\tau)d\tau, \quad \beta_2 = \left(\frac{\int_0^h q(\tau)d\tau}{2}\right)^2, \\ \beta_3 = \dfrac{1}{2}\displaystyle\int_0^h q(\tau)\int_0^\tau q(s)dsd\tau - \left(\frac{\int_0^h q(\tau)d\tau}{2}\right)^2 - \frac{3}{2}q(h), \\ \beta_4 = 2q(h), \end{cases}$$

and $R_{4,b}(\lambda) = O(\frac{1}{\lambda^{3/2}})$ as $\lambda \to +\infty$.

Finally, we may conclude that

$$\begin{aligned} &\frac{\sqrt{\lambda - d^2}\partial_y\phi_b^2(h,\lambda)}{(\lambda-d^2)\phi_b^2(h,\lambda) + (\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b^2(h,\lambda)} \frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda_{l_0}^b-\Gamma^2}}}{\sqrt{\lambda-\lambda_{l_0}^b-\Gamma^2}} \\ &= \frac{\sin^2\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} e^{-\alpha|X'-X|\sqrt{\lambda}} \\ &+ \frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\sqrt{\lambda}}\Bigg[\beta_1\frac{\sin\sqrt{\lambda}h\cos\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} \\ &\qquad + \alpha|X-X'|\frac{(\lambda_{l_0}^b+\Gamma^2)}{2}\frac{\sin^2\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h}\Bigg] \\ &+ \frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\lambda}\Bigg[\beta_2\frac{1}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} + \beta_3\frac{\sin^2\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} \\ &\qquad + \beta_4\frac{\sin^4\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} \\ &\qquad + \alpha|X-X'|\beta_1\frac{(\lambda_{l_0}^b+\Gamma^2)}{2}\frac{\sin\sqrt{\lambda}h\cos\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h}\Bigg] \\ &+ \alpha^2 R_{1,b}^\alpha(\lambda,\Gamma,X'-X)\frac{\sin^2\sqrt{\lambda}h}{1+((\frac{\varepsilon_2}{\varepsilon_1(h)})^2-1)\sin^2\sqrt{\lambda}h} + R_{5,b}^\alpha(\lambda,\Gamma,X'-X), \end{aligned}$$

where $R_{1,b}^\alpha(\lambda,\Gamma,X'-X) = O(\frac{1}{\lambda})$, and $R_{5,b}^\alpha(\lambda,\Gamma,X'-X)$ is uniform in $\alpha \in D_{\alpha_0}(0)$, $\Gamma \in D_{\delta_0}(0)$, and $(X-X') \in [-2,2]$.

Let us now introduce the following functions. For $X > 0$ let

$$E_\eta^0(X) = \int_{d^2}^{+\infty} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} e^{-X\sqrt{\lambda}}d\lambda,$$

$$E_\eta^1(X) = \int_{d^2}^{+\infty} \frac{\sin\sqrt{\lambda}h\cos\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\sqrt{\lambda}}d\lambda,$$

$$E_\eta^2(X) = \int_{d^2}^{+\infty} \frac{1}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\lambda}d\lambda,$$

$$E^3_\eta(X) = \int_{d^2}^{+\infty} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\lambda} d\lambda,$$

$$E^4_\eta(X) = \int_{d^2}^{+\infty} \frac{\sin^4\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\lambda} d\lambda,$$

$$E^5_\eta(X) = \int_{d^2}^{+\infty} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\sqrt{\lambda}} d\lambda,$$

$$E^6_\eta(X) = \int_{d^2}^{+\infty} \frac{\sin\sqrt{\lambda}h\cos\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} \frac{e^{-X\sqrt{\lambda}}}{\lambda} d\lambda.$$

By the same arguments as we went through in the proof of Lemma 4.3 we may quite easily show that the following holds.

LEMMA 4.11. *Suppose that* $|\eta| < 1$. *Then we have*

$$E^0_\eta(X) = \frac{e_0}{X^2} + f_0 + O(X),$$

$$E^1_\eta(X) = f_1 + O(X),$$

$$E^2_\eta(X) = e_1 \ln X + f_2 + O(X),$$

$$E^3_\eta(X) = e_2 \ln X + f_3 + O(X),$$

$$E^4_\eta(X) = e_3 \ln X + f_4 + O(X),$$

$$E^5_\eta(X) = \frac{e_4}{X} + f_5 + O(X),$$

$$E^6_\eta(X) = O(1),$$

where

$$e_0(\eta) = 2a_0(\eta),$$

$$f_0(\eta) = (1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C^p_k(-2)^p \sum_{q=1}^{p+1} \frac{w_q^{p+1}}{q^2}\eta^k - \int_0^{d^2} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h} d\lambda,$$

$$f_1(\eta) = (1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C^p_k(-2)^p \frac{w_0^{p+1} - \sin^{2(p+1)} hd}{h(p+1)}\eta^k,$$

$$e_1(\eta) = (1-\eta)\left(2 - \sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^p (-2)^{p+1} w_0^{p+1}\eta^k\right),$$

$$f_2(\eta) = (1-\eta)\left(\int_{d^2}^{+\infty} \frac{e^{-\sqrt{\lambda}}}{\lambda} d\lambda + 2\sum_{n=1}^{+\infty}\frac{(-d)^n}{n!n} + \sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^p (-2)^{p+1}\left(\int_0^d \frac{\sin^{2p} h\nu}{\nu} d\nu - w_0^p \ln h - \sum_{q=1}^{p} w_q^p \ln 4q^2\right)\eta^k\right),$$

$$e_2(\eta) = -2a_0(\eta),$$

$$f_3(\eta) = 2a_1(\eta) - \int_0^{d^2} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h}\frac{d\lambda}{\lambda},$$

$$e_3(\eta) = (1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^{p+1}(-2)^{p+2} w_0^{p+2}\eta^k,$$

$$f_4(\eta) = -(1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^{p+1}(-2)^{p+2} w_0^{p+2}\eta^k \ln h - (1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^{p+1}(-2)^{p+2}\left(\sum_{q=1}^{p+2} w_q^{p+2}\ln 4q^2 + d_{p+1}\right)\eta^k - \int_{d^2}^{+\infty} \frac{\sin^4\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h}\frac{d\lambda}{\lambda},$$

$$e_4(\eta) = -h(1-\eta)\sum_{k=0}^{+\infty}\sum_{p=0}^{k} C_k^{p}(-2)^{p+1} w_0^{p+1}\eta^k,$$

$$f_5(\eta) = -\int_{d^2}^{+\infty} \frac{\sin^2\sqrt{\lambda}h}{\cos^2\sqrt{\lambda}h + \frac{1+\eta}{1-\eta}\sin^2\sqrt{\lambda}h}\frac{d\lambda}{\sqrt{\lambda}}.$$

Here the terms $O(X)$ and $O(1)$ are uniform in $X \in [0,2]$ and holomorphic with respect to $\Gamma \in \overline{D_{\delta_0}(0)}$.

We are now ready to proceed with the following proof.

Proof of Theorem 4.9. We begin by deriving an asymptotic formula for $b_\alpha(\Gamma; X, X')$ when α approaches 0. Let us define

$$c_l^b = \frac{1}{2i}\frac{\sqrt{d^2-\lambda_l^b}\,\partial_y\phi_b^2(h,\lambda_l^b)}{\frac{\varepsilon_2}{\varepsilon_1(h)}\phi_b^2(h,\lambda_l^b) + \sqrt{d^2-\lambda_l^b}\int_0^h \phi^2(y,\lambda_l^b)dy}, \qquad 1 \le l \le m_b.$$

With this definition we may rewrite the expression of the kernel $b_\alpha(\Gamma; X', X)$ as follows:

$$b_\alpha(\Gamma; X, X') = \alpha^2 \frac{2}{\varepsilon_2} c^b_{l_0} \frac{e^{i\alpha|X'-X|\Gamma}}{\Gamma} + \alpha^2 \frac{2}{\varepsilon_2} \sum_{l=1, l\neq l_0}^{m_b} c^b_l \frac{e^{i\alpha|X'-X|\sqrt{\lambda^b_{l_0}-\lambda^b_l+\Gamma^2}}}{\sqrt{\lambda^b_{l_0}-\lambda^b_l+\Gamma^2}}$$
$$-\frac{\alpha^2\varepsilon_2}{2\pi\varepsilon_1^2(h)} \int_{d^2}^{+\infty} \frac{\sqrt{\lambda-d^2}\partial_y\phi_b^2(h,\lambda)}{(\lambda-d^2)\phi_b^2(h,\lambda)+(\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b^2(h,\lambda)} \frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}}}{\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}} d\lambda.$$

We start with estimating the third term in the last expression. We have

$$\frac{\sqrt{\lambda-d^2}}{\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}} e^{-\alpha|X'-X|\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}} = e^{-\alpha|X'-X|\sqrt{\lambda}}$$
$$+\alpha|X-X'|\frac{(\lambda^b_{l_0}+\Gamma^2)}{2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\sqrt{\lambda}} + \frac{(\lambda^b_{l_0}+\Gamma^2-d^2)}{2}\frac{e^{-\alpha|X'-X|\sqrt{\lambda}}}{\lambda}$$
$$+\alpha^2 R^\alpha_{1,b}(\lambda,\Gamma,X'-X) + R^\alpha_{2,a}(\lambda,\Gamma,X'-X),$$

where $R^\alpha_{1,b}(\lambda,\Gamma,X'-X) = O(\frac{1}{\lambda})$, and $R^\alpha_{2,b}(\lambda,\Gamma,X'-X) = O(\frac{1}{\lambda^{3/2}})$ when $\lambda \to +\infty$. The remainders $O(\frac{1}{\lambda^s})$, for $s = 1, 3/2$, are uniform in $\alpha \in D_{\alpha_0}(0)$, $\Gamma \in D_{\delta_0}(0)$, and $(X - X') \in [-2, 2]$. A forward application of the last lemma yields

$$-\frac{\alpha^2}{2\pi}\int_{d^2}^{+\infty} \frac{\sqrt{\lambda-d^2}\partial_y\phi_b^2(h,\lambda)}{(\lambda-d^2)\phi_b^2(h,\lambda)+(\frac{\varepsilon_2}{\varepsilon_1(h)})^2\partial_y\phi_b^2(h,\lambda)} \frac{e^{-\alpha|X'-X|\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}}}{\sqrt{\lambda-\lambda^b_{l_0}-\Gamma^2}} d\lambda$$
$$= -\frac{a_0}{\pi}\frac{1}{(X'-X)^2} - \frac{1}{2\pi}(\beta_2 e_1+\beta_3 e_2+\beta_4 e_3)\alpha^2\ln\alpha$$
$$-\frac{1}{2\pi}\Big(f_0+\beta_1 f_1+\beta_2 f_2+\beta_3 f_3+\beta_4 f_4+\frac{(\lambda^b_{l_0}+\Gamma^2)e_4}{2}$$
$$+\ (\beta_2 e_1+\beta_3 e_2+\beta_4 e_3)\ln|X'-X|\Big)\alpha^2 + O(\alpha^3\ln\alpha),$$

and, therefore, we finally have

$$b_\alpha(\Gamma; X, X') = -\frac{a_0\varepsilon_2}{\pi\varepsilon_1^2(h)}\frac{1}{(X'-X)^2} + b_1\alpha^2\ln\alpha$$
$$+\ \Big(b_2(\Gamma; X, X')\alpha^2 + \frac{2c^b_{l_0}}{\varepsilon_1(h)}\frac{1}{\Gamma}\Big)\alpha^2 + O(\alpha^3\ln\alpha),$$

where

$$\begin{cases} b_1 = -\dfrac{\varepsilon_2}{2\pi\varepsilon_1^2(h)}(\beta_2 e_1+\beta_3 e_2+\beta_4 e_3), \\ b_2(\Gamma; X, X') = -\dfrac{\varepsilon_2}{2\pi\varepsilon_1^2(h)}\Big(f_0+\beta_1 f_1+\beta_2 f_2+\beta_3 f_3+\beta_4 f_4\dfrac{(\lambda^b_{l_0}+\Gamma^2)e_4}{2} \\ \qquad\qquad +(\beta_2 e_1+\beta_3 e_2+\beta_4 e_3)\ln|X'-X|\Big) \\ \qquad +\frac{2}{\varepsilon_2}\sum_{l=1,l\neq l_0}^{m_b}\frac{c^b_l}{\sqrt{\lambda^a_{l_0}-\lambda^b_l+\Gamma^2}}. \end{cases}$$

Here the term $O(\alpha^3 \ln \alpha)$ is uniform in $X' - X \in [-2, 2]$ and holomorphic in $\Gamma \in \overline{D_{\delta_0}(0)}$, and so the proof of the second part of Theorem 4.9 is now over. By construction, we know that $\Gamma \to \mathcal{B}_\alpha(\Gamma)$ is meromorphic operator-valued in $D_{\delta_0}(0)$ and has a unique pole that is 0. Moreover, for every $\Gamma \in \overline{D_{\delta_0}(0)}/\{0\}$, $\mathcal{B}_\alpha(\Gamma)$ is an invertible operator. From the asymptotic expansion in Theorem 4.9, it immediately follows that $\mathcal{B}_\alpha(\Gamma)$ is a finitely meromorphic and of Fredholm type at $\Gamma = 0$ for small values of α. Then, it is the case in all the domain $D_{\delta_0}(0)$. □

We now study the existence and the localization of the characteristic values of the operator-valued function $\mathcal{B}_\alpha(\Gamma)$.

THEOREM 4.12. *There exists a constant $\alpha_0 > 0$ such that for $|\alpha| < \alpha_0$ we have*

$$\mathcal{M}(\mathcal{B}_\alpha(\Gamma), \partial D_{\delta_0}(0)) = 0,$$

and, therefore, there exists a unique characteristic value Γ_α^b of $\mathcal{B}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$ which is the unique resonance in this domain.

Proof. Since B_0 is an invertible operator it follows from Theorem 4.9 that $(B_0)^{-1}(\mathcal{B}_\alpha(\Gamma) - B_0) = O(\alpha^2 \ln \alpha)$ uniformly in $\Gamma \in \partial D_{\delta_0}(0)$. Therefore, there exists a constant α_0 such that for $|\alpha| \leq \alpha_0$ we have

$$|(B_0)^{-1}(\mathcal{B}_\alpha(\Gamma) - B_0)|_{\mathcal{L}(\widetilde{H}^{1/2}(]-1,1[), \widetilde{H}^{1/2}(]-1,1[))} < 1 \quad \forall\, \Gamma \in \partial D_{\delta_0}(0).$$

By the generalized Rouché theorem (see Theorem B.2 in Appendix B), we immediately obtain for all $|\alpha| \leq \alpha_0$ that

$$\mathcal{M}(\mathcal{B}_\alpha(\Gamma), \partial D_{\delta_0}(0)) = \mathcal{M}(\mathcal{B}_0, \partial D_{\delta_0}(0)) = 0.$$

Since 0 is the unique pole of $\mathcal{B}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$ there exists a unique characteristic value Γ_α^b in $D_{\delta_0}(0)$. Theorem 4.12 is then proved. □

We now derive an asymptotic expansion for Γ_α^b. Let us define

$$\mathcal{L}_b = -\frac{\pi \varepsilon_1^2(h)}{a_0 \varepsilon_2} B_0.$$

THEOREM 4.13. *There exists a positive constant α_0 such that, for $|\alpha| \leq \alpha_0$, we have*

$$\Gamma_\alpha^b = \frac{1}{2i\pi} \sum_{p=1}^{+\infty} \frac{1}{p} \mathrm{tr} \left[(\mathcal{B}_0)^{-p} \int_{\partial D_{\delta_0}} (\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))^p d\Gamma \right],$$

which gives

$$\Gamma_\alpha^b = 2\pi \frac{c_{l_0}^b \varepsilon_2}{a_0 \varepsilon_1(h)} \big(\mathcal{L}_b^{-1} 1/1\big) \alpha^2 + O(\alpha^4 \ln \alpha).$$

Proof. Recalling that $\mathcal{B}_\alpha(\Gamma)$ is a finitely meromorphic operator-valued function and of Fredholm type in $D_{\delta_0}(0)$, 0 is the unique pole of $\mathcal{B}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$, and Γ_α is the unique characteristic value of $\mathcal{B}_\alpha(\Gamma)$ in $D_{\delta_0}(0)$, the generalized Rouché theorem (see Theorem B.4 in Appendix B) immediately implies that

$$\Gamma_\alpha^b = \frac{1}{2i\pi} \mathrm{tr} \int_{\partial D_{\delta_0}} \Gamma (\mathcal{B}_\alpha(\Gamma))^{-1} \frac{\partial}{\partial \Gamma} \mathcal{B}_\alpha(\Gamma) d\Gamma.$$

Since, for $|\alpha| \leq \alpha_0$, we have

$$(\mathcal{B}_\alpha(\Gamma))^{-1} = \sum_{p=0}^{+\infty} (\mathcal{B}_0)^{-p} [(\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))(\mathcal{B}_0)^{-1}]^p,$$

the expression of Γ_α^b may be rewritten as follows:

$$\Gamma_\alpha^b = \frac{1}{2i\pi} \sum_{p=0}^{+\infty} \mathrm{tr} \left[(\mathcal{B}_0)^{-(p+1)} \int_{\partial D_{\delta_0}} \Gamma (\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))^p \frac{\partial}{\partial \Gamma} \mathcal{B}_\alpha(\Gamma) d\Gamma \right].$$

Now by writing

$$\frac{1}{p+1} \sum_{s=0}^{p} (\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))^s \frac{\partial}{\partial \Gamma} \mathcal{B}_\alpha(\Gamma) (\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))^{p-s} = -\frac{1}{p+1} \frac{\partial}{\Gamma} (\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))^{p+1}$$

and integrating by parts, we obtain the desired result. □

Next, we give an expression for the characteristic function corresponding to the value Γ_α^b. We will calculate the leading order term in this asymptotic expression.

Let

$$\phi_\alpha^b(X) = \frac{[\varepsilon v_\alpha](\alpha X)}{|[\varepsilon v_\alpha](\alpha X)|_{L^2(]-1,1[)}}$$

and

$$P_\alpha^b = \big(./\phi_\alpha^b(X)\big)_{L^2(]-1,1[)} \phi_\alpha^b(X)$$

denote the normalized characteristic function corresponding to the value Γ_α^b in $L^2(]-1,1[)$ and the orthogonal projection on $\mathrm{Ker}(\mathcal{B}_\alpha(\Gamma_\alpha^b))$, respectively.

THEOREM 4.14. *There exists a positive constant α_0 such that for $|\alpha| \leq \alpha_0$*

$$P_\alpha^b = P_0^b + 2\pi \frac{c_{l_0}^b \varepsilon_1^2(h)}{a_0 \varepsilon_2^2} \big(./1\big)_{L^2(]-1,1[)} \mathcal{L}_b^{-1} 1(X) \alpha^2 + O(\alpha^4 \ln \alpha),$$

where $P_0^b = \frac{1}{2}\big(./1\big)_{L^2(]-1,1[)}$.

Proof. The generalized Rouché theorem implies that

$$P_\alpha^b - P_0^b = \frac{1}{2i\pi} \int_{\partial D_{\delta_0}} (\mathcal{B}_\alpha(\Gamma))^{-1} \partial_\Gamma \mathcal{B}_\alpha(\Gamma)\, d\Gamma.$$

On the other hand, we have for $|\alpha| \leq \alpha_0$

$$(\mathcal{B}_\alpha(\Gamma))^{-1} = \sum_{p=0}^{+\infty} (\mathcal{B}_0)^{-p} [(\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))(\mathcal{B}_0)^{-1}]^p.$$

Therefore,

$$P_\alpha^b - P_0^b = \sum_{p=0}^{+\infty} (\mathcal{B}_0)^{-1} \frac{1}{2i\pi} \int_{\partial D_{\delta_0}} \big((\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma))(\mathcal{B}_0)^{-1}\big)^p \partial_\Gamma \mathcal{B}_\alpha(\Gamma)\, d\Gamma.$$

Theorem 4.9 yields

$$\mathcal{B}_0 - \mathcal{B}_\alpha(\Gamma) = -B_1\alpha^2\ln\alpha - \left(B_2(\Gamma) + \frac{B_{-1}}{\Gamma}\right)\alpha^2 + O(\alpha^3\ln\alpha).$$

Inserting the above identity into the expression of P_α^a gives

$$P_\alpha^b - P_0^b = -B_0^{-1}B_{-1} + O(\alpha^4\ln\alpha).$$

Hence

$$P_\alpha^b - P_0^b = 2\pi\frac{c_{l_0}^b\varepsilon_1^2(h)}{a_0\varepsilon_2^2}\big(./1\big)_{L^2(]-1,1[)}\mathcal{L}_b^{-1}1(X)\alpha^2 + O(\alpha^4\ln\alpha),$$

and the proof of the theorem is then complete. □

COROLLARY 4.15. *There exists a constant α_0 such that for $|\alpha| \le \alpha_0$*

$$\phi_\alpha^a(X) = \frac{1}{\sqrt{2}} + \sqrt{2}\pi\frac{c_{l_0}^b\varepsilon_1^2(h)}{a_0\varepsilon_2^2}\left(\mathcal{L}_b^{-1}1(X) - \frac{1}{2}\big(\mathcal{L}_b^{-1}1(X)/1\big)_{L^2(]-1,1[)}\right)\alpha^2 + O(\alpha^4\ln\alpha),$$

where the remainder $O(\alpha^4\ln\alpha)$ is uniform in $X \in [-1,1]$.

Proof. Theorem 4.14 gives

$$\big(1/\phi_\alpha^a(X)\big)_{L^2(]-1,1[)} = \sqrt{2}\left(1 + \pi\frac{c_{l_0}^b\varepsilon_1^2(h)}{a_0\varepsilon_2^2}\big(\mathcal{L}_b^{-1}1(X)/1\big)_{L^2(]-1,1[)}\right)\alpha^2 + O(\alpha),$$

which is exactly the identity stated in the corollary. □

Appendix A. Proof of Lemma 3.1. We only give the proof of Lemma 3.1. The proof for Lemma 3.2 follows exactly the same lines. To simplify notations, we will drop the subscript a.

Let $t > 0$ and $\lambda_{k,t}$, $k = 1, 2, \dots$, be the eigenvalues of the following Sturm–Liouville problem in the interval $]0,t[$ with homogeneous Dirichlet boundary condition at $y = t$:

$$\text{(A.1)}\qquad \begin{cases} \partial_{yy}g(y,\lambda;t) + (\lambda - q(y))g(y,\lambda;t) = 0 \quad \text{in }]0,h[\cup]h,t[,\\ [g(.,\lambda;t)] = 0 \quad \text{on } y = h,\\ \left[\dfrac{1}{\mu}\partial_y g(.,\lambda;t)\right] = 0 \quad \text{on } y = h,\\ g(0,\lambda;t) = 0 \quad \text{and} \quad g(t,\lambda;t) = 0. \end{cases}$$

From the properties of the solution g_a to (3.1), we have that $\lambda_{k,t}$ are the roots of

$$\text{(A.2)}\qquad g(t,\lambda_{k,t};t) = 0,$$

or equivalently

$$\text{(A.3)}\qquad \phi(h,\lambda_{k,t})\sqrt{\lambda_{k,t} - d^2} + \frac{\mu_2}{\mu_1}\partial_y\phi(h,\lambda_{k,t})\tanh\left(\sqrt{\lambda_{k,t} - d^2}(t-h)\right) = 0,$$

where ϕ is defined by (3.2).

We denote by $\hat{g}_{k,t}, k = 1, 2, \dots$, the corresponding eigenfunctions

$$\hat{g}_{k,t}(y) = g(y, \lambda_{k,t}), \quad y \in]0, +\infty[, \tag{A.4}$$

and introduce the weight

$$\frac{1}{r_{k,t}} = \int_0^t \hat{g}_{k,t}^2(y) \frac{dy}{\mu(y)}. \tag{A.5}$$

Let $f(y) \in L^2(0, +\infty; \frac{dy}{\mu(y)})$. Standard Sturm–Liouville theory allows us to write the Parseval identity for f:

$$\int_0^t f^2(y) \frac{dy}{\mu(y)} = \sum_{k=1}^{+\infty} \frac{1}{r_{k,t}} \left(\int_0^t f(y) \hat{g}_{k,t}(y) \frac{dy}{\mu(y)} \right)^2. \tag{A.6}$$

Let

$$\rho_t(\lambda) = \sum_{0 \le \lambda_{k,t} \le \lambda} \frac{1}{r_{k,t}}, \quad \lambda \in]0, +\infty[. \tag{A.7}$$

Then (A.6) takes the form

$$\int_0^t f^2(y) \frac{dy}{\mu(y)} = \int_0^{+\infty} F_t^2(\lambda) d\rho_t(\lambda), \tag{A.8}$$

where

$$F_t(\lambda) = \int_0^t f(y) g(\lambda, y) \frac{dy}{\mu(y)}.$$

We proceed by calculating the limit of $\rho_t(\lambda)$ as $t \to +\infty$.

LEMMA A.1. *Let*

$$\begin{aligned}
\rho(\lambda) &= \begin{cases} \displaystyle\sum_{0 < \lambda_k \le \lambda} \frac{1}{r_k}, & 0 < \lambda \le d^2, \\ \displaystyle\sum_{0 < \lambda_k \le d^2} \frac{1}{r_k} + \int_0^{\sqrt{\lambda - d^2}} r(\nu^2 + d^2) d\nu, & d^2 \le \lambda, \end{cases} \\
r_k &= \frac{2\mu_1 \sqrt{d^2 - \lambda_k}}{\frac{\mu_1}{\mu_2} \phi^2(h, \lambda) + 2\sqrt{d^2 - \lambda_k} \int_0^h \phi^2(h, \lambda_k) dy}, \quad 1 \le k \le m, \\
r(\lambda) &= \frac{1}{\pi} \frac{\mu_2 (\lambda - d^2)}{(\lambda - d^2)\phi^2(h, \lambda) + (\frac{\mu_2}{\mu_1})^2 \partial_y \phi^2(h, \lambda)}, \quad d^2 \le \lambda.
\end{aligned} \tag{A.9}$$

Then the function $\rho_t(\lambda)$ converges to $\rho(\lambda)$ uniformly with respect to λ in any finite interval in $]0, +\infty[$.

Proof. Isolated eigenvalues. The eigenvalues $t \to \lambda_{k,t}$ which belong to the interval $]0, d^2[$ satisfy (A.3). As $t \to +\infty$, the left-hand side of (A.3) converges uniformly in λ; hence the $\lambda_{k,t}$'s smaller than d^2 converge to the roots λ_k of (3.3) for $k = 1, \dots, m_a$. Moreover, by (A.5) we have that

$$\begin{aligned}
\frac{1}{r_{k,t}} &= \frac{1}{\mu_1} \int_0^h \phi^2(y, \lambda_{k,t}) dy \\
&+ \frac{1}{\mu_2 \sqrt{d^2 - \lambda_{k,t}}} \int_0^{(t-h)\sqrt{d^2 - \lambda_{k,t}}} \left(\phi(h, \lambda_{k,t}) \cosh \tau - \frac{\mu_2}{\mu_1} \frac{\partial_y \phi(h, \lambda_{k,t})}{\sqrt{d^2 - \lambda_{k,t}}} \sinh \tau \right)^2 d\tau,
\end{aligned}$$

so that the $r_{k,t}$'s converge to the values r_k's defined in (A.9) as $t \to +\infty$.

The continuous spectrum. For fixed $k = 1, 2, \dots$, any eigenvalue $\lambda_{k,t} > d^2$ converges to d^2 as $t \to +\infty$. Let $h_k(t) = (t-h)\sqrt{\lambda_{k,t} - d^2}$. If $\partial_y \phi(h, d^2) \neq 0$, then (A.3) implies that $h_k(t) \to k\pi$ and so $h_{k+1}(t) - h_k(t) \to \pi$ for $t \to +\infty$. We can write

$$r_{k,t}(\lambda) = \Big(\sqrt{\lambda_{k+1,t} - d^2} - \sqrt{\lambda_{k,t} - d^2}\Big)\hat{r}_{k,t}(\lambda),$$

where

$$\hat{r}_{k,t}(\lambda) = \frac{1}{h_{k+1}(t) - h_k(t)} \times$$

$$\frac{(\lambda - d^2)}{\frac{1}{\mu_1}\frac{(\lambda-d^2)}{t-h}\int_0^h \phi^2(y,\lambda)\, dy + \frac{1}{\mu_2}\frac{1}{\sqrt{\lambda - d^2}(t-h)}\int_0^{(t-h)\sqrt{d^2-\lambda_{k,t}}} \Big(\phi(h,\lambda_{k,t})\cos\tau - \frac{\mu_2}{\mu_1}\frac{\partial_y\phi(h,\lambda_{k,t})}{\sqrt{d^2-\lambda_{k,t}}}\sin\tau\Big)^2 d\tau}.$$

We can easily verify that $\hat{r}_{k,t}(\lambda)$ converges uniformly in compact subsets of $]0, +\infty[$ to $r(\lambda)$ and

$$\sum_{d^2 \le \lambda_{k,t} \le \lambda} (\hat{r}_{k,t}(\lambda_{k,t}) - r(\lambda_{k,t}))\left(\sqrt{\lambda_{k+1,t} - d^2} - \sqrt{\lambda_{k,t} - d^2}\right) \to 0, \tag{A.10}$$

as $t \to +\infty$. Let $\nu_{k,t} = \sqrt{\lambda_{k,t} - d^2}$. Then we have

$$\begin{aligned}\sum_{d^2 \le \lambda_{k,t} \le \lambda} r_{k,t} = &\sum_{d^2 \le \lambda_{k,t} \le \lambda} (\hat{r}_{k,t}(\lambda_{k,t}) - r(\lambda_{k,t}))\left(\sqrt{\lambda_{k+1,t} - d^2} - \sqrt{\lambda_{k,t} - d^2}\right) \\ &+ \sum_{0 \le \nu_{k,t} \le \sqrt{d^2-\lambda}} r(\nu_{k,t}^2 + d^2)(\nu_{k+1,t} - \nu_{k,t}).\end{aligned} \tag{A.11}$$

By (A.10) and the monotony of the sequence $\lambda_{k,t}$, we immediately obtain that

$$\lim_{t \to +\infty} \sum_{d^2 \le \lambda_{k,t} \le \lambda} r_{k,t} = \int_0^{\sqrt{\lambda - d^2}} r(\nu^2 + d^2) d\nu. \tag{A.12}$$

If $\partial_y \phi(h, d^2) = 0$, then since $\partial_y \phi(y, \lambda)$ is an analytic function of λ, by (A.3) we have that either $h_k(t) \to (k - 1/2)\pi$ or $(k + 1/2)\pi$ as $t \to +\infty$. Repeating the previous argument, we arrive at the same conclusion. ∎

A direct consequence of the last lemma gives that for any $\psi(\lambda) \in \mathcal{D}(\mathbb{R}_+)$ we have

$$\begin{aligned}&\lim_{t \to +\infty} \big(d\rho_t(\lambda)/\psi\big) = \big(d\rho(\lambda)/\psi\big) \\ &= \sum_{k=1}^m r_k \psi(\lambda_k) + \frac{1}{\pi}\int_{d^2}^{+\infty} \frac{\mu_2\sqrt{\lambda - d^2}}{(\lambda - d^2)\phi^2(h,\lambda) + (\frac{\mu_2}{\mu_1})^2 \partial_y \phi^2(h,\lambda)} \psi(\lambda) d\lambda,\end{aligned}$$

and so the inversion formula holds for any continuous function with compact support on $\mathbb{R}_+$.

Let us now complete the proof of Lemma 3.1 by proving that it holds for any $f \in L^2(\mathbb{R}_+, \frac{dy}{\mu(y)})$. This will be obtained by a limiting process from the corresponding formula, derived for smooth functions with compact support.

We know that there exists a sequence $\{f_n(y)\}_n$ of functions of class $\mathcal{C}^2(]0,h[\cup]h,+\infty[)$, which satisfy the conditions $f_n(0)=0$, are equal to zero outside the interval $[0,n]$, $\frac{\mu_1}{\mu_2}f_n'(h^+)=f_n'(h^-)$, $f_n(h^+)=f_n(h^-)$, and

$$\lim_{t\to+\infty}\int_0^{+\infty}\{f_n(y)-f(y)\}^2\frac{dy}{\mu(y)}=0. \tag{A.13}$$

Applying the Parseval identity to these functions, we obtain for any large value of t $(t\geq n)$ that

$$\int_0^n f_n^2(y)\frac{dy}{\mu(y)}=\int_0^{+\infty}\check{F}_n^2(\lambda)d\rho_t(\lambda), \tag{A.14}$$

where

$$\check{F}_n(\lambda)=\int_0^n f_n(y)g(y,\lambda)\frac{dy}{\mu(y)}. \tag{A.15}$$

Multiply (3.1) by $f_n(y)$ and integrate by parts twice to get

$$\check{F}_n(\lambda)=-\frac{1}{\lambda}\int_0^t(f_n''(y)-q(y)f_n(y))g(y,\lambda)\frac{dy}{\mu(y)}. \tag{A.16}$$

Therefore for a finite $N>0$ we have

$$\begin{aligned}
&\int_{\lambda>N}\check{F}_n^2(\lambda)d\rho_t(\lambda)\\
&\leq\frac{1}{N^2}\int_{\lambda>N}\left\{\int_0^t(f_n''(y)-q(y)f_n(y))g(y,\lambda)\frac{dy}{\mu(y)}\right\}^2d\rho_t(\lambda)\\
&<\frac{1}{N^2}\int_0^{+\infty}\left\{\int_0^t(f_n''(y)-q(y)f_n(y))g(y,\lambda)\frac{dy}{\mu(y)}\right\}^2d\rho_t(\lambda)\\
&=\frac{1}{N^2}\int_0^n(f_n''(y)-q(y)f_n(y))^2\frac{dy}{\mu(y)}.
\end{aligned}$$

From this bound and (A.14) we obtain

$$\left|\int_0^n f_n^2(y)\frac{dy}{\mu(y)}-\int_0^N\check{F}_n^2(\lambda)d\rho_t(\lambda)\right|\leq\frac{1}{N^2}\int_0^n(f_n''(y)-q(y)f_n(y))^2\frac{dy}{\mu(y)}. \tag{A.17}$$

Lemma A.1 leads to

$$\int_0^N\check{F}_n^2(\lambda)d\rho_t(\lambda)\to\int_0^N\check{F}_n^2(\lambda)d\rho(\lambda) \tag{A.18}$$

as $t\to+\infty$. Passing to the limit in (A.17) we find the inequality

$$\left|\int_0^n f_n^2(y)\frac{dy}{\mu(y)}-\int_0^N\check{F}_n^2(\lambda)d\rho(\lambda)\right|\leq\frac{1}{N^2}\int_0^n(f_n''(y)-q(y)f_n(y))^2\frac{dy}{\mu(y)}. \tag{A.19}$$

Finally, letting $N\to+\infty$ in this inequality, we obtain

$$\int_0^{+\infty}f_n^2(y)\frac{dy}{\mu(y)}=\int_0^{+\infty}\check{F}_n^2(\lambda)d\rho(\lambda). \tag{A.20}$$

Since

$$\int_0^{+\infty} \{f_n(y) - f_m(y)\}^2 \frac{dy}{\mu(y)} \to 0 \tag{A.21}$$

as $n, m \to +\infty$, it follows that

$$\lim_{n,m\to+\infty} \int_0^{+\infty} \{\check{F}_n(\lambda) - \check{F}_m(\lambda)\}^2 d\rho(\lambda) = 0. \tag{A.22}$$

We denote by $\mathcal{H}_\rho$ the space of functions which are square integrable with respect to $\rho(\lambda)$. Now, we will show that $\mathcal{H}_\rho$ is a complete space. Let $\eta_p(\lambda)$ be a sequence of functions in $\mathcal{H}_\rho$ which satisfies

$$\lim_{p,q\to+\infty} \int_0^{+\infty} \{\eta_p(\lambda) - \eta_q(\lambda)\}^2 d\rho(\lambda) = 0. \tag{A.23}$$

The last identity implies

$$\lim_{p,q\to+\infty} \{\eta_p(\lambda_k) - \eta_q(\lambda_k)\}^2 = 0, \quad 1 \le k \le m, \tag{A.24}$$

and

$$\lim_{p,q\to+\infty} \frac{1}{\pi} \int_{d^2}^{+\infty} \frac{\mu_2\sqrt{\lambda - d^2}}{(\lambda - d^2)\phi^2(h,\lambda) + \frac{\mu_1^2}{\mu_2^2}\partial_y\phi^2(h,\lambda)} \{\eta_p(\lambda) - \eta_q(\lambda)\}^2 d\lambda = 0. \tag{A.25}$$

The completeness of $\mathbb{R}_+$ and $L^2(\mathbb{R}_+)$ gives that there exists a unique function $\eta(\lambda)$ such that $\eta_p(\lambda) \to \eta(\lambda)$ in $\mathcal{H}_\rho$ as $p \to +\infty$. Then, the relation (A.22) implies the existence of a limit function $F(\lambda)$ in $\mathcal{H}_\rho$ satisfying the Parseval identity

$$\int_0^{+\infty} f^2(y) \frac{dy}{\mu(y)} = \int_0^{+\infty} F^2(\lambda) d\rho(\lambda). \tag{A.26}$$

We will now show that $F_n(\lambda) = \int_0^n f(y)g(y,\lambda)\frac{dy}{\mu(y)}$ converges to $F(\lambda)$ in $\mathcal{H}_\rho$. Let $g_n(\lambda) = f(y)$ for $0 \le y \le n$ and $g_n(y) \equiv 0$ for $y > n$. Since $g_n(y) \in L^2(0, +\infty; \frac{dy}{\mu(y)})$, there exists $G_n(\lambda)$ in $\mathcal{H}_\rho$ such that

$$\int_0^{+\infty} \{f(y) - g_n(y)\}^2(y) \frac{dy}{\mu(y)} = \int_0^{+\infty} \{F(\lambda) - G_n(\lambda)\}^2 d\rho(\lambda). \tag{A.27}$$

But

$$G_n(\lambda) = \int_0^n f(y)g(y,\lambda)\frac{dy}{\mu(y)}.$$

Hence we obtain

$$\int_0^{+\infty} \{F(\lambda) - F_n(\lambda)\}^2 d\rho(\lambda) = \int_n^{+\infty} f^2(y) \frac{dy}{\mu(y)} \to 0 \tag{A.28}$$

as $n \to +\infty$. The following results hold.

LEMMA A.2. *Let $f(y) \in L^2(0,+\infty;\frac{dy}{\mu(y)})$. There exists a nondecreasing function $\rho(\lambda)$, which does not depend on $f(x)$, and a function $F(\lambda)$ (the generalized Fourier transform of $f(y)$) such that*

$$\int_0^{+\infty} f^2(y)\frac{dy}{\mu(y)} = \int_0^{+\infty} F^2(\lambda)d\rho(\lambda). \tag{A.29}$$

The function $F(\lambda)$ is the limit in quadratic mean relative to $d\rho(\lambda)$ of the sequence of continuous functions $F_n(\lambda) = \int_0^n f(y)g(y,\lambda)\frac{dy}{\mu(y)}$:

$$\lim_{t\to+\infty}\int_0^{+\infty}\{F(\lambda) - F_n(\lambda)\}^2 d\rho(\lambda) = 0. \tag{A.30}$$

LEMMA A.3. *Let $f(y)$ be a continuous function, and suppose that the integral $\int_0^{+\infty} F(\lambda)g(y,\lambda)d\rho(\lambda)$ converges absolutely and uniformly with respect to y in any finite interval. Then*

$$f(y) = \int_0^{+\infty} F(\lambda)g(y,\lambda)d\rho(\lambda), \quad y \in]0,+\infty[. \tag{A.31}$$

Appendix B. The generalized Rouché theorem. For convenience we recall the main results of Ghoberg and Sigal in [2].

B.1. Notations and definitions. Let $\mathcal{H}$ and $\mathcal{H}'$ be two Banach spaces, and let $\mathcal{L}(\mathcal{H},\mathcal{H}')$ be the algebra of all bounded-valued functions acting from $\mathcal{H}$ into $\mathcal{H}'$.

Let λ_0 be a fixed complex value in $\mathbb{C}$. We denote by $\mathcal{A}(\lambda)$ an operator-valued function acting from $D_\varepsilon(\lambda_0)$ into $\mathcal{L}(\mathcal{H},\mathcal{H}')$, where $D_\varepsilon(\lambda_0)$ is a disc of center λ_0 and radius $\varepsilon > 0$.

λ_0 is called a *characteristic* value of $\mathcal{A}(\lambda)$ if

(i) $\mathcal{A}(\lambda)$ is holomorphic in some neighborhood of λ_0, except possibly at this point itself;

(ii) there exists a vector-valued function $\phi(\lambda)$: $D_\varepsilon(\lambda_0) \to \mathcal{H}$ holomorphic at λ_0 and that verifies $\phi(\lambda_0) \neq 0$, such that $\mathcal{A}(\lambda)\phi(\lambda)$ is a holomorphic at λ_0 and vanishes at this point. $\phi(\lambda)$ is called a *root* function of $\mathcal{A}(\lambda)$ associated with λ_0, and the vector $\phi_0 = \phi(\lambda_0)$ is called an eigenvector. The closure of the linear set of eigenvectors corresponding to λ_0 is denoted by $\mathrm{Ker}\mathcal{A}(\lambda_0)$.

Suppose that λ_0 is a characteristic value of the function $\mathcal{A}(\lambda)$ and $\phi(\lambda)$ is a root function satisfying (ii). Then there exists a number $m(\phi) \geq 1$ and a vector-valued function $\psi(\lambda) : D_\varepsilon(\lambda_0) \to \mathcal{H}$ holomorphic such that

$$\mathcal{A}(\lambda)\phi(\lambda) = (\lambda - \lambda_0)^{m(\phi)}\psi(\lambda),$$
$$\psi(\lambda_0) \neq 0.$$

The number $m(\phi)$ is called the *multiplicity* of the root function $\phi(\lambda)$. Let ϕ_0 be an eigenvector corresponding to λ_0 and let

$$\mathcal{R}(\phi_0) = \{m(\phi); \phi(\lambda) \text{ is a root function such } \phi(\lambda_0) = \phi_0\}.$$

Then by rank of ϕ_0 we mean $\mathrm{rank}(\phi_0) = \max \mathcal{R}(\phi_0)$. Suppose that $n = \dim\mathrm{Ker}\mathcal{A}(\lambda_0) < +\infty$ and that the ranks of all vectors in $\mathrm{Ker}\mathcal{A}(\lambda_0)$ are finite. A system of eigenvectors ϕ_0^j, $j = 1,\dots,n$, is called a *canonical system of eigenvectors* of $\mathcal{A}(\lambda)$ associated to λ_0

if the ranks possess the following property: $\operatorname{rank}(\phi_0^j)$ is the maximum of the ranks of all eigenvectors in some direct complement in $\dim\operatorname{Ker}\mathcal{A}(\lambda_0)$ of the linear span of the vectors $\phi_0^1, \dots, \phi_0^{j-1}$. Let $r_j = \operatorname{rank}(\phi_0^j)$. Then $(r_j)_j$ determines the function $\mathcal{A}(\lambda)$ uniquely. We call

$$N(\mathcal{A}(\lambda_0)) = \sum_{j=1}^{n} r_j$$

the *null multiplicity of the characteristic* value λ_0 of $\mathcal{A}(\lambda)$. If λ_0 is not a characteristic value of $\mathcal{A}(\lambda)$, we put $N(\mathcal{A}(\lambda_0)) = 0$.

Suppose that $\mathcal{A}^{-1}(\lambda)$ exists and is holomorphic in some neighborhood of λ_0, except possibly at this point itself. Then the number

$$M(\mathcal{A}(\lambda_0)) = N(\mathcal{A}(\lambda_0)) - N(\mathcal{A}^{-1}(\lambda_0))$$

is called the *multiplicity* of the characteristic value λ_0 of $\mathcal{A}(\lambda)$. Suppose that λ_1 is a pole of the operator-valued function. The Laurent expansion of $\mathcal{A}(\lambda)$ in λ_1 is given by

$$\mathcal{A}(\lambda) = \sum_{j \geq -s} (\lambda - \lambda_1)^j A_j.$$

If in the last expression the operators A_{-j}, $j = 1, \dots, s$, are finite-dimensional, then $\mathcal{A}(\lambda)$ is called *finitely meromorphic* at λ_1.

The operator-valued function $\mathcal{A}(\lambda)$ is said to be of Fredholm type at the point λ_1 if the operator A_0 in the last expansion is a Fredholm operator. If $\mathcal{A}(\lambda)$ is holomorphic at the point λ_0 and the operator $\mathcal{A}(\lambda_0)$ is invertible, then λ_0 is called a *regular point* of $\mathcal{A}(\lambda)$.

B.2. Main results. The point λ_0 is called a *normal point* of $\mathcal{A}(\lambda)$ if there exists a constant $0 < \varepsilon_0 \leq \varepsilon$ such that $\mathcal{A}(\lambda)$ is finitely meromorphic and of Fredholm type at λ_0 and all the points of $D_{\varepsilon_0}(\lambda_0) - \{\lambda_0\}$ are regular for $\mathcal{A}(\lambda)$, where $D_{\varepsilon_0}(\lambda_0)$ is a disc of center λ_0 and radius $\varepsilon_0 > 0$.

LEMMA B.1. *Every normal point λ_0 of $\mathcal{A}(\lambda)$ is a normal point of $\mathcal{A}^{-1}(\lambda)$.*

Let $\partial D_{\varepsilon_0}$ be the contour bounding the domain $D_{\varepsilon_0}(\lambda_0)$. An operator-valued function $\mathcal{A}(\lambda)$ which is finitely meromorphic and of Fredholm type in $D_{\varepsilon_0}(\lambda_0)$ and continuous at $\partial D_{\varepsilon_0}$ is called *normal with respect to* $\partial D_{\varepsilon_0}$ if the operator $\mathcal{A}(\lambda)$ is invertible in $\overline{D_{\varepsilon_0}(\lambda_0)}$, except for a finite number of points of $D_{\varepsilon_0}(\lambda_0)$ which are normal points of $\mathcal{A}(\lambda)$. Now, if $\mathcal{A}(\lambda)$ is normal with respect to the contour $\partial D_{\varepsilon_0}$ and λ_i, $i = 1, \dots, \sigma$, are all its characteristic values and poles lying in $D_{\varepsilon_0}(\lambda_0)$, we put

$$\mathcal{M}(\mathcal{A}(\lambda); \partial D_{\varepsilon_0}) = \sum_{i=1}^{\sigma} M(\mathcal{A}(\lambda_i)).$$

THEOREM B.2. *Suppose that the operator-valued $\mathcal{A}(\lambda)$ is normal with respect to $\partial D_{\varepsilon_0}$; then we have*

$$\mathcal{M}(\mathcal{A}(\lambda); \partial D_{\varepsilon_0}) = \frac{1}{2i\pi} \operatorname{tr} \int_{\partial D_{\varepsilon_0}} \mathcal{A}^{-1}(\lambda) \frac{d}{d\lambda} \mathcal{A}(\lambda) d\lambda.$$

By tr we mean the trace of operator which is the sum of all its nonzero characteristic values, see [2, p. 609] for an exact statement.

The operator generalization of the Rouché theorem is stated below.

THEOREM B.3. *Let $\mathcal{A}(\lambda)$ be an operator-valued function which is normal with respect to $\partial D_{\varepsilon_0}$. If an operator-valued function $S(\lambda)$ which is finitely meromorphic in $D_{\varepsilon_0}(\lambda_0)$ and continuous at $\partial D_{\varepsilon_0}$ satisfies the condition*

$$|\mathcal{A}^{-1}(\lambda)S(\lambda)|_{\mathcal{L}(\mathcal{H},\mathcal{H})} < 1, \quad \lambda \in \partial D_{\varepsilon_0},$$

then $\mathcal{A}(\lambda) + S(\lambda)$ is also normal with respect to $\partial D_{\varepsilon_0}$, and

$$\mathcal{M}(\mathcal{A}(\lambda); \partial D_{\varepsilon_0}) = \mathcal{M}(\mathcal{A}(\lambda) + S(\lambda); \partial D_{\varepsilon_0}).$$

The generalization of the Steinberg theorem is given by the following.

THEOREM B.4. *Suppose that $\mathcal{A}(\lambda)$ is an operator-valued function which is finitely meromorphic and of Fredholm type in the domain $D_{\varepsilon_0}(\lambda_0)$. If the operator $\mathcal{A}(\lambda)$ is invertible at one point of D_{ε_0}, then $\mathcal{A}(\lambda)$ has a bounded inverse for all $\lambda \in D_{\varepsilon_0}$, except possibly for certain isolated points.*

Finally, the following result is central.

THEOREM B.5. *Suppose that $\mathcal{A}(\lambda)$ is an operator-valued function which is normal with respect to $\partial D_{\varepsilon_0}$. Let $f(\lambda)$ be a scalar function which is analytic in $D_{\varepsilon_0}(\lambda_0)$ and continuous in $\overline{D_{\varepsilon_0}(\lambda_0)}$. Then*

$$\frac{1}{2i\pi}\ \mathrm{tr}\ \int_{\partial D_{\varepsilon_0}} f(\lambda)\mathcal{A}^{-1}(\lambda)\frac{d}{d\lambda}\mathcal{A}(\lambda)d\lambda = \sum_{j=1}^{\sigma} M(\mathcal{A}(\lambda_j))f(\lambda_j),$$

where λ_j, $j = 1, \ldots, \sigma$, are all the points in $D_{\varepsilon_0}(\lambda_0)$ which are either poles or characteristic values of $\mathcal{A}(\lambda)$.

A HYPERBOLIC SYSTEM OF EQUATIONS OF BLOOD FLOW IN AN ARTERIAL NETWORK*

WEIHUA RUAN†, M. E. CLARK‡, MEIDE ZHAO‡, AND ANTHONY CURCIO‡

Abstract. We study a coupled system of the Navier–Stokes equation and the equation of conservation of mass in a network. The system models the blood circulation in arterial networks. A special feature of the system is that the equations are coupled through boundary conditions at joints of the network. We use a fixed point method to prove the existence and uniqueness of the classic solution to the initial-boundary value problem and discuss the continuity of dependence of the solution and its derivatives on initial, boundary, and forcing functions and their derivatives. We develop a numerical scheme that generates discretized solutions, and we also prove the convergence of the scheme.

Key words. arterial network, blood flow, hyperbolic partial differential equations, initial-boundary value problems, numerical scheme

1. Introduction.

In this paper, we study a system of one-spatial-dimensional first-order quasi-linear hyperbolic partial differential equations defined on networks. By network, we mean a finite collection of smooth curves joining a finite number of vertices, and with a direction assigned to each curve (see Figure 1.1). The mathematical system arises from a long-term study of fluid dynamical models that simulate blood flow in arterial networks (cf. [1, 2, 9, 11, 13, 17, 18, 19, 20, 21, 22, 23, 24, 25] and

references therein). Recently, these models have been used in technologies for medical diagnostics [3, 6, 7, 8]. In particular, a technology called CANVAS (computer-assisted noninvasive vascular analysis and simulation) has been developed to help stroke patients. CANVAS uses data from magnetic resonance imaging to determine volumetric flow within vessels in the patient's brain [26]. The vessel flows are used to determine the boundary conditions of the model [8]. This approach is based on a model formulated by Clark and Kufahl [9, 13]. The technology has displayed its capability in helping doctors predict outcomes of major medical procedures. It is the extensive applications of these models that motivate their mathematical study. Of particular importance are whether the mathematical system is well posed (solution exists, is unique, and is stable), and whether the solutions generated by the computer algorithm approximate the true solutions.

In this paper, we study a generalization of a model given by [20, 23, 24], prove the existence and uniqueness of the solution, prove the continuous dependence of the solution on the initial, boundary, and forcing functions, and develop a numerical scheme that approximates the solution.

To explain our system, let us first describe the original model of [20, 23, 24]. Suppose that an arterial network consists of n vessels. We parameterize each vessel with a spatial variable $x \in (0,1)$ in accordance with the assigned direction of blood flow through the vessel. In the vessel, the flow of blood is governed by the one-spatial-dimensional equation of conservation of mass and an approximation of the Navier–Stokes momentum equation:

$$\begin{aligned} &\frac{\partial Q_i}{\partial x} + \frac{\partial A_i}{\partial t} = 0, \\ &\frac{\partial Q_i}{\partial t} + \alpha_i \frac{\partial}{\partial x}\left(\frac{Q_i^2}{A_i}\right) = -\frac{A_i}{\rho_i}\frac{\partial P_i}{\partial x} - \frac{\kappa_i Q_i}{A_i}, \end{aligned} \qquad x \in (0,1)\,,\ t > 0, \tag{1.1}$$

where Q_i is the flow rate, P_i is the pressure, A_i is the cross-sectional area of the vessel, and α_i, ρ_i, κ_i are positive constants. The above equations are valid if we assume that the radial component of the fluid velocity is far less than the axial component and that the axial velocity profile is proportional to $1-(r/R)^{\gamma}$ (R being the radius of the vessel) for some $\gamma \neq 0$. The latter assumption is satisfied by the Poiseuille flow profile considered in [9] and the plug flow profile considered in [17, 18]. (The reader is referred to [18, 19, 25] for a derivation of the above equations from three-dimensional mass balance and Navier–Stokes equations.)

The initial conditions are given by

$$P_i\,(0,x) = P_i^I\,(x)\,, \quad Q_i\,(0,x) = Q_i^I\,(x)\,, \quad i = 1,\ldots,n.$$

At each end of the vessel, depending on whether it is a source, an internal junction, or a terminal, a boundary condition is imposed. At a source end, either the pressure

$$P_i\,(0,t) = P_i^B\,(t) \tag{1.2}$$

or the flow

$$Q_i\,(0,t) = Q_i^B\,(t) \tag{1.3}$$

is specified. Various source ends may have different types of boundary conditions. At an internal junction, suppose $j_1,\ldots,j_\nu$ are the incoming vessels to and $j_{\nu+1},\ldots,j_\mu$

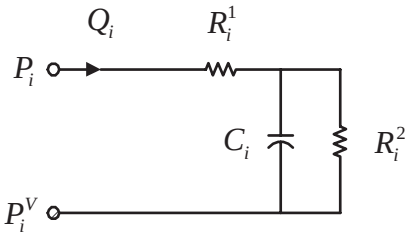

FIG. 1.2. *Windkessel model for a terminal boundary condition.*

are the outgoing vessels from the junction. We have mass and pressure continuities at junctions given by

$$\begin{aligned} &\sum_{l=1}^{\nu} Q_{j_l}(1,t) = \sum_{l'=\nu+1}^{\mu} Q_{j_{l'}}(0,t), \\ &P_{j_l}(1,t) = P_{j_{l'}}(0,t), \quad 1 \le l \le \nu,\ \nu+1 \le l' \le \mu. \end{aligned} \tag{1.4}$$

At a terminal end, we may either specify the pressure,

$$P_i(1,t) = P_i^B(t), \tag{1.5}$$

or the flow,

$$Q_i(1,t) = Q_i^B(t), \tag{1.6}$$

or use the windkessel model of peripheral beds [13, 20, 24] as the boundary condition,

$$\frac{\partial P_i}{\partial t} - \eta_i \frac{\partial Q_i}{\partial t} + \delta_i P_i - \varepsilon_i Q_i = W_i^B(t), \quad x = 1, \tag{1.7}$$

where η_i, δ_i, and ε_i are positive constants and W_i^B is a continuous function. This equation models the peripheral beds by a circuit that consists of a resistance R_i^1 in series with the parallel combination of a resistance R_i^2 and a capacitor C_i; see Figure 1.2. The resulting equation is

$$C_i \frac{\partial}{\partial t}\left(P_i - P_i^V\right) - R_i^1 C_i \frac{\partial Q_i}{\partial t} + \frac{P_i - P_i^V}{R_i^2} - \frac{R_i^1}{R_i^2} Q_i = 0,$$

where P_i^V is the venous pressure. This can be rewritten into (1.7). Again, boundary conditions for different terminals need not be the same.

Finally, the cross-sectional area A_i of the ith vessel is a function of x and P_i. A particular example used in [9, 13] is

$$A_i(x, P_i) = A_i^0(x) + \beta \ln \frac{P_i}{P_i^0},$$

where β is a positive constant and A_i^0 is a positive function which represents the cross-sectional area at certain constant pressure P_i^0.

In this paper, we study a more general system, which consists of the equations

$$\begin{aligned} &\frac{\partial P_i}{\partial t} + a_i \frac{\partial Q_i}{\partial x} = f_i, \\ &\frac{\partial Q_i}{\partial t} + b_i \frac{\partial P_i}{\partial x} + 2c_i \frac{\partial Q_i}{\partial x} = g_i, \end{aligned} \qquad x \in (0,1),\ t > 0, \tag{1.8}$$

and the initial and boundary conditions described above. For convenience, we also use the vector form

$$(U_i)_t + B_i (U_i)_x = F_i, \tag{1.9}$$

where $U_i = (P_i, Q_i)$, $F_i = (f_i, g_i)$, and

$$B_i = \begin{pmatrix} 0 & a_i \\ b_i & 2c_i \end{pmatrix}.$$

Equation (1.1) is a special case of this system, where

$$a_i = \frac{1}{(A_i)_{P_i}}, \quad b_i = \frac{A_i}{\rho_i} - \frac{\alpha_i Q_i^2 (A_i)_{P_i}}{A_i^2}, \quad c_i = \frac{\alpha_i Q_i}{A_i}, \quad f_i = 0, \quad g_i = \frac{Q_i^2 (A_i)_x}{A_i^2} - \frac{\kappa_i Q_i}{A_i}.$$

We do not assume any particular form for these functions, only that they are general differentiable functions of (x, t, P_i, Q_i). A basic assumption is $a_i > 0$. Other assumptions will follow.

This problem is interesting not only in fluid mechanics but also in mathematics. Navier–Stokes equations and conservation laws have been studied for over a century. Initial-boundary value problems of such equations in a one-dimensional network have been studied for decades [1, 9, 18, 20, 24, 25]. However, so far, most analyses on the models have been performed numerically rather than mathematically. To give a mathematical analysis is challenging. Unlike the problem of fluid flow in a rigid tube network, the distensibility of vessels greatly increases the complexity of the problem (cf. [19]). For example, as is well known, a first-order quasi-linear system of hyperbolic equations on a finite one-dimensional spatial interval need not have a solution. Even if it has a solution for an interval of time, the solution may not exist for all time. A particular example is given by Čanić [4]. In a network, it is important to know whether the coupling at junctions poses problems to solvability. The effect of the Windkessel boundary condition (1.7) on the solvability also needs to be examined.

In this paper, we study the existence and uniqueness of the local solution, develop a numerical scheme to approximate the solution, and prove the convergence of the scheme. This is the first step towards an analysis of the system. We consider only classic solutions (i.e., solutions whose derivatives are continuous and satisfy the differential equations) in this paper. The problems of existence and uniqueness of the weak solution are interesting but also more difficult. In particular, it is more difficult to establish the convergence of the scheme to the weak solution; this will be the subject of our future study. (See [4] for an example of a numerical scheme that gives a good approximation of the weak solution to a scaler initial-value problem.)

This paper is divided into two parts. The first part consists of sections 2 and 3, which deal with the problem of solvability using a fixed point approach. Substituting a pair of functions (p_i, q_i) for (P_i, Q_i) in the coefficients a_i, b_i, c_i and forcing functions f_i, g_i, the system becomes linear. That is, all the functions a_i, etc., are independent of unknowns. If the linear system has a unique solution, then one can establish a mapping from (p_i, q_i) to the linear problem solution (P_i, Q_i). If one also shows that this mapping has a unique fixed point, then the fixed point is necessarily the unique solution of the quasilinear system. Hence, we shall first give a condition for the linear system to have a unique solution, then examine under what conditions the mapping has a unique fixed point. We investigate the first aspect of the problem in section 2 and the latter in section 3. We also prove a result on the continuity of dependence

of solutions on the initial, boundary, and forcing functions for linear and quasi-linear systems. Thus, we complete the analysis of the well-posedness of the problem. In the second part of the paper, which consists of section 4 only, we give a numerical scheme that approximates the solution and prove its convergence. Our scheme is a set of finite-difference equations based on the normal form of the differential equations. Although these approaches are standard in the analysis of quasi-linear equations, the network feature of the system and the peculiarities of the boundary conditions make the problem more complicated. In the final section, we give a short discussion.

2. The linear system. In this section, we analyze (1.8) as a linear system with a_i, b_i, c_i, f_i, and g_i independent of P_i and Q_i. We give conditions for the system to have a unique global solution. The conditions are most naturally given in terms of the eigenvalues of the matrix B_i, which have the form

$$\lambda_i^R = c_i + u_i, \quad \lambda_i^L = c_i - u_i,$$

where

$$u_i = \sqrt{c_i^2 + a_i b_i}.$$

These eigenvalues are real if

$$c_i^2 + a_i b_i > 0, \quad x \in (0,1), \quad t > 0, \quad i = 1, \ldots, n. \tag{2.1}$$

In this case,

$$\lambda_i^L(x,t) < \lambda_i^R(x,t) \tag{2.2}$$

and the system is hyperbolic. Under this condition, we show that the linear system has a unique solution if

$$\lambda_i^L(x,t) < 0, \quad \lambda_i^R(x,t) > 0, \quad x = 0, 1, \ i = 1, \ldots, n.$$

This is clearly equivalent to

$$a_i b_i > 0, \quad t \geq 0, \quad i = 1, \ldots, n, \tag{2.3}$$

at $x = 0, 1$ only. It need not hold for $x \in (0,1)$.

THEOREM 2.1. *Assume that the functions a_i, b_i, c_i, f_i, and g_i are independent of (P_i, Q_i). Suppose that these functions and the initial and boundary functions P_i^I, Q_i^I, P_i^B, Q_i^B, and W_i^B all have bounded first-order derivatives. Suppose also that $a_i > 0$ and that the conditions* (2.1) *and* (2.3) *hold. Then, for any $T > 0$ there is a unique solution in a bounded subset of the space $C\left([0,1] \times [0,T], \mathbb{R}^{2n}\right)$ to the linear system* (1.8) *with the initial and boundary conditions given in section* 1.

Proof. We first show that the system has a unique solution for $0 < t < \delta$ for some $\delta > 0$. The proof is based on the method of characteristics and a fixed point principle. For systems defined on only one branch, this is a standard approach. In our case, special care is needed to handle the junction condition (1.4) and the Windkessel boundary condition (1.7).

Consider the ith branch of the network. From any point (τ, ξ) on the left, right, and lower boundary of the rectangle $D =: [0,1] \times [0,T]$, we construct the left-going

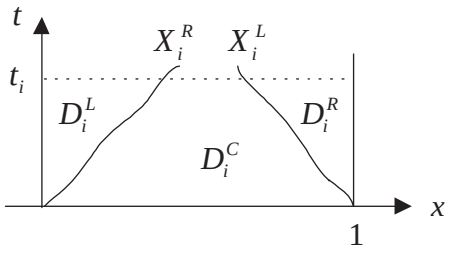

FIG. 2.1. *Three parts of* D_i.

and right-going characteristic curves $x = x_i^L(t;\xi,\tau)$ and $x = x_i^R(t;\xi,\tau)$ by

$$\frac{dx_i^L}{dt} = \lambda_i^L\big(x_i^L, t\big), \quad x_i^L(\tau) = \xi,$$
$$\frac{dx_i^R}{dt} = \lambda_i^R\big(x_i^R, t\big), \quad x_i^R(\tau) = \xi,$$

respectively, where λ_i^L and λ_i^R are the two eigenvalues of the matrix B_i. By the uniqueness of solutions of these differential equations, a left-going characteristic curve cannot intersect with another left-going characteristic curve, and the same is true for right-going characteristic curves. Let X_i^L and X_i^R be the right-most left-going and left-most right-going characteristic curves:

$$x = x_i^L(t;1,0) \quad \text{and} \quad x = x_i^R(t;0,0)$$

starting from the lower boundary of D, respectively. It can be shown from (2.2) that the two curves can have at most one intersection. Let t_i be the value of t at the intersection. If the two curves do not intersect in D, we simply define $t_i = T$. By condition (2.3), X_i^L cannot reach the right vertical line $x = 1$, and X_i^R cannot reach the vertical line $x = 0$ at any $t > 0$. Thus, the rectangle $D_i =: [0,1] \times [0,t_i]$ can be divided into three parts:

$$D_i = D_i^L \cup D_i^C \cup D_i^R,$$

where D_i^L is between the vertical line $x = 0$ and the characteristic curve X_i^R, D_i^C is between the two characteristic curves, and D_i^R is between X_i^L and $x = 1$ (see Figure 2.1). We show that there is a $\delta_i \le t_i$ such that the solution (P_i, Q_i) for the ith branch exists in the restriction of D_i to the strip $\{0 \le t \le \delta_i\}$.

We first observe that the initial conditions alone determine the solution completely in the central region D_i^C. This follows from the theory of first-order linear hyperbolic systems and the fact that from any point $(x,t) \in D_i^C$ the two characteristic curves, followed backwards, must land on the horizontal line $t = 0$. This imperative is a consequence of (2.2). To extend the solution to other parts of D_i, we make a change of unknowns and derive a set of integral equations. Note that $l_i^R =: (-\lambda_i^L, a_i)$ and $l_i^L =: (-\lambda_i^R, a_i)$ are the left eigenvectors of B_i corresponding to λ_i^R and λ_i^L, respectively. Introduce new unknowns

$$r_i = l_i^R U_i \equiv -\lambda_i^L P_i + a_i Q_i, \quad s_i = l_i^L U_i \equiv -\lambda_i^R P_i + a_i Q_i. \tag{2.4}$$

The system (1.8) can be written in terms of r_i and s_i by multiplying the left eigenvectors by (1.9) and substituting in

$$P_i = \frac{1}{2u_i}\left(r_i - s_i\right), \quad Q_i = \frac{1}{2u_i a_i}\left(\lambda_i^R r_i - \lambda_i^L s_i\right). \tag{2.5}$$

This results in the equations

$$\partial_i^R r_i = F_i^R\left(x,t,r_i,s_i\right), \quad \partial_i^L s_i = F_i^L\left(x,t,r_i,s_i\right), \tag{2.6}$$

where

$$\partial_i^R = \frac{\partial}{\partial t} + \lambda_i^R \frac{\partial}{\partial x}, \quad \partial_i^L = \frac{\partial}{\partial t} + \lambda_i^L \frac{\partial}{\partial x}, \tag{2.7}$$

and

$$F_i^R\left(x,t,r_i,s_i\right) = l_i^R F_i + \left(\partial_i^R l_i^R\right) U_i, \quad F_i^L\left(x,t,r_i,s_i\right) = l_i^L F_i + \left(\partial_i^L l_i^L\right) U_i. \tag{2.8}$$

(A differential operator acting on a vector means that it acts on each component of the vector.)

Let $(x,t) \in D_i$. We integrate the first equation of (2.6) along the right-going characteristic curve $x^R\left(t;\xi,\tau\right)$, which passes through (x,t) and reaches the left or lower boundary of D_i at (ξ,τ). It can be shown that for $(x,t) \in D_i^C \cup D_i^R$, $\tau = 0$, and for $(x,t) \in D_i^L$, $\xi = 0$. In the former case, we obtain

$$r_i\left(x,t\right) = r_i^I\left(\xi\right) + \int_0^t F_i^R\left(x_i^R\left(t';\xi,0\right),t',r_i,s_i\right)dt'. \tag{2.9}$$

In the latter case, we have

$$r_i\left(x,t\right) = r_i\left(0,\tau\right) + \int_\tau^t F_i^R\left(x_i^R\left(t';0,\tau\right),t',r_i,s_i\right)dt'. \tag{2.10}$$

Similarly, by integrating the second equation of (2.6) along the left-going characteristic curve $x_i^L\left(t;\xi,\tau\right)$ that passes through both (x,t) and (ξ,τ) (which is on either the right or lower boundary of D_i), the equations are

$$s_i\left(x,t\right) = s_i^I\left(\xi\right) + \int_0^t F_i^L\left(x_i^L\left(t';\xi,0\right),t',r_i,s_i\right)dt' \quad \text{if } (x,t) \in D_i^L \cup D_i^C \tag{2.11}$$

and

$$s_i\left(x,t\right) = s_i\left(1,\tau\right) + \int_\tau^t F_i^L\left(x_i^L\left(t';1,\tau\right),t',r_i,s_i\right)dt' \quad \text{if } (x,t) \in D_i^R. \tag{2.12}$$

These are the integral equations we need.

For any $\delta_i \le t_i$, we use D_{i,δ_i}^L, D_{i,δ_i}^C, and D_{i,δ_i}^R to denote the restrictions of D_i^L, D_i^C, and D_i^R, respectively, to the strip $\{0 \le t \le \delta_i\}$. We first extend the solution to a left region D_{i,δ_i}^L where δ_i is to be determined. For this, we need the boundary condition on the left end of the branch. The left end is either a source or a junction.

For a source with the pressure boundary condition (1.2), we define $\hat{s}_i = s_i/\varepsilon$, where $\varepsilon < 1$ is any constant. Using the first equation of (2.5) in the integral equations

(2.10) and (2.11),

(2.13)
$$\begin{pmatrix} r_i(x,t) \\ \hat{s}_i(x,t) \end{pmatrix} = \begin{pmatrix} 2u_i(0,\tau) P_i^B(\tau) + \varepsilon \hat{s}_i(0,\tau) + \int_\tau^t F_i^R\left(x_i^R(t';0,\tau), t', r_i, \varepsilon \hat{s}_i\right) dt' \\ \frac{1}{\varepsilon} s_i^I(\xi) + \frac{1}{\varepsilon} \int_0^t F_i^L\left(x_i^L(t';\xi,0), t', r_i, \varepsilon \hat{s}_i\right) dt' \end{pmatrix}.$$

This is a fixed point equation for $(r_i, \hat{s}_i)$ if we define the right-hand side as a mapping of an operator K on $(r_i, \hat{s}_i)$ in a bounded subset of $C(D^L_{i,\delta_i} \cup D^C_{i,\delta_i}, \mathbb{R}^2)$. In a standard approach, it can be shown that K is a contraction mapping if δ_i is sufficiently small. Hence, the fixed point exists and is unique. Therefore, the solution (r_i, s_i) can be uniquely extended to $D^L_{i,\delta_i} \cup D^C_{i,\delta_i}$.

For a source with the flow boundary condition (1.3), we define $\hat{s}_i = s_i/\varepsilon$, where $\varepsilon > 0$ and is so small that

$$\varepsilon \left| \frac{\lambda_i^L(0,\tau)}{\lambda_i^R(0,\tau)} \right| < 1, \quad \tau \in (0, t_i).$$

The fixed point equation is then

(2.14)
$$\begin{pmatrix} r_i(x,t) \\ \hat{s}_i(x,t) \end{pmatrix} = \begin{pmatrix} \frac{2a_i u_i(0,\tau)}{\lambda_i^R(0,\tau)} Q_i^B(\tau) + \frac{\lambda_i^L(0,\tau)}{\lambda_i^R(0,\tau)} \varepsilon \hat{s}_i(0,\tau) + \int_\tau^t F_i^R\left(x_i^R(t';0,\tau), t', r_i, \varepsilon \hat{s}_i\right) dt' \\ \frac{1}{\varepsilon} s_i^I(\xi) + \frac{1}{\varepsilon} \int_0^t F_i^L\left(x_i^L(t';\xi,0), t', r_i, \varepsilon \hat{s}_i\right) dt' \end{pmatrix}.$$

By a similar argument, the solution can again be uniquely extended.

If the left end of the branch is a junction, we shall extend the solution simultaneously on all the branches that are connected to the same junction. Thus, also extend the solution to D^R_{i,δ_i} on the branches incoming to the junction. Let $j_1, \ldots, j_\nu$ be the incoming and $j_{\nu+1}, \ldots, j_\mu$ the outgoing branches at the junction. Equations (1.4) and (2.5) give rise to a $2\mu \times \mu$ homogeneous system of linear equations for $r_i(1,\tau)$, $s_i(1,\tau)$, $i = j_1, \ldots, j_\nu$, and $r_i(0,\tau)$, $s_i(0,\tau)$, $i = j_{\nu+1}, \ldots, j_\mu$:

$$\frac{1}{u_1(1,\tau)} (r_1(1,\tau) - s_1(1,\tau)) - \frac{1}{u_i(1,\tau)} (r_i(1,\tau) - s_i(1,\tau)) = 0, \quad i = j_2, \ldots, j_\nu,$$

$$\frac{1}{u_1(1,\tau)} (r_1(1,\tau) - s_1(1,\tau)) - \frac{1}{u_i(0,\tau)} (r_i(0,\tau) - s_i(0,\tau)) = 0, \quad i = j_{\nu+1}, , \ldots, j_\mu,$$

$$\sum_{l=1}^{\nu} \frac{1}{u_{j_l} a_{j_l}} \left(\lambda_{j_l}^R r_{j_l} - \lambda_{j_l}^L s_{j_l}\right)(1,\tau) - \sum_{l'=\nu+1}^{\mu} \frac{1}{u_{j_{l'}} a_{j_{l'}}} \left(\lambda_{j_{l'}}^R r_{j_{l'}} - \lambda_{j_{l'}}^L s_{j_{l'}}\right)(0,\tau) = 0.$$

This system can be solved for $s_{j_1}(1,\tau), \ldots, s_{j_\nu}(1,\tau)$, $r_{j_{\nu+1}}(0,\tau), \ldots, r_{j_\mu}(0,\tau)$ because the coefficient matrix

$$\begin{pmatrix} -\frac{1}{u_{j_1}(1,\tau)} & \frac{1}{u_{j_2}(1,\tau)} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ -\frac{1}{u_{j_1}(1,\tau)} & 0 & \cdots & -\frac{1}{u_{j_\mu}(0,\tau)} \\ -\frac{\lambda_{j_1}^L(1,\tau)}{u_{j_1} a_{j_1}(1,\tau)} & -\frac{\lambda_{j_2}^L(1,\tau)}{u_{j_2} a_{j_2}(1,\tau)} & \cdots & -\frac{\lambda_{j_\mu}^R(0,\tau)}{u_{j_\mu} a_{j_\mu}(0,\tau)} \end{pmatrix}$$

has the determinant

$$\frac{(-1)^{\nu+1}}{\prod_{l=1}^{\nu} u_{j_l}(1,\tau)\prod_{l'=\nu+1}^{\mu} u_{j_{l'}}(0,\tau)}\left(-\sum_{l=1}^{\nu}\frac{\lambda_{j_l}^{L}(1,\tau)}{a_{j_l}(1,\tau)}+\sum_{l'=\nu+1}^{\mu}\frac{\lambda_{j_{l'}}^{R}(0,\tau)}{a_{j_{l'}}(0,\tau)}\right).$$

Since $\lambda_i^L < 0 < \lambda_i^R$ at the junction, the determinant is not zero. Hence, we can express $s_{j_1}(1,\tau),\dots,s_{j_\nu}(1,\tau)$, $r_{j_{\nu+1}}(0,\tau),\dots,r_{j_\mu}(0,\tau)$ in terms of other unknowns as

$$s_i(1,\tau)=\sum_{l=1}^{\nu} m_{j_l}^{i}(\tau)\, r_{j_l}(1,\tau)+\sum_{l'=\nu+1}^{\mu} m_{j_{l'}}^{i}(\tau)\, s_{j_{l'}}(0,\tau),\quad i=j_1,\dots,j_\nu,$$

$$r_i(0,\tau)=\sum_{l=1}^{\nu} n_{j_l}^{i}(\tau)\, r_{j_l}(1,\tau)+\sum_{l'=\nu+1}^{\mu} n_{j_{l'}}^{i}(\tau)\, s_{j_{l'}}(0,\tau),\quad i=j_{\nu+1},\dots,j_\mu,$$

for some functions m_j^i, n_j^i. Choose an $\varepsilon>0$ such that

$$\varepsilon\max\left\{\sum_{l=1}^{\mu}\left|m_{j_l}^{i}(\tau)\right|,\sum_{l=1}^{\mu}\left|n_{j_l}^{i}(\tau)\right|\right\}<1,\quad i=j_1,\dots,j_\mu,\ \tau\in[0,t_i],$$

and introduce

$$\hat r_{j_l}=\frac{r_{j_l}}{\varepsilon},\quad \hat s_{j_{l'}}=\frac{s_{j_{l'}}}{\varepsilon},\quad l=1,\dots,\nu,\ l'=\nu+1,\dots,\mu.$$

Then, in view of (2.9)–(2.12), the integral equations for the 2μ unknowns $\hat r_{j_l}$, s_{j_l}, $r_{j_{l'}}$, $\hat s_{j_{l'}}$, $l=1,\dots,\nu$, $l'=\nu+1,\dots,\mu$, constitute a fixed point equation, $w=Kw$, where

$$w=\left(\hat r_{j_1},\dots,\hat r_{j_\nu},s_{j_1},\dots,s_{j_\nu},r_{j_{\nu+1}},\dots,r_{j_\mu},\hat s_{j_{\nu+1}},\dots,\hat s_{j_\mu}\right) \tag{2.15}$$

and

$$\begin{aligned}Kw=\Bigg(&\frac{1}{\varepsilon}r_{j_1}^{I}(\xi_{j_1})+\frac{1}{\varepsilon}\int_0^t F_{j_1}^{R}\left(x_{j_1}^{R},t',\varepsilon\hat r_{j_1},s_{j_1}\right)dt',\dots,\\ &\varepsilon\left(\sum_{k=1}^{\nu} m_{j_k}^{1}\hat r_{j_k}(1,\tau)+\sum_{k'=\nu+1}^{\mu} m_{j_{k'}}^{1}\hat s_{j_{k'}}(0,\tau)\right)\\ &+\int_\tau^t F_{j_1}^{L}\left(x_{j_1}^{L},t',\varepsilon\hat r_{j_1},s_{j_1}\right)dt',\dots,\\ &\varepsilon\left(\sum_{k=1}^{\nu} n_{j_k}^{1}\hat r_{j_k}(1,\tau)+\sum_{k'=\nu+1}^{\mu} n_{j_{k'}}^{1}\hat s_{j_{k'}}(1,\tau)\right)\\ &+\int_\tau^t F_{j_{\nu+1}}^{R}\left(x_{j_{\nu+1}}^{R},t',r_{j_{\nu+1}},\varepsilon\hat s_{j_{\nu+1}}\right)dt',\dots,\\ &\frac{1}{\varepsilon}s_{j_{\nu+1}}^{I}\left(\xi_{j_{\nu+1}}\right)+\frac{1}{\varepsilon}\int_0^t F_{j_{\nu+1}}^{L}\left(x_{j_{\nu+1}}^{L},t',r_{j_{\nu+1}},\varepsilon\hat s_{j_{\nu+1}}\right)dt',\dots\Bigg).\end{aligned} \tag{2.16}$$

It can be shown by a standard argument that K is a contraction mapping in the space

$$X_j=:\prod_{l=1}^{\nu} C\left(D_{j_l,\delta_j}^{C}\cup D_{j_l,\delta_j}^{R},\mathbb{R}^2\right)\times\prod_{l=\nu+1}^{\mu} C\left(D_{j_l,\delta_j}^{L}\cup D_{j_l,\delta_j}^{L},\mathbb{R}^2\right)$$

if δ_j is sufficiently small. Hence, it has a unique fixed point in X_j. This extends the solution (r_i, s_i) for the neighboring branches of the junction.

We now extend the solution (r_i, s_i) to a right region D^R_{i,δ_i}. This has already been considered if the right end is a junction. Thus, only terminal ends need to be discussed. For the boundary condition of either (1.5) or (1.6) type, the argument is similar to the above discussion about source ends. We only sketch the steps in these two cases. The boundary condition of (1.7) type, however, requires more effort.

If condition (1.5) is assumed, then, by (2.5),

$$s_i(1,t) = r_i(1,t) - 2u_i P_i^B(t).$$

Let $\hat{r}_i = r_i/\varepsilon$ with $0 < \varepsilon < 1$. Then, the fixed point equation for $(\hat{r}_i, s_i)$ has the form

(2.17)
$$\begin{pmatrix} \hat{r}_i(x,t) \\ s_i(x,t) \end{pmatrix} = \begin{pmatrix} \frac{1}{\varepsilon} r_i^I(\xi) + \frac{1}{\varepsilon}\int_0^t F_i^R\left(t', x_i^R(t';\xi,0), \varepsilon\hat{r}_i, s_i\right) dt' \\ \varepsilon\hat{r}_i(1,\tau) - 2u_i(1,\tau) P_i^B(\tau) + \int_\tau^t F_i^L\left(t', x_i^L(t';1,\tau), \varepsilon\hat{r}_i, s_i\right) dt' \end{pmatrix}.$$

As before, the mapping defined by the right-hand side is contractive if δ_i is small enough. Hence, the solution is uniquely extended into D^R_{i,δ_i}. If condition (1.6) is assumed, we find again from (2.5) that

$$\lambda_i^L s_i(1,t) = \lambda_i^R r_i(1,t) - 2u_i(1,t) a_i(1,t) Q_i^B(t).$$

Since $\lambda_i^L(1,t) < 0$, the equation can be uniquely solved for s_i. Choose $\varepsilon > 0$ sufficiently small such that

$$\varepsilon\left|\frac{\lambda_i^R(1,\tau)}{\lambda_i^L(1,\tau)}\right| < 1 \quad \text{for } \tau \in [0,t_i],$$

and let $\hat{r}_i = r_i/\varepsilon$. The fixed point equation for $(\hat{r}_i, s_i)$ has the form

(2.18)
$$\begin{pmatrix} \hat{r}_i(x,t) \\ s_i(x,t) \end{pmatrix} = \begin{pmatrix} \frac{1}{\varepsilon} r_i^I(\xi) + \frac{1}{\varepsilon}\int_0^t F_i^R\left(x_i^R(t';\xi,0), t', \varepsilon\hat{r}_i, s_i\right) dt' \\ \frac{\lambda_i^R(1,\tau)}{\lambda_i^L(1,\tau)}\varepsilon\hat{r}_i(1,\tau) - \frac{2a_i u_i(1,\tau)}{\lambda_i^L(1,\tau)} Q_i^B(\tau) + \int_\tau^t F_i^L\left(x_i^L(t';1,\tau), t', \varepsilon\hat{r}_i, s_i\right) dt' \end{pmatrix}.$$

Again, the mapping is contractive in a bounded subset of $C(D^C_{i,\delta_i} \cup D^R_{i,\delta_i}, \mathbb{R}^2)$ if δ_i is sufficiently small. Thus, the solution is uniquely extended to D^R_{i,δ_i}.

In the case where the boundary condition (1.7) is assumed, we integrate it with respect to t to obtain

$$(P_i - \eta_i Q_i)(1,t) = \left(P_i^I - \eta_i Q_i^I\right)(1) + \int_0^t \left(W_i^B(t') - \delta_i P_i(1,t') + \varepsilon_i Q_i(1,t')\right) dt'.$$

Substituting (2.5) into this equation, we can write

$$\begin{aligned} &m_i(t) r_i(1,t) - n_i(t) s_i(1,t) \\ &\quad = m_i(0) r_i^I(1) - n_i(0) s_i^I(1) + \int_0^t H_i(t', r_i(1,t'), s_i(1,t'))\, dt', \end{aligned}$$

where

$$m_i(t) = \frac{a_i(1,t) - \eta_i \lambda_i^R(1,t)}{2a_i u_i(1,t)}, \quad n_i(t) = \frac{-a_i(1,t) + \eta_i \lambda_i^L(1,t)}{2a_i u_i(1,t)}$$

and

$$H_i(t,r,s) = W_i^B(t) + \frac{\varepsilon_i \lambda_i^R(1,t) - \delta_i a_i(1,t)}{2a_i u_i(1,t)} r - \frac{\varepsilon_i \lambda_i^L(1,t) - \delta_i a_i(1,t)}{2a_i u_i(1,t)} s.$$

Since $a_i > 0$, $u_i > 0$, $\eta_i > 0$, and $\lambda_i^L(1,t) < 0$, it follows that $n_i(t) < 0$. Hence, there exists $\varepsilon > 0$ such that

$$\varepsilon \left| \frac{m_i(\tau)}{n_i(\tau)} \right| < 1 \quad \text{for } \tau \in [0, t_i].$$

Let $\hat{r}_i = r_i/\varepsilon$. The integral equations for $\hat{r}_i$ and s_i then have the form

(2.19)

$$\begin{aligned}
\hat{r}_i(x,t) &= \frac{1}{\varepsilon} r_i^I(\xi) + \frac{1}{\varepsilon} \int_0^t F_i^R\left(x_i^R(t';\xi,0), t', \varepsilon \hat{r}_i, s_i\right) dt', \\
s_i(x,t) &= \varepsilon \frac{m_i(\tau)}{n_i(\tau)} \hat{r}_i(1,\tau) - \frac{1}{n_i(\tau)} \left(M_i + \int_0^t H_i\left(t', \varepsilon \hat{r}_i(1,t'), s_i(1,t')\right) dt' \right) \\
&\qquad + \int_\tau^t F_i^L\left(x_i^L(t';1,\tau), t', \varepsilon \hat{r}_i, s_i\right) dt',
\end{aligned}$$

where $M_i = m_i(0) r_i^I(1) - n_i(0) s_i^I(1)$ is a constant. The extension of the solution to D_{i,δ_i}^R is thus guaranteed.

Finally, if we let δ be the minimum of all δ_i occurring above, we see that $\delta > 0$, and the solution exists and is unique in $(x,t) \in D_\delta =: [0,1] \times [0,\delta]$. Observe that δ depends only on the bounds of the system functions (e.g., a_i), the initial and boundary functions (e.g., P_i^I), and their first-order derivatives in $D = [0,1] \times [0,T]$. Hence, it is independent of t, and we can extend the solution successively in the time intervals $[0,\delta]$, $[\delta, 2\delta]$, etc. In this way, the solution is obtained in D in a finite number of steps. □

It can be seen from the above proof that the linear system need not have a solution if condition (2.3) fails at any end point of a branch. In the quasilinear case, since a_i and b_i depend on the unknowns P_i and Q_i, this condition may fail at some time. Therefore the solution does not generally exist for all time.

We next derive an estimate of the deviation of the solution in term of the deviations of the initial, boundary, and forcing functions. This estimate is needed in the next section. For any vector function $v = (v_1, \ldots, v_k)$ defined in $C(X; \mathbb{R}^k)$ we use $|v|_{C(X)}$ to denote the norm $\max_i\{|v_i|_{C(X)}\}$, where X represents a closed subset of either $\mathbb{R}$ or $\mathbb{R}^2$ and $|v_i|_{C(X)}$ is the maximum norm.

LEMMA 2.2. *Let $U = (P,Q)$ and $\tilde{U} = (\tilde{P}, \tilde{Q})$ be two solutions of the linear problem* (1.9) *with different initial, boundary, and forcing functions. Suppose the conditions of Theorem* 2.1 *hold for both solutions. Then there exists a constant $M > 0$, independent of initial, boundary, and forcing functions, such that*

$$\begin{aligned}
&\left| U - \tilde{U} \right|_{C(D_\delta)} \\
&\le M \left(\left| P^I - \tilde{P}^I \right|_{C[0,1]} + \left| Q^I - \tilde{Q}^I \right|_{C[0,1]} + \left| P^B - \tilde{P}^B \right|_{C[0,\delta]} + \left| Q^B - \tilde{Q}^B \right|_{C[0,\delta]} \right. \\
&\qquad \left. + \delta \left| f - \tilde{f} \right|_{C(D_\delta)} + \delta \left| g - \tilde{g} \right|_{C(D_\delta)} + \delta \left| W - \tilde{W} \right|_{C[0,\delta]} \right)
\end{aligned} \tag{2.20}$$

Proof. We need prove (2.20) only for a $\delta \leq \min_i \{\delta_i\}$, where δ_i represents the constants occurring in the proof of Theorem 2.1. This is because for larger δ we can divide the interval $[0, \delta]$ into subintervals, each having a length less than $\min_i \{\delta_i\}$, and apply (2.20) in each subinterval. We can then take the maximum on each side of the inequalities to derive the inequality in $[0, \delta]$. In what follows, D_δ^C, D_δ^L, and D_δ^R are the restrictions of D_i^C, D_i^L, and D_i^R, respectively, to the strip $\{0 \leq t \leq \delta\}$.

By linearity, $U - \tilde{U}$ is the solution of the system with the initial, boundary, and forcing functions $P_i^I - \tilde{P}_i^I$, $Q_i^I - \tilde{Q}_i^I$, $P_i^B - \tilde{P}_i^B$, $Q_i^B - \tilde{Q}_i^B$, $W_i^B - \tilde{W}_i^B$, $f_i - \tilde{f}_i$, and $g_i - \tilde{g}_i$. Let r_i, $\hat{r}_i$, s_i, $\hat{s}_i$ be defined as in the proof of Theorem 2.1, corresponding to $U - \tilde{U}$. We show that these quantities have upper bounds in the form of the right-hand side of (2.20) in D_δ^C, D_δ^L, and D_δ^R.

In D_δ^C, (2.9) and (2.11) hold. Notice that the functions F_i^R and F_i^L are linear in r_i and s_i. Hence, there exists a constant M (we will use M generically for any constant bounds that are independent of solutions) such that

$$R_i^C(t) + S_i^C(t) \leq \left|r_i^I\right|_{C[0,1]} + \left|s_i^I\right|_{C[0,1]} + M \int_0^t \left(R_i^C(t') + S_i^C(t') + T_i^C(t')\right) dt',$$

where

$$R_i^C(t) = \sup_{\{x:(x,t)\in D_\delta^C\}} |r_i(x,t)|, \quad S_i^C(t) = \sup_{\{x:(x,t)\in D_\delta^C\}} |s_i(x,t)|, \tag{2.21}$$

and

$$T_i^C(t) = \sup_{\{x:(x,t)\in D_\delta^C\}} \left(\left|f_i(x,t) - \tilde{f}_i(x,t)\right| + |g_i(x,t) - \tilde{g}_i(x,t)|\right). \tag{2.22}$$

Hence, by Gronwall's inequality (see, e.g., [16, p. 327]),

$$R_i^C(t) + S_i^C(t) \leq M\left(\left|r_i^I\right|_{C[0,1]} + \left|s_i^I\right|_{C[0,1]} + \delta \sup_{t\in(0,\delta)} T_i^C(t)\right)$$

for $t \in [0, \delta]$. This proves that R_i^C and S_i^C have upper bounds in the form of the right-hand side of (2.20).

In D_δ^L, if the left end is a source, we use either (2.13) or (2.14) according to the type of the boundary condition. The resulting inequality has the form

$$\begin{aligned} &R_i^L(t) + \hat{S}_i^L(t) \\ &\quad \leq \sigma \hat{S}_i^L(t) + M\left(\left|s_i^I\right|_{C[0,1]} + \left|\xi_i^B\right|_{C[0,\delta]} + \int_0^t \left(R_i^L(\tau) + \hat{S}_i^L(\tau) + T_i^L(\tau)\right) d\tau\right), \end{aligned}$$

where ξ_i^B is either P_i^B or Q_i^B, depending on the boundary condition, and R_i^L, $\hat{S}_i^L$, and T_i^L are defined in the same way as in (2.21)–(2.22), with D_δ^C substituted by $D_\delta^L \cup D_\delta^C$, and $\sigma > 0$ is a positive constant such that $\sigma = \varepsilon$ if the boundary condition is (1.2) and

$$\sigma = \varepsilon \sup_{t\in(0,\delta)} \left|\frac{\lambda_i^L(0,t)}{\lambda_i^R(0,t)}\right| < 1$$

if the boundary condition is (1.3). Replacing M by $(1-\sigma)M$, we can write

$$R_i^L(t) + \hat{S}_i^L(t) \leq M\left(\left|s_i^I\right|_{C[0,1]} + \left|\xi_i^B\right|_{C[0,\delta]} + \int_0^t \left(R_i^L(\tau) + \hat{S}_i^L(\tau) + T_i^L(\tau)\right) d\tau\right).$$

Hence, by Gronwall's inequality,

$$R_i^L(t) + \hat{S}_i^L(t) \le M\left(\left|s_i^I\right|_{C[0,1]} + \left|\xi_i^B\right|_{C[0,\delta]} + \delta \max_{t\in(0,\delta)} T_i^L(t)\right).$$

This proves that both $R_i^L(t)$ and $S_i^L(t)$ have upper bounds in the form of the right-hand side of (2.20).

If the left end is a junction, the solutions on the branches $j_1, \ldots, j_\mu$ connecting to the junction constitute fixed points of the operator K, which is defined in (2.16). Let

$$W(t) = \sum_{l=1}^{\nu}\left(\hat{R}_{j_l}^R(t) + S_{j_l}^R(t)\right) + \sum_{l'=\nu+1}^{\mu}\left(R_{j_{l'}}^L(t) + \hat{S}_{j_{l'}}^L(t)\right),$$

where $\hat{R}_i^R$ and S_i^R are defined as in (2.21) with D_δ^C substituted by $D_\delta^C \cup D_\delta^R$. Then, from $w = Kw$, we can deduce

$$\begin{aligned} W(t) \le{}& \sigma\left(\sum_{l=1}^{\nu}\hat{R}_{j_l}^R(t) + \sum_{l'=\nu+1}^{\mu}\hat{S}_{j_{l'}}^L(t)\right) \\ &+ M\left(\sum_{l=1}^{\nu}\left|r_{j_l}^I\right|_{C[0,1]} + \sum_{l'=\nu}^{\mu}\left|s_{j_{l'}}^I\right|_{C[0,1]} + \int_0^t (W(\tau) + T(\tau))\,d\tau\right), \end{aligned}$$

where

$$T(\tau) = \sum_{l=1}^{\nu} T_{j_l}^R(\tau) + \sum_{l'=\nu+1}^{\mu} T_{j_{l'}}^L(\tau)$$

and $T_i^R(t)$ is defined as in (2.22) with D_δ^C substituted by $D_\delta^C \cup D_\delta^R$. Replacing M by $(1-\sigma)M$, we obtain

$$W(t) \le M\left(\sum_{l=1}^{\nu}\left|r_{j_l}^I\right|_{C[0,1]} + \sum_{l'=\nu}^{\mu}\left|s_{j_{l'}}^I\right|_{C[0,1]} + \int_0^t (W(\tau) + T(\tau))\,d\tau\right).$$

Hence, by Gronwall's inequality,

$$W(t) \le M\left(\sum_{l=1}^{\nu}\left|r_{j_l}^I\right|_{C[0,1]} + \sum_{l'=\nu}^{\mu}\left|s_{j_{l'}}^I\right|_{C[0,1]} + \delta \max_{t\in(0,\delta)} T(t)\right).$$

This leads to an upper bound in the form of the right-hand side of (2.20) for $R_i^R(t)$, $S_i^R(t)$, $i = j_1, \ldots, j_\nu$, and $R_i^L(t)$, $S_i^L(t)$, $i = j_{\nu+1}, \ldots, j_\mu$.

The only remaining case is when the right end of the branch is a terminal. The fixed point equation to be used is either (2.17), (2.18), or (2.19), depending on the type of the boundary condition. In the former two cases, the treatment is similar to that for sources. Hence, we consider only the third case. From (2.19), we obtain

$$\begin{aligned} &\hat{R}_i^R(t) + S_i^R(t) \\ &\quad \le \sigma\hat{R}_i^R(t) + M\left(\left|r_i^I\right|_{C[0,1]} + \int_0^t \left(\hat{R}_i^R(t') + S_i^R(t') + \left|W_i^B(t')\right| + T_i^R(t')\right)dt'\right), \end{aligned}$$

where

$$\sigma = \varepsilon \max_{t\in[0,\delta]} \left| \frac{m_i(t)}{n_i(t)} \right| < 1.$$

Hence, by Gronwall's inequality,

$$\hat{R}_i^R(t) + S_i^R(t) \le M \left(\left| r_i^I \right|_{C[0,1]} + \delta \max_{t\in(0,\delta)} T_i^R(t) + \delta \max_{t\in(0,\delta)} \left| W_i^B(t) \right| \right),$$

which gives the desired upper bounds of R_i^R and S_i^R.

We have, thus, obtained an upper bound in the form of the right-hand side of (2.20) for the quantities $|r_i - \tilde{r}_i|_{C(D_\delta)}$ and $|s_i - s_i|_{C(D_\delta)}$. The conclusion of the lemma follows now from (2.5). □

3. The quasilinear system. In this section, we study the quasilinear system where the coefficients a_i, b_i, c_i, f_i, and g_i depend on both (x,t) and (P_i, Q_i). Under certain conditions, we show that the system has a unique local solution. We then present a theorem on the continuity of dependence of the solution on initial, boundary, and forcing functions.

The basic idea in the proof of the existence of a solution is to construct an iterative sequence. Substituting any vector function (p_i, q_i) for (P_i, Q_i) in a_i, etc., the system becomes linear. Thus, we can use Theorem 2.1 to get a solution (P_i, Q_i). This defines a mapping S from $u =: (p_i, q_i)$ to $U =: (P_i, Q_i)$, and the solution for the quasilinear system is a fixed point of S. If there is a subset of a Banach space that is invariant under S, then we can construct a sequence

$$u_{k+1} = Su_k, \quad k = 0, 1, \ldots .$$

In the case where the limit exists and is unique, it gives rise to fixed point of S. This is our approach in this section.

In this approach, conditions (2.1) and (2.3) are repeatedly used. One might want to impose them for all the values of the variables. This would give the existence and uniqueness for the global solution, as in the case of the linear system. However, such a requirement is so restrictive that even the original system (1.1) cannot meet it. Therefore, we will impose them only for $t = 0$, and obtain the local solution for the quasilinear system.

THEOREM 3.1. *Assume that the initial and boundary functions P_i^I, Q_i^I, P_i^B, Q_i^B, W_i^B and the system functions a_i, b_i, c_i, f_i, g_i all have continuous first-order derivatives with respect to each variable. Suppose that $a_i > 0$ for all the values of its arguments, and that conditions* (2.1) *and* (2.3) *hold at $t = 0$. Suppose also that the initial functions P_i^I, Q_i^I satisfy any relevant boundary conditions at $t = 0$. Then, for some $\delta > 0$, there is a unique solution for $0 \le t < \delta$ to the quasilinear system* (1.8) *with the initial and boundary conditions described in section* 1.

Proof. We first consider the simpler case where $U^I =: (P^I, Q^I) = 0$. Let $v = \{v_i\}$, $v_i = (p_i, q_i)$ be a family of vector functions (not necessarily constituting a solution) that satisfy the initial and boundary conditions. Substitute v for U in the functions a_i, b_i, c_i, f_i, and g_i. Then, the system becomes linear, and we can invoke Theorem 2.1 to obtain a solution U to the linear system. This defines a mapping $S : v \mapsto U$. A solution of the quasilinear system is then a fixed point of S. We will choose a subset X_{δ,M_0} of a Banach space such that (1) $SX_{\delta,M_0} \subset X_{\delta,M_0}$ and (2) S is contracting in X_{δ,M_0}. For any scalar or vector function $f \in C^k(D_\delta)$, let $|f|_{k,\delta}$ denote the maximum norm of all

the kth-order derivatives of f in D_δ. (If f is a vector function, $|f|_{k,\delta} = \max_i\{|f_i|_{k,\delta}\}$.) Let $C_B(D_\delta, \mathbb{R}^{2n})$ denote the subset of the vector-valued functions in $C(D_\delta, \mathbb{R}^{2n})$ that satisfy the initial and boundary conditions. We seek X_{δ,M_0} in the form

$$X_{\delta,M_0} = \left\{ v \in C_B\left(D_\delta, \mathbb{R}^{2n}\right) : \ |v|_{0,\delta} \le M_0, |v|_{1,\delta} \le M_1 \right\}, \tag{3.1}$$

where M_0 is an arbitrary positive constant and M_1 is a constant to be determined. Note that, by the vanishing initial condition, for any M_1, $|U|_{1,\delta} \le M_1$ implies $|U|_{0,\delta} \le M_1\delta$. Hence, for any M_0, we can ensure $|U|_{0,\delta} \le M_0$ by reducing δ. It remains, therefore, only to show that for M_1 sufficiently large and δ sufficiently small, $|v|_{1,\delta} \le M_1$ implies $|Sv|_{1,\delta} \le M_1$. Throughout this proof, we use M to represent any positive constant that may depend on M_1 but is otherwise independent of v and δ, and use $\tilde{M}$ for any constant that is independent of M_1, v, and δ. The values of M or $\tilde{M}$ in different occurrences need not be equal.

Let $U = Sv$, and let r_i and s_i be defined by (2.4). On each branch, we show that

$$\max\left\{\left|(r_i)_x\right|, \left|(s_i)_x\right|\right\} \le M_1 \tag{3.2}$$

and

$$\max\left\{\left|(r_i)_t\right|, \left|(s_i)_t\right|\right\} \le M_1 \tag{3.3}$$

in D_δ^C, D_δ^L, and D_δ^R if M_1 is large and δ is small. (Recall that D_δ^C, etc., are the intersections $D_i^C \cap D_\delta$, etc., respectively.) In fact, only (3.2) needs to be shown. To see this, first observe that the vanishing initial condition and the compatibility of the initial and boundary conditions gives

$$\max_i \left\{ \left|P_i^B\right|_{C[0,\delta]}, \left|Q_i^B\right|_{C[0,\delta]} \right\} \le M\delta.$$

Hence, we obtain from Lemma 2.2 with $\tilde{U} = 0$ that

$$|U|_{0,\delta} \le M\delta. \tag{3.4}$$

From (2.6) and (2.8), there are constants $\tilde{M}$ and M such that

$$\begin{aligned} \left|\partial_i^R r_i\right| &\le \left|l_i^R F_i\right| + \left|\partial_i^R l_i^R\right| |U_i| \le \tilde{M} + M\delta, \\ \left|\partial_i^L s_i\right| &\le \left|l_i^L F_i\right| + \left|\partial_i^L l_i^L\right| |U_i| \le \tilde{M} + M\delta \end{aligned} \tag{3.5}$$

for each $i = 1, \ldots, n$. Hence, (3.3) follows from (3.2), (3.5), and the definition of ∂_i^L and ∂_i^R in (2.7). We also note that (2.5) and (3.5) imply

$$\left|\partial_i^R U_i\right|_{0,\delta} \le \tilde{M} + M\delta, \quad \left|\partial_i^R U_i\right|_{0,\delta} \le \tilde{M} + M\delta \tag{3.6}$$

for all i. This will be used later.

We first consider the middle region D_δ^C, where the solution (r_i, s_i) satisfies the integral equations (2.9) and (2.11) with $r_i^I = s_i^I = 0$. Differentiating the equations with respect to x, we have

$$\begin{aligned} (r_i)_x &= \left(l_i^R\right)_x U_i(x,t) + \int_0^t \left[\left(l_i^R F_i\right)_x + \left(\partial_i^R l_i^R\right)(U_i)_x - \left(l_i^R\right)_x \left(\partial_i^R U_i\right)\right] \left(x_i^R\right)_x dt, \\ (s_i)_x &= \left(l_i^L\right)_x U_i(x,t) + \int_0^t \left[\left(l_i^L F_i\right)_x + \left(\partial_i^L l_i^L\right)(U_i)_x - \left(l_i^L\right)_x \left(\partial_i^L U_i\right)\right] \left(x_i^L\right)_x dt. \end{aligned} \tag{3.7}$$

Here, we used an identity from [10, p. 469]:

$$\begin{aligned}\frac{d}{d\xi}\int_a^b f\left(x\left(t\right),t\right)Dg\left(x\left(t\right),t\right)dt&\\ =f\left(x\left(b\right),b\right)g_x\left(x\left(b\right),b\right)x_\xi\left(b\right)-f\left(x\left(a\right),a\right)g_x\left(x\left(a\right),a\right)x_\xi\left(a\right)&\\ +\int_a^b\left[f_x\left(x\left(t\right),t\right)Dg\left(x\left(t\right),t\right)-Df\left(x\left(t\right),t\right)g_x\left(x\left(t\right),t\right)\right]x_\xi\left(t\right)dt,&\end{aligned}\tag{3.8}$$

where $x\left(t\right)$ is a function such that $x\left(b\right)=\xi$ and $D=\frac{\partial}{\partial t}+x'\left(t\right)\frac{\partial}{\partial x}$. (Here and below, $x'\left(t\right)=dx/dt$.) Let

$$R_i^C\left(t\right)=\sup_{\left\{x:(x,t)\in D_\delta^C\right\}}\left\{\left|\left(r_i\right)_x\left(x,t\right)\right|\right\},\quad S_i^C\left(t\right)=\sup_{\left\{x:(x,t)\in D_\delta^C\right\}}\left\{\left|\left(s_i\right)_x\left(x,t\right)\right|\right\}.\tag{3.9}$$

From (3.4), (3.6), and (3.7), we derive

$$R_i^C\left(t\right)+S_i^C\left(t\right)\le M\delta+M\int_0^t\left(1+R_i^C\left(t'\right)+S_i^C\left(t'\right)\right)dt'$$

for $t\in[0,\delta]$. Hence, Gronwall's inequality gives

$$\left|\left(r_i\right)_x\right|\le M\delta e^{M\delta},\quad \left|\left(s_i\right)_x\right|\le M\delta e^{M\delta}$$

in D_δ^C. This proves (3.2) in D_δ^C if M_1 is sufficiently large and δ is sufficiently small.

We next consider the left triangular region D_δ^L in the case where the branch is connected to a source. Let $\hat{s}_i=s_i/\varepsilon$ for any $\varepsilon>0$. Then, the pair $(r_i,\hat{s}_i)$ satisfies the fixed point equations of either (2.13) or (2.14), depending on the type of the boundary condition. Differentiating the equations with respect to x and using a slightly modified version of (3.8), we have

$$\begin{aligned}\left(r_i\right)_x&=\left(\zeta_i-l_i^RF_i-\left(\partial_i^Rl_i^R\right)U_i\right)\left(0,\tau\right)\tau_x+\left(l_i^R\right)_xU_i\left(x,t\right)-\left(l_i^R\right)_xU_i\left(x_i^R\right)_x\left(0,\tau\right)\\ &\quad+\int_\tau^t\left[\left(l_i^RF_i\right)_x+\left(\partial_i^Rl_i^R\right)\left(U_i\right)_x-\left(l_i^R\right)_x\left(\partial_i^RU_i\right)\right]\left(x_i^R\right)_xdt,\\ \left(\hat{s}_i\right)_x&=\frac{1}{\varepsilon}\left(l_i^L\right)_xU_i\left(t,x\right)+\frac{1}{\varepsilon}\int_0^t\left[\left(l_i^LF_i\right)_x+\left(\partial_i^Ll_i^L\right)\left(U_i\right)_x-\left(l_i^L\right)_x\left(\partial_i^LU_i\right)\right]\left(x_i^L\right)_xdt,\end{aligned}\tag{3.10}$$

where

$$\zeta_i=2\left(u_iP_i^B\right)_t+\varepsilon\left(\hat{s}_i\right)_t$$

if the boundary condition is given by (1.2), and

$$\zeta_i=2\left(\frac{a_iu_i}{\lambda_i^R}Q_i^B\right)_t+\varepsilon\left(\frac{\lambda_i^L}{\lambda_i^R}\right)_t\hat{s}_i+\varepsilon\left(\frac{\lambda_i^L}{\lambda_i^R}\right)\left(\hat{s}_i\right)_t$$

if the boundary condition is given by (1.3). (Modification of (3.8) is caused by the lower limit of the integral in the first equation of (3.10), which also depends on x.) This equation is valid for any ε. Thus, we may choose ε so small that

$$\sigma=:\varepsilon\left|\lambda_i^L\tau_x\left(0,t\right)\right|\max\left\{1,\left|\left(\frac{\lambda_i^L\left(0,t\right)}{\lambda_i^R\left(0,t\right)}\right)\right|\right\}<1,\quad t\in\left[0,\delta\right].$$

To proceed further, we need an estimate of $|\tau_x(0,t)|$. Observe that $\tau(x)$ satisfies the equation

$$x_i^R(\tau; x, t) = 0,$$

where $x_i^R(\tau; x, t)$ is the solution of the initial value problem

$$\frac{dx_i^R}{ds} = \lambda_i^R\left(x_i^R, s\right), \quad x_i^R(t; x, t) = x.$$

By differentiation,

$$\lambda_i^R(0, \tau(x))\,\tau_x + \left.\frac{\partial x_i^R}{\partial x}\right|_{(\tau(x);x,t)} = 0. \tag{3.11}$$

Let $w_i = \partial x_i^R/\partial x$. Then w_i is the solution of the linear equation

$$\frac{dw_i}{ds} = \left(\lambda_i^R\right)_x\left(x_i^R(s; x, t), s\right) w_i, \quad w_i(t) = 1.$$

Solving the equation,

$$w_i(s) = \exp\left(\int_t^s \left(\lambda_i^R\right)_x\left(x_i^R(s'; x, t), s'\right) ds'\right).$$

Returning to (3.11), we find

$$\tau_x = \frac{-1}{\lambda_i^R(0, \tau(x))} \exp\left(\int_t^{\tau(x)} \left(\lambda_i^R\right)_x\left(x_i^R(s'; x, t), s'\right) ds'\right).$$

Observe that $0 < \tau(x) < t \le \delta$ and the integrand is bounded. Hence,

$$|\tau_x| \le \tilde{M} e^{M\delta}. \tag{3.12}$$

This is the estimate we need. By this estimate, for any M_1, we can choose δ small enough such that the constants σ and ε are independent of M_1. Let $R_i^L(t)$ and $\hat{S}_i^L(t)$ be defined as in (3.9) except that s_i is substituted by $\hat{s}_i$ and D_δ^C is substituted by $D_\delta^L \cup D_\delta^C$. We derive from (3.10) and the identity

$$(\hat{s}_i)_t = \partial_i^L \hat{s}_i - \lambda_i^L (\hat{s}_i)_x$$

that

$$R_i^L(t) + \hat{S}_i^L(t) \le \sigma \hat{S}_i^L(t) + \tilde{M} + M\delta + M\int_0^t \left(1 + R_i^L(t') + \hat{S}_i^L(t')\right) dt'.$$

Replacing M and $\tilde{M}$ by $M(1-\sigma)$ and $\tilde{M}(1-\sigma)$, respectively, and applying Gronwall's inequality, we obtain

$$R_i^L(t) + \hat{S}_i^L(t) \le \left(\tilde{M} + M\delta\right) e^{M\delta}.$$

Since $|s_i| \le |\hat{s}_i|$, it follows that

$$\max\left\{|(r_i)_x|, |(s_i)_x|\right\} \le \left(\tilde{M} + M\delta\right) e^{M\delta}$$

in $D_\delta^L \cup D_\delta^C$. This proves (3.2) in $D_\delta^L \cup D_\delta^C$ if M_1 is large and δ is small.

We next consider the case where the left end of the branch is a junction. As before, we shall simultaneously consider the branches that are connected to the same junction.This also includes the right triangular regions D_δ^R for the branches that are

connected to the junction from the left. We consider the fixed point equation $w = Kw$, where w and Kw are defined in (2.15) and (2.16), respectively. Differentiating the equations, we obtain (3.10) in $D_\delta^L \cup D_\delta^C$ for $i = j_{\nu+1}, \ldots, j_\mu$ and

(3.13)

$$(\hat{r}_i)_x = \frac{1}{\varepsilon}\left(l_i^R\right)_x U_i(t,x) + \frac{1}{\varepsilon}\int_0^t \left[\left(l_i^R F_i\right)_x + \left(\partial_i^R l_i^R\right)(U_i)_x - \left(l_i^R\right)_x \left(\partial_i^R U_i\right)\right]\left(x_i^R\right)_x dt,$$

$$\begin{aligned}(s_i)_x = {} & \left(\theta_i - l_i^L F_i - \left(\partial_i^L l_i^L\right) U_i\right)(1,\tau)\,\tau_x + \left(l_i^L\right)_x U_i(x,t) - \left(l_i^L\right)_x U_i\left(x_i^L\right)_x(1,\tau) \\ & + \int_\tau^t \left[\left(l_i^L F_i\right)_x + \left(\partial_i^L l_i^L\right)(U_i)_x - \left(l_i^L\right)_x \left(\partial_i^L U_i\right)\right]\left(x_i^L\right)_x dt\end{aligned}$$

in $D_\delta^C \cup D_\delta^R$ for $i = j_1, \ldots, j_\nu$, where

$$\begin{aligned}\zeta_i = {} & \varepsilon \sum_{l=1}^{\nu} \left(\left(n_{j_l}^i\right)_t \hat{r}_{j_l}(1,\tau) + n_{j_l}^i \left(\hat{r}_{j_l}\right)_t\right) \\ & + \varepsilon \sum_{l'=\nu+1}^{\mu} \left(\left(n_{j_{l'}}^i\right)_t \hat{s}_{j_{l'}}(0,\tau) + n_{j_{l'}}^i \left(\hat{s}_{j_{l'}}\right)_t(0,\tau)\right), \\ \theta_i = {} & \varepsilon \sum_{l=1}^{\nu} \left(\left(m_{j_l}^i\right)_t \hat{r}_{j_l}(1,\tau) + m_{j_l}^i \left(\hat{r}_{j_l}\right)_t\right) \\ & + \varepsilon \sum_{l'=\nu+1}^{\mu} \left(\left(m_{j_{l'}}^i\right)_t \hat{s}_{j_{l'}}(0,\tau) + m_{j_{l'}}^i \left(\hat{s}_{j_{l'}}\right)_t(0,\tau)\right),\end{aligned}$$

and m_j^i, n_j^i are defined in the proof of Theorem 2.1. Note that the estimate (3.12) holds for τ_x in both (3.10) and (3.13), although in the latter case, τ is the t-coordinate of the intersection of the left-going characteristic curve x_i^L with the vertical line $x = 1$. The derivation is identical. Hence, there is a constant ε, independent of M_1, such that for $t \in [0, \delta]$,

$$\begin{aligned}\varepsilon\,|\tau_x| \left(\sum_{k=1}^{\nu} \left|m_{j_k}^i(t)\right| + \sum_{k'=\nu+1}^{\mu} \left|m_{j_{k'}}^i(t)\right|\right) < 1, \\ \varepsilon\,|\tau_x| \left(\sum_{k=1}^{\nu} \left|n_{j_k}^i(t)\right| + \sum_{k'=\nu+1}^{\mu} \left|n_{j_{k'}}^i(t)\right|\right) < 1.\end{aligned}$$

Let σ be the maximum of the quantities on the left-hand side of the above inequalities. Define $\hat{R}_i^R$, S_i^R, R_i^L, and $\hat{S}_i^L$ as in (3.9), with obvious modifications. We see that the function

$$W(t) = \sum_{l=1}^{\nu} \left(\hat{R}_{j_l}^R(t) + S_{j_l}^R(t)\right) + \sum_{l'=\nu+1}^{\mu} \left(R_{j_{l'}}^L(t) + \hat{S}_{j_{l'}}^L(t)\right)$$

satisfies the inequality

$$\begin{aligned}(1-\sigma)\,W(t) &\le \sum_{l=1}^{\nu} \left((1-\sigma)\,\hat{R}_{j_l}^R(t) + S_{j_l}^R(t)\right) + \sum_{l'=\nu+1}^{\mu} \left(R_{j_{l'}}^L(t) + (1-\sigma)\,\hat{S}_{j_{l'}}^L(t)\right) \\ &\le \tilde{M} + M\delta + M\int_0^t (1 + W(t'))\,dt'.\end{aligned}$$

Hence, by rescaling and using Gronwall's inequality, we achieve

$$W(t) \leq \left(\tilde{M} + M\delta\right) e^{M\delta}.$$

This proves that

$$\max\left\{\left|\left(r_i\right)_x\right|, \left|\left(s_i\right)_x\right|\right\} \leq M_1$$

in D_δ^R for $i = j_1, \ldots, j_\nu$ and in D_δ^L for $i = j_{\nu+1}, \ldots, j_\mu$ if M_1 is sufficiently large and δ is sufficiently small. Thus, we have proved (3.2) in this case.

It remains to treat the branches that are connected to terminals. If the terminal boundary condition is either (1.5) or (1.6), the argument is parallel to the one given above for sources. Hence, we consider only the case where the boundary condition is (1.7). The fixed point equation in this case is (2.19). Differentiating (2.19) with respect to x gives (3.13) with

$$\zeta_i = \varepsilon \left(\frac{m_i}{n_i}\right)_t \tau_x \hat{r}_i(1,\tau) + \varepsilon \frac{m_i}{n_i} \tau_x \left(\hat{r}_i\right)_t (1,\tau) - \left(\frac{1}{n_i}\right)_t \int_0^t H_i\left(t', r_i(1,t'), s_i(1,t')\right) dt'.$$

Let δ be sufficiently small such that $|\tau_x|$ is bounded by a constant independent of M_1. Choose $\varepsilon > 0$ such that

$$\sigma =: \varepsilon \left|\lambda_i^R(1,t)\right| \left|\frac{m_i}{n_i} \tau_x(1,t)\right| < 1$$

for $t \in [0, \delta]$. Note that $(\frac{m_i}{n_i})_t$ and $(\frac{1}{n_i})_t$ are bounded (by a constant depending on M_1). Hence,

$$\hat{R}_i^R(t) + S_i^R(t) \leq \sigma \hat{R}_i^R(t) + \tilde{M} + M\delta + M \int_0^t \left(1 + \hat{R}_i^R(t') + S_i^R(t')\right) dt'.$$

This leads to

$$\hat{R}_i^R(t) + S_i^R(t) \leq \left(\tilde{M} + M\delta\right) e^{M\delta}$$

in D_δ^R upon rescaling of constants. Hence, (3.2) holds in D_δ^R.

This completes the proof of (3.2) for all cases. By choosing appropriate values of M_1 and δ, we thus obtain a set X_{δ,M_0} in the form of (3.1), which is invariant under the mapping S.

We now show that S is a contraction in X_{δ,M_0}. Let $U = Sv$, $\tilde{U} = S\tilde{v}$ for some $v, \tilde{v} \in X_\delta$, and let $W = U - \tilde{U}$. W satisfies the vanishing initial and external boundary conditions, and its differential equations take the form of (1.8) with the coefficients

$$a_i = a_i(x,t,v), \; b_i = b_i(x,t,v), \; c_i = c_i(x,t,v)$$

and the forcing functions f_i and g_i replaced by

$$\hat{f}_i =: f_i(x,t,v) - f_i(x,t,\tilde{v}) + \left(a_i(x,t,v) - a_i(x,t,\tilde{v})\right) \frac{\partial \tilde{Q}_i}{\partial x} \tag{3.14}$$

and

$$\begin{aligned} \hat{g}_i =: {} & g_i(x,t,v) - g_i(x,t,\tilde{v}) + \left(b_i(x,t,v) - b_i(x,t,\tilde{v})\right) \frac{\partial \tilde{P}_i}{\partial x} \\ & + 2\left(c_i(x,t,v) - c_i(x,t,\tilde{v})\right) \frac{\partial \tilde{Q}_i}{\partial x}, \end{aligned} \tag{3.15}$$

respectively. By the Lipschitz property and the boundedness $|\tilde{U}|_{1,\delta} \le M_1$, there is a constant M such that

$$|\hat{f}|_{0,\delta} \le M\,|v-\tilde{v}|_{0,\delta}\,, \quad |\hat{g}|_{0,\delta} \le M\,|v-\tilde{v}|_{0,\delta}\,.$$

Hence, by Theorem 2.2,

$$|Sv - S\tilde{v}|_{0,\delta} \le M\delta\,|v-\tilde{v}|_{0,\delta}\,.$$

Therefore, S is contracting in X_{δ,M_0} if δ is sufficiently small.

The rest is standard (cf., e.g., [10]). Starting with a $v_0 \in X_{\delta,M_0}$, we generate an iterative sequence $v_{k+1} = Sv_k$. Clearly, each v_k lies in X_{δ,M_0}, and the sequence converges uniformly. The limit then satisfies the integral equations in the proof of Theorem 2.1 and, hence, is differentiable. Therefore, it is the solution of the quasi-linear differential equations. This proves the existence and uniqueness of the solution when $U^I = 0$.

If $U^I \neq 0$, we regard U^I as a vector function of x and t and introduce $\tilde{U} = U - U^I$. It follows that $\tilde{U}$ is a solution of the quasi-linear equations (1.8), with the forcing functions $\tilde{f}_i$ and $\tilde{g}_i$ given by

$$\tilde{f}_i = f_i - \left(Q_i^I\right)_x a_i, \quad \tilde{g}_i = g_i - \left(P_i^I\right)_x b_i - \left(Q_i^I\right)_x 2c_i$$

and the boundary functions given by

$$\tilde{P}_i^B = P_i^B - P_i^I, \quad \tilde{Q}_i^B = Q_i^B - Q_i^I, \quad \tilde{W}_i^B = W_i^B - \delta_i P_i^I + \varepsilon_i Q_i^I.$$

Since $\tilde{U}$ has vanishing initial values, it can be uniquely solved for an interval of $t \in [0,\delta]$. This gives rise to a solution U. ∎

Remark. Examples can be constructed to show that if the condition (2.3) fails at $t = 0$, then the local solution need not exist or may be not unique. In particular, if (2.3) fails at a source end, then the system is underdetermined, and if it fails at a terminal end, the system is overdetermined. See section 5 for further discussion.

We next give a result for the continuity of dependence of the solution and its derivatives on the initial, boundary, and forcing functions and their derivatives. This follows from an argument similar to the proofs of Lemma 2.2 and Theorem 3.1.

COROLLARY 3.2. *Let $U = (P,Q)$ and $\tilde{U} = (\tilde{P},\tilde{Q})$ be two solutions of the quasi-linear problem of Theorem* 3.1. *Suppose the conditions of that theorem hold for the initial and boundary functions of both solutions. Then there exists a constant $M > 0$, independent of initial, boundary, and forcing functions, such that*

$$\begin{aligned}
&\left|U-\tilde{U}\right|_{k,\delta} \\
&\le M\left(\left|P^I-\tilde{P}^I\right|_{C^k[0,1]} + \left|Q^I-\tilde{Q}^I\right|_{C^k[0,1]} + \left|P^B-\tilde{P}^B\right|_{C^k[0,\delta]} + \left|Q^B-\tilde{Q}^B\right|_{C^k[0,\delta]}\right. \\
&\qquad\qquad \left. + \delta\left|f-\tilde{f}\right|_{C^k\left(\overline{D_\delta}\right)} + \delta\,|g-\tilde{g}|_{C^k\left(\overline{D_\delta}\right)} + \delta\left|W-\tilde{W}\right|_{C^k[0,\delta]}\right) \qquad (3.16)
\end{aligned}$$

for $k = 0, 1$.

Proof. For $k = 0$, the result follows from substituting one of the solutions into the coefficients, modifying the forcing functions by (3.14)–(3.15), and using Lemma 2.2. For $k = 1$, we differentiate the equations and apply the lemma to the resulting equations for the derivatives of the solution. The process is standard and is omitted. ∎

4. A finite-difference scheme. In this section, we present a finite-difference scheme that computes discretized solutions and also prove the convergence of the scheme.

The scheme is based on the equations in (2.6). Substituting (2.4) and (2.8) into (2.6), we obtain the normal form of the equations

$$-\lambda_i^L P_{i,t} + a_i Q_{i,t} + \lambda_i^R \left(-\lambda_i^L P_{i,x} + a_i Q_{i,x}\right) = d_i^R,$$

$$-\lambda_i^R P_{i,t} + a_i Q_{i,t} + \lambda_i^L \left(-\lambda_i^R P_{i,x} + a_i Q_{i,x}\right) = d_i^L,$$

where

$$d_i^R(x,t,P_i,Q_i) = -\lambda_i^L f_i + a_i g_i, \qquad d_i^L(x,t,P_i,Q_i) = -\lambda_i^R f_i + a_i g_i.$$

Let h and k be the spatial and temporal step sizes, respectively. Hence, $hN = 1$ for some integer N. We impose the finite-difference equations as

$$\begin{aligned} &\frac{1}{k}\left[-\lambda_{i,n}^{L,m}\left(p_{i,n}^{m+1} - p_{i,n}^{m}\right) + a_{i,n}^{m}\left(q_{i,n}^{m+1} - q_{i,n}^{m}\right)\right] \\ &\quad + \frac{\lambda_{i,n}^{R,m}}{h}\left[-\lambda_{i,n}^{L,m}\left(p_{i,n}^{m} - p_{i,n-1}^{m}\right) + a_{i,n}^{m}\left(q_{i,n}^{m} - q_{i,n-1}^{m}\right)\right] = d_{i,n}^{R,m} \end{aligned} \tag{4.1}$$

for $n = 1, \ldots, N$ and

$$\begin{aligned} &\frac{1}{k}\left[-\lambda_{i,n}^{R,m}\left(p_{i,n}^{m+1} - p_{i,n}^{m}\right) + a_{i,n}^{m}\left(q_{i,n}^{m+1} - q_{i,n}^{m}\right)\right] \\ &\quad + \frac{\lambda_{i,n}^{L,m}}{h}\left[-\lambda_{i,n}^{L,m}\left(p_{i,n+1}^{m} - p_{i,n}^{m}\right) + a_{i,n}^{m}\left(q_{i,n+1}^{m} - q_{i,n}^{m}\right)\right] = d_{i,n}^{L,m} \end{aligned} \tag{4.2}$$

for $n = 0, \ldots, N-1$, where $a_{i,n}^m$, etc., are the values of the respective functions a_i, etc., at the point $\left(nh, mk, p_{i,n}^m, q_{i,n}^m\right)$. (In this section, n is always the running index for the spatial variable, not the number of branches.) The initial condition is simply

$$p_{i,n}^0 = P_i^I(nh), \quad q_{i,n}^0 = Q_i^I(nh). \tag{4.3}$$

If for a fixed m the quantities $p_{i,n}^m$ and $q_{i,n}^m$ are constructed for $n = 0, \ldots, N$, then (4.1) and (4.2) determine $p_{i,n}^{m+1}$ and $q_{i,n}^{m+1}$ for $n = 1, \ldots, N-1$. The quantities for $n = 0$ and N are determined by boundary conditions. At a source end, if the boundary condition is given by (1.2), we impose

$$p_{i,0}^{m+1} = P_i^B((m+1)k) \tag{4.4}$$

and solve $q_{i,0}^{m+1}$ from (4.2) with $n = 0$. If the boundary condition is (1.3), we impose

$$q_{i,0}^{m+1} = Q_i^B((m+1)k) \tag{4.5}$$

and solve $p_{i,0}^{m+1}$ from (4.2). At a junction with $j_1, \ldots, j_\nu$ incoming branches and $j_{\nu+1}, \ldots, j_\mu$ outgoing branches, we prescribe

$$p_{j_1,N}^{m+1} = p_{j_{l'},0}^{m+1} =: p^{m+1} \tag{4.6}$$

for $l = 1, \ldots, \nu$, $l' = \nu+1, \ldots, \mu$, and

$$\sum_{l=1}^{\nu} q_{j_l,N}^{m+1} = \sum_{l'=\nu+1}^{\mu} q_{j_{l'},0}^{m+1}. \tag{4.7}$$

These equations are solved jointly with (4.1) at $n = N$ for $i = j_1, \ldots, j_\nu$, and with (4.2) at $n = 0$ for $i = j_{\nu+1}, \ldots, j_\mu$. The reason that the quantities p^{m+1}, $q^{m+1}_{j_l,N}$, and $q^{m+1}_{j_{l'},0}$ can be uniquely solved is that the coefficient matrix

$$\begin{pmatrix} 0 & R_1 & R_2 \\ -\frac{1}{k}S_1 & \frac{1}{k}A_1 & 0 \\ -\frac{1}{k}S_2 & 0 & \frac{1}{k}A_2 \end{pmatrix}$$

with

$$\begin{aligned} &R_1 = (1, \ldots, 1), \quad R_2 = (-1, \ldots, -1), \\ &S_1 = \left(\lambda^{L,m}_{j_1,N}, \ldots, \lambda^{L,m}_{j_\nu,N}\right)^T, \quad S_2 = \left(\lambda^{R,m}_{j_1,0}, \ldots, \lambda^{R,m}_{j_\nu,0}\right)^T, \\ &A_1 = \operatorname{diag}\left(a^m_{j_1,N}, \ldots, a^m_{j_\nu,N}\right), \quad A_2 = \operatorname{diag}\left(a^m_{j_{\nu+1},0}, \ldots, a^m_{j_\mu,0}\right) \end{aligned}$$

has the determinant

$$\frac{1}{k^\mu}\left(-\sum_{l=1}^{\nu}\frac{\lambda^{L,m}_{j_l,N}}{a^m_{j_l,N}} + \sum_{l'=\nu+1}^{\mu}\frac{\lambda^{R,m}_{j_{l'},0}}{a^m_{j_{l'},0}}\right)\prod_{l=1}^{\nu}a^m_{j_l,N}\prod_{l'=\nu+1}^{\mu}a^m_{j_{l'},0} > 0.$$

(Here we used the fact $\lambda^L_i < 0$, $\lambda^R_i > 0$, and $a_i > 0$.) At a terminal end with the boundary condition (1.5) (resp., (1.6)), we impose

$$p^{m+1}_{i,N} = P^B_i\left((m+1)\,k\right) \quad \left(\text{resp., } q^{m+1}_{i,N} = Q^B_i\left((m+1)\,k\right)\right) \tag{4.8}$$

and solve the other quantity from (4.1) with $n = N$. If the boundary condition is (1.7), we impose

$$\begin{aligned} &\frac{1}{k}\left(p^{m+1}_{i,N} - p^m_{i,N}\right) - \frac{\eta_i}{k}\left(q^{m+1}_{i,N} - q^m_{i,N}\right) + \frac{\delta_i}{2}\left(p^{m+1}_{i,N} + p^m_{i,N}\right) \\ &\qquad - \frac{\varepsilon_i}{2}\left(q^{m+1}_{i,N} + q^m_{i,N}\right) = W^B_i\left(\left(m + \frac{1}{2}\right)k\right). \end{aligned} \tag{4.9}$$

Together with (4.1) for $n = N$, the values of $p^{m+1}_{i,N}$ and $q^{m+1}_{i,N}$ are uniquely determined. This is because the coefficient matrix has the determinant

$$\det\begin{pmatrix} -\frac{\lambda^{L,m}_{i,N}}{k} & \frac{a^m_{i,N}}{k} \\ \frac{1}{k} + \frac{\delta_i}{2} & -\frac{\eta_i}{k} - \frac{\varepsilon_i}{2} \end{pmatrix} < 0.$$

(One might suspect that the simpler condition

$$\frac{1}{k}\left(p^{m+1}_{i,N} - p^m_{i,N}\right) - \frac{\eta_i}{k}\left(q^{m+1}_{i,N} - q^m_{i,N}\right) + \delta_i p^m_{i,N} - \varepsilon_i q^m_{i,N} = W^B_i\,(mk) \tag{4.10}$$

would also suffice. It indeed can determine unique values of $p^{m+1}_{i,N}$ and $q^{m+1}_{i,N}$. However, we are unable to prove the convergence of the scheme with this condition. The difficulty will be clear from the proof of the next theorem.)

It is clear that for any step sizes h and k this scheme generates a discretized solution as long as λ^L_i remains negative at $x = 0$ and $x = 1$. We show that if the ratio k/h is fixed and sufficiently small, then in a time interval the solutions for the

finite-difference equations converge to the solution of the original system of differential equations (1.8) as $h \to 0$.

THEOREM 4.1. *Suppose that the conditions of Theorem* 3.1 *hold and that*

$$a_i(x,t,p,q) > 0, \quad \lambda_i^L(x,t,p,q) < 0$$

for all $(x,t) \in [0,1] \times [0,\delta]$ *and* $(p,q) \in \mathbb{R}^2$, *where* $\delta > 0$ *appears in Theorem* 3.1. *Suppose also that the initial and boundary functions* P_i^I, Q_i^I, P_i^B, Q_i^B, *and* W_i^B *have continuous second derivatives. Let* $\sigma > 0$ *be a positive constant such that*

$$\sigma \max\left\{ \left|\lambda_i^L\right|_{0,\delta}, \left|\lambda_i^R\right|_{0,\delta} \right\} < 1, \tag{4.11}$$

and let the ratio $k/h = \sigma$ *be fixed. Then there is a constant* $\delta_0 > 0$ *such that, as* $h \to 0$, *the solutions of the finite-difference scheme described above converge to the solution of the differential equation* (1.8) *in the strip* $0 \le t \le \delta_0$.

Remark. The condition of $a_i > 0$, $\lambda_i^L < 0$ for all (p,q) is stronger than needed. One may require only that the inequalities hold in a certain range of (p,q) containing the solution (P_i, Q_i) in its interior. The theorem is stated as above to simplify the argument.

Proof. By Theorem 3.1, the system of differential equations has a solution (P_i, Q_i) in D_δ for some $\delta > 0$. Since the initial and boundary functions have continuous second derivatives, it can be shown using standard arguments that the solution (P_i, Q_i) has continuous second-order derivatives in D_δ. (Reduce δ if necessary.) By Taylor's theorem and $k = \sigma h$, we can write

$$\begin{aligned} &\frac{1}{k}\left[-\tilde{\lambda}_{i,n}^{L,m}\left(P_{i,n}^{m+1} - P_{i,n}^m\right) + \tilde{a}_{i,n}^m\left(Q_{i,n}^{m+1} - Q_{i,n}^m\right)\right] \\ &\quad + \frac{\tilde{\lambda}_{i,n}^{R,m}}{h}\left[-\tilde{\lambda}_{i,n}^{L,m}\left(P_{i,n}^m - P_{i,n-1}^m\right) + \tilde{a}_{i,n}^m\left(Q_{i,n}^m - Q_{i,n-1}^m\right)\right] = \tilde{d}_{i,n}^{R,m} + O(h) \end{aligned} \tag{4.12}$$

for $n = 1, \ldots, N$, and

$$\begin{aligned} &\frac{1}{k}\left[-\tilde{\lambda}_{i,n}^{R,m}\left(P_{i,n}^{m+1} - P_{i,n}^m\right) + \tilde{a}_{i,n}^m\left(Q_{i,n}^{m+1} - Q_{i,n}^m\right)\right] \\ &\quad + \frac{\tilde{\lambda}_{i,n}^{L,m}}{h}\left[-\tilde{\lambda}_{i,n}^{R,m}\left(P_{i,n}^m - P_{i,n-1}^m\right) + \tilde{a}_{i,n}^m\left(Q_{i,n}^m - Q_{i,n-1}^m\right)\right] = \tilde{d}_{i,n}^{L,m} + O(h) \end{aligned} \tag{4.13}$$

for $n = 0, \ldots, N-1$, where $P_{i,n}^m$ and $Q_{i,n}^m$ are the values of the corresponding functions at the point (nh, mk), and $\tilde{\lambda}_{i,n}^{L,m}$, etc., represent the values of the corresponding functions at the point $\left(nh, mk, P_{i,n}^m, Q_{i,n}^m\right)$. Let

$$u_{i,n}^m = P_{i,n}^m - p_{i,n}^m, \quad v_{i,n}^m = Q_{i,n}^m - q_{i,n}^m.$$

Our task is to show

$$u_{i,n}^m \to 0, \quad v_{i,n}^m \to 0$$

as $h \to 0$ and $k = \sigma h$. We prove it by showing that there are positive constants δ_0, h_0, and M, independent of m, such that

$$\left|u_{i,n}^m\right| \le Mh, \quad \left|v_{i,n}^m\right| \le Mh \tag{4.14}$$

if $h \le h_0$, $k = \sigma h$, and $0 \le mk \le \delta_0$.

We first derive some recursive relations. Subtract (4.1) and (4.2) from (4.12) and (4.13), respectively, and use the Lipschitz property and the boundedness of the derivatives of P_i and Q_i. In this way we obtain

$$\begin{aligned}
&\frac{1}{k}\left[-\lambda_{i,n}^{L,m}\left(u_{i,n}^{m+1}-u_{i,n}^{m}\right)+a_{i,n}^{m}\left(v_{i,n}^{m+1}-v_{i,n}^{m}\right)\right]\\
&\qquad+\frac{\lambda_{i,n}^{R,m}}{h}\left[-\lambda_{i,n}^{L,m}\left(u_{i,n}^{m}-u_{i,n-1}^{m}\right)+a_{i,n}^{m}\left(v_{i,n}^{m}-v_{i,n-1}^{m}\right)\right]\\
&\quad=O\left(h\right)+\tilde{d}_{i,n}^{R,m}-d_{i,n}^{R,m}+\left(\tilde{\lambda}_{i,n}^{L,m}-\lambda_{i,n}^{L,m}\right)\frac{P_{i,n}^{m+1}-P_{i,n}^{m}}{k}\\
&\qquad-\left(\tilde{a}_{i,n}^{m}-a_{i,n}^{m}\right)\frac{Q_{i,n}^{m+1}-Q_{i,n}^{m}}{k}+\left(\tilde{\lambda}_{i,n}^{R,m}\tilde{\lambda}_{i,n}^{L,m}-\lambda_{i,n}^{R,m}\lambda_{i,n}^{L,m}\right)\frac{P_{i,n}^{m}-P_{i,n-1}^{m}}{h}\\
&\qquad-\left(\tilde{\lambda}_{i,n}^{R,m}\tilde{a}_{i,n}^{m}-\lambda_{i,n}^{R,m}a_{i,n}^{m}\right)\frac{Q_{i,n}^{m}-Q_{i,n-1}^{m}}{h}\\
&\quad=O\left(h\right)+O\left(u_{i,n}^{m}\right)+O\left(v_{i,n}^{m}\right)
\end{aligned}\tag{4.15}$$

and, similarly,

$$\begin{aligned}
&\frac{1}{k}\left[-\lambda_{i,n}^{R,m}\left(u_{i,n}^{m+1}-u_{i,n}^{m}\right)+a_{i,n}^{m}\left(v_{i,n}^{m+1}-v_{i,n}^{m}\right)\right]\\
&\qquad+\frac{\lambda_{i,n}^{L,m}}{h}\left[-\lambda_{i,n}^{R,m}\left(u_{i,n+1}^{m}-u_{i,n}^{m}\right)+a_{i,n}^{m}\left(v_{i,n+1}^{m}-v_{i,n}^{m}\right)\right]\\
&\qquad\qquad=O\left(h\right)+O\left(u_{i,n}^{m}\right)+O\left(v_{i,n}^{m}\right).
\end{aligned}\tag{4.16}$$

Introduce

$$r_{i,n}^{m}=-\lambda_{i,n}^{L,m-1}u_{i,n}^{m}+a_{i,n}^{m-1}v_{i,n}^{m},\qquad s_{i,n}^{m}=-\lambda_{i,n}^{R,m-1}u_{i,n}^{m}+a_{i,n}^{m-1}v_{i,n}^{m}.$$

One can show that (4.14) is equivalent to

$$\left|r_{i,n}^{m}\right|\le Mh,\quad \left|s_{i,n}^{m}\right|\le Mh.\tag{4.17}$$

(Throughout the proof of this theorem, we use M to denote any positive constant that is independent of m.) Using the identity

$$-\lambda_{i,n}^{L,m}u_{i,l}^{m}+a_{i,n}^{m}v_{i,l}^{m}=r_{i,l}^{m}+\left(\lambda_{i,l}^{L,m-1}-\lambda_{i,n}^{L,m}\right)u_{i,l}^{m}+\left(a_{i,l}^{m-1}-a_{i,n}^{m}\right)v_{i,l}^{m},$$

together with

$$\begin{aligned}
\lambda_{i,l}^{L,m-1}-\lambda_{i,n}^{L,m}&=O\left(k\right)+O\left(p_{i,l}^{m-1}-p_{i,n}^{m}\right)+O\left(q_{i,l}^{m-1}-q_{i,n}^{m}\right),\\
a_{i,l}^{m-1}-a_{i,n}^{m}&=O\left(k\right)+O\left(p_{i,l}^{m-1}-p_{i,n}^{m}\right)+O\left(q_{i,l}^{m-1}-q_{i,n}^{m}\right),
\end{aligned}$$

and

$$\begin{aligned}
p_{i,l}^{m-1}-p_{i,n}^{m}&=-u_{i,l}^{m-1}+u_{i,n}^{m}+\left(P_{i,l}^{m-1}-P_{i,n}^{m}\right),\\
q_{i,l}^{m-1}-q_{i,n}^{m}&=-v_{i,l}^{m-1}+v_{i,n}^{m}+\left(Q_{i,l}^{m-1}-Q_{i,n}^{m}\right)
\end{aligned}$$

for $l = n-1,\ n,\ n+1$, we can write

$$\begin{aligned}
-\lambda_{i,n}^{L,m} u_{i,l}^m + a_{i,n}^m v_{i,l}^m &= r_{i,l}^m + u_{i,l}^m O(k) + v_{i,l}^m O(k) + u_{i,l}^m O\left(u_{i,l}^{m-1}, u_{i,n}^m, v_{i,l}^{m-1}, v_{i,n}^m\right) \\
&\quad + v_{i,l}^m O\left(u_{i,l}^{m-1}, u_{i,n}^m, v_{i,l}^{m-1}, v_{i,n}^m\right), \\
-\lambda_{i,n}^{R,m} u_{i,l}^m + a_{i,n}^m v_{i,l}^m &= s_{i,l}^m + u_{i,l}^m O(k) + v_{i,l}^m O(k) + u_{i,l}^m O\left(u_{i,l}^{m-1}, u_{i,n}^m, v_{i,l}^{m-1}, v_{i,n}^m\right) \\
&\quad + v_{i,l}^m O\left(u_{i,l}^{m-1}, u_{i,n}^m, v_{i,l}^{m-1}, v_{i,n}^m\right),
\end{aligned}$$

where

$$O(u_{i,l}^{m-1}, u_{i,n}^m, v_{i,l}^{m-1}, v_{i,n}^m) = O(u_{i,l}^{m-1}) + O(u_{i,n}^m) + O(v_{i,l}^{m-1}) + O(v_{i,l}^m).$$

Substituting these relations into (4.15) and (4.16), we obtain

$$\begin{aligned}
r_{i,n}^{m+1} &= r_{i,n}^m - \sigma\lambda_{i,n}^{R,m}\left(r_{i,n}^m - r_{i,n-1}^m\right) + O_{i,n,n-1}^m, \qquad n = 1, \dots, N, \\
s_{i,n}^{m+1} &= s_{i,n}^m - \sigma\lambda_{i,n}^{L,m}\left(s_{i,n+1}^m - s_{i,n}^m\right) + O_{i,n,n+1}^m, \qquad n = 0, \dots, N-1,
\end{aligned} \tag{4.18}$$

for $m \geq 1$, where

$$\begin{aligned}
O_{i,n,n-1}^m &= O\left(h^2\right) + h\left(O\left(u_{i,n}^m\right) + O\left(v_{i,n}^m\right)\right) + u_{i,n-1}^m O(h) + v_{i,n-1}^m O(h) \\
&\quad + u_{i,n-1}^m O\left(u_{i,n-1}^{m-1}, u_{i,n}^m, v_{i,n-1}^{m-1}, v_{i,n}^m\right) + v_{i,n-1}^m O\left(u_{i,n-1}^{m-1}, u_{i,n}^m, v_{i,n-1}^{m-1}, v_{i,n}^m\right)
\end{aligned}$$

and $O_{i,n,n+1}^m$ is defined similarly, with $n-1$ substituted by $n+1$. These are the recursive relations we need.

We now prove (4.17). Assume $\delta_0 < \sigma/2$; then, $mk \leq \delta_0$ implies $m < N - m$. The proof will be divided into three cases: (1) $m \leq n \leq N-m$, (2) $0 \leq n < m$, and (3) $N - m < n \leq N$. It may be helpful to compare the argument below with the proof of Theorem 2.1, in which the region D_i is divided into D_i^C, D_i^L, and D_i^R.

Case 1: $m \leq n \leq N-m$. Let

$$e_m = \max_{m \leq n \leq N-m} \left\{\left|r_{i,n}^m\right|, \left|s_{i,n}^m\right|\right\}.$$

In view of (4.11), the coefficients of $r_{i,n}^m$, $r_{i,n-1}^m$, $s_{i,n}^m$, and $s_{i,n+1}^m$ in (4.18) are all nonnegative. Hence, from (4.18),

$$e_{m+1} \leq e_m + C\left(h^2 + he_m + e_m e_{m-1} + e_m^2\right), \quad m \geq 1, \tag{4.19}$$

where $C > 0$ is a constant. By initial condition (4.3),

$$u_{i,n}^0 = v_{i,n}^0 = 0.$$

Thus, $e_0 = 0$. Also, by (4.18) with $m = 0$,

$$\begin{aligned}
r_{i,n}^1 &= O(h^2) \qquad \text{for } n = 1, \dots, N, \\
s_{i,n}^1 &= O(h^2) \qquad \text{for } n = 0, \dots, N-1.
\end{aligned} \tag{4.20}$$

This implies $e_1 = O(h^2)$. Consider the linear difference equation with initial condition

$$E_{m+1} = (1 + 3Ch)\, E_m + Ch^2, \quad m \geq 1, \quad E_1 = C_0 h^2,$$

where C_0 is so large that $e_1 \le C_0 h^2$. It has the solution

$$\begin{aligned} E_{m+1} &= C_0 h^2 \left(1+3Ch\right)^m + \frac{h}{3}\left(\left(1+3Ch\right)^m - 1\right) \\ &\le h\left(C_0 h e^{3Chm} + \frac{1}{3}e^{3Chm} - 1\right). \end{aligned}$$

Let δ_0 be so small that $e^{3C\delta_0/\sigma} < 4$. Then there is an $h_0 > 0$ such that $E_m \le h$ for all $h \le h_0$ and $mk \le \delta_0$. This implies that

$$E_{m+1} \ge E_m + C\left(h^2 + hE_m + E_m E_{m-1} + E_m^2\right), \quad E_1 \ge e_1.$$

Hence,

$$e_m \le E_m \le h,$$

which leads to (4.17) with $M = 1$ in Case 1.

Case 2: $0 \le n < m$. The proof in this case depends on the type of boundary condition at the left end of the branch. Suppose that the end is a source with the boundary condition (4.4). Let

$$e_m = \max_{0\le n\le N-m}\left\{\left|r_{i,n}^m\right|, \left|s_{i,n}^m\right|\right\}.$$

(As was the case in the proof of Theorem 2.1, it is more convenient to include the central trapezoidal part $m \le n \le N-m$.) Hence, from (4.18),

$$\begin{aligned} \left|r_{i,n}^{m+1}\right| &\le |e_m| + C\left(h^2 + he_m + e_m e_{m-1} + e_m^2\right) \quad \text{for } n = 1, \dots, N-m, \\ \left|s_{i,n}^{m+1}\right| &\le |e_m| + C\left(h^2 + he_m + e_m e_{m-1} + e_m^2\right) \quad \text{for } n = 0, \dots, N-m. \end{aligned} \tag{4.21}$$

Since, by (4.4), $u_{i,0}^m = 0$, it follows that $r_{i,0}^m = s_{i,0}^m$ for all m. Therefore, e_m satisfies the same difference inequality (4.19). We also have $e_1 = O(h^2)$ by (4.20). Thus, the above analysis gives $e_m \le h$.

Suppose that the boundary condition is given by (4.5); then $v_{i,0}^m = 0$ and

$$r_{i,0}^m = \frac{\lambda_{i,0}^{L,m-1}}{\lambda_{i,0}^{R,m-1}} s_{i,0}^m$$

for all $m \ge 1$. Let $\hat{r}_{i,n}^m = r_{i,n}^m / M$, where M is sufficiently large such that

$$M > \max_m \left\{\left|\frac{\lambda_{i,0}^{L,m}}{\lambda_{i,0}^{R,m}}\right|\right\}.$$

Then (4.18) still holds, with r substituted by $\hat{r}$. Let

$$e_m = \max_{0\le n\le N-m}\left\{\left|\hat{r}_{i,n}^m\right|, \left|s_{i,n}^m\right|\right\}.$$

We again have (4.21) and

$$\left|\hat{r}_{i,0}^{m+1}\right| \le \left|s_{i,0}^{m+1}\right| \le |e_m| + C\left(h^2 + he_m + e_m e_{m-1} + e_m^2\right).$$

Hence, e_m satisfies (4.19) again. Therefore,

$$\left|r_{i,n}^m\right| \le Mh, \quad \left|s_{i,n}^m\right| \le h.$$

Suppose that the left end is a junction. We shall simultaneously treat all the branches connected to the same junction. Let $j_1, \dots, j_\nu$ be the incoming branches and $j_{\nu+1}, \dots, j_\mu$ the outgoing branches. It is easy to see that the boundary conditions (4.6)–(4.7) are satisfied if p and q are substituted by u and v, respectively. Using the identities

$$u_{i,n}^{m+1} = \frac{r_{i,n}^{m+1} - s_{i,n}^{m+1}}{\lambda_{i,n}^m}, \quad v_{i,n}^{m+1} = \frac{\lambda_{i,n}^{R,m} r_{i,n}^{m+1} - \lambda_{i,n}^{L,m} s_{i,n}^{m+1}}{a_{i,n}^m \lambda_{i,n}^m}, \tag{4.22}$$

where

$$\lambda_{i,n}^m = \lambda_{i,n}^{R,m} - \lambda_{i,n}^{L,m} > 0,$$

the equations for r and s have the form

$$\begin{aligned}
&\frac{1}{\lambda_{j_1,N}^m}\left(r_{j_1,N}^{m+1} - s_{j_1,N}^{m+1}\right) - \frac{1}{\lambda_{i,N}^m}\left(r_{i,N}^{m+1} - s_{i,N}^{m+1}\right) = 0, \quad i = j_2, \dots, j_\nu,\\
&\frac{1}{\lambda_{j_1,N}^m}\left(r_{j_1,N}^{m+1} - s_{j_1,N}^{m+1}\right) - \frac{1}{\lambda_{i,0}^m}\left(r_{i,0}^{m+1} - s_{i,0}^{m+1}\right) = 0, \qquad i = j_{\nu+1}, \dots, j_\mu,\\
&\sum_{l=1}^{\nu} \frac{1}{a_{j_l,N}^m \lambda_{j_l,N}^m}\left(\lambda_{j_l,N}^{R,m} r_{j_l,N}^{m+1} - \lambda_{j_l,N}^{L,m} s_{j_l,N}^{m+1}\right)\\
&\qquad - \sum_{l'=\nu+1}^{\mu} \frac{1}{a_{j_{l'},0}^m \lambda_{j_{l'},0}^m}\left(\lambda_{j_{l'},0}^{R,m} r_{j_{l'},0}^{m+1} - \lambda_{j_{l'},0}^{L,m} s_{j_{l'},0}^{m+1}\right) = 0.
\end{aligned}$$

The system can be solved for $s_{j_1,N}^{m+1}, \dots, s_{j_\nu,N}^{m+1}, r_{j_{\nu+1},0}^{m+1}, \dots, r_{j_\mu,0}^{m+1}$ because the coefficient matrix

$$\begin{pmatrix}
-\frac{1}{\lambda_{j_1,N}^m} & \frac{1}{\lambda_{j_2,N}^m} & \cdots & 0\\
\vdots & \vdots & \ddots & \vdots\\
-\frac{1}{\lambda_{j_1,N}^m} & 0 & \cdots & -\frac{1}{\lambda_{j_\mu,0}^m}\\
-\frac{\lambda_{j_1,N}^{L,m}}{\lambda_{j_1,N}^m a_{j_1,N}^m} & -\frac{\lambda_{j_2,N}^{L,m}}{\lambda_{j_2,N}^m a_{j_2,N}^m} & \cdots & -\frac{\lambda_{j_\mu,0}^{R,m}}{\lambda_{j_\mu,0}^m a_{j_\mu,0}^m}
\end{pmatrix}$$

has the determinant

$$\frac{(-1)^{\nu+1}}{\prod_{l=1}^{\nu} \lambda_{j_l,N}^m \prod_{l'=\nu+1}^{\mu} \lambda_{j_{l'},0}^m}\left(-\sum_{l=1}^{\nu} \frac{\lambda_{j_l,N}^{L,m}}{a_{j_l,N}^m} + \sum_{l'=\nu+1}^{\mu} \frac{\lambda_{j_{l'},0}^{R,m}}{a_{j_{l'},N}^m}\right) \neq 0.$$

(Here we used $\lambda_{i,n}^m > 0$, $a_{i,n}^m > 0$, $\lambda_{i,n}^{R,m} > 0$, and $\lambda_{i,n}^{L,m} < 0$.) Let the solution be written as

$$\begin{aligned}
s_{i,N}^{m+1} &= \sum_{l=1}^{\nu} m_{j_l}^i r_{j_i,N}^{m+1} + \sum_{l'=\nu+1}^{\mu} m_{j_{l'}}^i s_{j_{l'},0}^{m+1}, \qquad i = j_1, \dots, j_\nu,\\
r_{i,0}^{m+1} &= \sum_{l=1}^{\nu} n_{j_l}^i r_{j_i,N}^{m+1} + \sum_{l'=\nu+1}^{\mu} n_{j_{l'}}^i s_{j_{l'},0}^{m+1}, \qquad i = j_{\nu+1}, \dots, j_\mu.
\end{aligned} \tag{4.23}$$

Choose a constant M such that

$$M > \max_{i=j_1,\ldots,j_\mu} \left\{ \sum_{l=1}^{\mu} \left| m_{j_l}^i \right|, \sum_{l=1}^{\mu} \left| n_{j_l}^i \right| \right\},$$

and introduce

$$\hat{s}_{j_l,n}^m = s_{j_l,n}^m / M, \quad \hat{r}_{j_{l'},n}^m = r_{j_{l'},n}^m / M$$

for $l = 1, \ldots, \nu$, $l' = \nu+1, \ldots, \mu$. Equations in (4.18) still hold if $\hat{s}_{j_l,n}^m$ and $\hat{r}_{j_{l'},n}^m$ are substituted for $s_{j_l,n}^m$ and $r_{j_{l'},n}^m$, respectively. Let e_m denote the maximum of the quantities

$$\max_{\substack{m \le n \le N \\ 1 \le l \le \nu}} \left\{ \left| r_{j_l,n}^m \right|, \left| \hat{s}_{j_l,n}^m \right| \right\}, \quad \max_{\substack{0 \le n \le N-m \\ \nu+1 \le l' \le \mu}} \left\{ \left| \hat{r}_{j_{l'},n}^m \right|, \left| s_{j_{l'},n}^m \right| \right\}.$$

(Notice again the inclusion of the middle part $m \le n \le N-m$.) Since the coefficients of r and s are all positive, it is easy to see that

$$\left| r_{j_l,n}^{m+1} \right| \le e_m + C\left(h^2 + h e_m + e_m e_{m-1} + e_m^2\right)$$

for $l = 1, \ldots, \nu$, $n = m, \ldots, N$ and

$$\left| s_{j_{l'},n}^{m+1} \right| \le e_m + C\left(h^2 + h e_m + e_m e_{m-1} + e_m^2\right)$$

for $l = \nu+1, \ldots, \mu$, $n = 0, \ldots, m$. Similar inequalities can be derived for $|\hat{s}_{j_l,n}^{m+1}|$, $l = 1, \ldots, \nu$, $n = m, \ldots, N-1$, and for $|\hat{r}_{j_{l'},n}^{m+1}|$, $l' = \nu+1, \ldots, \mu$, $n = 1, \ldots, m$. Furthermore, by (4.23),

$$\left| \hat{s}_{j_l,N}^{m+1} \right| = \frac{1}{M} \left| \sum_{l=1}^{\nu} m_{j_l}^i r_{j_i,N}^{m+1} + \sum_{l'=\nu+1}^{\mu} m_{j_{l'}}^i s_{j_{l'},0}^{m+1} \right| \le \max_{\substack{1 \le l \le \nu \\ \nu+1 \le l' \le \mu}} \left\{ \left| r_{j_l,N}^{m+1} \right|, \left| s_{j_{l'},0}^{m+1} \right| \right\},$$

$$\left| \hat{r}_{j_l,N}^{m+1} \right| = \frac{1}{M} \left| \sum_{l=1}^{\nu} n_{j_l}^i r_{j_i,N}^{m+1} + \sum_{l'=\nu+1}^{\mu} n_{j_{l'}}^i s_{j_{l'},0}^{m+1} \right| \le \max_{\substack{1 \le l \le \nu \\ \nu+1 \le l' \le \mu}} \left\{ \left| r_{j_l,N}^{m+1} \right|, \left| s_{j_{l'},0}^{m+1} \right| \right\}.$$

Therefore, we achieve again the difference inequality (4.19) for e_m. Hence, $e_m \le h$, and consequently,

$$\left| r_{i,n}^m \right| \le h, \quad \left| s_{i,n}^m \right| \le Mh.$$

This not only proves (4.17) for Case 2, but also for the part of Case 3 where the right endpoint is a junction.

Case 3: $N - m \le n \le N$. It remains only to discuss the case where the right end is a terminal. If the boundary condition is given by (4.8), the results follow from arguments similar to those in Case 2, when the source end boundary condition is either (4.4) or (4.5). Thus, we shall discuss only the case when the boundary condition is given by (4.9), which corresponds to the Windkessel-type boundary condition (1.7) for the differential equations.

From (1.7), we derive

$$\frac{1}{k}\left(P_{i,N}^{m+1}-P_{i,N}^{m}\right)-\frac{\eta_i}{k}\left(Q_{i,N}^{m+1}-Q_{i,N}^{m}\right)+\frac{\delta_i}{2}\left(P_{i,N}^{m+1}+P_{i,N}^{m}\right)$$
$$-\frac{\varepsilon_i}{2}\left(Q_{i,N}^{m+1}+Q_{i,N}^{m}\right)=W_i^B\left(\left(m+\frac{1}{2}\right)k\right)+O\left(k^2\right).$$

Subtracting (4.9) from above yields

$$\frac{1}{k}(u_{i,N}^{m+1}-u_{i,N}^{m})-\frac{\eta_i}{k}(v_{i,N}^{m+1}-v_{i,N}^{m})+\frac{\delta_i}{2}(u_{i,N}^{m+1}+u_{i,N}^{m})-\frac{\varepsilon_i}{2}(v_{i,N}^{m+1}+v_{i,N}^{m})=O(k^2).$$

Let

$$f^m=\left(1+\frac{\delta_i k}{2}\right)u_{i,N}^{m}-\left(\eta_i+\frac{\varepsilon_i k}{2}\right)v_{i,N}^{m},\quad m=0,1,\ldots.$$

The equation for f^m has the form

$$f^{m+1}=f^m+k\left(\varepsilon_i v_{i,N}^{m}-\delta_i u_{i,N}^{m}\right)+O\left(k^3\right).$$

Since $f^0=0$, the difference equation has the solution

$$f^{m+1}=k\sum_{j=0}^{m}\left(\varepsilon_i v_{i,N}^{j}-\delta_i u_{i,N}^{j}\right)+O\left(k^2\right).$$

From (4.22), we obtain

$$s_{i,N}^{m+1}=\frac{M_i^m}{N_i^m}r_{i,N}^{m+1}-\frac{k}{N_i^m}\sum_{j=0}^{m}\left(\varepsilon_i v_{i,N}^{j}-\delta_i u_{i,N}^{j}\right)+O\left(k^2\right),\tag{4.24}$$

where

$$M_i^m=\frac{1}{\lambda_{i,n}^m}\left(1+\frac{\delta_i k}{2}-\left(\eta_i+\frac{\varepsilon_i k}{2}\right)\frac{\lambda_{i,n}^{R,m}}{a_{i,n}^m}\right),$$
$$N_i^m=\frac{1}{\lambda_{i,n}^m}\left(1+\frac{\delta_i k}{2}-\left(\eta_i+\frac{\varepsilon_i k}{2}\right)\frac{\lambda_{i,n}^{L,m}}{a_{i,n}^m}\right).$$

(Notice that $N_i^m>0$, and hence (4.24) is valid.) Let $\hat{s}_{i,n}^m=s_{i,n}^m/M$, where M is a constant to be determined later. Also let

$$e_m=\max_{\substack{m\le n\le N\\ 0\le j\le m}}\left\{\left|r_{i,n}^{j}\right|,\left|\hat{s}_{i,n}^{j}\right|\right\}.$$

Unlike previous cases where e_m depends on the mth level quantities, here it is more convenient to let e_m be the maximum of all the lower level quantities. Then, by (4.18) modified with $\hat{s}$ substituted for s,

$$\left|r_{i,n}^{m+1}\right|\le e_m+C\left(h^2+he_m+e_me_{m-1}+e_m^2\right)\tag{4.25}$$

for $n=m,\ldots,N$ and

$$\left|\hat{s}_{i,n}^{m+1}\right|\le e_m+C\left(h^2+he_m+e_me_{m-1}+e_m^2\right)$$

for $n = m, \ldots, N-1$, where C is a positive constant. Also, by (4.24) and the relation $mk \leq \delta_0$,

$$\left|\hat{s}_{i,N}^{m+1}\right| \leq \frac{1}{M}\left|\frac{M_i^m}{N_i^m}\right|\left|r_{i,N}^{m+1}\right| + \delta_0 C' e_m + O\left(h^2\right),$$

where $C' > 0$ is constant. Hence, from (4.25) we see that if M is sufficiently large and δ_0 is sufficiently small, we can ensure

$$\left|\hat{s}_{i,N}^{m+1}\right| \leq e_m + C\left(h^2 + he_m + e_m e_{m-1} + e_m^2\right).$$

(This is where the simpler boundary condition (4.10) fails. Instead of $O\left(h^2\right)$, it can provide only $O(h)$, which is inconsistent with (4.19).) Thus, e_m satisfies the relation (4.19), which leads to $e_m \leq h$. We have, thus, shown that

$$\left|r_{i,n}^m\right| \leq h, \quad \left|s_{i,n}^m\right| \leq Mh.$$

This completes the proof of Case 3, and also of the entire theorem. ∎
