5. Discussion. We have given a rather thorough treatment to the initial-boundary value problem of the first-order quasilinear system (1.8) with various source and terminal boundary conditions. From our results, it can be seen that the junction condition (1.4), which stems from the conservation of mass and Navier–Stokes momentum, is consistent with the differential equations. Also, the Windkessel-type terminal boundary condition does not cause problems for the solvability. However, due to the nature of the first-order hyperbolic equations, the existence of a global solution generally is not guaranteed (cf. [14, 15]). This problem may disappear if more accurate models are used. For example, in (1.8) and its special case (1.1), only the effect of viscosity on the wall of the vessels is taken into consideration. If we include viscosity more comprehensively, a term of $\mu\nabla^2 Q_i$ appears in the right-hand sides of the second equations of (1.8) and (1.1). The system then becomes parabolic instead of hyperbolic. It is well known that parabolic systems have better regularity properties than hyperbolic ones. Therefore, it may be possible to prove the existence of a global solution. Another possible approach is to use the results of Čanić and Kim [5] that shock waves can develop only in an unrealistically long vessel. With appropriate a priori estimates, one might find a range of lengths of vessels within which global solutions exist. We are currently investigating these issues.

We have developed a numerical scheme for the computation of solutions and proved its convergence. Although our scheme uses a nonstaggered method similar to the one developed by Raines, Jaffrin, and Shapiro [23, 24], they are substantially different. (By nonstaggered, we mean that the values of P_i and Q_i are approximated at the same mesh points, unlike the staggered method developed in [9, 13].) This is because ours is based on the normal form of the equations and takes into account the characteristic directions. This might explain why our scheme converges even if the network has loops, while the other can break down (cf. [13]).

A VARIATIONAL APPROACH TO NONRIGID MORPHOLOGICAL IMAGE REGISTRATION*

M. DROSKE† AND M. RUMPF†

Abstract. A variational method for nonrigid registration of multimodal image data is presented. A suitable deformation will be determined via the minimization of a morphological, i.e., contrast invariant, matching functional along with an appropriate regularization energy. The aim is to correlate the morphologies of a template and a reference image under the deformation. Mathematically, the morphology of images can be described by the entity of level sets of the image and hence by its Gauss map. A class of morphological matching functionals is presented which measure the defect of the template Gauss map in the deformed state with respect to the deformed Gauss map of the reference image. The problem is regularized by considering a nonlinear elastic regularization energy. Existence of homeomorphic, minimizing deformation is proved under assumptions on the class of admissible deformations. With respect to actual medical applications, suitable generalizations of the matching energies and the boundary conditions are presented. Concerning the robust implementation of the approach, the problem is embedded in a multiscale context. A discretization based on multilinear finite elements is discussed, and the first numerical results are presented.

Key words. image processing, image registration, mathematical morphology, nonlinear elasticity

1. Introduction.

Nowadays classical image acquisition machinery, such as computer tomography and magnetic resonance tomography, and a variety of novel sources for images, such as functional magnetic resonance imaging (MRI), three dimensional ultrasound, or densiometric computer tomography (DXA), deliver various three dimensional images of the same human body. Due to different body positioning, temporal differences of the image generation, and differences in the measurement process, the images frequently cannot simply be overlaid. Indeed, corresponding structures are situated at usually nonlinearly transformed positions. In case of intraindividual registration, the variability of the anatomy cannot be described by a rigid transformation, since many structures like, e.g., the brain cortex, may evolve very differently in the growing process. Frequently, if the image modality differs, there is also no correlation of image intensities at corresponding positions. What still remains, at least partially, is the local image structure or "morphology" of corresponding objects. Thus, the matching of two dimensional and especially three dimensional images—also known as image registration—with respect to their morphology is one of the fundamental tasks in image processing.

One aims to correlate two images—a reference image R and a template image T—via an energy relaxation over a set of, in general, nonrigid spatial deformations. Let us denote the reference image by $R : \Omega \to \mathbb{R}$ and the template image by $T : \Omega \to \mathbb{R}$. Here, both images are supposed to be defined on a bounded domain $\Omega \in \mathbb{R}^d$ for $d = 1, 2$, or 3 with Lipschitz boundary and satisfy the *cone condition* (cf., e.g., [4]). We ask

for a deformation $\phi : \Omega \to \Omega$ such that $T \circ \phi$ is optimally correlated to R. There is a large and diverse body of literature on registration. In particular, Grenander, Miller, and coworkers contributed different physically motivated and mathematically profound approaches [12, 11, 24, 21, 32]. For an overview, in particular, on the mathematical modeling, see the references therein. For unimodal images one defines similarity measures, for instance, by the simple choice $\|T \circ \phi - R\|^2_{L^2}$ [15, 28, 33, 41]. In case T and R are images of different modality, we are left to define what is meant by the correlation of local structures in the image.

Viola and Wells [45], Wells et al. [47], and Collignon et al. [16] presented an information theoretic approach for registration of multimodal images. It is based on the idea of maximizing the so-called mutual information of the deformed template image and the reference image. The mutual information consists of the entropies of both images and the negative joint entropy. It can be interpreted as a measure of variability and uncertainty. Thus, the joint entropy of the images is low, where one image can stochastically be well described by the other and vice versa. Since the entropies of random variables are integrals containing the corresponding density functions, here the intensities, the corresponding local structure analysis is rather implicitly encoded in the global functionals. Viola and Wells performed the maximization process by using a stochastic descent method in which the gradients are computed via a Parzen windowing function, while Collignon et al. used Powell's method for the optimization. The method is currently restricted to an expression in global parametric form such as rigid transformations or a lower dimensional space of smooth deformations. A different approach of image registration via the matching of objects in images is due to Monasse [35]. He classifies objects by moments, and a registration is achieved by aligning these moments under scaling and rigid body motion.

Here, we introduce a different approach based on the definition of a matching energy, which effectively measures the local morphological "defect" of the deformed template and the reference image. The congruence of the shapes instead of the equality of the intensities is the main object of the registration approach presented here. First, let us define the morphology $M[I]$ of an image I as the set of level sets of I:

$$M[I] := \{\mathcal{M}^I_c \,|\, c \in \mathbb{R}\}, \tag{1.1}$$

where $\mathcal{M}^I_c := \{x \in \Omega \,|\, I(x) = c\}$ is a single level set for the gray value c. (For a general overview on image morphology, we refer to [40].) That is, $M[\gamma \circ I] = M[I]$ for any reparametrization $\gamma : \mathbb{R} \to \mathbb{R}$ of the gray values. Obviously, $M[I]$ is uniquely identified by the set of tangent spaces $\mathcal{T}_x\mathcal{M}^I_{I(x)}$ of all level sets $\mathcal{M}^I_c$ or up to the orientation by the normal field N_I on $\mathcal{M}^I_c$. Hence, again up to the orientation, the morphology $M[I]$ can be identified with the normal map (Gauss map)

$$N_I : \Omega \to \mathbb{R}^d;\ x \mapsto \frac{\nabla I}{\|\nabla I\|}\,. \tag{1.2}$$

Two images I_1 and I_2 are called morphologically equivalent if $M[I_1] = M[I_2]$. Let us emphasize that we deal here with classical level sets, which might not be defined everywhere. The problem related to vanishing image gradients and thus undefined normals will be addressed in section 4, where we allow for such singularities as long as the measure of the corresponding set in appropriate terms is not too large. A weaker definition of level sets has been introduced by Caselles, Coll, and Morel [10]. They consider the so-called upper topographic map $\{\{x \,|\, \phi(x) \geq \lambda\} \,|\, \lambda \in \mathbb{R}\}$ to characterize

the morphology of an image ϕ. This map uniquely describes the morphology, and they prove stability with respect to discretization and quantization.

Morphological methods in image processing are characterized by an invariance with respect to the morphology. Explicitly speaking, a method is called morphological if, when it is applied to morphologically identical images, the resulting images are still morphologically identical [1, 39, 43]. Hence, such methods only affect the morphology of the image, which coincides with the geometry of the level sets. Now, aiming for a morphological registration method, we will ask for a deformation $\phi : \Omega \to \Omega$ such that

$$M[T \circ \phi] = M[R] \,.$$

Thus, we try to align the normal fields (cf. Desolneux, Moisan, and Morel [19], where tangent spaces are identified in rigorous statistical terms). We set up a matching functional which locally measures the twist of the tangent spaces of the template image at the deformed position and the deformed reference image or the defect of the corresponding normal fields. See Figure 1 for an example of a registration on a pair of images for which a smooth deformation ϕ exists such that $T \circ \phi$ and R are morphologically equivalent. Figure 2 shows the known exact deformation and the deformation computed by the method we propose here.

As known from other approaches, the corresponding minimization, if settled over an infinite dimensional space of deformations and not ab initio restricted to a small finite dimensional function space, turns out to be ill posed [8, 44]. Hence, we have to ask for a suitable regularization. Various regularization approaches have been considered in the literature [11, 12, 18, 26]. On one hand, a regularization of the energy is taken into account, typically adding a convex energy functional based on gradients to the actual matching energy. The regularization energy is regarded as a penalty for "elastic stresses" resulting from the deformation of the images. This competitive approach is related to the well-known classical Tikhonov regularization of the originally ill-posed problem. On the other hand, viscous flow techniques are taken into account. They compute smooth paths from some initial deformation towards the set of minimizers of the matching energy [15, 27].

The paper is organized as follows. In section 2 the morphological matching energies are discussed, and in section 3 the regularization via nonlinear elasticity functionals will be introduced. Then, in section 4 we prove existence of homeomorphic, minimizing deformations. With respect to the actual application to medical data, the model is further generalized in sections 5 and 6, where an additional feature-based matching functional is introduced and generalized boundary conditions are discussed. Finally, in section 7 we describe the finite element discretization and the minimization algorithm.

In the present paper, we will prove the existence of a minimizing deformation for a variational approach, which is formulated for three dimensional images. It is left to the reader to transfer the assumptions and the existence results to the simpler two dimensional case. Here and in what follows we make use of the summation convention. That is, we implicitly sum over every index which appears twice in an expression.

Let us emphasize that the focus of the paper is on the presentation of a new concept in morphological image registration. Details on the implementation will be discussed in a forthcoming publication. Hence, the computational results are currently restricted to two dimensions.

2. A morphological registration energy. In this section we will construct a suitable matching energy, which measures the defect of the morphology of the refer-

ence image R and the deformed template image T. Thus, with respect to the above identification of morphologies and normal fields, we ask for a deformation ϕ such that

$$N_T \circ \phi \,||\, N_R^{\phi}, \tag{2.1}$$

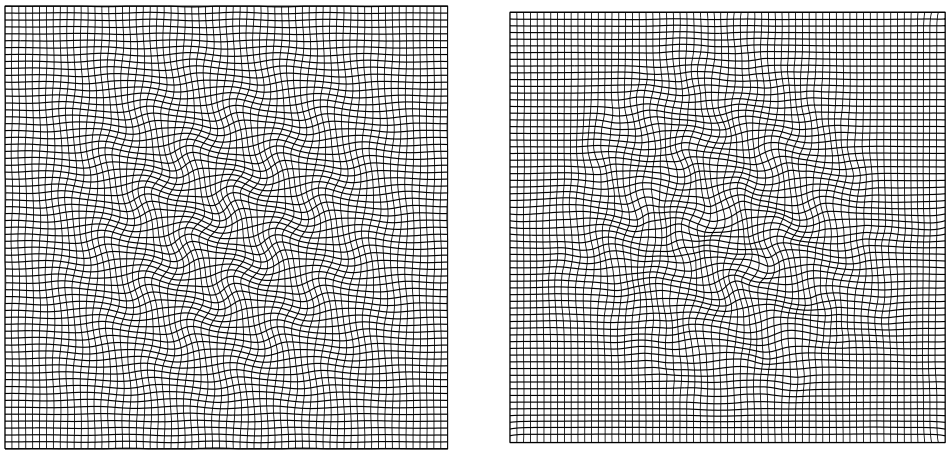

FIG. 2. *Exact deformation ψ (left) and computed deformation ϕ for the example in Figure* 1.

where N_R^ϕ is the transformed normal of the reference image R on $\mathcal{T}_{\phi(x)}\phi(\mathcal{M}^R_{R(x)})$ at position $\phi(x)$. From the transformation rule for the exterior vector product $D\phi\, u \wedge D\phi\, v = \operatorname{Cof} D\phi(u \wedge v)$ for all $v, w \in \mathcal{T}_x\mathcal{M}^R_{R(x)}$, one derives

$$N_R^\phi = \frac{\operatorname{Cof} D\phi\, N_R}{\|\operatorname{Cof} D\phi\, N_R\|},$$

where $\operatorname{Cof} A = \det A \cdot A^{-T}$ for invertible $A \in \mathbb{R}^{d,d}$. In a variational setting, optimality can be expressed in terms of energy minimization. Hence, we consider a matching energy

$$E_m[\phi] := \int_\Omega g(N_T \circ \phi, N_R, \operatorname{Cof} D\phi)\, \mathrm{d}\mu$$

for some function $g : S^{d-1} \times S^{d-1} \times \mathbb{R}^{d,d} \to \mathbb{R}^+;\ (u, v, A) \mapsto g(u, v, A)$. Here S^{d-1} denotes the unit sphere in $\mathbb{R}^d$ and μ the Lebesgue measure. This matching energy depends on the deformation of normal fields, and we are going to relax the energy via a minimizing deformation for fixed image morphologies and hence fixed normal fields. Recently, in image restoration or inpainting, energies have been introduced which depend on the normal fields of images represented by BV functions [5, 6, 7]. There, the energy is minimized over an appropriate set of BV functions on a destroyed image region.

As a boundary condition we require $\phi = \mathbb{1}$ on $\partial\Omega$, where $\mathbb{1}$ indicates the identity mapping on Ω and simultaneously the identity matrix. So far, we have assumed that the normal fields N_T and N_R are well defined on the whole domain Ω. To be not too restrictive with respect to the space of images, we have to take into account the problem of degenerate Gauss maps. Hence, let us define the set $\mathcal{D}_I := \{x \in \Omega \,|\, \nabla I = 0\}$ for $I = T$ or R, where no image normal can be defined. At first, we resolve this problem of undefined normals at least formally by introducing a 0-homogeneous extension $g_0 : \mathbb{R}^d \times \mathbb{R}^d \times \mathbb{R}^{d,d} \to \mathbb{R}^+$ of g in the first and second argument:

$$g_0(v, w, A) = \begin{cases} 0, & v = 0 \text{ or } w = 0, \\ g(\frac{v}{\|v\|}, \frac{w}{\|w\|}, A), & \text{else.} \end{cases} \tag{2.2}$$

Based on g_0 we can redefine the matching energy E_m and obtain

$$E_m[\phi] := \int_\Omega g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi)\, \mathrm{d}\mu. \tag{2.3}$$

In the later analysis we have to take special care of the singularity of g_0 for eliminating the first or second argument. Indeed, we will assume that the measure of D_T and D_R is in a suitable sense sufficiently small. Furthermore, in the existence theory we will explicitly control the impact of these sets on the energy. As a first choice for the energy density g, let us consider

$$g(v, w, A) := \left(v - \frac{Aw}{\|Aw\|} \right)^2 \tag{2.4}$$

for $v, w \in S^{d-1}$, which corresponds to the energy

$$\int_\Omega \|N_T \circ \phi - N_R^\phi\|^2 .$$

We observe that the energy E_m vanishes if $T \circ \phi = \gamma \circ R$ for a monotone gray value transformation $\gamma : \mathbb{R} \to \mathbb{R}$. If we want E_m to vanish also for nonmonotone transformations γ, we are lead to the symmetry assumption:

$$g(v, w, A) = g(-v, w, A) = g(v, -w, A) . \tag{2.5}$$

Example 2.1. A useful class of matching functionals E_m is obtained choosing functions g which depend on the scalar product $v \cdot u$ or alternatively on $(\mathbb{1} - v \otimes v)u$ (where $\mathbb{1} - v \otimes v = (\delta_{ij} - v_i\, v_j)_{ij}$ denotes the projection of u onto the plane normal to v) for $u = \frac{Aw}{\|Aw\|}$ and $v, w \in S^{d-1}$, i.e.,

$$g(v, w, A) = \hat{g}\left((\mathbb{1} - v \otimes v) \frac{Aw}{\|Aw\|} \right). \tag{2.6}$$

Let us remark that $\hat{g}((\mathbb{1} - v \otimes v)u)$ is convex in u if $\hat{g}$ is convex. With respect to arbitrary gray value transformations mapping morphologically identical images onto each other, we might consider $\hat{g}(s) = \|s\|^\gamma$ for some $\gamma \geq 1$.

3. Hyperelastic, polyconvex regularization. Suppose a minimizing deformation ϕ of E_m is given. Then, obviously for any deformation ψ which exchanges the level sets $\mathcal{M}_c^R$ of the image R, the concatenation $\psi \circ \phi$ still is a minimizer. But ψ can be arbitrarily irregular. Hence, minimizing solely the matching energy is an ill-posed problem. Thus, we consider a regularized energy

$$E[\phi] = E_m[\phi] + E_{reg}[\phi] . \tag{3.1}$$

Due to the fact that the matching energy already includes first order derivatives of the deformation ϕ, one might consider a regularization energy which involves higher order derivatives of ϕ [34]. In particular, the existence of minimizers would basically rely on usual compactness arguments. But on the background of elasticity theory, we aim to model the image domain as an elastic body responding to forces induced by the matching energy. Hence, we have to confine ourselves to energies as they appear in the usual mechanical approach to elastic bodies. It will turn out in section 4 that we have nice consistency of the type of nonlinearity in the matching energy with

respect to the Jacobian of the deformation and the well-known structure of nonlinear elastic functionals. We have to emphasize that we do not attempt to model the actual material of the objects represented by the image.

At first, let us briefly recall some background from elasticity. For details we refer to the comprehensive introductions in the books by Ciarlet [13] and Marsden and Hughes [31]. We interpret Ω as an isotropic elastic body and suppose that the regularization energy plays the role of an elastic energy while the matching energy can be regarded as an external potential contributing to the energy. Furthermore we suppose $\phi = \mathbb{1}$ to represent the stress free deformation. Let us consider the deformation of length, area, and volume under a deformation ϕ. It is well known that the norm of the Jacobian of the deformation $\|D\phi\|_2$ controls the isotropically averaged change of length under the deformation, where $\|A\|_2 := \operatorname{tr}(A^T A) = \sum_{i,j} A_{ij} A_{ij}$ for $A \in \mathbb{R}^{d,d}$. Second, the local volume transformation under a deformation ϕ is represented by $\det D\phi$. If $\det D\phi$ changes sign, self-penetration may be observed. Furthermore for $d = 3$, the norm of the matrix of the cofactors of the Jacobian of the deformation $||\operatorname{Cof} D\phi||_2 = \operatorname{tr}(\operatorname{Cof} D\phi^T \operatorname{Cof} D\phi)$ is the proper measure for the averaged change of area.

Example 3.1. Based on these considerations, we can define a simple physically reasonable isotropic elastic energy for $d = 3$, which separately cares about length, area, and volume deformation and especially penalizes volume shrinkage:

$$E_{reg}[\phi] := \int_\Omega a||D\phi||_2^p + b||\operatorname{Cof} D\phi||_2^q + \Gamma(\det D\phi)\,\mathrm{d}\mu \tag{3.2}$$

with $\Gamma(D) \to \infty$ for $D \to 0, \infty$, e.g., $\Gamma(D) = \gamma D^2 - \delta \ln D$. In nonlinear elasticity such material laws have been proposed by Ogden [38], and for $p = q = 2$ we obtain the Mooney–Rivlin model [13].

More general than in the above example, we will consider a so-called polyconvex energy functional (see [17])

$$E_{reg}[\phi] := \int_\Omega W(D\phi, \operatorname{Cof} D\phi, \det D\phi)\,\mathrm{d}\mu, \tag{3.3}$$

where $W : \mathbb{R}^{d,d} \times \mathbb{R}^{d,d} \times \mathbb{R} \to \mathbb{R}$ is supposed to be convex. Besides suitable growth conditions to be stated later, we furthermore assume that W and thereby $E_{reg}[\phi]$ again penalizes volume shrinkage, i.e., $W(A, C, D) \overset{D\to 0}{\longrightarrow} \infty$. This will enable us to successfully control singularity sets. Such energies have already been introduced to the related optical flow problem by Hinterberger et al. [29]. However, their focus was neither on morphological registration nor on the control of singularity sets.

4. An existence result. In this section we will discuss under which conditions there exists a minimizing deformation of the total energy $E[\cdot]$. Let us emphasize that the problem stated here significantly differs from most other regularized image registration problems, e.g., all intensity based approaches, where the matching energy is defined solely in terms of the deformation ϕ and the regularization energy is of higher order and considers the Jacobian $D\phi$ of the deformation. In our case already the matching energy incorporates the cofactor of the Jacobian. Thus, with respect to the direct method in the calculus of variations, we cannot use standard compactness arguments due to Rellich's embedding theorem to deal with the matching energy on a minimizing sequence [17]. Instead, we will need suitable convexity assumptions on the function g.

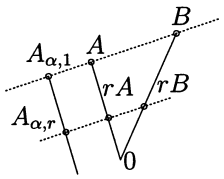

FIG. 3. *Construction as of the proof in Remark* 4.1.

Remark 4.1 (lack of lower semicontinuity for certain functionals E_m). Recalling Example 2.1, we might wish to choose a matching energy with an integrand $g_0(v,w,A) := \hat{g}((\mathbb{1} - \frac{v}{\|v\|} \otimes \frac{v}{\|v\|})\frac{Aw}{\|Aw\|})$ for $\hat{g} \in C^0(\mathbb{R}^d, \mathbb{R}^+_0)$. It is well known that the essential condition to ensure weak sequential lower semicontinuity of functionals depending on the Jacobian of a deformation is quasi-convexity [36, 37]. With our special choice of the class of energies (2.3), this requires the convexity of g in the argument A (cf. [17, sect. 5.1]).

We easily verify that a function

$$f : \mathbb{R}^{d,d} \to \mathbb{R}; A \mapsto f(A)$$

that is 0-homogeneous on $\mathbb{R}^{d,d}$ and convex has to be constant, and thus an existence result for our image matching problem via the direct calculus of variations can only be expected for trivial matching energies, i.e., for $\hat{g} \equiv \text{const}$. Indeed, suppose $A, B \in \mathbb{R}^{d,d}$ with $f(A) - f(B) = \delta > 0$ and define $A_{\alpha,r} := r\,A + \alpha\,(A - B)$ for $r > 0$ and $\alpha > 0$; then for $s = \frac{\alpha}{r}$ we obtain (cf. Figure 3)

$$\begin{aligned} f(A_{\alpha,r}) &= f(r\,A + s\,r\,(A - B)) \\ &\geq f(r\,A) + s\,(f(r\,A) - f(r\,B)) \\ &= f(A) + \frac{\alpha}{r}(f(A) - f(B)) = f(A) + \frac{\alpha\,\delta}{r} \to \infty \end{aligned}$$

for $r \to 0$. Finally, we deduce $f(A-B) = \infty$, which contradicts our assumptions on f. Thus, the definition of the matching energy via the above integrand $\hat{g}((\mathbb{1} - v \otimes w)\frac{Aw}{\|Aw\|})$ and especially our first choice of a matching energy in (2.4) are not appropriate with respect to a positive answer to the question of existence of minimizers via direct methods.

So far, we have not discussed the singularities of the normal fields. Hence, let us introduce assumptions which allow the normals to be undefined on a small set. Indeed, we take into account the space of bounded functions I, which are differentiable and whose gradients are unequal to zero on $\Omega \setminus \mathcal{D}_I$. In particular, the set of degenerate points is defined as $\mathcal{D}_I := \{x \in \Omega \,|\, \nabla I = 0\}$. We suppose that for the Lebesgue measure μ,

$$\mu(B_\epsilon(\mathcal{D}_I)) \overset{\epsilon \to 0}{\longrightarrow} 0\,,$$

where $B_\epsilon(\mathcal{D}_I) := \bigcup\{B_\epsilon(x) \,|\, x \in \mathcal{D}_I\}$. Let us introduce a corresponding set of functions

$$\mathcal{I}(\Omega) := \Big\{ I : \Omega \to \mathbb{R} \;\Big|\; I \in C^1(\bar{\Omega}), \exists\, \mathcal{D}_I \subset \Omega \text{ such that } \nabla I \neq 0 \text{ on } \Omega \setminus \mathcal{D}_I, \\ \mu(B_\epsilon(\mathcal{D}_I)) \overset{\epsilon \to 0}{\longrightarrow} 0 \Big\}\,.$$

The existence proof for minimizers of nonlinear elastic energies via the calculus of variations and direct methods dates back to the work of Ball [3]. In particular, the incorporated control of the volume transformation in this theory turns out to be the key to proving existence of minimizing, continuous, and injective deformations for the image matching problem discussed here. We consider the following energy (cf. (2.3) and (3.3)):

$$E[\phi] := E_m[\phi] + E_{reg}[\phi]\,, \tag{4.1}$$

with

$$E_{reg}[\phi] := \int_\Omega W(D\phi, \operatorname{Cof} D\phi, \det D\phi)\ \mathrm{d}\mu,$$
$$E_m[\phi] := \int_\Omega g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi)\,\mathrm{d}\mu$$

for g_0 defined in (2.2).

Let us denote by L^p for $p \in [1,\infty]$ the usual Lebesgue spaces of functions on Ω into $\mathbb{R}$, $\mathbb{R}^d$, and $\mathbb{R}^{d,d}$, respectively; by $\|\cdot\|_p$, the corresponding norm; and by $H^{1,p}$, the Banach space of functions in L^p with weak first derivatives also in L^p. For ease of presentation, we do not exploit the full generality of the corresponding existence theory. Here the reader is, for instance, referred to [3, 4, 14, 22, 23, 46]. We confine ourselves to a basic model and state the following theorem.

THEOREM 4.2 (existence of minimizing deformations). *Suppose $d = 3$ and $T, R \in \mathcal{I}(\Omega)$ and consider the total energy defined in* (4.1) *for deformations ϕ in the set of admissible deformations*

$$\mathcal{A} := \{\phi : \Omega \to \Omega \mid \phi \in H^{1,p}(\Omega), \operatorname{Cof} D\phi \in L^q(\Omega),$$
$$\det D\phi \in L^r(\Omega), \det D\phi > 0 \text{ a.e. in } \Omega, \phi = \mathbb{1} \text{ on } \partial\Omega\},$$

where p, $q > 3$ and $r > 1$. Suppose $W : \mathbb{R}^{3,3} \times \mathbb{R}^{3,3} \times \mathbb{R}^+ \to \mathbb{R}$ is convex and there exist constants $\beta, s \in \mathbb{R}$, $\beta > 0$, and $s > \frac{2q}{q-3}$ such that

$$W(A,C,D) \geq \beta\left(\|A\|_2^p + \|C\|_2^q + D^r + D^{-s}\right) \quad \forall A, C \in \mathbb{R}^{3,3},\ D \in \mathbb{R}^+. \tag{4.2}$$

Furthermore, assume that $g_0(v,w,A) = g(\frac{v}{\|v\|}, \frac{w}{\|w\|}, A)$ for some function $g : S^2 \times S^2 \times \mathbb{R}^{3,3} \to \mathbb{R}_0^+$, which is continuous in $\frac{v}{\|v\|}$, $\frac{w}{\|w\|}$ and convex in A, and for a constant $m < q$ the estimate

$$g(v,w,A) - g(u,w,A) \leq C_g\ \|v-u\|\ (1 + \|A\|_2^m)$$

holds for all $u, v, w \in S^2$ and $A \in \mathbb{R}^{3,3}$. Then $E[\cdot]$ attains its minimum over all deformations $\phi \in \mathcal{A}$ and the minimizing deformation ϕ is a homeomorphism and, in particular, $\det D\phi > 0$ *a.e. in* Ω.

Proof. The proof of this result is based on the well-known weak continuity results for the principle invariants of the Jacobian of the deformation. We observe that the total energy is polyconvex. Furthermore, the volume of the neighborhood sets $B_\epsilon(\mathcal{D}_T)$ and $B_\epsilon(\mathcal{D}_R)$ of the singularity sets $\mathcal{D}_T$ and $\mathcal{D}_R$, respectively, can be controlled. Hence, we can basically confine ourselves to a set where the integrand fulfills Carathéodory's conditions. At first, let us recall some well-known, fundamental weak convergence results: Given a sequence of deformations $(\phi^k)_k$ in $H^{1,p}$, with $\operatorname{Cof} D\phi^k \in L^q$ and $\det D\phi^k \in L^r$, such that the sequence converges weakly in the sense $\phi^k \rightharpoonup \phi$ in $H^{1,p}$,$\operatorname{Cof} D\phi^k \rightharpoonup C$ in L^q, and $\det D\phi^k \rightharpoonup D$ in L^r, then $C = \operatorname{Cof} D\phi$ and $D = \det D\phi$

(weak continuity). For the proof we refer to Ball [3] or the book of Ciarlet [13, sect. 7.5, 7.6].

The proof of the theorem proceeds in four steps.

Step 1. Due to the assumption on the image set $\mathcal{I}(\Omega)$, $E_m[\phi]$ is well defined for $\phi \in \mathcal{A}$. In particular, $g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi)$ is measurable. Obviously $\mathbb{1} \in \mathcal{A}$ and $E[\mathbb{1}] < \infty$; thus $\underline{E} := \inf_{\phi\in\mathcal{A}} E[\phi] < \infty$, and due to the growth conditions and the assumption of g we furthermore get $\underline{E} \geq 0$. Let us consider a minimizing sequence $(\phi^k)_{k=0,1,\ldots} \subset \mathcal{A}$ with $E[\phi^k] \to \inf_{\phi\in\mathcal{A}} E[\phi]$. We denote by $\overline{E}$ an upper bound of the energy E on this sequence. Due to the growth condition on W we get that $\{(D\phi^k, \operatorname{Cof} D\phi^k, \det D\phi^k)\}_{k=0,1,\ldots}$ is uniformly bounded in $L^p(\Omega) \times L^q(\Omega) \times L^r(\Omega)$. By Poincaré's inequality applied to $(\phi^k - \mathbb{1})$ we obtain that $\{\phi^k\}_{k=0,1,\ldots}$ is uniformly bounded in $H^{1,p}(\Omega)$. Because of the reflexivity of $L^p \times L^q \times L^r$ for p, q, $r > 1$, we can extract a weakly convergent subsequence, again denoted by an index k, such that

$$(D\phi^k, \operatorname{Cof} D\phi^k, \det D\phi^k) \rightharpoonup (D\phi, C, D)$$

in $L^p \times L^q \times L^r$ with $C : \Omega \to \mathbb{R}^{3\times 3}$, $D : \Omega \to \mathbb{R}$. Applying the above results on weak convergence, we achieve $C = \operatorname{Cof} D\phi$ and $D = \det D\phi$. In addition, by Rellich's embedding theorem we know that $\phi^k \to \phi$ strongly in $L^p(\Omega)$, and by Sobolev's embedding theorem we obtain $\phi \in C^0(\bar{\Omega})$.

Step 2. Next, we control the set where the volume shrinks by a factor of more than ϵ for the limit deformation. Let us define

$$S_\epsilon = \{x \in \Omega \,|\, \det D\phi \leq \epsilon\}$$

for $\epsilon \geq 0$. Let as assume without loss of generality that the sequence of energy values $E[\phi^k]$ is monotone decreasing and that for given $\epsilon > 0$ we denote by $k(\epsilon)$ the smallest index such that

$$E[\phi^k] \leq E[\phi^{k(\epsilon)}] \leq \underline{E} + \epsilon \qquad \forall k \geq k(\epsilon)\,.$$

From Step 1 we know that $\Psi^k := (D\phi^k, \operatorname{Cof} D\phi^k, \det D\phi^k)$ converges weakly to $\Psi := (D\phi, \operatorname{Cof} D\phi, \det D\phi)$ in $L^p \times L^q \times L^r$. Hence, applying Mazur's lemma, we obtain a sequence of convex combinations of Ψ^k and ϕ^k which converges strongly to Ψ and ϕ in $L^p \times L^q \times L^r \times L^p$. Thus, there exists a family of weights $((\lambda_i^k)_{k(\epsilon)\leq i\leq k})_{k\geq k(\epsilon)}$ with $\lambda_i^k \geq 0$, $\sum_{k(\epsilon)}^k \lambda_i^k = 1$, such that

$$\lambda_i^k \Psi^i \to \Psi \;\text{ and }\; \lambda_i^k \phi^i \to \phi\,.$$

Now, taking into account the growth conditions, the convexity of W, and Fatou's lemma, we estimate

$$\begin{aligned}
\beta\epsilon^{-s}\mu(S_\epsilon) &\leq \beta \int_{S_\epsilon} (\det D\phi)^{-s}\,\mathrm{d}\mu \leq \int_{S_\epsilon} W(\Psi)\,\mathrm{d}\mu \\
&= \int_{S_\epsilon} \liminf_{k\to\infty} W(\lambda_i^k \Psi^i)\,\mathrm{d}\mu \leq \int_{S_\epsilon} \liminf_{k\to\infty} \lambda_i^k W(\Psi^i)\,\mathrm{d}\mu \\
&\leq \liminf_{k\to\infty} \lambda_i^k \int_{S_\epsilon} W(\Psi^i)\,\mathrm{d}\mu \\
&\leq \liminf_{k\to\infty} \lambda_i^k \int_{\Omega} W(\Psi^i) + g_0(\nabla T \circ \phi^i, \nabla R, \operatorname{Cof} D\phi^i)\,\mathrm{d}\mu \\
&\leq \overline{E}
\end{aligned}$$

and claim $\mu(S_\epsilon) \leq \frac{\bar{E}\epsilon^s}{\beta}$. As one consequence, S_0 is a null set and we know that $\det D\phi > 0$ a.e. on Ω. Thus, taking this together with the results from Step 1, we de-

duce that the limit deformation ϕ is in the set of admissible deformation $\mathcal{A}$. Following Ball [4], we furthermore obtain that ϕ is injective and ϕ is a homeomorphism.

Step 3. Now, we deal with the singularity set of the images T. By our assumption on the image set $\mathcal{I}(\Omega)$, we know that for given $\delta > 0$ there exist $\epsilon_T > 0$ such that $\mu(B_{\epsilon_T}(\mathcal{D}_T)) \leq \delta$. From this and the injectivity (cf. Theorem 1(ii) in [4]), we especially deduce the estimate

$$\begin{aligned}\mu\left(\phi^{-1}(B_{\epsilon_T}(\mathcal{D}_T)) \setminus S_\epsilon\right) &\leq \frac{1}{\epsilon}\int_{\phi^{-1}(B_{\epsilon_T}(\mathcal{D}_T))} \det D\phi \,\mathrm{d}\mu \\ &= \frac{1}{\epsilon}\int_{B_{\epsilon_T}(\mathcal{D}_T)} \mathrm{d}\mu \leq \frac{\delta}{\epsilon}\,.\end{aligned}$$

Hence, we can control the preimage of $B_\epsilon(\mathcal{D}_T)$ with respect to ϕ but restricted to $\Omega \setminus S_\epsilon$. Due to the continuous differentiability of both images T and R, we can assume that

$$\|\nabla T(x)\| \geq \gamma(\epsilon) \text{ on } \Omega \setminus B_\epsilon(\mathcal{D}_T), \tag{4.3}$$

where $\gamma : \mathbb{R}_0^+ \to \mathbb{R}$ is a strictly monotone function with $\gamma(0) = 0$.

Step 4. Due to Egorov's theorem and the strong convergence of ϕ^k in $L^p(\Omega)$, there is a set K_ϵ with $\mu(K_\epsilon) < \epsilon$ such that a subsequence, again denoted by ϕ^k, converges uniformly on $\Omega \setminus K_\epsilon$. Let us now define the set

$$R_{\epsilon,\delta} := \phi^{-1}(B_{\epsilon_T}(\mathcal{D}_T)) \cup S_\epsilon \cup K_\epsilon\,,$$

whose measure can be estimated in terms of ϵ and δ, i.e.,

$$\mu(R_{\epsilon,\delta}) \leq \frac{\delta}{\epsilon} + \frac{\bar{E}\epsilon^s}{\beta} + \epsilon\,.$$

On $\Omega \setminus R_{\epsilon,\delta}$ the sequence $(\nabla T \circ \phi^k)_{k=0,1,\dots}$ converges uniformly to $\nabla T \circ \phi$. Next, from the assumption on g and the 0-homogeneous extension property of g_0, we deduce that

$$|g_0(u,w,A) - g_0(v,w,A)| \leq C_\gamma \,\|u-v\|\,(1 + \|A\|_2^m) \tag{4.4}$$

for $u, v, w \in \mathbb{R}^3$, $A \in \mathbb{R}^{3,3}$, and $\|u\|\,, \|v\|\,, \|w\| \geq \gamma$. To use this estimate for $u = \phi^k$ and $v = \phi$ below, we assume that $k(\epsilon)$ is large enough such that $\phi^k(x) \in \Omega \setminus B_{\frac{\epsilon_T}{2}}(\mathcal{D}_T)$ for $x \in \Omega \setminus R_{\epsilon,\delta}$ and

$$C_{\gamma(\frac{\epsilon_T}{2})} \left\|\nabla T \circ \phi^k - \nabla T \circ \phi\right\|_{\infty,\Omega\setminus K_\epsilon} \leq \epsilon$$

for all $k \geq k(\epsilon)$. Now we are able to estimate $E[\phi]$ using especially the convexity of W and $g(v,w,\cdot)$, the estimate (4.4), and Fatou's lemma:

$$\begin{aligned}E[\phi] &= \int_\Omega W(\Psi) + g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi)\,\mathrm{d}\mu \\ &\leq \int_\Omega \liminf_{k\to\infty} \lambda_i^k W(\Psi^i)\,\mathrm{d}\mu + 2\,C_g \int_{R_{\epsilon,\delta}} 1 + \|\operatorname{Cof} D\phi\|^m \,\mathrm{d}\mu \\ &\quad + \int_{\Omega\setminus R_{\epsilon,\delta}} \liminf_{k\to\infty} \lambda_i^k g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi^i)\,\mathrm{d}\mu \\ &\leq \liminf_{k\to\infty} \lambda_i^k \int_\Omega W(\Psi^i)\,\mathrm{d}\mu + b(\mu(R_{\epsilon,\delta})) \\ &\quad + \liminf_{k\to\infty} \lambda_i^k \int_{\Omega\setminus R_{\epsilon,\delta}} g_0(\nabla T \circ \phi, \nabla R, \operatorname{Cof} D\phi^i) - g_0(\nabla T \circ \phi^i, \nabla R, \operatorname{Cof} D\phi^i) \\ &\qquad\qquad + g_0(\nabla T \circ \phi^i, \nabla R, \operatorname{Cof} D\phi^i)\,\mathrm{d}\mu,\end{aligned}$$

where $b(s) := 2\,C_g(s + (\frac{\bar{E}}{\beta})^{\frac{m}{q}} s^{1-\frac{m}{q}})$. Here we have, in particular, used the a priori estimate $\|\mathrm{Cof}\, D\phi\|_{q,\Omega} \le (\frac{\bar{E}}{\beta})^{\frac{1}{q}}$. We estimate further and obtain

$$\begin{aligned} E[\phi] &\le \liminf_{k\to\infty} \lambda_i^k \int_\Omega W(\Psi^i) + g_0(\nabla T \circ \phi^i, \nabla R, \mathrm{Cof}\, D\phi^i)\,\mathrm{d}\mu + 2\,b(\mu(R_{\epsilon,\delta})) \\ &\quad + C_{\gamma(\frac{\epsilon_T}{2})} \limsup_{k\to\infty} \int_{\Omega\setminus R_{\epsilon,\delta}} \left\|\nabla T\circ\phi - \nabla T\circ\phi^k\right\| \left(1 + \left\|\mathrm{Cof}\, D\phi^k\right\|_2^m\right) \mathrm{d}\mu \\ &\le \liminf_{k\to\infty} \lambda_i^k E[\phi^i] + 2\,b(\mu(R_{\epsilon,\delta})) + \epsilon\, b(\mu(\Omega)) \\ &\le \underline{E} + \epsilon + 2\,b(\mu(R_{\epsilon,\delta})) + \epsilon\, b(\mu(\Omega))\,. \end{aligned}$$

Finally, for given $\bar{\epsilon}$ we choose ϵ, then δ, the dependent ϵ_T small enough, and $k(\bar{\epsilon})$ large enough to ensure that

$$\epsilon + 2\,b(\mu(R_{\epsilon,\delta})) + \epsilon\, b(\mu(\Omega)) \le \bar{\epsilon}$$

and get $E[\phi] \le \underline{E} + \bar{\epsilon}$. This holds true for an arbitrary choice of $\bar{\epsilon}$. Thus we conclude

$$E[\phi] \le \underline{E} = \inf_{\phi\in\mathcal{A}} E[\phi]\,,$$

which is the desired result. □

Remark 4.3. From the proof we have seen that the assumptions on the reference image could be weakened considerably compared to the template image. With respect to the applications, we do not detail this difference here.

Example 4.4. Let us consider

$$g(v, w, A) = \|(\mathbb{1} - v\otimes v)\cdot Aw\|^\gamma \tag{4.5}$$

for $1 \le \gamma < q$. Hence, we obtain an admissible matching energy

$$E_m[\phi] = \int_\Omega \|(\mathbb{1} - (N_T\circ\phi)\otimes(N_T\circ\phi))\cdot \mathrm{Cof}\, D\phi\, N_R\|^\gamma$$

(cf. Example 2.1). Applying Theorem 4.2, we can establish the existence of a minimizing deformation. Recalling Remark 4.1, we recognize that scaling the original energy density by an additional factor $\|\mathrm{Cof}\, D\phi N_R\|^\gamma$ turns the minimization task into a feasible problem. This corresponds to a modification of the area element on the level sets $\mathcal{M}_c^R$. Indeed, $\|\mathrm{Cof}\, D\phi N_R\|$ is the change of the area element at a position x on $\mathcal{M}^R_{R(x)}$ under the deformation.

5. An additional feature-based registration energy. As the energy $E_m[\phi]$ depends on the directions of the image normals only, its minimization will lead to an alignment of the level sets of the two images. However, the alignment of significant level sets, which correspond to significant features, is not taken into account by the energy. In medical applications, such features may be boundaries of organs, bones, or tissue structures. Hence, we will incorporate an additional energy which measures the quality of the match of certain clearly detectable features. Suppose $\mathcal{F}_T$ and $\mathcal{F}_R$ are corresponding selected feature sets in the images T and R. These feature sets may be computed in a previous segmentation step applying, for instance, an active contour algorithm [9, 20] (cf. Figure 4 for an example of a pair of corresponding feature sets).

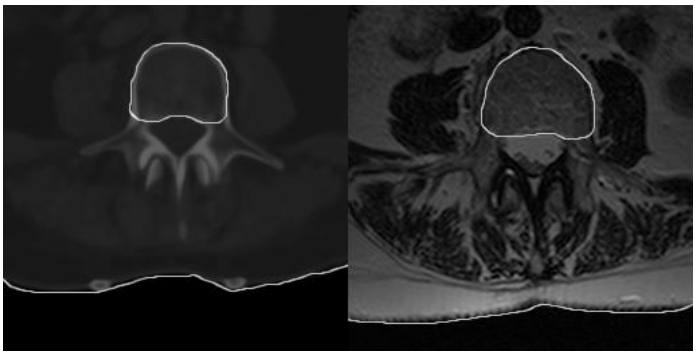

FIG. 4. *Feature sets $\mathcal{F}_R$ and $\mathcal{F}_T$ superimposed on darkened corresponding images for better visibility (cf. Figure* 6 *for registration results).*

We are aiming to penalize a nonproper match of these two sets by a suitable energy. They would be ideally matched if

$$\mathcal{F}_T = \phi(\mathcal{F}_R).$$

The following energy measures the matching quality for a general deformation ϕ:

$$E_f[\phi] = \int_\Omega |d(\phi(\cdot), \mathcal{F}_T) - d(\cdot, \mathcal{F}_R)|^2 \, \mathrm{d}\mu \,, \tag{5.1}$$

where $d(x, A) := \hat{d} \circ \mathrm{dist}(x, A)$ is a function $\hat{d}$ of the distance of a point x from a set $A \subset \Omega$. We suppose $\hat{d} : \mathbb{R}_0^+ \to \mathbb{R}_0^+$ to be monotone and $\hat{d}(0) = 0$. In particular, E_f vanishes in case of a perfect match. A suitable choice is $\hat{d}(s) = \alpha s^\delta$ with $0 < \delta \leq 1$ and $\alpha > 0$. We use this energy as a third term in the regularized problem (3.1).

COROLLARY 5.1 (existence of minimizers in the presence of a feature matching energy). *Suppose the assumptions of Theorem* 4.2 *hold. Furthermore, let $\hat{d} : \mathbb{R}_0^+ \to \mathbb{R}_0^+$ be continuous, and consider*

$$E[\phi] = E_m[\phi] + E_{reg}[\phi] + E_f[\phi] \,. \tag{5.2}$$

Then $E[\cdot]$ attains its minimum over all deformations $\phi \in \mathcal{A}$, the minimizing deformation ϕ is a homeomorphism, and, furthermore, $\det D\phi > 0$ *a.e. in* Ω.

Proof. Due to the Lipschitz continuity of $\mathrm{dist}(\cdot, A)$ for arbitrary sets $A \subset \Omega$ with $A \neq \emptyset$ and the continuity of $\hat{d}$, the integrand of E_f is uniformly continuous in ϕ. Hence, the proof of Theorem 4.2 can easily be generalized. ∎

The overall energy will therefore not only align the directions correctly but also penalize displaced features. In this setting it is thus possible to incorporate some a priori knowledge to improve the matching results. Let us emphasize that the morphological registration provides good results if the morphologies encoded by the normal fields of the two images actually coincide up to a deformation. But in cases where the images of different modalities reveal similar but different geometrical structures, which are not strictly equivalent in terms of mathematical morphology, a weak form of "landmarks" is recommendable to support the matching.

6. Generalized boundary conditions. So far we have imposed boundary conditions of Dirichlet type on $\partial\Omega$ for the deformation. This might be a reasonable assumption in the case of objects located in the center of the image at a considerable

distance from the boundary (cf. Figure 1). If the objects cover the whole image domain, we cannot assume that the requested deformation obeys these artificial boundary conditions. In fact, structures visible close to the boundary in the reference image R will not be present in the template image T and vice versa. Hence, we ask for more general boundary conditions. With these applications in mind, we have to tolerate deformations $\phi(\Omega) \not\subset \Omega$ in the admissible set of deformations. But the integrand of the matching energy is defined only on $\phi^{-1}(\mathrm{Im}\,(\phi) \cap \Omega)$. Hence, we replace $\int_\Omega g_0(\cdot)$ by $\int_{\Omega^\phi} g_0(\cdot)$, where $\Omega^\phi := \{x \in \Omega \,|\, \phi(x) \in \Omega\}$, and obtain the new matching energy

$$\tilde{E}_m[\phi] := \int_{\Omega^\phi} g_0(\nabla T \circ \phi, \nabla R, \mathrm{Cof}\, D\phi)\, \mathrm{d}\mu. \tag{6.1}$$

Taking into account this reformulated matching energy, we are basically facing two problems:

(i) Considering a total energy $E[\phi] = \tilde{E}_m[\phi] + E_{reg}[\phi]$, we are lead to irrelevant, trivial solutions. Indeed, taking into account a simple translation ϕ_{trans} with $\phi_{trans}(\Omega) \cap \Omega = \emptyset$, one obtains $\tilde{E}_m[\phi_{trans}] = 0$. Hence, we no longer measure the matching of relevant image features. We propose to avoid this problem by incorporating the above feature energy $E_f[\phi]$, which can be regarded as a weak boundary condition. Indeed, if $\alpha \to \infty$, we enforce an interior boundary condition on the feature sets, i.e., $\phi(\mathcal{F}_R) = \mathcal{F}_T$.

(ii) Injectivity can no longer be expected for a minimizing deformation. It might happen that parts of the domain Ω fold over each other under a deformation ϕ, although ϕ is locally injective, i.e., $\det D\phi > 0$ (cf. the exposition of this problem in [13, sect. 7.9]). Following Ciarlet and Necas [14], we introduce an additional condition on the set of admissible deformations:

$$\int_\Omega \det D\phi \le \mu(\phi(\Omega))\,.$$

Then, we expect the minimizer of the energy $E = \tilde{E}_m + E_{reg} + E_f$ to be injective on Ω, whereas on $\partial\Omega$ we might observe self-contact. In the actual applications considered so far we have not detected any lack of global injectivity due to overlapping parts of the deformed domain. Hence, there was no need to incorporate this nonlinear contact condition in the algorithm.

7. Multiscale minimization and discretization. The total energy is highly nonlinear. Especially the matching energy E_m with the nonlinearity $\nabla T \circ \phi$ depending on the complexity of image data will usually lead to multiple at-least-local minima. Hence, in order to ensure a robust and efficient minimization, we have to consider a global minimization strategy, which is capable of computing large deformations which minimize the total registration energy. Here we propose a continuous annealing method based on a scale of registration problems

$$\tilde{E}^\sigma[\phi] := \tilde{E}^\sigma_m[\phi] + E_{reg}[\phi] + E_f[\phi]\,,$$

where $\sigma > 0$ is the scale parameter. This enables us to compute global instead of only local deformations and usually avoid a tedious preregistration step. The definition of the energy scales for the matching energy is based on a scale space approach for the underlying images (cf. [2]). We choose

$$E^\sigma_m[\phi] := \int_{\Omega^\phi} g_0(\nabla T^\sigma \circ \phi, \nabla R^\sigma, \mathrm{Cof}\, D\phi)\, \mathrm{d}\mu\,,$$

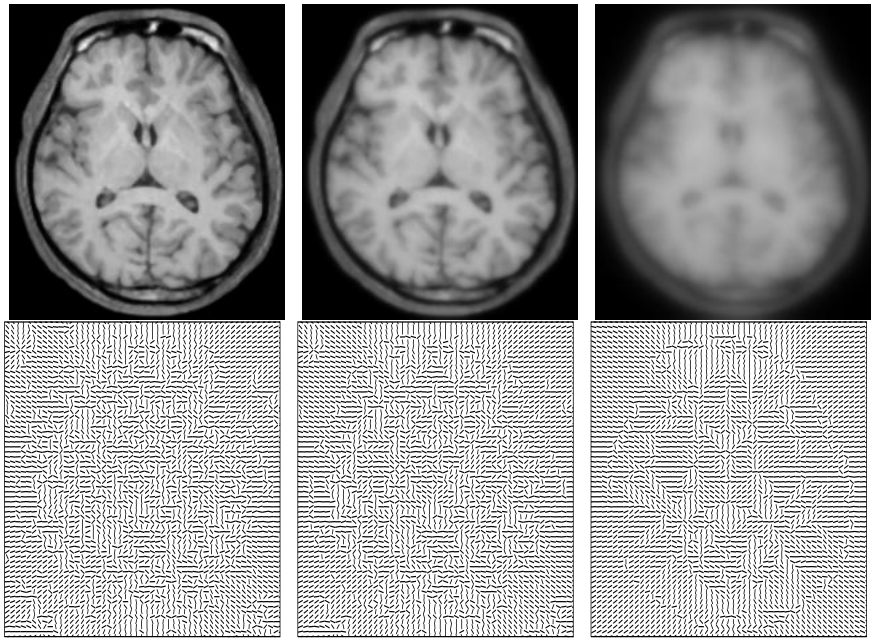

FIG. 5. *Image and the Gauss map and the corresponding grid for the brain slice at scales* $\sigma = h, 2h, 8h$.

where $I^\sigma := G^\sigma[I]$ for $I = T, R$ and G^σ denotes the convolution with a "Gaussian" filter of width σ (cf. Figure 5 for a multiscale of images and the corresponding effect on the Gauss maps N_T^σ and N_R^σ). In fact, we consider the heat equation semigroup and set $I^\sigma := u(\sigma^2/2)$, where u is the solution of the initial boundary value problem

$$\begin{aligned} \partial_t u - \Delta u &= 0 \qquad \text{in } \mathbb{R}^+ \times \Omega\,, \\ \partial_\nu u(t,\cdot) &= 0 \qquad \text{on } \mathbb{R}^+ \times \partial\Omega\,, \\ u(0,\cdot) &= I \qquad \text{in } \Omega\,, \end{aligned} \tag{7.1}$$

and ν denotes the outer normal on $\partial\Omega$. Concerning the spatial discretization, we deal with images as piecewise bilinear, continuous functions on a regular quadrilateral grid. We use the same discrete function space to define discrete nonrigid deformations. Energy functionals and their gradients are numerically evaluated using a midpoint quadrature rule on the grid cells. We assume $\Omega = [0,1]^2$ and start with an initial coarse mesh $\mathcal{M}_0 = \{\Omega\}$, which is iteratively refined by uniform subdivision, where each element is divided into four squares. This refinement process generates sequences of nested meshes $\mathcal{M}_l$, with $0 \le l \le l_{\max}$, consisting of quadrilateral elements E_l^i $(0 \le i < 4^l)$ of edge length $h_l = 2^{-l}$. The set of vertices of $\mathcal{M}_l$ is denoted by $\mathcal{N}_l$. Let V_l be the corresponding space of piecewise bilinear, continuous finite element functions. Suppose $\{\Psi_l^i\}_{i \le (2^l+1)^2}$ to be the nodal basis of V_l. The discrete gradient $\operatorname{grad}_{V_l} \tilde{E}^\sigma \in V_l^2$ of E on grid level l for a deformation $\Phi \in V_l^2$ is then defined by

$$(\operatorname{grad}_{V_l} \tilde{E}^\sigma[\Phi], \Psi_l^j e_k)_h = \langle (\tilde{E}^\sigma)'[\Phi], \Psi_l^j e_k \rangle$$

TABLE 7.1

To obtain a stable descent in the gradient descent algorithm of the global energy E^σ, the derivative in the direction of the descent direction d, i.e., $(d, gradE^\sigma[\phi])_h$, ought to be ≤ 0 in the scalar product. We have shown the impact of the smoothing parameter α for different scales on $\gamma(-d, gradE^\sigma[\phi])$, where $\gamma(u,v) := \frac{u}{\|u\|} \cdot \frac{v}{\|v\|}$. These values have been determined considering the first 50 steps of the gradient descent of the test example. We list the smallest value $\gamma_{\min}$ and the average value γ_{average}.

Scale $\alpha[h_{l_{\max}}]$	0.25	0.5	1.0	2.0	3.0	4.0	5.0
$\gamma_{\min}$	0.9954	0.9585	0.8265	0.6588	0.58481	0.5438	0.5171
γ_{average}	0.9951	0.9556	0.8177	0.6447	0.5586	0.5116	0.4825

for all $j \leq (2^l+1)^2$ and $k = 1, 2$. Here $(\cdot,\cdot)_h$ denotes the usual lumped mass product on V_l and e_k the canonical basis in $\mathbb{R}^2$. Then, on level l the necessary condition for $\Phi^l \in V_l^2$ to be a minimizer of $\tilde{E}^\sigma$ over V_l is given by

$$\operatorname{grad}_{V_l} E^\sigma[\Phi] = 0 \quad \text{for } \Phi \in V_l.$$

Now, we introduce multiple discrete scales. Therefore, we replace the filter G^σ by its discrete counterpart, replacing problem (7.1) by a single implicit Euler time step with time step size $\frac{\sigma^2}{2}$ for a usual finite element discretization with lumped masses (cf. [42]). We denote the corresponding solution operator on the finite element space V_l by $G_l^\sigma : V_l \to V_l$. On each scale, we apply a gradient descent algorithm to minimize the energy. Here we might consider a sequence of scales

$$\sigma^k = 2^{-k}\sigma_0$$

for $k = 0, \ldots, n$. Obviously, solving a coarse scale minimization process on a fine grid introduces a serious amount of redundancy. It is much more efficient to perform such computations also on coarse grid levels. Thus, we introduce a function l_k which selects for each scale an appropriate grid level. In particular, we choose

$$l_k := \min\{l = 0, \ldots, l_{\max} \,|\, h(l) \leq \gamma\sigma_k\}$$

for a scalar $\gamma > 0$, e. g., $\gamma = 1$, which controls the ratio of the cell size $h(l)$ with respect to a filter width σ_k. On each scale we compute the minimum Φ^k of E^{σ_k} over $V_{l_k}^2$ by a gradient descent method and consider the standard prolongation of $\Phi^{k-1} \in V_{l_{k-1}}$ onto V_{l_k} as the initial value if $l_k \neq l_{k-1}$. It turns out to be suitable to regularize the contribution of the matching energy to the descent direction. Hence, a descent direction $d \in V_{l_k}$ at a position $\Phi \in V_{l_k}^2$ is computed by

$$d := -G_{l_k}^\alpha[\operatorname{grad}_{V_{l_k}} E_m^{\sigma_k}[\Phi]] - \operatorname{grad}_{V_{l_k}} \tilde{E}_{reg}[\Phi] - \operatorname{grad}_{V_{l_k}} E_f[\Phi],$$

where $\alpha > 0$ controls the amount of smoothing of the gradient for the registration energy. We have to ensure

$$(d, \operatorname{grad}\tilde{E}^{\sigma_k}[\Phi])_h \leq 0$$

in order to observe stable descent (cf. Table 7.1).

As step size control we consider Armijo's rule [30]. Let us remark that the smoothing by Gaussian convolution is solved efficiently and independently of the filter width σ

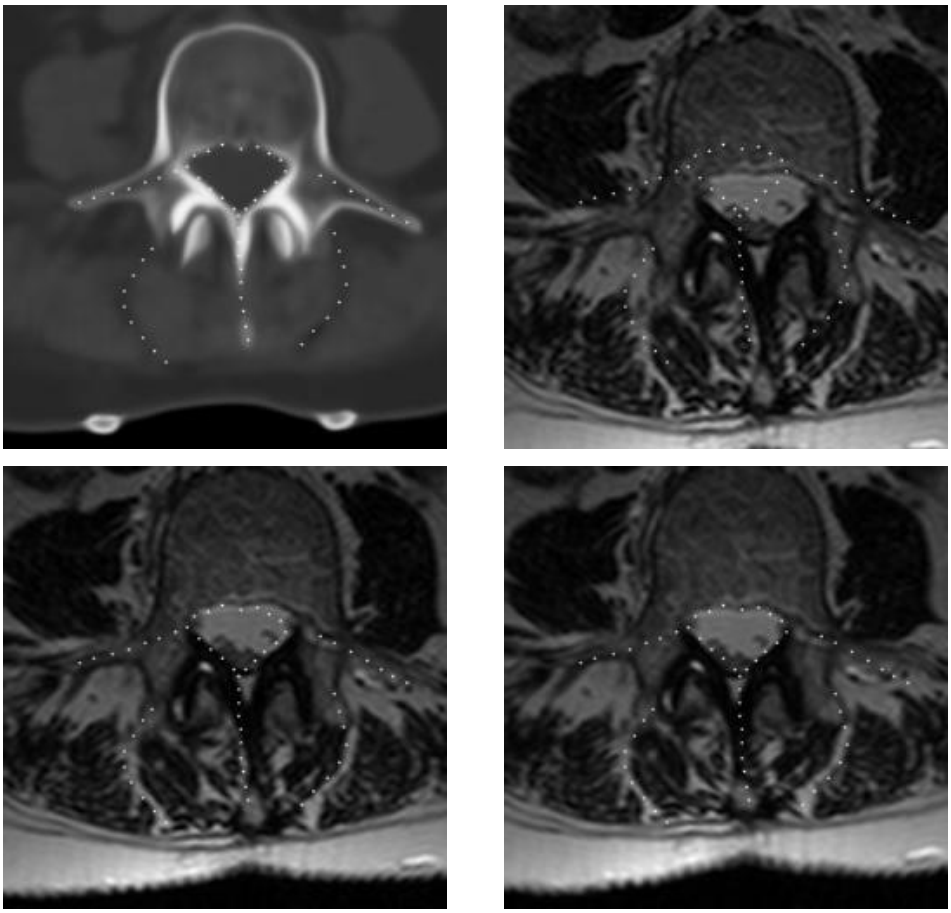

FIG. 6. *Sectional morphological registration on a pair of MR and CT images of a human spine. Dotted lines mark certain features visible in the reference image. They are repeatedly drawn at the same position in the other images. Top left: reference, CT; top right: template, MR, with clearly visible misfit of structures marked by the dotted lines. Bottom left: deformed template after feature-based registration $T \circ \phi_f$, where ϕ_f is the result of a feature-based preregistration (cf. Figure 4 for the feature sets used in this example). Bottom right: deformed template $T \circ \phi$ after final registration, where the dotted feature lines nicely coincide with the same features in the deformed template MR image. All images have a resolution of* 257^2.

by a multigrid solver for the heat equation [25]. In the computation for the registration of real magnetic resonance (MR) and computed tomography (CT) images of a human spine (cf. Figures 6, 7, 8), we chose the parameter α to be $5h_{l_{\max}}$. Furthermore, concerning the elastic regularization that we so far held on to, the Mooney–Rivlin energy, i.e., $p = 2$, q does not have to be specified since the second term of W is redundant in two dimensions. The choices for the further parameters are $a = 0.45$, $\gamma = \frac{1}{2}$, $\delta = 1$. To improve the method's performance we first relax the feature-based energy $E_f[\cdot] + E_{reg}[\cdot]$ to identify an appropriate initial deformation. Then, we continue with the minimization of the global energy $E[\cdot]$.

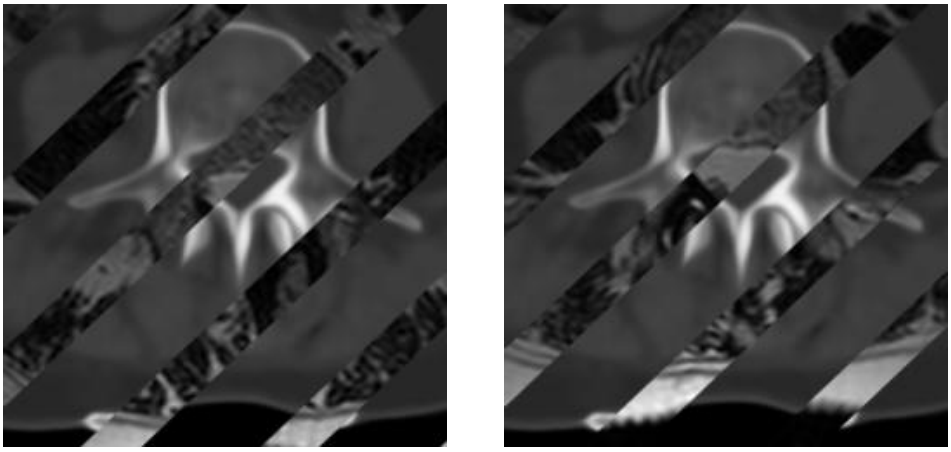

FIG. 7. *Comparison of superimposed template and reference before (left) and after (right) registration.*

Finally, the minimization algorithm can be written in pseudo code as follows.

ALGORITHM 7.1 (multiscale minimization algorithm).

$\Phi_0 := \mathbb{1}$
foreach $k = 0, \dots, n$ **do**
  set level to l_k and grid $\mathcal{M}_{l_k}$
  if $k > 0$ **and** $l_k > l_{k-1}$, **then**
1 prolongate Φ^{k-1} on grid $\mathcal{M}_{l_{k-1}}$ to $\Phi^{k,0}$ on grid $\mathcal{M}_{l_k}$
  end
2 $T_{\sigma_k} := G_{l_k}^{\sigma_k}[T]$, $R_{\sigma_k} := G_{l_k}^{\sigma_k}[R]$,
3 $N_{T_{\sigma_k}} := \frac{\nabla T_{\sigma_k}}{\|\nabla T_{\sigma_k}\|}$, $N_{R_{\sigma_k}} := \frac{\nabla R_{\sigma_k}}{\|\nabla R_{\sigma_k}\|}$,
  $i = 0$
  repeat
4 $d^{k,i} := -G_{l_k}^{\alpha}[\mathrm{grad}_{V_{l_k}} \tilde{E}_m^{\sigma_k}[\Phi^{k,i}]] - \mathrm{grad}_{V_{l_k}} E_{reg}[\Phi^{k,i}] - \mathrm{grad}_{V_{l_k}} E_f[\Phi^{k,i}]$
5 *line-search*: choose step size δ by Armijo's rule
6 $\Phi^{k,i+1} := \Phi^{k,i} + \delta\, d^{k,i}$
  $i := i + 1$
  until $(\|d^{k,i}\| \le TOL$ **or** $i > MAXITER)$;
  $\Phi^k = \Phi^{k,i}$
end

Acknowledgments. The authors thank C. Schaller from the University Hospital at Bonn for many valuable discussions on medical morphology and for providing real data sets. We also thank R. Lachner from BrainLab for providing the test data set, and Ulrich Clarenz and Günther Grün for helpful comments on an early version of the manuscript.

ANALYSIS OF TRANSIENT ELECTROMAGNETIC SCATTERING FROM OVERFILLED CAVITIES*

TRI VAN† AND AIHUA WOOD‡

Abstract. In this paper, we consider the time-domain scattering problem of a two-dimensional overfilled cavity embedded in the infinite ground plane. The problem is first discretized in time by the β, γ Newmark time-marching scheme. At each time step, the variational formulation of the semidiscrete problem is derived via a nonlocal boundary condition to truncate the infinite problem domain. Existence and uniqueness of the variational solutions are established. Error analysis of the fully discrete problem is performed. Stability criteria of the time-stepping scheme are also obtained.

Key words. transient scattering, overfilled cavities in the infinite ground plane, time-domain finite element method, Newmark time-marching, error estimates, stability analysis

1. Introduction. The development of mathematical and numerical methods to accurately predict the radar signature of a target is an important area of research in electromagnetics. Of particular interest is the study of electromagnetic scattering from cavities and the calculation of their radar cross sections (RCS). This is because cavity RCS often dominates a target's overall RCS and is computationally challenging. One of the main difficulties in numerically approximating solutions involving cavities is the appearance of spurious modes caused by interior resonances. A variety of techniques have been developed to simulate the scattering by cavities. They include high and low frequency methods [9, 16, 6, 23, 20], the method of moments [29, 19, 30], the time-domain finite difference method [7], the finite element method [15, 22], and several hybrid methods [21, 14, 5]. These methods are limited to a certain range of frequencies and/or small/simple cavities. Recently, the hybrid finite element–boundary integral (FE-BI) methods have gained increasing popularity for their ability to model large and complex cavities [12, 13, 11, 18, 17]. Most of the results reported in the engineering literature appear experimental in nature. Mathematical treatment of scattering problems involving cavities can be found in [2, 3, 4, 25, 28, 27]. It is a common assumption that the cavity opening coincides with the aperture on an infinite ground plane, hence simplifying the modelling of the exterior (to the cavity) domain. This severely limits the application of these methods since many cavity openings are not planar. This paper aims to develop a solid mathematical technique that is capable of characterizing the scattering by overfilled cavities.

In particular, we seek to determine the fields scattered by the protruding cavity upon a given incident wave. Our method decomposes the entire infinite solution domain to two subdomains: the infinite upper half plane over the perfect electrically

conducting (PEC) ground plane exterior to the hemisphere enclosing the cavity aperture, and the cavity plus the hemisphere region. The problem is solved exactly in the infinite subdomain, while the other is solved using finite elements. The two regions are coupled over the hemisphere via the introduction of a boundary operator exploiting the field continuity over material interfaces. Other FE-BI schemes, such as those reported in [12] and [11], employ image theory to produce conformal boundaries and hence limit the size of the finite element computational domain. The trade-off, however, is the complexity of the integral equation, which can be very expensive in order to achieve good accuracy. By using the semicircular boundary, exact series solutions are possible which can be accurately computed and are error-controllable. For protruding cavity problems, boundary conditions based on series representations appear more desirable.

In section 1 we discretize the problem in time using the Newmark time-stepping scheme. A similar scheme has been successfully implemented for the scattering by cavities embedded in the infinite ground plane [26]. The key point in the proof of the well-posedness of the resulting semidiscrete problem is the derivation and careful examination of the properties of the boundary operator. The problem is fully discretized in section 4, where stability criteria and error estimates are obtained. We believe this is the first thorough mathematical treatment of scattering problems involving overfilled cavities. It provides a solid mathematical foundation for researchers in both the applied mathematics and the engineering communities to develop accurate and efficient numerical solvers for RCS predictions for targets of a cavity nature. The paper is concluded in section 5.

2. Problem setting. Let $\Omega \subset \mathbb{R}^2$ be the cross section of a z-invariant cavity (or trough) in the infinite ground plane such that its fillings of relative permittivity $\varepsilon_r \geq 1$ protrude above the ground plane. Let $(\boldsymbol{E}^i, \boldsymbol{H}^i)$ be an electromagnetic wave incident on the cavity to generate the scattered field $(\boldsymbol{E}^s, \boldsymbol{H}^s)$. The scattering problem is to find $(\boldsymbol{E}^s, \boldsymbol{H}^s)$.

In the rest of the paper, we denote S as the cavity wall, Γ as the cavity aperture so that $\partial\Omega = S \cup \Gamma$. The infinite ground plane excluding the cavity opening is denoted as Γ_{ext}. Finally, the infinite homogeneous region above the cavity is denoted as $\mathcal{U} = \mathbb{R}^2_+ \setminus \Omega$.

Due to the uniformity in the z-axis, the scattering problem can be decomposed into two fundamental polarizations: transverse magnetic (TM) and transverse electric (TE). Its solution then can be expressed as a linear combination of the solutions to TM and TE problems. In the TM polarization, the magnetic field $\boldsymbol{H}$ is transverse to the z-axis so that $\boldsymbol{E}$ and $\boldsymbol{H}$ are of the form

$$\boldsymbol{E} = (0, 0, E_z), \quad \boldsymbol{H} = (H_x, H_y, 0).$$

In this case, the nonzero component of the total field, also denoted as $\boldsymbol{E}$, satisfies the following equation:

$$\text{(TM)} \quad \begin{cases} -\Delta E_z + \varepsilon_r \dfrac{\partial^2 E_z}{\partial t^2} &= 0 \quad \text{in } \Omega \cup \mathcal{U} \times (0, \infty), \\ E_z &= 0 \quad \text{on } S \cup \Gamma_{ext} \times (0, \infty), \\ E_z|_{t=0} = E_0, \qquad & \left.\dfrac{\partial E_z}{\partial t}\right|_{t=0} = E_{t,0}, \end{cases}$$

where ε_r is the relative electric permittivity, E_0 and $E_{t,0}$ are given initial conditions. The homogeneous region $\mathcal{U}$ above the protruding cavity is assumed to be air, and hence

its permittivity is $\varepsilon_r = 1$. In $\mathcal{U}$, the total field can be decomposed as $E_z = E_z^i + E_z^r + E_z^s$, where E_z^i is the incident field, E_z^r the reflected field, and E_z^s the scattered field. The reflected field exists due to the presence of the infinite ground plane. The incident and reflected electric fields satisfy

$$E_z^i + E_z^r = 0 \quad \text{on } \Gamma_{ext} \subset \{(x, y) : y = 0\}.$$

The scattered field E_z^s solves

$$(\mathrm{TM}^s) \quad \begin{cases} -\Delta E_z^s + \dfrac{\partial^2 E_z^s}{\partial t^2} &= 0 \quad \text{in } \mathcal{U} \times (0, \infty), \\ E_z^s &= E_z - E_z^i - E_z^r \quad \text{on } \Gamma \times (0, \infty), \\ E_z^s &= 0 \quad \text{on } \Gamma_{ext} \times (0, \infty) \end{cases}$$

and satisfies the radiation condition at infinity, that is,

$$\lim_{r \to \infty} \sqrt{r} \left(\frac{\partial E_z^s}{\partial r} + \frac{1}{c} \frac{\partial E_z^s}{\partial t} \right) = 0, \quad t > 0. \tag{2.1}$$

The components of $\boldsymbol{H}$ can be obtained in terms of E_z and its partial derivatives by using Maxwell's equations.

Similarly, in the TE polarization, the electric field $\boldsymbol{E}$ is transverse to the z-axis and hence

$$\boldsymbol{E} = (E_x, E_y, 0), \quad \boldsymbol{H} = (0, 0, H_z).$$

The nonzero component of the total magnetic field, also denoted by $\boldsymbol{H}$, satisfies the following equation:

$$(\mathrm{TE}) \quad \begin{cases} -\nabla \cdot \left(\frac{1}{\varepsilon_r} \nabla H_z \right) + \dfrac{\partial^2 H_z}{\partial t^2} &= 0 \quad \text{in } \Omega \cup \mathcal{U} \times (0, \infty), \\ \dfrac{\partial H_z}{\partial n} &= 0 \quad \text{on } S \cup \Gamma_{ext} \times (0, \infty), \\ H_z|_{t=0} = H_0, & \dfrac{\partial H_z}{\partial t}|_{t=0} = H_{t,0}, \end{cases}$$

where H_0 and $H_{t,0}$ are given initial conditions. In U_R, the total magnetic field can be decomposed into $H_z = H_z^i + H_z^r + H_z^s$, where

$$\frac{\partial H_z^i}{\partial y} + \frac{\partial H_z^s}{\partial y} = 0 \quad \text{on } \{(x, y) : y = 0\}.$$

The scattered field solves

$$(\mathrm{TE}^s) \quad \begin{cases} -\Delta H_z^s + \dfrac{\partial^2 H_z^s}{\partial t^2} &= 0 \quad \text{in } \mathcal{U} \times (0, \infty), \\ \dfrac{\partial H_z^s}{\partial n} &= 0 \quad \text{on } \Gamma_{ext}, \\ \dfrac{\partial H_z^s}{\partial n} &= \dfrac{1}{\varepsilon_r} \dfrac{\partial H_z}{\partial n} - \dfrac{\partial H_z^i}{\partial n} - \dfrac{\partial H_z^r}{\partial n} \quad \text{on } \Gamma \times (0, \infty), \end{cases}$$

where $\frac{\partial}{\partial n}$ is the normal derivative on Γ. The scattered magnetic field also satisfies the same radiation condition defined in (2.1). The components of $\boldsymbol{E}$ can be obtained in terms of H_z and its partial derivatives by using Maxwell's equations.

In the next section, we apply the Newmark time-marching scheme to temporally discretize (TM), (TM^s), (TE), and (TE^s). The resulting equations are called *semi-discrete* equations since only the time variable t is discretized.

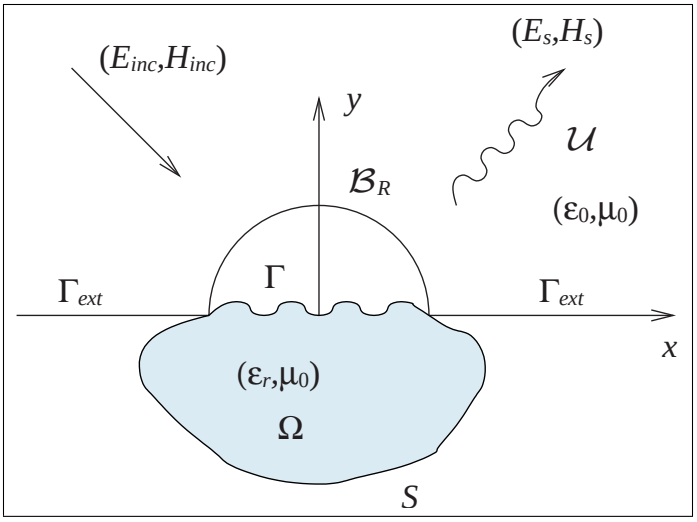

FIG. 1. *Cavity setting.*

3. Semidiscrete problems. First, let $\mathcal{B}_R$ be a semicircle of radius R large enough to completely enclose the overfilled portion of the cavity (see Figure 1). We denote the region bounded by $\mathcal{B}_R$ and the cavity wall S as Ω_R. Hence, this region Ω_R consists of the cavity and the homogeneous part between $\mathcal{B}_R$ and Γ. Let U_R be the homogeneous region outside of Ω_R, that is, $U_R = \{(r,\theta) : r > R, 0 < \theta < \pi\}$.

In this section, the TM and TE equations are discretized in time by using the Newmark time-marching scheme. The Newmark algorithm is a two-step algorithm and can be used in predictor-corrector form [31, 32]. At each time step, we construct a nonlocal boundary condition on the semicircle $\mathcal{B}_R$ to couple the solution in the infinite domain exterior to $\mathcal{B}_R$ and the solution in the bounded domain inside $\mathcal{B}_R$. The boundary condition enables us to reduce the infinite problem domain into a bounded one. The Newmark scheme is defined by the following.

Let $\mathcal{N}$ be a positive integer, $\Delta t = T/\mathcal{N}$ be the temporal step size, and $t_{n+1} = (n+1)\Delta t$ for $n = 0, 1, 2, \ldots, \mathcal{N}-1$. Denote u^{n+1}, $\dot{u}^{n+1}$, and $\ddot{u}^{n+1}$ as the approximations of u, $\frac{\partial u}{\partial t}$, and $\frac{\partial^2 u}{\partial t^2}$ at $t = t_{n+1}$, respectively. These approximations are related by

$$u^{n+1} = u^n + \Delta t \dot{u}^n + \frac{\Delta t^2}{2}\left[2\beta\ddot{u}^{n+1} + (1-2\beta)\ddot{u}^n\right], \quad 0 \le n \le \mathcal{N}-1,$$
$$\dot{u}^{n+1} = \dot{u}^n + \Delta t\left[\gamma\ddot{u}^{n+1} + (1-\gamma)\ddot{u}^n\right], \quad 0 \le n \le \mathcal{N}-1,$$

where γ and β are parameters to be determined to guarantee stability of the time-marching scheme.

3.1. TM polarization. For convenience, we denote u^i as the incident field E_z^i, u^r the reflected field E_z^r, u the total field E_z, and u^s the scattered field E_z^s. The semidiscrete problem is to find u^{n+1}, $n = 0, 1, \ldots, \mathcal{N}$ such that we have the following:

Prediction

$$\tilde{u}^{n+1} = u^n + \Delta t \dot{u}^n + \frac{(\Delta t)^2}{2}(1-2\beta)\ddot{u}^n, \tag{3.1}$$

$$\tilde{\dot{u}}^{n+1} = \dot{u}^n + \Delta t(1-\gamma)\ddot{u}^n, \tag{3.2}$$

Solution

$$\text{(3.3)}\qquad \begin{cases} -\Delta u^{n+1} + \alpha^2 \varepsilon_r u^{n+1} &= \alpha^2 \varepsilon_r \tilde{u}^{n+1} \quad \text{in } \Omega_R, \\ u^{n+1} &= 0 \quad \text{on } S, \\ u^{n+1} &= u^{s,n+1} + u^{i,n+1} + u^{r,n+1} \quad \text{on } \mathcal{B}_R, \end{cases}$$

Correction

$$\ddot{u}^{n+1} = \alpha^2 (u^{n+1} - \tilde{u}^{n+1}), \tag{3.4}$$

$$\dot{u}^{n+1} = \tilde{\dot{u}}^{n+1} + \Delta t \gamma \ddot{u}^{n+1}, \tag{3.5}$$

where $\alpha^2 = \frac{1}{\Delta t^2 \beta}$. The scattered field $u^{s,n+1}$ satisfies the following *exterior problem*:

$$\text{(3.6)}\qquad \begin{cases} -\Delta u^{s,n+1} + \alpha^2 u^{s,n+1} &= \alpha^2 \tilde{u}^{s,n+1} \quad \text{in } U_R, \\ u^{s,n+1}(R,\theta) &= g(R,\theta) \quad \text{on } \mathcal{B}_R, \\ u^{s,n+1} &= 0 \quad \text{on } \Gamma_{ext}, \end{cases}$$

where $g \overset{\text{def}}{=} u^{n+1} - u^{i,n+1} - u^{r,n+1}$, and

$$\lim_{r\to\infty} \sqrt{r} \left(\frac{\partial u^{s,n+1}}{\partial r} + \frac{1}{c} \dot{u}^{s,n+1} \right) = 0. \tag{3.7}$$

3.1.1. Exterior problem and transparent boundary condition. For brevity, we omit the superscript $n+1$ in u^{n+1} in the remainder of the section. To solve the exterior problem (3.6), we set, in the polar coordinates (r,θ),

$$u^s(r,\theta) = \sum_{m=1}^{\infty} A_m(r) \sin 2m\theta, \quad r \geq R,\ \theta \in [0,\pi],$$

where $A_m(r)$ is to be determined. We choose the sine series expansion because u^s vanishes on Γ_{ext}, i.e., $\theta = 0, \pi$ and $r \geq R$. By substituting the sine series into (3.6), we obtain the nonhomogeneous equation with a Dirichlet boundary condition

$$\text{(3.8)}\qquad \begin{cases} \left[\dfrac{d^2}{dr^2} + \dfrac{1}{r}\dfrac{d}{dr} - \left(\alpha^2 + \dfrac{4m^2}{r^2} \right) \right] A_m(r) &= \alpha^2 \tilde{f}_m^s(r), \quad r \in (R,\infty), \\ A_m(R) &= g_m(R), \end{cases}$$

where f_m^s and g_m are the coefficients of the sine series expansions of $\tilde{u}^s$ and g, respectively. The solution to (3.8) can be expressed as

$$A_m(r) = A_m^{\mathrm{h}}(r) + A_m^{\mathrm{p}}(r), \tag{3.9}$$

where $A_m^{\mathrm{h}}(r)$ is the solution of the homogeneous counterpart of (3.8) and $A_m^{\mathrm{p}}(r)$ is the solution of (3.8) with homogeneous boundary condition $A_m^{\mathrm{p}}(R) = 0$. To be more precise, A_m^{h} and A_m^{p} solve, respectively,

$$\text{(3.10)}\qquad \begin{cases} \left[\dfrac{d^2}{dr^2} + \dfrac{1}{r}\dfrac{d}{dr} - \left(\alpha^2 + \dfrac{4m^2}{r^2} \right) \right] A_m^{\mathrm{h}}(r) &= 0, \quad r \in (R,\infty), \\ A_m^{\mathrm{h}}(R) &= g_m(R) \end{cases}$$

and

$$\left\{ \begin{array}{rcl} \left[\dfrac{d^2}{dr^2}+\dfrac{1}{r}\dfrac{d}{dr}-\left(\alpha^2+\dfrac{4m^2}{r^2}\right)\right] A_m^{\mathrm{p}}(r) &=& \alpha^2 \tilde{f}_m^s(r), \quad r\in(R,\infty), \\ A_m^{\mathrm{p}}(R) &=& 0. \end{array} \right. \tag{3.11}$$

Equation (3.10) is a modified Bessel's equation of order $2m$. By the boundary condition and noting that the solution is bounded near infinity by the radiation condition, we have

$$A_m^{\mathrm{h}}(r) = \frac{g_m(R)}{K_{2m}(\alpha R)} K_{2m}(\alpha r), \quad r \geq R. \tag{3.12}$$

The solution to (3.11) can be obtained by applying the Green's function method as discussed in [10]. The Green's function associated to (3.11) is defined by

$$G_m(r,r') = \left\{ \begin{array}{ll} \dfrac{k_m(r')l_m(r)}{r'^2 W_m(r')}, & r \geq r', \\ \dfrac{l_m(r')k_m(r)}{r'^2 W_m(r')}, & r \leq r', \end{array} \right. \tag{3.13}$$

where

$$\begin{aligned} k_m(r') &= K_{2m}(\alpha r'), \\ l_m(r') &= I_{2m}(\alpha r')K_{2m}(\alpha R) - K_{2m}(\alpha r')I_{2m}(\alpha R), \\ W_m(r') &= l_m(r')k_m'(r') - k_m(r')l_m'(r'). \end{aligned}$$

Note that $G_m(R,r') = 0$ for all $r' \leq R$ and $G_m(r,R) = 0$ for $r \leq R$. Therefore, the solution to (3.11) is of the form

$$A_m^{\mathrm{p}}(r) = \alpha^2 \int_R^\infty G_m(r,r')\tilde{f}_m^s(r')dr', \quad r \geq R. \tag{3.14}$$

Consequently,

$$A_m(r) = \frac{g_m(R)}{K_{2m}(\alpha R)} K_{2m}(\alpha r) + \alpha^2 \int_R^\infty G_m(r,r')\tilde{f}_m^s(r')dr'.$$

Therefore, the scattered field u^s can be expressed explicitly by

$$u^s(r,\theta) = \sum_{m=1}^\infty \left[\frac{g_m(R)}{K_{2m}(\alpha R)} K_{2m}(\alpha r) + \alpha^2 \int_R^\infty G_m(r,r')\tilde{f}_m^s(r')dr' \right] \sin m\theta,$$

where

$$\begin{aligned} g_m(R) &= \frac{2}{\pi}\int_0^\pi (u - u^i - u^r)(R,\theta')\sin 2m\theta' d\theta', \\ f_m^s(r') &= \frac{2}{\pi}\int_0^\pi \tilde{u}^s(r',\theta')\sin 2m\theta' d\theta'. \end{aligned}$$

By using

$$\begin{aligned} \sin 2m\theta \sin 2m\theta' &= \frac{1}{2}[\cos 2m(\theta-\theta') - \cos 2m(\theta+\theta')] \\ &=: \frac{1}{2}C(\theta,\theta'), \end{aligned}$$

we can write

$$u^s(r,\theta) = \frac{2}{\pi}\sum_{m=1}^{\infty}\left\{\frac{K_{2m}(\alpha r)}{K_{2m}(\alpha R)}\int_0^{\pi} C(\theta,\theta')(u-u^i-u^r)(R,\theta')d\theta' + \alpha^2\int_R^{\infty} dr' G_m(r,r')\int_0^{\pi} d\theta' C(\theta,\theta')\tilde{u}^s(r',\theta')\right\}.$$

Taking the partial derivative $\frac{\partial}{\partial r}$ of u^s yields

$$\frac{\partial u^s}{\partial r} = \mathcal{T}(u-u^i-u^r) + \Phi(\tilde{u}^s), \quad r \geq R,\ \theta \in [0,\pi], \tag{3.15}$$

where $\mathcal{T}$ is a linear operator defined by

$$\mathcal{T}(v) = \frac{1}{\pi}\sum_{m=1}^{\infty}\alpha\frac{K'_{2m}(\alpha r)}{K_{2m}(\alpha R)}\int_0^{\pi} C(\theta,\theta')v(\theta')d\theta' \quad \forall v \in H^{1/2}(\mathcal{B}_R)$$

and

$$\Phi(\tilde{u}^s) = \frac{\alpha^2}{\pi}\sum_{m=1}^{\infty}\int_R^{\infty} dr'\frac{\partial G_m(r,r')}{\partial r}\int_0^{\pi} d\theta' C(\theta,\theta')\tilde{u}^s(r',\theta').$$

We now construct the nonlocal boundary condition on $\mathcal{B}_R$ using (3.15). Define the Sobolev spaces $H^{1/2}(\mathcal{B}_{\mathcal{R}})$ and $H^{-1/2}(\mathcal{B}_{\mathcal{R}})$, respectively, as

$$H^{1/2}(\mathcal{B}_R) = \left\{\phi : \sum_{m=0}^{\infty}\sqrt{1+m^2}|\phi_m|^2 < \infty\right\}, \tag{3.16}$$

$$H^{-1/2}(\mathcal{B}_R) = \left\{\phi : \sum_{m=0}^{\infty}\frac{1}{\sqrt{1+m^2}}|\phi_m|^2 < \infty\right\}, \tag{3.17}$$

where

$$\phi_m = \phi_m^c + i\phi_m^s = \frac{2}{\pi}\int_0^{\pi}\phi(\theta)e^{i2m\theta}d\theta.$$

Let $\mathcal{T}_R$ be the restriction of $\mathcal{T}$ to $\mathcal{B}_R$ so that $\mathcal{T}_R : H^{1/2}(\mathcal{B}_R) \to H^{-1/2}(\mathcal{B}_R)$, and let it be defined by

$$\mathcal{T}_R g(\theta) = \frac{1}{\pi}\sum_{m=1}^{\infty}\alpha\frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)}\int_0^{\pi} C(\theta,\theta')g(\theta')d\theta', \tag{3.18}$$

where $\theta \in [0,\pi]$.

PROPOSITION 3.1. *The operator $\mathcal{T}_R$ is symmetric and bounded, that is,*

$$\langle \mathcal{T}_R g, \phi\rangle = \langle \mathcal{T}_R\phi, g\rangle,$$
$$\|\mathcal{T}_R g\|_{H^{-1/2}(\mathcal{B}_R)} \leq C\|g\|_{H^{1/2}(\mathcal{B}_R)} \quad \forall g \in H^{1/2}(\mathcal{B}_R),$$

where C is a constant.

Proof. By definition, we have

$$\|\mathcal{T}_R g\|_{H^{-1/2}(\mathcal{B}_R)} = \sup_{\phi\in H^{1/2}(\mathcal{B}_R)}\frac{|\langle \mathcal{T}_R g,\phi\rangle|}{\|\phi\|_{H^{1/2}(\mathcal{B}_R)}},$$

where

$$\langle \mathcal{T}_R g, \phi \rangle = \frac{1}{\pi} \sum_{m=1}^{\infty} \alpha \frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)} \int_0^{\pi} d\theta \phi(\theta) \int_0^{\pi} d\theta' C(\theta, \theta') g(\theta').$$

By writing $\cos 2m(\theta \pm \theta') = \mathrm{Re}\{e^{i2m\theta} e^{\pm i2m\theta'}\}$, we have

$$\langle \mathcal{T}_R g, \phi \rangle = \frac{1}{2} \sum_{m=1}^{\infty} \alpha \frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)} \phi_m^s g_m^s;$$

thus, $\mathcal{T}_R$ is symmetric and

$$|\langle \mathcal{T}_R g, \phi \rangle| \le \frac{1}{2} \sqrt{\sum_{m=1}^{\infty} \alpha \left| \frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)} (\phi_m^s)^2 \right|} \sqrt{\sum_{m=1}^{\infty} \alpha \left| \frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)} (g_m^s)^2 \right|}.$$

For sufficiently large m, $\alpha \frac{K'_{2m}(\alpha R)}{K_{2m}(\alpha R)} < \sqrt{1+m^2}$ (see [1]). Hence there exists a constant C independent of ϕ and g such that

$$|\langle \mathcal{T}_R g, \phi \rangle| \le C \|\phi\|_{H^{1/2}(\mathcal{B}_R)} \|g\|_{H^{1/2}(\mathcal{B}_R)}.$$

This proves the proposition. □

Hence we can easily see that on $\mathcal{B}_R$ the normal derivative of the total electric field satisfies the following continuity condition:

$$\begin{aligned} \left.\frac{\partial u}{\partial r}\right|_{r=R} &= \left.\frac{\partial u^i}{\partial r}\right|_{r=R} + \left.\frac{\partial u^r}{\partial r}\right|_{r=R} + \left.\frac{\partial u^s}{\partial r}\right|_{r=R} \\ &= \frac{\partial}{\partial r}(u^i + u^r)|_{r=R} + \mathcal{T}_R(u - u^i - u^r) + \Phi_R(\tilde{u}^s), \end{aligned} \tag{3.19}$$

where Φ_R is the restriction of Φ to $r = R$. Equation (3.19) is the transparent boundary condition on $\mathcal{B}_R$. It enables one to couple the total field in the infinite homogeneous domain U_R to the total field in the bounded domain Ω_R through the operator $\mathcal{T}_R$. We can rewrite the boundary value problem (3.3) as

$$\begin{cases} -\Delta u^{n+1} + \alpha^2 \varepsilon_r u^{n+1} = \alpha^2 \varepsilon_r \tilde{u}^{n+1} & \text{in } \Omega_R, \\ u^{n+1} = 0 \quad \text{on } S, \\ \dfrac{\partial u^{n+1}}{\partial r} - \mathcal{T}_R u^{n+1} = \dfrac{\partial u^{i,n+1}}{\partial r} + \dfrac{\partial u^{r,n+1}}{\partial r} \\ \qquad + \Phi_R(\tilde{u}^{s,n+1}) - \mathcal{T}_R(u^{i,n+1} + u^{r,n+1}) \quad \text{on } \mathcal{B}_R. \end{cases} \tag{3.20}$$

Next, we solve (3.20) by a variational method.

3.1.2. Variational formulation. Define the subspace V of $L^2(\Omega_R)$ by

$$V = \{v \in H^1(\Omega_R) : v|_S = 0\}$$

equipped with the H^1-norm, that is,

$$\|u\|_V = \|u\|_{H^1(\Omega_R)}.$$

The variational formulation of (3.3), or equivalently (3.20), is to find $u \in V$ such that

$$b_{TM}(u,v) = F(v) \quad \forall v \in V, \tag{3.21}$$

where

$$b_{TM}(u,v) = \int_\Omega (\nabla u \cdot \nabla v + \alpha^2 \varepsilon_r uv)\, dxdy - \int_{\mathcal{B}_R} \mathcal{T}_R(u) v\, d\theta, \tag{3.22}$$

$$F(v) = \alpha^2 \int_\Omega \varepsilon_r \tilde{u} v\, dxdy + \int_{\mathcal{B}_R} Hv\, d\theta + \int_{\mathcal{B}_R} \Phi_R(\tilde{u}^s) v d\theta, \tag{3.23}$$

with

$$H = \frac{\partial u^i}{\partial r}\Big|_{r=R} + \frac{\partial u^r}{\partial r}\Big|_{r=R} - \mathcal{T}_R(u^i|_{r=R} + u^r|_{r=R}).$$

We note that $F(v)$ in (3.23) contains the solution and its time derivatives in the previous time step through the term $\Phi_R(\tilde{u}^s)$.

THEOREM 3.2. *The variational problem* (3.21) *has a unique solution* $u \in V$ *and*

$$\|u\|_V \le C \left(\|\varepsilon_r \tilde{u}\|_{L^2(\Omega_R)} + \|u^i\|_V + \|u^r\|_V + \|\tilde{u}^s\|_V \right).$$

Proof. Since $\langle \mathcal{T}_R g, g \rangle \le 0$ and $\mathcal{T}_R : H^{1/2}(\mathcal{B}_R) \to H^{-1/2}(\mathcal{B}_R)$ is bounded, the symmetric bilinear form is coercive and bounded. Thus, by the Lax–Milgram lemma, (3.21) has a unique solution and

$$\|u\|_V \le C \|F\|_{V'}.$$

Standard trace theory then gives

$$\|F\|_{V'} \le C \left(\|\varepsilon_r \tilde{u}\|_{L^2(\Omega_R)} + \|u^i\|_V + \|u^r\|_V + \|\tilde{u}^s\|_V \right).$$

This proves the theorem. ∎

The Newmark time-marching algorithm for (3.20) can be described as follows:

1. Form the system matrix K from the bilinear forms b_{TM}.
   Time-loop: for $n = 0, 1, 2 \ldots$
   2. Compute the predicted values $\tilde{u}^{n+1}$, $\tilde{\dot{u}}^{n+1}$ in the interior Ω_R.
   3. Compute the predicted values $\tilde{u}^{n+1}$, $\tilde{\dot{u}}^{n+1}$ in the exterior region $\mathcal{U}_R$.
   4. Form the right-hand side vector F^{n+1}.
   5. Solve (3.21): $Ku^{n+1} = F^{n+1}$ (in Ω_R).
   6. Compute the solution u^{n+1} in the exterior $\mathcal{U}_R$.
   7. Correct $\ddot{u}^{n+1}$ and $\dot{u}^{n+1}$ in Ω_R.
   8. Correct $\ddot{u}^{n+1}$ and $\dot{u}^{n+1}$ in $\mathcal{U}_R$.

The term $\ddot{u}^0$ can be approximated as

$$\ddot{u}^0 = \frac{\dot{u}^0 - \dot{u}^{-1}}{\Delta t},$$

with $\dot{u}^{-1} = 0$; that is, all fields are assumed to be zero for $t < 0$.

3.2. TE polarization. As in the TM case, we denote u^i as the incident field H_z^i, u^r reflected field H_z^r, u total field H_z, and u^s scattered field H_z^s. It is known that

$$\frac{\partial u^i}{\partial y} + \frac{\partial u^r}{\partial y} = 0 \quad \text{on } \Gamma_{ext}.$$

The semidiscrete problem is to find u^{n+1}, $n = 0, 1, 2, \ldots, \mathcal{N}$, such that we have the following:

Prediction

$$\tilde{u}^{n+1} = u^n + \Delta t \dot{u}^n + \frac{(\Delta t)^2}{2}(1 - 2\beta)\ddot{u}^n, \tag{3.24}$$

$$\tilde{\dot{u}}^{n+1} = \dot{u}^n + \Delta t(1 - \gamma)\ddot{u}^n, \tag{3.25}$$

Solution

$$\begin{cases} -\nabla \cdot (\varepsilon_r^{-1} \nabla u^{n+1}) + \alpha^2 u^{n+1} &= \alpha^2 \tilde{u}^{n+1} \quad \text{in } \Omega_R, \\ \dfrac{\partial u^{n+1}}{\partial n} &= 0 \quad \text{on } S, \\ u^{n+1} &= u^{s,n+1} + u^{i,n+1} + u^{r,n+1} \quad \text{on } \mathcal{B}_R, \end{cases} \tag{3.26}$$

Correction

$$\ddot{u}^{n+1} = \alpha^2 (u^{n+1} - \tilde{u}^{n+1}), \tag{3.27}$$

$$\dot{u}^{n+1} = \tilde{\dot{u}}^{n+1} + \Delta t \gamma \ddot{u}^{n+1}, \tag{3.28}$$

where $\alpha^2 = \frac{1}{\Delta t^2 \beta}$.

The scattered field $u^{s,n+1}$ satisfies the exterior problem

$$\begin{cases} -\Delta u^{s,n+1} + \alpha^2 u^{s,n+1} &= \alpha^2 \tilde{u}^{s,n+1} \quad \text{in } U_R, \\ \dfrac{\partial u^{s,n+1}}{\partial r} &= 0 \quad \text{on } \Gamma_{ext}, \\ \dfrac{\partial u^{s,n+1}}{\partial r} &= h(R, \theta) \quad \text{on } \mathcal{B}_R, \end{cases} \tag{3.29}$$

where

$$h = \frac{\partial u^{n+1}}{\partial r} - \frac{\partial u^{i,n+1}}{\partial r} - \frac{\partial u^{r,n+1}}{\partial r},$$

and the radiation condition

$$\lim_{r \to \infty} \sqrt{r} \left(\frac{\partial u^{s,n+1}}{\partial r} + \frac{1}{c} \dot{u}^{s,n+1} \right) = 0.$$

In the next subsection, we construct the scattered field in U_R and then use it to construct the Dirichlet-to-Neumann mapping on $\mathcal{B}_R$. Again, the superscripts $n + 1$ are temporarily omitted for brevity.

3.2.1. Exterior problem and transparent boundary condition. We expand the scattered field in U_R as

$$u^s(R, \theta) = \sum_{m=0} B_m(r) \cos 2m\theta, \quad r \geq R, \ \theta \in [0, \pi], \tag{3.30}$$

where $B_m(r)$ is to be determined. Here the cosine series expansion is chosen because $\frac{\partial u^s}{\partial y}$ vanishes for $\theta = 0, \pi$ and $r \geq R$. By substituting (3.30) into (3.29), we obtain the nonhomogeneous equation with a Neumann boundary condition

$$\begin{cases} \left[\dfrac{d^2}{dr^2} + \dfrac{1}{r}\dfrac{d}{dr} - \left(\alpha^2 + \dfrac{4m^2}{r^2}\right)\right] B_m(r) &= \alpha^2 \tilde{f}_m^c(r), \quad r \in (R, \infty), \\ B_m'(R) &= h_m(R), \end{cases} \tag{3.31}$$

where f_m^c and h_m are the coefficients of the cosine series expansions of $\tilde{u}^s$ and h, respectively. The solution to (3.31) can be written as

$$B_m(r) = B_m^{\mathrm{h}}(r) + B_m^{\mathrm{p}}(r),$$

where $B_m^{\mathrm{h}}(r)$ and $B_m^{\mathrm{p}}(r)$ solve, respectively,

$$\begin{cases} \left[\dfrac{d^2}{dr^2} + \dfrac{1}{r}\dfrac{d}{dr} - \left(\alpha^2 + \dfrac{4m^2}{r^2}\right)\right] B_m^{\mathrm{h}}(r) &= 0, \quad r \in (R, \infty), \\ B_m'(R) &= h_m(R) \end{cases} \tag{3.32}$$

and

$$\begin{cases} \left[\dfrac{d^2}{dr^2} + \dfrac{1}{r}\dfrac{d}{dr} - \left(\alpha^2 + \dfrac{4m^2}{r^2}\right)\right] B_m^{\mathrm{p}}(r) &= \alpha^2 \tilde{f}_m^c(r), \quad r \in (R, \infty), \\ B_m'(R) &= 0. \end{cases} \tag{3.33}$$

Again, by applying the boundary and radiation conditions to the general solution of the modified Bessel's equation (3.32), we obtain

$$B_m^{\mathrm{h}}(r) = \frac{h_m(R)}{\alpha K_{2m}'(\alpha R)} K_{2m}(\alpha r). \tag{3.34}$$

Equation (3.33) can be solved by applying the Green's function method. The Green's function associated to this equation is defined by

$$G_m(r, \xi) = \begin{cases} \dfrac{k_m(\xi) l_m(r)}{\xi^2 W_m(\xi)}, & r \geq \xi, \\ \dfrac{l_m(\xi) k_m(r)}{\xi^2 W_m(\xi)}, & r \leq \xi, \end{cases} \tag{3.35}$$

where

$$\begin{aligned} k_m(\xi) &= K_{2m}(\alpha\xi), \\ l_m(\xi) &= \alpha[I_{2m}(\alpha\xi) K_{2m}'(\alpha R) - K_{2m}(\alpha\xi) I_{2m}'(\alpha R)], \\ W_m(\xi) &= l_m(\xi) k_m'(\xi) - k_m(\xi) l_m'(\xi). \end{aligned}$$

Hence the particular solution is of the form

$$B_m^{\mathrm{p}}(r) = \alpha^2 \int_R^\infty G_m(r, r') \tilde{f}_m^c(r') dr', \quad r \geq R.$$

Consequently, the scattered field u^s can be expressed as

$$u^s(r, \theta) = \sum_{m=0}^{\infty} \left[\frac{h_m(R)}{\alpha K_{2m}'(\alpha R)} K_{2m}(\alpha r) + \alpha^2 \int_R^\infty G_m(r, r') \tilde{f}_m^c(r') dr'\right] \cos 2m\theta,$$

where

$$h_m(R) = \frac{2}{\pi}\int_0^\pi \left(\frac{\partial u}{\partial r} - \frac{\partial u^i}{\partial r} - \frac{\partial u^r}{\partial r}\right)(R,\theta')\cos 2m\theta'\, d\theta',$$
$$\tilde{f}_m^c(r') = \frac{2}{\pi}\int_0^\pi \tilde{u}(r',\theta')\cos 2m\theta'\, d\theta'.$$

Using the identity $\cos 2m\theta \cos 2m\theta' = \frac{1}{2}[\sin 2m(\theta+\theta') - \sin 2m(\theta-\theta')] = \frac{1}{2}S(\theta,\theta')$ yields

$$u^s(r,\theta) = \mathcal{S}\left(\frac{\partial u}{\partial r} - \frac{\partial u^i}{\partial r} - \frac{\partial u^r}{\partial r}\right) + \Psi(\tilde{u}^s) \quad \text{in } U_R,$$

where $\mathcal{S}$ is the mapping defined by

$$\mathcal{S}g(\theta) = \frac{1}{\pi}\sum_{m=0}^{\infty}\left[\frac{K_{2m}(\alpha r)}{\alpha K'_{2m}(\alpha R)}\int_0^\pi S(\theta,\theta')g(\theta')\, d\theta'\right],$$

and

$$\Psi(\tilde{u}^s)(r,\theta) = \alpha^2\sum_{m=0}^{\infty}\int_R^\infty dr' G_m(r,r')\int_0^\pi d\theta' S(\theta,\theta')\tilde{u}^s(r',\theta').$$

Denote $\mathcal{S}_R$ as the restriction of $\mathcal{S}$ on $\mathcal{B}_R$ such that

$$\mathcal{S}_R g = \frac{1}{\pi}\sum_{m=0}^{\infty}\left[\frac{K_{2m}(\alpha R)}{\alpha K'_{2m}(\alpha R)}\int_0^\pi S(\theta,\theta')g(\theta')\, d\theta'\right]$$

for all $g \in H^{-1/2}(\mathcal{B}_R)$. We can show the following proposition.

PROPOSITION 3.3. *The operator $\mathcal{S}_R : H^{-1/2}(\mathcal{B}_R) \to H^{1/2}(\mathcal{B}_R)$ is symmetric and bounded.*

The proof of the proposition is similar to that of $\mathcal{T}_R$ and is omitted for brevity. Thus, the boundary condition on $\mathcal{B}_R$ can be defined as

$$u^s(R,\theta) = \mathcal{S}_R\left(\frac{\partial u}{\partial r}\right) - \mathcal{S}_R\left(\frac{\partial u^i}{\partial r}\right) - \mathcal{S}_R\left(\frac{\partial u^r}{\partial r}\right) + \Psi_R(\tilde{u}^s)(r,\theta),$$

where Ψ_R is the restriction of Ψ on $\mathcal{B}_R$. Consequently, by the continuity condition on $\mathcal{B}_R$ we have

$$\begin{aligned} u|_{r=R^-} &= u|_{r=R^+} = u^i|_{r=R} + u^r|_{r=R} + u^s|_{r=R} \\ &= u^i|_{r=R} + u^r|_{r=R} + \mathcal{S}_R\left(\frac{\partial u}{\partial r}\right) - \mathcal{S}_R\left(\frac{\partial u^i}{\partial r}\right) - \mathcal{S}_R\left(\frac{\partial u^r}{\partial r}\right) + \Psi_R(\tilde{u}^s). \end{aligned} \tag{3.36}$$

Thus, the boundary value problem for TE can be rewritten as

$$\begin{cases} -\nabla\cdot\left(\dfrac{1}{\varepsilon_r}\nabla u\right) + \alpha^2 u &= \alpha^2\tilde{u} \quad \text{in } \Omega_R, \\ \dfrac{\partial u}{\partial n} &= 0 \quad \text{on } S, \\ u - \mathcal{S}_R\left(\dfrac{\partial u}{\partial r}\right) &= u^i + u^r + \Psi_R(\tilde{u}^s) - \mathcal{S}_R\left(\dfrac{\partial u^i}{\partial r} + \dfrac{\partial u^r}{\partial r}\right) \quad \text{on } \mathcal{B}_R. \end{cases} \tag{3.37}$$

The next subsection is devoted to the variational formulation of (3.37).

3.2.2. Variational formulation. For convenience, we set

$$v = u - (u^i + u^r + \hat{\Psi}(\tilde{u}^s)) \quad \text{in } \Omega_R, \tag{3.38}$$

where $\hat{\Psi}(\tilde{u}^s)$ is the extension of $\Psi(\tilde{u}^s)$ into Ω_R. By direct computation, we can show that

$$\mathcal{S}_R\left(\frac{\partial \Psi_R}{\partial r}(\tilde{u}^s)\right) = 0 \quad \text{on } \mathcal{B}_R.$$

Hence the boundary value problem (3.37) can be written in terms of v as

$$\begin{cases} -\nabla\cdot\left(\dfrac{1}{\varepsilon_r}\nabla v\right) + \alpha^2 v &= \alpha^2\tilde{u} + \phi \quad \text{in } \Omega_R, \\ \dfrac{\partial v}{\partial n} &= -h \quad \text{on } S, \\ [1.5ex]v - \mathcal{S}_R\left(\dfrac{\partial v}{\partial r}\right) &= 0 \quad \text{on } \mathcal{B}_R, \end{cases} \tag{3.39}$$

where

$$\phi = \nabla\cdot\left[\frac{1}{\varepsilon_r}\nabla(u^i + u^r + \hat{\Psi}(\tilde{u}^s))\right] - \alpha^2(u^i + u^r + \hat{\Psi}(\tilde{u}^s)),$$

and

$$h = \frac{\partial(u^i + u^r + \hat{\Psi}(\tilde{u}^s))}{\partial n} \quad \text{on } S.$$

Hence we can define the variational space

$$W = \left\{ w \in H^1(\Omega_R) : w|_{\mathcal{B}_R} = \mathcal{S}_R\left(\frac{\partial w}{\partial r}\right) \text{ on } \mathcal{B}_R \right\} \tag{3.40}$$

with H^1-norm. The variational form of the boundary value equation (3.39) is to find $v \in W$ such that

$$b_{TE}(v, w) = F(w) \quad \forall w \in W, \tag{3.41}$$

where

$$b_{TE}(v, w) = \int_{\Omega_R}\left(\frac{1}{\varepsilon_r}\nabla v\cdot\nabla w + \alpha^2 uw\right)\, dxdy - \int_{B_R}\frac{\partial v}{\partial r}\mathcal{S}_R\left(\frac{\partial w}{\partial r}\right)\, d\theta, \tag{3.42}$$

and

$$F(w) = \int_{\Omega_R}(\alpha^2\tilde{u} + \phi)w\, dxdy - \int_S hw dS.$$

THEOREM 3.4. *The variational problem* (3.41) *has a unique solution in* W *defined by* (3.40) *and*

$$\|u\|_W \le C(\|\tilde{u}\|_{L^2(\Omega_R)} + \|u^i\|_W + \|u^r\|_W + \|\tilde{u}^s\|_W).$$

Proof. Since $\langle \mathcal{S}_R g, g\rangle \le 0$ and $\mathcal{S}_R : H^{-1/2}(\mathcal{B}_R) \to H^{1/2}(\mathcal{B}_R)$ is bounded, the symmetric bilinear form $a(u, w)$ in (3.41) is coercive and bounded. Hence the existence and uniqueness follow from the Lax–Milgram theorem. ∎

The time-marching procedure is the same as in the TM case.

4. Fully discrete problem. In this section, we consider the variational problems (3.21) and (3.41) by using finite element methods. Finite element error estimates and the stability of the Newmark scheme of the TM problem are presented. The arguments for the TE case, which are similar, are omitted here.

4.1. Finite element error analysis. Assume that Ω_R is covered by a family of quasi-uniform triangular meshes τ_h, where h is the mesh size, that is,

$$h = \max_{K\in\tau_h} h_K,$$

where h_K is the diameter of the element $K \in \tau_h$.

In the TM case, we consider the finite-dimensional subspace

$$V_h = \{v_h \in H^1(\Omega_R) : v_h|_K \text{ is linear }, K \in \tau_h\}.$$

We note that V_h is closed in V and $V_h \to V$ as $h \to 0$. The fully discrete problem is to find $u_h^n \in V_h$, $n = 1, 2, \ldots, \mathcal{N}$, such that

$$b(u_h^n, v_h) = F^n(v_h) \quad \forall v_h \in V_h, \tag{4.1}$$

where $b(u_h^n, v_h)$ and $F^n(v_h)$ are as defined in (3.22) and (3.23), respectively. Here, the subscript TM in $b(\cdot,\cdot)$ is omitted for brevity. We recall that the bilinear form b is coercive and continuous. Hence by Céa's lemma [8, pp. 36–69], the fully discrete problem (4.1) has a unique solution $u_h^n \in V_h$ and

$$\|u^n - u_h^n\|_V \le C \inf_{v_h\in V_h} \|u^n - v_h\|_V. \tag{4.2}$$

Since ε_r is discontinuous in Ω_R, the solution $u^n \notin H^2(\Omega_R)$, the inequality (4.2) does not yield a convergence rate in terms of h. In fact, since $V_h \to V$ for any $\epsilon > 0$, there is an $h_0 = h_0(\epsilon, u^n)$ such that for $0 < h < h_0$ there exists $v_h \in V_h$ satisfying

$$\|u^n - v_h\|_V \le \epsilon.$$

By (4.2), we have

$$\|u^n - u_h^n\|_V \le C\epsilon \quad \forall h < h_0(\epsilon, u^n).$$

Thus, the finite element solution u_h^n converges to u^n in V but not uniformly. We have the following.

THEOREM 4.1. *Let $u^n \in V$ and $u_h^n \in V_h$ be the solutions to* (3.21) *and* (4.1), *respectively, for $F^n \in V'$. Then given $\epsilon > 0$, there is an $h_0 = h_0(\epsilon)$ such that for all $0 < h < h_0$ we have*

$$\|u^n - u_h^n\|_{L^2(\Omega_R)} \le \epsilon \|u^n - u_h^n\|_V. \tag{4.3}$$

Furthermore, if $\varepsilon_r \in L^\infty(\Omega_R)$, hence $\varepsilon_r \tilde{u}^n \in L^2(\Omega_R)$, then there exists an $h_1 = h_1(\epsilon) > 0$ such that for all $0 < h < h_1$ we have

$$\|u^n - u_h^n\|_V \le C\epsilon \|F^n\|_{L^2(\Omega_R)}, \tag{4.4}$$

where C is a positive constant independent of h. Consequently, we have

$$\|u^n - u_h^n\|_{L^2(\Omega)} \le C\epsilon^2 \|F^n\|_{L^2(\Omega_R)}.$$

We first consider the following lemma.

LEMMA 4.2. *Let Λ be the set of solutions $w \in V$ to*

$$b(w, v) = (\psi, v) \quad \forall v \in V, \tag{4.5}$$

where $\|\psi\|_{L^2(\Omega_R)} = 1$. Then Λ is compact in V.

Proof. Since $w \in V$ is the solution to (4.5), it satisfies

$$\|w\|_V \leq C\|\psi\|_{L^2(\Omega_R)}.$$

Thus, the solution mapping $G : \psi \to G\psi = w$ is continuous from the dual space V' to $V \subset H^1(\Omega_R)$. Furthermore, the embedding, $I : \ L^2(\Omega_R) \subset V'$, is compact. It implies that $\Lambda \subset G \circ I(\{\psi \in L^2(\Omega_R) : \|\psi\|_{L^2(\Omega_R)} = 1\})$ is compact in V. ∎

We now prove the theorem.

Proof. By viewing $u^n - u_h^n$ as a linear functional in $L^2(\Omega_R)$, we have

$$\|u^n - u_h^n\|_{L^2(\Omega_R)} = \sup_{\|\psi\|_{L^2(\Omega_R)}=1} (u^n - u_h^n, \psi).$$

Let $w \in V$ be the solution to

$$b(v, \eta) = (\psi, \eta) \quad \forall \eta \in V.$$

Then

$$\|w\|_V \leq C\|\psi\|_{L^2(\Omega_R)}.$$

Thus, for $v_h \in V_h$, by the boundedness of the bilinear form $b(\cdot, \cdot)$, we have

$$\begin{aligned} |(u^n - u_h^n, \psi)| &= |b(u^n - u_h^n, w)| = |b(u^n - u_h^n, w - v_h)| \\ &\leq C\|u^n - u_h^n\|_V \|w - v_h\|_V. \end{aligned}$$

By the density property of V_h in V, we can choose v_h such that $\|w - v_h\|_V \leq \epsilon\|w\|_V$. We then obtain

$$|(u^n - u_h^n, \psi)| \leq C\epsilon\|u^n - u_h^n\|_V \|w\|_V \leq C\epsilon\|u^n - u_h^n\|_V \|\psi\|_{L^2(\Omega_R)}.$$

Thus

$$\|u^n - u_h^n\|_{L^2(\Omega_R)} \leq C\epsilon\|u^n - u_h^n\|_V.$$

This proves the estimate (4.3).

Next, we set

$$\hat{F}^n = \frac{F^n}{\|F^n\|_{L^2(\Omega_R)}}, \quad \hat{u}^n = \frac{u^n}{\|F^n\|_{L^2(\Omega_R)}}, \quad \hat{u}_h^n = \frac{u_h^n}{\|F^n\|_{L^2(\Omega_R)}}.$$

Then, we have

$$\begin{aligned} b(\hat{u}^n, v) &= \hat{F}^n(v) \quad \forall v \in V, \\ b(\hat{u}_h^n, v_h) &= \hat{F}^n(v_h) \quad \forall v_h \in V. \end{aligned}$$

By Céa's lemma,

$$\|\hat{u}^n - \hat{u}_h^n\|_V \leq C \inf_{v_h \in V_h} \|\hat{u}^n - v_h\|_V.$$

Since the set $\hat{\Lambda} = \{\hat{u}^n : b(\hat{u}^n, \phi) = \hat{F}^n(\phi), \|\hat{F}^n\|_{L^2(\Omega_R)} = 1\}$ is compact in V, we have, for $0 < h < h_0(\epsilon)$,

$$\inf_{v_h \in V_h} \|\hat{u}^n - v_h\|_V \leq \epsilon.$$

Thus

$$\|\hat{u}^n - \hat{u}_h^n\|_V \leq C\epsilon,$$

which implies that

$$\|u^n - u_h^n\|_V \leq C\epsilon \|F^n\|_{L^2(\Omega_R)}.$$

This completes the proof. ∎

4.2. Stability analysis. For stability analysis, we express the Newmark scheme in a three-step formulation. We start with

$$\begin{aligned} -\Delta u^{n+2} + \alpha^2 \varepsilon_r u^{n+2} &= \alpha^2 \varepsilon_r \tilde{u}^{n+2} \\ &= \alpha^2 \varepsilon_r \left[u^{n+1} + \Delta t \dot{u}^{n+1} + \frac{\Delta t^2}{2}(1-2\beta)\ddot{u}^{n+1} \right]. \end{aligned}$$

Using (3.5) to remove $\dot{u}^{n+1}$ and then (3.2) to remove $\tilde{\ddot{u}}^{n+1}$, we obtain

$$\begin{aligned} &-\Delta u^{n+2} + \alpha^2 \varepsilon_r u^{n+2} \\ &\quad = \alpha^2 \varepsilon_r \left[u^{n+1} + \Delta t(\dot{u}^n + \Delta t(1-\gamma)\ddot{u}^n) + \Delta t^2 \gamma + \frac{\Delta t^2}{2}(1-2\beta)\ddot{u}^{n+1} \right]. \end{aligned}$$

Using (3.1) to remove $\dot{u}^n$ and then (3.4) to remove $\ddot{u}^{n+1}$ and $\ddot{u}^n$ separately, and finally applying (3.3) to remove $\tilde{u}^{n+1}$ and $\tilde{u}^n$ separately, we obtain

$$\begin{aligned} &-\beta \Delta u^{n+2} - (\tfrac{1}{2} - 2\beta + \gamma)\Delta u^{n+1} - (\tfrac{1}{2} + \beta - \gamma)\Delta u^n \\ &+ \beta \alpha^2 \varepsilon_r (u^{n+2} - 2u^{n+1} + u^n) = 0. \end{aligned}$$

Adapting u_h^n for $u^n \in V_h$, we have the following variational form of the above equation:

$$\begin{aligned} &\tfrac{1}{\Delta t^2}\Big(\varepsilon_r(u_h^{n+2} - 2u_h^{n+1} + u_h^n), v_h\Big) \\ &+ a\Big(\beta u_h^{n+2} + (\tfrac{1}{2} - 2\beta + \gamma)u_h^{n+1} + (\tfrac{1}{2} + \beta - \gamma)u_h^n, v_h\Big) \\ &= \beta G^{n+2}(v_h) + (\tfrac{1}{2} - 2\beta + \gamma)G^{n+1}(v_h) + (\tfrac{1}{2} + \beta - \gamma)G^n(v_h) \quad \forall v_h \in V_h, \end{aligned} \tag{4.6}$$

where

$$a(u_h^n, v_h) = \int_{\Omega_R} \nabla u_h^n \cdot \nabla v_h \, dx - \int_{\mathcal{B}_R} \mathcal{T}_R(u_h^n) v_h \, d\theta,$$

and

$$G^n(v_h) = \int_{\mathcal{B}_R} H^n v_h d\theta - \int_{\mathcal{B}_R} \Phi_R(\tilde{u}_h^{s,n}) \, v_h \, d\theta.$$

It's clear that the bilinear form $a(u_h^n, v_h)$ is symmetric and coercive. Thus the eigenvalue problem

$$a(w_h, v_h) = \lambda_h(w_h, v_h) \quad \forall v_h \in V_h \tag{4.7}$$

has positive eigenvalues and corresponding orthonormal eigenvectors:

$$0 < \lambda_{h,1} \le \lambda_{h,2} \le \cdots \le \lambda_{h,M} < \infty,$$

$$w_{h,1}, w_{h,2}, \ldots, w_{h,M},$$

where $\dim V_h = M$.

Without confusion, we write $w_i = w_{h,i}$ and $\lambda_i = \lambda_{h,i}$. Substituting w_i for v_h in (4.6), noting that

$$a(u_h^n, w_i) = a(w_i, u_h^n) = \lambda_i(w_i, u_h^n) = \lambda_i(u_h^n, w_i)$$

yields

$$\begin{aligned}
&\tfrac{1}{\Delta t^2}(\varepsilon_r(u^{n+2} - 2u^{n+1} + u_h^n), w_i) \\
&+\lambda_i(\beta u_h^{n+1} + (\tfrac{1}{2} - 2\beta + \gamma)u_h^{n+1} + (\tfrac{1}{2} + \beta - \gamma)u_h^n, w_i) \\
&= \beta G^{n+2}(w_i) + (\tfrac{1}{2} - 2\beta + \gamma)G^{n+1}(w_i) + (\tfrac{1}{2} + \beta - \gamma)G^n(w_i) \\
&\equiv \Psi^n.
\end{aligned} \tag{4.8}$$

We observe that ε_r can be considered a constant and hence, without loss of generality, let $\varepsilon_r = 1$. Indeed, for $1 < \varepsilon_r \in L^\infty(\Omega_R)$, we may consider the weighted space $L^2(\Omega_R, \varepsilon_r)$ with the inner product

$$(u, v)_{\varepsilon_r} = (\varepsilon_r u, v) = (u, \varepsilon_r v).$$

We then consider the following eigenvalue equation: find λ_h and $u_h \in V_h$ such that

$$a(u_h, v_h) = \lambda_h(u_h, v_h)_{\varepsilon_r} \quad \forall v_h \in V_h. \tag{4.9}$$

Since $a(\cdot, \cdot)$ is symmetric and coercive, (4.9) has positive eigenvalues λ_i and corresponding orthonormal eigenvectors w_i, $i = 1, 2, \ldots, M$, such that

$$(w_i, w_j)_{\varepsilon_r} = \delta_{ij}.$$

Hence, by substituting $u_h^n = \sum_{i=1}^M u_i^n w_{h,i}$ into (4.8), we obtain for $i = 1, 2, \ldots, M$,

$$\tfrac{1}{\Delta t^2}(u_i^{n+2} - 2u_i^{n+1} + u_i^n) + \lambda_i\left(\beta u_i^{n+2} + \left(\tfrac{1}{2} - 2\beta + \gamma\right)u_i^{n+1} + \left(\tfrac{1}{2} + \beta - \gamma\right)u_i^n\right) = 0, \tag{4.10}$$

that is,

$$\begin{aligned}
u_i^{n+2} &= \frac{\frac{2}{\Delta t^2} - \lambda_i(\frac{1}{2} - 2\beta + \gamma)}{\frac{1}{\Delta t^2} + \lambda_i\beta}u_i^{n+1} - \frac{\frac{1}{\Delta t^2} + \lambda_i(\frac{1}{2} + \beta - \gamma)}{\frac{1}{\Delta t^2} + \lambda_i\beta}u_i^n \\
&\equiv \eta u_i^{n+1} - \kappa u_i^n.
\end{aligned}$$

Thus (4.10) can be written in a matrix form as

$$\begin{pmatrix} u_i^{n+2} \\ u_i^{n+1} \end{pmatrix} = \begin{pmatrix} \eta & -\kappa \\ 1 & 0 \end{pmatrix} \begin{pmatrix} u_i^{n+1} \\ u_i^n \end{pmatrix} \equiv B \begin{pmatrix} u_i^{n+1} \\ u_i^n \end{pmatrix}.$$

By denoting

$$X_i^n = \begin{pmatrix} u_i^{n+1} u_i^n \end{pmatrix}$$

for $n = 1, 2, \ldots, N$, $i = 1, 2, \ldots, M$, we obtain the recursive relation

$$X_i^{n+1} = B(\lambda_i) X_i^n,$$

or equivalently

$$X_i^{n+1} = B^n X_i^0. \tag{4.11}$$

For stability analysis we wish to establish conditions on β, γ, and Δt such that $|X_i^n| = (|u_i^{n+1}|^2 + |u_i^n|^2)^{1/2}$ for all i, and hence $|u^n| = (\sum_{i=1}^M |u_i^n|^2)^{1/2}$, is bounded independent of n.

We observe that, if B is diagonalizable with the spectral radius $\rho(B) \leq 1$, then

$$|X^n| = |B^n X^0| \leq \|G^{-1}\| \rho^n(B) \|G\| |X^0| \leq C$$

for some matrix G. For simplicity, we seek conditions on β, γ, and Δt such that B has distinct eigenvalues (hence diagonalizable) of lengths less than 1.

We shall assume that $\beta \geq 0$. We consider the characteristic equation of B:

$$\det(\mu I - B) = \mu^2 - \mu\eta + \kappa = 0.$$

The solutions μ_1, μ_2 are

$$\mu_{1,2} = \frac{\eta \pm \sqrt{\eta^2 - 4\kappa}}{2}.$$

We consider the following two cases.

Case 1. Suppose $\Delta = \eta^2 - 4\kappa < 0$. Then $\mu_1 = \bar{\mu}_2$ and $|\mu_1| = |\mu_2| = \sqrt{\kappa}$. Thus we require $\kappa \leq 1$, which implies that $\gamma \geq \frac{1}{2}$. We have

$$\Delta = \left[2 - \lambda_i \Delta t^2 \left(\frac{1}{2} - 2\beta + \gamma\right)\right]^2 - 4(1 + \lambda_i \Delta t^2 \beta)\left[1 + \lambda_i \Delta t^2 \left(\frac{1}{2} + \beta - \gamma\right)\right] < 0,$$

which is

$$-4\lambda_i \Delta t^2 + (\lambda_i \Delta t^2)^2 [(1+\gamma)^2 - 4\beta] < 0,$$

or

$$\lambda_i \Delta t^2 \left[\frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2 - \beta\right] < 1,$$

or equivalently

$$\frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2 - \beta < \frac{1}{\lambda_i \Delta t^2} \quad \forall i = 1, 2, \ldots, M.$$

Case 2. Suppose $\Delta > 0$, that is,

$$\frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2 - \beta > \frac{1}{\lambda_i \Delta t^2} \quad \forall i = 1, 2, \ldots, M. \tag{4.12}$$

Without loss of generality, $\mu_1 < \mu_2$. Let

$$-1 \le \mu_1 = \frac{\eta}{2} - \frac{\sqrt{\Delta}}{2} < \frac{\eta}{2} + \frac{\sqrt{\Delta}}{2} = \mu_2 \le 1.$$

The inequality $\mu_1 \ge -1$ implies $1 + \eta + \kappa \ge 0$, or

$$\frac{\gamma}{2} - \beta \le \frac{1}{\lambda_i \Delta t^2}. \tag{4.13}$$

$\mu_2 \le 1$ implies $1 - \eta + \kappa \ge 0$. So we require $\kappa \ge -1$, which implies

$$\frac{1}{2}\left(\gamma - \frac{1}{2} - 2\beta\right) \le \frac{1}{\lambda_i \Delta t^2}. \tag{4.14}$$

By combining (4.13) and (4.14), we have

$$\frac{\gamma}{2} - \beta - \frac{1}{4} \le \frac{1}{\lambda_i \Delta t^2}. \tag{4.15}$$

However, the inequalities (4.12) and (4.15) are inconsistent, so we ignore Case 2.

Thus, $X^n = B^n X^0$ is stable if

$$\gamma \ge \frac{1}{2} \quad \text{and} \quad \frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2 - \beta < \frac{1}{\lambda_i \Delta t^2}, \quad i = 1, 2, \ldots, M. \tag{4.16}$$

We summarize the above analysis in the following theorem.

THEOREM 4.3. *The Newmark scheme for the TM variational problem is stable if* $\gamma \ge \frac{1}{2}$, $\beta \ge 0$, *and*

$$\frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2 - \beta < \frac{1}{\lambda_i \Delta t^2}, \quad i = 1, 2, \ldots, M, \tag{4.17}$$

where $\lambda_{h,i}$ *are the eigenvalues of* $a(w, v_h) = \lambda_h (w, v_h)$ *for all* $v_h \in V_h$.

Remark 4.4. By assuming the value $\gamma = \frac{1}{2}$, one achieves an $\mathcal{O}(\Delta t^2)$ error rate, but this is not always the best value to use. The finite element discretization of the problem tends to create a stiff system of ordinary differential equations. Standard theory in finite elements indicate that the modes corresponding to the higher frequencies become more and more inaccurate as we move up the spectrum (see [24, pp. 244–256] and [31, pp. 63–65]). In practice, a value of γ larger than $\frac{1}{2}$ is often used in order to damp out the higher frequencies while preserving the more accurate lower ones.

5. Conclusion. In this paper, the two-dimensional time-dependent TM and TE scattering problems of an overfilled cavity in the infinite ground plane are considered. In each case, the problem was first discretized in time by the Newmark time-marching scheme. At each time step $t = t_n$, the partial differential equations defined in an infinite domain are solved. Transparent boundary conditions are constructed using the pseudodifferential operators $\mathcal{T}_R$ for TM and $\mathcal{S}_R$ for TE to reduce the computational domain to the bounded region Ω_R. Variational formulations for both polarizations are derived. Existence and uniqueness of both the semidiscrete and the fully discrete solutions, u^n and u_h^n, are obtained. Error estimates in both the H^1-norm, $\|u^n - u_h^n\|_{H^1}$, and L^2-norm, $\|u^n - u_h^n\|_{L^2}$, $n = 0, 1, \ldots, \mathcal{N}$, are achieved. Stability criteria for

the time-marching scheme are established. In particular, the scheme is shown to be unconditionally stable if $\gamma \geq \frac{1}{2}$ and

$$\beta > \frac{1}{4}\left(\frac{1}{2} + \gamma\right)^2.$$

THE DETERMINATION OF THE SURFACE IMPEDANCE OF A PARTIALLY COATED OBSTACLE FROM FAR FIELD DATA*

FIORALBA CAKONI† AND DAVID COLTON†

Abstract. A variational method is given for determining the essential supremum of the surface impedance of a partially coated perfect conductor from a knowledge of the far field pattern of the time-harmonic electric field at fixed frequency. It is assumed that the shape of the scatterer has been determined (e.g., by solving the far field equation and using the linear sampling method). Numerical examples are given for the scalar case with constant surface impedance.

Key words. inverse scattering problem, impedance boundary condition, electromagnetic waves

1. Introduction. In order to avoid detection by radar, hostile objects are often partially coated by a material designed to reduce the radar cross section of the scattered wave. From the point of view of target identification a key question to answer is, given the shape of a scattering obstacle (which can be determined, for example, by the linear sampling method [2], [3]), is the obstacle coated or not and if so what are the electrical properties of the coating? The simplest example of such a problem is the case of a perfect conductor that is partially coated by a dielectric. In this case the direct scattering problem is a mixed boundary value problem for Maxwell's equations where on the coated part of the boundary the electromagnetic field satisfies an impedance boundary condition [9], [12] and on the remaining part of the boundary the tangential component of the total electric field vanishes. The inverse problem of determining whether or not the obstacle is coated, and, if so, what the values of the surface impedance are, is complicated by the fact that the extent of the coating (if indeed the object is coated at all!) is not known a priori.

In this paper we will provide a variational method for determining the essential supremum of the surface impedance (which may be zero if the scatterer is not coated!) from a knowledge of the far field pattern of the scattered electric field corresponding to a time-harmonic incident plane wave at fixed frequency. In the special case where the surface impedance is a constant, this of course yields this constant. However, in neither case does our method provide information on how much of the scattering obstacle is coated. (In particular, there could be no coating at all or the entire obstacle could be coated!) Our analysis is based on our recent investigations of the inverse scattering problem for partially coated obstacles where the aim was to determine the shape of the scattering obstacle with unknown boundary condition from a knowledge of the electric far field pattern [2], [3]. As we show in this paper, the far field equation that was used in [2] and [3] to determine the shape can also be used in conjunction with a variational method to determine the essential supremum of the surface impedance on the coated portion of the boundary. Although for the sake of exposition we assume in

this paper that we have full-aperture far field data, we point out at the end of section 3 how all of our results remain valid for the practical case of limited-aperture data.

Given the shape of the scattering obstacle, the problem of determining lower bounds for the surface impedance in the scalar case when the obstacle is completely coated has previously been considered by Colton and Kress [6] (full-aperture scattering data) and Colton and Piana [8] (limited-aperture scattering data). In particular, the paper of Colton and Piana has had a strong influence on the approach used in the present paper. We also draw the reader's attention to a recent paper of Akduman and Kress [1], where a potential theoretic method is given for determining the surface impedance in the case when the shape of the scatterer is known and the obstacle is completely coated.

The plan of our paper is as follows. We first consider the scattering of time-harmonic plane waves by a partially coated infinite cylinder (which in fact can be totally coated, partially coated or not coated at all). This leads to the investigation of a mixed boundary value problem for the two-dimensional Helmholtz equation in the exterior of a bounded domain D with Lipschitz boundary Γ. Assuming the surface impedance $\lambda = \lambda(x)$ on the coated portion Γ_I of Γ is in $L_\infty(\Gamma_I)$, we derive a variational method for determining ess sup $\lambda(x)$ from a knowledge of the far field pattern of the scattered wave. We then extend this result to the case of Maxwell's equations in $\mathbb{R}^3$. In the final section of our paper we consider several numerical examples in the scalar case when the surface impedance is a constant.

2. The scalar case. We consider the scattering of an electromagnetic time harmonic plane wave by a perfectly conducting infinite cylinder that is (partially) coated by an inhomogeneous dielectric material. This leads to a mixed boundary value problem for the Helmholtz equation [2]. In particular let $D \subset \mathbb{R}^2$ be an open bounded region with Lipschitz boundary Γ such that $\mathbb{R}^2 \setminus \overline{D}$ is connected. We assume that the boundary Γ has a Lipschitz dissection $\Gamma = \Gamma_D \cup \Pi \cup \Gamma_I$, where Γ_D and Γ_I are disjoint, relatively open subsets of Γ, having Π as their common boundary in Γ (see e.g., [10]). Furthermore, boundary conditions of Dirichlet and impedance type with the surface impedance a bounded measurable function $\lambda \in L_\infty(\Gamma_I)$ are specified on Γ_D and Γ_I, respectively. We assume that the surface impedance is positive and uniformly bounded, i.e., $\lambda(x) \geq \lambda_0 > 0$ for $x \in \Gamma_I$. Let ν denote the unit outward normal vector defined almost everywhere on $\Gamma_D \cup \Gamma_I$. The total field $u = u^s + e^{ikx\cdot d}$ given as the sum of the unknown scattered wave and incident plane wave satisfies

$$\Delta u + k^2 u = 0 \qquad \text{in} \qquad \mathbb{R}^2 \setminus \overline{D}, \tag{2.1a}$$

$$u = 0 \qquad \text{on} \qquad \Gamma_D, \tag{2.1b}$$

$$\frac{\partial u}{\partial \nu} + i\lambda(x)u = 0 \qquad \text{on} \qquad \Gamma_I, \tag{2.1c}$$

where $k > 0$ is the wave number and d is a unit vector describing the incident direction. Moreover, the scattered field u^s satisfies the Sommerfeld radiation condition

$$\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial u^s}{\partial r} - iku^s\right) = 0 \tag{2.2}$$

uniformly in $\hat{x} = x/|x|$ with $r = |x|$.

The well-posedness of the exterior mixed boundary value problem is established in [2] (in [2] λ was assumed to be constant, but all the results remain valid if $\lambda = \lambda(x) \in L_\infty(\Gamma_I)$). In particular it is shown that the direct scattering problem (2.1a)–(2.2) has a unique solution $u \in H_{loc}(D_e)$.

It is easy to see [5] that the scattered field has the asymptotic behavior

$$u^s(x) = \frac{e^{ikr}}{\sqrt{r}} u_\infty(\hat{x}, d) + O(r^{-3/2}), \tag{2.3}$$

where u_∞ is the *far field pattern* of the scattered wave. The far field pattern defines the far field operator $F : L^2(\Omega) \to L^2(\Omega)$ by

$$(Fg)(\hat{x}) := \int_\Omega u_\infty(\hat{x}, d) g(d) ds(d), \qquad g \in L^2(\Omega). \tag{2.4}$$

The corresponding interior mixed boundary value problem is also studied in [2]. In particular we consider the following problem: find $u_z \in H^1(D)$ that satisfies

$$\Delta u_z + k^2 u_z = 0 \qquad \text{in} \qquad D, \tag{2.5a}$$

$$u_z = -\Phi(\cdot, z) \qquad \text{on} \qquad \Gamma_D, \tag{2.5b}$$

$$\frac{\partial u_z}{\partial \nu} + i\lambda(x) u_z = -\frac{\partial \Phi(\cdot, z)}{\partial \nu} - i\lambda(x)\Phi(\cdot, z) \qquad \text{on} \qquad \Gamma_I \tag{2.5c}$$

for a fixed $z \in D$, where Φ is the fundamental solution to the Helmholtz equation defined by

$$\Phi(x, z) := \frac{i}{4} H_0^{(1)}(k|x - z|) \tag{2.6}$$

with $H_0^{(1)}$ being a Hankel function of the first kind of order zero. Then in [2] it is shown that (2.5a)–(2.5c) has a unique solution $u_z \in H^1(D)$ provided $\Gamma_I \neq \emptyset$ and $\lambda \neq 0$.

Next we introduce the far field equation

$$(Fg)(\hat{x}) = \gamma e^{-ik\hat{x}\cdot z}, \qquad g \in L^2(\Omega), \quad z \in D, \tag{2.7}$$

where $\gamma = \frac{e^{i\pi/4}}{\sqrt{8\pi k}}$ and $\gamma e^{-ik\hat{x}\cdot z}$ is the far field pattern of $\Phi(x, z)$.

A Herglotz wave function with kernel $g \in L^2(\Omega)$ is an entire solution of the Helmholtz equation defined by

$$v_g(x) = \int_\Omega e^{ikx\cdot d} g(d) ds(d), \qquad x \in \mathbb{R}^2.$$

The following theorem is proved in [2].

THEOREM 2.1. *Let $\epsilon > 0$, $z \in D$, and u_z be the unique solution of* (2.5a)–(2.5c). *Then there exists a Herglotz wave function $v_{g_\epsilon^z}$ with kernel $g_\epsilon^z \in L^2(\Omega)$ such that*

$$\|u_z - v_{g_\epsilon^z}\|_{H^1(D)} \leq \epsilon. \tag{2.8}$$

Moreover, there exists a positive constant $c > 0$ independent of ϵ such that

$$\|(Fg_\epsilon^z)(\hat{x}) - \gamma e^{-ik\hat{x}\cdot z}\|_{L^2(\Omega)} \leq c\epsilon. \tag{2.9}$$

Now let us define w_z by

$$w_z := u_z + \Phi(\cdot, z). \tag{2.10}$$

In particular, since $u_z \in H^1(D)$ and $z \in D$, we have that $w_z|_\Gamma \in H^{\frac{1}{2}}(\Gamma)$, $\frac{\partial w_z}{\partial \nu}|_\Gamma \in H^{-\frac{1}{2}}(\Gamma)$, and

$$w_z|_{\Gamma_D} = 0 \qquad \text{and} \qquad \left(\frac{\partial w_z}{\partial \nu} + i\lambda w_z\right)|_{\Gamma_I} = 0 \tag{2.11}$$

interpreted in the sense of the trace theorem.

LEMMA 2.2. *For every two points z_1 and z_2 in D we have that*

$$2\int_{\Gamma_I} w_{z_1}\lambda(x)\overline{w}_{z_2}\,ds = -4k\pi|\gamma|^2 J_0(k|z_1 - z_2|) + i\left(u_{z_1}(z_2) - \overline{u}_{z_2}(z_1)\right), \tag{2.12}$$

where u_{z_1}, w_{z_1} and u_{z_2}, w_{z_2} are defined by (2.5a)–(2.5c) *and* (2.10)*, respectively, and J_0 is a Bessel function of order zero.*

Proof. Let z_1 and z_2 be two points in D and u_{z_1}, w_{z_1} and u_{z_2}, w_{z_2} the corresponding functions defined by (2.5a)–(2.5c) and (2.10). From (2.11) we have that

$$\begin{aligned}
2i\int_{\Gamma_I} w_{z_1}\lambda(x)\overline{w}_{z_2}\,ds &= \int_\Gamma \left(w_{z_1}\frac{\partial \overline{w}_{z_2}}{\partial \nu} - \overline{w}_{z_2}\frac{\partial w_{z_1}}{\partial \nu}\right) ds \\
&= \int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right) ds \\
&+ \int_\Gamma \left(u_{z_1}\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial u_{z_1}}{\partial \nu}\right) ds \\
&+ \int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{u}_{z_2}}{\partial \nu} - \overline{u}_{z_2}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right) ds.
\end{aligned}$$

From Green's theorem applied to the radiating solution $\Phi(\cdot,z)$ of the Helmholtz equation in D_e and the uniformity of the asymptotic relation (2.3) we have (see [7])

$$\begin{aligned}
&\int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right) ds = -2ik\int_\Omega \Phi_\infty(\cdot,z_1)\overline{\Phi_\infty(\cdot,z_2)}ds \\
&= -2ik\int_\Omega |\gamma|^2 e^{-ik\hat{x}\cdot z_1}e^{ik\hat{x}\cdot z_2}\,ds = -4ik\pi|\gamma|^2 J_0(k|z_1 - z_2|).
\end{aligned}$$

Now from the representation formula for u_{z_1} and u_{z_2} we obtain

$$2i\int_{\Gamma_I} w_{z_1}\lambda(x)\overline{w}_{z_2}\,ds = -4ik\pi|\gamma|^2 J_0(k|z_1 - z_2|) + \overline{u}_{z_2}(z_1) - u_{z_1}(z_2).$$

Finally, dividing both sides of the above relation by i yields the result. ∎

In the following let us consider a ball $B_r \subset D$ of radius r contained in D and denoted by

$$\mathcal{W} := \left\{ f \in L^2(\Gamma_I) : \begin{array}{c} f = w_z|_{\Gamma_I} \text{ with } w_z = u_z + \Phi(\cdot,z), \\ z \in B_r \text{ and } u_z \text{ the solution of (2.5a)–(2.5c)} \end{array} \right\}.$$

Now we are ready to prove the main result of this section.

THEOREM 2.3. *Let $\lambda \in L_\infty(\Gamma_I)$ be the surface impedance of the scattering problem* (2.1a)–(2.2)*. Then*

$$\|\lambda\|_{L_\infty(\Gamma_I)} = \sup_{\substack{z_i\in B_r\\ \alpha_i\in\mathbb{C}}} \frac{\sum_{i,j}\alpha_i\overline{\alpha_j}\left[-4\pi k|\gamma|^2 J_0(k|z_i-z_j|)+i\left(u_{z_i}(z_j)-\overline{u}_{z_j}(z_i)\right)\right]}{2\|\sum_i \alpha_i\left(u_{z_i}+\Phi(\cdot;z_i)\right)\|^2_{L^2(\Gamma)}}, \tag{2.13}$$

where u_z is the solution to (2.5a)–(2.5c) *and the sums are arbitrary finite sums.*

Proof. First we show that $\mathcal{W}$ is complete in $L^2(\Gamma_I)$. To this end let φ be a function in $L^2(\Gamma_I)$ such that for every $z \in B_r$

$$\int_{\Gamma_I} w_z\varphi\, ds = 0.$$

Construct $v \in H^1(D)$ as the unique solution of the interior mixed boundary value problem [2]

$$\begin{aligned} \Delta v + k^2 v &= 0 \quad \text{in} \quad D,\\ v &= 0 \quad \text{on} \quad \Gamma_D,\\ \frac{\partial v}{\partial \nu} + i\lambda(x)v &= \varphi \quad \text{on} \quad \Gamma_I. \end{aligned}$$

Then for every $z \in B_r$, using the boundary conditions and the integral representation formula, we have that

$$\begin{aligned} 0 = \int_{\Gamma_I} w_z\varphi\, ds &= \int_{\Gamma_I} w_z\left(\frac{\partial v}{\partial\nu}+i\lambda v\right) ds = \int_{\Gamma} w_z\left(\frac{\partial v}{\partial\nu}+i\lambda v\right) ds\\ &= \int_\Gamma \left(u_z\frac{\partial v}{\partial\nu}+i\lambda u_z v+\Phi(\cdot,z)\frac{\partial v}{\partial\nu}+i\lambda\Phi(\cdot,z)v\right) ds\\ &= \int_\Gamma \left[u_z\frac{\partial v}{\partial\nu}+v\left(-\frac{\partial u_z}{\partial\nu}-\frac{\partial\Phi(\cdot,z)}{\partial\nu}-i\lambda\Phi(\cdot,z)\right)\right] ds\\ &+ \int_\Gamma \left(\Phi(\cdot,z)\frac{\partial v}{\partial\nu}+i\lambda v\Phi(\cdot,z)\right) ds = v(z). \end{aligned}$$

Now the unique continuation principle implies that $v(z) = 0$ for all $z \in D$, whence from the trace theorem $\varphi = 0$.

We now show that

$$\|\lambda\|_{L_\infty(\Gamma_I)} := \operatorname{ess\,sup}\lambda = \sup_{f\in L^2(\Gamma_I)} \frac{1}{\|f\|^2_{L^2(\Gamma_I)}}\int_{\Gamma_I}\lambda(x)|f|^2 ds.$$

The theorem then follows from Lemma 2.2 and the denseness of $\mathcal{W}$ in $L^2(\Gamma_I)$ by fixing first z_2 and then z_1 and considering linear combinations of w_z for different $z \in B_r$ together with the fact that $\|w_z\|_{L^2(\Gamma)} = \|w_z\|_{L^2(\Gamma_I)}$. (Note that w_{z_1} and w_{z_2} are not orthogonal with respect to $\lambda(x)$ and hence two different points are needed.) To prove the above identity, let $C = \operatorname{ess\,sup}\lambda > 0$. Obviously,

$$\frac{1}{\|f\|^2_{L^2(\Gamma_I)}}\int_{\Gamma_I}\lambda(x)|f|^2 ds \le C \qquad \forall f \in L^2(\Gamma_I).$$

Now for every $0 < \epsilon < C$ the set $M_\epsilon = \{x \in \Gamma_I : |\lambda(x)| \geq C - \epsilon\}$ has a positive measure and for an $f_\epsilon \in L^2(\Gamma_I)$ supported in M_ϵ we have

$$\frac{1}{\|f_\epsilon\|^2_{L^2(\Gamma_I)}} \int_{\Gamma_I} \lambda(x)|f_\epsilon|^2 ds \geq (C - \epsilon),$$

which ends the proof. □

Given that D is known (for example, by using the far field equation and the linear sampling method as discussed in [2]), u_z in the right-hand side of (2.13) still cannot be computed since it depends on the unknown function λ. However, from Theorem 2.1, we can use in (2.13) an approximation to u_z given by the Herglotz wave function v_{g^z} with kernel g^z being the (regularized) solutions of the far field equation (2.7).

In the particular case where the surface impedance is a positive constant $\lambda > 0$ we can further simplify the formula (2.13). In particular, fix an arbitrary point $z_0 \in B_r$ and consider $z_1 = z_2 = z_0$. Then (2.12) simply becomes

$$\lambda = \frac{-2k\pi|\gamma|^2 - \operatorname{Im}(u_{z_0}(z_0))}{\|u_{z_0} + \Phi(\cdot; z_0)\|^2_{L^2(\Gamma)}}. \tag{2.14}$$

Note that the expressions on the right-hand sides of (2.13) and (2.14) can be used as a target signature to detect if an obstacle is coated or not. In particular an object is coated if and only if the numerator is nonzero.

3. The vector case. We now turn our attention to the electromagnetic scattering problem for a (partially) coated perfect conductor in $\mathbb{R}^3$. In particular let $D \subset \mathbb{R}^3$ be a bounded region with boundary Γ such that $D_e := \mathbb{R}^3 \setminus \overline{D}$ is connected. Each simply connected piece of D is assumed to be a Lipschitz curvilinear polyhedron. Moreover, we assume that the boundary $\Gamma = \Gamma_D \cup \Pi \cup \Gamma_I$ is split into two disjoint parts Γ_D and Γ_I having Π as their possible common boundary in Γ and that each part Γ_D and Γ_I can be written as the union of a finite number of open smooth faces $(\Gamma_D^j)_{j=1,\ldots,N_D}$ and $(\Gamma_I^j)_{j=1,\ldots,N_I}$, respectively, where e_{ij} denotes the common edge of two adjacent faces Γ^i and Γ^j. Let ν denote the unit outward normal defined almost everywhere on Γ.

The direct scattering problem for the scattering of a time-harmonic electromagnetic plane wave by a partially coated obstacle D is to find an electric field E and a magnetic field $H := \frac{1}{ik}\operatorname{curl} E$ such that

$$\operatorname{curl}\operatorname{curl} E - k^2 E = 0 \quad \text{in} \quad \mathbb{R}^3 \setminus \overline{D}, \tag{3.1a}$$

$$\nu \times E = 0 \quad \text{on} \quad \Gamma_D, \tag{3.1b}$$

$$\nu \times \operatorname{curl} E - i\lambda(x)(\nu \times E) \times \nu = 0 \quad \text{on} \quad \Gamma_I, \tag{3.1c}$$

where the surface impedance $\lambda \in L_\infty(\Gamma_I)$ satisfies $\lambda(x) \geq \lambda_0 > 0$. The total electric field E is given by

$$E = E^i + E^s, \tag{3.2}$$

where E^s is the scattered field satisfying the Silver–Müller radiation condition

$$\lim_{r\to\infty} (\operatorname{curl} E^s \times x - ikrE^s) = 0 \tag{3.3}$$

uniformly in $\hat{x} = x/|x|$, where $r = |x|$ and the incident field E^i is given by

$$E^i(x) := \frac{i}{k}\operatorname{curl}\operatorname{curl} p e^{ikx\cdot d} = ik(d \times p) \times d e^{ikx\cdot d}, \tag{3.4}$$

where $k > 0$ is the wave number, d is a unit vector giving the direction of propagation, and p is the polarization vector. The well-posedness of the direct problem is established in [3] (in [3] λ was assumed to be constant, but all the results remain valid if $\lambda = \lambda(x) \in L_\infty(\Gamma_I)$). In particular it is shown that there exists a unique solution E, and $H = \frac{1}{ik}\operatorname{curl} E$ of (3.1a)–(3.4), and, moreover, $E \in X(D_e \cap B_R, \Gamma_I)$ for every ball of radius R containing D, where $X(D_e \cap B_R, \Gamma_I)$ is the Sobolev space defined by

$$X(D_e \cap B_R, \Gamma_I) := \{u \in H(\operatorname{curl}, D_e \cap B_R) \,:\, \nu \times u|_{\Gamma_I} \in L_t^2(\Gamma_I)\}$$

with

$$H(\operatorname{curl}, D_e \cap B_R) := \{u \in (L^2(D_e \cap B_R))^3 \,:\, \operatorname{curl} u \in (L^2(D_e \cap B_R))^3\},$$

$$L_t^2(\Gamma_I) := \{u \in (L^2(\Gamma_I))^3 \,:\, \nu \cdot u = 0 \quad \text{on} \quad \Gamma_I\}.$$

The scattered electric field E^s has the asymptotic behavior [5]

$$E^s(x) = \frac{e^{ik|x|}}{|x|}\left\{E_\infty(\hat{x}, d, p) + O\left(\frac{1}{|x|}\right)\right\}$$

as $|x| \to \infty$, where E_∞ is a tangential vector field defined on the unit sphere Ω and known as the *electric far field pattern*. The electric far field operator $F : L_t^2(\Omega) \to L_t^2(\Omega)$ is then defined by

$$(Fg)(\hat{x}) := \int_\Omega E_\infty(\hat{x}, d, g(d)) ds(d), \qquad \hat{x} \in \Omega, \tag{3.5}$$

for $g \in L_t^2(\Omega)$. Note that by superposition Fg is the electric far field pattern of the exterior mixed boundary value problem corresponding to the electromagnetic Herglotz pair with kernel ikg as incident field. An *electromagnetic Herglotz pair* is defined to be a pair of vector fields of the form

$$E_g(x) = \int_\Omega e^{ikx\cdot d} g(d) ds(d), \qquad H_g(x) = \frac{1}{ik}\operatorname{curl} E_g(x), \tag{3.6}$$

where $g \in L_t^2(\Omega)$. It is easily seen that E_g, H_g is a solution of Maxwell's equations $\operatorname{curl} E - ikH = 0$, $\operatorname{curl} H + ikE = 0$ in $\mathbb{R}^3$. Now let us consider the electric dipole with polarization q defined by

$$E_e(x, z, q) := \frac{i}{k}\operatorname{curl}_x \operatorname{curl}_x q\, \Phi(x, z), \qquad H_e(x, z, q) := \operatorname{curl}_x q\, \Phi(x, z), \tag{3.7}$$

where Φ is the fundamental solution of the Helmholtz equation in $\mathbb{R}^3$ defined by

$$\Phi(x, z) := \frac{1}{4\pi}\frac{e^{ik|x-z|}}{|x-z|}, \quad x \neq z \quad \text{and} \quad x, z \in \mathbb{R}^3.$$

If $z \in D$, then $E_e(x,z,q)$ and $H_e(x,z,q)$ satisfy Maxwell's equations in $\mathbb{R}^3 \setminus \overline{D}$, and the corresponding electric far field pattern $E_{e,\infty}(\hat{x},z,q)$ is given by

$$E_{e,\infty}(\hat{x},z,q) = \frac{ik}{4\pi}(\hat{x}\times q)\times \hat{x}\, e^{-ik\hat{x}\cdot z}. \tag{3.8}$$

As in the scalar case, we also need the interior mixed boundary value problem corresponding to the scattering problem which is studied in detail in [3]. (For the case when either $\Gamma_I = \emptyset$ or $\Gamma_D = \emptyset$, see [11].) In particular, let $E_z \in X(D,\Gamma_I)$ be the unique solution of

$$\operatorname{curl}\operatorname{curl} E_z - k^2 E_z = 0 \quad \text{in} \quad D, \tag{3.9a}$$

$$\nu \times [E_z + E_e(\cdot,z,q)] = 0 \quad \text{on} \quad \Gamma_D, \tag{3.9b}$$

$$\nu \times \operatorname{curl}(E_z + E_e(\cdot,z,q)) - i\lambda[\nu\times(E_z+E_e(\cdot,z,q))]\times\nu = 0 \quad \text{on } \Gamma_I \tag{3.9c}$$

for a fixed but arbitrary $z \in D$. Define

$$W_z := E_z + E_e(\cdot,z,q) \tag{3.10}$$

and let $u_T := (\nu\times u)\times\nu$ be the tangential component of a function $u \in H(\operatorname{curl},D)$. Note that $(W_z)_T|_{\Gamma_I} \in L_t^2(\Gamma_I)$ and that W_z depends on the artificial polarization q as well. We now look for a solution to the far field equation

$$Fg(\hat{x}) = E_{e,\infty}(\hat{x},z,q), \qquad z \in D, \tag{3.11}$$

where F is given by (3.5). We have the following result (see [3, Thm. 3.2]).

THEOREM 3.1. *For every $\epsilon > 0$ and $z \in D$ there exists an electric Herglotz wave function $E_{g_\epsilon^z}$ with kernel $g_\epsilon^z \in L_t^2(\Omega)$ such that*

$$\|E_z - ikE_{g_\epsilon^z}\|_{X(D,\Gamma_I)} \le \epsilon, \tag{3.12}$$

where E_z is the solution of (3.9a)–(3.9c). *Moreover, there exists a positive constant $c > 0$ independent of ϵ such that*

$$\|(Fg_\epsilon^z)(\hat{x}) - E_{e,\infty}(\hat{x},z,q)\|_{L_t^2(\Omega)} \le c\epsilon. \tag{3.13}$$

Our next aim is to find a relation that connects the surface impedance λ with E_z.

LEMMA 3.2. *For every two points z_1 and z_2 in D and polarization $q \in \mathbb{R}^3$ we have that*

$$2\int_{\Gamma_I} (W_{z_1})_T \cdot \lambda(\overline{W}_{z_2})_T\, ds = -\|q\|^2 A(z_1,z_2,k,q) + k\left(q\cdot E_{z_1}(z_2) + q\cdot \overline{E}_{z_2}(z_1)\right),$$

where E_{z_1}, E_{z_2} and W_{z_1}, W_{z_2} are defined by (3.9a)–(3.9c) *and* (3.10), *respectively, and $A(z_1,z_2,k,q)$ is a computable number depending only on z_1, z_2, k, and q.*

Proof. By applying the second vector Green's formula and using the boundary conditions for E_{z_1} and E_{z_2} on Γ we obtain

$$\begin{aligned}
2i\int_{\Gamma_I} (W_{z_1})_T \cdot \lambda(\overline{W}_{z_2})_T\, ds &= \int_\Gamma \left(\nu\times W_{z_1}\cdot\operatorname{curl}\overline{W}_{z_2} - \nu\times\overline{W}_{z_2}\cdot\operatorname{curl} W_{z_1}\right) ds \\
&= \int_\Gamma \left(\nu\times E_e(\cdot,z_1,q)\cdot\operatorname{curl}\overline{E_e(\cdot,z_2,q)} - \nu\times\overline{E_e(\cdot,z_2,q)}\cdot\operatorname{curl} E_e(\cdot,z_1,q)\right) ds \\
&\quad + \int_\Gamma \left(\nu\times E_{z_1}\cdot\operatorname{curl}\overline{E_e(\cdot,z_2,q)} - \nu\times\overline{E_e(\cdot,z_2,q)}\cdot\operatorname{curl} E_{z_1}\right) ds \\
&\quad + \int_\Gamma \left(\nu\times E_e(\cdot,z_1,q)\cdot\operatorname{curl}\overline{E}_{z_2} - \nu\times\overline{E}_{z_2}\cdot\operatorname{curl} E_e(\cdot,z_1,q)\right) ds.
\end{aligned} \tag{3.14}$$

One can easily see that if $E \in H(\mathrm{curl}, D)$ and $H = \frac{1}{ik}\mathrm{curl}\, E$ is a solution of Maxwell's equations and $z \in D$, we have

$$\begin{aligned}&\nu \times E_e(y,z,q) \cdot \mathrm{curl}_y\, \overline{E}(y) = -\frac{i}{k}(-ik)\mathrm{curl}_z\, \mathrm{curl}_z\, q\Phi(y,z) \cdot (\nu \times \overline{H}(y))\\ &= -q \cdot \mathrm{curl}_z\, \mathrm{curl}_z\, \Phi(y,z)(\nu \times \overline{H}(y))\end{aligned}$$

and

$$\nu \times \overline{E}(y) \cdot \mathrm{curl}_y\, E_e(y,z,q) = ik\nu \times \overline{E}(y) \cdot H_e(y,z,q) = ikq \cdot \mathrm{curl}_z \Phi(y,z)(\nu \times \overline{E}(y)),$$

and therefore from the Stratton–Chu formula

$$\int_\Gamma \left(\nu \times E_e(y,z,q) \cdot \mathrm{curl}_y\, \overline{E}(y) - \nu \times \overline{E}(y) \cdot \mathrm{curl}_y\, E_e(y,z,q)\right) = ikq \cdot \overline{E}(z). \tag{3.15}$$

Moreover (see [7]),

$$\begin{aligned}&\int_\Gamma \left(\nu \times E_e(\cdot,z_1,q) \cdot \mathrm{curl}\, \overline{E_e(\cdot,z_2,q)} - \nu \times \overline{E_e(\cdot,z_2,q)} \cdot \mathrm{curl}\, E_e(\cdot,z_1,q)\right) ds\\ &\quad = -2ik \int_\Omega E_{e,\infty}(\cdot,z_1,q) \cdot \overline{E_{e,\infty}(\cdot,z_2,q)} ds\\ &\quad = -\frac{ik^3}{8\pi^2} \int_\Omega ((\hat{x} \times q) \times \hat{x}) \cdot ((\hat{x} \times q) \times \hat{x})\, e^{-ik\hat{x}\cdot(z_1-z_2)} ds \qquad (3.16)\\ &\quad = -\frac{ik^3}{8\pi^2} \int_\Omega (\|q\|^2 - (\hat{x} \cdot q)^2)\, e^{-ik\hat{x}\cdot(z_1-z_2)} ds := -i\|q\|^2 A(z_1,z_2,k,q),\end{aligned}$$

where by straightforward calculations

$$A(z_1,z_2,k,q) = \frac{k^3}{6\pi}\left[2j_0(k|z_1-z_2|) + j_2(k|z_1-z_2|)(3\cos^2\phi - 1)\right] \tag{3.17}$$

with j_0 and j_2 being spherical Bessel functions of order 0 and 2, respectively, and ϕ is the angle between $(z_1 - z_2)$ and q. Hence using (3.15) and (3.16) in (3.14) and dividing both sides of (3.14) by i yield the result. ∎

Next we consider a subset $\mathcal{E}$ of $L_t^2(\Gamma_I)$ defined by

$$\mathcal{E} := \left\{ f \in L_t^2(\Gamma_I) : \begin{array}{c} f = (W_z)_T|_{\Gamma_I} \text{ with } W_z = E_z + E_e(\cdot,z,q), \\ z \in B_r,\ E_z \text{ the solution of (3.9a)–(3.9c) and } q \in \mathbb{R}^3 \end{array} \right\},$$

where B_r is a ball of radius r contained in D.

LEMMA 3.3. *$\mathcal{E}$ is complete in $L_t^2(\Gamma_I)$.*

Proof. Let $\varphi \in L_t^2(\Gamma_I)$ such that for every $z \in B_r$

$$\int_{\Gamma_I} (W_z)_T \cdot \varphi\, ds = 0.$$

Let $E \in X(D, \Gamma_I)$ be the solution of the interior mixed boundary value problem [3]

$$\begin{aligned}&\mathrm{curl}\, \mathrm{curl}\, E - k^2 E = 0 \quad \text{in} \quad D,\\ &\nu \times E = 0 \quad \text{on} \quad \Gamma_D,\\ &\nu \times \mathrm{curl}\, E - i\lambda E_T = \varphi \quad \text{on} \quad \Gamma_I.\end{aligned}$$

Then for $z \in B_r$ and $q \in \mathbb{R}^3$, using the fact that $(W_z)_T = E_T = 0$ on Γ_D, the second vector Green's formula, and (3.15), we have that

$$
\begin{aligned}
0 &= \int_{\Gamma_I} (W_z)_T \cdot \varphi \, ds = \int_{\Gamma} W_z \cdot (\nu \times \operatorname{curl} E - i\lambda E_T) \, ds \\
&= \int_{\Gamma} [E_z \cdot (\nu \times \operatorname{curl} E) - i\lambda E_z \cdot E_T + E_e(\cdot, z, q) \cdot (\nu \times \operatorname{curl} E) - i\lambda E_e(\cdot, z, q) \cdot E_T] \, ds \\
&= \int_{\Gamma} [E_z \cdot (\nu \times \operatorname{curl} E) - E \cdot (\nu \times \operatorname{curl} E_z)] \, ds \\
&+ \int_{\Gamma} [-E \cdot (\nu \times \operatorname{curl} E_e(\cdot, z, q)) + i\lambda E_T \cdot E_e(\cdot, z, q)] \, ds \\
&+ \int_{\Gamma} [E_e(\cdot, z, q) \cdot (\nu \times \operatorname{curl} E) - i\lambda E_e(\cdot, z, q) \cdot E_T] \, ds \\
&= \int_{\Gamma} [E_e(\cdot, z, q) \cdot (\nu \times \operatorname{curl} E) - E \cdot (\nu \times \operatorname{curl} E_e(\cdot, z, q))] \, ds \\
&= -\int_{\Gamma} [(\nu \times E_e(\cdot, z, q)) \cdot \operatorname{curl} E - (\nu \times E) \cdot \operatorname{curl} E_e(\cdot, z, q)] \, ds = ikq \cdot E(z).
\end{aligned}
$$

Thus $q \cdot E(z) = 0$ holds for all polarizations $q \in \mathbb{R}^3$ and $z \in B_r$, and hence $E(z) = 0$ for $z \in B_r$. By the unique continuation principle for the solution of Maxwell's equations in D we now see that $E \equiv 0$ in D, whence, by the trace theorem, $\varphi \equiv 0$, which proves the lemma. □

Combining Lemmas 3.2 and 3.3, we can prove in the same way as in the last part of the proof of Theorem 2.3 the main result of this section.

THEOREM 3.4. *Let $\lambda \in L_\infty(\Gamma_I)$ be the surface impedance of the scattering problem* (3.1a)–(3.4). *Then*

$$
\begin{aligned}
&\|\lambda\|_{L_\infty(\Gamma_I)} \\
&= \sup_{\substack{z_i \in B_r,\, q \in \mathbb{R}^3 \\ \alpha_i \in \mathbb{C}}} \frac{\sum_{i,j} \alpha_i \overline{\alpha_j} \left[-\|q\|^2 A(z_i, z_j, k, q) + k \left(q \cdot E_{z_i}(z_j) + q \cdot \overline{E}_{z_j}(z_i) \right) \right]}{2 \| \sum_i \alpha_i (W_{z_i})_T \|^2_{L_t^2(\Gamma)}},
\end{aligned} \tag{3.18}
$$

where $W_z = E_z + E_e(\cdot, z, q)$ with E_z being the solution to (3.9a)–(3.9c), *$A(z_i, z_j, k, q)$ is given by* (3.17), *and the sums are arbitrary finite sums.*

In the particular case where λ is a positive constant and setting $z_1 = z_2 = z_0 \in B_r$, we obtain the following formula for constant surface impedance:

$$
\lambda = \frac{-\frac{k^2}{6\pi} \|q\|^2 + k \operatorname{Re} (q \cdot E_{z_0})}{\|(W_{z_0})_T\|^2_{L_t^2(\Gamma)}}, \tag{3.19}
$$

where $W_{z_0} = E_{z_0} + E_e(\cdot, z_0, q)$ with E_{z_0} being the solution of (3.9a)–(3.9c) corresponding to $z_0 \in B_r$.

In both cases (3.18) and (3.19) E_z cannot be computed since λ appears in the boundary conditions. However, from Theorem 3.1 we can approximate E_z by the electric field ikE_{g^z} of the Herglotz electromagnetic pair with kernel ikg^z, where g^z is a (regularized) solution of the far field equation (3.11) for $z \in B_r \subset D$ and E_∞ is the measured far field data (we again assume that D is known by using the far field equation (3.11) and the linear sampling method as discussed in [3]). We note that, as

in the scalar case, the numerator on the right-hand side of (3.18) and (3.19) can be used as a target signature to detect whether or not a object is coated.

We conclude this section by remarking that, in both scalar and vector cases, it suffices to know only the far field data for a limited-aperture $\Omega_0 \subset \Omega$. In particular, in sections 2.3 and 3.2 of [4] it is proved that a Herglotz wave function and an electromagnetic Herglotz pair and their first derivatives can be approximated uniformly on a compact subset of a disk B_R of radius R by a Herglotz wave function and an electromagnetic Herglotz pair, respectively, with kernel supported in a subset $\Omega_0 \subset \Omega$. The kernel of this new Herglotz wave function can now be used in place of g_ϵ^z in Theorems 2.1 and 3.1, and therefore the corresponding $v_{g_\epsilon^z}$ and $E_{g_\epsilon^z}$ can be used as approximations of u_z and E_z, respectively, in the above formulas.

4. Numerical examples. In this section we give some results of numerical experiments performed in the scalar case when the surface impedance λ is a constant. As shown in section 2, an approximation for λ is given by

$$\frac{-2k\pi|\gamma|^2 - \operatorname{Im}\left(v_{g^z}(z)\right)}{\|v_{g^z} + \Phi(\cdot; z)\|^2_{L^2(\Gamma)}}, \qquad z = (x, y) \in D, \tag{4.1}$$

where $v_{g^z} = \int_0^{2\pi} g^z(d) e^{ik(x\cos\theta + y\sin\theta)} d\theta$, $d = (\cos\theta, \sin\theta)$, and the kernel g^z is the solution of the far field equation

$$\int_0^{2\pi} u_\infty(d, \hat{x}) g^z(d) d\theta = \gamma e^{-ik\hat{x}\cdot z}, \qquad z \in B_r \subset D.$$

The far field data is generated by the method of integral equations and is corrupted by random noise. We fix $k = 3$, select a domain D, boundaries Γ_D and Γ_I (in most of our examples $\Gamma_D = \emptyset$), and a constant λ and then solve the corresponding forward problem. We compute the far field pattern for 100 incident directions and observation directions equally distributed on the unit circle and add random noise of 1% or 10% to the Fourier coefficients of the far field pattern. Tikhonov regularization and the Morozov discrepancy principle are then used to solve the ill-posed discrete far field equation (see section 4 of [2] for details). We choose the sampling points z on a uniform grid of 101×101 points in the square region $[-5,\ 5]^2$ and compute the corresponding g^z. To visualize the obstacle we plot the level curves of the inverse of the discrete ℓ_2 norm of g (note that by the linear sampling method the boundary of the obstacle is characterized as the set of points where the L^2-norm of g starts to become large; see [2]). Then we compute (4.1) at the sampling points in the disk centered at the origin with radius 0.5 (in our examples this circle is always inside D). Although (4.1) is theoretically a constant, because of the ill-posed nature of the far field equation we evaluated (4.1) at all the grid points z in the disk and exhibit the maximum, the average, and the median of the computed values of (4.1). In all tested cases there are some outliers for the minimum value but this is not the case for the maximum. The average and median of the numbers obtained by evaluating (4.1) at the sampling points show that these numbers accumulate near the maximum value and that the average, median, and maximum each provides a reasonable approximation to the true impedance.

For our examples we select two scatterers shown in Figure 4.1 (the kite and the peanut).

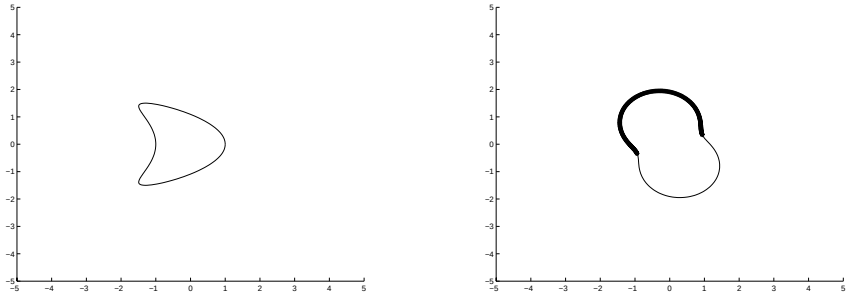

FIG. 4.1. *The boundary of the scatterers used in this study: kite/peanut. When a mixed condition is used for the peanut, the thicker portion of the boundary is* Γ_D.

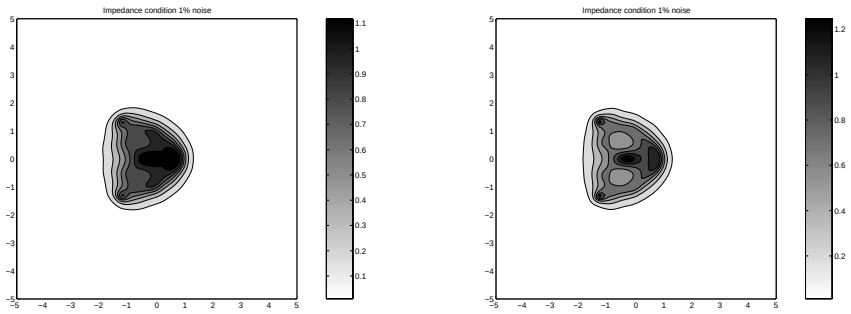

FIG. 4.2. *These figures show the reconstruction of a kite with impedance boundary condition with* 1% *noise: on the left with* $\lambda = 5$ *and on the right with* $\lambda = 9$.

We have obviously left open a number of interesting numerical questions, e.g., what is observed when $\lambda = 0$, what is the dependence of the algorithm on the wave number k, etc. In particular, the examples given here are preliminary in nature. Note that only in the example of the peanut do we consider an object that is really partially coated.

4.1. The kite. We consider the impedance boundary value problem for the kite described by the equation (the left curve in Figure 4.1)

$$x(t) = (1.5\sin(t), \cos(t) + 0.65\cos(2t) - 0.65), \qquad 0 \le t \le 2\pi,$$

with impedance $\lambda = 2$, $\lambda = 5$, and $\lambda = 9$. In Figure 4.2 we show two examples of the reconstructed kite (the reconstructions for the other tested cases look similar). Note that the reconstruction of the boundary is quite accurate so one obtains a good guess for the equation of the boundary Γ of the scatterer. In the numerical results for the reconstructed λ shown in Tables 4.1 and 4.2 we use the exact boundary Γ when we compute the $L^2(\Gamma)$-norm that appears in the denominator of (4.1).

4.2. The peanut. Next we consider a peanut described by the equation (the right curve in Figure 4.1)

$$x(t) = \left(\sqrt{\cos^2(t) + 4\sin^2(t)}\,\cos(t), \quad \sqrt{\cos^2(t) + 4\sin^2(t)}\,\sin(t), \qquad 0 \le t \le 2\pi\right)$$

rotated by $\pi/9$. Here we choose the surface impedance $\lambda = 2$ and $\lambda = 5$ and consider the case of a totally coated peanut (i.e., impedance boundary value problem) as well as

TABLE 4.1
The reconstruction of the surface impedance λ for the kite with 1% noise.

	Maximum	Average	Median
λ=2	2.050	1.975	1.982
λ=5	4.976	4.679	4.787
λ=9	8.883	8.342	8.403

TABLE 4.2
The reconstruction of the surface impedance λ for the kite with 10% noise.

	Maximum	Average	Median
λ=2	2.043	1.960	1.957
λ=5	4.858	4.513	4.524
λ=9	9.0328	8.013	7.992

of a partially coated peanut (i.e., mixed Dirichlet-impedance boundary value problem with Γ_I being the lower half of the peanut as shown in Figure 4.1). Two examples of the reconstructed peanut are presented in Figure 4.3 where, as expected, one notices that for the mixed case the Dirichlet portion of the boundary is more visible. In practice the exact boundary is not available to compute the $L^2(\Gamma)$-norm in (4.1). As suggested by the reconstruction of the peanut, the natural guess for the boundary of the scatterer is the ellipse shown by dashed line in Figure 4.4. So we also examine the sensitivity of our formula on the approximation of the boundary by using this ellipse for computing $\|v_{g^z} + \Phi(\cdot; z)\|_{L^2(\Gamma)}$ in (4.1). The recovered values of λ for our experiments are shown in Tables 4.3 and 4.4.

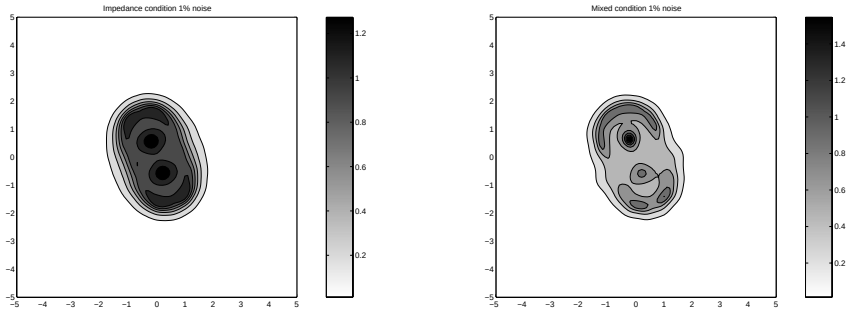

FIG. 4.3. *The figure on the left shows the reconstruction of a peanut with impedance boundary condition with $\lambda = 5$. The figure on the right shows the reconstruction of a peanut with mixed condition with $\lambda = 5$ on the impedance part. Both examples are for $k = 3$ with 1% noise.*

4.3. Conclusions. We have presented the results of some numerical experiments for the scalar case with constant surface impedance. The only a priori information we use is that the coating is homogeneous. Our results suggest that the maximum, median, and average values obtained by evaluating (4.1) at a set of sampling points in a disk closely approximate the true value of λ. We have further shown that even if the boundary of the scatterer is not known exactly, reasonable approximations to the impedance can still be obtained. Numerical experiments need to be done in $\mathbb{R}^3$ and for the nonhomogeneous coating where the scheme is a variational problem. This will be the subject of a forthcoming work.

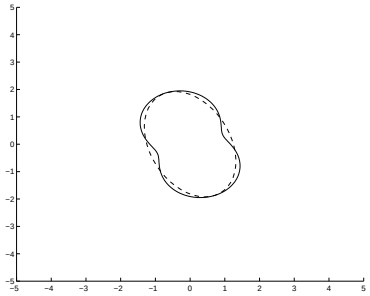

FIG. 4.4. *The dashed line is the approximated boundary we use for computing* $\|v_{g^z} + \Phi(\cdot; z)\|_{L^2(\Gamma)}$ *in* (4.1) *in the case of a peanut with impedance boundary condition.*

ANALYSIS OF THE RESPONSE MATRIX FOR AN EXTENDED TARGET*

HONGKAI ZHAO†

Abstract. In this paper we study the response matrix obtained from the interelement response of an active array of transducers that can send out signals and record reflected signals. In particular we analyze the eigenvalues and eigenvectors of the response matrix corresponding to the acoustic field reflected by an extended target, the size of which is comparable to the wavelength. We show that the eigenvalues are not well separated for a single extended target in general. However, when both the size of the target and the size of the active array are small compared to the distance from the array to the target, it is shown that the eigenvalues are well separated and that the leading eigenvalues and eigenvectors can be characterized in terms of the location and dimension of the target. Numerical experiments are presented to verify the analysis.

1. Introduction.

Active arrays have been used and studied in many applications such as medical imaging, nondestructive testing, seismic imaging, and target detection and recognition for sonar or radar systems. The types of signals (or wave fields) and devices vary by application. For example, in medical imaging ultrasound is mostly used, in sonar systems or underwater communications acoustic waves are typically used, in radar systems or wireless communications electromagnetic waves are used, and in other applications optics or lasers may be used. The typical setup of an active array is illustrated in Figure 1.1. The most important function of the active array is that each element in the array can both send out a signal and record the reflected signal. Such an active array can be used to probe a medium by sending out waves to illuminate reflective targets. Information about the targets can be extracted from the reflected signal. One of the key observations, which is explained in the next section, is that the reflected signal recorded at the array is related to the output signal of the array by a matrix, the response matrix. In many applications the response matrix can be obtained from the interelement response, i.e., the response received at one transducer corresponding to an impulse sent out from another transducer. Moreover, the product of the response matrix and its adjoint corresponds to the time reversal operator that has been studied extensively in [15, 14, 13, 12, 16, 17, 4, 3, 6, 1]. Understanding the structure of the response matrix, such as its eigenvalues and eigenvectors, is crucial for applications using active arrays.

In [15, 14, 13] an iterative time reversal procedure is proposed and analyzed for detecting and selectively focusing on targets. After recording the reflected signal, reversing it in time, and then sending it out to the medium for a few iterations, the wave field will automatically focus on the "strongest" scatterer. The whole physical procedure can be viewed as a power method for finding the leading eigenvector of the

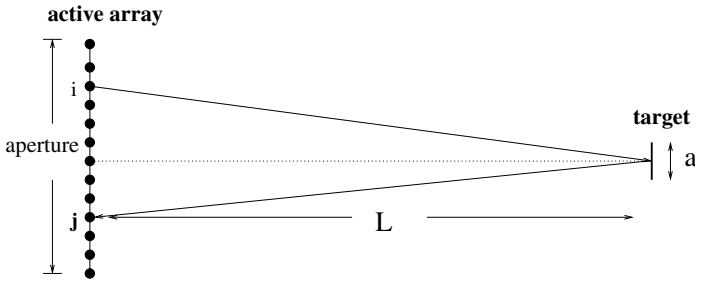

FIG. 1.1. *The setup of an active array.*

response matrix. For well-resolved point scatterers, whose sizes are small compared to those of the wavelength, it can be shown that each eigenvector of the response matrix corresponds to the wave field at the array due to a point source located at one of the scatterers. Instead of a physical iterated time reversal procedure, which can generate a physical wave field that focuses on a selective target, we can also analyze the response matrix on a computer for the detection or imaging of targets. For example, singular value decomposition (SVD) of the response matrix and subspace projection were used in [6] for detecting the locations of targets. In all these methods and their analyses the scatterers are considered as point-like scatterers so that the response matrix can be cleanly decomposed as the tensor product of the Green's function corresponding to each scatterer. It should be pointed out that in many applications the eigenvalues and eigenvectors of the response matrix may also depend on material properties. In [4, 3] it was shown that the compressibility and density contrast causes different scattered waves and generates more than one eigenstate even for a small spherical scatterer. However, the geometry of a general extended scatterer was not taken into account in an explicit way.

In this paper we will study the eigenvalues and eigenvectors of the response matrix corresponding to a single extended target. We show that in some asymptotic regimes, the leading eigenvalues and eigenvectors are well separated into groups and can be characterized in terms of the location and geometry of the target. Numerical tests match well with our analysis and show that our formulas can work well in more general situations. In the future we will study multiple targets, different designs of the arrays, imaging procedures for both locations and sizes of extended targets, and the effect of random inhomogeneity in the medium and self-averaging in the time domain.

Here is the outline of this paper. First, the response matrix and its basic properties for point scatterers are briefly reviewed in section 2. In section 3 the eigenvalues and eigenvectors of the response matrix corresponding to an extended scatterer are analyzed in some asymptotic regimes. In section 4 we study the effect of alignment between the active array and the target. Finally we show numerical experiments to verify our analysis in section 5.

2. The response matrix of an active array. Define the interelement response $p_{ij}(t)$ to be the reflected signal at the jth transducer corresponding to an impulse sent out from the ith transducer. For an array consisting of N transducers, the matrix $P(t) = [p_{ij}(t)]_{N\times N}$ is called the response matrix. If the medium is static, we have $p_{ij}(t) = p_{ji}(t)$ due to spatial reciprocity. If we assume the medium and the array response are linear, for an output signal $\vec{e}(t) = [e_1(t), e_2(t), \ldots, e_N(t)]^T$, where $e_i(t)$ is the output signal at the ith transducer and T means transpose, the reflected signal

at the array is

$$\vec{r}(t) = [r_1(t), r_2(t), \ldots, r_N(t)]^T = P(t) * \vec{e}(t).$$

Here $*$ denotes convolution in time. The convolution in time domain becomes the multiplication in frequency domain,

$$\vec{r}(\omega) = P(\omega)\vec{e}(\omega),$$

where ω is the frequency and $P(\omega)$ is the Fourier transform of $P(t)$. We follow the derivations in [14, 6] to illustrate the basic structure of the response matrix $P(\omega)$ for point scatterers in the medium. Denote $G(\boldsymbol{\xi}, \boldsymbol{x})$ to be Green's function of the medium for frequency ω, which represents the wave field at $\boldsymbol{x}$ for a point source located at $\boldsymbol{\xi}$. Due to the spatial reciprocity, $G(\boldsymbol{x}, \boldsymbol{\xi}) = G(\boldsymbol{\xi}, \boldsymbol{x})$. Here we suppress the dependence of Green's function on the frequency.

Assuming there are M point scatterers located at $\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_M$ in the medium with reflectivity $\tau_1, \tau_2, \ldots, \tau_M$, if we neglect the multiple scattering among the scatterers, then for a signal $\vec{e}(\omega) = [e_1(\omega), e_2(\omega), \ldots, e_N(\omega)]^T$ sent out from the active array, the reflected signal at the jth transducer is

$$r_j(\omega) = \sum_{k=1}^{M} \sum_{i=1}^{N} G(\boldsymbol{\xi}_j, \boldsymbol{x}_k)\tau_k G(\boldsymbol{\xi}_i, \boldsymbol{x}_k) e_i(\omega),$$

where $\boldsymbol{\xi}_1, \boldsymbol{\xi}_2, \ldots, \boldsymbol{\xi}_N$ are the locations of the transducers. If we define the illumination vectors, $\vec{g}_k, k = 1, 2, \ldots, M$, to be

$$\vec{g}_k = [G(\boldsymbol{\xi}_1, \boldsymbol{x}_k), G(\boldsymbol{\xi}_2, \boldsymbol{x}_k), \ldots, G(\boldsymbol{\xi}_N, \boldsymbol{x}_k)]^T,$$

i.e., the wave field at the array of transducers corresponding to a point source at the kth scatterer, we have

$$P(\omega) = \sum_{k=1}^{M} \tau_k \vec{g}_k \vec{g}_k^T \quad \text{and} \quad \vec{r}(\omega) = P(\omega)\vec{e}(\omega). \tag{2.1}$$

Due to the spatial reciprocity, $P(\omega)$ is symmetric. If we do time reversal, which is phase conjugation in frequency domain, for the reflected signal and send it back to the medium, the new reflected signal is $P(\omega)\overline{P(\omega)\vec{e}(\omega)}$, where $\bar{}$ denotes complex conjugation. Another phase conjugation gives the second time reversed output signal $\overline{P(\omega)}P(\omega)\vec{e}(\omega)$ in terms of the original output signal $\vec{e}(\omega)$. So $R(\omega) = \overline{P(\omega)}P(\omega) = P^*(\omega)P(\omega)$ is called the time reversal matrix (operator), where $*$ denotes the adjoint. $R(\omega)$ is a Hermitian matrix and from (2.1) we have

$$R(\omega) = \sum_{k=1}^{M} \overline{\tau_k \vec{g}_k \vec{g}_k^T} \sum_{k'=1}^{M} \tau_{k'} \vec{g}_{k'} \vec{g}_{k'}^T = \sum_{k'=1}^{M} \sum_{k=1}^{M} \Lambda_{k,k'} \bar{\vec{g}}_k \vec{g}_{k'}^T, \tag{2.2}$$

where

$$\Lambda_{k,k'} = \overline{\tau}_k \tau_{k'} \langle \vec{g}_k, \vec{g}_{k'} \rangle = \overline{\tau}_k \tau_{k'} \bar{\vec{g}}_k^T \vec{g}_{k'}.$$

All medium properties are embedded in Green's function in the above formulations. From representations (2.1) and (2.2), we can easily see that both the response matrix $P(\omega)$ and the time reversal matrix $R(\omega)$ are of rank M, if $M < N$, and that

any eigenvector corresponding to a nonzero eigenvalue is a linear combination of the illumination vectors $\vec{g}_k, k = 1, 2, \ldots, M$. We then define the point spread function

$$\Gamma(\boldsymbol{x}', \boldsymbol{x}) = \sum_{i=1}^{N} \overline{G(\boldsymbol{\xi}_i, \boldsymbol{x}')} G(\boldsymbol{\xi}_i, \boldsymbol{x}). \tag{2.3}$$

$\Gamma(\boldsymbol{x}', \boldsymbol{x})$ is exactly the wave field at point $\boldsymbol{x}$ after phase conjugation of the signal received at the active array corresponding to a point source at point $\boldsymbol{x}'$ and sending it back to the medium. The scatterers are well resolved by the active array means

$$\Gamma(\boldsymbol{x}_k, \boldsymbol{x}_{k'}) = \overline{\vec{g}_k^T} \vec{g}_{k'} \approx 0 \text{ if } k \neq k';$$

i.e., the wave field corresponding to the time reversal of a point source at one scatterer is almost zero at all other scatterers. Then $\vec{g}_k$ ($\overline{\vec{g}_k}$) are the left (right) singular vectors for $P(\omega)$ with singular values $|\tau_k| \|\vec{g}_k\|^2$ since

$$P(w)\overline{\vec{g}_k} = \tau_k \|\vec{g}_k\|^2 \vec{g}_k, \quad P^*(w)\vec{g}_k = \overline{\tau}_k \|\vec{g}_k\|^2 \overline{\vec{g}_k}.$$

Similarly it can be shown that $\overline{\vec{g}_k}$ is the eigenvector for the Hermitian matrix $R(\omega)$ with eigenvalue $|\tau_k|^2 \|\vec{g}_k\|^4$. In a homogeneous medium, the focusing property of the point spread function $\Gamma(\boldsymbol{x}', \boldsymbol{x})$ is dictated by the diffraction limit, which is proportional to wavelength and propagation distance and is inversely proportional to the size (aperture) of the active array. However, if the medium is inhomogeneous and random, the resolution of time reversal can beat the diffraction limit. The superresolution phenomenon is both observed in experiments [7, 5, 8, 9, 11] and theoretically analyzed in [7, 2]. It is shown in [2] that the effective aperture can be much larger than the physical size of the array due to multipathing in an inhomogeneous medium, and that the superresolution for time reversal is statistically stable in the time domain due to self-averaging of different frequencies in a broadband signal.

In [15, 14, 13], a physical iterative time reversal procedure (D.O.R.T.) was used to focus selectively on reflective targets in a real medium. The procedure is equivalent to the power method for finding the leading eigenvector of the time reversal matrix. Since physical time reversal is used, we do not need to know the medium. However, for selective focusing, the targets have to be well resolved by the active array. This procedure is useful for automatic target detection/destruction in practice. In [6] an algorithm for imaging point targets in the medium on computers using an active array was developed. However all these formulations and analyses assume the targets are point scatterers so that the response matrix and time reversal matrix have the simple structure in (2.1) and (2.2), respectively. In this paper we will analyze the eigenvalues and eigenvectors of the response matrix corresponding to an extended target.

3. The SVD of the response matrix for an extended target. In general the response matrix for an extended target does not have a simple decomposition as in the case for point targets. To simplify the analysis, we assume that each transducer of the active array can be viewed as a point source and the target is a perfect reflector with a normal reflectivity that is equal to 1. In this case the scattered field can be represented as an integral over the illuminated surface. So the response matrix can be written as

$$P_{ij}(\omega) = \int_{\Omega} G(\boldsymbol{\xi}_i, \boldsymbol{x}) G(\boldsymbol{\xi}_j, \boldsymbol{x}) \tau(\boldsymbol{x}; \boldsymbol{\xi}_i, \boldsymbol{\xi}_j) d\boldsymbol{x}, \tag{3.1}$$

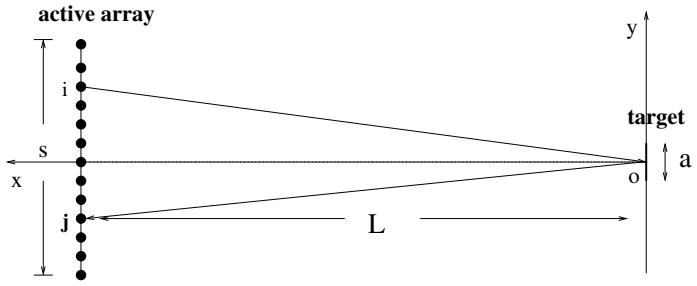

FIG. 3.1.

where Ω is the part of the surface that can be illuminated by the active array, and $\tau(\boldsymbol{x};\boldsymbol{\xi}_i,\boldsymbol{\xi}_j)$ is a reflectivity kernel that depends on the incidence and outgoing angle, i.e., the angle between the normal of the surface at $\boldsymbol{x}$ and the vectors $\boldsymbol{\xi}_i-\boldsymbol{x}$ and $\boldsymbol{\xi}_j-\boldsymbol{x}$, respectively.

In many applications, such as target detections using a sonar or radar system, wireless or underwater communications, and geophysics imaging, the distance between the target and the active array is much larger than the wavelength or sizes of the target and array. Let L be the distance between the array and the target, s be the size of the array, a be the size of the target, and $k=\frac{\omega}{c}$ be the wave number, where c is the wave speed. In our study we consider the case where

- the wavelength is comparable to the size of the array and the size of the extended target, i.e., $ka\sim O(1),\ ks\sim O(1)$;
- the wavelength is small compared to the distance between the array and the target, i.e., $\frac{1}{kL}\sim\frac{s}{L}\sim\frac{a}{L}\sim o(1)$.

In this case the wave from a transducer is almost planar when it reaches the target. Furthermore we assume the target is a planar target and lies in a plane that is parallel to the plane of the array. Since the size of the array and the size of the target are much smaller than the propagation distance, both the incidence and outgoing angles are small. We first neglect the reflectivity kernel and approximate the response matrix by

$$P_{ij}(k)=\int_{\Omega}G(\boldsymbol{\xi}_i,\boldsymbol{x})G(\boldsymbol{\xi}_j,\boldsymbol{x})d\boldsymbol{x}. \tag{3.2}$$

We will put in a reflectivity kernel later.

For simplicity we start with a one-dimensional target and array in a homogeneous medium as illustrated in Figure 3.1. We expand Green's function $G(\boldsymbol{\xi}_i,\boldsymbol{x})$ in free space at a point $\boldsymbol{x}=(0,y)$ on the target in powers of $\frac{1}{L}$. The expansion actually involves powers of ka, ks, which are $O(1)$, and powers of $\frac{a}{L},\frac{s}{L}$, which are $o(1)$.

$$\begin{aligned}G(\boldsymbol{\xi}_i,\boldsymbol{x})&=\frac{e^{ik|\boldsymbol{\xi}_i-\boldsymbol{x}|}}{4\pi|\boldsymbol{\xi}_i-\boldsymbol{x}|}=\frac{e^{ik\sqrt{L^2+(\eta_i-y)^2}}}{4\pi\sqrt{L^2+(\eta_i-y)^2}}\\&=\tilde{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\frac{e^{\frac{ik(-2\eta_i y+y^2)}{2L}+O(\frac{1}{L^3})}}{1-\frac{2\eta_i y-y^2}{2L^2+\eta_i^2}+O(\frac{1}{L^4})}=\tilde{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\frac{e^{\frac{ik(-2\eta_i y+y^2)}{2L}+O(\frac{1}{L^3})}}{1-\frac{2\eta_i y-y^2}{2L^2}+O(\frac{1}{L^4})},\end{aligned} \tag{3.3}$$

where $\boldsymbol{o}=(0,0)$ is the center of the target, $\boldsymbol{\xi}_i=(L,\eta_i)$ is the location of the ith trans-

ducer, and $\tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) = \frac{e^{ikL(1+\frac{\eta_i^2}{2L^2})}}{4\pi L(1+\frac{\eta_i^2}{2L^2})}$ is the parabolic approximation of Green's function $G(\boldsymbol{\xi}_i, \boldsymbol{o})$. Here we can use the two-dimensional Green's function, which is a Hankel function of the first kind, but instead we use the three-dimensional Green's function for simplicity and consistency with later analysis. Further expanding in $\frac{1}{L}$, we have

$$G(\boldsymbol{\xi}_i, \boldsymbol{x}) = \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \left[1 + \frac{ik(y^2 - 2\eta_i y)}{2L} - \frac{k^2(y^2 - 2\eta_i y)^2}{8L^2} - \frac{y^2 - 2\eta_i y}{2L^2} + O(\frac{1}{L^3}) \right]. \tag{3.4}$$

Now the response matrix becomes

$$\begin{aligned}
P_{ij}(k) &= \int_{-\frac{a}{2}}^{\frac{a}{2}} G(\boldsymbol{\xi}_i, \boldsymbol{x}) G(\boldsymbol{\xi}_j, \boldsymbol{x}) dy \\
&= \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) \int_{-\frac{a}{2}}^{\frac{a}{2}} \left[1 + \frac{iky^2}{L} - \frac{k^2(\eta_i + \eta_j - y)^2 y^2}{2L^2} + \frac{(\eta_i + \eta_j - y)y}{L^2} + O\left(\frac{1}{L^3}\right) \right] dy \\
&= \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) \int_{-\frac{a}{2}}^{\frac{a}{2}} \left(1 + \frac{iky^2}{L} - \frac{k^2 y^4}{2L^2} - \frac{y^2}{L^2} \right) dy \\
&\quad - \frac{k^2}{L^2} \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) \eta_i \eta_j \int_{-\frac{a}{2}}^{\frac{a}{2}} y^2 dy - \frac{k^2}{2L^2} \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) (\eta_i^2 + \eta_j^2) \int_{-\frac{a}{2}}^{\frac{a}{2}} y^2 dy \\
&\quad + O\left(\frac{1}{L^3}\right).
\end{aligned} \tag{3.5}$$

Denote $\alpha(a, k, L) = \int_{-\frac{a}{2}}^{\frac{a}{2}} (1 + \frac{iky^2}{L} - \frac{k^2 y^4}{2L^2} - \frac{y^2}{L^2}) dy \approx a$. So the response matrix can be decomposed as

$$P(k) = \alpha(a, k, L) \vec{\tilde{g}} \vec{\tilde{g}}^T - \frac{k^2 a^3}{12L^2} \vec{\tilde{g}}_1 \vec{\tilde{g}}_1^T - \frac{k^2 a^3}{24L^2} \left[\vec{\tilde{g}}_2 \vec{\tilde{g}}^T + \vec{\tilde{g}} \vec{\tilde{g}}_2^T \right] + O\left(\frac{1}{L^3}\right), \tag{3.6}$$

where

$$\begin{aligned}
\vec{\tilde{g}} &= [\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_1 &= [\eta_1 \tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2 \tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N \tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_2 &= [\eta_1^2 \tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2^2 \tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N^2 \tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T.
\end{aligned} \tag{3.7}$$

The leading term $a \vec{\tilde{g}} \vec{\tilde{g}}^T$ corresponds to a point scatterer at the center of the extended target with a total reflectivity proportional to the size of the target. Moreover, if the center of the array is aligned with the center of the target, $\vec{\tilde{g}}$ and $\vec{\tilde{g}}_2$ are even in η while $\vec{\tilde{g}}_1$ is odd in η, so we have

$$\vec{\tilde{g}}_1^T \vec{\tilde{g}} = \vec{\tilde{g}}_1^T \vec{\tilde{g}}_2 = 0.$$

From the orthogonality condition we can separate the second term from the other terms in the matrix decomposition formula (3.6). Moreover, since the size of array s is small compared to the distance L, the parabolic factor $\frac{\eta^2}{L^2}$ is very flat, and $\vec{g}_2$ is approximately aligned with $\vec{g}$. Most of the term $\frac{k^2 a^3}{24L^2} [\vec{\tilde{g}}_2 \vec{\tilde{g}}^T + \vec{\tilde{g}} \vec{\tilde{g}}_2^T]$ is absorbed in

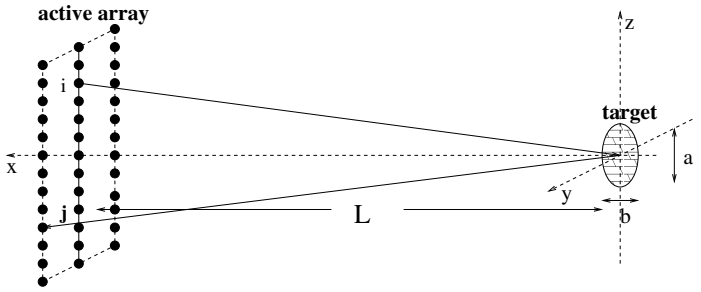

FIG. 3.2.

the leading term as a small perturbation. In particular the contribution of this term together with other high-order terms in $\alpha(a,k,L)$ tends to make the amplitude of the first eigenvalue smaller. This will be verified by numerical experiments in section 5.

From the analysis, we see that

$$P\bar{\vec{g}} \approx a\|\vec{g}\|^2\vec{g}, \quad P^*\vec{g} \approx a\|\vec{g}\|^2\bar{\vec{g}},$$
$$P\bar{\vec{g}}_1 \approx -\tfrac{a^3k^2}{12L^2}\|\vec{g}_1\|^2\vec{g}_1, \quad P^*\vec{g}_1 \approx -\tfrac{a^3k^2}{12L^2}\|\vec{g}_1\|^2\bar{\vec{g}}_1,$$

and

- the dominant singular value λ_1 has a magnitude $|\lambda_1| \approx a\|\vec{g}\|^2$, and the associated left singular vector is the illumination vector $\bar{\vec{g}}$;
- the second dominant singular value λ_2 has a magnitude $|\lambda_2| \approx \frac{a^3k^2}{12L^2}\|\vec{g}_1\|^2$, and the associated left singular vector is $\bar{\vec{g}}_1$.

When we extend the above analysis to a two-dimensional planar target and array as illustrated in Figure 3.2, the calculation is similar but messier. First pick a point $\boldsymbol{o}$ on the target as the origin and choose two orthogonal directions in the plane of the target as y and z axes. Let $\boldsymbol{x} = (0, y, z)$ denote a point on the target and $\boldsymbol{\xi}_i = (L, \eta_i, \zeta_i)$ denote the coordinates of the ith transducer. The situation becomes more complicated due to the coupling of different directions. We have

$$G(\boldsymbol{\xi}_i, \boldsymbol{x}) = \frac{e^{ik\sqrt{L^2+(\eta_i-y)^2+(\zeta_i-z)^2}}}{4\pi\sqrt{L^2+(\eta_i-y)^2+(\zeta_i-z)^2}} = \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o})$$
$$\times\left[1+\frac{ik(y^2-2\eta_i y+z^2-2\zeta_i z)}{2L}-\frac{k^2(y^2-2\eta_i y+z^2-2\zeta_i z)^2}{8L^2}\right.$$
$$\left.-\frac{y^2-2\eta_i y+z^2-2\zeta_i z}{2L^2}+O\left(\frac{1}{L^3}\right)\right],$$

where $\tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) = \frac{e^{ikL(1+\frac{\eta_i^2+\zeta_i^2}{2L^2})}}{4\pi L(1+\frac{\eta_i^2+\zeta_i^2}{2L^2})}$ is again the parabolic approximation of Green's function, and

$$G(\boldsymbol{\xi}_i, \boldsymbol{x})G(\boldsymbol{\xi}_j, \boldsymbol{x}) = \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o})\tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) \times \left\{1+\frac{ik[y^2-(\eta_i+\eta_j)y+z^2-(\zeta_i+\zeta_j)z]}{L}\right.$$
$$\left.-\frac{k^2[y^2-(\eta_i+\eta_j)y+z^2-(\zeta_i+\zeta_j)z]^2}{2L^2}-\frac{y^2-(\eta_i+\eta_j)y+z^2-(\zeta_i+\zeta_j)z}{L^2}+O\left(\frac{1}{L^3}\right)\right\}.$$

So the response matrix is

$$
\begin{aligned}
&P_{ij}(k) = \int_\Omega G(\boldsymbol{\xi}_i, \boldsymbol{x}) G(\boldsymbol{\xi}_j, \boldsymbol{x}) dydz = \tilde{G}(\boldsymbol{\xi}_i, \boldsymbol{o}) \tilde{G}(\boldsymbol{\xi}_j, \boldsymbol{o}) \\
&\times \left[\int_\Omega \left(1 + \frac{ik(y^2+z^2)}{L} - \frac{k^2(y^2+z^2)^2}{2L^2} - \frac{y^2+z^2}{L^2} \right) dydz \right. \\
&-\eta_i\eta_j \int_\Omega \frac{k^2y^2}{L^2} dydz - \zeta_i\zeta_j \int_\Omega \frac{k^2z^2}{L^2} dydz \\
&-(\eta_i^2+\eta_j^2) \int_\Omega \frac{k^2y^2}{2L^2} dydz - (\zeta_i^2+\zeta_j^2) \int_\Omega \frac{k^2z^2}{2L^2} dydz \\
&+(\eta_i+\eta_j) \int_\Omega \left(-\frac{iky}{L} + \frac{k^2(y^2+z^2)y}{L^2} + \frac{y}{L^2} \right) dydz \\
&+(\zeta_i+\zeta_j) \int_\Omega \left(-\frac{ikz}{L} + \frac{k^2(y^2+z^2)z}{L^2} + \frac{z}{L^2} \right) dydz \\
&\left. -(\eta_i\zeta_i + \eta_i\zeta_j + \eta_j\zeta_i + \eta_j\zeta_j) \int_\Omega \frac{k^2yz}{L^2} dydz + O\left(\frac{1}{L^3}\right) \right].
\end{aligned}
$$

Denote

$$
\begin{aligned}
\vec{\tilde{g}} &= [\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_{1y} &= [\eta_1\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2\tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N\tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_{1z} &= [\zeta_1\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \zeta_2\tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \zeta_N\tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_{2y} &= [\eta_1^2\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2^2\tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N^2\tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_{2z} &= [\zeta_1^2\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \zeta_2^2\tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \zeta_N^2\tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T, \\
\vec{\tilde{g}}_{2yz} &= [\eta_1\zeta_1\tilde{G}(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2\zeta_2\tilde{G}(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N\zeta_N\tilde{G}(\boldsymbol{\xi}_N, \boldsymbol{o})]^T.
\end{aligned} \tag{3.8}
$$

The response matrix can be decomposed as

$$
\begin{aligned}
&P(k) = \vec{\tilde{g}}\vec{\tilde{g}}^T \int_\Omega \left(1 + \frac{ik(y^2+z^2)}{L} - \frac{k^2(y^2+z^2)^2}{2L^2} - \frac{y^2+z^2}{L^2} \right) dydz \\
&-\vec{\tilde{g}}_{1y}\vec{\tilde{g}}_{1y}^T \int_\Omega \frac{k^2y^2}{L^2} dydz - \vec{\tilde{g}}_{1z}\vec{\tilde{g}}_{1z}^T \int_\Omega \frac{k^2z^2}{L^2} dydz \\
&- \left(\vec{\tilde{g}}_{2y}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{2y}^T \right) \int_\Omega \frac{k^2y^2}{2L^2} dydz - \left(\vec{\tilde{g}}_{2z}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{2z}^T \right) \int_\Omega \frac{k^2z^2}{2L^2} dydz \\
&+ \left(\vec{\tilde{g}}_{1y}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{1y}^T \right) \int_\Omega \left(-\frac{iky}{L} + \frac{k^2(y^2+z^2)y}{L^2} + \frac{y}{L^2} \right) dydz \\
&+ \left(\vec{\tilde{g}}_{1z}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{1z}^T \right) \int_\Omega \left(-\frac{ikz}{L} + \frac{k^2(y^2+z^2)z}{L^2} + \frac{z}{L^2} \right) dydz \\
&- \left(\vec{\tilde{g}}_{1y}\vec{\tilde{g}}_{1z}^T + \vec{\tilde{g}}_{1z}\vec{\tilde{g}}_{1y}^T + \vec{\tilde{g}}_{2yz}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{2yz}^T \right) \int_\Omega \frac{k^2yz}{L^2} dydz + O\left(\frac{1}{L^3}\right).
\end{aligned} \tag{3.9}
$$

The above formula shows the decomposition of the response matrix in any coordinate system. Again the leading term corresponds to a point scatterer. The decomposition of the response matrix is not obvious from this general expression since the two directions and the center are coupled together. However, if we choose $\boldsymbol{o}$ to be the mass center of the target, we have

$$\int_\Omega y dydz, \qquad \int_\Omega z dydz = 0.$$

Now we have an extra freedom of rotation of the y and z axes around $\boldsymbol{o}$. Denote the integral $R(\theta) = \int_\Omega yzdydz$ as a function of rotation angle θ. Since $R(\theta) = -R(\theta \pm \pi/2)$, we must have at least two θ such that $\int_\Omega yzdydz = 0$. Due to this symmetry and cancellations, the following terms are usually small:

$$\int_\Omega y^p z^q dydz \approx 0 \text{ for } (p,q) \in \{(1,2),(2,1),(0,3),(3,0)\}.$$

Hence the decomposition of the response matrix can be simplified as

$$\begin{aligned} P(k) \approx{}& \vec{\tilde{g}}\vec{\tilde{g}}^T \int_\Omega dydz - \frac{k^2}{L^2}\vec{\tilde{g}}_{1y}\vec{\tilde{g}}_{1y}^T \int_\Omega y^2 dydz \\ &- \frac{k^2}{L^2}\vec{\tilde{g}}_{1z}\vec{\tilde{g}}_{1z}^T \int_\Omega z^2 dydz - \frac{k^2}{2L^2}\left[\vec{\tilde{g}}_{2y}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{2y}^T\right] \int_\Omega y^2 dydz \\ &- \frac{k^2}{2L^2}\left[\vec{\tilde{g}}_{2z}\vec{\tilde{g}}^T + \vec{\tilde{g}}\vec{\tilde{g}}_{2z}^T\right] \int_\Omega z^2 dydz + O\left(\frac{1}{L^3}\right). \end{aligned} \tag{3.10}$$

Again, if the array of transducers is symmetric with respect to the y and z axes, we have the following orthogonality properties defined in the sense of complex inner product as in the one-dimensional case:

$$\vec{\tilde{g}}_{1y} \perp \vec{\tilde{g}},\ \vec{\tilde{g}}_{2y},\ \vec{\tilde{g}}_{2z}, \quad \vec{\tilde{g}}_{1z} \perp \vec{\tilde{g}},\ \vec{\tilde{g}}_{2y},\ \vec{\tilde{g}}_{2z}, \quad \vec{\tilde{g}}_{1y} \perp \vec{\tilde{g}}_{1z}.$$

In this case we have

- the dominant singular value λ_1 has a magnitude $|\lambda_1| \approx \|\vec{\tilde{g}}\|^2 \int_\Omega dydz$ with the illumination $\vec{\tilde{g}}$ as the singular vector;
- the next two dominant singular values have magnitudes $|\lambda_2| \approx \frac{k^2}{L^2}\|\vec{\tilde{g}}_{1y}\|^2 \int_\Omega y^2 dydz$ and $|\lambda_3| \approx \frac{k^2}{L^2}\|\vec{\tilde{g}}_{1z}\|^2 \int_\Omega z^2 dydz$, respectively, and the corresponding singular vectors are $\vec{\tilde{g}}_{1y}$ and $\vec{\tilde{g}}_{1z}$, respectively.

The two symmetric axes of the target are intrinsic and are independent of the artificial y and z axes we choose. The directions of the two symmetric axes with respect to the artificial y and z axes we choose are embedded in the response matrix and can be extracted from the leading singular vectors, as will be shown later from the numerical experiments in section 5. Essentially these formulas suggest that we can find both the location and size of an extended target as well as the symmetric axes and a few moments with respect to these axes using the leading singular values and singular vectors of the response matrix. In practice, ratios of the singular values are more robust and can be used to determine aspect ratios.

For a three-dimensional scatterer for which the Born approximation is valid, the integration over the scatterer will be in three dimensions. Using similar analysis

for the response matrix, we will get a third singular value and singular vector that corresponds to the third dimension in the second group of leading singular values and singular vectors. In practice, the depth information is often relatively weak due to a small glancing aperture and is more difficult to capture from the response matrix. Especially when the distance between the active array and the target is long, we would see an effective planar shape of the target. In [17], careful numerical simulations are done to analyze the eigenvalues and eigenvectors of the response matrix and illustrate very similar behavior to our results here.

For a medium with weak random inhomogeneity, it is shown that for a long propagation distance, Green's function is a modification of the homogeneous Green's function with an attenuation factor due to multiple scattering [10]. So the behaviors of the response matrix and its eigenvalues and eigenvectors should be similar. We will analyze these situations in a future study.

Now we take into account the variation of reflectivity due to different incident and outgoing angles. In particular we choose a special reflectivity kernel

$$\tau(\boldsymbol{x};\boldsymbol{\xi}_i,\boldsymbol{\xi}_j)=\cos\theta_i(\boldsymbol{x})\cos\theta_j(\boldsymbol{x}),$$

where $\theta_i(\boldsymbol{x})$ is the angle between $\boldsymbol{x}-\boldsymbol{\xi}_i$ and the normal at $\boldsymbol{x}$. At a point $\boldsymbol{x}$ on a one-dimensional target,

$$\cos\theta_i(\boldsymbol{x})=\frac{L}{\sqrt{L^2+(\eta_i-y)^2}}=\frac{1}{1+\frac{\eta_i^2}{2L^2}}\left(1-\frac{y^2-2\eta_i y}{2L^2}\right)+O\left(\frac{1}{L^4}\right).$$

If we plug this asymptotic expansion back into the response matrix expression (3.1) and denote

$$\breve{G}(\boldsymbol{\xi}_i,\boldsymbol{o})=\tilde{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\frac{1}{1+\frac{\eta_i^2}{2L^2}},$$

we have

$$\begin{aligned}P_{ij}(k)&=\breve{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\breve{G}(\boldsymbol{\xi}_j,\boldsymbol{o})\int_{-\frac{a}{2}}^{\frac{a}{2}}\left[1+\frac{iky^2}{L}-\frac{k^2(\eta_i+\eta_j-y)^2y^2}{2L^2}+\frac{2(\eta_i+\eta_j-y)y}{L^2}+O\left(\frac{1}{L^3}\right)\right]dy\\&=\breve{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\breve{G}(\boldsymbol{\xi}_j,\boldsymbol{o})\int_{-\frac{a}{2}}^{\frac{a}{2}}\left(1+\frac{iky^2}{L}-\frac{k^2y^4}{2L^2}-\frac{2y^2}{L^2}\right)dy\\&\quad-\frac{k^2}{L^2}\breve{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\breve{G}(\boldsymbol{\xi}_j,\boldsymbol{o})\eta_i\eta_j\int_{-\frac{a}{2}}^{\frac{a}{2}}y^2dy-\frac{k^2}{2L^2}\breve{G}(\boldsymbol{\xi}_i,\boldsymbol{o})\breve{G}(\boldsymbol{\xi}_j,\boldsymbol{o})(\eta_i^2+\eta_j^2)\int_{-\frac{a}{2}}^{\frac{a}{2}}y^2dy\\&\quad+O\left(\frac{1}{L^3}\right),\end{aligned}$$

which is almost exactly the same as (3.5). Now if we define the new illumination vectors to be

$$\begin{aligned}\vec{\breve{g}}&=[\breve{G}(\boldsymbol{\xi}_1,\boldsymbol{o}),\breve{G}(\boldsymbol{\xi}_2,\boldsymbol{o}),\ldots,\breve{G}(\boldsymbol{\xi}_N,\boldsymbol{o})]^T,\\\vec{\breve{g}}_1&=[\eta_1\breve{G}(\boldsymbol{\xi}_1,\boldsymbol{o}),\eta_2\breve{G}(\boldsymbol{\xi}_2,\boldsymbol{o}),\ldots,\eta_N\breve{G}(\boldsymbol{\xi}_N,\boldsymbol{o})]^T,\\\vec{\breve{g}}_2&=[\eta_1^2\breve{G}(\boldsymbol{\xi}_1,\boldsymbol{o}),\eta_2^2\breve{G}(\boldsymbol{\xi}_2,\boldsymbol{o}),\ldots,\eta_N^2\breve{G}(\boldsymbol{\xi}_N,\boldsymbol{o})]^T,\end{aligned}\tag{3.11}$$

and $\alpha(a,k,L)=\int_{-\frac{a}{2}}^{\frac{a}{2}}(1+\frac{iky^2}{L}-\frac{k^2y^4}{2L^2}-\frac{2y^2}{L^2})dy$, we have exactly the same decomposition of the response matrix as in (3.6). For a more general reflectivity kernel,

$$\tau(\boldsymbol{x};\boldsymbol{\xi}_i,\boldsymbol{\xi}_j)=f(\theta_i(\boldsymbol{x}),\theta_j(\boldsymbol{x}))=\tilde{f}\left(\frac{1}{\sqrt{1+\left(\frac{\eta_i-y}{L}\right)^2}},\frac{1}{\sqrt{1+\left(\frac{\eta_j-y}{L}\right)^2}}\right),$$

we can use power expansion in $\frac{1}{L}$ to get the explicit formulas. The extension to a two-dimensional target is exactly the same.

4. Alignment of the array and the target. In the above analysis, the geometric decomposition of the response matrix for an extended target utilizes the symmetry and alignment of the active array with the target. In most applications, neither the geometry nor the location of the target is known. Hence the alignment of the active array with the target and how it affects the decomposition of the response matrix are important questions in practice. For a general two-dimensional target there are two alignments; one is the alignment of the center and the other is the alignment of the lines of symmetry. The center and symmetry of the target are intrinsic while the center and symmetry of the active array can be maneuvered. In fact, if the geometry of the active array is designed properly, such as in the shape of a disc, the array is symmetric with respect to any orthogonal coordinate system whose origin is at the center of the array. We will see from numerical tests in section 5 that the two symmetric directions are automatically embedded in the singular vectors of the response matrix and can be found easily. Now the only issue becomes the alignment of the center of the array and the center of the target.

We study the simple case of a one-dimensional target illustrated in Figure 4.1. Our previous decomposition of the response matrix (3.6) is not changed. Hence the leading term in the decomposition is still approximately $a\vec{g}\vec{g}^T$, where a is the size of the target and $\vec{g}$ is the corresponding illumination vector. Now we analyze how much the orthogonality property is violated if the shift in the alignment of the center of the array and the center of the target is small compared to the size of the active array. We will also verify this using numerical experiments in section 5.

When the distance between the target and the active array L is large compared to the size of the array s, i.e., when the aperture $\frac{s}{L}$ is small, we have $G(\boldsymbol{\xi}_i,\boldsymbol{o})\approx G(\tilde{\boldsymbol{o}},\boldsymbol{o})$,

FIG. 4.1.

where $\tilde{\boldsymbol{o}}$ is the center of the array and $\boldsymbol{o}$ is the center of the target. So

$$\vec{\tilde{g}} = [G(\boldsymbol{\xi}_1, \boldsymbol{o}), G(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, G(\boldsymbol{\xi}_N, \boldsymbol{o})]^T \approx G(\tilde{\boldsymbol{o}}, \boldsymbol{o})[1, 1, \ldots, 1]^T,$$

$$\vec{\tilde{g}}_1 = [\eta_1 G(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2 G(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N G(\boldsymbol{\xi}_N, \boldsymbol{o})]^T \approx G(\tilde{\boldsymbol{o}}, \boldsymbol{o})[\eta_1, \eta_2, \ldots, \eta_N]^T,$$

$$\vec{\tilde{g}}_2 = [\eta_1^2 G(\boldsymbol{\xi}_1, \boldsymbol{o}), \eta_2^2 G(\boldsymbol{\xi}_2, \boldsymbol{o}), \ldots, \eta_N^2 G(\boldsymbol{\xi}_N, \boldsymbol{o})]^T \approx G(\tilde{\boldsymbol{o}}, \boldsymbol{o})[\eta_1^2, \eta_2^2, \ldots, \eta_N^2]^T.$$

Let ds be the separation space between two adjacent transducers and $|G| = |G(\tilde{\boldsymbol{o}}, \boldsymbol{o})|$; then

$$\|\vec{\tilde{g}}\| \approx \sqrt{\int_{-s/2-\delta}^{s/2-\delta} |G|^2 dy/ds} = |G|\sqrt{\frac{s}{ds}},$$

$$\|\vec{\tilde{g}_1}\| \approx \sqrt{\int_{-s/2-\delta}^{s/2-\delta} |G|^2 y^2 dy/ds} = |G|\sqrt{\frac{(s/2-\delta)^3 + (s/2+\delta)^3}{3ds}},$$

$$\|\vec{\tilde{g}_2}\| \approx \sqrt{\int_{-s/2-\delta}^{s/2-\delta} |G|^2 y^4 dy/ds} = |G|\sqrt{\frac{(s/2-\delta)^5 + (s/2+\delta)^5}{5ds}},$$

and

$$\left|\left\langle \frac{\vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}, \frac{\vec{\tilde{g}}_1}{\|\vec{\tilde{g}}_1\|} \right\rangle\right| \approx \frac{|\int_{-s/2-\delta}^{s/2-\delta} |G|^2 y dy/ds|}{\|\vec{\tilde{g}}\|\|\vec{\tilde{g}}_1\|} = \frac{[(s/2+\delta)^2 - (s/2-\delta)^2]/2}{\sqrt{[(s/2-\delta)^3 + (s/2+\delta)^3]s/3}} \le 2\sqrt{3}\frac{\delta}{s},$$

where

$$\alpha^3 + \beta^3 = (\alpha+\beta)(\alpha^2 - \alpha\beta + \beta^2),$$
$$\alpha^2 - \alpha\beta + \beta^2 \ge (\alpha+\beta)^2/4$$

is used. Similarly we have

$$\left|\left\langle \frac{\vec{\tilde{g}}_1}{\|\vec{\tilde{g}}_1\|}, \frac{\vec{\tilde{g}}_2}{\|\vec{\tilde{g}}_2\|} \right\rangle\right| \approx \frac{[(s/2+\delta)^4 - (s/2-\delta)^4]/4}{\sqrt{[(s/2-\delta)^3+(s/2+\delta)^3]/3}\sqrt{[(s/2-\delta)^5+(s/2+\delta)^5]/5}} \le 2\sqrt{15}\frac{\delta}{s},$$

where

$$\alpha^5 + \beta^5 = (\alpha+\beta)(\alpha^4 - \alpha^3\beta + \alpha^2\beta^2 - \alpha\beta^3 + \beta^4),$$
$$\alpha^4 - \alpha^3\beta + \alpha^2\beta^2 - \alpha\beta^3 + \beta^4 \ge (\alpha^2+\beta^2)^2/4$$

is used. So the orthogonality condition deteriorates approximately linearly in $\frac{\delta}{s}$. The larger the size of the active array is, the more robust the decomposition of the response matrix is. Also it appears from the numerical experiments that the even part of $\vec{\tilde{g}}_1$ is absorbed in the first singular vector as a perturbation and the odd part of $\vec{\tilde{g}}_1$ becomes the second singular vector. Since the first term, $a\vec{\tilde{g}}\vec{\tilde{g}}^T$, in the response matrix decomposition is dominant and more robust to the center shift, we can first use the leading term to estimate the center of the target and then adjust the center of the array toward the estimated center of the target to get a better estimation of the size in imaging.

5. Numerical experiments. In this section we use numerical examples to verify our analysis on the leading eigenvalues and eigenvectors of the response matrix for an extended target. In particular we will demonstrate the relation between the eigenvectors and the illumination vectors and verify the formulas for the leading eigenvalues. Some of the numerical examples also show that our analysis is quite accurate even for more general setups. In our numerical examples, the response matrix of an extended target was formed using the integral

$$P_{ij} = \int_{\Omega} G(\boldsymbol{\xi}_i, \boldsymbol{x}) G(\boldsymbol{\xi}_j, \boldsymbol{x}) d\boldsymbol{x},$$

where $\boldsymbol{\xi}_i, \boldsymbol{\xi}_j$ are the positions of the ith and jth transducers, respectively, and

$$G(\boldsymbol{\xi}, \boldsymbol{x}) = \frac{e^{ik|\boldsymbol{\xi}-\boldsymbol{x}|}}{4\pi|\boldsymbol{\xi}-\boldsymbol{x}|}$$

is the three-dimensional Green's function for a homogeneous medium. We use a simple quadrature for the integral on the target, denoted by Ω, with a grid size h that resolves both the wavelength and the target. In all of our numerical setups we use fixed wavelength $\lambda = 0.5m$ and wavenumber $k = \frac{2\pi}{\lambda} = 4\pi$. We vary the size of the active array s, the propagation distance L, and the size of the target relative to the wavelength, i.e., ka, to verify our analysis and formulas. The SVD of the response matrix is done by MATLAB. Note that the singular vectors computed by SVD in MATLAB (1) are always normalized to have a unit L_2 norm, and (2) have an arbitrary phase shift. Also the phase plot is up to a 2π shift.

In the following, we present numerical examples of one-dimensional arrays and targets in 5.1 as well as two-dimensional arrays and targets in 5.2.

5.1. One-dimensional arrays and targets. In this section we present numerical results in one dimension. We show the spectrum of the response matrix and the asymptotic formulas for the top two singular values as well as the top two singular vectors and their relations to the illumination vectors.

Example 1. In this example we show the spectrum of the response matrix for a single one-dimensional extended target. Figure 5.1 shows the loglog plot of the magnitudes of all singular values of the response matrix corresponding to a different target size a and propagation distance L. The size of the array is $s = 10m$ and the transducers are placed a half-wavelength apart; i.e., there are $\frac{2s}{\lambda} = 40$ transducers. We see that the top two singular values are well separated from each other and from the other singular values in the asymptotic regime which we discussed earlier.

Example 2. In this example we demonstrate the relation between the top two singular vectors of the response matrix and the corresponding illumination vectors. We also verify the formulas for the top two singular values numerically. The basic setup is illustrated in Figure 3.1 with $L = 500m, k = 4\pi, ka = 16, s = 40m$. The transducers are a half-wavelength apart. In Figure 5.2, we plot the magnitude and phase for each component of the top two singular vectors and compare them to the illumination vectors. Figure 5.2(a) plots the magnitude and phase of the first singular vector against the illumination vector $\vec{\tilde{g}}$ defined in (3.7). Figure 5.2(b) plots the magnitude and phase of the second singular vector against the illumination vector $\vec{\tilde{g}}_1$ defined in (3.7). The correspondence and pattern similarities are striking.

Denoting $\vec{v}_1, \vec{v}_2$ to be the top two singular vectors with singular values λ_1, λ_2

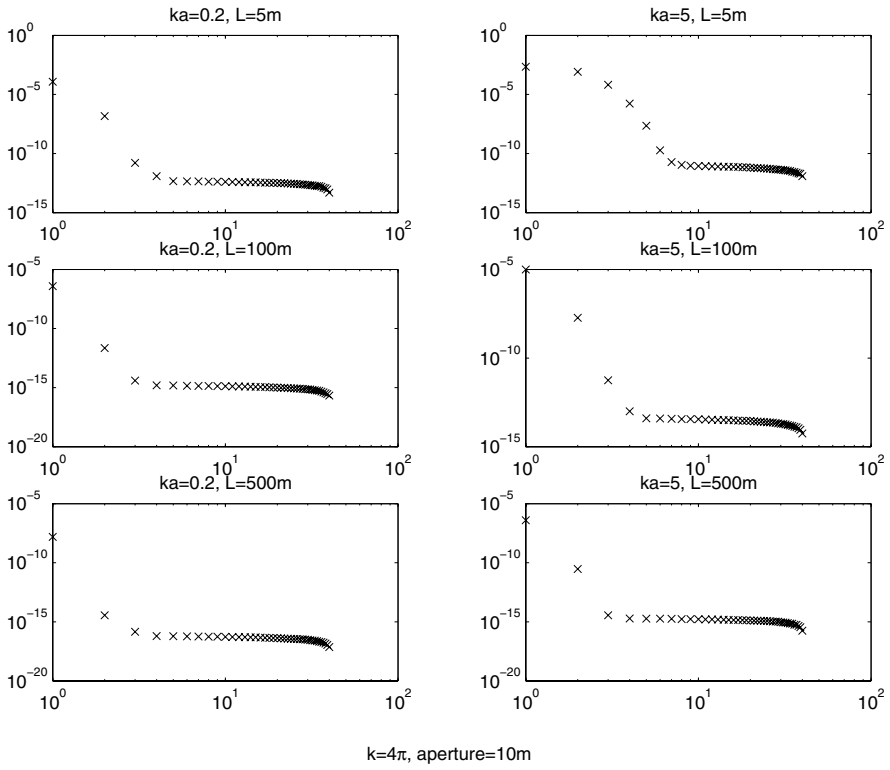

FIG. 5.1. *Plots of the magnitudes of eigenvalues.*

computed by MATLAB, we have numerically

$$\begin{bmatrix} \left|\frac{\bar{\vec{v}}_1^T \vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\bar{\vec{v}}_1^T \vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\bar{\vec{v}}_2^T \vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\bar{\vec{v}}_2^T \vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 6.2058 \times 10^{-16} \\ 1.0124 \times 10^{-15} & 1 \end{bmatrix},$$

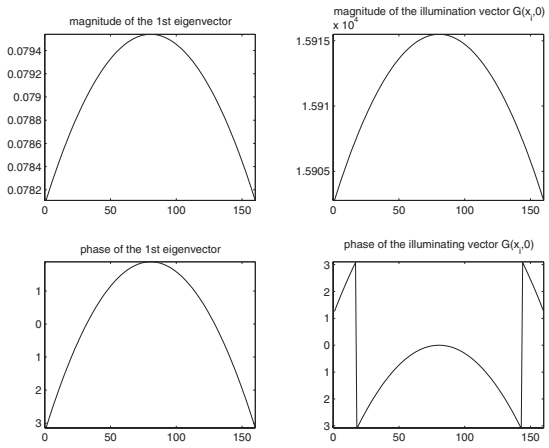
$$|\lambda_1| = 5.0848 \times 10^{-6}, \quad a\|\vec{\tilde{g}}\|^2 = 5.1575 \times 10^{-6},$$

$$|\lambda_2| = 5.9370 \times 10^{-8}, \quad \tfrac{a^3 k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 5.9393 \times 10^{-8}.$$

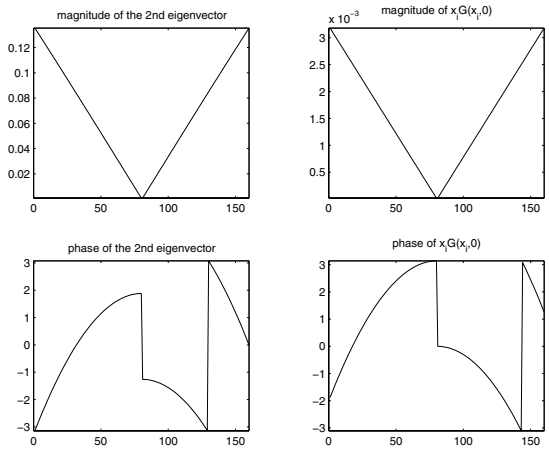
We see an almost perfect orthogonality condition up to machine accuracy. Our asymptotic formulas for the leading singular values are also very accurate. Moreover, the illumination vector $\vec{\tilde{g}}_2$ defined in (3.7) has the following relation with the first three singular vectors of the response matrix:

$$\left|\frac{\bar{\vec{v}}_1^T \vec{\tilde{g}}_2}{\|\vec{\tilde{g}}_2\|}\right| = 0.7418, \quad \left|\frac{\bar{\vec{v}}_2^T \vec{\tilde{g}}_2}{\|\vec{\tilde{g}}_2\|}\right| = 6.6258 \times 10^{-14}, \quad \left|\frac{\bar{\vec{v}}_3^T \vec{\tilde{g}}_2}{\|\vec{\tilde{g}}_2\|}\right| = 0.6706;$$

i.e., $\vec{\tilde{g}}_2$ is mostly absorbed in $\vec{v}_1$ as a small perturbation. We also see that the asymptotic formula $a\|\vec{\tilde{g}}\|^2$ overestimates $|\lambda_1|$ a little bit due to higher order perturbations, as was explained in section 3. From the following examples we can see that the overestimation tends to be more when ka becomes larger and less when L becomes larger.



(a)



(b)

FIG. 5.2. (a) *The phase and magnitude of the first eigenvector and* (b) *the phase and magnitude of the second eigenvector.*

Now we vary the setup by changing one parameter at a time. First we increase the size of the target $ka = 50$, and we have

$$\begin{bmatrix} \left|\frac{\vec{v}_1^T \vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_1^T \vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\vec{v}_2^T \vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_2^T \vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 0.9988 & 1.1532 \times 10^{-16} \\ 1.3101 \times 10^{-16} & 0.9996 \end{bmatrix},$$

$$|\lambda_1| = 1.4434 \times 10^{-5}, \quad a\|\vec{g}\|^2 = 1.6117 \times 10^{-5},$$

$$|\lambda_2| = 1.6083 \times 10^{-6}, \quad \frac{a^3 k^2}{12L^2}\|\vec{g}_1\|^2 = 1.8125 \times 10^{-6}.$$

Next we increase the distance between the array and the target L to 10,000m,

and we have

$$\begin{bmatrix} \left|\frac{\vec{v}_1^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_1^T\vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\vec{v}_2^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_2^T\vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 2.9737\times 10^{-17} \\ 9.8603\times 10^{-14} & 1 \end{bmatrix},$$

$$|\lambda_1| = 1.2867\times 10^{-8}, \quad a\|\vec{\tilde{g}}\|^2 = 1.2901\times 10^{-8},$$

$$|\lambda_2| = 3.7649\times 10^{-13}, \quad \tfrac{a^3k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 3.7157\times 10^{-13}.$$

Finally, when we increase the separation distance between the transducers to $2\lambda = 1m$, we have

$$\begin{bmatrix} \left|\frac{\vec{v}_1^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_1^T\vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\vec{v}_2^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_2^T\vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 1.3157\times 10^{-17} \\ 5.0919\times 10^{-16} & 1 \end{bmatrix},$$

$$|\lambda_1| = 1.2706\times 10^{-6}, \quad a\|\vec{\tilde{g}}\|^2 = 1.2893\times 10^{-6},$$

$$|\lambda_2| = 1.5401\times 10^{-8}, \quad \tfrac{a^3k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 1.5415\times 10^{-8}.$$

In our numerical tests it seems that we can further increase the separation between transducers.

Example 3. In this example we test how the alignment of the array and the target affects our formula for the response matrix decomposition. Figure 5.3 shows plots of the top two singular vectors when the center of the target is not aligned with the center of the array with a shift of $3m$. The setup is the same as the above example with $L = 500m,\ s = 40m$. We see asymmetries in the plots. We have numerically

$$\begin{bmatrix} \left|\frac{\vec{v}_1^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_1^T\vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\vec{v}_2^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_2^T\vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 0.2440 \\ 0.0059 & 0.9698 \end{bmatrix},$$

$$|\lambda_1| = 5.0770\times 10^{-6}, \quad a\|\vec{\tilde{g}}\|^2 = 5.1573\times 10^{-6},$$

$$|\lambda_2| = 5.9377\times 10^{-8}, \quad \tfrac{a^3k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 6.3343\times 10^{-8}.$$

When we increase the shift of the center to $6m$, we have

$$\begin{bmatrix} \left|\frac{\vec{v}_1^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_1^T\vec{g}_1}{\|\vec{g}_1\|}\right| \\ \left|\frac{\vec{v}_2^T\vec{g}}{\|\vec{g}\|}\right| & \left|\frac{\vec{v}_2^T\vec{g}_1}{\|\vec{g}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 0.9999 & 0.4479 \\ 0.0119 & 0.8940 \end{bmatrix},$$

$$|\lambda_1| = 5.0536\times 10^{-6}, \quad a\|\vec{\tilde{g}}\|^2 = 5.1567\times 10^{-6},$$

$$|\lambda_2| = 5.9398\times 10^{-8}, \quad \tfrac{a^3k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 7.5192\times 10^{-8}.$$

As was analyzed in section 4, the orthogonality condition does not hold anymore. The sensitivity depends linearly on the shift relative to the size of the array which

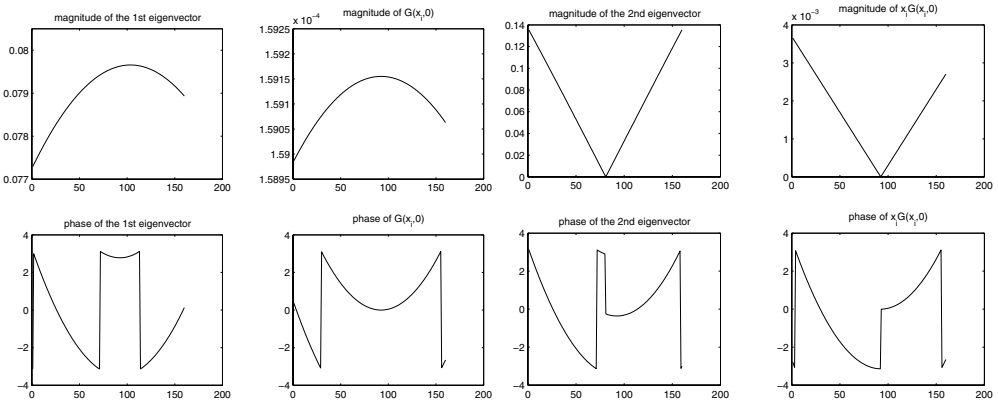


FIG. 5.3. (a) *The phase and magnitude of the first eigenvector and* (b) *the phase and magnitude of the second eigenvector.*

agrees with the numerical results very well. From the tests we can also see that the first singular vector is quite robust and agrees with the illumination vector $\vec{\tilde{g}}$ fairly well. The second singular vector is more sensitive to the shift. It appears that the second singular vector contains only the asymmetric part of $\vec{\tilde{g}}_1$.

Example 4. In this example, we show that we can get subwavelength information about the size of a target. The setup is: $L = 10m, k = 4\pi, ka = 0.1, s = 2m$. There are only eight transducers in the array. Numerically we have

$$\begin{bmatrix} \left|\frac{\vec{\overline{v}}_1^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\overline{v}}_1^T \vec{\tilde{g}}_1}{\|\vec{\tilde{g}}_1\|}\right| \\ \left|\frac{\vec{\overline{v}}_2^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\overline{v}}_2^T \vec{\tilde{g}}_1}{\|\vec{\tilde{g}}_1\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 5.0849 \times 10^{-17} \\ 4.2743 \times 10^{-10} & 1 \end{bmatrix},$$

$$|\lambda_1| = 3.7834 \times 10^{-6}, \quad a\|\vec{\tilde{g}}\|^2 = 4.0143 \times 10^{-6},$$

$$|\lambda_2| = 1.8716 \times 10^{-11}, \quad \frac{a^3k^2}{12L^2}\|\vec{\tilde{g}}_1\|^2 = 1.4290 \times 10^{-11}.$$

The actual size of the target is $a = 0.008m$. From our formula, the estimation of the size is: $\frac{|\lambda_1|}{\|\vec{\tilde{g}}\|^2} = 0.0075m$, or, $(\frac{12L^2|\lambda_2|}{k^2\|\vec{\tilde{g}}_1\|^2})^{1/3} = 0.0087m$. Clearly we achieve subwavelength accuracy from the experiment.

5.2. Two-dimensional arrays and targets. In this section we present numerical experiments for two-dimensional extended targets. The harmonic wave used is as before with fixed wavelength $\lambda = 0.5m$ and wavenumber $k = 4\pi$.

Example 1. In this example, we use a square array, each side of which is $10m$ long. The transducers are placed on a rectangular grid whose grid size is one wavelength; i.e., there are 20 rows and 20 columns of transducers and the total number of transducers is 400. So the size of the response matrix is 400×400. The distance between the array and the target is $L = 500m$, and the target is an ellipse with two major axes which are $2a = 1.2732m(ka = 8)$ and $2b = 0.6366m(kb = 4)$ long, respectively.

In the first test, the center and two sides of the square array are aligned with the center and two major axes of the ellipse. We define the two sides of the array as y and

z axes, respectively, with the y axis parallel to the longer major axis of the ellipse. Figure 5.4(a) is the plot of the magnitudes of the singular values of the response matrix. We see the top three singular values are well separated from the other ones. Figure 5.5 compares the amplitude and phase of the top two singular vectors with the two illumination vectors defined in (3.8). We skip the plot of the third singular vector and the corresponding illumination vector since it is similar to the plot of the second singular vector. We see that for each row or column of the transducers, the plot is very similar to the previous plots for one-dimensional arrays and targets.

Let $\vec{v}_1, \vec{v}_2, \vec{v}_3$ be the top three eigenvectors with eigenvalues $\lambda_1, \lambda_2, \lambda_3$, and $\vec{\tilde{g}}, \vec{\tilde{g}}_{1y}, \vec{\tilde{g}}_{1z}$ be the three illumination vectors defined in (3.8). We have numerically

$$\begin{bmatrix} \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 3.9885 \times 10^{-17} & 2.1706 \times 10^{-17} \\ 7.1030 \times 10^{-17} & 1 & 3.3406 \times 10^{-15} \\ 2.4696 \times 10^{-17} & 3.3394 \times 10^{-15} & 1 \end{bmatrix},$$

$$|\lambda_1| = 6.0744 \times 10^{-6}, \quad |\Omega| \|\vec{\tilde{g}}\|^2 = \pi ab \|\vec{\tilde{g}}\|^2 = 6.4498 \times 10^{-6},$$

$$|\lambda_2| = 3.5652 \times 10^{-9}, \quad \tfrac{k^2}{L^2} \|\vec{\tilde{g}}_{1y}\|^2 \textstyle\int_\Omega y^2 = \frac{\pi a^3 b k^2}{4L^2} \|\vec{\tilde{g}}_{1y}\| = 3.8019 \times 10^{-9},$$

$$|\lambda_3| = 8.8290 \times 10^{-10}, \quad \tfrac{k^2}{L^2} \|\vec{\tilde{g}}_{1z}\|^2 \textstyle\int_\Omega z^2 = \frac{\pi a b^3 k^2}{4L^2} \|\vec{\tilde{g}}_{1z}\| = 9.5047 \times 10^{-10}.$$

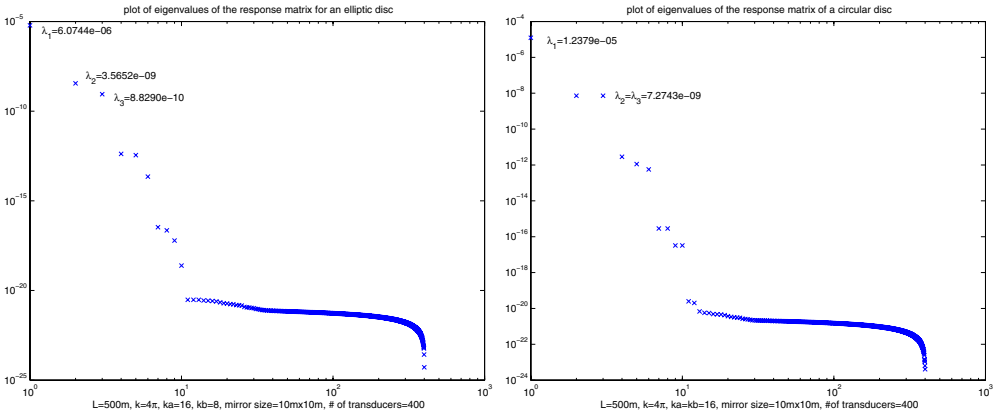
Now we rotate the ellipse by $\frac{\pi}{6}$ so that the two sides of the square array, i.e., our defined y and z axes, are no longer parallel to the two major axes of the ellipse. We have numerically

$$\begin{bmatrix} \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 9.0735 \times 10^{-17} & 2.3222 \times 10^{-17} \\ 5.4091 \times 10^{-17} & 0.8661 \ (\approx \frac{\sqrt{3}}{2}) & 0.4999 \ (\approx \frac{1}{2}) \\ 3.6460 \times 10^{-17} & 0.4999 & 0.8661 \end{bmatrix},$$

$$|\lambda_1| = 6.0744 \times 10^{-6}, \quad |\lambda_2| = 3.5648 \times 10^{-9}, \quad |\lambda_3| = 8.8302 \times 10^{-10}.$$

The reason that we do not have orthogonality correspondence between $\vec{v}_2, \vec{v}_3$ and $\vec{\tilde{g}}_{1y}, \vec{\tilde{g}}_{1z}$ is because the y and z axes that we choose artificially do not correspond to those two major axes, which are the two intrinsic symmetry lines of the ellipse. The angle ($\frac{\pi}{6}$) between $\vec{v}_2$ and $\vec{\tilde{g}}_{1y}$ is exactly the angle between the y axis and the longer major axis. All the other numerical numbers in the above matrix become clear too. The amplitudes of the three top singular values are not changed since the center of the target is unchanged and so are the integrals on the target for the eigenvalues. The numerical results verify our analysis perfectly. Both the dimension and the symmetry of the target are embedded in the response matrix. The above orthogonality matrix can be used to find the line of symmetry of the object in imaging.

Now we move the elliptic target further away from the array with $L = 2000m$.



(a) (b)

FIG. 5.4. *Eigenvalue plot for a rectangular array:* (a) *for an elliptic target and* (b) *for a circular target.*

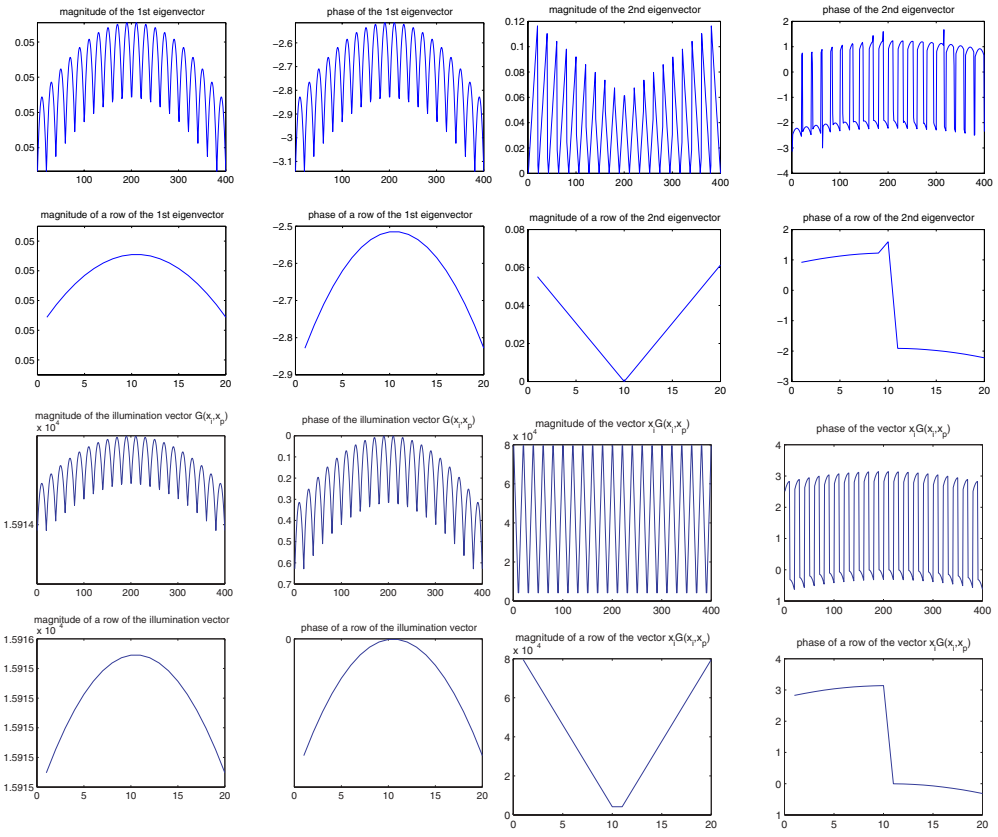


FIG. 5.5. *Amplitude and phase plot of the top eigenvectors and the corresponding illumination vectors.*

We have

$$|\lambda_1| = 1.4469 \times 10^{-6}, \quad |\Omega|\|\vec{\tilde{g}}\|^2 = \pi ab\|\vec{\tilde{g}}\|^2 = 1.6126 \times 10^{-6},$$

$$|\lambda_2| = 5.0757 \times 10^{-11}, \quad \tfrac{k^2}{L^2}\|\vec{\tilde{g}}_{1y}\|^2 \int_\Omega y^2 = \tfrac{\pi a^3 bk^2}{4L^2}\|\vec{\tilde{g}}_{1y}\| = 5.6509 \times 10^{-11},$$

$$|\lambda_3| = 1.2402 \times 10^{-11}, \quad \tfrac{k^2}{L^2}\|\vec{\tilde{g}}_{1z}\|^2 \int_\Omega z^2 = \tfrac{\pi ab^3 k^2}{4L^2}\|\vec{\tilde{g}}_{1z}\| = 1.4127 \times 10^{-11}.$$

Example 2. In this example, we replace the elliptic target by a circular one with radius $a = b = 0.6366m(ka = kb = 8)$ and $L = 500m$. The eigenvalue of the response matrix is plotted in Figure 5.4(b). We have

$$\begin{bmatrix} \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 2.8620 \times 10^{-17} & 2.7358 \times 10^{-17} \\ 3.9876 \times 10^{-17} & 0.7071(\approx \frac{\sqrt{2}}{2}) & 0.7071 \\ 1.4545 \times 10^{-16} & 0.7071 & 0.7071 \end{bmatrix},$$

$$|\lambda_1| = 1.2379 \times 10^{-5}, \qquad |\Omega|\|\vec{\tilde{g}}\|^2 = \pi ab\|\vec{\tilde{g}}\|^2 = 1.2900 \times 10^{-5},$$

$$|\lambda_2| = |\lambda_3| = 7.2743 \times 10^{-9}, \quad \tfrac{k^2}{L^2}\|\vec{\tilde{g}}_{1y}\|^2 \int_\Omega y^2 = \tfrac{\pi a^3 bk^2}{4L^2}\|\vec{\tilde{g}}_{1y}\| = 7.6038 \times 10^{-9}.$$

In this case, the reason that we do not have orthogonality correspondence between $\vec{v}_2, \vec{v}_3$ and $\vec{\tilde{g}}_{1y}, \vec{\tilde{g}}_{1z}$ is due to grid orientation of our square array. Any two orthogonal radial directions can be the symmetric axes for the circular disc; our square array picks up those two diagonal ones. Or we can interpret it in the following way: since the second and third singular values are equal, the associated singular vectors are not unique and any linear combination of the singular vectors is also a singular vector. MATLAB just chooses a particular combination.

Example 3. In this example, we use the same setup as in Example 1 except that the center of the array is not aligned with the center of the target. The two major axes of the ellipse are parallel to the two sides of the square array. But the center of the ellipse is shifted by $(2m, 2m)$ in the yz plane. The distance is still $L = 500m$. We have numerically

$$\begin{bmatrix} \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_1^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_2^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \\ \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}}{\|\vec{\tilde{g}}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1y}}{\|\vec{\tilde{g}}_{1y}\|}\right| & \left|\frac{\vec{\bar{v}}_3^T \vec{\tilde{g}}_{1z}}{\|\vec{\tilde{g}}_{1z}\|}\right| \end{bmatrix} = \begin{bmatrix} 1 & 0.5496 & 0.5501 \\ 7.7302 \times 10^{-4} & 0.8354 & 4.9318 \times 10^{-4} \\ 1.9175 \times 10^{-4} & 3.8425 \times 10^{-5} & 0.8351 \end{bmatrix},$$

$$|\lambda_1| = 6.0703 \times 10^{-6}, \quad |\Omega|\|\vec{\tilde{g}}\|^2 = \pi ab\|\vec{\tilde{g}}\|^2 = 6.4496 \times 10^{-6},$$

$$|\lambda_2| = 3.5646 \times 10^{-9}, \quad \tfrac{k^2}{L^2}\|\vec{\tilde{g}}_{1y}\|^2 \int_\Omega y^2 = \tfrac{\pi a^3 bk^2}{4L^2}\|\vec{\tilde{g}}_{1y}\| = 5.4526 \times 10^{-9},$$

$$|\lambda_3| = 8.8251 \times 10^{-10}, \quad \tfrac{k^2}{L^2}\|\vec{\tilde{g}}_{1z}\|^2 \int_\Omega z^2 = \tfrac{\pi ab^3 k^2}{4L^2}\|\vec{\tilde{g}}_{1z}\| = 1.3632 \times 10^{-9}.$$

Again we see that the asymptotic formulas for the first singular vector and singular value are more robust with respect to the center shift.

6. Conclusion. The response matrix of an active array for an extended target is studied. It is shown that the leading singular values and their corresponding singular vectors of the response matrix are related to the location and geometry of the extended target. Asymptotic formulas are derived for the leading singular values and singular vectors. Here we consider only a homogeneous medium and a single target. In the future we will study the effect of random inhomogeneities and multiple targets. We will develop imaging procedures that can detect both locations and sizes of extended targets using an active array.

Acknowledgments. The author would like to thank Chrysoula Tsogka for an interesting discussion that started the work. The author would also like to thank the referees for many helpful suggestions.

ASYMPTOTIC BEHAVIOR OF THE NUMBER OF LOST MESSAGES*

VYACHESLAV M. ABRAMOV†

Abstract. The goal of the paper is to study asymptotic behavior of the number of lost messages. Long messages are assumed to be divided into a random number of packets which are transmitted independently of one another. An error in transmission of a packet results in the loss of the entire message. Messages arrive to the $M/GI/1$ finite buffer model and can be lost in two cases as either at least one of its packets is corrupted or the buffer is overflowed. With the parameters of the system typical for models of information transmission in real networks, we obtain theorems on asymptotic behavior of the number of lost messages. We also study how the loss probability changes if redundant packets are added. Our asymptotic analysis approach is based on Tauberian theorems with remainder.

1. Introduction.

1.1. Review of the literature and general description of the system.

Long messages in Internet protocols that have to be transmitted are divided into small packets. Upon transmission each packet is transformed by providing additional information related to a given message. Because of the bit errors in transmission of the packet, the message can be lost. The loss probability of a message plays a significant role in the evaluation of network performance and design of network topology.

There are a number of papers in which the loss probability of a message has been studied. Cidon, Khamisy, and Sidi [11] derived recurrence relations for the loss probabilities of packets in a message giving the numerical results for the $M/M/1/n$ buffer model. The complexity of recurrence calculations of that paper are $O(nm^2)$, where m is the size of a message and n is the buffer capacity. Considering the same model, Gurewitz, Sidi, and Cidon [13] obtained another representation for the loss probability by using the ballot theorem (e.g., Takács [17]). In the framework of the same model Altman and Jean-Marie [7] give a comprehensive analysis for the multidimensional generating function of the loss probabilities based on the recurrence relations of the paper of Cidon, Khamisy, and Sidi [11] and analyze the effect of adding redundant packets. Studying a slightly more general model with several sources, Ait-Hellal et al. [6] obtained some asymptotic results and studied the effect of adding redundancy to the loss probability. The aforementioned papers [6], [7], [11], [13] all discuss the problem of complexity of calculations as well as the required memory to store intermediate variables.

In real communication networks the capacity is large. Therefore, asymptotic analysis of the number of lost messages is necessary. The present paper provides asymptotic analysis with sequential application to redundancy of the following model. Assume that each message is divided into a random number of packets each of which

*Received by the editors April 9, 2002; accepted for publication (in revised form) July 21, 2003; published electronically March 11, 2004.

†Department of Mathematics, The Faculty of Exact Sciences, Tel Aviv University, Tel Aviv 69978, Israel, and College of Judea and Samaria, Ariel 44837, Israel (vyachesl@inter.net.il).

is forwarded to the buffer. For the ith message denote its random number of packets by ν_i. We assume that the sequence $\nu_i \geq 1$, $i \geq 1$, consists of independently and identically distributed integer random variables. The interarrival times between messages have an exponential distribution with parameter λ. The buffer can contain only N packets; that is, if immediately before the arrival of message of l packets there are L packets in the buffer, then the message is accepted only if $L + l \leq N$; otherwise the message of l packets is lost. The loss of a message can also occur if at least one packet in a message is corrupted. In this case we assume that if there is enough space, then the message does occupy the buffer, but it is hidden and therefore lost. The probability that at least one packet in a message is corrupted is denoted by p.

In general loss communication networks, a transmission time typically depends on the number of packets in a message. To be realistic we must study a general queueing system with service time depending on batch size. The analysis of such a system is a hard problem. On the other hand, the model with a fixed number of packets in a message, leading to the standard $M/GI/1/n$ queueing system, is not realistic. Therefore, in the following we assume additionally that the random variables ν_i have fixed upper and lower bounds ν^{upper} and ν^{lower}, i.e., $\mathbf{P}\{\nu^{lower} \leq \nu_i \leq \nu^{upper}\} = 1$. This assumption can be considered as a compromise between these two cases. It has a real application in some communication technologies, especially in optical local networks, where a number of small messages following the same direction are combined as one message (bus).[1] Outgoing from the local network, the bus continues on its way being processed by the Internet protocols. When the difference between ν^{upper} and ν^{lower} for the messages is not large, then assuming that a transmission time is independent of the message size seems appropriate.

1.2. Formulation of the model in terms of the queueing theory. In terms of the queueing theory the model can be described as follows. We assume that messages arrive to the finite buffer $M/GI/1$ queue with random number of waiting places ζ. The input rate is equal to λ, and the service time distribution is $B(x)$ with the expectation b. By a queueing system with random number of waiting places we mean the following. We denote

$$\zeta = \inf\left\{ m : \sum_{i=1}^{m} \nu_i \leq N \right\},$$

and according to the assumption $\mathbf{P}\{\nu^{lower} \leq \nu_i \leq \nu^{upper}\} = 1$, there are two fixed values ζ^{upper} and ζ^{lower} depending on N, and $\mathbf{P}\{\zeta^{lower} \leq \zeta \leq \zeta^{upper}\} = 1$.

Let $\zeta_1, \zeta_2, \ldots,$ be a strictly stationary and ergodic sequence of random variables, $\mathbf{P}\{\zeta_i = j\} = \mathbf{P}\{\zeta = j\}$, $\zeta^{lower} \leq j \leq \zeta^{upper}$. If ξ_i is the number of messages in the queue immediately before arrival of the ith message, then the message is lost if $\xi_i > \zeta_i$. Otherwise it joins the queue. We assume that $\xi_1 = 0$.

The existence of the stationary queue-length distribution, i.e.,

$$\mathbf{P}\{\bar{q} = j\} = \lim_{i \to \infty} \mathbf{P}\{\xi_i = j | \xi_1 < \infty\}, \qquad j = 0, 1, \ldots, \zeta^{upper}, \tag{1.1}$$

is shown in the following. The special case when $\mathbf{P}\{\nu_i = l\} = 1$ leads to the standard $M/GI/1/n$ queueing system, where $n = \lfloor N/l \rfloor$ is the integer part of N/l.

[1] For example, one of such technologies was developed in Orika Optical Networks Limited, where the author worked during 2000–2001.

It is also assumed that each message is marked with probability p. We study the asymptotic behavior of the loss probability under assumptions that $\mathbf{E}\zeta$ increases to infinity and p vanishes. The details of these assumptions are clarified in the following consideration. The loss probability is the probability that the message is either marked or lost because of overflowing the queue. We study the cases where the traffic (offered load) $\varrho = \lambda b$ is less than, equal to, and greater than 1.

1.3. Advantages of the approach and methodology. Our approach is based on the asymptotic analysis of the loss queueing systems in the earlier paper of the author (see Abramov [3]). The main method is an application of modern Tauberian theorems with remainder. For the relevant works devoted to asymptotic analysis of the loss and controlled systems with Poisson input, see Abramov [1], [2], Tomkó [18], and other papers. The asymptotic analysis of the $GI/M/1/n$ queueing system was studied in [4], [9], [10]. The advantages of the approach of the present paper are the following.

First, our model is more general than the model from the aforementioned papers: This paper discusses the case of a non-Markovian buffer model where a message contains a random batch of packets, while the aforementioned papers studied a Markovian model with fixed batch size.

Second, the work in [6], [7], [11], [13] discusses a more difficult problem of consecutive losses, remaining in a framework of the standard $M/M/1/n$ queueing system. The present paper flexibly discusses the stationary losses for a nonstandard queueing model with the random number of waiting places. That queueing system belongs to the special class of queueing systems with losses that is exactly defined below.

Third, our asymptotic analysis is much simpler than that of the other papers; our final results and their representation are simple and clear as well.

The traditional approach to asymptotic analysis, based on the final value theorem for z transform, enables us to obtain the main term of asymptotic relation and, in certain cases, a remainder. The modern Tauberian theorems enable us to obtain stronger asymptotic relations using some additional assumptions. These additional assumptions are realistic for the queueing systems considered here, and our asymptotic results are stronger than the earlier asymptotic results obtained for the $M/GI/1/n$ queueing system with the aid of the final value theorem for z transform (see relation (4.15) for its comparison with (4.14)). For some other results related to asymptotic analysis of the $M/GI/1/n$ and $GI/M/1/n$ queueing systems with the aid of the final value theorem, see the bibliography notes and references in Abramov [1].

1.4. What is the main result in this paper? The paper contains a number of theoretical results on the asymptotic behavior of characteristics of the busy period of the system (section 4) and loss probability (section 5). These theoretical results are then used to conclude the effect of adding redundant packets in order to decrease the loss probability.

Although the theoretical results of the paper, related to the cases where the offered load $\varrho < 1$, are standard, the conclusion about adding redundancy is extremely simple and interesting nevertheless. Namely, the stationary loss probability is expressed only via the probability that there is a corrupted packet in the message. This enables us to conclude that adding a number of redundant packets can decrease the loss probability *with the rate of geometric progression* while $\varrho < 1$.

Then the case when ϱ is close to 1 is very important for the performance analysis. For example, it can be a result of adding a number of redundant packets when initially

$\varrho < 1$. That is, to achieve a maximum decrease in the loss probability we allow an increase in the offered load up to the critical value.

Therefore, the results on redundancy, related to the case where $\varrho = 1+\varepsilon$ ($\varepsilon > 0$) is slightly greater than 1, are extremely important. The usefulness of the case $\varrho = 1+\varepsilon$ is that it enables us to obtain more exact conclusions on redundancy based on asymptotic results with remainder. Then, the usefulness of the purely theoretical case $\varrho > 1$ is that it is an intermediate result helping us to study the transient behavior, related to the case $\varrho = 1 + \varepsilon$ for small $\varepsilon > 0$.

1.5. Conclusion on adding redundant packets. The results of the paper enable us to make conclusions on the effect of adding redundant packets as follows. Let ϱ denote the offered load of the system before adding a redundant packet, and let $\breve{\varrho} > \varrho$ be the value of the offered load after adding a redundant packet. While $\breve{\varrho}$ remains not greater than 1, adding redundant packets is profitable. It decreases the loss probability with the rate of a geometric progression. Adding a redundant packet remains profitable if the value $\breve{\varrho} = 1 + \varepsilon$, where ε is a small value of a higher order than p. In some cases adding a redundant packet decreases the loss probability even when the value ε has the same order as p. These cases are studied in section 6.

1.6. The organization of the paper. The paper is organized as follows. There are six sections, with the first an introduction. In section 2 we introduce the class of queueing systems with a random number of waiting places and study the characteristics of the system busy period. The results on the expectations of random variables of the busy period (the number of processed messages, the number of refused messages, etc.) are given by Lemma 2.1. In section 3 we present a number of auxiliary results and the Tauberian theorems with remainder. These results are then used to prove a number of theorems on the asymptotic behavior of the characteristics of the system given on a busy period which in turn are given in section 4. Section 5 presents the results on asymptotic behavior of the loss probabilities under different assumptions. In section 6 we discuss adding redundancy. The central question here is, *How is the loss probability decreased or increased if we add redundant packets into the message*?

2. Characteristics of the system given on a busy period. The aim of this section is to deduce the explicit representations for characteristics of the system during a busy period such as the expected duration of a busy period, expected number of served and lost customers during a busy period, and so on. The queueing system described in section 1.2 is not standard, and the explicit representation for its characteristics cannot be obtained traditionally. Therefore, below we introduce a special class of queueing systems Σ containing the system studied in the paper and described in section 1.2. It will be shown in this section that the above characteristics are the same for all queueing systems of the class Σ. Hence, one can take any queueing system, a representative of class Σ, having a more simple structure than the original system, and study it instead of the original system.

For the sake of convenience, we denote by $\mathcal{S}_1$ the system described in section 1.2. Let $B(x)$ be the probability distribution function of a processing time (in the queueing terminology, a service time), and let λ be the parameter of Poisson input. We also set $\varrho_j = \lambda^j \int_0^\infty x^j \mathrm{d}B(x)$, $j = 1, 2, \ldots$, and $\varrho_1 = \varrho$.

In order to study the characteristics of the system $\mathcal{S}_1$ we introduce a set of systems Σ containing $\mathcal{S}_1$ as an element. The set Σ is a set of $M/GI/1$ queueing systems where λ is the rate of Poisson input, $B(x)$ is the probability distribution function of a service time, and the family of sequences $\{\zeta_i\}$ is more general than in $\mathcal{S}_1$. Each sequence ζ_1,

$\zeta_2, \ldots$ is a family of identically distributed random variables, governing the rejection process and having the same distribution as the random variable ζ. If this sequence is as defined in section 1.2, then we have a description of our system $\mathcal{S}_1$. In order to define the set Σ more exactly, we use the notation for the queueing system $\mathcal{S}_1$ and also introduce the following.

Let ξ_i denote the number of messages in the system $\mathcal{S}_1$ immediately before arrival of the ith message, $\xi_1 = 0$, and let s_i denote the number of service completions between the ith and $i+1$st arrivals. It is clear that

$$\xi_{i+1} = \xi_i - s_i + \mathbf{I}\{\xi_i \le \zeta_i\}, \tag{2.1}$$

where the term $\mathbf{I}\{\xi_i \le \zeta_i\}$ indicates that the ith message is accepted, and obviously s_i is not greater than $\xi_i + \mathbf{I}\{\xi_i \le \zeta_i\}$.

Consider a new queueing system $\mathcal{S}$ as above with the Poisson input rate λ and the probability distribution function of a service $B(x)$, but with the sequence $\widetilde{\zeta}_1, \widetilde{\zeta}_2, \ldots$. Here we assume that the sequence $\{\widetilde{\zeta}_i\}$ is an *arbitrary dependent* sequence of random variables consisting of identically distributed random variables as the random variable ζ. Let $\widetilde{\xi}_i$ denote the number of messages immediately before arrival of the ith message ($\widetilde{\xi}_1 = 0$), and let $\widetilde{s}_i$ denote the number of service completions between the ith and $i+1$st arrivals. Thus, we assume that the initial conditions of both queueing systems $\mathcal{S}_1$ and $\mathcal{S}$ are the same: $\xi_1 = \widetilde{\xi}_1$.

Analogously to (2.1) we have

$$\widetilde{\xi}_{i+1} = \widetilde{\xi}_i - \widetilde{s}_i + \mathbf{I}\{\widetilde{\xi}_i \le \widetilde{\zeta}_i\}. \tag{2.2}$$

Definition. We say that the queueing system $\mathcal{S}$ belongs to the set Σ of queueing systems if $\mathbf{E}\widetilde{\xi}_i = \mathbf{E}\xi_i$, $\mathbf{E}\widetilde{s}_i = \mathbf{E}s_i$, and $\mathbf{P}\{\widetilde{\xi}_i \le \widetilde{\zeta}_i\} = \mathbf{P}\{\xi_i \le \zeta_i\}$ for all $i \ge 1$.

Consider an example of queueing systems belonging to the set Σ, where the sequence $\{\widetilde{\zeta}_i\}$ is strictly stationary but not ergodic. The example is a queueing system with $\widetilde{\zeta}_1 = \widetilde{\zeta}_2 = \ldots$, which we denote by $\mathcal{S}_2$. The example below is artificial rather than realistic, however, its main goal is to help us to show the existence of necessary stationary queue-length probabilities for the queueing system $\mathcal{S}_1$ and to obtain the explicit representations for those probabilities as well.

For $\mathcal{S}_2$ we find by induction for all $i \ge 1$ that

$$\mathbf{E}\widetilde{s}_i = \mathbf{E}s_i, \tag{2.3}$$

$$\mathbf{P}\{\widetilde{\xi}_i \le \widetilde{\zeta}_i\} = \mathbf{P}\{\xi_i \le \zeta_i\}, \tag{2.4}$$

and

$$\mathbf{E}\widetilde{\xi}_i - \mathbf{E}\widetilde{s}_i + \mathbf{P}\{\widetilde{\xi}_i \le \widetilde{\zeta}_i\} = \mathbf{E}\xi_i - \mathbf{E}s_i + \mathbf{P}\{\xi_i \le \zeta_i\}. \tag{2.5}$$

Relations (2.3)–(2.5) show that the queueing system $\mathcal{S}_2 \in \Sigma$. It follows from the definition that if the stationary loss probability exists for at most one of the queueing systems $\mathcal{S} \in \Sigma$, then it exists for all queueing systems of Σ and it is the same. Then, the properties of the queueing system $\mathcal{S}_2$ enable us to conclude similar properties of all queueing systems belonging to the set Σ, including $\mathcal{S}_1$. For example, it is not difficult to show that the expected busy period is the same for all queueing systems of the class Σ. Indeed, let $\widetilde{A}$, $\widetilde{S}$, and $\widetilde{R}$ denote the number of arrived, served, and refused

customers (because of overflowing the buffer) during a busy cycle $\widetilde{C}$, respectively. We have the equations

$$\mathbf{E}\widetilde{A} = \mathbf{E}\widetilde{S} + \mathbf{E}\widetilde{R} = \lambda \mathbf{E}\widetilde{C}, \tag{2.6}$$

$$b\mathbf{E}\widetilde{S} = \mathbf{E}\widetilde{C} - \frac{1}{\lambda}, \tag{2.7}$$

where b is the expected service time. Since the loss probability is the same for all queueing systems $\mathcal{S} \in \Sigma$, then the fraction $\mathbf{E}\widetilde{R}/\mathbf{E}\widetilde{C}$ is the same for all $\mathcal{S} \in \Sigma$ as well. Therefore, it follows from equations (2.6) and (2.7) that the expected duration of a busy period, $\mathbf{E}\widetilde{T} = \mathbf{E}\widetilde{C} - \lambda^{-1}$, is the same for all queueing systems $\mathcal{S} \in \Sigma$.

Recall that for queueing system $\mathcal{S}_2$ we have $\widetilde{\zeta_1}{=}\widetilde{\zeta_2} = \ldots$, i.e., the random variable ζ is modeled once at the initial time moment. Let $\widetilde{T}_\zeta$ denote a busy period of this system. Then, the total expectation formula enables us to write

$$\mathbf{E}\widetilde{T}_\zeta = \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{E}T_K \mathbf{P}\{\zeta = K\}, \tag{2.8}$$

where $\mathbf{E}T_K$ is the expected busy period of an $M/GI/1/K$ queueing system with the same sequence of interarrival and service times, and $\mathbf{P}\{\zeta = K\} = \mathbf{P}\{\zeta_j = K\}$. In turn, the expectation $\mathbf{E}T_K$ is determined from the following recurrence relation:

$$\mathbf{E}T_K = \sum_{j=0}^{K} \pi_j \mathbf{E}T_{K-j+1}, \quad \mathbf{E}T_0 = b, \quad \pi_i = \int_0^\infty \mathrm{e}^{-\lambda x} \frac{(\lambda x)^i}{i!} \mathrm{d}B(x) \tag{2.9}$$

(see Tomkó [18], Cooper and Tilt [12], and Abramov [1], [3]), where b is the expectation of a service time.

Now, let T_ζ denote a busy period for the queueing system $\mathcal{S}_1$. According to the above conclusion that $\mathbf{E}T_\zeta = \mathbf{E}\widetilde{T}_\zeta$, and in view of (2.8), we have

$$\mathbf{E}T_\zeta = \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{E}T_K \mathbf{P}\{\zeta = K\}, \tag{2.10}$$

where $\mathbf{E}T_K$ are determined from (2.9).

Along with the notation T_ζ for the busy period of the system $\mathcal{S}_1$, we let I_ζ be an idle period and let P_ζ, M_ζ, R_ζ be the characteristics of the system on a busy period: the number of processed messages, the number of marked messages, the number of refused messages, respectively. Here and later we use the following terminology. The term *refused* message is used for the case of overflowing the buffer. Then the term *lost* message is used for the case where a message is either refused or marked. The number of lost messages during a busy period is denoted by L_ζ. Analogously, by loss probability we mean the probability when an arrival message is lost.

LEMMA 2.1. *For the expectations* $\mathbf{E}T_\zeta$, $\mathbf{E}P_\zeta$, $\mathbf{E}M_\zeta$, $\mathbf{E}R_\zeta$ *we have the following representations:*

$$\mathbf{E}P_\zeta = \frac{\lambda}{\varrho} \mathbf{E}T_\zeta, \tag{2.11}$$

$$\mathbf{E}M_\zeta = p\mathbf{E}P_\zeta, \tag{2.12}$$

$$\mathbf{E}R_\zeta = (\varrho - 1)\mathbf{E}P_\zeta + 1. \tag{2.13}$$

Proof. Relations (2.11) and (2.12) follow immediately from Wald's identity. In order to prove (2.13) note that the number of arrivals during a busy cycle equals the number of processed messages during a busy period plus the number of refused messages during a busy period (see relation (2.6)). According to Wald's identity the expected number of arrivals during a busy cycle equals $\lambda(\mathbf{E}T_\zeta + \mathbf{E}I_\zeta)$. Therefore taking into account that $\mathbf{E}I_\zeta = \lambda^{-1}$ from (2.11), we have

$$\mathbf{E}R_\zeta = (\varrho - 1)\mathbf{E}P_\zeta + 1,$$

and the result is proved. □

For the alternative proof of (2.13) see Abramov [3]. (See also the proof in [5].)

3. Auxiliary results. Tauberian theorems with remainder. It is seen from relations (2.10) and (2.9) and Lemma 2.1 that the characteristics of the system during a busy period can be studied in a framework of the recurrence relation

$$Q_k = \sum_{i=0}^{k} r_i Q_{k-i+1}, \tag{3.1}$$

where r_i are nonnegative numbers, $r_0 + r_1 + \cdots = 1$, $r_0 > 0$, and $Q_0 \neq 0$ is an arbitrary real number. Below we recall a number of results on asymptotic behavior of that sequence (3.1).

The known results on representation (3.1) are asymptotic theorems by Takács [17]. Lemma 3.1 below joins two results by Takács: Theorem 5 of [17, p. 22] and relation (35) [17, p. 23]. The results of Takács [17] were then developed by Postnikov [14, sect. 25], [15, sect. 25] (see Lemma 3.2 and Lemma 3.3 below).

Let $r(z) = \sum_{i=0}^{\infty} r_i z^i$, $|z| \leq 1$, $\gamma_m = r^{(m)}(1-0) = \lim_{z\uparrow 1} r^{(m)}(z)$ ($r^{(m)}(z)$ is the mth derivative of $r(z)$). Note that if we denote $Q(z) = \sum_{i=0}^{\infty} Q_i z^i$, then it follows from (3.1) that

$$Q(z) = \frac{Q_0 r(z)}{r(z) - z}.$$

LEMMA 3.1 (Takács [17]). *If $\gamma_1 < 1$, then*

$$\lim_{k\to\infty} Q_k = \frac{Q_0}{1 - \gamma_1}. \tag{3.2}$$

If $\gamma_1 = 1$ and $\gamma_2 < \infty$, then

$$\lim_{k\to\infty} \frac{Q_k}{k} = \frac{2Q_0}{\gamma_2}. \tag{3.3}$$

If $\gamma_1 > 1$, then

$$\lim_{k\to\infty} \Big(Q_k - \frac{Q_0}{\delta^k [1 - r'(\delta)]} \Big) = \frac{Q_0}{1 - \gamma_1}, \tag{3.4}$$

where δ is the least (absolute) root of the equation $z = r(z)$.

LEMMA 3.2 (Postnikov [14], [15]). *Let $\gamma_1 = 1$, $\gamma_3 < \infty$. Then as $k \to \infty$,*

$$Q_k = \frac{2Q_0}{\gamma_2} k + O(\log k). \tag{3.5}$$

LEMMA 3.3 (Postnikov [14], [15]). *Let $\gamma_1 = 1$, $\gamma_2 < \infty$ and $r_0 + r_1 < 1$. Then as $k \to \infty$,*

$$Q_{k+1} - Q_k = \frac{2Q_0}{\gamma_2} + o(1). \tag{3.6}$$

4. Asymptotic results for characteristics of the system during a busy period. This section provides a number of results on asymptotic behavior of characteristics of the system. The first three theorems are related to the case as N increases to infinity, where the cases $\varrho < 1$, $\varrho = 1$, and $\varrho > 1$ are considered. The next two theorems discuss the case when the value ϱ is close to the critical value 1, and as $N \to \infty$, it tends to 1. The last theorem of this section, Theorem 4.6, provides the asymptotic result for the special case when the number of packets in a message is a constant value.

Let us now study the asymptotic behavior of the expectations $\mathbf{E}P_\zeta$, $\mathbf{E}M_\zeta$, and $\mathbf{E}R_\zeta$. We write $\zeta = \zeta(N)$, pointing out the dependence on parameter N. As the buffer size N increases to infinity, both ζ^{lower} and ζ^{upper} tend to infinity, and together with them, $\zeta(N)$ a.s. tends to infinity. Then we have the following.

THEOREM 4.1. *If $\varrho < 1$, then*

$$\lim_{N\to\infty} \mathbf{E}P_{\zeta(N)} = \frac{1}{1-\varrho}. \tag{4.1}$$

If $\varrho = 1$ and $\varrho_2 < \infty$, then

$$\lim_{N\to\infty} \frac{\mathbf{E}P_{\zeta(N)}}{\mathbf{E}\zeta(N)} = \frac{2}{\varrho_2}. \tag{4.2}$$

If $\varrho > 1$, then

$$\lim_{N\to\infty} \Big[\mathbf{E}P_{\zeta(N)} - \frac{1}{\mathbf{E}\varphi^{\zeta(N)}[1 + \lambda\beta'(\lambda - \lambda\varphi)]}\Big] = \frac{1}{1-\varrho}, \tag{4.3}$$

where $\beta(z) = \int_0^\infty e^{-zx} dB(x)$ and φ is the least (absolute) root of functional equation $z - \beta(\lambda - \lambda z) = 0$.

Proof. From (2.9), (2.10), and (2.11) we have

$$\mathbf{E}P_\zeta = \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{E}P_K \mathbf{P}\{\zeta = K\},$$

where

$$\mathbf{E}P_K = \sum_{j=0}^{K} \pi_j \mathbf{E}P_{K-j+1}, \quad \mathbf{E}P_0 = 1,$$

$$\pi_j = \int_0^\infty e^{-\lambda x} \frac{(\lambda x)^j}{j!} dB(x).$$

Then applying Lemma 3.1 we have the following. In the case $\varrho < 1$, taking into account that $\zeta(N) \overset{a.s.}{\to} \infty$ as $N \to \infty$, we obtain

$$\lim_{N\to\infty} \mathbf{E}P_{\zeta(N)} = \lim_{N\to\infty} \mathbf{E}P_N = \frac{1}{1-\varrho}.$$

Relation (4.1) is proved.

In the case $\varrho_2 < \infty$ and $\varrho = 1$ we have

$$\lim_{N\to\infty} \frac{\mathbf{E}P_{\zeta(N)}}{N} = \lim_{N\to\infty} \frac{1}{N} \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{P}\{\zeta(N) = K\}\mathbf{E}P_K$$

$$= \lim_{N\to\infty} \frac{1}{N} \sum_{K=\zeta^{lower}}^{\zeta^{upper}} K\mathbf{P}\{\zeta(N) = K\}\frac{2}{\varrho_2} = \frac{2}{\varrho_2} \lim_{N\to\infty} \frac{\mathbf{E}\zeta(N)}{N}.$$

Therefore,

$$\lim_{N\to\infty} \frac{\mathbf{E}P_{\zeta(N)}}{\mathbf{E}\zeta(N)} = \frac{2}{\varrho_2},$$

and relation (4.2) is proved.

In the case $\varrho > 1$ for large N we obtain

$$\mathbf{E}P_{\zeta(N)} = \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{P}\{\zeta(N) = K\}\mathbf{E}P_K$$

$$= \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{P}\{\zeta(N) = K\}\frac{1}{\varphi^K[1 + \lambda\beta'(\lambda - \lambda\varphi)]} + \frac{1}{1-\varrho} + o(1)$$

$$= \frac{1}{\mathbf{E}\varphi^{\zeta(N)}[1 + \lambda\beta'(\lambda - \lambda\varphi)]} + \frac{1}{1-\varrho} + o(1).$$

Therefore,

$$\lim_{N\to\infty} \Big[\mathbf{E}P_{\zeta(N)} - \frac{1}{\mathbf{E}\varphi^{\zeta(N)}[1 + \lambda\beta'(\lambda - \lambda\varphi)]}\Big] = \frac{1}{1-\varrho},$$

and relation (4.3) is proved. Theorem 4.1 is completely proved. □

THEOREM 4.2. *If $\varrho = 1$ and $\varrho_3 < \infty$, then*

$$\mathbf{E}P_{\zeta(N)} = \frac{2}{\varrho_2}\mathbf{E}\zeta(N) + O(\log N). \tag{4.4}$$

Proof. Applying Lemma 3.2, for large N we have

$$\mathbf{E}P_{\zeta(N)} = \sum_{K=\zeta^{lower}}^{\zeta^{upper}} \mathbf{P}\{\zeta(N) = K\}\mathbf{E}P_K$$

$$= \sum_{K=\zeta^{lower}}^{\zeta^{upper}} K\mathbf{P}\{\zeta(N) = K\}\frac{2}{\varrho_2} + O\{\mathbf{E}[\log\zeta(N)]\}$$

$$= \frac{2}{\varrho_2}\mathbf{E}\zeta(N) + O\{\mathbf{E}[\log \zeta(N)]\}$$

$$= \frac{2}{\varrho_2}\mathbf{E}\zeta(N) + O(\log N).$$

and we obtain relation (4.4). Theorem 4.2 is proved. □

In turn for $\mathbf{E}R_\zeta$ we have the following theorem.

THEOREM 4.3. *If $\varrho < 1$, then*

$$\lim_{N\to\infty} \mathbf{E}R_{\zeta(N)} = 0. \tag{4.5}$$

If $\varrho = 1$, then for all $N \geq 0$

$$\mathbf{E}R_{\zeta(N)} = 1. \tag{4.6}$$

If $\varrho > 1$, then

$$\lim_{N\to\infty} \Big[\mathbf{E}R_{\zeta(N)} - \frac{\varrho - 1}{\mathbf{E}\varphi^{\zeta(N)}[1 + \lambda\beta'(\lambda - \lambda\varphi)]}\Big] = 0. \tag{4.7}$$

Proof. The proof of this theorem is analogous to that of the proof of Theorem 4.1. It follows by application of Lemma 3.1 and relation (2.13) of Lemma 2.1. □

THEOREM 4.4. *Let $\varrho = 1 + \varepsilon$, $\varepsilon > 0$, and $\varepsilon\zeta(N) \to C > 0$ a.s. as $\varepsilon \to 0$ and $N \to \infty$. Assume also that $\varrho_3 = \varrho_3(N)$ is a bounded sequence, and there exists $\tilde{\varrho}_2 = \lim_{N\to\infty} \varrho_2(N)$. Then*

$$\mathbf{E}P_{\zeta(N)} = \frac{e^{2C/\tilde{\varrho}_2} - 1}{\varepsilon} + O(1), \tag{4.8}$$

$$\mathbf{E}R_{\zeta(N)} = e^{2C/\tilde{\varrho}_2} + o(1). \tag{4.9}$$

Proof. It was shown in Subhankulov [16, p. 326], that if $\varrho = 1 + \varepsilon$, $\varepsilon > 0$, $\varepsilon \to 0$, $\varrho_3(N)$ is a bounded sequence, and there exists $\tilde{\varrho}_2 = \lim_{N\to\infty} \varrho_2(N)$, then

$$\varphi = 1 - \frac{2\varepsilon}{\tilde{\varrho}_2} + O(\varepsilon^2). \tag{4.10}$$

Applying (4.10) after some algebra we have

$$1 + \lambda\beta'(\lambda - \lambda\varphi) = \varepsilon + O(\varepsilon^2). \tag{4.11}$$

Then the statements of the theorem follow by applying expansions (4.10) and (4.11) to (4.3) and (4.7). □

THEOREM 4.5. *Let $\varrho = 1 + \varepsilon$, $\varepsilon > 0$, and $\varepsilon\zeta(N) \to 0$ as $\varepsilon \to 0$ and $N \to \infty$. Assume also that $\varrho_3 = \varrho_3(N)$ is a bounded sequence, and there exists $\tilde{\varrho}_2 = \lim_{N\to\infty} \varrho_2(N)$. Then*

$$\mathbf{E}P_{\zeta(N)} = \frac{2}{\tilde{\varrho}_2}\mathbf{E}\zeta(N) + O(1), \tag{4.12}$$

$$\mathbf{E}R_{\zeta(N)} = 1 + o(1). \tag{4.13}$$

Proof. The results follow by expanding (4.8) and (4.9) for small C. □

Special case. If each message contains the same number of packets, say l, then we have the usual $M/GI/1/n$ queueing system, where $n = \lfloor N/l \rfloor$ is the integer part of N/l. For that queueing system all the results in Theorems 4.1–4.5 hold, by replacing $\zeta(N)$ (or $\mathbf{E}\zeta(N)$) by n.

For example, asymptotic relation (4.7) appears as

$$\lim_{n\to\infty} \Big(\mathbf{E}R_n - \frac{\varrho - 1}{\varphi^n[1 + \lambda\beta'(\lambda - \lambda\varphi)]} \Big) = 0. \tag{4.14}$$

Notice that using the final value theorem for z transform, Azlarov and Tahirov [8] obtain the estimation

$$\mathbf{E}R_n = \frac{\varrho - 1}{\varphi^n[1 + \lambda\beta'(\lambda - \lambda\varphi)]} \Big[1 + O\Big(\frac{2\varphi}{1+\varphi} \Big)^n \Big], \tag{4.15}$$

weaker than (4.14).

The theorem below is related to the case of the usual queueing systems only, when the number of packets in a message is fixed. Namely, we have the following.

THEOREM 4.6. *If $\varrho = 1$ and $\varrho_2 < \infty$, then*

$$\mathbf{E}P_{n+1} - \mathbf{E}P_n = \frac{2}{\varrho_2} + o(1), \quad n \to \infty, \tag{4.16}$$

where the index $n+1$ says that P_{n+1} is the number of processed messages during a busy period of the $M/GI/1/n+1$ queueing system.

Proof. The result will follow from Lemma 3.3 if we show that $\beta(\lambda) - \lambda\beta'(\lambda) < 1$. Taking into account that for each $\lambda > 0$,

$$\begin{aligned} \sum_{i=0}^{\infty} \frac{(-\lambda)^i}{i!} \beta^{(i)}(\lambda) &= \sum_{i=0}^{\infty} \int_0^{\infty} \mathrm{e}^{-\lambda x} \frac{(\lambda x)^i}{i!} \mathrm{d}B(x) \\ &= \int_0^{\infty} \sum_{i=0}^{\infty} \mathrm{e}^{-\lambda x} \frac{(\lambda x)^i}{i!} \mathrm{d}B(x) = 1, \end{aligned} \tag{4.17}$$

and all terms

$$\pi_i = \frac{(-\lambda)^i}{i!} \beta^{(i)}(\lambda)$$

are nonnegative, from (4.17) we find that

$$\beta(\lambda) - \lambda\beta'(\lambda) \le 1. \tag{4.18}$$

Thus, the required statement will be proved if we show that for some $\lambda_0 > 0$ the equality

$$\beta(\lambda_0) - \lambda_0\beta'(\lambda_0) = 1 \tag{4.19}$$

is not a case. Indeed, since the function $\beta(\lambda) - \lambda\beta'(\lambda)$ is an analytic function, then according to the maximum absolute value principle for analytic functions, $\beta(\lambda) - \lambda\beta'(\lambda) = 1$ holds for all $\lambda > 0$. Therefore identity (4.19) means that $\pi_i = 0$ for all $i \ge 2$ and for all $\lambda > 0$. Therefore, (4.19) is valid if and only if $\beta(\lambda)$ is a linear function, i.e., $\beta(\lambda) = c_0 + c_1\lambda$, c_0 and c_1 are some constants. However, since $|\beta(\lambda)| \le 1$ we obtain $c_0 = 1$ and $c_1 = 0$, and $\beta(\lambda) \equiv 1$. This is the trivial case where the probability distribution function $B(x)$ is concentrated in point 0. Therefore (4.19) is not a case, and $\beta(\lambda) - \lambda\beta'(\lambda) < 1$. The theorem is proved. □

5. Asymptotic theorems for the loss probabilities. In this section we study the asymptotic behavior of the loss probability by using renewal arguments. The results of this section correspond to those of the previous section. We discuss the behavior of the system for the same cases as $N \to \infty$, as well as when the parameter ρ is close to the critical value 1 and tends to 1 as $N \to \infty$. The theorems of this section are important for our conclusion on adding redundancy, which is given in the next section.

According to renewal arguments the loss probability is determined as

$$\Pi_\zeta = \frac{\mathbf{E}L_\zeta}{\mathbf{E}R_\zeta + \mathbf{E}P_\zeta} = \frac{\mathbf{E}R_\zeta + \mathbf{E}M_\zeta}{\mathbf{E}R_\zeta + \mathbf{E}P_\zeta} = \frac{\mathbf{E}R_\zeta + p\mathbf{E}P_\zeta}{\mathbf{E}R_\zeta + \mathbf{E}P_\zeta}. \tag{5.1}$$

(Recall that L_ζ is the number of lost messages during a busy period.)

THEOREM 5.1. *If* $\varrho < 1$

$$\lim_{N\to\infty} \Pi_{\zeta(N)} = p. \tag{5.2}$$

(Recall that p *is the probability that a message is erroneous because one of its packets is corrupted.)*

Limiting relation 5.2 *is also valid when* $\varrho = 1$ *and* $\varrho_2 < \infty$.

If $\varrho > 1$, *then*

$$\Pi_{\zeta(N)} = \frac{p+\varrho-1}{\varrho}\,\frac{(\varrho-1)+p[1+\lambda\beta'(\lambda-\lambda\varphi)]\mathbf{E}\varphi^{\zeta(N)}}{(\varrho-1)+[1+\lambda\beta'(\lambda-\lambda\varphi)]\mathbf{E}\varphi^{\zeta(N)}} + o(\mathbf{E}\varphi^{\zeta(N)}). \tag{5.3}$$

Proof. The proof follows from Theorems 4.1 and 4.3. □

THEOREM 5.2. *If* $\varrho = 1$ *and* $\varrho_3 < \infty$, *then as* $N \to \infty$

$$\Pi_{\zeta(N)} = p + \frac{(1-p)\varrho_2}{2\mathbf{E}\zeta(N)} + O\Big(\frac{\log N}{N^2}\Big). \tag{5.4}$$

Proof. From (5.1) we have

$$\Pi_{\zeta(N)} = \frac{\mathbf{E}R_{\zeta(N)}}{\mathbf{E}R_{\zeta(N)} + \mathbf{E}P_{\zeta(N)}} + \frac{p\mathbf{E}P_{\zeta(N)}}{\mathbf{E}R_{\zeta(N)} + \mathbf{E}P_{\zeta(N)}} \tag{5.5}$$

$$= \frac{1}{1+\mathbf{E}P_{\zeta(N)}} + \frac{p\mathbf{E}P_{\zeta(N)}}{1+\mathbf{E}P_{\zeta(N)}}.$$

As $N \to \infty$ from Theorem 4.2 we obtain

$$\frac{1}{1+\mathbf{E}P_{\zeta(N)}} = \frac{\varrho_2}{2\mathbf{E}\zeta(N)} + O\Big(\frac{\log N}{N^2}\Big), \tag{5.6}$$

$$\frac{p\mathbf{E}P_{\zeta(N)}}{1+\mathbf{E}P_{\zeta(N)}} = p - \frac{p\varrho_2}{2\mathbf{E}\zeta(N)} + O\Big(\frac{\log N}{N^2}\Big). \tag{5.7}$$

Combining these two asymptotic relations (5.6) and (5.7) we obtain the statement of Theorem 5.2. Theorem 5.2 is proved. □

Note. Under assumptions of Theorem 5.2 assume additionally that $p \to 0$. If $pN \to C > 0$, then

$$\Pi_{\zeta(N)} = \frac{C}{N} + \frac{\varrho_2}{2\mathbf{E}\zeta(N)} + O\Big(\frac{\log N}{N^2}\Big).$$

If $pN \to 0$, then

$$\Pi_{\zeta(N)} = \frac{\varrho_2}{2\mathbf{E}\zeta(N)} + O\Big(p + \frac{\log N}{N^2}\Big).$$

The theorem below also assumes that $p \to 0$. Our result here is the following.

THEOREM 5.3. *Let $\varrho = 1 + \varepsilon$, $\varepsilon > 0$, and $\varepsilon\zeta(N) \to C > 0$ as $\varepsilon \to 0$ and $N \to \infty$, and $p \to 0$. Assume also that $\varrho_3 = \varrho_3(N)$ is a bounded sequence, and there exists $\tilde{\varrho}_2 = \lim_{n\to\infty} \varrho_2(N)$.*

(i) *If $p/\varepsilon \to D \geq 0$, then we have*

$$\Pi_{\zeta(N)} = \left(D + \frac{e^{2C/\widetilde{\varrho}_2}}{e^{2C/\widetilde{\varrho}_2} - 1}\right)\varepsilon + o(\varepsilon). \tag{5.8}$$

(ii) *If $p/\varepsilon \to \infty$, then we have*

$$\Pi_{\zeta(N)} = p + O(\varepsilon). \tag{5.9}$$

Proof. In the case (i) we have

$$p\mathbf{E}P_{\zeta(N)} + \mathbf{E}R_{\zeta(N)} = (D+1)\mathrm{e}^{2C/\widetilde{\varrho}_2} - D + o(1), \tag{5.10}$$

and

$$\mathbf{E}P_{\zeta(N)} + \mathbf{E}R_{\zeta(N)} = \frac{\mathrm{e}^{2C/\widetilde{\varrho}_2} - 1}{\varepsilon} + O(1). \tag{5.11}$$

Therefore from (5.10) and (5.11) we have

$$\Pi_{\zeta(N)} = \left(D + \frac{\mathrm{e}^{2C/\widetilde{\varrho}_2}}{\mathrm{e}^{2C/\widetilde{\varrho}_2} - 1}\right)\varepsilon + o(\varepsilon),$$

and relation (5.8) is proved.

In the case (ii) we have

$$p\mathbf{E}P_{\zeta(N)} + \mathbf{E}R_{\zeta(N)} = \frac{pc}{\varepsilon} + O(1), \tag{5.12}$$

and

$$\mathbf{E}P_{\zeta(N)} + \mathbf{E}R_{\zeta(N)} = \frac{c}{\varepsilon} + O(1), \tag{5.13}$$

where $c = \exp(2C/\widetilde{\varrho}_2)/(\exp(2C/\widetilde{\varrho}_2) - 1)$. Relation (5.9) follows. □

THEOREM 5.4. *Let $\varrho = 1 + \varepsilon$, $\varepsilon > 0$, and $\varepsilon\zeta(N) \to 0$ as $\varepsilon \to 0$ and $N \to \infty$, and $p \to 0$. Assume also that $\varrho_3 = \varrho_3(N)$ is a bounded sequence, and there exists $\tilde{\varrho}_2 = \lim_{n\to\infty} \varrho_2(N)$.*

(i) *If* $p/\varepsilon \to D \geq 0$, *then we have*

$$\Pi_{\zeta(N)} = p + \frac{\widetilde{\varrho}_2}{2\mathbf{E}\zeta(N)} + o\Big(\frac{1}{N}\Big). \tag{5.14}$$

(ii) *If* $p/\varepsilon \to \infty$, *then we have* (5.9).

Proof. The proof of (5.14) follows by expanding (5.8) for small C. The proof in case (ii) trivially follows from (5.12) and (5.13). □

Special case. In the case where each message contains exactly l packets, $n = \lfloor N/l \rfloor$, we obtain the following:

THEOREM 5.5. *If* $\varrho = 1$ *and* $\varrho_2 < \infty$, *then as* $n \to \infty$

$$\Pi_{n+1} - \Pi_n = \frac{\frac{1}{n(n+1)}\ \frac{2}{\varrho_2}(p-1)}{\Big(\frac{2}{\varrho_2} + \frac{1}{n+1}\Big)\Big(\frac{2}{\varrho_2} + \frac{1}{n}\Big)} + o\Big(\frac{1}{n^2}\Big). \tag{5.15}$$

Proof. The proof follows by applying Theorem 4.5 and taking into account the fact that $\mathbf{E}R_n = 1$ for all $n \geq 0$ (see [3] or Lemma 2.1). □

6. Adding redundant packets. We now investigate the effect of adding redundant packets. We assume that adding a redundant packet to the message decreases the probability p that a message is corrupted and increases the offered load and the number of packets in a message. The new parameters of the system after adding a redundant packet are denoted by adding the symbol $\breve{}$ above. For example, $\breve{p}$ is a probability that a message contains a corrupted packet and $\breve{\varrho}$ is the offered load. It follows from Theorem 5.1 that if $\breve{\varrho} \leq 1$ the stationary loss probability coincides with $\breve{p}$. This means that if adding a redundant packet to the message decreases the probability p by γ times, then the same effect is achieved with the loss probability. Thus, adding a number of redundant packets while $\varrho < 1$ can decrease the loss probability geometrically.

In the case where both $\varrho > 1$ and $\breve{\varrho} > 1$, adding a redundant packet to the message changes the stationary loss probability to approximately

$$\frac{\varrho(\breve{p} + \breve{\varrho} - 1)}{\breve{\varrho}(p + \varrho - 1)}.$$

In practice the values p and $\breve{p}$ are small, and even if adding redundant packets can slightly decrease the stationary loss probability, the effect of that action is not considerable.

The case where $\varrho < 1$ and $\breve{\varrho} > 1$ is especially interesting if $\breve{\varrho} = 1 + \delta$, and δ is a small value. For example, if δ is so small that both $\delta\zeta(N)$ and δ/p are also negligible, then a redundant packet decreases the loss probability by approximately the same amount as in the case when both $\varrho < 1$ and $\breve{\varrho} < 1$. However, if δ is of the same order as p or $1/\zeta(N)$, then the special analysis based on the corresponding cases of Theorems 5.3 and 5.4 is necessary. Here we do not provide the details.

Let us consider the cases when both $\varrho > 1$ and $\breve{\varrho} > 1$, where $\varrho = 1 + \varepsilon$ and $\breve{\varrho} = 1 + \breve{\varepsilon}$, and ε and $\breve{\varepsilon}$ are small values as in Theorem 5.3, both satisfying (i). Then the stationary loss probability is changed to approximately

$$\frac{\mathrm{e}^{2C/\widetilde{\varrho}_2} - 1}{\mathrm{e}^{2\breve{C}/\breve{\varrho}_2} - 1}\ \frac{(\mathrm{e}^{2\breve{C}/\breve{\varrho}_2} - 1)\breve{p} + \mathrm{e}^{2\breve{C}/\breve{\varrho}_2}\breve{\varepsilon}}{(\mathrm{e}^{2C/\widetilde{\varrho}_2} - 1)p + \mathrm{e}^{2C/\widetilde{\varrho}_2}\varepsilon} \tag{6.1}$$

times.

For the sake of simplicity let us assume that $\breve{C}/\breve{\varrho}_2 = C/\widetilde{\varrho}_2$. Then (6.1) reduces to

$$\frac{(\mathrm{e}^{2C/\widetilde{\varrho}_2}-1)\breve{p}+\mathrm{e}^{2C/\widetilde{\varrho}_2}\breve{\varepsilon}}{(\mathrm{e}^{2C/\widetilde{\varrho}_2}-1)p+\mathrm{e}^{2C/\widetilde{\varrho}_2}\varepsilon}. \tag{6.2}$$

If we assume that

$$p-\breve{p}=\frac{\mathrm{e}^{2C/\widetilde{\varrho}_2}}{\mathrm{e}^{2C/\widetilde{\varrho}_2}-1}(\breve{\varepsilon}-\varepsilon),$$

then the stationary loss probability remains at approximately the same value, and if

$$p-\breve{p}>\frac{\mathrm{e}^{2C/\widetilde{\varrho}_2}}{\mathrm{e}^{2C/\widetilde{\varrho}_2}-1}(\breve{\varepsilon}-\varepsilon),$$

then the stationary loss probability decreases, otherwise if

$$p-\breve{p}<\frac{\mathrm{e}^{2C/\widetilde{\varrho}_2}}{\mathrm{e}^{2C/\widetilde{\varrho}_2}-1}(\breve{\varepsilon}-\varepsilon),$$

then the stationary loss probability increases.

OPTIMAL LOCALIZATION OF EIGENFUNCTIONS IN AN INHOMOGENEOUS MEDIUM*

DAVID C. DOBSON† AND FADIL SANTOSA‡

Abstract. The problem of creating eigenfunctions which are localized arises in the study of photonic bandgap structures. A model problem, that of finding material inhomogeneity in a domain so that one of its Dirichlet eigenfunctions is localized, is considered in this work. The most difficult aspect, that of formulating the problem, is described, and well-posed variational problems are given. A computational approach, based on gradient descent with projection and trajectory continuation, is devised to solve the optimization problem. Numerical examples are provided which demonstrate the capability of the computational method.

Key words. mode localization, optimal design, defect modes

1. Introduction.

We study a problem arising in the design of optical devices that exploit the photonic bandgap phenomenon. This phenomenon occurs in the optical wavelength regime in certain nanostructures with periodic index of refraction. Such materials, called photonic bandgap (PBG) structures by John [8] and Yablonovitch [12], are conceived to be optical analogues of electronic semiconductors. By introducing patterned defects into a photonic bandgap structure, it is possible to control the propagation of light within the structure. Photonic bandgap structures are anticipated to play important roles in future generations of optical devices.

Photonic bandgap phenomenon refers to the existence of a certain frequency band in which waves having frequency in that band cannot propagate in the medium. A bandgap can be created in a medium with periodic structure [7]. If a bandgap exists, it is possible to create a standing wave with frequency in the gap by introducing a so-called "point defect." In its simplest form, a point defect is a localized perturbation to the underlying periodic index of refraction. It is known that such a standing wave will be spatially localized [4]. Optimizing the properties of localized modes is the subject of this work.

To be specific, let us consider the transverse electric-mode for electromagnetic waves in two dimensions. The medium is characterized by the real dielectric property $\epsilon_{\rm p}(x)$, which is unit periodic. It is assumed that the medium $\epsilon_{\rm p}(x)$ has a bandgap. That is, the spectral problem

$$\Delta u + \omega^2 \epsilon_{\rm p}(x) u = 0, \quad x \in \mathbb{R}^2,$$

has a continuous spectrum with a gap.

A defect is modeled by a localized perturbation $\eta(x)$ with compact support; thus the governing equation now takes the form

$$\Delta u + \omega^2 (\epsilon_{\rm p}(x) + \eta(x)) u = 0. \tag{1.1}$$

The stability theorem (see, e.g., [10]) states that the essential spectrum of the perturbed problem is equal to that of the periodic problem. One can interpret the result as saying that the perturbation can only create an additional discrete spectrum.

Defect modes are solution pairs $(\omega, u(x))$ to (1.1) which have the property that ω is in the frequency gap of the periodic medium, and $u(x)$ decays exponentially away from the defect. The existence of these defect modes has been addressed in the work of Figotin and Klein [6] (see also a review of mathematical results on photonic bandgap structures in [10, 5]). It is known, for example, that if the perturbation $\eta(x)$ is sufficiently strong and the frequency bandgap is sufficiently large, then a defect mode can be created.

In this work, we address a more practical question, that of finding $\eta(x)$ so that the defect mode produced has desired attributes. For example, we may wish to create a defect mode that concentrates energy in the smallest spatial region, which is useful in applications for enhancing nonlinear optical effects, or we may wish to create a defect mode with a specific frequency.

We note that one possible way of creating defect modes that are highly localized is to start with an underlying periodic medium that has a large gap. The theoretical results of Figotin and Klein (see, e.g., [6]) state that localization length is minimized by creating a defect mode whose frequency is as far away as possible from the band edge. Maximization of bandgaps has been treated in the work of Cox and Dobson [2, 3]. However, this previous work does not address the issue of how to create defect modes with specified properties.

To simplify the analysis and computation even further, we pose a model problem on a bounded domain Ω. We will look at the Dirichlet eigenvalue problem in the domain and attempt to find material properties that lead to eigenfunctions that are "most localized." This model problem avoids the difficulty of dealing with the original unbounded domain and also lumps the discovery of $\epsilon(x)$ and $\eta(x)$ in a single formulation. It also avoids the issue of explicitly satisfying the conditions needed to create defect modes in a photonic bandgap structure.

We believe that this simple model problem exhibits many of the challenges posed by the original problem and feel that the more complex physics of light can be treated by the approach we propose in this work. Moreover, the eigenfunctions, when highly localized, can be interpreted in terms of unbounded photonic bandgap structures. This is because defect modes in photonic bandgap structures are highly localized and can be well approximated by functions which are zero outside of a bounded domain.

The paper is organized as follows. We first provide a statement of the optimal design problem. In section 3 we investigate conditions under which mathematically sound formulations of the design problem can be posed. We find two well-posed formulations, each of which has some practical deficiencies. In section 4, we present a numerical method for solving the optimal design problem which explicitly assumes a finite-dimensional implementation. The method does not directly solve either of the two optimization problems formulated in section 3 but could be adapted to do so and is quite efficient at finding good designs. We show numerical examples of designs created by our approach. We find the results quite startling in the sense that the process often produces what appears to be a periodic structure with a defect. The paper ends with a discussion section that outlines some open theoretical and computational issues.

2. Problem description. We assume that the dielectric coefficient $\epsilon(x)$ of the medium satisfies $0 < \epsilon_0 \leq \epsilon(x) \leq \epsilon_1 < \infty$. We are interested in modes $u \in H_0^1(\Omega)$

satisfying the Dirichlet eigenvalue problem

$$-\Delta u = \lambda \epsilon\, u \quad \text{in } \Omega, \tag{2.1a}$$

$$u = 0 \quad \text{on } \partial\Omega \tag{2.1b}$$

for some eigenvalue λ. Here Ω is a simply connected bounded domain in $\mathbb{R}^2$ with Lipschitz continuous boundary. The quantity ϵu^2 is proportional to energy density in the medium. Normalizing the eigenfunctions to have unit energy in the domain, we specify

$$\int_\Omega \epsilon u^2 = 1. \tag{2.2}$$

Associated with problem (2.1) is the following variational problem: find $u \in H_0^1(\Omega)$ such that

$$a(u,v) = \lambda b(\epsilon; u, v) \quad \text{for all } v \in H_0^1(\Omega), \tag{2.3}$$

where

$$a(u,v) = \int_\Omega \nabla u \cdot \nabla v, \quad b(\epsilon; u, v) = \int_\Omega \epsilon\, uv.$$

The symmetric bilinear form $a(u,v)$ defines an associated L^2–self-adjoint operator A through the formula $a(u,v) = \langle Au, v\rangle$. It is well known that A has a compact self-adjoint inverse $A^{-1} : L^2(\Omega) \to L^2(\Omega)$, and the problem (2.3) is equivalent to

$$v = \lambda A^{-1/2} B(\epsilon) A^{-1/2} v,$$

where $B(\epsilon)$ is defined by $b(\epsilon; u, v) = \langle B(\epsilon)u, v\rangle$.

The admissible class of dielectric coefficient is defined

$$\mathcal{A} = \{\epsilon \in L^\infty(\Omega) : 0 < \epsilon_1 \le \epsilon(x) \le \epsilon_2, \ \text{ a.e.}\}.$$

Since the operator $A^{-1/2} B A^{-1/2}$ is compact and self-adjoint, the spectral theorem implies that for each given $\epsilon \in \mathcal{A}$, problem (2.3) admits an infinite sequence of non-negative real eigenvalues

$$0 < \lambda_0(\epsilon) \le \lambda_1(\epsilon) \le \lambda_2(\epsilon) \le \cdots, \tag{2.4}$$

listed according to multiplicity, and associated eigenfunctions $u_j(\epsilon)$, $j = 1, 2, \ldots, \infty$, (assumed to be scaled so that $\int \epsilon u_j^2 = 1$). For each fixed ϵ, the set of eigenfunctions $\{u_j(\epsilon)\}$ forms an orthogonal basis for $L^2(\Omega)$, although the sequence $u_j(\epsilon)$ is not uniquely defined, due to sign ambiguities and the possibility of multiple eigenvalues.

Our goal is to find material parameters $\epsilon \in \mathcal{A}$ such that a particular corresponding eigenfunction $u(\epsilon)$ is "most localized" at a particular point. We measure the degree of localization by the moment

$$J(\epsilon, u) = \int_\Omega w \epsilon u^2,$$

where w is some fixed prescribed weight function. In the numerical experiments to follow, we will assume $0 \in \Omega$ and take $w(x) = |x|^2$.

3. Optimization problems. The purpose of this section is to investigate conditions under which a well-defined optimization problem can be formulated. In the minimization method to be described in the following section, we will specifically make use of the finite-dimensionality of the numerical implementation in order to justify the algorithm. Before doing so, it is important to understand the difficulties associated with the underlying problem before discretization.

Without some constraints, the problem of minimizing $J(\epsilon, u(\epsilon))$ over $\mathcal{A}$ is not well-posed. By considering eigenfunctions corresponding to higher and higher frequencies, a sequence ϵ_n could be constructed which drives $J(\epsilon_n)$ to zero, but for which ϵ_n does not converge in $\mathcal{A}$. For example, one could choose ϵ_n to be a sequence of truncated photonic bandgap structures with point defects, with spatial frequency tending toward infinity. To ensure existence of a solution, we must further constrain the problem. We will consider two ways of imposing constraints, leading to a "global problem" and a "local problem."

3.1. Global problem. For each fixed $\epsilon \in \mathcal{A}$, the sequence of eigenvalues $\lambda_k(\epsilon)$, $k = 0, 1, 2, \ldots$, as in (2.4), is well defined. Choose some $N < \infty$. Define

$$E_N(\epsilon) = \{u \in H_0^1(\Omega) : \ u \text{ is an eigenfunction associated with some } \lambda_j(\epsilon),\ j \le N, \text{ satisfying } \int \epsilon u^2 = 1\}.$$

Note that $E_N(\epsilon)$ is finite-dimensional for each ϵ, but its dimension may change as ϵ is varied due to multiple eigenvalues. The global problem we consider is

$$\inf_{\epsilon \in \mathcal{A}} \min_{u \in E_N(\epsilon)} J(\epsilon, u) = \int_\Omega w\epsilon u^2. \tag{3.1}$$

PROPOSITION 3.1. *Problem* (3.1) *admits a solution* $\epsilon \in \mathcal{A}$.

Proof. By Proposition 4.3.i in Cox and McLaughlin [1], each eigenvalue $\lambda_j(\epsilon)$ is weak$*$ L^∞ continuous over $\mathcal{A}$. Also $\mathcal{A}$ is weak$*$ compact, so

$$\sup_{\epsilon \in \mathcal{A}} \lambda_N(\epsilon) = C < \infty.$$

The variational problem (2.3) then immediately gives a uniform upper bound on $\|u\|_{H^1(\Omega)}$ for all $u \in E_N(\epsilon)$, independent of $\epsilon \in \mathcal{A}$. Considering then a minimizing sequence ϵ_n with some subsequence (still denoted ϵ_n) converging weak$*$ to some $\epsilon \in \mathcal{A}$, any corresponding minimizing eigenfunctions $u_n \in E_N(\epsilon_n)$ have a subsequence (again indexed by n) such that u_n converges weakly in $H_0^1(\Omega)$ (hence strongly in $L^2(\Omega)$) to some u in $H_0^1(\Omega)$. Since $u_n^2 \to u^2$ in L^1, it follows that $J(\epsilon_n, u_n) \to J(\epsilon, u)$. Finally, the fact that $u \in E_N(u)$ follows easily from (2.3). ∎

The global problem (3.1) is interesting in that it seeks an absolute minimum over all admissible designs with a prescribed upper bound on frequency. This is very close to the problem that we would like to solve computationally. It does, however, have some drawbacks. First, nothing in the problem formulation prevents solutions from occurring at a multiple eigenvalue, in which one eigenfunction is localized while others are not. Second, the problem is computationally awkward, since the objective function is not everywhere differentiable.

Next we propose another problem which removes each of these drawbacks but introduces a new objection in that it is "local."

3.2. Local problem. Choose some $\epsilon_0 \in \mathcal{A}$ which yields an associated eigenvalue $\lambda_k(\epsilon_0)$ such that

$$\min_j |\lambda_k(\epsilon_0) - \lambda_j(\epsilon_0)| \geq 2\delta > 0.$$

In other words, the kth eigenvalue is distinct and separated from the other eigenvalues by 2δ. Then define a new admissible set

$$\mathcal{A}_\delta = \{\epsilon \in \mathcal{A} : \min_j |\lambda_k(\epsilon) - \lambda_j(\epsilon)| \geq \delta\},$$

where it is assumed that the eigenvalues are ordered according to multiplicity as in (2.4). Thus $\mathcal{A}_\delta$ contains a set of material parameters for which the kth eigenvalue is always distinct and bounded away from all other eigenvalues. Note that $\mathcal{A}_\delta$ is not empty, since it at least contains ϵ_0. Because of the weak$*$ continuity of $\lambda(\epsilon)$, it follows that $\mathcal{A}_\delta$ is weak$*$ compact. Unfortunately, however, it is not necessarily convex. Nevertheless, we can formulate the "local problem"

$$\inf_{\epsilon \in \mathcal{A}_\delta} J(\epsilon) = \int_\Omega w\epsilon u_k^2, \tag{3.2}$$

where $\pm u_k$ is a basis eigenfunction which spans the one-dimensional eigenspace associated with $\lambda_k(\epsilon)$, again normalized so that $\int \epsilon u_k^2 = 1$.

PROPOSITION 3.2. *Problem* (3.2) *admits a solution* $\epsilon \in \mathcal{A}_\delta$.

Proof. The proof follows essentially the same direct method argument as Proposition 3.1. The key point is that the weak$*$ continuity of $\lambda_k(\epsilon)$ establishes both the compactness of $\mathcal{A}_\delta$ and the fact that $\sup_{\epsilon \in \mathcal{A}_\delta} \lambda_k(\epsilon) < \infty$. The latter fact yields the uniform H_0^1 upper bound on the eigenfunctions, and the argument follows that of Proposition 3.1. □

The advantage of this problem formulation is that it excludes multiple eigenvalues and the associated changes in dimension of eigenspaces as ϵ moves through the design space. The disadvantage is that due to the nonconvexity of the admissible set $\mathcal{A}_\delta$, any derivative-based minimization method would be forced to search for solutions locally near the known design ϵ_0.

4. A minimization method. In this section, we introduce a computational method which can be adapted for solving either problem (3.1) or problem (3.2). However, as pointed out in the previous section, each problem has some practical deficiencies. The method developed here is a somewhat more general algorithm which starts with an eigenfunction of an initial design medium ϵ and iteratively decreases the objective function associated with this particular eigenfunction as it updates the medium. The algorithm handles the situation when the eigenvalue associated with the eigenfunction becomes a repeated eigenvalue at some design and can be viewed as a steepest descent approach with trajectory continuation. The continuation is needed to track the same eigenfunction as the algorithm explores the admissible designs through the iterations.

From now on, we tacitly assume that the eigenproblem (2.1) has been discretized, for example, by finite differences, into a corresponding matrix eigenproblem

$$Au = \lambda S(\epsilon)u, \tag{4.1}$$

where u and ϵ now represent finite-dimensional vectors, and $S(\epsilon)$ is a diagonal matrix which multiplies the entries of u pointwise by the elements in ϵ. Most of the following still carries through when A and S are infinite-dimensional operators. Assume that the discretization makes A and S symmetric and positive definite.

4.1. Derivative calculation. In preparing to compute derivatives of the objective function, it will be helpful to reformulate the eigenproblem in such a way that ϵ does not appear explicitly in the normalization constraint (2.2). Let b be the vector with entries $b_j = 1/\sqrt{\epsilon_j}$, and let B be the diagonal matrix with b on the main diagonal. Thus $S(\epsilon)^{-1/2} = B$. It will simplify the following calculations to consider the vector b as our design variable. Set $v = B^{-1}u$. The eigenproblem (4.1) with normalization of the eigenvector can then be equivalently stated as

$$\begin{aligned} BABv - \lambda v &= 0, \\ \langle v, v\rangle &= 1. \end{aligned}$$

Note that for any eigenpair (λ, v) satisfying this problem, we have $\lambda = \langle v, BABv\rangle$. Given a design vector b, and any associated eigenvector $v(b)$, we can then consider the objective function

$$J(b) = \frac{1}{2}\langle v(b), Wv(b)\rangle, \tag{4.2}$$

where $v(b)$ solves

$$BABv - \langle v, BABv\rangle v = 0, \tag{4.3a}$$

$$\langle v, v\rangle = 1. \tag{4.3b}$$

Here, W is a symmetric matrix which represents multiplication by the weight function w on the discretized vector v.

Let δb be a small perturbation in b. The linearized response $DJ(b)(\delta b)$ in the objective $J(b)$ is

$$DJ(b)(\delta b) = \langle \delta v, Wv\rangle,$$

where δv is the linearized response in v to δb. Differentiating (4.3), we find that δv satisfies

$$\begin{aligned} &BAB\delta v - \langle v, BABv\rangle \delta v - 2\langle BABv, \delta v\rangle v \\ &\quad = -(\delta B)ABv - BA(\delta B)v + \langle v, (\delta B)ABv\rangle v + \langle v, BA(\delta B)v\rangle v, \end{aligned} \tag{4.4}$$

where $\delta B = DB(b)(\delta b)$ is simply the diagonal matrix with δb on the diagonal.

Now define an adjoint vector q as the solution to the equation

$$BABq - \langle v, BABv\rangle q - 2\langle q, v\rangle BABv = Wv. \tag{4.5}$$

Assuming that the unit eigenvector v is associated with a simple eigenvalue, the operator $BAB - \langle v, BABv\rangle I$ has a one-dimensional null space, spanned by v. Also $BABv = \lambda v$, so the third term is the rank-one projection $-2\lambda vv^T$. The sum of the three operators acting on q thus has a trivial null space, and the adjoint equation has a unique solution q.

By a straightforward calculation using (4.4) and (4.5) we then have

$$\begin{aligned} DJ(b)(\delta b) &= \langle \delta v, Wv\rangle \\ &= -\langle \delta b, \operatorname{diag}(q)ABv\rangle - \langle \delta b, \operatorname{diag}(v)ABq\rangle + 2\langle q, v\rangle\langle \delta b, \operatorname{diag}(v)ABv\rangle. \end{aligned}$$

Setting

$$g = \operatorname{diag}(q)ABv - \operatorname{diag}(v)ABq + 2\langle q, v\rangle \operatorname{diag}(v)ABv, \tag{4.6}$$

we have $DJ(b)(\delta b) = \langle \delta b, g\rangle$; hence we identify the vector g with the *gradient* of J.

4.2. Gradient descent. As mentioned above, the gradient g (4.6) is not necessarily well defined unless the eigenvector v used in the objective is associated with a simple eigenvalue.

The (negative) gradient at a given point b gives a direction to move in the design space which will result in a *particular* eigenvector becoming more localized. It is important to note that the same calculation above applies to *any* eigenvector $v(b)$, provided it is associated with a simple eigenvalue. This actually creates an algorithmic problem: suppose we implement a simple gradient descent algorithm in which steps are iteratively taken in the direction of $-g$. One would expect that in moving through the design space, eigenvalues will cross, and it may quickly become unclear which eigenvector we are supposed to be localizing. If we jump back and forth between different eigenvectors during the course of the optimization, there should be no expectation of convergence. In fact, this behavior was observed in preliminary numerical experiments.

A solution to the problem of tracking eigenvectors is provided by the following theorem.

THEOREM 4.1 (Kato, [9]). *Let $T(\tau)$ be a symmetric $N \times N$ matrix whose entries are analytic functions of τ. Then there exist N holomorphic vector-valued functions $\{v_j(\tau)\}_{j=1}^N$ which are orthonormal eigenvectors for T.*

Notice that the matrix $T(\tau) = (B - \tau \operatorname{diag}(g))A(B - \tau \operatorname{diag}(g))$, which results from a step in the direction of $-g$, satisfies the hypothesis of Theorem 4.1. Thus as we take a step along the direction $-g$, whatever eigenvector we are optimizing can be continued as an analytic function of the step length, *even if the associated eigenvalue crosses with other eigenvalues*. This observation leads to the following algorithm.

Basic Algorithm

1. Choose an initial design b_0 and a distinct eigenvalue $\lambda_k(b_0)$, with associated eigenvector v_0. Set $n = 0$. Choose a step parameter $\tau > 0$.
2. Compute the gradient g of $J(b_n)$, associated with the distinct eigenvector v_n.
3. Let $u = \operatorname{argmin}\{\|\pm u - v_n\| : u$ is an eigenvector of $\operatorname{diag}(b_n - \tau g) A \operatorname{diag}(b_n - \tau g)$, with $\langle u, u\rangle = 1\}$.
4. If $J(u) < J(v_n)$, then
   $v_{n+1} = u$,
   $b_{n+1} = P(b_n - \tau g)$,
   else $\tau = \tau/2$.
5. Set $n = n+1$ and check for convergence. If no convergence and τ is not too small, continue with step 2.

The idea in step 3 is to select, out of all eigenvectors at the next iterate, the one closest to the current eigenvector (modulo sign). Since each eigenvector varies analytically with respect to the step length, and the new eigenvectors are mutually orthogonal, for small enough step length we are guaranteed that this will select the analytic continuation of the current eigenvector.

The operator P in step 4 simply projects the step back into the admissible set, i.e., P is defined by $P(b) = \max\{\min\{b, b_1\}, b_0\}$, where $b_0 = 1/\sqrt{\epsilon_1}$ is the lower bound for b, and $b_1 = 1/\sqrt{\epsilon_0}$ is the upper bound.

This basic algorithm solves neither the global problem nor the local problem described in section 3 but instead tracks along a single well-defined eigenvector, which

thanks to Theorem 4.1, can be followed all over the design space. The algorithm could be modified to find approximate local minima for either of the problems in section 3 but the basic implementation described here seems to be more versatile and of greater practical use.

5. Numerical results. To implement the basic algorithm, problem (2.1) was discretized by a simple 5-point finite difference scheme on a uniform square grid. Each step in the basic algorithm is then a relatively straightforward linear algebra operation. Our implementation uses Matlab with sparse matrix data structures wherever possible. For efficiency, eigenvalues and eigenvectors are found iteratively, using data from the previous optimization step as starting points. The adjoint equation (4.5) is also solved iteratively, using a biconjugate gradient algorithm. In the following we illustrate the results of three numerical experiments.

In the first experiment, we start with a homogeneous initial design $\epsilon(x) \equiv 1$. After discretizing problem (2.1) on a 112×112 grid, the first several eigenvalues and eigenvectors were computed. The homogeneous medium admits numerous multiple eigenvalues. A distinct eigenvalue λ_{11} was chosen whose associated eigenvector v_0 has the energy distribution pictured in Figure 5.1(b). The initial value of the objective was $J(v_0) \approx 6.44 \times 10^{-1}$. The initial gradient g is shown in Figure 5.1(a). We set the upper and lower bounds on $\epsilon(x)$ at $\epsilon_1 = 8$ and $\epsilon_0 = 1$. After approximately 2000 iterations of the algorithm, the design shown in Figure 5.2(a) was obtained, with energy density as pictured in Figure 5.2(b). The algorithm produced a localized eigenfunction despite the poorly localized initial guess. This was the case in all of our experiments: the algorithm does not seem to require a "good" initial guess. The final value of the objective was $J(v_f) \approx 9.71 \times 10^{-2}$.

For the second experiment, we begin again with a homogeneous background on a 112×112 grid, but now with a single point material defect centered at the origin, as shown in Figure 5.3(a). The inclusion separates some of the eigenvalues and provides more variety for the choice of initial eigenvectors. An eigenvector v_0 associated with a distinct eigenvalue λ_{22}, whose frequency is somewhat higher than in the previous

example, was chosen. The energy density of the initial eigenvector is pictured in Figure 5.3(b). The initial value of the objective was $J(v_0) \approx 6.59 \times 10^{-1}$. The material constraints were set at $\epsilon_1 = 8$ and $\epsilon_0 = 1$. After approximately 3000 iterations, the design shown in Figure 5.4 was obtained. Perhaps the most interesting feature of this example is the nearly periodic structure of the design away from the defect, resembling a photonic bandgap structure. The final value of the objective was $J(v_f) \approx 8.91 \times 10^{-2}$. This example achieves higher energy density at the origin than the previous example, due to the higher frequency of the mode.

For the final numerical experiment, we take as an initial guess a hexagonal

photonic bandgap structure with localized point defect as shown in Figure 5.5(a). The white areas in the image represent dielectric coefficient $\epsilon_1 = 9$; the black areas (holes) are $\epsilon_0 = 1$. The gray defect hole is filled with a material with $\epsilon = 5$. This structure, with periodic boundary conditions, exhibits a complete photonic bandgap for E-parallel wave propagation in a narrow frequency range and admits a localized mode with most of the energy concentrated within the defect. Such a localized mode, calculated by a "supercell" method with periodic boundary conditions, is pictured in Figure 5.5(b). The structure, discretized on a 96×96 grid, was taken as the initial design b_0. We then changed to Dirichlet boundary conditions, recalculated the

FIG. 5.6. *Final values for the third experiment.*

modes, and identified that one (and only one) localized eigenvector v_0 which had energy density similar to Figure 5.5(b). This localized mode v_0 was taken as the eigenfunction to optimize. The initial value of the objective was $J(v_0) \approx 3.97 \times 10^{-1}$. After nearly 10000 iterations, the structure b_f in Figure 5.6(a) was obtained, with eigenfunction energy density v_f shown in Figure 5.6(b). The final value of the objective was $J(v_f) \approx 4.57 \times 10^{-2}$. The irregularities in the outer ring of the design may be due to the influence of the Dirichlet boundary conditions; i.e., it is possible that on a larger domain the optimal solution would be concentric annuli.

The large number of iterations exhibited by the algorithm in each of the previous examples is partly due to obvious deficiencies in the algorithm and partly due to inherent difficulties with the problem. The main weaknesses of the algorithm are poor step size control and inefficient parameterization of the design space. The numerical experiments presented here suggest that optimal designs are "bang-bang," i.e., optimal $\epsilon(x)$ designs take on only the values ϵ_1 or ϵ_0 (analysis to support this assertion will be presented in another paper). For this reason, an approach based on a level-set parameterization of the designs (see [11]) would probably be more efficient.

The large number of iterations required by the algorithm is also a symptom of the inherent ill-conditioning of the problem. Near an optimal design, modal energy decays very rapidly away from the origin. It follows from (4.6) that the magnitude of the gradient also decays rapidly with increasing $|x|$. The objective J is thus increasingly insensitive to changes in the design away from the origin. As the algorithm iterates, rapid local "convergence" near the center of the picture is normally observed (producing large decreases in J), followed by extremely slow changes further away from the origin, and much smaller decreases in J.

In computing the examples above, eigenvalue crossings often occurred as the iteration proceeded. The algorithm had no problems tracking the correct eigenvector through the crossings. In the second example, a nearby eigenvalue asymptotically approached the eigenvalue being optimized but never crossed. When the iteration stopped, the distance between the two was less than 10^{-4}, so that a small perturbation of the design could result in the eigenspace associated with the optimized eigenvector

becoming multidimensional.

6. Discussion. We studied a simplified version of a problem arising in the design of photonic bandgap devices. The problem solved involves finding a distribution of the material properties in an inhomogeneous medium such that one of its Dirichlet eigenfunctions is highly localized. We describe two versions of well-posed optimization problems associated with the design problem. A numerical method, which essentially is a descent algorithm with trajectory following, is devised to solve the problem numerically. We demonstrate the behavior of the algorithm in several examples.

We find that the results are remarkable not only in that we find a highly localized eigenfunction, but that the resulting medium resembles a photonic bandgap structure consisting of a periodic background and a defect. It is important, however, to emphasize that the designs produced by this algorithm are *not* themselves necessarily photonic bandgap structures. Each structure obviously supports modes other than the highly localized state which is optimized. If the defect design is inserted in an infinitely periodic photonic bandgap structure, the other modes may propagate, or they may remain localized, depending on the bandgap frequencies of the surrounding structure.

This demonstration project points to several research directions. First, as described in the previous section, it would be desirable to develop a faster algorithm for solving the optimization procedure. Second, the approach described in this work should be applied to a more realistic model governed by the vector Maxwell equations.

Finally, as pointed out in the numerical examples, the basic computational approach does not control the separation between the frequency of the localized mode and that of neighboring modes. As a practical consequence, particularly when losses are included, the frequency response of the structure to broadband sources may be somewhat spread out, without the narrow peak associated with high quality resonators. The *quality factor* "Q" of a resonator (or resonance) is usually defined to be inversely proportional to the width of the peak. For some engineering applications, it would be useful to modify this approach to produce designs for defect resonances with a specified quality factor "Q." This could be achieved by controlling the distance between the optimized eigenvalue and its neighbors across a family of eigenproblems associated with various propagation directions through the structure.

A DIFFUSE INTERFACE MODEL FOR ALLOYS WITH MULTIPLE COMPONENTS AND PHASES*

HARALD GARCKE†, BRITTA NESTLER‡, AND BJÖRN STINNER†

Abstract. A nonisothermal phase field model for alloys with multiple phases and components is derived. The model allows for arbitrary phase diagrams. We relate the model to classical sharp interface models by formally matched asymptotic expansions. In addition we discuss several examples and relate our model to the ones already existing.

Key words. phase field models, sharp interface models, phase transitions, partial differential equations, alloy systems, matched asymptotic expansions

1. Introduction.

The phase field method is a powerful methodology to describe phase transition phenomena. The method has been used to describe solidification processes [7, 34] as well as microstructure evolution in solids [15] and liquid-liquid interfaces [28]. There are phase field models for pure substances [7, 34] and binary alloys [9, 21] for eutectic, peritectic, and monotectic systems [45, 31, 32, 33, 39]. Furthermore, the evolution of grain boundaries also can be modelled by phase field models or order parameter models [12, 16]. For recent reviews of phase field methods we refer to [13, 5, 14].

Traditionally the evolution of interfaces, such as the liquid-solid interface, has been modelled as a moving boundary problem. This means that pure phases are separated by a sharp interface. In the phases, partial differential equations, e.g., describing mass and heat diffusion, are solved. These equations are coupled by boundary conditions on the interface, such as the Stefan condition demanding energy balance and the Gibbs–Thomson equation. Across the sharp interface certain quantities (e.g., the heat flux, the concentration or the energy) may suffer jump discontinuities.

In phase field models the individual phases are distinguished by one or more so-called phase fields. In different phases the phase fields attain different values and interfaces are now modelled by a diffuse interface; i.e., the phase fields and all other quantities do not jump across an interface, but they change smoothly on a very thin transition layer (the diffuse interface). For example, for a solid-liquid phase transition we choose a phase field taking the value one in the solid and zero in the liquid; across an interface, the phase field varies smoothly from one to zero.

The use of diffuse interface models to describe interfacial phenomena dates back to van der Waals [42], Landau and Ginzburg [26], and Cahn and Hilliard [10]. In the theory of solidification this idea was introduced by Langer [27] and Caginalp [7]. Caginalp and Fife [8] used asymptotic expansions to relate the phase field models

proposed by Langer to classical free boundary problems in the sharp interface limit. This relation has also been rigorously established for some cases (see, for example, [38, 41] and the references therein).

Since the original phase field model is not derived from thermodynamical principles, a number of so-called thermodynamically consistent phase field models were proposed in the 1990s (see Penrose and Fife [34], Alt and Pawlow [2], Wang et al. [44]). All of these models guarantee a positive entropy production.

The classical asymptotics leads to restrictions on parameters which often makes it difficult to perform practical computations of realistic solidification processes. This is particularly true in the regime of small undercooling. In recent years Karma and Rappel [23, 24] (see also [25, 1, 30]) used the so-called thin interface asymptotics to realize numerical simulations in this regime. There, the Gibbs–Thomson equation is approximated to a higher order and the temperature profile in the interfacial region is recovered with a higher accuracy when compared to the classical asymptotics. Further numerical simulations (see [35, 36, 37]) confirm the superiority of this approach in the case of small undercooling.

So far, generalizing this approach to more general situations (see the discussion in [25]) and, in particular, extending the approach to phase field systems handling multiple phases are still an open problem. Therefore, as a first step, we apply classical sharp interface asymptotics to handle general systems with multiple phases and components. The task of making this approach more efficient by the use of thin interface asymptotics is left to further research.

The aim of this paper is to derive a phase field model that

- is thermodynamically consistent,
- allows for an arbitrary number of phases and components,
- is defined solely via the bulk free energies of the individual phases, the surface energy densities (surface entropy densities, respectively) of the interfaces, and diffusion and mobility coefficients, and
- yields classical moving boundary problems in the sharp interface limit.

The third requirement enables us to define the full set of phase field evolution equations by quantities which (in principal) can be measured. Since the bulk free energies determine the phase diagrams (see, e.g., Chalmers [11], Haasen [22]) our model can be used to model phase transitions for arbitrary phase diagrams. We note that in a multi-phase field model computing the surface free energy densities (or surface entropy densities) is difficult. Here one can make use of the studies by Garcke, Nestler, and Stoth [18], in which free energies for phase field methods with good calibration properties have been developed. This means that for given surface free energies (also called surface tensions) one can calibrate the parameters in the free energies of the phase field model in such a way that the sharp interface limit is defined via the given surface tensions. In particular the sharp interface problem is defined with the help of the surface free energies.

In the following section we introduce the phase field model in its full generality and state the corresponding sharp interface model. In section 3 we give examples and relate the model we propose to models already existing in the literature. Furthermore, we discuss a variety of different applications for the new model. Due to its general formulation, the model has the capability to describe phase transformation processes in nonisothermal multicomponent alloys as well as in grain structure evolution. Different phases and different crystal orientations can be distinguished at the same time by an appropriate choice of the phase field variables. This allows us to treat

effects occurring on different length scales such as eutectic grains and interdendritic structures.

Finally, we show in section 4 via formally matched asymptotic expansions that the phase field model yields the sharp interface model in the limit when the interfacial thickness tends to zero.

2. The models. We consider a domain $\Omega \subset \mathbf{R}^d$, $d \in \{1, 2, 3\}$, and we assume that the system has N components with M different phases possible.

2.1. The phase field model. The phase field model is based on an entropy functional of the form

$$S(e, c, \phi) = \int_\Omega \left(s(e, c, \phi) - \left(\varepsilon a(\phi, \nabla\phi) + \frac{1}{\varepsilon} w(\phi) \right) \right) dx. \tag{1}$$

We assume that the bulk entropy density s depends on the internal energy density e, the concentrations of the N components c_i, $1 \le i \le N$, and the phase field variable $\phi = (\phi_\alpha)_{\alpha=1}^M$. The variable ϕ_α denotes the local fraction of phase α, and we require that the concentrations of the components and the phase field variables fulfill the constraints

$$\sum_{i=1}^N c_i = 1, \quad \sum_{\alpha=1}^M \phi_\alpha = 1. \tag{2}$$

It will be convenient to use the free energy as a thermodynamical potential. We therefore postulate the Gibbs relation

$$df = -s dT + \sum_i \mu_i dc_i + \sum_\alpha r_\alpha d\phi_\alpha \tag{3}$$

(see Alt and Pawlow [3], who show that the Gibbs relation is a consequence of the entropy principle). Here, T is the temperature, $\mu_i = f_{,c_i}$ are the chemical potentials, and $r_\alpha = f_{,\phi_\alpha}$ are potentials due to the appearance of different phases.

We set

$$e = f + sT, \tag{4}$$

and hence

$$de = Tds + \sum_i \mu_i dc_i + \sum_\alpha r_\alpha d\phi_\alpha, \tag{5a}$$

$$ds = \frac{1}{T} de - \sum_i \frac{\mu_i}{T} dc_i - \sum_\alpha \frac{r_\alpha}{T} d\phi_\alpha. \tag{5b}$$

If we interpret s as a function of (e, c, ϕ), then we have

$$s_{,e} = \frac{1}{T}, \quad s_{,c_i} = \frac{-\mu_i}{T}, \quad s_{,\phi_\alpha} = \frac{-r_\alpha}{T}.$$

Later it will be convenient to switch among the variables (T, c, ϕ), (e, c, ϕ), (T, μ, ϕ), and $(-\frac{1}{T}, \frac{1}{T}\mu, \phi)$, and we therefore assume for the rest of this paper that

- $c \mapsto f(T, c, \phi)$ is strictly convex,
- $T \mapsto f(T, c, \phi)$ is strictly concave.

This will make the above exchanges of variables possible.

We note that given the free energy densities of the pure phases, we obtain the total free energy as a suitable interpolation of the free energies f_α, i.e., such that $f(T, c, e_\alpha) = f_\alpha(T, c)$, with e_α being the αth coordinate vector.

So far we have neglected interfacial effects. The thermodynamics of the interface gives additional contributions to entropy and free energy. Let us first consider how interfacial contributions are accounted for in a sharp interface model. Let $\Gamma_{\alpha\beta}$ denote an interface between phases α and β and let $\nu_{\alpha\beta}$ denote the unit normal at $\Gamma_{\alpha\beta}$ pointing into the β-phase. Then in sharp interface models an interfacial term

$$-\sum_{\substack{\alpha<\beta\\ \alpha,\beta=1}}^{M} \int_{\Gamma_{\alpha\beta}} \gamma_{\alpha\beta}(\nu_{\alpha\beta}) d\mathcal{H}^{d-1} \tag{6}$$

with a positive function $\gamma_{\alpha\beta}$ on S^{d-1} is added to the entropy (see [29], [43]). The notation $d\mathcal{H}^{d-1}$ indicates integration with respect to the $(d-1)$-dimensional surface measure.

In diffuse interface models the surface entropy functional (6) is replaced by a Ginzburg–Landau type functional of the form

$$-\int_\Omega \left(\varepsilon a(\phi, \nabla\phi) + \frac{1}{\varepsilon} w(\phi) \right) dx. \tag{7}$$

Here, a is the gradient energy density which is assumed to be homogeneous of degree two in the second variable; i.e.,

$$a(\phi, \eta X) = \eta^2 a(\phi, X) \quad \forall (\phi, X) \in \mathbf{R}^M \times \mathbf{R}^{d\times M} \text{ and } \forall \eta \in \mathbf{R}^+,$$

and w is a nonconvex function with exactly M global minima at the points $e_\beta = (\delta_{\alpha,\beta})_{\alpha=1}^M$, $1 \le \beta \le M$, with $w(e_\alpha) = 0$. It has been shown under appropriate assumptions on a that the functional (7) converges to the perimeter functional (6) when ε converges to zero. We refer to [18], [19] and section 3 for appropriate choice of a and w. We assume in this paper that a and w and, hence, the interfacial contributions to the entropy, do not depend on (T, c), but these dependences can be included, leading to a much more complicated model.

Our goal is to derive balance equations,

$$\partial_t e = -\nabla \cdot J_0 \qquad \text{(energy balance)}, \tag{8a}$$

$$\partial_t c_i = -\nabla \cdot J_i \qquad \text{(mass balances, } i = 1, \dots, N), \tag{8b}$$

that are coupled to

$$\partial_t \phi_\alpha = \textit{right-hand side (RHS)} \tag{8c}$$

in such a way that the second law of thermodynamics is fulfilled in an appropriate local version. Here, J_0 is the energy flux and $J_1, \dots, J_N$ are the fluxes of the components $c_1, \dots, c_N$. In order to derive appropriate expressions for the fluxes $J_0, \dots, J_N$, we use the generalized thermodynamic potentials (compare (5b)) $\frac{\delta S}{\delta e} = \frac{1}{T}$ and $\frac{\delta S}{\delta c_i} = \left(\frac{-\mu_i}{T}\right)$, which will drive the evolution. Now we appeal to nonequilibrium thermodynamics and postulate that the fluxes are linear functions of the thermodynamic driving forces

$\nabla\frac{\delta S}{\delta e}, \nabla\frac{\delta S}{\delta c_1}, \ldots, \nabla\frac{\delta S}{\delta c_N}$ to obtain

$$J_0 = L_{00}(T,c,\phi)\nabla\frac{\delta S}{\delta e} + \sum_{j=1}^{N} L_{0j}(T,c,\phi)\nabla\frac{\delta S}{\delta c_j}$$

$$= L_{00}(T,c,\phi)\nabla\frac{1}{T} + \sum_{j=1}^{N} L_{0j}(T,c,\phi)\nabla\frac{-\mu_j}{T}, \tag{9a}$$

$$J_i = L_{i0}(T,c,\phi)\nabla\frac{\delta S}{\delta e} + \sum_{j=1}^{N} L_{ij}(T,c,\phi)\nabla\frac{\delta S}{\delta c_j}$$

$$= L_{i0}(T,c,\phi)\nabla\frac{1}{T} + \sum_{j=1}^{N} L_{ij}(T,c,\phi)\nabla\frac{-\mu_j}{T} \tag{9b}$$

with mobility coefficients

$$(L_{ij})_{i,j=0,\ldots,N}.$$

To fulfill the constraint $\sum_{i=1}^{N} c_i = 1$ during the evolution, we assume

$$\sum_{i=1}^{N} L_{ij} = 0, \qquad j = 0,\ldots,N, \tag{10}$$

which implies $\sum_{i=1}^{N} J_i = 0$, and, hence, $\partial_t(\sum_{i=1}^{N} c_i) = \nabla\cdot(\sum_{i=1}^{N} J_i) = 0$. We further assume that L is symmetric (Onsager relations). In addition, L is assumed to be positive semidefinite; i.e.,

$$\sum_{i,j=0}^{N} L_{ij}\xi_i\xi_j \geq 0 \qquad \forall \xi = (\xi_0,\ldots,\xi_N) \in \mathbf{R}^{N+1}. \tag{11}$$

This condition will later ensure that an entropy inequality is satisfied. We note that we include cross effects between mass and energy diffusion in the model. One can neglect them by setting $L_{i0} = 0$ and $L_{0j} = 0$ for all $i,j \in \{1,\ldots,N\}$.

For the nonconserved phase field variables $\phi_1,\ldots,\phi_M$, we assume that the evolution is such that the system locally tends to maximize entropy conserving concentration and energy at the same time. Therefore we postulate

$$\begin{aligned} \omega\varepsilon\partial_t\phi_\alpha &= \frac{\delta S}{\delta\phi_\alpha} - \lambda \\ &= \varepsilon\big(\nabla\cdot a_{,X_\alpha}(\phi,\nabla\phi) - a_{,\phi_\alpha}(\phi,\nabla\phi)\big) - \frac{1}{\varepsilon}w_{,\phi_\alpha}(\phi) - \frac{f_{,\phi_\alpha}}{T} - \lambda, \end{aligned} \tag{12}$$

where we denote with $a_{,X_\alpha}$ the derivative with respect to the variables corresponding to $\nabla\phi_\alpha$. ω is (in this paper) a constant kinetic coefficient and λ is an appropriate Lagrange multiplier such that the constraint $\sum_{\alpha=1}^{M}\phi_\alpha = 1$ is satisfied; i.e.,

$$\lambda = \frac{1}{M}\sum_{\alpha}\left[\varepsilon\left(\nabla\cdot a_{,X_\alpha} - a_{,\phi_\alpha}\right) - \frac{1}{\varepsilon}w_{,\phi_\alpha} - \frac{f_{,\phi_\alpha}}{T}\right]. \tag{13}$$

Relevant for the dynamics are the variational derivatives of S that take the constraints (2) into account. We can therefore reformulate (9b) and (12) in terms of

the projection of $(\frac{\delta S}{\delta e}, \frac{\delta S}{\delta c_j}, \frac{\delta S}{\delta \phi_\alpha})$ onto the tangent space of the linear subspace whose elements satisfy the constraints. Defining

$$\Sigma^K = \{d \in \mathbf{R}^K : \quad \sum_{k=1}^{K} d_k = 1\},$$

and its tangent space

$$T\Sigma^K = \{d \in \mathbf{R}^K : \quad \sum_{k=1}^{K} d_k = 0\},$$

the constraints (2) read as $c \in \Sigma^N$ and $\phi \in \Sigma^M$. In the following, P^K will denote the projection onto $T\Sigma^K$. Then the relevant quantities for the definition of the fluxes are

$$\left(P^N\Big(-\frac{1}{T}\mu\Big)\right)_i = -\frac{1}{T}\left(\mu_i - \frac{1}{N}\sum_j \mu_j\right) = -\frac{1}{T}\frac{1}{N}\sum_j(\mu_i - \mu_j),$$

whereas there are no changes to $\frac{\delta S}{\delta e}$. We note that the quantities

$$\overline{\mu}_i = \frac{1}{N}\sum_j(\mu_i - \mu_j)$$

can be interpreted as generalized chemical potential differences. For two components we obtain $\overline{\mu}_1 = (\mu_1 - \mu_2)/2$, i.e., the usual chemical potential difference multiplied by the factor $1/2$.

With the above notation we can rewrite the fluxes as

$$J_0 = L_{00}(T,c,\phi)\nabla\frac{1}{T} + \sum_{j=1}^{N} L_{0j}(T,c,\phi)\nabla\frac{-\bar{\mu}_j}{T},$$

$$J_i = L_{i0}(T,c,\phi)\nabla\frac{1}{T} + \sum_{j=1}^{N} L_{ij}(T,c,\phi)\nabla\frac{-\bar{\mu}_j}{T}.$$

Similarly we can rewrite (12) as

$$\omega\varepsilon\partial_t\phi = P^M\left[\varepsilon\big(\nabla\cdot a_{,X}(\phi,\nabla\phi) - a_{,\phi}(\phi,\nabla\phi)\big) - \frac{1}{\varepsilon}w_{,\phi}(\phi) - \frac{f_{,\phi}}{T}\right].$$

Altogether the total entropy density is given by

$$\text{bulk entropy} + \text{surface entropy} = s(e,c,\phi) - \left(\varepsilon a(\phi,\nabla\phi) + \frac{1}{\varepsilon}w(\phi)\right),$$

and a straightforward computation shows (setting $\mu_0 = -1$)

$$\begin{aligned}
\partial_t(\text{entropy}) &= \partial_t\left(s(e,c,\phi) - \varepsilon a(\phi,\nabla\phi) - \frac{1}{\varepsilon}w(\phi)\right)\\
&= \sum_{i,j=0}^{N}\nabla\frac{-\mu_i}{T}\cdot L_{ij}\nabla\frac{-\mu_j}{T} - \nabla\cdot\left(\sum_{i,j=0}^{N}\frac{-\mu_i}{T}L_{ij}\nabla\frac{-\mu_j}{T}\right)\\
&\quad + \omega\varepsilon\sum_\alpha\left(\partial_t\phi_\alpha\right)^2 - \varepsilon\sum_\alpha\nabla\cdot\left(a_{,X_\alpha}\partial_t\phi_\alpha\right)\\
&\geq -\nabla\cdot\left(\sum_{i=0}^{N}\frac{-\mu_i}{T}J_i - \varepsilon\sum_{\alpha=1}^{M}a_{,X_\alpha}\partial_t\phi_\alpha\right).
\end{aligned}$$

The above inequality shows that the local entropy production is positive where the entropy flux J_s is given by

$$J_s = \sum_{i=0}^{N} \left(\frac{-\mu_i}{T} J_i \right) - \varepsilon \sum_{\alpha=1}^{M} a_{,p_\alpha} \partial_t \phi_\alpha. \tag{14}$$

The first term represents the entropy flux due to mass and energy diffusion, and the second one is due to moving phase boundaries (compare [2]). We refer to Alt and Pawlow [3], who show that for conserved phase fields (they call them order parameters) either the energy flux or the entropy flux has to depend on $\partial_t \phi$ in order to describe phase transitions.

2.2. The sharp interface model. In section 4 we use the method of asymptotic expansions to relate the phase field model of the previous subsection to the sharp interface model which we state in the following. We obtain that when the domain Ω is separated in phase regions $\Omega_1,\ldots,\Omega_M$ occupied by the pure phases $1,\ldots,M$ such that in every phase Ω_α, $\alpha = 1,\ldots,M$, the following evolution equations hold:

$$\partial_t e^\alpha = -\nabla \cdot \left(L^\alpha_{00}(T^\alpha, c^\alpha)\, \nabla \frac{1}{T^\alpha} - \sum_{j=1}^{N} L^\alpha_{0j}(T^\alpha, c^\alpha)\, \nabla \frac{\mu^\alpha_j}{T^\alpha} \right) \quad \text{(energy balance)}, \tag{15}$$

$$\partial_t c^\alpha_i = -\nabla \cdot \left(L^\alpha_{i0}(T^\alpha, c^\alpha)\, \nabla \frac{1}{T^\alpha} - \sum_{j=1}^{N} L^\alpha_{ij}(T^\alpha, c^\alpha)\, \nabla \frac{\mu^\alpha_j}{T^\alpha} \right) \forall i \ \text{(mass balances)}. \tag{16}$$

These equations can be formulated in the variables (T, μ) (in which case the internal energy e^α and the concentrations c^α are given as $e^\alpha = e^\alpha(T^\alpha, \mu^\alpha)$ and $c^\alpha = c^\alpha(T^\alpha, \mu^\alpha)$) or, more commonly, in the variables (T, c) (in which case the internal energy e^α and the chemical potentials μ^α are given as $e^\alpha = e^\alpha(T^\alpha, c^\alpha)$ and $\mu^\alpha = c^\alpha(T^\alpha, c^\alpha)$).

On a (smooth) boundary $\Gamma_{\alpha\beta}$ between two phases α and β we have (assuming an isotropic surface energy)

$$T^\alpha = T^\beta =: T \qquad \text{(continuity of temperature)}, \tag{17}$$

$$\bar\mu^\alpha_i = \bar\mu^\beta_i =: \bar\mu_i \quad \forall i \qquad \text{(continuity of chemical potentials)}, \tag{18}$$

$$[e]^\beta_\alpha\, v = [J_0]^\beta_\alpha \cdot \nu \qquad \text{(energy balance)}, \tag{19}$$

$$[c_i]^\beta_\alpha\, v = [J_i]^\beta_\alpha \cdot \nu \quad \forall i \qquad \text{(mass balances)}, \tag{20}$$

$$m_{\alpha\beta}\, v = \gamma_{\alpha\beta}\kappa + \frac{[f]^\beta_\alpha - \sum_i \bar\mu_i\, [c_i]^\beta_\alpha}{T} \quad \text{(Gibbs–Thomson relation)}. \tag{21}$$

Here, $\nu = \nu_{\alpha\beta}$ is the unit normal pointing into β, v is the speed of Γ in this direction, and κ is the mean curvature. The quantities

$$\bar\mu^\alpha_i = \mu^\alpha_i - \frac{1}{N} \sum_{j=1}^{N} \mu^\alpha_j = \frac{1}{N} \sum_{j=1}^{N} (\mu^\alpha_i - \mu^\alpha_j), \tag{22}$$

where $\mu^\alpha_i = f^\alpha_{,c_i}(T, c)$ are the generalized chemical potential differences in phase α, and $[\cdot]^\beta_\alpha$ denotes the jump of the quantity in the brackets across the interface. The quantity

$\gamma_{\alpha\beta}$ is the surface entropy density and the relation between the surface entropy and the entropy density in the phase field model is given by

$$\gamma_{\alpha\beta} = \inf_{p} \left\{ 2 \int_{-1}^{1} \sqrt{w(p)} \sqrt{a(p, p' \otimes \nu)} \right\}, \tag{23}$$

where the infimum is taken over all Lipschitz continuous functions p connecting the minima of w corresponding to the phases adjacent to the interface, i.e., $p(-1) = e_\alpha$ and $p(1) = e_\beta$. The kinetic coefficient $m_{\alpha\beta}$ can also be expressed in terms of the minimizer p (see [17]).

In general, a and w might depend on temperature and on the concentrations leading to a temperature- and concentration-dependent surface entropy in the sharp interface limit. In this case, the surface terms would also enter the internal energy.

For a thin interface analysis of a partially linearized model for pure substances we refer to [30]. Performing a thin interface analysis for our model would require studying higher order corrections of fields like s, f, T, and c in the interface region. We do not pursue this issue further at this stage.

We note that the Gibbs–Thomson equation can be derived by locally maximizing entropy, conserving concentration and energy at the same time. For a stationary flat interface the equations (17), (18), and (21) yield the classical equilibrium for phase boundaries. The equilibrium condition at a flat boundary at rest separating phases α and β is

$$\bar{\mu}_i^\alpha = \bar{\mu}_i^\beta \qquad \text{for all} \quad i = 1, \dots, N.$$

In addition the temperature has to be the same and (see (21))

$$[f]_\alpha^\beta - \sum_i \bar{\mu}_i \, [c_i]_\alpha^\beta = 0.$$

For M phases to be in equilibrium we therefore have $(N+1)(M-1)$ conditions. For each phase we can choose $N-1$ components and the temperature. All together there are

$$MN - (N+1)(M-1) = N - M + 1$$

degrees of freedom. This is the *Gibbs phase rule*. We note that for two component systems the equilibrium conditions between two phases lead to the well-known common tangent construction.

Finally, at triple junctions where three phases α, β, and δ meet, a force balance of the form

$$\gamma_{\alpha\beta}\tau_{\alpha\beta} + \gamma_{\beta\delta}\tau_{\beta\delta} + \gamma_{\delta\alpha}\tau_{\delta\alpha} = 0 \tag{24}$$

has to hold (compare [19]). Here, $\tau_{\alpha\beta}, \tau_{\beta\delta}$, and $\tau_{\delta\alpha}$ are the tangents to the interfaces $\Gamma_{\alpha\beta}, \Gamma_{\beta\delta}$, and $\Gamma_{\delta\alpha}$. All are assumed to either point in the direction of the triple junction or point away from the triple junction at the same time. It can be easily seen that this force balance is equivalent to certain angle conditions at the triple junction.

In the appendix we will demonstrate that the entropy does not decrease for solutions of the above problem. In particular, for a closed system we obtain, using

appropriate transport theorems and assuming $m \geq 0$ and $L = (L_{ij})_{i,j=1,\dots,N}$ is positive semidefinite, the following:

$$\frac{d}{dt}\Big(\int_\Omega s(e,c)dx - \int_\Gamma \gamma d\mathcal{H}^{d-1}\Big) = \int_\Omega \Big(\nabla\frac{1}{T}\cdot J_0 + \sum_i \nabla\frac{-\bar{\mu}_i}{T}\cdot J_i\Big)dx, \\ + \int_\Gamma mv^2 d\mathcal{H}^{d-1} \quad \geq 0,$$

where the integral over Γ is an integral over all possible interfaces.

3. Examples. In this section we will first demonstrate that the phase field method is able to model systems with a very general class of phase diagrams. In the way it is formulated, the model can describe systems with concave entropies $s_\alpha(e,c)$ in the pure phases. This corresponds to free energies $f_\alpha(T,c)$ which are convex in c and concave in T. In the case where $f(T,c)$ is not convex in the variable c, the free energy needs to contain gradients of the concentrations (as in the Cahn–Hilliard model).

We will first give a rather general example, which already covers most examples in practice, and then discuss relations to existing models and possible partial linearizations of the system.

3.1. Possible choices of the free energy. Choosing the phase field ϕ such that $\phi = e_M$ corresponds to the liquid phase, we define bulk free energies for the individual phases by

$$f_\alpha(T,c) = \sum_{i=1}^N \left(c_i L_i^\alpha \frac{T - T_i^\alpha}{T_i^\alpha} + \frac{R}{v_m} T c_i \ln(c_i)\right) - c_v T(\ln(T) - 1)$$

with $L_i^M = 0$, and L_i^α, $i = 1,\dots,N$, $\alpha = 1,\dots,M-1$, being the latent heat per unit volume of the phase transition from phase α to the liquid phase of the pure component i. Furthermore, T_i^α, $i = 1,\dots,N$, $\alpha = 1,\dots,M-1$, is the melting temperature of the ith component in the phase α, and c_v is the specific heat, which is assumed to be independent of c and ϕ; the molar volume v_m is supposed to be a constant, and R is the gas constant. Then we define the total free energy density as follows:

$$f(T,c,\phi) := \sum_{\alpha=1}^M \sum_{i=1}^N \left(c_i L_i^\alpha \frac{T - T_i^\alpha}{T_i^\alpha} h(\phi_\alpha)\right) \\ + \sum_{i=1}^N \left(\frac{R}{v_m} T c_i \ln(c_i)\right) - c_v T(\ln(T) - 1), \tag{25}$$

where h is a monotone function on $[0,1]$ that satisfies $h(0) = 0$ and $h(1) = 1$. Examples are $h(\phi) = \phi$ and $h(\phi) = \phi^2(3 - 2\phi)$. The last one has the property $h'(0) = h'(1) = 0$ which is suitable for phase field models as we will see below. With this choice of h the function f is an interpolation of the individual free energy densities f_α.

We can calculate

$$s = -f_{,T} = -\sum_{\alpha=1}^M \sum_{i=1}^N \left(c_i \frac{L_i^\alpha}{T_i^\alpha} h(\phi_\alpha)\right) - \sum_{i=1}^N \left(\frac{R}{v_m} c_i \ln(c_i)\right) + c_v \ln(T), \tag{26}$$

so that

$$e = f + Ts = -\sum_{\alpha=1}^{M}\sum_{i=1}^{N}(c_i L_i^\alpha h(\phi_\alpha)) + c_v T. \tag{27}$$

We note that if $L_i^\alpha = L^\alpha$ for all components i, then e does not depend on c. The chemical potentials are given as

$$\mu_i(T,c,\phi) = f_{,c_i}(T,c,\phi) = \sum_{\alpha=1}^{M}\left(L_i^\alpha \frac{T-T_i^\alpha}{T_i^\alpha}h(\phi_\alpha)\right) + \frac{R}{v_m}T(\ln(c_i)+1). \tag{28}$$

Expressions for the quantities above in the pure phases are obtained by setting $\phi_\alpha = e_\alpha$. For example, we have

$$\mu_i^\alpha = \partial_{c_i} f_\alpha = \partial_{c_i} f(T,c,e_\alpha) = L_i^\alpha \frac{T-T_i^\alpha}{T_i^\alpha} + \frac{R}{v_m}T(\ln(c_i)+1)$$

for the chemical potential of the ith component in the phase α.

Now we give some examples for the terms modelling interfacial contributions to the free energy. The simplest form of the gradient energy is

$$a(\phi,\nabla\phi) = |\nabla\phi|^2 = \sum_{\alpha=1}^{M}|\nabla\phi_\alpha|^2.$$

However, it has been shown [17, 19, 39] that gradient energies of the form

$$a(\phi,\nabla\phi) = \sum_{\substack{\alpha,\beta=1\\ \alpha<\beta}} A_{\alpha\beta}(\phi_\alpha\nabla\phi_\beta - \phi_\beta\nabla\phi_\alpha),$$

where $A_{\alpha\beta}$ are convex functions that are homogeneous of degree two, are more convenient with respect to the calibration of parameters in the phase field model to the surface terms in the sharp interface model. A choice that leads to isotropic surface terms is

$$a(\phi,\nabla\phi) = \sum_{\alpha<\beta}\frac{\tilde\gamma_{\alpha\beta}}{\tilde m_{\alpha\beta}}|\phi_\alpha\nabla\phi_\beta - \phi_\beta\nabla\phi_\alpha|^2$$

with constants $\tilde\gamma_{\alpha\beta}$ and $\tilde m_{\alpha\beta}$ that can be related to $\gamma_{\alpha\beta}$ and $m_{\alpha\beta}$ in (21) (cf. [17]). For the bulk potential one may take the standard multiwell potential

$$w_{st}(\phi) = 9\sum_{\alpha<\beta}\tilde m_{\alpha\beta}\tilde\gamma_{\alpha\beta}\phi_\alpha^2\phi_\beta^2$$

or a higher order variant

$$\tilde w_{st}(\phi) = w_{st}(\phi) + \sum_{\alpha<\beta<\delta}\gamma_{\alpha\beta\delta}\phi_\alpha^2\phi_\beta^2\phi_\delta^2.$$

For practical computations the multiobstacle potential yields good calibration properties. It is defined by

$$w_{ob}(\phi) = \frac{16}{\pi^2}\sum_{\alpha<\beta}\tilde m_{\alpha\beta}\tilde\gamma_{\alpha\beta}\phi_\alpha\phi_\beta$$

with a higher order variant

$$\tilde{w}_{ob}(\phi) = w_{ob}(\phi) + \sum_{\alpha<\beta<\delta} \gamma_{\alpha\beta\delta}\phi_\alpha\phi_\beta\phi_\delta,$$

where w_{ob} and $\tilde{w}_{ob}$ are defined to be infinity whenever ϕ is not on the Gibbs simplex $G = \{d \in \Sigma^M : d_\alpha \geq 0\}$. We refer to [18] and [19] for a further discussion of the properties of the surface terms.

3.2. Possible choices of the mobility matrix. Here we give an example only for the part of the mobility matrix $(L_{ij})_{i,j=0,\dots,N}$ that defines mass diffusion resulting from chemical potential differences; i.e., we do not specify $L_{i0} = L_{0i}$ for $0 \leq i \leq N$. An example for those terms, which in particular define cross effects between mass and energy diffusion, will be given in section 3.4.

If $l_i(c_i, T, \phi)$ are the nonnegative bare mobilities of the pure components, we can argue as in [4] to obtain

$$L_{ij}(T, c, \phi) = l_i(T, c_i, \phi)\left(\delta_{ij} - \Big(\sum_{q=1}^{N} l_q(T, c_q, \phi)\Big)^{-1} l_j(T, c_j, \phi)\right), \quad 1 \leq i, j \leq N.$$

To give a simple example, we assume that all bare mobilities are the same constant (e.g., $l_i(T, c_i, \phi) = 1$). Hence

$$(L_{ij})_{i,j=1}^N = id - \frac{1}{N}\mathbf{1} \otimes \mathbf{1},$$

where $\mathbf{1} = (1, \dots, 1)$ and $\otimes$ is the tensor product. Often it is more reasonable to assume that the bare mobilities l_i are linear in c_i, and in the simplest case ($l_i(T, c_i, \phi) = c_i$) we obtain

$$(L_{ij})_{i,j=1}^N = (c_i(\delta_{ij} - c_j))_{i,j=1}^N.$$

Choosing a free energy of the form (25) and taking (28) into account, we get the following equations for the concentrations:

$$\begin{aligned}\partial_t c_i = -\nabla \cdot \Bigg[& L_{i0}\nabla\frac{1}{T} + \sum_{j=1}^{N} c_i(\delta_{ij} - c_j)\nabla\Big(- \sum_{\alpha=1}^{M}\left(L_j^\alpha\left(\frac{1}{T_j^\alpha} - \frac{1}{T}\right)h(\phi_\alpha)\right) \\ & - \frac{R}{v_m}(\ln(c_j) + 1)\Big)\Bigg] \\ = \nabla \cdot & \left[L_{i0}\nabla\frac{1}{T} + \sum_{\alpha=1}^{M}\sum_{j=1}^{N} L_{ij}\nabla\Big(L_j^\alpha\left(\frac{1}{T_j^\alpha} - \frac{1}{T}\right)h(\phi_\alpha)\Big)\right] + \frac{R}{v_m}\Delta c_i.\end{aligned}$$

3.3. Relation to the Penrose–Fife model. In this subsection we will demonstrate that our model includes the model of Penrose and Fife [34] as a special case. In this case there is only one component, and we can neglect the variable c. There are two phases, so we will write the equations in terms of the solid fraction $\psi = \phi_1$. Then by (2), $\phi_2 = 1 - \psi$.

The first phase, the solid one, is characterized by $\phi = 1$; hence $\psi = 1$. We assume its free energy density to be

$$f^s = L\frac{T - T_m}{T_m} - c_v T(\ln(T) - 1),$$

where T_m is the melting temperature and L the latent heat of the solid-liquid phase transition. The second phase, the liquid one, is characterized by $\phi = e_2$; therefore $\psi = 0$, and we take the free energy density to be

$$f^l = -c_v T(\ln(T) - 1).$$

We have

$$f(T, \psi) = L\frac{T - T_m}{T_m} h(\psi) - c_v T(\ln(T) - 1);$$

hence

$$s(T, \psi) = -\frac{L}{T_m} h(\psi) + c_v \ln(T)$$

so that $e(T, \psi) = -Lh(\psi) + c_v T$. The evolution equation for the energy density yields

$$c_v \partial_t T - Lh'(\psi)\partial_t \psi = -\nabla \cdot \left(L_{00} \nabla \frac{1}{T} \right).$$

Now we choose $L_{00} = c_v K_2 T^2$, $\lambda(\psi) = Lh'(\psi)/c_v$, and

$$a(\phi, \nabla\phi) = \frac{c}{2}|\nabla\phi|^2 = \frac{c}{2}(|\nabla\phi_1|^2 + |\nabla\phi_2|^2),$$

where $c = \kappa_1 c_v/(2\varepsilon)$ for some constant κ_1. Setting $\omega = 1$, $K_1 = c_v/(2\varepsilon)$ and

$$s_0(\psi) = -\frac{1}{\varepsilon c_v} w(\psi, 1 - \psi) - \frac{L}{c_v T_m} h(\psi).$$

We arrive at the system

$$\begin{aligned} \partial_t \psi &= K_1 \left(\frac{\lambda(\psi)}{T} + s_0'(\psi) + \kappa_1 \Delta\psi \right), \\ \partial_t T - \lambda(\psi)\partial_t \psi &= K_2 \Delta T \end{aligned}$$

which is the model of Penrose and Fife [34, Chapter 6].

3.4. A linearized model. In this subsection we are going to partially linearize our model. This is done in such a way that the evolution equations in the pure phases are linear and they indeed reduce to standard linear diffusion equations. We restrict ourselves to binary systems but a generalization to higher order systems is straightforward.

We denote by $c = c_1$ the concentration of the first component; therefore $c_2 = 1 - c$. Using that L is symmetric and the algebraic constraints (10), we obtain

$$L_{01} = L_{10} = -L_{02} = -L_{20} \qquad \text{and} \qquad L_{11} = L_{22} = -L_{12} = -L_{21}.$$

Furthermore, we introduce the chemical potential difference

$$\mu = f_{,c} = f_{,c_1} - f_{,c_2} = \mu_1 - \mu_2.$$

Then the conservation laws for energy and concentration read (up to a factor 2 in the last term of the right-hand sides)

$$\partial_t e = -\nabla \cdot L_{00} \nabla \frac{1}{T} - \nabla \cdot L_{10} \nabla \frac{-f_{,c}}{T}, \tag{29}$$

$$\partial_t c = -\nabla \cdot L_{10} \nabla \frac{1}{T} - \nabla \cdot L_{11} \nabla \frac{-f_{,c}}{T}. \tag{30}$$

Choosing

$$L_{11} = D\frac{T}{f_{,cc}}, \quad L_{10} = L_{01} = e_{,c} D \frac{T}{f_{,cc}}, \quad \text{and} \quad L_{00} = e_{,c}^2 D \frac{T}{f_{,cc}} + KT^2,$$

the system (29)–(30) reduces to

$$\partial_t e = \nabla \cdot \left(K \nabla T + e_{,c} D \nabla c + e_{,c} D \frac{f_{,c\phi}}{f_{,cc}} \nabla \phi \right), \tag{31}$$

$$\partial_t c = \nabla \cdot \left(D \nabla c + D \frac{f_{,c\phi}}{f_{,cc}} \nabla \phi \right). \tag{32}$$

Here K and D are coefficients that may depend on ϕ. Equations (31) and (32) then have to be coupled to the phase field system (12).

We assume as in (27) that the internal energy density is affine linear in the variables (T, c). Then the system (31)–(32) reduces in regions where ϕ is constant, i.e., in the pure phases, to (here K and D are constants)

$$c_v \partial_t T = \nabla \cdot K \nabla T = K \Delta T, \quad \partial_t c = \nabla \cdot D \nabla c = D \Delta c.$$

Here c_v is the specific heat. These are classical linear diffusion equations for temperature (Fourier's law) and concentration (Fick's law).

3.5. Relation to the Caginalp model. If we further linearize the system it can be seen that our model leads to a generalization of the original phase field model [7] to the case of alloy solidification. We consider a three-phase system for a binary alloy. We choose the free energy density

$$f(T, c, \phi) = \Big(\kappa \frac{c}{2} - \sum_{\alpha=1}^{3} L_1^\alpha \phi_\alpha \Big) cT - c_v T(\ln(T) - 1) - \sum_{\alpha=1}^{3} L_2^\alpha \phi_\alpha,$$

where L_2^α are latent heat coefficients and L_1^α and κ, respectively, are coefficients entering the chemical potentials. Then we get

$$\begin{aligned} s &= -f_{,T} = -\Big(\kappa \frac{c}{2} - \sum_{\alpha=1}^{3} L_1^\alpha \phi_\alpha \Big) c + c_v \ln(T), \\ e &= f + Ts = c_v T - \sum_\alpha L_2^\alpha \phi_\alpha, \\ \frac{\mu}{T} &= \frac{f_{,c}}{T} = \kappa c - \sum_\alpha L_1^\alpha \phi_\alpha, \\ \frac{r_\alpha}{T} &= \frac{f_{,\phi_\alpha}}{T} = -L_1^\alpha c - \frac{L_2^\alpha}{T}. \end{aligned}$$

Choosing the mobility matrix as in the previous subsection we obtain

$$\partial_t e = \partial_t \Big(c_v T - \sum_\alpha L_2^\alpha \phi_\alpha \Big) = \nabla \cdot (K \nabla T),$$
$$\partial_t c = \nabla \cdot D \nabla \Big(\kappa c - \sum_\alpha L_1^\alpha \phi_\alpha \Big).$$

For the gradient energy we take the isotropic function $a(\phi, \nabla\phi) = \frac{1}{2}\sum_\alpha |\nabla\phi_\alpha|^2$. Then the equations for the phase field variables are

$$\omega\varepsilon\partial_t\phi_\alpha = \varepsilon\Delta\phi_\alpha - \frac{1}{\varepsilon} w_{,\phi_\alpha}(\phi) + L_1^\alpha c + \frac{L_2^\alpha}{T} - \lambda,$$

where λ is the Lagrange multiplier (13). Now we linearize the term $\frac{1}{T}$ in the above equation around a temperature T_m to obtain

$$\omega\varepsilon\partial_t\phi_\alpha = \varepsilon\Delta\phi_\alpha - \frac{1}{\varepsilon} w_{,\phi_\alpha}(\phi) + L_1^\alpha c + L_2^\alpha \left(\frac{1}{T_m} - \frac{1}{T_m^2}(T - T_m) \right) - \lambda.$$

The equations for (T, c) are linear and all terms in the equation for ϕ are linear except for the term $w_{,\phi_\alpha}$. A complete linearization cannot be expected because systems with moving interfaces can never be linear, as can be easily seen for the sharp interface model.

Finally, we note that this simplification of the model leads to a linearized phase diagram; in particular, the magnitude of the jump of the concentration in the sharp interface model is constant for each of the phase boundaries.

3.6. Fields of application. In this paragraph, we comment on the generality of the presented phase field model, on the new features, and on the various different applications to solidification processes, microstructure formation, and polycrystalline grain growth. With the phase field model set up for an arbitrary number of alloy components and phases in a nonisothermal system, the set of governing equations is able to describe the coupled heat and mass diffusion processes as well as the phase transformations in multicomponent systems. Due to the flexibility to choose parameters in the gradient and in the potential free energy, the model consists of enough degrees of freedom to prescribe the physics of each phase boundary and interface separately by defining values for appropriate surface energies $\tilde{\gamma}_{\alpha\beta}$ and for the mobilities $\tilde{m}_{\alpha\beta}$. The model allows for both kinetic and surface energy anisotropies. Different types of anisotropy such as smooth and crystalline expressions corresponding to Wulff shapes with a different number of vertices can be realized in three dimensions. Considering the application point of view, the effect of the type and strength of anisotropy on the growth structure can be investigated. Examples of experimentally observed anisotropic characteristics in eutectic systems are tilted or spiral phase formations and the growth of neighboring eutectic grains.

The phase field variables ϕ_α can represent different phases and different grains of orientational variants at the same time. Therefore, phenomena such as eutectic grain formation involving different length scales (grains on the larger scale and a eutectic structure on a smaller scale) and interpretations of the nonconserved order parameters can be described using the new model. A main focus of application in future development is the two- and three-dimensional numerical simulation of solidification in multicomponent alloy systems with arbitrary phase diagrams. By choosing the

specific thermodynamical quantities—the latent heats of fusion L_i^α and the melting temperatures T_i^α—and by inserting these data as input parameters for the numerical simulations, different types of phase transformations, such as peritectics, eutectics, and monotectics, are modelled. In particular, the stability of ternary eutectic lamellae with phase arrays of different period length and phase permutations will be investigated by phase field simulations in a forthcoming paper. The results of computed structures are compared with a generalization of the classical Jackson–Hunt theory for ternary eutectics. The occurrence of a ternary phase impurity leads to the formation of eutectic colonies. The resulting complex structure is of multiscale type and can also be modelled with the new approach.

4. Relating the models by asymptotic expansions. By matched asymptotic expansions we want to establish the relation between the phase field model and the sharp interface model that were described in section 2. We are going to generalize methods developed by Caginalp and Fife [8], Bronsard, Garcke, and Stoth [6], Garcke and Novick-Cohen [20], and Garcke, Nestler, and Stoth [17]. We restrict ourselves to two space dimensions, i.e., $d = 2$, but generalizations are possible.

Since the quantities $(T, \bar{\mu})$ are continuous across a phase boundary it will be convenient to use them in the asymptotic expansions. More precisely we will use the variables ϕ and $u = (\frac{-1}{T}, \frac{\bar{\mu}_1}{T}, \dots, \frac{\bar{\mu}_N}{T})$. Since $f(T, \cdot, \phi)$ is strictly convex and $f(\cdot, c, \phi)$ is strictly concave, we obtain that the mappings

$$(T, c, \phi) \mapsto (u, \phi) \quad \text{and} \quad (e, c, \phi) \mapsto (u, \phi)$$

are both invertible and an exchange of variables between these quantities is possible.

We will use the variables (u, ϕ) in the asymptotics but the equations can always be reinterpreted with respect to the variables (T, c, ϕ) or (e, c, ϕ). We write the conservation laws as

$$\partial_t c_i(u, \phi) = \nabla \cdot \sum_{j=0}^{N} L_{ij}(u, \phi) \nabla u_j, \quad 0 \le i \le N,$$

where we have set $c_0 = e$.

The phase field equations are

$$\omega \varepsilon \partial_t \phi = P^M \Big[\varepsilon \big(\nabla \cdot a_{,X}(\phi, \nabla\phi) - a_{,\phi}(\phi, \nabla\phi) \big) - \frac{1}{\varepsilon} w_{,\phi}(\phi) + u_0 f_{,\phi}(T(u, \phi), c(u, \phi), \phi) \Big].$$

We assume that the matrix $L = (L_{ij})_{i,j=0}^N$ is strictly positive definite for all arguments on the space

$$H^N := \Big\{ d = (d_i)_{i=0}^N \in \mathbf{R}^{N+1} : \sum_{i=1}^{N} d_i = 0 \Big\} = \mathbf{R} \times T\Sigma^N.$$

In addition, we will frequently make use of the fact that a is homogeneous of degree two in the variable X. In particular, we have (cf. [17])

$$a_{,X}(\phi, \eta X) : X = 2\eta a(\phi, X), \tag{33}$$

$$a_{,\phi}(\phi, \eta X) : X = \eta^2 a_{,\phi}(\phi, X), \tag{34}$$

$$a(\phi, 0) = 0, \tag{35}$$

$$a_{,X}(\phi, 0) = 0. \tag{36}$$

4.1. Outer expansion. We expect, based on experiences from numerical simulations, that several phases arise which are separated by diffuse interfaces whose thickness is of order ε. We will see that these phases correspond to the M minima of the potential w. In such a phase, away from an interface to another phase, we consider an outer expansion in the bulk region. For a function b in (t,x) we present the ansatz

$$b_{out}(t,x) = \sum_{K=0}^{\infty} \varepsilon^K b_{out}^K(t,x). \tag{37}$$

In this way we expand the variables u_j and ϕ_α, $0 \le j \le N$, $1 \le \alpha \le M$. For the constraints $\phi \in \Sigma^M$ and $u \in H^N$ to be satisfied we assume

$$\begin{aligned} &\phi_{out}^0 \in \Sigma^M, \quad \phi_{out}^K \in T\Sigma^M, \quad K \ge 1, \\ &u_{out}^K \in H^N, \quad K \ge 0. \end{aligned}$$

First we consider the equation for the phase field variables. We expand $P^M w_{,\phi}(\phi)$ as

$$P^M w_{,\phi}(\phi) = P^M w_{,\phi}(\phi_{out}^0) + \varepsilon (P^M w_{,\phi})_{,\phi}(\phi_{out}^0) \cdot \phi_{out}^1 + O(\varepsilon^2).$$

To leading order $O(\varepsilon^{-1})$ the equation (12) becomes

$$0 = P^M w_{,\phi}(\phi_{out}^0) = w_{,\phi}(\phi_{out}^0) - \frac{1}{M} \left(\sum_{\alpha=1}^{M} w_{,\phi_\alpha}(\phi_{out}^0) \right) \mathbf{1}. \tag{38}$$

As we are searching for stable solutions for this equation, ϕ_{out}^0 is one of the base vectors $\{e_\beta\}_{1 \le \beta \le M}$. We can conclude that to leading order the whole domain Ω is partitioned into phases which are characterized by the M possible values of ϕ_{out}^0.

The $O(1)$-equations for the conserved variables are $(0 \le i \le N)$

$$\partial_t c_i(u_{out}^0, \phi_{out}^0) = \nabla \cdot \sum_{j=0}^{N} L_{ij}(u_{out}^0, \phi_{out}^0) \nabla u_{j,out}^0. \tag{39}$$

Boundary conditions for these equations will be obtained by matching with the inner expansion. One should note that we have expanded the coefficients L_{ij} in $(u_{out}^0, \phi_{out}^0)$ in the same way as $P^M w_{,\phi}$ in ϕ_{out}^0. In phase α, i.e., at points where $\phi_{out}^0 = e_\alpha$, we write $L_{ij}^\alpha(u) = L_{ij}(u, e_\alpha)$. Then the $O(1)$-equations become

$$\partial_t c_i(u_{out}^0, e_\alpha) = \nabla \cdot \sum_{j=0}^{N} L_{ij}^\alpha(u_{out}^0) \nabla u_{j,out}^0.$$

Since $c_0 = e$, $u_0 = -\frac{1}{T}$, and $u_j = \frac{\mu_j}{T}$ we obtain (15) and (16). We note that an upper index in (15) and (16) refers to the phase, whereas an upper index in this section refers to the order in the expansion.

4.2. Inner expansion. Now we consider an interfacial region where two phases meet. Without loss of generality we assume that $\phi_{out}^0 = e_1$ in one of the outer regions, denoted by Ω_1, and $\phi_{out}^0 = e_2$ in the other one, denoted by Ω_2. We assume that these two regions are separated by a family $\{\Gamma_t\}_t$ of evolving smooth curves. Let ψ be a smooth function such that $s \mapsto \psi(t,s)$ is an arc-length parametrization of Γ_t. The

unit tangential vector $\tau(t,x)$ on Γ_t in $x=\psi(t,s)$ is given by $\tau(t,x)=\partial_s\psi(t,s)$, and the unit normal $\nu(t,x)$ on Γ_t in $x=\psi(t,s)$ is such that (ν,τ) is positively oriented. We choose the orientation in the parametrization ψ such that ν points into Ω_1.

Since the parametrization is smooth, it is possible to introduce new space coordinates $(z(t,x),s(t,x))$ in a strip S around Γ_t in the following way. We define $r(t,x)=d(x,\Gamma_t)$ to be the signed distance between a point x and Γ_t; i.e., r is positive in Ω_1 and negative in Ω_2. Then the variable z is defined by $z(t,x)=\frac{1}{\varepsilon}r(t,x)$. Let P_t be the projection of S onto Γ_t. Then by the smoothness of Γ_t one can use the strip S narrow enough such that there is exactly one $s(t,x)$ for every $x\in S$ such that $P_t(x)=\psi_t(s)$. The following holds:

$$\begin{aligned}\nabla_x z(t,x)&=\frac{1}{\varepsilon}\nu(t,P_t(x)),\\ \nabla_x s(t,x)&=\tau(t,P_t(x))+O(\varepsilon).\end{aligned}$$

In the new variables (t,z,s) we present for some real function b in (t,x) the ansatz

$$b_{in}(t,x)=\sum_{K=0}^{\infty}\varepsilon^K b_{in}^K(t,z(t,x),s(t,x)). \tag{40}$$

Introducing the notation $\nu(P_t(x))=\nu(t,s(t,x))$ and, similarly, $\tau(P_t(x))=\tau(t,s(t,x))$, we obtain

$$\nabla_x b_{in}(t,z(t,x),s(t,x))=\frac{1}{\varepsilon}[\partial_z b_{in}(t,z,s)]\nu(t,s)+[\partial_s b_{in}(t,z,s)]\tau(t,s)+O(\varepsilon),$$

and for some vector field $\vec{b}$ we have

$$\nabla_x\cdot\vec{b}(t,z(t,x),s(t,x))=\frac{1}{\varepsilon}(\partial_z\vec{b}(t,z,s))\cdot\nu(t,s)+(\partial_s\vec{b}(t,z,s))\cdot\tau(t,s)+O(\varepsilon).$$

Moreover, it follows that

$$\begin{aligned}\partial_t z(t,x)&=\partial_t\frac{1}{\varepsilon}d(x,\Gamma_t)=-\frac{1}{\varepsilon}v(P_t(x)),\\ \partial_t s(t,x)&=-v_\tau(P_t(x))+O(\varepsilon),\end{aligned}$$

where v is the normal velocity and v_τ the tangential velocity. We note that v_τ depends on the parametrization, whereas v is an intrinsic quantity. This leads to

$$\frac{d}{dt}b_{in}^K(t,z(t,x),s(t,x))=\partial_t b_{in}^K(t,z,s)-\frac{1}{\varepsilon}v\partial_z b_{in}^K(t,z,s)-v_\tau\partial_s b_{in}^K(t,z,s)+O(\varepsilon).$$

Now we expand ϕ and u in the variables (t,z,s) and we assume

$$\begin{aligned}&\phi_{in}^0\in\Sigma^M,\quad \phi_{in}^K\in T\Sigma^M,\quad K\geq 1,\\ &u_{in}^K\in H^N,\quad K\geq 1,\end{aligned}$$

to ensure that the constraints on ϕ and u are satisfied. Taking a Taylor expansion of L_{ij} around (u_{in}^0,ϕ_{in}^0) and writing $L_{ij}^{0,in}=L_{ij}(u_{in}^0,\phi_{in}^0)$, we obtain from the conservation laws for mass and energy to lowest order, i.e., $O(\varepsilon^{-2})$,

$$0=\frac{d}{dz}\left(\sum_{j=0}^{N}L_{ij}^{0,in}\partial_z u_{j,in}^0\right),\quad 0\leq i\leq N, \tag{41}$$

where we used that $\partial_z \nu = 0$. Integrating yields

$$L\partial_z u^0_{in} = k \tag{42}$$

for some vector $k \in \mathbf{R}^{N+1}$. Later, the matching with the outer solution will give $k = 0$.

We have

$$\partial_z \nu = 0, \quad \partial_z \tau = 0, \quad \partial_s \tau = \kappa\nu, \quad \partial_s \nu = -\kappa\tau,$$

where κ is the curvature of Γ_t. Concerning the sign of the curvature we note that for a circle of radius r whose normal is outward oriented (with our orientation the tangent is then running counterclockwise) the curvature is $-1/r$.

Hence the $O(\varepsilon^{-1})$-equations of the conserved quantities are

$$\begin{aligned} -v\partial_z c_i(u^0_{in}, \phi^0_{in}) = &-\kappa \left(\sum_{j=0}^{N} L^{0,in}_{ij} \partial_z u^0_{j,in} \right) + \frac{d}{dz} \left(\sum_{j=0}^{N} L^{0,in}_{ij} \partial_z u^1_{j,in} \right) \\ &+ \frac{d}{dz} \left(\sum_{j=0}^{N} ((L_{ij})^{0,in}_{,u} \cdot u^1_{j,in} + (L_{ij})^{0,in}_{,\phi} \cdot \phi^1_{in}) \partial_z u^0_{j,in} \right). \end{aligned} \tag{43}$$

These equations will further simplify when an expression for u^0_{in} has been derived.

Now we consider the equations for the phase field variables. As done in [17] we expand the a-terms in $(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu)$, the w-term in ϕ^0_{in}, and the f-term in (u^0_{in}, ϕ^0_{in}). To leading order $O(\varepsilon^{-1})$ we then obtain the equation

$$0 = \frac{d}{dz} \left(P^M a_{,X}(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu) \right) \nu - P^M a_{,\phi}(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu) - P^M w_{,\phi}(\phi^0_{in}). \tag{44}$$

Multiplying this equation with $\partial_z \phi^0_{in} \in T\Sigma^M$ gives

$$0 = \frac{d}{dz} \left(a_{,X}(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu) : (\partial_z \phi^0_{in} \otimes \nu) - a(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu) - w(\phi^0_{in}) \right). \tag{45}$$

The equation of order $O(1)$ is

$$\begin{aligned} -\omega v \partial_z \phi^0_{in} = &\frac{d}{dz} \left[(P^M a_{,X})_{,\phi} \cdot \phi^1_{in} \right. \\ &\left. + (P^M a_{,X})_{,X} : (\partial_s \phi^0_{in} \otimes \tau + \partial_z \phi^1_{in} \otimes \nu) \right] \nu + \frac{d}{ds} (P^M a_{,X}) \tau \\ &- (P^M a_{,\phi})_{,\phi} \cdot \phi^1_{in} - (P^M a_{,\phi})_{,X} : (\partial_s \phi^0_{in} \otimes \tau + \partial_z \phi^1_{in} \otimes \nu) \\ &- (P^M w_{,\phi})_{,\phi} \cdot \phi^1_{in} + P^M u^0_{0,in} f_{,\phi}(T(u^0_{in}, \phi^0_{in}), c(u^0_{in}, \phi^0_{in}), \phi^0_{in}), \end{aligned} \tag{46}$$

where w and all its derivatives are evaluated in ϕ^0_{in} and a and its derivatives in $(\phi^0_{in}, \partial_z \phi^0_{in} \otimes \nu)$.

4.3. Matching and resulting jump conditions. For some quantity $b(t, x)$ we gave by (37) and (40) expansions in bulk regions, respectively, in a strip around an interface between such regions. Now we want to match these expansions in an overlap domain. We will need the matching conditions of order zero and one. For the outer expansions in Ω_1 and Ω_2 we will use the subscripts b_{out1} and b_{out2}.

We observe that near Γ_t we can express the functions $b^K_{out}(t,x)$ in the variables (t,z,s). By expanding in a Taylor series at the point $(0,s(t,x))$ which corresponds to the boundary point $\psi_t(s(t,x)) \in \Gamma_t$ (remember that $z(t,x) = \frac{1}{\varepsilon} r(t,x)$ and $\partial_r = \nu \cdot \nabla_x$), we obtain

$$\begin{aligned} b^K_{out}(t,x) &= b^K_{out}(t, r(t,x), s(t,x)) \\ &= b^K_{out}(t,0,s(t,x)) + r\partial_r(b^K_{out})(t,0,s(t,x)) + O(r^2) \\ &= b^K_{out}(t,0,s(t,x)) + \varepsilon z(\nabla_x b^K_{out}(t,0,s(t,x)) \cdot \nu(t,0,s(t,x))) + O(\varepsilon^2), \end{aligned}$$

where $b^K_{out}(t,0,s)$ and $\nabla_x b^K_{out}(t,0,s)$ mean the evaluation in $(t, P_t(x))$. We get

$$b_{out}(t,x) = b^0_{out}(t,0,s) + \varepsilon \left(z(\nabla_x b^0_{out}(t,0,s) \cdot \nu(t,s)) + b^1_{out}(t,0,s) \right) + O(\varepsilon^2).$$

Now we consider an intermediate variable $z_\varepsilon = \eta(\varepsilon) z$ for some $z > 0$, where $\eta(\varepsilon)$ is some function in ε in the overlap domain of validity of the two expansions (which we suppose to exist); i.e., $\eta = o(1)$ and $\varepsilon = o(\eta)$. Because of $z = r/\varepsilon$ we have $z_\varepsilon \to \pm\infty$ as $\varepsilon \to 0$.

We substitute the variable z in our expansions by this intermediate variable z_ε and consider their difference; the expansions of u match if, in the limit as $\varepsilon \to 0$, the terms of every order ε^K vanish. For the $O(1)$-terms this means

$$\begin{aligned} 0 &\overset{!}{=} \lim_{\varepsilon \searrow 0} \left(b^0_{out1}(t,0,s) - b^0_{in}(t,z_\varepsilon,s) \right) = \lim_{z_\varepsilon \to \infty} \left(b^0_{out1}(t,0,s) - b^0_{in}(t,z_\varepsilon,s) \right), \\ 0 &\overset{!}{=} \lim_{\varepsilon \nearrow 0} \left(b^0_{out2}(t,0,s) - b^0_{in}(t,z_\varepsilon,s) \right) = \lim_{z_\varepsilon \to -\infty} \left(b^0_{out2}(t,0,s) - b^0_{in}(t,z_\varepsilon,s) \right), \end{aligned}$$

while for the $O(\varepsilon^1)$-terms the matching condition is

$$\begin{aligned} 0 &\overset{!}{=} \lim_{z_\varepsilon \to \infty} \left(z_\varepsilon \nabla_x b^0_{out1}(t,0,s) \cdot \nu(t,s) + b^1_{out1}(t,0,s) - b^1_{in}(t,z_\varepsilon,s) \right), \\ 0 &\overset{!}{=} \lim_{z_\varepsilon \to -\infty} \left(z_\varepsilon \nabla_x b^0_{out2}(t,0,s) \cdot \nu(t,s) + b^1_{out2}(t,0,s) - b^1_{in}(t,z_\varepsilon,s) \right). \end{aligned}$$

First we apply the matching conditions on the functions $u^0_{j,in}$, $0 \le j \le N$, solving the differential equations (42). The assumption on L yields

$$\partial_z u^0_{in} = L^{-1} k.$$

By the matching conditions of order zero, u^0_{in} must be bounded if $|z| \to \infty$. Then the assumption on L necessarily gives $k = 0$ so that u^0_{in} is constant.

Since u^0_{in} is constant, we obtain that $u^0_{out1}(t,0,s) = u^0_{out2}(t,0,s)$ and hence u, and therefore the temperature and the chemical potential differences are in the sharp interface limit continuous across an interface.

Now, due to $\partial_z u^0_{j,in} = 0$, the $O(\varepsilon^{-1})$-equations (44) for the conserved variables simplify to

$$-v \partial_z c_i(u^0_{in}, \phi^0_{in}) = \frac{d}{dz} \left(\sum_{j=0}^{N} L_{ij}(u^0_{in}, \phi^0_{in}) \partial_z u^1_{j,in} \right).$$

Integrating with respect to z from $-\infty$ to ∞ (or, more correctly, integrating from $-R$ to R and then considering the limit as $R \to \infty$) and using that $v(t,s)$ is independent

of z, we obtain

$$v\left[c_i(u^0_{in},\phi^0_{in})\right]^{z\nearrow\infty}_{z\searrow-\infty} = -\left[\sum_{j=0}^{N} L_{ij}(u^0_{in},\phi^0_{in})\partial_z u^1_{j,in}\right]^{z\nearrow\infty}_{z\searrow-\infty}.$$

As has been shown in [8, 6] the matching conditions of order one for the $b^1_{j,in}$ yield

$$\partial_z b^1_{j,in} \to \nabla_x b^0_{j,out1}\cdot\nu \qquad \text{for} \qquad z\to\infty \tag{47}$$

and

$$\partial_z b^1_{j,in} \to \nabla_x b^0_{j,out2}\cdot\nu \qquad \text{for} \qquad z\to-\infty, \tag{48}$$

where the right-hand sides are evaluated in $(t,x)=(t,\psi_t(s))$ or, in the other coordinates, in $(t,r,s)=(t,0,s(t,x))$. In fact, these are the boundary values of $\nabla_x u^0_{j,out\beta}\cdot\nu$, $\beta\in\{1,2\}$, on Γ_t. After matching for the phase field variables ϕ we obtain

$$\begin{aligned}
v[c_i]^1_2 &= v\big(c_i(u^0_{out1},\phi^0_{out1}) - c_i(u^0_{out2},\phi^0_{out2})\big)(t,x)\\
&= v\left[c_i(u^0_{in},\phi^0_{in})\right]^{z\nearrow\infty}_{z\searrow-\infty}\\
&= -\Big(\sum_{j=0}^{N} L^{0,out1}_{ij}\nabla_x u^0_{j,out1} - L^{0,out2}_{ij}\nabla_x u^0_{j,out2}\Big)(t,x)\cdot\nu(t,x)\\
&= \big(J_i(u^0_{out1},\phi^0_{out1}) - J_i(u^0_{out2},\phi^0_{out2})\big)(t,x)\cdot\nu(t,x)\\
&= [J_i]^1_2\cdot\nu.
\end{aligned}$$

We will refer to this fact as the jump condition for the inner energy density $e=c_0$ and the concentrations c_i, $1\le i\le N$.

4.4. Matching and the Gibbs–Thomson relation. In the bulk regions we have $\phi^0_{out\beta}=e_\beta$, $\beta\in\{1,2\}$. Hence for each s, we have to solve equation (44) of second order in z with respect to the boundary conditions e_1 for $z\to\infty$ and e_2 for $z\to-\infty$.

By integrating (45) and using (35), (36) and $w(e_1)=w(e_2)=0$ we obtain

$$0 = a_{,X}(\phi^0_{in},\partial_z\phi^0_{in}\otimes\nu) : (\partial_z\phi^0_{in}\otimes\nu) - a(\phi^0_{in},\partial_z\phi^0_{in}\otimes\nu) - w(\phi^0_{in}).$$

Using (33) we deduce

$$a(\phi^0_{in},\partial_z\phi^0_{in}\otimes\nu) = w(\phi^0_{in}), \tag{49}$$

which is known as equipartition of energy. We set

$$\begin{aligned}
&C^{0,1}_{\alpha\beta}([-1,1],\Sigma^M) =\\
&\left\{p:[-1,1]\to\Sigma^M \mid p \text{ Lipschitz continuous, } p(-1)=e_\alpha \text{ and } p(1)=e_\beta\right\},
\end{aligned} \tag{50}$$

and define the surface entropy for some $e\in\mathbf{R}^n$ to be

$$\gamma_{\alpha\beta}(e) = \inf\left\{2\int_{-1}^{1}\sqrt{w(p)}\sqrt{a(p,p'\otimes e)}(y)dy \mid p\in C^{0,1}_{\alpha\beta}\right\}. \tag{51}$$

As shown in [40, 17], if a minimizer exists for $e = \nu(t,s)$, then a reparametrization of the minimizer fulfills (44) and, in addition,

$$\gamma_{2,1}(\nu) = \int_{-\infty}^{\infty} \left(a(\phi_{in}^0, \partial_z \phi_{in}^0 \otimes \nu) + w(\phi_{in}^0) \right) dz. \tag{52}$$

Now we want to deduce the Gibbs–Thomson law. We multiply the equation (44) for ϕ_{in}^0 by $\partial_z \phi_{in}^1 \in T\Sigma^M$ and the equation (47) for ϕ_{in}^1 by $\partial_z \phi_{in}^0 \in T\Sigma^M$. Observe that we can drop the projections P^M. Then we sum up the two equations and integrate from $-\infty$ to ∞ with respect to z. Some straightforward calculations together with the matching conditions for the boundary values yield the following solvability condition for equation (47):

$$\begin{aligned} -\omega v \int_{-\infty}^{\infty} (\partial_z \phi_{in}^0(z,s))^2 = \frac{d}{ds} \left(\int_{-\infty}^{\infty} a_{,X}(\phi_{in}^0(z,s), \partial_z \phi_{in}^0(z,s) \otimes \nu(s)) \cdot \partial_z \phi_{in}^0(z,s) dz \right) \tau(s) \\ + \int_{-\infty}^{\infty} u_{0,in}^0 f_{,\phi}(T(u_{in}^0, \phi_{in}^0) c(u_{in}^0, \phi_{in}^0), \phi) \cdot \partial_z \phi_{in}^0 dz. \end{aligned} \tag{53}$$

Using that $u_{0,in}^0$ and $\bar{u}_{in}^0 = (u_{1,in}^0, \dots, u_{N,in}^0)$ are independent of z, the last term on the RHS of (53) yields

$$\begin{aligned} &\int_{-\infty}^{\infty} u_{0,in}^0 f_{,\phi}(T_{in}^0, c_{in}^0, \phi_{in}^0) \cdot \partial_z \phi_{in}^0 dz \\ &= \int_{-\infty}^{\infty} \left(\frac{d}{dz} \left(u_{0,in}^0 f(T_{in}^0, c_{in}^0, \phi_{in}^0) \right) - u_{0,in}^0 f_{,c}(T_{in}^0, c_{in}^0, \phi_{in}^0) \cdot \partial_z c_{in}^0 \right) dz \\ &= \int_{-\infty}^{\infty} \left(\frac{d}{dz} \left(u_{0,in}^0 f(T_{in}^0, c_{in}^0, \phi_{in}^0) \right) + \bar{u}_{in}^0 \cdot \partial_z c_{in}^0 \right) dz \\ &= \left[u_{0,in}^0 f(T_{in}^0, c_{in}^0, \phi_{in}^0) + \bar{u}_{in}^0 \cdot c_{in}^0 \right]_{z \searrow -\infty}^{z \nearrow \infty} \\ &=: \left[u_0^0 \left(f(T^0, c^0, \phi^0) - f_{,c}(T^0, c^0, \phi^0) \cdot c^0 \right) \right]_2^1. \end{aligned}$$

Here we use the abbreviation $T_{in}^0 = T(u_{in}^0, \phi_{in}^0)$, $c_{in}^0 = c(u_{in}^0, \phi_{in}^0)$, $T^0 = T(u^0, \phi^0)$, and $c^0 = c(u^0, \phi^0)$. Finally, as $[c^0] \in T\Sigma^N$ we obtain

$$\int_{-\infty}^{\infty} u_{0,in}^0 f_{,\phi}(T_{in}^0, c_{in}^0, \phi_{in}^0) \cdot \partial_z \phi_{in}^0 dz = -\left(\frac{[f^0]_2^1 - \mu^0 \cdot [c^0]_2^1}{T^0} \right)(t,x).$$

Calculating the total derivative of $\gamma_{2,1}$, which becomes with (52)

$$D\gamma_{2,1}(\nu) = \int_{-\infty}^{\infty} a_{,X} \cdot \partial_z \phi_{in}^0 dz,$$

and setting

$$m(\nu) = \omega \int_{-\infty}^{\infty} (\partial_z \phi_{in}^0)^2 dz,$$

we reduce the solvability condition to (writing $\nabla_s \cdot g = (\partial_s g) \cdot \tau$ for the surface divergence of some vector field g on Γ_t)

$$m(\nu) v = -\nabla_s \cdot D\gamma_{2,1}(\nu) + \frac{[f^0]_2^1 - \mu^0 \cdot [c^0]_2^1}{T^0}.$$

Considering ν and γ as functions in an angle $\theta \in [0, 2\pi)$, i.e., setting $\nu(\theta) = (\cos(\theta), \sin(\theta))$ and $\hat{\gamma}(\theta) = \gamma(\nu(\theta))$, one can derive (see [17])

$$\nabla_s \cdot D\gamma_{2,1}(\nu) = -(\hat{\gamma}_{2,1}(\theta) + \hat{\gamma}''_{2,1}(\theta))\kappa$$

with the curvature $\kappa = -\nabla_s \cdot \nu$ which may be inserted into the solvability condition to yield

$$m(\nu)v = (\hat{\gamma}_{2,1}(\theta) + \hat{\gamma}''_{2,1}(\theta))\kappa + \frac{[f^0]_2^1 - \mu^0 \cdot [c^0]_2^1}{T^0}.$$

Finally, the force balance at triple junctions (24) can be derived as in [17]. Therefore, all equations defining the sharp interface model have been derived by asymptotic expansions.

5. Appendix. In this appendix we will show that for the sharp interface model described in section 2 the entropy does not decrease in time. We consider a situation where a bounded domain Ω is partitioned into M phases $\Omega_1(t), \dots, \Omega_M(t)$ which are separated by smooth boundaries $\Gamma_{\alpha\beta}(t) = \overline{\Omega}_\alpha \cap \overline{\Omega}_\beta \cap \Omega$. For simplicity we restrict ourselves to two space dimensions, but the calculations can also be done in higher dimensions.

Given some domain $R(t) \subset \Omega$ with smooth boundary $\partial R(t)$ and a smooth evolving curve $\Gamma(t) \subset \Omega$ with normal velocity v, we will make use of the following transport identities:

$$\frac{d}{dt}\left(\int_{\Gamma(t)} \gamma \, d\mathcal{H}^1\right)\Big|_{t=t_0} = -\int_{\Gamma(t_0)} \gamma\kappa v \, d\mathcal{H}^1 + \sum_{endpoints} \dot{p} \cdot \tau \quad \text{and}$$

$$\frac{d}{dt}\left(\int_{R(t)} u \, dx\right)\Big|_{t=t_0} = \int_{R(t_0)} \partial_t u \, dx + \int_{\partial R(t_0)} uv \, d\mathcal{H}^1(x)$$

for some smooth function $u = u(t, x)$ and some constant γ; κ is the curvature of the interface Γ, and ν is the unit normal. By $\dot{p}$ we denote the velocity of the endpoints of Γ and by τ the exterior tangent vector to $\Gamma(t)$ at the endpoints.

Let the evolution in each phase be given by

$$\partial_t e^q = -\nabla \cdot J_0^q, \quad \partial_t c_i^q = -\nabla \cdot J_i^q, \quad 1 \le i \le N, \quad 1 \le q \le M,$$

with the fluxes given in (15) and (16). We assume that the functions are smooth in their domain Ω_q and that the fluxes vanish at the external boundary of Ω. Observe that $-\partial_t c = \nabla \cdot J \in T\Sigma^N$. Then

$$\begin{aligned}
\frac{d}{dt}\left(\int_{\Omega(t)} s(e,c) \, dx\right)\Big|_{t=t_0} &= \sum_\alpha \int_{\Omega_\alpha(t_0)} \partial_t s(e,c) \, dx - \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} [s]_\alpha^\beta v \, d\mathcal{H}^1 \\
&= \sum_\alpha \int_{\Omega_\alpha(t_0)} \Big(s_{,e}\partial_t e + \sum_i s_{,c_i}\partial_t c_i\Big) \, dx - \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} [s]_\alpha^\beta v \, d\mathcal{H}^1 \\
&= -\sum_\alpha \int_{\Omega_\alpha(t_0)} \left(\frac{1}{T}\nabla \cdot J_0 + \sum_i \frac{-\bar{\mu}_i}{T}\nabla \cdot J_i\right) dx \\
&\quad - \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} [s]_\alpha^\beta v \, d\mathcal{H}^1
\end{aligned}$$

$$= \sum_\alpha \int_{\Omega_\alpha(t_0)} \nabla \frac{1}{T} \cdot J_0 + \sum_i \nabla \frac{-\bar{\mu}_i}{T} \cdot J_i \, dx$$
$$+ \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} \left(\left[\frac{1}{T} J_0 + \sum_i \frac{-\bar{\mu}_i}{T} J_i \right]_\alpha^\beta \cdot \nu - [s]_\alpha^\beta v \right) d\mathcal{H}^1.$$

The fact that L is positive semidefinite leads to

$$\nabla \frac{1}{T} \cdot J_0 + \sum_i \nabla \frac{-\bar{\mu}_i}{T} \cdot J_i \geq 0.$$

In addition, we make use of the continuity conditions (17), (18) and the jump conditions (19), (20) to obtain

$$\frac{d}{dt} \left(\int_{\Omega(t)} s(e,c)\, dx \right) \Big|_{t=t_0} \geq \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} \left(\frac{1}{T} [e]_\alpha^\beta v + \sum_i \frac{-\bar{\mu}_i}{T} [c_i]_\alpha^\beta v - \frac{[Ts]_\alpha^\beta}{T} v \right) d\mathcal{H}^1$$
$$= \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} \frac{[f]_\alpha^\beta - \sum_i \mu_i [c_i]_\alpha^\beta}{T} v \, d\mathcal{H}^1.$$

Furthermore, we have

$$\frac{d}{dt} \left(- \int_{\Gamma_{\alpha\beta}(t)} \gamma_{\alpha\beta}\, d\mathcal{H}^1 \right) \Big|_{t=t_0} = \int_{\Gamma_{\alpha\beta}(t_0)} \gamma_{\alpha\beta} \kappa v \, d\mathcal{H}^1 - \sum_{endpoints} \dot{p} \cdot \tau_{\alpha\beta} \gamma_{\alpha\beta}$$

so that we get

$$\frac{d}{dt} S \Big|_{t=t_0} = \frac{d}{dt} \left(\int_{\Omega(t)} s(e,c)\, dx - \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t)} \gamma_{\alpha\beta}\, d\mathcal{H}^1 \right) \Big|_{t=t_0}$$
$$\geq \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} \left(\frac{[f]_\alpha^\beta - \sum_i \mu_i [c_i]_\alpha^\beta}{T} + \gamma_{\alpha\beta} \kappa \right) v \, d\mathcal{H}^1$$
$$= \sum_{\alpha<\beta} \int_{\Gamma_{\alpha\beta}(t_0)} m(\nu) v^2 \, d\mathcal{H}^1 \geq 0.$$

In the last equality we used the Gibbs–Thomson relation (21), the fact that the mobility coefficient m is supposed to be positive, the force balance at triple junctions (24), and the fact that in a closed system the interfaces intersect the exterior boundary by a 90° angle condition (compare [6] and the references therein).

TRAVELING SOLITONS IN THE DAMPED-DRIVEN NONLINEAR SCHRÖDINGER EQUATION*

I. V. BARASHENKOV† AND E. V. ZEMLYANAYA‡

Abstract. The well-known effect of the linear damping on the moving nonlinear Schrödinger soliton (even when there is a supply of energy via the spatially homogeneous driving) is to quench its momentum to zero. Surprisingly, the zero momentum does not necessarily mean zero velocity. We show that two or more parametrically driven damped solitons can form a complex traveling with zero momentum at a nonzero constant speed.

All traveling complexes we have found so far have turned out to be unstable. Thus, the parametric driving is capable of sustaining the uniform motion of damped solitons, but some additional agent is required to stabilize it.

Key words. traveling waves, nonlinear Schrödinger equation, parametric driving, dissipative solitons, bifurcations

1. Introduction.

The amplitude of a nearly harmonic wave propagating in a nonlinear dispersive medium satisfies a nonlinear Schrödinger equation. Confining ourselves to the generic, cubic nonlinearity of the "focusing" type, the resulting nonlinear Schrödinger equation is of the form

$$i\Psi_t + \Psi_{xx} + 2|\Psi|^2\Psi = -i\gamma\Psi, \quad \gamma > 0. \tag{1.1}$$

The $-i\gamma\Psi$ term in the right-hand side accounts for dissipative losses (which were assumed to be small in the derivation of (1.1)). In the underlying physical system the dissipation is compensated for by pumping the energy into the system, in one way or another. The pumping is modeled by adding a driving term to the right-hand side of (1.1).

Like a simple pendulum, the distributed system can be driven externally or parametrically. The typical form of the corresponding amplitude equation is

$$i\Psi_t + \Psi_{xx} + 2|\Psi|^2\Psi = he^{i\Omega t} - i\gamma\Psi, \tag{1.2}$$

and

$$i\Psi_t + \Psi_{xx} + 2|\Psi|^2\Psi = h\overline{\Psi}e^{2i\Omega t} - i\gamma\Psi, \tag{1.3}$$

respectively. (The overline in the right-hand side of (1.3) indicates complex conjugation.) Both the externally and parametrically driven nonlinear Schrödinger equations

arise in a great variety of physical contexts. In particular, the parametric equation (1.3) describes the nonlinear Faraday resonance in a vertically oscillating water tank [1, 2, 3, 4, 5, 6, 7, 8, 9, 10] and the effect of phase-sensitive amplifiers on solitons in optical fibers [11, 12, 13, 14]. The same equation controls the magnetization waves in an easy-plane ferromagnet placed in a combination of a static and microwave field [15] and the amplitude of synchronized oscillations in vertically vibrated pendula lattices [16, 17, 18, 19, 20].

Both equations (1.2) and (1.3) exhibit soliton solutions [21, 22, 23, 24, 1, 2, 15], stable and unstable [15, 22], which can also form (stable and unstable) multisoliton complexes [25, 26, 27, 28, 29]. All localized solutions that have been found so far were nonpropagating. In fact, it is widely accepted that the nonlinear Schrödinger solitons simply *cannot* travel in the presence of dissipation. This perception is based mainly on the rate equation

$$\dot{P} = -2\gamma P, \tag{1.4}$$

which is straightforward from (1.2) and (1.3). Here P is the total field momentum,

$$P = \frac{i}{2}\int_{-\infty}^{\infty} (\overline{\Psi}_x \Psi - \Psi_x \overline{\Psi}) dx. \tag{1.5}$$

In the undamped case ($\gamma = 0$) the momentum is conserved; however, if $\gamma > 0$, P decays to zero and this seems to suggest that a solitary wave, initially moving with a nonzero velocity, will have to slow down and eventually stop [30].

Another indication that only quiescent solitons are possible in the damped-driven Schrödinger equation comes ostensibly from the singular [2, 31] and inverse scattering-based perturbation theory [21, 32, 33]. Here we should mention, however, that these techniques are well developed only in the one-soliton sector and in the case of several well-separated solitons. They either make use of the smallness of the perturbation in the right-hand sides of (1.2) and (1.3) [2, 21, 32] or utilize an explicit form of the perturbed soliton (to study its stability and bifurcation) [33]. In any case, the resulting finite-dimensional system of equations for the parameters of the soliton and radiation leads to the conclusion that the soliton's velocity has to decay to zero as $t \to \infty$.

Meanwhile, the moving solitary waves could play a significant role in a variety of physical situations modeled by the damped-driven nonlinear Schrödinger equations. Stable traveling waves could compete with nonpropagating localized attractors; unstable ones might arise as long-lived transients and intermediate states in spatiotemporal chaotic regimes. Both types of moving solitary waves could mediate energy dissipation in damped-driven systems. One more reason for not rejecting the unstable solutions outright is their possible persistence within the (directly or parametrically driven) Ginzburg–Landau equations of which the Schrödinger equations (1.2) and (1.3) are special cases [35, 36, 37, 38, 39, 40, 41, 42, 43]. The diffusion and nonlinear damping (the terms $ic_1\Psi_{xx}$ and $-ic_2|\Psi|^{2n}\Psi$, to be added to the right-hand sides of (1.2) and (1.3)) are known to have a stabilizing effect on the Ginzburg–Landau pulses; hence the unstable Schrödinger solitons may gain stability as they are continued to nonzero positive c_1 and c_2.

The purpose of this paper is to show that the damped-driven nonlinear Schrödinger equations do support solitary waves traveling with nonzero velocities. For the demonstration of this fact we confine our study to the *parametrically* driven Schrödinger only. The *externally* driven equation is left as an object of future research.

Two complementary strategies will be pursued to achieve our goal. First, in section 3, we consider the *motionless damped* solitons ($V = 0$, $\gamma \neq 0$) and derive the condition under which they can be continued to nonzero velocity. Having identified values of γ for which this condition is satisfied, we perform the numerical continuation obtaining a branch of solitary waves with nonzero V and γ. Our second approach is presented in section 4; the idea is to continue *undamped traveling* waves ($\gamma = 0$, $V \neq 0$) to nonzero dampings. We show that this is possible only if the traveling wave has zero momentum. For complexes with $P = 0$, we then carry out the numerical continuation in γ. Finally, in section 5 we discuss the consistency of results obtained within these two complementary approaches.

We examined, numerically, the stability of all solutions obtained within both approaches. The general framework of the stability analysis is outlined in section 2. Results of this analysis are presented along with results of the numerical continuation. Section 6 summarizes the conclusions of our study.

2. Mathematical preliminaries. For purposes of this paper we transform equation (1.3) to an autonomous form. First, we normalize the driving frequency Ω to unity; after that, the substitution $\Psi(x,t) = e^{it}\psi(x,t)$ takes (1.3) to

$$i\psi_t + \psi_{xx} + 2|\psi|^2\psi - \psi = h\overline{\psi} - i\gamma\psi. \tag{2.1}$$

This is the representation of the parametrically driven damped nonlinear Schrödinger equation that we are going to work with in this paper. We confine ourselves to uniformly traveling solutions of the form

$$\psi(x,t) = \psi(x - Vt) \equiv \psi(\xi), \tag{2.2}$$

where $\psi(\xi) \to 0$ as $|\xi| \to \infty$. These satisfy an ordinary differential equation,

$$-iV\psi_\xi + \psi_{\xi\xi} + 2|\psi|^2\psi - \psi = h\overline{\psi} - i\gamma\psi. \tag{2.3}$$

The analytical part of this paper deals mainly with identifying those of the previously found solutions of (2.3) with $V = 0$ or $\gamma = 0$ which can be continued in V and γ, respectively. The actual continuation will be carried out numerically. Our numerical method employs a predictor-corrector continuation algorithm with a fourth-order accurate Newtonian solver. Typically, the infinite line was approximated by an interval $(-100, 100)$. The discretization step size was typically 0.005. The numerical residual was set to be 10^{-10}; that is, the grid solution would be deemed accurate if the difference between the left- and right-hand sides in (2.3) were smaller than 10^{-10}.

Along with the continuation of solutions in V and γ, we will be analyzing their stability to small perturbations. To this end, we linearize (2.1) in the comoving frame of reference. Letting $\psi(x,t) = u(\xi) + iv(\xi) + \delta\psi(\xi,t)$, where u and v are the real and imaginary parts of the solution that we are linearizing about, and assuming that the linear perturbation depends on time exponentially,

$$\delta\psi(\xi,t) = e^{\lambda t}\left[\delta u(\xi) + i\delta v(\xi)\right],$$

we arrive at an eigenvalue problem

$$\mathcal{H}_0\,\vec{y} = (\lambda + \gamma)J\,\vec{y}, \tag{2.4}$$

where the operator $\mathcal{H}_0$ is defined by

$$\mathcal{H}_0 = \begin{pmatrix} -\partial_\xi^2 + 1 + h - 6u^2 - 2v^2 & -V\partial_\xi - 4uv \\ V\partial_\xi - 4uv & -\partial_\xi^2 + 1 - h - 6v^2 - 2u^2 \end{pmatrix}, \tag{2.5}$$

the skew-symmetric matrix J is

$$J = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix},$$

and the column vector $\vec{y}(\xi) = (\delta u, \delta v)^T$. The eigenvalue problem (2.4) was solved by expanding δu and δv over a Fourier basis, typically with 500 modes, on the interval $(-50, 50)$.

The last point that we need to touch upon in this preliminary section is the integrals of motion of (1.3), or, more precisely, the quantities which are conserved in the absence of dissipation. When $\gamma = 0$, (1.3) conserves the momentum (given by (1.5) where one only needs to replace $\Psi \to \psi$) and energy,

$$E = \int_{-\infty}^{\infty} (|\psi_x|^2 + |\psi|^2 - |\psi|^4 + h \ \mathrm{Re}\, \psi^2)\, dx. \tag{2.6}$$

In the damped case, the momentum decays according to the rate equation (1.4) while the energy satisfies

$$\dot{E} = 2\gamma \left(\int_{-\infty}^{\infty} |\psi|^4 dx - E \right). \tag{2.7}$$

3. Continuation of damped solitons to nonzero velocities.

3.1. Continuability criterion. Our first strategy is to attempt to continue stationary solutions with nonzero γ to nonzero V. Two basic soliton solutions, denoted ψ_+ and ψ_-, are available explicitly:

$$\begin{aligned} \psi_\pm(x) &= e^{-i\theta_\pm} A_\pm \,\mathrm{sech}\,(A_\pm x)\,, \\ A_\pm &= \sqrt{1 \pm \sqrt{h^2 - \gamma^2}}, \\ \theta_+ = \frac{1}{2} \arcsin \frac{\gamma}{h}, &\quad \theta_- = \frac{\pi}{2} - \theta_+. \end{aligned} \tag{3.1}$$

The two solitons can form a variety of stationary complexes. These are denoted, symbolically, by $\psi_{(++)}$, $\psi_{(--)}$, $\psi_{(+-+)}$, $\psi_{(-+-)}$, and so on [29]. Let $\psi_0(x)$ be a particular complex; we want to find out whether it can be continued in V. Assuming there is a solution $\psi(\xi; V)$ such that $\psi(\xi; 0) \equiv \psi_0(\xi)$ $(= \psi_0(x))$, we expand $\psi(\xi; V)$ in powers of V as

$$\psi(\xi; V) = e^{-i\theta} \big\{ u_0(\xi) + iv_0(\xi) + V[u_1(\xi) + iv_1(\xi)] + V^2[u_2(\xi) + iv_2(\xi)] + \cdots \big\}, \tag{3.2}$$

where the constant phase θ will be chosen at a later stage. We also expand h and γ: $h = h_0 + h_1 V + \cdots$, $\gamma = \gamma_0 + \gamma_1 V + \cdots$. Substituting into (2.3), the order V^1 gives

$$\mathcal{L} \begin{pmatrix} u_1 \\ v_1 \end{pmatrix} = \begin{pmatrix} v_0' \\ -u_0' \end{pmatrix} + \mathcal{B} \begin{pmatrix} u_0 \\ v_0 \end{pmatrix}, \tag{3.3}$$

where the operator $\mathcal{L}$ has the form

$$\mathcal{L} = \begin{pmatrix} -\partial_x^2 + 1 + h_0 \cos 2\theta - 6u_0^2 - 2v_0^2 & \gamma_0 + h_0 \sin 2\theta - 4u_0 v_0 \\ -\gamma_0 + h_0 \sin 2\theta - 4u_0 v_0 & -\partial_x^2 + 1 - h_0 \cos 2\theta - 2u_0^2 - 6v_0^2 \end{pmatrix}, \tag{3.4}$$

the constant matrix $\mathcal{B}$ is given by

$$\mathcal{B} = \begin{pmatrix} -h_1 \cos 2\theta & -\gamma_1 - h_1 \sin 2\theta \\ \gamma_1 - h_1 \sin 2\theta & h_1 \cos 2\theta \end{pmatrix},$$

and the primes over u_0 and v_0 indicate derivatives with respect to x. (In (3.3) and (3.4) we have replaced ξ with x as ξ coincides with x for $V = 0$.) According to Fredholm's alternative, (3.3) has a bounded solution $u_1(x), v_1(x)$ if and only if the vector in the right-hand side is orthogonal to the kernel of the Hermitian-conjugate operator $\mathcal{L}^\dagger$:

$$\int (y, w) \begin{pmatrix} v_0' \\ -u_0' \end{pmatrix} dx + \int (y, w)\, \mathcal{B} \begin{pmatrix} u_0 \\ v_0 \end{pmatrix} dx = 0. \tag{3.5}$$

Here $\vec{y}(x) = (y, w)^T$ is the eigenvector of $\mathcal{L}^\dagger$ associated with the zero eigenvalue: $\mathcal{L}^\dagger \vec{y} = 0$. That the operator $\mathcal{L}^\dagger$ has a zero eigenvalue follows from the fact that the operator $\mathcal{L}$ has one—namely, the translation eigenvalue corresponding to the eigenvector $(u_0', v_0')^T$. Equation (3.5) gives a necessary continuability condition of damped quiescent solitons to nonzero velocities.

3.2. Noncontinuability of the "building blocks." It is quite easy to check that when $\gamma_0 \neq 0$, the individual ψ_+ and ψ_- solitons (the basic "building blocks" of which all complexes are constructed) are *not* continuable to nonzero V. Choosing $\theta = \theta_+$ for the ψ_+ soliton and $\theta = \theta_-$ for the ψ_- (where $\theta_\pm$ are to be computed from the bottom formula in (3.1) with $\gamma = \gamma_0$ and $h = h_0$), we get $v_0(x) = 0$, $\gamma_0 - h_0 \sin 2\theta = 0$ and so the 2×2 matrix $\mathcal{L}$, (3.4), becomes upper triangular. The zero mode of $\mathcal{L}^\dagger$ can now be readily found.

Consider, for instance, the ψ^+ case. The zero mode satisfies

$$\begin{pmatrix} -\partial_x^2 + A_+^2 - 6u_0^2 & 0 \\ 2\gamma_0 & -\partial_x^2 + A_-^2 - 2u_0^2 \end{pmatrix} \begin{pmatrix} y \\ w \end{pmatrix} = 0,$$

and hence $y(x) = u_0'(x)$, and $w(x)$ is found from

$$(-\partial_x^2 + A_-^2 - 2u_0^2) w = -2\gamma u_0'(x). \tag{3.6}$$

Using the explicit expression for $u_0(x)$, $u_0(x) = A_+ \mathrm{sech}(A_+ x)$, the operator in the left-hand side of (3.6) can be written as $A_+^2(L_0 - \epsilon)$, where $\epsilon = 2h_0 \cos(2\theta_+)/A_+^2$, L_0 is given by

$$L_0 = -\partial_X^2 + 1 - 2\mathrm{sech}^2 X,$$

and $X = A_+ x$. The operator L_0 has familiar spectral properties; in particular it has a single discrete eigenvalue $E_0 = 0$ associated with an even eigenfunction $z_0 = \mathrm{sech} X$, while its continuous spectrum occupies the semiaxis $E_k \geq 1$. Consequently, for $0 < \epsilon < 1$ (that is, for $h_0 < \sqrt{1 + \gamma_0^2}$), the operator $L_0 - \epsilon$ is invertible and a bounded solution $w(x)$ of (3.6) exists and is unique. It can be found explicitly, but this is not really necessary for our purposes. All we need to know is that, since L_0 is a parity-preserving operator, $w(x)$ has the same parity as the right-hand side in (3.6), i.e., it is an odd function. For that reason the second integral in (3.5) vanishes and the necessary continuability condition reduces to

$$\gamma \int u_0'(x)(L_0 - \epsilon)^{-1} u_0'(x) dx = 0. \tag{3.7}$$

This quadratic form can be easily evaluated by expanding $u_0'(x)$ over eigenfunctions of the operator L_0:

$$u_0'(x) = \int_{-\infty}^{\infty} U(k) z_k(X) dk,$$

where $L_0 z_k(X) = (1+k^2) z_k(X)$. (The "discrete" eigenfunction $z_0(X)$ does not appear in the expansion as it has the opposite parity to $u_0'(x)$.) Utilizing the orthonormality of the eigenfunctions, the continuability condition (3.7) is transformed into

$$\gamma \int \frac{|U(k)|^2}{k^2 + 1 - \epsilon} dk = 0. \tag{3.8}$$

As $\epsilon < 1$, this condition obviously cannot be satisfied (unless $\gamma = 0$).

In the case of the ψ_- soliton, the analysis is similar. In this case, the continuability condition (3.8) is replaced by

$$\gamma \int \frac{|U(k)|^2}{k^2 + (1-\epsilon)^{-1}} dk = 0,$$

and this cannot be met for the same reason as for (3.8).

3.3. Continuation of the complexes. Turning to the *complexes* of the solitons ψ_+ and ψ_-, the phase of the complex varies with x and therefore the matrix $\mathcal{L}$ cannot be made triangular no matter how we choose the constant θ in (3.2). For this reason, aggravated by the fact that the multisoliton solutions are not available explicitly, the continuability condition (3.5) cannot be verified analytically. Resorting to the help of a computer, we evaluated the eigenfunction $\vec{y}(x)$ associated with the zero eigenvalue of the operator $\mathcal{L}^\dagger$ numerically. (Here we set $\theta = \theta_+$.)

All dissipative soliton complexes found in [29] were symmetric; that is, the corresponding u and v are *even* functions of x. Therefore, the operator $\mathcal{L}^\dagger$, whose potential part is made up of $u(x)$ and $v(x)$, is parity preserving and all its eigenfunctions pertaining to nonrepeated eigenvalues are either even or odd. As we move along a continuous branch of solutions, the parity of the eigenfunction has to change continuously. Since the parity equals either $+1$ (for even functions) or -1 (for odd functions), the only opportunity left to it by the continuity argument is to remain constant on the entire branch. For that reason it is sufficient to determine the parity of the eigenfunction for one specific value of h and then we will know it at all other points. Our numerical calculation shows that the eigenfunction $\vec{y}(x)$ is *odd* on all branches reported in [29]. Consequently, the second term in (3.5) is always zero and we only need to evaluate the first term.

The vanishing of the term involving coefficients h_1 and γ_1 in (3.5) implies that it was not really necessary to expand h and γ in powers of V. This fact has a simple geometric interpretation. As we will see below, for the fixed γ the continuable solutions occur only at isolated values of h and hence they exist only for h and γ lying on continuous curves in the (h, γ)-plane. Each curve results from an intersection of some surface in the three-dimensional (h, γ, V)-space with the $(V = 0)$-plane. The fact that one does not have to alter h and γ when continuing the solution to nonzero V indicates that these surfaces are orthogonal to the $(V = 0)$-plane along their curves of intersection.

Having found the solution $\psi(x) = u(x) + iv(x)$ at representative points along each branch, we obtained the eigenfunction $\vec{y}(x)$ at these points and evaluated what

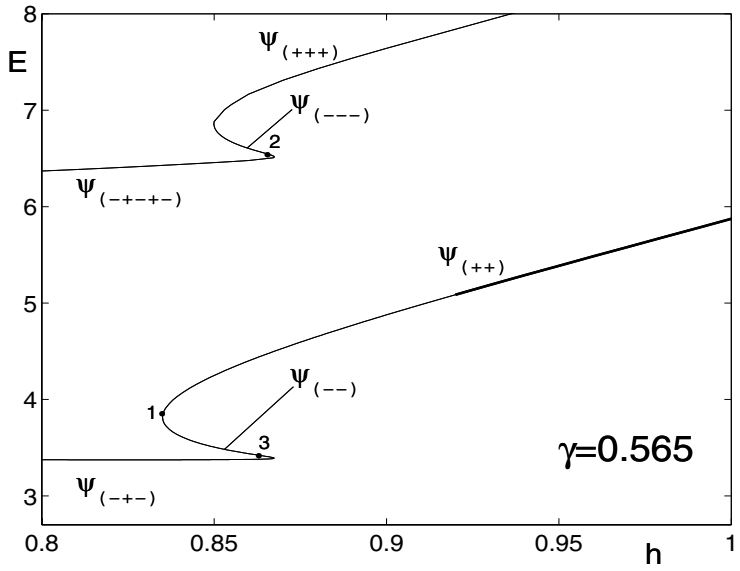

FIG. 3.1. *A fragment of the bifurcation diagram for stationary multisoliton complexes (adapted from* [29]*.) Shown is the energy* (2.6) *of the complex as a function of* h*. The bottom branch pertains to symmetric two-soliton complexes* $\psi_{(++)}$ *and* $\psi_{(--)}$ *and a three-soliton solution* $\psi_{(-+-)}$*; the top branch includes the three-soliton states* $\psi_{(+++)}$ *and* $\psi_{(---)}$*, as well as a five-soliton solution* $\psi_{(-+-+-)}$*. The thick curve corresponds to stable and thin curves to unstable solutions, respectively. The black dots indicate points where the integral* (3.9) *equals zero and therefore moving solitons are allowed to bifurcate off.*

remains of the integral (3.5):

$$\int (yv_0' - wu_0')\,dx \equiv I(h). \tag{3.9}$$

The integral I is a continuous function of h, and it was not difficult to find points on the curve at which it changes from positive to negative values, or vice versa.

We examined two branches of multisoliton solutions obtained previously [29] (Figure 3.1). The integral $I(h)$ was found to change its sign at three points, marked by black dots in the figure. (Although it may seem from the figure that I equals zero right at the turning points, in actual fact zeros of I do not *exactly* coincide with the turning points.) We were indeed able to numerically continue our solutions in V from each of these three points. Results are presented in Figure 3.2, (a)–(c).

The point "1" in Figure 3.1 corresponds to the stationary complex $\psi_{(++)}$ and lies just above the turning point where the $\psi_{(++)}$ turns into $\psi_{(--)}$. (The turning point has $h = 0.83504217$ while $I(h) = 0$ for $h = 0.8353$.) This solution has four positive real eigenvalues in the spectrum of the associated linearized operator and hence is unstable. The $\gamma(V)$ curve which results from the continuation of this solution in V is shown in Figure 3.2(a). As V grows from zero, the solution loses its even symmetry (see the inset to Figure 3.2(a)) while the four positive eigenvalues collide, pairwise, and become two complex conjugate pairs with positive real parts. After reaching a maximum velocity of approximately 0.65, the curve turns back toward $V = 0$, with γ first growing but then also turning toward $\gamma = 0$. The solution transforms into a (strongly overlapped) $\psi_{(+-)}$ complex. As V and γ tend to their zero values,

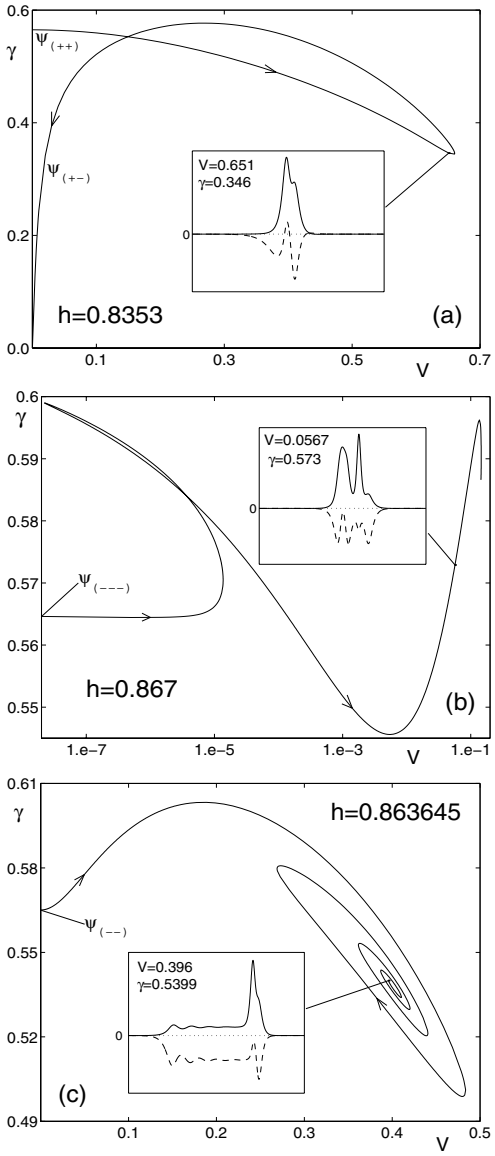

FIG. 3.2. *Bifurcation curves branching off the points marked by black dots in Figure* 3.1. *The curves illustrate the relation between the value of the damping γ and velocity V at which the wave may travel for that γ. Each curve begins at the point $\gamma = 0.565$ on the vertical axis. The insets show representative solutions at internal points of each branch. (Solid line: real part; dashed line: imaginary part.) Note the logarithmic scale of V in* (b). *Here, and in all other diagrams, arrows indicate our direction of continuation.*

the separation between the ψ_+ and ψ_- constituent solitons in the complex grows to infinity. The spectrum becomes the union of the eigenvalues of the individual ψ_+ and ψ_- solitons; in particular, it includes a complex-conjugate pair with a positive real part, and a positive real eigenvalue. Thus the entire branch shown in Figure 3.2(a) is unstable.

One more comment that we need to make here concerns the validity of the

continuation scenario presented in Figure 3.2(a) for other values of h. Note that if we chose a smaller value of γ in Figure 3.1, the value of h corresponding to the point "1" would also be smaller. (For example, for $\gamma = 0.548$ the integral $I(h)$ vanishes at the point $h = 0.82$.) For this smaller h the final product of the continuation turns out to be not a pair of infinitely separated stationary ψ_+ and ψ_- but a totally different complex. This is discussed below in section 5; see also Figures 4.2(c) and 5.1.

Another branch bifurcates off at the point marked "2" in Figure 3.1. Here $h = 0.867$. The corresponding $\gamma(V)$ diagram is displayed in Figure 3.2(b). As we move along the branch departing from $V = 0$, the original stationary complex $\psi_{(---)}$ transforms into a solution displaying three widely separated peaks in its real part: one corresponding to a strongly overlapping complex $\psi_{(-+-)}$, the next one to the ψ_+, and the last one to the ψ_- soliton. After passing a turning point, the curve is reapproaching, tangentially, the $(V = 0)$-axis. However, having reached $V = 2.2 \times 10^{-8}$, it suddenly turns back and the velocity starts to grow again. The separation between the solitons decreases and the solution can now be interpreted as a strongly overlapping four-soliton complex $\psi_{(+++-)}$ (shown in the inset to Figure 3.2(b)). As we continue further, the four constituent solitons regroup into two complexes, $\psi_{(++)}$ and $\psi_{(+-)}$. The distance between the two complexes grows rapidly, and, for certain finite V and γ (at the endpoint of the curve in Figure 3.2(b)), becomes infinite. At this point we have two coexisting solutions, $\psi_{(++)}$ and $\psi_{(+-)}$, and so this point corresponds to the point of self-intersection of the curve shown in Figure 3.2(a). Continuing the two solutions separately, from the endpoint of the curve in Figure 3.2(b), we reproduce the diagram of Figure 3.2(a) for a slightly different value of h (i.e., for $h = 0.867$).

The entire branch shown in Figure 3.2(b) is unstable. The start-off stationary solution $\psi_{(---)}$ has three positive real eigenvalues in its spectrum; one of these persists for all V and γ while the other two collide and form a complex-conjugate pair with a positive real part.

The branch continuing from the point "3" in Figure 3.1, for which $h = 0.863645$, leads to the least expected solutions. The resulting $\gamma(V)$ curve is shown in Figure 3.2(c). For points lying on the "spiral" part of the curve, the function $\psi(x)$ is equal to a constant in a relatively large but finite region, and is zero outside that region. (See the inset to Figure 3.2(c).) The constant is $\psi^{(0)} = (A_-/\sqrt{2})e^{-i\theta_-}$; it defines a stationary spatially uniform solution to (2.1). (This flat background is unstable with respect to the continuous spectrum perturbations. Figuratively speaking, our pulse solution $\psi(x)$ represents a "droplet" of the unstable phase in the stable one.) On one side (at the rear of the pulse) the zero background is connected to the background $\psi^{(0)}$ by a kink-like interface. In the front of the pulse, the interface has the character of a large-amplitude excitation, with the shape resembling the $\psi_{(+-)}$ complex. As the curve $\gamma(V)$ spirals toward its "focus" in Figure 3.2(c), the length of the region where $\psi(x) = \psi^{(0)}$ is growing. The entire branch is unstable; the start-off $\psi_{(--)}$ solution already has two real positive eigenvalues in its spectrum and more appear as we move along the branch. Those additional positive eigenvalues are remnants of the "unstable" interval of the continuous spectrum of the flat nonzero solution $\psi^{(0)}$.

4. Continuation of traveling waves to nonzero dampings.

4.1. Continuability conditions. When $\gamma = 0$, equation (2.3) has a plethora of localized solutions with nonzero V [34], and our second strategy will be to attempt to continue these nondissipative traveling waves to nonzero γ. We start with establishing the necessary and sufficient conditions for such a continuation.

A set of the *necessary* conditions can be derived easily using two integral charac-

teristics of (2.1), the momentum,

$$P = (i/2)\int(\overline{\psi}_x\psi - \psi_x\overline{\psi})dx, \tag{4.1}$$

and energy (2.6). No matter whether γ equals zero or not, the uniformly traveling solitary waves (i.e., solutions of the form (2.2)) satisfy $\dot{P} = \dot{E} = 0$. Using these relations in (1.4) and (2.7) with $\gamma \neq 0$, we get

$$P = 0 \tag{4.2}$$

and

$$E = \int |\psi|^4 dx. \tag{4.3}$$

Equations (4.2) and (4.3) have to be satisfied by the undamped solutions continuable to nonzero γ.

In fact, (4.2) and (4.3) are not independent. Indeed, multiplying (2.3) by $\overline{\psi}$, adding its complex conjugate, and integrating, gives an identity

$$E - \int |\psi|^4 dx = VP. \tag{4.4}$$

Letting $P = 0$ in (4.4), equation (4.3) immediately follows. Thus we can keep $P = 0$ as the *only* necessary condition for the continuability to nonzero γ; (4.3) is satisfied as soon as (4.2) is in place.

It turns out that $P = 0$ is also a *sufficient* condition. To show this, we expand the field $\psi = u + iv$ in powers of γ:

$$u = u_0 + \gamma u_1 + \gamma^2 u_2 + \cdots, \quad v = v_0 + \gamma v_1 + \gamma^2 v_2 + \cdots,$$

substitute into (2.3), and equate coefficients of like powers. (We also could have expanded h and V in γ, but, similarly to the continuation in V described in the previous section, the terms with coefficients h_1 and V_1 cancel out of the resulting continuability condition.) At the order $\mathcal{O}(\gamma^1)$, we obtain

$$\mathcal{H}_0 \begin{pmatrix} u_1 \\ v_1 \end{pmatrix} = \begin{pmatrix} -v_0 \\ u_0 \end{pmatrix}. \tag{4.5}$$

Here the Hermitian operator $\mathcal{H}_0$ is as in (2.5) where we only need to attach zero subscripts to u and v:

$$\mathcal{H}_0 = \begin{pmatrix} -\partial_\xi^2 + 1 + h - 6u_0^2 - 2v_0^2 & -V\partial_\xi - 4u_0v_0 \\ V\partial_\xi - 4u_0v_0 & -\partial_\xi^2 + 1 - h - 2u_0^2 - 6v_0^2 \end{pmatrix}. \tag{4.6}$$

Since the operator $\mathcal{H}_0$ has a zero eigenvalue, with the translation mode as an associated eigenvector, (4.5) is solvable only if its right-hand side is orthogonal to (u_0', v_0'):

$$\int (u_0', v_0') \begin{pmatrix} -v_0 \\ u_0 \end{pmatrix} d\xi \quad = 0. \tag{4.7}$$

(Here the prime indicates the derivative with respect to ξ.) The expression in the left-hand side of (4.7) coincides with (4.1) written in terms of the real and imaginary parts of ψ, and so the solvability condition (4.7) is simply $P = 0$.

Now assume that P is equal to zero so that a bounded solution to (4.5) exists. All traveling waves found in [34] have even real and odd imaginary parts: $u_0(-x) = u_0(x)$, $v_0(-x) = -v_0(x)$. Noticing that the diagonal elements of the operator $\mathcal{H}_0$ are parity-preserving while the off-diagonal elements change their sign under the $\xi \to -\xi$ reflection, we conclude that $u_1(x)$ is odd and $v_1(x)$ is even.

Proceeding to the order $\mathcal{O}(\gamma^2)$, we have

$$\mathcal{H}_0 \begin{pmatrix} u_2 \\ v_2 \end{pmatrix} = \begin{pmatrix} -v_1 + u_0[6u_1^2 + 2v_1^2] + 4v_0u_1v_1 \\ u_1 + v_0[2u_1^2 + 6v_1^2] + 4u_0u_1v_1 \end{pmatrix}. \tag{4.8}$$

The top entry in the right-hand side of (4.8) is even and the bottom one odd; hence the right-hand side is orthogonal to the null vector (u_0', v_0') and a bounded solution $u_2(\xi), v_2(\xi)$ exists. This time the u-component is even and the v-component odd: $u_2(-\xi) = u_2(\xi)$, $v_2(-\xi) = -v_2(\xi)$.

It is not difficult to verify that this parity alternation property guarantees the boundedness of $u_n(\xi)$ and $v_n(\xi)$ for all n. Therefore, (2.3) has a localized solution ($\psi(\xi) \to 0$ as $|\xi| \to \infty$) for sufficiently small γ. Thus if we have an undamped soliton traveling with zero momentum, it can be continued to nonzero values of γ.

4.2. Continuable solutions: The bifurcation diagram of the undamped nonlinear Schrödinger. In this subsection we review the $P(V)$ law for the undamped solitons and solitonic complexes [34]. Of interest, of course, are points where the graph crosses the V-axis, i.e., where $P(V) = 0$.

The simplest solutions arising for $V = 0$ are, obviously, our stationary fundamental solitons ψ_+ and ψ_-. These are given by (3.1), where one only needs to set $\gamma = 0$:

$$\psi_+(x) = A_+ \mathrm{sech}\,(A_+x), \quad \psi_-(x) = iA_- \mathrm{sech}\,(A_-x),$$

with $A_\pm^2 = 1 \pm h$. Both ψ_+ and ψ_- have zero momenta and therefore are continuable to nonzero γ. However, the continuation does not produce any traveling waves in this case; all we get is our static damped solitons $\psi_\pm$, equation (3.1).

Next, both ψ_+ and ψ_- admit continuation to nonzero V (for the fixed $\gamma = 0$) [34]. As V is increased to

$$c = \sqrt{2 + 2\sqrt{1 - h^2}},$$

the width of the soliton ψ_- increases, its amplitude decreases, and the soliton gradually transforms into the trivial solution, $\psi \equiv 0$. On the resulting branch, the momentum vanishes only for $V = 0$ and $V = c$ and therefore, no dissipative branches can bifurcate off the traveling ψ_- soliton.

We now turn to the soliton ψ_+. When $h < 0.28$, its fate is similar to that of the ψ_-: as $V \to c$, the soliton spreads out and merges with the zero solution. The momentum equals zero at only two points, $V = 0$ and $V = c$; for $0 < V < c$, the momentum is positive.

For $h > 0.28$, the transformation of the ψ_+ is more promising from the present viewpoint (see the dashed curve in Figure 4.1). As V is increased from zero, the momentum grows, then the branch turns back toward the $V = 0$ axis. For some $V < 0$ the momentum reaches its maximum and then decreases to zero. The point $V = V_1$ where $P(V_1) = 0$ is of interest to us, as a branch of damped solitons can bifurcate off at this point (and it really does; see subsection 4.4). Continuing beyond

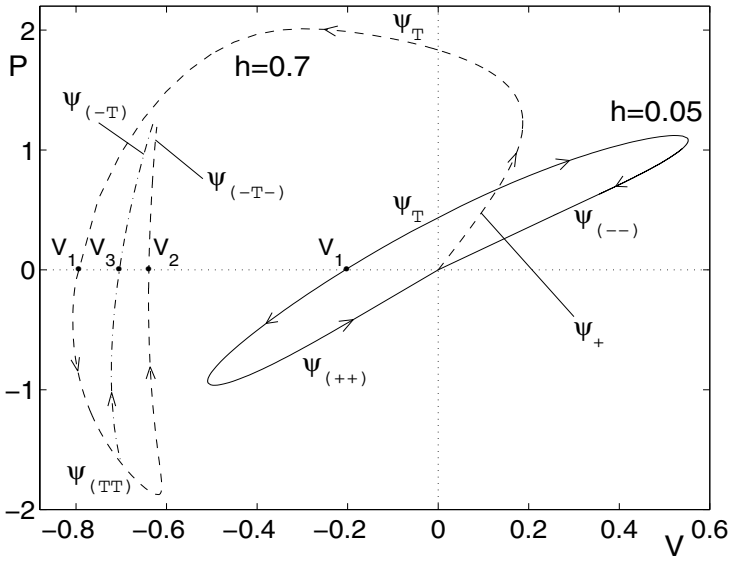

FIG. 4.1. *The momentum of the undamped traveling wave as a function of its velocity (a combined and advanced version of two diagrams from* [34]*). The dashed and dash-dotted curves pertain to the case of large driving strengths (here exemplified by* $h = 0.7$*). The starting point* $P = V = 0$ *of the dashed curve corresponds to the stationary undamped* ψ_+ *soliton, which then transforms to the twist, then to a bound state of two twists, and then to a complex of a twist and two* ψ_- *solitons. (This curve appeared in* [34]*.) The dash-dotted offshoot is our new contribution to the diagram; it corresponds to an asymmetric solution,* $\psi_{(-T)}$*, detaching from the* $\psi_{(TT)}$ *curve. The solid curve pertains to the case of small driving amplitudes (here* $h = 0.05$*). (This curve also appeared in* [34]*.) The points of its intersection with the* P*-axis correspond to stationary twist solitons; continuing each of these counterclockwise gives rise to a bound state of two* ψ_+*'s, while when continued clockwise each twist transforms into a complex of two* ψ_-*'s. More solution curves can be generated by the mapping* $V \to -V$*,* $P \to -P$*.*

V_1, the curve $P(V)$ turns toward $V = 0$ and then, after one more turning point, we have another zero crossing: $P(V_2) = 0$. This is how far we have managed to advance in our previous work [34].

At this point we need to mention that the ψ_+ and ψ_- are not the only quiescent solitons for $\gamma = 0$. The dashed $P(V)$ curve in Figure 4.1 is seen to have one more intersection with the P-axis, apart from the one at the origin. The corresponding solution represents a symmetric strongly overlapping complex of the ψ_+ and ψ_- solitons and was coined "twist" (symbolically ψ_T) in [34]. The twist soliton arises both for h greater and smaller than 0.28. In the former region the twist obtains from the V-continuation of the ψ_+ soliton, while for $h < 0.28$, it is not connected to the ψ_+. (See the solid curve in Figure 4.1.) The continuation of the twist in V in the case $h < 0.28$ gives rise to a new branch of the undamped solutions which has a point of intersection with the $(P = 0)$-axis, at some $V = V_1$. A dissipative traveling wave is bifurcating off at this value of velocity; see the next subsection. We are using the same notation, V_1, in the small- and large-h cases in Figure 4.1 to emphasize the similarity of the resulting $\gamma(V)$ curves in the two cases; see below.

Returning to the case of large h, the entire dashed curve in Figure 4.1 corresponds to symmetric solutions, $\psi(-\xi) = \overline{\psi}(\xi)$. It turns out that there are also nonsymmetric solutions; these were missed in [34]. The real part of a nonsymmetric solution is not

even, and the imaginary part is not odd. In particular, a pair of asymmetric solutions arise in a pitchfork bifurcation of the complex $\psi_{(TT)}$; see the dash-dotted offshoot from the dashed curve in Figure 4.1. (The two asymmetric solutions are related by the transformation $\psi(\xi) \to \overline{\psi}(-\xi)$; they obviously have equal momenta and hence are represented by the same curve.) Continuing the asymmetric branch we have the third zero crossing, at $V = V_3$. When continued to positive P, the asymmetric solution acquires the form of a complex of ψ_- and ψ_T solitons, with the intersoliton separation growing as P is increased. (Note that although the dashed and dash-dotted curves end at nearby points, they are *not* connected.) Our numerical analysis shows that branches of damped solitons do indeed detach at V_1, V_2, and V_3; these will be described in the next two subsections.

4.3. Numerical continuation: Small driving amplitudes. For small h, $h < 0.28$, our continuation departs from the twist soliton moving with the velocity V_1 (the point of intersection of the solid curve with the horizontal axis in Figure 4.1). The real part of this solution is even and the imaginary part odd: $\psi(-x) = \overline{\psi}(x)$. As we continue to nonzero γ, this symmetry is lost; a typical profile at the internal points looks like a nonsymmetric complex of the ψ_- and ψ_+ and is displayed in the inset to Figure 4.2(a). The rest of Figure 4.2(a) shows the resulting $\gamma(V)$ relation. As γ grows, the negative velocity of the traveling wave decreases in modulus. However, the damping cannot be increased beyond a certain limit value; as we reach it, the $\gamma(V)$-curve turns down (Figure 4.2(a)). As V and γ tend to zero, the separation between the ψ_- and ψ_+ solitons in the complex grows without bounds.

These transformations of the solution are reflected by the behavior of the linearized eigenvalues in the eigenvalue problem (2.4). At the point $V = V_1$, $\gamma = 0$ of the $\gamma(V)$ curve, the twist solution has a quadruplet of complex eigenvalues $\pm\lambda, \pm\overline{\lambda}$ which dissociates into two pairs of complex-conjugate eigenvalues $\lambda_1, \overline{\lambda}_1$ and $\lambda_2, \overline{\lambda}_2$ (with $\operatorname{Re}\lambda_1 < 0$ and $\operatorname{Re}\lambda_2 > 0$) as γ deviates from zero. As we move toward the maximum of the curve, the imaginary parts of λ_1 and λ_2 decrease and the four complex eigenvalues move onto the real axis. At the point of maximum, one of the resulting two positive eigenvalues crosses to the negative real axis, but the other one persists all the way to $V = -0$ and $\gamma = +0$. Therefore the spectrum of eigenvalues on the "downhill" portion of the curve is a union of eigenvalues of the ψ_- and ψ_+ solitons. The conclusion of the eigenvalue analysis is that the traveling complex whose bifurcation diagram is exhibited in Figure 4.2(a) is unstable for all V and γ.

4.4. Numerical continuation: Large driving amplitudes. For $h > 0.28$ we have three starting points with $P = 0$ corresponding to two intersections of the dashed curve and one of the dash-dotted curve with the horizontal axis in Figure 4.1.

The $\gamma(V)$ curve emanating out of the point V_1 is the top, arc-shaped, curve in Figure 4.2(b). For $V = V_1$ and $\gamma = 0$ the solution is symmetric and its shape resembles two strongly overlapping twists. The linearized spectrum includes two complex quadruplets. As γ deviates from zero, the symmetry is lost and the solution starts looking like an asymmetric complex of two pulses. The two complex quadruplets become four complex-conjugate pairs of eigenvalues, two with positive and two with negative real parts. Two of these pairs (one with $\operatorname{Re}\lambda > 0$ and one with $\operatorname{Re}\lambda < 0$) move on to the real axis. After that, one positive real eigenvalue crosses to the negative semiaxis, while the complex pair with $\operatorname{Re}\lambda > 0$ crosses into the $\operatorname{Re}\lambda < 0$ half-plane but then returns to $\operatorname{Re}\lambda > 0$. As $V, \gamma \to 0$, the separation between the ψ_- and ψ_+ solitons comprising this complex increases, and eventually the two constituents diverge to infinities. On the "downhill" portion of the curve, the spectrum is a union of

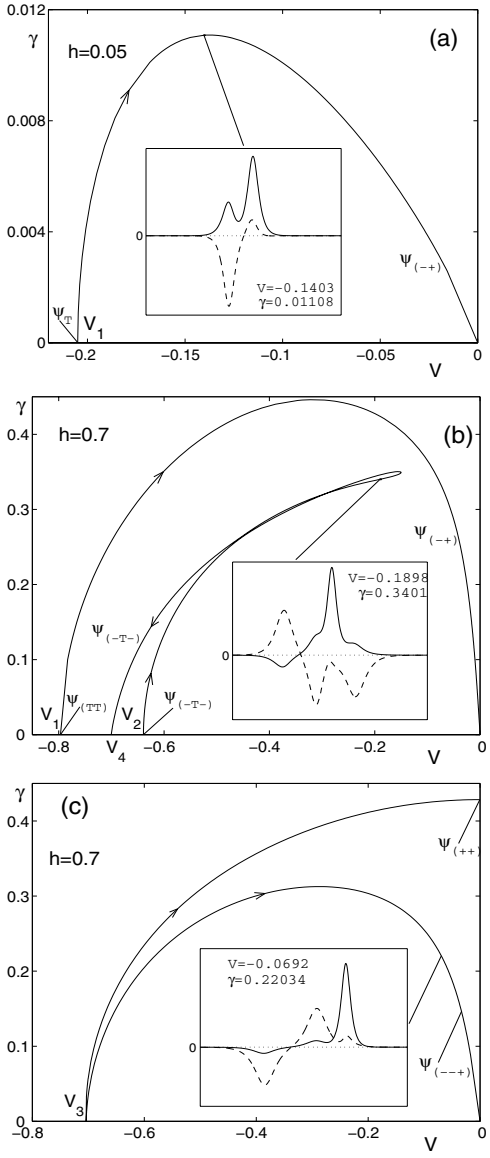

FIG. 4.2. *Results of the numerical continuation of the undamped traveling solitons to nonzero* γ. (a): *small* h; (b),(c): *large* h. *The inset displays a representative solution at one of the internal points of the curve. (Solid line: real part; dashed line: imaginary part.) Each curve shown has a positive-velocity counterpart which arises by the mirror reflection* $V \to -V$ *of the figure.*

the spectra of the individual ψ_- and ψ_+ solitons; in particular, it includes a positive real eigenvalue and a complex quadruplet. Since there are eigenvalues with $\operatorname{Re}\lambda > 0$ for all V, the entire branch is unstable.

The second undamped traveling wave with zero momentum (point V_2 on the bifurcation diagram Figure 4.1) corresponds to a symmetric ($\psi(-x) = \overline{\psi}(x)$) complex of two ψ_- and one twist soliton, symbolically $\psi_{(-T-)}$. The spectrum includes three complex quadruplets. As we continue in γ and V, the symmetry is lost but the

solution still looks like a complex of three solitons (see the inset to Figure 4.2(b)). The bottom, spike-shaped, curve in Figure 4.2(b) depicts the corresponding $\gamma(V)$ relation. Unlike the branch starting at the value $V = V_1$, this solution cannot be continued to zero velocities. Instead, the $\gamma(V)$ curve turns back and, as γ approaches zero from above, V tends to a negative value V_4, with $|V_4| > |V_2|$. For sufficiently small γ the corresponding solution consists of two ψ_- solitons and a twist in between, with the intersoliton separations growing to infinity as $\gamma \to 0$, $V \to V_4$. The associated eigenvalues perform rather complicated movements on the complex plane; skipping the details, it suffices to mention that "unstable" eigenvalues (real positive or complex with positive real parts) are present for all V. Hence the entire branch is unstable.

Finally, the point V_3 on Figure 4.1 represents *two* nonequivalent asymmetric solutions with zero momentum, $\psi_1(\xi)$ and $\psi_2(\xi)$, with $\psi_2(\xi) \equiv \overline{\psi}_1(-\xi)$. Consequently, there are *two* distinct $\gamma(V)$-branches coming out of this point (Figure 4.2(c)). One of these corresponds to a complex of two solitons; when continued to $V = 0$, it gives rise to the symmetric complex $\psi_{(++)}$ with nonzero γ. (See the top curve in Figure 4.2(c).) Continuing the other asymmetric solution to $V = 0$, the corresponding value of γ reaches a maximum at $|V| \sim 0.3$ and then tends to zero (the bottom curve in Figure 4.2(c)). For sufficiently small V and γ this solution represents a complex $\psi_{(--+)}$ (shown in the inset to Figure 4.2(c)). As $V, \gamma \to 0$, the intersoliton separation tends to infinity. Turning to the eigenvalues, the start-off solution at the point V_3 has two complex quadruplets and a real positive eigenvalue in its spectrum. When we continue along the top curve in Figure 4.2(c), two complex eigenvalues move on to the positive real axis, so we end up with three positive eigenvalues. When we continue along the bottom curve, the movements of the eigenvalues are more involved but some of them always remain in the "unstable" half-plane, $\operatorname{Re}\lambda > 0$. The upshot of the eigenvalue analysis is that both curves represent only unstable solutions.

5. Consistency of the two approaches. To complete our classification of damped traveling solitons, we need to comment on what may seem to be an inconsistency between results obtained within the above two complementary approaches. The solution representing the well-separated ψ_+ and ψ_- solitons reported in sections 3 and 4 can be reached by continuing both off the ($\gamma = 0$)- and ($V = 0$)-axes. (This branch connecting to the origin on the (V, γ)-plane appears in both Figures 3.2(a) and 4.2(b).) Although such a curve should obviously not depend on the starting point of the continuation, one notices that the $\psi_{(+-)}$ branches "flowing into the origin" in Figures 3.2(a) and 4.2(b) behave differently when traced backward (i.e., away from $V = \gamma = 0$). While the curve in Figure 3.2(a) intersects the γ-axis, its counterpart in Figure 4.2(b) crosses the other, V-, axis. (Here the reader should not be confused by the fact that the $\psi_{(+-)}$ branch in Figure 3.2(a) is shown for positive values and its counterpart in Figure 4.2(b) for negative values of V. In view of the $\xi \to -\xi$, $V \to -V$ invariance of (2.3), to each γ there correspond *two* traveling waves, one with positive and the other with negative values of V, respectively. Therefore, one should mirror-reflect Figure 4.2(b) prior to comparing it to Figure 3.2(a). This reflection maps the solution $\psi_{(-+)}$ of Figure 4.2(b) to the $\psi_{(+-)}$ of Figure 3.2(a).)

To resolve the paradox, one needs to note that the two figures correspond to different values of h: Figure 3.2(a) to $h = 0.8353$ and Figure 4.2(b) to $h = 0.7$. It turns out that a qualitative change of behavior occurs for h somewhere between these values, more precisely between 0.82 and 0.8275. For $h = 0.82$ and smaller (in particular, for $h = 0.7$) the $\gamma(V)$ curve has the form of an arc shown in Figure 4.2(b) (i.e., it crosses the V-axis as $|V|$ is increased), while for $h = 0.8275$ and greater, the

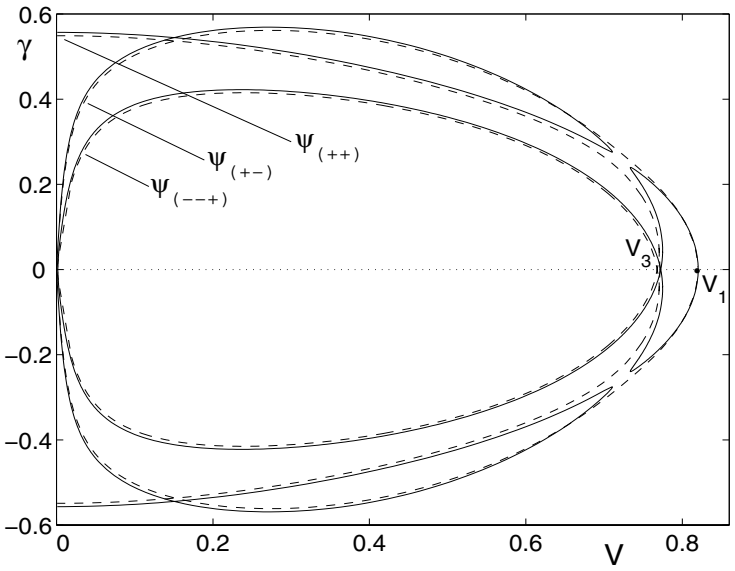

FIG. 5.1. *The comparison of the bifurcation diagrams for* $h = 0.82$ *and* $h = 0.8275$. *Solid curve:* $h = 0.8275$*; dashed curve:* $h = 0.82$. *Although the points of intersection of the dashed and solid curves with the* V*-axis do not coincide, i.e.,* $V_3(0.8275) \neq V_3(0.82)$ *and* $V_1(0.8275) \neq V_1(0.82)$*, they are quite close to each other and hence we mark them as a single point (*V_3 *and* V_1*, respectively). The branches coming out of the point* V_2 *on the* V*-axis are omitted for visual clarity. Note the shape of the dashed and solid curves near* $V \sim 0.7$*,* $\gamma \sim 0.3$*, characteristic of phase portraits of two-dimensional dynamical systems in the neighborhood of saddle points.*

curve is already loop-shaped and does not reach to $\gamma = 0$. This change of behavior, accounting for the above "inconsistency," is illustrated by Figure 5.1 which compares the $\gamma(V)$ relations for $h = 0.82$ and $h = 0.8275$. Figure 5.1 also serves to illustrate the different outcomes of the continuation of the complex $\psi_{(++)}$ for $h = 0.8353$ and smaller h. (We note that for $h = 0.8353$ the continuation of the motionless $\psi_{(++)}$ produces a pair of infinitely separated solitons ψ_+ and ψ_- (Figure 3.2(a)) while for $h = 0.7$, the curve departing from the same type of starting point (i.e., from $\psi_{(++)}$) ends up at the undamped asymmetric solution traveling with nonzero velocity V_3 (Figure 4.2(c)).)

The above differences in behavior result from the presence of a saddle point on the (V, γ)-plane, in the gap between the two lobes of the solid curve in Figure 5.1. Indeed, the dashed and solid curves can be seen as sections of the surface $h = h(\gamma, V)$ by the horizontal planes $h = 0.82$ and $h = 0.8275$, respectively. The gap in the upper solid curve is then accounted for by letting $h = h_0 + x^2 - y^2$ in the vicinity of the gap. Here the constant h_0 lies somewhere between 0.82 and 0.8275, and (x, y) is a pair of suitably chosen orthogonal coordinates on the (V, γ)-plane.

6. Conclusions. One of the conclusions of this work is that by clustering into complexes, solitons (or, equivalently, solitary pulses) can adjust their total momentum to zero. By doing so they can travel with nonzero speed in the presence of damping—without violating the momentum decay law, $\dot{P} = -\gamma P$. Two identical solitons traveling at the same speed in the same direction have equal momenta; therefore, in order to arrange for $P = 0$ the traveling complex inevitably has to include solitons of different varieties (i.e., both ψ_+'s and ψ_-'s). Consequently, the real and

imaginary parts of the traveling complex will always be represented by *asymmetric* functions of $\xi = x - Vt$.

Although the possibility of nondecelerated motion may be out of line with the common perception of the soliton dynamics in weakly damped Hamiltonian equations, moving pulses are not unknown in *strongly* dissipative systems. A suitable example is given by the complex Ginzburg–Landau equation. Asymmetric Ginzburg–Landau pulses, uniformly traveling with nonzero velocities, were reported in [44].

All moving solutions that we have found in this paper turned out to be unstable. This instability admits a simple qualitative explanation—at least, for small dampings. In the undamped situation, the ψ_- solitons are unstable when traveling with small velocities while the ψ_+'s become unstable when moving sufficiently fast [34]. In the presence of dissipation the traveling wave has to include solitons of both varieties; on the other hand, the eigenvalues corresponding to small nonzero γ should remain close to their ($\gamma = 0$)-counterparts. Therefore the spectrum of the traveling complex will "inherit" unstable eigenvalues of either ψ_- (for small velocities) or ψ_+ (for large velocities).

Thus, despite the fact that the parametric driver can sustain the uniform motion of a damped soliton, an additional agent (such as, possibly, the diffusion and/or a nonlinear damping term) is required to make this motion stable. Here it is appropriate to refer, again, to the complex Ginzburg–Landau equation. Stable Ginzburg–Landau pulses arise as a result of a delicate balance of the whole series of terms, including dispersion, cubic and quintic conservative nonlinearity, diffusion, cubic gain, and linear and quintic nonlinear damping [44, 45, 46, 47]. In a similar way, the gain/loss and spreading/steepening balances of the damped-driven traveling solitons could be restored by adding one or several missing agents.

Acknowledgment. We thank Nora Alexeeva for her advice on numerics.

A BOUND ON THE TOTAL VARIATION OF THE CONSERVED QUANTITIES FOR SOLUTIONS OF A GENERAL RESONANT NONLINEAR BALANCE LAW*

JOHN HONG† AND BLAKE TEMPLE‡

Abstract. We introduce a new potential interaction functional and use it to define a new Glimm-type functional that bounds the total variation of the conserved quantities at time $t > 0$ by the total variation at time $t = 0+$ in Glimm approximate solutions of a general resonant nonlinear balance law.

Key words. shock waves, resonance, Glimm scheme, balance laws

AMS subject classification. 35L65

DOI. 10.1137/S0036139902405249

1. Introduction.

In [13], Isaacson and Temple introduced the 2×2 system

$$\begin{aligned} a_t &= 0, \\ u_t + f(a,u)_x &= a' g(a,u) \end{aligned} \tag{1.1}$$

as a general nonlinear balance law that models resonance between a nonlinear wave field and a stationary source (cf. [5, 7, 8, 9, 10, 11, 14, 17, 19, 20, 21, 22, 23, 25, 26]). Here a and u are assumed to be scalar valued, and resonance occurs at states $U_* = (a_*, u_*)$, where the nonlinear wave speed $\lambda = f_u$ vanishes. Assume further that f and g are smooth functions and that the following conditions are satisfied at the state U_*:

$$f_u(U_*) = 0, \tag{1.2}$$

$$g(U_*) - f_a(U_*) \neq 0 \quad \text{(w.l.o.g. assume } g(U_*) - f_a(U_*) > 0), \tag{1.3}$$

$$f_{uu}(U_*) \neq 0 \quad \text{(w.l.o.g. assume } f_{uu}(U_*) < 0), \tag{1.4}$$

and

$$g_u(U_*) \neq 0. \tag{1.5}$$

It was shown in [13] that the generic conditions (1.2)–(1.5) imply that the structure of elementary wave curves (shock waves, rarefaction waves, and standing waves) and the solution of the Riemann problem (the initial value problem when the initial data consists of constant states U_L, U_R, separated by a discontinuity) are canonical[1] in a neighborhood Ω of the state U_*; cf. [16, 13, 24]. (The cases $g_u > 0$ and $g_u < 0$ are

[1]Here we show that the condition $f_a \neq 0$, stated as a condition for genericity in [13], is not required, except by (1.3) in the case $g = 0$; cf. the construction of the zero speed shock curve below.

qualitatively different.) Here $a' \equiv a_x \equiv \frac{da}{dx}$, and $a = a(x)$ is an inhomogeneous term that is treated as a variable so that (1.1) takes the form of a system of two equations that expresses the dependence of the solution on the source a.

In this paper we introduce a new potential interaction functional and use it to construct a nonlinear Glimm functional that is positive decreasing on solutions of (1.1) and bounds the total variation of the conserved quantity u in terms of the initial data for all time $t > 0$. We show that the functional is always locally finite at time $t = 0+$ of the random choice method, and so the limit solution will be of bounded total variation for all time so long as this functional is bounded uniformly at $t = 0+$ as the mesh length $\Delta x \to 0$. This then gives a condition on the initial data that guarantees the solution will be of bounded total variation in u for all time. Moreover, the potential interaction estimate can be interpreted as the best possible estimate for the increase in total variation in u that can occur due to the interaction of an initial set of waves, taking no account of the initial distances between the waves or the times at which pairs of waves will interact. As part of our proof, we show that the only potential for increase of total variation is due to the interaction of rarefaction waves and standing waves. An immediate consequence of this is a proof that *the total variation of u at any $t > 0$ will be uniformly bounded by a constant times the total variation of u at $t = 0+$ in any weak solution of* (1.1) *generated by the generalized Glimm method, which initially consists entirely of shock waves and standing waves.*

The lack of a total variation estimate in the conserved quantities is the main obstacle to extending the results in [25, 13] to systems of equations (that is, when u is a vector instead of a scalar), and this is the primary motivation for our work. An important example of a system of form (1.1) is given by the equations for compressible Euler flow in a variable area duct:

$$
\begin{aligned}
&a_t = 0,\\
&\rho_t + (\rho u)_x = -\frac{a'}{a}\rho u,\\
&(\rho u)_t + (\rho u^2 + p)_x = -\frac{a'}{a}\rho u^2,\\
&(\rho E)_t + (\rho E u + p u)_x = -\frac{a'}{a}(\rho E u + p u),
\end{aligned}
\tag{1.6}
$$

where ρ is the density, p is the pressure, E is the energy density, and $a(x)$ is the diameter of the duct at position x [2]. It is a mathematical open problem to show that wave strengths remain bounded in the time evolution of solutions of (1.6) in a neighborhood of a point of resonance U_* when the flow is transonic; cf. [1]. The main thrust of this paper is thus to establish total variation estimates for (1.1) that can be extended to a general class of systems of form (1.1), which includes (1.6). Now the total variation in the conserved quantity u at time $t > 0$ in a solution of (1.1) is not in general bounded by any uniform constant times the total variation of u at time zero in the presence of resonance. In fact, solutions of the linearization of (1.1) about $U = U_*$ grow unboundedly as $t \to \infty$ [13]. In [25, 13] a time independent bound on the supnorm and global existence of weak solutions is demonstrated based on obtaining a time independent total variation estimate for solutions in the coordinate system of Riemann invariants,[2] which is related to the conserved variables $U = (a, u)$ by a *singular* coordinate transformation. These estimates do not carry over naturally to

[2]The fact that solutions are bounded at all is thus a purely nonlinear effect.

systems like (1.6), in which u is a vector. Indeed, Glimm's method indicates that a time independent bound on the total variation of the conserved quantities is needed to extend the analysis to systems. To establish a bound on the total variation of the conserved quantity U, we introduce a singular transformation *of the coordinate system of Riemann invariants* and give essentially the best possible bound on the total variation at time $t > 0$ in terms of the initial data in these coordinates, which are regular with respect to the coordinates of conserved quantities. Our method of analysis is then to adapt the linear functional introduced in [25, 13] over to these new coordinates (which requires a correction term for the wave strengths of certain standing waves in order to make the linear part of the functional continuous) and then to add a potential interaction term for rarefaction wave-standing wave interactions to account for the fact that the functional is not contractive (decreasing in time) in these new coordinates. The total variation bounds on the solutions imply supnorm bounds, and these bounds help explain why, as waves interact due to the nonlinearity of wave speeds, solutions of the nonlinear problem (1.1) do not blow up like the resonant linear equation but rather decay to time asymptotic wave patterns given by the solutions of the Riemann problem.

We use the notation $U = (a, u),\ \mathcal{F} = (0, f),\ G = (0, a'g)$ so that the initial value problem for (1.1) is a special case of the general initial value problem,

$$\begin{aligned} &U_t + \mathcal{F}(U)_x = G(U), \\ &U(x, 0) = U_0(x). \end{aligned} \tag{1.7}$$

The advantage of treating systems in the form (1.1) instead of general systems of form (1.7) is that for system (1.1) we can define a generalized Riemann problem and analyze solutions by Glimm-type methods that can be applied, in principle, to systems of equations. The point of incorporating the a' term in front of g on the right-hand side of (1.1) is that it ensures that standing waves can be rescaled into discontinuities [13, 6]. It was shown in [6] that in the strictly hyperbolic regime, general source terms can be treated like contact discontinuities in such a way that the Riemann problem of Lax, and the random choice method of Glimm, both extend *virtually unchanged* to systems of the form (1.1)—that is, general systems with sources can be treated numerically just as the source-free equations. Of course, since the right-hand side of (1.1) involves the derivative a', there is no classical weak formulation of (1.1) when a is discontinuous—you cannot multiply a delta function by a discontinuous function in the classical theory of distributions; cf. [3]. Thus, the generalized Riemann problems used to construct the Glimm approximates are *weaker than weak* solutions of the equations; cf. [6]. To justify the method, it is important to show that the limits of approximate solutions of the generalized Glimm method are veritable weak solutions of (1.1) *when system* (1.1) *has a weak formulation*, namely, when $a(x)$ is Lipschitz continuous. This is accomplished in [6].[3] The interesting point to make here is that because the Riemann problems are based on approximating $a(x)$ by piecewise constant states, it follows that the Glimm scheme approximates can give only a C^0 and not a C^1 approximation of $a(x)$, and thus a' is not well approximated in L^1. Even so, Hong showed in [6] that for any test function ϕ, the residual and, in particular, $\int_{t\geq 0} a'g(a, u)\phi(x, t)dxdt$ converges not by L^1 convergence (as in Glimm's original results) but weakly, by *oscillation*, when a is Lipschitz continuous; cf. [21]. This argument, appropriately modified for the resonant

[3]Note also that every a of bounded variation can be approximated by a Lipschitz continuous function.

case considered here, is presented in section 6 below. Interestingly, three mollification parameters are needed to conclude the proof of convergence of the residual in section 6.

In section 2 we review the results in [13]; we define the regular transformation $(a, u) \to (a, w)$ and the linear functional $L_w(J)$ and compare these to the singular transformation $(a, u) \to (a, z)$ and linear functional $L_z(J)$ defined in [25, 13].[4] We then review the solution of the Riemann problem and construct the admissible solution $[U_L, U_R]$ based on an L_w minimization principle that is finer than the L_z minimization principle introduced in [13]. The L_w minimization is required for the subsequent analysis. The nonuniqueness of solutions of the Riemann problem even in the presence of the classical entropy condition for the nonlinear waves reflects an interesting instability in the time asymptotics of solutions of (1.1).

In section 3 we construct the approximate solutions $U_{\Delta x}$ by the generalized Glimm method. For a given approximate solution, the functionals $L_w(J)$ and $L_z(J)$ both sum the strengths of waves that cross an I-curve J with weight factors according to whether the wave is a nonlinear wave, a *weak* standing wave, or a *strong* standing wave, respectively; cf. [25].[5] The purpose of the weight factors is to make $L_z([U_L, U_R])$ and $L_w([U_L, U_R])$ continuous functions of U_L and U_R for the admissible solution of the Riemann problem $[U_L, U_R]$ (cf. [16, 24] and (2.1) below). Now it was shown in [13] that the weight factors $1, 2$, and 4 on nonlinear waves, weak standing waves, and strong standing waves, respectively, suffice to make L_z continuous (these weights were introduced in [25]). We show here that in the case $g = 0$, the weight factors $1, 2, 4$ also suffice to make $L_w([U_L, U_R])$ continuous functions of U_L and U_R. However, when $g_u \neq 0$, we must adjust the definition of strength for the standing waves in order to preserve continuity when the standing wave curves diverge from the zero speed shock curves; cf. [13]. It was shown in [13] that the functional L_z is positive and nondecreasing across interaction diamonds Δ that lie between successive I-curves J_1 and J_2 in an approximate Glimm scheme solution, and $L_z(J)$ bounds the total variation in (a, z) of the solution along J [24, 4]. On the other hand, $L_w(J)$ bounds the total variation in (a, w) (and hence also the total variation in (a, u)) along an I-curve J but does not decrease across interaction diamonds.

In section 4 we define the interaction potential $d(\gamma_0, \gamma_r)$ between a rarefaction wave γ_r and a standing wave γ_0, and in section 5 we define the nonlocal Glimm functional, $P(J) = \sum_{(\alpha,\beta)\in App(J)} d(\gamma_0^\alpha, \gamma_r^\beta)$, and prove that the functional $F(J) = L_w(J) + P(J)$ decreases across interaction diamonds Δ, where the sum is taken over all approaching waves that cross J in a Glimm approximate solution. From this we establish the total variation bound for the generalized Glimm approximates and thus conclude the main total variation bound in the conserved variables (a, u) for solutions of the resonant nonlinear system (1.1). It is fortunate that at the transitions between regions where the structure of the admissible solution Riemann problem changes, the Riemann problem *never* involves rarefaction waves. Moreover, rarefaction waves are never created by interaction, and thus, since the potential interaction functional P only requires the potential for rarefaction waves to interact with standing waves, it follows that the continuity of both P and F is also maintained as states cross

[4] The functionals L_z were labeled "F" in [25] and [13], but we refer to these as L_z here because they contain no potential interaction term and are therefore linear on sequences of elementary waves; cf. [4].

[5] A standing wave is *strong* if the jump in u across the wave has the same sign as the jump in u across a shock wave and *weak* if the jump has the same sign as the jump in u across a rarefaction wave; cf. [13].

transitional boundaries between different regions of the Riemann problem.

In section 6 we modify the argument in [6] and prove the convergence of the residual when a is Lipschitz continuous.

2. Review of the Riemann problem. The Riemann problem is the initial value problem with initial data given at $t = 0$ by the jump discontinuity

$$U_0(x) = \begin{cases} U_L = (a_L, u_L) & \text{if } x < 0, \\ U_R = (a_L, u_L) & \text{if } x > 0. \end{cases} \tag{2.1}$$

The solution of the Riemann problem for (1.1), assuming (1.2)–(1.5), was first described in [13]. The solutions that minimize L_z were constructed within the class of shock waves, rarefaction waves, and standing waves, and the solution was thereby shown to have a canonical structure for pairs of states U_L and U_R in a sufficiently small neighborhood of U_*. In this section we review the solution of the Riemann problem and define the functionals L_z and L_w.

To motivate this, we note that by [13], near a point of resonance U_* of system (1.1), solutions of (2.1) have an interesting multiplicity of solutions even when the standard entropy condition for shocks is imposed on the nonlinear waves. An additional admissibility condition is required to fix a unique solution. For system (1.1) in the case $g = 0$, uniqueness is implied by the Lax entropy condition for shocks, together with the condition that the wave curves for the waves that solve the Riemann problem should lie between the values of a on the left and right; cf. [13]. This is a natural condition if one views the discretization of a as approximating a smooth duct—the time asymptotic wave pattern will depend on the interior structure of the duct as well as the left and right most diameters. However, when $g \neq 0$, system (1.1) has a more interesting and nontrivial multiplicity of solutions of the Riemann problem: in certain cases, there is a multiplicity of three distinct solutions of the Riemann problem that preserve the bounds in a from the left and right, and these reduce to two possible solutions at boundary cases. The main purpose of this section is to define the functional L_w and show that the following admissibility condition is sufficient to pick out a unique solution of the Riemann problem (except of course for a dual ambiguity at the boundary regions where the qualitative wave structure changes).

DEFINITION 2.1. *A solution of the Riemann problem* (2.1) *is called* admissible *if it minimizes L_w among all other solutions of the Riemann problem that preserve the bounds in a and contain only Lax entropy shocks.*[6]

In contrast, the admissibility criterion in [13], which requires that L_z be minimized, still leaves some ambiguity in cases where there are three solutions. We let $[U_L, U_R]$ denote the admissible solution of the Riemann problem, and we will show that $[U_L, U_R]$ always consists of three elementary waves: a negative speed nonlinear wave followed by a single standing wave followed by a positive speed nonlinear wave. However, in two cases diagrammed in Figures 15 and 17, the standing wave must be taken to be what we call a *triple composite standing wave*, a wave that consists of a standing wave followed by a zero speed shock wave followed by a second standing wave.

To start, let γ denote an arbitrary elementary wave, and let subscripts $q = 0, r, s$ identify the wave as a standing wave, rarefaction wave, or shock wave, respectively.

[6] Unlike L_z, L_w is *not* minimized on solutions among all connected sequences of elementary waves that take U_L to U_R, and if it were, $F(J) = L_w(J)$ would decrease on solutions, and no potential interaction term would be required in our analysis; cf. [13].

A wave γ is determined by its left and right states, and we say that $\gamma_a \cdots \gamma_b$ is a *connected* sequence of elementary waves that takes U_L to U_R if the right state of any wave in the list is equal to the left state of its successor in the list, and U_L, U_R is the left, right state of the first, last wave in the list, respectively. Thus the admissible solution of the Riemann problem $[U_L, U_R]$ is just a particular connected sequence of elementary waves that takes U_L to U_R. Two connected sequences of elementary waves $\gamma_a \cdots \gamma_b$ and $\bar{\gamma}_a \cdots \bar{\gamma}_b$ are said to be *similar* if they both take U_L to U_R, in which case we write $\gamma_a \cdots \gamma_b \sim \bar{\gamma}_a \cdots \bar{\gamma}_b$. For a nonlinear wave γ that takes U_L to U_R, we say that $\gamma \sim \gamma^a \gamma^b$ is a *partition* of the wave γ if the state U_M, the right state of γ^a and the left state of γ^b, lies strictly between U_L and U_R in the (a, u)-plane. (We allow both rarefaction waves and shock waves to be partitioned.)

To begin the review of the Riemann problem, we first remind the reader that system (1.1) has standing wave solutions that can be rescaled into discontinuities so that the standing waves can be treated like a family of contact discontinuities in the theory of hyperbolic conservation laws [13, 6]. Indeed, let $(a(x), u(x))$ be a standing wave (i.e., time independent) solution of (1.1). Then

$$\frac{d}{dx} f = a' g,$$

which is equivalent to

$$f_a da + f_u du = g da.$$

We rewrite this as

$$(f_a - g) da + f_u du = 0. \tag{2.2}$$

The nondegeneracy assumption (1.3) implies that $f_a - g \neq 0$ in a neighborhood of U_*, and therefore (2.2) is equivalent to the autonomous ODE

$$\frac{da}{du} = \frac{f_u}{g - f_a}. \tag{2.3}$$

This equation has a unique solution through each point in a neighborhood of U_* in the (a, u)-plane. Thus, for any solution $a = a_s(u)$ of (2.3) and any smooth function $\varphi(x)$, the curve $u = \varphi(x), a = a_s(\varphi(x))$ is a standing wave solution of (1.1). Moreover, if $a_L = a_s(u_L)$ and $a_R = a_s(u_R)$, then the standing wave discontinuity

$$U(x,t) = \begin{cases} (a_L, u_L) & \text{if } x < 0, \\ (a_R, u_R) & \text{if } x > 0 \end{cases} \tag{2.4}$$

is obtained as a limit of smooth solutions; specifically, if $\varphi_\epsilon(x) \to \varphi_0(x)$, where

$$\varphi_0(x) = \begin{cases} u_L & \text{if } x < 0, \\ \\ u_R & \text{if } x > 0, \end{cases}$$

then $U_\epsilon = (a_s(\varphi_\epsilon(x)), \varphi_\epsilon(x)) \to U(x,t)$. Thus we can view the standing wave discontinuities defined in (2.4) as a family of elementary waves for system (1.1), similar to a family of contact discontinuities.

The standing wave curves define solutions of (2.2). Note that for a standing wave,

$$\frac{da}{du} = 0 \text{ if and only if } f_u = 0. \tag{2.5}$$

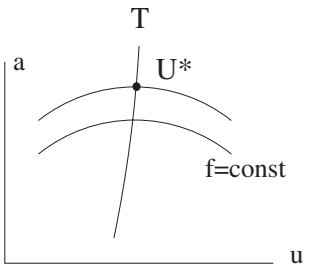

FIG. 1.

Moreover, if $da/du = 0$, then

$$\frac{d^2a}{du^2} = \frac{f_{uu}}{g - f_a} < 0. \tag{2.6}$$

Thus, $d^2a/du^2 < 0$ in a neighborhood of U_*.

DEFINITION 2.2. *The* transition curve $\mathcal{T}$ *associated with system* (1.1) *is the set*

$$\mathcal{T} = \{(a, u) : \lambda \equiv f_u = 0\}. \tag{2.7}$$

Since $f_{uu} \neq 0$, the implicit function theorem implies that (in a neighborhood of U_*) $\mathcal{T}$ is a smooth curve passing through U_*, which we denote by

$$u = u_{\mathcal{T}}(a). \tag{2.8}$$

The curve $\mathcal{T}$ comprises the states near U_* for which the nonlinear wave speed $\lambda \equiv f_u$ is zero. By (2.5) and (2.6), the standing wave curves $u \mapsto (a_s(u), u)$ are convex down, cross $\mathcal{T}$ transversally, and maximize a on $\mathcal{T}$ in some neighborhood of U_*. (The notation comes from [7]. See Figure 1.)

We now define the zero speed shock curve corresponding to a given standing wave curve. By our choice of signs ($f_{uu} < 0$ and $g - f_a > 0$), the entropy shock waves (see [24]) for the nonlinear scalar conservation law $u_t + f(a, u)_x = 0$ jump always from left to right in the (x, t)-plane and (a, u)-plane simultaneously; thus, by the Rankine–Hugoniot jump relation for shocks,

$$s[u] = [f],$$

the zero speed shocks ($s = 0$) cross $\mathcal{T}$ from left to right at a constant value of f.

Now, for a given standing wave $a = a_s(u)$ and a given state (a, u) on this standing wave, define $\bar{u}$ to be the value of u such that the state $(a, \bar{u})$ lies on the opposite side of $\mathcal{T}$ at the same a-level and on the same standing wave curve as the given state (a, u). If the state $U = (a, u)$ lies on the left-hand side of $\mathcal{T}$ (we write $U < \mathcal{T}$), then define $\tilde{u}$ to be the value of u such that the state $(a, \tilde{u})$ lies on the right-hand side of $\mathcal{T}$ and at the same level a, but on the same constant f curve as the given state (a, u). That is, for $U < \mathcal{T}$, $\bar{u}$ satisfies

$$a_s(\bar{u}) = a_s(u), \tag{2.9}$$

and $\tilde{u}$ satisfies

$$f(a, \tilde{u}) = f(a, u) \tag{2.10}$$

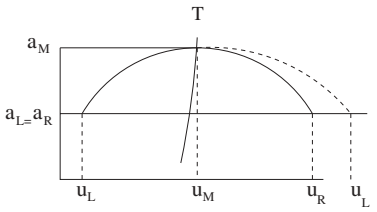

FIG. 2.

(see Figure 1).

DEFINITION 2.3. *Let $a = a_s(u)$ be a standing wave curve. Then, (assuming $f_{uu} < 0$) the zero speed shock curve corresponding to standing wave curve a_s is the curve (lying to the right of $\mathcal{T}$) defined by*

$$\{\tilde{u} : f(a, \tilde{u}) = f(a, u) \text{ where } u \le u_{\mathcal{T}}(a) \text{ and } \tilde{u} \ge u_{\mathcal{T}}(a)\}.$$

(When $f_{uu} > 0$, we change to $u \ge u_{\mathcal{T}}(a)$ and $\tilde{u} \le u_{\mathcal{T}}(a)$.)

LEMMA 2.4. *If $g_u < 0$, then for each standing wave curve $a = a_s(u)$, the corresponding zero speed shock curve lies to the right of the standing wave curve in the (a, u)-plane. That is, if (a, u) satisfies $a = a_s(u)$ with $u < u_{\mathcal{T}}(a)$, then*

$$f(a, \bar{u}) < f(a, \tilde{u}) = f(a, u). \tag{2.11}$$

If $g_u > 0$, then the corresponding zero speed shock curve lies to the left of the standing wave curve in the (a, u)-plane. That is,

$$f(a, \bar{u}) > f(a, \tilde{u}) = f(a, u). \tag{2.12}$$

For example, in the case $g_u < 0$, Lemma 2.4 implies that the zero speed shock curve lies above and to the right of the standing wave curve $a_s(u)$ (see Figure 2). (For a proof of Lemma 2.4, see [13, Lemma 2.4, p. 13], and note that the condition $f_a \neq 0$ was not required.)

We now define the nonsingular coordinate w and functional L_w and formulate the L_w minimization principle to select a unique admissible solution of the Riemann problem. To construct L_w, we first construct w and a functional L_w^* that is analogous to the construction of the singular coordinate z and functional L_z defined in [25, 13], and then we obtain L_z by modifying L_w^* so that $L_w^*[U_L, U_R]$ depends continuously on U_L and U_R. To start, we first review the construction of z and L_z for system (1.1).

The coordinate z is based on the singular coordinate system of nonlinear hyperbolic wave curves ($a =$constant) and standing wave curves ($a = a_s(u)$) as observed in the (a, u)-plane and is defined as follows. For each point (a, u), let $(a_{\mathcal{T}}, u_{\mathcal{T}})$ denote the unique point where the standing wave curve through (a, u) crosses $\mathcal{T}$, and set

$$z(a, u) = \operatorname{sgn}(u - u_{\mathcal{T}})|a - a_{\mathcal{T}}|.$$

Using this, define the strength $|\gamma|_z$ of an elementary wave γ by

$$|\gamma|_z = \begin{cases} |z(U_R) - z(U_L)| & \text{if } \gamma \text{ is a nonlinear wave,} \\ 2|z(U_R) - z(U_L)| & \text{if } \gamma \text{ is a weak standing wave,} \\ 4|z(U_R) - z(U_L)| & \text{if } \gamma \text{ is a strong standing wave.} \end{cases} \tag{2.13}$$

Here a standing wave is *weak* if the jump in u across the wave is in the direction of a rarefaction wave ($u_R < u_L$ since we assume $f_{uu} < 0$) and is *strong* if the jump in u across the wave is in the direction of a shock wave ($u_R > u_L$ when $f_{uu} < 0$); cf. [25, 21]. For a sequence of elementary waves $\gamma_1, \dots, \gamma_n$, define

$$L_z[\gamma_1, \dots, \gamma_n] = \sum_{i=1}^{n} |\gamma_i|_z. \tag{2.14}$$

Analogously, define the nonsingular coordinate w by

$$w(a,u) = \begin{cases} u - u_{\mathcal{T}} & \text{if } u < \mathcal{T}, \\ u_{\mathcal{T}} - \bar{u} & \text{if } u > \mathcal{T} \end{cases}$$

and the strength $|\gamma|_w$ of an elementary wave γ by

$$|\gamma|_w^* = \begin{cases} |w(U_R) - w(U_L)| & \text{if } \gamma \text{ is a nonlinear wave,} \\ 2|w(U_R) - w(U_L)| & \text{if } \gamma \text{ is a weak standing wave,} \\ 4|w(U_R) - w(U_L)| & \text{if } \gamma \text{ is a strong standing wave.} \end{cases} \tag{2.15}$$

For a sequence of elementary waves $\gamma_1, \dots, \gamma_n$, define

$$L_w^*[\gamma_1, \dots, \gamma_n] = \sum_{i=1}^{n} |\gamma_i|_w^*. \tag{2.16}$$

We next show that the change in w across an elementary wave bounds the change in u across the wave in any neighborhood Ω of U_* that is sufficiently small.[7] This is guaranteed by the simpler condition stated in the following lemma. (Since the change in u across a nonlinear wave is equal to the change in w across the wave, the only issue is with the standing waves.)

LEMMA 2.5. *Let γ_0 denote a standing wave with left state U_L and right state U_R, both states lying on one side of the transition curve. Then for Ω sufficiently small, there exists a constant $c > 1$ such that the condition $U_L, U_R \in \Omega$ implies that the absolute change in u across γ_0 between a_L and a_R is always that constant times larger than the absolute change in u along the transition curve $\mathcal{T}$ between a_L and a_R.*

Proof. We verify the lemma in the case diagrammed in Figure 3 (other cases are similar). Thus we show that for Ω sufficiently small, there exists $c > 1$ such that if $U_L, U_R \in \Omega$, then $|DF| > c|GG'|$. (We use the notation that $|DF|$ denotes the absolute change in u between states D and F.) But $|DF| = |DC|$ is the change in u across the wave γ_0. Thus, by construction of the standing wave curves, we know that

$$\frac{du}{da} = \frac{g - f_a}{f_u}$$

along a standing wave curve, so by the mean value theorem

$$|DC| = \frac{g - f_a}{f_u} |a_R - a_L|, \tag{2.17}$$

[7] We treat the local problem here because it demonstrates that the analysis is generic in a neighborhood of any state U_*, but all of this can be globalized to apply to any neighborhood Ω where the solution of the Riemann problem has the canonical structure described in section 2 such that Lemma 2.5 applies.

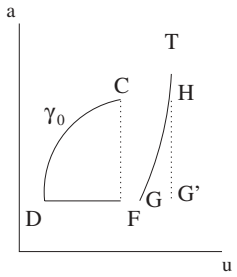

FIG. 3.

where it is understood that $\frac{g-f_a}{f_u}$ is evaluated at some point in Ω. Also $|GG'| = |GH|$ is the change in u along $\mathcal{T}$ between a_L and a_R. Since G and H lie on $\mathcal{T}$, we have $f_u(H) = f_u(G) = 0$, and so differentiating and using the mean value theorem we obtain that

$$|GH| = \frac{f_{ua}}{f_{uu}}|a_R - a_L|. \tag{2.18}$$

Since f_u can be taken arbitrarily small in a neighborhood of $\mathcal{T}$, it follows from (2.17) and (2.18) that there exists a constant $c > 1$ such that $|DC| > c|GH|$ so long as $U_L, U_R \in \Omega$. □

COROLLARY 2.6. *Assume that Ω is sufficiently small so that Lemma 2.5 holds. Then there exists a constant $c > 0$ such that, if $U_L, U_R \in \Omega$, then*

$$c^{-1}|u_L - u_R| < |\gamma|_* < c|u_L - u_R|. \tag{2.19}$$

Proof. The second inequality in (2.19) is clear by construction. We verify the first inequality in (2.19) in the case of a standing wave $|\gamma_0|$ diagrammed in Figure 3. (Again, there is no issue for nonlinear waves, and the cases for other standing waves are similar, because we always assume that standing waves do not cross $\mathcal{T}$). In the case of Figure 3, $|\gamma_0| = 4\{|w(C) - w(D)|\}$. However,

$$\begin{aligned}\frac{1}{4}|\gamma_0| = |w(C) - w(D)| &= ||CH| - |DG|| = ||FG'| - |DG|| = ||DF| - |GG'|| \\ &\geq \left||DF| - c^{-1}|DF|\right| = \left(1 - \frac{1}{c}\right)|DF| = \left(1 - \frac{1}{c}\right)|u(F) - u(D)|\end{aligned}$$

for the $c > 1$ of Lemma 2.5. It follows that

$$|u_L - u_R| \leq \frac{1}{4}\left(1 - \frac{1}{c}\right)^{-1}|\gamma_0|,$$

which proves the corollary. □

From here on out, we always assume that all states lie in a region Ω where lemma 2.5 and Corollary 2.6 apply.

In order to deduce the solution of the Riemann problem from a minimization principle, we will use the following property of the functional L^*_w.

LEMMA 2.7. *Let points A, B, C, D denote the vertices of a region in U-space bounded on either side by standing wave curves and above and below by nonlinear wave curves such that the region lies entirely on one side of the transition curve.*

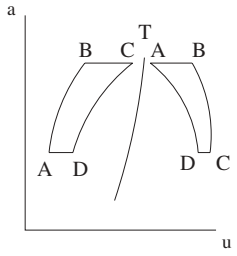

FIG. 4.

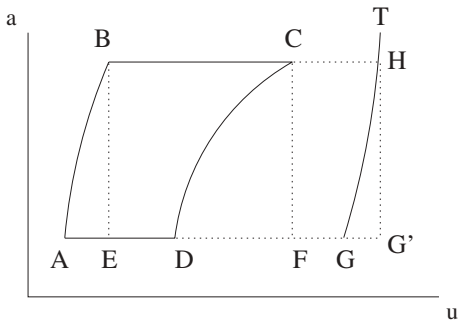

FIG. 5.

Assume that the vertices of the two possible such regions of this type are labeled with the orientation shown in Figure 4. *Then*

$$L_w^*(A \to B \to C) \le L_w^*(A \to D \to C), \tag{2.20}$$

$$L_w^*(D \to A \to B) \le L_w^*(D \to C \to B). \tag{2.21}$$

(Again, we use the convention that an elementary wave can be denoted by the left and right states of the wave separated by an arrow.)

Proof. We verify (2.20) in the case diagrammed in Figure 5, which is similar to Figure 3 of Lemma 2.5. (The other cases are similar.) Referring to Figure 5, we can estimate

$$\begin{aligned} L_w^*(A \to D \to C) - L_w^*(A \to B \to C) \\ &= |AD| + 4|w(C) - w(D)| - |EF| - 4|w(B) - w(A)| \\ &= |AE| - |DF| + 4||CH| - |DG|| - 4||BH| - |AG||. \end{aligned} \tag{2.22}$$

But by Lemma 2.5,

$$\begin{aligned} ||CH| - |DG|| &= |DF| - |GG'|, \\ ||BH| - |AG|| &= |AE| - |GG'|. \end{aligned}$$

Substituting these into (2.22) gives

$$\begin{aligned} L_w^*(A \to D \to C) - L_w^*(A \to B \to C) \\ &= 3|DF| - 4|GG'| + |AE| - 4|AE| + 4|GG'| \\ &= 3|DF| - 3|AE| \ge 0, \end{aligned}$$

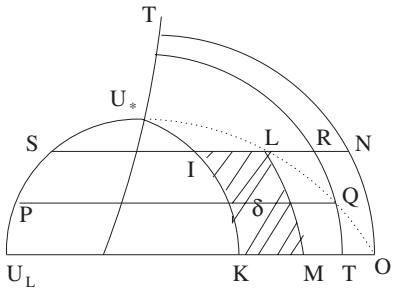

FIG. 6.

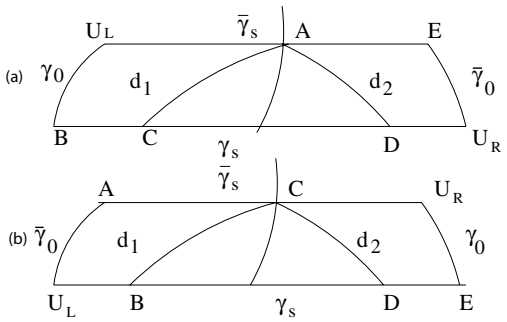

FIG. 7.

where we have used $|AE| \geq |GG'|$ by Lemma 2.5 to conclude the last line. □

The following is a simple corollary of Lemma 2.7.

COROLLARY 2.8. *If γ_a and γ_b are two standing waves on the same side of $\mathcal{T}$ that pass between the same values of a, then $L_w^*(\gamma_a) > L_w^*(\gamma_b)$ if γ_a is the wave closer to the transition curve $\mathcal{T}$.*

The next lemma provides an important continuity property of the functional L_w^* for waves that cross the transition curve.

LEMMA 2.9. *Consider the interaction $\bar{\gamma}_0 + \bar{\gamma}_s \to \gamma_s + \gamma_0$ diagrammed in Figure* 7(a)*. Then, referring to the points referenced in that diagram, we have*

$$L_w^*(U_L \to A \to U_R) = L_w^*(U_L \to E \to U_R) \tag{2.23}$$

and

$$\begin{aligned} d_1 &\equiv L_w^*(U_L \to B \to C) - L_w^*(U_L \to A \to C) \\ &= L_w^*(D \to C \to U_R) - L_w^*(D \to E \to U_R) \equiv d_2. \end{aligned} \tag{2.24}$$

Moreover, statement (2.23) *also holds for the analogous points diagrammed in Figure* 7(b)*, together with*

$$\begin{aligned} d_1 &\equiv L_w^*(U_L \to A \to C) - L_w^*(U_L \to B \to C) \\ &= L_w^*(A \to D \to U_R) - L_w^*(A \to E \to U_R) \equiv d_2. \end{aligned} \tag{2.25}$$

Proof. We verify (2.23) and (2.25). For (2.23), let F and G denote the points such that $L_w^*(A \to U_R) = L_w^*(F \to G)$. Then by the $1, 2, 4$ weightings on wave strengths, it

follows that $|\bar{\gamma}_0|_* = L_w^*(U_L \to A) = L_w^*(U_L \to F) + L_w^*(G \to E) + L_w^*(E \to U_R)$. This is enough to verify (2.23). For (2.25), note that $L_w^*(U_L \to A \to U_R) = d_1 + L_w^*(U_L \to B \to C \to U_R) = d_1 + L_w^*(U_L \to D \to C \to U_R) = d_1 - d_2 + L_w^*(U_L \to E \to U_R)$, so by (2.23), $d_1 = d_2$. □

We now define L_w in terms of L_w^*. To this end, note that because of Lemma 2.7, the functional $L_w^*([U_L, U_R])$ will be a continuous function of U_L and U_R on the admissible solution of the Riemann problem *only in the case* when $g_u \equiv 0$, and in this case, we can take $L_w \equiv L_w^*$. However, when $g_u \neq 0$, we show below that the functional $L_w([U_L, U_R])$ will not be continuous everywhere (for any choice of admissible solution of the Riemann problem) due to the divergence of the zero speed shock curve from the standing wave curves when $g_u \neq 0$. Moreover, we must modify the definition of wave strength for the triple composite standing waves, (described by the wave $U_L \to P \to Q \to R$ in Figure 15 and Figure 17, when $g_u < 0$ and $g_u > 0$, respectively) in order to insure that L_w is minimized on a triple composite standing wave. The idea is to first modify the strength of a triple composite standing wave to be equal to the strength of the two waves (a positive speed shock wave followed by a standing wave on the right when $g_u < 0$, and a standing wave on the left followed by a negative speed shock wave when $g_u > 0$) that *would* solve the same Riemann problem in the case $g_u = 0$. We call these two waves the *projection* of the triple composite wave γ_0, and label it $P(\gamma_0)$. By so changing the wave strength, we introduce a new discontinuity in the functional L_w^* that must be corrected for. Thus, to modify L_w^* into a continuous functional L_w, we must further add a compensating term $\delta(\gamma_0)$ to each standing wave γ_0 on the right, left when $g_u < 0$, $g_u > 0$, respectively. (We label a triple composite standing wave as being on the left, right of $\mathcal{T}$ according to the side of $\mathcal{T}$ on which the standing wave in $P(\gamma_0)$ falls. Thus, triple composite standing waves lie on the right, left of $\mathcal{T}$ when $g_u < 0$, $g_u > 0$, respectively.) Thus, the strategy for modifying L_w^* into a continuous functional L_w at triple composite standing waves is to redefine the strength of a triple composite standing wave $|\gamma_0| = |P(\gamma_0)|_* + \delta(\gamma_0)$, where $P(\gamma_0)$ and $\delta(\gamma_0)$ are appropriately defined below.

So assume first that $g_u < 0$. We first show that L_w^* is discontinuous under perturbation of a zero speed shock wave followed by a strong standing wave on the right of $\mathcal{T}$; cf. Figure 8. Indeed, referring to Figure 8, the elementary waves defined by $U_L \to U_M \to U_R$ and $U_L \to E \to U_R$ both must serve as admissible solutions of the Riemann problem, but $L_w^*(U_L \to U_M \to U_R) \neq L_w^*(U_L \to I \to K \to U_R) = L_w^*(U_L \to E \to U_R)$. We correct for this in the case $g_u < 0$ by modifying the definition of wave strength for strong standing waves ($u_L < u_R$) on the *right* of $\mathcal{T}$ by exactly the amount required to make L_w^* continuous.

To make this precise, let U_L and U_R denote the left and right states of a strong standing wave γ_0 on the right of $\mathcal{T}$. Let $f(a, u) = f(a_L, u_R)$ define the unique zero speed shock curve that passes through the state U_L, and for our purposes here, let U_* denote the unique point where this zero speed shock curve intersects the transition curve $\mathcal{T}$. The state $U_* = (a_*, u_*)$ is determined by the conditions $f(a_*, u_*) = f(a_L, u_L)$ and $u_* = u_{\mathcal{T}}(a_*)$; cf. Figure 9. Let $a_s(u)$ denote the unique standing wave curve that emanates from the point U_*. The curve a_s lies to the left of the standing shock curve emanating from U_* because $g_u < 0$. Now define the points I and K that lie on the standing wave curve a_s to the right of $\mathcal{T}$, at levels a_L and a_R, respectively (again see Figure 9). Since I and K are determined by γ_0 alone, we can define

$$\delta(\gamma_0) = L_w^*(I \to K \to U_R) - L_w^*(I \to U_L \to U_R) \tag{2.26}$$

for any strong standing wave γ_0 lying to the right of $\mathcal{T}$ in the case $g_u < 0$. (Note

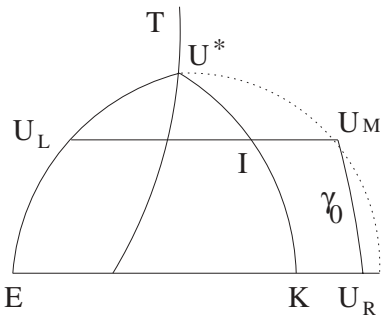

FIG. 8.

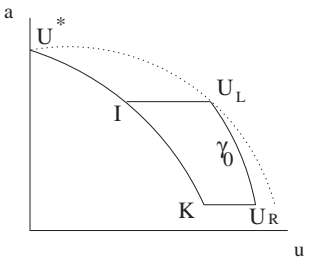

FIG. 9.

that $\delta(\gamma_0)$ depends only on U_L and U_R across the standing wave and is exactly the deficit between $L_w^*(U_L \to U_M \to U_R)$ and $L_w^*(U_L \to E \to U_R)$ encountered in Figure 8. Note also that $\delta(\gamma_0) = 0$ when $U_L \in \mathcal{T}$, because $|\gamma_0|$ reduces to $|\gamma_0|_*$ in this limit.) Thus, in the case $g_u < 0$, we define the modified strength $|\gamma_0|$ of a *strong standing wave on the right of* $\mathcal{T}$ by the rule

$$|\gamma_0|_w = |\gamma_0|_w^* + \delta(\gamma_0), \tag{2.27}$$

where $d(\gamma_0)$ is defined in (2.26).

Consider next the triple composite standing waves in the case $g_u < 0$. The main examples are given by $\gamma_0 \equiv U_L \to P \to Q \to R$ in Figures 15 and 6, the general case isolated in Figure 6. In both diagrams, $R = U_R$ denotes the right state of the triple composite standing wave γ_0. In these cases, the projection $P(\gamma_0)$ is given by $P(\gamma_0) = U_L \to T \to R$. We now show that the value of $L_w^*(P(\gamma_0))$ is discontinuous as $U_L = R$ varies from R to I along the line segment SN in Figure 6. Indeed, as $P(\gamma_0)$ varies from $U_L \to T \to R$ to $U_L \to M \to L$, the solution of the Riemann problem changes to $U_L \to S \to L$ and then to $U_L \to K \to I$. Thus for continuity, we require that $L_w(U_L \to S \to L) = L_w(U_L \to M \to L)$. But $L_w^*(U_L \to S \to L) = L_w^*(U_L \to K \to I \to L) = L_w^*(U_L \to M \to L) + \delta$, where $\delta = \delta(\gamma_0) = L_w^*(K \to I \to L) - L_w^*(K \to M \to L)$. Thus, for the general weak standing wave $U_L \to U_R$ on the right of $\mathcal{T}$ when $g_u < 0$, diagrammed in Figure 10, define

$$\delta = \delta(\gamma_0) = L_w^*(K \to I \to U_R) - L_w^*(K \to U_L \to U_R). \tag{2.28}$$

We take this as defining $\delta(\gamma_0)$ for any weak standing wave on the right of $\mathcal{T}$ that takes U_L to U_R, where for triple composite waves, (2.28) is assumed to apply to the weak standing wave on the right in $P(\gamma_0)$. (Note that the points K and I in Figure

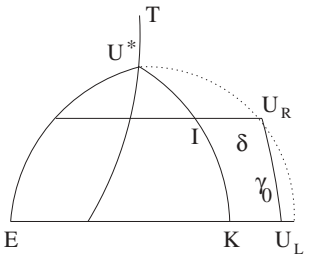

FIG. 10.

10 are determined by U_L and U_R alone.) To put this all together, let $P(\gamma_0) = \gamma_0$ for any standing wave that is not triple composite, and let $\delta(\gamma_0)$ be defined in (2.26) and (2.28) for strong and weak standing waves on the right of $\mathcal{T}$. Then we define the modified strength $|\gamma|$ of an elementary wave γ in the case $g_u < 0$ by

$$|\gamma|_w = \begin{cases} |P(\gamma)|^*_w + \delta(\gamma) & \text{if } \gamma \text{ is a standing wave on the right of } \mathcal{T}, \\ |\gamma|^*_w & \text{otherwise,} \end{cases} \tag{2.29}$$

where $d(\gamma)$ is defined in (2.26) and (2.28). For a sequence of elementary waves $\gamma_1, \ldots, \gamma_n$, we define the modified linear functional

$$L_w[\gamma_1, \ldots, \gamma_n] = \sum_{i=1}^{n} |\gamma_i|_w. \tag{2.30}$$

This completes the definition of L_w in the case $g_u < 0$. We now define the modified linear functional L_w in the case $g_u > 0$.

So assume now that $g_u > 0$. We show first that L^*_w is discontinuous under perturbation of a strong standing wave on the left of $\mathcal{T}$ followed by a zero speed shock wave; cf. Figure 11. Referring to Figure 11, we see that both $U_L \to U_M \to U_R$ and $U_L \to E \to U_R$ both solve the Riemann problem, but $L^*_w(U_L \to U_M \to U_R) = L^*_w(U_L \to K \to I \to U_R) \neq L^*_w(U_L \to E \to U_R)$. To correct for this in the case $g_u > 0$, we modify the definition of wave strength for strong standing waves on the *left* of $\mathcal{T}$ by exactly the amount required to make L^*_w continuous.

To make this precise, let U_L and U_R denote the left and right states of a strong ($u_L < u_R$) standing wave γ_0 on the left of $\mathcal{T}$. In this case, let $a_s(u)$ denote the unique standing wave curve that passes through the states U_L and U_R, and let $U_* = (a_*, u_*)$ denote the unique point at which this standing curve a_s intersects the transition curve $\mathcal{T}$. Let $f(a, u) = f(a_*, u_*)$ define the unique zero speed shock curve that passes through the state U_*, defined to the right of $\mathcal{T}$, and let $I = (a_\#, u_\#)$ denote the state on this zero speed shock curve at level a_R; cf. Figure 12. Thus, I is determined by the condition that $I > \mathcal{T}$, together with $a_\# = a_R$, and $f(a_*, u_*) = f(a_R, u_\#)$. (Note that the zero speed shock curve emanating from U_* lies to the left of the standing wave curve emanating from U_* because $g_u > 0$.) Now define the state K to be the state at level a_L on the standing wave curve through I lying on the right-hand side of the transition curve $\mathcal{T}$ on the opposite side from U_L (see Figure 12). Since I and K are determined by γ_0 alone, we can define

$$\delta(\gamma_0) = L^*_w(\bar{U}_L \to K \to I) - L^*_w(\bar{U}_L \to \bar{U}_R \to I), \tag{2.31}$$

which is defined for any strong standing wave γ_0 lying to the left of $\mathcal{T}$ in the case $g_u > 0$. (Note that this is exactly the deficit between $L^*_w(U_L \to K \to I)$ and $L^*_w(U_L \to$

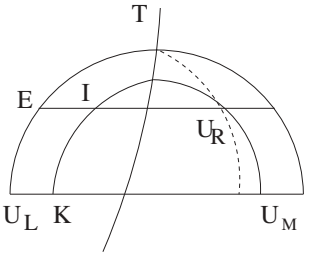

FIG. 11.

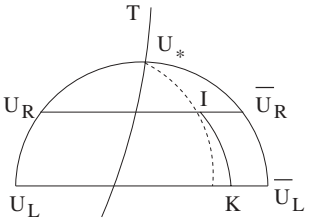

FIG. 12.

$U_R \to I$) in Figure 12. Note also that as before, $\delta(\gamma_0) = 0$ when $U_R \in \mathcal{T}$, $|\gamma_0|$ reduces to $|\gamma_0|_*$ in this limit.) Thus, in the case $g_u > 0$, we define the modified strength $|\gamma_0|$ of a strong standing wave on the left of $\mathcal{T}$ by the rule $|\gamma_0|_w = |\gamma_0|^*_w + \delta(\gamma_0)$.

Consider finally the triple composite standing wave $\gamma_0 \equiv U_L \to P \to Q \to R$ in Figure 17, isolated in Figure 13, for the case $g_u > 0$. In both diagrams, $R = U_R$ denotes the right state of the triple composite standing wave γ_0. In this case, the projection $P(\gamma_0)$ is given by $P(\gamma_0) = U_L \to T \to R$. We now show that the value of $L^*_w(P(\gamma_0))$ is discontinuous as $U_L = R$ varies from R to I along the line segment SN in Figure 13. Indeed, as $P(\gamma_0)$ varies from $U_L \to T \to R$ to $U_L \to M \to L$, the solution of the Riemann problem changes to $U_L \to M \to L$ and then to $U_L \to K \to I$. Thus, for continuity, we require that $L_w(U_L \to M \to L) = L_w(U_L \to T \to L)$. But $L^*_w(U_L \to M \to L) + \delta = L^*_w(U_L \to T \to L)$, where $\delta = \delta(\gamma_0) = L^*_w(M \to K \to I) - L^*_w(M \to L \to I)$. Thus, for the general weak standing wave $U_L \to U_R$ on the left of $\mathcal{T}$ when $g_u > 0$, diagrammed in Figure 14, define

$$\delta = \delta(\gamma_0) = L^*_w(I \to K \to \bar{U}_R) - L^*_w(I \to \bar{U}_L \to \bar{U}_R). \tag{2.32}$$

We take this as defining $\delta(\gamma_0)$ for any weak standing wave on the left of $\mathcal{T}$ that takes U_L to U_R, where for triple composite waves, (2.32) is assumed to apply to the weak standing wave on the left in $P(\gamma_0)$. (Again, note that the points K and I in Figure 14 are determined by U_L and U_R alone.) To put this together, let $P(\gamma_0) = \gamma_0$ for any standing wave that is not triple composite, and let $\delta(\gamma_0)$ be defined in (2.31) and (2.32) for strong and weak standing waves on the right of $\mathcal{T}$. Then we define the modified strength $|\gamma|$ of an elementary wave γ in the case $g_u > 0$ by

$$|\gamma|_w = \begin{cases} |P(\gamma)|^*_w + \delta(\gamma) & \text{if } \gamma \text{ is a standing wave on the left of } \mathcal{T}, \\ |\gamma|^*_w & \text{otherwise,} \end{cases} \tag{2.33}$$

where $d(\gamma)$ is defined in (2.31) and (2.32). For a sequence of elementary waves

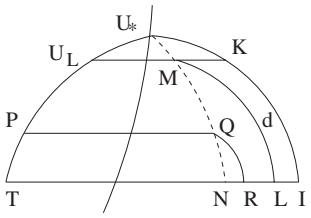

FIG. 13.

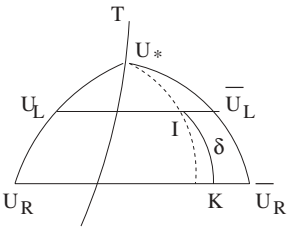

FIG. 14.

$\gamma_1, \ldots, \gamma_n$, again define the modified linear functional

$$L_w[\gamma_1, \ldots, \gamma_n] = \sum_{i=1}^{n} |\gamma_i|_w. \tag{2.34}$$

This completes the definition of L_w for the case $g_u > 0$ and so completes the definition of L_w in general.

We can now present in detail the admissible solution of the Riemann problem based on the L_w minimization principle. The solutions $[U_L, U_R]$ that are admissible by Definition 2.1 are diagrammed in Figures 15–18 for the cases $g_u < 0, g_u > 0$ and U_L to the left of $\mathcal{T}$, U_L to the right of $\mathcal{T}$. The solutions that minimize L_z are pointed out for comparison.[8] The cases $g_u < 0$ and $g_u > 0$ are qualitatively different because of the location of the zero speed shock curve. To read the diagrams, start at U_L and follow the arrows to an arbitrary state U_R. The wave curves traversed then give the elementary waves in the solution of the Riemann problem going from left to right in the (x,t)-plane. In the limit as g tends to zero, these diagrams reduce to those for the resonant homogeneous system $u_t + f(a,u)_x = 0$ [10, 12].

In Figures 15–18, the solid convex down curves denote standing wave curves, and the dotted curve to the right of $\mathcal{T}$ denotes the zero speed shock curve corresponding to the standing wave curve through U_L. In Figures 15 and 16, the dotted line falls to the right of the standing wave curve through U_L because $g_u < 0$. Similarly, in Figures 17 and 18, it falls to the left because $g_u > 0$. We discuss the multiplicity of solutions in Figures 15–17 below. In Figure 18, solutions are unique.

In each of Figures 15–17, there is a region of right states U_R for which there are multiple solutions of the Riemann problem that minimize the total variation in a.

[8] In [13] it was shown that the solutions of the Riemann problem that minimize L_z actually minimize L_z over all sequences of connected elementary waves that connect U_L to U_R. This essentially implies that L_z is nonincreasing on solutions. On the other hand, this is not the case for the solutions of the Riemann problem that minimize L_w, and this explains why a potential interaction term is required to construct a decreasing functional that incorporates L_w.

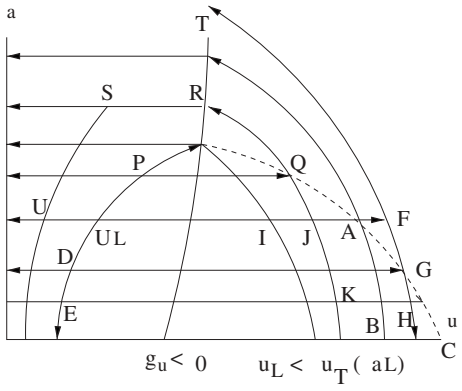

FIG. 15.

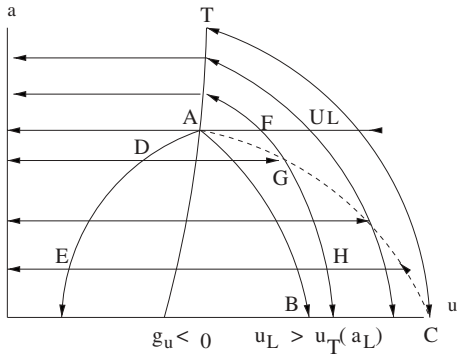

FIG. 16.

In the region of multiple solutions, there is always a multiplicity of three solution in the interior of the region, but this reduces to a multiplicity of two on the boundary of the region. The L_w minimization principle rules out every four wave solution, *except for* the two special cases labeled by $U_L \to P \to Q \to R$ in Figures 15 and 17. However, in both cases, the zero speed wave in the solution of the Riemann problem always consists of a standing wave followed by a zero speed shock wave followed by another standing wave (all zero speed) and the monotonicity in a is preserved across triple composite standing waves. From the point of view of wave interactions, such composite waves interact like a single wave, and so in our discussion below, we will treat triple composite standing waves as *a single standing wave*. With this convention, (and allowing waves to have zero strength), the admissible solution of the Riemann problem always consists of three elementary waves: a negative speed nonlinear wave followed by a single standing wave, followed by a positive speed nonlinear wave.

Discussion of Figure 15 [$g_u < 0$; U_L to the left of $\mathcal{T}$]. A multiplicity of solutions occurs when U_R lies within the interior of the region ABC, e.g., $U_R = H$. The three solutions are: $U_L \to F \to H$, $U_L \to D \to G \to H$, and $U_L \to E \to H$. (Here, e.g., $U_L \to F$ denotes the elementary shock wave taking U_L on the left to F on the right. Since F lies to the right of the zero speed shock curve (the dotted line), and since $f_{uu} < 0$, $U_L \to F$ is a shock wave of negative speed.) All of these solutions have the same L_z-value, but only the solution $U_L \to F \to H$ minimizes

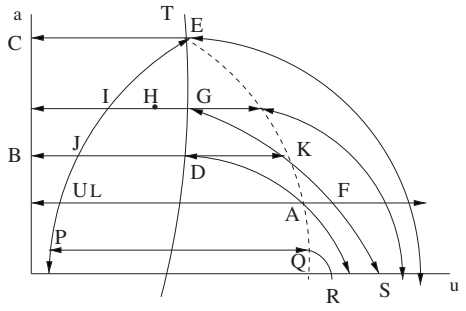

FIG. 17.

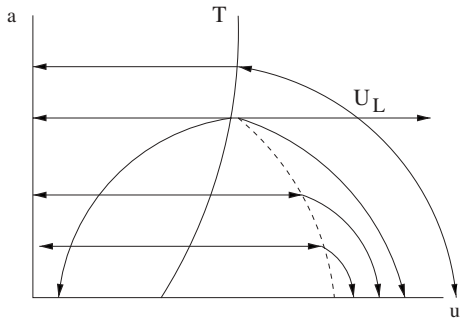

FIG. 18.

L_w. Indeed, consider region U_L, F, H, E of Figure 15, which is described in Figure 19. $L_w(U_L \to F \to H) - L_w(U_L \to E \to H) = L_w^*(U_L \to F \to H) + \delta(F \to H) - L_w^*(U_L \to E \to H) = L_w^*(U_L \to F \to H) + \delta(F \to H) - L_w^*(U_L \to I \to K \to H) = L_w^*(I \to F \to H) - L_w^*(I \to K \to H) + \delta(F \to H) = L_w^*(I \to F \to H) - L_w^*(M \to F \to H) + L_w^*(M \to N \to H) - L_w^*(I \to K \to H) = L_w^*(I \to M \to N) - L_w^*(I \to K \to N) < 0$ by Lemma 2.7. Similarly we can show that $L_w(U_L \to F \to H) - L_w(U_L \to D \to G \to H) < 0$. It follows that $U_L \to F \to H$ is the unique solution of the Riemann problem selected by the L_w minimization principle.

Discussion of Figure 16 [$g_u < 0$; U_L to the right of $\mathcal{T}$]. A multiplicity of solutions that minimize the total variation in a (but do not necessarily minimize L_z) occurs when U_R lies within the interior of the region ABC, e.g., $U_R = H$. The three solutions are $U_L \to F \to H$, $U_L \to A \to E \to H$, and $U_L \to A \to D \to G \to H$. The L_z-value is minimized only on the first of these, and thus in this case the L_z minimization principle selects a unique admissible solution. The functional L_w is also minimized on the solution $U_L \to F \to H$. For example, referring to Figure 20, $L_w(U_L \to F \to H) - L_w(U_L \to A \to E \to H) = L_w^*(F \to H) + \delta(F \to H) - L_w^*(F \to A \to B \to H)$. But $\delta(F \to H) = L_w^*(I \to K) + L_w^*(K \to H) - L_w^*(F \to H) - L_w^*(F \to I)$, $L_w^*(K \to H) - L_w^*(B \to H) = -L_w^*(B \to K)$, and $L_w^*(I \to K) \le L_w^*(A \to B)$ (by the Corollary to Lemma 2.7). Substituting these as inequalities into the previous line gives $L_w(U_L \to F \to H) - L_w(U_L \to A \to E \to H) \le -[L_w^*(F \to I) + L_w^*(F \to A) + L_w^*(B \to K)] < 0$. The case for $L_w(U_L \to F \to H) - L_w(U_L \to A \to D \to G \to H) < 0$ is similar.

Discussion of Figure 17 [$g_u > 0$; U_L to the left of $\mathcal{T}$]. A multiplicity of solutions that minimize the total variation in a occurs when U_R lies within the

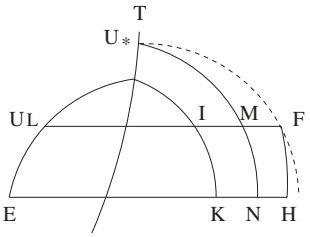

FIG. 19.

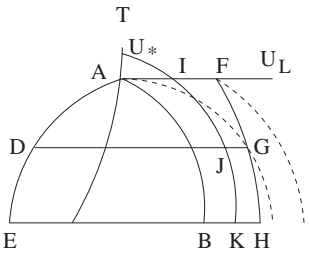

FIG. 20.

interior of the region CEADB, e.g., $U_R = H$. The three solutions are $U_L \to I \to H$, $U_L \to F \to G \to H$, and $U_L \to J \to K \to G \to H$. In this case the L_z and L_w minimization principles both pick out the unique solution $U_L \to I \to H$. Note that on the boundary, say $U_R = M$, where the wave structure changes, there is a multiplicity of *two* distinct solutions, $U_L \to I \to M$ and $U_L \to N \to M$, and at this boundary, the L_z and L_w values of both solutions are equal, a requirement for the continuity of the functionals with respect to U_L and U_R. (cf. the paragraph preceding (2.29)). As an example, we verify that $L_w(U_L \to I \to H) - L_w(U_L \to F \to G \to H) < 0$, (see Figure 21). To this end, write $L_w(U_L \to I \to H) - L_w(U_L \to F \to G \to H) = L_w^*(U_L \to I \to H) + \delta(U_L \to I) - L_w^*(U_L \to L \to G \to H) = L_w^*(U_L \to I) + L_w^*(I \to H) + [L_w^*(U_L \to P) + L_w^*(P \to Q) - L_w^*(U_L \to I) - L_w^*(I \to Q)] - L_w^*(U_L \to L) - L_w^*(L \to G) - L_w^*(G \to H) = L_w^*(P \to Q \to H) - L_w^*(P \to L \to G) - L_w^*(G \to H) < 0$ by Lemma 2.7.

Discussion of Figure 18 [$g_u > 0$; U_L to the right of $\mathcal{T}$]. In this case the solution that minimizes the total variation in a is unique.

We now summarize the main results regarding the solution of the Riemann problem.

PROPOSITION 2.10. *The admissible solution of the Riemann problem $[U_L, U_R]$ always consists of a sequence of three connected waves, a negative speed nonlinear wave γ_1 followed by a standing wave γ_0 followed by a positive speed nonlinear wave γ_2, where we allow $\gamma_i = 0$, and we treat the composite zero speed waves of type $U_L \to P \to Q \to R$ in Figure 15 as a single wave γ_0. We write*

$$[U_L, U_R] = \gamma_1\gamma_0\gamma_2. \tag{2.35}$$

PROPOSITION 2.11. *The functional $L_w([U_L, U_R])$ is a continuous function of U_L and U_R throughout the domain Ω.*

PROPOSITION 2.12. *The convex side, (i.e., lower side when $f_{uu} < 0$), of each standing wave curve is an invariant region for admissible solutions of the Riemann*

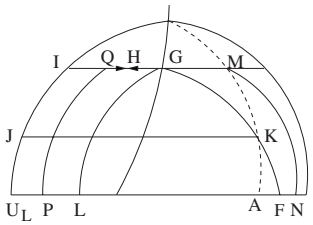

FIG. 21.

problem.

Proof. Proposition 2.10 is clear by construction. The proof of Propositions 2.11 has been indicated above and follows directly via a case by case inspection of the Riemann problem. Note that the continuity of L_w follows upon verifying that the only places where $L_w^*([U_L, U_R])$ is discontinuous were identified in the discussion following Corollary 2.8, and the deficit was accounted for by the correction term $\delta(\gamma)$. Proposition 2.12 follows immediately from the fact that all intermediate states in the admissible solution of the Riemann problem lie on the convex side of the outer of the two standing wave curves through U_L and U_R. □

Proposition 2.12 implies an L^∞ bound on Glimm approximate solutions generated by the admissible solution of the Riemann problem.

3. The generalized Glimm method. In this section we construct the approximate Glimm scheme solutions $U_{\Delta x}(x,t)$ and prove the compactness of approximate solutions under the assumption that the initial data is of bounded total variation in (a,z) (which implies that the initial data is of bounded total variation in (a,w)). We call this a generalized Glimm scheme because the standing waves are generalized weak solutions of system (1.1) due to the presence of the a' in the term $a'g$ on the right-hand side of (1.1). The proof of convergence of the residual must be modified because a piecewise constant approximation of $a(x)$ does not give an L^∞ approximation of $a'g$, and so the residual does not converge strongly, but rather weakly. This argument was first given in the strictly hyperbolic case in [6], and for completeness, we include the argument adapted to the problem here (in section 6).

To begin, assume that the initial data $U_0(x)$ takes values in a neighborhood Ω which lies below a standing wave curve and above a curve $a = \text{const}$ contained within a neighborhood of U_*, where the unique solution of the Riemann problem exists as constructed in the previous section, and small enough so that Lemmas 2.4–2.7 and Propositions 2.10–2.12 hold throughout Ω. Since Ω is an invariant region for Riemann problems, it follows that Ω is also an invariant region for the Glimm scheme, which is therefore defined for all time for any mesh length. To construct the approximate solutions, first discretize $R \times [0,\infty)$ by spatial mesh length Δx and time mesh length Δt such that

$$\frac{\Delta x}{\Delta t} = \lambda, \tag{3.1}$$

where

$$\lambda \equiv 2 \sup_{(a,u)\in\Omega} \left\{ \left| \frac{\partial f}{\partial u} \right| \right\}. \tag{3.2}$$

We let $x_i = i\Delta x$, $t_j = j\Delta t$ so that (x_i, t_j) denote the mesh points of the approximate

solution. Define

$$S_j = \{(x,t) : t_j \le t < t_{j+1}\}.$$

The approximate solution $U_{\Delta x}$ generated by the Glimm scheme is defined as follows. First, fix a sample sequence $\theta = \{\theta_{ij}\} \in \Theta$, where Θ denotes the infinite product of intervals $(0,1)$ indexed by mesh points (with Lebesgue measure) so that $\Theta = \Pi(0,1)_{ij}$ and $\theta_{ij} \in (0,1)$, $-\infty < i < \infty$, $j \ge 0$ [4, 24]. (We randomize in space and time to facilitate the proof of convergence of the residual; cf. [25]). To initiate the scheme at $j = 0$, approximate the initial data by piecewise constant states by setting

$$U_i^0 = U_{\Delta x}(x,0) = U_0(x_i + \theta_{i0}\Delta x), \quad x_i < x < x_{i+1}. \tag{3.3}$$

Assuming that $U_{\Delta x}(x,t)$ has been constructed for $(x,t) \in \bigcup_{j=0}^{j-1} S_j$, then define $U_{\Delta x}$ in S_j as the solution of (1.1) with the initial values

$$U_i^j = U_{\Delta x}(x,t_j+) = U_{\Delta x}(x_i + \theta_{ij}\Delta x, t_j-), \quad x_i < x < x_{i+1}. \tag{3.4}$$

In other words, at each time t_j, a piecewise constant approximation $U_{\Delta x}(x,t_j+)$ is obtained by sampling the solution $U_{\Delta x}(x,t_j-)$ in each interval of the mesh at time level t_j, so that the solution in S_j can be constructed by solving the Riemann problems $[U_{i-1}^j, U_i^j]$ posed at each point of discontinuity $(x_i,t_j), i \in Z$. The Courant–Friedrichs–Levy restriction (3.1) ensures that the Riemann problem solutions in each S_j do not interact before time t_{j+1} [13].

We need to define the I-curves for the analysis of the nonlocal functional F defined below; cf. [4]. An I-curve J is a continuous space-like piecewise linear curve in the (x,t)-plane that connects adjacent mesh points of type $(x_i + \theta_j\Delta x, t_j)$ to ones of type $(x_i, t_{j+1/2})$, where $(x_i, t_{j+1/2}) = (i\Delta x, (j+1/2)\Delta t)$. Given an I-curve J_1 that extends from $i = -\infty$ to $i = +\infty$, we obtain a successor J_2 of J_1 by lifting the point $(x_i, t_{j-1/2})$ to the point $(x_i, t_{j+1/2})$ when the points $(x_{i-1} + \theta_j\Delta x, t_j)$ and $(x_i + \theta_j\Delta x, t_j)$ both lie on J_1. We call the region $(x_i, t_{j-1/2}), (x_i, t_{j+1/2}), (x_{i-1} + \theta_j\Delta x, t_j), (x_i + \theta_j\Delta x, t_j)$ between J_1 and J_2 the interaction diamond Δ. We let J^j denote the I-curve that contains all of the sample points $(x_i + \theta_j\Delta x, t_j)$ at time level t_j. The I-curve J^j crosses all of the waves in the Riemann problems posed in $U_{\Delta x}$ at time level t_j, and the I-curve J^j can be obtained by a sequence of successive I-curves. (Note that lifting the mesh point $(x_i + \theta_j\Delta x, t_j)$ to $(x_i + \theta_j\Delta x, t_{j+1})$ when mesh points $(x_{i-1}, t_{j+1/2})$ and $(x_i, t_{j+1/2})$ both lie on J, does not change the waves that J crosses, and so we can consider these to be equivalent.) It follows that to show that a functional F satisfies $F(J^j) \le F(J^0)$, it suffices only to prove that $F(J_2) \le F(J_1)$ for any pair of successive mesh curves J_1 and J_2 [4].

We have the following theorem; cf. [13].

THEOREM 3.1. *If the neighborhood Ω containing U_* is chosen to be small enough, then the Glimm approximate solutions $U_{\Delta x}(x,t)$ are defined for all time. Moreover,*

$$L_z(J^{j+1}) \le L_z(J^j) \tag{3.5}$$

for each $j \ge 0$, where J^j identifies the sequence of elementary waves appearing in the approximate solution $U_{\Delta x}$ in the strip S_j, and L_z is defined in (2.14).

Proof. The proof of (3.5) was given in [13]. The supnorm bound on solutions follows from Proposition 2.11 which asserts the existence of convex invariant regions for Riemann problems in a neighborhood of U_*. The main point in the proof of (3.5)

is that the solutions of the Riemann problems used in the construction of the Glimm approximate solutions are admissible solutions of the Riemann problem, and so were selected to minimize the L_z-value of the elementary waves among all possible solutions of the Riemann problem. But L_z has the further property of being minimized on the solution of the Riemann problem among all connected sequences of elementary waves that take U_L to U_R. (This was proven in [13].) Using this, estimate (3.5) follows because L_z decreases across any interaction diamond Δ_{ij} lying between the two successive I-curves J_1 and J_2 with interaction diamond centered on (x_i, t_j). Indeed, the Glimm scheme replaces the sequence of waves that take U^j_{i-1} to U^j_i at time level t_j- by the waves that solve the Riemann problem $[U^j_{i-1}, U^j_i]$ at $t = t_j +$. □

Theorem 3.1 leads directly to the following compactness result for approximate solutions generated by the Glimm method.

THEOREM 3.2. *Assume that the initial data $U_0(x) \in \Omega$ satisfies the condition $\mathrm{Var}_z\{U_0(\cdot)\} = V_z < \infty$ and $\mathrm{Var}\{a(\cdot)\} = V_a < \infty$. Then $U_{\Delta x}(x,t) \in \Omega$ for all $x, t \geq 0$, $\mathrm{Var}_z\{U_{\Delta x}(\cdot,t)\} < 4V_z$ for all $t \geq 0$, and a subsequence of $\{U_{\Delta x}\}$ converges boundedly, almost everywhere, to a bounded measurable function $U(x,t)$ as Δx tends to zero.*

Proof. See Theorem 3.2 [18]. □

From here on out we assume that $U_{\Delta x}(x,t)$ is a sequence of Glimm approximate solutions that converges boundedly, pointwise almost everywhere to a function $U(x,t)$, and satisfies the estimate

$$\mathrm{Var}_z\{U_{\Delta x}(\cdot,t)\} < 4V_z. \tag{3.6}$$

In section 6 we conclude this argument by showing that the limit function $U(x,t)$ is a classical weak solution of (1.1) when a' has no delta function singularities.

4. The interaction potential $d(\gamma_0, \gamma_r)$. Assume that $U_{\Delta x}(x,t)$ is an approximate Glimm scheme solution starting from initial data $U_0(x)$ of bounded total variation in (a,u) and hence (a,w) as well. Then the total variation in (a,z) of $U_{\Delta x}(\cdot,0)$ is uniformly bounded, and hence the existence theory of section 3 applies. Thus, without loss of generality, we can assume that $U_{\Delta x} \to U$, where $U(x,t)$ is a weak solution of (1.1) of bounded total variation in z at each fixed time. (The convergence is in L^1_{loc} at each fixed time, uniformly on compact sets.) We now estimate the growth of the total variation in w (and hence in u) in the approximate solutions $U_{\Delta x}(x,t)$.

Our idea is to use the functional L_w to estimate the total variation in w at each time in an approximate solution $U_{\Delta x}(x,t)$. The problem of estimating L_w is more difficult than the problem of estimating L_z because in the case of L_w, it is *not* true that $L_w(J_{j+1}) \leq L_w(J_j)$ across interactions. The point is that L_w is minimized on the admissible solution of the Riemann problem among all solutions of the Riemann problem, but it is *not* minimized on the admissible solution of the Riemann problem among all connected sequences of elementary waves that take U_L to U_R, even if there is just a single standing wave within the sequence. Indeed, if a fast rarefaction wave followed by a slow standing wave interacts to produce a slow standing wave followed by a fast rarefaction wave, then L_w increases across this interaction. This is because rarefaction wave-standing wave interactions, in which incoming and outgoing waves all lie on one side of $\mathcal{T}$, always have the effect of moving the standing wave closer to the transition curve—this increases the L_w because it shifts the total variation in u from the nonlinear waves to the standing waves, which are weighted by the larger factors of 2 and 4 over the weight on the nonlinear waves. We verify this in two examples below. The remarkable fact that the functional L_w increases *only* on rarefaction

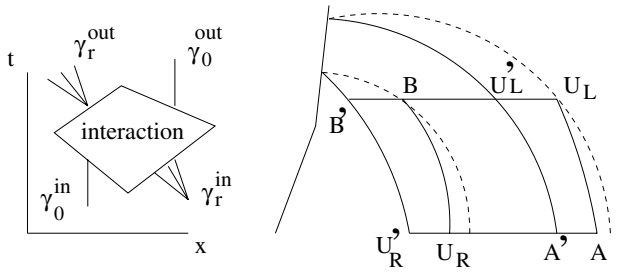

FIG. 22.

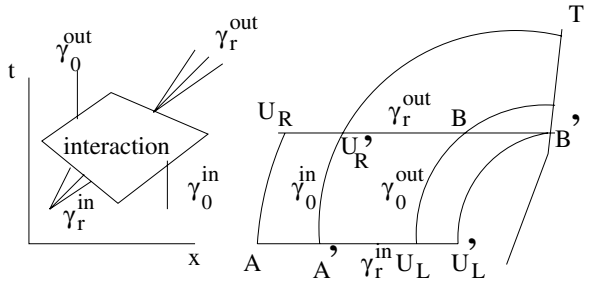

FIG. 23.

wave/standing wave interactions, and is nonincreasing on *all other* interactions, is discussed after the examples. Our strategy is then to define a potential for the increase in L_w due to the interaction of a standing wave and a rarefaction wave and to prove that L_w plus the sum of all potential interaction terms define a nonlocal functional F that bounds the total variation in w and decrease across interactions.

We begin by verifying that L_w increases on rarefaction wave/standing wave interactions in two salient examples: the case when $g_u < 0$ and the standing wave is a strong standing wave on the right of $\mathcal{T}$, and the case when $g_u > 0$ and the standing wave is a strong standing wave on the left of $\mathcal{T}$. These two examples clarify the problem of bounding the increase in L_w on interactions. So consider first the interaction diagrammed in Figure 22, the case when $g_u < 0$, and a standing wave γ_0^{IN} starting to the left of a negative speed rarefaction wave γ_r^{IN} interacts to produce a negative speed rarefaction wave γ_r^{OUT} followed by a standing wave γ_0^{OUT}. (For simplicity we assume in this example that all waves lie to the right of $\mathcal{T}$.) Then $[U_L, U_R] = (\gamma_r^{OUT}, \gamma_0^{OUT})$, but $L_w(\gamma_r^{OUT}, \gamma_0^{OUT}) - L_w(\gamma_r^{IN}, \gamma_0^{IN}) = L_w^*(\gamma_r^{OUT}) + L_w^*(\gamma_0^{OUT}) + \delta(\gamma_0^{OUT}) - L_w^*(\gamma_r^{IN}) - L_w^*(\gamma_0^{IN}) - \delta(\gamma_0^{IN}) = L_w^*(U_L \to B \to U_R) + \delta(\gamma_0^{OUT}) - L_w^*(U_L \to A \to U_R) - \delta(\gamma_0^{IN}) = L_w^*(U_L' \to B' \to U_R') - L_w^*(U_L' \to A' \to U_R') > 0$ by Lemma 2.7.

Consider next the case of the interaction diagrammed in Figure 23, the case when $g_u > 0$, and a positive speed rarefaction wave γ_r^{IN} starts to the left of a standing wave γ_0^{IN} and interacts to produce a standing wave γ_0^{OUT} followed by (that is, to the left of) a positive speed rarefaction wave γ_r^{OUT}. (Again, for simplicity, we assume in this example that all waves lie to the left of $\mathcal{T}$.) Then $[U_L, U_R] = (\gamma_0^{OUT}, \gamma_r^{OUT})$, but $L_w(\gamma_0^{OUT}, \gamma_r^{OUT}) - L_w(\gamma_0^{IN}, \gamma_r^{IN}) = L_w^*(\gamma_0^{OUT}) + \delta(\gamma_0^{OUT}) + L_w^*(\gamma_r^{OUT}) - L_w^*(\gamma_0^{IN}) -$

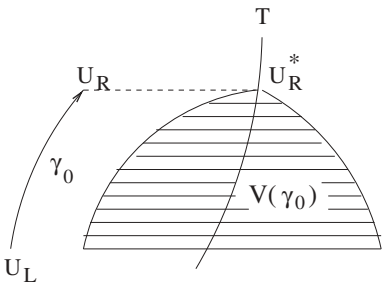

FIG. 24.

$\delta(\gamma_0^{IN}) - L_w^*(\gamma_r^{IN}) = L_w^*(U_L \to B \to U_R) + \delta(\gamma_0^{OUT}) - L_w^*(U_L \to A \to U_R) - \delta(\gamma_0^{IN}) = L_w^*(U_L' \to B' \to U_R') - L_w^*(U_L' \to A' \to U_R') > 0$ by Lemma 2.7. One can verify that L_w is nonincreasing on shock wave-standing wave interactions that lie on one side of $\mathcal{T}$ by similar examples. This concludes the examples.

What is remarkable is that the increase in L_w due to rarefaction wave-standing wave interactions that are not transonic (that is, all waves in the interaction lie entirely on the same side of $\mathcal{T}$) accounts for *all* of the ways L_w can increase, even for complicated transonic wave interactions that carry waves across the transition curve. The proof that we need only a potential interaction term for nontransonic rarefaction wave-standing wave interactions is a consequence of our proof below that the nonlocal functional F is nonincreasing on all interactions, but in the proof it is difficult to see the reason for the decrease in the functional in the complicated case when the interactions are transonic. To motivate the argument, consider a standing wave γ_0 that takes $U_L = (a_L, u_L)$ to $U_R = (a_R, u_R)$. Then this wave lies entirely on one side of $\mathcal{T}$, or else it is a composite wave of type $U_L \to P \to Q \to R$ of Figure 15. Let $a_* = \max\{a_L, a_R\}$, and let $U_* = (a_*, u_*)$ denote the point on $\mathcal{T}$ that lies at level $a = a_*$. Consider now the region $V(\gamma_0)$ that lies below the standing wave curves on the left and right of $\mathcal{T}$ that pass through the state $U = U_*$; cf. Figure 24. The claim then is that any rarefaction wave that lies in the region $V(\gamma_0)$ in an approximate solution that contains the wave γ_0 cannot interact with γ_0 in such a way as to produce an increase in L_w. For example, one can verify that when the connected sequence of waves $\gamma_r\gamma_0$ or $\gamma_0\gamma_r$ interact to produce the waves in the Riemann problem $[U_L, U_R]$, L_w will be nonincreasing and the wave γ_r will be eliminated by the interaction when γ_r in $V(\gamma_0)$. This helps explain why we needn't include such portions of the rarefaction wave in the definition of the interaction potential $d(\gamma_0, \gamma_r)$ below.

We now define $d(\gamma_0, \gamma_r)$, the potential for the increase in L_w due to the interaction of a standing wave γ_0 that *approaches* a rarefaction wave γ_r; cf. [4]. (Although there is an ordering of the waves in the (x,t)-plane implied by the condition that two waves approach, we assume no ordering in d, so that $d(\gamma_0, \gamma_r) \equiv d(\gamma_r, \gamma_0)$.) So assume that γ_0 and γ_r are waves that cross the same I-curve J in an approximate Glimm scheme solution $U_{\Delta x}$. We say that γ_0 and γ_r *approach* on J if the faster of the two waves is positioned to the left of the slower wave on J in the (x,t)-plane. Any two such waves will interact at a later time in the approximate solution $U_{\Delta x}$. Note that standing waves always have zero speed, and to make the definition of approaching unambiguous, assume that all rarefaction waves have purely positive or negative speed by treating any rarefaction wave that crosses $\mathcal{T}$ as two separate waves by partitioning such a rarefaction wave into its positive and negative speed parts. (In this case, the wave

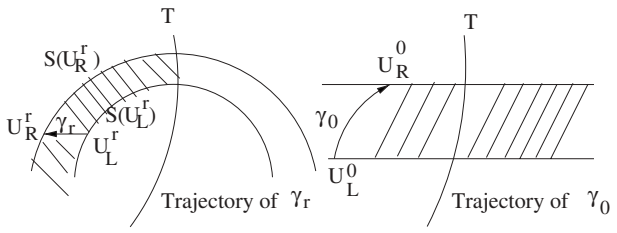

FIG. 25.

will be partitioned at the point where the wave crosses $\mathcal{T}$ since this is the curve of zero characteristic speed.) If α and β are indices that identify two waves that cross J, then we write $(\alpha, \beta) \in App(J)$ if γ^α approaches γ^β on J.

In order to define $d(\gamma_0, \gamma_r)$ for two approaching waves γ_0 and γ_r, we first define what we call the interaction region $\Delta(\gamma_0, \gamma_r)$, the region in U-space where the interaction of γ_r and γ_0 will take place (assuming the rarefaction wave is not canceled out before the interaction occurs). To this end, we first define what we call the *trajectory* of the waves γ_r and γ_0. If the waves interact, then the interaction will occur within the region determined by the intersection of the two trajectories. Since the standing wave curves and nonlinear wave curves act like Riemann invariants for the system (1.1), it follows that when a rarefaction wave interacts with a standing wave, the standing wave is just translated along the nonlinear wave curves and the rarefaction wave is translated along the standing wave curves. Thus let $\gamma_0 = [U_L^0, U_R^0]$ and $\gamma_r = [U_L^r, U_R^r]$ denote a standing wave and a rarefaction wave, respectively. In the case when the standing wave γ_0 is a composite wave of type $U_L \to P \to Q \to R$ of Figure 15, we define

$$d(\gamma_0, \gamma_r) = d(\gamma_0', \gamma_r), \tag{4.1}$$

where γ_0' denotes the standing wave in the projection $P(\gamma_0)$ (e.g., $\gamma_0' = \mathcal{T} \to R$ in Figure 15). Thus to define $d(\gamma_0, \gamma_r)$, it suffices to assume that the standing wave γ_0 lies entirely on one side of $\mathcal{T}$ (admissible, noncomposite standing waves do not cross the transition curve), and we can assume that the rarefaction wave γ_r lies entirely on one side of $\mathcal{T}$ because rarefaction waves are partitioned so as to have unambiguous positive or negative speed. For the rarefaction wave γ_r let $\mathcal{S}(U_L^r), \mathcal{S}(U_R^r)$ denote the standing wave curves that pass through states U_L^r, U_R^r, respectively. We can now define the *trajectory* of a rarefaction wave γ_r and a standing wave γ_0; cf. Figure 25.

DEFINITION 4.1. *Let $\gamma_r = [U_L^r, U_R^r]$ denote a rarefaction wave that lies entirely one side of the transition curve, say $\gamma_r \le \mathcal{T}$ or $\gamma_r \ge \mathcal{T}$. Then the* trajectory $Traj(\gamma_r)$ *of γ_r is the region in U-space between the two standing wave curves $\mathcal{S}(U_L^r)$ and $\mathcal{S}(U_R^r)$, intersected with $u \le \mathcal{T}$ or $u \ge \mathcal{T}$, according to whether $\gamma_r \le \mathcal{T}$ or $\gamma_r \ge \mathcal{T}$, respectively.*

DEFINITION 4.2. *The trajectory $Traj(\gamma_0)$ of a standing wave γ_0 is the region between the curves $a = a_L^0$ and $a = a_R^0$, i.e., the region between the two nonlinear wave curves through U_L^0 and U_R^0, respectively.*

We note that $Traj(\gamma_r)$ includes only the region on the side of $\mathcal{T}$ that contains the wave γ_r because a rarefaction wave cannot cross $\mathcal{T}$ without being canceled out by a shock wave, but $Traj(\gamma_0)$ contains the region on both sides of $\mathcal{T}$ because a standing wave can cross $\mathcal{T}$ as a result of interaction. It follows that the interaction of γ_0 and γ_r can only take place on the side of $\mathcal{T}$ that contains γ_r.

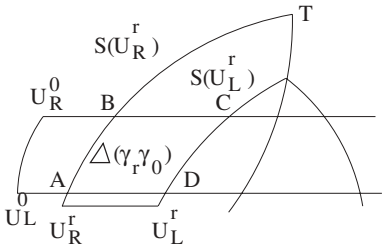

FIG. 26.

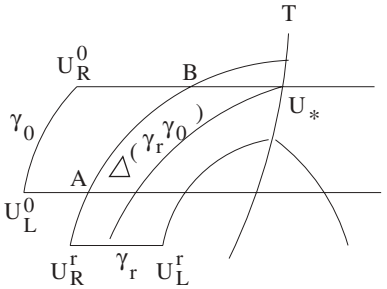

FIG. 27.

We now define the interaction region $\Delta(\gamma_0, \gamma_r)$. To this end, consider the region equal to the intersection between $Traj(\gamma_r)$ and $Traj(\gamma_0)$, which lies entirely on the same side of $\mathcal{T}$ as the rarefaction wave γ_r. If there exists a full set of four intersection points between the curves $\mathcal{S}(U_L^r), \mathcal{S}(U_R^r)$ and $a = a_L^0$, $a = a_R^0$ that all lie on the same side of $\mathcal{T}$ as the wave γ_r (diagrammed A, B, C, D in Figure 26), then define the interaction region $\Delta(\gamma_0, \gamma_r)$ to be the region $ABCD$, which is exactly equal to the intersection of the trajectory of γ_0 and the trajectory of γ_r. If the curves $\mathcal{S}(U_L^r), \mathcal{S}(U_R^r)$ and $a = a_L^0$, $a = a_R^0$ do not intersect in four distinct points on the same side of $\mathcal{T}$ as γ_r, we must modify the definition of $\Delta(\gamma_0, \gamma_r)$ to account for the fact that portions of the rarefaction wave γ_r will be canceled out before γ_0 can interact with the standing wave γ_0. To this end, let U_* denote the highest point on $\mathcal{T}$ where the trajectory of γ_0 intersects $\mathcal{T}$, i.e., let $U_* = (a_{max}, u_{\mathcal{T}}(a_{max}))$, where $a_{max} = \max\{a_L^0, a_R^0\}$; see Figure 27. Consider then the standing wave $\mathcal{S}(U_*)$ that passes through the point U_*, and ask whether $\mathcal{S}(U_*)$ lies within the trajectory of γ_r. If it does not (which means the trajectory of γ_r lies below U_*), then we say that the interaction region $\Delta(\gamma_0, \gamma_r) = \phi$, the empty set; that is, there is no potential for interaction of the waves γ_r and γ_0. If $\mathcal{S}(U_*)$ does lie within the trajectory of γ_r, then let $\Delta(\gamma_0, \gamma_r)$ denote the intersection of the trajectory of γ_0 with the trajectory of γ_r and *take away* all points U that lie below the standing wave curve $\mathcal{S}(U_*)$. In this case, $\Delta(\gamma_0, \gamma_r) = ABU_*D$, as diagrammed in Figure 27. This completes the definition of $\Delta(\gamma_0, \gamma_r)$. Note that in every case, $\Delta(\gamma_0, \gamma_r)$ consists of a region on the side of the transition curve that contains γ_r, bounded on the right and left by standing wave curves and above and below by nonlinear wave curves, determined by four vertices, which we label $ABCD$ as in Figure 28.

Now for any approaching waves γ_r and γ_0 (assuming rarefaction waves are partitioned at points where they cross $\mathcal{T}$), define $d(\gamma_0, \gamma_r)$ in terms of $\Delta(\gamma_0, \gamma_r)$ as follows.

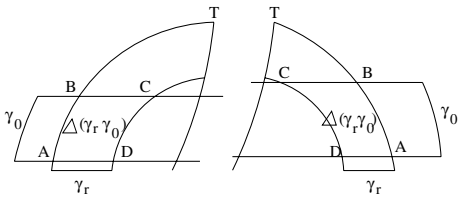

FIG. 28.

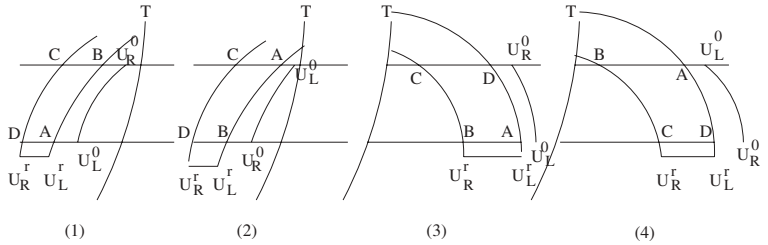

FIG. 29.

The interaction potential $d(\gamma_0, \gamma_r)$ is equal to the change in L_w between the waves that enter and the waves that leave the interaction region $\Delta(\gamma_0, \gamma_r)$, as determined by the orientation of the original waves γ_0 and γ_r. That is, there is only one way to project the waves γ_r and γ_0 to incoming waves on the boundary of $\Delta(\gamma_0, \gamma_r)$ so that γ_r is projected to a rarefaction wave, γ_0 is projected to a standing wave that preserves the increasing/decreasing of a across the wave, and the projected waves define a connected sequence of waves that preserve the left/right orientation of the original waves γ_r and γ_0. Thus, there are four cases in which γ_r and γ_0 can approach, labeled in Figure 29. These are determined by whether a increases or decreases across the standing wave γ_0 and whether the wave γ_r lies to the left or right of $\mathcal{T}$. In the four cases (1)–(4) labeled in Figure 29, $d(\gamma_0, \gamma_r)$ in each case is defined by

$$d(\gamma_0, \gamma_r) = L_w(A \to B \to C) - L_w(A \to D \to C). \tag{4.2}$$

Therefore, assuming that all rarefaction waves have been partitioned at points on $\mathcal{T}$, equation (4.2) defines $d(\gamma_0, \gamma_r)$ for any pair of approaching waves γ_r and γ_0, and we set $d(\gamma_0, \gamma_r) = 0$ for any pair of nonapproaching waves. For our arguments below, we wish to index the waves in an approximate Glimm scheme solution as they are given in the solution of the Riemann problems themselves, without further partitioning. Thus for a rarefaction wave γ_r that crosses $\mathcal{T}$ and is partitioned into $\gamma_r = \gamma_r^a \gamma_r^b$ at the point where it crosses $\mathcal{T}$, we say γ_r approaches a standing wave γ_0 if γ_r^a approaches γ_0 or γ_r^b approaches γ_0, and we define $d(\gamma_0, \gamma_r) = d(\gamma_0, \gamma_r^a) + d(\gamma_0, \gamma_r^b)$. It follows that for *any partitioning* of a rarefaction wave $\gamma_r = \gamma_r^a \cdots \gamma_r^b$, we have that $d(\gamma_0, \gamma_r) = d(\gamma_0, \gamma_r^a) + \cdots + d(\gamma_0, \gamma_r^b)$. This completes the definition of $d(\gamma_0, \gamma_r)$ for any pair of waves γ_0, γ_r that crosses an I-curve J in an approximate Glimm scheme solution of (1.1).

We note that the potential $d(\gamma_0, \gamma_r)$ is symmetric, $d(\gamma_0, \gamma_r) = d(\gamma_r, \gamma_0)$, and is constructed so that if a standing wave γ_0 is displaced to $\hat{\gamma}_0$ by interaction with a nonlinear wave and a rarefaction wave γ_r is displaced to $\hat{\gamma}_r$ by interaction with a standing wave, then (assuming no cancellation of shock and rarefaction waves) $d(\gamma_0, \gamma_r) = d(\hat{\gamma}_0, \hat{\gamma}_r)$. Thus, $d(\gamma_0, \gamma_r)$ is invariant under such interactions even though $|\gamma_0|_w \neq |\hat{\gamma}_0|_w$ and

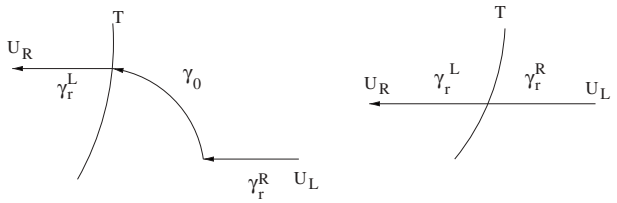

FIG. 30.

$|\gamma_r|_w \neq |\hat{\gamma}_r|_w$. Remarkably, this statement holds even when γ_0 is a composite wave of form $U_L \to P \to Q \to R$ of Figure 15. Therefore, even though wave strengths change as waves evolve in the solution, the potential interaction between waves is constructed so as to be an invariant of interactions (assuming no cancellation of rarefaction waves by shock waves).

The following proposition gives the main property that tells how rarefaction wave trajectories change when waves interact. To state the proposition, note that the rarefaction waves in any admissible solution of the Riemann problem $[U_L, U_R]$ can always be partitioned into a positive speed rarefaction wave γ_r^L on the left of $\mathcal{T}$ and a negative speed rarefaction wave γ_r^L on the right of $\mathcal{T}$. The fact that one can always uniquely identify exactly two such waves for every choice of U_L and U_R (allowing for one or both of the waves to be zero) can be verified directly in Figures 15–18. (Recall that a rarefaction wave cannot cross $\mathcal{T}$ in any admissible solution of the Riemann problem unless the standing wave is zero, in which case the solution is a single rarefaction wave γ_r that can be partitioned into $\gamma_r \sim \gamma_r^R \gamma_r^L$; cf. Figure 30.)

PROPOSITION 4.3. *Let γ_r^L and γ_r^R denote the left and right rarefaction waves in the solution of the Riemann problem $[U_L, U_R]$, and let $\bar{\gamma}_1\bar{\gamma}_0\bar{\gamma}_2$ be any connected sequence of elementary waves that takes U_L to U_R such that $\bar{\gamma}_1$, $\bar{\gamma}_2$ are nonlinear waves and $\bar{\gamma}_0$ is a standing wave. Then $Traj(\gamma_r^L) \subseteq Traj(\bar{\gamma}_r^L)$ and $Traj(\gamma_r^R) \subseteq Traj(\bar{\gamma}_r^R)$, where $\bar{\gamma}_r^L$ and $\bar{\gamma}_r^R$ denote the union of all left and right rarefaction waves, respectively, among $\bar{\gamma}_i$, i=1, 2.*

Proof. The proof of Proposition 4.3, which can be verified case by case from the admissible solution of the Riemann problem, is postponed until the appendix. ∎

5. The nonlocal functional. In this section we define the nonlocal functional $F(J)$ that bounds the total variation in w for the waves that cross an I-curve J in an approximate Glimm scheme solution. We then prove that F is nonincreasing on approximate solutions. To start, let J denote a fixed I-curve, and for notational convenience let Λ be an index set such that γ_q^α, $\alpha \in \Lambda$, $q \in \{0, r, s\}$, lists all of waves that cross J. Here $q = 0, r, s$ means that the wave is a standing wave, rarefaction wave, or shock wave, respectively, so that, for example, $\{\gamma_0^\alpha\}_{\alpha\in\Lambda}$ denotes the set of all standing waves that cross J, etc. (To achieve such an indexing just allow for arbitrarily many zero waves.) Thus the local functional $L_w(J)$ is defined by

$$L_w(J) = \sum_{\alpha\in\Lambda, q\in\{0,r,s\}} |\gamma_q^\alpha|_w. \tag{5.1}$$

Define the functional $F(J)$ by

$$F(J) = L_w(J) + P(J), \tag{5.2}$$

where $P(J)$ is the nonlocal potential interaction functional defined by

$$P(J) = \sum_{(\alpha,\beta)\in App(J)} d(\gamma_0^\alpha, \gamma_r^\beta), \tag{5.3}$$

where we use the notation $(\alpha, \beta) \in App(J)$ if and only if γ_0^α approaches γ_r^β on J. Since $F(J)$ is determined by the connected sequence of waves that cross J, we can similarly define $F(\gamma_a \cdots \gamma_b)$ for any connected sequence of elementary waves. (Two waves in the sequence *approach* if the left wave is faster than the right wave in the sequence, etc.) Then, for example, $F([U_L, U_R]) = L_w([U_L, U_R])$ because the solution of the Riemann problem contains no pairs of approaching waves. We now prove the following theorem.

THEOREM 5.1. *If J_2 is a successor of J_1 in an approximate Glimm scheme solution of system* (1.1)*, then*

$$F(J_2) - F(J_1) \le 0. \tag{5.4}$$

The proof of Theorem 5.1 is a consequence of the following lemma. (We think of bar, tilde, and hat as identifying incoming waves and unbarred waves as representing outgoing waves, and $[U_L, U_R]$ denotes the admissible solution of the Riemann problem, where the strength of each zero speed composite wave γ_0 has a strength equal to the strength of the waves in its projection $P(\gamma_0)$.)

PROPOSITION 5.2. *Let $\bar\gamma_1\bar\gamma_0\bar\gamma_2$ denote any connected sequence of three elementary waves that takes U_L to U_R such that $\bar\gamma_1, \bar\gamma_2$ are nonlinear waves, and $\bar\gamma_0$ is a standing wave.*

$$F(\gamma_1\gamma_0\gamma_2) \le F(\bar\gamma_1\bar\gamma_0\bar\gamma_2), \tag{5.5}$$

where $\gamma_1\gamma_0\gamma_2 = [U_L, U_R]$.

The proofs of Propositions 4.3 and 5.2 involve a case by case study of the Riemann problem and will be dealt with together in the appendix. Assuming Propositions 4.3 and 5.2, we now give the following proof.

Proof of Theorem 5.1. Assume that Propositions 4.3 and 5.2 hold, and assume that J_2 is an immediate successor of J_1 in the approximate Glimm scheme solution $U_{\Delta x}$ of system (1.1). We show that $F(J_2) \le F(J_1)$. Let Δ denote the interaction diamond between J_1 and J_2, let J_1', J_2' denote the restriction of J_1, J_2 to the region Δ, respectively, and let J_0 denote the restrictions of J_1 and J_2 to the region *outside* Δ; cf. [4, 24]. Thus we write $J_1 = J_0 \cup J_1'$ and $J_2 = J_0 \cup J_2'$. Note that since we use an unstaggered grid, the states U_L and U_R that lie at the right and left vertices of Δ are consecutive sample points at some time level t_j in the approximate solution $U_{\Delta x}$, and thus there is at most one standing wave between U_L and U_R on both J_1' and J_2'. It follows that there are at most five incoming waves that cross J_1', i.e., at most two nonlinear waves $\bar\gamma_1^a$ and $\bar\gamma_1^b$, followed by a standing wave $\bar\gamma_0$, followed by at most two nonlinear waves $\bar\gamma_2^a\bar\gamma_2^b$. (Subscripts $1, 2$ denote nonlinear waves, and subscript 0 denotes a standing wave.) Thus let $\bar\gamma_1^a\bar\gamma_1^b\bar\gamma_0\bar\gamma_2^a\bar\gamma_2^b$ denote the connected sequence of elementary waves that take U_L to U_R and cross the curve J_1', the incoming waves for the interaction diamond Δ. The waves that leave the interaction diamond Δ cross J_2' and hence solve the Riemann problem $[U_L, U_R]$.

Now first let $\bar\gamma_1$ and $\bar\gamma_2$ denote the nonlinear waves such that $\bar\gamma_1 \sim \bar\gamma_1^a\bar\gamma_1^b$ and $\bar\gamma_2 \sim \bar\gamma_2^a\bar\gamma_2^b$. Define $\bar J_1'$ to be the I-curve obtained by replacing the waves on J_1' by the

waves $\bar\gamma_1\bar\gamma_0\bar\gamma_2$, and set $\bar J_1 = J_0 \cup \bar J_1'$. Then the proof of Theorem 5.1 is complete once we prove the following claim.

CLAIM. *The following inequalities hold:*

$$F(J_2) \le F(\bar J_1) \le F(J_1). \tag{5.6}$$

Proof of claim. The second inequality holds because in replacing the nonlinear waves $\bar\gamma_i^a\bar\gamma_i^b$ by $\bar\gamma_i$, $i = 1, 2$, there can be no increase in wave strength—only a cancellation of wave strength can occur, this happening when one of $\bar\gamma_i^a, \bar\gamma_i^b$ is a shock wave and the other is a rarefaction wave. Thus $L_w(\bar J_1) - L_w(J_1) \le 0$. Moreover, since the potential $d(\gamma_0, \gamma_r)$ is in general independent of the partitioning of the nonlinear wave γ_r, it follows that $d(\gamma_0, \bar\gamma_i) \le d(\gamma_0, \bar\gamma_i^a) + d(\gamma_0, \bar\gamma_i^b)$ for any standing wave γ_0 on J_0, $i = 1, 2$. From this it readily follows that $P(\bar J_1) - P(J_1) \le 0$, and hence $F(\bar J_1) - F(J_1) = L_w(\bar J_1) - L_w(J_1) + P(\bar J_1) - P(J_1) \le 0$.

To verify that $F(J_2) \le F(\bar J_1)$, write

$$F(J_2) - F(\bar J_1) = F(J_2') - F(\bar J_1') + P(J_2', J_0) - P(\bar J_1', J_0) + P(J_2', J_2') - P(\bar J_1', \bar J_1'). \tag{5.7}$$

(Here we use the notation that if $J_a, J_b \subset J$, then $P(J_a, J_b) = \sum d(\gamma^\alpha, \gamma^\beta)$, where the sum is taken over all approaching waves on J such that $\gamma^\alpha \in J_a$, $\gamma^\beta \in J_b$.) But $P(J_2', J_2') = 0$ because the solution of the Riemann problem contains no approaching waves, and by Proposition 5.2, $F(J_2') - F(\bar J_1') \le 0$. Moreover, $P(J_2', J_0) \le P(\bar J_1', J_0)$ because, by Proposition 4.3, the trajectories of the rarefaction waves on $\bar J_1'$ contains the trajectories of the rarefactions waves on J_2'; hence there will be an interaction potential between rarefaction waves in $\bar J_1'$ and standing waves in J_0 that cancels any interaction potential between rarefaction waves in J_2' and standing waves in J_0. Thus (5.7), $F(J_2) - F(\bar J_1) \le 0$, and the proof of the claim is complete. □

The final theorem follows directly from Theorem 5.1.

THEOREM 5.3. *If the initial I-curve $J_{t=0}$ satisfies $F(J_{t=0}) < \infty$ in a Glimm approximate solution $U_{\Delta x}$, then the total variation of $U_{\Delta x}(\cdot, t) <$ const.$F(J_{t=0})$ for all $t > 0$.*

6. Convergence of the residual. In this section we give the proof of convergence of the residual for the approximate Glimm scheme solution constructed in section 3. The residual for system (1.1) is defined by

$$R(a, u, \varphi) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} \{u\varphi_t + f\varphi_x + a'g\varphi\}\ dx\,dt + \int_{-\infty}^{+\infty} u_0(x)\varphi(x, 0)\ dx. \tag{6.1}$$

Then (a, u) is a *weak solution* of (1.1) if and only if $R(a, u, \varphi) = 0$ for all compactly supported smooth test functions $\varphi = \varphi(x, t)$. Assume that $U_{\Delta x}$ is a sequence of Glimm approximate solutions that satisfy

$$\mathrm{Var}_z U_{\Delta x}(\cdot, t) < V_z \tag{6.2}$$

for some constant V_z independent of Δx (cf. (3.6)), and assume $U_{\Delta x}(x, t) = (a_{\Delta x}(x), u_{\Delta x}(x, t)) \to U(x, t) = (a(x), u(x, t))$ piecewise a.e. and in L^1_{loc} at each fixed time, uniformly on compact sets (the conclusion of the Oleinik compactness argument; cf. [25]). Note that for fixed initial data, $U_{\Delta x}$ is a function of both Δx and the sample sequence $\theta = \{\theta_{ij}\} \in \Theta$. Assume that $a(x)$ is Lipschitz continuous, so that there exists a constant M such that

$$|a(x) - a(y)| \le M|x - y| \text{ for all } x, y \in \mathbf{R}, \tag{6.3}$$

$$|a(x) - a_{\Delta x}(x)| \le M\Delta x \text{ for all } x \in \mathbf{R}. \tag{6.4}$$

For an approximate solution $U_{\Delta x}$, define

$$R_{\Delta x}(a_{\Delta x}, u_{\Delta x}, \varphi) \equiv \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} \{u_{\Delta x}\varphi_t + f(a_{\Delta x}, u_{\Delta x})\varphi_x + a' g(a_{\Delta x}, u_{\Delta x})\varphi\}\, dx\, dt + \int_{-\infty}^{+\infty} u_{\Delta x}(x,0)\varphi(x,0)\, dx \tag{6.5}$$

(obtained by replacing U by $U_{\Delta x}$ in (6.1) everywhere except at a'). We prove the following theorem; cf. [4].

THEOREM 6.1. *There exists a set $\mathcal{N}$ of measure zero in Θ such that, if $\theta \in \Theta/\mathcal{N}$, then*

$$R(a, u, \varphi) = \lim_{\Delta x \to 0} R_{\Delta x}(a_{\Delta x}, u_{\Delta x}, \varphi) = 0 \tag{6.6}$$

for all test functions φ of compact support in $-\infty < x < \infty$, $t \geq 0$. Thus, in particular, passing the limit through the integral sign, we conclude that $U(x,t)$ is a weak solution of (1.7).

Proof of Theorem 6.1. To start, let γ_{ij}^1 and γ_{ij}^2 denote the negative and positive speed waves positioned at mesh point (x_i, t_j) in the approximate solution $U_{\Delta x}$. Let $U_{ij}(x,t)$ denote the approximate solution $U_{\Delta x}$ restricted to the mesh rectangle $\mathcal{R}_{ij} = [x_i, x_{i+1}) \times [t_j, t_{j+1})$, and let $\mathrm{Var}_z U_{ij}$ and $\mathrm{Var}_u U_{ij}$ denote the total variation of U_{ij} in x at fixed time $t \in (t_j, t_{j+1})$, $x_i \leq x < x_{i+1}$. For the proof of Theorem 6.1, we introduce three regularization parameters $\epsilon, \hat{\epsilon}$, and δ, whose values will be chosen at the end: ϵ is a regularization parameter for the standing waves described below; $\hat{\epsilon}$ measures distance to the transition curve so that

$$S(\hat{\epsilon}) \equiv \{U : |U - \mathcal{T}| \leq \hat{\epsilon}\};$$

and δ is a mollification parameter for $g_{\Delta x}$ (so that we can integrate the source term in (6.6) by parts),

$$(g \cdot U_{\Delta x})_\delta = (g \cdot U_{\Delta x}) * \psi_\delta,$$

where $\psi_\delta = (\frac{1}{\delta^2})\psi(\frac{x}{\delta}, \frac{t}{\delta})$ denotes the standard convolution kernel supported on $|(x,t)| \leq \delta$.

For the mollification of the standing waves, let $U_{\Delta x}^\epsilon(x,t) \equiv (a_\epsilon(x), u_{\Delta x}^\epsilon(x,t))$ denote the regularization of $U_{\Delta x}$ obtained by translating γ_{ij}^1 (respectively, γ_{ij}^2) $\epsilon\Delta x$ units to the left (respectively, right) at each mesh point (x_i, t_j) and then replacing each standing wave discontinuity γ_{ij}^0 at (x_i, t_j) by the smoothed out standing wave on the interval $x_i - \epsilon\Delta x < x < x_i + \epsilon\Delta x$, as described in the discussion after (2.4). Thus, states on the smoothed out standing wave $\gamma_{ij}^{0,\epsilon}$ lie on the standing wave curve between the same left and right states as γ_{ij}^0 so that $\mathrm{Var}_z U_{ij}^\epsilon = \mathrm{Var}_z U_{ij}$ and $\mathrm{Var}_u U_{ij}^\epsilon = \mathrm{Var}_u U_{ij}$. (Indeed, recall that in Section 2, standing wave discontinuities were constructed as limits of smooth standing waves under rescaling into discontinuities; cf. [6].) Since U^ϵ satisfies the same total variation bounds as $U_{\Delta x}$, by taking appropriate subsequences, we can assume that at each $\epsilon > 0$, $\lim_{\Delta x \to 0} U_{\Delta x}^\epsilon = U^\epsilon$, where convergence is in the same sense as $U_{\Delta x} \to U$. (We are forced to introduce $U_{\Delta x}^\epsilon$ because our approximate solutions are constructed to (formally) meet (6.6) with $a'_{\Delta x}$, not a'.)

We use the following lemmas.

LEMMA 6.2. *There exists a constant $C_0 > 0$ and a function $\hat{K}(\hat{\epsilon})$ independent of Δx such that*

$$\mathrm{Var}_u U_{\Delta x}(\cdot,t) \le C_0\hat{\epsilon} + \hat{K}(\hat{\epsilon})\mathrm{Var}_z U_{\Delta x}(\cdot,t), \tag{6.7}$$

$$\int_E |U^\epsilon_{\Delta x} - U_{\Delta x}|\,dx\,dt \le C_0|E|\epsilon, \tag{6.8}$$

$$\left|\frac{\partial}{\partial x}(g\cdot U^\epsilon_{\Delta x})_\delta\right| \le \frac{C_0}{\delta}. \tag{6.9}$$

By (6.8) we know that $\int_E |U^\epsilon - U|\,dxdt < O(1)\epsilon$ for each compact set E.[9]

Proof. Estimate (6.7) follows from the fact that the mapping $(a,z) \to (a,u)$ is one-to-one and regular except at the transition curve $\mathcal{T}$ and any wave that lies entirely within $S(\hat{\epsilon})$ has amplitude order $\hat{\epsilon}$; cf. [25]. For (6.8), observe that $meas\{(x,t) \in E : U^\epsilon_{\Delta x} \ne U_{\Delta x}\} = O(1)|E|\epsilon$, where $|E|$ denotes the measure of the set E. Estimate (6.9) follows directly from the definition of convolution. ∎

LEMMA 6.3. *For every compact set E in $-\infty < x < \infty$, $t \ge 0$, there exists a function $K(\epsilon)$ independent of δ such that*

$$\int_E |(g\cdot U^\epsilon_{\Delta x})_\delta - (g\cdot U^\epsilon_{\Delta x})|\,dxdt = \int_E |(g\cdot U^\epsilon)_\delta - (g\cdot U^\epsilon)|\,dxdt + o(\Delta x)K(\epsilon), \tag{6.10}$$

$$\int_E |(g\cdot U^\epsilon_{\Delta x})_\delta - (g\cdot U_{\Delta x})|\,dxdt = \int_E |(g\cdot U^\epsilon)_\delta - (g\cdot U)|\,dxdt + o(\Delta x)K(\epsilon). \tag{6.11}$$

Here we mean that $o(\Delta x)$ is independent of $\epsilon, \hat{\epsilon}$, and δ, and $\lim_{\Delta x\to 0} o(\Delta x) = 0$.

Proof. Both (6.10) and (6.11) follow directly from the convergence of $U^\epsilon_{\Delta x} \to U^\epsilon$ and $U_{\Delta x} \to U$. ∎

The next lemma is the main step in the proof of Theorem 6.1.

LEMMA 6.4. *Let*

$$R^\epsilon_\phi \equiv R(a_\epsilon, u^\epsilon_{\Delta x}, \varphi) = \int\int_{t\ge 0} U^\epsilon_{\Delta x}\phi_t + f(U^\epsilon_{\Delta x})\phi_x + a'_\epsilon g(U^\epsilon_{\Delta x})\phi\,dxdt + \int_{-\infty}^{+\infty} U_0(x)\phi(x,0)dx, \tag{6.12}$$

and write $R^\epsilon_\phi \equiv R^\epsilon_\phi(\theta)$ to express the dependence on $\theta \in \Theta$ when Δx and ϕ are fixed. Then there exists a constant C_1 such that

$$\int_\Theta \left(R^\epsilon_\phi\right)^2 d\theta \le O(1)\left\{\hat{\epsilon} + \hat{K}(\hat{\epsilon})\Delta x + \epsilon(C_0\hat{\epsilon} + \hat{K}(\hat{\epsilon}))^2\right\}. \tag{6.13}$$

Proof of Lemma 6.4. Since $U^\epsilon_{\Delta x}$ is an exact solution in each strip $t_j < t < t_{j+1}$, integrating (6.13) over each mesh rectangle $\mathcal{R}_{ij}$ gives

$$R^\epsilon_\phi = \sum_{i,j} D^\epsilon_{ij}(\theta, \Delta x, \phi), \tag{6.14}$$

[9] We use the notation that C_0, C_1 denote constants that can depend on the equations and the initial data but are independent of $\epsilon, \hat{\epsilon}, \delta, \Delta x$, and the test function ϕ, while $O(1)$ denotes a constant that is independent of $\epsilon, \hat{\epsilon}, \delta$, and Δx, the convergence parameters.

where for $j > 0$,

$$D^\epsilon_{ij}(\theta, \Delta x, \phi) = \int_{x_i}^{x_{i+1}} \left\{U^\epsilon_{\theta,\Delta x}(x, t_j+) - U^\epsilon_{\theta,\Delta x}(x, t_j-)\right\} \phi(x, t_j-) dx$$
$$\equiv \int_{x_i}^{x_{i+1}} [U^\epsilon_{ij}]\phi| dx \tag{6.15}$$

and

$$D^\epsilon_{i0}(\theta, \Delta x, \phi) = \int_{x_i}^{x_{i+1}} \left\{U^\epsilon_{\theta,\Delta x}(x, 0) - U_0(x)\right\} \phi(x, 0) dx$$
$$\equiv \int_{x_i}^{x_{i+1}} [U^\epsilon_{i0}]\phi| dx. \tag{6.16}$$

(We take definitions (6.14)–(6.16) as applying also at $\epsilon = 0$, $U^0_{\Delta x} = U_{\Delta x}$.) It follows directly from (6.15) and (6.16) that

$$\left|D^\epsilon_{ij}(\theta, \Delta x, \phi)\right| \le |\mathrm{Supp}(\phi)|\ ||\phi||_\infty \Delta x \mathrm{Var}_u U^\epsilon_{ij}. \tag{6.17}$$

Now let $O(1)$ denote a constant that is independent of $\epsilon, \hat{\epsilon}, \delta$, and Δx.

Claim. *The following estimate holds:*

$$\left|\int_\Theta D^\epsilon_{ij} D^\epsilon_{kl} d\theta\right| \equiv |\langle D^\epsilon_{ij}, D^\epsilon_{kl}\rangle| \le O(1)\epsilon \Delta x^2 \cdot \mathrm{Var}_u U^\epsilon_{ij} \cdot \mathrm{Var}_u U^\epsilon_{kl}. \tag{6.18}$$

Proof of claim. First, neglecting higher order terms in Δx, we can assume without loss of generality that ϕ is constant on mesh rectangles, $\phi = \phi_{ij} = \text{const}$ on $\mathcal{R}_{ij}$. Following the argument in [6], we first note that if $j < l$, then U_{ij} is independent of a_{kl}, and so we can pass da_k through the integral to the factor $\int_0^1 \int_{x_k}^{x_{k+1}} D_{kl} dx da_k$, which is equal to zero as in Glimm's original argument. Thus,

$$\int_\Theta D^\epsilon_{ij} D_{kl} d\theta = 0. \tag{6.19}$$

Therefore,

$$\begin{aligned} \left|\langle D^\epsilon_{ij}, D^\epsilon_{kl}\rangle\right| &= \left|\langle D^\epsilon_{ij}, D^\epsilon_{kl}\rangle - \langle D^\epsilon_{ij}, D_{kl}\rangle\right| \\ &= \left|\langle D^\epsilon_{ij}, D^\epsilon_{kl} - D_{kl}\rangle\right| \le ||D^\epsilon_{ij}||_\infty ||D^\epsilon_{kl} - D_{kl}||_\infty \\ &\le O(1)\mathrm{Var}_u U^\epsilon_{ij} ||D^\epsilon_{kl} - D_{kl}||_\infty \Delta x. \end{aligned} \tag{6.20}$$

But

$$||D^\epsilon_{kl} - D_{kl}||_\infty \le \int_{x_k}^{x_{k+1}} |[U^\epsilon_{kl}] - [U_{kl}]|\ |\phi| dx \le O(1)\epsilon \Delta x \mathrm{Var}_u U_{kl}, \tag{6.21}$$

and using this in (6.20) gives

$$\left|\langle D^\epsilon_{ij}, D^\epsilon_{kl}\rangle\right| \le O(1)\epsilon \Delta x^2 \cdot \mathrm{Var}_u U_{ij} \cdot \mathrm{Var}_u U_{ij} \tag{6.22}$$

as claimed.

Thus we can estimate

$$\int_\Theta \left(R_\phi^\epsilon\right)^2 d\theta = \int_\Theta \left(\sum_{ij} D_{ij}^\epsilon\right)^2 d\theta$$

$$= \sum_i \int_\Theta \left(D_{ij}^\epsilon\right)^2 d\theta + \sum_{ij,kl} \int_\Theta D_{ij}^\epsilon D_{kl}^\epsilon d\theta \tag{6.23}$$

$$= I + II, \tag{6.24}$$

where

$$|I| \le \sum_{ij} \left(\int_{x_i}^{x_{i+1}} [U_{ij}^\epsilon]\phi dx\right)^2 \le O(1) \sum_{ij} \Delta x^2 \left(\mathrm{Var}_u U_{ij}^\epsilon\right)^2$$

$$\le O(1)\left\{C_0\hat{\epsilon} + \hat{K}(\hat{\epsilon})\right\}\Delta x \tag{6.25}$$

and

$$|II| \le \sum_{ij,kl} O(1)\epsilon\Delta x^2 \cdot \mathrm{Var}_u U_{ij} \cdot \mathrm{Var}_u U_{kl}$$

$$\le \sum_{ij,kl} O(1)\epsilon\Delta x^2 \cdot (C_0\hat{\epsilon} + \hat{K}(\hat{\epsilon}))^2. \tag{6.26}$$

Thus

$$|I| + |II| \le O(1)\left\{\hat{\epsilon} + \hat{K}(\hat{\epsilon})\Delta x + \epsilon(C_0\hat{\epsilon} + \hat{K}(\hat{\epsilon}))^2\right\}, \tag{6.27}$$

which verifies (6.13) of Lemma 6.4. □

Now that we have an estimate for R_ϕ^ϵ in Lemma 6.4; we obtain an estimate for $R_\phi \equiv R_{\Delta x}(a_{\Delta x}, u_{\Delta x}, \varphi)$ by estimating the difference $|R_\phi^\epsilon - R_\phi|$,

$$|R_\phi| \le \left|R_\phi^\epsilon - R_\phi\right| + \left|R_\phi^\epsilon\right|. \tag{6.28}$$

LEMMA 6.5. *The following estimate holds:*

$$\left|R_\phi^\epsilon - R_\phi\right| \le O(1)\left\{\epsilon + o(\Delta x)K(\epsilon) + \frac{\Delta x}{\delta}\right.$$
$$+ \int\int_E |(g\cdot U^\epsilon)_\delta - g(U^\epsilon)|\, dx\, dt$$
$$\left. + \int\int_E |(g\cdot U^\epsilon)_\delta - g(U)|\, dx\, dt\right\}, \tag{6.29}$$

where E denotes the support of ϕ and $O(1)$ denotes a constant independent of $\epsilon, \hat{\epsilon}, \delta$, and Δx.

Proof of Lemma 6.5. Starting with (6.5) and (6.12), we obtain

$$\left|R_\phi^\epsilon - R_\phi\right| \le \int\int_{t\ge 0} |U_{\Delta x}^\epsilon - U_{\Delta x}|\, |\phi_t|\, dx\, dt$$
$$+ \int\int_{t\ge 0} |f(U_{\Delta x}^\epsilon) - f(U_{\Delta x})|\, |\phi_x|\, dx\, dt$$
$$+ \left|\int\int_{t\ge 0} \{a_\epsilon' g(U_{\Delta x}^\epsilon) - a' g(U_{\Delta x})\}\, \phi\, dx\, dt\right|$$

$$= I_1 + I_2 + I_3. \tag{6.30}$$

It follows from (6.9) that

$$|I_1| \le O(1)\epsilon, \tag{6.31}$$

$$|I_2| \le O(1)\epsilon, \tag{6.32}$$

and it remains to estimate I_3. But

$$\begin{aligned} |I_3| &\le \int\int_{t\ge 0} |a'_\epsilon|\,|g(U^\epsilon_{\Delta x}) - (g\cdot U^\epsilon_{\Delta x})_\delta|\,|\phi|\,dx\,dt \\ &\qquad + \int\int_{t\ge 0} |a'_\epsilon|\,|(g\cdot U^\epsilon_{\Delta x})_\delta - g(U_{\Delta x})|\,|\phi|\,dx\,dt \\ &\qquad\qquad + \left|\int\int_{t\ge 0} \frac{d}{dx}(a_\epsilon - a)\,(g\cdot U^\epsilon_{\Delta x})_\delta\,\phi\,dx\,dt\right| \\ &= I_{3a} + I_{3b} + I_{3c}, \end{aligned}$$

and using Lemma 6.3 we obtain

$$|I_{3a}| \le O(1)\left\{\frac{1}{\epsilon}\int\int_{t\ge 0} |(g\cdot U^\epsilon)_\delta - g(U^\epsilon)|\;dx\,dt + o(\Delta x)K(\epsilon)\right\} \tag{6.33}$$

and

$$|I_{3b}| \le O(1)\left\{\int\int_{t\ge 0} |(g\cdot U^\epsilon)_\delta - g(U)|\;dx\,dt + o(\Delta x)K(\epsilon)\right\}. \tag{6.34}$$

Finally, integrating I_{3c} by parts and using (6.9) we obtain

$$|I_{3c}| \le O(1)\int\int_{t\ge 0} |a_\epsilon - a|\left|\frac{d}{dx}(g\cdot U^\epsilon)_\delta\right|\,dx\,dt \le O(1)\frac{\Delta x}{\delta}. \tag{6.35}$$

Putting (6.31)–(6.35) into (6.30) yields (6.29) of Lemma 6.5. □

We can now give the following proof.

Proof of Theorem 6.1. To establish (6.6) for $R_{\Delta x}(a_{\Delta x}, u_{\Delta x}, \varphi) \equiv R_\phi$, we show that

$$\lim_{\Delta x\to 0}\int_\Theta R_\phi^2\,d\theta = 0. \tag{6.36}$$

To this end, using (6.28) we can write

$$\begin{aligned} \int_\Theta R_\phi^2\,d\theta &\le 2\int_\Theta \left(R^\epsilon_\phi\right)^2\,d\theta + 2\int_\Theta \left|R^\epsilon_\phi - R_\phi\right|^2\,d\theta \\ &\le O(1)\left\{\hat\epsilon + \left[\hat K(\hat\epsilon)\Delta x\right]_1 + \left[\epsilon(\hat\epsilon + \hat K(\hat\epsilon)\right]_2\right\} \\ &\quad + O(1)\left\{\left[\epsilon + \int\int_E |(g\cdot U^\epsilon)_\delta - g(U^\epsilon)|\;dx\,dt \right.\right. \\ &\qquad\qquad + \left.\int\int_E |(g\cdot U^\epsilon)_\delta - g(U)|\;dx\,dt\right]_3 \\ &\qquad\qquad\qquad + \left.\left[o(\Delta x)K(\epsilon) + \frac{\Delta x}{\delta}\right]_4\right\}^2, \end{aligned} \tag{6.37}$$

where we have applied (6.13) and (6.29). Now let τ be any small positive number. Then, to make $\int_\Theta R_\phi^2\,d\theta < \tau$, choose $\hat\epsilon, \epsilon, \delta$ and $\Delta x \ll 1$ in order as follows (the brackets and $O(1)$ refer to quantities defined in (6.37)). First choose $\hat\epsilon \ll 1$ so that

$$O(1)\hat\epsilon < \frac{\tau}{4}; \tag{6.38}$$

choose $\epsilon < \epsilon_0 \ll 1$ so that

$$O(1)\,[\cdot]_2 < \frac{\tau}{4}; \tag{6.39}$$

choose $\epsilon \ll \epsilon_0$ and $\delta \ll 1$ so that

$$[\cdot]_3 < \frac{1}{2}\sqrt{\left\{\frac{\tau/4}{O(1)}\right\}}; \tag{6.40}$$

finally, choose $\Delta x \ll 1$ so that

$$[\cdot]_1 < \frac{\tau}{4} \quad \text{and} \quad [\cdot]_4 < \frac{1}{2}\sqrt{\left\{\frac{\tau/4}{O(1)}\right\}}. \tag{6.41}$$

Putting (6.38)–(6.41) into (6.37), we obtain

$$\int_\Theta R_\phi^2\,d\theta < \frac{\tau}{4} + \frac{\tau}{4} + \frac{\tau}{4} + \frac{1}{2}\left(\frac{\tau}{4} + \frac{\tau}{4}\right) < \tau. \tag{6.42}$$

From (6.42) we conclude (6.36), from which we conclude that $R_\phi \to 0$ off a set of measure zero in Θ. Theorem 6.1 now follows by taking a countable dense set of test functions, extracting a set of measure for each one, and taking $\theta \in \Theta/\mathcal{N}$, where $\mathcal{N}$ is the union of the measure zero sets for each of the countable list of test functions; cf. [4]. This completes the proof of Theorem 6.1. □

7. Appendix. In this appendix, we verify Propositions 4.3 and 5.2.

Proof of Proposition 4.3. Let $\bar\gamma_1\bar\gamma_0\bar\gamma_2$ be any connected sequence of incoming waves that take $U_L \to U_R$, and let $[U_L, U_R] = \gamma_1\gamma_0\gamma_2$. To verify the proposition, we can list the sixteen possibilities for $\bar\gamma_1\bar\gamma_0\bar\gamma_2$ according to whether γ_i are shock waves or rarefaction waves ($i = 1, 2$, four cases), whether γ_0 lies to the left or right of $\mathcal{T}$, and whether a increases or decreases across γ_0. (Since the issue involves only the location of the standing wave curves, it is not important whether $g_u > 0$ or $g_u < 0$.) In each case it is easy to verify that the rarefaction waves in the solution of the Riemann problem lie within the standing wave curves that bound the rarefaction waves among the incoming waves $\bar\gamma_1\bar\gamma_0\bar\gamma_2$. It follows that $Traj(\gamma_r^L) \subseteq Traj(\bar\gamma_r^L)$ and $Traj(\gamma_r^R) \subseteq Traj(\bar\gamma_r^R)$ in each case. The details are omitted. □

Proof of Proposition 5.2. We show that $F(\gamma_1\gamma_0\gamma_2) \le F(\bar\gamma_1\bar\gamma_0\bar\gamma_2)$ for any connected sequence of incoming waves $\bar\gamma_1\bar\gamma_0\bar\gamma_2$ that take U_L to U_R, where the outgoing waves $\gamma_1\gamma_0\gamma_2 = [U_L, U_R]_P$. (Recall that $[U_L, U_R]_P$ is obtained from $[U_L, U_R]$ by replacing every triple composite wave by its projection. Note that no wave can precede or follow, a triple composite wave in $[U_L, U_R]$ when $g_u < 0$ or $g_u > 0$, respectively, so that $[U_L, U_R]_P$ always consists of three waves $\gamma_1\gamma_0\gamma_2$.) We verify $F(\gamma_1\gamma_0\gamma_2) \le F(\bar\gamma_1\bar\gamma_0\bar\gamma_2)$ in four salient cases diagrammed in Figure 31. All other cases follow by a concatenation of these cases.

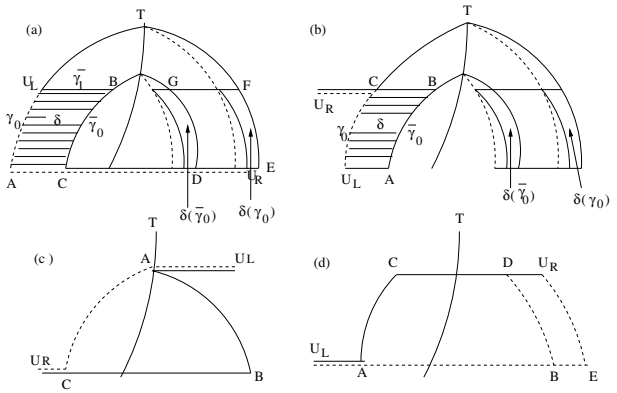

FIG. 31.

Cases (a) and (b) of Figure 31 deal with regular interactions in which the standing waves lie on the same side of $\mathcal{T}$ before and after interaction (the case $\gamma_0, \bar\gamma_0 < \mathcal{T}$ is considered). The point here is that when $\bar\gamma_0$ interacts with a shock wave (Case (a)) F decreases because L_w^* decreases on standing wave–shock wave interactions, and this decrease dominates the change in the corrective terms $\delta(\bar\gamma_0)$ and $\delta(\gamma_0)$ which were added to make L_w continuous. Cases (c) and (d) deal with the case when the standing waves $\bar\gamma_0$ and γ_0 lie on opposite sides of the transition curve, and the crossing occurs by rarefaction wave and shock wave, respectively. We now discuss the cases (a)–(d) of Figure 31 in detail.

Case (a). In this case, $F([U_L, U_R]_P) - F(\bar\gamma_1\bar\gamma_0\bar\gamma_2) = L_w(U_L \to A \to C) - L_w(U_L \to B \to C)$. When $g_u < 0$, $\delta(\bar\gamma_0) = 0 = \delta(\gamma_0)$ because these correction terms are added to standing waves on the right of $\mathcal{T}$ in this case. So when $g_u < 0$, $L_w(U_L \to A \to C) - L_w(U_L \to B \to C) = L_w^*(U_L \to A \to C) - L_w^*(U_L \to B \to C) < 0$ by Lemma 2.7. On the other hand, when $g_u > 0$, we have $L_w(U_L \to A \to C) - L_w(U_L \to B \to C) = L_w^*(U_L \to A \to C) - L_w^*(U_L \to B \to C) + \delta(\gamma_0) - \delta(\bar\gamma_0) - \delta < 0$, because $\delta + \delta(\gamma_0) - \delta(\bar\gamma_0) < 0$ by Lemma 2.7. (That is, the decrease $-\delta$ in L_w^* due to interaction with the shock wave $A \to C$ dominates the change $\delta(\gamma_0) - \delta(\bar\gamma_0)$.)

Case (b). In this case, $F([U_L, U_R]_P) - F(\bar\gamma_1\bar\gamma_0\bar\gamma_2) = L_w(U_L \to C) - L_w(U_L \to A \to B \to C)$. (Here, $d_r(\bar\gamma_0, \bar\gamma_2) = 0$ because the waves $\bar\gamma_0$ and $\bar\gamma_2$ do not approach.) Now if $g_u < 0$, then $\delta(\gamma_0) = 0 = \delta(\bar\gamma_0)$ (because these correction terms are added to the waves on the right of $\mathcal{T}$ when $g_u < 0$), so we have $L_w(U_L \to C) - L_w(U_L \to A \to B \to C) = L_w^*(U_L \to C) - L_w^*(U_L \to A \to B \to C) \le 0$ by Lemma 2.7. On the other hand, when $g_u > 0$ we have $L_w(U_L \to C) = L_w^*(U_L \to C) + \delta(\gamma_0)$ and $L_w(U_L \to A \to B \to C) = L_w^*(U_L \to A \to B \to C) + \delta(\bar\gamma_0)$. But $L_w^*(\gamma_0) + L_w^*(C \to B) - L_w^*(U_L \to A \to B) = -\delta < 0$, and so $L_w^*(\gamma_0) - L_w^*(U_L \to A \to B \to C) \le -\delta - L_w^*(C \to B)$. Thus, $L_w(U_L \to C) - L_w(U_L \to A \to B \to C) = -\delta - L_w^*(C \to B) + \delta(\gamma_0) - \delta(\bar\gamma_0) \le 0$ as claimed.

Case (c). In this case, $F([U_L, U_R]_P) - F(\bar\gamma_1\bar\gamma_0\bar\gamma_2) = L_w(A \to C) - L_w(A \to B \to U_R) \le L_w^*(A \to B \to C) - L_w^*(A \to B \to U_R) = -L_w^*(C \to U_R) < 0$ by Lemma 2.7. (Here, $d_r(\bar\gamma_0, \bar\gamma_2) = 0$ because $B \to C$ lies below the standing wave curve through $\bar\gamma_0$, and $C \to U_R$ does not approach $\bar\gamma_0$.)

Case (d). In this case, choose D between C and U_R and B between A and E such that A, C, B, D lie on the same standing wave curve and $L_w(A \to C \to D) = L_w(A \to B \to D)$. Then $F([U_L, U_R]_P) - F(\bar\gamma_1\bar\gamma_0\bar\gamma_2) = L_w(A \to E \to U_R) - L_w(A \to$

$C \to U_R) = L_w(A \to E \to U_R) - L_w(A \to B \to D \to U_R) = L_w(B \to E \to U_R) - L_w(B \to D \to U_R) \le 0$ by the analysis of Case (a) (that is, we reduced the problem to the case of regular interaction on the right of $\mathcal{T}$).

A PARAMETER IDENTIFICATION PROBLEM OF MIXED TYPE RELATED TO THE MANUFACTURE OF CAR WINDSHIELDS*

PHILIPP KÜGLER†

Abstract. We study the identification of a parameter in a fourth-order elliptic partial differential equation that models the optimal design of car windshields to be manufactured by the sagging process. Considered as a second-order equation for the unknown parameter, the problem is of mixed type, i.e., changing between elliptic and hyperbolic. Numerical routines for directly solving this equation are not available. In this paper we both theoretically and numerically show that the inverse problem can instead be solved in a stable way by means of a (derivative free) iterative regularization method. The course of the iteration nevertheless depends markedly on the mixed type of the second-order equation.

Key words. nonlinear parameter identification, iterative regularization, PDE of mixed type

1. Introduction.

Transforming automotive glass from a flat sheet into a curved car windshield is a challenging subject for industrial and academic research. The resulting change in the glass surface area leads to deformations that may cause optical distortions of unacceptable refractive and reflective quality. A related problem that the manufacturer faces is the limited formability of the glass. Hence, not every shape designed at the manufacturer's drawing table can be (immediately) realized in practice and thus costly shape corrections may become necessary.

One industrial method favored for the manufacture of car windshields is the sag bending process: A sheet of glass is put over a rigid frame with the desired edge curvature and is heated from above. The glass becomes viscous and sags under its own weight; the final shape of the glass depends on the viscosity distribution of the glass obtained by varying the temperature. Hence, given a desired target shape, the task is to find the appropriate temperature distribution in order to achieve that goal; see, e.g., [11].

Although the sag bending process operates in the viscous regime, the viscous-elastic analogy allows us to consider the Young's modulus E, a spatially varying glass material parameter, to be proportional to the viscosity; see [12]. Then, since the latter is a function of the temperature (see [8]), the sag bending process can in a first approximation also be controlled in terms of E, where the bending of the glass sheet is described by means of the linear elastic plate theory. Hence, our inverse problem is to identify the parameter E for a given target shape $\hat{w}$, where its solution can finally be used in order to compute the appropriate temperature distribution.

In section 2, we discuss the fourth-order elliptic direct bending problem, for which we shall consider two types of boundary conditions on the fastening of the glass sheet. In section 3, we show that the inverse parameter identification problem can be solved by a (recently developed derivative free) iterative regularization method, whose

†Industrial Mathematics Institute, Johannes Kepler University Linz, Altenbergerstrasse 69, 4040 Linz, Austria (kuegler@indmath.uni-linz.ac.at).

convergence can be established under rather natural assumptions. We also discuss the so-called direct approach, which leads to a second-order partial differential equation of mixed type for the unknown parameter E. Due to the changes between elliptic and hyperbolic regions in dependence on the desired target shape $\hat{w}$, it is an open problem how to directly solve this parameter PDE. However, both the convergence rate analysis of the derivative free iterative method and the numerical tests in section 4 show that this mixed PDE type is reflected in the iterative algorithm. Taking care of this special feature is of independent mathematical interest but also might help to improve existing routines for the control of the sag bending process.

2. The direct problem of bending a plate. In a first model based on the viscous-elastic analogy and the linearized elasticity theory (see, e.g., [12], [2], and [8]), the sag bending process can be controlled in terms of the Young's modulus E, a spatially varying and positive glass material parameter. Then, the displacements w of the glass sheet are described by the fourth-order elliptic PDE

$$\frac{t^3}{12(1-\nu^2)}\{(E(w_{xx}+\nu w_{yy}))_{xx}+(E(w_{yy}+\nu w_{xx}))_{yy} + 2(1-\nu)(Ew_{xy})_{xy}\} = f \text{ in } \Omega, \tag{2.1}$$

where t denotes the thickness of the glass plate, $\Omega \subset R^2$ represents its midplane, $\nu \in (0, 0.5)$ is the glass Poisson ratio, and f denotes gravity. As boundary conditions on w we consider either

$$w|_{\partial\Omega} = 0, \quad \frac{\partial w}{\partial n} = 0 \tag{2.2}$$

for a clamped plate, or

$$w|_{\partial\Omega} = 0, \quad M_n = 0 \text{ on } \partial\Omega \tag{2.3}$$

for a simply supported plate; i.e., the moment M_n vanishes such that the plate is allowed to freely rotate around the tangent to $\partial\Omega$. In the case of a rectangular frame, the second condition in (2.3) simplifies to

$$w_{xx} + \nu w_{yy} = 0 \quad \text{along the edges with } y = \text{constant}, \tag{2.4}$$

$$w_{yy} + \nu w_{xx} = 0 \quad \text{along the edges with } x = \text{constant} \tag{2.5}$$

due to the positivity of E; see [9]. For our further discussion, a Hilbert space setup is of advantage; hence we next turn to the weak formulation of (2.1). Denoting by Y_0 a closed subspace of the Hilbert space $Y = H^2(\Omega)$ and considering f as an element of the dual space Y_0^*, the displacement $w \in Y_0$ can be sought as the solution of the operator equation

$$A(E)w = f \text{ in } Y_0^*, \tag{2.6}$$

where $A(E) : Y_0 \to Y_0^*$ is defined via the symmetric bilinear form

$$\langle A(E)w, v\rangle = \int_\Omega \frac{Et^3}{12(1-\nu^2)}\left[(w_{xx}+w_{yy})(v_{xx}+v_{yy}) - (1-\nu)(w_{xx}v_{yy}+w_{yy}v_{xx}-2w_{xy}v_{xy})\right] dxdy \tag{2.7}$$

on $Y_0 \times Y_0$. The space Y_0 is determined by the boundary conditions on w under consideration, where

$$Y_0 = \{w \in Y \,|\, w|_{\partial\Omega} = 0\} \tag{2.8}$$

corresponds to (2.3) and

$$Y_0 = \left\{ w \in Y \,|\, w|_{\partial\Omega} = 0 \,\wedge\, \frac{\partial w}{\partial n} = 0 \right\} \tag{2.9}$$

represents (2.2). The next theorem shows that, given an appropriate parameter E, problem (2.6) is uniquely solvable.

THEOREM 2.1. *For any Young's modulus E belonging to the set*

$$\tilde{Q} = \left\{ E \in H^1(\Omega) \,|\, \underline{\gamma} \le E \le \bar{\gamma} \right\}, \tag{2.10}$$

where $\underline{\gamma}, \bar{\gamma}$ are positive constants, the direct problem (2.6) *admits a unique solution in Y_0.*

Proof. Simple manipulations of the bilinear form (2.7) yield that the operator $A(E)$ is continuous in the sense

$$|\langle A(E)w, v\rangle| \le \alpha_2 \|w\| \|v\|, \quad w, v \in Y,\ E \in \tilde{Q}, \tag{2.11}$$

with a positive constant $\alpha_2 = \alpha_2(\bar{\gamma})$. Furthermore, since $v \in Y_0$ (both for (2.8) and (2.9)), with v a polynomial of degree one, implies $v = 0$, we can apply the theorem on equivalent norms in order to obtain the ellipticity

$$\langle A(E)w, w\rangle \ge \alpha_1 \|w\|^2, \quad w, v \in Y_0,\ E \in \tilde{Q}, \tag{2.12}$$

with a positive constant $\alpha_1 = \alpha_1(\underline{\gamma})$. For details we refer to [10]. Hence, by virtue of the Lax–Milgram lemma (see, for instance, [17]) problem (2.6) admits a unique solution in Y_0 for any $E \in \tilde{Q}$. ∎

In the following we denote the unique solution of (2.6) by w_E in order to emphasize its dependence on the parameter E.

3. The inverse problem. Having introduced the direct problem (2.1), (2.6) as a first model for describing the bending of the glass sheet resulting from the sag bending process, we now discuss the associated inverse windshield problem. Given a target shape $\hat{w}$ that satisfies either the boundary condition (2.2) or (2.3), we want to find a positive Young's modulus $E = E(x, y)$ such that the corresponding direct problem admits $\hat{w}$ as its solution.

In this section, we first introduce and analyze a derivative free *iterative* regularization method, which then in fact allows us to numerically solve the inverse windshield problem in a stable way. This strategy is based on minimizing the deviation between a computed forward solution of the PDE and the desired target shape. We also focus on the *direct* approach, where the idea is to consider the state equation as a second-order (partial differential) equation for the unknown parameter. Since this equation then is of mixed type, numerical concepts for its solution are unavailable. Nevertheless, this approach demands special attention since the mixed type is also reflected in the iterative method.

3.1. The iterative approach. Introducing the set of admissible parameters

$$Q = \left\{ E \in X \,|\, \underline{\gamma} \leq E \leq \bar{\gamma} \right\}, \tag{3.1}$$

where X is a Hilbert space, and the parameter-to-output map

$$F : Q \to Y, E \to w_E,$$

where w_E denotes the solution of the direct problem (2.6), the inverse windshield problem can be formulated as the nonlinear operator equation

$$F(E) = \hat{w}. \tag{3.2}$$

In the following, we assume that *the exact data* $\hat{w} \in Y_0$ are attainable by a parameter $E_* \in Q$, i.e., that the windshield is manufacturable. Note that this does not imply that the solution E_* of (3.2) has to be unique. Already translated to the underlying real world problem, several solutions may even be of advantage since they give more freedom in choosing the strategy for heating the glass. Target shapes that would also be accepted as $\hat{w}$ by the car producer are taken into account as *perturbed data* $w^\delta \in Y_0$, where δ in

$$\|\hat{w} - w^\delta\| \leq \delta \tag{3.3}$$

has to be understood as a level of tolerance for the outcome of the bending process.

Parameter identification problems such as (3.2) are typically ill-posed in the sense that their solution does not depend continuously on the data. Hence, data but also round-off errors may be amplified by an arbitrarily large error if one applies methods to (3.2) that are only suited for well-posed problems; see [3]. In order to overcome these instabilities one has to use *regularization* methods. Iterative techniques—especially advantageous for nonlinear problems—are mostly based on a successive minimization of the output least-squares functional

$$E \to \frac{\lambda}{2} \|F(E) - w^\delta\|^2, \tag{3.4}$$

where λ is a scaling parameter; see the survey given in [5]. Though the initial guess E_0 is always supposed to lie in a neighborhood of E_*, i.e.,

$$E_* \in \mathcal{B}_{\rho/2}(E_0), \tag{3.5}$$

where ρ is chosen such that $\mathcal{B}_\rho(E_0) \subset Q$ is satisfied, stability can be enforced, i.e., a reliable approximation to the solution of (3.2) can be obtained, only if the iteration is stopped at the right time depending on δ. Denoting the iterates by E_k^δ, the discrepancy principle (see, for instance, [3] or [7]) suggests determining the stopping index $k_*(\delta)$ by

$$\|w^\delta - F(E_{k_*}^\delta)\| \leq \tau\delta < \|w^\delta - F(E_k^\delta)\|, \quad 0 \leq k < k_*, \tag{3.6}$$

for some sufficiently large $\tau > 0$. The (final) residual $w^\delta - F(E_{k_*}^\delta)$ then is of the order of the tolerance level, which is the best we should ask for.

All the classical iterative regularization methods for solving (3.2), (3.3) in a stable way, like the Landweber method,

$$E_{k+1}^\delta = E_k^\delta + \lambda F'(E_k^\delta)^*(w^\delta - F(E_k^\delta)) \tag{3.7}$$

(see [7]), which allow a comprehensive analysis of their convergence behavior, require the existence of the Fréchet derivative of F and further conditions on F'; see [5], which usually are hard to verify for parameter identification problems in higher dimensions. Instead, we apply the *derivative free* Landweber method,

$$E_{k+1}^{\delta} = E_k^{\delta} + \lambda L(E_k^{\delta})^*(w^{\delta} - w_k), \tag{3.8}$$

introduced in [9], where $L(E)^*$ denotes the Hilbert space adjoint of the linear operator

$$L(E) : X \to Y_0,\ h \to -JA(h)w_E \tag{3.9}$$

for $E \in Q$. Thereby, w_k is used as an abbreviation for $F(E_k^{\delta})$, $A(h)$ is defined by (2.7), and $J : Y_0^* \to Y_0$ represents the duality map. For the windshield problem it is of interest to approximate the given target shape also in terms of its second derivatives, since the related curvatures characterize the final optical quality of the windshield. Hence, it is appropriate to use the full Y-topology in building the adjoint operator of (3.9) (as well as in (3.3)).

In the following, we choose the Hilbert space $X = H^s(\Omega)$ with $s > d/2$ such that $X \subset L^{\infty}(\Omega)$ is satisfied. Obviously, we have $Q \subset \tilde{Q}$ such that (2.11) and (2.12) especially hold for Q and the forward operator F in fact is well defined. Furthermore, definition (2.7) yields

$$A(\cdot)u \in \mathcal{L}(X, Y_0^*) \tag{3.10}$$

because of

$$\langle A(h)v, w\rangle \le c\|h\|\|v\|\|w\|, \quad h \in X, v, w \in Y, \tag{3.11}$$

where c denotes the embedding constant. Together with (2.6) and (2.7), this also implies that the iteration operator is locally bounded, i.e.,

$$\|L(E)\| \le \hat{L}, \qquad E \in \mathcal{B}_{\rho}(E_0), \tag{3.12}$$

with $\hat{L} = c\|f\|/\alpha_1$.

In establishing convergence of the iterates of (3.8), we follow the basic concept of [7]. However, since we do not resort to strong conditions on the Fréchet derivative of F, we still have to proceed in a different manner. The first result shows that the error in the parameter is monotonically decreasing as long as the discrepancy principle is obeyed.

PROPOSITION 3.1. *Assume that E_* is a solution of* (3.2) *in $\mathcal{B}_{\rho/2}(E_0)$, and let λ and τ be chosen such that*

$$2\left(\alpha_1 - \frac{\alpha_2}{\tau}\right) - \lambda\hat{L}^2 \ge D \tag{3.13}$$

holds, where D is a fixed positive constant. In case of perturbed data w^{δ} satisfying (3.3)*, we denote by k_* the stopping index of the iteration according to the discrepancy principle* (3.6) *with τ satisfying* (3.13)*. Then we have*

$$\|E_* - E_{k+1}^{\delta}\| \le \|E_* - E_k^{\delta}\|, \ \ 0 \le k < k_*, \tag{3.14}$$

and

$$\sum_{k=0}^{k_*-1} \|w^{\delta} - w_k\|^2 \le \frac{\rho^2}{4\lambda D}. \tag{3.15}$$

For $\delta = 0$ (with $\tau = \infty$ in (3.13)), we have

$$\sum_{k=0}^{\infty} \|\hat{w} - w_k\|^2 \le \frac{\rho^2}{4\lambda D}. \tag{3.16}$$

Proof. Given $\|E_0 - E_*\| \le \rho/2$, we assume

$$\|E_k^\delta - E_*\| \le \rho/2$$

for $k < k_*(\delta)$ and argue by induction. Then, the iteration step (3.8) is well defined, yielding

$$\begin{aligned} &\|E_* - E_{k+1}^\delta\|^2 - \|E_* - E_k^\delta\|^2 \\ &\quad = -2\lambda(L(E_k^\delta)(E_* - E_k^\delta), w^\delta - w_k) + \lambda^2 \|L(E_k^\delta)^*(w^\delta - w_k)\|^2. \end{aligned} \tag{3.17}$$

The following considerations play the decisive role in our analysis and are only possible for the special iteration operator (3.9). Because of this operator's definition, (3.10), and

$$A(E_*)\hat{w} = A(E_k^\delta)w_k \ \text{ in } \ Y_0^*,$$

we get

$$\begin{aligned} &-(w^\delta - w_k, L(E_k^\delta)(E_* - E_k^\delta)) \\ &\quad = \langle w^\delta - w_k, A(E_* - E_k^\delta)w_k\rangle \\ &\quad = \langle w^\delta - w_k, A(E_*)w_k - A(E_*)\hat{w}\rangle \\ &\quad = -\langle w^\delta - w_k, A(E_*)w^\delta - A(E_*)w_k\rangle + \langle w^\delta - w_k, A(E_*)w^\delta - A(E_*)\hat{w}\rangle \\ &\quad \le -\alpha_1\|w^\delta - w_k\|^2 + \alpha_2\|w^\delta - w_k\|\|w^\delta - \hat{w}\|, \end{aligned} \tag{3.18}$$

where the inequality holds because of (2.12) and (2.11). Using (3.18) in (3.17), we obtain

$$\begin{aligned} &\|E_* - E_{k+1}^\delta\|^2 - \|E_* - E_k^\delta\|^2 \\ &\le \|w^\delta - w_k\|\lambda\left(2\alpha_2\delta - 2\alpha_1\|w^\delta - w_k\| + \lambda\hat{L}^2\|w^\delta - w_k\|\right). \end{aligned}$$

Following the discrepancy principle (3.6), we get from (3.13) that

$$\|E_* - E_{k+1}^\delta\|^2 + \lambda D\|w^\delta - w_k\|^2 \le \|E_* - E_k^\delta\|^2$$

for $k < k_* = k_*(\delta)$. This implies assertion (3.14) and $E_{k+1}^\delta \in \mathcal{B}_{\rho/2}(E_*) \subset \mathcal{B}_\rho(E_0)$. Furthermore, we can conclude that

$$\lambda D \sum_{k=0}^{k_*-1} \|w^\delta - w_k\|^2 \le \sum_{k=0}^{k_*-1} \left(\|E_k^\delta - E_*\|^2 - \|E_{k+1}^\delta - E_*\|^2\right)$$

holds, which leads to the inequality

$$k_*\tau^2\delta^2 \le \sum_{k=0}^{k_*-1} \|w^\delta - w_k\|^2 \le \frac{\rho^2}{4\lambda D}$$

and finally to assertion (3.16). ∎

Hence, the monotonicity of the iterates, which is the foundation for the forthcoming convergence results, can be guaranteed under natural assumptions already associated with the solvability of the direct problem. We see that condition (3.13) can always be satisfied by choosing the λ sufficiently small and τ sufficiently large. Note that, in case of perturbed data, the use of a "large" τ in the discrepancy principle (3.6) might cause a premature termination of the iteration, a problem that is also present when using other iterative methods, e.g., (3.7). However, our choice of τ in (3.13) no longer involves (in practical situations) unknown constants that are linked to conditions on F'; compare to [7].

The estimation (3.16) shows that, in the absence of data noise, the residual norms of the iterates tend to zero for $k \to \infty$; hence, if the iteration converges, the limit certainly is a solution of the inverse windshield problem. In the case of perturbed data, (3.15) yields the existence of a unique stopping index k_* such that $\|w^\delta - w_k\| > \tau\delta$ holds for all $k < k_*$ but is violated at $k = k_*$.

The next theorem shows that, for precise data, the iterates E_k in fact converge to a solution of the inverse windshield problem. Furthermore, in the presence of data perturbations, the discrepancy principle (3.6) renders the derivative free Landweber iteration (3.8) a regularization method; i.e., we have $E^\delta_{k_*(\delta)} \to E_*$ as $\delta \to 0$.

THEOREM 3.2 (convergence). *Let $\delta = 0$ in (3.3). If (3.2) is solvable in $\mathcal{B}_{\rho/2}(E_0)$, then E_k converges to a solution $E_* \in \mathcal{B}_{\rho/2}(E_0)$ of (3.2), i.e.,*

$$E_k \to E_*, \quad k \to \infty. \tag{3.19}$$

In the case of perturbed data w^δ satisfying (3.3), let the iteration (3.8) be stopped at $k_*(\delta)$, according to the discrepancy principle (3.6), (3.13). Then

$$E^\delta_{k_*(\delta)} \to E_*, \quad \delta \to 0. \tag{3.20}$$

Proof. Again we can follow [7], but once more we require only the properties of the PDE-operator $A(E)$. For exact data, the basic idea is to verify that E_k is a Cauchy sequence. If $\tilde{E}$ denotes any solution of (3.2) in $\mathcal{B}_{\rho/2}(E_0)$, i.e., $w_{\tilde{E}} = \hat{w}$, the crucial ingredient for the proof is

$$\begin{aligned}(\hat{w} - w_r, L(E_r)(\tilde{E} - E_l)) &= -\langle A(\tilde{E} - E_l)w_r, \hat{w} - w_r\rangle \\ &= -\langle A(\tilde{E} - E_r)w_r, \hat{w} - w_r\rangle - \langle A(E_r - E_l)w_r, \hat{w} - w_r\rangle \\ &= \langle A(\tilde{E})\hat{w} - A(\tilde{E})w_r, \hat{w} - w_r\rangle \\ &\quad - \langle A(E_l)w_l - A(E_l)w_r, \hat{w} - w_r\rangle, \end{aligned} \tag{3.21}$$

which holds because of (3.9), (3.10), and

$$\begin{aligned} A(E_r)w_r &= A(\tilde{E})\hat{w} \ \text{ in } \ Y_0^*, \\ A(E_r)w_r &= A(E_l)w_l \ \text{ in } \ Y_0^*. \end{aligned}$$

Given (3.21), one can show as in [7] that $E_k - \tilde{E}$ and hence E_k are Cauchy sequences. Denoting the limit of E_k by E_*, we obtain that E_* is a solution of (3.2) since the residues $\hat{w} - w_k$ converge to zero for $k \to \infty$; see Proposition 3.1.

In the case of perturbed data, the proof given in [7] is independent of the iteration operator and therefore also applies to (3.8). ∎

Hence, the derivative free iteration (3.8) in combination with (3.6) provides a numerically stable algorithm for solving the inverse windshield problem. In order to

make it more transparent, we build the inner product in X of both sides with a test function $h \in X$. Using (3.9) and rearranging the terms then yields

$$(E_{k+1}^\delta - E_k^\delta, h) = -\lambda \frac{t^3}{12(1-\nu^2)} \left\{ \int_\Omega h(w_{kxx}(w^\delta - w_k)_{xx} + w_{kyy}(w^\delta - w_k)_{yy}) dxdy \right.$$
$$+ \int_\Omega \nu h(w_{kxx}(w^\delta - w_k)_{yy} + w_{kyy}(w^\delta - w_k)_{xx}) dxdy$$
$$\left. + \int_\Omega 2(1-\nu) h w_{kxy}(w^\delta - w_k)_{xy} dxdy \right\}. \tag{3.22}$$

As opposed to (3.7), where $F'(E_k^\delta)^*$ also requires us to solve (2.6) with f replaced by the current residual $w^\delta - F(E_k^\delta)$, (3.8) calls only for the computation of w_k. In that sense, the total number of "direct problems" to be solved is cut in half by (3.8).

3.2. The direct approach. Given a target shape $\hat{w}$, one also might look for a solution of the inverse problem by considering (2.1) as a PDE for E, i.e.,

(3.23)
$$((\hat{w}_{xx} + \nu\hat{w}_{yy})E)_{xx} + 2(1-\nu)(\hat{w}_{xy}E)_{xy} + ((\hat{w}_{yy} + \nu\hat{w}_{xx})E)_{yy} = \frac{12(1-\nu^2)}{t^3} f \text{ in } \Omega.$$

Usually, parameter identification problems are, when regarded as equations for the unknown parameter, of first order; i.e., the parameter appears at most up to its first derivatives. However, we now face an inverse problem that is of second order in the parameter. The type of (3.23) depends on the sign of

$$\bar{\Delta} = (\hat{w}_{xx} + \nu\hat{w}_{yy}) \cdot (\hat{w}_{yy} + \nu\hat{w}_{xx}) - (1-\nu)^2 \hat{w}_{xy}^2 : \tag{3.24}$$

(3.23) is elliptic where $\bar{\Delta} > 0$ and hyperbolic where $\bar{\Delta} < 0$. Note that the type depends in fact on the given target shape $\hat{w}$. The discriminant $\bar{\Delta}$ can also be written as

$$\bar{\Delta} = 4\nu \left(\frac{\hat{w}_{xx} + \hat{w}_{yy}}{2} \right)^2 + (1-\nu)^2 (\hat{w}_{xx}\hat{w}_{yy} - \hat{w}_{xy}^2), \tag{3.25}$$

where

$$C_G = \hat{w}_{xx}\hat{w}_{yy} - \hat{w}_{xy}^2$$

is the Gaussian curvature and

$$C_m = \frac{1}{2}(\hat{w}_{xx} + \hat{w}_{yy})$$

is the mean curvature of the shape.

Concentrating on rectangular frames—experiences identified them as the most problematic ones for the sag bending process—we next follow [16] in order to demonstrate that the direct approach for the inverse windshield problem leads to PDEs that are always of mixed type. Furthermore, we will see that there is a significant difference in the type between shapes satisfying (2.2) and those fulfilling (2.3).

In the simply supported case, (2.3), (2.4), (2.5), and the positivity of E imply that the product of $(\hat{w}_{xx} + \nu\hat{w}_{yy})$ and $(\hat{w}_{yy} + \nu\hat{w}_{xx})$ in (3.24) is zero on any simply

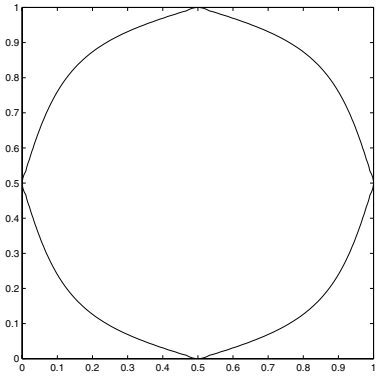

FIG. 1. *The simply supported case: an elliptic center area with adjacent hyperbolic corners.*

supported edge. Hence, $\bar{\Delta} \leq 0$ holds on the edges and (3.23) gets hyperbolic or parabolic there.

On the other hand, windshields usually have a positive Gaussian curvature C_G in their interior; i.e., choosing an interior point, its neighborhood lies on only one side of the tangential plane. Then, (3.25) shows that $\bar{\Delta} > 0$ such that the parameter (3.23) is elliptic in these regions. As a consequence, the equation type changes from hyperbolic near the edges to elliptic near the center of the region. Furthermore, it is shown in [16] that there is only one parabolic curve, i.e., a line defined by the points satisfying $\bar{\Delta} = 0$, and that it intersects each of the four sides of the squared frame at a single point. Hence, (3.23) is elliptic in the center and hyperbolic next to the corners of the frame. This typical behavior is illustrated in Figure 1.

In the clamped case (2.2), the equation for E will be elliptic in the center region according to the positive Gaussian curvature C_G of the target shape. However, along the edges of the frame, the situation is significantly different. For a rectangular frame, the zero gradient condition on the boundary becomes $w_x = 0$ and $w_y = 0$ on the edges $x = const.$ and $y = const.$, respectively. Concentrating on a single edge, e.g., $x = const.$, and differentiating $w_x = 0$ as well as the zero deflection condition $w = 0$ with respect to y, we obtain that w_y, w_{yy}, and w_{xy} also vanish along that edge. However, the discriminant $\bar{\Delta}$ (see (3.25)) there reduces to

$$\bar{\Delta}_{x=const.} = \nu w_{xx}^2,$$

such that (3.23) cannot be hyperbolic along that edge. In fact, since w_{xx} vanishes only at the ends of the edge $x = const.$, the equation is elliptic along the edge and parabolic only at the very corners. Nevertheless, it is shown in [16] that the elliptic regions near the frame and in the center are divided by a hyperbolic ring. In contrast to the simply supported case, there now exist two distinct parabolic lines, where the outer one does not touch the edges of the domain Ω at all. A typical formation of the elliptic and hyperbolic regions is shown in Figure 2.

Facing a second-order PDE of mixed type, questions concerning existence, uniqueness, and stability of a solution to (3.23) arise. Naturally, one would call for boundary conditions for E on $\partial\Omega$ in case of a purely elliptic equation ($\bar{\Delta} > 0$ on Ω) and for Cauchy data on a suitable (noncharacteristic) part $\Gamma \subset \partial\Omega$ in a purely hyperbolic case ($\bar{\Delta} < 0$ on Ω). But for the present problem (3.23) with $\hat{w}$ satisfying (2.2) or

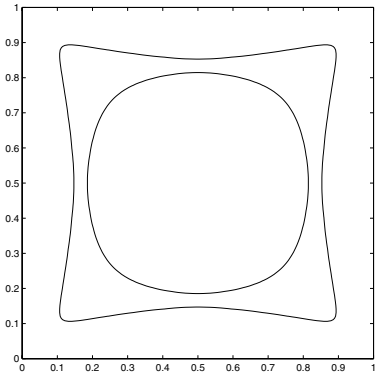

FIG. 2. *The clamped case: a hyperbolic ring between two elliptic areas.*

(2.3), it is not at all obvious how to proceed. The study in [16] of the characteristics of (3.23), where the two characteristic directions are given by

$$\frac{dy}{dx} = \frac{(1-\nu)\hat{w}_{xy} \pm \sqrt{(1-\nu)^2\hat{w}_{xy}^2 - (\hat{w}_{xx} + \nu\hat{w}_{yy}) \cdot (\hat{w}_{yy} + \nu\hat{w}_{xx})}}{\hat{w}_{xx} + \nu\hat{w}_{yy}}$$

(see [13]), gave some additional insight—for instance, although (3.23) is hyperbolic near the corners of the frame in the simply supported case, one cannot prescribe Cauchy data due to the fact that the edges are characteristics. However, it is not even clear whether side conditions on E should be prescribed at all.

So far, results about existence, uniqueness, or stability with respect to the data $\hat{w}$ of a solution to problem (3.23) are available only for special symmetric cases; see [14]. Since, in particular, numerical techniques for solving the equation of mixed type are unavailable, the direct approach (at the moment) is not suited to solving the inverse windshield problem. Nevertheless, returning to our iterative approach (3.8), we shall see that the features of the direct approach must not be neglected.

3.3. A first theoretical link. In general, the convergence in (3.19), (3.20) for iterative regularization methods may be arbitrarily slow; see [15]. Rate estimates can be obtained only under additional assumptions on the quality of the initial guess E_0 that are often difficult to comprehend; see [5]. Enhancing (3.8) by an additional stabilizing term, i.e., considering

$$E_{k+1}^\delta = E_k^\delta + L(E_k^\delta)^*(w^\delta - w_k) - \beta_k(E_k^\delta - E_0)$$

with a certain nonnegative sequence of decaying parameters β_k, the convergence rates

$$\|E_k - E_*\| = \mathcal{O}(\sqrt{\beta_k}) \qquad \text{(for exact data) and}$$
$$\|E_{k_*(\delta)}^\delta - E_*\| = \mathcal{O}(\sqrt{\beta_{k_*(\delta)}})$$

could be proven in [9] under the so-called *weak source condition*

$$\exists u \in Y_0, \quad E_* - E_0 = L(E_*)^* u. \tag{3.26}$$

In order to gain more insight into (3.26), we use the definition of $L(E_*)$ and multiply both sides by an arbitrary element $h \in X$. Then condition (3.26) assumes the

existence of a source function $u \in Y_0$ such that

$$\begin{aligned}\frac{12(1-\nu^2)}{t^3}(E_* - E_0, h) = &- \int_\Omega h(\hat{w}_{xx}u_{xx} + \hat{w}_{yy}u_{yy})dxdy \\ &- \int_\Omega \nu h(\hat{w}_{xx}u_{yy} + \hat{w}_{yy}u_{xx})dxdy \\ &- 2\int_\Omega (1-\nu)h\hat{w}_{xy}u_{xy}d\vec{x}\end{aligned}$$

holds. If $E_* - E_0$ is sufficiently smooth and if the boundary values of the initial guess E_0 coincide with those of E_*, we obtain

$$(E_* - E_0, h) = \int_\Omega N_X^* N_X (E_* - E_0) \cdot h \, dx, \tag{3.27}$$

where N_X denotes the linear operator that generates the norm in X, e.g., $N_X^* N_X = (I - \Delta - \Delta^2)$ for $X = H^2(\Omega)$. Hence, the weak source condition can be understood as a solvability condition for the second-order differential equation

$$\begin{aligned}-\frac{12(1-\nu^2)}{t^3}N_X^* N_X(E_* - E_0) = &(\hat{w}_{xx}u_{xx} + \hat{w}_{yy}u_{yy}) \\ &+ \nu(\hat{w}_{xx}u_{yy} + \hat{w}_{yy}u_{xx}) \\ &+ 2(1-\nu)\hat{w}_{xy}u_{xy}\end{aligned}$$

for the unknown function $u \in Y_0$. Rearranging the terms on the right-hand side, we end up with

$$\begin{aligned}-\frac{12(1-\nu^2)}{t^3}N_X^* N_X(E_* - E_0) = &(\hat{w}_{xx} + \nu\hat{w}_{yy})u_{xx} + (\hat{w}_{yy} + \nu\hat{w}_{xx})u_{yy} \\ &+ 2(1-\nu)\hat{w}_{xy}u_{xy}.\end{aligned} \tag{3.28}$$

Now, building the discriminant of (3.28) shows that the type of (3.28) is identical to that of the second-order PDE (3.23) for E.

Although we assume the attainability of the target shape $\hat{w}$, which can in fact be understood as a solvability assumption for the parameter equation (3.23), this does not automatically imply the solvability of (3.28), since lower-order terms in the unknown function are missing in the latter. We also mention that the boundary conditions for a possible solution of (3.28) are already determined by the space Y_0. Since both (2.2) and (2.3) are natural boundary conditions for a fourth-order equation, they might be inappropriate for (3.28).

Nevertheless, (3.28) gives a first theoretical coupling between the direct and the iterative approaches to solving the inverse windshield problem. The next section shows that the inverse problem can be practically solved by our iterative method (3.8), but it also numerically confirms the influence of the mixed type of (3.23) on the course of the iteration. We emphasize that the relation between the parameter PDE and the iterative regularization method is specific neither to the windshield problem nor to method (3.8). We refer to [4], where the classical Landweber iteration (3.7) was applied to a second-order parameter identification problem with a type ranging from purely hyperbolic to purely elliptic in dependence on the given target.

4. Numerical experiments.

4.1. Preliminaries. Though the windshield problem yields only strictly mixed type equations (3.23), still the significant difference between the simply supported and the hyperbolic situation allows us both to test the iterative method and to numerically investigate the influence of the equation type on its outcome. For that purpose, neither the thickness t of the plate, the right-hand side f, the Poisson ratio ν, nor the scaling of the parameter E are of relevance. With $\nu = 0.5$, the direct problem (2.6) then turns into

$$\int_\Omega E\Big[(w_{xx}+w_{yy})(v_{xx}+v_{yy}) - \frac{1}{2}(w_{xx}v_{yy}+w_{yy}v_{xx}-2w_{xy}v_{xy})\Big]\,dxdy = \int_\Omega \tilde{f}v\,dxdy, \qquad v\in Y_0, \tag{4.1}$$

with the solution space given by either (2.8) or (2.9). The use of a nonphysical right-hand side $\tilde{f}$, i.e., not including gravity force, facilitates the construction of test examples for which the solution of the inverse problem is analytically known.

Although the convergence analysis of (3.8), and of the methods discussed in [5], applied to the windshield problem would require a parameter space satisfying $X \subset L^\infty(\Omega)$ (see (3.1)), we choose $X = H^1(\Omega)$ for the numerics. On the one hand, this allows us to keep the numerical effort low (since the use of higher-order elements for the parameter is avoided), and on the other hand, it responds to the natural wish to keep regularity sufficient for the direct problem; compare to (2.10). All our tests have shown that the iterates remain in the domain $\tilde{Q}$ of the parameter-to-output map F without the use of a projection operator.

As a last small deviation from our theoretical foundations, we shall use a line search algorithm (see [6]) in order to accelerate (3.8). This results in an iteration index dependent "scaling" parameter λ_k. (Compared to a constant λ as required by the theory, this has no other influence on the course of the iteration than speeding it up; see [9].) In other words, the iteration finally reads as

$$E_{k+1}^\delta = E_k^\delta + \lambda_k \bar{E}_k, \tag{4.2}$$

where *the update* $\bar{E}_k$ satisfies

$$(\bar{E}_k,h) = -\int_\Omega h\Big\{(w_{kxx}(w^\delta-w_k)_{xx}+w_{kyy}(w^\delta-w_k)_{yy}) + \frac{1}{2}(w_{kxx}(w^\delta-w_k)_{yy}+w_{kyy}(w^\delta-w_k)_{xx}) + w_{kxy}(w^\delta-w_k)_{xy}\Big\}\,dxdy; \tag{4.3}$$

compare to (3.22). Due to the choice $X = H^1(\Omega)$, equation (4.3) can be considered as the weak formulation of

$$\bar{E}_k - \Delta\bar{E}_k = -\Big\{(w_{kxx}(w^\delta-w_k)_{xx}+w_{kyy}(w^\delta-w_k)_{yy}) + \frac{1}{2}(w_{kxx}(w^\delta-w_k)_{yy}+w_{kyy}(w^\delta-w_k)_{xx}) + w_{kxy}(w^\delta-w_k)_{xy}\Big\} \ \text{ in } \ \Omega, \tag{4.4}$$

$$\frac{\partial\bar{E}_k}{\partial n} = 0 \ \text{ on } \ \partial\Omega. \tag{4.5}$$

Hence, one iteration step for solving the inverse windshield problem consists of the following:

1. Given E_k^δ, calculate the solution w_k of the direct problem.
2. Build the residual $w^\delta - w_k$, and solve problem (4.4), (4.5) for the update $\bar{E}_k$.
3. Then, the new iterate E_{k+1}^δ is given by (4.2).

We emphasize that the second-order PDE (4.4) for $\bar{E}_k$ is purely elliptic, and hence the iterative algorithm never requires us to solve the second-order equation (3.23) for the parameter; thus there is no obvious connection to the mixed type resulting from the direct approach. The boundary condition (4.5) shows that the boundary flux $\frac{\partial E_0}{\partial n}$ of the initial guess E_0 is maintained during the whole iteration.

All computations to be presented in the following are based on the PDE Toolbox of MATLAB, using the finite element method. For the parameter we chose the built-in linear ansatz functions, while the solutions of the direct problem were represented by means of the discrete Kirchhoff triangle; see [1]. Furthermore, a regular and uniform triangular mesh with 665 nodes was used for $\Omega = [0,1] \times [0,1]$.

4.2. Simply supported vs. clamped target shape. For the numerical test we consider a clamped target shape

$$\hat{w}_C = -25(x^2 - 2x^3 + x^4)(y^2 - 2y^3 + y^4), \tag{4.6}$$

a simply supported target shape

$$\hat{w}_S = -(x - 2x^3 + x^4)(y - 2y^3 + y^4), \tag{4.7}$$

and a true parameter

$$E_* = 1 + x + 2y \tag{4.8}$$

on the unit square. The right-hand side $\tilde{f}$ in (4.1) is chosen such that $F(E_*) = \hat{w}_C$ or $F(E_*) = \hat{w}_S$ holds, respectively. Though in fact we treat two different direct problems, one for the simply supported and one for the clamped plate, this is no barrier for testing our algorithm and for comparing the respective inverse problems with respect to the parameter PDE structure. The elliptic and hyperbolic regions of (3.23) corresponding to $\hat{w}_S$ and $\hat{w}_C$ are those shown in Figures 1 and 2.

Ignoring data perturbations for the moment, we choose

$$E_0 = 4 \tag{4.9}$$

as an initial guess, meaning a relative deviation from E_* of approximately 80% measured with respect to the norm in X. The course of the iterations is documented in Figures 3 and 4, where the relative error

$$\frac{\|E_* - E_k\|}{\|E_*\|} \tag{4.10}$$

in the parameter, but also the relative error in the output, i.e.,

$$\frac{\|\hat{w} - w_k\|}{\|\hat{w}\|}, \tag{4.11}$$

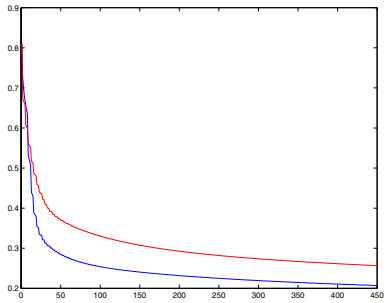

FIG. 3. (4.10) *vs.* k.

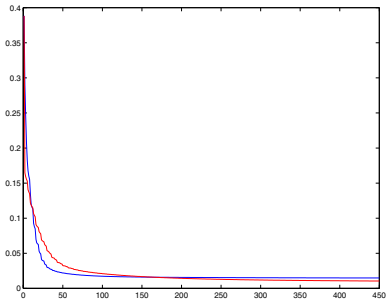

FIG. 4. (4.11) *vs.* k.

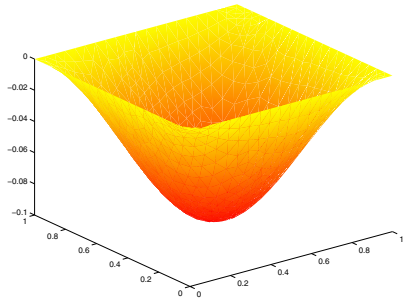

FIG. 5. *Computed output* w_{450}*, simply supported.*

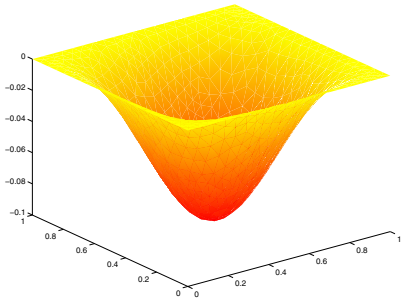

FIG. 6. *Computed output* w_{450}*, clamped.*

is plotted against the iteration index. (The relative error in the $L^2(\Omega)$-norm is approximately tenth part of that shown.) The simply supported case is represented by the upper line, the clamped case by the lower one. Figure 4 shows that the simply supported and the clamped target shapes are approximated with nearly the same quality by our method. The relative error is smaller than 2%, which is remarkable since the deviation in (4.11) is measured with respect to $H^2(\Omega)$. Regarding the relative error in the parameter, we observe a first difference between the simply supported and the clamped situation. Starting both computations from (4.9), it is an open question why the "clamped" error is significantly lower than the "simply supported" one.

Figures 5 and 6 confirm the quality of the computed outputs, while the corresponding parameters E_{450} are shown in Figures 7 and 8. In fact, the total $L^2(\Omega)$-deviations between E_* and E_{450} are nearly identical, while the total deviations in the gradient are higher in the simply supported case than in the clamped one. The oscillations along the boundary $\partial\Omega$ in both cases are caused by the attempt to satisfy the boundary condition

$$\frac{\partial E_k}{\partial n} = 0$$

due to the initial guess (4.9); compare to (4.5).

Not knowing the boundary values of the solution E_* (as in the previous example), one might think of an iteration procedure that ignores them entirely. For that purpose

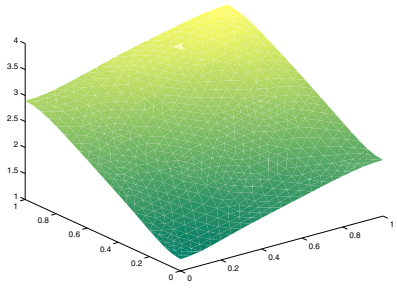

FIG. 7. E_{450}, *simply supported example.*

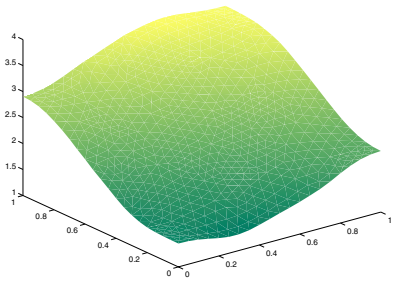

FIG. 8. E_{450}, *clamped example.*

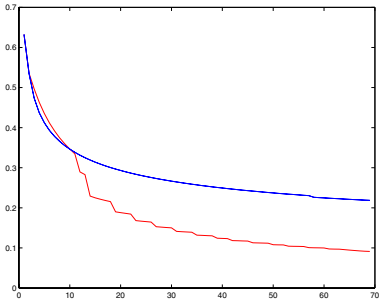

FIG. 9. (4.13) *vs.* k, *simply supported vs. clamped.*

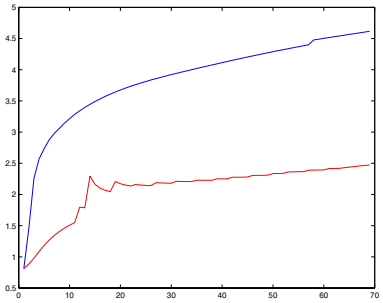

FIG. 10. (4.10) *vs.* k, *simply supported vs. clamped.*

we could use the $L^2(\Omega)$-inner product in the left-hand side of (4.3), resulting in the update rule

$$\begin{aligned}\bar{E}_k = -\Big\{ & (w_{k\,xx}(w^\delta - w_k)_{xx} + w_{k\,yy}(w^\delta - w_k)_{yy}) \\ & + \frac{1}{2}(w_{k\,xx}(w^\delta - w_k)_{yy} + w_{k\,yy}(w^\delta - w_k)_{xx}) \\ & + w_{k\,xy}(w^\delta - w_k)_{xy}\Big\} \quad \text{in } \Omega.\end{aligned} \tag{4.12}$$

Algorithm (4.12) can be related to the abstract formulation (3.8) by building the adjoint of the iteration operator $L(E_k^\delta)$ with respect to only the rougher space $L^2(\Omega)$. As opposed to (4.4), equation (4.12) does not describe a boundary value problem for the update $\bar{E}_k$. Though the parameters are still considered as elements belonging to $H^1(\Omega)$, boundary traces of the initial guess are not maintained during the iteration (at least not in an obvious way). Figures 9 and 10 show the performance of the iteration when using only the update rule (4.12), where the relative error

$$\frac{\|E_* - E_k\|_{L^2(\Omega)}}{\|E_*\|_{L^2(\Omega)}} \tag{4.13}$$

is plotted versus k in Figure 9, while the error (4.10) with respect to $H^1(\Omega)$ is recorded in Figure 10. The error behavior of the outputs w_k is similar to that shown in

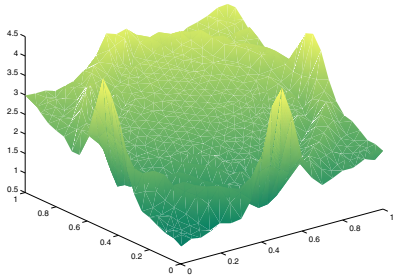

FIG. 11. E_{69}, *simply supported example.*

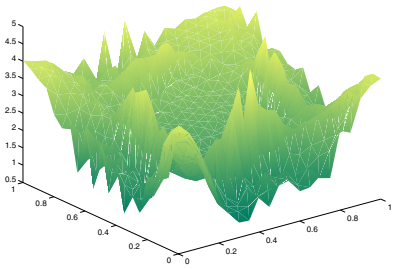

FIG. 12. E_{69}, *clamped example.*

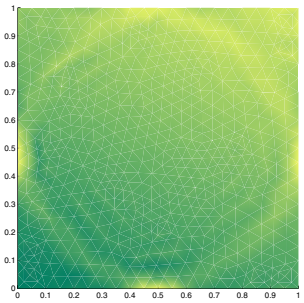

FIG. 13. E_{69}, *top view, simply supported.*

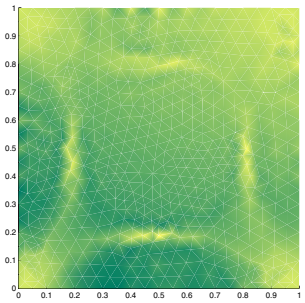

FIG. 14. E_{69}, *top view, clamped.*

Figure 4; hence we concentrate on only the parameters E_k. The $L^2(\Omega)$-error in the simply supported situation (lower line) now lies below its clamped counterpart (upper line), a ranking opposed to that shown in Figure 3. Regarding the $H^1(\Omega)$-norm, the iteration shows a divergent behavior; i.e., the error increases from the very beginning, leading to highly oscillating parameters, as illustrated in Figures 11 and 12. In these figures, dark shading means small errors, while light tone represents large deviations from the true parameter. Views of the computed solutions from above are given in Figures 13 and 14; a comparison to the elliptic and hyperbolic regions (see Figures 1 and 2) in the respective parameter PDE shows that its mixed type is reflected in the error structure of the iterative solutions. The parabolic line in Figure 1 is clearly observable in Figure 13, but the two parabolic lines bordering the hyperbolic ring in Figure 2 are also reflected in Figure 14. In particular the parabolic points lying on $\partial\Omega$ are highlighted: While in the simply supported example the iterates stay with the initial value of E_0 at the parabolic midpoints of each side of the frame and exactly reach the solution at the very corners, the parameters are left completely unchanged at the parabolic corners in the clamped case.

From the discussion of the direct approach in section 3 we know that the second derivatives of any solution of the direct problem, i.e., especially w_{kxx}, w_{kyy}, and w_{kxy}, vanish at the parabolic boundary points, both in the simply supported and the clamped situation. Hence, the right-hand side in (4.12) is zero at these points such that the initial guess E_0 cannot change there, explaining the behavior shown in Figures 11 and 12 along $\partial\Omega$. For that reason, these results cannot be improved by choosing a finer grid when staying with (4.12); on the contrary, the peaks would get even sharper. Concerning the interior of Ω, the parabolic lines for w_k are not fixed

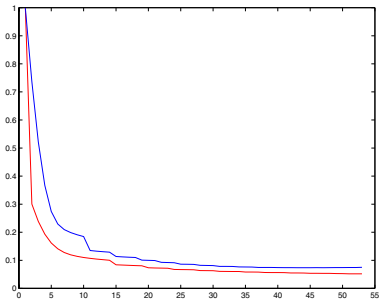

FIG. 15. (4.10) *vs.* k.

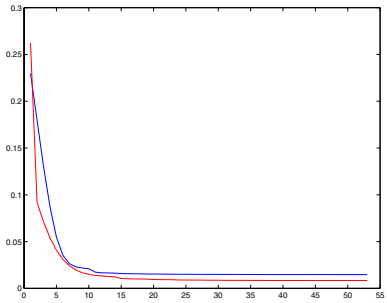

FIG. 16. (4.11) *vs.* k.

but tend during the iteration towards those of the target $\hat{w}$, as shown in Figures 1 and 2. Hence, their influence on (4.12) is not as strong as that of the nonchanging parabolic boundary points, at which the peaks in Figures 11 and 12 are highest.

We summarize our observations by

$$\bar{E}_k \approx 0 \Leftrightarrow \bar{\Delta} = 0,$$

where $\bar{\Delta}$ is the discriminant of the parameter PDE (3.23), finally suggesting that the parameter cannot be identified along the parabolic lines determined by $\bar{\Delta} = 0$. This lack of identifiability also exists during the iteration based on update (4.4), (4.5) but is then blurred out due to the smoothing effect of the PDE for $\bar{E}_k$.

Considering the direct approach for solving the inverse problem via the second-order PDE (3.23), the question of whether or what kind of boundary conditions on E should be prescribed is unanswered. This automatically translates into an uncertainty about the "right inner product" for the left-hand side in (4.3). However, as opposed to the direct approach, the iterative process at least allows us to test several choices. So far, we have considered two possibilities, namely, the neglect of boundary conditions via (4.12) and the prescription of Neumann data via (4.5). Aiming at a smooth approximation of the parameter—motivated by the motivating sag bending process and only then suitable for translation into a heating procedure—the latter variant is certainly preferable. If the boundary values of the solution (or the desired) E_* are given, we could use this information by a further manipulation of the iterative process (4.2). Restricting the test functions h in (4.3) from the space $H^1(\Omega)$ to $H_0^1(\Omega)$, we again can interpret (4.3) as the weak formulation of the elliptic PDE (4.4) for the update $\bar{E}_k$ but now with

$$\bar{E}_k = 0 \ \text{ on } \ \partial\Omega \tag{4.14}$$

as its boundary condition. Then the Dirichlet traces of the initial guess E_0 are maintained during the iteration. In terms of formulation (3.8), equation (4.4) in combination with (4.14) can be understood as building the adjoint of the iteration operator with respect to $H_0^1(\Omega)$.

The course of the iteration using (4.14) with an initial guess

$$E_0 = E_* + \frac{3}{2}\sin(\pi x)\sin(\pi y)$$

is recorded in Figures 15 and 16. The relative errors in the parameter and the output now are nearly identical in the simply supported (lower line) and the clamped situation

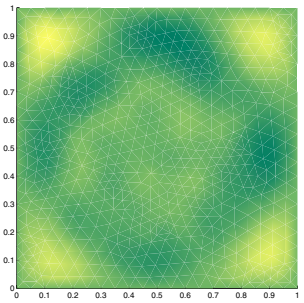

FIG. 17. $E_* - E_{53}$, *simply supported, top view.*

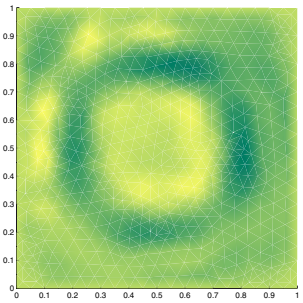

FIG. 18. $E_* - E_{53}$, *clamped, top view.*

TABLE 4.1
The data error.

	δ	$\frac{\|w^\delta - \hat{w}\|}{\|\hat{w}\|}$	$\frac{\|w^\delta - \hat{w}\|_{H^1(\Omega)}}{\|\hat{w}\|_{H^1(\Omega)}}$	$\frac{\|w^\delta - \hat{w}\|_{L^2(\Omega)}}{\|\hat{w}\|_{L^2(\Omega)}}$
$w = w_S$	0.292	0.293	0.012	0.001
$w = w_C$	0.417	0.29	0.02	0.002

(upper line); furthermore, they are (of course) lower than their counterparts from Figures 3 and 4. Nevertheless, the difference between the simply supported and the clamped examples becomes apparent when viewing the absolute error between E_* and the respectively computed parameters E_{53} from the top, as illustrated in Figures 17 and 18. Once again, the structure of the mixed type parameter PDE (3.23) is reflected in the results obtained by the iterative parameter identification method.

Finally, we briefly comment on the influence of data perturbations on the inverse windshield problem. Staying with the update rule (4.14), which led to the best results in the noise free situation, we now consider random perturbations w_C^δ and w_S^δ of the exact data (4.6) and (4.7). The respective relative data errors are given in Table 4.1. Though the errors are about 29% when measured with respect to the full $H^2(\Omega)$-norm, they are less than 0.5% if the perturbations are considered only in $L^2(\Omega)$. The numbers in the table also show that for approximating the given target shield (whether exact or perturbed) the full $H^2(\Omega)$-norm is indeed the appropriate one. Only then can errors in the second-order derivatives and the related curvature terms be minimized, which is essential for the optical quality of the windshield. Figures 19 and 20 now show the behavior that is typical for any iterative parameter identification method in the presence of data noise. While the relative error (4.11) (with $\hat{w}$ replaced by w^δ) in the output is monotonically decreasing, the error in the parameter shows a semiconvergent behavior (even though the true boundary values were fixed). Hence, a reliable approximation of E_* can be obtained only by stopping the iteration at the right time, for instance, according to the discrepancy principle (3.6). Furthermore, Figure 19 indicates that the iteration for the clamped case (upper line) is more sensitive to data perturbations than for the simply supported one (lower line).

The theoretical and numerical results presented in this paper clearly demonstrate that the inverse windshield problem (3.2) can be solved in a stable way by the derivative free iteration method (3.8) under natural assumptions and with minimal effort. Furthermore, we have seen that the direct approach, though methodologically differ-

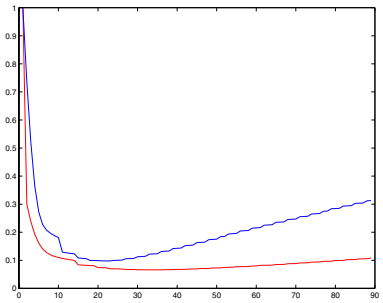

FIG. 19. (4.10) *vs.* k.

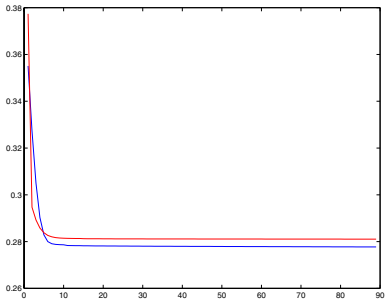

FIG. 20. (4.11) *vs.* k.

ent and (so far) not admitting a numerical implementation, is coupled to the iteration. A better understanding of its mixed type structure is of mathematical interest in its own right, but might also help to further improve the performance of the iterative algorithm.

Acknowledgment. I'd like to express my gratitude to Prof. Heinz W. Engl and the group of J. R. Ockendon for bringing the windshield problem to my attention and for fruitful discussions about the two approaches.

ON THE SOLUTION TO THE RIEMANN PROBLEM FOR THE COMPRESSIBLE DUCT FLOW*

NIKOLAI ANDRIANOV† AND GERALD WARNECKE†

Abstract. The quasi-one-dimensional Euler equations in a duct of variable cross section form probably one of the simplest nonconservative systems. We consider the Riemann problem for it and discuss its properties. In particular, for some initial conditions, the solution to the Riemann problem appears to be nonunique. In order to rule out the nonphysical solutions, we provide two-dimensional computations of the Euler equations in a duct of corresponding geometry and compare them with the one-dimensional (1D) results. Then, the physically relevant 1D solutions satisfy a kind of entropy rate admissibility criterion.

Key words. nozzle flow, nonstrictly hyperbolic, resonance

1. Introduction.

In recent decades, considerable attention has been paid to both theoretical and numerical investigations of systems of conservation laws. This interest is caused by a wide range of applications for conservation laws, like fluid mechanics, astrophysics, meteorology, etc. However, there is an important class of problems which is described by the *nonconservative* systems, i.e., systems which cannot be written in divergence form. The example which we have in mind is two-phase flows.

The theory of nonconservative systems is still under development. The same can be said about the numerical methods for such systems. Here, we consider probably one of the simplest nonconservative systems, the system of the Euler equations in a duct of variable cross section. In [4] we have shown that this system can be formally obtained from the Baer–Nunziato model of two-phase flows [5], which describes the flame spread and the deflagration-to-detonation transition (DDT) in gas-permeable, reactive granular materials. Therefore, the results of [4] to a certain extent will also hold for the Euler equations in a duct of variable cross section. Conversely, a number of results which we present here are also valid for the Baer–Nunziato model in [4].

One can distinguish two parts in the system of Euler equations in a duct. These are a strictly hyperbolic system and an additional equation, which states that the cross section does not change in time. The resulting system appears to be only nonstrictly hyperbolic, with the *resonant behavior* when one of the nonlinear wave families has a zero wave speed. Such resonant systems have been studied before; see Isaacson and Temple [14, 15] and the references therein. We refer also to a recent work of Goatin and LeFloch [12] for a study of the Riemann problem for nonconservative resonant systems.

There are several difficulties concerning the solution of nonconservative systems. Due to the presence of nonconservative terms, one cannot use the definition of a weak solution from the theory of conservation laws. A general definition based on the theory

of nonconservative products was given in Dal Maso, LeFloch, and Murat [10]. In the particular case of the Riemann problem for the Euler equations in a duct, it appears that the system of governing equations is locally equivalent to some conservative system. This allows us to give a corresponding definition of the weak solution; see section 3.

It appears that, for certain initial conditions, the solution to the Riemann problem is not unique, despite the fact that all shocks locally satisfy a usual entropy criterion. We discuss the conditions which lead to nonuniqueness. For the selection of a physically relevant solution we compare some examples with two-dimensional (2D) duct flow computations. It appears that the 1D solutions picked out by 2D computations satisfy a kind of entropy rate admissibility criterion in analogy to that of Dafermos [8].

The paper is organized as follows. In section 2 we carry out the characteristic analysis of the system of governing equations. In section 3 we introduce the notion of a weak solution for the Riemann problem. In section 4 we discuss the structure of the Riemann solution and point out the conditions which lead to uniqueness and nonuniqueness. Finally, in section 5 we propose a criterion in order to select the physically relevant solution to the Riemann problem. We justify this criterion by comparing the 1D exact solutions with the computations of the Euler equations in a duct of corresponding geometry, averaged over the cross section.

2. Mathematical analysis. The system of Euler equations in a duct of variable cross section can be written in the following form:

$$\mathbf{u}_t + \mathbf{f}(\mathbf{u})_x = \mathbf{h}(\mathbf{u})A_x, \tag{2.1}$$

where

$$\mathbf{u} = \begin{bmatrix} A \\ A\rho \\ A\rho v \\ A\rho E \end{bmatrix}, \qquad \mathbf{f}(\mathbf{u}) = \begin{bmatrix} 0 \\ A\rho v \\ A(\rho v^2 + p) \\ Av(\rho E + p) \end{bmatrix}, \qquad \mathbf{h}(\mathbf{u}) = \begin{bmatrix} 0 \\ 0 \\ p \\ 0 \end{bmatrix}. \tag{2.2}$$

In (2.1), $A = A(x)$ is the variable cross section, ρ is the density, v the velocity, p the pressure, and $E = e + v^2/2$ the specific total energy. We assume that the gas obeys the stiffened gas equation of state (EOS)

$$e = \frac{p + \gamma\pi}{\rho(\gamma - 1)}, \tag{2.3}$$

where γ and π are thermodynamic constants. When $\pi = 0$, we recover the usual ideal gas EOS.

Usually, the cross section $A = A(x)$ is assumed to be given a priori; see, e.g., Zucrow and Hoffman [18]. In (2.1), we consider it as an additional unknown, and we add the trivial equation $A_t = 0$ to determine it. The advantages of this approach are twofold. First, the system (2.1) belongs to the class of *resonant* systems; see Isaacson and Temple [14, 15]. Thus, one can use the results of [14, 15] for the system (2.1). Secondly, as we have noted in [4], system (2.1) can be formally obtained from the governing equations for the Baer–Nunziato model of two-phase flows [5]. Since system (2.1) is much simpler than the two-phase flow model [5], one can gain deeper insight into the structure of the model [5] by studying (2.1).

A particular issue about system (2.1) is the presence of the *nonconservative term* $p\,\partial A/\partial x$. Due to this term, one cannot write (2.1) in divergence form. Consequently,

one cannot define a weak solution and find the Rankine–Hugoniot conditions in the usual way, as it is done for systems of conservation laws.

In what follows, we will consider the Riemann problem for (2.1), i.e., equip it with piecewise constant initial data

$$\mathbf{u}(x,0) = \begin{cases} \mathbf{u}_L, & x \le x_0, \\ \mathbf{u}_R, & x > x_0. \end{cases} \tag{2.4}$$

As usual, we will assume that the Riemann problem (2.1), (2.4) admits self-similar solutions, i.e.,

$$\mathbf{u}(x,t) = \mathbf{u}(\xi), \quad \xi = \frac{x - x_0}{t}. \tag{2.5}$$

To carry out the characteristic analysis of (2.1), it is convenient to use the primitive variables

$$\mathbf{v} = (A, \rho, v, \eta)^T, \tag{2.6}$$

where $\eta = (p + \pi)/\rho^\gamma$ is the isentrope. Then, for smooth solutions, the system (2.1) is equivalent to

$$\mathbf{v}_t + \mathbf{A}(\mathbf{v})\mathbf{v}_x = 0, \tag{2.7}$$

where

$$\mathbf{A} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ \rho v/A & v & \rho & 0 \\ 0 & c^2/\rho & v & \dfrac{1}{\rho}\dfrac{\partial p}{\partial \eta} \\ 0 & 0 & 0 & v \end{bmatrix}, \tag{2.8}$$

and $c = \sqrt{\gamma(p+\pi)/\rho}$ is the sound speed. The eigenvalues of $\mathbf{A}$ are

$$\lambda_0 = 0, \qquad \lambda_1 = v - c, \qquad \lambda_2 = v, \qquad \lambda_3 = v + c, \tag{2.9}$$

and the corresponding eigenvectors are

$$\mathbf{r}_0 = \begin{bmatrix} A(v^2 - c^2)/(vc^2) \\ -v\rho/c^2 \\ 1 \\ 0 \end{bmatrix}, \quad \mathbf{r}_1 = \begin{bmatrix} 0 \\ 1 \\ -c/\rho \\ 0 \end{bmatrix}, \quad \mathbf{r}_2 = \begin{bmatrix} 0 \\ -\dfrac{\partial p}{\partial \eta} \\ 0 \\ c^2 \end{bmatrix}, \quad \mathbf{r}_3 = \begin{bmatrix} 0 \\ 1 \\ c/\rho \\ 0 \end{bmatrix}. \tag{2.10}$$

Note that situations are possible in which one of λ_1, λ_2, or λ_3 coincides with λ_0. Moreover, when λ_1 or λ_3 coincide with λ_0, the corresponding eigenvectors become linearly dependent. In this case a parabolic degeneracy occurs. To summarize, the system of governing equations (2.1) is hyperbolic away from the points where either $\lambda_1 = \lambda_0$ or $\lambda_3 = \lambda_0$. Note that system (2.1) is nonstrictly hyperbolic when $\lambda_2 = \lambda_0$.

We can easily see that the 1-, 2-, and 3-characteristic fields are exactly the same as for the usual one-dimensional Euler equations. The 1- and 3-characteristic fields are genuinely nonlinear, and the 2-field is linearly degenerate. The Riemann invariants for these fields coincide with those of the Euler equations.

It is obvious that the 0-characteristic field is linearly degenerate. In the solution to the Riemann problem (2.1), (2.4), this field corresponds to a stationary contact discontinuity. The condition $A_t = 0$ in (2.1) implies that A can have a jump only across the stationary 0-contact and is constant to the left and to the right of it. Therefore, away from the 0-contact the term $p\,\partial A/\partial x$ disappears, and we are left with a conservation law there. Then, for a shock wave with nonzero speed, we can use the usual Rankine–Hugoniot conditions.

Using the expression for the eigenvector $\mathbf{r}_0$, we can find the following two 0-Riemann invariants, which are constant across the 0-contact,

$$\begin{aligned} \eta &= \text{const}, \\ \frac{v^2}{2} + \frac{c^2}{\gamma - 1} &= \text{const}\,. \end{aligned} \tag{2.11}$$

In order to find the third one, we can, e.g., rewrite the system (2.1) in matrix form,

$$\mathbf{u}_t + \mathbf{B}(\mathbf{u})\mathbf{u}_x = 0,$$

where $\mathbf{u}$ is given by (2.2), and calculate the eigenvectors of $\mathbf{B}$. Then the third 0-Riemann invariant is

$$A\rho v = \text{const}\,. \tag{2.12}$$

The three relations (2.11), (2.12) express the constancy of entropy, Bernoulli's law, and conservation of mass, respectively.

There exist at most two solutions to the system (2.11), (2.12); see [2]. We determine which solution will be admissible using the following criterion.

DEFINITION 2.1 (evolutionarity criterion). *Consider a discontinuity Σ in a physical flow, which is governed by a $d \times d$ hyperbolic system. Denote the number of characteristics incoming to Σ by n and coinciding with Σ by c. Further, denote the number of unknown variables on both sides of Σ together with the speed of Σ by $N = 2d + 1$, and the number of relations across Σ by m. Then Σ is called* evolutionary *if*

$$N = n + c + m.$$

For the evolutionary discontinuity Σ, all N variables on it can be found using $n+c$ relations along the incoming and coinciding characteristics, and m relations across Σ. Therefore, Σ is well determined in the flow; i.e., it *evolves* in time.

The notion of *evolutionarity* goes back to at least Landau and Lipschitz [16, paragraph 88], who studied the stability of shock waves in gas dynamics. Evolutionary discontinuities are discussed in the context of magnetohydrodynamics [11] and two-phase flow [4].

In order for a contact discontinuity to be evolutionary, the number of characteristics impinging on it from the one side must be equal to the number of characteristics leaving it from the other side. For a 0-contact in the solution to the Riemann problem (2.1), (2.4), this is equivalent to the fact that the eigenvalues (2.9) on both sides of the 0-contact do not change their sign.

For a strictly hyperbolic system, the evolutionarity criterion is equivalent to the Lax shock condition. For resonant hyperbolic systems, i.e., for systems of type (2.1), it is equivalent to the criterion of Isaacson and Temple [14, 15]; see also Goatin and LeFloch [12]. For proofs of the above statements, see [2].

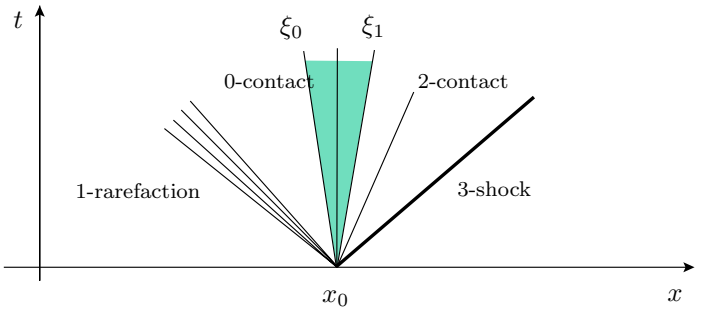

FIG. 1. *A typical Riemann problem for the* 1*D Euler equations in a duct.*

3. Weak solution to the Riemann problem. As we have mentioned above, for the Riemann problem (2.1), (2.4) the nonconservative term $p\,\partial A/\partial x$ plays a role only across one wave in the solution, the stationary 0-contact. In the rest of domain, A is constant and equal to its left or right value. Therefore, everywhere away from the stationary contact the system (2.1) reduces to the usual 1D Euler equations

$$\mathbf{u}_t + \mathbf{f}(\mathbf{u})_x = 0, \tag{3.1}$$

where

$$\mathbf{u} = \begin{bmatrix} \rho \\ \rho v \\ \rho E \end{bmatrix}, \qquad \mathbf{f}(\mathbf{u}) = \begin{bmatrix} \rho v \\ \rho v^2 + p \\ v(\rho E + p) \end{bmatrix}. \tag{3.2}$$

For the system (3.1), we can define a weak solution in the usual manner.

On the other hand, across the stationary contact, the relations (2.11), (2.12) hold. Let us look for a conservative system of equations such that the Rankine–Hugoniot conditions for this system are exactly (2.11), (2.12). Remember that across the stationary contact the flow is isentropic; see (2.11). As long as some other waves do not coincide with the stationary contact, we can choose a small sector around the stationary contact where the flow is isentropic, too. Consider Figure 1 for a typical Riemann problem. The solution in the sector, bounded by the rays ξ_0 and ξ_1 around the stationary contact, is governed by the relations (2.11), (2.12). In the left and right parts of this sector, system (2.1) is equivalent to the system

$$\begin{aligned} A_t &= 0, \\ (A\rho)_t + (A\rho v)_x &= 0, \\ (A\rho E)_t + (Av(\rho E + p))_x &= 0, \\ \eta_t + v\eta_x &= 0. \end{aligned} \tag{3.3}$$

Note that the last equation in (3.3) is trivially satisfied everywhere in the sector, since the flow is isentropic there. Therefore, system (3.3) may be rewritten as

$$\mathbf{U}_t + \mathbf{F}(\mathbf{U})_x = 0, \tag{3.4}$$

where

$$\mathbf{U} = \begin{bmatrix} A \\ A\rho \\ A\rho E \end{bmatrix}, \qquad \mathbf{F}(\mathbf{U}) = \begin{bmatrix} 0 \\ A\rho v \\ Av(\rho E + p) \end{bmatrix}. \tag{3.5}$$

The Rankine–Hugoniot conditions for this system across a zero-speed discontinuity, augmented with the condition $\eta = \text{const}$, are exactly the relations (2.11), (2.12). Since the system (3.4) is in divergence form, we can use the usual definition of a weak solution for it. Note that the approach we have used here is exactly the same as that of [4].

Consider a system of conservation laws

$$\mathbf{u}_t + \mathbf{f}(\mathbf{u})_x = 0, \tag{3.6}$$

where the pair $(\mathbf{u}, \mathbf{f}(\mathbf{u}))$ are either $(\mathbf{u}, \mathbf{f}(\mathbf{u}))$ in (3.2) or $(\mathbf{U}, \mathbf{F}(\mathbf{U}))$ in (3.5), and let us restrict ourselves to self-similar solutions $\mathbf{u}(x,t) = \mathbf{u}(\xi)$, $\xi = (x - x_0)/t$ of that system. Then, for the smooth solutions, system (3.6) is equivalent to

$$-\mathbf{u}_\xi \xi + \mathbf{f}(\mathbf{u})_\xi = 0. \tag{3.7}$$

Consider the Riemann problem for (3.7); i.e., augment (3.7) with constant initial data

$$\mathbf{u}(-\infty) = \mathbf{u}_L, \qquad \mathbf{u}(\infty) = \mathbf{u}_R. \tag{3.8}$$

If we multiply (3.7) by a test function $\phi \in C_0^1(]\xi_0, \xi_1[)$ and integrate over all ξ, we get

$$\int_{\xi_0}^{\xi_1} (\mathbf{u}(\phi\,\xi)_\xi - \mathbf{f}(\mathbf{u})\phi_\xi)\, d\xi = 0. \tag{3.9}$$

Now $\mathbf{u}$ does not need to be differentiable anymore, and we can use it to define a weak solution to the Riemann problem (3.7), (3.8). Remember, that *locally* the *non-conservative* system (2.1) can be reduced to a *conservative* one, either (3.1) or (3.4). Thus, we can give a definition of a *global* weak solution to the Riemann problem (2.1), (2.4) as a composition of the weak solutions to the conservative systems (3.1) and (3.4).

DEFINITION 3.1. *Consider a sector, bounded by the rays ξ_0 and ξ_1, such that the stationary contact lies in it, and assume that it is the only ray of discontinuity there. Then, a function $\mathbf{u} = \mathbf{u}(\xi) \in L^\infty_{\text{loc}}(\mathbb{R})$ is called a* weak solution of the Riemann problem (2.1), (2.4) *if for any small $\epsilon > 0$ the following hold:*

1. *To the left of ξ_0, i.e., $\xi \in]-\infty, \xi_0]$,*

$$\int_{-\infty}^{\xi_0} (\mathbf{u}(\phi\,\xi)_\xi - \mathbf{f}(\mathbf{u})\phi_\xi)\, d\xi = 0 \quad \textit{for all } \phi \in C_0^1(]-\infty, \xi_0 + \epsilon[),$$

$\mathbf{u}(\xi) = \mathbf{u}(x,t)$, $\mathbf{f}(\mathbf{u}) = \mathbf{f}(\mathbf{u})$, and $\mathbf{u}$, $\mathbf{f}(\mathbf{u})$ are given by (3.2).

2. *To the right of ξ_1, i.e., $\xi \in [\xi_1, \infty[$,*

$$\int_{\xi_1}^{\infty} (\mathbf{u}(\phi\xi)_\xi - \mathbf{f}(\mathbf{u})\phi_\xi)\, d\xi = 0 \quad \textit{for all } \phi \in C_0^1(]\xi_1 - \epsilon, \infty[),$$

$\mathbf{u}(\xi) = \mathbf{u}(x,t)$, $\mathbf{f}(\mathbf{u}) = \mathbf{f}(\mathbf{u})$, and $\mathbf{u}$, $\mathbf{f}(\mathbf{u})$ are given by (3.2).

3. *Inside of the sector, bounded by ξ_0 and ξ_1, i.e., $\xi \in [\xi_0, \xi_1]$,*

$$\int_{\xi_0}^{\xi_1} (\mathbf{u}(\phi\,\xi)_\xi - \mathbf{f}(\mathbf{u})\phi_\xi)\, d\xi = 0 \quad \textit{for all } \phi \in C_0^1(]\xi_0 - \epsilon, \xi_1 + \epsilon[),$$

$\mathbf{u}(\xi) = \mathbf{U}(x,t)$, $\mathbf{f}(\mathbf{u}) = \mathbf{F}(\mathbf{U})$, and $\mathbf{U}$, $\mathbf{F}(\mathbf{U})$ are given by (3.5).

Remark 1. Note that, in the sector bounded by $\xi_0 - \epsilon$ and $\xi_0 + \epsilon$, statements 1 and 3 coincide, and in the sector bounded by $\xi_1 - \epsilon$ and $\xi_1 + \epsilon$, points 2 and 3 coincide.

Remark 2. In [10], Dal Maso, LeFloch, and Murat introduce a notion of the nonconservative product and give a definition of a weak solution to a general nonconservative system on its basis. In particular, this applies also to the system (2.1). In contrast to the definition of [10], we have used some physical observations in Definition 3.1, which are valid only for systems of a certain structure like (2.1) or for the Baer–Nunziato model we considered in [4]. Therefore, Definition 3.1 might be helpful in choosing a criterion for a physically admissible solution to the Riemann problem for such systems.

4. Nonuniqueness of the Riemann solution. It appears that the solution to the Riemann problem (2.1), (2.4) is in general nonunique; for the same left and right states $\mathbf{u}_L$, $\mathbf{u}_R$, one can get completely different Riemann solutions. As was pointed out by Isaacson and Temple [15], the reason for this behavior is that system (2.1) is nonstrictly hyperbolic and nonconservative. For system (2.1) without the term $p\,\partial A/\partial x$, i.e., for a nonstrictly hyperbolic *conservative* system, they showed that the Riemann solution is unique in a neighborhood of a state where one of the nonlinear wave speeds vanishes. On the other hand, there are examples of nonstrictly hyperbolic systems that are conservative but still have a nonunique Riemann solution; see, e.g., Dafermos [9, Chapter IX].

The solution to the Riemann problem (2.1), (2.4) becomes nonunique when the mutual position of the waves, configuration of the Riemann problem, can change; see Figure 2 for the four possible cases. The problem of nonuniqueness arises from the fact that for certain sets of initial data more than one configuration is possible. In this light it makes sense to consider the conditions that lead to the different configurations of the Riemann problem.

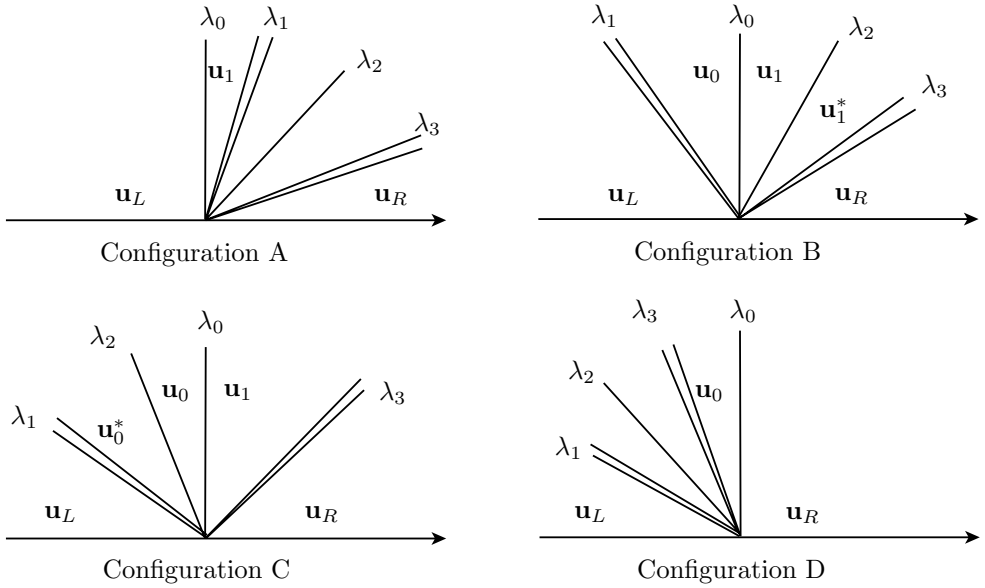

FIG. 2. *Possible configurations of the Riemann problem.*

In what follows, we will make extensive use of the wave curves for the Riemann problem (2.1), (2.4). These are the curves in the (v,p)-plane which represent the states which can be connected to $\mathbf{u}_L$, $\mathbf{u}_R$ by the admissible waves. It can be shown that the 1-curve, shock or rarefaction, is strictly increasing, and the 3-curve is strictly decreasing; see, e.g., Godlewski and Raviart [13]. Further, the left and right states of the 2-wave are projected to the same point in the (v,p)-plane. Therefore, the Riemann problem for the usual Euler equations (2.1), (2.4) with $A_L = A_R$ has a unique solution; see, e.g., [13, Theorem 3.1, p. 134].

In the solution of the Riemann problem with $A_L \neq A_R$, a jump appears across the stationary contact λ_0; i.e., there is a new wave in the solution of the Riemann problem. In [4], we have shown that the flow inside this wave is analogous to the stationary isentropic flow in the converging-diverging nozzle. For convenience, we repeat the main consequences of this fact here as follows:

- the stationary contact can be viewed as a porous film of infinitesimal thickness;
- each pore is a converging-diverging nozzle, and the cross sections on each side of it are A_L and A_R, respectively;
- the velocity inside a pore does not change its sign; moreover, if the flow is sub(super)sonic at the inlet, it is also sub(super)sonic at the outlet;
- in the direction of increasing cross section, the gas flow is accelerated and expanded when it is supersonic, and decelerated and compressed when it is subsonic.

For a given left state $\mathbf{u}_0$ of the stationary contact we can represent the 0-wave curve parametrically by A as follows:

$$\begin{cases} \rho = \rho(A;\mathbf{u}_0), \\ v = v(A;\mathbf{u}_0), \\ p = p(A;\mathbf{u}_0), \end{cases} \tag{4.1}$$

where the states must satisfy (2.11). The 3D curve (4.1) will be regular if the corresponding derivatives are continuous, therefore locally bounded, and nonzero simultaneously, i.e., if the tangent vector does not vanish,

$$\left(\frac{\partial\rho}{\partial A}, \frac{\partial v}{\partial A}, \frac{\partial p}{\partial A}\right) \neq 0. \tag{4.2}$$

We will formulate the following lemma under these conditions; later on, we will discuss situations when they are violated.

LEMMA 4.1. *Consider the Riemann problem* (2.1), (2.4) *with the stiffened gas EOS* (2.3), *and denote the states connected by the* 0*-wave by* $\mathbf{u}_0$ *and* $\mathbf{u}_1$. *Assume that the conditions* (4.2) *are fulfilled. The flow velocity* v *inside the* 0*-wave does not change its sign, and is either subsonic or supersonic everywhere in the flow. Denote its* signed Mach number *by* $\mathrm{M} = \frac{v}{c}$. *Then for the* 0*-wave curve* (4.1) *the following statements are true:*

1. *The* 0*-wave curve is strictly increasing (decreasing) in* p *if* $v < 0$ (> 0).
2. *The* 0*-wave curve is convex (concave) with respect to* p *if* $|\mathrm{M}| > 1$ (< 1).
3. *For increasing (decreasing) velocities and pressures in* $\mathbf{u}_0$, *the velocities and pressures in* $\mathbf{u}_1$ *also increase (decrease) and vice versa.*

4. *For the states* $\mathbf{u}_0$ *and* $\mathbf{u}_1$*,*

$$\begin{cases} \rho_0 \to \bar{\rho}, \\ v_0 \to 0, \\ p_0 \to \bar{p}, \end{cases} \iff \begin{cases} \rho_1 \to \bar{\rho}, \\ v_1 \to 0, \\ p_1 \to \bar{p} \end{cases}$$

for all $\bar{\rho}, \bar{p} > 0$.

Proof. We take (4.1) and fix $\mathbf{u}_0$ so that ρ, v, and p depend only on A. Since the flow inside the 0-wave is analogous to the converging-diverging flow (see [4]), we take the following relations from Courant and Friedrichs [7, (145.05) and (145.08)]:

$$\frac{dA}{A} + \frac{d\rho}{\rho} + \frac{dv}{v} = 0, \tag{4.3}$$

$$\frac{dA}{A} = \left(\frac{v^2}{c^2} - 1\right)\frac{dv}{v}, \tag{4.4}$$

where A is the variable cross section of a pore (see above) and ρ, c, and v are the corresponding parameters of the flow in the pore. Then (4.4) leads to

$$\frac{dv}{dA} = \frac{vc^2}{A(v^2 - c^2)}. \tag{4.5}$$

By the definition of the sound speed

$$\left.\frac{dp}{d\rho}\right|_{\eta} = c^2, \quad \text{i.e.,} \quad \frac{d\rho}{\rho} = \frac{dp}{\rho c^2}.$$

Substituting this into (4.3), we obtain

$$\frac{dp}{dA} = \rho c^2\left(-\frac{1}{A} - \frac{1}{v}\frac{dv}{dA}\right) = -\frac{\rho v^2 c^2}{A(v^2 - c^2)}. \tag{4.6}$$

Analogously,

$$\frac{d\rho}{dA} = -\frac{\rho v^2}{A(v^2 - c^2)}. \tag{4.7}$$

Now we see when the 0-wave curve will be regular, i.e., the conditions (4.2) will be fulfilled. From (4.5), (4.6), and (4.7) it follows that this will happen when either

$$v \neq 0 \qquad \text{or} \qquad |v| \neq c. \tag{4.8}$$

From now on, when discussing 0-wave curves, we will always assume that the conditions (4.8) are fulfilled unless stated otherwise.

Consider the system of ordinary differential equations (4.5), (4.6), (4.7):

$$\frac{d}{dA}\begin{pmatrix}\rho \\ v \\ p\end{pmatrix} = \frac{1}{A(v^2 - c^2)}\begin{pmatrix}-\rho v^2 \\ vc^2 \\ -\rho v^2 c^2\end{pmatrix} \tag{4.9}$$

with the initial data

$$\begin{cases} \rho(A_0) = \rho_0, \\ v(A_0) = v_0, \\ p(A_0) = p_0. \end{cases}$$

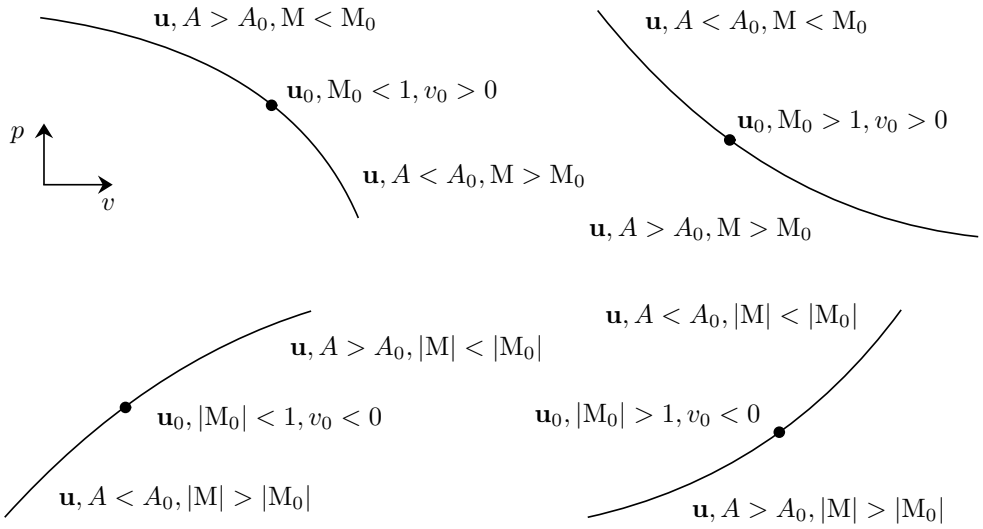

FIG. 3. *The* 0-curves *in the* (v, p)*-plane, parametrized with* A*, connect the states* $\mathbf{u}_0$ *and* $\mathbf{u}$*. Depending on* v_0 *and* M_0*, the curves exhibit different behavior.*

A straightforward calculation shows that, under conditions (4.8), the functions on the right-hand side of (4.9) are differentiable for $A > 0$. Then by the existence and uniqueness theorem there exists a unique integral curve of (4.9) as long as the right-hand side is Lipschitz continuous. This curve is nothing else but the 0-wave curve, passing through the point $\mathbf{u}_0$. Note that all states with $v = 0$ are stationary points of the system (4.9). Therefore, the solutions may approach such states only asymptotically.

From (4.5) and (4.6) we obtain

$$\frac{dp}{dv} = -\rho v,$$

and thus the statement 1 is proved.

For the proof of the statement 2 we calculate, using (4.5) and (4.6),

$$\frac{d^2p}{dv^2} = -\frac{d\rho}{dv}v - \rho = \rho\left(\frac{v^2}{c^2} - 1\right),$$

which gives the desired result. The possible 0-waves are presented in Figure 3.

Using $\eta = \frac{p+\pi}{\rho^\gamma}$ in the relations (2.11) across the 0-wave, we get

$$v_1 = v_0 \frac{A_0}{A_1}\left(\frac{p_0}{p_1}\right)^{1/\gamma},$$
$$p_1 = p_0\left(\frac{A_0 v_0}{A_1 v_1}\right)^{\gamma}.$$

Note that v_0 and v_1 always have the same sign; cf. (2.11). Differentiating the above

equations with respect to v_0 and p_0, respectively, we get

$$\frac{\partial v_1}{\partial v_0} = \frac{A_0}{A_1}\left(\frac{p_0}{p_1}\right)^{1/\gamma} > 0,$$
$$\frac{\partial p_1}{\partial p_0} = \left(\frac{A_0 v_0}{A_1 v_1}\right)^{\gamma} > 0,$$

thus proving statement 3.

For statement 4, it is enough to prove only "$\Longrightarrow$", since the statement is symmetric with respect to subscripts 0 and 1. Using $\eta = \frac{p+\pi}{\rho^\gamma}$ and $c^2 = \frac{\gamma(p+\pi)}{\rho}$ in the relations (2.11), we obtain

$$A_0(p_0+\pi)^{1/\gamma} v_0 = A_1(p_1+\pi)^{1/\gamma} v_1, \tag{4.10}$$

$$\frac{p_0+\pi}{\rho_0^\gamma} = \frac{p_1+\pi}{\rho_1^\gamma}, \tag{4.11}$$

$$\frac{v_0^2}{2} + \frac{\gamma\eta^{1/\gamma}(p_0+\pi)^{1-1/\gamma}}{\gamma-1} = \frac{v_1^2}{2} + \frac{\gamma\eta^{1/\gamma}(p_1+\pi)^{1-1/\gamma}}{\gamma-1}. \tag{4.12}$$

First, we wish to show that p_1 remains bounded, i.e., $p_1 \not\to \infty$. We prove this by contradiction, i.e., assuming that p_1 is unbounded. Then by statement 1 the pressure p_1 must exceed p_0, $p_1 > p_0$. Using that the left-hand side of (4.12) is bounded, the estimate

$$\frac{v_1^2}{2} + \frac{\gamma\eta^{1/\gamma}(p_1+\pi)^{1-1/\gamma}}{\gamma-1} > \frac{\gamma\eta^{1/\gamma}(p_1+\pi)^{1-1/\gamma}}{\gamma-1}$$

will give us the desired result that $p_1 < \text{const}$, since γ, $\pi > 0$ are constants, and η is constant along the 0-curve.

Now (4.10) implies that $v_1 \to 0$. Using this in (4.12), we get $p_1 \to \bar{p}$. Finally, by (4.11) we also have $\rho_1 \to \bar{\rho}$, which proves statement 4. ∎

Let us represent in the (v,p)-plane the possible scenarios of the solution of the Riemann problem (2.1), (2.4) which can lead to a solution in the form of Configuration B; see Figure 2. For this configuration, the 0-wave is next to the 1-wave. In the (v,p)-plane this means that the possible 0-curves necessarily start from the 1-wave curve. The correct 0-wave curve, i.e., the one which gives the solution to the Riemann problem (2.1), (2.4), connects the 1- and 3-curves in the (v,p)-plane. Figures 4 and 5 represent the wave curves for Configuration B.

Denote the states connected by the 0-curve by $\mathbf{u}_0$ and $\mathbf{u}_1$, and let $\mathbf{u}_0$ lie on the 1-curve. Observe that not all states $\mathbf{u}_0$ come into consideration. Indeed, by the definition of Configuration B, the velocities in the states $\mathbf{u}_0$ and $\mathbf{u}_1$ must be nonnegative. In Configuration B the 1-wave has a nonpositive velocity, and therefore the right-hand velocity $v_0 - c_0$ of its characteristic family must also be nonpositive, $v_0 - c_0 \le 0$. In terms of the Mach number, this means that $\mathrm{M}_0 \le 1$. Therefore, the candidates for $\mathbf{u}_0$ have necessarily $0 \le \mathrm{M}_0 \le 1$. This gives rise to the following definition.

DEFINITION 4.2. *Consider the Riemann problem* (2.1), (2.4). *Let us call the* 3*-curve crossing the* 1*-curve in the point with* $v = 0$ *the* left-bounding 3-curve. *Further, the following hold:*

1. *If* $A_L < A_R$, *consider the state* $\mathbf{u}_0$ *on the* 1*-curve with* $\mathrm{M}_0 = 1$, *connected with the state* $\mathbf{u}_1$ *with* $\mathrm{M}_1 < 1$ *by the* 0*-wave. Let us call the* 3*-curve passing through* $\mathbf{u}_1$ *the* right-bounding 3-curve*; see Figure* 4.

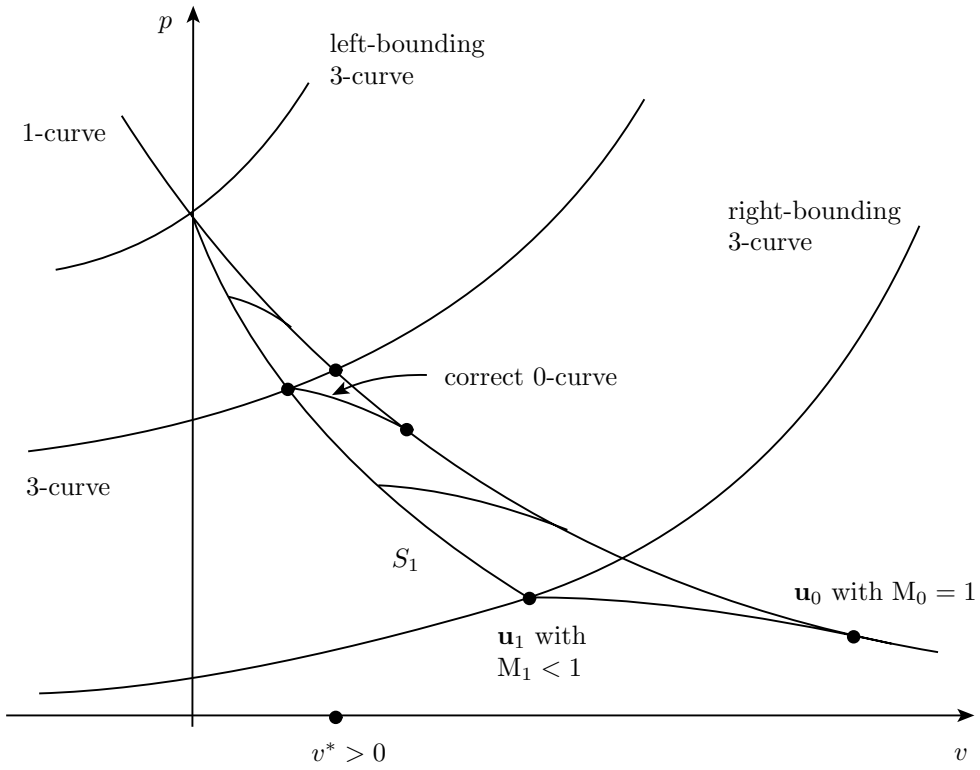

FIG. 4. *The wave curves for Configuration B with* $A_L < A_R$.

2. *If* $A_L > A_R$, *consider the state* $\mathbf{u}_0$ *on the* 1*-curve with* $\mathrm{M}_0 < 1$, *connected with the state* $\mathbf{u}_1$ *with* $\mathrm{M}_1 = 1$ *by the* 0*-wave. Let us call the* 3*-wave passing through this state* $\mathbf{u}_1$ *the* right-bounding 3-curve*; see Figure* 5.

Remark 3. We cannot use the results of Lemma 4.1 in Definition 4.2, since the parametrization (4.1) of the 0-wave will be singular for $\mathrm{M} = 1$; cf. (4.8). However, taking v as the 0-curve parameter in a neighborhood of sonic points, i.e., replacing (4.9) by the system

$$\frac{d}{dv}\begin{pmatrix} A \\ \rho \\ p \end{pmatrix} = \begin{pmatrix} A\,(v^2 - c^2)/(vc^2) \\ -\rho v/c^2 \\ -\rho v \end{pmatrix},$$

one can show that the length of the 0-wave curve remains finite.

Now we are ready to establish when the solution to the Riemann problem (2.1), (2.4) in form of Configuration B is possible.

THEOREM 4.3. *Consider the Riemann problem* (2.1), (2.4) *with the stiffened gas EOS* (2.3). *If the* 1- *and* 3*-curves intersect in the point* (v^*, p^*) *with* $v^* > 0$, *then the following scenarios are possible:*

1. *If the point* (v^*, p^*) *lies between the left- and right-bounding* 3*-curves of Definition* 4.2, *then Configuration B is realizable for all* $\mathbf{u}_L$ *on the* 1- *and for all* $\mathbf{u}_R$ *on the* 3*-curve. Moreover, the solution of this kind is unique, and Configuration C for the same Riemann problem is not realizable.*

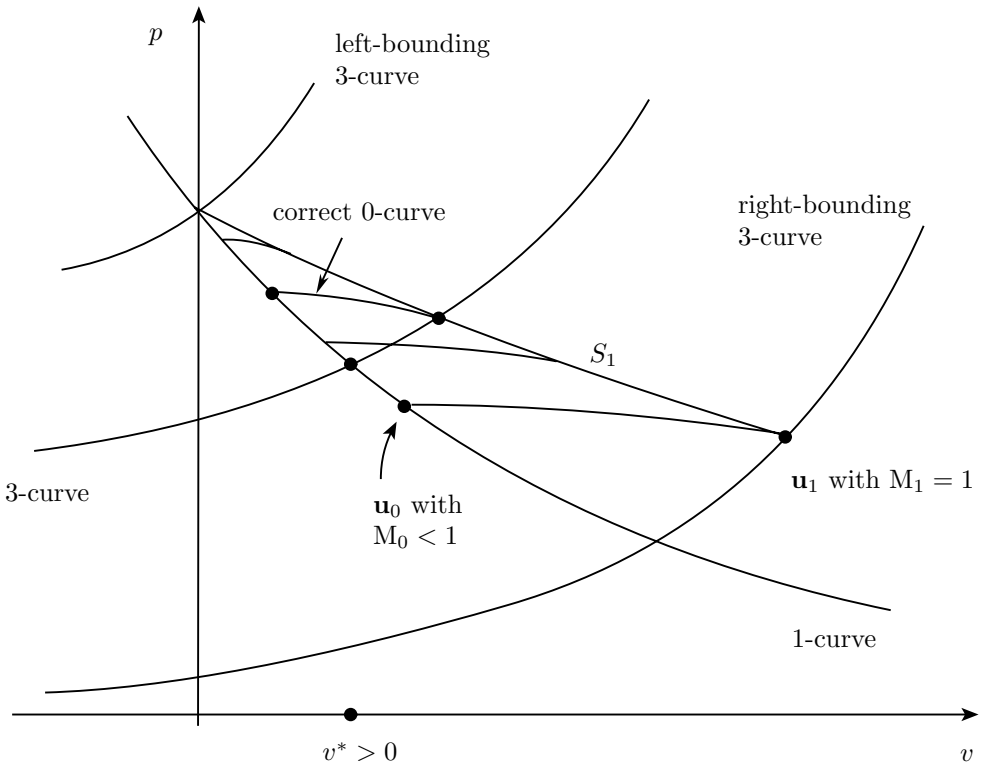

FIG. 5. *The wave curves for Configuration B with* $A_L > A_R$.

2. *If the point* (v^*, p^*) *lies to the right of the right-bounding* 3*-curve, then there exists no solution to the Riemann problem* (2.1), (2.4) *in form of Configuration B.*

3. *If Configuration A is realizable, then* $\mathrm{M}_L > 1$.

4. *If Configuration D is realizable, then* $\mathrm{M}_R < -1$.

Proof. 1. For Configuration B the states $\mathbf{u}_0$ must lie on the 1-curve. They are connected to the states $\mathbf{u}_1$ by 0-curves, such that these states $\mathbf{u}_1$ lie between the left- and right-bounding 3-curves; see Figures 4 and 5. Denote the projection of the set of all $\mathbf{u}_1$ to the (v, p)-plane by

$$S_1 = \{(v_1, p_1) : \mathbf{u}_1 = (A_1, \rho_1, v_1, p_1)^T\};$$

see Figures 4, 5. The set S_1 is defined pointwise, with each point (v_1, p_1) belonging to different integral curves of (4.9). Therefore, S_1 lies on the differentiable integral surface, obtained by taking all integral curves of (4.9) such that $\mathbf{u}_1$ are between the left- and right-bounding 3-curves.

Let us show that S_1 itself is a differentiable curve. All points $\mathbf{u}_1$ are given implicitly by the system (2.11), which can be rewritten as

$$\begin{aligned} F_1 &:= A_1\rho_1 v_1 - A_0\rho_0 v_0 = 0, \\ F_2 &:= \frac{p_1 + \pi}{\rho_1^\gamma} - \frac{p_0 + \pi}{\rho_0^\gamma} = 0, \\ F_3 &:= \frac{v_1^2}{2} + \frac{c_1^2}{\gamma - 1} - \frac{v_0^2}{2} - \frac{c_0^2}{\gamma - 1} = 0. \end{aligned} \tag{4.13}$$

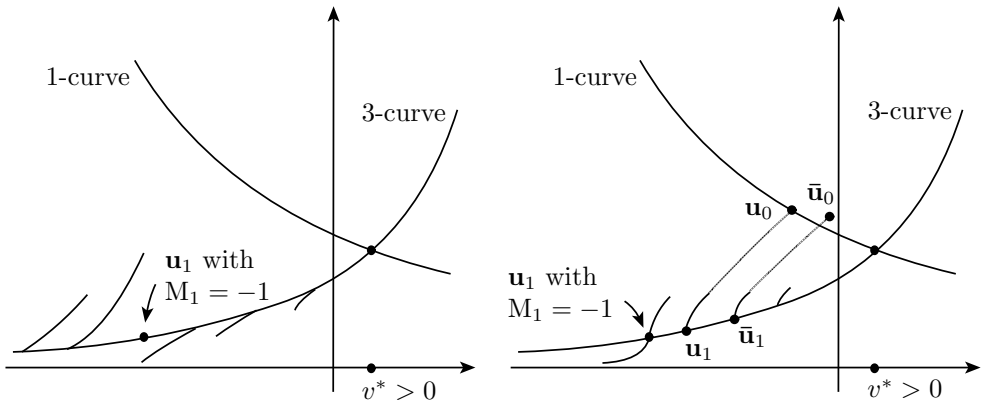

FIG. 6. *Configuration C is impossible if the* 1- *and* 3*-wave curves intersect in a state with* $v^* > 0$. *Left*: *case* $A_L < A_R$. *Right*: *case* $A_L > A_R$.

The functions F_1, F_2, F_3 are differentiable with respect to all their arguments for $\rho > 0$, and the points $\mathbf{u}_0$ lie on the *smooth* 1-wave curve. We can calculate the Jacobian determinant of the system (4.13):

$$J = \left| \frac{\partial(F_1, F_2, F_3)}{\partial(\rho_1, v_1, p_1)} \right| = \frac{A_1}{\rho_1^\gamma}(c_1^2 - v_1^2).$$

Note that $J \neq 0$ unless $\mathbf{u}_1$ lies on the right-bounding 3-curve, which is excluded by the assumptions of the theorem. Then, by the implicit function theorem, S_1 will be a differentiable curve locally at every point (v_1, p_1).

From Lemma 4.1 it follows that the mapping $(v_0, p_0) \mapsto (v_1, p_1)$ is one-to-one. Since the points $\mathbf{u}_0$ lie on the strictly decreasing 1-wave curve, S_1 will also be strictly decreasing; see statement 3 of Lemma 4.1. Also, S_1 will approach the point on the 1-curve with $v = 0$ asymptotically; see statement 4 of Lemma 4.1. Since the 3-wave is strictly increasing, there exists a unique intersection point with S_1; see Figures 4 and 5. This gives the solution to the Riemann problem (2.1), (2.4) in the framework of Configuration B.

Let us show that Configuration C for the same Riemann problem (2.1), (2.4) is impossible. Consider first the case $A_L < A_R$; see Figure 6 (left). If Configuration C were realizable, then the 0-wave would be next to the 3-wave; see Figure 2. In the (v, p)-plane, this means that the possible states $\mathbf{u}_1$ must lie on the 3-curve, and the velocities in $\mathbf{u}_1$ would be negative. This follows from the fact that the eigenvalue v_0 for the 2-wave is negative and $\operatorname{sign} v_0 = \operatorname{sign} v_1$. The states $\mathbf{u}_1$ with $\mathrm{M}_1 < -1$ are not admissible by the definition of Configuration C. Indeed, then we would have $v_1 + c_1 < 0$, so that the 3-wave is either a sonic rarefaction (i.e., there is a sign change in the characteristic speed $v + c$) or a shock with negative speed. Both these cases are excluded; see Figure 2. Note that the 0-wave, starting from the $\mathbf{u}_1$ on the 3-wave, can never intersect the 1-wave, since for the case $A_L < A_R$ it points in the opposite direction; see Figure 6 (left).

Now consider the case $A_L > A_R$; see Figure 6 (right). The only possibility for Configuration C to be realizable would be if the state $\mathbf{u}_1$ on the 3-curve with $v_1 < 0$, $|\mathrm{M}_1| < 1$ were connected with the 1-curve via the 0-curve. Assume that this is true, i.e., there exists a state $\mathbf{u}_1$ with $v_1 < 0$, $|\mathrm{M}_1| < 1$, connected to $\mathbf{u}_0$ with $v_0 < 0$ on

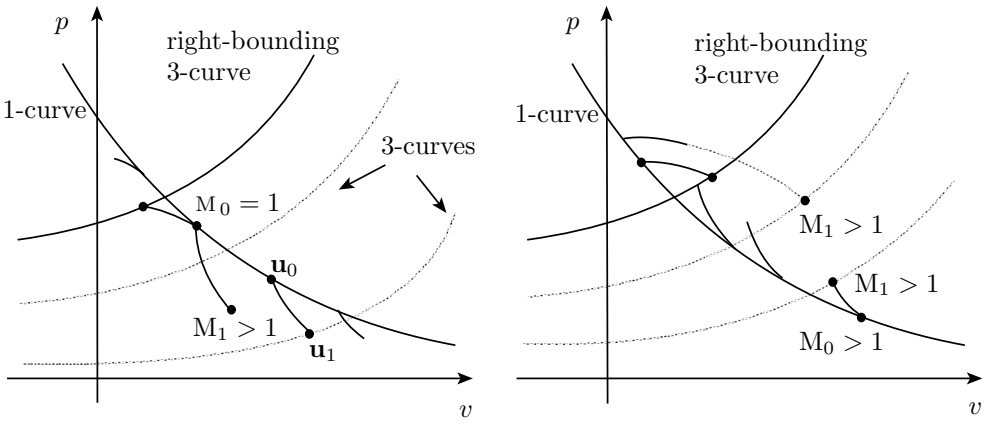

FIG. 7. *Configuration B is impossible if the* 1- *and* 3-*wave curves intersect in a state with* $v^* > 0$. *Left*: *case* $A_L < A_R$. *Right*: *case* $A_L > A_R$.

the 1-curve. Now let us move this state $\mathbf{u}_1$ towards the p-axis, so that it will become some state $\bar{\mathbf{u}}_1$, connected with $\bar{\mathbf{u}}_0$ by the 0-curve. As we move closer to the p-axis, the length L of the 0-curve, connecting $\bar{\mathbf{u}}_1$ with $\bar{\mathbf{u}}_0$, will remain positive by statement 3 of Lemma 4.1, since we have assumed that the 1- and 3-curves intersect in the point with $v^* > 0$; see Figure 6 (right). This contradicts statement 4 of Lemma 4.1, which states that L should shrink to zero. Thus, we have a unique way of connecting the 1- and 3-curves in the form of Configuration B, which is the intersection point of S_1 with the 3-curve.

2. This statement becomes obvious when we consider Figure 7. The 3-curve must lie to the right of the right-bounding 3-curve. For the case $A_L < A_R$, the state $\mathbf{u}_0$ on the 1-curve can be connected to a 3-curve only if $\mathrm{M}_0 > 1$; see Figure 7 (left). This is impossible by the definition of Configuration B. Indeed, in case $\mathrm{M}_L < 1$ we would have a sonic rarefaction in the solution of the Riemann problem. However, this is only possible if $A_L = A_R$; see [4]. In case $\mathrm{M}_L > 1$, we would have Configuration A.

For the case $A_L > A_R$, the 0-curve can connect the 1- and 3-curves if either

(i) the 0-curve crosses the right-bounding 3-curve or

(ii) the state $\mathbf{u}_L$ is supersonic with positive velocity, $\mathrm{M}_L > 1$.

For the first case, the 0-curve would connect the subsonic state $\mathbf{u}_0$ with a supersonic one, which is impossible; see the properties of the 0-wave above. For the second case we would have Configuration A.

3. We prove this statement by giving several examples, obtained with CONSTRUCT [3]. Consider the Riemann problem for (2.1) with the following initial data:

(4.14)

A_L	ρ_L	v_L	p_L	A_R	ρ_R	v_R	p_R
0.8	0.2069	3.991	0.07	0.3	0.1354	−3.1666	0.0833

closed with the EOS (2.3) with $\gamma = 1.4$ and $\pi = 0$. The wave curves for this Riemann problem are presented in Figure 8 (top). Observe that for these initial data both Configurations A and B are possible. Configuration A is realized when the left state $\mathbf{u}_L$ is connected first to the state $\bar{\mathbf{u}}_1$ with the 0-curve, and $\bar{\mathbf{u}}_1$ is then connected with $\bar{\mathbf{u}}^*$ via the 1-shock with speed $s = 0.948 > 0$. Note that if this speed were negative, then Configuration A with these initial data would be not realizable; cf. Figure 2. Since the intersection point of 1- and 3-curves lies between the left- and right-bounding waves

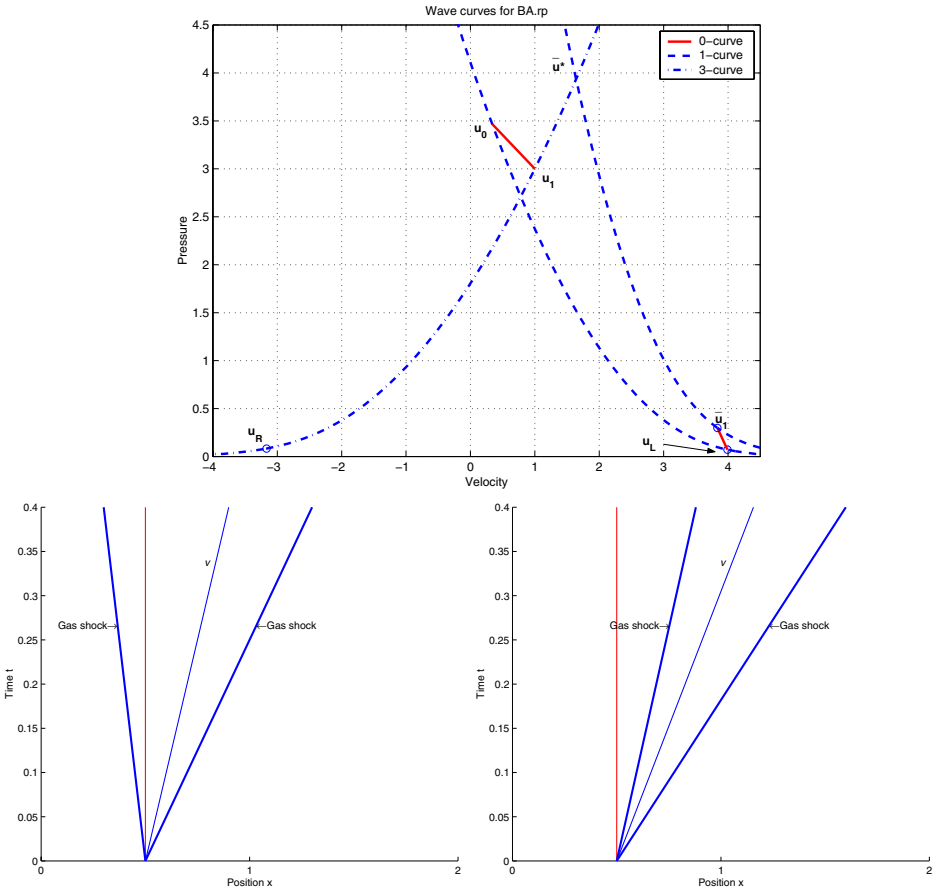

FIG. 8. *Top*: *the wave curves for the Riemann problem* (2.1), (4.14). *Bottom*: *the corresponding wave configurations B and A in the* (x,t)*-plane.*

(not shown in Figure 8), Configuration B is also possible. For this configuration, the left state $\mathbf{u}_L$ is connected with $\mathbf{u}_0$, and the latter is connected with $\mathbf{u}_1$. Both wave configurations in the (x,t)-plane are shown in Figure 8 (bottom).

However, if we slightly modify the initial data (4.14), we can easily obtain a Riemann problem with a unique solution. For instance, for the Riemann problem (2.1) with initial data

(4.15)

A_L	ρ_L	v_L	p_L	A_R	ρ_R	v_R	p_R
0.8	0.2069	3.0	0.2	0.3	0.1354	−3.1666	0.0833

,

also closed with the EOS (2.3) with $\gamma = 1.4$ and $\pi = 0$, only Configuration B is possible. Indeed, consider the wave curves for this Riemann problem in Figure 9. Again, the state $\mathbf{u}_L$ is first connected to the state $\bar{\mathbf{u}}_1$ with the 0-curve; from $\bar{\mathbf{u}}_1$, we draw the 1-curve until the intersection with the 3-curve, passing through $\mathbf{u}_R$. However, the corresponding wave will be a shock with negative speed $s = -0.198$. Therefore, Configuration A is now not possible. Configuration D is not possible for similar reasons. Since the 1- and 3-curves intersect between the corresponding left- and right-bounding 3-curves (not shown in Figure 9), Configuration B is possible for

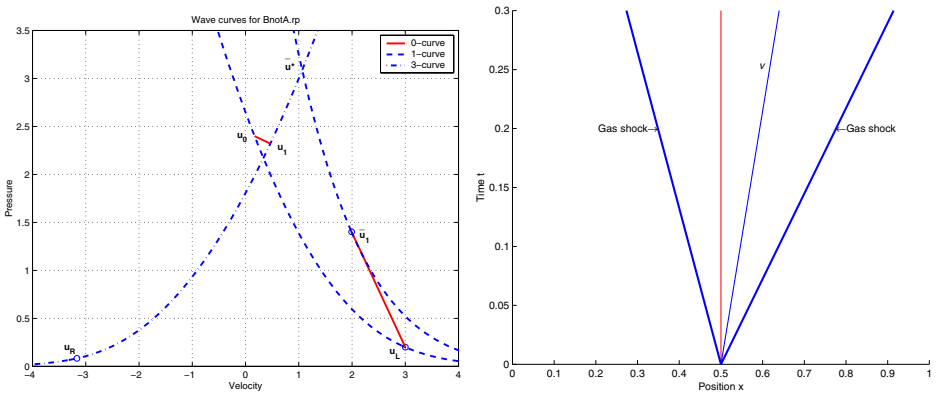

FIG. 9. *The wave curves the for the Riemann problem* (2.1), (4.15).

the Riemann problem (2.1), (4.15). The waves in the (x,t)-plane for this Riemann problem are shown in Figure 9 (right).

4. Consider the following Riemann initial data:

(4.16)

A_L	ρ_L	v_L	p_L	A_R	ρ_R	v_R	p_R
0.3	0.2	3.3	1	0.8	0.2	-4	0.07

.

Reasoning as above, we can show that the Riemann problem (2.1), (4.16), closed with the EOS (2.3) with $\gamma = 1.4$ and $\pi = 0$, has a nonunique solution in form of either Configuration B or Configuration D. The wave curves and the wave configurations are shown in Figure 10. □

For Configuration C, the results are completely analogous. The wave curves are presented in Figures 11 and 12. As for Configuration B, one can introduce the left- and right-bounding curves.

DEFINITION 4.4. *Consider the Riemann problem* (2.1), (2.4). *Let us call the* 1*-curve crossing the* 3*-curve in the point with* $v = 0$ *the* right-bounding 1-curve. *Further,*

1. *if* $A_L < A_R$, *consider the state* $\mathbf{u}_1$ *on the* 3*-curve with* $|\mathrm{M}_1| < 1$, *connected with the state* $\mathbf{u}_0$ *with* $\mathrm{M}_0 = -1$ *by the* 0*-wave. Let us call the* 1*-curve passing through this state* $\mathbf{u}_0$ *the* left-bounding 1-curve*; see Figure* 11.

2. *if* $A_L > A_R$, *consider the state* $\mathbf{u}_1$ *on the* 3*-curve with* $\mathrm{M}_1 = -1$, *connected with the state* $\mathbf{u}_0$ *with* $|\mathrm{M}_0| < 1$ *by the* 0*-wave. Let us call the* 1*-curve passing through* $\mathbf{u}_0$ *the* left-bounding 1-curve*; see* Figure 12.

Analogously to Theorem 4.3 we have the following result.

THEOREM 4.5. *Consider the Riemann problem* (2.1), (2.4) *with the stiffened gas EOS* (2.3). *If the* 1*- and* 3*-curves intersect in the point* (v^*, p^*) *with* $v^* < 0$, *then the following scenarios are possible:*

1. *If the point* (v^*, p^*) *lies between the left- and right-bounding* 1*-curves of Definition* 4.4, *then Configuration C is realizable, for all* $\mathbf{u}_L$ *on the* 1*- and all* $\mathbf{u}_R$ *on the* 3*-curve. Moreover, the solution of this kind is unique, and Configuration B for the same Riemann problem is not realizable.*

2. *If the point* (v^*, p^*) *lies to the left of the left-bounding* 1*-curve, then there exists no solution to the Riemann problem* (2.1), (2.4) *in form of Configuration C.*

3. *If Configuration A can be realized, then* $\mathrm{M}_L > 1$.

4. *If Configuration D can be realized, then* $\mathrm{M}_R < -1$.

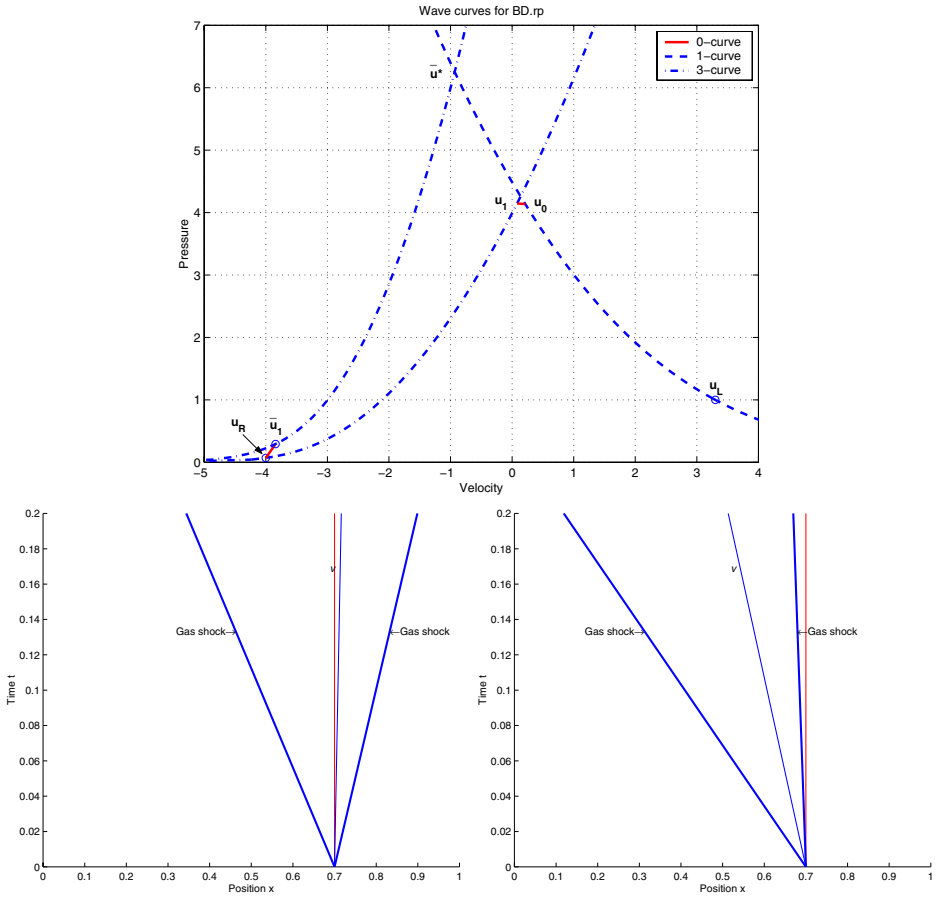

FIG. 10. *Top*: *the wave curves for the Riemann problems* (2.1), (4.16). *Bottom*: *the corresponding wave configurations B and D in the* (x,t)*-plane.*

Proof. The proof is analogous to that of Theorem 4.3. ∎

Theorem 4.3 states that the solution to the Riemann problem (2.1), (2.4) will be nonunique if for some initial data both Configurations B and A, or B and D, are realizable. Analogously, Theorem 4.5 says that for some initial data both Configurations C and A, or C and D, are possible. In all these cases the nonuniqueness appears when the mutual position of 0- and k-waves, $k = 1, 3$, changes. According to the analysis of Isaacson and Temple [15] (see also Goatin and LeFloch [12]), there can be a third wave configuration. It includes a "triple discontinuity," which consists of the 0-wave followed by a k-shock with zero speed, followed by another 0-wave. However, it is not obvious whether such a "triple discontinuity" will be evolutionary. It is not clear how to determine the number of relations across this discontinuity, as well as the number of characteristics impinging on it or leaving it. Therefore, we do not consider such "triple discontinuity" in the present work.

5. Which solution to take? To understand the origin of the nonuniqueness of the Riemann solution for the Euler equations in a duct of variable cross section, it is advantageous to consider analogous situations for other models. An immediate example is given by the usual Euler equations of gas dynamics. They are obtained

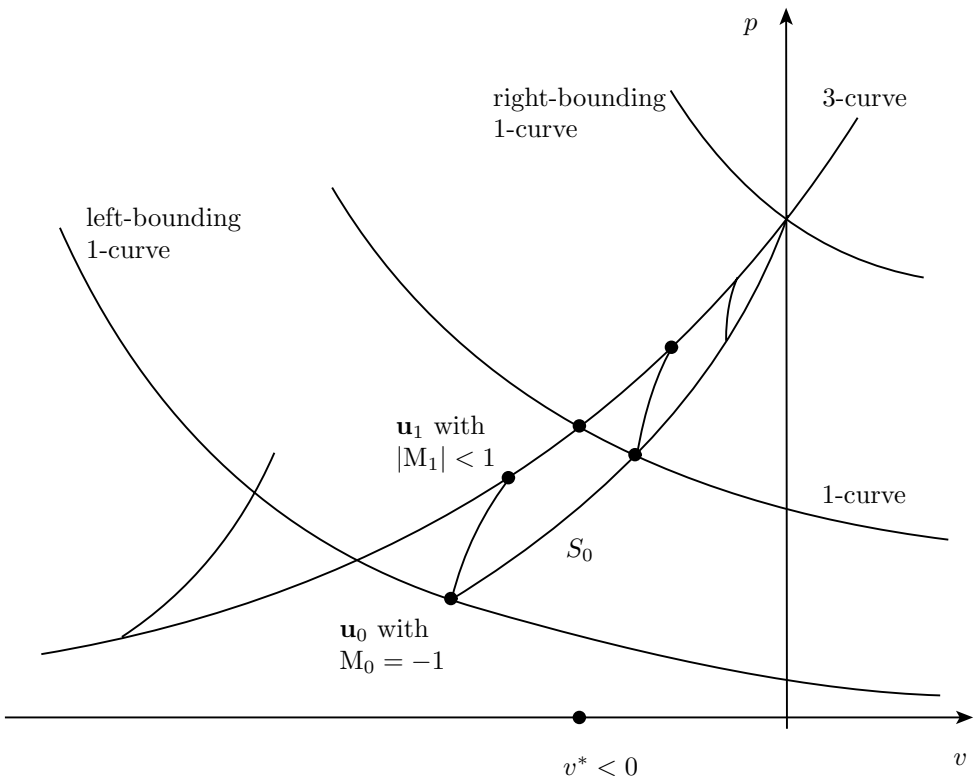

FIG. 11. *The wave curves for Configuration C with $A_L < A_R$. If the point (v^*, p^*) lies between the left- and right-bounding* 1*-curves, there exists a unique solution in the form of Configuration C.*

as the inviscid approximation to (in general viscous) fluid flows. It is well known that this approximation leads to nonunique discontinuous solutions, and therefore to nonunique solutions for Riemann problems. One needs to use an additional criterion, an entropy condition, in order to select the physically relevant solution. In fact, one possible way of obtaining an entropy condition is to add a viscous term to the Euler equations, i.e., to model the original viscous flow. Then the limit of solutions for vanishing viscosity will yield the physical entropy solution; see, e.g., Godlewski and Raviart [13].

For the Euler equations in a duct of variable cross section, the situation is somewhat analogous. In addition to neglecting viscosity, we have also neglected the multidimensional (2D or 3D) effects. In this light it is not surprising that we obtained nonuniqueness of the solutions to the Riemann problem. Roughly speaking, we have lost too much information on the truly multidimensional flow. However, one might hope to get a criterion for choosing the physically relevant solution by considering multidimensional effects, similarly to the limiting procedure for the usual Euler equations. One possible way would be to add to the system of governing equations some terms that would model these effects. For example, these terms might be obtained using the statistical ensemble averaging techniques in the spirit of recent work of Abgrall and Saurel [1]. This could be an interesting topic of future research.

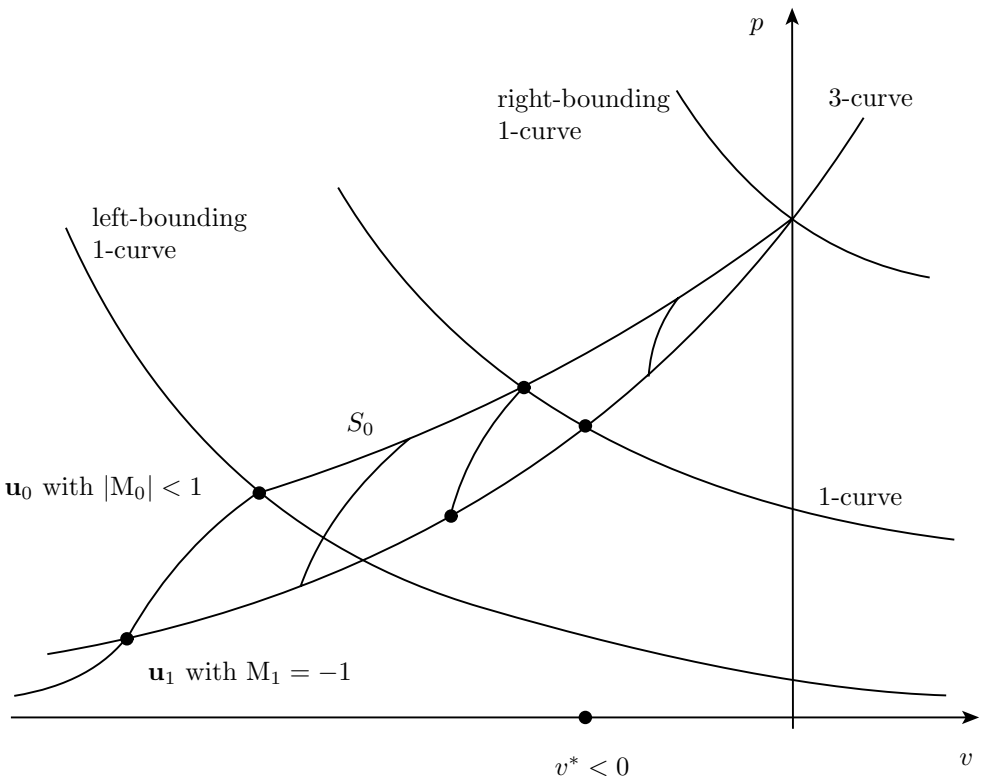

FIG. 12. *The wave curves for Configuration C with $A_L > A_R$.*

Here, we follow a more straightforward approach: We compare the results of the quasi-one-dimensional Euler equations in a duct of variable cross section with multidimensional computations of the usual Euler equations in a tube of corresponding geometry, averaged over the tube cross section. To this end, we employ the popular software package CLAWPACK provided by LeVeque [6, 17]. In the calculations below we have used CLAWPACK with a second order method and Roe's Riemann solver.

5.1. Diverse Riemann problems for the 1D model.

Nonuniqueness between Configurations A and B. Consider the 1D Riemann problem (2.1), (4.14), which has already been studied in section 4. This problem has a nonunique solution in the form of either Configuration A or Configuration B; see Figure 8. With CLAWPACK, we solve the 2D analogue of this 1D Riemann problem, i.e., the usual Euler equations in the corresponding 2D computational domain. The 2D solution on the 200×100 grid and the comparison of the averaged 2D solution with the exact solution to the 1D Riemann problem (2.1), (4.14) are shown in Figure 13 (top). We see that the 1D model slightly overestimates the 3-shock speed. Also, due to rich 2D motion in the left section of the domain, the 1D prediction of the position of 1-shock is quite approximate. The same can be said about the approximation of the flow near the jump in the cross section. However, the numerical solution clearly picks up Configuration B in the 1D solution of the Riemann problem (2.1), (4.14); see Figure 13.

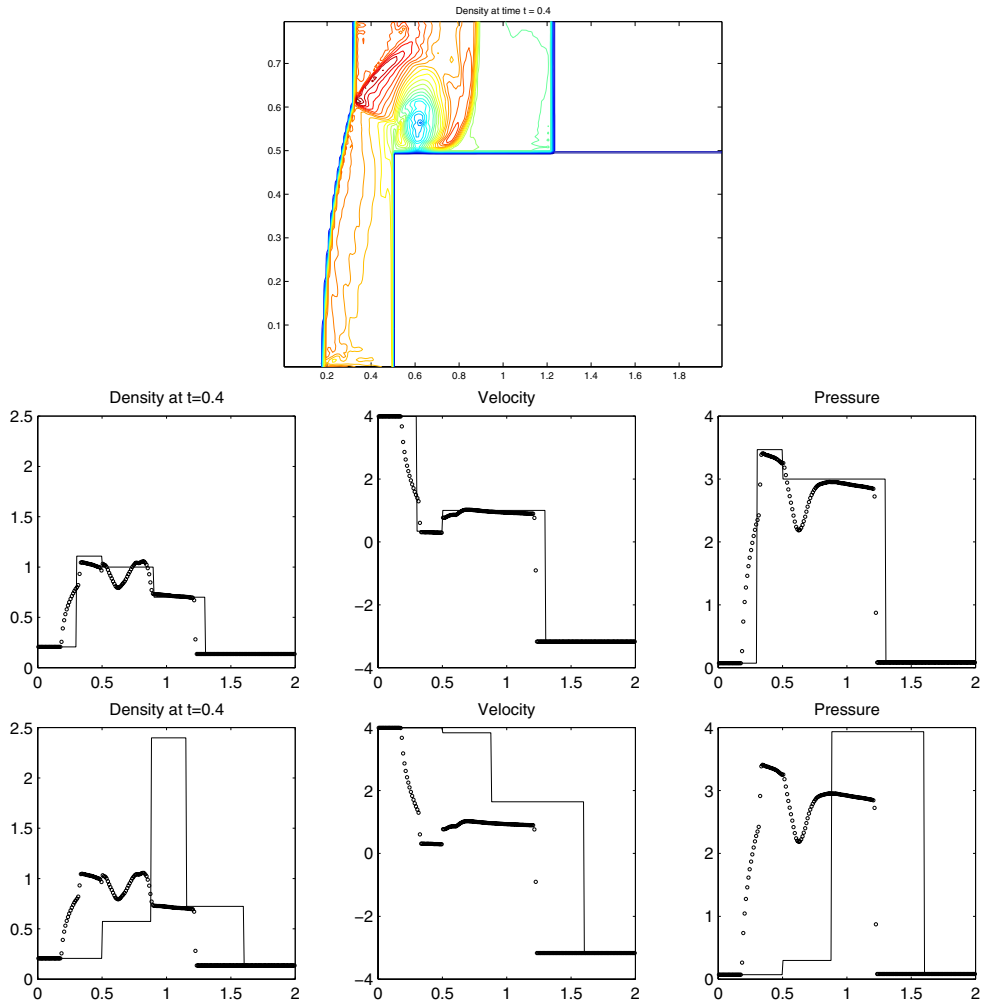

FIG. 13. *Top*: *the density contours of the* 2*D solution to the Riemann problem* (2.1), (4.14). *Middle*: *comparison of the averaged* 2*D solution (dots) with the* 1*D exact solution in the form of Configuration B (line). Bottom*: *comparison of the averaged* 2*D solution (dots) with the* 1*D exact solution in form of Configuration A (line).*

Unique solution in the form of Configuration B. As we established in section 4, the Riemann problem (2.1), (4.15) has a unique solution in form of Configuration B. The comparison of the averaged 2D solution on a 100×100 grid with the exact solution to the 1D Riemann problem is shown in Figure 14. Again, we observe that the shock speeds are slightly different; however, the main features of the 2D flow are correctly represented by the 1D model.

Nonuniqueness between Configurations B and D. The solution to the 1D Riemann problem (2.1), (4.16) is nonunique: It can be either Configuration B or Configuration D. Again, we calculate the corresponding 2D problem on a 100×100 grid and obtain the results shown in Figure 15. We see that the exact 1D solution for Configuration B perfectly fits the averaged 2D solution. On the other hand, the 1D solution for Configuration D has nothing in common with the averaged 2D solution.

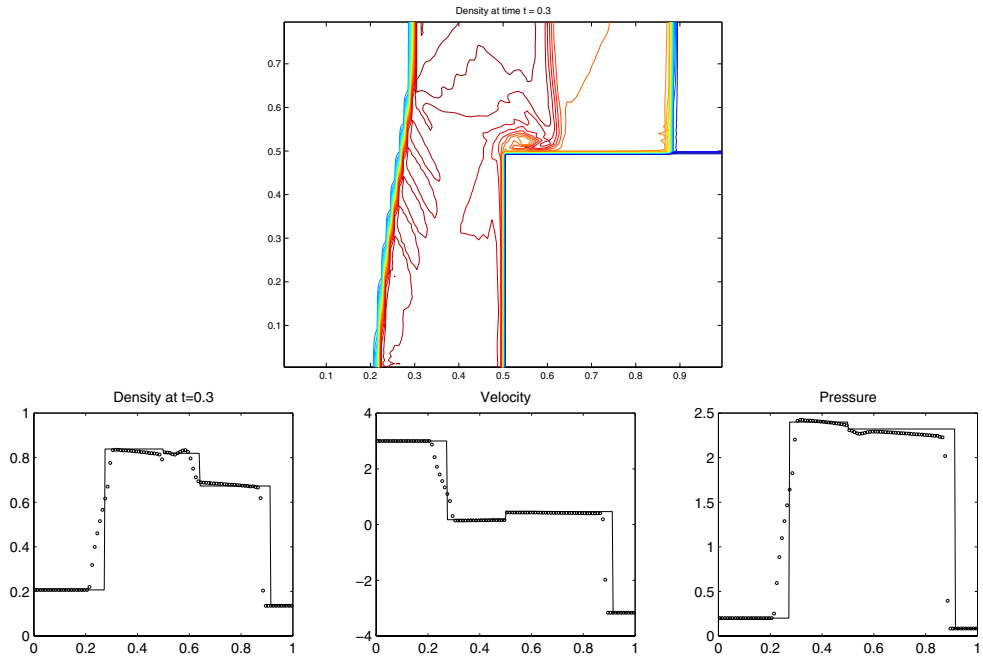

FIG. 14. *Top*: *the density contours of the* 2*D solution to the Riemann problem* (2.1), (4.15). *Bottom*: *the comparison of the averaged* 2*D solution (dots) with the* 1*D exact solution (line).*

5.2. A criterion for realizable solutions. The preceding computations show that for all configurations of Riemann problems the 1D solution can differ significantly from the 2D one. However, if the 1D solution to a Riemann problem is not unique, the 2D calculations clearly pick out one of the 1D solutions. In what follows, we will call the corresponding 1D Riemann solutions *physically relevant*. Let us investigate what distinguishes these solutions from the physically nonrelevant ones.

A classical way to exclude physically irrelevant solutions is to use a notion of entropy. However, one cannot use the entropy inequality used in the theory of conservation laws for the nonconservative system (2.1). In the particular case of the Riemann problem, one can use the approach of section 3 to define the entropy inequality. Note also that *locally* each discontinuity in the solution to the Riemann problems is entropy-satisfying; i.e., the entropy increases across shocks. However, it does not help to rule out the physically irrelevant solutions. This suggests an idea of using a *global* entropy condition.

A global entropy condition was proposed by Dafermos [8, 9], who called it the *entropy rate admissibility criterion*. It states that not only should the entropy increase but also it should be increasing at the maximum rate. The rigorous definition of this criterion can be applied only for the conservation laws. However, we can use the general idea for the nonconservative system (2.1) as well.

As a measure of the entropy increase rate, we use the jump in the isentrope $\eta = \frac{p+\pi}{\rho^\gamma}$ across shocks. These jumps are always positive. Then, our calculations show that physically relevant solutions, i.e., the ones picked out by 2D calculations, indeed have the maximal increase in entropy in comparison with the other solutions. This may be seen as an analogy of the entropy rate admissibility criterion of Dafermos [8].

Since the Euler equations in a duct can be formally obtained from the governing

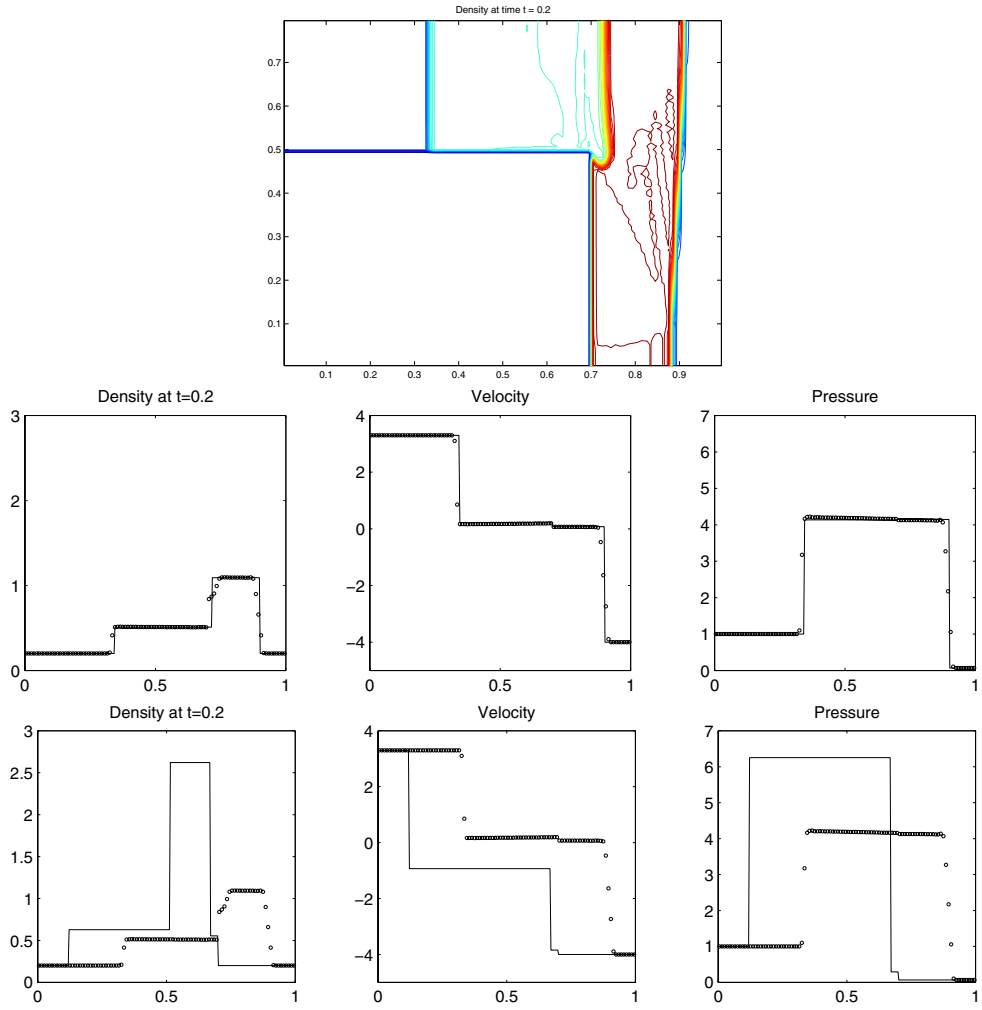

FIG. 15. *Top*: *the density contours of the* 2*D solution to the Riemann problem* (2.1), (4.16). *Middle*: *the comparison of the averaged* 2*D solution (dots) with the* 1*D exact solution in the form of Configuration B (line). Bottom*: *the comparison of the averaged* 2*D solution (dots) with the* 1*D exact solution in the form of Configuration D (line).

equations for the Baer–Nunziato model of two-phase flows [5], the solution to the Riemann problem for the Baer–Nunziato model will in general also not be unique. Therefore, the analysis of the Euler equations for a duct of variable cross section, and in particular the above criterion, can help in investigating the properties of the governing equations for the Baer–Nunziato model.

COMPLETE ELECTRODE MODEL OF ELECTRICAL IMPEDANCE TOMOGRAPHY: APPROXIMATION PROPERTIES AND CHARACTERIZATION OF INCLUSIONS*

NUUTTI HYVÖNEN†

Abstract. In electrical impedance tomography one tries to recover the spatial admittance distribution inside a body from boundary measurements. In theoretical considerations it is usually assumed that the boundary data consists of the Neumann-to-Dirichlet map; when conducting real-world measurements, the obtainable data is a linear finite-dimensional operator mapping electrode currents onto electrode potentials. In this paper it is shown that when using the complete electrode model to handle electrode measurements, the corresponding current-to-voltage map can be seen as a discrete approximation of the traditional Neumann-to-Dirichlet operator. This approximating link is utilized further in the special case of constant background conductivity with inhomogeneities: It is demonstrated how inclusions with strictly higher or lower conductivities can be characterized by the limit behavior of the range of a boundary operator, determined through electrode measurements, when the electrodes get infinitely small and cover all of the object boundary.

Key words. electrical impedance tomography, inverse boundary value problems, electrode models, variational principles

DOI. 10.1137/S0036139903423303

1. Introduction.

The problem of electrical impedance tomography is as follows: Gather information about the admittance tensor σ in the elliptic equation

$$\nabla \cdot \sigma \nabla u = 0 \quad \text{in } \Omega$$

using measurements of current and potential on the boundary $\partial\Omega$. In mathematical analysis of this problem it is usually assumed that the obtainable data are all possible pairs of Neumann and Dirichlet boundary values, i.e., the linear Neumann-to-Dirichlet map. In particular, all uniqueness and reconstruction results have been formulated using this so-called *continuum model* (CM)—for more details we refer to the review paper [1]. However, when conducting real-life measurements with electrodes, one can control only the net currents through certain surface patches and measure the corresponding potentials on the electrodes, and so the real-life data consists, essentially, of a finite-dimensional linear electrode current-to-electrode voltage operator.

In this work we model the electrode measurements with the *complete electrode model* (CEM) [9], which has been shown to predict experimental data reasonably well [9] and also give fairly good numerical reconstructions for both experimental and simulated data [12], [11]. Our first goal is to show that the CEM forward problem can, actually, be seen as a Galerkin approximation of the CM forward problem, meaning that the forward solutions for both of these models can be obtained from the very same variational formulation using different function spaces. As a consequence, the forward solution of CEM, with correctly chosen electrode currents, may be considered an approximation for the forward solution of CM corresponding to a given current

distribution—or the other way around—with the correspondence getting better as the electrodes get smaller and cover a larger portion of the object boundary. Section 2 considers these matters.

The second objective is to use the approximating link between the different forward models to modify the factorization method for characterizing inclusions, introduced and justified in [3] for electrical impedance tomography and, earlier, in [7] for inverse scattering, to the framework of the CEM. To be more precise, in section 3 the special case of constant background conductivity with inclusions of strictly higher or lower conductivities is considered. It is demonstrated how the inhomogeneities can be characterized by comparing the boundary values of a dipole-like singular solution and the range of a boundary operator, obtained through electrode measurements, as the electrodes grow in number, get infinitely small, and cover all of the object boundary.

2. Approximation properties of the CEM. In this section we aim to show that the CEM can be seen as a finite element approximation of the CM of impedance tomography. In the first subsection, we will introduce the different forward models and consider some of their basic properties. The second subsection will explain how one can approximate the forward solution of CM by the forward solution of CEM with correctly chosen input currents. In the final subsection, we will survey the resemblance between the current-to-potential boundary maps of CM and CEM.

2.1. Forward models. When performing mathematical analysis of the electrical impedance tomography problem, it is traditionally assumed that one is able to use any input current distribution from Sobolev space $H^{-1/2}$ resulting in boundary potentials of class $H^{1/2}$. On the other hand, when conducting real-world measurements, one can control only the net currents fed through a finite number of electrodes and measure the corresponding electrode potentials. In particular, one does not know the exact distribution of the current penetrating the object boundary.

2.1.1. Continuum forward model. Let $\Omega \subset \mathbb{R}^n$, $n = 2, 3$, with a smooth boundary be our open bounded region of interest and let $\sigma : \Omega \to \mathbb{C}^{n\times n}$ be the corresponding admittance tensor. The forward problem of impedance tomography with continuous boundary measurements is as follows: For $f \in H_0^{-1/2}(\partial\Omega)$ find $u \in H^1(\Omega)/\mathbb{C}$ that satisfies weakly

$$\nabla \cdot \sigma\nabla u = 0 \quad \text{in } \Omega, \quad \nu \cdot \sigma\nabla u = f \quad \text{on } \partial\Omega, \tag{2.1}$$

where ν is the outer unit normal on $\partial\Omega$ and

$$H_0^{-1/2}(\partial\Omega) = \{v \in H^{-1/2}(\partial\Omega) \mid \langle v, \mathbf{1}\rangle_{L^2(\partial\Omega)} = 0\},$$

where $\langle \phi, \psi\rangle_{L^2(\partial\Omega)} = \int_{\partial\Omega} \phi\overline{\psi}dS$ denotes the dual pairing of the spaces $H^{-1/2}(\partial\Omega)$ and $H^{1/2}(\partial\Omega)$. In what follows, we also shall use this same notation for the L^2 inner product.

If it is assumed that the admittance tensor $\sigma \in \mathbb{C}^{n\times n}$ satisfies

$$\mathrm{Re}(\sigma x \cdot \overline{x}) \geq c|x|^2, \quad |\sigma x \cdot \overline{x}| \leq C|x|^2, \quad c, C > 0, \tag{2.2}$$

for all $x \in \mathbb{C}^n$ almost everywhere in Ω, then forward problem (2.1) has a unique solution that depends continuously on the boundary data.

THEOREM 2.1. *Let $f \in H_0^{-1/2}(\partial\Omega)$ and assume that inequalities* (2.2) *hold. Then forward problem* (2.1) *has a unique solution $u \in H^1(\Omega)/\mathbb{C}$, for which*

$$||u||_{H^1(\Omega)/\mathbb{C}} \leq C\,||f||_{H^{-1/2}(\partial\Omega)}.$$

Proof. For proof we refer to [10]. ∎

Before we can go any further with our analysis, we need to introduce the trace spaces on subsets of the boundary $\partial\Omega$. Below we will list only the basic definitions; for more information the reader should consult [4] and the references cited therein. For $\Gamma \subset \partial\Omega$ we define

$$H^{1/2}(\Gamma) = \{v|_\Gamma \mid v \in H^{1/2}(\partial\Omega)\}.$$

We denote the dual space of $H^{1/2}(\Gamma)$ by $\tilde{H}^{-1/2}(\Gamma)$, and note that $\tilde{H}^{-1/2}(\Gamma)$ can be identified with

$$H^{-1/2}_{\overline{\Gamma}}(\partial\Omega) = \{v \in H^{-1/2}(\partial\Omega) \mid \operatorname{supp} v \in \overline{\Gamma}\}.$$

In what follows, $\langle\cdot,\cdot\rangle_{L^2(\Gamma)}$ will denote either the dual pairing between $\tilde{H}^{-1/2}(\Gamma)$ and $H^{1/2}(\Gamma)$ or the $L^2(\Gamma)$ inner product. Finally, $\tilde{H}^{-1/2}_0(\Gamma)$ is defined to be the subspace of $\tilde{H}^{-1/2}(\Gamma)$ over which the dual evaluation with $\mathbf{1} \in H^{1/2}(\Gamma)$ vanishes.

Let us consider briefly the following question. If we are trying to use some given input current pattern $f \in H_0^{-1/2}(\partial\Omega)$ but we are only able to conduct current through a part of the boundary $\Gamma \subset \partial\Omega$ how much does this imperfection affect the forward solution? To begin with, we must choose how to restrict the current f onto the subset Γ; using $f|_\Gamma$ is not usually an option since all the current that goes into the object Ω must come out. Thus, in order to obtain reasonable currents on Γ, we define a L^2-orthogonal projection operator $P_1 : H_0^{-1/2}(\partial\Omega) \to \tilde{H}_0^{-1/2}(\Gamma) \subset H_0^{-1/2}(\partial\Omega)$, where the inclusion is achieved through zero continuation, by

$$P_1 f = f|_\Gamma + \frac{1}{|\Gamma|}\langle f, \mathbf{1}\rangle_{L^2(\partial\Omega\setminus\overline{\Gamma})}. \tag{2.3}$$

THEOREM 2.2. *Assume that $\sigma \in \mathbb{C}^{n\times n}$ satisfies* (2.2)*, and let u^0 be the solution of* (2.1) *corresponding to a given current pattern $f \in H_0^{-1/2}(\partial\Omega)$. Further, let u be the solution of problem* (2.1) *associated with the approximating input current $P_1 f \in H_0^{-1/2}(\partial\Omega)$. Then we have the estimate*

$$\left|\left|u^0 - u\right|\right|_{H^1(\Omega)/\mathbb{C}} \leq \frac{C}{|\Gamma|^{1/2}} \left|\left|f\right|\right|_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})},$$

where $C > 0$ can be chosen independently of the geometry of Γ as a subset of $\partial\Omega$.

Proof. For $f \in H_0^{-1/2}(\partial\Omega)$ we have

$$\begin{aligned}
\left|\left|f - P_1 f\right|\right|_{H^{-1/2}(\partial\Omega)} &\leq \frac{1}{|\Gamma|}\left|\langle f, \mathbf{1}\rangle_{L^2(\partial\Omega\setminus\overline{\Gamma})}\right| \left|\left|\mathbf{1}\right|\right|_{\tilde{H}^{-1/2}(\Gamma)} + \left|\left|f\right|\right|_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})} \\
&\leq \left(\frac{\left|\left|\mathbf{1}\right|\right|_{H^{1/2}(\partial\Omega\setminus\overline{\Gamma})} \left|\left|\mathbf{1}\right|\right|_{\tilde{H}^{-1/2}(\Gamma)}}{|\Gamma|} + 1\right) \left|\left|f\right|\right|_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})} \\
&\leq \frac{C}{|\Gamma|^{1/2}} \left|\left|f\right|\right|_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})},
\end{aligned}$$

where $C > 0$ can, clearly, be chosen independently of the geometry of Γ. Thus, the claim follows by applying Theorem 2.1 to the difference of the solutions $u^0 - u$. ∎

In a sense the result of Theorem 2.2 is quite natural: The discrepancy in the forward solution is bounded by the norm of the current that we were not able to use.

2.1.2. Complete electrode forward model. Next, we will introduce the CEM, which has been shown to model real-world electrode measurements reasonably well [9]. Assume that the boundary of the investigated object Ω is smooth and partially covered with electrodes $e_m \subset \partial\Omega$, $1 \le m \le M$, which are identified by the parts of the surface that they cover and assumed to be ideal conductors. The union of the electrode patches is denoted by $\Gamma_e = \cup_m e_m \subset \partial\Omega$. All electrodes are used for both current injection and voltage measurement, and the current and voltage patterns are denoted by $\{I_m\}, \{U_m\} \subset \mathbb{C}$, $1 \le m \le M$, respectively. To make the model even more flexible, we assume that on $\Gamma_n \subset \partial\Omega$, $\Gamma_n \cap \Gamma_e = \emptyset$, the current input is given in the continuous sense; i.e., on Γ_n the data belongs to $\tilde{H}^{-1/2}(\Gamma_n)$. Note that this kind of Neumann boundary is not usually included in the formulation of the CEM; here we introduce it to lighten our work load in section 3.

When conducting measurements with electrodes, a thin highly resistive layer is formed at the electrode-object interface [9]. It is characterized by the contact impedance $z : \partial\Omega \to \mathbb{C}$ that in our framework is assumed to be an integrable function satisfying

$$\mathrm{Re} z \ge z_0 > 0, \quad |z| \le z_1 < \infty, \tag{2.4}$$

almost everywhere on $\partial\Omega$. Note that the value of z between the electrodes indicates the fictitious value of the contact impedance, i.e., the value of the contact impedance if an electrode were present.

Traditionally, the electrode currents and potentials are handled as vectors of $\mathbb{C}^M$ [9]. However, encouraged by the fact that in CM the boundary potentials and currents are elements of L^2-based Sobolev spaces, in this work we interpret the electrode currents and potentials as elements of the subspace

$$T = \left\{ V \in L^2(\Gamma_e) \mid V = \sum_{m=1}^{M} \chi_{e_m} V_m,\ V_m \in \mathbb{C},\ 1 \le m \le M \right\} \subset L^2(\partial\Omega). \tag{2.5}$$

In what follows, we will also use the subspace

$$T_0 = \left\{ V \in T \,\middle|\, \int_{\partial\Omega} V dS = 0 \right\} \subset L^2_0(\partial\Omega), \tag{2.6}$$

to which the electrode currents belong if there is no Neumann boundary Γ_n.

With this convention the forward problem corresponding to the CEM is as follows. For input currents $I \in T$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $I + g \in H_0^{-1/2}(\partial\Omega)$, find $(u^e, U^e) \in (H^1(\Omega) \oplus T)/\mathbb{C}$ that satisfies weakly

$$\begin{gathered} \nabla \cdot \sigma \nabla u^e = 0 \ \text{ in } \Omega, \quad \nu \cdot \sigma \nabla u^e = 0 \ \text{ on } \partial\Omega \setminus (\overline{\Gamma}_e \cup \overline{\Gamma}_n), \quad \nu \cdot \sigma \nabla u^e = g \ \text{ on } \Gamma_n, \\ u^e + z\nu \cdot \sigma \nabla u^e = U^e \ \text{ on } \Gamma_e, \quad \frac{1}{|e_m|} \int_{e_m} \nu \cdot \sigma \nabla u^e dS = I_m, \ \ 1 \le m \le M. \end{gathered} \tag{2.7}$$

Note that the above formulation of the complete electrode forward problem differs from the one in [9] by the scaling factor $1/|e_m|$ in the last equation of (2.7). However, the underlying physical interpretation stays the same: In [9] the net currents through electrodes were used; here we use the average currents. For more thorough physical justification of (2.7), the reader should consult [9].

THEOREM 2.3. *Assume that* (2.2) *and* (2.4) *hold and let* $I \in T$ *and* $g \in \tilde{H}^{-1/2}(\Gamma_n)$, *with* $I + g \in H_0^{-1/2}(\partial\Omega)$, *be given current patterns. Then problem* (2.7)

has a unique solution $(u^e, U^e) \in (H^1(\Omega) \oplus T)/\mathbb{C}$. *Further, this solution depends continuously on the data; i.e.,*

$$\inf_{c\in\mathbb{C}}\{||u^e - c||^2_{H^1(\Omega)} + ||U^e - c||^2_{L^2(\Gamma_e)}\}^{1/2} \leq C\{||I||_{L^2(\Gamma_e)} + ||g||_{\tilde{H}^{-1/2}(\Gamma_n)}\}, \tag{2.8}$$

where $C > 0$ *can be chosen independently of the geometry of* Γ_e *as a subset of* $\partial\Omega$.

By using material in [9], one could easily provide a proof for Theorem 2.3. However, since we have included the Neumann data on Γ_n in our model and, in addition, we are trying to build a connection between the complete electrode forward problem (2.7) and the continuum forward problem (2.1), we prefer a slightly different working order and postpone the proof until subsection 2.2.

2.2. Approximating with the CEM. In this subsection we aim to show that the CEM can be viewed as a real-world finite element approximation of the mathematically more tractable CM. To be more precise, with the help of the orthogonal projection $P_2 : L^2(\Gamma_e) \to T$ given by

$$P_2 f = \sum_{m=1}^{M} \chi_{e_m} \frac{1}{|e_m|} \int_{e_m} f dS, \quad f \in L^2(\Gamma_e), \tag{2.9}$$

we may write the main result of this subsection as follows in Theorem 2.4.

THEOREM 2.4. *Assume that* σ *and* z *satisfy* (2.2) *and* (2.4)*, respectively. Let* $f \in H_0^{-1/2}(\partial\Omega)$*, with* $f|_{\Gamma_e} \in L^2(\Gamma_e)$*, be a given input current and let* $u^0 \in H^1(\Omega)/\mathbb{C}$ *be the corresponding solution of* (2.1)*. Further, let* $(u^e, U^e) \in (H^1(\Omega) \oplus T)/\mathbb{C}$ *be the unique solution of* (2.7) *with the input currents* $P_2(P_1 f)|_{\Gamma_e} \in T$ *and* $(P_1 f)|_{\Gamma_n} \in \tilde{H}^{-1/2}(\Gamma_n)$*, where* P_2 *is given by* (2.9) *and* P_1 *by* (2.3) *with* $\Gamma = \Gamma_e \cup \Gamma_n$*. Then it holds that*

$$\left|\left|u^0 - u^e\right|\right|_{H^1(\Omega)/\mathbb{C}} \leq C\left\{\frac{1}{|\Gamma|^{1/2}}\,||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})} + \inf_{V\in T}\left|\left|U^0 - V\right|\right|_{L^2(\Gamma_e)/\mathbb{C}}\right\},$$

where $C > 0$ *can be chosen independently of the geometry of* Γ_e *as a subset of* $\partial\Omega$*, the subspace* $T \subset L^2(\Gamma_e)$ *is given in* (2.5)*, and* $U^0 = u^0|_{\Gamma_e} + zf|_{\Gamma_e}$.

Theorem 2.4 tells us, roughly speaking, that for a given current pattern the best correspondence between the solutions of the forward problems (2.1) and (2.7) is obtained when the electrodes are as small as possible and the gaps between the adjacent electrodes are as narrow as possible.

In order to prove Theorem 2.4, we need, first of all, a suitable variational problem: For $f \in L^2(\Gamma_e)$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $f + g \in H_0^{-1/2}(\partial\Omega)$, find $(u, U) \in H = (H^1(\Omega) \oplus L^2(\Gamma_e))/\mathbb{C}$ such that

$$B((u, U), (v, V)) = F(v, V) \quad \text{for all } (v, V) \in H, \tag{2.10}$$

where

$$B((u, U), (v, V)) = \int_\Omega \sigma\nabla u \cdot \nabla\overline{v} dx + \int_{\Gamma_e} \frac{1}{z}(U - u)(\overline{V} - \overline{v}) dS, \tag{2.11}$$

and

$$F(v, V) = \int_{\Gamma_e} f\overline{V} dS + \int_{\Gamma_n} g\overline{v} dS, \tag{2.12}$$

where the latter term is to be interpreted in the sense of the dual pairing between $\tilde{H}^{-1/2}(\Gamma_n)$ and $H^{1/2}(\Gamma_n)$. To keep the motivation high, note that variational equation (2.10) is quite similar to the variational formulation of the complete electrode forward problem in [9], the only clear difference being the space from which the solution is sought. We claim that (2.10) has a unique solution with some interesting properties.

Before we can prove the unique solvability of (2.10), we still need to introduce an inner product on $H = (H^1(\Omega) \oplus L^2(\Gamma_e)/\mathbb{C}$, namely,

$$((u,U),(v,V))_{*H} = \int_\Omega \nabla u \cdot \nabla \overline{v} dx + \int_{\Gamma_e} (U-u)(\overline{V}-\overline{v}) dS, \tag{2.13}$$

with the corresponding norm

$$||(v,V)||^2_{*H} = ((v,V),(v,V))_{*H}. \tag{2.14}$$

The following lemma tells us that the above inner product and norm are well defined and concordant with the conventional quotient norm of H given by

$$||(v,V)||_H = \inf_{c\in\mathbb{C}} \{||v-c||^2_{H^1(\Omega)} + ||V-c||^2_{L^2(\Gamma_e)}\}^{1/2}.$$

LEMMA 2.5. *The sesquilinear map* $(\cdot,\cdot)_{*H} : H \times H \to \mathbb{C}$ *given by* (2.13) *defines an inner product which is concordant with the quotient topology of* $H = (H^1(\Omega) \oplus L^2(\Gamma_e))/\mathbb{C}$. *In consequence,* H *is a Hilbert space.*

Proof. Clearly, $(\cdot,\cdot)_{*H} : H \times H \to \mathbb{C}$ is well defined and satisfies all the inner product axioms. Hence, the only thing we need to show, in order to prove the claim, is that the usual quotient norm $||(\cdot,\cdot)||_H$ and the norm $||(\cdot,\cdot)||_{*H}$ defined in (2.14) are equivalent.

Let $(v,V) \in H$ be arbitrary. With the help of the trace theorem [5], we may estimate

$$\begin{aligned} ||(v,V)||_{*H} &\le ||\nabla v||_{L^2(\Omega)} + ||V-v||_{L^2(\Gamma_e)} \\ &\le ||v-c||_{H^1(\Omega)} + ||v-c||_{L^2(\Gamma_e)} + ||V-c||_{L^2(\Gamma_e)} \\ &\le C \left\{ ||v-c||^2_{H^1(\Omega)} + ||V-c||^2_{L^2(\Gamma_e)} \right\}^{1/2}. \end{aligned}$$

Since this holds for every $c \in \mathbb{C}$, we actually have

$$||(v,V)||_{*H} \le C\, ||(v,V)||_H\,. \tag{2.15}$$

On the other hand, by using the trace theorem and Poincaré's inequality [5], we get

$$\begin{aligned} ||(v,V)||^2_H &\le \inf_{c\in\mathbb{C}} \left\{ ||v-c||^2_{H^1(\Omega)} + 2\,||v-c||^2_{L^2(\Gamma_e)} \right\} + 2\,||V-v||^2_{L^2(\Gamma_e)} \\ &\le C \inf_{c\in\mathbb{C}} ||v-c||^2_{H^1(\Omega)} + 2\,||V-v||^2_{L^2(\Gamma_e)} \\ &\le C\, ||(v,V)||^2_{*H}\,. \end{aligned}$$

Combining this with (2.15) completes the proof. □

COROLLARY 2.6. *Assume that* (2.2) *and* (2.4) *hold. Then the sesquilinear form* $B : H \times H \to \mathbb{C}$ *given in* (2.11) *is continuous as follows:*

$$|B((u,U),(v,V))| \le C\, ||(u,U)||_H\, ||(v,V)||_H\,, \quad (u,U),(v,V) \in H,$$

and coercive as follows:

$$|B((v,V),(v,V))| \geq c\,||(v,V)||_H^2\,, \quad (v,V) \in H,$$

where the positive constants c and C can be chosen independently of the geometry of Γ_e as a subset of $\partial\Omega$.

Proof. The claim is a straightforward consequence of Lemma 2.5 together with inequalities (2.2) and (2.4). ∎

Next we aim at showing that the functional F on the right-hand side of (2.10) is continuous. To begin with, we extend the trace theorem for the quotient Sobolev spaces as follows in Lemma 2.7.

LEMMA 2.7. *The quotient trace map*

$$Tr : H^1(\Omega)/\mathbb{C} \to H^{1/2}(\partial\Omega)/\mathbb{C}, \quad v \mapsto v|_{\partial\Omega},$$

is bounded.

Proof. The claim is a straightforward consequence of the traditional trace theorem and Poincaré's inequality. ∎

LEMMA 2.8. *Let $f \in L^2(\Gamma_e)$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$ with $f+g \in H_0^{-1/2}(\partial\Omega)$. Then the linear functional $F : H \to \mathbb{C}$ given in* (2.12) *is well defined and continuous.*

Proof. Let us first show that $F : H \to \mathbb{C}$ is well defined. Consider two representatives (v,V) and $(v+c, V+c)$ of the same equivalence class in H. Since $f+g \in H_0^{-1/2}(\partial\Omega)$, we have

$$F(v+c,V+c) = \int_{\Gamma_e} f\overline{V}\,dS + \int_{\Gamma_n} g\overline{v}\,dS + \overline{c}\langle f+g, \mathbf{1}\rangle_{L^2(\partial\Omega)} = F(v,V). \tag{2.16}$$

Further, by the use of (2.16) and Lemma 2.7, we may estimate, for an arbitrary $(v,V) \in H$,

$$\begin{aligned} |F(v,V)| &= \inf_{c\in\mathbb{C}} \left| \int_{\Gamma_e} f(\overline{V}+\overline{c})dS + \int_{\Gamma_n} g(\overline{v}+\overline{c})dS \right| \\ &\leq \inf_{c\in\mathbb{C}} \{ ||f||_{L^2(\Gamma_e)}\, ||V+c||_{L^2(\Gamma_e)} + ||g||_{\tilde{H}^{-1/2}(\Gamma_n)}\, ||v+c||_{H^{1/2}(\Gamma_n)} \} \\ &\leq C\{ ||f||_{L^2(\Gamma_e)} + ||g||_{\tilde{H}^{-1/2}(\Gamma_n)} \}\, ||(v,V)||_H\,, \end{aligned} \tag{2.17}$$

where $C > 0$ can be chosen independently of the geometry of Γ_e as a subset of $\partial\Omega$. This completes the proof. ∎

Now we have introduced enough weaponry to consider the solvability of (2.10).

LEMMA 2.9. *Assume that* (2.2) *and* (2.4) *hold and let $f \in L^2(\Gamma_e)$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $f+g \in H_0^{-1/2}(\partial\Omega)$, be given current patterns. Then variational equation* (2.10) *has a unique solution $(u,U) \in H = (H^1(\Omega) \oplus L^2(\Gamma_e))/\mathbb{C}$. Further, the first component of this solution, $u \in H^1(\Omega)/\mathbb{C}$, is the unique solution of the continuum forward problem* (2.1) *with the input current $f+g$, and the second component satisfies $U = u|_{\Gamma_e} + zf$.*

Proof. The existence of a unique solution for (2.10) is a straight consequence of the Lax–Milgram lemma [13], Corollary 2.6, and Lemma 2.8.

Let $u^0 \in H^1(\Omega)/\mathbb{C}$ be the unique solution of (2.1) corresponding to the input current $f+g \in H_0^{-1/2}(\partial\Omega)$ and define $(u^0, U^0) = (u^0, u^0|_{\Gamma_e} + zf) \in H$. For an

arbitrary $(v, V) \in H$, it holds that

$$\begin{aligned} B((u^0, U^0), (v, V)) &= \int_{\partial\Omega} \nu \cdot \sigma \nabla u^0 \overline{v} dS + \int_{\Gamma_e} f(\overline{V} - \overline{v}) dS \\ &= \int_{\Gamma_e} (\nu \cdot \sigma \nabla u^0 - f)\overline{v} dS + \int_{\Gamma_e} f\overline{V} dS + \int_{\Gamma_n} \nu \cdot \sigma \nabla u^0 \overline{v} dS \\ &= \int_{\Gamma_e} f\overline{V} dS + \int_{\Gamma_n} g\overline{v} dS = F(v, V), \end{aligned}$$

where we used Green's formula. Thus, $(u^0, U^0) \in H$ is a solution to (2.10), which completes the proof. ∎

Now, it is time to return to the complete electrode forward problem. Note that $H' = (H^1(\Omega) \oplus T)/\mathbb{C}$, where T is defined by (2.5), is a subspace of $H = (H^1(\Omega) \oplus L^2(\Gamma_e))/\mathbb{C}$. Thus, the variational problem: For $f \in L^2(\Gamma_e)$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $f + g \in H_0^{-1/2}(\partial\Omega)$, find $(u, U) \in H'$ so that

$$B((u, U), (v, V)) = F(v, V) \quad \text{for all } (v, V) \in H', \tag{2.18}$$

where B and F are defined in (2.11) and (2.12), respectively, can be considered a Galerkin approximation for variational problem (2.10). We claim that the unique solution for this approximating variational problem is in fact the unique solution for the complete electrode forward problem (2.7) with a suitable electrode current.

LEMMA 2.10. *Assume that* (2.2) *and* (2.4) *hold and let* $f \in L^2(\Gamma_e)$ *and* $g \in \tilde{H}^{-1/2}(\Gamma_n)$, *with* $f + g \in H_0^{-1/2}(\partial\Omega)$, *be given current patterns. Then variational equation* (2.18) *has a unique solution* $(u^e, U^e) \in H' = (H^1(\Omega) \oplus T)/\mathbb{C}$ *which is also the unique solution of the complete electrode forward problem* (2.7) *corresponding to the input currents* $P_2 f \in T$, *where* P_2 *is given by* (2.9), *and* $g \in \tilde{H}^{-1/2}(\Gamma_n)$.

Proof. By Corollary 2.6 and Lemma 2.8, the sesquilinear form $B : H \times H \to \mathbb{C}$ is continuous and coercive, and the linear functional $F : H \to \mathbb{C}$ is continuous. In consequence, the restrictions $B : H' \times H' \to \mathbb{C}$ and $F : H' \to \mathbb{C}$ have these same properties. Further, since H' is a closed subspace of the Hilbert space H, it is also a Hilbert space, and so the unique existence of a solution to (2.18) follows from the Lax–Milgram lemma [13].

To prove that variational problem (2.18) is equivalent to the complete electrode forward problem (2.7) with the electrode current $P_2 f \in T$, we write the left-hand side of (2.18) componentwise; i.e., for $(u, U), (v, V) \in H'$ we have

$$B((u, U), (v, V)) = \int_\Omega \sigma \nabla u \cdot \nabla \overline{v} dS + \sum_{m=1}^{M} \int_{e_m} \frac{1}{z}(U_m - u)(\overline{V}_m - \overline{v}) dS.$$

With the same tactic, the right-hand side of (2.18) can be transformed into

$$F(v, V) = \sum_{m=1}^{M} \int_{e_m} f\overline{V}_m dS + \int_{\Gamma_n} g\overline{v} dS = \sum_{m=1}^{M} |e_m|(P_2 f)_m \overline{V}_m + \int_{\Gamma_n} g\overline{v} dS.$$

With this convention, the claimed equivalence between problems (2.7) and (2.18) follows by the same line of reasoning as in the proof of Proposition 3.1 in [9], with only slight alterations caused by the excess Neumann term on the right-hand side of (2.18). ∎

Now we have also the means to prove Theorem 2.3.

Proof of Theorem 2.3. For the given current patterns $I \in T \subset L^2(\Gamma_e)$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $I + g \in H_0^{-1/2}(\partial\Omega)$, the unique existence of the solution $(u^e, U^e) \in H' = (H^1(\Omega) \oplus T)/\mathbb{C}$ for (2.7) follows from the equivalence between problems (2.18) and (2.7), considered in the proof of Lemma 2.10, by choosing $f = I$ in (2.18) and noting that $P_2 I = I$. Further, by using Corollary 2.6 and equation (2.17), we may estimate

$$\begin{aligned} ||(u^e, U^e)||_H^2 &\leq C|B((u^e, U^e), (u^e, U^e))| \\ &= C|F(u^e, U^e)| \\ &\leq C\{||I||_{L^2(\Gamma_e)} + ||g||_{\tilde{H}^{-1/2}(\Gamma_n)}\} \, ||(u^e, U^e)||_H \,, \end{aligned}$$

where the functional F, defined in (2.12), corresponds to currents $f = I$ and g. This completes the proof. □

There are a few things worth noticing. First, the solution $(u^e, U^e) \in H'$ of (2.7) satisfies

$$\nu \cdot \sigma \nabla u^e|_{\Gamma_e} = \frac{1}{z}(U^e - u^e|_{\Gamma_e}).$$

In particular, $\nu \cdot \sigma \nabla u^e|_{\Gamma_e} \in L^2(\Gamma_e)$. Second, the correspondence between problems (2.7) and (2.18) gives the complete electrode forward problem a variational formulation: For $I \in T$ and $g \in \tilde{H}^{-1/2}(\Gamma_n)$, with $I + g \in H_0^{-1/2}(\partial\Omega)$, find $(u^e, U^e) \in H'$ so that

$$B((u^e, U^e), (v, V)) = \int_{\Gamma_e} I\overline{V} dS + \int_{\Gamma_n} g\bar{v} dS \tag{2.19}$$

for all $(v, V) \in H'$.

Now we have derived the means to approximate the forward solution of the CM (2.1) by the forward solution of the complete electrode problem (2.7) with a correctly chosen electrode current pattern. First we will consider the case when no current is conducted through $\partial\Omega \setminus (\overline{\Gamma}_e \cup \overline{\Gamma}_n)$.

THEOREM 2.11. *Assume that σ and z satisfy* (2.2) *and* (2.4)*, respectively. Let $f \in H_0^{-1/2}(\partial\Omega)$, with $f|_{\Gamma_e} \in L^2(\Gamma_e)$ and $f|_{\partial\Omega\setminus(\overline{\Gamma}_e \cup \overline{\Gamma}_n)} = 0$, be a given input current and let $u \in H^1(\Omega)/\mathbb{C}$ be the corresponding solution of* (2.1)*. Further, let $(u^e, U^e) \in H' = (H^1(\Omega) \oplus T)/\mathbb{C}$ be the unique solution of* (2.7) *with the input currents $P_2(f|_{\Gamma_e}) \in T$ and $f|_{\Gamma_n} \in \tilde{H}^{-1/2}(\Gamma_n)$, where P_2 is given in* (2.9)*. Then it holds that*

$$||(u - u^e, U - U^e)||_H \leq C \inf_{V \in T} ||U - V||_{L^2(\Gamma_e)/\mathbb{C}} \,,$$

where $C > 0$ can be chosen independently of the geometry of Γ_e as a subset of $\partial\Omega$, the subspace $T \subset L^2(\Gamma_e)$ is given in (2.5)*, and $U = u|_{\Gamma_e} + zf|_{\Gamma_e}$.*

Proof. To begin with, note that, according to Lemma 2.9, the pair $(u, U) \in H = (H^1(\Omega) \oplus L^2(\Gamma_e))/\mathbb{C}$ satisfies the variational equation

$$B((u, U), (v, V)) = \int_{\Gamma_e} f\overline{V} dS + \int_{\Gamma_n} f\bar{v} dS \quad \text{for all } (v, V) \in H,$$

and, on the other hand, Lemma 2.10 tells us that (u^e, U^e) satisfies the very same equation with the space H replaced by the subspace H'. Since the sesquilinear form $B : H \times H \to \mathbb{C}$ is continuous and coercive, it follows from Cea's lemma [2] that

$$||(u - u^e, U - U^e)||_H \leq C \inf_{(v,V) \in H'} ||(u - v, U - V)||_H \,. \tag{2.20}$$

Choosing $v = u$ on the right-hand side of (2.20), we obtain

$$\begin{aligned}\inf_{(v,V)\in H'} ||(u-v, U-V)||_H &\leq \inf_{V\in T}\inf_{c\in\mathbb{C}} \left\{ ||c||^2_{H^1(\Omega)} + ||(U-V)-c||^2_{L^2(\Gamma_e)} \right\}^{1/2} \\ &= \inf_{V\in T} ||U-V||_{L^2(\Gamma_e)/\mathbb{C}}\,. \end{aligned} \tag{2.21}$$

Hence, combining (2.20) and (2.21), the claim follows. □

The following corollary also tells us that the normal derivative of the solution to (2.1) can be approximated with the normal derivative of the solution to (2.7).

COROLLARY 2.12. *Suppose that the assumptions of Theorem* 2.11 *are valid. Then, using the same notation as in Theorem* 2.11*, we have the estimate*

$$||f - \nu\cdot\sigma\nabla u^e||_{L^2(\Gamma_e)} = ||\nu\cdot\sigma\nabla u - \nu\cdot\sigma\nabla u^e||_{L^2(\Gamma_e)} \leq C \inf_{V\in T} ||U-V||_{L^2(\Gamma_e)/\mathbb{C}}\,.$$

Proof. Due to the boundary conditions of (2.7) and the way we have defined U in Theorem 2.11, we may estimate

$$\begin{aligned} ||\nu\cdot\sigma(\nabla u - \nabla u^e)||_{L^2(\Gamma_e)} &\leq C\,||z\nu\cdot\sigma(\nabla u - \nabla u^e)||_{L^2(\Gamma_e)} \\ &= C\,||(U-U^e)-(u-u^e)||_{L^2(\Gamma_e)} \\ &\leq C \inf_{c\in\mathbb{C}}\{||(U-U^e)-c||_{L^2(\Gamma_e)} + ||c-(u-u^e)||_{L^2(\Gamma_e)}\} \\ &\leq C\,||(u-u^e, U-U^e)||_H\,, \end{aligned}$$

where we took advantage of the trace theorem [5]. The claim follows by combining this with Theorem 2.11. □

Finally, it is time to provide a proof for Theorem 2.4 by combining Theorem 2.11 with Theorem 2.2.

Proof of Theorem 2.4. Let $u \in H^1(\Omega)/\mathbb{C}$ be the solution to the continuum forward problem (2.1) corresponding to the input current $P_1 f \in \tilde{H}_0^{-1/2}(\Gamma)$, where P_1 is defined by (2.3), and define $U = (u + zP_1 f)|_{\Gamma_e}$. According to Theorems 2.2 and 2.11, we can estimate

$$\begin{aligned} \big|\big|u^0 - u^e\big|\big|_{H^1(\Omega)/\mathbb{C}} &\leq \big|\big|u^0 - u\big|\big|_{H^1(\Omega)/\mathbb{C}} + ||u-u^e||_{H^1(\Omega)/\mathbb{C}} \\ &\leq C\left\{ \frac{1}{|\Gamma|^{1/2}}\,||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})} + \inf_{V\in T} ||U-V||_{L^2(\Gamma_e)/\mathbb{C}} \right\}, \end{aligned} \tag{2.22}$$

where the latter term may be divided into two parts by using the triangle inequality

$$\inf_{V\in T} ||U-V||_{L^2(\Gamma_e)/\mathbb{C}} \leq \inf_{V\in T} \big|\big|U^0 - V\big|\big|_{L^2(\Gamma_e)/\mathbb{C}} + \big|\big|U^0 - U\big|\big|_{L^2(\Gamma_e)/\mathbb{C}}\,. \tag{2.23}$$

Further, by using (2.3), (2.4), Lemma 2.7, Theorem 2.2, and the way U^0 and U are defined, we deduce that

$$\begin{aligned} \big|\big|U^0 - U\big|\big|_{L^2(\Gamma_e)/\mathbb{C}} &\leq \big|\big|u^0 - u\big|\big|_{L^2(\Gamma_e)/\mathbb{C}} + ||z(f-P_1 f)||_{L^2(\Gamma_e)/\mathbb{C}} \\ &\leq C\,\big|\big|u^0 - u\big|\big|_{H^1(\Omega)/\mathbb{C}} + \frac{1}{|\Gamma|}\left|\langle f, \mathbf{1}\rangle_{L^2(\partial\Omega\setminus\overline{\Gamma})}\right| ||z||_{L^2(\Gamma_e)/\mathbb{C}} \\ &\leq \left\{ \frac{C}{|\Gamma|^{1/2}} + \frac{z_1}{|\Gamma|}\,||\mathbf{1}||_{H^{1/2}(\partial\Omega\setminus\overline{\Gamma})}\,||\mathbf{1}||_{L^2(\Gamma_e)} \right\} ||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})} \\ &\leq \frac{C}{|\Gamma|^{1/2}}\,||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma})}\,. \end{aligned} \tag{2.24}$$

The claim follows by combining (2.22), (2.23), and (2.24). □

2.3. Comparing current-to-voltage maps. It is time to move on to consider the current-to-potential maps corresponding to CM and CEM. In order to keep things simple, in this subsection we assume that there is no Neumann boundary; the introduction of Γ_n in (2.7) was just a technical detail that is useful for us in the next section—usually, it does not play any part in real-world measurements. As a further simplification, we assume that all used current patterns are square integrable.

When dealing with the inverse problem for the CM, it is usually assumed that the known data is the linear Neumann-to-Dirichlet map, i.e., the operator that maps the applied current pattern onto the boundary potential

$$\Lambda_\sigma : f \mapsto u_\sigma^0|_{\partial\Omega}, \tag{2.25}$$

which is isomorphic from $H_0^{-1/2}(\partial\Omega)$ onto $H^{1/2}(\partial\Omega)/\mathbb{C} \sim H_0^{1/2}(\partial\Omega)$ and depends nonlinearly on σ. On the other hand, when conducting real-life measurements with the CEM, the only information one is able to obtain is the linear relation between the applied average currents $I_m \in \mathbb{C}$, $1 \le m \le M$, and the electrode voltages $U_m^e \in \mathbb{C}$, $1 \le m \le M$, given by

$$R_\sigma I = U^e,$$

where $R_\sigma : T_0 \to T/\mathbb{C}$ can be expressed in matrix form since $T_0, T/\mathbb{C} \sim \mathbb{C}^{M-1}$. The next challenge is to build some kind of approximating link between the operators Λ_σ and R_σ.

Assume that there is no Neumann boundary; i.e., $\Gamma_n = \emptyset$ in (2.7). By combining R_σ with the projection

$$P = P_2 P_1 : L_0^2(\partial\Omega) \to T_0, \tag{2.26}$$

where T_0 is given by (2.6), and the projections P_1, with $\Gamma = \Gamma_e$, and P_2 are defined in (2.3) and (2.9), respectively, we get the map

$$R_\sigma P : L_0^2(\partial\Omega) \to T/\mathbb{C}, \quad f \mapsto U_\sigma^e = (u_\sigma^e + z\nu \cdot \sigma \nabla u_\sigma^e)|_{\Gamma_e},$$

where $(u_\sigma^e, U_\sigma^e) \in (H^1(\Omega) \oplus T)/\mathbb{C}$ is the solution of (2.7) corresponding to the electrode current Pf and the admittance σ.

The resemblance between the operators Λ_σ and $R_\sigma P$ is quite apparent. However, $R_\sigma P$ is not a pure current-to-voltage map, which prevents us from using Theorem 2.4 to investigate the situation further. Luckily, in many of the reconstruction algorithms for the CM, one does not use merely Λ_σ but the difference [1]

$$\Lambda_\sigma - \Lambda_{\mathbf{1}} : f \mapsto (u_\sigma^0 - u_{\mathbf{1}}^0)|_{\partial\Omega}, \tag{2.27}$$

where $\Lambda_{\mathbf{1}}$ is the Neumann-to-Dirichlet map corresponding to the unit admittance distribution, and $u_{\mathbf{1}}^0 \in H^1(\Omega)/\mathbb{C}$ is the associated forward solution for the input current $f \in L_0^2(\partial\Omega)$. For the complete electrode counterpart, we get the formula

$$(R_\sigma - R_{\mathbf{1}})P : f \mapsto (u_\sigma^e - u_{\mathbf{1}}^e + z\nu \cdot (\sigma \nabla u_\sigma^e - \nabla u_{\mathbf{1}}^e))|_{\Gamma_e}, \tag{2.28}$$

which is, actually, quite close to (2.27).

THEOREM 2.13. *Assume that σ and z satisfy* (2.2) *and* (2.4)*, respectively, and let $f \in L_0^2(\partial\Omega)$ be a given current pattern. It holds that*

$$||((\Lambda_\sigma - \Lambda_{\mathbf{1}}) - (R_\sigma - R_{\mathbf{1}})P)f||_{L^2(\Gamma_e)/\mathbb{C}} \le \tag{2.29}$$

$$C\left\{ \frac{1}{|\Gamma_e|^{1/2}} ||f||_{\tilde{H}^{-1/2}(\partial\Omega \setminus \overline{\Gamma}_e)} + \inf_{V \in T} ||U_\sigma^0 - V||_{L^2(\Gamma_e)/\mathbb{C}} + \inf_{V \in T} ||U_{\mathbf{1}}^0 - V||_{L^2(\Gamma_e)/\mathbb{C}} \right\},$$

where the boundary operators are defined by (2.27) *and* (2.28)*, and* $U_\sigma^0 = u_\sigma^0|_{\Gamma_e} + zf|_{\Gamma_e}$, $U_{\mathbf{1}}^0 = u_{\mathbf{1}}^0|_{\Gamma_e} + zf|_{\Gamma_e}$*, where* u_σ^0 *and* $u_{\mathbf{1}}^0$ *are the solutions of the continuum forward problem* (2.1) *corresponding to the input current* f *and the impedance tensors* σ *and* $\mathbf{1}$*, respectively.*

Proof. With the help of (2.27) and (2.28), the left-hand side of (2.29) can be divided into three parts as follows:

$$\begin{aligned}||((\Lambda_\sigma - \Lambda_{\mathbf{1}}) - (R_\sigma - R_{\mathbf{1}})P)f||_{L^2(\Gamma_e)/\mathbb{C}} \le \left|\left|u_\sigma^0 - u_\sigma^e\right|\right|_{L^2(\Gamma_e)/\mathbb{C}} + \left|\left|u_{\mathbf{1}}^0 - u_{\mathbf{1}}^e\right|\right|_{L^2(\Gamma_e)/\mathbb{C}} \\ + ||z\nu \cdot (\sigma\nabla u_\sigma^e - \nabla u_{\mathbf{1}}^e)||_{L^2(\Gamma_e)/\mathbb{C}}\,. \end{aligned} \tag{2.30}$$

For the first term on the right-hand side of (2.30), it follows from Lemma 2.7 and Theorem 2.4 that

$$\left|\left|u_\sigma^0 - u_\sigma^e\right|\right|_{L^2(\Gamma_e)/\mathbb{C}} \le C\left\{\frac{1}{|\Gamma_e|^{1/2}}\,||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma}_e)} + \inf_{V\in T}\left|\left|U_\sigma^0 - V\right|\right|_{L^2(\Gamma_e)/\mathbb{C}}\right\}.$$

By the same means, we get an exactly similar estimate for the second term on the right-hand side of (2.30).

In order to handle the third term on the right-hand side of (2.30), let $u_\sigma, u_{\mathbf{1}} \in H^1(\Omega)/\mathbb{C}$ be the solutions of (2.1) with the input current $P_1 f \in L_0^2(\Gamma_e)$, where $P_1 : L_0^2(\partial\Omega) \to L_0^2(\Gamma_e)$ is defined by (2.3) with $\Gamma = \Gamma_e$, for the admittances σ and $\mathbf{1}$, respectively, and define $U_\sigma = u_\sigma|_{\Gamma_e} + zP_1 f$ and $U_{\mathbf{1}} = u_{\mathbf{1}}|_{\Gamma_e} + zP_1 f$. We use Corollary 2.12 to estimate

$$\begin{aligned}||z\nu \cdot (\sigma\nabla u_\sigma^e - \nabla u_{\mathbf{1}}^e)||_{L^2(\Gamma_e)/\mathbb{C}} &\le ||z(\nu\cdot\sigma\nabla u_\sigma^e - P_1 f)||_{L^2(\Gamma_e)} + ||z(P_1 f - \nu\cdot\nabla u_{\mathbf{1}}^e)||_{L^2(\Gamma_e)} \\ &\le C\left\{\inf_{V\in T}||U_\sigma - V||_{L^2(\Gamma_e)/\mathbb{C}} + \inf_{V\in T}||U_{\mathbf{1}} - V||_{L^2(\Gamma_e)/\mathbb{C}}\right\} \\ &\le C\left\{\frac{1}{|\Gamma_e|^{1/2}}\,||f||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma}_e)} + \inf_{V\in T}\left|\left|U_\sigma^0 - V\right|\right|_{L^2(\Gamma_e)/\mathbb{C}}\right. \\ &\quad \left. + \inf_{V\in T}\left|\left|U_{\mathbf{1}}^0 - V\right|\right|_{L^2(\Gamma_e)/\mathbb{C}}\right\},\end{aligned}$$

where we also use assumption (2.4) and inequality (2.24) from the proof of Theorem 2.4. The claim follows by combining the estimates for the terms on the right-hand side of (2.30). ∎

Again it is advisable to note a couple of things. First, the above theorem could also have been formulated for currents $f \in H_0^{-1/2}(\partial\Omega)$ with $f|_{\Gamma_e} \in L^2(\Gamma_e)$; the notation would have been even more cumbersome, however. Second, the images of the boundary maps are compared only on $\Gamma_e \subset \partial\Omega$ since in a real-life measurement situation one is not measuring anything outside the electrodes and, thus, there is nothing to compare on $\partial\Omega\setminus\overline{\Gamma}_e$. Third, the correspondence between the maps $\Lambda_\sigma - \Lambda_{\mathbf{1}}$ and $R_\sigma - R_{\mathbf{1}}$ gets better when the area covered by the electrodes gets larger and the electrodes get smaller.

3. Characterizing inclusions. In this section we demonstrate how the boundary map $R_\sigma - R_{\mathbf{1}}$, considered in the previous subsection, can be used to characterize an inclusion $D \subset \Omega$ with conductivity significantly higher or lower than the constant background conductivity. The section is organized as follows. We begin by introducing our framework and listing some basic properties of R_σ. Section 3.1 presents a factorization of $R_\sigma - R_{\mathbf{1}}$ into three parts. In section 3.2 the operators needed in the

factorization are investigated further and, finally, in section 3.3 we provide the characterization for the inclusion. This work can be seen as a discrete version of article [3]; also, the mathematical methods used here resemble to some extent those in [3].

Our object $\Omega \subset \mathbb{R}^n$, $n = 2, 3$, is assumed to be isotropic with a conductivity $0 < \sigma \leq C$ and a smooth boundary, and the used input current is assumed to be nonvariating in time. Further, we assume that the contact impedance $z : \partial\Omega \to \mathbb{R}$ is strictly positive and bounded. Let the subspaces $T \subset L^2(\partial\Omega)$ and $T_0 \subset L^2_0(\partial\Omega)$ be defined by (2.5) and (2.6), respectively, with the multiplier field $\mathbb{C}$ replaced by $\mathbb{R}$. Then, according to Theorem 2.3, for every $I \in T_0$ the complete electrode forward problem

$$\begin{aligned} &\nabla \cdot \sigma \nabla u = 0 \ \text{ in } \Omega, \quad \nu \cdot \sigma \nabla u = 0 \ \text{ on } \partial\Omega \setminus \overline{\Gamma}_e, \\ &u + z\nu \cdot \sigma \nabla u = U \ \text{ on } \Gamma_e, \quad \frac{1}{|e_m|} \int_{e_m} \nu \cdot \sigma \nabla u dS = I_m, \ \ 1 \leq m \leq M, \end{aligned} \tag{3.1}$$

has a unique solution $(u, U) \in H^1(\Omega) \oplus T_0$, where we have specified the ground level of the potential in an obvious way. The corresponding boundary map $R_\sigma : T_0 \to T_0$ is defined through $R_\sigma I = U$.

We emphasize the resemblance between R_σ and its continuous counterpart Λ_σ, given in (2.25), by showing that R_σ inherits some basic characteristics of Λ_σ.

LEMMA 3.1. *The operator $R_\sigma : T_0 \to T_0$ is self-adjoint and positive. Furthermore, R_σ is monotonically decreasing; i.e.,*

$$\langle I, R_\sigma I \rangle_{L^2(\partial\Omega)} > \langle I, R_{\tilde{\sigma}} I \rangle_{L^2(\partial\Omega)},$$

for $\sigma \leq \tilde{\sigma}$, $\sigma \neq \tilde{\sigma}$ on a set of nonzero measure, and $I \neq 0$.

Proof. The result follows by imitating the proof of Lemma 2.1 in [3] with the help of the weak formulation of (3.1) given by (2.19). □

Since T_0 is a finite-dimensional subspace of $L^2_0(\partial\Omega)$, the monotonicity property of Lemma 3.1 implies that $R_\sigma - R_{\tilde{\sigma}} : T_0 \to T_0$ has a bounded inverse if the assumptions of Lemma 3.1 are valid.

COROLLARY 3.2. *Let $\sigma \leq \tilde{\sigma}$, and $\sigma \neq \tilde{\sigma}$ on a set of nonzero measure. Then $R_\sigma - R_{\tilde{\sigma}} : T_0 \to T_0$ is strictly positive. In particular, $R_\sigma - R_{\tilde{\sigma}}$ is bijective and has a bounded inverse.*

Proof. From the monotonicity property of Lemma 3.1 we straight away obtain

$$\langle I, (R_\sigma - R_{\tilde{\sigma}}) I \rangle_{L^2(\partial\Omega)} > 0,$$

for every $I \in T_0$, $I \neq 0$. Since T_0 is finite-dimensional and $R_\sigma - R_{\tilde{\sigma}}$ is linear, this induces the estimate

$$\langle I, (R_\sigma - R_{\tilde{\sigma}}) I \rangle_{L^2(\partial\Omega)} \geq c \, ||I||^2_{L^2(\partial\Omega)}, \quad c > 0. \tag{3.2}$$

The injectivity, or, equivalently, the bijectivity, of $R_\sigma - R_{\tilde{\sigma}} : T_0 \to T_0$ follows trivially from (3.2), which completes the proof. □

3.1. Factorization of $R_\sigma - R_1$. From now on we assume that the conductivity inside Ω is of the form

$$\sigma = \begin{cases} \kappa & \text{in } D, \\ 1 & \text{in } \Omega \setminus \overline{D}, \end{cases} \tag{3.3}$$

where $\kappa \neq 1$ is a positive constant and D is an open connected subset of Ω with a smooth connected boundary and $\partial D \cap \partial\Omega = \emptyset$. Our aim is to prove the following theorem.

THEOREM 3.3. *Assume that the conductivity inside Ω is of the form given in (3.3). Then the difference of the boundary maps $R_\sigma, R_{\mathbf{1}} : T_0 \to T_0$ can be factorized as $R_\sigma - R_{\mathbf{1}} = LFL'$, where $L : H_0^{-1/2}(\partial D) \to T_0$ is continuous and surjective, its adjoint operator $L' : T_0 \to H_0^{1/2}(\partial D)$ is continuous and injective, and $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ is self-adjoint, bijective, and either positive or negative definite.*

Before we can introduce the operators needed for the above factorization, we must consider some notational details. On the inner boundary ∂D we define

$$v^{\pm}(x) = \lim_{t\to 0^+} v(x \pm t\nu) \quad \text{and} \quad \frac{\partial v}{\partial \nu}^{\pm}(x) = \lim_{t\to 0^+} \nu \cdot \nabla v(x \pm t\nu),$$

for $x \in \partial D$ with $\nu(x)$ the unit normal pointing out of D, and further,

$$[v]_{\partial D} = v^+ - v^- \quad \text{and} \quad \left[\sigma \frac{\partial v}{\partial \nu}\right]_{\partial D} = \frac{\partial v}{\partial \nu}^{+} - \kappa \frac{\partial v}{\partial \nu}^{-}.$$

Let us now define L and L'. By replacing Ω with $\Omega \setminus \overline{D}$ and choosing $\Gamma_n = \partial D$ in (2.7) and Theorem 2.3, we note that for every $\phi \in H_0^{-1/2}(\partial D)$ the boundary value problem

$$\begin{aligned} &\Delta v = 0 \ \text{ in } \Omega \setminus \overline{D}, \quad \frac{\partial v}{\partial \nu} = 0 \ \text{ on } \partial\Omega \setminus \overline{\Gamma}_e, \quad \frac{\partial v}{\partial \nu}^{+} = \phi \ \text{ on } \partial D, \\ &v + z\frac{\partial v}{\partial \nu} = V \ \text{ on } \Gamma_e, \quad \frac{1}{|e_m|}\int_{e_m} \frac{\partial v}{\partial \nu} dS = 0, \quad 1 \le m \le M, \end{aligned} \tag{3.4}$$

has a unique solution $(v, V) \in H^1(\Omega \setminus \overline{D}) \oplus T_0$, where we have fixed the ground level of the potential. Thus, we may define the operator L by

$$L : H_0^{-1/2}(\partial D) \to T_0, \quad \phi \mapsto V. \tag{3.5}$$

With $I' \in T_0$, let us next consider the boundary value problem

$$\begin{aligned} &\Delta v' = 0 \ \text{ in } \Omega \setminus \overline{D}, \quad \frac{\partial v'}{\partial \nu} = 0 \ \text{ on } \partial\Omega \setminus \overline{\Gamma}_e, \quad \frac{\partial v'}{\partial \nu}^{+} = 0 \ \text{ on } \partial D, \\ &v' + z\frac{\partial v'}{\partial \nu} = V' \ \text{ on } \Gamma_e, \quad \frac{1}{|e_m|}\int_{e_m} \frac{\partial v'}{\partial \nu} dS = -I'_m, \quad 1 \le m \le M, \end{aligned} \tag{3.6}$$

which, according to Theorem 2.3, also has a unique solution $(v', V') \in H^1_{0,\partial D}(\Omega \setminus \overline{D}) \oplus T$, where

$$H^1_{0,\partial D}(\Omega \setminus \overline{D}) = \left\{ u \in H^1(\Omega \setminus \overline{D}) \;\middle|\; \int_{\partial D} u dS = 0 \right\}. \tag{3.7}$$

We define L' by

$$L' : T_0 \to H_0^{1/2}(\partial D), \quad I' \mapsto v'|_{\partial D}. \tag{3.8}$$

The following lemma shows that L and L' are bounded and adjoint, and have the mapping properties advertised above.

LEMMA 3.4. *The operators* $L : H_0^{-1/2}(\partial D) \to T_0$ *and* $L' : T_0 \to H_0^{1/2}(\partial D)$ *defined by* (3.5) *and* (3.8)*, respectively, are bounded* (*independently of the geometry of* Γ_e) *and adjoint. Further,* L *is surjective and* L' *is injective.*

Proof. We begin with the boundedness of L. For $\phi \in H_0^{-1/2}(\partial D)$ let $(v, V) \in H^1(\Omega \setminus \overline{D}) \oplus T_0$ be the unique solution of (3.4), suggested by Theorem 2.3. From the continuous dependence on the data (2.8) and since $V \in T_0 \subset L_0^2(\Gamma_e)$, it follows that

$$||V||_{L^2(\Gamma_e)} = ||V||_{L^2(\Gamma_e)/\mathbb{R}} \leq ||(v,V)||_{(H^1(\Omega\setminus\overline{D})\oplus L^2(\Gamma_e))/\mathbb{R}} \leq C\,||\phi||_{H^{-1/2}(\partial D)}\,,$$

which proves the continuity of $L : H_0^{-1/2}(\partial D) \to T_0$.

Next we shall prove that $L' : T_0 \to H_0^{1/2}(\partial D)$ is the adjoint of L. Let $(v, V) \in H^1(\Omega \setminus \overline{D}) \oplus T_0$ and $(v', V') \in H^1_{0,\partial D}(\Omega \setminus \overline{D}) \oplus T$ be the unique solutions of (3.4) and (3.6), respectively. Then it holds that

$$\begin{aligned}
\langle I', L\phi\rangle_{L^2(\partial\Omega)} &= \int_{\Gamma_e} \left(I' + \frac{\partial v'}{\partial \nu}\right) V dS - \int_{\Gamma_e} \frac{\partial v'}{\partial \nu} V dS \\
&= -\int_{\Gamma_e} \frac{\partial v'}{\partial \nu} V dS = -\int_{\Gamma_e} \frac{\partial v'}{\partial \nu}\left(v + z\frac{\partial v}{\partial \nu}\right) dS \\
&= -\int_{\Gamma_e} \frac{\partial v'}{\partial \nu} v dS - \int_{\Gamma_e} \left(z\frac{\partial v'}{\partial \nu} - V'\right)\frac{\partial v}{\partial \nu} dS \\
&= -\int_{\Gamma_e} \frac{\partial v'}{\partial \nu} v dS + \int_{\Gamma_e} v' \frac{\partial v}{\partial \nu} dS \\
&= -\int_{\partial D} \frac{\partial v'}{\partial \nu}^{+} v dS + \int_{\partial D} v' \frac{\partial v}{\partial \nu}^{+} dS = \langle L'I', \phi\rangle_{L^2(\partial D)},
\end{aligned}$$

where we used the boundary conditions that the pairs (v, V) and (v', V') satisfy together with Green's formula. Since L is bounded and L' is its adjoint operator, L' is also bounded.

The injectivity of L' is easy to obtain: Let $I' \in T_0$ be such that $L'I' = v'|_{\partial D} = 0$, which means, according to (3.6), that the Cauchy data of v' vanishes on ∂D. Since v' is harmonic in $\Omega \setminus \overline{D}$, this implies that $v' = 0$ from which it also follows that $I' = 0$. In addition, due to the finite-dimensionality of $\mathcal{R}(L)$, we have $T_0 = \mathcal{N}(L')^{\perp} = \overline{\mathcal{R}(L)} = \mathcal{R}(L)$, which proves the surjectivity of L. This completes the proof. ∎

Last but not least, let us introduce $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$. Let $\psi \in H_0^{1/2}(\partial D)$ and assume that $(w_\sigma, W_\sigma) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$ is the solution of the diffraction problem

$$\begin{aligned}
&\Delta w = 0 \ \text{ in } \Omega \setminus \partial D, \quad \frac{\partial w}{\partial \nu} = 0 \ \text{ on } \partial\Omega \setminus \overline{\Gamma}_e, \quad w + z\frac{\partial w}{\partial \nu} = W \ \text{ on } \Gamma_e, \\
&[w]_{\partial D} = \psi, \quad \left[\sigma \frac{\partial w}{\partial \nu}\right]_{\partial D} = 0, \quad \frac{1}{|e_m|}\int_{e_m} \frac{\partial w}{\partial \nu} dS = 0, \ \ 1 \leq m \leq M.
\end{aligned} \tag{3.9}$$

We define F by the mapping rule $\psi \mapsto \frac{\partial (w_\sigma - w_{\mathbf{1}})}{\partial \nu}^{+}|_{\partial D}$, where $w_{\mathbf{1}}$ is the solution of (3.9) with σ replaced by the unit conductivity $\mathbf{1}$.

Because the outer boundary condition of (3.9) is not of standard form, one must convince oneself that w_σ and $w_{\mathbf{1}}$, and thereby $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$, are actually well defined. The following two technical lemmas and a corollary answer all the necessary questions.

LEMMA 3.5. *For $\psi \in H_0^{1/2}(\partial D)$, diffraction problem* (3.9) *has a unique solution $(w_\sigma, W_\sigma) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$. Further,*

$$\left|\left| \frac{\partial w_\sigma}{\partial \nu}^+ \right|\right|_{H^{-1/2}(\partial D)} \leq C \, ||\psi||_{H^{1/2}(\partial D)}, \tag{3.10}$$

where $C > 0$ is independent of the geometry of Γ_e as a subset of $\partial\Omega$.

Proof. To start with, note that the corresponding traditional diffraction problem

$$\Delta w = 0 \ \text{ in } \Omega \setminus \partial D, \quad \frac{\partial w}{\partial \nu} = 0 \ \text{ on } \partial\Omega,$$
$$[w]_{\partial D} = \psi, \quad \left[\sigma \frac{\partial w}{\partial \nu}\right]_{\partial D} = 0$$

has a unique solution $w_0 \in H^1_{0,\partial\Omega}(\Omega \setminus \partial D)$ (cf. [8]), where the space is defined in equivalence with (3.7). Encouraged by this, we consider the following boundary value problem:

$$\begin{gathered} \nabla \cdot \sigma \nabla w = 0 \ \text{ in } \Omega, \quad \frac{\partial w}{\partial \nu} = 0 \ \text{ on } \partial\Omega \setminus \overline{\Gamma}_e, \\ w + z \frac{\partial w}{\partial \nu} = W - w_0 \ \text{ on } \Gamma_e, \quad \frac{1}{|e_m|} \int_{e_m} \frac{\partial w}{\partial \nu} dS = 0, \ \ 1 \leq m \leq M, \end{gathered} \tag{3.11}$$

and try to show that it has a unique solution $(w_e, W_e) \in (H^1(\Omega) \oplus T)/\mathbb{R}$.

From considerations in section 2.2, it follows in a straightforward manner that problem (3.11) is equivalent to the variational problem

$$B((w, W), (v, V)) = \int_{\Gamma_e} \frac{1}{z} w_0 (V - v) dS, \tag{3.12}$$

for all $(v, V) \in (H^1(\Omega) \oplus T)/\mathbb{R}$, where the bilinear form B is defined in (2.11). Since, according to Corollary 2.6, $B : (H^1(\Omega) \oplus T)/\mathbb{R} \times (H^1(\Omega) \oplus T)/\mathbb{R} \to \mathbb{R}$ is continuous and coercive, and the right-hand side of (3.12) clearly defines a continuous linear functional on $(H^1(\Omega) \oplus T)/\mathbb{R}$, equation (3.12) has a unique solution $(w_e, W_e) \in (H^1(\Omega) \oplus T)/\mathbb{R}$ due to the Lax–Milgram lemma [13]. Now, it is easy to see that $(w_0 + w_e, W_e) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$ satisfies the electrode diffraction problem given in (3.9) because of the continuity conditions that w_e and $\sigma \frac{\partial w_e}{\partial \nu}$ must satisfy on ∂D [8]. In particular, (3.9) has at least one solution.

Assume now that $(w_\sigma, W_\sigma) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$ is a solution of diffraction problem (3.9) corresponding to $\psi \in H_0^{1/2}(\partial D)$. Then, due to Green's formula and positivity of z, w_σ satisfies

$$\begin{aligned} \left|\left| \sigma^{1/2} \nabla w_\sigma \right|\right|^2_{L^2(\Omega)} &= \int_{\partial D} w_\sigma^- \kappa \frac{\partial w_\sigma}{\partial \nu}^- dS - \int_{\partial D} w_\sigma^+ \frac{\partial w_\sigma}{\partial \nu}^+ dS + \int_{\partial\Omega} w_\sigma \frac{\partial w_\sigma}{\partial \nu} dS \\ &= \int_{\partial D} (w_\sigma^- - w_\sigma^+) \frac{\partial w_\sigma}{\partial \nu}^+ dS + \int_{\Gamma_e} \left(W_\sigma - z \frac{\partial w_\sigma}{\partial \nu} \right) \frac{\partial w_\sigma}{\partial \nu} dS \\ &= - \int_{\partial D} \psi \frac{\partial w_\sigma}{\partial \nu}^+ dS - \int_{\Gamma_e} z \frac{\partial w_\sigma}{\partial \nu}^2 dS \\ &\leq ||\psi||_{H^{1/2}(\partial D)} \left|\left| \frac{\partial w_\sigma}{\partial \nu}^+ \right|\right|_{H^{-1/2}(\partial D)}, \end{aligned} \tag{3.13}$$

where we used the jump and boundary conditions of (3.9). Due to the boundedness of the mapping (see p. 381 in [5]),

$$H(\mathrm{div}, \Omega \setminus \overline{D}) \to H^{-1/2}(\partial D), \quad \mathbf{v} \mapsto (\nu \cdot \mathbf{v})^+|_{\partial D}, \tag{3.14}$$

where $H(\mathrm{div}, \Omega \setminus \overline{D}) = \{\mathbf{v} \in L^2(\Omega \setminus \overline{D})^n \,|\, \nabla \cdot \mathbf{v} \in L^2(\Omega \setminus \overline{D})\}$, it is true that

$$\left|\left| \frac{\partial w_\sigma}{\partial \nu}^+ \right|\right|_{H^{-1/2}(\partial D)} \leq C \, ||\nabla w_\sigma||_{L^2(\Omega)} \,, \tag{3.15}$$

where $C > 0$ has nothing to do with Γ_e. Using this once in (3.13), we get

$$||\nabla w_\sigma||_{L^2(\Omega)} \leq C \, ||\psi||_{H^{1/2}(\partial D)} \,, \tag{3.16}$$

from which it follows that the only solution of (3.9) corresponding to $\psi = 0$ is the zero element of $(H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$. Consequently, diffraction problem (3.9) has a unique solution. Together with (3.15), (3.16) also proves (3.10), which completes the proof. □

COROLLARY 3.6. *For $\psi \in H_0^{1/2}(\partial D)$, the solution of diffraction problem* (3.9)*, $(w_\sigma, W_\sigma) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$, is the unique minimizer of the energy functional*

$$E_\sigma(w, W) = \int_{\Omega \setminus \overline{D}} |\nabla w|^2 dx + \kappa \int_D |\nabla w|^2 dx + \int_{\Gamma_e} \frac{1}{z} |W - w|^2 dS$$

over the subset

$$H_\psi = \{(w, W) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R} \mid [w]_{\partial D} = \psi\}.$$

Proof. Let $(w, W) \in H_\psi$ be arbitrary and denote the difference $(w - w_\sigma, W - W_\sigma)$ by (v, V). In consequence, $(v, V) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$ with $[v]_{\partial D} = 0$ and we may write

$$\begin{aligned} E_\sigma(w, W) = E_\sigma(w_\sigma, W_\sigma) + E_\sigma(v, V) + 2 \Bigg\{ & \int_{\Omega \setminus \overline{D}} \nabla w_\sigma \cdot \nabla v dx + \kappa \int_D \nabla w_\sigma \cdot \nabla v dx \\ & + \int_{\Gamma_e} \frac{1}{z} (W_\sigma - w_\sigma)(V - v) dS \Bigg\}. \end{aligned} \tag{3.17}$$

We claim that the mixed terms on the right-hand side of (3.17) vanish.

Indeed, by Green's formula

$$\begin{aligned} \int_{\Omega \setminus \overline{D}} \nabla w_\sigma \cdot \nabla v dx + \kappa \int_D \nabla w_\sigma \cdot \nabla v dx &= \int_{\partial \Omega} \frac{\partial w_\sigma}{\partial \nu} v dS + \int_{\partial D} \left(\kappa \frac{\partial w_\sigma}{\partial \nu}^- - \frac{\partial w_\sigma}{\partial \nu}^+ \right) v dS \\ &= \int_{\Gamma_e} \frac{\partial w_\sigma}{\partial \nu} v dS, \end{aligned} \tag{3.18}$$

due to the jump condition of the normal derivative in (3.9). On the other hand,

$$\int_{\Gamma_e} \frac{1}{z} (W_\sigma - w_\sigma)(V - v) dS = \int_{\Gamma_e} \frac{\partial w_\sigma}{\partial \nu} (V - v) dS = - \int_{\Gamma_e} \frac{\partial w_\sigma}{\partial \nu} v dS, \tag{3.19}$$

which, together with (3.17), (3.18), and the positivity of E_σ, implies that

$$E_\sigma(w, W) \geq E_\sigma(w_\sigma, W_\sigma). \tag{3.20}$$

Since $E_\sigma(v,V)=0$ implicates that v, with $[v]_{\partial D}=0$, is constant on Ω and that $V=v|_{\Gamma_e}$, the inequality in (3.20) is strict for $(w,W)\neq(w_\sigma,W_\sigma)$ in H_ψ, which completes the proof. ∎

LEMMA 3.7. *The operator $F:H_0^{1/2}(\partial D)\to H_0^{-1/2}(\partial D)$ is well defined, continuous, self-adjoint, and bijective, with a continuous inverse operator $F^{-1}:H_0^{-1/2}(\partial D)\to H_0^{1/2}(\partial D)$. In addition, the operator $\operatorname{sgn}(1-\kappa)F:H_0^{1/2}(\partial D)\to H_0^{-1/2}(\partial D)$ is positive. Furthermore, there exist constants $C^+,C^->0$, independent of the geometry of Γ_e as a subset of $\partial\Omega$, such that*

$$||F||\le C^+,\quad \left|\left|F^{-1}\right|\right|\le C^-. \tag{3.21}$$

Proof. For $\psi\in H_0^{1/2}(\partial D)$, let $(w_\sigma,W_\sigma),(w_{\mathbf{1}},W_{\mathbf{1}})\in(H^1(\Omega\setminus\partial D)\oplus T)/\mathbb{R}$ be the solutions of (3.9) corresponding to the conductivities σ and $\mathbf{1}$, respectively. First of all, according to the divergence theorem,

$$\int_{\partial D}\frac{\partial(w_\sigma-w_{\mathbf{1}})}{\partial\nu}^{+}dS=\int_{\partial\Omega}\frac{\partial(w_\sigma-w_{\mathbf{1}})}{\partial\nu}dS=0,$$

from which it follows that $\frac{\partial(w_\sigma-w_{\mathbf{1}})}{\partial\nu}^{+}|_{\partial D}\in H_0^{-1/2}(\partial D)$. Together with Lemma 3.5, this proves that F is well defined and continuous and that the first part of (3.21) holds.

Next we want to establish the self-adjointness. To this end, for $\psi_1,\psi_2\in H_0^{1/2}(\partial D)$ let $(w_1,W_1),(w_2,W_2)$ be the corresponding solutions of diffraction problem (3.9) with the conductivity σ. By using Green's formula and the boundary conditions of (3.9), we may write

$$\begin{aligned}\int_{\partial D}\frac{\partial w_1}{\partial\nu}^{+}\psi_2dS&=\int_{\partial D}\frac{\partial w_1}{\partial\nu}^{+}w_2^+dS-\int_{\partial D}\kappa\frac{\partial w_1}{\partial\nu}^{-}w_2^-dS\\&=\int_{\partial\Omega}\left(\frac{\partial w_1}{\partial\nu}w_2-w_1\frac{\partial w_2}{\partial\nu}\right)dS+\int_{\partial D}\left(w_1^+\frac{\partial w_2}{\partial\nu}^{+}-\kappa w_1^-\frac{\partial w_2}{\partial\nu}^{-}\right)dS\\&=\int_{\Gamma_e}\frac{\partial w_1}{\partial\nu}\left(W_2-z\frac{\partial w_2}{\partial\nu}\right)dS-\int_{\Gamma_e}\frac{\partial w_2}{\partial\nu}\left(W_1-z\frac{\partial w_1}{\partial\nu}\right)dS\\&\quad+\int_{\partial D}(w_1^+-w_1^-)\frac{\partial w_2}{\partial\nu}^{+}dS=\int_{\partial D}\psi_1\frac{\partial w_2}{\partial\nu}^{+}dS.\end{aligned}$$

Since this holds also for $\mathbf{1}$ as conductivity, we actually have

$$\langle F\psi_1,\psi_2\rangle_{L^2(\partial D)}=\langle F\psi_2,\psi_1\rangle_{L^2(\partial D)};$$

i.e., F is self-adjoint.

Next we prove the positiveness of $\operatorname{sgn}(1-\kappa)F:H_0^{1/2}(\partial D)\to H_0^{-1/2}(\partial D)$. For $\psi\in H_0^{1/2}(\partial D)$, $\psi\neq0$, let (w_σ,W_σ) and $(w_{\mathbf{1}},W_{\mathbf{1}})$ be the solutions of (3.9) corresponding to the conductivities σ and $\mathbf{1}$, respectively. By careful use of Green's formula and the jump conditions of (3.9), we deduce

$$\begin{aligned}-\int_{\partial D}\frac{\partial w_\sigma}{\partial\nu}^{+}\psi dS&=\kappa\int_{\partial D}\frac{\partial w_\sigma}{\partial\nu}^{-}w_\sigma^-dS-\int_{\partial D}\frac{\partial w_\sigma}{\partial\nu}^{+}w_\sigma^+dS\\&=\int_{\Omega\setminus\overline{D}}|\nabla w_\sigma|^2dx+\kappa\int_D|\nabla w_\sigma|^2dx-\int_{\Gamma_e}\frac{\partial w_\sigma}{\partial\nu}w_\sigma dS\\&=E_\sigma(w_\sigma,W_\sigma),\end{aligned}$$

where the last equality follows from a slight modification of (3.19) in the proof of Corollary 3.6. Since similar reasoning also applies for $(w_{\mathbf{1}}, W_{\mathbf{1}})$, we have altogether

$$\langle F\psi, \psi\rangle_{L^2(\partial D)} = E_{\mathbf{1}}(w_{\mathbf{1}}, W_{\mathbf{1}}) - E_\sigma(w_\sigma, W_\sigma). \tag{3.22}$$

Assume first that $\kappa > 1$. Then, according to Corollary 3.6, it holds that

$$E_{\mathbf{1}}(w_{\mathbf{1}}, W_{\mathbf{1}}) < E_{\mathbf{1}}(w_\sigma, W_\sigma) \le E_\sigma(w_\sigma, W_\sigma).$$

Similarly, for $\kappa < 1$ we have

$$E_\sigma(w_\sigma, W_\sigma) < E_\sigma(w_{\mathbf{1}}, W_{\mathbf{1}}) \le E_{\mathbf{1}}(w_{\mathbf{1}}, W_{\mathbf{1}}).$$

Together with (3.22), these estimates prove the claim.

Then it is time to concentrate on the invertibility of F, beginning with the injectivity. Let $\psi \in H_0^{1/2}(\partial D)$ be such that $F\psi = 0$, meaning that the restricted difference $((w_\sigma - w_{\mathbf{1}})|_{\Omega\setminus\overline{D}}, W_\sigma - W_{\mathbf{1}}) \in (H^1(\Omega\setminus\overline{D}) \oplus T)/\mathbb{R}$ of the solutions to (3.9) satisfies boundary value problem (3.4) with $\phi = 0$. Thus, it follows from the unique solvability of (3.4) (see Theorem 2.3) that $w_\sigma = w_{\mathbf{1}} + c$, $c \in \mathbb{R}$, on $\Omega\setminus\overline{D}$, and as a consequence $w_\sigma^- = w_\sigma^+ - \psi = w_{\mathbf{1}}^+ - \psi + c = w_{\mathbf{1}}^- + c$ on ∂D. Hence, from the unique solvability of the Dirichlet problem

$$\Delta w = 0 \quad \text{in } D, \quad w = w_{\mathbf{1}}^- \quad \text{on } \partial D,$$

it follows that $w_\sigma = w_{\mathbf{1}} + c$ also in D. Combining these with the jump conditions of the normal derivatives in (3.9), on ∂D we have

$$\frac{\partial w_\sigma}{\partial \nu}^- = \frac{\partial w_{\mathbf{1}}}{\partial \nu}^- = \frac{\partial w_{\mathbf{1}}}{\partial \nu}^+ = \frac{\partial w_\sigma}{\partial \nu}^+ = \kappa \frac{\partial w_\sigma}{\partial \nu}^-;$$

i.e, all these normal derivatives must vanish. In consequence, (w_σ, W_σ) satisfies (3.4) with $\phi = 0$ in $\Omega\setminus\overline{D}$ and, in addition, w_σ satisfies Neumann problem with zero input current in D, meaning that $w_\sigma|_{\Omega\setminus\overline{D}}$ and $w_\sigma|_D$ equal constants. Hence, $\psi = w_\sigma^+ - w_\sigma^- \in H_0^{1/2}(\partial D)$ equals a constant which must be zero due to the normalization condition. Thus, $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ is injective.

Next we move on to prove the surjectivity of F. For arbitrarily chosen $\phi \in H_0^{-1/2}(\partial D)$ we aim to construct $\psi \in H_0^{1/2}(\partial D)$ such that $F\psi = \phi$. First, we define an auxiliary pair $(v, V) \in (H^1(\Omega\setminus\overline{D}) \oplus T)/\mathbb{R}$ as the unique solution of (3.4) with the input current ϕ on ∂D, and we continue v to D as the unique H^1-solution of the Dirichlet problem

$$\Delta v = 0 \quad \text{in } D, \quad v^- = v^+ \quad \text{on } \partial D. \tag{3.23}$$

Hence, $(v, V) \in (H^1(\Omega\setminus\partial D) \oplus T)/\mathbb{R}$ with $[v]_{\partial D} = 0$. Further, we define $\varphi = \phi - \kappa \frac{\partial v}{\partial \nu}^-|_{\partial D}$ and note that $\varphi \in H_0^{-1/2}(\partial D)$ since $\int_{\partial D} \frac{\partial v}{\partial \nu}^- dS = 0$ due to the divergence theorem.

The next step is to define the diffraction solution corresponding to the unit conductivity. In the exterior domain $\Omega\setminus\overline{D}$ we choose $(w_{\mathbf{1}}, W_{\mathbf{1}}) \in (H^1(\Omega\setminus\overline{D}) \oplus T)/\mathbb{R}$ to be the unique solution of (3.4) with $\phi = \frac{1}{\kappa-1}\varphi$, whereas in the inner domain D we define $w_{\mathbf{1}}$ to be the unique H^1-solution of the Neumann problem

$$\Delta w_{\mathbf{1}} = 0 \quad \text{in } D, \quad \frac{\partial w_{\mathbf{1}}}{\partial \nu}^- = \frac{1}{\kappa - 1}\varphi \quad \text{on } \partial D, \quad \int_{\partial D} w_{\mathbf{1}}^- dS = \int_{\partial D} w_{\mathbf{1}}^+ dS. \tag{3.24}$$

Clearly, $(w_{\mathbf{1}}, W_{\mathbf{1}}) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$. As mentioned above, $(w_{\mathbf{1}}, W_{\mathbf{1}})$ plays here the role of the solution to diffraction problem (3.9) with conductivity $\mathbf{1}$ and, hence, we set $\psi = [w_{\mathbf{1}}]_{\partial D}$, which belongs to $H_0^{1/2}(\partial D)$ because of the normalization condition in (3.24). It is a straightforward task to check that the pairs $(w_{\mathbf{1}}, W_{\mathbf{1}}), (w_\sigma, W_\sigma) = (w_{\mathbf{1}} + v, W_{\mathbf{1}} + V) \in (H^1(\Omega \setminus \partial D) \oplus T)/\mathbb{R}$ satisfy diffraction problem (3.9) for the conductivities $\mathbf{1}$ and σ, respectively. Moreover, it holds that

$$F\psi = \frac{\partial (w_\sigma - w_{\mathbf{1}})^+}{\partial \nu}|_{\partial D} = \frac{\partial v^+}{\partial \nu}|_{\partial D} = \phi,$$

which proves that $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ is surjective.

It is a consequence of the open mapping theorem that the inverse of the bijective bounded linear operator F is also bounded. Moreover, by walking the above constructional proof of the surjectivity in the opposite direction and using the continuous dependence on the boundary data of (3.4), (3.23), and (3.24), one easily sees that $F^{-1} : H_0^{-1/2}(\partial D) \to H_0^{1/2}(\partial D)$ is, actually, uniformly bounded with respect to the choice of the electrode configuration, i.e., with respect to the geometry of Γ_e as a subset of $\partial\Omega$. This completes the proof. ∎

Now we have gathered enough weaponry to prove the factorization of $R_\sigma - R_{\mathbf{1}}$.

Proof of Theorem 3.3. For a fixed electrode current $I \in T_0$ denote by (u_σ, U_σ), $(u_{\mathbf{1}}, U_{\mathbf{1}}) \in H^1(\Omega) \oplus T_0$ the solutions of the complete electrode forward problem, given in (3.1), with conductivities σ and $\mathbf{1}$, respectively. Since $u_\sigma - u_{\mathbf{1}}$ is harmonic in $\Omega \setminus \overline{D}$, it follows easily by using the divergence theorem and the complete electrode boundary conditions that

$$\int_{\partial D} \frac{\partial (u_\sigma - u_{\mathbf{1}})^+}{\partial \nu} dS = \int_{\partial \Omega} \frac{\partial (u_\sigma - u_{\mathbf{1}})}{\partial \nu} dS = 0.$$

Thus, $((u_\sigma - u_{\mathbf{1}})|_{\Omega \setminus \overline{D}}, U_\sigma - U_{\mathbf{1}})$ solves (3.4) for $\phi = \frac{\partial (u_\sigma - u_{\mathbf{1}})^+}{\partial \nu}|_{\partial D}$ and, in particular,

$$L\left(\frac{\partial (u_\sigma - u_{\mathbf{1}})^+}{\partial \nu}|_{\partial D} \right) = U_\sigma - U_{\mathbf{1}} = (R_\sigma - R_{\mathbf{1}})I.$$

By introducing the operator $G_\sigma : I \mapsto \frac{\partial u_\sigma}{\partial \nu}^+|_{\partial D}$ and setting $G = G_\sigma - G_{\mathbf{1}}$, we have so far derived the factorization

$$R_\sigma - R_{\mathbf{1}} = LG. \tag{3.25}$$

Note that G is a well-defined bounded operator from T_0 to $H_0^{-1/2}(\partial D)$ due to Theorem 2.3 and (3.14).

The next task is to calculate the dual operator $G'_\sigma : H_0^{1/2}(\partial D) \to T_0$ of G_σ. To this end, consider $(w_\sigma, W_\sigma) \in H^1(\Omega \setminus \partial D) \oplus T_0$ the solution of diffraction problem (3.9), with a fixed ground level of the potential, corresponding to $\psi \in H_0^{1/2}(\partial D)$. With the help of the jump conditions $[u_\sigma]_{\partial D} = \left[\sigma \frac{\partial u_\sigma}{\partial \nu}\right]_{\partial D} = 0$ (cf. [8]), $\left[\sigma \frac{\partial w_\sigma}{\partial \nu}\right]_{\partial D} = 0$, Green's formula, and the boundary conditions on u_σ and w_σ, we deduce

$$\begin{aligned}
\langle G_\sigma I, \psi \rangle_{L^2(\partial D)} &= \int_{\partial D} \frac{\partial u_\sigma}{\partial \nu}^+ w_\sigma^+ dS - \int_{\partial D} \kappa \frac{\partial u_\sigma}{\partial \nu}^- w_\sigma^- dS \\
&= \int_{\partial D} \left(\frac{\partial w_\sigma}{\partial \nu}^+ u_\sigma^+ - \kappa \frac{\partial w_\sigma}{\partial \nu}^- u_\sigma^- \right) dS + \int_{\partial \Omega} \left(\frac{\partial u_\sigma}{\partial \nu} w_\sigma - \frac{\partial w_\sigma}{\partial \nu} u_\sigma \right) dS
\end{aligned}$$

$$= \int_{\Gamma_e} \frac{\partial u_\sigma}{\partial \nu} w_\sigma dS + \int_{\Gamma_e} \frac{\partial w_\sigma}{\partial \nu}(U_\sigma - u_\sigma) dS = \int_{\Gamma_e} \frac{\partial u_\sigma}{\partial \nu} \left(w_\sigma + z \frac{\partial w_\sigma}{\partial \nu} \right) dS$$
$$= \int_{\Gamma_e} \left(\frac{\partial u_\sigma}{\partial \nu} - I \right) W_\sigma dS + \int_{\Gamma_e} I W_\sigma dS = \langle I, W_\sigma \rangle_{L^2(\partial\Omega)},$$

which shows that $G'_\sigma \psi = W_\sigma$. Hence, with $(w_{\mathbf{1}}, W_{\mathbf{1}}) \in H^1(\Omega \setminus \partial D) \oplus T_0$ the solution of diffraction problem (3.9) corresponding to ψ and the unit conductivity, we have

$$G'\psi = W_\sigma - W_{\mathbf{1}}.$$

The restriction $((w_\sigma - w_{\mathbf{1}})|_{\Omega \setminus \overline{D}}, W_\sigma - W_{\mathbf{1}}) \in H^1(\Omega \setminus \overline{D}) \oplus T_0$ solves (3.4) for $\phi = \frac{\partial (w_\sigma - w_{\mathbf{1}})}{\partial \nu}^+ |_{\partial D} \in H_0^{-1/2}(\partial D)$, which means that

$$L \left(\frac{\partial (w_\sigma - w_{\mathbf{1}})}{\partial \nu}^+ |_{\partial D} \right) = W_\sigma - W_{\mathbf{1}} = G'\psi. \tag{3.26}$$

Due to the way $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ is defined and since $\psi \in H_0^{1/2}(\partial D)$ was chosen arbitrarily, relation (3.26) is equivalent to $LF = G'$. Taking the transpose of this and plugging it into (3.25), we thus obtain

$$R_\sigma - R_{\mathbf{1}} = LF'L' = LFL',$$

which is what we set out to prove. □

3.2. Some further properties of F, L, and L'. We define a new boundary operator by

$$|R_\sigma - R_{\mathbf{1}}| = \operatorname{sgn}(1 - \kappa)(R_\sigma - R_{\mathbf{1}}). \tag{3.27}$$

Due to the way we have defined our conductivity in (3.3), it follows trivially from Lemma 3.1 and Corollary 3.2 that $|R_\sigma - R_{\mathbf{1}}| : T_0 \to T_0$ is self-adjoint and strictly positive. Denoting the operator $\operatorname{sgn}(1 - \kappa)F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ by $|F|$, it follows from Theorem 3.3 that this new boundary operator can be factorized as $|R_\sigma - R_{\mathbf{1}}| = L|F|L'$. In the next subsection we will use the operator $|R_\sigma - R_{\mathbf{1}}|$ to characterize the inclusion D. However, to be successful in this task, we must devote the ongoing subsection to further investigations of $|F|$, L, and L'.

LEMMA 3.8. *The operator $|F| : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ can be given as $|F| = F^{1/2}(F^{1/2})'$, where $F^{1/2} : L_0^2(\partial D) \to H_0^{-1/2}(\partial D)$ and $(F^{1/2})' : H_0^{1/2}(\partial D) \to L_0^2(\partial D)$ are bounded, bijective, and dual to each other. Further, it holds that*

$$\left|\left| F^{1/2} \right|\right| \leq C^+ \sqrt{C^-}, \quad \left|\left| F^{-1/2} \right|\right| \leq \sqrt{C^-},$$

where $C^+, C^- > 0$ are the constants introduced in Lemma 3.7.

Proof. Since $H_0^{1/2}(\partial D) \hookrightarrow L_0^2(\partial D) \hookrightarrow H_0^{-1/2}(\partial D)$ is a Gelfand triple and since $|F|^{-1} : H_0^{-1/2}(\partial D) \to H_0^{1/2}(\partial D)$ is isomorphic, self-adjoint, and positive, it follows from material in [3] that there exists a factorization

$$|F|^{-1} = (F^{-1/2})' F^{-1/2},$$

where $F^{-1/2} : H_0^{-1/2}(\partial D) \to L_0^2(\partial D)$ and $(F^{-1/2})' : L_0^2(\partial D) \to H_0^{1/2}(\partial D)$ are bounded, bijective, and dual to each other, with

$$\left|\left|F^{-1/2}\right|\right| = \left|\left|(F^{-1/2})'\right|\right| \leq \left|\left|F^{-1}\right|\right|^{1/2} \leq \sqrt{C^-}. \tag{3.28}$$

Further, for $\eta \in L_0^2(\partial D)$ we may estimate

$$\left|\left|F^{1/2}\eta\right|\right|_{H^{-1/2}(\partial D)} = \left|\left||F|(F^{-1/2})'\eta\right|\right|_{H^{-1/2}(\partial\Omega)} \leq C^+\sqrt{C^-}\,||\eta||_{L^2(\partial D)},$$

where we used Lemma 3.7 and (3.28). ∎

In what follows we denote by $\mathcal{N}(L)^\perp \subset H_0^{-1/2}(\partial D)$ the orthogonal complement of $\mathcal{N}(L) \subset H_0^{-1/2}(\partial D)$ with respect to the inner product of the Hilbert space $H^{-1/2}(\partial D)$. Let $Q : \mathcal{R}(FL') \to \mathcal{N}(L)^\perp$ be an orthogonal projection; i.e., for $\phi \in \mathcal{R}(FL') \subset H_0^{-1/2}(\partial D)$,

$$Q\phi = \phi_\perp \in \mathcal{N}(L)^\perp \quad \text{with } L\phi_\perp = L\phi. \tag{3.29}$$

Note that Q is well defined due to the projection theorem [6]. In addition, we claim that Q is a bijection.

COROLLARY 3.9. *The orthogonal projection $Q : \mathcal{R}(FL') \to \mathcal{N}(L)^\perp$ defined by* (3.29) *is bijective with the norm estimates*

$$||Q|| \leq 1, \quad \left|\left|Q^{-1}\right|\right| \leq (C^+C^-)^2, \tag{3.30}$$

where $C^+, C^- > 0$ are the constants introduced in Lemma 3.7.

Proof. To begin with, note that the left-hand inequality of (3.30) is obvious. In order to obtain the right-hand inequality, let $\phi \in \mathcal{R}(FL') = \mathcal{R}(|F|L')$ and $\phi_\perp = Q\phi \in \mathcal{N}(L)^\perp$, and note that $\phi - \phi_\perp \in \mathcal{N}(L)$. In consequence, we may write

$$\begin{aligned} ||\phi_\perp||_{H^{-1/2}(\partial D)} &\geq \sup_{||\psi||_{H^{1/2}}=1, \psi\in\mathcal{R}(L')} \langle \phi_\perp, \psi\rangle_{L^2(\partial D)} \\ &= \sup_{||\psi||_{H^{1/2}}=1, \psi\in\mathcal{R}(L')} \langle \phi, \psi\rangle_{L^2(\partial D)}. \end{aligned}$$

Further, since $|F|^{-1}\phi \in \mathcal{R}(L')$, we have

$$||\phi_\perp||_{H^{-1/2}(\partial D)} \geq \frac{1}{||\,|F|^{-1}\phi||_{H^{1/2}(\partial D)}} \langle \phi, |F|^{-1}\phi\rangle_{L^2(\partial D)} = \frac{\left|\left|F^{-1/2}\phi\right|\right|^2_{L^2(\partial D)}}{||\,|F|^{-1}\phi||_{H^{1/2}(\partial D)}},$$

and so we finally obtain

$$||\phi_\perp||_{H^{-1/2}(\partial D)} \geq \frac{||\phi||_{H^{-1/2}(\partial D)}}{\left|\left|F^{1/2}\right|\right|^2 ||\,|F|^{-1}||} \geq \frac{1}{(C^+C^-)^2}\,||\phi||_{H^{-1/2}(\partial D)} \tag{3.31}$$

by Lemmas 3.7 and 3.8.

According to Lemmas 3.4 and 3.7, $L : H_0^{-1/2}(\partial D) \to T_0$ is surjective, $L' : T_0 \to H_0^{1/2}(\partial D)$ is injective, and $F : H_0^{1/2}(\partial D) \to H_0^{-1/2}(\partial D)$ is bijective. Thus, $\dim(\mathcal{N}(L)^\perp) = \dim(\mathcal{R}(FL')) = \dim(T_0) < \infty$, and so the bijectivity of $Q : \mathcal{R}(FL') \to \mathcal{N}(L)^\perp$ follows from its injectivity that is guaranteed by (3.31), which provides also the needed norm estimate for Q^{-1}. ∎

To end this subsection, we make a few comments about the inverse operators of L and L' defined in (3.5) and (3.8), respectively. Since $L : H_0^{-1/2}(\partial D) \to T_0$ is noninjective and $L' : T_0 \to H_0^{1/2}(\partial D)$ is nonsurjective, they do not have inverse operators as such. However, the restrictions $L : \mathcal{R}(FL') \to T_0$ and $L' : T_0 \to \mathcal{R}(L')$ do have bounded inverses due to the bijectivity of $R_\sigma - R_{\mathbf{1}} = LFL' : T_0 \to T_0$ and finite-dimensionality of T_0. In what follows, we will denote by L^{-1} and $(L')^{-1}$ the inverses of these restrictions, i.e.,

$$L^{-1} : T_0 \to \mathcal{R}(FL'), \quad (L')^{-1} : \mathcal{R}(L') \to T_0, \tag{3.32}$$

with $LL^{-1} = \mathrm{id}$, $L^{-1}L|_{\mathcal{R}(FL')} = \mathrm{id}$ and $L'(L')^{-1} = \mathrm{id}$, $(L')^{-1}L' = \mathrm{id}$. With this notation, we can factorize $|R_\sigma - R_{\mathbf{1}}|^{-1} : T_0 \to T_0$, which exists according to Lemma 3.2, as

$$|R_\sigma - R_{\mathbf{1}}|^{-1} = (L')^{-1}|F|^{-1}L^{-1} = (L')^{-1}(F^{-1/2})'F^{-1/2}L^{-1},$$

due to Theorem 3.3 and Lemma 3.8.

3.3. Characterizing the inclusion. Before we can formulate and prove the main result of this section, we need to introduce some new concepts. Let $\{\mathcal{T}_M\}$ be a sequence of electrode configurations, meaning that

$$\mathcal{T}_M = \{e_1^M, \ldots, e_M^M \subset \partial\Omega \mid e_l^M \cap e_m^M = \emptyset \text{ if } l \neq m\}, \quad \Gamma_M = \cup_{m=1}^M e_m^M,$$

for each $1 \leq M < \infty$, satisfying the following conditions: $d(e_m^M) \leq \beta_M$ for all $1 \leq m \leq M$,

$$|\partial\Omega \setminus \Gamma_M|, \ \beta_M \to 0 \quad \text{when } M \to \infty, \tag{3.33}$$

where $d(e_m^M)$ is the diameter of e_m^M, i.e., $d(e_m^M) = \sup_{x,y\in e_m^M} |x-y|$. The subspaces T^M and T_0^M, corresponding to the electrode configuration $\mathcal{T}_M$, are defined in accordance with (2.5) and (2.6), respectively, and the associated orthogonal projections $P_1^M : L_0^2(\partial\Omega) \to L_0^2(\Gamma_M)$, $P_2^M : L_0^2(\Gamma_M) \to T_0^M$, and $P^M : L_0^2(\partial\Omega) \to T_0^M$ are given by obvious modifications of (2.3), (2.9), and (2.26). We also will use a similar index notation for other operators depending on the used electrode configuration.

Let $y \in \Omega$ be a parameter and $\hat{\alpha} \in \mathbb{R}^n$ a unit vector, and consider the solution Φ_y of the following homogenous Neumann problem:

$$\Delta\Phi(x) = \hat{\alpha} \cdot \nabla\delta(x-y) \quad \text{in } \Omega, \quad \frac{\partial\Phi}{\partial\nu} = 0 \quad \text{on } \partial\Omega, \quad \int_{\partial\Omega} \Phi dS = 0, \tag{3.34}$$

where δ is the delta functional. Physically Φ_y corresponds to the electromagnetic potential created by a dipole point source at y pointing in the direction $\hat{\alpha}$. It is a well-known fact that (3.34) is uniquely solvable with $\Phi_y \in C^\infty(\Omega \setminus \{y\})$ and Φ_y singular at y.

Assume that (3.33) is valid and let $\{\alpha_M\} \subset \mathbb{R}_+$ be a sequence of regularization parameters. Consider the minimizing sequence $\{I^M\} \subset L_0^2(\partial\Omega)$, $I^M \in T_0^M$, of the Tikhonov functionals

$$\left|\left||R_\sigma^M - R_{\mathbf{1}}^M|^{1/2} I - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \, ||I||^2_{L^2(\partial\Omega)}, \quad I \in T_0^M, \ 1 \leq M < \infty, \tag{3.35}$$

where $|R_\sigma^M - R_{\mathbf{1}}^M|^{1/2} : T_0^M \to T_0^M$ is the unique, positive, self-adjoint, bijective square root of $|R_\sigma^M - R_{\mathbf{1}}^M|$ defined in (3.27). Since $R_\sigma^M - R_{\mathbf{1}}^M$ can be obtained through boundary measurements, so can $|R_\sigma^M - R_{\mathbf{1}}^M|^{1/2}$ and, hence, the behavior of the sequence

$\{I^M\}$ is something that can be observed by noninvasive methods. The following theorem characterizes the inclusion D by the limit behavior of $\{I^M\}$.

THEOREM 3.10. *Assume that* (3.33) *holds and the contact impedance z is smooth. Let $\{I^M\} \subset L^2_0(\partial\Omega)$, $I^M \in T^M_0$, be the minimizing sequence for the functionals* (3.35) *and assume that $\{\alpha_M\} \subset \mathbb{R}_+$ converges to zero but is such that the sequence*

$$\left\{ \frac{\inf_{V \in T^M} ||\Phi_y - V||^2_{L^2(\partial\Omega)}}{\alpha_M} \right\}$$

is bounded. Then $y \in D$ if and only if the sequence $\{I^M\}$ is bounded in $L^2_0(\partial\Omega)$.

In real life one is, naturally, not able to construct a sequence of electrode configurations with the properties given in (3.33). However, when conducting measurements with a fixed setting of electrodes that are relatively small and cover a large portion of the object boundary, Theorem 3.10 gives a reason to believe that the electrode currents needed for minimizing functional (3.35), with a fixed small $\alpha > 0$, are larger when $y \in \Omega \setminus D$ than when $y \in D$. This observation leads to a possibility of numerical implementation that will be considered in forthcoming articles.

The following simple lemma shows that the conditions of Theorem 3.10 are reasonable. One could also quite easily derive a quantitative estimate to suggest an a priori choice of regularization parameters α_M in Theorem (3.10) but for simplicity we content ourselves with a mere convergence result.

LEMMA 3.11. *Let $f \in C^\infty(\partial\Omega)$ and assume that $\{\mathcal{T}_M\}$ satisfies* (3.33). *Then it holds that*

$$\inf_{V \in T^M} ||f - V||_{L^2(\partial\Omega)} \to 0,$$

when M goes to infinity.

Proof. The claim is a straightforward consequence of the good behavior of $\{\mathcal{T}_M\}$ given by (3.33). ∎

The rest of this section is devoted to the proof of Theorem 3.10. Let L^M be the operator defined in (3.5) corresponding to the electrode configuration $\mathcal{T}_M$. We define the associated limit operator $\tilde{L} : H_0^{-1/2}(\partial D) \to H_0^{1/2}(\partial\Omega)$ by

$$\tilde{L}\phi = v|_{\partial\Omega}, \quad \phi \in H_0^{-1/2}(\partial D),$$

where $v \in H^1_{0,\partial\Omega}(\Omega \setminus \overline{D})$ is the unique solution of the boundary value problem

$$\Delta v = 0 \quad \text{in } \Omega \setminus \overline{D}, \quad \frac{\partial v}{\partial \nu}^+ = \phi \quad \text{on } \partial D, \quad \frac{\partial v}{\partial \nu} = 0 \quad \text{on } \partial\Omega. \tag{3.36}$$

The adjoint of $\tilde{L}$ is $\tilde{L}' : H_0^{-1/2}(\partial\Omega) \to H_0^{1/2}(\partial D)$ [3],

$$\tilde{L}'\phi' = v'|_{\partial D}, \quad \phi' \in H_0^{-1/2}(\partial\Omega), \tag{3.37}$$

where $v' \in H^1_{0,\partial D}(\Omega \setminus \overline{D})$ is the unique solution of the boundary value problem

$$\Delta v' = 0 \quad \text{in } \Omega \setminus \overline{D}, \quad \frac{\partial v'}{\partial \nu} = -\phi' \quad \text{on } \partial\Omega, \quad \frac{\partial v}{\partial \nu}^+ = 0 \quad \text{on } \partial D.$$

The first step of our proof is to characterize the inclusion D by the operator sequence $\{L_M\}$ with the help of known mapping properties of $\tilde{L}$ and $\tilde{L}'$.

Assume that $\{\alpha_M\}$ is a sequence of positive regularization parameters that converges to zero and consider the following Tikhonov functionals:

$$\left|\left|L^M\phi-\Phi_y\right|\right|^2_{L^2(\partial\Omega)}+\alpha_M\left|\left|\phi\right|\right|^2_{H^{-1/2}(\partial D)},\quad 1\le M\le\infty. \tag{3.38}$$

Since $L^M : H_0^{-1/2}(\partial D)\to T_0^M\subset L_0^2(\partial\Omega)$ is continuous for every $M\in\mathbb{N}$, it is well known that each of these functionals has a unique minimizer $\phi^M\in H_0^{-1/2}(\partial D)$. We intend to show that, for a correctly chosen sequence of regularization parameters $\{\alpha_M\}$, the behavior of the minimizer sequence $\{\phi^M\}$ at infinity determines uniquely whether y belongs to the inclusion D or not. We begin with the case when $y\in\Omega\setminus D$.

LEMMA 3.12. *Assume that $y\in\Omega\setminus D$, the contact impedance z is smooth, and $\{\alpha_M\}\subset\mathbb{R}_+$ converges to zero. Let $\{\phi^M\}\subset H_0^{-1/2}(\partial D)$ be the minimizing sequence for the functionals* (3.38). *Then it holds that*

$$\left|\left|\phi^M\right|\right|_{H^{-1/2}(\partial D)}\to\infty,$$

as M goes to infinity.

Proof. First, we will show that $L^M\phi^M$ converges to $\Phi_y|_{\partial\Omega}$ as M goes to infinity. Let $\epsilon>0$ be given. Since $\tilde{L}'$ defined in (3.37) is clearly injective, we have $\overline{\mathcal{R}(\tilde{L})}=\mathcal{N}(\tilde{L}')^\perp=H_0^{1/2}(\partial\Omega)$, where the orthogonal complement is taken with respect to the dual pairing between $H_0^{-1/2}(\partial\Omega)$ and $H_0^{1/2}(\partial\Omega)$. Hence, $\mathcal{R}(\tilde{L})$ is dense in $H_0^{1/2}(\partial\Omega)$ and, thus, also in $L_0^2(\partial\Omega)$. In consequence, we can choose $\phi^\epsilon\in H_0^{-1/2}(\partial D)$ such that

$$\left|\left|\tilde{L}\phi^\epsilon-\Phi_y\right|\right|^2_{L^2(\partial\Omega)}<\frac{\epsilon^2}{6}. \tag{3.39}$$

Note also that $\tilde{L}\phi^\epsilon\in C^\infty(\partial\Omega)\cap H_0^{1/2}(\partial\Omega)$ due to the regularity theory of elliptic partial differential equations [10].

Since $\tilde{L}\phi^\epsilon\in H_0^{1/2}(\partial\Omega)$ and $L^M\phi^\epsilon\in L_0^2(\Gamma_M)$, by using the projection $P_1^M : L_0^2(\partial\Omega)\to L_0^2(\Gamma_M)$, defined by (2.3), we can estimate

$$\begin{aligned}\left|\left|(\tilde{L}-L^M)\phi^\epsilon\right|\right|_{L^2(\Gamma_M)}&\le\left|\left|\tilde{L}\phi^\epsilon-P_1^M(\tilde{L}\phi^\epsilon)\right|\right|_{L^2(\Gamma_M)}+\left|\left|P_1^M(\tilde{L}-L^M)\phi^\epsilon\right|\right|_{L^2(\Gamma_M)}\\&\le C\left\{\frac{|\partial\Omega\setminus\overline{\Gamma}_M|^{1/2}}{|\Gamma_M|^{1/2}}\left|\left|\tilde{L}\phi^\epsilon\right|\right|_{L^2(\partial\Omega\setminus\overline{\Gamma}_M)}+\left|\left|(\tilde{L}-L^M)\phi^\epsilon\right|\right|_{L^2(\Gamma_M)/\mathbb{R}}\right\}\\&\le C\left\{\frac{|\partial\Omega\setminus\overline{\Gamma}_M|^{1/2}}{|\Gamma_M|^{1/2}}\left|\left|\tilde{L}\phi^\epsilon\right|\right|_{L^2(\partial\Omega\setminus\overline{\Gamma}_M)}+\inf_{V\in T^M}\left|\left|\tilde{L}\phi^\epsilon-V\right|\right|_{L^2(\Gamma_M)}\right\},\end{aligned}$$

where the second-to-last inequality follows from (2.3), by using the Schwarz inequality, and the fact that $P_1^M(\tilde{L}-L^M)\phi^\epsilon\in L_0^2(\Gamma_M)$, and the last inequality follows from Lemma 2.7 and Theorem 2.11 applied on boundary value problems (3.36) and (3.4). Thus, according to Lemma 3.11, we can choose $M_0\in\mathbb{N}$ in such a way that

$$\left|\left|(L^M-\tilde{L})\phi^\epsilon\right|\right|^2_{L^2(\partial\Omega)}\le\frac{C}{|\Gamma_M|}\inf_{V\in T^M}\left|\left|\tilde{L}\phi^\epsilon-V\right|\right|^2_{L^2(\partial\Omega)}<\frac{\epsilon^2}{6}, \tag{3.40}$$

and, in addition,

$$\alpha_M\left|\left|\phi^\epsilon\right|\right|^2_{H^{-1/2}(\partial D)}<\frac{\epsilon^2}{3} \tag{3.41}$$

for all $M \geq M_0$. Consequently, due to estimates (3.39), (3.40), (3.41), and the triangle inequality, for every $M \geq M_0$ it holds that

$$\begin{aligned}\left|\left|L^M\phi^M - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \left|\left|\phi^M\right|\right|^2_{H^{-1/2}(\partial D)} \\ \leq \left|\left|L^M\phi^\epsilon - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \left|\left|\phi^\epsilon\right|\right|^2_{H^{-1/2}(\partial D)} < \epsilon^2.\end{aligned}$$

In particular, since $\epsilon > 0$ was chosen arbitrarily, we have obtained

$$\left|\left|L^M\phi^M - \Phi_y\right|\right|_{L^2(\partial\Omega)} \to 0,$$

when M goes to infinity.

Next, we will use contradiction: Assume that the minimizing sequence $\{\phi^M\}$ is bounded in $H_0^{-1/2}(\partial D)$. In consequence, it follows from fundamental functional analysis [6] that $\{\phi^M\}$ has a subsequence $\{\phi^{M_k}\}_{k=1}^\infty$ that converges weakly to some distribution $\phi' \in H_0^{-1/2}(\partial D)$. Our goal is to show that $\tilde{L}\phi' = \Phi_y|_{\partial\Omega}$, which is a contradiction due to the singularity of Φ_y at $y \in \Omega \setminus D$ [3].

Let $g \in C^\infty(\partial\Omega) \cap L^2_0(\partial\Omega)$ be arbitrary and write it in two parts as $g = P_1^{M_k} g + (I - P_1^{M_k})g$, where $P_1^{M_k}$ is defined by (2.3). Then we have

$$\langle L^{M_k}\phi^{M_k}, g\rangle_{L^2(\partial\Omega)} = \langle L^{M_k}\phi^{M_k}, P^{M_k}g\rangle_{L^2(\partial\Omega)} + \langle L^{M_k}\phi^{M_k}, (I - P_1^{M_k})g\rangle_{L^2(\Gamma_{M_k})}, \tag{3.42}$$

where we used the fact that $L^{M_k}\phi^{M_k}$ is constant over each $e_m^{M_k}$ and zero elsewhere, and the way P^{M_k} is defined in (2.26). Due to the uniform boundedness of the operators $\{L^{M_k}\} \subset \mathcal{L}(H_0^{-1/2}(\partial D), L^2_0(\partial\Omega))$ (see Lemma 3.4) and of the sequence $\{\phi^M\} \subset H_0^{-1/2}(\partial D)$, the second term on the right-hand side of (3.42) can be estimated by the Schwarz inequality as follows:

$$\begin{aligned}\left|\langle L^{M_k}\phi^{M_k}, (I - P_1^{M_k})g\rangle_{L^2(\Gamma_{M_k})}\right| &\leq \frac{C}{|\Gamma_{M_k}|}\left\{\int_{\Gamma_{M_k}}\left|\int_{\partial\Omega\setminus\overline{\Gamma}_{M_k}} g dS\right|^2 dS\right\}^{1/2} \\ &\leq \frac{C}{|\Gamma_{M_k}|^{1/2}}|\partial\Omega \setminus \Gamma_{M_k}|\,||g||_\infty \to 0,\end{aligned}$$

when k goes to infinity due to (3.33). On the other hand, for the first term on the right-hand side of (3.42) we may write

$$\begin{aligned}\langle L^{M_k}\phi^{M_k}, P^{M_k}g\rangle_{L^2(\partial\Omega)} &= \langle \phi^{M_k}, (L^{M_k})' P^{M_k} g\rangle_{L^2(\partial D)} \\ &= \langle \phi^{M_k}, ((L^{M_k})' P^{M_k} - \tilde{L}')g\rangle_{L^2(\partial D)} + \langle \phi^{M_k}, \tilde{L}' g\rangle_{L^2(\partial D)}.\end{aligned} \tag{3.43}$$

Let $(v^{M_k}, V^{M_k}) \in H^1_{0,\partial D}(\Omega \setminus \overline{D}) \oplus T^{M_k}$ and $v \in H^1_{0,\partial D}(\Omega \setminus \overline{D})$ be the solutions corresponding to the operator current pairs $((L^{M_k})', P^{M_k}g)$ and $(\tilde{L}', g)$, respectively; i.e., by (3.8) and (3.37), $(L^{M_k})' P^{M_k} g = v^{M_k}|_{\partial D}$ and $\tilde{L}' g = v|_{\partial D}$. Since $\phi^{M_k} \in H_0^{-1/2}(\partial D)$, by a slight variation of Lemma 2.7 and Theorem 2.4, we have

$$\begin{aligned}\left|\langle \phi^{M_k}, ((L^{M_k})' P^{M_k} - \tilde{L}')g\rangle_{L^2(\partial D)}\right| &\leq \left|\left|\phi^{M_k}\right|\right|_{H^{-1/2}(\partial D)} \left|\left|v^{M_k} - v\right|\right|_{H^{1/2}(\partial D)/\mathbb{R}} \\ &\leq C\left|\left|v^{M_k} - v\right|\right|_{H^1(\Omega\setminus\overline{D})/\mathbb{R}} \\ &\leq C\left\{\inf_{V\in T^{M_k}} ||(v - zg) - V||_{L^2(\Gamma_{M_k})}\right. \\ &\quad \left. + \frac{1}{|\Gamma_{M_k}|^{1/2}}\,||g||_{\tilde{H}^{-1/2}(\partial\Omega\setminus\overline{\Gamma}_{M_k})}\right\} \to 0,\end{aligned}$$

when k goes to infinity by Lemma 3.11 and (3.33) since $v|_{\partial\Omega} - zg \in C^\infty(\partial\Omega)$ due to the assumptions on z and g, and the regularity theory of elliptic partial differential equations [10]. Finally, due to the weak convergence of $\{\phi^{M_k}\}$, the second term on the right-hand side of (3.43) satisfies

$$\langle \phi^{M_k}, \tilde{L}' g\rangle_{L^2(\partial D)} \to \langle \phi', \tilde{L}' g\rangle_{L^2(\partial D)} = \langle \tilde{L}\phi', g\rangle_{L^2(\partial\Omega)},$$

when k goes to infinity.

Putting the above estimates together, we have established that

$$\langle L^{M_k}\phi^{M_k}, g\rangle_{L^2(\partial\Omega)} \to \langle \tilde{L}\phi', g\rangle_{L^2(\partial\Omega)} = \langle \Phi_y, g\rangle_{L^2(\partial\Omega)} \quad \text{when } k \to \infty,$$

for all $g \in C^\infty(\partial\Omega) \cap L^2_0(\partial\Omega)$, by the first part of the proof. This means that $\tilde{L}\phi' = \Phi_y|_{\partial\Omega}$ almost everywhere on $\partial\Omega$, which is the contradiction we were looking for. ∎

Then it is the turn of $y \in D$.

LEMMA 3.13. *Assume that $y \in D$ and let $\{\alpha_M\} \subset \mathbb{R}_+$ be such that the sequence*

$$\left\{ \frac{\inf_{V\in T^M} ||\Phi_y - V||^2_{L^2(\partial\Omega)}}{\alpha_M} \right\} \tag{3.44}$$

is bounded. Then the sequence of the minimizers $\{\phi^M\} \subset H_0^{-1/2}(\partial D)$ for (3.38) *also is bounded.*

Proof. To begin with, note that $\frac{\partial\Phi_y}{\partial\nu}^+|_{\partial D} \in H_0^{-1/2}(\partial D)$ due to the divergence theorem. Since $L^M \frac{\partial\Phi_y}{\partial\nu}^+ \in L^2_0(\Gamma_M)$ and, clearly, $\tilde{L}\frac{\partial\Phi_y}{\partial\nu}^+ = \Phi_y|_{\partial\Omega} \in H_0^{1/2}(\partial\Omega)$, as in the proof of Lemma 3.12, we have the estimate

$$\left|\left| L^M \frac{\partial\Phi_y}{\partial\nu}^+ - \Phi_y \right|\right|^2_{L^2(\partial\Omega)} = \left|\left| (L^M - \tilde{L})\frac{\partial\Phi_y}{\partial\nu}^+ \right|\right|^2_{L^2(\partial\Omega)} \leq \frac{C}{|\Gamma_M|} \inf_{V\in T^M} ||\Phi_y - V||^2_{L^2(\partial\Omega)}.$$

Thus, due to the minimizing property of the sequence $\{\phi^M\} \subset H_0^{-1/2}(\partial D)$, for every $M \in \mathbb{N}$, we have

$$\begin{aligned} &\left|\left|L^M\phi^M - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \left|\left|\phi^M\right|\right|^2_{H^{-1/2}(\partial D)} \\ &\qquad \leq \frac{C}{|\Gamma_M|} \inf_{V\in T^M} ||\Phi_y - V||^2_{L^2(\partial\Omega)} + \alpha_M \left|\left| \frac{\partial\Phi_y}{\partial\nu}^+ \right|\right|^2_{H^{-1/2}(\partial D)}. \end{aligned} \tag{3.45}$$

Forgetting the first term on the left-hand side of (3.45) and dividing by α_M, we get

$$\left|\left|\phi^M\right|\right|^2_{H^{-1/2}(\partial D)} \leq C\frac{\inf_{V\in T^M} ||\Phi_y - V||^2_{L^2(\partial\Omega)}}{\alpha_M|\Gamma_M|} + \left|\left| \frac{\partial\Phi_y}{\partial\nu}^+ \right|\right|^2_{H^{-1/2}(\partial D)},$$

for every $M \in \mathbb{N}$. Together with assumptions (3.44) and (3.33), this proves the claim. ∎

If the operator sequence $\{L^M\}$ is known, Lemmas 3.12 and 3.13 give us the means to find the inclusion D. However, to know $\{L^M\}$ is to know the shape of the boundary ∂D. Luckily, the operators L^M and $|R^M_\sigma - R^M_{\mathbf{1}}|^{1/2}$ are closely related, and so Lemmas 3.12 and 3.13 give us the weaponry to write out the proof for Theorem 3.10.

Proof of Theorem 3.10. Let us define a new sequence $\{\tilde{\phi}^M\} \subset H_0^{-1/2}(\partial D)$, $\tilde{\phi}^M \in \mathcal{R}(F^M(L^M)')$, by

$$\tilde{\phi}^M = (L^M)^{-1}|R^M_\sigma - R^M_{\mathbf{1}}|^{1/2} I_M, \quad 1 \leq M < \infty,$$

where $(L^M)^{-1}$ is given by (3.32). We get a simple relation between the norms of I^M and $\tilde{\phi}^M$:

$$\begin{aligned}\left|\left|I^M\right|\right|^2_{L^2(\partial\Omega)} &= \langle |R^M_\sigma - R^M_{\mathbf{1}}|^{-1/2} L^M \tilde{\phi}^M, |R^M_\sigma - R^M_{\mathbf{1}}|^{-1/2} L^M \tilde{\phi}^M \rangle_{L^2(\partial\Omega)} \\ &= \langle \tilde{\phi}^M, (L^M)' |R^M_\sigma - R^M_{\mathbf{1}}|^{-1} L^M \tilde{\phi}^M \rangle_{L^2(\partial D)} \\ &= \langle \tilde{\phi}^M, (L^M)' ((L^M)')^{-1} |F^M|^{-1} (L^M)^{-1} L^M \tilde{\phi}^M \rangle_{L^2(\partial D)} \\ &= \langle \tilde{\phi}^M, |F^M|^{-1} \tilde{\phi}^M \rangle_{L^2(\partial D)} = \left|\left|(F^M)^{-1/2} \tilde{\phi}^M\right|\right|^2_{L^2(\partial D)}.\end{aligned}$$

In consequence, since the sequence $\{I^M\}$ minimizes the functionals (3.35), the sequence $\{\tilde{\phi}^M\}$ minimizes the functionals

$$\left|\left|L^M\phi - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \left|\left|(F^M)^{-1/2}\phi\right|\right|^2_{L^2(\partial D)}, \quad 1 \le M < \infty, \tag{3.46}$$

within the subspaces $\mathcal{R}(F^M(L^M)')$, respectively. Indeed, if $\hat{\phi}^M \in \mathcal{R}(F^M(L^M)')$ gave a smaller value for functional (3.46), then one easily sees that $|R^M_\sigma - R^M_{\mathbf{1}}|^{-1/2} L^M \hat{\phi}^M \in T^M_0$ would give a smaller value than I^M for functional (3.35), which is a contradiction.

We define yet a new sequence by $\{\phi^M\} = \{Q^M \tilde{\phi}^M\}$, where $Q^M : \mathcal{R}(F^M(L^M)') \to \mathcal{N}(L^M)^\perp \subset H^{-1/2}_0(\partial D)$ is defined by (3.29). Here and in the rest of this proof the orthogonal complement $\mathcal{N}(L^M)^\perp$ is taken with respect to the $H^{-1/2}$ inner product. By similar reasoning as above, one sees that this new sequence minimizes the functionals

$$\left|\left|L^M\phi - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M \left|\left|(F^M)^{-1/2}(Q^M)^{-1}\phi\right|\right|^2_{L^2(\partial D)}, \quad 1 \le M < \infty,$$

over the subspaces $\mathcal{N}(L^M)^\perp$, respectively. Now, Lemma 3.8 and Corollary 3.9 tell us that there exists a sequence of functionals $\{C_M\}$, $C_M : \mathcal{N}(L^M)^\perp \to \mathbb{R}$, such that

$$\left|\left|(F^M)^{-1/2}(Q^M)^{-1}\phi\right|\right|_{L^2(\partial D)} = C_M(\phi)\, ||\phi||_{H^{-1/2}(\partial D)}, \quad c \le C_M \le C,$$

for all $M \in \mathbb{N}$ and $\phi \in \mathcal{N}(L^M)^\perp$, where c and C are positive constants independent of M. Thus, the sequence $\{\phi^M\}$ also minimizes the functionals

$$\left|\left|L^M\phi - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \alpha_M C^2_M(\phi)\, ||\phi||^2_{H^{-1/2}(\partial D)}, \quad 1 \le M < \infty, \tag{3.47}$$

over the subspaces $\mathcal{N}(L^M)^\perp \subset H^{-1/2}_0(\partial D)$, respectively. In particular, if we define $C_M(\phi) = C$ for $\phi \in H^{-1/2}_0(\partial D) \setminus \mathcal{N}(L^M)^\perp$, the sequence $\{\phi^M\}$ minimizes functionals (3.47) over the whole space $H^{-1/2}_0(\partial D)$. It is an easy consequence of the upper and lower bounds for $\{C_M\}$ that $\{\phi^M\}$ is bounded in $H^{-1/2}_0(\partial D)$ if and only if $y \in D$.

Let $\{\phi^M_c\}, \{\phi^M_C\} \subset H^{-1/2}_0(\partial D)$ be the minimizing sequences for the functionals

$$\left|\left|L^M\phi - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + \frac{1}{2}\alpha_M c^2\, ||\phi||^2_{H^{-1/2}(\partial D)}, \quad 1 \le M < \infty,$$

and

$$\left|\left|L^M\phi - \Phi_y\right|\right|^2_{L^2(\partial\Omega)} + 2\alpha_M C^2\, ||\phi||^2_{H^{-1/2}(\partial D)}, \quad 1 \le M < \infty,$$

respectively. It follows from Lemmas 3.12 and 3.13 that each of these sequences is bounded if and only if $y \in D$. Let us shorten our strenuous notations by $\Psi_M(\phi) = \left|\left|L^M\phi - \Phi_y\right|\right|_{L^2(\partial\Omega)}$ and note that due to the minimizing properties of the sequences $\{\phi^M\}$ and $\{\phi_c^M\}$, for every $M \in \mathbb{N}$, we have

$$\Psi_M^2(\phi^M) + \alpha_M C_M^2(\phi^M) \left|\left|\phi^M\right|\right|_{H^{-1/2}(\partial D)}^2 \leq \Psi_M^2(\phi_c^M) + \alpha_M C_M^2(\phi_c^M) \left|\left|\phi_c^M\right|\right|_{H^{-1/2}(\partial D)}^2,$$

and

$$\Psi_M^2(\phi^M) + \frac{1}{2}\alpha_M c^2 \left|\left|\phi^M\right|\right|_{H^{-1/2}(\partial D)}^2 \geq \Psi_M^2(\phi_c^M) + \frac{1}{2}\alpha_M c^2 \left|\left|\phi_c^M\right|\right|_{H^{-1/2}(\partial D)}^2.$$

By subtracting the second of these inequalities from the first one and arranging terms, we get

$$\left|\left|\phi^M\right|\right|_{H^{-1/2}(\partial D)}^2 \leq \frac{C_M^2(\phi_c^M) - \frac{1}{2}c^2}{C_M^2(\phi^M) - \frac{1}{2}c^2} \left|\left|\phi_c^M\right|\right|_{H^{-1/2}(\partial D)}^2 \leq \frac{2C^2 - c^2}{c^2} \left|\left|\phi_c^M\right|\right|_{H^{-1/2}(\partial D)}^2.$$

On the other hand, by similar means we deduce that

$$\left|\left|\phi^M\right|\right|_{H^{-1/2}(\partial D)}^2 \geq \frac{2C^2 - C_M^2(\phi_C^M)}{2C^2 - C_M^2(\phi^M)} \left|\left|\phi_C^M\right|\right|_{H^{-1/2}(\partial D)}^2 \geq \frac{C^2}{2C^2 - c^2} \left|\left|\phi_C^M\right|\right|_{H^{-1/2}(\partial D)}^2.$$

From the above estimates it follows that $\{\phi^M\} \subset H_0^{-1/2}(\partial D)$ is bounded if and only if $y \in D$.

Finally, walking the above path of reasoning backwards, one sees that

$$\left|\left|I^M\right|\right|_{L^2(\partial\Omega)} = \left|\left|(F^M)^{-1/2}(Q^M)^{-1}\phi^M\right|\right|_{L^2(\partial D)},$$

and so the claim follows from the uniform boundedness of the operator sequences $\{(F^M)^{1/2}\}$, $\{(F^M)^{-1/2}\}$, and $\{Q^M\}$, $\{(Q^M)^{-1}\}$ given in Lemma 3.8 and Corollary 3.9, respectively. □

We end this section, and at the same time the whole work, by noting that one could easily modify Theorem 3.10 for the case of multiple inclusions by using the means described in [3].

SIMULATION BY DIFFUSION ON A MANIFOLD WITH BOUNDARY: APPLICATIONS TO ULTRASONIC PRENATAL MEDICAL IMAGING*

DANIEL M. KEENAN† AND PAULA A. SHORTER‡

Abstract. Consider the ultrasonic imaging of a fetal head, a standard procedure for assessing the growth and development of the fetus in utero. The size and shape of certain cross sections of the skull are particularly important in such assessments. The technician/radiologist spatially moves an ultrasonic transducer over the pregnant woman's abdomen and acquires three-dimensional information from the real-time two-dimensional video images. The ability to draw conclusions from such images is built upon an acquired practical knowledge as to what is bone, what is tissue, and what is sensor noise. Can one mechanize this intuitive understanding which allows the technician/radiologist to delineate between inherent biological variation and variation due to sensor noise, and in so doing, reconstruct the fetal head? The approach of the present paper is that of a probabilistic recovery of the fetal head. The "space of realizable fetal heads" is viewed as the result of similarity (translation × scale × rotation) transformations being applied to a given fetal head prototype. A model of the ultrasonic imaging of a fetal head is formulated and prior knowledge is incorporated, resulting in an a posteriori probability measure on the "space of realizable fetal heads." Sampling from this probability measure is achieved and justified via a time-homogeneous diffusion on a Riemannian, compact, simply connected, oriented manifold with boundary. The discretization of the diffusion is implemented into code, and the algorithm is applied to actual ultrasound prenatal images.

Key words. medical image processing, stochastic differential equations, manifold with boundary, stochastic optimization

1. Introduction.

Within a medical imaging context, consider the prenatal ultrasound imaging of a fetal head. The transducer is moved, resulting in a spatial sequence of two-dimensional ultrasound images. In Figure 1, a sequence of eight such images (taken in roughly parallel planes, perpendicular to the spine of the fetus) is displayed proceeding clockwise from the jawline (top left) upward to the top of the head (bottom left). The technician/radiologist is able to observe the images in "real time," and they are stored on video at a rate of 33 frames per second. The objectives of the ultrasonic exam are to detect any potential abnormalities and to monitor the growth of the fetus via certain measurements of the fetal skull. Can one automate this process by mechanizing the technician's intuitive understanding of the inherent biological variation as well as the variation due to sensor noise? We develop a beginning formulation for such a methodology and apply it to the displayed ultrasound images.

One measurement commonly taken is the diameter of the fetal skull in a specified plane, located just above the ears. This measurement is called the biparietal diameter (BPD), and the plane is referred to as the BPD plane (pictured in the top row of

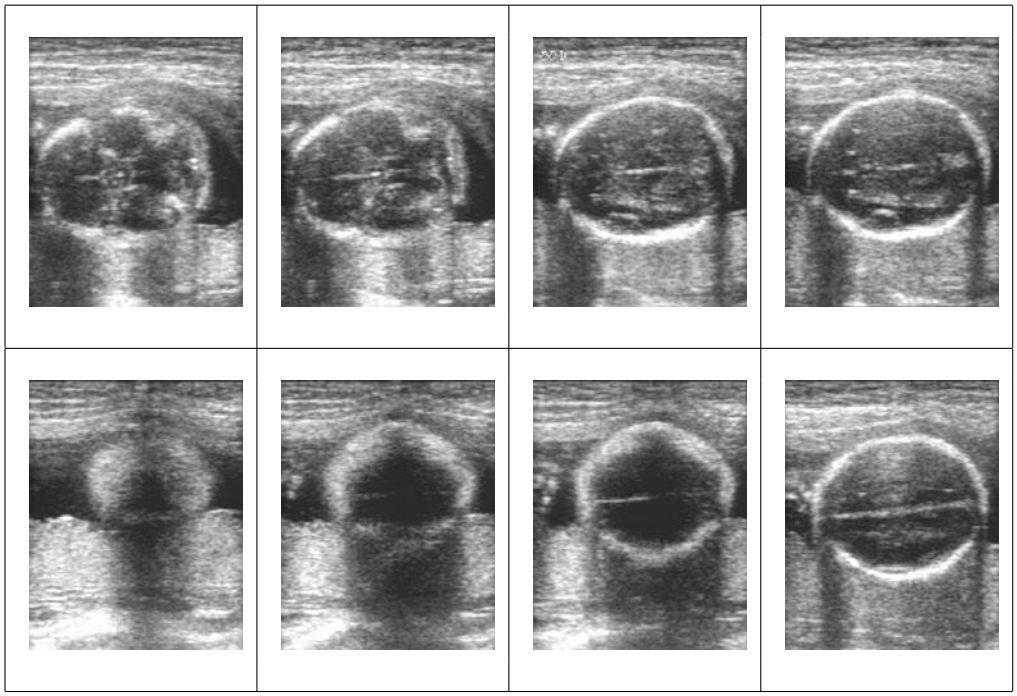

FIG. 1. *Ultrasound images of a fetal head. Images proceed clockwise from the jawline (top left) upward to the top of the head (bottom left).*

Figure 1, second from the right). Ideally, in order to automate measurements such as the BPD, the entire head would be reconstructed from the "ultrasound movie," and any measurements or other assessments would be made on the reconstructed head. That way, for example, even if one does not actually observe the BPD cross section, one would still be able to estimate the BPD measurement.

With the advent of telemedicine, where ultrasonic imaging may well be done remotely by the radiologist, possibly even in a semiautomated manner, being able to estimate the BPD under such conditions will be important. Another consideration is whether, by the incorporation of knowledge which allows for the distinction between what is bone, what is tissue, and what is sensor noise, it might be possible to perform prenatal ultrasonic assessments earlier in the development of the fetus. Traditionally, prenatal ultrasonic examinations of the fetal head are not performed until the bones of the fetal skull have calcified sufficiently to allow for visual recognition.

In the present context, imagine the collection of "realizable variations in form" of a fetal head. A basic strategy would then be to optimize over this collection, finding that variation which most likely could have produced the acquired two-dimensional ultrasound images. The difficulty is that it is computationally infeasible to store all such potential fetal head representations and search through them by brute force. The methodology presented in this paper is an attempt to do such a search in a semi-intelligent manner.

We consider this collection, $\overline{\Theta}(\mathcal{T})$, to be the result of a family of transformations, $\overline{\Theta}$, applied to a given fetal head template, $\mathcal{T}$. The transformations are assumed to be characterized by a compact manifold with boundary. In our particular application, the transformations are those of location $\times$ scale $\times$ rotation, but the formulation and

justification are established in a broader context. The resulting manifold structure is a consequence of the space of rotations $SO(3)$, and the boundary arises from the boundary of the space of allowable translations and/or from that of the space of possible scalings. A probability measure incorporating prior knowledge about fetal heads as well as the information provided by the acquired ultrasound images will be constructed on $\overline{\Theta}$. The ability to sample from this measure (stochastic relaxation; see [6], [7]) is the basis of the approach. The reconstruction will be obtained via such sampling.

More and more today, the stochastic modeling of complex phenomena requires formulations in terms of manifolds. The usual reason for this is that various nonlinear constraints inherent to the structure cannot be excluded or linearized. In pattern theory (see, e.g., [7], [8], [29]), a fundamental formulation of a parameter space is as a product of low-dimensional Lie groups, and when one takes into account certain global constraints, the resulting parameter space will be a submanifold (of the product) with boundary.

Below, our parameter space will be a manifold, assumed to be Riemannian, finite-dimensional, compact, connected, oriented, and with boundary. Having specified such a space (call it $\overline{\Theta} = \Theta \cup \partial\Theta$), one would then develop a likelihood function which describes how the data came about (i.e., a model of the technology) and a prior probability measure describing a priori knowledge of the parameter. Their joint interaction results in a posterior probability measure π on $\overline{\Theta}$.

After developing the posterior probability measure π, we develop methods for sampling from this posterior measure (with respect to a reference measure) via the "objective function"

$$h(\cdot) = -\ln q(\cdot),$$

where q is the posterior density function on $\overline{\Theta}$. The sampling will be achieved by running a discretization of a time-homogeneous diffusion on $\overline{\Theta}$. In a linear space, the diffusion would be defined by the Langevin equation

$$d\,X_t = -\frac{1}{2}\,\nabla h(X_t)dt \,+\, dW_t, \tag{1.1}$$

where $\{W_t, t \geq 0\}$ is a standard Wiener process. Heuristically thinking of h as a potential energy, the above diffusion would be defined by a Fokker–Planck equation for which $q = e^{-h}$ is the time-independent (i.e., steady-state) solution. To make this precise, one needs to prove an ergodic theorem (see section 8).

On a Riemannian manifold with boundary, the above diffusion in linear space is replaced by the diffusion $\{\theta_t, t \geq 0\}$ generated by the operator

$$A = \frac{1}{2}(\Delta - \nabla h) \tag{1.2}$$

and the boundary operator

$$L = \frac{\partial}{\partial n} \qquad \text{(derivative in the normal direction)},$$

where ∇ and Δ are the gradient and Laplacian on $\overline{\Theta}$, and there is reflection at the boundary.

In section 6, we discuss a practical issue that can arise in settings where the imaging is done in dimensions that are not specifically calculated (as can occur in

ultrasound). Since the original space $\overline{\Theta}$ is not completely determined in practice, in order to actually implement a discretization of the time-homogeneous diffusion process on $\overline{\Theta}$, we must run our algorithm on a normalized space, $\overline{\Theta}_0$, via a transformation of units. The consequence is that a scaling factor (from a change of variables) may be needed in order to put the gradient and the Brownian motion on the same scale.

2. Overview of algorithm and related literature.

2.1. Procedure: Simulation from the posterior measure π. The time-homogeneous diffusion $\{\theta_t, t \geq 0\}$ on $\overline{\Theta}$ will be shown to be ergodic with invariant measure π (whose density is q). Hence θ_t, for large t, represents (in an asymptotic sense) sampling from the desired posterior measure π, where π incorporates prior knowledge about θ and information from the observed data (in the present case, the ultrasound images).

2.2. Analysis: Automation of the BPD measurement. Recall that the motivating objective of our work is to automate various processes involved in the prenatal ultrasonic monitoring of fetal growth and development. In particular, the problem considered is that of automatically determining the BPD measurement of a fetus, given a sequence of two-dimensional ultrasound images of the fetal head. The approach taken here is to probabilistically recover the three-dimensional fetal head and then to acquire the BPD measurement from the recovered (estimated) head. An estimate for the "true" fetal head is obtained by sampling from the posterior measure on $\overline{\Theta}$ as described above.

We implement and apply a discretization of the diffusion $\{\theta_t, t \geq 0\}$ to actual ultrasound images of a fetal head. Each run of the algorithm results in an estimated "true" three-dimensional fetal head from which BPD measurements can be taken.

Note. To establish the theoretical basis for the present algorithm, an alternative approach could be pursued. One could imbed (by Whitney's theorem [34]) the d-dim manifold in $\mathbb{R}^N$ for some N, extend the function on the imbedded surface to a function on a larger N-dim rectangle without introducing any new global minima, and then apply the result of Geman and Hwang [5] in $\mathbb{R}^N$. (The present authors have, in fact, established such results.) The difficulty with such an approach is that the geometry of the imbedded surface could (and ordinarily would) be quite different from that of the original manifold, and the value of N needs to potentially be much larger ($2d$ or $2d+1$). One could consider an isometric imbedding (Nash's theorem [30]), but then the required dimension is even larger ($n(3n+11)/2$). The addition of a boundary in the present case complicates things even further. From a practical perspective, if one wants a theoretical structure for which the geometry is directly applicable to the construction of the algorithm, then it is most natural to establish the results directly, within the context of Riemannian geometry.

Our theoretical result can be viewed as a generalization to the time-homogeneous case for a manifold of the results of Geman and Hwang [5], who considered a compact rectangle in $\mathbb{R}^d$, and Chiang, Hwang, and Sheu [4], who extended the previous result to the case of all of $\mathbb{R}^d$. The focus of those papers was primarily on the time-inhomogeneous case, where dW_t is replaced by $c(t)dW_t$ with $c^2(t) \propto 1/(1+\ell n\, t)$ slowly decreasing to zero, as in simulated annealing. In Shorter [32] and Keenan and Shorter [21], we consider stochastic relaxation and simulated annealing on a manifold without boundary; the motivation of the latter is to perform maximum likelihood estimation (MLE) and MAP estimation for such examples as described in the next section. Holley, Kusuoka, and Stroock [14] consider continuous-time annealing on

a compact manifold, but with different goals in mind. Grenander and Miller [12] and Srivastava et al. [33] consider parameter spaces consisting of a countable union of Lie groups, each of a different dimension, and construct jump-diffusion processes, where the jumps are between the different Lie groups. There is no boundary to the manifolds within their formulations.

3. Prenatal ultrasonic assessment.

3.1. Ultrasound imaging. The underlying principles of ultrasound imaging are essentially the same as those in other echo ranging systems, where the range to an object is determined by knowing the speed at which sound is traveling in the given medium and measuring the amount of time required for a generated sound pulse to travel to and echo back from the object. Specifically in medical ultrasound, the transducer (the vibrating source that creates ultrasound waves) produces a short pulse of ultrasound, typically three or four vibrations, at a frequency in the 2–10 MHz range. The pulse propagates away from the transducer into the patient in the plane of the transducer.

One of the primary reasons that ultrasound can be used to accurately image structures within the human body is that the speed of sound (c) in different human soft tissues is very similar. Thus, in medical ultrasound c can be taken to be constant (usually 1540ms^{-1}), since in most cases the ultrasound wave is propagating through soft tissue of one kind or another. In prenatal ultrasonic examinations of the fetal head, the constant c is still taken to be 1540ms^{-1}, despite the significant presence of bone. In this case, the accuracy of the approximation is spared by the fact that the bones of the fetal skull are less calcified than in postnatal life.

As an ultrasound wave propagates through tissue, its direction and intensity change due to several processes, reflection being the most informative. Under certain circumstances, when an ultrasound wave encounters a boundary between different media (called an interface), it is redirected according to the laws characterizing optical reflection (the process occurring when light strikes a reflecting surface). The redirected wave, now referred to as an echo, reflects off of the interface at an angle equal to the angle of incidence. The various factors affecting the process of reflection at a particular interface include the size, roughness, and orientation of the interface. For optimum reflection, the interface must be large and smooth relative to the wavelength and oriented perpendicularly to the incident wave.

The intensity of the echo differs from that of the incident wave because not all of the incoming energy is reflected at an interface. A portion of the energy is reflected, but the rest is transmitted into the next medium, unaffected by the interface, where it is available for reflection by deeper structures. The fraction of the energy which is reflected depends upon the change in certain acoustic properties of the medium from one side of the boundary to the other.

For example, an echo reflecting from a boundary between two different soft tissues will have low intensity, while the transmitted wave will retain most of the original energy. At soft tissue/bone and soft tissue/air interfaces, however, most of the energy is reflected, resulting in strong (high intensity) echoes and weak (low intensity) transmitted waves. When the fraction of energy reflected is very large, "shadowing" occurs, where no structures beyond the interface are imaged because almost no energy is transmitted through the interface.

The same transducer that transmitted the original ultrasound pulse now acts as the receiver of its echoes. Many echoes, however, will not be detected. If the angle of reflection (equivalently, the angle of incidence) is very large at all, then the echo

may well miss the transducer and not be detected. Even if the reflected direction of the echo does point toward the transducer, the echo still may not be received if its intensity upon reflection is too low to sustain a detectable signal all the way back to the transducer. For those echoes that are received by the transducer, the imaging system is able to detect both the travel time and intensity of the wave. Travel time obviously gives the range to the object producing the echo, and intensity provides information about the reflectivity of the object. The form in which these values are displayed depends upon the particular type of ultrasound imaging system being used.

The imaging system considered here is called a B-scanner. The B-scanner produces recognizable two-dimensional images of anatomical sections. B-scan images are referred to as "slices" since what is being viewed in such images is the intersection of a plane (the plane of the transducer) with the three-dimensional object being imaged.

One ultrasound pulse creates one "scan line" of a B-scan image, extending from the transducer outward in the original direction of the wave. Each reflected echo from this pulse is plotted as a bright dot along the scan line at a distance equal to the calculated range of the object from the transducer. The intensity information is displayed using varying degrees of brightness (hence the name B (for brightness)-mode); the greater the amplitude, the greater the brightness of the dot. Therefore, a highly reflective interface will be imaged very brightly, while less reflective interfaces will be displayed less brightly.

A common arrangement of the scan lines is to make all of the scan lines parallel, creating a rectangular image. This format is produced by a "linear scanner" and is the format usually chosen for use in prenatal ultrasound. The simplest electronic arrangement that achieves the linear format consists of an array of small independent transducers lined up side by side, forming a "linear array probe." Each transducer in the array fires and receives its own scan line, corresponding to a single column in the image.

For the purposes of storage and display, the B-scan image is digitized and written into a matrix of memory (typically of sizes near 256×256 or 512×512). A given pixel corresponds to a single dot in the displayed image, and the integer gray scale value corresponding to the brightness of that dot is the measurement stored at that pixel location. The gray scale values are integers ranging from 0 to 255, where 0 denotes black, 255 denotes white, and the values between correspond to varying levels of gray. We henceforth can regard ultrasound images as $M \times K$ matrices whose components are integers ranging from 0 to 255.

The description given above of the process of ultrasonic imaging is, of course, greatly simplified. For example, there are several additional processes, besides reflection, which affect the direction and intensity of an ultrasound wave as it propagates through tissue. Two such processes are absorption (where a portion of the energy of a wave is lost as it is converted into heat) and scattering. Unlike reflection, which occurs at interfaces, scattering and absorption occur throughout the path of a wave.

Typically within regions of soft tissue there are many "targets" which are very small and rough. When an ultrasound wave strikes these targets, reflection does not occur since the process of reflection requires large flat targets. Scattering, however, does occur at such targets, resulting in relatively weak echoes redirected (scattered) in almost all directions. Most of the wave's energy is transmitted through the scattering point unchanged, but the intensity of the scattered echoes is often high enough to be detected by the receiver, producing dim discontinuous images of various soft tissue regions.

Regardless of the form of energy used by an imaging system, the digital images

produced are not "true" sampled versions of what is really there. For our purposes, the term "noise" will be used to describe all forms of degradation and distortion of the image. These include errors occurring in the sensing mechanism, blurring as a result of scattering, and artifacts such as shadowing, clutter (nonrandom scene structure other than an object of interest), and randomness inherent in both the physical system as well as the sensing and recording devices.

We can speak of a "true" or "ideal" image as the image we would obtain in an ideal system without noise, but the actual digital images produced by an imaging system will always contain some noise. We will call these actual images "noisy images." Specifically in ultrasound imaging systems, we notice that the images produced are very noisy.

(References for the material presented in this section include [13] and [24].)

3.2. BPD measurements. Ultrasonic imaging is particularly well suited for use in prenatal medicine because of its safety advantages and the membranous nature of some fetal bones. Doctors perform prenatal ultrasonic examinations to estimate gestational age as well as monitor the growth and development of the fetus in utero. Fetal growth is characterized by numerous anatomic changes, but measuring the change in size of various anatomic structures has become the primary means of assessing this growth. Since ultrasonic images are two-dimensional, the most practical measures of size are circumferences, diameters, and areas of anatomic planes. Of these three parameters, diameters are the least difficult to actually measure.

The most extensively studied diameter in the fetus is the BPD. This is a specific diameter of the fetal skull on the plane through the head located just above the ears, which contains both frontal and occipital bones of the skull. Referring again to Figure 1, the ultrasound image pictured in the top row, second from the right, was taken at the BPD plane.

BPD measurements for an individual fetus are useful in the growth evaluation or age estimation of that fetus only when compared to previous BPD measurements of the same fetus and/or standard growth curves and standard BPD charts. It is critical, therefore, that BPDs be consistently reproducible according to a standard measurement technique. The most difficult aspect of achieving this is reproducibly selecting the anatomical plane on which the measurement will be made.

An anatomic approach is commonly used as the standard method for selecting the BPD plane. In this approach, several intracranial landmarks are identified and used as guides in maneuvering the scan plane into the proper position. First, the relative position of the fetal spine and head is determined. The orbits are then identified, and the scan plane is guided into a lateral axial position at the base of the fetal skull. Once this is done, the scan plane is moved up the head, remaining parallel to the plane at the base of the skull. Various anatomical structures are noted and minor adjustments are made to keep the scan plane parallel until the BPD plane is finally reached, at approximately the level of the lateral ventricles.

A fundamental difficulty is the fact that BPD measurements are extremely sensitive to variations in the selected plane. Inaccuracies as large as one cm have been recorded for measurements taken on planes other than the ideal BPD plane. In order to obtain global reproducibility of these measurements, therefore, one must look toward automating the processes involved. The approach of this paper hopes to overcome the difficulties inherent in the present process by presenting, implementing, and justifying a procedure for automation.

(References for the material presented in this section include [3] and [23].)

4. A probabilistic model for ultrasonic imaging of a fetal head. Our approach uses the general methodology of a *deformable template* (see [9], [10], [11], [12]), which attempts to utilize high-level prior knowledge about an object being imaged by assuming the existence of a known reference object, called a template ($\mathcal{T}$). A space of possible transformations is defined in order to preserve certain characteristic features of the template, and it is assumed that the "true" object being imaged can be obtained by applying a transformation from this space to the template. Hence, the space of "deformed" templates (objects resulting from applying transformations to the template) constitutes the set of all possible "true" objects. An actual image acquired with a sensing device is then a noisy degradation of a "true" image generated from a particular deformed template via some model-specific mapping.

4.1. Construction of the template and space of transformations. The simplest possible formulation of the probabilistic recovery of the fetal head is to imagine the fetal head as being known, except for its location, orientation, and scale—that is, known up to a similarity transformation. Thus, in the framework described above, the template, $\mathcal{T}$, is taken to be a three-dimensional approximation of an "average" fetal head, and all possible locations, scales, and rotations of the fetal head make up the space of transformations, $\overline{\Theta}$. Given a sequence of ultrasound images, an estimate is made from this space of transformations, which, when applied to $\mathcal{T}$, constitutes the recovered fetal head.

4.1.1. The space of transformations, $\overline{\Theta}$. One can view the fetal skull as being contained in a known compact three-dimensional rectangle, say, $B_1 = \prod_{j=1}^{3} [0, L_j]$. If we assume that $B_2 = [L_4, L_5]$ is a known range of scale, then $\overline{\Theta}$ and the image of $\mathcal{T}$ under $\overline{\Theta}$ (call it $\overline{\Theta}(\mathcal{T})$) are given as

$$\overline{\Theta} = B_1 \times B_2 \times SO(3),$$
$$\overline{\Theta}(\mathcal{T}) = \{\theta(\mathcal{T}),\, \theta \in \overline{\Theta}\}.$$

Even this case is not as straightforward as it may seem. Methods can be developed which extract some crude information in the preprocessing stage concerning the location and scale of an object. However, this is not true in the case of an object's orientation. It is the rotation part of the parameter which ordinarily is very difficult to estimate. Systematic searches through the space of possible locations, scales, and rotations, even when crude initial estimates are made concerning location and scale, are extremely time-consuming. Additional difficulties arise due to the fact that biological and man-made objects often have many approximate symmetries which create local maxima for the likelihood. It is necessary, therefore, to search the space of transformations ($\overline{\Theta}$) in a semi-intelligent manner. Since $SO(3)$ is not a linear space, the search must also fully consider the geometry of the manifold $SO(3)$.

4.1.2. The template, $\mathcal{T}$. Two different fetal head templates were constructed. The first is a polyhedral approximation of an "average" fetal head, (V, P), where V contains 162 vertices and P contains 320 index triplets representing the 320 triangular faces of this polyhedron. The edge and face structures are those resulting from refinements of the icosahedral graph structure (see [10]). The fetal head template was constructed from a mold of an authentic fetal skull borrowed from the University of Virginia Medical Center Anatomy Laboratory. Using a Polhemus 3D Digitizer, the locations of 162 points on the surface of the skull model were recorded and taken as the 162 vertices of the polyhedron. The resulting polyhedron is displayed (from four different views) in the first row of Figure 2. As a three-dimensional object, the polyhedral

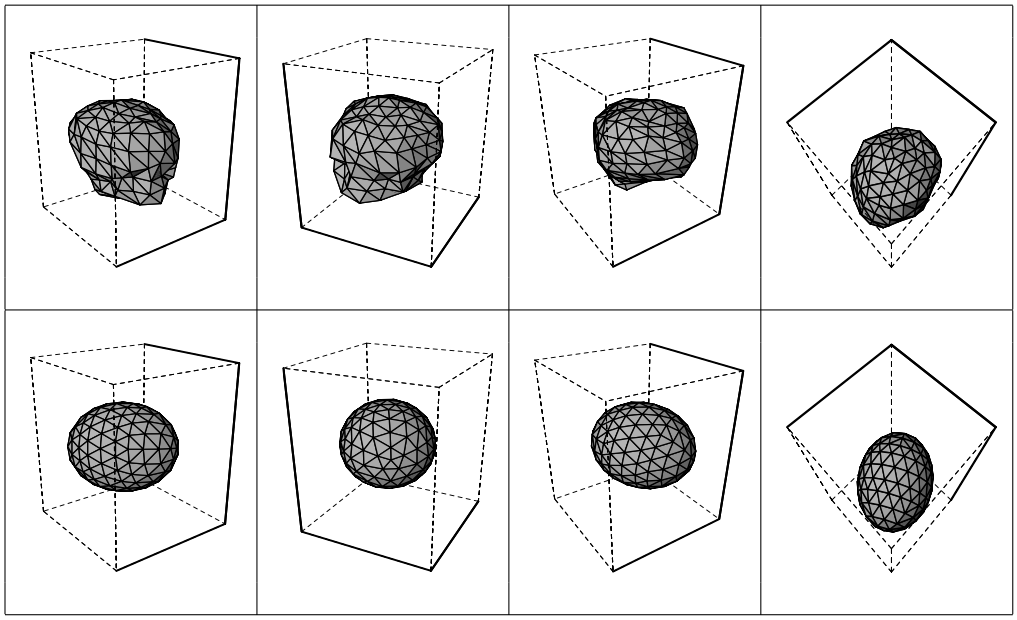

FIG. 2. *Fetal head templates. The polyhedral template is viewed from four different angles in the top row, and the ellipsoid template is viewed from four different angles in the bottom row.*

template provides a surprisingly good approximation of a fetal head. When generating "true" images, however, such a template results in a model-specific mapping that is computationally very complex, since it requires calculating the intersection of the polyhedron with a plane.

The second fetal head template is simply an ellipsoid. Representing the template as the solution to an implicit surface equation (e.g., as an ellipsoid) greatly reduces the level of complexity, and, depending upon the three-dimensional object, may result in a relatively small loss or even a gain in the accuracy of the approximation. The authors plan to use both templates in further investigations; in the present paper, only the ellipsoidal model is used.

The ellipsoid template, $\mathcal{T}$, is defined by

$$\mathcal{T} = \left\{ (x, y, z) \in \mathbb{R}^3 : \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1 \right\},$$

where a, b, and c are positive constants which determine the dimensions of the ellipsoid along the x, y, and z axes, respectively. These constants are taken to be a fixed part of the template and hence represent some prior knowledge about the general shape of a fetal head. Their values were estimated beforehand so that the dimensions of several ellipses, obtained by intersecting the ellipsoid with particular planes, most closely matched the corresponding dimensions of a fetal head in several two-dimensional ultrasound slices acquired under controlled conditions. The resulting ellipsoid (displayed from four different views in the second row of Figure 2) is a surprisingly accurate model for at least the top half of a fetal head (the relevant region for this problem). In addition, having an analytic expression for the template allows for quick and easy determination of normals to the surface, as well as whether a particular point lies on, inside, or outside the template, which greatly lowers the

complexity of certain crucial calculations.

4.2. A model for ultrasonic imaging (construction of a likelihood function). Given the ultrasound data images, we wish to estimate the unknown true parameter, $\theta^* \in \overline{\Theta}$ (say, with estimate $\hat{\theta} \in \overline{\Theta}$), and in so doing, indirectly recover the associated deformed template, $\hat{\theta}(\mathcal{T})$, and hence a plausible "true" object. As mentioned in the introduction of this paper, our estimation procedure involves sampling from the posterior measure, π, on $\overline{\Theta}$. In order to construct the posterior distribution, we must first model the ultrasonic imaging technology by defining the "model-specific mapping" which generates "true" images from a given deformed template, $\theta(\mathcal{T})$. Once this is done and a model for the degradation of an image is constructed, a family of density functions can be introduced which are indexed over the space of transformations, $\overline{\Theta}$, and which describe the distribution on the space of images, given a particular transformation, $\theta \in \overline{\Theta}$. The density functions then give rise to a likelihood function on $\overline{\Theta}$, given the data images. The details of the development described above are provided in this section.

4.2.1. The data images. Eight frames from a complete real-time ultrasonic fetal head examination are shown in Figure 1. These eight ultrasound images constitute our collection of data images. They were taken in roughly parallel planes. Approximate distances between the planes were calculated from information available on the video. Hence, it can be assumed that the ultrasound data images represent known planes within the three-dimensional rectangle, B_1.

Let $D^{(k)}$, $k = 1, \ldots, N$, be the N data images. Recall that the images produced are noisy degradations of "true" images, and they are stored as matrices (of size $M \times K$, say) whose components are integer gray scale values ranging from 0 to 255. Hence, for $k = 1, \ldots, N$,

$$D^{(k)} = \{d_{ij}^{(k)}\}_{M \times K},$$

where each $d_{ij}^{(k)}$ is an integer value in $[0, 255]$. We can assume, without loss of generality, that the box B_1 is oriented so that the data images, $D^{(k)}$, occur in parallel xz-planes within the box, specifically located at "slice planes," $y = y_k$, $k = 1, \ldots, N$.

4.2.2. A model for the degradation of an image. We will assume that degradation of an image is modeled by additive Gaussian noise at each pixel location. Given a particular $\theta \in \overline{\Theta}$, one can think of creating a noisy image by adding Gaussian noise (with mean zero) to each pixel value of the "true" image obtained from the template deformed by the transformation θ.

In addition, assume the independence of individual pixel measurements given the "true" image. This is not an unreasonable assumption, and since the "true" image is obtained from a particular transformation via the model-specific mapping, it is equivalent to assuming the independence of pixel measurements given a particular $\theta \in \overline{\Theta}$. Therefore, given the transformation $\theta \in \overline{\Theta}$, for $i = 1, \ldots, M$, $j = 1, \ldots, K$, $k = 1, \ldots, N$,

$$\{X_{ij}^{(k)} = \text{ integer gray level at pixel location } (i, j) \text{ of image taken in plane } y = y_k\}$$

are independent random variables with normal distributions given by

$$X_{ij}^{(k)} \sim N(\mu_{ij}^{(k)}(\theta), \sigma),$$

where the standard deviation, σ, is a fixed constant (estimated from the data images prior to analysis). Keep in mind that the actual acquired ultrasound image $D^{(k)} = \{d_{ij}^{(k)}\}$ is one realization of the matrix of random variables $\{X_{ij}^{(k)}\}$.

4.2.3. The model-specific mapping (modeling the technology). Clearly for $k = 1, \ldots, N$ the matrix of integer values $\{\mu_{ij}^{(k)}(\theta)\}$ constitutes the "true" image obtained from the template deformed by the transformation θ. In other words, it is the "expected" or "mean" image created by the model-specific mapping, given the transformation θ. Define

$$I(i, y_k, j|\theta) = \mu_{ij}^{(k)}(\theta)$$

for $i = 1, \ldots, M$, $j = 1, \ldots, K$, $k = 1, \ldots, N$. Let us refer to $\{I(i, y_k, j|\theta)\}_{M\times K}$ as the "mean image" at the slice plane $y = y_k$, given the transformation θ.

We will now consider the construction of the mean image, $\{I(i, y_k, j|\theta)\}_{M\times K}$. Recall that $\mathcal{T}$ is simply an ellipsoid,

$$\mathcal{T} = \left\{(x, y, z) \in \mathbb{R}^3 : \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1\right\},$$

where a, b, and c are positive constants which determine the dimensions of the ellipsoid along the x, y, and z axes, respectively. Let Ψ be defined as

$$\Psi(x, y, z) = \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} - 1.$$

For $i = 1, \ldots, M$, $j = 1, \ldots, K$, $k = 1, \ldots, N$, and $\theta = (\bar{X}, Y) \in \overline{\Theta}$ ($\bar{X} = (X_1, X_2, X_3, X_4)$, where $(X_1, X_2, X_3) \in B_1$ is the location, $X_4 \in B_2$ is the scale, and $Y \in SO(3)$ is the rotation), define

$$I(i, y_k, j|\theta) = \beta \cdot \exp\left\{-\alpha \cdot \Psi^2\left(Y^{-1}\left(\frac{1}{X_4}\left((x_i, y_k, z_j) - (X_1, X_2, X_3)\right)\right)\right)\right\},$$

where $x_i = \frac{i}{M} \cdot L_1, z_j = \frac{j}{K} \cdot L_3$ (which splits the xz-plane into a lattice of pixel locations).

The function I, as it is defined above, assigns pixel values to points in the three-dimensional space, B_1. The brightest value, β (typically taken to be 255 = white), is assigned to those points which lie directly on the ellipsoid $\theta(\mathcal{T})$. The brightness values then decrease continuously (as on the normal density curve) as one moves away from $\theta(\mathcal{T})$ in the normal and negative normal directions. This model creates a two-dimensional mean image which is brightest at the intersection of the plane $y = y_k$ with the ellipsoid $\theta(\mathcal{T})$, and which has a slowly dimming band around this intersection giving the template some "thickness." Notice that the constant α controls the bandwidth and the constant β controls the maximum gray level assigned.

Upon actual implementation of this model, it was discovered that having the pixel values decrease all the way to zero (black) was creating images that, when compared to real ultrasound images, were far too dark. Therefore, the model was adjusted so that gray level values decrease down to a fixed value of $\beta_1 > 0$ as one moves inward in the normal direction away from the ellipsoid $\theta(\mathcal{T})$, and down to a fixed value of $\beta_2 > 0$ as one moves outward in the normal direction away from the ellipsoid. The particular values used for β_1 and β_2 are estimated from the actual images before the algorithm is run. The adjusted definition for the function I is given below. Notice

that the change increases the minimum gray level (to β_1 or β_2) while keeping the maximum gray level fixed at β.

$$I(i, y_k, j|\theta) = \begin{cases} (\beta - \beta_2) \cdot \exp\{-\alpha \cdot \Psi^2\} + \beta_2 & \text{if } (x_i, y_k, z_j) \text{ lies outside } \theta(\mathcal{T}), \\ (\beta - \beta_1) \cdot \exp\{-\alpha \cdot \Psi^2\} + \beta_1 & \text{if } (x_i, y_k, z_j) \text{ lies inside/on } \theta(\mathcal{T}). \end{cases}$$

See Figures 3 and 4 for illustrations of the model-specific mapping and degradation model described above. Notice in Figure 4 that neither the model-specific mapping nor the image degradation model attempts to capture any of the artifacts in the interior of the fetal head clearly present in the actual ultrasound images. Some of these artifacts are reflections from intracranial anatomical structures. Those structures that are consistently present and prominent in the typical fetal head during the appropriate age-range could be built into the model-specific mapping. We may attempt to implement such additional structures in the model-specific mapping for future refinements of our algorithm. In the current algorithm, however, we have found that focusing the model on the roughly ellipsoidal and well-formed fetal skull captures information that, because of its large continuous nature, provides strong direction to the gradient-descent algorithm.

4.2.4. The likelihood function. Given the distribution of the family of random variables $\{X_{ij}^{(k)}\}$, we can write down the likelihood function L on the parameter space $\overline{\Theta}$. For each $\theta \in \overline{\Theta}$,

$$L(\theta \mid D^{(1)}, D^{(2)}, \ldots, D^{(N)}) \propto \exp\left\{ -\frac{1}{2\sigma^2} \left(\sum_{k=1}^{N} \sum_{i=1}^{M} \sum_{j=1}^{K} \left(d_{ij}^{(k)} - I(i, y_k, j|\theta) \right)^2 \right) \right\}$$

describes the likelihood L of the transformation θ, given the sequence of data images $D^{(1)}, D^{(2)}, \ldots, D^{(N)}$. Then the negative log likelihood is given by

$$-\ln\, L(\theta \mid D^{(1)}, D^{(2)}, \ldots, D^{(N)}) = \frac{1}{2\sigma^2} \left(\sum_{k=1}^{N} \sum_{i=1}^{M} \sum_{j=1}^{K} \left(d_{ij}^{(k)} - I(i, y_k, j|\theta) \right)^2 \right) + \text{ const.}$$

5. The algorithm.

5.1. Procedure: Generating realizations from the posterior distribution. A prior distribution on $\overline{\Theta}$ may also be constructed, incorporating additional prior knowledge about the fetal head. Given $p(\theta)$, a prior density on $\overline{\Theta}$, and the likelihood function defined above, Bayes' formula yields a posterior density function q on $\overline{\Theta}$, given the sequence of data images $D^{(1)}, D^{(2)}, \ldots, D^{(N)}$:

$$q(\theta|D^{(1)}, D^{(2)}, \ldots, D^{(N)}) \propto L(\theta|D^{(1)}, D^{(2)}, \ldots, D^{(N)}) \times p(\theta).$$

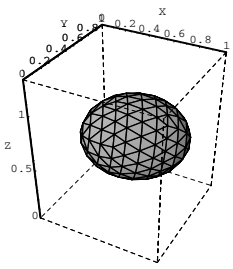
We may then define the "objective function" $h(\cdot)$ via the following relationship:

$$e^{-h(\theta)} = q(\theta) \qquad \text{or} \qquad h(\theta) = -\ln q(\theta).$$

In practice, because of the immense amount of information in the likelihood, we have used a uniform prior on $\overline{\Theta}$.

Recall that sampling from the posterior distribution will be achieved by running the manifold version of "$d\,\theta_t = -\frac{1}{2}\,\nabla h(\theta_t)dt + dW_t$." The resulting diffusion process on the manifold $\overline{\Theta}$ is generated by the operator

$$A = \frac{1}{2}(\,\Delta - \nabla h)$$



Ellipsoid template, $\mathcal{T}$.

$\mathcal{T} = \left\{(x, y, z) \in \mathbb{R}^3 : \ \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1\right\}$, where a, b, and c are positive constants.

FIG. 4. *A model for the degradation of an image. We model the degradation of an image by additive Gaussian noise at each pixel location. Given a particular transformation, one can think of creating a noisy image by adding Gaussian noise (with mean zero) to each pixel value of the "mean image" obtained from the template deformed by the transformation. Such a process leads to the following construction: Given a transformation* θ*, the family of random variables* $\{X_{ij}^{(k)}\}$*, giving the gray level values for each pixel location* (i, j) *in slice plane* $y = y_k$*, are independent and normally distributed:* $X_{ij}^{(k)} \sim N(\mu_{ij}^{(k)}(\theta), \sigma)$*, where the matrix of integer values* $\{\mu_{ij}^{(k)}(\theta)\}$ *constitutes the mean image obtained from the template deformed by* θ*, and* σ *is the image degradation standard deviation.*

and boundary operator

$$L = \frac{\partial}{\partial n} \qquad \text{(derivative in the normal direction)}.$$

The function h is a real-valued function on $\overline{\Theta} = B_1 \times B_2 \times SO(3)$. At algorithmic time t, denote the value of $\theta(\in \overline{\Theta})$ as θ_t. Let $X_t \in B_1 \times B_2$ denote the location and scale part of θ_t and $Y_t \in SO(3)$ the rotation part. Then $\theta_t = (X_t, Y_t)$. Let $h_Y(X)$ represent the function $h(\theta)$ on $B_1 \times B_2$ with $Y \in SO(3)$ fixed and X varying over $B_1 \times B_2$. Similarly, let $h_X(Y)$ represent the function $h(\theta)$ on $SO(3)$ with $X \in B_1 \times B_2$ fixed and Y varying over $SO(3)$.

Let $so(3)$ denote the Lie algebra of skew-symmetric matrices and J the canonical isomorphism $J: \mathbb{R}^3 \to so(3)$ given by

$$J(x_1, x_2, x_3) = \begin{pmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{pmatrix}.$$

For $A \in so(3)$, let $\exp(A)$ be defined as

$$\exp(A) = \sum_{n=0}^{\infty} \frac{A^n}{n!}.$$

Also, for $Y \in SO(3)$, let L_Y denote left translation by Y. Then the function $h_X : SO(3) \to \mathbb{R}^3$ can locally (near $Y \in SO(3)$) be viewed as the following composition:

$$\begin{array}{ccccccccc} \mathbb{R}^3 & \xrightarrow{J} & so(3) & \xrightarrow{\exp} & SO(3) & \xrightarrow{L_Y} & SO(3) & \xrightarrow{h_X} & \mathbb{R}. \\ \text{Near} & & \text{Near} & & \text{Near} & & \text{Near} & & \\ \text{zero} & & \text{zero} & & \text{identity} & & Y & & \end{array}$$

The gradient of h_X at a point $Y \in SO(3)$ is obtained by analytically calculating the (exact) gradient of the mapping diagrammed above, which then gets "pushed" across by the differential maps of J and exp.

Let $\delta t_i = t_i - t_{i-1}$ be the time step size and $N_p(0,1)$ be a realization from a p-variate standard normal distribution. The *algorithm* on the manifold $\overline{\Theta} = B_1 \times B_2 \times SO(3)$ is given by

$$\theta_{t_{i+1}} = (X_{t_{i+1}}, Y_{t_{i+1}}), \tag{5.1}$$

$$X_{t_{i+1}} = X_{t_i} - \frac{1}{2}(\delta t_i)\nabla h_{Y_{t_i}}(X_{t_i}) + \sqrt{\delta t_i} N_4(0,1), \tag{5.2}$$

$$Y_{t_{i+1}} = Y_{t_i} \times \exp\left[J\left\{ -\frac{1}{2}(\delta t_i)\nabla h_{X_{t_i}}(Y_{t_i}) \right\} + J\{\sqrt{\delta t_i} N_3(0,1)\} \right], \tag{5.3}$$

with reflection at the boundary of $\overline{\Theta}$ in the normal direction.

This algorithm is a discretization of the time-homogeneous diffusion process θ_t on the manifold $\overline{\Theta} = B_1 \times B_2 \times SO(3)$. The construction of a discrete approximation to Brownian motion on $SO(3)$ was considered by McKean [26]. Our algorithm is a version of that one with $-\frac{1}{2}\nabla h$ added as drift. For the $\{Y_t, t \geq 0\}$ part of θ_t, the above algorithm is the product injection formula for a stochastic flow on $SO(3)$ (see [26], [27]), except that now we have as the drift term a vector field which is not invariant, which makes a big difference.

For large t, θ_t is taken as a realization from the posterior distribution, π, on $\overline{\Theta}$, given the actual ultrasound images. This realization represents our estimate $\hat{\theta}$ of the "true" location, scale, and rotation of the fetal head. Applying the estimated transformation $\hat{\theta}$ to the ellipsoid template $\mathcal{T}$ yields an estimated (recovered) fetal head, $\hat{\theta}(\mathcal{T})$. In section 8, general theorems are proven which justify this methodology. Running the algorithm to obtain a sample from the distribution, π, is justified by proving that the time-homogeneous diffusion process converges weakly to the distribution π.

Figures 5 and 6 illustrate the time evolution of a single realization. The algorithm is run for 2000 steps in this example. In Figure 5, four of these steps are shown. In Figure 6, all 2000 steps of the same run are pictured via individual graphs of the time evolution of location, scale, and rotation. The final value, θ_{2000}, represents a single realization from the distribution π on $\overline{\Theta}$. Loosely speaking, the fetal head template will deform, trying to "best fit" the spatial sequence of ultrasound images while adhering to those constraints which define what are allowable deformations ($\overline{\Theta}$). Such a method can be expected to be broadly applicable to the general realm of object recognition in image processing and computer vision.

Note that different estimation procedures can be applied using the generated realizations from the posterior distribution π. It is clear from the graphs in Figure 6 that, even when the diffusion process converges quickly, choosing a specific large value of t for which $\hat{\theta} = \theta_t$ results in an estimated transformation that varies randomly (approximately according to the measure π). These estimates may vary a little (if the data is very strong) or they may vary a great deal. In either case, to account for the random variation, an "average" may be calculated from a simulated sample consisting of a finite number of generated realizations. However, how one calculates an average in the case of the rotation parameter is not clear. In our particular application, it would be possible (and appropriate) to recover an "average" fetal head by simply applying the average scale value obtained from the simulated sample to the fetal head template.

5.2. More general deformations. The above algorithm should move the template skull into the right location, overall size (scale), and orientation; this is really just the first stage. Local deformations would then be applied so that different regions of the template would be allowed to deform differently but still with certain local and/or global characteristics being preserved. For example, in the fetal skull context, the detection of Spina Bifida, where the cross section is *lemon shaped*, would require a deformation of the fetal skull template by means other than a similarity transformation. In [11] such local deformations, similar to elasticity theory, were proposed and appear to be applicable to this problem.

Recently, the general idea of transitions between global and local deformations has been made more rigorous and systematically implementable with the concept of the "group cascade." Its goal was not to speed up convergence, but rather to develop a framework, broadly applicable in biomedical settings, in which one could obtain a realistic representation of inherent biological variability [25].

6. Application of the algorithm: Reconstructing a fetal skull and calculating the BPD.

6.1. Analysis. In the general methodology of *deformable templates*, if one's aim is to gain some kind of structural understanding of an acquired two-dimensional image, then a "true" image can be generated from the (indirectly) estimated "true" object via the model-specific mapping. This particular "true" image is then taken as the noiseless

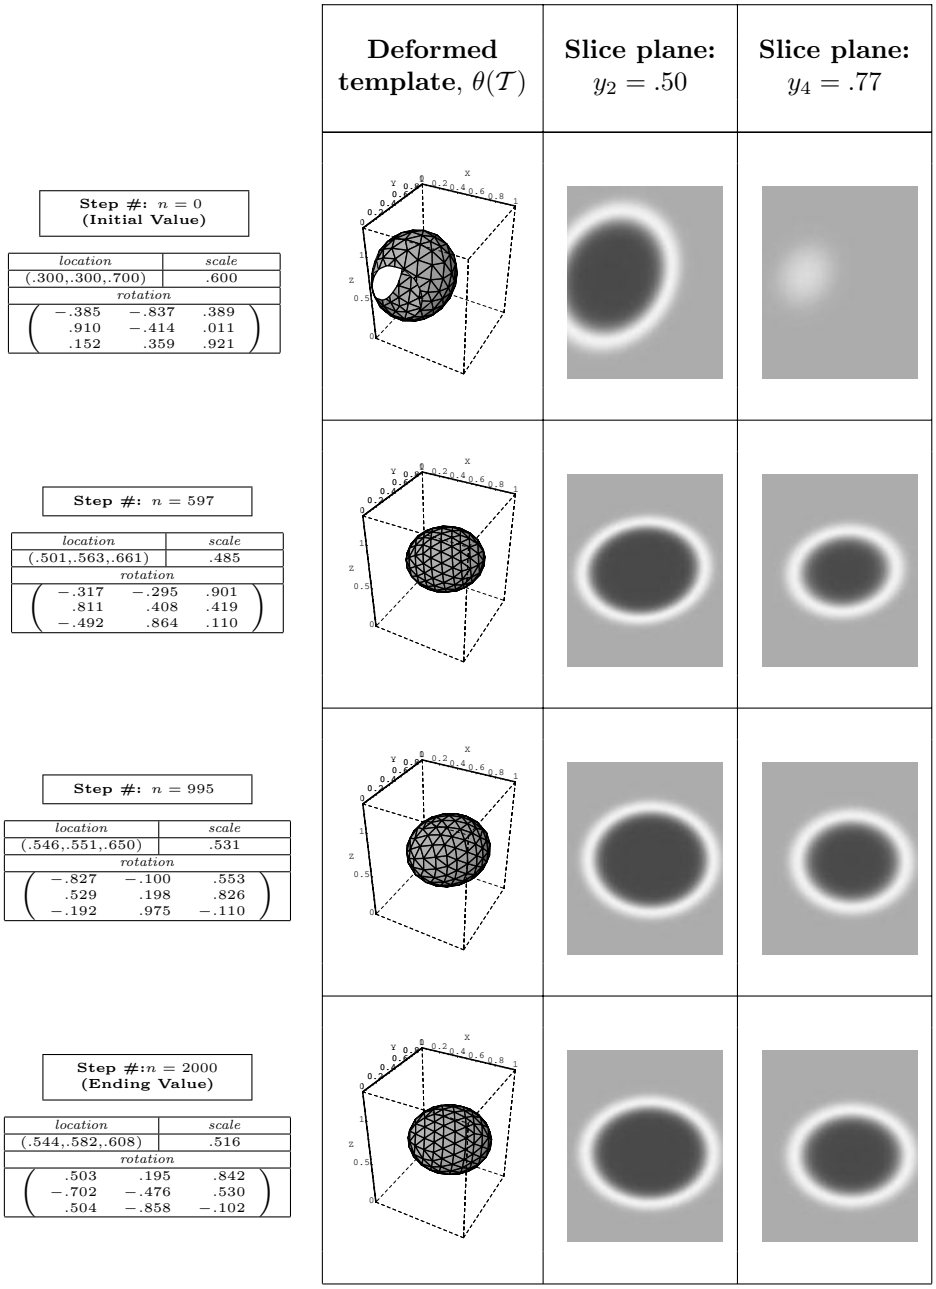

FIG. 5. *Time evolution of one realization. The figures shown above illustrate the value of the process at four distinct time steps within a single simulation. Column* 1 *shows the three-dimensional ellipsoid template transformed by the appropriate value of* θ. *Columns* 2 *and* 3 *show the intersection of the deformed template with the two slice planes,* y_2 *and* y_4, *thus creating "mean images," which are compared to the corresponding true ultrasound images in the algorithm. This particular simulation consists of* 2000 *steps of size* $\delta t = 1.0 \times 10^{-7}$.

Transformation space coordinate	**Full evolution** (2000 steps)	**Initial segment** (First 200 steps)
Spatial location: x-coordinate		Spatial location: y-coordinate		Spatial location: z-coordinate		Scale coordinate		Rotation parameter		
FIG. 6. *Time evolution of one realization—a closer look. The figures shown above illustrate in greater detail the time evolution of the same realization as that pictured in Figure* 5. *Each row contains two graphs of the time evolution of a single coordinate of the parameter space. The second column contains a full plot of each parameter coordinate as a function of the iteration step. The third column contains just the first* 200 *steps of the process, providing a magnified view of the convergence. Each of these graphs also displays, as a reference, a line indicating the true value of the parameter coordinate. The three spatial location coordinates and the scale coordinate are displayed in the first four rows. In the last row, the evolution of the rotation parameter is illustrated via a single function giving the cosine of the angle between the major axes of the ellipsoids obtained by applying the true rotation and by applying the current value of the rotation parameter.*

restored image. One distinct advantage of this type of methodology is that, since the restored image is generated from a deformed template, it contains all structural information contained in the template (see [1], [9], [28]). For example, landmarks defined on the template are mapped (via the composition of a transformation and the model-specific mapping) into corresponding landmarks in the restored image and can therefore be automatically located, or associated geometric measurements can be automatically made.

In the present case, however, it is the structure of the three-dimensional fetal head itself which is of interest and *not* the structure of the two-dimensional image. Recall that an eventual objective is to automatically measure the BPD of the fetal head, which is a two-dimensional diameter measurement, but since the data images are taken in predefined planes, the appropriate ultrasound slice for measuring the BPD (at the level of the BPD plane) is not necessarily included among the acquired data images. Therefore, restoring the data images is of no use in this problem since these particular images do not necessarily contain the desired information.

The information must come from the structure of the recovered "true" fetal head. As in the image restoration case described above, when using this methodology we have access to structural information in the recovered fetal head because it is generated from the original fetal head template. This would not necessarily be the case if we were, for instance, "reconstructing" the fetal head from acquired two-dimensional ultrasound slices by, in a sense, filling in the gaps. The BPD plane can be defined on the fetal head template and can be mapped (via a transformation alone in this case) to the corresponding BPD plane on any deformed template. Thus, we stop short of generating a "true" image and instead take the BPD measurement on the indirectly estimated deformed three-dimensional fetal head template.

Notice that the transformations in the current model include only locating, scaling, and rotating. Of these, only scaling affects the structure of the template. Since structure is what we are interested in, it might seem that estimation of location and rotation is completely unnecessary. However, it becomes clear that the scale of the template cannot be accurately recovered without also simultaneously recovering the location and rotation.

6.2. Results.

6.2.1. A normalized parameter space. In practice, because ultrasound imaging is typically done in dimensions that are not specifically calculated, a transformation of units, ξ, is necessary to take us from the original actual parameter space, $\overline{\Theta} = B_1 \times B_2 \times SO(3)$, to a normalized parameter space, $\overline{\Theta}_0 = B_1^0 \times B_2^0 \times SO(3)$, where $B_1^0 = [0,1]^3$ and $B_2^0 = [0,1]$. Since the original space $\overline{\Theta}$ is not completely determined in practice, in order to actually implement a discretization of the time-homogeneous diffusion process on $\overline{\Theta}$, we must run our algorithm on the normalized space, $\overline{\Theta}_0$, via a transformation of units.

Consider the linear transformation, $\xi : \overline{\Theta} \to \overline{\Theta}_0$. Recall that q is the posterior density function on the original space, $\overline{\Theta}$. The posterior density on the normalized space is given by

$$q_0(u) = q(\xi^{-1}(u)) \cdot |J(u)| \quad \text{for } u \in \overline{\Theta}_0,$$

where $|J(u)|$ is the Jacobian of the transformation ξ.

If we define $h_0(u) = -\ln q_0(u) = h(\xi^{-1}(u)) + \text{const}$ for $u \in \overline{\Theta}_0$, then

$$\nabla_u h_0(u) = \nabla_u(h(\xi^{-1}(u))) = \nabla_x h(\xi^{-1}(u)) \cdot \frac{\partial \xi^{-1}}{\partial u_i}(u) = \tau \cdot \nabla_x h(\xi^{-1}(u))$$

for a constant τ, assuming for computational reasons that $\frac{\partial \xi^{-1}}{\partial u_i}(u) = \tau \cdot I$, where I is the identity matrix. This simplification involves assuming that the transformation of units, ξ, scales identically in all parameters (including $SO(3)$).

We can now write the diffusion on $\overline{\Theta}_0$ as

$$dZ_t = -\frac{1}{2}\nabla h_0(Z_t)dt + dW_t,$$

where $\{W_t, t \geq 0\}$ is a standard Wiener process on $\overline{\Theta}_0$. Equivalently,

$$dZ_t = -\frac{1}{2}\tau \nabla_x h(\xi^{-1}(Z_t))dt + dW_t.$$

We see that when our diffusion is run on the normalized parameter space, we must multiply the gradient piece of the algorithm by the unknown constant τ.

6.2.2. Running the algorithm. To test the algorithm itself, independent of our model for ultrasonic imaging, a sample location, scale, and rotation value (say, $\theta^* \in \overline{\Theta}$) were chosen, and noisy simulated data images were created from the deformed template $\theta^*(\mathcal{T})$ via our model-specific mapping and degradation model. The algorithm was then run using these simulated images as data, rather than the actual acquired ultrasound images. Various algorithm parameters were adjusted for each of these test runs on simulated data, and the runs were repeated until the realizations produced were fairly well concentrated around the chosen test value, θ^*.

One parameter of particular interest is the constant discussed above, τ. This constant, a result of a transformation of units, is multiplied by the gradient piece of the algorithm. Without this constant multiple, our Brownian motion and gradient terms would be on different scales. The constant τ, therefore, has the effect of balancing the deterministic and stochastic parts of the algorithm.

Since typically the constant τ cannot be calculated, it must be estimated via the process discussed in the first paragraph above, in which partial test runs of the algorithm are observed, and then the value of the constant is adjusted until the realizations produced are fairly well concentrated around the chosen test value. Recall that we made estimates for σ, the standard deviation of the image degradation model, by analyzing the data images prior to running the algorithm. If those estimates are inaccurate, there will be a correction factor, which will appear as a constant multiple in front of the gradient. Therefore, our constant τ may also potentially incorporate any correction necessary for our estimate of σ.

In Figure 7, some realizations run on simulated data are pictured which illustrate the importance of the parameter τ. For example, if τ is too small, then the Brownian motion is overemphasized in the process. The balancing effect of τ is evident when one views runs of the algorithm at various values of the constant (Figure 7). In Figure 8, the same runs are pictured via individual graphs of the time evolution of location, scale, and rotation. This provides a more detailed look at the effects of τ on convergence. Notice the varying effects among each coordinate of the parameter space. For example, the time evolution of the convergence in the x-coordinate of the location parameter may look quite different than that of the scale parameter. This

Step #	$\tau = .00005$	$\tau = .01$	$\tau = .0005$	$\tau = .001$
Initial value: $n = 0$				$n = 297$				Ending value: $n = 1000$				Sample test value: θ^*				
FIG. 7. *The effects of varying the parameter τ. The figures shown above illustrate four different realizations running (on simulated data) at four different values of the parameter τ. Each column shows the ellipsoid template, $\mathcal{T}$, transformed by the nth value of θ_t in that realization (for three n values), and compares the ending ellipsoid (shown in row 3) to the sample "true" ellipsoid, $\theta^*(\mathcal{T})$ (shown in row 4). The realization pictured in column 1 has a very small τ value, overemphasizing the Brownian motion, which causes the template to jump out of the viewing box. The realization pictured in column 2 has a very large τ value. With the Brownian motion underemphasized, this realization falls into a local minimum and is unable to escape. The τ values used in the realizations pictured in columns 3 and 4 perform better. Column 3 illustrates a realization which jumps out of a local minimum that it falls into early on but then continues to jump around the test value θ^*. Column 4 illustrates a realization which converges nicely to a θ value which is very close to the test value θ^*.*

Transformation space coordinate	**Parameter value** $\tau = .01$	**Parameter value** $\tau = .0005$	**Parameter value** $\tau = .001$
Location: x-coordinate			Location: y-coordinate			Location: z-coordinate			Scale coordinate			Rotation parameter			
FIG. 8. *The effects of varying the parameter—a closer look. The figures shown above illustrate in greater detail the time evolution of three of the four runs pictured in Figure* 7. *Each row contains a plot of a single coordinate of the parameter space as a function of iteration step, and each column corresponds to the different values of the constant* τ *used. The full run in each case pictured above is* 1000 *steps. No further information was provided by these more detailed graphs in the case of* $\tau = .00005$ *from Figure* 7, *so it was not included in this figure. Note, however, the following details illuminated by the graphs provided for the other three* τ *values: For* $\tau = .01$, *one can clearly see convergence into a local minimum in each component of the paramter space. Comparing the effects of* $\tau = .0005$ *and* $\tau = .001$, *one can see (in each of the plots) slightly more scatter about the "true" value for* $\tau = .0005$.

is surely a result of using a single constant multiple for the constant τ rather than a matrix of values, a simplifying assumption made in the previous subsection. A single value cannot balance all dimensions of the parameter space equally well. However, making this practical approximation does not seem to significantly affect the overall success of the algorithm but merely alters the relative speed of convergence in the five distinct dimensions of the parameter space.

To test our model for ultrasonic imaging, the algorithm was run using the actual acquired ultrasound images as data. After adjusting various parameters in the test cases mentioned above, further refinement was necessary during the first runs on real ultrasound data since the change in the data images (from simulated data to real ultrasound data) caused changes in the shape of the likelihood function. Unlike the runs on simulated data, it was difficult to determine the degree of success for the runs on real ultrasound data because the true value of $\theta \in \overline{\Theta}$ is, of course, unknown. Therefore, in order to assess a particular estimate $\hat{\theta}$ (a realization from the posterior distribution π on $\overline{\Theta}$), noiseless "restored" images were generated from the deformed template $\hat{\theta}(\mathcal{T})$ via the model-specific mapping and were compared with the corresponding ultrasound images. If the slices generated from the estimated fetal head ($\hat{\theta}(\mathcal{T})$) match the corresponding ultrasound images fairly well, then one would assume that a slice at the BPD level would also well approximate the actual fetal head at the two-dimensional BPD plane. This would, in turn, indicate that the BPD measurement taken on the deformed template is a good estimate for the actual BPD.

Overall, the results of the algorithm appear quite promising. Again, this is merely a first step in our stated goal (see the introduction)—that is, to automate the process by which a technician, in a prenatal ultrasonic examination of the fetal skull, utilizes his or her intuitive understanding of what is bone, what is tissue, and what is sensor noise in assessing the developing fetal skull.

7. Summary. A general formulation was presented by which one could incorporate a priori information into modeling, where the parameterization of the models is described by a compact manifold with boundary. The formulation was driven by the specific problem of reconstructing a fetal head from a sequence of ultrasound frames obtained during a prenatal exam. An important question is whether one can automate the intuitive understanding of the technician/radiologist as to what is bone, what is tissue, and what is sensor noise. In the present application, one issue is whether ultrasound imaging could be performed prior to the development of the skull. To do this, one must use all available knowledge as to what is bone, what is tissue, and what is sensor noise. Moreover, with the advent of medical imaging being performed remotely (telemedicine), the issue of what can and cannot be reasonably and properly automated in medical imaging is becoming more and more important.

The approach of the present paper is that of a probabilistic recovery of the fetal head. The "space of all possible fetal heads" is viewed as the result of similarity (translation, scale, rotation) transformations being applied to a given fetal head template. A model of the ultrasonic imaging of a fetal head is formulated and prior knowledge is incorporated, resulting in an a posteriori probability measure. A method for sampling from this measure is then constructed and justified. The complication is that the measure is on a Riemannian, compact, simply connected, oriented manifold with boundary. A discretization of a time-homogeneous diffusion process was implemented into code in the particular case of interest, that of $\overline{\Theta} = B_1 \times B_2 \times SO(3)$. The algorithm was then applied to simulated images, as well as to actual ultrasound prenatal images.

Two particular future applications concern robotics and protein structure. Consider "active" robotics, where the movement of a robot arm is not preprogrammed but acts dynamically within a changing environment. A representation of the arm is then provided by the "product" of the location and orientation of each of the N links of the robot arm. Moreover, each link of a robot arm is constrained not only by the fact that the links are connected end-to-end but, more importantly, that one link cannot pass through another. The result is a configuration space which is a submanifold with boundary of a finite product of such Lie groups.

Second, consider the computational biological approach to protein structure determination. For a variety of reasons, tertiary and quarternary structures have been determined for only a relatively small number of proteins. An alternative approach is to infer structural characteristics by comparison to potential evolutionary relatives whose three-dimensional structures are known. Many monomer proteins are built up from motifs (α-helices, β-strands) which are connected by links whose structure is very flexible. Similarly, the subunits of multimer proteins are usually held together by weak interactions, with flexibility in their realizable relative orientations. In the alternative approach, a potential energy is defined and a distance is calculated between the $C_\alpha - C_\alpha$ backbone of the protein of interest and that of a candidate of known three-dimensional structure from within a protein database. This distance is taken as a measure of structural dissimilarity. One aspect of such programs as Dali and FSSP [15], [16] is to find a candidate from the database and an approximate rigid motion of the configuration which minimizes the distance between the two. Ideally, one would like to have an algorithm which would allow for both rotations and scale differences and which would treat each submotif or subunit separately, with the allowable combinations of transformations being somewhat constrained. The present methodology may provide some basis for such an approach.

8. Stochastic relaxation on a manifold with boundary. We assume that $\overline{\Theta}$ is a compact regular domain (see [2]), in the sense that there exists an n-dimensional, orientable manifold N of class C^∞, with Θ being a d-dimensional domain in N, whose closure $\overline{\Theta}$ is compact and whose boundary $\partial\Theta = \overline{\Theta} - \Theta$ consists of a finite number of hypersurfaces, each of dimension $d-1$ and of class C^3. Let $\overline{\Theta}$ be a compact, connected, oriented, smooth, d-dimensional, Riemannian manifold with boundary and with metric g.

Let $C^\infty(\overline{\Theta})$ denote the class of infinitely differentiable functions from $\overline{\Theta}$ to $\mathbb{R}$. Let Ω be the natural volume element of the oriented Riemannian manifold $\overline{\Theta}$, and let ν be the Borel measure associated with Ω. Integration of functions on $\overline{\Theta}$ (which is integration of d-forms on $\overline{\Theta}$) can be viewed as Lebesgue–Stieltjes integration on $\overline{\Theta}$ with respect to ν:

$$\int_{\overline{\Theta}} f = \int_{\overline{\Theta}} f\ \Omega = \int_{\overline{\Theta}} f(\theta)\ \nu(d\theta) \qquad \text{for all } f \in C(\overline{\Theta}).$$

Let π be a Borel probability measure on $\overline{\Theta}$ which has a strictly positive density function, $q(x) \in C^\infty(\overline{\Theta})$, with respect to ν, and define $h(x) = -\ln q(x)$. Let

$$A = \frac{1}{2}(\,\Delta - \nabla h)$$

with domain $\mathcal{D}(A) = C^2(\overline{\Theta})$ and where ∇h is the gradient of the function h. What is to be shown is that the algorithm is sampling from the measure $q = e^{-h}$. In the

situation described in section 6.2.1, where the normalized parameter space $\overline{\Theta}_0$ is used and a change of variables is involved, all the above conditions are satisfied, where h is replaced by h_0 (properly balancing the gradient and stochastic terms).

Consider the Cauchy problem for the following parabolic equation: For a given $f \in C(\overline{\Theta})$, find u such that

$$\frac{\partial}{\partial t}u(t,x) = A\,u(t,x), \quad t > 0, x \in \Theta; \tag{8.1}$$

boundary condition (reflecting barrier):

$$Lu(t,x) = \frac{\partial}{\partial n}u(t,x) = 0, \quad t > 0, x \in \partial\Theta; \tag{8.2}$$

initial condition:

$$\lim_{t \downarrow 0} u(t,x) = f(x) \ \text{ (uniformly in) } x \in \overline{\Theta}. \tag{8.3}$$

PROPOSITION 1 (see Ito [18], [19], [20]; Sato and Ueno [31]). *The fundamental solution for the above Cauchy problem, constructed by Ito,*

$$p : (0,\infty) \times \overline{\Theta} \times \overline{\Theta} \to \mathbf{R},$$

satisfies the following properties:

1. *For a fixed $(t,x) \in (0,\infty) \times \overline{\Theta}$, $p(t,x,y)$ is continuous in y;*
2. *for any $f \in C(\overline{\Theta})$,*

$$u(t,x) = \int_{\overline{\Theta}} p(t,x,y) f(y)\, d\nu(y) \tag{8.4}$$

is continuous on $(0,\infty) \times \overline{\Theta}$ and continuously differentiable in $t \in (0,\infty)$ and $C^2(\overline{\Theta})$ for a fixed $t \in (0,\infty)$;

3. *$p(t,x,y)$ is strictly positive (in our case of reflection at the boundary) and satisfies*

$$p(t+s,x,y) = \int_{\overline{\Theta}} p(t,x,z) p(s,z,y)\, d\nu(y);$$

4.

$$\int_{\overline{\Theta}} p(t,x,y) d\nu(y) = 1. \tag{8.5}$$

Proof. For the proof, see Ito [18], [19], [20] and Sato and Ueno [31]. □

Note. Under boundary conditions other than reflection at the boundary, strict positivity of the density is not ensured, in that the process can then spend "local time" on the boundary (see [18, section 9]).

Let $\overline{A}$ denote the smallest closed extension in $C(\overline{\Theta})$ of A and denote its domain by $\mathcal{D}(\overline{A})$. To apply the Hille–Yosida theory in the present case of (A, L), one needs to construct the semigroup on $C(\overline{\Theta})$ whose Green's operators $\{G_\alpha\}$ satisfy $(\alpha - \overline{A})G_\alpha u = u$ and $LG_\alpha u(x) = 0$ for $x \in \partial\Theta$. In [31], Sato and Ueno present such a construction. For $f \in C(\overline{\Theta})$ and $\alpha \geq 0$, from the equation $(\alpha - \overline{A})u = f$ and $u = 0$ on $\partial\Theta$, one obtains the minimal resolvent for this translated Poisson equation, $\{G_\alpha^{min}\}$. Similarly,

for $\phi \in C(\partial\Theta)$ and $\alpha \geq 0$, from the equation $(\alpha - \overline{A})u = 0$ and $u = \phi$ on $\partial\Theta$, one obtains the resolvent for this translated Dirichlet problem, $\{H_\alpha\}$. Let the extensions of LG_α^{min} and LH_α be denoted by $\overline{LG_\alpha^{min}}$ and $\overline{LH_\alpha}$. Denote the domain of $\overline{LH_\alpha}$, which does not depend on α, by $\tilde{\mathcal{D}}$. Let $\hat{L}$ be the unique operator for which $\hat{L} = L$ on $C^{2,\kappa}(\overline{\Theta})$, $\hat{L}G_\alpha^{min} f = \overline{LG_\alpha^{min}} f$ for $f \in C(\overline{\Theta})$, and $\hat{L}H_\alpha\phi = \overline{LH_\alpha}\phi$ for $\phi \in \tilde{\mathcal{D}}$. Let the domain $\mathcal{D}(\hat{L})$ (which $\supset C^{2,\kappa}(\overline{\Theta})$) be given by all functions of the form $\sum_{i=1}^n G_{\alpha_i}^{min} f_i + H_{\beta_i}\phi_i$, $f_i \in C(\overline{\Theta})$, $\phi_i \in \tilde{\mathcal{D}}$, $\alpha_i \geq 0, \beta_i \geq 0, 1 \leq i \leq n$. Finally, let $\overline{A}_{\hat{L}}$ be the restriction of $\overline{A}$ to the subset $\mathcal{D}(\overline{A}_{\hat{L}}) = \{u | u \in \mathcal{D}(\hat{L})$ and $Lu = 0\}$ of $\mathcal{D}(\overline{A})$. In [31], Sato and Ueno show that $\overline{A}_{\hat{L}}$ is the infinitesimal generator for the semigroup on $C(\overline{\Theta})$ whose Green's operators $\{G_\alpha\}$ satisfy $(\alpha - \overline{A})G_\alpha u = u$ and $LG_\alpha u(x) = 0$ for $x \in \partial\Theta$. It is further shown that it is the infinitesimal generator for our desired Markov process. The collection of C^∞ functions f on $\overline{\Theta}$ such that $Lf = 0$ for $x \in \partial\Theta$ are dense in the $dom(\overline{A}_{\hat{L}})$.

PROPOSITION 2 (see Sato and Ueno [31]). *Under the conditions of Proposition 1 above, there is a time-homogeneous (Feller) Markov process* $X = (X_t, W, B_t, \{P(t,x,\cdot) : x \in \overline{\Theta}\}, t \geq 0\}$ *with infinitesimal generator* $\overline{A}_{\hat{L}}$, *and the probability transition measures* $P(t,x,\cdot)$ *of* X_t *have the fundamental solution* $p(t,x,y)$ *as a probability density with respect to the volume element measure* ν: $P(t,x,dy) = p(t,x,y)\nu(dy)$ *for all* $t \geq 0$ *and all* $x \in \overline{\Theta}$.

Proof. For the proof, see Sato and Ueno [31]. □

The goal of this section is to show the weak convergence of the transition probability of X_t, $\{P(t,x,\cdot)\}$ to the probability measure π. The following theorem gives the desired result.

THEOREM 3. *Let the family of measures* $\{P(t,x,\cdot) : x \in \overline{\Theta}, t \geq 0\}$ *be the transition probability of the diffusion process* X_t, *with generator* $A = \frac{1}{2}(\Delta - \nabla h)$ *and boundary operator* $L = \frac{\partial}{\partial n}$. *Then for each* x, $\{P(t,x,\cdot)\}$ *converges weakly to the probability measure* π *as* $t \to \infty$, *where* $q(x) \in C^\infty(\overline{\Theta})$ *is the strictly positive density function of* π *with respect to* ν *and* $h(x) = -\ln q(x)$. *More precisely, for all* $x \in \overline{\Theta}$, *and for any bounded measurable function* f *on* $\overline{\Theta}$,

$$T_t f(x) \stackrel{\text{def}}{=} \int_{\overline{\Theta}} f(y)P(t,x,dy) \to \int_{\overline{\Theta}} f(y)\pi(dy) \quad \text{as } t \to \infty.$$

Proof. The manifold $\overline{\Theta}$ is a compact, complete, separable metric space. Moreover, by the above propositions, there exist a Borel measure ν on $\overline{\Theta}$ and a strictly positive function $p(t,x,y)$ continuous in $(t,x,y) \in (0,\infty) \times \overline{\Theta}^2$ such that the transition probability $P(t,x,dy)$ equals $p(t,x,y)\ \nu(dy)$. By Theorem 1.3.4 of [22], in the case of a time-homogeneous Feller process (X_t) satisfying this condition on a locally compact, complete, separable metric space, X_t is either transient or recurrent in the sense of Harris. With $\overline{\Theta}$ compact, X_t cannot be transient, since $I_{\overline{\Theta}(X_t)} \equiv 1$, and the definition of transient would require that for any compact $K \subset \overline{\Theta}$

$$\sup_{x \in K} E_x \left[\int_0^\infty I_K(X_t)dt \right] < \infty \qquad (I_K \text{ is the indicator function of } K).$$

Therefore, X_t is recurrent in the sense of Harris, and by Theorem 1.3.5 of [22], X_t has a (T_t)-invariant probability measure Λ, and in particular, it is unique. Finally, since X_t is a Feller process satisfying the above stated condition, it has the following property given by Theorem 1.3.10 of [22]. For any bounded measurable function

f on $\overline{\Theta}$,

$$T_t f(x) \to \int_{\overline{\Theta}} f d\Lambda \quad \text{as t} \to \infty$$

holds for every $x \in \overline{\Theta}$. Then it is clear that for every $x \in \overline{\Theta}$, $\{P(t,x,\cdot)\}$ converges weakly to the unique invariant probability measure $\Lambda(\cdot)$.

Therefore, it remains only to show that $\Lambda = \pi$. Recall that (A, L) and h are

$$A = \frac{1}{2}(\Delta - \nabla h), \quad L = \frac{\partial}{\partial n}, \quad \text{and} \quad h(x) = -\ln q(x),$$

where $q(x) \in C^\infty(M)$ is the strictly positive density function of π with respect to ν, the Borel measure associated with the Riemannian volume element, Ω. The operator $\overline{A}_{\hat{L}}$ is the infinitesimal generator of the Feller semigroup $\{T_t, t \geq 0\}$ from Propositions 1 and 2. Recall that $f \in dom(\overline{A}_{\hat{L}})$ satisfy $Lf = 0$.

A measure μ is an invariant measure of an (A, L)-diffusion if and only if

$$\int_{\overline{\Theta}} \overline{A}_{\hat{L}} f(x) \mu(dx) = 0 \quad \text{for all } f \in dom(\overline{A}_{\hat{L}}) \qquad \text{(Ikeda and Watanabe [17]).}$$

Because the collection of $C^\infty(\overline{\Theta})$ functions f on $\overline{\Theta}$ such that $Lf = 0$ for $x \in \partial\Theta$ are dense in the $dom(\overline{A}_{\hat{L}})$, it suffices to verify for such f that

$$\int_{\overline{\Theta}} Af(x)\mu(dx) = 0 \quad \text{for all } f \in C^\infty(\overline{\Theta}), Lf = 0.$$

Notice that

$$\begin{aligned}
\int_{\overline{\Theta}} \overline{A}_{\hat{L}} f(x)\ \pi(dx) &= \int_{\overline{\Theta}} (Af) q(x)\ \nu(dx) = \frac{1}{2}\int_{\overline{\Theta}} q(\Delta - \nabla h) f(x)\, \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \left(q\Delta f - q(\nabla h)\, f\right)(x)\ \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \left(q\Delta f - q \cdot g(\nabla f, \nabla h)\right)(x)\, \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \left(q\Delta f - q \cdot g\left(\nabla f, -\frac{1}{q}(\nabla q)\right)\right)(x)\ \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \left(q\Delta f + g(\nabla f, \nabla q)\right)(x)\ \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \operatorname{div}\left(q(\nabla f)\right)(x)\ \nu(dx) \\
&= \frac{1}{2}\int_{\overline{\Theta}} \operatorname{div}\left(q(\nabla f)\right)\ \Omega,
\end{aligned}$$

since $h = -\ln q$ and $\nabla(-\ln q) = -\frac{1}{q}(\nabla q)$. However, for a C^∞ vector field X on $\overline{\Theta}$, $\operatorname{div} X\ \Omega = d(i(X)\Omega)$, where $i(X)\Omega$ is the interior product of X with Ω. Hence,

$$\begin{aligned}
\int_{\overline{\Theta}} (\overline{A}_{\hat{L}} f)\ d\pi &= \frac{1}{2}\int_{\overline{\Theta}} d(i(q\,\nabla f)\Omega) \\
&= \frac{1}{2}\int_{\partial\Theta} i(q(\nabla f))\Omega \qquad \text{by Stokes' theorem.}
\end{aligned}$$

Most importantly, since $\frac{\partial f}{\partial n} = 0$, it follows that ∇f has a zero normal component and hence, at each $x \in \partial\Theta$, ∇f lies in the tangential component of the tangent space $T_x(\overline{\Theta})$, which is $T_x(\partial\Theta)$. Consequently, the interior product $i(q\,\nabla f)\Omega$ at each $x \in \partial\Theta$ consists of n vectors in an $(n-1)$-dimensional space, and thus $i(q\,\nabla f)\Omega = 0$. Consequently,

$$\int_{\overline{\Theta}} (\overline{A}_{\hat{L}} f)\, d\pi = \frac{1}{2} \int_{\partial\Theta} i(q(\nabla f))\Omega = 0.$$

Therefore, since X_t is the diffusion process generated by the operators (A, L), the measure π is an invariant probability measure of X_t. By the uniqueness of the invariant probability measure Λ, we must have $\Lambda = \pi$. □

EXACT SIMILARITY SOLUTIONS OF COUPLED NONSTEADY NAVIER–STOKES AND ENERGY EQUATIONS IN LIQUIDS*

SHIMON HABER†

Abstract. Exact similarity solutions are obtained for coupled Navier–Stokes and energy equations that govern the time-dependent motion of a gravitation-free viscous liquid with variable density in one- and three-dimensional (1D and 3D) spaces. The 1D case deals with propagation and diffusion of an initial algebraic density hump C/x that is subjected to a constant flow rate at the origin. We demonstrate that the initial temperature distribution is convected without being diffused at very long times. We also demonstrate that two different propagation velocities exist for short and long times. The 3D case addresses the implosion of an insulated closed system with an initial radially symmetric algebraic density hump C/r^3. We demonstrate that if viscous dissipation and liquid compressibility terms are neglected in the energy equation, very strong shock-like pressure distributions may occur that may lead to a "black hole" within a finite time.

A comprehensive analysis is also carried out for density fields with an initial, r^n, radially symmetric distribution in 1D, 2D, and 3D spaces. A first integral is obtained for all n's in a 2D space. A phase-space solution is utilized to depict the system evolution and stability for any value of n. It also allows us to consider intriguing aphysical negative density fields, manifesting a peculiar periodic solution for the 3D ($n = 0$) case that mimics a prey-predator problem.

1. Introduction.

To date, very few *exact* analytical solutions are known for the nonsteady motion of viscous *liquids* with variable densities, owing to the fact that the governing Navier–Stokes equations are nonlinear and coupled with the energy equation. To circumvent this difficulty, numerical solvers have frequently been used but have rarely been verified against exact analytical solutions of nontrivial flow problems that encompass the interplay between viscosity, inertia, temperature, and density fields. Analytical expressions have been obtained in the past using extremely effective similarity methods; alas, in most previous cases, only an approximate set of the Navier–Stokes equations has been employed. Similarity solutions were also criticized due to the fact that, to quote Barenblatt (1979), "In nonlinear problems, exact special solutions sometimes *appear* to be useless; since there is no principle of superposition, one cannot immediately find a solution of the problem with arbitrary initial conditions." Notwithstanding, Barenblatt emphasizes the importance of similarity solutions, as they may "represent the asymptotics of a wide class of other more general solutions." Burger's nonlinear equation (see Whitham (1974)) is a celebrated attempt to describe approximately the combined effects of nonlinear density propagation and diffusion under the assumption of small amplitude disturbances. A similarity solution was obtained for the case of an initial hump, a problem that is also addressed in this paper, only here we employ the full Navier–Stokes equations. Barenblatt (1979) addresses the problem of thermal flame propagation in gaseous mixtures. An approximate equation is obtained for the propagating wave front (the

†Department of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa, 32000, Israel (mersh01@techunix.technion.ac.il).

inner flow approximation), and the analysis indicates how to obtain the long time propagation velocity. It is interesting to note that, since the propagating velocity is much smaller than the speed of sound, the author assumes that the gas density depends only upon temperature, and the pressure field is treated as an independent variable. In addition, the functional forms of the velocity and temperature fields are generally obtained before employment of the momentum equation. The latter is used to obtain the pressure field and the value of the long time propagation velocity. We follow to some extent a similar approach, where the velocity and density (temperature) fields are addressed first and the pressure distribution is consequently obtained. More recently, similarity methods were also employed by Canright and Morris (1993) (addressing the buoyant instability of a viscous film over a passive fluid, an attempt to describe the behavior of lava lakes and mantle convection), Romero and Yost (1996) (who obtained a similarity solution for a capillary-driven flow in a V-shaped surface groove), Woods and Fitzgerald (1997) (who described the temperature field as liquid spreads from a line source into a porous rock with a time-dependent liquid injection), Koehler et al. (1998) (who obtained a similarity solution for the drainage of liquid foams under gravity), Witelski and Bernoff (1999) and Zhang and Lister (1999) (who addressed the stability of van der Waals–driven thin film rupture), and Christopher and Wang (2001) (who simulated the Marangoni convection around a vapor bubble during nucleation and growth), to name a few.

The objective of this communication is to present an *exact* analytic solution for *liquid* fields or *incompressible* gases such that their density is a function of temperature only while the pressure field can be treated as an independent variable. The fields are radially symmetric and are governed by the fully coupled nonlinear Navier–Stokes and energy equations under a minimal set of assumptions. The solution illustrates the interplay between the convective, diffusive, and temporal terms of the equations and the effects of the phenomenological coefficients on the flow variables. To achieve this goal, we assume that the flow and temperature fields satisfy a particular set of initial and boundary conditions and that the density is inversely proportional to the temperature field, a relation commonly satisfied by liquids and by ideal incompressible gases. Despite these obvious limitations of the solution class, we shall demonstrate that the results possess remarkable features (mentioned in the abstract) of general physical significance. In particular, in cases where a moving sharp interface is assumed to divide the flow field into two regions of distinct densities, the model elucidates the effect of a diffused density front. (Obviously, far from the interface the model is no longer valid and can no longer describe the flow field faithfully.) Thus, for instance, the exact 1D solution shows a surprising resemblance to a certain region of the flow generated in a shock tube despite the fact that the latter addresses compressible flow (see a broader discussion in section 5). Moreover, one of the possible 3D radially symmetric solutions elucidates a process that resembles the behavior of the flow field near the liquid interface surrounding an expanding bubble, only here the adiabatic interface is considered to be diffused. We also believe that the radially symmetric solutions are a necessary first step if stability to small nonradially symmetric initial density disturbances, heat sources, Coriolis accelerations, etc., is to be explored. Incorporation of the radial gravity term in the momentum equation and the foregoing asymmetric disturbances (not accounted for in this paper) can be employed to model diffused asymmetrical interfacial phenomena in earth science (see Gerald (1971), Davies (1999)).

Finally, the exact solutions can probably be utilized as benchmarks to verify the accuracy of numerical solvers since they encompass the combined effects of inertia, viscosity, heat convection, and diffusion in an unsteady flow field. (This latter suggestion

must, for the time being, be tested with care, since the solution's stability has not been addressed in this paper.)

The paper is divided into four main parts. Section 2 defines the governing equations and the simplifying assumptions used to derive them. Section 3 presents the method we used to derive the particular exact similarity solutions of the coupled Navier–Stokes and energy equations in 1D, 2D, and 3D spaces. Section 4 analyzes a broader family of radially symmetric problems. Utilizing a phase map analysis proves that these similarity solutions can never be chaotic. Section 5 discusses and summarizes the main results.

2. Statement of problem. A common set of equations governing the motion of Newtonian liquids includes the mass conservation equation,

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{2.1}$$

the linear momentum equation,

$$\rho \left(\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) = -\nabla p + \mu \nabla^2 \mathbf{v} + \left(\kappa + \frac{\mu}{3} \right) \nabla (\nabla \cdot \mathbf{v}) + \rho \mathbf{g}, \tag{2.2}$$

the energy conservation equation,

$$\rho c_p \left(\frac{\partial T}{\partial t} + \mathbf{v} \cdot \nabla T \right) = k \nabla^2 T, \tag{2.3}$$

and the equation describing the relation between temperature and density,

$$\rho = \frac{\rho_0}{[1 + \gamma \rho_0 (T - T_0)]}, \tag{2.4}$$

where ρ, p, T, and $\mathbf{v}$ denote the density, pressure, temperature, and velocity fields; μ and κ stand for the fixed fluid shear and bulk viscosities; and c_p and k stand for the fixed specific heat and thermal conductivity coefficients. Notice that in (2.3) we neglected the viscous dissipation and the temperature increase with compression terms. The exclusion of the energy dissipation term is justified in most cases, except for flow fields that are subjected to very high shear rates (e.g., flows in journal bearings). The omission of the compressibility term is suited to liquids that satisfy (2.4), and consequently, the ratio of their specific heats, c_p/c_v, is unity.

For γ, ρ_0, and T_0 constants, (2.4) applies to many liquids and tacitly implies that the liquid is incompressible in the sense that the density does not vary with pressure. Accordingly, the pressure field must be regarded as an independent variable (Aris (1962, p. 111)). Thus, (2.1)–(2.4) constitute a consistent set of four equations for the four unknown fields ρ, p, T, and $\mathbf{v}$.

3. Method of solution. We assume that the velocity field is irrotational and guess that it possesses the following form:

$$\mathbf{v} = \frac{k}{c_p} \nabla \frac{1}{\rho}. \tag{3.1}$$

Substituting (3.1) into the mass conservation equation (2.1) results in a second order nonlinear equation for the density field,

$$\frac{\partial \rho}{\partial t} + \frac{k}{\rho^2 c_p} \nabla \rho \cdot \nabla \rho = \frac{k}{\rho c_p} \nabla^2 \rho. \tag{3.2}$$

Remarkably, (3.2) is also recovered if we rewrite the energy equation (2.3) utilizing (2.4) and (3.1) for the velocity field. Thus, the energy and mass conservation equations collapse into a single equation (3.2). *This result is the crux of the analysis.* Notice that Hopf (1950), Cole (1951), and Camacho and Brenner (1995) utilized a similar idea to derive a solution for the diffusion equation, where they assumed that the velocity field is proportional to $\nabla(\ln\rho)$. If (3.1) and (3.2) are substituted into (2.2), the following equation for the pressure is obtained:

$$\left(\frac{c_p}{k}\right)^2\nabla p = P_r\nabla[\nabla^2\rho^{-1}] - \rho\nabla[\rho^{-1}\nabla^2\rho^{-1} - 0.5\nabla\rho^{-1}\cdot\nabla\rho^{-1}] + \left(\frac{c_p}{k}\right)^2\rho\mathbf{g}, \tag{3.3}$$

where the Prandtl number $P_r = \tilde{\mu}c_p/k$ is based on the modified viscosity $\tilde{\mu} = \kappa + 4\mu/3$. Equation (3.3) cannot always be solved for the pressure since an irrotational solution for the velocity field would generally not satisfy the momentum equation. However, a solution for the pressure may be found in 1D Cartesian problems, in radially symmetric 2D and 3D problems, and in case the gravity field is radially symmetric. The latter is commonly encountered in earth sciences such as mantle convection under the earth lithosphere (Davies (1999)). Henceforth, we shall focus on these simplified cases. We also define the following dimensionless variables: $\hat{\rho} = \rho/\rho_0$, $\hat{\mathbf{r}} = \mathbf{r}/a$, $\hat{t} = kt/(\rho_0 c_p a^2)$, $\hat{\mathbf{v}} = (\rho_0 c_p a/k)\mathbf{v}$, and $\hat{p} = (c_p^2\rho_0 a^2/k^2)p$, where a is a given length-scale. (The caret symbol will be used to describe dimensionless quantities.)

3.1. A similarity solution for the propagation and diffusion of an *n*th order polynomial hump in an *m*-dimensional space. From (3.2), the radially symmetric mass/energy conservation equation in an m-dimensional space is

$$\frac{\partial\hat{\rho}}{\partial\hat{t}} + \frac{1}{\hat{\rho}^2}\left(\frac{\partial\hat{\rho}}{\partial\hat{r}}\right)^2 = \frac{1}{\hat{\rho}}\hat{\nabla}^2\hat{\rho}, \tag{3.4}$$

where the dimensionless Laplace operator is

$$\hat{\nabla}^2 = \frac{\partial^2}{\partial\hat{r}^2} + \frac{m-1}{\hat{r}}\frac{\partial}{\partial\hat{r}}.$$

From (2.2), the corresponding momentum equation is

$$\frac{\partial\hat{p}}{\partial\hat{r}} = (P_r - 1)\frac{\partial}{\partial\hat{r}}\hat{\nabla}^2\frac{1}{\hat{\rho}} - \hat{\rho}\frac{m-1}{\hat{r}}\left[\frac{\partial(1/\hat{\rho})}{\partial\hat{r}}\right]^2 + B\hat{\rho}, \tag{3.5}$$

where $B = a^3c_p^2\rho_0^2 g_r/k^2$ is the dimensionless gravity number based upon the radial gravity acceleration g_r (considered negative if pointing toward the origin). Generally, g_r will depend on the whole field distribution of ρ and thereby on the global geometrical configuration of the flow field. Such an additional complication is avoided in this paper (to be addressed in a subsequent paper), and henceforth we shall investigate the microgravity case for which B is negligibly small (i.e., the flow is *not* buoyancy driven). Notice that if the local distribution of the density field is known and $B = 0$, the pressure field can readily be obtained. Indeed, for the 1D ($m = 1$) case, the explicit distribution of the density field is not required, and a straightforward integration of (3.5) is possible.

To obtain a solution of the nonlinear partial differential equation (3.4) is a formidable task. Indeed, it is well known that a general solution representation does not exist for partial differential equations. At most, what we hope to obtain is a solution

class that can be applied to a given domain and boundary conditions. Our task is made easier if we tailor the boundary conditions a posteriori to make them fit the solution. In what follows we focus on some similarity solutions of (3.4) and, in particular, on the case in which the initial density field is a hump described by $\hat{\rho} = C_1 \hat{r}^n$ at $\hat{t} = 0$. In this case a similarity solution exists that possesses the form

$$\hat{\rho} = \hat{r}^n g(\eta), \qquad \eta = \frac{\hat{r}}{\hat{t}^{1/(n+2)}}, \tag{3.6}$$

where η is the appropriate similarity variable. Introducing (3.6) into (3.4) results in a second order, ordinary, nonlinear differential equation for g,

$$gg'' - (g')^2 + \frac{\eta^{n+1} g^2 g'}{n+2} + \frac{n(m-2)g^2}{\eta^2} + \frac{(m-1)g'g}{\eta} = 0, \tag{3.7}$$

where the prime symbol stands for differentiation with respect to η.

Equation (3.7) possesses a simple *particular* solution[1] that contains no free constants of integration,

$$g = (4 - 2m)\eta^{-n-2}. \tag{3.8}$$

A *general* solution of (3.7) for any n and m that includes two independent integration constants is probably impossible. Notwithstanding, (3.7) can be solved analytically for the parameter sets $(m, n) = (1, -1)$ and $(m, n) = (3, -3)$. The first set describes the case of an initial density hump $\rho(\hat{x}, t = 0) = C_1/\hat{x}$ propagating in 1D space. The second case addresses the propagation of an initial density hump $\hat{\rho}(\hat{r}, t = 0) = C_1/\hat{r}^3$ in 3D space.

3.2. The exact 1D solution for the propagation of an initial hump.

$$\rho(\hat{x}, t = 0) = \frac{C_1}{\hat{x}} \quad \text{or} \quad \rho(\hat{x}, t = 0) = \frac{C_1}{\hat{x} + \alpha}.$$

In case $n = -1$ and $m = 1$, namely for an initial 1D density hump $\hat{\rho}(\hat{x}, 0) = C_1/\hat{x}$ ($\hat{x}$ stands for the 1D spatial coordinate instead of $\hat{r}$), a *general analytical* solution of (3.7) can be obtained. A step-by-step derivation is as follows: Divide (3.7) by g^2 and define $u = g'/g$; consequently, rewrite (3.7) as $u' + g' + 1/\eta^2 = 0$. Thus, a first integral $u + g - 1/\eta = C_1$ exists, where C_1 is an arbitrary constant. In terms of the unknown function g, the latter equation can be rewritten in the form $g' - (C_1 + 1/\eta)g = -g^2$, which is a nonlinear Bernoulli equation. Defining a new dependent variable $h = 1/g$, the latter equation transforms into the simple linear equation, $h' + (C_1 + 1/\eta)h = 1$. Its straightforward solution eventually yields

$$g = \left[\frac{C_2 e^{-C_1 \eta}}{\eta} + \frac{1}{C_1} - \frac{1}{(\eta C_1^2)} \right]^{-1}, \tag{3.9}$$

where C_1 and C_2 are arbitrary constants. Consequently, the solution for the density field with $n = -1$ is

$$\hat{\rho} = \left(C_2 \hat{t} e^{-C_1 \hat{x}/\hat{t}} + \frac{\hat{x}}{C_1} - \frac{\hat{t}}{C_1^2} \right)^{-1}.$$

[1] The solution is particular in the sense that it does not possess any free constants of integration and cannot be obtained from the general solution by a particular choice of the constants.

A more general expression can be obtained if $\hat{x}$ is replaced with $\hat{x}+\alpha$:

$$\hat{\rho}=\left(C_2\hat{t}e^{-C_1(\hat{x}+\alpha)/\hat{t}}+\frac{\hat{x}+\alpha}{C_1}-\frac{\hat{t}}{C_1^2}\right)^{-1}, \tag{3.10}$$

where $\alpha>0$ is an arbitrary constant. Equation (3.10) satisfies a more general initial condition $\hat{\rho}(\hat{x},\hat{t}=0)=C_1/(\hat{x}+\alpha)$ that is nonsingular for all $\hat{x}>0$. (This transformation is possible since, in case $m=1$, (3.4) contains only differentials of x.)

Notice that the particular solution (3.8) is still valid here but cannot be obtained from a specific choice of the constants, a common occurrence in nonlinear equations (Bender and Orszag (1978, p. 4)).

From (3.1) and (3.5) the solutions for the velocity and pressure fields are

$$\hat{v}_x=-C_1C_2\exp\left[\frac{-C_1(\hat{x}+\alpha)}{\hat{t}}\right]+\frac{1}{C_1}, \tag{3.11}$$

$$\frac{\partial\hat{p}}{\partial\hat{x}}=-(P_r-1)C_1^3C_2\hat{t}^{-2}e^{-C_1(\hat{x}+\alpha)/\hat{t}}. \tag{3.12}$$

A specific choice of the constants C_1 and C_2 defines a nontrivial solution for the propagation and diffusion of an initial density hump $\hat{\rho}(\hat{x},0)=C_1/(\hat{x}+\alpha)$, with liquid injected at $x=0$ at a rate $\hat{v}_x=-C_1C_2\exp(-C_1\alpha/\hat{t})+1/C_1$ that readily reaches a fixed value. Notice that if $C_2=1/C_1^2$ and $\alpha=0$, the solution describes the behavior of an insulated closed system at $x=0$ for all times.

Equation (3.10) is a remarkable solution of the Navier–Stokes and energy equations. It possesses short *and* long time behavior of a propagating wave. For short times, the density distribution propagates with velocity $\hat{u}_P=1/C_1$, while for long times the propagation velocity changes into $\hat{u}_P=1/C_1-C_2C_1$. Figure 1 illustrates the density distribution for various times and locations. It vividly demonstrates that the maximum density value (normalized for position) propagates and reaches downstream locations as time evolves.

3.3. The exact 3D solution of a propagating initial hump $\boldsymbol{\rho(\hat{r},t=0)=C_1/\hat{r}^3}$. For an initial density distribution $\hat{\rho}(\hat{r},0)=C_1/\hat{r}^3$, a general *analytical* solution of (3.7) in a 3D space exists,[2]

$$g(\eta)=\eta^3e^{C_1/\eta}\left\{C_2+\int_\eta^{\eta_1}\eta e^{C_1/\eta}d\eta\right\}^{-1}, \tag{3.13}$$

where $\eta=\hat{r}\hat{t}$ and C_1 and C_2 are two arbitrary constants of integration. Hence,

$$\hat{\rho}=\hat{t}^3e^{C_1/\eta}\left\{C_2+\int_\eta^{\eta_1}\eta e^{C_1/\eta}d\eta\right\}^{-1}. \tag{3.14}$$

Substitution of (3.13) into (3.1) and (3.3) yields the expressions for the velocity and the pressure fields:

$$\hat{v}_r=\frac{\hat{r}(C_1/g-1)}{\hat{t}}, \tag{3.15}$$

$$\frac{\partial\hat{p}}{\partial\hat{r}}=(P_r-1)\left[\frac{C_1^2(C_1-4\eta)}{g\eta^3}-\frac{C_1^2}{\eta^3}+\frac{C_1}{\eta^2}\right]-\frac{2g}{\eta^2}\left(\frac{C_1}{g}-1\right)^2. \tag{3.16}$$

[2]The solution process is similar to that used for the 1D case (see section 3.2), only here define $u=\eta^2g'/g$ and proceed accordingly.

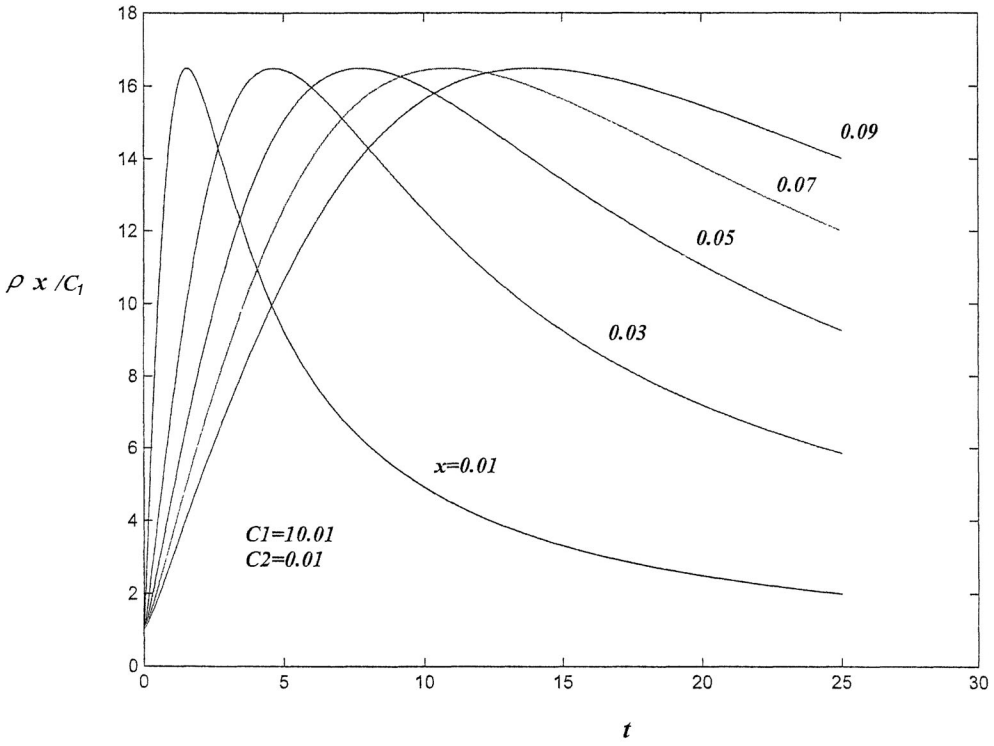

FIG. 1. *The evolution of the density field for a* 1*D case in which the initial density is given by* $\hat{\rho}(\hat{x}, \hat{t} = 0) = C_1/\hat{x}$. *The similarity parameter is* $\eta = \hat{x}/\hat{t}$ *(see* (3.10)*).*

At the limit $\eta \to 0_+$ and $C_1 > 0$ the inverse of g can asymptotically be expanded, $1/g = [1 + 3\eta/C_1 + 12(\eta/C_1)^2 + 60(\eta/C_1)^3 + \cdots]/C_1$. Hence for $\hat{t} \to 0_+$ and r held fixed, $\hat{\rho} \to C_1\hat{r}^{-3}$, $\hat{v}_r \to 3\hat{r}^2/C_1$, and $\partial\hat{p}/\partial\hat{r} \to 6(2P_r - 5)/C_1$. Similarly, for $\hat{r} \to 0$ and $\hat{t}$ held fixed, the radial velocity $\hat{v}_r$ vanishes. Hence, (3.14) is a nontrivial solution for the propagation and diffusion of an initial radially symmetric density hump $\hat{\rho}(\hat{r}, \hat{t} = 0) = C_1/\hat{r}^3$ with no liquid sources or sinks at $r = 0$. The solution may experience a blow-up at a finite time when the expression in curly brackets in (3.14) vanishes. Before blow-up occurs, for long times $\eta > \eta_1$, where η_1 satisfies the condition $\exp(C_1/\eta_1) = O(1)$, the solution no longer depends directly upon the initial condition (the value of C_1), and the density distribution possesses approximately the following functional form:

$$\hat{\rho} = \hat{t}^3 \left\{C - 0.5\eta^2\right\}^{-1}, \tag{3.17}$$

which eventually becomes singular after a finite time. If, however, the time-space domain is limited to $0 < \eta \leq \eta_1$ and $C_2 > 0$, the solution yields finite density and velocity fields. An interesting case arises if we choose a solution domain $0 < \eta < \eta_1$ with $g(\eta_1) = C_1$. In this case $v_r(\eta_1)$ and $[\partial T/\partial r]_{\eta=\eta_1}$ vanish at the domain boundaries, and the solution describes a *closed insulated* system with an initial algebraic density hump, $C_1/\hat{r}^3$, that *implodes* within a finite time at a rate proportional to $1/\hat{t}^2$. In Figures 2 and 3 we picked $\eta_1 = C_1 = 1$ and $C_2 = e$, which results in $g(\eta_1 = 1) = C_1 = 1$. Figure 2 describes the finite value of g obtained for all η in the space-time

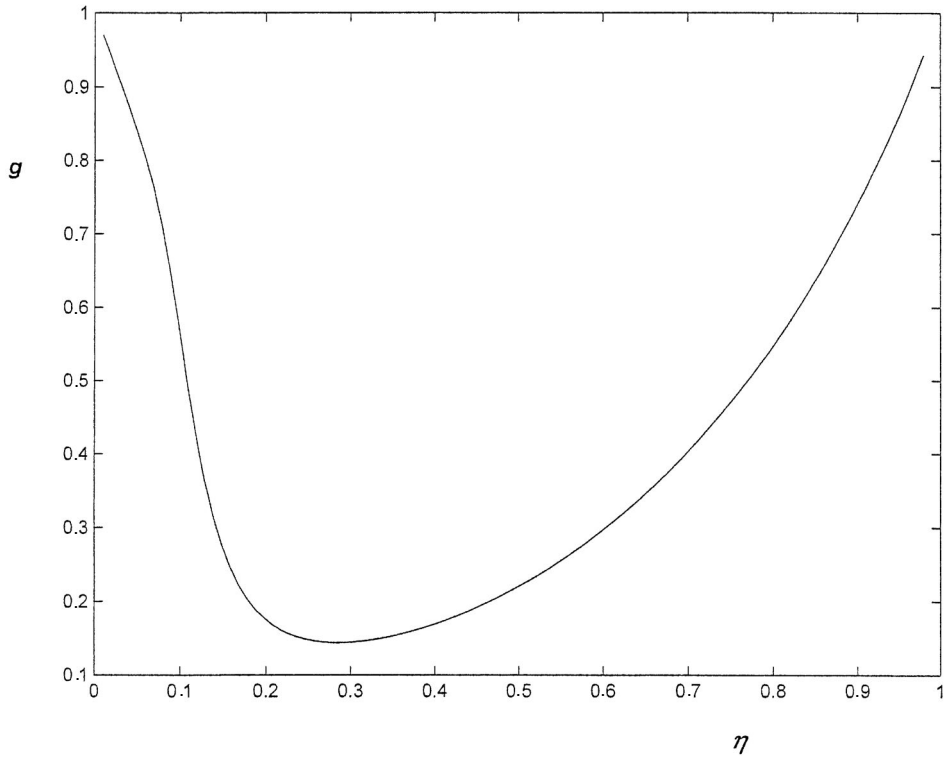

FIG. 2. *The density field for a 3D case in which the initial density is given by* $\hat{\rho}(\hat{r}, \hat{t} = 0) = C_1/\hat{r}^3$, *where* $C_1 = 1$, $\eta_1 = 1$, *and* $C_2 = e$. *The similarity parameter is* $\eta = \hat{r}\hat{t}$.

domain $0 < \hat{r}\hat{t} < 1$ (the density distribution is equal to $g/\hat{r}^3$). Figure 3 illustrates the resulting pressure gradient distribution. The figures exhibit steep gradients in the density and pressure fields that resemble diffused shock waves. Initially, the space extends to infinity, storing infinite mass. As time evolves, the system's spatial domain shrinks, a process that is accompanied by a strong flow respreading the density field, while no flow is permitted through the boundaries.

These results raise an interesting question. Can "black holes" exist in liquid systems obeying the Navier–Stokes equations? Obviously, this cannot be the case, since, at the last stages of the implosion process, strong velocity gradients exist, and it is no longer correct to assume that viscous dissipation and heating due to compressibility effects are negligibly small. Thus, the energy equation (2.3) no longer faithfully represents the energy balance in the system.

Equation (3.14) with negative $\hat{t}$ values ($-\infty < \hat{t} < 0$) describes a whole new class of solutions. Figure 4 illustrates the solution for a density field that resembles the behavior of the fluid near the adiabatic interface of an expanding bubble in which the interface is described by a diffused domain rather than by a distinct jump in the density field.

4. Phase-space analysis. Equation (3.7) can be drastically simplified utilizing the following transformations:

$$G = \frac{\eta^{n+2} g}{n+2}, \quad U = \frac{\eta g'}{g}, \quad w = \ln \eta. \tag{4.1}$$

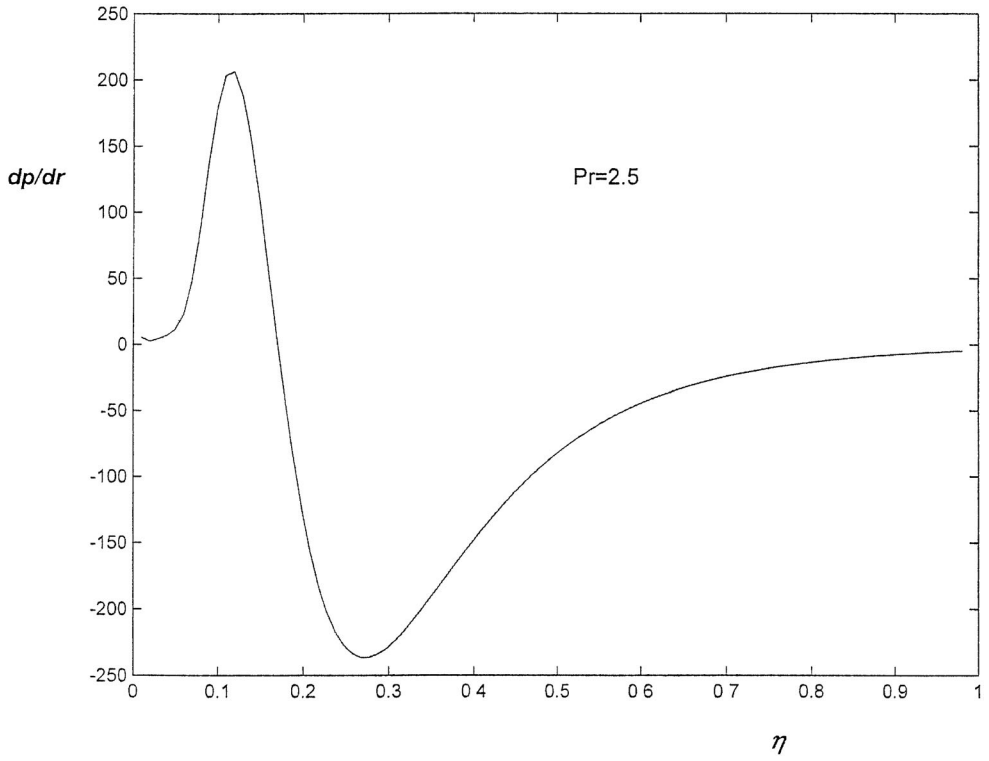

FIG. 3. *The pressure field for a 3D case in which the initial density is given by* $\hat{\rho}(\hat{r}, \hat{t} = 0) = C_1/\hat{r}^3$, *where* $C_1 = 1$, $\eta_1 = 1$, *and* $C_2 = e$. *The similarity parameter is* $\eta = \hat{r}\hat{t}$.

Substituting (4.1) into (3.7) yields an equivalent set of two first order nonlinear equations in G and U that is amenable to a simple analysis in the G-U phase-space:

$$\begin{aligned} \frac{dG}{dw} &= (n+2)G + UG, \\ \frac{dU}{dw} &= (2-m)U - UG + n(2-m). \end{aligned} \tag{4.2}$$

System (4.2) possesses a close resemblance to the well-known equations governing the prey-predator problem. For U positive and $n > -2$, the growth-rate of predator G depends upon its natural birth-rate $(n+2)$ and upon the abundance of the prey population U. For $m < 2$ the growth-rate of the prey population depends upon its rate of birth $(2-m)$ and a fixed rate, $n(2-m)$, of influx or outflow of its members for $n > 0$ or $-2 < n < 0$, respectively. Its decrease in population is directly related to predator population. For U negative, the roles of the predator and prey are exchanged. System (4.2) also manifests that chaotic solutions are impossible for any value of n or m since the order of the system is exactly 2 (no explicit dependency on w exists). System (4.2) possesses two equilibrium points A and B for which G and U have the following values:

$$\begin{aligned} \overline{G}_{\mathrm{A}} &= 0, & \overline{U}_{\mathrm{A}} &= -n, \\ \overline{G}_{\mathrm{B}} &= -2(m-2)/(n+2), & \overline{U}_{\mathrm{B}} &= -n-2. \end{aligned} \tag{4.3}$$

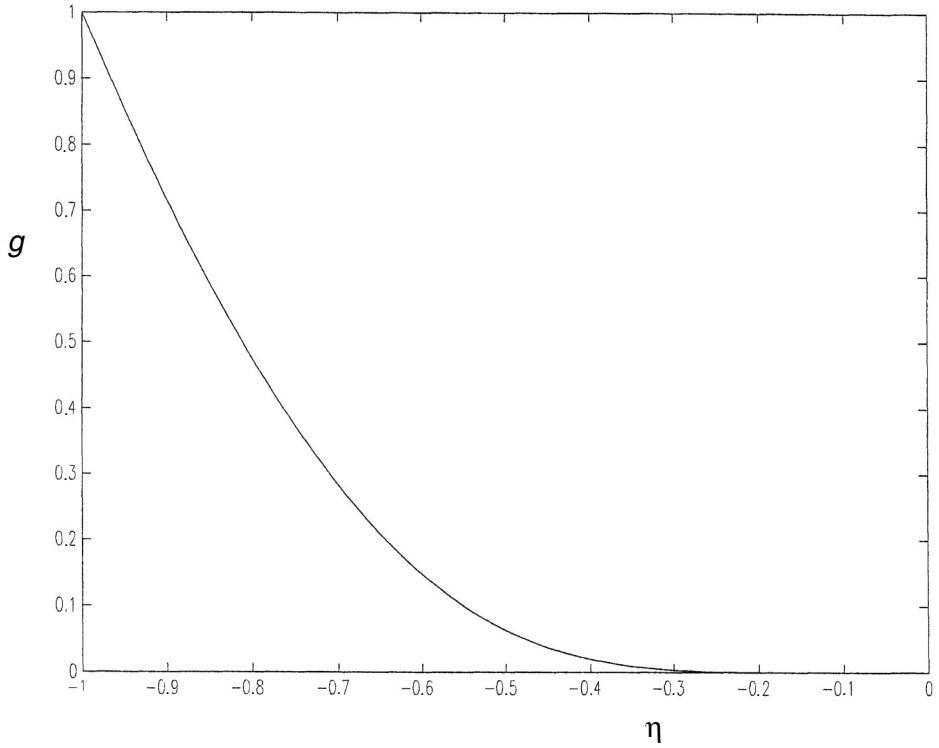

FIG. 4. *The density field for a 3D case for negative times* $-\infty < \hat{t} < 0$*;* $C_1 = 1$*,* $\eta_1 = -1$*, and* $C_2 = -1/e$*. The similarity parameter is* $\eta = \hat{r}\hat{t}$*.*

A simple linear stability analysis of system (4.2) proves that A is an unstable node if $m < 2$, and a saddle point if $m > 2$ (for any value of n). Point B demonstrates a much richer behavior. If $m < 2$, B is a saddle point. If $m > 2$, point B could be a center, a stable node or a stable spiral, an unstable node or an unstable spiral, depending upon the values of n and m. If $n < n_2$, B is a stable spiral. If $n_2 < n < -2$, B is a stable node. If $-2 < n < n_1$, B is an unstable node. If $n_1 < n < 0$, B is an unstable spiral. If $n = 0$, B is a center, and if $n > 0$, B is a stable spiral. The parameters n_1 and n_2 ($n_1 > n_2$) are $n_{1,2} = (16 \pm \sqrt{32m - 64})/(m - 10)$. Notice that $n = -2$ is excluded from the analysis since it degenerates to the particular solution. In case $m = 2$ (the 2D axisymmetric problem) linear stability analysis is not feasible, and we treat it separately in section 4.2. Figure 5 summarizes the above conclusions and depicts the type and stability of points A and B in the $m \times n$ plane. Notice that we treated m as a continuous parameter despite the fact that it may normally possess integral values only. In the following we explicitly explore the similarity solutions for $m = 1, 2, 3$ that pertain to flow fields in 1D, 2D, and 3D spaces, respectively.

4.1. Similarity solutions for 1D flows. A phase-plane analysis of (4.2) for $m = 1$ yields trajectories for flows in a 1D space. The phase-maps are depicted in Figure 6 for typical values of n. Notice that positive values of the density field correspond to positive values of G if $n > -2$ and negative values of G if $n < -2$. It is interesting to note that the two spaces of positive and negative densities do not

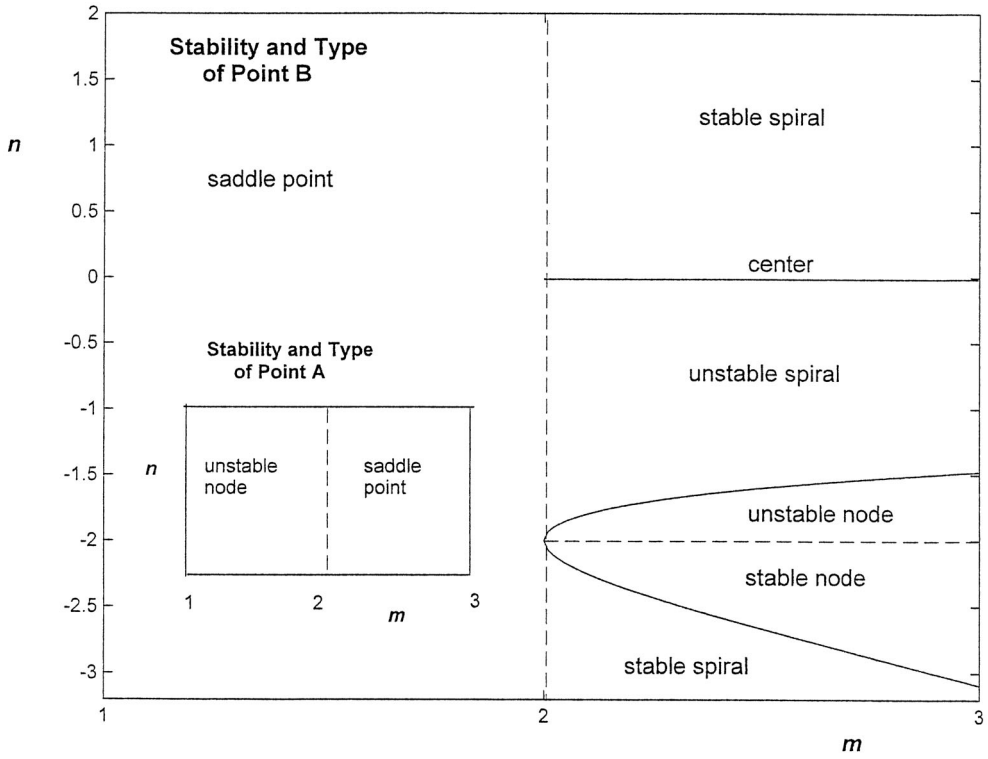

FIG. 5. *Type and stability of the fixed points A and B of system* (4.2) *in the* $m \times n$ *plane (*m *defines the dimension of the flow space, whereas* n *stands for the polynomial order of the initial density distribution).*

interact, and a trajectory that started initially in one space will always remain in that space (a comforting idea?).

In case $n = 0$ (depicted in Figure 6(c)) a simple separation of variables makes it possible to obtain a first integral of (4.2),

$$Ge^{-G} = CU^2 e^U, \tag{4.4}$$

where C is a constant of integration. Further analytic integration of this transcendental equation is a formidable task.

4.2. Similarity solutions for 2D axisymmetric flows. For 2D axisymmetric flows ($m = 2$), a simple separation of variables of (4.2) yields a general first integral for all $n \neq -2$,

$$G = -(n+2)\ln|U| - U + C, \tag{4.5}$$

where C is an arbitrary constant of integration. Hence, from (4.2),

$$w = \int \frac{dU}{U[(n+2)\ln|U| + U - C]} + w_0. \tag{4.6}$$

Figures 7(a,b) illustrate a single trajectory in phase space for $n = -3$ and $n = 1$, respectively. A particular value of C is chosen so that the $G = 0$ coordinate is

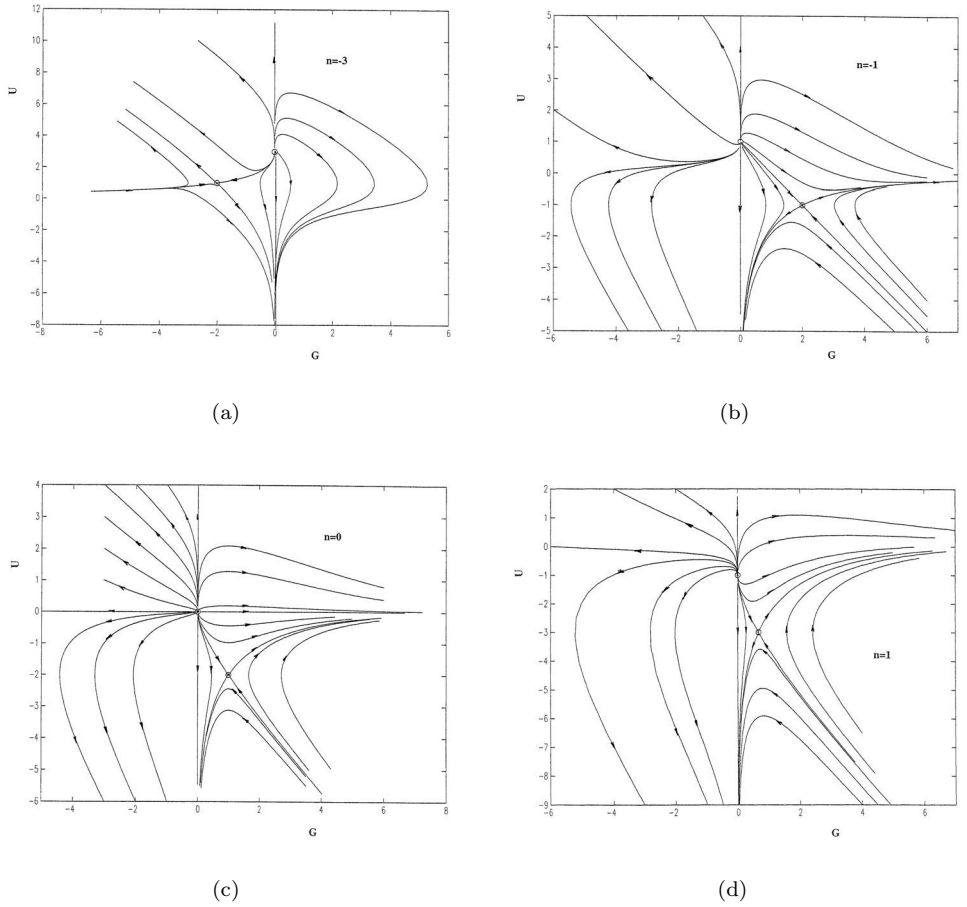

FIG. 6. *Phase-maps of one-dimensional flow cases for various values of* n. tangent to the trajectory. For $n = -3$ only the left-half plane, $G < 0$, corresponds to positive density values. Hence, the shown trajectory is a separatrix that approaches a degenerate saddle point $(0, 1)$ and partitions the phase space into two regions: Points above the separatrix reach a zero density within a finite time, while points below it approach infinity. Similar conclusions can be drawn for the $n = 1$ case. Here, however, the right-half plane, $G > 0$, corresponds to positive density values, and the region below the separatrix, which approaches $(0, -3)$, pertains to points that reach zero density within a finite time. Varying C in (4.5) yields similar trajectories that are shifted along the G-axis and may cross the $G = 0$ line. Namely, in 2D cases trajectories may cross from positive to negative aphysical density spaces.

4.3. Similarity solutions for 3D radially symmetric flows. A general similarity solution for radially symmetric problems in three dimensions can be derived analogously. A phase-plane analysis of (4.2) for $m = 3$ yields the desired trajectories. Phase-maps are depicted in Figure 8 for typical values of n that validate the classification of point B (see Figure 5). Again, positive values of the density field correspond

FIG. 7. *Phase maps of 2D flow cases for two values of n.* (a) $n = -3$, (b) $n = 1$. *Only one trajectory is shown. Other trajectories are identical to the one shown and are a parallel shift along the G-axis. For the particular chosen value C* (4.5) *the trajectory touches the G-axis.*

to positive values of G for $n > -2$ and negative values of G for $n < -2$. Notice that, similar to the 1D cases, no interaction between positive and negative density spaces is possible. Very intriguing phase-maps are obtained for negative densities, an obviously aphysical domain of the solution. A periodic solution is obtained for $n = 0$ (see Figure 8(e)); alas, it survives only if we allow negative densities.

5. Conclusions. Explicit nontrivial analytical solutions (3.10) and (3.14) are obtained for 1D ($n = -1$) and 3D ($n = -3$) initial density humps in liquid flow fields. The 1D solution shows that the initial density distribution C_1/x is convected without being diffused at very short times, then diffuses at intermediate times, and then is recovered at long times; the last effect is remarkable behavior of a solution for the nonlinear convection-diffusion equation. In case $C_2 = C_1^{-2}$ and $\alpha = 0$ the solution describes the propagation velocity of a density (temperature) disturbance in the positive half space with zero back pressure at $\hat{x} \to \infty$. The effect of infinite initial density at $x = 0$ is short-lived and can be neglected, quite similar to analyses which employ the Dirac delta function to describe particle concentrations at $t = 0$ in diffusion problems, etc. A comparison with Barenblatt's (1979) general analyses of similarity solutions reveals that the long time propagation velocity should depend on n and can be predicted quite simply by exploring the similarity parameter η. Namely, the density distribution can be expressed as a function of $\ln(\eta)$ or $\ln(\hat{x}) - (1/(n+2))\ln(\hat{t}) + c$. Thus, a propagation velocity in the $\ln(\hat{x})$, $\ln(\hat{t})$ space is equal to $1/(n+2)$. However, in the x, t domain the constant c is paramount and is generally unknown. We show that two essential propagation velocities exist for short and long times ($\hat{u}_P = 1/C_1$ and $\hat{u}_P = 1/C_1 - C_2C_1$, respectively) that cannot be predicted unless a full solution is obtained.

It is also interesting to note that the flow region near the contact line in a shock tube may asymptotically be compared with our simple 1D model despite the fact that the former deals with compressible fluid. The initial density distribution in a shock tube possesses two distinct regions, separated by a diaphragm. However, after the diaphragm is broken, the known theory predicts that *four* main regions exist and a

traveling distinct contact line (not to be confused with the pressure shock; see Shapiro (1954, p. 1007)) separates the two inner regions between the rarefaction and the pressure shock waves. In these two regions the pressure is constant, while the temperature and density fields are discontinuous across the contact line, the latter moving with a constant downstream velocity. Notice that, despite the fact that the fluid is compressible, within the two foregoing regions and for ideal gases, the temperature is inversely proportional to the density since the pressure is uniformly distributed. At the boundaries of these two regions (the rarefaction and the shock waves) a constant flow enters and exits the system. All of the foregoing boundary conditions are nearly satisfied by our 1D model if we assume that $P_r = 1$, keeping the pressure field uniform (see (3.12)). The initial density distribution is obviously different. However, the contact line is, in reality, a diffused region, and a sharp contact line that separates the two density fields is an approximate theoretical description of the field. In our 1D example we focus on the effect of an initially diffused density shock that may mimic the flow field within the two regions adjacent to the contact line. The analytical results of the 1D example show that a flow that possesses an initially diffused density profile has an additional feature; the traveling velocity of the density disturbance has different values for short and long times, unlike the case of a distinct contact line that possesses a unique constant traveling velocity.

The 3D solution exhibits extremely steep gradients in the density and pressure fields that resemble diffused shock waves. A prototypical solution describes a *closed insulated* system with an initial algebraic density hump, $C_1/\hat{r}^3$, that *implodes* within a finite time at a rate proportional to $1/\hat{t}^{\,2}$. Such an unexpected behavior may give rise to a rather interesting question: Are "black holes" possible in liquid systems satisfying the Navier–Stokes equations? In reality this unusual result is an artifact of the assumptions that the terms describing the energy dissipation and fluid compressibility can be omitted from the energy conservation equation. Similarly, a solution was derived for negative times that may provide an insight about the flow field near a diffused adiabatic interfacial region of an expanding bubble.

Similarity solutions for density fields that possess initially r^n (n-arbitrary) humps are also analyzed. The particular form of the governing set of two first order ordinary differential equations (4.2) proves that these similarity solutions can never be *chaotic*. Phase-maps illustrate the trajectories of such systems in 1D, 2D, and 3D flow fields. A formal analytical solution is also obtained for 2D axisymmetric flows (see (4.5), (4.6)). Of particular interest is the 3D ($n = 0$) periodic solution that is obtained for negative densities and mimics the well-known prey-predator problem. It is interesting to note that trajectories do not cross the $G = 0$ axis in 1D and 3D flow problems. Hence, positive and negative density spaces do not interact and are completely separated worlds. Also note that there is no qualitative difference between the different cases shown in Figure 8 for the half plane that pertains to positive (physical) densities, despite the fact that the critical point changes type. In 2D flow problems, trajectories may cross the $G = 0$ axis, and negative and positive density spaces may interact.

Finally, we suggest that (3.10) and (3.14) may also be used to define benchmark problems by which the accuracy of numerical solvers can be verified. One must, however, be cautious in employing the latter, since the stability of solutions (3.10) and (3.14) has not been investigated.

DISPERSIVE WAVE ATTENUATION DUE TO OROGRAPHIC FORCING*

JUAN CARLOS MUÑOZ GRAJALES† AND ANDRÉ NACHBIN‡

Abstract. The O'Doherty–Anstey (ODA) approximation was originally formulated in the seismological literature for acoustic pulse propagation through a disordered stratified medium [*Geophys. Prospecting*, 19 (1971), pp. 430–458]. It explains the mechanism for amplitude attenuation (and pulse shaping) promoted by the variable coefficient, conservative hyperbolic model. This work generalizes the one-dimensional ODA theory for linear weakly dispersive water waves forced by a disordered orography. The analysis is performed through the recently formulated terrain-following Boussinesq system. This is achieved by applying the invariant imbedding method. As a result, dispersion alters the medium's correlation function which controls the apparent attenuation mechanism. On the other hand, orography affects the dispersive mechanism for the Airy function–like formation. A nonlinear Boussinesq solver was implemented, and theoretical results were validated for different values of the parameters of interest. The theoretical results are in very good agreement with the small amplitude simulations. In particular, the approximate theory was able to capture a good part of the forward scattering radiation. Moreover, through numerical experiments the theory is pushed beyond its expected regime and captures the attenuation of small amplitude solitons due to orographic forcing.

Key words. dispersive waves, inhomogeneous media, asymptotic theory

1. Introduction.

Wave-topography interaction has been the subject of considerable mathematical research. The physical applications range from coastal surface waves [18] to atmospheric flows over mountain ranges [2, 7]. In particular, the interaction of waves with fine features of the topography is of great interest. As pointed out in the introduction to [7], the "representation ... of subgrid-scale orographic processes is recognized as crucial to numerical weather prediction at all time ranges." In the atmospheric literature *orography* implies mountain ranges [2]. Our study is therefore focused on the effect of small-scale orographic features, which we call the *microstructure*. A mathematical theory is described and its robustness validated numerically. As surface gravity waves propagate from deep to shallow waters, they are transformed due to shoaling, refraction, diffraction, and reflection. In order to concentrate on the main scattering mechanism connected with the pulse shaping phenomenon to be described, we consider the normal incidence of surface pulse shaped waves. These waves propagate over topographies containing a smooth slowly varying profile together with disordered small-scale features. Our goal is to capture the wave-microstructure interaction.

The main result is that the disordered medium fluctuations cause the propagating pulse to broaden as it travels. Due to multiple scattered energy, the pulse appears to

diffuse about a moving center. The amount of broadening and attenuation is proportional to the traveling distance and depends on the disorder's correlation function. In what follows we refer to the transformation of the pulse due to the medium's microscale fluctuations as *pulse shaping*.

The theory for pulse shaping was originally derived in the context of acoustic wave propagation in the earth's crust [25]. It is known as the O'Doherty–Anstey (ODA) approximation. In the acoustic wave applications several authors have analyzed the spreading of a pulse due to microscale variations in the medium parameters (cf., for example, the work by Clouet and Fouque [9], Papanicolaou and Sølna [27], and Lewicki, Burridge, and de Hoop [15]). The motivation for modeling in terms of a random medium is that a detailed description of microscale medium fluctuations is often not known. Using a stochastic model, uncertainties about a specific medium are translated into uncertainties about a transmitted pulse shape in a systematic way [1]. Stochastic modeling has been used by Nachbin for long weakly dispersive surface wave problems [22, 24].

This work generalizes the one-dimensional ODA theory for linear weakly dispersive water waves when forced by a disordered orography. The analysis is performed through the recently formulated terrain-following Boussinesq system [23]. This is achieved by applying the invariant imbedding method. As a result, dispersion alters the medium's correlation function, which controls the apparent attenuation mechanism. On the other hand, orography affects the dispersive mechanism for the Airy function–like formation. A nonlinear Boussinesq solver was implemented, and theoretical results were validated for different values of the parameters of interest. Details of the numerical method and a larger range of experiments will be presented elsewhere [20]. The theoretical results presented here are in very good agreement with the small amplitude simulations. This amounts to solving the nonlinear Boussinesq system with data on a small amplitude-to-depth ratio. In particular, the approximate theory was able to capture a good part of the forward scattering radiation.

This paper is organized as follows. In section 2 we present the terrain-following Boussinesq system. In section 3 the pulse shaping ODA theory is formulated in detail. Section 4 contains five sets of numerical experiments validating the theory and generating further insight into it. The conclusions are given in section 5. A three-part appendix is intended to provide further detail for the reader.

2. The linearized terrain-following Boussinesq model. We start by presenting the potential theory formulation for Euler's equations with a free surface and an impermeable bottom topography. In the potential theory model the fluid is assumed to be inviscid, incompressible, and irrotational. Let variables with physical dimensions be denoted with a tilde. We introduce the length scales σ (a typical pulse width or wavelength), h_0 (a typical depth), a (a typical wave amplitude), ℓ (the horizontal length scale for bottom irregularities), and L (the total length of the rough region or the total propagation distance). The acceleration due to gravity is denoted by g, and the reference shallow water speed is $c_0 = \sqrt{gh_0}$. Dimensionless variables are then defined in a standard fashion [23, 29]:

$$\tilde{x} = \sigma x, \quad \tilde{y} = h_0\, y, \quad \tilde{t} = \left(\frac{\sigma}{c_0}\right) t, \quad \tilde{\eta} = a\, \eta, \quad \tilde{\phi} = \left(\frac{g\sigma a}{c_0}\right) \phi, \quad \tilde{h} = h_0\, H\left(\frac{\tilde{x}}{\ell}\right).$$

The velocity potential $\phi(x, y, t)$ and wave elevation $\eta(x, t)$ satisfy the dimensionless equations (see [29])

$$\beta\, \phi_{xx} + \phi_{yy} = 0 \quad \text{for} \quad -H(x/\gamma) < y < \alpha\eta(x, t),$$

with the nonlinear free surface conditions

$$\eta_t + \alpha\phi_x\eta_x - \frac{1}{\beta}\phi_y = 0,$$

$$\eta + \phi_t + \frac{\alpha}{2}\left(\phi_x^2 + \frac{1}{\beta}\phi_y^2\right) = 0$$

at $y = \alpha\eta(x,t)$. The parameter $\alpha = a/h_0$ controls the strength of nonlinear effects, and $\beta = h_0^2/\sigma^2$ the level of dispersion. The length scale for the bottom inhomogeneities ℓ leads to the dimensionless parameter $\gamma = \ell/\sigma$. The Neumann condition at the impermeable bottom is

$$\phi_y + \frac{\beta}{\gamma}\, H'(x/\gamma)\phi_x = 0.$$

The bottom topography is described by $y = -H(x/\gamma)$, where

$$H(x/\gamma) \;=\; \begin{cases} 1 + n(x/\gamma) & \text{when } \; 0 < x < L, \\ 1 & \text{when } \; x \le 0 \;\text{ or }\; x \ge L. \end{cases}$$

The bottom profile is described by the function $-n(x/\gamma)$. The topography is rapidly varying when $\gamma \ll 1$. The undisturbed depth is given by $y = -1$, and the topography can be of large amplitude, provided that $|n| < 1$. We do not need to assume that the fluctuations n are small, nor continuous, nor slowly varying.

In past years Boussinesq-type equations have been employed to model surface wave propagation in shallow channels. Such models are weakly nonlinear, weakly dispersive approximations to the full potential theory equations. Peregrine [26] in 1967 deduced a model valid for channels of slowly varying depth, whereas Hamilton [14] in 1977 derived a set of equations valid for arbitrary orographies. The latter used an appropriate curvilinear coordinate system and applied a perturbation approach to the linear potential theory equations retaining the lowest-order effects of dispersion. The change of variables uses a conformal mapping from a strip in the complex $(\xi, \tilde{\zeta})$-plane to the complex z-plane ($z = x + i\tilde{y}$; $\tilde{y} \equiv \beta^{1/2} y$) (see [23]). Hamilton also outlines the formulation of a weakly nonlinear model by considering a Lagragian functional. In this direction, using dimensionless variables and Hamilton's conformal mapping strategy, the potential theory equations are first cast in a fixed orthogonal curvilinear coordinates $(\xi, \tilde{\zeta})$ as (see [23])

$$\phi_{\xi\xi} \;+\; \phi_{\tilde{\zeta}\tilde{\zeta}} \;=\; 0, \qquad\qquad -\sqrt{\beta} < \tilde{\zeta} < \alpha\sqrt{\beta}N(\xi,t), \tag{2.1}$$

with free surface conditions

$$|J|N_t + \alpha\phi_\xi N_\xi - \frac{1}{\sqrt{\beta}}\phi_{\tilde{\zeta}} = 0 \tag{2.2}$$

and

$$\phi_t + \eta + \frac{\alpha}{2|J|}\left(\phi_\xi^2 + \phi_{\tilde{\zeta}}^2\right) = 0 \tag{2.3}$$

at $\tilde{\zeta} = \alpha\sqrt{\beta}N(\xi,t)$. The bottom condition is

$$\phi_{\tilde{\zeta}} = 0 \qquad \text{at } \; \tilde{\zeta} = -\sqrt{\beta}. \tag{2.4}$$

The Jacobian for the $(\xi, \tilde{\zeta}) \to (x, \tilde{y})$ coordinate transformation is represented by $|J|$. Details can be found in Nachbin [23], where the potential theory equations given above are approximated as the ($O(\alpha)$, $O(\beta)$: respectively, weakly nonlinear, weakly dispersive) terrain-following Boussinesq system

$$M(\xi)\eta_t + \left(\left(1 + \frac{\alpha\eta}{M(\xi)}\right)u\right)_\xi = 0,$$
$$u_t + \eta_\xi + \frac{\alpha}{2}\left(\frac{u^2}{M(\xi)^2}\right)_\xi - \frac{\beta}{3}u_{\xi\xi t} = 0.$$

The metric term $M(\xi)$ is defined by

$$M(\xi) \equiv \tilde{y}_{\tilde{\zeta}}(\xi, 0).$$

When $\alpha = 0$ the system above reduces to

$$M(\xi)\eta_t + u_\xi = 0, \tag{2.5}$$
$$u_t + \eta_\xi - \frac{\beta}{3}u_{\xi\xi t} = 0.$$

Here ξ and t are the space and time coordinates, respectively; $\eta = \eta(\xi, t)$ is the wave elevation; and $u = u(\xi, t)$ is the weighted depth-averaged terrain-following velocity [23]. The variable coefficient $M(\xi)$ is a smooth orography-dependent function which appears as a consequence of the changes of variables [23]. When the parameter β is small, we are in the shallow channel/long wave regime. Equivalently, this is called the weakly dispersive regime.

In the next section we will analyze the linear ($\alpha = 0$) Boussinesq system for a large range of dispersive effects, expressed through the parameter β. It is very important to note that for $\beta > 0.25$ we are in the *deep water* regime. The particle-orbits decay exponentially with depth as shown in Dean and Dalrymple [5, Chapter 4, on linear potential theory]. Hence in this regime there is no wave-topography interaction. Thus the fact that the Boussinesq system is an $O(\beta)$ approximation to the potential theory is not much of a limitation for dispersive wave-topography interaction. Moreover, for large time intervals dispersive effects will be strongly displayed in the solutions even for small values of β (cf. Appendix A). Even though the theory we have developed is linear, in our numerical experiments we will consider nontrivial values of α, as will be discussed in the corresponding subsections.

3. The linear pulse shaping theory. In this section we generalize the ODA approximation from linear acoustic waves to the linear weakly dispersive system (2.5). The weakly dispersive Boussinesq system is forced by a rapidly varying orography expressed through the variable coefficient $M(\xi)$. We consider a technique analogous to Berlyand and Burridge's acoustic work [3], which we apply successfully to dispersive waves for two reasons. First, system (2.5) can be written equivalently as two coupled KdV-type equations for the transmitted and reflected fields. These linearized KdV-type equations can be viewed as a dispersive perturbation to those obtained by Berlyand and Burridge; namely, a propagating pulse will slowly disperse with a given (known) rate (cf. Appendix A, (A.4)). Second, the pulse's effective propagation velocity is bounded, and all Fourier modes have positive phase speeds bounded by 1. These two properties described allow us to apply the *invariant imbedding approach* [19], taking the propagation distance as the *imbedding parameter*.

In what follows, solutions u, η to (2.5) will be assumed to be smooth enough and absolutely integrable. This requirement is necessary to justify the use of the Fourier transform and the Fourier inversion formula.

We start by performing the change of variables

$$x = \int_0^{\xi} \frac{1}{C_o(s)} ds, \quad t' = t$$

in system (2.5). Here $C_o(s) = \sqrt{1/M(s)}$ is the *local wave speed* and x is the *travel time*. Dropping the primes, system (2.5) becomes

$$\begin{aligned} & C_o^{-1/2}\, \eta_t + C_o^{1/2}\, u_x = 0, \\ & C_o^{1/2}\, u_t + C_o^{-1/2}\, \eta_x - \frac{\beta}{3C_o^{1/2}} \left(u_{xxt}\, \frac{1}{C_o} + \left(\frac{1}{C_o} \right)_x u_{xt} \right) = 0. \end{aligned} \tag{3.1}$$

We adopt the *wave mode splitting*

$$R = C_o^{1/2} u + C_o^{-1/2} \eta, \tag{3.2}$$

$$L = -C_o^{1/2} u + C_o^{-1/2} \eta. \tag{3.3}$$

Differentiating (3.2) and (3.3) with respect to x and t and using (3.1) and the fact that $u = (R - L)/(2C_o^{1/2})$ leads to the coupled wave mode system

$$\begin{aligned} R_t + R_x &= p(x) \left(\frac{R - L}{2C_o^{1/2}} \right)_{xxt} + q(x) \left(\frac{R - L}{2C_o^{1/2}} \right)_{xt} - r(x) L, \\ L_x - L_t &= p(x) \left(\frac{R - L}{2C_o^{1/2}} \right)_{xxt} + q(x) \left(\frac{R - L}{2C_o^{1/2}} \right)_{xt} - r(x) R, \end{aligned} \tag{3.4}$$

where the variable coefficients are

$$p(x) = \frac{\beta}{3C_o^{3/2}(x)}, \quad q(x) = -\frac{\beta C_{o,x}(x)}{3C_o^{5/2}(x)}, \quad \text{and} \quad r(x) = \frac{C_{o,x}(x)}{2C_o(x)}.$$

The initial conditions for system (3.4) are

$$R(x, 0) = R_o(x), \quad L(x, 0) = 0.$$

Note that when the bottom is flat ($r \equiv 0$) and $\beta = 0$ (no dispersion), equations (3.4) identify R with a wave propagating to the right (transmitted wave) and L with a wave propagating to the left (reflected wave). For variable depths we adopt the same terminology. Moreover, this terminology is also consistent for system (3.4), in the weakly dispersive regime ($0 < \beta \ll 1$) and $r \equiv 0$, since the left-propagating signal L is negligible if the initial data corresponds to a right-going wave (see Appendix A).

Several decompositions of the Boussinesq equations into a pair of KdV equations were introduced by Mattioli in [16] and [17]. We point out that system (3.4) has some advantages with respect to those decompositions. First, unlike system (3.4), the Boussinesq equations used by Mattioli are not valid as an asymptotic approximation of the potential theory equations for arbitrary rapidly varying or nondifferentiable orographies. Second, in contrast to system (3.4), the linear dispersion relation for Mattioli's model results in unstable short waves with amplitude tending to infinity.

In order to set our forthcoming results in a wave propagating frame let us introduce the change of variables

$$\tau = t - x, \quad x' = x,$$

where τ is the time-delay variable. Again abandoning the primes, equations (3.4) become

$$\begin{aligned} R_x = {} & p\left(\frac{R-L}{2C_o^{1/2}}\right)_{\tau\tau\tau} - 2p\left(\frac{R-L}{2C_o^{1/2}}\right)_{x\tau\tau} + p\left(\frac{R-L}{2C_o^{1/2}}\right)_{xx\tau} \\ & - q\left(\frac{R-L}{2C_o^{1/2}}\right)_{\tau\tau} + q\left(\frac{R-L}{2C_o^{1/2}}\right)_{x\tau} - rL, \\ L_x - 2L_\tau = {} & p\left(\frac{R-L}{2C_o^{1/2}}\right)_{\tau\tau\tau} - 2p\left(\frac{R-L}{2C_o^{1/2}}\right)_{x\tau\tau} + p\left(\frac{R-L}{2C_o^{1/2}}\right)_{xx\tau} \\ & - q\left(\frac{R-L}{2C_o^{1/2}}\right)_{\tau\tau} + q\left(\frac{R-L}{2C_o^{1/2}}\right)_{x\tau} - rR. \end{aligned} \tag{3.5}$$

Let $\widehat{f}(\omega)$ denote the Fourier transform of $f(\tau)$ in the time-delay variable τ:

$$\widehat{f}(\omega) = \int_{-\infty}^{\infty} e^{-i\omega\tau} f(\tau)\, d\tau.$$

Take the Fourier transform in τ of (3.5). Manipulate the resulting system in order to obtain first-order equations for the travel time-evolution of the Fourier modes. This goal is achieved by first subtracting the two equations giving

$$\widehat{R}_x - \widehat{L}_x = r\widehat{R} - 2i\omega\widehat{L} - r\widehat{L}. \tag{3.6}$$

Moreover, by differentiating this equation with respect to x, we find

$$\begin{aligned} \widehat{R}_{xx} - \widehat{L}_{xx} = {} & r'(x)\widehat{R} - r'(x)\widehat{L} - 2iw\widehat{R}_x + 2iwr(x)\widehat{R} \\ & + 4w^2\widehat{L} - 4iwr(x)\widehat{L} + r^2(x)\widehat{R} - r^2(x)\widehat{L}. \end{aligned} \tag{3.7}$$

This expression can be used to eliminate the second order x-derivatives in the first Fourier transformed equation arising from (3.5). This is a crucial step in order to apply the invariant imbedding approach, which requires a first-order system of ordinary differential equations (ODE). Using the fact that the time frequency range $|\omega| < C_o(x)\sqrt{3/\beta}$ (see Appendix A), we solve for $\widehat{R}_x$ to obtain

$$\widehat{R}_x = \zeta(x,\omega)\widehat{L} + \gamma(x,\omega)\widehat{R}, \tag{3.8}$$

where

$$\zeta(x,\omega) = \frac{id(x)\omega^3 + e(x)\omega^2 - 2r(x)}{2(1 - d(x)\ \omega^2)}, \quad \gamma(x,\omega) = \frac{\frac{-i\beta\omega^2}{3C_o^2(x)}(\omega - 4ir(x))}{2\left(1 - \frac{\beta\omega^2}{3C_o^2(x)}\right)},$$

$$d(x) = \frac{\beta}{3C_o^2(x)} \quad \text{and} \quad e(x) = -\frac{\beta}{3C_o^3(x)}C_{o,x}(x).$$

Putting (3.8) into (3.6) and solving for $\widehat{L}_x$ results in

$$\widehat{L}_x = (2i\omega + \bar{\gamma}(x,\omega))\widehat{L} + \bar{\zeta}(x,\omega)\widehat{R}, \tag{3.9}$$

where $\bar{\zeta}(x,w)$ and $\bar{\gamma}(x,w)$ denote the complex conjugates of $\zeta(x,w)$ and $\gamma(x,w)$, respectively. As claimed above, (3.8) and (3.9) give the evolution in x (travel time) of each Fourier mode, corresponding to the transmitted and reflected fields.

Next, suppose that we want to calculate $L(x_o,\tau) = L(x_o,\tau;T)$ for $0 \le \tau \le T$. At this step we apply the *invariant imbedding approach* [19] to system (3.8) and (3.9). To do so we imbed the relevant inhomogeneous region inside a homogeneous medium so that we can give appropriate boundary conditions at the border of the medium's slab $[x_o, x_o + X]$, say

$$\widehat{R}(x_o,\omega;T) = \widehat{h}(\omega), \tag{3.10}$$

$$\widehat{L}(x_o + X,\omega;T) = 0. \tag{3.11}$$

Boundary condition (3.11) means that no reflection is expected at the downstream travel time location x_o+X when $0 < \tau = t - x_o < T$. In other words, the signal did not have enough time to arrive at this point and to produce a medium's response. This is true at least for some $X > 0$ large enough (depending on T) due to the pulse's finite (effective) velocity mentioned earlier. Linearity of ODE system (3.8)–(3.9) and the invariant imbedding technique [19] guarantees the existence of a function $K(x,\omega;T)$ (called the *reflection kernel*) such that

$$\widehat{L}(x,\omega;T) = \widehat{K}(x,\omega;T)\ \widehat{R}(x,\omega;T) \tag{3.12}$$

and satisfying the Riccati-type equation

$$\widehat{K}_x = \bar{\zeta}(x,\omega) + 2i\omega\Gamma(x,\omega)\widehat{K} - \zeta(x,\omega)\widehat{K}^2, \tag{3.13}$$

with

$$\Gamma(x,\omega) = \frac{2 - d(x)\omega^2}{2(1 - d(x)\omega^2)}.$$

From (3.11) we obtain an appropriate initial condition for (3.13):

$$\widehat{K}(x_o + X,\omega;T) = 0. \tag{3.14}$$

Notice that (3.12) allows us to solve for the reflected signal $L(x_o,\tau;T)$ in terms of the reflection kernel $K(x_o,\tau;T)$ and the transmitted pulse $R(x_o,\tau;T)$ for $0 \le \tau \le T$. This function K contains all the information about medium's reflection properties. We also remark that the boundary value problem (3.8), (3.9), (3.10), (3.11) has been reduced to solving the initial value problem (3.13)–(3.14) in reversed direction from the travel time location $x_o + X$ up to the time of interest x_o.

In general it is not possible to solve explicitly for $\widehat{K}$ from (3.13), so we adopt an approximation. To this end we present the following generalization to the lemma given by Berlyand and Burridge [3].

LEMMA 3.1. *Let y satisfy the Riccati equation*

$$y'(s) = -A(s) - 2i\omega B(s)y(s) + \bar{A}(s)y^2(s), \quad 0 \le s \le s_o, \tag{3.15}$$

subject to the initial condition $y(0) = 0$. *Here* $\bar{A}(s)$ *denotes the complex conjugate of* $A(s)$. *Hence the solution can be expressed as*

$$y(s_o) = -\int_0^{s_o} e^{-2i\omega \int_{s'}^{s_o} B(\xi)d\xi} A(s')ds' + E(s_o), \tag{3.16}$$

where the error term is

$$E(s_o) = \int_0^{s_o} \bar{A}(s') e^{-2i\omega \int_{s'}^{s_o} B(\xi)d\xi} y^2(s')ds'.$$

Set

$$v(s_o) = \sup_{0\le s\le s_o} \left| \int_0^s e^{2iw \int_0^{s'} B(\xi)d\xi} A(s')ds' \right| \quad \textit{and} \quad V(s) = \int_0^s |A(s')|\, ds'.$$

If $v(s_o)V(s) < 1$, *then*

$$|E(s)| \le \frac{v^2(s_o)V(s)}{1 - v(s_o)V(s)}, \quad 0 \le s \le s_o. \tag{3.17}$$

Proof. Multiplying (3.15) by its integrating factor and integrating both sides from 0 to s yields

$$\begin{aligned} &\int_0^s e^{2i\omega \int_0^{s'} B(\xi)d\xi} y'(s')ds' + 2iw \int_0^s B(s') e^{2i\omega \int_0^{s'} B(\xi)d\xi} y(s')ds' \\ &= -\int_0^s e^{2iw \int_0^{s'} B(\xi)d\xi} A(s')ds' + \int_0^s \bar{A}(s') e^{2i\omega \int_0^{s'} B(\xi)d\xi} y^2(s')ds'. \end{aligned}$$

Consequently,

$$\begin{aligned} &\int_0^s \frac{d}{ds'} \left(e^{2i\omega \int_0^{s'} B(\xi)d\xi} y(s') \right) ds' = e^{2i\omega \int_0^s B(\xi)d\xi} y(s) \\ &= -\int_0^s e^{2i\omega \int_0^{s'} B(\xi)d\xi} A(s')ds' + \int_0^s \bar{A}(s') e^{2i\omega \int_0^{s'} B(\xi)d\xi} y^2(s')ds'. \end{aligned} \tag{3.18}$$

Now solving for $y(s)$ and evaluating at $s = s_o$, in (3.18) we arrive at (3.16).

To achieve estimate (3.17) we start with

$$\begin{aligned} E(s) &= \int_0^s \bar{A}(s') e^{-2i\omega \int_{s'}^{s} B(\xi)d\xi} y^2(s')ds' \\ &= e^{-2i\omega \int_0^s B(\xi)d\xi} \int_0^s \bar{A}(s') e^{2i\omega \int_0^{s'} B(\xi)d\xi} y^2(s')ds'. \end{aligned}$$

Let

$$Y(s) = \int_0^s |A(s')|\, |y(s')|^2\, ds'. \tag{3.19}$$

Hence

$$|E(s)| = \left| \int_0^s \bar{A}(s') e^{2i\omega \int_0^{s'} B(\xi)d\xi} y^2(s')ds' \right| \le Y(s). \tag{3.20}$$

Differentiating (3.19) with respect to s,

$$Y'(s) = |A(s)|\,|y(s)|^2. \tag{3.21}$$

Note that from (3.16) and (3.20)

$$|y(s)| \le v(s_o) + Y(s), \quad 0 \le s \le s_o. \tag{3.22}$$

Thus substituting (3.22) into (3.21) leads to

$$Y'(s) \le |A(s)|\,(v(s_o) + Y(s))^2. \tag{3.23}$$

By integrating (3.23) from 0 to s, we obtain

$$\int_0^s \frac{Y'(s)}{(v(s_o) + Y(s'))^2} ds' \le \int_0^s |A(s')|\, ds' = V(s).$$

Therefore,

$$\frac{1}{v(s_o)} - \frac{1}{v(s_o) + Y(s)} \le V(s).$$

Thus if $v(s_o)V(s) < 1$, equation (3.20) gives

$$|E(s)| \le Y(s) \le \frac{v^2(s_o)V(s)}{1 - v(s_o)V(s)}, \quad 0 \le s \le s_o.$$

This concludes the lemma's proof. □

We now apply these results to our Riccati equation. For brevity the argument T will be omitted in what follows. We apply the lemma above to the reflection kernel's problem (3.13)–(3.14) by letting $y(s) = \widehat{K}(x(s), \omega)$, $A(s) = \bar{\zeta}(x(s), \omega)$, $B(s) = \Gamma(x(s), \omega)$, and $s = x_o + X - x$, $s_o = X$. We deduce that

$$\widehat{K}(x, \omega) = -\int_x^{x+X} e^{2i\omega \int_{x'}^{x} \Gamma(s,\omega)\, ds} \bar{\zeta}(x', \omega) dx' + E(x, \omega), \tag{3.24}$$

with an error term given by

$$E(x, \omega) = \int_x^{x+X} e^{2i\omega \int_{x'}^{x} \Gamma(s,\omega)\, ds} \zeta(x', \omega) \widehat{K}^2(x', \omega) dx'.$$

Also

$$v(x_o, \omega) = \sup_{x_o \le x \le x_o + X} \left| \int_x^{x_o+X} e^{2i\omega \int_{x'}^{x_o+X} \Gamma(s,\omega)\, ds} \bar{\zeta}(x', \omega) dx' \right|$$

and

$$V(x_o, \omega) = \int_{x_o}^{x_o+X} |\zeta(x', \omega)|\, dx'.$$

Then, in the cases where $v(x_o, \omega)V(x_o, \omega) < 1$, the error bound follows.

Now we solve for $\widehat{R}(x_o,\omega)$ at an arbitrary point x_o by using (3.24) and (3.12) in (3.8). It results that

$$\widehat{R}_x(x,\omega)=\left(\zeta(x,\omega)\left(-\int_x^{x+X} e^{2i\omega\int_{x'}^{x}\Gamma(s,\omega)\,ds}\bar{\zeta}(x',\omega)dx'+E(x,\omega)\right)+\gamma\right)\ \widehat{R}(x,\omega).$$

Solving this initial value problem with $\widehat{R}(0,\omega)=\widehat{f}(\omega)$, then

$$\widehat{R}(x_o,\omega)=\widehat{f}(\omega)\ \exp\left[-\int_0^{x_o}\int_x^{x+X}\zeta(x,\omega)e^{2i\omega\ \int_{x'}^{x}\Gamma(s,\omega)\,ds}\ \bar{\zeta}(x',\omega)dx'+\gamma(x,\omega)\ dx\right]$$

$$\cdot\exp\left[\int_0^{x_o}\zeta(x,\omega)\ E(x,\omega)\,dx\right]. \tag{3.25}$$

For general rapidly varying orographies and $\beta\ll 1$ the error function $E(x,\omega)$ is small (see Appendix C), even though the error estimate (3.17) is not useful in this case. Estimate (3.17) is sharp, for instance, when the function describing the medium properties (the metric coefficient $M(x)$ in system (2.5)) is taken to be piecewise constant on travel-time intervals with equal length (called a *Goupillaud medium*) [21].

Therefore, (3.25) leads to the *generalized ODA approximation*

$$\widehat{R}(x_o,\omega)\approx\widehat{f}(\omega)e^{-x_o(a_\beta(x_o,\omega)+b(x_o,\omega))}, \tag{3.26}$$

where

$$a_\beta(x_o,\omega)=\frac{1}{x_o}\int_0^{x_o}\int_x^{x+X}\zeta(x,\omega)e^{2i\omega\int_{x'}^{x}\Gamma(s,\omega)\,ds}\bar{\zeta}(x',\omega)dx'\,dx, \tag{3.27}$$

$$b(x_o,\omega)=-\frac{1}{x_o}\int_0^{x_o}\gamma(x,\omega)\,dx. \tag{3.28}$$

Using approximation (3.26), we can obtain an expression for $R(x_o,\tau)$ (the transmitted field in our applications) by using the Fourier inversion formula. Thus for $0\le\tau\le T$

$$R(x_o,\tau)\approx\frac{1}{2\pi}\int_{-\infty}^{\infty}\widehat{f}(\omega)e^{-x_o(a_\beta(x_o,\omega)+b(x_o,\omega))}e^{i\omega\tau}d\omega. \tag{3.29}$$

Note that the exponential factor in (3.29) accounts for the wave attenuation at travel time x_o. As mentioned above, the error estimate given above is not always sharp. For this reason the error term $E(x_o,\omega)$ is calculated numerically in Appendix C. Furthermore, for dispersion parameter β small enough and constant depth ($r(x)\equiv 0$) we have that $a_\beta=O(\beta^2)$ and $b=O(\beta)$. Hence for variable depths it is reasonable to approximate the medium's dispersive correlation function $a_\beta(x_o,\omega)$ by the medium's hyperbolic correlation function $a_0(x_o,\omega)$; that is,

$$a_\beta(x_o,\omega)\approx\frac{1}{x_o}\int_0^{x_o}\int_x^{x+X}r(x)e^{2i\omega(x-x')}r(x')dx'\ dx\equiv a_0(x_o,\omega). \tag{3.30}$$

This approximation, valid for small values of β, is not a limitation of the theory but enables numerical efficiency in the evaluation of the Fourier integrals. Note that this hyperbolic version is easier to compute than the dispersive formula (3.27). In the

latter the function ζ depends on the frequency ω. Therefore the Fourier-type integral in a_β cannot be computed rapidly by using the FFT (fast Fourier transform). On the other hand, the integral in (3.30) can be easily evaluated by the FFT algorithm because in this case the coefficient $r(x)$ is frequency-independent. In Appendix B we detail the numerical computation of the Fourier-type integral in coefficient $a_\beta(x_o, \omega)$. The accuracy of approximation (3.30) will be verified in section 4 showing that the leading-order dispersive effects are controlled by coefficient $b(x_o, \omega)$.

The numerical experiments in section 4 will show that approximation (3.29) captures very well not only the wave front but also part of the forward scattering radiation. The parameter X in (3.27) (or (3.30)) regulates to what extent the incoherent signal is recovered.

If $\beta = 0$, then $b(x_o, \omega) \equiv 0$, and the approximation given by (3.26) reduces to

$$\widehat{R}(x_o, \omega) \approx \widehat{f}(\omega) e^{-x_o a_0(x_o, \omega)}, \tag{3.31}$$

where

$$a_0(x_o, \omega) = \frac{1}{x_o} \int_0^{x_o} \int_x^{x+X} r(x) e^{2i\omega(x-x')} r(x') dx' \, dx,$$

as in Berlyand and Burridge's work [3]. We recall that when $\beta \neq 0$, the hyperbolic medium's correlation function $a_0(x_o, \omega)$ (which controls the attenuation mechanism) is altered and an extra attenuation term $b(x_o, \omega)$ appears due to the model's dispersion.

4. Numerical validation of the generalized ODA theory. Consider the nonlinear terrain-following Boussinesq system deduced by Nachbin [23],

$$\begin{aligned} &M(\xi)\eta_t + \left(\left(1 + \frac{\alpha\eta}{M(\xi)} \right) u \right)_\xi = 0, \\ &u_t + \eta_\xi + \frac{\alpha}{2} \left(\frac{u^2}{M(\xi)^2} \right)_\xi - \frac{\beta}{3} u_{\xi\xi t} = 0. \end{aligned} \tag{4.1}$$

We recall that when $\alpha = 0$, system (4.1) reduces to (2.5). Nevertheless, for our numerical validation experiments we will use the nonlinear Boussinesq system in a small α regime. Two types of initial data are considered. We study the propagation of Gaussian-shaped disturbances of the form

$$u(\xi, 0) = \eta(\xi, 0) = e^{-(\xi - \xi_o)^2/\epsilon},$$

where the parameter ξ_o controls the pulse's initial position and $\epsilon > 0$ its effective width. Furthermore, we also consider solitary waves of the form

$$\begin{aligned} \eta(\xi, 0) &= A_1 \, \mathrm{sech}^2(B(\xi - \xi_o)) + A_2 \, \mathrm{sech}^4(B(\xi - \xi_o)), \\ u(\xi, 0) &= A \, \mathrm{sech}^2(B(\xi - \xi_o)), \end{aligned}$$

with A_1, A_2, A, and B constants (to be defined in Experiment 2). These are approximate solutions to system (4.1) with $M \equiv 1$ (see [28]).

Except in some special cases (for instance, when $M \equiv 1, \alpha = 0$, or $\beta = 0$), finding the solution of system (4.1) is a nontrivial problem. To solve system (4.1) numerically we will use a finite difference solver introduced by Wei and Kirby [28]. This scheme will be used to perform numerical experiments in order to validate the theory developed in the previous sections.

First we rewrite system (4.1) in a more convenient way, as

$$\begin{aligned} \eta_t &= E(u,\eta), \\ V_t &= F(u,\eta), \end{aligned} \tag{4.2}$$

where

$$\begin{aligned} E(u,\eta) &= -\frac{1}{M(\xi)}\left(\left(1+\frac{\alpha\eta}{M(\xi)}\right)u\right)_\xi, \\ F(u,\eta) &= -\eta_\xi - \frac{\alpha}{2}\left(\frac{u^2}{M(\xi)^2}\right)_\xi, \end{aligned} \tag{4.3}$$

and V is an intermediate variable defined by

$$V = u - \frac{\beta}{3}u_{\xi\xi}.$$

To evaluate the boundary values we use the radiation conditions by Engquist and Majda (see [8])

$$\begin{aligned} u_t - u_\xi &= 0 \quad \text{at} \quad \xi = \xi_{\min}, \\ u_t + u_\xi &= 0 \quad \text{at} \quad \xi = \xi_{\max}, \end{aligned} \tag{4.4}$$

where $\xi_{\min}$ and $\xi_{\max}$ denote the left and right ends, respectively, of the computational domain.

The evolution system above is solved by using an efficient predictor-corrector scheme. The $V \to u$ change of variables is done with an efficient (tridiagonal) ODE numerical scheme. Details, numerical properties, and further numerical experiments are presented elsewhere [20, 21].

We now describe several experiments validating the dispersive pulse-shaping ODA theory.

Experiment 1 (Flat channel and effectively linear regime). In these experiments the pulse is assumed to propagate over a flat bottom ($M \equiv 1$). In Appendix A (cf. (A.6) and (A.7)) we show that if, in addition, $\alpha = 0$, we can explicitly solve system (4.1) by using the Fourier transform technique. Flat channel solutions are employed to verify the numerical method's accuracy regarding dispersive and stability properties.

In Figure 4.1 we see that the exact solution η (for $\alpha = 0$, $\beta = 0.03$) and the numerical solution (for $\alpha = 0.001$, $\beta = 0.03$) are in very good agreement at $t = 40$. After 40 length-units into the flat channel, the right-propagating Gaussian has developed an Airy-like oscillatory tail (cf. Appendix A). The dispersive properties of the numerical scheme are very good.

For this experiment the numerical parameters are $J = 4000$ (spatial mesh points; $\Delta\xi = 0.0125$) and $N = 5000$ (time mesh points; $\Delta t = 0.008$). As mentioned above, this test shows that the code is capturing the (effectively linear) dispersive regime very well when α is small enough.

We repeat the experiment above for $\alpha = 0.001$, $\beta = 0.0005$, and $t = 40$. Dispersion has been decreased substantially. Now the effective hyperbolic regime is clearly observed in Figure 4.2.

Radiation conditions (4.4) also proved to absorb appropriately waves leaving the computational domain. It was observed that reflected waves produced by the computational boundaries were negligible.

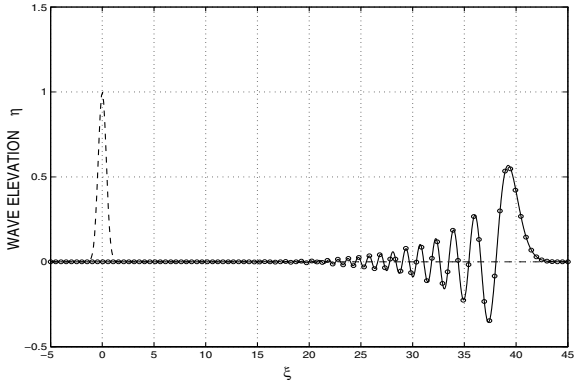

FIG. 4.1. *Dashed line: initial pulse,* $\eta(\xi,0) = u(\xi,0) = e^{-\xi^2/0.3}$. *Solid line: numerical solution for* $\alpha = 0.001$, $\beta = 0.03$, *and* $t = 40$. *Open circles: exact solution.*

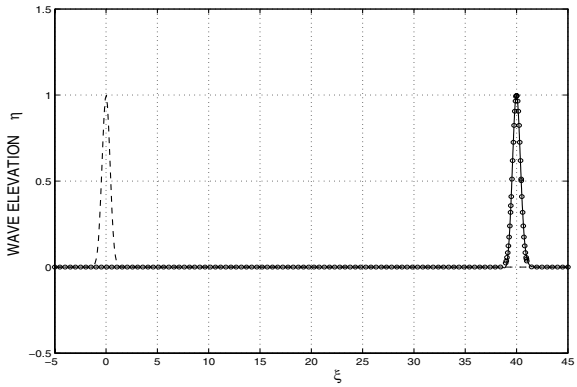

FIG. 4.2. *Dashed line: initial disturbance,* $\eta(\xi,0) = u(\xi,0) = e^{-\xi^2/0.3}$. *Solid line: numerical solution for* $\alpha = 0.001$, $\beta = 0.0005$, *and* $t = 40$. *Open circles: initial Gaussian pulse translated to* $\xi = 40$.

Experiment 2 (Flat channel and weakly nonlinear regime/solitary wave). We now study system (4.1) in the case that $M \equiv 1$, $0 < \alpha \ll 1$ (weakly nonlinear regime), and $0 < \beta \ll 1$ (weakly dispersive regime). Under these hypotheses it is possible to obtain an approximate solution of system (4.1) which has the analytical form

$$\begin{aligned} \eta(\xi,t) &= A_1 \operatorname{sech}^2(B(\xi - Ct - \xi_o)) + A_2 \operatorname{sech}^4(B(\xi - Ct - \xi_o)), \\ u(\xi,t) &= A \operatorname{sech}^2(B(\xi - Ct - \xi_o)), \end{aligned} \tag{4.5}$$

where

$$A_1 = \frac{C^2-1}{\alpha C^2} = \frac{1}{C^2}, \quad A_2 = \frac{(C^2-1)^2}{\alpha C^2} = \frac{\alpha}{C^2}, \quad C = \sqrt{1+\alpha}, \quad A = \frac{C^2-1}{\alpha C} = \frac{1}{C},$$

and

$$B = \left\{ \frac{C^2-1}{(4/3)\beta C^2} \right\}^{1/2} = \left\{ \frac{\alpha}{(4/3)\beta C^2} \right\}^{1/2}.$$

Note that $A_1 + A_2 = 1$. See Wei and Kirby [28] for details.

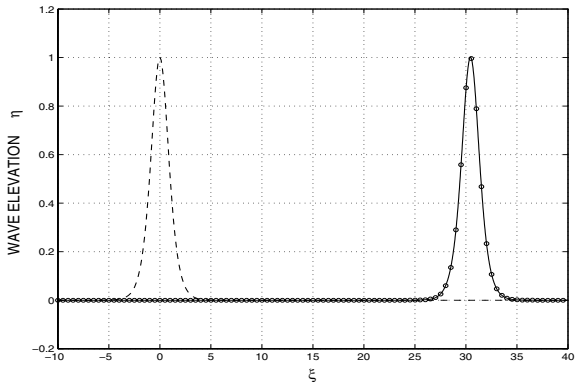

FIG. 4.3. *Solitary wave propagating over a flat bottom. Dashed line: initial disturbance* $\eta(\xi,0) = A_1\ sech^2(B\xi) + A_2\ sech^4(B\xi)$. *Solid line: numerical solution for* $\alpha = 0.03$, $\beta = 0.03$, *and* $t = 30$. *Open circles: analytical solution* (4.5).

In Figure 4.3 we show the analytical solution η given by (4.5) for $\alpha = \beta = 0.03$ and $t = 30$. The initial soliton position is set to be $\xi_o = 0$. The numerical solution is also included in this plot. The numerical parameters are $J = 2000$, $N = 2500$, $\Delta\xi = 0.025$, $\Delta t = 0.012$. Note that we have the same dispersion level as in the first simulation presented in Experiment 1. Now weak nonlinearity prevents the formation of an oscillatory tail.

Observe that the pulse's propagation velocity is $C \approx 1.0149$, in agreement with solution (4.5). The code reproduces very well the weakly dispersive, weakly nonlinear evolution of the soliton.

Experiment 3 (Disordered orography/hyperbolic regime). In Experiments 1 and 2, in which the channel's bottom was assumed to be flat, the orography-dependent coefficient $M(\xi)$ was taken to be $M \equiv 1$. For variable depths the computation of function $M(\xi)$ involves the solution of a change-of-variables problem (conformal mapping), which is not an easy task. For this reason, in next experiments, the smooth orography coefficient $M(\xi)$ will be synthesized directly as a piecewise linear function, ignoring (for the time being) its dependence on the original orography. In [20] we describe in detail how a numerical conformal mapping tool [6] is used in order to obtain a "nonsynthetic" $M(\xi)$. Nevertheless, synthetic $M(\xi)$ proves to be useful (i.e., efficient) for observing the phenomena we are interested in and for validating the theory. The synthesized orography coefficient is conceived as

$$M(\xi) = 1 + \delta\mu(\xi/\ell),$$

where μ is a mean-zero coefficient constructed using a random number generator. The fluctuation level is indicated by δ and its correlation length by ℓ. In the following experiments we use $\delta = 0.5$ and $\ell = 0.1$.

The numerical experiments are performed over a channel defined in the interval $[-15, 70]$. The fluctuations of the synthetic coefficient $M(\xi)$ cover the interval [5, 45]. The data for the right-propagating Gaussian is such that $\xi_o = -5$ and $\epsilon = 0.05$. The numerical solution is plotted as a function of the time-delay variable τ after propagating over 20 units of length and is presented in Figure 4.4. Note the wave

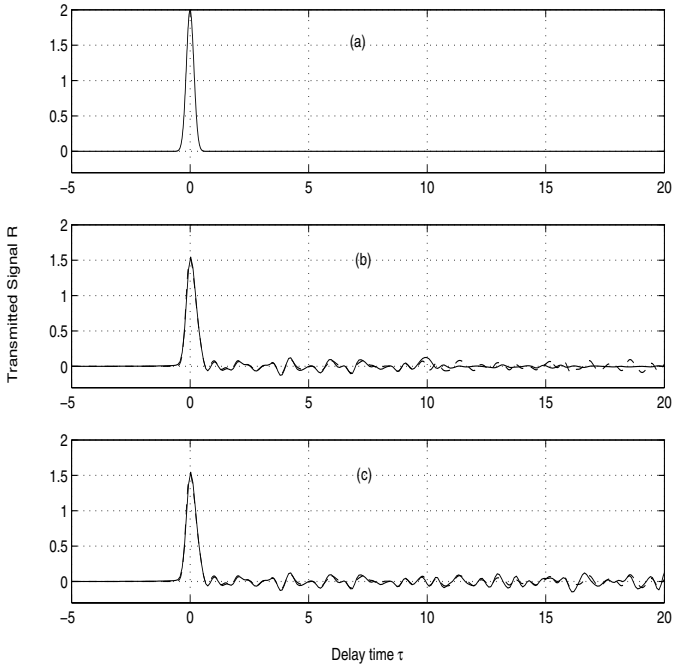

FIG. 4.4. *Pulse propagating over a synthetic disordered rapidly varying topography.* (a) *Initial disturbance* $R(0,\tau) = 2e^{-\tau^2/0.05}$. (b) *Solid line: ODA approximation* (3.31) *for* $X = 5$*; dashed line: numerical solution for* $\alpha = 0.001$, $\beta = 0$ *at* $\xi = 20$. (c) *Solid line: ODA approximation* (3.31) *for* $X = 20$*; dashed line: numerical solution at* $\xi = 20$ *and* α, β *as in* (b).

attenuation due to the orographic forcing. The transmitted signal has amplitude 1.5 (smaller than 2.0, the initial amplitude). The agreement between the numerical solution of the full nonlinear equations (with small α) and the linear theory is very good (Figure 4.4(b)). We also point out an outstanding feature of the theory, not noticed in previous work [3]. The linear hyperbolic ODA approximation is able to capture the forward scattering radiation, which is the incoherent coda behind the transmitted Gaussian. Theory and numerical experiment agree over the delay time interval up to approximately $\tau = 10$.

To verify the robustness of the theory we increase the size of the disordered medium's slab used in the invariant imbedding theory (namely, the variable X). In Figure 4.4(c) we plot the same numerical solution as above but compared with a theoretical result using an increased slab size (up to $X = 20$). The approximate theory captures an even larger segment of the forward scattering radiation beyond $\tau = 15$.

Experiment 4 (Disordered orography/dispersive regime). This set of experiments is important for two reasons. (A) It shows that we are able to properly compute the interaction of dispersive water waves with rapidly varying orographies. With previously known Boussinesq models (such as [26]) this was not possible. The classic Boussinesq equation [26] is not valid for orographies with large slopes. Moreover, its variable coefficient multiplies the highest derivative term, and this generates numerical noise as the orography's slope increases. This has been shown for a periodic topography in [20]. The same experiment was performed for the terrain-following

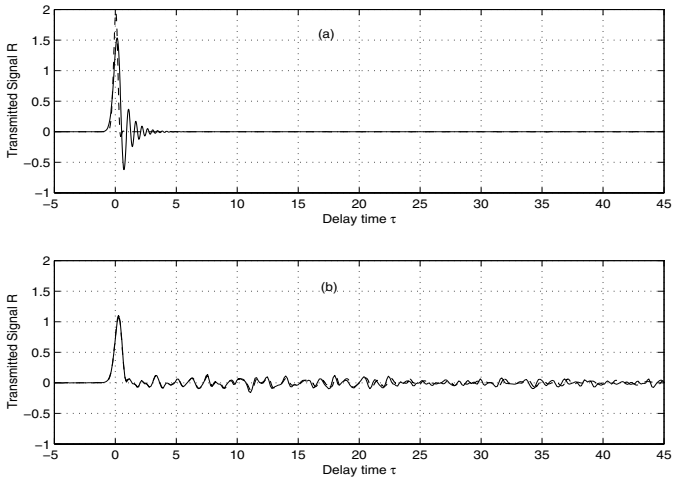

FIG. 4.5. (a) *Dashed line: initial disturbance. Solid line: solution for* $M \equiv 1$ *(flat bottom) at* $\xi = 40$. (b) *Pulse propagating over a synthetic disordered rapidly varying orography. Dashed line: numerical solution at* $\xi = 40$. *Solid line: generalized ODA approximation* (3.29) *for* $X = 20$. *In all experiments* $\alpha = 0.001$, $\beta = 0.0005$.

Boussinesq system where the metric term is positioned away from the third order (dispersive) term. No numerical noise was observed. (B) We illustrate the theoretical results in the regime for which they were deduced. Hence these linear experiments validate the nonlinear numerical model for the terrain-following Boussinesq equation in the presence of a random orography. This is important also since the code will be used (as a scientific computing tool) beyond the regime of validity of the linear theory.

In the first experiment we consider the dispersion to be very weak ($\beta = 0.0005$). Figure 4.5(a) clearly shows that a very short oscillatory tail develops when the pulse propagates in a flat channel. The final amplitude of the transmitted pulse is about 1.5. The amplitude decay in this case is entirely due to dispersion, as discussed in Appendix A, through the Airy kernel. However, in the presence of orographic forcing an additional attenuation is observed (Figure 4.5(b)). In this case the final amplitude is about 1. Note that no Airy-like oscillatory tail develops. This was systematically observed in several experiments and can be explained through the concept of *localization* [24]. The localization length of a Fourier mode is a *characteristic propagation distance* after which the transmission coefficient is negligible. The bulk of the energy is in the reflected signal. Moreover, high frequency components have small localization lengths. This means they are quickly filtered (back) by the disordered medium. In the context of the ODA theory this was phrased in a slightly different way by Berlyand and Burridge [3]. They called a layered random medium a *stratigraphic Gaussian filter*. As presented here, the transmitted pulse can be written as the convolution of its initial Fourier content with a Gaussian kernel. The Gaussian kernel is the leading-order approximation to the kernel in (3.29) with $\beta = 0$ (see [20, 21]). Applying this notion to our current problem, we have that disorder filters the higher part of the Fourier content of the incoming pulse. Hence the oscillatory tail (which is of high frequency content) has been converted into the incoherent part of the wave. Again the agreement between the numerical solution and the ODA theory is very good.

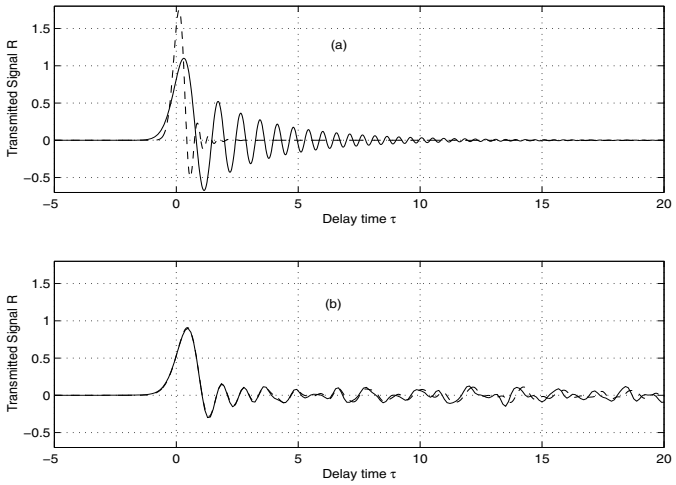

FIG. 4.6. (a) *Dashed line: initial disturbance. Solid line: solution for* $M \equiv 1$ *(flat bottom) at* $\xi = 40$. (b) *Pulse propagating over a synthetic disordered rapidly varying orography. Dashed line: numerical solution at* $\xi = 40$. *Solid line: generalized ODA approximation* (3.29) *for* $X = 20$. *In all experiments* $\alpha = 0.001$, $\beta = 0.002$.

In the next validation experiment the level of dispersion has been increased four times ($\beta = 0.002$). In Figure 4.6(a) we have the initial pulse profile and the numerical solution after propagation over 40 units of a flat channel. We observe a long oscillatory tail due to the higher dispersion level. Note that dispersion is not as small as the value of β might indicate at first sight. After large propagation distances the (small) phase lag (at higher frequencies) has accumulated in a nontrivial fashion.

To compute the theoretical ODA approximation we need the incoming pulse in time at the origin. Actually we need its Fourier content $\hat{f}(\omega)$. To be consistent with our mathematical theory we position the initial Gaussian profile (in space) to the left of the origin at time t_o, allow it to propagate over a flat portion of the channel, and record it in time at the origin. The starting time t_o is chosen so that the resulting pulse $f(\tau)$ will be centered at $\tau = 0$. This gives us the correct incoming pulse (in time) for the theoretical formula to be used. Hence the incoming pulse displays a mild oscillatory tail as displayed by Figure 4.6(a). In Figure 4.6(b) we compare the numerical solution with the generalized ODA approximation. The dispersive wave attenuation can again be observed, in particular if we examine the envelope of the Airy-like solution.

Experiment 5 (Disordered orography/solitary wave). We are now in a position to explore the (linear) generalized ODA theory beyond its regime of validity. We consider a weakly nonlinear weakly dispersive wave, namely a soliton. Using (4.5), it is easy to see that we have

$$f(\tau) = \left(\frac{1}{C^2} + \frac{1}{C}\right) \operatorname{sech}^2(B\tau) + \frac{\alpha}{C^2} \operatorname{sech}^4(B\tau)$$

in order to evaluate the ODA approximation (3.29).

In order to slowly push away from the regime of validity of our theory we choose small values for the respective parameters $\alpha = \beta = 0.001$. This amount of dispersion

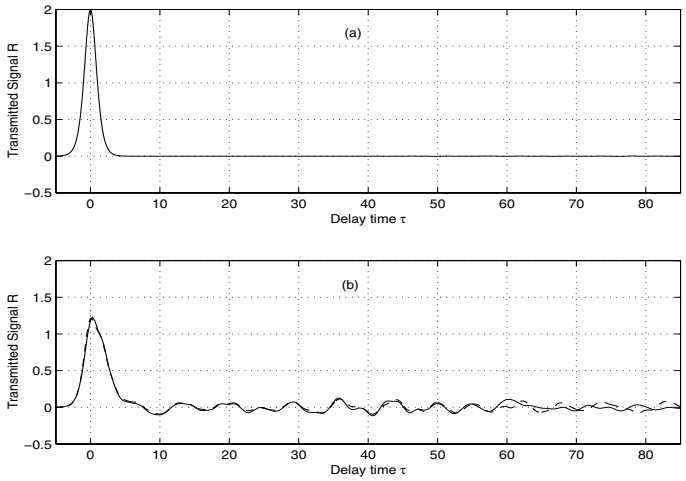

FIG. 4.7. *Soliton propagating over a synthetic disordered rapidly varying orography.* (a) *Initial soliton* $f(\tau)$. (b) *Dashed line: numerical solution for* $\alpha = 0.001$, $\beta = 0.001$ *at* $\xi = 150$. *Solid line: generalized ODA approximation* (3.29) *for* $X = 30$.

is enough to produce an oscillatory coda, as was observed in previous experiments. But now, for the particular data considered, this coda will not appear due to the perfect balance between the α and β terms. The oscillatory coda seen in Figure 4.7(b) is due entirely to forward scattering of energy generated by the interaction of the soliton with the disordered medium. Because the soliton is wider than the Gaussian (used before) we adopt $\ell = 0.6$. This keeps the wave/inhomogeneities ratio equal to approximately 10 ($\gamma = 0.1$) as in all other experiments. The orography coefficient covers the [5, 245] interval, and the amplitude of fluctuations is $\delta = 0.5$. In Figure 4.7(b) we present the excellent agreement between the theory and the numerical solution.

It is worthwhile recalling that the solitary wave (4.5) is an approximate solution to the Boussinesq equations as presented by Wei and Kirby [28] in their appendix. In [28, p. 255] they discuss solitary-wave propagation over a flat bottom and analyze the effects, under the corresponding approximation, of increasing the soliton's amplitude (namely, the nonlinearity parameter α, denoted there by δ). They observed that for $\alpha = 0.1$ the initial profile specified by (4.5) undergoes a rapid adjustment to a slightly higher solitary wave with a very small dispersive tail. This dispersive tail is not noticeable in their experiment [28, Figure 2(a)] after the soliton has propagated over 55 pulsewidths (450 length units). Nevertheless the amplitudes of the tail and of the rapid deviation from the initial solitary wave height both increase with increasing α. As explained in [28], this is partially because the fourth-order ODE used to develop the analytical solution is only asymptotically equivalent to the Boussinesq model used in the computations. In particular, for $\alpha = 0.3$ Wei and Kirby show that the corresponding evolution for (4.5) is far from a traveling wave solution.

As pointed out before, the ODA theory developed is linear, while these experiments are performed beyond the linear regime. Hence in our experiments we will gradually increase the values of α, but we will be far from the "problematic regime" indicated by Wei and Kirby [28]. In our second experiment with solitons, and to

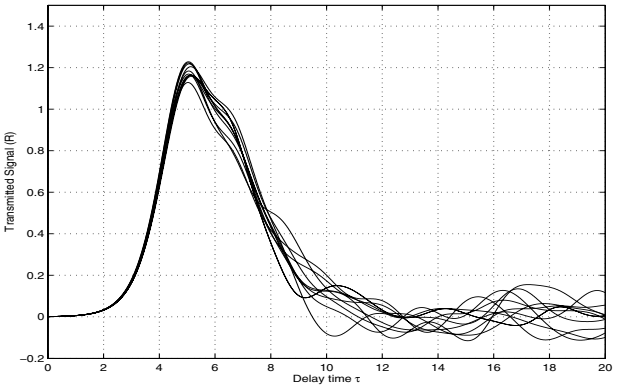

FIG. 4.8. *Transmitted pulse stabilization observed at a fixed medium's station ($\xi = 150$; 25 pulse widths). The same initial soliton ($\alpha = \beta = 0.002$) propagated over ten different realizations of the topography. The transmitted pulse shape is effectively deterministic, while the coda is random.*

further move away from the linear regime, we double the nonlinearity and dispersive parameters accordingly. We will now investigate the effect of different realizations of the medium. In Figure 4.8 we present the results for ten different realizations of the disordered topography. We observe the stabilization of the transmitted pulse: the pulse shaping of the front is independent of the specific realization. This has been proved for the linear hyperbolic case [15]. Stabilization in the linear dispersive regime has been recently proved in [10]. The present framework has been extended, through a stochastic analysis, to include stabilization [10] for the time-reversed refocusing of dispersive waves. No stabilization theory is yet available for solitons though.

As already mentioned, the solitary wave profile (4.5) is not an exact traveling wave solution to the corresponding, constant coefficient, Boussinesq system. Nevertheless the balance between weak nonlinearity and weak dispersion is maintained for large time intervals. If dispersion were not present, a Burgers-type nonlinearity ($\eta_t + \alpha\eta\eta_x = 0$) would force the solitary wave profile (4.5) to eventually break. For an initial profile denoted as $\eta(x,0) = f(x)$ the critical time t_c is known to be $t_c = -1/(\alpha f')$ for the maximum value of the negative slope of $f(x)$. For $f(x)$ given by (4.5), with $\alpha = \beta = \varepsilon$, the maximum value of the negative slope is at $\tilde{x}$ such that $\tanh(B\tilde{x}) = -z$, where

$$z = \left(\frac{1 + C + 2\alpha}{3 + 3C + 10\alpha}\right)^{1/2},$$

$$f'(\tilde{x}) = -\left(\frac{3}{(1+\varepsilon)^3}\right)^{1/2}\left[\frac{1-z^2}{z^2}\left((1+C)z + 2\varepsilon\left(\frac{1-z^2}{z}\right)\right)\right], \quad \text{with} \quad C = \sqrt{1+\varepsilon},$$

and $t_c \approx 1/(4\varepsilon)$. Hence if dispersion were switched off, the solitary wave would break after 50 length units (approximately 8.33 pulse widths), when $\varepsilon = \alpha = 0.005$, as will be used in the following experiment.

In our last experiment we further increase nonlinearity and dispersion to $\alpha = \beta = 0.005$. The result is presented in Figure 4.9. As observed in Experiment 4, disorder attenuates the effect of dispersion in this weakly nonlinear experiment. Note the soliton steepening at the wave front due to the attenuation of the dispersive mechanism. The attenuated wave front predicted by the linear theory does not match

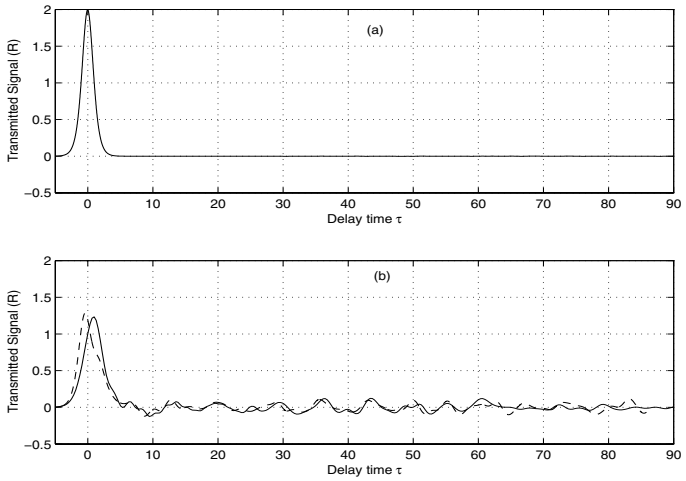

FIG. 4.9. *Soliton propagating over a synthetic disordered rapidly varying orography.* (a) *Initial soliton* $f(\tau)$. (b) *Dashed line: numerical solution for* $\alpha = 0.005$, $\beta = 0.005$ *at* $\xi = 150$. *Solid line: generalized ODA approximation* (3.29) *for* $X = 30$.

the nonlinear numerical front as before. Note also that dispersion has not been fully switched off or else a shock would have formed in finite time according to the discussion above. More experiments with solitary waves, including time-reversal and refocusing, are presented in [20].

The study of solitary waves moving over disordered topography is of great interest. In this work we have presented only scientific computing results. A complete theoretical understanding is of interest and will be considered in the future. Recently progress has been made in this direction [10, 11]. Theoretical results for nonlinear localization and soliton propagation in random media are recent and more focused on the nonlinear Schrödinger (NLS) equation. A very good source of references can be found through the work of Garnier [12, 13]. We are not aware of any results regarding solitons for the Boussinesq system (or equation).

5. Conclusion. We have formulated a generalization of the ODA theory for linear weakly dispersive waves. The theory has been validated numerically and pushed beyond its linear regime of validity. In particular, both the theoretical expressions and the numerical experiments have been able to capture the apparent diffusion of small amplitude solitary waves. This is a theme of great interest: soliton propagation in disordered media. Further mathematical analysis is needed to fully understand this problem.

Nevertheless this work has stimulated new theoretical results in the stochastic formulation for time-reversed dispersive wave refocusing [10] and also for the ODA and time-reversed refocusing [11] of weakly nonlinear hyperbolic waves. The authors [11] have shown that, to leading order, the transmitted pulse is governed by a viscous Burgers equation. The "apparent viscosity" depends on statistics of the random medium. This important result reports on a weakly nonlinear ODA theory for nondispersive waves. Therefore the regularizing effect is entirely due to the "apparent viscosity" promoted by the disordered orography. But it still does not apply to solitons. Details of the "apparently viscous" theory, including additional nonlinear experiments, are presented in [11].

Appendix A. Solutions for the linear KdV equation and the linear Boussinesq model.

The linear KdV equation. Consider the initial value problem

$$u_t + u_x + \gamma u_{xxx} = 0, \tag{A.1}$$

$$u(x,0) = f(x), \tag{A.2}$$

where γ is a nonzero constant. Using a Fourier transform in x, the solution for (A.1) and (A.2) is given by

$$u(x,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\left(\int_{-\infty}^{\infty} e^{i(k(x-t-y)+\gamma k^3 t)}dk\right) f(y)dy. \tag{A.3}$$

Making a convenient change of variables, the inner integral in (A.3) can be expressed in terms of the Airy function to give

$$u(x,t) = \frac{1}{(3t\gamma)^{1/3}}\int_{-\infty}^{\infty} \mathrm{Ai}\left(\frac{x-t-y}{(3t\gamma)^{1/3}}\right) f(y)dy. \tag{A.4}$$

The Airy kernel gives the rate in time at which a pulse $f(x)$ will spread due to dispersion. This is useful information for the invariant imbedding technique used in the ODA theory.

The linear Boussinesq model. Now we study the linearization of system (4.1) for constant depth:

$$\begin{aligned} &\eta_t + u_\xi = 0,\\ &u_t + \eta_\xi - \frac{\beta}{3}u_{\xi\xi t} = 0, \end{aligned} \tag{A.5}$$

with the initial conditions

$$\eta(\xi,0) = u(\xi,0) = f(\xi).$$

Analogously to the KdV equation, we can apply the Fourier transform technique to obtain the Fourier coefficients

$$\begin{aligned} \hat{\eta}(k,t) = \frac{\hat{f}(k)}{2}\Bigg[&\left(1-\sqrt{1+(\beta/3)k^2}\right)e^{\frac{ikt}{\sqrt{1+\beta/3k^2}}}\\ &+\left(1+\sqrt{1+(\beta/3)k^2}\right)e^{\frac{-ikt}{\sqrt{1+\beta/3k^2}}}\Bigg], \end{aligned} \tag{A.6}$$

$$\begin{aligned} \hat{u}(k,t) = \frac{\hat{f}(k)}{2\sqrt{1+(\beta/3)k^2}}\Bigg[&\left(1+\sqrt{1+(\beta/3)k^2}\right)e^{\frac{-ikt}{\sqrt{1+\beta/3k^2}}}\\ &-\left(1-\sqrt{1+(\beta/3)k^2}\right)e^{\frac{ikt}{\sqrt{1+\beta/3k^2}}}\Bigg]. \end{aligned} \tag{A.7}$$

We point out that in the hyperbolic case ($\beta = 0$) the above initial data gives rise to (only) a right-propagating mode. In the dispersive case a negligible left-propagating mode is always present in this type of data. Notice that, because of (A.6), (A.7), and

$$\frac{1}{\sqrt{1+(\beta/3)k^2}} = 1 - (k^2/6)\beta + O(\beta^2),$$

we have that

$$\widehat{L}(t,k) = \hat{\eta}(t,k) - \hat{u}(t,k) = O(\beta) \approx 0,$$

provided that β is small enough. For the hyperbolic case the left-propagating mode is identically zero.

The dispersion relation for system (A.5) is

$$\omega_{\pm} = \omega_{\pm}(k) = \pm \frac{k}{\sqrt{1 + \frac{\beta}{3}k^2}}, \tag{A.8}$$

where ω_+ and ω_- represent Fourier modes propagating to the right and left, respectively. In contrast to the KdV equation, the phase velocity is

$$C_k^{\pm} = \frac{\omega_{\pm}}{k} = \pm \frac{1}{\sqrt{1 + \frac{\beta}{3}k^2}},$$

which does not switch signs and is bounded by one. Furthermore, $\omega_+ = \omega_+(k)$ coincides up to $O(k^3)$ with the dispersion relation for the KdV equation above with $\gamma = \beta/6$. Note also that, for waves generated in space, the range of possible time frequencies is bounded by $(3/\beta)^{1/2}$ for all k. As a consequence, solutions u, η of system (A.5) are band-limited functions in t. This fact justifies why frequencies ω higher than $\sqrt{3/\beta}$ are not considered in the analysis presented in section 3.

Appendix B. Numerical computation of coefficients $a_\beta(x_o, \omega)$ and $b(x_o, \omega)$. As mentioned in section 3, the numerical computation of the dispersive coefficient $a_\beta(x_o, \omega)$ is expensive. To override this difficulty, and use the FFT, we approximated $a_\beta(x_o, \omega)$ by the hyperbolic medium's correlation function $a_0(x_o, \omega)$, which corresponds to the leading-order term of a Taylor series expansion of a_β around $\beta = 0$. The numerical experiments in section 4 showed the high accuracy of this approximation.

To compute coefficient $a_0(x_o, \omega)$ as in (3.30) we rewrite it as

$$a_0(x_o, \omega) = \int_0^X \Phi(\eta) e^{-2i\omega\eta} d\eta, \tag{B.1}$$

where

$$\Phi(\eta) = \frac{1}{x_o} \int_0^{x_o} r(x) r(x + \eta) dx.$$

We know by the correlation theorem that

$$\int_{-\infty}^{\infty} r(x) r(x + \eta) dx = F^{-1}[\hat{r}\bar{\hat{r}}](\eta),$$

where the hat denotes the Fourier transform, F^{-1} the inverse Fourier transform, and the bar indicates complex conjugation. Therefore function Φ defined above can be computed by using the FFT algorithm, letting the coefficient $r(x)$ be zero outside the interval $[0, x_o]$. This is consistent with the invariant imbedding approach. We must append enough zeros to the tail of the sampled coefficient $r(x)$ (zero padding) in order

to eliminate the overlapping phenomenon that appears due to the fact that $r(x)$ is not a periodic function. The FFT assumes periodicity in both physical and frequency domains (see Brigham [4]). The cost of computing the discrete correlation function results in only three FFT evaluations, which is faster than an ordinary computation of the integral defining Φ for each value of η. The numerical code to perform the discrete correlation can be found in [4].

Once the function Φ is known, the windowed Fourier transform in (B.1) is evaluated by using only one FFT. Analogously to the discrete correlation, zero padding outside the interval $[0, X]$ is required on the sampling of function Φ.

To evaluate the generalized ODA approximation presented in section 3 we also need the dispersive coefficient $b(x_o, \omega)$. To make its computation faster we rewrite it in the more compact form

$$b(x_o,\omega) = -\frac{\beta}{6x_o}\int_0^{\xi(x_o)} \frac{-i\omega^3 M^{3/2}(\xi) + M'(\xi)\omega^2}{1-(\beta/3)M(\xi)\omega^2}\,d\xi, \tag{B.2}$$

where the upper limit $\xi(x_o)$ denotes the spatial position in the medium corresponding to the travel time x_o. Thus we need compute only once the coefficients $M(\xi)$, $M^{3/2}(\xi)$, and $M'(\xi)$, which can be stored at the beginning. The integral in (B.2) is approximated by the trapezoidal method for roughly 2^{14} frequencies in the range $|\omega| < C_o(x_o)\sqrt{3/\beta}$. Since $b(x_o, -\omega) = \overline{b(x_o, \omega)}$, only positive frequencies need to be evaluated.

Appendix C. Error estimation of the pulse shaping theory. In section 3 the reflection kernel K was decomposed according to the result of Lemma 3.1. In the derivation of the generalized ODA approximation (under the hypotheses of rapidly varying orography and weakly dispersive regime $0 < \beta \ll 1$) we retained only the first term on the right-hand side of the decomposition, leading to the approximation

$$\widehat{K}(x,\omega) \approx -\int_x^{x+X} e^{2i\omega\int_{x'}^{x}\Gamma(s,\omega)\,ds}\bar{\zeta}(x',\omega)dx'. \tag{C.1}$$

We wish to give numerical evidence showing the accuracy of this approximation. First, observe that the reflection kernel K can be computed by solving numerically the Riccati equation

$$\widehat{K}_x = \bar{\zeta}(x,\omega) + 2i\omega\Gamma(x,\omega)\widehat{K} - \zeta(x,\omega)\widehat{K}^2,$$

subject to

$$\widehat{K}(x_o + X, \omega; T) = 0.$$

(See the definitions of coefficients Γ and ζ in section 3.) Consequently, we can evaluate the error function $E(x_o, \omega)$ at any time x_o and frequency ω. The results are presented in Figure C.1, where we compare the norm of function $E(x_o, \omega)$ to that of approximation (C.1) at point $\xi = 40$, with $X = 20$ and $\beta = 0.005$. We see that the error function is negligible over all frequencies. The parameters used for the orography considered here are $L = 240$ (total length of the rough bottom), $\ell = 0.6$ (scale of variation of the orography), and $\delta = 0.5$ (amplitude of orography's fluctuations).

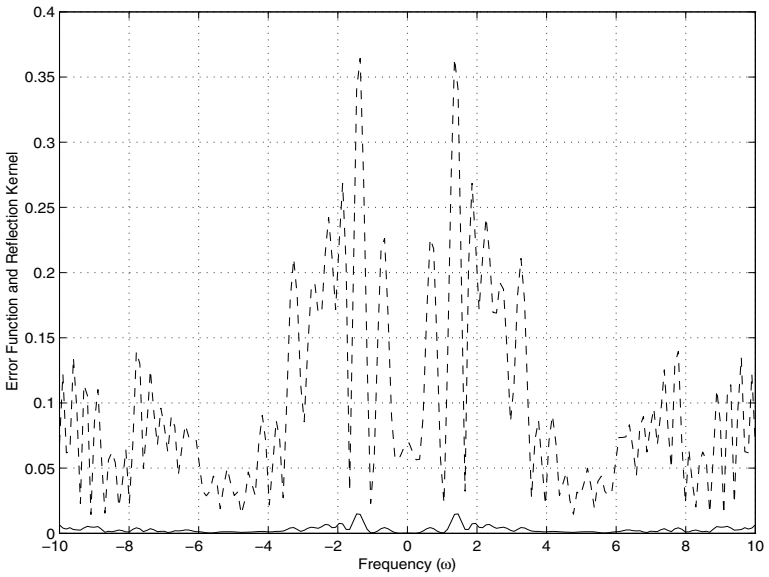

FIG. C.1. *Solid line: error norm for* $\beta = 0.005$, $X = 20$ *at* $\xi = 40$. *Dashed line: norm of approximation* (C.1) *for the same parameters.*

HOMOGENIZED NON-NEWTONIAN VISCOELASTIC RHEOLOGY OF A SUSPENSION OF INTERACTING PARTICLES IN A VISCOUS NEWTONIAN FLUID*

L. BERLYAND† AND E. KHRUSLOV‡

Abstract. Our study is motivated by an attempt to develop a rigorous mathematical model of a suspension highly filled with a large number of small solid particles, which *interact* due to surface forces. We use asymptotic analysis in the small parameter ϵ and consider irregular (nonperiodic) geometries for which the sizes of particles and the distances between them are of order ϵ. We present conditions under which the homogenization of a Newtonian fluid with interacting particles leads to a single medium which is an anisotropic, non-Newtonian viscoelastic fluid with memory described by a relaxation term. We derive formulas for the calculation of the effective viscosity tensor and the relaxation integral kernel. For periodic arrays of particles we show how this tensor can be explicitly computed and compute the distribution of the relaxation times, which is the main quantity of interest in the rheological studies. We also show how the particles' shapes affect this distribution.

Key words. homogenization, non-Newtonian fluids, suspensions, relaxation time, viscoelasticity, interaction, surface forces

1. Introduction.

In this work we propose a rigorous mathematical model of polymer compounds highly filled with a large number of small particles, which *interact* due to the surface forces (e.g., Van der Waals or London forces). Such polymer compounds (e.g., carbon black or silica particles in a polymer matrix) are widely used in industry, and their properties have been the subject of studies in polymer science and engineering literature (see, for example, comprehensive review articles [4], [19]).

Similar questions arise in the study of colloidal suspensions of a large number of small *interacting* particles in a fluid. Such suspensions are ubiquitous, and control of their rheology is vital to the commercial success of many products (see, e.g., [5], [17] and references therein). Here we are interested in the suspensions of solid particles in fluid when particles do not clump together (do not gel).

The key common feature in both the polymer compounds and the suspensions is the *interaction* between particles due to surface forces. Our main focus is to develop a rigorous mathematical model which shows how the interaction affects the homogenized medium. We also provide an approximation for the effective (overall) viscoelastic properties of the mixture and compute, in particular, the relaxation times for several specific arrays of particles.

We start from a mathematical model of the suspension. It consists of the time dependent Stokes equations for an incompressible viscous fluid, the boundary conditions on the fluid/particle interfaces, and the balance of linear and angular momentums for

each particle. The latter two balance equations incorporate the interaction forces. The key ingredient is the introduction of an appropriate potential energy functional which describes particle-particle interaction. Roughly speaking, this functional takes into account the fact that for sufficiently close pairs of particles there is an attractive/repulsive force between each point on the surfaces of both particles.

This system of equations is completed by appropriate initial conditions and the boundary conditions on the external boundary, which correspond to the relaxation measurements.

Note that, while for colloidal suspensions the Stokes equations provide a natural description of the fluid phase, for polymer compounds it is natural to consider viscoelastic (non-Newtonian) equations for the fluid phase. However, under special circumstances, when the relaxation times in the fluid phase are very small (short fading memory) in comparison with other characteristic times in the system (e.g., for external forces), one can still use Stokes equations to characterize the fluid phase.

We use asymptotic analysis in the small parameter ϵ and consider the geometries for which the sizes of particles and the distances between them are of order ϵ. We show that if the strength of the interaction forces is of order of ϵ, then homogenization of a Newtonian fluid with interacting particles leads to a single medium, which is an anisotropic, non-Newtonian viscoelastic fluid with memory described by a relaxation term. We derive formulas for calculation of the effective viscosity tensor and the relaxation integral kernel. For periodic arrays of particles we show how this tensor can be explicitly computed and compute the distribution of the relaxation times, which is the main quantity of interest in the rheological studies. We also show how particles' shapes affect this distribution.

It follows from our analysis that for a weaker interaction the anisotropic effect vanishes in the homogenization limit. The case of stronger interaction is somewhat trivial; that is, it can be shown that the homogenized limit is zero, since the effective medium becomes stiff. Therefore our main focus is on the order ϵ interaction case when homogenization results in a drastic change in the constitutive equations. We restrict our attention to the case of a Newtonian fluid phase because our main focus is on showing how the interaction between the particles gives rise to viscoelastic relaxation in the effective medium. However, our approach is applicable for the non-Newtonian viscoelastic fluid filled by solid particles.

We remark here that the fact that homogenization of elastic and fluid phases can lead to effective viscoelastic behavior (with or without memory) was observed by many authors in various problems. For example, in [3] it was rigorously proved that incompressible viscous fluid in an elastic porous medium has an overall viscoelastic behavior. This work justified the formal asymptotic result obtained earlier in [2]. Also for dynamic problems of oscillations of a mixture of an elastic solid phase and viscous fluid phase the effective viscoelastic equations were rigorously derived in a series of works (see [16], [15] and references therein). A comprehensive mathematical study of elastic/viscoelastic composites that leads to a several types of effective viscoelastic behavior, including a threshold phenomenon, is presented in [14]. In all these works the viscoelastic overall behavior is obtained due to the presence of an elastic phase as well as a viscous fluid phase or viscoelastic phase.

In our work the solid phase consists of absolutely rigid particles, and the overall viscoelastic behavior is due to the *interaction* between particles and viscosity of the fluid phase. While this phenomenon was studied both theoretically and experimentally in the physics literature (see [4], [19], [17] and references therein), it was not obtained as the result of a mathematical homogenization procedure. In this paper we

present a model of interacting solid particles in a viscous fluid and derive the effective viscoelastic model as a homogenization limit. Our approach rigorously justifies this asymptotic limit for very generic nonperiodic geometries and provides new computational formulas for the viscoelastic kernel and the relaxation times. Furthermore, we analyzed this formula analytically and arrived at an interesting qualitative conclusion that the symmetry of particles affects the number of relaxation times. The issue of relaxation times is of importance for the rheological community [5] and was brought to our attention in the context of this work by R. Lakes. Thus our work provides (a) mathematical justification for qualitative observations previously made in physics literature and (b) formulas for effective properties which can be used as a tool for their numerical evaluation.

2. Formulation of the problem. Let Ω be a bounded domain in $\mathbb{R}^3$ with piecewise smooth boundary $\partial\Omega$. This domain is occupied by a composite medium, which is a suspension of a large number of small rigid particles Q_ϵ^i $(i = 1, \dots N_\epsilon)$ in a viscous incompressible fluid. The boundary $S_\epsilon^i = \partial Q_\epsilon^i$ of each particle is smooth. The small parameter $\epsilon > 0$ characterizes the array of particles so that $d_\epsilon^i = O(\epsilon)$ and $N^\epsilon = O\left(\frac{1}{\epsilon^3}\right)$, where d_ϵ^i are diameters of the particles Q_ϵ^i. Thus the average distances between neighboring particles are of order of ϵ. The location of a particle Q_ϵ^i is characterized by the position of its center of mass $\underline{x}^i$ and the vector of its three Euler angles $\underline{\alpha}^i = (\alpha_1^i, \alpha_2^i, \alpha_3^i)$.

When the fluid is at rest the system of particles Q_ϵ^i is in equilibrium, which is described by the system of vectors $\underline{x}_\epsilon^i$ and $\underline{\alpha}_\epsilon^i$ $(i = 1, \dots, N_\epsilon)$. The equilibrium is determined by the minimum of the potential energy $H_\epsilon(\underline{x}^i, \underline{\alpha}^i)$, which describes the pairwise interaction between the particles and between the particles and the boundary $\partial\Omega$:

$$H_\epsilon(\underline{x}_\epsilon^i, \underline{\alpha}_\epsilon^i) = \min H_\varepsilon(\underline{x}^i, \underline{\alpha}^i).$$

The interaction between particles is determined by the surface forces such as Van der Waals forces and London forces; see [5]. The total interaction energy H_ε is the sum of the interactions between pairs of points $\underline{x} \in S_\varepsilon^i$ and $\underline{y} \in S_\varepsilon^j$. Since the particles are rigid, the displacement (translation and rotation) $\delta\underline{x}$ of each point $\underline{x} \in S_\varepsilon^i$ is determined by the following equality:

$$\delta\underline{x} = \underline{u}^i + \underline{\theta}^i \times (\underline{x} - \underline{x}_\varepsilon^i)\,,$$

where $\underline{u}^i = \underline{x}^i - \underline{x}_\varepsilon^i$ is the displacement of the center of mass of the particle Q_ε^i and $\underline{\theta}^i$ is the vector, which determines the rotation of the particle about some axis oriented along the vector $\underline{\theta}^i$. For small displacements the vector $\underline{\theta}^i$ is related to the increments of the Euler's angles $\delta\alpha^i = \alpha^i - \alpha_\varepsilon^i$ by the standard kinematic relations $\underline{\theta}^i = \underline{\underline{R}}\ \underline{\delta\alpha}^i$, where matrix $\underline{\underline{R}}$ depends on $\underline{\alpha}_\varepsilon^i$; see [6].

Thus near the equilibrium we write the potential energy due to the interaction between the particles in the following form (a quadratic approximation):

$$H_{v\varepsilon}(\underline{x}^i, \underline{\alpha}^i) = H_{v\varepsilon}(\underline{x}_\varepsilon^i, \underline{\alpha}_\varepsilon^i) + \frac{1}{2}\sum_{\substack{i,j \\ j\neq i}} \int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \langle \underline{\underline{C}}_\varepsilon^{ij}(\underline{x}, \underline{y}) \left[\underline{u}^i + \underline{\theta}^i \times (\underline{x} - \underline{x}_\varepsilon^i)\right.$$

$$\left. - \underline{u}^j - \underline{\theta}^j \times (\underline{y} - \underline{x}_\varepsilon^j)\right], \left[\underline{u}^i + \underline{\theta}^i \times (\underline{x} - \underline{x}_\varepsilon^i) - \underline{u}^j - \underline{\theta}^j \times (\underline{y} - \underline{x}_\varepsilon^j)\right]\rangle dS_x\, dS_y + \text{h.o.t.} \tag{2.1}$$

Here $\underline{u}^i = \underline{x}^i - \underline{x}_\varepsilon^i$, $\underline{\theta}^i = \underline{\underline{R}}[\underline{\alpha}^i - \underline{\alpha}_\varepsilon^i]$, $\langle\ ,\ \rangle$ stands for the dot product in $\mathbb{R}^3$, $\underline{\underline{C}}_\varepsilon^{ij}(\underline{x}, \underline{y})$ are symmetric nonnegative 3×3 matrices, and h.o.t. stands for higher order terms.

It is natural to assume that if two points $\underline{x}$ and $\underline{y}$ move as end points of a rigid rod, that is, their displacements are given by

$$\underline{u}(\underline{x}) = \underline{a} + \underline{b} \times \underline{x} \qquad \text{and} \qquad \underline{u}(\underline{y}) = \underline{a} + \underline{b} \times \underline{y}, \tag{2.2}$$

where $\underline{a}$ and $\underline{b}$ are constant vectors, then their interaction energy is zero, that is, the matrix $\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y})$ satisfies the following condition:

$$\langle \underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y})[\underline{b} \times (\underline{x} - \underline{y})], [\underline{b} \times (\underline{x} - \underline{y})] \rangle = 0. \tag{2.3}$$

In this work we assume that up to a scalar factor $a^{ij}_{\varepsilon}(\underline{x}, \underline{y}) > 0$ the matrix $\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y})$ corresponds to the operator of projection on the unit vector $\underline{\ell}(x, y) = (\underline{x} - \underline{y})/|\underline{x} - \underline{y}|$; that is, for any unit vector $\underline{v}$

$$\underline{\underline{C}}^{ij}_{\varepsilon}\, \underline{v} = a^{ij}_{\varepsilon}(\underline{x}, \underline{y})\ P_{xy}\underline{v} := a^{ij}_{\varepsilon}(\underline{x}, \underline{y}) \langle \underline{\ell}(\underline{x}, \underline{y}), \underline{v} \rangle \underline{\ell}(\underline{x}, \underline{y}), \tag{2.3$'$}$$

where P_{xy} is the projection operator and $a^{ij}_{\varepsilon}(\underline{x}, \underline{y})$ is a nonnegative bounded function $a^{ij}_{\varepsilon}(\underline{x}, \underline{y}) \in L^{\infty}(S^i_{\varepsilon} \times S^j_{\varepsilon})$. Clearly (2.3′) implies (2.3). We consider the short-range interactions (see condition (a_3) below) and assume that the matrices $\underline{\underline{C}}^{ij}_{\varepsilon}$ satisfy the following conditions:

$$\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y}) = \underline{\underline{C}}^{ji}_{\varepsilon}(\underline{y}, \underline{x}). \tag{2.4}$$

Observe that the interaction energy (2.1) is invariant under translations and rotations of the system of particles as a whole. In other words, the system of particles connected by "virtual springs" which represent the interaction has a continuum of nonlocalized equilibriums if not clamped to some external boundary.

In order to obtain a localized equilibrium $\{\underline{x}^i_{\varepsilon}, \underline{\theta}^i_{\varepsilon}, i = 1, \dots N_{\varepsilon}\}$ we take into account interaction between some particles and the external boundary $\partial\Omega$ (e.g., particles in a boundary layer of thickness ε and "fully visible" from the boundary). Figure 2.1 illustrates the interaction between a particle Q^i_{ε} and a piece of the boundary $\partial\Omega^i_{\varepsilon}$ (a quasiparticle), which "sees" this particle.

Then, in addition to the (volume) energy (2.1), we need to take into account the energy due to the interaction with $\partial\Omega$, for which in the quadratic approximation can be written in the following form:

$$\begin{aligned} H_{b\varepsilon}(\underline{u}^i, \underline{\theta}^i, \underline{u}) = \sum_{\substack{i,j \\ i \neq j}} \int_{S^i_{\varepsilon}} \int_{\partial\Omega^j_{\varepsilon}} < \underline{\underline{C}}^{ij}(\underline{x}, \underline{y})[\underline{u}^i_{\varepsilon} + \underline{\theta}^i_{\varepsilon} \times (\underline{x} - \underline{x}^i_{\varepsilon}) - \underline{u}(\underline{y})], \\ [\underline{u}^i_{\varepsilon} + \underline{\theta}^i_{\varepsilon} \times (\underline{x} - \underline{x}^i_{\varepsilon}) - \underline{u}(y)] > dS_x dS_y, \end{aligned} \tag{2.5}$$

where $\partial\Omega^i_{\varepsilon}$ are "pieces" of the external boundary $\partial\Omega$ (size of $\partial\Omega^i_{\varepsilon} \sim \varepsilon$), $\underline{u}(y, t) = \int_0^t \underline{v}(y, t)dt$ is the displacement vector, $\underline{v}(y, t)$ is the velocity vector on $\partial\Omega$, and summation in i is taken over particles close to the boundary $\partial\Omega$ (see Figure 2.1).

Thus the total interaction energy $H_{\varepsilon} = H_{\varepsilon}(\underline{u}^i, \underline{\theta}^i, \underline{u})$ is the sum of the volume and the boundary parts:

$$H_{\varepsilon}(u^i, \theta^i, u) = H_{v\varepsilon}(\underline{u}^i, \underline{\theta}^i) + H_{b\varepsilon}(\underline{u}^i, \underline{\theta}^i, \underline{u}). \tag{2.6}$$

Note that the pieces $\partial\Omega^i_{\varepsilon}$ can be viewed as "flat, nonrigid particles" (quasiparticles) which are glued to the boundary $\partial\Omega$. The total number of quasiparticles and

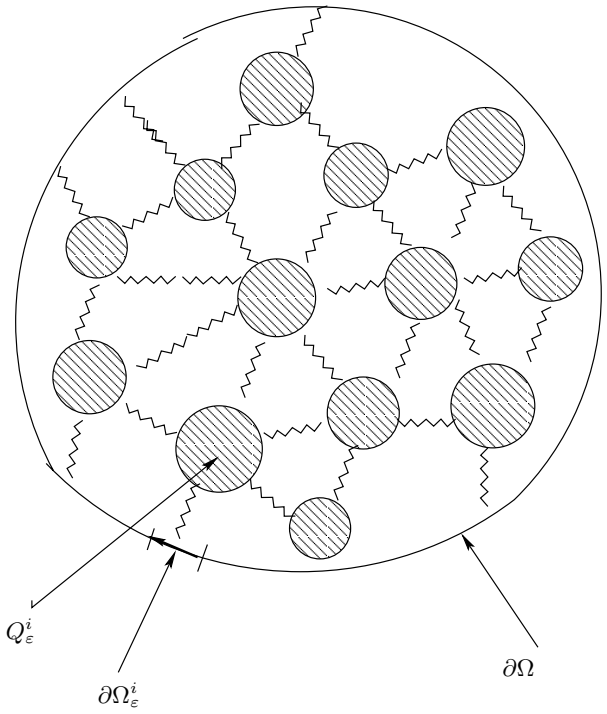

FIG. 2.1. *Domain Ω and its boundary.*

the particles which interact with them is of order $O(\varepsilon^{-2}) \ll N_\varepsilon \sim O(\varepsilon^{-3})$. Unless otherwise is specified, we will use the same notation Q_ε^j and $S_\varepsilon^j = \partial Q_\varepsilon^j$ for both particles and quasiparticles. Note that the energy (2.1) in the variables $\underline{u}^i, \underline{\theta}^i$ can also be rewritten in the following form, which is convenient for further considerations:

$$
\begin{aligned}
H_{v\varepsilon}(\underline{u}^i, \underline{\theta}^i) &= H_{v\varepsilon}(0,0) + \frac{1}{2}\sum_{\substack{i,j\\ i\neq j}} \langle \underline{\underline{C}}_{1\varepsilon}^{ij}[\underline{u}^i - \underline{u}^j], [\underline{u}^i - \underline{u}^j]\rangle \\
&+ \sum_{\substack{i,j\\ i\neq j}} \langle \underline{\underline{C}}_{2\varepsilon}^{ij}[\underline{u}^i - \underline{u}^j], \underline{\theta}^i\rangle + \sum_{\substack{i,j\\ i\neq j}} \langle \underline{\underline{C}}_{3\varepsilon}^{ij}\underline{\theta}^i, \underline{\theta}^i\rangle + \sum_{\substack{i,j\\ i\neq j}} \langle \underline{\underline{C}}_{4\varepsilon}^{ij}\underline{\theta}^i, \underline{\theta}^j\rangle,
\end{aligned} \tag{2.7}
$$

where

$$
\begin{cases}
\underline{\underline{C}}_{1\varepsilon}^{ij} = \displaystyle\int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \underline{\underline{C}}_{\varepsilon}^{ij}(\underline{x},\underline{y})\,dS_x dS_y, \\
\underline{\underline{C}}_{2\varepsilon}^{ij} = \displaystyle\int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \underline{\underline{A}}^T(\underline{x} - \underline{x}_\varepsilon^i)\underline{\underline{C}}_{\varepsilon}^{ij}(\underline{x},\underline{y})\,dS_x dS_y, \\
\underline{\underline{C}}_{3\varepsilon}^{ij} = \displaystyle\int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \underline{\underline{A}}^T(\underline{x} - \underline{x}_\varepsilon^i)\underline{\underline{C}}^{ij}(\underline{x},\underline{y})\underline{\underline{A}}(\underline{x} - \underline{x}_\varepsilon^i)\,dS_x dS_y, \\
\underline{\underline{C}}_{4\varepsilon}^{ij} = -\displaystyle\int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \underline{\underline{A}}^T(\underline{y} - \underline{x}^j)\underline{\underline{C}}^{ij}(\underline{x},\underline{y})\underline{\underline{A}}(\underline{x} - \underline{x}^i)\,dS_x dS_y.
\end{cases} \tag{2.8}
$$

Here we introduced a skew symmetric matrix $\underline{\underline{A}}(x)$ defined by

$$\underline{\theta} \times \underline{x} = \underline{\underline{A}}(\underline{x})\underline{\theta} \tag{2.9}$$

and pulled the constant translation and rotation vectors outside the integral.

We introduce the following notation: $\Omega_\varepsilon = \Omega \backslash \cup_{i=1}^{N_\varepsilon} Q_\varepsilon^i$ is the domain occupied by the fluid; ρ_s, ρ_f are the specific mass density of the solid particles and the fluid, respectively; μ is the dynamic viscosity of the fluid; $m_\varepsilon^i = \rho_s |Q_\varepsilon^i|$ is the mass of a particle Q_ε^i; and $\underline{\underline{I}}_\varepsilon$ is the tensor of inertia of a particle Q_ε^i.

Then we write a linearized system of equations that describes the dynamics of the suspension (viscous fluid filled by the interacting particles):

$$\rho_f \frac{\partial \underline{v}_\varepsilon}{\partial t} - \mu \Delta \underline{v}_\varepsilon = \nabla p_\varepsilon \quad \text{in } \Omega_\varepsilon, \tag{2.10}$$

$$\operatorname{div} \underline{v}_\varepsilon = 0 \quad \text{in } \Omega_\varepsilon, \tag{2.11}$$

$$\underline{v}_\varepsilon = \underline{\dot{u}}_\varepsilon^i + \underline{\dot{\theta}}_\varepsilon^i \times (\underline{x} - \underline{x}_\varepsilon^i), \quad \underline{x} \in Q_\varepsilon^i, \quad i = 1, \dots N_\varepsilon, \tag{2.12}$$

$$m_\varepsilon^i \underline{\ddot{u}}_\varepsilon^i = -\int_{S_\varepsilon^i} \underline{\underline{\sigma}}[\underline{v}_\varepsilon]\underline{\nu}\, dS - \nabla_{u^i} H_\varepsilon, \tag{2.13}$$

$$\underline{\underline{I}}_\varepsilon^i \underline{\ddot{\theta}}_\varepsilon^i = -\int_{S_\varepsilon^i} (\underline{x} - \underline{x}_\varepsilon^i) \times \underline{\underline{\sigma}}[\underline{v}_\varepsilon]\underline{\nu}\, dS_x - \nabla_{\theta^i} H_\varepsilon. \tag{2.14}$$

Conditions (2.13)–(2.14) hold for all particles Q_ε^i located inside the domain Ω but not for the quasiparticles $\partial\Omega_\varepsilon^i$ (see Figure 2.1). Here $\underline{v}_\varepsilon = \underline{v}_\varepsilon(\underline{x}, t)$ is the velocity of the fluid, $p_\varepsilon = p_\varepsilon(\underline{x}, t)$ is the pressure, $\underline{u}_\varepsilon^i$ is the displacement of the center of mass of a particle Q_ε^i, and $\underline{\theta}_\varepsilon^i$ is the rotation vector of Q_ε^i. We also use the following notation: $\dot{u}_\varepsilon^i = du_\varepsilon^i/dt$ and $\ddot{u}_\varepsilon^i = d^2u_\varepsilon^i/dt^2$ for the velocity and the acceleration, respectively, of the center of mass of Q_ε^i; $\dot{\theta}_\varepsilon^i$ for the instant angular velocity of Q_ε^i; and $\underline{\nu}$ for the unit inner normal vector to the surface $S_\varepsilon^i = \partial Q_\varepsilon^i$. The stress tensor in the fluid $\underline{\underline{\sigma}}[v_\varepsilon]$ is a symmetric second rank tensor defined as follows (see [7]):

$$\sigma_{ik} = \mu \left[\frac{\partial v_{\varepsilon i}}{\partial x_k} + \frac{\partial v_{\varepsilon k}}{\partial x_i} \right] - p_\varepsilon \delta_{ik} \quad (i, k = 1, 2, 3). \tag{2.15}$$

The equations (2.12) represent the nonslip condition at the fluid-particle interfaces $S_\varepsilon^i = \partial Q_\varepsilon^i$, $i = 1, \dots N_\varepsilon$. Using this condition, one can naturally extend the velocity field $\underline{v}_\varepsilon$ into the particles Q_ε^i. Equations (2.13) and (2.14) represent the balance of linear and angular momentums. In (2.14) we assume that the tensor of inertia $\underline{\underline{I}}_\varepsilon^i$ is constant, since we consider linearization for small displacements. The first (integral) terms in the right-hand side (RHS) of (2.13)–(2.14) are due to the forces exerted on the particles by the fluid, and the second terms are due to the interaction between the particles (surface or Van der Waals forces).

The system (2.10)–(2.14) is supplemented by the initial conditions

$$\begin{cases} \underline{v}_\varepsilon(\underline{x}, 0) = \underline{v}_{\varepsilon 0}(\underline{x}), \quad \underline{x} \in \Omega_\varepsilon, \\ \underline{u}_\varepsilon^i(0) = 0,\ \underline{\dot{u}}_\varepsilon^i(0) = \underline{u}_{\varepsilon 1}^i,\ \underline{\theta}_\varepsilon^i(0) = 0,\ \underline{\dot{\theta}}_\varepsilon^i(0) = \underline{\theta}_{\varepsilon 1},\ \underline{x} \in Q_\varepsilon^i \quad \text{(on the particles)}, \end{cases} \tag{2.16}$$

and the boundary conditions on the external boundary

$$\underline{v}_\varepsilon(\underline{x},t) = \underline{f}(\underline{x},t), \quad \underline{x} \in \partial\Omega, \quad t \geq 0. \tag{2.17}$$

We consider the boundary function $\underline{f}(\underline{x},t)$, which is sufficiently smooth (e.g., $\underline{f}(\underline{x},t) \in C^2(\partial\Omega)$) and decays sufficiently fast as $t \to \infty$. Since the fluid is incompressible, we have

$$\int_{\partial\Omega} \langle \underline{f}(\underline{x},t), \underline{\nu}(x)\rangle \, dS_x = 0, \tag{2.18}$$

where $\underline{\nu}(x)$ is the unit normal to $\partial\Omega$ at a point $x \in \partial\Omega$.

The boundary condition (2.17) corresponds to experimental measurements in which the macroscopic rheological properties of the compound are determined when the rate of change of the displacement at the external boundary is prescribed. Then one measures the normal stresses (the response) on the boundary (relaxation measurements).

Another type of experiment, when the load forces (stresses) are prescribed at the external boundary and the displacements are measured (creep measurements [7]), corresponds to the boundary conditions

$$\underline{\underline{\sigma}}[\underline{v}_\varepsilon] \cdot \underline{\nu}(\underline{x}) = \underline{f}_\varepsilon(\underline{x}), \quad \underline{x} \in \partial\Omega, \tag{2.19}$$

for the system (2.10)–(2.16).

The main goal of our work is to obtain the homogenized problem for the initial boundary value problem (2.10)–(2.18) in the limit as $\varepsilon \to 0$ and to establish the convergence of its solutions $\underline{u}_\varepsilon$ to the solution $\underline{u}$ of the homogenized problem, which is a single macroscopic medium with new effective (rheological) properties. We also show how to compute these properties for particular geometries if the interaction matrix $\underline{\underline{C}}^{ij}(\underline{x},\underline{y})$ is known.

Both initial boundary value problems (2.10)–(2.18) and (2.10)–(2.16), (2.19) can be studied using the homogenization approach developed in this work for the boundary condition (2.17).

3. Mesocharacteristic and formulation of the main result. In order to formulate the main result we first formulate two conditions, which describe the geometry of the particles.

(a_1) Each particle Q^i_ε is obtained by ε-rescaling of a body from a collection $\mathcal{M}$, where $\mathcal{M} = \{Q^{(m)}, m = 1, 2, \dots M\}$ is a finite collection of convex bodies in $\mathbb{R}^3$, with smooth boundaries $S^{(m)} = \partial Q^{(m)}$; that is, $Q^i_\varepsilon = \underline{\underline{R}}^i \underline{\underline{T}}^i_\varepsilon Q^{(m_i)}$, $Q^{(m_i)} \in \mathcal{M}$, and R^i and T^i_ε are the rotation and the translation operators, respectively. Thus, the diameters of the particles $d^i_\varepsilon = \varepsilon$ diam $(Q^{(m_i)})$, $1 \leq m_i \leq M$, and the area $|S^i_\varepsilon|$ of a particle Q^i_ε can be bounded as follows: $|S^i_\varepsilon| < C\varepsilon^2$, $C > 0$, is independent on ε.

(a_2) Let $B(Q^i_\varepsilon)$ be a ball of minimal radius such that $Q^i_\varepsilon \subseteq B(Q^i_\varepsilon)$, and let r^i_ε be the distance from $B(Q^i_\varepsilon)$ to other minimal balls and the boundary $\partial\Omega$, $r^i_\varepsilon =$ dist $\{B(Q^i_\varepsilon), \bigcup_{j\neq i} B(Q^j_\varepsilon) \bigcup \partial\Omega\}$.

We assume that the following inequalities hold,

$$C_1\varepsilon \leq r^i_\varepsilon \leq C_2\varepsilon\,, \tag{3.1}$$

where the constants C_1 and C_2 do not depend on ε ($0 < C_1 < C_2 < \infty$), and that as $\varepsilon \to 0$ the particles densely fill the domain Ω (get into any finite subdomain for

sufficiently small ε). The condition (3.1) means that the particles do not form clusters and do not come too close to the boundary $\partial\Omega$.

We next present two more conditions which describe the nature and the magnitude of the interaction between the particles. First, we consider only short-range interactions so that the matrix-functions $\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x},\underline{y})$ (see (2.1)) satisfy the following condition:

(a_3)

$$\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x},\underline{y}) \equiv 0 \quad \text{if dist } (Q^i_\varepsilon, Q^j_\varepsilon) \geq C\varepsilon, \tag{3.2}$$

where $0 < C < \infty$ does not depend on ε. Here the constant C is chosen in such a way that each particle interacts with its nearest neighbors only, for an appropriate definition of the nearest neighbor.

Second, we consider the case when the entries of the matrix-functions $\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x},\underline{y})$ are of order $O(\varepsilon^{-3})$. More precisely, the scalar function $a^{ij}_{\varepsilon}(\underline{x},\underline{y})$ in the condition (2.3′) can be written as follows:

(a_4)

$$a^{ij}_{\varepsilon}(\underline{x},\underline{y}) = \varepsilon^{-3} a^{ij}_0(\underline{x},\underline{y}), \tag{3.3}$$

where $a^{ij}_0(\underline{x},\underline{y})$ is a bounded nonnegative function.

We remark here that our proof applies also for the weaker interactions $a^{ij}_{\varepsilon} = o(\varepsilon^{-3})a^{ij}_0$; however, the interactions of order ε^{-3} lead to the most interesting rheological properties of the effective medium (viscoelasticity and memory), whereas weaker interactions lead to the effective viscosity with no memory.

We introduce a mesoscopic characteristic of the suspension (the fluid-particle compound). This *mesocharacteristic* plays the key role in our consideration. Roughly speaking, it allows us to compute the energy of the compound in some mesoscopic cube of size $h : \varepsilon \ll h \ll 1$, which is a so-called representative volume element. In other words, the size h is much larger than the microscale ε and much smaller than the macroscopic size of the system so that effective properties in this volume element provide correct rheological properties of the compound locally. The mesocharacteristic is motivated by experimental techniques in which one cuts out a certain piece of a compound and measures its properties in order to evaluate the overall properties of the compound.

We now define the mesocharacteristic rigorously using the variational formulation presented below in (4.8) (parameter λ is introduced in (4.1)–(4.6)).

Let $K^{\underline{\xi}}_h = K(\underline{\xi}, h)$ be a cube of side length $h > 0$ such that $\varepsilon \ll h \ll 1$ centered at a point $\underline{\xi} \in \Omega$. The orientation of the cube is arbitrary but independent of $\underline{\xi}$ and h. For the sake of definiteness we assume that the edges of this cube are parallel to the coordinate axis.

Introduce the following class of functions

$$\mathcal{J}_\varepsilon[K^{\underline{\xi}}_h] = \{\underline{w}_\varepsilon \in H^1(K^{\underline{\xi}}_h), \quad \underline{w}_\varepsilon = \underline{a}^i_\varepsilon + \underline{b}^i_\varepsilon \times (\underline{x} - \underline{x}^i_\varepsilon) \quad \text{on } Q^i_\varepsilon \cap K^{\underline{\xi}}_h\}, \tag{3.4}$$

where $\underline{a}^i_\varepsilon$ and $\underline{b}^i_\varepsilon$ are arbitrary constant vectors, and consider a minimization problem in the class $\mathcal{J}_\varepsilon(K^{\underline{\xi}}_h)$ for the following functional:

$$\begin{aligned} &A_{\varepsilon h}[\underline{u}_\varepsilon, \underline{\underline{T}}, \underline{\xi}, \lambda, \tau] \\ &\quad = E_{K^{\underline{\xi}}_h}[\underline{u}_\varepsilon, \underline{u}_\varepsilon] + h^{-2-\tau} \int_{K_h{}^{\underline{\xi}}} \left| \underline{u}_\varepsilon - \sum_{p,q=1}^{3} \underline{\psi}^{pq}(\underline{x} - \underline{\xi}) T_{pq} \right|^2 dx + \frac{1}{\lambda} I^{\varepsilon}_{K^{\underline{\xi}}_h}[\underline{u}_\varepsilon, \underline{u}_\varepsilon], \end{aligned} \tag{3.5}$$

where $e_{k\ell}[\underline{u}] = \frac{1}{2}[\frac{\partial u_k}{\partial x_\ell} + \frac{\partial u_\ell}{\partial x_k}]$ is the deformation rate of the fluid moving with velocity $\underline{u}$, $\underline{\underline{T}} = \{T_{pq}\}$ is an arbitrary symmetric second rank tensor with constant components T_{pq}, λ and τ are arbitrary positive numbers, and the matrix-functions $\underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y})$ are defined in (2.1).

Hereafter we use the following notation:

$$E_G[\underline{u}_\varepsilon, \underline{v}_\varepsilon] = 2\mu \int_G \int \sum_{k,l=1}^{3} e_{kl}[\underline{u}_\varepsilon] e_{kl}[\underline{v}_\varepsilon] d\underline{x}, \tag{3.6}$$

$$I^{\varepsilon}_G[\underline{u}_\varepsilon, \underline{v}_\varepsilon] = \frac{1}{2} \sum_{ij} \int_{S^i_\varepsilon} \int_{S^j_\varepsilon} \langle \underline{\underline{C}}^{ij}_{\varepsilon}(\underline{u}(\underline{x}) - \underline{u}(\underline{y})), \underline{v}(\underline{x}) - \underline{v}(\underline{y}) \rangle dS^i_x dS^j_y, \tag{3.7}$$

$$\underline{\psi}^{pq}(\underline{x}) = \frac{1}{2}(x_p \underline{e}^q + x_q \, \underline{e}^p) - \frac{\delta_{pq}}{3} \sum_{n=1}^{3} x_n \underline{e}^n \,, \tag{3.8}$$

where $p, q = 1, 2, 3$; $\underline{e}^q$ are the basis vectors so that $\underline{x} = \sum_{q=1}^{3} x_q \underline{e}^q$; and δ_{pq} stands for the Kronecker delta symbol. It is easy to check that $\operatorname{div} \underline{\psi}^{pq} = 0$. The sum $\sum_{ij}$ in (3.7) is taken over all particles located inside the domain G.

LEMMA 3.1. *For any constant tensor $\underline{\underline{T}}$ there exists the unique minimizer $\underline{u}(\underline{x}) = \underline{u}(\underline{x}, \underline{\underline{T}})$ (dependence on the parameters $\varepsilon, h, \underline{\xi}, \lambda$, and τ is suppressed) of the functional* (3.5) *in the class $\mathcal{J}_\varepsilon[K^{\underline{\xi}}_h]$. The minimum value of this functional is a quadratic function of the tensor $\underline{\underline{T}} = \{T_{pq}\}$, and the following representation holds:*

$$\min_{\underline{u}_\varepsilon \in \mathcal{J}_\varepsilon[K^{\underline{\xi}}_h]} A_{\varepsilon h}[\underline{u}_\varepsilon, \underline{\underline{T}}, \underline{\xi}, \lambda, \tau] = \sum_{npqr=1}^{3} a_{npqr}(\underline{\xi}, \lambda, \varepsilon, h, \tau) T_{np} \, T_{qr} \,, \tag{3.9}$$

where $a_{npqr}(\xi, \lambda, \varepsilon, h, \tau)$ are the components of a 4th rank tensor, defined as

$$\begin{aligned} a_{npqr}(\underline{\xi}, \lambda; \varepsilon, h, \tau) &= E_{K^{\underline{\xi}}_h}[\underline{u}^{np}, \underline{u}^{qr}] \\ &+ \int_{K^{\underline{\xi}}_h} h^{-2-\tau} \langle \underline{u}^{np}(\underline{x}) - \underline{\psi}^{np}(\underline{x} - \underline{\xi}), \underline{u}^{qr}(\underline{\xi}) - \underline{\psi}^{qr}(\underline{x} - \xi) \rangle d\underline{x} + \frac{1}{\lambda} I_{K^{\underline{\xi}}_h}[\underline{u}^{np}, \underline{u}^{qr}]. \end{aligned} \tag{3.10}$$

Here $\underline{u}^{np}(\underline{x})$ is the minimizer of the functional $A_{\varepsilon h}[\underline{u}, \underline{\underline{T}}, \lambda, \underline{\xi}, \tau]$ when $\underline{\underline{T}} = \frac{1}{2}(\underline{e}^n \otimes \underline{e}^p + \underline{e}^p \otimes \underline{e}^n)$.

This lemma is proved in [1]. We now briefly outline the proof. First we show that the class $\mathcal{J}_\varepsilon[K^{\underline{\xi}}_h]$ is not empty by an explicit construction of a function $\underline{\psi}^{np}_{\varepsilon}(\underline{x})$ from this class. This is done by an appropriate modification of the function $\underline{\psi}^{np}(\underline{x} - \underline{\xi})$. Next we generalize this construction to obtain a dense in $\mathcal{J}_\varepsilon[K^{\underline{\xi}}_h]$ set of functions starting from an arbitrary function $w(\underline{x}) \in C^1(K^{\underline{\xi}}_h)$. Using the function $\underline{\psi}^{np}_{\varepsilon}(\underline{x})$, we construct a comparison function $\hat{\underline{u}}_\varepsilon(\underline{x}, \underline{\underline{T}}) = \sum_{np} \underline{\psi}^{np}_{\varepsilon}(\underline{x}) T_{np} \in \mathcal{J}_\varepsilon[K^{\underline{\xi}}_h]$ for an arbitrary constant tensor $\underline{\underline{T}} = \{T_{np}\}$. Substitution of this function into the functional (3.9) provides a uniform in $\varepsilon \le \hat{\varepsilon}(h)$ upper bound:

$$0 < A_{\varepsilon h}[\hat{\underline{u}}_\varepsilon, \underline{\underline{T}}, \underline{\xi}, \lambda, \tau] < Ch^3. \tag{3.11}$$

Now we can use standard techniques to establish existence and compactness of a minimizing sequence, which implies existence of a minimizer $\underline{u}_\varepsilon$ of the problem (3.9); the lemma follows.

From (3.10) we obtain that the tensor $\{a_{npqr}(x,\lambda;\varepsilon,h,\tau)\}$ is invariant with respect to the permutation of pairs of indexes as well as permutation of indexes in each pair; that is,

$$a_{npqr} = a_{qrnp} = a_{pnqr} = \cdots .$$

This tensor describes macroscopic rheological properties of the suspension (compound). It depends on the space variable $\underline{x} \in \Omega$ if the suspension is inhomogeneous on the macroscale (e.g., for periodic structures there is no dependence on $\underline{x}$; see section 7), and on the spectral parameter λ.

We provide a heuristic basis for the introduction of the mesocharacteristic (3.5).

First, as we have mentioned earlier, if a compound can be described within the effective single medium approach, then the rheological properties of the compound can be determined by calculation or measurements in some representative volume element of an intermediate mesoscale h, which is why we choose cube $K_h^{\underline{\xi}}$.

Next, observe that the sum of the first and the third term in (3.5) represents the energy of the compound (suspension). The minimizer u_ε of (3.5) is "close," up to an additive constant, to the true global minimizer $\underline{v}_\varepsilon$ of the variational problem, which corresponds to (2.10)–(2.18) if the tensor $\underline{\underline{T}}$ is chosen appropriately. Now one should choose $\underline{\underline{T}}$. If the single medium homogenized description is possible, then $\underline{v}_\varepsilon(\underline{x})$ is "close" to some smooth (homogenized) function $\underline{v}(\underline{x})$, which depends only on macroscopic variable $\underline{x}$ and does not depend on ε, so that it does not vary on the microscale ε. We then minimize the energy of the compound, adding the constraint that the minimizer $\underline{u}_\varepsilon$ is "close" to the linear part $L(\underline{x})$ (the differential) of the global minimizer $\underline{v}(\underline{x})$, so that $|\underline{u}_\varepsilon - \underline{v}(\underline{x})| = \circ(h) \sim h^{1+\tau/2}$, $h \to 0$ for some $\tau > 0$. This condition is imposed by introducing the penalty term (the second term in (3.5)).

We consider arrays of the particles Q_ε^i such that for all $\underline{x} \in \Omega$, each $\lambda > 0$, and some real number $\tau > 0$ the following limits exist:

$$(\mathrm{b}_1) \quad \lim_{h\to 0} \underline{\lim_{\varepsilon\to 0}} \frac{a_{npqr}(\underline{x},\lambda;\varepsilon,h,\tau)}{h^3} = \lim_{h\to 0} \overline{\lim_{\varepsilon\to 0}} \frac{a_{npqr}(\underline{x},\lambda;\varepsilon,h,\tau)}{h^3} = a_{npqr}(\underline{x},\lambda),$$

where $a_{npqr}(\underline{x},\lambda)$ is a continuous function of $\underline{x} \in \Omega$ and $\lambda > 0$ is a parameter.

LEMMA 3.2. *If the condition* (b_1) *holds for some* $\tau > 0$, *then it also holds for any* $\tau > 0$ *and the limit* (b_1) *does not depend on* τ. *The functions* $a_{npqr}(\underline{x},\lambda)$ *are defined for* $\lambda > 0$ *and can be analytically extended into the complex plane with a cut along the negative semiaxis* $\lambda \le 0$. *The extended functions can be represented in the form*

$$a_{npqr}(\underline{x},\lambda) = a^0_{npqr}(\underline{x}) + a^1_{npqr}(\underline{x},\lambda)$$

so that in the domain $\Phi_\delta = \{\lambda \in \mathbf{C} : |arg\lambda - \pi| \ge \delta > 0\}$ *for any* $\delta > 0$ *the following bound holds:*

$$|a^1_{npqr}(\underline{x},\lambda)| < C\left(\frac{1}{|\lambda|^{1/2}}\right) \quad as\ \lambda \to \infty, \tag{3.12}$$

where $C > 0$ *does not depend on* λ.

This lemma is proved in [1]. The key idea of the proof is to present the Euler–Lagrange boundary value problem, which corresponds to the minimization problem

(3.9), in abstract operator form (a Friedrichs extension) in the appropriate Hilbert space $\tilde{\mathcal{J}}_\varepsilon[K_h^\xi]$. Roughly speaking, the space $\tilde{\mathcal{J}}_\varepsilon[K_h^\xi]$ consists of functions from $W_2^2(K_h^\xi)$ which satisfy the boundary conditions of the Euler–Lagrange problem and the divergence-free conditions. Due to the presence of the factor $1/\lambda$ in (3.5), the obtained operator equation in the Hilbert space $\tilde{\mathcal{J}}_\varepsilon[K_h^\xi]$ is an operator pencil. Then analyticity and estimate (3.12) follow from known results for operator pencils in an abstract Hilbert space [9, Chapter 7].

It follows from Lemma 3.2 that the functions $a_{npqr}(\underline{x},\lambda)$ are inverse Laplace transforms

$$a_{npqr}(\underline{x},\lambda)=\int_0^\infty e^{-\lambda t}\widehat{a}_{npqr}(x,t)dt \tag{3.13}$$

of the functions

$$\widehat{a}_{npqr}(\underline{x},t)=a^0_{npqr}(\underline{x})\delta(t)+\widehat{a}^1_{npqr}(\underline{x},t), \tag{3.14}$$

where $\delta(t)$ is the Dirac delta-function and $\widehat{a}^1_{npqr}(\underline{x},t)$ are locally summable in t for $t\geq 0$.

We introduce one more characteristic which describes the distribution of the masses in the suspension.

Denote by $\chi_\varepsilon(\underline{x})$ the characteristic function of the domain Ω_ε, occupied by the fluid, and by $\chi^i_\varepsilon(\underline{x})$-the characteristic function of a particle Q^i_ε, and introduce

$$\rho_\varepsilon(\underline{x})=\rho_f\chi_\varepsilon(\underline{x})+\rho_s\sum_{i=1}^{N_\varepsilon}\chi^i_\varepsilon(\underline{x}). \tag{3.15}$$

We consider the arrays of particles such that for any $\underline{x}\in\Omega$ the following limit exists:

$$\lim_{h\to\infty}\lim_{\varepsilon\to 0}\frac{1}{h^3}\int_{K^{\underline{x}}_h}\rho_\varepsilon(\underline{\xi})d\xi=\rho(\underline{x}), \tag{b_2}$$

where $\rho(\underline{x})>0$ is a continuous function which describes the limiting density of the suspension. Note that the condition (b_2) holds for very generic geometries. In particular, for periodic structures (section 7) $\rho(\underline{x})=$ const. and is easy to compute.

We are now in a position to formulate the main mathematical result of this paper and discuss its physical consequences. We construct the vector function

$$\underline{\tilde{v}_\varepsilon}(\underline{x},t)=\chi_\varepsilon(\underline{x})\underline{v}_\varepsilon(\underline{x},t)+\sum_i\chi^i_\varepsilon(\underline{x})\left[\underline{\dot{u}}^i_\varepsilon+\underline{\dot{\theta}}^i_\varepsilon(t)\times(\underline{x}-\underline{x}^i_\varepsilon)\right] \tag{3.16}$$

using the solutions $\{\underline{v}_\varepsilon(\underline{x},t),\underline{u}^i_\varepsilon(t),\theta^i_\varepsilon(t),\ i=1,\dots N_\varepsilon\}$ of the problem (3.1)–(3.9).

THEOREM 3.3. *Let the conditions* (a_1)–(a_4) *and* (b_1)–(b_2) *hold. Suppose that the initial functions in the problem* (2.10)–(2.17) *converge as* $\varepsilon\to 0$ *to a vector function* $\underline{v}_0(\underline{x})\in L_2(\Omega)$,

$$\underline{\tilde{v}_\varepsilon}(\underline{x},0)\to\underline{v}_0(\underline{x})\quad \textit{in } L_2(\Omega)\quad \textit{as } \varepsilon\to 0, \tag{3.17}$$

where $\underline{\tilde{v}_\varepsilon}(\underline{x},0)=\underline{\tilde{v}_\varepsilon}(\underline{x},t)|_{t=0}$ *and* $\underline{\tilde{v}_\varepsilon}(\underline{x},t)$ *is defined by* (3.16).

Then the functions $\underline{v}_\varepsilon(x,t)$ *converge in* $L_2(\Omega)$ *for all* $t<\infty$ *to a vector function* $\underline{v}(\underline{x},t)$*, which is a solution of the following homogenized problem:*

$$\rho(\underline{x})\frac{\partial \underline{v}}{\partial t}-\left\{\sum_{n,p,q,r}\frac{\partial}{\partial x_p}[a^0_{npqr}(\underline{x})e_{qr}[\underline{v}]] + \int_0^t \widehat{a}^1_{npqr}(x,t-\tau)e_{qr}[\underline{v}(\underline{x},\tau)]d\tau\right\}\underline{e}^n=\nabla p,\quad x\in\Omega,\ t>0, \tag{3.18}$$

$$\operatorname{div}\underline{v}=0,\quad \underline{x}\in\Omega,\quad t>0, \tag{3.19}$$

$$\underline{v}(\underline{x},t)=f(\underline{x},t),\quad \underline{x}\in\partial\Omega,\ t>0, \tag{3.20}$$

$$\underline{v}(\underline{x},0)=\underline{v}_0(\underline{x}),\quad \underline{x}\in\Omega, \tag{3.21}$$

where the components of the tensors $\{a^0_{npqr}(\underline{x})\}$ *and* $\{\widehat{a}^1_{npqr}(\underline{x},t)\}$ *are defined by* (3.9)–(3.14) *and the condition* (b_1).

In order to explain the physical meaning of the homogenized problem it is convenient to rewrite (3.18)–(3.19) in terms of the displacements $\underline{u}(\underline{x},t)=\int_0^t \underline{v}(\underline{x},t)d\tau$. Then

$$\rho(x)\frac{\partial^2 \underline{u}}{\partial t^2}-\left\{\sum_{n,p,q,r=1}^{3}\frac{\partial}{\partial x_p}[a^0_{npqr}(\underline{x})\dot{e}_{qr}[\underline{u}]] + \int_0^t \widehat{a}_{npqr}(\underline{x},t-\tau)\dot{e}_{qr}[\underline{u}]d\tau\right\}\underline{e}^n=\nabla p, \tag{3.18$'$}$$

$$\operatorname{div}\underline{u}=0, \tag{3.19$'$}$$

where $\dot{e}_{qr}[\underline{u}]=\frac{\partial}{\partial t}e_{qr}$.

Recall (see [8]) that the strain-stress relation in linear viscoelasticity has the form

$$\underline{\underline{\sigma}}(t)=\int_{-\infty}^{t}C(t-\tau)\underline{\underline{\dot{e}}}(\tau)d\tau, \tag{3.22}$$

where $C(t)$ is the fourth rank relaxation tensor. If $C(t)$ is a delta-function $k\delta(t)$, then $\underline{\underline{\sigma}}=k\underline{\underline{\dot{e}}}$ and we obtain the constitutive relation for a Newtonian fluid. If $C(t)$ does not depend on t, then (3.22) reduces to Hooke's law for an elastic solid. Thus the second term (the sum) in (3.18′) or (3.18) describes the effective Newtonian fluid with the effective viscosity tensor a^0_{npqr}, while the third term (the integral) describes the effective viscoelastic behavior with the effective relaxation tensor $\hat{a}^1_{npqr}$. Now we see that the homogenized equations (3.18′) or (3.18) suggest the following qualitative picture for the effective single phase medium. On a short time scale the integral terms in (3.18′) or (3.18) are small, and therefore the homogenized problem describes an incompressible fluid with anisotropic viscosity tensor a^0_{npqr}. On a longer time scale (intermediate scale) both the viscosity term and the relaxation term become significant, and the homogenized medium is an isotropic viscoelastic fluid with memory

(relaxation). Finally, on a very large time scale, provided that $f(x,t)$ has finite support in time, $\underline{u}(\underline{x},t)$ and $\underline{v}(\underline{x},t)$ become time independent, and therefore the $\dot{e}_{qr}(\underline{u})$ term is negligible. In addition, the kernel $\widehat{a}_{npqr}(\underline{x},t-\tau)$ also becomes time independent, and integration in (3.18′) or (3.18) yields to the equations for an incompressible elastic medium.

The tensors $\{a^0_{npqr}(\underline{x})\}$ and $\{\widehat{a}^1_{npqr}(\underline{x},t)\}$ are called the *effective viscosity* and the *effective relaxation* tensors, respectively [7]. Both tensors incorporate the information about the geometric array of the particles, the strength of the interparticle interactions, and the viscosity of the fluid phase.

We now provide a heuristic explanation of the choice of scaling in the condition (a_4). If the entries of the pairwise interaction matrices are such that the pairwise interaction energy is $\sup_{\|u\|=1}\langle \underline{\underline{C}}^{ij}_{1\varepsilon}\underline{u},\underline{u}\rangle \sim \varepsilon$, then both tensors $\{a^0_{npqr}(\underline{x})\}$ and $\{\widehat{a}^1_{npqr}(\underline{x},t)\}$ are positive and finite, which implies that the "fluid-particle" suspension in the homogenization limit behaves as a viscoelastic incompressible medium.

If these matrices have large entries $\sup_{\|u\|=1}\langle \underline{\underline{C}}^{ij}_{1}\underline{u},\underline{u}\rangle\varepsilon^{-1} \to \infty$ as $\varepsilon \to 0$, then the homogenized medium becomes absolutely rigid, so that if the velocity at the external boundary $\partial\Omega$ is zero, then the displacements and velocities of all points in Ω are zero (in the homogenized limit $\varepsilon \to 0$). Finally, if $\sup_{\|u\|=1}\langle \underline{\underline{C}}^{ij}_{1\varepsilon}\underline{u},\underline{u}\rangle \ll \varepsilon$, then the interaction does not affect the homogenized medium.

In sections 4–5 we prove Theorem 3.3. To this end we use the Laplace transform to obtain a time independent analogue of the problem (2.10)–(2.17) (with the spectral parameter $\lambda > 0$) and then analyze a variational formulation of this problem. Next we study the asymptotic behavior of the variational problem as $\varepsilon \to 0$, obtain the limiting (homogenized) functional, and write down the corresponding Euler–Lagrange equations. In this presentation we formulate techinical lemmas and estimates, whose detailed proofs can be found in [1].

In section 6 we discuss analytical dependence of the solutions of these equations in the parameter λ, and, by taking the inverse Laplace transform, we obtain the homogenized time dependent problem.

In section 7 we consider a periodic structure, prove existence of the limits in (b_2), and show that the computation of the viscosity and the relaxation tensors amounts to solving a cell problem. The cell problem can be solved using standard numerical techniques. We also analyze this problem analytically and obtain the distribution of the relaxation times, which is the main quantity of interest in rheological studies of filled polymers and suspensions.

4. Variational formulation of the homogenization problem. Take the Laplace transform $t \to \lambda$ in the problem (2.10)–(2.17). For simplicity we keep the same notation: $\underline{v}_\varepsilon(\underline{x},t) \to \underline{v}_\varepsilon(\underline{x},\lambda)$, $p_\varepsilon(\underline{x},t) \to p_\varepsilon(\underline{x},\lambda)$, $\underline{u}^i_\varepsilon(t) \to \underline{u}^i_\varepsilon(\lambda)$, $\underline{\theta}^i_\varepsilon(t) \to \underline{\theta}^i_\varepsilon(\lambda)$, $\underline{f}(\underline{x},t) \to \underline{f}(\underline{x},\lambda)$. Then, taking into account (2.8), (2.1), (2.5), (2.7), and (2.16), we obtain the following problem:

$$-\mu\Delta\underline{v}_\varepsilon + \lambda\rho_f\underline{v}_\varepsilon - \nabla p_\varepsilon = \rho_f\underline{v}_{\varepsilon 0}(\underline{x}), \quad \underline{x}\in\Omega_\varepsilon, \tag{4.1}$$

$$\operatorname{div}\underline{v}_\varepsilon = 0, \quad \underline{x}\in\Omega, \tag{4.2}$$

$$\underline{v}_\varepsilon = \lambda[\underline{u}^i_\varepsilon + \underline{\theta}^i_\varepsilon \times (\underline{x}-\underline{x}^i_\varepsilon)], \quad \underline{x}\in Q^i_\varepsilon, \tag{4.3}$$

$$\lambda^2 m_\varepsilon^i \underline{u}_\varepsilon^i = -\int_{S_\varepsilon^i} \underline{\underline{\sigma}}[\underline{v}_\varepsilon]\cdot\underline{\nu} dS - \frac{1}{\lambda}\sum_{j,j\neq i}\int_{S_\varepsilon^i}\int_{S_\varepsilon^j} \underline{\underline{C}}_\varepsilon^{ij}(\underline{x},\underline{y})[\underline{v}_\varepsilon(\underline{x})-\underline{v}_\varepsilon(\underline{y})]dS_x dS_y + m_\varepsilon^i \underline{u}_{\varepsilon 1}^i, \quad i=1,2,\dots N_\varepsilon, \tag{4.4}$$

$$\lambda^2 I_\varepsilon^i \underline{\theta}_\varepsilon^i = -\int_{S_\varepsilon^i} (\underline{x}-\underline{x}_\varepsilon^i)\times\underline{\underline{\sigma}}[\underline{v}_\varepsilon]\cdot\underline{\nu} dS - \frac{1}{\lambda}\sum_{j,j\neq i}\int_{S_\varepsilon^i}\int_{S_\varepsilon^i} \underline{\underline{C}}_\varepsilon^{ij}(\underline{x},\underline{y})[\underline{v}_\varepsilon(\underline{x})-\underline{v}_\varepsilon(\underline{y})]dS_x dS_y + I_\varepsilon^i \underline{\theta}_\varepsilon^i, \quad i=1,2,\dots N_\varepsilon, \tag{4.5}$$

$$\underline{v}_\varepsilon = \underline{f}(\underline{x},\lambda) \quad \text{on } \partial\Omega. \tag{4.6}$$

We extend the velocity function $\underline{v}_\varepsilon(\underline{x},\lambda)$ onto the particles according to (4.3) and keep the same notation $\underline{v}_\varepsilon = \underline{v}_\varepsilon(\underline{x},\lambda)$ for the extended functions. Then $\underline{v}_\varepsilon \in H^1(\Omega)$ and $\operatorname{div}\underline{v}_\varepsilon = 0$ in Ω. Denote by $\mathcal{J}_\varepsilon^f(\Omega)$ the class of divergence-free vector functions from $H^1(\Omega)$, which satisfy the rigid displacement conditions (2.2) on the particles Q_ε^i and take the prescribed values $\underline{f}(\underline{x},\lambda)$ on $\partial\Omega$.

Consider the minimization problem

$$\Phi_\varepsilon[\underline{v}_\varepsilon] = \min_{\underline{v}'_\varepsilon\in\mathcal{J}_\varepsilon^f(\Omega)} \Phi_\varepsilon[\underline{v}'_\varepsilon] \tag{4.7}$$

for the following functional:

$$\Phi_\varepsilon[\underline{v}_\varepsilon] = E_\Omega[\underline{v}_\varepsilon,\underline{v}_\varepsilon] + \int_\Omega [\lambda\langle\rho_\varepsilon\underline{v}_\varepsilon,\underline{v}_\varepsilon\rangle - 2\langle\rho_\varepsilon\underline{v}_{\varepsilon 0},\underline{v}_\varepsilon\rangle]d\underline{x} + \frac{1}{\lambda} I_\Omega^\varepsilon[\underline{v}_\varepsilon,\underline{v}_\varepsilon], \tag{4.8}$$

where $\lambda>0$, $\tilde{\underline{v}}_{\varepsilon 0} = \tilde{\underline{v}}_\varepsilon(\underline{x},0)$, $\rho_\varepsilon(\underline{x})$, and $\underline{v}_\varepsilon(\underline{x},t)$ are defined in (3.16), (3.17).

LEMMA 4.1. *There exists a unique minimizer $\underline{v}_\varepsilon = \underline{v}_\varepsilon(\underline{x},\lambda)$ of the functional* (4.8) *in the class $\mathcal{J}_\varepsilon^f(\Omega)$. This minimizer provides the solution $\{\underline{v}_\varepsilon(\underline{x},\lambda)\chi_\varepsilon(\underline{x}), \underline{v}_\varepsilon(\underline{x},\lambda)\chi_\varepsilon^i(\underline{x})\}$ of the boundary value problem* (4.1)–(4.6).

This lemma can be proved by standard techniques of calculus of variations [10], [18].

Introduce the homogenized functional

$$\Phi_0[\underline{v}] = \int_\Omega \left\{ \sum_{k,\ell=1}^3 a_{npqr}(\underline{x},\lambda) e_{np}[\underline{v}] e_{qr}[\underline{v}] + \lambda\langle\rho\underline{v},\underline{v}\rangle - 2\langle\rho\underline{v}_0,\underline{v}\rangle \right\} dx, \tag{4.9}$$

where the tensor $a_{npqr}(\underline{x},\lambda)$ and the function $\rho=\rho(\underline{x})$ are defined by the conditions (b_1)–(b_2), and the vector-function $\underline{v}_0(\underline{x})$ is defined by the condition (3.17).

Denote by $\mathcal{J}^f(\Omega)$ a class of the divergence-free functions from $W_2^1(\Omega)$ that are equal to $\underline{f}(\underline{x},\lambda)$ on $\partial\Omega$, and introduce the variational problem for the functional (4.9) in this class:

$$\Phi_0[\underline{v}] = \min_{\underline{v}'_\varepsilon\in\mathcal{J}^f(\Omega)} \Phi[\underline{v}']. \tag{4.10}$$

THEOREM 4.2. *Suppose that the conditions* (a_1)–(a_4), (b_1)–(b_2), *and* (3.17) *hold. Then the minimizers* $\underline{v}_\varepsilon(\underline{x},\lambda)$ *of the problem* (4.7) *converge weakly in* $H^1(\Omega)$ *(strongly in* $L_2(\Omega)$*) as* $\varepsilon \to 0$ *to the minimizer* $\underline{v}(\underline{x},\lambda)$ *of the homogenized problem* (4.10).

This theorem is the key result of this paper, and its proof is outlined in section 5. It follows from standard techniques of calculus of variations that if the functions $a_{npqr}(\underline{x},\lambda)$ are sufficiently smooth (e.g., in $C^1(\Omega)$), then the minimizer $\underline{v}(\underline{x},\lambda)$ of the problem (4.10) is the solution of the following boundary value problem:

$$-\sum_{n,p,q,r} \frac{\partial}{\partial x_r}\left[a_{npqr}(\underline{x},\lambda)e_{np}[\underline{v}]\right]\underline{e}^n + \lambda\rho\underline{v} - \nabla p = \rho\underline{v}_0\,, \quad x \in \Omega, \tag{4.11}$$

$$\operatorname{div}\underline{v} = 0, \tag{4.12}$$

$$\underline{v}(\underline{x},\lambda) = \underline{f}(\underline{x},\lambda), \qquad x \in \partial\Omega. \tag{4.13}$$

Remark 4.1. If $a_{npqr}(\underline{x},\lambda)$ is not sufficiently smooth in $\underline{x}$, then $\underline{v}(\underline{x},\lambda)$ is a generalized (weak) solution of the problem (4.11)–(4.13).

Applying the inverse Laplace transform, one can see that the main homogenization Theorem 3.3 for the time-dependent problem is obtained from this theorem. The key step here is to establish necessary analytical properties in λ of the functions $a_{npqr}(\underline{x},\lambda)$ and $\underline{v}(\underline{x},\lambda)$ for complex λ, which is done in [1] and briefly outlined in section 6 below.

5. Convergence theorem for stationary problems.

5.1. Compactness of the solutions $\{v_\epsilon,\ \epsilon > 0\}$ of the problem (4.7) in $H^1(\Omega)$. We use the following lemma to obtain the boundedness of the solutions $\{v_\epsilon,\ \epsilon > 0\}$.

LEMMA 5.1. *Suppose that the domain* $\Omega_\epsilon = \Omega \setminus \cup_i Q^i_\epsilon$ *satisfies the conditions* (a_1)–(a_2). *Then for any function* $\underline{f}(x) \in C^2(\partial\Omega)$ *satisfying the condition* (2.18) *there exists a function* $\underline{f}_\epsilon(\underline{x}) \in H^1(\Omega)$ *such that* $\operatorname{div}\underline{f}_\epsilon(\underline{x}) = 0$ *in* Ω, $\underline{f}_\epsilon(\underline{x}) = \underline{f}(\underline{x})$ *on* $\partial\Omega$, $\underline{f}_\varepsilon(\underline{x}) = \underline{f}^i_\varepsilon$ *on the minimal balls* $B(Q^i_\varepsilon)$, *and*

$$\|\underline{f}_\varepsilon\|_{H^1(\Omega)} < C, \qquad I^\varepsilon_\Omega[\underline{f}_\varepsilon, \underline{f}_\varepsilon] < C, \tag{5.1}$$

where $C > 0$ *does not depend on* ε.

We apply this lemma to the function $f(\underline{x},\lambda)$, which is Laplace transform of the boundary function $\underline{f}(\underline{x},t)$ (from (2.17)) in time. Then, we find a function $\underline{f}_\varepsilon(\underline{x}) \in \mathcal{J}^f_\varepsilon(\Omega)$ (admissible for the problem (4.7)) and satisfying (5.1).

Let $\underline{v}_\varepsilon = \underline{v}_\varepsilon(\underline{x},\lambda)$ be a solution of the problem (4.7); i.e., the functional Φ_ε in the class $\mathcal{J}^f_\varepsilon(\Omega)$ attains its minimum on $\underline{v}_\varepsilon$. Since $\underline{f}_\varepsilon \in \mathcal{J}^f_\varepsilon(\Omega)$, the following inequality holds:

$$\Phi_\varepsilon[\underline{v}_\varepsilon] \le \Phi_\varepsilon[\underline{f}_\varepsilon].$$

With this inequality, taking into account (4.8) and the nonnegativity of the matrices $\underline{\underline{C}}^{ij}_\varepsilon(\underline{x})$, we obtain

$$E_\Omega[\underline{v}_\varepsilon, \underline{v}_\varepsilon] + 2\mu\int_\Omega \lambda\langle\rho_\varepsilon\underline{v}_\varepsilon, \underline{v}_\varepsilon\rangle d\underline{x} \le |\Phi_\varepsilon[\underline{f}_\varepsilon]| + 2\|\rho_\varepsilon\tilde{\underline{v}}_{\varepsilon 0}\|_{L_2(\Omega)}\|\underline{v}_\varepsilon\|_{L_2(\Omega)}. \tag{5.2}$$

Next we use the second Korn inequality (see [13])

$$\|\underline{v}_\varepsilon\|^2_{H^1(\Omega)} \le \mathcal{C}\left(E_\Omega[\underline{v}_\varepsilon, \underline{v}_\varepsilon] + \|\underline{v}_\varepsilon\|_{L_2(\Omega)}\right), \tag{5.3}$$

where $\mathcal{C}$ depends on domain Ω only. Then, since $\mu > 0$, $\lambda > 0$, $\rho_\varepsilon(\underline{x}) \ge \min\{\rho_f, \rho_s\} > 0$, we find from (5.2)

$$\|\underline{v}_\varepsilon\|^2_{H^1(\Omega)} \le \mathcal{C}_1\left(|\Phi_\varepsilon[\underline{f}_\varepsilon]| + \|\rho_\varepsilon \tilde{\underline{v}}_{\varepsilon 0}\|_{L_2(\Omega)}\|\underline{v}_\varepsilon\|_{H^1(\Omega)}\right),$$

from which it follows that

$$\|\underline{v}_\varepsilon\|_{H^1(\Omega)} \le \mathcal{C}_2\left(|\Phi_\varepsilon(\underline{f}_\varepsilon)|^{\frac{1}{2}} + \|\rho_\varepsilon \tilde{\underline{v}}_{\varepsilon 0}\|_{L_2(\Omega)}\right), \tag{5.4}$$

where the constants $\mathcal{C}_1$ and $\mathcal{C}_2$ do not depend on ε, $\tilde{\underline{v}}_{\varepsilon 0} = \tilde{\underline{v}}_\varepsilon(\underline{x}, 0)$ and we have used the notation (3.6).

Now we use the second inequality in (5.1), the convergence (3.17) of $\tilde{\underline{v}}_{\varepsilon 0}$, and the uniform boundedness of $\rho_\varepsilon(\underline{x})$ in ε to obtain $\Phi_\varepsilon[\underline{f}_\varepsilon] < C$. Combing the latter inequality with (5.4), we get

$$\|\underline{v}_\varepsilon\|_{H^1(\Omega)} < C.$$

Therefore the set of the functions $\{\underline{v}_\varepsilon(\underline{x}), \varepsilon > 0\}$ is weakly compact in $H^1(\Omega)$.

Let us select a sequence $\{\underline{v}_{\varepsilon_k}(\underline{x}), \varepsilon_k \to 0\}$ weakly convergent in $H^1(\Omega)$ to the function $\underline{v}(\underline{x}) \in H^1(\Omega)$.

Due to embedding theorem, $\underline{v}(\underline{x}) = \underline{f}(\underline{x})$ at $\underline{x} \in \partial\Omega$ and $\underline{v}_{\varepsilon_k}(\underline{x})$ converges to $\underline{v}(\underline{x})$ strongly in $L_2(\Omega)$. In subsections 5.2–5.3 we show that $\underline{v}(\underline{x})$ is a solution of the minimization problem (4.10). Since this problem, due to nonnegativity of the tensor $\{a_{npqr}(\underline{x})\}$ and the condition $\lambda > 0$, has the unique solution; then, using the weak compactness of $\{\underline{v}_\varepsilon(\underline{x}, \lambda),\ \varepsilon > 0\}$, we conclude that $\underline{v}_\varepsilon \to v$ weakly in $H^1(\Omega)$ and strongly in $L_2(\Omega)$ as $\varepsilon \to 0$.

5.2. The upper bound. Denote by $\mathcal{J}^f_\varepsilon(\Omega)$ and $\mathcal{J}^f(\Omega)$ the spaces of admissible functions for the original and the homogenized variational problems (4.8)–(4.7) and (4.9)–(4.10), respectively. The goal of this subsection is to show that for any $\underline{w} \in \mathcal{J}^f(\Omega) \cap C^2$

$$\lim_{\varepsilon\to 0} \Phi_\varepsilon[\underline{v}_\varepsilon] \le \Phi_0[\underline{w}] \quad \forall\, \underline{w} \in \mathcal{J}^t(\Omega). \tag{5.5}$$

This is done by constructing a quasiminimizer $\underline{w}_{\varepsilon h} \in \mathcal{J}^f_\varepsilon(\Omega)$, $\underline{w}_{\varepsilon h} \to \underline{w}$ in $L_2(\Omega)$ as $\varepsilon \ll h \to 0$ so that

$$\Phi_\varepsilon[\underline{v}_\varepsilon] \le \Phi_\varepsilon[\underline{w}_{\varepsilon h}]. \tag{5.6}$$

Due to explicit construction of the quasiminimizer $\underline{w}_{\varepsilon h}$, it is possible to obtain the limiting inequality

$$\overline{\lim_{h\to 0}\lim_{\varepsilon\to 0}}\Phi_\varepsilon[\underline{w}_{\varepsilon h}] \le \Phi_0[\underline{w}]. \tag{5.7}$$

In particular, we will choose $\underline{w} = \underline{v}$, where $\underline{v}$ is the minimizer of the limiting functional Φ_0 and $\underline{v}_{\varepsilon_k} \rightharpoonup \underline{v}$. Note that (5.6) and (5.7) imply (5.5).

The key point in this step is the construction of the quasiminimizer $\underline{w}_{\varepsilon h}$. We now describe main ideas behind this construction. Choose a mesoscale parameter h such that $\varepsilon \ll h \ll 1$ and cover the domain Ω by a family of cubes K^α_h centered at the points $\underline{x}^\alpha$ of a cubic lattice with period $h - \delta$, $\delta = o(h)$, $h \to 0$, so that the cubes overlap. In each cube consider the mesocharacteristic (3.5). Minimizer $u^\alpha_{\varepsilon h}$ of the mesocharacteristic functional (see (3.9) with $\underline{\xi} = \underline{x}^\alpha$) is "close" (up to an additive constant) to the true minimizer $\underline{v}_\varepsilon$ (restricted to the cube K^α_h) if the tensor

$\underline{\underline{T}}$ in (3.5) is chosen so that $\underline{u}^\alpha_{\varepsilon h}$ is "close" to the linear symmetric part of the global homogenized minimizer $\underline{v}(\underline{x})$. In other words, we minimize the energy of the original problem in the perforated domain with an additional condition that the minimizer is smooth, i.e., close up to quadratic terms in h, to the linear function mentioned above. This condition is enforced by the penalty in term (3.5), and thus we obtain the quasiminimizer in each cube K^α_h. Now we need to "glue" them together, in order to obtain a globally smooth quasiminimizer. For this purpose we use a nested partition $K^\alpha_{h'} \subset K^\alpha_h$, $h' = h - 2\delta$, so that the cubes $K^\alpha_{h'}$ do not intersect each other. We retain the functions $\underline{u}^\alpha_{\varepsilon h}$ inside the cubes $K^\alpha_{h'}$ and modify them in the "thin" layers $K^\alpha_n \backslash K^\alpha_{h'}$ so that the obtained function $\underline{z}_{\varepsilon h}(\underline{x})$ is globally smooth (from $H^1(\Omega)$ and satisfies the rigid conditions on the particles Q^i_ε). However, $\operatorname{div} \underline{z}_{\varepsilon h}$ is no longer zero in the layers $K^\alpha_h \backslash K^\alpha_{h'}$, where the minimizers have been modified. To fix this, we introduce an additional function $\zeta_{\varepsilon h}(x)$ so that $\operatorname{div} \zeta_{\varepsilon h} = \operatorname{div} \underline{z}_{\varepsilon h}$ in the layers $K^\alpha_h \backslash K^\alpha_{h'}$, $\operatorname{div} \zeta_{\varepsilon h} = 0$ in $\cup_\alpha K^\alpha_{h'}$, and $\|\zeta_{\varepsilon h}\|_{H^1(\Omega)}$ is small so that its contribution to the energy of the global quasiminimizer is negligible, since $\operatorname{vol}(\cup_\alpha K^\alpha_h \backslash K^\alpha_{h'}) \to 0$ as $h \to 0$. Thus we obtain a quasiminimizer $\underline{w}_{\varepsilon h} = \underline{z}_{\varepsilon h} + \underline{\zeta}_{\varepsilon h} \in \mathcal{J}^f_\varepsilon(\Omega)$, and (5.6) holds. Here we use a special partition of unity, which preserves the rigid body conditions on the particles.

We now derive the inequality (5.6). Consider a cover of the domain Ω by cubes $K_\alpha = K(\underline{x}^\alpha, h)$ centered at the points $\underline{x}^\alpha$ and with the side length h, oriented along the coordinate axes. The centers $\underline{x}^\alpha$ form cubic lattice of the period $h - \delta$ ($0 < \varepsilon \le \delta \le h$). Let $K'_\alpha(\underline{x}^\alpha, h')$ be a concentric with K_α cube of side length $h' = h - 2\delta$; then $K'_\alpha = K_\alpha \backslash \cup_{\beta \ne \alpha} K_\beta$.

We will need three technical lemmas for constructing the function $\underline{w}_{\varepsilon h}(\underline{x}) \in \mathcal{J}^f_\varepsilon(\underline{x})$.

LEMMA 5.2 (special partition of unity). *Suppose the condition* (a_2) *holds. Then it is possible to construct the special partition of unity which corresponds to the cover* $\cup_\alpha K(\underline{x}^\alpha, h)$*, i.e., to construct the set of functions* $\{\varphi^\alpha_{\varepsilon h}(\underline{x}),\ \alpha = 1, 2, \dots\}$ *which satisfies the following conditions:*

1. $\varphi^\alpha_{\varepsilon h}(\underline{x}) \in C^2(\mathbb{R}^3)$,
2. $0 \le \varphi^\alpha_{\varepsilon h}(\underline{x}) \le 1$ *everywhere and*

$$\varphi^\alpha_{\varepsilon h}(\underline{x}) = \begin{cases} 1 \text{ inside } K'_\alpha, \\ 0 \text{ outside } K_\alpha, \end{cases}$$

3. $\sum_\alpha \varphi^\alpha_{\varepsilon h}(\underline{x}) = 1$ *in* $\mathbb{R}^3$,
4. $|\nabla \varphi^\alpha_{\varepsilon h}(\underline{x})| < \frac{C}{\delta}$ *in* $\mathbb{R}^3$,
5. $\varphi^\alpha_{\varepsilon h}(\underline{x}) = C^i_\varepsilon$ *when* $\underline{x} \in B(Q^i_\varepsilon)$,

where C^i_ε *are constants* ($0 \le C^i_\varepsilon \le 1$) *and* C *does not depend on* ε, δ, *or* h.

LEMMA 5.3. *Let the domain* $\Omega_\varepsilon = \Omega \backslash \cup_i Q^i_\varepsilon$ *satisfy conditions* (a_1)–(a_2). *Then for any function* $\underline{F}_\varepsilon(\underline{x}) \in L_2(\Omega)$ *which satisfies the conditions*

1. $\underline{F}_\varepsilon(\underline{x}) = 0$ *at* $x \in \cup_i B(Q^i_\varepsilon)$,
2. $\int_\Omega \underline{F}_\varepsilon(\underline{x}) dx = 0$,

there exists a function $\underline{\zeta}_\varepsilon(\underline{x}) \in H^1_0(\Omega)$ *such that* $\operatorname{div} \underline{\zeta}_\varepsilon(\underline{x}) = \underline{F}_\varepsilon$, $x \in \Omega$, $\underline{\zeta}_\varepsilon(\underline{x}) = \underline{\zeta}^i_\varepsilon$ *for* $\underline{x} \in B(Q^i_\varepsilon)$, *and* $\|\underline{\zeta}_\varepsilon\|_{H^1(\Omega)} \le C \|\underline{F}_\varepsilon\|_{L_2(\Omega)}$, *where* $\underline{\zeta}^i_\varepsilon$ *are constant vectors and* C *does not depend on* ε.

LEMMA 5.4. *Let the domain* $\Omega_\varepsilon = \Omega \backslash \cup_i Q^i_\varepsilon$ *satisfy conditions* (a_1), (a_2). *Then for any divergence-free function* $\underline{w}(\underline{x}) \in C^2(\Omega)$ *there exists such a function* $\underline{w}_\varepsilon(\underline{x}) \in H^2(\Omega)$ *that* $\operatorname{div} \underline{w}_\varepsilon = 0$ *in* Ω, $\underline{w}_\varepsilon(\underline{x}) = \underline{w}(\underline{x})$ *on* $\partial\Omega$, *and* $\underline{w}_\varepsilon(\underline{x})$ *is equal to the constant vectors* $\underline{w}^i_\varepsilon$ *on the balls* $B(Q^i_\varepsilon)$ ($\underline{w}^i_\varepsilon$ *is equal the mean value of* $\underline{w}(\underline{x})$ *on* $B(Q^i_\varepsilon)$). *In addition,*

the following inequalities are valid:

$$\|\underline{w}_\varepsilon - \underline{w}\|_{L_2(\Omega)} < C\varepsilon \quad \textit{and} \quad \|\underline{w}_\varepsilon\|_{H^1(G)} \le C\|\underline{w}\|_{H^1(G)}, \tag{5.8}$$

where the constants C do not depend on ε and $G \subset \Omega$ is any subdomain in Ω.

We now construct the function $\underline{w}_{\varepsilon h}(\underline{x})$. For any divergence-free in Ω function $\underline{w}(\underline{x}) \in C^2(\Omega)$, which is equal to $\underline{f}(\underline{x})$ on $\partial\Omega$, we wish to construct a function $\underline{w}_{\varepsilon h}(\underline{x}) \in \mathcal{J}^f_\varepsilon(\Omega)$, which is close to $\underline{w}(\underline{x}) \in \mathcal{J}^f(\underline{x})$ (in metric $L_2(\Omega)$) when ε and h are small enough ($\varepsilon \ll h \ll 1$).

A straightforward calculation shows that any function $\underline{w}(\underline{x}) \in C^2(K^\alpha)$ can be represented in the form

$$\begin{aligned} \underline{w}(\underline{x}) = \underline{w}(\underline{x}^\alpha) &+ \sum_{p,q=1} e_{pq}[\underline{w}(\underline{x}^\alpha)]\psi^{pq}(\underline{x} - \underline{x}^\alpha) \\ &+ \sum_{p,q} \omega_{pq}[\underline{w}(\underline{x}^\alpha)]\varphi^{pq}(\underline{x} - \underline{x}^\alpha) + \sigma^\alpha, \end{aligned} \tag{5.9}$$

where $\sigma^\alpha = O(|x - \underline{x}^\alpha|^2)$, and we introduce the notations for the symmetric and antisymmetric parts of $\nabla\underline{w}(\underline{x})$, respectively:

$$e_{pq}[\underline{w}(\underline{x}^\alpha)] = \frac{1}{2}\left[\frac{\partial w_p}{\partial x_q}(\underline{x}^\alpha) + \frac{\partial w_q}{\partial x_p}(\underline{x}^\alpha)\right], \tag{5.10}$$

$$\omega_{pq}[\underline{w}(\underline{x}^\alpha)] = \frac{1}{2}\left[\frac{\partial w_p}{\partial x_q}(\underline{x}^\alpha) - \frac{\partial w_q}{\partial x_p}(\underline{x}^\alpha)\right]. \tag{5.11}$$

Linear function $\underline{\psi}^{pq}(\underline{x})$ is defined by the equalities (3.8) and

$$\underline{\varphi}^{pq}(\underline{x}) = \frac{1}{2}[x_p e^q - x_q e^p], \tag{5.12}$$

and they both are divergence-free.

The first and the second sums in (5.9) are usually called the deformational and the rotational parts, respectively, of the velocity field $\underline{w}(\underline{x})$.

We need to construct a divergence-free function $\underline{w}_{\varepsilon h}(\underline{x})$, which satisfies the condition (2.12) on Q^i_ε and approximates $\underline{w}(\underline{x})$ as $\varepsilon \ll h \to 0$. Note that the second sum in the RHS of (5.9) satisfies (2.12), but the first sum does not, because the functions $\underline{\psi}^{pq}(\underline{x} - \underline{x}^\alpha)$ do not satisfy (2.12). However, the function $\underline{u}^{\alpha,pq}_{\varepsilon h}(\underline{x})$, which minimizes functional (3.5) in the class $\mathcal{J}_\varepsilon(K(\underline{x}^\alpha, h))$ when $T = \frac{1}{2}(e^p \otimes e^q + e^q \otimes e^p)$, and according to Lemma 5.4 (see below) is "close" to $\underline{\psi}^{pq}(\underline{x} - \underline{x}^\alpha)$ when $\varepsilon \ll h \ll 1$, does not satisfy (2.12). That is why, when constructing $\underline{w}_{\varepsilon h}(\underline{x})$ in cubes $K_\alpha = K(\underline{x}^\alpha, h) \subsetneq \Omega$, we replace $\underline{\psi}^{pq}(\underline{x} - \underline{x}^\alpha)$ by $\underline{u}^{\alpha,pq}_{\varepsilon h}(\underline{x})$ in the formula (5.9).

Further, we glue together the functions $\underline{w}_{\varepsilon h}(\underline{x})$ defined in each cube K_α by a special partition of unity $\{\varphi^\alpha_{\varepsilon h}(\underline{x})\}$ constructed in Lemma 5.2 which guaranties the rigid displacement conditions on Q^ε_i.

However, this construction does not ensure that $\underline{w}_{\varepsilon h}(\underline{x}) = \underline{w}(\underline{x}) = \underline{f}(\underline{x})$ on $\partial\Omega$. Also, since we used the partition of unity, the divergence-free condition is not guaranteed. Therefore, we use a simpler construction on the cubes K_α that intersect $\partial\Omega$. To ensure that the construction is divergence-free (without violation of all other requirements), we add the function $\underline{\zeta}_{\varepsilon h}(\underline{x})$, whose existence is established in Lemma 5.3.

Thus, we construct the quasiminimizer $\underline{w}_{\varepsilon h}(\underline{x})$ as follows:

$$\underline{w}_{\varepsilon h}(\underline{x}) = \sum{}' \left\{ \underline{w}(\underline{x}^\alpha) + \sum_{n,p=1}^{3} (e_{np}[\underline{w}(\underline{x}^\alpha)]\underline{u}_{\varepsilon h}^{\alpha,np}(\underline{x}) + \omega_{np}[\underline{w}(\underline{x}^\alpha)]\underline{\varphi}^{pq}(\underline{x}-\underline{x}^\alpha)) \right\} \varphi_{\varepsilon h}^{\alpha}(\underline{x})$$

$$+ \sum{}'' \underline{w}_\varepsilon(\underline{x})\varphi_{\varepsilon h}^{\alpha}(\underline{x}) + \underline{\zeta}_{\varepsilon h}(\underline{x}) \equiv \underline{z}_{\varepsilon h}(\underline{x}) + \underline{\zeta}_{\varepsilon h}(\underline{x}), \tag{5.13}$$

where the sum $\sum'_\alpha$ is taken over the interior cubes (which lie inside the domain Ω), sum $\sum''_\alpha$ is taken over the cubes,which intersect the boundary $\partial\Omega$, and in the partition of unity $\varphi_{\varepsilon h}^{\alpha}(\underline{x})$ we choose $\delta = h^{1+\tau/2}$, $0 < \tau < 2$. The function $\underline{w}_\varepsilon(\underline{x}) \in H^1(\Omega)$ is constructed according to Lemma 5.4.

We now construct the function $\underline{\zeta}_{\varepsilon h}(\underline{x})$. Due to (5.13), the function $\underline{z}_{\varepsilon h}(\underline{x}) \in H^1(\Omega)$ is equal $\underline{w}(\underline{x})$ on the boundary $\partial\Omega$, and since $\int_\Omega \langle \underline{w}, \underline{\nu}\rangle dS = 0$, we have $\int_\Omega \operatorname{div} \underline{z}_{\varepsilon h} dx = 0$.

Moreover, using the properties of the functions $\underline{u}_{\varepsilon h}^{\alpha,np}(\underline{x})$, $\omega_{np}[\underline{w}(\underline{x}^\alpha)]\underline{\varphi}^{pq}(\underline{x}-\underline{x}^\alpha)$, $\underline{w}_\varepsilon(\underline{x})$, and the functions $\varphi_{\varepsilon h}^{\alpha}(\underline{x})$, we obtain

$$\operatorname{div} z_\varepsilon(\underline{x}) = 0 \quad \text{if} \quad \underline{x} \in B(Q_\varepsilon^i).$$

Therefore, applying Lemma 5.3 to the function $\underline{F}_\varepsilon(\underline{x}) = -\operatorname{div} \underline{z}_{\varepsilon h}$, we construct the divergence-free function $\underline{\zeta}_{\varepsilon h}(\underline{x})$, which is equal to the constant vectors $\underline{\zeta}_{\varepsilon h}^i$ on the balls $B(Q_\varepsilon^i)$ and zero on $\partial\Omega$. Thus the construction (5.13) guarantees that $\underline{w}_{\varepsilon h}(\underline{x}) \in \mathcal{J}_\varepsilon^f(\Omega)$.

Let us calculate the functional (4.8) on the function $\underline{w}_{\varepsilon h}(\underline{x}) \in \mathcal{J}_\varepsilon^f(\Omega)$ ($\varepsilon \ll \delta = h^{1+\frac{\tau}{2}} \ll h \ll 1$).

The next lemma shows that the contribution from the function $\underline{\zeta}_{\varepsilon h}(\underline{x})$ is negligible.

LEMMA 5.5. *The following equalities hold:*

$$\lim_{h\to 0} \overline{\lim}_{\varepsilon\to 0} \|\underline{\zeta}_{\varepsilon h}\|_{H^1(\Omega)} = I_\Omega[\underline{\zeta}_{\varepsilon h}, \underline{\zeta}_{\varepsilon h}] = 0.$$

To calculate $e_{k\ell}[\underline{w}_{\varepsilon h}]$ were rewrite (5.13) as follows:

$$w_{\varepsilon h}(\underline{x}) = w(\underline{x}) + \sum_\alpha{}' \left\{ \sum_{np=1}^{3} e_{np}[\underline{w}(\underline{x}^\alpha)](u_{\varepsilon h}^{\alpha,np}(\underline{x}) - \underline{\psi}^{\alpha,np}(\underline{x})) - \underline{\sigma}^\alpha(\underline{x}) \right\} \varphi_{\varepsilon h}^{\alpha}(\underline{x})$$

$$+ \sum_\alpha{}'' (w_\varepsilon(\underline{x}) - w(\underline{x}))\varphi_{\varepsilon h}^{\alpha}(\underline{x}) + \underline{\zeta}_{\varepsilon h}(\underline{x}). \tag{5.14}$$

Using Lemma 5.5, we distinguish the leading term in $e_{k\ell}[\underline{w}_{\varepsilon h}(\underline{x})]$,

$$e_{k\ell}[\underline{w}_{\varepsilon h}(\underline{x})] = \sum_\alpha{}' \sum_{n,p=1}^{3} e_{np}[\underline{w}(\underline{x}^\alpha)]e_{k\ell}[u_{\varepsilon h}^{\alpha,np}]\varphi_{\varepsilon h}^{\alpha}(\underline{x}) + L(\varepsilon,h), \tag{5.15}$$

where $\lim_{h\to 0} \overline{\lim}_{\varepsilon\to 0} \|L(\varepsilon,h)\|_{L_2(\Omega)} = 0$, and compute the bulk and the interaction energies:

(5.16)

$$E_\Omega[\underline{w}_{\varepsilon h}, \underline{w}_{\varepsilon h}] = \sum_\alpha{}' \sum_{n,p,q,r=1}^{3} e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)]E_{K'_\alpha}[\underline{u}_{\varepsilon h}^{\alpha,pn}, \underline{u}_{\varepsilon h}^{\alpha,qr}] + L_1(\varepsilon,h),$$

$$I_\Omega^\varepsilon[\underline{w}_{\varepsilon h}, \underline{w}_{\varepsilon h}] \le \sum_\alpha{}' \sum_{n,p,q,r} e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)] \cdot I_{K'_\alpha}^\varepsilon[\underline{u}_{\varepsilon h}^{\alpha,np}, \underline{u}_{\varepsilon h}^{\alpha,qr}] + L_2(\varepsilon,h). \tag{5.17}$$

Here $\lim_{h\to 0} \overline{\lim}_{\varepsilon\to 0} L_i(\varepsilon,h) = 0$, $i = 1,2$, and we have used the notation (3.6).

Combining (5.16) and (5.17), we estimate the bulk and the interaction energy in $\Phi_\varepsilon[\underline{w}_{\varepsilon h}]$:

$$
\begin{aligned}
&E_\Omega[\underline{w}_{\varepsilon h},\underline{w}_{\varepsilon h}]+\frac{1}{\lambda}I^\varepsilon_\Omega[\underline{w}_{\varepsilon h},\underline{w}_{\varepsilon h}]\\
&\le \sum_\alpha{}' \sum_{n,p,q,r} e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)]\Bigg\{2\mu\int_{K_\alpha}\sum_{k,\ell}e_{k\ell}[(\underline{u}^{\alpha,np}_{\varepsilon h}(\underline{x})]e_{n\ell}[\underline{u}^{\alpha,qr}_{\varepsilon h}(\underline{x})]dx\\
&\qquad\qquad +\frac{1}{\lambda}I^\varepsilon_{K_\alpha}[\underline{u}^{\alpha,np}_{\varepsilon h},\underline{u}^{\alpha,qr}_{\varepsilon h}]\Bigg\}\\
&\le \sum_\alpha{}' \sum_{n,p,q,r} e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)]\Bigg\{2\mu\int_{K_\alpha}\Bigg[\sum_{k,\ell}e_{k\ell}[\underline{u}^{\alpha,np}_{\varepsilon h}(\underline{x})]e_{k\ell}[\underline{u}^{\alpha,qr}_{\varepsilon h}(\underline{x})]\\
&\quad +h^{-2-\tau}\langle\underline{u}^{\alpha,np}_{\varepsilon h}(\underline{x})-\underline{\psi}^{\alpha,np}(\underline{x}),\underline{u}^{\alpha qr}_{\varepsilon h}(\underline{x})-\underline{\psi}^{\alpha,qr}(\underline{x})\rangle\Bigg]dx+\frac{1}{\lambda}I^\varepsilon_{K_\alpha}[\underline{u}^{\alpha np}_{\varepsilon h},\underline{u}^{\alpha qr}_{\varepsilon h}]\Bigg\}+o(1)\\
&= \sum_\alpha{}' \sum_{n,p,q,r} a_{npqr}(\underline{x}^\alpha,\lambda,\varepsilon,h)e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)]+o(1)\quad(\varepsilon\ll h\ll 1).
\end{aligned}
\tag{5.18}
$$

Here we use the definition of $a_{npqr}(\underline{x},\lambda,\varepsilon,h)$ (see Lemma 3.1) and add to the RHS of the first inequality in (5.18) a positive term which corresponds to the penalty term in the mesocharacteristic.

Finally we use (5.18) to estimate the functional (4.8):

$$
\begin{aligned}
\Phi_\varepsilon[\underline{w}_{\varepsilon h}]\le{}&\sum_\alpha{}' h^3\sum_{n,p,q,r}\frac{a_{npqr}(\underline{x}^\alpha,\lambda,\varepsilon,h)}{h^3}\,e_{np}[\underline{w}(\underline{x}^\alpha)]e_{qr}[\underline{w}(\underline{x}^\alpha)]\\
&+\lambda\int_\Omega\langle\rho_\varepsilon w_{\varepsilon h},w_{\varepsilon h}\rangle dx-2\int_\Omega\langle\rho_\varepsilon v_{\varepsilon 0},w_{\varepsilon h}\rangle dx+\Delta(\varepsilon,h),
\end{aligned}
\tag{5.19}
$$

where the remainder $\Delta(\varepsilon,h)$ satisfies the equality

$$
\lim_{h\to 0}\overline{\lim}_{\varepsilon\to 0}\Delta(\varepsilon,h)=0.
$$

We now pass to the limit in (5.19) first as $\varepsilon\to 0$ and then as $h\to 0$. Taking into account that $\underline{w}(\underline{x})\in C^2(\overline{\Omega})$ and using the conditions (b_1), (b_2), (3.17), and $\lim_{h\to 0}\overline{\lim}_{\varepsilon\to 0}\|w_{\varepsilon h}(\underline{x})-\underline{w}(\underline{x})\|^2_{L_2(\Omega)}=0$ (verified by a direct calculation), we obtain

$$
\lim_{h\to 0}\overline{\lim}_{\varepsilon\to 0}\Phi_\varepsilon[\underline{w}_{\varepsilon h}]\le\Phi_0[\underline{w}]\,,
$$

where the functional $\Phi_0[\underline{w}]$ is defined by the equality (4.9). Since $\underline{w}_{\varepsilon h}\in\mathcal{J}^f_\varepsilon(\Omega)$ and $\underline{v}_\varepsilon(\underline{x})$ is the solution of the minimization problem (4.7), inequality (5.6) is established for any function $\underline{w}(\underline{x})\in\mathcal{J}^f(\Omega)\cap C^2(\Omega)$. Since the class $\mathcal{J}^f(\Omega)\cap C^2(\Omega)$ is dense in $\mathcal{J}^f(\Omega)$ in the metric $H^1(\Omega)$, this inequality holds for any function $\underline{w}\in\mathcal{J}^f(\Omega)$.

5.3. The lower bound. We begin with a short overview and then present actual technical constructions which are quite lengthy. The goal of this step is to establish the following lower bound:

$$
\underline{\lim}_{\varepsilon=\varepsilon_k\to 0}\Phi_\varepsilon[\underline{v}_\varepsilon]\ge\Phi_0[\underline{v}],
\tag{5.20}
$$

where $\underline{v}$ is the weak limit of $\underline{v}_\varepsilon$ as $\varepsilon = \varepsilon_k \to 0$. To this end we partition the domain Ω into cubes K_h^α (as opposed to the covering by intersecting cubes in subsection 5.2). Then the energy of the global minimizer $\underline{v}_\varepsilon$ in each cube K_h^α is bounded below by the mesocharacteristic (3.5) with the proper choice of the tensor $\underline{\underline{T}}$ (from the linear symmetric part of the limiting function $\underline{v}(x)$).

More precisely, we modify the function $\underline{v}_\varepsilon(\underline{x})$ in K_h^α so that the modified function $\underline{u}_\varepsilon^\alpha$ satisfies the following conditions:

(i) $\underline{u}_\varepsilon^\alpha \in \mathcal{J}_\varepsilon^f(K_h^\alpha)$ ($\underline{u}_\varepsilon^\alpha$ is an admissible function for the variational problem (3.5)).

(ii) $\left|A_{\varepsilon h}[\underline{u}_\varepsilon^\alpha, \underline{\underline{T}}, \underline{x}^\alpha, \tau] - (\text{total energy of } \underline{v}_\varepsilon^\alpha \text{ in } K_h^\alpha)\right| = o(h^3)$, $h \to 0$.

(iii) $\underline{u}_\varepsilon^\alpha$ is closed to the symmetric part (5.9) of $\nabla \underline{v}$ defined by (5.9) when $\underline{w} = \underline{v}$.

Then (i) and (3.5)–(3.10) imply

$$A_{\varepsilon h}[\underline{u}_\varepsilon^\alpha, \underline{\underline{T}}, \underline{x}^\alpha, \tau] \geq \sum_{npqr} a_{npqr}(\underline{x}^\alpha, \lambda, \varepsilon, h, \tau) T_{np}\, T_{qn}. \tag{5.21}$$

We now describe the modification of $\underline{u}_\varepsilon^\alpha$ and the corresponding choice of the tensor $\underline{\underline{T}}$ in the penalty term of (3.5).

Represent the limiting function $\underline{v}(\underline{x})$ in the form ($x \in K_h^\alpha$)

$$\begin{aligned} \underline{v}(\underline{x}) &= \underline{v}(\underline{x}^\alpha) + \sum_{k\ell} e_{k\ell}[\underline{v}(\underline{x}^\alpha)]\underline{\psi}^{k\ell} \\ &+ \sum_{k\ell} \omega_{k\ell}(v(\underline{x}^\alpha))\underline{\varphi}^{k\ell} + O(h^2) := \underline{v}(\underline{x}^\alpha) + S + A + O(h^2), \end{aligned} \tag{5.22}$$

where the linear part in (5.22) in decomposed into symmetric and antisymmetric parts and both are divergence-free (see the definitions of $\psi^{k\ell}$ in (3.8) and $\phi^{k\ell}$ in Lemma 5.2). Note that in the standard decomposition $\nabla \underline{u} = \overline{\frac{1}{2}(\nabla \underline{u} + \nabla \underline{u}^T)} + \frac{1}{2}(\nabla \underline{u} - \nabla \underline{u}^T)$ the symmetric part is not necessarily divergence-free but $\operatorname{div} \underline{v} = 0$ in (5.22) (weakly). We now describe the main idea of the construction of $\underline{u}_\varepsilon^\alpha$. Choose $\underline{u}_\varepsilon^\alpha$ in the form

$$\underline{u}_\varepsilon^\alpha = \underline{v}_\varepsilon(\underline{x}) - \underline{v}(\underline{x}^\alpha) - A\,, \tag{5.23}$$

where A is defined in (5.22). Then the RHS of (5.23) is close to the symmetric part S of the $\nabla \underline{v}(\underline{x})$. This is sufficient to make the penalty term in (3.5) small. Indeed, only the symmetric part S of the deformation enters the penalty term in the mesocharacteristic (3.5) since the antisymmetric part A (the rotational part) does not contribute to the energy. Due to (5.23), $e_{k\ell}[\underline{u}_\varepsilon^\alpha] = e_{k\ell}[\underline{v}_\varepsilon]$ in K^α and $I^\varepsilon_{K^\alpha}[\underline{v}_\varepsilon, \underline{v}_\varepsilon] = I^\varepsilon_{K^\alpha}[\underline{u}_\varepsilon^\alpha, \underline{u}_\varepsilon^\alpha]$. We choose $T_{np} = e_{np}[\underline{v}(x^\alpha)]$. Then the penalty term in the LHS of (5.21) becomes small, the interaction term in the LHS of (5.21) is simplified due to the condition (2.3), and the inequality (5.21) follows. Summing up over all cubes in the partition and passing to the limit $\varepsilon \ll h \to 0$ yields (5.20).

We now present the detailed derivation of the lower bound (5.20). We prove (5.20) when the function $\underline{v}(\underline{x})$ is the weak limit in $H^1(\Omega)$ of solutions $\underline{v}_\varepsilon(\underline{x})$ of the problem (4.7) in some subsequence $\{\varepsilon_k \to 0,\ k = 1, 2, \dots\}$. First, we assume for simplicity that the limiting function $\underline{v}(\underline{x})$ is smooth enough, namely, $\underline{v}(\underline{x}) \in C^2(\Omega) \cap \mathcal{J}^f(\Omega)$.

Then we partition the domain Ω by the nonintersecting cubes $K_\alpha = K(\underline{x}^\alpha, h)$ centered at the points $\underline{x}^\alpha$ aligned along the coordinate axes. In each internal with respect to the Ω cube (which does not intersect $\partial\Omega$) consider a function

$$\underline{u}_\varepsilon^\alpha(\underline{x}) = \underline{v}_\varepsilon(\underline{x}) - \left\{ \underline{v}(\underline{x}^\alpha) + \sum_{p,q} \omega_{pq}[\underline{w}(\underline{x}^\alpha)]\varphi^{pq}(\underline{x} - \underline{x}^\alpha) \right\}, \tag{5.24}$$

where we have used the notation (5.11) for the rigid rotation part.

Clearly $\underline{u}_\varepsilon(\underline{x}) \in \mathcal{J}_\varepsilon(K_\alpha)$ (admissible for the functional (3.9)). Therefore, (3.10) implies (5.21) for any tensor $T = \{T_{np}\}_{n,p=1}^3$. Set $T_{np} = e_{np}[\underline{v}(\underline{x}^\alpha)]$. Then, taking into account the form (3.5) of the functional $A_{\varepsilon h}$, the form (5.24) of the function $\underline{u}_\varepsilon^\alpha(\underline{x})$, and the condition (2.3), we obtain

$$\int_{K_\alpha} \left\{ 2\mu \sum_{k,\ell} e_{k\ell}^2[\underline{v}_\varepsilon] + h^{-2-\tau} \left| \underline{u}_\varepsilon^\alpha(\underline{x}) - \sum_{n,p=1}^3 e_{np}[v(\underline{x}^\alpha)] \underline{\psi}^{\alpha,np}(\underline{x}) \right|^2 \right\} dx$$

$$+ \frac{1}{2\lambda} I_{K_\alpha^\varepsilon}^\varepsilon[\underline{v}_\varepsilon, \underline{v}_\varepsilon] \geq \sum_{n,p,q,r} a_{npqr}(\underline{x}^\alpha, \lambda; \varepsilon, h, \tau) e_{np}[v(\underline{x}^\alpha)] e_{qr}[v(\underline{x}^\alpha)] \,. \tag{5.25}$$

Next we note that the penalty term is small, namely (5.24), and the convergence of $\underline{v}_{\varepsilon_k} \to \underline{v}$ implies

$$\lim_{\varepsilon = \varepsilon_k \to 0} \int_{K_\alpha} \left| \underline{u}_\varepsilon^\alpha(\underline{x}) - \sum_{n,p=1}^3 e_{np}[v(\underline{x}^\alpha)] \underline{\psi}^{\alpha,np}(\underline{x}) \right|^2 dx = O(h^7) \,. \tag{5.26}$$

Now we sum over all cubes and take into account (4.8), (5.25)–(5.26) to conclude that if $\varepsilon_k \leq \widehat{\epsilon}(h)$, then

$$\Phi_\varepsilon[\underline{v}_\varepsilon] \geq {\sum_\alpha}' \sum_{n,p,q,r=1}^3 a_{npqr}(\underline{x}^\alpha, \lambda; \varepsilon, h, \tau) e_{np}[v(\underline{x}^\alpha)] e_{qr}[v(\underline{x}^\alpha)]$$

$$+ \int_\Omega \{ \lambda \langle \underline{v}_\varepsilon, \underline{v}_\varepsilon \rangle - 2 \langle \rho_\varepsilon \underline{v}_{\varepsilon 0}, \underline{v}_\varepsilon \rangle \} \, dx + O(h^{2-\tau}) \,. \tag{5.27}$$

Note that, according to our assumption, $\tau < 2$. Then we pass to the limit in (5.27) first in $\varepsilon_k \to 0$ and then in $h \to 0$. Taking into account that $\underline{v}(\underline{x}) \in C^2(\Omega)$ and using the conditions (b_1), (b_2), (3.17), and the convergence $\underline{v}_\varepsilon(\underline{x}) \to \underline{v}(\underline{x})$ in $L_2(\Omega)$ as $\varepsilon = \varepsilon_k \to 0$, we obtain

$$\varliminf_{\varepsilon = \varepsilon_k \to 0} \Phi_\varepsilon[\underline{v}_\varepsilon] \geq \int_\Omega \left\{ \sum_{n,p,q,r} a_{npqr}(\underline{x}, \lambda) e_{np}[\underline{v}(\underline{x})] e_{qr}[\underline{v}(\underline{x})] \right.$$

$$\left. + \lambda \langle \underline{v}(\underline{x}), \underline{v}(\underline{x}) \rangle - 2 \langle \rho(\underline{x}) \underline{v}_0(\underline{x}), \underline{v}(\underline{x}) \rangle \right\} dx = \Phi_0[\underline{v}]. \tag{5.28}$$

Thus, we have obtained the required inequality (5.20) under the assumption that $\underline{v} \in C^1(\overline{\Omega})$. The proof for a nonsmooth case $\underline{v} \in H^1$ is more technical, although its scheme is the same: it is necessary to construct smooth approximations $\underline{v} \approx \underline{v}^\sigma$ and $\underline{v}_\varepsilon \approx \underline{v}_\varepsilon^\sigma$ for some small $\sigma > 0$. The above scheme is applied to the approximations when passing to the limit first as $\varepsilon \ll h \to 0$ and then as $\sigma \to 0$. The details of this construction are presented in [1].

6. Analyticity in the spectral parameter of the mesocharacteristic and the solutions. In Theorem 4.2 we established the convergence of the solutions $\underline{v}_\varepsilon(\underline{x}, \lambda)$ to the homogenized solution $\underline{v}(\underline{x}, \lambda)$ as $\varepsilon \to \infty$ for real $\lambda > 0$. To prove the main Theorem 3.3 we need to apply the inverse Laplace transform to get the convergence of $\underline{v}_\varepsilon(\underline{x}, t)$ to $\underline{v}(\underline{x}, \lambda)$. Thus we need to show that $\underline{v}_\varepsilon(\underline{x}, \lambda)$ can be analytically extended into the complex plane (more precisely, into $\mathbf{C} \setminus \mathbf{R}^-$).

The extension procedure is quite technical, and here we only outline it. The details are presented in [1]. First we formulate the problem (2.10)–(2.14) in an abstract operator form in an appropriate Hilbert space. For a cell problem, the analogous abstract form is obtained below in Lemmas 7.5 and 7.6. The operator formulation of the problem (2.10)–(2.14) leads to an operator bundle of the form $(\mathbf{I}+\lambda A_{1\varepsilon}+\frac{1}{\lambda}A_{2\varepsilon}\underline{v}_\varepsilon = f_\varepsilon)$, where $\mathbf{I}$ is the unity operator and $A_{1\varepsilon}$ and $A_{2\varepsilon}$ are compact operators. Using well-known results from the operator bundle theory [9, Chapter 7], we show that $\underline{v}_\varepsilon(\underline{x},\lambda)$ is analytic in $\mathbf{C}\setminus\mathbf{R}^-$ and

$$\|\underline{v}_\varepsilon\|^2_{L_2(\Omega)} < \frac{C}{|\lambda|}. \tag{6.1}$$

Using analogous abstract operator theory considerations and the Vitaly theorem [11], we prove Lemma 3.2. Furthermore, we establish a bound analogous to (6.1) and show analyticity in λ of the homogenized solution $\underline{v}(\underline{x},\lambda)$ in $\mathbf{C}\setminus\mathbf{R}^-$. The Vitaly theorem yields that the convergence results from Theorem 4.2 hold for complex λ in $\mathbf{C}\setminus\mathbf{R}^-$. Finally, we apply the inverse Laplace transform (with an appropriate choice of the integration contour specified in [1]) to show that Theorem 4.2 implies Theorem 3.3.

7. Periodic structures. We now present a case when all the conditions (a_1)–(a_4), (b_1), (b_2) in Theorem 3.3 are satisfied and the Laplace transform $\{a_{npqr}(\underline{x},\lambda)\}$ of the effective tensor $\{a_{npqr}(\underline{x},t)\}$ does not depend on x and can be computed by solving the so-called cell problems.

We consider a periodic array when particles Q^i_ε are obtained by a homothetic compression by the factor ε of a fixed body Q with diameter $d \le 1/2$ and center of mass at the origin. All particles are identically oriented in space, and their centers of mass x^i_ε form a cubic lattice L_ε with period ε.

We are interested in the case of short-range interactions when each particle interacts only with neighboring 3^n-1, $n=2,3$, particles (a schematic image for $n=2$ is given in Figure 7.1) and the corresponding interaction matrix $\underline{\underline{C}}^{ij}_{k\varepsilon}$ does not change under translations of the lattice L_ε, i.e., $\underline{\underline{C}}^{ij}_{k\varepsilon} = \underline{\underline{C}}^{i+l,j+l}_{k\varepsilon}$. We also assume that $\underline{\underline{C}}^{ij}_{1\varepsilon} = \varepsilon\underline{\underline{C}}^{ij}_1$, $\underline{\underline{C}}^{ij}_{2\varepsilon} = \varepsilon^2\underline{\underline{C}}^{ij}_2$, $\underline{\underline{C}}^{ij}_{3\varepsilon} = \varepsilon^3\underline{\underline{C}}^{ij}_3$, and $\underline{\underline{C}}^{ij}_{4\varepsilon} = \varepsilon^3\underline{\underline{C}}^{ij}_4$. Thus both the geometry and the interactions are ε-periodic.

Consider a particle Q^i_ε placed inside a cube K^i_ε of side length ε so that both the particle and the cube are centered at the point $\underline{x}^i_\varepsilon$. Then $D^i_\varepsilon = K^i_\varepsilon \setminus Q^i_\varepsilon$ (see Figure 7.1) is a periodicity cell filled with the fluid. To obtain the standard unit cell we rescale D^i_ε by the factor ε^{-1} and shift its center to the origin. Then the domain $D = K\setminus Q$ is a unit periodicity cell, where K is the cube of side length 1 centered at the origin and Q is a domain in K with diameter $d<1/2$ and boundary $\partial Q \in C^2$.

Let us consider the boundary value problem in $D = K\setminus Q$, the so-called cell problem:

$$-\mu\Delta\underline{u}^{qr} + \nabla p^{qr} = 0, \qquad \underline{x}\in K\setminus Q, \tag{7.1}$$

$$\operatorname{div}\underline{u}^{qr} = 0, \qquad \underline{x}\in K\setminus Q, \tag{7.2}$$

$$\underline{u}^{qr} = -\underline{\psi}^{qr}(\underline{x}) + \underline{b}^{qr}\times\underline{x}, \quad x\in\partial Q, \tag{7.3}$$

$$\int_{\partial Q}\underline{x}\times(\underline{\underline{\sigma}}[\underline{u}^{qr}]\cdot\underline{\nu})dS = -\frac{1}{\lambda}\underline{\underline{C}}\,\underline{b}^{qr}, \tag{7.4}$$

$$\underline{u}^{qr}(\underline{x})\big|_{\Gamma_i^-} = \underline{u}^{qr}(\underline{x})\big|_{\Gamma_i^+}, \quad \underline{\underline{\sigma}}[\underline{u}^{qr}(\underline{x})]\big|_{\Gamma_i^-} = \underline{\underline{\sigma}}[\underline{u}^{qr}(\underline{x})]\big|_{\Gamma_i^+}. \tag{7.5}$$

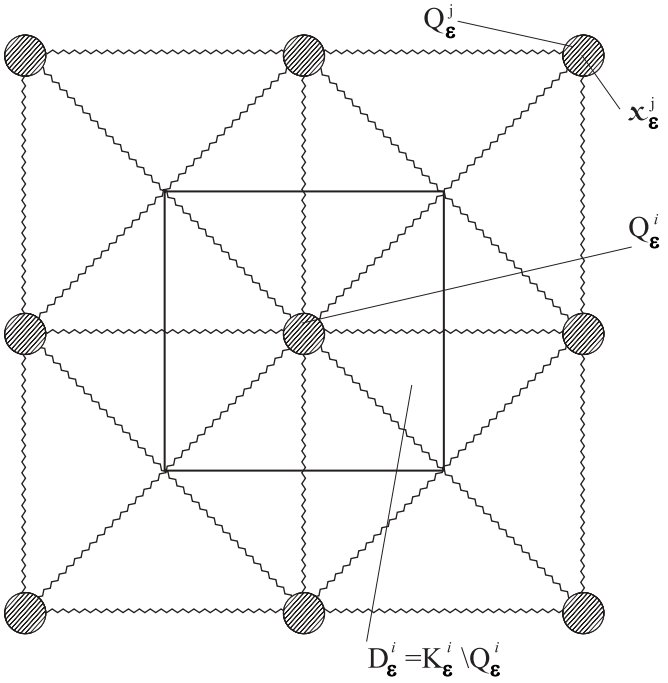

FIG. 7.1. *Two-dimensional periodic structure.*

Here $\underline{\underline{\sigma}}[\underline{u}]$ is the stress tensor defined by (2.15), $\underline{\psi}^{qr}(\underline{x})$ are functions defined by (3.8), $\underline{\nu}$ is the unit outward normal to ∂D, $\underline{b}^{qr}$ are arbitrary constant vectors, and $\underline{\underline{C}}$ is the following matrix:

$$\underline{\underline{C}} = \sum_j{}' \frac{\underline{\underline{C}}_{3\varepsilon}^{ij} - \underline{\underline{C}}_{4\varepsilon}^{ij}}{\varepsilon^3} = \sum_j{}' \underline{\underline{C}}_3^{ij} - \underline{\underline{C}}_4^{ij}, \tag{7.4$'$}$$

where $C_{3\varepsilon}^{ij}$, $C_{4\varepsilon}^{ij}$ are interaction matrices defined in (2.8), the sum $\sum_j'$ is taken over all neighbors of Q_ε^i, and due to periodicity $\underline{\underline{C}}$ does not depend on i. Γ_i^- and Γ_i^+ are opposite faces of the cube K ($i = 1, 2, 3$).

LEMMA 7.1. *The problem* (7.1)–(7.5) *for any* $\lambda > 0$ *has the unique solution (up to an additive constant in the pressure* p^{qr}*)* $\{\underline{u}^{qr}(\underline{x}), \underline{b}^{qr}, p^{qr}(\underline{x})\}$*, such that* $\underline{u}^{qr}(\underline{x}) \in C^{2+\alpha}\overline{(K \setminus Q)}$*,* $p^{qr} \in C^{1+\alpha}\overline{(K \setminus Q)}$*,* $\alpha > 0$*, and it admits a periodic extension on* $\mathbb{R}^3$*.*

The proof of this lemma uses standard variational techniques and is presented in [1].

The following theorem allows us to compute the effective properties of the suspension.

THEOREM 7.2. *For the periodic structure described above there exist the limits in the condition* (b_1)*, the components of limiting tensor* $\{a_{npqr}(\underline{x}, \lambda)\}$ *are constants with respect to* $\underline{x}$*, and they can be calculated as follows:*

$$a_{npqr}(\lambda) = \mu \mathbf{I}_{npqr} + \frac{1}{\lambda} \sum_j{}' \langle \underline{\underline{C}}_1^{ij} \underline{\psi}^{np}(\underline{x}^j), \underline{\psi}^{qr}(\underline{x}^j) \rangle$$

$$+ 2\mu \int_K \sum_{k,l=1}^{3} e_{kl}[\underline{u}^{np}(\underline{x}, \lambda)] e_{kl}[\underline{u}^{qr}(\underline{x}, \lambda)] dx + \frac{1}{\lambda} \langle \underline{\underline{C}} \underline{b}^{np}, \underline{b}^{qr} \rangle. \tag{7.6}$$

Here $\mathbf{I}_{npqr}$ *are components of the fourth rank tensor defined by*

$$\mathbf{I}_{npqr} = \frac{1}{2}(\delta_{nq}\delta_{pr} + \delta_{nr}\delta_{pq}) - \frac{1}{3}\delta_{np}\delta_{qr}. \tag{7.7}$$

The constant matrices $\underline{\underline{C}}_1^{ij} = \frac{1}{2\varepsilon}\underline{\underline{C}}_{1\varepsilon}^{ij}$ *and* $\underline{\underline{C}}$ *(see* (7.4′) *and* (2.8)*) do not depend on* ε*;* $\underline{x}^j$ *are the centers of mass of the neighbors to* Q^i *particles, i.e.,* $\underline{x}^j = \sum_{k=1}^3 n_k^j e^k$*,* $n_k^j = 0, \pm 1$*; and* $\underline{u}^{np}(\underline{x}, \lambda)$ *is the solution of the cell problem* (7.1)–(7.5) *extended onto* Q *by* (7.3).

Remark 7.1. Clearly in the periodic case the limits in condition (b_2) exist, and the limiting density ρ is the following constant:

$$\rho = \rho_s|Q| + \rho_f(1 - |Q|),$$

where $|Q|$ is the volume of the particle Q.

Outline of the proof of Theorem 7.2. Let K_h^ξ be a cube of the side length $h \gg \varepsilon$ centered at the point $\xi \in \Omega$. Consider a function in K_h^ξ

$$\underline{U}_\varepsilon^{qr}(\underline{x}) = \underline{\psi}^{qr}(\underline{x} - \underline{\xi}_\varepsilon) + \varepsilon \underline{\widetilde{u}}^{qr}\left(\frac{\underline{x} - \underline{\xi}_\varepsilon}{\varepsilon}, \lambda\right), \tag{7.8}$$

where $\underline{\widetilde{u}}^{qr}(\underline{x}, \lambda)$ is a periodic extension of the solution $\underline{u}^{qr}(\underline{x}, \lambda)$ of the cell problem (7.1)–(7.5) (see Lemma 7.1); $\underline{\xi}_\varepsilon = \underline{x}_\varepsilon^i$ is the nearest to $\underline{\xi}$ center of mass of particles Q_ε^i. Using the properties of the functions $\underline{\psi}^{qr}(\underline{x})$ and $\underline{u}^{qr}(\underline{x}, \lambda)$, we have

$$\operatorname{div} \underline{\widetilde{u}}_\varepsilon^{qr}(\underline{x}, \lambda) = 0$$

in $K_{h\varepsilon}^\xi = K_h^\xi \setminus \cup_i Q_\varepsilon^i$. On the boundaries of the particles Q_ε^j,

$$\underline{U}_\varepsilon^{qr}(\underline{x}, \lambda) = \underline{\psi}^{qr}(\underline{x}_\varepsilon^j - \underline{\xi}_\varepsilon) + \underline{b}(\lambda)^{qr} \times (\underline{x} - \underline{x}_\varepsilon^j), \quad \underline{x} \in S_\varepsilon^j, \tag{7.9}$$

where $\underline{b}(\lambda)^{qr}$ is a constant vector from (7.3). We extend $\underline{U}_\varepsilon^{qr}(\underline{x}, \lambda)$ on the particles Q_ε^j, using (7.9). Then we have

$$\operatorname{div} \underline{U}_\varepsilon^{qr}(\underline{x}) = 0 \quad \text{in } K_h^\xi. \tag{7.10}$$

We seek a function $\underline{\hat{u}}_\varepsilon^{qr}(\underline{x}, \lambda)$ that minimizes the functional (3.5) for $T = \frac{1}{2}(\underline{e}^q \otimes \underline{e}^r + \underline{e}^r \otimes \underline{e}^q)$ in the form

$$\underline{\hat{u}}_\varepsilon^{qr}(\underline{x}, \lambda) = \underline{U}_\varepsilon^{qr}(\underline{x}, \lambda) + \underline{v}_\varepsilon^{qr}(\underline{x}, \lambda), \tag{7.8′}$$

where $\underline{U}_\varepsilon^{qr}(\underline{x}, \lambda)$ is defined by (7.8). Next we obtain a variational problem for the corrector $\underline{v}_\varepsilon^{qr}(\underline{x}, \lambda)$. Analysis of this problem shows that $E_{K_h^\xi}[\underline{v}_\varepsilon^{qr}(\underline{x}, \lambda), \underline{v}_\varepsilon^{qr}(\underline{x}, \lambda)]$ and $I_{K_h^\xi}[\underline{v}_\varepsilon^{qr}(\underline{x}, \lambda), \underline{v}_\varepsilon^{qr}(\underline{x}, \lambda)]$ vanish in the limit $\varepsilon \to 0$ and $h \to 0$ ($\varepsilon \ll h$), and therefore the first term on the RHS of (7.8′) is the leading one and the second is a small corrector.

Substituting (7.8′) into (3.10), we obtain

$$\begin{aligned}
\frac{1}{h^3} a_{npqr}(\xi, \lambda, \varepsilon, h) &= E_{K_h^\xi}[\underline{U}_\varepsilon^{np}, \underline{U}_\varepsilon^{qr}] + \frac{1}{\lambda} I_{K_h^\xi}[\underline{U}_\varepsilon^{np}, \underline{U}_\varepsilon^{qr}] \\
&+ H[\underline{U}_\varepsilon^{np} - \underline{\psi}^{np}, \underline{U}_\varepsilon^{qr} - \underline{\psi}^{qr}] + E_{K_h^\xi}[\underline{U}_\varepsilon^{np}, \underline{v}_\varepsilon^{qr}] + E_{K_h^\xi}[\underline{U}_\varepsilon^{qr}, \underline{v}_\varepsilon^{np}] \\
&+ \frac{1}{\lambda} I_{K_h^\xi}[\underline{U}_\varepsilon^{np}, \underline{v}_\varepsilon^{qr}] + \frac{1}{\lambda} I_{K_h^\xi}[\underline{U}_\varepsilon^{qr}, \underline{v}_\varepsilon^{np}] + H[\underline{U}_\varepsilon^{np} - \underline{\psi}^{np}, \underline{v}^{qr}] \\
&+ H[\underline{U}_\varepsilon^{qr} - \underline{\psi}^{qr}, \underline{v}^{np}] + E_{K_h^\xi}[\underline{v}_\varepsilon^{np}, \underline{v}_\varepsilon^{qr}] + \frac{1}{\lambda} I_{K_h^\xi}[\underline{v}_\varepsilon^{np}, \underline{v}_\varepsilon^{qr}] + H[\underline{v}_\varepsilon^{np}, \underline{v}_\varepsilon^{qr}].
\end{aligned} \tag{7.11}$$

Here we have used the notation of (3.6)–(3.7) and introduced the notation $H[\underline{u},\underline{v}] = h^{-2-\tau}\int_{K_h^\xi}\langle \underline{u},\underline{v}\rangle dx$.

On the RHS of (7.11) only the first two terms provide a nonzero contribution in the limit $\varepsilon \to 0$ and $h \to 0$ ($\varepsilon \ll h$). The remaining terms vanish in this limit, which can be shown by a direct calculation. We now calculate these nonvanishing terms. Using (7.8), we can write

$$E_{K_h^\xi}[\underline{U}_\varepsilon^{np}, \underline{U}_\varepsilon^{qr}] = E_{K_h^\xi}[\underline{\psi}_\varepsilon^{np}, \underline{\psi}_\varepsilon^{qr}] + E_{K_h^\xi}[\widetilde{\underline{u}}_\varepsilon^{np}, \widetilde{\underline{u}}_\varepsilon^{qr}]$$

$$+ E_{K_h^\xi}[\underline{\psi}_\varepsilon^{np}, \widetilde{\underline{u}}_\varepsilon^{qr}] + E_{K_h^\xi}[\underline{\psi}_\varepsilon^{qr}, \widetilde{\underline{u}}_\varepsilon^{np}], \tag{7.12}$$

where $\underline{\psi}_\varepsilon^{np} = \underline{\psi}^{np}(\underline{x} - \underline{\xi}_\varepsilon)$, $\widetilde{\underline{u}}_\varepsilon^{np} = \varepsilon\widetilde{\underline{u}}(\frac{\underline{x}-\underline{\xi}_\varepsilon}{\varepsilon}, \lambda)$.

Integration by parts shows that the third and fourth terms on the RHS of (7.12) are equal to zero, and we calculate the first two terms.

To simplify the calculation we assume that the cube K_h^ξ can be partitioned into an integer number of elementary cubes (cells) K_ε^j. Then, taking into account the linearity of $\underline{\psi}^{np}(\underline{x})$ and periodicity of $\widetilde{\underline{u}}^{np}(\underline{x})$, we obtain

$$E_{K_h^\xi}[\underline{\psi}_\varepsilon^{np}, \underline{\psi}_\varepsilon^{qr}] = \frac{\mu}{h^3}\sum_j 2\varepsilon^2 \int_{K_\varepsilon^j} \sum_{k,l=1}^3 e_{kl}\left[\underline{\psi}^{np}\left(\frac{\underline{x} - \underline{x}_\varepsilon^i}{\varepsilon}\right)\right] e_{kl}\left[\underline{\psi}^{qr}\left(\frac{\underline{x} - \underline{x}_\varepsilon^i}{\varepsilon}\right)\right] dx$$

$$= 2\mu \int_K \sum_{k,l=1}^3 e_{kl}[\underline{\psi}^{np}] e_{kl}[\underline{\psi}^{qr}(\underline{x})] dx = \mu \mathbf{I}_{\mathbf{npqr}}, \tag{7.13}$$

$$E_{K_h^\xi}[\widetilde{\underline{u}}_\varepsilon^{np}, \widetilde{\underline{u}}_\varepsilon^{qr}] = \frac{\mu}{h^3}\sum_j 2\varepsilon^2 \int_{K_\varepsilon^j} \sum_{k,l=1}^3 e_{kl}\left[\underline{u}^{np}\left(\frac{\underline{x} - \underline{x}_\varepsilon^i}{\varepsilon}\right)\right] e_{kl}\left[\underline{u}^{qr}\left(\frac{\underline{x} - \underline{x}_\varepsilon^i}{\varepsilon}\right)\right] dx$$

$$= 2\mu \int_K \sum_{k,l=1}^3 e_{kl}[\underline{u}^{np}(\underline{x}, \lambda)] e_{kl}[\underline{u}^{qr}(\underline{x}, \lambda)] dx. \tag{7.14}$$

Here we take into account that the number of summands in $\sum_j$ is equal to $\frac{h^3}{\varepsilon^3}$ and $\widetilde{\underline{u}}^{np}(\underline{x})$ are extended on Q by (7.3), and also we use the notation (7.7).

Using (7.9), (2.8), and the linearity of $\underline{\psi}^{np}(\underline{x})$, we obtain

$$I[\underline{U}_\varepsilon^{np}, \underline{U}_\varepsilon^{qr}] = \frac{1}{2h^3}\sum_{ij}\left\langle \underline{\underline{C}}_{1\varepsilon}^{ij}\underline{\psi}^{np}(\underline{x}_\varepsilon^i - \underline{x}_\varepsilon^j), \underline{\psi}^{qr}(\underline{x}_\varepsilon^i - \underline{x}_\varepsilon^j)\right\rangle$$

$$+ \frac{1}{2h^3}\sum_{ij}\left\langle \left(\underline{\underline{C}}_{3\varepsilon}^{ij} - \underline{\underline{C}}_{4\varepsilon}^{ij}\right)\underline{b}^{np}, \underline{b}^{qr}\right\rangle = \sum_j{}' \left\langle \underline{\underline{C}}_1^{ij}\underline{\psi}^{np}(\underline{x}^j), \underline{\psi}^{qr}(\underline{x}^j)\right\rangle + \langle C\underline{b}^{np}, \underline{b}^{qr}\rangle, \tag{7.15}$$

where the matrices C_1^{ij}, C and the points $\underline{x}^j$ are defined in the formulation of Theorem 7.2. (see also Figure 7.1).

Combining (7.13)–(7.15), we obtain (7.6). The detailed proof is presented in [1].

THEOREM 7.3. *Tensor* $\{a_{npqr}(\lambda)\}$ *obtained in Theorem* 7.2 *can be represented in*

the form

$$a_{npqr}(\lambda) = \mu \mathbf{I}_{npqr} + 2\mu \int_K \sum_{k,l=1}^{3} e_{kl}[\underline{u}_0^{np}] e_{kl}[\underline{u}_0^{qr}] dx$$

$$+\frac{1}{\lambda} \left\{ \sum_j{}' \langle \underline{\underline{C}}_1^{ij} \underline{\psi}^{np}(\underline{x}^j) \underline{\psi}^{qr}(\underline{x}^j) \rangle + \langle \underline{\underline{C}} \underline{b}_0^{np}, \underline{b}_0^{qr} \rangle \right\} + a^1_{npqr}(\lambda). \tag{7.16}$$

Here

$$a^1_{npqr}(\lambda) = 2\mu \left\{ \int_K \sum_{k,l=1}^{3} e_{kl}[\underline{u}_0^{np}(\underline{x})] e_{kl}[\underline{v}^{qr}(\underline{x},\lambda)] dx \right.$$

$$\left. + \int_K \sum_{k,l=1}^{3} e_{kl}[\underline{v}^{np}(\underline{x},\lambda)] e_{kl}[\underline{u}_0^{qr}(\underline{x})] dx + \int_K \sum_{k,l=1}^{3} e_{kl}[\underline{v}^{np}(\underline{x},\lambda)] e_{kl}[\underline{v}^{qr}(\underline{x},\lambda)] dx \right\}$$

$$+\frac{1}{\lambda} \left[\langle \underline{\underline{C}} \underline{b}_0^{np}, \underline{d}^{qr}(\lambda) \rangle + \langle \underline{\underline{C}} \underline{d}^{np}(\lambda), \underline{b}_0^{qr} \rangle + \langle \underline{\underline{C}} \underline{d}^{np}(\lambda), \underline{b}_0^{qr} \rangle \right], \tag{7.17}$$

where the function $\underline{u}_0^{np}(\underline{x})$ *and the constant vector* $\underline{b}_0^{qr}$ *solve the cell problem*

$$-\mu \Delta \underline{u}_0^{np} + \nabla p_0^{np} = 0, \quad \underline{x} \in K \setminus Q,$$
$$\operatorname{div} \underline{u}_0^{np} = 0, \quad \underline{x} \in K,$$
$$\underline{u}_0^{np} = -\underline{\psi}^{np}(\underline{x}) + \underline{b}_0^{np} \times \underline{x}, \quad \underline{x} \in Q, \quad \underline{b}_0 \in \ker \underline{\underline{C}},$$
$$\underline{\underline{\sigma}}_0 := \int_{\partial Q} \underline{x} \times (\underline{\underline{\sigma}}[\underline{u}_0^{np}] \cdot \underline{\nu}) dS \perp \ker \underline{\underline{C}}, \tag{7.18}$$

function $\underline{v}^{np}(\underline{x},\lambda)$ *and vector* $\underline{d}^{np}(\lambda)$ *are the solution of the problem*

$$-\mu \Delta \underline{v}^{np} + \nabla p_0^{np} = 0, \quad \underline{x} \in K \setminus Q,$$
$$\operatorname{div} \underline{v}^{np} = 0, \quad \underline{x} \in K,$$
$$\underline{v}^{np} = \underline{d}(\lambda) \times \underline{x}, \quad \underline{x} \in Q, \quad \underline{d}(\lambda) \perp \ker \underline{\underline{C}},$$
$$\int_{\partial Q} \underline{x} \times (\underline{\underline{\sigma}}[\underline{v}^{np}] \cdot \underline{\nu}) dS + \frac{1}{\lambda} \underline{\underline{C}} \underline{d} = -\underline{\underline{\sigma}}_0 \perp \ker \underline{\underline{C}}, \tag{7.19}$$

$\underline{v}^{np}(\underline{x},\lambda)$ *and* $\underline{\underline{\sigma}}[\underline{v}^{np}]$ *as well as* $\underline{u}_0$ *and* $\underline{\underline{\sigma}}[\underline{u}_0]$ *are periodic in the cube* K*, and* $\underline{\nu}$ *is the inner normal vector to* ∂Q*.*

Proof of Theorem 7.3. Comparison of (7.18)–(7.19) and (7.1)–(7.5) shows that due to linearity the solution of problem (7.1)–(7.5) can be represented in the form

$$\underline{u}^{np}(\underline{x},\lambda) = \underline{u}_0^{np}(\underline{x}) + \underline{v}^{np}(\underline{x},\lambda), \tag{7.20}$$

$$\underline{b}^{np}(\lambda) = \underline{b}_0^{np}(\lambda) + \underline{d}^{np}(\lambda), \tag{7.21}$$

where $\{\underline{u}_0^{np}(\underline{x}), \underline{b}_0^{np}\}$ is the solution of problem (7.18), which does not depend on λ, and $\{\underline{v}^{np}(\underline{x},\lambda), \underline{d}^{np}(\lambda)\}$ is the solution of problem (7.19). Each of these problems has a unique solution. Indeed $\{\underline{u}_0^{np}, \underline{b}^{np}\}$ minimizes the functional

$$I_0 = 2\mu \int_K \sum_{k,l=1}^{3} e_{kl}^2[\underline{u}^{np}] dx$$

in the class of divergence-free in K and periodic functions which are equal to $-\psi^{np}(\underline{x}) + \underline{b} \times \underline{x}$ on Q, with $\underline{b} \in \ker \underline{\underline{C}}$ ($\underline{\underline{C}} = \sum(\underline{\underline{C}}^{ij}_{3\varepsilon} - \underline{\underline{C}}^{ij}_{4\varepsilon})/(2\varepsilon^3)$), and $\{\underline{v}^{np}(\underline{x}, \lambda), \underline{d}^{np}(\underline{x}, \lambda)\}$ minimizes the functional

$$I = 2\mu \int_K \sum_{k,l=1}^{3} e^2_{kl}[\underline{v}^{np}] + \frac{1}{\lambda}\langle \underline{\underline{C}}\underline{d}, \underline{d}\rangle + 2\langle \underline{\underline{\sigma}}_0, \underline{d}\rangle$$

in the class of divergence-free in K and periodic functions equal to $\underline{d} \times \underline{x}$ on Q, $\underline{d} \perp \ker \underline{\underline{C}}$. Note that the pressure does not appear in the above variational formulations and can be computed from the Stokes equation. To obtain (7.16) we substitute (7.20)–(7.21) into (7.6). Theorem 7.3 follows.

We now obtain a detailed characterization of the tensor $\{a^1_{npqr}(\lambda)\}$. The following Theorem 7.4 and Proposition 7.7 show how this characterization allows us to get explicit formulas for the effective viscoelastic properties. Indeed, taking the inverse Laplace transform of the representation (7.16), we observe that the first two terms do not depend on λ and together represent the homogenized tensor of the effective viscosity a^0_{npqr} (see (3.18)); the term with the factor λ^{-1} (the sum in brackets in (7.16)) is the effective elasticity tensor. Tensor $a^1_{npqr}(\lambda)$ represents the memory term, and the numbers $-\lambda_k$ are inverse relaxation times of the effective viscoelastic medium. These numbers are the eigenvalues of the spectral problem which is obtained from (7.19) by setting $\underline{\underline{\sigma}}_0 = 0$ in the last equation in (7.19).

THEOREM 7.4. *The functions $a^1_{npqr}(\lambda)$ obtained in Theorem* 7.3 *are meromorphic in $\mathbf{C} \setminus 0$ with poles at the points $\lambda_k < 0$ ($\lambda_k \to -0, k \to \infty$). The numbers $\lambda_k < 0$ are the eigenvalues of the spectral problem which corresponds to the cell problem* (7.19) *when $\underline{\underline{\sigma}}_0 = 0$.*

Proof of Theorem 7.4. In short, the proof of this theorem consists of the introduction of an operator and a functional space which correspond to the problem (7.19), followed by the standard spectral analysis.

Let us denote by $\mathcal{J}_C(K)$ the closure in $L_2^{per}(K)$ of the set of divergence-free functions from $H^1_{per}(K)$ equal to $\underline{d} \times \underline{x}$ in subdomains Q, where $\underline{d} \perp \ker \underline{\underline{C}}$. The spaces $L_2^{per}(K)$ and $H^1_{per}(K)$ of periodic on K functions is defined in [12]. Next we introduce the space $G(K)$ as a set of functions of the form $\mathrm{grad}\varphi(\underline{x}) + \chi_Q(\underline{x})\underline{\psi}(\underline{x})$, where the function $\varphi(\underline{x}) \in H^1_{per}(K)$ and $\underline{\psi}(\underline{x})$ is a function orthogonal in $L_2(Q)$ to functions of the form $\underline{d} \times \underline{x}$, $\underline{d} \perp \ker \underline{\underline{C}}$.

The next lemma is a straightforward generalization of the standard Weyl decomposition [12] and can be proved analogously. It reduces to the Weyl decomposition in the absence of the rigid inclusion Q.

LEMMA 7.5. *The following orthogonal decomposition holds:*

$$L_2^{per}(K) = \mathcal{J}_C(K) \oplus G(K).$$

Let us introduce the operator $\hat{A}$ acting from $\mathcal{J}_C(K) \cap H^2(K \setminus Q)$ into $L_2(K)$:

$$\hat{A}\underline{u} = \begin{cases} -\mu\delta\underline{u}, & \underline{x} \in K \setminus Q, \\ B_0[\underline{u}] \times \underline{x}, & \underline{x} \in Q. \end{cases}$$

Here vector $B_0[\underline{u}]$ is defined by the equation

$$B_0[\underline{u}] = (I)^{-1} \int_{\partial Q} \underline{x} \times (\underline{\underline{\sigma}}[\underline{u}] \cdot \underline{\nu}) dS,$$

where I is the tensor of inertia of the body Q with the density $\rho_s = 1$ ($\sigma^0_{ik} = \mu e_{ik}(\underline{v})$).

Let P_C be the operator of orthogonal projection on the subspace $\mathcal{J}_C(K)$. Let us define an operator

$$\widetilde{A} = P_C \hat{A}.$$

Direct calculations show that

$$\widetilde{A}\underline{u} = \begin{cases} -\mu\Delta\underline{u} + \nabla p, & \underline{x} \in K \setminus Q, \\ B_0[\underline{u}] \times \underline{x} + (I)^{-1} \int_{\partial Q} (\underline{x} \times \underline{\nu})\, p dS \times \underline{x}, & \underline{x} \in Q. \end{cases}$$

Introduce an operator A as the Friedrichs extension of the operator $\widetilde{A}$.

LEMMA 7.6. *Operator A is self-adjoint in $\mathcal{J}_C(K)$, invertible, and has a compact inverse operator.*

We now introduce an operator

$$A_1 = P_C \hat{A}_1, \tag{7.22}$$

where $\hat{A}_1$ is a bounded operator acting from $\mathcal{J}_C(K)$ into $L_2^{per}(K)$ by the formula

$$\hat{A}_1 \underline{u} = \chi_Q(\underline{x}) \left[I^{-1} \underline{\underline{C}} \underline{d} \times \underline{x} \right],$$

where $\underline{u}$ is defined on Q by the equation $\underline{u} = \underline{d} \times \underline{x}$, $\underline{d} \perp \ker \underline{\underline{C}}$. Taking into account the symmetry of the matrices $\underline{\underline{C}}^{ij}_{3\varepsilon}$, $\underline{\underline{C}}^{ij}_{4\varepsilon}$ (which follows from (2.8)), $C^T = C$, $(\underline{\underline{C}}^{ij}_{3\varepsilon})^T = \underline{\underline{C}}^{ji}_{3\varepsilon}$, $(\underline{\underline{C}}^{ij}_{4\varepsilon})^T = \underline{\underline{C}}^{ji}_{4\varepsilon}$, the periodicity property $\underline{\underline{C}}^{i+k,j+k}_{\varepsilon}(\underline{x}, \underline{y}) = \underline{\underline{C}}^{ij}_{\varepsilon}(\underline{x}, \underline{y})$, a $\underline{k}$-arbitrary integer vector, and (7.4′), we obtain

$$\langle \underline{\underline{C}} \underline{b}, \underline{d} \rangle = \langle \underline{b}, \underline{\underline{C}} \underline{d} \rangle, \tag{7.23}$$

$$\langle \underline{\underline{C}} \underline{b}, \underline{b} \rangle \geq 0 \tag{7.24}$$

for any $\underline{b}, \underline{d} \in \mathbf{R}^3$.

Then since $\underline{b} \perp \ker \underline{\underline{C}}$, we get from (7.24)

$$\langle \underline{\underline{C}} \underline{b}, \underline{b} \rangle > 0, \quad \underline{b} \neq 0. \tag{7.25}$$

Using the definitions of the operator $\hat{A}_1$ and the tensor of inertia $\underline{\underline{I}}$, we show that the operator A_1 defined by (7.22) is a self-adjoint and positive operator in $\mathcal{J}_C(K)$. Indeed,

$$\begin{aligned} (\hat{A}_1 \underline{u}, \underline{v}) &= \int_K \chi_Q(\underline{x}) \langle \underline{\underline{I}} \underline{\underline{C}} \underline{b} \times \underline{x}, \underline{d} \times \underline{x} \rangle dx \\ &= \int_Q \langle I^{-1} \underline{\underline{C}} \underline{b} \times \underline{x}, \underline{d} \times \underline{x} \rangle dx = \langle \underline{\underline{C}} \underline{b}, \underline{d} \rangle = \langle \underline{b}, \underline{\underline{C}} \underline{d} \rangle = (\underline{u}, \hat{A}_1 \underline{v}) \end{aligned} \tag{7.26}$$

and

$$(\hat{A}_1 \underline{u}, \underline{u}) > 0$$

for any $\underline{u}$, $\underline{v} \in \mathcal{J}_C(K)$ ($\underline{u}(\underline{x}) = \underline{b} \times \underline{x}$, $\underline{v} = \underline{d} \times \underline{x}$, $\underline{x} \in Q$, and $\underline{b}, \underline{d} \perp \ker \underline{\underline{C}}$); $(\hat{A}_1 \underline{u}, \underline{v})$ is the dot product in $L_2(K)$.

Similarly we can represent the projection of function $-(\underline{\underline{\sigma}}_0 \times \underline{x})\chi_Q(\underline{x})$ on the subspace $\mathcal{J}_C(K)$:

$$\underline{f}_0 = -P_C[(\underline{\underline{\sigma}}_0 \times \underline{x})\chi_Q(\underline{x})] = \begin{cases} \operatorname{grad} p, \\ -\underline{\underline{\sigma}}_0 \times \underline{x} + I^{-1} \int_{\partial Q} (\underline{x} \times \underline{\nu}) p ds \times \underline{x}. \end{cases}$$

Then the problem (7.19) can be written in the operator form in the space $\mathcal{J}_C(K)$:

$$A\underline{v} + \frac{1}{\lambda} A_1 \underline{v} = \underline{f}_0 \tag{7.27}$$

or equivalently as

$$(B - \lambda I)\underline{v} = \lambda \underline{g}_0, \qquad \underline{g}_0 = A^{-1} f_0, \tag{7.27$'$}$$

where $B = -A^{-1}A_1$ is a compact operator in $\mathcal{J}_C(K)$ whose spectrum consists of the eigenvalues $\lambda_k \neq 0$ with the only accumulation point at 0.

Operator B in bounded and self-adjoint in the energy space H_A of the operator A, that is,

$$(B\underline{u}, \underline{v})_A = (\underline{u}, B\underline{v})_A,$$

and due to the positivity of the operator A_1,

$$(B\underline{u}, \underline{u})_A = -(A_1\underline{u}, \underline{u})_{L_2(K)} < 0.$$

Thus eigenvalues λ_k are negative and the corresponding eigenfunctions are orthogonal in energy space H_A. Eigenfunctions corresponding to multiple eigenvalues can be chosen to be orthogonal in H_A. Due to the Gilbert–Schmidt theorem, the system of eigenfunctions $\{\varphi_k\}$ is complete in $\mathcal{J}_C(K)$. Taking into account this fact, we can easily find the solution $\underline{v}$ of (7.27$'$):

$$\underline{v}(\underline{x}, \lambda) = -\lambda \sum_{k=1}^{\infty} \frac{C_k}{\lambda - \lambda_k} \varphi_k(\underline{x}), \quad C_k = (A\varphi_k, \underline{g}_0). \tag{7.28}$$

Thus, the solution of problem (7.19) is a meromorphic function in the complex plane λ.

Substituting (7.28) into (7.17), we obtain an explicit representation for a^1_{npqr},

$$a^1_{npqr}(\lambda) = \sum_{i=1}^{\infty} \frac{\lambda A_i^{npqr} + C_i^{npqr}}{\lambda - \lambda_i} + \sum_{i,j=1}^{\infty} \frac{\lambda^2 A_{ij}^{npqr} + \lambda C_{ij}^{npqr}}{(\lambda - \lambda_i)(\lambda - \lambda_j)},$$

where the first sum and the second sum correspond to the linear and quadratic terms in (7.17), respectively, and

$$\begin{aligned} A_i^{npqr} &= 2\mu \int_K \sum_{k,l} \left(e_{kl}[\underline{u}_0^{np}] C_i^{qr} + e_{kl}[\underline{u}_0^{qr}] C_i^{np} \right) e_{kl}[\varphi_i] dx, \\ A_{ij}^{npqr} &= 2\mu \int_K \sum_{kl} e_{kl}^2[\varphi_i] C_i^{np} C_j^{qr} dx, \\ C_i^{npqr} &= 2\mu \left\{ \langle \underline{\underline{C}} \underline{b}_0^{np}, \underline{d}_i \rangle C_i^{qr} + \langle \underline{\underline{C}} \underline{d}_i, \underline{b}_0^{qr} \rangle C_i^{np} \right\}, \\ C_{ij}^{npqr} &= 2\mu \langle \underline{\underline{C}} \underline{d}_i, \underline{d}_j \rangle C_i^{np} C_j^{qr}. \end{aligned} \tag{7.29}$$

Finally, we distinguish the λ independent part in $a^1_{npqr}(\lambda)$,

$$a^1_{npqr}(\lambda) = a^{10}_{npqr} + a^{11}_{npqr}(\lambda),$$

where

$$\begin{cases} a^{10}_{npqr} & = \sum_i A_i^{npqr} + \sum_{i,j} A_{ij}^{npqr}, \\ a^{11}_{npqr}(\lambda) & = \sum_i \frac{\lambda_i A_i^{npqr} + C_i^{npqr}}{\lambda - \lambda_i} \\ & \quad + 2\sum_{ij} \frac{(\lambda(\lambda_i+\lambda_j) - \lambda_i\lambda_j)A_{ij}^{npqr} + \lambda C_{ij}^{npqr}}{(\lambda-\lambda_i)(\lambda-\lambda_j)}. \end{cases} \tag{7.30}$$

Then

$$a^{11}_{npqr}(\lambda) = O\left(\frac{1}{\lambda}\right) \quad \text{as} \quad |\lambda| \to \infty.$$

Taking the inverse Laplace transform of $a^1_{npqr}(\lambda)$, we obtain

$$a^1_{npqr}(t) = a^{10}_{npqr}\delta(t) + \sum_{i=1}^{\infty} B_i^{npqr} e^{\lambda_i t}, \tag{7.31}$$

where, according to (7.30),

$$B_i^{npqr} = \lambda_i(A_i^{npqr} + A_{ii}^{npqr}) + C_i^{npqr} + C_{ii}^{npqr} + 2\sum_{j>i} \frac{\lambda_i^2 A_{ij}^{npqr} + \lambda_i C_{ij}^{npqr}}{\lambda_i - \lambda_j} \tag{7.32}$$

and Theorem 7.4 is proved.

We now use Theorems 7.3 and 7.4 to obtain an explicit representation for the relaxation tensor.

PROPOSITION 7.7. *The following representation for the effective tensor* (3.14) *holds:*

(7.33)

$$\hat{a}_{npqr}(t) = a^0_{npqr}\delta(t) + a^1_{npqr}\chi(t) + \sum_{i=1}^{\infty} B_i^{npqr} e^{\lambda_i t} \quad (\lambda_i < 0,\ \lambda_i \to -0, \quad \text{as } i \to \infty),$$

where

$$a^0_{npqr} = \mu \mathbf{I}_{npqr} + 2\mu \int_K \sum_{kl} e_{kl}[\underline{u}_0^{np}] e_{kl}[\underline{u}_0^{qr}] dx + a^{10}_{npqr},$$

$$a^1_{npqr} = \sum_j{}' \langle C_1^{ij} \underline{\psi}^{np}(\underline{x}^j) \underline{\psi}^{qr}(\underline{x}^j) \rangle + \langle \underline{\underline{C}} \underline{b}_0^{np}, \underline{b}_0^{qr} \rangle.$$

Constant tensors a^{10}_{npqr} *and* B_i^{npqr} *are defined in* (7.30), (7.32), *and* (7.29).

The representation (7.33) follows from (7.16) and (7.31).

An important question for the effective rheology of a composite medium is whether there are infinitely many relaxation times present. We now show that the presence of finite relaxations times $-\lambda_i^{-1}$ is caused by the asymmetry of the particles Q^i_ε. Roughly speaking, our calculations show that the finite relaxation times arise due to

the rotation of particles in a symmetric flow, and the effect of this rotation is negligible (to the leading term in the homogenization limit) if particles are symmetric.

PROPOSITION 7.8. *Suppose that the periodicity cell K is invariant with respect to reflections about all three coordinate planes (e.g., a spherical particle Q in a cubic periodicity cell K). Then the effective tensor $a_{npqr}(t)$ defined in* (4.8) *can be computed as follows:*

$$a_{npqr}(t) = a^0_{npqr}\delta(t) + a^1_{npqr}\chi(t), \tag{7.34}$$

where $\delta(t)$ is the Dirac delta-function and $\chi(t)$ is the Heaviside function.

$$a^0_{npqr} = \mu \mathbf{I}_{npqr} + 2\mu \int_K \sum e_{kl}[\underline{u}^{np}_0] e_{kl}[\underline{u}^{qr}_0] dx,$$

$$a^1_{npqr} = \sum_j \langle C^{ij}_1 \underline{\psi}^{np}(\underline{x}^j) \underline{\psi}^{qr}(\underline{x}^j) \rangle,$$

and $\underline{u}^{np}_0(\underline{x})$ is the solution of the problem (7.18) *for $\underline{\underline{C}} \equiv 0$ and $\underline{b}^{np}_0 = 0$.*

We now outline the proof of this proposition. (The details are presented in [1].) Assume that particles Q^i_ε are spherical balls. Then in the problem (7.18), Q is a ball, and taking into account the invariance of this problem under $x_i \to -x_i$, $i = 1, 2, 3$, transformations and the uniqueness of its solution, we conclude that $\underline{b}_0 = 0$ and $\underline{\underline{\sigma}}_0 = 0$. Then it follows from the uniqueness of the solution of the problem (7.19) that $\underline{v}(\underline{x}, \lambda) \equiv 0$ and $\underline{d}(\lambda) = 0$. Next (7.17) implies that $a^1_{npqr}(\lambda) = 0$, and according to (7.31), $a^{10}_{npqr} = 0$ and $B^{npqr}_i = 0$. Thus, in the case of the balls, the effective tensor $a_{npqr}(t)$ has the form (7.34). Note that the equality (7.34) means that in the case of symmetric particles the effective medium is viscoelastic with no memory.

Acknowledgments. Part of this work was done when E. K. was visiting Penn State University. His visit was supported by NSF grant DMS-9971999. We are pleased to thank A. Leonov who brought to our attention the problem of polymeric compounds with interacting filling particles and suggested that we develop a mathematical model for such compounds. We are also grateful to R. Lakes for discussions on the viscoelastic properties of composites and to A. Leonov for very helpful discussions.

SEMI-INFINITE ARRAYS OF ISOTROPIC POINT SCATTERERS. A UNIFIED APPROACH*

C. M. LINTON† AND P. A. MARTIN‡

Abstract. We solve the two-dimensional problem of acoustic scattering by a semi-infinite periodic array of identical isotropic point scatterers, i.e., objects whose size is negligible compared to the incident wavelength and which are assumed to scatter incident waves uniformly in all directions. This model is appropriate for scatterers on which Dirichlet boundary conditions are applied in the limit as the ratio of wavelength to body size tends to infinity. The problem is also relevant to the scattering of an E-polarized electromagnetic wave by an array of highly conducting wires. The actual geometry of each scatterer is characterized by a single parameter in the equations, related to the single-body scattering problem and determined from a harmonic boundary-value problem. Using a mixture of analytical and numerical techniques, we confirm that a number of phenomena reported for specific geometries are in fact present in the general case (such as the presence of shadow boundaries in the far field and the vanishing of the circular wave scattered by the end of the array in certain specific directions). We show that the semi-infinite array problem is equivalent to that of inverting an infinite Toeplitz matrix, which in turn can be formulated as a discrete Wiener–Hopf problem. Numerical results are presented which compare the amplitude of the wave diffracted by the end of the array for scatterers having different shapes.

1. Introduction.

Many methods exist for studying wave interactions with finite arrays of scatterers. For some simple geometries, methods based on separation of variables can be used. For example, the scattering of a plane wave by an arbitrary finite array of circular cylinders can be reduced to the solution of a rapidly convergent infinite system of linear equations.

For more complicated geometries a different method is needed. One possibility is to express the solution to the multiple scattering problem in terms of the individual scattering characteristics of the elements that make up the array. This leads to the so-called T-matrix approach, which has been used extensively in acoustics and in other fields. Another technique is to formulate the problem as an integral equation by, for example, representing the solution as a distribution of dipoles over all the scatterers. This leads to an integral equation of the second kind for the unknown dipole strength. Discretization of the integral equations typically leads to large, full systems of algebraic equations.

As the size of an array increases, solutions to scattering problems rapidly become computationally expensive. In contrast, the case of an infinite periodic array excited by a plane wave is usually a much simpler proposition. This is because the periodicity allows us to formulate the problem on a single "cell" of the array, with periodic boundary conditions. In terms of integral equations this necessitates the use of a

more complicated Green's function, the efficient computation of which may be an issue; see [16].

Methods by which solutions to infinite array scattering problems can be applied to shed light on associated large finite array problems have been applied previously in the design of large phased array antennas, early examples using a Fourier windowing approach [13, 24], in which some fairly crude assumptions are made about the field near each scatterer. Recently, methods based on integral equations have been devised in which the basic idea is to formulate an integral equation for the difference between the infinite array and finite array solutions; see [26, 21], for example. For large finite one-dimensional arrays this leads to problems formulated on semi-infinite arrays. Associated with these so-called fringe integral equation methods is the analysis of Green's functions for semi-infinite arrays; see [5, 6, 17].

Scattering by a semi-infinite array is thus a problem of considerable interest from both a practical and a theoretical point of view, and very few results are available. Perhaps the only attempt at a general theory is that of Millar [18, 19] based on the analysis of a nonlinear integral equation. Some results have been derived previously for the case of small, widely spaced circular cylinders [12, 11] and for the strip grating at low frequencies [22, 23]. In this paper we consider the general case of a semi-infinite array of identical scatterers which are each small with respect to the incident wavelength and under the assumption of Dirichlet boundary conditions on the scatterers. This problem was considered in [20], where a number of asymptotic results were derived. Our approach is based on Foldy's method [8], which since 1945 has found wide application in multiple scattering problems; for a recent application, see [2], for example. We show that the problems considered in [12, 11] and [22, 23] are special cases, and we construct a general system of equations in which the geometry of the scatterer is characterized by a single parameter. The system of equations can be inverted numerically or, since it is of Toeplitz type, it can be solved explicitly via the discrete Wiener–Hopf technique.

The semi-infinite array problem is closely related to the fully infinite array (i.e., diffraction grating) problem and, following a description of Foldy's method in section 2, we next solve this for the same class of scatterers in section 3. The semi-infinite grating problem is formulated in section 4, including a detailed description of the form of the far field and of the behavior at resonance frequencies. Finally, in section 5 we show how the integral equation approach used in [22, 23] reduces to exactly the same equations as those found in section 4. Many of the technical details are relegated to the appendices.

2. Foldy's method. The classic work on acoustic scattering by semi-infinite gratings is that of Hills and Karp [12, 11], who consider small sound-soft circular cylinders. Their formulation is based on a technique due to Foldy [8]. Foldy considers isotropic point scatterers, meaning that "in the neighborhood of the jth scatterer," the scattered field "will behave like" $A_j G(\mathbf{r}-\mathbf{r}_j)$, where the jth scatterer is centered at $\mathbf{r}_j$, A_j is an unknown amplitude, and G is the free-space Green's function; in two dimensions $G(\mathbf{r}) = H_0(kr)$, where $r = |\mathbf{r}|$ and $H_0 \equiv H_0^{(1)}$ is a Hankel function. Foldy represents the total field as

$$u(\mathbf{r}) = u_{\mathrm{inc}}(\mathbf{r}) + \sum_j A_j G(\mathbf{r}-\mathbf{r}_j), \tag{2.1}$$

where the sum is over all the scatterers. The so-called external field is

$$u_n(\mathbf{r}) \equiv u(\mathbf{r}) - A_n G(\mathbf{r}-\mathbf{r}_n) = u_{\rm inc}(\mathbf{r}) + \sum_{\substack{j \\ j\neq n}} A_j G(\mathbf{r}-\mathbf{r}_j), \tag{2.2}$$

which can be regarded as the "incident field" for the nth scatterer.

Now, characterize the scattering properties of the scatterers by

$$A_n = f_n u_n(\mathbf{r}_n), \tag{2.3}$$

where f_n is "the scattering coefficient for the nth scatterer." Thus, the scattered field is determined by the value of the external field at the center of the scatterer, $\mathbf{r}_n$, together with the quantity f_n (which we will come back to later). Then, (2.2) gives

$$u_n(\mathbf{r}) = u_{\rm inc}(\mathbf{r}) + \sum_{\substack{j \\ j\neq n}} f_j u_j(\mathbf{r}_j) G(\mathbf{r}-\mathbf{r}_j).$$

Evaluating this equation at $\mathbf{r}_n$ gives, after using (2.3),

$$f_n^{-1} A_n = u_{\rm inc}(\mathbf{r}_n) + \sum_{\substack{j \\ j\neq n}} A_j G(\mathbf{r}_n-\mathbf{r}_j), \tag{2.4}$$

which is a linear system of algebraic equations for the amplitudes A_j. The total field is then given by (2.1). When the scatterers are identical $f_n = f_0$, say. This quantity depends on the geometry of the scatterers and is discussed next.

The parameter f_0. The problem of scattering by a small sound-soft cylinder is a problem of low-frequency asymptotics. Using the general theory of Kleinman and Vainberg [14], we find that

$$u_{\rm sc}(\mathbf{r}) \approx f_0 u_{\rm inc}(\mathbf{0}) H_0(kr), \tag{2.5}$$

where the origin is inside the cylinder's cross section S and

$$-\frac{1}{f_0} = \frac{2{\rm i}}{\pi}(\ln k\ell - \delta). \tag{2.6}$$

The complex constant δ occurs in the asymptotic approximation

$$H_0(w) = \frac{2{\rm i}}{\pi}(\ln w - \delta) + O(w^2 \log w) \quad \text{as } w \to 0;$$

thus, $\delta = \ln 2 - C + {\rm i}\pi/2$, where $C \approx 0.5772$ is Euler's constant. The length ℓ in (2.6) depends on the geometry of S. It is determined by solving the following two-dimensional exterior Dirichlet problem for Laplace's equation: $\nabla^2 v = 0$ outside S, $v = 0$ on S, and

$$v = \ln(r/\ell) + o(1) \quad \text{as } r \to \infty.$$

Thus, for an ellipse with semimajor axis a and semiminor axis b, we obtain

$$\ell = \frac{1}{2}(a+b).$$

In particular, for circles of radius a, we have $\ell = a$, and then (2.6) is consistent with $-f_0^{-1} = H_0(ka)$, which is the approximation used by Hills and Karp [12]. Note that our formula for f_0, (2.6), does not depend on the orientation of S.

Let us make a few remarks. First, the approximation (2.5) is a rigorous, asymptotic approximation, valid for small sound-soft cylinders of any cross section. It is not merely a far-field result, but is valid in the near field too. It states that soft cylinders scatter isotropically—the scattered field does not depend on the direction of observation. None of these results is true for sound-hard cylinders (Neumann problem) or for penetrable cylinders (transmission problem), and thus Foldy's original method should be modified for nonsoft cylinders.

3. Infinite grating. We begin with the grating problem and consider the scattering of a plane wave

$$u_{\rm inc} = \mathrm{e}^{\mathrm{i}(\beta x + \alpha y)}, \tag{3.1}$$

where $\alpha = k\sin\psi$ and $\beta = k\cos\psi$, by an infinite row of identical scatterers, located at $(x, y) = (ms, 0)$, $m = 0, \pm1, \pm2, \ldots$, where s is the spacing. We will use polar coordinates (r_m, θ_m) centered on the mth scatterer and defined by

$$x - ms = r_m\cos\theta_m, \qquad y = r_m\sin\theta_m,$$

and we will write (r, θ) for (r_0, θ_0). In terms of (r_m, θ_m) the incident wave is

$$u_{\rm inc} = I_m \mathrm{e}^{\mathrm{i}kr_m\cos(\theta_m - \psi)}, \tag{3.2}$$

where

$$I_m = \mathrm{e}^{\mathrm{i}\beta ms}.$$

For future convenience we define the scattering angles ψ_m, $m = 0, \pm1, \pm2, \ldots$, by

$$\psi_m = \arccos\left(\frac{\beta_m}{k}\right), \qquad \beta_m = \beta + \frac{2m\pi}{s}.$$

If $|\beta_m| < k$, i.e., if

$$-1 < \cos\psi + \frac{2m\pi}{ks} < 1,$$

we say that $m \in \mathcal{M}$ and then $0 < \psi_m < \pi$. These correspond to the angles at which plane waves are scattered from an infinite grating; see (3.9) below. If $|\beta_m| > k$, then ψ_m is no longer real and the appropriate branch of the arccos function is given by

$$\arccos t = \begin{cases} \mathrm{i}\,\mathrm{arccosh}\, t, & t > 1, \\ \pi - \mathrm{i}\,\mathrm{arccosh}(-t), & t < -1, \end{cases} \tag{3.3}$$

with $\mathrm{arccosh}\, t = \ln(t + \sqrt{t^2 - 1})$ for $t > 1$.

Let us apply Foldy's method to the problem of the scattering of a plane wave by an infinite row of identical (small) sound-soft scatterers. The system (2.4) becomes (with B_n as the unknowns)

$$f_0^{-1}B_n = u_{\rm inc}(ns, 0) + \sum_{\substack{m=-\infty \\ m\neq n}}^{\infty} B_m H_0(ks|m-n|), \quad n = 0, \pm1, \pm2, \ldots . \tag{3.4}$$

We have $u_{\rm inc}(ms,0) = \mathrm{e}^{\mathrm{i}\beta sm} = I_m$, and quasi-periodicity (see (3.2)) gives $B_m = I_m B_0$, and then (3.4) gives

$$-f_0^{-1}B_0 + B_0 \sum_{\substack{m=-\infty \\ m\neq n}}^{\infty} H_0(ks|m-n|)I_{m-n} = -1, \quad n = 0, \pm 1, \pm 2, \ldots . \tag{3.5}$$

Hence, $B_0 = (f_0^{-1} - \sigma(\psi))^{-1}$, where

$$\sigma(\psi) = \sum_{\substack{m=-\infty \\ m\neq n}}^{\infty} H_0(ks|m-n|)I_{m-n} = \sum_{j=1}^{\infty}(I_j + I_{-j})H_0(kjs). \tag{3.6}$$

It will be convenient to define a quantity $\mathcal{K}$ by

$$\mathcal{K} = -1/B_0 = \sigma(\psi) - f_0^{-1}, \tag{3.7}$$

so that $B_n = -I_n/\mathcal{K}$.

The far field. From (2.1)

$$u = u_{inc} - \frac{1}{\mathcal{K}} \sum_{m=-\infty}^{\infty} I_m H_0(kr_m).$$

If we insert the integral representation (A.1), we get

$$u = u_{inc} - \frac{1}{\mathcal{K}} \sum_{m=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\beta ms} \int_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)} \mathrm{e}^{\mathrm{i}k(x-ms)t}\, \mathrm{d}t.$$

Now use the Poisson summation formula (B.1) to get

$$u = u_{inc} - 2 \sum_{m=-\infty}^{\infty} \frac{\mathrm{e}^{\mathrm{i}kr\cos(\theta - \mathrm{sgn}(y)\psi_m)}}{ks\mathcal{K}\sin\psi_m}, \tag{3.8}$$

where we have used $\gamma(\beta_m/k) = -\mathrm{i}\sin\psi_m$. Note that $-\mathrm{i}\psi_m$ is real and positive if $|\beta_m/k| > 1$, and so the terms in the sum for these values of m decay as $|y| \to \infty$. The far field involves only those m for which $m \in \mathcal{M}$ and thus, as $y \to \pm\infty$,

$$u \sim u_{inc} - 2 \sum_{m\in\mathcal{M}} \frac{\mathrm{e}^{\mathrm{i}kr\cos(\theta \mp \psi_m)}}{ks\mathcal{K}\sin\psi_m}. \tag{3.9}$$

The scattered field, which is symmetric about the x-axis, thus consists of a number of plane waves, that number increasing as ks increases. In $y > 0$, these waves make angles ψ_m with the positive x-axis. For sufficiently small ks there is just one plane wave corresponding to $m = 0$.

Resonance. For large j we have

$$(I_j + I_{-j})H_0(kjs) \sim (\mathrm{e}^{\mathrm{i}j\beta s} + \mathrm{e}^{-\mathrm{i}j\beta s})\sqrt{\frac{2}{\pi jks}}\mathrm{e}^{\mathrm{i}(kjs - \frac{1}{4}\pi)},$$

and so the sum in (3.6) fails to converge if $(k \pm \beta)s = 2n\pi$ for some integer n. This condition corresponds to $\beta_n = \pm k$ for some integer n, which implies that $\psi_n = 0$ or

$\psi_n = \pi$. An alternative expression for $\sigma(\psi)$ is given in (C.1), which shows that as ψ_n approaches 0 or π,

$$\mathcal{K} \sim \sigma(\psi) \sim 2(ks \sin \psi_n)^{-1}.$$

Such a situation is termed resonance, and all the coefficients B_m tend to zero in this limit. The field is not zero, though. Indeed, from (3.8) we have

$$u = u_{\rm inc} - \mathrm{e}^{\mathrm{i}kx \cos \psi_n}$$

in this limit, so that the scattered field reduces to a wave propagating along the grating, either towards $x = \infty$ ($\psi_n = 0$) or towards $x = -\infty$ ($\psi_n = \pi$). For simplicity, we will exclude the possibility that ks is an integer multiple of π so that we cannot satisfy $\cos \psi_n = -1$ and $\cos \psi_m = 1$ simultaneously.

4. Semi-infinite grating. Suppose now that we have a semi-infinite grating of scatterers located along the positive x-axis at $(x, y) = (ms, 0)$, $m = 0, 1, 2, \ldots$. Again, as the scatterers are identical, we have $f_m \equiv f_0$. Then, the scattered field is given from (2.1) by

$$u_{\rm sc} = \sum_{n=0}^{\infty} A_n H_0(kr_n), \tag{4.1}$$

where the coefficients A_n are found to satisfy

$$A_n - f_0 \sum_{\substack{m=0 \\ m \neq n}}^{\infty} A_m H_0(ks|m-n|) = f_0 I_n, \quad n = 0, 1, 2, \ldots , \tag{4.2}$$

which is equivalent to [12, (3.1-1)] (apart from a missing A_n) and [20, (41)]. If we write $A_n = I_n B_0 + C_n$, where $B_0 = -\mathcal{K}^{-1}$ is the solution to the corresponding infinite grating problem, then we find that, for $n = 0, 1, 2, \ldots$,

$$C_n - f_0 \sum_{\substack{m=0 \\ m \neq n}}^{\infty} C_m H_0(ks|m-n|) = \frac{f_0}{\mathcal{K}} \sum_{j=n+1}^{\infty} I_{n-j} H_0(kjs). \tag{4.3}$$

Both (4.2) and (4.3) can be written in terms of Toeplitz matrices, which can be inverted either directly using numerical truncation or via the discrete Wiener–Hopf technique as described in Appendix E. Note that in order to compute the slowly convergent sum on the right-hand side of (4.3) we use (C.2).

For large n, the sum over j on the right-hand side of (4.3) satisfies

$$\sum_{j=n+1}^{\infty} I_{n-j} H_0(kjs) \sim -\sqrt{\frac{2}{\pi kns}}\, \frac{\mathrm{e}^{-\frac{1}{4}\mathrm{i}\pi} \mathrm{e}^{\mathrm{i}ksn}}{[1 - (-1)^q \mathrm{e}^{-\mathrm{i}(k-\beta)s/2}]},$$

where we have used the asymptotic form for the Hankel function with large argument and (D.1), and q is such that $2q\pi < (k - \beta)s < 2(q + 1)\pi$ (i.e., $\beta_q < k < \beta_{q+1}$). One might expect, therefore, that $C_n = O(n^{-1/2})$ as $n \to \infty$. In fact, calculations show that $C_n = O(n^{-3/2})$ as $n \to \infty$. The same decay rate is observed in [22] and is consistent with behavior in the equivalent half-plane problem. The reason for this faster-than-expected decay is the presence of the phase $\exp(\mathrm{i}ksn)$ in the large n behavior of the right-hand side; see (E.8), (E.10), and (E.12).

The far field. The approximation $C_m = 0$ leads to what is known as the Kirchhoff solution. In this case, (4.1) becomes, after the substitution of the integral representation for the Hankel function given by (A.1) and use of (B.2),

$$u_{\rm sc}^{\rm K} = \frac{\mathrm{i}}{\pi\mathcal{K}} \int\!\!\!\!\!\!-_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)} \frac{\mathrm{e}^{\mathrm{i}kxt}}{1-\mathrm{e}^{\mathrm{i}s(\beta-kt)}}\,\mathrm{d}t.$$

The total field is given by

$$u_{\rm sc} = u_{\rm sc}^{\rm K} - \frac{\mathrm{i}}{\pi}\int_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)} \mathrm{e}^{\mathrm{i}kxt} \sum_{n=0}^{\infty} C_n \mathrm{e}^{-\mathrm{i}knst}\,\mathrm{d}t.$$

From (F.1), for $-\pi < \theta < \pi$,

(4.4)
$$u_{\rm sc}^{\rm K}(r,\theta) \sim \frac{\mathrm{e}^{\mathrm{i}(kr-\frac{1}{4}\pi)}}{\mathcal{K}(\mathrm{e}^{\mathrm{i}ks(\cos\psi-\cos\theta)}-1)}\sqrt{\frac{2}{\pi kr}} - \sum_{\substack{m\in\mathcal{M}\\ \psi_m>|\theta|}} \frac{2\mathrm{e}^{\mathrm{i}kr\cos(|\theta|-\psi_m)}}{ks\mathcal{K}\sin\psi_m} \quad \text{as } kr\to\infty,$$

with the addition of the correction term $\tilde{I}$ given by (F.2) when $|\theta|$ is close to ψ_p, and

$$u_{\rm sc} \sim u_{\rm sc}^{\rm K} + \sqrt{\frac{2}{\pi kr}}\mathrm{e}^{\mathrm{i}(kr-\frac{1}{4}\pi)} \sum_{n=0}^{\infty} C_n \mathrm{e}^{-\mathrm{i}kns\cos\theta}. \tag{4.5}$$

Just as in the infinite grating problem, the scattered field is symmetric about the x-axis. To simplify the discussion of the far field we will assume that $y > 0$ (i.e., $0 < \theta < \pi$). If we define

$$\tilde{H}(kr) = \sqrt{\frac{2}{\pi kr}}\mathrm{e}^{\mathrm{i}(kr-\frac{1}{4}\pi)}$$

and

$$g(\theta,\psi) = \frac{1}{\mathcal{K}(\mathrm{e}^{\mathrm{i}ks(\cos\psi-\cos\theta)}-1)} + \sum_{n=0}^{\infty} C_n \mathrm{e}^{-\mathrm{i}kns\cos\theta}, \tag{4.6}$$

then we have

$$u_{\rm sc} \sim g(\theta,\psi)\tilde{H}(kr) - \sum_{\substack{m\in\mathcal{M}\\ \psi_m>\theta}} \frac{2\mathrm{e}^{\mathrm{i}kr\cos(\theta-\psi_m)}}{ks\mathcal{K}\sin\psi_m}. \tag{4.7}$$

The far field thus consists of a circular wave of "amplitude" $g(\theta,\psi)$ and a set of plane waves. These plane waves propagate in the same directions as for the infinite grating but do not exist everywhere. The plane wave making an angle ψ_m with the positive x-axis is found only in the sector $\theta < \psi_m$. It is apparent that the coefficients C_n affect only the circular wave, but that the plane wave field is determined solely by the Kirchhoff solution. In the numerical results presented below we will thus focus only on the circular wave.

The lines $\theta = \psi_m$ are known as shadow boundaries, and the circular wave becomes infinite as the shadow boundaries are approached. In fact near these lines we should add a term to $g(\theta,\psi)$ given from (F.2) by

$$\tilde{g}(r,\theta,\psi) = \frac{\mathrm{i}(1+2\mathrm{i}\zeta_p\mathrm{e}^{-\mathrm{i}\zeta_p^2}F(\zeta_p))}{2ks\mathcal{K}\sin\frac{1}{2}(\theta-\psi_p)\sin\psi_p},$$

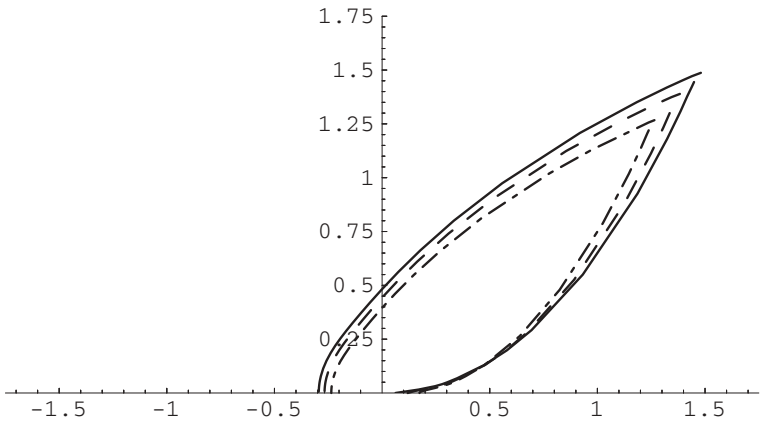

FIG. 4.1. *The amplitude of the circular wave, $|g(\theta,\psi)+\tilde{g}(r,\theta,\psi)|$, for three different scatterers when $ka=0.05$, $ks=2$, $kr=20$, and $\psi=\pi/4$. The solid line corresponds to an array of circles of radius a, the dashed line corresponds to ellipses with $a/b=2$, and the dash-dot line corresponds to plates of length $2a$.*

where $\zeta_p = \sqrt{2kr}\sin\frac{1}{2}|\theta-\psi_p|$ and F is the Fresnel integral defined in (F.3). The combination $g+\tilde{g}$ is bounded as $\theta\to\psi_p$ for any r, but the limit is different from each side. Since $F(0)=\frac{1}{2}\sqrt{\pi}\exp(\mathrm{i}\pi/4)$, the discontinuity in $g+\tilde{g}$ as θ passes through ψ_p exactly cancels the extra residue contribution that appears in the sum in (4.7) as the shadow boundary is crossed.

Hills and Karp [12] introduced the characteristic angles $\psi_m(0)$. These are the real scattering angles when the incident wave angle is zero, i.e.,

$$\psi_m(0)=\arccos\left(1+\frac{2m\pi}{ks}\right),\quad m=-[ks/\pi],\ldots,-1,0.$$

It follows from (4.6) and (E.13) that in the full solution the circular wave vanishes in these directions, i.e., $g(\psi_m(0),\psi)=0$. Hills and Karp state this result only for large ks, but it is true for any value of ks, provided that the Wiener–Hopf factorization described in Appendix E exists. Calculations in [22] suggest that this result is true for moderate values of ks (about 3.5) but perhaps not for small ks (about 0.7). Our calculations based on (4.3) indicate that $g(0,\psi)=0$ for all ks. (For $ks<\pi$ there is only one characteristic angle, namely, $\theta=0$.)

In Figures 4.1–4.3 we show as polar plots the amplitude of the circular wave, $|g(\theta,\psi)+\tilde{g}(r,\theta,\psi)|$, for three different scatterers when $ka=0.05$, $\psi=\pi/4$, and $kr=20$. In Figure 4.1, $ks=2$ and the scatterers are fairly close together, whereas in Figure 4.3, $ks=10$ and the scatterers are well separated. Figure 4.2 represents an intermediate case with $ks=5$. In each case the three different (discontinuous) curves correspond to an array of circles of radius a (solid lines), ellipses with semimajor axis a and semiminor axis $\frac{1}{2}a$ (dashed lines), and plates of length $2a$ (dash-dot lines). The quantity f_0 is calculated from (2.6) in each case with $\ell=a$, $\frac{3}{4}a$, and $\frac{1}{2}a$, respectively.

It can be seen that the general form of each of the curves is the same but that circles produce the diffracted wave with the largest amplitude, while the plates produce the smallest effect. The scales on the three figures are not the same, and it is clear that the amplitude of the diffracted wave generally diminishes as ks increases (though not necessarily for a given observation angle). The numerical results were obtained by direct truncation of (4.3) and checked against (E.10). In order to represent the zeros

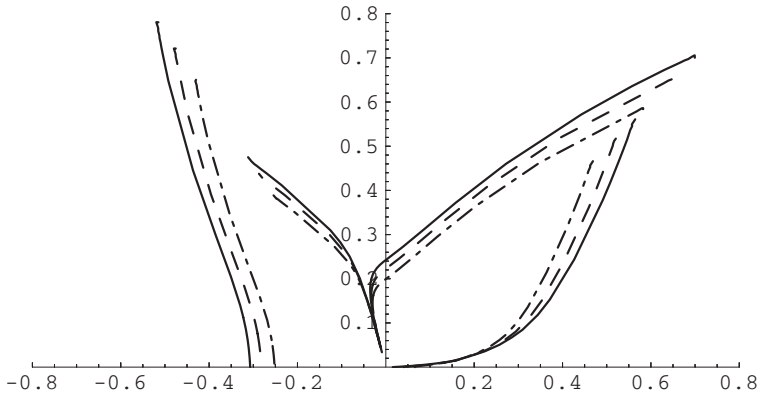

FIG. 4.2. *The amplitude of the circular wave, $|g(\theta,\psi)+\tilde{g}(r,\theta,\psi)|$, for three different scatterers when $ka = 0.05$, $ks = 5$, $kr = 20$, and $\psi = \pi/4$. The solid line corresponds to an array of circles of radius a, the dashed line corresponds to ellipses with $a/b = 2$, and the dash-dot line corresponds to plates of length $2a$.*

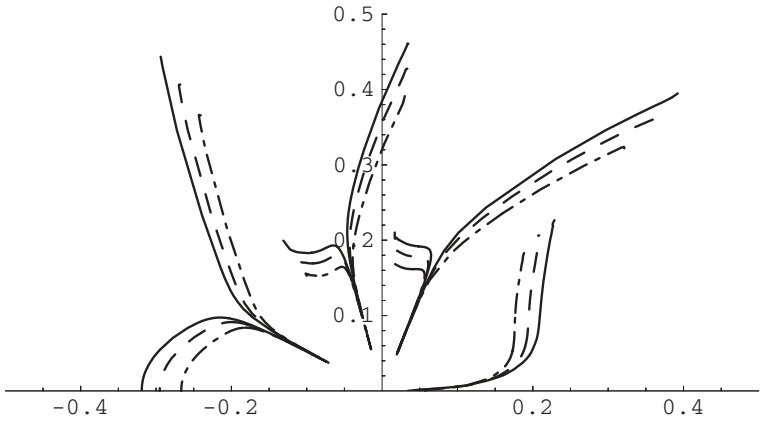

FIG. 4.3. *The amplitude of the circular wave, $|g(\theta,\psi)+\tilde{g}(r,\theta,\psi)|$, for three different scatterers when $ka = 0.05$, $ks = 10$, $kr = 20$, and $\psi = \pi/4$. The solid line corresponds to an array of circles of radius a, the dashed line corresponds to ellipses with $a/b = 2$, and the dash-dot line corresponds to plates of length $2a$.*

in the directions $\psi_m(0)$ with reasonable accuracy, a 200×200 system of equations was used, though the main features of the solution are accurately represented if a much smaller truncation is used.

In Figure 4.1 there is just one predominant scattering direction corresponding to the direction of the incident wave, and the amplitude of the wave is zero for $\theta = \psi_0(0) = 0$. In Figure 4.2 there are two predominant scattering directions corresponding to $\psi_0 = \pi/4$ and $\psi_{-1} = \arccos(1/\sqrt{2} - 2\pi/5) \approx 0.685\pi$. The amplitude of the wave is zero in the directions $\psi_0(0) = 0$ and $\psi_{-1}(0) = \arccos(1 - 2\pi/5) \approx 0.583\pi$. In Figure 4.3 there are three predominant scattering directions corresponding to $\psi_0 = \pi/4$, $\psi_{-1} = \arccos(1/\sqrt{2} - \pi/5) \approx 0.475\pi$, and $\psi_{-2} = \arccos(1/\sqrt{2} - 2\pi/5) \approx 0.685\pi$. The amplitude of the wave is zero in the directions $\psi_0(0) = 0$, $\psi_{-1}(0) = \arccos(1 - \pi/5) \approx 0.379\pi$, $\psi_{-2}(0) = \arccos(1 - 2\pi/5) \approx 0.583\pi$, and $\psi_{-3}(0) = \arccos(1 - 3\pi/5) \approx 0.846\pi$.

Inward and outward resonance. For fixed n the sum on the right-hand side of (4.3) converges unless $(k-\beta)s = 2m\pi$ for some integer m (in other words, unless $\psi_m = 0$ for some integer m). Following Hills and Karp [12], we call this *inward resonance*. We also use the term *outward resonance* for the case when $\psi_m = \pi$ for some integer m. In either situation $1/\mathcal{K} = 0$. Provided we do not have inward resonance, $C_n \to 0$ as $n \to \infty$.

For outward resonance, we get simply $C_n = 0$ and

$$u_{\rm sc} = u_{\rm sc}^{\rm K} = -\frac{1}{\mathcal{K}} \sum_{m=0}^{\infty} I_m H_0(kr_m) = \frac{\mathrm{i}}{\pi\mathcal{K}} \int\!\!\!\!\!\!\diagup_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)} \frac{\mathrm{e}^{\mathrm{i}kxt}}{1-\mathrm{e}^{\mathrm{i}s(\beta-kt)}}\,\mathrm{d}t.$$

As $\psi_n \to \pi$ we have $\mathcal{K} \sim 2/(ks\sin\psi_n)$, and in order to find the singular behavior of the integral in this limit (which corresponds to one of the poles of the integrand coinciding with the branch point of γ at $t=-1$; the branch cut extending to $-\mathrm{i}\infty$) we deform the contour so that it passes above the pole at β_n/k and thus pick up a contribution $2\pi\mathrm{i}\mathrm{e}^{-\mathrm{i}kx}/(ks\sin\psi_n)$, the remaining integral being finite. Thus, for outward resonance, we obtain

$$u_{\rm sc} = -\mathrm{e}^{-\mathrm{i}kx}$$

in agreement with [12, (3.6-1)].

In the inward resonance case $\psi_n \to 0$, the same arguments show that the Kirchhoff solution $u_{\rm sc}^{\rm K}$ approaches $-\mathrm{e}^{\mathrm{i}kx}$, but the region of existence shrinks to the line $\theta = 0$, and this no longer represents the total scattered field; see [11]. We have not considered the case where inward and outward resonance occur together (which can only happen if ks is an integer multiple of π). Some results for this case can be found in [20].

5. Semi-infinite strip grating. Here we will demonstrate that the analysis given in [22, 23] for a semi-infinite strip grating can be reduced to the general form given in section 4. Consider first an infinite set of strips $S_n = (ns-a, ns+a)$, $n = 0, \pm1, \pm2, \ldots$ $(s > 2a)$, on which we have $u = 0$ and write $S = \bigcup_{n=-\infty}^{\infty} S_n$. We wish to solve the Helmholtz equation in $y > 0$ with

$$\begin{aligned} \frac{\partial u_{\rm sc}}{\partial y} &= 0 \qquad \text{on } y = 0,\ x \notin S, \\ u_{\rm sc} &= -\mathrm{e}^{\mathrm{i}\beta x} \quad \text{on } y = 0,\ x \in S. \end{aligned}$$

Define $v_{\rm sc}(x) \equiv \partial u_{\rm sc}/\partial y|_{y=0}$. Then we have the integral equation

$$\int_S v_{\rm sc}(\xi) G(x-\xi, 0)\,\mathrm{d}\xi = -\mathrm{e}^{\mathrm{i}\beta x}, \quad x \in S,$$

where $G(X,Y) = -\frac{1}{2}\mathrm{i}H_0(k\sqrt{X^2+Y^2})$ is the free-space Green's function. Equivalently, since $v_{\rm sc}(\xi + ms) = I_m v_{\rm sc}(\xi)$,

$$\sum_{m=-\infty}^{\infty} I_m \int_{-a}^{a} v_{\rm sc}(\xi) G(x-\xi-ms, 0)\,\mathrm{d}\xi = -\mathrm{e}^{\mathrm{i}\beta x}, \quad |x| < a,$$

which can be written

$$\int_{-a}^{a} v_{\rm sc}(\xi) G_\beta(x-\xi, 0)\,\mathrm{d}\xi = -\mathrm{e}^{\mathrm{i}\beta x}, \quad |x| < a, \tag{5.1}$$

where we have defined

$$G_\beta(X,Y)=\sum_{m=-\infty}^{\infty} I_m G(X-ms,Y)=-\frac{\mathrm{i}}{ks}\sum_{m=-\infty}^{\infty}\frac{\mathrm{e}^{\mathrm{i}k|Y|\sin\psi_m}\mathrm{e}^{\mathrm{i}\beta_m X}}{\sin\psi_m}$$

using (B.1). The scattered field is then represented by

$$u_{\mathrm{sc}}(x,y)=\int_S v_{\mathrm{sc}}(\xi)G(x-\xi,y)\,\mathrm{d}\xi=\int_{-a}^{a} v_{\mathrm{sc}}(\xi)G_\beta(x-\xi,y)\,\mathrm{d}\xi.$$

Now consider a semi-infinite set of strips $S_n=(ns-a,ns+a)$, $n=0,1,2,\ldots$ $(s>2a)$, and write $S^+=\bigcup_{n=-\infty}^{\infty}S_n$. We have

$$\int_{S^+} v_{\mathrm{sc}}^+(\xi)G(x-\xi,0)\,\mathrm{d}\xi=-\mathrm{e}^{\mathrm{i}\beta x},\quad x\in S^+,$$

and

$$u_{\mathrm{sc}}^+(x,y)=\int_{S^+} v_{\mathrm{sc}}^+(\xi)G(x-\xi,y)\,\mathrm{d}\xi. \tag{5.2}$$

Write $u_{\mathrm{sc}}^+=\phi+u_{\mathrm{sc}}$ and $\nu(x)\equiv\partial\phi/\partial y|_{y=0}$. Then the integral equation becomes

$$\sum_{m=0}^{\infty}\int_{-a}^{a}\nu(\xi+ms)G(x-\xi-ms,0)\,\mathrm{d}\xi+\int_{-a}^{a}v_{\mathrm{sc}}(\xi)G_\beta^+(x-\xi,0)\,\mathrm{d}\xi=-\mathrm{e}^{\mathrm{i}\beta x},\quad x\in S^+, \tag{5.3}$$

where we have defined

$$G_\beta^+(X,Y)=\sum_{m=0}^{\infty}I_m G(X-ms,Y)=-\frac{1}{2\pi}\int\!\!\!\!\!\!\diagup_{-\infty}^{\infty}\frac{\mathrm{e}^{-k\gamma(t)|Y|}}{\gamma(t)}\frac{\mathrm{e}^{\mathrm{i}kXt}}{1-\mathrm{e}^{\mathrm{i}s(\beta-kt)}}\,\mathrm{d}t, \tag{5.4}$$

using (B.2). Equation (5.3) is the starting point for the numerical calculations given in [22, 23]. Alternatively, using (5.1),

$$\sum_{m=0}^{\infty}\int_{-a}^{a}\nu(\xi+ms)G(x-\xi-ms,0)\,\mathrm{d}\xi=\int_{-a}^{a}v_{\mathrm{sc}}(\xi)G_\beta^-(x-\xi,0)\,\mathrm{d}\xi,\quad x\in S^+, \tag{5.5}$$

where $G_\beta^-=G_\beta-G_\beta^+$.

Under the assumption that $ka\ll 1$, we make the approximations (as in [22, 23])

$$v_{\mathrm{sc}}(x)=\frac{2\mathrm{i}B}{\pi\sqrt{a^2-x^2}},\qquad \nu(x+ms)=\frac{2\mathrm{i}C_m}{\pi\sqrt{a^2-x^2}},\quad m=0,1,2,\ldots,$$

with $|x|<a$ in all cases. To determine B we average (5.1) so that

$$\frac{2\mathrm{i}B}{\pi}\int_{-a}^{a}\int_{-a}^{a}\frac{G_\beta(x-\xi,0)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x=-\int_{-a}^{a}\mathrm{e}^{\mathrm{i}\beta x}\,\mathrm{d}x=-\frac{2}{\beta}\sin\beta a\approx -2a$$

or

$$B=-\left(\sum_{m=-\infty}^{\infty}I_m\mathcal{G}_m\right)^{-1}, \tag{5.6}$$

where we have defined

$$\mathcal{G}_n = \frac{\mathrm{i}}{\pi a}\int_{-a}^{a}\int_{-a}^{a}\frac{G(x-\xi-ns,0)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x, \tag{5.7}$$

for which approximate values, valid for $ka \ll 1$, can be derived; see (G.1) and (G.2).

To determine C_m we average (5.5) so that for each $n = 0, 1, 2, \ldots$

$$\sum_{m=0}^{\infty} C_m \int_{ns-a}^{ns+a}\int_{-a}^{a}\frac{G(x-\xi-ms,0)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x = B\int_{ns-a}^{ns+a}\int_{-a}^{a}\frac{G_\beta^-(x-\xi,0)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x$$

or

$$\sum_{m=0}^{\infty} C_m\mathcal{G}_{m-n} = B\sum_{m=-\infty}^{-1} I_m\mathcal{G}_{m-n},$$

which, once B is determined from (5.6), is an infinite system of algebraic equations for the unknowns.

If we substitute the approximate values for $\mathcal{G}_n$ ($n > 0$) from (G.2), we get $B = -1/(\mathcal{G}_0 + \sigma(\psi))$, and then

$$C_n + \frac{1}{\mathcal{G}_0}\sum_{\substack{m=0\\ \neq n}}^{\infty} C_m H_0(k|n-m|s) = -\frac{1/\mathcal{G}_0}{\mathcal{G}_0+\sigma(\psi)}\sum_{j=n+1}^{\infty} I_{n-j}H_0(kjs), \tag{5.8}$$

which is of exactly the same form as (4.3), since $\mathcal{G}_0 = -1/f_0$ (compare (G.1) and (2.6) with $\ell = a/2$).

The field is then given, from (5.2), by

$$\begin{aligned} u_{\mathrm{sc}}^+(x,y) &= \int_{S^+}(\nu(\xi)+v_{\mathrm{sc}}(\xi))G(x-\xi,y)\,\mathrm{d}\xi \\ &= \frac{2\mathrm{i}}{\pi}\sum_{m=0}^{\infty} C_m\int_{-a}^{a}\frac{G(x-\xi-ms,y)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi + \frac{2\mathrm{i}B}{\pi}\int_{-a}^{a}\frac{G_\beta^+(x-\xi,y)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi. \end{aligned}$$

The last integral is, using (5.4),

$$-\frac{1}{2\pi}\fint_{-\infty}^{\infty}\int_{-a}^{a}\frac{\mathrm{e}^{-\mathrm{i}k\xi t}\,\mathrm{d}\xi}{\sqrt{a^2-\xi^2}}\frac{\mathrm{e}^{\mathrm{i}kxt-k\gamma(t)|y|}}{\gamma(t)(1-\mathrm{e}^{\mathrm{i}s(\beta-kt)})}\,\mathrm{d}t = -\frac{1}{2}\fint_{-\infty}^{\infty}\frac{J_0(kat)\mathrm{e}^{\mathrm{i}kxt-k\gamma(t)|y|}}{\gamma(t)(1-\mathrm{e}^{\mathrm{i}s(\beta-kt)})}\,\mathrm{d}t$$

and similarly for the first integral so that

$$\begin{aligned} u_{\mathrm{sc}}^+(x,y) = &-\frac{\mathrm{i}}{\pi}\sum_{m=0}^{\infty} C_m\int_{-\infty}^{\infty}\frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)}J_0(kat)\mathrm{e}^{\mathrm{i}k(x-ms)t}\,\mathrm{d}t \\ &-\frac{\mathrm{i}B}{\pi}\fint_{-\infty}^{\infty}\frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)}\frac{J_0(kat)\mathrm{e}^{\mathrm{i}kxt}}{1-\mathrm{e}^{\mathrm{i}s(\beta-kt)}}\,\mathrm{d}t, \end{aligned}$$

which, via the results in Appendix F and utilizing the fact that $ka \ll 1$, leads to precisely the same far-field asymptotics as that given in (4.5).

Note that exactly the same far-field is generated for a semi-infinite array of angled plates, since f_0 is independent of the plate orientation. Indeed, the plates in the array may all be oriented in different directions.

6. Conclusion. Using a mixture of analysis (discrete Wiener–Hopf) and computation, we have studied the problem of acoustic scattering by a semi-infinite periodic array of identical isotropic point scatterers, i.e., scatterers which are small compared to the incident wavelength and on which Dirichlet boundary conditions are applied. The actual geometry is characterized by a single parameter in the equations, related to the single-body scattering problem. Numerical results have been presented which show the effect of the shape of the scatterer on the form of the circular wave diffracted by the end of the array.

Computations for semi-infinite arrays under less restrictive assumptions than that of isotropic point scatterers do not appear to be available in the literature, and we are currently extending the techniques developed in this paper to study problems in which the size of the individual scatterers is not necessarily small, and to include boundary conditions other than those of Dirichlet type.

Appendix A. Integral representations for Hankel functions. We start from the integral representation, valid for $0 < \theta < \pi$ (i.e., $y > 0$),

$$H_0(kr) = -\frac{\mathrm{i}}{\pi}\int_{-\infty}^{\infty+\mathrm{i}\pi} \mathrm{e}^{\mathrm{i}kx\cosh\alpha}\mathrm{e}^{ky\sinh\alpha}\,\mathrm{d}\alpha.$$

This integral can be converted into a single integral along the real axis. We first split the integral into three parts, namely $(-\infty, 0)$, $(0, \mathrm{i}\pi)$, and $(\mathrm{i}\pi, \infty + \mathrm{i}\pi)$, and make the substitutions $\alpha = -\operatorname{arccosh} t$, $\alpha = \mathrm{i}\arccos t$, and $\alpha = \mathrm{i}\pi + \operatorname{arccosh}(-t)$, respectively. This leads, noting that $H_0(kr)$ is symmetric in y, to

$$H_0(kr) = -\frac{\mathrm{i}}{\pi}\int_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)}\mathrm{e}^{\mathrm{i}kxt}\,\mathrm{d}t, \tag{A.1}$$

valid for all y, where

$$\gamma(t) = \begin{cases} -\mathrm{i}\sqrt{1-t^2}, & |t| \le 1, \\ \sqrt{t^2-1}, & |t| > 1. \end{cases} \tag{A.2}$$

Appendix B. Summation formulas. We can define two generalized functions by

$$\sum_{m=1}^{\infty}\cos mu = -\frac{1}{2} + \pi\sum_{m=-\infty}^{\infty}\delta(u-2m\pi), \qquad \sum_{m=1}^{\infty}\sin mu = \frac{1}{2}\cot\frac{1}{2}u$$

(see [9, section 2.4] for more details), from which we can construct the generalized functions

$$\sum_{m=-\infty}^{\infty}\mathrm{e}^{\pm\mathrm{i}mu} = 2\pi\sum_{m=-\infty}^{\infty}\delta(u-2m\pi)$$

and

$$\sum_{m=0}^{\infty}\mathrm{e}^{\pm\mathrm{i}mu} = \frac{1}{1-\mathrm{e}^{\pm\mathrm{i}u}} + \pi\sum_{m=-\infty}^{\infty}\delta(u-2m\pi).$$

Hence

$$\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty} f(u)\mathrm{e}^{-\mathrm{i}mu}\,\mathrm{d}u = 2\pi\sum_{m=-\infty}^{\infty} f(2m\pi), \tag{B.1}$$

which is the Poisson summation formula, and

$$\sum_{m=0}^{\infty}\int_{-\infty}^{\infty} f(u)\mathrm{e}^{-\mathrm{i}mu}\,\mathrm{d}u = \int\!\!\!\!\!\!-_{-\infty}^{\infty}\frac{f(u)}{1-\mathrm{e}^{-\mathrm{i}u}}\,\mathrm{d}u + \pi\sum_{m=-\infty}^{\infty} f(2m\pi) = \int\!\!\!\!\!\!-_{-\infty}^{\infty}\frac{f(u)}{1-\mathrm{e}^{-\mathrm{i}u}}\,\mathrm{d}u, \tag{B.2}$$

where the notation means that the contour passes below the poles of the integrand.

Appendix C. Schlömilch series. The quantity $\sigma(\psi)$ is defined by (3.6). An alternative representation is

$$\sigma(\psi) = -1 - \frac{2\mathrm{i}}{\pi}\left(C + \ln\frac{ks}{4\pi}\right) + \frac{2}{ks\sin\psi_0} + \sum_{\substack{m=-\infty\\ m\neq 0}}^{\infty}\left(\frac{2}{ks\sin\psi_m} + \frac{\mathrm{i}}{\pi|m|}\right), \tag{C.1}$$

where $C \approx 0{\cdot}5772$ is Euler's constant. The efficient computation of this series is discussed in [16].

Another important series is

$$S = \sum_{m=1}^{\infty}\mathrm{e}^{-\mathrm{i}m\beta s}H_0(kms).$$

To derive an alternative representation more convenient for computation we write

$$\begin{aligned} 2S - \sigma &= \sum_{m=1}^{\infty}(\mathrm{e}^{-\mathrm{i}m\beta s} - \mathrm{e}^{\mathrm{i}m\beta s})H_0(kms)\\ &= \sum_{m=-\infty}^{\infty}(\mathrm{e}^{-\mathrm{i}|m|\beta s} - \mathrm{e}^{-\mathrm{i}m\beta s})H_0(k|m|s) = \sum_{m=-\infty}^{\infty} f(2m\pi), \end{aligned}$$

where

$$f(u) = (\mathrm{e}^{-\mathrm{i}|u|\beta s/2\pi} - \mathrm{e}^{-\mathrm{i}u\beta s/2\pi})H_0(k|u|s/2\pi).$$

The Poisson summation formula (B.1) then gives

$$\begin{aligned} 2S - \sigma &= \frac{1}{2\pi}\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty}(\mathrm{e}^{-\mathrm{i}|u|\beta s/2\pi} - \mathrm{e}^{-\mathrm{i}u\beta s/2\pi})H_0(k|u|s/2\pi)\mathrm{e}^{-\mathrm{i}mu}\,\mathrm{d}u\\ &= \frac{1}{s}\sum_{m=-\infty}^{\infty}\int_{-\infty}^{\infty}(\mathrm{e}^{-\mathrm{i}|v|\beta} - \mathrm{e}^{-\mathrm{i}v\beta})H_0(k|v|)\mathrm{e}^{-\mathrm{i}m2\pi v/s}\,\mathrm{d}v\\ &= \frac{1}{s}\sum_{m=-\infty}^{\infty}\int_{0}^{\infty}(\mathrm{e}^{-\mathrm{i}v\beta_{-m}} - \mathrm{e}^{\mathrm{i}v\beta_m})H_0(kv)\,\mathrm{d}v\\ &= \frac{4}{\pi ks}\left(\frac{\frac{1}{2}\pi - \psi}{\sin\psi} + \sum_{m=1}^{\infty}\left[\frac{\frac{1}{2}\pi - \psi_m}{\sin\psi_m} + \frac{\frac{1}{2}\pi - \psi_{-m}}{\sin\psi_{-m}}\right]\right), \end{aligned} \tag{C.2}$$

where we have used [10, equations 6.671(7), (11)]. Note that

$$\frac{\frac{1}{2}\pi-\psi_m}{\sin\psi_m}+\frac{\frac{1}{2}\pi-\psi_{-m}}{\sin\psi_{-m}}\sim\frac{\beta ks^2}{4m^2\pi^2}\left(\pi\mathrm{i}-2-2\ln\left(\frac{4m\pi}{ks}\right)\right)+O(m^{-3})\quad\text{as } m\to\infty.$$

As $\psi_p\to 0$ for some integer p,

$$S\sim 2(ks\sin\psi_p)^{-1}, \tag{C.3}$$

but as $\psi_p\to\pi$, S is bounded since the singularity in the sum in (C.2) exactly cancels that in σ.

Appendix D. Asymptotics of a sum. Consider the sum

$$S_p=\sum_{j=p+1}^{\infty}\frac{\mathrm{e}^{\mathrm{i}j\theta}}{j^{1/2}}.$$

Denote by Γ_p the contour which runs from $\mathrm{i}(p+\frac{1}{2})-\infty$ to $\mathrm{i}(p+\frac{1}{2})+\infty$ and is closed in the upper half-plane. Then, provided $0<\theta<2\pi$,

$$\begin{aligned}S_p&=\frac{1}{2\pi\mathrm{i}}\left\{-2\pi\mathrm{i}^{\frac{1}{2}}\int_{\Gamma_p}\frac{\mathrm{e}^{\theta t}\,\mathrm{d}t}{t^{\frac{1}{2}}(1-\mathrm{e}^{2\pi t})}\right\}=-\frac{1}{\mathrm{i}^{\frac{1}{2}}}\int_{\mathrm{i}(p+\frac{1}{2})-\infty}^{\mathrm{i}(p+\frac{1}{2})+\infty}\frac{\mathrm{e}^{\theta t}\,\mathrm{d}t}{t^{\frac{1}{2}}(1-\mathrm{e}^{2\pi t})}\\&=-\frac{\mathrm{e}^{\mathrm{i}\theta(p+\frac{1}{2})}}{\mathrm{i}^{\frac{1}{2}}}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\theta u}\,\mathrm{d}u}{[u+\mathrm{i}(p+\frac{1}{2})]^{\frac{1}{2}}(1+\mathrm{e}^{2\pi u})}\\&\sim\frac{\mathrm{i}\mathrm{e}^{\mathrm{i}\theta(p+\frac{1}{2})}}{p^{\frac{1}{2}}}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\theta u}\,\mathrm{d}u}{1+\mathrm{e}^{2\pi u}}=\frac{\mathrm{i}\mathrm{e}^{\mathrm{i}\theta(p+\frac{1}{2})}}{2p^{\frac{1}{2}}\sin\frac{1}{2}\theta}=\frac{-p^{-\frac{1}{2}}\mathrm{e}^{\mathrm{i}\theta p}}{1-\mathrm{e}^{-\frac{\mathrm{i}\theta}{2}}}\quad\text{as } p\to\infty.\end{aligned}$$

If $2m\pi<\theta<2(m+1)\pi$,

$$\sum_{j=p+1}^{\infty}\frac{\mathrm{e}^{\mathrm{i}j\theta}}{j^{\frac{1}{2}}}=\sum_{j=p+1}^{\infty}\frac{\mathrm{e}^{\mathrm{i}j(\theta-2m\pi)}}{j^{\frac{1}{2}}}\sim\frac{-p^{-\frac{1}{2}}\mathrm{e}^{\mathrm{i}\theta p}}{1-(-1)^m\mathrm{e}^{-\frac{\mathrm{i}\theta}{2}}}\quad\text{as } p\to\infty. \tag{D.1}$$

Appendix E. Inversion of symmetric Toeplitz matrices. Each of (4.2), (4.3), and (5.8) is of the form

$$\sum_{m=0}^{\infty}T_{nm}X_m=R_n,\quad n=0,1,2,\dots, \tag{E.1}$$

i.e., $\mathbf{T}X=R$, where $\mathbf{T}$ is a Toeplitz matrix whose elements are given by $T_{nm}=T_{mn}=t_{n-m}$ with

$$t_m=\begin{cases}1, & m=0,\\ -f_0H_0(k|m|s), & \text{otherwise.}\end{cases}$$

The matrix $\mathbf{T}$ can be inverted using the discrete Wiener–Hopf technique; the symmetry of $\mathbf{T}$ is not required for this approach but it simplifies the analysis. Here we follow the method as described in [27]. No fully rigorous theory appears to exist which includes the particular matrix $\mathbf{T}$ that occurs in our problem. If the elements of the matrix satisfied $\sum|t_m|<\infty$, or the function $\sum t_m\exp(\mathrm{i}m\theta)<\infty$ for all $\theta\in(-\pi,\pi)$,

then we could appeal to the general theory given in [4], [15, section 13]. It is assumed throughout this appendix that we are dealing with a nonresonant case.

First we rewrite (E.1) as

$$\sum_{m=-\infty}^{\infty} t_{n-m} X_m^+ = R_n^+ + R_n^-, \quad n = 0, \pm 1, \pm 2, \dots ,$$

where X_n^+ and R_n^+ are equal to X_n and R_n, respectively, when $n \geq 0$, and are zero if $n < 0$ and $R_n^- = 0$ for $n \geq 0$, but are otherwise unknown. If we multiply the nth equation by z^n and then sum over n, we get, after writing $n = m + \nu$ on the left-hand side,

$$\sum_{\nu=-\infty}^{\infty} \sum_{m=-\infty}^{\infty} t_\nu X_m^+ z^{m+\nu} = \sum_{n=-\infty}^{\infty} R_n^+ z^n + \sum_{n=-\infty}^{\infty} R_n^- z^n,$$

which can be written

$$K(z) X_+(z) = R_+(z) + R_-(z), \tag{E.2}$$

where $X_+(z) = \sum_{n=-\infty}^{\infty} X_n^+ z^n = \sum_{n=0}^{\infty} X_n z^n$, $R_+(z) = \sum_{n=0}^{\infty} R_n z^n$, $R_-(z) = \sum_{n=-\infty}^{-1} R_n^- z^n$, and

$$K(z) = \sum_{\nu=-\infty}^{\infty} t_\nu z^\nu = 1 - f_0 \sum_{\substack{\nu=-\infty \\ \nu \neq 0}}^{\infty} H_0(ks|\nu|) z^\nu.$$

Note that

$$K(\mathrm{e}^{\pm \mathrm{i} ks \cos\theta}) = 1 - f_0 \sigma(\theta), \tag{E.3}$$

where $\sigma(\theta)$ is given by either (3.6) or (C.1), and, in particular, $K(\mathrm{e}^{\pm \mathrm{i}\beta s}) = -f_0 \mathcal{K}$, where $\mathcal{K}$ is defined by (3.7). Here $X_+(z)$ is analytic in some disk centered on the origin, and it is reasonable to assume that the radius of convergence is greater than or equal to one. Similar remarks pertain to $R_+(z)$. On the other hand, we can assume that $R_-(z)$ is analytic in the region exterior to the unit disk. One device that can be used in scattering problems is to let the wavenumber k have a small positive imaginary part, which is equivalent to allowing for a small amount of dissipation in the acoustic medium. This will ensure that the plus functions are analytic for $|z| < \rho_2$ and the minus functions are analytic for $|z| > \rho_1$, with $\rho_1 < 1 < \rho_2$. The solution is then obtained by letting the imaginary part of k tend to zero at the end of the calculation. This also takes care of the fact that in our case $K(z)$ actually has singularities on the unit circle, namely inverse square-root branch points at $z = \exp(\pm \mathrm{i} ks)$.

The solution method is based on a factorization $K(z) = K_+(z) K_-(z)$, where $K_+(z)$ (resp., $K_-(z)$) is analytic and nonzero inside (resp., outside) and on $|z| = 1$. Given such a factorization we have $\ln K(z) = \ln K_+(z) + \ln K_-(z) = q_+(z) + q_-(z)$, say, where $q_+(z)$ (resp., $q_-(z)$) is analytic inside (resp., outside) and on $|z| = 1$. From Cauchy's integral formula, writing $q = q_+ + q_-$,

$$q_-(z) = q_-(\infty) - \frac{1}{2\pi \mathrm{i}} \oint_{|\zeta|=1} \frac{q(\zeta)}{\zeta - z} \, \mathrm{d}\zeta, \quad |z| > 1.$$

Here we must assume that it is possible to choose a single-valued branch of $\ln K(z)$ in some neighborhood of the unit circle. Note that $K(z) = K(1/z)$, so we can normalize the factorization by requiring that $K_+(z) = K_-(1/z)$, in which case $q_+(z) = q_-(1/z)$. It follows that

$$q_+(z) = q_+(0) - \frac{1}{2\pi \mathrm{i}} \oint_{|\zeta|=1} \frac{zq(\zeta)}{z\zeta - 1}\,\mathrm{d}\zeta, \quad |z| < 1.$$

The required factorization of $K(z)$ (which is unique) is thus given by

$$\begin{aligned} K_+(z) &= \frac{1}{\lambda_0} \exp\left(\frac{1}{2\pi \mathrm{i}} \oint_{|\zeta|=1} \frac{z \ln K(\zeta)}{1 - z\zeta}\,\mathrm{d}\zeta\right), \quad |z| < 1, \\ K_-(z) &= \frac{1}{\lambda_0} \exp\left(\frac{1}{2\pi \mathrm{i}} \oint_{|\zeta|=1} \frac{\ln K(\zeta)}{z - \zeta}\,\mathrm{d}\zeta\right), \quad |z| > 1, \end{aligned} \tag{E.4}$$

where $\lambda_0 = \mathrm{e}^{-q_+(0)}$. However, from Cauchy's integral formula

$$q_+(0) = \frac{1}{2\pi \mathrm{i}} \oint_{|z|=1} \frac{q_+(z)}{z}\,\mathrm{d}z = \frac{1}{4\pi \mathrm{i}} \oint_{|z|=1} \frac{q_+(z) + q_-(z)}{z}\,\mathrm{d}z,$$

and thus we have

$$\lambda_0 = \exp\left(-\frac{1}{4\pi \mathrm{i}} \oint_{|z|=1} \frac{\ln K(z)}{z}\,\mathrm{d}z\right).$$

With this factorization we can rearrange (E.2) as follows:

$$K_+ X_+ - \left(\frac{R_+}{K_-}\right)_+ = \left(\frac{R_+}{K_-}\right)_- + \frac{R_-}{K_-}, \tag{E.5}$$

in which we have further separated the function $R_+(z)/K_-(z)$ into the sum of a function analytic inside $|z| = 1$ and one analytic outside this circle. Liouville's theorem then implies that both sides must equal a constant. The sum-split of R_+/K_- is performed so that $(R_+/K_-)_-$ tends to zero as $z \to \infty$. We also have $R_-/K_- \to 0$ since $K_-(z)$ tends to a nonzero constant in this limit, and so both sides of (E.5) must in fact be zero.

We have thus established that $X_+ = (R_+/K_-)_+/K_+$ and hence that

$$X_m^+ = \frac{1}{2\pi \mathrm{i}} \oint_{|z|=1} \frac{(R_+/K_-)_+(z)}{K_+(z)} z^{-m-1}\,\mathrm{d}z.$$

Now $(R_+/K_-)_+(z) = \sum_{n=0}^{\infty} R_n (z^n/K_-)_+(z)$ and

$$\left(\frac{z^n}{K_-}\right)_+(z) = \sum_{j=0}^{\infty} a_j^{(n)} z^j \quad \text{with } a_j^{(n)} = \frac{1}{2\pi \mathrm{i}} \oint_{|z|=1} \frac{z^{n-j-1}}{K_-(z)}\,\mathrm{d}z,$$

the final integral being zero if $j > n$, since then the integrand is regular and nonzero for $|z| > 1$ and decays at infinity faster than $1/z$. Thus we have

$$X_m^+ = \frac{1}{2\pi \mathrm{i}} \sum_{n=0}^{\infty} R_n \oint_{|z|=1} \sum_{j=0}^{n} a_j^{(n)} \frac{z^{j-m-1}}{K_+(z)}\,\mathrm{d}z. \tag{E.6}$$

Now if we define $\lambda_\mu = a_{n-\mu}^{(n)}$ (with $\lambda_\mu = 0$ if $\mu < 0$), then

$$\lambda_\mu = \frac{1}{2\pi \mathrm{i}} \oint_{|z|=1} \frac{z^{\mu-1}}{K_-(z)}\,\mathrm{d}z,$$

and so λ_μ, $\mu = 0, 1, 2, \ldots$, are the coefficients in the Laurent series for $1/K_-(z)$, i.e., $[K_-(z)]^{-1} = \sum_{\mu=0}^{\infty} \lambda_\mu z^{-\mu}$, from which

$$\frac{1}{K_+(z)} = \frac{1}{K_-(1/z)} = \sum_{\mu=0}^{\infty} \lambda_\mu z^\mu. \tag{E.7}$$

Note that $\lambda_0 = 1/K_+(0)$, in agreement with (E.4). The coefficients λ_μ can be calculated without knowledge of the functions $K_\pm$ since

$$\lambda_\mu = \frac{1}{\mu!}\frac{\mathrm{d}^\mu}{\mathrm{d}z^\mu}\left[\frac{1}{K_+(z)}\right]_{z=0},$$

and the right-hand side can be evaluated from (E.4) in terms of the weakly singular integrals

$$\int_{-\pi}^{\pi} \mathrm{e}^{-\mathrm{i}m\theta} \ln[K(\mathrm{e}^{\mathrm{i}\theta})]\,\mathrm{d}\theta, \quad m = 0, 1, \ldots .$$

In order to compute K on the unit circle we use (E.3) and (C.1).

The presence of square-root singularities in $K(z)$ at $z = \exp(\pm \mathrm{i}ks)$ implies, after letting the imaginary part of k tend to zero, a singularity in $K_+(z)$ at $z = \exp(-\mathrm{i}ks)$, i.e.,

$$[K_+(\mathrm{e}^{-\mathrm{i}ks})]^{-1} = \sum_{\mu=0}^{\infty} \lambda_\mu \mathrm{e}^{-\mathrm{i}\mu ks} = 0. \tag{E.8}$$

The function $[K_+(z)]^{-1}$ is smooth everywhere on the unit circle except at the point $z = \exp(-\mathrm{i}ks)$, where its derivative has a square-root singularity. We thus expect (see [25, p. 441]) that

$$\lambda_\mu = O(\mu^{-3/2}) \quad \text{as } \mu \to \infty.$$

If (E.7) is substituted into (E.6), we get

$$X_m^+ = \frac{1}{2\pi \mathrm{i}} \sum_{n=0}^{\infty} R_n \oint_{|z|=1} \sum_{j=0}^{n} \lambda_{n-j} z^{j-m-1} \sum_{\mu=0}^{\infty} \lambda_\mu z^\mu \,\mathrm{d}z = \sum_{n=0}^{\infty} R_n \sum_{j=0}^{\min(n,m)} \lambda_{n-j}\lambda_{m-j}. \tag{E.9}$$

We have thus shown that the elements of the (symmetric) inverse matrix $\mathbf{T}^{-1}$ (written T_{mn}^{-1}, $m \geq 0$, $n \geq 0$) are given by

$$T_{mn}^{-1} = \sum_{j=0}^{\min(m,n)} \lambda_{n-j}\lambda_{m-j}.$$

The final expression in (E.9) can be rearranged to give

$$X_m = \sum_{p=0}^{\infty} \sum_{q=0}^{m} \lambda_p \lambda_q R_{m+p-q}. \tag{E.10}$$

The method of Hills and Karp [12]. For the particular case of (4.2), we have $R_n = f_0 I_n$ and so

$$R_+(z) = \sum_{n=0}^{\infty} R_n z^n = \frac{f_0}{1 - z\mathrm{e}^{\mathrm{i}\beta s}}.$$

This is the analytic continuation of the series into the entire complex plane except the point $z = \exp(-\mathrm{i}\beta s)$. Note that, assuming k to have a positive imaginary part, the singularity at $z = \exp(-\mathrm{i}\beta s)$ is exterior to the unit circle. With $A_+(z) = \sum_{n=0}^{\infty} A_n z^n$ we then have

$$K(z)A_+(z) = \frac{f_0}{1 - z\mathrm{e}^{\mathrm{i}\beta s}} + R_-(z). \tag{E.11}$$

Equation (E.11) is [12, (3.1-3)]. It is a single equation for two unknown functions, namely $A_+(z)$ and $R_-(z)$.

The split into plus and minus functions can now be carried out more simply than in the general case. We have

$$K_+(z)A_+(z) - \frac{f_0}{K_-(\mathrm{e}^{-\mathrm{i}\beta s})(1 - z\mathrm{e}^{\mathrm{i}\beta s})} = \frac{f_0}{(1 - z\mathrm{e}^{\mathrm{i}\beta s})}\left(\frac{1}{K_-(z)} - \frac{1}{K_-(\mathrm{e}^{-\mathrm{i}\beta s})}\right) + \frac{R_-(z)}{K_-(z)},$$

and Liouville's theorem shows that both sides are zero so that

$$A_+(z) = \frac{f_0}{K_+(z)K_-(\mathrm{e}^{-\mathrm{i}\beta s})(1 - z\mathrm{e}^{\mathrm{i}\beta s})}.$$

It follows that

$$A_m = \frac{f_0 I_m}{K_-(\mathrm{e}^{-\mathrm{i}\beta s})} \sum_{q=0}^{m} \lambda_q I_{-q} = f_0 I_m \sum_{p=0}^{\infty} \lambda_p I_p \sum_{q=0}^{m} \lambda_q I_{-q}$$

in agreement with (E.10).

Now, since $A_n = I_n B_0 + C_n$ and $B_0 = -1/\mathcal{K} = f_0/K(\exp(\pm\mathrm{i}\beta s))$,

$$\sum_{n=0}^{\infty} C_n z^n \equiv C_+(z) = \frac{f_0}{K_-(\mathrm{e}^{-\mathrm{i}\beta s})(1 - z\mathrm{e}^{\mathrm{i}\beta s})}\left(\frac{1}{K_+(z)} - \frac{1}{K_+(\mathrm{e}^{-\mathrm{i}\beta s})}\right).$$

The coefficients C_n decay at the same rate as λ_n, i.e.,

$$C_n = O(n^{-\frac{3}{2}}) \quad \text{as } n \to \infty, \tag{E.12}$$

and for exactly the same reasons. This decay rate for the edge effects was noted in [20, equation 76]. From (E.8), we have

$$C_+(\mathrm{e}^{-\mathrm{i}ks}) = -\frac{f_0}{K(\mathrm{e}^{-\mathrm{i}\beta s})(1 - \mathrm{e}^{\mathrm{i}(\beta - k)s})},$$

or equivalently,

$$\sum_{n=0}^{\infty} C_n \mathrm{e}^{-\mathrm{i}nks} = \frac{1}{\mathcal{K}(1 - \mathrm{e}^{\mathrm{i}ks(\cos\psi - 1)})}. \tag{E.13}$$

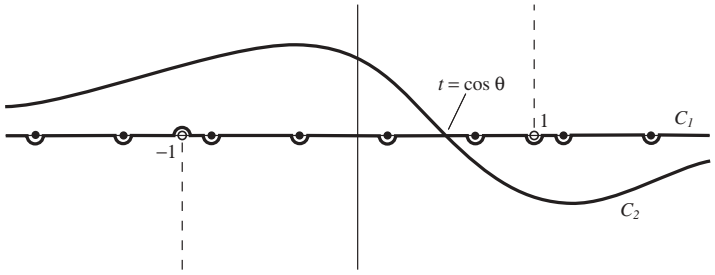

FIG. F.1. *Contours C_1 and C_2. The dashed lines are branch cuts for the function $\gamma(t)$, and the solid circles are zeros of $1 - \mathrm{e}^{\mathrm{i}s(\beta - kt)}$ (i.e., $t = \beta_m/k$).*

Appendix F. Asymptotics of an integral. Consider the integral

$$I(kr) = \int_{-\infty}^{\infty} \frac{\mathrm{e}^{-k\gamma(t)y}\mathrm{e}^{\mathrm{i}kxt} f(t)}{\gamma(t)(1 - \mathrm{e}^{\mathrm{i}s(\beta - kt)})}\,\mathrm{d}t = \int_{C_1} \frac{f(t)\mathrm{e}^{krg(t)}}{\gamma(t)(1 - \mathrm{e}^{\mathrm{i}s(\beta - kt)})}\,\mathrm{d}t,$$

where $y = r\sin\theta > 0$,

$$g(t) = -\gamma(t)\sin\theta + \mathrm{i}t\cos\theta,$$

and C_1 is the contour shown in Figure F.1. Here the branch of $\gamma(t)$ (defined for real t by (A.2)) is indicated by the branch cuts shown in the figure, and f is assumed regular throughout the complex t-plane. We will assume that $|\beta_m/k| \neq 1$ holds for all m so that none of the poles of the integrand coincide with the branch points of γ. The function g has one simple saddle point in the complex t-plane at $t = \cos\theta$ and

$$g(\cos\theta) = \mathrm{i}, \qquad g''(\cos\theta) = -\mathrm{i}/\sin^2\theta.$$

In order to derive the asymptotics of I for large kr we need to deform the contour C_1 into the path of steepest descent. This is the curve on which $\operatorname{Imag} g = 1$, which passes through the saddle point, making an angle $-\pi/4$ with the positive real t-axis. This curve crosses the real axis again at $t = 1/\cos\theta$. In deforming the contour, we pick up contributions from the poles on the real axis over which we pass. Only those poles between -1 and 1 give any contribution in the limit as $kr \to \infty$, the others leading to exponentially small terms. Hence we can deform the contour back down to the real axis to produce C_2 without affecting the asymptotics.

Hence, as $kr \to \infty$,

$$\begin{aligned} I(kr) &\sim \int_{C_2} \frac{f(t)\mathrm{e}^{krg(t)}}{\gamma(t)(1 - \mathrm{e}^{\mathrm{i}s(\beta - kt)})}\,\mathrm{d}t + 2\pi\mathrm{i} \sum_{\substack{m\in\mathcal{M} \\ \beta_m < k\cos\theta}} \frac{f(\beta_m/k)\mathrm{e}^{\mathrm{i}kr\cos(\theta - \psi_m)}}{ks\sin\psi_m} \\ &\sim \frac{f(\cos\theta)\mathrm{e}^{krg(\cos\theta) - \frac{1}{4}\pi\mathrm{i}}}{-\mathrm{i}\sin\theta(1 - \mathrm{e}^{\mathrm{i}s(\beta - k\cos\theta)})}\sqrt{\frac{2\pi}{kr|g''(\cos\theta)|}} \\ &\quad + 2\pi\mathrm{i} \sum_{\substack{m\in\mathcal{M} \\ \cos\psi_m < \cos\theta}} \frac{f(\beta_m/k)\mathrm{e}^{\mathrm{i}kr\cos(\theta - \psi_m)}}{ks\sin\psi_m} \\ &= \frac{\mathrm{i}f(\cos\theta)\mathrm{e}^{\mathrm{i}(kr - \frac{1}{4}\pi)}}{1 - \mathrm{e}^{\mathrm{i}ks(\cos\psi - \cos\theta)}}\sqrt{\frac{2\pi}{kr}} + 2\pi\mathrm{i} \sum_{\substack{m\in\mathcal{M} \\ \psi_m > \theta}} \frac{f(\beta_m/k)\mathrm{e}^{\mathrm{i}kr\cos(\theta - \psi_m)}}{ks\sin\psi_m}, \end{aligned} \tag{F.1}$$

where we have used $\gamma(\cos\theta) = -\mathrm{i}\sin\theta$ and the asymptotics of the integral along the steepest descent contour are given, for example, by [7, equation 4.2.1b]. To obtain the asymptotics valid for $y < 0$ we simply replace θ by $-\theta$ in (F.1). It is implicit in the above that the saddle point of g does not coincide with any of the zeros of $1 - \mathrm{e}^{\mathrm{i}s(\beta-kt)}$. In other words, we have assumed that $|\theta| \neq \psi_m$ for any integer m.

Uniform asymptotics valid as $\psi_p \to |\theta|$ can be obtained; see [7, section 4.4], for example. A lengthy calculation shows that we must add a term

$$\tilde{I} = \frac{\sqrt{\pi}\mathrm{e}^{\mathrm{i}(kr-\frac{1}{4}\pi)}}{ks\zeta_p \sin\psi_p} \operatorname{sgn}(|\theta| - \psi_p) f(\beta_p/k) \left(1 + 2\mathrm{i}\zeta_p \mathrm{e}^{-\mathrm{i}\zeta_p^2} F(\zeta_p)\right) \tag{F.2}$$

to the right-hand side of (F.1). Here $\zeta_p = \sqrt{2kr}\sin(\frac{1}{2}||\theta| - \psi_p|)$, and

$$F(v) = \int_v^\infty \mathrm{e}^{\mathrm{i}u^2}\,\mathrm{d}u \quad \left(0 < \arg u < \frac{1}{2}\pi \text{ as } u \to \infty\right) \tag{F.3}$$

is a Fresnel integral. Since (see [3, p. 67])

$$F(v) \sim \frac{\mathrm{i}}{2v}\mathrm{e}^{\mathrm{i}v^2}\left(1 + \sum_{n=1}^{\infty} \frac{(2n-1)!!}{(2\mathrm{i}v^2)^n}\right) \quad \text{as } v \to \infty, \quad -\frac{1}{2}\pi < \arg v < \pi,$$

we have

$$\tilde{I} \sim -\frac{\sqrt{\pi}\mathrm{e}^{\mathrm{i}(kr-\frac{1}{4}\pi)}}{2\mathrm{i}ks\zeta_p^3 \sin\psi_p} \operatorname{sgn}(|\theta| - \psi_p) f(\beta_p/k) \quad \text{as } \zeta_p \to \infty.$$

Appendix G. The quantities $\mathcal{G}_n$. From (5.7), we have

$$\mathcal{G}_n = \frac{1}{2\pi a}\int_{-a}^{a}\int_{-a}^{a} \frac{H_0(k|x - \xi - ns|)}{\sqrt{a^2 - \xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x.$$

For $n = 0$, with $ka \ll 1$, we can approximate this by

$$\begin{aligned}\mathcal{G}_0 &\approx \frac{1}{2\pi^2 a}\int_{-a}^{a}\int_{-a}^{a} \frac{\pi + 2\mathrm{i}(C + \ln\frac{1}{2}k|x-\xi|)}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x \\ &= 1 + \frac{2\mathrm{i}C}{\pi} + \frac{\mathrm{i}}{\pi^2 a}\int_{-a}^{a}\int_{-a}^{a} \frac{\ln\frac{1}{2}k|x-\xi|}{\sqrt{a^2-\xi^2}}\,\mathrm{d}\xi\,\mathrm{d}x = 1 + \frac{2\mathrm{i}}{\pi}\left(C + \ln\frac{1}{4}ka\right).\end{aligned} \tag{G.1}$$

In [22] the $O((ka)^2)$ terms in $\mathcal{G}_0$ are also evaluated, but this seems to be inconsistent with the level of approximation being used. For $n \neq 0$ we use Neumann's addition theorem [1, equation 9.1.75], which shows that

$$H_0(k|n|s \pm k(x-\xi)) = \sum_{m=-\infty}^{\infty} H_{\pm m}(k|n|s) J_m(k(x-\xi)) \approx H_0(k|n|s)$$

since $ka \ll 1$. Hence

$$\mathcal{G}_n \approx H_0(k|n|s). \tag{G.2}$$

SELECTIVE ACOUSTIC FOCUSING USING TIME-HARMONIC REVERSAL MIRRORS*

CHRISTOPHE HAZARD† AND KARIM RAMDANI‡

Abstract. A mathematical study of the focusing properties of acoustic fields obtained by a time-reversal process is presented. The case of time-harmonic waves propagating in a nondissipative medium containing sound-soft obstacles is considered. In this context, the so-called D.O.R.T. method (decomposition of the time-reversal operator in French) was recently proposed to achieve selective focusing by computing the eigenelements of the *time-reversal operator*. The present paper describes a justification of this technique in the framework of the far field model, i.e., for an ideal time-reversal mirror able to reverse the far field of a scattered wave. Both cases of closed and open mirrors, that is, surrounding completely or partially the scatterers, are dealt with. Selective focusing properties are established by an asymptotic analysis for small and distant obstacles.

Key words. acoustic scattering, time-reversal, far field operator, small obstacles

DOI. 10.1137/S0036139903428732

1. Introduction.

Acoustic time-reversal has known in the last few years a significant growth of interest, covering a large number of applications (medical imaging, nondestructive testing, etc.). The main idea of this phenomenon is to take advantage of the reversibility of the wave equation in a nondissipative unknown medium to backpropagate signals to the sources that emitted them. Today, the physical literature (cf. [9] for more details) on this topic is quite rich. Meanwhile, some mathematical works started to deal with different aspects of time-reversal phenomena: see, for instance, [2, 4] for time-reversal in the time domain, [14] for time-reversal in the frequency domain, and [15] for time-reversal in random media.

In this work, we present a mathematical analysis of the so-called D.O.R.T. method (decomposition of the time-reversal operator in French), detailed in [16] to achieve selective focusing on diffracting obstacles using time-reversal mirrors (TRM) which are able to emit and receive acoustic waves. In the frequency domain, this method can be described as follows: the TRM first emits an acoustic wave in a homogeneous and nondissipative medium containing some unknown obstacles, and then measures the diffracted field. The measured field is then conjugated (reversing time amounts to a conjugation when the time dependence is of the form $e^{i\omega t}$), and re-emitted. The time-reversal operator T is the operator obtained by iterating this procedure twice. The experimental results obtained in [16] show that the number of nonzero (or significant) eigenvalues of T is exactly the number of obstacles contained in the propagation medium. Furthermore, the corresponding eigenvectors generate incident waves that focus selectively on the obstacles. Our aim here is to present a mathematical justification of these results related to selective focusing using TRMs; we will show that these results are not true in general, but do hold for small and distant obstacles with distinct reflectivities.

Let us point out that the inverse problem which consists of recovering the location of the obstacles from the scattering data is not dealt with in this paper. We are mainly concerned with qualitative properties of the eigenvectors of the time-reversal operator. The eigenvectors corresponding to significant eigenvalues span some kind of *relevant subspace* in the sense that they contain nearly all the information about the obstacles which can be extracted from the time-reversal operator. The others span the so-called *noise subspace*, which represents some kind of quasi-null space. This point of view meets the basics of the so-called MUSIC algorithm used in signal processing and imaging, and its generalization, the linear sampling method (LSM), used in inverse scattering (for a short presentation of these methods, see, for instance, [3], and for more details, cf. [12]). These methods answer the inverse problem by using a convenient characterization of the relevant subspace. In the context of scattering, the link between the scattering data and the unknown locations of the obstacles is made by means of point sources: if the radiated field produced by a given point source has a nonzero component in the relevant subspace, the point belongs to one scatterer, otherwise it is outside. But as mentioned in [3], both MUSIC and LSM use the noise subspace: the question of recovering the geometric information directly from the relevant subspace remains open.

The paper is organized as follows. We first deal with a TRM which entirely surrounds the obstacles. In section 2, we describe the mathematical model used to analyze time-reversal phenomena in the framework of time harmonic waves in the far field model, i.e., for an ideal TRM able to reverse the asymptotic behavior at large distance of a scattered wave. This will in particular lead us to express the time-reversal operator by means of the far field operator, well known in scattering theory. Section 3 recalls some results obtained in [14], concerning the global focusing properties of the eigenvectors of the time-reversal operator. The main result of the paper, which concerns selective focusing, is given in section 4. It provides a mathematical justification of the D.O.R.T. method for the problem of scattering by several small and distant obstacles. In section 5, we generalize the results obtained in the previous sections to the case of open mirrors (i.e., mirrors which do not completely surround the scatterers). The main ingredient for the proof of our main result is formula (4.2), which provides the asymptotic behavior of the scattering amplitude for the diffraction by many small obstacles. This formula, which is of independent interest, is proved in the appendix.

2. Mathematical setting of the problem and definition of the time-reversal operator. Consider a TRM completely surrounding a collection of sound-soft obstacles, located in a homogeneous medium of celerity c. During the emission step, the TRM illuminates the obstacles with an incident wave u_I which is supposed to be a Herglotz wave. Such waves are superpositions of planes waves $u_I^\alpha(x) = \exp(ik\alpha\cdot x)$ of direction $\alpha \in S^2$ (S^2 denotes the unit sphere in $\mathbb{R}^3$, $k = \omega/c$ is the wavenumber, and ω is the frequency). More precisely, given a directional distribution $f \in L^2(S^2)$, we suppose that the incident field emitted by the TRM has the form

$$u_I(x) = \int_{S^2} f(\alpha)\, u_I^\alpha(x)\, d\alpha = \int_{S^2} f(\alpha)\, e^{ik\alpha\cdot x}\, d\alpha. \tag{2.1}$$

We assume that the TRM is located far enough from the obstacles, so that its influence on the diffracted field can be neglected. Moreover, the TRM is supposed to measure the far field corresponding to the diffracted field.

Let Ω denote the propagation domain located outside the obstacles and let ν be the outgoing normal to Ω on its boundary $\Gamma = \partial\Omega$. When illuminated by the incident plane wave $u_I^\alpha(x) = e^{ik\alpha\cdot x}$ of direction $\alpha \in S^2$, the obstacles generate the diffracted field u_D^α that solves the classical Dirichlet exterior problem:

$$\left\{\begin{array}{rcll} \Delta u_D^\alpha + k^2 u_D^\alpha &=& 0, & (\Omega)\\ u_D^\alpha &=& -u_I^\alpha, & (\Gamma)\\ \lim\limits_{R\longrightarrow+\infty}\displaystyle\int_{S_R}\left|\frac{\partial u_D^\alpha}{\partial\nu} - iku_D^\alpha\right|^2 dx &=& 0, & \end{array}\right.$$

where S_R is the sphere $\{x \in \mathbb{R}^3;\ \|x\| = R\}$ and where $\partial u_D^\alpha/\partial\nu$ denotes the radial derivative of u_D^α on S_R.

It is well known (cf. [7]) that the far field asymptotics of the diffracted field in a given direction $\beta \in S^2$ is given by the formula

$$u_D^\alpha(\beta\|x\|) = \frac{e^{ik\|x\|}}{\|x\|}A(\alpha,\beta) + O(\|x\|^{-2}),$$

where the bound $O(\|x\|^{-2})$ is uniform for all $\beta \in S^2$, and where $A(\alpha,\beta)$ is known as the *scattering amplitude*. This function satisfies some remarkable properties (cf. [7]), which are summarized in the following.

PROPOSITION 2.1. *The scattering amplitude $A(\cdot,\cdot)$ is given by the formula*

$$A(\alpha,\beta) = \frac{1}{4\pi}\int_\Gamma \frac{\partial u_T^\alpha}{\partial\nu}(y)\,\overline{u_I^\beta(y)}\,d\Gamma_y, \tag{2.2}$$

where $u_T^\alpha = u_I^\alpha + u_D^\alpha$ denotes the total field associated with the incident field u_I^α. Furthermore, $A(\cdot,\cdot)$ defines an analytic function on $S^2\times S^2$ and satisfies the reciprocity relation

$$A(\alpha,\beta) = A(-\beta,-\alpha). \tag{2.3}$$

Remark 1. This reciprocity relation simply states that the behavior of the diffracted field observed in the direction β when the scatterers are illuminated by a plane wave of direction α, is identical to its behavior in the direction $-\alpha$ under an incident plane wave with direction $-\beta$. This property is a direct consequence of the symmetry of the Green function of the diffraction problem (which follows itself from the self-adjointness of the Dirichlet Laplacian).

Note that in (2.2), the integral actually represents the duality product between $H^{1/2}(\Gamma)$ and $H^{-1/2}(\Gamma)$ since $\partial u_T^\alpha/\partial\nu$ belongs to the latter in general. We keep this simplified notation in what follows.

By linearity, it follows from the results above that when illuminated by the Herglotz wave (2.1) associated with a given directional distribution $f \in L^2(S^2)$, the scattering obstacles generate the diffracted field u_D

$$u_D(x) = \int_{S^2} f(\alpha)\,u_D^\alpha(x)\,d\alpha.$$

Furthermore, the asymptotic behavior of u_D is given by the formula

$$u_D(\beta\|x\|) = \frac{e^{ik\|x\|}}{\|x\|}Ff(\beta) + O(\|x\|^{-2}),$$

where the far field $Ff(\beta)$ in the direction $\beta \in S^2$ is simply given by the relation

$$Ff(\beta) = \int_{S^2} A(\alpha, \beta)\, f(\alpha)\, d\alpha. \tag{2.4}$$

The integral operator $F : L^2(S^2) \longrightarrow L^2(S^2)$ with kernel $A(\cdot, \cdot)$ is known in the literature as the *far field operator*. Its properties are given in the following.

PROPOSITION 2.2. *The far field operator $F : L^2(S^2) \longrightarrow L^2(S^2)$ defined by equation* (2.4) *is a compact and normal operator. Its adjoint is the operator $F^* : L^2(S^2) \longrightarrow L^2(S^2)$ defined by*

$$F^* f = \overline{RF\overline{Rf}} \quad \forall f \in L^2(S^2), \tag{2.5}$$

where R is the symmetry operator defined by $Rf(\alpha) = f(-\alpha)\ \forall \alpha \in S^2$.

Proof. The compactness of the integral operator F follows immediately from the analyticity of its kernel $A(\cdot, \cdot)$. The fact that F is a normal operator is a well-known result, which is proved, for instance, in [5] (see Corollary 2.5). The adjoint F^* of F is the integral operator with kernel

$$A^*(\alpha, \beta) = \overline{A(\beta, \alpha)} = \overline{A(-\alpha, -\beta)},$$

where we have used the reciprocity relation (2.3). Formula (2.5) follows. □

Remark 2. In fact, in [5], it is proved more precisely that

$$FF^* = F^*F = \frac{2\pi}{ik}(F - F^*). \tag{2.6}$$

Since the far field operator F is related to the scattering matrix by the relation $S = I + (ik/2\pi)F$, formula (2.6) can be seen as an equivalent formulation of the fact that the scattering operator S is unitary, which is a classical result in scattering theory (cf. [13]).

We are now able to give a rigorous definition of the time-reversal operator. During the time-reversal process, when a Herglotz wave associated with a density $f \in L^2(S^2)$ is emitted by the TRM, the far field corresponding to the diffracted field is measured, conjugated, and then re-emitted by the TRM. The new emission is characterized by the Herglotz wave associated with the density $g \in L^2(S^2)$ defined by

$$g = \overline{RFf}.$$

In this relation, the presence of the symmetry operator R is due to the fact that during the time-reversal process, the far field measured in a given direction $\beta \in S^2$ is used to define the new incident plane wave in the direction $-\beta$. The time-reversal operator T is then obtained by iterating this scheme once again, and thus, we have

$$Tf = \overline{RFg} = \overline{RF\overline{RFf}}.$$

Thanks to (2.5) and using the fact that F is a normal operator, we finally get the following.

PROPOSITION 2.3. *The time-reversal operator $T : L^2(S^2) \longrightarrow L^2(S^2)$ is given by*

$$T = F^*F = FF^*. \tag{2.7}$$

It is the integral operator with kernel

$$t(\alpha,\beta) = \frac{1}{4\pi}\int_{\Gamma\times\Gamma} j_0(k\|y-z\|)\,\frac{\partial u_T^\alpha}{\partial\nu}(y)\,\overline{\frac{\partial u_T^\beta}{\partial\nu}(z)}\;d\Gamma_y\,d\Gamma_z, \tag{2.8}$$

where $u_T^\alpha = u_I^\alpha + u_D^\alpha$ *denotes the total field associated with the incident field* u_I^α*, and* $j_0(\xi) = \sin(\xi)/\xi$ *is the spherical Bessel function of order* 0.

Proof. Since (2.7) has been already proved, we only have to show the second part of the proposition. From (2.7), it follows that T is the integral operator with kernel

$$t(\alpha,\beta) = \int_{S^2} A(\alpha,\gamma)\,\overline{A(\beta,\gamma)}\,d\gamma. \tag{2.9}$$

Substituting expression (2.2) of the scattering amplitude in the above relations and inverting the integrals over S^2 with the integrals over Γ, we find that

$$t(\alpha,\beta) = \frac{1}{(4\pi)^2}\int_{\Gamma\times\Gamma}\left(\int_{S^2}\overline{u_I^\gamma(y)}\,u_I^\gamma(z)\,d\gamma\right)\frac{\partial u_T^\alpha}{\partial\nu}(y)\,\overline{\frac{\partial u_T^\beta}{\partial\nu}(z)}\;d\Gamma_y\,d\Gamma_z.$$

Equation (2.8) follows then from the identity (cf. [1, p. 155])

$$\int_{S^2}\overline{u_I^\gamma(y)}\,u_I^\gamma(z)\,d\gamma = \int_{S^2} e^{ik\gamma\cdot(z-y)}\,d\gamma = 4\pi j_0(k\|y-z\|). \tag{2.10}$$

□

3. Global focusing. The time-reversal operator $T = F^*F : L^2(S^2) \longrightarrow L^2(S^2)$ is clearly a positive and self-adjoint operator. Moreover, by Proposition 2.2, it is also a compact operator. Besides the value 0, its spectrum is thus constituted of a finite or countable sequence of positive eigenvalues admitting 0 as the only possible accumulation point. In this section, we see how these eigenvectors can be used to generate incident waves that focus acoustic on the diffracting obstacles. These global focusing results (namely Propositions 3.2 and 3.3) actually are a reformulation of results obtained in [14]. First, we recall a classical result from linear operators theory (see, for instance, [20, p. 442]).

PROPOSITION 3.1. *Let* N *be a compact and normal on a Hilbert space* H*. If* $\lambda_1, \lambda_2, \dots$ *is the sequence of all nonzero eigenvalues of* N*, arranged such that* $|\lambda_1| \geq |\lambda_2| \geq \cdots$*, and if* $\varphi_1, \varphi_2, \dots$ *is a corresponding orthonormal sequence of eigenvectors, then* $|\lambda_1|^2 \geq |\lambda_2|^2 \geq \cdots$ *is the sequence of all nonzero eigenvalues of* $N^*N = NN^*$*, and* $\varphi_1, \varphi_2, \dots$ *is a corresponding orthonormal sequence of eigenvectors.*

This proposition shows that the nonzero eigenvalues of the time reversal operator $T = F^*F = FF^*$ are exactly the positive numbers $|\lambda_1|^2 \geq |\lambda_2|^2 \geq \cdots$, where the complex numbers $(\lambda_p)_{p\geq 1}$ denote the nonzero eigenvalues of the normal compact far field operator F. Furthermore, the corresponding eigenvectors $(f_p)_{p\geq 1}$ of F are exactly the eigenvectors of $T = F^*F$. Consequently, it suffices to analyze the focusing properties of the eigenvectors of the far field F to obtain the same results for the time reversal operator T.

Let us first deal with the largest eigenvalue of the far field operator. Then, we have the following.

PROPOSITION 3.2. *Let* λ_1 *be the largest eigenvalue (in modulus) of* F*, and let* $f_1 \in L^2(S^2)$ *be an eigenvector of* F *associated with* λ_1*. Then,*

$$\sup_{f\in L^2(S^2)\,,\,f\neq 0}\frac{\|Ff\|^2_{L^2(S^2)}}{\|f\|^2_{L^2(S^2)}} = \frac{\|Ff_1\|^2_{L^2(S^2)}}{\|f_1\|^2_{L^2(S^2)}} = |\lambda_1|^2.$$

In other words, the incident Herglotz wave $u_I^1(x) = \int_{S^2} f_1(\alpha)\, e^{ik\alpha\cdot x}\, d\alpha$ *is, among all the possible Herglotz waves, the one that maximizes the energy scattered by the obstacles.*

Proof. The proposition is a straightforward consequence of the Min-Max principle. Indeed, applying this principle to the positive self-adjoint and bounded operator $T = F^*F$, we can write that the largest eigenvalue $|\lambda_1|^2$ of T satisfies

$$|\lambda_1|^2 = \sup_{f\in L^2(S^2)\,,\, f\neq 0} \frac{(Tf,f)_{L^2(S^2)}}{\|f\|^2_{L^2(S^2)}} = \sup_{f\in L^2(S^2)\,,\, f\neq 0} \frac{\|Ff\|^2_{L^2(S^2)}}{\|f\|^2_{L^2(S^2)}}. \qquad \square$$

Roughly speaking, this result says that the "best" way to illuminate a family of obstacles with Herglotz waves is to use a Herglotz wave u_I^1 corresponding to an eigenvector f_1 of F (or T) associated with its largest eigenvalue λ_1. The physical reason explaining this property is that the incident field generated by an eigenvector f_p associated with any eigenvalue $\lambda_p \neq 0$ of F, focuses on the obstacles. More precisely, the following result holds true (see [14]).

PROPOSITION 3.3. *Let* $\lambda_p \neq 0$ *be an eigenvalue of* F *and* $f_p \in L^2(S^2)$, $f_p \neq 0$, *an eigenvector of* F *associated with* λ_p. *Then, the Herglotz wave* $u_{I,p}$ *associated with* f_p *and defined by* $u_{I,p}(x) = \int_{S^2} f_p(\alpha)\, u_I^\alpha(x)\, d\alpha = \int_{S^2} f_p(\alpha)\, e^{ik\alpha\cdot x}\, d\alpha$, *has the following form:*

$$u_{I,p}(x) = \frac{1}{\lambda_p} \int_\Gamma j_0(k\|x-y\|)\, \frac{\partial u_{T,p}}{\partial \nu}(y)\, d\Gamma_y, \tag{3.1}$$

where $u_{T,p} = u_{I,p} + u_{D,p}$ *denotes the total field associated with the incident field* $u_{I,p}$.

Proof. Since $f_p(\beta) = \lambda_p^{-1} F f_p(\beta) = \lambda_p^{-1} \int_{S^2} A(\alpha,\beta)\, f_p(\alpha)\, d\alpha$, we obtain by using expression (2.2) of $A(\alpha,\beta)$ that

$$\begin{aligned} f_p(\beta) &= (4\pi\lambda_p)^{-1} \int_{S^2} \int_\Gamma \frac{\partial u_T^\alpha}{\partial \nu}\, \overline{u_I^\beta}\, d\Gamma\; f_p(\alpha)\, d\alpha \\ &= (4\pi\lambda_p)^{-1} \int_\Gamma \int_{S^2} \frac{\partial u_T^\alpha}{\partial \nu}\, f_p(\alpha)\, d\alpha\; \overline{u_I^\beta}\, d\Gamma. \end{aligned}$$

But by superposition, the integral $\int_{S^2} \partial u_T^\alpha/\partial\nu\, f_p(\alpha)\, d\alpha$ is nothing but the normal derivative of the total field $u_{T,p}$ associated with the incident field $u_{I,p}$, and thus

$$f_p(\beta) = (4\pi\lambda_p)^{-1} \int_\Gamma \frac{\partial u_{T,p}}{\partial \nu}\, \overline{u_I^\beta}\, d\Gamma. \tag{3.2}$$

We can now obtain the expression of the incident field generated by the eigenvector f_p. From (3.2), we have

$$\begin{aligned} u_{I,p}(x) &= \int_{S^2} f_p(\beta)\, u_I^\beta(x)\, d\beta \\ &= (4\pi\lambda_p)^{-1} \int_{S^2} \int_\Gamma \frac{\partial u_{T,p}}{\partial \nu}\; \overline{u_I^\beta}\, d\Gamma\; u_I^\beta(x)\, d\beta \\ &= (4\pi\lambda_p)^{-1} \int_\Gamma \left(\int_{S^2} u_I^\beta(x)\, \overline{u_I^\beta(y)}\, d\beta \right) \frac{\partial u_{T,p}}{\partial \nu}(y)\, d\Gamma_y. \end{aligned}$$

Formula (3.1) follows then from identity (2.10). $\square$

Since $j_0(\xi) = \sin(\xi)/\xi$, formula (3.1) shows that, as expected, the incident field $u_{I,p}(x)$ generated by an eigenvector f_p of F (or T) decreases like $r(x)^{-1}$ if $r(x)$ denotes the distance of x to the obstacles. In this sense, one can say that $u_{I,p}$ focuses on the obstacles located in the propagation medium. Furthermore, the quality of this focusing (given by the amplitude of the far field) is exactly given by the magnitude of the eigenvalue λ_p, since

$$|\lambda_p| = \frac{\|Ff_p\|_{L^2(S^2)}}{\|f_p\|_{L^2(S^2)}}.$$

4. Selective focusing. The aim of this section is to propose a mathematical justification of the so-called D.O.R.T. method presented in [16] and briefly described in the introduction of this paper. Roughly speaking, we answer the two following questions.

(i) Is the number of obstacles contained in a homogeneous medium equal to the number of "significant" eigenvalues of the far field operator F (or, equivalently, to those of the time-reversal operator $T = F^*F = FF^*$)?

(ii) If so, do the associated eigenvectors selectively focus on the obstacles?

As can be seen from the numerical experiments presented in [6], the answer to the first question is, in general, negative (there can be several "significant" eigenvalues even when there is just one scatterer). We will confirm this result by studying in subsection 4.1 the special case of a single spherical obstacle. Nevertheless, we will show that the answer becomes positive provided the obstacles considered are small enough. Under this assumption, we show in subsection 4.2 that selective focusing can be achieved using the eigenvectors of the far field operator.

4.1. Diffraction by a single spherical obstacle. In this subsection, we deal with the case where the scatterer is a sphere of radius $a > 0$. For this particular geometry, an explicit formula can be obtained for the eigenvalues of the far field mapping and thus for those of the time-reversal operator. The results of this subsection are classical and can be found, for instance, in [7]. In particular, formula (3.30) in [7] shows that for any given density

$$f = \sum_{n=0}^{+\infty} \sum_{m=-n}^{n} a_n^m Y_n^m \in L^2(S^2),$$

we have

$$Ff(\beta) = \sum_{n=0}^{+\infty} \sum_{m=-n}^{n} \frac{4i\pi}{k} \frac{j_n(ka)}{h_n^1(ka)} a_n^m Y_n^m(\beta).$$

Here Y_n^m denotes the usual spherical harmonics, j_n and h_n^1 are, respectively, the spherical Bessel and Hankel functions of order n.

Since the spherical harmonics constitute an orthonormal basis of $L^2(S^2)$, this formula shows that the following result holds.

PROPOSITION 4.1. *The eigenvalues of the far field operator F in the case of a single sound-soft spherical scatterer of radius a are given by*

$$\lambda_n = \frac{4i\pi}{k} \frac{j_n(ka)}{h_n^1(ka)} \qquad \forall n \geq 1. \tag{4.1}$$

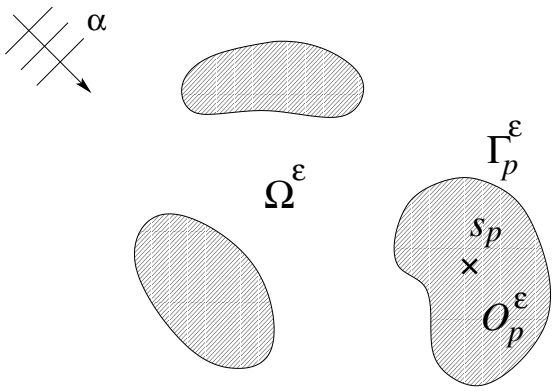

FIG. 4.1.

The eigenspace associated with the eigenvalue λ_n is the vector space of dimension $2n+1$ with basis Y_n^m, for $|m| \leq n$.

Remark 3. Equation (4.1) shows that the eigenvalues λ_n of the far field operator F satisfy $|\lambda_n| \leq 4\pi/k$ (recall that $h_n^1 = j_n + iy_n$). This property can also be obtained from the fact that the scattering operator $S = I + (ik/2\pi)F$ is unitary. Indeed, this property implies that the eigenvalues λ_n lie on the circle of radius $4\pi/k$ centered at $(0, 2\pi/k)$.

Proposition 4.1 shows in particular that *the number of nonzero eigenvalues is not necessarily equal to the number of obstacles*. However, in the case of a point scatterer or in the case of the low-frequency scattering (both cases which correspond to the asymptotic limit $ka \longrightarrow 0$), this result becomes true. Indeed, using the asymptotic behavior of Bessel and Hankel functions, we easily see that the eigenvalues λ_n given by (4.1) satisfy

$$\lambda_n \sim -\frac{4\pi^2}{k} \frac{(ka/2)^{2n+1}}{\Gamma(n+1/2)\Gamma(n+3/2)}$$

when ka goes to zero (and n is fixed). Thus, λ_{n+1}/λ_n decreases like $(ka)^2$, and hence, one can consider that the only significant eigenvalue in the limit case $ka \longrightarrow 0$ is the largest one λ_1. This observation suggests that the number of nonzero eigenvalues can be related to the number of obstacles when the obstacles are small. The next subsection provides a justification of this statement.

4.2. Diffraction by several small obstacles. Consider a family of obstacles $\{\mathcal{O}_p^\varepsilon;\ p = 1, N\}$ depending on a small parameter ε, where each $\mathcal{O}_p^\varepsilon$ is the image of a reference open set $\mathcal{O}_p$ (which is assumed to contain the origin) by a dilation of ratio ε centered at a given point $s_p \in \mathbb{R}^3$ (see Figure 4.1):

$$\mathcal{O}_p^\varepsilon = \left\{ x \in \mathbb{R}^3;\ \xi = \frac{x - s_p}{\varepsilon} \in \mathcal{O}_p \right\}.$$

Of course the "centers" s_p are chosen different so that for small enough ε, the obstacles do not intersect.

The main ingredient to show that selective focusing can be achieved using the eigenvectors of the far field operator when ε is small enough is given by the following

result, which provides the asymptotic behavior of the scattering amplitude $A^\varepsilon(\alpha,\beta)$ associated with the family of obstacles $\{\mathcal{O}_p^\varepsilon\}$.

PROPOSITION 4.2. *There exist N positive constants $C_1,\dots,C_N$ depending only on the geometry of the reference obstacles $\mathcal{O}_1,\dots,\mathcal{O}_N$ (called the "capacities" of these obstacles) such that*

$$\frac{A^\varepsilon(\alpha,\beta)}{\varepsilon} = A^{(1)}(\alpha,\beta) + O(\varepsilon) \quad \textit{with} \quad A^{(1)}(\alpha,\beta) = \frac{-1}{4\pi}\sum_{p=1,N} C_p\, u_I^\alpha(s_p)\,\overline{u_I^\beta(s_p)}, \tag{4.2}$$

where the bound $O(\varepsilon)$ is uniform for all $\alpha,\beta\in S^2$.

For the sake of clarity, the—rather technical—proof of this proposition is given in the appendix.

Remark 4. The capacity of a spherical soft obstacle of radius a is $C = 4\pi a$ (since the solution to (A.7) is simply given in this case by $V(x) = a/\|x\|$).

Thanks to Proposition 4.2, we know that the far field operator F^ε of the family of obstacles $\{\mathcal{O}_p^\varepsilon;\ p=1,N\}$ satisfies

$$\left\|\varepsilon^{-1}F^\varepsilon - F^{(1)}\right\|_{\mathcal{L}(L^2(S^2))} = \sup_{f\in L^2(S^2)\setminus\{0\}} \frac{\|(\varepsilon^{-1}F^\varepsilon - F^{(1)})f\|_{L^2(S^2)}}{\|f\|_{L^2(S^2)}} = O(\varepsilon),$$

where $F^{(1)}$ is the integral operator on $L^2(S^2)$ with kernel $A^{(1)}$:

$$F^{(1)}f\,(\beta) = \int_{S^2} A^{(1)}(\alpha,\beta)\, f(\alpha)\, d\alpha.$$

Since F^ε is compact and normal, perturbation theory [11] ascertains the continuity of any finite system of eigenvalues as well as of the associated total eigenprojection. More precisely, assume that $\lambda^{(1)}$ is an isolated eigenvalue of $F^{(1)}$ with finite multiplicity m, which implies that $\lambda^{(1)}\neq 0$.

(i) Then for small enough ε, the spectrum of $\varepsilon^{-1}F^\varepsilon$ can be separated into two parts. On one hand, the so-called $\lambda^{(1)}$-*group* consists of $m'\le m$ eigenvalues λ_j^ε, with $j=1$ to m', having a constant multiplicity m_j for $\varepsilon\neq 0$, and which are continuous near $\varepsilon = 0$, namely

$$|\lambda_j^\varepsilon - \lambda^{(1)}| = O(\varepsilon).$$

Moreover, the total multiplicity $\sum_{j=1,m'} m_j$ of the $\lambda^{(1)}$-group coincide with the multiplicity m of $\lambda^{(1)}$. On the other hand, the complementary of the $\lambda^{(1)}$-group in the spectrum of $\varepsilon^{-1}F^\varepsilon$ lies outside a vicinity of $\lambda^{(1)}$.

(ii) The total projection P^ε for the $\lambda^{(1)}$-group, i.e., the sum of the orthogonal projections on the eigenspaces associated with the λ_j^ε, is continuous at $\varepsilon = 0$, and

$$\left\|P^\varepsilon - P^{(1)}\right\|_{\mathcal{L}(L^2(S^2))} = O(\varepsilon),$$

where $P^{(1)}$ is the eigenprojection associated with $\lambda^{(1)}$.

Notice that in general, one cannot assert the existence of a continuous family of eigenvectors associated respectively with the λ_j^ε. However, for our particular choice of geometric perturbation (ε-dilation), such a result holds, since the perturbation actually is analytic with respect to ε (which is easily deduced from the appendix). But this result is of poor practical interest.

An eigenvalue of $\varepsilon^{-1}F^\varepsilon$ either belongs to some $\lambda^{(1)}$-group for a nonzero eigenvalue $\lambda^{(1)}$ of $F^{(1)}$, or vanishes as ε tends to 0. In the latter case, the above result does not apply; perturbation theory only provides the continuity of nonstationary eigenelements. So it remains to study the spectral properties of $F^{(1)}$, whose *degenerate kernel* will be rewritten in the form

$$A^{(1)}(\alpha,\beta) = -\sum_{p=1,N} C_p\,\overline{e_p(\alpha)}\,e_p(\beta), \quad \text{where} \quad e_p(\alpha) = \frac{e^{-ik\alpha\cdot s_p}}{2\sqrt{\pi}} \ (p=1,N). \tag{4.3}$$

Remark 5. Each e_p appears as a normalized function of $L^2(S^2)$ corresponding to an incident Herglotz wave $u_{I,p}$ which focuses on the pth obstacle, for

$$u_{I,p}(x) = \int_{S^2} e_p(\alpha)\,u_I^\alpha(x)\,d\alpha = 2\sqrt{\pi}\,j_0(k\|x-s_p\|),$$

by virtue of (2.10).

The above expression of $A^{(1)}$ then yields

$$F^{(1)}f = -\sum_{p=1,N} C_p\ (f,e_p)_{L^2(S^2)}\ e_p. \tag{4.4}$$

Proposition 4.3. *The limit far field operator* (4.4) *is a negative self-adjoint operator with finite rank N (the number of obstacles) and whose spectral radius cannot be smaller than the greatest capacity C_p of the obstacles.*

In the case where the wavelength $\ell = 2\pi/k$ is small compared with the minimum distance $d = \min_{1\le p\ne q\le N}\|s_p - s_q\|$ between the obstacles, the family $\{e_p;\ p=1,N\}$ defined in (4.3) *provides an approximate basis of eigenvectors associated with the approximate eigenvalues $\{-C_p;\ p=1,N\}$:*

$$F^{(1)}e_p = -C_p\,e_p + O\left(\frac{\ell}{d}\right). \tag{4.5}$$

Proof. The bilinear form associated with $F^{(1)}$,

$$(F^{(1)}f,f')_{L^2(S^2)} = -\sum_{p=1,N} C_p\ (f,e_p)_{L^2(S^2)}\ \overline{(f',e_p)_{L^2(S^2)}},$$

is clearly negative and self-adjoint, and so is $F^{(1)}$. The range of $F^{(1)}$ is spanned by $\{e_p;\ p=1,N\}$. To see that this family is linearly independent, suppose that

$$\sum_{p=1,N} z_p\,e_p = 0 \text{ with } z_p\in\mathbb{C}.$$

It is clear that the function $e_p\in L^2(S^2)$ is nothing but the far field corresponding to a point source located at the point s_p. Consequently, the above relation simply states that we have chosen a superposition of point sources located at the points $(s_p)_{p=1,N}$ whose far field vanishes. Thus, by Rellich's lemma, the field is identically zero. Hence, all the coefficients $(z_p)_{p=1,N}$ of the linear combination must also vanish. The linear independence of the family $\{e_p;\ p=1,N\}$ is thus established.

The lower bound for the spectral radius follows from the fact that

$$\left|(F^{(1)}e_q,e_q)_{L^2(S^2)}\right| = \sum_{p=1,N} C_p\,\left|\ (e_p,e_q)_{L^2(S^2)}\right|^2 \ge C_q \quad \text{for } q=1,N,$$

since the e_p are normalized in $L^2(S^2)$. On the other hand, nothing can be said in general about the gap between 0 and the other eigenvalues, which may be arbitrarily close to the former. This actually depends on the constructive or destructive interactions between the different obstacles, which are measured by the following scalar products (see (2.10)):

$$(e_p, e_q)_{L^2(S^2)} = j_0(k\|s_p - s_q\|) = \frac{\sin(k\|s_p - s_q\|)}{k\|s_p - s_q\|}.$$

These relations show in particular that

$$(e_p, e_q)_{L^2(S^2)} = \begin{cases} 1 & \text{for } q = p, \\ O\left(\dfrac{\ell}{d}\right) & \text{for } q \neq p, \end{cases}$$

which means that $\{e_p;\ p = 1, N\}$ is close to an orthogonal basis of the range of $F^{(1)}$ when $\ell \ll d$. The estimate (4.5) follows: each e_p is an approximate eigenvector. □

What are the practical consequences of the above results as regards selective focusing? Mainly that the eigenvectors of the time-reversal operator (or the far field operator) will produce selective focusing acoustic waves if

(i) the obstacles are small enough, compared to the wavelength,

(ii) the smallest distance between them is large, compared again to the wavelength,

(iii) their capacities are all distinct.

Indeed in this case all the nonzero eigenvalues of $F^{(1)}$ will be simple: the diagonalization of the time-reversal operator will then yield approximations of the focusing densities e_p.

But if one of these assumptions is missing, the nice focusing properties will disappear, at least for some groups of eigenvectors.

On one hand, if the interactions between the obstacles become significant, i.e., when $d/\ell = O(1)$, these properties may reduce to the purely global focusing presented in section 3. In particular, for very low frequencies, the situation $\varepsilon \ll d \ll \ell$ may occur. In this case we have

$$e_p = \tilde{e} + O\left(\frac{d}{\ell}\right) \quad \text{with } \tilde{e}(\alpha) = \frac{e^{-ik\,\alpha\cdot\tilde{s}}}{2\sqrt{\pi}},$$

where $\tilde{s}$ may be chosen as a convex combination of the s_p. As a consequence

$$F^{(1)} f = -\left(\sum_{p=1,N} C_p\right)\ (f, \tilde{e})_{L^2(S^2)}\ \tilde{e} + O\left(\frac{d}{\ell}\right),$$

which shows that the cluster of obstacles behaves like a unique obstacle which accumulates their respective capacities; only one significant eigenvalue of the time-reversal operator may be observed. Of course, for several distant clusters, we shall recover selective focusing on each cluster.

On the other hand, if some of the obstacles have neighboring capacities, the time-reversal operator may admit nonsimple eigenvalues. In this situation, the diagonalization of the latter cannot choose the selective focusing densities among all their linear combinations which compose the corresponding eigenspace.

5. Open time-reversal mirrors. In this section, we consider the case of a TRM that does not entirely surround the obstacle. Given a subset $\widehat{S}$ of S^2, we assume that the TRM can emit plane waves of directions $\alpha \in \widehat{S}$, and measures the far field in the opposite directions $\beta \in (-\widehat{S})$. One emission-diffraction-reception cycle is described by the directional far field operator

$$\widehat{F} = \widehat{P}_- \, F \, \widehat{P}_+^* : L^2(+\widehat{S}) \longrightarrow L^2(-\widehat{S}),$$

where $\widehat{P}_\pm$ are the restriction operators from $L^2(S^2)$ to $L^2(\pm\widehat{S})$, and thus their respective adjoints $\widehat{P}_\pm^* : L^2(\pm\widehat{S}) \longrightarrow L^2(S^2)$ are the operators of continuation by 0 outside $\pm\widehat{S}$. Note here that $\widehat{F}$ appears as the integral operator

$$\widehat{F}f(\beta) = \int_{+\widehat{S}} A(\alpha,\beta)\, f(\alpha)\, d\alpha \quad \text{for } \beta \in -\widehat{S}.$$

The time-reversal operator $\widehat{T}$ in the case of an open TRM is then defined by

$$\widehat{T}f = \overline{\widehat{R}\,\widehat{F}\overline{\widehat{R}\,\widehat{F}f}},$$

where $\widehat{R} : L^2(-\widehat{S}) \longrightarrow L^2(+\widehat{S})$ is the restriction of the symmetry operator defined in section 2 (*i.e.*, $\widehat{R}f(\alpha) = f(-\alpha)$ for $\alpha \in \widehat{S}$).

But one can easily check that $\widehat{R}\,\widehat{P}_- = \widehat{P}_+ R$ and $\widehat{P}_+^*\,\widehat{R} = R\,\widehat{P}_-^*$, and since these operators commute with the conjugation, we have by virtue of (2.5)

$$\widehat{F}^* f = \widehat{P}_+ F^* \widehat{P}_-^* f = \overline{\widehat{P}_+ R F \overline{R \widehat{P}_-^* f}} = \overline{\widehat{R}\,\widehat{P}_- F \widehat{P}_+^* \overline{\widehat{R} f}} = \overline{\widehat{R}\,\widehat{F}\,\overline{\widehat{R} f}}.$$

Hence, we can state the following result.

PROPOSITION 5.1. *The time-reversal operator $\widehat{T}$ for an open TRM is given by*

$$\widehat{T} = \widehat{F}^* \widehat{F} : L^2(\widehat{S}) \longrightarrow L^2(\widehat{S}).$$

Thus, it is the integral operator with kernel

$$\widehat{t}(\alpha,\beta) = \int_{-\widehat{S}} A(\alpha,\gamma)\, \overline{A(\beta,\gamma)}\, d\gamma \quad \text{for } \alpha,\beta \in \widehat{S}. \tag{5.1}$$

Moreover, $\widehat{T}$ defines a compact positive and self-adjoint operator.

Besides the value 0, the spectrum $\widehat{T}$ is thus constituted of a finite or countable sequence of positive eigenvalues $(\widehat{\mu}_p)_{p\geq 1}$ admitting 0 for only possible accumulation point. The largest eigenvalue $\widehat{\mu}_1$ of $\widehat{T}$ is thus given by

$$\widehat{\mu}_1 = \sup_{f \in L^2(\widehat{S})\,,\, f\neq 0} \frac{\left(\widehat{T}f, f\right)_{L^2(\widehat{S})}}{\|f\|^2_{L^2(S^2)}} = \sup_{f \in L^2(\widehat{S})\,,\, f\neq 0} \frac{\|\widehat{F}f\|^2_{L^2(-\widehat{S})}}{\|f\|^2_{L^2(+\widehat{S})}}.$$

This expression shows in particular that the incident field corresponding to an eigenvector associated with this eigenvalue maximizes the diffracted field in the direction of the TRM. Our goal now is to see if the global and selective properties proved respectively in sections 3 and 4 for closed mirrors still hold in the case of an open TRM. The

main difference between both situations is that in the latter one, the directional far field operator $\widehat{F}$ is not anymore normal (the range of $\widehat{F}^*\widehat{F}$ is contained in $L^2(\widehat{S})$, when that of $\widehat{F}\widehat{F}^*$ is contained in $L^2(-\widehat{S})$). Consequently, the eigenelements of $\widehat{T} = \widehat{F}^*\widehat{F}$ cannot be directly related to those of $\widehat{F}$. Contrary to the case of a closed TRM, the spectral analysis need thus to be carried on the time reversal operator and not on the far field one. Nevertheless, as we are going to see now, all the focusing results obtained previously still hold.

5.1. Global focusing. In this subsection, we prove a global focusing property similar to the one given in Proposition 3.3. More precisely, we have the following result.

PROPOSITION 5.2. *Let $\widehat{\mu}_p \neq 0$ be an eigenvalue of $\widehat{T}$ and $\widehat{f}_p \in L^2(\widehat{S})$ be a corresponding eigenvector. Then, the Herglotz wave $\widehat{u}_{I,p}$ associated with $\widehat{f}_p$ and defined by $\widehat{u}_{I,p}(x) = \int_{\widehat{S}} \widehat{f}_p(\alpha)\, u_I^\alpha(x)\, d\alpha$ can be written in the form*

$$\widehat{u}_{I,p}(x) = \int_\Gamma \widehat{\jmath}(k(x-y))\, h_p(y)\, d\Gamma \tag{5.2}$$

for some density h_p, where

$$\widehat{\jmath}(k(x-y)) = \int_{\widehat{S}} u_I^\beta(x)\, \overline{u_I^\beta(y)}\, d\beta = \int_{\widehat{S}} e^{ik\beta\cdot(x-y)}\, d\beta. \tag{5.3}$$

Proof. Like in the proof of Proposition 3.3, formula (5.2) will be proved if we can write $\widehat{f}_p$ in the form

$$\widehat{f}_p(\beta) = \int_\Gamma h_p\, \overline{u_I^\beta}\, d\Gamma \tag{5.4}$$

for a given density h_p. Indeed, if such a relation holds, then

$$\widehat{u}_{I,p}(x) = \int_{\widehat{S}} \widehat{f}_p(\beta)\, u_I^\beta(x)\, d\beta = \int_{\widehat{S}} \int_\Gamma h_p\, \overline{u_I^\beta}\, d\Gamma\ u_I^\beta(x)\, d\beta.$$

Equation (5.2) follows then by inverting the integrals over $\widehat{S}$ and Γ.

Thus, it only remains to prove (5.4). We first write that for all $\beta \in \widehat{S}$,

$$\widehat{f}_p(\beta) = \frac{1}{\widehat{\mu}_p}\widehat{T}\widehat{f}_p(\beta) = \frac{1}{\widehat{\mu}_p}\int_{\widehat{S}} \widehat{t}(\alpha,\beta)\widehat{f}_p(\alpha)\, d\alpha. \tag{5.5}$$

Thanks to the reciprocity relation (2.3), formula (5.1) can be written

$$\widehat{t}(\alpha,\beta) = \int_{-\widehat{S}} A(\alpha,\gamma)\, \overline{A(-\gamma,-\beta)}\, d\gamma.$$

Using the integral representation (2.2) in the above relation, we get after some simple computations that

$$\widehat{t}(\alpha,\beta) = \int_\Gamma h_p^\alpha\, \overline{u_I^\beta}\, d\Gamma, \tag{5.6}$$

where the density h_p^α is given by

$$h_p^\alpha(x) = \frac{1}{(4\pi)^2} \int_{-\widehat{S}} \int_\Gamma \frac{\partial u_T^\alpha}{\partial \nu} \, \overline{u_I^\gamma} \, d\Gamma \, \overline{\frac{\partial u_T^{-\gamma}}{\partial \nu}(x)} \, d\gamma.$$

Combining (5.5) and (5.6), one obtains the claimed relation (5.4), with the density $h_p(x) = \widehat{\mu}_p^{-1} \int_{\widehat{S}} h_p^\alpha(x) \, \widehat{f}_p(\alpha) \, d\alpha$. ∎

It is well known in oscillatory integrals theory that the function $\widehat{\jmath}(x)$ defined by (5.3) satisfies (one can use the stationary phase theorem; see, for instance, Theorem 1 in [19, p. 322])

$$\widehat{\jmath}(x) = \mathcal{O}\left(\|x\|^{-1}\right). \tag{5.7}$$

In the directions which are not covered by the TRM (i.e., when $x/\|x\| \notin \pm S$), one can in fact obtain a faster decay for $\widehat{\jmath}(x)$, since we have then $\widehat{\jmath}(x) = \mathcal{O}\left(\|x\|^{-3/2}\right)$.

Thanks to (5.7), formula (5.2) shows thus that the incident field generated by an eigenvector of $\widehat{T}$ focuses on the obstacles located in the propagation medium.

5.2. Diffraction by several small obstacles. Now we turn to the analysis of the selective focusing in the case of a TRM partially surrounding several small obstacles. The assumptions made on the geometry of the small scatterers are identical to those made in section 4. Let us recall that the main difference with section 4 is that since $\widehat{F}$ is not normal, the spectral analysis can no longer be achieved on $\widehat{F}$ but has to be carried out directly on the time-reversal operator $\widehat{T}$. In this subsection, we are going to see that the selective focusing results obtained in section 4 can be extended to the case of an open mirror.

Using the asymptotic formula (4.2) of the scattering amplitude, one easily gets that the kernel $\widehat{t}^{\,\varepsilon}(\alpha,\beta)$ of the time-reversal operator $\widehat{T}^\varepsilon = (\widehat{F}^\varepsilon)^* \widehat{F}^\varepsilon$ satisfies

$$\frac{\widehat{t}^{\,\varepsilon}(\alpha,\beta)}{\varepsilon^2} = \widehat{t}^{\,(1)}(\alpha,\beta) + O(\varepsilon),$$

where

$$\widehat{t}^{\,(1)}(\alpha,\beta) = \int_{-\widehat{S}} A^{(1)}(\alpha,\gamma) \, \overline{A^{(1)}(\beta,\gamma)} \, d\gamma \qquad \forall \alpha,\beta \in \widehat{S}$$

and where $A^{(1)}(\cdot,\cdot)$ is the degenerate kernel defined in (4.2). Since $\widehat{T}^\varepsilon$ is compact and self-adjoint, classical results of perturbation theory show again that for small ε, the spectral elements of $\varepsilon^{-2}\widehat{T}^\varepsilon$ can be approximated by those of the integral operator $\widehat{T}^{(1)}$ with kernel $\widehat{t}^{\,(1)}(\cdot,\cdot)$, which also reads $\widehat{T}^{(1)} = (\widehat{F}^{(1)})^* \widehat{F}^{(1)}$, where the operator $\widehat{F}^{(1)} : L^2(\widehat{S}) \longrightarrow L^2(-\widehat{S})$ is defined by

$$\widehat{F}^{(1)} f(\beta) = -\sum_{p=1,N} C_p \, (f, e_p)_{L^2(\widehat{S})} \, e_p(\beta) \qquad \text{for } \beta \in -\widehat{S}.$$

If we define the normalized functions $\{\widehat{e}_p;\ p = 1, N\}$ in $L^2(\widehat{S})$ and $L^2(-\widehat{S})$ by

$$\widehat{e}_p(\alpha) = (4\pi\widehat{r}\,)^{-1/2} \, e^{-ik\alpha\cdot s_p}, \tag{5.8}$$

where $\widehat{r} = \mathrm{mes}(\widehat{S})/(4\pi)$ is the *opening ratio* of the TRM, then

$$\widehat{F}^{(1)} f = -\widehat{r} \sum_{p=1,N} C_p \, (f, \widehat{e}_p)_{L^2(\widehat{S})} \, \widehat{e}_p \ \text{ in } L^2(-\widehat{S}). \tag{5.9}$$

Hence, for all $f \in L^2(\widehat{S})$, we have

$$\widehat{T}^{(1)} f = \widehat{r}^{\,2} \sum_{q=1,N} C_q \left(\sum_{p=1,N} C_p \, (f, \widehat{e}_p)_{L^2(\widehat{S})} (\widehat{e}_p, \widehat{e}_q)_{L^2(-\widehat{S})} \right) \widehat{e}_q. \tag{5.10}$$

We can now state the main result of this subsection.

PROPOSITION 5.3. *The limit time reversal operator* $\widehat{T}^{(1)} : L^2(\widehat{S}) \longrightarrow L^2(\widehat{S})$ *defined by* (5.10) *is a self-adjoint operator with finite rank* N *(the number of obstacles).*

Furthermore, if the wavelength $\ell = 2\pi/k$ *is small compared with the minimum distance between the obstacles, the family* $\{\widehat{e}_p;\ p = 1, N\}$ *defined in* (5.8) *provides an approximate basis of eigenvectors of* $\widehat{T}^{(1)}$ *associated with the approximate eigenvalues* $(\widehat{r}\, C_p)^2$*:*

$$\widehat{T}^{(1)} \widehat{e}_p = (\widehat{r}\, C_p)^2 \, \widehat{e}_p + O\left(\frac{\ell}{d}\right). \tag{5.11}$$

Proof. The fact that $\widehat{T}^{(1)}$ is of rank N follows from the fact that the family $\{\widehat{e}_p; p = 1, N\}$ is linearly independent in $L^2(\widehat{S})$(see the proof of Proposition 5.3). Equation (5.11) follows from (5.10) combined with the fact that

$$(\widehat{e}_p, \widehat{e}_q)_{L^2(\widehat{S})} = \overline{(\widehat{e}_p, \widehat{e}_q)_{L^2(-\widehat{S})}} = \begin{cases} 1 & \text{for } p = q, \\ O\left(\dfrac{\ell}{d}\right) & \text{for } p \neq q. \end{cases}$$

The last estimate follows from the relation

$$(\widehat{e}_p, \widehat{e}_q)_{L^2(\widehat{S})} = (4\pi\hat{r})^{-1} \int_{\widehat{S}} e^{ik\beta\cdot(s_p - s_q)} \, d\beta = (4\pi\hat{r})^{-1} \widehat{\jmath}(k(s_p - s_q))$$

and from the decay property (5.7) of $\widehat{\jmath}$ for $p \neq q$. ∎

Remark 6. Contrary to the case of a closed mirror (compare Propositions 4.3 and 5.3), we have not been able to compare the spectral radius of $\hat{T}^{(1)}$ with the greatest value taken by the quantities $(\hat{r}C_p)^2$.

As in the case of a closed mirror, Proposition 5.3 shows that the eigenvectors of the time-reversal operator for an open mirror will produce selective focusing acoustic waves if

(i) the obstacles are small enough, compared to the wavelength,
(ii) the smallest distance between them is large, compared to the wavelength,
(iii) their capacities are all distinct.

Indeed in this case all the nonzero eigenvalues of $\widehat{T}^{(1)}$ will be simple: the diagonalization of the time-reversal operator will then yield approximations of the focusing densities $\widehat{e}_p$ since each $\widehat{e}_p$ generates an incident Herglotz wave $\widehat{u}_{I,p}$ which focuses on the pth obstacle for

$$\widehat{u}_{I,p}(x) = \int_{\widehat{S}} \widehat{e}_p(\alpha) \, u_I^{\alpha}(x) \, d\alpha = \frac{1}{\sqrt{4\pi\widehat{r}}} \, \widehat{\jmath}(k(x - s_p)) = O\left(\frac{\ell}{\|x - s_p\|}\right).$$

Appendix A. Asymptotics for small obstacles. We detail here a constructive proof of the asymptotic behavior (4.2) of the scattering amplitude for small obstacles, claimed in Proposition 4.2. This result is formally derived in other papers (see, e.g.,

[17, 18]). A more abstract proof based on potential theory was recently proposed in [8].

The idea of our proof is to rewrite the scattering problem as a *regular* perturbation of a Fredholm equation in a *fixed* Hilbert space, in the sense that it does not depend on the size, say ε, of the obstacles:

$$(I + \mathbb{K}^\varepsilon)\varphi^\varepsilon = g^\varepsilon. \tag{A.1}$$

We obtain such a formulation by means of a variant of the integral method introduced by Jami and Lenoir [10], which has the advantage to involve nonsingular kernels, contrary to usual integral equations (for which perturbation theory requires more complicated arguments).

Consider the family of obstacles $\{\mathcal{O}_p^\varepsilon;\ p = 1, N\}$ introduced in subsection 4.2. We denote by Γ_p^ε (respectively, Γ_p) the boundary of $\mathcal{O}_p^\varepsilon$ (respectively, of $\mathcal{O}_p$), $\Gamma^\varepsilon = \bigcup_{p=1,N} \Gamma_p^\varepsilon$ and $\mathcal{O}^\varepsilon = \bigcup_{p=1,N} \mathcal{O}_p^\varepsilon$. Our exterior Dirichlet problem for the diffracted field u^ε reads

$$\begin{cases} \Delta u^\varepsilon + k^2 u^\varepsilon = 0 \ \text{ in } \mathbb{R}^3 \setminus \overline{\mathcal{O}^\varepsilon}, \\ u^\varepsilon = f \ \text{ on } \Gamma^\varepsilon, \\ R.C., \end{cases} \tag{A.2}$$

where $R.C.$ stands for the outgoing radiation condition, and $f = -u_I^\alpha$ is the Dirichlet datum associated with an incident plane wave $u_I^\alpha(x) = \exp(ik\alpha\cdot x)$ of direction $\alpha \in S^2$.

Reduction to a bounded domain. Around each reference obstacle $\mathcal{O}_p$, we delimit a bounded part D_p of its exterior by a fictitious boundary Σ_p which does not intersect Γ_p. We denote by D_p^ε and Σ_p^ε the images of D_p and Σ_p by the same dilation as for $\mathcal{O}_p^\varepsilon$, as well as $D^\varepsilon = \bigcup_{p=1,N} D_p^\varepsilon$ and $\Sigma^\varepsilon = \bigcup_{p=1,N} \Sigma_p^\varepsilon$.

The Jami–Lenoir method consists of introducing a transparent boundary condition on Σ^ε which is derived from the usual integral representation of u^ε. Here, in order to get rid of the normal derivative of u^ε on Γ^ε, the single-layer potential is re-expressed as a volume potential by Green's formula. Indeed it is easy to see that near Σ^ε we have

$$u^\varepsilon = f \overset{\Gamma^\varepsilon}{*} \frac{\partial G_k}{\partial \nu} + k^2 u^\varepsilon \overset{D^\varepsilon}{*} (\chi^\varepsilon G_k) - \nabla u^\varepsilon \overset{D^\varepsilon}{*} \nabla(\chi^\varepsilon G_k),$$

where the different "convolutions" represent, respectively, the surface double-layer potential

$$\left\{ f \overset{\Gamma^\varepsilon}{*} \frac{\partial G_k}{\partial \nu} \right\}(x) = \int_{\Gamma^\varepsilon} f(y)\, \frac{\partial G_k}{\partial \nu_y}(x-y)\, d\gamma_y$$

and the volume potentials

$$\begin{aligned} \{u^\varepsilon \overset{D^\varepsilon}{*} (\chi^\varepsilon G_k)\}(x) &= \int_{D^\varepsilon} u^\varepsilon(y)\, \chi^\varepsilon(y) G_k(x-y)\, dy, \\ \{\nabla u^\varepsilon \overset{D^\varepsilon}{*} \nabla(\chi^\varepsilon G_k)\}(x) &= \int_{D^\varepsilon} \nabla u^\varepsilon(y) \cdot \nabla_y(\chi^\varepsilon(y) G_k(x-y))\, dy. \end{aligned}$$

In the above expressions, G_k stands for the outgoing Green function of $\Delta + k^2$, *i.e.*, $G_k(x) = -\exp(ik|x|)/(4\pi|x|)$, and χ^ε denotes a family of regular cutoff functions $(\chi_p^\varepsilon)_{p=1,\dots,N}$ defined by the ε-dilation: $\chi_p^\varepsilon(x) = \chi_p((x - s_p)/\varepsilon)$ if $x \in D_p^\varepsilon$, where each

χ_p is equal to 1 in a vicinity of Γ_p and 0 in a vicinity of Σ_p. Note that these integrals involve regular kernels when x is near Σ^ε.

As a consequence if u^ε solves (A.2), its restriction v^ε to D^ε satisfies

$$\text{(A.3)}\quad \left\{ \begin{array}{l} \Delta v^\varepsilon + k^2 v^\varepsilon = 0 \ \text{ in } D^\varepsilon, \\ v^\varepsilon = f \ \text{ on } \Gamma^\varepsilon, \\ Z^\varepsilon v^\varepsilon = Z^\varepsilon \left\{ f \overset{\Gamma^\varepsilon}{*} \dfrac{\partial G_k}{\partial \nu} + \ k^2 v^\varepsilon \overset{D^\varepsilon}{*} (\chi^\varepsilon G_k) - \nabla v^\varepsilon \overset{D^\varepsilon}{*} \nabla(\chi^\varepsilon G_k) \right\} \ \text{ on } \Sigma^\varepsilon, \end{array} \right.$$

where Z^ε stands for the boundary operator $(\partial/\partial\nu + i/\varepsilon)$ on Σ^ε.

Conversely, the solution to this problem extends outside Σ^ε (by the integral representation) to the solution to (A.2) (thanks to the term involving i/ε which prevents the so-called *irregular frequencies* from being real; see [10]).

The limiting process. In order to work in a functional framework independent of ε, we perform in each subdomain D_p^ε the change of variable $\xi = (x - s_p)/\varepsilon$. By denoting $\varphi_p^\varepsilon(\xi) = v^\varepsilon(x)$ and $f_p^\varepsilon(\xi) = f(x)$, for $x \in D_p^\varepsilon$, as well as

$$G_{pq}^\varepsilon(\xi,\eta) = G_k(s_p - s_q + \varepsilon(\xi - \eta)) \text{ for } \xi \in \overline{D_p} \text{ and } \eta \in \overline{D_q},$$

problem (A.3) amounts to a family of N problems set on the domains D_p coupled by the transparent boundary conditions written on Σ_p:

$$\text{(A.4)}\quad \left\{ \begin{array}{l} \Delta \varphi_p^\varepsilon + (\varepsilon k)^2 \varphi_p^\varepsilon = 0 \ \text{ in } D_p, \\ \varphi_p^\varepsilon = f_p^\varepsilon \ \text{ on } \Gamma_p, \\ Z\varphi_p^\varepsilon = Z \displaystyle\sum_{q=1,N} \left\{ \varepsilon f_q^\varepsilon \overset{\Gamma_q}{*} \frac{\partial G_{pq}^\varepsilon}{\partial \nu} \right. \\ \qquad\qquad \left. + \ \varepsilon^3 k^2 \varphi_q^\varepsilon \overset{D_q}{*} (\chi_q G_{pq}^\varepsilon) - \varepsilon \nabla \varphi_q^\varepsilon \overset{D_q}{*} \nabla(\chi_q G_{pq}^\varepsilon) \right\} \ \text{ on } \Sigma_p, \end{array} \right.$$

where $Z = (\partial/\partial\nu + i)$ on Σ_p.

We are now able to define the formal limit of the latter problem. Let G_0 be the limit of $G_{\varepsilon k}$ when ε tends to 0, i.e., $G_0(x) = -1/(4\pi|x|)$. Notice that

$$\text{(A.5)}\quad \begin{array}{ll} G_{pq}^\varepsilon(\xi,\eta) = G_k(s_p - s_q) + O(\varepsilon) & \text{if } p \neq q, \\ G_{pp}^\varepsilon(\xi,\eta) = \varepsilon^{-1} G_0(\xi - \eta) + O(1) & \text{if } p = q, \end{array}$$

where these formulas hold uniformly in any compact subset of $\overline{D_p} \times \overline{D_q}$ which does not contain points of the diagonal when $p = q$, and can be derived with respect to ξ or η. Hence the formal limit of problem (A.4) reads as

$$\text{(A.6)}\quad \left\{ \begin{array}{l} \Delta \varphi_p^0 = 0 \ \text{ in } D_p, \\ \varphi_p^0 = f_p^0 = -e^{ik\alpha\cdot s_p} \ \text{ on } \Gamma_p, \\ Z\varphi_p^0 = Z \left\{ f_p^0 \overset{\Gamma_p}{*} \dfrac{\partial G_0}{\partial \nu} - \nabla \varphi_p^0 \overset{D_p}{*} \nabla(\chi_p G_0) \right\} \ \text{ on } \Sigma_p, \end{array} \right.$$

which correspond to a family of uncoupled problems. Each of them amounts to solving an exterior Laplace equation. More precisely, we can write that $\varphi_p^0 = -u_I^\alpha(s_p)\, V_p$, where V_p is the *static* potential solution to

$$\text{(A.7)}\quad \left\{ \begin{array}{l} \Delta V_p = 0 \ \text{ in } \mathbb{R}^3 \setminus \mathcal{O}_p, \\ V_p = 1 \ \text{ on } \Gamma_p, \\ V_p = O(1/x) \ \text{ as } |x| \to \infty. \end{array} \right.$$

Convergence. Consider the closed subspace of the usual Sobolev space $H^1(D_p)$ given by $\mathcal{H}_p = \{\psi_p \in H^1(D_p);\ \psi_p = 0 \text{ on } \Gamma_p\}$. The variational formulation of (A.4) appears as a coupled system of variational equations:

$$\begin{aligned}
&\text{Find } \varphi_p^\varepsilon \in f_p^\varepsilon + \mathcal{H}_p,\ p = 1, N, \text{ such that}\\
&\int_{D_p} \nabla\varphi_p^\varepsilon \cdot \overline{\nabla\psi_p} - (\varepsilon k)^2 \int_{D_p} \varphi_p^\varepsilon\, \overline{\psi_p} + i \int_{\Sigma_p} \varphi_p^\varepsilon\, \overline{\psi_p}\, d\sigma\\
&+ \int_{\Sigma_p} Z \left\{ \sum_{q=1,N} \varepsilon^3 k^2 \varphi_q^\varepsilon \overset{D_q}{*} (\chi_q G_{pq}^\varepsilon) - \varepsilon \nabla\varphi_q^\varepsilon \overset{D_q}{*} \nabla(\chi_q G_{pq}^\varepsilon) \right\} \overline{\psi_p}\, d\sigma\\
&= \int_{\Sigma_p} Z \left\{ \sum_{q=1,N} \varepsilon f_q^\varepsilon \overset{\Gamma_q}{*} \frac{\partial G_{pq}^\varepsilon}{\partial\nu} \right\} \overline{\psi_p}\, d\sigma \quad \forall \psi_p \in \mathcal{H}_p,\ p = 1, N.
\end{aligned}$$

Adding these equations yields the announced Fredholm equation (A.1) in the Hilbert space $\mathcal{H} = \mathcal{H}_1 \times \cdots \times \mathcal{H}_N$ which can be equipped with the scalar product

$$(\varphi, \psi) = \sum_{p=1,N} \int_{D_p} \nabla\varphi_p \cdot \overline{\nabla\psi_p}.$$

Indeed, define $\varphi^\varepsilon = (\varphi_1^\varepsilon, \ldots, \varphi_N^\varepsilon)$, $f^\varepsilon = (f_1^\varepsilon, \ldots, f_N^\varepsilon)$ and, respectively, the operator $\mathbb{K}^\varepsilon$ defined in $\mathcal{H}$ and $g^\varepsilon \in \mathcal{H}$ by

$$\begin{aligned}
(\mathbb{K}^\varepsilon\varphi, \psi) &= \sum_{p=1,N} -(\varepsilon k)^2 \int_{D_p} \varphi_p\, \overline{\psi_p} + i \int_{\Sigma_p} \varphi_p\, \overline{\psi_p}\, d\sigma\\
&+ \int_{\Sigma_p} Z \left\{ \sum_{q=1,N} \varepsilon^3 k^2 \varphi_q \overset{D_q}{*} (\chi_q G_{pq}^\varepsilon) - \varepsilon \nabla\varphi_q \overset{D_q}{*} \nabla(\chi_q G_{pq}^\varepsilon) \right\} \overline{\psi_p}\, d\sigma\\
(g^\varepsilon, \psi) &= \sum_{p=1,N} \int_{\Sigma_p} Z \left\{ \sum_{q=1,N} \varepsilon f_q^\varepsilon \overset{\Gamma_q}{*} \frac{\partial G_{pq}^\varepsilon}{\partial\nu} \right\} \overline{\psi_p}\, d\sigma
\end{aligned}$$

for all $\varphi = (\varphi_1, \ldots, \varphi_N)$ and $\psi = (\psi_1, \ldots, \psi_N)$ in $\mathcal{H}$. Then our coupled system reads as follows:

$$\text{Find } \varphi^\varepsilon \in f^\varepsilon + \mathcal{H} \text{ such that } (I + \mathbb{K}^\varepsilon)\varphi^\varepsilon = g^\varepsilon. \tag{A.8}$$

And of course we have a similar expression of the limit problem (A.6) with

$$\begin{aligned}
(\mathbb{K}^0\varphi, \psi) &= \sum_{p=1,N} i \int_{\Sigma_p} \varphi_p\, \overline{\psi_p}\, d\sigma - \int_{\Sigma_p} Z \left\{ \nabla\varphi_p \overset{D_p}{*} \nabla(\chi_q G_0) \right\} \overline{\psi_p}\, d\sigma,\\
(g^0, \psi) &= \sum_{p=1,N} \int_{\Sigma_p} Z \left\{ f_p^0 \overset{\Gamma_p}{*} \frac{\partial G_0}{\partial\nu} \right\} \overline{\psi_p}\, d\sigma.
\end{aligned}$$

Note that the uniqueness of the solution to (A.2) (respectively, (A.7)) implies that $I + \mathbb{K}^\varepsilon$ (respectively, $I + \mathbb{K}^0$) is injective, and thus bijective thanks to the following.

LEMMA A.1. *$\mathbb{K}^\varepsilon$ defines a family of compact operators in $\mathcal{H}$ which satisfies*

$$\|\mathbb{K}^\varepsilon - \mathbb{K}^0\| = \sup_{\varphi,\psi\in\mathcal{H}\setminus\{0\}} \frac{(\mathbb{K}^\varepsilon - \mathbb{K}^0)\varphi, \psi)}{\|\varphi\|\|\psi\|} = O(\varepsilon). \tag{A.9}$$

Proof. Consider, for instance, the part of $\mathbb{K}^\varepsilon$ corresponding to the operator $\mathbb{T}^\varepsilon_{pq}$ given by

$$\begin{aligned}(\mathbb{T}^\varepsilon_{pq}\varphi,\psi) &= \int_{\Sigma_p} Z\left\{\varepsilon\nabla\varphi_q \overset{D_q}{*} \nabla(\chi_q G^\varepsilon_{pq})\right\}\overline{\psi_p}\,d\sigma \\ &= \int_{\Sigma_p}\int_{D_q} \nabla\varphi_q(\eta)\cdot\nabla_\eta(\varepsilon\chi_q(\eta)Z_\xi G^\varepsilon_{pq}(\xi-\eta))\,d\eta\,\overline{\psi_p}\,d\sigma_\xi.\end{aligned}$$

We detail the proof only for the latter; similar arguments can be used for the other terms involved in the definition of $\mathbb{K}^\varepsilon$.

The compactness of $\mathbb{T}^\varepsilon_{pq}$ can be easily deduced from that of its adjoint. Indeed, using Schwarz inequality yields

$$\begin{aligned}\|(\mathbb{T}^\varepsilon_{pq})^*\psi\| &= \sup_{\varphi\in\mathcal{H}\setminus\{0\}}\frac{(\mathbb{T}^\varepsilon_{pq}\varphi,\psi)}{\|\varphi\|} \le C^\varepsilon_{pq}\,\|\psi\|_{L^2(\Sigma_p)}, \quad \text{where} \\ C^\varepsilon_{pq} &= \left(\int_{\Sigma_p}\int_{D_q}\left\|\nabla_\eta\{\varepsilon\chi_q(\eta)Z_\xi G^\varepsilon_{pq}(\xi-\eta)\}\right\|^2 d\eta\,d\sigma_\xi\right)^{1/2}.\end{aligned}$$

But the trace operator is compact from $H^1(D_q)$ to $L^2(\Sigma_p)$, which implies the compactness of $(\mathbb{T}^\varepsilon_{pq})^*$ in $\mathcal{H}$.

If $p\neq q$, formula (A.5) shows that $C^\varepsilon_{pq}=O(\varepsilon)$, and consequently the same holds for $\|\mathbb{T}^\varepsilon_{pq}\| = \|(\mathbb{T}^\varepsilon_{pq})^*\|$. If $p=q$, the limit operator is given by

$$(\mathbb{T}^0_{pp}\varphi,\psi) = \int_{\Sigma_p} Z\left\{\nabla\varphi_p \overset{D_p}{*} \nabla(\chi_p G_0)\right\}\overline{\psi_p}\,d\sigma,$$

since (A.5) shows in this case (again by Schwarz inequality) that

$$\left|((\mathbb{T}^\varepsilon_{pp}-\mathbb{T}^0_{pp})\varphi,\psi)\right| \le \varepsilon\,C\,\|\nabla\varphi\|_{L^2(D_p)}\,\|\psi\|_{L^2(\Sigma_p)}.$$

Hence $\|\mathbb{T}^\varepsilon_{pp}-\mathbb{T}^0_{pp}\| = O(\varepsilon)$. ∎

Lemma A.1 turns our problem into one of the simplest situations of perturbation theory [11]: the use of the Neumann series readily shows that

$$\|(I+\mathbb{K}^\varepsilon)^{-1}-(I+\mathbb{K}^0)^{-1}\| = O(\varepsilon).$$

It remains to notice that $\|f^\varepsilon - f^0\|$ and $\|g^\varepsilon - g^0\|$ are also of order ε, from which we conclude that

$$\|\varphi^\varepsilon-\varphi^0\| = O(\varepsilon). \tag{A.10}$$

The scattering amplitude. Thanks to formula (2.2), the local convergence expressed by the latter result also provides the far field asymptotics. Here, using our homothetic changes of variables, the scattering amplitude reads

$$A^\varepsilon(\alpha,\beta) = \frac{-\varepsilon}{4\pi}\sum_{p=1,N}\int_{\Gamma_p}\frac{\partial}{\partial\nu}(\varphi^\varepsilon_p(\alpha)-f^\varepsilon_p(\alpha))\,\overline{f^\varepsilon_p(\beta)}\,d\gamma.$$

On one hand, (A.10) implies that $\partial\varphi^\varepsilon_p(\alpha)/\partial\nu$ tends to $\partial\varphi^0_p(\alpha)/\partial\nu = -u^\alpha_I(s_p)\,\partial V_p/\partial\nu$ in $H^{-1/2}(\Gamma_p)$ (recall that V_p is defined in (A.7)). On the other hand, $f^\varepsilon_p(\alpha)$ tends to

the constant function $f_p^0(\alpha) = -u_I^\alpha(s_p)$. Hence

$$A^\varepsilon(\alpha,\beta) \;=\; \frac{-\varepsilon}{4\pi}\sum_{p=1,N} C_p\, u_I^\alpha(s_p)\,\overline{u_I^\beta(s_p)} \;+\; O(\varepsilon^2), \quad \text{where}$$

$$C_p \;=\; \int_{\Gamma_p} \frac{\partial V_p}{\partial \nu}\, d\gamma \;=\; \int_{\mathbb{R}^3\setminus\mathcal{O}_p} |\nabla V_p|^2$$

is referred to as the *capacity* of the obstacle $\mathcal{O}_p$. Proposition 4.2 is thus proved.

Acknowledgments. The authors would like to thank the referees for their valuable comments and suggestions.

INTERLAYER EXCHANGE COUPLING FOR FERROMAGNETS THROUGH SPACERS*

KAMEL HAMDACHE† AND MOUHCINE TILIOUA†

Abstract. We consider the interlayer exchange coupling between two ferromagnetic layers mediated by a nonmagnetic spacer layer. We adopt the theoretical model which is based on a macroscopic description using the Landau–Lifshitz equations and the Hoffmann boundary conditions characterizing the interlayer exchange coupling between the interfaces of the ferromagnetic films. An asymptotic study of such a layered system for either small or large spacer thicknesses is presented. The asymptotic problem and the boundary conditions at interfaces both for the magnetization and the magnetic field are characterized.

Key words. thin films, magnetic multilayers, bilinear coupling, Hoffmann's boundary condition, thin and thick nonmagnetic spacers

1. Introduction.

The interlayer exchange coupling (IEC) between ferromagnetic layers separated by a nonmagnetic spacer has been the subject of intense research in the past few years both on the experimental side and on the theoretical side due to its great impact on the recording and electronics industries. In the literature, the energy density (per unit surface) used to characterize the IEC is of the form $J_1(1 - m \cdot m') + J_2(1 - (m \cdot m')^2)$, where J_1 and J_2 are parameters describing the kind and the strength of the coupling and m and m' are the magnetization vectors at the inner surfaces of the bilayer stack just facing each other. The magnetization satisfies the saturation constraint $|m(t, x)| = 1$ for all time and in any point of the domain. If J_1 dominates, then the coupling is of ferromagnet or antiferromagnet type for $J_1 > 0$ or $J_1 < 0$, respectively, see, for example, [25], [18]. The first term in the energy is called bilinear, and the second one biquadratic, coupling. We notice, by using the saturation constraint, that these energies may be written as $J_1|m - m'|^2/2$ and $J_2|m - m'|^2|m + m'|^2/4$. The coefficients J_1 and J_2 depend generally on the thickness of the magnetic layers, see, for instance, Barnaś [6], Barnaś and Bulka [5], or Grünberg and Pierce [16]. The interested reader can find complementary information in the various review papers on this subject which have been published recently; see, for example, Stiles [28], [29], Demokritov [14], Bruno [9], [10], Camley [11], Camley and Stamps [12], Hartmann [18], Hubert and Schäfer [23], and the references therein. We also refer for a systematic experimental study to de Vries [32]. Some numerical results can be found in a paper by Labrune and Belliard [24].

In the present work we focus attention on the case in which $J_2 = 0$. Thus we consider only the bilinear coupling. However, recent experimental measurements of J_2 in some multilayered systems predict that J_2 under certain conditions cannot be neglected [7]. In order to simplify the presentation of the model equations, we will neglect the effect of the surface anisotropy energy on thin films; we may refer to [17] for some results including this effect. We restrict ourselves to the case of

magnetic/nonmagnetic multilayered structures, and we discuss the existence theory and the asymptotic behavior of the solutions when the thickness 2ε of the cylinder representing the nonmagnetic spacer is such that ε tends to either 0 or 1. We shall see that for very small spacer thicknesses the magnetic interlayer coupling becomes important. We refer to [19] for an overview in the case where the medium is a stack of magnetic media. Nevertheless, in [33] the authors indicate the main physical and experimental reasons why it is preferable that the coupling should be through an interlayer material (metallic, nonmagnetic, semiconductor, etc.) instead of there being a direct contact between the ferromagnetic slabs.

Before proceeding with the mathematical description of the model, a few clarifying comments are needed with regard to notation. We consider $B \subset \mathbb{R}^2$ a bounded and regular open set representing the cross section of the cylinder $\Omega = B \times (-1,1)$ of $\mathbb{R}^3$. The generic point of $\mathbb{R}^3$ is denoted by $x = (\hat{x}, x_3)$ with $\hat{x} = (x_1, x_2) \in B$. We assume that a ferromagnetic material occupies the domains $\Omega_\varepsilon^- = B \times (-1, -\varepsilon)$ and $\Omega_\varepsilon^+ = B \times (\varepsilon, 1)$ separated by a nonmagnetic spacer of thickness $2\varepsilon > 0$ occupying the domain $\Omega_\varepsilon^0 = B \times (-\varepsilon, \varepsilon)$. In what follows, S^2 represents the unit sphere of $\mathbb{R}^3$, and we set $\Omega_\varepsilon = \Omega_\varepsilon^- \cup \Omega_\varepsilon^+$. The magnetization field is denoted by $M(t,x)$, which belongs to S^2 almost everywhere, and the magnetic polarization is given by $\chi(\Omega_\varepsilon)M$, where $\chi(\Omega_\varepsilon)$ is the characteristic function of Ω_ε while in Ω_ε^0 it vanishes. The motion of the magnetization field M is governed by the Landau–Lifshitz–Gilbert equations; see [1], [8], for example. We have

$$\begin{cases} \dfrac{1}{1+\alpha^2}\Big(\partial_t M - \alpha M \times \partial_t M\Big) = -M \times \mathcal{H}(M) \quad \text{in } \mathbb{R}^+ \times \Omega_\varepsilon, \\ M(0,x) = M_0(x) \quad \text{in } \Omega_\varepsilon, \qquad \dfrac{\partial M}{\partial n} = 0 \quad \text{on } \partial\Omega_\varepsilon \setminus \{x_3 = \pm\varepsilon\}, \end{cases} \tag{1.1}$$

where the symbol $\times$ denotes the vector cross product in $\mathbb{R}^3$. The parameter $\alpha > 0$ depends on the gyromagnetic parameter $\zeta > 0$ and the phenomenological parameter $\beta > 0$. Indeed, the usual Landau–Lifshitz equation $\partial_t M = -\zeta M \times \mathcal{H} - \beta M \times (M \times \mathcal{H})$ may be written in the Landau–Lifshitz–Gilbert equivalent form $\partial_t M = \alpha M \times \partial_t M - \alpha_2 M \times \mathcal{H}$ with $\alpha = \beta/\zeta$ and $\alpha_2 = \zeta(1+\alpha^2)$. In (1.1) we set $\zeta = 1$. The initial magnetization M_0 satisfies the condition $|M_0(x)|^2 = 1$ for almost every $x \in \Omega_\varepsilon$, and the total magnetic excitation $\mathcal{H}(M)$ is given by

$$\mathcal{H}(M) = \operatorname{div}(A \operatorname{grad} M) + \psi(M) + \operatorname{grad}\varphi + H_0. \tag{1.2}$$

The term $M \times \operatorname{div}(A \operatorname{grad} M)$ is well defined if M is regular. We may write it, using the saturation condition $|M(t,x)|^2 = 1$ a.e., in the weaker form $\operatorname{div}(M \times A \operatorname{grad} M)$, which is well defined if $\operatorname{grad} M$ belongs to $\mathbb{L}^2(\Omega)$ with respect to the space variable. The first term on the right-hand side of (1.2) is called the exchange magnetic field, where A is the exchange variable coefficient satisfying the usual ellipticity condition in Ω_ε. The second term is the bulk anisotropy field (which generally is taken as linear with respect to M), and $\operatorname{grad}\varphi$ is the demagnetizing field, satisfying in the magnetostatic approximation of the Maxwell equations

$$\begin{cases} \operatorname{div}(\operatorname{grad}\varphi + \chi(\Omega_\varepsilon)M) = 0 \quad \text{for } x_3 > -1, \\ \dfrac{\partial \varphi}{\partial x_3} + \chi(B) M \cdot \mathbf{u}_3 = 0 \quad \text{on } x_3 = -1, \end{cases} \tag{1.3}$$

where we have set $(\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3)$ to represent the canonical basis of $\mathbb{R}^3$. Note that the potential φ satisfies the transmission boundary conditions at the interfaces $x_3 = \pm\varepsilon$

and $x_3 = 1$. Indeed, (1.3) is set in the whole space $\mathbb{R}^3$, but if one assumes that our material is set on a substrate represented by the half-space $x_3 < -1$ with infinite conductivity, then the boundary condition satisfied by the potential φ is the one given in (1.3). The transmission boundary conditions mean that φ and $\frac{\partial \varphi}{\partial x_3} + \chi(B)M \cdot \mathbf{u}_3$ are continuous across the interfaces $x_3 = -\varepsilon$, $x_3 = \varepsilon$, and $x_3 = 1$. The last term H_0 on the right-hand side of (1.2) is the applied magnetic field. In what follows, without loss of generality and since we are dealing with the dynamic of the magnetization field, we assume $H_0 = 0$. Equations (1.1) are supplemented by coupling conditions for M at the interfaces $x_3 = \pm\varepsilon$. These conditions couple the layers of the domains Ω_ε^+ and Ω_ε^-. This is given by the so-called Hoffmann interlayer exchange coupling law [20], [21], which can be written as follows:

$$M(\pm\varepsilon) \times \left(\mp A \frac{\partial M(\pm\varepsilon)}{\partial x_3} - JM(\mp\varepsilon) \right) = 0. \tag{1.4}$$

The constant J (previously denoted J_1) is the interlayer exchange constant, which may depend on the thickness 2ε of the nonmagnetic spacer. This boundary condition takes the form

$$\mp A \frac{\partial M(\pm\varepsilon)}{\partial x_3} - JM(\mp\varepsilon) + J(M(\pm\varepsilon) \cdot M(\mp\varepsilon))M(\pm\varepsilon) = 0. \tag{1.5}$$

We wish to point out that the condition (1.4) is also called the modified Rado–Weertman boundary condition. It has been reported by Hoffmann [20]; see also [22], [27].

This paper is organized as follows. In section 2, we discuss the existence of global solutions of the Landau–Lifshitz equation (1.1)–(1.3) with Hoffmann boundary condition (1.4). We follow the classical proof given by [3], [31]. The main difference is related to the interlayer coupling boundary condition satisfied in our model. We give a priori estimates for the solutions and for the energy equality satisfied by the solutions, which plays a crucial role in the next sections.

Section 3 deals with the asymptotic behavior of solutions when the thickness parameter ε tends either to 0 or 1. Let us specify the results obtained. We first introduce the changes of variable which transform the domains $\Omega_\varepsilon^\pm$ and Ω_ε^0 into the domains $\Omega^\pm$ and Ω^0, which are independent of ε, but (1.1)–(1.3) become equations with variable coefficients depending on ε; see (3.9), (3.10), and (3.11). We then analyze the behavior of the model when the thickness parameter $\varepsilon \to 0$. For this behavior we assume that the coefficient J is independent of ε. Passing to the limit in the potential equation, we show that the limit potential satisfies a magnetostatic Maxwell equation set in $\mathbb{R}^2 \times (-1, -1/2)$ and $\mathbb{R}^2 \times (1/2, \infty)$. The solution satisfies a new boundary condition with regularizing effect. This boundary condition couples the interfaces $z = 1/2$ and $z = -1/2$; see Theorem 3.3. In the domains $B \times (-1, -1/2)$ and $B \times (1/2, 1)$ the magnetization field satisfies the Landau–Lifshitz equations together with the Hoffmann interlayer exchange coupling law at the interfaces $z = -1/2$ and $z = 1/2$; see Theorem 3.4.

The second purpose of section 3 is to examine the behavior of thick spacers corresponding to the case where $\varepsilon \to 1$. This means that the thickness $1 - \varepsilon$ of the two ferromagnetic domains tends to 0, and both domains are coupled with a very weak IEC. In this case the coefficient appearing in front of the interlayer exchange energy is $-J/2(1 - \varepsilon)$. To get uniform bounds for the solutions of the problem we assume that the interlayer parameter J is of order $1 - \varepsilon$. More precisely we assume

that $J = (1-\varepsilon)j$, where $j > 0$ is independent of ε. Hence, when $\varepsilon \to 1$, we get two magnetization fields m^+ and m^- satisfying the same initial data and solving Landau–Lifshitz equations in the cross section B of the domain with the effective magnetic field

$$\mathcal{H}^{\pm}(m^{\pm}) = \widehat{\operatorname{div}}(a^{\pm}\widehat{\operatorname{grad}}\, m^{\pm}) + \psi(m^{\pm}) + \widehat{\operatorname{grad}}\,\phi^{\pm} - \chi(B)m^{\pm}\cdot \mathbf{u}_3\mathbf{u}_3 + jm^{\mp}.$$

The potential $\phi^{\pm}$ is given by $\phi^{\pm}(\hat{x}) = \phi(\hat{x}, \pm 1/2)$, where $\phi(\hat{x}, z)$ solves in each slab S^{∞} and S^0 a new magnetostatic equation; see Theorem 3.7. The effect induced by the thin layer behavior for each magnetization is the same as that described first by Gioia and James [15] and later by Ammari, Halpern, and Hamdache [4]; Hamdache and Tilioua [17]; Alicandro and Leone [2] in different frameworks. The Gioia–James effect takes the form $-\chi(B)m^{\pm}\cdot \mathbf{u}_3\mathbf{u}_3$, which penalizes the out-of-plane component of the demagnetizing term $\widehat{\operatorname{grad}}\,\phi^{\pm}$. Moreover, in our result the potential $\phi^{\pm}$ is obtained as the trace at the interface $z = \pm 1/2$ of the potential ϕ. The second effect appearing is due to the Hoffmann IEC law. It takes the form of a coupling bulk anisotropy energy and links the two ferromagnetic films. The magnetizations m^+ and m^- satisfy Landau–Lifshitz equations in the domain B and are associated with the same initial data $m_0(\hat{x})$ and with the magnetic excitation $\mathcal{H}^{\pm}$ containing the bulk anisotropy field $-jm^{\mp}$ due to the interlayer exchange coupling law; see Theorem 3.9. We finally conclude this work with some remarks and comments.

Throughout, we use the following notation: $\mathbb{L}^2(\Omega) = (L^2(\Omega))^3$ an $\mathbb{H}^1(\Omega) = (H^1(\Omega))^3$ are the usual Hilbert spaces equipped with the norm $|\cdot|$ and $\|\cdot\|$, respectively. We denote by $(\cdot;\cdot)$ the scalar product of $\mathbb{L}^2(\Omega)$.

2. Global existence results. In this section, we omit the parameter ε where it is not necessary. We shall solve problem (1.1)–(1.4) by using the nonlinear Galerkin method; see, for example, Lions [26], Tartar [30].

We introduce the following spectral problem: find $(\lambda, U) \in \mathbb{R}^+ \times \mathbb{H}^1(\Omega)$ such that

$$\begin{cases} -\operatorname{div}(A\operatorname{grad} U) + \gamma U = \lambda U \quad \text{in } \Omega, \\ \\ \mp A\dfrac{\partial U(\pm\varepsilon)}{\partial x_3} - JU(\mp\varepsilon) = 0 \quad \text{in } B, \\ \\ A\dfrac{\partial U}{\partial n} = 0 \quad \text{on } \partial\Omega^{\pm} \setminus \{x_3 = \pm\varepsilon\}, \end{cases} \tag{2.1}$$

where $\gamma > 0$ is sufficiently large and $\Omega = \Omega_{\varepsilon}^- \cup \Omega_{\varepsilon}^+$. Recall that the coefficient $A(x)$ satisfies the ellipticity condition

$$0 < a_1 \le A(x) \le a_2 \quad \text{for almost every } x \in \Omega, \tag{2.2}$$

and the parameter J is assumed to be independent of ε and such that

$$J > 0. \tag{2.3}$$

The weak formulation of the problem (2.1) takes, for all $V \in \mathbb{H}^1(\Omega)$, the form

$$\begin{cases} a_{\gamma}(U,V) + \mathcal{I}(U,V) = \lambda(U;V), \text{ with} \\ \\ a_{\gamma}(U,V) = \displaystyle\int_{\Omega} A\operatorname{grad} U \operatorname{grad} V \; dx + \gamma \int_{\Omega} U\cdot V \; dx, \\ \\ \mathcal{I}(U,V) = -J\displaystyle\int_B \Big(U(-\varepsilon)\cdot V(\varepsilon) \; + U(\varepsilon)\cdot V(-\varepsilon)\Big)\, d\hat{x}, \end{cases} \tag{2.4}$$

where $\operatorname{grad} U \operatorname{grad} V = \partial_{x_j} U_i \partial_{x_j} V_i$. A classical estimate shows that for all $U \in \mathbb{H}^1(\Omega)$ we have

$$|\mathcal{I}(U,U)| \le J(\beta|\operatorname{grad} U|^2 + C_\beta |U|^2) \tag{2.5}$$

for all $\beta > 0$ with $C_\beta \to +\infty$ as $\beta \to 0$. We choose $\beta > 0$ and $\gamma > 0$ in order to have $c_1 := a_1 - J\beta > 0$ and $c_2 := \gamma - JC_\beta > 0$. Hence, we get, for all $U \in \mathbb{H}^1(\Omega)$, the estimate

$$a_\gamma(U,U) + \mathcal{I}(U,U) \ge c_1 |\operatorname{grad} U|^2 + c_2 |U|^2. \tag{2.6}$$

Notice that c_1 and c_2 are independent of ε. Moreover, for U and V in $\mathbb{H}^1(\Omega)$ we have for all $\beta > 0$ the following inequality:

$$|\mathcal{I}(U,V)| \le J(\beta|\operatorname{grad} U|^2 + C_\beta |U|^2)^{1/2} (\beta|\operatorname{grad} V|^2 + C_\beta |V|^2)^{1/2}. \tag{2.7}$$

Fixing $\beta > 0$, there exists $c_3 > 0$ independent of ε such that for all $U, V \in \mathbb{H}^1(\Omega)$ we have

$$|a_\gamma(U,V) + \mathcal{I}(U,V)| \le c_3 \|U\| \|V\|. \tag{2.8}$$

The bilinear form $a_\gamma(U,V) + \mathcal{I}(U,V)$ is continuous on $\mathbb{H}^1(\Omega) \times \mathbb{H}^1(\Omega)$ and coercive on $\mathbb{H}^1(\Omega)$ for γ large. Let $\mathcal{A}_{int} : \mathbb{H}^1(\Omega) \to \mathbb{H}^1(\Omega)'$ be the linear operator defined by

$$\langle \mathcal{A}_{int} U, V \rangle_{\mathbb{H}^1(\Omega)' \times \mathbb{H}^1(\Omega)} = a_\gamma(U,V) + \mathcal{I}(U,V),$$

where $\mathbb{H}^1(\Omega)'$ is the dual space of $\mathbb{H}^1(\Omega)$. Then $\mathcal{A}_{int}$ is an isomorphism from $\mathbb{H}^1(\Omega)$ into $\mathbb{H}^1(\Omega)'$, and its inverse $\mathcal{A}_{int}^{-1}$ is a compact operator from $\mathbb{L}^2(\Omega)$ into $\mathbb{L}^2(\Omega)$. Since the bilinear form $a_\gamma(U,V) + \mathcal{I}(U,V)$ is symmetric, the operator $\mathcal{A}_{int}$ also is, and we have

$$\langle \mathcal{A}_{int} U, V \rangle_{\mathbb{H}^1(\Omega)' \times \mathbb{H}^1(\Omega)} = \langle U, \mathcal{A}_{int} V \rangle_{\mathbb{H}^1(\Omega) \times \mathbb{H}^1(\Omega)'}$$

for all $U, V \in \mathbb{H}^1(\Omega)$. Hence, it follows that operator $\mathcal{A}_{int}$ is self-adjoint on its natural domain $D(\mathcal{A}_{int})$. We obtain the following result.

LEMMA 2.1. *There exists an uncountable set of solutions* $(\lambda_k, U_k)_{k\in\mathbb{N}} \subset \mathbb{R}^+ \times \mathbb{H}^1(\Omega)$ *of problem* (2.1) *such that* $c_2 < \lambda_k \to +\infty$ *as* $k \to +\infty$. *Moreover, the eigenvectors* U_k *associated to the eigenvalues* λ_k *form an orthonormal basis of* $\mathbb{L}^2(\Omega)$, *and* $\lambda_k^{-1/2} U_k$ *an orthogonal basis of* $\mathbb{H}^1(\Omega)$.

In the remainder we proceed along the lines of the global existence proof given by Visintin [31] and Alouges and Soyeur [3]; see also Carbou and Fabrie [13]. We briefly describe the main steps of the proof. First we introduce the penalized problem

$$\begin{cases} \dfrac{1}{1+\alpha^2}\Big(\alpha \partial_t M + M \times \partial_t M\Big) = \mathcal{H}(M) + \nu M\Big(1 - |M|^2\Big) & \text{in } \mathbb{R}^+ \times \Omega_\varepsilon^\pm, \\ M(0,x) = M_0(x) \quad \text{in } \Omega_\varepsilon^\pm, \qquad \dfrac{\partial M}{\partial n} = 0 \quad \text{on } \partial\Omega_\varepsilon^\pm \setminus \{x_3 = \pm\varepsilon\}, \\ \mp A \dfrac{\partial M(\pm\varepsilon)}{\partial x_3} - JM(\mp\varepsilon) = 0 \quad \text{in } B, \end{cases} \tag{2.9}$$

where the parameter $\nu > 0$ is fixed. To solve this problem we use the nonlinear Galerkin method (see [26], [30]) by introducing the approximated problem

$$\begin{cases} \dfrac{1}{1+\alpha^2}\Big(\alpha\partial_t M^N + M^N \times \partial_t M^N\Big) \\ \qquad\qquad = \mathcal{H}(M^N) + \nu M^N\Big(1 - |M^N|^2\Big) \quad \text{in } \mathbb{R}^+ \times \Omega_\varepsilon^\pm, \\ M^N(0,x) = M_0^N(x) \quad \text{in } \Omega_\varepsilon^\pm, \end{cases} \tag{2.10}$$

where M_0^N is the projection of M_0 in the space $\mathcal{V}^N = \{V = \sum_{k=1}^N v_k U_k\}$. The solution M^N satisfies the interlayer coupling boundary condition at the interfaces $x_3 = \pm\varepsilon$ and the homogeneous Neumann boundary condition on the remaining part of the boundary of Ω.

Let us give some remarks on the proof. Proceeding as in [31], [3], we deduce that the sequence of solutions M^N converges to M weakly-$\star$ in $L^\infty(\mathbb{R}^+, \mathbb{H}^1(\Omega))$, and $\partial_t M^N$ converges to $\partial_t M$ weakly in $L^2(\mathbb{R}^+, \mathbb{L}^2(\Omega))$. Using the strong convergence of the traces $M^N(\pm\varepsilon)$ in $\mathbb{L}^2_{\text{loc}}(\mathbb{R}^+ \times B)$, we may pass to the limit in the boundary integral $\pm J \int_{\mathbb{R}^+\times B} M^N(\pm\varepsilon) \times M^N(\mp\varepsilon)\phi \, d\hat{x}dt$, where ϕ is a test function. Using the integration by parts, we deduce that M satisfies the interlayer coupling boundary in the following sense: $\int_{\mathbb{R}^+} \langle (\mp A\partial_{x_3} M(\pm\varepsilon) - JM(\mp\varepsilon)), M(\pm\varepsilon) \times \phi\rangle_{\mathbb{H}^{-1/2}(B)\times\mathbb{H}^{1/2}(B)} \, dt = 0$. We get the following existence result.

THEOREM 2.2. *Let $M_0 \in \mathbb{H}^1(\Omega_\varepsilon)$ be such that $|M_0(x)|^2 = 1$ for almost every $x \in \Omega_\varepsilon$, and let $\psi : \mathbb{R}^3 \to \mathbb{R}^3$, $\psi(M) = \operatorname{grad}\Psi(M)$ be a continuous gradient function such that $0 \le \Psi(M) \le \Psi_\infty < \infty$ for all $M \in S^2$. Then there exists a global solution $M \in L^\infty(\mathbb{R}^+, \mathbb{H}^1(\Omega_\varepsilon))$ of problem (1.1)–(1.4) such that $|M(t,x)|^2 = 1$ for almost every $(t,x) \in \mathbb{R}^+ \times \Omega_\varepsilon$, $\partial_t M \in L^2(\mathbb{R}^+, \mathbb{L}^2(\Omega_\varepsilon))$, and $\operatorname{grad}\varphi \in L^\infty(\mathbb{R}^+, \mathbb{L}^2(\mathbb{R}^2 \times (-1,\infty)))$. Moreover, for all $t \ge 0$, the following energy equality holds:*

$$\mathcal{E}(t) + \frac{2\alpha}{1+\alpha^2}\int_0^t \int_{\Omega_\varepsilon} |\partial_t M(s)|^2 \, dxds = \mathcal{E}(0), \tag{2.11}$$

where the total energy $\mathcal{E}(t)$ is expressed by $\mathcal{E}(t) = \mathcal{E}_{exc}(t) + \mathcal{E}_{vol}(t) + \mathcal{E}_{dm}(t) + \mathcal{E}_{int}(t)$ with

$$\begin{aligned} &\mathcal{E}_{exc}(t) = \int_{\Omega_\varepsilon} A|\operatorname{grad} M|^2 \, dx, \qquad \mathcal{E}_{vol}(t) = \int_{\Omega_\varepsilon} \Psi(M) \, dx, \\ &\mathcal{E}_{int}(t) = -J\int_B M(-\varepsilon)\cdot M(\varepsilon) \, d\hat{x}, \qquad \mathcal{E}_{dm}(t) = \int_{\mathbb{R}^2}\int_{-1}^{\infty} |\operatorname{grad}\varphi|^2 \, dx. \end{aligned} \tag{2.12}$$

The magnetization M satisfies the Landau–Lifshitz–Gilbert equation in the sense of distributions where the exchange contribution is written in the weak form $\operatorname{div}(M \times A \operatorname{grad} M)$.

Remark. Notice that if we add to both sides of (2.11) the quantity $J|B|$, where $|B|$ is the Lebesgue measure of the cross section B, then the IEC energy $\mathcal{E}_{int}$ can be replaced by the right interlayer exchange energy $J\int_B (1 - M(-\varepsilon)\cdot M(\varepsilon)) \, d\hat{x} = (J/2)\int_B |M(-\varepsilon) - M(\varepsilon)|^2 \, d\hat{x}$ for all $t \ge 0$.

The initial magnetic field $\operatorname{grad}\varphi_0(x)$ satisfies the compatibility problem

$$\begin{cases} \operatorname{div}(\operatorname{grad}\varphi_0 + \chi(\Omega_\varepsilon)M_0) = 0 \ \text{ for } x_3 > -1, \\ \dfrac{\partial\varphi_0}{\partial x_3} + \chi(B)M_0 \cdot \mathbf{u}_3 = 0 \ \text{ on } x_3 = -1. \end{cases} \tag{2.13}$$

It follows that $\mathcal{E}_{dm}(0)$ is given by

$$\mathcal{E}_{dm}(0) = \int_{\mathbb{R}^2} \int_{-1}^{\infty} |\operatorname{grad} \varphi_0|^2 \, dx = - \int_{\Omega_\varepsilon} M_0 \cdot \operatorname{grad} \varphi_0 \, dx, \tag{2.14}$$

which implies that $|\operatorname{grad} \varphi_0|_{\mathbb{L}^2(\mathbb{R}^2 \times (-1,\infty))} \leq (2(1-\varepsilon)|B|)^{1/2}$, and then the initial demagnetization energy satisfies

$$0 \leq \mathcal{E}_{dm}(0) \leq 2(1-\varepsilon)|B|. \tag{2.15}$$

The initial interlayer exchange energy satisfies

$$|\mathcal{E}_{int}(0)| \leq J|B|. \tag{2.16}$$

One observes that if the initial magnetization is assumed to be such that $M_0(-\varepsilon) \cdot M_0(\varepsilon) \geq 0$, then we get $\mathcal{E}_{int}(0) \leq 0$.

The initial volume anisotropy energy satisfies

$$0 \leq \mathcal{E}_{vol}(0) \leq 2\Psi_\infty(1-\varepsilon)|B|. \tag{2.17}$$

The initial exchange energy is such that

$$0 \leq \mathcal{E}_{exc}(0) < a_2 |\operatorname{grad} M_0|^2_{\mathbb{L}^2(\Omega_\varepsilon)} \leq a_2 \delta, \tag{2.18}$$

where $\delta > 0$ is independent of ε, by assuming, for example, that M_0 is the restriction to Ω_ε of $M_0 \in \mathbb{H}^1(\Omega)$.

Hence the following uniform estimates with respect to ε hold.

COROLLARY 2.3. *Let $M_0 \in \mathbb{H}^1(\Omega)$ be such that $|M_0(x)|^2 = 1$ for almost every $x \in \Omega_\varepsilon$. Then there exists $C > 0$ independent of ε such that*

$$\begin{aligned} &\|\operatorname{grad} M^\varepsilon\|_{L^\infty(\mathbb{R}^+, \mathbb{L}^2(\Omega_\varepsilon))} + \|\partial_t M^\varepsilon\|_{L^2(\mathbb{R}^+, \mathbb{L}^2(\Omega_\varepsilon))} \\ &+ \|\operatorname{grad} \varphi^\varepsilon\|_{L^\infty(\mathbb{R}^+, \mathbb{L}^2(\mathbb{R}^2 \times (-1,\infty)))} \leq C \end{aligned} \tag{2.19}$$

and $|M^\varepsilon(t,x)|^2 = 1$ for almost every $(t,x) \in \mathbb{R}^+ \times \Omega_\varepsilon$.

In the next section we will discuss the behavior of the solutions $(M^\varepsilon, \varphi^\varepsilon)$ in the two cases $\varepsilon \to 0$ and $\varepsilon \to 1$.

3. Convergences. The nonmagnetic spacer occupies the domain Ω^0_ε. We introduce the following change of variables:

$$\begin{cases} z = x_3 \ \text{ if } x_3 \geq 1, \\ z = \dfrac{1}{2(1-\varepsilon)}(x_3 + 1 - 2\varepsilon) \in \left[\dfrac{1}{2}, 1\right] \quad \text{if } \ \varepsilon \leq x_3 \leq 1, \\ z = \dfrac{1}{2\varepsilon} x_3 \in \left[-\dfrac{1}{2}, \dfrac{1}{2}\right] \ \text{ if } \ -\varepsilon \leq x_3 \leq \varepsilon, \\ z = \dfrac{1}{2(1-\varepsilon)}(x_3 - 1 + 2\varepsilon) \in \left[-1, -\dfrac{1}{2}\right] \ \text{ if } \ -1 \leq x_3 \leq -\varepsilon. \end{cases} \tag{3.1}$$

We set

$$\begin{aligned} &G^+ = B \times \left(\frac{1}{2}, 1\right), \ G^- = B \times \left(-1, -\frac{1}{2}\right), \\ &G^0 = B \times \left(-\frac{1}{2}, \frac{1}{2}\right), \qquad G = G^+ \cup G^- \end{aligned} \tag{3.2}$$

and introduce for $t \geq 0$ and $(\hat{x}, z) \in G$ the new functions

$$m^\varepsilon(t,\hat{x},z) = \begin{cases} M(t,\hat{x},2(1-\varepsilon)z + 2\varepsilon - 1) \ \text{ in } \mathbb{R}^+ \times G^+, \\ \\ M(t,\hat{x},2(1-\varepsilon)z - 2\varepsilon + 1) \ \text{ in } \mathbb{R}^+ \times G^-. \end{cases} \tag{3.3}$$

We also define the rescaled exchange coefficient a^ε by

$$a^\varepsilon(\hat{x},z) = \begin{cases} A(\hat{x},2(1-\varepsilon)z + 2\varepsilon - 1) \ \text{ in } G^+, \\ \\ A(\hat{x},2(1-\varepsilon)z - 2\varepsilon + 1) \ \text{ in } G^-. \end{cases} \tag{3.4}$$

We assume that $A \in L^\infty(B, C^0([-1,1]))$. Note that a^ε satisfies the coerciveness condition (2.2).

We also introduce the slabs of $\mathbb{R}^3$,

$$\begin{cases} S^- = \mathbb{R}^2 \times (-1,-1/2),\ S^0 = \mathbb{R}^2 \times (-1/2,1/2),\ S^+ = \mathbb{R}^2 \times (1/2,1), \\ \\ S^\infty = \mathbb{R}^2 \times (1,\infty) \text{ and } S^{+,\infty} = \mathbb{R}^2 \times (1/2,\infty),\ S^{-,\infty} = \mathbb{R}^2 \times (-1,\infty), \end{cases} \tag{3.5}$$

and for $(t,\hat{x},z) \in \mathbb{R}^+ \times \mathbb{R}^3_+$ the functions

$$\phi^\varepsilon(t,\hat{x},z) = \begin{cases} \varphi(t,\hat{x},z) \ \text{ if } z \geq 1, \\ \\ \varphi(t,\hat{x},2(1-\varepsilon)z + 2\varepsilon - 1) \ \text{ if } \dfrac{1}{2} \leq z \leq 1, \\ \\ \varphi(t,\hat{x},2\varepsilon z) \ \text{ if } -\dfrac{1}{2} \leq z \leq \dfrac{1}{2}, \\ \\ \varphi(t,\hat{x},2(1-\varepsilon)z - 2\varepsilon + 1) \ \text{ if } -1 \leq z \leq -\dfrac{1}{2}. \end{cases} \tag{3.6}$$

We finally define $\sigma^\varepsilon(z)$ and $\nu^\varepsilon(z)$ by setting

$$\sigma^\varepsilon(z) = \begin{cases} 1 \ \text{ if } z \geq 1, \\ \\ \dfrac{1}{4(1-\varepsilon)^2} \ \text{ if } \ -1 \leq z \leq -\dfrac{1}{2} \ \text{ or } \ \dfrac{1}{2} < z < 1, \\ \\ \dfrac{1}{4\varepsilon^2} \text{ if } -\dfrac{1}{2} \leq z \leq \dfrac{1}{2} \end{cases} \tag{3.7}$$

and

$$\nu^\varepsilon(z) = \begin{cases} 0 \ \text{ if } \ -\dfrac{1}{2} < z < \dfrac{1}{2} \text{ or } z \geq 1, \\ \\ \dfrac{1}{2(1-\varepsilon)} \ \text{ if } \dfrac{1}{2} \leq z \leq 1 \text{ or } -1 \leq z \leq -\dfrac{1}{2}. \end{cases} \tag{3.8}$$

The potential ϕ^ε satisfies in $\mathbb{R}^+ \times S^{-,\infty}$ the equations

$$\begin{cases} \widehat{\operatorname{div}}\Big(\widehat{\operatorname{grad}}\,\phi^\varepsilon + \chi(G)\widehat{m}^\varepsilon\Big) + \partial_z(\sigma^\varepsilon \partial_z \phi^\varepsilon + \nu^\varepsilon \chi(G) m^\varepsilon \cdot \mathbf{u}_3) = 0, \\ \\ \dfrac{1}{2(1-\varepsilon)} \partial_z \phi^\varepsilon + \chi(B) m^\varepsilon \cdot \mathbf{u}_3 = 0 \quad \text{at } z = -1, \end{cases} \tag{3.9}$$

with the usual transmission boundary conditions at the interfaces $z = 1$ and $z = \pm 1/2$. The operators $\widehat{\mathrm{div}}$ and $\widehat{\mathrm{grad}}$ represent the divergence and the gradient operators, respectively, with respect to the variable $\hat{x}$ and $\widehat{m} = (m_1, m_2, 0)$, where (m_1, m_2) are the first two components of m. The vector $\widehat{\mathrm{grad}}\,\phi$ may also be considered as a 2-D vector or a 3-D vector where the third component is 0.

The magnetic excitation $\mathcal{H}$ defined in G by (1.2) becomes

$$\begin{aligned}\mathcal{H}^\varepsilon(m^\varepsilon) &= \widehat{\mathrm{div}}(a^\varepsilon \widehat{\mathrm{grad}}\, m^\varepsilon) + \frac{1}{4(1-\varepsilon)^2}\partial_z(a^\varepsilon \partial_z m^\varepsilon) \\ &\quad + \psi(m^\varepsilon) + \widehat{\mathrm{grad}}\,\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\partial_z \phi^\varepsilon \mathbf{u}_3,\end{aligned} \tag{3.10}$$

and the interlayer exchange boundary condition takes the form

$$m^\varepsilon(\pm 1/2) \times \left(\mp \frac{a^\varepsilon}{2(1-\varepsilon)} \partial_z m^\varepsilon(\pm 1/2) - J m^\varepsilon(\mp 1/2) \right) = 0. \tag{3.11}$$

The Landau–Lifshitz equations are rewritten in the same form as (1.1), and the effective magnetic field is denoted by $\mathcal{H}^\varepsilon(m^\varepsilon)$.

Global existence of solutions $(m^\varepsilon, \phi^\varepsilon)$ of the new system is guaranteed by Theorem 2.2 proved in section 2. We shall describe the behavior of such solutions first when $\varepsilon \to 0$ (the thin nonmagnetic case), and then when $\varepsilon \to 1$ (the thick nonmagnetic case).

3.1. Asymptotic behavior with thin nonmagnetic spacers. We investigate here the case when $\varepsilon \to 0$. The energy estimate (2.11) satisfied by the solutions becomes

$$\mathcal{E}^\varepsilon(t) + \frac{2\alpha}{1+\alpha^2} \int_0^t \int_G |\partial_t m^\varepsilon(s)|^2 \, dx ds = \mathcal{E}^\varepsilon(0), \tag{3.12}$$

where the total energy $\mathcal{E}^\varepsilon(t)$ is expressed by $\mathcal{E}^\varepsilon(t) = \mathcal{E}^\varepsilon_{exc}(t) + \mathcal{E}^\varepsilon_{vol}(t) + \mathcal{E}^\varepsilon_{dm}(t) + \mathcal{E}^\varepsilon_{int}(t)$ with

$$\begin{cases} \mathcal{E}^\varepsilon_{exc}(t) = \displaystyle\int_G a^\varepsilon |\widehat{\mathrm{grad}}\, m^\varepsilon|^2 \, dx + \frac{1}{4(1-\varepsilon)^2} \int_G a^\varepsilon |\partial_z m^\varepsilon|^2 \, dx, \\ \mathcal{E}^\varepsilon_{vol}(t) = \displaystyle\int_G \Psi(m^\varepsilon) \, dx, \\ \mathcal{E}^\varepsilon_{int}(t) = -\dfrac{J}{2(1-\varepsilon)} \displaystyle\int_B m^\varepsilon \left(-\frac{1}{2}\right) \cdot m^\varepsilon \left(\frac{1}{2}\right) \, d\hat{x}, \\ \mathcal{E}^\varepsilon_{dm}(t) = \displaystyle\int_{S^{-,\infty}} |\widehat{\mathrm{grad}}\,\phi^\varepsilon|^2 \, dx + \int_{S^{-,\infty}} \sigma^\varepsilon |\partial_z \phi^\varepsilon|^2 \, dx, \end{cases} \tag{3.13}$$

where $\sigma^\varepsilon(z)$ is defined by (3.7) and $a^\varepsilon(\hat{x}, z)$ is defined in G by (3.4).

Let us discuss the uniform boundedness with respect to ε of the initial energy $\mathcal{E}^\varepsilon(0)$. We assume that the initial magnetization m_0^ε is independent of the variable z and is such that $m_0^\varepsilon(\hat{x})$ is uniformly bounded in $\mathbb{H}^1(B)$. It follows that $\partial_z m_0^\varepsilon = 0$ and then $\mathcal{E}^\varepsilon_{exc}(0) = \int_G a^\varepsilon |\widehat{\mathrm{grad}}\, m_0^\varepsilon|^2 \, dx \le C$, where $C > 0$ is independent of ε since, by (2.2), we have $0 < a_1 \le a^\varepsilon(\hat{x}, z) \le a_2$ for almost every $(\hat{x}, z)$. We may weaken this hypothesis if we assume, for example, that $m_0^\varepsilon(\hat{x}, z) = m_0(\hat{x}, (1-\varepsilon)z)$ but, to simplify the presentation, we use our strong hypothesis on m_0^ε. Next, we have $\mathcal{E}^\varepsilon_{vol}(0) \le C$ and

$|\mathcal{E}^\varepsilon_{int}(0)| = \frac{J}{2(1-\varepsilon)}|B| \le C$, where $C > 0$ is independent of ε. It remains to consider the initial potential $\phi^\varepsilon_0 = \phi^\varepsilon_{|t=0}$, which satisfies the equation

$$\begin{cases} \widehat{\operatorname{div}}(\widehat{\operatorname{grad}}\,\phi^\varepsilon_0 + \chi(G)\widehat{m}^\varepsilon_0) + \partial_z(\sigma^\varepsilon\partial_z\phi^\varepsilon_0 + \nu^\varepsilon\chi(G)m^\varepsilon_0\cdot\mathbf{u}_3) = 0 \quad \text{in} \quad S^{-,\infty}, \\ \dfrac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon_0 + \chi(B)m^\varepsilon_0\cdot\mathbf{u}_3 = 0 \ \text{ at } \ z=-1. \end{cases} \tag{3.14}$$

In what follows we denote by $C > 0$ various constants which are independent of ε. The energy relation associated with (3.14) is

$$\begin{aligned} &\int_{S^{-,\infty}} |\widehat{\operatorname{grad}}\,\phi^\varepsilon_0|^2\,dx + \int_{S^{-,\infty}} \sigma^\varepsilon|\partial_z\phi^\varepsilon_0|^2\,dx = \\ &\qquad = -\int_G \widehat{m}^\varepsilon_0\cdot\widehat{\operatorname{grad}}\,\phi^\varepsilon_0\,dx - \frac{1}{2(1-\varepsilon)}\int_G m^\varepsilon_0\cdot\mathbf{u}_3\partial_z\phi^\varepsilon_0\,dx, \end{aligned} \tag{3.15}$$

which, by the Cauchy–Schwarz inequality, gives the estimate

$$\mathcal{E}^\varepsilon_{dm}(0) \le 2|G|. \tag{3.16}$$

The above results can be stated as follows.

LEMMA 3.1. *Let $m^\varepsilon_0(\hat{x},z) = m^\varepsilon_0(\hat{x}) \in \mathbb{H}^1(B)$ such that $\|m^\varepsilon_0\|_{\mathbb{H}^1(B)} \le C$ and $|m^\varepsilon_0(\hat{x})|^2 = 1$ a.e. Then there exists a $C > 0$ independent of ε such that the initial energy $\mathcal{E}^\varepsilon(0) = \mathcal{E}^\varepsilon_0$ satisfies the estimate*

$$0 \le \mathcal{E}^\varepsilon_0 \le C. \tag{3.17}$$

From (3.12) and Lemma 3.1 we deduce the following uniform bounds.

LEMMA 3.2. *Under the hypotheses of Lemma* 3.1, *it holds that*

$$\begin{cases} |\operatorname{grad} m^\varepsilon|_{L^\infty(\mathbb{R}^+,\mathbb{L}^2(G))} + |\partial_t m^\varepsilon|_{L^2(\mathbb{R}^+,\mathbb{L}^2(G))} \le C, \\ |\widehat{\operatorname{grad}}\,\phi^\varepsilon|_{L^\infty(\mathbb{R}^+,\mathbb{L}^2(S^{-,\infty}))} + |\partial_z\phi^\varepsilon|_{L^\infty(\mathbb{R}^+,L^2(S^{-,\infty}\setminus S^0))} \le C, \\ |\partial_z\phi^\varepsilon|_{L^\infty(\mathbb{R}^+,L^2(S^0))} \le C\ \varepsilon. \end{cases} \tag{3.18}$$

For a subsequence still denoted $(m^\varepsilon,\phi^\varepsilon)$ we deduce the convergences

$$\begin{cases} m^\varepsilon \rightharpoonup m \text{ weakly}-\star \ \text{ in } L^\infty(\mathbb{R}^+,\mathbb{H}^1(G))\cap\mathbb{L}^\infty(\mathbb{R}^+\times G), \\ \partial_t m^\varepsilon \rightharpoonup \partial_t m \text{ weakly } \ \text{in } L^2(\mathbb{R}^+,\mathbb{L}^2(G)), \\ m^\varepsilon \to m \text{ strongly } \ \text{in } L^2_{\text{loc}}(\mathbb{R}^+,\mathbb{L}^2(G)); \end{cases} \tag{3.19}$$

the last strong convergence is a consequence of the classical use of Aubin's compactness lemma. For the magnetic field we have

$$\begin{cases} \widehat{\operatorname{grad}}\,\phi^\varepsilon \rightharpoonup \widehat{\operatorname{grad}}\,\phi \text{ weakly}-\star \text{ in } L^\infty(\mathbb{R}^+,\mathbb{L}^2(S^{-,\infty})), \\ \partial_z\phi^\varepsilon \rightharpoonup \partial_z\phi \text{ weakly}-\star \ \text{ in } L^\infty(\mathbb{R}^+,L^2(S^{-,\infty}\setminus S^0)), \\ \partial_z\phi^\varepsilon \to \partial_z\phi = 0 \text{ strongly } \ \text{in } L^\infty(\mathbb{R}^+,L^2(S^0)), \\ \Theta^\varepsilon := \dfrac{1}{2\varepsilon}\partial_z\phi^\varepsilon \rightharpoonup 0 \text{ weakly}-\star \ \text{ in } L^\infty(\mathbb{R}^+,L^2(S^0)). \end{cases} \tag{3.20}$$

Indeed, the potential ϕ^ε converges weakly-$\star$ to ϕ in $L^\infty(\mathbb{R}^+, H^1_\rho(S^{-,\infty}))$, where $H^1_\rho(S^{-,\infty}) = \{g \in \mathcal{D}'(S^{-,\infty}),\ \operatorname{grad} g \in \mathbb{L}^2(S^{-,\infty}), \text{and } \rho g \in L^2(S^{-,\infty})\}$ denotes the weighted Sobolev space with $\rho(x) = (1+|\hat{x}|+|z|)^{-1}$. This space describes the behavior, when $|x| \to \infty$, of the potentials ϕ^ε and ϕ. In particular, ϕ^ε converges to ϕ weakly-$\star$ in $L^\infty(\mathbb{R}^+, L^2_{\rm loc}(S^{-,\infty}))$.

We prove the last assertion of (3.20). We multiply (3.9) first by 2ε then by $g \in \mathcal{D}(\mathcal{O})$ with $\mathcal{O} = \mathbb{R}^+ \times S^{-,\infty}$. Integrating by parts, we get

$$\begin{aligned} 2\varepsilon \left(\int_{\mathcal{O}} \widehat{\operatorname{grad}}\, \phi^\varepsilon \widehat{\operatorname{grad}}\, g \; dxdt + \int_{\mathcal{O}\setminus(\mathbb{R}^+\times S^0)} \sigma^\varepsilon \partial_z \phi^\varepsilon \partial_z g \; dxdt \right) + \int_{\mathbb{R}^+\times S^0} \Theta^\varepsilon \partial_z g \; dxdt \\ = -2\varepsilon \int_{\mathbb{R}^+\times G} \Big(\widehat{m}^\varepsilon \cdot \widehat{\operatorname{grad}}\, g + \nu^\varepsilon m^\varepsilon \cdot \mathbf{u}_3 \partial_z g \Big) dxdt. \end{aligned} \tag{3.21}$$

Hence, passing to the limit, we deduce that the weak-$\star$ limit Θ of the sequence Θ^ε satisfies $\partial_z \Theta = 0$. Then Θ is independent of the variable z, and since $\Theta \in L^\infty(\mathbb{R}^+, \mathbb{L}^2(S^0))$ and $S^0 = \mathbb{R}^2 \times (-1/2, 1/2)$, we get $\Theta = 0$. The following theorem gives a characterization of the potential ϕ.

THEOREM 3.3. *Let ϕ be the weak-$\star$ limit in $L^\infty(\mathbb{R}^+, H^1_\rho(S^{-,\infty}))$ of the sequence ϕ^ε. Let ϕ^+ and ϕ^- be the restrictions of ϕ to $\mathbb{R}^+ \times S^{+,\infty}$ and $\mathbb{R}^+ \times S^-$, respectively. Then $(\phi^+, \phi^-) \in L^\infty(\mathbb{R}^+, H^1_\rho(S^{+,\infty}) \times H^1_\rho(S^-))$ satisfies the coupled magnetostatic equations*

$$\begin{cases} \widehat{\operatorname{div}} \left(\widehat{\operatorname{grad}}\, \phi^+ + \chi(G^+) \widehat{m}^+ \right) + \partial_z \left(\sigma(z) \partial_z \phi^+ + \nu(z) \chi(G^+) m^+ \cdot \mathbf{u}_3 \right) = 0 \text{ in } \mathbb{R}^+ \times S^{+,\infty}, \\ \widehat{\operatorname{div}} \left(\widehat{\operatorname{grad}}\, \phi^- + \chi(G^-) \widehat{m}^- \right) + \partial_z \left(\dfrac{1}{4} \partial_z \phi^- + \dfrac{1}{2} \chi(G^-) m^- \cdot \mathbf{u}_3 \right) = 0 \ \text{ in } \mathbb{R}^+ \times S^-, \\ \partial_z \phi^+(1^-) + 2\chi(B) m(1^-) \cdot \mathbf{u}_3 = 4 \partial_z \phi^+(1^+), \\ \partial_z \phi^-(-1) + 2\chi(B) m^-(-1) \cdot \mathbf{u}_3 = 0 \end{cases} \tag{3.22}$$

and the coupling relations

$$\begin{cases} \phi^-(-1/2) = \phi^+(1/2), \\ (\partial_z \phi^+ + 2\chi(B) m^+ \cdot \mathbf{u}_3)_{|z=1/2} - (\partial_z \phi^- + 2\chi(B) m^- \cdot \mathbf{u}_3)_{|z=-1/2} = -4\ \widehat{\Delta} \phi^+(1/2), \end{cases} \tag{3.23}$$

where $m^\pm$ is the restriction of m to $G^\pm$. The restriction ϕ^0 of ϕ to $\mathbb{R}^+ \times S^0$ is independent of the variable z and is given by

$$\phi^0(t, \hat{x}) = \phi^-(t, \hat{x}, -1/2) = \phi^+(t, \hat{x}, 1/2) \text{ a.e.} \tag{3.24}$$

Proof. In $\mathbb{R}^+ \times S^0$ the function Θ^ε defined in (3.20) satisfies

$$\partial_z \Theta^\varepsilon = -2\varepsilon \widehat{\Delta} \phi^\varepsilon. \tag{3.25}$$

It follows that $\partial_z \Theta^\varepsilon$ is uniformly bounded in $L^\infty(\mathbb{R}^+, L^2(-1/2, 1/2; H^{-1}_{\rm loc}(\mathbb{R}^2)))$. Then Θ^ε belongs to the space $L^\infty(\mathbb{R}^+, H^1(-1/2, 1/2; H^{-1}_{\rm loc}(\mathbb{R}^2)))$. Using the trace theorems, it follows that $\Theta^\varepsilon(\pm 1/2^\pm)$ is well defined in $L^\infty(\mathbb{R}^+, H^{-1}_{\rm loc}(\mathbb{R}^2))$. Moreover, thanks to the convergences (3.19)–(3.20), we deduce that $\Theta^\varepsilon \rightharpoonup 0$ weakly-$\star$ in

$L^\infty(\mathbb{R}^+, H^1(-1/2, 1/2; H^{-1}_{\rm loc}(\mathbb{R}^2)))$. Consequently, we obtain $\Theta^\varepsilon(\pm 1/2^\pm) \rightharpoonup 0$ weakly-$\star$. Hence, we get, at least in the sense of distributions, the following convergence:

$$\frac{1}{2\varepsilon}\partial_z\phi^\varepsilon(\pm 1/2^\pm) \rightharpoonup 0. \tag{3.26}$$

Let us consider problem (3.9). Using test functions $g(t,\hat{x},z)$ first in $\mathcal{D}(\mathbb{R}^+\times S^{+,\infty})$ then in $\mathcal{D}(\mathbb{R}^+ \times S^-)$ and taking into account the convergences of (3.19)–(3.20), it is easy to see that ϕ^+ and ϕ^- satisfy, in the sense of distributions, the following equations:

$$\widehat{\rm div}\left(\widehat{\rm grad}\,\phi^+ + \chi(G^+)\widehat{m}^+\right) + \partial_z\left(\sigma(z)\partial_z\phi^+ + \nu(z)\chi(G^+)m^+\cdot\mathbf{u}_3\right) = 0 \tag{3.27}$$

in $\mathbb{R}^+ \times S^{+,\infty}$, where $\sigma(z) = 1$, $\nu(z) = 0$ if $z > 1$ and $\sigma(z) = 1/4$, $\nu(z) = 1/2$ if $1/2 < z < 1$, and

$$\begin{aligned}\widehat{\rm div}\left(\widehat{\rm grad}\,\phi^- + \chi(G^-)\widehat{m}^-\right) + \partial_z\left(\frac{1}{4}\partial_z\phi^- + \frac{1}{2}\chi(G^-)m^-\cdot\mathbf{u}_3\right) = 0 \ \text{ in } \mathbb{R}^+\times S^-,\\ \partial_z\phi^- + 2\chi(B)m^-\cdot\mathbf{u}_3 = 0 \quad \text{at } z=-1.\end{aligned}$$

It remains to couple this set of equations. Let ϕ^0 be the restriction of ϕ to $\mathbb{R}^+\times S^0$. We have shown that ϕ^0 is independent of the variable z in the domain S^0. The transmission boundary conditions satisfied by ϕ^ε at the interfaces $z = \pm 1/2$ and $z = 1$ are the following:

$$\begin{aligned}&\left[\sigma^\varepsilon\partial_z\phi^\varepsilon + \nu^\varepsilon\chi(B)m^\varepsilon\cdot\mathbf{u}_3\right]_{z=\pm 1/2} = \left[\sigma^\varepsilon\partial_z\phi^\varepsilon + \nu^\varepsilon\chi(B)m^\varepsilon\cdot\mathbf{u}_3\right]_{z=1} = 0,\\ &\left[\phi^\varepsilon\right]_{z=\pm 1/2} = \left[\phi^\varepsilon\right]_{z=1} = 0.\end{aligned} \tag{3.28}$$

In (3.28), [ ] denotes the jump across the interfaces. Passing to the limit in the continuity condition of ϕ^ε at the interfaces $z = \pm 1/2$, we get the result

$$\phi^0(t,\hat{x}) = \phi^-(t,\hat{x},-1/2) = \phi^+(t,\hat{x},1/2) \text{ a.e.} \tag{3.29}$$

Since ϕ^0 is independent of the variable z in the domain $\mathbb{R}^+\times S^0$, we use, in the weak formulation of (3.9), test functions $g \in \mathcal{D}(\mathbb{R}^+\times\mathbb{R}^2)$, which are independent of the variable z. An integration by parts gives

$$\begin{aligned}&\int_{\mathbb{R}^+\times S^0}\widehat{\rm grad}\,\phi^\varepsilon\widehat{\rm grad}\,g\ dxdt\\ &= \int_{\mathbb{R}^+\times\mathbb{R}^2}\left(\frac{1}{4\varepsilon^2}\partial_z\phi^\varepsilon(1/2^-) - \frac{1}{4\varepsilon^2}\partial_z\phi^\varepsilon(-1/2^+)\right)g(t,\hat{x})\ d\hat{x}dt.\end{aligned} \tag{3.30}$$

From (3.28) we can write that

$$\begin{aligned}\frac{1}{\varepsilon^2}\partial_z\phi^\varepsilon(1/2^-) &= \frac{1}{(1-\varepsilon)^2}\partial_z\phi^\varepsilon(1/2^+) + \frac{2}{(1-\varepsilon)}\chi(B)m^\varepsilon(1/2^+)\cdot\mathbf{u}_3,\\ \frac{1}{\varepsilon^2}\partial_z\phi^\varepsilon(-1/2^+) &= \frac{1}{(1-\varepsilon)^2}\partial_z\phi^\varepsilon(-1/2^-) + \frac{2}{(1-\varepsilon)}\chi(B)m^\varepsilon(-1/2^-)\cdot\mathbf{u}_3;\end{aligned} \tag{3.31}$$

then we replace (3.31) in (3.30). We pass to the limit in (3.30) by using the fact that $\partial_z\phi^\varepsilon(\pm 1/2^\pm)$ converges to $\partial_z\phi^\pm(\pm 1/2^\pm)$ in the sense of distributions. We get the

equation

$$\int_{\mathbb{R}^+\times\mathbb{R}^2} \widehat{\operatorname{grad}}\,\phi^0\ \widehat{\operatorname{grad}}\,g\ d\hat{x}dt = \int_{\mathbb{R}^+\times\mathbb{R}^2} \left[\left(\frac{1}{4}\partial_z\phi^+(1/2) + \frac{1}{2}\chi(B)m^+(1/2)\cdot\mathbf{u}_3\right)\right.$$
$$\left. - \left(\frac{1}{4}\partial_z\phi^-(-1/2) + \frac{1}{2}\chi(B)m^-(-1/2)\cdot\mathbf{u}_3\right)\right] g\ d\hat{x}dt. \tag{3.32}$$

This result implies, after an integration by parts, the equation

$$\begin{cases} 4\widehat{\Delta}\phi^0 + \Big[(\partial_z\phi^+(1/2) + 2\chi(B)m^+(1/2)) \\ \qquad -(\partial_z\phi^-(-1/2) + 2\chi(B)m^-(-1/2)\cdot\mathbf{u}_3)\Big] = 0 \ \text{ in } \mathbb{R}^+\times\mathbb{R}^2. \end{cases} \tag{3.33}$$

Finally, using (3.29), we get the coupling boundary condition

$$(\partial_z\phi^+(1/2) + 2\chi(B)m^+(1/2)) - (\partial_z\phi^-(-1/2) + 2\chi(B)m(-1/2)\cdot\mathbf{u}_3)$$
$$= -4\widehat{\Delta}\phi^+(1/2) = -4\widehat{\Delta}\phi^-(-1/2). \tag{3.34}$$

We conclude the proof of the theorem by passing to the limit in the transmission boundary condition at the interface $z = 1$. We get

$$\partial_z\phi^+(1^-) + 2\chi(B)m(1^-)\cdot\mathbf{u}_3 = 4\partial_z\phi^+(1^+). \tag{3.35}$$

The proof of the theorem is then complete. □

We now are able to pass to the limit in Landau–Lifshitz equations. Let $F \in \mathcal{D}(Q)$ be a test function where $Q = \mathbb{R}^+\times\Omega$ and $\Omega = B\times(-1,1)$. The following weak formulation is associated with Landau–Lifshitz equations:

$$\begin{cases} \dfrac{1}{1+\alpha^2}\displaystyle\int_Q \chi(G)(\partial_t m^\varepsilon - \alpha m^\varepsilon\times\partial_t m^\varepsilon)F\ dxdt \\ = \displaystyle\int_Q \chi(G)m^\varepsilon\times a^\varepsilon\widehat{\operatorname{grad}}\,m^\varepsilon\widehat{\operatorname{grad}}\,F\ dxdt \\ + \dfrac{1}{4(1-\varepsilon)^2}\displaystyle\int_Q \chi(G)m^\varepsilon\times a^\varepsilon\partial_z m^\varepsilon\partial_z F\ dxdt \\ - \displaystyle\int_Q \chi(G)m^\varepsilon\times\Big(\psi(m^\varepsilon) + \widehat{\operatorname{grad}}\,\phi^\varepsilon + \dfrac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon\mathbf{u}_3\Big)F\ dxdt \\ - \dfrac{J}{2(1-\varepsilon)}\displaystyle\int_{\mathbb{R}^+\times B} m^\varepsilon(1/2^+)\times m^\varepsilon(-1/2^-)\Big(F(1/2^+) - F(-1/2^-)\Big)\ d\hat{x}dt, \end{cases} \tag{3.36}$$

where we set $G = G^+\cup G^-$. By the definition of a^ε (see (3.4)) we have the convergence

$$a^\varepsilon \to a \quad \text{a.e.}, \tag{3.37}$$

where

$$a(\hat{x},z) = \begin{cases} A(\hat{x},2z+1) & \text{in } G^-, \\ A(\hat{x},2z-1) & \text{in } G^+. \end{cases} \tag{3.38}$$

This result and (3.19)–(3.20) give the following result.

THEOREM 3.4. *Let $(m^\varepsilon, \phi^\varepsilon)$ be a global solution of problem* (1.1) *with* (3.9)–(3.10) *satisfying the interlayer exchange boundary condition* (3.11). *Let (m, ϕ) be the weak-$\star$ limit of a subsequence of $(m^\varepsilon, \phi^\varepsilon)$. Then (m, ϕ) satisfies in $\mathbb{R}^+ \times G$ the equations*

$$\begin{cases} \partial_t m - \alpha m \times \partial_t m = -(1+\alpha^2) m \times \mathcal{H}_0(m) \ \text{ in } \mathbb{R}^+ \times (G^- \cup G^+), \\ m(0,x) = m_0(x), \qquad \dfrac{\partial m}{\partial n} = 0 \text{ on } \partial\Omega \setminus \{z = \pm 1/2\}, \\ m(\pm 1/2) \times \Big(\mp a \partial_z m(\pm 1/2) - 2Jm(\mp 1/2) \Big) = 0 \text{ in } B, \\ \mathcal{H}_0(m) = \widehat{\operatorname{div}}(a\ \widehat{\operatorname{grad}}\, m) + \dfrac{1}{4}\partial_z(a\ \partial_z m) + \psi(m) + \widehat{\operatorname{grad}}\, \phi + \dfrac{1}{2}\partial_z \phi\ \mathbf{u}_3 \ \text{ in } G, \end{cases}$$

where ϕ is the solution of the magnetostatic equations (3.22)–(3.23).

Remark. Notice that the potential ϕ solves the magnetostatic equations in the disjoint domains S^- and $S^{+,\infty}$. These domains are coupled together by a Ventcel-type boundary condition given in Theorem 3.3 linking the interfaces $z = -1/2$ and $z = 1/2$. The magnetization m satisfies the Hoffmann IEC law with the coefficient $2J$ instead of J due to the change of variable used.

3.2. Asymptotic behavior with large nonmagnetic spacers. The aim of this subsection is to discuss the behavior of the problem when $\varepsilon \to 1$. The estimates satisfied by the solutions $(m^\varepsilon, \phi^\varepsilon)$ are given by the energy estimate (3.12)–(3.13). Let us discuss the admissibility criterion for the initial data m_0^ε. The compatibility condition for ϕ_0^ε is given by (3.14). The condition that m_0^ε is independent of the variable $z \in G$ ensures that $\mathcal{E}_{exc}^\varepsilon(0) \le C$ and $\mathcal{E}_{int}^\varepsilon(0) = -\frac{J}{2(1-\varepsilon)}|B|$. Since we have $\mathcal{E}_{vol}^\varepsilon(0) \le C$, it remains to show that under this condition on m_0^ε we have $\mathcal{E}_{dm}^\varepsilon(0) \le C$ uniformly with respect to ε. This follows from estimates (3.15)–(3.16). As in subsection 3.1, $C > 0$ denotes various constants which are independent of ε.

LEMMA 3.5. *Let $m_0^\varepsilon \in \mathbb{H}^1(B)$ such that m_0^ε is uniformly bounded in $\mathbb{H}^1(B)$ and satisfies $|m_0^\varepsilon(\hat{x})|^2 = 1$ a.e. in B. Then we have*

$$\mathcal{E}_{exc}^\varepsilon(0) + \mathcal{E}_{vol}^\varepsilon(0) + \mathcal{E}_{dm}^\varepsilon(0) \le C, \qquad |\mathcal{E}_{int}^\varepsilon(0)| \le C\frac{J}{1-\varepsilon}. \tag{3.39}$$

Moreover, the solutions $(m^\varepsilon, \phi^\varepsilon)$ associated with m_0^ε satisfy, for all $t \ge 0$, the estimates

$$0 \le \mathcal{E}_{exc}^\varepsilon(t) + \mathcal{E}_{vol}^\varepsilon(t) + \mathcal{E}_{dm}^\varepsilon(t) \le C\left(1 + \frac{J}{1-\varepsilon}\right), \qquad |\mathcal{E}_{int}^\varepsilon(t)| \le C\left(1 + \frac{J}{1-\varepsilon}\right). \tag{3.40}$$

In what follows this subsection, we assume that the interlayer exchange coefficient J satisfies the hypothesis

$$J = j(1-\varepsilon),\ j > 0, \tag{3.41}$$

where j is independent of ε.

The energy estimate (3.12) and (3.13) imply the following uniform bounds.

LEMMA 3.6. *Under the hypotheses of Lemma* 3.5 *and* (3.40), *the solutions*

$(m^\varepsilon, \phi^\varepsilon)$ satisfy the following estimates:

$$\begin{cases} |\widehat{\operatorname{grad}} m^\varepsilon|_{L^\infty(\mathbb{R}^+,\mathbb{L}^2(G))} + |\partial_t m^\varepsilon|_{L^2(\mathbb{R}^+,\mathbb{L}^2(G))} \le C, \\ |\widehat{\operatorname{grad}} \phi^\varepsilon|_{L^\infty(\mathbb{R}^+,\mathbb{L}^2(S^{-,\infty}))} + |\partial_z \phi^\varepsilon|_{L^\infty(\mathbb{R}^+,L^2(S^0\cup S^\infty))} \le C, \\ |\partial_z m^\varepsilon|_{L^\infty(\mathbb{R}^+,\mathbb{L}^2(G))} + |\partial_z \phi^\varepsilon|_{L^\infty(\mathbb{R}^+,L^2(S^-\cup S^+))} \le C(1-\varepsilon). \end{cases} \tag{3.42}$$

There exists a subsequence still denoted $(m^\varepsilon, \phi^\varepsilon)$ such that the following convergences hold:

$$\begin{cases} m^\varepsilon \rightharpoonup m \text{ weakly}-\star \text{ in } L^\infty(\mathbb{R}^+, \mathbb{H}^1(G)) \cap \mathbb{L}^\infty(\mathbb{R}^+ \times G), \\ \partial_t m^\varepsilon \rightharpoonup \partial_t m \text{ weakly in } L^2(\mathbb{R}^+, \mathbb{L}^2(G)), \\ \partial_z m^\varepsilon \to 0 \text{ strongly in } L^\infty(\mathbb{R}^+, \mathbb{L}^2(G)), \\ m^\varepsilon \to m \text{ strongly in } L^2_{\mathrm{loc}}(\mathbb{R}^+, \mathbb{L}^2(G)) \end{cases} \tag{3.43}$$

and

$$\begin{cases} \widehat{\operatorname{grad}} \phi^\varepsilon \rightharpoonup \widehat{\operatorname{grad}} \phi \text{ weakly}-\star \text{ in } L^\infty(\mathbb{R}^+, \mathbb{L}^2(S^{-,\infty})), \\ \partial_z \phi^\varepsilon \to 0 \text{ strongly in } L^\infty(\mathbb{R}^+, L^2(S^- \cup S^+)), \\ \partial_z \phi^\varepsilon \rightharpoonup \partial_z \phi \text{ weakly}-\star \text{ in } L^\infty(\mathbb{R}^+, L^2(S^0 \cup S^\infty)). \end{cases} \tag{3.44}$$

Let us first consider the behavior of the potential ϕ^ε when $\varepsilon \to 1$. We have the following characterization of the potential limit ϕ.

We denote by ϕ^-, ϕ^0, ϕ^+, and ϕ^∞ the restrictions of ϕ to the domains $\mathbb{R}^+ \times S^-$, $\mathbb{R}^+ \times S^0$, $\mathbb{R}^+ \times S^+$, and $\mathbb{R}^+ \times S^\infty$, respectively, and $m^\pm$ the restriction of m to $\mathbb{R}^+ \times G^\pm$. Notice that $\phi^\pm$ and $m^\pm$ are independent of the variable z.

THEOREM 3.7. *We assume that the hypotheses of Lemma* 3.6 *are fulfilled. Let ϕ^ε be the solution of* (3.9) *and ϕ its weak-$\star$ limit. Then we have*

$$\begin{cases} \phi^+(\hat{x}) = \phi^\infty(\hat{x}, 1) = \phi^0(\hat{x}, 1/2) \text{ a.e.}, \\ \phi^-(\hat{x}) = \phi^0(\hat{x}, -1/2) \text{ a.e.} \end{cases} \tag{3.45}$$

Moreover, the couple (ϕ^∞, ϕ^0) satisfies, for all $t \ge 0$, the problem

$$\begin{cases} \widehat{\Delta} \phi^\infty + \partial_z^2 \phi^\infty = 0 \text{ in } \mathbb{R}^+ \times S^\infty, \\ \widehat{\Delta} \phi^0 + \dfrac{1}{4} \partial_z^2 \phi^0 = 0 \text{ in } \mathbb{R}^+ \times S^0, \end{cases} \tag{3.46}$$

with the coupling boundary conditions

$$\begin{cases} \phi^\infty(1) = \phi^0(1/2), \\ \partial_z \phi^\infty(1) - \dfrac{1}{4} \partial_z \phi^0(1/2) = -\dfrac{1}{2} \widehat{\operatorname{div}}(\widehat{\operatorname{grad}} \phi^\infty(1) + \chi(B) \widehat{m}^+), \\ \partial_z \phi^0(-1/2) = -2 \widehat{\operatorname{div}}(\widehat{\operatorname{grad}} \phi^0(-1/2) + \chi(B) \widehat{m}^-). \end{cases} \tag{3.47}$$

Furthermore, setting $\Theta_\varepsilon^\pm = \frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon_{|S^\pm}$ *the restriction to* $\mathbb{R}^+ \times S^\pm$*, we have the convergence*

$$\Theta_\varepsilon^\pm \rightharpoonup -\chi(G^\pm)m^\pm \cdot \mathbf{u}_3 \text{ weakly}-\star \text{ in } L^\infty(\mathbb{R}^+, L^2(S^\pm)). \tag{3.48}$$

Proof. Estimates (3.43) and (3.44) show that the restriction of ϕ to $\mathbb{R}^+ \times S^\pm$ and the magnetization m are independent of the variable z. We shall pass to the limit in each slab where the potential ϕ^ε is defined.

In the domains $\mathbb{R}^+ \times S^\pm$, the potential ϕ^ε satisfies the equation

$$\partial_z\left(\frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon + \chi(G^\pm)m^\varepsilon \cdot \mathbf{u}_3\right) = -2(1-\varepsilon)\ \widehat{\operatorname{div}}\Big(\widehat{\operatorname{grad}}\,\phi^\varepsilon + \chi(G^\pm)\widehat{m}^\varepsilon\Big). \tag{3.49}$$

Let $\Theta_\varepsilon^\pm = \frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon_{|S^\pm}$ be defined as previously. By Lemma 3.6, we have $\Theta_\varepsilon^\pm \rightharpoonup \Theta^\pm$ weakly-$\star$ in $L^\infty(\mathbb{R}^+, L^2(S^\pm))$. Passing to the limit in (3.49) by using the estimates given in Lemma 3.6, one deduces that $\Theta^\pm$ satisfies the equation

$$\partial_z(\Theta^\pm + \chi(G^\pm)m(\hat{x}) \cdot \mathbf{u}_3) = 0 \text{ in } \mathbb{R}^+ \times S^\pm. \tag{3.50}$$

Consequently, we have $\Theta^\pm + \chi(G^\pm)m(\hat{x}) \cdot \mathbf{u}_3 = C^\pm(t, \hat{x})$, where the unknown functions $C^\pm$ are independent of the variable z. Next, since the transmission boundary conditions at the interfaces $z = \pm 1/2^\pm$ take the form

$$\Theta_\varepsilon^\pm(\pm 1/2^\pm) + \chi(B)m^\varepsilon(\pm 1/2^\pm) \cdot \mathbf{u}_3 = \frac{1-\varepsilon}{2\varepsilon^2}\partial_z\phi^\varepsilon(\pm 1/2^\mp), \tag{3.51}$$

we deduce, by using the convergences given in (3.44), that $\partial_z\phi^\varepsilon(\pm 1/2^\mp) \rightharpoonup \partial_z\phi(\pm 1/2^\mp)$ and $\Theta^\varepsilon(\pm 1/2^\pm) \rightharpoonup \Theta(\pm 1/2^\pm)$ in the sense of distributions. Hence, we get

$$\Theta^\pm(\pm 1/2) + \chi(B)m(\pm 1/2) \cdot \mathbf{u}_3 = 0, \tag{3.52}$$

and finally (3.50) gives the result

$$\Theta^\pm(t, \hat{x}, z) = -\chi(G^\pm)\ m(t, \hat{x}) \cdot \mathbf{u}_3 \text{ in } \mathbb{R}^+ \times S^\pm. \tag{3.53}$$

Now we are dealing with the equation satisfied by $\phi^\pm$ in $\mathbb{R}^+ \times S^\pm$. (Recall that $\phi^\pm$ is independent of z.) Let $g \in \mathcal{D}(\mathbb{R}^+ \times \mathbb{R}^2)$ be a test function which is independent of the variable z. Multiplying (3.49) by g and integrating by parts, we get

$$\begin{cases} \displaystyle\int_{\mathbb{R}^+\times S^+} (\widehat{\operatorname{grad}}\,\phi^\varepsilon + \chi(G^+)\widehat{m}^\varepsilon)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dzdt \\ \displaystyle= \int_{\mathbb{R}^+\times\mathbb{R}^2}\left(\frac{1}{(2(1-\varepsilon))^2}\partial_z\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\chi(B)m^\varepsilon \cdot \mathbf{u}_3\right)(1^-)g\ d\hat{x}dt \\ \displaystyle- \int_{\mathbb{R}^+\times\mathbb{R}^2}\left(\frac{1}{(2(1-\varepsilon))^2}\partial_z\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\chi(B)m^\varepsilon \cdot \mathbf{u}_3\right)(1/2^+)g\ d\hat{x}dt. \end{cases} \tag{3.54}$$

Using the transmission boundary conditions at the interfaces $z = 1$ and $z = 1/2$, (3.54) then becomes

$$\begin{aligned} &\int_{\mathbb{R}^+\times S^+} (\widehat{\operatorname{grad}}\,\phi^\varepsilon + \chi(G^+)\widehat{m}^\varepsilon)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dzdt \\ &= \int_{\mathbb{R}^+\times\mathbb{R}^2} \partial_z\phi^\varepsilon(1^+)g\ d\hat{x}dt - \int_{\mathbb{R}^+\times\mathbb{R}^2} \frac{1}{(2\varepsilon)^2}\partial_z\phi^\varepsilon(1/2^-)g\ d\hat{x}dt. \end{aligned} \tag{3.55}$$

Passing to the limit by using Lemma 3.6, we get the equation

$$\begin{aligned}&\frac{1}{2}\int_{\mathbb{R}^+\times\mathbb{R}^2}(\widehat{\operatorname{grad}}\,\phi^+ + \chi(B)\widehat{m}^+)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dt\\ &=\int_{\mathbb{R}^+\times\mathbb{R}^2}\partial_z\phi^\infty(1)g\ d\hat{x}dt-\int_{\mathbb{R}^+\times\mathbb{R}^2}\frac{1}{4}\partial_z\phi^0(1/2)g\ d\hat{x}dt.\end{aligned}\tag{3.56}$$

Using the continuity of the potential across the interfaces $z=1$, $z=\pm 1/2$, we deduce that ϕ satisfies the continuity property

$$\phi^+(\hat{x},1)=\phi^\infty(\hat{x},1),\ \phi^0(\hat{x},1/2)=\phi^+(\hat{x},1/2),\ \phi^0(\hat{x},1/2)=\phi^-(\hat{x},1/2)\ \text{a.e.}\tag{3.57}$$

Integrating by parts in (3.55) and recalling that m is independent of the variable z in $\mathbb{R}^+\times G^+$, we get the transmission boundary condition coupling the interfaces $z=1$ and $z=1/2$:

$$\partial_z\phi^\infty(1)-\frac{1}{4}\partial_z\phi^0(1/2)=-\frac{1}{2}\widehat{\operatorname{div}}(\widehat{\operatorname{grad}}\,\phi^\infty(1)+\chi(B)\widehat{m}^+).\tag{3.58}$$

Let us consider the convergence of the restriction of ϕ^ε to the domain $\mathbb{R}^+\times S^-$. We proceed as we did previously in the domain $\mathbb{R}^+\times S^+$ and recall that ϕ^ε satisfies at $z=-1$ the Neumann homogeneous boundary condition. We get

$$\begin{aligned}&\int_{\mathbb{R}^+\times S^-}(\widehat{\operatorname{grad}}\,\phi^\varepsilon+\chi(G^-)\widehat{m}^\varepsilon)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dzdt\\ &=\int_{\mathbb{R}^+\times\mathbb{R}^2}\left(\frac{1}{(2(1-\varepsilon))^2}\partial_z\phi^\varepsilon+\frac{1}{2(1-\varepsilon)}\chi(B)m^\varepsilon\cdot\mathbf{u}_3\right)(-1/2^-)g\ d\hat{x}dt,\end{aligned}\tag{3.59}$$

which gives, by using the transmission condition at the interface $z=-1/2$,

$$\begin{aligned}&\int_{\mathbb{R}^+\times S^-}(\widehat{\operatorname{grad}}\,\phi^\varepsilon+\chi(G^-)\widehat{m}^\varepsilon)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dzdt\\ &=\int_{\mathbb{R}^+\times\mathbb{R}^2}\frac{1}{(2\varepsilon)^2}\partial_z\phi^\varepsilon(-1/2^+)g\ d\hat{x}dt.\end{aligned}\tag{3.60}$$

We pass to the limit in the equation. To do that we use the fact that ϕ and m are independent of the variable z in S^-, and we use the continuity of the potential ϕ at the interface $z=-1/2$. We get the equation

$$2\int_{\mathbb{R}^+\times\mathbb{R}^2}(\widehat{\operatorname{grad}}\,\phi^0+\chi(B)\widehat{m}^-)(\widehat{\operatorname{grad}}\,g)\ d\hat{x}dt=\int_{\mathbb{R}^+\times\mathbb{R}^2}\partial_z\phi^0(-1/2^+)g\ d\hat{x}dt\tag{3.61}$$

or, equivalently, the boundary condition at the interface $z=-1/2$, by using the fact that $\phi^-(\hat{x})=\phi^0(\hat{x},-1/2)$:

$$\partial_z\phi^0(-1/2^+)=-2\widehat{\operatorname{div}}(\widehat{\operatorname{grad}}\,\phi^0+\chi(B)\widehat{m}^-).\tag{3.62}$$

Next, we pass to the limit in the equations satisfied by the potential ϕ^ε in $\mathbb{R}^+\times S^0$ and $\mathbb{R}^+\times S^\infty$, which satisfies the equations

$$\begin{cases}\widehat{\operatorname{div}}(\widehat{\operatorname{grad}}\,\phi^\varepsilon)+\dfrac{1}{4\varepsilon^2}\partial_z^2\phi^\varepsilon=0\ \text{ in }\ \mathbb{R}^+\times S^0,\\ \widehat{\operatorname{div}}(\widehat{\operatorname{grad}}\,\phi^\varepsilon)+\partial_z^2\phi^\varepsilon=0\ \text{ in }\ \mathbb{R}^+\times S^\infty.\end{cases}\tag{3.63}$$

It follows that the potential ϕ satisfies the equations (recall the interface continuity equalities (3.57))

$$\begin{cases} \widehat{\Delta}\phi^0 + \dfrac{1}{4}\partial_z^2\phi^0 = 0 \ \text{ in } \mathbb{R}^+ \times S^0, \\ \widehat{\Delta}\phi^\infty + \partial_z^2\phi^\infty = 0 \ \text{ in } \mathbb{R}^+ \times S^\infty, \\ \phi^\infty(1) = \phi^0(1/2). \end{cases} \tag{3.64}$$

Hence, the theorem is proved. □

The local magnetic excitation $\mathcal{H}^\varepsilon(m^\varepsilon)$ involves the magnetic field

$$\widehat{\operatorname{grad}}\,\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon \mathbf{u}_3$$

in $S^\pm$. When $\varepsilon \to 1$, we get the following convergence result.

LEMMA 3.8. *The magnetic field satisfies the convergence*

$$\left(\widehat{\operatorname{grad}}\,\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon \mathbf{u}_3\right)_{|\mathbb{R}^+\times S^\pm} \rightharpoonup (\widehat{\operatorname{grad}}\,\phi^\pm - \chi(G^\pm) m\cdot \mathbf{u}_3\mathbf{u}_3)_{|\mathbb{R}^+\times S^\pm} \tag{3.65}$$

weakly-$\star$ in $L^\infty(\mathbb{R}^+, \mathbb{L}^2(S^\pm))$.

Now, we may pass to the limit in the Landau–Lifshitz equations. Arguing that, in the limit, $m^\pm$ is independent of z, we use test functions of the type $F^\varepsilon(t,\hat{x},z) = F(t,\hat{x}) + 2(1-\varepsilon)F_0(t,\hat{x})h(2(1-\varepsilon)z)$, where $h \in \mathcal{D}([-1,1])$ and $F, F_0 \in \mathcal{D}(B)$. The weak formulation of the problem reads in each domain $Q^\pm = \mathbb{R}^+ \times G^\pm$ as follows:

$$\begin{cases} \dfrac{1}{1+\alpha^2}\displaystyle\int_{Q^\pm} (\partial_t m^\varepsilon - \alpha m^\varepsilon \times \partial_t m^\varepsilon)\ (F + h^\varepsilon(z)F_0)dxdt \\ = \displaystyle\int_{Q^\pm} m^\varepsilon \times (a^\varepsilon \widehat{\operatorname{grad}}\, m^\varepsilon)(\widehat{\operatorname{grad}}\, F + h^\varepsilon(z)\widehat{\operatorname{grad}}\, F_0)\ dxdt \\ + \displaystyle\int_{Q^\pm} m^\varepsilon \times (a^\varepsilon \partial_z m^\varepsilon)F_0 h'(2(1-\varepsilon)z)\ dxdt \\ - \displaystyle\int_{Q^\pm} m^\varepsilon \times \left(\psi(m^\varepsilon) + \widehat{\operatorname{grad}}\,\phi^\varepsilon + \frac{1}{2(1-\varepsilon)}\partial_z\phi^\varepsilon \mathbf{u}_3\right)(F + h^\varepsilon(z)F_0)\ dxdt \\ - \dfrac{j}{2}\displaystyle\int_{\mathbb{R}^+\times B} m^\varepsilon(\pm 1/2) \times m^\varepsilon(\mp 1/2)\Big(F + h^\varepsilon(\pm(1-\varepsilon))F_0\Big)\ d\hat{x}dt, \end{cases} \tag{3.66}$$

where we have set $h^\varepsilon(z) = 2(1-\varepsilon)h(2(1-\varepsilon)z)$ and used the IEC boundary condition at the interfaces $z = \pm 1/2$:

$$m^\varepsilon(\pm 1/2) \times \left(\mp\frac{a^\varepsilon}{2(1-\varepsilon)}\partial_z m^\varepsilon(\pm 1/2) - j(1-\varepsilon)m^\varepsilon(\mp 1/2)\right) = 0. \tag{3.67}$$

We pass to the limit in each term of the weak formulation (3.66). By using

Lemmas 3.6 and 3.8, we get

$$
\begin{cases}
\dfrac{1}{1+\alpha^2}\displaystyle\int_{\mathbb{R}^+\times B}\left(\partial_t m^\pm - \alpha m^\pm\times\partial_t m^\pm\right)\ F d\hat{x}dt \\
=\displaystyle\int_{\mathbb{R}^+\times B} m^\pm\times(a^\pm\widehat{\operatorname{grad}}\, m^\pm)\widehat{\operatorname{grad}}\, F\ d\hat{x}dt \\
-\displaystyle\int_{\mathbb{R}^+\times B} m^\pm\times\left(\psi(m^\pm)+\widehat{\operatorname{grad}}\,\phi^\pm-\chi(B)(m^\pm\cdot\mathbf{u}_3)\mathbf{u}_3\right)\ F\ d\hat{x}dt \\
-j\displaystyle\int_{\mathbb{R}^+\times B} m^\pm\times m^\mp\ F\ d\hat{x}dt,
\end{cases}
\tag{3.68}
$$

where we used the strong convergence

$$
a^\varepsilon_{|G^\pm}\to a^\pm(\hat{x})=A(\hat{x},\pm 1)\quad\text{a.e.}
\tag{3.69}
$$

Gathering all results of this subsection, we get the following convergence theorem.

THEOREM 3.9. *Let $m^\pm$ be the weak-$\star$ limit in $L^\infty(\mathbb{R}^+,\mathbb{H}^1(G^\pm))$ of a subsequence of $m^\varepsilon_{|G^\pm}$. Then the couple (m^+,m^-) is independent of the variable z and satisfies $|m^\pm(t,\hat{x})|^2=1$ a.e. Moreover, (m^+,m^-) satisfies in $\mathbb{R}^+\times B$ the Landau–Lifshitz–Gilbert equations*

$$
\begin{cases}
\partial_t m^\pm-\alpha m^\pm\times\partial_t m^\pm=-(1+\alpha^2)m^\pm\times\mathcal{H}^\pm(m^\pm), \\
\\
m^\pm(0,\hat{x})=m_0(\hat{x}),\qquad \dfrac{\partial m^\pm}{\partial n}=0\ \text{on}\ \partial B,
\end{cases}
\tag{3.70}
$$

where the total magnetic field $\mathcal{H}^\pm(m^\pm)$ is given by

$$
\mathcal{H}^\pm(m^\pm)=\widehat{\operatorname{div}}(a^\pm\ \widehat{\operatorname{grad}}\, m^\pm)+\psi(m^\pm)+\widehat{\operatorname{grad}}\,\phi^\pm-\chi(B)m^\pm\cdot\mathbf{u}_3\ \mathbf{u}_3+jm^\mp.
\tag{3.71}
$$

Furthermore, the potential $\phi^\pm(t,\hat{x})$ is given by Theorem 3.7.

4. Concluding remarks. The results obtained can be applied without difficulty to the case of the full Maxwell system. In this study we have considered a plane interface between layers. It would be very interesting to extend this analysis to a more general case of interfacial roughness, especially in films with compensated interfaces, which play an important role in giant magnetoresistance (GMR) [18], [23]. Note that the magnetic multilayers with GMR have attracted a lot of interest due to their high density information storage and retrieval capacities. Also, as already said in the introduction, we have limited ourselves to bilinear coupling. Thus one may consider a more general energy coupling density which takes into account the biquadratic effect recently discovered in layered magnetic systems [14]. It is mostly expressed [18], [23] (see also the introduction) as $J_1(1-m^+\cdot m^-)+J_2(1-(m^+\cdot m^-)^2)$, where m^+ and m^- are the magnetization vectors at the inner surfaces of the first and the second magnetic slabs, respectively. To take into account that energy, we use the following boundary condition at the interfaces $+$ and $-$ facing each other:

$$
m^\pm\times\left(A\frac{\partial m^\pm}{\partial n^\pm}-J_1m^\mp-J_2(m^+\cdot m^-)m^\mp\right)=0.
$$

Considering the problem with this energy and the roughness of interfaces, the asymptotic behavior of the interlayer coupling will be difficult to approach and will require more detailed studies.

Acknowledgments. We greatly appreciate the remarks and comments of the anonymous referee. We thank her/him for a careful reading of the first draft of this paper and for many helpful suggestions for improving the overall presentation.

CURVATURE-INDUCED DISPERSION IN ELECTRO-OSMOTIC SERPENTINE FLOWS*

EHUD YARIV†, HOWARD BRENNER‡, AND SANGTAE KIM§

Abstract. Flow and transport phenomena occurring within serpentine microchannels are analyzed for both two- and three-dimensional curvilinear configurations. The microfluidic conduit is modeled as a spatially periodic "thin" channel, enabling asymptotic expansions of the pertinent transport fields in terms of a small parameter ϵ, representing the ratio of channel (half-)width to curvilinear channel length per serpentine period. The electric potential distribution, as well as the attendant electro-osmotic flow field, is calculated for the limiting case where the Debye layer thickness is small relative to the channel width. Generalized Taylor–Aris dispersion theory is employed to calculate the serpentine-scale velocity and dispersivity of a charged point-size colloidal Brownian particle ("molecule") entrained in the solvent Stokes flow engendered by the electrokinetic forces. These respective macrotransport coefficients are expressed, inter alia, in terms of quadratures of the local curvature within a unit cell of the serpentine device.

Key words. electro-osmosis, asymptotic expansions, Taylor dispersion

1. Introduction.

Conventional chromatographic separation schemes exploit the differences in mean solute velocity with which the various species move throughout the chromatograph (into which they were introduced simultaneously). As the average separation distance between species increases linearly with channel length, it is desirable to maximize the available length between the entrance and exit of a solute molecule within the device. In microfluidic devices, constrained by chip-size limitations, improved chromatographic efficiency can therefore be achieved by folding the otherwise straight separation channel into the shape of a serpentine channel [12, 13, 5]. In attempting to optimize chip layout design it is obviously useful to qualitatively understand the transport factors which distinguish curvilinear channels from their rectilinear counterparts, whose chromatographic properties are well understood [3]. This is the goal of the present paper.

The major drawback of all chromatographic separation devices lies in the increased band-broadening experienced by the solute sample over and above that due to purely molecular diffusion alone. This increased solute spread results from the Taylor-dispersion mechanism, whereby Brownian solute particles sample different streamlines (in particular their concomitant axial velocities) within the channel cross section. The cross-sectional velocity variance is generally greater in curved channels than in comparably straight channels [2, 8]. Thus, while Taylor effects also exist in straight channels (especially in pressure-driven flows), channel curvature could significantly modify these convective-dispersion effects. Accordingly, one of the main foci of the present

paper lies in examining the relevant enhancement of solute dispersion associated with the curvature of the serpentine channel.

A systematic analysis of solute dispersion accompanying pressure-driven flows in serpentine channels was recently carried out by [22], using macrotransport theory [3] for spatially periodic systems. All other things being equal, the mean axial solute velocity $\overline{U}^*$ and dispersivity $\overline{D}^*$ in the direction of net flow were found to be proportional to the corresponding quantities for the straight unfolded channel, the constants of proportionality for these two macrotransport parameters being L/l (< 1) and $(L/l)^2$, respectively. The factor L/l constitutes the inverse of the "tortuosity," namely the ratio of serpentine channel length, l, to its projected (rectilinear) channel length in the direction of net flow, L. These results are easily rationalized in terms of the combined effects arising from the extended total serpentine channel length and the decreased effective cross-sectional area of the curved channel. Since only leading-order terms were evaluated by [22], their results are based upon a Poiseuillian velocity profile, with no dependence upon curvature-induced deviations from it.

Practical microfluidic separation devices employ ionic solutions as the solvent phase, acting as a buffer for the chemically sensitive solute molecules. As the boundaries of the channel are usually charged (as a consequence of the presence of electrolytes), it is common practice to use external electric fields to drive the bulk flow. The resulting electro-osmotic flow represents a balance between the animating electrical body forces, concentrated within the Debye double-layer, and the retarding viscous stresses. Use of electro-osmotic flows eliminates the need for inefficient micropumps in favor of electrodes. Moreover, the length-scale on which the velocity field varies cross-sectionally across the double-layer is extremely small compared with typical channel widths. Thus, the velocity profile is substantially uniform over the major portion of the channel cross section. For such "plug flows" the only source of solute dispersion is axial molecular diffusion. We seek, inter alia, to calculate the additional Taylor–Aris dispersion arising in curvilinear channels (over that occurring in straight channels), wherein the velocity field deviates from a plug flow owing to channel curvature.

Furthermore, if the solute particles are charged, the electric field operates as an external force field (albeit indirectly, owing to the presence of a Debye double-layer around the particles). As a result of the lateral (and perhaps longitudinal) variations of the electric field in a curved channel, the electrophoretic particle velocity (relative to the already nonuniform velocity field) depends upon the local position of the particle within the channel. (This electrophoretic velocity is related to the electric field through the particle's electrophoretic mobility.) This constitutes yet another source of solute Taylor dispersion, which, similarly to that arising from the nonuniform solvent velocity field, is absent in electro-osmotic flows in straight channels. As nonuniformities of both velocity and electric field occur in electro-osmotic flows in curved channels, each may individually contribute to the resulting Taylor dispersion. It is the purpose of this paper to provide the required analysis for such phenomena, at least for solute particles that can be regarded as being effectively "point-size" compared with the channel width.

This paper addresses the transport of a charged solute Brownian particle entrained in an electro-osmotic flow occurring within a curved serpentine channel of uniform width, modeled as a two-dimensional spatially periodic conduit. (The periodicity assumption, reflecting the configurationally serpentine character of the device, removes the need to deal with finite size "end effects" in real microfluidic devices, at least for channels consisting of a sufficiently large number of turns.) In contrast to the

specific conduit geometries (toroids and helices) analyzed to date for pressure-driven flows in curvilinear channels of circular cross section [2, 8], we consider here the general case of an arbitrary nonuniform local curvature—that is, where channel curvature varies with distance along the center-line of the serpentine device. Attention is focused upon situations where the channel width is small compared with the characteristic local radius of curvature,[1] which circumstances are assumed (either explicitly or implicitly) in all previous attempts to analyze turn-induced dispersion [5, 10, 16]. The present contribution entails a rigorous description of the generic channel geometry via channel-fixed curvilinear coordinates. This allows for the systematic use of regular asymptotic expansions of the pertinent transport fields, enabling a straightforward perturbation solution of the coupled flow-electrostatics problem.

Using the solvent velocity and electric fields thereby derived, generalized Taylor–Aris dispersion theory [3] is invoked to evaluate the effective macrotransport coefficients $\overline{U}^*$ and $\overline{D}^*$ serving to quantify the net unidirectional global solute transport through the serpentine device as a whole. Since Taylor dispersion is absent during electro-osmotic "plug flow" in a straight channel (at least in circumstances where the Debye layer is thin compared with the channel width and where wall effects are negligible), the counterparts of the "zeroth-order" tortuosity-induced effects, analyzed by [22] for pressure-driven flows, are trivial in the present case. Thus, leading-order Taylor dispersion is associated with (first-order) curvature-induced velocity deviations from a plug flow. Owing to the dependence of curvature upon curvilinear position along the channel, both $\overline{U}^*$ and $\overline{D}^*$ are expressed as quadratures of the local channel curvature $k(s)$ within a unit cell of the serpentine device, s being a length parameter measured along the (center-line of the) curved channel. Inasmuch as typical solute particles (such as DNA molecules) encountered in microfluidic devices are small compared with the device's channel width [24], we concentrate—in this initial communication—on the case of "point-size" particles. This furnishes the dominant effect upon $\overline{D}^*$. Wall effects upon both $\overline{U}^*$ and $\overline{D}^*$, arising from the finite size of particles relative to channel width, will be discussed in a subsequent publication.

Section 2 deals with the specification of a general curvilinear channel geometry, one which lends itself to analytic manipulation. Explicitly, channel-fixed tangent-normal coordinates are constructed, and the required scalar and vector operators evaluated. Description of the physical problem governing both the flow and electric potential fields, as well as the accompanying asymptotic analysis, is outlined in section 3 for an arbitrary two-dimensional curved channel geometry. This analysis provides both the electric and vector velocity fields, expressed in the respective forms of regular perturbation expansions in the small parameter ϵ, representing the dimensionless curvilinear channel width. Using these data, in section 4 we perform the requisite macrotransport analyses, resulting in evaluation of the macrotransport coefficients $\overline{U}^*$ and $\overline{D}^*$ in terms of the specified global parameters characterizing the system as a whole. In section 5 we generalize the preceding two-dimensional analysis to a three-dimensional configuration, wherein the serpentine channel possesses a circular cross section of uniform radius. The relationship between the present macrotransport results and the single-turn models which appear in the literature is discussed in section 6. Results are summarized at section 7.

[1] Cases lacking this fundamental disparity in scales are amenable only to numerical analysis, which cannot be expected to provide qualitative insights comparable to those resulting from the present analytical investigation.

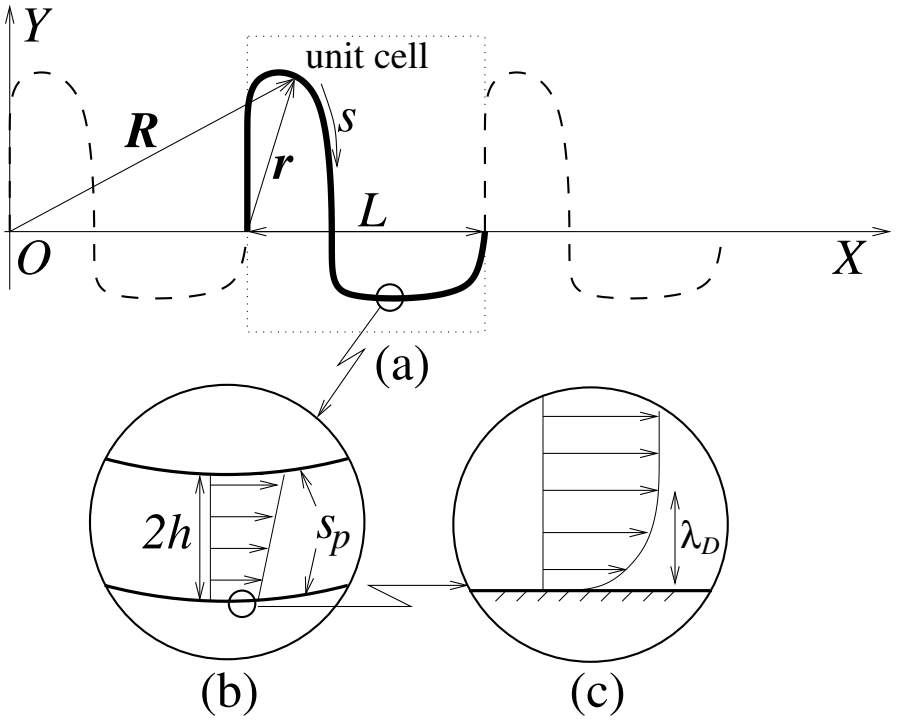

FIG. 1. *Serpentine geometry:* (a) *L-scale;* (b) *h-scale; and* (c) *Debye layer scale.*

2. Channel geometry. The present analysis addresses electro-osmotic transport processes occurring in a spatially periodic two-dimensional curved channel of uniform width, depicted in Figure 1. The unidirectional periodicity of the channel is captured by the presence of a repetitive "unit cell," characterized by the lattice vector $L\hat{\boldsymbol{X}}$, with $\hat{\boldsymbol{X}}$ a unit vector in the X-direction and L the unit-cell rectilinear length, measured along X. The curvilinear arc-length of the channel along its center-line for one period is denoted by l ($l \geq L$, with equality holding only for a straight channel). The "global" position vector $\boldsymbol{R}_n$ of the nth unit cell ($-\infty < n < \infty$) relative to an arbitrary origin O (situated, say, at the entrance to the cell labeled $n = 0$) is given by $\boldsymbol{R}_n = nL\hat{\boldsymbol{X}}$. The vector $\boldsymbol{r}$ is used to denote the "local" position within the fluid domain of this particular cell. The position vector $\boldsymbol{R} = (X, Y)$ of a point lying within the nth cell may thus be represented as $\boldsymbol{R}_n + \boldsymbol{r}$.

In order to define the channel geometry unambiguously it is necessary to specify the configuration of the boundaries (in some parametric form) of a single unit cell. We begin with a plane curve Γ, serving to define the center-line of the channel. This curve is given by the following parametric description of the local position vector

$$\boldsymbol{r} = \boldsymbol{r}_c(s), \tag{2.1}$$

wherein the parameter s denotes arc-length measured along Γ ($0 \leq s \leq l$). The unit vector normal to the osculating plane (pointing out of the page) is denoted by $\hat{\boldsymbol{k}}$, whereas the unit vector tangent to Γ is given by

$$\hat{\boldsymbol{s}} = \frac{d\boldsymbol{r}_c}{ds}. \tag{2.2}$$

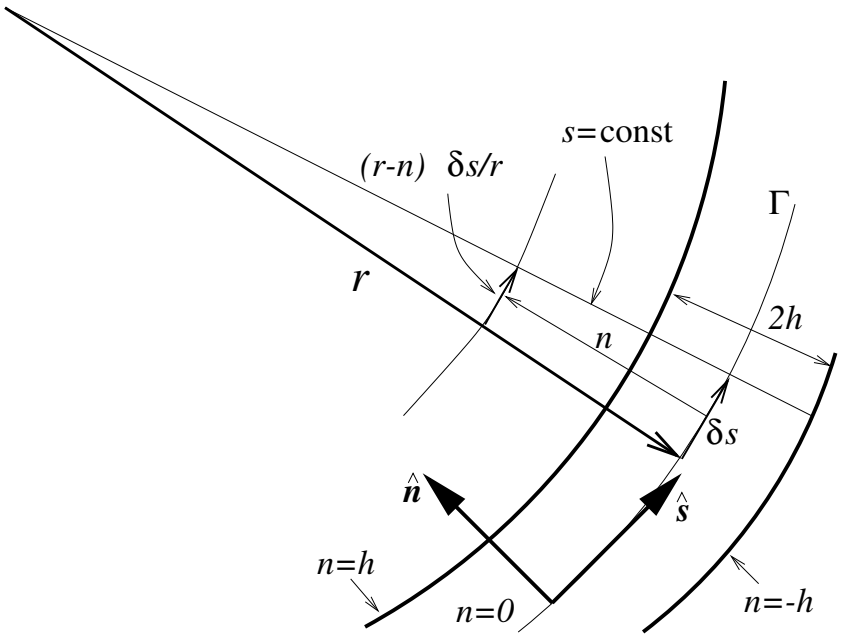

FIG. 2. *Tangent-normal local curvilinear orthogonal coordinate system.*

The principal unit normal to Γ, namely $\hat{\boldsymbol{n}}$, is defined by the requirement that the triad $(\hat{\boldsymbol{s}}, \hat{\boldsymbol{n}}, \hat{\boldsymbol{k}})$, in that order, form a right-handed orthonormal system. The unit vectors $\hat{\boldsymbol{s}}$ and $\hat{\boldsymbol{n}}$ are related by the Serret–Frenet relations [1],

$$\frac{d\hat{\boldsymbol{s}}}{ds} = k\hat{\boldsymbol{n}}, \tag{2.3a}$$

$$\frac{d\hat{\boldsymbol{n}}}{ds} = -k\hat{\boldsymbol{s}}, \tag{2.3b}$$

wherein $k(s)$ is the (algebraically signed) curvature.

The lateral boundaries of the serpentine channel, denoted by s_p, are defined as the locus of points situated at a distance h from Γ. Every point on Γ is thus associated with two boundary points, located at distances h in the $\hat{\boldsymbol{n}}$ and $-\hat{\boldsymbol{n}}$ directions, respectively.[2] The length $2h$ is thus to be interpreted as the channel "width." Moreover, this procedure may be generalized to construct a local system of orthogonal, "tangent-normal," coordinates (s, n). This is achieved by applying the same type of translation from points on Γ, but at an arbitrary, algebraically signed distance, say n, normal to Γ. Every point $\boldsymbol{r}$ in the vicinity of the center-line may be identified with a pair of coordinates s (signifying distance traversed along the center-line) and n. These local coordinates are defined only within the fluid domain, say τ_0, of a single unit cell $(0 \le s \le l,\ -h \le n \le h)$. The geometry of the channel is schematically presented in Figure 2 (for a positive curvature).

The family of curves $s = \text{const}$ constitutes a collection of straight lines, which

[2]These boundaries are well defined only for $h < |k|^{-1}$. In the following analysis, however, we concentrate on the asymptotic limit $h \ll |k|^{-1}$. In that case the straight segments normal to Γ do not intersect. As such, any ambiguity is appropriately removed to a degree consistent with our eventual asymptotic solutions.

is atypical for coordinate systems normally used to describe curvilinear geometries. The appearance of such straight coordinate curves in the present context is related to the fact that only lateral "width" constraints are involved in the specification of the channel boundaries. As the orthogonal pair of tangent and normal unit vectors, say, $\hat{\boldsymbol{s}}(s,n)$ and $\hat{\boldsymbol{n}}(s,n)$, are independent of n, each is identical to its corresponding center-line value, namely, $\hat{\boldsymbol{s}}(s)$ and $\hat{\boldsymbol{n}}(s)$.

By definition, the local position vector at the point (s,n) is given by

$$\boldsymbol{r}(s,n) = \boldsymbol{r}_c(s) + n\,\hat{\boldsymbol{n}}(s). \tag{2.4}$$

Use of (2.3) yields the differential vector displacement between the neighboring points (s,n) and $(s+ds, n+dn)$, namely,

$$d\boldsymbol{r} = \hat{\boldsymbol{s}}(1-nk)\,ds + \hat{\boldsymbol{n}}\,dn. \tag{2.5}$$

The metrical coefficient, $|d\boldsymbol{r}|/ds$, associated with the coordinate s is thus given by $1-nk$. Since the (algebraically signed) radius of curvature is given by $r = 1/k$, this coefficient may be expressed as $(r-n)/r$, a result which was to be anticipated (see Figure 2). The gradient operator appropriate to the tangent-normal coordinate system is thus given by

$$\boldsymbol{\nabla} = \hat{\boldsymbol{n}}\frac{\partial}{\partial n} + \hat{\boldsymbol{s}}\frac{1}{1-nk}\frac{\partial}{\partial s}. \tag{2.6}$$

This result may also be obtained from the invariant definition of the gradient of a generic function f, namely,

$$\boldsymbol{\nabla} f \triangleq \lim_{V\to 0} \frac{\int_{\partial V} dA\; \boldsymbol{n}\, f}{V},$$

wherein $\boldsymbol{n}$ is a unit vector normal to the boundary ∂V of V; see the elementary "volume" element depicted in Figure 3. Use of (2.6) in conjunction with (2.3) yields [11] the following expression for the Laplacian of a generic scalar field $f(n,s)$,

$$\nabla^2 f = \frac{\partial^2 f}{\partial n^2} - \frac{k}{1-nk}\frac{\partial f}{\partial n} + \frac{1}{(1-nk)^2}\frac{\partial^2 f}{\partial s^2} + \frac{n}{(1-nk)^3}\frac{dk}{ds}\frac{\partial f}{\partial s}. \tag{2.7}$$

Note that the generic geometric construction outlined in this section is, in fact, not restricted to periodic configurations. In particular, if k is uniform along the channel (i.e., s-independent), the curve Γ forms a circular arc, possessing a radius $r = 1/k$. The operators (2.6)–(2.7) then degenerate to their respective polar-coordinate counterparts, wherein the radial and azimuthal coordinates, say ρ and θ, are given by $r-n$ and s/r, respectively. (The latter operators are, obviously, independent of k.)

3. Electrokinetics. Consider a periodic electrolyte-filled serpentine channel, whose nonconducting boundary is assumed to possess a uniform surface charge density. Electric potential difference is applied across the two ends of the channel, resulting in the establishment of an electric field, $\boldsymbol{E} = -\boldsymbol{\nabla}\phi$.

The presence of different ionic species, combined with the surface charge, results in regions near the boundaries displaying sharp variations in electric field intensity and ionic species concentrations. This region constitutes the Debye double-layer. The length-scale, say, λ_D (see Figure 1), associated with this variation is of the order of

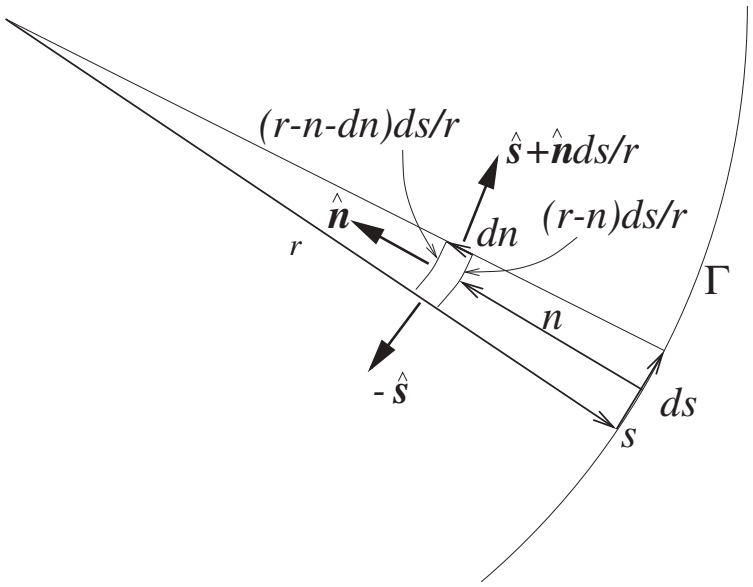

FIG. 3. *Elementary "volume" (areal) element centered about* (n, s).

nanometers for typical values of buffer ionic concentration [21]. This length is extremely small compared with typical channel widths, the latter being of the order of tens of microns [5]. We therefore assume, henceforth, that $\lambda_D/h \to 0$. The matching conditions for the ensuing λ_D-scale "double-layer" fields provide the pertinent boundary conditions for the h-scale analysis [14]. The first is that the electric field normal to the boundary vanishes:

$$\frac{\partial \phi}{\partial n} = 0; \tag{3.1}$$

the second is the well-known Smoluchowski equation,

$$\boldsymbol{v} = \frac{\varepsilon_{el}\zeta}{\mu}\boldsymbol{\nabla}\phi, \tag{3.2}$$

relating the (local) values of the fluid velocity $\boldsymbol{v}$ to the electric field. In the above, ε_{el} is the electrolyte permittivity and μ the (presumably uniform) fluid viscosity. The "zeta potential" ζ is the (uniform) excess potential of the charged surface relative to the (local) value of the potential outside the Debye layer. Equation (3.2) serves as a "slip-condition" imposed upon the velocity field.

The flow domain in the present problem thus corresponds to the "outer" region of the double-layer, wherein deviations from charge neutrality are exponentially small. In this region the Poisson equation degenerates to the Laplace equation,

$$\nabla^2 \phi = 0, \tag{3.3}$$

and electrical body forces are absent from the Navier–Stokes equations. For typical Reynolds numbers encountered in microfluidic devices it is common to assume Stokes flow [24], whence the pertinent flow equations become

$$\boldsymbol{\nabla} \cdot \boldsymbol{v} = 0, \tag{3.4}$$

$$\mu \nabla^2 \boldsymbol{v} = \boldsymbol{\nabla} p, \tag{3.5}$$

wherein $p(\boldsymbol{r})$ is the pressure field.

Owing to the periodicity of the channel, the electric field and local pressure gradient are both spatially periodic, resulting in the following conditions:

$$\boldsymbol{\nabla}\phi(\boldsymbol{R}+L\hat{\boldsymbol{X}})-\boldsymbol{\nabla}\phi(\boldsymbol{R})=\boldsymbol{0},$$
$$\boldsymbol{\nabla}p(\boldsymbol{R}+L\hat{\boldsymbol{X}})-\boldsymbol{\nabla}p(\boldsymbol{R})=\boldsymbol{0},$$

which are each valid for all points $\boldsymbol{R}$ in the fluid domain of the serpentine channel. The former condition is equivalent to the requirement that

$$\phi(\boldsymbol{R})=\tilde{\phi}(\boldsymbol{R})+V\frac{X}{L},$$

where $\tilde{\phi}(\boldsymbol{R})$ is a spatially periodic function (possessing a period of length L in the $\hat{\boldsymbol{X}}$ direction), and V is a constant, representing the voltage difference across a unit cell. The corresponding "jump" condition, expressed in the local coordinate system, is simply

$$\phi(n,s=l)-\phi(n,s=0)=V \qquad \forall n\in[-h,h]\,. \tag{3.6}$$

The analogous condition imposed upon p, reflecting the absence of an externally applied pressure difference, is

$$p(n,s=l)-p(n,s=0)=0 \qquad \forall n\in[-h,h]\,. \tag{3.7}$$

Owing to the periodicity of the serpentine geometry, we expect on the basis of (3.7) that the resulting flow field will be periodic; that is,

$$\boldsymbol{v}(n,s=l)-\boldsymbol{v}(n,s=0)=\boldsymbol{0} \qquad \forall n\in[-h,h]\,. \tag{3.8}$$

This, however, does not constitute an additional condition, inasmuch as the problem is already uniquely defined by (3.1)–(3.7). As such, (3.8) will be satisfied automatically.

Inasmuch as any irrotational flow field identically satisfies the Stokes equations (with no pressure gradients), it is obvious that the electro-osomtic velocity field is simply proportional to the electric field, namely,

$$\boldsymbol{v}\equiv\frac{\varepsilon_{el}\zeta}{\mu}\boldsymbol{\nabla}\phi.$$

The similarity between the two fields in the present problem arises from: (i) the lack of any pressure differences in the system (cf. (3.7)) and (ii) the uniformity of the zeta potential over the channel walls. This so-called "similitude" was discussed by [19] for the case of electro-osmosis and by [18] for the case of electrophoresis; it reduces the present electrokinetic analysis to the solution of the Neumann-type boundary-value problem governing the electric potential.

3.1. Normalization. We normalize length variables with h, velocities with the characteristic electro-osmotic velocity,

$$v_0=\frac{\varepsilon_{el}\zeta}{\mu}\frac{V}{l}, \tag{3.9}$$

and the electric potential with V. The dimensionless unit-cell potential problem thereby posed is thus governed by Laplace's equation in the fluid domain,

$$\nabla^2\phi=0, \tag{3.10}$$

the Neumann-type boundary condition,

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{\nabla}\phi = 0 \quad \text{at} \quad n = \pm 1, \tag{3.11}$$

and the periodicity conditions,

$$\phi(n, s = \epsilon^{-1}) - \phi(n, s = 0) = 1 \qquad \forall n \in [-1, 1]\,. \tag{3.12}$$

In the above,

$$\epsilon \triangleq \frac{h}{l} \tag{3.13}$$

is the dimensionless "aspect-ratio" of the unit cell. Once this problem is solved, the fluid velocity field is given by

$$\boldsymbol{v} = \frac{1}{\epsilon}\boldsymbol{\nabla}\phi. \tag{3.14}$$

Consider the asymptotic limit $\epsilon \ll 1$, corresponding to the case of "thin" channels. It is obvious in such circumstances (see (3.12)) that the appropriate choice of a dimensionless center-line coordinate is $S = \epsilon s$, rather[3] than s. We focus on the case where the center-line radius of curvature is of order l; we thus normalize the dimensional curvature (now a function of S) by l^{-1}. The problem reformulation, wherein all fields appearing therein are functions of n, S, and ϵ, consists of the following: (i) Laplace's equation,

$$\frac{\partial^2\phi}{\partial n^2} - \frac{\epsilon k}{1 - \epsilon n k}\frac{\partial\phi}{\partial n} + \frac{\epsilon^2}{(1 - \epsilon n k)^2}\frac{\partial^2\phi}{\partial S^2} + \frac{\epsilon^3 n}{(1 - \epsilon n k)^3}\frac{dk}{dS}\frac{\partial\phi}{\partial S} = 0; \tag{3.15}$$

(ii) the channel walls boundary conditions (at $n = \pm 1$),

$$\frac{\partial\phi}{\partial n} = 0; \tag{3.16}$$

and (iii) the serpentine periodicity condition

$$\phi(n, S = 1; \epsilon) - \phi(n, S = 0; \epsilon) = 1 \qquad \forall n \in [-1, 1]\,. \tag{3.17}$$

3.2. Asymptotic solutions. Expand the ϵ-dependent terms in the Laplace equation (3.15) into Taylor series in ϵ, so as to obtain the expression

$$\begin{aligned}\frac{\partial^2\phi}{\partial n^2} - \epsilon k\frac{\partial\phi}{\partial n} + \epsilon^2\left(\frac{\partial^2\phi}{\partial S^2} - nk^2\frac{\partial\phi}{\partial n}\right) + \epsilon^3\left(2nk\frac{\partial^2\phi}{\partial S^2} - n^2k^3\frac{\partial\phi}{\partial n} + n\frac{dk}{dS}\frac{\partial\phi}{\partial S}\right)\\ + \epsilon^4\left(3n^2k\frac{\partial^2\phi}{\partial S^2} - n^3k^4\frac{\partial\phi}{\partial n} + 3n^2k\frac{dk}{dS}\frac{\partial\phi}{\partial S}\right) + \cdots = 0.\end{aligned} \tag{3.18}$$

Next, expand ϕ into the asymptotic power series

$$\phi(n, S; \epsilon) \sim \phi^{(0)}(n, S) + \epsilon\phi^{(1)}(n, S) + \epsilon^2\phi^{(2)}(n, S) + \cdots\,. \tag{3.19}$$

[3]In general the coordinate S should appear as an additional "slow" variable. However, the emerging solvability conditions (required to eliminate the secular terms appearing in such a multiple-scale approach) result in the absence of any dependence upon the "fast" variable s. This is expected, as no mechanism exists in the present context for pronounced longitudinal variations along the length of the channel.

Substitution of (3.19) into (3.18) yields a system of equations which can be solved recursively in conjunction with use of the various respective orders of the boundary condition (3.16), namely,

$$\frac{\partial \phi^{(i)}}{\partial n} = 0 \quad \text{at} \quad n = \pm 1 \qquad (i = 0, 1, 2, \dots), \tag{3.20}$$

together with the "decomposed" periodicity conditions,

$$\left.\begin{array}{c} \phi^{(0)}(n, S=1) - \phi^{(0)}(n, S=0) = 1, \\ \phi^{(i)}(n, S=1) - \phi^{(i)}(n, S=0) = 0 \qquad (i = 1, 2, \dots) \end{array}\right\} \qquad \forall n \in [-1, 1]\,. \tag{3.21}$$

Owing to the presence of the "slow" variable S, the ensuing solution possesses a straightforward multiple-scale structure. The "solvability conditions" for the S-dependence of each of the functions $\phi^{(i)}$ naturally result upon application of the periodicity condition (3.21) at the ϵ^{i+2}-order problem. The potential ϕ was evaluated to $O\left(\epsilon^4\right)$, which is sufficient for the present macrotransport analysis. Details of the calculations are presented in the appendix. The resulting solution is

$$\begin{aligned} \phi \sim S + \frac{\epsilon^2}{3}\left[S\int_0^1 k^2(x)\,dx - \int_0^S k^2(x)\,dx\right] \\ + \epsilon^3\left[\frac{3n-n^3}{6}\frac{dk}{dS} + C(S)\right] + \epsilon^4\left[\frac{7}{24}(2n^2-n^4)k\frac{dk}{dS} + D(S)\right] + \mathcal{O}(\epsilon^5), \end{aligned} \tag{3.22}$$

wherein $C(S)$ and $D(S)$ are arbitrary periodic functions of S, which do not affect the leading- and first-order macrotransport coefficients. Their S-dependence, which is required if higher-order corrections are sought, may be obtained from the respective analyses of the $\mathcal{O}(\epsilon^5)$ and $\mathcal{O}(\epsilon^6)$ problems. Since the entire unit cell is identified with a line in the leading-order approximation, the corresponding zeroth-order solution for the Laplace equation, appearing in the leading-order term above, was to be expected. It obviously corresponds to a uniform electric field along the channel. The $\mathcal{O}(\epsilon^2)$ term embodies longitudinal nonuniformities in the electric field, resulting from curvature effects. Lateral variations in the electric potential are manifested only at the $\mathcal{O}(\epsilon^3)$ level of approximation.

Substitution of (3.22) into (3.14) provides the following velocity field:

$$u(n, s; \epsilon) \sim \epsilon^2 \frac{1-n^2}{2}\frac{dk}{dS} + \frac{7}{6}\epsilon^3 n(1-n^2)k\frac{dk}{dS} + \mathcal{O}(\epsilon^4), \tag{3.23a}$$

$$v(n, s; \epsilon) \sim 1 + \epsilon n k(S) + \epsilon^2\left[\left(n^2 - \frac{1}{3}\right)k^2(S) + \frac{1}{3}\int_0^1 k^2(x)\,dx\right] + \mathcal{O}(\epsilon^3). \tag{3.23b}$$

The leading-order solution constitutes an electro-osmotic plug flow, corresponding to curvature-free geometry. The first correction to this uniform field (cf. [10]) is a locally homogeneous shear (as in Couette flow), with a positive tangential velocity existing near to the inner boundary.

4. Macrotransport analysis. Following the preceding calculation of the electro-osmotic velocity field, macrotransport theory for spatially periodic systems [3] is used to evaluate the phenomenological coefficients characterizing the transport of a colloidal Brownian particle undergoing convection, diffusion, and electromigration processes. The two solute particle transport coefficients of interest are, respectively,

its mean particle velocity vector $\boldsymbol{U}^*$ and dispersivity dyadic $\overline{\mathbf{D}}^*$. The latter quantity, stochastically characterizing the variance in the actual instantaneous particle position relative to its mean position $\overline{\boldsymbol{U}}^* t$, results from the (longitudinal) molecular diffusion of the particle (characterized by the diffusion coefficient D) as well as from the convective Taylor dispersion mechanism. This dispersion arises from the lateral (and perhaps longitudinal) flow and electric field nonuniformities in conjunction with the molecular diffusion. While the Taylor mechanism may dominate for certain convective-diffusive processes, it is obviously absent during curvature-free electro-osmotic plug flow occurring in straight channels. In the present case, where net (i.e., "global") solute motion occurs only in the X-direction, and where $\hat{\boldsymbol{X}}$ is the only vector involved in the global specification of the serpentine geometry, it is anticipated (and confirmed; cf. (4.31), (4.43)) that $\overline{\boldsymbol{U}}^*$ and $\overline{\mathbf{D}}^*$ possess the respective "unidirectional" forms

$$\overline{\boldsymbol{U}}^* = \hat{\boldsymbol{X}}\overline{U}^*, \quad \overline{\mathbf{D}}^* = \hat{\boldsymbol{X}}\hat{\boldsymbol{X}}\overline{D}^*. \tag{4.1}$$

Taylor–Aris macrotransport analyses are asymptotic in nature, valid only when the diffusive unit-cell sampling time-scale, l^2/D, is small compared with the "global" solute holdup time, $\mathcal{O}(Nl/v_0)$, occurring within the entire serpentine system (of projected length NL, where N denotes the number of periods comprising the finite-size chip). As such, these analyses naturally conform with the present model of a serpentine device, consisting of numerous turns, $N \gg 1$. The quantities $\overline{\boldsymbol{U}}^*$ and $\overline{\mathbf{D}}^*$, which characterize the transient global transport of solute through the serpentine system, are evaluated using the local solutions of a pair of steady-state equations within the unit-cell domain τ_0, these being defined in the subsequent paragraphs. In that context we temporarily abandon the dimensionless notation previously used.

Evaluation of $\overline{\boldsymbol{U}}^*$, using the macrotransport scheme of [3] for periodic systems, requires calculating the long-time probability flux density vector field $\boldsymbol{J}_0^\infty(\boldsymbol{r})$, governed by the steady-state conservation equation

$$\boldsymbol{\nabla} \cdot \boldsymbol{J}_0^\infty = 0. \tag{4.2}$$

Constitutively, this flux vector possesses the convective-diffusive form,

$$\boldsymbol{J}_0^\infty = \boldsymbol{U}(\boldsymbol{r}) P_0^\infty - \mathbf{D}(\boldsymbol{r}) \cdot \boldsymbol{\nabla} P_0^\infty, \tag{4.3}$$

wherein $P_0^\infty(\boldsymbol{r})$ is the long-time intracellular probability density field, $\mathbf{D}$ is the local molecular diffusivity dyadic, and $\boldsymbol{U}$ is the local velocity vector of the solute particle when situated at $\boldsymbol{r}$. On the lateral boundaries s_p of the unit cell the flux vector satisfies the no-flux condition,

$$\hat{\boldsymbol{n}} \cdot \boldsymbol{J}_0^\infty = 0 \quad \text{on} \quad s_p, \tag{4.4}$$

whereas at the endpoints of the unit cell, P_0^∞ satisfies the jump condition,

$$P_0^\infty(n, s = 0) = P_0^\infty(n, s = l) \qquad \forall n \in [-h, h]\,. \tag{4.5}$$

In addition, P_0^∞ satisfies the normalization condition

$$\int_{\tau_0} P_0^\infty \, d^2\boldsymbol{r} = 1, \tag{4.6}$$

with τ_0 the unit-cell domain and $d^2\boldsymbol{r}$ a two-dimensional "volume" element. Knowledge of the resulting field $P_0^\infty(\boldsymbol{r})$, defined by the above system of equations, enables one to compute $\overline{\boldsymbol{U}}^*$ via the unit-cell quadrature,

$$\overline{\boldsymbol{U}}^* = \int_{\tau_0} \boldsymbol{J}_0^\infty \, d^2\boldsymbol{r}. \tag{4.7}$$

In the presence of an external force field $\boldsymbol{F}$ acting on the particle, the field $\boldsymbol{U}$ required in (4.3) is represented as

$$\boldsymbol{U} = \boldsymbol{U}'(\boldsymbol{r}) + \mathbf{M}(\boldsymbol{r}) \cdot \boldsymbol{F}(\boldsymbol{r}), \tag{4.8}$$

wherein $\boldsymbol{U}'(\boldsymbol{r})$ is the velocity of the particle in the absence of the force (which, in general, may differ from the undisturbed solvent velocity field $\boldsymbol{v}(\boldsymbol{r})$, owing to nonzero particle-size wall effects) and $\mathbf{M}$ is the particle mobility dyadic.

Calculation of $\overline{\mathbf{D}}^*$ requires knowledge of the so-called vector $\boldsymbol{B}(\boldsymbol{r})$-field, arising from deviations of the particle position $\boldsymbol{R}$ at time t from its mean value, $\overline{\boldsymbol{U}}^* t$, at that time. The $\boldsymbol{B}$-field is governed by the steady-state equation

$$\boldsymbol{\nabla} \cdot (P_0^\infty \mathbf{D} \cdot \boldsymbol{\nabla} \boldsymbol{B}) - \boldsymbol{J}_0^\infty \cdot \boldsymbol{\nabla} \boldsymbol{B} = P_0^\infty \overline{\boldsymbol{U}}^*, \tag{4.9}$$

and is subject to the jump condition

$$\boldsymbol{B}(n, s = l) - \boldsymbol{B}(n, s = 0) = -L\hat{\boldsymbol{X}} \qquad \forall n \in [-h, h] \tag{4.10}$$

as well as the no-flux condition

$$\hat{\boldsymbol{n}} \cdot (P_0^\infty \mathbf{D} \cdot \boldsymbol{\nabla} \boldsymbol{B}) = \mathbf{0} \quad \text{on} \quad s_p. \tag{4.11}$$

Equations (4.9)–(4.11) serve to define the $\boldsymbol{B}$-field, albeit only to within an arbitrary additive constant. This constant proves irrelevant, since the evaluation of $\overline{\mathbf{D}}^*$ through the following unit-cell quadrature involves only the gradients of this field. Explicitly,

$$\overline{\mathbf{D}}^* = \int_{\tau_0} P_0^\infty \, (\boldsymbol{\nabla} \boldsymbol{B})^\dagger \cdot \mathbf{D} \cdot (\boldsymbol{\nabla} \boldsymbol{B}) \, d^2\boldsymbol{r}. \tag{4.12}$$

In the present "point-size" particle case, wall effects are neglected. In such circumstances the mobility (as well as the diffusivity) is isotropic and spatially uniform (that is, $\mathbf{M}(\boldsymbol{r}) \equiv M\mathbf{I}$, $\mathbf{D}(\boldsymbol{r}) \equiv D\mathbf{I}$, with $\mathbf{I}$ the dyadic idemfactor), and the solute velocity is accordingly given by

$$\boldsymbol{U}(\boldsymbol{r}) = \boldsymbol{v}(\boldsymbol{r}) + M\boldsymbol{F}(\boldsymbol{r}). \tag{4.13}$$

Consider the transport of a nonconducting colloidal Brownian particle possessing a uniform surface charge density. Owing to this charge, the particle motion is governed by both the bulk flow and the electric field, the latter representing the present counterpart of the generic external force field appearing in (4.13). The size of the particle is assumed small compared with the width $2h$, corresponding to a "point-size" particle. The (dimensional) particle electrophoretic velocity relative to the carrier fluid is given by $M_e\boldsymbol{E}$, where M_e is the electrophoretic mobility. In the limit of a thin Debye layer at the particle surface, this mobility is given by the well-known Smoluchowski relation [14, 23],

$$M_e = \frac{\varepsilon_{el}\zeta_p}{\mu}, \tag{4.14}$$

wherein ζ_p denotes the (uniform) excess potential, relative to ϕ, at the particle surface.[4] The dimensionless counterpart of (4.13) is thus (see (3.14))

$$\boldsymbol{U} = \epsilon^{-1}(1-\alpha)\boldsymbol{\nabla}\phi, \tag{4.15}$$

where $\alpha = \zeta_p/\zeta$. The case $\alpha = 0$ corresponds to an inert particle, one which is unaffected by the presence of the electric field.

To effect a dimensionless formulation, P_0^∞ is normalized with $1/\tau_0$, where $\tau_0 = 2hl$ is the solvent-filled domain of a unit cell. The solute probability flux (normalized by v_0/τ_0) is then

$$\boldsymbol{J}_0^\infty = \epsilon^{-1}(1-\alpha)P_0^\infty\boldsymbol{\nabla}\phi - Pe^{-1}\boldsymbol{\nabla}P_0^\infty, \tag{4.16}$$

wherein

$$Pe = \frac{hv_0}{D} \tag{4.17}$$

is a hybrid Péclet number.

The dimensionless solute probability density field P_0^∞ is here governed by: (i) the solute conservation equation

$$\boldsymbol{\nabla}\cdot\left[\epsilon^{-1}(1-\alpha)P_0^\infty\boldsymbol{\nabla}\phi - Pe^{-1}\boldsymbol{\nabla}P_0^\infty\right] = 0; \tag{4.18}$$

(ii) the no-flux boundary condition

$$\hat{\boldsymbol{n}}\cdot\left[\epsilon^{-1}(1-\alpha)P_0^\infty\boldsymbol{\nabla}\phi - Pe^{-1}\boldsymbol{\nabla}P_0^\infty\right] = 0 \quad \text{at} \quad n = \pm 1; \tag{4.19}$$

and (iii) the unit-cell normalization condition (cf. (4.6))

$$\frac{1}{2}\int_{\tau_0} P_0^\infty \, d^2\boldsymbol{r} = 1, \tag{4.20}$$

wherein the volume element $d^2\boldsymbol{r}$ has been normalized with lh.

It is natural to normalize $\boldsymbol{B}$ with l. The resulting dimensionless $\boldsymbol{B}$-field thus satisfies the equation

$$Pe^{-1}\boldsymbol{\nabla}\cdot(P_0^\infty\boldsymbol{\nabla}\boldsymbol{B}) - \boldsymbol{J}_0^\infty\cdot\boldsymbol{\nabla}\boldsymbol{B} = \epsilon P_0^\infty\overline{\boldsymbol{U}}^*, \tag{4.21}$$

and is subject to the jump condition

$$\boldsymbol{B}(n, S=1;\epsilon) - \boldsymbol{B}(n, S=0;\epsilon) = -\frac{L}{l}\hat{\boldsymbol{X}}, \qquad \forall n \in [-1,1]\,, \tag{4.22}$$

as well as the no-flux condition

$$P_0^\infty\,\hat{\boldsymbol{n}}\cdot\boldsymbol{\nabla}\boldsymbol{B} = \boldsymbol{0} \quad \text{at} \quad n = \pm 1. \tag{4.23}$$

[4] In circumstances wherein the solute particle is comparable in size to Debye layer thickness, Smoluchowski's approximation breaks down; nevertheless, the relation (4.14) may still be used in such situations, with ζ_p representing an effective zeta potential.

4.1. Mean solute velocity. It is easy to verify, using (3.10) and (3.11), that the trial solution

$$P_0^\infty = 1 \tag{4.24}$$

satisfies the boundary-value problem (4.18)–(4.20). This result is nonintuitive, since both the electric and solvent velocity fields are nonuniform in the n- (and s-) directions. However, it is easily verified that $P_0^\infty = \text{const}$ is, in fact, the only solution of the generic transport problem (4.2)–(4.8), at least for point-size particles, provided that (i) the force field is divergence-free; (ii) the force field has a null normal component on the walls; and (iii) the solvent velocity satisfies an impenetrability condition on the walls. In the present case, satisfaction of conditions (i) and (ii) (see (3.10), (3.11)) is associated with the assumption that $\lambda_D/h \to 0$. Satisfaction of condition (ii) is unique to electrophoretic motion in electro-osmotic flows.

In terms of the local (n, S) coordinate system, the probability density flux vector is given by the expression

$$\begin{aligned} \boldsymbol{J}_0^\infty &= \hat{\boldsymbol{n}}\left[\epsilon^{-1}(1-\alpha)\frac{\partial\phi}{\partial n}P_0^\infty - Pe^{-1}\frac{\partial P_0^\infty}{\partial n}\right] \\ &+ \hat{\boldsymbol{s}}\left[\frac{1-\alpha}{1-\epsilon nk}\frac{\partial\phi}{\partial S}P_0^\infty - \frac{\epsilon Pe^{-1}}{1-\epsilon nk}\frac{\partial P_0^\infty}{\partial S}\right]. \end{aligned} \tag{4.25}$$

Substitution of the preceding expressions for ϕ and P_0^∞ gives, with $\boldsymbol{J}_0^\infty = \hat{\boldsymbol{n}}J_n + \hat{\boldsymbol{s}}J_s$, the component fluxes

(4.26a)
$$J_n = \epsilon^2\frac{1-\alpha}{2}\frac{dk}{dS} + \epsilon^3\frac{7(1-\alpha)}{6}k\frac{dk}{dS}n(1-n^2) + \mathcal{O}\left(\epsilon^4\right),$$

(4.26b)
$$J_s = (1-\alpha) + \epsilon(1-\alpha)nk + \epsilon^2(1-\alpha)\left[\left(n^2-\frac{1}{3}\right)k^2 + \frac{1}{3}\int_0^1 k^2(S)\,dS\right] + \mathcal{O}\left(\epsilon^3\right).$$

The mean solute velocity (normalized with v_0) is given by the expression (cf. (4.7))

$$\overline{\boldsymbol{U}}^* = \frac{1}{2}\int_{\tau_0} \boldsymbol{J}_0^\infty\, d^2\boldsymbol{r}. \tag{4.27}$$

From (4.26), together with the relation $d^2\boldsymbol{r} = (1-\epsilon nk)\,dn\,dS$, we obtain $\overline{\boldsymbol{U}}^*$ in the form of an asymptotic series,

$$\overline{\boldsymbol{U}}^* \sim \overline{\boldsymbol{U}}^{(0)} + \epsilon\overline{\boldsymbol{U}}^{(1)} + \epsilon^2\overline{\boldsymbol{U}}^{(2)} + \mathcal{O}\left(\epsilon^3\right), \tag{4.28}$$

in which

$$\overline{\boldsymbol{U}}^{(0)} = (1-\alpha)\int_0^1 \hat{\boldsymbol{s}}(S)\,dS,$$

$$\overline{\boldsymbol{U}}^{(1)} = \boldsymbol{0},$$

$$\overline{\boldsymbol{U}}^{(2)} = \frac{1}{3}(1-\alpha)\left[\int_0^1 \hat{\boldsymbol{n}}(S)\frac{dk}{dS}\,dS + \left(\int_0^1 k^2(S)\,dS\right)\left(\int_0^1 \hat{\boldsymbol{s}}(S)\,dS\right) - \int_0^1 \hat{\boldsymbol{s}}k^2(S)\,dS\right].$$

The first integral appearing in the above brackets may be transformed via use of the identity

$$\int_0^1 \hat{\boldsymbol{n}}(S)\frac{dk}{dS}\,dS = -\int_0^1 k(S)\frac{d\hat{\boldsymbol{n}}}{dS}\,dS,$$

which follows upon integration by parts in conjunction with the "periodicity" of both $\hat{\boldsymbol{n}}$ and k.

With $\boldsymbol{r}_c$ (see (2.1)) normalized via l, the dimensionless parametric equation for the curve Γ is given by

$$\boldsymbol{r} = \epsilon^{-1}\boldsymbol{r}_c(S). \tag{4.29}$$

Thus, the dimensionless counterparts of (2.2)–(2.3) are

$$\frac{d\boldsymbol{r}_c}{dS} = \hat{\boldsymbol{s}}, \quad \frac{d\hat{\boldsymbol{s}}}{dS} = k\hat{\boldsymbol{n}}, \quad \frac{d\hat{\boldsymbol{n}}}{dS} = -k\hat{\boldsymbol{s}}. \tag{4.30}$$

Use of (4.29) and (4.30) eventually yields

$$\overline{\boldsymbol{U}}^* = \overline{U}^*\hat{\boldsymbol{X}}, \tag{4.31}$$

wherein

$$\overline{U}^* = (1-\alpha)\frac{L}{l}\left[1 + \frac{\epsilon^2}{3}\int_0^1 k^2(S)\,dS + \mathcal{O}(\epsilon^3)\right]. \tag{4.32}$$

The $\mathcal{O}(1)$ term accords with intuitive "tortuosity" effects [22], associated with the ratio l/L (> 1) of the curvilinear/rectilinear distances traversed by the solute particle during the same period of time. For typical microfluidic devices this ratio is $\mathcal{O}(1)$. The coefficient $1-\alpha$ reflects the combined effects of electro-osmosis and electrophoresis, such effects being either counteractive or cooperative, according to whether the channel wall and solute particle possess like $(\alpha > 0)$ or unlike $(\alpha < 0)$ charges, respectively. As $\boldsymbol{v}^{(1)}$ is an odd function of n, the explicit functional dependence of the mean velocity upon the curvature appears only at the $\mathcal{O}(\epsilon^2)$ term.

4.2. Dispersivity. Assume the following trial solution for the $\boldsymbol{B}$-field:

$$\boldsymbol{B} = \hat{\boldsymbol{X}}B(n,S;\epsilon). \tag{4.33}$$

Substitution of the above representation into (4.21)–(4.23), in conjunction with use of (4.24), yields the following set of equations governing B, expressed in terms of the local coordinates:

$$\begin{aligned} Pe^{-1}&\left[\frac{\partial^2 B}{\partial n^2} - \frac{\epsilon k}{1-\epsilon nk}\frac{\partial B}{\partial n} + \frac{\epsilon^2}{(1-\epsilon nk)^2}\frac{\partial^2 B}{\partial S^2} + \frac{\epsilon^3 n}{(1-\epsilon nk)^3}\frac{dk}{dS}\frac{\partial B}{\partial S}\right] \\ &- J_n\frac{\partial B}{\partial n} - \frac{\epsilon}{1-\epsilon nk}J_s\frac{\partial B}{\partial S} = \epsilon\overline{U}^*, \end{aligned} \tag{4.34}$$

$$\frac{\partial B}{\partial n} = 0 \quad \text{at} \quad n = \pm 1, \tag{4.35}$$

$$B(n,S=1)-B(n,S=0)=-\frac{L}{l}\qquad\forall n\in[-1,1]\,. \tag{4.36}$$

The ϵ-dependent terms in (4.34) may be expanded into Taylor series, and terms of like order in ϵ collected together, to obtain

$$\begin{aligned}&Pe^{-1}\frac{\partial^2 B}{\partial n^2}-J_n\frac{\partial B}{\partial n}+\epsilon\left(-Pe^{-1}k\frac{\partial B}{\partial n}-J_s\frac{\partial B}{\partial S}-\overline{U}^*\right)\\&+\epsilon^2\left(-Pe^{-1}nk^2\frac{\partial B}{\partial n}+Pe^{-1}\frac{\partial^2 B}{\partial S^2}-nkJ_s\frac{\partial B}{\partial S}\right)\\&+\epsilon^3\left(-Pe^{-1}n^2k^3\frac{\partial B}{\partial n}+2Pe^{-1}nk\frac{\partial^2 B}{\partial S^2}+Pe^{-1}n\frac{dk}{dS}\frac{\partial B}{\partial S}-n^2k^2J_s\frac{\partial B}{\partial S}\right)\\&+\mathcal{O}\left(\epsilon^4\right)=0.\end{aligned} \tag{4.37}$$

Assume the following trial expansion for B:

$$B(n,S;\epsilon)\sim B^{(0)}(n,S)+\epsilon B^{(1)}(n,S)+\epsilon^2 B^{(2)}(n,S)+\cdots\,. \tag{4.38}$$

Substitution into (4.37) of equations (4.26), (4.32), and (4.38) yields a system of equations which can be solved recursively in conjunction with use of the various orders of the boundary condition (4.35), namely,

$$\frac{\partial B^{(i)}}{\partial n}=0\quad\text{at}\quad n=\pm1\qquad(i=0,1,2,\dots), \tag{4.39}$$

together with the decomposed jump condition (4.36),

$$\left.\begin{array}{c}B^{(0)}(n,S=1)-B^{(0)}(n,S=0)=-L/l,\\B^{(i)}(n,S=1)-B^{(i)}(n,S=0)=0\qquad(i=1,2,\dots)\end{array}\right\}\qquad\forall n\in[-1,1]\,. \tag{4.40}$$

As the solution scheme for the present boundary-value problem closely resembles that already given for the Laplace equation governing ϕ (see appendix), we omit details. Calculations up to $\mathcal{O}(\epsilon^2)$ yield[5]

$$B^{(0)}=-\frac{L}{l}S, \tag{4.41a}$$

$$B^{(1)}=0, \tag{4.41b}$$

$$B^{(2)}=\frac{L}{l}(1-\alpha)Pe\frac{3n-n^3}{3}k(S). \tag{4.41c}$$

Calculation of $\overline{\mathbf{D}}^*$ (normalized with D) requires effecting the quadrature (cf. (4.12))

$$\overline{\mathbf{D}}^*=\frac{1}{2\epsilon^2}\int_{\tau_0}P_0^\infty\,(\boldsymbol{\nabla B})^\dagger\cdot(\boldsymbol{\nabla B})\,d^2\boldsymbol{r}. \tag{4.42}$$

Introduction of the preceding expression obtained for $\boldsymbol{B}$ eventually yields

$$\overline{\mathbf{D}}^*=\hat{\boldsymbol{X}}\hat{\boldsymbol{X}}\,\overline{D}^*, \tag{4.43}$$

[5]Since $\boldsymbol{B}$ is defined only to within an additive constant, we conveniently set $B^{(i)}(n,S=0)=0$.

wherein $\overline{D}^*$, represented as the sum of respective "molecular" and "convective" contributions, is

$$\overline{D}^* = \overline{D}^M + \overline{D}^C, \tag{4.44}$$

in which

$$\overline{D}^M = \left(\frac{L}{l}\right)^2 \left[1 + \frac{\epsilon^2}{3}\int_0^1 k^2(S)\,dS + \mathcal{O}\left(\epsilon^3\right)\right], \tag{4.45a}$$

$$\overline{D}^C = \frac{8\epsilon^2}{15}\left(\frac{L}{l}\right)^2 (1-\alpha)^2 Pe^2 \int_0^1 k^2(S)\,dS + \mathcal{O}\left(\epsilon^3\right). \tag{4.45b}$$

Whereas the (dimensional) molecular dispersion coefficient is directly proportional to the solute particle's molecular diffusivity D, the comparable convective coefficient is inversely proportional to D. The $\mathcal{O}(1)$ term in $\overline{D}^M$ represents the combined "tortuosity" effects of the extended curvilinear channel length and the decreased effective width of the serpentine channel [22]. The $\overline{D}^C$ term of $\mathcal{O}\left(\epsilon^2\right)$ constitutes the natural extension to the constant-radius results of [10].

The convective coefficient (4.45b), which vanishes for curvature-free (i.e., rectilinear) electro-osmotic plug flow, constitutes a nonnegative contribution originating from second-order curvature effects. These arise from comparable first-order curvature corrections to the otherwise uniform flow and electric fields, both of which are laterally antisymmetric (see, e.g., (3.23b)). Whereas, to terms of dominant order, this results in a null contribution to the average solute velocity (see (4.32)), the corresponding variance in the Brownian particle position, which constitutes a quadratic term, does not vanish.

As a simple example of the use of the present results, consider the case where each period of the serpentine channel consists of two semicircular arcs, each possessing a (dimensional) radius $L/4$. (This geometry can also approximate spiral channel configurations; see [6].) The total channel length is therefore given by $l = \pi L/2$, and the curvature is equal to $\pm 4/L$. As would be expected, the discontinuity in k does not affect the value of the integrals in (4.45). The dimensionless magnitude of $|k|$ is equal almost everywhere to $4(l/L)$; this readily yields $\overline{D}^C = 128\epsilon^2(1-\alpha)^2 Pe^2/15$.

5. Circular cross-section. Sections 2–4 furnished the flow and subsequent macrotransport analyses for laterally unbounded serpentine devices, eventually resulting in the macrotransport coefficients $\overline{\boldsymbol{U}}^*$ and $\overline{\mathbf{D}}^*$. While the two-dimensional configuration analyzed thus far is predominant in microfluidic devices [7], the present asymptotic scheme may be easily generalized for three-dimensional flows, emphasizing the generic nature of the analysis. In this section we demonstrate the extension of previous analysis to serpentine devices possessing circular cross sections, which constitute another simple laterally bounded channel geometry.

5.1. Geometry. Consider a serpentine channel of uniform circular cross section, as in Figure 4. As in the comparable two-dimensional case, it is convenient to focus on the planar center-line curve Γ defining the axis of the channel. The boundary s_p of this channel consists of the locus of circles of radius h centered about Γ and lying normal to it. This construction may be generalized to define a "radial" coordinate, say ρ, whereby the surface $\rho = \text{const}$ constitutes the collection of circles of radius ρ centered about Γ and lying normal to it. Consequently, it is natural to adopt a

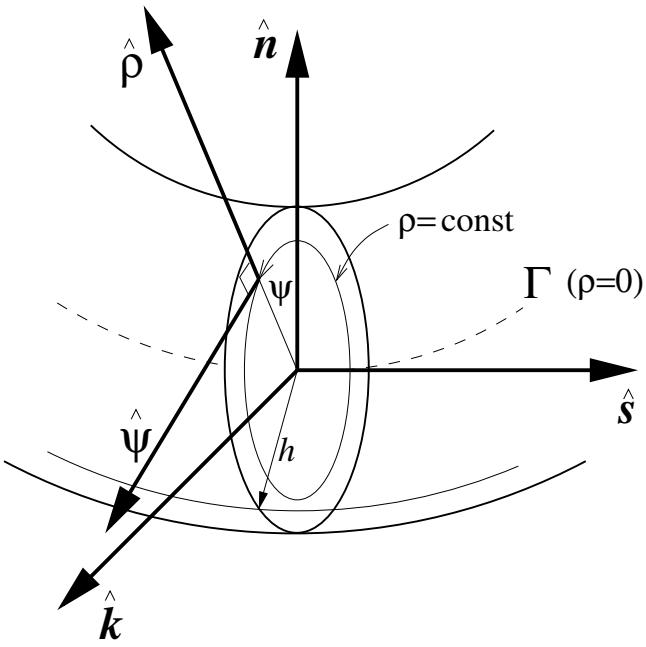

FIG. 4. *Curvilinear cylindrical-like coordinate system.*

system of local cylindrical coordinates, (ρ, ψ, s), appropriate to the configuration of the present serpentine channel. The surface $\psi = \text{const}$ corresponds to the collection of rays originating from Γ and lying normal to it, forming an angle ψ relative to the osculating plane. (The positive sense of ψ is taken to lie in the counter-clockwise direction from $\hat{\boldsymbol{n}}$ to $\hat{\boldsymbol{k}}$.)

Define the respective radial and azimuthal unit vectors associated with the coordinates ρ and ψ,

$$\hat{\boldsymbol{\rho}} = \hat{\boldsymbol{n}}(s)\cos\psi + \hat{\boldsymbol{k}}\sin\psi, \tag{5.1a}$$

$$\hat{\boldsymbol{\psi}} = -\hat{\boldsymbol{n}}(s)\sin\psi + \hat{\boldsymbol{k}}\cos\psi. \tag{5.1b}$$

The triad $(\hat{\boldsymbol{\rho}}, \hat{\boldsymbol{\psi}}, \hat{\boldsymbol{s}})$, in that order, form a right-handed orthonormal system. The position vector at the point (ρ, ψ, s) is given by

$$\boldsymbol{r}\,(\rho, \psi, s) = \boldsymbol{r}_c(s) + \rho\hat{\boldsymbol{\rho}}(\psi, s). \tag{5.2}$$

Use of (2.3b) and (5.1) yields the differential vector displacement $d\boldsymbol{r}$ between the neighboring points (ρ, ψ, s) and $(\rho + d\rho, \psi + d\psi, s + ds)$:

$$d\boldsymbol{r} = \hat{\boldsymbol{\rho}}\, d\rho + \hat{\boldsymbol{\psi}}\rho\, d\psi + \hat{\boldsymbol{s}}\,(1 - \rho k\cos\psi)\; ds.$$

The metrical coefficients associated with the coordinates (ρ, ψ, s) are thus given by $(1, \rho, 1 - \rho k\cos\psi)$, respectively, whence the gradient operator appropriate to the serpentine cylindrical coordinate system (cf. (2.6)) is

$$\boldsymbol{\nabla} = \hat{\boldsymbol{\rho}}\frac{\partial}{\partial\rho} + \hat{\boldsymbol{\psi}}\frac{1}{\rho}\frac{\partial}{\partial\psi} + \hat{\boldsymbol{s}}\frac{1}{1 - \rho k\cos\psi}\frac{\partial}{\partial s}. \tag{5.3}$$

Use of (5.3) yields [17] the following expression for the Laplacian of a generic scalar field $f(\rho,\psi,s)$:

$$\nabla^2 f = \frac{\partial^2 f}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial f}{\partial\rho} - \frac{k\cos\psi}{1-\rho k\cos\psi}\frac{\partial f}{\partial\rho} + \frac{1}{\rho^2}\frac{\partial^2 f}{\partial\psi^2} + \frac{k\sin\psi}{\rho\,(1-\rho k\cos\psi)}\frac{\partial f}{\partial\psi} + \frac{1}{(1-\rho k\cos\psi)^2}\frac{\partial^2 f}{\partial s^2} + \frac{\rho\cos\psi}{(1-\rho k\cos\psi)^3}\frac{dk}{ds}\frac{\partial f}{\partial s}. \tag{5.4}$$

In the case of a uniform (i.e., s-independent) curvature k, these expressions degenerate to their respective counterparts in toroidal coordinates (cf. [2]).

5.2. Electro-osmotic flow. The mathematical formulation of the present electrokinetic problem possesses a structure similar to that encountered in the two-dimensional case, (3.1)–(3.7), as all length variables are normalized here with ρ_0, rather than a. Thus, $\epsilon = \rho_0/l$ (cf. (3.13)). In the nondimensionalization, all length variables are normalized with h, the cylinder radius. With $S = \epsilon s$, the dimensionless reformulation of the potential problem in terms of the local coordinates (ρ,ψ,S) consists of (i) Laplace's equation in the fluid domain:

$$\frac{\partial^2\phi}{\partial\rho^2} + \frac{1}{\rho}\frac{\partial\phi}{\partial\rho} - \frac{\epsilon k\cos\psi}{1-\epsilon\rho k\cos\psi}\frac{\partial\phi}{\partial\rho} + \frac{1}{\rho^2}\frac{\partial^2\phi}{\partial\psi^2} + \frac{\epsilon k\sin\psi}{\rho\,(1-\epsilon\rho k\cos\psi)}\frac{\partial\phi}{\partial\psi} + \frac{\epsilon^2}{(1-\epsilon\rho k\cos\psi)^2}\frac{\partial^2\phi}{\partial S^2} + \frac{\epsilon^3\rho\cos\psi}{(1-\epsilon\rho k\cos\psi)^3}\frac{dk}{dS}\frac{\partial\phi}{\partial S} = 0; \tag{5.5}$$

(ii) the channel wall boundary conditions (at $\rho = 1$),

$$\frac{\partial\phi}{\partial n} = 0; \tag{5.6}$$

and (iii) the serpentine periodicity conditions

$$\phi(\rho,\psi,S=1;\epsilon) - \phi(\rho,\psi,S=0;\epsilon) = 1 \qquad \forall(\rho,\psi)\in[0,1]\times[0,2\pi]\,. \tag{5.7}$$

In the limit $\epsilon \ll 1$ the above problem may be solved using perturbation expansions in powers of ϵ. The analysis is similar to that of section 3.2, whence we omit details. The electric potential is eventually found to be given by the expression

$$\phi = S + \frac{\epsilon^2}{4}\left[S\int_0^1 k^2(x)\,dx - \int_0^S k^2(x)\,dx\right] + \epsilon^3\left[\frac{3\rho-\rho^3}{8}\frac{dk}{dS}\cos\psi + E(S)\right] + \epsilon^4\left[\frac{1}{192}k\frac{dk}{dS}\left(42\rho^2 - 21\rho^4 + 52\rho^2\cos 2\psi - 26\rho^4\cos 2\psi\right) + F(S)\right] + \mathcal{O}\left(\epsilon^5\right), \tag{5.8}$$

wherein $E(S)$ and $F(S)$ are arbitrary periodic functions of S (cf. (3.22)). Substitution into (3.14) yields the velocity components

$$u = \frac{3\epsilon^2}{8}\frac{dk}{dS}(1-\rho^2)\cos\psi + \frac{\epsilon^3}{48}k\frac{dk}{dS}\left(\rho-\rho^3\right)(21+26\cos 2\psi) + \mathcal{O}\left(\epsilon^4\right), \tag{5.9a}$$

$$v = \frac{\epsilon^2}{8}\frac{dk}{dS}(\rho^2-3)\sin\psi + \frac{13\epsilon^3}{48}k\frac{dk}{dS}\left(\rho^3-2\rho\right)\sin 2\psi + \mathcal{O}\left(\epsilon^4\right), \tag{5.9b}$$

$$w = 1 + \epsilon\rho k(S)\cos\psi + \frac{\epsilon^2}{4}\left[(2\rho^2-1)k^2(S) + 2\rho^2 k^2(S)\cos 2\psi + \int_0^1 k^2(x)\,dx\right] + \mathcal{O}\left(\epsilon^3\right). \tag{5.9c}$$

5.3. Macrotransport analysis. The (dimensional) equations governing the transport of a colloidal Brownian particle are posed by equations (4.2)–(4.15), with minor modifications reflecting the three-dimensional nature of the present problem. To effect the dimensionless formulation, normalize P_0^∞ with $1/\tau_0$, where $\tau_0 = \pi h^2 l$ is the volume of a unit cell. The solute probability flux (normalized with v_0/τ_0) is then given by (4.16), with Pe given by (4.17). Accordingly, P_0^∞ is governed by the solute conservation equation

$$\boldsymbol{\nabla}\cdot\left[\epsilon^{-1}(1-\alpha)P_0^\infty\boldsymbol{\nabla}\phi - Pe^{-1}\boldsymbol{\nabla}P_0^\infty\right] = 0, \tag{5.10}$$

the no-flux boundary condition

$$\hat{\boldsymbol{\rho}}\cdot\left[\epsilon^{-1}(1-\alpha)P_0^\infty\boldsymbol{\nabla}\phi - Pe^{-1}\boldsymbol{\nabla}P_0^\infty\right] = 0 \quad \text{at} \quad \rho = 1, \tag{5.11}$$

and the unit-cell normalization condition (cf. (4.20))

$$\frac{1}{\pi}\int_{\tau_0} P_0^\infty\, d^3\boldsymbol{r} = 1, \tag{5.12}$$

wherein the volume element $d^3\boldsymbol{r}$ has been normalized with $h^2 l$.

The dimensionless $\boldsymbol{B}$-field (normalized with l) is governed by the differential equation

$$Pe^{-1}\boldsymbol{\nabla}\cdot(P_0^\infty\boldsymbol{\nabla}\boldsymbol{B}) - \boldsymbol{J}_0^\infty\cdot\boldsymbol{\nabla}\boldsymbol{B} = \epsilon P_0^\infty\overline{\boldsymbol{U}}^*, \tag{5.13}$$

the boundary condition

$$P_0^\infty\,\hat{\boldsymbol{n}}\cdot\boldsymbol{\nabla}\boldsymbol{B} = \boldsymbol{0} \quad \text{at} \quad \rho = 1, \tag{5.14}$$

and the jump condition

$$\boldsymbol{B}(\rho,\psi,S=1;\epsilon) - \boldsymbol{B}(\rho,\psi,S=0;\epsilon) = -\frac{L}{l}\hat{\boldsymbol{X}} \qquad \forall(\rho,\psi)\in[0,1]\times[0,2\pi]. \tag{5.15}$$

As the arguments leading to the identity (4.24) are independent of the unit-cell specific geometry, the identity continues to prevail in the present problem. The probability flux in terms of the local (ρ,ψ,s) coordinate system is therefore given by

$$\begin{aligned}\boldsymbol{J}_0^\infty &\triangleq \hat{\boldsymbol{\rho}}J_\rho + \hat{\boldsymbol{\psi}}J_\psi + \hat{\boldsymbol{s}}J_s\\ &= \hat{\boldsymbol{\rho}}\epsilon^{-1}(1-\alpha)\frac{\partial\phi}{\partial\rho} + \hat{\boldsymbol{\psi}}\epsilon^{-1}(1-\alpha)\frac{\partial\phi}{\rho\partial\psi} + \hat{\boldsymbol{s}}\frac{1-\alpha}{1-\epsilon\rho k\cos\psi}\frac{\partial\phi}{\partial S}.\end{aligned} \tag{5.16}$$

Substitution of (5.8) yields

(5.17)

$$\begin{aligned}J_\rho &= \frac{3\epsilon^2}{8}(1-\alpha)\frac{dk}{dS}(1-\rho^2)\cos\psi + \frac{\epsilon^3}{48}(1-\alpha)k\frac{dk}{dS}(\rho-\rho^3)(21+26\cos 2\psi) + \mathcal{O}\left(\epsilon^4\right),\\ J_\psi &= \frac{\epsilon^2}{8}(1-\alpha)\frac{dk}{dS}(\rho^2-3)\sin\psi + \frac{13\epsilon^3}{48}(1-\alpha)k\frac{dk}{dS}(\rho^3-2\rho)\sin 2\psi + \mathcal{O}\left(\epsilon^4\right),\\ J_s &= (1-\alpha) + \epsilon(1-\alpha)\rho k\cos\psi + \frac{\epsilon^2}{4}(1-\alpha)\left[2\rho^2k^2 + 2\rho^2k^2\cos 2\psi - k^2 + \int_0^1 k^2(x)\,dx\right]\\ &\quad + \mathcal{O}\left(\epsilon^3\right).\end{aligned}$$

The mean solute velocity is given by the expression (cf. (4.27))

$$\bar{\boldsymbol{U}}^* = \frac{1}{\pi}\int_{\tau_0} \boldsymbol{J}_0^\infty \, d^3\boldsymbol{r}. \tag{5.18}$$

In conjunction with the expression

$$d^3\boldsymbol{r} = (1-\epsilon\rho k\cos\psi)\, d\rho\, d\psi\, dS,$$

for the volume element, substitution of (5.17) into (5.18) eventually yields

$$\bar{\boldsymbol{U}}^* = \hat{\boldsymbol{X}}\bar{U}^*,$$

wherein (cf. (4.31))

$$\bar{U}^* = (1-\alpha)\frac{L}{l}\left[1+\frac{\epsilon^2}{4}\int_0^1 k^2(S)\, dS + \mathcal{O}(\epsilon^3)\right]. \tag{5.19}$$

Similarly to (4.33), we assume the following trial solution for the $\boldsymbol{B}$-field:

$$\boldsymbol{B} = \hat{\boldsymbol{X}} B(\rho,\psi,S;\epsilon).$$

Substitution of the preceding into (5.13)–(5.14) furnishes the differential equation

$$Pe^{-1}\nabla^2 B - J_\rho\frac{\partial B}{\partial\rho} - J_\psi\frac{\partial B}{\rho\partial\psi} - \frac{\epsilon}{1-\epsilon\rho k\cos\psi}J_s\frac{\partial B}{\partial S} = \epsilon\bar{U}^*, \tag{5.20}$$

the boundary condition

$$\frac{\partial B}{\partial\rho} = 0 \quad \text{at} \quad \rho = 1, \tag{5.21}$$

and the jump condition

$$B(\rho,\psi,S=1) - B(\rho,\psi,S=0) = -\frac{L}{l} \qquad \forall(\rho,\psi)\in[0,1]\times[0,2\pi], \tag{5.22}$$

governing the scalar B-field. Expansion of B into an asymptotic series, similar to (4.38), eventually yields the solution

$$B \sim -\frac{L}{l}S + \epsilon^2\frac{L}{l}(1-\alpha)Pe\frac{3\rho-\rho^3}{4} + \mathcal{O}(\epsilon^3). \tag{5.23}$$

Performing the quadrature in the expression for the dispersivity (cf. (4.42)), namely,

$$\overline{\mathbf{D}}^* = \frac{1}{\pi\epsilon^2}\int_{\tau_0} P_0^\infty\, (\boldsymbol{\nabla}\boldsymbol{B})^\dagger\cdot(\boldsymbol{\nabla}\boldsymbol{B})\; d^2\boldsymbol{r}, \tag{5.24}$$

eventually yields the anticipated form, (4.43)–(4.44), wherein (cf. (4.45))

$$\bar{D}^M = \left(\frac{L}{l}\right)^2\left[1+\frac{\epsilon^2}{4}\int_0^1 k^2(S)\, dS + \mathcal{O}\left(\epsilon^3\right)\right], \tag{5.25a}$$

$$\bar{D}^C = \frac{5\epsilon^2}{48}\left(\frac{L}{l}\right)^2(1-\alpha)^2Pe^2\int_0^1 k^2(S)\, dS + \mathcal{O}\left(\epsilon^3\right). \tag{5.25b}$$

6. Comparison with existing literature. Here, we compare our results with those obtained using alternative models of turn-induced dispersion phenomena. Initial investigations (see, e.g., [13]) employed intuitive kinematical models to obtain the "skew" produced by a constant-radius turn, neglecting transverse diffusion. This skew, quantifying the extent of distortion accompanying the introduction of an initially uniform band of solute into a pre-existing flow, was attributed to two additive sources: transverse variation in electric field strength, and overall migration distance within the turn (the so-called "racetrack effect"). Culbertson, Jacobson, and Ramsey [5] accounted for molecular diffusion using empirical expressions, for which the coefficients appearing therein were obtained from a fit with experimental data. Those authors proposed the use of "complementary" turns to reduce dispersion in systems operating at large Péclet numbers.

Griffiths and Nilson [10] provided an analytical model for diffusion effects in a constant-radius turn. Their curvature-induced shear-flow expression is equivalent to the present $v^{(1)}$ (see (3.23b)). The authors have calculated solute variance following a single turn. The variance for small Péclet numbers was evaluated using a method-of-moments formula, whereas that in the opposite extreme of large Péclet numbers was calculated using a kinematical skewing model. A composite expression for the variance, presumably valid for all Péclet numbers, was suggested, having the form of a fractional expression, which degenerates to the desired forms in the respective limits of small and large Péclet numbers. This solution was compared with both numerical Monte Carlo simulations as well as with the experimental data of [5].

In a related paper, Molho et al. [16] presented a two-dimensional single-turn dispersion model. The added variance, resulting from a single turn, was obtained using a method-of-moments approach. These authors postulated an initially symmetric solute band, thus enabling the solution of the advective-diffusion equation. The resulting variance was found to be a function of both Péclet number and turn length. It was further purposed that superposition of this dispersivity with the purely molecular dispersion occurring in the straight segments of the channel would provide a valid model for channel geometries consisting of more than one turn.

Obviously, all of the above-mentioned studies have employed the assumption of small curvature, either explicitly or implicitly (via use of an equivalent expression for the curvature-induced shear $v^{(1)}$). However, owing to the absence of a rigorous specification of the curvilinear geometry, the preceding analyses take account of curvature effects in a rather intuitive manner, thereby embodying only leading-order effects for small curvature.[6] This contrasts with the present asymptotic scheme, which allows for systematic expansions in ϵ.

Considerable effort has been expended in the above-mentioned studies to correlate and otherwise reconcile single-turn models with both simulation and experimental results. The underlying idea in those studies is that the total variance occurring in a multiturn system can be obtained by simply superposing the respective expressions appropriate to the several geometrical elements of which the serpentine system is composed (e.g., single-radius turns and straight segments). This procedure is appropriate for small Péclet numbers, $Pe \ll 1$, where the analyte plug can achieve a stationary state before encountering the next turn.

[6] For example, both the convective and diffusive terms appearing in the solute transport equation of [16] are incomplete owing to the failure to recognize that neither the gradient operator nor the concomitant Laplacian operator possesses "standard" Cartesian forms when expressed in curvilinear coordinates. The missing terms in their expressions (cf. (2.6)–(2.7)) vanish only for zero curvature.

The present analysis does not require that the Péclet number be strictly small. Nevertheless, the applicability of these results to the large Péclet number case is limited by the time-scale disparity underlying macrotransport analyses. The disparity assumption (see the discussion following (4.1)) may be written in the dimensionless form $Pe \ll N\epsilon$. Thus, for practical devices operating at large Pe, many turns would prove necessary for N-independent behavior to be established.

It is therefore obvious that the single- and multi-turn approaches provide similar results in the case of small Péclet number transport in a single turn. There, the diffusive unit-cell time-scale, l^2/D, is small compared with the transit time around the turn, $\mathcal{O}(l/v_0)$. Solute distribution thus achieves a stationary state almost instantaneously, which is exactly the assumption upon which macrotransport theory is based (which, for $Pe \sim \mathcal{O}(1)$, requires $N \gg 1$). In that case, and for constant-radius turns (spatially uniform curvature), the present dispersion coefficient (4.45b) can be expressed as arising from a superposition of "single-turn contributions," each having a form similar to the intermediate expression (15) of [10].

Several of the cited papers dealing with curved geometries have also proposed schemes for minimizing solute dispersion. Obviously, one way would be to increase the radius of curvature, for example, by using spiral geometries [6]. Another interesting method for reducing shear-induced dispersion invokes the use of a sinusoidal wavy channel wall at the inner track of the channel turn [9]. The resulting extension of the inner track length leads to a reduced average velocity on that side of the channel, thus reducing the curvature-induced shear. The wavy geometry lends itself to analytic analysis, the latter having been employed to suggest optimal channel shapes. Finally, a simple and effective way to reduce plug dispersion entails the use of narrow curved segments [20]. Obviously, constant-radius models are inadequate to describe the latter geometry, which is therefore analyzed alternatively using molecular dynamics simulations. This point demonstrates the benefit of extending our robust scheme to more complex geometries, for example, to the case of nonconstant channel width.

7. Concluding remarks. Electrokinetics, in conjunction with macrotransport theory, has been employed within the asymptotic framework of a regular perturbation scheme to obtain the mean velocity and dispersivity of a charged colloidal point-size Brownian particle entrained in an electro-osmotic solvent Stokes flow taking place within a thin serpentine channel. The results obtained apply to arbitrarily shaped (albeit periodic) channel configurations. The present electro-osmotic analysis extends the leading-order tortuosity results previously obtained by [22] (for nonelectro-osmotic, pressure-driven solvent flows). Explicitly, the combined contributions of both velocity and electric field deviations to the serpentine-scale macrotransport coefficients $\overline{U}^*$ and $\overline{D}^*$ have been evaluated. Unsurprisingly, our main contribution to the existing literature resides in the expression obtained for (the convective part of) $\overline{D}^*$, as no velocity variance—and hence no Taylor dispersion—is present in the leading-order electro-osmotic flow occurring in straight channel geometries (at least for thin Debye double-layers and point-size solute particles).

While only leading-order curvature corrections were obtained in the present contributions, the generic asymptotic scheme may be utilized to obtain higher-order terms, thus extending the range of applicability of the macrotransport description. Moreover, since the asymptotic scheme results in *regular* perturbation expansions in ϵ, it is expected that addition of such terms would extend the scheme's range of validity even to $\epsilon \lesssim 1$, thus providing dispersion models which are valid for "tight"

turns. Obviously, the validity of such extensions depends upon the neglect of inertial flow effects. It is also important to note that whereas the common thin-channel assumption is essential for the solution of the electrokinetic problem, this assumption is by no means necessary for the macrotransport analysis. Thus, the present scheme can, in principle, be employed for any periodic cell geometry, possibly requiring numerical solution of Laplace's equation.

The present analysis, while limited to idealized geometries, outlines a generic scheme for the subsequent evaluation of device-scale macrotransport coefficients appropriate to realistic chip geometries, incorporating both electro-osmotic and electrophoretic effects. The present flow-electrostatics solution scheme may also be used in conjunction with more realistic models, involving finite-size solute particles (relative to the channel width), for which steric volume-exclusion effects, as well as hydrodynamic [4, 15] (and perhaps colloidal [14]) wall effects, would serve to modify the preceding macrotransport analysis.

Appendix. Solution of the two-dimensional electrostatic problem.

The $\mathcal{O}(1)$ and $\mathcal{O}(\epsilon)$ problem. The leading-order problem is posed by the requirements that

$$\frac{\partial^2 \phi^{(0)}}{\partial n^2} = 0,$$
$$\frac{\partial \phi^{(0)}}{\partial n} = 0 \quad \text{at} \quad n = \pm 1.$$

This necessitates that

$$\frac{\partial \phi^{(0)}}{\partial n} = 0 \qquad \forall n \in [-1, 1],$$

or, alternatively,

$$\phi^{(0)} = \phi^{(0)}(S).$$

As a consequence of the latter condition, the $\mathcal{O}(\epsilon)$ problem is identical in form to the preceding $\mathcal{O}(1)$ problem, eventually yielding

$$\phi^{(1)} = \phi^{(1)}(S).$$

The $\mathcal{O}(\epsilon^2)$ problem. The solutions of the pertinent equations

$$\frac{\partial^2 \phi^{(2)}}{\partial n^2} = -\frac{d^2 \phi^{(0)}}{dS^2},$$
$$\frac{\partial \phi^{(2)}}{\partial n} = 0 \quad \text{at} \quad n = \pm 1,$$

supplemented by the periodicity condition

$$\phi^{(0)}(n, S = 1) - \phi^{(0)}(n, S = 0) = 1,$$

are

$$\phi^{(2)} = \phi^{(2)}(S)$$

and[7]

$$\phi^{(0)}(S) = S. \tag{A.1}$$

The $\mathcal{O}(\epsilon^3)$ problem. Here, the relevant equations

$$\frac{\partial^2 \phi^{(3)}}{\partial n^2} = -n\frac{dk}{dS} - \frac{d^2\phi^{(1)}}{dS^2},$$
$$\frac{\partial \phi^{(3)}}{\partial n} = 0 \quad \text{at} \quad n = \pm 1,$$

supplemented by the periodicity condition

$$\phi^{(1)}(n, S = 1) - \phi^{(1)}(n, S = 0) = 0,$$

furnish the following solutions:

$$\phi^{(3)}(n, S) = \frac{3n - n^3}{6}\frac{dk}{dS} + C(S)$$

and

$$\phi^{(1)} \equiv 0. \tag{A.2}$$

Here, $C(S)$ is an arbitrary (albeit "periodic"[8]) function of S. Its S-dependence may, if desired, be established from analysis of the $\mathcal{O}(\epsilon^5)$ problem.

The $\mathcal{O}(\epsilon^4)$ problem. Using similar arguments, the governing equations

$$\frac{\partial^2 \phi^{(4)}}{\partial n^2} = \frac{1 - 7n^2}{2}k\frac{dk}{dS} - \frac{d^2\phi^{(2)}}{dS^2},$$
$$\frac{\partial \phi^{(4)}}{\partial n} = 0 \quad \text{at} \quad n = \pm 1,$$

supplemented by the periodicity condition

$$\phi^{(2)}(n, S = 1) - \phi^{(2)}(n, S = 0) = 0,$$

furnish the following solutions:

$$\phi^{(4)}(n, S) = \frac{7}{24}(2n^2 - n^4)k\frac{dk}{dS} + D(S)$$

and

$$\phi^{(2)}(S) = \frac{1}{3}\left[S\int_0^1 k^2(x)\,dx - \int_0^S k^2(x)\,dx\right]. \tag{A.3}$$

Here, $D(S)$ is an arbitrary (albeit "periodic") function of S. If desired, it may be evaluated from analysis of the $\mathcal{O}(\epsilon^6)$ problem.

Acknowledgment. The authors are grateful to Eli Lilly and Company for their financial support and encouragement.

[7]Since ϕ is defined only to within an additive constant, we conveniently set $\phi^{(i)}(n, S = 0) = 0$.
[8]By "periodic" it is meant that $C(0) = C(1)$.

GEOMETRICAL OPTICS APPROXIMATION FOR NONLINEAR EQUATIONS*

F. BASS†, V. FREILIKHER†, A. A. MARADUDIN‡, AND V. PROSENTSOV†

Abstract. A wide class of nonlinear equations is studied in the geometrical optics approximation. It is shown that a nonlinear equation with coefficients dependent on the amplitude of the function sought can be reduced to a system of quasi-linear equations of the gas-dynamics type. As an illustration, the Hamilton–Jacobi equation with a specific form of the nonlinear operator has been solved, and the propagation of monochromatic waves and of point source radiation in nonlinear media has been studied.

Key words. nonlinear equations, quasi-linear equations, geometrical optics approximation, Hamilton–Jacobi equation

The geometrical optics approximation is an efficient and popular method in different areas of modern physics (acoustic and electromagnetic wave propagation, quantum mechanics, etc.). Due to its simplicity and reasonable accuracy, this method is frequently applied to the solution of various specific nonlinear problems [1], [2], [3], [4]. In this paper we propose a modification of the geometrical optics approximation applicable to an arbitrary form of a nonlinear equation (differential, integral, or finite difference) when the nonlinearity depends on the modulus of the unknown function.

1. The method. The basic equation of our problem is

$$\widehat{H}\left\{\rho, \mathbf{R}, \frac{\partial}{\partial \mathbf{R}}\right\}\Psi(\mathbf{R}) = 0, \tag{1.1}$$

where $\widehat{H}$ is a nonlinear operator, $\Psi(\mathbf{R})$ is the function to be found, $\mathbf{R} = \{\mathbf{r}(R_1, R_2, R_3), R_4\}$ is the four-dimensional space-time vector, $\mathbf{r}$ is the three-dimensional spatial radius vector, R_4 is the time component, and $\rho = |\Psi|^2$. Note that the operator $\widehat{H}$ is nonlinear with respect to the unknown function. However, it could depend (linearly) on derivatives of any order (including infinite series), which enables not only differential equations, but nonlinear integral and finite difference equations as well, to be studied.

In what follows it is expedient to deal with the integral form of (1.1). To do this we represent $\Psi(\mathbf{R})$ in the form of a Fourier integral

$$\Psi(\mathbf{R}) = \int \widetilde{\Psi}(\mathbf{K}) e^{i\mathbf{KR}} d\mathbf{K}, \tag{1.2}$$

substitute (1.2) in (1.1), and obtain

$$\int K\left\{\rho, \mathbf{R}, \mathbf{R}-\mathbf{R}'\right\} \Psi(\mathbf{R}') d\mathbf{R}' = 0. \tag{1.3}$$

Here the kernel K is given by

$$K(\rho, \mathbf{R}, \mathbf{R}-\mathbf{R}') = \frac{1}{(2\pi)^4} \int H\left\{\rho, \mathbf{R}, i\mathbf{K}\right\} e^{i\mathbf{K}(\mathbf{R}-\mathbf{R}')} d\mathbf{K}, \tag{1.4}$$

where the function $H\left\{\rho, \mathbf{R}, i\mathbf{K}\right\}$ is obtained from the operator $\widehat{H}\left\{\rho, \mathbf{R}, \frac{\partial}{\partial \mathbf{R}}\right\}$by replacing the differential operator $\frac{\partial}{\partial \mathbf{R}}$ by the vector $i\mathbf{K}$. Obviously, the four-dimensional vector $\mathbf{K}$ has the form $\mathbf{K} = \{\mathbf{k}(K_1,K_2,K_3), -\omega)$. Solutions of (1.3) can be represented in the following form:

$$\Psi(\mathbf{R}) = \rho^{1/2}(\mathbf{R}) e^{iS(\mathbf{R})}. \tag{1.5}$$

When the kernel in (1.3) is a sharp function of $(\mathbf{R}-\mathbf{R}')$ in comparison with $\Psi(\mathbf{R}')$, the functions $\rho(\mathbf{R}')$ and $S(\mathbf{R}')$ can be expanded in power series in the vicinity of the point $\mathbf{R}$. Simple (though rather lengthy) calculations yield the following set of equations:

$$\frac{\partial}{\partial \mathbf{R}} \rho \upsilon = 0, \tag{1.6}$$

$$H\left\{\rho, \mathbf{R}, i\mathbf{P}\right\} = 0, \tag{1.7}$$

where $\frac{\partial}{\partial \mathbf{R}}$ is a vector with components $\{\frac{\partial}{\partial R_1}, \ldots, \frac{\partial}{\partial R_4}\}$, $\boldsymbol{\upsilon} = \frac{\partial H}{\partial \mathbf{P}}$, and $\mathbf{P} = \frac{\partial S}{\partial \mathbf{R}}$.

These equations are valid if the following inequalities hold:

$$\begin{aligned} &\frac{R_k}{S\rho}\left|\frac{\partial \rho}{\partial R_k}\right| \ll 1, \\ &\frac{R_k^n}{S^n}\left|\frac{\partial^n S}{\partial R_k^n}\right| \ll 1, \qquad n = 1, 2. \end{aligned} \tag{1.8}$$

Relations (1.8) are the usual conditions for the applicability of the quasi-classical method.

Equations (1.6) and (1.7) are the continuity equation and (nonlinear) Hamilton–Jacobi equation, respectively. Equation (1.7) can by transformed (by differentiation with respect to **R)** into the form of an equation of motion that has the form

$$\boldsymbol{\upsilon}\, \frac{\partial \mathbf{P}}{\partial \mathbf{R}} + \xi \frac{\partial \rho}{\partial \mathbf{R}} = \mathbf{F}, \tag{1.9}$$

where $\xi = \frac{\partial H}{\partial \rho}$ and $\mathbf{F} = -\frac{\partial H}{\partial \mathbf{R}}$. Note that the classical-mechanical interpretation of the parameters $\boldsymbol{\upsilon}$, $\mathbf{P}$, $\mathbf{F}$, and H is that they are the four-dimensional velocity, momentum, force, and Hamilton function, respectively.

The set of geometrical optics equations related to $\mathbf{P}$ is quasi-linear, and it may be transformed to a linear set with the help of a hodographic transformation, when H is independent of $\mathbf{R}$ and $\mathbf{F} = 0$ [5], [6]. The system of equations (1.6) and (1.7)

may be rewritten in a form analogous to gas-dynamics equations [7], [8]. To do this we represent all solutions of (1.7) in the form

$$P_4 = -h(\mathbf{r}, t, \rho, \mathbf{p}), \tag{1.10}$$

($t \equiv R_4$ is time, $\mathbf{r} = \{R_1, R_2, R_3\}, \mathbf{p} = \{p_1, p_2, p_3\}$ is the three-dimensional momentum vector) and then differentiate the equality obtained, (1.10), with respect to $\mathbf{r}$. This yields the following equation of motion:

$$\frac{\partial \mathbf{p}}{\partial t} + \mathbf{u}\frac{\partial \mathbf{p}}{\partial \mathbf{r}} + \xi\frac{\partial \rho}{\partial \mathbf{r}} = \mathbf{f}, \tag{1.11}$$

where

$$\mathbf{u} = \frac{\partial h}{\partial \mathbf{p}}, \quad \xi = \frac{\partial h}{\partial \rho}, \quad \mathbf{f} = -\frac{\partial h}{\partial \mathbf{r}}.$$

The functions $\mathbf{u}$ and $\mathbf{f}$ are the three-dimensional velocity and force, respectively. The continuity equation in these variables reads as

$$\frac{\partial \rho}{\partial t} + \frac{\partial (\rho \mathbf{u})}{\partial \mathbf{r}} = 0. \tag{1.12}$$

Equations (1.11) and (1.12) look (at least formally) like the well-known system of gas-dynamical equations for the density ρ and $\mathbf{p}$. The important difference is that in our case the Hamiltonian depends (due to the nonlinearity) on ρ and, therefore, the coefficient ξ in the equation of motion (1.11) is defined by the Hamilton function, while in gas dynamics it should be found from some additional conditions—for example, from the equation of state [5]. Note that, while in gas dynamics ξ is equal to the square of the velocity of sound, here it arises from the nonlinearity in the Hamiltonian and has no general physical meaning (ξ can, for example, be negative for some $h(\rho)$). It should also be noted that the vector coefficient $\mathbf{f}$ on the right-hand side of (1.11) (external force in gas dynamics) arises in the case under consideration from the spatial inhomogeneity of the Hamiltonian.

The geometrical optics method developed above can be generalized for more complex equations, such as

$$\widehat{H}\left\{\mathbf{R}, \left(\widehat{H}_i\Psi\right)^n \times \left(\widehat{H}_k\Psi^*\right)^n, \frac{\partial}{\partial \mathbf{R}}\right\}\Psi = 0, \tag{1.13}$$

where $\widehat{H}_i$ and $\widehat{H}_k$ are nonlinear operators introduced by (1.1). It is easy to see that if $\widehat{H}_i = \widehat{H}_k = \text{const}$ and $n = 1$, (1.13) takes the form (1.1).

2. Examples.

2.1. Nonlinear Hamilton–Jacobi equation. If a Hamilton–Jacobi equation can be represented as

$$\widehat{H}\Psi = \widehat{H}_0\left\{\rho, \frac{\partial}{\partial \mathbf{R}}\right\}\Psi(\mathbf{R}) + \widehat{H}'\left\{\rho, \mathbf{R}, \frac{\partial}{\partial \mathbf{R}}\right\}\Psi(\mathbf{R}) = 0, \tag{2.1}$$

where $\left|\widehat{H}_0\Psi\right| \gg \left|\widehat{H}'\Psi\right|$, it is expedient to seek solutions of (1.7) and (2.1) in the form

$$\Psi(\mathbf{R}) = (\rho_0 + \rho'(\mathbf{R}))^{1/2} e^{i(\mathbf{P}_0\mathbf{R} + S'(\mathbf{R}))}, \tag{2.2}$$

where $\mathbf{P}_0$ and ρ are constants, and $|\frac{\partial S'}{\partial \mathbf{R}}| \ll |\mathbf{P}_0|$, $|\rho'| \ll |\rho_0|$. H_0 is independent of $\mathbf{R}$, and hence $\mathbf{F} = 0$. Such a problem arises, for example, in studies of wave propagation in a nonlinear homogeneous on average ($\widehat{H}_0$ is independent of $\mathbf{R}$) medium with weak fluctuations of the dielectric constant.

After substitution of the expression (2.2) into (1.6) and (1.7) and linearization of the equations obtained with respect to S' and ρ', we find the following equations for S' and ρ':

$$\rho'(\mathbf{R}) = -\frac{H'(\rho_0, \mathbf{R}, i\mathbf{P}_0)}{\xi_0} - \frac{\upsilon_{0n}}{\xi_0}\frac{\partial S'(\mathbf{R})}{\partial R_n}, \tag{2.3}$$

$$\beta_m \frac{\partial \rho'(\mathbf{R})}{\partial R_m} = -\rho_0 \left(\frac{\partial \upsilon_{0m}}{\partial P_{0n}} \frac{\partial^2 S'(\mathbf{R})}{\partial R_m \partial R_n} + \frac{\partial \upsilon'_m}{\partial R_m} \right), \tag{2.4}$$

where

$$\beta_m = \frac{\partial(\rho_0 \upsilon_{0m})}{\partial \rho_0}, \qquad \upsilon_{0m} = \frac{\partial H_0(\rho_0, i\mathbf{P}_0)}{\partial P_{0m}},$$
$$\xi_0 = \frac{\partial H_0(\rho_0, i\mathbf{P}_0)}{\partial \rho_0}, \qquad \upsilon'_m = \frac{\partial H'(\rho_0, \mathbf{R}, i\mathbf{P}_0)}{\partial P_{0m}}.$$

Substituting ρ' from (2.3) into (2.4) we obtain the equation for S',

$$\eta_{mn}\frac{\partial^2 S'(\mathbf{R})}{\partial R_m \partial R_n} = \beta_m \frac{\partial H'(\rho_0, \mathbf{R}, i\mathbf{P}_0)}{\partial R_m} - \rho_0 \xi_0 \frac{\partial \upsilon'_m}{\partial R_m} = \Phi(\mathbf{R}), \tag{2.5}$$

where $\eta_{mn} = \xi_0 \rho_0 \frac{\partial \upsilon_{0m}}{\partial P_{0n}} - \upsilon_{0n}\beta_m$. Equation (2.5) is a partial differential equation of the second order with constant coefficients. It can be solved with the help of a Fourier transformation. Assuming the solution in the form

$$S'(\mathbf{R}) = \int \widetilde{S}'(\mathbf{K}) e^{i\mathbf{K}\mathbf{R}} d\mathbf{K} \tag{2.6}$$

and substituting it into (2.5) we obtain

$$\widetilde{S}'(\mathbf{K}) = -\frac{\widetilde{\Phi}(\mathbf{K})}{\eta_{mn} K_m K_n}, \tag{2.7}$$

where $\widetilde{S}'(\mathbf{K})$ and $\widetilde{\Phi}(\mathbf{K})$ are the Fourier transforms of $S'(\mathbf{R})$ and $\Phi(\mathbf{R})$, respectively. Thus, $S'(\mathbf{R})$ can be represented as

$$S'(\mathbf{R}) = \int G(\mathbf{R} - \mathbf{R}')\Phi(\mathbf{R}')d\mathbf{R}', \tag{2.8}$$

where the Green function $G(\mathbf{R} - \mathbf{R}')$ is given by [9]

$$G(\mathbf{R} - \mathbf{R}') = \frac{1}{(2\pi)^4} \int \frac{e^{i\mathbf{K}(\mathbf{R}-\mathbf{R}')}}{\eta_{mn} K_m K_n} d\mathbf{K}, \tag{2.9}$$

and ρ' is found by substituting (2.9) into (2.3). Here the nonlinearity shows itself in the dependence of the tensor η_{mn} on ρ_0 and P_0.

In the case that $\mathbf{R}$ is a one- or three-dimensional vector, results can be obtained immediately:

$$S'(R_1) = \frac{1}{\eta_{11}} \int_0^{R_1} [\beta_1 H'(\rho_0, R_1, iP_{01}) - \rho_0 \xi_0 v_1'] \, dR_1,$$

$$\rho'(R_1) = -\frac{1}{\xi_0} \left[1 + \frac{v_{01}\beta_1}{\eta_{11}}\right] H'(\rho_0, R_1, iP_{01}) + \frac{v_{01}\rho_0 v_1'}{\eta_{11}} \tag{2.10}$$

and

$$S'(\mathbf{r}) = \int G(\mathbf{r} - \mathbf{r}') \left[\beta_m \frac{\partial H'(\rho_0, \mathbf{r}', i\mathbf{p}_0)}{\partial R_m'} - \rho_0 \xi_0 \frac{\partial v_m'}{\partial R_m'}\right] d\mathbf{r}'$$

$$\rho'(\mathbf{r}) = -\frac{H'(\rho_0, \mathbf{r}, i\mathbf{p}_0)}{\xi_0} - \frac{v_{0m}}{\xi_0} \int \frac{\partial G(\mathbf{r} - \mathbf{r}')}{\partial R_m} \left[\beta_m \frac{\partial H'(\rho_0, \mathbf{r}', i\mathbf{p}_0)}{\partial R_m'} - \rho_0 \xi_0 \frac{\partial v_m'}{\partial R_m'}\right] d\mathbf{r}',$$

where the Green function is [7]

$$\mathbf{G}(\mathbf{r} - \mathbf{r}') = \frac{1}{4\pi \sqrt{|\eta| \, \eta_{mn}^{-1} (R_m - R_m')(R_n - R_n')}}. \tag{2.11}$$

In the linear limit, when $\xi_0 = 0$ and $\boldsymbol{v}_0$ is independent of ρ_0, so that $\beta = \boldsymbol{v}_0$, we obtain from (2.5)

$$\boldsymbol{v}_0 \frac{\partial S'}{\partial \mathbf{R}} = -H'(\mathbf{R}). \tag{2.12}$$

If one of the axes (call it R_v) is directed along the vector $\boldsymbol{v}_0$, (2.12) takes the form

$$\frac{\partial S'(R_v, \mathbf{R}_\perp)}{\partial R_v} = -\frac{1}{v_0} H'(R_v, \mathbf{R}_\perp), \tag{2.13}$$

and its solution is

$$S' = -\frac{1}{v_0} \int_0^{R_v} H'(R_v, \mathbf{R}_\perp) dR_v, \tag{2.14}$$

where $R_\perp$ is the three-dimensional vector perpendicular to $\boldsymbol{v}_0$. Hence it follows that the linear case can be reduced to a one-dimensional problem.

2.2. Plane waves in nonlinear media. The fundamental property of a plane wave is that its phase and amplitude are functions of a scalar product $\zeta = \mathbf{R} \bullet \mathbf{q}$, where $\mathbf{q}$ is a (four-dimensional) wave vector. In this case the Hamilton–Jacobi equation has the form

$$H\left\{\zeta, \rho, \frac{\partial S}{\partial \mathbf{R}}\right\} = 0. \tag{2.15}$$

We seek the solution of (2.15) in the form

$$\rho = \rho(\zeta), \; S(\mathbf{R}) = \mathbf{P}_0 \mathbf{R} + \varphi(\zeta). \tag{2.16}$$

Substitution of (2.16) into (1.6) and (1.7) gives

$$H\{\zeta, \rho, p_\zeta, \mathbf{P}_0\} = 0,$$
$$\rho v(\zeta, \rho, p_\zeta, \mathbf{P}_0) = \mathbf{j}, \tag{2.17}$$

where $p_\zeta = \frac{\partial \varphi}{\partial \zeta}$. The second equation in (2.17) is the flux conservation law. The constant $\mathbf{j}$ (flux) should be found from the initial conditions. If at $t = 0$, for example, $\rho = \rho_0$ and $\boldsymbol{v} = \boldsymbol{v}_0$, the flux $\mathbf{j} = \rho_0 \boldsymbol{v}_0$. Equations (2.17) are a system of ordinary differential equations with respect to ρ and p_ζ that in general may have several solutions, some of which could be unstable. This question will be considered in greater detail below.

Now we employ the general theory presented above to study the propagation of a monochromatic wave in a nonlinear medium. Consider a medium whose parameters depend only on ζ, and wave propagation is described by the Helmholtz equation

$$\widehat{H}\Psi(\zeta) = \left[\frac{d^2}{d\zeta^2} + w(\zeta, \rho)\right]\Psi(\zeta) = 0, \tag{2.18}$$

where $w(\zeta, \rho)$ (the permittivity of the medium) is an arbitrary function of its arguments. In this case (1.6) and (1.7) lead to the following equations:

$$p_\zeta^2 = w(\zeta, \rho), \qquad \rho p_\zeta = j. \tag{2.19}$$

This is a generalization of the WKB method to the nonlinear case [10]. Substituting p_ζ from the second equation of the set (2.19) into the first one, we obtain the following equation for ρ:

$$\rho^2 w(\zeta, \rho) = j^2. \tag{2.20}$$

To proceed farther the explicit form of $w(\zeta, p)$ should be specified. Assuming that w has the Kerr form,

$$w(\zeta, \rho) = w_1(\zeta) + w_2(\zeta)\rho, \tag{2.21}$$

and substituting w from (2.21) into (2.20), we obtain a cubic equation for determining ρ:

$$\rho^2[w_1(\zeta) + w_2(\zeta)\rho] = j^2. \tag{2.22}$$

This equation has three solutions. If these solutions are real and positive, phase hysteresis takes place. This situation was investigated in [11]. Note that in our case the step will move; i.e., a shock wave will propagate. When $\rho \gg |\frac{w_1}{w_2}|$, the first term in (2.22) can be neglected, and ρ is given by

$$\rho = \frac{j^{2/3}}{w_2^{1/3}(\zeta)}. \tag{2.23}$$

When ρ is known, S can be found from the second equation of the set (2.19) as

$$S(\zeta) \equiv \int_0^\zeta p_\zeta d\zeta = j^{1/3} \int_0^\zeta \sqrt[3]{w_2(\zeta)}\, d\zeta. \tag{2.24}$$

Combining (2.23) and (2.24), we obtain for ψ

$$\psi(\zeta) = \frac{j^{1/6}}{w_2^{1/6}} \exp\left[ij^{1/3}\int_0^\zeta w_2^{1/3}(\zeta)d\zeta\right]. \tag{2.25}$$

Another limiting case, $\rho \ll |\frac{w_1}{w_2}|$, corresponds to the result obtained in the WKB approximation in the linear theory [10]. One can see that, in contrast to the results of linear geometrical optics, in the case under consideration the solution $\psi(\zeta)$ is defined by the nonlinearity, $w_2(\zeta)$. The functional dependencies of the amplitude and phase on w are also different: in the linear case $\rho \sim w^{1/2}(\zeta)$ (not $\sim w_1^{-1/3}(\zeta)$ as it is in (2.23)), and the integrand in the phase integral is equal to $w_1^{1/2}(\zeta)$ (in contrast to $w_2^{1/3}(\zeta)$ in (2.25)).

2.3. Point-like antenna in a nonlinear medium. We next consider the radiation of a point-like source in a spherically symmetric nonlinear medium. When the antenna is located at the origin ($r = 0$), the monochromatic spherically symmetric field is described by the Helmholtz equation

$$\Delta\psi(r) + w(r,\rho)\psi(r) = \delta(r). \tag{2.26}$$

Assuming that $w(r,\rho)$ is finite for all r and ρ, we will seek the spherically symmetric solution that at $r \neq 0$ satisfies the equation

$$\frac{1}{r^2}\frac{d}{dr}\frac{d\psi(r)}{dr} + w(r,\rho)\psi(r) = 0, \tag{2.27}$$

which after the substitution $\psi(r) = \widetilde{\psi}(r)/r$ takes the form

$$\frac{d^2\widetilde{\psi}(r)}{dr^2} + w(r,\omega)\widetilde{\psi}(r) = 0,\ (\widetilde{\rho} = \left|\widetilde{\psi}\right|^2). \tag{2.28}$$

Equation (2.28) is similar to (2.18), which was investigated previously. Therefore, if we represent the spherically symmetric solution of (2.26) as

$$\psi(r) = \frac{\widetilde{\rho}^{1/2}}{r}e^{iS}, \tag{2.29}$$

$\widetilde{\rho}$ and S can be found from (2.19) with ζ replaced by r. It only remains to calculate the constant j. To this end we note that in the vicinity of the source $w \approx w(0,\widetilde{\rho}(0)) \equiv w_0$, where $\widetilde{\rho}(0)$ is the (known) intensity of the source, and the solution of (2.26) has the form

$$\psi(r) = \frac{\sqrt{\widetilde{\rho}(0)}}{r}e^{i\sqrt{w_0}r}. \tag{2.30}$$

Employing (2.19) we obtain

$$j = \widetilde{\rho}(0)\sqrt{w_0}. \tag{2.31}$$

3. Conclusions. A geometrical optics approximation has been developed for nonlinear equations of a rather general form. By the use of this method, solutions of a nonlinear Hamilton–Jacobi equation have been found, and the propagation of plane and spherical waves in nonlinear media has been studied.

STATISTICAL STABILITY IN TIME REVERSAL*

GEORGE PAPANICOLAOU†, LEONID RYZHIK‡, AND KNUT SØLNA§

Abstract. When a signal is emitted from a source, recorded by an array of transducers, time-reversed, and re-emitted into the medium, it will refocus approximately on the source location. We analyze the refocusing resolution in a high frequency remote-sensing regime and show that, because of multiple scattering in an inhomogeneous or random medium, it can improve beyond the diffraction limit. We also show that the back-propagated signal from a spatially localized narrow-band source is self-averaging, or statistically stable, and relate this to the self-averaging properties of functionals of the Wigner distribution in phase space. Time reversal from spatially distributed sources is self-averaging only for broad-band signals. The array of transducers operates in a remote-sensing regime, so we analyze time reversal with the parabolic or paraxial wave equation.

1. Introduction.

In time reversal experiments, a signal emitted by a localized source is recorded by an array and then re-emitted into the medium time-reversed, that is, the tail of the recorded signal is sent back first. In the absence of absorption, the re-emitted signal propagates back toward the source and focuses approximately on it. This phenomenon has numerous applications in medicine, underwater acoustics, and elsewhere and has been extensively studied in the literature, both from the experimental and theoretical points of view [12, 13, 14, 15, 16, 20, 24, 25, 31]. Recently time reversal has been also the subject of active mathematical research in the context of wave propagation and imaging in random media [2, 3, 4, 5, 7, 8, 9, 32]. A schematic description of a time reversal experiment is presented in Figure 1.1.

For a point source in a homogeneous medium, the size of the refocused spot is approximately $\lambda L/a$, where λ is the central wavelength of the emitted signal, L is the distance between the source and the transducer array, and a is the aperture of the array. We assume here that the array is operating in the remote-sensing regime $a \ll L$. Multiple scattering in a randomly inhomogeneous medium creates *multipathing*, which means that the transducer array can capture waves that were initially moving away from it but got scattered onto it by the inhomogeneities. As a result, the array captures a wider aperture of rays emanating from the original source and appears to be larger than its physical size. Therefore, somewhat contrary to intuition, the inhomogeneities of the medium do not destroy the refocusing but enhance its resolution. The refocused spot is now $\lambda L/a_e$, where $a_e > a$ is the *effective* size of the

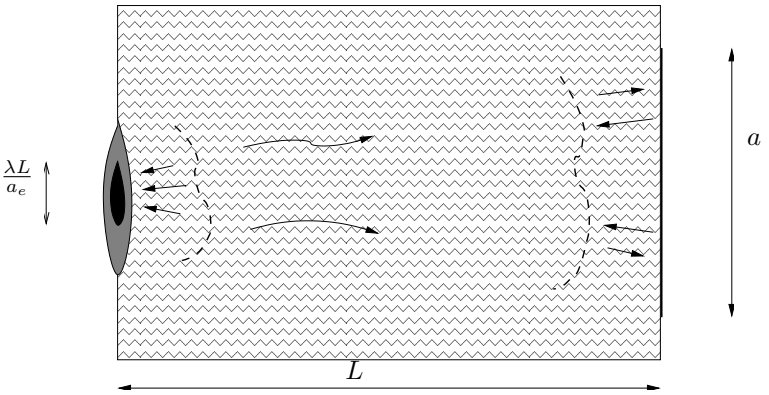

FIG. 1.1. *A pulse propagates toward a time reversal array of size a. The propagation distance L is large compared to a. The ambient medium has a randomly varying index of refraction with a typical correlation length that is small compared to L. The signal is time-reversed at the array and sent back into the medium. The back-propagated signal refocuses with spot size $\lambda L/a_e$, where a_e is the effective aperture of the array (see section* 3.3*) and $a_e > a$.*

array in the randomly scattering medium, and depends on L. The enhancement of refocusing resolution by multipathing is called *superresolution* [7]. The time-reversed pulse is also *self-averaging*, and refocusing near the source is therefore *statistically stable*, which means that it does not depend on the particular realization of the random medium. There is some loss of energy in the refocused signal because of scattering away from the array, but this can be overcome by amplification, up to a point.

The purpose of this paper is to explore in detail the mathematical basis of pulse stabilization, beyond what was done in [7]. We want to explore in particular in what regime of parameters statistical stability is observed in time reversal. We show here that for high frequency waves in a remote-sensing regime, spatially localized sources lead to statistically stable superresolution in time reversal even for narrow-band signals. We also show that, when the source is spatially distributed, only for broad-band signals do we have statistical stability in time reversal. The regime where our analysis holds is a high frequency one, more appropriate to optical or infrared time reversal than to ultrasound, sonar, or microwave radar. In this regime we can make precise what "spatially localized" or "distributed" means (see section 3.1). The numerical simulations in [7] and [8], which are set in an ultrasound or underwater sound regime, indicate that time reversal is not statistically stable for narrow-band signals even for localized sources. Only for broad-band signals is time reversal statistically stable in the regime of ultrasound experiments or sonar.

If the aperture of the transducer array is small with $a/L \ll 1$, the Fresnel number $L/(ka^2)$ is of order one, and the random inhomogeneities are weak, which is often the case, we may analyze wave propagation in the paraxial or parabolic approximation [29]. The wave field is then given approximately by

$$u(t, \mathbf{x}, z) = \frac{1}{2\pi} \int e^{i\omega(z/c_0 - t)} \psi(z, \mathbf{x}; \omega/c_0) d\omega, \tag{1.1}$$

where the complex amplitude ψ satisfies the parabolic or Schrödinger equation

$$2ik\psi_z + \Delta_{\mathbf{x}}\psi + k^2(n^2 - 1)\psi = 0. \tag{1.2}$$

Here $\mathbf{x} = (x, y)$ are the coordinates transverse to the direction of propagation z, the wave number $k = \omega/c_0$, and $n(\mathbf{x}, z) = c_0/c(\mathbf{x}, z)$ is the random index of refraction relative to a reference speed c_0. The fluctuations of the refraction index,

$$\sigma\mu\left(\frac{\mathbf{x}}{l}, \frac{z}{l}\right) = n^2(\mathbf{x}, z) - 1, \tag{1.3}$$

are assumed to be a stationary random field with mean zero, variance σ^2, correlation length l, and normalized covariance with dimensionless arguments

$$R(\mathbf{x}, z) = E\{\mu(\mathbf{x} + \mathbf{x}', z + z')\mu(\mathbf{x}', z')\}. \tag{1.4}$$

A convenient tool for the analysis of wave propagation in a random medium is the Wigner distribution [19, 28] defined by

$$W(z, \mathbf{x}, \mathbf{p}) = \frac{1}{(2\pi)^d} \int_{\mathbb{R}^d} e^{i\mathbf{p}\cdot\mathbf{y}} \psi\left(\mathbf{x} - \frac{\mathbf{y}}{2}, z\right) \overline{\psi\left(\mathbf{x} + \frac{\mathbf{y}}{2}, z\right)} d\mathbf{y}, \tag{1.5}$$

where $d = 1$ or 2 is the transverse dimension and the bar denotes complex conjugate. The Wigner distribution may be interpreted as phase space wave energy, and it is particularly well suited for high frequency asymptotics and random media [28]. The quantity of principal interest in time reversal, the time-reversed and back-propagated wave field, can also be expressed in terms of the Wigner distribution (see section 3.1). The self-averaging properties of the back-propagated field are related to the self-averaging properties of functionals of the Wigner distribution in the form of integrals of W over the wave numbers $\mathbf{p}$.

In the next section we introduce a precise scaling that corresponds to (a) high frequency, (b) long propagation distance, (c) narrow beam propagation, and (d) weak random fluctuations. In the asymptotic limit where the small parameters go to zero, the Wigner distribution satisfies a stochastic partial differential equation (SPDE), a Liouville–Ito equation, that has the form

$$dW(z, \mathbf{x}, \mathbf{p}; k) = \left(-\frac{\mathbf{p}}{k} \cdot \nabla_{\mathbf{x}} W + \frac{k^2 D}{2} \Delta_{\mathbf{p}} W\right) dz - \frac{k}{2} \nabla_{\mathbf{p}} W \cdot d\mathbf{B}(\mathbf{x}, z), \tag{1.6}$$

where $\mathbf{B}(\mathbf{x}, z)$ is a vector-valued Brownian field with covariance

$$E\{B_i(\mathbf{x}_1, z_1) B_j(\mathbf{x}_2, z_2)\} = -\left(\frac{\partial^2 R_0(\mathbf{x}_1 - \mathbf{x}_2)}{\partial x_i \partial x_j}\right) z_1 \wedge z_2, \tag{1.7}$$

where $z_1 \wedge z_2 = \min\{z_1, z_2\}$, and in the isotropic case

$$D = -\frac{R_0''(0)}{4}, \quad R_0(\mathbf{x}) = \int_{-\infty}^{\infty} R(\mathbf{x}, s) ds. \tag{1.8}$$

In section 2.5 we analyze this SPDE in the asymptotic limit of small correlation length for $\mathbf{B}(\mathbf{x}, z)$ in the transverse variables $\mathbf{x}$ and show that $W(z, \mathbf{x}, \mathbf{p}; k)$'s with different wave vectors $\mathbf{p}$ are uncorrelated. From this decorrelation property, we deduce that for localized sources the time-reversed back-propagated field is self-averaging, even for narrow-band signals. For distributed sources, it is self-averaging only for broad-band signals. We show in detail in section 3 how the asymptotic theory is used in time reversal. In Appendix A we introduce other scalings which lead to the same averaged SPDE, but we do not analyze them in detail.

Throughout the paper we define the Fourier transform by

$$\hat{f}(\mathbf{k}) = \int d\mathbf{x} e^{-i\mathbf{k}\cdot\mathbf{x}} f(\mathbf{x})$$

so that

$$f(\mathbf{x}) = \int \frac{d\mathbf{k}}{(2\pi)^d} e^{i\mathbf{k}\cdot\mathbf{x}} \hat{f}(\mathbf{k}).$$

2. Scaling and asymptotics.

2.1. The rescaled problem. To carry out the asymptotic analysis we begin by rewriting the Schrödinger equation (1.2) in dimensionless form. Let L_z and $L_{\mathbf{x}}$ be characteristic length scales in the propagation direction, as, for example, the distance L between the source and the transducer array for L_z and a multiple of the array size a for L_x. We introduce a dimensionless wave number $k' = k/k_0$ with $k_0 = \omega_0/c_0$ and ω_0 a central frequency. We rescale $\mathbf{x}$ and z by $\mathbf{x} = L_{\mathbf{x}}\mathbf{x}'$, $z = L_z z'$ and rewrite (1.2) in the new coordinates, dropping primes:

$$2ik\frac{\partial\psi}{\partial z} + \frac{L_z}{k_0 L_{\mathbf{x}}^2}\Delta\psi + k^2 k_0 L_z \sigma\mu\left(\frac{\mathbf{x}L_{\mathbf{x}}}{l}, \frac{zL_z}{l}\right)\psi = 0. \tag{2.1}$$

The physical parameters that characterize the propagation problem are (a) the central wave number k_0, (b) the strength of the fluctuations σ, and (c) the correlation length l. We now introduce three dimensionless variables

$$\delta = \frac{l}{L_{\mathbf{x}}}, \quad \varepsilon = \frac{l}{L_z}, \quad \gamma = \frac{1}{k_0 l}, \tag{2.2}$$

which are the reciprocals of the *transverse scale* relative to correlation length, the reciprocal of the *propagation distance* relative to correlation length, and the central *wave length* relative to the correlation length. We will assume that the dimensionless parameters γ, σ, ε, and δ are small:

$$\gamma \ll 1; \quad \sigma \ll 1; \quad \delta \ll 1; \quad \varepsilon \ll 1. \tag{2.3}$$

This is a regime of parameters where superresolution phenomena can be observed.

To make the scaling more precise we introduce the Fresnel number

$$\theta = \frac{L_z}{k_0 L_{\mathbf{x}}^2} = \gamma\frac{\delta^2}{\varepsilon}. \tag{2.4}$$

We can then rewrite the Schrödinger equation (2.1) in the form

$$2ik\theta\psi_z + \theta^2\Delta_{\mathbf{x}}\psi + \frac{k^2\delta}{\varepsilon^{1/2}}\mu\left(\frac{\mathbf{x}}{\delta}, \frac{z}{\varepsilon}\right)\psi = 0, \tag{2.5}$$

provided that we relate ε to σ and δ by

$$\varepsilon = \sigma^{2/3}\delta^{2/3} \tag{2.6}$$

so that $\varepsilon \to 0$ is a white noise limit. One way that the asymptotic regime (2.3) can be realized is with the ordering

$$\theta \ll \varepsilon \ll \delta \ll 1\ , \tag{2.7}$$

and $\gamma \ll \sigma^{4/3}\delta^{-2/3}$, corresponding to the high frequency limit. We see from the scaled Schrödinger equation (2.5) that this regime can be given the following interpretation. We have first a *high frequency* limit $\theta \to 0$, then a *white noise* limit $\varepsilon \to 0$, and then a *broad beam* limit $\delta \to 0$. We will analyze in detail and interpret these limits in the following sections. Another scaling in which (2.3) is realized is $\varepsilon \ll \theta \ll \delta \ll 1$. This is a regime in which the white noise limit is carried out first, then the high frequency limit, and then the broad beam limit. We do not analyze this case here. Additional comments on scaling are provided in Appendix A.

It is instructive to express the constraints (2.6) and (2.7) in terms of the dimensional parameters of the problem. First, both the size of the transverse scale $L_{\mathbf{x}}$ and the propagation distance L_z should be much larger than the correlation length l of the medium. Moreover, (2.6) implies that the longitudinal and transverse scales should be related by

$$\frac{L_z}{L_{\mathbf{x}}} = \frac{\delta}{\varepsilon} = \left(\frac{\delta}{\sigma^2}\right)^{1/3} \gg 1$$

so that we are indeed in the beam approximation. The first inequality in (2.7) implies that

$$\frac{L_z}{L_{\mathbf{x}}} \ll \sqrt{k_0 l} = \frac{1}{\sqrt{\gamma}},$$

and, with the above choice of L_z, this implies that

$$\frac{\gamma^{3/2}}{\sigma^2} \ll \frac{L_{\mathbf{x}}}{l} \ll \frac{1}{\sigma^2}.$$

2.2. The high frequency limit. A convenient tool for the study of the high frequency limit, especially in random media, is the Wigner distribution. It is often used in the context of energy propagation [19, 28], but it is also useful in analyzing time reversal phenomena [2, 3, 5, 7]. Let $\phi_\theta(\mathbf{x})$ be a family of functions oscillating on a small scale θ. The Wigner distribution is a function of the physical space coordinate $\mathbf{x}$ and wave vector $\mathbf{p}$ defined as

$$W_\theta(\mathbf{x},\mathbf{p}) = \int_{\mathbb{R}^d} \frac{d\mathbf{y}}{(2\pi)^d} e^{i\mathbf{p}\cdot\mathbf{y}} \phi_\theta\left(\mathbf{x} - \frac{\theta\mathbf{y}}{2}\right) \overline{\phi_\theta\left(\mathbf{x} + \frac{\theta\mathbf{y}}{2}\right)}. \tag{2.8}$$

The family W_θ is bounded in the space of Schwartz distributions $\mathcal{S}'(\mathbb{R}^d \times \mathbb{R}^d)$ if the functions ϕ_θ are uniformly bounded in $L^2(\mathbb{R}^d)$. Therefore, there exists a subsequence $\theta_k \to 0$ such that W_{θ_k} converges weakly as $k \to \infty$ to a limit measure $W(\mathbf{x},\mathbf{p})$. This limit $W(\mathbf{x},\mathbf{p})$ is nonnegative and is customarily interpreted as the limit phase space energy density because

$$|\phi_{\theta_k}(\mathbf{x})|^2 \to \int_{\mathbb{R}^d} W(\mathbf{x},\mathbf{p}) d\mathbf{p} \quad \text{as } k \to 0 \tag{2.9}$$

in the weak sense. This allows us to think of $W(\mathbf{x},\mathbf{p})$ as a local energy density.

Let $W_\theta(z,\mathbf{x},\mathbf{p})$ be the Wigner distribution of the solution ψ of the Schrödinger equation (2.5), in the transversal space-variable $\mathbf{x}$. A straightforward calculation

shows that $W_\theta(z,\mathbf{x},\mathbf{p})$ satisfies in a weak sense the linear evolution equation

$$\begin{aligned}\frac{\partial W_\theta}{\partial z}+\frac{\mathbf{p}}{k}\cdot\nabla_{\mathbf{x}}W_\theta \\ =\frac{ik\delta}{2\sqrt{\varepsilon}}\int e^{i\mathbf{q}\cdot\mathbf{x}/\delta}\hat{\mu}\left(q,\frac{z}{\varepsilon}\right)\frac{W_\theta\left(\mathbf{p}-\frac{\theta\mathbf{q}}{2\delta}\right)-W_\theta\left(\mathbf{p}+\frac{\theta\mathbf{q}}{2\delta}\right)}{\theta}\frac{d\mathbf{q}}{(2\pi)^d}.\end{aligned} \tag{2.10}$$

In the limit $\theta\to 0$, the solution converges weakly in $\mathcal{S}'$, for each realization, to the (weak) solution of the random Liouville equation

$$\frac{\partial W}{\partial z}+\frac{\mathbf{p}}{k}\cdot\nabla_{\mathbf{x}}W+\frac{k}{2\sqrt{\varepsilon}}\nabla_{\mathbf{x}}\mu\left(\frac{\mathbf{x}}{\delta},\frac{z}{\varepsilon}\right)\cdot\nabla_{\mathbf{p}}W=0. \tag{2.11}$$

The initial condition at $z=0$ is $W(0,\mathbf{x},\mathbf{p})=W_I(\mathbf{x},\mathbf{p})$, the limit Wigner distribution of the initial wave function.

2.3. The white noise limit. In this section we take the white noise limit $\varepsilon\to 0$ in the random Liouville equation (2.11) whose solution we now denote by W_ε. We can do this using the asymptotic theory of stochastic differential equations and flows [22, 6, 21, 26] as follows. Using the method of characteristics, the solution of the Liouville equation (2.11) may be written in the form

$$W_\varepsilon(z,\mathbf{x},\mathbf{p})=W_I(\mathbf{X}_\varepsilon(z;\mathbf{x},\mathbf{p}),\mathbf{P}_\varepsilon(z;\mathbf{x},\mathbf{p})),$$

where the processes $\mathbf{X}_\varepsilon(z;\mathbf{x},\mathbf{p})$ and $\mathbf{P}_\varepsilon(z;\mathbf{x},\mathbf{p})$ are solutions of the characteristic equations

$$\frac{d\mathbf{X}_\varepsilon}{dz}=-\frac{1}{k}\mathbf{P}_\varepsilon,\quad \frac{d\mathbf{P}_\varepsilon}{dz}=-\frac{k}{2\sqrt{\varepsilon}}\nabla_{\mathbf{x}}\mu\left(\frac{\mathbf{X}_\varepsilon}{\delta},\frac{z}{\varepsilon}\right)$$

with the initial conditions $\mathbf{X}_\varepsilon(0)=\mathbf{x}$ and $\mathbf{P}_\varepsilon(0)=\mathbf{p}$. We assume here that the fluctuation process $\mu(\mathbf{x},z)$ is twice differentiable. The asymptotic theory of random differential equations with rapidly oscillating coefficients implies that, under suitable conditions on μ, in the limit $\varepsilon\to 0$, the processes $\mathbf{X}_\varepsilon$, $\mathbf{P}_\varepsilon$ converge weakly (in the probabilistic sense) and uniformly on compact sets in $\mathbf{x},\mathbf{p}$ to the limit processes $\mathbf{X}(z)$, $\mathbf{P}(z)$ that satisfy a system of stochastic differential equations

$$d\mathbf{P}=-\frac{k}{2}d\mathbf{B}(z),\quad d\mathbf{X}=-\frac{1}{k}\mathbf{P}dz,\quad \mathbf{X}(0)=\mathbf{x},\quad \mathbf{P}(0)=\mathbf{p}.$$

The random process $\mathbf{B}(z)$ is a Brownian motion with the covariance function

$$\begin{aligned}E\left\{B_i(z_1)B_j(z_2)\right\}&=-\frac{\partial^2R_0(0)}{\partial x_i\partial x_j}dsz_1\wedge z_2\\ &=\delta_{ij}\left(-R_0''(0)\right)z_1\wedge z_2,\end{aligned} \tag{2.12}$$

in the isotropic case, where

$$R_0(\mathbf{x})=\int_{-\infty}^{\infty}R(\mathbf{x},s)ds \tag{2.13}$$

is a function of $|\mathbf{x}|$. This implies that the average Wigner distribution $W_\varepsilon^{(1)}(z,\mathbf{x},\mathbf{p}) = E\{W_\varepsilon(z,\mathbf{x},\mathbf{p})\}$ converges as $\varepsilon \to 0$ uniformly on compact sets to the solution of the advection-diffusion equation in phase space

$$\frac{\partial W^{(1)}}{\partial z} + \frac{\mathbf{p}}{k}\cdot\nabla_{\mathbf{x}} W^{(1)} = \frac{k^2 D}{2}\Delta_{\mathbf{p}} W^{(1)} \tag{2.14}$$

with the initial data $W^{(1)}(0,\mathbf{x},\mathbf{p}) = W_I(\mathbf{x},\mathbf{p})$. Here the diffusion coefficient D is given by

$$D = -\frac{R_0''(0)}{4}. \tag{2.15}$$

The one-point moments $E\left\{[W_\varepsilon(z,\mathbf{x},\mathbf{p})]^N\right\}$ converge as $\varepsilon \to 0$ to the functions $W^{(N)}(z,\mathbf{x},\mathbf{p})$ that satisfy the same equation (2.14) but with the initial data $W^{(N)}(0,\mathbf{x},\mathbf{p}) = [W_0(\mathbf{x},\mathbf{p})]^N$. This is similar to the spot dancing phenomenon [11], where all one-point moments are governed by the same Brownian motion. In particular we have that

$$W^{(2)}(z,\mathbf{x},\mathbf{p}) \neq \left[W^{(1)}(z,\mathbf{x},\mathbf{p})\right]^2$$

so that the process W_ε does not converge to a deterministic one, in the strong sense pointwise.

2.4. Multipoint moment equations. As in the previous section, we may also study the white noise limit $\varepsilon \to 0$ of the higher moments of $W_\varepsilon(z,\mathbf{x},\mathbf{p})$ at different points

$$W_\varepsilon^{(N)}(z,\mathbf{x}^1,\dots,\mathbf{x}^N,\mathbf{p}^1,\dots,\mathbf{p}^N) = E\left\{[W_\varepsilon(z,\mathbf{x}^1,\mathbf{p}^1)]^{r_1}\cdot\ldots\cdot[W_\varepsilon(z,\mathbf{x}^N,\mathbf{p}^N)]^{r_N}\right\}.$$

Here the points $(\mathbf{x}^m,\mathbf{p}^m)$ are all distinct, and $(\mathbf{x}^n,\mathbf{p}^n) \neq (\mathbf{x}^m,\mathbf{p}^m)$. We may account for moments that have different powers of W_ε at different points by taking different powers r_j of $W_\varepsilon(\mathbf{x}^j,\mathbf{p}^j)$.

We now consider the joint process $(\mathbf{X}_\varepsilon(z;\mathbf{x}^m,\mathbf{p}^m),\mathbf{P}_\varepsilon(z;\mathbf{x}^m,\mathbf{p}^m))$, $m = 1,\dots,N$. As $\varepsilon \to 0$, it converges to the solution of the system of stochastic differential equations

$$d\mathbf{P}_i^m = -\frac{k}{2}\sum_{n=1}^{N}\sum_{j=1}^{d}\sigma_{ij}\left(\frac{\mathbf{X}^m-\mathbf{X}^n}{\delta}\right)dB_j^n(z), \quad d\mathbf{X}^m = -\frac{1}{k}\mathbf{P}^m dz, \tag{2.16}$$

with the initial conditions

$$\mathbf{X}^m(0) = \mathbf{x}^m, \quad \mathbf{P}^m(0) = \mathbf{p}^m.$$

The d-dimensional Brownian motions $\mathbf{B}^m$, $m = 1,\dots,N$, have the standard covariance tensor

$$E\left\{B_i^m(z_1)B_j^n(z_2)\right\} = \delta_{mn}\delta_{ij}z_1\wedge z_2, \quad i,j = 1,\dots,d,\ m,n = 1,\dots,N.$$

The symmetric tensor $\sigma_{ij}(\mathbf{x})$ is determined from

$$\sum_{k=1}^{d}\sigma_{ik}(\mathbf{x})\sigma_{jk}(\mathbf{x}) = -\left(\frac{\partial^2 R_0(\mathbf{x})}{\partial x_i \partial x_j}\right). \tag{2.17}$$

We assume that (2.17) has a solution that is differentiable in $\mathbf{x}$, which is compatible with the fact that the matrix on the right is, by Bochner's theorem, nonnegative definite.

The moments $W_\varepsilon^{(N)}$ converge as $\varepsilon \to 0$ to the solution of the advection-diffusion equation

$$\frac{\partial W^{(N)}}{\partial z} + \sum_{m=1}^{N} \frac{\mathbf{p}^m}{k} \cdot \nabla_{\mathbf{x}^m} W^{(N)} = \frac{k^2 D}{2} \sum_{m=1}^{N} \Delta_{\mathbf{p}^m} W^{(N)} - \frac{k^2}{4} \sum_{\substack{n,m=1 \\ n>m}}^{N} \sum_{i,j=1}^{d} \frac{\partial^2 R_0((\mathbf{x}^n - \mathbf{x}^m)/\delta)}{\partial x_i \partial x_j} \frac{\partial^2 W^{(N)}}{\partial p_i^n \partial p_j^m} \tag{2.18}$$

with the initial data

$$W^{(N)}(0, \mathbf{x}_1, \ldots, \mathbf{x}^N, \mathbf{p}^1, \ldots, \mathbf{p}^N) = [W_I(\mathbf{x}^1, \mathbf{p}^1)]^{r_1} \cdot \ldots \cdot [W_I(\mathbf{x}^N, \mathbf{p}^N)]^{r_N}.$$

From (2.18) we can calculate moments of functionals of W_ε of the form

$$W_{\varepsilon,\phi}(z) = \int W_\varepsilon(z, \mathbf{x}, \mathbf{p}) \phi(\mathbf{x}, \mathbf{p}) d\mathbf{x} d\mathbf{p}.$$

For example, as $\varepsilon \to 0$, we have that

$$E\left\{[W_{\varepsilon,\phi}(z)]^2\right\} \to \int W^{(2)}(z, \mathbf{x}_1, \mathbf{p}_1, \mathbf{x}_2, \mathbf{p}_2) \phi(\mathbf{x}_1, \mathbf{p}_1) \phi(\mathbf{x}_2, \mathbf{p}_2) d\mathbf{x}_1 d\mathbf{p}_1 d\mathbf{x}_2 d\mathbf{p}_2.$$

A convenient way to deal not only with the limit of N-point moments but also with the full limit process $W(z, \mathbf{x}, \mathbf{p})$, at all points $\mathbf{x}, \mathbf{p}$ simultaneously, is provided by the theory of stochastic flows [23]. For this we need to show that $W_\varepsilon(z, \mathbf{x}, \mathbf{p})$ converges weakly (in the probabilistic sense) as $\varepsilon \to 0$ to the process $W(z, \mathbf{x}, \mathbf{p})$ that satisfies the SPDE

$$dW_\delta = \left[-\frac{\mathbf{p}}{k} \cdot \nabla_{\mathbf{x}} W_\delta + \frac{k^2 D}{2} \Delta_{\mathbf{p}} W_\delta \right] dz - \frac{k}{2} \nabla_{\mathbf{p}} W_\delta \cdot d\mathbf{B}\left(\frac{\mathbf{x}}{\delta}, z\right). \tag{2.19}$$

Here the Gaussian random field $\mathbf{B}(\mathbf{x}, z)$ has covariance

$$E\{B_i(\mathbf{x}_1, z_1) B_j(\mathbf{x}_2, z_2)\} = -\left(\frac{\partial^2 R_0(\mathbf{x}_1 - \mathbf{x}_2)}{\partial x_i \partial x_j} \right) z_1 \wedge z_2.$$

We call (2.19) the Liouville–Ito equation. It allows us to treat all equations of the form (2.18) simultaneously, and it is a convenient tool for simulation and analysis. The dimensionless wave number k can be scaled out of (2.19) by writing $W(z, \mathbf{x}, \mathbf{p}; k) = W(z, \mathbf{x}, \frac{\mathbf{p}}{k}; 1)$ so that we need only consider (2.19) with $k = 1$. We will use this scaling in section 3.1.

Note that unlike the single Brownian motion (2.12) that governs the evolution of one-point moments, the Brownian field that enters the SPDE (2.19) depends explicitly on the dimensionless correlation length δ in the transverse direction. Therefore, the limit process also depends on δ, and we denote it by W_δ.

2.5. Statistical stability in the broad beam limit. We will now consider the limit $\delta \to 0$ of the process $W_\delta(z, \mathbf{x}, \mathbf{p})$ when the transverse dimension $d \geq 2$. We are particularly interested in the behavior of functionals of W_δ as $\delta \to 0$. The analysis of one-point moments in section 2.3 showed that they do not depend on δ and are governed by a standard Brownian motion. Therefore the process W_δ does not have a pointwise deterministic limit. However, we will show that functionals of W_δ become deterministic in the limit $\delta \to 0$. We refer to this phenomenon as *statistical stabilization* and give conditions for it to happen. Stabilization plays an important role in time reversal, imaging, and other applications, as discussed in the introduction.

THEOREM 2.1. *Assume that $\phi(\mathbf{p})$ is a smooth test function of rapid decay, the transverse correlation function $R_0(\mathbf{x})$ has compact support, the initial Wigner distribution $W_I(\mathbf{x}, \mathbf{p})$ is uniformly bounded and Lipschitz continuous, and the transverse dimension $d \geq 2$. Define*

$$I_{\delta,\phi}(z, \mathbf{x}) = \int W_\delta(z, \mathbf{x}, \mathbf{p}) \phi(\mathbf{p}) d\mathbf{p}. \tag{2.20}$$

Then

$$\lim_{\delta \to 0} E\left\{I^2_{\delta,\phi}(z, \mathbf{x})\right\} = E^2\left\{I_{\delta,\phi}(z, \mathbf{x})\right\}, \tag{2.21}$$

where $E\{I_{\delta,\phi}(z, \mathbf{x})\}$ is independent of δ.

The independence of δ for the expectation of $I_{\delta,\phi}(z, \mathbf{x})$ follows immediately from taking expectations in the stochastic differential equation (2.19). The assumption of compact support for $R_0(\mathbf{x})$ is not essential but simplifies the proof. We have already noted that the Wigner distribution W_δ itself does not stabilize. However, (2.21) implies that

$$\lim_{\delta \to 0} \mathrm{Var}\left\{I_{\delta,\phi}\right\} = \lim_{\delta \to 0} E\left\{I^2_{\delta,\phi}(z)\right\} - E^2\left\{I_{\delta,\phi}\right\} = 0. \tag{2.22}$$

Therefore, any smooth functional of the form (2.20) stabilizes in the limit $\delta \to 0$; that is,

$$I_{\delta,\phi} \approx E\{I_{\delta,\phi}\} \tag{2.23}$$

in mean square, and the expectation of $I_{\delta,\phi}$ does not depend on δ. We prove Theorem 2.1 in Appendix B.

In the applications of the asymptotic theory to time reversal, we need functionals $I_{\delta,\phi}$ not only of the form (2.20), but also of the form

$$J_\delta(z, \mathbf{x}) = \int W_\delta(z, \mathbf{x}, \mathbf{p}) d\mathbf{p}. \tag{2.24}$$

We need to show that such functionals are well defined with probability one and to analyze their behavior as $\delta \to 0$. This is done in the following theorem.

THEOREM 2.2. *Under the same hypotheses of Theorem* 2.1, *and with a nonnegative initial Wigner distribution $W_I \geq 0$, the functional J_δ is bounded, continuous, and nonnegative with probability one. In the limit $\delta \to 0$, we have*

$$\lim_{\delta \to 0} E\left\{J^2_\delta(z, \mathbf{x})\right\} = E^2\left\{J_\delta(z, \mathbf{x})\right\}, \tag{2.25}$$

where $E\{J_\delta(z, \mathbf{x})\}$ does not depend on δ.

The proof of this theorem is given in Appendix B.

What is important in both Theorems 2.1 and 2.2 is that we do integrate over the wave numbers $\mathbf{p}$ because there is no pointwise stabilization. In time reversal applications, as in section 3.1, we actually need Theorem 2.2 when the integration is only over a line segment in $\mathbf{p}$ space, and the dimension of the latter is $d \geq 2$. Its proof follows from the one of Theorem 2.2.

3. Application to time reversal in a random medium. We will now apply these results to the time reversal problem [7] described in the introduction. A wave emitted from the plane $z = 0$ propagates through the random medium and is recorded on the time reversal mirror at L. It is then *reversed* in time and re-emitted into the medium. The back-propagated signal refocuses approximately at the source, as shown in Figure 1.1. There are two striking features of this refocusing in random media. One is that it is statistically stable; that is, it does not depend on the particular realization. The other is superresolution; that is, the refocused spot is tighter than in the deterministic case. We discuss these two issues in this section.

3.1. The time-reversed and back-propagated field. We assume that the wave source at $z = 0$ is distributed on a scale σ_s around a point $\mathbf{x}_0$; that is,

$$\psi_\theta(z=0,\mathbf{x};k) = e^{i\mathbf{p}_0\cdot(\mathbf{x}-\mathbf{x}_0)/\theta}\psi_0\left(\frac{\mathbf{x}-\mathbf{x}_0}{\sigma_s};k\right),$$

where ψ_0 is a rapidly decaying and smooth function of $\mathbf{x}$ and k. The width of the source σ_s could be large or small compared to the Fresnel number θ, and this affects the statistical stability of the time-reversed back-propagated field, as we explain in this section. The Green's function, $G_\theta(z,\mathbf{x},\xi;k)$, solves the parabolic wave equation (2.5) with a point source at $(\mathbf{x},z) = (\xi,0)$. Using its symmetry properties and the fact that time reversal $t \to -t$ is equivalent to $\omega \to -\omega$ or $k \to -k$, the back-propagated time-reversed field on the plane of the source has the form

$$\begin{aligned}(3.1)\quad &\psi_\theta^B(L,\mathbf{x}_0,\xi;k)\\ &= \int\!\!\int G_\theta(L,\mathbf{x},\mathbf{x}_0+\theta\xi;k)\overline{G_\theta(L,\mathbf{x}_0+\eta,\mathbf{x};k)}e^{-i\mathbf{p}_0\cdot\eta/\theta}\psi_0\left(\frac{\eta}{\sigma_s};-k\right)\chi_A(\mathbf{x})d\mathbf{x}d\eta.\end{aligned}$$

The complex field amplitude ψ_θ^B is evaluated at $\mathbf{x}_0+\theta\xi$, in the plane $z = 0$. We scale the observation point off $\mathbf{x}_0$ by θ because we expect that the spot size of the refocused signal will be comparable to the lateral spread of the initial wave function. We denote by χ_A the aperture function of the time reversal mirror. It could be its characteristic function, occupying the region A in the plane $z = L$,

$$\chi_A(\mathbf{x}) = \begin{cases} 1, & \mathbf{x}\in A,\\ 0, & \mathbf{x}\notin A,\end{cases}$$

or a more general aperture function like a Gaussian. The time reversal mirror is located in the plane $z = L$.

After changing variables, the back-propagated field is given by

$$\begin{aligned}&\psi_\theta^B(L,\mathbf{x}_0,\xi;k)\\ &= \theta^d\int G_\theta(L,\mathbf{x},\mathbf{x}_0+\theta\xi;k)\overline{G_\theta(L,\mathbf{x},\mathbf{x}_0+\theta\eta;k)}e^{-i\mathbf{p}_0\cdot\eta}\psi_0\left(\frac{\theta\eta}{\sigma_s};-k\right)\chi_A(\mathbf{x})d\mathbf{x}d\eta\\ &= \theta^d\int G_\theta(L,\mathbf{x}_0+\theta\xi,\mathbf{x};k)\overline{G_\theta(L,\mathbf{x}_0+\theta\eta,\mathbf{x};k)}e^{-i\mathbf{p}_0\cdot\eta}\psi_0\left(\frac{\theta\eta}{\sigma_s};-k\right)\chi_A(\mathbf{x})d\mathbf{x}d\eta.\end{aligned}$$

It is now convenient to introduce the Wigner distribution

(3.2)
$$W_\theta(z,\mathbf{x}_0,\mathbf{p};k)=\int \frac{\theta^d e^{i\mathbf{p}\cdot\mathbf{y}}}{(2\pi)^d} G_\theta(z,\mathbf{x}_0-\mathbf{y}\theta/2,\mathbf{x};k)\overline{G_\theta(z,\mathbf{x}_0+\mathbf{y}\theta/2,\mathbf{x};k)}\chi_A(\mathbf{x})d\mathbf{x}d\mathbf{y},$$

and express the back-propagated field as

(3.3)
$$\begin{aligned}&\psi_\theta^B(L,\mathbf{x}_0,\xi;k)\\ &\quad=\int e^{i\mathbf{p}\cdot(\xi-\eta)}W_\theta\left(L,\mathbf{x}_0+\frac{\theta(\xi+\eta)}{2},\mathbf{p};k\right)e^{-i\mathbf{p}_0\cdot\eta}\psi_0\left(\frac{\theta\eta}{\sigma_s};-k\right)d\mathbf{p}d\eta.\end{aligned}$$

The Wigner distribution is scaled differently here from in (2.8) because of the way we have scaled the source function.

In the high frequency limit $\theta\to 0$, $W_\theta(z,\mathbf{x},\mathbf{p};k)$ tends to $W(z,\mathbf{x},\mathbf{p};k)$, which solves the random Liouville equation (2.11). Then, in the white noise limit, it solves the Liouville–Ito equation (2.19). The mean of W solves (2.14), in the high frequency and white noise limit, with initial data

(3.4)
$$W(0,\mathbf{x},\mathbf{p};k)=\frac{\chi_A(\mathbf{x})}{(2\pi)^d}.$$

Let

(3.5)
$$\beta=\frac{\sigma_s}{\theta}$$

be the ratio of the width of the source to the Fresnel number and assume that it remains fixed as $\theta\to 0$. In this limit, the time-reversed and back-propagated field is given by

(3.6)
$$\begin{aligned}\psi^B(L,\mathbf{x}_0,\xi;k)&=\int e^{i\mathbf{p}\cdot(\xi-\eta)}W\left(L,\mathbf{x}_0,\frac{\mathbf{p}}{k}\right)e^{-i\mathbf{p}_0\cdot\eta}\psi_0(\eta/\beta;-k)d\mathbf{p}d\eta\\ &=\int e^{i\mathbf{p}\cdot\xi}W\left(L,\mathbf{x}_0,\frac{\mathbf{p}}{k}\right)\beta^d\hat{\psi}_0(\beta(\mathbf{p}+\mathbf{p}_0);-k)d\mathbf{p}.\end{aligned}$$

Here we have used the scaling $W(z,\mathbf{x},\mathbf{p};k)=W(z,\mathbf{x},\frac{\mathbf{p}}{k};1)$ in (2.19), and we have dropped the last argument $k=1$.

3.2. Statistical stability. From the form (3.6) of the back-propagated and time-reversed field we see that when $\beta=O(1)$ (or small), which means that σ_s is comparable to the Fresnel number θ (or smaller), we can apply the results of section 2.5 and conclude that it is statistically stable or self-averaging in the broad beam limit $\delta\to 0$. Theorems 2.1 and 2.2 are exactly what is needed for this. The fact that the initial function (3.4) may be discontinuous at the boundary of the set A is not a problem. This is because we may approximate the function χ_A from above and below by two smooth positive functions, to which we may apply Theorems 2.1 and 2.2, and then use the maximum principle to deduce the decorrelation property when the initial data is χ_A. We have, therefore,

$$\psi^B(L,\mathbf{x}_0,\xi;k)\approx\langle\psi^B(L,\mathbf{x}_0,\xi;k)\rangle$$

in the sense of convergence in probability or in mean square, in the broad beam limit $\delta\to 0$, for each fixed frequency $\omega=kc_0$. Statistical stability of time reversal does

not depend on having a broad-band signal if the source is localized in space. This is true in the regime of parameters reflected by the scaling $\theta \ll \varepsilon \ll \delta$ considered here, which is a high frequency regime encountered in optical or infrared applications like ladar. The numerical experiments in [7] and [8] are closer to the regime of ultrasound experiments [16] and in underwater sound propagation, which is different from the high frequency regime analyzed here.

For distributed sources, the parameter β is large, and we cannot apply Theorems 2.1 and 2.2 to (3.6). It is necessary for statistical stability in this case to have broad-band signals. For β large, the time-reversed and back-propagated signal in the time domain has the form

$$\begin{aligned}(3.7)\quad &\psi^B(L,\mathbf{x}_0,\xi,t)\\ &= (2\pi)^d e^{-i(\mathbf{p}_0\cdot\xi+k_0c_0t)}\psi_0(\xi/\beta)\int W\left(L,\mathbf{x}_0,\frac{\mathbf{p}_0}{k_0+k}\right)e^{-ikc_0t}\hat{g}(-c_0k)\frac{c_0dk}{2\pi}\\ &= (2\pi)^d e^{-i(\mathbf{p}_0\cdot\xi+\omega_0t)}\psi_0(\xi/\beta)\int W\left(L,\mathbf{x}_0,\frac{c_0\mathbf{p}_0}{\omega_0+\omega}\right)e^{-i\omega t}\hat{g}(-\omega)\frac{d\omega}{2\pi}\end{aligned}$$

with $\hat{g}(c_0k)$ the Fourier transform of the initial pulse relative to the central frequency $\omega_0 = c_0k_0$. This means that we have replaced the actual wave number k by k_0+k, or ω by $\omega_0+\omega$, with the new ω, the baseband frequency, bounded by Ω, the bandwidth, $|\omega| \le \Omega < \omega_0$. The integration is over the bandwidth $[-\Omega,\Omega]$. This integral is well defined with probability one and is self-averaging in the broad beam limit $\delta \to 0$ by Theorem 2.2 and the remark following it. We will compute its average in section 3.4.

3.3. The effective aperture of the array. From the explicit expression for the Green's function of (2.14), with $k=1$,

$$\begin{aligned}W^{(1)}(z,\mathbf{x},\mathbf{p};\mathbf{x}^0,\mathbf{p}^0) = &\int \frac{d\mathbf{w}d\mathbf{r}}{(2\pi)^{2d}}\exp\left(i\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}^0)+i\mathbf{r}\cdot(\mathbf{p}-\mathbf{p}^0)-iz\mathbf{w}\cdot\mathbf{p}^0\right)\\ &\times\exp\left(-\frac{Dz}{2}\left[r^2+z\mathbf{r}\cdot\mathbf{w}+\frac{w^2z^2}{3}\right]\right),\end{aligned}$$

and with the time reversal mirror a distance L from the source and $\mathbf{x}_0=0$, it follows from (3.6) that

$$\begin{aligned}(3.8)\quad &\langle\psi^B(L,\xi;k)\rangle\\ &= \int\frac{d\mathbf{p}d\mathbf{y}d\mathbf{w}}{(2\pi)^{2d}}e^{i\mathbf{p}\cdot\xi}\beta^d\hat{\psi}_0(\beta(\mathbf{p}-\mathbf{p}_0);-k)\chi_A(\mathbf{y})\exp\left[-i\mathbf{w}\cdot\mathbf{y}-iL\mathbf{w}\cdot\frac{\mathbf{p}}{k}-\frac{DL^3w^2}{6}\right].\end{aligned}$$

The high frequency white noise limit of the *self-averaging* time-reversed and back-propagated field is therefore given by a convolution

$$(3.9)\qquad \langle\psi^B(L,\xi;k)\rangle = \psi_0^\beta(\cdot,-k)*\mathcal{W}(\cdot)(\xi)$$

with

$$(3.10)\qquad \mathcal{W}(\eta) = \mathcal{W}(\eta;L,k) = \frac{k^d}{(2\pi L)^d}\hat{\chi}_A(\eta k/L)\ e^{-\eta^2/(2\sigma_M^2)},$$

the *point spread function*, and

$$(3.11)\qquad \psi_0^\beta(\eta,-k) = e^{-i\mathbf{p}_0\cdot\eta}\psi_0(\eta/\beta)\hat{g}(-kc_0)$$

with $\psi_0(\eta/\beta)$ the spatial source distribution function and $\hat{g}$ the Fourier transform of the pulse shape function $g(t)$. This notation is consistent with (3.7), with the time factor $e^{-ik_0c_0t}$ omitted, along with the horizontal phase e^{ikz}, which cancels in time reversal. We have also introduced the refocused *spot size* with multipathing

$$\sigma_M^2 = \frac{3}{DLk^2} = \frac{L^2}{k^2a_e^2} \tag{3.12}$$

and the *effective aperture* $a_e = a_e(L)$,

$$a_e = \sqrt{\frac{DL^3}{3}}, \tag{3.13}$$

which we now interpret.

If the time reversal mirror is the whole plane $z = L$, then $\chi_A \equiv 1$ and

$$\left\langle \psi^B(L,\xi;k) \right\rangle = \psi_0^\beta(\xi,-k).$$

In this case, the back-propagated field is the source field reversed in time, both in the random and in the deterministic case. The point spread function $\mathcal{W}$ determines the resolution of the refocused signal for a time reversal mirror of finite aperture. Multipathing in a random medium gives rise to the Gaussian factor (3.12) whose variance is σ_M^2. We can give an interpretation of this variance, or spot size, as follows. For a square time reversal mirror of size a, the Fourier transform of χ_A is the sinc function so that

$$\mathcal{W}(\eta_1,\eta_2;L,k) = \frac{1}{\pi\eta_1}\sin\left(\frac{\eta_1 ka}{2L}\right)\frac{1}{\pi\eta_2}\sin\left(\frac{\eta_2 ka}{2L}\right)e^{-(\eta_1^2+\eta_2^2)/(2\sigma_M^2)}.$$

For a deterministic medium ($D = 0$), the Rayleigh resolution is the distance η_F to the first zero of the sine, the first Fresnel zone in either direction,

$$\eta_F = \frac{2\pi L}{ka} = \frac{\lambda L}{a}.$$

In general, if χ_A is supported by a region of size a, we may define the Fresnel resolution, or the Fresnel *spot size*, by

$$\sigma_F = \frac{L}{ka}.$$

For *weak multipathing*, we have $\sigma_M \gg \sigma_F$ and

$$\mathcal{W}(\eta;L,k) \sim \left(\frac{k}{2\pi L}\right)^d \hat{\chi}_A(\eta k/L)\ ,$$

which is the diffractive point spread function whose integral over $\eta \in R^d$ is one. If, however, we have *strong multipathing*, $\sigma_M \ll \sigma_F$, then we may approximate $\hat{\chi}_A(\eta k/L)$ by $\hat{\chi}_A(0) = a^d$ in (3.10), and the point spread function becomes

$$\mathcal{W}(\eta;L,k) \sim \left(\frac{ka}{2\pi L}\right)^d e^{-|\eta|^2/(2\sigma_M^2)}.$$

By writing the variance (spot size) σ_M^2 in the form (3.12) we can interpret a_e as an effective aperture of the time reversal mirror. We can rewrite the point spread function in terms of a normalized Gaussian as

$$\mathcal{W}(\eta; L, k) \sim \left(\frac{\sigma_M}{\sqrt{2\pi}\sigma_F}\right)^d \frac{e^{-|\eta|^2/(2\sigma_M^2)}}{(2\pi\sigma_M^2)^{d/2}}$$

with the factor in front of the normalized Gaussian also equal to

$$\left(\frac{a}{\sqrt{2\pi}a_e}\right)^d.$$

This means that, when there is strong multipathing, the integral of the point spread function over R^d is equal not to one but to this ratio, which can be much smaller than one if $a_e \gg a$. Multipathing produces a tighter point spread function, but there is also loss of energy, as of course we should expect.

A more direct interpretation for the effective aperture can be given if the time reversal mirror has a Gaussian aperture function

$$\chi_A(\eta) = e^{-|\eta|^2/(2a^2)}.$$

The point spread function $\mathcal{W}$ now has the form

$$\mathcal{W}(\eta; L, k) = \left(\frac{ka}{\sqrt{2\pi}L}\right)^d e^{-|\eta|^2/(2\sigma_g^2)},$$

with

$$\sigma_g = \frac{L}{ka_g},$$

and the effective aperture a_g given by

$$a_g = \sqrt{a^2 + \frac{DL^3}{3}} = \sqrt{a^2 + a_e^2}.$$

Clearly, $a_g \approx a_e$ when there is strong multipathing and $a_e \gg a$. Written with a normalized Gaussian, the point spread function for a Gaussian aperture has the form

$$\mathcal{W}(\eta) = \left(\frac{a}{a_g}\right)^d \frac{e^{-|\eta|^2/(2\sigma_g^2)}}{(2\pi\sigma_g^2)^{d/2}}.$$

3.4. Broad-band time reversal for distributed sources. For a distributed source, its support σ_s is large compared to the Fresnel number θ, so the ratio $\beta = \sigma_s/\theta$ is large. In this case we can compute the average of (3.7) the same way as we did in (3.8), and we find that

$$\begin{aligned}(3.14)\quad &\langle \Psi^B(L, \mathbf{x}_0, \xi, t)\rangle \\ &= (2\pi)^d e^{-i(\mathbf{p}_0\cdot\xi + k_0 c_0 t)}\psi_0(\xi/\beta)\int \left\langle W\left(L, \mathbf{x}_0, \frac{\mathbf{p}_0}{k_0+k}\right)\right\rangle e^{-ikc_0 t}\hat{g}(-c_0 k)\frac{c_0 dk}{2\pi} \\ &= e^{-i(\mathbf{p}_0\cdot\xi + k_0 c_0 t)}\psi_0(\xi/\beta)\int \frac{d\mathbf{y}d\mathbf{w}c_0 dk}{(2\pi)^{d+1}}\chi_A(\mathbf{y})e^{i(\frac{L\mathbf{w}\mathbf{p}_0}{k_0+k} - \mathbf{w}\cdot\mathbf{y} - kc_0 t)}e^{-\frac{DL^3 w^2}{6}}\hat{g}(-c_0 k).\end{aligned}$$

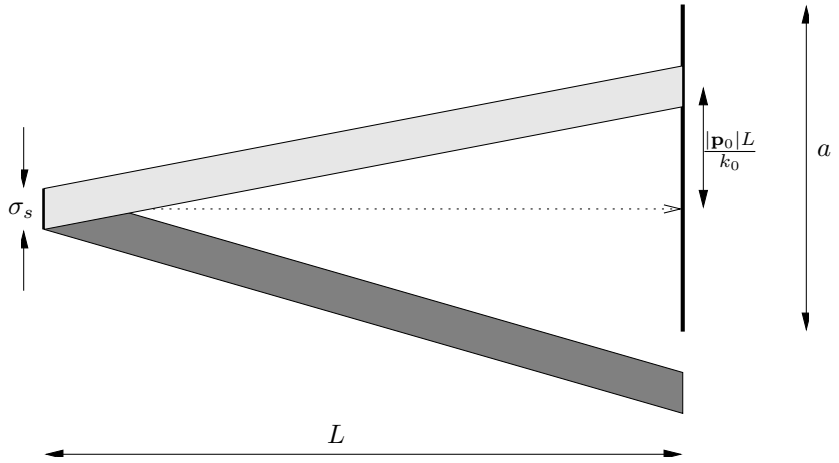

FIG. 3.1. *A directed field propagates from a distributed source of size σ_s toward the time reversal mirror of size a. The time-reversed back-propagated field depends on the location of the mirror relative to the direction of the propagating beam.*

The $\mathbf{y}$ integral on the right gives the Fourier transform of the aperture function $\chi_A(\mathbf{y})$, so with $\omega_0 = c_0 k_0$ and a change of variable from k to $\omega = c_0 k$, we have

$$\begin{aligned}(3.15)\qquad &\langle \Psi^B(L, \mathbf{x}_0, \xi, t)\rangle \\ &= e^{-i(\mathbf{p}_0\cdot\xi+\omega_0 t)}\psi_0(\xi/\beta)\int \frac{d\omega}{2\pi} e^{-i\omega t}\hat{g}(-\omega)\ \chi_A * \left(\frac{e^{-x^2/(2a_e^2)}}{(2\pi a_e^2)^{d/2}}\right)\left(\frac{Lc_0\mathbf{p}_0}{\omega_0+\omega}\right).\end{aligned}$$

Here the star denotes convolution with respect to the spatial variables $\mathbf{x}$, and a_e is the effective aperture defined by (3.13).

When multipathing is weak, we can ignore the Gaussian factor in the convolution and we have

$$\begin{aligned}(3.16)\qquad &\langle \Psi^B(L, \mathbf{x}_0, \xi, t)\rangle \\ &= e^{-i(\mathbf{p}_0\cdot\xi+\omega_0 t)}\psi_0(\xi/\beta)\int \frac{d\omega}{2\pi} e^{-i\omega t}\hat{g}(-\omega)\ \chi_A\left(\frac{Lc_0\mathbf{p}_0}{\omega_0+\omega}\right).\end{aligned}$$

In the opposite case, when there is strong multipathing and the effective aperture is much larger than the physical one, $a_e \gg a$, we have

$$\begin{aligned}(3.17)\qquad &\langle \Psi^B(L, \mathbf{x}_0, \xi, t)\rangle \\ &= e^{-i(\mathbf{p}_0\cdot\xi+\omega_0 t)}\psi_0(\xi/\beta)\left(\frac{a}{\sqrt{2\pi}a_e}\right)^d \int \frac{d\omega}{2\pi} e^{-i\omega t}\hat{g}(-\omega) e^{-\frac{1}{2}(\frac{Lc_0\mathbf{p}_0}{a_e(\omega_0+\omega)})^2}.\end{aligned}$$

To interpret these results, we note first that a distributed source function of the form (3.11) can be considered as a phased array emitting an inhomogeneous plane wave, a beam, in the direction $(k, \mathbf{p}_0)$, within the paraxial or parabolic approximation. The ratio $|\mathbf{p}_0|/k$ is the tangent of the angle the direction vector makes with the z axis, and $L|\mathbf{p}_0|/k$ is the transverse distance of the beam center to the center of the phased array (see Figure 3.1). If for each ω the beam displacement vector $Lc_0\mathbf{p}_0/(\omega_0+\omega)$

is inside the set A occupied by the time reversal array, then we recover at the source the full pulse in (3.16), time-reversed,

$$\langle \Psi^B(L, \mathbf{x}_0, \xi, t)\rangle = e^{-i(\mathbf{p}_0\cdot\xi+\omega_0 t)}\psi_0(\xi/\beta)g(-t).$$

If, however, for some frequencies the transverse displacement vector is outside the time reversal array, these frequencies will be nulled in the integration and a distorted time pulse will be received at the source. Depending on the position of the time reversal mirror relative to the beam, high or low frequencies may be nulled.

In a strongly multipathing medium, the situation is quite different because the expression (3.17), or more generally (3.15), now holds. Even if the beam from the phased array does not intercept the time reversal mirror at all, we will still get a time-reversed signal at the source but with a much diminished amplitude. If the beam falls entirely within the time reversal mirror, then the time-reversed pulse will be a distorted form of $g(-t)$, with its amplitude reduced by the factor $(a/a_e)^d$. An interesting and important application of the time reversal of a beam in a random medium is the possibility of *estimating* the effective aperture a_e by pointing the beam in different directions toward the time reversal mirror, measuring the time-reversed signal that back-propagates to the source, that is, to the phased array, and inferring a_e by fitting the measurements to (3.15).

4. Summary and conclusions. We have analyzed and explained two important phenomena associated with time reversal in a random medium:

- superresolution of the back-propagated signal due to multipathing,
- self-averaging that gives a statistically stable refocusing.

Our analysis is based on a specific asymptotic limit (see section 2.1), where the longitudinal distance of propagation is much larger than the size of the time reversal mirror, which in turn is much larger than the correlation length of the medium, fluctuations in the index of refraction are weak, and the wave length is short compared to the correlation length. This asymptotic regime is more relevant to optical or infrared time reversal than it is to sonar or ultrasound. We have related the self-averaging properties of the back-propagated signal to those of functionals of the Wigner distribution. Self-averaging of these functionals implies the statistical stability of the time-reversed and back-propagated signal in the frequency domain, provided that the source function is not too broad compared to the Fresnel number (2.4). Time reversal refocusing of waves emitted from a distributed source is self-averaging only in the time domain.

We apply our theoretical results about stochastic Wigner distributions to time reversal and discuss in detail superresolution and statistical stability in section 3.

Appendix A. The white noise limit and the parabolic approximation. We collect here some comments on the scaling analysis of section 2.1 and refer to [1, 27, 33] for additional comments and results on scaling and asymptotics in the high frequency and white noise regime.

The dimensionless parameters $\delta, \varepsilon, \gamma$ introduced by (2.2) in section 2.1, along with the Fresnel number θ defined by (2.4), lead to the scaled parabolic wave equation (2.5). If we do not make the parabolic approximation and keep the ψ_{zz} term, we have the scaled Helmholtz equation, with the phase e^{ikz} removed,

$$\frac{\varepsilon^2\theta^2}{\delta^2}\psi_{zz} + 2ik\theta\psi_z + \theta^2\Delta_{\mathbf{x}}\psi + \frac{k^2\delta}{\varepsilon^{1/2}}\mu\left(\frac{\mathbf{x}}{\delta}, \frac{z}{\varepsilon}\right)\psi = 0. \tag{A.1}$$

Here, as in (2.5), we relate the strength of the fluctuations σ to ε and δ by (2.6). Is the parabolic approximation valid in the ordering (2.7), $\theta \ll \varepsilon \ll \delta \ll 1$, that we have analyzed? The answer is yes, but not before both θ *and* ε limits have been taken, in which case the scaled Wigner distribution (2.8) converges to the Liouville–Ito process that is defined by the SPDE (2.19).

It is in the white noise limit $\varepsilon \to 0$, with Fresnel number θ and δ fixed, that the parabolic approximation is valid for (A.1), as was pointed out in [1]. This is easily seen if the random fluctuations μ are differentiable in z. The parabolic approximation is clearly not valid in the high frequency limit $\theta \to 0$, before the white noise limit $\varepsilon \to 0$ is also taken. In the white noise limit, the wave function $\psi(z, \mathbf{x})$ satisfies an Ito–Schrödinger equation

$$2ik\theta d_z\psi + \theta^2 \Delta_{\mathbf{x}} \psi dz + \frac{ik^3\delta^2}{4\theta} R_0(0)\psi dz + k^2\delta\psi d_z B\left(\frac{\mathbf{x}}{\delta}, z\right) = 0. \tag{A.2}$$

Here R_0 is the integrated covariance of the fluctuations μ given by (2.15) and (2.13), and the Brownian field $B(\mathbf{x}, z)$ has covariance

$$\langle B(\mathbf{x}, z_1) B(\mathbf{y}, z_2)\rangle = R_0(\mathbf{x} - \mathbf{y}) z_1 \wedge z_2.$$

This Ito–Schrödinger equation is the result of the central limit theorem applied to (A.1). Let

$$B^\varepsilon(\mathbf{x}, z) = \frac{1}{\sqrt{\varepsilon}} \int_0^z \mu\left(\mathbf{x}, \frac{s}{\varepsilon}\right) ds.$$

Then, as $\varepsilon \to 0$, this process converges weakly, under suitable hypotheses, to the Brownian field $B(\mathbf{x}, z)$ with the above covariance. The extra term in (A.2) is the Stratonovich correction.

The white noise limit for SPDEs is analyzed in [10] and a rigorous theory of the Ito–Schrödinger equation is given in [11]. The ergodic theory of the Ito–Schroedinger equation is explored in [17]. Wave propagation in the parabolic approximation with white noise fluctuations is considered in detail in [18, 30].

The scaled Wigner distribution for the process ψ, defined by (2.8), satisfies the stochastic transport equation

$$\begin{aligned} &d_z W_\theta(z, \mathbf{x}, \mathbf{p}) + \frac{\mathbf{p}}{k} \cdot \nabla_x W_\theta(z, \mathbf{x}, \mathbf{p}) dz \\ &= \frac{k^2\delta^2}{4\theta^2} \int \frac{d\mathbf{q}}{(2\pi)^d} \hat{R}_0(\mathbf{q}) \left(W_\theta\left(z, \mathbf{x}, \mathbf{p} + \frac{\theta\mathbf{q}}{\delta}\right) - W_\theta(z, \mathbf{x}, \mathbf{p}) \right) dz \\ &+ \frac{ik\delta}{2\theta} \int \frac{d\mathbf{q}}{(2\pi)^d} e^{i\mathbf{q}\cdot\mathbf{x}/\delta} \left(W_\theta\left(z, \mathbf{x}, \mathbf{p} - \frac{\theta\mathbf{q}}{2\delta}\right) - W_\theta\left(z, \mathbf{x}, \mathbf{p} + \frac{\theta\mathbf{q}}{2\delta}\right) \right) d_z \hat{B}(\mathbf{q}, z), \end{aligned} \tag{A.3}$$

which is derived from (A.2) using the Ito calculus. The Wigner process W_θ converges in the limit $\theta \to 0$ to the Liouville–Ito process defined by the SPDE (2.19).

Appendix B. Decorrelation of the Wigner process.

B.1. Proof of Theorem 2.1. We give here the proof of Theorems 2.1 and 2.2. We consider Theorem 2.1 first. It will follow from the Lebesgue dominated convergence theorem if we show that for $\mathbf{p}_1 \neq \mathbf{p}_2$

$$E\{W_\delta(z, \mathbf{x}, \mathbf{p}_1) W_\delta(z, \mathbf{x}, \mathbf{p}_2)\} - E\{W_\delta(z, \mathbf{x}, \mathbf{p}_1)\} E\{W_\delta(z, \mathbf{x}, \mathbf{p}_2)\} \to 0 \tag{B.1}$$

as $\delta \to 0$ because the function W_δ is uniformly bounded and $E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)\}$ does not depend on δ. Furthermore, the correlation function at the same spatial point, but for two different values of the wave vector, $U_\delta^{(2)}(z,\mathbf{x},\mathbf{p}_1,\mathbf{p}_2) = E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\}$, is the solution of (2.18) with $N=2$ and the initial data

$$W_\delta^{(2)}(0,\mathbf{x}_1,\mathbf{p}_1,\mathbf{x}_2,\mathbf{p}_2) = W_I(\mathbf{x}_1,\mathbf{p}_1)W_I(\mathbf{x}_2,\mathbf{p}_2),$$

evaluated at $\mathbf{x}_1 = \mathbf{x}_2 = \mathbf{x}$. Therefore, $U_\delta^{(2)}$ may be represented as

$$U_\delta^{(2)}(z,\mathbf{x}_1,\mathbf{p}_1,\mathbf{x}_2,\mathbf{p}_2) = E\left\{W_I(\mathbf{X}_\delta^1(z),\mathbf{P}_\delta^1(z))W_I(\mathbf{X}_\delta^2(z),\mathbf{P}_\delta^2(z))\right\}.$$

The processes $\mathbf{X}_\delta^{1,2}$ and $\mathbf{P}_\delta^{1,2}$ satisfy the system of stochastic differential equations (2.16), which may be more explicitly written as

$$\begin{aligned}
d\mathbf{P}_\delta^1 &= -\left[\sigma(0)d\mathbf{B}^1(z) + \frac{1}{2}\sigma\left(\frac{\mathbf{X}_\delta^1 - \mathbf{X}_\delta^2}{\delta}\right)d\mathbf{B}^2(z)\right], \\
d\mathbf{P}_\delta^2 &= -\left[\sigma(0)d\mathbf{B}^2(z) + \frac{1}{2}\sigma\left(\frac{\mathbf{X}_\delta^2 - \mathbf{X}_\delta^1}{\delta}\right)d\mathbf{B}^1(z)\right], \\
d\mathbf{X}_\delta^1 &= -\mathbf{P}_\delta^1 dz, \quad d\mathbf{X}_\delta^2 = -\mathbf{P}_\delta^2 dz
\end{aligned} \tag{B.2}$$

with the initial conditions $\mathbf{X}_\delta^{1,2}(0) = \mathbf{x}$, $\mathbf{P}_\delta^m(0) = \mathbf{p}_m$, $m = 1,2$. Here $\sigma^2(0) = D$, the diffusion coefficient (2.15), and the coupling matrix $\sigma(\mathbf{x})$ is given by (2.17). Recall that $W_\delta(z,\mathbf{x},\mathbf{p},k) = W_\delta(z,\mathbf{x},\mathbf{p}/k;1)$, and we need only consider the case $k=1$.

It is convenient to introduce the processes $\mathbf{X}^{1,2}$ and $\mathbf{P}^{1,2}$ that are solutions of (2.16) with no coupling,

$$\begin{aligned}
&d\mathbf{P}^m = -\sigma(0)d\mathbf{B}^m(z), \quad d\mathbf{X}^m = -\mathbf{P}^m dz, \\
&\mathbf{X}^{1,2}(0) = \mathbf{x}, \quad \mathbf{P}^m(0) = \mathbf{p}_m, \quad m = 1,2,
\end{aligned} \tag{B.3}$$

and define the deviations of the solutions of the coupled system of stochastic differential equations (B.2) from those of (B.3): $\mathbf{Z}_\delta^m = \mathbf{X}_\delta^m - \mathbf{X}^m$, $\mathbf{S}_\delta^m = \mathbf{P}_\delta^m - \mathbf{P}^m$. Then we have

$$\begin{aligned}
&d\mathbf{S}_\delta^1 = -\frac{1}{2}\sigma\left(\frac{\mathbf{X}_\delta^1 - \mathbf{X}_\delta^2}{\delta}\right)d\mathbf{B}^2(z), \quad d\mathbf{S}_\delta^2 = -\frac{1}{2}\sigma\left(\frac{\mathbf{X}_\delta^2 - \mathbf{X}_\delta^1}{\delta}\right)d\mathbf{B}^1(z), \\
&d\mathbf{Z}_\delta^1 = -\mathbf{S}_\delta^1 dz, \quad d\mathbf{Z}_\delta^2 = -\mathbf{S}_\delta^2 dz
\end{aligned} \tag{B.4}$$

with the initial data $\mathbf{S}_\delta^m(0) = \mathbf{Z}^m(0) = 0$. Define

$$\begin{aligned}
&\mathcal{V}(\mathbf{X}^1,\mathbf{X}^2,\mathbf{P}^1,\mathbf{P}^2,\mathbf{Z}_\delta^1,\mathbf{Z}_\delta^2,\mathbf{S}_\delta^1,\mathbf{S}_\delta^2) \\
&= W_I(\mathbf{X}^1 + \mathbf{Z}_\delta^1, \mathbf{P}^1 + \mathbf{S}_\delta^1)W_I(\mathbf{X}^2 + \mathbf{Z}_\delta^2, \mathbf{P}^2 + \mathbf{S}_\delta^2) - W_I(\mathbf{X}^1,\mathbf{P}^1)W_I(\mathbf{X}^2,\mathbf{P}^2).
\end{aligned} \tag{B.5}$$

Then we have, with the above notation,

$$\begin{aligned}
&E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\} - E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)\}E\{W_\delta(z,\mathbf{x},\mathbf{p}_2)\} \\
&= E\left\{\mathcal{V}(\mathbf{X}^1(z),\mathbf{X}^2(z),\mathbf{P}^1(z),\mathbf{P}^2(z),\mathbf{Z}_\delta^1(z),\mathbf{Z}_\delta^2(z),\mathbf{S}_\delta^1(z),\mathbf{S}_\delta^2(z))\right\} \\
&\le CE\left\{|\mathbf{Z}_\delta^1(z)| + |\mathbf{Z}_\delta^2(z)| + |\mathbf{S}_\delta^1(z)| + |\mathbf{S}_\delta^2(z)|\right\}
\end{aligned} \tag{B.6}$$

since W_I is a Lipschitz function.

Let us assume for simplicity that the correlation function $R(\mathbf{x})$ has compact support inside the set $|\mathbf{x}| \le M$. Then the coupling term in (B.2) is nonzero only when $|\mathbf{X}_\delta^1 - \mathbf{X}_\delta^2| \le M\delta$. We introduce the processes $\mathbf{Q}_\delta = \mathbf{P}_\delta^1 - \mathbf{P}_\delta^2$ and $\mathbf{Y}_\delta = \mathbf{X}_\delta^1 - \mathbf{X}_\delta^2$ that govern (B.4). They satisfy the stochastic differential equations

$$d\mathbf{Q}_\delta = -\left[\sigma(0) - \frac{1}{2}\sigma\left(\frac{\mathbf{Y}_\delta}{\delta}\right)\right] d\tilde{\mathbf{B}}, \quad d\mathbf{Y}_\delta = -\mathbf{Q}_\delta dz, \tag{B.7}$$
$$\mathbf{Q}_\delta(0) = \mathbf{p}_1 - \mathbf{p}_2, \ \mathbf{Y}_\delta(0) = 0$$

with $\tilde{\mathbf{B}} = \mathbf{B}^1 - \mathbf{B}^2$ being a Brownian motion.

In order to prove the theorem, we show that the coupling term $\sigma(\cdot)$ in (B.2) introduces only lower order correction terms; that is, $\mathbf{S}_\delta^m$ and $\mathbf{Z}_\delta^m$ are small. We first show that after a small "time" τ, the points $\mathbf{X}_\delta^m$ are driven apart since $\mathbf{Q}_\delta(0) = \mathbf{P}_\delta^1(0) - \mathbf{P}_\delta^2(0) \neq 0$. Then we show that after the points have separated the probability that they come close so that the coupling term $\sigma(\cdot)$ becomes nonzero is small. This "nonrecurrence" condition requires that the spatial dimension $d \ge 2$. It follows that to leading order, the points $\mathbf{X}_\delta^m$ are uncorrelated when $d \ge 2$ and that the coupling term introduces only lower order corrections. A similar argument for $d = 1$ would require an estimate of the time that points that are originally separated in the spatial variable spend near each other, where the coupling term in (B.2) is not zero.

We need the following two lemmas. The first one shows that particles that start at the same point $\mathbf{x}$, with different initial directions $\mathbf{p}_1$ and $\mathbf{p}_2$, get separated with a large probability.

LEMMA B.1. *Let $\mathbf{Y}_\delta$, $\mathbf{Q}_\delta$ solve* (B.7) *with $\mathbf{Y}_\delta(0) = 0$, $\mathbf{Q}_\delta(0) = \mathbf{q} \neq 0$. Then for any $\varepsilon > 0$ there exists $\tau_0(\varepsilon) > 0$ that depends only on $\mathbf{q} = \mathbf{p}_1 - \mathbf{p}_2$ but not on δ so that we have $P(|\mathbf{Y}_\delta(\tau)| \ge \frac{|\mathbf{q}|\tau}{2}) \ge 1 - \varepsilon$ for all $\tau \le \tau_0(\varepsilon)$.*

The second lemma shows that, after the particles are separated, the probability that they come close to each other is small.

LEMMA B.2. *Given any fixed $r > 0$ and $z > 0$, if $\mathbf{Y}_\delta$, $\mathbf{Q}_\delta$ solve* (B.7) *with $|\mathbf{Y}_\delta(0)| \ge r$, $\mathbf{Q}_\delta(0) = \mathbf{q} \neq 0$, then $P\left(\inf_{0\le s\le z} |\mathbf{Y}_\delta(s)| \le M\delta\right) \to 0$ as $\delta \to 0$.*

We prove Theorem 2.1 before proving Lemmas B.1 and B.2.

Proof. Let z and $\mathbf{q} = \mathbf{p}_1 - \mathbf{p}_2$ be fixed and defined as above. Given $\varepsilon > 0$, then for any $\tau < \tau_0(\varepsilon)$ (with τ_0 as defined in Lemma B.1), Lemma B.2 and the Markov property of the Brownian motion imply that

$$P\left(\mathbf{S}_\delta^m(z) = \mathbf{S}_\delta^m(\tau) \Big| |\mathbf{Y}_\delta(\tau)| \ge \frac{\tau|\mathbf{q}|}{2}\right) \ge 1 - \varepsilon$$

and

$$P\left(\mathbf{Z}_\delta^m(z) = \mathbf{Z}_\delta^m(\tau) + (z-\tau)\mathbf{S}_\delta^m(\tau) \Big| |\mathbf{Y}_\delta(\tau)| \ge \frac{\tau|\mathbf{q}|}{2}\right) \ge 1 - \varepsilon$$

for $\delta < \delta_0(\tau, \varepsilon)$. Furthermore,

$$E\left\{|\mathbf{Z}_\delta^1(\tau)| + |\mathbf{Z}_\delta^2(\tau)| + |\mathbf{S}_\delta^1(\tau)| + |\mathbf{S}_\delta^2(\tau)| \Big| |\mathbf{Y}_\delta(\tau)| \ge \frac{\tau|\mathbf{q}|}{2}\right\} \tag{B.8}$$
$$\le E\left\{|\mathbf{Z}_\delta^1(\tau)| + |\mathbf{Z}_\delta^2(\tau)| + |\mathbf{S}_\delta^1(\tau)| + |\mathbf{S}_\delta^2(\tau)|\right\}/(1-\varepsilon) \le C\tau$$

because the function σ is uniformly bounded. Therefore, we have

$$E\left\{\mathcal{V}(\mathbf{X}^1, \mathbf{X}^2, \mathbf{P}^1, \mathbf{P}^2, \mathbf{Z}_\delta^1, \mathbf{Z}_\delta^2, \mathbf{S}_\delta^1, \mathbf{S}_\delta^2)\right\}$$

$$= E\left\{\mathcal{V}(\mathbf{X}^1,\mathbf{X}^2,\mathbf{P}^1,\mathbf{P}^2,\mathbf{Z}^1_\delta,\mathbf{Z}^2_\delta,\mathbf{S}^1_\delta,\mathbf{S}^2_\delta)\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right\}P\left(|\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right) \tag{B.9}$$

$$+E\left\{\mathcal{V}(\mathbf{X}^1,\mathbf{X}^2,\mathbf{P}^1,\mathbf{P}^2,\mathbf{Z}^1_\delta,\mathbf{Z}^2_\delta,\mathbf{S}^1_\delta,\mathbf{S}^2_\delta)\Big||\mathbf{Y}_\delta(\tau)|\leq\frac{\tau|\mathbf{q}|}{2}\right\}P\left(|\mathbf{Y}_\delta(\tau)|\leq\frac{\tau|\mathbf{q}|}{2}\right)=I+II.$$

The second term above is small because the probability for $\mathbf{Y}_\delta(\tau)$ to be very small is bounded by Lemma B.1. More precisely, given $\varepsilon>0$ and $\tau<\tau_0(\varepsilon)$, Lemma B.1 implies that

$$II\leq C\varepsilon. \tag{B.10}$$

The first term in (B.9) corresponds to the more likely scenario that $\mathbf{Y}_\delta$ at time τ has left the ball of radius $\tau|\mathbf{q}|/2$. We estimate it as follows. The probability that $\mathbf{Y}_\delta$ re-enters the ball of radius $M\delta$ is small according to Lemma B.2. Moreover, if $\mathbf{Y}_\delta$ stays outside this ball, the difference variables $\mathbf{Z}^m$ and $\mathbf{S}^m$ are bounded in terms of their values at time τ. The latter are small if τ is small. More precisely, using (B.8), we choose τ so small that

$$E\left\{|\mathbf{Z}^1_\delta(\tau)|+|\mathbf{Z}^2_\delta(\tau)|+|\mathbf{S}^1_\delta(\tau)|+|\mathbf{S}^2_\delta(\tau)|\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right\}\leq\varepsilon.$$

Then we obtain

$$I\leq E\left\{\mathcal{V}(\mathbf{X}^1,\mathbf{X}^2,\mathbf{P}^1,\mathbf{P}^2,\mathbf{Z}^1_\delta,\mathbf{Z}^2_\delta,\mathbf{S}^1_\delta,\mathbf{S}^2_\delta)\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right\}$$

$$\leq E\left\{\mathcal{V}(\mathbf{X}^1,\mathbf{X}^2,\mathbf{P}^1,\mathbf{P}^2,\mathbf{Z}^1_\delta,\mathbf{Z}^2_\delta,\mathbf{S}^1_\delta,\mathbf{S}^2_\delta)\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\text{ and }\inf_{\tau\leq s\leq z}|\mathbf{Y}_\delta(s)|\leq M\delta\right\}$$

$$\times P\left(\inf_{\tau\leq s\leq z}|\mathbf{Y}_\delta(s)|\leq M\delta\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right)$$

$$+E\left\{|\mathbf{Z}^1_\delta(z)|+|\mathbf{Z}^2_\delta(z)|+|\mathbf{S}^1_\delta(z)|+|\mathbf{S}^2_\delta(z)|\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\text{ and }\inf_{\tau\leq s\leq z}|\mathbf{Y}_\delta(s)|\geq M\delta\right\}$$

$$\times P\left(\inf_{\tau\leq s\leq z}|\mathbf{Y}_\delta(s)|\geq M\delta\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right)=I_1+I_2.$$

The term I_1 goes to zero as $\delta\to0$ by Lemma B.2. However, if the conditions in I_2 hold, then

$$\mathbf{S}^m_\delta(z)=\mathbf{S}^m_\delta(\tau),\quad\mathbf{Z}^m_\delta(z)=\mathbf{Z}^m_\delta(\tau)-\frac{1}{k}(z-\tau)\mathbf{S}^m_\delta(\tau).$$

Therefore, the term I_2 may be bounded with the help of (B.8) by

$$I_2\leq E\left\{|\mathbf{Z}^1_\delta(z)|+|\mathbf{Z}^2_\delta(z)|+|\mathbf{S}^1_\delta(z)|+|\mathbf{S}^2_\delta(z)|\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\text{ and }\inf_{\tau\leq s\leq z}|\mathbf{Y}_\delta(s)|\geq M\delta\right\}$$

$$\leq CE\left\{|\mathbf{Z}^1_\delta(\tau)|+|\mathbf{Z}^2_\delta(\tau)|+|\mathbf{S}^1_\delta(\tau)|+|\mathbf{S}^2_\delta(\tau)|\Big||\mathbf{Y}_\delta(\tau)|\geq\frac{\tau|\mathbf{q}|}{2}\right\}\leq C\tau.$$

Putting together (B.9), (B.10), and the above bounds on I_1 and I_2, we obtain

$$E\left\{|\mathbf{Z}^1_\delta(z)|+|\mathbf{Z}^2_\delta(z)|+|\mathbf{S}^1_\delta(z)|+|\mathbf{S}^2_\delta(z)|\right\}\leq C\varepsilon$$

for $\delta<\bar{\delta}$, and Theorem 2.1 follows from (B.6). □

B.2. Proofs of Lemmas B.1 and B.2. We first prove Lemma B.1.

Proof. We write

$$Q_\delta(z) = \mathbf{q} - \int_0^z \left(\sigma(0) - \frac{1}{2}\sigma(\mathbf{Y}(s)/\delta)\right)\, d\tilde{\mathbf{B}}(s) \;\equiv\; \mathbf{q} + \tilde{\mathbf{Q}}_\delta(z)$$

so that

$$\mathbf{Y}_\delta(t) = -\mathbf{q}t - \int_0^t \tilde{\mathbf{Q}}_\delta(s)ds.$$

Then we have

$$P\left(\sup_{0\le s\le\tau} |\tilde{\mathbf{Q}}_\delta(s)| \;>\; r\right) \le C\tau/r^2 \tag{B.11}$$

and hence

$$P\left(|\mathbf{Y}_\delta(\tau) + \tau\mathbf{q}| > r\tau\right) \le P\left(\sup_{0\le s\le\tau} |\tilde{\mathbf{Q}}_\delta(s)| > r\right) \le C\tau/r^2.$$

We let $r = |\mathbf{q}|/2$ in the above formula and obtain

$$P\left(|\mathbf{Y}_\delta(\tau)| < \frac{\tau|\mathbf{q}|}{2}\right) \le \frac{C}{|\mathbf{q}|^2}\tau,$$

and the conclusion of Lemma B.1 follows. ∎

Finally, we prove Lemma B.2.

Proof. Let τ_δ be the first time $\mathbf{Y}_\delta(z)$ enters the ball of radius $M\delta$,

$$\tau_\delta = \inf\left\{z :\; |\mathbf{Y}_\delta(z)| \le M\delta\right\},$$

with $\mathbf{Y}_\delta(0) = \mathbf{Y}^0 \neq 0$. For $0 < \alpha < 1$, let $\Delta z = \delta^{1-\alpha}$, $n = \lceil z/\Delta z\rceil$, $J_i = (i\Delta z, (i+1)\Delta z)$, and $p < 1$. Note that, until the time τ_δ, the process $(\mathbf{Y}_\delta, \mathbf{Q}_\delta)$ coincides with the process $(\mathbf{Y}, \mathbf{Q})$ governed by (B.7) without the coupling term $\sigma(\mathbf{Y}_\delta/\delta)$. We find

$$P(\tau_\delta < z) \le \sum_{i=0}^{n-1} \left\{ P\left(|\mathbf{Y}(i\Delta z)| < M\delta^p\right) + P\left(\inf_{s\in J_i} |\mathbf{Y}(s)| < M\delta \;\middle|\; |\mathbf{Y}(i\Delta z)| \ge M\delta^p\right)\right\}.$$

The process $\mathbf{Y}(s)$ is Gaussian with mean $\mathbf{Y}^0$ and variance $\mathcal{O}(s^2)$. Therefore, there is a $\bar\delta > 0$ such that for $\delta < \bar\delta$

$$P(|\mathbf{Y}(i\Delta z)| < M\delta^p) \le C\delta^{dp}.$$

If we assume

$$p < 1 - \alpha, \tag{B.12}$$

then also

$$\begin{aligned} P(\tau_\delta < z) &\le nC\left(\delta^{dp} + P\left(\sup_{0<s<\Delta z} |\mathbf{Y}(s) - \mathbf{Y}^0| \ge M[\delta^p - \delta]\right)\right) \\ &\le C\left(\delta^{dp+\alpha-1} + \delta^{\alpha-1}\frac{E\left\{\mathbf{B}(\delta z)^{2r}\right\}\Delta z^{2r}}{(\delta^p - \delta)^{2r}}\right) \\ &\le C\left[\delta^{dp+\alpha-1} + \delta^{\alpha-1-rp+3r(1-\alpha)/2}\right]. \end{aligned}$$

Note that, with $p < 1 - \alpha$ and r large enough, there is a $q > 0$ so that

$$P(\tau_\delta < z) \le C\delta^q$$

if $d \ge 2$, and Lemma B.2 follows. ∎

B.3. Proof of Theorem 2.2. We need to first show that

$$J_\delta(z,\mathbf{x}) = \int W_\delta(z,\mathbf{x},\mathbf{p})d\mathbf{p} \tag{B.13}$$

is finite with probability one. The stochastic flow $(\mathbf{X}_\delta(z,\mathbf{x},\mathbf{p}),\mathbf{P}_\delta(z,\mathbf{x},\mathbf{p})$ is continuous in $(z,\mathbf{x},\mathbf{p})$ with probability one, so $W_\delta(z,\mathbf{x},\mathbf{p}) = W_I(\mathbf{X}_\delta(z,\mathbf{x},\mathbf{p}),\mathbf{P}_\delta(z,\mathbf{x},\mathbf{p}))$ is bounded and continuous. It is, moreover, nonnegative if $W_I \geq 0$. We know that

$$\int E\{W_\delta(z,\mathbf{x},\mathbf{p})\}d\mathbf{p}$$

is finite and independent of δ, and the order of integration and expectation can be interchanged by Tonelli's theorem. This theorem implies in addition that $J_\delta(z,\mathbf{x})$ is finite with probability one.

We can now consider

$$E\{J_\delta^2(z,\mathbf{x})\} = \int E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\}d\mathbf{p}_1 d\mathbf{p}_2.$$

The integrand is bounded by an integrable function uniformly in δ because

$$E\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\} \leq E^{1/2}\{W_\delta^2(z,\mathbf{x},\mathbf{p}_1)\}E^{1/2}\{W_\delta(z,\mathbf{x},\mathbf{p}_2)\};$$

the right side does not depend on δ and is integrable. Therefore, by the Lebesgue dominated convergence theorem and the results of the previous section, we have that

$$\lim_{\delta\to 0} E\{J_\delta^2(z,\mathbf{x})\} = E^2\{J_\delta(z,\mathbf{x})\}$$

and the right side does not depend on δ. This completes the proof of Theorem 2.2.

STRUCTURE FROM MOTION: A NEW LOOK FROM THE POINT OF VIEW OF INVARIANT THEORY*

PIERRE-LOUIS BAZIN† AND MIREILLE BOUTIN‡

Abstract. We present a novel simple formulation of the problem of 3D object reconstruction from images. In this formulation, the object is seen as lying at the intersection of the projection of orbits of custom built Lie group actions. The group parameters correspond to unknown irrelevant quantities such as the camera orientation, the depth parameters of the object with respect to the camera, and the focal length. We then use an algorithmic method based on moving frames à la Fels–Olver to obtain a fundamental set of invariants of these group actions. The invariants are used to define a set of equations determining the 3D object, thus providing a mathematical formulation of the problem where the irrelevant parameters do not appear.

Key words. structure from motion, group action, invariants, moving frame, pinpoint camera, orthographic camera

1. Introduction.

This paper has two goals. Its first goal is to illustrate the potential of using the formalism of invariant theory in certain applications. This potential is, at this point, rather unexploited, and we hope to set a trend with these results. Its second goal is to provide new insights on the problem of structure from motion through a novel formulation in terms of group actions.

The problem of structure from motion is rather old and well studied. It consists of reconstructing an object from a set of pictures of this object (e.g., a movie). In this paper, we consider the case of objects represented by an ordered set of points in $\mathbb{R}^3$ and assume that the camera parameters (position and orientation of the camera, focal length) are unknowns.

The concept of invariance is of major importance in modern geometry. In the field of computer vision, invariants of classical groups have been used in the design of methods of object recognition and reconstruction for more than a decade (see [12, 13]). In particular, the invariants of the projective and affine transformation groups have been widely used [16, 21, 18]. However, invariant theory can also deal with a variety of other group actions such as the ones we encounter in the problem of structure from motion.

For our purposes, invariants are defined as real-valued functions on a manifold M which remain unchanged under the action (denoted by $*$) of a group G on M. The case of Lie group actions is particularly interesting. (The reader unfamiliar with the concept of Lie group actions may refer to [8] for an introduction.) When the Lie group action satisfies certain conditions, there exists a finite set of *fundamental* invariants $I_1, \ldots, I_N$, which are local coordinates for the quotient space M/G. In other words, for any point $z \in M$, there exists a neighborhood U of z, which can be written as

$U = U_1 \times U_2$, where U_1 is coordinatized by the value of the invariants and U_2 is coordinatized by some (or all) of the group parameters. A modern theory of moving frames recently developed by Fels and Olver [5, 6] provides us with a systematic way to obtain a set of fundamental invariants for any (regular) Lie group action.

One reason for interest in being able to obtain a set of fundamental invariants in a systematic manner is the following. Many problems involve unknown irrelevant parameters. Often, one needs to solve for these irrelevant parameters only because they are involved in the intermediate steps of the solution process, although they do not appear in the final solution. When the irrelevant parameters can be seen as group parameters transforming the other unknowns of the problem, using the coordinates provided by the invariants is a simple way to eliminate them. In these circumstances, the moving frame method is used as a computational method to eliminate unwanted unknowns in a set of equations.

For example, suppose that given the values of $x_1, x_2, y_1, y_2 \in \mathbb{R}$, one is interested in finding the values of the unknowns z_1 and $z_2 \in \mathbb{R}$. Assume that there exist parameters u and $v \in \mathbb{R}$ for which a set of equations of the type

$$\left.\begin{array}{rcl} z_1 & = & f_1(x_1, x_2, u), \\ z_2 & = & f_2(x_1, x_2, u), \\ z_1 & = & g_1(y_1, y_2, v), \\ z_2 & = & g_2(y_1, y_2, v) \end{array}\right\} \tag{1.1}$$

holds. Since we are not interested in the values of u and v, it would be desirable to eliminate these two variables from (1.1). Suppose that the functions f_1 and f_2 correspond to an action of $\mathbb{R}$ on $\mathbb{R}^2$ parameterized by u,

$$\begin{pmatrix} z_1 \\ z_2 \end{pmatrix} = u * \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}.$$

If this group action satisfies certain conditions (to be explained in section 3), then there exists an invariant $I : \mathbb{R}^2 \to \mathbb{R}$ such that the equation

$$I(x_1, x_2) = I(z_1, z_2)$$

can be used in place of the first two equations of (1.1). Similarly, if g_1 and g_2 correspond to an action of $\mathbb{R}$ on $\mathbb{R}^2$ parameterized by v which satisfies the correct conditions, then we can find another invariant $J : \mathbb{R}^2 \to \mathbb{R}$ such that the equation

$$J(y_1, y_2) = J(z_1, z_2)$$

can be used in place of the last two equations of (1.1). We thus see that the solution (z_1, z_2) of our problem lies at the intersection of two orbits: these are the orbit through (x_1, x_2) under the group action defined by f_1 and f_2 and the orbit through (y_1, y_2) under the group action defined by g_1 and g_2.

The problem of structure from motion is one that involves many irrelevant unknowns. For example, the camera parameters used for taking each picture are irrelevant since we are merely interested in the structure of the object. It turns out that many of the irrelevant unknowns of this problem can be seen as group parameters acting on the other unknowns and eliminated using the moving frame method.

We begin our exposition in section 2 with a summary of the relevant theoretical aspects of the theory of moving frames and its application to the computation of (joint) invariants. In section 3, we consider the problem of structure from motion when the

pictures are taken using a pinpoint camera (perspective projections). We reformulate the problem in terms of a Lie group action and use a fundamental set of invariants of this group action to get rid of most of the irrelevant parameters. (As will be explained, it is impossible to get rid of all of them.) In the case of a fixed-focus camera, the invariants describe the object with nonlinear equations involving the object points and the camera centers; the camera orientation and the depth parameters of the object with respect to the camera are included in the group parameters and thus eliminated from the problem. Eliminating the camera orientation parameters in the case of a simultaneously translating and rotating camera is known to be difficult, unless vanishing points are identified. By contrast, the invariant framework easily takes care of this problem. In addition, the invariant formulation leads to a simple test to identify camera motions that are pure rotations.

The nonlinear equations given by the invariants can be solved with regular bundle adjustment techniques [20] where the nonlinear system of equations is viewed as an optimization problem in the unknown parameters. Efficient optimization techniques like the Levenberg–Marquardt algorithm are available to solve such problems. After presenting a practical example of three-dimensional (3D) object reconstruction using the invariant framework and such an optimization technique, we finish section 3 by showing how to deal with the case of a variable focus in a similar fashion.

Of course, approaches other than this *direct* one exist for structure from motion. For example, one can describe the perspective projection in projective space where it is expressed by simple matrix equations. With projective coordinates, projective relations and constraints such as the epipolar constraint or the trifocal tensor can be used to recover both the underlying shape and camera motion from a set of multilinear equations [9]. In section 4, we apply our invariant-based method to a formulation using projective coordinates. We obtain a set of invariants involving the projective coordinates of the object points and the camera centers, which are, in fact, much simpler than the invariants of the Euclidean approach used in section 3.

Other existing approaches use an affine approximation of the projection in order to simplify the problem. This leads to factorization techniques [19] based on the SVD. In section 5, we apply our method to the case of orthographic projections and obtain a set of linear invariants involving only the object points and the directions of the normals to the camera planes. Our equations can be solved with similar factorization techniques but involve fewer and simpler parameters than the ones in [19].

Our invariant-based approach actually applies to types of cameras other than the ones discussed here. For instance, the model used in section 3 works for any central projection, whether or not the image points lie on a plane. We hope that the sample cases presented here will convince the reader of the usefulness and versatility of this group theoretic approach to eliminating unknowns and inspire new applications of invariants.

2. Definitions and theoretical foundations. Let M be an m-dimensional smooth (Hausdorff) manifold and G be an r-dimensional Lie group. Denote by e the identity in G. Let $* : G \times M \to M$ be an action of G on M, i.e., a map $(g, z) \mapsto g * z$ such that $e * z = z$ for all $z \in M$ and $(gh) * z = g * (h * z)$ for all $z \in M$ and all $g, h \in G$.

DEFINITION 2.1. *An* invariant *is a function $I : M \to \mathbb{R}$ which remains unchanged under the action of the group. In other words,*

$$I(g * z) = I(z) \text{ for all } z \in M \text{ and all } g \in G.$$

A local invariant *is a function $I : U \to \mathbb{R}$ for some open subset $U \subset M$ such that*

$$I(g * z) = I(z) \text{ for all } z \in U \text{ and all } g \in G \text{ s.t. } g * z \in U.$$

DEFINITION 2.2. *We say that G acts* semiregularly *on M if all orbits have the same dimension. If, in addition, any point $p_0 \in M$ is surrounded by an arbitrarily small neighborhood whose intersection with the orbit through p_0 is connected, then we say that G acts* regularly.

The following theorem, due to Frobenius [7], is of central importance to our approach. A proof can be found in [14]. It provides us with a simple way of characterizing the orbits using invariants.

THEOREM 2.3 (Frobenius theorem). *If G acts on an open set $O \subset M$ semiregularly with s-dimensional orbits, then for all $p_0 \in O$ there exist $m - s$ functionally independent local invariants $I_1, \ldots, I_{m-s}$ defined on a neighborhood U of p_0 such that any other local invariant H defined near p_0 is a function $H = f(I_1, \ldots, I_{m-s})$. If G acts regularly on O, then we can choose $I_1, \ldots, I_{m-s}$ to be global invariants on O. In that case, two points $p_1, p_2 \in O$ are in the same orbit relative to G if and only if $I_i(p_1) = I_i(p_2)$ for all $i = 1, \ldots, m - s$.*

By *functional independence* of the (smooth) functions $I_1, \ldots, I_{m-s}$ on an open set O, we simply mean that the Jacobian matrix of $I_1, \ldots, I_{m-s}$ has maximal rank $m - s$ on an open and dense subset of O. The set $\{I_1, \ldots, I_{m-s}\}$ is often called a *complete fundamental set of invariants on O*. Note that a complete fundamental set of invariants is not unique.

As we shall consider actions on multiple points, we are interested in the case where $M = \mathcal{V} \times \mathcal{V} \times \cdots \times \mathcal{V}$ (n-times) $=: \mathcal{V}^{\times(n)}$ is the Cartesian product of n copies of a manifold $\mathcal{V}$.

DEFINITION 2.4. *We say that G acts* diagonally *on $\mathcal{V}^{\times(n)}$ if there exists an action $\cdot$ of G on $\mathcal{V}$ such that for any $g \in G$, any $n \in \mathbb{N}$, and any $z_1, \ldots, z_n \in \mathcal{V}$, the action $g * (z_1, \ldots, z_n)$ can be written as*

$$g * (z_1, \ldots, z_n) = (g \cdot z_1, \ldots, g \cdot z_n).$$

The group actions we will define for our object-camera systems are not diagonal actions. However, for each of these actions there is a normal subgroup H of G (the subgroup generating the translations along the rays of light) such that G/H acts diagonally. So for all practical purposes, we shall ultimately have to deal with diagonal group actions.

In our approach to structure from motion, invariants are used to obtain equations that must be satisfied by the object and the camera. The more invariants we have, the more equations need to be satisfied. We need enough equations to completely determine the object. Observe that the dimension of the orbit is bounded by the dimension of the group. So in the case of a diagonal action, taking more and more copies of $\mathcal{V}$ (i.e., more and more points) allows for the existence of as many invariants as necessary. The question that remains is as follows: How can we obtain an expression for these invariants? Thanks to a new formulation of Cartan's theory of moving frames [4, 5, 6], this problem can be solved in an algorithmic fashion. We now summarize some of the relevant aspects of the theory of moving frames, including how moving frames can be used as a tool to obtain a complete set of fundamental invariants.

DEFINITION 2.5. *A* (right) moving frame *is a map $\rho : M \to G$ which is (right) equivariant; i.e., $\rho(g * z) = \rho(z)g^{-1}$ for all $g \in G$ and $z \in M$.*

Unfortunately moving frames do not exist for all group actions.

THEOREM 2.6. *A moving frame exists if and only if the action of the group satisfies*

$$\{g \in G | \exists z \in M, g * z = z\} = \{e\},$$

where e denotes the identity in G. This property is called freeness *of the group action.*

Demanding freeness of the group action is very strong. It appears that, in order to be able to deal with the generic cases, we need to relax this condition a little bit.

DEFINITION 2.7. *A* local moving frame *is a map $\rho : M \to G$ such that $\rho(g * z) = \rho(z)g^{-1}$ for all $g \in N_e$, a neighborhood of the identity $e \in G$, and all $z \in M$.*

THEOREM 2.8. *A local moving frame exists if and only if there exists a neighborhood N_e of the identity in $e \in G$ such that*

$$\{g \in N_e | \exists z \in M, g * z = z\} = \{e\}$$

or, equivalently, if and only if for all $z \in M$, the dimension of the orbit through z is equal to r, the dimension of G. This property is called local freeness *of the group action.*

We are now interested in determining a condition on the action of G on M which guarantees that the diagonal action will be locally free on a sufficiently large number of copies of M.

DEFINITION 2.9. *We say that G acts on M* effectively *if*

$$\{g \in G | \quad g * p = p \text{ for all } p \in M\} = \{e\}.$$

We say that G acts on M locally effectively *if*

$$\{g \in G | \quad g * p = p \text{ for all } p \in M\} \text{ is a discrete subgroup of } G.$$

Many groups do not act effectively. However, given G acting noneffectively on M, we can consider $\tilde{G} = G/G_M$, where $G_M = \{g \in G | g * z = z \text{for all } z \in M\}$, which acts in essentially the same way as G except that it acts effectively. Unfortunately, effectiveness is not sufficient to guarantee that the diagonal action eventually becomes locally free.

DEFINITION 2.10. *We say that G acts* effectively on subsets of *M if, for any open subset $U \subset M$,*

$$\{g \in G | \quad g * p = p \text{ for all } p \in U\} = \{e\}.$$

We say that G acts locally effectively on subsets of *M if, for any open subset $U \subset M$,*

$$\{g \in G | \quad g * p = p \text{ for all } p \in M\} \text{ is a discrete subgroup of } G.$$

Observe that effectiveness on subsets implies effectiveness. The converse, of course, holds for all analytic group actions. However, this is not true in general (see [2] for a counterexample).

THEOREM 2.11 (see [2]). *If a group G acts on a manifold $\mathcal{V}$ locally effectively on subsets, then there exists $n \in N^+$ such that the induced diagonal action of G on $\mathcal{V}^{\times(n)}$ is locally free on an open and dense subset of $\mathcal{V}^{\times(n)}$. This is equivalent to saying that the orbit dimension is equal to the dimension of G on this open and dense subset. We denote by n_0 the minimal integer for which this is true.*

This means that any group action that is effective on subsets (e.g., any analytic group action, once the subgroup acting trivially is moded out) will be locally free on a sufficiently large number of copies of the manifold and a local moving frame will exist on this product.

We now explain how to construct a (local) moving frame and to obtain a complete fundamental set of invariants. A more detailed exposition can be found in [14, Chapter 8]. Let $g = (g_1, \dots, g_r)$ be local coordinates for G in a neighborhood of the identity. Suppose that G acts regularly on M. For simplicity, let us assume in addition that the orbits of G have the same dimension r as G itself. In other words, we are assuming that the action is locally free. Shortly after, we will explain how to deal with the case of merely regular actions using a simple variation of the following algorithm.

- *Step* 1. Write down the group transformation equations $\bar{x} = g * x$ explicitly.

$$\begin{cases} \bar{x}_1 &= f_1(g_1, \dots, g_r, x_1, \dots, x_m), \\ &\vdots \\ \bar{x}_m &= f_m(g_1, \dots, g_r, x_1, \dots, x_m). \end{cases}$$

- *Step* 2. Choose constants $c_1, \dots, c_r \in \mathbb{R}$ and set r of the transformed coordinates equal to those constants. For simplicity, we relabel the coordinates and write

$$\begin{cases} f_1(g_1, \dots, g_r, x_1, \dots, x_m) &= c_1, \\ &\vdots \\ f_r(g_1, \dots, g_r, x_1, \dots, x_m) &= c_r. \end{cases} \tag{2.1}$$

  These equations are called the *normalization equations.*
- *Step* 3. Solve the normalization equations for $g = (g_1, \dots, g_r)$. The solution $g = \rho(x)$ is a moving frame.
- *Step* 4. Compute the action of the moving frame on the remaining coordinates. The set of resulting functions,

$$\begin{cases} \bar{x}_{r+1}\big|_{g=\rho(x)} &= I_1(x_1, \dots, x_m), \\ &\vdots \\ \bar{x}_m\big|_{g=\rho(x)} &= I_{m-s}(x_1, \dots, x_m), \end{cases}$$

  is a complete fundamental set of local invariants.

The choice of constants in Step 2 is somewhat arbitrary; we are free to choose any numbers for which a solution to the normalization equations exists, provided that these constants define a cross-section (i.e., provided that the normalization equations define a submanifold which is transversal to the orbits). To simplify the solution process, it is usually a good idea to choose as many constants as possible to be zero.

If the action is not free but merely regular, we can still find a system of functionally independent local invariants. We proceed as follows. Let s be the dimension of the orbits of G ($s < r$). We solve the s equations $f_1(g, x) = c_1, \dots, f_s(g, x) = c_s$ for s of the group parameters and replace them in the remaining equations $\overline{x}_{s+1} = f_{s+1}(g, x), \dots, \overline{x}_m = f_m(g, x)$ to get the $m-s$ invariants. The other group parameters $g_{s+1}, \dots, g_r$ will not appear in the final expressions. This procedure is called a *partial moving frame normalization method.*

Equipped with these tools, obtaining invariants becomes a simple systematic procedure. We can thus feel free to consider any Lie group action imaginable and try to obtain its invariants. As we have seen, in theory, the invariants can always be found provided that the group action is locally effective on subsets (which we can always arrange in the case of analytic group actions). Of course, in practice, computational difficulties can be encountered in explicitly determining the invariants. Fortunately, the invariants are easily computed for the problem of structure from motion.

3. The case of a perspective camera. Let us assume that we are given t sets of n ordered points $p_1^\tau, \ldots, p_n^\tau \in \mathbb{R}^2$, $\tau = 1, \ldots, t$, which represent t pictures of a 3D unknown object made of n ordered points $\mathcal{O}_1, \mathcal{O}_2, \ldots, \mathcal{O}_n \in \mathbb{R}^3$. We would like to determine the points $\mathcal{O}_1, \mathcal{O}_2, \ldots, \mathcal{O}_n$ from these pictures. One possible way to try to solve this problem would be to define an equivalence relation between all the possible pictures of an object and to find functions depending on the picture points which are constant on each equivalence class. Characteristics of the object could be inferred from these functions, regardless of the camera position relative to the object. To define such an equivalence class, one could try to use the orbits of a group action; in other words, one could look for *invariants* of a group action that is transitive on the set of pictures of any given object, i.e., *view invariants*.

Unfortunately, as is commonly known in the vision community, *view invariants do not exist for* $3D$ *point sets of arbitrary size (in general position).* One can still build invariants for specific objects (for instance, planar sets of points, pencils of lines, etc.) but not for arbitrary shapes. The problem is that the set of pictures of any object intersects with the set of pictures of other objects. Observe that if a view invariant I takes a constant value c for all pictures of an object O, then I is also equal to c on the set of pictures of any object whose set of pictures intersects with the set of pictures of O. One can actually show [3] that any equivalence relation between all the pictures of each object defines a unique equivalence class on the space of pictures, and thus any view invariant is trivial. From a group point of view, this means that any group action that is transitive on the set of pictures of any object must be transitive on the set of *all* pictures.

Another way to try to solve this problem would be to use the reverse approach: try to characterize all the possible objects corresponding to a given picture. It would be useful to find functions which are constant on equivalence classes that include all the objects corresponding to a given picture. However, it is easy to see that such equivalence classes of objects are in one to one correspondence with the equivalence classes of pictures discussed above and thus that only one such equivalence class can exist. There are therefore no *object invariants*. Nevertheless, given a view of an object, one *can* infer information about the object, so there must be a way to overcome this difficulty.

The trick is to define an equivalence relation on a higher dimensional space, lifting the set of objects of different pictures to different *"heights"* in the extra dimensions. For this, we can use the three extra dimensions provided by the camera center position. More precisely, we can construct a Lie group action on the object points and the camera center which summarizes what is unknown about the object-camera system given a picture of an object and knowing the mechanism used by the camera. Invariants of this group action prove to be sufficient for solving the problem of recovering the object coordinates in $\mathbb{R}^3$.

So let us think for a moment about the process of taking a picture. This process involves, first, the placement of a camera in space. Then, particles of light start from

each point of the object and travel on a straight line in the direction of the camera center, leaving their trace on a film, i.e., on the intersection of the picture plane and the travel lines. So, to the picture-camera system placed somewhere in $\mathbb{R}^3$, there corresponds a set of n straight lines in $\mathbb{R}^3$ representing the paths of light going from the object to the camera center (sometimes referred to as a "ray bundle").

This process can be seen as a result of the action of a group composed of an action of the special Euclidean group $SE(3)$ (i.e., the group of rotations and translations in $\mathbb{R}^3$) and an action of $\mathbb{R}^n$ on the camera center and the image points (in three dimensions). Here is how.

Given is a two-dimensional (2D) image depicting n points $p_1, \dots, p_n \in \mathbb{R}^2$. We assume this picture was taken by a camera with fixed internal parameters. These parameters can be calibrated beforehand so that the focal length is $\mathcal{F} = 1$[1] and the 2D image coordinates match the 3D coordinates as defined below. We embed the picture-camera system in $\mathbb{R}^3$ by setting the camera center to be $\tilde{p}_0 = (0, 0, 0)$ and the picture points $\tilde{p}_i$'s to be $\tilde{p}_i = p_i \times \mathcal{F}$. This is, in general, not the actual position in which the picture was taken. However, there exists a rigid transformation $g \in SE(3)$ acting diagonally on $(\mathbb{R}^3)^{\times n}$ such that $g * (\tilde{p}_0, \tilde{p}_1, \dots, \tilde{p}_n) = (\mathfrak{P}_0, \mathfrak{P}_1, \dots, \mathfrak{P}_n)$ corresponds to the actual position of the picture-camera system at the moment where the picture was taken. Once the picture points are in this position, we know that we can move each of them independently along each ray of light so as to go back to its source on the object. This way, the picture can be mapped onto the object.

In summary, the mapping is given by the transformation

$$\bar{P}_0 = RP_0 + T, \tag{3.1}$$

$$\bar{P}_i = R(P_i + \lambda_i(P_i - P_0)) + T \text{ for } i = 1, \dots, n, \tag{3.2}$$

with $R \in SO(3)$ a rotation, $T \in \mathbb{R}^3$ a translation, and $\lambda_i \in \mathbb{R}$ a factor of depth, applied to $P_0 = \tilde{p}_0$ and $P_i = \tilde{p}_i$ for $i = 1, \dots, n$. As one can check, this mapping is actually a group action: we have an action of $\mathbb{R}^n$ (parameterized by the λ's) commuting with an action of $SE(3)$ (parameterized by rotations R and translations T). Therefore, this defines an action of the $(6 + n)$-dimensional Lie group $SE(3) \times \mathbb{R}^n$ on the $(3n + 3)$-dimensional manifold $(\mathbb{R}^3)^{\times(n+1)}$.

We would like to determine where $\mathfrak{P}_0$ and the $\mathcal{O}_i$'s lie. Given a picture, it is of course impossible to determine the camera center and object points $(\mathfrak{P}_0, \mathcal{O}_1, \dots, \mathcal{O}_n)$. However, we know to which orbit under the action of $SE(3) \times \mathbb{R}^n$ they belong, since they belong to the same orbit as the (embedding of the) picture-camera system!

Assuming that the picture points are distinct, then the group action is regular and the orbits are six-dimensional for $n = 1$ and $(6+n)$-dimensional as soon as $n \geq 2$. Therefore, by Theorem 2.3, there are $2n - 3$ fundamental invariants whenever $n \geq 2$ and these invariants can be used to characterize the orbits. We follow the steps of the moving frame normalization method to obtain them. We set

$$\begin{aligned} \bar{P}_0 &= (0, 0, 0)^T, \\ (0, 1, 0)\bar{P}_1 &= 0, \\ (0, 0, 1)\bar{P}_1 &= 0, \\ (0, 0, 1)\bar{P}_2 &= 0, \\ \text{and } (1, 0, 0) \cdot \bar{P}_i &= 1 \text{ for all } i = 1, \dots, n. \end{aligned}$$

[1]The value is arbitrary. It simply fixes the overall scale of the 3D reconstruction.

Solving for the group parameters, we obtain

$$
\begin{aligned}
T &= -RP_0, \\
R &= R_1 R_2 R_3, \\
R_1 &= \begin{pmatrix} 1 & 0 & 0 \\ 0 & \frac{f}{\sqrt{f^2+g^2}} & \frac{g}{\sqrt{f^2+g^2}} \\ 0 & -\frac{g}{\sqrt{f^2+g^2}} & \frac{f}{\sqrt{f^2+g^2}} \end{pmatrix}, \\
R_2 &= \begin{pmatrix} \frac{\sqrt{x_1^2+y_1^2}}{\sqrt{x_1^2+y_1^2+z_1^2}} & 0 & \frac{z_1}{\sqrt{x_1^2+y_1^2+z_1^2}} \\ 0 & 1 & 0 \\ \frac{-z_1}{\sqrt{x_1^2+y_1^2+z_1^2}} & 0 & \frac{\sqrt{x_1^2+y_1^2}}{\sqrt{x_1^2+y_1^2+z_1^2}} \end{pmatrix}, \\
R_3 &= \begin{pmatrix} \frac{x_1}{\sqrt{x_1^2+y_1^2}} & \frac{y_1}{\sqrt{x_1^2+y_1^2}} & 0 \\ -\frac{y_1}{\sqrt{x_1^2+y_1^2}} & \frac{x_1}{\sqrt{x_1^2+y_1^2}} & 0 \\ 0 & 0 & 1 \end{pmatrix}, \\
\lambda_i &= \frac{1}{(R(P_i-P_0))_x} - 1,
\end{aligned}
\tag{3.3}
$$

where $f = \frac{-y_1x_2+x_1y_2}{\sqrt{x_1^2+y_1^2}}$, $g = \frac{z_2(x_1^2+y_1^2)-z_1(x_1x_2+y_1y_2)}{\sqrt{x_1^2+y_1^2}\sqrt{x_1^2+y_1^2+z_1^2}}$, $(x_1, y_1, z_1)^T = P_1 - P_0$, and $(x_2, y_2, z_2)^T = P_2 - P_0$. These group parameters define a moving frame MF. Substituting the moving frame into the transformation equations, we get

$$
\begin{aligned}
\bar{P}_0\big|_{MF} &= (0,0,0)^T, \\
\bar{P}_1\big|_{MF} &= (1,0,0)^T, \\
\bar{P}_2\big|_{MF} &= \begin{pmatrix} 1 \\ \frac{f\sqrt{x_1^2+y_1^2+z_1^2}(x_1y_2-x_2y_1)+g[z_2(x_1^2+y_1^2)-z_1(x_1x_2+y_1y_2)]}{(x_1x_2+y_1y_2+z_1z_2)\sqrt{x_1^2+y_1^2}\sqrt{f^2+g^2}} \\ 0 \end{pmatrix}, \\
\bar{P}_i\big|_{MF} &= \begin{pmatrix} 1 \\ \frac{f\sqrt{x_1^2+y_1^2+z_1^2}(x_1y_i-x_iy_1)+g[z_i(x_1^2+y_1^2)-z_1(x_1x_i+y_1y_i)]}{(x_1x_i+y_1y_i+z_1z_i)\sqrt{x_1^2+y_1^2}\sqrt{f^2+g^2}} \\ \frac{g\sqrt{x_1^2+y_1^2+z_1^2}(x_iy_1-x_1y_i)+f[z_i(x_1^2+y_1^2)-z_1(x_1x_i+y_1y_i)]}{(x_1x_i+y_1y_i+z_1z_i)\sqrt{x_1^2+y_1^2}\sqrt{f^2+g^2}} \end{pmatrix}
\end{aligned}
$$

for all $i = 3, \ldots, n$, where $(x_i, y_i, z_i) = P_i - P_0$. Each component of these vectors is an invariant of the group action.

These expressions have an easy geometric interpretation. Since $\sqrt{f^2+g^2} =$

$\frac{\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|}{\sqrt{x_1^2+y_1^2+z_1^2}}$, we can rewrite the above system as

$$\begin{aligned}
\bar{P}_0\big|_{MF} &= (0,0,0)^T,\\
\bar{P}_1\big|_{MF} &= (1,0,0)^T,\\
\bar{P}_2\big|_{MF} &= \begin{pmatrix} 1 \\ \frac{\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|}{(x_1,y_1,z_1)\cdot(x_2,y_2,z_2)} \\ 0 \end{pmatrix},\\
\bar{P}_i\big|_{MF} &= \begin{pmatrix} 1 \\ \frac{[(x_1,y_1,z_1)\times(x_i,y_i,z_i)]\cdot[(x_1,y_1,z_1)\times(x_2,y_2,z_2)]}{[(x_1,y_1,z_1)\cdot(x_i,y_i,z_i)]\,\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|} \\ \frac{(x_i,y_i,z_i)\cdot[(x_2,y_2,z_2)\times(x_1,y_1,z_1)]\|(x_1,y_1,z_1)\|}{[(x_1,y_1,z_1)\cdot(x_i,y_i,z_i)]\,\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|} \end{pmatrix},
\end{aligned}$$

where $\cdot$ represents the scalar product between two vectors.

We now see that the components of $\bar{P}_2\big|_{MF}$ and $\bar{P}_i\big|_{MF}$ are sine or cosine of angles between the directions spanned by $\overline{P_1P_0}$, $\overline{P_2P_0}$, $\overline{P_iP_0}$ and the directions orthogonal to them. These are clearly invariant by translation, rotation, and motion along the projection lines. As a fundamental set, we simply pick the only $2n-3$ nonconstant invariants:

$$\begin{aligned}
I_2 &= \frac{\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|}{(x_1,y_1,z_1)\cdot(x_2,y_2,z_2)},\\
I_i &= \frac{[(x_1,y_1,z_1)\times(x_i,y_i,z_i)]\cdot[(x_1,y_1,z_1)\times(x_2,y_2,z_2)]}{[(x_1,y_1,z_1)\cdot(x_i,y_i,z_i)]\,\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|},\\
J_i &= \frac{(x_i,y_i,z_i)\cdot[(x_2,y_2,z_2)\times(x_1,y_1,z_1)]\|(x_1,y_1,z_1)\|}{[(x_1,y_1,z_1)\cdot(x_i,y_i,z_i)]\,\|(x_1,y_1,z_1)\times(x_2,y_2,z_2)\|}
\end{aligned}$$

for $i=3,\dots,n$.

Each picture taken defines a point in $\mathbb{R}^3\times(\mathbb{R}^3)^{\times(n)}$ and therefore determines an orbit of our group action. Each orbit is characterized by the set of $2n-3$ equations given by the invariants. More precisely, indexing the pictures with the discrete parameter $\tau=1,\dots,t$, we have

$$\begin{aligned}
I_i(P_0^\tau,P_1,\dots,P_n) &= \alpha_i^\tau \text{ for } i=2,\dots,n,\\
J_j(P_0^\tau,P_1,\dots,P_n) &= \beta_j^\tau \text{ for } j=3,\dots,n
\end{aligned}$$

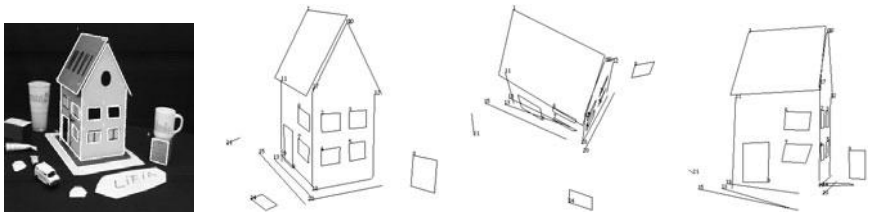
for appropriate constants α_i^τ's and β_j^τ's. These constants are prescribed by the pictures: since the picture-camera system itself belongs to the orbits, we have

$$\begin{aligned}
\alpha_i^\tau &= I_i(\tilde{p}_0^\tau,\tilde{p}_1^\tau,\dots,\tilde{p}_n^\tau),\\
\beta_j^\tau &= J_j(\tilde{p}_0^\tau,\tilde{p}_1^\tau,\dots,\tilde{p}_n^\tau).
\end{aligned}$$

We are interested in solving the equations

$$\begin{aligned}
I_i(\mathfrak{P}_0^\tau,\mathcal{O}_1,\dots,\mathcal{O}_n) &= \alpha_i^\tau \text{ for } i=2,\dots,n,\\
J_j^\tau(\mathfrak{P}_0^\tau,\mathcal{O}_1,\dots,\mathcal{O}_n) &= \beta_j^\tau \text{ for } j=3,\dots,n
\end{aligned}$$

for $\tau=1,\dots,t$. We have a system of $(2n-3)t$ (nonlinear) equations with $3n+3t$ unknowns, the solution of which is determined up to a rotation and translation of the 3D camera-object system as a whole, which we can fix arbitrarily, thus eliminating



a b c d

FIG. 3.1. *A reconstruction example:* (a) *The first of six images, with line and rectangle features drawn;* (b) *a similar view of the* 3*D reconstructed features;* (c) *a top view;* (d) *a side view of the reconstruction.*

six variables.[2] For $n > 3$ and $t \geq \frac{3n-6}{2n-6}$, the number of equations is greater than the number of unknowns, so we can try to solve them.

Experiments with real video images have been performed (see Figure 3.1) using a sequential nonlinear optimization technique based on the Levenberg–Marquardt algorithm [15]. The points used as picture points $(\tilde{p}_0^\tau, \tilde{p}_1^\tau, \ldots, \tilde{p}_n^\tau)$ are the endpoints of lines and rectangles drawn on Figure 3.1(a). These points have been obtained in successive images with a simple tracking procedure [1]. We computed the values of all the invariants $(\alpha_i^\tau, \beta_j^\tau)$ using these points and solved the $(2n-3)t$ nonlinear equations for the unknowns $(\mathfrak{P}_0^\tau, \mathcal{O}_1, \ldots, \mathcal{O}_n)$. The solution gave us the reconstructed 3D object, namely, the set of lines and rectangles defined by $(\mathcal{O}_1, \ldots, \mathcal{O}_n)$. Although the bottom and left elements are not perfectly replaced due to noise in the input picture points, the reconstructed object is visually correct in any view. In particular, there is no global distortion, as one would fear in the case of projective reconstructions. The computations take only a few minutes.

Observe that our camera-system does not take into account the angle of the camera; the orientation of the image plane was only included in the group parameters (not on the space acted on) and thus factored out of the problem in the invariant formulation. Besides the advantage of not having to solve for this unwanted unknown, we also obtain the following lemma.

LEMMA 3.1. *The motion of the camera between two pictures is a pure rotation (i.e., a rotation around the center of projection* P_0*) if and only if the values of the invariants* $\{I_i, J_j | i = 2, \ldots, n,\ j = 3, \ldots, n\}$ *evaluated on any corresponding points in the two views are equal.*

Proof. Invariance of our invariants under pure rotations is obvious from the construction of the invariants.

To prove that equality of our invariants evaluated on all corresponding points guarantees that the camera motion is a pure rotation, observe that the first invariant I_2 is the tangent of the angle between the lines $\overline{\mathfrak{P}_0\mathcal{O}_1}$ and $\overline{\mathfrak{P}_0\mathcal{O}_2}$. Its value remains constant for fixed $\mathcal{O}_1, \mathcal{O}_2$ only if $\mathfrak{P}_0$ moves along a circle around the $\overline{\mathcal{O}_1\mathcal{O}_2}$ axis. This holds for all possible choices of $\mathcal{O}_1$ and $\mathcal{O}_2$, so the camera center must lie somewhere on the intersection of a set of circles, which can be taken to intersect at merely one point to guarantee that the camera center does not move. □

Tomasi and Kanade [19] identify two problems related to using the traditional *direct* approach to structure from motion in a noisy context. First there is the fact

[2]However, we should keep in mind that the choice of these variables will affect the numerical resolution [10].

that, when the camera motion is small, the effects of a camera rotation and translation are hard to distinguish. Second, obtaining the shape by comparing depths is sensitive to noise, since the depth can be considerably larger than the dimensions of the shape. Note that both these difficulties are bypassed by our approach, since the depths and the rotation of the camera do not appear in our equations. We also provide a new formulation in Euclidean space that involves quantities independent of any choice of world coordinate system, removing the so-called *gauge problem*.

Unfortunately, the nonlinearity of the invariants is a serious drawback. As one can tell from the orbit structure of this group action, this is inherent to the problem as formulated. One might want to ask whether there exist coordinates which lead to simpler expressions for the invariants. For example, we could use an inductive moving frame construction [11] in order to obtain invariants of one subgroup of $SE(3) \times \mathbb{R}^n$, say, either $SE(3)$ or $\mathbb{R}^n$, and use these invariants as new coordinates on which the remaining group coordinates are acting. The resulting invariants are actually much simpler in these coordinates. However, it turns out that *each* of these new coordinates would involve the camera center. One would thus need to define a new set of coordinates for *each* picture so there would always be more unknown coordinates than equations. These invariants are thus not useful for recovering the structure from a set of pictures, although they could be good tools for analyzing the motion of an object taken by a fixed or even rotating camera.

Another way of obtaining simpler equations is to work in projective coordinates. However, as a trade-off, projective coordinates require using more variables. We will discuss this other method in the next section, but first we generalize the Euclidean coordinate approach to the case of a variable focal length.

3.1. Letting the focal distance vary. It is a bit more complicated to set up the group transformation equations in the case where the focal length is allowed to vary from one image to the next. One way to do this is the following. Consider P_M, the closest point to P_0 on the image plane, i.e., the embedding of the middle point of the picture. Changing the focal distance corresponds to transforming P_M into a point P'_M with a real parameter α according to the rule

$$P'_M = P_M + \alpha(P_M - P_0).$$

The induced action on the P_i's can be taken as a rotation about the center of camera P_0 which preserves the distance to the camera center. More precisely, each P_i is moved to a new point P'_i in such a way that $\|P'_i - P_0\| = \|P_i - P_0\|$ and that its transformed picture point is $\tilde{p}'_i = \tilde{p}_i + \alpha(P_M - P_0)$. Since the picture point is given by $p_i = P_0 + \frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)}$, we find that

$$P'_i = P_0 + \|P_i - P_0\| \quad \frac{\frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)} + \alpha(P_M - P_0)}{\left\| \frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)} + \alpha(P_M - P_0) \right\|}.$$

Combining translations of the P_i's along the line P_iP_0 together with rotations and translations of the line arrangement as a whole, we get the following $(n+7)$-dimen-

sional Lie group action:

$$\begin{aligned}
\bar{P}_0 &= RP_0 + T,\\
\bar{P}_M &= R\left(P_M + \alpha(P_0 - P_M)\right) + T,\\
\bar{P}_i &= R\left(P_0 + (1+\lambda_i)\|P_i - P_0\| \frac{\frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)} + \alpha(P_M - P_0)}{\left\|\frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)} + \alpha(P_M - P_0)\right\|}\right) + T.
\end{aligned}$$

Observe that the change of focal length parameterized by α commutes with the action of each λ_i on P_i because it preserves the norm $\|P_i - P_0\|$.

We apply the previous moving frame normalization technique by setting

$$\begin{aligned}
\bar{P}_0 &= (0,0,0)^T,\\
\bar{P}_M &= (1,0,0)^T,\\
\bar{P}_1 \cdot (0,0,1) &= 0,\\
\text{and } \bar{P}_i \cdot (1,0,0) &= 1 \text{ for all } i = 1,\dots,n.
\end{aligned}$$

The corresponding group parameters are similar to (3.3) for R and T, except that $(x_1, y_1, z_1)^T$ and $(x_2, y_2, z_2)^T$ must be replaced by $(u_1, v_1, w_1)^T = P_M - P_0$ and $(u_2, v_2, w_2)^T = P_1 - P_0$. The other parameters are

$$\alpha = \frac{1}{\|P_M - P_0\|} - 1,$$

$$\lambda_i = \frac{\left\|\frac{P_i - P_0}{(P_i - P_0)\cdot(P_M - P_0)} + \alpha(P_M - P_0)\right\|}{\|P_i - P_0\|\|P_M - P_0\| + \frac{\|P_i - P_0\|}{\|P_M - P_0\|}} - 1 \text{ for all } i = 1,\dots,n.$$

Substituting these group parameters into the equations for the $\bar{P}_i$'s, we obtain the following complete fundamental set of invariants:

$$I_1 = \frac{\|(P_M - P_0)\times(P_1 - P_0)\|}{(P_1 - P_0)\cdot(P_M - P_0)\left(1 + \|P_M - P_0\| - \|P_M - P_0\|^2\right)},$$

$$I_i = \frac{(P_M - P_0)\times(P_i - P_0)\cdot(P_M - P_0)\times(P_1 - P_0)}{\|(P_M - P_0)\times(P_1 - P_0)\|(P_i - P_0)\cdot(P_M - P_0)\left(1 + \|P_M - P_0\| - \|P_M - P_0\|^2\right)},$$

$$J_i = \frac{(P_i - P_0)\cdot\left[(P_1 - P_0)\times(P_M - P_0)\right]\|P_M - P_0\|}{\|(P_M - P_0)\times(P_1 - P_0)\|(P_i - P_0)\cdot(P_M - P_0)\left(1 + \|P_M - P_0\| - \|P_M - P_0\|^2\right)}$$

for $i = 2,\dots,n$.

Observe that solving for P_M and P_0 implies solving for the focal length. Therefore, the focal length has not been removed in this formulation. Having to solve for the focal length is undesirable since it can induce numerical instabilities. We can actually completely include the focal length in the group parameters by letting $v = \frac{P_M - P_0}{\|P_M - P_0\|}$ and $\gamma = \alpha\|P_M - P_0\|^2$. Then γ can be seen as a new group parameter $\gamma \in \mathbb{R}_{\neq -1}$ in the group action given by

$$\begin{aligned}
\bar{P}_0 &= RP_0 + T,\\
\bar{v} &= Rv,\\
\bar{P}_i &= R\left(P_0 + (1+\lambda_i)\|P_i - P_0\| \frac{P_i - P_0 + \left(\gamma(P_i - P_0)\cdot v\right)v}{\|P_i - P_0 + \left(\gamma(P_i - P_0)\cdot v\right)v\|}\right) + T.
\end{aligned}$$

One can check that the group action parameterized by γ is compatible with the group structure of $\mathbb{R}_{\neq -1}$ with group multiplication $\circ$ given by

$$\gamma_1 \circ \gamma_2 = \gamma_1 + \gamma_2 + \gamma_1\gamma_2 \text{ for all } \gamma_1, \gamma_2 \in \mathbb{R}_{\neq -1}.$$

We have an action of the $(7+n)$-dimensional Lie group $SE(3) \times \mathbb{R}_{\neq -1} \times \mathbb{R}^n$ on a $(3n+5)$-dimensional space; there are $2n-2$ fundamental invariants. To obtain these invariants, we start by setting $\bar{P}_0 = (0,0,0)^T$ and solve for T. We then set $\bar{v} = (1,0,0)^T$ and the third component of $\bar{P}_1$ to zero and solve for the rotation matrix R. We skip the details of these computations since they are very similar to the previous cases. Substituting these group parameters into the other transformation equations, we obtain

$$\bar{P}_i = (1+\lambda_i)\|P_i - P_0\| \begin{pmatrix} F_i \cdot v \\ \frac{(v \times F_i)\cdot(v \times F_1)}{\|v \times F_1\|} \\ \frac{F_i \cdot (v \times F_1)}{\|v \times F_1\|} \end{pmatrix} \text{ for } i = 2, \ldots, n,$$

$$\bar{P}_1 = (1+\lambda_1)\|P_1 - P_0\| \begin{pmatrix} F_1 \cdot v \\ \|v \times F_1\| \\ 0 \end{pmatrix},$$

where F_i represents the fraction

$$F_i = \frac{P_i - P_0 + (\gamma(P_i - P_0)\cdot v)v}{\|P_i - P_0 + (\gamma(P_i - P_0)\cdot v)v\|} \text{ for } i = 1, \ldots, n.$$

We then set the first component of each $\bar{P}_i$ to one for $i = 1, \ldots, n$ and solve for the λ_i's. (For this, we need to assume that $(P_i - P_0)\cdot v \neq 0$.) Substituting these λ_i's into the transformation equations, we get

$$\bar{P}_i = \begin{pmatrix} 1 \\ \frac{(v \times F_i)\cdot(v \times F_1)}{\|v \times F_1\| F_i \cdot v} \\ \frac{F_i \cdot (v \times F_1)}{\|v \times F_1\| F_i \cdot v} \end{pmatrix} = \begin{pmatrix} 1 \\ \frac{(v \times (P_i - P_0))\cdot(v \times (P_1 - P_0))}{\|v \times (P_1 - P_0)\|(1+\gamma)(P_i - P_0)\cdot v} \\ \frac{(P_i - P_0)\cdot(v \times (P_1 - P_0))}{\|(v \times (P_1 - P_0))\|(1+\gamma)(P_i - P_0)\cdot v} \end{pmatrix} \text{ for } i = 2, \ldots, n,$$

$$\bar{P}_1 = \begin{pmatrix} 1 \\ \frac{\|v \times F_1\|}{F_1 \cdot v} \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ \frac{\|v \times (P_1 - P_0)\|}{(1+\gamma)(P_1 - P_0)\cdot v} \\ 0 \end{pmatrix}.$$

Provided that $P_1 - P_0$ is not parallel to v, we can finish obtaining the moving frame by setting the second component of $\bar{P}_1$ to one and solving for γ. Substituting this γ into the two nonconstant components of each P_i, we obtain the following two invariants:

$$I_i = \frac{v \cdot (P_1 - P_0)(v \times (P_i - P_0)) \cdot (v \times (P_1 - P_0))}{v \cdot (P_i - P_0)\|v \times (P_1 - P_0)\|^2},$$

$$J_i = \frac{v \cdot (P_1 - P_0)(P_i - P_0) \cdot (v \times (P_1 - P_0))}{v \cdot (P_i - P_0)\|v \times (P_1 - P_0)\|^2}$$

for $i = 2, \ldots, n$. In a similar way as for the case of a fixed focal length, when the number of pictures t and the number of object points n are large enough, these invariants provide a number of equations which are, in most cases, sufficient to solve for $P_1, \ldots, P_n$ and P_0^τ, v^τ for $\tau = 1, \ldots, t$.

4. Using projective coordinates. The projective space $\mathbb{P}^3$ is the set $\{(x,y,z,w) \in \mathbb{R}^4 \setminus \{(0,0,0,0)\}\}$ modulo multiplication by a scalar multiple in $\mathbb{R}\setminus\{0\}$. If $(x,y,z,w) \in \{\mathbb{R}^4 \setminus \{(0,0,0,0)\}\}$, then the coset of (x,y,z,w) in $\mathbb{P}^3$ is denoted by $(x : y : z : w)$. Consider the chart U of $\mathbb{P}^3$ defined by $\{(x : y : z : w) \in \mathbb{P}^3 | w \neq 0\}$. The map $\phi : U \to \mathbb{R}^3$ defined by

$$\phi(x : y : z : w) = \left(\frac{x}{w}, \frac{y}{w}, \frac{z}{w}\right)$$

provides coordinates for the chart U. In other words, Euclidean coordinates of $\mathbb{R}^3$ are local coordinates for a piece of $\mathbb{P}^3$. One way to obtain simpler invariants is to work directly in $\mathbb{R}^4\setminus\{(0,0,0,0)\}$ (i.e., in projective coordinates) by choosing representatives (x_0,y_0,z_0,w_0) and (x_i,y_i,z_i,w_i) in $\{(x,y,z,w) \in \mathbb{R}^4 | w \neq 0\}$ for the camera center and the object points, respectively.

Consider the following action of $SE(3) \times \mathbb{R}^n$ on $n+1$ copies of $\mathbb{R}^4$:

$$\begin{pmatrix} \bar{x}_0 \\ \bar{y}_0 \\ \bar{z}_0 \\ \bar{w}_0 \end{pmatrix} = \begin{pmatrix} & R & & T \\ 0 & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} \bar{x}_0 \\ \bar{y}_0 \\ \bar{z}_0 \\ \bar{w}_0 \end{pmatrix},$$

$$\begin{pmatrix} \bar{x}_i \\ \bar{y}_i \\ \bar{z}_i \\ \bar{w}_i \end{pmatrix} = \begin{pmatrix} & R & & T \\ 0 & 0 & 0 & 1 \end{pmatrix} \left[\begin{pmatrix} x_i \\ y_i \\ z_i \\ w_i \end{pmatrix} + \lambda_i \left(\begin{pmatrix} x_i \\ y_i \\ z_i \\ w_i \end{pmatrix} - \begin{pmatrix} x_0 \\ y_0 \\ z_0 \\ w_0 \end{pmatrix} \right) \right]$$
$$\text{for } i = 1, \ldots, n,$$

where $R \in SO(3)$ is a 3×3 rotation matrix, $T \in \mathbb{R}^3$ represents a translation, and the $\lambda_i \in \mathbb{R}$ are the depth parameters. Since lines through the origin are mapped to lines through the origin, this induces an action on $\mathbb{P}^3$. In local coordinates ϕ for the chart U, this corresponds exactly to the action defined by (3.1) and (3.2). Assuming that the object points are pairwise distinct (and, of course, also distinct from the camera center), then, as soon as the number of object points $n \geq 2$, the orbits are $(6+n)$-dimensional both on $(\mathbb{R}^4)^{\times(n+1)}$ and on $(\mathbb{P}^3)^{\times(n+1)}$. There are therefore $3n-2$ fundamental invariants in projective coordinates.

To obtain a fundamental set of invariants, we start by setting $\omega_i = 1$ for all i's, and $\bar{P}_0 = (0,0,0)^T$. Provided that all $w_i \neq w_0$, the corresponding group parameters are $\lambda_i = \frac{1-w_i}{w_i-w_0}$ and $T = -\frac{1}{w_0}R$. For simplicity, we let $\beta_i = \frac{1-w_i}{w_i-w_0}$. We then set the second and third components of $\bar{P}_1$ to zero and the third component of $\bar{P}_2$ to zero and solve for the rotation matrix R to finish obtaining the moving frame. Substituting the moving frame into the transformation equations, we obtain

$$\begin{aligned}
(\bar{x}_0, \bar{y}_0, \bar{z}_0, \bar{w}_0)|_{MF} &= (0,0,0,w_0), \\
(\bar{x}_1, \bar{y}_1, \bar{z}_1, \bar{w}_1)|_{MF} &= (\|Q_1\|, 0, 0, 1), \\
(\bar{x}_2, \bar{y}_2, \bar{z}_2, \bar{w}_2)|_{MF} &= \left(\frac{Q_2 \cdot Q_1}{\|Q_1\|}, \frac{\|Q_2 \times Q_1\|}{\|Q_1\|}, 0, 1\right), \\
(\bar{x}_i, \bar{y}_i, \bar{z}_i, \bar{w}_i)|_{MF} &= \begin{pmatrix} \frac{Q_i \cdot Q_1}{\|Q_1\|} \\ \frac{(Q_1 \times Q_i) \cdot (Q_1 \times Q_2)}{\|Q_1\| \|Q_1 \times Q_2\|} \\ \frac{Q_i \cdot (Q_1 \times Q_2)}{\|Q_1 \times Q_2\|} \\ 1 \end{pmatrix}^T \\
&\text{for } i = 3, \ldots, n,
\end{aligned}$$

where $\cdot$ represents the scalar product between two vectors and $Q_i = (1+\beta_i)P_i - (\beta_i + \frac{1}{w_0})P_0$. As a complete set of fundamental invariants, we can take, in addition to the coordinate w_0, the functions

$$H_i = Q_i \cdot Q_1 \text{ for } i = 1, \dots, n,$$
$$I_i = (Q_1 \times Q_i) \cdot (Q_1 \cdot Q_2) \text{ for } i = 2, \dots, n,$$
$$J_i = Q_i \cdot (Q_1 \times Q_2) \text{ for } i = 3, \dots, n.$$

The invariants are thus functions of the object points P_i's, the β_i's, and the camera center projective coordinates P_0 and w_0. For every picture, the parameter w_0 can be fixed arbitrarily to any value other than zero. Given t pictures, the unknowns are thus the P_i's, β_i^τ's, and P_0^τ for $i = 1, \dots, n$ and $\tau = 1, \dots, n$, while the invariants provide $t(3n-3)$ equations. With enough points and enough pictures, we obtain more equations than unknowns.

5. The case of an orthographic camera. The orthographic camera is an approximation of the perspective camera. In this model, we assume that the camera center lies at infinity, and so the rays of light are parallel to each other.

Let $v = (v_x, v_y, v_z)^T$ be the unit direction vector of the rays of light and let $P_1, \dots, P_n$ represent the object points in $\mathbb{R}^3$. Any picture of the object provides some information about the structure of the object. What remains unknown is the orientation and the position of the camera at the moment when the picture was taken, as well as the distance from the camera plane to each object point. The following action of $SE(3) \times \mathbb{R}^n$ on $\{(v, P_1, \dots, P_n) \in (\mathbb{R}^3)^{\times(n+1)}$ such that $|v| = 1\}$ summarizes what is unknown about the object given a picture:

$$\bar{v} = Rv,$$
$$\bar{P}_i = R(P_i + \lambda_i v) + T \text{ for } i = 1, \dots, n,$$

where $R \in SO(3)$ is a rotation matrix, $T \in \mathbb{R}^3$ represents a translation, and the real numbers $\lambda_1, \dots, \lambda_n$ are the depth parameters. More precisely, given a picture $p_1, \dots, p_n$, the orbit passing through

$$P_i = (p_i, 0) \text{ for } i = 1, \dots, n,$$
$$v = (0, 0, 1)$$

(i.e., the embedding of the picture in $\mathbb{R}^3$) under this group action corresponds to all possible 3D objects that could have been used to take this picture.

To obtain the invariants of this group action, we set $\bar{P}_1 = (0, 0, 0)^T$, the first component of each $\bar{P}_i$ to zero, the second and third components of $\bar{P}_1$ to zero, and the third component of $\bar{P}_1$ to zero. We use the partial moving frame normalization method and, in order to obtain a moving frame, solve for all parameters except λ_1, which does not appear in the final expressions. Substituting this moving frame in the

group transformation equations, we obtain

$$\begin{aligned}
\bar{v}\big|_{MF} &= (1,0,0)^T,\\
\bar{P}_1\big|_{MF} &= (0,0,0)^T,\\
\bar{P}_2\big|_{MF} &= \begin{pmatrix} 1 \\ \|(P_2-P_1)-[(P_2-P_1)\cdot v]v\| \\ 0 \end{pmatrix},\\
\bar{P}_i\big|_{MF} &= \begin{pmatrix} 1 \\ (P_i-P_1)\cdot \frac{(P_2-P_1)-[(P_2-P_1)\cdot v]v}{\|(P_2-P_1)-[(P_2-P_1)\cdot v]v\|} \\ (P_i-P_1)\cdot\left(v\times \frac{(P_2-P_1)-[(P_2-P_1)\cdot v]v}{\|(P_2-P_1)-[(P_2-P_1)\cdot v]v\|}\right) \end{pmatrix} \text{ for } i=1,\dots,n.
\end{aligned}$$

A fundamental set of invariants is given by the nonconstant components of these vectors. Observe that some of these expressions are fractions. However, their denominator is actually one of the invariants of the fundamental set. We can thus simply get rid of the denominator and take the following functions as our fundamental set of invariants:

$$\begin{aligned}
I_2 &= \|(P_2-P_1)-[(P_2-P_1)\cdot v]v\|,\\
I_i &= (P_i-P_1)\cdot[(P_2-P_1)-[(P_2-P_1)\cdot v]v] \text{ for } i=3,\dots,n,\\
J_i &= (P_i-P_1)\cdot[v\times(P_2-P_1)] \text{ for } i=3,\dots,n.
\end{aligned}$$

Given pictures $p_1^\tau,\dots,p_n^\tau\in\mathbb{R}^2$, we let v^τ for $\tau=1,\dots,n$ be the direction vectors of the rays of light of the camera. The object points $P_1,\dots,P_n$ and direction vectors v^τ thus satisfy the matrix equation

$$\begin{pmatrix} (P_2-P_1)-[(P_2-P_1)\cdot v^\tau]v^\tau \\ v^\tau\times(P_2-P_1) \end{pmatrix}\begin{pmatrix} P_2-P_1, & P_3-P_1, & \dots, & P_n-P_1 \end{pmatrix} = \begin{pmatrix} \alpha_2^\tau, & \alpha_3^\tau, & \dots, & \alpha_n^\tau \\ \beta_2^\tau, & \beta_3^\tau, & \dots, & \beta_n^\tau \end{pmatrix},$$

where the α's and β's are constants prescribed by the pictures. For solving these equations, we can make a change of variable and let the two entries of the leftmost matrix be two unknown parameters m_1^τ and m_2^τ subject to the condition $|m_1^\tau|+|m_2^\tau|\le|P_2-P_1|$. We obtain a factorization equation, like the one introduced by Tomasi and Kanade [19], with a different formulation. Note that our system involves only the normal to the camera plane, i.e., two parameters, while theirs involves all three parameters specifying the orientation of the camera.

6. Conclusion. This paper presented applications of a systematic technique invented by Fels and Olver for building invariants of a Lie group action. We started by summarizing this technique. We then showed how to formulate the problem of structure from motion in three different settings (Euclidean coordinates, projective coordinates, and orthographic projections) in terms of Lie group actions. In each setting, the group parameters included unknown unwanted parameters of the problem. These parameters were removed from the equations by reformulating the problem using invariants of these group actions.

The orbit structure and the invariants of the group action provide interesting insights on the geometry of the projections. They also provide a formalization for similar results obtained more empirically [17]. For solving the structure from motion

problem, our results relate to several well-known techniques but eliminate additional unnecessary parameters, sometimes difficult to remove otherwise. Further work is now ongoing to make such invariant systems more computationally attractive for various practical applications.

Acknowledgments. Both authors would like to thank David Cooper for support, encouragement, and stimulating discussions, as well as David Mumford and Jean Ponce for their useful comments.

CONGESTION REDUX*

J. M. GREENBERG†

Abstract. In this paper we analyze a class of second-order traffic models and show that these models support stable oscillatory traveling waves typical of the waves observed on a congested roadway. The basic model has trivial or constant solutions where cars are uniformly spaced and travel at a constant equilibrium velocity that is determined by the car spacing. The stable traveling waves arise because there is an interval of car spacing for which the constant solutions are unstable. These waves consist of a smooth part where both the velocity and spacing between successive cars are increasing functions of a Lagrange mass index. These smooth portions are separated by shock waves that travel at computable negative velocity.

Key words. conservation laws, traffic congestion, follow-the-leader

1. Introduction. In the last several years a number of authors [1, 2, 3, 4, 5, 6, 7, 8, 9] have advanced "higher order" traffic models in an attempt to characterize strong permanent waves which appear in congested traffic. At the continuum level all of these authors have worked with models of the following form:

$$\frac{\partial s}{\partial t} - \frac{\partial u}{\partial m} = 0 \tag{1.1}$$

and

$$\epsilon \frac{\partial u}{\partial t} = \epsilon P'(s) \frac{\partial u}{\partial m} + V(s) - u. \tag{1.2}$$

Here $t \geq 0$ is time, m is a Lagrangian mass coordinate which gives the car index, and $\epsilon > 0$ has the interpretation of a relaxation time. The velocity of the mth car at time t is $u(m,t)$, and $s(m,t) \geq L > 0$ is a measure of the spacing between successive cars. Finally, the function $s \to V(s)$ has the interpretation of an "equilibrium" velocity, and the term $\epsilon P'(s)\frac{\partial u}{\partial m}$ appearing in (1.2) is typically referred to as the anticipatory acceleration. All authors assume that $P'(s) \geq 0$ on $s \geq L$. The parameter $L > 0$ has the interpretation of the length of a car on the roadway.

The trajectory of the mth car is given as the solution of

$$\frac{\partial x}{\partial t} = u \quad \text{and} \quad x(m,0) = x_0(m), \tag{1.3}$$

where $x_0(m)$ is the position of the mth car at $t = 0$. $s(m,t)$ is related to $x(m,t)$ by

$$s(m,t) = \frac{\partial x}{\partial m}(m,t) \tag{1.4}$$

and measures the spacing between successive cars.

The hypothesis that $P'(s) \geq 0$ implies that the system (1.1) and (1.2) is hyperbolic with wave speeds $c = -P'(s) \leq 0$ and $c = 0$ and thus information propagates from right to left. This observation implies that when constructing finite difference schemes for (1.1) and (1.2) the appropriate spatial differences should be downwind, i.e., that

$$s(m,t) \doteq \frac{x(m+\Delta m,t) - x(m,t)}{\Delta m} \tag{1.5}$$

and

$$\frac{\partial u}{\partial m}(m,t) \doteq \frac{u(m+\Delta m,t) - u(m,t)}{\Delta m}. \tag{1.6}$$

If one chooses to discretize (1.1)–(1.4) spatially, keep time continuous, and, moreover, choose $\Delta m = 1$ (recalling that cars are really discrete entities), one is led to the classic follow-the-leader system

$$\frac{dx_m}{dt} = u_m \tag{1.7}$$

and

$$\epsilon \frac{du_m}{dt} = \epsilon P'(x_{m+1} - x_m)(u_{m+1} - u_m) + V(x_{m+1} - x_m) - u_m \tag{1.8}$$

studied by traffic engineers. On the other hand, if one lets

$$\rho(x,t) = \frac{1}{s(m,t)} \quad \text{and} \quad v(x,t) = u(m,t) \tag{1.9}$$

when

$$x = x(m,t), \tag{1.10}$$

one finds that as functions of x and t the functions ρ and v satisfy

$$\frac{\partial \rho}{\partial t} + \frac{\partial}{\partial x}(\rho v) = 0 \tag{1.11}$$

and

$$\epsilon \left(\frac{\partial v}{\partial t} + (v + \rho \mathcal{R}_{,\rho}(\rho)) \frac{\partial v}{\partial x} \right) = W(\rho) - v, \tag{1.12}$$

where

$$\mathcal{R}(\rho) \stackrel{def}{=} P(1/\rho) \quad \text{and} \quad W(\rho) \stackrel{def}{=} V(1/\rho). \tag{1.13}$$

Of course

$$\rho^2 \mathcal{R}_{,\rho}(\rho) = -P'(s = 1/\rho) \leq 0 \quad \text{and} \quad \rho^2 W_{,\rho}(\rho) = -V'(s = 1/\rho) \leq 0. \tag{1.14}$$

References [2, 3, 4, 5] dealt primarily with the case where $P(\cdot)$ and $V(\cdot)$ were monotone increasing on $s \geq L$ and had the following additional properties:

$$V(L^+) = 0 \quad \text{and} \lim_{s \to \infty} V(s) = v_\infty \tag{1.15}$$

and

$$0 < V'(s) \le P'(s),\ P''(s) < 0 \quad \text{and} \quad V''(s) < 0,\ L < s < \infty. \tag{1.16}$$

In that series of papers the authors established a variety of results about the system (1.1)–(1.4) and its discrete counterpart (1.7)–(1.8), notably that the constant solutions

$$s(m,t) \equiv s_0 > L \quad \text{and} \quad u(m,t) \equiv V(s_0) \tag{1.17}$$

were stable in the L_∞ norm.

Bando et al. [6] considered the discrete system (1.7)–(1.8) when $P'(\cdot) \equiv 0$ and found that the steady solutions (1.7)–(1.8) were linearly unstable if $0 < V'(s_0)$ was large enough and linearly stable otherwise. The continuous system (1.1)–(1.2) with $P'(\cdot) \equiv 0$ supports a stronger conclusion, namely, that all steady solutions are linearly unstable and this is a defect in that model. In that same paper, Bando and his coauthors also exhibited large amplitude oscillatory solutions to (1.7) and (1.8) in the case where

$$V(s) = \frac{v_\infty \left(\tanh\left(\frac{s-rL}{\delta}\right) + \tanh\left(\frac{(r-1)L}{\delta}\right)\right)}{\left(1 + \tanh\left(\frac{(r-1)L}{\delta}\right)\right)}, s \ge L \tag{1.18}$$

when

$$r > 1, \quad v_\infty > 0, \quad \text{and} \quad \delta > 0. \tag{1.19}$$

These solutions are reminiscent of the strong permanent waves seen in congested traffic. The authors' calculations gave no indication of the propagation speeds of these waves.

Finally, Greenberg, Klar, and Rascle [7] considered the system (1.1)–(1.2) when

$$P(s) = v_\infty \left(1 - L/s\right), \quad 0 < L \le s \tag{1.20}$$

and

$$V(s) = \begin{cases} \mu v_\infty \left(1 - L/s\right), & L \le s < s_* \\ \\ v_\infty \left(1 - L/s\right), & s_* < s < \infty, \end{cases} \tag{1.21}$$

where $0 < \mu < 1$ and $v_\infty > 0$. The trivial equilibria for this model are

$$s = s_0 \quad \text{and} \quad u \equiv V(s_0) \quad \text{when} \quad s_0 \ne s_* \tag{1.22}$$

and

$$s = s_* \quad \text{and any} \quad u = u_* \text{ in the interval } \left(\mu v_\infty \left(1 - L/s_*\right),\ v_\infty \left(1 - L/s_*\right)\right). \tag{1.23}$$

The former equilibria are stable and the latter unstable. In [7] the authors established the existence of stable periodic traveling waves (the ring-road scenario) of large amplitude which propagate with speed $c = -P'(s_*)$. These waves were functions of $\xi = m - ct$ and were composed of a smooth increasing portion satisfying

$$s(-m_a^+) = s_a, \quad s(0) = s_*, \quad \text{and} \quad s(M_a^-) = S_a. \tag{1.24}$$

The numbers $s_a < s_* < S_a$ were not arbitrary. They satisfied

$$\frac{P(S_a) - P(s_a)}{S_a - s_a} = P'(s_*), \tag{1.25}$$

and the numbers m_a and M_a satisfied

$$k\,(m_a + M_a) = M \quad \text{and} \quad k\int_{m_a}^{M_a} s(\xi)d\xi = l. \tag{1.26}$$

Here M represents the number of cars on the ring-road, l is the length of the ring-road, and $k \geq 1$ is an integer which gives the number of increasing segments per period. These waves have jump discontinuities at the points $\{m_a \pm n\,(m_a + M_a)\}_{n=0}^{\infty}$ and (1.25) guarantees that the Rankine–Hugoniot conditions for (1.1)–(1.2) hold across the discontinuities. These waves also satisfy the Lax entropy condition across the shocks, namely, the condition that $S_a > s_a$.

Our goal in the remainder of this paper is to show that the results of [7] were no fluke; that is, they were not an artifact of the jump discontinuity in the equilibrium velocity function defined in (1.21) but rather were generic. In the remainder of this paper we shall limit ourselves to the analysis of (1.1)–(1.2) when $P(\cdot)$ and $V(\cdot)$ are both increasing on $[L, \infty)$ and satisfy the normalization conditions

$$P(L^+) = V(L^+) = 0 \quad \text{and} \quad \lim_{s\to\infty} V(s) = v_\infty > 0. \tag{1.27}$$

We shall assume that $V'(\cdot)$ has an isolated single maximum at $s_* > L$, that

$$V''(s) > 0, \quad L \leq s < s_* \quad \text{and } V''(s) < 0, \quad s_* < s < \infty, \tag{1.28}$$

that the difference $(P' - V')\,(\cdot)$ has two isolated zeros at points s_1 and s_2 satisfying $L < s_1 < s_* < s_2 < \infty$, and, finally, that $(P' - V')(\cdot) > 0$ on $(L, s_1) \cup (s_2, \infty)$.

In section 2 we shall give a simple argument showing that for s_0 in (s_1, s_2), the constant solution defined in (1.17) is unstable. We shall also show that if the initial data for s lies in this interval, then s approximately evolves via a convective backwards heat equation, thus confirming the instability of the constant solutions. This latter result will be established by using a Chapman–Enskog expansion of the solutions of (1.1) and (1.2). In section 3 we shall show how to construct the large amplitude periodic traveling wave solutions to (1.1)–(1.2) reminiscent of the waves seen in congested traffic. These solutions are similar in structure to those obtained in [7]. Section 4 will be devoted to numerical simulations. Here we shall limit ourselves to

$$P(s) = \lambda(1 - L/s), \quad L \leq s, \tag{1.29}$$

and $V(\cdot)$ given by (1.18). We shall demonstrate that for nonconstant initial data taking on values in the unstable interval (s_1, s_2), solutions converge to traveling waves. These simulations will be run on the follow-the-leader model (1.7)–(1.8). Comprehensive surveys on this vast subject may be found in Helbing [8] and Nagel, Wagner, and Woesler [9].

2. Linear stability of (1.17). We look for solutions of (1.1)–(1.2) of the form

$$s = s_0 + \delta_1 A \quad \text{and} \quad u = V(s_0) + \delta_1 W, \tag{2.1}$$

where $0 < \delta_1 \ll 1$. To leading order in δ_1 we find that A satisfies

$$\epsilon\left(\frac{\partial^2 A}{\partial t^2} - P'(s_0)\frac{\partial^2 A}{\partial t \partial m}\right) = V'(s_0)\frac{\partial A}{\partial m} - \frac{\partial A}{\partial t}. \tag{2.2}$$

If we look for solutions of (2.2) of the form

$$A = \exp(ikm + \lambda t), \tag{2.3}$$

we find that λ and k satisfy

$$\epsilon\lambda^2 + (1 - ik\epsilon P'(s_0))\,\lambda - ikV'(s_0) = 0. \tag{2.4}$$

Moreover, if we write $\lambda = \alpha + i\beta$ (with α and β real), we obtain

$$\epsilon(\alpha^2 - \beta^2) + \alpha + k\epsilon P'(s_0)\beta = 0 \tag{2.5}$$

and

$$2\epsilon\alpha\beta + \beta - k\epsilon P'(s_0)\alpha - kV'(s_0) = 0. \tag{2.6}$$

If we restrict our attention to the case where $0 < \epsilon \ll 1$, we find one root goes as

$$\lambda_1 = -\frac{1}{\epsilon} + ik(P' - V')(s_0) + 0(\epsilon) \tag{2.7}$$

and the other as

$$\lambda_2 = ikV'(s_0) - \epsilon k^2 V'(s_0)(P' - V')(s_0) + 0(\epsilon^2) \tag{2.8}$$

and it is the latter identity which allows us to conclude that the system is linearly stable when $(P' - V')(s_0) > 0$ and linearly unstable when $(P' - V')(s_0) < 0$.

A similar conclusion may be reached if we apply a Chapman–Enskog procedure to (1.1) and (1.2) when $0 < \epsilon \ll 1$. Specifically, we seek solutions to (1.1) and (1.2) where u is of the form

$$u = U^1 = u^0 + \epsilon u^1 \tag{2.9}$$

and u^0 and u^1 are independent of ϵ and functionals of s. Insertion of the ansatz (2.9) into (1.2) yields

$$\begin{aligned} &u^0 = V(s), u^1 = V'(s)\left(P'(s) - V'(s)\right)\frac{\partial s}{\partial m} \quad \text{and} \\ &U^1 = V(s) + \epsilon V'(s)\left(P'(s) - V'(s)\right)\frac{\partial s}{\partial m}. \end{aligned} \tag{2.10}$$

Then s is determined by solving

$$\frac{\partial s}{\partial t} = \frac{\partial}{\partial m}\left(V(s) + \epsilon V'(s)\left(P'(s) - V'(s)\right)\frac{\partial s}{\partial m}\right). \tag{2.11}$$

This latter equation has a strong maximum principle so long as the initial data for s satisfies either

$$L \le s(m,0) < s_1 \quad \text{for all } m \tag{2.12}$$

or

$$s_2 \le s(m,0) < \infty \quad \text{for all } m \tag{2.13}$$

because in either of these cases the diffusion coefficient, $V'(s)(P'(s) - V'(s))$, is positive. On the other hand, when $s_1 < s < s_2$, the diffusion coefficient is negative and this yields explosive growth of the solution, confirming the instability of the constant solution (1.17) when $s_1 < s_0 < s_2$.

3. Large amplitude periodic traveling waves. In this section we seek solutions to (1.1) and (1.2) that are functions of

$$\xi = m + ct, \quad c > 0, \tag{3.1}$$

which are periodic in ξ with periodic M, the number of cars on the ring-road. The conversation structure of (1.1) implies that the $s(\cdot)$ component of the solution satisfies

$$\int_0^M s(\xi)d\xi = l, \tag{3.2}$$

where l is the length of the ring-road.

Insertion of the ansatz (3.1) into (1.1) implies that $u(\cdot)$ and $s(\cdot)$ satisfy

$$u(\xi) = u_\# + c(s(\xi) - s_\#), \tag{3.3}$$

and we insist that

$$u_\# = V(s_\#) \quad \text{and} \quad s(0) = s_\# \in (s_1, s_2). \tag{3.4}$$

The relations (3.3) and (3.4) further imply that

$$\epsilon c\,(c - P'(s))\,\frac{ds}{d\xi} = (V(s) - V(s_\#) - c(s - s_\#))\,. \tag{3.5}$$

We seek a solution to (3.4) and (3.5) which is increasing on $-m_a < \xi < M_a$, where $-m_a < 0 < M_a$. For speeds $0 < c < V'(s_\#)$, we see that the right-hand side of (3.5) satisfies

$$\text{sign } (V(s) - V(s_\#) - c(s - s_\#)) = \text{sign } (s - s_\#) \tag{3.6}$$

for $|s - s_\#|$ small enough, and thus to obtain an increasing solution to (3.4) and (3.5) on some interval containing $\xi = 0$ in its interior we are compelled to choose

$$c = P'(s_\#). \tag{3.7}$$

This choice of c, together with the hypothesis that $P''(\cdot) < 0$, guarantees that

$$\text{sign } (P'(s_\#) - P'(s)) = \text{ sign } (s - s_\#), \tag{3.8}$$

and thus, with this choice of c, we are guaranteed a solution of (3.4) and (3.5) defined in some interval $-\tilde{m}_a < \xi < \tilde{M}_a$, where $-\tilde{m}_a < 0 < \tilde{M}_a$. Moreover, this solution satisfies

$$\frac{ds}{d\xi}(0) = \frac{-\left(V'(s_\#) - P'(s_\#)\right)}{\epsilon P'(s_\#)P''(s_\#)} > 0 \tag{3.9}$$

for $s_1 < s_\# < s_2$.

We shall now refine the observations of the preceding paragraphs. If

$$V(L) - V(s_2) - P'(s_2)(L - s_2) > 0, \tag{3.10}$$

we let $\bar{s}$ in (s_1, s_2) be the unique solution of

$$V(L) - V(\bar{s}) - P'(\bar{s})(L - \bar{s}) = 0, \tag{3.11}$$

whereas, if

$$V(L) - V(s_2) - P'(s_2)(L - s_2) \leq 0, \tag{3.12}$$

we let

$$\bar{s} = s_2. \tag{3.13}$$

In either case, for any $s_\#$ in $(s_1, \bar{s})$ we let $L < s_-(s_\#) < s_\# < s_+(s_\#)$ be the other two solutions of

$$V(s_\pm) - V(s_\#) - P'(s_\#)(s_\pm - s_\#) = 0. \tag{3.14}$$

We of course have

$$V(s) - V(s_\#) - P'(s_\#)(s - s_\#) < 0, \quad s_-(s_\#) < s < s_\#, \tag{3.15}$$

and

$$V(s) - V(s_\#) - P'(s_\#)(s - s_\#) > 0, \quad s_\# < s < s_+(s_\#). \tag{3.16}$$

For any s_a in $(s_-(s_\#), s_\#)$ we now let $S(s_a) > s_\#$ be the unique solution of

$$\frac{P(S(s_a)) - P(s_a)}{S(s_a) - s_a} = P'(s_\#) \tag{3.17}$$

and note that

$$\frac{dS(s_a)}{ds_a} = \frac{(P'(s_\#) - P'(s_a))}{(P'(s_\#) - P'(S(s_a)))} < 0. \tag{3.18}$$

We also let $\underline{s}(s_\#)$ be the smallest value of $s_a \geq s_-(s_\#)$ such that $S(s_a) \leq s_+(s_\#)$ and for any s_a in $(\underline{s}(s_\#), s_\#)$ we let

$$-m_a = \epsilon P'(s_\#) \int_{s_a}^{s_\#} \frac{(P'(r) - P'(s_\#))\, dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} < 0 \tag{3.19}$$

and

$$M_a = \epsilon P'(s_\#) \int_{s_\#}^{S(s_a)} \frac{(P'(s_\#) - P'(r))dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} > 0. \tag{3.20}$$

We note that one of the integrals (3.19) or (3.20) or both diverge as $s_a \to \underline{s}(s_\#)^+$. For any ξ in $(-m_a, M_a)$, the solution to (3.4) and (3.5) is given by the quadrature formula

$$\epsilon P'(s_\#) \int_{s_\#}^{s(\xi)} \frac{(P'(s_\#) - P'(r))\, dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} = \xi, \tag{3.21}$$

and the solution is extended to $(-\infty, \infty)$ by insisting that the periodicity condition

$$s\left(\xi \pm n(m_a + M_a)\right) = s(\xi), \quad n = 0, 1, \dots, \tag{3.22}$$

holds. As constructed, the solution has jump discontinuities as the points $M_a \pm n(m_a + M_a)$, $n = 0, 1, \dots$, and (3.17), (3.19), and (3.20) guarantee that the Rankine–Hugoniot condition for (1.1) and (1.2) holds across these discontinuities. The Lax

entropy condition that $s^-\left(M_a \pm n(m_a + M_a)\right) > s^+\left(M_a \pm n(m_a + M_a)\right)$ is also guaranteed since

$$s^-(M_a \pm n(m_a + M_a)) = S(s_a) > s_a = s^+(M_a \pm n(m_a + M_a)). \tag{3.23}$$

What remains to be shown is that for integers $k = 1, 2, \ldots$ we can choose s_a in $(\underline{s}(s_\#), s_\#)$ and $s_\#$ in $(s_1, \overline{s})$ so that

$$k(m_a + M_a) = M \tag{3.24}$$

and

$$\int_0^M s(\xi)d\xi = l. \tag{3.25}$$

The integer k represents the number of increasing segments per period.

We start by analyzing (3.24). Equations (3.19) and (3.20) imply that solving (3.24) is equivalent to solving

$$k\epsilon P'(s_\#)\int_{s_a}^{S(s_a)} \frac{(P'(s_\#) - P'(r))\,dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} \stackrel{def}{=} F(s_\#, s_a) = M. \tag{3.26}$$

We observe for any $s_\#$ in $(s_1, \overline{s})$ that

$$F(s_\#, s_\#) = 0, \tag{3.27}$$

$$\begin{aligned}\frac{\partial F}{\partial s_a}(s_\#, s_a) = k\epsilon P'(s_\#)\Bigg(&\frac{(P'(s_\#) - P'(S(s_a))S'(s_a))}{(V(S(s_a)) - V(s_\#) - P'(s_\#)\,(S(s_a) - s_\#))} \\ &+ \frac{(P'(s_a) - P'(s_\#))}{(V(s_a) - V(s_\#) - P'(s_\#)(s_a - s_\#))}\Bigg)\end{aligned} \tag{3.28}$$

for any s_a in $(\underline{s}(s_\#), s_\#)$, and, finally, that

$$\lim_{s_a \to \underline{s}(s_\#)^+} F(s_\#, s_a) = +\infty. \tag{3.29}$$

Then (3.27)–(3.29) guarantee that for each $s_\#$ in $(s_1, \overline{s})$ there is a unique number $s_a(s_\#)$ in $(\underline{s}(s_\#), s_\#)$ satisfying (3.26). Thus, solving (3.24) and (3.25) is equivalent to finding an $s_\#$ in $(s_1, \overline{s})$ such that

$$k\epsilon P'(s_\#)\int_{s_a(s_\#)}^{S(s_a(s_\#))} \frac{(P'(s_\#) - P'(r))\,r dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} = l. \tag{3.30}$$

The last identity is a consequence of (3.25) and the fact that on $(-m_a, M_a)$

$$\frac{d\xi}{dr} = \frac{k\epsilon P'(s_\#)\,(P'(s_\#) - P'(r))}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))}. \tag{3.31}$$

If we exploit the fact that $s_a(s_\#)$ satisfies (3.26), we find that solving (3.30) is equivalent to solving

$$Ms_\# + k\epsilon P'(s_\#)\int_{s_a(s_\#)}^{S(s_a(s_\#))} \frac{(P'(s_\#) - P'(r))\,(r - s_\#)dr}{(V(r) - V(s_\#) - P'(s_\#)(r - s_\#))} = l. \tag{3.32}$$

To get some idea about the range of the function defined by the left-hand side of (3.32) we note that

$$\text{sign}\left(\frac{(P'(s_\#)-P'(r))\,(r-s_\#)}{(V(r)-V(s_\#))-P'(s_\#)(r-s_\#)}\right)=\text{sign}\;(r-s_\#) \tag{3.33}$$

and that for r close to $s_\#$

$$\frac{(P'(s_\#)-P'(r))\,(r-s_\#)}{(V(r)-V(s_\#)-P'(s_\#)(r-s_\#))}\sim\frac{-P''(s_\#)(r-s_\#)}{(V'-P')\,(s_\#)}. \tag{3.34}$$

So long as $s_1<s_\#<\overline{s}$ we have $s_-(s_\#)<s_a(s_\#)$ and $S(s_a(s_\#))<s_+(s_\#)$ and the integrand $\frac{(P'(s_\#)-P'(r))(r-s_\#)}{(V(r)-V(s_\#)-P'(s_\#)(r-s_\#))}$ is nonsingular. In this case the function defined by the left-hand side of (3.32) is approximately given by

$$Ms_\#-\frac{k\epsilon P'(s_\#)P''(s_\#)(S(s_a(s_\#))-s_a(s_\#))(S(s_a(s_\#))+s_a(s_\#)-2s_\#)}{2(V'-P')(s_\#)}. \tag{3.35}$$

This last identity is instructive, especially in the situation where $P''(\cdot)$ is approximately constant. In that case $S(s_a(s_\#))+s_a(s_\#)-2s_\#$ is approximately zero and thus the function defined by (3.35) approximately reduces to $Ms_\#$. Equation (3.30) then approximately becomes

$$Ms_\#=l. \tag{3.36}$$

This sort of analysis on the function defined by the left-hand side of (3.30) is all we could manage with the degree of generality allowed on the functions $P(\cdot)$ and $V(\cdot)$. Though not particularly sharp it gives a fair indication of when (3.24) and (3.25) are solvable.

4. Simulations. All computations in this section were run with the follow-the-leader model (1.7) and (1.8) when

$$P(s)=\lambda\left(1-\frac{L}{s}\right),\quad L\le s, \tag{4.1}$$

and

$$V(s)=v_\infty\frac{\left(\tanh\left(\frac{s-rL}{\delta}\right)+\tanh\left(\frac{(r-1)L}{\delta}\right)\right)}{\left(1+\tanh\left(\frac{(r-1)L}{\delta}\right)\right)}. \tag{4.2}$$

The specific parameters used were

$$L=15\text{ feet}, \tag{4.3}$$

$$\lambda=150\text{ feet/sec }=102.2727\ldots\text{ mph}, \tag{4.4}$$

$$v_\infty=100\text{ feet/sec }=68.1818\ldots\text{ mph}, \tag{4.5}$$

$$\delta=15\text{ feet}, \tag{4.6}$$

and

$$r=3. \tag{4.7}$$

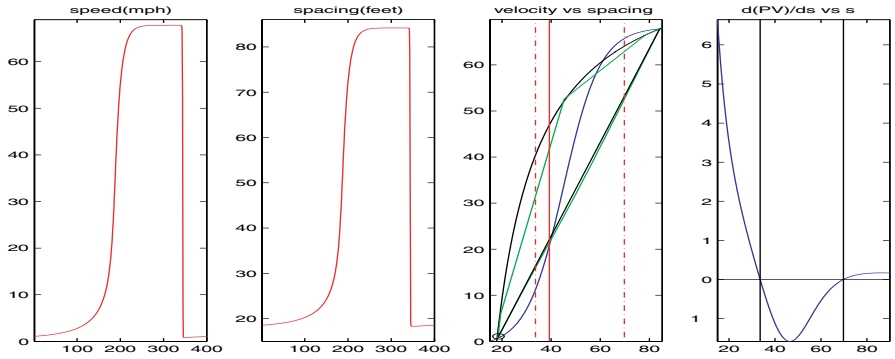

FIG. 1.

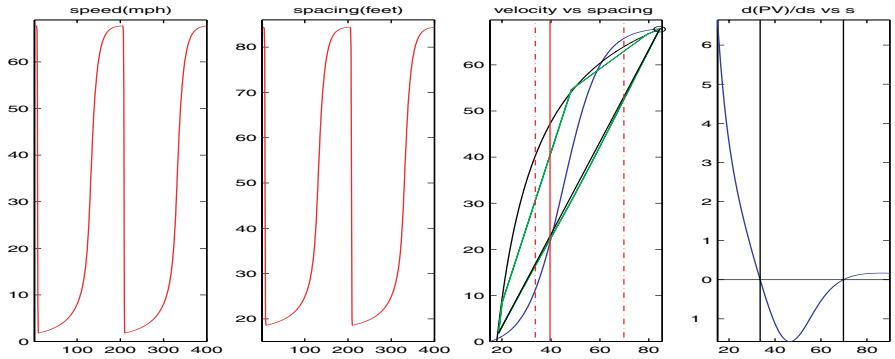

FIG. 2.

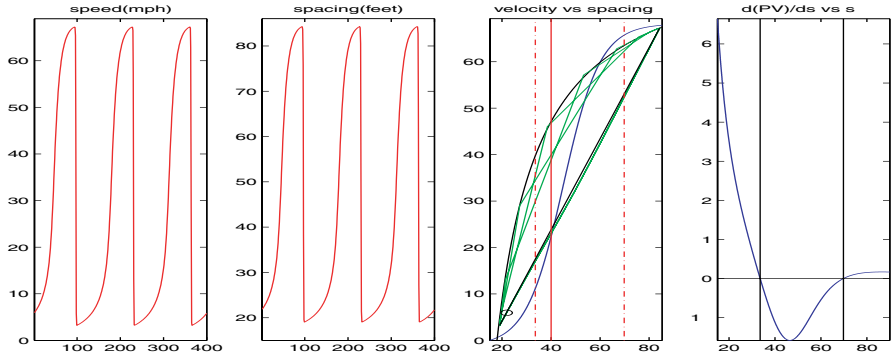

FIG. 3.

For initial data, we choose three sets of data

$$x_m^{(k)}(0) = 45m + 30 \sum_{j=0}^{m-1} \sin\left(\frac{kj\pi}{200}\right) \tag{4.8}$$

and

$$u_m^{(k)}(0) = 35 \text{ feet/sec} \tag{4.9}$$

for $m = 0, \pm 1, \pm 2, \dots$ and $k = 1, 2$, and 3. The observation that

$$x_{m+400}^{(k)}(0) = x_m^{(k)}(0) + 18000 \tag{4.10}$$

implies that we may interpret the data as initial data for a ring-road with 400 cars which is of length 18000 feet.

For our choice of parameter values the unstable region for $(P' - V')(\cdot)$ is the interval $33.59625\ldots < s < 69.8215$ and our data has initial car spacings

$$s_m^{(k)}(0) = x_{m+1}^{(k)}(0) - x_m^{(k)}(0) \tag{4.11}$$

which lie in that interval. A graph of $s \to (P' - V')(s)$ is shown in the fourth panel of Figures 1–3. Simulations were run with relaxation times

$$\epsilon = 1,\ 5,\ \text{and } 10. \tag{4.12}$$

We show the spatially periodic solutions at time $t = 1$ hour when $\epsilon = 10$ seconds. Figures 1, 2, and 3 correspond to the initial data indexed by $k = 1, 2$, and 3, respectively. The solution indexed by each particular k has k discontinuities per period after one hour. Run over a longer period, they all revert to a solution with one discontinuity per period.

The first two frames in each figure are self-explanatory. In the third frame of each figure we plot the curve $m \to (s_m = x_{m+1} - x_m, u_m)$. This curve is shown in green. The blue curve is the equilibrium curve $s \to (s, V(s))$ and the black concave curve is a suitably normalized image of $P(\cdot)$. The circle -o- is the image of (s_1, u_1).

SURFACE GREEN'S FUNCTIONS FOR AN INCOMPRESSIBLE, TRANSVERSELY ISOTROPIC ELASTIC HALF-SPACE*

RICHARD S. CHADWICK†, BRETT SHOELSON†, AND HONGXUE CAI†

Abstract. The surface displacements produced by normal and tangential point loads applied to the surface of an incompressible, transversely isotropic material are considered when anisotropy is produced by a single family of fibers oriented perpendicular to the surface normal. Three elastic constants (two shear moduli and a fiber modulus) characterize the linear elasticity of such a material. The problems are solved analytically in two-dimensional Fourier transform space, and explicit surface displacement formulae are given for the inverses in physical space. Simple relations are given as asymptotic expansions for weak anisotropy. Computed surface displacement patterns are illustrated, and the application of the results to atomic force microscopy is discussed.

Key words. anisotropic material, asymptotic analysis, elastic material, Green's functions

1. Introduction.

The present problem is motivated by recent interest in using the atomic force microscope (AFM) as a microindenter of biological samples with the intent of determining the local elastic moduli of the tissue (Dimitriadis et al. (2002), Chadwick (2002)). The condition of material incompressibility can hold for biological samples when the time required to deform the tissue is small compared to the time required for water to flow out of it. Also, structural fibers do not penetrate biological membranes, which typically form the surfaces that are probed by the AFM. It seems, therefore, that the present problem is the simplest relevant departure from an isotropic half-space. A recent account of Green's functions for anisotropic materials is given by Pan and Yuan (2000). While the case of point loading of a compressible, transversely isotropic elastic half-space with fibers oriented in the direction of the surface normal has been well studied for normal loads (Lekhnitskii (1963), Willis (1966), Conway, Farnham, and Ku (1967), Green and Zerna (1968)) and tangential loads (Chen (1965), Turner (1980)), the present problem has apparently not received much specific attention. Here we use the stress-strain relation of Spencer (1984), the Fourier transform formalism developed by Willis (1966), and the inversion method developed by Barnett and Lothe (1975) for general anisotropic bodies. Spencer's stress-strain formalism has the advantages of avoiding a sometimes delicate limiting process needed to treat the incompressible case, and also having a more physical interpretation of the elastic constants, compared to the more general formalism used by Willis (1966), for example. Also, Willis, being interested in the Hertzian problem, did not need to invert the point force solutions. Barnett and Lothe (1975) developed their inversion method in conjunction with the Stroh formalism for crystal symmetry

classes, as they describe and extend. The Stroh formalism, with hexagonal symmetry, can also be used to study problems of biological interest such as we consider here.

2. Formulation. We consider a half-space (x, y, z) with the elastic material in the domain $z < 0$. Let the fibers run in a direction specified by the unit vector $\overrightarrow{a}$. The stress-strain relation of the material is given by Spencer (1984),

$$\sigma_{ij} = -pI_{ij} + 2\mu_T e_{ij} + E_f a_k e_{kl} a_l a_i a_j + 2(\mu_L - \mu_T)(a_i a_k e_{kj} + e_{ik} a_k a_j), \tag{2.1}$$

where p is an isotropic pressure term required for an incompressible material; I_{ij} is the unit tensor; e_{ij} is the strain tensor $\frac{1}{2}(\partial u_i/\partial x_j + \partial u_j/\partial x_i)$, where the u_i are displacements; and E_f, μ_T, and μ_L are the fiber modulus and the shear moduli normal and parallel to the fiber direction, respectively. Introducing the displacement components (u, v, w) and taking $\overrightarrow{a} : (0, 1, 0)$, so that fibers run in the y direction, the stress components are

$$\sigma_{xx} = -p + 2\mu_T \frac{\partial u}{\partial x}, \quad \sigma_{yy} = -p + (E_f + 4\mu_L - 2\mu_T)\frac{\partial v}{\partial y}, \quad \sigma_{zz} = -p + 2\mu_T \frac{\partial w}{\partial z}, \tag{2.2}$$

$$\sigma_{xy} = \mu_L \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} \right), \quad \sigma_{zy} = \mu_L \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right), \quad \sigma_{xz} = \mu_T \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right). \tag{2.3}$$

Substitution of (2.2), (2.3) into the equations of equilibrium $\partial \sigma_{ij}/\partial x_j = 0$, and using the condition of incompressibility $\partial u_i/\partial x_i = 0$, yields the following system:

$$(2\mu_T - \mu_L)\frac{\partial^2 u}{\partial x^2} + \mu_L \frac{\partial^2 u}{\partial y^2} + \mu_T \frac{\partial^2 u}{\partial z^2} + (\mu_T - \mu_L)\frac{\partial^2 w}{\partial x \partial z} - \frac{\partial p}{\partial x} = 0, \tag{2.4}$$

$$\mu_L \frac{\partial^2 v}{\partial x^2} + (E_f + 3\mu_L - 2\mu_T)\frac{\partial^2 v}{\partial y^2} + \mu_L \frac{\partial^2 v}{\partial z^2} - \frac{\partial p}{\partial y} = 0, \tag{2.5}$$

$$\mu_T \frac{\partial^2 w}{\partial x^2} + \mu_L \frac{\partial^2 w}{\partial y^2} + (2\mu_T - \mu_L)\frac{\partial^2 w}{\partial z^2} + (\mu_T - \mu_L)\frac{\partial^2 u}{\partial x \partial z} - \frac{\partial p}{\partial z} = 0, \tag{2.6}$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0. \tag{2.7}$$

To complete the formulation we consider three separate surface stress conditions:

$$\sigma_{xz}(x, y, 0) = \delta(x)\delta(y), \quad \sigma_{yz}(x, y, 0) = 0, \quad \sigma_{zz}(x, y, 0) = 0, \tag{2.8}$$

$$\sigma_{xz}(x, y, 0) = 0, \quad \sigma_{yz}(x, y, 0) = \delta(x)\delta(y), \quad \sigma_{zz}(x, y, 0) = 0, \tag{2.9}$$

$$\sigma_{xz}(x, y, 0) = 0, \quad \sigma_{yz}(x, y, 0) = 0, \quad \sigma_{zz}(x, y, 0) = -\delta(x)\delta(y), \tag{2.10}$$

where $\delta(x_i)$ denotes the Dirac delta function. In each case all stress components must decay as $z \to -\infty$. The conditions specified by (2.8) represent a point shear force acting in a cross-fiber direction (see Problem 1), those specified by (2.9) represent a point shear force acting in the fiber direction (Problem 2), and those specified by (2.10) represent a compressive point normal force (Problem 3).

3. Solutions in Fourier transform space. Following Willis (1966), we take Fourier transforms in the x and y directions. Thus

$$\overline{U}(\xi,\eta,z)=\frac{1}{2\pi}\int\int_{-\infty}^{\infty}u(x,y,z)e^{[i(\xi x+\eta y)]}dxdy, \tag{3.1}$$

with similar expressions for $\overline{V}$, $\overline{W}$, and $\overline{P}$, the transforms of v, w, and p. Transforming the set (2.4)–(2.7) yields a system of coupled ordinary differential equations in z. Assuming a solution form $\overline{U}(\xi,\eta,z)=U(\xi,\eta)\exp[i\lambda z]$, and similarly for the other transformed variables, gives the homogeneous algebraic system

$$\begin{aligned}
-[(2-\beta)\xi^2+\beta\eta^2+\lambda^2]U+(1-\beta)\xi\lambda W+\frac{i\xi P}{\mu_T}&=0,\\
-[\beta\xi^2+(\alpha+3\beta-2)\eta^2+\beta\lambda^2]V+\frac{i\eta P}{\mu_T}&=0,\\
(1-\beta)\xi\lambda U-[\xi^2+\beta\eta^2+(2-\beta)\lambda^2]W-\frac{i\lambda P}{\mu_T}&=0,\\
i\xi U+i\eta V-i\lambda W&=0,
\end{aligned} \tag{3.2}$$

which has solutions, provided that the determinant of the matrix $\underline{M}$ of coefficients of U, V, W, and P is zero. Here we have introduced the ratios of elastic moduli: $\alpha=E_f/\mu_T$ and $\beta=\mu_L/\mu_T$. The determinant is a sixth-order polynomial in λ that turns out to be bicubic and factorable:

$$(\lambda^2+\xi^2+\beta\eta^2)[\beta\lambda^4+(\alpha\eta^2+2\beta\eta^2+2\beta\xi^2)\lambda^2+\beta\eta^4+(\alpha+2\beta)\xi^2\eta^2+\beta\xi^4]=0. \tag{3.3}$$

Of the six roots, which occur in complex conjugate pairs, we choose those that have negative imaginary parts to ensure decay of stress as $z\to-\infty$. Thus, from the first factor we obtain

$$\lambda_1=-i\sqrt{\xi^2+\beta\eta^2}, \tag{3.4}$$

while from the second, which is biquadratic, we find

$$\begin{aligned}
\lambda_2&=-i\sqrt{\xi^2+\eta^2\left[1+\frac{\alpha}{2\beta}(1+\phi)\right]},\\
\lambda_3&=-i\sqrt{\xi^2+\eta^2\left[1+\frac{\alpha}{2\beta}(1-\phi)\right]},
\end{aligned} \tag{3.5}$$

where $\phi=\sqrt{1+4\frac{\beta}{\alpha}}$. Note that each of the three radicands is positive for positive elastic moduli. Corresponding to each of these roots are three vectors $\overrightarrow{b_i}:(U_i,V_i,W_i,P_i)$, that are the eigenvectors corresponding to the zero eigenvalues of the matrices $\underline{M}(\lambda_i)$, $i=1,2,3$. These vectors have the following components: $\overrightarrow{b_1}:(\lambda_1/\xi,0,1,0)$, $\overrightarrow{b_2}:(U_2,V_2,(\xi U_2+\eta V_2)/\lambda_2,1)$, and $\overrightarrow{b_3}:(U_3,V_3,(\xi U_3+\eta V_3)/\lambda_3,1)$, where

$$\begin{aligned}
V_2&=\frac{i}{\eta[2(\beta-1)+\frac{1}{2}\alpha(1-\phi)]},\\
U_2&=\frac{\beta\xi V_2[2(\beta-1)+\alpha(1-\phi)]}{\eta[2\beta(\beta-1)-\alpha(1+\phi)]},
\end{aligned} \tag{3.6}$$

and

$$V_3 = \frac{i}{\eta[2(\beta-1)+\frac{1}{2}\alpha(1+\phi)]}, \tag{3.7}$$
$$U_3 = \frac{\beta\xi V_3[2(\beta-1)+\alpha(1+\phi)]}{\eta[2\beta(\beta-1)-\alpha(1-\phi)]}.$$

The general solution for the transformed variables $\overrightarrow{\Psi} : (\overline{U}, \overline{V}, \overline{W}, \overline{P})$ is the superposition of the three eigenvectors, i.e.,

$$\Psi_j(\xi,\eta,z) = \sum_{n=1}^{3} A_n b_{nj} e^{i\lambda_n z}, \quad j = 1,2,3,4, \tag{3.8}$$

where $\Psi_1 = \overline{U}$, $\Psi_2 = \overline{V}$, ... , and b_{nj} denotes the jth component of the eigenvector $\overrightarrow{b_n}$. The A_n are arbitrary functions of (ξ,η) that will be evaluated by applying the three stress boundary conditions appropriate for each problem. Using (2.2), (2.3), (3.1), and (3.8), the transformed surface stresses are

$$\overline{\sigma_{xz}}(\xi,\eta,0) = i\mu_T \sum_{n=1}^{3} A_n(\lambda_n b_{n1} - \xi b_{n3}), \tag{3.9}$$
$$\overline{\sigma_{yz}}(\xi,\eta,0) = i\mu_L \sum_{n=1}^{3} A_n(\lambda_n b_{n2} - \eta b_{n3}),$$
$$\overline{\sigma_{zz}}(\xi,\eta,0) = \mu_T \sum_{n=1}^{3} A_n(2i\lambda_n b_{n3} - b_{n4}).$$

The solution of Problem 1 is obtained by solving the linear system (3.9) for A_1, A_2, A_3 when the left-hand sides are set to $1/(2\pi)$, 0 , 0, respectively. Similarly, for Problems 2 and 3 the left-hand sides are set to 0, $1/(2\pi)$, 0, and 0, 0, $-1/(2\pi)$, respectively.

4. Fourier inversions. We now adopt the more concise notation $G_{ij}(x,y)$ or $G_{ij}(r,\varphi)$ in polar coordinates to denote the Green's tensor that represents the surface displacement component in the ith direction ($i = 1,2,3$) due to a point force in the jth problem or direction ($j = 1,2,3$), and $\bar{G}_{ij}(\xi,\eta)$ or $\bar{G}_{ij}(\rho,\theta)$ to denote the corresponding transforms. Willis (1966), Barnett and Lothe (1975), and Pan and Yuan (2000) have shown for compressible general anisotropic materials that the $\bar{G}_{ij}$ are homogeneous of degree -1 in ρ, i.e., $\bar{G}_{ij}(\rho,\theta) = \rho^{-1}\bar{g}_{ij}(\theta)$. It is easily seen that this result carries over to the present incompressible case. This is important because it enables a great simplification of the inversions into physical space:

$$G_{ij}(x,y) = \frac{1}{2\pi}\int\int_{-\infty}^{\infty} \bar{G}_{ij}(\xi,\eta) e^{-i(\xi x+\eta y)} d\xi d\eta, \tag{4.1}$$
$$G_{ij}(r,\varphi) = \frac{1}{2\pi}\int_0^{2\pi}\int_0^{\infty} \rho^{-1}\bar{g}_{ij}(\theta) e^{-i\rho r\cos(\theta-\varphi)} \rho d\rho d\theta,$$

where polar coordinates $\xi = \rho\cos\theta$, $\eta = \rho\sin\theta$, and $x = r\cos\varphi$, $y = r\sin\varphi$ have been introduced. The radial integration is accomplished via the identity used by Barnett and Lothe (1975):

$$\int_0^{\infty} e^{-i\rho r\cos(\theta-\varphi)} d\rho = \pi\delta(r\cos(\theta-\varphi)) - iP\frac{1}{r\cos(\theta-\varphi)}, \tag{4.2}$$

where P denotes the principal value. Furthermore, Barnett and Lothe introduced the functional identity

$$\delta(r\cos(\theta-\varphi)) = \frac{\delta(\theta-\varphi\pm\frac{\pi}{2})}{|r\sin(\theta-\varphi)|}. \tag{4.3}$$

These two identities lead directly to the inversion formula

$$G_{ij}(r,\varphi) = \frac{1}{4\pi\mu_T r}\bar{g}_{ij}(\theta)|_{\varphi\pm\frac{\pi}{2}} - \frac{i}{4\pi^2\mu_T r}P\int_0^{2\pi}\frac{\bar{g}_{ij}(\theta)}{\cos(\theta-\varphi)}d\theta. \tag{4.4}$$

The first term of the inversion formula is simply the sum of two ninety-degree rotations of the functions in transform space, while the second term is a principal value integral. In the present problem we note the following symmetry properties of the $\bar{g}_{ij}(\theta)$ in terms of their Fourier series expansions on $0 \le \theta \le 2\pi$: $\bar{g}_{11}, \bar{g}_{22}$, and $\bar{g}_{33}$ have cosine series expansions in even multiples of θ; $\bar{g}_{12}$ and $\bar{g}_{21}$ have sine series expansions in even multiples of θ; $\bar{g}_{13}$ and $\bar{g}_{31}$ have cosine series expansions in odd multiples of θ; and $\bar{g}_{23}$ and $\bar{g}_{32}$ have sine series expansions in odd multiples of θ. The principal-value integrals vanish for those functions that have an expansion in even multiples of θ, while the sum of the two ninety-degree rotations are additive for those functions. Thus G_{11}, G_{22}, G_{33}, G_{12}, and G_{21} simply reduce to

$$G_{ij}(r,\varphi) = \frac{1}{2\pi\mu_T r}\bar{g}_{ij}\left(\varphi+\frac{\pi}{2}\right). \tag{4.5}$$

For the remaining off-diagonal terms $\bar{g}_{13}$, $\bar{g}_{31}$, $\bar{g}_{23}$, and $\bar{g}_{32,}$which have expansions in odd multiples of θ, the sum of the two ninety-degree rotations cancels, and their principal-value integrals can be evaluated using the following formulae given by Barnett and Lothe (1975):

$$P\int_0^{2\pi}\frac{\cos(2n+1)}{\sin(\theta-\theta_0)}d\theta = -2\pi\sin(2n+1)\theta_0, \tag{4.6}$$

$$P\int_0^{2\pi}\frac{\sin(2n+1)}{\sin(\theta-\theta_0)}d\theta = 2\pi\cos(2n+1)\theta_0, \tag{4.7}$$

where $n = 0, 1, 2, \ldots$. Thus G_{13} and G_{23} reduce to the sums

$$G_{13}(r,\varphi) = \frac{1}{2\pi\mu_T r}\sum_{n=0}^{\infty} c_n \sin\left[\left(2n+1\right)(\varphi+\frac{\pi}{2})\right] \tag{4.8}$$

$$G_{23}(r,\varphi) = -\frac{1}{2\pi\mu_T r}\sum_{n=0}^{\infty} s_n \cos\left[\left(2n+1\right)(\varphi+\frac{\pi}{2})\right] \tag{4.9}$$

where the c_n are the Fourier cosine coefficients of $-i\bar{g}_{13}$, and the s_n are the Fourier sine coefficients of $-i\bar{g}_{23}$. We will see in the following sections that $G_{12} = G_{21,}$ $G_{13} = G_{31}$, and $G_{32} = G_{23}$.

5. Asymptotic results for small anisotropy. Although the exact expressions for the transformed surface displacements are quite unwieldy and are not displayed here, they can be easily obtained using Mathematica (Wolfram Research, Chicago, IL). As an independent check on the exact method given in section 4, it turns out that Mathematica can invert the transformed surface displacements term by term when

they are expanded in a Taylor series about $\alpha = 0$ and $\beta = 1$ for small anisotropy. Here we summarize the results, where an expanded surface displacement in transform space is immediately followed by its corresponding inverse transform into physical space. The method for obtaining these inverses is described in the appendix.

PROBLEM 1.

$$
\begin{aligned}
2\pi\mu_T U(\xi,\eta) &= \frac{\xi^2+2\eta^2}{2(\xi^2+\eta^2)^{3/2}} - (\beta-1)\frac{\eta^2}{2(\xi^2+\eta^2)^{3/2}} - \alpha\frac{5\xi^2\eta^4}{16(\xi^2+\eta^2)^{7/2}} + \cdots, \\
2\pi\mu_T u(x,y,0) &= \frac{y^2+2x^2}{2(y^2+x^2)^{3/2}} - (\beta-1)\frac{x^2}{2(y^2+x^2)^{3/2}} - \alpha\frac{5y^2x^4}{16(y^2+x^2)^{7/2}} + \cdots, \\
2\pi\mu_T V(\xi,\eta) &= -\frac{\xi\eta}{2(\xi^2+\eta^2)^{3/2}} + (\beta-1)\frac{\xi\eta}{2(\xi^2+\eta^2)^{3/2}} + \alpha\frac{\xi\eta^3(6\xi^2+\eta^2)}{16(\xi^2+\eta^2)^{7/2}} + \cdots, \\
2\pi\mu_T v(x,y,0) &= \frac{yx}{2(y^2+x^2)^{3/2}} - (\beta-1)\frac{yx}{2(y^2+x^2)^{3/2}} - \alpha\frac{yx^3(6y^2+x^2)}{16(y^2+x^2)^{7/2}} + \cdots, \\
2\pi\mu_T W(\xi,\eta) &= i(\beta-1)\frac{\xi\eta^2}{2(\xi^2+\eta^2)^2} + i\alpha\frac{\xi\eta^4}{8(\xi^2+\eta^2)^3} + \cdots, \\
2\pi\mu_T w(x,y,0) &= (\beta-1)\frac{x(x^2-y^2)}{4(y^2+x^2)^2} + \alpha\frac{x(3x^4-6x^2y^2-y^4)}{64(y^2+x^2)^3} + \cdots.
\end{aligned} \tag{5.1}
$$

PROBLEM 2.

$$
\begin{aligned}
2\pi\mu_T U(\xi,\eta) &= -\frac{\xi\eta}{2(\xi^2+\eta^2)^{3/2}} + (\beta-1)\frac{\xi\eta}{2(\xi^2+\eta^2)^{3/2}} + \alpha\frac{\xi\eta^3(6\xi^2+\eta^2)}{16(\xi^2+\eta^2)^{7/2}} + \cdots, \\
2\pi\mu_T u(x,y,0) &= \frac{yx}{2(y^2+x^2)^{3/2}} - (\beta-1)\frac{yx}{2(y^2+x^2)^{3/2}} - \alpha\frac{yx^3(6y^2+x^2)}{16(y^2+x^2)^{7/2}} + \cdots, \\
2\pi\mu_T V(\xi,\eta) &= \frac{2\xi^2+\eta^2}{2(\xi^2+\eta^2)^{3/2}} - (\beta-1)\frac{2\xi^2+\eta^2}{2(\xi^2+\eta^2)^{3/2}} - \alpha\frac{\eta^2(8\xi^4+4\xi^2\eta^2+\eta^4)}{16(\xi^2+\eta^2)^{7/2}} + \cdots, \\
2\pi\mu_T v(x,y,0) &= \frac{2y^2+x^2}{2(y^2+x^2)^{3/2}} - (\beta-1)\frac{2y^2+x^2}{2(y^2+x^2)^{3/2}} - \alpha\frac{x^2(8y^4+4y^2x^2+x^4)}{16(y^2+x^2)^{7/2}} + \cdots, \\
2\pi\mu_T W(\xi,\eta) &= -i(\beta-1)\frac{\xi^2\eta}{2(\xi^2+\eta^2)^2} - i\alpha\frac{\xi^2\eta^3}{8(\xi^2+\eta^2)^3} + \cdots, \\
2\pi\mu_T w(x,y,0) &= -(\beta-1)\frac{y(y^2-x^2)}{4(y^2+x^2)^2} + \alpha\frac{y(3x^4-6x^2y^2-y^4)}{64(y^2+x^2)^3} + \cdots.
\end{aligned} \tag{5.2}
$$

PROBLEM 3.

$$
\begin{aligned}
2\pi\mu_T U(\xi,\eta) &= i(\beta-1)\frac{\xi\eta^2}{2(\xi^2+\eta^2)^2} + i\alpha\frac{\xi\eta^4}{8(\xi^2+\eta^2)^3} + \cdots, \\
2\pi\mu_T u(x,y,0) &= (\beta-1)\frac{x(x^2-y^2)}{4(y^2+x^2)^2} + \alpha\frac{x(3x^4-6x^2y^2-y^4)}{64(y^2+x^2)^3} + \cdots, \\
2\pi\mu_T V(\xi,\eta) &= -i(\beta-1)\frac{\xi^2\eta}{2(\xi^2+\eta^2)^2} - i\alpha\frac{\xi^2\eta^3}{8(\xi^2+\eta^2)^3} + \cdots, \\
2\pi\mu_T v(x,y,0) &= (\beta-1)\frac{y(x^2-y^2)}{4(y^2+x^2)^2} + \alpha\frac{y(3x^4-6x^2y^2-y^4)}{64(y^2+x^2)^3} + \cdots,
\end{aligned} \tag{5.3}
$$

$$2\pi\mu_T W(\xi,\eta) = -\frac{1}{2(\xi^2+\eta^2)^{1/2}} + (\beta-1)\frac{\eta^2}{2(\xi^2+\eta^2)^{3/2}} + \alpha\frac{\eta^4}{16(\xi^2+\eta^2)^{5/2}} + \cdots,$$

$$2\pi\mu_T w(x,y,0) = -\frac{1}{2(y^2+x^2)^{1/2}} + (\beta-1)\frac{x^2}{2(y^2+x^2)^{3/2}} + \alpha\frac{x^4}{16(y^2+x^2)^{5/2}} + \cdots.$$

Notice that the formulae reduce to the well-known results for an incompressible isotropic material (cf. Landau and Lifshitz (1975, pp. 29–30)) when $\alpha = 0$ and $\beta = 1$.

6. Symmetry properties of Green's tensor. Reverting back to the $G_{ij}(x,y)$ notation, we see from the preceding asymptotic formulae the surprising result that $G_{ij}(x,y) = G_{ji}(x,y)$ for $i \neq j$. This is also true for the *exact* transformed displacements, according to logical comparisons in Mathematica. Should we be surprised by this result, and how general is it? The Green's tensor is symmetric for an isotropic half-space and infinite medium (Landau and Lifshitz (1975, pp. 29–30)), as well as for a half-space with cubic crystal symmetry (Portz and Maradudin (1977)). However, other authors do not mention this symmetry for general anisotropic half-space problems. Courant and Hilbert (1962, pp. 393–394) indicate that a Green's tensor has this symmetry property when the differential system is self-adjoint. As we shall show, this symmetry depends upon whether or not a reciprocal theorem exists in the form

$$\int\int_S \overrightarrow{\sigma}\cdot\overrightarrow{u^*}\,dS = \int\int_S \overrightarrow{\sigma^*}\cdot\overrightarrow{u}\,dS,$$

where $\overrightarrow{u}$ and $\overrightarrow{u^*}$ are the respective surface displacements resulting from two different surface stress vectors $\overrightarrow{\sigma}$ and $\overrightarrow{\sigma^*}$, applied to an elastic body having a surface S. Such a reciprocal relation has been attributed to Betti for elastic systems and Rayleigh for more general dynamic systems (see Timoshenko (1930, pp. 351–355)). A similar relation for incompressible creeping viscous flow was established by Lorentz (see Happel and Brenner (1965, pp. 85–87)). The reciprocal theorem can be shown to hold not only for the elastic solid considered here, but also for a general linear anisotropic elastic solid having the stress-strain relation $\sigma_{ij} = c_{ijkl}e_{kl}$. The geometry of the body can also be arbitrary. To see this, consider the quadratic form $\sigma_{ij}e^*_{ij} = c_{ijkl}e_{kl}e^*_{ij} = c_{klij}e^*_{ij}e_{kl} = \sigma^*_{kl}e_{kl} = \sigma^*_{ij}e_{ij}$, noting that the switch $c_{ijkl} = c_{klij}$ is permissible since the strain energy $\frac{1}{2}\,c_{ijkl}e_{ij}e_{kl}$ must be invariant to the switch. Consider further, from the definition of strain, $\sigma_{ij}e^*_{ij} = \frac{1}{2}\,\sigma_{ij}\partial u^*_i/\partial x_j + \frac{1}{2}\,\sigma_{ij}\partial u^*_j/\partial x_i = \frac{1}{2}\,\sigma_{ij}\partial u^*_i/\partial x_j + \frac{1}{2}\,\sigma_{ji}\partial u^*_j/\partial x_i = \sigma_{ij}\partial u^*_i/\partial x_j$, where symmetry of the stress tensor $\sigma_{ij} = \sigma_{ji}$ has been used. Therefore $\sigma_{ij}e^*_{ij}$ can be written in the divergence form $\sigma_{ij}e^*_{ij} = \partial(\sigma_{ij}u^*_i)/\partial x_j$, since $\partial\sigma_{ij}/\partial x_j = 0$ is the condition of static equilibrium. Therefore $\partial(\sigma_{ij}u^*_i)/\partial x_j = \partial(\sigma^*_{ij}u_i)/\partial x_j$, which is the condition of self-adjointness. Integrating over the volume of the body and applying the divergence theorem gives the surface integral form of the reciprocal relation. The symmetry of Green's tensor follows from this relation when the stress vectors are due to point forces. A breakdown of the reciprocal theorem evidently occurs in problems involving elastic inclusions and inhomogeneities (Eshelby (1961)) and lattice defects (Eshelby (1956)). In such cases the difference between the two sides of the reciprocal theorem is identified with an interaction energy.

7. Surface displacement patterns. We calculate surface displacements using the formulae given in section 4. Surface displacement patterns are displayed graphically as superpositions of contour plots for the displacement component normal to

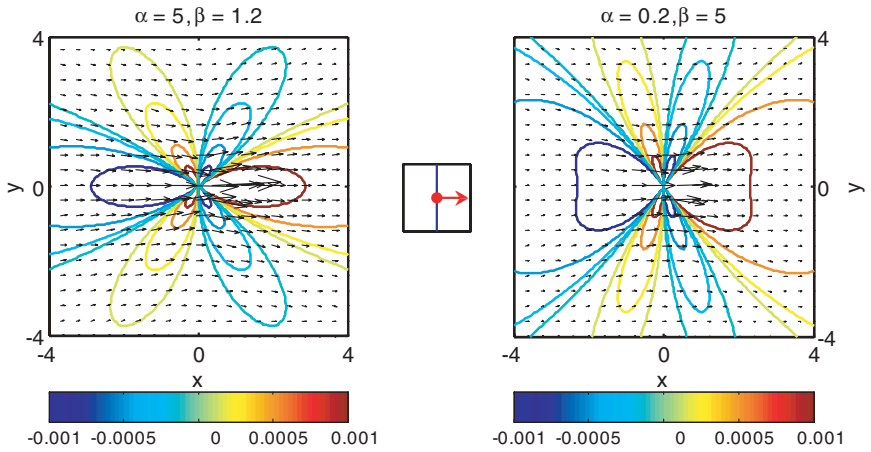

FIG. 1. *In Problem* 1, *a shear point force is applied at the origin, with the force oriented normal to the y-directed family of fibers. The center inset shows the fiber orientation, and the force direction is shown by the red arrow. The contours represent w, the z-directed deformation of the surface of the material, where the in-plane displacements are shown as arrows.*

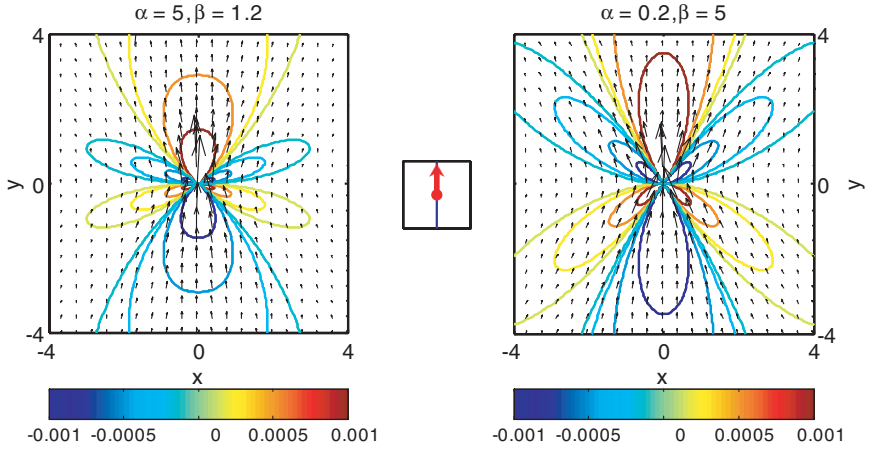

FIG. 2. *In Problem* 2, *a shear point force is applied at the origin, oriented in the direction of the fibers.*

the surface, together with quiver plots for the in-plane displacements. Patterns for Problems 1–3 are shown in Figures 1–3, respectively. Each figure comprises two panels. In the left panel, $\alpha = 5$ and $\beta = 1.2$; in this case the fiber modulus E_f is 5 times larger than the transverse shear modulus μ_T, while the longitudinal shear modulus μ_L is 1.2 times larger than μ_T. In the right panel, $\alpha = 0.2$, $\beta = 5$; in this case E_f is 5 times smaller than μ_T, while μ_L is 5 times larger than μ_T. The left panels therefore depict surface displacements induced by surface point forces in a material in which

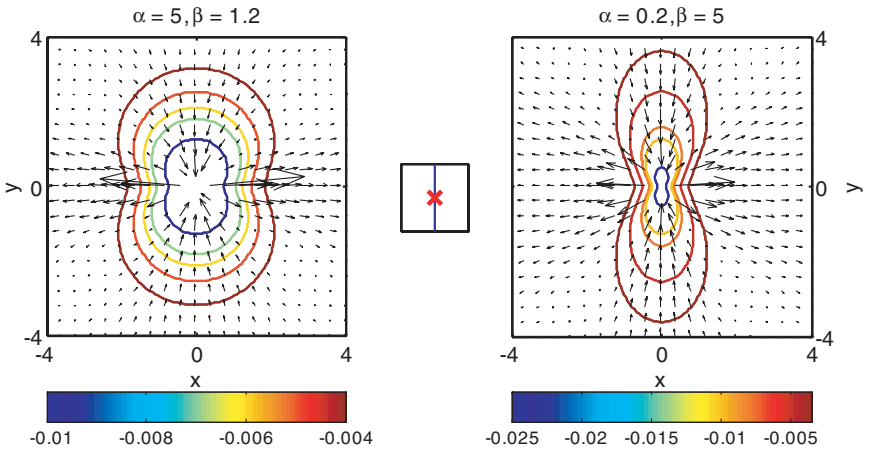

FIG. 3. *In Problem* 3*, a normal point load is applied at the origin. The red "x" in the center inset depicts a force directed into the surface of the half-space.*

fibers are relatively stiff compared to the surrounding matrix, while the right panels show the response of a material whose matrix is relatively stiff in a direction normal to relatively compliant fibers. Figure 4 comprises a triad of panels representing Problems 1–3 for the set of parameters $\alpha = 10$, $\beta = 0.2$. These parameters could be representative of a biological gel-like tissue having embedded, directed collagenous fibers.

8. Discussion. It is of interest to outline how the Green's functions found in this paper might be used to extract the three elastic moduli of isolated small samples of biological material using the AFM. The AFM piezo/cantilever system can be used to apply normal or tangential loads, the magnitudes of which can be determined by measuring the deflections induced by the bending or twisting of calibrated cantilevers using the laser/photodetector system of the instrument. The AFM can also map topographic variations of the sample surface on a nanometer scale. The following strategies can be used to sequentially determine μ_T, μ_L, and E_f. Since elements of the Green's tensor $G_{ij}(x, y)$ represent surface displacements in the ith direction that result from a unit point force at the origin acting in the jth direction, the surface displacements resulting from a force $\vec{f}$ acting at the origin are $u_i(x, y) = G_{ij}(x, y)f_j$. By applying a known tangential force of magnitude f_1 in the cross-fiber direction, and noting that $G_{11}(0, y)$ does not involve μ_L or E_f (cf. section 5), we can estimate the transverse shear modulus μ_T by fitting measured surface displacements $u_1(0, y)$ to a function of $1/y$. If the tangential force were applied by the AFM cantilever, then $u_1(0, y)$ could be measured by optical imaging of microspheres, for example. Alternatively, if the tangential force were applied by another calibrated probe, then the AFM cantilever would be available for scanning the topography before and after application of the force. Subtraction and postprocessing of two topographic images would then provide an estimate of $u_1(0, y)$, provided that the signal-to-noise ratio were large enough. Similarly, $G_{11}(x, 0)$ does not involve E_f, so the longitudinal shear modulus μ_L can be estimated by fitting measured surface displacements $u_1(x, 0)$ to a function of $1/x$. Finally, applying a known tangential force of magnitude f_2 in

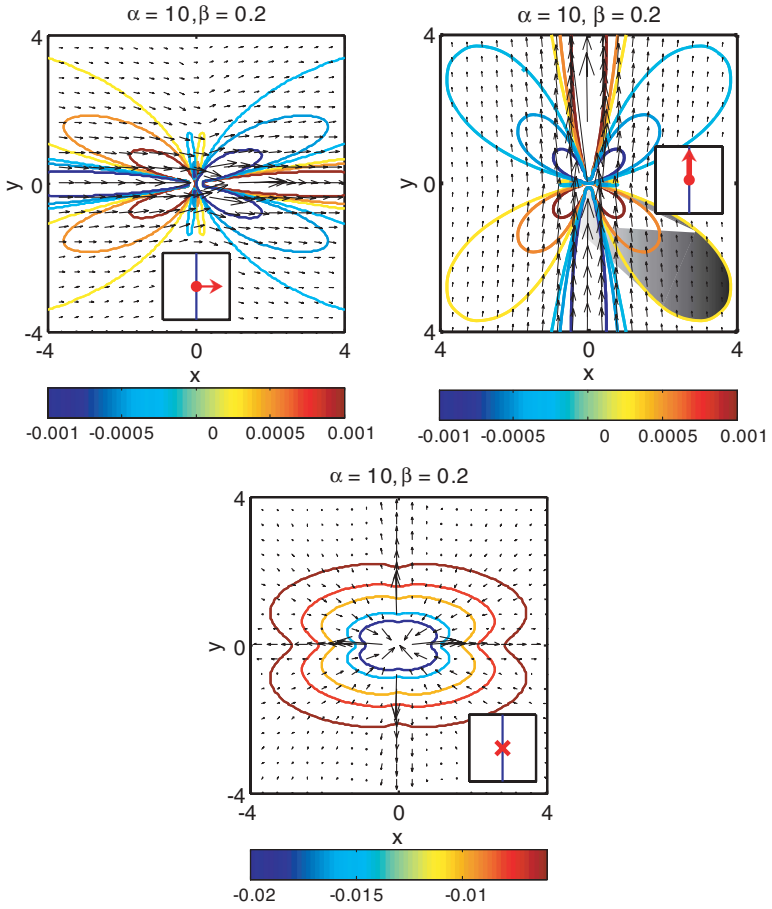

FIG. 4. *Surface displacement patterns for Problems* 1–3. *Parameters are thought to be representative of a biological gel-like material having directed, embedded collagenous fibers.*

the fiber direction and fitting measured values of $u_2(x,0)$ to a function of $1/x$ could provide an estimate of E_f via the $G_{22}(x,0)$ function. Other strategies using only a normal force of magnitude f_3 can be devised using $G_{33}(0,y)$, $G_{13}(x,x)$, etc.

Finally, it is worth estimating the distance from the probe in terms of the contact radius a, at which the point-force solution should provide a good approximation to the contact problem. For an isotropic, incompressible material, the ratio of the normal displacement resulting from Hertzian contact (outside the contact region) to that from a normal point force is given by

$$\frac{3}{4}\zeta\left[(2-\zeta^2)\sin^{-1}\frac{1}{\zeta}+\sqrt{\zeta^2-1}\right]=1+\frac{1}{10\zeta^2}+\cdots \qquad \text{as } \zeta\to\infty,$$

where $\zeta = r/a$. From this relationship, we see that the point-force solution is very quickly approached only a few contact radii away from the origin.

Appendix. Evaluation of some inverse Fourier transforms. Mathematica can invert two key transform types, from which all of the results in section 5 can be

obtained. One is the remarkable result that transformed functions having the form

$$F_m(\xi,\eta) = \frac{\eta^{2m}}{(\xi^2+\eta^2)^{m+\frac{1}{2}}}, \quad m = 0, 1, \dots, \tag{A.1}$$

have inverse transforms in x, y space that are simply rotations of $\pi/2$ radians of the function itself; i.e.,

$$f_m(x,y) = F_m^{-1}(\xi,\eta) = \frac{x^{2m}}{(y^2+x^2)^{m+\frac{1}{2}}}, \quad m = 0, 1, \dots. \tag{A.2}$$

Inverse transforms of

$$F_{mn}(\xi,\eta) = \frac{\eta^{2m-n}\xi^n}{(\xi^2+\eta^2)^{m+\frac{1}{2}}}, \quad m = 0, 1, \dots, n = 1, 2, \dots, \tag{A.3}$$

can be easily evaluated by recursively integrating $f_m(x,y)$ with respect to y and differentiating the result with respect to x, e.g.,

$$f_{31}(x,y) = \frac{\partial}{\partial x}\int \frac{x^6}{(y^2+x^2)^{\frac{7}{2}}}dy = -\frac{yx^5}{(y^2+x^2)^{\frac{7}{2}}}, \tag{A.4}$$

$$f_{32}(x,y) = -\frac{\partial}{\partial x}\int \frac{yx^5}{(y^2+x^2)^{\frac{7}{2}}}dy = \frac{y^2x^4}{(y^2+x^2)^{\frac{7}{2}}}, \quad \text{etc.}$$

Note that these inverses also exhibit a simple rotation property. Inverse transforms of

$$H_{mn}(\xi,\eta) = \frac{\eta^{2m-1-n}\xi^n}{(\xi^2+\eta^2)^m}, \quad m = 2, 3, \dots, \ n = 1, 2, \tag{A.5}$$

can be found directly by Mathematica:

$$h_{mn}(x,y) = H_{mn}^{-1}(\xi,\eta) = \frac{poly_{2m-1}(x,y)}{(y^2+x^2)^m}, \quad m = 2, 3, \dots, \ n = 1, 2, \tag{A.6}$$

where $poly_{2m-1}(x,y)$ is a polynomial, homogeneous of degree $2m-1$, e.g.,

$$h_{21}(x,y) = \frac{-i}{2}\frac{x(x^2-y^2)}{(y^2+x^2)^2}, \qquad h_{31}(x,y) = \frac{-i}{8}\frac{x(3x^4-6x^2y^2-y^4)}{(y^2+x^2)^3}, \tag{A.7}$$

$$h_{32}(x,y) = \frac{i}{8}\frac{y(3x^4-6x^2y^2-y^4)}{(y^2+x^2)^3}.$$

Acknowledgment. The authors are extremely grateful to an anonymous reviewer whose comments lead to a great improvement in this study.

POINT DYNAMICS IN A SINGULAR LIMIT OF THE KELLER–SEGEL MODEL 1: MOTION OF THE CONCENTRATION REGIONS*

J. J. L. VELÁZQUEZ†

Abstract. The purpose of this paper is to study a singular perturbation limit of a Keller–Segel system that generates blow-up in finite time. The main question that is addressed is the description of the evolution of the solutions of this problem beyond the blow-up time for the limit problem if a suitable parameter $\varepsilon > 0$ approaches zero. This problem is studied using matched asymptotic expansions. The resulting limit solution can be described beyond the blow-up time by means of the motion of a set of points whose dynamics is coupled with a parabolic-elliptic system of equations.

Key words. chemotaxis, singular perturbations, Keller–Segel model

AMS subject classifications. 35K45, 35B25, 92B05

DOI. 10.1137/S0036139903433888

1. Introduction.

Chemotactic aggregation has received a lot of attention in recent decades, both from experimental and theoretical viewpoints (cf., for instance, [1, 4, 5, 7, 8, 10, 11, 13, 20, 28, 34, 37, 39, 42, 44, 45]).

A particular model that has been extensively used in several studies of chemotaxis is the well-known Keller–Segel one (cf. [28]). A property of the Keller–Segel system that has been considered often is the fact that for suitable choices of the chemotactic function, solutions of this problem might blow-up in finite time (cf. [3, 17, 18, 24, 25, 26, 27, 32, 33]). More detailed references about recent results concerning blow-up in chemotaxis models can be found in [5, 16, 47] and references therein.

Blow-up is a property that cannot be expected to take place for the magnitudes that describe the behavior of biological or physical systems. Usually, in many problems in applied mathematics blow-up occurs only for some approximation of the real problem, and it indicates the presence not of a real singularity, but rather of a change in the orders of magnitude of the values of some quantity that characterizes the state of a system. For instance, this is a well-established fact in combustion theory, where blow-up just means that the values of the temperature and other physical magnitudes rise several orders of magnitude when ignition takes place (cf. [30]). Blow-up usually takes place in physical or biological models if they are approximations of more realistic models, usually containing some small parameter, say $\varepsilon > 0$, that cannot exhibit singular behaviors unless this parameter is set to zero. Suppose that for $\varepsilon = 0$ the limit problem can develop singularities in finite time. The behavior of the complete model for $\varepsilon > 0$ usually is similar to that of the limit model away from the singularities. However, the features of the problem with $\varepsilon > 0$ but small are usually very different from those of the limit problem near the singularities. The presence of blow-up just indicates that the approximations that led to that simpler model where blow-up takes place are not valid anymore near the singularity and that the whole dynamics of the complete model needs to be taken into account there.

The goal of this paper is to study by means of matched asymptotic expansions the behavior of the solutions of a system of partial differential equations of the Keller–Segel type. The problem under consideration will contain a parameter $\varepsilon \geq 0$. If $\varepsilon = 0$ the problem exhibits blow-up in finite time. It will be shown that the original model, in a suitable asymptotic limit, can describe in a rather detailed manner the formation and motion of some regions where the mass of the cells is concentrated. In particular a set of equations describing the motion of these points will be obtained. Since the solutions of the considered model blow-up if the singular perturbation parameter is set to zero, the behavior of the solutions derived here can be considered as some kind of "continuation beyond blow-up" for the solutions of the original system.

The precise problem that will be considered in this paper is the following:

$$\frac{\partial u}{\partial t} = \Delta u - \nabla(G_\varepsilon(u)\nabla v),\ x \in \mathbb{R}^2,\ t > 0, \tag{1.1}$$

$$\Delta v + u = 0,\ x \in \mathbb{R}^2,\ t > 0, \tag{1.2}$$

where u denotes the concentration of the organism and v is the concentration of the chemical secreted by it. In this particular version of the system a term v_t in the right-hand side of (1.2) has been neglected. This assumption is usually made in the study of the Keller–Segel model because diffusion for the organism is usually much slower than diffusion of the chemical that can be assumed to be at equilibrium. We will make the following choice of chemotactic function:

$$G_\varepsilon(u) = \frac{1}{\varepsilon} Q(\varepsilon u), \tag{1.3}$$

where $\varepsilon > 0$ is a small parameter, and the function $Q(\xi)$ is an increasing function satisfying

$$Q(s) = s - \alpha s^2 + \dots \quad \text{as } s \to 0, \tag{1.4}$$

$$Q(s) \sim L \quad \text{as } s \to \infty, \tag{1.5}$$

where $L > 0$ is a given number. A typical example would be $Q(s) = \frac{s}{1+s}$. In other words, instead of assuming that the chemotactic function $G_\varepsilon(u)$ increases without limit as the concentration of the organism becomes high, it will be assumed that the mobility of the organism saturates to a constant value. Another choice of $G_\varepsilon(u)$ certainly would be possible, but we will use this particular one just for the sake of simplicity.

The idea of replacing the linear function u by a function $G_\varepsilon(u)$ preventing cell density collapse has been used in [21]. More complicated models that would avoid blow-up also can be found in [6]. A rigorous study of the continuation of the solutions for the Keller–Segel model beyond the blow-up time in radial cases has been undertaken in [41].

The choice of the function $G_\varepsilon(u)$ in (1.1) is not motivated by some strong biological reason, but it has been basically made on mathematical grounds, to avoid collapse of the solutions.

System (1.1)–(1.5) is a particular case of the Keller–Segel model. Let us remark that for $\varepsilon = 0$ the system (1.1)–(1.5) formally becomes

$$\frac{\partial u}{\partial t} = \Delta u - \nabla(u\nabla v),\ x \in \mathbb{R}^2,\ t > 0, \tag{1.6}$$

$$\Delta v + u = 0,\ x \in \mathbb{R}^2,\ t > 0. \tag{1.7}$$

It is known that solutions of the problem (1.6), (1.7) might blow-up in a finite time $T > 0$ (cf. [9, 17, 27, 32]). As long as u, v remain bounded, the limit from (1.1)–(1.5) to (1.6), (1.7) does not pose any serious mathematical problem. However, the situation becomes mathematically more interesting for times $t > T$, because the solutions of (1.1)–(1.5) are globally defined in time, something that does not occur for the solutions of (1.6), (1.7). It is then natural to ask what happens to the solutions of (1.1)–(1.5) as $\varepsilon \to 0$ and $t > T$. This is the problem that will be addressed in this paper using asymptotic expansions.

Aggregation processes in real biological systems are complex processes involving many diverse ingredients. One of the most extensively studied problems is the aggregation of *Dictyostelium discoideum*. Many characteristics of that aggregation process are not included in simple models such as (1.1)–(1.5); one such characteristic is that the chemical does not propagate in a simple diffusive manner as indicated by (1.2), but rather by means of a sophisticated chemical oscillatory process (cf. [31, 38, 46]). On the other hand, aggregation of *Dictyostelium discoideum* does not occur by means of continuous densities u as occurs in (1.1)–(1.5), but on the contrary cells aggregate in some characteristic streams where cells move towards the center (cf. [38]). In any case, simple continuous models like (1.1)–(1.5) have been extensively used and provide some understanding of some features of the aggregation process in *Dictyostelium discoideum* and other organisms (cf., for instance, [22, 23, 29]).

The plan of this article is as follows. Section 2 describes the structure of some steady states associated to (1.1)–(1.5). Section 3 provides a description of the motion of regions with high densities of u that will be called concentration regions. In section 3, a system of equations that describes the dynamics of such a concentration region is derived. The well-posedness of such a system of equations has been proved in [48]. Finally, in the appendix a rigorous proof of some asymptotic properties of the steady states that have been formally derived in section 2 is provided.

In a second part of this paper (cf. [49]) the relation between the results of the present paper and the blow-up mechanism for (1.6), (1.7) is considered. The second paper studies how the blow-up process for (1.6), (1.7) is stopped for times close enough to the blow-up time if (1.6), (1.7) are replaced by (1.1), (1.2). In particular, it is seen that blow-up for (1.6), (1.7) yields for (1.1), (1.2) the formation of concentration regions that evolve later according to the equations derived in the present paper.

2. Steady states. In this section, as a preliminary step, we study radial steady state solutions of (1.1), (1.2). More precisely we consider the radial solutions of the system

$$\Delta \bar{u} - \nabla(G_\varepsilon(\bar{u})\nabla \bar{v}) = 0, \ x \in \mathbb{R}^2, \tag{2.1}$$

$$\Delta \bar{v} + \bar{u} = 0, \ x \in \mathbb{R}^2, \tag{2.2}$$

where $G_\varepsilon(u)$ is as in (1.3)–(1.5), and where from now on bars will be introduced above the functions that denote steady states. The scaling structure of $G_\varepsilon(u)$ in (1.3) suggests introducing the new set of variables

$$\bar{u} = \frac{1}{\varepsilon}\bar{U}, \tag{2.3}$$

$$x = \sqrt{\varepsilon} y \tag{2.4}$$

that transforms (2.1), (2.2) into

$$\Delta_y \bar{U} - \nabla_y (Q(\bar{U}) \nabla_y \bar{v}) = 0, \ y \in \mathbb{R}^2, \tag{2.5}$$

$$\Delta_y \bar{v} + \bar{U} = 0, \ y \in \mathbb{R}^2. \tag{2.6}$$

Let us write $r = |y|$. The main result obtained in this section is given in the following theorem.

THEOREM 2.1. *Suppose that $Q(\cdot) \in C^1(\mathbb{R}^+)$ is an increasing function satisfying* (1.4). *Let us assume also that $\frac{Q(s)}{s}$ is a decreasing function. Then, for each $M > 8\pi$ there exists a unique radial solution (up to rigid displacements) such that*

$$\int_{\mathbb{R}^2} \bar{U}(y; M) d^2 y = M.$$

The function $\bar{U}(y; M) = \bar{U}(r; M)$ is decreasing on r and its asymptotic behavior as $r \to \infty$ is given by

$$\bar{U}(r; M) \sim \frac{k(M)}{r^{\frac{M}{2\pi}}} \ \text{ as } \ r \to \infty.$$

Proof of Theorem 2.1. For radial solutions, integration of (2.5) in $\mathbb{R}^2$ yields

$$r \frac{\partial \bar{U}}{\partial r} - Q(\bar{U}) r \frac{\partial \bar{v}}{\partial r} = c, \tag{2.7}$$

where c is a real constant to be determined. If we assume that $\bar{U}$ has a finite amount of mass in $\mathbb{R}^2$ it would follow that $c = 0$.

On the other hand, we can write (2.6) for radial solutions as

$$\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial \bar{v}}{\partial r} \right) + \bar{U} = 0. \tag{2.8}$$

Plugging (2.7) (with $c = 0$) into (2.8) we obtain

$$\frac{1}{r} \frac{\partial}{\partial r} \left(\frac{r}{Q(\bar{U})} \frac{\partial \bar{U}}{\partial r} \right) + \bar{U} = 0 \tag{2.9}$$

that has to be solved with the additional condition

$$\frac{\partial \bar{U}}{\partial r}(0) = 0. \tag{2.10}$$

Assume that

$$\bar{U}(0) = \lambda, \ \lambda > 0. \tag{2.11}$$

Problem (2.9)–(2.11) can be analyzed using standard ODE theory. We will denote from now on as $\bar{U}(r; \lambda)$ the unique solution of (2.9)–(2.11), although by convenience we will drop the dependence on λ if it is clear from the context. Notice that we can rewrite (2.9) as

$$\frac{1}{Q(\bar{U})} \frac{\partial^2 \bar{U}}{\partial r^2} - \frac{Q'(\bar{U})}{(Q(\bar{U}))^2} \left(\frac{\partial \bar{U}}{\partial r} \right)^2 + \frac{1}{Q(\bar{U})} \frac{\partial \bar{U}}{\partial r} + \bar{U} = 0; \tag{2.12}$$

examining the sign of $\frac{\partial^2 \bar{U}}{\partial r^2}$ at the possible points where $\frac{\partial \bar{U}}{\partial r} = 0$, we see that $\bar{U}$ is decreasing as long as it remains positive. We then have three possibilities. Either $\bar{U}$ vanishes at some $r_0 > 0$, or $\lim_{r\to\infty} \bar{U}(r) = \bar{U}_0 > 0$, or $\lim_{r\to\infty} \bar{U}(r) = 0$. In order to exclude the possibility of $\bar{U}$ vanishing at a finite value $r_0 > 0$ we argue as follows. Since $\bar{U} \le \lambda$ for $0 \le r \le r_0$, by multiplying (2.9) by r and integrating we obtain

$$r\frac{\partial}{\partial r}[S(\bar{U})] \ge -\frac{\lambda r^2}{2}, \tag{2.13}$$

where $S(\bar{U}) = -\int_{\bar{U}}^1 \frac{d\xi}{Q(\xi)}$. Notice that $S(\bar{U}) = \log(\bar{U}) + O(1)$ as $\bar{U} \to 0^+$. Dividing (2.13) by r and integrating in the interval $[0, r]$, we arrive at

$$S(\bar{U}(r)) \ge S(\lambda) - \frac{\lambda r^2}{4}. \tag{2.14}$$

Therefore if $\bar{U}(r_0) = 0$, the left-hand side of (2.14) converges to $-\infty$ as $r \to r_0^+$ and the right-hand side remains bounded, yielding a contradiction.

Suppose then that $\lim_{r\to\infty} \bar{U}(r) = \bar{U}_0 > 0$. Thus for r large enough (2.9) could be approximated as

$$\frac{\partial}{\partial r}\left(\frac{r}{Q(\bar{U}_0)}\frac{\partial \bar{U}}{\partial r}\right) + \bar{U}_0 r = 0.$$

Integrating this equation twice one would obtain the following asymptotics for U to the leading order:

$$\bar{U} \sim -\frac{\bar{U}_0 r^2}{4},$$

but, since this asymptotics implies that $\bar{U}$ changes sign for large r we would derive a contradiction again. Therefore, the only possibility that has been left is $\bar{U}(r) > 0$ for any $r > 0$ and $\lim_{r\to\infty} \bar{U}(r) = 0$.

We can then compute in a more detailed manner the asymptotics of $\bar{U}(r)$ as $r \to \infty$. Notice that to the leading order (2.9) can be written for $r \to \infty$ as

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial(\bar{V})}{\partial r}\right) + e^{\bar{V}} = 0, \tag{2.15}$$

where we have written $\bar{V} = \log(\bar{U})$. Equation (2.15), which is known as Emden's equation and also as Bratu's equation, can be transformed into an autonomous differential equation by means of the change of variables

$$\bar{V} = -2\log(r) + \bar{W},\ r = e^{\xi}$$

that transforms (2.15) into

$$\frac{\partial^2 \bar{W}}{\partial \xi^2} + e^{\bar{W}} = 0. \tag{2.16}$$

This equation can be explicitly solved. Standard analysis of the Hamiltonian system (2.16) shows that its solutions behave asymptotically as

$$\bar{W} \sim -\theta\xi + C + o(1) \ \text{ as } \ \xi \to \infty,$$

where θ, C are real constants, and $\theta > 0$. In the original set of variables this asymptotics reads as

$$\bar{U} \sim \frac{k(\lambda)}{r^{\beta(\lambda)}} \text{ as } r \to \infty, \tag{2.17}$$

where λ is as in (2.11) and $\beta(\lambda) = 2 + \theta > 2$.

It is possible to derive a relation between $\beta(\lambda)$ and the mass of the function $\bar{U}$. Integration of (2.9) in a ball $B_R(0)$ yields

$$\int_{B_R(0)} \bar{U} d^2x = -\int_{\partial B_R(0)} \frac{1}{Q(\bar{U})} \frac{\partial \bar{U}}{\partial r} dS_x. \tag{2.18}$$

Using (1.4) and (2.17) we obtain the asymptotics

$$\frac{1}{Q(\bar{U})} \frac{\partial \bar{U}}{\partial r} \sim -\beta(\lambda) \frac{1}{r} \text{ as } r \to \infty.$$

Therefore, taking the limit $R \to \infty$ in (2.18) we obtain

$$\int_{\mathbb{R}^2} \bar{U} d^2x = 2\pi\beta(\lambda). \tag{2.19}$$

This shows that the coefficient $\beta(\lambda) > 2$ is uniquely determined by the mass of $\bar{U}$.

It turns out that for a rather large class of functions $Q(\xi)$ the function $\beta(\lambda)$ (or, equivalently, the mass of $\bar{U}$) is increasing with respect to λ. For instance, this property is satisfied if the following assumption holds:

$$\frac{Q(s)}{s} \text{ is decreasing with respect to } s. \tag{2.20}$$

For example, the function $Q(s) = \frac{s}{1+s}$ satisfies this assumption. Suppose that (2.20) is satisfied. We define

$$H(\xi, \lambda) \equiv \lambda Q\left(\frac{\xi}{\lambda}\right) = \xi \frac{Q(s)}{s},$$

where $s = \frac{\xi}{\lambda}$. We remark that under the assumption (2.20) $H(\xi, \lambda)$ is increasing on λ for each ξ fixed. If we assume also that $Q(s)$ is differentiable, (2.20) would imply that $Q'(s) - \frac{Q(s)}{s} < 0$ for $s > 0$. Combining this inequality with (1.4), the following inequalities hold:

$$Q(s) < s \text{ for } s > 0, \tag{2.21}$$

$$Q'(s) < 1 \text{ for } s > 0. \tag{2.22}$$

We will assume also that $Q(s)$ is an increasing function. Then

$$Q'(s) > 0 \text{ for } s > 0. \tag{2.23}$$

In order to conclude the proof of Theorem 2.1 we need some information concerning the asymptotics of $M(\lambda)$ for $\lambda \to 0^+$ and $\lambda \to \infty$. The following result will conclude the proof of the theorem.

PROPOSITION 2.2. *Suppose that* (1.3), (2.20) *hold. Let us denote as* $U(r,\lambda)$ *the solution of* (2.9)–(2.11). *Then the function* $M(\lambda) \equiv \int_{\mathbb{R}^2} U(r,\lambda) d^2x$ *is strictly increasing on* λ. *Moreover,*

$$\lim_{\lambda\to 0^+} M(\lambda) = 8\pi, \ \lim_{\lambda\to\infty} M(\lambda) = +\infty. \tag{2.24}$$

A rigorous proof of Proposition 2.2 will be given in the appendix. Using formal asymptotics we will now derive the behavior of the solutions of (2.9)–(2.11) as $\lambda \to 0^+$ and $\lambda \to \infty$ since some of these asymptotic properties will be used later.

In the case $\lambda \to 0^+$ we remark that the monotonicity of $\bar{U}(r;\lambda)$ on r as well as (2.11) shows that $\lim_{\lambda\to 0^+} \bar{U}(r,\lambda) = 0$. We can then approximate to the leading order $Q(\bar{U})$ by $\bar{U}$ in (2.9). More precisely, we introduce new variables φ, ξ by means of

$$\bar{U} = \frac{\lambda}{8}\varphi, \ r = \frac{\sqrt{8}}{\sqrt{\lambda}}\xi. \tag{2.25}$$

The factors $\sqrt{8}$, 8 have been introduced here just to obtain some of the formulae in forthcoming computations normalized in a convenient manner. Plugging (2.25) in (2.9) and taking the limit $\lambda \to 0^+$, (2.9) becomes

$$\frac{1}{\xi}\frac{\partial}{\partial\xi}\left(\frac{\xi}{\varphi_0}\frac{\partial\varphi_0}{\partial\xi}\right) + \varphi_0 = 0, \tag{2.26}$$

where $\varphi_0(\xi;\lambda) = \lim_{\lambda\to 0^+} \varphi(\xi;\lambda)$.

This equation has to be complemented with the boundary conditions (cf. (2.10), (2.11))

$$\varphi_0(0) = 8, \ \frac{\partial\varphi_0}{\partial\xi}(0) = 0. \tag{2.27}$$

The solution of (2.26), (2.27) is given by

$$\varphi_0 = \frac{8}{(1+\xi^2)^2}. \tag{2.28}$$

Then

$$\bar{U}(r;\lambda) \sim \frac{\lambda}{(1+\frac{\lambda r^2}{8})^2} \ \text{ as } \ \lambda \to 0^+ \tag{2.29}$$

whence the first formula from (2.24) follows. We will later need, in the study of the mechanism of the formation of the concentration regions, the first higher correction to (2.29). To this end, we just expand U, or, equivalently, φ in powers of λ. By assumption $Q(s)$ satisfies (1.4). We then look for φ in the form

$$\varphi = \varphi_0 + \frac{\alpha\lambda}{8}\varphi_1 + \dots, \tag{2.30}$$

where φ_0 is given by (2.28) and satisfies (2.26), (2.27). Standard computations show that φ_1 satisfies

$$\frac{1}{\xi}\frac{\partial}{\partial\xi}\left(\frac{\xi}{\varphi_0}\frac{\partial\varphi_1}{\partial\xi}\right) - \frac{1}{\xi}\frac{\partial}{\partial\xi}\left(\frac{\xi\varphi_1}{(\varphi_0)^2}\frac{\partial\varphi_0}{\partial\xi}\right) + \varphi_1 = -\frac{1}{\xi}\frac{\partial}{\partial\xi}\left(\xi\frac{\partial\varphi_0}{\partial\xi}\right), \tag{2.31}$$

$$\varphi_1(0) = 0. \tag{2.32}$$

A particular homogeneous solution of (2.31) can be obtained using the fact that there exists a transformation group of rescalings associated to (2.26). More precisely, given $\varphi_0(\xi)$, a solution of (2.26), it is possible to compute a one-parameter family of solutions given by $\varphi_{0,\lambda}(\xi) = \lambda\varphi_0(\sqrt{\lambda}\xi)$. Differentiating this formula, as well as the equation (2.26) with respect to λ at the particular value $\lambda = 1$, we obtain that the following function solves the homogeneous part of (2.31):

$$\varphi_{1,h}(\xi) = \left[\frac{16}{(1+\xi^2)^3} - \frac{8}{(1+\xi^2)^2}\right]. \tag{2.33}$$

The analysis of (2.31), (2.32) becomes simpler using as variable the mass of φ. This is commonly done in the study of radial solutions of the Keller–Segel model. Let us define

$$m(\xi) = \int_0^\xi \eta\varphi_1(\eta)d\eta. \tag{2.34}$$

Using (2.31) it then follows after some computations that m solves

$$\frac{1}{\varphi_0}\frac{\partial^2 m}{\partial\xi^2} - \left(\frac{\varphi_{0,\xi}}{\varphi_0^2} + \frac{1}{\varphi_0\xi}\right)\frac{\partial m}{\partial\xi} + m = -\xi\varphi_{0,\xi}. \tag{2.35}$$

A solution of the homogeneous equation associated to (2.35) can be obtained by applying the transformation (2.34) to (2.33). After multiplying the resulting solution by a constant due to the linearity of the problem we obtain

$$m_h(\xi) = \frac{\xi^2}{(1+\xi^2)^2}.$$

The solution of (2.35) can then be obtained using the standard variation of constants method. Looking for solutions of (2.35) in the form $m(\xi) = m_h(\xi)f(\xi)$ and using the fact that the boundary condition (2.32) combined with (2.31) implies $m(\xi) = O(\xi^2)$ as $\xi \to 0^+$, we obtain, after some computations,

$$m(\xi) = \frac{16}{3}\frac{\xi^2}{(1+\xi^2)^3}[\xi^4 + 4\xi^2 + 2(\xi^2+1)\log(\xi^2+1)]. \tag{2.36}$$

Using (2.34) and (2.36) it would be possible to compute $\varphi_1(\xi)$. Notice, however, that it will be more relevant for us to compute just the asymptotics of $M(\lambda)$ as $\lambda \to 0^+$. The definition (2.34) implies that the total contribution of $\varphi_1(\xi)$ to the mass $M(\lambda)$ is $\frac{\pi\alpha m(\infty)}{4}$ (cf. (2.30)). Using (2.36) it then follows that

$$M(\lambda) = 8\pi + \frac{4\pi\alpha\lambda}{3} + o(\lambda) \text{ as } \lambda \to 0^+. \tag{2.37}$$

The computed asymptotics (2.29), (2.37) will be useful in describing the formation of regions with high values of u.

Let us remark that the asymptotics of the solutions of (2.9)–(2.10) can be derived using standard asymptotic methods. It turns out that

$$M(\lambda) \sim \frac{2\pi a\lambda\nu_1}{\sqrt{L}} \text{ as } \lambda \to \infty, \tag{2.38}$$

where $a = |\frac{\partial J_0}{\partial r}(\nu_1)| = 0.51914750\ldots$, and ν_1 is the first root of the Bessel function J_0. □

3. Singular points dynamics. In this section we will formally derive a limit problem that describes the evolution of some solutions of (1.1)–(1.5) as $\varepsilon \to 0^+$.

Notice that the analysis of the steady states in section 2 shows the existence of stationary solutions of (1.1)–(1.2) having their mass concentrated in regions of size $\sqrt{\varepsilon}$ and an amount of mass $M \in (8\pi, +\infty)$. Our goal is to describe asymptotically solutions of (1.1)–(1.5) containing finite amounts of mass of u that are concentrated near some particular points $x_j(t)$. These regions will be termed from now on as concentration regions or singular points. In the neighborhoods of these singular points, solutions will be described by means of the steady states described in section 2. Although there are several differences at the technical level some of the ideas used in this section are closely related to the study of the so-called spike dynamics in reaction-diffusion equations that has been studied by several authors in both steady and evolution settings (cf. [2, 35, 36, 40, 50, 51]).

It is interesting to remark also that the evolution laws for the concentration regions have some analogies with the motion of a set of point vortices, a problem that has been thoroughly studied (cf. [43]). The analogies and differences of the resulting limit problem with the problem of vortex dynamics will be discussed in more detail below.

3.1. Global existence of solutions if $\varepsilon > 0$. The solutions of (1.1)–(1.5), in contrast to those of (1.6), (1.7), are globally defined in time in the following proposition.

PROPOSITION 3.1. *For any $u_0(\cdot) \in L^1(\mathbb{R}^2) \cap L^\infty(\mathbb{R}^2) \cap C^\alpha(\mathbb{R}^2)$, $u_0 \geq 0$, $0 < \alpha < 1$, for any $Q(\cdot) \in C^1(\mathbb{R}^+)$ satisfying (1.4), (1.5), and for any $\varepsilon > 0$, there exists a unique solution $u(\cdot) \in C([0,\infty], L^\infty(\mathbb{R}^2)) \cap C^\infty((0,\infty) \times \mathbb{R}^2)$ of (1.1)–(1.3) satisfying $u(x,t) = u_0(x)$ with v uniquely determined by means of the formula*

$$v(x,t) = -\frac{1}{2\pi} \int_{\mathbb{R}^2} \log(|x-y|) u(y,t) d^2y. \tag{3.1}$$

Remark 3.2. The choice of a particular v is required because for each given u, the solution of (1.2) is not uniquely determined without suitable growth estimates at infinity for v.

Proof of Proposition 3.1. Local existence can be obtained using classical methods of semigroup theory (cf. [15]). Indeed, (1.1), (1.2) can be rewritten as the fixed point problem

$$u(\cdot) = e^{t\Delta} u_0(\cdot) - \int_0^t e^{(t-s)\Delta} [\nabla (G_\varepsilon(u) \nabla v(\cdot, s))] ds \tag{3.2}$$

with v given by (3.1) and where $e^{t\Delta}$ is the heat semigroup in the whole plane that is given by the formula

$$e^{t\Delta} f(x) = \frac{1}{4\pi t} \int_{\mathbb{R}^2} e^{-\frac{(x-y)^2}{4t}} f(y) d^2y.$$

Classical potential theory (cf. [14]) shows that

$$\|\nabla v(\cdot, s)\|_{L^\infty(\mathbb{R}^2)} \leq C \|u(\cdot, s)\|_{L^\infty(\mathbb{R}^2)}. \tag{3.3}$$

On the other hand, regularity theory for parabolic equations (cf. [12]) yields

$$\left\|\nabla (e^{t\Delta} f(\cdot))\right\|_{L^\infty(\mathbb{R}^2)} \leq \frac{C}{\sqrt{t}} \|f(\cdot)\|_{L^\infty(\mathbb{R}^2)}. \tag{3.4}$$

Estimates (3.3), (3.4) can be used as it is usual in semigroup theory (cf. [15]) to obtain existence and uniqueness of a solution of (3.2) in $C([0,\infty], L^\infty(\mathbb{R}^2) \cap C^\alpha(\mathbb{R}^2))$. By classical regularity theory this solution is a classical solution (cf. [12]).

In order to show global existence notice that as long as u, solution of (1.1)–(1.3), is bounded in $L^\infty(\mathbb{R}^2)$, we have

$$\int_{\mathbb{R}^2} u(x,t)d^2x = \int_{\mathbb{R}^2} u_0(x)d^2x. \tag{3.5}$$

Using potential theory it follows that for this range of times

$$\|\nabla v(\cdot,t)\|_{L^\infty(\mathbb{R}^2)} \le C \int_{\mathbb{R}^2} u_0(x)d^2x. \tag{3.6}$$

On the other hand, using the boundedness Q, Q', as well as (1.2), we obtain

$$|\nabla(G_\varepsilon(u)\nabla v)| \le C\left(|\nabla v| + \frac{1}{\varepsilon}u\right).$$

The global boundedness of u, v (cf. (3.5), (3.6)) as well as regularity theory for parabolic equations then implies

$$\|u(\cdot,t)\|_{L^\infty(\mathbb{R}^2)} \le \frac{C}{\varepsilon}\int_{\mathbb{R}^2} u_0(x)d^2x,\ t>0 \tag{3.7}$$

whence the global existence of a classical solution follows. □

Remark 3.3. Estimate (3.7) is optimal in its ε dependence as will be checked in the asymptotic formulae computed in the next subsection.

3.2. Derivation of the equations of motion of the concentration regions. We now compute the "outer limit" that describes the solutions of (1.1)–(1.5) away from the concentration regions. Assuming for the moment that a given solution can be described by a family of concentration regions placed at some points $x = x_j(t)$, $j = 1, 2, \dots N$, having, respectively, masses $M_j(t)$, we can approximate u in the region $|x - x_j(t)| \gg \sqrt{\varepsilon}$ as

$$u \approx \sum_{j=1}^{N} M_j(t)\delta(x - x_j(t)) + u_{reg}(x,t), \tag{3.8}$$

where $M_j(t) > 8\pi,\ j = 1, 2, \dots N$, and $u_{reg}(x,t)$ is a bounded function that will be described in more detail later. To fix ideas we will assume that $u(\cdot,0) \in L^1(\mathbb{R}^2)$ and that problem (1.1)–(1.5) is solved in $\mathbb{R}^2 \times \mathbb{R}^+$. Moreover, as indicated in Proposition 3.1, we will determine uniquely v, solution of (1.2), by means of (3.1). Using (3.8), (3.1) it would follow that

$$v(x,t) \approx -\frac{1}{2\pi}\sum_{j=1}^{N} M_j(t)\log(|x - x_j(t)|) + v_{reg}(x,t), \tag{3.9}$$

where

$$v_{reg}(x,t) = -\frac{1}{2\pi}\int_{\mathbb{R}^2} \log(|x-y|)u_{reg}(y,t)d^2y. \tag{3.10}$$

By assumption in the outer region, $|x - x_j(t)| \gg \sqrt{\varepsilon}$, $u \ll \varepsilon^{-1}$, and therefore we can use the following approximation (cf. (1.3)):

$$G_\varepsilon(u) \approx u \ \text{ as } \ \varepsilon \to 0^+.$$

Taking into account (1.1) and (3.9) we then obtain the following equation for u_{reg} in the outer region as $\varepsilon \to 0^+$:

$$\frac{\partial u_{reg}}{\partial t} = \Delta u_{reg} + \frac{1}{2\pi} \sum_{j=1}^{N} M_j(t) \frac{(x - x_j(t))}{|x - x_j(t)|^2} \cdot \nabla u_{reg} - \nabla(u_{reg} \nabla v_{reg}), \tag{3.11}$$

where we have approximated u by u_{reg} in the outer region and where v_{reg} is given by (3.10).

It is interesting to remark that near any of the points $x = x_i(t)$, (3.11) can be approximated locally as

$$\frac{\partial u_{reg}}{\partial t} = \Delta u_{reg} + \frac{M_i(t)}{r_i} \cdot \frac{\partial u_{reg}}{\partial r_i} + \text{higher order terms},$$

where $r_i = |x - x_i(t)| \ll 1$. In other words, problem (3.11) behaves locally, near each point $x_i(t)$ as the heat equation in "space dimension" $(2 + \frac{M_i(t)}{2\pi})$. This feature suggests that (3.10), (3.11) complemented with suitable initial data is a well-posed mathematical problem (at least locally in time). This fact will be shown rigorously in [48]. The only crucial information needed at this stage is that problem (3.10), (3.11) admits solutions with bounded u_{reg}.

In order to compute the motion of the singular points, and also to show that the "ansatz" (3.8) leads to reasonable solutions of the original problem (1.1)–(1.5), we need to study in a detailed manner the "inner region" near each point $x = x_i(t)$. To this end we introduce a new set of inner variables:

$$u(x,t) = \frac{1}{\varepsilon} U(\xi, \tau), \tag{3.12}$$

$$x = x_i(t) + \sqrt{\varepsilon}\xi, \ t = \varepsilon\tau. \tag{3.13}$$

Using these variables (1.1)–(1.3) becomes

$$\frac{\partial U}{\partial \tau} - \sqrt{\varepsilon} \dot{x}_i(t) \nabla_\xi U = \Delta_\xi U - \nabla_\xi (Q(U) \nabla_\xi v), \tag{3.14}$$

$$\Delta_\xi v + U = 0. \tag{3.15}$$

We need to complement (3.14), (3.15) with suitable matching conditions. Notice that for bounded u_{reg}, there exists $\lim_{x \to x_i(t)} \nabla_x v_{reg}(x,t) = \nabla_x v_{reg}(x_i(t), t)$ (cf. (3.10)). Using (3.9) and (3.13) we obtain the following outer approximation for ∇v:

$$\nabla_\xi v \approx -\frac{M_i(t)}{2\pi} \cdot \frac{\xi}{|\xi|^2} + A_i(t)\sqrt{\varepsilon} \ \text{ as } \ |\xi| \gg 1, \ |x - x_i(t)| \ll 1, \tag{3.16}$$

where $A_i(t)$ is the vector

$$A_i(t) = -\sum_{j=1,\, j \neq i}^{N} \frac{M_j(t)}{2\pi} \cdot \frac{(x_i(t) - x_j(t))}{|x_i(t) - x_j(t)|^2} + \nabla_x v_{reg}(x_i(t), t). \tag{3.17}$$

The intuitive meaning of (3.16), (3.17) is rather clear. Indeed, notice that $A_i(t)$ is basically the "gravitational field" (that in the context of this problem is a "chemical field") induced by the singular points different from $x_i(t)$ plus a contribution due to the regular part of the concentration of organisms $u_{reg}(x_i(t), t)$.

To further simplify the problem (3.14)–(3.16) we introduce an auxiliary function ψ such that

$$v = \sqrt{\varepsilon} A_i(t) \cdot \xi + \psi.$$

Using this new variable instead of v, problem (3.14)–(3.16) becomes

$$\frac{\partial U}{\partial \tau} = \Delta_\xi U - \nabla_\xi (Q(U) \nabla_\xi \psi) + \sqrt{\varepsilon}[\dot{x}_i(t) \nabla_\xi U - A_i(t) \nabla_\xi (Q(U))], \tag{3.18}$$

$$\Delta_\xi \psi + U = 0, \tag{3.19}$$

$$\nabla_\xi \psi \sim -\frac{M_i(t)}{2\pi} \cdot \frac{\xi}{|\xi|^2} \text{ as } |\xi| \gg 1. \tag{3.20}$$

Notice that in the inner scale the time scale for stabilization of solutions to steady states is of order $t \approx \varepsilon$ (cf. (3.13)). Since these times are much shorter than those expected for having important variations of $z_i(t)$, $A_i(t)$, $M_i(t)$, we will assume that $z_i(t)$, $A_i(t)$, $M_i(t)$ are frozen and U, ψ have reached their equilibrium state in the time scale τ. In other words, we will approximate (3.18)–(3.20) by means of the steady state problem

$$\Delta_\xi U - \nabla_\xi (Q(U) \nabla_\xi \psi) + \sqrt{\varepsilon}[\dot{x}_i(t) \nabla_\xi U - A_i(t) \nabla_\xi (Q(U))] = 0, \tag{3.21}$$

$$\Delta_\xi \psi + U = 0 \tag{3.22}$$

complemented with (3.20). Since, as it will be checked below, the solutions of (3.21), (3.22) are close to the solutions of (2.5), (2.6) it follows that the main assumption that is implicitly made here is that the steady states obtained in section 2 are stable. The energy arguments in section 5 of [47] indicate that this is so.

In the limit $\varepsilon \to 0^+$ we can approximate (3.20)–(3.22) by means of the equation for the steady states described in section 2 (cf. (2.5), (2.6)):

$$\Delta_\xi \bar{U} - \nabla_\xi (Q(\bar{U}) \nabla_\xi \bar{v}) = 0, \tag{3.23}$$

$$\Delta_\xi \bar{v} + \bar{U} = 0, \tag{3.24}$$

$$\nabla_\xi \bar{v} \sim -\frac{M_i(t)}{2\pi} \cdot \frac{\xi}{|\xi|^2} \text{ as } |\xi| \gg 1. \tag{3.25}$$

It has been shown in section 2 that under assumption (2.20) the problem (3.23)–(3.25) admits a unique radial solution for each $M_i(t) > 8\pi$. Therefore we then obtain to the leading order the following approximation for U:

$$U \approx \bar{U}(\xi; \lambda_i(t)), \tag{3.26}$$

where we recall that $\bar{U}(\xi; \lambda)$ is the unique solution of (2.9)–(2.11). Notice that we are assuming that the value of λ_i that uniquely characterizes $\bar{U}$ is not fixed but changes in time. Moreover, we are assuming that this change of λ_i takes place in the time scale t. The fact that this is the right time scale for λ_i will be checked later "a posteriori," verifying the consistency of the derived asymptotics.

Our next goal is to show by means of a perturbative argument that it is possible to obtain solutions close to $(\bar{U}, \bar{\psi})$ and ε small enough for each value of $A_i(t)$ if $\dot{x}_i(t)$ is computed using a suitable compatibility condition. To this end we look for solutions of (3.23)–(3.25) in the form

$$U = \bar{U} + \sqrt{\varepsilon} U_1 + \varepsilon U_2 + \dots , \tag{3.27}$$

$$\psi = \bar{v} + \sqrt{\varepsilon} v_1 + \varepsilon v_2 + \dots . \tag{3.28}$$

Using these expansions and (3.21), (3.22) we obtain

$$\begin{aligned} -\Delta_\xi U_1 + \nabla_\xi (Q'(\bar{U}) \nabla_\xi \bar{v} U_1) + \nabla_\xi (Q(\bar{U}) \nabla_\xi v_1) = \\ \left[\dot{x}_i(t) \nabla_\xi \bar{U} - A_i(t) \nabla_\xi (Q(\bar{U})) \right] \equiv h, \end{aligned} \tag{3.29}$$

$$\Delta_\xi v_1 + U_1 = 0, \tag{3.30}$$

$$\begin{aligned} &- \Delta_\xi U_2 + \nabla_\xi (Q'(\bar{U}) \nabla_\xi \bar{v} U_2) + \nabla_\xi (Q(\bar{U}) \nabla_\xi v_2) \\ &= -\frac{\partial \bar{U}}{\partial \lambda} \frac{d\lambda}{dt}(t) + \nabla_\xi \left(Q'(\bar{U}) \nabla_\xi v_1 + \frac{1}{2} Q''(\bar{U}) \nabla_\xi \bar{v} U_1^2 \right) \\ &\quad + (A_i(t) \nabla_\xi (Q'(\bar{U}) U_1) - \dot{x}_{i,1}(t) \nabla_\xi \bar{U} - \dot{x}_{i,0}(t) \nabla_\xi U_1), \end{aligned} \tag{3.31}$$

$$0 = U_2 + \Delta_\xi v_2. \tag{3.32}$$

We begin analyzing the system (3.29)–(3.30). To this end it is convenient to rewrite this system in a more convenient manner. We define

$$F = U_1 - Q(\bar{U}) v_1. \tag{3.33}$$

Notice that (2.7) (with $c = 0$) implies $\nabla_\xi \bar{U} = Q(\bar{U}) \nabla_\xi \bar{v}$. Taking this into account (3.29), (3.30) become

$$\Delta_\xi F - \nabla_\xi \left(\frac{Q'(\bar{U}) \nabla_\xi \bar{U}}{Q(\bar{U})} F \right) + h = 0. \tag{3.34}$$

On the other hand, (3.30) can be rewritten as

$$\Delta_\xi v_1 + Q(\bar{U}) v_1 + F = 0. \tag{3.35}$$

Differentiating (3.24) with respect to ξ_k, $k = 1, 2$, and using that $\nabla_\xi \bar{U} = Q(\bar{U}) \nabla_\xi \bar{v}$, we obtain that $z_k = \frac{\partial \bar{v}}{\partial \xi_k}$ solves the equation

$$\Delta_\xi z_k + Q(\bar{U}) z_k = 0$$

or, in an equivalent manner, the functions z_i are eigenfunctions associated to a zero eigenvalue of the homogeneous part of (3.35) considering F as a source there. Therefore in order to solve the problem (3.34), (3.35) we need to impose the following compatibility condition:

$$\int_{\mathbb{R}^2} F z_k d^2\xi = \int_{\mathbb{R}^2} F \frac{\partial \bar{v}}{\partial \xi_k} d^2\xi = 0, \ k = 1, 2. \tag{3.36}$$

We need to reformulate the compatibility condition (3.36) in terms of function h in (3.34). To this end we define functions g_k as the solutions of the following equation:

$$\Delta_\xi (g_k) + \frac{Q'(\bar{U}) \nabla_\xi \bar{U}}{Q(\bar{U})} \cdot \nabla_\xi (g_k) = \frac{\partial \bar{v}}{\partial \xi_k}, \ k = 1, 2, \tag{3.37}$$

satisfying

$$g_k(\xi) = O(|\xi|) \text{ as } |\xi| \to 0, \tag{3.38}$$

$$g_k(\xi) = o(1) \text{ as } |\xi| \to \infty. \tag{3.39}$$

The main properties of the functions $g_k(\xi)$ are contained in the result that follows in Lemma 3.4.

LEMMA 3.4. *Problem* (3.37)–(3.39) *is uniquely solvable. The corresponding solutions have the form* $g_k(\xi) = \bar{g}(r)\frac{\xi_k}{|\xi|}$, *where* $r = |\xi|$ *and* $\bar{g}(r) > 0$ *for* $r > 0$ *and satisfies*

$$\bar{g}(r) = O(r) \text{ as } r \to 0, \tag{3.40}$$

$$\bar{g}(r) = o(1) \text{ as } r \to \infty. \tag{3.41}$$

Proof. Taking into account (3.37) it follows that $\bar{g}(r)$ solves

$$\bar{g}''(r) + \frac{1}{r}\bar{g}'(r) - \frac{\bar{g}(r)}{r^2} + \frac{Q'(\bar{U}(r))\bar{U}'(r)}{Q(\bar{U}(r))} \cdot \bar{g}'(r) = \bar{v}'(r). \tag{3.42}$$

Taking into account that (3.42) is a first order equation for $\bar{g}'(r)$ it follows that there exists at least one solution of (3.42) such that $\bar{g}(r) = O(r)$ as $r \to 0$ and $\bar{g}(r) = o(1)$ as $r \to \infty$. Uniqueness follows by means of a standard maximum principle argument. Uniqueness for (3.37)–(3.39) follows also by the maximum principle. Moreover, since $\bar{v}'(r) < 0$ it follows that $\bar{g}(r)$ solution of (3.42) is positive, since otherwise, due to the asymptotics of $\bar{g}$ as $r \to 0$ and $r \to \infty$, it would follow that $\bar{g}$ would have a negative minimum, but this is impossible due to the maximum principle argument. This concludes the proof of the lemma. ∎

Taking into account that the decay of g_i and their smoothness at the origin provide integrability for the integrals appearing in (3.36), we obtain that

$$\begin{aligned}\int_{\mathbb{R}^2} h g_k d^2\xi &= \int_{\mathbb{R}^2} \left[\Delta_\xi F - \nabla_\xi \left(\frac{Q'(\bar{U})\nabla_\xi \bar{U}}{Q(\bar{U})} F\right)\right] g_k d^2\xi \\ &= \int_{\mathbb{R}^2} F\left[\Delta_\xi(g_k) + \frac{Q'(\bar{U})\nabla_\xi \bar{U}}{Q(\bar{U})} \cdot \nabla_\xi(g_k)\right] d^2\xi \\ &= \int_{\mathbb{R}^2} F \frac{\partial \bar{v}}{\partial \xi_i} d^2\xi.\end{aligned}$$

The compatibility condition (3.36) then implies

$$\int_{\mathbb{R}^2} h g_k d^2\xi = 0, \ k = 1, 2. \tag{3.43}$$

Using (3.29) and (3.43) we obtain the following formula for $\dot{x}_i(t)$ to the leading order as $\varepsilon \to 0^+$:

$$\dot{x}_i(t) \int_{\mathbb{R}^2} g_k \nabla_\xi \bar{U} d^2\xi = A_i(t) \int_{\mathbb{R}^2} g_k \nabla_\xi (Q(\bar{U})) d^2\xi, \ k = 1, 2.$$

Since the angular dependence of g_k and $\frac{\partial \bar{U}}{\partial \xi_k}$ is the same, it follows that

$$\dot{x}_i(t) = \Gamma(M_i) A_i(t), \tag{3.44}$$

where we have defined

$$\Gamma(M) \equiv \frac{\int_{\mathbb{R}^2} g_1(\xi,\lambda(M))\frac{\partial}{\partial\xi_1}(Q(\bar U(\xi,\lambda(M))))d^2\xi}{\int_{\mathbb{R}^2} g_1(\xi,\lambda(M))\frac{\partial\bar U}{\partial\xi_1}(\xi,\lambda(M))d^2\xi},\ M>8\pi, \tag{3.45}$$

where $\lambda=\lambda(M)$ is the only value of λ associated to a given value of the mass $M>8\pi$ (cf. (2.11) and Proposition 2.2).

Relation (3.44) provides the law of motion for the concentration regions placed at $x=x_i(t)$, $i=1,\dots,N$.

For further reference we derive some estimates for $\Gamma(M)$ that will be included in the following lemma.

LEMMA 3.5. *The function* $\Gamma(M)$ *defined by* (3.45) *has the following properties:*

$$0<\Gamma(M)<1, \tag{3.46}$$

$$\lim_{M\to 8\pi^+}\Gamma(M)=1, \tag{3.47}$$

$$\lim_{M\to\infty}\Gamma(M)=0. \tag{3.48}$$

Proof. Using (3.45) we obtain

$$\Gamma(M)=\frac{\int_{\mathbb{R}^2} g_1 Q'(\bar U)\frac{\partial\bar U}{\partial\xi_1}d^2\xi}{\int_{\mathbb{R}^2} g_1\frac{\partial\bar U}{\partial\xi_1}d^2\xi}.$$

As indicated before, g_1 and $\frac{\partial\bar U}{\partial\xi_1}$ have a similar angular dependence $\cos(\theta)$. Moreover, as indicated in Lemma 3.4, g_1 can be written as $g_1=\bar g_1(|\xi|)\frac{\xi_1}{|\xi|}$ with $\bar g_1$ having a constant sign. Moreover, $\frac{\partial\bar U}{\partial\xi_1}=\bar U'(|\xi|)\frac{\xi_1}{|\xi|}$. Since $\bar U$ is decreasing on $|\xi|$ we obtain that $\frac{g_1\frac{\partial\bar U}{\partial\xi_1}}{\int_{\mathbb{R}^2} g_1\frac{\partial\bar U}{\partial\xi_1}d^2\xi}>0$. Therefore (2.22), (2.23), and (3.45) yield (3.46). The asymptotics (3.47) and (3.48) are a consequence of the asymptotics of $\bar U$ as $\lambda\to 0$ and $\lambda\to\infty$ as well as (1.4), (1.5) and the regularity properties of $Q(s)$. ∎

It is interesting to notice that the monotonicity of $\Gamma(M)$ on M as well as (3.44) implies that for a given value of $A_i(t)$ its effect on the velocity of the singular point is smaller. In other words, it is harder to move larger singular points, as could be expected in an intuitive manner.

We remark that the expansion (3.27), (3.28) loses its validity for $|\xi|$ large. Indeed (2.17), (2.19) imply $\bar U\sim\frac{\bar K(M_i)}{|\xi|^{\frac{M_i}{2\pi}}}$ as $|\xi|\gg 1$. Therefore for large $|\xi|$ we can approximate (3.34) as

$$\Delta_\xi F+\frac{M_i}{2\pi}\cdot\frac{\xi}{|\xi|^2}\nabla_\xi F=\frac{(\dot x_i(t)-A_i(t))M_i}{2\pi}\cdot\frac{\xi}{|\xi|^{\frac{M_i}{2\pi}+2}}.$$

The asymptotics for the solutions of this problem is given by

$$F\sim\frac{(\dot x_i(t)-A_i(t))\bar K(M_i)}{|\xi|^{\frac{M_i}{2\pi}-1}}\cdot\frac{\xi}{|\xi|}\ \text{ as }\ |\xi|\gg 1. \tag{3.49}$$

On the other hand, the leading terms in (3.35) as $|\xi|\to\infty$ are $\Delta_\xi v_1+F=0$. Using (3.49), as well as the fact that the angular dependence of v_1 is the same as that of $\dot x_i(t)\cdot\frac{\xi}{|\xi|}$, it follows that $v_1=O(\frac{1}{|\xi|})$ as $|\xi|\to\infty$. Therefore $U_1\sim F$ as $|\xi|\to\infty$. Taking into account (2.17) it then follows that the asymptotics (3.27) breaks down at distances $|\xi|\sim\frac{1}{\sqrt{\varepsilon}}$ or, equivalently, for $|x-x_i(t)|\approx 1$.

3.3. Computation of the rate of change of the concentration regions. Notice that the set of equations (3.10), (3.11), (3.44), (3.45) describes a set of equations for the concentration regions coupled with the external fields u_{reg}, v_{reg} that has to be completed with the evolution law for the mass of the concentration regions $M_i(t)$. Computing the evolution law for $M_i(t)$ is equivalent to computing that of $\lambda_i(t)$ (cf. (3.26)). This can be done by means of a matching condition between the outer contribution due to U_2 (cf. (3.27)) and the inner contribution due to u_{reg}. Although this detailed computation is interesting, in order to check the consistency of the obtained asymptotics we will compute the rate of change of $M_i(t)$ by means of a simpler argument in Lemma 3.6 that consists of directly computing the derivative of $M_i(t)$ using the asymptotics already computed.

LEMMA 3.6. *For the formal solutions of* (1.1)–(1.5) *that behave asymptotically as in* (3.8) *the rate of change of the mass of the concentration regions is given by*

$$\frac{dM_i(t)}{dt} = u_{reg}(x_i(t),t)M_i(t),\ i=1,\dots,N. \tag{3.50}$$

The time scale for stabilization of u in regions close to the concentration region is, up to logarithmic terms, of order ε. This is much shorter than the time scale associated to the macroscopic evolution of the system that is of order one. Therefore, in order to compute the amount of mass lost by $u_{reg}(x,t)$ in a neighborhood of each concentration region we can assume that it can be described by a steady state. We then fix $\delta>0$ small, and integrate (3.11) in a ball $B_\delta(x_i(t))$. After some integrations by parts we obtain

$$\begin{aligned}\frac{d}{dt}&\left(\int_{\mathcal{U}\setminus B_\delta(x_i(t))} u_{reg}d^2x\right)\\ &= -\int_{\partial B_\delta(x_i(t))}\frac{\partial u_{reg}}{\partial n}dS_x - \frac{1}{2\pi}\sum_{j=1}^N M_j(t)\int_{\partial B_\delta(x_i(t))} u_{reg}\frac{(x-x_j(t))\cdot n}{|x-x_j(t)|^2}dS_x\\ &\quad+\int_{\partial B_\delta(x_i(t))} u_{reg}\frac{\partial v_{reg}}{\partial n}dS_x + \int_{\partial\mathcal{U}} f(x,t)dS_x,\end{aligned} \tag{3.51}$$

where $\mathcal{U}$ is a domain whose size is of order one containing only the concentration region $x_i(t)$ and $f(x,t)$ are the fluxes of u away from $\mathcal{U}$. Notice that the last term on the right-hand side of (3.51) does not contribute to the variation of the mass of the concentration region in $x=x_i(t)$. On the other hand, the regularity properties of u_{reg}, v_{reg} (cf. [48]), show that in the limit $\delta\to 0$, the contribution of the first and third term on the right-hand side of (3.51) approaches zero. The same occurs with the contributions in the second term, except for the one due to $j=i$. Then, taking into account that the flux of u lost for u_{reg} yields an increase in $M_i(t)$, we obtain

$$\frac{dM_i(t)}{dt} = \frac{M_i(t)}{2\pi}\lim_{\delta\to 0}\left(\int_{\partial B_\delta(x_i(t))} u_{reg}(x,t)\frac{(x-x_i(t))\cdot n}{|x-x_i(t)|^2}dS_x\right),$$

and taking into account that $\int_{\partial B_\delta(x_i(t))}\frac{(x-x_i(t))\cdot n}{|x-x_i(t)|^2}dS_x = 2\pi$, we arrive at (3.50). ∎

Notice that since $\frac{dM_i(t)}{dt}\geq 0$, the mass of each concentration region is an increasing function, as could be expected on account of the attractive character for the organisms.

We summarize here the main result concerning the motion of the concentration regions as a formal theorem, with the understanding that the proof has been obtained only at the level of formal asymptotics.

THEOREM 3.7 (formal). *Suppose that u solves* (1.1)–(1.5). *It is possible to obtain formal asymptotic expansions for the solutions of* (1.1)–(1.5) *that in the limit $\varepsilon \to 0$ behave asymptotically as in* (3.8), *where the dynamics of u_{reg}, $x_i(t)$, $M_i(t)$ is given by the following set of equations:*

$$\frac{\partial u_{reg}}{\partial t} = \Delta u_{reg} + \frac{1}{2\pi}\sum_{j=1}^{N} M_j(t)\frac{(x - x_j(t))}{|x - x_j(t)|^2}\cdot \nabla u_{reg} - \nabla(u_{reg}\nabla v_{reg}), \tag{3.52}$$

$$v_{reg}(x,t) = -\frac{1}{2\pi}\int_{\mathbb{R}^2} \log(|x-y|)u_{reg}(y,t)d^2y, \tag{3.53}$$

$$\dot{x}_i(t) = \Gamma(M_i(t))A_i(t),\ i = 1,\dots,N, \tag{3.54}$$

$$A_i(t) = -\sum_{j=1,\, j\neq i}^{N} \frac{M_j(t)}{2\pi}\cdot\frac{(x_i(t) - x_j(t))}{|x_i(t) - x_j(t)|^2} + \nabla_x v_{reg}(x_i(t),t),\ i = 1,\dots,N, \tag{3.55}$$

$$\frac{dM_i(t)}{dt} = u_{reg}(x_i(t),t)M_i(t),\ i = 1,\dots,N, \tag{3.56}$$

where function $\Gamma(M)$ is given in (3.45).

Remark 3.8. Notice that all the dependence of the limit problem in the particular shape of the nonlinearity $G_\varepsilon(u)$ is contained in $\Gamma(M)$.

Remark 3.9. As indicated below there are some analogies between (3.52)–(3.56) and the equations for the evolution of a set of point vortices (cf. [43]). In both cases a set of points moves with a velocity that can be obtained by adding the contributions of the other points. In both cases the interaction between the points decays according to the law $\frac{1}{r}$. A first difference is that in the case of the concentration regions obtained above the interaction between points follows a Newtonian gravitational law. On the contrary, in the case of vortices this interaction law should be replaced by the formula of the velocity induced by a fluid at a given point by a vortex line, which must be computed using Biot–Savart's law. In (3.52)–(3.56) there is also a background field u_{reg} interacting with the concentration regions. It is possible to also imagine situations in fluid mechanics where a background vorticity field could interact with a set of point vortices. There are, of course, several differences between both problems, but also enough analogies to suggest that perhaps some of the methods of analysis used in the theory of point vortices could have some usefulness for the study of (3.52)–(3.56).

Remark 3.10. The set of equations (3.52)–(3.56) is the main result of section 3. This problem defines an evolution problem for the points $x = x_i(t)$, whose dynamics is coupled with that of the fields u_{reg}, v_{reg}. Due to the fact that the domain where the problem has to be solved is not prescribed, but is part of the problem to be solved, the mathematical well-posedness of this system of equations is not standard. A rigorous analysis of the well-posedness of this problem can be found in [48]. This well-posedness result can be expected only locally in time because there are at least two different ways in which the solution of the problem (3.52)–(3.56) might develop singularities in a finite time. First, solutions could have additional blow-ups analogous to those considered in [17, 18, 19] at points where u, v are bounded for previous times. On the other hand, concentration regions could coalesce and merge in a finite time. Indeed, if two concentration regions at positions $x_k(t), x_\ell(t)$ are close enough, their

motion could be approximated by means of the system of ODEs (cf. (3.55))

$$\dot{x}_k(t) = -\frac{\Gamma(M_k(t))M_\ell(t)}{2\pi} \cdot \frac{(x_k(t) - x_\ell(t))}{|x_k(t) - x_\ell(t)|^2},$$
$$\dot{x}_\ell(t) = -\frac{\Gamma(M_\ell(t))M_k(t)}{2\pi} \cdot \frac{(x_\ell(t) - x_k(t))}{|x_\ell(t) - x_k(t)|^2}.$$

Therefore

$$\frac{d}{dt}(x_k(t) - x_\ell(t)) = -\frac{(\Gamma(M_\ell(t))M_k(t) + \Gamma(M_\ell(t))M_k(t))}{2\pi} \cdot \frac{(x_\ell(t) - x_k(t))}{|x_\ell(t) - x_k(t)|^2}.$$

Since the coalescence process is rather fast, the masses of the concentration regions can be considered to be constant during the process. If we denote the coalescence time as t^*, then it follows that

$$|x_\ell(t) - x_k(t)| \sim \sqrt{C(t^* - t)} \text{ as } t \to t^*, \tag{3.57}$$

where $C = \frac{(\Gamma(M_\ell(t^*))M_k(t^*) + \Gamma(M_\ell(t^*))M_k(t^*))}{4\pi}$. It then follows that the velocities of the concentration regions would become singular at $t = t^*$. One could also imagine coalescence of more than two concentration regions simultaneously, but such events should be "nongeneric." Clearly, in the original problem (1.1)–(1.5) functions u, v would have a complicated shape during this process that will not be considered here. In particular this analysis does not establish in a completely rigorous manner that the solutions of (1.1)–(1.5) would collapse as indicated in (3.57) if $\varepsilon > 0$. In a strict sense (3.57) holds only for the limit equations (3.52)–(3.56). In order to obtain rigorous coalescence results for the solutions (1.1)–(1.5) a careful analysis of the dynamics of two merging concentration regions should be made. It is unlikely that this could be achieved by means of explicit analytic formulae. In particular the quasi-steady approximation (3.21)–(3.22) would not hold during the whole coalescence process.

3.4. Analysis of a boundary layer in the inner region. In order to conclude this section we will verify that due to (3.56) (cf. (3.50)) it is possible to match the inner expansion (3.27) with the outer contribution of u as $x \to x_i(t)$ that is just given by $u_{reg}(x_i(t), t)$. This will be done to check the consistency of the computed asymptotics. In order to avoid tedious computations just a sketch of the main arguments will be given. We recall that (U_2, v_2) solves the system (3.31), (3.32). We introduce a new variable as

$$F_2 = U_2 - Q(\bar{U})v_2. \tag{3.58}$$

Then (3.31) becomes

$$\begin{aligned} &-\Delta_\xi F_2 + \nabla_\xi(Q'(\bar{U})\nabla_\xi \bar{v} F_2) \\ &= -\frac{\partial \bar{U}}{\partial \lambda}\frac{d\lambda}{dt}(t) + \nabla_\xi\left(Q'(\bar{U})\nabla_\xi v_1 + \frac{1}{2}Q''(\bar{U})\nabla_\xi \bar{v} U_1^2\right) \\ &-\dot{x}_{i,1}(t)\nabla_\xi \bar{U} + (A_i(t)\nabla_\xi(Q'(\bar{U})U_1) - \dot{x}_{i,0}(t)\nabla_\xi U_1). \end{aligned} \tag{3.59}$$

Let us denote as θ the angle that makes a given direction with the direction of $A_i(t)$. In another words, given a vector ξ, we define θ by means of

$$A_i(t) \cdot \frac{\xi}{|\xi|} = |A_i(t)| \cos(\theta). \tag{3.60}$$

Taking into account the invariance under rotations of (3.29) and (3.30), and also that the term h in (3.29) has the form $h(\xi,t)=\tilde{h}(r,t)\cos(\theta)$, where $r=|\xi|$, it follows, using separation of variables, that U_1, v_1 have the particular form

$$U_1=\tilde{U}_1(r)\cos(\theta),\ v_1=\tilde{v}_1(r)\cos(\theta), \tag{3.61}$$

where $\tilde{U}_1(r)$, $\tilde{v}_1(r)$ solve a system of ordinary differential equations whose precise form will not be needed here, and where from now on, by simplicity, we will not write explicitly the dependence of the different functions on t,λ. The only relevant information about $\tilde{U}_1(r)$, $\tilde{v}_1(r)$ that we will need is that both functions are bounded in compact sets, and that, due to (3.30), (3.33), and (3.49), they satisfy the inequalities

$$\tilde{U}_1=O\left(\frac{1}{r^{\frac{M_i}{2\pi}-1}}\right),\ \tilde{v}_1=O\left(\frac{1}{r}\right)\ \text{ as }\ r\to\infty. \tag{3.62}$$

We now proceed to simplify the different terms on the right-hand side of (3.59). First, notice that $\bar{U}=\bar{U}(r;\lambda)$ is radial for each λ. Therefore $\frac{\partial\bar{U}}{\partial\lambda}$ is a radial function. On the other hand, using the formula $\cos^2(\theta)=\frac{1+\cos(2\theta)}{2}$, as well as the formulae for the gradient and the divergence of a function in polar coordinates, it can be seen after some computations that

$$\nabla_\xi\left(Q'(\bar{U})\nabla_\xi v_1+\frac{1}{2}Q''(\bar{U})\nabla_\xi\bar{v}U_1^2\right)=\frac{1}{2r}\frac{\partial}{\partial r}(rf_0(r))+f_1(r)\cos(2\theta)\\ +f_2(r)\sin(2\theta),$$

where f_2, f_3 are bounded functions that decay fast enough as $r\to\infty$ and $f_0(r)$ is given by

$$f_0(r)=Q'(\bar{U}(r))\tilde{U}_1(r)\tilde{v}_1'(r)+\frac{1}{2}Q''(\bar{U}(r))\bar{v}'(r)(\tilde{U}_1(r))^2. \tag{3.63}$$

The term $-\dot{x}_{i,1}(t)\nabla_\xi\bar{U}$ gives a contribution with the angular dependence $\cos(\theta)$. The contribution of this term can be analyzed exactly as it was analyzed for the terms U_1, v_1. Finally, using (3.54) and (3.60), as well as the formulae $\cos^2(\theta)=\frac{1+\cos(2\theta)}{2}$, $\sin^2(\theta)=\frac{1-\cos(2\theta)}{2}$, it follows after some computations that the last term in (3.59) can be written as

$$(A_i(t)\nabla_\xi(Q'(\bar{U})U_1)-\dot{x}_{i,0}(t)\nabla_\xi U_1)=\frac{1}{r}\frac{\partial}{\partial r}(rg_0(r))+g_1(r)\cos(2\theta),$$

where $g_0(r)$, $g_1(r)$ are bounded functions, $g_1(r)$ decays fast enough as $r\to\infty$, and $g_0(r)$ satisfies

$$g_0(r)=\frac{|A_i(t)|}{2}[\Gamma(M_i)\tilde{U}_1(r)-Q'(\bar{U}(r))\tilde{U}_1(r)]=O\left(\frac{1}{r^{\frac{M_i}{2\pi}-1}}\right)\ \text{ as }\ r\to\infty. \tag{3.64}$$

Function F_2 can be decomposed as $F_2=\tilde{F}_{2,0}(r)+\tilde{F}_{2,1}(r)\cos(\theta)+\tilde{F}_{2,2,1}(r)\cos(2\theta)+\tilde{F}_{2,2,2}(r)\sin(2\theta)$. The main contribution to U_2 as $r\to\infty$ is due to the radial term $\tilde{F}_{2,0}(r)$ that solves the ODE

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial\tilde{F}_{2,0}}{\partial r}\right)-\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{Q'(\bar{U})\bar{U}'}{Q(\bar{U})}\tilde{F}_{2,0}\right)\\ +\frac{1}{r}\frac{\partial}{\partial r}(r(g_0(r)+f_0(r)))=\frac{\partial\bar{U}}{\partial\lambda}\dot{\lambda}_i(t).$$

We can write $\tilde{F}_{2,0} = \tilde{F}_{2,0,1} + \tilde{F}_{2,0,2}$, where $\tilde{F}_{2,0,1}$, $\tilde{F}_{2,0,2}$ solve, respectively, the equations

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \tilde{F}_{2,0,1}}{\partial r}\right) - \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{Q'(\bar{U})\bar{U}'}{Q(\bar{U})}\tilde{F}_{2,0,1}\right) + \frac{1}{r}\frac{\partial}{\partial r}(r(g_0(r)+f_0(r))) = 0 \tag{3.65}$$

and

$$\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial \tilde{F}_{2,0,2}}{\partial r}\right) - \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{Q'(\bar{U})\bar{U}'}{Q(\bar{U})}\tilde{F}_{2,0,2}\right) = \frac{\partial \bar{U}}{\partial \lambda}\dot{\lambda}_i(t). \tag{3.66}$$

Integrating (3.65) once it is possible to find $\tilde{F}_{2,0,1}$ in an elementary manner. After some elementary computations we obtain

$$\tilde{F}_{2,0,1} = aQ(\bar{U}) - Q(\bar{U}(r)) \cdot \int_0^r \frac{[g_0(\eta)+f_0(\eta)]}{Q(\bar{U}(\eta))}d\eta,$$

where a is a real constant. Using (1.4), (2.17), (3.63), (3.64) and the fact that $\frac{M_i}{2\pi} > 4$, it follows that $\lim_{r\to\infty} \tilde{F}_{2,0,1} = 0$. It remains only to compute the contribution due to $\tilde{F}_{2,0,2}$. To this end, notice that after multiplying (3.66) by r, integrating, and after solving the resulting differential equation we arrive at

$$\tilde{F}_{2,0,2} = \dot{\lambda}_i(t)Q(\bar{U}(r))\int_0^r \left[\int_0^\eta \xi\frac{\partial \bar{U}}{\partial \lambda}(\xi)d\xi\right]\frac{d\eta}{\eta Q(\bar{U}(\eta))} + bQ(\bar{U}(r)),$$

where b is a real number. Using (1.4), (2.17) it follows that

$$\begin{aligned}\lim_{r\to\infty}\tilde{F}_{2,0,2} &= \left[\dot{\lambda}_i(t)\int_0^\infty s\frac{\partial \bar{U}}{\partial \lambda}(s)ds\right]\lim_{r\to\infty}\left[Q(\bar{U}(r))\int_0^r \frac{d\eta}{\eta Q(\bar{U}(\eta))}\right] \\ &= \frac{2\pi\dot{\lambda}_i(t)}{M_i(t)}\int_0^\infty s\frac{\partial \bar{U}}{\partial \lambda}(s)ds.\end{aligned}$$

To compute $\int_0^\infty s\frac{\partial \bar{U}}{\partial \lambda}(s)ds$ we differentiate (2.9) with respect to λ. Multiplying by r and integrating on $r > 0$, we then obtain

$$\begin{aligned}\int_0^\infty s\frac{\partial \bar{U}}{\partial \lambda}(s)ds &= \lim_{r\to\infty}\left[\frac{r}{\bar{U}^2}\frac{\partial \bar{U}}{\partial \lambda}\frac{\partial \bar{U}}{\partial r} - \frac{r}{\bar{U}}\frac{\partial}{\partial r}\left(\frac{\partial \bar{U}}{\partial \lambda}\right)\right] \\ &= -\lim_{r\to\infty}\left[r\frac{\partial}{\partial r}\left(\frac{\partial(\log(\bar{U}))}{\partial \lambda}\right)\right] = \frac{M_i'(\lambda)}{2\pi}.\end{aligned}$$

Therefore

$$\lim_{r\to\infty}\tilde{F}_{2,0,2} = \frac{1}{M_i(t)}\frac{dM_i(t)}{dt}.$$

Then using (1.4), (2.17), (3.32), (3.58) as well as the fact that the only term in F_2 that yields a nonzero contribution in the matching condition is $\tilde{F}_{2,0,2}$ we obtain the matching condition

$$U_2 \sim \frac{1}{M_i(t)}\frac{dM_i(t)}{dt}$$

as $|\xi| \gg 1$, $|x - x_i(t)| \ll 1$. Taking into account (2.17), (3.12), (3.27), and (3.49) we obtain the matching condition

$$u_{inner} \sim \frac{1}{M_i(t)} \frac{dM_i(t)}{dt},$$

as $|\xi| \gg 1$, $|x - x_i(t)| \ll 1$. Assuming, as we would expect, that u_{inner} coincides with $u_{reg}(x_i(t), t)$ that provides the outer contribution to u as $\varepsilon \to 0^+$, we then obtain the equation

$$u_{reg}(x_i(t), t) = \frac{1}{M_i(t)} \frac{dM_i(t)}{dt}$$

that is equivalent to (3.56). Therefore the consistency of the computed asymptotics follows.

4. Concluding remarks. In this paper a system of equations for the dynamics of a set of points whose evolution is coupled with a parabolic-elliptic system has been derived (cf. (3.52)–(3.56)). This system has been obtained by taking as the starting point a singular perturbation problem for a system of equations of the Keller–Segel type (cf. (1.6), (1.7)). The manner in which these singular points can develop in a finite time by means of a blow-up mechanism for the solutions of the limit problem has also been described. The significance of the derived results is that they provide a natural way of continuing the solutions of the limit problem (1.1), (1.2) after Dirac mass formation takes place for this model.

5. Appendix: Proof of Proposition 2.2. In this appendix we prove Proposition 2.2. Let us define $F(r) = \int_0^r \xi U(\xi) d\xi$. Using (2.9) we obtain

$$F_{rr} - \frac{F_r}{r} + Q\left(\frac{F_r}{r}\right) F = 0, \tag{5.1}$$

and (2.11) implies

$$F(r) \sim \frac{\lambda r^2}{2} \quad \text{as} \quad r \to 0^+. \tag{5.2}$$

We will denote as $F(r)$ the solution of (5.1), (5.2), although occasionally the notation $F(r, \lambda)$ will be used if the dependence on λ plays a crucial role.

Let us introduce the new variable

$$r = e^{\xi - \frac{1}{2}\log(\lambda)}. \tag{5.3}$$

Using ξ as the new variable, (5.1) becomes

$$F_{\xi\xi} - 2F_\xi + \frac{e^{2\xi}}{\lambda} Q(\lambda e^{-2\xi} F_\xi) F = 0, \tag{5.4}$$

or, in an equivalent manner,

$$F_\xi = V, \tag{5.5}$$

$$V_\xi = 2V - \frac{e^{2\xi}}{\lambda} Q(\lambda e^{-2\xi} V) F, \tag{5.6}$$

where (5.2) implies the condition

$$F \sim \frac{e^{2\xi}}{2},\ V \sim e^{2\xi} \ \text{ as } \ \xi \to -\infty. \tag{5.7}$$

Notice that assumption (2.20) implies

$$\frac{e^{2\xi}}{\lambda} Q(\lambda e^{-2\xi} V) < \lim_{\theta \to \infty} \left[\theta Q\left(\frac{V}{\theta}\right) \right] = V. \tag{5.8}$$

Let us denote as $(\bar{F}, \bar{V})$ the solution of

$$\bar{F}_\xi = \bar{V}, \tag{5.9}$$

$$\bar{V}_\xi = 2\bar{V} - \bar{V}\bar{F} \tag{5.10}$$

satisfying (5.7). Function $(\bar{F}, \bar{V})$ is easily computed and is given by

$$\bar{F} = \frac{4}{(1 + 8e^{-2\xi})},\ \bar{V} = \frac{64e^{-2\xi}}{(1 + 8e^{-2\xi})^2},\ \bar{V} = 2\bar{F} - \frac{(\bar{F})^2}{2}.$$

On the other hand, using (5.8) it follows, arguing by comparison, that (F, V) satisfies

$$V > 2F - \frac{F^2}{2},\ F > 0. \tag{5.11}$$

Actually, a similar argument can be applied to any two values of λ. Given $\lambda_1 < \lambda_2$, let us consider the corresponding solutions of (5.5)–(5.7) and let us denote them as (F_1, V_1), (F_2, V_2), respectively. Using (5.1), (5.2) it follows that

$$F_i(r) \sim \frac{\lambda_i r^2}{2} - \frac{Q(\lambda_i)\lambda_i}{16} r^4 + \dots \ \text{ as } \ r \to 0, \ \ i = 1, 2,$$

or, equivalently, using (5.3),

$$F_i \sim \frac{e^{2\xi}}{2} - \frac{Q(\lambda_i)}{16\lambda_i} e^{4\xi} \ \text{ as } \ \xi \to -\infty,\ i = 1, 2, \tag{5.12}$$

$$V_i \sim e^{2\xi} - \frac{Q(\lambda_i)}{4\lambda_i} e^{4\xi} \ \text{ as } \ \xi \to -\infty,\ i = 1, 2. \tag{5.13}$$

Therefore

$$V_i = 2F_i - \frac{Q(\lambda_i)}{2\lambda_i} (F_i)^2 + \dots \ \text{ as } \ \xi \to -\infty,\ i = 1, 2. \tag{5.14}$$

By (2.20), $\frac{Q(\lambda_1)}{\lambda_1} > \frac{Q(\lambda_2)}{\lambda_2}$. Then, for F small enough we have

$$V_2(F) > V_1(F). \tag{5.15}$$

We can deduce some general properties of F, the solution of (5.1), (5.2). Combining (5.5), (5.11) we easily obtain

$$\liminf_{r \to \infty} F(r) \geq 4 \tag{5.16}$$

for any $\lambda > 0$. Using (5.1) we obtain $F_{rr} \leq \frac{F_r}{r}$, whence $\frac{F_r}{r} \leq C$. Notice that (1.3), (1.4) imply $Q(\xi) \geq \beta\xi$ for $\xi \in (0, C)$. Using these estimates and (5.16) it then follows using (5.1) that

$$F_{rr} - \frac{\beta}{r} F_r \leq 0$$

for some $\beta < 1$ and r large enough. Then $F_r \leq C_1 + C_2 r$, whence $\lim_{r\to\infty}(\frac{F_r}{r}) = 0$. Therefore, it is possible to approximate (5.1) as $r \to \infty$, by means of the equation $F_{rr} - \frac{F_r}{r} + \frac{FF_r}{r} = 0$. Moreover, since $F \geq 4 - \delta_0$, as $r \to \infty$ for some $\delta_0 > 0$, it then follows that F approaches a constant value as $r \to \infty$:

$$\lim_{r\to\infty} F(r) = M(\lambda) < +\infty. \tag{5.17}$$

In order to show the monotonicity of $M(\lambda)$ we will show that (5.15) is satisfied for all the values of F, and not only for small values of F. Suppose that there exists $\tilde{F} > 0$ such that $V_2(\tilde{F}) = V_1(\tilde{F}) \equiv \tilde{V}$. Let us denote as $\xi_i(\tilde{F})$, $i = 1, 2$, the corresponding value of ξ where this identity is reached. Using (5.5) it follows that

$$\int_{F_i(\xi)}^{\tilde{F}} \left(\frac{1}{V_i(f)} - \frac{1}{2f} \right) df + \frac{1}{2} \log \left(\frac{\tilde{F}}{F_i(\xi)} \right) = \xi_i(\tilde{F}) - \xi, \ i = 1, 2.$$

Using (5.7) and taking the limit $\xi \to -\infty$ it then follows that

$$\int_0^{\tilde{F}} \left(\frac{1}{V_i(f)} - \frac{1}{2f} \right) df + \frac{1}{2} \log(\tilde{F}) = \xi_i(\tilde{F}), \ i = 1, 2. \tag{5.18}$$

Using (5.15) we then obtain that $\xi_2(\tilde{F}) < \xi_1(\tilde{F})$. Since $\lambda_2 > \lambda_1$ it follows from (2.20) that

$$\frac{e^{2\xi_2(\tilde{F})}}{\lambda_2} Q(\lambda_2 e^{-2\xi_2(\tilde{F})} \tilde{V}) < \frac{e^{2\xi_1(\tilde{F})}}{\lambda_1} Q(\lambda_1 e^{-2\xi_1(\tilde{F})} \tilde{V}),$$

and using (5.5), (5.6) we then obtain that at the intersection point $(\tilde{F}, \tilde{V})$ it holds that

$$\frac{dF_1}{d\xi}(\xi_1(\tilde{F})) = \frac{dF_2}{d\xi}(\xi_2(\tilde{F})),$$
$$\frac{dV_1}{d\xi}(\xi_1(\tilde{F})) < \frac{dV_2}{d\xi}(\xi_2(\tilde{F})),$$

or, equivalently, $\frac{dV_1}{dF} < \frac{dV_2}{dF}$. However, this is impossible due to (5.15) that was satisfied for $0 < F < \tilde{F}$. Hence, (5.15) holds during the whole evolution of the trajectories in the upper plane. Using this, it then follows that

$$\frac{M(\lambda_1)}{2\pi} = F_\infty \equiv \lim_{r\to\infty} F_1(r) \leq \lim_{r\to\infty} F_2(r) = \frac{M(\lambda_2)}{2\pi}.$$

Actually, this inequality is strict. In order to show that, we argue as follows. Notice that (5.15) and (5.18) imply

$$\xi_2(F) < \xi_1(F). \tag{5.19}$$

Combining (5.5) and (5.6) we obtain

$$\frac{dV_i}{dF} = 2 - \frac{e^{2\xi_i(F)}}{\lambda_i} Q(\lambda_i e^{-2\xi_i(F)} V_i) \frac{F}{V_i},\ i = 1, 2, \tag{5.20}$$

where $V_i = V_i(F)$. Using (5.19) and taking into account (2.20) as well as the fact that $\lambda_2 > \lambda_1$, it follows that

$$\frac{e^{2\xi_2(F)}}{\lambda_2} Q(\lambda_2 e^{-2\xi_2(F)} V_2) < \frac{e^{2\xi_1(F)}}{\lambda_1} Q(\lambda_1 e^{-2\xi_1(F)} V_2).$$

On the other hand, (2.20) and (5.15) imply

$$\frac{Q(aV_2)}{V_2} = \frac{V_1}{V_2} \frac{Q\left(a \frac{V_1}{V_1/V_2}\right)}{V_1} < \frac{Q(aV_1)}{V_1}.$$

Therefore

$$\frac{e^{2\xi_2(F)}}{\lambda_2} \frac{Q(\lambda_2 e^{-2\xi_2(F)} V_2)}{V_2} < \frac{e^{2\xi_1(F)}}{\lambda_1} \frac{Q(\lambda_1 e^{-2\xi_1(F)} V_1)}{V_1}. \tag{5.21}$$

Using (5.20) and (5.21) we obtain

$$\frac{d(V_2 - V_1)}{dF} = \left[\frac{e^{2\xi_1(F)}}{\lambda_1} \frac{Q(\lambda_1 e^{-2\xi_1(F)} V_1)}{V_1} - \frac{e^{2\xi_2(F)}}{\lambda_2} \frac{Q(\lambda_2 e^{-2\xi_2(F)} V_2)}{V_2} \right] > 0, \tag{5.22}$$

an inequality that remains valid as long as $V_i(F),\ i = 1, 2$. Combining (5.15), (5.22) we then obtain that since $V_1(F_\infty) = 0$, we have $V_2(F) > 0$. Henceforth

$$\lim_{r \to \infty} F_2(r) > F_\infty.$$

In order to conclude the proof of Proposition 2.2 it remains to show that $\lim_{\lambda \to 0^+} M(\lambda) = 8\pi$ and $\lim_{\lambda \to \infty} M(\lambda) = \infty$ (or, in an equivalent manner, $F(\infty, \lambda) \to 4$ as $\lambda \to 0^+$, $F(\infty, \lambda) \to \infty$ as $\lambda \to \infty$). In section 2 we have already obtained these asymptotics in a formal manner. We provide here a rigorous proof of them. Taking into account the monotonicity of $V(F)$ on λ it follows that $V(F) \to \bar{V}(F)$ as $\lambda \to 0^+$, where $(\bar{F}, \bar{V})$ is the solution of (5.9), (5.10) satisfying (5.7), whence the computation concerning the first limit follows. On the other hand, a comparison argument shows that $F \leq \frac{e^{2\xi}}{2}$, $V \leq e^{2\xi}$. For ξ of order one (perhaps large) and V positive of order one, we have (cf. (1.3)) $\frac{e^{2\xi}}{\lambda} Q(\lambda e^{-2\xi} V) \to 0$ as $\lambda \to \infty$. Taking into account (5.5), (5.6) it then follows that F becomes arbitrarily large if λ is large. Henceforth $\lim_{\lambda \to \infty} F(\infty, \lambda) = \infty$. □

POINT DYNAMICS IN A SINGULAR LIMIT OF THE KELLER–SEGEL MODEL 2: FORMATION OF THE CONCENTRATION REGIONS*

J. J. L. VELÁZQUEZ†

Abstract. This paper continues the analysis started in the first part of this article (cf. [J. J. L. Velázquez, *SIAM J. Appl. Math.*, 64 (2004), pp. 1198–1223]). It was seen there, using the method of matched asymptotics, that a regularized version of the Keller–Segel system admits, for a suitable asymptotic limit, solutions with some regions of high concentrations for the cell density. This paper considers the relation between the phenomenon of blow-up for the limit problem and the dynamics of the concentration regions described in [J. J. L. Velázquez, *SIAM J. Appl. Math.*, 64 (2004), pp. 1198–1223]. In particular, this paper analyzes the precise way in which the regularization introduced in the Keller–Segel system stops the aggregation process and yields the formation of concentration regions.

Key words. chemotaxis, singular perturbations, matched asymptotics

1. Introduction.

The purpose of this paper is to continue the analysis begun in [22]. That paper studied a regularized version of a Keller–Segel model whose solutions blow-up in finite time.

A characteristic feature of some of the models that have been introduced in the literature to describe chemotactic aggregation is that in some cases their solutions blow-up in a finite time. This is a well-known fact, for instance, for the Keller–Segel model (cf. [16]). In particular, the study of blow-up for this model has received a lot of attention in recent years (cf. [1], [2], [3], [5], [6], [7], [8], [9], [10], [12], [13], [14], [15], [17], [18], [19], [21]).

The presence or absence of blow-up for each particular form of the Keller–Segel model, as well as the asymptotics of the solutions near the blow-up time, depends very sensitively on the choice of the aggregation function that measures cell sensitivity to the gradient of chemicals. In particular, for chemotactic functions that are linear in the cell concentration, the solutions of the resulting Keller–Segel model yield in some general circumstances Dirac mass aggregation in finite time (cf. [8], [9]).

In [22] we addressed the problem of describing the behavior of the solutions of a Keller–Segel system whose chemotactic function behaves linearly for values of the cell concentration that are not too high but are saturating to a constant value for high cell concentrations.

In a more precise manner, the problem considered in this paper is the following:

$$\frac{\partial u}{\partial t} = \Delta u - \nabla(G_\varepsilon(u)\nabla v), \quad x \in \mathbb{R}^2,\ t > 0, \tag{1.1}$$

$$\Delta v + u = 0, \quad x \in \mathbb{R}^2,\ t > 0, \tag{1.2}$$

where u denotes the concentration of the organism and v is the concentration of the

chemical secreted by it. We will make the following choice of chemotactic function:

$$G_\varepsilon(u) = \frac{1}{\varepsilon} Q(\varepsilon u), \tag{1.3}$$

where $\varepsilon > 0$ is a small parameter, and the function $Q(\xi)$ is an increasing function satisfying

$$Q(s) = s - \alpha s^2 + \cdots \quad \text{as } s \to 0, \tag{1.4}$$

$$Q(s) \sim L \quad \text{as } s \to \infty, \tag{1.5}$$

where $L > 0$, $\alpha > 0$ are given numbers. A typical example would be $Q(s) = \frac{s}{1+s}$. In other words, instead of assuming that the chemotactic function $G_\varepsilon(u)$ increases without limit as the concentration of the organism becomes high, it will be assumed that the mobility of the organism saturates to a constant value. Other choices of $G_\varepsilon(u)$ would be certainly possible, but we will use this particular one just for the sake of simplicity.

System (1.1)–(1.5) is a particular case of the Keller–Segel model. Let us remark that for $\varepsilon = 0$ the system (1.1)–(1.5) formally becomes

$$\frac{\partial u}{\partial t} = \Delta u - \nabla(u \nabla v), \quad x \in \mathbb{R}^2,\ t > 0, \tag{1.6}$$

$$\Delta v + u = 0, \quad x \in \mathbb{R}^2,\ t > 0. \tag{1.7}$$

It is known that solutions of the problem (1.6), (1.7) might blow-up in a finite time $T > 0$ (cf. [4], [8], [15], [17]). As long as u, v remain bounded, the limit from (1.1)–(1.5) to (1.6), (1.7) does not pose any serious mathematical problem. However, the situation becomes mathematically more interesting for times $t > T$, because the solutions of (1.1)–(1.5) are globally defined in time, something that does not occur for the solutions of (1.6), (1.7). It is then natural to ask what happens to the solutions of (1.1)–(1.5) as $\varepsilon \to 0$ and $t > T$.

In [22] it was seen that it is possible to obtain using matched asymptotics a set of solutions of the regularized problem (1.1)–(1.5) that in the limit $\varepsilon \to 0$ can be decomposed in a regular part plus a set of "concentration regions" where the values of u are very high, containing an amount of mass of order one in a very localized region. Such solutions behave asymptotically as

$$u \approx \sum_{i=1}^{N} M_i(t) \delta(x - x_i(t)) + u_{reg}(x,t), \tag{1.8}$$

where $u_{reg}(x,t)$ is a bounded function.

The detailed dynamics of the points $x_i(t)$, as well as their masses $M_i(t)$ and the values of $u_{reg}(x,t)$, has been derived in [22].

The goal of this paper is to verify that the fact that the solutions of (1.6), (1.7) might blow-up in a finite time provides a mechanism of transition between bounded solutions of (1.1)–(1.5), i.e., solutions containing only the regular part $u_{reg}(x,t)$ and solutions containing concentration regions as in (1.8). More precisely, we will describe how the blow-up mechanism described in [8], [9] evolves in a short transition time to a region of high density as those described in [22].

The detailed manner in which this transition from a "blowing up" regime evolves to a "quasi-steady regime" characterized by high cell densities depends on some details

of the function $Q(\cdot)$ given above. Nevertheless, only a few characteristics of the function $Q(\cdot)$ play a crucial role, namely, the precise quadratic corrective behavior as $s \to 0$ given in (1.4). The analysis in this paper should be modified for nonlinearities $Q(\cdot)$ having corrective behaviors different from the one given in (1.4). In any case, the goal of this paper is not to obtain the most general description of the transition between the blowing up regime and the quasi-steady regime, but only to point out that this feature takes place and to describe methods for performing the analysis of such transitions.

In section 2 of this paper the main characteristics of the blow-up mechanism for (1.6), (1.7) obtained in [8], [9] will be recalled. Section 3 summarizes some of the basic properties of the stationary states of (1.1)–(1.5) that have been derived in [22]. Section 4 describes in a detailed manner the transition between the blowing up regime and the quasi-steady regime.

2. Formation of concentration regions: The limit $\varepsilon = 0$. In this section we recall the mechanism of Dirac mass formation described in [8], [9] for the system (1.6), (1.7).

The main idea of this section is the following. For u bounded we can approximate (1.1), (1.2) in the limit $\varepsilon \to 0$ by the simpler model (1.6), (1.7).

It is a well-known fact that solutions of (1.6), (1.7) might develop singularities in finite time (cf. [4], [8], [15], [17]). Moreover, such solutions develop Dirac masses containing exactly the amount of mass 8π (cf. [8], [9], [18]) in a finite time, which will be denoted henceforth as $t = T > 0$.

Let us state in Theorem 2.1 the main result that will be recalled in this section.

THEOREM 2.1. *There exists a solution of* (1.6), (1.7) *that yields concentration of an amount of mass* 8π *at the origin. The asymptotics of this solution near the origin is given by*

$$u(x,t) \sim \frac{8}{(T-t)(\varepsilon(|\log(T-t)|))^2} \frac{1}{\left(1 + \frac{|x|^2}{(T-t)(\varepsilon(|\log(T-t)|))^2}\right)^2}$$

for $|x| = O(\varepsilon(|\log(T-t)|)\sqrt{(T-t)})$ *and* $t \to T^-$, *where the asymptotics* $\varepsilon(\tau)$ *is given by*

$$\varepsilon(\tau) \sim 2e^{-\frac{2+\gamma}{2}} e^{-\sqrt{\tau/2}} \left(1 + O\left(\frac{\log(\tau)}{\sqrt{\tau}}\right)\right) \quad \text{as } \tau \to \infty \tag{2.1}$$

and where $\gamma = 0.5772156\ldots$ *is the classical Euler constant.*

Theorem 2.1 has been proved rigorously in [8]. In this section we will just provide a formal description of the considered solution. Two other different ways of computing asymptotic descriptions of the sought-for solutions can be found in [9], [21]. Nevertheless, the variables used in this section to compute the asymptotics of the desired solution are more convenient than the previous ones, keeping in mind the analysis in section 4.

Formal proof of Theorem 2.1. It is convenient to introduce a "mass variable" as is usually done in the study of radial problems. Let $M(r,t)$ be

$$M(r,t) = \int_0^r \xi u(\xi,t) d\xi. \tag{2.2}$$

The name "mass variable" is due to the fact that $M(r,t)$ is, except for a factor 2π, the amount of mass of u in a ball of radius $B_r(0)$.

Differentiating (2.2) and using (1.2) we obtain

$$u(r,t) = \frac{1}{r}\frac{\partial M}{\partial r}, \tag{2.3}$$

$$\frac{\partial v}{\partial r} = -\frac{M}{r}. \tag{2.4}$$

Integrating (1.1) in a ball $B_r(0)$ and using (2.3), (2.4) we obtain

$$\frac{\partial M}{\partial t} = r\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial M}{\partial r}\right) + G_\varepsilon\left(\frac{M_r}{r}\right)M. \tag{2.5}$$

In the limit $\varepsilon = 0$, (2.5) becomes

$$\frac{\partial M}{\partial t} = r\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial M}{\partial r}\right) + \frac{MM_r}{r}, \tag{2.6}$$

that is, the parabolic equation that we would obtain applying the transformation (2.2) to the system (1.6), (1.7).

A crucial role in the analysis of the considered singularity formation mechanism is played by the steady state

$$\bar{M}(r) = \frac{4r^2}{r^2+1}. \tag{2.7}$$

In order to study the sought-for singularity formation mechanism it is convenient to introduce self-similar variables

$$M(r,t) = \bar{\Phi}\left(\frac{r}{\sqrt{T-t}}, -\log(T-t)\right), \quad \bar{y} = \frac{r}{\sqrt{T-t}}, \quad \bar{\tau} = -\log(T-t), \tag{2.8}$$

where $t = T$ is the blow-up time. The reason for writing bars above all the variables is that a set of slightly different variables (without bars) will be used later in section 4 to analyze the problem in the case $\varepsilon > 0$. In this set of variables (2.6) becomes

$$\bar{\Phi}_{\bar{\tau}} = \bar{y}\frac{\partial}{\partial \bar{y}}\left(\frac{1}{\bar{y}}\frac{\partial \bar{\Phi}}{\partial \bar{y}}\right) - \frac{1}{2}\bar{y}\bar{\Phi}_{\bar{y}} + \frac{1}{\bar{y}}\bar{\Phi}\bar{\Phi}_{\bar{y}}. \tag{2.9}$$

The singular solution described in [8] behaves like the steady state (2.7) in the region $|\bar{y}| \to 0$ after a suitable rescaling. In order to compute in a precise manner the size of such a region we introduce a new variable by means of

$$\bar{\xi} = \frac{\bar{y}}{\bar{\delta}(\bar{\tau})}, \tag{2.10}$$

where the undetermined function $\bar{\delta}(\bar{\tau})$ approaches zero as $\bar{\tau} \to \infty$.

Using $\bar{\xi}$ as a new space variable (1.6) reads as

$$\bar{\Phi}_{\bar{\tau}} = \frac{1}{\bar{\delta}^2}\left[\bar{\xi}\frac{\partial}{\partial \bar{\xi}}\left(\frac{1}{\bar{\xi}}\frac{\partial \bar{\Phi}}{\partial \bar{\xi}}\right) + \frac{1}{\bar{\xi}}\bar{\Phi}\frac{\partial \bar{\Phi}}{\partial \bar{\xi}}\right] + \frac{\bar{\delta}_{\bar{\tau}}}{\bar{\delta}}\bar{\xi}\frac{\partial \bar{\Phi}}{\partial \bar{\xi}} - \frac{\bar{\xi}}{2}\frac{\partial \bar{\Phi}}{\partial \bar{\xi}}. \tag{2.11}$$

In order to compute $\bar{\delta}(\bar{\tau})$ we need to obtain two terms in the asymptotics of $\bar{\Phi}(\bar{\xi},\bar{\tau})$ as $\bar{\tau} \to \infty$. By assumption, to the leading order, we have $\bar{\Phi}(\bar{\xi},\bar{\tau}) \to \bar{M}(\bar{\xi})$ as $\bar{\tau} \to \infty$. It is then natural to try an expansion of the form

$$\bar{\Phi}(\bar{\xi},\bar{\tau}) = \bar{M}(\bar{\xi}) + \psi(\bar{\xi},\bar{\tau}) + \cdots, \tag{2.12}$$

where $|\psi| \ll 1$ as $\bar{\tau} \to \infty$. Linearizing and keeping only the leading terms in (1.6) we obtain

$$\bar{\xi}\frac{\partial}{\partial\bar{\xi}}\left(\frac{1}{\bar{\xi}}\frac{\partial\psi}{\partial\bar{\xi}}\right)+\frac{1}{\bar{\xi}}\bar{M}(\bar{\xi})\frac{\partial\psi}{\partial\bar{\xi}}+\frac{1}{\bar{\xi}}\psi\frac{\partial\bar{M}}{\partial\bar{\xi}}=\left(\frac{\bar{\delta}^2}{2}-\bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\bar{\xi}\frac{\partial\bar{M}}{\partial\bar{\xi}}. \tag{2.13}$$

Since $\varphi(\bar{\xi})=\frac{\bar{\xi}^2}{(\bar{\xi}^2+1)^2}$ solves the homogeneous problem associated to (1.6), we can solve this problem by looking for solutions in the form

$$\psi(\bar{\xi},\bar{\tau})=\varphi(\bar{\xi})F(\bar{\xi},\bar{\tau}). \tag{2.14}$$

Therefore

$$\bar{\xi}\frac{\partial}{\partial\bar{\xi}}\left(\frac{1}{\bar{\xi}}\frac{\partial F}{\partial\bar{\xi}}\right)+\frac{4}{(\bar{\xi}^2+1)}\left(\frac{1}{\bar{\xi}}\frac{\partial F}{\partial\bar{\xi}}\right)=8\left(\frac{\bar{\delta}^2}{2}-\bar{\delta}\bar{\delta}_{\bar{\tau}}\right). \tag{2.15}$$

We can assume without loss of generality that $F(0,\bar{\tau})=0$. Otherwise ψ would contain a contribution of the form $F(0,\bar{\tau})\varphi(\bar{\xi})$, where by hypothesis, $F(0,\bar{\tau})\to 0$ as $\bar{\tau}\to\infty$. Since the homogeneous solution $\varphi(\bar{\xi})$ is associated to the infinitesimal changes of $\bar{M}(\bar{\xi})$ due to the application of the rescaling group of (2.6), it would be possible to eliminate $F(0,\bar{\tau})$ by means of a change of $\bar{\delta}(\bar{\tau})$. In an equivalent way, the choice $F(0,\bar{\tau})=0$ is just a way of prescribing $\bar{\delta}(\bar{\tau})$ in a precise manner. In particular, using (2.2) and (1.6), it follows that the choice $F(0,\bar{\tau})=0$ is equivalent to setting $\frac{8}{(\bar{\delta}(\bar{\tau}))^2}=u(0,t)$. The factor 8 has been introduced in order to obtain some simpler formulae later.

Solving (2.15) with the additional condition $F(0,\bar{\tau})=0$ we obtain

$$F(\bar{\xi},\bar{\tau})=4\left(\frac{\bar{\delta}^2}{2}-\bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\int_0^{\bar{\xi}}\frac{(\eta^2+1)^2}{\eta^3}\left[\log(\eta^2+1)-\frac{\eta^2}{\eta^2+1}\right]d\eta. \tag{2.16}$$

Standard computations yield the following asymptotics for $F(\bar{\xi},\bar{\tau})$ as $\bar{\xi}\to\infty$:

$$F(\bar{\xi},\bar{\tau})\sim 4\left(\frac{\bar{\delta}^2}{2}-\bar{\delta}\bar{\delta}_{\bar{\tau}}\right)[\bar{\xi}^2\log(\bar{\xi})-\bar{\xi}^2+O((\log(\bar{\xi}))^2)]\quad\text{as }\bar{\xi}\to\infty. \tag{2.17}$$

Combining (2.8), (2.12) and the asymptotics (2.17) we obtain the following matching condition:

$$\bar{\Phi}(\bar{\xi},\bar{\tau})\sim\frac{4\bar{\xi}^2}{(\bar{\xi}^2+1)}+4\left(\frac{\bar{\delta}^2}{2}-\bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\left[\log(\bar{\xi})-1+O\left(\frac{(\log(\bar{\xi}))^2}{\bar{\xi}^2}\right)\right] \tag{2.18}$$

for $\bar{\xi}\gg 1$, $\bar{y}\ll 1$, $\bar{\tau}\to\infty$.

We now describe the asymptotics of $\bar{\Phi}$ on the "outer region" $\bar{y}\sim 1$. To this end we linearize (1.6) around its limit value $\bar{\Phi}_\infty=4$. More precisely, let us write

$$\bar{\Phi}=4+\psi. \tag{2.19}$$

Then ψ solves

$$\psi_{\bar{\tau}}=\psi_{\bar{y}\bar{y}}+\frac{3}{\bar{y}}\psi_{\bar{y}}-\frac{\bar{y}\psi_{\bar{y}}}{2}+\frac{(\bar{\Phi}-4)}{\bar{y}}\bar{\Phi}_{\bar{y}}. \tag{2.20}$$

At first glance it could seem possible to neglect the term $\frac{(\bar\Phi-4)}{\bar y}\bar\Phi_{\bar y} = \frac{\psi\psi_{\bar y}}{\bar y}$ that is quadratic on ψ. It turns out, however, that this is not possible, because this term yields a relevant contribution in the region $\bar y \approx \bar\delta(\bar\tau)$. Using the approximation $\bar\Phi \sim \bar M(\bar\xi)$ in the region $\bar y \approx \bar\delta(\bar\tau)$ we obtain

$$\frac{(\bar\Phi-4)}{\bar y}\bar\Phi_{\bar y} \approx -\frac{1}{\bar\delta^2}\cdot\frac{32}{(\bar\xi^2+1)^3} \quad \text{as } \bar\tau\to\infty.$$

Notice that the operator $\partial^2_{\bar y}+\frac{3}{\bar y}\partial_{\bar y}$ that appears on the right-hand side of (1.7) is the Laplacian acting on radial functions in four spatial dimensions. Since $\frac{(\bar\Phi-4)}{\bar y}\bar\Phi_{\bar y}$ is concentrated in the region $\bar y \approx \bar\delta(\bar\tau)$ it would be natural to approximate this term by some kind of Dirac mass function, but due to the dimensionality of the Laplacian operator in (1.7) the mass of the singular part has to be computed in four dimensions. Using the fact that $\Gamma \equiv \int_{\mathbb{R}^4}\frac{d^4\bar\xi}{(\bar\xi^2+1)^3} = \frac{\pi^2}{2}$, it is natural to approximate (2.20) as

$$\psi_{\bar\tau} = \psi_{\bar y\bar y} + \frac{3}{\bar y}\psi_{\bar y} - \frac{\bar y\psi_{\bar y}}{2} - 32\Gamma(\bar\delta(\bar\tau))^2\delta^{(4)}(\bar y), \tag{2.21}$$

where $\delta^{(4)}(\bar y)$ is a four-dimensional Dirac mass. In order to study (1.7) it is convenient to decompose ψ as

$$\psi(\bar y,\bar\tau) = \bar a_0(\bar\tau) + Q(\bar y,\bar\tau), \tag{2.22}$$

where $\langle Q,1\rangle = 0$, and where from now on,

$$\langle f,g\rangle = \int_{\mathbb{R}^4} f(\bar y)g(\bar y)e^{-\frac{|\bar y|^2}{4}}d^4\bar y. \tag{2.23}$$

It then follows that

$$\dot a_0(\bar\tau) = -\frac{32\Gamma}{\langle 1,1\rangle}(\bar\delta(\bar\tau))^2 = -(\bar\delta(\bar\tau))^2, \tag{2.24}$$

where we have used the fact that $\langle 1,1\rangle = 32\Gamma$.

Notice that $\psi\to 0$ as $\bar\tau\to\infty$. Therefore

$$\bar a_0(\bar\tau) = \int_{\bar\tau}^{\infty}(\bar\delta(s))^2 ds. \tag{2.25}$$

On the other hand, $Q(\bar y,\bar\tau)$ solves

$$Q_{\bar\tau} = Q_{\bar y\bar y} + \frac{3}{\bar y}Q_{\bar y} - \frac{\bar yQ_{\bar y}}{2} - 32\Gamma(\bar\delta(\bar\tau))^2\left[\delta^{(4)}(\bar y) - \frac{1}{\langle 1,1\rangle}\right]. \tag{2.26}$$

The function $\bar\delta(\bar\tau)$ does not contain exponential factors in its asymptotics (cf. [8]), or in a more precise way, we can assume that $|\frac{\bar\delta_{\bar\tau}}{\bar\delta}| \ll 1$. It then follows that we can approximate $Q(\bar y,\bar\tau)$ as the unique solution of

$$0 = Q_{\bar y\bar y} + \frac{3}{\bar y}Q_{\bar y} - \frac{\bar yQ_{\bar y}}{2} - 32\Gamma(\bar\delta(\bar\tau))^2\left[\delta^{(4)}(\bar y) - \frac{1}{\langle 1,1\rangle}\right] \tag{2.27}$$

satisfying $\langle Q, 1\rangle = 0$. The general solution of (2.27) is

$$Q(\bar{y},\bar{\tau}) = (\bar{\delta}(\bar{\tau}))^2 \left[-\frac{4}{\bar{y}^2} + 2\log(\bar{y}) + B\right],$$

where $B \in \mathbb{R}$ has to be obtained using the orthogonality condition $\langle Q, 1\rangle = 0$. It then follows, after some computations, that $B = \gamma - \log(4)$, where $\gamma = 0.577215\ldots$, is the standard Euler constant. Therefore

$$Q(\bar{y},\bar{\tau}) = \Omega(\bar{y})(\bar{\delta}(\bar{\tau}))^2, \tag{2.28}$$

where $\Omega(\bar{y}) \equiv [-\frac{4}{\bar{y}^2} + 2\log(\bar{y}) + \gamma - \log(4)]$.

In order to obtain a matching condition between the inner and the outer expansion we need to compute an additional term in the asymptotics of $Q(\bar{y},\bar{\tau})$. We write

$$Q(\bar{y},\bar{\tau}) = \Omega(\bar{y})(\bar{\delta}(\bar{\tau}))^2 + R(\bar{y},\bar{\tau}), \tag{2.29}$$

where R satisfies

$$2\bar{\delta}\bar{\delta}_{\bar{\tau}}\Omega(\bar{y}) + R_{\bar{\tau}} = R_{\bar{y}\bar{y}} + \frac{3}{\bar{y}}R_{\bar{y}} - \frac{\bar{y}R_{\bar{y}}}{2}, \quad \langle R, 1\rangle = 0. \tag{2.30}$$

The "algebraic-like" behavior of R (i.e., the absence of exponential terms), suggests that approximating $R(\bar{y},\bar{\tau})$ to the leading order as $R(\bar{y},\bar{\tau}) = \bar{\delta}\bar{\delta}_{\bar{\tau}}W(\bar{y})$, where $W(\bar{y})$, solves

$$2\Omega(\bar{y}) = W_{\bar{y}\bar{y}} + \frac{3}{\bar{y}}W_{\bar{y}} - \frac{\bar{y}W_{\bar{y}}}{2}, \quad \langle W, 1\rangle = 0. \tag{2.31}$$

It is possible to obtain an explicit formula for $W(\bar{y})$, but since it will not be needed for our purposes we will not pursue that here. The only information that we will need about $W(\bar{y})$ is the asymptotics

$$W(\bar{y}) \sim -4\log(\bar{y}) + \zeta + o(1) \quad \text{as } \bar{y} \to 0, \tag{2.32}$$

where ζ is a real number whose precise numerical value will not be of relevance here.

Let us summarize. We have obtained the following asymptotics for $\bar{\Phi}$ in the region $\bar{y} \sim 1$ (cf. (2.19), (2.22), (2.25), (2.28)):

$$\bar{\Phi}(\bar{y},\bar{\tau}) = \int_{\bar{\tau}}^{\infty} (\bar{\delta}(s))^2 ds + \Omega(\bar{y})(\bar{\delta}(\bar{\tau}))^2 + \bar{\delta}(\bar{\tau})\bar{\delta}_{\bar{\tau}}(\bar{\tau})W(\bar{y}) + \cdots \tag{2.33}$$

as $\bar{\tau} \to \infty$.

Using the asymptotics of $\Omega(\bar{y})$, $W(\bar{y})$ as $\bar{y} \to 0^+$ we obtain the following outer matching condition:

$$\begin{aligned}\bar{\Phi}(\bar{y},\bar{\tau}) \sim 4 - \frac{4(\bar{\delta}(\bar{\tau}))^2}{\bar{y}^2} + \int_{\bar{\tau}}^{\infty} (\bar{\delta}(s))^2 ds + 2(\bar{\delta}(\bar{\tau}))^2\log(\bar{y}) \\ +(\gamma - \log(4))(\bar{\delta}(\bar{\tau}))^2 - 4\bar{\delta}(\bar{\tau})\bar{\delta}_{\bar{\tau}}(\bar{\tau})\log(\bar{y}) + \zeta\bar{\delta}(\bar{\tau})\bar{\delta}_{\bar{\tau}}(\bar{\tau}) + \cdots\end{aligned} \tag{2.34}$$

for $\bar{\delta}(\bar{\tau}) \ll |\bar{y}| \ll 1$ and $\bar{\tau} \to \infty$.

On the other hand, using that $\bar{\xi} = \frac{\bar{y}}{\bar{\delta}(\bar{\tau})}$ as well as (1.6) we obtain the following inner matching condition:

$$\begin{aligned}\bar{\Phi}(\bar{y},\bar{\tau}) \sim 4 - \frac{4(\bar{\delta}(\bar{\tau}))^2}{\bar{y}^2} + 4\left(\frac{\bar{\delta}^2}{2} - \bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\log(\bar{y}) - 4\left(\frac{\bar{\delta}^2}{2} - \bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\log(\bar{\delta}) \\ - 4\left(\frac{\bar{\delta}^2}{2} - \bar{\delta}\bar{\delta}_{\bar{\tau}}\right) + \cdots\end{aligned} \tag{2.35}$$

for $\bar{\delta}(\bar{\tau}) \ll |\bar{y}| \ll 1$ and $\bar{\tau} \to \infty$.

Matching (2.34), (2.35) we obtain the following integral equation:

$$\begin{aligned}\int_{\bar{\tau}}^{\infty} (\bar{\delta}(s))^2 ds + (\gamma - \log(4))(\bar{\delta}(\bar{\tau}))^2 + \zeta\bar{\delta}(\bar{\tau})\bar{\delta}_{\bar{\tau}}(\bar{\tau}) \\ = -2(\bar{\delta}^2 - 2\bar{\delta}\bar{\delta}_{\bar{\tau}})\log(\bar{\delta}) - 2(\bar{\delta}^2 - 2\bar{\delta}\bar{\delta}_{\bar{\tau}}).\end{aligned} \tag{2.36}$$

The solution of (2.36) that approaches zero as $\bar{\tau} \to \infty$ behaves asymptotically as

$$\bar{\delta}(\bar{\tau}) \sim 2e^{-\frac{(\gamma+2)}{2}} e^{-\sqrt{\frac{\bar{\tau}}{2}}}(1 + o(1)) \quad \text{as } \bar{\tau} \to \infty. \tag{2.37}$$

Using the set of original variables x, t (cf. (2.8)), (2.37) means that the mass is concentrated in a region of size

$$|x| \sim 2e^{-\frac{(\gamma+2)}{2}}\sqrt{T-t}\, e^{-\sqrt{\frac{|\log(T-t)|}{2}}}(1 + o(1)) \quad \text{as t} \to \text{T}^-, \tag{2.38}$$

that is, exactly the size computed in [21]. A similar formula, where some of the numerical constants have not been computed in so detailed a manner and containing some typographical mistakes, can be found in [9]. This concludes the description of the formal argument behind the proof of Theorem 2.1. □

Let us remark that the blow-up profile $M(r,T)$ can also be computed. To this end we argue as follows. We fix $\bar{y}_0 > 0$ large enough and t_0 close to T. Taking into account (2.8) and (2.34) it follows that

$$M(r,t_0) \sim 4 + \int_{\bar{\tau}_0}^{\infty} (\bar{\delta}(s))^2 ds$$

for $r \sim \bar{y}_0\sqrt{T-t_0}$, $\bar{\tau}_0 = -\log(T-t_0)$. Using (2.37) we obtain the approximation

$$M(r,t_0) \sim 4 + 4e^{-(\gamma+2)}\sqrt{2\bar{\tau}_0}\, e^{-\sqrt{2\bar{\tau}_0}}, \quad r \sim \bar{y}_0\sqrt{T-t_0}. \tag{2.39}$$

Notice that for $t_0 < t < T$, (2.6) implies that $M(r,t)$ remains nearly constant on a set of the form $r \in [(\bar{y}_0 - C)\sqrt{T-t_0}, (\bar{y}_0 + C)\sqrt{T-t_0}]$ if $C < \bar{y}_0$ and C, $\bar{y}_0$ are chosen large enough. This is due to the fact that for times $(T-t_0)$, perturbations propagate at most distances of order $\sqrt{T-t_0}$ for the solutions of the parabolic equation (2.6). Using this fact, as well as (2.39), it follows that

$$M(r,T) \sim 4 + 4e^{-(\gamma+2)}\sqrt{2\bar{\tau}_0}\, e^{-\sqrt{2\bar{\tau}_0}}, \quad r \sim \bar{y}_0\sqrt{T-t_0}.$$

Since $\bar{\tau}_0 = -\log(\frac{r^2}{\bar{y}_0}) \sim -\log(r^2)$ as $r \to 0^+$ for each fixed $\bar{y}_0$, we have

$$M(r,T) \sim 4 + 8e^{-(\gamma+2)}\sqrt{|\log(r)|}\, e^{-2\sqrt{|\log(r)|}} \tag{2.40}$$

as $r \to 0^+$.

To conclude this section, let us remark that it is also possible to compute the asymptotics of $M(r,t)$ for $t \to T^+$, something that will be needed in order to derive a description of the precise manner in which the concentration region begins to increase its mass. Notice that the asymptotics (2.40), as well as the definition of $M(r,t)$ (cf. (2.2)), indicates the presence of a Dirac mass placed at $r = 0$, with a total amount of mass 8π. Actually, it is possible to obtain the desired asymptotics as follows. Near the origin $M \sim 4$, whence (2.6) can be approximated by the linear equation $M_t = M_{rr} + \frac{3}{r} M_r$ that is just the usual heat equation in dimension four. More precisely, replacing M by the new variable

$$\varphi = M - 4 \tag{2.41}$$

and neglecting quadratic terms on φ in (2.6), we obtain the equation

$$\varphi_t = \varphi_{rr} + \frac{3}{r}\varphi_r. \tag{2.42}$$

This equation can be solved using as initial data the function φ in (2.40), (2.41) and caloric kernels. Therefore, to the leading order,

$$\varphi(r,t) = \frac{1}{(4\pi(t-T))^2} \int_{\mathbb{R}^4} e^{-\frac{(x-\bar{\xi})^2}{4(t-T)}} \varphi(|\bar{\xi}|, T) d^4\bar{\xi}, \tag{2.43}$$

where $r = |x|$ and $\varphi(r,T) \sim 8e^{-(\gamma+2)}\sqrt{|\log(r)|}e^{-2\sqrt{|\log(r)|}}$ as $r \to 0^+$. In order to compute the asymptotics of $\varphi(r,t)$ as $t \to T^+$ it is convenient to deal in a different manner with the regions $|x| \le C\sqrt{t-T}$ and $|x| \gg \sqrt{t-T}$. Let us define $\bar{y} = \frac{x}{\sqrt{t-T}}$. Notice that (2.43) implies

$$\varphi(r,t) = \frac{1}{(4\pi)^2} \int_{\mathbb{R}^4} e^{-\frac{(\bar{y}-\eta)^2}{4}} \varphi(|\eta|\sqrt{t-T}, T) d^4\eta.$$

Using this formula, we obtain for $|\bar{y}| \le C$ the asymptotics

$$\begin{aligned} \varphi(r,t) \sim{}& 4e^{-(\gamma+2)}\sqrt{2|\log(t-T)|}e^{-\sqrt{2|\log(t-T)|}} \cdot \\ &\cdot \left\{ 1 - \frac{1}{\sqrt{|\log(t-T)|}} \frac{1}{(4\pi)^2} \int_{\mathbb{R}^4} e^{-\frac{(\bar{y}-\eta)^2}{4}} \log(|\eta|) d^4\eta + \cdots \right\} \end{aligned} \tag{2.44}$$

as $t \to T^+$.

Assume on the contrary that $\sqrt{t-T} \ll |x| \ll 1$. We then define $\bar{y}$ by means of

$$|\bar{\xi}| = r_0 + \bar{y}\sqrt{t-T},$$

where $r_0 = |x|$, $\sqrt{t-T} \ll r_0 \ll 1$.

Using the asymptotics of $\varphi(r,T)$ it follows that

$$\varphi(|\bar{\xi}|, T) \sim \varphi(r_0, T)$$

as $r_0 \to 0$. Using this as well as (2.43) it then follows that

$$\varphi(r_0,t) \sim \varphi(r_0,T) \sim 8e^{-(\gamma+2)}\sqrt{|\log(r_0)|}e^{-2\sqrt{|\log(r_0)|}}. \tag{2.45}$$

It is not hard to check that (2.44) and (2.45) match for $|\bar{y}| \gg 1$.

For further reference we notice that we have found the following formula for the amount of mass concentrated at the concentration region (cf. (2.44)):

$$m(t) \sim 8\pi \left(1 + e^{-(\gamma+2)}\sqrt{2|\log(t-T)|}e^{-\sqrt{2|\log(t-T)|}} + \cdots\right) \quad \text{as t} \to \text{T}^+. \tag{2.46}$$

3. Steady states. In this section, we recall the basic properties of the steady states of (1.1), (1.2) that have been obtained in [22]. More precisely we consider the radial solutions of the system

$$\Delta\bar{u} - \nabla(G_\varepsilon(\bar{u})\nabla\bar{v}) = 0, \quad x \in \mathbb{R}^2, \tag{3.1}$$

$$\Delta\bar{v} + \bar{u} = 0, \quad x \in \mathbb{R}^2, \tag{3.2}$$

where $G_\varepsilon(u)$ is as in (1.3)–(1.5), and where from now on bars will be introduced above the functions that denote steady states. The scaling structure of $G_\varepsilon(u)$ in (1.3) suggests introducing the new set of variables

$$\bar{u} = \frac{1}{\varepsilon}\bar{U}, \tag{3.3}$$

$$x = \sqrt{\varepsilon}y \tag{3.4}$$

that transforms (3.1), (3.2) into

$$\Delta_y\bar{U} - \nabla_y(Q(\bar{U})\nabla_y\bar{v}) = 0, \quad y \in \mathbb{R}^2, \tag{3.5}$$

$$\Delta_y\bar{v} + \bar{U} = 0, \quad y \in \mathbb{R}^2. \tag{3.6}$$

Let us write $r = |y|$. The following result has been obtained in [22].

THEOREM 3.1. *Suppose that $Q(\cdot) \in C^1(\mathbb{R}^+)$ is an increasing function satisfying* (1.4). *Let us assume also that $\frac{Q(s)}{s}$ is a decreasing function. Then, for each $M > 8\pi$ there exists a unique radial solution (up to translations) such that*

$$\int_{\mathbb{R}^2} \bar{U}(y;M)d^2y = M.$$

The function $\bar{U}(y;M) = \bar{U}(r;M)$ is decreasing on r and its asymptotic behavior as $r \to \infty$ is given by

$$\bar{U}(r;M) \sim \frac{k(M)}{r^{\frac{M}{2\pi}}} \quad \text{as } r \to \infty$$

for some suitable $k(M) > 0$.

In some of the computations below it will be convenient to use $\bar{U}(0;M)$ instead of M in order to characterize the steady states. In Theorem 3.2 we summarize the results that will be used in forthcoming sections and that have been proved in [22].

THEOREM 3.2. *Suppose that $\bar{U}(0;M) = \lambda$. Then, in the limit $\lambda \to 0$ the following asymptotics holds:*

$$\bar{U}(0;M) \sim \frac{\lambda}{8}\left(\varphi_0(\xi) + \frac{\alpha\lambda}{8}\varphi_1(\xi) + \cdots\right), \quad \xi = \frac{\sqrt{\lambda}r}{\sqrt{8}}, \tag{3.7}$$

uniformly in bounded regions of ξ, where α is as in (1.4) *and*

$$\varphi_0(\xi) = \frac{8}{(1+\xi^2)^2}, \qquad \varphi_1(\xi) = \frac{32}{3}\left[\frac{\xi^4 + 10\xi^2 + 2\ln(1+\xi^2) - 2\xi^4\ln(1+\xi x^2)}{(1+\xi^2)^4}\right]. \tag{3.8}$$

Moreover,

$$M = 8\pi + \frac{4\pi\alpha\lambda}{3} + o(\lambda) \quad \text{as } \lambda \to 0^+. \tag{3.9}$$

4. Formation of concentration regions: The limit $\varepsilon \to 0^+$.

4.1. Sketch of the main argument and preliminary results. Standard continuity results on the initial data for PDEs show that as long as the solutions of (1.6), (1.7) are bounded, the solutions of (1.1)–(1.5) converge to the solutions of (1.6), (1.7) as $\varepsilon \to 0^+$. On the other hand, it has been shown in [22] that the solutions of (1.6), (1.7) are globally bounded in time for any $\varepsilon > 0$ fixed. It also has been seen in [22] that there exist formal solutions of (1.1)–(1.5) containing "Dirac masses" for the cell density in some particular regions. In this section it will be confirmed that as one approaches the blow-up time the solutions of (1.1)–(1.5) make a transition between the blowing up behavior obtained for $\varepsilon = 0$ recalled in section 2 of this paper and the "quasi-steady behavior" for regions of high density that is in the basis of the dynamics described in [22].

We will restrict our analysis to radial solutions. In the general nonradial case computations become much more cumbersome, but on the other hand, irrelevant changes arise (cf. [21]). Restricting the analysis to radially symmetric situations does not suppose an important loss of generality because the transition described here occurs very fast and during these times the displacements of the concentration regions would be very small.

In all the analysis made in this paper the only blow-up mechanism that will be considered is the one described in section 2. It is not known if this blow-up mechanism is the only one that can take place for this equation in the two-dimensional case. It is known that for two-dimensional solutions blow-up for the system (1.6), (1.7) can occur only by means of the aggregation of a finite amount of mass at a point (cf. [18]).

If the blow-up mechanism considered here had been unstable it would not be realistic to describe the formation of concentration regions by means of the methods considered in this paper. The question of the stability of this blow-up mechanism has been addressed using asymptotic analysis in [21].

The goal of this section is to study the precise manner in which the blow-up mechanism described in section 2 is regularized for $\varepsilon > 0$ small due to the boundedness of $G_\varepsilon(u)$ in (1.1). Global well-posedness for (1.1)–(1.5) has been proved in [22].

As a preliminary step, it is possible to obtain a rough estimate of the time scales for which the approximation (1.6), (1.7) stops being valid. The term $G_\varepsilon(\frac{M_r}{r})$ differs most from its limit value in the region $r \approx 0$. We will approximate M in that region using (2.8), (1.6). Therefore $M(r,t) \sim \bar{M}(\frac{r}{\sqrt{T-t}\bar{\delta}(\bar{\tau})})$, where $\bar{\delta}(\bar{\tau})$ is as in (2.37). Whence $\frac{M_r}{r} \sim \frac{1}{(T-t)(\bar{\delta}(\bar{\tau}))^2}\frac{\bar{M}_{\bar{\xi}}}{\bar{\xi}}$. Recalling that $G_\varepsilon(s) = \frac{Q(\varepsilon s)}{\varepsilon}$, it would follow that the approximation $G_\varepsilon(s) \sim s$ ceases being valid if $\frac{\varepsilon M_r}{r}$ becomes of order one, i.e., for $\frac{\varepsilon}{(T-t)(\bar{\delta}(\bar{\tau}))^2} \sim 1$, or in an equivalent manner $(T-t) \sim \varepsilon e^{\sqrt{2|\log(\varepsilon)|}}$. Using (2.38), it would follow that the width of the region occupied for the concentration region would be of order $|x| \sim \sqrt{\varepsilon}$, something that agrees with the size of a developed concentration region as computed in [22].

Actually, the precise computation of the size of the transition between the "blow-up regime" described in section 4 and the "quasi-steady regime" described in [22] is more involved due to the presence of many logarithmic terms in the singularity formation mechanism (cf. (2.37), (2.38)), albeit the main rationale behind the forthcoming computations is basically the elementary computation above.

There are some related mathematical results that have been studied by some authors. In [11] a model has been introduced that also avoids large values of the

chemotactic function for large values of u. On the other hand, in [20] the authors study, using rigorous methods, a possible way of extending the solutions of (1.6), (1.7) for radial solutions. Although the approach and methods used in these papers are different from the one here, some of the basic ideas there are rather close to the approach of this paper.

In order to describe in detail the unfolding of the concentration region starting from the blow-up mechanism described in (1.6), (1.7) we will use the asymptotics of the steady states of (2.5) whose total mass approaches 8π. Such asymptotics has been recalled in section 3, Theorem 3.2. Let us describe here those results using as the variable the mass function $M(r)$ instead of the concentration u. Let us denote as $M_\lambda(r)$ with $\lambda > 0$ the steady state of (2.5) uniquely defined by means of the condition $U(0; M) = \lambda$. By (2.2) we have

$$M_\lambda(r) \sim \frac{\lambda r^2}{2} \quad \text{as } r \to 0^+. \tag{4.1}$$

Combining (3.8) and (2.2) we obtain the following asymptotics for $M_\lambda(r)$ as $\lambda \to 0^+$:

$$M_\lambda(r) \sim \frac{4\bar{\xi}^2}{1+\bar{\xi}^2} + \frac{\alpha\lambda}{8} m(\bar{\xi}) + \cdots \quad \text{as } \lambda \to 0^+, \tag{4.2}$$

where $\bar{\xi} = \frac{\sqrt{\lambda}}{\sqrt{8}} r$ and α is as in (3.7). Therefore

$$M_\lambda(\infty) \sim 4 + \frac{2\alpha\lambda}{3} + \cdots \quad \text{as } \lambda \to 0^+, \tag{4.3}$$

which is just another way of writing (3.9).

4.2. Quadratic terms in the chemotactic function stop aggregation.

4.2.1. Derivation of a differential equation for the size of the concentration region. To describe the unfolding mentioned above we begin analyzing the effect of the boundedness of $Q(\cdot)$ in the computations of section 2. If we just keep the first corrective order, instead of approximating $Q(s)$ just by s, we could approximate $Q(s)$ by $s - \alpha s^2$ as long as $\frac{|\varepsilon M_r|}{r} \ll 1$. In another way, we approximate (2.5) as

$$M_t = M_{rr} - \frac{M_r}{r} + \frac{M M_r}{r} - \alpha\varepsilon M \left(\frac{M_r}{r}\right)^2. \tag{4.4}$$

Our first goal is to compute in a detailed manner the effect of the term $\alpha\varepsilon M(\frac{M_r}{r})^2$ in the aggregation process described in section 2. To this end, it is convenient to make a small change of variables, replacing T in (2.8) by some suitable T_ε to be described in detail later. Clearly, if $\varepsilon > 0$, T_ε does not have the meaning of a blow-up time because the solutions of (4.4) do not blow-up in that case. The variable T_ε will be that suitable time scale satisfying $T_\varepsilon \sim T$ that characterizes when the transition between the blow-up regime described in section 2 and the "quasi-steady regime" in [22] has already taken place.

We define a new set of variables as follows:

$$\begin{aligned} M(r,t) &= \Phi\left(\frac{r}{\sqrt{T_\varepsilon - t}}, -\log(T_\varepsilon - t)\right), \quad y = \frac{r}{\sqrt{T_\varepsilon - t}}, \\ \tau &= -\log(T_\varepsilon - t) + \log\left(\frac{T_\varepsilon}{T}\right), \quad \xi = \frac{r}{\delta(\tau)\sqrt{T_\varepsilon - t}}. \end{aligned} \tag{4.5}$$

The term $\log(\frac{T_\varepsilon}{T})$ in the definition of τ has been added just to obtain the normalization $\tau = \bar{\tau} = -\log(T)$ for $t = 0$.

The term $-\alpha\varepsilon M(\frac{M_r}{r})^2$ will be more relevant in the region $r \approx 0$. It will then be convenient to rewrite (4.4) using the variable ξ in (4.5). Using this variable, (4.4) becomes

$$\delta^2 \frac{\partial M}{\partial \tau} + \left(\frac{\delta^2}{2} - \delta\delta_\tau\right)\xi M_\xi = M_{\xi\xi} - \frac{M_\xi}{\xi} + \frac{M M_\xi}{\xi} - \frac{\alpha\varepsilon}{(T_\varepsilon - t)\delta^2} M \left(\frac{M_\xi}{\xi}\right)^2. \tag{4.6}$$

For $\varepsilon = 0$, M could be approximated to the leading order as $\bar{M}(\xi)$ for $\tau \to \infty$, where $\bar{M}(\xi)$ is as in (2.7). We can expect this approximation to remain valid to the leading order as long as $\frac{\alpha\varepsilon}{(T_\varepsilon - t)\delta^2} \ll 1$. Taking into account the structure of (2.7) it would be natural to look for approximations of M in the form

$$M(\xi, \tau) = \bar{M}(\xi) + \left(\frac{\delta^2}{2} - \delta\delta_\tau\right) W_1(\xi) + \frac{\alpha\varepsilon}{(T_\varepsilon - t)\delta^2} W_2(\xi) + \cdots, \tag{4.7}$$

where $W_1(\xi)$, $W_2(\xi)$ satisfy, respectively,

$$W_{1,\xi\xi} - \frac{1}{\xi} W_{1,\xi} + \frac{\bar{M}}{\xi} W_{1,\xi} + \frac{\bar{M}_\xi}{\xi} W_1 = \xi \bar{M}_\xi, \tag{4.8}$$

$$W_{2,\xi\xi} - \frac{1}{\xi} W_{2,\xi} + \frac{\bar{M}}{\xi} W_{2,\xi} + \frac{\bar{M}_\xi}{\xi} W_2 = \bar{M}\left(\frac{\bar{M}_\xi}{\xi}\right)^2, \tag{4.9}$$

$$W_i(\xi) = o(\xi^2), \quad \xi \to 0^+, \ i = 1, 2. \tag{4.10}$$

Arguing as in [22, section 2], it follows that

$$W_1(\xi) = \frac{4\xi^2}{(\xi^2+1)^2} \int_0^\xi \frac{(1+\eta^2)^2}{\eta^3} \left[\log(1+\eta^2) - \frac{\eta^2}{(1+\eta^2)}\right] d\eta, \tag{4.11}$$

$$W_2(\xi) = m(\xi) = \frac{16}{3} \frac{\xi^2}{(\xi^2+1)^3} (\xi^4 + 4\xi^2 + 2(\xi^2+1)\log(\xi^2+1)). \tag{4.12}$$

Using (4.7) as well as (2.7), (4.11), and (4.12) we obtain the following matching condition:

$$M(\xi, \tau) \sim 4 - \frac{4}{\xi^2} + 4\left(\frac{\delta^2}{2} - \delta\delta_\tau\right)[\log(\xi) - 1] + \frac{16\alpha\varepsilon}{3(T_\varepsilon - t)\delta^2} + \cdots \tag{4.13}$$

as $|\xi| \gg 1$, $|y| \ll 1$.

Expansion (4.7) is not valid if $|x| \sim \sqrt{T_\varepsilon - t}$ as it also happened in section 2. Notice that as long as $\frac{\alpha\varepsilon}{(T_\varepsilon - t)\delta^2} \ll 1$ we can argue as in that section and approximate M as 4. Using then the self-similar variables (2.8) we obtain the following equation for ψ defined as in (1.6):

$$\psi_\tau = \psi_{yy} + \frac{3}{y}\psi_y - \frac{y\psi_y}{2}, \quad y > 0. \tag{4.14}$$

On the other hand, since $\psi \sim -\frac{4\delta^2}{|y|^2}$ as $\delta \ll |y| \ll 1$ (cf. (4.13)), we would obtain that ψ satisfies approximately (2.27) if we want to compute ψ in the region $|y| \sim 1$.

We decompose $\psi(y, \tau)$ as in (2.22), where $a_0(\tau)$ solves (2.24) and $Q(y, \tau)$ satisfies (2.26). As long as $|\delta\delta_\tau| \ll \delta^2$ we can approximate, as in section 2, $Q(y, \tau)$ by means

of the solution of (2.30), (2.31). Therefore, arguing exactly as in section 2, we would arrive at an outer matching condition similar to (2.34) with $\int_\tau^\infty (\delta(s))^2 ds$ replaced by $a_0(\tau)$ there. Matching that expansion with (4.13) we arrive at the following equation:

$$\begin{aligned} a_0(\tau) + (\gamma - \log(4))(\delta(\tau))^2 + \zeta\delta(\tau)\delta_\tau(\tau) \\ = -2(\delta^2 - 2\delta\delta_\tau)\log(\delta) \\ -2(\delta^2 - 2\delta\delta_\tau) + \frac{16\alpha\varepsilon}{3(T_\varepsilon - t)(\delta(\tau))^2} + \cdots . \end{aligned} \tag{4.15}$$

It is interesting to compare (4.15) with (2.36). Notice that the additional term $\frac{16\alpha\varepsilon}{3(T_\varepsilon - t)(\delta(\tau))^2}$ appears due to the presence of corrective terms $Q(s)$ as $s \to 0^+$. Notice that (4.15) has to be complemented with the analogue of (1.7) that we rewrite here by convenience as

$$a_{0,\tau}(\tau) = -(\delta(\tau))^2. \tag{4.16}$$

System (4.15), (4.16) provides a description of the solutions of (2.5) as long as $|\delta_\tau| \ll \delta$. It is important to remark that in the case $\varepsilon > 0$, it is not natural to assume that $\lim_{\tau\to\infty} a_0(\tau) = 0$, since for $\varepsilon > 0$, ψ does not need to approach zero as $\tau \to \infty$. Therefore, in order to determine $a_0(\tau)$ uniquely we will then use its asymptotics for the range of times where the regularizing terms of $Q(s)$ did not begin to act yet. We recall that (2.37), (4.16) imply, for $\varepsilon = 0$, the following asymptotics of $a_0(\tau)$:

$$a_0(\tau) \sim 4e^{-(\gamma+2)}\sqrt{2\bar\tau}e^{-\sqrt{2\bar\tau}}(1 + o(1)) \quad \text{as } \bar\tau \to \infty. \tag{4.17}$$

In order to simplify system (4.15), (4.16) it is convenient to eliminate some numerical constants by means of the following change of variables,

$$\delta(\tau) = 2e^{-\frac{(\gamma+2)}{2}} b(\tau), \qquad a_0(\tau) = 4e^{-(\gamma+2)}\hat a_0(\tau), \tag{4.18}$$

that transforms (4.15), (4.16) into

$$\hat a_0 + \nu b b_\tau + O(b_\tau^2 + b b_{\tau\tau}) = -2(b^2 - 2bb_\tau)\log(b) + \frac{\alpha e^{2(\gamma+2)}\varepsilon e^\tau}{3} \cdot \frac{T}{T_\varepsilon} \cdot \frac{1}{b^2}, \tag{4.19}$$

$$(\hat a_0)_\tau = -b^2, \tag{4.20}$$

where $\nu = \zeta - 4 + 2(\gamma + 2 - \log(4))$.

We now study the precise manner in which the last term in (4.19) and, in general, replacing $G_\varepsilon(s)$ by s in (1.1) modify the dynamics of $\delta(\tau)$, $a_0(\tau)$ (equivalently, b, $\hat a_0(\tau)$). As a first step we need to compute the change of $\delta(\tau)$ due to the fact that instead of solving (1.1), (1.2) with $G_\varepsilon(s)$ we use s instead. To the leading order we approximate $G_\varepsilon(s)$ by $s - \alpha\varepsilon s^2$. By assumption we solve (1.1), (1.2) with the same initial data $u_0(x)$ but choose either $\varepsilon = 0$ or $\varepsilon > 0$. Using the set of self-similar variables (4.5), (4.4) becomes

$$\Phi_\tau = \Phi_{yy} - \frac{y\Phi_y}{2} - \frac{\Phi_y}{y} + \frac{\Phi\Phi_y}{y} - \alpha\varepsilon e^\tau \frac{T}{T_\varepsilon}\Phi\left(\frac{\Phi_y}{y}\right)^2 \tag{4.21}$$

with initial data $\Phi_0(\tau) = u_0(\frac{r}{\sqrt{T_\varepsilon}})$. Notice that in the case $\varepsilon = 0$, (4.21) would be equivalent to (1.6) (with $\bar y$ replaced by y and $\bar\tau$ by τ). The corresponding initial data for $\varepsilon = 0$ would be $\bar\Phi(\bar y, -\log(T)) = \bar\Phi_0(\bar y) = u_0(\frac{r}{\sqrt{T}})$.

Let us write $\psi(\bar{y},\bar{\tau}) = \Phi(\bar{y},\bar{\tau}) - \bar{\Phi}(\bar{y},\bar{\tau})$. Notice that we are not choosing the independent variables for Φ as (y,τ) but instead we are taking as variables for this function the ones associated to $\bar{\Phi}$. This will simplify some computations later. To the leading order ψ solves

$$\psi_{\bar{\tau}} = \psi_{\bar{y}\bar{y}} - \frac{\bar{y}\psi_{\bar{y}}}{2} - \frac{\psi_{\bar{y}}}{\bar{y}} + \bar{\Phi}\frac{\psi_{\bar{y}}}{\bar{y}} + \frac{\bar{\Phi}_{\bar{y}}}{\bar{y}}\psi - \frac{\alpha\varepsilon T e^{\bar{\tau}}}{T_\varepsilon}\bar{\Phi}\left(\frac{\bar{\Phi}_{\bar{y}}}{\bar{y}}\right)^2 \tag{4.22}$$

with initial data

$$\psi(\bar{y}, -\log(T)) = -\frac{1}{2T}\bar{y}u_0'(\bar{y})(T_\varepsilon - T). \tag{4.23}$$

The difference ψ cannot be computed using the approximation (4.22), (4.23) near the blow-up time. However, we intend to use this approximation only as long as ψ is small enough compared with $\bar{\Phi}$. For later times the use of the whole nonlinear problem will be needed.

The next set of arguments is reminiscent of those used in [21], although with a different set of functions. Using the inner variable $\bar{\xi} = \frac{y}{\bar{\delta}(\tau)}$, (4.22) becomes

$$\bar{\delta}^2\psi_{\bar{\tau}} + \left(\frac{\bar{\delta}^2}{2} - \bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\bar{\xi}\psi_{\bar{\xi}} = \psi_{\bar{\xi}\bar{\xi}} - \frac{\psi_{\bar{\xi}}}{\bar{\xi}} + \bar{\Phi}\frac{\psi_{\bar{\xi}}}{\bar{\xi}} + \frac{\bar{\Phi}_{\bar{\xi}}}{\bar{\xi}}\psi - \frac{\alpha\varepsilon T e^{\bar{\tau}}}{T_\varepsilon\bar{\delta}^2}\bar{\Phi}\left(\frac{\bar{\Phi}_{\bar{\xi}}}{\bar{\xi}}\right)^2. \tag{4.24}$$

We expand ψ in a series of terms having different relative sizes. We write

$$\psi = \psi_0 + \psi_1 + \cdots, \tag{4.25}$$

where ψ_0, ψ_1 solve the problems

$$\psi_{0,\bar{\xi}\bar{\xi}} - \frac{\psi_{0,\bar{\xi}}}{\bar{\xi}} + \bar{\Phi}\frac{\psi_{0,\bar{\xi}}}{\bar{\xi}} + \frac{\bar{\Phi}_{\bar{\xi}}}{\bar{\xi}}\psi_0 = 0, \tag{4.26}$$

$$\psi_{1,\bar{\xi}\bar{\xi}} - \frac{\psi_{1,\bar{\xi}}}{\bar{\xi}} + \bar{\Phi}\frac{\psi_{1,\bar{\xi}}}{\bar{\xi}} + \frac{\bar{\Phi}_{\bar{\xi}}}{\bar{\xi}}\psi_1 = \psi_{0,\tau} + \left(\frac{\bar{\delta}^2}{2} - \bar{\delta}\bar{\delta}_{\bar{\tau}}\right)\bar{\xi}\psi_{0,\bar{\xi}} + \frac{\alpha\varepsilon T e^{\bar{\tau}}}{T_\varepsilon\bar{\delta}^2}\bar{\Phi}\left(\frac{\bar{\Phi}_{\bar{\xi}}}{\bar{\xi}}\right)^2. \tag{4.27}$$

We choose ψ_0 in such a way that $\lim_{\xi\to 0^+}\frac{\psi(\bar{\xi},\bar{\tau})}{\psi_0(\bar{\xi},\bar{\tau})} = 1$. Since ψ, ψ_0, ψ_1 behave quadratically in $\bar{\xi}$ as $\bar{\xi}\to 0^+$ this means that we are assuming that $\psi_k(\bar{\xi},\bar{\tau}) = o(\bar{\xi}^2)$ as $\bar{\xi}\to 0^+$, $k = 1, 2, \ldots$.

The required solution of (4.26) is then given by

$$\psi_0(\bar{\xi},\bar{\tau}) = A(\bar{\tau})\varphi(\bar{\xi}), \tag{4.28}$$

where

$$\varphi(\bar{\xi}) = \frac{\bar{\xi}^2}{(\bar{\xi}^2+1)^2} \tag{4.29}$$

and $A(\bar{\tau}) = \lim_{\bar{\xi}\to 0}(\frac{\psi(\bar{\xi},\bar{\tau})}{\bar{\xi}^2})$. We can then solve (4.27) using variation of constants. After some computations we finally obtain the following:

$$\psi_1(\bar{\xi},\bar{\tau}) = \{W_1(\bar{\xi}) + W_2(\bar{\xi}) + W_3(\bar{\xi})\}\varphi(\bar{\xi}), \tag{4.30}$$

where

$$W_1(\bar\xi) \equiv \frac{A_{\bar\tau}\bar\delta^2}{2}\int_0^{\bar\xi}\frac{(\eta^2+1)}{\eta^3}((\eta^2+1)\log(\eta^2+1)-\eta^2)d\eta,$$
$$W_2(\bar\xi) \equiv A\left(\frac{\bar\delta^2}{2}-\bar\delta\bar\delta_{\bar\tau}\right)\int_0^{\bar\xi}\left(\frac{1+2\eta^2}{\eta}-\frac{(\eta^2+1)^2}{\eta^3}\log(\eta^2+1)\right)d\eta,$$
$$W_3(\bar\xi) \equiv \frac{16\alpha\varepsilon e^{\bar\tau}\left(\frac{T}{T_\varepsilon}\right)}{3\bar\delta^2}\left(\frac{\bar\xi^4+4\bar\xi^2}{\bar\xi^2+1}+2\log(\bar\xi^2+1)\right).$$

Using (4.25), (4.28), (4.29), (4.30) we can compute the asymptotics of $\psi(\bar\xi,\bar\tau)$ as $\bar\xi\to\infty$. We then deduce the following matching condition for the inner solution $\psi(\bar\xi,\bar\tau)$:

$$\psi(\bar\xi,\bar\tau)\sim \frac{A(\bar\tau)}{\bar\xi^2}+\left[\frac{A_{\bar\tau}\bar\delta^2}{2}+A\left(\bar\delta\bar\delta_{\bar\tau}-\frac{\bar\delta^2}{2}\right)\right]\left(\log(\bar\xi)-\frac{3}{2}\right) + \frac{A_{\bar\tau}\bar\delta^2}{4}+\frac{16\alpha T\varepsilon e^{\bar\tau}}{3T_\varepsilon\bar\delta^2}+\cdots \tag{4.31}$$

for $1\ll\bar\xi\ll\frac{1}{\bar\delta^2}$.

We now proceed to obtain an outer expansion for ψ. Taking into account the outer expansion for $\bar\Phi$ obtained in section 2 (cf. (2.34)) and neglecting terms of the form $O(\bar\delta^2\psi)$ as well as the term $\frac{\alpha T\varepsilon e^{\bar\tau}}{T_\varepsilon}\bar\Phi(\frac{\bar\Phi_{\bar y}}{\bar y})^2$ that will be negligible compared with $\bar\delta^4$ in the range of times where we will use the approximation of ψ currently under computation, we obtain the following equation for ψ:

$$\psi_{\bar\tau}=\psi_{\bar y\bar y}+\frac{3}{\bar y}\psi_{\bar y}-\frac{\bar y\psi_{\bar y}}{2}. \tag{4.32}$$

The matching condition (4.31) suggests that the order of magnitude of ψ is $A\bar\delta^2$. It is then convenient to introduce a new function G by means of the formula $\psi=A\bar\delta^2G$. Function G satisfies to the leading order

$$\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}G+G_{\bar\tau}=G_{\bar y\bar y}+\frac{3}{\bar y}G_{\bar y}-\frac{\bar yG_{\bar y}}{2}. \tag{4.33}$$

Notice that the exponential growth of the last term in (4.31) indicates that for $\bar\tau$ large, A grows like $e^{\bar\tau}$, with perhaps some algebraic-like corrections. On the other hand, one can expect that A should contain some contribution behaving like those of the homogeneous part of (4.24). The leading part of such contributions also grows like $e^{\bar\tau}$, due to the fact that those terms are associated to changes in the blow-up time for solutions of (2.6) (see the related analysis in [21]). In another manner, it should be $\lim_{\tau\to\infty}\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}=1$. It is then natural to look for expansions for G in the form

$$G(\bar y,\bar\tau)=G_0(\bar y,\bar\tau)+G_1(\bar y,\bar\tau)+\cdots, \tag{4.34}$$

where (cf. (4.33))

$$G_0=G_{0,\bar y\bar y}+\frac{3}{\bar y}G_{0,\bar y}-\frac{\bar yG_{0,\bar y}}{2}, \tag{4.35}$$

$$\left[\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}-1\right]G_0+(G_{0,\bar\tau})+G_1=G_{1,\bar y\bar y}+\frac{3}{\bar y}G_{1,\bar y}-\frac{\bar yG_{1,\bar y}}{2}. \tag{4.36}$$

Higher order corrections would provide contributions of order $O((\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}-1)^2+(\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2})_{\bar\tau})$. Our goal is to include in G_0 the singular contributions of G as $\bar y\to 0^+$. We then select G_0 satisfying the matching condition $G_0\sim\frac{1}{\bar y^2}$ as $\bar y\to 0^+$. We also assume that the corresponding solutions of (4.35), (4.36) do grow exponentially as $\bar y\to\infty$ because such growths would rule out the possibility of getting matchings with bounded solutions in the region $x\sim 1$. It then follows that

$$G_0(\bar y,\bar\tau)=\frac{1}{\bar y^2}. \tag{4.37}$$

We can then easily solve (4.36). Taking into account (4.31) it follows that we have to choose G_1 bounded as $\bar y\to 0$. The corresponding solution of (4.36) is given by

$$G_1(\bar y,\bar\tau)=-\left(\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}-1\right)\frac{1}{\bar y^2}\int_0^{\bar y}\upsilon e^{\frac{\upsilon^2}{4}}\left(\int_\upsilon^\infty e^{-\frac{\eta^2}{4}}\frac{d\eta}{\eta}\right)d\upsilon. \tag{4.38}$$

Computing the asymptotics of G_1 as $\bar y\to 0$, and also using (4.37) as well as the fact that $\psi=A\bar\delta^2G$, we finally obtain the following matching condition for $\psi(\bar y,\bar\tau)$:

$$\psi\sim\frac{A\bar\delta^2}{\bar y^2}-\frac{A\bar\delta^2}{2}\left(\frac{(A\bar\delta^2)_{\bar\tau}}{A\bar\delta^2}-1\right)\left[-\frac12\log(\bar y)+\frac14(1+\log(4)-\gamma)\right]+\cdots \tag{4.39}$$

as $\bar y\to 0^+$. We then use $\bar\xi=\frac{\bar y}{\bar\delta}$ in order to match (4.31) with (4.39) to derive the following differential equation for $A(\bar\tau)$:

$$\begin{aligned}&-\left(\frac32+\log(\bar\delta)\right)\left(\frac{A_{\bar\tau}\bar\delta^2}{2}+A\left(\bar\delta\bar\delta_{\bar\tau}-\frac{\bar\delta^2}{2}\right)\right)+\frac{A_{\bar\tau}\bar\delta^2}{4}+\frac{16\alpha\varepsilon e^{\bar\tau}\left(\frac{T}{T_\varepsilon}\right)}{3\bar\delta^2}\\ &\quad=-\frac12(1+\log(4)-\gamma)\left[\frac{A_{\bar\tau}\bar\delta^2}{2}+A\left(\bar\delta\bar\delta_{\bar\tau}-\frac{\bar\delta^2}{2}\right)\right]\\ &\qquad+O\left(\left[\left(\frac{A_{\bar\tau}}{A}-1\right)^2+\left(\frac{\bar\delta_{\bar\tau}}{\bar\delta}\right)^2+\left(\frac{A_{\bar\tau}}{A}\right)_{\bar\tau}+\left(\frac{\bar\delta_{\bar\tau}}{\bar\delta}\right)_{\bar\tau}\right]A\bar\delta^2\right).\end{aligned} \tag{4.40}$$

This is the desired equation that will be used to study the evolution of the size of the concentration region during the transition between the blow-up regime and the quasi-steady regime.

4.2.2. Study of the solutions of the differential equation describing the size of the transition region. In this subsection we study the consequences of (4.40). As a first step notice that we can simplify this expression using the change of variables $\bar\delta=2e^{-\frac{(\gamma+2)}{2}}\bar b$. Equation (4.40) then becomes

$$\begin{aligned}&-\log(\bar b)\left(\frac{A_{\bar\tau}\bar b^2}{2}+A\left(\bar b\bar b_{\bar\tau}-\frac{\bar b^2}{2}\right)\right)+\frac{A_{\bar\tau}\bar b^2}{4}+\frac{16\alpha\varepsilon e^{\bar\tau}\left(\frac{T}{T_\varepsilon}\right)}{3\bar\delta^2}\\ &\quad=O\left(\left[\left(\frac{A_{\bar\tau}}{A}-1\right)^2+\left(\frac{\bar b_{\bar\tau}}{\bar b}\right)^2+\left(\frac{A_{\bar\tau}}{A}\right)_{\bar\tau}+\left(\frac{\bar b_{\bar\tau}}{\bar b}\right)_{\bar\tau}\right]A\bar b^2\right).\end{aligned}$$

The asymptotics for the solutions of this equation can be obtained using the change of variables $A=e^{\bar\tau}h$, in order to eliminate the exponential growth of A. Using

(2.37) it follows that

$$A(\bar\tau) \sim -\frac{2e^{2(\gamma+2)}\alpha\varepsilon}{3}\left(\frac{T}{T_\varepsilon}\right)e^{\bar\tau}e^{2\sqrt{2\bar\tau}} + C_\varepsilon e^{\bar\tau} \quad \text{as } \bar\tau \to \infty, \tag{4.41}$$

where C_ε is a real constant to be determined later.

Let us compute now the precise manner in which $\delta(\tau)$ differs from $\bar\delta(\bar\tau)$ due to the change of Φ to $\bar\Phi$ previously computed. We recall that $\psi(\bar y,\bar\tau) = \Phi(\bar y,\bar\tau) - \bar\Phi(\bar y,\bar\tau)$. On the other hand, we have defined $\delta(\tau)$ by means of the normalization $\Phi(y,\tau) \sim 4\xi^2 = 4(\frac{y}{\delta(\tau)})^2$ for $y \ll \delta(\tau)$, with $\xi = \frac{r}{\sqrt{T_\varepsilon - t(\delta(\tau))}}$, (cf. (4.7), (4.10)). The definition of $\bar\delta(\bar\tau)$ is similar, namely, $\bar\Phi(\bar y,\bar\tau) \sim 4(\frac{\bar y}{\bar\delta(\bar\tau)})^2$ for $\bar y \ll \bar\delta(\bar\tau)$. Since $\bar y$, $\bar\tau$ above have been used as dummy variables in the difference $\Phi(\bar y,\bar\tau) - \bar\Phi(\bar y,\bar\tau)$, we obtain, using (4.28), that

$$\Phi(\bar y,\bar\tau) \sim 4\left(\frac{\bar y}{\bar\delta(\bar\tau)}\right)^2 + A(\bar\tau)\left(\frac{\bar y}{\bar\delta(\bar\tau)}\right)^2$$

for $\bar y \ll \bar\delta(\bar\tau)$. Then $\frac{4}{(\delta(\bar\tau))^2} \sim \frac{4+A(\bar\tau)}{(\bar\delta(\bar\tau))^2}$ or also, using Taylor's theorem, $\delta(\bar\tau) \sim \bar\delta(\bar\tau)(1 - \frac{A(\bar\tau)}{8})$ as $\bar\tau \to \infty$. Using the relations between δ, b and $\bar\delta$, $\bar b$, as well as (4.18), (4.41), we obtain the following asymptotics for $b(\bar\tau)$:

$$b(\bar\tau) \sim e^{-\sqrt{\frac{\bar\tau}{2}}}\left(1 + \frac{e^{2(\gamma+2)}\alpha\varepsilon}{12}\left(\frac{T}{T_\varepsilon}\right)e^{\bar\tau}e^{2\sqrt{2\bar\tau}} - \frac{C_\varepsilon}{8}e^{\bar\tau}\right) \quad \text{as } \bar\tau \to \infty. \tag{4.42}$$

At this point, it remains only to compute the value of C_ε. Notice that the linearity of (4.22), (4.23) on $\varepsilon(\frac{T}{T_\varepsilon})$, $(T - T_\varepsilon)$ implies for C_ε the functional dependence $C_\varepsilon = C_1\varepsilon(\frac{T}{T_\varepsilon}) + C_2(T - T_\varepsilon)$, where C_1, C_2 are fixed real constants. The precise value of C_1 will not be relevant here and therefore it will not be computed in detail. However, the value of C_2 will be needed later, and therefore we proceed to compute it. In order to do this we would need to solve (4.22), (4.23), dropping the last term in (4.22). Notice however, that the argument that yields to (4.22), (4.23) implies that this problem is equivalent to computing the change in $\bar\delta(\bar\tau)$ due to using the variables (4.5) instead of (2.8) in the solution of (1.6). In order to do this, notice that by definition of $\bar\delta(\bar\tau)$,

$$\bar M(r,t) \sim \frac{4r^2}{(T-t)(\bar\delta(\bar\tau))^2} \quad \text{for } \mathrm{r} \ll \sqrt{\mathrm{T} - \mathrm{t}},\ \mathrm{t} \to \mathrm{T}^-. \tag{4.43}$$

On the other hand, let us denote as $\hat\delta(\tau)$ the corresponding function, which would be obtained in a similar manner, but assuming that the set of variables (4.5) is used instead. In another way, we assume that

$$\bar M(r,t) \sim \frac{4r^2}{(T_\varepsilon - t)(\tilde\delta(\tau))^2} \quad \text{for } \mathrm{r} \ll \sqrt{\mathrm{T}_\varepsilon - \mathrm{t}}, \approx \to \mathrm{T}_\varepsilon^-. \tag{4.44}$$

In order to compute the value of C_2 we need to compute the difference between $\hat\delta$ and $\bar\delta$ to the linear order for times not too close to the blow-up time. More precisely, let us assume that $|T - t| \gg |T_\varepsilon - T|$. Formulae (4.43), (4.44) combined with Taylor's expansion imply for this range of times that

$$\hat\delta(\tau) = \bar\delta(\bar\tau) + \frac{(T - T_\varepsilon)}{2}e^{\bar\tau}\bar\delta(\bar\tau) + \cdots. \tag{4.45}$$

It remains to estimate the correction due to the change of variables from $\bar\tau$ to τ, in order to have both functions $\bar\delta$, $\hat\delta$ written in the same variables. Notice that $|\bar\delta_{\bar\tau}| = O(\frac{\bar\delta}{\sqrt{\bar\tau}})$ and, on the other hand, $\tau - \bar\tau = O((T-T_\varepsilon)e^{\bar\tau})$ for $|T-t| \gg |T_\varepsilon - T|$. Henceforth $\bar\delta(\bar\tau) - \bar\delta(\tau) = O(\frac{(T-T_\varepsilon)e^{\bar\tau}\bar\delta(\bar\tau)}{\sqrt{\bar\tau}})$, and since this term is negligible compared with $\frac{(T-T_\varepsilon)}{2}e^{\bar\tau}\bar\delta(\bar\tau)$, we can ignore the fact that in different sides of (4.45) we are using different variables. We then finally obtain

$$\hat\delta(\bar\tau) = \bar\delta(\bar\tau) + \frac{(T-T_\varepsilon)}{2}e^{\bar\tau}\bar\delta(\bar\tau) + \cdots .$$

Using then the analogue of (4.42) that would be obtained for this problem, it then follows that $C_2 = -4$. Due to the linearity of the problem, we can then rewrite (4.42) as

$$\begin{aligned} b(\bar\tau) \sim e^{-\sqrt{\frac{\bar\tau}{2}}} \Bigg(1 + \frac{e^{2(\gamma+2)}\alpha}{12}\left(\frac{T}{T_\varepsilon}\right)\varepsilon e^{\bar\tau}e^{2\sqrt{2\bar\tau}} \\ + \left(C_3\frac{T}{T_\varepsilon}\varepsilon + \frac{(T-T_\varepsilon)}{2}\right)e^{\bar\tau}\Bigg) \quad \text{as } \bar\tau \to \infty, \end{aligned} \tag{4.46}$$

where $C_3 = -\frac{C_1}{8}$ is a real constant.

Remark 4.1. It is rather natural to ask if it would not be possible to simplify the rather cumbersome argument that yields (4.46) using instead the ODEs (4.19), (4.20) that provide a description of the width of the region where the mass is concentrated. The idea would be to use the fact that $b = \bar b(\tau)$, $\hat a_0(\tau) = \int_\tau^\infty (\bar b(s))ds$ provide a solution of (4.19), (4.20), with $\bar b = \frac{\bar\delta}{2e^{-\frac{(\gamma+2)}{2}}}$ and $\varepsilon = 0$. Linearizing around this solution in (4.19), (4.20) it would be possible to derive a linear set of ODEs that in principle could be used to derive (4.46). Actually such a method can be used to derive the term $\frac{4\alpha\varepsilon(\frac{T}{T_\varepsilon})e^{\bar\tau}e^{2\sqrt{2\bar\tau}}}{3(2e^{-\frac{(\gamma+2)}{2}})^4}$ in (4.46). Unfortunately, the last terms of (4.46) cannot be derived in that manner. The reason is the following. In (4.19) there are corrective terms that are neglected in the computations. A typical representative term of this type of term is, for instance, $bb_{\tau\tau}$. Suppose that we write $b = \bar b + \kappa$ and formally linearize. The term $bb_{\tau\tau}$ would generate terms in the linearized problem having the form $\bar b\kappa_{\tau\tau}$, whose effect should be compared with some of the terms arising from the leading terms in (4.19); a typical one would have the form $\bar b\log(\bar b)\kappa$. It is not hard to see, linearizing in the term $-2(b^2 - 2bb_\tau)\log(b)$, that κ contains as its main factor a term growing exponentially. However, the term $\bar b\kappa_{\tau\tau}$, as well as the relative sizes of the terms $\bar b$ and $\bar b\log(\bar b)$ (whose order is $\frac{1}{\sqrt{\bar\tau}}$), would generate "algebraic-like" corrections that would modify the exponential growth of κ. In particular, it would not be possible to determine using such a linearization argument if the last term in (4.46) has exactly the functional dependence $e^{\bar\tau}$ or, say, $e^{\bar\tau}(\bar\tau)^a$ for some $a > 0$. Unfortunately, this information will be relevant later. On the other hand, this problem could not be solved by just computing one additional term in the matching conditions that yields (4.19), because the same problem would be produced by $bb_{\tau\tau\tau}$ and similar corrective terms. The real reason for the difficulty lies in the exponential growth of the correction κ. This difficulty does not arise in computing b by means of (4.19) because b is an "algebraic-like" (in contrast with "exponential") function, and therefore differentiating on τ we obtain smaller functions as $\tau \to \infty$. This makes it possible to neglect terms like $bb_{\tau\tau}$ and similar ones. This argument illustrates some

difficulties that might lie in a naive handling of equations that have been derived by means of formal arguments and explains why the tortuous path that led to (4.46) has been used.

4.3. Regularizing terms yield a fully developed concentration region. After deriving (4.46) we now study another problem that we must consider in order to describe the process of concentration region formation. A crucial argument in the derivation of (4.19), (4.20) is the assumption $|\delta_\tau| \ll \delta$ or, equivalently, $|b_\tau| \ll b$. However, the exponential growth of the corrective terms in (4.46) implies that this assumption fails if $\bar\tau$ is large enough. In order to study the precise manner in which this failure takes place we use a standard boundary layer argument. We introduce a new set of variables by means of

$$b = e^{-\sqrt{\frac{\tau_\varepsilon}{2}}} h, \quad \hat a_0 = \sqrt{2\tau_\varepsilon} e^{-\sqrt{2\tau_\varepsilon}} \varphi, \quad \bar\tau = \tau_\varepsilon + s, \tag{4.47}$$

where τ_ε is defined by the following formula:

$$\frac{\alpha e^{2(\gamma+2)} \varepsilon e^{\tau_\varepsilon} e^{2\sqrt{2\tau_\varepsilon}}}{3} = \sqrt{2\tau_\varepsilon}. \tag{4.48}$$

This change of variables transforms (4.19), (4.20) into

$$\begin{aligned} &\sqrt{2\tau_\varepsilon}\varphi + \nu h h_s + O(h_s^2 + h h_{ss}) \\ &\qquad = \sqrt{2\tau_\varepsilon}(h^2 - 2hh_s) - 2\log(h)(h^2 - 2hh_s) + \sqrt{2\tau_\varepsilon}\frac{e^s}{h^2}, \end{aligned} \tag{4.49}$$

$$\varphi_s = -\frac{h^2}{\sqrt{2\tau_\varepsilon}} \tag{4.50}$$

whence, since $\tau_\varepsilon \to \infty$, we obtain to the leading order the problem

$$\varphi = h^2 - 2hh_s + \frac{e^s}{h^2}, \tag{4.51}$$

$$\varphi_s = 0. \tag{4.52}$$

Using (4.17) and (4.48) we obtain the matching condition $\varphi \to 1$ as $s \to -\infty$. The system (4.51), (4.52) can then be reduced to the ODE

$$1 = h^2 - 2hh_s + \frac{e^s}{h^2}. \tag{4.53}$$

On the other hand, (4.46) provides, after some computations, the following matching condition:

$$h(s) \sim 1 + \frac{s}{2}e^s + \left(\frac{3}{2} \frac{(T - T_\varepsilon)\sqrt{2\tau_\varepsilon} e^{-2(\gamma+2)}}{\alpha \varepsilon e^{2\sqrt{2\tau_\varepsilon}}} + \frac{\sqrt{2\tau_\varepsilon}}{4} \right) e^s + \cdots \tag{4.54}$$

as $s \to -\infty$. Notice that in deriving (4.54) we are assuming that $(T - T_\varepsilon) \ll 1$, and therefore $\frac{T}{T_\varepsilon} \to 1$. Notice also that we are neglecting the contribution of the term $C_3 \frac{T}{T_\varepsilon} \varepsilon e^{\bar\tau}$ in (4.46) that is negligible if compared with the previous term there.

Before finding the explicit solution of (4.53), (4.54) we briefly discuss its range of validity. Notice that in deriving (4.19), (4.20) we repeatedly use the assumption $|\delta_\tau| \ll \delta$ or, equivalently, $|h_s| \ll h$. This requirement is valid as $s \to -\infty$, but it will

be lost as s becomes of order one. It turns out, however, that the validity of (4.53) can be extended until the range of times in which h becomes of order one. In order to check this, we examine the changes that are required in the previous arguments that led to (4.19), (4.20) if the condition $|\delta_\tau| \ll \delta$ is lost. First, we remark that expansion (4.13) remains valid even if $|\delta_\tau| \sim \delta$, as long as δ remains small. However, if $|\delta_\tau| \sim \delta$, it is not possible to approximate the solutions of (4.22) by means of those of (2.20). We are then forced to study the complete solution of (4.22) as soon as the requirement $|\delta_\tau| \ll \delta$ is lost. Also using the asymptotics of $Q(y,\tau)$ we are then led to study the following problem instead of (2.27):

$$Q_s = Q_{yy} + \frac{3}{y}Q_y - \frac{yQ_y}{2} - 32\Gamma(\delta(s))^2\left[\delta^{(4)}(y) - \frac{1}{\langle 1,1\rangle}\right], \tag{4.55}$$

$$Q(y,s) = (\delta(s))^2\Omega(y) \quad \text{as } s \to -\infty, \tag{4.56}$$

where (4.18), (4.47), (4.54) provide a matching condition for $\delta(s)$ as $s \to -\infty$.

It is possible to write an explicit formula for $Q(y,s)$ using caloric kernels, as well as the following asymptotics for $Q(y,s)$ as $y \to 0^+$:

$$Q(y,s) \sim -\frac{4(\delta(s))^2}{y^2} + 4\left(\frac{\delta^2}{2} - \delta\delta_s\right)\log(y) + \lambda(s) + o(1), \tag{4.57}$$

where $\lambda(s)$ depends on the values of $\delta(\tilde{s})$ for $\tilde{s} \le s$. It would be possible to write this dependence using an explicit integral formula but this will not be needed. The only relevant information that we need at this point is that as far as $h(\tilde{s})$ remains bounded for $\tilde{s} \le s$ (equivalently, $|\delta(\tilde{s})| = O(e^{-\sqrt{\frac{\tau_\varepsilon}{2}}})$ for $\tilde{s} \le s$), then $|\lambda(s)| = O(e^{-\sqrt{2\tau_\varepsilon}})$. If we then match the asymptotics (4.13) with (4.57) we derive the following equation that would generalize (4.15) for $|\delta_\tau| \sim \delta$:

$$a_0(s) + \lambda(s) = -2(\delta^2 - 2\delta\delta_s)\log(\delta) - 2(\delta^2 - 2\delta\delta_s) + \frac{16\alpha\varepsilon}{3(T_\varepsilon - t)\delta^2}. \tag{4.58}$$

Using (4.18), (4.47) as well as the above-mentioned fact that $|\lambda(s)| = O(e^{-\sqrt{2\tau_\varepsilon}})$, it follows that to the leading order (4.53) remains valid as long as $h = O(1)$.

Having asserted the validity of (4.53) in the desired region of times we proceed to solve it with the matching condition (4.54). To this end we introduce a new variable $w = h^2e^{-s}$. Writing (4.53) in terms of w instead of h we would obtain

$$e^s w_s = \frac{1}{w} - 1$$

that is a separable equation with solution

$$w + \log(w-1) = e^{-s} + C, \tag{4.59}$$

where C is a real number. Deriving (4.59) we are implicitly assuming that $w > 1$, a property that can be expected at least for $s \to -\infty$ due to (4.54).

Using (4.59) we obtain the following asymptotics for $h(s)$:

$$h(s) \sim 1 + \frac{s}{2}e^s + \frac{C}{2}e^s + \cdots \quad \text{as } s \to -\infty, \tag{4.60}$$

$$h(s) \sim Ke^{\frac{s}{2}} + \cdots \quad \text{as } s \to \infty, \tag{4.61}$$

where

$$e^{K^2}(K^2-1)=e^C. \tag{4.62}$$

Combining (4.54) and (4.60) we then obtain the following value of C:

$$C=\frac{3(T-T_\varepsilon)\sqrt{2\tau_\varepsilon}e^{-2(\gamma+2)}}{\alpha\varepsilon e^{2\sqrt{2\tau_\varepsilon}}}+\frac{\sqrt{2\tau_\varepsilon}}{2}. \tag{4.63}$$

Notice that for any $C>0$ the solution of (4.53) is defined globally for $-\infty<x<\infty$. Indeed, notice that h cannot approach zero for a finite value of s because (4.53) implies that for h small enough h_s is positive. On the other hand, (4.53) implies that h_s is linearly bounded on h for h large.

At this point we need to choose T_ε. We will choose T_ε in such a way that C in (4.63) approaches $-\infty$ as $\varepsilon\to 0$. In another way, we assume that

$$\varepsilon e^{2\sqrt{2\tau_\varepsilon}}\sim\varepsilon e^{2\sqrt{2\log(\frac{1}{\varepsilon})}}\ll(T_\varepsilon-T)\ll 1. \tag{4.64}$$

At first glance the choice (4.64) might look a bit artificial, but on the contrary it turns out that it is rather natural. Choosing T_ε in this manner we will obtain that K in (4.61), (4.62) approaches its minimum value $K=1$ as $\varepsilon\to 0$. As we will show briefly, this choice of K (i.e., $K\approx 1$) will imply that for $t\approx T_\varepsilon$, $M(r,t)$ behaves approximately near the origin as one of the steady states $M_\lambda(r)$ described at the beginning of this section (cf. (4.1), (2.37)), having an amount of mass $4+a_0(\tau_\varepsilon)$ (cf. (4.3)). If the choice $K\approx 1$ had not been made, $M(r,T_\varepsilon)$ would have a width much larger than the steady state associated to mass $4+a_0(\tau_\varepsilon)$ or, in a more precise manner, it would not be possible to describe $M(r,T_\varepsilon)$ using a steady state. The choice of (4.64) essentially means that T_ε has been chosen close to T but at the same time $|T_\varepsilon-T|$ is large enough to allow stabilization of the solutions to steady states. Of course, if T_ε is not chosen satisfying (4.64) the aspect of the solution would not change. However, at $t=T_\varepsilon$, $M(r,T_\varepsilon)$ would not yet be a steady state, and some additional analysis would be required to describe how such approximation to a steady state would take place. The choice (4.64) (or $K\approx 1$) just simplifies the description of $M(r,t)$ in an analytical manner. Some intuitive understanding of the choice of T_ε can be acquired if we assume instead in a provisional manner that $T_\varepsilon=T$. In that case (4.63) would imply that $C=\frac{\sqrt{2\tau_\varepsilon}}{2}\to\infty$, and in that case $K\to\infty$. Therefore the width of the region where the mass is distributed would be larger (cf. (4.61)). In other words, the term $-\alpha\varepsilon M(\frac{M_r}{r})^2$ in (4.4) slows down the process of chemotactic aggregation as it could be expected.

Taking into account (4.18), (4.47) as well as the asymptotics (4.61) we obtain

$$\delta(s)\sim Ke^{-\sqrt{\frac{\tau_\varepsilon}{2}}}e^{\frac{s}{2}}=Ke^{-\sqrt{\frac{\tau_\varepsilon}{2}}}e^{-\frac{\tau_\varepsilon}{2}}e^{\frac{\bar\tau}{2}}\quad\text{as } s=\bar\tau-\tau_\varepsilon\to\infty, \tag{4.65}$$

where due to our choice of T_ε, K has to be set as one.

In order to describe the asymptotics of M (or Φ) as $s\to\infty$ we remark that as long as $\delta(s)\ll 1$ we can use the approximation (4.14) with the matching condition $\psi\sim-\frac{4\delta^2}{y^2}$ as $y\to 0^+$. It is natural to decompose ψ as in (2.22). Functions $a_0(s)$, $Q(y,s)$ evolve according to the equations (2.24), (2.26), respectively. To the leading order, and taking into account (4.50) (cf. also (4.18), (4.47)), $a_0(s)$ remains approximately constant if s remains of order one. However, this ceases being so if $s\to\infty$, due to the

exponential growth of $\delta(s)$. Integrating (2.24) we obtain the following approximation for $a_0(s)$:

$$a_0(s) \approx a_0(\tau_\varepsilon) - K^2 e^{-\sqrt{2\tau_\varepsilon}} e^s \tag{4.66}$$

for s of order one, or larger. Function $Q(y,s)$ can be approximated in the form $e^s W(y)$ as $s \to \infty$. It is easier to compute this approximation in the following manner. Formula (4.66) suggests looking for approximations of ψ in the form

$$\psi = a_0(\tau_\varepsilon) + (\delta(s))^2 Z(y)$$

with Z satisfying

$$Z = Z_{yy} + \frac{3}{y} Z_y - \frac{y Z_y}{2} - 32\Gamma \delta^{(4)}(y). \tag{4.67}$$

The solution of (4.67) can be computed explicitly as

$$Z = -\frac{4}{y^2}.$$

Therefore, to the leading order

$$\psi \sim a_0(\tau_\varepsilon) - \frac{4(\delta(s))^2}{y^2} \quad \text{as } s \to \infty,\ y \gg \delta(s). \tag{4.68}$$

Summarizing, using (1.6) and (4.68) we obtain that in the range of times $\tau_\varepsilon \leq \tau$, and as long as $\delta(s) \ll 1$, we can approximate Φ as

$$\Phi \approx 4 + a_0(\tau_\varepsilon) - \frac{4(\delta(s))^2}{y^2} \quad \text{for } y \gg \delta(s), \tag{4.69}$$

where in (4.69) we will understand that only the larger of the terms $a_0(\tau_\varepsilon)$, $\frac{4(\delta(s))^2}{y^2}$ is meaningful. In a more precise manner (4.69) means $\Phi = 4 + a_0(\tau_\varepsilon) - \frac{4(\delta(s))^2}{y^2} + o(\max\{a_0(\tau_\varepsilon), \frac{(\delta(s))^2}{y^2}\})$, where by assumption y is bounded and satisfies $y \gg \delta(s)$. Due to the exponential growth of $\delta(s)$ (cf. (4.65)), the term $\frac{4(\delta(s))^2}{y^2}$, which initially is negligible if y is of order one, becomes the dominant one as s grows.

If $y \sim \delta(s)$, Φ might be approximated using (4.7), a formula that matches (4.69) in the intermediate region $\delta(s) \ll y \ll 1$. In particular, to the leading order Φ is approximately a steady state in the region $y \sim \delta(s)$.

Approximation (4.69) is valid as long as $e^{-\sqrt{2\tau_\varepsilon}} e^s$ remains small, because as soon as this quantity becomes of order one $\delta(s)$ becomes of order one (cf. (4.65)), and Φ cannot be approximated by means of (4.13) anymore. Let us define s_ε by means of $e^{-\sqrt{2\tau_\varepsilon}} e^{s_\varepsilon} = 1$. Formulae (4.65) and (4.69) provide an approximation of Φ as long as $s \ll s_\varepsilon$. In the original variables, such an approximation would be valid for $t < t_\varepsilon$, $T - t_\varepsilon = O(e^{-(\tau_\varepsilon + \sqrt{2\tau_\varepsilon})})$.

We finally proceed to compute $M(r, T_\varepsilon)$ in a way analogous to that in the case $\varepsilon = 0$. In the region $|x| \geq e^{-\frac{\tau_\varepsilon}{2}} \approx \sqrt{\varepsilon} \frac{e^{\sqrt{2\log(\frac{1}{\varepsilon})}}}{(\log(\frac{1}{\varepsilon}))^{\frac{1}{4}}}$, we can argue exactly as in section 2 since $a_0(\tau)$ remains almost constant for t between t_ε and T_ε. On the other hand, for $|x| \leq e^{-\frac{\tau_\varepsilon}{2}}$ we can use the fact that Φ is already close to a steady state (cf. (4.65)),

and the solution continues being close to a steady state for $t \le t_\varepsilon$. Actually, it is interesting to note that the steady state that has been reached is the one associated to the amount of mass $4 + a_0(\tau_\varepsilon)$ (cf. (4.3) and (4.69)). Indeed, the asymptotics (4.3) gives a width for the steady state $(\delta(s))^2 \sim 4K^2 e^{-(\gamma+2)} e^{-\sqrt{2\tau_\varepsilon}+s}$, or, in the original variables, $|x|^2 \sim 4K^2 e^{-(\gamma+2)} e^{-\sqrt{2\tau_\varepsilon}-\tau_\varepsilon}$, where $K \approx 1$. Taking into account the form in which the parameter ε appears in (2.5), it turns out that the value of the parameter λ (cf. (4.1)) for a steady state with width $(\delta(s))^2$ is

$$\lambda \sim \frac{8\varepsilon e^{\bar\tau}}{(\delta(s))^2} \sim \frac{6e^{-(\gamma+2)}\sqrt{2\tau_\varepsilon}}{\alpha K^2} e^{-\sqrt{2\tau_\varepsilon}} \sim \frac{6e^{-\gamma}}{\alpha K^2} e^{-\sqrt{2\log(\frac{1}{\varepsilon})}} \sqrt{2\log\left(\frac{1}{\varepsilon}\right)}. \tag{4.70}$$

The mass associated to this value of λ is (cf. (4.3))

$$\begin{aligned} M_\lambda(\infty) &\sim 4 + \frac{2\alpha}{3}\lambda \sim 4 + 4e^{-(\gamma+2)}\sqrt{2\tau_\varepsilon} e^{-\sqrt{2\tau_\varepsilon}} \\ &\sim 4 + 4e^{-\gamma} e^{-\sqrt{2\log(\frac{1}{\varepsilon})}} \sqrt{2\log\left(\frac{1}{\varepsilon}\right)}, \end{aligned} \tag{4.71}$$

where we have used the fact that $K \approx 1$, which coincides exactly with the asymptotics of M in the outer region $|y| \gg \delta$. In a more precise manner for times $(T_\varepsilon - t) \le e^{-\tau_\varepsilon - s_\varepsilon}$ in a region close to the origin, M becomes close to a steady state of (2.5) having the mass concentrated in a region of size $|x| \sim \sqrt{\varepsilon}\frac{e^{\sqrt{\frac{1}{2}\log(\frac{1}{\varepsilon})}}}{(\log(\frac{1}{\varepsilon}))^{\frac{1}{4}}} \equiv \chi(\varepsilon)$. Notice that $\chi(\varepsilon) \gg \sqrt{\varepsilon}$; therefore the size of this steady state is still much larger than the developed concentration region described in [22]. This is due to the fact that this concentration region has a mass that is still very close to 8π.

Finally we describe the evolution of $M(r,t)$ for $\varepsilon\frac{e^{\sqrt{2\log(\frac{1}{\varepsilon})}}}{(\log(\frac{1}{\varepsilon}))^{\frac{1}{2}}} \ll t - T_\varepsilon \ll 1$. Notice that in a region with size $|x| \approx O(\sqrt{\varepsilon}\frac{e^{\sqrt{\frac{1}{2}\log(\frac{1}{\varepsilon})}}}{(\log(\frac{1}{\varepsilon}))^{\frac{1}{4}}})$, solutions stabilize to equilibrium solutions in times of order $\varepsilon\frac{e^{\sqrt{2\log(\frac{1}{\varepsilon})}}}{(\log(\frac{1}{\varepsilon}))^{\frac{1}{2}}}$. For longer times we can then assume that the inner region has already stabilized to the value of the steady state associated to the value of the mass M in the corresponding outer region. Therefore, if $t > T_\varepsilon$, the inner region just follows the steady state having the mass given by the "outer behavior" computed in (2.46). Since in the outer region $G_\varepsilon(\frac{M_r}{r})$ can be approximated as $\frac{M_r}{r}$, it then follows that the corresponding solution can be approximated by the solution of (2.6). The inner region has a size of order $|x| \le \chi(\varepsilon)$ for times $t \le \bar t_\varepsilon$, where $\sqrt{|\log(\bar t_\varepsilon - T_\varepsilon)|}e^{-\sqrt{2|\log(\bar t_\varepsilon - T\varepsilon)|}} \sim e^{-\sqrt{2\log(\frac{1}{\varepsilon})}}\sqrt{\log(\frac{1}{\varepsilon})}$ or, in an equivalent manner, $\bar t_\varepsilon - T_\varepsilon \sim \varepsilon$. If $t \ge \bar t_\varepsilon$ the asymptotics (2.44) cannot be assumed to be constant anymore and the steady state that describes the inner layer begins to be modified. The width of the region occupied for the concentration regions can then be computed using (4.3) as well as (2.44). Such width turns out to be given by

$$\lambda \sim \frac{6}{\alpha} e^{-(\gamma+2)}\sqrt{2|\log(t - T_\varepsilon)|}e^{-\sqrt{2|\log(t-T_\varepsilon)|}} \quad \text{as } \varepsilon \ll t - T_\varepsilon \ll 1,$$

where λ is as in (4.1).

Notice that, as it could be expected, λ becomes of order one for $|t - T_\varepsilon|$ of order one.

5. Concluding remarks. This paper continues the analysis begun in [22]. The question considered in both papers is to study the effect of cutting off the chemotactic function for large values of cell concentration. For linear chemotactic functions it is known that the Keller–Segel model yields formation of Dirac masses in finite time. If the chemotactic function is assumed to saturate, solutions of the Keller–Segel system are global in time. It was seen in [22], using matched asymptotics, that solutions of this last system can exhibit some concentration regions that interact among themselves and with the surrounding cells. The dynamics of such regions has been studied in [22] in detail. This paper describes how the transition between the blowing up solutions of limit system (1.6), (1.7) and the type of solutions described in [22] takes place.

PARAMETER ESTIMATION OF THE HODGKIN–HUXLEY GATING MODEL: AN INVERSION PROCEDURE*

GUAN JUN WANG† AND JACQUES BEAUMONT†

Abstract. The Hodgkin–Huxley (HH) gating model has been extensively employed over the last half century to describe bioelectricity phenomena related to normal and impaired electrophysiological functions. Since the HH gating model is relatively empirical, the associated modelling methodology requires estimating model parameters (including functions of membrane voltage) from experimental data. Until now, as is the case for most nonlinear models, parameter estimation has been carried out through nonlinear least square fitting, which presents important limitations for the modelling methodology.

Here we pursue a different approach to the estimation problem, which allows us to overcome all the limitations inherent to nonlinear fitting. As initially introduced by Beaumont, Roberge, and Leon [*Math. Biosci.*, 115 (1993), pp. 65–101], instead of fitting we invert the solution. Specifically, model parameters (including functions of membrane voltage) are obtained from multiple transformations (or modals) applied to the solution, or equivalently, from an experimental data set. Such transformations enable one to deduce, for a given data point, disjoint ranges of parameter values which allow the model to exactly reproduce the solution. Using sufficiently large data sets and continuity criteria, it is possible to narrow down estimates to a specific value.

Our main results are (i) a more accurate estimation procedure; (ii) the ability to determine whether a data set sufficiently constrains the model, i.e., whether it is complete; (iii) if it is not, the possibility to identify a model family capable of reproducing the entire data set; and (iv) stimulation protocols which can produce complete data sets.

Key words. Hodgkin–Huxley model, nonlinear parameter estimation, membrane current kinetics, inverse problem

1. Introduction.

The elucidation of dynamic changes in membrane conductance at the origin of cell excitability as well as its modelling by Hodgkin and Huxley [18], and the introduction of patch clamp techniques by Neher and Sackmann (see [15] for a detailed description), are among the most important discoveries of the last century in bioelectricity. In their classical study [18], Hodgkin and Huxley introduced a nonlinear model (the HH model) which describes current kinetics as a function of membrane channel states. While relatively empirical, the HH model has provided many insights into various bioelectric phenomena. In fact, both patch clamp techniques and gating models like the HH model are still the basic tools employed in investigations of bioelectric phenomena, e.g., the initiation and perpetuation of cardiac arrhythmias [4, 5, 29, 27, 28, 20, 16, 13, 10], the effect of electrical shocks on the evolution of cardiac arrhythmias [7, 33, 25, 21], neuromuscular control [12], coding of visual [19, 14, 31] as well as auditory signals [8, 9], cognitive functions like memory [1] and learning [24, 32, 23, 30], and finally brain diseases [22].

In practice, there are two modes for membrane current recording: one for analysis of channel populations, and another one for isolated channels. Here, we are concerned

only with the electrical activity of a channel population. To date, the HH gating model has been the most popular way to represent such activity. An alternative to this model is the deterministic Markovian model [26]. The Markovian model describes the biophysics of the gating process by treating membrane channels as entities exhibiting multiple voltage-dependent transitions between discrete states, and thus it is in better agreement with experimentation [26]. Also, several details of the current kinetics cannot be reproduced with an HH model [26]. However the link between changes in channel conformation and current kinetics is far from being obvious, and arguments based on current kinetics were not supported by an extensive mathematical analysis.

Because the HH model is relatively empirical, its parameters can only be estimated from experimental data. In mathematical terms we are facing an inverse problem, i.e, given only the solution of a nonlinear ODE (HH model), estimate its initial conditions and parameters. Until now, parameter estimation has followed the practice introduced by Hodgkin and Huxley [18], where parameters are obtained from currents recorded during voltage clamp stimulations (voltage clamp data). In such protocols, the membrane potential is held constant for an interval of time sufficiently long for the current flow to reach a steady state. Then time-dependent currents are recorded following the application of a test potential. Sets of currents are generated by varying the holding or test potentials. In experimental studies, it has become a common practice to approximate the parameters associated with the steady state functions of the model from currents obtained by varying the holding potential, and the time constants by fitting exponentials to the rising or decaying phase of the currents. A mathematical analysis has shown that this approach may provide a good approximation to several model parameters if specific conditions are respected [2]. If they are not, the error may be very large [2]. The weakness of this approach was also reported by Willms and colleagues [34, 35] (it is referred to as the disjoint method in their paper).

If appropriately performed, nonlinear least square fitting of voltage clamp data can produce good estimates, even in the presence of Gaussian noise [34, 35]. Nevertheless, nonlinear fitting has important drawbacks. The existence of local minima in the merit function to be optimized is particularly problematic. While the parameters are estimated with voltage clamp data, in most applications, the model is employed in other conditions to simulate the generation and transmission of electrical impulses in biological tissues. Although parameter values associated with various local minima may allow good reproduction of the voltage clamp data at the origin of the fit, they may produce different predictions when inserted in a more macroscopic model. This becomes a serious limitation when, for example, studying how channel mutations may render the myocardium more susceptible to the initiation of various arrhythmias. Considering two limitations of voltage clamp data sets, the range of inverse solutions can be large. First, voltage clamp data are relatively imprecise due to imperfect voltage control, space clamp, and seal between the mouth of the pipette and the cell membrane [15]. These errors are difficult to correct, and taking them into consideration by accepting a variation in the solution, even if small, may lead to large variations in the model parameters. Second, we do not know whether a voltage clamp data set produced by current practice constrains the HH gating model sufficiently. In fact, from the theory developed here it will become evident that it does not in most cases.

Following earlier studies [2, 3], we present here an inversion procedure which overcomes all the difficulties inherent to nonlinear fitting. The estimation problem requires evaluation of one constant and, for each state variable included in the model,

two functions of membrane voltage, namely the steady state and the time constant. We introduce transformations which, when applied to voltage clamp data sets obtained by keeping the test potential constant, allow estimation of steady states. Once these functions are evaluated, we bound the inverse solution by applying other transformations to complementary data sets. Interestingly, the bounds delineate disjoint ranges of valid parameter values. For any point taken within these bounds, we can associate to it a time constant. Due to the existence of disjoint ranges, inversion of the time constants produces a structure with multiple branches. When the data set is complete, it is possible to deduce a function from such a structure. Important outcomes of the study are the ability to determine whether a voltage clamp data set is complete or not, and to identify a set of protocols which can produce a complete data set. Both elements are, we believe, important for experimental design and for the development of a systematic modelling methodology.

The paper is organized as follows. For the sake of completeness we introduce the model and various definitions in section 2. In section 3 we introduce transformations that allow estimation of the steady state functions. Finally, transformations to bound the inverse solution and to estimate the time constants are derived in section 4.

2. Preliminaries. In the HH gating model, a given channel is composed of several molecular components (gates). These change state under the influence of the electrostatic potential existing across the cell membrane (V). Each molecular component has two states: closed (C) or open (O). The channel is open when all its molecular components are in the open state. Otherwise it is closed. Such behavior is represented by the following state diagram:

$$C_i \underset{\beta_i(V)}{\overset{\alpha_i(V)}{\rightleftharpoons}} O_i, \tag{2.1}$$

where V is the membrane potential and $\alpha(V)$ and $\beta(V)$ are, respectively, the forward and backward rates of transition between the open (O) and closed (C) states of the molecular gate i. The law of mass action governs the dynamical changes between the two states. Precisely, the variable y represents the fraction of a population of gates in the open state, the kinetics of which obeys

$$\frac{dy_i(V,t)}{dt} = \alpha_i(V)\,(1 - y_i(V,t)) - \beta_i(V) y_i(V,t). \tag{2.2}$$

We refer to the variables y_i as the gating variables. When in the open state, the channel is seen as a resistive barrier to the passage of ions and has a fixed maximal conductance denoted by $\bar{g}$. We assume $\bar{g}$ constant, but, as will be clear later, the method applies as well when $\bar{g}$ is a function of voltage, as long as this function is known. The driving force for the passage of ions across the channel is the electrochemical gradient, which is given by $V - e_k$, where e_k is the Nernst potential related to an ion species "k" [11, Chap. 2]. The membrane current for an ion species "k," denoted by $I_k(V,t)$, is

$$I_k(V,t) = \bar{g}_k \left(\prod_{n=0}^{\bar{n}(k)} y_{k,n}(V,t)^{\lambda_{k,n}} \right) (V - e_k), \tag{2.3}$$

where $\bar{n}(k)$ is the number of distinct molecular gates of a channel, and $\lambda_{k,n}$ the number of similar components of a molecular gate n in a channel k.

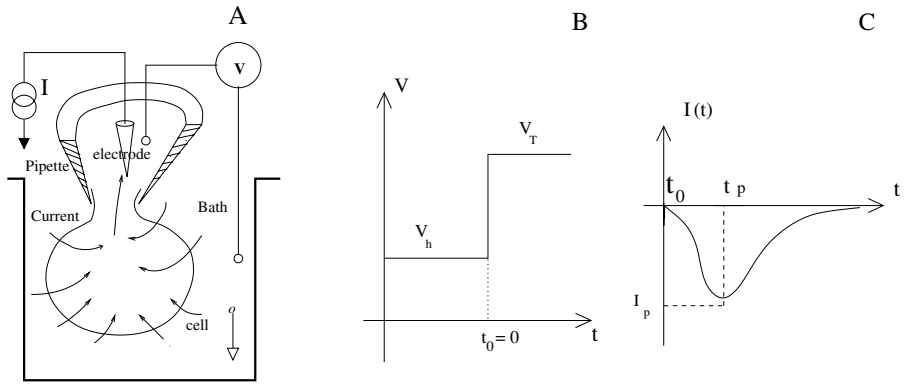

FIG. 2.1. A: *Setup for voltage clamp experiment.* B: *Stimulation protocol.* C: *Typical current wave shape.*

Data at the basis of the parameter estimation are membrane currents recorded in isolated cells during voltage clamp stimulation. The experimental setup is illustrated in Figure 2.1 and described in detail in [15]. Briefly, cells are isolated, then a pipette is apposed against the membrane surface, and suction is applied to break the membrane under the pipette tip. The interior of the pipette is then in continuum with the intracellular space. An electronic feedback circuit allows one to simultaneously impose potential and record current on the electrode placed inside the pipette. The voltage clamp stimulation (Figure 2.1B) consists of clamping the membrane potential at a holding potential V_H for an interval of time sufficiently long for ionic fluxes to reach steady state. Then at t_0 a step to a test potential V_T is applied. The membrane current is recorded just after the application of the step. In the following we assume that only one type of membrane channel produces the current. Thus we use only one subscript to refer to the gating variables. In these conditions, the time course of a gating variable y_i is given by

$$y_i(t; V_H, V_T) = s_i(V_T) + (s_i(V_H) - s_i(V_T))\, e^{-t/\tau_i(V_T)}, \tag{2.4}$$

where $s_i(V)$ and $\tau_i(V)$ are, respectively, the steady state and time constant associated to the gating variables y_i. They are related to the forward and backward rates of transition by

$$s(V) = \frac{\alpha(V)}{\alpha(V) + \beta(V)} \quad \text{and} \quad \tau(V) = \frac{1}{\alpha(V) + \beta(V)}. \tag{2.5}$$

Because $s(V)$ and $\tau(V)$ are parameters more directly measurable, the format

$$\frac{dy(V,t)}{dt} = \frac{s(V) - y(V,t)}{\tau(V)} \tag{2.6}$$

for the expression governing the dynamical changes in y_i is preferred. It is an experimental fact that, for the great majority of membrane channels, $s_i(V)$ are monotonic functions exhibiting sigmoidal shape. They are commonly parameterized by

$$s(V) \approx \frac{1}{1 + e^{(V - V_0)/s_f}}, \tag{2.7}$$

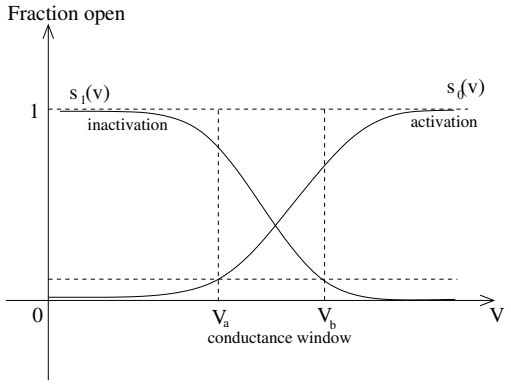

FIG. 2.2. *Steady state functions $s_i(V)$ of a two-component gating model.*

which for reasons unknown to these authors is called a Boltzmann function. Although there exist some arguments justifying parameterizing $s_i(V)$ with the above function [6], [17, Chap. 2], here we assume only that $s_i(V)$ is monotonic.

When $s_i(V)$ is monotonically increasing/decreasing with the membrane potential, we refer to the related gating variable (y_i) as an activation/inactivation gate (Figure 2.2). In this paper we deal with gating models incorporating only two gates, one activation and one inactivation gate, which is a situation frequently encountered in bioelectricity. We term the voltage range where $\prod_{n=0}^{\bar{n}} s_n^{\lambda_n}(V) > 1\%$ the conductance window. To simplify the writing, we denote $s_i(V_a) \equiv s_a^i$ and similarly for the time constants $\tau_i(V_a) \equiv \tau_a^i$, where V_a refers to a specific membrane voltage. For an HH model with one activation (y_0) and one inactivation gate (y_1), the current waveform during a voltage clamp stimulation has at most two extrema. The time coordinates of the peak currents are given by the zeros of

$$\delta(t) = \frac{\tau_T^0 \lambda_1}{\tau_T^1 \lambda_0} \frac{s_T^0}{(s_T^0 - s_H^0)} e^{t/\tau_T^0} + \frac{s_T^1}{(s_T^1 - s_H^1)} e^{t/\tau_T^1} - \left(1 + \frac{\tau_T^0 \lambda_1}{\tau_T^1 \lambda_0}\right), \tag{2.8}$$

which has a critical point at

$$t_c = \frac{\tau_T^0 \tau_T^1}{\tau_T^0 - \tau_T^1} \ln\left[\frac{\lambda_0 s_T^1 (s_T^0 - s_H^0)}{\lambda_1 s_T^0 (s_H^1 - s_T^1)}\right]. \tag{2.9}$$

At the critical point,

$$\left.\frac{d^2\delta(t)}{dt^2}\right|_{t=t_c} = \left(\frac{1}{\tau_T^0} - \frac{1}{\tau_T^1}\right) \left[\frac{\lambda_0 (s_T^0 - s_H^0)}{s_T^0}\right]^{\frac{\tau_T^0}{(\tau_T^1 - \tau_T^0)}} \left[\frac{s_T^1}{\lambda_1 (s_H^1 - s_T^1)}\right]^{\frac{\tau_T^1}{(\tau_T^0 - \tau_T^1)}}. \tag{2.10}$$

The reader should consult [2] for more details about (2.8)–(2.10).

Below, we denote time derivatives with a dot above the differentiated variables. For an arbitrary couple V_H, V_T, we denote the membrane current by $I(t)$, $J(t) \equiv \dot{I}(t)/I(t)$, and $I_N(t; t_r) \equiv I(t)/I(t_r)$, where t is a continuous variable and t_r a given reference time within the recording interval $[t_a, t_b]$. Sometimes it is necessary to specify the potentials of the voltage clamp stimulation associated with a current. In this case we denote the current by $I(t; V_H, V_T)$, where the potentials on the right of the semicolon are in the order in which they are applied in time during stimulation. A similar notation applies to any function derived from such a current, e.g.,

$J(t) \rightarrow J(t; V_H, V_T)$, $I_N(t; t_r) \rightarrow I_N(t, t_r; V_H, V_T)$. Transformations derived below are applied to sets of functions (or currents) which share similar properties. Examples of such sets are $I(t)$ acquired through repetitive application of voltage clamp steps where only one potential of the step is varied at each stimulation. We denote sets by indicating the voltage partition associated with the stimulation sequence in the arguments. For example, we denote by $I(t; [V_{H0} \cdots V_{Hn}], V_T)$, $[V_{H0} \cdots V_{Hn}]$, a partition of $[V_{H0}, V_{Hn}]$, and similarly when V_T is varied. Sets of functions derived from a set of currents are denoted analogously, e.g., $J(t; [V_{H0} \cdots V_{Hn}], V_T)$, $I_N(t, t_r; [V_{H0} \cdots V_{Hn}], V_T)$. We denote by $\Omega_{t,V}$ the space $t \in [t_a, t_b]$, $V \in [V_{H0}, V_{Hn}]$ generated during the acquisition of $I(t; [V_{H0} \cdots V_{Hn}], V_T)$ or $I(t; V_H, [V_{T0 \ldots} V_{Tn}])$. The context always makes clear what is intended as the V axis of $\Omega_{t,V}$. Finally, since λ_i are integers, and based on experimental observations they are small (i.e., $\lambda_i < 6$), in our estimation procedure we assume these constants to be known.

3. Estimation of the steady states, $s_i(V)$. Since the expression of any $I(t; V, V_T) \in I(t; [V_{H0} \cdots V_{Hn}], V_T)$, $V \in [V_{H0} \cdots V_{Hn}]$, differs only in s_H^i (see (2.4)), the data set $I(t; [V_{H0} \cdots V_{Hn}], V_T)$ poses considerable constraints on the model parameters. Here we exploit this property to evaluate $s_i(V)$.

THEOREM 3.1. *For any $I(t)$ and associated $J(t)$, $t \in [t_a, t_b]$, obtained from a single step stimulation,*

$$\frac{s_H^i}{s_T^i} = 1 - \frac{J(t_r) + \lambda_{\bar{\imath}}/\tau_T^{\bar{\imath}}(1 - \varepsilon_{\bar{\imath}}(t_r))}{J(t_r) + \lambda_i/\tau_T^i + \lambda_{\bar{\imath}}/\tau_T^{\bar{\imath}}(1 - \varepsilon_{\bar{\imath}}(t_r))}\, e^{t_r/\tau_T^i}, \qquad t_r \in [t_a, t_b],\ i \in [0, 1],\ \bar{\imath} = 1 - i, \tag{3.1}$$

where

$$\varepsilon_j(t_r) = \frac{s_T^j}{s_T^j + (s_H^j - s_T^j)e^{-t_r/\tau_T^j}}, \qquad t_r \in [t_a, t_b],\ j \in [0, 1]. \tag{3.2}$$

Proof. Take the derivative with respect to time of (2.3), divide the resulting expression by (2.3), and replace in the latter $dy_i(V,t)/dt$ by (2.6). It follows that

$$J(t) = \frac{\lambda_0}{y_0}\frac{dy_0}{dt} + \frac{\lambda_1}{y_1}\frac{dy_1}{dt} = -\frac{\lambda_0}{\tau_T^0}(1 - \varepsilon_0(t)) - \frac{\lambda_1}{\tau_T^1}(1 - \varepsilon_1(t)). \tag{3.3}$$

Solve $\varepsilon_i(t)$ for s_H^i/s_T^i; (3.1) follows immediately. ∎

Interesting simplifications occur when the following holds.

CONDITION 3.2. $\mathrm{Max}\{\varepsilon_1(t; V, V_T)\} \leq \varepsilon_{th} \ll 1$ *over a set* $I(t; V, V_T)$, $t, V \in \Omega_{t,V}$.

Here dependence on $s_1(V)$ is eliminated in (3.3). The counterpart to this condition is the following.

CONDITION 3.3. $\mathrm{Max}\{\varepsilon_0(t; V, V_T)\} \leq \varepsilon_{th} \ll 1$ *over a set* $I(t; V, V_T)$ $t, V \in \Omega_{t,V}$.

Fortunately, stimulation sequences producing currents satisfying these conditions exist.

PROPOSITION 3.4. *Condition* 3.2 *is satisfied if*

$$\left[\frac{I(t_a; V, V_T)}{I(t_{max}; V, V_T) + I(t_b; V, V_T)}\right]^{1/\lambda_1} < \epsilon_{th}, \qquad t_{max}, V \in \Omega_{t,V},\ V < V_T, \tag{3.4}$$

and 3.3 *if*

$$\left[\frac{I(t_a; V, V_T)}{I(t_{max}; V, V_T) + I(t_b; V, V_T)}\right]^{1/\lambda_0} < \epsilon_{th}, \qquad t_{max}, V \in \Omega_{t,V},\ V > V_T, \tag{3.5}$$

where $t \in [t_a, t_b]$, $t_a < t_{max} < t_b$, $I(t_{max}) = \mathrm{Max}\{I(t)\}$, $I_{t_a} > I_{t_b}$.

Proof. If in a single step stimulation sequence the currents are acquired in the space $\Omega_{t,V}$, which also satisfies $V_H < V_T$, then $d\epsilon_0(t)/dt < 0$, $d\epsilon_1(t)/dt > 0$, $\epsilon_0(t) \in (1, \infty)$, $\epsilon_1(t) \in (0, 1)$. Remarking that $\epsilon_j(t) = s_T^j / y_j(t)$, then

$$\frac{I(t_a)}{I(t_{max}) + I(t_b)} = \frac{\epsilon_0^{\lambda_0}(t_{max})\epsilon_1^{\lambda_1}(t_{max}) + \epsilon_0^{\lambda_0}(t_b)\epsilon_1^{\lambda_1}(t_b)}{\epsilon_0^{\lambda_0}(t_a)\epsilon_1^{\lambda_1}(t_a)}. \tag{3.6}$$

Using the monotonicity of $\epsilon_j(t)$, the fact that $\epsilon_1(t)$ is bounded, and that the left member of 3.6 as well as $\epsilon_j^{\lambda_j}(t)$ are positive functions,

$$\begin{aligned} \frac{I(t_a)}{I(t_{max}) + I(t_b)} &> \frac{\epsilon_0^{\lambda_0}(t_{max})}{\epsilon_0^{\lambda_0}(t_a)} + \frac{\epsilon_0^{\lambda_0}(t_b)\epsilon_1^{\lambda_1}(t_b)}{\epsilon_0^{\lambda_0}(t_a)\epsilon_1^{\lambda_1}(t_a)} \\ &> \epsilon_1^{\lambda_1}(t_a)\left[\frac{\epsilon_0^{\lambda_0}(t_{max})}{\epsilon_0^{\lambda_0}(t_a)}\frac{\epsilon_0^{\lambda_0}(t_a)}{\epsilon_0^{\lambda_0}(t_b)} + \frac{\epsilon_1^{\lambda_1}(t_b)}{\epsilon_1^{\lambda_1}(t_a)}\right] > \epsilon_1^{\lambda_1}(t_b) \\ &= [\mathrm{Max}\{\epsilon_1(t)\}]^{\lambda_1}, \quad t \in \{t_a, t_b\}. \end{aligned} \tag{3.7}$$

The same applies to Condition 3.3 when currents are acquired in a space $\Omega_{t,V}$ satisfying $V > V_T$. The proof easily follows from the above and is left to the reader. ∎

Interestingly, due to the structure of the HH gating model, most of the relations developed for the estimation of $s_i(V)$ are symmetric with respect to Conditions 3.2 and 3.3.

DEFINITION 3.5 (symmetric expression). *Take two arbitrary sets of currents* $\mathcal{I}_1$ *and* $\mathcal{I}_2$ *respectively satisfying some conditions* $\mathcal{C}_1$ *and* $\mathcal{C}_2$. *Assume expressions* $\mathcal{E}_1$ *and* $\mathcal{E}_2$ *are obtained from the application of the same transformations respectively to* $\mathcal{I}_1$ *and* $\mathcal{I}_2$. *We say that* $\mathcal{E}_1$ *and* $\mathcal{E}_2$ *have a symmetric structure or simply are symmetric with respect to the conditions* $\mathcal{C}_1$ *and* $\mathcal{C}_2$ *if* $\mathcal{E}_1$ *can be obtained from* $\mathcal{E}_2$, *and vice versa, simply by interchanging the indices* 0 *and* 1 *of each parameter and function.*

Obviously (3.1) is symmetric with respect to Conditions 3.2 and 3.3.

We now deduce modals which allow us to evaluate τ_T^i in (3.1).

LEMMA 3.6. *Consider a set* $I(t; V, V_T)$, $t, V \in \Omega_{t,V}$, *which satisfies Condition* 3.2. *Then for any* $J(t, V, V_T)$ *and* $I_N(t, t_r; V, V_T)$, $t, V \in \Omega_{t,V}$, *deduced from this set,*

$$J(t; t_r; V, V_T) = \frac{\frac{\lambda_0}{\tau_T^0}\left(J(t_r; V, V_T) + \frac{\lambda_1}{\tau_T^1}\right)e^{-(t-t_r)/\tau_T^0}}{\left(J(t_r; V, V_T) + \frac{\lambda_0}{\tau_T^0} + \frac{\lambda_1}{\tau_T^1}\right) - \left(J(t_r; V, V_T) + \frac{\lambda_1}{\tau_T^1}\right)e^{\frac{-(t-t_r)}{\tau_T^0}}} - \frac{\lambda_1}{\tau_T^1}, \tag{3.8}$$

$$\begin{aligned} I_N(t; t_r; V, V_T)^{\frac{1}{\lambda_0}} = \frac{\tau_T^0}{\lambda_0}\Bigg[&\left(J(t_r; V, V_T) + \frac{\lambda_0}{\tau_T^0} + \frac{\lambda_1}{\tau_T^1}\right) \\ &- \left(J(t_r; V, V_T) + \frac{\lambda_1}{\tau_T^1}\right)e^{\frac{-(t-t_r)}{\tau_T^0}}\Bigg]\, e^{\frac{-\lambda_1(t-t_r)}{\lambda_0\tau_T^1}}. \end{aligned} \tag{3.9}$$

Furthermore, both (3.8) *and* (3.9) *are symmetric with respect to Conditions* 3.2 *and* 3.3.

Proof. Equation (3.8) follows from substituting (3.1) into (3.3). To obtain (3.9), integrate (3.8) in the interval $[t_r, t]$, take the exponential of the resulting expression, and elevate each member to the power $1/\lambda_0$. Symmetry of (3.8) and (3.9) with respect to Conditions 3.2 and 3.3 follows from symmetry of (3.1) to the same conditions. ∎

Expressions of Lemma 3.6 provide two independent relations dependent on two unknowns: τ_T^0 and τ_T^1. Thus we search for combinations of (3.8) and (3.9) which allow one to factor these unknowns.

THEOREM 3.7. *For any $I_N(t;t_r;V,V_T)$ and $J(t_r;V,V_T)$ deduced from $I(t;V,V_T)$, $t,V\in\Omega_{t,V}$, $t_r\in[t_a,t_b]$, which satisfies Condition* 3.2*,*

$$I_N^{\frac{1}{\lambda_0}}(t,t_r;V,V_T)-1=\theta_0\left(-\lambda_0\frac{dI_N(t,t_r;V,V_T)}{dt}+J(t_r;V,V_T)\right)-\theta_1\int_{t_r}^{t}I_N(t,t_r;V,V_T)dt, \tag{3.10}$$

with

$$\theta_0=\frac{\tau_T^0\tau_T^1}{(2\lambda_1\tau_T^0+\lambda_0\tau_T^1)}\quad\text{and}\quad\theta_1=\frac{\lambda_1}{\lambda_0\tau_T^1}\left(\frac{\lambda_1\tau_T^0+\lambda_0\tau_T^1}{2\lambda_1\tau_T^0+\lambda_0\tau_T^1}\right), \tag{3.11}$$

from (3.11) *we have*

$$\tau_T^0=\frac{\theta_0\lambda_0}{(1-4\lambda_0\theta_0\theta_1)^{1/2}},\qquad\tau_T^1=\frac{2\lambda_1\theta_0}{1-(1-4\lambda_0\theta_0\theta_1)^{1/2}}, \tag{3.12}$$

where (3.10)–(3.12) *are symmetric with respect to Conditions* 3.2 *and* 3.3.

Proof. Consider a set $I(t,V,V_T)$, $t,V\in\Omega_{t,V}$, satisfying Condition 3.2. Solve (3.9) for $e^{-(1/\tau_T^0+\lambda_1/(\lambda_0\tau_T^1))(t-t_r)}$. Then substitute the resulting expression into the derivative of (3.9). This leads to

$$\frac{dI_N(t,t_r;V,V_T)^{\frac{1}{\lambda_0}}}{dt}=\frac{\left(1+\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}{\tau_T^0}\left[\frac{\left(\frac{\tau_T^0}{\lambda_0}J(t_r)+1+\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}{\left(1+\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}e^{\frac{-\lambda_1}{\lambda_0\tau_T^1}(t-t_r)}-I_N(t,t_r;V,V_T)^{\frac{1}{\lambda_0}}\right]. \tag{3.13}$$

From the integration of (3.13) in the interval $[t_r,t]$ we have

$$I_N(t,t_r;V,V_T)^{\frac{1}{\lambda_0}}-1=-\frac{\left(\frac{\tau_T^0}{\lambda_0}J(t_r;V,V_T)+1+\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}{\left(\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}\left(e^{\frac{\lambda_1}{\lambda_0\tau_T^1}(t-t_r)}-1\right)$$
$$-\frac{\left(1+\frac{\tau_T^0\lambda_1}{\tau_T^1\lambda_0}\right)}{\tau_T^0}\int_{t_r}^{t}I_N(t,t_r;V,V_T)^{1/\lambda_0}dt. \tag{3.14}$$

Solve for $e^{(-\lambda_1/(\lambda_0\tau_T^1))(t-t_r)}$ using (3.13) and substitute the resulting expression into (3.14); formula (3.10) follows. Finally, symmetry of (3.13) and (3.14) with respect to Conditions 3.2 and 3.3 follows from the symmetry of (3.9) with respect to the same conditions. ∎

In practice the above procedure does not provide satisfying results when the conductance window is very narrow, a situation that is commonly encountered in bioelectricity (e.g., sodium current of many tissues from human and most animal species). In such an instance, the range of holding potentials for which it is possible to record a current and to satisfy Conditions 3.2 or 3.3 allows one to estimate only

the very foot of $s_i(V)$. To overcome this problem, we further develop a procedure introduced by Beaumont, Roberge, and Lemieux [3], which is based on an analytical expression for the normalized currents and their derivative.

THEOREM 3.8. *Consider a set $I(t;V,V_T)$, satisfying Condition* 3.2*, and $J(t;V,V_T)$, $t,V\in\Omega_{t,V}$, deduced from this set. Then*

$$\frac{I(t;V,V_T)}{I(t;V_R,V_T)}=\left[\frac{s_1(V)}{s_R^1}\right]^{\lambda_1}\left[\frac{J(t;V_R,V_T)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}}{J(t;V,V_T)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}}\right]^{\lambda_0},\ V_R\in[V_{H0}\cdots V_{Hn}], \tag{3.15}$$

where (3.15) *is symmetric with respect to Conditions* 3.2 *and* 3.3.

Proof. Consider any $I(t;V_H,V_T)\in I(t;V,V_T)$, $t,V\in\Omega_{t,V}$, satisfying Condition 3.2. Solve (3.3) for e^{-t/τ_i} and substitute the resulting expression into (2.4). Then at $t_r\in[t_a,t_b]$,

$$y_0(t_r;V,V_T)=s_T^0\frac{\frac{\lambda_0}{\tau_T^0}}{J(t_r;V,V_T)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}}, \tag{3.16}$$

$$y_1(t_r;V,V_T)=s_H^1\left[\frac{J(t_r;V,V_T)+\frac{\lambda_1}{\tau_T^1}}{J(t_r;V,V_T)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}}\,\frac{s_T^0}{s_T^0-s_H^0}\right]^{\tau_T^0/\tau_T^1}. \tag{3.17}$$

Substitute (3.16) and (3.17) into (2.3). Evaluate the resulting expression at two different potentials, and divide one of them by the other; then (3.15) follows. Symmetry of (3.15) with respect to Conditions 3.2 and 3.3 follows from symmetry of (3.16) and (3.17), which in turn follows from symmetry of (3.3) with respect to the same conditions. ∎

Theorem 3.8 is complementary to Theorem 3.1 in the sense that it provides, for the same set, information about $s_{\bar{\imath}}(V)$, $\bar{\imath}=1-i$. Fortunately, the conditions of application for each theorem are the same.

There remains another problem with the practical application of Theorems 3.1 and 3.8. Under restrictions imposed by Conditions 3.2 and 3.3, some models may not produce currents detectable by available instrumentation. This occurs with Condition 3.3 in a step simulation when $\tau_T^0<\tau_T^1$, $V_T<V_a$, $V_H>V_b$. In other words, during a step stimulation, the gate which is closing reacts more rapidly to changes in membrane potential than the one which is opening. This is the case for the sodium channel of cardiac cells of most animal species. To remedy this problem, we propose modifying the stimulation protocol by inserting a conditioning pulse prior to the application of the test pulse. The protocol is illustrated in Figure 3.1.

In this double step stimulation we consider ν to be an independent variable, and ν_r an arbitrary value along the ν axis. To be consistent with the notation introduced here, we denote an arbitrary current by $I(t;\nu_r)$, a current produced with specific potentials by $I(t;\nu_r;V_H,V_C,V_T)$, and sets of currents produced by varying either V_H or ν in a stimulation sequence, respectively, by $I(t;\nu_r;[V_{H0}\cdots V_{Hn}],V_C,V_T)$ and $I(t;[\nu_0\cdots\nu_n];V_H,V_C,V_T)$, where $[\nu_0\cdots\nu_n]$ is a partition of $[\nu_0,\nu_n]$, $\nu_n>\nu_0$. In this last case the acquisition space is denoted by $\Omega_{t,\nu}$. As with the single step stimulation, a similar notation applies to functions or sets deduced from these sets. Finally, we still denote the recording interval during the application of the test pulse by $[t_a,t_b]$.

Although the addition of a conditioning pulse complicates the analytical expression for the membrane current, it is still possible to express $s_i(V)$ as a function of various modals of the current.

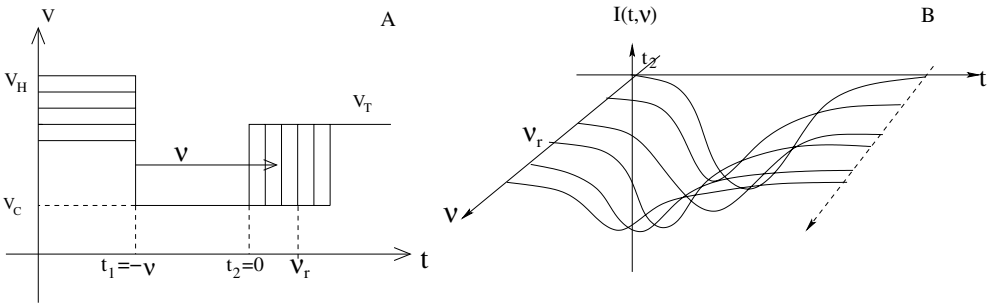

FIG. 3.1. A: *Voltage clamp protocol, which includes the insertion of a conditioning pulse (potential V_C and duration ν) prior to the application of a test pulse.* B: *Typical current traces.*

THEOREM 3.9. *For any $I(t,\nu_r) \in I(t;\nu_r,V,V_C,V_T)$ and $J(t,\nu_r) \in J(t;\nu_r,V,V_C,V_T)$, $t,V \in \Omega_{t,V}$, deduced from the same set,*

$$\frac{s_H^i}{s_T^i} = \frac{s_C^i}{s_T^i} - \left(\frac{s_C^i}{s_T^i} - 1\right) e^{\frac{\nu_r}{\tau_c^i}} - \frac{\left(J(t_r;\nu_r) + \frac{\lambda_{\bar\imath}}{\tau^{\bar\imath}}(1-\psi_{\bar\imath}(t_r;\nu_r))\right)}{\left(J(t_r;\nu_r) + \frac{\lambda_i}{\tau_T^i} + \frac{\lambda_{\bar\imath}}{\tau_T^{\bar\imath}}(1-\psi_{\bar\imath}(t_r;\nu_r))\right)} e^{\left(\frac{t_r}{\tau_T^i}+\frac{\nu_r}{\tau_C^i}\right)},$$

$$t_r \in [t_a,t_b],\ i \in [0,1],\ \bar\imath = i-1, \tag{3.18}$$

with

$$\psi_j(t_r;\nu_r) = \frac{s_T^j}{s_T^j + (s_C^j - s_T^j)e^{\frac{-t_r}{\tau_T^j}} + (s_H^j - s_C^j)e^{-\left(\frac{t_r}{\tau_T^j}+\frac{\nu_r}{\tau_c^j}\right)}}, \qquad t_r \in [t_a,t_b]. \tag{3.19}$$

Proof. The time course of $y_i(t)$, $t \in [t_a,t_b]$, in a double step voltage clamp stimulation is given by

$$y_i(t,\nu_r) = s_T^i + (s_C^i - s_T^i)e^{\frac{-t}{\tau_T^i}} + (s_H^i - s_C^i)e^{-\left(\frac{t}{\tau_T^i}+\frac{\nu_r}{\tau_C^i}\right)}. \tag{3.20}$$

Inserting (3.20) and its derivative into (3.3), we get

$$J(t,\nu_r) = -\frac{\lambda_0}{\tau_T^0}(1-\psi_0(t;\nu_r)) - \frac{\lambda_1}{\tau_T^1}(1-\psi_1(t;\nu_r)). \tag{3.21}$$

Solving $\psi_i(t;\nu_r)$ in (3.21) for $(s_H^i/s_T^i - s_C^i/s_T^i)$, (3.18) follows immediately. ∎

As with the single step stimulation, interesting simplifications occur when the following holds.

CONDITION 3.10. $\mathrm{Max}\{\psi_1(t;\nu;V,V_C,V_T)\} \le \psi_{th} \ll 1$ *over a set* $I(t;\nu;V,V_C,V_T)$, $t,V \in \Omega_{t,V}$ *or* $t,\nu \in \Omega_{t,\nu}$.

Here $s_1(V)$ is eliminated in (3.18). The counterpart to this condition is the following.

CONDITION 3.11. $\mathrm{Max}\{\psi_0(t;\nu;V,V_C,V_T)\} \le \psi_{th} \ll 1$ *over a set* $I(t;\nu;V,V_C,V_T)$, $t,V \in \Omega_{t,V}$ *or* $t,\nu \in \Omega_{t,\nu}$.

Fortunately, double step stimulation sequences producing currents satisfying these conditions exist.

PROPOSITION 3.12. *Condition* 3.10 *is satisfied in* $t,V \in \Omega_{t,V}$ *or* $t,\nu \in \Omega_{t,\nu}$ *when*

$$\left[\frac{I(t_a;\nu;V,V_C,V_T)}{I(t_{max};\nu;V,V_C,V_T) + I(t_b;\nu;V,V_C,V_T)}\right]^{1/\lambda_1} < \psi_{th} \quad \text{if } V,V_C \le V_T, \tag{3.22}$$

and Condition 3.11 *is satisfied when*

$$\left[\frac{I(t_a;\nu;V,V_C,V_T)}{I(t_{max};\nu;V,V_C,V_T)+I(t_b;\nu;V,V_C,V_T)}\right]^{1/\lambda_0} < \psi_{th} \quad \text{if } V,V_C \geq V_T. \tag{3.23}$$

Proof. The proof follows from the proof of the existence of Conditions 3.2 and 3.3. If in a double step stimulation sequence currents are acquired in the space $\Omega_{t,V}$ or $\Omega_{t,\nu}$ which also satisfy $V,V_C \leq V_T$, then $d\psi_0(t)/dt \leq 0$, $d\psi_1(t)/dt \geq 0$, $\psi_0(t) \in (\infty,1)$, $\psi_1(t) \in (0,1)$. Remarking that $\psi_j(t) = s_T^j/y_j(t)$, it becomes obvious that inequalities derived in the proof of the existence of Conditions 3.2 and 3.3 apply as well here, when replacing $\epsilon_j(t)$ by $\psi_j(t)$.

Similarly a condition exists, (2.3), for currents acquired in the space $\Omega_{t,V}$ or $\Omega_{t,\nu}$, if for each current $V,V_C \geq V_T$. □

Finally, relation (3.18) is symmetric with respect to Conditions 3.10 and 3.11, a property that follows from symmetry of (3.21) with respect to the same conditions.

The ability to extract information for estimation of $s_i(V)$ from currents acquired in double step stimulations allows experimentalists to design experiments where acquisition of bioelectric signals is more amenable to currently available instrumentation. However, since utilization of Theorem 3.9 requires knowing s_C^i/s_T^i, V_C should be set to a value where it is possible to record currents satisfying either Condition 3.2 or 3.3 during single step stimulation. For some models such a condition may be impossible to meet. To circumvent this problem, we look for new stimulation protocols which can provide more freedom as to the values at which V_C can be set. First, we remark that the expression of several modals of membrane currents acquired with double step stimulation can be simplified when $V_H = V_T$. Specifically, we claim the following.

LEMMA 3.13. *Take a set* $I(t;\nu;V_T,V_C,V_T)$ *satisfying Condition* 3.10. *Then for any* $J(t;\nu_r;V_T,V_C,V_T) \in J(t;\nu;V_T,V_C,V_T)$, $t,\nu \in \Omega_{t,\nu}$,

$$\frac{s_C^0}{s_T^0} = 1 - \left(\frac{J(t_r,\nu_r)+\frac{\lambda_1}{\tau_T^1}}{J(t_r,\nu_r)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}}\right)\left(\frac{e^{\frac{t_r}{\tau_T^0}}}{1-e^{\frac{-\nu_r}{\tau_c^0}}}\right), \tag{3.24}$$

$$J(t,\nu) = \frac{\left(\frac{\lambda_0}{\tau_T^0}\right)\left(J(t_r,\nu_r)+\frac{\lambda_1}{\tau_T^1}\right)h(\nu;\nu_r)e^{\frac{-(t-t_r)}{\tau_T^0}}}{\left(J(t_r,\nu_r)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}\right)-\left(J(t_r,\nu_r)+\frac{\lambda_1}{\tau_T^1}\right)h(\nu;\nu_r)e^{\frac{-(t-t_r)}{\tau_T^0}}} - \frac{\lambda_1}{\tau_T^1}, \tag{3.25}$$

$$h(\nu;\nu_r) = \frac{1-e^{\frac{-\nu}{\tau_C^0}}}{1-e^{\frac{-\nu_r}{\tau_C^0}}}, \tag{3.26}$$

where (3.24)–(3.26) *are symmetric with respect to Conditions* 3.10 *and* 3.11. *Furthermore* (3.25) *is satisfied for at most one value of* τ_C^0.

Proof. Equation (3.24) is obtained by setting $s_H^0 = s_T^0$ in (3.18). Substituting (3.24) into (3.21) in which we impose $s_H^0 = s_T^0$, and $\psi_1(t;\nu) = 0$, we get (3.21). Symmetry of (3.24) and (3.25) with respect to Conditions 3.10 and 3.11 follows from the symmetry of (3.18) and (3.21) to the same conditions. To demonstrate the uniqueness of τ_C^0, solve (3.25) for $h(\nu)$, which leads to

$$\rho(t,\nu)e^{\frac{-\nu_r}{\tau_c^0}} - e^{\frac{-\nu}{\tau_c^0}} = \rho(t,\nu) - 1, \tag{3.27}$$

$$\rho(t,\nu) = \frac{\left(J(t_r,\nu_r)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}\right)\left(J(t,\nu)+\frac{\lambda_1}{\tau_T^1}\right)}{\left(J(t,\nu)+\frac{\lambda_0}{\tau_T^0}+\frac{\lambda_1}{\tau_T^1}\right)\left(J(t_r,\nu_r)+\frac{\lambda_1}{\tau_T^1}\right)}. \tag{3.28}$$

For a specific time $t_0 \in [t_a, t_b]$ we search for a value of τ_C^0 satisfying the above relation. Since the left member of (3.27) is equal to $\rho(t,\nu) - 1$ as $1/\tau_C^0 \to 0$, approaches 0 as $1/\tau_C^0 \to \infty$, and has an extrema at

$$\tau_C^0 = \frac{(\nu - \nu_r)}{\ln\left(\nu/(\rho(t,\nu)\nu_r)\right)}, \tag{3.29}$$

(3.27) admits at most one solution for τ_C^0 at any given time. □

In summary, the estimation of $s_i(V)$ proceeds as follows. Take sets $I(t; V, V_T)$, $t, V \in \Omega_{t,V}$ with $V < V_T$ and $t, V \in \Omega_{t,V}$ with $V > V_T$. Use Theorems 3.7, 3.1, and 3.8 to estimate $s^i(V)/s_T^i$. If the range over which $s_i(V)/s_T^i$ can be evaluated is too narrow, augment the data suite at the origin of the estimation with sets $I(t; \nu_r; V, V_C, V_T)$, $t, V \in \Omega_{t,V}$, and $I(t; \nu; V_T, V_C, V_T)$, $t, \nu \in \Omega_{t,\nu}$, for which either $V, V_C > V_T$ or $V, V_C < V_T$. Use Lemma 3.13 and Theorem 3.9 to evaluate $s_i(V)/s_T^i$. Repeat the same procedure with different values of V_C until the range over which $s_i(V)/s_T^i$ can be evaluated is sufficiently large to appropriately define $s_i(V)$.

4. Estimation of the time constants, $\tau_i(V)$. Transformations of the previous section enable us to estimate all model parameters. However, all of them require the test potential of the stimuli (single or double step) to be outside the conductance window. Since estimation of $\tau_i(V)$ requires analyzing currents generated at any test potential, we need to develop other transformations which do not present any constraints as to where V_T can be set. From this point we assume $s_i(V)$ known and take advantage of this situation to develop an inversion procedure for $\tau_i(V)$. The basic idea consists of determining ranges of possible values of the model parameter $R = 1/\bar{g}$. We show that there exist disjoint ranges for R which enable the model to reproduce a data point. To any value of R picked within the allowed ranges, we associate a finite number of time constants which enable the model to reproduce a given data point. From these time constants and continuity criteria, we determine functions of voltage which complete the parameter estimation.

The cornerstone of the inversion is provided below.

THEOREM 4.1. *For an arbitrary data point taken on $I(t_r)$, $t_r \in [t_a, t_b]$,*

$$\prod_{i \in \bar{\mathcal{A}}} \gamma_i(y_i; V_H, V_T) \;=\; e^{t_r J(t_r)} \prod_{i \in \mathcal{A}} \gamma_i(y_i; V_H, V_T) \tag{4.1}$$

with

$$\gamma_i \;=\; \begin{cases} \left[\frac{s_T^i - s_H^i}{s_T^i - y_i}\right]^{\frac{\lambda_i (s_T^i - y_i)}{y_i}} & \text{if } i \in \mathcal{A}, \\ \left[\frac{s_T^i - s_H^i}{y_i - s_T^i}\right]^{\frac{\lambda_i (y_i - s_T^i)}{y_i}} & \text{if } i \in \bar{\mathcal{A}}, \end{cases} \tag{4.2}$$

where $\mathcal{A}$ is the set of indices for which sign $ds_i(V)/dV =$ sign $(V_T - V_H)$, *and $\bar{\mathcal{A}}$ its complement. The functions γ_i are defined in the range $y_i \in [s_H^i, s_T^i]$, they are equal to unity at each end of their domain, and they have one and only one extremum.*

Proof. Substitute (2.6) into (3.3) to get

$$J(t) = -\sum_{i=0}^{\bar{n}} \left(\frac{\lambda_i}{\tau_i} \frac{y_i - s_T^i}{y_i} \right). \tag{4.3}$$

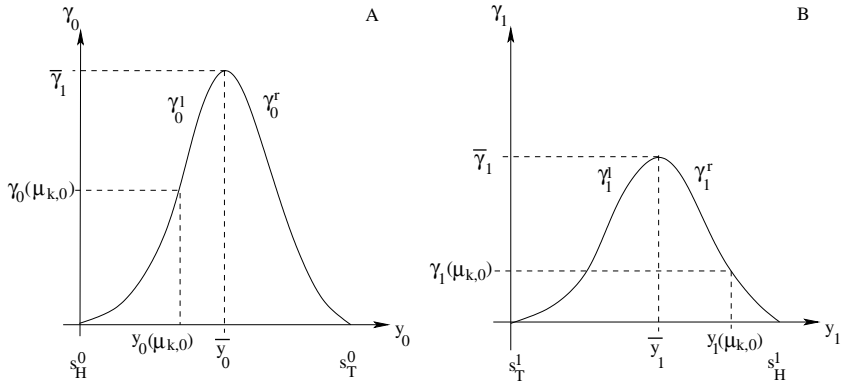

FIG. 4.1. *Functions* $\gamma_0(y_0)$ (A) *and* $\gamma_1(y_1)$ (B). *Segments on the left and right sides of the extrema are respectively denoted* γ_i^l, γ_i^r, $i \in [0,1]$.

Solve (2.4) for $1/\tau_T^i$ and substitute the resulting expression into (4.3); (4.1) follows immediately. One may easily verify that $\gamma_i(y_i)$ has one and only one extremum at

$$\bar{y}_i = s_T^i \ln\left[\frac{s_T^i - s_H^i}{s_T^i - \bar{y}_i}\right], \tag{4.4}$$

$\gamma_i = 1$ at $y_i = s_H^i, s_T^i$, and that

$$\gamma(\bar{y}_i) = \begin{cases} e^{\frac{\lambda_i(s_T^i - \bar{y}_i)}{s_T^i}} & \text{if } i \in \mathcal{A}, \\ e^{\frac{\lambda_i(\bar{y}_i - s_T^i)}{s_T^i}} & \text{if } i \in \bar{\mathcal{A}}. \end{cases} \tag{4.5}$$

The reader is referred to [2] for more details about the above derivations. □

Typical functions γ are shown in Figure 4.1. Theorem 4.1 provides a restriction on y_i with respect to a data point. Note that the latter is a generalization of a relation derived in Beaumont, Roberge, and Leon [2]. We use a parameter $\mu \in [0,1]$ to refer to a specific couple $(\gamma_0(\mu), \gamma_1(\mu))$ satisfying (4.1). Specifically, $[\gamma_a^i, \gamma_b^i]$ is the range of γ_i over which (4.1) can be satisfied. It is defined by

$$\left[\gamma_a^0, \gamma_b^0\right] = \left[\mathrm{Max}(1, e^{-tJ(t)}), \mathrm{Min}(\bar{\gamma}_0, e^{-tJ(t)}\bar{\gamma}_1)\right], \tag{4.6}$$

$$\left[\gamma_a^1, \gamma_b^1\right] = \left[\mathrm{Max}(1, e^{tJ(t)}), \mathrm{Min}(\bar{\gamma}_1, e^{tJ(t)}\bar{\gamma}_0)\right]. \tag{4.7}$$

The parameter μ of the parametric form of (4.1),

$$\gamma_i(\mu) = \gamma_a^i + (\gamma_b^i - \gamma_a^i)\mu, \qquad \mu \in [0,1], \tag{4.8}$$

allows us to systematically sweep this range (see Figure 4.2).

For the sake of the description of the inversion procedure, we introduce functions $\gamma_i^l(y_i)$ and $\gamma_i^r(y_i)$, which are the left and right (with respect to the extremum) branches of $\gamma_i(y_i)$ (Figure 4.1). Inversion of the left and right branches of these functions are respectively denoted by $y_i = \gamma_i^{-l}(\gamma_i)$ and $y_i = \gamma_i^{-r}(\gamma_i)$. Now we use Theorem 4.1 to bound ranges of $R = 1/\bar{g}$ allowing the model to reproduce a given data point. First we define

$$R_{m,n}(\mu) = \frac{V - e_k}{I(t_r; V_H, V_T)} \left[\gamma_0^{-m}(\gamma_0(\mu))\right]^{\lambda_0} \left[\gamma_1^{-n}(\gamma_1(\mu))\right]^{\lambda_1}, \tag{4.9}$$

$$m, n \in [(l,l),(r,r),(l,r),(r,l)],\ \mu \in [0,1].$$

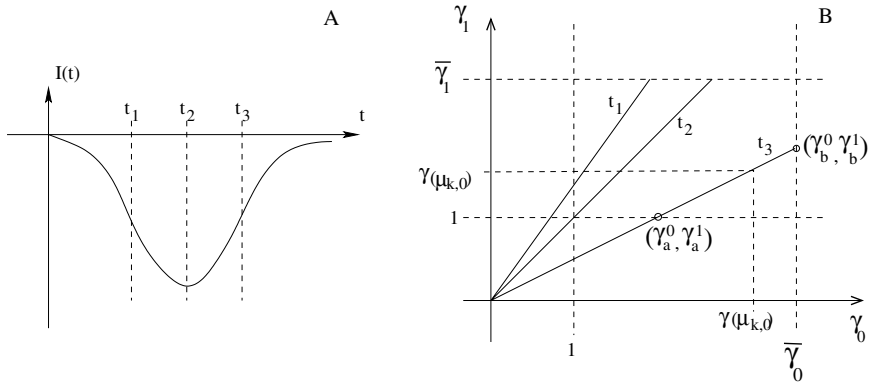

FIG. 4.2. *Implication of Theorem* 4.1. A: *Current trace in time.* B: *Geometrical construction associated with* (4.2) *for the three specific data points shown in* A.

Note that the order of the indices in $R_{mn}(\mu)$ matters. The first index is related to gating variable 0 and the second to gating variable 1.

From (4.10) it is obvious that $R_{m,m}(\mu)$, $m \in [l, r]$, are monotonic, and $R_{m,n}(\mu)$, $m, n \in [l, r]$, $m \neq n$, can be, and in fact are most of the time, nonmonotonic. Note that the line (4.8) crosses either the axis $\gamma_0 = \gamma_b^0$ or $\gamma_1 = \gamma_b^1$ of the (γ_0, γ_1) plane (Figure 4.2). Therefore each function $R_{m,n}(\mu = 1)$, $m, n \in [l, r]$, $m \neq n$, intersects either $R_{ll}(\mu = 1)$ or $R_{rr}(\mu = 1)$ at $\mu = 1$.

The functions $R_{m,n}(\mu)$ $m, n \in [(l, l), (r, r), (l, r), (r, l)]$ allow us to bound the inverse solution in $\mu \in [0, 1]$.

DEFINITION 4.2 (Bounds$\{R(\mu)\}$). *Ranges of* R *for which it is possible to invert the solution are denoted by* Bounds$\{R(\mu)\}$. *Such bounds are evaluated from the functions* $R_{m,n}(\mu)$, $m, n \in [(l, l), (r, r), (l, r), (r, l)]$. *Formally, when* $R_{l,r(\mu)}$ *and* $R_{r,l}(\mu)$, $\mu \in [0, 1]$, *intersect,*

$$\text{Bounds}\{R(\mu)\} = [\text{Min}\{R_{ll}(\mu)\}, \text{Max}\{R_{rr}(\mu)\}], \quad \mu \in [0, 1]. \tag{4.10}$$

However, when they don't intersect, the bounds are constituted by two disjoint ranges. Specifically, if $\gamma_0(\bar{y}_0) > \gamma_1(\bar{y}_1)$, *then* $R_{l,l}(\mu = 1) = R_{l,r}(\mu = 1)$, $R_{r,r}(\mu = 1) = R(r, l)(\mu = 1)$, *and*

$$\begin{aligned}\text{Bounds}\{R(\mu)\} = {} & [\text{Min}\{R_{ll}(\mu)\}, \text{Max}\{R_{l,r}(\mu)\}] \\ & \cup [\text{Min}\{R_{r,l}(\mu)\}, \text{Max}\{R_{,rr}(\mu)\}], \ \ \mu \in [0, 1];\end{aligned} \tag{4.11}$$

if $\gamma_0(\bar{y}_0) < \gamma_1(\bar{y}_1)$, *then* $R_{l,l}(\mu = 1) = R_{r,l}(\mu = 1)$, $R_{r,r}(\mu = 1) = R(l, r)(\mu = 1)$, *and*

$$\begin{aligned}\text{Bounds}\{R(\mu)\} = {} & [\text{Min}\{R_{ll}(\mu)\}, \text{Max}\{R_{r,l}(\mu)\}] \\ & \cup [\text{Min}\{R_{l,r}(\mu)\}, \text{Max}\{R_{r,r}(\mu)\}], \ \ \mu \in [0, 1].\end{aligned} \tag{4.12}$$

Due to the nature of $R_{m,n}(\mu)$, $m, n \in [l, r]$, $m \neq n$, in general their inversion at a specific $R_k \in \text{Bounds}\{R(\mu)\}$ leads to a set of coordinates μ, which we denote by $[\mu_{k0} \cdots \mu_{kn}] = R^{-1}(R_k)$ (Figure 4.3). To this set correspond couples $\gamma_0(\mu_{k,i}), \gamma_1(\mu_{k,i})$ (Figure 4.2). For each of these couples we can obtain a specific value of y_i by inverting the appropriate branch of $\gamma_i(y_i)$ (Figure 4.1). Since the steady states are known, the time constants $\tau_i(V)$ follow from (2.4).

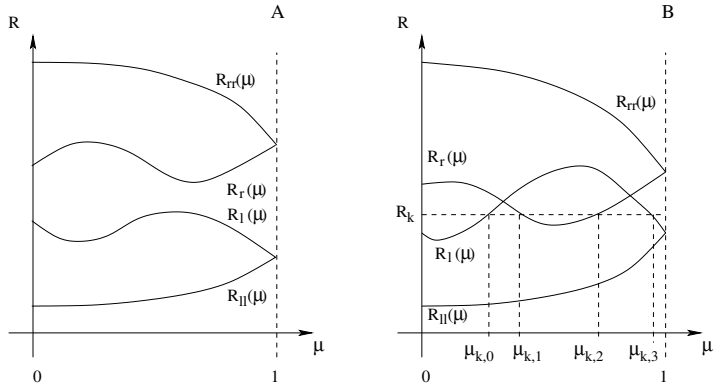

FIG. 4.3. *Functions $R_{ij}(\mu)$ built with the* 4 *different branches of the functions γ. See text for more details about the construction. Functions $R_r(\mu)$ and $R_l(\mu)$ may* (A) *or may not* (B) *intersect.*

From the above, the general inversion procedure should be obvious to the reader. Take sets $I(t; V_H, V)$, $t, V \in \Omega_{t,V}$. Find Bounds$\{R(\mu)\}$ over $\Omega_{t,V}$. The inverse solution ($R_k = 1/\bar{g}$) lies within the global bounds, which are the intersection of Bounds$\{R(\mu)\}$ evaluated in $\Omega_{t,V}$. We refer to these global bounds by Bounds$\{R(\mu)\} \cap \Omega_{t,V}$. If the data sufficiently constrain the model, Bounds$\{R(\mu)\} \cap \Omega_{t,V}$ should be very narrow. Then for each $R_k \in$ Bounds$\{R(\mu)\} \cap \Omega_{t,V}$ (ideally one value), evaluate the time constants, i.e., invert $\gamma_i(\mu)$, then $\gamma_i(y_i)$, and solve (2.4) for $\tau_i(V)$. Even if the bounds are very narrow, the inversion of $\tau_i(V)$ produces a structure with multiple branches along the V axis since inversion $R^{-1}(R_k)$ is not unique. Because the inverse solution exists, at least one root of such structure should traverse $[V_{T0}, V_{Tn}]$. If the data set does not sufficiently constrain the model, then several branches may traverse $[V_{T0}, V_{Tn}]$.

Inversion of $R_{m,n}(\mu)$ $m, n \in [l, r]$, $m \neq n$, requires determining the location of all extrema of each function. In Beaumont, Roberge, and Leon [2] it was shown that when $e^{tJ(t)} = 1$ (i.e., for peak currents), these functions have at most two extrema. At this time, it has not been possible to generalize the proof for the case where $e^{tJ(t)} \neq 1$. However, below we devise a numerical algorithm which allows us to determine the number of extrema and locate all of them. First, we state the following.

THEOREM 4.3. *For any data point taken on $I(t_r; V_H; V_T)$, $t_r \in [t_a, t_b]$, at the extrema of $R_{mn}(\mu)$, $m \neq n$, $m, n \in [l, r]$, $\mu \in [0, 1]$,*

$$\sigma_0^m(\mu) = \sigma_1^n(\mu), \qquad m \neq n,\ m, n \in [l, r], \tag{4.13}$$

with

$$\sigma_i(y_i) = \left[\frac{s_T^i - y_i}{s_T^i - s_H^i}\right]^{s_T^i/y_i}, \qquad \sigma_i^m(\mu) = \left[\frac{s_T^i - y_i^m(\mu)}{s_T^i - s_H^i}\right]^{s_T^i/y_i^m(\mu)}, \tag{4.14}$$

and

$$y_i^m(\mu) = \gamma_i^{-m}(\gamma_i(\mu)), \quad m \in [l, r]\ \ i \in [0, 1]. \tag{4.15}$$

Functions $\sigma_i^m(\mu)$ are monotonic with sign $d\sigma_0^m(\mu)/d\mu$ = sign $d\sigma_1^n(\mu)/d\mu$ if $m \neq n$, and are bounded between in $\mu[0, 1]$.

Proof. From the derivative chain rule we have

$$\frac{\partial R_{mn}(\mu)}{\partial \mu} = 0 \quad \rightarrow \quad \frac{y_0^m(\mu)}{\lambda_0\left(\gamma_b^0 - \gamma_a^0\right)} \frac{d\gamma_0^m}{dy_0} = \frac{-y_1^n(\mu)}{\lambda_1\left(\gamma_b^1 - \gamma_a^1\right)} \frac{d\gamma_1^n}{dy_1}. \tag{4.16}$$

Since $\partial \gamma_i^j(y_i)/\partial y_i \neq 0$, $j \in [l, r]$, $i \in [0, 1]$,

$$\frac{d\gamma_i^{-j}(\gamma_i)}{d\gamma_i} = \frac{dy_i}{d\gamma_i^j} = \frac{1}{d\gamma_i^j/dy_i}, \qquad i, j \in [l, r]. \tag{4.17}$$

Inserting $d\gamma_i^j(y_i)/dy_i$, $j \in [l, r]$, into (4.16), we get (4.13).

We now examine the shape of $\sigma_i(\mu)$ in $\mu \in [0, 1]$. From $d\sigma_i(y_i)/dy_i = 0$ we have

$$e^{\frac{-y_i}{(s_T^i - y_i)}} = \frac{(s_T^i - y_i)}{(s_T^i - s_H^i)}. \tag{4.18}$$

The left and right terms of (4.18) are monotonic. The left term is bounded between $[0, 1]$ in the range $y_i \in [s_H^i, s_T^i]$, and is 0 at $y_i = s_T^i$. Since its second derivative is positive in this range, (4.18) cannot be satisfied, and therefore $\sigma_i(y_i)$ is monotonic. Since

$$\frac{d\sigma_i^m(\mu)}{d\mu} = \frac{d\gamma(\mu)}{d\mu} \frac{\frac{d\sigma_1^m(y_i)}{dy_i}}{\frac{d\gamma_i^m(y_i)}{dy_i}}, \tag{4.19}$$

$\operatorname{sign} d\sigma_0(y_0)/dy_0 \neq \operatorname{sign} d\sigma_1(y_1)/dy_1$, and $\operatorname{sign} d\gamma_0^m(y_0)/dy_0 \neq \operatorname{sign} d\gamma_1^n(y_1)/dy_1$, then $\operatorname{sign} d\sigma_0^m(\mu)/d\mu = \operatorname{sign} d\sigma_1^n(\mu)/d\mu$, $m, n \in [l, r]$, $m \neq n$, $\mu \in [0, 1]$. □

We are now ready to expose the algorithm for the determination of the extrema of $R_{mn}(\mu)$, $m, n \in [l, r]$, $m \neq n$. In this algorithm we need to invert $\sigma_i^m(\mu)$, $m \in [l, r]$, $i \in [0, 1]$. We denote the inversion by $\mu_k = \sigma_i^{-m}(\sigma_k)$, σ_k being a specific value of σ.

ALGORITHM 4.4.

1. *Take a function $R_{mn}(\mu)$, $m, n \in [l, r]$, $m \neq n$, $\mu \in [0, 1]$.*
2. *Start at an arbitrary point $\mu_k \in [0, 1]$.*
3. *If $\sigma_0^m(\mu_k) > \sigma_1^n(\mu_k)$, then $p = m$, $q = n$, $j = 0$, and $k = 1$. Else $p = n$, $q = m$, $j = 1$, $k = 0$.*
4. *If functions $\sigma_0^m(\mu)$ and $\sigma_1^n(\mu)$ have multiple intersections, they form loops within which one can move until crossing points are reached. Specifically, to move right along the μ axis, i.e., $\mu_k \rightarrow \mu_{k+1}$ with $\mu_{k+1} > \mu_k$, proceed as follows: $\mu_{k+1} = \sigma_j^{-p}\left(\sigma_k^q(\mu_k)\right)$.*
5. *Move left along the μ axis, i.e., $\mu_k \rightarrow \mu_{k-1}$ with $\mu_{k-1} < \mu_k$ as follows: $\mu_{k-1} = \sigma_k^{-q}\left(\sigma_j^p(\mu_k)\right)$.*
6. *Repeat step 4 to obtain $\mu_{k+1} \rightarrow \mu_{k+2}$, and step 5 to obtain $\mu_{k-1} \rightarrow \mu_{k-2}$, until an intersection between $\sigma_0^m(\mu)$ and $\sigma_1^n(\mu)$ is found or until an end point of the search interval is reached.*
7. *Repeat these operations starting from step 4 until the excursion performed over the μ-axis covers the search interval, i.e., $[0, 1]$.*

As mentioned in the previous section, for some models it is not possible to obtain measurable currents when V_T of a step voltage clamp simulation is outside the conductance window. In this case, we can proceed as for the estimation of $s_i(V)$ by interpolating a conditioning pulse prior to the application of the test pulse. Fortunately, the theory developed in this section is still applicable. It requires only

$$s_H^i \rightarrow s_C^i + (s_H^i - s_C^i)e^{-\nu/\tau_C^i}, \tag{4.20}$$

which operation can be performed before starting the inversion of the time constants.

5. Conclusions. Procedures currently used to estimate the parameters of the HH gating model are all based on nonlinear least square fitting. It is well known that this approach has several drawbacks. Namely, the parameters obtained in this manner may correspond to a local minimum of the merit function undergoing minimization. Thus not only may estimates lack accuracy, but there is no way to know whether other minima exist. Knowing the existence of such minima is important for the modelling methodology because, considering the experimental error, several of them may correspond to plausible inverse solutions. In this case gating model predictions related to each minimum need to be examined. If model predictions are too wide-ranging, then additional experiments need to be performed to obtain more specific current kinetics. While this is a highly desirable approach to the modelling of bioelectric phenomena, it is not possible to pursue in practice due to the inability to locate, in a rigorous manner, minima of the objective function.

Here, we have proposed an inversion methodology which overcomes all these limitations. The procedure is accurate because it guarantees that the model will exactly reproduce the data set. If the solution does not sufficiently constrain the model, bounds for the inverse solution are large, and it is possible to identify a model family capable of accurately reproducing the data set at the origin of the estimation. In addition, since the inversion relates the functions of the model ($s_i(V)$ and $\tau_i(V)$) to the experimental data, the estimation procedure specifies in which potential range current kinetics need to be better characterized. In other words the estimation method may help to design experiments.

Is the inverse solution of the HH gating model with respect to a given voltage clamp data set unique? Answering this question is not trivial, but is crucial for the modelling methodology. As we have stressed above, due to the existence of multiple inverse solutions, conclusions drawn from simulation results can be entirely erroneous. At this point it should be clear to the reader that if the data set does not probe the steady states and time constants over a potential range sufficiently large to define these functions appropriately, the model is under-determined. Unfortunately this seems to be the case with most data sets employed in common practice.

Furthermore, incomplete data sets result in an inverse solution which is characterized by disjoint ranges of valid values. Consequently in this case very different models can reproduce a given experimental data set well. This warrants great care in drawing conclusions from simulations carried out with macroscopic models. This said, in many cases the lack of data is due to the technical difficulties discussed in section 4. Here we have provided means to analyze data generated with more elaborate protocols (double step) than the conventional step stimulation. We believe this will provide experimentalists the flexibility they need to overcome the difficulties commonly encountered.

Acknowledgment. We are grateful to Dr. Lawrence J. Lardy from the Department of Mathematics at Syracuse University for fruitful discussions and for assisting with the preparation of this manuscript.

SINGULAR PERTURBATIONS FOR BOUNDARY VALUE PROBLEMS ARISING FROM EXOTIC OPTIONS*

AYTAC ILHAN†, MATTIAS JONSSON‡, AND RONNIE SIRCAR†

Abstract. We study the pricing of three exotic derivative securities (barrier, lookback, and passport options) which can be characterized by boundary value PDE problems in the context of popular Markovian stochastic volatility models of stock prices. By extending the fast mean-reverting asymptotic analysis in [J.-P. Fouque, G. Papanicolaou, and K. R. Sircar, *Derivatives in Financial Markets with Stochastic Volatility*, Cambridge University Press, London, 2000], the usual "Greek" correction to the Black–Scholes prices of these contracts is further corrected by a boundary integral term that is rapidly computed numerically. In the case of the passport option, the asymptotic method is effective in accounting for stochastic volatility effects in a simple and robust fashion even in the presence of a highly nonlinear embedded stochastic control problem.

Key words. stochastic volatility, asymptotic approximations, option pricing

1. Introduction.

In this paper we describe a framework for approximating the prices of certain path-dependent derivative securities to take into account the observed "implied volatility skew," which contains information about the market's view of the asymmetry and leptokurtosis in stock price returns. The pricing problems for these exotic options are characterized by boundary value problems for PDEs, under the class of stochastic volatility diffusion models we consider here. Our examples are a barrier option, a lookback option, and a passport option, whose prices solve Dirichlet, mixed, and Neumann boundary value problems, respectively. From the point of view of the practical application, there is a need for a quick calculation from which a trader can quote a price to a client. The approximation method used here is computationally fast and robust to specific modeling of the unobserved stochastic volatility process. The analysis extends the singular perturbation approximations for stochastic volatility models studied in [13].

1.1. Empirical foundation.

The basis of the approximations is a rapid time-scale of fluctuation in the stock price volatility relative to the time horizon of the options contract. Such a fast scale has been identified in market data in [16, 1, 4], for example, and is convenient for constructing approximations over times when other, slower, factors in the volatility can be considered relatively benign. Extension of the approach in [13] to incorporate a slower scale is begun in [15]. Asymptotic analysis of a different type of exotic path-dependent contract, Asian options, is studied in [12].

In [16], we studied high-frequency S&P 500 data over the period of a year. The result, using both variogram and spectral methods, was the clear presence of a fast

time-scale of volatility fluctuation, corresponding to a characteristic mean-reversion time on the order of a few days.

There is also considerable evidence of a slower scale. Many empirical studies have looked at low-frequency (daily) data, with the data necessarily ranging over a period of years, and have found a *low* rate of volatility mean-reversion. (These analyses of data at lower frequencies over longer time periods primarily pick up a slower time-scale of fluctuation and do not identify scales at the same order as the sampling frequency.) Often, the slow factor half-life is found to be on the order of 70–90 days in equity indices [10].

The combined conclusion has led recently to the study of *two-factor stochastic volatility models* [4], where one factor is slowly mean-reverting and the other is fast mean-reverting. Another recent empirical study [1], this time of exchange rate dynamics, finds "the evidence points strongly toward two-factor [volatility] models with one highly persistent factor and one quickly mean-reverting factor."

In the option-pricing asymptotics presented here, we focus on the effect of the fast volatility scale. This corresponds to assuming the lifetime of the derivative is on the order of the typical half-life of the slow factor, or less, because that factor would act approximately like a constant.

1.2. Alternative approaches. There are a number of other approaches to stochastic volatility modeling, and we briefly discuss only the more common ones here. Volatility models built on diffusions were introduced in the literature in the late 1980s by Hull and White [23], among others. One popular class of models builds on the Feller process model introduced in this context by Heston [20] because call option prices can be solved for in closed form up to a Fourier inversion.

Typically a lot of emphasis is placed on fitting the models very closely to observed implied volatilities (see subsection 1.3 for the definition), and not surprisingly, models with more degrees of freedom perform better in this regard. For example, the models studied in [2, 9] include jumps in stochastic volatility on top of a Heston-type model. However, little attention is paid to the stability of the estimated parameters over time, and it is the usual practice in the industry simply to recalibrate each day.

The approach taken here, based on modeling volatility in terms of its characteristic scales rather than specific distributions, sacrifices some of the goodness of in-sample fit to current data for greater stability properties. It also allows for efficient computation of approximations to prices of exotic contracts, such as considered here. Otherwise, these prices have to be found by simulations or numerical solution of a high-dimensional PDE associated with the full stochastic volatility model. Other authors have also studied this approximation [5] or applied it in different contexts, for example, pricing volatility derivatives [22] or analyzing trading volume [21].

1.3. Calibration from market-implied volatilities. The three options studied here are called exotic (and are listed in increasing order of "exoticness") because they are less heavily traded than standard "vanilla" call and put options. Lookbacks and passport options are usually sold as over-the-counter products. However, market vanilla option prices contain valuable information about the market's perception of future risks. This is typically expressed in units of implied volatility. Given the observed price C_{obs} of a European call option, which gives the holder the right but not the obligation to buy one unit of stock for strike price K on date T, the implied volatility I is defined as that volatility which equates the Black–Scholes option pricing

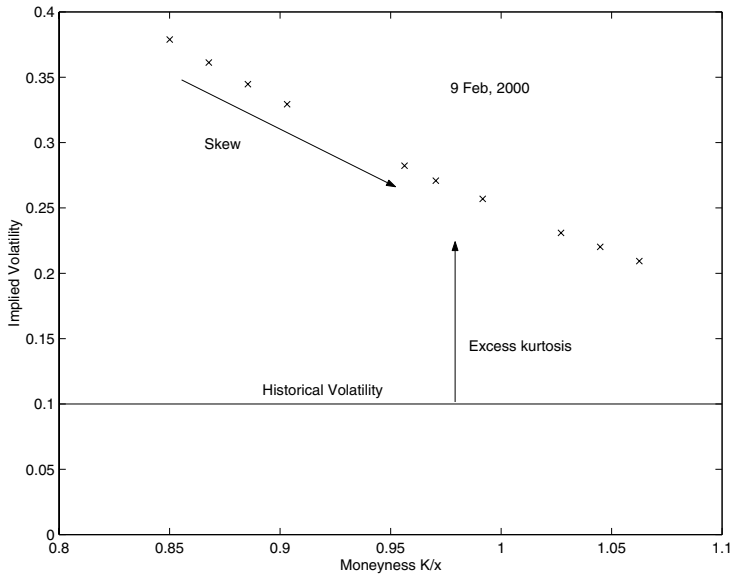

FIG. 1.1. *Implied volatility as a function of moneyness for fixed maturity options. The skew represents asymmetry in the returns distribution of the stock, and the increase in level over historical volatility is due to the excess kurtosis over lognormal models.*

formula $C^{BS}(t, X_t; K, T; I)$ to this price:

$$C^{BS}(t, X_t; K, T; I) = C_{\text{obs}}.$$

Here, t denotes the current time and X_t the current stock price.

A basic problem in financial engineering, given the market's implied volatilities, is to find prices of exotic contracts that are consistent with the principle of *no arbitrage*. (In general, there is no unique solution without making further assumptions on an underlying model.)

Under a large class of fast mean-reverting stochastic volatility models, it is shown in [13] that the implied volatility surface $I(K, T)$ (that is, I considered as a function of the option's strike price K and maturity date T for fixed t and X_t) is approximated by an affine function of the log-moneyness-to-maturity ratio (LMMR):

$$I \approx a \times \text{LMMR} + b, \quad \text{LMMR} = \frac{\log(K/X_t)}{T - t}, \tag{1.1}$$

where a and b are some market constants to be estimated by fitting this formula to option implied volatility data. See Figure 1.1.

Then, given estimates of the slope a and the intercept b, we consider the problem of finding consistent approximations for various exotic options. The cases of American and Asian options, as well as barriers, were studied in [13]. The latter contained an error in the calculation, and we include it here, corrected and in a somewhat different format from the subsequent erratum to [13], as our starting point.

When the formula (1.1) is fitted to certain regimes of S&P 500 implied volatility data, the estimated parameters a and b have good stability properties [13, 14]. This is particularly important for pricing path-dependent securities as considered here, because they depend not just on a one-time distribution of the stock price, but also

on the evolution of the process. The stability and goodness-of-fit, particularly to short-dated options, can be improved by including time-dependent periodic factors, as is done in [14].

Given the condensation of the pricing measure contained in a and b, we show that the asymptotic correction term in these boundary value problems is explicit up to a one-dimensional integral, which can be computed very quickly. It is then easy to gauge the impact of, for example, the slope of the implied volatility skew, measured by a, on the prices of these path-dependent contracts, as we illustrate numerically. The upshot of the analysis is that one obtains the usual asymptotic correction terms to the Black–Scholes prices of the exotics (which can be expressed in terms of the "Greeks," or partial derivatives of the Black–Scholes prices) plus an additional boundary integral term that corrects the Greek correction for skew effects.

1.4. Hedging. Another important problem is hedging the risk of a position in exotic options using the underlying asset and perhaps other vanilla options which are liquidly traded. While this is a well-defined problem in a complete market model (for example, the constant volatility Black–Scholes model), and the hedging ratio, the number of stocks held in order to hedge perfectly, is a by-product of the pricing problem, this is not the case in incomplete market models, such as with stochastic volatility, where the additional randomness driving the volatility cannot be hedged because volatility is not a tradeable asset. Many studies on hedging in incomplete markets model the preferences of the individual or institutional hedger through a loss function. The hedging strategies are found as solutions of a stochastic control problem of minimizing the expected loss for a given initial hedging capital. We do not discuss these approaches in this paper. The example of minimizing expected shortfall is studied in [11], and asymptotic approximations in the case of fast mean-reverting stochastic volatility are constructed in [26].

For the Black–Scholes model, the hedging ratio for a barrier or lookback option is given by the Delta (the partial derivative with respect to x, the stock price) of the option price. It is natural to consider the same quantity, replacing the Black–Scholes price by the asymptotic approximation of the stochastic volatility price we derive here; such an approach was developed in [13, Chapter 7]. This type of strategy is not self-financing, but the value of the hedging portfolio is close to the value of the option. These are discussed in sections 2.5 and 3.5. The hedging problem for a passport option is discussed in section 4.6.

2. Barrier options. A *barrier option* is a path-dependent claim whose payoff depends on whether or not the underlying asset price hits a specified value before the maturity date. One example of a barrier option is the *down-and-out call option*, which gives the holder the right to buy the underlying asset on expiration date T for strike price K unless the asset price has hit the barrier B at some time before T, in which case the contract expires worthless. The payoff at expiration T can be written as

$$h(X_T) = (X_T - K)^+ \mathbf{1}_{\left\{\min_{0\le t\le T} X_t \ge B\right\}},$$

where $\mathbf{1}$ denotes the indicator function.

2.1. Asymptotic approximation. The fast mean-reverting stochastic volatility approximation for barrier options was studied in [13]. In this paper, we give a brief review, which derives the relevant PDE problems to solve for the terms in the

asymptotic expansion. In this case, the boundary condition arises naturally due to the structure of the option.

We shall look at stochastic volatility models in which volatility (σ_t) is driven by an ergodic process (Y_t) that approaches its unique invariant distribution at an exponential rate $1/\varepsilon$. The size of this rate captures the volatility decorrelation speed, and in particular we shall be interested in asymptotic approximations when ε is small, which describes *fast* mean-reverting volatility.

As explained in [13], it is convenient for exposition to take a specific simple example for (Y_t) and allow the generality of the modeling to be in the unspecified relation between volatility and this process: $\sigma_t = f(Y_t)$, where f is some positive (and sufficiently regular) function, bounded above and away from zero. Further, taking (Y_t) to be a Markovian Itô process allows us to simply model the asymmetry, or fatter left-tails of returns distributions, by incorporating a negative correlation between asset price and volatility shocks. We shall thus take (Y_t) to be a mean-reverting Ornstein–Uhlenbeck (OU) process, so that the stochastic volatility models we consider are

$$\begin{aligned} dX_t &= \mu X_t\,dt + f(Y_t)X_t\,dW_t, \\ dY_t &= \frac{1}{\varepsilon}(m - Y_t)\,dt + \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\left(\rho\,dW_t + \sqrt{1-\rho^2}\,dZ_t\right), \end{aligned} \tag{2.1}$$

where (X_t) is the stock price process. Here (W_t) and (Z_t) are independent standard Brownian motions on a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, and ρ is the instantaneous correlation between asset price and volatility shocks that captures the skew, asymmetry, or leverage effect. The asymptotic results as they are used are *not* specific to the choice of the OU diffusion process, nor do they depend on specifying f. In this scaling, the invariant density of Y is Gaussian, $\mathcal{N}(m, \nu^2)$, which does not depend on ε. Throughout the paper, we adopt the standard practice of denoting the initial values of the processes X and Y with lowercase letters, x and y.

The model (2.1) describes an *incomplete* market, meaning that not all contingent claims can be replicated by trading only in the underlying stock, the volatility process being untradeable. This has profound consequences for pricing, hedging, and calibration problems for derivative securities. By standard no-arbitrage pricing theory [8], there is more than one possible equivalent martingale (or risk-neutral pricing) measure $\mathbb{P}^{\star(\gamma)}$ because the volatility is not a traded asset; the nonuniqueness is denoted by the dependence on γ, which we identify as the market price of volatility risk.

By Girsanov's theorem, $(W_t^\star, Z_t^\star)$ defined by

$$W_t^\star = W_t + \int_0^t \frac{(\mu - r)}{f\,(Y_s)} ds, \qquad Z_t^\star = Z_t + \int_0^t \gamma_s ds$$

are independent Brownian motions under a measure $\mathbb{P}^{\star(\gamma)}$ defined by

$$\frac{d\mathbb{P}^{\star\,(\gamma)}}{d\mathbb{P}} = \exp\left(-\int_0^T \frac{(\mu - r)}{f\,(Y_s)} dW_s - \int_0^T \gamma_s dZ_s - \frac{1}{2}\int_0^T \left[\left(\frac{(\mu - r)}{f\,(Y_s)}\right)^2 + \gamma_s^2\right] ds\right),$$

assuming (γ_t) is a nonanticipating process with sufficient regularity.

In particular, γ_t is the risk premium factor from the *second* source of randomness Z that drives the volatility. As explained in [13], we take the view that the market selects a pricing measure identified by a particular γ which is reflected in liquidly

traded around-the-money European option prices. Other derivative securities must be priced with respect to this measure, if there are to be no arbitrage opportunities. We shall assume that the market price of volatility risk γ_t is a bounded function of the state Y_t: $\gamma_t = \gamma(Y_t)$. In general, it may be a more complicated function of time and the paths of the two Brownian motions, but we make the assumption that (X, Y) remains a time-homogeneous Markov process under the pricing measure and that Y remains a Markov process by itself under $\mathbb{P}^{\star(\gamma)}$. This simplification implies, in particular, that the market parameters V_2^{ε} (defined in (2.11) below) and, consequently, the implied volatility calibration parameter b in (1.1) do not depend on time or the level of the stock price x. The effects of this assumption are reflected in fitting the model to data; the performance study in [14] shows that the fitted b is typically quite stable.

Under $\mathbb{P}^{\star(\gamma)}$, (X, Y) evolves according to

$$dX_t = rX_t dt + f(Y_t)X_t dW_t^{\star}, \tag{2.2}$$

$$dY_t = \left[\frac{1}{\varepsilon}(m - Y_t) - \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(Y_t)\right] dt + \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\left(\rho\, dW_t^{\star} + \sqrt{1-\rho^2}\, dZ_t^{\star}\right), \tag{2.3}$$

where

$$\Lambda(Y_t) = \rho\frac{(\mu - r)}{f\,(Y_t)} + \sqrt{1-\rho^2}\,\gamma(Y_t).$$

We also define the infinitesimal generator $\mathcal{L}^{\varepsilon}$ of (X, Y) under this measure and write it grouped in powers of ε as follows:

$$\mathcal{L}^{\varepsilon} = \frac{1}{\varepsilon}\mathcal{L}_0 + \frac{1}{\sqrt{\varepsilon}}\mathcal{L}_1 + \mathcal{L}_2, \tag{2.4}$$

$$\mathcal{L}_0 = \nu^2\frac{\partial^2}{\partial y^2} + (m - y)\frac{\partial}{\partial y}, \tag{2.5}$$

$$\mathcal{L}_1 = \sqrt{2}\nu\rho f(y)x\frac{\partial^2}{\partial x \partial y} - \sqrt{2}\nu\Lambda(y)\frac{\partial}{\partial y}, \tag{2.6}$$

$$\mathcal{L}_2 = \frac{\partial}{\partial t} + \frac{1}{2}f(y)^2x^2\frac{\partial^2}{\partial x^2} + r\left(x\frac{\partial}{\partial x} - \cdot\right). \tag{2.7}$$

Here $\mathcal{L}_0$ is the infinitesimal generator of the mean-reverting OU process, $\mathcal{L}_1$ contains the mixed derivative (from the correlation) and the market price of risk γ, and $\mathcal{L}_2$ is the Black–Scholes partial differential operator $\mathcal{L}_{BS}(f(y))$ at the volatility level $f(y)$.

The price $P(t, x, y)$ of the down-and-out barrier call option satisfies

$$\mathcal{L}^{\varepsilon}P = 0 \quad \text{in } x > B \text{ and } t < T,$$

with a terminal condition at $t = T$, $P(T, x, y) = (x - K)^+$, and a boundary condition at $x = B$, $P(t, B, y) = 0$. The latter expresses the knock-out condition on the barrier.

An asymptotic analysis detailed in [13] shows that the fast mean-reverting approximation (in the limit $\varepsilon \downarrow 0$) for the barrier option is given by

$$P(t, x, y) \approx P^{(0)}(t, x) + \widetilde{P^{(1)}}(t, x).$$

Here, $P^0(t, x)$ is the Black–Scholes price of the option with constant volatility parameter $\bar{\sigma}$, which is related to the original volatility model by

$$\bar{\sigma}^2 = \langle f^2 \rangle,$$

where $\langle\cdot\rangle$ denotes averaging with respect to the invariant density of Y, $\mathcal{N}(m,\nu^2)$. Notice that, under the fast volatility scaling, the first two terms of the expansion do not depend on y, the level of the unobservable process Y. Therefore, $P^{(0)}$ is the solution of the homogenized boundary value problem

$$\begin{aligned} \mathcal{L}_{BS}(\bar\sigma)P^{(0)} &= 0 \quad \text{in } x > B \text{ and } t < T, \\ P^{(0)}(T,x) &= (x-K)^+, \\ P^{(0)}(t,B) &= 0. \end{aligned} \tag{2.8}$$

We can obtain a formula for $P^{(0)}(t,x)$ by the method of images (see [29], for example)

$$P^{(0)}(t,x) = C^{BS}(t,x;\bar\sigma) - \left(\frac{x}{B}\right)^{1-k} C^{BS}(t,B^2/x;\bar\sigma), \tag{2.9}$$

where $k = 2r/\bar\sigma^2$ and $C^{BS}(t,x;\bar\sigma)$ is the Black–Scholes pricing formula for *a call option*, with the volatility parameter $\bar\sigma$:

$$\begin{aligned} C^{BS}(t,x;\bar\sigma) &= xN(d_1) - Ke^{-r(T-t)}N(d_2), \\ d_1 &= \frac{\log(x/K) + \left(r + \frac{1}{2}\bar\sigma^2\right)(T-t)}{\bar\sigma\sqrt{T-t}}, \\ d_2 &= d_1 - \bar\sigma\sqrt{T-t}, \end{aligned}$$

and N denotes the standard cumulative normal distribution function.

2.2. First-order correction. From the asymptotic calculations in [13], the stochastic volatility correction $\widetilde{P^{(1)}}(t,x)$, which is of order $\sqrt{\varepsilon}$, satisfies the PDE problem

$$\begin{aligned} \mathcal{L}_{BS}(\bar\sigma)\widetilde{P^{(1)}} &= \mathcal{A}P^{(0)} \quad \text{in } x > B \text{ and } t < T, \\ \widetilde{P^{(1)}}(T,x) &= 0, \\ \widetilde{P^{(1)}}(t,B) &= 0, \end{aligned}$$

where $\mathcal{A}$ is defined as

$$\mathcal{A} = V_3^\varepsilon x\frac{\partial}{\partial x}\left(x^2\frac{\partial^2}{\partial x^2}\right) + V_2^\varepsilon x^2\frac{\partial^2}{\partial x^2}, \tag{2.10}$$

$$V_2^\varepsilon = -\frac{\nu\sqrt{\varepsilon}}{\sqrt{2}}\left\langle \Lambda\phi'\right\rangle, \tag{2.11}$$

$$V_3^\varepsilon = \frac{\rho\nu\sqrt{\varepsilon}}{\sqrt{2}}\left\langle f\phi'\right\rangle, \tag{2.12}$$

and $\phi(y)$ is a solution of $\mathcal{L}_0\phi(y) = f(y)^2 - \bar\sigma^2$. As shown in [13], the boundedness assumptions on f and γ imply that we can choose ϕ to have a bounded first derivative.

The interpretations of the two market constants above are as follows: V_2^ε contains the effect of the market price of volatility risk; V_3^ε contains the effect of the correlation, or skew, ρ. In the case of zero correlation, $V_3^\varepsilon = 0$ and our correction formulas (2.19), (3.10), and (4.18) below simplify and do not require numerical integration. However, in equity markets, ρ is typically estimated to be negative.

In practice, we do not use the homogenization formulas (2.11) and (2.12) to obtain V_3^ε and V_2^ε from a specific stochastic volatility model. Rather, they are calibrated

from liquid European options prices, or the implied volatility surface using the LMMR formula (1.1). As computed in [13], V_3^ε and V_2^ε are obtained from a and b in (1.1), and from the long-run mean historical volatility $\bar{\sigma}$ estimated from stock returns, by

$$V_2^\varepsilon = -\bar{\sigma}\left(a\left(r - \frac{1}{2}\bar{\sigma}^2\right) + (b - \bar{\sigma})\right),$$
$$V_3^\varepsilon = -a\bar{\sigma}^3.$$

The problem of solving this boundary value problem with a source term can be simplified to a one-dimensional integral by defining

$$\hat{P}(t,x) = \widetilde{P^{(1)}} + \frac{V_3^\varepsilon}{\bar{\sigma}} x P^{(0)}_{x\bar{\sigma}} + \frac{V_2^\varepsilon}{\bar{\sigma}} P^{(0)}_{\bar{\sigma}}$$

for $x \geq B$. Then $\hat{P}(t,x)$ solves

$$\begin{aligned} \mathcal{L}_{BS}(\bar{\sigma})\hat{P}(t,x) &= 0 \quad \text{in } x > B \text{ and } t < T, \\ \hat{P}(T,x) &= 0, \\ \hat{P}(t,B) &= \frac{V_3^\varepsilon}{\bar{\sigma}} g(t), \end{aligned} \tag{2.13}$$

where we define

$$g(t) = x P^{(0)}_{x\bar{\sigma}}\big|_{x=B}. \tag{2.14}$$

This is because the barrier option Vega $\mathcal{V} = P^{(0)}_{\bar{\sigma}}$ solves the PDE problem

$$\begin{aligned} \mathcal{L}_{BS}(\bar{\sigma})\mathcal{V} &= -\bar{\sigma}x^2 P^{(0)}_{xx} \quad \text{in } x > B \text{ and } t < T, \\ \mathcal{V}(T,x) &= 0, \\ \mathcal{V}(t,B) &= 0, \end{aligned}$$

as can be seen by formally differentiating (2.8) with respect to $\bar{\sigma}$. Differentiating again with respect to x, we can see that the Vega of the hedge $U = x P^{(0)}_{x\bar{\sigma}}$ satisfies

$$\mathcal{L}_{BS}(\bar{\sigma})U = -\bar{\sigma}x\frac{\partial}{\partial x}(x^2 P^{(0)}_{xx}), \qquad U(T,x) = 0,$$

but $U(t,B) \neq 0$ in general.

2.3. Interpretation of the Greeks. In the case of a regular option without a barrier boundary condition, the correction to the price is given by

$$\widetilde{P^{(1)}} = -\frac{V_3^\varepsilon}{\bar{\sigma}} x P^{(0)}_{x\bar{\sigma}} - \frac{V_2^\varepsilon}{\bar{\sigma}} P^{(0)}_{\bar{\sigma}},$$

which corresponds to the alternative formulation

$$\widetilde{P^{(1)}} = -(T-t)\left(V_3^\varepsilon x\frac{\partial}{\partial x}\left(x^2\frac{\partial^2}{\partial x^2}\right) + V_2^\varepsilon x^2\frac{\partial^2}{\partial x^2}\right)P^{(0)}$$

given in [13] because

$$\mathcal{V} = \bar{\sigma}(T-t)x^2 P^{(0)}_{xx}, \tag{2.15}$$

$$x P^{(0)}_{x\bar{\sigma}} = \bar{\sigma}(T-t)x\frac{\partial}{\partial x}(x^2 P^{(0)}_{xx}). \tag{2.16}$$

While it is intuitive to present the asymptotic correction in terms of the so-called Greeks $P^{(0)}_{\bar\sigma}$ and $P^{(0)}_{x\bar\sigma}$, intuition can be misleading because, here, these terms are evaluated at the long-run mean volatility $\bar\sigma$, and not at (an estimate of) the current volatility level $f(Y_t)$. In other words, these terms represent sensitivity to the global mean volatility rather than local sensitivity, which is how the Greeks are usually employed in practice. The asymptotic calculation has highlighted the Vega and Vega of the Delta $P^{(0)}_{x\bar\sigma}$ as primary measures of the effect of stochastic volatility on pricing in the fast mean-reversion limit, but the current volatility level is unimportant to this order. It is analogous to a central limit theorem correction to a law of large numbers.

In the case of path-dependent options considered here, these Greek terms do not comprise the whole correction, and the term $\hat P$, which can be represented as a boundary integral as we shall see below, plays an important role.

2.3.1. Calculation. The problem (2.13) can be transformed to a constant coefficient backward heat equation by the simple transformations $\eta = \log(x/B)$ and

$$\hat P(t,x) = \frac{V_3^\varepsilon}{\bar\sigma} v(t,\eta) \exp\left(-\frac{1}{8}\bar\sigma^2(1+k)^2(T-t) + \frac{1}{2}(1-k)\eta\right).$$

Then $v(t,\eta)$ solves

$$\begin{aligned} v_t + \frac{1}{2}\bar\sigma^2 v_{\eta\eta} &= 0 \quad \text{in } \eta > 0 \text{ and } t < T,\\ v(T,\eta) &= 0,\\ v(t,0) &= \tilde g(t), \end{aligned} \tag{2.17}$$

where

$$\tilde g(t) = e^{\frac{1}{8}\bar\sigma^2(1+k)^2(T-t)} B^{-\frac{1}{2}(1-k)} g(t).$$

By Duhamel's theorem (see [3, page 31], for instance), the solution is given by the one-dimensional integral

$$v(t,\eta) = \frac{1}{\bar\sigma\sqrt{2\pi}} \int_t^T \frac{\eta}{(s-t)^{3/2}} e^{-\eta^2/2\bar\sigma^2(s-t)} \tilde g(s)\,\mathrm{d}s. \tag{2.18}$$

We obtain the correction to the barrier price as

$$\begin{aligned} \widetilde{P^{(1)}}(t,x) = &-\frac{V_3^\varepsilon}{\bar\sigma} x P^{(0)}_{x\bar\sigma}(t,x) - \frac{V_2^\varepsilon}{\bar\sigma} P^{(0)}_{\bar\sigma}(t,x)\\ &+\frac{V_3^\varepsilon}{\bar\sigma}\frac{x}{B}\log\left(\frac{x}{B}\right)\frac{1}{\bar\sigma\sqrt{2\pi}}\int_t^T e^{-\frac{1}{2}d_B(s-t)^2}\frac{g(s)}{(s-t)^{3/2}}\,\mathrm{d}s, \end{aligned} \tag{2.19}$$

where

$$d_B(\tau) = \frac{\log(x/B)}{\bar\sigma\sqrt{\tau}} + \frac{1}{2}(1+k)\bar\sigma\sqrt{\tau}.$$

Explicit formulas for $g(t)$ and $\widetilde{P^{(1)}}(t,x)$ are given in Appendix A. These are illustrated in Figures 2.1 and 2.2. As depicted in Figure 2.1, the effect of changing the slope of the

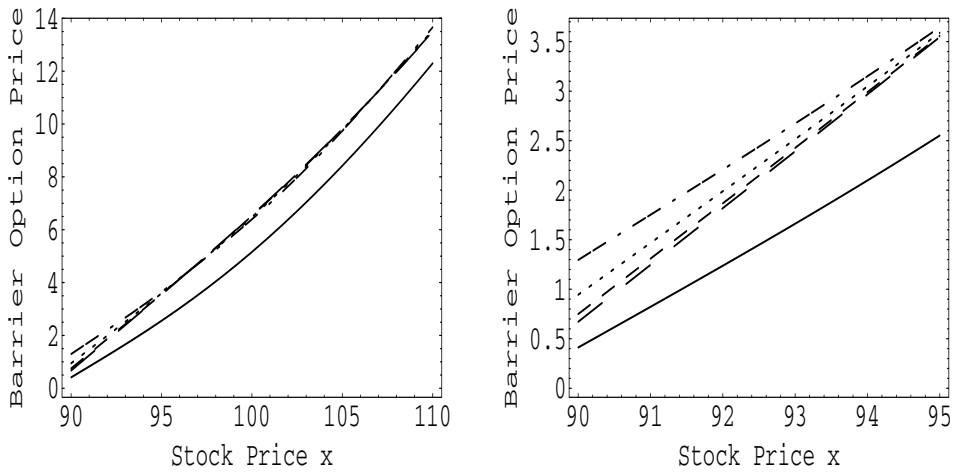

FIG. 2.1. *Effect of changing the slope of the skew a on down-and-out call option price. The parameters used for pricing the contract are* $K = 100$, $B = 89$, $T = 0.5$, $\bar{\sigma} = 0.17$, $b = 0.23$. *As shown more closely in the right figure, near the barrier, making a more negative increases the price. This effect reverses at higher stock prices. In the figures, the solid line shows the corresponding Black–Scholes price. In the right figure, the values of a reading upwards after the Black–Scholes pricing curve are* $a = -0.02, -0.04, -0.09, -0.18$.

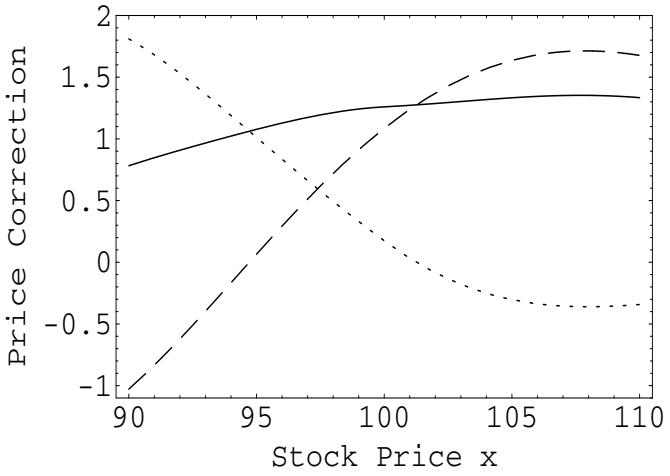

FIG. 2.2. *The first-order correction for down-and-out call option at time* $t = 0$. *The parameters used for pricing the contract are as in Figure* 2.1 *with* $a = -0.154$. *The solid line shows the first-order correction* $\widetilde{P^{(1)}}$, *the dotted line is* $\hat{P}$, *and the dashed line is the contribution of the Greek terms to* $\widetilde{P^{(1)}}$ *in* (2.19).

implied volatility curve has a mixed structure. For the stock prices that are further away from the strike price, where there is a small possibility of having a positive payoff, making a more negative increases the price. For the stock prices that are around the strike price, this effect is reversed. An increase in b, which can also be interpreted as using a higher volatility as we push up the implied volatility curve, increases the corrected price.

2.4. Convergence. In the case of a smooth payoff-at-maturity function, the proof of the convergence result

$$|P(t,x,y) - (P^{(0)}(t,x) + \widetilde{P^{(1)}}(t,x))| = \mathcal{O}(\varepsilon)$$

at a fixed point (t,x,y) is obtained by an adaptation of the proof given in [13, section 5.4]. Here the sense of convergence is with $t < T$, $x > B$, and $y \in \mathbb{R}$ fixed and as $\varepsilon \downarrow 0$, as is needed in the finance application.

The error $Z^\varepsilon(t,x,y)$ defined by

$$P = P^{(0)} + \sqrt{\varepsilon}P^{(1)} + \varepsilon P^{(2)} + \varepsilon^{3/2}P^{(3)} - Z^\varepsilon$$

satisfies

$$\begin{aligned}
\mathcal{L}^\varepsilon Z^\varepsilon &= \varepsilon(\mathcal{L}_1 P^{(3)} + \mathcal{L}_2 P^{(2)}) + \varepsilon^{3/2}\mathcal{L}_2 P^{(3)},\\
Z^\varepsilon(T,x,y) &= \varepsilon P^{(2)}(T,x,y) + \varepsilon^{3/2}P^{(3)}(T,x,y),\\
Z^\varepsilon(t,B,y) &= \varepsilon P^{(2)}(t,B,y) + \varepsilon^{3/2}P^{(3)}(t,B,y),
\end{aligned}$$

using the definitions of $P^{(0)}(t,x)$, $P^{(1)}(t,x)$ and choosing $P^{(2)}(t,x,y)$ and $P^{(3)}(t,x,y)$ as solutions of

$$\mathcal{L}_0 P^{(2)} + \mathcal{L}_2 P^{(0)} = 0, \tag{2.20}$$

$$\mathcal{L}_0 P^{(3)} = -(\mathcal{L}_1 P^{(2)} + \mathcal{L}_2 P^{(1)}), \tag{2.21}$$

respectively. The latter can be chosen to be at most logarithmically growing in y by the properties of the Poisson equations (2.20) and (2.21) and the assumed boundedness of f and Λ. The result follows from the maximum principle because smoothness of the payoff implies $P^{(2)}$ and $P^{(3)}$ are smooth with bounded derivatives.

When the payoff is only continuous as in the case of the barrier call option here, the argument of [17] can be adapted to show that

$$|P(t,x,y) - (P^{(0)}(t,x) + \widetilde{P^{(1)}}(t,x))| = \mathcal{O}(\varepsilon^{1-p})$$

for any $p > 0$. This involves a regularization of the payoff, which can be conveniently done by replacing the nonsmooth call payoff $(x-K)^+$ by the Black–Scholes barrier option price $P^{(0)}(T-\delta, x; \bar{\sigma})$ a small time $\delta > 0$ from maturity. This payoff is smooth and zero at the barrier $x = B$, and we can utilize the explicit Black–Scholes barrier option pricing formula (2.9) to easily estimate the blow-up rates of derivatives at $x = K$ as $\delta \downarrow 0$ and $t \to T$.

The important point is that the barrier price $P^{(0)}$ is smooth in $x > B$ and its derivatives have finite limits as $x \to B^+$. Therefore the presence of the knock-out barrier introduces no further complications.

The only further adaptation to the proof in [17] that needs to be made is in showing that the solution of the regularized problem converges to the solution of the unregularized problem as $\delta \downarrow 0$ at a rate independent of ε. This can be achieved by a rotation of coordinates so that the two solutions can be written as expectations of functionals of independent processes (ξ, Y), where $\xi = X - F(Y)$ and $F' = \frac{\sqrt{\varepsilon}\rho}{\nu\sqrt{2}}f$, stopped on a curved boundary. (Such a transformation is not computationally convenient but is useful to derive regularity properties.) The result follows by conditioning on the subordinating process Y and ε-independent moments of this process.

2.5. Hedging. As mentioned in section 1.4, one possible hedging strategy is to hold

$$\Delta_t^\varepsilon := \frac{\partial}{\partial x}(P^{(0)} + \widetilde{P^{(1)}})(t, X_t)$$

stocks at time t, and $e^{-rt}(P^{(0)} + \widetilde{P^{(1)}} - \Delta_t^\varepsilon X_t)$ units of account in the bank. This is not a self-financing strategy, but the value of the hedging portfolio remains close to the price of the barrier option under the assumption of fast volatility mean-reversion, as shown in [13, Chapter 7].

It is well known that certain popular hedging strategies based on the Greeks Delta, Vega, and Gamma run into trouble when the stock price is close to the barrier because these derivatives do not converge to zero as $x \downarrow B$. The asymptotic methods we consider here are not intended to remedy this problem, and indeed we would expect the approximations to be less effective close to the barrier because the assumption of the remaining lifetime of the option being long compared with the characteristic half-life of the volatility breaks down. This is similar to the situation when the option is close to maturity (see [13, section 5.5] for a discussion). In these cases, boundary layer effects are important (see [22] for an analysis).

3. Lookback options. *Lookback options* are path-dependent options whose payoff depends on the realized maximum or minimum of the underlying asset price during the life of the option. One example of this class of options is the *floating strike lookback put*, which pays the difference of the realized maximum of the underlying asset during the option's life and the asset price itself at the expiration time T. Its payoff is $J_T - X_T$, where we define the running maximum $J_t = \max_{0 \le s \le t} X_s$. Pricing equations for lookback options in the Black–Scholes constant volatility model were first given and solved in [18]. A combination of a lookback call (paying the difference between the terminal stock price and the minimum) and a lookback put can be used to model trading strategies employed by many trend-following hedge funds, as discussed in [6], for example. Davydov and Linetsky [7] derive the closed-form solutions for Laplace transforms of the prices of lookback options in the case of the constant elasticity of variance (CEV) model. This is a complete market model in which the volatility process is a power function of the stock price: $\sigma_t = \kappa S_t^\gamma$. Linetsky [27] studies the construction of spectral expansions for the same model.

In a stochastic volatility environment, the price $P(t, x, J, y)$ of this option satisfies

$$\mathcal{L}^\varepsilon P = 0 \quad \text{in } x < J \text{ and } t < T,$$

with a terminal condition $P(T, x, J, y) = J - x$ and a boundary condition at $x = J$, $P_J(t, J, J, y) = 0$. The derivation of the boundary condition is given in [18], expressing the fact that the price of the lookback option for $X_t = J_t$ is insensitive to small changes in J_t because the realized maximum at time T is larger than the realized maximum at time t with probability one.

The problem of finding $P(t, x, J, y)$ can be reduced to a two (space)-dimensional boundary value problem with the following similarity reduction:

$$\xi = x/J \qquad \text{and} \qquad P(t, x, J, y) = JQ(t, \xi, y).$$

We can express $Q(t,\xi,y)$ as the solution of

$$\begin{aligned}\left(\frac{1}{\varepsilon}\mathcal{L}_0+\frac{1}{\sqrt{\varepsilon}}\mathcal{L}_1+\mathcal{L}_2\right)Q=0 \quad &\text{for } \xi<1 \text{ and } t<T,\\ Q(T,\xi,y)&=1-\xi,\\ (Q_\xi-Q)(t,1,y)&=0,\end{aligned}$$

where, in a slight abuse of notation, we redefine $\mathcal{L}_1$ and $\mathcal{L}_2$ to be the same as (2.6) and (2.7), but with ξ replacing x.

3.1. Asymptotic approximation. Our approximation for the lookback price is

$$Q(t,\xi,y)\approx Q^{(0)}(t,\xi)+\widetilde{Q^{(1)}}(t,\xi),$$

where $P^{(0)}(t,x,J)=JQ^{(0)}(t,x/J)$ is the Black–Scholes price of the option with volatility parameter $\bar\sigma$. That is, following the usual asymptotic analysis such as in [13], $Q^{(0)}$ solves

$$\begin{aligned}\langle\mathcal{L}_2\rangle Q^{(0)}=Q^{(0)}_t+\frac{1}{2}\bar\sigma^2\xi^2Q^{(0)}_{\xi\xi}+r(\xi Q^{(0)}_\xi-Q^{(0)})=0 \quad &\text{in } \xi<1 \text{ and } t<T,\\ Q^{(0)}(T,\xi)&=1-\xi,\\ (Q^{(0)}_\xi-Q^{(0)})(t,1)&=0.\end{aligned}\tag{3.1}$$

The correction term solves

$$\widetilde{Q^{(1)}_t}+\frac{1}{2}\bar\sigma^2\xi^2\widetilde{Q^{(1)}_{\xi\xi}}+r\left(\xi\widetilde{Q^{(1)}_\xi}-\widetilde{Q^{(1)}}\right)=\mathcal{A}Q^{(0)} \quad \text{in } \xi<1 \text{ and } t<T,\tag{3.2}$$

with $\widetilde{Q^{(1)}}(T,\xi)=1-\xi$ and

$$\left(\widetilde{Q^{(1)}}-\widetilde{Q^{(1)}_\xi}\right)(t,1)=0.$$

Here, the operator $\mathcal{A}$ is as in (2.10), but with ξ replacing x.

3.2. Zero-order term. Although the pricing formula $P^{(0)}(t,x,J)$ for a lookback put is well known, we will start by deriving $P^{(0)}(t,x,J)$, as the transformations will also be useful in the derivation of $\widetilde{P^{(1)}}(t,x,J)=J\widetilde{Q^{(1)}}(t,x/J)$.

The PDE problem (3.1) can be transformed to a PDE with constant coefficients by using logarithmic variables. That is, defining

$$\eta=\log\xi, \qquad u^{(0)}(t,\eta)=Q^{(0)}(t,\xi),$$

we find $u^{(0)}(t,\eta)$ to satisfy

$$u^{(0)}_t+\frac{1}{2}\bar\sigma^2u^{(0)}_{\eta\eta}+\left(r-\frac{1}{2}\bar\sigma^2\right)u^{(0)}_\eta-ru^{(0)}=0 \quad \text{in } \eta<0 \text{ and } t<T,\tag{3.3}$$

with the conditions

$$\begin{aligned}u^{(0)}(T,\eta)&=1-e^\eta,\\ (u^{(0)}_\eta-u^{(0)})(t,0)&=0.\end{aligned}$$

We first find $w^{(0)}(t,\eta) = u_\eta^{(0)}(t,\eta) - u^{(0)}(t,\eta)$, which solves the (Dirichlet) boundary value problem

$$w_t^{(0)} + \frac{1}{2}\bar{\sigma}^2 w_{\eta\eta}^{(0)} + \left(r - \frac{1}{2}\bar{\sigma}^2\right) w_\eta^{(0)} - r w^{(0)} = 0 \quad \text{in } \eta < 0 \text{ and } t < T,$$

with the conditions $w^{(0)}(T,\eta) = -1$ and $w^{(0)}(t,0) = 0$. The solution for $w^{(0)}(t,\eta)$ can be found via the method of images

$$w^{(0)}(t,\eta) = e^{-r(T-t)}[e^{(1-k)\eta} N(c_1(T-t)) - N(c_2(T-t))], \tag{3.4}$$

where

$$c_1(\tau) = \frac{\eta}{\bar{\sigma}\sqrt{\tau}} + \frac{1}{2}(1-k)\bar{\sigma}\sqrt{\tau} \qquad \text{and} \qquad c_2(\tau) = \frac{-\eta}{\bar{\sigma}\sqrt{\tau}} + \frac{1}{2}(1-k)\bar{\sigma}\sqrt{\tau}.$$

Restoring all transformations, we get, in the notation of [29],

$$P^{(0)} = -x + x(1+k^{-1})N(d_7) + Je^{-r(T-t)}\left(N(d_5) - k^{-1}\left(\frac{x}{J}\right)^{1-k} N(d_6)\right), \tag{3.5}$$

where

$$d_5 = \frac{\log(J/x) - (r - \frac{1}{2}\bar{\sigma}^2)(T-t)}{\bar{\sigma}\sqrt{T-t}}, \qquad d_6 = \frac{\log(x/J) - (r - \frac{1}{2}\bar{\sigma}^2)(T-t)}{\bar{\sigma}\sqrt{T-t}},$$
$$d_7 = \frac{\log(x/J) + (r + \frac{1}{2}\bar{\sigma}^2)(T-t)}{\bar{\sigma}\sqrt{T-t}}.$$

3.3. First-order correction. Analogous to the zero-order calculation, we define

$$\eta = \log\xi, \qquad u^{(1)}(t,\eta) = \widetilde{Q^{(1)}}(t,\xi),$$

and from (3.2) find $u^{(1)}(t,\eta)$ to satisfy

$$u_t^{(1)} + \frac{1}{2}\bar{\sigma}^2 u_{\eta\eta}^{(1)} + \left(r - \frac{1}{2}\bar{\sigma}^2\right) u_\eta^{(1)} - r u^{(1)} = \tilde{\mathcal{A}} u^{(0)} \quad \text{in } \eta < 0 \text{ and } t < T, \tag{3.6}$$
$$u^{(1)}(T,\eta) = 0,$$
$$(u_\eta^{(1)} - u^{(1)})(t,0) = 0,$$

where

$$\tilde{\mathcal{A}} = V_3^\varepsilon\left(\frac{\partial^3}{\partial\eta^3} - \frac{\partial^2}{\partial\eta^2}\right) + V_2^\varepsilon\left(\frac{\partial^2}{\partial\eta^2} - \frac{\partial}{\partial\eta}\right).$$

Defining $\mathcal{L}_{LB}$ by

$$\mathcal{L}_{LB} = \frac{\partial}{\partial t} + \frac{1}{2}\bar{\sigma}^2\frac{\partial^2}{\partial\eta^2} + \left(r - \frac{1}{2}\bar{\sigma}^2\right)\frac{\partial}{\partial\eta} - r\cdot,$$

we can verify by differentiating (3.3) with respect to $\bar{\sigma}$ that

$$\mathcal{L}_{LB} u_{\bar{\sigma}}^{(0)} = -\bar{\sigma}(u_{\eta\eta}^{(0)} - u_\eta^{(0)}) \qquad \text{and} \qquad \mathcal{L}_{LB} u_{\eta\bar{\sigma}}^{(0)} = -\bar{\sigma}(u_{\eta\eta\eta}^{(0)} - u_{\eta\eta}^{(0)})$$

with $u^{(0)}_{\bar\sigma}(T,\eta) = (u^{(0)}_{\eta\bar\sigma} - u^{(0)}_{\bar\sigma})(t,0) = 0$ and with $u^{(0)}_{\eta\bar\sigma}(T,\eta) = 0$, but $(u^{(0)}_{\eta\eta\bar\sigma} - u^{(0)}_{\eta\bar\sigma})(t,0) \neq 0$ in general.

This motivates us to define $\hat u(t,\eta)$ by

$$\frac{V_3^\varepsilon}{\bar\sigma}\hat u = u^{(1)} + \frac{1}{\bar\sigma}(V_3^\varepsilon u^{(0)}_{\eta\bar\sigma} + V_2^\varepsilon u^{(0)}_{\bar\sigma}).$$

We find that $\hat u$ solves

$$\begin{gathered}\hat u_t + \frac{1}{2}\bar\sigma^2\hat u_{\eta\eta} + \left(r - \frac{1}{2}\bar\sigma^2\right)\hat u_\eta - r\hat u = 0 \quad \text{in } \eta < 0 \text{ and } t < T,\\ \hat u(T,\eta) = 0,\\ (\hat u_\eta - \hat u)(t,0) = g(t),\end{gathered}$$

where we define

$$g(t) = (u^{(0)}_{\eta\eta\bar\sigma} - u^{(0)}_{\eta\bar\sigma})\big|_{\eta=0} = w^{(0)}_{\eta\bar\sigma}\big|_{\eta=0}. \tag{3.7}$$

Defining $\hat w = \hat u_\eta - \hat u$, $\hat w(t,\eta)$ solves the Dirichlet boundary value problem

$$\begin{gathered}\hat w_t + \frac{1}{2}\bar\sigma^2\hat w_{\eta\eta} + \left(r - \frac{1}{2}\bar\sigma^2\right)\hat w_\eta - r\hat w = 0 \quad \text{in } \eta < 0 \text{ and } t < T,\\ \hat w(T,\eta) = 0,\\ \hat w(t,0) = g(t).\end{gathered}$$

Following the analysis leading to (2.18), we can write

$$\hat w(t,\eta) = -\frac{\eta e^\eta}{\bar\sigma\sqrt{2\pi}}\int_t^T e^{-\frac{1}{2}c_3(s-t)^2}\frac{g(s)}{(s-t)^{3/2}}\,\mathrm{d}s, \tag{3.8}$$

where

$$c_3(\tau) = \frac{\eta}{\bar\sigma\sqrt{\tau}} + \frac{1}{2}\bar\sigma(1+k)\sqrt{\tau}.$$

This formula, together with a Taylor expansion of g, yields $\hat w_\eta(t,0) = \frac{1}{2}(1-k)g(t)$.

To recover $\hat u(t,\eta)$, we use

$$\hat u(t,\eta) = \int_0^\eta e^{\eta-z}\hat w(t,z)\,\mathrm{d}z + e^\eta h(t), \tag{3.9}$$

where

$$h'(t) = -\frac{1}{2}\bar\sigma^2\hat w_\eta(t,0) - rg(t), \quad h(T) = 0.$$

Therefore

$$h(t) = \frac{1}{2}\left(r + \frac{1}{2}\bar\sigma^2\right)\int_t^T g(s)\,ds.$$

Restoring the transformations, the first-order correction is given as

$$\widetilde{P^{(1)}}(t,x,J) = -\frac{V_3^\varepsilon}{\bar\sigma}xP^{(0)}_{x\bar\sigma}(t,x) - \frac{V_2^\varepsilon}{\bar\sigma}P^{(0)}_{\bar\sigma}(t,x) + \frac{V_3^\varepsilon}{\bar\sigma}J\hat u(t,\log(x/J)). \tag{3.10}$$

Explicit formulas for the Greeks and g are given in Appendix B.

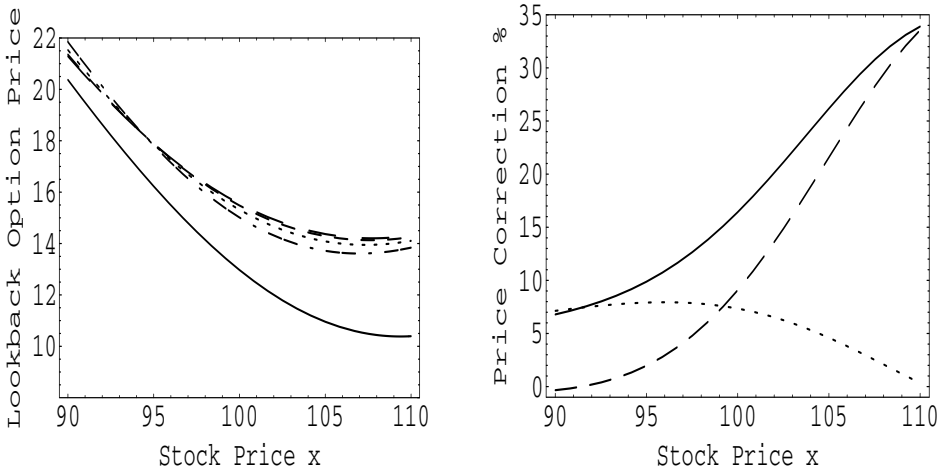

FIG. 3.1. *The left graph shows the effect of changing the slope of the skew a on the lookback put option price. The parameters of the contract are* $T = 0.5$, $\bar{\sigma} = 0.17$, $b = 0.23$. *The current running maximum is* $J = 111$. *The solid line shows the corresponding Black–Scholes price; the values of a reading downward at the right of the graph are* $a = -0.02, -0.04, -0.09, -0.18$. *When the stock price is near to its running maximum, making a more negative decreases the option price. The right graph shows the percentage of first-order correction to the Black–Scholes price for the lookback put option at time* $t = 0$. *The parameters of the contract are as in the left figure with* $a = -0.154$. *The solid line shows the whole first-order correction, the dashed line shows the contribution of the Greek terms in* (3.10), *and the dotted line shows the remainder, i.e., the boundary correction.*

Figure 3.1 illustrates the effect of the two parts of the correction, and for various skew slopes. As in the case of the barrier option, the effect of changing a has a mixed structure. For stock prices that are close to the running maximum, that is, when there is a potential of going above the running maximum, making a more negative decreases the price. For smaller stock prices, the effect is reversed. An increase in the intercept of the implied volatility curve increases the price, as in the barrier option case.

3.4. Convergence. From (3.5), second and higher derivatives of $P^{(0)}$ with respect to x blow up as $t \to T$ and $x \to J$, similar to the Black–Scholes price of an at-the-money European call option. Therefore the proof of a convergence result of the form

$$\left| P(t,x,J,y) - (P^{(0)}(t,x,J) + \widetilde{P^{(1)}}(t,x,J)) \right| = \mathcal{O}(\varepsilon^{1-p})$$

for any $p > 0$ at a fixed point (t,x,J,y) requires the regularization techniques in [17], which are discussed in section 2.4.

3.5. Hedging. In the Black–Scholes model, the hedging strategy for the lookback option is again given by the Delta of the option price (see [29], for example). Following our discussion in section 1.4, we can again consider the hedging strategy consisting of

$$\Delta_t^\varepsilon = \frac{\partial}{\partial x}\left(P^{(0)} + \widetilde{P^{(1)}}\right)(t, X_t, J_t)$$

stocks and the amount $e^{-rt}((P^{(0)} + \widetilde{P^{(1)}})(t, X_t, J_t) - \Delta_t^\varepsilon X_t)$ in the bank account. As in [13, Chapter 7], the portfolio is not self-financing but its value is close to the value

of the lookback option. We do not consider optimal hedges involving other options and loss measurement functions in this paper.

4. Passport options. A passport option allows its holder to trade the stock continuously, starting with initial capital v, and collect his or her profit at the expiration date T, if any, with losses written off. Its price is studied by Hyer, Lipton-Lifschitz, and Pugachevsky [24], where they assumed a log-normal process for the underlying stock. They derive and solve the Hamilton–Jacobi–Bellman equation for the price. Shreve and Vecer [28] used probabilistic techniques to price this option as well as other variants. Henderson and Hobson [19] analyzed passport option pricing under stochastic volatility models where they assume independence of the volatility driving process from the stock price process. They give the price analytically using power series expansion methods for different volatility models.

Let $(q_t)_{0\le t\le T}$ be a possible trading strategy, where q_t is the number of stocks held in the trading account at time t. Additionally, $-1 \le q_t \le 1$ at all times, so the trader is restricted to be at most long or short one stock at any time. Let (V_t) be the value of the holder's portfolio so that

$$dV_t = rV_t\,dt + q_t f(Y_t) X_t\,dW_t^\star, \tag{4.1}$$

written in terms of the risk-neutral Brownian motion $W^\star$ because cash flows are priced under $\mathbb{P}^{\star(\gamma)}$. The payoff of the passport option is simply V_T^+ and so the *no-arbitrage* pricing function $P(t,x,y,v)$ of the contract is given by

$$P(t,x,y,v) = \sup_{|q|\le 1} \mathbb{E}^{\star(\gamma)}\{e^{-r(T-t)}V_T^+ \mid X_t = x,\ Y_t = y,\ V_t = v\}.$$

Assuming P has one continuous derivative in t and is twice continuously differentiable in the spatial variables, P solves the Hamilton–Jacobi–Bellman PDE

$$\frac{\partial P}{\partial t} + \sup_{|q|\le 1} \mathcal{L}_{x,y,v}^{(q)} P = 0,$$

where $\mathcal{L}_{x,y,v}^{(q)}$ is the infinitesimal generator of (X,Y,V), plus the discounting term:

$$\begin{aligned}\mathcal{L}_{x,y,v}^{(q)} = {} & \frac{1}{2} f(y)^2 x^2 \left(\frac{\partial^2}{\partial x^2} + 2q\frac{\partial^2}{\partial x \partial v} + q^2 \frac{\partial^2}{\partial v^2}\right) \\ & + \rho \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}} f(y) x \left(\frac{\partial^2}{\partial x \partial y} + q\frac{\partial^2}{\partial y \partial v}\right) + \frac{1}{2}\frac{\nu^2}{\varepsilon}\frac{\partial^2}{\partial y^2} \\ & + r\left(x\frac{\partial}{\partial x} + v\frac{\partial}{\partial v}\right) + \left(\frac{1}{\varepsilon}(m-y) - \frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(y)\right)\frac{\partial}{\partial y} - r\cdot .\end{aligned}$$

The terminal condition is $P(T,x,y,v) = v^+$, and the domain is $t < T$, $x > 0$, $-\infty < y, v < \infty$.

The PDE above can be derived directly (see [24], for instance) by setting up a hedged portfolio of the passport option, another vanilla option, and the underlying stock, and assuming that the holder of the passport option trades the stock optimally.

4.1. Similarity reduction. We first take advantage of a natural homogeneity in the problem. From (2.2) and (4.1), we see that scaling X and V by a common factor, say θ, as in

$$X \mapsto \theta X, \qquad V \mapsto \theta V,$$

does not change those equations. In other words, $P(t,\theta x,y,\theta v)=\theta P(t,x,y,v)$, and so we look for a solution of the form

$$P(t,x,y,v)=xQ(t,\xi,y),\quad \xi=v/x,$$

for some function Q.

Substituting this form gives that $Q(t,\xi,y)$ solves the PDE problem

$$\begin{aligned} Q_t+\sup_{|q|\le 1}\left\{\frac{1}{2}f(y)^2(q-\xi)^2Q_{\xi\xi}+\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)(q-\xi)Q_{\xi y}\right\}\\ +\frac{1}{2}\frac{\nu^2}{\varepsilon}Q_{yy}+\left[\frac{1}{\varepsilon}(m-y)-\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(y)+\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)\right]Q_y=0,\\ Q(T,\xi,y)=\xi^+ \end{aligned} \tag{4.2}$$

in the domain $t<T$, $-\infty<\xi,y<\infty$. Notice that r has disappeared from the problem because the transformations $Q=P/x$ and $\xi=v/x$ mean that we are using the stock price as our numeraire, which grows at rate r under the risk-neutral measure.

Consider the quadratic (in q) term in (4.2):

$$\frac{1}{2}f(y)^2(q-\xi)^2Q_{\xi\xi}+\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)(q-\xi)Q_{\xi y}. \tag{4.3}$$

Assuming that $Q_{\xi\xi}>0$ for $t<T$, the maximum of this quadratic over $q\in[-1,1]$ is at the boundaries: $q^*=\pm1$ at each point in the domain. Therefore $(q^*)^2=1$ and the sup term in (4.2) can be replaced by

$$\frac{1}{2}f(y)^2(1+\xi^2)Q_{\xi\xi}-\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)\xi Q_{\xi y}+f(y)^2\left|\xi Q_{\xi\xi}-\frac{\rho\nu\sqrt{2}}{\sqrt{\varepsilon}f(y)}Q_{\xi y}\right|.$$

Let $R(t,\xi,y)$ be the solution to PDE (4.2) with terminal condition $R(T,\xi,y)=|\xi|$. It is then straightforward to verify that the function $\frac{1}{2}(\xi+R(t,\xi,y))$ satisfies both the PDE and the terminal condition in (4.2), so we have

$$Q(t,\xi,y)=\frac{1}{2}(\xi+R(t,\xi,y)). \tag{4.4}$$

The PDE problem for R is therefore

$$\begin{aligned} R_t+\frac{1}{2}f(y)^2(1+\xi^2)R_{\xi\xi}-\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)\xi R_{\xi y}+\frac{1}{2}\frac{\nu^2}{\varepsilon}R_{yy}\\ +\left[\frac{1}{\varepsilon}(m-y)-\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}\Lambda(y)+\rho\frac{\nu\sqrt{2}}{\sqrt{\varepsilon}}f(y)\right]R_y\\ +f(y)^2\left|\xi R_{\xi\xi}-\frac{\rho\nu\sqrt{2}}{\sqrt{\varepsilon}f(y)}R_{\xi y}\right|=0,\\ R(T,\xi,y)=|\xi|. \end{aligned} \tag{4.5}$$

Observe that (4.5) is unchanged by the transformation $\xi\mapsto-\xi$. As a consequence, $R(t,\xi,y)$ is an even function of ξ. This property carries over to the first two terms of our expansion, where we will take advantage of it.

4.2. Asymptotic expansion. We derive the asymptotic expansion for this option pricing function to highlight the differences with the calculation for the previous two cases given in [13]. See [26, 25] for approximations for stochastic control problems from hedging and portfolio optimization.

The expansion is written here for R, but applies, with obvious modifications to the terminal condition, for Q. Under the usual fast mean-reversion scaling, we rewrite the PDE (4.2) as

$$\left(\frac{1}{\varepsilon}\mathcal{L}_0 + \frac{1}{\sqrt{\varepsilon}}\mathcal{L}_1 + \mathcal{L}_2\right) R + \mathrm{NL}^\varepsilon = 0,$$

where $\mathcal{L}_0$, $\mathcal{L}_1$, and $\mathcal{L}_2$ are the linear differential operators

$$\begin{aligned}
\mathcal{L}_0 &= \nu^2 \frac{\partial^2}{\partial y^2} + (m-y)\frac{\partial}{\partial y},\\
\mathcal{L}_1 &= -\sqrt{2}\,\rho\nu f(y)\xi \frac{\partial^2}{\partial \xi \partial y} + \sqrt{2}\,\nu(\rho f(y) - \Lambda(y))\frac{\partial}{\partial y},\\
\mathcal{L}_2 &= \frac{\partial}{\partial t} + \frac{1}{2} f(y)^2 (1+\xi^2)\frac{\partial^2}{\partial \xi^2},
\end{aligned}$$

and NL^ε is the nonlinear term

$$\mathrm{NL}^\varepsilon = f(y)^2 \left| \xi R_{\xi\xi} - \frac{\rho\nu\sqrt{2}}{\sqrt{\varepsilon}\, f(y)} R_{\xi y} \right|.$$

We look for an expansion

$$R = R^{(0)} + \sqrt{\varepsilon} R^{(1)} + \varepsilon R^{(2)} + \cdots,$$

valid for small $\varepsilon > 0$. Inserting the series and comparing terms of $\mathcal{O}(\varepsilon^{-1})$ gives

$$\mathcal{L}_0 R^{(0)} = 0.$$

This is an ODE in y, and from the properties of $\mathcal{L}_0$, the only solutions with reasonable growth at infinity are constants in y. Therefore we take $R^{(0)} = R^{(0)}(t,\xi)$, independent of y. Hence, in the expansion of NL^ε,

$$\mathrm{NL}^\varepsilon = f(y)^2 \left| -\frac{\rho\nu\sqrt{2}}{\sqrt{\varepsilon}\, f(y)} R^{(0)}_{\xi y} + \xi R^{(0)}_{\xi\xi} - \frac{\rho\nu\sqrt{2}}{f(y)} R^{(1)}_{\xi y} + \mathcal{O}(\sqrt{\varepsilon}) \right|,$$

the $\mathcal{O}(\varepsilon^{-1/2})$ disappears.

Comparing terms of $\mathcal{O}(\varepsilon^{-1/2})$ therefore gives

$$\mathcal{L}_0 R^{(1)} + \mathcal{L}_1 R^{(0)} = 0.$$

Since $\mathcal{L}_1$ takes y-derivatives, this reduces to

$$\mathcal{L}_0 R^{(1)} = 0,$$

which implies that $R^{(1)}$ also does not depend on y. Now

$$\mathrm{NL}^\varepsilon = f(y)^2 \left| \xi R^{(0)}_{\xi\xi} + \sqrt{\varepsilon}\left(\xi R^{(1)}_{\xi\xi} - \frac{\rho\nu\sqrt{2}}{f(y)} R^{(2)}_{\xi y}\right) + \mathcal{O}(\varepsilon) \right|, \tag{4.6}$$

including the next order. The $\mathcal{O}(1)$ terms of the expansion in the PDE give

$$\mathcal{L}_0 R^{(2)} + \mathcal{L}_1 R^{(1)} + \mathcal{L}_2 R^{(0)} + f(y)^2 |\xi| R^{(0)}_{\xi\xi} = 0, \tag{4.7}$$

where we have assumed that $R^{(0)}_{\xi\xi} \geq 0$; that is, the leading term inherits the convexity

of R in ξ. The second term $\mathcal{L}_1 R^{(1)} = 0$ because $R^{(1)}$ does not depend on y. We view (4.7) as a Poisson equation for $R^{(2)}$. For there to be a solution, the source term must be centered with respect to the invariant distribution of the OU process (Y_t), namely,

$$\langle \widetilde{\mathcal{L}_2} \rangle R^{(0)} = 0, \tag{4.8}$$

where we define

$$\begin{aligned}\widetilde{\mathcal{L}_2} &= \mathcal{L}_2 + f(y)^2 |\xi| \frac{\partial^2}{\partial \xi^2} \\ &= \frac{\partial}{\partial t} + \frac{1}{2} f(y)^2 (1 + |\xi|)^2 \frac{\partial^2}{\partial \xi^2}.\end{aligned}$$

The averaged operator simply replaces $f(y)^2$ by the constant $\bar{\sigma}^2$. Therefore $R^{(0)}$, when transformed back, gives the passport option pricing function with the constant long-run average volatility $\bar{\sigma}$. To move to the next order, we formally linearize the expression (4.6) for NL^ε as follows:

$$\mathrm{NL}^\varepsilon = f(y)^2 \left(|\xi| R^{(0)}_{\xi\xi} + \sqrt{\varepsilon}\, \mathrm{sgn}(\xi) \left[\xi R^{(1)}_{\xi\xi} - \frac{\rho\nu\sqrt{2}}{f(y)} R^{(2)}_{\xi y} \right] \right) + \mathcal{O}(\varepsilon).$$

Now comparing terms in the expanded PDE of $\mathcal{O}(\sqrt{\varepsilon})$ gives

$$\mathcal{L}_0 R^{(3)} + \mathcal{L}_1 R^{(2)} + \mathcal{L}_2 R^{(1)} + \mathrm{sgn}(\xi) \left[\xi f(y)^2 R^{(1)}_{\xi\xi} - \rho\nu\sqrt{2} f(y) R^{(2)}_{\xi y} \right] = 0.$$

This is a Poisson equation for $R^{(3)}$ whose solvability condition gives

$$\begin{aligned}\langle \widetilde{\mathcal{L}_2} \rangle R^{(1)} &= -\left\langle \left(\mathcal{L}_1 - \rho\nu\sqrt{2}\, f\, \mathrm{sgn}(\xi) \frac{\partial^2}{\partial \xi \partial y} \right) R^{(2)} \right\rangle \\ &= \nu\sqrt{2} \left\langle \left(\rho f\, \mathrm{sgn}(\xi)(1 + |\xi|) \frac{\partial^2}{\partial \xi \partial y} - (\rho f - \Lambda) \frac{\partial}{\partial y} \right) R^{(2)} \right\rangle.\end{aligned} \tag{4.9}$$

As in section 2.2, let $\phi(y)$ be a solution to $\mathcal{L}_0 \phi = f(y)^2 - \bar{\sigma}^2$. Then (4.7) gives

$$R^{(2)} = -\frac{1}{2} \phi(y)(1 + |\xi|)^2 R^{(0)}_{\xi\xi} + D(t, \xi)$$

for some function D that does not depend on y. Substituting and computing the right side of (4.9) gives a combination of second and third derivatives of $R^{(0)}$ in the ξ variable.

As usual, we absorb the $\sqrt{\varepsilon}$ term into the correction and call $\widetilde{R^{(1)}} = \sqrt{\varepsilon} R^{(1)}$. Then $\widetilde{R^{(1)}}(t, \xi)$ solves

$$\begin{aligned}\widetilde{R^{(1)}_t} + \frac{1}{2} \bar{\sigma}^2 (1 + |\xi|)^2 \widetilde{R^{(1)}_{\xi\xi}} = &- (V_3^\varepsilon - V_2^\varepsilon)(1 + |\xi|)^2 R^{(0)}_{\xi\xi} \\ &- V_3^\varepsilon\, \mathrm{sgn}(\xi)(1 + |\xi|)^3 R^{(0)}_{\xi\xi\xi},\end{aligned} \tag{4.10}$$

where V_2^ε and V_3^ε are the market group parameters defined in (2.11) and (2.12). The terminal condition is $\widetilde{R^{(1)}}(T, \xi) = 0$.

4.3. Zero-order term. Again we start by finding the zero-order approximation. We work with $R(t, \xi, y)$ and recover $Q(t, \xi, y)$ using (4.4). Thus $R^{(0)}$ satisfies

$$R^{(0)}_t + \frac{1}{2} \bar{\sigma}^2 (1 + |\xi|)^2 R^{(0)}_{\xi\xi} = 0 \quad \text{in } -\infty < \xi < \infty \text{ and } t < T, \tag{4.11}$$

$$R^{(0)}(T, \xi) = |\xi|. \tag{4.12}$$

It follows that $R^{(0)}(t,\cdot)$ is even at all times, so by the smoothing properties of (4.11) we have $R^{(0)}_\xi(t,0)=0$ for $t<T$. Hence we can solve

$$\begin{aligned} R^{(0)}_t+\frac{1}{2}\bar\sigma^2(1+\xi)^2R^{(0)}_{\xi\xi}&=0 \quad \text{in } \xi>0 \text{ and } t<T,\\ R^{(0)}(T,\xi)&=\xi,\\ R^{(0)}_\xi(t,0)&=0, \end{aligned} \tag{4.13}$$

and obtain the solution in $\xi<0$ by the even extension.

We transform to constant coefficients via

$$\eta=\log(1+\xi), \qquad R^{(0)}(t,\xi)=u^{(0)}(t,\eta).$$

Then $u^{(0)}(t,\eta)$ solves the Neumann boundary value problem

$$\begin{aligned} u^{(0)}_t+\frac{1}{2}\bar\sigma^2(u^{(0)}_{\eta\eta}-u^{(0)}_\eta)&=0 \quad \text{in } \eta>0 \text{ and } t<T,\\ u^{(0)}(T,\eta)&=e^\eta-1,\\ u^{(0)}_\eta(t,0)&=0. \end{aligned} \tag{4.14}$$

Similar to the case of lookback option, we first find the partial derivative $w^{(0)}=u^{(0)}_\eta$, which solves a Dirichlet boundary value problem. Using the method of images, we find $w^{(0)}(t,\eta)$ as

$$w^{(0)}(t,\eta)=e^\eta N(c_5(T-t))-N(c_6(T-t)),$$

where

$$c_5(\tau)=\frac{\eta}{\bar\sigma\sqrt{\tau}}+\frac{1}{2}\bar\sigma\sqrt{\tau} \qquad \text{and} \qquad c_6(\tau)=\frac{-\eta}{\bar\sigma\sqrt{\tau}}+\frac{1}{2}\bar\sigma\sqrt{\tau}. \tag{4.15}$$

Restoring all the transformations gives $P^{(0)}(t,x,v)$ as

$$P^{(0)}=\frac{1}{2}\left[v+xu^{(0)}\left(t,\log\left(1+\frac{|v|}{x}\right)\right)\right],$$

which can be written in the notation of [28] as

$$\begin{aligned} P^{(0)}=\frac{1}{2}\Big[&v+(x+|v|)N(d_+)-xN(d_-)\\ &+x\bar\sigma\sqrt{T-t}\,N'(d_-)-x\bar\sigma\sqrt{T-t}\,d_-N(-d_-)\Big], \end{aligned}$$

where

$$d_\pm=\frac{\log\left(1+\frac{|v|}{x}\right)}{\bar\sigma\sqrt{T-t}}\pm\frac{1}{2}\bar\sigma\sqrt{T-t}.$$

4.4. First-order correction. The first-order correction $\widetilde{R^{(1)}}$ satisfies the PDE

$$\widetilde{R^{(1)}_t}+\frac{1}{2}\bar\sigma^2(1+|\xi|)^2\widetilde{R^{(1)}_{\xi\xi}}=-(V^\varepsilon_3-V^\varepsilon_2)(1+|\xi|)^2R^{(0)}_{\xi\xi}-V^\varepsilon_3(1+|\xi|)^3R^{(0)}_{\xi\xi\xi},$$

with terminal condition $\widetilde{R^{(1)}}(T,\xi)=0$. Thus $\widetilde{R^{(1)}}$ is again an even function of ξ, and we can solve

$$\widetilde{R^{(1)}_t}+\frac{1}{2}\bar\sigma^2(1+\xi)^2\widetilde{R^{(1)}_{\xi\xi}}=-(V^\varepsilon_3-V^\varepsilon_2)(1+\xi)^2R^{(0)}_{\xi\xi}-V^\varepsilon_3(1+\xi)^3R^{(0)}_{\xi\xi\xi},$$

with the terminal condition $\widetilde{R^{(1)}}(T,\xi)=0$ and the boundary condition $\widetilde{R^{(1)}_{\xi}}(t,0)=0$ in $\xi>0$, $t<T$. We will subtract the "particular solution" at a later stage when it becomes easier to identify.

Applying the same set of transformations, namely,

$$\eta=\log(1+\xi),\qquad \widetilde{R^{(1)}}(t,\xi)=u^{(1)}(t,\eta),$$

we get from (4.7) that

$$\begin{aligned} u^{(1)}_t+\frac{1}{2}\bar{\sigma}^2(u^{(1)}_{\eta\eta}-u^{(1)}_{\eta})&=\tilde{\mathcal{A}}u^{(0)}\quad \text{in } \eta>0 \text{ and } t<T,\\ u^{(1)}(T,\eta)&=0,\\ u^{(1)}_{\eta}(t,0)&=0, \end{aligned}\tag{4.16}$$

where

$$\tilde{\mathcal{A}}=-V_3^{\varepsilon}\left(\frac{\partial^3}{\partial\eta^3}-\frac{\partial^2}{\partial\eta^2}\right)+(V_2^{\varepsilon}+V_3^{\varepsilon})\left(\frac{\partial^2}{\partial\eta^2}-\frac{\partial}{\partial\eta}\right).$$

Defining $\mathcal{L}_p$ by

$$\mathcal{L}_p=\frac{\partial}{\partial t}+\frac{1}{2}\bar{\sigma}^2\left(\frac{\partial^2}{\partial\eta^2}-\frac{\partial}{\partial\eta}\right),$$

we can verify by differentiating (4.14) that

$$\mathcal{L}_p u^{(0)}_{\bar{\sigma}}=-\bar{\sigma}(u^{(0)}_{\eta\eta}-u^{(0)}_{\eta})\qquad\text{and}\qquad \mathcal{L}_p u^{(0)}_{\eta\bar{\sigma}}=-\bar{\sigma}(u^{(0)}_{\eta\eta\eta}-u^{(0)}_{\eta\eta}).$$

Moreover, $u^{(0)}_{\bar{\sigma}}=u^{(0)}_{\eta\bar{\sigma}}=u^{(0)}_{\eta\eta\bar{\sigma}}=0$ for $t=T$ and $u^{(0)}_{\eta\bar{\sigma}}(t,0)=0$ but $u^{(0)}_{\eta\eta\bar{\sigma}}(t,0)\neq 0$ in general. This motivates us to define $\hat{u}$ by

$$\frac{V_3^{\varepsilon}}{\bar{\sigma}}\hat{u}=u^{(1)}-\frac{V_3^{\varepsilon}}{\bar{\sigma}}u^{(0)}_{\eta\bar{\sigma}}-\left(\frac{V_2^{\varepsilon}}{\bar{\sigma}}+\frac{V_3^{\varepsilon}}{\bar{\sigma}}\right)u^{(0)}_{\bar{\sigma}}.$$

Further, defining $\hat{w}=\hat{u}_{\eta}$ to reduce to a Dirichlet boundary value problem, we find that $\hat{w}(t,\eta)$ solves

$$\begin{aligned} \hat{w}_t+\frac{1}{2}\bar{\sigma}^2\left(\hat{w}_{\eta\eta}-\hat{w}_{\eta}\right)&=0\quad \text{in } \eta>0 \text{ and } t<T,\\ \hat{w}(T,z)&=0,\\ \hat{w}(t,0)&=g(t), \end{aligned}$$

where

$$g(t)=-u^{(0)}_{\eta\eta\bar{\sigma}}\big|_{\eta=0}=-w^{(0)}_{\eta\bar{\sigma}}\big|_{\eta=0}.\tag{4.17}$$

The rest of the calculation is similar to the analysis in section 3.3. Following the same steps and restoring all transformations, we obtain the first-order correction for the passport option as

$$\begin{aligned} \widetilde{P^{(1)}}(t,x,v)=&-\frac{V_3^{\varepsilon}}{\bar{\sigma}}\left(1+\frac{x}{|v|}\right)xP^{(0)}_{x\bar{\sigma}}-\left(\frac{V_2^{\varepsilon}}{\bar{\sigma}}-\frac{V_3^{\varepsilon}}{\bar{\sigma}}\frac{x}{|v|}\right)P^{(0)}_{\bar{\sigma}}\\ &+\frac{1}{2}\frac{V_3^{\varepsilon}}{\bar{\sigma}}x\hat{u}\left(t,\log\left(1+\frac{|v|}{x}\right)\right). \end{aligned}\tag{4.18}$$

Explicit formulas for the Greeks and g are given in Appendix C.

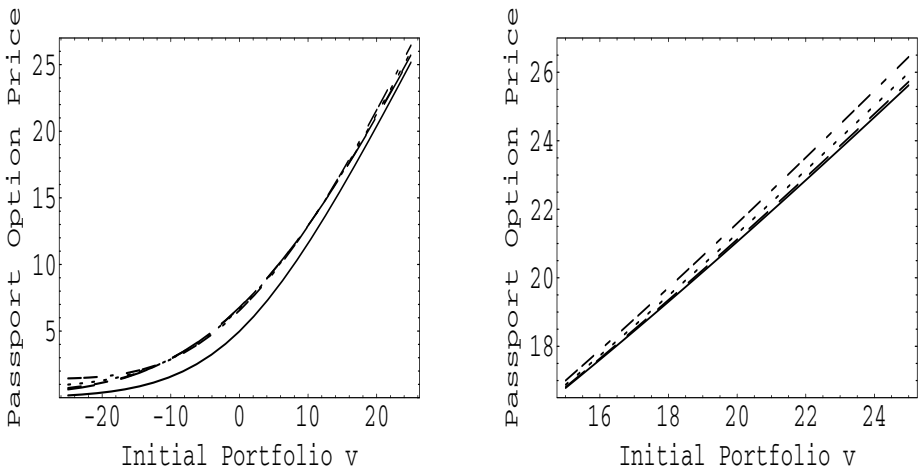

FIG. 4.1. *The left graph illustrates the effect of changing the slope of the skew a on the passport option price. The parameters of the contract are $x = 100$, $T = 0.5$, $\bar{\sigma} = 0.17$, and $b = 0.23$. As $|v|$ gets larger, making a more negative increases the option value, while this effect reverses as $|v|$ gets closer to 0. The right figure shows more closely the upper right corner of the left figure. The solid line shows the corresponding Black–Scholes price; the values of a reading upwards after the Black–Scholes pricing curve are $a = -0.02, -0.04, -0.09, -0.18$.*

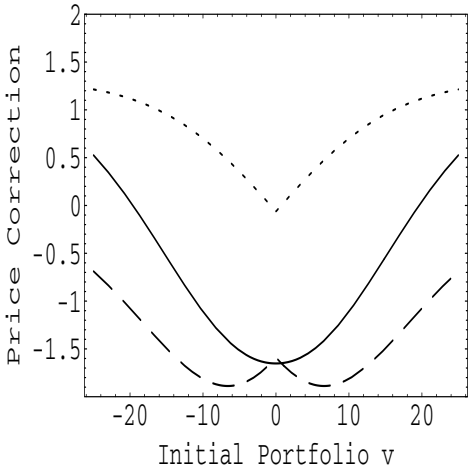

FIG. 4.2. *The first-order correction for the passport option at time $t = 0$. The parameters of the contract are as in Figure* 4.1 *with $a = -0.154$. The solid line shows the full first-order correction, the dashed line shows the contribution of the Greek terms in* (4.18)*, and the dotted line shows the remainder, i.e., the boundary correction.*

Figures 4.1 and 4.2 illustrate the effect of the correction and the slope of the implied volatility skew analyzed as a function of current wealth. As in the previous cases, the effect of changing a has a mixed structure. When the wealth is too large or too small, making a more negative increases the option value. For the wealth level that is close to zero, the reverse is observed. The effect of a higher b is to increase the price, as in the other cases.

4.5. Convergence. The existence of a classical solution to the strongly nonlinear PDE (4.5) is an open question. If such a solution exists so that $R_\xi = 0$ at $\xi = 0$ for $t < T$, then one can write a *nonlinear* error equation for Z^ε defined by

$$R = R^{(0)} + \sqrt{\varepsilon} R^{(1)} + \varepsilon R^{(2)} + \varepsilon^{3/2} R^{(3)} - Z^\varepsilon$$

with suitable terminal and boundary conditions. Under regularity hypotheses on the solution, a *weak* convergence result may be obtained by introducing test functions in (ξ, y). The convergence is necessarily weak in this case because of the sense in which the expansion of the $|\cdot|$ function can be used.

4.6. Hedging. Hedging a passport option differs from the viewpoint of the writer and the holder. The trading strategy of the holder is defined as the maximizer in the definition of the price. This quantity q^* is always plus or minus one, according to the optimizer of the quadratic expression (4.3). The hedging strategy of the seller in the case of a complete market with constant volatility $\bar\sigma$ is $P_x^{(0)} + q^* P_v^{(0)}$, given the strategy of the holder. In the case of a complete market this type of strategy perfectly replicates the payoff if the holder is trading optimally.

As in the barrier and lookback cases, this strategy could be adapted to our corrected price so that the value of the hedging portfolio remains close to the price of the option. Another strategy that also depends only on the calibrated parameters V_2^ε and V_3^ε but focuses on reducing the hedging error, the difference between the option payout, and the hedging portfolio at maturity, is discussed in [13, section 7.2].

Appendix A. Formulas for barrier option correction. Here we include the following explicit formulas for the terms in (2.19). Namely, $g(t)$, defined in (2.14), is given by

$$g(t) = -\left[\frac{2\log\frac{B}{K}}{\bar\sigma^2(T-t)}\mathcal{V}^{BS}(t,B) + \frac{4r}{\bar\sigma^3}C^{BS}(t,B)\right],$$

and the Greeks of the barrier option are given by

$$\begin{aligned}
P_{\bar\sigma}^{(0)}(t,x) &= \mathcal{V}^{BS}(t,x) - \left(\frac{x}{B}\right)^{1-k}\mathcal{V}^{BS}\left(t,\frac{B^2}{x}\right) - \frac{4r}{\bar\sigma^3}\log\frac{x}{B}\left(\frac{x}{B}\right)^{1-k} C^{BS}\left(t,\frac{B^2}{x}\right),\\
P_{x\bar\sigma}^{(0)}(t,x) &= C_{x\bar\sigma}^{BS}(t,x) + \left(\frac{x}{B}\right)^{-k}\left(\frac{k-1}{B}\mathcal{V}^{BS}\left(t,\frac{B^2}{x}\right) + \frac{B}{x}C_{x\bar\sigma}^{BS}\left(t,\frac{B^2}{x}\right)\right)\\
&\quad -\frac{4r}{\bar\sigma^3}\left(\frac{x}{B}\right)^{-k}\frac{1}{B}\left(1-k\log\frac{x}{B}\right)C^{BS}\left(t,\frac{B^2}{x}\right)\\
&\quad +\frac{4r}{\bar\sigma^3}\left(\frac{x}{B}\right)^{-(k+1)}\log\frac{x}{B}\Delta^{BS}\left(t,\frac{B^2}{x}\right),
\end{aligned}$$

where $\Delta^{BS}(t,x)$, $\mathcal{V}^{BS}(t,x)$, $C_{x\bar\sigma}^{BS}(t,x)$ are the Greeks of a call option that has the same parameters:

$$\begin{aligned}
\Delta^{BS}(t,x) &= C_x^{BS}(t,x) = N(d_1),\\
\mathcal{V}^{BS}(t,x) &= C_{\bar\sigma}^{BS}(t,x;\bar\sigma) = xe^{-\frac{1}{2}d_1^2}\frac{\sqrt{T-t}}{\sqrt{2\pi}},\\
C_{x\bar\sigma}^{BS}(t,x) &= \frac{\mathcal{V}^{BS}(t,x)}{x}\left(1-\frac{d_1}{\bar\sigma\sqrt{T-t}}\right).
\end{aligned}$$

Appendix B. Formulas for lookback option correction. The formula for $g(t)$ in the case of the lookback option, defined in (3.7), is

$$g(t) = \frac{2k}{\bar{\sigma}} e^{-r(T-t)} N\left(\frac{1}{2}(1-k)\bar{\sigma}\sqrt{T-t}\right) - 2\frac{e^{-\frac{1}{8}(1+k)^2\bar{\sigma}^2(T-t)}}{\bar{\sigma}^2\sqrt{2\pi(T-t)}}.$$

And the Greek terms for this option referred to in (3.10) are

$$P^{(0)}_{\bar{\sigma}}(t,x) = -Je^{-r(T-t)}\left(\frac{x}{J}\right)^{1-k}\left(\frac{\bar{\sigma}}{r} + \frac{2}{\bar{\sigma}}\log\frac{x}{J}\right)N(d_6(T-t)) + \frac{\bar{\sigma}}{r}xN(d_7(T-t)),$$

$$\begin{aligned} P^{(0)}_{x\bar{\sigma}}(t,x) = {} & \left(\frac{4r}{\bar{\sigma}^3}\log\frac{x}{J} - \frac{\bar{\sigma}}{r} - \frac{2}{\bar{\sigma}}\log\frac{x}{J}\right)\frac{J}{x}N(d_6(T-t)) \\ & - \frac{2\log\frac{x}{J}}{\bar{\sigma}^2\sqrt{T-t}}\frac{J}{x}N'(d_6(T-t)) + \frac{\bar{\sigma}}{r}\frac{J}{x}N(d_7(T-t)). \end{aligned}$$

Appendix C. Formulas for passport option correction. In the case of the passport option, $g(t)$ defined in (4.17) is simply given by

$$g(t) = 2\frac{e^{-\frac{1}{8}\bar{\sigma}^2(T-t)}}{\bar{\sigma}^2\sqrt{2\pi(T-t)}}.$$

The Greek terms used in (4.18) are as follows:

$$P^{(0)}_{\bar{\sigma}}(t,x) = x\bar{\sigma}(T-t)N(d_-) + 2x\sqrt{T-t}N'(d_-),$$

$$P^{(0)}_{x\bar{\sigma}}(t,x) = \frac{P^{(0)}_{\bar{\sigma}}(t,x)}{x} - \frac{2|v|\log\left(1+\frac{|v|}{x}\right)}{(x+|v|)\bar{\sigma}^2\sqrt{T-t}}N'(d_-).$$

MODELLING ANNULAR MICROMIXERS*

JAMES P. GLEESON†, OLIVIA M. ROCHE†, JONATHAN WEST‡, AND ANNE GELB§

Abstract. Magnetohydrodynamic mixing of two fluids in an annular microchannel is modelled as a two-dimensional laminar convection-diffusion problem and examined using asymptotic analysis and numerical simulation. The time T required for mixing of a plug of solute depends on the Péclet number Pe and on the geometry of the annulus. Three scaling regimes are identified: purely diffusive, Taylor-dispersive, and convection-dominated; each has a characteristic power-law dependence of T upon Pe. Consequences of these results for optimal micromixer design are discussed.

Key words. laminar mixing, convection-diffusion, asymptotic analysis, microfluidics

1. Introduction. Recent advances in microfluidic and lab-on-a-chip technology have led to increased interest in laminar mixing of fluids [1, 2, 3]. Efficient mixing is vital for chemical reactions, but turbulence is absent at the low Reynolds numbers common in microscale devices, and molecular diffusion mixes on an unacceptably slow timescale. In this paper we discuss the mathematical modelling of an annular magnetohydrodynamic (MHD) micromixer, prototypes of which are under development at the Irish National Microelectronics Research Centre [4]. The device consists of an annular channel (see Figures 1 and 2), with inner and outer walls acting as electrodes and with an electromagnet underneath, which provides a vertical magnetic field. A radial electric field is imposed by applying a potential difference across the inner and outer electrodes, and the electric and magnetic fields produce an azimuthal Lorentz force, which acts as a pumping mechanism for the fluid [5].

The idealized mixing action of this device is illustrated in Figure 1: in the absence of molecular diffusion, the initially separated fluids are convected through each other, increasing the interfacial length between them (linearly in time), and so promoting the mixing action of diffusion. In reality, the actions of convection and diffusion are felt simultaneously, and the goal of this paper is to examine their effect upon the efficiency of the mixer. The discussion here is limited to two dimensions, where the idealized limit of infinite depth has been taken. Previous studies of MHD pumping in an annulus have been motivated by liquid-metal flows and their stability [5, 6], but to our knowledge this is the first investigation of the mixing effects in an annular geometry.

2. Notation and equations. The geometry of the annulus is shown in Figure 2. The radius of the center-line is R, and ρ represents the half-width of the channel; thus the inner wall is located at $r = R - \rho$, and the outer wall at $r = R + \rho$. We describe the geometry using the nondimensional parameter

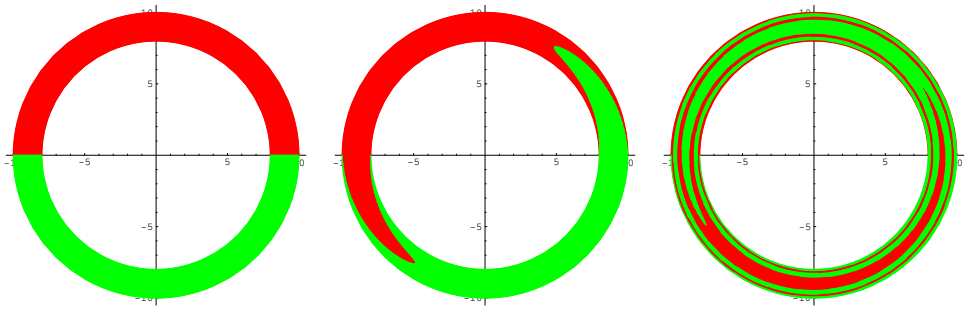

FIG. 1. *Operation of an idealized micromixer at three times, neglecting diffusion.*

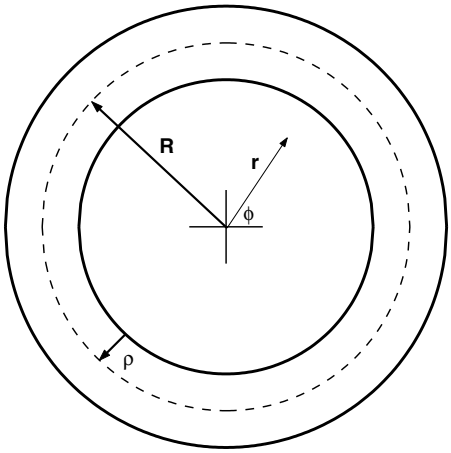

FIG. 2. *Annular geometry, showing the center-line radius R and the channel half-width ρ.*

$$\gamma = \frac{\rho}{R}, \tag{1}$$

which satisfies $0 < \gamma < 1$. Note that the limit $\gamma \to 0$ corresponds to a locally straight channel, and γ approaches 1 as the annulus becomes a punctured disk.

The fluid velocity in the micromixer is found by solving the steady Navier–Stokes equations in the presence of the MHD body force [6]. In the two-dimensional case considered here, this reduces to an ordinary differential equation for the azimuthal velocity $v(r)$, all other velocity components being zero:

$$\frac{d^2v}{dr^2} + \frac{1}{r}\frac{dv}{dr} - \frac{v}{r^2} = -\frac{\alpha}{r}, \tag{2}$$

where α represents the MHD forcing (specifically, $\alpha = -BI/4\pi h\eta$, where I and B are the root-mean-square current and magnetic field strengths, h is the channel depth, and η is the absolute viscosity of the fluid). The solution of (2) satisfying no-slip boundary conditions at the walls $r = R - \rho$ and $r = R + \rho$ is

$$v(r) = \frac{\omega}{8R\rho r}\left[\frac{1}{4} - \frac{(R^2-\rho^2)^2}{16R^2\rho^2}\left(\ln\frac{R-\rho}{R+\rho}\right)^2\right]^{-1} \times \left[(R^2-\rho^2)^2 \ln\frac{R-\rho}{R+\rho} + r^2(R-\rho)^2 \ln\frac{r}{R-\rho} + r^2(R+\rho)^2 \ln\frac{R+\rho}{r}\right], \tag{3}$$

where the velocity is characterized by an average angular velocity ω, which is related to the MHD forcing parameter α by

$$\omega = \alpha \left[\frac{1}{4} - \frac{(R^2 - \rho^2)^2}{16 R^2 \rho^2} \left(\ln \frac{R - \rho}{R + \rho} \right)^2 \right]. \tag{4}$$

The profile (3) reduces to the parabolic Poiseuille profile for a straight channel when $\gamma \to 0$,

$$v(r) \approx \frac{3\omega R}{2\rho^2}(r - R + \rho)(R + \rho - r), \tag{5}$$

with maximum at $r = R$:

$$v_{\max} = \frac{3}{2}\omega R. \tag{6}$$

The mixing of a plug of solute into a surrounding solvent is governed by the convection-diffusion equation (assuming both fluid phases have similar density, viscosity, etc.)

$$\frac{\partial c}{\partial t} + \nabla \cdot (\mathbf{u} c) - \kappa \nabla^2 c = 0, \tag{7}$$

where $\mathbf{u}(\mathbf{x}, t)$ is the fluid velocity vector, $c(\mathbf{x}, t)$ is the concentration of the solvent, and κ is the molecular diffusion coefficient. In the annular micromixer the convection-diffusion equation may be written in polar coordinates,

$$\frac{\partial c}{\partial t} + \frac{v(r)}{r}\frac{\partial c}{\partial \phi} - \frac{\kappa}{r}\frac{\partial}{\partial r}\left(r \frac{\partial c}{\partial r} \right) - \frac{\kappa}{r^2}\frac{\partial^2 c}{\partial \phi^2} = 0, \tag{8}$$

with no-flux boundary conditions at the walls:

$$\begin{aligned} \frac{\partial c}{\partial r}(R - \rho, \phi, t) &= 0, \\ \frac{\partial c}{\partial r}(R + \rho, \phi, t) &= 0. \end{aligned} \tag{9}$$

In the following sections we examine solutions of (8) using analytical, asymptotic, and numerical methods.

The dimensionless parameter used to compare the importance of convection and diffusion in (7) is the Péclet number, which we define for our system as

$$Pe = \frac{\omega R \rho}{\kappa}. \tag{10}$$

Note that ωR is the characteristic linear velocity, while ρ is the smallest linear dimension in the system. Two natural groupings of parameters to give a dimensional time will be used in what follows: the diffusion time R^2/κ, which measures the time for azimuthal mixing by diffusion in the absence of convection, and the convection time ω^{-1}, which is representative of the timescale of rotation of the fluid. The choice of appropriate time-scaling depends on whether diffusion or convection is dominant—we initially choose ω^{-1} but will consider the alternative in section 6.

A completely mixed solute-solvent system has the initial concentration $c(\mathbf{x}, 0)$ of solute spread evenly over the whole annulus. We define mixing efficiency using the timescale over which the concentration profile evolves to the uniform state. In order to measure the deviation from uniformity, we first introduce two averaging procedures, each operating on a function $f(r, \phi)$ defined on the annulus. Radial averaging is denoted by an overbar,

$$\overline{f} = \frac{1}{2R\rho} \int_{R-\rho}^{R+\rho} f(r, \phi) r dr, \tag{11}$$

and angle brackets signify angular averaging,

$$\langle f \rangle = \frac{1}{2\pi} \int_0^{2\pi} f(r, \phi) d\phi. \tag{12}$$

Thus the average value of the concentration over the whole annulus is

$$\langle \overline{c} \rangle = \frac{1}{4\pi R\rho} \int_{R-\rho}^{R+\rho} \int_0^{2\pi} c(r, \phi, t) r \, d\phi \, dr. \tag{13}$$

In fact, it is straightforward to show from the convection-diffusion equation that $\langle \overline{c} \rangle$ is a constant—the total amount of solute is not changed over time but is simply redistributed evenly over the annulus.

In the following sections we adopt a simple initial concentration,

$$c(r, \phi, 0) = 1 + \cos \phi, \tag{14}$$

for ease of asymptotic analysis. Later we show that the asymptotic results also apply to other initial conditions, for instance to the condition used in Figure 1:

$$c(r, \phi, 0) = \begin{cases} 1 & \text{if } 0 \le \phi < \pi, \\ 0 & \text{if } \pi \le \phi < 2\pi. \end{cases} \tag{15}$$

A *mixing measure* $m(t)$ is a positive function of time characterizing the deviation of the concentration at time t from its uniformly mixed state $\langle \overline{c} \rangle$. Define $m(t)$ by

$$m(t) = \frac{\left\langle \overline{(c(r, \phi, t) - \langle \overline{c} \rangle)^2} \right\rangle}{\left\langle \overline{(c(r, \phi, 0) - \langle \overline{c} \rangle)^2} \right\rangle}, \tag{16}$$

so that $m(0) = 1$, and $m(t) \to 0$ as $t \to \infty$. The time T_M for $m(t)$ to decay from 1 to a specified value M is called the *mixing time* and is defined by the condition

$$m(T_M) = M. \tag{17}$$

From the point of view of experimentalists and design engineers, it is desirable to have simple formulas relating the mixing time T_M to the Péclet number Pe and the geometry ratio γ of the micromixer. We proceed to obtain asymptotic approximations to the solution of (8), and hence scaling laws for the mixing times T_M.

3. Low Péclet numbers. When the Péclet number (10) is sufficiently small, diffusive effects completely dominate convective motion. The mixing time by diffusion alone may be calculated by solving the diffusion equation

$$\frac{\partial c}{\partial t} - \frac{\kappa}{r}\frac{\partial}{\partial r}\left(r\frac{\partial c}{\partial r}\right) - \frac{\kappa}{r^2}\frac{\partial^2 c}{\partial \phi^2} = 0 \tag{18}$$

in the annulus, i.e., neglecting the convective term in (8). A series solution can be written as

$$c = \langle \bar{c} \rangle + \sum_{n=1}^{\infty}\sum_{j=1}^{\infty} e^{-\kappa\lambda_{nj}t} G_n\left(r\sqrt{\lambda_{nj}}\right)\left[\alpha_{nj}\cos(n\phi) + \beta_{nj}\sin(n\phi)\right], \tag{19}$$

where the α_{nj} and β_{nj} are constants (determined from the initial condition) and λ_{nm} are eigenvalues determined by the conditions

$$\frac{dG_n}{dr} = 0 \quad \text{at } r = R-\rho \text{ and } r = R+\rho. \tag{20}$$

The eigenfunctions G_n are given in terms of Bessel functions as

$$G_n(r\sqrt{\lambda}) = J_n(r\sqrt{\lambda}) - Y_n(r\sqrt{\lambda})\left[\frac{J_{n-1}\left((R-\rho)\sqrt{\lambda}\right) - J_{n+1}\left((R-\rho)\sqrt{\lambda}\right)}{Y_{n-1}\left((R-\rho)\sqrt{\lambda}\right) - Y_{n+1}\left((R-\rho)\sqrt{\lambda}\right)}\right]. \tag{21}$$

For the single-mode initial condition (14), only the $n = 1$ term of the double sum is present in (19). Consequently, the mixing measure (16) in this case is

$$m(t) = \sum_{j=1}^{\infty} e^{-2\kappa\lambda_{1j}t}\frac{\overline{G_1\left(r\sqrt{\lambda_{1j}}\right)}^2}{\overline{G_1\left(r\sqrt{\lambda_{1j}}\right)}^2}. \tag{22}$$

The form of $m(t)$ at large times t is dominated by the first term ($j = 1$) in this sum. Indeed, in the limit $\gamma \to 0$, we have

$$m(t) \sim \exp(-2\kappa\lambda_{11}t) \quad \text{as } t \to \infty, \tag{23}$$

with the eigenvalue given by

$$\lambda_{11} = \frac{1}{R^2}\left[1 + \frac{1}{3}\gamma^2 + O(\gamma^4)\right] \text{ for } \gamma \ll 1. \tag{24}$$

The asymptotic mixing time T_M as defined in (17) then follows from (23) and (24),

$$T_M \sim \frac{1}{2\kappa\lambda_{11}}\ln\left(\frac{1}{M}\right) \quad \text{as } M \to 0, \tag{25}$$

and so the nondimensional mixing time is

$$\omega T_M \approx \frac{Pe}{2\gamma}\ln\left(\frac{1}{M}\right)\left[1 - \frac{1}{3}\gamma^2 + \cdots\right] \quad \text{for } \gamma \ll 1. \tag{26}$$

4. Intermediate Péclet numbers. In this section we follow and adapt Taylor's arguments [7] (see also [8]) to derive an effective dispersion under certain conditions on the Péclet number, and we clearly identify the limits of validity. We note that Nunge, Lin, and Gill [9] have derived a Taylor dispersion coefficient in a curved channel (matching our (35)), but they do not investigate for which values of Pe the analysis is valid. These bounding values of Pe assume great importance in our later analysis, so we follow Taylor's original formulation to understand when the approximations break down.

Consider a reference frame rotating with angular velocity ω, i.e., with azimuthal angle measured by

$$\phi' = \phi - \omega t. \tag{27}$$

The convection-diffusion equation (8) in this rotating frame is

$$\frac{\partial c}{\partial t} + \left(\frac{v(r)}{r} - \omega\right)\frac{\partial c}{\partial \phi'} - \frac{\kappa}{r}\frac{\partial}{\partial r}\left(r\frac{\partial c}{\partial r}\right) - \frac{\kappa}{r^2}\frac{\partial^2 c}{\partial \phi'^2} = 0, \tag{28}$$

with boundary conditions as before. We will work in this rotating frame for the remainder of this section and thus drop the prime on ϕ. Following Taylor, we assume that the concentration is quasi-steady in the rotating frame, with angular gradient $\frac{\partial c}{\partial \phi}$ independent of r. Moreover, the effect of azimuthal diffusion is neglected compared to radial diffusion. The resulting equation is readily integrated twice to yield

$$c = c(R-\rho,\phi) + \frac{1}{\kappa}\frac{\partial c}{\partial \phi}\int_{R-\rho}^{r}\frac{1}{r_2}\int_{R-\rho}^{r_2}\left[v(r_1) - \omega r_1\right] dr_1\, dr_2. \tag{29}$$

We take the radial mean (as defined in (11)) to allow us to eliminate $c(R-\rho,\phi)$ and obtain

$$c = \overline{c} + \frac{1}{\kappa}\frac{\partial c}{\partial \phi}\left[g(r) - \overline{g}\right], \tag{30}$$

having used the notation

$$g(r) = \int_{R-\rho}^{r}\frac{1}{r_2}\int_{R-\rho}^{r_2}\left[v(r_1) - \omega r_1\right] dr_1\, dr_2 \tag{31}$$

for brevity. The average flux of solvent through the line $\phi =$ constant (in the moving frame) is given by the radial average of the product of the concentration and angular velocity ω' (also relative to the moving frame):

$$\begin{aligned}\overline{J} &= \overline{c\,\omega'} \\ &= \frac{1}{2R\rho}\int_{R-\rho}^{R+\rho}\left[\overline{c} + \frac{1}{\kappa}\frac{\partial c}{\partial \phi}\left(g(r) - \overline{g}\right)\right]\left[\frac{v}{r} - \omega\right] r\, dr \\ &= \frac{1}{\kappa}\frac{\partial c}{\partial \phi}\frac{1}{2R\rho}\int_{R-\rho}^{R+\rho}\left(v(r) - \omega r\right) g(r) dr. \end{aligned} \tag{32}$$

If we assume

$$\frac{\partial c}{\partial \phi} \approx \frac{\partial \overline{c}}{\partial \phi}, \tag{33}$$

this implies that the radial mean concentration in the moving frame is governed by a one-dimensional diffusion equation

$$\frac{\partial \overline{c}}{\partial t} = D \frac{\partial^2 \overline{c}}{\partial \phi^2}, \tag{34}$$

where D is the Taylor dispersion coefficient for the annulus, defined by

$$\begin{aligned} D &= \frac{1}{\kappa} \frac{1}{2R\rho} \int_{R-\rho}^{R+\rho} (v(r) - \omega r)\, g(r)\, dr \\ &= \frac{1}{\kappa} \frac{1}{2R\rho} \int_{R-\rho}^{R+\rho} (v(r) - \omega r) \int_{R-\rho}^{r} \frac{1}{r_2} \int_{R-\rho}^{r_2} [v(r_1) - \omega r_1]\, dr_1\, dr_2\, dr. \end{aligned} \tag{35}$$

This integral may be calculated for the velocity (3); after some algebra we find

$$\begin{aligned} D = {} & \frac{\omega^2 R^2}{24\kappa\gamma} \left[4\gamma^2 - (1-\gamma^2)^2 \ln\left(\frac{1-\gamma}{1+\gamma}\right) \right]^{-2} \\ & \times \left[48\gamma^5(1+\gamma^2) + 120\gamma^4(1-\gamma^2)^2 \ln\frac{1+\gamma}{1-\gamma} - 72\gamma^3(1-\gamma^2)^2(1+\gamma^2) \left(\ln\frac{1+\gamma}{1-\gamma}\right)^2 \right. \\ & \left. - 6\gamma(1-\gamma^2)^4(1+\gamma^2) \left(\ln\frac{1+\gamma}{1-\gamma}\right)^4 + (1-\gamma^2)^4(3+10\gamma^2+3\gamma^4) \left(\ln\frac{1+\gamma}{1-\gamma}\right)^5 \right]. \end{aligned} \tag{36}$$

In the $\gamma \ll 1$ limit, this reduces to

$$D \approx \omega Pe \left[\frac{2}{105}\gamma + \frac{346}{1576}\gamma^3 \cdots \right]. \tag{37}$$

The solution of the one-dimensional diffusion equation (34) with initial condition from (14) is straightforward. Having found $\overline{c}$, we can calculate the concentration c and thus the mixing measure $m(t)$ from (30) and (16), respectively. The mixing measure has an exponential tail,

$$m(t) \sim \exp(-2Dt) \quad \text{as } t \to \infty, \tag{38}$$

and so the mixing time T_M is

$$T_M \sim \frac{1}{2D} \ln\left(\frac{1}{M}\right) \quad \text{as } M \to 0 \tag{39}$$

in the Taylor dispersion regime. From (37), this yields the (nondimensional) asymptotic form

$$\omega T_M \approx \frac{1}{\gamma Pe} \ln\left(\frac{1}{M}\right) \frac{105}{4} \left[1 - \frac{18165}{1576}\gamma^2 + \cdots \right] \text{ for } \gamma \ll 1 \tag{40}$$

when the assumptions made above are valid.

The range of Pe for which the above approximate analysis holds will prove to be of great interest in later sections, so we now examine carefully the two basic assumptions that were made and cast these into conditions on Pe for the result (40) to hold.

The first condition stems from the requirement that the azimuthal diffusion be negligible compared to the radial diffusion; effectively, this requires that the coefficient

of $\frac{\partial^2 c}{\partial \phi^2}$ in (28), actually its radial average, should be much less than the dispersion coefficient (35):

$$\kappa \ll D\overline{r^2}. \tag{41}$$

Consider this condition when $\gamma \ll 1$, using the first term of (37):

$$\begin{aligned} \kappa &\ll \frac{2}{105}\gamma\omega Pe R^2 \\ \iff Pe^2 &\gg \frac{105}{2}. \end{aligned} \tag{42}$$

The resulting condition $Pe \gg 7.2$ is analogous to that in a straight capillary; see, for instance, [8].

The second important approximation is the replacement of $\frac{\partial c}{\partial \phi}$ by $\frac{\partial \overline{c}}{\partial \phi}$ in (33). This is valid if the coefficient of $\frac{\partial c}{\partial \phi}$ in (30) is very small. The order of magnitude of this coefficient is $\overline{g}/\kappa$, and so the condition is

$$\frac{1}{\kappa}\frac{1}{2R\rho}\int_{R-\rho}^{R+\rho} r \int_{R-\rho}^{r} \frac{1}{r_2}\int_{R-\rho}^{r_2} [v(r_1) - \omega r_1]\, dr_1\, dr_2\, dr \ll 1. \tag{43}$$

Again, this yields a simple condition if $\gamma \ll 1$:

$$\begin{aligned} \frac{1}{15}\frac{\omega\rho^2}{\kappa} &\ll 1 \\ \iff Pe &\ll \frac{15}{\gamma}. \end{aligned} \tag{44}$$

Thus (42) and (44) provide rough bounds on Pe for the lower and upper ranges of validity of the Taylor dispersion approximations.

5. Convection-dominated mixing: $Pe \gg 1$. When molecular diffusion is small compared to convective effects, i.e., at large Péclet number, (8) is singularly perturbed. Mixing of a scalar at high Péclet numbers is a topic that has attracted much attention recently, with particular attention paid to the mixing of a passive scalar (as in our case), or vorticity (an active scalar), in the spiral flow field of a vortex [10, 11, 12]. In this section we apply approximation approaches based upon these works to understand the mixing speed in the annular micromixer.

As in previous sections, we examine the asymptotic limit of small γ, i.e., neglecting higher order effects of the channel curvature. Accordingly, (8) is rewritten using the nondimensional variables

$$\begin{aligned} \tilde{r} &= \frac{r-R}{\rho}, \\ \tilde{t} &= \omega t. \end{aligned} \tag{45}$$

Note that the nondimensional radial variable $\tilde{r}$ lies between -1 and 1, with $\tilde{r} = 0$ in the center of the channel. Taking the limit of small γ and using (5), equation (8) reduces to

$$\frac{\partial c}{\partial \tilde{t}} + \frac{3}{2}\left(1 - \tilde{r}^2\right)\frac{\partial c}{\partial \phi} - \epsilon\frac{\partial^2 c}{\partial \tilde{r}^2} = 0, \tag{46}$$

where $\epsilon = (\gamma Pe)^{-1}$ is a small parameter when Pe is sufficiently large.

It is well known [10, 11, 12] that scalar mixing occurs in vortex spiral flows on times scaling as $Pe^{1/3}$. Here we follow [10] to show that a similar scaling arises in the annular mixer, at least for early times. We consider the scalar evolving according to (46), and introduce the notation $\Omega(\tilde{r}) = 3/2(1-\tilde{r}^2)$ for the azimuthal velocity. In the complete absence of molecular diffusion, i.e., if $\epsilon = 0$, the evolution of the nth angular mode from an initial condition of

$$c(\tilde{t}=0) = \exp[in\phi] \tag{47}$$

is given by simple angular convection:

$$c = \exp\left[in\phi - in\Omega(\tilde{r})\tilde{t}\right]. \tag{48}$$

In order to include the effects of nonzero diffusion, we follow [10] and introduce a Lagrangian angular variable:

$$\theta = \phi - \Omega(\tilde{r})\tilde{t}. \tag{49}$$

The derivatives in (46) are then modified as follows:

$$\begin{aligned} \frac{\partial}{\partial \tilde{t}} &\to \frac{\partial}{\partial \tilde{t}} - \Omega\frac{\partial}{\partial\theta}, \\ \frac{\partial}{\partial \phi} &\to \frac{\partial}{\partial\theta}, \\ \frac{\partial}{\partial \tilde{r}} &\to \frac{\partial}{\partial \tilde{r}} - \Omega' \tilde{t}\frac{\partial}{\partial\theta}. \end{aligned} \tag{50}$$

Thus (46) becomes

$$\frac{\partial c}{\partial \tilde{t}} = \epsilon\left(\frac{\partial}{\partial \tilde{r}} - \Omega'\tilde{t}\frac{\partial}{\partial\theta}\right)^2 c, \tag{51}$$

and if the second term in parentheses dominates the first, we obtain

$$\frac{\partial c}{\partial \tilde{t}} = \epsilon\Omega'^2\tilde{t}^2\frac{\partial^2 c}{\partial\theta^2}. \tag{52}$$

The solution of this equation satisfying the initial condition (47) is

$$\begin{aligned} c &= \exp\left[in\theta - \epsilon n^2\Omega'^2\tilde{t}^3/3\right] \\ &= \exp\left[in\phi - in\Omega\tilde{t} - \epsilon n^2\Omega'^2\tilde{t}^3/3\right]. \end{aligned} \tag{53}$$

Noting that $\Omega' = -3\tilde{r}$ and $n = 1$ in our example, the mixing measure $m(t)$ can be calculated from (16) to yield (restoring dimensional variables)

$$m(t) = \frac{\sqrt{\pi}}{2}F\left(\frac{6\omega^3 t^3}{\gamma Pe}\right), \tag{54}$$

where F is defined as the monotonic function

$$F(x) = x^{-1/2}\mathrm{erf}(x^{1/2}). \tag{55}$$

The nondimensional mixing time corresponding to a mixing measure value of M is therefore

$$\omega T_M \approx \left[\frac{\gamma Pe}{6} F^{-1}\left(\frac{2M}{\sqrt{\pi}}\right)\right]^{1/3}, \tag{56}$$

and note in particular that this increases as $Pe^{1/3}$ when M and γ are fixed.

The approximation made to obtain (52) from (51) has limited validity, and so the $Pe^{1/3}$ scaling obtained in (56) is not expected to hold for all times. In particular, we note that $\Omega'(\tilde{r}) = 0$ at the center of the channel, and so (52) is not accurate there. An analogous situation was considered recently [13] for scalar mixing in a vortex: the vanishing azimuthal velocity at the center of the vortex is shown there to render the approximate solution (53) invalid at large times. A different approach is required: we follow [13] and [14] in seeking a solution of (46) of the form

$$c = g(\tilde{t}) \exp\left[in\phi - \frac{3}{2} in\tilde{t} - if(\tilde{t})\tilde{r}^2\right], \tag{57}$$

where the functions $g(\tilde{t})$ and $f(\tilde{t})$ are to be determined, subject to initial conditions $g(0) = 1$, $f(0) = 0$. This form for c can be motivated by noting that if $g \equiv 1$ and $f \equiv 0$, then (57) would be an exact solution of (46) if the azimuthal velocity Ω had no $\tilde{r}$-dependence. In fact, $f(\tilde{t})$ and $g(\tilde{t})$ can be found so that (57) is an exact solution of (46). Substituting (57) into (46) and taking $n = 1$ for the initial condition (14), we find first order equations for f and g:

$$\begin{aligned} \frac{df}{d\tilde{t}} &= -4i\epsilon f^2 - \frac{3}{2}, \\ \frac{dg}{d\tilde{t}} &= -2i\epsilon f g. \end{aligned} \tag{58}$$

Solutions satisfying the initial conditions are given by

$$\begin{aligned} f(\tilde{t}) &= \frac{3(1+i)}{2} \frac{1}{\mu} \tanh\left(\frac{-1+i}{2}\mu\tilde{t}\right), \\ g(\tilde{t}) &= \left[\cosh\left(\frac{-1+i}{2}\mu\tilde{t}\right)\right]^{-\frac{1}{2}}, \end{aligned} \tag{59}$$

where we have written $\mu = 2\sqrt{3\epsilon}$ for clarity. After some manipulation, using (57) in (16) yields a mixing measure

$$m = \sqrt{\frac{\pi}{6}}\mu \left[\sinh(\mu\tilde{t}) - \sin(\mu\tilde{t})\right]^{-\frac{1}{2}} \operatorname{erf}\left[\sqrt{\frac{3}{\mu}}\sqrt{\frac{\sinh(\mu\tilde{t}) - \sin(\mu\tilde{t})}{\cosh(\mu\tilde{t}) + \cos(\mu\tilde{t})}}\right]. \tag{60}$$

When $\mu\tilde{t} \ll 1$, this reduces to

$$\begin{aligned} m &\approx \sqrt{\frac{\pi}{2}} \left(\mu^2\tilde{t}^3\right)^{-\frac{1}{2}} \operatorname{erf}\left[\frac{1}{\sqrt{2}} \left(\mu^2\tilde{t}^3\right)^{\frac{1}{2}}\right] \\ &= \frac{\sqrt{\pi}}{2} F\left(\frac{6\omega^3 t^3}{\gamma Pe}\right), \end{aligned} \tag{61}$$

as in (54). The corresponding scaling for T_M is given by (56) and applies for values of M large enough so that $\mu\tilde{t} \ll 1$.

For $\mu\tilde{t} \gg 1$, the solution (60) decays exponentially in time:

$$m \approx \sqrt{\frac{\pi}{3}\mu}\,\mathrm{erf}\left[\sqrt{\frac{3}{\mu}}\right]\exp\left[-\frac{1}{2}\mu\tilde{t}\right], \tag{62}$$

and for large Péclet numbers $\mu \ll 1$, so the asymptotic mixing time is given (in dimensional variables) by

$$\omega T_M \approx \frac{1}{4}\sqrt{\frac{\gamma Pe}{3}}\ln\left[\frac{4\pi^2}{3M^4}\frac{1}{\gamma Pe}\right]. \tag{63}$$

Note that this mixing time scales as $Pe^{1/2}\ln Pe$ for fixed M and γ. This longer timescale replaces the $Pe^{1/3}$ scaling given by (56) when the mixing time T_M is sufficiently large that the $\mu\tilde{t} \gg 1$ asymptotics are important—this is relevant when we seek a level of mixing M that is sufficiently small. Physically, this new scaling emerges as a consequence of the vanishing of the differential rotation rate at the center of the channel: $\Omega'(0) = 0$; see [13] for a detailed discussion of the analogous problem at the vortex centers. Over short timescales (with $\mu\tilde{t} \ll 1$), the advective stretching and diffusion mix the scalar with time scaling as $Pe^{1/3}$. This convection-enhanced mixing is most effective near the sides of the channel, where the scalar is stretched into thin lamellae; see Figure 1(right-most panel). The more persistent scalar structure at the center of the channel is destroyed only on the longer timescales ($\mu\tilde{t} \gg 1$), leading to the $Pe^{1/2}\ln Pe$ scaling in (63). It is noteworthy that neither (53) nor (57) satisfy the no-flux boundary conditions (9) at the walls of the channel. However, numerical simulations (see section 6) indicate that this does not have an appreciable effect upon the accuracy of the asymptotic formulas. This is a consequence of the fast mixing of the scalar near the walls, so that any error in the boundary conditions is dominated by the slower-mixing scalar structure in the channel center.

6. Numerical simulations. To check the asymptotic results derived in previous sections, and to extend our analysis to cases with initial conditions other than the simple form (14), we solve the convection-diffusion equation (8) numerically. A decomposition into a finite number N of Fourier modes in the azimuthal angle is employed,

$$c(r,\phi,t) = \frac{1}{2}g_0(r,t) + \sum_{n=1}^{N} g_n(r,t)\cos(n\phi) + h_n(r,t)\sin(n\phi), \tag{64}$$

and substitution into (8) yields partial differential equations for g_n and h_n. Having solved the system of equations for the Fourier coefficients, the full concentration field may be constructed from (64), or the mixing measures may be evaluated more directly from (16) by integrating over the angle and normalizing $m(0)$ to unity:

$$m(t) = \overline{\left(\frac{g_0}{2} - \langle\overline{c}\rangle\right)^2 + \frac{1}{2}\sum_{n=1}^{N} g_n^2 + h_n^2}. \tag{65}$$

Logarithmic plots of $m(t)$ as a function of time at various Pe values are shown in Figure 3 for $\gamma = 0.05$. For comparison we plot also the asymptotic forms of $m(t)$, using (23) in the diffusive regime, (38) in the Taylor regime, and (54) and (60) in the convective regime. The asymptotic formulas fit the numerical results well, with

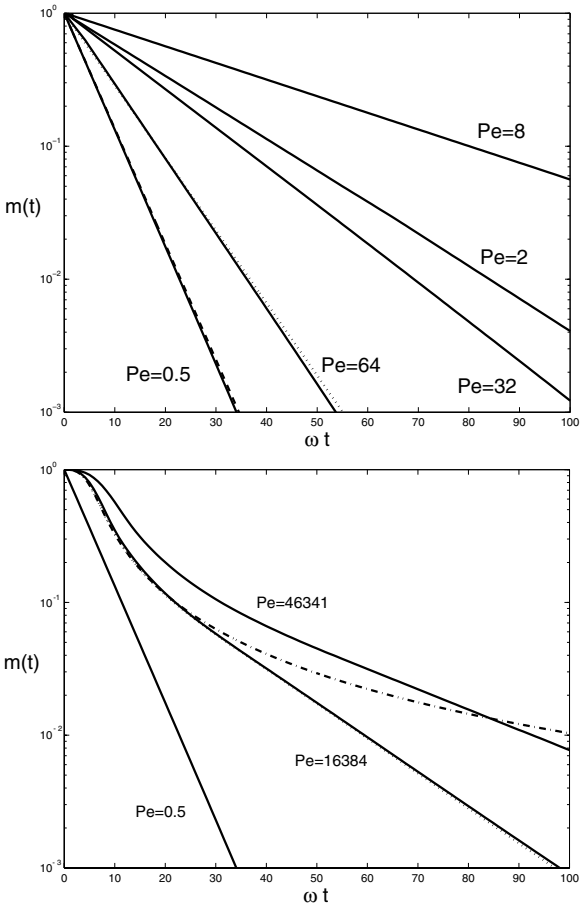

FIG. 3. *Mixing measure $m(t)$ as a function of nondimensional time, calculated in numerical simulations with $\gamma = 0.05$ and various Péclet numbers as shown. Asymptotic predictions are also shown for $Pe = 0.5$ (dashed) using* (23) *and $Pe = 64$ (dotted) using* (38) *in the upper panel. In the lower panel the asymptotic formulas* (54) *(dot-dash) and* (60) *(dotted) are shown for $Pe = 16384$.*

the exception of (54), which, as noted in section 5, is limited to early times. Taking account of the vanishing differential rotation rate at the center of the channel leads to (60), which matches the numerical results very well (the dotted line being almost indistinguishable from the solid).

From the numerical solution for $m(t)$, it is straightforward to calculate the mixing times T_M required for the measure to decay from its initial value of 1 to the value M. We choose three values of M for comparison with the asymptotic predictions—$M = 0.3$, 0.1, and 0.01—and investigate a wide range of Péclet numbers. For fixed values of γ and M, the asymptotic analysis of the previous sections predicts a mixing time proportional to Pe in the diffusion-dominated regime, to Pe^{-1} in the Taylor dispersion regime, and to either $Pe^{1/3}$ or $Pe^{1/2} \ln Pe$ when convection dominates. The numerical values of nondimensional times ωT_M are plotted in Figure 4 along with the straight lines corresponding to the formulas (26), (40), and (56) for all three values of M. Note the excellent agreement with predictions, except for the lowest value of M, when the approximation (54) no longer accurately describes the time evolution of $m(t)$. For this value of M the asymptotic result (63) is plotted with a dotted line and is found

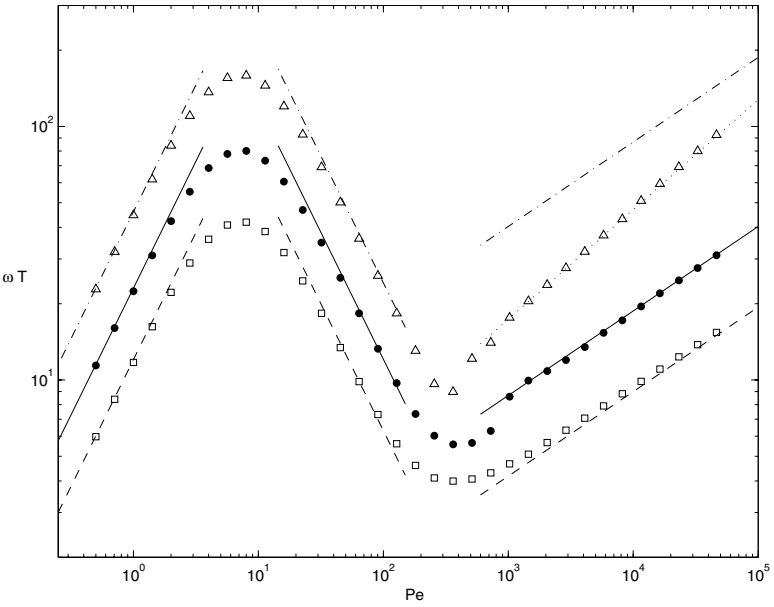

FIG. 4. *Nondimensional mixing times as a function of Péclet number, for* $\gamma = 0.05$. *Asymptotic results are shown as lines, and numerical results as symbols for values of the mixing measure:* $M = 0.3$ *(dashed line; squares),* $M = 0.1$ *(solid line, points), and* $M = 0.01$ *(dot-dash line, triangles). The long-time asymptotic result* (63) *is also plotted as a dotted line for the case of* $M = 0.01$.

to closely match the numerical results.

Because much of our analysis has concentrated on the $\gamma \to 0$ limit, it is worthwhile comparing numerics and asymptotics for a larger value of γ, noting that the maximum possible value of γ is 1. In Figure 5 we plot the results for $\gamma = 0.2$ and find that in general the correspondence between predicted and numerical values is excellent. However, we note that the limits on the Taylor regime now preclude the formation of a clear Pe^{-1} scaling range.

Another simplification in the analysis concerns the initial condition (14), which consists of only a single harmonic of the azimuthal variable. In order to examine the robustness of our predictions, we numerically solve the convection-diffusion equation for initial condition (15), replacing the discontinuous function by hyperbolic tangents to avoid Gibbs oscillations. The decay of the mixing measure is still dominated by the first angular harmonic, and so the mixing times are remarkably close to the asymptotic estimates; see Figure 6. We therefore expect the formulas to be useful for rather general initial distributions of the solute.

The nondimensional time ωT_M used in Figures 3–6 may be replaced by the alternative nondimensionalization mentioned in section 2, i.e., the diffusion time $\kappa T_M / R^2$. The timescales are related by

$$\frac{\kappa T_M}{R^2} = \frac{\gamma}{Pe}\,\omega T_M, \tag{66}$$

and so the data of, for example, Figure 4 is easily recast in terms of the diffusion time; see Figure 7. The relevant mixing times in the diffusive, Taylor, and convective

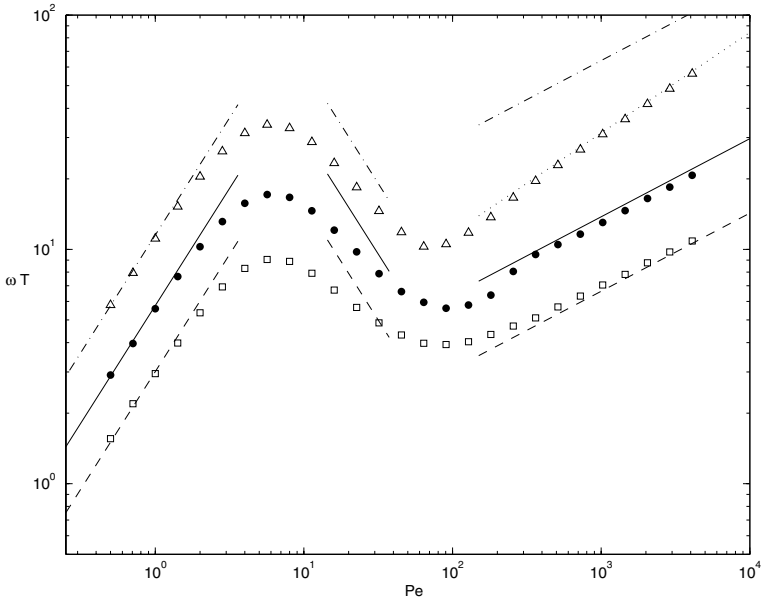

FIG. 5. *Nondimensional mixing times as a function of Péclet number for* $\gamma = 0.2$. *Asymptotic results are shown as lines, and numerical results as symbols for values of the mixing measure:* $M = 0.3$ *(dashed line; squares),* $M = 0.1$ *(solid line, points), and* $M = 0.01$ *(dot-dash line, triangles). The long-time asymptotic result* (63) *is also plotted as a dotted line for the case of* $M = 0.01$.

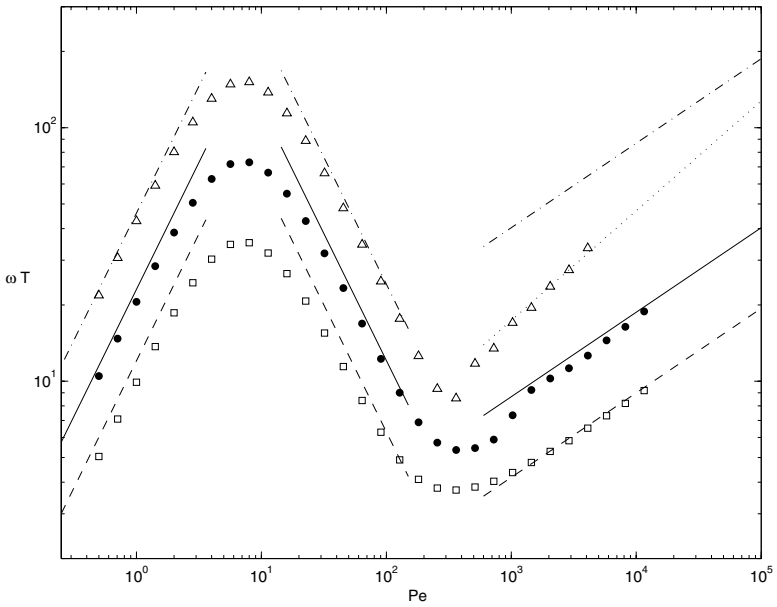

FIG. 6. *Nondimensional mixing times as a function of Péclet number, for* $\gamma = 0.05$ *and an initial concentration given by* (15) *(slightly smoothed). Asymptotic results are shown as lines, and numerical results as symbols for values of the mixing measure:* $M = 0.3$ *(dashed line; squares),* $M = 0.1$ *(solid line, points), and* $M = 0.01$ *(dot-dash line, triangles). The long-time asymptotic result* (63) *is also plotted as a dotted line for the case of* $M = 0.01$.

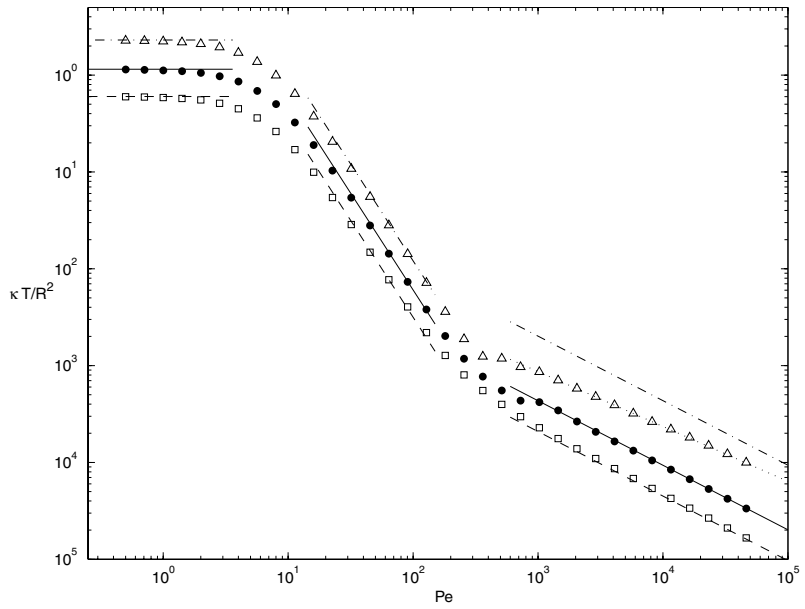

FIG. 7. *Mixing times nondimensionalized by the diffusion time, $\kappa T/R^2$, as a function of Péclet number, for $\gamma = 0.05$. Asymptotic results are shown as lines, and numerical results as symbols for values of the mixing measure: $M = 0.3$ (dashed line; squares), $M = 0.1$ (solid line, points), and $M = 0.01$ (dot-dash line, triangles). The long-time asymptotic result* (70) *is also plotted as a dotted line for the case of $M = 0.01$.*

regimes are thus found by multiplying (26), (40), (56), and (63) by γ/Pe, yielding

$$\frac{\kappa T_M}{R^2} \approx \frac{1}{2}\ln\left(\frac{1}{M}\right)\left[1 - \frac{1}{3}\gamma^2 + \cdots\right] \tag{67}$$

for $Pe \ll 7.2$ and

$$\frac{\kappa T_M}{R^2} \approx \frac{1}{Pe^2}\ln\left(\frac{1}{M}\right)\frac{105}{4}\left[1 - \frac{18165}{1576}\gamma^2 + \cdots\right] \tag{68}$$

for $7.2 \ll Pe \ll 15/\gamma$. For the highest Péclet numbers $Pe \gg 15/\gamma$, we obtained two asymptotic forms, the first valid for short times (moderate M values),

$$\frac{\kappa T_M}{R^2} \approx Pe^{-\frac{2}{3}}\gamma^{\frac{4}{3}}\left[\frac{1}{6}F^{-1}\left(\frac{2M}{\sqrt{\pi}}\right)\right]^{1/3}, \tag{69}$$

and the second for longer times (smaller M values),

$$\frac{\kappa T_M}{R^2} \approx Pe^{-\frac{1}{2}}\gamma^{\frac{3}{2}}\frac{1}{4\sqrt{3}}\ln\left[\frac{4\pi^2}{3M^4}\frac{1}{\gamma Pe}\right]. \tag{70}$$

Figure 7 is especially of interest to experimentalists working with a particular solute and solvent (so that κ is fixed) while varying the rate of rotation velocity ω of the micromixer to change Pe. The mixing time is seen to decrease from the diffusion time through the Taylor regime (at a rate proportional to Pe^{-2}), and then continue to decrease at a slower rate beyond the Taylor regime. The slower rate corresponds

to a $Pe^{-2/3}$ scaling when (54) is valid, i.e., for $M \geq 0.1$, but is closer to $Pe^{-1/2} \ln Pe$ for very small values of M.

From our analysis of the limits of validity of the Taylor dispersion description (see (44)), we can estimate the end of the Taylor regime as $15\gamma^{-1}$ for small γ. Of interest to the micromixer designer is the influence of the geometry ratio γ: since the mixing time decreases as Pe^{-2} until $Pe \approx 15\gamma^{-1}$, it seems advisable to decrease γ as much as possible in order to achieve faster mixing at lower velocities. However, this approach is overly simplistic, since the Péclet number also depends on γ—the linear velocity in the channel decreases with decreasing ρ, all other things being equal. A problem of great relevance to experimentalists is to find the optimal annular geometry to give the lowest possible mixing time for a given species, and given values of the electric and magnetic pumping fields (so κ and α are fixed). Suppose that the "footprint" R of the device is chosen; then we must find the channel half-width ρ to minimize the mixing time. Since Pe may be shown to increase monotonically with ρ, we conclude from Figure 7 that the mixing time decreases as the channel width increases. Practical considerations such as the minimal inner radius for effective electrodes will also provide an upper bound on the acceptable geometry ratio γ.

7. Summary. Laminar mixing in a two-dimensional annulus has been examined by asymptotic analysis and numerical simulation of the convection-diffusion equation (8). The mixing measure defined in (16) has been shown to decay exponentially in the diffusion and Taylor regimes (see (23) and (38)), with time constants given in terms of the Péclet number and the ratio γ characterizing the annulus geometry. Corresponding mixing times T_M are predicted to scale as Pe^0 and Pe^{-2} relative to the azimuthal diffusion time; see (67) and (68). Figures 3–7 demonstrate the robustness of these predictions by comparing them to numerical simulations. In the convection-dominated regime, asymptotic analysis modelled upon studies of mixing in vortices yields the mixing measure (60), with two interesting subregimes for the mixing time: a $Pe^{-2/3}$ dependence for early times, crossing over to a $Pe^{-1/2} \ln Pe$ scaling at longer times, as shown in (69) and (70), respectively. These predictions are again found to agree well with numerical results. Although the asymptotic formulas were derived in the limit $\gamma \to 0$, we find that they also yield good predictions for larger values of γ (Figure 5).

An important limitation of the present analysis is the assumption that all motion is two-dimensional; it is known [15, 16] that the dispersion in a channel of finite depth may not equal the value calculated by assuming the depth to be infinite. Work incorporating three-dimensional effects may yield further insight into this important problem.

TOTAL BOUNDED VARIATION REGULARIZATION AS A BILATERALLY CONSTRAINED OPTIMIZATION PROBLEM*

M. HINTERMÜLLER† AND K. KUNISCH‡

Abstract. It is demonstrated that the predual for problems with total bounded variation regularization terms can be expressed as a bilaterally constrained optimization problem. Existence of a Lagrange multiplier and an optimality system are established. This allows us to utilize efficient optimization methods developed for problems with box constraints in the context of bounded variation formulations. Here, in particular, the primal-dual active set method, considered as a semismooth Newton method, is analyzed, and superlinear convergence is proved. As a by-product we obtain that the Lagrange multiplier associated with the box constraints acts as an edge detector. Numerical results for image denoising and zooming/resizing show the efficiency of the new approach.

Key words. total bounded variation, predual, semismooth Newton methods, box constraints, image reconstruction

1. Introduction and notation.

This work is concerned with the study of the problem

$$\left\{\begin{array}{ll}\min & \frac{1}{2}\int_\Omega |Ku-f|^2dx+\frac{\alpha}{2}\int_\Omega |u|^2dx+\beta\int_\Omega |\mathrm{D}u| \\ \text{over} & u\in \mathrm{BV}(\Omega),\end{array}\right. \tag{1.1}$$

where Ω is a simply connected domain in $\mathbb{R}^2$ with Lipschitz continuous boundary $\partial\Omega$, $f\in \mathrm{L}^2(\Omega)$, $\beta>0$, $\alpha\geq 0$ are given, and $\mathrm{K}\in\mathcal{L}(\mathrm{L}^2(\Omega))$. By K^* we denote the adjoint of K. We assume that K^*K is invertible or $\alpha>0$. Further, $\mathrm{BV}(\Omega)$ denotes the space of functions of bounded variation. A function u is in $\mathrm{BV}(\Omega)$ if the BV seminorm defined by

$$\int_\Omega |Du| = \sup\left\{\int_\Omega u\ \mathrm{div}\,\vec{v} : \vec{v}\in (C_0^\infty(\Omega))^2,\ |\vec{v}(x)|_{\ell^\infty}\leq 1\right\}$$

is finite. It is well known [16] that $\mathrm{BV}(\Omega)\subset \mathrm{L}^2(\Omega)$ for $\Omega\subset\mathbb{R}^2$, and that $u\mapsto |u|_{L^2}+\int_\Omega |\mathrm{D}u|$ defines a norm on $\mathrm{BV}(\Omega)$. If $K=$ *identity*, then (1.1) is the well-known image restoration problem with BV-regularization term. It consists of recovering the true image u from the noisy image f. It is well known [9] that (1.1) admits a unique solution $u^*\in\mathrm{BV}(\Omega)$. BV-regularization, differently from regularization by means of $\int_\Omega |\nabla u|^2\,dx$, for example, is known to be preferable due to its ability to preserve edges in the original image during the reconstruction process. Since the pioneering work in [23], the literature on (1.1) has grown tremendously. We give some selected references [1, 5, 7, 12, 14, 18] and refer to the recent monograph [25] for further references.

The original formulation has been extended in various directions including concepts of reconstruction of images with multiple scales; see, e.g., [2, 4, 6, 19].

Despite its favorable properties for reconstruction of images, and especially images with blocky structure, problem (1.1) poses some severe difficulties. On the analytical level these are related to the fact that (1.1) is posed in a nonreflexive Banach space, the dual of which is difficult to characterize [16, 19], and on the numerical level the optimality system related to (1.1) consists of a nonlinear partial differential equation, which is not directly amenable to numerical implementations.

In the present work we show the remarkable result that while the dual of the nonreflexive Banach space problem (1.1) has a complicated measure theoretic structure, its predual can be characterized in a well-known Hilbert space setting. Specifically, the predual to (1.1) is a quadratic optimization problem with bilateral constraints. For such problems the literature provides a variety of possible algorithms. Here we describe and analyze two variants of semismooth Newton methods. We prove their superlinear convergence and provide numerical examples for some denoising and zooming problems. In practice these algorithms are globally convergent without the need for line searches. As a by-product we obtain that the Lagrange multiplier associated with the box constraints acts as an edge detector. We show numerically that the edge detecting property does not require any postprocessing on the multiplier such as thresholding or sharpening techniques.

Let us briefly mention a few alternatives that have been investigated for treating (1.1) numerically. In [23] a time marching scheme to solve the necessary optimality condition related to (1.1) is used. Time marching is also essential for the work in, e.g., [6]. In [19, 26] fixed point iteration schemes are applied to the optimality system using primal variables only. The optimality system based on the primal and dual variables is the basis for the schemes in [19] and [8]. In the former an augmented Lagrangian-based active set strategy is used; in the latter a Newton method is applied. Compared to the formulations used in earlier work, ours appears to have the advantage of being of significantly simpler structure since only a quadratic problem with affine box constraints must be solved. In earlier work, if analysis is carried out, then frequently $\int_\Omega |\mathrm{D}u|$ is replaced by

$$\int_\Omega \sqrt{\delta + |\nabla u|^2}\, dx, \tag{1.2}$$

for $\delta > 0$. In our approach the algorithms are well posed for $\delta = 0$, and for the discretized formulations we have superlinear convergence, still with $\delta = 0$.

The paper is organized as follows. In the remainder of this section we recall some facts from convex analysis and summarize the function space notation that will be used. In section 2 we characterize the predual of (1.1) in the sense of Fenchel. We shall point out the close connection, for 1D (one–dimensional) problems, between our algorithm and the taut-string algorithm well known in nonparametric regression analysis [11, 21]. Section 3 is devoted to the description and convergence proof for a class of regularized problems. Semismooth Newton methods for the predual problems are developed in section 4. Superlinear convergence for the regularized infinite-dimensional problems, and for the discretized predual problems without extra regularization, is proved. Section 5 is devoted to a numerical feasibility study of our results.

We recall the Fenchel duality theorem in infinite-dimensional spaces in a form that is convenient for our work; see, e.g., [3, 13] for details. Let V and Y be Banach spaces with topological duals denoted by V^* and Y^*, respectively. Further, let $\Lambda \in \mathcal{L}(V, Y)$

and let $\mathcal{F} : V \to \mathbb{R} \cup \{\infty\}$, $\mathcal{G} : Y \to \mathbb{R} \cup \{\infty\}$ be convex lower semicontinuous functionals not identically equal to ∞, and assume that there exists $v_0 \in V$ such that $\mathcal{F}(v_0) < \infty$, $\mathcal{G}(\Lambda v_0) < \infty$, and $\mathcal{G}$ is continuous at Λv_0. Then we have

$$\inf_{u \in V} \mathcal{F}(u) + \mathcal{G}(\Lambda u) = \sup_{p \in Y^*} -\mathcal{F}^*(\Lambda^* p) - \mathcal{G}^*(-p), \tag{1.3}$$

where $\mathcal{F}^* : V^* \to \mathbb{R} \cup \{\infty\}$ denotes the conjugate of $\mathcal{F}$ defined by

$$\mathcal{F}^*(v^*) = \sup_{v \in V} \langle v, v^* \rangle_{V,V^*} - \mathcal{F}(v).$$

Under the conditions imposed on $\mathcal{F}$ and $\mathcal{G}$, it is known that the problem on the right-hand side of (1.3) admits a solution. Moreover, $(\bar{u}, \bar{p})$ are solutions to the two optimization problems in (1.3) if and only if

$$\Lambda^* \bar{p} \in \partial \mathcal{F}(\bar{u}), \tag{1.4a}$$

$$-\bar{p} \in \partial \mathcal{G}(\Lambda \bar{u}), \tag{1.4b}$$

where $\partial \mathcal{F}$ denotes the subdifferential of the convex functional $\mathcal{F}$.

To compute, formally, the Fenchel dual to (1.1) we set $\Lambda = \nabla$,

$$\mathcal{F}(u) = \frac{1}{2}|\mathrm{K}u - f|^2 + \frac{\alpha}{2}|u|^2 \qquad \textit{and} \qquad \mathcal{G}(\vec{p}) = \beta \int_\Omega |\vec{p}|_{\ell^1} dx,$$

where u and $\vec{p}$ denote a scalar and a 2D vector-valued function, respectively. Further, $|\cdot|$ denotes the $L^2(\Omega)$-norm and $|\cdot|_{\ell^1}$ stands for the ℓ^1-norm on $\mathbb{R}^n$. For the convex conjugates we find

$$\mathcal{F}^*(v) = \frac{1}{2}(v + \mathrm{K}^* f, B^{-1}(v + \mathrm{K}^* f)) - \frac{1}{2}|f|^2 \quad \text{and} \quad \mathcal{G}^*(\vec{p}) = \mathrm{I}_{[-\beta\vec{1}, \beta\vec{1}]}(\vec{p}),$$

where $\vec{1}$ is the 2D vector field with 1 in both coordinates, $B = \alpha\,\mathrm{I} + \mathrm{K}^*\mathrm{K}$, and

$$\mathrm{I}_{[-\beta\vec{1}, \beta\vec{1}]}(\vec{p}) = \begin{cases} 0 & \text{if } -\beta\vec{1} \le \vec{p}(x) \le \beta\vec{1} \qquad \text{for almost every (a.e.) } x \in \Omega, \\ \infty & \text{otherwise.} \end{cases}$$

Thus, formally the dual to (1.1) is given by

$$\begin{cases} \inf \ \frac{1}{2}|\operatorname{div} \vec{p} + \mathrm{K}^* f|_B^2 \\ \text{s.t.} \ -\beta\vec{1} \le \vec{p}(x) \le \beta\vec{1} \qquad \text{for a.e. } x \in \Omega, \end{cases} \tag{1.5}$$

where $|v|_B^2 = (v, B^{-1}v)$, and the relationship (1.4) applied to the solutions of (1.1) and (1.5) implies that

$$\operatorname{div} \vec{p} = Bu - \mathrm{K}^* f, \quad \vec{p} = \beta \left(\frac{u_{x_i}}{|u_{x_i}|} \right)_{i=1}^n \qquad \text{on } \{x : u_{x_i}(x) \neq 0 \text{ for all } i\}. \tag{1.6}$$

The functional analytic statement corresponding to (1.6) is given in (2.3), (2.4) below.

We note that nondifferentiability due to the BV-term in (1.1) is replaced by the bilateral constraints in the formal dual (1.5).

In the next section we shall put (1.5) into a proper functional analytical framework. For this purpose we require some notation which we summarize next. Let $\mathbb{L}^2(\Omega) = \mathrm{L}^2(\Omega) \times \mathrm{L}^2(\Omega)$ endowed with the Hilbert space inner product structure and

norm. If the context suggests to do so, then we shall distinguish between vector fields $\vec{v} \in \mathbb{L}^2(\Omega)$ and scalar functions $v \in \mathrm{L}^2(\Omega)$ by using an arrow on top of the letter. Analogously we set $\mathbb{H}_0^1(\Omega) = H_0^1(\Omega) \times H_0^1(\Omega)$. We denote $L_0^2(\Omega) = \{v \in \mathrm{L}^2(\Omega) : \int_\Omega v dx = 0\}$, $H_0(\mathrm{div}) = \{\vec{v} \in \mathbb{L}^2(\Omega) : \mathrm{div}\,\vec{v} \in \mathrm{L}^2(\Omega), \vec{v} \cdot n = 0 \text{ on } \partial\Omega\}$, where n is the outer normal to $\partial\Omega$. The space $H_0(\mathrm{div})$ is endowed with $|\vec{v}|^2_{H_0(\mathrm{div})} = |\vec{v}|^2_{\mathbb{L}^2(\Omega)} + |\,\mathrm{div}\,\vec{v}|^2_{L^2}$ as norm. Further, we put $H_0(\mathrm{div}\,0) = \{\vec{v} \in H_0(\mathrm{div}) : \mathrm{div}\,\vec{v} = 0 \text{ almost everywhere in } \Omega\}$. It is well known that

$$\mathbb{L}^2(\Omega) = \mathrm{grad}\; H^1(\Omega) \oplus H_0(\mathrm{div}\,0); \tag{1.7}$$

cf. [10, p. 216], for example. Moreover,

$$H_0(\mathrm{div}) = H_0(\mathrm{div}\,0)^\perp \oplus H_0(\mathrm{div}\,0), \tag{1.8}$$

with

$$H_0(\mathrm{div}\,0)^\perp = \{\vec{v} \in \mathrm{grad}\, H^1(\Omega) : \mathrm{div}\,\vec{v} \in L^2(\Omega), \vec{v} \cdot n = 0 \text{ on } \partial\Omega\},$$

and $\mathrm{div} : H_0(\mathrm{div}\,0)^\perp \subset H_0(\mathrm{div}) \to L_0^2(\Omega)$ is a homeomorphism. In fact, it is injective by construction, and for every $f \in L_0^2(\Omega)$ there exists, by the Lax–Milgram lemma, $\varphi \in H^1(\Omega)$ such that

$$\mathrm{div}\,\nabla\varphi = f \text{ in } \Omega, \qquad \nabla\varphi \cdot n = 0 \text{ on } \partial\Omega,$$

with $\nabla\varphi \in H_0(\mathrm{div}\,0)^\perp$. Hence, by the closed mapping theorem we have

$$\mathrm{div} \in \mathcal{L}(H_0(\mathrm{div})^\perp, L_0^2(\Omega)).$$

Finally, let $\mathrm{P}_{\mathrm{div}}$ and $\mathrm{P}_{\mathrm{div}^\perp}$ denote the orthogonal projections in $\mathbb{L}^2(\Omega)$ onto $H_0(\mathrm{div}\,0)$ and $\mathrm{grad}\, H^1(\Omega)$, respectively. Note that the restrictions of $\mathrm{P}_{\mathrm{div}}$ and $\mathrm{P}_{\mathrm{div}^\perp}$ to $H_0(\mathrm{div}\,0)$ coincide with the orthogonal projections in $H_0(\mathrm{div})$ onto $H_0(\mathrm{div}\,0)$ and $H_0(\mathrm{div}\,0)^\perp$.

2. The Fenchel predual. The section is devoted to the study of the problems

$$\begin{cases} \min & \dfrac{1}{2}|\,\mathrm{div}\,\vec{p} + \mathrm{K}^* f|_B^2 \quad \text{over } \vec{p} \in H_0(\mathrm{div}) \\ \text{s.t.} & -\beta\vec{1} \le \vec{p} \le \beta\vec{1}, \end{cases} \tag{2.1}$$

and

$$\begin{cases} \min & \dfrac{1}{2}|\,\mathrm{div}\,\vec{p} + \mathrm{K}^* f|_B^2 + \frac{\gamma}{2}|\mathrm{P}_{\mathrm{div}}\vec{p}|^2 \quad \text{over } \vec{p} \in H_0(\mathrm{div}) \\ \text{s.t.} & -\beta\vec{1} \le \vec{p} \le \beta\vec{1}, \end{cases} \tag{2.2}$$

where $\gamma > 0$ is given, and we recall that for $v \in \mathrm{L}^2(\Omega)$ we set $|v|_B^2 = (v, B^{-1}v)_{L^2}$.

PROPOSITION 2.1. *Both* (2.1) *and* (2.2)*, admit a solution. The solution to* (2.2) *is unique.*

Proof. Existence of a solution to (2.1) as well as (2.2) can be proved by standard arguments. To verify uniqueness of the solution to (2.2) we note that the set of feasible $\vec{p}$ is convex. Hence it suffices to verify strict convexity of $J(\vec{p}) = \frac{1}{2}|\,\mathrm{div}\,\vec{p} + \mathrm{K}^* f|_B^2 + \frac{\gamma}{2}|\mathrm{P}_{\mathrm{div}}\vec{p}|^2$. To ascertain strict convexity of J we use the fact that the second derivative satisfies

$$J''(\vec{p}, \vec{p}) = |\,\mathrm{div}\,\vec{p}\,|_B^2 + \gamma|\mathrm{P}_{\mathrm{div}}\vec{p}\,|^2 \ge \kappa|\vec{p}\,|^2_{H_0(\mathrm{div})}$$

for a constant $\kappa > 0$ independent of $\vec{p} \in H_0(\mathrm{div})$. Here we have used (1.6) and the subsequent comments. Hence J is even uniformly convex, and uniqueness follows. ∎

THEOREM 2.2. *The Fenchel dual to* (2.1) *is given by* (1.1)*, and the solutions* u^* *of* (1.1) *and* $\vec{p}^*$ *of* (2.1) *are related by*

$$Bu^* = \mathrm{div}\,\vec{p}^* + \mathrm{K}^* f, \tag{2.3}$$

$$\langle (-\mathrm{div})^* u^*, \vec{p} - \vec{p}^* \rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} \le 0 \quad \textit{for all } \vec{p} \in H_0(\mathrm{div}), \tag{2.4}$$

with $-\beta\vec{1} \le \vec{p} \le \beta\vec{1}$.

Alternatively, (2.1) can be considered as the predual of the original problem (1.1). If (2.1) is a zero-residue problem, i.e., $\vec{p}^*$ satisfies $\mathrm{div}\,\vec{p}^* = -\mathrm{K}^* f$, then the additional penalty term in (2.2) chooses from among all solutions the one which minimizes $|\mathrm{P}_{\mathrm{div}}\vec{p}^*|$.

Proof of Theorem 2.2. We apply Fenchel duality as recalled in section 1 with $V = H_0(\mathrm{div})$, $Y = Y^* = \mathrm{L}^2(\Omega)$, $\Lambda = -\mathrm{div}$, $\mathcal{G} : Y \to \mathbb{R}$ given by $\mathcal{G}(v) = \frac{1}{2}|v - \mathrm{K}^* f|_B^2$, and $\mathcal{F} : V \to \mathbb{R}$ defined by $\mathcal{F}(\vec{p}\,) = \mathrm{I}_{[-\beta\vec{1},\beta\vec{1}]}(\vec{p}\,)$. The convex conjugate $\mathcal{G}^* : L^2(\Omega) \to \mathbb{R}$ of $\mathcal{G}$ is given by

$$\mathcal{G}^*(v) = \frac{1}{2}|\mathrm{K}v + f|^2 + \frac{\alpha}{2}|v|^2 - \frac{1}{2}|f|^2.$$

Further, the conjugate $\mathcal{F}^* : H_0(\mathrm{div})^* \to \mathbb{R}$ of $\mathcal{F}$ is given by

$$\mathcal{F}^*(\vec{q}) = \sup_{\vec{p} \in S_1} \langle \vec{q}, \vec{p}\,\rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} \quad \text{for } \vec{q} \in H_0(\mathrm{div})^*, \tag{2.5}$$

where $S_1 = \{\vec{p} \in H_0(\mathrm{div}) : -\beta\vec{1} \le \vec{p} \le \beta\vec{1}\}$. Let us set

$$S_2 = \{\vec{p} \in C_0^1(\Omega) \times C_0^1(\Omega) : -\beta\vec{1} \le \vec{p} \le \beta\vec{1}\}.$$

The set S_2 is dense in the topology of $H_0(\mathrm{div})$ in S_1. In fact, let $\vec{p}$ be an arbitrary element of S_1. Since $(\mathcal{D}(\Omega))^2$ is dense in $H_0(\mathrm{div})$ (see, e.g., [15, p. 26]), there exists a sequence $\vec{p}_n \in (\mathcal{D}(\Omega))^2$ converging in $H_0(\mathrm{div})$ to $\vec{p}$. Let $\mathcal{P}$ denote the canonical projection in $H_0(\mathrm{div})$ onto the closed convex subset S_1 and note that, since $\vec{p} \in S_1$,

$$\begin{aligned} |\vec{p} - \mathcal{P}\vec{p}_n|_{H_0(\mathrm{div})} &\le |\vec{p} - \vec{p}_n|_{H_0(\mathrm{div})} + |\vec{p}_n - \mathcal{P}\vec{p}_n|_{H_0(\mathrm{div})} \\ &\le 2|\vec{p} - \vec{p}_n|_{H_0(\mathrm{div})} \to 0 \qquad \text{for } n \to \infty. \end{aligned}$$

Hence $\lim_{n\to\infty} |\vec{p} - \mathcal{P}\vec{p}_n|_{H_0(\mathrm{div})} = 0$ and S_2 is dense in S_1. Returning to (2.5), we have for $v \in \mathrm{L}^2(\Omega)$ and $(-\mathrm{div})^* \in \mathcal{L}(\mathrm{L}^2(\Omega), V^*)$,

$$\mathcal{F}^*((-\mathrm{div})^* v) = \sup_{\vec{p} \in S_2} (v, -\mathrm{div}\,\vec{p}\,),$$

which can be $+\infty$. By the definition of the functions of bounded variation it is finite if and only if $v \in \mathrm{BV}(\Omega)$ (see [16, p. 3]) and

$$\mathcal{F}^*((-\mathrm{div})^* v) = \beta \int_\Omega |\mathrm{D}v| < \infty \quad \text{for } v \in \mathrm{BV}(\Omega).$$

The dual problem to (2.1) is found to be

$$\min\ \frac{1}{2}|\mathrm{K}u - f|^2 + \frac{\alpha}{2}|u|^2 + \beta \int_\Omega |\mathrm{D}u| \quad \text{over } u \in \mathrm{BV}(\Omega).$$

From (1.4), moreover, we find

$$\langle(-\operatorname{div})^* u^*, \vec{p} - \vec{p}^*\rangle_{H_0(\operatorname{div})^*, H_0(\operatorname{div})} \le 0 \quad \text{for all } p \in S_1$$

and

$$Bu^* = \operatorname{div} \vec{p}^* + \mathrm{K}^* f. \qquad \square$$

We obtain the following optimality system.

COROLLARY 2.3. *Let $\vec{p}^* \in H_0(\operatorname{div})$ be a solution to (2.1). Then there exists $\vec{\lambda}^* \in H_0(\operatorname{div})^*$ such that*

$$\operatorname{div}^* B^{-1} \operatorname{div} \vec{p}^* + \operatorname{div}^* B^{-1} \mathrm{K}^* f + \vec{\lambda}^* = 0, \tag{2.6}$$

$$\langle \vec{\lambda}^*, \vec{p} - \vec{p}^*\rangle_{H_0(\operatorname{div})^*, H_0(\operatorname{div})} \le 0 \quad \textit{for all } \vec{p} \in H_0(\operatorname{div}), \tag{2.7}$$

with $-\beta\vec{1} \le \vec{p} \le \beta\vec{1}$.

For convenience we also specify the variational form of (2.6) which holds in $H_0(\operatorname{div})^*$:

$$(B^{-1} \operatorname{div} \vec{p}^*, \operatorname{div} \vec{v}\,)_{L^2} + (B^{-1}\mathrm{K}^* f, \operatorname{div} \vec{v}\,)_{L^2} + \langle \vec{\lambda}^*, \vec{v}\,\rangle_{H_0(\operatorname{div})^*, H_0(\operatorname{div})} = 0$$

for all $\vec{v} \in H_0(\operatorname{div})$.

Proof of Corollary 2.3. Set $\vec{\lambda}^* = -\operatorname{div}^* u^* \in H_0(\operatorname{div})^*$ and apply $\operatorname{div}^* B^{-1}$ to obtain (2.6). For this choice of $\vec{\lambda}^*$, equation (2.7) follows from (2.4). $\square$

The optimality system for (2.2) is given next.

COROLLARY 2.4. *Let $\vec{p}^* \in H_0(\operatorname{div})^*$ denote the solution to (2.2). Then there exists $\vec{\lambda}^* \in H_0(\operatorname{div})^*$ such that*

$$\operatorname{div}^* B^{-1} \operatorname{div} \vec{p}^* + \operatorname{div}^* B^{-1} \mathrm{K}^* f + \gamma P_{\operatorname{div}} \vec{p}^* + \vec{\lambda}^* = 0, \tag{2.8}$$

$$\langle \vec{\lambda}^*, \vec{p} - \vec{p}^*\rangle_{H_0(\operatorname{div})^*, H_0(\operatorname{div})} \le 0 \quad \textit{for all } \vec{p} \in H_0(\operatorname{div}), \tag{2.9}$$

with $-\beta\vec{1} \le \vec{p} \le \beta\vec{1}$.

Proof. We only sketch the proof here since the assertion will also follow from the proof of Theorem 3.1 below. By (1.6), every $\vec{v} \in H_0(\operatorname{div})$ can be decomposed according to $\vec{v} = \vec{v}_1 + \vec{v}_2 \in H_0(\operatorname{div} 0)^\perp \oplus H_0(\operatorname{div} 0)$. The functional in (2.2) is then separable, and (2.2) can be expressed as

$$\min_{\vec{p} \in H_0(\operatorname{div})} \mathcal{F}(\vec{p}) + \mathcal{G}_1(\Lambda_1 \vec{p}_1) + \mathcal{G}_2(\Lambda_2 \vec{p}_2),$$

where $\mathcal{F}$ is defined in the proof of Theorem 2.2, $\mathcal{G}_1$ and Λ_1 coincide with $\mathcal{G}$ and Λ from the proof of Theorem 2.2, and we set

$$\mathcal{G}_2 : \mathbb{L}^2(\Omega) \to \mathbb{R}, \quad \mathcal{G}_2(\vec{p}) = \frac{\gamma}{2} |\vec{p}\,|^2_{\mathbb{L}^2(\Omega)},$$

$\Lambda_2 \in \mathcal{L}(H_0(\operatorname{div} 0), \mathbb{L}^2(\Omega))$ with Λ_2 the canonical injection. From general results in convex analysis (e.g., [13, p. 61]), there exist $\vec{u}_1^* \in \mathbb{L}^2(\Omega)$ and $\vec{u}_2^* \in \mathbb{L}^2(\Omega)$ such that

$$\begin{aligned} B\vec{u}_1^* &= \operatorname{div} \vec{p}_1^* + \mathrm{K}^* f = \operatorname{div} \vec{p}^* + \mathrm{K}^* f, \\ -\vec{u}_2^* &= \gamma \vec{p}_2^* = \gamma P_{\operatorname{div}} \vec{p}^* \end{aligned}$$

and

$$\langle -\operatorname{div}^* \vec{u}_1^* + \vec{u}_2^*, \vec{p} - \vec{p}^* \rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} \le 0 \qquad \text{for all } \vec{p} \in S_1.$$

The claim follows with $\vec{\lambda}^* = -\operatorname{div}^* \vec{u}_1^* + \vec{u}_2^*$. □

We end this section with the following remarks.

Remark 1.

- In our numerical tests, in many cases we can set $\gamma = 0$. This suggests the conjecture that the constraints $-\beta\vec{1} \le \vec{p} \le \beta\vec{1}$ imply some type of uniqueness.
- We point out the close connection between (2.1) and the taut-string algorithm well known in regression analysis [11, 21]. Here we have K = I, $\alpha = 0$. A continuous version of the taut-string algorithm can be expressed as

$$\begin{cases} \min \displaystyle\int_0^1 \sqrt{1 + |w_x|^2}\, dx, \\ \text{s.t. } F - \beta \le w \le F + \beta, \end{cases} \tag{2.10}$$

where $F(x) = \int_0^x f(s)ds$. The denoised image u is obtained from $u = w_x$. Observe that the change of variables $p = w - F$ transforms (2.10) into

$$\begin{cases} \min \displaystyle\int_0^1 \sqrt{1 + |p_x + f|^2}\, dx, \\ \text{s.t. } -\beta \le p \le \beta \end{cases} \tag{2.11}$$

and $u = p_x + f$. Thus, except for the square root in (2.11), we obtain (2.1).

3. A family of regularized problems. To treat (2.1) and (2.2) numerically one can discretize these box constrained problems and implement one's algorithm of choice for the resulting finite-dimensional quadratic optimization problems with affine constraints. With such an approach the infinite-dimensional structure tends to get covered up. One of the features that can be pointed out by considering (2.6) and (2.8) of the optimality systems is that the leading differential operator is not smoothing (see (1.7)) as it is for obstacle-type problems, nor is it a compact perturbation of the identity operator as, for instance, for control constrained optimal control problems [17]. This complicates the convergence analysis for semismooth Newton algorithms; see [17, 24]. Therefore we describe in this section a family of approximating problems which have more amenable properties for Newton-type algorithms in an infinite-dimensional setting. A second difficulty with (2.1), (2.2) is related to the fact that β will typically be chosen as a small constant so that the resulting problems are close to bottleneck problems. We shall see in section 5 that the algorithms we propose are able to deal efficiently with such constraints.

As announced above, we focus in this section on a family of approximating problems given by

$$\begin{cases} \min \ \dfrac{1}{2c}|\nabla\vec{p}|^2 + \dfrac{1}{2}|\operatorname{div}\vec{p} + \mathrm{K}^* f|_B^2 + \dfrac{\gamma}{2}|\mathrm{P}_{\mathrm{div}}\vec{p}|^2 \\ \qquad + \dfrac{1}{2c}|\max(0, c(\vec{p} - \beta\vec{1}))|^2 + \dfrac{1}{2c}|\min(0, c(\vec{p} + \beta\vec{1}))|^2 \text{ over } \vec{p} \in \mathbb{H}_0^1(\Omega), \end{cases} \tag{3.1}$$

where $c > 0$. Let $\vec{p}_c$ denote the unique solution to (3.1). It satisfies the optimality

condition

$$-\frac{1}{c}\Delta\vec{p}_c - \nabla B^{-1}\operatorname{div}\vec{p}_c - \nabla B^{-1}\mathrm{K}^* f + \gamma \mathrm{P}_{\mathrm{div}}\vec{p}_c + \vec{\lambda}_c = 0, \tag{3.2a}$$

$$\vec{\lambda}_c = \max(0, c(\vec{p}_c - \beta\vec{1})) + \min(0, c(\vec{p}_c + \beta\vec{1})). \tag{3.2b}$$

Next we address convergence as $c \to \infty$.

THEOREM 3.1. *The family $\{(\vec{p}_c, \vec{\lambda}_c)\}_{c>0}$ converges weakly in $H_0(\mathrm{div}) \times \mathbb{H}_0^1(\Omega)^*$ to the unique solution $(\vec{p}^*, \vec{\lambda}^*)$ of (2.8), (2.9). Moreover, the convergence of $\vec{p}_c$ to $\vec{p}^*$ is strong in $H_0(\mathrm{div})$.*

Proof. Recall the variational form of (2.8) given by

$$(\operatorname{div}\vec{p}^*, \operatorname{div}\vec{v}\,)_B + (\mathrm{K}^* f, \operatorname{div}\vec{v}\,)_B + \gamma(\mathrm{P}_{\mathrm{div}}\vec{p}^*, \mathrm{P}_{\mathrm{div}}\vec{v}\,) + \langle \vec{\lambda}^*, \vec{v}\,\rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} = 0 \tag{3.3}$$

for all $\vec{v} \in H_0(\mathrm{div})$. To verify uniqueness, let us suppose that $(\vec{p}_i, \vec{\lambda}_i) \in H_0(\mathrm{div}) \times H_0(\mathrm{div})^*$, $i = 1, 2$, are two solution pairs to (2.8), (2.9). For $\delta\vec{p} = \vec{p}_2 - \vec{p}_1$, $\delta\vec{\lambda} = \vec{\lambda}_2 - \vec{\lambda}_1$ we have

$$(B^{-1}\operatorname{div}\delta\vec{p}, \operatorname{div}\vec{v}\,) + \gamma(\mathrm{P}_{\mathrm{div}}\delta\vec{p}, \mathrm{P}_{\mathrm{div}}\vec{v}\,) + \langle \delta\vec{\lambda}, \vec{v}\,\rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} = 0 \tag{3.4}$$

for all $\vec{v} \in H_0(\mathrm{div})$, and

$$\langle \delta\vec{\lambda}, \delta\vec{p}\,\rangle_{H_0(\mathrm{div})^*, H_0(\mathrm{div})} \geq 0.$$

With $\vec{v} = \delta\vec{p}$ in (3.4) we obtain

$$|B^{-1}\operatorname{div}\delta\vec{p}\,|^2 + \gamma|\mathrm{P}_{\mathrm{div}}\delta\vec{p}\,|^2 \leq 0,$$

and hence $\vec{p}_1 = \vec{p}_2$. From (3.3) we deduce that $\vec{\lambda}_1 = \vec{\lambda}_2$. Thus uniqueness is established, and we can henceforth rely on subsequential arguments.

In the following computation we consider the coordinates $\vec{\lambda}_c^i$, $i = 1, 2$, of $\vec{\lambda}_c$. We have for the pointwise a.e. evaluation at $x \in \Omega$

$$\begin{aligned}\vec{\lambda}_c^i\,\vec{p}_c^i &= \big(\max(0, c(\vec{p}_c^i - \beta)) + \min(0, c(\vec{p}_c^i + \beta))\big)\,\vec{p}_c^i \\ &= \begin{cases} c(\vec{p}_c^i - \beta)\vec{p}_c^i & \text{if } \vec{p}_c^i \geq \beta, \\ 0 & \text{if } |\vec{p}_c^i| = \beta, \\ c(\vec{p}_c^i + \beta)\vec{p}_c^i & \text{if } \vec{p}_c^i \leq \beta. \end{cases}\end{aligned}$$

It follows that

$$(\vec{\lambda}_c^i, \vec{p}_c^i)_{\mathrm{L}^2(\Omega)} \geq \frac{1}{c}|\vec{\lambda}_c^i|^2_{\mathrm{L}^2(\Omega)} \quad \text{for } i = 1, 2,$$

and consequently

$$(\vec{\lambda}_c, \vec{p}_c)_{\mathbb{L}^2(\Omega)} \geq \frac{1}{c}|\vec{\lambda}_c|^2_{\mathbb{L}^2(\Omega)} \quad \text{for every } c > 0. \tag{3.5}$$

From (3.2) and (3.5) we deduce that

$$\frac{1}{c}|\nabla\vec{p}_c|^2 + |\operatorname{div}\vec{p}_c|_B^2 + \gamma|\mathrm{P}_{\mathrm{div}}\vec{p}_c|^2 \leq |\operatorname{div}\vec{p}_c|_B|\mathrm{K}^* f|_B$$

and hence

$$\frac{1}{c}|\nabla \vec{p}_c|^2 + \frac{1}{2}|\operatorname{div} \vec{p}_c|_B^2 + \gamma |\mathrm{P}_{\mathrm{div}} \vec{p}_c|^2 \le \frac{1}{2}|\mathrm{K}^* f|_B. \tag{3.6}$$

We further estimate

$$\begin{aligned} |\vec{\lambda}_c|_{\mathbb{H}_0^1(\Omega)^*} &= \sup_{|\vec{v}\,|_{\mathbb{H}_0^1(\Omega)}=1} \langle \vec{\lambda}_c, \vec{v} \rangle_{\mathbb{H}_0^1(\Omega)^*, \mathbb{H}_0^1(\Omega)} \\ &\le \sup_{|\vec{v}|_{\mathbb{H}_0^1(\Omega)}=1} \Big\{ \frac{1}{c}|\nabla \vec{p}_c||\nabla \vec{v}\,| + |\operatorname{div} \vec{p}_c|_B |\operatorname{div} \vec{v}\,|_B + |\mathrm{K}^* f|_B |\operatorname{div} \vec{v}\,|_B \\ &\qquad + \gamma |\mathrm{P}_{\mathrm{div}} \vec{p}_c|\,|\mathrm{P}_{\mathrm{div}} \vec{v}\,| \Big\}. \end{aligned}$$

From (3.6) we deduce the existence of a constant K independent of $c \ge 1$ such that

$$|\vec{\lambda}_c|_{\mathbb{H}_0^1(\Omega)^*} \le K. \tag{3.7}$$
