We have not embedded our model in neoclassical economic theory; we have simply made some plausible assumptions. We shall show, in section 2, that with reasonable values of the parameters, our model fits the archaeological data for Easter Island

closely. In the rest of the paper, we elaborate upon what we consider our model's other virtue: its exceptionally rich dynamics. We expect that this feature of the model makes it valuable as an example of the sorts of behavior that even a simple two-dimensional population model can exhibit.

Discussions of mathematical models like ours—models of the interaction of a human population and its resources—often include speculation about implications of the analysis for the population of the earth as a whole. We shall do this too, but with misgivings; models like ours do not capture the causes of the growth and advancement of modern technological societies. For example, one of the premises of our model is that resources grow and flourish independent of humans, that the only effect that the humans have on the resources is that the humans harvest them. This is a simplification even for the case of the Easter Islanders, who probably engaged in some of the cultivation of resources that is a hallmark of technological civilizations. For modern civilization, even the idea of resources as something given, apart from humans, is wrong; human ingenuity turns natural materials and phenomena into resources. Finally, at the most abstract level, models like ours do not even address the essential issues of the survival of a species that does things like construct mathematical models of its interaction with its environment.

That said, our model suggests a scenario not often considered for the overpopulation of the Earth. If a population overuses its resources (for our model, if $h > c$), the population will become large while the resources decrease. This situation results in a gradual exponential population growth for an extended period of time and then a sudden catastrophic elimination of the population. (See Figure 2.)

In section 2 we compare numerical approximations of solutions to archaeological data of Easter Island. In section 3 we prove our main theorem and describe general behavior of solutions.

2. Archaeological data of Easter Island and the world population. In this section we compare the population of Easter Island and the population predicted by a numerical solution of (1). We also provide a projection of the world population under the assumption the humans are overusing their resources. It is well accepted that numerical models do not provide accurate numbers for projecting human populations, in part because the constants (growth rate, etc.) for human populations depend on ever-changing social and technological factors. However, mathematical models do provide the approximate "shape" of the graph of a human population. We provide the Easter Island model in part as confirmation that the shape of solutions to (1) is reasonable for the human population and apply a solution with this shape to the world's human population.

A good summary of Easter Island history is given in Cohen's excellent text [4] on global population:

> The best current estimate is that the population began with a boatload of settlers in the first half millennium after Christ, perhaps around 400 A.D. The population remained low until about A.D. 1100. Growth then accelerated and the population then doubled every century until about 1400. Slower growth continued until at most 6000 to 8000 people occupied the island around 1600. The maximum population may have reached 10,000 people in A. D. 1680. A Decline then set in. Jean François de Galaup Comte de La Pérouse, who visited the island in 1786, estimated a population of 2000, and this estimate is now accepted as roughly correct.

The graph of population as a function of time for a numerical approximation to system 1 is shown in Figure 1. Note that the solution matches Cohen's historical estimate until around 1780. However, the population of Easter Island did not actually disappear as it does in the model. We expect that once the population became small enough, factors other than those considered in the model became important for the population. For example, records suggest that the people on Easter Island changed their diet to smaller animals and grasses after their larger ecosystem was destroyed.

In the numerical solution graphed in Figure 1 we used $a = .0044$, which is consistent with historical observations of developing countries prior to the second world war. We took the island's carrying capacity, K, to be $70,000$. It has been estimated (see [4]) that the amount of fertile land needed to supply food for one person is approximately 350 square meters, varying to a great degree depending on the type of land and climate. The area of Easter Island is approximately 166,000,000 square meters. If all of it were fertile and if it were farmed efficiently, there would be enough food for 475,000 people. Since only some of the land is farmable, this makes our approximation of $K = 70,000$ reasonable. The values $c = 0.001$ and $h = 0.025$ are more difficult to justify; we chose these values to fit the data. Note, however, that h is on the order of the reciprocal of a lifespan as suggested in section 1.

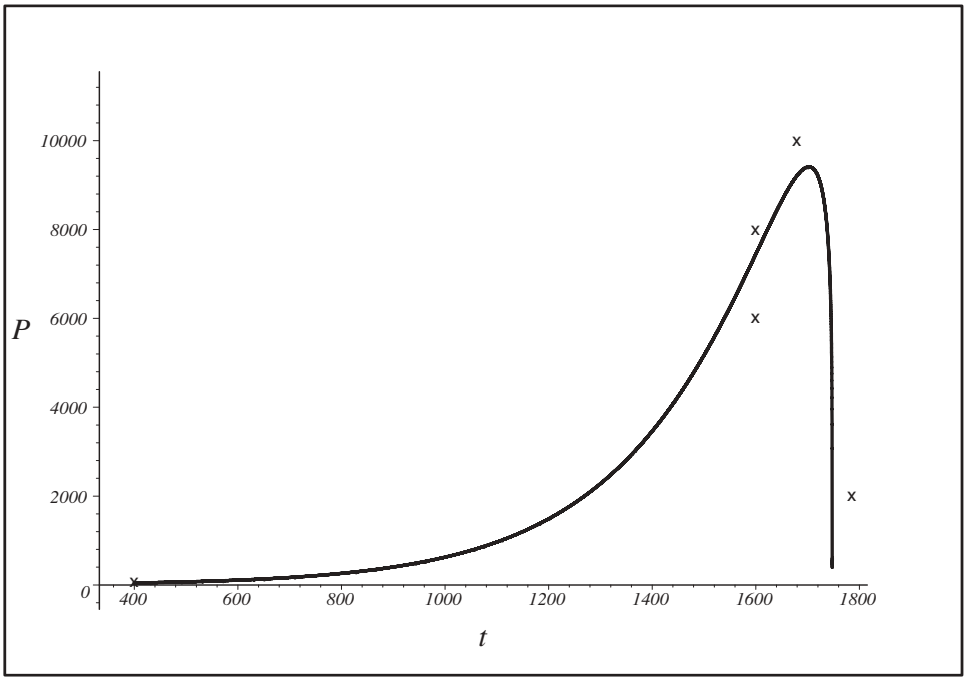

FIG. 1. *The graph of population versus time for a solution to* (1) *modeling the population of Easter Island. Each "x" is a data point approximated using archaeology.*

We do not claim that Figure 1 proves that the population of Easter Island evolved according to the dynamics of (1). But we think it suggests that these equations do provide a reasonable model for an isolated population with limited self-replenishing resources.

A numerical approximation of the world's population using (1) is shown in Figure 2. All of the units are in billions. We assume that the Earth's population in

the year 2000 is 6 (billion). For this approximation we use the carrying capacity of the Earth as $K = 1000$. Approximations to the carrying capacity of the Earth vary widely, as do definitions of what the carrying capacity means. Estimations vary from 1 billion to 1,000 billion, (see [4]), and we choose the upper limit. The growth rate of the Earth's human population has been in the range from 1.73 to over 2 (again, see [4]). We use a conservative estimate of $a = 1.5$. We choose c and h to model a situation where humans are barely overusing resources, $h = 0.6,\ c = 0.5$. The model suggests that the Earth's human population will grow steadily until it reaches a maximum of 350 billion in the year 2350, and then over the next 20 years the population will decrease until either extinction or another model, such as small local farmers, becomes appropriate. As stated earlier, we make no claim to the accuracy of these numbers other than that the prospect of a collapse of a population, instead of a gradual leveling off, is an important scenario to consider. Recall that by Figure 5, the long term behavior of the solution, extinction or equilibrium, depends only on the harvesting rate and the growth rate of the resources.

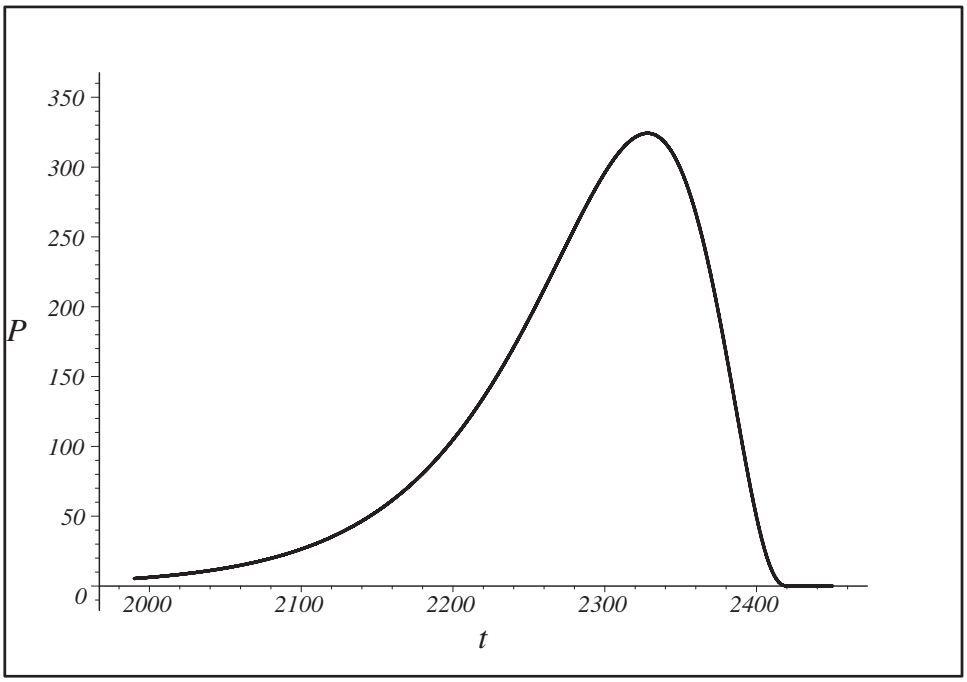

FIG. 2. *The graphs of population and resources versus time for a solution to* (1) *modeling the world's population.*

3. Analysis of the equations. Solutions of (1) fall into three qualitatively different categories: solutions that are asymptotic to an equilibrium point with $P, R > 0$, solutions that approach the singularity at $P = R = 0$, and periodic solutions. A characterization of solutions for various values of h and c is given in Figure 5.

The nullclines provide some insight into the behavior of the system. The nullcline on which $\mathrm{d}P/\mathrm{d}t = 0$ consists of the lines

$$P = 0, \quad P = R.$$

The nullcline on which $\mathrm{d}R/\mathrm{d}t = 0$ is the parabola $P = (c/h)R\left(1 - \frac{R}{K}\right)$ or

$$P = \frac{-c}{hK}R^2 + \frac{c}{h}R$$

(this can be determined by setting $\mathrm{d}R/\mathrm{d}t = 0$ and solving for P). These nullclines are shown, along with the direction field and a numerically integrated solution, in Figures 3 and 4. The parabola $P = (\frac{-c}{hK})R^2 + \frac{c}{h}R$ always intersects the line $P = 0$ at $(0,0)$ and $(K,0)$. The point $(K,0)$ is an equilibrium point, but the point $(0,0)$ is a singular point. The parabola $P = (\frac{-c}{hK})R^2 + \frac{c}{h}R$ intersects the line $P = R$ at $(0,0)$ and, if $c > h$, at $(\frac{K}{c}(c-h), \frac{K}{c}(c-h))$. A characterization of solutions is given in Figure 5.

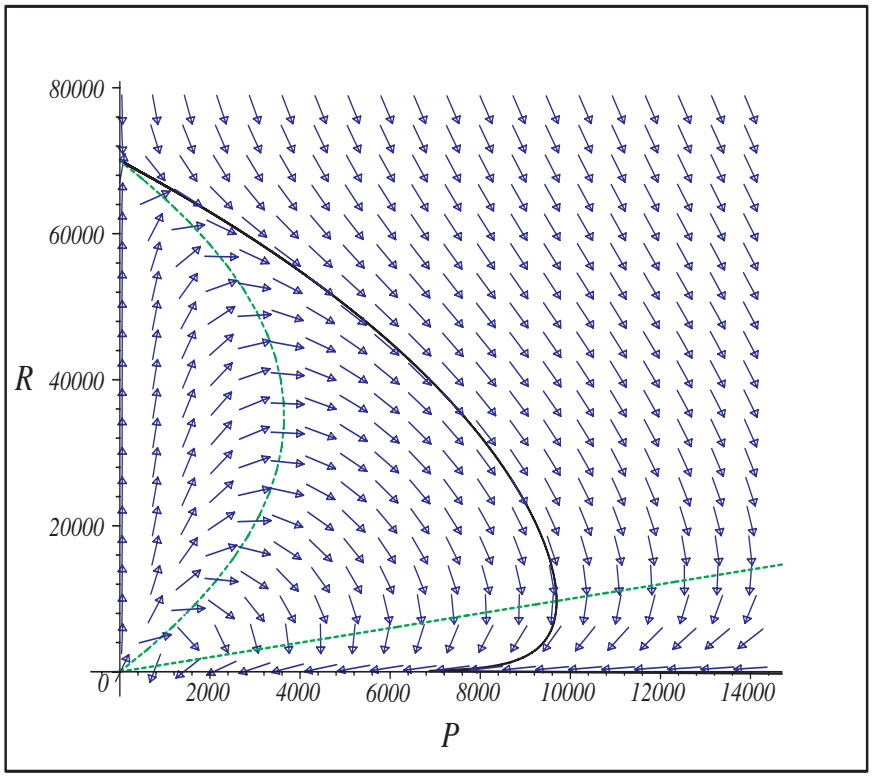

FIG. 3. *The direction field for* (1) *is shown along with the nullclines and one numerically integrated solution. The constants are* $a = .004, c = .01, K = 25000, h = .015$. *The initial condition for the solution is* $P = 75, R = K$, *which were approximately the values when settlers first landed on Easter Island.*

We simplify the equations without loss of generality by rescaling time so that $a = 1$. This puts the differential equations in the form

$$\frac{\mathrm{d}P}{\mathrm{d}t} = P\left(1 - \frac{P}{R}\right), \tag{3}$$

$$\frac{\mathrm{d}R}{\mathrm{d}t} = cR\left(1 - \frac{R}{K}\right) - hP. \tag{4}$$

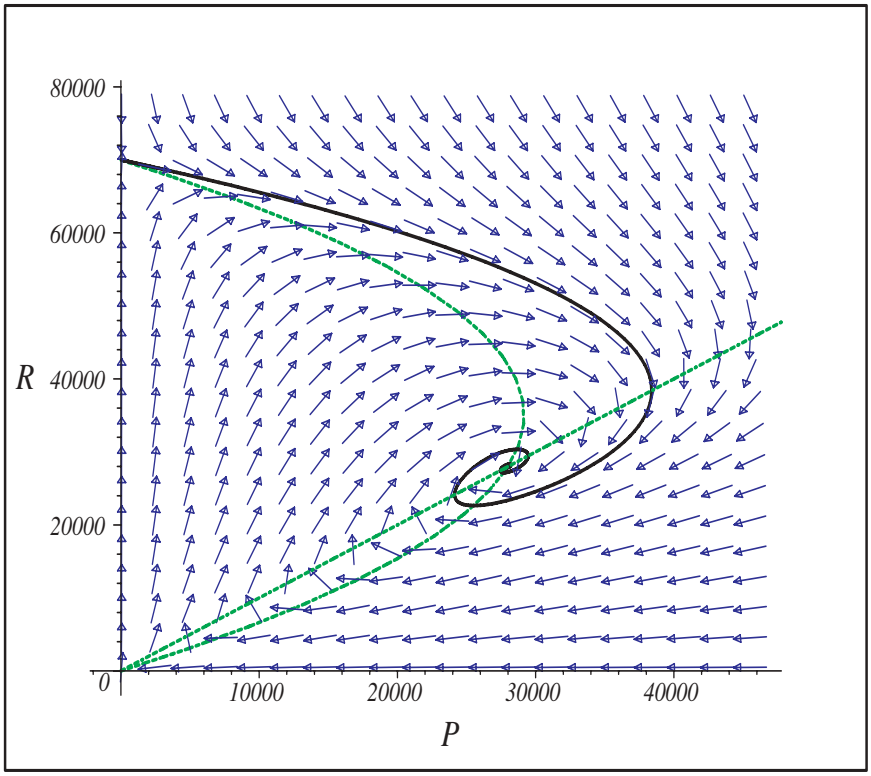

FIG. 4. *The direction field for* (1) *is shown along with the nullclines and one numerically integrated solution. The constants are* $a = .004, c = .01, K = 25000, h = .005$. *The initial condition for the solution is* $P = 75, R = K$, *which were approximately the values when settlers first landed on Easter Island. (Note that the singularity along the* P*-axis causes improperly drawn vectors along the* P*-axis.)*

We are most concerned about solutions that approach the origin, solutions that correspond to the disappearance of both the resources and the population. Standard local analysis near $(0, 0)$ is not possible because of the singularity there. We blow up this singularity through a change of variables. Let

$$z = P, \qquad \xi = P/R. \tag{5}$$

The equations in these new coordinates are

$$z' = z(1 - \xi), \qquad \xi' = (h - 1)\xi^2 + (1 - c)\xi + \frac{c}{K}z. \tag{6}$$

Note that the new system is free of singularities. We are most interested in values of the new coordinates for which P and R are both positive. For these values the change of variables is invertible. Note that the change of variables takes the first quadrant in P, R-coordinates to the first quadrant in z, ξ-coordinates, it takes vertical lines to themselves, and it is the identity mapping ($z = P, \xi = R$) along the parabola

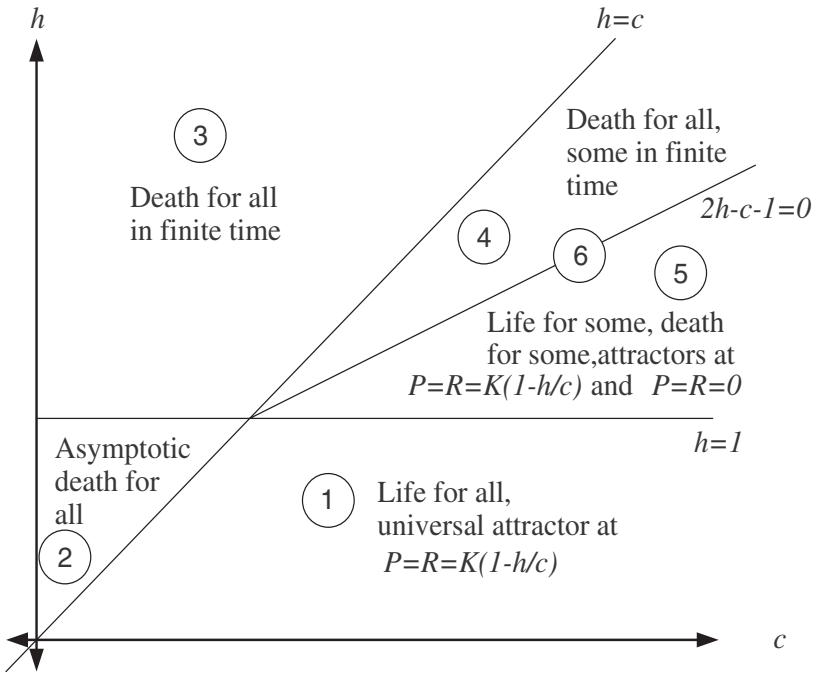

FIG. 5. *The long-term behavior of solutions depending on the growth rate of resources, c, and the harvesting rate, h. The number in each region indicates the corresponding proposition.*

$P = R^2$. Also, the region near $(0,0)$ with $P, R > 0$ has been "blown up" to the region near the positive ξ-axis. In particular, if an orbit approaches (0,0) with P and R asymptotically proportional to each other, the corresponding orbit in (z, ξ) will approach the point $(0, \Theta)$, where Θ is the asymptotic proportion. If P approaches 0 faster than R, we have $\xi \to 0$, and if P approaches 0 slower than P, we get $\xi \to \infty$. Behavior near the positive P-axis is obscured. However, behavior here is easy to understand in P, R-coordinates: the equation for the resources reduces to a logistic equation and the population grows.

We denote the first quadrant $\{(z, \xi) \,|\, z > 0, \xi > 0\}$ by Ω and denote the region $\{(z, \xi) \,|\, z \geq 0, \xi > 0\}$ by Ω^*. Although the positive ξ-axis does not correspond to distinct values of P and R—the whole axis corresponds to $P = R = 0$—we need it to analyze asymptotic behavior. Our main tool will be the Lyapunov function $\lambda : \Omega \to \mathbb{R}$,

$$\lambda(z, \xi) = z^{2h-2} \left(\frac{K}{2c} \xi^2 - \frac{K}{c} \xi + \frac{z}{2h-1} + \frac{K}{2c} - \frac{K(1-h/c)}{2h-2} \right),$$

the properties of which will be established in Lemma 2. First we establish some qualitative behavior of the system. By linearizing the system about the point $\{(z, \xi)\}$ we obtain the Jacobian

$$J = \begin{bmatrix} 1-\xi & z \\ \dfrac{c}{K} & 2(h-1)\xi + 1 - c \end{bmatrix}.$$

The equilibrium points of our system are

- $(0,0)$, at which J has eigenvalues 1 and $1-c$;
- $(0, \frac{c-1}{h-1})$, at which J has eigenvalues $\frac{h-c}{h-1}$ and $c-1$;
- $(K(1-h/c),1)$, at which J has eigenvalues $\frac{2h-c-1\pm\sqrt{(2h-c-1)^2-4(c-h)}}{2}$.

The behavior of solutions depends in a surprisingly complex way on the constants h and c. This dependence is summarized in Figure 5. Our main tools in establishing this characterization are Lemma 2, which establishes the properties of a Lyapunov function, and Lemma 3.

We shall begin our analysis with some lemmas about basic structural features of the system. We shall then use these lemmas to characterize the qualitative behavior of the system for various values of h and c.

LEMMA 1. *The regions Ω and Ω^* are both positive invariant. That is, if a solution is in one of these regions initially, then it remains in the region as long as it exists.*

Proof. The ξ-axis is invariant and the vector field is pointing into the first quadrant along the positive z-axis. Specifically, if $z>0$ and $\xi=0$, then $z'=z$ and $\xi'=\frac{c}{K}>0$. If $z=0$ and $\xi>0$, then $z'=0$ and $\xi'=(h-1)\xi^2+(1-c)\xi$. ∎

Note that the regions are not negative invariant and that it is possible that orbits become unbounded in finite time.

LEMMA 2. *Let*

$$\lambda(z,\xi)=z^{2h-2}\left(\frac{K}{2c}\xi^2-\frac{K}{c}\xi+\frac{z}{2h-1}+\frac{K}{2c}-\frac{K(1-h/c)}{2h-2}\right).$$

(a) *If $2h-c-1=0$, λ is constant on trajectories in Ω.*
(b) *If $2h-c-1<0$, λ is strictly decreasing on trajectories in Ω that are not equilibria.*
(c) *If $2h-c-1>0$, λ is strictly increasing on trajectories in Ω that are not equilibria.*

Proof. A direct (but not short) computation yields

$$\lambda'=(2h-c-1)(K/c)(\xi-1)^2z^{2h-2},$$

where $'$ denotes the derivative with respect to time. Statement (a) follows directly from this computation.

To prove (b), assume $2h-c-1<0$. Note that $\lambda'<0$ except when $\xi=1$. By differentiating twice more, we obtain

$$\begin{aligned}
\lambda'' = {} & (2h-c-1)\frac{K}{c}[2(\xi-1)(\xi')z^{2h-2}+(\xi-1)^2(2h-2)z^{2h-1}z'],\\
\lambda''' = {} & (2h-c-1)\frac{K}{c}[2(\xi')(\xi')z^{2h-2}+2(\xi-1)(\xi'')z^{2h-2}\\
& +2(\xi-1)(\xi')(2h-2)z^{2h-1}z'+2(\xi-1)(\xi')(2h-1)z^{2h-1}z'\\
& +(\xi-1)^2(2h-2)(2h-1)z^{2h}(z')^2+2(\xi-1)(\xi')(2h-1)z^{2h-1}z'').
\end{aligned}$$

When $\xi=1$, we have $\lambda''=0$ and λ''' is strictly negative unless $\xi'=0$. Since the only points with $\xi=1$ and $\xi'=0$ are equilibria, statement (b) follows. Statement (c) is proven similarly. ∎

If x_e is an equilibrium point, a function L defined on a neighborhood of x_e is called a Lyapunov function if it has a minimum at x_e and is strictly decreasing on all trajectories other than x_e. The existence of a Lyapunov function establishes x_e as an attractor or a stable equilibrium (see [7].) When the level sets of L are compact and

x_e is a global minimum, the point x_e is a global attractor. Since the level sets of λ are not all compact, we use topological methods to understand global behavior.

We say that an orbit $\gamma(t)$ is *positively bounded* if the positive orbit $O^+(\gamma) = \{\gamma(t) \,|\, t > 0\}$ is bounded. We say that γ is *positively unbounded* if $O^+(\gamma)$ is unbounded. Lemma 2 allows us to prove Lemma 3, which characterizes the long term behavior of positively bounded solutions.

LEMMA 3. *Suppose that* $2h-c-1 \neq 0$. *Any positively bounded solution beginning in* Ω *is asymptotic to an equilibrium point (in* Ω^**).*

Proof. The ω-limit set of a solution curve is defined to be

$$\omega(\gamma) = \cap_{s>0}\overline{\cup_{t>s}\gamma(t)},$$

where the overbar denotes closure. It is a standard result [7] that a point p is in $\omega(\gamma)$ if and only if there is a sequence $\{t_n\}$ with $t_n \to \infty$ as $n \to \infty$ such that $\gamma(t_n) \to p$. This follows directly from the definition of $\omega(\gamma)$. Another standard result [7] is that any positively bounded solution has a nonempty ω-limit set. This result follows from the Bolzano–Weierstrass theorem applied to the set $\{\gamma(n) \,|\, n \in \mathbb{N}\}$. Define the ω_Ω-limit set of γ by $\omega_\Omega(\gamma) = \omega(\gamma) \cap \Omega$.

For this proof let $\gamma(t) = (z(t), \xi(t))$ denote a positively bounded solution of the differential equation beginning from an initial condition in Ω. Since λ is strictly monotonic on trajectories and continuous on Ω, it must be constant on the ω_Ω-limit set of any solution. Hence the ω_Ω-limit set of any solution is the (possibly empty) union of equilibrium points.

We claim that if $\omega_\Omega(\gamma)$ contains an equilibrium point $p \in \Omega$, then $\omega(\gamma) = p$. For any $\delta > 0$ there is a time $s \in \mathbb{R}$ such that $\gamma(t) \in B_\delta(p)$ for all $t > s$. Were this not so, then for every $\delta > 0$ the set $\partial(B_\delta(p)) \cap \gamma$ (where $\partial(B_\delta(p)) = \{(z, \xi) \,|\, z^2 + \xi^2 = \delta\}$) would be infinite and hence have a limit point in $\partial(B_\delta(p))$, which we call p_δ. Then $p_\delta \in \omega(\gamma)$ for each δ, and the limit of p_δ as $\delta \to 0$ is p. Since our equilibrium points are isolated, infinitely many of these points are nonequilibrium points, which is impossible.

We have shown that $\omega(\gamma)$ either is a single equilibrium point in Ω or is contained in $\Omega^* - \Omega$. We claim that if $\omega(\gamma) \subseteq \Omega^* - \Omega$, then it consists of a single equilibrium point. Let $p \in \Omega^* - \Omega$ such that p is not an equilibrium point. Since $\Omega^* - \Omega$ is the positive ξ-axis, p is either in the stable manifold or in the unstable manifold of an equilibrium point in $\Omega^* - \Omega$. If p is in the stable or unstable manifold of a sink or source, then it cannot be an ω-limit point of an orbit in Ω. Suppose that p is in the unstable manifold of an equilibrium point $p_e \in \Omega^* - \Omega$ and $p \in \omega(\gamma)$ for some $\gamma(t)$. The unstable manifold of p_e in Ω consists of an orbit extending into Ω. By the Lambda lemma (see [6]), this orbit is in $\omega(\lambda)$, contradicting our earlier assertion that the only points of $\omega(\gamma)$ in Ω are equilibrium points. Similarly, p cannot be in the stable manifold of a saddle. Hence, an ω-limit set of a positively bounded orbit in Ω is a single equilibrium point. ∎

In the next two lemmas we characterize unbounded solutions.

LEMMA 4. *If* $h < 1$, *then all orbits are positively bounded.*

Proof. Suppose that $\gamma(t)$ is positively unbounded. We claim that either $\xi \to \infty$ or $z \to \infty$. Otherwise, there exist an $M > 0$ and a sequence $t_1, t_2, \ldots$ with $t_n \to \infty$ as $n \to \infty$ such that $||\gamma(t_n)|| < M$ for all n. Then by the Bolzano–Weierstrass theorem the set $\{\gamma(t_n) \,|\, n \in \mathbb{N}\}$ would have a limit point $x_0 \in B_M((0,0))$. This limit point would be in the ω-limit set of γ. By the argument in the proof of Lemma 3, $\gamma(t)$ would have to be asymptotic to x_0 and γ would be bounded.

The Poincaré sphere is a standard tool for analyzing the behavior of a two-dimensional differential equation near infinity. (See [7, p. 169].) A simple calculation using the Poincaré sphere shows that for $h < 1$ there are no orbits asymptotic to infinity. In the notation of [7], $P_2(X,Y) = -XY$, $Q_2(X,Y) = (h-1)Y^2$, and hence the only equilibrium points on the circle at infinity are $\pm(1,0,0)$ and $\pm(0,1,0)$, and none of these have a stable manifold which intersects Ω. □

LEMMA 5. *If $h > 1$, then any positively unbounded orbit has the property that $z(t) \to 0$ and $\xi(t) \to \infty$ as $t \to t_*$ for some finite t_*. Moreover, if $\xi > \max\{1, \frac{c-1}{h-1}\}$ at any time along an orbit, then the orbit is positively unbounded.*

Proof. Assume $h > 1$. Consider an orbit with initial condition (z_0, ξ_0) with $z > 0$ and $\xi > \max\{1, \frac{c-1}{h-1}\}$. We will show that any such orbit has the property that $z(t) \to 0$ and $\xi(t) \to \infty$ as $t \to t_* < \infty$. For such an orbit,

$$\begin{aligned}\xi' &= (h-1)\xi\left(\xi + \frac{1-c}{h-1}\right) + \frac{c}{K}z \\ &> (h-1)\xi\left(\xi + \frac{1-c}{h-1}\right) > 0.\end{aligned}$$

Hence, $\xi(t) > \max\{1, \frac{c-1}{h-1}\}$ and $\xi'(t) > (h-1)\xi(\xi + \frac{1-c}{h-1}) > 0$ for all $t > 0$.

The differential inequality $\xi' \geq (h-1)\xi(\xi + \frac{1-c}{h-1})$ implies that ξ behaves like a solution of $x' = x^2$; it approaches infinity in finite time. More precisely, this differential inequality can be integrated to yield

$$\left(\frac{\xi(\xi_0 + \frac{1-c}{h-1})}{\xi_0(\xi + \frac{1-c}{h-1})}\right)^{\frac{1}{1-c}} > e^t,$$

which implies that $\xi \to \infty$ before $t = (\ln(\xi_0 + \frac{1-c}{h-1}) - \ln(\xi_0))/(1-c) < \ln(\frac{h-c}{h-1})/(1-c) < \infty$.

We now show that $z(t) \to 0$ for this orbit. Since $z' = z(1-\xi)$ and $\xi \to \infty$, it follows that $z(t)$ is eventually monotonic decreasing. Since $z(t)$ is bounded below by 0, $z(t)$ converges to some value $z_* \geq 0$. Since $\xi' = (h-1)\xi^2 + (1-c)\xi + \frac{c}{K}z$ and z is bounded, $\xi(t)$ is eventually monotonic increasing. Without loss of generality, assume that the initial condition for this orbit is (z_0, ξ_0) and that z is monotonic decreasing and ξ is monotonic increasing for all $t \geq 0$. The positive orbit $(z(t), \xi(t))$, $t \geq 0$, then corresponds to the graph of a function $z = f(\xi)$, $f : (\xi_0, \infty) \to (z_*, z_0)$. Then

$$\frac{\mathrm{d}f}{\mathrm{d}\xi} = \frac{\mathrm{d}z/\mathrm{d}t}{\mathrm{d}\xi/\mathrm{d}t} < 0,$$

and by the fundamental theorem of calculus

$$\begin{aligned}z_0 - z_* &= \int_{\xi_0}^{\infty} f'(\xi)\mathrm{d}\xi \\ &= \int_{\xi_0}^{\infty} \frac{f(\xi)(1-\xi)}{(h-1)\xi^2 + (1-c)\xi + \frac{c}{K}f(\xi)}\mathrm{d}\xi.\end{aligned} \tag{7}$$

Note that $f'(\xi) < 0$ because $\xi' > 0$ and $z' < 0$. Since $z_* \leq f(\xi) \leq z_0$ for all ξ,

$$\frac{f(\xi)(1-\xi)}{(h-1)\xi^2 + (1-c)\xi + \frac{c}{K}f(\xi)} < \frac{z_*(1-\xi)}{(h-1)\xi^2 + (1-c)\xi + \frac{c}{K}z_0}.$$

Observe that

$$\lim_{\xi\to\infty} \frac{\frac{z_*(1-\xi)}{(h-1)\xi^2+(1-c)\xi+\frac{c}{K}z_*}}{\frac{-1}{\xi}} \geq \frac{z_*}{(h-c)} \geq 0,$$

with equality if and only if $z_* = 0$. If $z_* \neq 0$, the limit comparison test for indefinite integrals implies that the integral in (7) diverges because the integral

$$\int_{\xi_0}^{\infty} \frac{-1}{\xi} \mathrm{d}\xi$$

diverges. This is a contradiction since $z_0 - z_*$ is finite. Hence $z(t) \to z_* = 0$.

Now consider an orbit with initial condition (z_0, ξ_0) with $z_0 > 0$ and $\xi_0 \leq \max\{1, \frac{c-1}{h-1}\}$. We will show that if $\xi(t)$ is bounded, then so is $z(t)$. This will complete the proof of the $h > 1$ portion of the lemma. Suppose, to obtain a contradiction, that $z(t)$ is unbounded for some orbit $(z(t), \xi(t))$. Since the set $\xi' = 1$ is a parabola opening to the left, there is some M such that if $z > M$, then $\xi' > 1$. Since $z(t)$ is unbounded and $z'(t) = z(\xi - 1) < z$, there are times $t_a < t_b$ with $z(t) > M$ for all $t \in [t_a, t_b]$ and $t_b - t_a > \max\{1, \frac{c-1}{h-1}\}$. Since Ω is positive invariant, $\xi(t_a) > 0$. Hence,

$$\xi(t_b) > \xi(t_b) - \xi(t_a) = \int_{t_a}^{t_b} \xi' \mathrm{d}t > \int_{t_a}^{t_b} 1 \mathrm{d}t > t_b - t_a > \max\left\{1, \frac{c-1}{h-1}\right\}.$$

Therefore, by the previous assertion, $\xi(t) \to \infty$ and $z(t) \to 0$. This proves that $z(t)$ is bounded for positive time for all orbits. □

In the course of this proof, we have established an upper bound on the time a population takes to disappear if the orbit begins in Ω with $\xi > \max\{1, \frac{c-1}{h-1}\}$. Specifically, $\xi \to \infty$ before $t = (\ln(\xi_0 + \frac{1-c}{h-1}) - \ln(\xi_0))/(1-c) < \ln(\frac{h-c}{h-1})/(1-c)$. This implies that $P(t), R(t) \to 0$ while $t < \ln(\frac{h-c}{h-1})/(1-c) < \infty$.

PROPOSITION 1. *Suppose that $h < c$ and $h < 1$. Then all solutions beginning in Ω are asymptotic to the stable equilibrium at $(z, \xi) = (\Gamma, 1)$, where $\Gamma = K(1 - h/c)$. Hence, in P, R-coordinates, all solutions beginning in the first quadrant are asymptotic to the equilibrium at $(P, R) = (\Gamma, \Gamma)$.*

Proof. Since $h < 1$, by Lemma 4 every solution is bounded and approaches an equilibrium solution. For these parameter values the equilibrium solutions in Ω^* are $(0, 0)$, $(K(1 - h/c), 1)$, and possibly $(0, \frac{c-1}{h-1})$. The only equilibrium with a nonempty stable manifold in Ω is $(K(1 - h/c), 1)$. Hence, all solutions are asymptotic to this equilibrium. □

PROPOSITION 2. *If $h > c$ and $h < 1$, then $(z, \xi) \to (0, \frac{c-1}{h-1})$ as $t \to \infty$ for all solutions. Hence, $(P, R) \to (0, 0)$ as $t \to \infty$ with*

$$\frac{P}{R} \sim \frac{c-1}{h-1}.$$

Proof. Since $h < 1$, by Lemma 4 all solutions are bounded. The only equilibrium point in Ω^* with a nonempty stable manifold in Ω is $(0, \frac{c-1}{h-1})$. By Lemma 3, all solutions are asymptotic to $(0, \frac{c-1}{h-1})$. □

An alternative proof of Proposition 2 is based on the Lyapunov function

$$L = \frac{1}{2}\left(\xi + \frac{1-c}{h-1}\right)^2 + \frac{c}{K}z$$

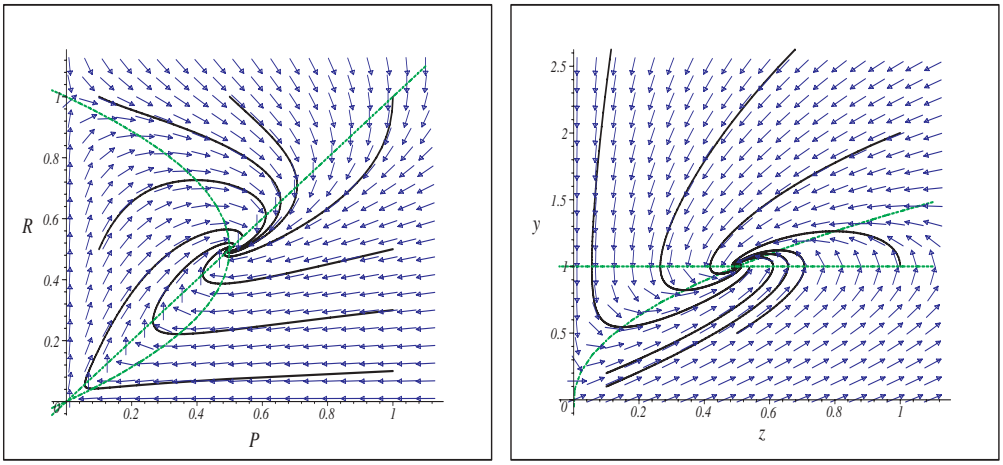

FIG. 6. *The phase planes with* $c = 1$, $h = 0.5$, *and* $K = 1$ *satisfying the hypothesis of Proposition* 1. *The nullclines are indicated by dashed lines.*

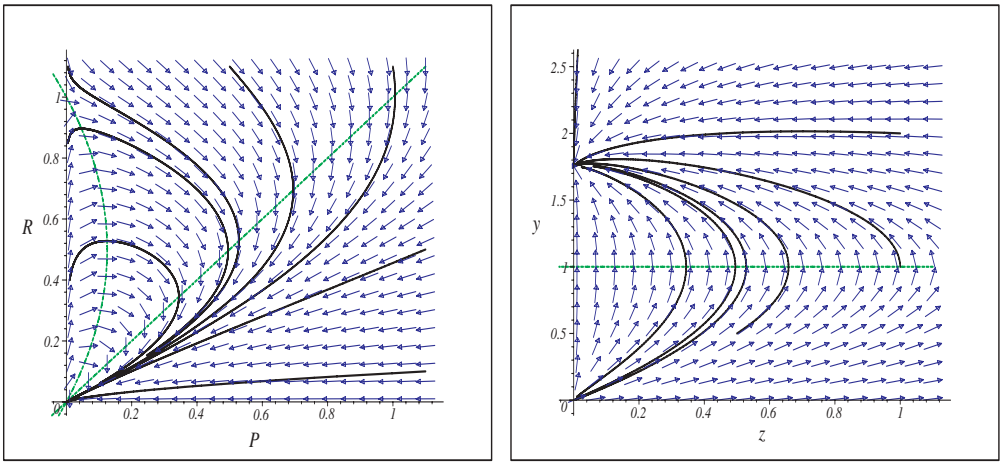

FIG. 7. *The phase planes with* $c = 0.3$, $h = 0.6$, *and* $K = 1$ *satisfying the hypothesis of Proposition* 2. *The same set of initial conditions is used for the solutions shown in each coordinate system. The nullclines are indicated by dashed lines.*

with

$$\frac{\mathrm{d}L}{dt} = (h-1)\xi\left(\xi + \frac{1-c}{h-1}\right)^2 + \frac{c}{K}\left(\frac{h-c}{h-1}\right)z,$$

which is negative when $c < h < 1$. Moreover, the level sets of L are compact. This constitutes an alternate proof that $(0, \frac{c-1}{h-1})$ is a global attractor.

PROPOSITION 3. *If* $h > c$ *and* $h > 1$, *then* $z \to 0$ *and* $\xi \to \infty$ *in finite time for all solutions. Hence,* (P, R) *goes to the singularity at* $(0, 0)$ *in finite time with*

$$\frac{P}{R} \to \infty.$$

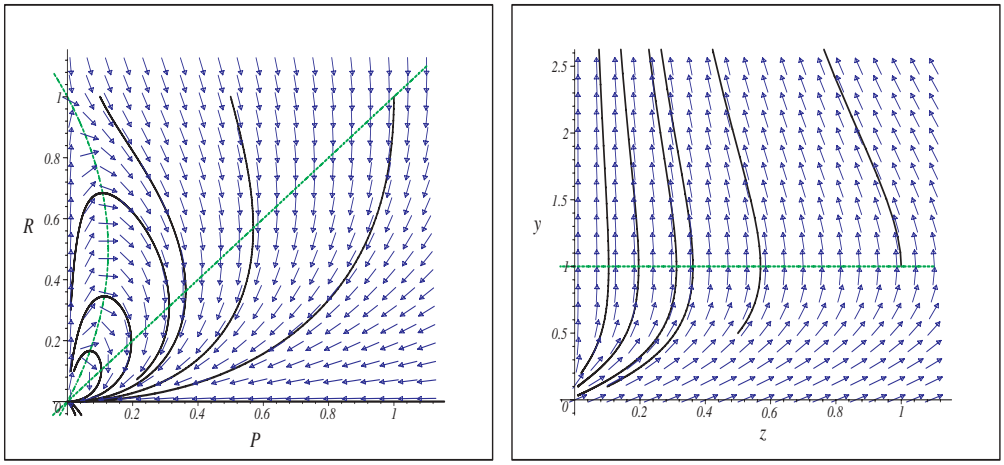

FIG. 8. *The phase planes with $c = 1$, $h = 2$, and $K = 1$ satisfying the hypothesis of Proposition 3. The nullclines are indicated by dashed lines.*

Proof. For our parameter values the only equilibrium solutions in Ω^* are $(0,0)$ and possibly $(0, \frac{c-1}{h-1})$. The equilibrium $(0,0)$ is unstable and $(0, \frac{c-1}{h-1})$ is unstable if $(0, \frac{c-1}{h-1}) \in \Omega^*$. Therefore, there are no solutions in Ω that are asymptotic to an equilibrium solution. By Lemma 3, all solutions are unbounded. By Lemma 5, $z(t) \to 0$ and $\xi(t) \to \infty$ in finite time for all solutions. □

PROPOSITION 4. *Suppose that $h < c$, $h > 1$, and $2h - c - 1 > 0$. For almost every solution, $z(t) \to 0$ and $\xi(t) \to \infty$ in finite time. There is one solution with $\xi(t) \to \frac{c-1}{h-1}$ and one unstable equilibrium solution at $(K(1 - h/c), 1)$.*

In P, R-coordinates, almost every solution goes to the singularity at $(0,0)$ in finite time with

$$\frac{P}{R} \to \infty.$$

There is one solution that is asymptotic to $(0,0)$ with $P/R \sim \frac{c-1}{h-1}$ and one unstable equilibrium solution at $(K(1 - h/c), K(1 - h/c))$.

Proof. For our parameter values the equilibrium solutions in Ω^* are $(0,0)$, $(0, \frac{c-1}{h-1})$, and $(K(1 - h/c), 1)$. The equilibrium at $(0,0)$ is a saddle with its stable manifold contained in $\Omega^* - \Omega$. The equilibrium at $(0, \frac{c-1}{h-1})$ is a saddle, and its stable manifold is a solution extending into Ω. The equilibrium at $(K(1 - h/c), 1)$ is unstable. Therefore, all solutions except $(K(1 - h/c), 1)$ and the stable manifold $(0, \frac{c-1}{h-1})$ are unbounded by Lemma 3. By Lemma 5, $z(t) \to 0$ and $\xi(t) \to \infty$ in finite time for these solutions. □

PROPOSITION 5. *Suppose that $h < c$, $h > 1$, and $2h - c - 1 < 0$. Let A denote the region*

$$0 < z < \frac{-K(2h-1)}{2c}\left(\xi^2 - 2\xi + \frac{2h-c-1}{h-1}\right).$$

All orbits that intersect A approach the equilibrium point $(\Gamma, 1)$ asymptotically; in fact, these solutions constitute the basin of attraction of this sink. The single solution stable manifold of $(0, \frac{c-1}{h-1})$ is a separatrix. All other solutions have the property that $z \to 0$, $\xi \to \infty$ in finite time.

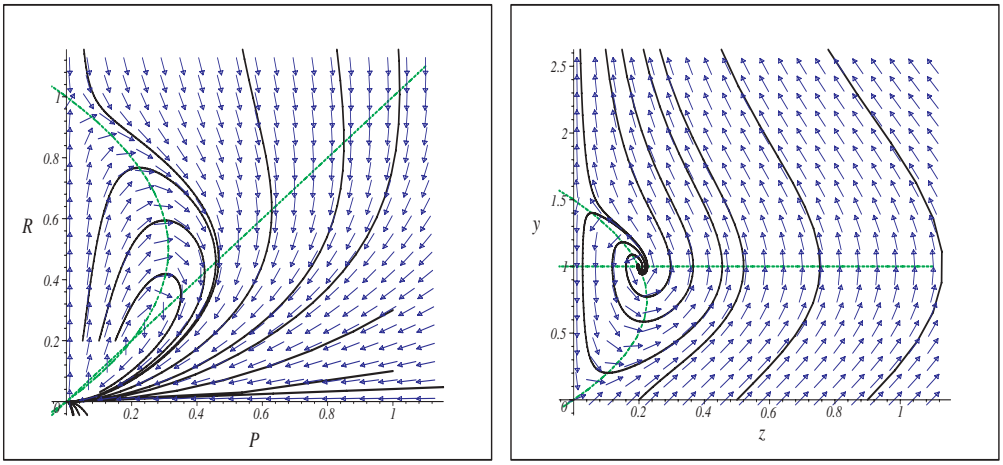

FIG. 9. *The phase planes with $c = 2.5$, $h = 2$, and $K = 1$ satisfying the hypothesis of Proposition 4. The nullclines are indicated by dashed lines.*

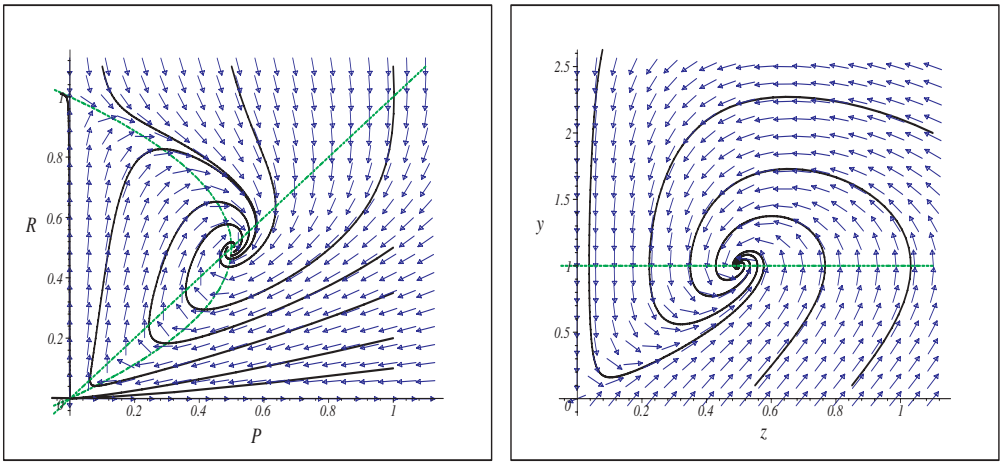

FIG. 10. *The phase planes with $c = 3$, $h = 1.5$, and $K = 1$ satisfying the hypothesis of Proposition 5. The nullclines are indicated by dashed lines.*

In P, R-coordinates, there is an open set of orbits which are asymptotic to the equilibrium at $(P, R) = (\Gamma, \Gamma)$. There is an open set of orbits which approach $(0, 0)$ in finite time. There is a single solution that is asymptotic to $(0, 0)$ with $P/R \sim \frac{c-1}{h-1}$ as $t \to \infty$, and this solution is the separatrix between the two open sets.

Proof. By solving $\lambda = 0$ we obtain

$$z = \frac{-K(2h-1)}{2c}\left(\xi^2 - 2\xi + \frac{2h-c-1}{h-1}\right).$$

It is easy to see that $\lambda < 0$ on A and $(\Gamma, 1) \in A$. Observe that the only equilibrium point in $\overline{A}$ whose stable manifold has a nonempty intersection with A is $(\Gamma, 1)$. Since $\lambda'(t) < 0$ for all orbits in Ω by Lemma 2, all orbits are forward asymptotic to $(\Gamma, 1)$.

The stable manifold of $(0, \frac{c-1}{h-1})$ in Ω is a single orbit. Denote this orbit by $\alpha(t)$.

Near $(0, \frac{c-1}{h-1})$, there is a well-defined notion of above and below α. Orbits just above α follow the unstable manifold of $(0, \frac{c-1}{h-1})$ up the ξ-axis. Eventually $\xi(t) > \frac{c-1}{h-1}$ for these solutions. Since $2h-c-1 < 0$, we have $c-1 > 2(h-1)$ and $\frac{c-1}{h-1} = \max\{1, \frac{c-1}{h-1}\}$. Therefore, $\xi(t) \max\{1, \frac{c-1}{h-1}\}$ for each of these solutions and $z(t) \to 0$, $\xi(t) \to \infty$ by Lemma 5.

Orbits just below α follow the unstable manifold of $(0, \frac{c-1}{h-1})$ down the ξ-axis into the region A, and these orbits are asymptotic to $(\Gamma, 1)$. Therefore, α is the separatrix between orbits asymptotic to $(\Gamma, 1)$ and ones that approach $(0, \infty)$ in finite time. By Lemmas 3 and 5, every orbit is asymptotic to $(\Gamma, 1)$, $(0, \frac{c-1}{h-1})$, or $(0, \infty)$. □

PROPOSITION 6. *Suppose that $h < c$, $h > 1$, and $2h - c - 1 = 0$. Let A denote the region*

$$0 < z < \frac{-K(2h-1)}{2c}\left(\xi^2 - 2\xi\right).$$

There is a heteroclinic orbit from $(0,0)$ to $(0, \frac{c-1}{h-1})$. The boundary of A consists of this orbit, a heteroclinic orbit in $\Omega^* - \Omega$ from $(0,0)$ to $(0, \frac{c-1}{h-1})$, and these two equilibrium points. All orbits inside A are periodic. All orbits outside of A approach $(0, \infty)$ in finite time.

In P, R-coordinates, there is a heteroclinic orbit from $(K, 0)$ to $(0, 0)$. This orbit together with the orbit in the R-axis from $(0,0)$ to $(K, 0)$ and these two equilibrium points forms a limit cycle. Orbits within this limit cycle are all periodic. Orbits outside of this limit cycle approach $(0, 0)$ in finite time.

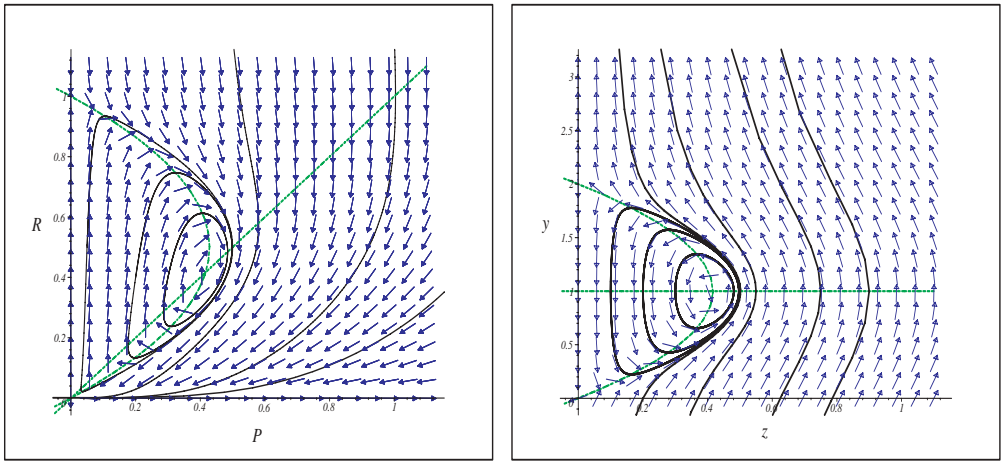

FIG. 11. *The phase planes with $c = 6$, $h = 3.5$, and $K = 1$ satisfying the hypothesis of Proposition 6. The nullclines are indicated by dashed lines.*

Proof. For this case, $\lambda'(t) = 0$ by Lemma 2, so λ is an integral of the system. We want to show that it is a nondegenerate integral. The gradient of λ is

$$\nabla\lambda = \left((2h-2)z^{2h-3}\left(\frac{K}{2c}\xi^2 - \frac{K}{c}\xi + \frac{z}{2h-1} + \frac{K}{2c} - \frac{K(1-h/c)}{2h-2}\right) + \frac{z^{2h-2}}{2h-1}, z^{2h-2}\frac{K}{c}(\xi - 1)\right).$$

Since $\partial\lambda/\partial\xi = z^{2h-2}\frac{K}{c}(\xi - 1)$, if $\nabla\lambda = 0$ in Ω, then $\xi = 1$. Substituting $\xi = 1$ into $\partial\lambda/\partial z = 0$ gives $z = \Gamma$. Hence, the only point in Ω where $\nabla\lambda = \mathbf{0}$ is the equilibrium $(\Gamma, 1)$, and λ is nondegenerate.

From (3) with $2h - c - 1 = 0$, solving $\lambda = 0$, we get

$$z = \frac{-K(2h-1)}{2c}\left(\xi^2 - 2\xi\right).$$

This is a parabola opening to the left. It intersects the ξ-axis at $\xi = 0, \frac{c-1}{h-1}$. Since λ is constant along solutions, this parabola is a heteroclinic orbit.

By direct computation, $\lambda(1, \Gamma) = \frac{-\Gamma^{2h-1}}{(2h-2)(2h-1)}$. The orbits with $\frac{-\Gamma^{2h-1}}{(2h-2)(2h-1)} < \lambda < 0$ are nested periodic orbits in A that enclose convex regions containing $(1, \Gamma)$. This follows from differentiation of λ.

There are no equilibria outside $\overline{A}$. Hence, by the Poincaré–Bendixson theorem, all orbits outside of A are unbounded. By Lemma 5, all of these orbits approach $(0, \infty)$ in finite time. □

In conclusion we note that our system undergoes a degenerate Hopf bifurcation when $h < c$, $h > 1$, and $2h - c - 1$ changes sign. The equilibrium at $(K(1 - h/c), 1)$ changes from a spiral source for $2h - c - 1 > 0$ to a spiral sink for $2h - c - 1 > 0$. When such a transition occurs through a classic Hopf bifurcation, a single periodic orbit emerges from (or contracts to) the equilibrium point. The Hopf bifurcation theorem (see [7]) identifies a large class of conditions under which such bifurcations occur. Our system falls through the cracks of the theorem; the theorem applies to all systems except those whose Taylor coefficients at the equilibrium satisfy a certain equation, and the Taylor coefficients of our system satisfy that equation.

PROJECTIVE GEOMETRY OF HUMAN MOTION, WITH AN APPLICATION TO INJURY RISK*

H. LAURIE† AND R. PENNE‡

Abstract. We give an exposition of Plücker vectors for a system of joint axes in projective 3-space. We use Plücker vectors to analyze dependencies among joint axes and in particular to show that two rotational joints rigidly joined by a bar and each with 3 degrees of freedom always form a 5-dimensional system. We introduce the concept of reduced redundancy in a dependent set of projective Lines and argue that reduced redundancy in the axes of a body position increases injury risk. We apply this to a simple two-joint model of bowling in cricket and show by analysis of some experimental data that reduced redundancy around ball release is observed in some cases.

Key words. Plücker coordinates, human motion, reduced redundancy, injury risk

DOI. 10.1137/S0036139903429658

1. Introduction. A variety of techniques exist for the mathematical analysis of human motion, including techniques that are also used in robotics [15, 2]. However, to our knowledge, nobody has yet employed the formalisms and insights of projective geometry, well known in robotics [18, 3].

We are motivated by the analysis of certain complicated athletic effects achieved by throwlike motions, such as a topspin serve in tennis and an away-swinger in cricket. It is clear that the brief interval ending in the release of the ball is crucial: after release, the ball is in free fall, except for some aerodynamic and gyroscopic effects. Thus the athlete must release the ball in a particular state of motion (translational as well as rotational).

Several questions arise: By what movements of the joints does a given athlete achieve a given effect? Is there more than one way to achieve a given effect? Do some effects require motions that are inherently more risky than others, and if so, can this risk be characterized analytically?

Many of these questions can be illuminated by using techniques from the mathematics of robotics, in which the following are possible: a simple description which unifies all aspects of the motion of the athlete and the ball, a representation in which rotation and translation are easily combined, and a level of generality at which all cases of reduced mobility can be found (and explicitly calculated).

In this report, we analyze what appears to us be a simple, interesting case: the motion of a cricketer's arm (much simplified) near the moment of delivery. We regard the hips as fixed, the torso as rigid, and the waist and shoulder as joints, each of which provides 3 degrees of freedom. Alert readers will notice that we ignore the elbow, wrist, and fingers, as well as any contact motion of the ball in the hand prior to release. For our purposes, it is assumed that the requirements of a given delivery have prescribed the motion at the center of the wrist. However, we will see that in our

model in all positions there are only 5 degrees of freedom for the motion of the ball. Consequently, our system of 6 axes possesses intrinsic redundancy by design! It can be regarded as the solution of nature to the human desire to accomplish complicated motions. Indeed, kinematic redundancy offers an opportunity to distribute stress over many joints (see also [15]). Our main result is to prove the existence of special positions where *reduced redundancy* occurs: that is, for a given motion the amount of rotation about one or more joint axes is fixed, while there is some freedom in distributing motion about the remaining joint axes. These positions should not be confused with standard kinematic singularities, as no decrease of mobility is involved; 5 degrees of freedom are always maintained. We interpret reduced redundancy as a source of injury risk.

The paper is organized as follows: First, we describe the use of Plücker coordinates as a unified framework for computations concerning rotations and translations in many linked joints. Second, we describe a simplified model for the motion of an arm in the act of releasing a legal cricket delivery, a motion associated with risk of overuse injury [12, 14, 11]. Third, we analyze the degrees of freedom for the motion of the ball in this model, for the general case as well as all special cases; this includes a full analysis of reduced redundancy. Fourth, we discuss the analysis from two points of view: the prevention of injury and the forbidden motions of the wrist. Finally, we show that reduced redundancies indeed occur in real bowling actions by analyzing data from two bowlers with an injury history.

2. Plücker coordinates for human motion. Human motion is the result of rotations around joint axes, at least, infinitesimally in the first approximation (that is, neglecting the play in the joints and the deformation of bone, cartilage, and ligament). However, the desired motion of the end effector (in our case, the cricket ball) will in general have components of both rotation and translation. In projective geometry, translation can be rendered as rotation about an axis at infinity. In this view, all motions are rotations, and Plücker coordinates are merely a convenient way of describing them.

2.1. Projective points. In projective geometry, we identify all points on a line through the origin in $\mathbb{R}^4$ with a projective Point in the corresponding projective space $\mathbb{P}^3$. Thus the vector $\mathbf{x} = (\lambda a, \lambda b, \lambda c, \lambda d) \in \mathbb{R}^4$ corresponds to $\mathbf{p} \in \mathbb{P}^3$ for all $\lambda \neq 0$. Such a 4-vector is referred to as a set of homogeneous coordinates for $\mathbf{p}$. By the usual convention, the hyperplane $H{:}x_4 = 1$ in $\mathbb{R}^4$ is considered as (a copy of) affine 3-space. All Points of $\mathbb{P}^3$ which correspond to lines intersecting this hyperplane are called *finite points*, and these are identified with the affine point of H where they intersect. So for finite points,

$$(a, b, c, d) \sim (a/d, b/d, c/d, 1) \sim (a/d, b/d, c/d).$$

Notice that some lines through the origin in $\mathbb{R}^4$ do not intersect the hyperplane H, and therefore some projective Points are not finite. They are said to lie *at infinity*, and they are represented by homogeneous coordinates with 0 as the fourth coordinate: $(a, b, c, 0)$.

Similarly, planes through the origin of $\mathbb{R}^4$ correspond to Lines in $\mathbb{P}^3$. If such a plane is parallel to the hyperplane H, then it represents a Line at infinity. Finally, each 3-dimensional subspace of $\mathbb{R}^4$ is associated with a Plane in $\mathbb{P}^3$. The Plane corresponding to $x_4 = 0$ is the Plane at infinity of $\mathbb{P}^3$, and it contains all Points at infinity.

2.2. Plücker coordinates. From an algebraic point of view, a chosen set of homogeneous coordinates for a Point $\mathbf{p} \in \mathbb{P}^3$ represents a vector in the vector space $V = \mathbb{R}^4$. Now we can consider the *exterior algebra* built on V:

$$\wedge V = V^{(0)} \oplus V^{(1)} \oplus V^{(2)} \oplus V^{(3)} \oplus V^{(4)},$$

which enables us to make computations with scalars ($\mathbb{R} = V^{(0)}$), vectors ($V = V^{(1)}$), but also with more complicated objects called *antisymmetric tensors*, and this in the same framework. The *exterior product* $\wedge$ is a bilinear, antisymmetric operation on $\wedge V$, such that for $\mathbf{A} \in V^{(i)}$ and $\mathbf{B} \in V^{(j)}$ we get $\mathbf{A} \wedge \mathbf{B} \in V^{(i+j)}$ if $i + j \leq 4$ or $\mathbf{A} \wedge \mathbf{B} = \mathbf{0}$ otherwise (also in the case $i + j \leq 4$ it can happen that $\mathbf{A} \wedge \mathbf{B} = \mathbf{0}$ in $V^{(i+j)}$).

Example 1. The elements in $V^{(2)}$ (the so-called 2-tensors) are products $\mathbf{p} \wedge \mathbf{q}$ of vectors $\mathbf{p}$ and $\mathbf{q}$ in V, or linear combinations of these. Notice that $\mathbf{p} \wedge \mathbf{q} = \mathbf{0}$ in $V^{(2)}$ if $\mathbf{p}$ and $\mathbf{q}$ represent the same projective point, due to the antisymmetry.

For the reader who is not familiar with the exterior algebra it suffices to know for our purposes that each tensor can be regarded as just some vector, and $V^{(i)}$ as a real vector space of dimension $\binom{4}{i}$. For example, $V^{(2)} \cong \mathbb{R}^6$. Furthermore, using the standard basis of V, there is a canonical way to construct a basis for $V^{(i)}$. The corresponding coordinates arising in this manner for tensors are called *Plücker coordinates*.

Let us be more specific in the case of 2-tensors, because they will be needed most in this article. If $\mathbf{L} \in V^{(2)}$ then we have 6 Plücker coordinates for $\mathbf{L}$, by convention labeled by double-indices:

$$\mathbf{L} = (L_{12}, L_{13}, L_{14}, L_{23}, L_{24}, L_{34}).$$

In the special case that $\mathbf{L} = \mathbf{p} \wedge \mathbf{q}$ with $\mathbf{p} = (p_1, p_2, p_3, p_4)$ and $\mathbf{q} = (q_1, q_2, q_3, q_4)$, there is an easy rule to obtain the coordinates for $\mathbf{L}$: $L_{ij} = p_i q_j - p_j q_i$.

$$\mathbf{p} \wedge \mathbf{q} = \begin{pmatrix} p_1 q_2 - p_2 q_1 \\ p_1 q_3 - p_3 q_1 \\ p_1 q_4 - p_4 q_1 \\ p_2 q_3 - p_3 q_2 \\ p_2 q_4 - p_4 q_2 \\ p_3 q_4 - p_4 q_3 \end{pmatrix},$$

the elements of which are the 2×2 minors of the matrix $\left(\begin{smallmatrix} p_1 & p_2 & p_3 & p_4 \\ q_1 & q_2 & q_3 & q_4 \end{smallmatrix}\right)$ in lexicographic order. If $\mathbf{p}$ and $\mathbf{q}$ represent different projective Points, then $\mathbf{L} = \mathbf{p} \wedge \mathbf{q}$ represents the projective Line through these two Points. Of course, many other 2-tensors represent the same Line in $\mathbb{P}^3$. Indeed, we can use a multiple of $\mathbf{p}$ or $\mathbf{q}$ without changing the involved projective Points, or we can even choose another pair of Points on the same Line. Fortunately, the new 2-tensor $\mathbf{L}' = \mathbf{p}' \wedge \mathbf{q}'$ will always be a multiple of $\mathbf{L}$: $\mathbf{L}' = \alpha \mathbf{L}$. We conclude that the Plücker coordinates of $\mathbf{L}$ can be considered as a 6-tuple of homogeneous coordinates for the projective Line represented by $\mathbf{L}$. Notice that Lines at infinity are characterized by having Plücker coordinates with $L_{14} = L_{24} = L_{34} = 0$.

Because not every 2-tensor in $V^{(2)}$ can be written as the exterior product of two vectors in V, not every 6-tuple of Plücker coordinates represents a Line in $\mathbb{P}^3$. More precisely, one can prove that $(L_{12}, L_{13}, L_{14}, L_{23}, L_{24}, L_{34})$ corresponds to a projective line if and only if it differs from zero and the *Grassmann–Plücker relation* is satisfied:

$$L_{14} L_{23} - L_{24} L_{13} + L_{34} L_{12} = 0. \tag{GP}$$

Thus, "most" 6-tuples in $\mathbb{R}^6$ are not the Plücker coordinates of a projective Line. However, there is an interesting theorem, *Poinsot's central axis theorem*, which says that each 2-tensor $\mathbf{A}$ not obeying (GP) can be expressed as a sum $\mathbf{A} = \mathbf{L} + \mathbf{M}$ such that

1. $\mathbf{L}$ corresponds to a finite Line (not at infinity),
2. $\mathbf{M}$ corresponds to a Line at infinity,
3. Every affine Plane through $\mathbf{M}$ is perpendicular to $\mathbf{L}$.

Let us give one more illustration of Plücker coordinates. Given is a 2-tensor $\mathbf{A} = (A_{12}, A_{13}, A_{14}, A_{23}, A_{24}, A_{34})$ and a vector $\mathbf{p} =(p_1, p_2, p_3, p_4)$. Then $\mathbf{P} = \mathbf{A} \wedge \mathbf{p}$ belongs to the 4-dimensional space $V^{(3)}$: $\mathbf{P} = (P_{123}, P_{124}, P_{134}, P_{234})$, with

$$\begin{aligned} P_{123} &= A_{12}p_3 - A_{13}p_2 + A_{23}p_1, \\ P_{124} &= A_{12}p_4 - A_{14}p_2 + A_{24}p_1, \\ P_{134} &= A_{13}p_4 - A_{14}p_3 + A_{34}p_1, \\ P_{234} &= A_{23}p_4 - A_{24}p_3 + A_{34}p_2. \end{aligned}$$

In particular, if $\mathbf{A}$ represents a projective Line, which moreover does not contain the projective Point represented by $\mathbf{p}$, then $\mathbf{P}$ represents the projective Plane determined by this Line and this Point. If the Point lies on the Line, then $\mathbf{P} = \mathbf{0}$. In any case, if a 3-tensor differs from zero, it will represent a Plane in $\mathbb{P}^3$. Furthermore, it is the Plane at infinity if and only if $P_{124} = P_{134} = P_{234} = 0$. On the other hand, if $\mathbf{P} \in V^{(3)}$ represents a finite Plane, the vector $(P_{234}, -P_{134}, P_{124}) \in \mathbb{R}^3$ is perpendicular to the associated affine plane.

For a good introduction to Plücker coordinates and antisymmetric tensors, including the formal definitions, we refer to [18].

2.3. Dependencies among lines. A set of Lines in $\mathbb{P}^3$, finite or at infinity, is called independent (resp., dependent) if the corresponding 2-tensors are linearly independent (resp., dependent) in $V^{(2)}$ or, equivalently, if the corresponding Plücker coordinates are linearly independent (resp., dependent) in $\mathbb{R}^6$. These concepts are defined in algebraic terms; nevertheless, the possible dependencies among projective Lines have a transparent geometric characterization. We refer to [5] for a complete description of this. We quote only those situations that will be relevant for our analysis.

- Two Lines can only be dependent when they coincide.
- Three Lines are dependent if and only if they lie in the same Plane *and* go through the same Point.
- Four Lines are dependent if and only if at least one of the following cases occur:
  1. Three of the four Lines are dependent.
  2. The four Lines lie in the same Plane.
  3. The four Lines go through the same Point.
  4. Two of the Lines lie in a Plane α, intersecting in Point p, and the remaining two Lines lie in a Plane β, intersecting in Point q, such that the Planes α and β meet in the line pq.
  5. The four Lines belong to the same system of rulers on a quadratic surface.

In particular, if we are given two parallel Lines (intersecting at infinity), then a linear combination of their Plücker coordinates will always represent a Line in the

unique Plane through the given Lines, and which either lies at infinity, or which is parallel to the given Lines. Four parallel Lines in 3-space are always dependent.

Example 2. As an illustration, let us consider a situation of 4 Lines, with $\mathbf{L}_1, \mathbf{L}_2, \mathbf{L}_3$ concurrent (but not coplanar) through Point $\mathbf{p}$, and $\mathbf{L}_4$ not containing $\mathbf{p}$. Clearly, these 4 Lines are independent. By taking linear combinations of the 3 concurrent Lines we can generate any Line $\mathbf{L}$ through $\mathbf{p}$. Furthermore, if $\mathbf{L}$ happens to intersect $\mathbf{L}_4$ (in $\mathbf{q}$, say), then linear combinations of $\mathbf{L}$ and $\mathbf{L}_4$ generate Lines through $\mathbf{q}$, lying in the Plane determined by $\mathbf{L}$ and $\mathbf{L}_4$. If $\mathbf{L}$ and $\mathbf{L}_4$ do not intersect each other, then we cannot obtain new Lines by combining them (a violation of (GP)). We conclude that the Lines which depend on $\mathbf{L}_1, \mathbf{L}_2, \mathbf{L}_3, \mathbf{L}_4$, are exactly those that contain $\mathbf{p}$ or that lie in the Plane through $\mathbf{L}_4$ and $\mathbf{p}$.

Next, we will elaborate on a special case which will be important for the applications in this paper.

THEOREM 2.1. *Let* $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3$ *and* $\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3$ *be two triples of concurrent Lines in* $\mathbb{P}^3$ *through different Points* $\mathbf{w}$ *and* $\mathbf{s}$. *Assume moreover that* $\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3$ *are not coplanar, neither are* $\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3$. *Then the set* $\{\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3, \mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3\}$ *always has rank* 5. *Or more explicitly, these* 6 *Lines are always dependent but always contain a subset of* 5 *Lines which is independent.*

Proof. Choose a Plücker vector $\mathbf{P}$ to represent the Line $\mathbf{sw}$. By abuse of notation, we let $\mathbf{W}_1, \ldots, \mathbf{S}_3$ stand for the Plücker vectors of the corresponding lines as well. Then there exist linear combinations

$$\mathbf{P} = \alpha_1\mathbf{W}_1 + \alpha_2\mathbf{W}_2 + \alpha_3\mathbf{W}_3,$$
$$\mathbf{P} = \beta_1\mathbf{S}_1 + \beta_2\mathbf{S}_2 + \beta_3\mathbf{S}_3,$$

which gives rise to the claimed dependency:

$$\alpha_1\mathbf{W}_1 + \alpha_2\mathbf{W}_2 + \alpha_3\mathbf{W}_3 - \beta_1\mathbf{S}_1 - \beta_2\mathbf{S}_2 - \beta_3\mathbf{S}_3 = \mathbf{0}.$$

Next, we observe that at least one of $\{\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3\}$ does not pass through $\mathbf{w}$, say $\mathbf{S}_1$. From the example above we learn that $\{\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3, \mathbf{S}_1\}$ is a set of independent Lines, and moreover, the only Lines which are dependent on these 4 Lines are Lines through $\mathbf{w}$, or Lines in the Plane determined by $\mathbf{S}_1$ and $\mathbf{w}$. Because the triple $\{\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3\}$ is assumed to be nonplanar, it is impossible that both $\mathbf{S}_2$ and $\mathbf{S}_3$ depend on $\{\mathbf{W}_1, \mathbf{W}_2, \mathbf{W}_3, \mathbf{S}_1\}$, which completes the proof. ∎

2.4. Describing kinematics by Plücker coordinates. For a more extended exposition of the material presented in this paragraph, we refer to [18] and [4]. Consider a motion of a rigid body B in 3-space. Then, every point p of B traces a path, $p = p(t)$. If the motion is sufficiently *smooth* from a mathematical point of view, we can compute the derivative at a certain time t_0, giving us the infinitesimal motion of B at $t = t_0$. This results in a velocity vector $v_p = \dot{p}(t_0)$ for every point p of B. The rigidity of B can be translated into the statement that for every pair of its points $\{p, q\}$ the distance between these points must remain constant during the motion,

$$||p(t) - q(t)||^2 = \text{constant},$$

or infinitesimally (*preserved distance property*),

$$(v_p - v_q) \cdot (p - q) = 0. \tag{PDP}$$

From now on, when we use the term "motion," we always mean an infinitesimal rigid motion: the assignment of a velocity vector to every point of B such that (PDP) is

satisfied. Thus, we associate a vector v_p to every point p of B, taking (PDP) into account.

One important example of such a motion is a spatial rotation about the origin. Here, there is always a line A involved, the so-called axis of rotation, containing the origin. Points on A remain fixed (zero velocity vector), but for other points p the velocity v_p is perpendicular to the plane determined by A and p. As a matter of fact, the rotation is specified by a vector ω along A, such that $v_p = \omega \times p$ (vector cross product). The length of ω is called the angular velocity, and together with the distance of p from the axis A, it determines the length of v_p.

Another fundamental motion is a translation along a given vector v. Here, we have a constant velocity: for every point p we put $v_p = v$.

A crucial theorem says that every rigid motion is the composition of rotations and translations, or infinitesimally, the velocity vectors can be written as the sum of rotation velocities and/or translation velocities.

Consider a rotation about some axis A, not necessarily containing the origin. If we embed affine 3-space into $\mathbb{P}^3$, as described in section 2.1, then we can associate with A a projective line $\mathbf{A}$, and hence a Plücker vector $\mathbf{P}_A$. For each point p in $\mathbb{R}^3$ we choose the standard homogeneous coordinates for the associated projective point $\mathbf{p}$ (having $p_4 = 1$). Now we can define the "motion of $\mathbf{p}$" as the following 3-tensor:

$$M(\mathbf{p}) = \mathbf{M} = \mathbf{P}_A \wedge \mathbf{p} \in V^{(3)}.$$

To see that this makes sense, consider a vector $\mathbf{M} = (M_{123}, M_{124}, M_{134}, M_{234})$ of Plücker coordinates. This determines the vector $v_p = (M_{234}, -M_{134}, M_{124}) \in \mathbb{R}^3$, which is zero if $p \in A$, or else it is perpendicular to the plane determined by p and A. And indeed, as one can prove that (PDP) holds for these vectors, they represent a rotation about axis A. The unused coordinate M_{123} in $M(\mathbf{p})$ is determined by the fact that this 3-tensor corresponds to a plane through $\mathbf{p}$. Of course, the magnitude of the vectors v_p depends on the chosen Plücker coordinates $\mathbf{P}_A$ for $\mathbf{A}$, but then again there are an infinite number of possible rotations about axis A in $\mathbb{R}^3$. One can say that the magnitude of the chosen Plücker vector accounts for the involved angular velocity. We conclude that the 2-tensor $\mathbf{P}_A$ encodes both the rotation axis A and the angular velocity. Therefore, it is called the *center* of the motion. Taking a multiple of $\mathbf{P}_A$ does not change the axis, only the angular velocity. If you are interested in the velocity of a specific point p under this motion, just perform the exterior product $\mathbf{P}_A \wedge \mathbf{p}$, using standard homogeneous coordinates for $\mathbf{p}$.

Now that we have put spatial rotations in the setting of projective geometry, we can extend the notion of rotation axis. Indeed, we can take $\mathbf{A}$ to be a line at infinity, so if $\mathbf{P} = \mathbf{P}_A$, then $\mathbf{P}_{14} = \mathbf{P}_{24} = \mathbf{P}_{34} = \mathbf{0}$. If we copy the previous computations for some point p, we observe, surprisingly, that the last three Plücker coordinates of $M(\mathbf{p})$ do not depend on p. Therefore, we see that v_p is a constant vector if we perform a rotation about an axis at infinity, which must be a translation! More precisely, $v_p = (\mathbf{P}_{23}, -\mathbf{P}_{13}, \mathbf{P}_{12})$, a vector which is perpendicular to any plane in $\mathbb{R}^3$ whose projective extension contains the given axis at infinity $\mathbf{A}$. For the sake of uniformity, we will again call the 2-tensor $\mathbf{P}_A$ the center of the motion, and the 3-tensor $M(\mathbf{p})$ the motion itself of the point p.

Our arguments will directly take place in $\mathbb{P}^3$ or $\wedge\mathbb{R}^4$, but readers who like to switch to affine space now and then should remember

$$\begin{aligned} p = (p_1, p_2, p_3) &\longrightarrow \mathbf{p} = (p_1, p_2, p_3, 1), \\ v_p = (M_{234}, -M_{134}, M_{124}) &\longleftarrow M(\mathbf{p}) = (M_{123}, M_{124}, M_{134}, M_{234}). \end{aligned}$$

In this setting, the zero-tensor in $V^{(3)}$ corresponds to the zero velocity.

As mentioned before, composing two motions comes down to adding the velocity vectors in each point p. Let the corresponding centers of motion be denoted by $\mathbf{C}_1$ and $\mathbf{C}_2$, Plücker vectors in $\mathbb{R}^6$. Then the resulting motion of p equals

$$\mathbf{C}_1 \wedge \mathbf{p} + \mathbf{C}_2 \wedge \mathbf{p} = (\mathbf{C}_1 + \mathbf{C}_2) \wedge \mathbf{p}$$

due to a basic property of the exterior product. Now we can consider $\mathbf{C} = \mathbf{C}_1 + \mathbf{C}_2$ to be the center of the composite motion. This means that every Plücker vector $\mathbf{P}$ in $\mathbb{R}^6$ can play the part of a center of some motion. More precisely, if $\mathbf{P}$ represents a projective Line (satisfying (GP)), then it gives rise to a rotation (finite line) or a translation (line at infinity); otherwise it is the center of a composition of rotations and translations. As a consequence of Poinsot's central axis theorem (section 2.2) we can be even more specific in the latter case. To this end, we define a *screw motion* as the composition of a rotation (infinitesimal, of course) about some axis, and a translation (ditto) along the same axis. **If a motion is not a pure translation or rotation, then it is a screw motion.**

From now on, Plücker coordinates of 2-tensors (the space $\mathbb{R}^6$) are interpreted as centers of infinitesimal rigid motions.

3. A simple model for bowling a cricket delivery. Biomechanical models for cricket motions are not that rare, but few exist for bowling [1, 11]. For our purposes, a model simpler than either of these will suffice. We make the following assumptions about motion just prior to delivery:

1. There is no rotation in the elbow (as is required in a legal delivery).
2. There is no rotation in the wrist, and the state of motion of the ball upon release prescribes the motion of the so-called tool center (a term from robotics), which we take to be the wrist.
3. The spine is taken as rigid but free to rotate as if its base is attached to the pelvis in a ball joint (i.e., we ignore deformation of the torso), and the shoulder is rigidly joined to the spine.
4. The joint axes of both joints pass through the center of the joint.

For greater realism, one might add more joints; for example, it is known that the shoulder does rotate relative to the torso [8], and the ball might leave the hand in a contact motion. This is not conceptually difficult but is computationally and experimentally challenging. The same applies to relaxing assumption 4, to allow noncoincident joint axes. Still more challenging would be the direct modeling of muscle groups (as in [6, 16]), as this would increase the number of axes of rotation substantially, and one might be hard put to identify an axis of rotation for every muscle group, particularly those with attachments over more than one joint.

3.1. Introducing the joint axes of our model. With assumptions 1 to 4, the system reduces to two joints, which we call the waist (w) and the shoulder (s). Although in general w may be in motion, there is no loss of generality if we place w at the fixed origin and identify its joint axes with axes of a reference coordinate system XYZ. They are interpreted as follows: for a person standing, X points horizontally forward, Y horizontally points to the left, and Z points vertically along the spine, in our case upwards.

We choose units of length so that the right shoulder joint s is at $(0, -1, 1)$ in the system; since the torso is rigid, it stays there. The three joint axes through s follow the usual convention: We choose S_1 as the axis that passes through shoulder and

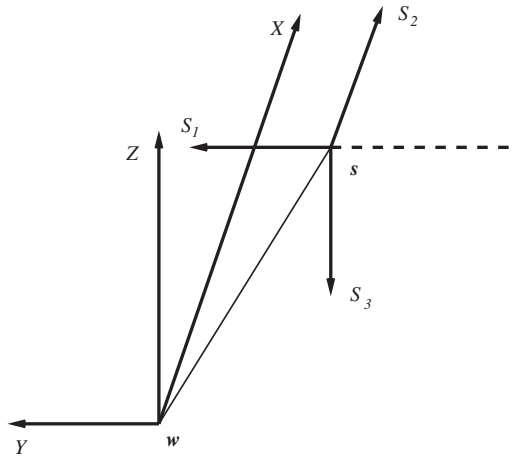

FIG. 3.1. *Configuration of joint axes in our simplified model of a right-handed cricket bowler, facing away from the reader.* **w** *is the waist joint and* **s** *is the shoulder joint. Distances are normalized so that the shoulder is at* $(0, -1, 1)$ *in the waist joint axes. The dashed line corresponds to the arm in standard position: horizontal, palm down. Note that the shoulder axes move with the arm so that* S_3 *is always pointing in the same direction as the palm.*

elbow, in the direction of the shoulder, and S_2, S_3 perpendicular to each other and to S_1 so that when the arm is extended sideways horizontally wrist down, S_2 points forwards and S_3 points downwards. This means that the $S_1S_2S_3$ system moves with the arm, and in particular that S_3 is always perpendicular to the palm. The general configuration is illustrated in Figure 3.1.

We note that some of our results below depend on the choice of shoulder axes. In particular, we find a case where rotation about the s_3 axis plays a significant role in predicting injury risk. This would be indefensible if all we knew of the shoulder joint was that it had 3 degrees of rotational freedom, because our result would disappear under many other apparently equivalent choice of axes.

However, we do know more about how the shoulder moves and about the motion of the arm of a fast bowler near the point of release. In that context, the $s_1s_2s_3$ system as described above is preferred and has intrinsic interpretation for two reasons. First, s_1 is an anatomically intrinsic axis in all rotations of the shoulder, because of the role of the rotator cuff, which are the only muscles that cause rotation around s_1. Second, during the final phase of the delivery of a fast ball in cricket, the bowler's arm moves in a plane. Near the moment of release, the direction of s_3 is tangential to this motion (since these bowlers aim for high speed deliveries), so the plane of motion is the s_1s_3 plane, and in that plane the motion is a pure rotation around the s_2 axis. By orthogonality to both the s_1 and s_2 axes, the s_3 axis is also intrinsic.

3.2. Plücker coordinates of the 6 joint axes. The positions of the waist and the shoulder are given by

$$w = \begin{pmatrix} 0 & 0 & 0 & 1 \end{pmatrix} \qquad \text{and} \qquad s = \begin{pmatrix} 0 & -1 & 1 & 1 \end{pmatrix}.$$

The directions of the joint axes are

$$\begin{aligned} W_1 &= \begin{pmatrix} 1 & 0 & 0 & 0 \end{pmatrix}, \\ W_2 &= \begin{pmatrix} 0 & 1 & 0 & 0 \end{pmatrix}, \\ W_3 &= \begin{pmatrix} 0 & 0 & 1 & 0 \end{pmatrix}, \\ S_1 &= \begin{pmatrix} a_1 & b_1 & c_1 & 0 \end{pmatrix}, \\ S_2 &= \begin{pmatrix} a_2 & b_2 & c_2 & 0 \end{pmatrix}, \\ S_3 &= \begin{pmatrix} a_3 & b_3 & c_3 & 0 \end{pmatrix}. \end{aligned}$$

The six centers of rotation are then

$$\begin{aligned} P_1 = W_1 \wedge w &= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 & 0 & 0 & 0 \end{pmatrix}, \\ P_2 = W_2 \wedge w &= \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 & 1 & 0 \end{pmatrix}, \\ P_3 = W_3 \wedge w &= \begin{pmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix}, \\ P_4 = S_1 \wedge s &= \begin{pmatrix} a_1 & b_1 & c_1 & 0 \\ 0 & -1 & 1 & 1 \end{pmatrix} = \begin{pmatrix} -a_1 & a_1 & a_1 & b_1 + c_1 & b_1 & c_1 \end{pmatrix}, \\ P_5 = S_2 \wedge s &= \begin{pmatrix} a_2 & b_2 & c_2 & 0 \\ 0 & -1 & 1 & 1 \end{pmatrix} = \begin{pmatrix} -a_2 & a_2 & a_2 & b_2 + c_2 & b_2 & c_2 \end{pmatrix}, \\ P_6 = S_3 \wedge s &= \begin{pmatrix} a_3 & b_3 & c_3 & 0 \\ 0 & -1 & 1 & 1 \end{pmatrix} = \begin{pmatrix} -a_3 & a_3 & a_3 & b_3 + c_3 & b_3 & c_3 \end{pmatrix}. \end{aligned}$$

We collect these in the columns of the motion matrix M:

$$M = \begin{pmatrix} 0 & 0 & 0 & -a_1 & -a_2 & -a_3 \\ 0 & 0 & 0 & a_1 & a_2 & a_3 \\ 1 & 0 & 0 & a_1 & a_2 & a_3 \\ 0 & 0 & 0 & b_1 + c_1 & b_2 + c_2 & b_3 + c_3 \\ 0 & 1 & 0 & b_1 & b_2 & b_3 \\ 0 & 0 & 1 & c_1 & c_2 & c_3 \end{pmatrix}.$$

All the information regarding configurations of the joints and possible motions can be found by analyzing M. More precisely, infinitesimally, the motion of the wrist is a composition of a rotation about w and a rotation about s (in our model). Thus, the center of this motion is a linear combination of the six Plücker coordinates which we assigned to the six given axes. This motivates us to define the column space of the matrix M to be the *motion space* (of the wrist in the given position of the human body), $\mathbb{MS}$. Recall from Theorem 2.1 that the matrix M always has rank equal to 5, implying a constant dimension of 5 for the motion space. Notice that we never obtain the full $\mathbb{R}^6$ as motion space in our model; this would require including further rotations in our model, such as about the elbow or the wrist.

3.3. Possible motions under the model. Suppose the human body (in particular, the torso and the bowling arm) is in a certain position. If one intends to propel the ball in some specific way, then this is accomplished by performing an infinitesimal motion with the hand. In our model, the only way to realize a hand motion is by means of rotations about the waist (3 joint axes) and/or about the shoulder (3 joint

axes). Every (infinitesimal) rotation about one of these 6 axes is given by an appropriate multiple of the corresponding Plücker vector. We conclude that the motion of the ball is controlled by a 2-tensor which is a linear combination of the 6 Plücker vectors of our model; that is, it belongs to the column space of the matrix M ($\mathbb{MS}$). In particular, a linear combination which gives the zero 2-tensor corresponds to not moving at all (the zero center of motion).

Clearly, the first two rows of M are equal in magnitude but opposite in sign. This implies that every possible motion is represented by a 2-tensor with opposite Plücker coordinates in the first two places,

$$\mathbf{B} = (-a, a, b, c, d, e),$$

or equivalently, a possible motion is a point of $\mathbb{R}^6$ in the hyperplane $\mathbb{H} : p_{12} = -p_{13}$, so $\mathbb{MS} \subset \mathbb{H}$. Furthermore, since both spaces have dimension 5, we can state that $\mathbb{MS} = \mathbb{H}$.

Example 3. Try to perform a *pure* translation with your hand along the Z-axis (the direction of the spine) by only using the waist joint and the shoulder joint. You will not succeed! The algebraic proof for this goes as follows. Each translation along Z is represented by a set of Plücker coordinates of the line at infinity of the XY-plane. This means that it is a multiple of

$$(1, 0, 0, 0) \wedge (0, 1, 0, 0) = (1, 0, 0, 0, 0, 0),$$

which is not a possible motion, because it does not belong to $\mathbb{H}$.

Example 4. In an analogous fashion we see that a *pure* translation along the Y-axis is not possible. Indeed, such a translation is always represented by a multiple of $(0, 1, 0, 0, 0, 0)$, the Plücker vector for the line at infinity of the XZ-plane.

Example 5. However, a translation along the X-axis appears to be possible (this is the direction perpendicular to the plane of the torso; fortunately for cricketers, this direction is the one they want the ball to go). Indeed, the corresponding 2-tensor is a multiple of $(0, 0, 1, 0, 0, 0)$, the line at infinity of YZ; hence it belongs to $\mathbb{MS}$. But how can this be accomplished in practice? Let L be the line through s and parallel to Y. Because the Plücker vector of L is a linear combination of the Plücker vectors of S_1, S_2, and S_3, any rotation about L can be realized. Notice that L lies in the YZ-plane, as does the shoulder joint s in our model. Because Y and L intersect at infinity, an appropriate linear combination of their Plücker vectors yields the line at infinity of YZ. We conclude that a pure translation along X can be realized by composing a rotation about Y and a rotation about L.

Forbidden motions are interesting for two reasons. First, they are a simple way of describing what is possible. Second, they have an associated injury risk: attempting forbidden motion will introduce extremely large stresses, and coming close to forbidden motion (in the sense of a path through the motion space) may also require large stresses, a well-known phenomenon in robotics [3].

3.4. Critical positions of the human body. In our model, the possible motions are supported by six joint axes, each with a natural physical interpretation. Giving the spatial positions of these six axes determines what we will call the "position of the human body." In the previous sections we explained that our analysis of cricket bowling comes down to exploring the linear relations between the Plücker coordinates of these six axes. To simplify computations we are entitled to make the fixed coordinate frame coincide with the three waist axes, and that is what we did in

section 3.2, yielding the simple structure of matrix M. So, in fact, by describing a body position we will mean the specification of the relative position of the shoulder axes with respect to the waist axes. It needs 3 parameters to be specified in order to fix the orientation of $S_1S_2S_3$ relative to $W_1W_2W_3$ $(= XYZ)$, for example the 3 Euler angles. Thus the very limited positions of the human body relevant to this paper can be regarded as points in a 3-dimensional space **Pos**.

3.5. Redundancy and supports. As a consequence of Theorem 2.1 we know that, in each position of the body, our six joint axes span a 5-dimensional space ($\mathbb{MS}$). We say that our kinematic system has a *generic redundancy*. Further, still in each position, basic linear algebra teaches us that we have a 1-dimensional space of linear dependencies between our six 2-tensors $(6 - 5 = 1)$. Redundancy in a model for human motion is also treated in [15], where the emphasis is also on the potential for fatigue management but the operational definition and mathematical treatment are different.

DEFINITION 3.1. *The* support *of a linear dependency among a set A of vectors is the subset of A consisting of exactly those vectors with nonzero coefficient in this dependency.*

In a given position of the body, each (nontrivial) linear dependency of the six joint axes is a multiple of every other one. Thus, we can define merely the "support of a body position" without specifying the linear dependency. Notice that, whatever position we are in, we always use the same notation for our six joints axes; hence the support can always be considered as a subset of $J = \{X, Y, Z, S_1, S_2, S_3\}$. This can be mathematically encoded in a map:

$$\mathbf{supp} : \mathbf{Pos} \to 2^J : p \mapsto \mathbf{supp}(p).$$

Before proceeding, let us explain the relevance of the this concept. Suppose the body is in some position p. Let $\mathbf{M} = (M_{12}, M_{13}, M_{14}, M_{23}, M_{24}, M_{34})$ be the motion in $\mathbb{MS}$ that we want to perform. This is achieved by finding appropriate coefficients (angular velocities):

$$\mathbf{M} = \alpha\mathbf{X} + \beta\mathbf{Y} + \gamma\mathbf{Z} + \sigma_1\mathbf{S}_1 + \sigma_2\mathbf{S}_2 + \sigma_3\mathbf{S}_3,$$

where the bold font reminds us of the fact that we switched to Plücker vectors (or 2-tensors). Now suppose that $\mathbf{supp}(p) = \{Y, Z, S_3\}$, corresponding to the following relation:

$$\lambda\mathbf{Y} + \mu\mathbf{Z} + \nu\mathbf{S}_3 = \mathbf{0}$$

with nonzero coefficients λ, μ, ν. Then we can realize the same motion $\mathbf{M}$ as

$$\mathbf{M} = \alpha\mathbf{X} + (\beta + k\lambda)\mathbf{Y} + (\gamma + k\mu)\mathbf{Z} + \sigma_1\mathbf{S}_1 + \sigma_2\mathbf{S}_2 + (\sigma_3 + k\nu)\mathbf{S}_3$$

with k an arbitrary constant. This means that the efforts done by Y, Z, and S_3 can be traded among each other, while the contributions by X, S_1, and S_2 are given by fixed coefficients with no chance for compensation. From this we learn two important things:

1. The concept of redundancy of joint axes is inherent to the human body. It is the solution supplied by nature to distribute the necessary efforts among the several joints for achieving a certain motion.
2. Positions in which the human body has abundant support are less strenuous than positions with limited support.

3.6. Critical positions. Now we arrive at the core of this paper. We will classify the possible supports in our model. A position of the human body is called *critical* if the support is smaller than expected, that is, smaller than in generic positions. We say that a critical position suffers from *redundancy with reduced support* or shortly, *reduced redundancy*. Our first observation says that the required work for joint axis X can never be compensated by one of the other five axes.

THEOREM 3.2. *For each position* $p \in \mathbf{Pos}$ *we have that* $X \notin \mathbf{supp}(p)$.

Proof. Since the shoulder joint s is assumed to lie in the YZ-plane, the Line $\mathbf{L} = sw$ is a linear combination of $\mathbf{Y}$ and $\mathbf{Z}$. And of course, $\mathbf{L}$ is a linear combination of $\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3$; hence the set $\{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}, \mathbf{Y}, \mathbf{Z}\}$ is dependent. Because the motion space $\mathbb{MS}$ has dimension 5 in every position, $\mathbf{X}$ cannot be a linear combination of $\mathbf{S}_1, \mathbf{S}_2, \mathbf{S}_3, \mathbf{Y}, \mathbf{Z}$; hence, it does not belong to the support. □

THEOREM 3.3. *Let* p *be a position of the human body. We distinguish three cases for the Line* $\mathbf{L} = sw$.

1. *The Line* $\mathbf{L}$ *is not contained in a plane determined by any two Lines of* $\{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}\}$. *In this case*
$$\mathbf{supp}(p) = \{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}, \mathbf{Y}, \mathbf{Z}\}.$$
2. *The Line* $\mathbf{L}$ *does not coincide with a line of* $\{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}\}$, *but it lies in the plane generated by two of them (*$\mathbf{L} \in \mathbf{S_i S_j}$*). Then*
$$\mathbf{supp}(p) = \{\mathbf{S_i}, \mathbf{S_j}, \mathbf{Y}, \mathbf{Z}\}.$$
3. *The Line* $\mathbf{L}$ *coincides with one of* $\{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}\}$ *(i.e.,* $\mathbf{L} = \mathbf{S_i}$*). Then*
$$\mathbf{supp}(p) = \{\mathbf{S_i}, \mathbf{Y}, \mathbf{Z}\}.$$

Proof. The claims are an immediate consequence of what is said in section 2.3.

In case 3, if $\mathbf{L} = \mathbf{S_i}$, then the Lines $\mathbf{Y}, \mathbf{Z}, \mathbf{S_i}$ are concurrent and coPlanar, and so they are dependent. The support cannot be smaller, because this would mean that at least two of these lines coincide.

In case 2, either Lines $\mathbf{S_i}, \mathbf{S_j}, \mathbf{Y}, \mathbf{Z}$ are coPlanar or the pairs $\{\mathbf{Y}, \mathbf{Z}\}$ and $\{\mathbf{S_i}, \mathbf{S_j}\}$ determine two Planes that meet in the line $\mathbf{sw}$ through their intersections. In both cases, the four Lines are dependent. Furthermore, no three of them are concurrent, implying that the support is not smaller.

In case 1, we can rule out the five possibilities for the dependency of four lines (section 2.3). We refer to Theorem 3.2 for the claim that $\{\mathbf{S_1}, \mathbf{S_2}, \mathbf{S_3}, \mathbf{Y}, \mathbf{Z}\}$ is a dependent set. □

Remark. Cases 2 and 3 of the previous theorem correspond to the critical positions of our model.

4. Reduced redundancy as injury risk. It is known that high levels of fitness are attained in many cricketers [13]; nevertheless, injuries are fairly common [10] and fatigue may play a significant role [7]. This is not the place to review the mechanisms of overuse injury (the interested reader is referred to [17] as a starting point). We adopt the common perspective that overuse injuries start as microinjuries such as bruised bone and microtorn ligament. We suggest that overuse is more likely in situations of reduced redundancy. In such cases, no compensation that reduces the strain on a microinjured site is possible. The subject, in repeating the action, is condemned to repeating, at the same intensity, a motion that already caused a microinjury. By contrast, the ability to achieve a desired motion with a range of different

joint rotations amounts to having the option of avoiding a motion that has caused a microinjury. The probability of overuse injury should decrease; hence, redundancy should correlate with reducing the risk of overuse injury. If so, then bowlers whose body position at ball release has more reduced redundancy than others should be at higher risk of injury, because such bowlers are less able to adapt. We also assume that microinjury is more likely in fatigued tissues, and hence adopt the view that reducing the probability of overuse injury is equivalent to reducing fatigue.

4.1. The role of the various joint axes. We interpret a joint axis that does not belong to the support in a given body position as a "necessary" axis of that position.

The joint axis X is through the "waist" joint and perpendicular to the pelvis; it is more or less parallel to the direction of the ball around the time of release. It is always a necessary axis, so for a particular desired motion, the amount of sideways bending of the spine is prescribed.[1] One implication of this is that injury risk due to this motion cannot be modified.

We noted above that a largely supported redundancy should help to reduce fatigue. Similarly, if an axis is necessary then no fatigue management can reduce the rate of tiring in structures involved in rotations around it. While the human body will have many more joint axes, our analysis suggests that bowlers will find it hard to compensate for fatigue related to rotation around the X-axis. Anecdotal evidence suggests that bowlers may attempt compensation by "falling over" as they tire. However, studies on changes in bowling action over long spells [9] have not reported rotation around this axis, so no scientific judgment is possible.

In critical positions we even suffer from reduced redundancy. The calculations for reduced redundancy depend on the choice of shoulder axes. We argued above that the s_1 axis is anatomically an intrinsic axis of rotation and that s_2 is dynamically an intrinsic axis of rotation for fast bowlers, because the motion of the arm is in the s_1s_3 plane around the time of delivery of a fast ball.

In the bowling of a cricket fast ball, the worst-case scenario of reduced redundancy is that S_1 passes through the waist joint, which corresponds to case 3 above and implies that rotation about the other two shoulder axes are prescribed in all motions. Let us consider the simplest (and also most common) example: a straight arm. For such bowlers, the most risky action is one in which wrist, elbow, shoulder, and waist all lie on the same line very near or at the moment of delivery. Their ability to modify the amount of rotation will be limited to axes S_1, Y, and Z; thus one expects overuse injury related to such rotations to be less common. So for them tradeoffs are only possible among axial rotations of the arm, twisting of the spine, and bending forward at the waist. On the other hand, coaches need to be aware that changing the rotation in one of these axes will cause compensation in the other two axes.

We note that this situation is avoided by releasing the ball either behind or in front of the plane of the torso (more on this below) by a round-arm action, where S_1 is nearer to horizontal, and by a very upright action, where S_1 is nearer to vertical. Vertical action is usually encouraged by coaches but in some cases may tend to align the wrist with shoulder and waist and so increase injury risk.

Furthermore, Y and Z are never necessary, so that the amount of twisting and bending (backwards/forwards, that is) can be modified. Thus, in case of excessive

[1]Some care is needed here: In our model, bending of the spine is approximated by rotation of an inflexible spine in the "waist" joint. It may be that more than one pattern of rotations of vertebrae can achieve the desired rotation.

rotation in these directions at the waist, it should be possible to modify the bowler's action to reduce these, no matter what the configuration of their joints at the moment of delivery. For instance, excessive twisting around the Z-axis during the delivery stride is currently regarded as a major source of injury risk (the "mixed" action, which starts with hips and shoulders facing forwards; then the shoulders rapidly rotate and counterrotate—see [9, 12] and many others). Our study suggests that bowlers using a mixed action should be able to change action with relative ease.

Finally, is it possible to deliver a cricket ball with a maximally supported redundancy? Yes, but such actions are unusual and discouraged by coaches. The Line $\mathbf{L}$ in the analysis above corresponds to the line through waist and shoulder; it is required that this line be perpendicular to none of the shoulder joint axes. For instance, suppose that at delivery, the X and S_3 axes are parallel (certainly an aim in some deliveries by fast- and medium- pace bowlers). Then the wrist should not be in the plane formed by spine and shoulder (otherwise case 2 applies: $\mathbf{L}$ perpendicular to $\mathbf{S}_2$ or, equivalently, $\mathbf{L}$ is a linear combination of $\mathbf{S_1}$ and $\mathbf{S_3}$). So these bowlers should deliver such balls from behind or in front of the torso (the former seems to be common). The other axes have similar requirements. $\mathbf{L}$ perpendicular to $\mathbf{S}_1$ would be an excessively round-arm action and perhaps unlikely (though it could occur in the slinging action of some fast bowlers). $\mathbf{L}$ perpendicular to $\mathbf{S}_3$ is perhaps harder to avoid but should still be rare; for instance a round-arm action with the palm down at the moment of release, which might occur in some spin bowling actions.

4.2. An example. We give an analysis of the action of two medium-fast bowlers, both from the youth academy and hence at risk of injury, as potentially elite medium-fast or fast bowlers. The data were kindly provided by Janine Gray of Sports Science Institute of South Africa, who collected the data on these two bowlers as part of a larger study. Both subjects were 17 years old and free of injury at the time the data were collected. Bowler B had a long history of injuries, some of them from noncricket activities. In particular, he had suffered a stress injury to the lower back, which was seen as due to cricket. Bowler A had never been injured. Their historical workloads were different—Bowler B had played cricket from early boyhood, while Bowler A was a recent recruit to the game.

For each bowler, reflectors were attached to the body surface. Under stroboscopic lighting (frequency 120 Hz), video cameras recorded the positions of the reflectors at intervals (interval length about 8 milliseconds). The following reflectors were used in the calculation below: two on the wrist, one on the shoulder, and three on the waist. The three waist coordinates were assumed to lie at the vertices of a symmetric trapezium, and the center of its circumrectangle was calculated to give w, the center of the waist joint. In calculating s, the center of the shoulder joint, we assumed that the shoulder is fixed relative to the waist, so a simple correction allowed us to move from the position of the reflector on the acromion to s. The midpoint of the two reflectors on the wrist provided the position of r, the center of the wrist. In Figures 4.1 and 4.2 we depict aspects of the raw data: wrist position as a function of time for both bowlers.

Calculation of redundancy then proceeds as follows. The simple subtraction $w-s$ and normalization gave us the unit vector $\mathbf{l}$, which gives the direction of the Line $\mathbf{L}$ through waist and shoulder. Similarly, $s-r$ gives $\mathbf{s_1}$, the direction of S_1. Since the wrist reflectors lie in the S_1S_2-plane as does $\mathbf{s_1}$, simple orthogonalization gives $\mathbf{s_2}$, and $\mathbf{s_3}$ is then available as the cross-product of $\mathbf{s_1}$ and $\mathbf{s_2}$. The dot products of $\mathbf{l}$ with the $\mathbf{s_i}$ are then calculated, giving the direction cosines of $\mathbf{l}$ in the $S_1S_2S_3$ axes. When

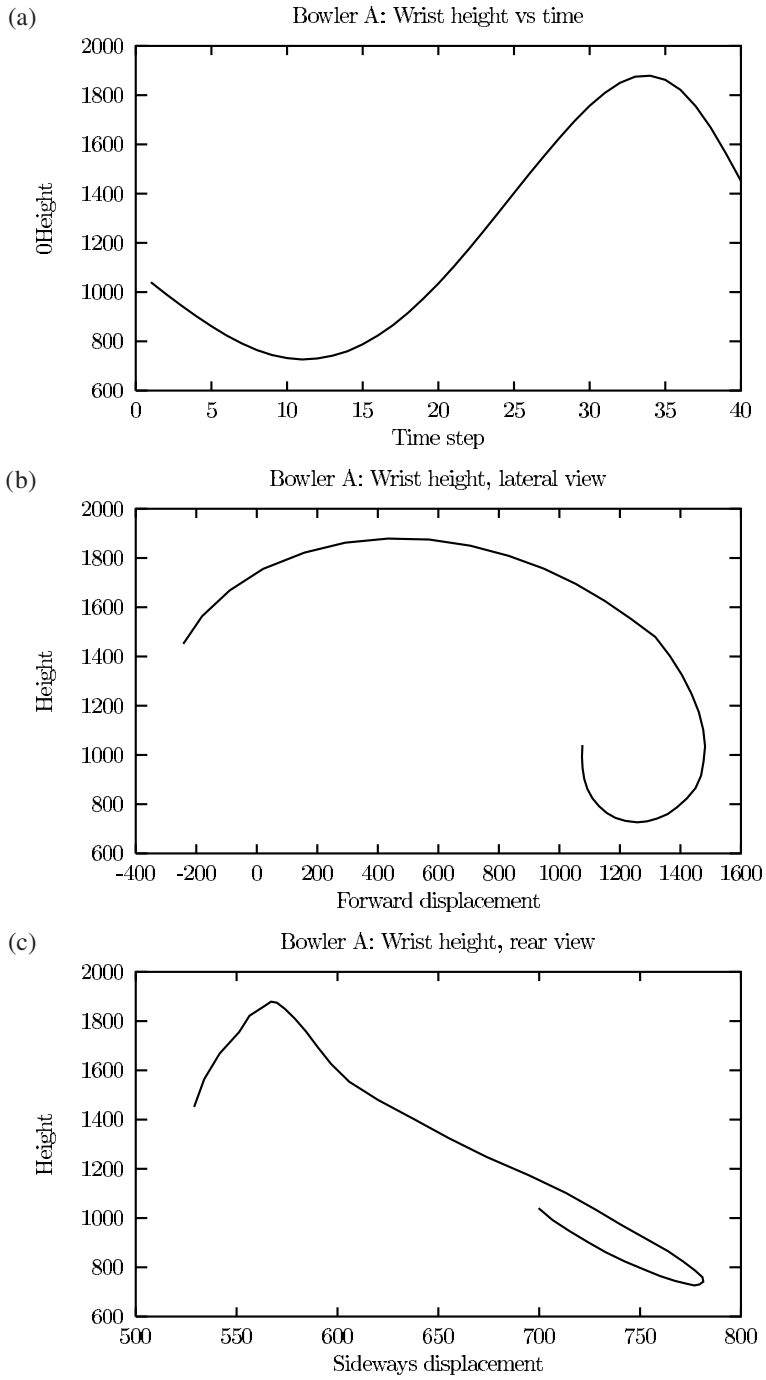

FIG. 4.1. *Wrist position as a function of time for Bowler A. The three diagrams give different aspects.* (a) *Wrist height as a function of time.* (b) *Wrist path in the YZ-plane (movement is leftward on diagram).* (c) *Wrist path in the XZ-plane. Height and displacement in millimeters; time steps* 0.83 *milliseconds apart.*

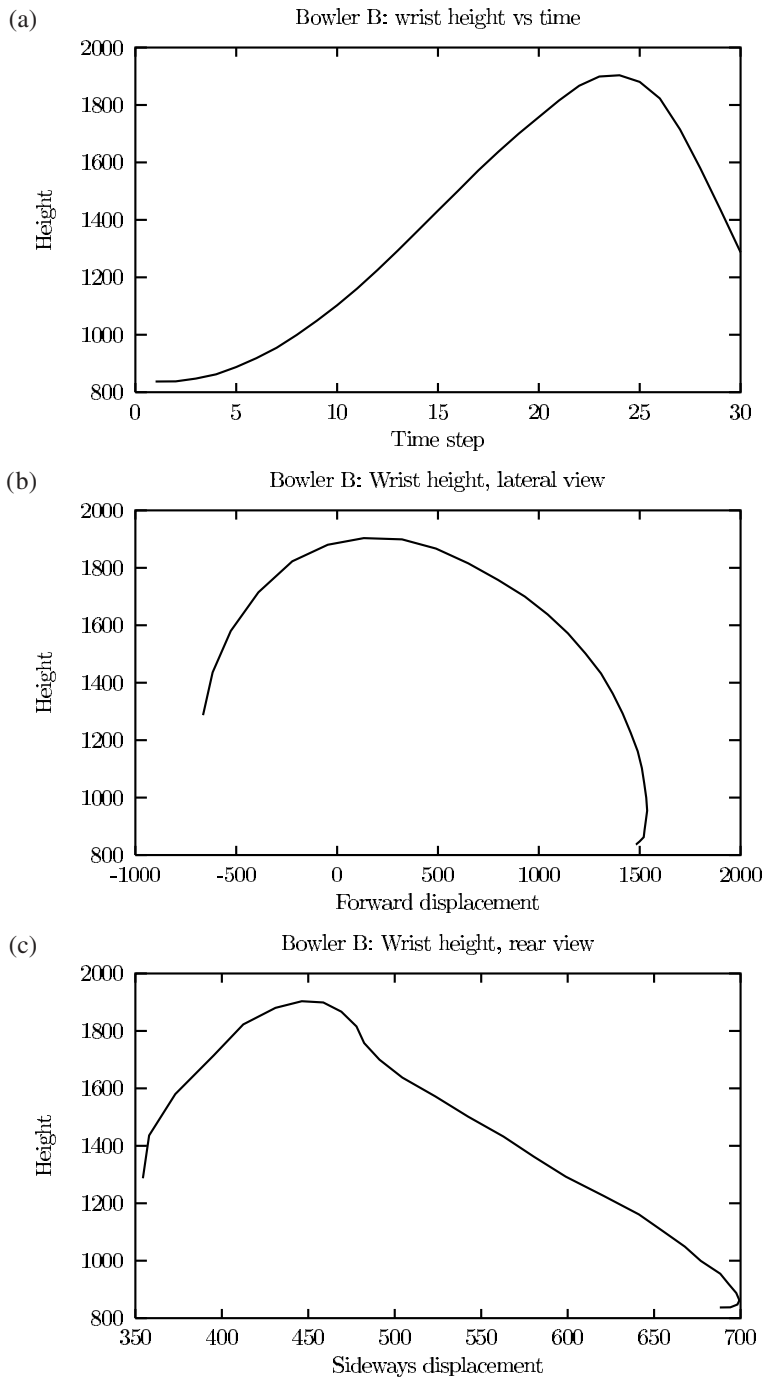

FIG. 4.2. *Wrist position as a function of time for Bowler B. The three diagrams give different aspects.* (a) *Wrist height as a function of time.* (b) *Wrist path in the* YZ*-plane.* (c) *Wrist path in the* XZ*-plane. Height and displacement in millimeters; time steps* 0.83 *milliseconds apart.*

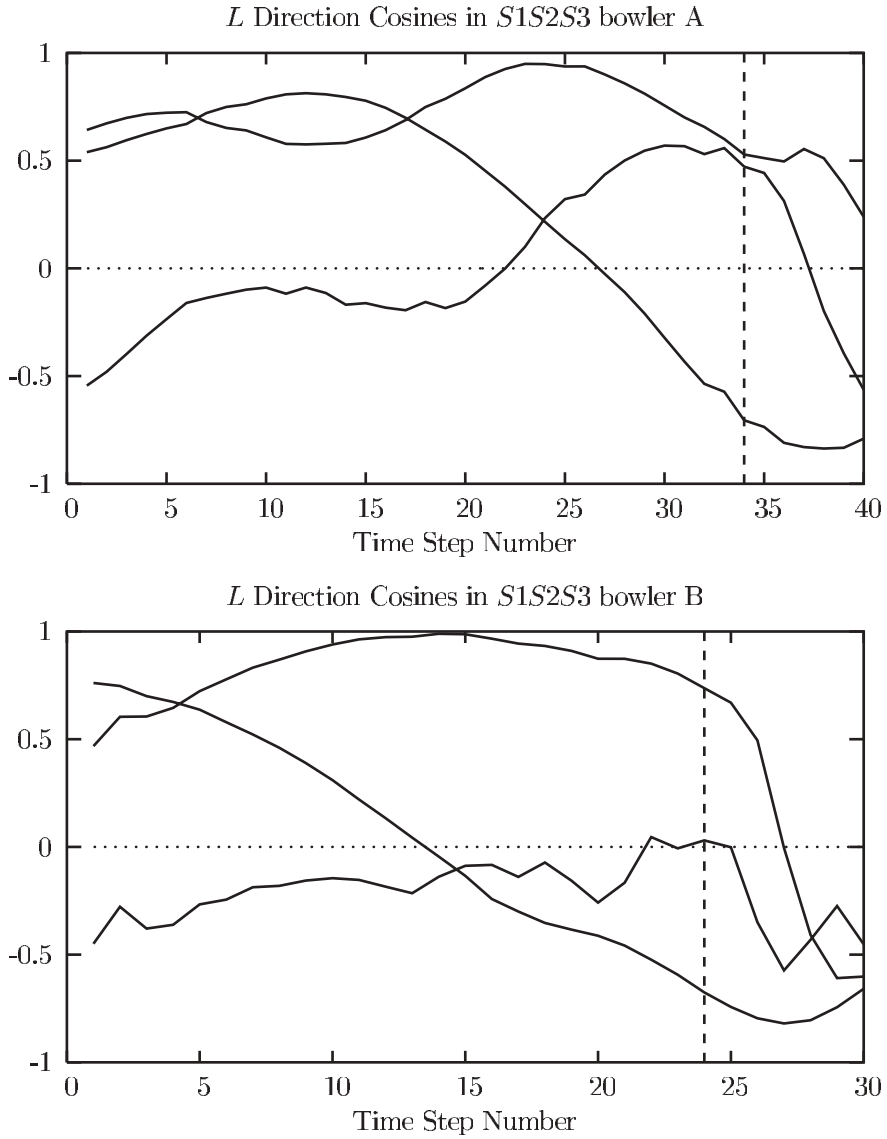

FIG. 4.3. *Reduced redundancy as revealed by the direction of the waist-shoulder line in shoulder coordinates. Curves give direction cosines of L, the line from waist to shoulder, in the axes S1, S2, and S3 of the shoulder; they are plotted against time steps (one unit of time is a few milliseconds). Vertical lines indicate the approximate points of release. Whenever one of the direction cosines goes to zero, reduction of redundancy occurs and the corresponding axis is absent from the support of the body position. Bowler A maintains full support until well after the moment of delivery, but Bowler B loses the S_3 axis from the support of the motion for about* 15 *milliseconds on either side of the moment of release.*

reduced redundancy occurs, then $\mathbf{l}$ is perpendicular to one or two of the $\mathbf{s_i}$—that is, one of the direction cosines is zero. This is easily spotted on a graph of direction cosines vs. time (see Figure 4.3).

The plots in Figure 4.3 cover approximately 0.4 s in time and forward motion of about 2 meters in space. Note that for Bowler A all three direction cosines stay well

away from zero in the period prior to release, but that for Bowler B the S_3 axis goes to zero about 15 milliseconds before release, and stays there for about 30 milliseconds. With respect to our choice of axes, Bowler B operates with reduced redundancy around the time of release of the ball, but not Bowler A. This suggests that Bowler B may be less able to modify his action to cope with fatigue. This is consistent with their injury history, as Bowler B indeed has had more injuries than Bowler A. However, it is also true that Bowler B has had much more opportunity for overuse than Bowler A, due to a far longer playing career. We hope to track both subjects to test whether indeed Bowler A will remain relatively free from overuse injury, as we predict.

ON THE GEOMETRIC FLOW OF KIRCHHOFF ELASTIC RODS*

CHUN-CHI LIN† AND HARTMUT R. SCHWETLICK‡

Abstract. Recently, rod theory has been applied to the mathematical modeling of bacterial fibers and biopolymers (e.g., DNA) to study their mechanical properties and shapes (e.g., supercoiling). In static rod theory, an elastic rod in equilibrium is the critical point of an elastic energy. This induces a natural question of how to find elasticae. In this paper, we focus on how to find the critical points by means of gradient flows. We relate a geometric function of curves to the isotropic Kirchhoff elastic energy of rods so that the generalized elastic curves are the centerlines of elastic rods in equilibrium. Thus, the variational problem for rods is formulated in curve geometry. This problem turns out to be a generalization of curve-straightening flows, which induce nonlinear fourth-order evolution equations. We establish the long time existence of length-preserving gradient flow for the geometric energy. Furthermore, by studying the asymptotic behavior, we show that the limit curves are the centerlines of the Kirchhoff elastic rods in equilibrium.

1. Introduction.

Recently, rod theory has been applied to the mathematical modeling of bacterial fibers and biopolymers (e.g., DNA) to study their mechanical properties and shapes (e.g., supercoiling). In static rod theory, an elastic rod in equilibrium is the critical point of an elastic energy. This induces a natural question of how to find elasticae. In our project, we ask the question, Starting from a given rod configuration Γ in $\mathbb{R}^3$, can we find the critical points of a Kirchhoff elastic energy, or the so-called elasticae, by means of geometric gradient flows? In order to keep the model problem in this paper simple, we consider only a special isotropic Kirchhoff elastic energy. For more general rod theory, readers are referred to [1].

Suppose $f : I = \mathbb{R}/\mathbb{Z} \to \mathbb{R}^3$ is the centerline of a closed rod. Let $\gamma = |\partial_x f|$, $ds = \gamma\, dx$ be the arclength element, and $\partial_s = \gamma^{-1}\partial_x$ be the arclength differentiation. Denote by $T = \partial_s f$ the unit tangent vector and by $\kappa = \partial_s^2 f$ the curvature vector of f. A rod configuration Γ is a framed curve described by $\{f(s); T(s), M_1(s), M_2(s)\}$, where the material frame $\{T, M_1, M_2\}$ forms an orthonormal frame field along f. Thus, we can write the skew-symmetric system

$$\begin{pmatrix} T' \\ M_1' \\ M_2' \end{pmatrix} = \begin{pmatrix} 0 & m_1 & m_2 \\ -m_1 & 0 & m \\ -m_2 & -m & 0 \end{pmatrix} \begin{pmatrix} T \\ M_1 \\ M_2 \end{pmatrix},$$

with arbitrary functions $m_1(s)$, $m_2(s)$, and $m(s)$. Consider the Kirchhoff elastic energy $\mathcal{E}$ of an isotropic rod Γ, defined by

$$\mathcal{E}[\Gamma] := \int_I \left(\alpha \cdot (m_1^2 + m_2^2) + \beta \cdot m^2\right) ds,$$

with material constants $\alpha > 0$ and $\beta \geq 0$. The term involving α gives the bending energy, while the term involving β gives the twisting energy.

Whenever a smooth curve f has no inflection points, the Frenet frame field $\{T, N, B\}$ along f is well defined. By using the Frenet frame field, it can be easily verified that

$$\mathcal{E}[\Gamma] = \int_I \left(\alpha |\kappa|^2 + \beta m^2\right) ds \tag{1.1}$$

(e.g., see [7]). A natural frame is an orthonormal frame field along a given curve f, which is uniquely determined by its initial data at a point and the skew-symmetric system,

$$\begin{pmatrix} T' \\ U' \\ V' \end{pmatrix} = \begin{pmatrix} 0 & u & v \\ -u & 0 & 0 \\ -v & 0 & 0 \end{pmatrix} \begin{pmatrix} T \\ U \\ V \end{pmatrix}$$

(see [3] or [7, p. 607]). A natural frame can be thought as a frame without twisting. As we denote by θ the angle from U to M_1 with $\theta(0) = 0$, one can verify that m is equal to the twisting rate, i.e., $m(s) = \theta'(s)$. Whenever f contains no inflection points, the Frenet frame is well defined along f. Denote by ϕ the angle from U to N; then it is easy to verify that the torsion of the curve satisfies $\tau = \phi'$. Denote by $\Psi := \theta - \phi$ the angle from N to M_1 and let $\triangle\Psi := \Psi(L) - \Psi(0)$, where L is the total length of f. By these notations, we have

$$Tw[\Gamma] = \int_I m \, ds = \triangle\Psi + \int_I \tau \, ds. \tag{1.2}$$

It is worth mentioning here that whenever f contains neither self-intersection nor inflection points, applying the so-called Fuller–Calugareanu–White formulas provides another approach to derive (1.2). This approach is less general and less direct, but it reveals the topological meaning of $\triangle\Psi$, although the total twisting number of Γ, $Tw[\Gamma]$, and the total torsion of f, $\int_I \tau \, ds$, are not topological invariants. We thus set up the boundary value problem by prescribing a real number, $\triangle\Psi$, which is called the endpoint condition of rod configurations in the rest of this paper. From above, we would like to emphasize that the bending energy and twisting energy interact as rod configurations achieving the critical points of the elastic energy. More precisely, the twisting depends on the centerlines of rods as well. Otherwise, the twisting energy and bending energy can be considered separately, and the resulting centerlines of rod elasticae would simply be curve elasticae.

In [7], Langer and Singer proposed to study the generalized elastic curves by introducing the geometric functional $\widetilde{\mathcal{F}}$ of curves $f : I \to \mathbb{R}^3$,

$$\widetilde{\mathcal{F}}[f] := \lambda_3 \mathcal{K}[f] + \lambda_2 \mathcal{T}[f] + \lambda_1 \mathcal{L}[f], \tag{1.3}$$

where

$$\mathcal{K}[f] := \int_I \frac{1}{2} |\kappa|^2 \, ds, \ \mathcal{T}[f] := \int_I \tau \, ds, \ \mathcal{L}[f] := \int_I ds,$$

and λ_i in (1.3) are Lagrange multipliers for $i = 1, 2$. According to their formulation, a generalized elastic curve f in equilibrium is a critical point of the elastic energy $\widetilde{\mathcal{F}}$

among the class of curves with fixed total torsion $\mathcal{T}[f] = T_0$ and length $\mathcal{L}[f] = L$. As long as λ_i together with the fixed total torsion T_0 fit certain relations, they showed that f is the centerline of an isotropic elastic rod in equilibrium. The problems considered in this paper and in (1.3) are closely related to curve straightening flows. To the authors' knowledge, curve straightening flows have been studied by Wen [9], Polden [8], Koiso [6], and Dziuk, Kuwert, and Schätzle [4]. At the beginning, we tried to apply the method used in the problems of curve straightening flows to the geometric functional $\widetilde{\mathcal{F}}$ proposed in [7]. However, an essential difficulty coming from the constraint of fixing the total torsion fails this approach. Namely, after multiplying the term of the first variation of the total torsion $\mathcal{T}[f]$ by its Lagrange multiplier, the method of L^2 curvature estimates combined with Gagliardo–Nirenberg-type interpolation inequalities used in the problems of curve straightening flows fails, because this term has higher power of derivatives in total than those from $\mathcal{K}[f]$.

In order to resolve the difficulty mentioned above, we propose another approach based on Theorem 1.1 below. We learn from [5] and [7] that a symmetric elastic rod (or, equivalently, an isotropic elastic rod) must have a constant twisting rate. Observe that among all isotropic rod configurations Γ with constant twisting rate $m = \frac{\mathcal{T}[f]+\triangle\Psi}{L}$, and fixed length L but without inflection points, we have the identity

$$\mathcal{E}[\Gamma] = \mathcal{G}_{\triangle\Psi,L}[f] := 2\alpha\mathcal{K}[f] + \frac{\beta}{L}\left(\mathcal{T}[f] + \triangle\Psi\right)^2.$$

Theorem 1.1 basically means that the equilibrium elastic rods must stay in the subclass of rod configurations with constant twisting rate and fixed length L. Thus, in order to find closed elastic rods of $\mathcal{E}$, we work with the geometric functional

$$\mathcal{F}[f] := \mathcal{G}_{\triangle\Psi,L}[f] + \lambda_1 \cdot (\mathcal{L}[f] - L), \tag{1.4}$$

where λ_1 is the Lagrange multiplier. It turns out that working with the functional $\mathcal{G}_{\triangle\Psi,L}$ of curves with fixed length L is more suitable than working directly with the rod energy $\mathcal{E}$ in our geometric approach.

THEOREM 1.1. *Let $f : I = \mathbb{R}/\mathbb{Z} \to \mathbb{R}^3$ be the centerline of a closed rod Γ. Assume f contains no inflection points. Then, subject to variations of fixed length L and endpoint condition $\triangle\Psi$ in* (1.2)*, Γ is an equilibrium of the elastic energy $\mathcal{E}$ if and only if f is a critical point of the geometric functional $\mathcal{F}$ and the twisting rate is equal to the constant $\frac{\triangle\Psi+\mathcal{T}[f]}{L}$.*

The inflection points in the above theorem simply mean points of zero curvature. We exclude the situation of the limit curves containing inflection points because our argument in Theorem 1.1 relies on the formulation of Frenet frames, which are ill-defined at an inflection point. By the first variational formulas in Lemma 3.1, we obtain, for the length-preserving L^2 gradient flow of $\mathcal{F}$ the evolution equation,

$$\partial_t f = \lambda_3 \cdot \left(-\nabla_s^2\kappa - \frac{|\kappa|^2}{2}\kappa\right) + \lambda_2(t) \cdot \nabla_s(T \times \kappa) + \lambda_1(t) \cdot \kappa, \tag{1.5}$$

where $f : [0,\infty) \times I \to \mathbb{R}^3$ has smooth initial data f_0. Here, the covariant derivative

$\nabla_s\eta$ denotes the normal component of $\partial_s\eta$, i.e., $\nabla_s\eta = \partial_s\eta - \langle\partial_s\eta, T\rangle T$, and

$$\lambda_1(t) := \frac{2\alpha\int_I \langle\kappa, \nabla_s^2\kappa + \frac{|\kappa|^2}{2}\kappa\rangle\, ds - \frac{2\beta}{L}(\mathcal{T}[f] + \triangle\Psi)\int_I \langle\kappa, \nabla_s(T\times\kappa)\rangle\, ds}{\int_I |\kappa|^2\, ds}, \tag{1.6}$$

$$\lambda_2(t) := \frac{2\beta}{L}(\mathcal{T}[f] + \triangle\Psi), \qquad L,\ \beta > 0, \tag{1.7}$$

$$\lambda_3 := 2\alpha, \qquad \alpha > 0. \tag{1.8}$$

Notice that $\lambda_1(t)$ in (1.6) is chosen so that $\frac{d}{dt}\mathcal{L}[f_t] = 0$ for all time. The following theorem is the main result of this paper.

THEOREM 1.2. *For any real number $\triangle\Psi$ and any smooth initial closed curve f_0, there exists a smooth solution to the L^2-gradient flow in* (1.5) *until the appearance of inflection points. With the assumption of no inflection points appearing during the flow, the curves subconverge to f_∞, an equilibrium of the energy functional $\mathcal{F}$, after reparametrization by arclength and translation. Furthermore, if f_∞ contains no inflection points, then f_∞ is the centerline of an equilibrium Kirchhoff elastic rod with constant total twisting rate $\frac{\mathcal{T}[f_\infty]+\triangle\Psi}{L}$.*

This paper is arranged as follows. In section 2 we introduce further notation and collect the results needed from [4]. Since most of these preliminaries follow the lines in [4], the reader is recommended to consult [4] for further details. In section 3 we present the proof of the main results. Finally, section 4 is devoted to the numerical treatment of the problem. We explain the algorithm we have used and show several computational results.

2. Preliminaries.

LEMMA 2.1 (Lemma 2.1 in [4]). *Suppose ϕ is any normal field along f and $f : [0,\epsilon)\times I \to \mathbb{R}^n$ is a time-dependent curve satisfying $\partial_t f = V + \varphi T$, where V is the normal velocity and $\varphi = \langle T, \partial_t f\rangle$. Then the following formulas hold:*

$$\nabla_s\phi = \partial_s\phi + \langle\phi,\kappa\rangle T, \tag{2.1}$$

$$\partial_t(ds) = (\partial_s\varphi - \langle\kappa, V\rangle)\ ds, \tag{2.2}$$

$$\partial_t\partial_s - \partial_s\partial_t = (\langle\kappa, V\rangle - \partial_s\varphi)\ \partial_s, \tag{2.3}$$

$$\partial_t T = \nabla_s V + \varphi\cdot\kappa, \tag{2.4}$$

$$\partial_t\phi = \nabla_t\phi - \langle\nabla_s V + \varphi\ \kappa, \phi\rangle T, \tag{2.5}$$

$$\nabla_t\kappa = \nabla_s^2 V + \langle\kappa, V\rangle\kappa + \varphi\cdot\nabla_s\kappa, \tag{2.6}$$

$$(\nabla_t\nabla_s - \nabla_s\nabla_t)\phi = (\langle\kappa, V\rangle - \partial_s\varphi)\nabla_s\phi + \langle\kappa,\phi\rangle\nabla_s V - \langle\nabla_s V,\phi\rangle\cdot\kappa. \tag{2.7}$$

LEMMA 2.2 (Lemma 2.2 in [4]). *Suppose $f : [0,\widehat{T})\times I \to \mathbb{R}^n$ moves in a normal direction with velocity $\partial_t f = V$, ϕ is a normal vector field along f, and $\nabla_t\phi + \nabla_s^4\phi = Y$. Then*

$$\frac{d}{dt}\frac{1}{2}\int_I |\phi|^2\ ds + \int_I \left|\nabla_s^2\phi\right|^2\ ds = \int_I \langle Y,\phi\rangle\ ds - \frac{1}{2}\int_I |\phi|^2\langle\kappa, V\rangle\ ds. \tag{2.8}$$

Furthermore, $\psi = \nabla_s\phi$ satisfies the equation

$$\nabla_t\psi + \nabla_s^4\psi = \nabla_s Y + \langle\kappa,\phi\rangle\nabla_s V - \langle\nabla_s V,\phi\rangle\kappa + \langle\kappa, V\rangle\psi. \tag{2.9}$$

For normal vector fields $\phi_1,\ldots,\phi_k$ along f, we denote by $\phi_1 * * * \phi_k$ a term of the type

$$\phi_1 * * * \phi_k = \begin{cases} \langle\phi_{i_1},\phi_{i_2}\rangle\cdots\langle\phi_{i_{k-1}},\phi_{i_k}\rangle & \text{for } k \text{ even},\\ \langle\phi_{i_1},\phi_{i_2}\rangle\cdots\langle\phi_{i_{k-2}},\phi_{i_{k-1}}\rangle\cdot\phi_{i_k} & \text{for } k \text{ odd}, \end{cases}$$

where $i_1, \dots, i_k$ is any permutation of $1, \dots, k$. Slightly more generally, we allow some of the ϕ_i to be functions, in which case the $*$-product reduces to multiplication. For a normal vector field ϕ along f, we denote by $P_\nu^\mu(\phi)$ any linear combination of terms of the type $\nabla_s^{i_1}\phi * \cdots * \nabla_s^{i_\nu}\phi$ with universal constant coefficients, where $\mu = i_1 + \cdots + i_\nu$ is the total number of derivatives. Notice that the following formulas hold:

$$\begin{cases} \nabla_s\left(P_b^a(\phi) * P_d^c(\phi)\right) = \nabla_s P_b^a(\phi) * P_d^c(\phi) + P_b^a(\phi) * \nabla_s P_d^c(\phi), \\ \\ P_b^a(\phi) * P_d^c(\phi) = P_{b+d}^{a+c}(\phi),\ \nabla_s P_d^c(\phi) = P_d^{c+1}(\phi). \end{cases} \tag{2.10}$$

Similarly, we denote by $Q_\nu^\mu(\kappa)$ the linear combination of $\partial_s^{i_1}\kappa * * * \partial_s^{i_\nu}\kappa$, where $i_1 + \cdots + i_\nu = \mu$.

The following lemma states the important interpolation inequality for higher order curvature functionals.

LEMMA 2.3 (Proposition 2.5 in [4]). *For any term $P_\nu^\mu(\kappa)$ with $\nu \geq 2$ which contains only derivatives of κ of order at most $k-1$, we have*

$$\int_I \left|P_\nu^\mu(\kappa)\right| \, ds \leq c\, \mathcal{L}[f]^{1-\mu-\nu} \|\kappa\|_2^{\nu-\gamma} \|\kappa\|_{k,2}^{\gamma}\ , \tag{2.11}$$

where $\gamma = \left(\mu + \frac{1}{2}\nu - 1\right)/k$, $c = c(n,k,\mu,\nu)$, and

$$\|\kappa\|_{k,p} := \sum_{i=0}^{k} \left\|\nabla_s^i \kappa\right\|_p, \qquad \left\|\nabla_s^i\kappa\right\|_p := \mathcal{L}[f]^{i+1-\frac{1}{p}} \left(\int_I \left|\nabla_s^i\kappa\right|^p \, ds\right)^{\frac{1}{p}}.$$

Moreover, if $\mu + \frac{1}{2}\nu < 2k+1$, then $\gamma < 2$ and we have for any $\varepsilon > 0$,

$$\int_I \left|P_\nu^\mu(\kappa)\right| \, ds \leq \varepsilon \int_I |\nabla_s^k \kappa|^2 \, ds + c\varepsilon^{\frac{-\gamma}{2-\gamma}} \left(\int_I |\kappa|^2 \, ds\right)^{\frac{\nu-\gamma}{2-\gamma}} + c\left(\int_I |\kappa|^2 \, ds\right)^{\mu+\nu-1}. \tag{2.12}$$

LEMMA 2.4 (Lemma 2.6 in [4]). *We have the identities*

$$\nabla_s\kappa - \partial_s\kappa = |\kappa|^2 T, \tag{2.13}$$

$$\nabla_s^m\kappa - \partial_s^m\kappa = \sum_{i=1}^{[\frac{m}{2}]} Q_{2i+1}^{m-2i}(\kappa) + \sum_{i=1}^{[\frac{m+1}{2}]} Q_{2i}^{m+1-2i}(\kappa)\, T. \tag{2.14}$$

LEMMA 2.5 (Lemma 2.7 in [4]). *Assume the bounds $\|\kappa\|_{L^2} \leq \Lambda_0$ and $\|\nabla_s^m\kappa\|_{L^1} \leq \Lambda_m$ for $m \geq 1$. Then for any $m \geq 1$ one has*

$$\left\|\partial_s^{m-1}\kappa\right\|_{L^\infty} + \|\partial_s^m\kappa\|_{L^1} \leq c_m(\Lambda_0, \dots, \Lambda_m). \tag{2.15}$$

3. Proof of the main results. The formulas in the next lemma can be directly verified by applying the general formulas in Lemma 2.1. Thus, we skip the detail of the computation and leave the verification to the reader.

LEMMA 3.1. *Let $f : I = \mathbb{R}/\mathbb{Z} \to \mathbb{R}^3$ represent a smooth curve in $\mathbb{R}^3$ without inflection points. Then, for any variation $f_\varepsilon(x) = f(x) + \varepsilon W(x)$, where f, $W \in$*

$C^\infty(I)$, *one has the following:*

$$\begin{aligned}
\tfrac{d}{d\varepsilon}\big\lfloor_{\varepsilon=0}\mathcal{L}[f_\varepsilon] &= -\int_I \langle \kappa, W\rangle \, ds + [\langle T, W\rangle]_0^L,\\
\tfrac{d}{d\varepsilon}\big\lfloor_{\varepsilon=0}\mathcal{T}[f_\varepsilon] &= -\int_I \langle \nabla_s (T\times\kappa), W\rangle \, ds\\
&\quad + \Big[\langle \nabla_s^2 (W - \langle W, T\rangle T) + \langle W, T\rangle \cdot \nabla_s \kappa, \tfrac{B}{|\kappa|}\rangle + \langle W, T\times\kappa\rangle\Big]_0^L,\\
\tfrac{d}{d\varepsilon}\big\lfloor_{\varepsilon=0}\mathcal{K}[f_\varepsilon] &= \int_I \langle \nabla_s^2\kappa + \tfrac{|\kappa|^2}{2}\kappa, W\rangle \, ds\\
&\quad + \Big[\langle T, W\rangle \cdot \tfrac{|\kappa|^2}{2} + \langle \kappa, \nabla_s (W - \langle W, T\rangle T)\rangle - \langle \nabla_s\kappa, W\rangle\Big]_0^L.
\end{aligned}$$

Proof of Theorem 1.1. If we perturb the rod configuration Γ of a given elastic rod in equilibrium without perturbing the centerline f, then

$$0 = \delta\mathcal{E}[\Gamma] = \beta\cdot\delta\int_I m^2 \, ds = 2\beta\cdot\int_I m\cdot(\delta m) \, ds. \tag{3.1}$$

By the endpoint condition in (1.2) and the formula $m(s) = \theta'(s)$, we conclude that m is a constant and

$$m = \frac{(\triangle\Psi + \mathcal{T}[f])}{L} = L^{-1}\int_I m \, ds.$$

Thus, any closed Kirchhoff elastic rod in equilibrium with endpoint condition $\triangle\Psi$ and length L belongs to the subclass of rod configurations $\mathcal{A}_{\triangle\Psi,L}$, where

$$\mathcal{A}_{\triangle\Psi,L} := \left\{\Gamma : m(s) = \frac{\triangle\Psi + \mathcal{T}[f]}{L},\ \mathcal{L}[f] = L\right\}.$$

Observe that for any rod configurations $\Gamma\in\mathcal{A}_{\triangle\Psi,L}$, we have

$$\mathcal{E}[\Gamma] = \mathcal{G}_{\triangle\Psi,L}[f]. \tag{3.2}$$

Now, perturbations of Γ preserving the length in the subclass of rod configurations $\mathcal{A}_{\triangle\Psi,L}$ induce the variational equation

$$\delta\left(\mathcal{G}_{\triangle\Psi,L}[f] + \lambda_1\cdot(\mathcal{L}[f] - L)\right) = 0,$$

where λ_1 is the Lagrange multiplier.

Conversely, by assuming that f is the critical point of $\mathcal{F}$, we have

$$\delta_L\mathcal{G}_{\triangle\Psi,L}[f] = 0,$$

where δ_L denotes perturbations of preserving the length. The rod configuration Γ has constant twisting rate $\frac{(\triangle\Psi+\mathcal{T}[f])}{L}$; therefore $\Gamma\in\mathcal{A}_{\triangle\Psi,L}$. Thus,

$$\delta_L\mathcal{E}[\Gamma] = \delta_L\mathcal{G}_{\triangle\Psi,L}[f] = 0. \qquad \square$$

Proof of Theorem 1.2. The proof is motivated by the arguments in [4]. Recalling that no inflection point is on the initial curve, the short time existence is a standard

argument. We thus skip it here and focus on the long time existence and asymptotic behavior.

To prove global bounds we wish to estimate higher Sobolev norms of the curvature. Their evolution is given by

$$\nabla_t \nabla_s^m \kappa = -\nabla_s^4 \nabla_s^m \kappa + \text{ tensors of lesser order.}$$

Therefore we arrive at

$$\frac{d}{dt}\frac{1}{2}\int_I \mid \nabla_s^m \kappa \mid^2 \, ds + \int_I \mid \nabla_s^{m+2} \kappa \mid^2 \, ds = \text{ terms of lesser order.}$$

It will not be necessary to compute the error terms explicitly; it is sufficient to keep track of their scaling. In other words, we have to know the order of the derivatives involved. Using the notation introduced before, the next lemma characterizes the error terms coming from the twist term, i.e., dealing with the new situation that the total torsion is included in our energy.

LEMMA 3.2. *For $m \geq 2$, we have the formula*

$$\begin{aligned}
\nabla_s^m (T \times \kappa) \;=\; & T \times \nabla_s^m \kappa + \sum_{a_1,b_1,c_1,d_1} \left[P_{b_1}^{a_1}(\kappa) \times P_{d_1}^{c_1}(\kappa) \right]^{\perp} \\
& + \sum_{i=1,2} \sum_{a_2^{(i)},b_2^{(i)},c_2^{(i)},d_2^{(i)},e_2^{(i)},f_2^{(i)}} \left[\left(P_{b_2^i}^{a_2^i}(\kappa) \times P_{d_2^i}^{c_2^i}(\kappa) \right) * P_{f_2^i}^{e_2^i}(\kappa) \right]^{\perp} \\
& + \sum_{i=1,2} \sum_{a_3^{(i)},b_3^{(i)},c_3^{(i)},d_3^{(i)}} \left(\left(T \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa) \right) * P_{d_3^{(i)}}^{c_3^{(i)}}(\kappa) \right),
\end{aligned}$$

where the sums are taken such that $(a_1 + c_1) + (b_1 + d_1)/2 = m$, $(a_2^{(i)} + c_2^{(i)} + e_2^{(i)}) + (b_2^{(i)} + d_2^{(i)} + f_2^{(i)})/2 = m - i$, and $(a_3^{(i)} + c_3^{(i)}) + (b_3^{(i)} + d_3^{(i)})/2 = m - i + 1/2$ for $i \in \{1, 2\}$.

Proof of Lemma 3.2. We first need the following formulas, which easily can be verified by applying (2.1). Assume $P_b^a(\phi)$ and $P_d^c(\phi)$ are normal vector fields; then

$$\text{(3.3)} \quad \begin{cases} \nabla_s \left(P_b^a(\phi) \times P_d^c(\phi) \right) = & [(\nabla_s P_b^a(\phi) + \langle \kappa, P_b^a(\phi) \rangle \cdot T) \times P_d^c(\phi) \\ & + P_b^a(\phi) \times (\nabla_s P_d^c(\phi) + \langle \kappa, P_d^c(\phi) \rangle \cdot T)]^{\perp}, \\ \nabla_s \left(T \times P_d^c(\phi) \right) = [\kappa \times P_d^c(\phi)]^{\perp} + T \times P_d^{c+1}(\phi), \end{cases}$$

where $[\cdots]^{\perp}$ denotes its normal component and $\times$ denotes the exterior product in $\mathbb{R}^3$. Notice that in (3.3), we use $+$ instead of $-$ for our convenience because the sign is meaningless as using universal constant coefficients in those terms, $P_\beta^\alpha(\phi)$.

Now the proof is an induction argument. As $m = 2$,

$$\nabla_s^2 (T \times \kappa) = T \times \nabla_s^2 \kappa + (\kappa \times \nabla_s \kappa)^{\perp} = T \times \nabla_s^2 \kappa + \left(P_1^0(\kappa) \times P_1^1(\kappa) \right)^{\perp}.$$

As $m \geq 3$, we apply (2.1), (2.10), and (3.3) in the following calculation:

$$\begin{aligned}
\nabla_s^m (T \times \kappa) \;&= \nabla_s \Bigg\{ T \times \nabla_s^{m-1} \kappa + \sum_{a_1,b_1,c_1,d_1} \left[P_{b_1}^{a_1}(\kappa) \times P_{d_1}^{c_1}(\kappa) \right]^{\perp} \\
&\quad + \sum_{i=1}^{2} \sum_{a_2^{(i)},b_2^{(i)},c_2^{(i)},d_2^{(i)},e_2^{(i)},f_2^{(i)}} \left[\left(P_{b_2^i}^{a_2^i}(\kappa) \times P_{d_2^i}^{c_2^i}(\kappa) \right) * P_{f_2^i}^{e_2^i}(\kappa) \right]^{\perp} \\
&\quad + \sum_{i=1}^{2} \sum_{a_3^{(i)},b_3^{(i)},c_3^{(i)},d_3^{(i)}} \left(\left(T \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa) \right) * P_{d_3^{(i)}}^{c_3^{(i)}}(\kappa) \right) \Bigg\} \\
&= \nabla_s \Bigg\{ I_1 + I_2 + \sum_{i=1}^{2} I_3^{(i)} + \sum_{i=1}^{2} I_4^{(i)} \Bigg\}.
\end{aligned}$$

1.

$$\nabla_s I_1 = \nabla_s \left[T \times \nabla_s^{m-1}\kappa\right] = T \times \nabla_s^m \kappa + \left[P_1^0(\kappa) \times P_1^{m-1}(\kappa)\right]^{\perp}.$$

2.

$$\begin{aligned}
\nabla_s I_2 &= \sum_{a_1,b_1,c_1,d_1} \nabla_s \left[P_{b_1}^{a_1}(\kappa) \times P_{d_1}^{c_1}(\kappa)\right]^{\perp} \\
&= \sum_{a_1,b_1,c_1,d_1} \nabla_s [P_{b_1}^{a_1}(\kappa) \times P_{d_1}^{c_1}(\kappa)] - \langle P_{b_1}^{a_1}(\kappa) \times P_{d_1}^{c_1}(\kappa), T\rangle \cdot \kappa \\
&= \sum_{a_1,b_1,c_1,d_1} [((P_{b_1}^{a_1+1}(\kappa) + P_{b_1+1}^{a_1}(\kappa)\, T) \times P_{d_1}^{c_1}(\kappa)) \\
&\quad + (P_{b_1}^{a_1}(\kappa) \times \left(P_{d_1}^{c_1+1}(\kappa) + P_{b_1+1}^{a_1}(\kappa)\, T\right)]^{\perp} + \left(T \times P_{b_1}^{a_1}(\kappa)\right) * P_{d_1+1}^{c_1}(\kappa) \\
&= \sum_{a,b,c,d} [P_b^a(\kappa) \times P_d^c(\kappa)]^{\perp} + \sum_{A,B,C,D} \left(T \times P_B^A(\kappa)\right) * P_D^C(\kappa),
\end{aligned}$$

where $(a+c)+(b+d)/2 = (a_1+c_1)+(b_1+d_1)/2+1$ and $(A+C)+(B+D)/2 = (a_1+c_1)+(b_1+d_1)/2+1/2$.

3.

$$\begin{aligned}
\nabla_s I_3^{(i)} &= \sum_{a_2^{(i)},b_2^{(i)},c_2^{(i)},d_2^{(i)},e_2^{(i)},f_2^{(i)}} \nabla_s \left[\left(P_{b_2^i}^{a_2^i}(\kappa) \times P_{d_2^i}^{c_2^i}(\kappa)\right) * P_{f_2^i}^{e_2^i}(\kappa)\right]^{\perp} \\
&= \sum_{a_2^{(i)},b_2^{(i)},c_2^{(i)},d_2^{(i)},e_2^{(i)},f_2^{(i)}} \nabla_s [(P_{b_2^{(i)}}^{a_2^{(i)}}(\kappa) \times P_{d_2^{(i)}}^{c_2^{(i)}}(\kappa)) * P_{f_2^{(i)}}^{e_2^{(i)}}(\kappa)] \\
&\qquad - \langle (P_{b_2^{(i)}}^{a_2^{(i)}}(\kappa) \times P_{d_2^{(i)}}^{c_2^{(i)}}(\kappa)) * P_{f_2^{(i)}}^{e_2^{(i)}}(\kappa), T\rangle \cdot \kappa \\
&= \sum_{a_2^{(i)},b_2^{(i)},c_2^{(i)},d_2^{(i)},e_2^{(i)},f_2^{(i)}} \nabla_s [(P_{b_2^{(i)}}^{a_2^{(i)}}(\kappa) \times P_{d_2^{(i)}}^{c_2^{(i)}}(\kappa))] * P_{f_2^{(i)}}^{e_2^{(i)}}(\kappa) \\
&\qquad + (P_{b_2^{(i)}}^{a_2^{(i)}}(\kappa) \times P_{d_2^{(i)}}^{c_2^{(i)}}(\kappa)) * \nabla_s P_{f_2^{(i)}}^{e_2^{(i)}}(\kappa) \\
&\qquad - \langle (P_{b_2^{(i)}}^{a_2^{(i)}}(\kappa) \times P_{d_2^{(i)}}^{c_2^{(i)}}(\kappa)) * P_{f_2^{(i)}}^{e_2^{(i)}}(\kappa), T\rangle \cdot \kappa \\
&= \sum_{a,b,c,d,e,f} [(P_b^a(\kappa) \times P_d^c(\kappa)) * P_f^e(\kappa)]^{\perp} + \sum_{A,B,C,D} \left(T \times P_B^A(\kappa)\right) * P_D^C(\kappa),
\end{aligned}$$

where $(a+c+e)+(b+d+f)/2 = (a_2^{(i)}+c_2^{(i)}+e_2^{(i)})+(b_2^{(i)}+d_2^{(i)}+f_2^{(i)})/2+1$ and $(A+C)+(B+D)/2 = (a_2^{(i)}+c_2^{(i)})+(b_2^{(i)}+d_2^{(i)})/2+1/2$.

4.

$$\begin{aligned}
\nabla_s I_4^{(i)} &= \sum_{a_3^{(i)},b_3^{(i)},c_3^{(i)},d_3^{(i)}} \nabla_s [(T \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa)) * P_{d_3^{(i)}}^{c_3^{(i)}}(\kappa)] \\
&= \sum_{a_3^{(i)},b_3^{(i)},c_3^{(i)},d_3^{(i)}} \{\partial_s [(T \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa)) * P_{d_3^{(i)}}^{c_3^{(i)}}(\kappa)]\}^{\perp} \\
&= \sum_{a_3^{(i)},b_3^{(i)},c_3^{(i)},d_3^{(i)}} \{(P_1^0(\kappa) \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa) + (T \times P_{b_3^{(i)}}^{a_3^{(i)}+1}(\kappa))) * P_{d_3^{(i)}}^{c_3^{(i)}}(\kappa)\}^{\perp} \\
&\qquad + (T \times P_{b_3^{(i)}}^{a_3^{(i)}}(\kappa)) * P_{d_3^{(i)}}^{c_3^{(i)}+1}(\kappa) \\
&= \sum_{a,b,c,d} [(P_b^a(\kappa) \times P_d^c(\kappa)) * P_f^e(\kappa)]^{\perp} + \sum_{A,B,C,D} \left(T \times P_B^A(\kappa)\right) * P_D^C(\kappa),
\end{aligned}$$

where $(a+c+e)+(b+d+f)/2=(a_3^{(i)}+c_3^{(i)})+(b_3^{(i)}+d_3^{(i)})/2+1/2$ and $(A+C)+(B+D)/2=(a_3^{(i)}+c_3^{(i)})+(b_3^{(i)}+d_3^{(i)})/2+1$.

The proof is finished by summing up all of these terms from part 1 through part 4. ∎

LEMMA 3.3 (corresponding to Lemma 2.3 in [4]). *Suppose*

$$\partial_t f = -\nabla_s^2\kappa+\sigma|\kappa|^2\kappa+\lambda_1\kappa+\lambda_2\nabla_s(T\times\kappa),$$

where σ, $\lambda_i\in\mathbb{R}$. Then, for $m\geq 0$, the derivatives of the curvature $\phi_m=\nabla_s^m\kappa$ satisfy

(3.4)
$$\begin{aligned}&\nabla_t\phi_m+\nabla_s^4\phi_m\\&=P_3^{m+2}(\kappa)+\sigma\cdot\left(P_3^{m+2}(\kappa)+P_5^m(\kappa)\right)+\lambda_1\cdot\left(\nabla_s^{m+2}\kappa+P_3^m(\kappa)\right)\\&\quad+\lambda_2\cdot\left(\nabla_s^{m+3}(T\times\kappa)+\nabla_s^{m+1}(T\times\kappa)*P_2^0(\kappa)+\cdots+\nabla_s^1(T\times\kappa)*P_2^m(\kappa)\right).\end{aligned}$$

The statement is still true when $\lambda_i=\lambda_i(t)$ depends on time.

Proof of Lemma 3.3. The case of $m=0$ follows from (2.6) and the definition of $\partial_t f$,

$$\begin{aligned}\nabla_t\kappa &= -\nabla_s^4\kappa+\sigma\cdot(\nabla_s^2(|\kappa|^2\kappa)+|\kappa|^4\kappa)+\lambda_1\cdot(\nabla_s^2\kappa+|\kappa|^2\kappa)\\&\quad+\lambda_2\cdot\left(\nabla_s^3(T\times\kappa)+\kappa\langle\kappa,\nabla_s(T\times\kappa)\rangle\right).\end{aligned}$$

For $m\geq 1$, (3.4) can be inductively derived by using (2.9),

$$\begin{aligned}&\nabla_t\phi_m+\nabla_s^4\phi_m\\&=\nabla_s[P_3^{m+1}(\kappa)+\sigma\cdot\left(P_3^{m+1}(\kappa)+P_5^{m-1}(\kappa)\right)+\lambda_1\cdot\left(\nabla_s^{m+1}\kappa+P_3^{m-1}(\kappa)\right)\\&\qquad+\lambda_2\cdot(\nabla_s^{m+2}(T\times\kappa)+\nabla_s^m(T\times\kappa)*P_2^0(\kappa)+\cdots+\nabla_s^1(T\times\kappa)*P_2^{m-1}(\kappa))]\\&\quad+\langle\kappa,\phi_{m-1}\rangle\cdot\nabla_s[-\nabla_s^2\kappa+\sigma|\kappa|^2\kappa+\lambda_1\kappa+\lambda_2\nabla_s(T\times\kappa)]\\&\quad-\langle\nabla_s[-\nabla_s^2\kappa+\sigma|\kappa|^2\kappa+\lambda_1\kappa+\lambda_2\nabla_s(T\times\kappa)],\phi_{m-1}\rangle\cdot\kappa\\&\quad+\langle\kappa,-\nabla_s^2\kappa+\sigma|\kappa|^2\kappa+\lambda_1\kappa+\lambda_2\nabla_s(T\times\kappa)\rangle\cdot\phi_m\\&=P_3^{m+2}(\kappa)+\sigma\cdot\left(P_3^{m+2}(\kappa)+P_5^m(\kappa)\right)+\lambda_1\cdot\left(\nabla_s^{m+2}\kappa+P_3^m(\kappa)\right)\\&\quad+\lambda_2\cdot(\nabla_s^{m+3}(T\times\kappa)+\nabla_s^{m+1}(T\times\kappa)*P_2^0(\kappa)+\cdots+\nabla_s^1(T\times\kappa)*P_2^m(\kappa)).\end{aligned}$$ ∎

By (2.8) and (3.4), we have

$$\begin{aligned}&\tfrac{d}{dt}\tfrac{1}{2}\int_I|\nabla_s^m\kappa|^2\,ds+\int_I|\nabla_s^{m+2}\kappa|^2\,ds+\lambda_1(t)\int_I|\nabla_s^{m+1}\kappa|^2\,ds\\&=\lambda_1(t)\int_I\langle\nabla_s^m\kappa,P_3^m(\kappa)\rangle\,ds+\int_I\langle\nabla_s^m\kappa,P_3^{m+2}(\kappa)+P_5^m(\kappa)\rangle\,ds\\&\quad+\lambda_2(t)\int_I\langle\nabla_s^m\kappa,\nabla_s^{m+3}(T\times\kappa)+\nabla_s^{m+1}(T\times\kappa)*P_2^0(\kappa)\\&\qquad+\cdots+\nabla_s^1(T\times\kappa)*P_2^m(\kappa)\rangle\,ds.\end{aligned}\tag{3.5}$$

Notice that estimating terms in (3.5) is the key argument of this paper. One can verify from Lemma 3.1 that

$$\begin{aligned}\tfrac{d}{dt}\mathcal{F}[f_t] &= 2\alpha\tfrac{d}{dt}\mathcal{K}[f]+\tfrac{2\beta}{L}(\mathcal{T}[f]+\triangle\Psi)\tfrac{d}{dt}\mathcal{T}[f]+\lambda_1(t)\cdot\tfrac{d}{dt}\mathcal{L}[f]\\&=\int_I\langle 2\alpha(\nabla_s^2\kappa+\frac{|\kappa|^2}{2}\kappa)-\lambda_2(t)\nabla_s(T\times\kappa)-\lambda_1(t)\kappa,\partial_t f\rangle\,ds\\&=-\int_I|2\alpha(-\nabla_s^2\kappa-\frac{|\kappa|^2}{2}\kappa)+\lambda_2(t)\nabla_s(T\times\kappa)+\lambda_1(t)\kappa|^2\,ds\\&\leq 0.\end{aligned}\tag{3.6}$$

Note that $\lambda_1(t)$ is chosen to fulfill $\mathcal{L}[f_t] \equiv L$. From (3.6), $\mathcal{F}[f_t]$ is nonincreasing as t is increasing. Thus,

$$\begin{aligned}\tfrac{\beta}{L}\left(\mathcal{T}[f_t]+\triangle\Psi\right)^2 &\le 2\alpha\mathcal{K}[f_t]+\tfrac{\beta}{L}\left(\mathcal{T}[f_t]+\triangle\Psi\right)^2\\ &= \mathcal{G}_{\triangle\Psi,L}[f_t]=\mathcal{F}[f_t]\le\mathcal{F}[f_0]\\ &= 2\alpha\mathcal{K}[f_0]+\tfrac{\beta}{L}\left(\mathcal{T}[f_0]+\triangle\Psi\right)^2.\end{aligned}$$

Therefore,

$$|\lambda_2(t)| = \frac{2\beta}{L}\left|\mathcal{T}[f]+\triangle\Psi\right| \le C\left(f_0,\triangle\Psi,\alpha,\beta,L\right) \tag{3.7}$$

is uniformly bounded. Furthermore, by (3.6),

$$\|\kappa\|_{L^2}^2 = 2\mathcal{K}[f_t] \le C\left(f_0,\alpha\right). \tag{3.8}$$

Thus $\|\kappa\|_{L^2}^2$ is uniformly bounded for any $t \ge 0$.

By applying (2.12), (3.7), (3.8), and Lemma 3.2, the sum of the last two terms in (3.5) satisfies the inequality

$$\begin{aligned}&\int_I \left\langle \nabla_s^m\kappa, P_3^{m+2}(\kappa)+P_5^m(\kappa)\right\rangle ds\\ &+\lambda_2(t)\int_I \left\langle \nabla_s^m\kappa, \nabla_s^{m+3}(T\times\kappa)+\nabla_s^{m+1}(T\times\kappa)*P_2^0(\kappa)\right.\\ &\qquad\left.+\cdots+\nabla_s^1(T\times\kappa)*P_2^m(\kappa)\right\rangle ds\\ &\le C\left(f_0,\triangle\Psi,\alpha,\beta,L\right)\cdot\left(\varepsilon\int_I\left|\nabla_s^{m+2}\kappa\right|^2 ds+C\left(f_0,m,\varepsilon\right)\right).\end{aligned} \tag{3.9}$$

Now we estimate the term involving $\lambda_1(t)$ on the right-hand side of (3.5). Since $\kappa=\partial_s^2 f$, by applying the Poincaré inequality to $\partial_s f$, we have the estimate

$$L\|\kappa\|_{L^2}^2 \ge 4\pi^2.$$

Thus, by applying (2.11) to the right-hand side of (1.6) involving $\lambda_1(t)$, we have the estimates

$$\begin{aligned}&|\lambda_1(t)|\\ &\le C\left(f_0,\triangle\Psi,\alpha,\beta,L\right)\cdot\int_I\left(\left|P_2^2(\kappa)\right|+\left|P_4^0(\kappa)\right|+\left|P_2^1(\kappa)\right|\right)ds\\ &\le C\cdot\left(\|\kappa\|_{m+2,2}^{\frac{2}{m+2}}\cdot\|\kappa\|_2^{2-\frac{2}{m+2}}+\|\kappa\|_{m+2,2}^{\frac{1}{m+2}}\cdot\|\kappa\|_2^{4-\frac{2}{m+2}}+\|\kappa\|_{m+2,2}^{\frac{1}{m+2}}\cdot\|\kappa\|_2^{2-\frac{1}{m+2}}\right)\end{aligned}$$

and

$$\left|\int_I\left\langle\nabla_s^m\kappa,P_3^m(\kappa)\right\rangle ds\right| \le \int_I\left|P_4^{2m}(\kappa)\right| ds \le c(m,L)\cdot\|\kappa\|_{m+2,2}^{2-\frac{3}{m+2}}\cdot\|\kappa\|_2^{2+\frac{3}{m+2}}.$$

Therefore,

$$\begin{aligned}&\left|\lambda_1(t)\int_I\left\langle\nabla_s^m\kappa,P_3^m(\kappa)\right\rangle ds\right|\\ &\le C\left(f_0,\triangle\Psi,\alpha,\beta,L,m\right)\cdot\left(\|\kappa\|_{m+2,2}^{2-\frac{1}{m+2}}+\|\kappa\|_{m+2,2}^{2-\frac{2}{m+2}}\right)\\ &\le \varepsilon\int_I\left|\nabla_s^{m+2}\kappa\right|^2 ds+C\left(f_0,\triangle\Psi,\alpha,\beta,L,m,\varepsilon\right),\end{aligned} \tag{3.10}$$

where the last inequality comes from applying Young's inequality and the inequality

$$\|\kappa\|_{k,2}^2 \leq c\,(k)\left(\left\|\nabla_s^k\kappa\right\|_2^2 + \|\kappa\|_2^2\right)$$

(can be yielded by a standard interpolation inequality; see [2]).

The remaining term in (3.5) to be estimated is $\lambda_1\,(t)\cdot\int_I \left|\nabla_s^{m+1}\kappa\right|^2\,ds$, which is the borderline case as applying the above estimates. In other words, the interpolation technique fails now. Instead, we use the observation that the total torsion is invariant under the rescaling; therefore, the rescaling argument in [4] still works. More precisely, it can be verified that as we rescale f by $f^{(\rho)} = p + \rho\,(f-p)$, we have the properties $\mathcal{K}\left[f^{(\rho)}\right] = \frac{1}{\rho}\mathcal{K}\,[f]$, $\mathcal{T}\left[f^{(\rho)}\right] = \mathcal{T}\,[f]$ and $\mathcal{L}\left[f^{(\rho)}\right] = \rho\mathcal{L}\,[f]$. Taking the derivative of $\mathcal{F}\left[f^{(\rho)}\right]$ at $\rho = 1$ and using (1.5), we have

$$2\alpha\mathcal{K}\,[f] - \lambda_1\mathcal{L}\,[f] = -\frac{d}{d\rho}\mathcal{F}\left[f^{(\rho)}\right]\lfloor_{\rho=1} = \int_I \left\langle \partial_t f, f-p\right\rangle\,ds.$$

Thus, as long as $p = p\,(t)$ is properly chosen, e.g., $p = L^{-1}\int_I f\,ds$, and by the energy identity

$$\frac{d}{dt}\mathcal{F}\,[f_t] = -\int_I \left|\partial_t f\right|^2\,ds, \tag{3.11}$$

one has the inequality

$$-\lambda_1\,(t) \leq L^{1/2}\left\|\partial_t f\right\|_{L^2},$$

which implies the estimate

$$\int_0^t \left(\lambda_1^-\,(\tau)\right)^2\,d\tau \leq C\,(f_0, \triangle\Psi, \alpha, \beta, L),$$

where $\lambda_1^-\,(t) = -\min\{0, \lambda_1\,(t)\}$. By applying integration by parts and the Hölder inequality, we have

$$-\lambda_1\int_I \left|\nabla_s^{m+1}\kappa\right|^2\,ds \leq \varepsilon\cdot\int_I \left|\nabla_s^{m+2}\kappa\right|^2\,ds + c\,(\varepsilon)\cdot\left(\lambda_1^-\right)^2\cdot\int_I \left|\nabla_s^m\kappa\right|^2\,ds. \tag{3.12}$$

Note that by applying the Poincaré inequality twice, we have

$$\int_I \left|\nabla_s^{m+2}\kappa\right|^2\,ds \geq \left(\frac{2\pi}{L}\right)^4\int_I \left|\nabla_s^m\kappa\right|^2\,ds. \tag{3.13}$$

Now, by (3.5), (3.9), (3.10), (3.12), (3.13), and a small enough number $\varepsilon = \varepsilon\,(f_0, \triangle\Psi, \alpha, \beta, L, m) > 0$, we have

$$\frac{d}{dt}\int_I \left|\nabla_s^m\kappa\right|^2\,ds + C_1\cdot\int_I \left|\nabla_s^m\kappa\right|^2\,ds \leq C_2\cdot\left(1 + \left(\lambda_1^-\,(t)^2\right)\cdot\int_I \left|\nabla_s^m\kappa\right|^2\,ds\right), \tag{3.14}$$

where we let $C_i = C_i\,(f_0, \triangle\Psi, \alpha, \beta, L, m) > 0$ for all $i \in \mathbb{Z}$, from now on. Let

$$u_m\,(t) := \exp\,(C_1\cdot t)\cdot\int_I \left|\nabla_s^m\kappa\right|^2\,ds.$$

By applying the Gronwall inequality to (3.14), we have

$$u_m(t) \le e^{a(t)} \cdot \left(u_m(0) + C_2 \cdot \int_0^t e^{C_1 \cdot \tau}\, d\tau \right),$$

where

$$a(t) = \int_0^t C_2 \cdot (\lambda_1^-(\tau))^2\, d\tau \le C(f_0, \triangle\Psi, \alpha, \beta, L, m).$$

Therefore, we obtain

$$\begin{aligned} \|\nabla_s^m \kappa\|_{L^2}^2(t) &\le C(f_0, \triangle\Psi, \alpha, \beta, L, m) \cdot (1 + e^{-C_1 \cdot t} \cdot \|\nabla_s^m \kappa\|_{L^2}^2(0)) \\ &\le C(f_0, \triangle\Psi, \alpha, \beta, L, m) \end{aligned} \tag{3.15}$$

for all $m \ge 0$. In addition, from the definition of λ_1 in (1.6), we conclude that $|\lambda_1| \le C(f_0, \triangle\Psi, \alpha, \beta, L)$. Notice that one has the estimate

$$\left\|\partial_s^{m-1}\kappa\right\|_{L^\infty} \le c \cdot \|\partial_s^m \kappa\|_{L^1} \quad \forall\ m \ge 1. \tag{3.16}$$

Now, by applying the induction argument on m, and using Lemmas 2.4 and 2.5, (3.15), (3.16), and the Hölder inequality, we derive the inequalities

$$\|\nabla_s^m \kappa\|_{L^\infty} + \|\partial_s^m \kappa\|_{L^\infty} \le C(f_0, \triangle\Psi, \alpha, \beta, L, m)\ \forall\ m \ge 0. \tag{3.17}$$

On the asymptotic behavior of the flow, we choose a subsequence of curves $f(t,\cdot)$ which converges smoothly to a curve f_∞, after reparametrizations of arclength and translations. Lemma 3.3 and (3.17) imply

$$\|\nabla_t(\nabla_s^m \kappa)\|_{L^\infty} \le C(f_0, \triangle\Psi, \alpha, \beta, L, m)\ \forall\ m \ge 0. \tag{3.18}$$

From (3.17) and (3.18), one sees that for $u(t) := \int_I |\partial_t f|^2\, ds$, the inequality

$$|u'(t)| \le C(f_0, \triangle\Psi, \alpha, \beta, L)$$

holds. On the other hand, the energy identity, (3.11), implies $u(t) \in L^1([0,\infty))$. Therefore, $u(t) \to 0$ as $t \to \infty$. In other words, f_∞ is independent of t and thus, by (1.5), is an equilibrium of $\mathcal{F}$. Now, by Theorem 1.1, the proof is finished. ∎

4. Numerical algorithm. We base our numerical treatment on the algorithm proposed in [4] and implement the new nonlinear term $\lambda_2 \nabla_s (T \times \kappa)$ explicitly in time.

First, observe that the divergence form of the main part in the evolution equation admits a weak formulation of the flow. In fact, we have

$$\nabla_s^2 \kappa + \tfrac{1}{2}|\kappa|^2 \kappa - \lambda_2 \nabla_s (T \times \kappa) = \partial_s \left(\partial_s \kappa + \tfrac{3}{2}|\kappa|^2 T - \lambda_2 T \times \kappa \right).$$

Second, the common way of avoiding higher order elements for the discretization is to rewrite the equation as a second-order system for position vector f and the mean curvature vector κ:

$$\partial_t f + \partial_s \left(\partial_s \kappa + \tfrac{3}{2}|\kappa|^2 T - \lambda_2 T \times \kappa \right) = \lambda_1 \kappa, \tag{4.1}$$

$$\partial_s^2 f = \kappa. \tag{4.2}$$

The weak form of the problem leads in one space dimension to a difference scheme. Decompose $I = \mathbb{R}/\mathbb{Z} = \cup_1^N I_j$ into intervals $I_j = [x_{j-1}, x_j)$, where x_j are the nodal points. We discretize the space $H^1(I, \mathbb{R}^3)$ by the space

$$X_h = \left\{ g \in C^0(I, \mathbb{R}^3) : g|_{I_j} \in_1 (I_j) \right\} = (\operatorname{span}\{\phi_1, \dots, \phi_N\})^n$$

of periodic piecewise affine functions spanned by the nodal basis functions $\phi_j \in X_h$ satisfying $\phi_j(x_i) = \delta_{ij}$. The discretization parameter is given by $h = \max_j h_j$, $h_j = |I_j|$. We use the pointwise interpolation $I_h g$, $g \in C^0(I, \mathbb{R}^3)$ uniquely defined by $I_h g \in X_h$ and $I_h g(x_j) = g(x_j)$ for all $j = 1, \dots, N$. A discrete (weak) solution to (4.1) is then a pair of functions $(f_h, \kappa_h) : [0, T] \to X_h \times X_h$,

$$f_h(x,t) = \sum_{j=1}^N f_j(t)\phi_j(x), \quad \kappa_h(x,t) = \sum_{j=1}^N \kappa_j(t)\phi_j(x)$$

satisfying for all $\phi_h, \psi_h \in X_h$ the weak problem

$$\begin{aligned} &\int_I \left(I_h(\partial_t f_h \phi_h)|\partial_x f_h| - \frac{\partial_x \kappa_h}{|\partial_x f_h|}\partial_x \phi_h - \frac{3}{2}|\kappa_h|^2 \frac{\partial_x f_h}{|\partial_x f_h|}\partial_x \phi_h \right) dx \\ &= \int_I \left(\lambda_1 \frac{\partial_x f_h}{|\partial_x f_h|} \times \kappa_h \partial_x \phi_h + \lambda_2 I_h(\kappa_h \phi_h)|\partial_x f_h| \right) dx = 0, \end{aligned} \tag{4.3}$$

$$-\int_I \frac{\partial_x f_h}{|\partial_x f_h|}\partial_x \psi_h dx = \int_I I_h(\kappa_h \psi_h)|\partial_x f_h| dx. \tag{4.4}$$

In the time direction we discretize semi-implicitly. In particular, the new nonlinear term $\lambda_2 \nabla_s (T \times \kappa)$ in our flow equation is treated explicitly. For functions defined on the time interval $[0, T]$ we use the notation $g^m = g(\cdot, mk)$, $kM = T$.

Algorithm. For given initial data $f_0(x)$ and nodal points of the parameterization x_j, $j = 1, \dots, N$ let $f_j^0 = f_0(x_j)$, $h_j^0 = |f_j^0 - f_{j-1}^0|$, and

$$\kappa_j^0 = \frac{2}{h_{j+1}^0(h_j^0 + h_{j+1}^0)} f_{j+1}^0 - \frac{2}{h_j^0 h_{j+1}^0} f_j^0 + \frac{2}{h_j^0(h_j^0 + h_{j+1}^0)} f_{j-1}^0,$$

where we use the extensions $f_0^0 = f_N^0$, $f_{N+1}^0 = f_1^0$, $h_0^0 = h_N^0$, $h_{N+1}^0 = h_1^0$.

For $m = 0, \dots, M-1$ we set

$$\begin{aligned} h_j^m &= |f_j^m - f_{j-1}^m|, \\ \beta_j^m &= |\kappa_{j-1}^m|^2 + \kappa_{j-1}^m \kappa_j^m + |\kappa_j^m|^2, \\ \gamma_j^m &= \frac{f_j^m - f_{j-1}^m}{h_j^m} \times \frac{\kappa_j^m + \kappa_{j-1}^m}{2}, \end{aligned}$$

and solve for $f_j^{m+1}, \kappa_j^{m+1}$ in

$$\begin{aligned}
\frac{\beta_j^m}{2h_j^m} f_{j-1}^{m+1} + \left(\frac{h_j^m + h_{j+1}^m}{2k} - \frac{\beta_j^m}{2h_j^m} - \frac{\beta_{j+1}^m}{2h_{j+1}^m} \right) f_j^{m+1} + \frac{\beta_{j+1}^m}{2h_{j+1}^m} f_{j+1}^{m+1} \\
+ \frac{1}{h_j^m} \kappa_{j-1}^{m+1} - \left(\frac{1}{h_j^m} + \frac{1}{h_{j+1}^m} + \frac{\lambda_1^m}{2}(h_j^m + h_{j+1}^m) + \lambda_2^m * \right) \kappa_j^{m+1} + \frac{1}{h_{j+1}^m} \kappa_{j+1}^{m+1} \\
= \frac{h_j^m + h_{j+1}^m}{2k} f_j^m + \lambda_2^m \left(\gamma_{j+1}^m - \gamma_j^m \right), \\
\frac{1}{h_j^m} f_{j-1}^{m+1} - \left(\frac{1}{h_j^m} + \frac{1}{h_{j+1}^m} \right) f_j^{m+1} + \frac{1}{h_{j+1}^m} f_{j+1}^{m+1} = \frac{h_j^m + h_{j+1}^m}{2} \kappa_j^m.
\end{aligned}$$

Here, the Lagrange multipliers are computed according to

$$\begin{aligned}
\lambda_2^m &= \frac{2\beta}{L^m}(\tau^m + \Delta\Psi), \\
\lambda_1^m &= -\frac{\sum_{j=1}^N \left(|\kappa_j^m - \kappa_{j-1}^m|^2 / h_j^m + (f_j^m - f_{j-1}^m) \cdot (\kappa_j^m - \kappa_{j-1}^m) \beta_j^m / 2h_j^m + \lambda_2^m \Gamma_j^m \right)}{\sum_{j=1}^N h_j^m \beta_j^m / 3},
\end{aligned}$$

where

$$\begin{aligned}
\Gamma_j^m &= \kappa_j^m \cdot (\gamma_{j+1}^m - \gamma_j^m), \\
\tau^m &= -3 \sum_{j=1}^N \Gamma_j^m / \beta_j^m, \\
L^m &= \sum_{j=1}^N h_j^m.
\end{aligned}$$

The algorithm is intrinsic in the sense that it does not explicitly depend on the grid parameter $h = \max_j h_j$. Nevertheless, during time evolution the distribution of nodes drift away from the equidistant grid. Thus, we redistribute the nodes tangentially according to arclength if the ratio $\max_j h_j / \min_j h_j$ exceeds 2.

We also mention that the linear system for $f_j^{m+1}, \kappa_j^{m+1}$ can be decoupled, giving a linear system for f_j^{m+1} alone. The tridiagonal structure of the matrices is then replaced by a five-diagonal structure, where the periodicity of the curve implies nonzero elements in the upper right and lower left corners. The implementation of a fifth-diagonal linear solver can easily be generalized to such a situation.

Computations and figures. Let us first note that numerical computations show that the flat circle is a stationary solution which continues to stay stable for small values of β. For increasing values of β the circle loses stability, and we observe nontrivial equilibria of nonzero total torsion.

Figure 4.1 shows a table of stationary states for given values of $\Delta\Psi$ in the interval $(-\pi, \pi)$. Observe that equilibria corresponding to the same absolute value of $\Delta\Psi$ bend into the opposite direction leading to a reflection symmetry w.r.t. the horizontal plane.

It is interesting to see that the issue of inflection points comes into play if $|\Delta\Psi|$ approaches the value π. Then the corresponding asymptotic stationary curve contains

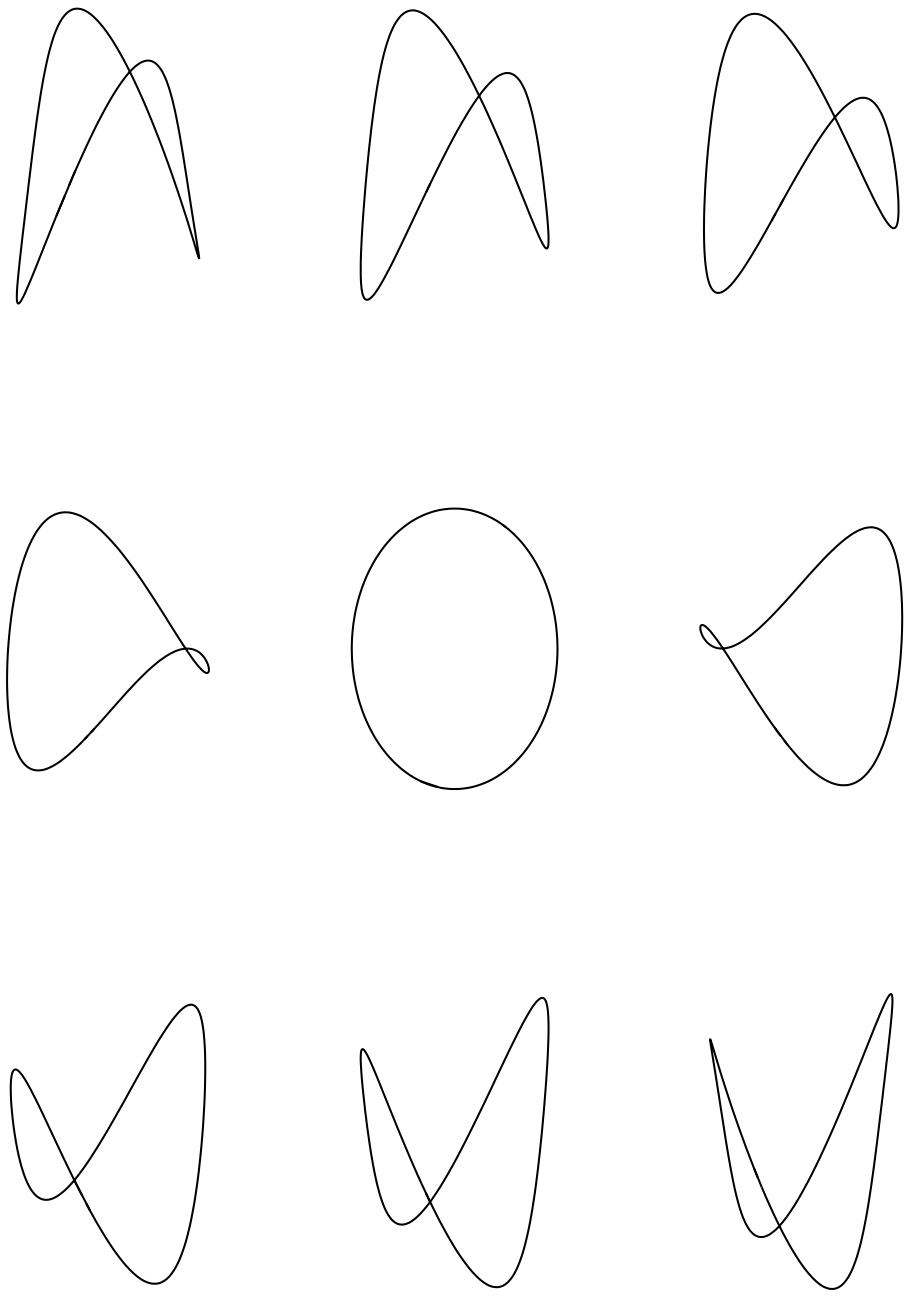

FIG. 4.1. *Stationary curves of length* 6.31 *for* $\beta = 35$ *and* $\Delta\Psi = -3.1, -2, -1, -0.5, 0, 0.5, 1, 2, 3.1$.

points having a very small magnitude of the curvature vector κ. We mentioned before that the flow equation and the computation of the torsion τ gets ill-defined in such a situation. We observe this problem also in our computations in the sense that the flow gets numerically unstable if curves with points of small $|\kappa|$ evolve.

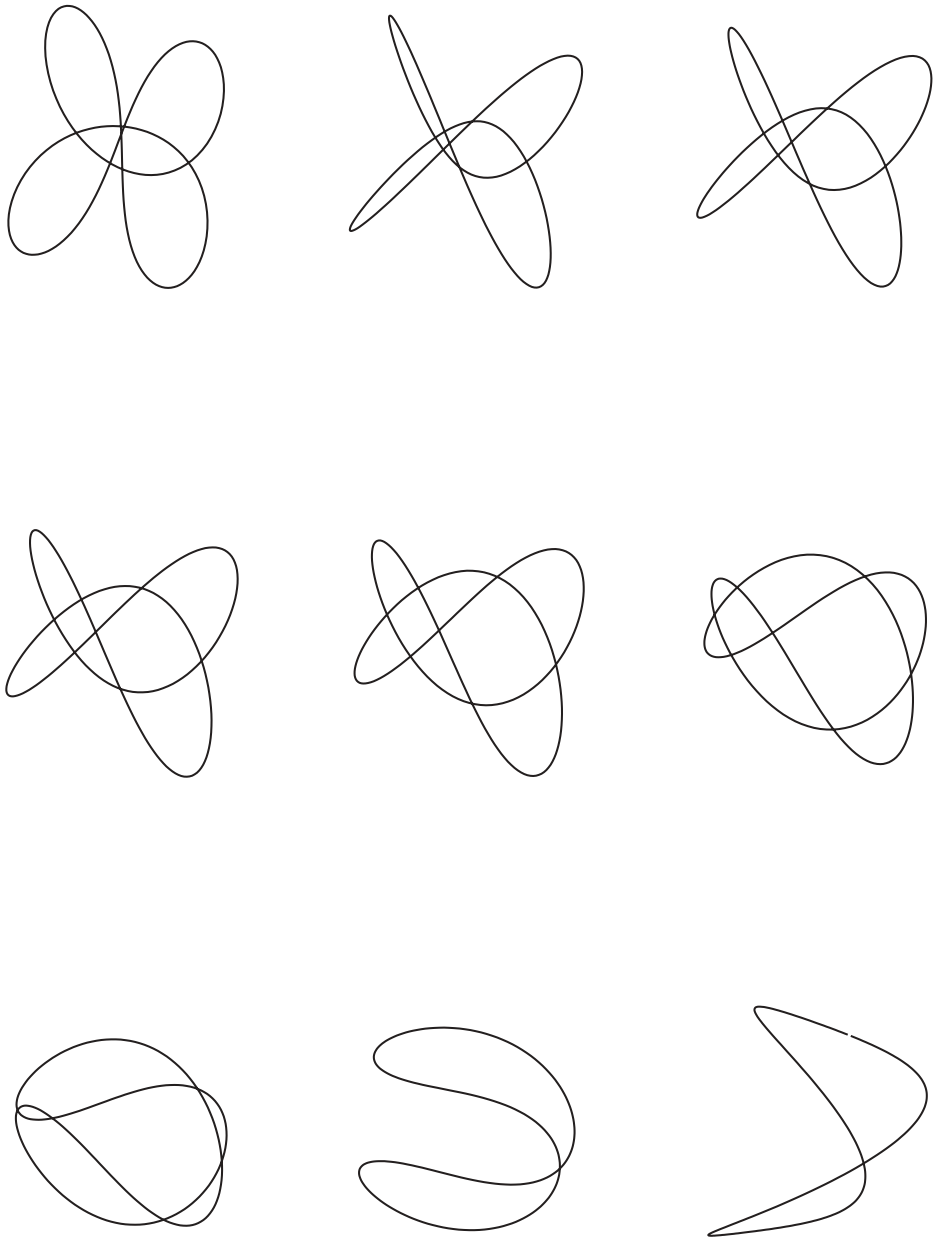

FIG. 4.2. *Evolution of a curve of length* 18.9 *under the flow with* $\beta = 60$, $\Delta\Psi = -2$ *at times* $t = 0, 1, 2, 3, 4, 6, 8, 13, 52$.

The next table in Figure 4.2 presents the evolution of a strongly bent initial curve unfolding along our flow to a stationary curve. Recalling the different lengths, the curve is similar (but not identical) to the one from Figure 4.1.

BIFURCATIONS OF A RATIO-DEPENDENT PREDATOR-PREY SYSTEM WITH CONSTANT RATE HARVESTING*

DONGMEI XIAO† AND LESLIE STEPHEN JENNINGS‡

Abstract. The ratio-dependent predator-prey model exhibits rich interesting dynamics due to the singularity of the origin. The objective of this paper is to study the dynamical properties of the ratio-dependent predator-prey model with nonzero constant rate harvesting. For this model, the origin is not an equilibrium. It is shown that numerous kinds of bifurcation occur for the model, such as the saddle-node bifurcation, the subcritical and supercritical Hopf bifurcations, Bogdanov–Takens bifurcation, the homoclinic bifurcation, and the heteroclinic bifurcation, as the values of parameters of the model vary. Hence, there are different parameter values for which the model has a limit cycle, or a homoclinic loop, or a heteroclinic orbit, or a separatrix connecting a saddle and a saddle-node. These results reveal far richer dynamics compared to the model with no harvesting.

Key words. ratio-dependent predator-prey system, constant rate harvesting, bifurcation, extinction, coexistence

1. Introduction.

In population dynamics, both ecologists and mathematicians are interested in the following Michaelis–Menten-type predator-prey model, the so-called ratio-dependent predator-prey model:

$$\begin{aligned} \dot{x} &= rx\left(1-\frac{x}{K}\right)-\frac{cxy}{my+x}, \\ \dot{y} &= y\left(-D+\frac{fx}{my+x}\right), \end{aligned} \tag{1.1}$$

where $x(t)$ and $y(t)$ represent population densities of prey and predator at time t, respectively. r, K, c, m, D, and f are positive constants. The prey grows with intrinsic growth rate r and carrying capacity K in the absence of predation. D, c, m, and f stand for the predator death rate, capturing rate, half saturation constant, and conversion rate, respectively. The reason for the model is that numerous field and laboratory experiments and observations (Abrams and Ginzburg [1], Arditi and Berryman [3], Arditi and Ginzburg [4], Arditi, Ginzburg, and Akcakaya [5], Akcakaya, Arditi, and Ginzburg [2], Cosner et al. [14], and Gutierrez [20]) showed that functional and numerical responses over typical ecological timescales ought to depend on the densities of both prey and predators, especially when predators must search for food (and therefore must share or compete for food). The suitable functional response is a *ratio-dependent* response function, which, roughly, the per capita predator growth rate should be a function of the ratio of prey to predator abundance. For more biological background concerning the model, the reader can refer to the above references

and the extensive references cited. The dynamics of system (1.1) has been studied extensively (Berezovskaya, Karev, and Arditi [7], Hsu, Hwang, and Kuang [21], Jost, Arino, and Arditi [22], Kuang [23], Kuang and Beretta [24], Xiao and Ruan [29], and references therein). Research on the ratio-dependent predator-prey model (1.1) revealed rich interesting dynamics such as deterministic extinction, existence of multiple attractors, and existence of a stable limit cycle. It was shown in [7], [21], and [29] that system (1.1) has very complicated dynamics close to the origin: there exist numerous kinds of topological structures in a neighborhood of the origin, including parabolic orbits, elliptic orbits, hyperbolic orbits, and any combination thereof, depending on the different values of parameters. Thus, the origin is a degenerate equilibrium with high codimension. Mathematically, from the point of view of bifurcation, it is a very interesting question what kinds of bifurcation will occur when system (1.1) is perturbed by a small constant term. From the perspective of biology, the complicated dynamics clearly indicates that for the ratio-dependent model, even if there is a positive equilibrium, both prey and predator can still go extinct for some values of parameters, and the extinction occurs in two distinct ways. One of the ways is that both species become extinct regardless of the initial densities such as the Gause's classic observation of mutual extinction. The other way is that both species will die out only if the initial prey/predator ratio is too low. Some researchers regard such interesting dynamics as "pathological behavior" and hope to remove it so as to guarantee the persistence of the system. From the point of view of human needs, the exploitation of biological resources and the harvesting of populations are commonly practiced in fishery, forestry, and wildlife management. There is a wide range of interest in the use of bioeconomic models to gain insight into the scientific management of renewable resources like fisheries and forestries. It is related to the optimal management of renewable resources (an excellent introduction to optimal management of renewable resources is given by Clark in [13]). Generally speaking, it is necessary to consider the harvesting of populations in some models. Taking into consideration the above two-fold reasons, we focus on the ratio-dependent predator-prey model with constant harvesting. For mathematical simplicity, let us first nondimensionalize system (1.1) as in Kuang and Beretta [24] with the following scaling:

$$t \to rt, \quad x \to x/K, \quad y \to my/K.$$

Then system (1.1) takes the form

$$\begin{aligned} \dot{x} &= x(1-x) - \frac{axy}{y+x}, \\ \dot{y} &= y\left(-d + \frac{bx}{y+x}\right), \end{aligned} \tag{1.2}$$

where $a = \frac{c}{mr}$, $b = \frac{f}{r}$, and $d = \frac{D}{r}$ are positive constants. For simplicity, in the following, we keep the biological implications of parameters a, b, and d the same as c, f, and D, respectively.

In this paper, we assume that the predator in the model (1.2) is not of commercial importance. The prey is continuously being harvested at a constant rate by a harvesting agency. The harvesting activity does not affect the predator population directly. It is obvious that the harvesting activity does reduce the predator population indirectly by reducing the availability of the prey to the predator.

We formulate the problem as:

$$\begin{aligned} \dot{x} &= x(1-x) - \frac{axy}{y+x} - h, \\ \dot{y} &= y\left(-d + \frac{bx}{y+x}\right), \end{aligned} \tag{1.3}$$

where h represents the rate of harvesting or removal; hence, $h > 0$.

The objective of this paper is to systematically study the dynamical properties of the ratio-dependent predator-prey model with constant harvesting. It will be better for us to determine how the constant harvesting affects the dynamics of system (1.3). The occurrence of change of structure, or bifurcation, in a system with parameters is a major way to predict global dynamics of the system. By making local calculations, we give bifurcation analysis for system (1.3) and show that system (1.3) can exhibit numerous kinds of bifurcation phenomena in terms of the original parameters in the model, including the bifurcation of cusp type of codimension 2 (i.e., Bogdanov–Takens bifurcation), the heteroclinic bifurcation, and the separatrix connecting a saddle-node and a saddle bifurcation. However, the ratio-dependent model (1.2) cannot undergo these bifurcations. From the point of view of the optimal management of renewable resources, the aim is to determine how much we can harvest without altering dangerously the harvested population. According to Clark in [13], the management of renewable resources has been based on the maximum sustainable yield (MSY), with the property that any larger harvest rate will lead to the depletion of the population (eventually to zero). If x is harvested by some process of overexploitation (i.e., $h > h_{MSY}$), then the prey species can be led to extinction. The most rapid recovery of the population is achieved by means of a moratorium on harvesting, i.e., $h = 0$. In this paper, qualitative and bifurcation analyses are combined to determine $h_{MSY} = \frac{1}{4}$ for the model (1.3). Biologically, when $h \geq \frac{1}{4}$, overharvesting of prey species occurs for model (1.3), which may lead to the collapse of the whole system. Hence, $0 < h < \frac{1}{4}$ is of interest for model (1.3). Another noteworthy prediction from model (1.3) is that prey and predator species cannot become extinct simultaneously (mutual extinction) for all values of parameters and initial values. This, however, contradicts the observation of mutual extinction for the ratio-dependent model (1.2). Thus, prey harvesting prevents mutual extinction as a possible outcome of predator-prey interaction and removes the "pathological behavior" of model (1.2).

This paper is organized as follows. In section 2, we study the existence of the equilibria and various types of dynamical behavior in the small neighborhood of the equilibrium for the model (1.3). Some proofs of various types of dynamics are placed in the appendices. We also describe the phase portraits and the biological ramifications of our results. In section 3 we consider all possible bifurcations of the model depending on all parameters. We show that the model exhibits the saddle-node bifurcation, the subcritical and supercritical Hopf bifurcations, the Bogdanov–Takens bifurcation of codimension 2, the separatrix connecting a saddle and a saddle-node bifurcation, and the heteroclinic bifurcation in terms of the original parameters. The paper ends with a brief discussion.

2. General phase portraits analysis of equilibria. In this section, we consider the ratio-dependent predator-prey system with a constant rate harvesting:

$$\begin{aligned} \dot{x} &= x(1-x) - \frac{axy}{y+x} - h \triangleq f_1(x,y), \\ \dot{y} &= y\left(-d + \frac{bx}{y+x}\right) \triangleq f_2(x,y), \end{aligned} \tag{2.1}$$

where a, h, d, and b are positive parameters. From the standpoint of biology, we are interested only in the dynamics of system (2.1) in the closed first quadrant R_+^2. Thus, we consider only the biologically meaningful initial condition

$$x(0) \geq 0, \quad y(0) \geq 0.$$

Straightforward computation shows that $f_1(x,y)$ and $f_2(x,y)$ are continuous and Lipschizian in the closed first quadrant R_+^2 if we let $f_1(0,0) = -h$, $f_2(0,0) = 0$. Hence, solution of (2.1) with nonnegative initial condition exists and is unique. It is also easy to see that the x-axis is invariant under the flow. However, this is not the case on the y-axis. All solutions touching the y-axis cross out of the first quadrant, and the origin $(0,0)$ is not an equilibrium of system (2.1). Thus, the first quadrant is no longer positively invariant under the flow generated by system (2.1), which makes the qualitative analysis of system (2.1) difficult.

First, let us begin to determine the location and number of the equilibria of system (2.1) in the first quadrant R_+^2. From system (2.1), we can see that there exists an equilibrium of system (2.1) in R_+^2 if and only if the equations

$$\begin{aligned} x(1-x) - \frac{axy}{y+x} - h &= 0, \\ y\left(-d + \frac{bx}{y+x}\right) &= 0 \end{aligned} \tag{2.2}$$

have a pair of nonnegative real solutions (x,y). It is clear that equations (2.2) have at most four pairs of nonnegative real solutions (x_i, y_i) and (x_i^*, y_i^*),

$$x_i = \frac{1 + (-1)^i\sqrt{1-4h}}{2}, \qquad y_i = 0;$$

$$x_i^* = \frac{b - a(b-d) + (-1)^i\sqrt{\Delta}}{2b}, \qquad y_i^* = \frac{b-d}{d}x_i^*,$$

where $i = 1, 2$, $\Delta = (a(b-d) - b)^2 - 4hb^2$. Therefore, we have the following simple lemma which describes the number and location of equilibria of system (2.1). The proof is omitted.

LEMMA 2.1.

(1) *System* (2.1) *has no equilibria in* R_+^2 *if* $h > \frac{1}{4}$.

(2) *System* (2.1) *has a unique equilibrium in* R_+^2, *which is* $(x_0, y_0) = (\frac{1}{2}, 0)$ *if* $h = \frac{1}{4}$.

(3) *System* (2.1) *has two equilibria in* R_+^2, *which are* (x_1, y_1) *and* (x_2, y_2) *if one of the following conditions holds:*

(3.i) $b \leq d$ *and* $0 < h < \frac{1}{4}$;

(3.ii) $b - d \geq \frac{b}{a}$ *and* $0 < h < \frac{1}{4}$;

(3.iii) $0 < b - d < \frac{b}{a}$ *and* $(\frac{a(b-d)-b}{2b})^2 < h < \frac{1}{4}$.

(4) *System* (2.1) *has three equilibria in* R^2_+, *which are* $(x^*, y^*) = (\frac{b-a(b-d)}{2b}, \frac{b-d}{d}x^*)$, (x_1, y_1), *and* (x_2, y_2) *if* $0 < b - d < \frac{b}{a}$ *and* $(\frac{a(b-d)-b}{2b})^2 = h < \frac{1}{4}$.

(5) *System* (2.1) *has four equilibria in* R^2_+, *which are* (x_1^*, y_1^*), (x_2^*, y_2^*), (x_1, y_1), *and* (x_2, y_2) *if* $0 < b - d < \frac{b}{a}$ *and* $0 < h < \min\{(\frac{a(b-d)-b}{2b})^2, \frac{1}{4}\}$.

When $h > \frac{1}{4}$, system (2.1) has no equilibria, and $\dot{x}(t) < 0$ in R^2_+. The dynamics of system (2.1) in R^2_+ is trivial and all orbits in R^2_+ will cross the y-axis and go out of R^2_+ in finite time. This implies that the prey species goes extinct, which in turn causes the extinction of the predator. Biological overharvesting occurs. When $0 < h \leq \frac{1}{4}$, system (2.1) has some equilibria, and there exist some initial values such that the population of prey in system (2.1) does not go extinct. Thus, $h_{MSY} = \frac{1}{4}$ for system (2.1) from Lemma 2.1.

Next we consider the dynamics of system (2.1) in the neighborhood of each equilibrium. The linear part of system (2.1) at these equilibria is determined by the matrix

$$Df(x, y) = \begin{pmatrix} 1 - 2x - \frac{ay^2}{(x+y)^2} & -\frac{ax^2}{(x+y)^2} \\ \frac{by^2}{(x+y)^2} & -d + \frac{bx^2}{(x+y)^2} \end{pmatrix},$$

where x and y are coordinates of these equilibria, respectively. More precisely, we have

$$Df(x_i, y_i) = \begin{pmatrix} (-1)^{i+1}\sqrt{1-4h} & -a \\ 0 & b - d \end{pmatrix},$$

and

$$Df(x_i^*, y_i^*) = \begin{pmatrix} \frac{a(b-d)d+(-1)^{i+1}\sqrt{\Delta}}{b^2} & -\frac{ad^2}{b^2} \\ \frac{(b-d)^2}{b} & \frac{d(b-d)}{b} \end{pmatrix}.$$

The dynamics of system (2.1) in the neighborhood of an equilibrium comes directly from the property of eigenvalues of the matrix $Df(x, y)$ at the equilibrium.

When $h = \frac{1}{4}$, system (2.1) has a unique equilibrium $(x_0, y_0) = (\frac{1}{2}, 0)$. The linear part of system (2.1) at (x_0, y_0) is determined by the matrix

$$Df(x_0, y_0) = \begin{pmatrix} 0 & -a \\ 0 & b - d \end{pmatrix}.$$

Using classical qualitative methods, it is straightforward to show that the equilibrium (x_0, y_0) is nonhyperbolic, i.e., it is degenerate. More precisely, we have the following theorem. The proof is placed in Appendix A.

THEOREM 2.2. *When* $h = \frac{1}{4}$, *system* (2.1) *has only a unique equilibrium* $(x_0, y_0) = (\frac{1}{2}, 0)$, *and*

(i) (x_0, y_0) *is a saddle-node of codimension* 1 *if* $b \neq d$;

(ii) (x_0, y_0) *is a degenerate saddle-node of codimension* 4 *if* $b = d$ *and* $2a - 5b \neq 0$.

Their phase portraits are shown in Figure 2.1.

Notice that the codimension of a degenerate equilibrium of vector field $v(x)$ is the codimension of the bifurcation at the degenerate equilibrium, which is the minimum number of the parameters necessary for vector field $v(x, \lambda)$ with parameter perturbation to be a universal unfolding of $v(x)$. However, it is very difficult to determine a universal unfolding of $v(x)$. Therefore, the following view is usually used to determine codimension of the bifurcation: suppose that S is the set of all structurally stable

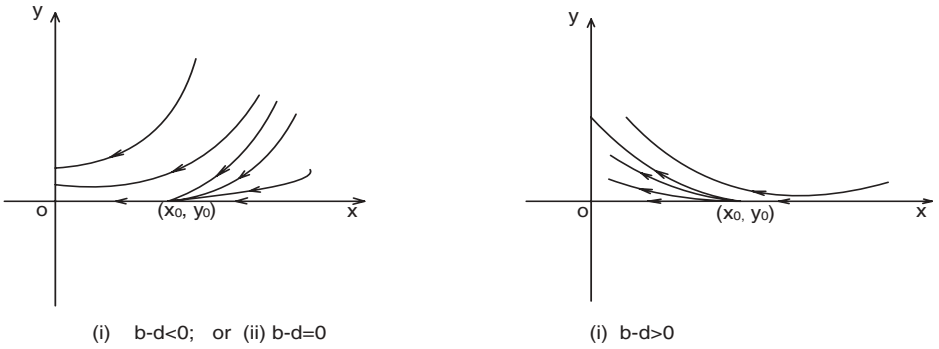

FIG. 2.1. *The phase portrait of system* (2.1) *with one equilibrium.*

vector fields in $C^1(E)$ (the set of all differential vector fields on E), and vector field $v(x)$ is in the complement of S. Then $v(x)$ belongs to the bifurcation set in $C^1(E)$ that is locally isomorphic to a manifold M in vector space or Banach space and the codimension of the bifurcation that occurs at $v(x)$ is equal to the codimension of the manifold M (cf. [19], [26]). The codimension in Theorem 2.3 is the codimension of the manifold.

In Theorem 2.2, $\dot{x} = -(x - \frac{1}{2})^2 - \frac{axy}{x+y} < 0$ in R^2_+, which implies that the prey species may go extinct as time increases for some initial values. And when $b \leq d$, predator death rate d is greater than the predator conversion rate b (i.e., the conversion efficiency of prey to predator), $\dot{y} < 0$. Hence, the predator species goes extinct as time increases for some initial values. But both cannot go to extinction simultaneously.

For sustainable development of resource, we assume that the harvesting agency has an obligation to the society and ecology of preserving the prey species. Hence, the harvesting rate h must satisfy $0 < h < \frac{1}{4}$. From Lemma 2.1 and using routine qualitative analysis, we have the following.

THEOREM 2.3. *If system* (2.1) *has only two equilibria, then the dynamics of system* (2.1) *is trivial in* R^2_+*, with no limit cycles in* R^2_+*. Each orbit of system* (2.1) *in* R^2_+ *goes to either one equilibrium on the* x*-axis or out of* R^2_+*. More precisely,*

(a) *if* $b < d$ *and* $0 < h < \frac{1}{4}$*, then system* (2.1) *has two equilibria* $(x_1, 0)$*, a hyperbolic saddle, and* $(x_2, 0)$*, a hyperbolic stable node;*

(b) *if* $b = d$ *and* $0 < h < \frac{1}{4}$*, then system* (2.1) *has two equilibria* $(x_1, 0)$ *and* $(x_2, 0)$*, both saddle-nodes;*

(c) *if* $0 < b - d < \frac{b}{a}$ *and* $(\frac{a(b-d)-b}{2b})^2 < h < \frac{1}{4}$ *(or* $b - d > \frac{b}{a}$ *and* $0 < h < \frac{1}{4}$*), then system* (2.1) *has two equilibria* $(x_1, 0)$*, a hyperbolic unstable node, and* $(x_2, 0)$*, a hyperbolic saddle.*

Their phase portraits are shown in Figure 2.2.

Biologically, system (2.1) is not persistent under the conditions of Theorem 2.3. The predator species goes extinct for some initial data or the prey species goes extinct for other initial data in R^2_+. Hence, for the persistence of the ecosystem, the equilibrium of the greatest interest would be an equilibrium interior to the first quadrant.

THEOREM 2.4. *Let* $h_0 = (\frac{a(b-d)-b}{2b})^2$*. If* $0 < b - d < \frac{b}{a}$ *and* $h = h_0 < \frac{1}{4}$*, then system* (2.1) *has three equilibria and no closed orbits in* R^2_+*. Moreover,*

(I) *if* $a \neq b$*, then system* (2.1) *has three equilibria in* R^2_+*, which are the saddle-node* $(x^*, y^*) = (\frac{b-a(b-d)}{2b}, \frac{b-d}{d}x^*) = (\sqrt{h_0}, \frac{b-d}{d}\sqrt{h_0})$*, the hyperbolic*

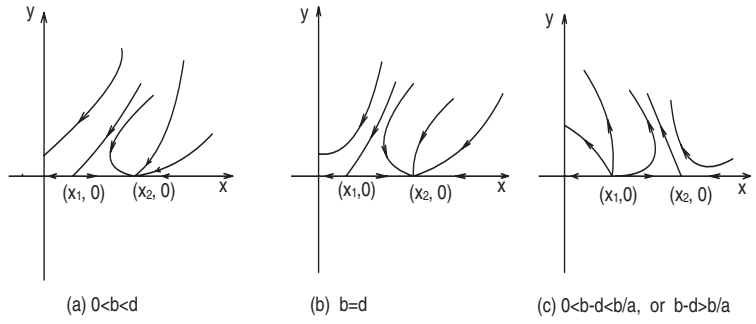

FIG. 2.2. *The phase portraits of system* (2.1) *with two equilibria.*

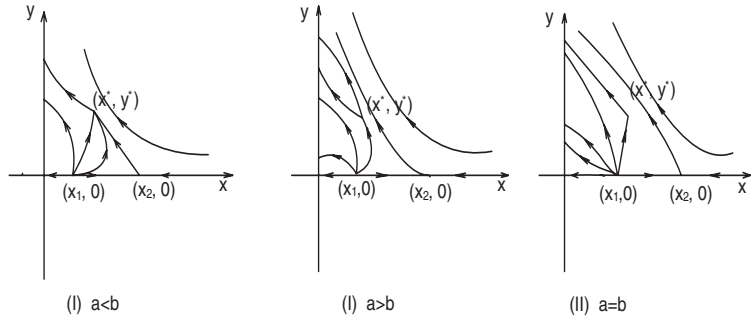

FIG. 2.3. *The phase portraits of system* (2.1) *with three equilibria.*

unstable node $(x_1, y_1) = (\frac{1-\sqrt{1-4h_0}}{2}, 0)$*, and the hyperbolic saddle* $(x_2, y_2) = (\frac{1+\sqrt{1-4h_0}}{2}, 0)$*;*

(II) *if* $a = b$*, then system* (2.1) *has three equilibria in* R^2_+*, which are the cusp* $(x^*, y^*) = (\sqrt{h_0}, \frac{b-d}{d}\sqrt{h_0})$ *of codimension* 2*, the hyperbolic unstable node* $(x_1, y_1) = (\frac{1-\sqrt{1-4h_0}}{2}, 0)$*, and the hyperbolic saddle* $(x_2, y_2) = (\frac{1+\sqrt{1-4h_0}}{2}, 0)$*.*

Their phase portraits are shown in Figure 2.3.

The proof of Theorem 2.4 is given in Appendix B. The outcome indicates that the predator species increases for all nonzero initial populations of predator except y^* when harvesting rate $h = h_0$ and the predator death rate is less than the predator conversion rate (i.e., $b > d$); however, the coexistence of predator species and prey species is possible only for some initial data and the condition that the predator capturing rate a is less than the predator conversion rate b (i.e., $a < b$). If $a > b$, the prey species goes extinct for almost all initial data in R^2_+.

If $0 < b - d < \frac{b}{a}$ and $0 < h < \min\{h_0, \frac{1}{4}\}$, then system (2.1) has two positive equilibria from Lemma 2.1. When system (2.1) has two positive equilibria, the global dynamics of system (2.1) is pretty complicated and many kinds of bifurcations will occur. We leave these to be discussed in the next section. Now we give the local dynamics of system (2.1) at the equilibria (x_1^*, y_1^*) and (x_2^*, y_2^*).

THEOREM 2.5. *If* $0 < b - d < \frac{b}{a}$ *and* $0 < h < \min\{h_0, \frac{1}{4}\}$*, then system* (2.1) *has four equilibria in* R^2_+ *as shown in Lemma* 2.1*. Moreover, the equilibria* $(x_2, 0)$ *and* (x_1^*, y_1^*) *are hyperbolic saddles, the equilibrium* $(x_1, 0)$ *is a hyperbolic unstable node, and the equilibrium* (x_2^*, y_2^*) *has the following three possibilities:*

(i) (x_2^*, y_2^*) *is a hyperbolic stable focus (or node) if either*

$$0 < b - d \le 1 < \frac{b}{a}$$

or, letting $h^* = \frac{(a(b-d)-b)^2 - (d(b-d)(a-b)/b)^2}{4b^2}$,

$$0 < b - d < \frac{b}{a} < 1, \qquad 0 < h < \min\left\{h_0,\ \frac{1}{4},\ h^*\right\};$$

(ii) (x_2^*, y_2^*) *is a weak focus or center if*

$$0 < b - d < \frac{b}{a} < 1, \qquad 0 < h = h^* < \min\left\{h_0,\ \frac{1}{4}\right\};$$

(iii) (x_2^*, y_2^*) *is a hyperbolic unstable focus (or node) if*

$$0 < b - d < \frac{b}{a} < 1, \qquad 0 < h^* < h < \min\left\{h_0,\ \frac{1}{4}\right\}.$$

3. The bifurcations of the model (2.1). In this section, we investigate the bifurcations that take place in system (2.1).

3.1. Saddle-node bifurcations. From Lemma 2.1 and Theorem 2.3, we have that

$$SN_1 = \left\{(a, b, d, h) :\ h = \frac{1}{4},\ b - d \neq 0,\ a > 0,\ b > 0,\ d > 0\right\}$$

is a *saddle-node bifurcation surface*. When the parameters pass from one side of the surface to the other side, the number of equilibria of system (2.1) changes from zero to two, and the two equilibria which are boundary equilibria are the hyperbolic saddle and node. This is the first saddle-node bifurcation surface of the model. The biological interpretation for the first saddle-node bifurcation is that $h_{MSY} = \frac{1}{4}$, the prey species is driven to extinction, and the system collapses for $h > \frac{1}{4}$, but the prey species do not go to extinction for some initial data when $0 < h < \frac{1}{4}$. On the other hand, from Theorems 2.4 and 2.5, we know that the surface

$$SN_2 = \left\{(a, b, d, h) :\ 0 < b - d < \frac{b}{a},\ h = h_0 < \frac{1}{4},\ a > 0,\ b > 0,\ d > 0\right\}$$

is a *saddle-node bifurcation surface*, which is the second saddle-node bifurcation the model undergoes. The saddle-node bifurcation yields two positive equilibria. This implies that there exists a critical harvest rate h_0 such that the predator species goes either extinct or out of R_+^2 in finite time when the harvest rate h is greater than h_0, and coexistence for model (2.1) is certain in the form of a positive equilibrium for certain choices of initial values when $0 < h < h_0$ and $0 < b - d < \frac{b}{a}$.

3.2. Hopf bifurcations. From the term (ii) of Theorem 2.5, we know that the positive equilibrium (x_2^*, y_2^*) of system (2.1) is a center-type nonhyperbolic equilibrium when $0 < b - d < \frac{b}{a} < 1$, $0 < h = h^* < \min\{h_0, \frac{1}{4}\}$. Hence, system (2.1) may undergo Hopf bifurcation. To determine the stability of the equilibrium and direction of Hopf bifurcation in this case, we must compute the Liapunov coefficients of the equilibrium.

We first translate the positive equilibrium (x_2^*, y_2^*) of system (2.1) to the origin. Then, system (2.1) in a neighborhood U of the origin can be written as

$$\begin{aligned}\dot{x} &= a_{10}x + a_{01}y + a_{20}x^2 + a_{11}xy + a_{02}y^2 \\ &\quad + a_{30}x^3 + a_{21}x^2y + a_{12}xy^2 + a_{03}y^3 + O_1(|(x,y)|^4), \\ \dot{y} &= b_{10}x + b_{01}y + b_{20}x^2 + b_{11}xy + b_{02}y^2 \\ &\quad + b_{30}x^3 + b_{21}x^2y + b_{12}xy^2 + b_{03}y^3 + O_2(|(x,y)|^4),\end{aligned} \tag{3.1}$$

where a_{ij} and b_{ij} are the coefficients of the power series expansions of $f_1(x,y)$ and $f_2(x,y)$ at (x_2^*, y_2^*) in U, respectively, $i,j = 0,1,2,3$. $O_k(|(x,y)|^4)$ is the same order infinity, $k = 1,2$. Hence, using the formula of the first Liapunov number σ for the focus at the origin of (3.1) in [26, p. 344], we have, after a tedious computation using Mathematica,

$$\sigma = \frac{3\pi d(b-d)Q}{4ab^9x_2^2\sqrt{\Delta_1^3}},$$

where $\Delta_1 = \frac{(a-b)(b-d)^2d^2}{b^3}$,

$$\begin{aligned}Q &= a^5(b-d)^8 + 2b^5(b-d)^3d^3 + 2a^4b(b-d)^5(-2b^2 + b(3+b)d - 2(1+b)d^2 + d^3) \\ &\quad + 2a^2b^3(b-d)(b^4(-2+d) + 18bd^4 - 9d^5 + 3b^3d(1+d) - b^2d^2(2+15d)) \\ &\quad + a^3b^2(b-d)^3(b(-2+d)d^2(-4+3d) + b^2d(-10 + (10-3d)d)) \\ &\quad + b^3(6 + (-4+d)d) - d^3(6 + (-4+d)d)) \\ &\quad + ab^4(44b^3d^3 - 79b^2d^4 + 62bd^5 - 18d^6 + b^4(1-9d^2)).\end{aligned}$$

By numerical calculation, we know there exist parameter values $(a,b,d) = (1, 0.5, 0.25)$, which satisfies the conditions of the term (ii) of Theorem 2.5, such that $\sigma = 465.961$. On the other hand, there exist parameter values $(a,b,d) = (4, 2, 1.85)$, which also satisfies the condition of the term (ii) of Theorem 2.5, such that $\sigma = -788.639$. Therefore, there exists an open set V_1 in the parameter space (a,b,d), such that $\sigma > 0$ and $0 < b-d < \frac{b}{a} < 1$, $0 < h^* < \min\{h_0, \frac{1}{4}\}$, i.e.,

$$V_1 = \left\{(a,b,d) : \ 0 < b-d < \frac{b}{a} < 1,\ 0 < h^* < \min\left\{h_0,\ \frac{1}{4}\right\},\ \text{and } \sigma > 0\right\}.$$

And there exists another open set V_2 in the parameter space (a,b,d), such that $\sigma < 0$ and $0 < b-d < \frac{b}{a} < 1$, $0 < h^* < \min\{h_0, \frac{1}{4}\}$, i.e.,

$$V_2 = \left\{(a,b,d) : \ 0 < b-d < \frac{b}{a} < 1,\ 0 < h^* < \min\left\{h_0,\ \frac{1}{4}\right\},\ \text{and } \sigma < 0\right\}.$$

This implies the following.

THEOREM 3.1.

(a) *If $h = h^*$, and if the parameter (a,b,d) is in V_1, then the equilibrium $(0,0)$ of system* (3.1) *is a weak focus of multiplicity* 1 and is unstable.

(b) If $h = h^*$, and if the parameter (a,b,d) is in V_2, then the equilibrium $(0,0)$ of system (3.1) is a weak focus of multiplicity 1 and is stable.

From Theorems 2.5 and 3.1, we know that the equilibrium (x_2^*, y_2^*) is a hyperbolic unstable focus if $(a,b,d) \in V_1$ and $h \geq h^*$, but the equilibrium (x_2^*, y_2^*) is a hyperbolic

stable focus if $(a,b,d) \in V_1$ and $0 < h < h^*$. Hence, when parameters pass from one side of the following surface to the other side, system (2.1) can undergo a subcritical Hopf bifurcation. An unstable limit cycle appears in the small neighborhood of (x_2^*, y_2^*) when $(a,b,d) \in V_1$ and $0 < h < h^*$. Thus, for some initial values, both species coexist for model (2.1) in the form of a positive equilibrium (x_2^*, y_2^*), and for other initial values, both species coexist for model (2.1) in the form of an oscillatory solution, which is unstable, when $(a,b,d) \in V_1$ and $0 < h < h^*$. The surface

$$H_b = \{(a,b,d,h) : \ h = h^*, \ (a,b,d) \in V_1\}$$

is called the *subcritical Hopf bifurcation surface* of system (2.1).

On the other hand, the equilibrium (x_2^*, y_2^*) is a hyperbolic stable focus if $(a,b,d) \in V_2$ and $0 < h \le h^*$, and the equilibrium (x_2^*, y_2^*) is a hyperbolic unstable focus if $(a,b,d) \in V_2$ and $h > h^*$. Hence, when parameters pass from one side of the following surface to the other side, system (2.1) can undergo a supercritical Hopf bifurcation. A stable limit cycle appears in the small neighborhood of (x_2^*, y_2^*) when $(a,b,d) \in V_2$ and $h > h^*$. Hence, the predator and the prey coexist for model (2.1) in the form of an oscillatory solution, which is stable, for some initial values when $(a,b,d) \in V_2$ and $h > h^*$. The surface

$$H_p = \{(a,b,d,h) : \ h = h^*, \ (a,b,d) \in V_2\}$$

is called the *supercritical Hopf bifurcation surface* of system (2.1).

Summarizing the above, we have the following.

THEOREM 3.2.

(i) *System* (2.1) *has at least one unstable limit cycle if* $0 < h < h^*$ *and* $(a,b,d) \in V_1$.

(ii) *System* (2.1) *has at least one stable limit cycle if* $h^* < h < \frac{1}{4}$ *and* $(a,b,d) \in V_2$.

Remark 3.1. Since there exist some parameter values such that $\sigma = 0$, system (2.1) maybe undergo *degenerate Hopf bifurcation* for some parameter values (cf. [6], [11], [12], and [26]).

3.3. The cusp bifurcation of codimension 2 (i.e., the Bogdanov–Takens bifurcation). From the item (II) of Theorem 2.4, we know that system (2.1) has a cusp (x^*, y^*) of codimension 2 when $h = h_0$, $a = b$, and $0 < b - d < \frac{b}{a}$. We now discuss if there exist the original parameters in system (2.1) such that system (2.1) exhibits Bogdanov–Takens bifurcation. We will show that a and h can be chosen as bifurcation parameters and system (2.1) can exhibit Bogdanov–Takens bifurcation.

Consider the system

$$\begin{aligned} \dot{u} &= u(1-u) - \frac{(b+\lambda_1)uv}{1+v} - (h_0 + \lambda_2), \\ \dot{v} &= v\left(-d + \frac{b}{1+v}\right) - v(1-u) + \frac{(b+\lambda_1)v^2}{1+v} + \frac{(h_0+\lambda_2)v}{u}, \end{aligned} \tag{3.2}$$

where λ_1 and λ_2 are very small parameters. When $\lambda_1 = \lambda_2 = 0$, system (3.2) has one positive equilibrium (u^*, v^*), which is a cusp of codimension 2.

Let $u_1 = u - u^*$, $v_1 = v - v^*$. Then system (3.2) becomes

$$\begin{aligned}\dot{u}_1 &= -\lambda_2 - \frac{\lambda_1 u^* v^*}{1+v^*} - \frac{(b+\lambda_1)u^* d^2}{b^2} v_1 - u_1^2 - \frac{(b+\lambda_1)d^2}{b^2} u_1 v_1 \\ &\quad + \frac{(b+\lambda_1)u^* d^3}{b^3} v_1^2 + O_1((u_1, v_1)^3), \\ \dot{v}_1 &= \frac{\lambda_1 v^{*2}}{1+v^*} + \frac{\lambda_2 v^*}{u^*} + \frac{d\lambda_1(b-d)}{b^2} v_1 + \frac{(b-d)}{du^*} u_1^2 + \frac{\lambda_1 d^3}{b^3} v_1^2 + O_2((u_1, v_1)^3).\end{aligned} \tag{3.3}$$

Next, we reduce system (3.3) to the normal form in successive steps. These steps are reminiscent of those performed in [28]. For simplicity, we omit the laborious steps and write down the normal form directly

$$\begin{aligned}\dot{u}_2 &= v_2, \\ \dot{v}_2 &= \mu_1(\lambda_1, \lambda_2) + \mu_2(\lambda_1, \lambda_2) v_2 + \frac{u^*(b-d)d^7}{2b^4} u_2^2 + \frac{2u^* d^2}{b} u_2 v_2 + O((\lambda, u_1, v_1)^3),\end{aligned} \tag{3.4}$$

where

$$\begin{aligned}\mu_1(\lambda_1, \lambda_2) &= \left(\frac{v^{*2}}{1+v^*} - \frac{d^4(b-d)}{4b^3} + \frac{d^9}{16b^8} + \frac{d^4 v^{*2}}{2(1+v^*)b^2} \right) \lambda_1 \\ &\quad + \left(\frac{v^*}{u^*} + \frac{v^* d^4}{2u^* b^2} \right) \lambda_2 + O_1((\lambda)^2), \\ \mu_2(\lambda_1, \lambda_2) &= \left(\frac{d(b-d)}{b^2} - \frac{d^6}{2b^4} + \frac{v^*}{1+v^*} + \frac{(b-d)d^5}{2b^4} - \frac{d^{10}}{4b^6} \right) \lambda_1 + \frac{1}{u^*} \lambda_2 + O_2((\lambda)^2).\end{aligned}$$

If the above parameter transformation from (λ_1, λ_2) to (μ_1, μ_2) is not singular in a small neighborhood of $(\lambda_1, \lambda_2) = (0, 0)$, then by the Bogdanov–Takens theory, system (3.4) is strongly topologically equivalent to

$$\begin{aligned}\dot{u}_3 &= v_3, \\ \dot{v}_3 &= \mu_1 + \mu_2 v_3 + u_3^2 + u_3 v_3.\end{aligned} \tag{3.5}$$

By numerical computation, we know that there exist some values of parameter (b, d) such that this parameter transformation is not singular in a small neighborhood of $(\lambda_1, \lambda_2) = (0, 0)$. Therefore, we have the following.

THEOREM 3.3. *When $0 < |h - h_0| \ll 1$, $0 < |a - b| \ll 1$, and $0 < b - d < \frac{b}{a}$, system (2.1) undergoes the cusp bifurcation of codimension 2 (i.e., the Bogadnov–Takens bifurcation). Hence, there exist values of the parameters (h, a, b, d) such that system (2.1) has a unique unstable limit cycle for some parameter values, and system (2.1) has an unstable homoclinic loop for other parameter values.*

We observe that in the model (2.1), the harvesting rate h plays the key role in determining the dynamics of (2.1). When the harvesting rate h tends to the critical harvesting rate h_0 and the predator capturing rate a tends to the predator conversion rate b, Theorem 3.3 says that if the predator death rate d satisfies $0 < b - d < \frac{b}{a}$, then there exist some values of parameters such that the prey and predator coexist in the form of a positive equilibrium or a periodic orbit with a finite period for different initial values, respectively. And there exist other values of parameters such that the prey and predator coexist in the form of a positive equilibrium for all initial values lying inside the homoclinic loop, and the prey and predator coexist in the form of a periodic orbit with infinite period for all initial values on the homoclinic loop.

3.4. The heteroclinic bifurcation and separatrix connecting a saddle-node and a saddle bifurcation. From Theorem 2.4, there may exist a separatrix connecting the saddle-node (x^*, y^*) and the saddle $(x_2, 0)$ when $a < b$, $0 < b - d < \frac{b}{a}$, and $h = h_0$. By Theorem 2.5, the saddle-node (x^*, y^*) separates into two hyperbolic equilibria, (x_1^*, y_1^*) and (x_2^*, y_2^*). Thus, when $a < b$, $0 < b - d < \frac{b}{a}$, and $0 < h < h_0$, the separatrix connecting is broken and the *separatrix connecting a saddle-node and a saddle bifurcation* occurs. There are only three possibilities for the separatrix of saddle $(x_2, 0)$ of system (2.1): (i) the separatrix of saddle $(x_2, 0)$ tends to the stable focus (x_2^*, y_2^*); (ii) there exists a heteroclinic orbit connecting saddles $(x_2, 0)$ and (x_1^*, y_1^*); (iii) the separatrix of saddle $(x_2, 0)$ goes out of the first quadrant. If possibility (ii) occurs, then system (2.1) undergoes the *heteroclinic bifurcation*. Because of technical problems, we cannot determine the exact bifurcation points.

The existence of the heteroclinic bifurcation and separatrix connecting a saddle-node and a saddle bifurcation implies that the prey and predator can coexist in the form of two positive equilibria for some initial values.

4. Discussion. Our systematic work on system (2.1) reveals that the ratio-dependent model with a constant rate harvesting is more interesting and richer in dynamics compared to the ratio-dependent model. It has been shown that the nonzero constant prey harvesting rate prevents mutual extinction as a possible outcome of predator-prey interaction. Biologically, there is still a lot of work to do in this area. For example, it would be interesting to see what the behavior of model (1.2) would be when the harvesting constant is in the predator equation. Ideally, we would be interested in studying model (1.2) with both predator and prey harvesting constants since we usually harvest, or would like to harvest, both populations. In [8], [9], and [10], Brauer and Soudack noticed some different types of dynamics whether the harvesting was in the prey or in the predator equation for a class of predator-prey system. Mathematically, we would like to point out here that our analysis of model (2.1) is a first look at the local bifurcations of the degenerate saddle-node of codimension 4, but it is far from complete. Many questions on the dynamics of the unfoldings of the saddle-node singularity of codimension 4 remain untouched. To the best of our knowledge, there are four kinds of Bogadnov–Takens-type singularity (cusp, saddle, focus, elliptic) of codimension 3, and the unfoldings of these singularities of codimension 3 are extremely complicated (cf. [19], [27], [12] and therein). The dynamical features of codimension 4 are so rich that a full description of the topology of the unfolding seems hopeless. Luckily, however, we see that there have been some perfect works that deal with the unfoldings of singularity of saddle (or cusp or elliptic) of codimension 4 (cf. [15], [16], [17], [18], [25]). In those papers, delicate results such as the limit cycles, their number, and bifurcation patterns are discussed. And it is interesting that the bifurcation of these singularities of codimension 4 can undergo the bifurcation of only the same type as singularity of codimension 3. Different from the known results of codimension 4, the bifurcation of the saddle-node singularity of codimension 4 can undergo the bifurcation of different-type singularity of codimension 3 from the following arguments. The canonical family of the saddle-node singularity of codimension 4 is

$$\begin{aligned} &\dot{x} = y, \\ &\dot{y} = \epsilon x^4 + \mu_3 x^2 + \mu_2 x + \mu_1 + y(\mu_4 + bx + cx^3), \end{aligned} \tag{4.1}$$

where $\epsilon = \pm 1$, $c, b > 0$ are parameters, and $0 < |\mu_i| \ll 1$, $i = 1, 2, \ldots, 4$, are small parameters.

The number of equilibrium points of system (4.1) depends on the number of real roots of

$$\epsilon x^4 + \mu_3 x^2 + \mu_2 x + \mu_1 = 0. \tag{4.2}$$

If (4.2) has a multiple real root with multiplicity 3, then system (4.1) has a singularity of codimension 3. The singularity can be saddle, focus, or elliptic depending on the different values of parameters (μ_1, μ_2, μ_3) and b, respectively. Thus, the unfoldings of the saddle-node singularity of codimension 4 should undergo the saddle, focus, and elliptic bifurcations of codimension 3 generally when the values of parameters vary. Its detailed qualitative and general dynamical picture of the unfoldings of the saddle-node singularity of codimension 4 remain to be seen. Naturally, these interesting topics should be pursued in the future.

It is a pity that system (2.1) does not have the singularity of codimension 3 for all possible values of original parameters in R_+^2. Thus, system (2.1) cannot be a universal unfolding of the saddle-node singularity of codimension 4. Hence, system (2.1) is only an unfolding of the saddle-node singularity of codimension 4, which leads to some bifurcations and loses some bifurcations for all possible values of parameters; for example, system (2.1) may undergo the separatrix connecting a saddle-node and a saddle bifurcation and the heteroclinic bifurcation according to the results of the saddle bifurcation of codimension 3 in [19] and [27], but system (2.1) cannot undergo the bifurcation of heteroclinic connections of two hyperbolic saddle which are produced by the saddle bifurcation of codimension 3.

Appendix A. Proof of Theorem 2.2. Since we consider the topological structure of orbits of system (2.1) in a small neighborhood of (x_0, y_0), we make the following change of variable:

$$u = x, \qquad v = \frac{y}{x}.$$

There exists a neighborhood $N_{(x_0,y_0)}$ of (x_0, y_0) such that system (2.1) in $N_{(x_0,y_0)}$ is differential homeomorphic to the following system in a neighborhood $\bar{N}_{(u_0,v_0)}$ of (u_0, v_0), where $u_0 = \frac{1}{2}$, $v_0 = 0$,

$$\begin{aligned} \dot{u} &= u(1-u) - \frac{auv}{1+v} - \frac{1}{4}, \\ \dot{v} &= v\left(-d + \frac{b}{1+v}\right) - v(1-u) + \frac{av^2}{1+v} + \frac{v}{4u}. \end{aligned} \tag{A.1}$$

Moving the equilibrium $(\frac{1}{2}, 0)$ to the origin, system (A.1) becomes

$$\begin{aligned} \dot{u} &= -\frac{1}{2}av - u^2 - auv + \frac{1}{2}av^2 + auv^2 - \frac{1}{2}av^3 - auv^3 + \frac{1}{2}av^4 + O((u,v)^5), \\ \dot{v} &= (b-d)v + (a-b)v^2 + 2u^2v + (b-a)v^3 + (a-b)v^4 - 4u^3v + O((u,v)^5). \end{aligned} \tag{A.2}$$

The conclusion (i) comes from straightforward analysis of system (A.2), as used in [30].

When $b - d = 0$, we use the procedure, used in [28], to reduce system (A.2) via the normal form method. Let

$$w_1 = -\frac{2}{a}u, \quad z_1 = v.$$

We have

$$\begin{aligned}\dot{w}_1 &= z_1 + \frac{a}{2}w_1^2 - aw_1z_1 - z_1^2 + aw_1z_1^2 + z_1^3 - aw_1z_1^3 - z_1^4 + O((w_1,z_1)^5),\\ \dot{z}_1 &= (a-b)z_1^2 + \frac{a^2}{2}w_1^2z_1 - (a-b)z_1^3 + \frac{1}{2}a^3w_1^3z_1 + (a-b)z_1^4 + O((w_1,z_1)^5).\end{aligned} \tag{A.3}$$

Consider the following C^∞ changes of coordinates in a small neighborhood of $(0,0)$ step by step

$$w_2 = w_1 + \frac{b}{2}w_1^2 + w_1z_1, \quad z_2 = z_1 + \frac{a}{2}w_1^2 - (a-b)w_1z_1;$$

$$w_3 = w_2 + \frac{a+ab+b^2}{6}w_2^3 - \frac{a-2b}{2}w_2^2z_2, \quad z_3 = z_2 + \frac{ab}{2}w_2^3 - \frac{ab-2a-b^2}{2}w_2^2z_2;$$

and

$$\begin{aligned}w_4 &= w_3,\\ z_4 &= z_3 + \left(\frac{1}{2}a^2b - \frac{1}{4}a^2 - \frac{3}{4}ab^2\right)w_3^4 + \left(\frac{1}{2}ab - \frac{1}{2}a^2 - a^2b + 2ab^2\right)w_3^3z_3\\ &\quad + \left(-a + 2a^2 - \frac{7}{2}ab + 5b^2\right)w_3^2z_3^2 + (4b-2a)w_3z_3^3 + O((w_3,z_3)^5).\end{aligned}$$

Then system (A.3) can be transformed into

$$\begin{aligned}\dot{w}_4 &= z_4,\\ \dot{z}_4 &= aw_4z_4 + \frac{1}{2}abw_4^2z_4 + \left(\frac{a^3}{2} - \frac{5}{4}a^2b\right)w_4^4\\ &\quad + \left(\frac{10}{3}a^2b - \frac{8}{3}ab^2 - \frac{7}{6}a^2 - a^3\right)w_4^3z_4 + \left(-a^2 + 3ab - a^2b + \frac{3}{2}ab^2 + \frac{5}{2}b^3\right)w_4^2z_4^2\\ &\quad + (4b-2a)z_4^4 + O((w_4,z_4)^5).\end{aligned} \tag{A.4}$$

The equilibrium $(0,0)$ of system (A.4) is a degenerate saddle-node of codimension 4 if $2a - 5b \neq 0$. The proof is completed.

Appendix B. Proof of Theorem 2.4. The existence of three equilibria comes from Lemma 2.1. Straightforward computing of the eigenvalues of the linear matrix at the equilibrium (x_1, y_1) and (x_2, y_2), respectively, reveals that (x_1, y_1) is a hyperbolic unstable node, and (x_2, y_2) is a hyperbolic saddle in both cases. Next, we determine only the various types of dynamical behavior of the equilibrium (x^*, y^*).

For simplicity, to reduce the normal form of system (2.1) at (x^*, y^*), we make the following change of variable

$$u = x, \quad v = \frac{y}{x}.$$

This transformation of variable is a differential homeomorphism in the interior of R_+^2. Thus, there exists a neighborhood $B_{(x^*,y^*)}$ of (x^*, y^*) such that system (2.1) in $B_{(x^*,y^*)}$ is differential homeomorphic to the following system in a neighborhood $\bar{B}_{(u^*,v^*)}$ of

(u^*, v^*), where $u^* = \frac{b-a(b-d)}{2b}$, $v^* = \frac{b-d}{d}$,

$$\begin{aligned} \dot{u} &= u(1-u) - \frac{auv}{1+v} - h_0 \triangleq \bar{f}_1(u,v), \\ \dot{v} &= v\left(-d + \frac{b}{1+v}\right) - v(1-u) + \frac{av^2}{1+v} + \frac{h_0 v}{u} \triangleq \bar{f}_2(u,v). \end{aligned} \tag{B.1}$$

It is clear that the functions $\bar{f}_1(u,v)$ and $\bar{f}_2(u,v)$ are analytic functions in $\bar{B}_{(u^*,v^*)}$. Let

$$u_1 = u - u^*, \qquad v_1 = v - v^*.$$

Then system (B.1) can be transformed into

$$\begin{aligned} \dot{u}_1 &= -\frac{au^*d^2}{b^2}v_1 - u_1^2 - \frac{ad^2}{b^2}u_1v_1 + \frac{au^*d^3}{b^3}v_1^2 + g_1(u_1,v_1), \\ \dot{v}_1 &= \frac{d(a-b)(b-d)}{b^2}v_1 + \frac{b-d}{du^*}u_1^2 + \frac{(a-b)d^3}{b^3}v_1^2 + g_2(u_1,v_1), \end{aligned} \tag{B.2}$$

where $g_i(u_1,v_1)$ is an analytic function with at least powers $u_1^j v_1^k$, $j+k \geq 3$, $i = 1,2$.

In the case (I), i.e., $a \neq b$, straightforward analysis, as used in [30], shows that (x^*, y^*) is a saddle-node and there exist three eigendirections of (x^*, y^*): $\theta_1 = \operatorname{arctg}(\frac{-(a-b)(b-d)}{adu^*})$, $\theta_2 = \pi$, and $\theta_3 = \pi + \operatorname{arctg}(\frac{-(a-b)(b-d)}{adu^*})$. Furthermore, when $a > b$, there exists a unique orbit in R_+^2 convergent to (x^*, y^*), and all other orbits in R_+^2 go out of R_+^2 by crossing the y-axis. Hence, there does not exist a separatrix connecting the saddle-node (x^*, y^*) and the saddle $(x_2, 0)$. When $a < b$, there exist many orbits in R_+^2 convergent to (x^*, y^*), and the other orbits in R_+^2 go out of R_+^2 by crossing the y-axis. In this case, there may exist a separatrix connecting the saddle-node (x^*, y^*) and the saddle $(x_2, 0)$. The phase portraits are shown in Figure 2.3 (both parts (I)).

In the case (II), i.e., $a = b$, let

$$u_2 = -\frac{b}{d^2u^*}u_1, \quad v_2 = v_1.$$

Then system (B.2) becomes

$$\begin{aligned} \dot{u}_2 &= v_2 + \frac{u^*d^2}{b}u_2^2 - \frac{d^2}{b}u_2v_2 - \frac{d}{b}v_2^2 + \bar{g}_1(u_2,v_2), \\ \dot{v}_2 &= \frac{u^*d^3(b-d)}{b^2}u_2^2 + \bar{g}_2(u_2,v_2), \end{aligned} \tag{B.3}$$

where $\bar{g}_i(u_2,v_2)$ is an analytic function with at least powers $u_2^j v_2^k$, $j+k \geq 3$, $i = 1,2$.

We make the following near-identity changes of variables of system (B.3) in a small neighborhood of $(0,0)$,

$$u_3 = u_2 + \frac{d^2}{2b}u_2^2 + \frac{d}{b}u_2v_2, \qquad v_3 = v_2 + \frac{u^*d^2}{b}u_2^2,$$

and

$$u_4 = u_3, \quad v_4 = v_3 + O_1(|(u_3,v_3)|^3).$$

Then by two steps, system (B.3) becomes the normal form of the cusp of codimension 2

$$\begin{aligned} \dot{u}_4 &= v_4, \\ \dot{v}_4 &= \frac{u^* d^3 (b-d)}{b^2} u_4^2 + \frac{2u^* d^2}{b} u_4 v_4 + O(|(u_4, v_4)|^3), \end{aligned} \tag{B.4}$$

where $O(|(u_4, v_4)|^3)$ is of the same order infinity.

Hence, the equilibrium $(0, 0)$ of system (B.4) is a cusp of codimension 2, i.e., the equilibrium (x^*, y^*) is a cusp of codimension 2, or a Bogdanov–Takens singularity. The phase portrait is shown in Figure 2.3 (II).

Since the closed orbit must include the equilibria in its interior and since the total sum of index of these equilibria equals one, system (2.1) does not have a closed orbit in R_+^2 under the conditions of (I) and (II). This completes the proof of the theorem.

Acknowledgment. The authors are greatly indebted to the anonymous referees for their careful reading and helpful comments, especially the referee who gave constructive suggestions for revision of the manuscript.

GEOMETRIC SINGULAR PERTURBATION APPROACH TO STEADY-STATE POISSON–NERNST–PLANCK SYSTEMS*

WEISHI LIU†

Abstract. Boundary value problems of a one-dimensional steady-state Poisson–Nernst–Planck (PNP) system for ion flow through a narrow membrane channel are studied. By assuming the ratio of the Debye length to a characteristic length to be small, the PNP system can be viewed as a singularly perturbed problem with multiple time scales and is analyzed using the newly developed geometric singular perturbation theory. Within the framework of dynamical systems, the global behavior is first studied in terms of limiting fast and slow systems. It is rather surprising that a *complete* set of integrals is discovered for the (nonlinear) limiting fast system. This allows a detailed description of the boundary layers for the problem. The slow system itself turns out to be a singularly perturbed one, too, which indicates that the singularly perturbed PNP system has three different time scales. A singular orbit (zeroth order approximation) of the boundary value problem is identified based on the dynamics of limiting fast and slow systems. An application of the geometric singular perturbation theory gives rise to the existence and (local) uniqueness of the boundary value problem.

Key words. singular perturbation, boundary layers, exchange lemma

1. Introduction. Poisson–Nernst–Planck (PNP) systems serve as basic electrodiffusion equations modeling, for example, ion flow through membrane channels, and transport of holes and electrons in semiconductors (see [1, 2, 11, 14] and references therein). In the context of ion flow through a membrane channel, the flow of ions is driven by their concentration gradients and by the electric field modeled together by the Nernst–Planck equations, and the electric field is in turn governed by the ion concentrations through the Poisson equation. To motivate the one-dimensional PNP system to be studied, we give a brief account of the modeling. We will be interested in flow of two types of ions through a narrow membrane channel. For practical purposes, the narrow membrane channel through which ions flow is tubelike with a small aspect ratio and, in this regard, it is natural to approximate the channel as a one-dimensional object (see, e.g., [1, 2]). Now consider flow of two types of ions, S_1 and S_2, with valences $\alpha > 0$ and $-\beta < 0$, passing through an ion channel viewed as a line segment. Let x be the coordinate along the channel normalized from $x = 0$ to $x = 1$. Denote the concentrations of S_1 and S_2 at location x and at time t by $c_1(t, x)$ and $c_2(t, x)$. Then the electric potential $\phi(t, x)$ in the channel at time t is determined by the Poisson equation

$$\frac{\partial^2 \phi}{\partial x^2} = -\frac{1}{\epsilon^2}(\alpha c_1 - \beta c_2),$$

where the parameter ϵ^2 is related to the ratio of the Debye length to a characteristic length scale. The flux densities, $\bar{J}_1$ and $\bar{J}_2$, of the two ions contributed from the concentration gradients of the two ions and the electric field satisfy the Nernst–Planck

equations

$$D_1\left(\frac{\partial c_1}{\partial x}+\alpha c_1\frac{\partial \phi}{\partial x}\right)=-\bar{J}_1,\quad D_1\left(\frac{\partial c_2}{\partial x}-\beta c_2\frac{\partial \phi}{\partial x}\right)=-\bar{J}_2,$$

where D_1 and D_2 are the diffusion constants of ions S_1 and S_2 relative to the membrane channel, together with the conservation of mass

$$\frac{\partial c_1}{\partial t}+\frac{\partial \bar{J}_1}{\partial x}=0,\quad \frac{\partial c_2}{\partial t}+\frac{\partial \bar{J}_2}{\partial x}=0.$$

Combining the above equations, we obtain the one-dimensional PNP system as a simplified model for flow of two ions through a narrow membrane channel:

$$\begin{aligned}&\epsilon^2\frac{\partial^2\phi}{\partial x^2}=-(\alpha c_1-\beta c_2),\quad \frac{\partial c_1}{\partial t}+\frac{\partial \bar{J}_1}{\partial x}=0,\quad \frac{\partial c_2}{\partial t}+\frac{\partial \bar{J}_2}{\partial x}=0,\\ &D_1\left(\frac{\partial c_1}{\partial x}+\alpha c_1\frac{\partial \phi}{\partial x}\right)=-\bar{J}_1,\quad D_1\left(\frac{\partial c_2}{\partial x}-\beta c_2\frac{\partial \phi}{\partial x}\right)=-\bar{J}_2.\end{aligned}\tag{1}$$

To understand the asymptotic behavior that is most relevant from a physical point of view, the first step is to study the steady-state problem. On one hand, steady-state solutions are among those that are responsible for the global structure of the full system and, on the other hand, they often represent asymptotic states of solutions of general initial conditions. In this work, we study boundary value problems of the one-dimensional steady-state PNP system. The corresponding system is

$$\begin{aligned}&\epsilon^2\frac{d^2\phi}{dx^2}=-(\alpha c_1-\beta c_2),\quad \frac{dJ_1}{dx}=0,\quad \frac{dJ_2}{dx}=0,\\ &\frac{dc_1}{dx}+\alpha c_1\frac{d\phi}{dx}=-J_1,\quad \frac{dc_2}{dx}-\beta c_2\frac{d\phi}{dx}=-J_2,\end{aligned}\tag{2}$$

where $J_1=\bar{J}_1/D_1$ and $J_2=\bar{J}_2/D_2$, and the boundary conditions are

$$\begin{aligned}&\phi(0)=v_0,\quad c_1(0)=L_1,\quad c_2(0)=L_2,\\ &\phi(1)=0,\quad c_1(1)=R_1,\quad c_2(1)=R_2.\end{aligned}\tag{3}$$

Many mathematical works have been done on the existence, uniqueness, and qualitative properties of boundary value problems even for high dimensional systems, and algorithms have been developed toward numerical approximations (see, e.g., [5, 6, 13, 7]). Under the assumption that $\epsilon \ll 1$, the problem can be viewed as a singularly perturbed system. Typical solutions of singularly perturbed systems exhibit different time scales; for example, boundary and internal layers (inner solutions) evolve at fast pace and regular layers (outer solutions) vary slowly. For the boundary value problems (2) and (3), there are two boundary layers, one at each end. Physically, near boundaries $x = 0$ and $x = 1$, the potential function $\phi(x)$ and the concentration functions $c_1(x)$ and $c_2(x)$ exhibit a large gradient or a sharp change. In [2], for $\alpha = \beta = 1$, the boundary value problem was studied using the method of matched asymptotic expansions as well as numerical simulations, which provide a good quantitative and qualitative understanding of the problem.

We also treat the problem as a singularly perturbed one by assuming $\epsilon \ll 1$ but for general α and β. Our approach uses the newly developed geometric singular perturbation theory (see, e.g., [4, 8, 10, 12]). The basic ideas behind this theory for boundary value problems are

(i) to derive, based on different time scales of the system, various limiting systems for $\epsilon = 0$ and examine their dynamical structures;
(ii) to construct a singular orbit (zeroth order approximation) consisting of orbits of limiting systems, which include boundary layers, regular layers, and, sometimes, internal layers;
(iii) to show that there are true solutions near the singular orbit for $\epsilon > 0$.

Since limiting systems essentially have lower order than the full system, it is often easier to study which make (i) useful. Understanding the dynamics of limiting subsystems allows one to carry out (ii). The most difficult part is the task (iii). It requires us to investigate the interaction between the fast and slow dynamics. A successful type of results is called the exchange lemma (see, e.g., [8, 10, 15, 12]). Its objective is to track the smooth configuration of an invariant manifold as it passes regions overlapping different time scales. For boundary value problems, two invariant manifolds, say, M_L and M_R, will be tracked: M_L will be the trace of one boundary under the flow, and M_R will be the trace of the other boundary. The existence of a solution for $\epsilon > 0$ is then reduced to the nontrivial intersection of M_L and M_R. This is where the exchange lemma comes in to play the crucial role. This approach provides not only a construction of a limiting solution but also a direct verification of the validity of the limiting solution.

The rest of the paper is organized as follows. Section 2 contains three subsections. In section 2.1, the PNP system (2) is rewritten as a singularly perturbed system of first order equations, and the boundary value problem is converted to a *connecting problem*. Two systems, slow and fast systems, with different scales are first identified according to different time scales, and some general aspects of dynamical system theory are laid out for the boundary value problem. The boundary layer behavior governed by the limiting fast system is studied in section 2.2. It is rather surprising that a complete set of integrals is discovered for the nonlinear limiting fast system which allows a detailed study of the boundary layer behavior. (The physical meanings of the integrals remain unclear.) The regular layers governed by the slow flow are analyzed in section 2.3. It turns out that the slow system itself is a singularly perturbed one which is examined using again the geometric singular perturbation theory. In section 3, we construct a singular orbit of the boundary value problem and apply the exchange lemma to show the existence and uniqueness of a solution near the singular orbit. A derivation of the integrals of the fast system is given in section 4 as an appendix.

2. A dynamical system framework.

2.1. A basis of geometric singular perturbation theory. We will recast the singularly perturbed PNP system into a system of first order equations. This singularly perturbed system corresponds to the slow scale which is suitable for understanding dynamics within the membrane channel. A fast scale system can be derived through a change of scale of the independent variable x, which can be used to capture the sharp boundary behavior. Slow and fast systems of the singularly perturbed PNP system are equivalent for $\epsilon \neq 0$, but their limits are not: they provide complementary limiting information for the full system. We begin with a dynamical system formulation of the singularly perturbed PNP system (2).

Denote derivatives with respect to x by overdot symbols and introduce

$$u = \epsilon\dot{\phi}, \quad v = \beta c_2 - \alpha c_1, \quad w = \alpha^2 c_1 + \beta^2 c_2, \quad \text{and} \quad \tau = x.$$

System (2) becomes

$$
\begin{aligned}
&\epsilon\dot{\phi} = u, \quad \epsilon\dot{u} = v, \quad \epsilon\dot{v} = uw - \epsilon(\beta J_2 - \alpha J_1),\\
&\epsilon\dot{w} = \alpha\beta uv + (\beta - \alpha)uw - \epsilon(\alpha^2 J_1 + \beta^2 J_2),\\
&\dot{J}_1 = 0, \quad \dot{J}_2 = 0, \quad \dot{\tau} = 1.
\end{aligned} \tag{4}
$$

System (4) will be treated as a dynamical system with the phase space $\mathbb{R}^7$, and the independent variable x will be viewed as time. The boundary condition (3) becomes

$$
\begin{aligned}
&\phi(0) = v_0, \quad v(0) = \beta L_2 - \alpha L_1, \quad w(0) = \alpha^2 L_1 + \beta^2 L_2, \quad \tau(0) = 0,\\
&\phi(1) = 0, \quad v(1) = \beta R_2 - \alpha R_1, \quad w(1) = \alpha^2 R_1 + \beta^2 R_2, \quad \tau(1) = 1.
\end{aligned} \tag{5}
$$

Formulation of high order equations into dynamical systems of first order equations is not unique. For the boundary value problem considered in this paper, two issues need particular attention. One is toward the derivative of $\phi(x)$. Since $\phi(x)$ is expected to have large derivatives near the boundaries, the introduction of $u = \epsilon\dot{\phi}$ seems natural. The introduction of a new variable $\tau = x$ is a special treatment for boundary value problems. The small price paid is the addition of an extra dimension with trivial dynamics to the phase space. The apparent advantage is that, to find a solution of the boundary value problem, one needs only an orbit from one boundary to the other without worrying how much time it takes the orbit to move from one side to the other: it is automatically 1 since, as a component of the orbit, $\tau = x$ will vary from 0 to 1. The change of variables from c_1 and c_2 to v and w is motivated purely from the analysis point of view.

Observe that by setting $\epsilon = 0$ in system (4), we get $u = v = 0$. The set $\mathcal{Z}_0 = \{u = v = 0\}$ is called *the slow manifold* which supports the regular layer of the boundary value problem. The regular layer will not satisfy all conditions in (5) if $\beta L_2 - \alpha L_1 \neq 0$ or $\beta R_2 - \alpha R_1 \neq 0$, and this defect has to be remedied by boundary layers. To examine boundary layer behavior, we will now derive a system, the fast system, with a time scale different from that of (4). This will be achieved through the following rescaling of time (independent variable) for dependent variables:

$$
\begin{gathered}
\Phi(\xi) = \phi(\epsilon\xi),\ U(\xi) = u(\epsilon\xi),\ V(\xi) = v(\epsilon\xi),\ W(\xi) = w(\epsilon\xi),\\
I_i(\xi) = J_i(\epsilon\xi), \ \text{ and } \ T(\xi) = \tau(\epsilon\xi).
\end{gathered}
$$

Note that capital letters for same dependent variables are used to indicate merely different time scales. In terms of ξ, we obtain *the fast system* of (4):

$$
\begin{aligned}
&\Phi' = U, \quad U' = V, \quad V' = UW - \epsilon(\beta I_2 - \alpha I_1),\\
&W' = \alpha\beta UV + (\beta - \alpha)UW - \epsilon(\alpha^2 I_1 + \beta^2 I_2),\\
&I_1' = 0, \quad I_2' = 0, \quad T' = \epsilon,
\end{aligned} \tag{6}
$$

where the prime symbol denotes the derivative with respect to the variable ξ. The limiting fast system at $\epsilon = 0$ is

$$
\begin{aligned}
&\Phi' = U, \quad U' = V, \quad V' = UW, \quad W' = \alpha\beta UV + (\beta - \alpha)UW,\\
&I_1' = 0, \quad I_2' = 0, \quad T' = 0.
\end{aligned} \tag{7}
$$

The slow manifold $\mathcal{Z}_0$ is precisely the set of equilibria of (7).

Now let B_L and B_R be the subsets of $\mathbb{R}^7$ defined, respectively, by

$$
\begin{aligned}
B_L =&\{\phi = v_0,\ v = \beta L_2 - \alpha L_1,\ w = \alpha^2 L_1 + \beta^2 L_2,\ \tau = 0\},\\
B_R =&\{\phi = 0,\ v = \beta R_2 - \alpha R_1,\ w = \alpha^2 R_1 + \beta^2 R_2,\ \tau = 1\}.
\end{aligned} \tag{8}
$$

The boundary value problem is then equivalent to the following *connecting problem*: finding a solution of (4) from B_L to B_R.

For $\epsilon > 0$, let M_L^ϵ be the union of all forward orbits of (4) starting from B_L and let M_R^ϵ be the union of all backward orbits starting from B_R. To obtain the existence and (local) uniqueness of a solution for the connecting problem, it thus suffices to show M_L^ϵ and M_R^ϵ intersect transversally. The intersection is exactly the orbit of a solution of the boundary value problem, and the transversality implies the local uniqueness. The strategy is to obtain a singular orbit and track the evolution of M_L^ϵ and M_R^ϵ along the singular orbit. As discussed in the introduction, a singular orbit will be a union of orbits of subsystems of (4) with different time scales.

The boundary layers will be two orbits of (7): one from B_L to $\mathcal{Z}_0$ in forward time along the stable manifold of $\mathcal{Z}_0$ and the other from B_R to $\mathcal{Z}_0$ in backward time along the unstable manifold of $\mathcal{Z}_0$. The two boundary layers will be connected by a regular layer on $\mathcal{Z}_0$, which is an orbit of a limiting system of (4). The next two subsections are devoted to the study of boundary layers and regular layers.

2.2. Fast dynamics and boundary layers. We start with the study of boundary layers governed by system (7). This system has many invariant structures that are useful for characterizing the global dynamics.

The slow manifold $\mathcal{Z}_0 = \{U = V = 0\}$ consisting entirely of equilibria of system (7) is a five-dimensional manifold of the phase space $\mathbb{R}^7$. For each equilibrium $z = (\Phi, 0, 0, W, I_1, I_2, T) \in \mathcal{Z}_0$, the linearization of system (7) has five zero eigenvalues corresponding to the dimension of $\mathcal{Z}_0$, and two eigenvalues in directions normal to $\mathcal{Z}_0$. The latter two eigenvalues and their associated eigenvectors are given by

$$
\lambda_\pm = \pm\sqrt{W} \ \text{ and } \ n_\pm = \Big((\pm\sqrt{W})^{-1}, 1, \pm\sqrt{W}, \pm(\beta-\alpha)\sqrt{W}, 0, 0, 0\Big)^\tau. \tag{9}
$$

Thus, every equilibrium has a one-dimensional stable manifold and a one-dimensional unstable manifold. The global configurations of the stable and unstable manifolds will be needed for the boundary layer behavior. For any constants I_1^*, I_2^*, and T^*, the set $\mathcal{N} = \{I_1 = I_1^*, I_2 = I_2^*, T = T^*\}$ is a four-dimensional invariant subspace of the phase space $\mathbb{R}^7$.

Surprisingly, system (7) possesses a complete set of integrals with which the dynamics can be fully analyzed; in particular, the stable and unstable manifolds can be characterized and the behavior of boundary layers can be described in detail.

PROPOSITION 2.1. (i) *System* (7) *has a complete set of six integrals given by*

$$
\begin{aligned}
&H_1 = W - (\beta-\alpha)V - \frac{\alpha\beta}{2}U^2,\ H_2 = \Phi - \frac{\ln|W+\alpha V|}{\beta},\\
&H_3 = |W+\alpha V|^\alpha |W-\beta V|^\beta,\ H_4 = I_1,\ H_5 = I_2,\ \ \textit{and}\ \ H_6 = T,
\end{aligned}
$$

where the argument of H_i's is $(\Phi, U, V, W, I_1, I_2, T)$.

(ii) *The stable and unstable manifolds $W^s(\mathcal{Z}_0)$ and $W^u(\mathcal{Z}_0)$ of $\mathcal{Z}_0$ are characterized as follows:*

$$
W^s(\mathcal{Z}_0) = \cup\{W^s(z^*) :\ z^* \in \mathcal{Z}_0\} \ \ \textit{and} \ \ W^u(\mathcal{Z}_0) = \cup\{W^u(z^*) :\ z^* \in \mathcal{Z}_0\}
$$

and, for $z^*=(\Phi^*,0,0,W^*,I_1^*,I_2^*,T^*)\in\mathcal{Z}_0$, *a point* $z=(\Phi,U,V,W,I_1,I_2,T)\in W^s(z^*)\cup W^u(z^*)$ *if and only if*

$$H_1(z)=W^*,\ H_2(z)=\Phi^*-\frac{\ln W^*}{\beta},\ H_3(z)=(W^*)^{\alpha+\beta},\ I_i=I_i^*,\ T=T^*.$$

(iii) *The stable manifold* $W^s(\mathcal{Z}_0)$ *intersects* B_L *transversally at points with*

$$U=-\text{sgn }(\beta L_2-\alpha L_1)\sqrt{\frac{2\alpha\beta(L_1+L_2)-2(\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}}}{\alpha\beta}} \tag{10}$$

and arbitrary I_1 *and* I_2, *where* sgn *is the sign function. The unstable manifold* $W^u(\mathcal{Z}_0)$ *intersects* B_R *transversally at points with*

$$U=\text{sgn }(\beta R_2-\alpha R_1)\sqrt{\frac{2\alpha\beta(R_1+R_2)-2(\alpha+\beta)(\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}}{\alpha\beta}} \tag{11}$$

and arbitrary I_1 *and* I_2. *Let* $N_L=B_L\cap W^s(\mathcal{Z}_0)$ *and* $N_R=B_R\cap W^u(\mathcal{Z}_0)$. *Then,*

$$\omega(N_L)=\left\{\left(v_0+\frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2},0,0,(\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}},I_1,I_2,0\right)\right\},$$

$$\alpha(N_R)=\left\{\left(\frac{1}{\alpha+\beta}\ln\frac{\alpha R_1}{\beta R_2},0,0,(\alpha+\beta)(\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}},I_1,I_2,1\right)\right\}$$

for all I_1 *and* I_2.

Proof. The statement (i) can be verified directly (see section 4 for a derivation of H_3). The statement (ii) is a simple consequence of (i) together with the fact that $\Phi(\xi)\to\Phi^*$, $W(\xi)\to W^*$, $U(\xi)\to 0$, and $V(\xi)\to 0$ as $\xi\to\infty$ for the stable manifold and as $\xi\to-\infty$ for the unstable manifold.

For the statement (iii), we present only the proof regarding the intersection of $W^s(\mathcal{Z}_0)$ and B_L. Suppose

$$z^0=(\Phi^0,U^0,V^0,W^0,I_1^0,I_2^0,0)=(v_0,U^0,\beta L_2-\alpha L_1,\alpha^2L_1+\beta^2L_2,I_1^0,I_2^0,0)$$

is a point in $B_L\cap W^s(\mathcal{Z}_0)$. Then, using the integrals H_1, H_2, and H_3, the solution $z(\xi)=(\Phi(\xi),U(\xi),V(\xi),W(\xi),I_1^0,I_2^0,0)$ of system (7) with initial condition $z(0)=z^0$ satisfies

$$\begin{aligned}
H_1(z(\xi))&=W(\xi)-(\beta-\alpha)V(\xi)-\frac{\alpha\beta}{2}U^2(\xi)=A,\\
H_2(z(\xi))&=\Phi(\xi)-\frac{\ln|W(\xi)+\alpha V(\xi)|}{\beta}=B,\\
H_3(z(\xi))&=|W(\xi)+\alpha V(\xi)|^\alpha|W(\xi)-\beta V(\xi)|^\beta=C
\end{aligned}$$

for some constants A, B, and C, and for all ξ. Since $U(\xi)\to 0$ and $V(\xi)\to 0$ as $\xi\to+\infty$, $W(+\infty)=A$ from $H_1(z(\xi))=A$, and hence, $C=A^{\alpha+\beta}$ from $H_3(z(\xi))=C$. Now using the equations $H_3(z(0))=C=A^{\alpha+\beta}$ and $H_2(z(0))=B$, we have

$$A=(\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}},\quad B=v_0-\frac{\ln\left((\alpha+\beta)\beta L_2\right)}{\beta}.$$

Then, from $H_1(z(0)) = A$ and $H_2(z(\infty)) = B$, one has

$$U^0 = -\text{sgn }(V^0)\sqrt{\frac{2(\alpha\beta(L_1+L_2)-A)}{\alpha\beta}} \text{ and } \Phi(+\infty) = v_0 + \frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2}.$$

The choice of the sign for U^0 comes from the consideration that the stable eigenvector n_- in (9) has U and V components with opposite signs. Thus, B_L and $W^s(\mathcal{Z}_0)$ intersect at the points with $U = U^0$ given above, and all I_1 and I_2. If $N_L = B_L \cap W^s(\mathcal{Z}_0)$, then $\omega(N_L) = \{(\Phi(+\infty), 0, 0, W(+\infty), I_1, I_2, 0)\}$. The above formulas for $\Phi(+\infty)$ and $W(+\infty) = A$ give the desired characterization of $\omega(N_L)$. Lastly, since the stable manifold is completely characterized, one can compute its tangent space at each intersection point to verify the transversality of the intersection. It is slightly complicated but straightforward. We will omit the detail here. □

Part (iii) of this result implies that the boundary layer on the left end will be an orbit of (7) from $(v_0, U_L, \beta L_2 - \alpha L_1, \alpha^2 L_1 + \beta^2 L_2, I_1, I_2, 0) \in B_L$ to the point

$$z_L = \left(v_0 + \frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2}, 0, 0, (\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}}, I_1, I_2, 0\right) \in \mathcal{Z}_0,$$

where U_L is given by the display (10) and I_1 and I_2 are arbitrary at this moment, and that on the right end will be a backward orbit of (7) from the point $(0, U_R, \beta R_2 - \alpha R_1, \alpha^2 R_1 + \beta^2 R_2, I_1, I_2, 1) \in B_R$ to the point

$$z_R = \left(\frac{1}{\alpha+\beta}\ln\frac{\alpha R_1}{\beta R_2}, 0, 0, (\alpha+\beta)(\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}, I_1, I_2, 1\right) \in \mathcal{Z}_0,$$

where U_R is given by the display (11) and I_1 and I_2 are arbitrary at this moment. It turns out that there is a unique pair of numbers I_1 and I_2 so that the corresponding points z_L and z_R can be connected by a regular layer solution on $\mathcal{Z}_0$. The regular orbit together with the two boundary layer orbits provides the singular orbit.

Remark 2.1. The integrals H_2 and H_3 imply that

$$\tilde{H}_2 = \Phi + \frac{\ln|W - \beta V|}{\alpha}$$

is also an integral which can be viewed as the symmetric part to H_2.

To find the explicit expressions of the boundary layers from B_L and B_R to $\mathcal{Z}_0$, there are certain technical difficulties. But for some special cases, for example, $\alpha = \beta$, or $\alpha = 2$ and $\beta = 1$, or $\alpha = 1$ and $\beta = 2$, the difficulty can be overcome. In particular, our results for the case $\alpha = \beta = 1$ agree with those in [2], and we provide the detail below for demonstration.

COROLLARY 2.2. *If $\alpha = \beta = 1$, then the expressions of the solutions from B_L and B_R to $\mathcal{Z}_0$ can be explicitly given.*

Proof. We will derive the solution from B_L to $\mathcal{Z}_0$ for general α and β first. Let $r = W + \alpha V$ and $s = W - \beta V$. Then, $r^\alpha s^\beta = A^{\alpha+\beta}$, where A is as in Proposition 2.1, $W = (\beta r + \alpha s)/(\alpha+\beta)$, and $V = (r-s)/(\alpha+\beta)$. Using the equations in (7), one gets

$$r' = \pm\sqrt{\frac{2\beta}{\alpha(\alpha+\beta)}}r\sqrt{\alpha r + \beta A^{\frac{\alpha+\beta}{\beta}}r^{-\frac{\alpha}{\beta}} - (\alpha+\beta)A}.$$

The technical difficulty mentioned above for general α and β is the integration of this equation. Once r is found, the rest can be explicitly solved. The equation can be integrated for the cases mentioned above. We now carry out the rest of the analysis for $\alpha = \beta = 1$.

Without loss of generality, we assume $L_2 > L_1$. Then, $A = 2\sqrt{L_1 L_2}$ and

$$r' = -\sqrt{r}(r - 2\sqrt{L_1 L_2}).$$

Solving the equation and using $r(0) = W(0) + V(0) = 2L_2$, one gets

$$r = \frac{A(1 + ce^{-\sqrt{A}\xi})^2}{(1 - ce^{-\sqrt{A}\xi})^2}, \quad \text{where} \quad c = \frac{L_2^{1/4} - L_1^{1/4}}{L_2^{1/4} + L_1^{1/4}}.$$

Thus,

$$s = \frac{A^2}{r} = \frac{A(1 - ce^{-\sqrt{A}\xi})^2}{(1 + ce^{-\sqrt{A}\xi})^2}, \; W = \frac{r+s}{2} = A\left(1 + \frac{8c^2 e^{-2\sqrt{A}\xi}}{(1 - c^2 e^{-2\sqrt{A}\xi})^2}\right),$$

$$V = \frac{r-s}{2} = \frac{4Ace^{-\sqrt{A}\xi}(1 + c^2 e^{-2\sqrt{A}\xi})}{(1 - c^2 e^{-2\sqrt{A}\xi})^2}, \; U = -\sqrt{2W - 2A} = -\frac{4\sqrt{A}ce^{-\sqrt{A}\xi}}{1 - c^2 e^{-2\sqrt{A}\xi}},$$

$$\Phi = B + \ln(W + V) = v_0 + \frac{1}{2}\ln\frac{L_1}{L_2} + 2\ln\left|\frac{1 + ce^{-\sqrt{A}\xi}}{1 - ce^{-\sqrt{A}\xi}}\right|.$$

The expression for Φ is obtained by either using the integral H_2 and the solutions for V and W or by directly integrating $\Phi' = U$ from U. □

2.3. Slow dynamics and regular layers. We now examine the slow flow in the vicinity of the slow manifold $\mathcal{Z}_0 = \{u = v = 0\}$ for regular layers. If we take $\epsilon = 0$ in system (4), we get $u = v = 0$ and

$$\dot{J}_1 = 0, \; \dot{J}_2 = 0, \; \dot{\tau} = 1.$$

The information on ϕ and w is lost. This indicates that the slow flow in the vicinity of $\mathcal{Z}_0$ is itself a singular perturbation problem. To see this, we zoom into an $O(\epsilon)$-neighborhood of $\mathcal{Z}_0$ by blowing up the u and v coordinates; that is, we make a scaling $u = \epsilon p$ and $v = \epsilon q$. System (4) becomes

$$\begin{aligned} &\dot{\phi} = p, \quad \epsilon\dot{p} = q, \quad \epsilon\dot{q} = pw - (\beta J_2 - \alpha J_1), \\ &\dot{w} = \epsilon\alpha\beta pq + (\beta - \alpha)pw - (\alpha^2 J_1 + \beta^2 J_2), \\ &\dot{J}_1 = 0, \quad \dot{J}_2 = 0, \quad \dot{\tau} = 1, \end{aligned} \tag{12}$$

which is indeed a singular perturbation problem. When $\epsilon = 0$, the system reduces to

$$\begin{aligned} &\dot{\phi} = p, \quad 0 = q, \quad 0 = pw - (\beta J_2 - \alpha J_1), \\ &\dot{w} = (\beta - \alpha)pw - (\alpha^2 J_1 + \beta^2 J_2), \\ &\dot{J}_1 = 0, \quad \dot{J}_2 = 0, \quad \dot{\tau} = 1. \end{aligned} \tag{13}$$

The dynamics of ϕ and w survives in this limiting process. For this system, the slow manifold is

$$\mathcal{S}_0 = \left\{ p = \frac{\beta J_2 - \alpha J_1}{w},\ q = 0 \right\}.$$

The corresponding fast system obtained by the scaling of time

$$\Phi(\xi) = \phi(\epsilon\xi),\ P(\xi) = p(\epsilon\xi),\ Q(\xi) = q(\epsilon\xi),\ \text{ and }\ W(\xi) = w(\epsilon\xi)$$

is

$$\begin{aligned} &\Phi' = \epsilon P, \quad P' = Q, \quad Q' = PW - (\beta I_2 - \alpha I_1), \\ &W' = \epsilon^2 \alpha\beta PQ + \epsilon(\beta - \alpha)PW - \epsilon(\alpha^2 I_1 + \beta^2 I_2), \\ &I_1' = 0, \quad I_2' = 0, \quad T' = 0. \end{aligned} \tag{14}$$

The limiting system of (14) when $\epsilon = 0$ is

$$\begin{aligned} &\Phi' = 0, \quad P' = Q, \quad Q' = PW - (\beta I_2 - \alpha I_1), \\ &W' = 0, \quad I_1' = 0, \quad I_2' = 0, \quad T' = 0. \end{aligned} \tag{15}$$

The slow manifold $\mathcal{S}_0$ is the set of equilibria of (15). The eigenvalues normal to $\mathcal{S}_0$ are $\lambda_\pm(p) = \pm\sqrt{W}$. In particular, the slow manifold $\mathcal{S}_0$ is normally hyperbolic, and hence, it persists for system (14) for $\epsilon > 0$ small (see [4]).

The limiting slow dynamic on $\mathcal{S}_0$ is governed by system (13), which reads

$$\dot\phi = \frac{\beta J_2 - \alpha J_1}{w}, \quad \dot w = -\alpha\beta(J_1 + J_2), \quad \dot J_i = 0, \quad \dot\tau = 1.$$

The general solution is characterized as follows: J_1 and J_2 are arbitrary constants, and

$$\begin{aligned} &\tau(x) = \tau_0 + x, \quad w(x) = \alpha_0 - \alpha\beta(J_1 + J_2)x, \\ &\phi(x) = \phi_0 - \frac{\beta J_2 - \alpha J_1}{\alpha\beta(J_1 + J_2)} \ln\left(1 - \frac{\alpha\beta(J_1 + J_2)}{\alpha_0} x\right), \end{aligned} \tag{16}$$

where $\tau_0 = \tau(0)$, $\phi(0) = \phi_0$, and $w(0) = \alpha_0$. Note that if $J_1 + J_2 = 0$, then $w(x) = \alpha_0$ and $\phi(x) = \phi_0 + (\beta J_2 - \alpha J_1)x/\alpha_0$. The latter is the limit of $\phi(x)$ in (16) as $J_1 + J_2 \to 0$. We thus use the unified formula (16) even if $J_1 + J_2 = 0$.

To identify the slow portion of the singular orbit on $\mathcal{S}_0$, we need to examine the ω-limit (resp., the α-limit) set of $M_L^\epsilon \cap W^s(\mathcal{S}_0)$ (resp., $M_R^\epsilon \cap W^u(\mathcal{S}_0)$) as $\epsilon \to 0$. To do this, we fix an $O(1)$-neighborhood of $\mathcal{S}_0$. In terms of U and V, this neighborhood is of order $O(\epsilon)$. For $\epsilon > 0$ small, the time taken in terms of ξ for M_L^ϵ and M_R^ϵ to evolve to any $O(\epsilon)$-neighborhood of $\{U = V = 0\}$ is of order $O(\epsilon|\ln\epsilon|)$. Thus, the λ-lemma (see [3]) implies that M_L^ϵ (resp., M_R^ϵ) is C^1 $O(\epsilon)$-close to M_L^0 (resp., M_R^0) in any $O(\epsilon)$-neighborhood of $\{U = V = 0\}$. Therefore, in an $O(1)$-neighborhood of $\mathcal{S}_0$ in terms of P and Q, M_L^ϵ (resp., M_R^ϵ) intersects $W^s(\mathcal{S}_0)$ (resp., $W^u(\mathcal{S}_0)$) transversally. And, by abusing the notation, if $N_L = M_L^0 \cap W^s(\mathcal{S}_0)$ and $N_R = M_R^0 \cap W^u(\mathcal{S}_0)$, then $\omega(N_L)$ and $\alpha(N_R)$ have the same descriptions as those in Proposition 2.1 with $U = V = 0$ replaced by $P = (\beta I_2 - \alpha I_1)/W$ and $Q = 0$.

The slow orbit should be one given by (16) that connects $\omega(N_L)$ and $\alpha(N_R)$. Let $\bar M_L$ (resp., $\bar M_R$) be the forward (resp., backward) image of $\omega(N_L)$ (resp., $\alpha(N_R)$) under the slow flow (13).

PROPOSITION 2.3. *$\bar{M}_L$ and $\bar{M}_R$ intersect transversally along the unique orbit given by* (16) *from $x = 0$ to $x = 1$ with*

$$\tau_0 = 0,\ \alpha_0 = (\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}},\ \phi_0 = v_0 + \frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2},$$

$$J_1 = \frac{\left(\ln\frac{R_1}{L_1} - \alpha v_0\right)\left((\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}} - (\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}\right)}{\frac{\alpha\beta}{\alpha+\beta}\ln\frac{R_1}{L_1} + \frac{\alpha^2}{\alpha+\beta}\ln\frac{R_2}{L_2}},$$

$$J_2 = \frac{\left(\ln\frac{R_2}{L_2} + \beta v_0\right)\left((\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}} - (\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}\right)}{\frac{\beta^2}{\alpha+\beta}\ln\frac{R_1}{L_1} + \frac{\alpha\beta}{\alpha+\beta}\ln\frac{R_2}{L_2}}.$$

Proof. We show first that $\bar{M}_L$ and $\bar{M}_R$ intersect along the orbit with the above characterization. In view of (16) and the descriptions for $\omega(N_L)$ and $\alpha(N_R)$ in Proposition 2.1, the intersection is uniquely determined by

$$\tau_0 = 0,\ \alpha_0 = w(0) = (\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}},$$

$$w(1) = (\alpha+\beta)(\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}},$$

$$\phi_0 = \Phi(0) = v_0 + \frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2},\ \Phi(1) = \frac{1}{\alpha+\beta}\ln\frac{\alpha R_1}{\beta R_2}.$$

Substituting into (16) gives

$$J_1 + J_2 = \frac{\alpha+\beta}{\alpha\beta}\left((\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}} - (\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}\right),$$

$$\beta J_2 - \alpha J_1 = \frac{(\alpha+\beta)\left((\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}} - (\alpha R_1)^{\frac{\beta}{\alpha+\beta}}(\beta R_2)^{\frac{\alpha}{\alpha+\beta}}\right)}{\frac{\beta}{\alpha+\beta}\ln\frac{R_1}{L_1} + \frac{\alpha}{\alpha+\beta}\ln\frac{R_2}{L_2}} \times\left(v_0 + \frac{1}{\alpha+\beta}\ln\frac{L_1R_2}{L_2R_1}\right),$$

which in turn yields the expressions for J_1 and J_2. To see the transversality of the intersection, it suffices to show that $\omega(N_L)\cdot 1$ (the image of $\omega(N_L)$ under the time one map of the flow of system (13)) is transversal to $\alpha(N_R)$ on $\mathcal{S}_0 \cap \{\tau = 1\}$. If we use (ϕ, w, J_1, J_2) as a coordinate system on $\mathcal{S}_0 \cap \{\tau = 1\}$, then the set $\omega(N_L)\cdot 1$ is given by $\{(\phi(J_1,J_2), w(J_1,J_2), J_1, J_2)\}$ with

$$\phi(J_1,J_2) = v_0 + \frac{1}{\alpha+\beta}\ln\frac{\alpha L_1}{\beta L_2} - \frac{\beta J_2 - \alpha J_1}{\alpha\beta(J_1+J_2)}\ln\left(1 - \frac{\alpha\beta(J_1+J_2)}{\alpha_0}\right),$$
$$w(J_1,J_2) = (\alpha+\beta)(\alpha L_1)^{\frac{\beta}{\alpha+\beta}}(\beta L_2)^{\frac{\alpha}{\alpha+\beta}} - \alpha\beta(J_1+J_2).$$

Thus, the tangent space to $\omega(N_L)\cdot 1$ restricted on $\mathcal{S}_0 \cap \{\tau = 1\}$ is spanned by $(\phi_{J_1}, w_{J_1}, 1, 0) = (\phi_{J_1}, -\alpha\beta, 1, 0)$ and $(\phi_{J_2}, w_{J_2}, 0, 1) = (\phi_{J_2}, -\alpha\beta, 0, 1)$. In view of the display in Proposition 2.1, the tangent space to $\alpha(N_R)$ restricted on $\mathcal{S}_0 \cap \{\tau = 1\}$ is spanned by $(0,0,1,0)$ and $(0,0,0,1)$. Note that $\mathcal{S}_0 \cap \{\tau = 1\}$ is four-dimensional.

Thus, it suffices to show that the above four vectors are linearly independent or, equivalently, $\phi_{J_1} \neq \phi_{J_2}$. The latter can be verified by a direct computation. Indeed, if $J_1 + J_2 \neq 0$ at the intersection points, then

$$\phi_{J_1} - \phi_{J_2} = \frac{\alpha + \beta}{\alpha\beta(J_1 + J_2)} \ln\left(1 - \frac{\alpha\beta(J_1 + J_2)}{\alpha_0}\right) \neq 0;$$

if $J_1 + J_2 = 0$ at the intersection points, then $\phi(J_1, J_2) = \phi_0 + (\beta J_2 - \alpha J_1)/\alpha_0$ and hence $\phi_{J_1} - \phi_{J_2} = -(\alpha + \beta)/\alpha_0 \neq 0$. □

3. Main result. Based on the study of the limiting behavior of boundary layers and regular layers in the previous section, we can easily construct a singular orbit (zeroth order approximation) of the boundary value problem. To show that there indeed exists a true solution near the singular orbit, we apply the exchange lemma to show M_L^ϵ and M_R^ϵ intersect around the singular orbit.

We now state the existence and uniqueness result of the boundary value problem, which also provides the description of a singular orbit.

THEOREM 3.1. *Assume that $\alpha L_1 \neq \beta L_2$ and $\alpha R_1 \neq \beta R_2$. For $\epsilon > 0$ small, the connecting problem* (4), (8) *has a unique solution near a singular orbit. The singular orbit is the union of two fast orbits of system* (7) *and one slow orbit of system* (13)*; more precisely, with both $I_1 = J_1$ and $I_2 = J_2$ given in Proposition* 2.3*,*

(i) *the fast orbit representing the limiting boundary layer at $x = 0$ lies on $B_L \cap W^s(\mathcal{Z}_0)$ from B_L to $\omega(N_L) \subset \mathcal{Z}_0$, whose starting point has the U-component given by* (10) *in Proposition* 2.1*;*

(ii) *the fast orbit representing the limiting boundary layer at $x = 1$ lies on $B_R \cap W^u(\mathcal{Z}_0)$ from B_R to $\alpha(N_R) \subset \mathcal{Z}_0$, whose starting point has the U-component given by* (11) *in Proposition* 2.1*;*

(iii) *the slow orbit on $\mathcal{S}_0$ connecting the two boundary layers from $x = 0$ to $x = 1$ is displayed in* (16) *together with the quantities in Proposition* 2.3*.*

Proof. The singular orbit which has been studied in sections 2.2 and 2.3 is summarized in (i), (ii), and (iii) of this theorem. It remains to show the existence and uniqueness of a solution near the singular orbit for $\epsilon > 0$. Recall that M_L^ϵ (resp., M_R^ϵ) is the union of all forward (resp., backward) orbits starting from B_L (resp., B_R). It suffices to show that, for $\epsilon > 0$ small, M_L^ϵ and M_R^ϵ intersect transversally with each other around the singular orbit. We note that the assumptions $\alpha L_1 \neq \beta L_2$ and $\alpha R_1 \neq \beta R_2$ imply that the vector field of (4) is not tangent to B_L and B_R and hence, M_L^ϵ and M_R^ϵ are smooth invariant manifolds.

For $\epsilon > 0$ small, the evolutions of M_L^ϵ and M_R^ϵ from B_L and B_R, respectively, to an ϵ-neighborhood of $\mathcal{Z}_0$ along the two boundary layers are governed by system (6). Since, for system (7), M_L^0 and M_R^0 intersect $W^s(\mathcal{Z}_0)$ and $W^u(\mathcal{Z}_0)$ transversally, we have that M_L^ϵ and M_R^ϵ intersect $W^s(\mathcal{Z}_0)$ and $W^u(\mathcal{Z}_0)$ transversally. As discussed in section 2.3, in terms of the blow-up coordinates, M_L^ϵ and M_R^ϵ intersect $W^s(\mathcal{S}_0)$ and $W^u(\mathcal{S}_0)$ transversally for system (14). And, if we denote $N_L = M_L^0 \cap W^s(\mathcal{S}_0)$ and $N_R = M_R^0 \cap W^u(\mathcal{S}_0)$, then the vector field on $\mathcal{S}_0$ is not tangent to $\omega(N_L)$ and $\alpha(N_R)$. Furthermore, the traces $\bar{M}_L$ and $\bar{M}_R$ of $\omega(N_L)$ and $\alpha(N_R)$, respectively, under the slow flow on $\mathcal{S}_0$ intersect transversally. All conditions for the exchange lemma (see [15] and also [10, 8, 9]) are satisfied, and hence, M_L^ϵ and M_R^ϵ intersect transversally. The intersection has dimension

$$\dim M_L^\epsilon + \dim M_R^\epsilon - 7 = 4 + 4 - 7 = 1,$$

which is the orbit of the unique solution for the connecting problem near the singular orbit. □

Remark 3.1. We have considered the situation that $\alpha L_1 \neq \beta L_2$ and $\alpha R_1 \neq \beta R_2$. In the case that $\alpha L_1 = \beta L_2$ or $\alpha R_1 = \beta R_2$, then B_L or B_R is on the slow manifold $\mathcal{S}_0$ and hence there is no boundary layer at $x = 0$ or $x = 1$.

4. Appendix. A derivation of the integral H_3 in Proposition 2.1. The complete set of six integrals of system (7) in Proposition 2.1 is crucial in the quantitative investigation of the boundary layers of the boundary value problem. The integrals H_1 and H_2 are relatively easy to guess. The integral H_3, although easily verified, is discovered through several observations. It may have some general interest, and we provide a formal derivation below.

We divide the W-equation by the V-equation from system (7) to get

$$\frac{dW}{dV} = \frac{\alpha\beta V}{W} + (\beta - \alpha),$$

which is a homogeneous equation of order zero. This leads to the substitution $W = yV$. From $dW = Vdy + ydV$ and the above equation one gets

$$\left(\frac{\alpha\beta V}{yV} + (\beta - \alpha)\right) dV = Vdy + ydV \quad \text{or} \quad -\frac{dV}{V} = \frac{ydy}{y^2 - (\beta - \alpha)y - \alpha\beta}.$$

Integrating both sides, we have, for some constant C,

$$-\ln V + C = \frac{\alpha}{\alpha + \beta} \ln|y + \alpha| + \frac{\beta}{\alpha + \beta} \ln|y - \beta|,$$

or, for some constant D,

$$V = \frac{D}{|y + \alpha|^{\frac{\alpha}{\alpha+\beta}} |y - \beta|^{\frac{\beta}{\alpha+\beta}}}, \quad W = \frac{Dy}{|y + \alpha|^{\frac{\alpha}{\alpha+\beta}} |y - \beta|^{\frac{\beta}{\alpha+\beta}}}.$$

Substitute $y = W/V$ to get

$$|W + \alpha V|^{\alpha} |W - \beta V|^{\beta} = D^{\alpha+\beta}.$$

This completes the derivation of the integral H_3.

THE DETERMINATION OF THE SURFACE CONDUCTIVITY OF A PARTIALLY COATED DIELECTRIC*

FIORALBA CAKONI†, DAVID COLTON†, AND PETER MONK†

Abstract. A variational method is given for determining the essential supremum of the surface conductivity of a partially coated anisotropic dielectric medium from a knowledge of the far field pattern of the time-harmonic electric field at fixed frequency corresponding to an incident plane wave. It is assumed that the shape of the scatterer has been determined (e.g., by solving the far field equation and using the linear sampling method). Numerical examples are given for the scalar case with constant surface conductivity.

Key words. inverse scattering problem, interior transmission problem, electromagnetic waves, mixed boundary value problems

1. Introduction.

In a previous paper in this journal [5], we considered the problem of determining the surface impedance of a perfect conductor that is partially coated with a dielectric from a knowledge of the far field pattern of the scattered electromagnetic wave corresponding to an incident time-harmonic plane wave at fixed frequency. Such problems are the simplest model for detecting hostile objects that have been partially coated with a dielectric in order to avoid detection by using such a coating to reduce the radar cross section of the scattered wave. In [5] it was shown that the solution of the far field equation that determines the shape of the scatterer by means of the linear sampling method [11] can also be used in conjunction with a variational method to determine the essential supremum of the surface impedance of the coated portion of the boundary, and numerical examples were given showing the viability of our method.

In this paper we consider the problem complementary to the one described above; i.e., we now wish to detect a benign object that has been partially coated by a thin conducting material in order to make it appear hostile [6]. An example of this is a wooden decoy in the shape of a tank that is partially coated by metallic paint. The problem is again to determine a coefficient (the surface conductivity) in the boundary condition from a knowledge of the far field pattern of the scattered electromagnetic wave corresponding to an incident time-harmonic plane wave. (The shape of the scatterer can again be determined by the linear sampling method.) However, the problem of determining the surface conductivity is considerably more complicated than the problem of determining the surface impedance of a coated perfect conductor since we now have a mixed boundary value problem for a penetrable obstacle. In particular, we now must consider an interior transmission problem with mixed boundary conditions, and the well-posedness of such problems is unknown.

The plan of our paper is as follows. After formulating the mathematical model for the scattering of time harmonic electromagnetic waves by an anisotropic medium

that is partially coated by a thin conducting layer, we consider the scalar case corresponding to the scattering of electromagnetic waves by an infinite cylinder. We first show that in this case both the direct scattering problem and the interior transmission problem are well posed. We then use these results to derive a variational formula for the determination of the essential supremum of the surface conductivity of the coated portion of the boundary from a knowledge of the far field pattern of the scattered time-harmonic magnetic field. Finally, we derive an analogous formula for determining the surface conductivity in the case of Maxwell's equations in $\mathbb{R}^3$ under the assumption that the interior transmission problem in this case is well posed. We conclude by presenting some numerical examples for the scalar case with constant surface conductivity.

2. Formulation of the direct and inverse scattering problem. We consider the scattering of time-harmonic electromagnetic waves with frequency ω from an infinitely long cylindrical anisotropic dielectric partially coated with a very thin layer of a highly conductive material. We assume that the electric permittivity ϵ_0 and magnetic permeability μ_0 of the exterior dielectric background medium are positive constants, whereas the scatterer has the same magnetic permeability μ_0 as the exterior medium but the electric permittivity ϵ and the conductivity σ are real 3×3 matrix valued functions. After an appropriate scaling [12], the total electric and magnetic fields E, H satisfy the time-harmonic homogeneous Maxwell equations in the exterior of the scatterer,

$$\begin{cases} \nabla \times E - ikH = 0, \\ \nabla \times H + ikE = 0, \end{cases} \tag{2.1}$$

and the interior electric and magnetic fields E_0, H_0 solve the following equations in the interior of the scattering object:

$$\begin{cases} \nabla \times E_0 - ikH_0 = 0, \\ \nabla \times H_0 + ikN(x)E_0 = 0, \end{cases} \tag{2.2}$$

where $k^2 = \epsilon_0\mu_0\omega^2$ and the index of refraction is given by $N(x) = \frac{1}{\epsilon_0}\big(\epsilon(x) + i\frac{\sigma(x)}{\omega}\big)$.

Let the real valued function $\eta > 0$ defined on the coated portion of the boundary of the scatterer describe the physical properties of the highly conductive coating (see [1]). As shown in [8], the tangential component of the electric field is continuous across the boundary

$$\nu \times E - \nu \times E_0 = 0, \tag{2.3}$$

while the tangential component of the magnetic field is continuous only on the uncoated part of the boundary

$$\nu \times H - \nu \times H_0 = 0 \tag{2.4}$$

and satisfies the following relation on the coated part of the boundary:

$$\nu \times H - \nu \times H_0 = \eta(x)(\nu \times E) \times \nu. \tag{2.5}$$

The exterior field E, H is given by

$$E = E^i + E^s, \qquad H = H^i + H^s, \tag{2.6}$$

where E^s, H^s is the scattered field satisfying the Silver–Müller radiation condition at infinity [12] and E^i, H^i is the given incident field.

Now we assume that the scatterer is an infinitely long cylinder with axis in the z-direction and that the incident electromagnetic field is a plane wave propagating in the direction perpendicular to the cylinder. Let the bounded domain $D \subset \mathbb{R}^2$ with Lipschitz boundary Γ be the cross section of the cylinder such that the exterior domain $D_e := \mathbb{R}^2 \setminus \overline{D}$ is connected. We denote by ν the outward unit normal to Γ defined almost everywhere on Γ. The boundary $\Gamma = \Gamma_1 \cup \Pi \cup \Gamma_2$ is split into two open disjoint parts Γ_1 and Γ_2 having Π as their possible common boundary in Γ. Here Γ_1 corresponds to the uncoated part and Γ_2 corresponds to the coated part. We assume that the dielectric is orthotropic; i.e., the matrix N is of the form

$$N = \begin{pmatrix} n_{11} & n_{12} & 0 \\ n_{21} & n_{22} & 0 \\ 0 & 0 & n_{33} \end{pmatrix},$$

and the functions N and η do not depend on z. If we consider incident waves such that the electric field is polarized perpendicular to the z-axis, then the magnetic fields have a component in only the z-direction, i.e.,

$$H^i = (0,\ 0,\ u^i), \quad H_0 = (0,\ 0,\ v), \quad H^s = (0,\ 0,\ u^s).$$

Assuming that N^{-1} exists and expressing the electric fields in terms of magnetic fields, (2.1)–(2.6) now lead to the following transmission problem for v and u:

$$\begin{aligned}
&\text{(i)} && \nabla\cdot A\nabla v + k^2 v = 0 && \text{in } D,\\
&\text{(ii)} && \Delta u + k^2 u = 0 && \text{in } D_e,\\
&\text{(iii)} && v - u = 0 && \text{on } \Gamma_1,\\
&\text{(iv)} && v - u = -i\eta \frac{\partial u}{\partial \nu} && \text{on } \Gamma_2,\\
&\text{(v)} && \frac{\partial v}{\partial \nu_A} - \frac{\partial u}{\partial \nu} = 0 && \text{on } \Gamma,\\
&\text{(vi)} && u = u^s + u^i, &&\\
&\text{(vii)} && \lim_{r\to\infty} \sqrt{r}\left(\frac{\partial u^s}{\partial r} - iku^s\right) = 0, &&
\end{aligned} \tag{2.7}$$

$r = |x|$, where u^s is the scattered field and u^i is the given incident field. In the case of plane waves the incident field is given by $u^i := e^{ikx\cdot d}$, $d \in \Omega := \{x : |x| = 1\}$. Moreover,

$$\frac{\partial v}{\partial \nu_A}(x) := \nu(x) \cdot A(x)\nabla v(x), \qquad x \in \Gamma,$$

$$A = \frac{1}{n_{11}n_{22} - n_{12}n_{21}} \begin{pmatrix} n_{11} & n_{21} \\ n_{12} & n_{22} \end{pmatrix},$$

and the radiation condition (2.7)(vii) holds uniformly with respect to $\hat{x} = x/|x|$. Note that A is not the inverse of a 2×2 submatrix N but rather comes from substituting $H_0 = (0, 0, v)$ into (2.2).

In the following we assume that A is a 2×2 matrix valued function whose entries are continuously differentiable functions in $\overline{D}$ such that A is symmetric, $\mathcal{R}e(\,\bar{\xi} \cdot A\,\xi\,) \geq \gamma|\xi|^2$, and $\mathcal{I}m(\,\bar{\xi} \cdot A\,\xi\,) \leq 0$ for all $\xi \in \mathbb{C}^2$ and $x \in \overline{D}$, where γ is a positive constant. Note that, due to the symmetry of A, we have $\mathcal{R}e(\,\bar{\xi} \cdot A\,\xi\,) = \bar{\xi} \cdot \mathcal{R}e(A)\,\xi$ and $\mathcal{I}m(\,\bar{\xi} \cdot A\,\xi\,) = \bar{\xi} \cdot \mathcal{I}m(A)\,\xi$. Moreover, we require that $\eta \in L_\infty(\Gamma_2)$ and $\eta(x) \geq \eta_0 > 0$ for all $x \in \Gamma_2$.

Let $H^1(D)$ and $H^1_{\rm loc}(D_e)$ denote the usual Sobolev spaces and $H^{\frac{1}{2}}(\Gamma)$ the corresponding trace space. For $\Gamma_2 \subset \Gamma$ we define

$$H^{\frac{1}{2}}(\Gamma_2) := \{u|_{\Gamma_2} : u \in H^{\frac{1}{2}}(\Gamma)\},$$

$$\tilde{H}^{\frac{1}{2}}(\Gamma_2) := \{u \in H^{\frac{1}{2}}(\Gamma_2) : \operatorname{supp} u \subseteq \overline{\Gamma}_2\},$$

and denote by $H^{-\frac{1}{2}}(\Gamma_2)$ and $\tilde{H}^{-\frac{1}{2}}(\Gamma_2)$ the dual spaces $(\tilde{H}^{\frac{1}{2}}(\Gamma_2))'$ and $(H^{\frac{1}{2}}(\Gamma_2))'$, respectively, with L^2 as a pivot space (for details, see [16]). We recall that a function in $\tilde{H}^{\frac{1}{2}}(\Gamma_2)$ and $\tilde{H}^{-\frac{1}{2}}(\Gamma_2)$ can be extended by zero to a function in $H^{\frac{1}{2}}(\Gamma)$ and $H^{-\frac{1}{2}}(\Gamma)$, respectively. Note that for $u \in H^1(D)$ with $\Delta u \in L^2(D)$ the trace $\frac{\partial u}{\partial \nu} \in H^{-\frac{1}{2}}(\Gamma)$ is well defined.

For later use we also define the Hilbert space

$$\mathbb{H}^1(D, \Gamma_2) := \left\{ u \in H^1(D) \quad \text{such that} \quad \frac{\partial u}{\partial \nu} \in L^2(\Gamma_2) \right\}$$

equipped with the usual graph norm

$$\|u\|^2_{\mathbb{H}^1(D,\Gamma_2)} := \|u\|^2_{H^1(D)} + \left\| \frac{\partial u}{\partial \nu} \right\|^2_{L^2(\Gamma_2)}.$$

The *forward scattering problem* reads: Given D, A, η as above and the incident field $u^i \in H^1_{\rm loc}(\mathbb{R}^2)$, find $v \in H^1(D)$ and $u \in H^1_{\rm loc}(D_e)$ that satisfy (2.7), where the boundary conditions are assumed in the sense of the trace operator. In what follows, we refer to this mixed transmission problem as (MTP).

It is known [12] that solutions of the Helmholtz equation that satisfy the Sommerfeld radiation condition (2.7)(vi) have the asymptotic behavior

$$u^s(x) = \frac{e^{ikr}}{\sqrt{r}} u_\infty(\hat{x}) + O(r^{-3/2}), \quad r \to \infty, \tag{2.8}$$

where $u_\infty(\hat{x})$ is the *far field pattern* of the radiating solution u^s. In the case of incident plane waves, $u_\infty(\hat{x})$ depends on the incident direction d, which we indicate by $u_\infty(\hat{x}, d)$. The *inverse scattering problem* we are concerned with is to determine D and η from a knowledge of the far field pattern $u_\infty(\hat{x}, d)$ of the scattered field u^s for $\hat{x}$, $-d \in \Omega_0$, where Ω_0 is a subset of the unit circle Ω. Note that no a priori knowledge of the amount of coating is required.

3. The direct scattering problem. First we want to show that the mixed transmission problem (2.7) is well posed.

LEMMA 3.1. *The problem* (MTP) *has at most one solution.*

Proof. Let $v \in H^1(D)$ and $u \in H^1_{\rm loc}(D_e)$ be the solution of (2.7) corresponding to the incident wave $u^i \equiv 0$. Applying Green's formula in D and $D_e \cap B_R$, where B_R is a disk of radius R containing D, and using the transmission conditions, we have

$$\begin{aligned}
&\int_D \left(\nabla \overline{v} \cdot A \nabla v - k^2 |v|^2\right) dy + \int_{D_e \cap B_R} \left(|\nabla u|^2 - k^2 |u|^2\right) dy \\
&\quad = \int_\Gamma \overline{v} \cdot \frac{\partial v}{\partial \nu_A} \, ds - \int_\Gamma \overline{u} \cdot \frac{\partial u}{\partial \nu} \, ds + \int_{S_R} \overline{u} \cdot \frac{\partial u}{\partial \nu} \, ds \\
&\quad = i \int_{\Gamma_2} \frac{1}{\eta} |v - u|^2 \, ds + \int_{S_R} \overline{u} \cdot \frac{\partial u}{\partial \nu} \, ds.
\end{aligned}$$

Now taking the imaginary part of both sides and using the fact that $\mathcal{I}m(A) \leq 0$ is a real valued matrix and $\eta \geq \eta_0 > 0$, we obtain

$$\mathcal{I}m \int_{S_R} u \cdot \frac{\partial \overline{u}}{\partial \nu} \, ds \geq 0.$$

Finally, an application of Rellich's lemma and the unique continuation principle yield $u = v = 0$. ∎

In order to give a variational formulation of the problem (MTP) we introduce the Dirichlet-to-Neumann map $\Lambda : H^{\frac{1}{2}}(S_R) \to H^{-\frac{1}{2}}(S_R)$, which maps $h \in H^{\frac{1}{2}}(S_R)$ to $\frac{\partial \tilde{u}}{\partial \nu}$, where $\tilde{u}$ solves the exterior Dirichlet problem for the Helmholtz equation in $\mathbb{R}^2 \backslash \overline{B}_R$ with Dirichlet boundary data h. The following result is known [12], [15].

LEMMA 3.2. *There exists an operator $\Lambda_0 : H^{\frac{1}{2}}(S_R) \to H^{-\frac{1}{2}}(S_R)$ such that*

$$\int_{S_R} \overline{\varphi} \, \Lambda_0 \varphi \, ds \leq 0 \tag{3.1}$$

and $\Lambda - \Lambda_0$ is a compact operator from $H^{\frac{1}{2}}(S_R)$ to $H^{-\frac{1}{2}}(S_R)$.

Integrating by parts the equations of (MTP) with a test function φ, we can put (MTP) into the following variational form: Find $w \in H^1(B_R \backslash \overline{\Gamma}_2)$ such that

$$\begin{aligned}
&\int_D \left(\nabla \overline{\varphi} \cdot A \nabla w - k^2 \overline{\varphi} \, w\right) dy + \int_{D_e \cap B_R} \left(\nabla \overline{\varphi} \cdot \nabla w - k^2 \overline{\varphi} \, w\right) dy \\
&\quad - \int_{\Gamma_2} \frac{i}{\eta} \, [\overline{\varphi}] \cdot [w] \, ds - \int_{S_R} \overline{\varphi} \, \Lambda w \, ds = - \int_{S_R} \overline{\varphi} \, \Lambda u^i \, ds + \int_{S_R} \overline{\varphi} \frac{\partial u^i}{\partial \nu} \, ds
\end{aligned} \tag{3.2}$$

for any function $\varphi \in H^1(B_R \backslash \overline{\Gamma}_2)$, where $[u] = u^+|_{\Gamma_2} - u^-|_{\Gamma_2}$ denotes the jump of u across Γ_2. Note that for $u \in H^1(B_R \backslash \overline{\Gamma}_2)$ the jump $[u] \in \tilde{H}^{\frac{1}{2}}(\Gamma_2)$. Let us denote by $\mathcal{A}_1$ and $\mathcal{A}_2$ the following sesquilinear forms:

$$\begin{aligned}
\mathcal{A}_1(w, \varphi) := &\int_D \left(\nabla \overline{\varphi} \cdot A \nabla w + \overline{\varphi} \, w\right) dy + \int_{D_e \cap B_R} \left(\nabla \overline{\varphi} \cdot \nabla w + \overline{\varphi} \, w\right) dy \\
&- \int_{\Gamma_2} \frac{i}{\eta} \, [\overline{\varphi}] \cdot [w] \, ds - \int_{S_R} \overline{\varphi} \, \Lambda_0 w \, ds
\end{aligned} \tag{3.3}$$

and

$$\mathcal{A}_2(w, \varphi) := - \int_{B_R} (k^2 + 1) \, \overline{\varphi} \, w \, dy - \int_{S_R} \overline{\varphi} \, (\Lambda_0 - \Lambda) w \, ds,$$

respectively. Then (3.2) becomes the following: Find $w \in H^1(B_R \backslash \overline{\Gamma}_2)$ such that

$$\mathcal{A}_1(w,\varphi) + \mathcal{A}_2(w,\varphi) = L(\varphi) \qquad \forall \varphi \in H^1(B_R \backslash \overline{\Gamma}_2), \tag{3.4}$$

where $L(\varphi)$ denotes the continuous antilinear form defined by the right-hand side of (3.2). Obviously if w is a solution of (3.4), then $v := w|_D$ and $u := w|_{B_R \cap D_e}$ satisfy the differential equations and the transmission conditions of (MTP). Then using Green's formula and the radiation condition, one can extend $w = u - u^i$ to a radiating solution of the Helmholtz equation in the exterior domain D_e (see, e.g., [15]).

Next we want to show that there exists a function $w \in H^1(B_R \backslash \overline{\Gamma}_2)$ that satisfies (3.4). The uniqueness of (3.4) is equivalent to the uniqueness of a solution to (MTP) (see Lemma 3.1). Note that, due to (2.7(iv)) and (2.7(v)), if $u \in H^1(D)$ and $v \in H^1_{\rm loc}(D^e)$ solve (2.7), then $w \in H^1(B_R \backslash \overline{\Gamma}_2)$. Using the classical trace theorems and Cauchy–Schwarz inequality, the chain of continuous imbeddings

$$\tilde{H}^{\frac{1}{2}}(\Gamma_2) \subset H^{\frac{1}{2}}(\Gamma_2) \subset L^2(\Gamma_2) \subset \tilde{H}^{-\frac{1}{2}}(\Gamma_2) \subset H^{-\frac{1}{2}}(\Gamma_2),$$

and the boundedness of A and η, we obtain

$$|\mathcal{A}_1(w,\varphi)| \le C_1 \|w\|_{H^1(B_R \backslash \overline{\Gamma}_2)} \|\varphi\|_{H^1(B_R \backslash \overline{\Gamma}_2)}$$

with $C_1 > 0$ independent of w and φ. Hence $\mathcal{A}_1$ is bounded. Furthermore, from the fact that $\mathcal{R}e(A)$ is positive definite together with Lemma 3.2, we obtain the following coercivity result:

$$\mathcal{R}e\left(\mathcal{A}_1(w,w)\right) \ge C_2 \|w\|^2_{H^1(B_R \backslash \overline{\Gamma}_2)},$$

where the constant $C_2 > 0$ does not depend on w.

Next, based on the Riesz representation theorem, we define an operator $K : H^1(B_R \backslash \overline{\Gamma}_2) \to H^1(B_R \backslash \overline{\Gamma}_2)$ by

$$(Kw,\ \varphi) = \mathcal{A}_2(w,\ \varphi) \qquad \forall w, \varphi \in H^1(B_R \backslash \overline{\Gamma}_2).$$

The compact embedding of $H^1(B_R \setminus \overline{\Gamma})$ into $L^2(B_R)$ and the compactness of the operator $\Lambda - \Lambda_0$ from Lemma 3.2 imply that the operator K is compact.

The above analysis shows that the Fredholm alternative can be applied to (3.2), which, together with the uniqueness of a solution to (3.2), implies the solvability of (3.2) and therefore the solvability of (2.7). Summarizing the above analysis, we have proved the following theorem.

THEOREM 3.3. *For any incident field $u^i \in H^1_{\rm loc}(\mathbb{R}^2)$ there exists a unique solution $(v,u) \in H^1(D) \times H^1_{\rm loc}(D_e)$ of* (MTP) *which depends continuously on u^i.*

3.1. The interior transmission problem. As will be seen in what follows, an important role in solving the inverse problem of determining D and η is played by the *interior transmission problem*: Given $f \in H^{\frac{1}{2}}(\Gamma)$, $h \in H^{-\frac{1}{2}}(\Gamma)$, and $r \in L^2(\Gamma_2)$, find $v \in H^1(D)$ and $w \in \mathbb{H}^1(D,\Gamma_2)$ such that

$$\begin{aligned}
&\text{(i)} && \nabla\cdot A\nabla v + k^2 v = 0 && \text{in } D,\\
&\text{(ii)} && \Delta w + k^2 w = 0 && \text{in } D,\\
&\text{(iii)} && v - w = f|_{\Gamma_1} && \text{on } \Gamma_1,\\
&\text{(iv)} && v - w = -i\eta \frac{\partial w}{\partial \nu} + f|_{\Gamma_2} + r && \text{on } \Gamma_2,\\
&\text{(v)} && \frac{\partial v}{\partial \nu_A} - \frac{\partial w}{\partial \nu} = h && \text{on } \Gamma.
\end{aligned} \tag{3.5}$$

In the remainder of the paper we will refer to (3.5) as (IMTP). The well-posedness of the interior transmission problem in the case when $\eta \equiv 0$ and $r = 0$ is established in [7]. Here we will adapt the variational approach used in [7] to our mixed transmission case. In order to avoid repetition we will only sketch the proof, emphasizing the changes due to the boundary terms involving η. We first modify (IMTP) to

$$\begin{aligned}
&\text{(i)} && \nabla\cdot A\nabla v - m\, v = \ell_1 && \text{in } D,\\
&\text{(ii)} && \Delta w - w = \ell_2 && \text{in } D,\\
&\text{(iii)} && v - w = f|_{\Gamma_1} && \text{on } \Gamma_1,\\
&\text{(iv)} && v - w = -i\eta\,\frac{\partial w}{\partial \nu} + f|_{\Gamma_2} + r && \text{on } \Gamma_2,\\
&\text{(v)} && \frac{\partial v}{\partial \nu_A} - \frac{\partial w}{\partial \nu} = h && \text{on } \Gamma,
\end{aligned} \tag{3.6}$$

where $m > 0$, $\ell_1 \in L^2(D)$, and $\ell_2 \in L^2(D)$. We will now reformulate (3.6) as an equivalent variational problem. To this end let

$$\mathbb{W}(D) = \{\mathbf{w} \in L^2(D)^2 \,:\, \nabla\cdot \mathbf{w} \in L^2(D), \text{ and } \operatorname{curl} \mathbf{w} = 0 \text{ and } \nu\cdot\mathbf{w}|_{\Gamma_2} \in L^2(\Gamma_2)\}$$

equipped with the natural norm

$$\|\mathbf{w}\|^2_{\mathbb{W}} = \|\mathbf{w}\|^2_{L^2} + \|\nabla\cdot\mathbf{w}\|^2_{L^2} + \|\nu\cdot\mathbf{w}\|^2_{L^2},$$

and denote by $\langle\cdot\,,\cdot\rangle$ the duality pairing between $H^{\frac{1}{2}}(\Gamma)$ and $H^{-\frac{1}{2}}(\Gamma)$. We also introduce the duality identity

$$\langle \varphi,\, \boldsymbol{\psi}\cdot\nu\rangle = \int_D \varphi\, \nabla\cdot\boldsymbol{\psi}\, dx + \int_D \nabla\varphi\cdot\boldsymbol{\psi}\, dx \tag{3.7}$$

for $(\varphi,\, \boldsymbol{\psi}) \in H^1(D)\times\mathbb{W}(D)$.

By doing exactly the same as in the proof of Theorem 3.3 in [7], one can show that the modified interior transmission problem (3.6) is equivalent to the following variational problem: Find $V = (v, \mathbf{w}) \in H^1(D)\times\mathbb{W}(D)$ such that

$$\mathcal{A}(V,\Psi) = L(\Psi), \qquad \Psi \in H^1(D)\times\mathbb{W}(D), \tag{3.8}$$

where the sesquilinear form $\mathcal{A}$ defined in $(H^1(D)\times\mathbb{W}(D))^2$ is given by

$$\begin{aligned}
\mathcal{A}(V,\Psi) = &\int_D A\nabla v\cdot\nabla\bar\varphi\, dx + \int_D m\, v\,\bar\varphi\, dx + \int_D \nabla\cdot\mathbf{w}\,\nabla\cdot\bar{\boldsymbol{\psi}}\, dx + \int_D \mathbf{w}\cdot\bar{\boldsymbol{\psi}}\, dx\\
&- i\int_{\Gamma_2} \eta\,(\mathbf{w}\cdot\nu)\,(\bar{\boldsymbol{\psi}}\cdot\nu), ds - \left\langle v,\, \bar{\boldsymbol{\psi}}\cdot\nu\right\rangle - \langle\bar\varphi,\, \mathbf{w}\cdot\nu\rangle
\end{aligned} \tag{3.9}$$

and the antilinear form L is given by

$$L(\Psi) = \int_D (\ell_1\,\bar\varphi + \ell_2\,\nabla\cdot\bar{\boldsymbol{\psi}})\, dx - i\int_{\Gamma_2} \eta\, r\,(\bar{\boldsymbol{\psi}}\cdot\nu) + \langle\bar\varphi,\, h\rangle - \left\langle f,\, \bar{\boldsymbol{\psi}}\cdot\nu\right\rangle.$$

The modified interior transmission problem (3.6) has a unique solution $(v, w) \in H^1(D)\times\mathbb{H}^1(D,\Gamma_2)$ if and only if the variational problem (3.8) has a unique solution $V \in H^1(D)\times W(D)$. If (v, w) is the unique solution (3.6), then $V = (v, \nabla w)$ is a

unique solution to (3.8). Conversely if V is the unique solution to (3.8), then the unique solution (v, w) to (3.6) is such that $V = (v, \nabla w)$.

Now assume that there exists a constant $\gamma > 1$ such that $\bar{\xi} \cdot \mathcal{R}e(A)\,\xi \geq \gamma|\xi|^2$ and choose $m > 1$. Classical trace theorems and Schwarz's inequality ensure the continuity of the sesquilinear form $\mathcal{A}$ and the antilinear form L. On the other hand, by taking the real and the imaginary part of $\mathcal{A}(V, V)$, we have from the assumptions on $\mathcal{R}e(A)$, $\mathcal{I}m(A)$, and η that

$$|\mathcal{A}(V,V)| \geq \gamma\|v\|^2_{H^1(D)} + \|\mathbf{w}\|^2_{L^2(D)} + \|\nabla\cdot\mathbf{w}\|^2_{L^2(D)} - 2\mathcal{R}e(\langle\bar{v},\, \nu\cdot\mathbf{w}\rangle) + \eta_0\|\nu\cdot\mathbf{w}\|^2_{L^2(\Gamma_2)}.$$

From the duality identity (3.7) and Schwarz's inequality we have

$$2\mathcal{R}e(\langle\bar{v},\, \nu\cdot\mathbf{w}\rangle) \leq |\,\langle\bar{v},\, \mathbf{w}\rangle\,| \leq \|v\|_{H^1(D)}(\|\mathbf{w}\|^2_{L^2(D)} + \|\nabla\cdot\mathbf{w}\|^2_{L^2(D)})^{\frac{1}{2}}.$$

Hence since $\gamma > 1$, we conclude that

$$|\mathcal{A}(V,V)| \geq \frac{\gamma-1}{\gamma+1}(\|v\|^2_{H^1(D)} + \|\mathbf{w}\|^2_{L^2(D)} + \|\nabla\cdot\mathbf{w}\|^2_{L^2(D)}) + \eta_0\|\nu\cdot\mathbf{w}\|^2_{L^2(\Gamma_2)},$$

which means that $\mathcal{A}$ is coercive; i.e.,

$$|\mathcal{A}(V,V)| \geq C(\|v\|^2_{H^1(D)} + \|\mathbf{w}\|^2_{W(D)}),$$

where $C = \min((\gamma-1)/(\gamma+1),\, \eta_0)$. Therefore from the Lax–Milgram theorem we have that the variational problem (3.8) is uniquely solvable, whence the modified interior transmission problem has a unique solution (u, v) that satisfies

$$\|v\|_{H^1(D)} + \|w\|_{\mathbb{H}^1(D,\Gamma_2)} \leq C(\|f\|_{H^{\frac{1}{2}}(\Gamma)} + \|h\|_{H^{-\frac{1}{2}}(\Gamma)} + \|r\|_{L^2(\Gamma_2)}),$$

where $C > 0$ is independent on f, h, r.

THEOREM 3.4. *Assume that* $\bar{\xi} \cdot \mathcal{R}e(A)\,\xi \geq \gamma|\xi|^2$ *with* $\gamma > 1$ *and* $\eta(x) \geq \eta_0 > 0$. *Then the Fredholm alternative can be applied to the problem* (IMTP).

Proof. Let us define

$$\mathcal{Y}(D) := \big\{(v,w) \in H^1(D)\times\mathbb{H}^1(D,\Gamma_2)\ :\ \nabla\cdot A\nabla v \in L^2(D) \text{ and } \Delta w \in L^2(D)\big\}$$

and consider the operator $\mathcal{G}$ from $\mathcal{Y}(D)$ into $L^2(D)\times L^2(D)\times H^{\frac{1}{2}}(\Gamma_1)\times L^2(\Gamma_2)\times H^{-\frac{1}{2}}(\Gamma)$ defined by

$$\mathcal{G}(v,w) = \left\{\nabla\cdot A\nabla v - mv,\ \Delta w - w,\ (v-w)|_{\Gamma_1},\ \left(v - w + i\eta\,\frac{\partial w}{\partial\nu}\right)_{\Gamma_2},\ \left(\frac{\partial v}{\partial\nu_A} - \frac{\partial w}{\partial\nu}\right)_{\Gamma}\right\},$$

where $m > 1$. We have shown that the inverse of $\mathcal{G}$ exists and is continuous. Since $\mathcal{G}$ is continuous, we deduce that $\mathcal{G}$ is a bijective operator. Now consider the operator $\mathcal{T}$ from $\mathcal{Y}(D)$ into $L^2(D)\times L^2(D)\times H^{\frac{1}{2}}(\Gamma_1)\times L^2(\Gamma_2)\times H^{-\frac{1}{2}}(\Gamma)$ defined by

$$\mathcal{T}(v,w) = \{(k^2+m)v,\ (k^2+1)w,\ 0,\ 0,\ 0\}.$$

By the compact embedding of $H^1(D)$ into $L^2(D)$, the operator $\mathcal{T}$ is compact. Hence $\mathcal{G}+\mathcal{T}$ is a Fredholm operator of index one, which proves the theorem. ∎

By modifying the variational approach of [9] in a similar way, one can also prove the following result.

THEOREM 3.5. *Assume that* $\bar{\xi}\cdot\mathcal{R}e(A^{-1})\,\xi \geq \gamma|\xi|^2$ *with* $\gamma > 1$. *Then the Fredholm alternative can be applied to the problem* (IMTP).

LEMMA 3.6. *Assume that* $\bar{\xi}\cdot\mathcal{I}m(A)\,\xi < 0$ *at a point* $x_0 \in D$ *and* $\eta \geq \eta_0 > 0$ *on* Γ_2. *Then* (IMTP) *has at most one solution.*

Proof. Let us consider the homogeneous problem (i.e., $f = h = r = 0$). Applying the divergence theorem to $\overline{v}$ and $A\nabla v$, making use of the boundary conditions, and applying Green's theorem for $\overline{w}$ and w, we obtain

$$\int_D \nabla\overline{v}\cdot A\nabla v\,dy - \int_D k^2|v|^2\,dy = \int_D |\nabla w|^2\,dy - \int_D k^2|w|^2\,dy + \int_{\Gamma_2} i\eta\left|\frac{\partial w}{\partial\nu}\right|^2 ds.$$

Hence

$$\mathcal{I}m\left(\int_D \nabla\overline{v}\cdot A\nabla v\,dy\right) = 0 \qquad \text{and} \qquad \int_{\Gamma_2}\eta\left|\frac{\partial w}{\partial\nu}\right|^2 ds = 0.$$

Since $\bar{\xi}\cdot\mathcal{I}m(A)\xi < 0$ in a small ball $B_{x_0} \subset D$, from the first equality we obtain that $\nabla v = 0$ in B_{x_0}, whence $v \equiv 0$ in D since the unique continuation principle holds for (3.5)(i). From the boundary conditions and the integral representation, formula w also vanishes in D. ∎

We summarize the above analysis in the following theorem.

THEOREM 3.7. *Assume that* $\bar{\xi}\cdot\mathcal{I}m(A)\,\xi < 0$ *at a point* $x_0 \in D$ *and* $\eta \geq \eta_0 > 0$. *In addition, assume that there exists a constant* $\gamma > 1$ *such that*

$$\textit{either} \quad \bar{\xi}\cdot\mathcal{R}e(A)\,\xi \geq \gamma|\xi|^2 \quad \textit{or} \quad \bar{\xi}\cdot\mathcal{R}e(A^{-1})\,\xi \geq \gamma|\xi|^2 \qquad \forall\,\xi\in\mathbb{C}^2.$$

Then the interior transmission problem (IMTP) *has a unique solution* (v, w) *which satisfies*

$$\|v\|^2_{H^1(D)} + \|w\|^2_{\mathbb{H}^1(D,\Gamma_2)} \leq C\left(\|f\|_{H^{\frac{1}{2}}(\Gamma)} + \|h\|_{H^{-\frac{1}{2}}(\Gamma)} + \|r\|_{L^2(\Gamma_2)}\right). \tag{3.10}$$

The values of k for which (IMTP) is not uniquely solvable are called the *transmission eigenvalues*. The latter may occur, for example, if $\bar{\xi}\cdot\mathcal{I}m(A)\,\xi = 0$ in D. In this case, from the proof of Lemma 3.6 we obtain that $\frac{\partial w}{\partial\nu} = 0$ on Γ_2, whence the eigenvalues of (IMTP) form a subset of the transmission eigenvalues corresponding to the (usual) interior transmission problem discussed in [7]. Moreover, if $\Gamma_2 = \Gamma$, then the eigenvalues of (IMTP) form a subset of the Neumann eigenvalues of $-\nabla\cdot A\nabla$.

4. The inverse problem. The inverse problem that we consider here is to determine *both* the shape of the scattering object D and the surface conductivity η from a knowledge of the far field pattern $u_\infty(\hat{x}, d)$ for all incident plane waves $u^i := e^{ikx\cdot d}$, $d \in \Omega$, and all observation directions $\hat{x} \in \Omega$. (Note that it suffices to know the far field pattern corresponding to all $d \in \Omega_1 \subset \Omega$ and all $\hat{x} \in \Omega_2 \subset \Omega$; of particular interest is the case $d = -\hat{x} \in \Omega_0 \subset \Omega$.) We start the investigation of the inverse problem by stating a uniqueness theorem for determining the support D.

THEOREM 4.1. *Let the domains* D^1 *and* D^2 *with the boundaries* Γ^1 *and* Γ^2, *respectively; the matrix valued functions* A_1 *and* A_2; *and the functions* η_1 *and* η_2 *determined on the portions* $\Gamma_2^1 \subseteq \Gamma^1$ *and* $\Gamma_2^2 \subseteq \Gamma^2$, *respectively* (*either* Γ_2^1 *or* Γ_2^2 *or both can possibly be empty sets*), *satisfy the assumptions of* (*MTP*) *in section* 2.

Moreover, let us assume that either $\bar{\xi}\cdot\Re(A_1)\,\xi \geq \gamma|\xi|^2$ *or* $\bar{\xi}\cdot\Re(A_1^{-1})\,\xi \geq \gamma|\xi|^2$, *and either* $\bar{\xi}\cdot\Re(A_2)\,\xi \geq \gamma|\xi|^2$ *or* $\bar{\xi}\cdot\Re(A_2^{-1})\,\xi \geq \gamma|\xi|^2$ *for some* $\gamma > 1$. *If the far field patterns* $u_\infty^1(\hat{x},d)$ *corresponding to the data* D^1, A_1, η_1 *and* $u_\infty^2(\hat{x},d)$ *corresponding to the data* D^2, A_2, η_2 *coincide for all* $\hat{x}, d \in \Omega$, *then* $D^1 \equiv D^2$.

This theorem is proved in [8] for the case of Maxwell's equations in $\mathbb{R}^3$. In the scalar case under consideration, one can adapt the approach of Hähner in [15] to prove the above theorem. Note that the main ingredient of Hähner's approach is the well-posedness of the (modified) interior transmission problem investigated in section 3.1.

The next question to ask is the uniqueness of the surface conductivity η. From the above theorem we can now assume that D is known. Furthermore, we require that for an arbitrarily choice of Γ_2, A, and η there exist at least one incident plane wave such that the corresponding total field u satisfies $\frac{\partial u}{\partial \nu}\big|_{\Gamma_0} \neq 0$, where $\Gamma_0 \subset \Gamma$ is an arbitrary portion of Γ. In the context of our application this is a reasonable assumption since otherwise the portion of the boundary where $\frac{\partial u}{\partial \nu}\big|_{\Gamma_0} = 0$ for all incident plane waves will behave like a perfect conductor, contrary to the assumption that the metallic coating is thin enough for the incident field to penetrate into D. We can prove the following result.

THEOREM 4.2. *Assume that* $\eta \in C(\overline{\Gamma}_2)$ *and that* k *is not a Neumann eigenvalue for* $-\nabla\cdot A\nabla$. *Then, under the above assumption and for fixed* D *and* A, *the surface conductivity* η *is uniquely determined from the far field pattern* $u_\infty(\hat{x},d)$ *for all* $\hat{x}, d \in \Omega$.

Proof. Let D and A be fixed, and suppose there exist $\eta_1 \in C(\overline{\Gamma}_2^1)$ and $\eta_2 \in C(\overline{\Gamma}_2^2)$ such that the corresponding scattered fields $u^{s,1}$ and $u^{s,2}$, respectively, have the same far field patterns $u_\infty^1(\hat{x},d) = u_\infty^2(\hat{x},d)$ for all $\hat{x}, d \in \Omega$. Then from Rellich's lemma, $u^{s,1} = u^{s,2}$ in $\mathbb{R}^2\backslash D$. Hence, from the transmission condition, the difference $V = v^1 - v^2$ satisfies

$$\nabla\cdot A\nabla V + k^2 V = 0 \quad \text{in } D, \tag{4.1}$$

$$\frac{\partial V}{\partial \nu_A} = 0 \quad \text{on } \Gamma, \tag{4.2}$$

$$V = -i(\tilde{\eta}_1 - \tilde{\eta}_2)\frac{\partial u^1}{\partial \nu} \quad \text{on } \Gamma, \tag{4.3}$$

where $\tilde{\eta}_1$ and $\tilde{\eta}_2$ are the extension by zero of η_1 and η_2, respectively, to the whole of Γ and $u^1 = u^{s,1} + u^i$. Assuming that k is not a Neumann eigenvalue for $-\nabla\cdot A\nabla$ (in particular, this is the case if $\mathcal{I}m(A) < 0$ at $x_0 \in D$, (4.1)), (4.2) implies that $V = 0$ in D, and hence (4.3) becomes

$$(\tilde{\eta}_1 - \tilde{\eta}_2)\frac{\partial u^1}{\partial \nu} = 0 \quad \text{on} \quad \Gamma$$

for all incident waves. Since for a given $\Gamma_0 \subset \Gamma$ there exists at least one incident plane wave such that $\frac{\partial u^1}{\partial \nu}\big|_{\Gamma_0} \neq 0$, the continuity of η_1 and η_2 in $\overline{\Gamma}_2^1$ and $\overline{\Gamma}_2^2$, respectively, implies that $\tilde{\eta}_1 = \tilde{\eta}_2$. ∎

We now define the *far field operator* $F : L^2(\Omega) \to L^2(\Omega)$ by

$$Fg(\hat{x}) := \int_\Omega u_\infty(\hat{x},d)g(d)\,ds(d) \tag{4.4}$$

and introduce the far field equation

$$(Fg)(\hat{x}) = \gamma e^{-ik\hat{x}\cdot z}, \quad g \in L^2(\Omega), \quad z \in D, \tag{4.5}$$

where $\gamma = \frac{e^{i\pi/4}}{\sqrt{8\pi k}}$ and $\gamma e^{-ik\hat{x}\cdot z}$ is the far field pattern of the fundamental solution $\Phi(x,z) := \frac{i}{4}H_0^{(1)}(k|x-z|)$ to the Helmholtz equation in $\mathbb{R}^2$, with $H_0^{(1)}$ being a Hankel function of the first kind of order zero. A reconstruction of D can be obtained by using the linear sampling method which characterizes the support D from a solution of the far field equation (4.5) (see, e.g., [3], [7]). Assuming that D is known, our goal is to provide a formula for computing the L_∞ norm of η in terms of the solution of the far field equation (4.5).

To this end, assuming that k is not a transmission eigenvalue, for $z \in D$ we denote by v_z and w_z the unique solution of the interior transmission problem

$$
\begin{aligned}
&\nabla\cdot A\nabla v_z + k^2 v_z = 0 && \text{in } D,\\
&\Delta w_z + k^2 w_z = 0 && \text{in } D,\\
&v_z - (w_z + \Phi(\cdot,z)) = 0 && \text{on } \Gamma_1,\\
&v_z - (w_z + \Phi(\cdot,z)) = -i\eta\,\frac{\partial}{\partial\nu}(w_z + \Phi(\cdot,z)) && \text{on } \Gamma_2,\\
&\frac{\partial v_z}{\partial \nu_A} - \frac{\partial}{\partial\nu}(w_z + \Phi(\cdot,z)) = 0 && \text{on } \Gamma.
\end{aligned}
\tag{4.6}
$$

We recall that a Herglotz wave function with kernel $g \in L^2(\Omega)$ is an entire solution of the Helmholtz equation defined by

$$
v_g(x) = \int_\Omega e^{ikx\cdot d} g(d)\,ds(d), \qquad x \in \mathbb{R}^2. \tag{4.7}
$$

The following theorem holds.

THEOREM 4.3. *Assume that k is not a transmission eigenvalue. Let $\epsilon > 0$, $z \in D$, and (w_z, v_z) be the unique solution of* (4.6). *Then there exists a Herglotz wave function $v_{g_\epsilon^z}$ with kernel $g_\epsilon^z \in L^2(\Omega)$ such that*

$$
\|w_z - v_{g_\epsilon^z}\|_{\mathbb{H}^1(D,\Gamma_2)} \le \epsilon. \tag{4.8}
$$

Moreover, there exists a positive constant $c > 0$ independent of ϵ and z such that

$$
\|(Fg_\epsilon^z)(\hat{x}) - \gamma e^{-ik\hat{x}\cdot z}\|_{L^2(\Omega)} \le c\epsilon. \tag{4.9}
$$

Proof. To prove the first part of the theorem we first show that the operator $\mathcal{H} : L^2(\Omega) \to H^{\frac{1}{2}}(\Gamma_1) \times L^2(\Gamma_2)$ defined by

$$
(\mathcal{H}g)(x) := \begin{cases} \displaystyle\int_\Omega e^{-iky\cdot\hat{x}} g(\hat{x})\,ds(\hat{x}), & y \in \Gamma_1,\\ \displaystyle\frac{\partial}{\partial\nu}\int_\Omega e^{-iky\cdot\hat{x}} g(\hat{x})\,ds(\hat{x}) + i\int_\Omega e^{-iky\cdot\hat{x}} g(\hat{x})\,ds(\hat{x}), & y \in \Gamma_2, \end{cases} \tag{4.10}
$$

has dense range. To this end it suffices to show that the corresponding dual operator $\mathcal{H}^* : \tilde{H}^{-\frac{1}{2}}(\Gamma_1) \times L^2(\Gamma_2) \to L^2(\Omega)$ defined by

$$
\langle \mathcal{H}g,\, \phi\rangle_{H^{\frac{1}{2}}(\Gamma_1),\tilde{H}^{-\frac{1}{2}}(\Gamma_1)} + \langle \mathcal{H}g,\, \psi\rangle_{L^2(\Gamma_2),L^2(\Gamma_2)} = \langle g,\, \mathcal{H}^*(\phi,\,\psi)\rangle_{L^2(\Omega),L^2(\Omega)}
$$

for all $g \in L^2(\Omega)$, $\phi \in \tilde{H}^{-\frac{1}{2}}(\Gamma_1), \psi \in L^2(\Gamma_2)$ is injective. By interchanging the order of integration, one can show that

$$
\mathcal{H}^*(\phi,\,\psi)(\hat{x}) = \int_\Gamma e^{-iky\cdot\hat{x}}\tilde{\phi}(y)\,ds(y) + \int_\Gamma \frac{\partial e^{-iky\cdot\hat{x}}}{\partial\nu}\tilde{\psi}(y)\,ds(y) + i\int_\Gamma e^{-iky\cdot\hat{x}}\tilde{\psi}(y)\,ds(y),
$$

where $\tilde{\phi} \in H^{-\frac{1}{2}}(\Gamma)$ and $\tilde{\psi} \in L^2(\Gamma)$ are the extension by zero to the whole boundary Γ of ϕ and ψ, respectively. Assume that $\mathcal{H}^*(\phi, \psi) = 0$. Since $\mathcal{H}^*(\phi, \psi)$ is, up to a constant, the far field pattern of the potential

$$P(x) = \int_\Gamma \Phi(x,y)\tilde{\phi}(y)\,ds(y) + \int_\Gamma \frac{\partial \Phi(x,y)}{\partial \nu}\tilde{\psi}(y)\,ds(y) + i\int_\Gamma \Phi(x,y)\tilde{\psi}(y)\,ds(y),$$

which satisfies the Helmholtz equation in D_e, from Rellich's lemma we have that $P(x) = 0$ in D_e. As $x \to \Gamma$, the following jump relations (in the L^2 limit sense [12], [16]) hold:

$$P^+ - P^-|_{\Gamma_1} = 0, \qquad P^+ - P^-|_{\Gamma_2} = \psi,$$

$$\frac{\partial P^+}{\partial \nu} - \frac{\partial P^-}{\partial \nu}\bigg|_{\Gamma_1} = -\phi, \qquad \frac{\partial P^+}{\partial \nu} - \frac{\partial P^-}{\partial \nu}\bigg|_{\Gamma_2} = -i\psi,$$

where by the superscript $+$ and $-$ we distinguish the limits obtained by approaching the boundary Γ from D^e and D, respectively. Using the fact that $P^+ = \frac{\partial P^+}{\partial \nu} = 0$, we see that P satisfies the Helmholtz equation and

$$P^-|_{\Gamma_1} = 0, \quad \frac{\partial P^-}{\partial \nu} + iP^-\bigg|_{\Gamma_2} = 0,$$

where the equalities are understood in the L^2 limit sense. Using Green's theorem and a parallel surface argument, one can conclude as in Theorem 2.1 in [3] that $P = 0$ in D, whence from the above jump relations $\phi = \psi = 0$.

Now let $w \in \mathbb{H}^1(D, \Gamma_2)$ be a solution of the Helmholtz equation in D. From the above we can approximate $w|_{\Gamma_1} \in H^{\frac{1}{2}}(\Gamma_1)$ and $\frac{\partial w}{\partial \nu} + iw|_{\Gamma_2} \in L^2(\Gamma_2)$ by $\mathcal{H}g$. Hence using the a priori estimate for the solution of the mixed boundary value problem for the Helmholtz equation (see Theorem 2.3 in [3]),

$$\|w\|_{H^1(D)} + \left\|\frac{\partial w}{\partial \nu}\right\|_{L^2(\Gamma_2)} \le C\left(\|w\|_{H^{\frac{1}{2}}(\Gamma_1)} + \left\|\frac{\partial w}{\partial \nu} + iw\right\|_{L^2(\Gamma_2)}\right),$$

we obtain that w can be approximated by a Herglotz wave function v_g with respect to the $\mathbb{H}^1(D, \Gamma_2)$-norm, which proves the first part of the theorem. Note that, by a change of variable, v_g defined by (4.7) can be written as $\int_\Omega e^{-ikx\cdot d} g(d)ds(d)$.

Next let $z \in D$. Then $\gamma e^{-ik\hat{x}\cdot z}$ is the far field pattern of the radiating solution $\Phi(x,z)$. Let w_z and v_z be the unique solution of (4.6). Obviously v_z and $\Phi(x,z)$ satisfy (MTP) with incident field the $H^1_{\mathrm{loc}}(\mathbb{R})$-extension of w_z. The well-posedness of (MTP) (section 3) together with the classical trace theorems and the approximation of w_z by a Herglotz wave function $v_{g_\epsilon^z}$ show that for every $\epsilon > 0$

$$\|(Fg_\epsilon^z)(\hat{x}) - \gamma e^{-ik\hat{x}\cdot z}\|_{L^2(\Omega)} \le c_1\|u^s_{g_\epsilon^z} - \Phi(\cdot, z)\|_{H^1(D_e \cap B_R)} \le c\|v_{g_\epsilon^z} - w_z\|_{H^1(D)} \le c\epsilon$$

for $c_1, c > 0$, where $u^s_{g_\epsilon^z}$ is the scattered field corresponding to $v_{g_\epsilon^z}$ as the incident wave. (Note that by superposition Fg_ϵ^z coincides with $u^s_{g_\epsilon^z}$.) This ends the proof. ∎

Now let us define W_z by

$$W_z := w_z + \Phi(\cdot, z). \tag{4.11}$$

In particular, since $w_z \in \mathbb{H}^1(D, \Gamma_2)$, $\Delta w_z \in L^2(D)$, and $z \in D$, we have that $W_z|_\Gamma \in H^{\frac{1}{2}}(\Gamma)$, $\frac{\partial W_z}{\partial \nu}|_\Gamma \in H^{-\frac{1}{2}}(\Gamma)$, and $\frac{\partial W_z}{\partial \nu}|_{\Gamma_2} \in L^2(\Gamma_2)$.

LEMMA 4.4. *For every two points z_1 and z_2 in D we have that*

$$
\begin{aligned}
(4.12)\qquad & -2\int_D \nabla v_{z_1}\cdot \mathcal{I}m(A)\nabla \overline{v}_{z_2}\,dx + 2\int_{\Gamma_2}\eta(x)\frac{\partial W_{z_1}}{\partial \nu}\frac{\partial \overline{W}_{z_2}}{\partial \nu}\,ds \\
& = -4k\pi|\gamma|^2 J_0(k|z_1-z_2|) + i\left(w_{z_1}(z_2)-\overline{w}_{z_2}(z_1)\right),
\end{aligned}
$$

where w_{z_1}, W_{z_1} and w_{z_2}, W_{z_2} are defined by (4.6) *and* (4.11)*, respectively, and J_0 is a Bessel function of order zero.*

Proof. Let z_1 and z_2 be two points in D and v_{z_1}, w_{z_1}, W_{z_1} and v_{z_2}, w_{z_2}, W_{z_2} the corresponding functions defined by (4.6) and (4.11). Applying the divergence theorem to $v_{z_1}, \overline{v}_{z_2}$ and using (4.6) together with the fact that A is symmetric, we have

$$
\begin{aligned}
\int_\Gamma \left(v_{z_1}\frac{\partial \overline{v}_{z_2}}{\partial \nu_{\overline{A}}} - \overline{v}_{z_2}\frac{\partial v_{z_1}}{\partial \nu_A}\right)ds &= \int_D \left(\nabla v_{z_1}\cdot \overline{A}\nabla \overline{v}_{z_2} - \nabla \overline{v}_{z_2}\cdot A\nabla v_{z_1}\right)dx \\
+\int_D \left(v_{z_1}\nabla\cdot \overline{A}\nabla \overline{v}_{z_2} - \overline{v}_{z_2}\nabla\cdot A\nabla v_{z_1}\right)dx &= -2i\int_D \nabla v_{z_1}\cdot \mathcal{I}m(A)\nabla \overline{v}_{z_2}\,dx.
\end{aligned}
$$

On the other hand, from the boundary conditions we have

$$
\begin{aligned}
&\int_\Gamma \left(v_{z_1}\frac{\partial \overline{v}_{z_2}}{\partial \nu_{\overline{A}}} - \overline{v}_{z_2}\frac{\partial v_{z_1}}{\partial \nu_A}\right)ds \\
&\quad = \int_\Gamma \left(W_{z_1}\frac{\partial \overline{W}_{z_2}}{\partial \nu} - \overline{W}_{z_2}\frac{\partial W_{z_1}}{\partial \nu}\right)ds - 2i\int_{\Gamma_2}\eta(x)\frac{\partial W_{z_1}}{\partial \nu}\frac{\partial \overline{W}_{z_2}}{\partial \nu}\,ds.
\end{aligned}
$$

Hence

$$
\begin{aligned}
&-2i\int_D \nabla v_{z_1}\cdot \mathcal{I}m(A)\nabla \overline{v}_{z_2}\,dx + 2i\int_{\Gamma_2}\eta(x)\frac{\partial W_{z_1}}{\partial \nu}\frac{\partial \overline{W}_{z_2}}{\partial \nu}\,ds \\
&\quad = \int_\Gamma \left(W_{z_1}\frac{\partial \overline{W}_{z_2}}{\partial \nu} - \overline{W}_{z_2}\frac{\partial W_{z_1}}{\partial \nu}\right)ds = \int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right)ds \\
&\qquad + \int_\Gamma \left(w_{z_1}\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial w_{z_1}}{\partial \nu}\right)ds + \int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{w}_{z_2}}{\partial \nu} - \overline{w}_{z_2}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right)ds.
\end{aligned}
$$

Green's theorem applied to the radiating solution $\Phi(\cdot,z)$ of the Helmholtz equation in D_e implies that [13]

$$
\begin{aligned}
&\int_\Gamma \left(\Phi(\cdot,z_1)\frac{\partial \overline{\Phi(\cdot,z_2)}}{\partial \nu} - \overline{\Phi(\cdot,z_2)}\frac{\partial \Phi(\cdot,z_1)}{\partial \nu}\right)ds = -2ik\int_\Omega \Phi_\infty(\cdot,z_1)\overline{\Phi_\infty(\cdot,z_2)}ds \\
&\quad = -2ik\int_\Omega |\gamma|^2 e^{-ik\hat{x}\cdot z_1}e^{ik\hat{x}\cdot z_2}\,ds = -4ik\pi|\gamma|^2 J_0(k|z_1-z_2|),
\end{aligned}
$$

and from the representation formula for w_{z_1} and w_{z_2} we now obtain

$$
\begin{aligned}
&-2i\int_D \nabla v_{z_1}\cdot \mathcal{I}m(A)\nabla \overline{v}_{z_2}\,dx + 2i\int_{\Gamma_2}\eta(x)\frac{\partial W_{z_1}}{\partial \nu}\frac{\partial \overline{W}_{z_2}}{\partial \nu}\,ds \\
&\quad = -4ik\pi|\gamma|^2 J_0(k|z_1-z_2|) + \overline{w}_{z_2}(z_1) - w_{z_1}(z_2).
\end{aligned}
$$

Dividing both sides of the above relation by i yields the result. ∎

In the following we consider a ball $B_r \subset D$ of radius r contained in D and define a subset of $L^2(\Gamma_2)$ by

$$\mathcal{V} := \left\{ f \in L^2(\Gamma_2) : \quad \begin{array}{l} f = \dfrac{\partial W_z}{\partial \nu}\Big|_{\Gamma_2} \text{ with } W_z = w_z + \Phi(\cdot, z), \\ z \in B_r \text{ and } w_z, v_z \text{ the solution of (4.6).} \end{array} \right\}$$

LEMMA 4.5. *Assuming that k is neither a transmission eigenvalue nor a Neumann eigenvalue for $-\nabla \cdot A\nabla$, then $\mathcal{V}$ is complete in $L^2(\Gamma_2)$.*

Proof. Let φ be a function in $L^2(\Gamma_2)$ such that for every $z \in B_r$

$$\int_{\Gamma_2} \frac{\partial W_z}{\partial \nu}\, \varphi \, ds = 0.$$

Construct $v \in H^1(D)$ and $w \in \mathbb{H}^1(D, \Gamma_2)$ as the unique solution of the interior transmission problem

$$\begin{array}{lll} \text{(i)} & \nabla \cdot A\nabla v + k^2 v = 0 & \text{in } D, \\ \text{(ii)} & \Delta w + k^2 w = 0 & \text{in } D, \\ \text{(iii)} & v - w = 0 & \text{on } \Gamma_1, \\ \text{(iv)} & v - w = -i\eta \dfrac{\partial w}{\partial \nu} + \varphi & \text{on } \Gamma_2, \\ \text{(v)} & \dfrac{\partial v}{\partial \nu_A} - \dfrac{\partial w}{\partial \nu} = 0 & \text{on } \Gamma. \end{array}$$

Then we have

$$\begin{aligned} 0 &= \int_{\Gamma_2} \frac{\partial W_z}{\partial \nu}\, \varphi \, ds = \int_{\Gamma} \frac{\partial W_z}{\partial \nu}\, (v - w)\, ds + i \int_{\Gamma_2} \eta \frac{\partial W_z}{\partial \nu} \frac{\partial w}{\partial \nu}\, ds \\ &= \int_{\Gamma} \frac{\partial W_z}{\partial \nu}\, v \, ds - \int_{\Gamma} \frac{\partial W_z}{\partial \nu}\, w \, ds + i \int_{\Gamma_2} \eta \frac{\partial W_z}{\partial \nu} \frac{\partial w}{\partial \nu}\, ds. \end{aligned} \tag{4.13}$$

Next from the equations for v_z and v, the divergence theorem, and the transmission conditions, we have

$$\begin{aligned} \int_{\Gamma} \frac{\partial W_z}{\partial \nu}\, v \, ds &= \int_{\Gamma} \frac{\partial v_z}{\partial \nu_A}\, v \, ds = \int_{\Gamma} \frac{\partial v}{\partial \nu_A}\, v_z \, ds \\ &= \int_{\Gamma} \frac{\partial w}{\partial \nu}\, W_z \, ds - i \int_{\Gamma_2} \eta \frac{\partial W_z}{\partial \nu} \frac{\partial w}{\partial \nu}\, ds. \end{aligned} \tag{4.14}$$

Finally, substituting (4.14) into (4.13) and using the integral representation formula yields

$$\begin{aligned} 0 &= \int_{\Gamma} \left(\frac{\partial w}{\partial \nu}\, W_z - \frac{\partial W_z}{\partial \nu}\, w \right) ds = \int_{\Gamma} \left(\frac{\partial w}{\partial \nu}\, w_z - \frac{\partial w_z}{\partial \nu}\, w \right) ds \\ &= \int_{\Gamma} \left(\frac{\partial w}{\partial \nu}\, \Phi(\cdot, z) - \frac{\partial \Phi(\cdot, z)}{\partial \nu}\, w \right) ds = w(z) \qquad \forall z \in B_r. \end{aligned} \tag{4.15}$$

The unique continuation principle for the Helmholtz equation now implies that $w = 0$ in D. Hence if k is not a Neumann eigenvalue corresponding to $-\nabla \cdot A\nabla$ (e.g., if

$\mathcal{I}m(A) < 0$ at a point $x_0 \in D$), then $v \equiv 0$ and therefore $\varphi = 0$, which proves the lemma. ∎

Now we are ready to prove the main result of this section.

THEOREM 4.6. *Let $\eta \in L_\infty(\Gamma_2)$ be the surface conductivity of* (MTP)*, and assume that $\mathcal{I}m(A) = 0$ in D and k is neither a transmission eigenvalue nor a Neumann eigenvalue for $-\nabla \cdot A\nabla$. Then*

$$\|\eta\|_{L_\infty(\Gamma_2)} = \sup_{\substack{z_i,\, z_j \in B_r \\ \alpha_i \in \mathbb{C}}} \frac{\sum_{i,j} \alpha_i \overline{\alpha_j} \left(-4\pi k|\gamma|^2 J_0(k|z_i - z_j|) + i w_{z_i}(z_j) - i\overline{w}_{z_j}(z_i)\right)}{2\| \sum_i \alpha_i \frac{\partial}{\partial \nu}(w_{z_i} + \Phi(\cdot; z_i))\|^2_{L^2(\Gamma_2)}}, \tag{4.16}$$

where w_z is such that (w_z, v_z) solves (4.6) *and the sums are arbitrary finite sums.*

Proof. We recall that

$$\|\eta\|_{L_\infty(\Gamma_2)} := \operatorname{ess\,sup} \eta = \sup_{f \in L^2(\Gamma_2)} \frac{1}{\|f\|^2_{L^2(\Gamma_2)}} \int_{\Gamma_2} \eta(x)|f|^2 ds.$$

The theorem then follows from Lemmas 4.4 and 4.5 by fixing first z_2 and then z_1 and considering linear combinations of $\frac{\partial W_z}{\partial \nu}$ for different $z \in B_r$. ∎

Given that D is known, w_z in the right-hand side of (4.16) still cannot be computed, since it depends on the unknown functions η and A. However, from Theorem 4.3, we can use in (4.16) an approximation to w_z given by the Herglotz wave function v_{g^z} with kernel g^z being the (regularized) solutions of the far field equation (4.5).

In the particular case where the coating is homogeneous, i.e., the surface conductivity is a positive constant $\eta > 0$, we can further simplify (4.16). In particular, fix an arbitrary point $z_0 \in B_r$ and consider $z_1 = z_2 = z_0$. Then (4.12) simply becomes

$$\eta = \frac{-2k\pi|\gamma|^2 - \mathcal{I}m\left(w_{z_0}(z_0)\right)}{\|\frac{\partial}{\partial \nu}(w_{z_0} + \Phi(\cdot; z_0))\|^2_{L^2(\Gamma_2)}}. \tag{4.17}$$

A drawback of (4.16) and (4.17) is that the extent of the coating Γ_2 is not known. Thus, in practice these expressions provide only a lower bound for $\|\eta\|_{L_\infty(\Gamma_2)}$. However, if the object is fully coated, that is, $\Gamma_2 = \Gamma$, we can compute an approximation of $\|\eta\|_{L_\infty(\Gamma_2)}$ by (4.12) and (4.17), where Γ_2 is replaced by of Γ.

5. Remarks on Maxwell's equations in $\mathbb{R}^3$. The analysis of the previous three sections for the case of scattering by an infinite cylinder can in principle be extended to the scattering of electromagnetic waves by a bounded dielectric in $\mathbb{R}^3$. In this case the direct scattering problem is given by (2.1)–(2.6), and the existence of a unique solution to this problem was established in [8]. The results for the inverse scattering problem for an infinite cylinder established in section 4 of this paper can in turn be extended to the case of Maxwell's equations in $\mathbb{R}^3$, *provided* that one can establish the existence of a unique solution to the interior transmission problem

$$\begin{aligned} &\nabla \times E_z - ikH_z = 0 \\ &\nabla \times H_z + ikE_z = 0 \end{aligned} \qquad \text{in } D, \tag{5.1}$$

$$\begin{aligned} &\nabla \times E_z^{\text{int}} - ikH_z^{\text{int}} = 0 \\ &\nabla \times H_z^{\text{int}} + ikN(x)E_z^{\text{int}} = 0 \end{aligned} \qquad \text{in } D, \tag{5.2}$$

together with the boundary relations

$$
\begin{aligned}
&\nu \times E_z^{\rm int} - \nu \times E_z = \nu \times E_e(\cdot, z, q) && \text{on } \Gamma,\\
&\nu \times H_z^{\rm int} - \nu \times H_z = \nu \times H_e(\cdot, z, q) && \text{on } \Gamma_1,\\
&\nu \times H_z^{\rm int} - \nu \times H_z = -\eta\,[\nu \times (E_z + E_e(\cdot, z, q)) \times \nu] + \nu \times H_e(\cdot, z, q) && \text{on } \Gamma_2,
\end{aligned}
\tag{5.3}
$$

where $E_e(\cdot, z, q)$, $H_e(\cdot, z, q)$ is the electric dipole defined by

$$
E_e(x, z, q) := \frac{i}{k} \nabla_x \times \nabla_x \times q\, \Phi(x, z), \qquad H_e(x, z, q) := \nabla_x \times q\, \Phi(x, z),
\tag{5.4}
$$

where $q \in \mathbb{R}^3$ is a constant vector and

$$
\Phi(x, z) := \frac{1}{4\pi} \frac{e^{ik|x-z|}}{|x - z|}.
$$

Unfortunately this result remains an open problem. (For the existence of a unique solution to a modified version of (5.1)–(5.3), see [8].)

Assuming the existence of a unique solution of (5.1)–(5.3), one can now proceed to derive the three-dimensional analogue of Theorem 4.6; i.e., if $\mathcal{I}m(N) = 0$ and k is not a transmission eigenvalue, then

$$
\|\eta\|_{L_\infty(\Gamma_2)} = \sup_{\substack{z_i \in B_r,\, q \in \mathbb{R}^3 \\ \alpha_i \in \mathbb{C}}} \frac{\sum_{i,j} \alpha_i \overline{\alpha_j} \left[-\|q\|^2 A(z_i, z_j, k, q) + q \cdot E_{z_i}(z_j) + q \cdot \overline{E}_{z_j}(z_i) \right]}{2 \| \sum_i \alpha_i\, \nu \times (E_{z_i} + E_e(\cdot, z_i, q)) \|^2_{L_t^2(\Gamma_2)}},
\tag{5.5}
$$

where $B_r \subset D$ is a ball of radius r;

$$
A(z_i, z_j, k, q) = \frac{k^2}{6\pi} \left[2 j_0(k|z_i - z_j|) + j_2(k|z_i - z_j|)(3\cos^2\phi - 1) \right],
\tag{5.6}
$$

j_0 and j_2 being spherical Bessel functions of order 0 and 2, respectively; ϕ is the angle between $(z_i - z_j)$ and q; and E_z, $E_z^{\rm int}$ is the unique solution of the interior transmission problem (5.1)–(5.3). In particular, E_z can be approximated by

$$
E_{g_z}(x) := ik \int_\Omega e^{ikx \cdot d} g_z(d) ds(d),
\tag{5.7}
$$

where $\Omega := \{x \in \mathbb{R}^3 : |x| = 1\}$ and g_z is the (regularized) solution of the *far field equation*

$$
\int_\Omega E_\infty(\hat{x}, d, g(d)) ds(d) = E_{e,\infty}(\hat{x}, z, q).
\tag{5.8}
$$

Here E_∞ is the electric far field pattern corresponding to the scattering problem (2.1)–(2.6), and $E_{e,\infty}$ is the electric far field pattern of the electric dipole (5.4). For details in the case of a perfect conductor coated by a dielectric, see section 3 of [5].

In the special case when η is a constant, (5.5) simplifies to

$$
\eta = \frac{-\frac{k^2}{6\pi}\|q\|^2 + \mathcal{R}e\,(q \cdot E_{z_0}(z_0))}{\|\nu \times (E_{z_0} + E_e(\cdot, z_0, q))\|^2_{L_t^2(\Gamma_2)}},
\tag{5.9}
$$

where z_0 is an arbitrary point in D.

6. Numerical examples. In this section we shall present some numerical tests of the inversion scheme using synthetic far field data for the Helmholtz equation. For a given scatterer, the far field data is computed by using a cubic finite element code to approximate the near field, and then employing a near to far field transformation [18]. The finite element computational domain is terminated by a rectilinear perfectly matched layer using a linear absorption function in the layer [2], [10].

Having computed approximate values of the far field pattern at N uniformly spaced points on the unit circle for N incoming waves, we have an $N \times N$ matrix $\mathcal{A}$ of approximate far field data

$$\mathcal{A}_{m,n} = u_{h,\infty}(d_m, d_n) \quad \text{where} \quad d_m = \left(\cos\left(\frac{2\pi(m-1)}{N}\right),\ \sin\left(\frac{2\pi(m-1)}{N}\right)\right)^T$$

for $1 \le m, n \le N$, where $u_{h,\infty}$ is the finite element far field pattern. To this we add further noise with parameter ϵ to obtain $\mathcal{A}_\epsilon$ using

$$(\mathcal{A}_\epsilon)_{m,n} = \mathcal{A}_{m,n}(1 + \epsilon(\xi_{1,m,n} + i\xi_{2,m,n})),$$

where $\xi_{1,m,n}$ and $\xi_{2,m,n}$ are given by a random number generator, uniformly distributed in the range $[-1, 1]$. Unless otherwise stated, $\epsilon = 0.01$ in these studies.

For a given sampling point z, the discrete far field equation is then to compute $\vec{g} = (g_1, \ldots, g_N)$ such that $\mathcal{A}_\epsilon \vec{g} = \vec{b}$, where

$$b_m = N\gamma \exp \frac{(-ik(z \cdot d_m))}{(2\pi)}, \qquad 1 \le m \le N.$$

This ill-conditioned problem is solved approximately using the Tikhonov regularization and the Morozov discrepancy principle as described, for example, in [14].

6.1. Exact knowledge of the boundary. We start as in [5], assuming an exact knowledge of the boundary in order to assess the accuracy of (4.17) without the added error of computing an approximation to the boundary of the scatterer. In this case, for a given scatterer, we compute $\vec{g}$ for $z = z_0$ using the Morozov method outlined in the previous section, and then approximate (4.17) using the trapezoidal rule with 100 integration points. After limited experiments, we choose $z_0 = (0, 0)^T$ (both upcoming examples have this point as their centroid).

To simplify the presentation, we have limited our discussion to two scatterers: an ellipse given by $x = 0.5\cos(s)$ and $y = 0.2\sin(s)$, $s \in [0, 2\pi]$, and the rectangle $[-0.5, 0.5] \times [0.4, 0.4]$. In (2.7) we choose $A = (1/4)I$. In all cases $k = 5$.

For the ellipse we consider either a fully coated or partially coated object. The partially coated boundary is shown in Figure 6.1. In Figure 6.2 we show results of the reconstruction of a range of conductivities η for the fully coated ellipse, partially coated ellipse, and fully coated rectangle. For each exact η we compute the far field data, add noise, and compute an approximation to w_{z_0}, as discussed before. Despite the noise on the data, η is well approximated in the case of the fully coated scatterers, provided that the conductivity is not too large. In all cases the approximation of η deteriorates for large conductivities, and as expected, (4.17) leads to an underestimate of η when the boundary is partially coated. These limited examples suggest that (4.17) provides a viable method for reconstructing η, provided that η is small enough and the boundary of the scatterer is known sufficiently accurately.

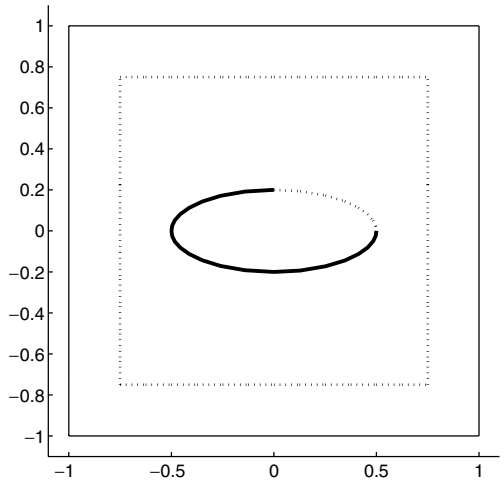

FIG. 6.1. *A diagram showing the coated portion of the partially coated ellipse as a thick line. The dotted square is the inner boundary of the PML, and the solid square is the boundary of the finite element computational domain.*

6.2. The ellipse. We now wish to investigate the solution of the full inverse problem. We start by using the standard linear sampling method to approximate the boundary of the scatterer. In particular we compute $1/\|\vec{g}\|$ for z on a uniform grid in the sampling domain. In the upcoming numerical results we have arbitrarily chosen $N = 61$, and we sample on a 101×101 grid on the square $[-1, 1] \times [-1, 1]$. This procedure takes around 10 seconds in MATLAB on an Apple G5 computer, so it is not time-consuming.

Having computed $\vec{g}$ for each sample point, we have a discrete level set function $1/\|\vec{g}\|$. Choosing a contour value C then provides a reconstruction of the support of the given scatterer. We extract the edge of the reconstruction and then fit this using a trigonometric polynomial of degree M, assuming that the reconstruction is star-like with respect to the origin. (For more advanced applications it would be necessary to

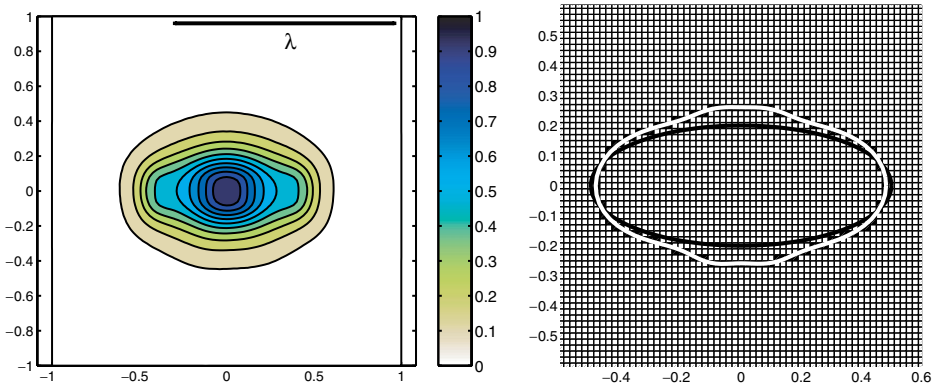

FIG. 6.3. *Illustration of the steps in the computation of η. First the standard linear sampling method is used to compute $1/\|\vec{g}\|$, as shown in panel* (a) *(the bar labeled λ shows the wavelength of the radiation). Choosing a cutoff C (in this case $C = 0.3$), the surface in panel* (a) *provides an approximation to the boundary of the scatterer shown as shaded blocks in panel* (b)*. Each square in this figure contains one sampling point z at its center. We also show in panel* (b) *the outline of the true scatterer as a smooth solid line, and as a white line the fit of the trigonometric series to the reconstruction. In this case C is chosen too small and the computed boundary lies outside the true scatterer.*

employ a more elaborate smoothing procedure.) Thus for an angle θ the radius of the reconstruction is given by

$$r(\theta) = \Re\left(\sum_{n=-M}^{M} r_n \exp(in\theta)\right),$$

where r is measured from the origin (since in all the examples here the origin is within the scatterer). The coefficients r_n are found using a least squares fit to the boundary identified in the previous step of the algorithm. Once we have a parameterization of the reconstructed boundary, we can compute the normal to the boundary and evaluate (4.17) for some choice of z_0 (in the examples always $z_0 = (0,0)^T$) using the trapezoidal rule with 100 points. This provides our reconstruction of η.

Figure 6.3 shows the main steps for evaluating our prediction of η for the ellipse. Here we choose $\eta = 1$ on the entire ellipse (fully coated). In (a) we see a plot of $1/\|\vec{g}\|$ (normalized so that the maximum value is 1) as a function of position. In this case the choice $\epsilon = 0.01$ for the additional error in the far field pattern gives an error of 1.3% in the spectral norm for $\mathcal{A}$.

We then make the arbitrary choice $C = 0.3$ (i.e., due to the normalization, the value is 0.3 times the maximum of $1/\|\vec{g}\|$). Figure 6.3(b) shows a plot of the pixels separating regions where $1/\|\vec{g}\| > C$ and $1/\|\vec{g}\| < C$. For clarity, we have graphed only the region $[-0.6, 0.6] \times [-0.6, 0.6]$. The black pixels in Figure 6.3(b) are then fitted using $M = 8$ in the trigonometric polynomial for $r(\theta)$, and the resulting curve is shown as a light curve on the figure. We also indicate, using a thick black line, the true ellipse. We have deliberately chosen a contour value C that does not give the best reconstruction of the ellipse so that the different geometric features can be easily seen. Using this reconstruction results in a predicted value of $\eta = 0.8372$ (compared to the true value $\eta = 1$).

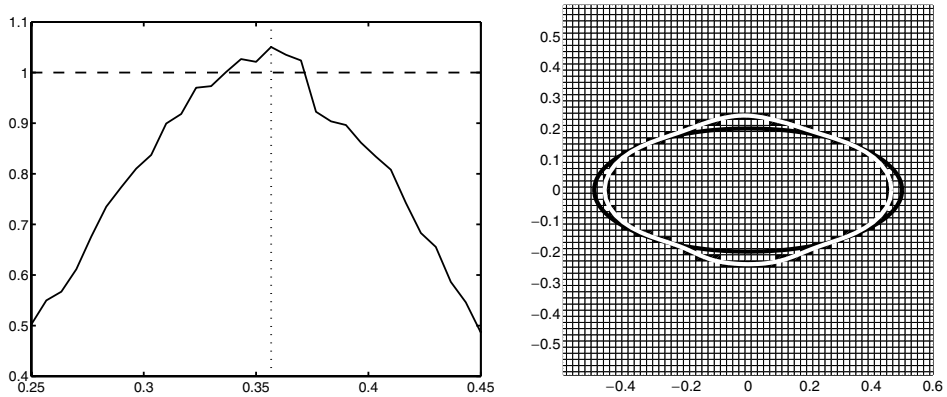

FIG. 6.4. *Panel* (a) *shows the computed value of* η *as a function of the cutoff* C*. The dashed line is the true value* $\eta = 1$*, and the dotted line marks the maximum predicted* η*. The corresponding reconstruction of the ellipse is shown in panel* (b) *using the same convention as in panel* (b) *of Figure* 6.3.

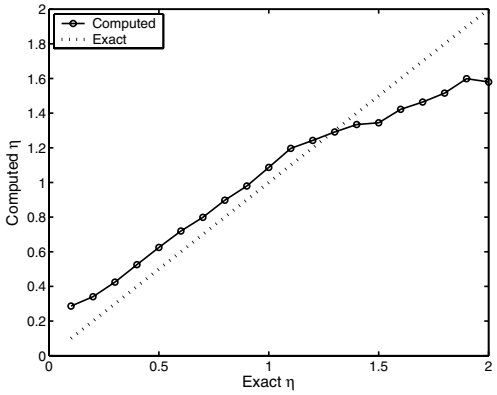

FIG. 6.5. *Reconstruction of a range of* η*. For each exact* η *we apply the reconstruction algorithm using a range of cutoffs and plot the corresponding reconstruction. An exact reconstruction would lie on the dotted line.*

With both scatterers in this study we have observed that a poor choice of the cutoff C tends to result in a predicted value of η that is too small. Therefore we now suggest sweeping through a range of values of C, and we find that the maximum value of η correlates with a good reconstruction of the scatterer and a better approximation of the true value of η. We show this in Figure 6.4 for the fully coated ellipse. The largest predicted value of η is $\eta = 1.05$ when $C = .3567$, and the reconstruction of the scatterer is better than choosing $C = 0.3$.

The reconstruction algorithm is next investigated for a range of values of η. For each exact η we apply the reconstruction algorithm using multiple cutoffs and plot the corresponding reconstruction of η. The results are shown in Figure 6.5 and should be compared to those in Figure 6.2(a). Given that the shape of the object and the parameter η are both being reconstructed, the results show reasonable agreement of the reconstruction up to approximately $\eta = 1.5$. For larger values of η the reconstruction deteriorates, perhaps because the field inside the scatterer diminishes as η

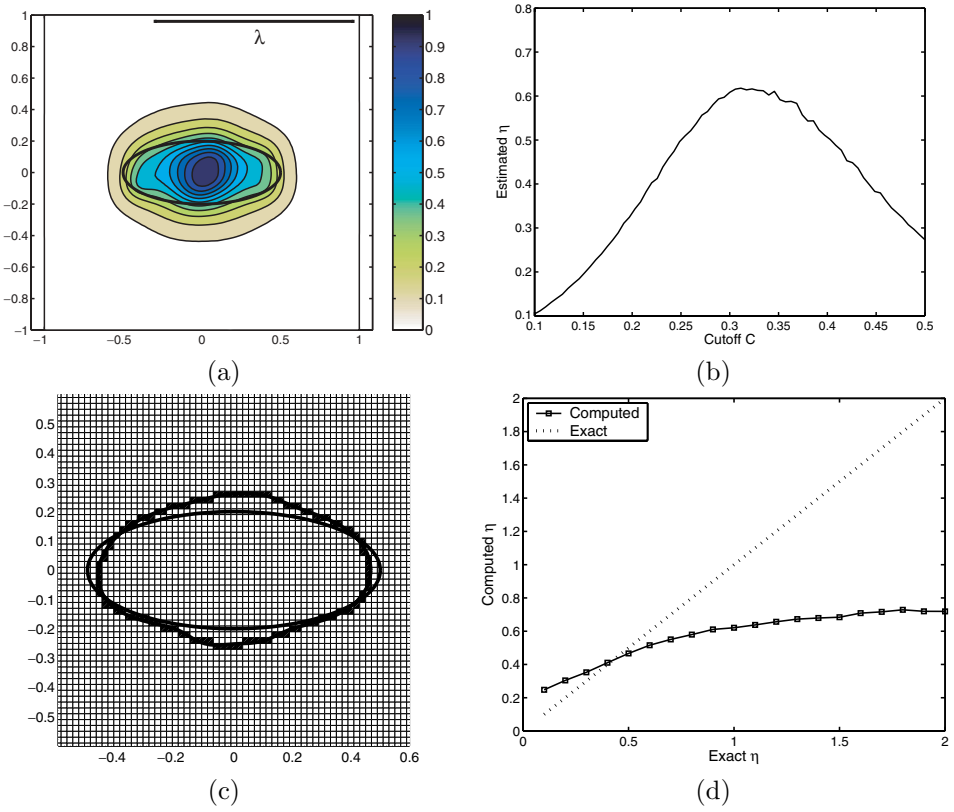

FIG. 6.6. *Reconstruction of the partially coated ellipse for* $\eta = 1$. (a) *The indicator function* $1/\|\vec{g}\|$ *resulting from the standard linear sampling method.* (b) *The computed value of* η *for a range of cutoffs* C. *The best reconstruction (maximum value of* η*) is* $\eta = 0.61793$ *when* $C = 0.3114$. (c) *The reconstruction of the ellipse using* $C = 0.3114$. (d) *The reconstruction of a range of* η*; this should be compared to Figure* 6.2(a).

increases. In this case the linear sampling method is able to provide a sufficiently accurate approximation of the ellipse so that the reconstruction of η in Figures 6.2 and 6.5 is of comparable accuracy.

Next we consider the partially coated ellipse (see Figure 6.1). The inversion algorithm is unchanged (both the boundary of the scatterer and η are reconstructed). The results are shown in Figure 6.6(a)–(c) when $\eta = 1$, and the results for a range of η are shown in Figure 6.6(d). The linear sampling method can still reconstruct the ellipse with reasonable fidelity despite the partial coating, and so the results in Figure 6.6(d) and Figure 6.2(a) are comparable. Recall that, for a partially coated obstacle, (4.17) provides only a lower bound for η.

6.3. Rectangular scatterer. Finally we show the reconstruction of the surface conductivity of the fully coated rectangular scatterer. Results for a range of η are shown in Figure 6.7. Comparing this to the reconstruction computed using the exact boundary (shown in Figure 6.2(b)), the results are much worse.

The deterioration of the results for the full inversion scheme can be explained by considering one choice of η in detail. In Figure 6.8 we show the full reconstruction procedure for $\eta = 1$. As in the case of the ellipse, we use the linear sampling method

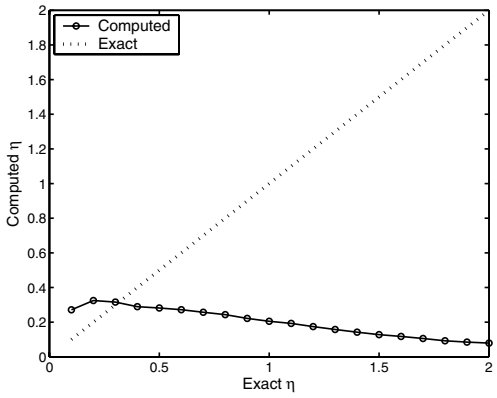

FIG. 6.7. *Results of reconstructing a range of conductivities for the fully coated rectangle. We plot the computed conductivity against its exact value. The results should be compared to Figure* 6.2(b)*, and are seen to be substantially worse than that case.*

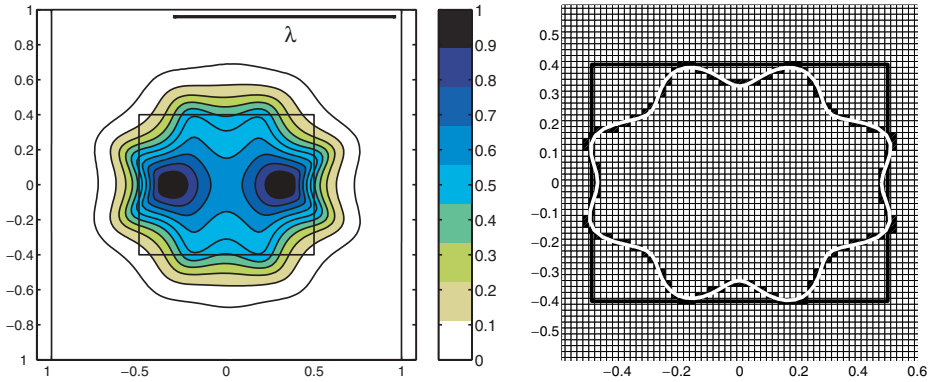

FIG. 6.8. *Details of the reconstruction of η when the exact value is $\eta = 0.5$.* (a) *The indicator function computed by the linear sampling method. Clearly, whatever the choice of C, the reconstruction of the scatterer will not provide an accurate normal.* (b) *The best reconstruction corresponding to $C = 0.52$, which yields the computed value of $\eta = 0.28$.*

to provide an indicator function for the boundary of the rectangle, but, compared to the ellipse, the reconstruction of the boundary shown in Figure 6.8(b) (at the best cutoff C) is now quite poor. From this reconstruction we need to compute the normal derivative of w_{z_0}. It is clear that this will be poorly approximated, and thus (4.17) will provide a poor approximation to η.

7. Conclusion. We have provided a method for estimating the surface conductivity of a scatterer from far field measurements. Numerical experiments show that this method can be combined with the linear sampling method to simultaneously identify the shape of the scatterer and the conductivity, provided that the shape of the scatterer can be computed with sufficient accuracy. Limitations include the fact that the method becomes inaccurate for large values of the surface conductivity, and the quality of the reconstruction of the conductivity can also be adversely influenced by the quality of the reconstruction of the scatterer. This may in part be due to the need to use the normal derivative of the Herglotz wave function in (4.17). We now

plan to investigate the use of the electric far field pattern, which should allow us to avoid the normal derivative. However considerable mathematical difficulties need to be overcome, and in particular the existence of a solution of the interior transmission problem is not known in this case.

THE EXISTENCE AND STABILITY OF SPIKE PATTERNS IN A CHEMOTAXIS MODEL*

B. D. SLEEMAN†, MICHAEL J. WARD‡, AND J. C. WEI§

Abstract. In the limit of small chemoattractant diffusivity ϵ, the existence, stability, and dynamics of spiky patterns in a chemotaxis model are studied in a bounded multidimensional domain. In this model, the transition probability density function $\Phi(w)$ is assumed to have a power law form $\Phi(w) = w^p$, and the production of chemoattractant w is assumed to saturate according to a Michaelis–Menten kinetic function. In the limit $\epsilon \to 0$, it is proved that there is a steady-state single boundary spike solution located at the maximum of the mean curvature of the boundary. Moreover, a steady-state interior spike solution is proved to concentrate at a maximum of the distance function. The single interior spike solution is shown to be metastable for certain ranges of p and the dimension N. The stability of a single boundary spike solution is also analyzed in detail. Finally, a formal asymptotic analysis is used to characterize the metastable interior spike dynamics in both a one-dimensional and a multidimensional domain.

Key words. chemotaxis, spike patterns, stability, nonlocal eigenvalue problems, metastability

1. Introduction.

In this paper, we investigate qualitative properties of a class of solutions to a special case of the following generalized chemotaxis system. Let $\Omega \subset \mathbb{R}^N$ be a bounded domain with boundary $\partial\Omega$. We seek solutions, $P \in \mathbb{R}$ and $W \in \mathbb{R}^{m+1}$, of the system

$$P_t = D\nabla \cdot \left(P\nabla \left(\log\left(\frac{P}{\Phi(W)} \right) \right) \right), \quad W_t = d\Delta W + F(P, W), \quad (x,t) \in \Omega \times (0,T), \tag{1.1}$$

subject to the "no-flux" boundary condition

$$P\nabla \left(\frac{\log P}{\Phi(W)} \right) \cdot \nu(x) = 0, \qquad \nabla W \cdot \nu(x) = 0. \tag{1.2}$$

Here $\nu(x)$ denotes the inward pointing normal to $\partial\Omega$. To close the system we prescribe the initial conditions

$$P(x,0) = P_0(x) > 0, \qquad W(x,0) = W_0(x) \geq 0, \qquad \text{for } x \in \overline{\Omega}.$$

In this system, D is a constant diffusion coefficient, d is a positive semidefinite diagonal matrix, P is a population density, $\log \Phi(W)$ is the chemotactical sensitivity function,

and W is a vector of nutrients or chemicals whose dynamics influences the movement of P. The function $\Phi(W)$ is a prescribed "transition probability function." This general system includes the so-called Keller–Segel model of biology [17]. To biologically motivate our study we begin by outlining two themes, one basic to developmental biology and the other from angiogenesis. Our contribution to the mathematical analysis of chemotactic systems is discussed at the end of the introduction.

A basic quality of all living systems is that they sense the environment in which they live and respond to it. The response often involves movement toward or away from an external stimulus. The mechanism for the response is called taxis. Any taxis involves two components: an external signal and the response of the organism to the signal. The response also involves two steps: the detection of the signal and the transduction of the external signal into an internal signal that triggers the response.

In many mathematical models analyzing taxis the signal is transported by diffusion, convection, or some other mechanism. There are, however, instances in which the organism seems to modify its environment in a strictly local manner and there is little or no transport of the modifying substance. A typical example of this is myxobacteria, which produce slime over which their cohorts can easily move. Myxobacteria are soil bacteria which glide on suitable surfaces or at air-water interfaces. Under starvation conditions they tend to move close together, forming complex patterns. Finally they aggregate to build fruiting bodies. Inside the fruiting bodies they survive as dormant myxospores. An account of this intriguing sequence of events can be found in [1].

A novel approach to the modeling of aggregation in myxobacteria is due to Othmer and Stevens [29]. Their inspiration and motivation comes from the work of Davis [6] concerning reinforced random walks. The models developed by Othmer and Stevens are of the form (1.1), (1.2) with $d = 0$ and have been studied in depth by Levine and Sleeman [19], who were able to provide some understanding of the numerical findings in [29], particularly with regard to aggregation, blow-up, and collapse of solutions.

More recently the idea of mathematical modeling based on the idea of reinforced random walks has been developed to gain some understanding of tumor angiogenesis. Angiogenesis is a morphogenetic process whereby new blood vessels are induced to grow out of a pre-existing vasculature. It is fundamental to the formation of any new blood vessels during embryonic development and contributes to the maintenance of tissue functionality in the adult (e.g., placental growth). Angiogenesis is also an important feature of various pathological processes such as wound healing and cancer progression. We are particularly interested in tumor angiogenesis.

Capillaries, which are the main microvessels involved in tumor angiogenesis, are composed of three components: (a) the basement membrane, which is a complex extra cellular matrix (ECM) encircling and supporting the cellular components; (b) the endothelial cells (EC), which form a monolayer of flattened and extended cells lining the lumen of the vessel and resting on the basement membrane; and (c) pericyte cells, which form a periendothelial cellular network embedded within the basement membrane.

The first event of tumor-induced angiogenesis is triggered by the secretion of a number of chemicals, collectively called tumor angiogenesis factors (TAFs) (cf. [4], [8], [9]) from a colony of cancerous cells of a solid tumor. These factors diffuse through the tissue, creating a chemotactic gradient which eventually reaches neighboring capillaries and other blood vessels. In response to TAFs the EC in nearby capillaries appear to thicken (i.e., aggregate) and produce a proteolytic enzyme, which in turn

degrades the basement membrane.

In response to the TAFs the normally smooth EC surface begins to develop pseudopodia which penetrate the weakened basement membrane. Capillary sprouts are formed by the accumulation of EC from the parent vessel. The sprouts grow in length, proliferate, form loops leading to microcirculation of blood (i.e., anastomoses); and also branch successively. The resulting capillary network continues to progress through the tissue ECM, forming a microvasculature, and eventually invades the tumor colony, leading to rapid growth and metastasis. The means of progress through the tissue ECM is via chemotaxis and haptotaxis.

Chemotaxis is the response of EC to chemical gradients set up by the TAFs. A major component of the tissue ECM is fibronectin. It has been verified experimentally that fibronectin stimulates directional migration of EC by establishing an adhesive gradient, i.e., via haptotaxis.

Mathematical modeling of the complex processes involved in tumor angiogenesis has been vigorously pursued in recent years. For recent overviews of some of the modeling ideas, see [36] and [33].

Driven by the need to understand the underlying biochemistry and also to attempt to bridge the gap between micro- and macrocellular events, Sleeman, together with Levine, Pamuk, Nilsen-Hamilton [20], [21], [22], Holmes [14], Plank [31], and Wallis [35], has modeled angiogenesis on the basis of reinforced random walks and Michaelis–Menten kinetics. In these modeling ideas, systems of equations of the form (1.1) play a crucial role.

Systems of the form (1.1) enjoy very rich dynamics. Consider, for example, the following two-component system in one space dimension

$$P_t = D\left(P_{xx} - a\left(P\frac{W_x}{W}\right)_x\right), \quad W_t = \lambda PW - \mu W \qquad \text{for } 0 < x < \ell,\ t > 0,$$

$$\frac{P_x}{P} - a\frac{W_x}{W} = 0 \qquad \text{for } x = 0, \ell,\ t > 0, \tag{1.3}$$

$$P(x,0) = P_0(x) > 0, \qquad W(x,0) = W_0(x) > 0 \qquad \text{for } 0 \le x \le \ell.$$

In [19] it is shown, among other things, that when $a = 1$, there are solution pairs (P, W) for which $P > 0$ but for which P blows up in finite time and that the power spectrum converges to that of the delta function in finite time. Indeed, it is possible to construct an explicit family of such solutions. When $a = -1$, there exist solution pairs (P, W) for which $P > 0$ and P collapses to a constant in infinite time but exponentially fast.

In this context we mention the related work of Rascle and Ziti [34]. In our notation they considered the following system in $\mathbb{R}^N$:

$$P_t = D_1\Delta P - \nabla \cdot [PW^{-\alpha}\nabla W], \quad W_t = D_2\Delta W - kW^m P. \tag{1.4}$$

Here all the constants are positive unless otherwise specified. They constructed similarity solutions of the form $(P, W) = ((T-t)^a P(\xi), (T-t)^b w(\xi))$, where $\xi = (T-t)^{-1}|x|^2$ for $x \in \mathbb{R}^N$ in one, two, or three space dimensions, when $0 < m < \alpha = 1$ and $D_2 = 0$. (Here $a, b \ge 0$.) When $D_1 = 0$ as well, they construct such solutions which blow up in infinite time in one and two dimensions. In the case $D_1 > 0$ they are able to construct only global self-similar solutions.

An important question which again is motivated by the need to understand how new capillaries sprout via angiogenesis from a preexisting vasculature is: Can we expect solutions of system (1.1) (with $d = 0$) to possess spatially nonconstant, piecewise constant aggregating solutions? Here we define aggregation as follows: $P(x,t)$ as a solution to (1.1), aggregates if it converges to a nonconstant steady state in finite or infinite time.

From numerical experiments, Othmer and Stevens [29] show that $P(x,t)$ can evolve to an aggregating solution through the formation of a "shock." In their experiments they consider system (1.1) with

$$\Phi(W) = \left(\frac{\beta + W}{\gamma + W}\right)^a, \qquad F(P,W) = \frac{PW}{1+\nu W} - \mu W + \gamma_r \frac{P}{1+P}. \tag{1.5}$$

In [19] it is argued that the seeds of such shock formation are already present in the case of the simpler system (1.3).

During the initiation of angiogenesis, as outlined above, the EC in capillaries near the tumor produce a proteolytic enzyme in response to the TAFs. While a detailed analysis of the process involved in angiogenesis initiation has been given in [20], a simple model involving only the EC and the proteolytic enzyme can be formulated. Such a model is of the form (1.1), in which P represents EC density and W is enzyme concentration. In this model d is small since in the capillary diffusion takes place on a much longer time scale than the kinetic reactions. This, of course, is not the case for the developing angiogenesis in the ECM.

It has been demonstrated recently by Holash et al. (cf. [13]) that once a tumor has become vascularized, the resulting capillary network may undergo periods of dramatic collapse and remodeling. Paradoxically, the coopted vasculature does not undergo angiogenesis to support the growing tumor, but instead regresses via a process that involves disruption of EC/smooth muscle cell interactions and EC apoptosis (i.e., programmed cell death). This vessel regression in turn results in necrosis within the central part of the tumor. However vigorous angiogenesis is initiated at the tumor boundary, rescuing the surviving tumor and supporting further growth. This behavior could be modeled by systems of the form (1.1) and suggests the existence of point-condensation solutions or spike-type patterns.

It is the purpose of this paper to investigate the existence, stability, and dynamics of the spike patterns in the following variant of (1.1) and (1.5). That is, we consider the system

$$\begin{cases} P_t = D_1 \nabla \cdot \left(P \nabla \left(\log \frac{P}{\Phi(W)} \right) \right), \quad W_t = D_2 \Delta W - \mu W + \frac{PW}{1+\gamma W} & \text{in } \Omega \times (0, +\infty), \\ \frac{\partial P}{\partial \nu} = \frac{\partial W}{\partial \nu} = 0 \quad \text{on } \partial\Omega \times (0, +\infty), \quad P(x,0) = P_0(x) \geq 0, \quad W(x,0) = W_0(x) \geq 0, \end{cases} \tag{1.6}$$

where $D_1 > 0$ and $D_2 > 0$ are two diffusion coefficients, $P(x,t)$ is the particle density of a particular species, $W(x,t)$ is the concentration of the "active agent," $\Omega \subset \mathbb{R}^N (N \leq 3)$ is a smooth and bounded domain, μ and γ are positive constants, and $\nu = \nu(x)$ is the unit normal derivative at $x \in \partial\Omega$. The term $\frac{W}{1+\gamma W}$ is a typical Michaelis–Menten saturating function. Throughout the paper, we take $\Phi(W) = W^p$, where $p > 1$, which corresponds to a logarithmic chemotactical sensitivity function.

We will show that the inclusion of a *small diffusion coefficient* D_2 can produce *stable* spiky patterns. By nondimensionalizing (1.6), we may assume, without loss of

generality, that

$$\mu = 1, \qquad D_1 = 1, \qquad D_2 = \epsilon^2 \ll 1. \tag{1.7}$$

In this new setting, (1.6) becomes

$$\begin{cases} P_t = \nabla \cdot \Big(P \nabla \Big(\log \frac{P}{W^p} \Big) \Big), \quad W_t = \epsilon^2 \Delta W - W + \frac{PW}{1+\gamma W} \quad \text{in } \ \Omega \times (0, +\infty), \\ \frac{\partial P}{\partial \nu} = \frac{\partial W}{\partial \nu} = 0 \quad \text{on } \ \partial\Omega \times (0, +\infty), \quad P(x,0) = P_0(x) \geq 0, \quad W(x,0) = W_0(x) \geq 0. \end{cases} \tag{1.8}$$

For $\gamma \gg 1$, (1.8) is the Keller–Segel model with a *logarithmic* chemotactical sensitivity function. A survey of the existence and regularity properties of solutions of the classic Keller–Segel model with a *linear* chemotactical sensitivity function, and for certain extensions of the basic model, is given in [15]. Results for global existence of solutions for the limiting model (1.8) where $\gamma \gg 1$ are surveyed in section 6.1.1 of [15]. Our results for the stability of spike-type patterns of (1.8) for $\gamma > 0$ are, to our knowledge, new. In particular, for certain ranges of p, we prove that an interior spike solution for (1.8) is metastable. The existence of metastable phenomena is known in certain reaction-diffusion systems, including the shadow Gierer–Meinhardt model (cf. [16] and [5]), but to our knowledge has never been shown previously in a chemotaxis system. After submission of this article, the occurrence of metastability has been shown asymptotically and numerically in [32] for the volume-filling chemotaxis model of [12] and [30].

Integrating the equation for P over Ω and using the Divergence theorem, we obtain

$$\int_\Omega P(x,t) = \int_\Omega P(x,0) = m. \tag{1.9}$$

This conservation of mass condition plays a central role in stabilizing nontrivial spatial patterns. To simplify the computations, we will assume that $m = 1$. The steady-state problem for (1.8) becomes

$$\begin{cases} \nabla \cdot \Big(P \nabla \Big(\log \frac{P}{W^p} \Big) \Big) = 0 & \text{in } \ \Omega, \\ \epsilon^2 \Delta W - W + \frac{PW}{1+\gamma W} = 0 & \text{in } \ \Omega, \\ \frac{\partial P}{\partial \nu} = \frac{\partial W}{\partial \nu} = 0 \text{ on } \ \partial\Omega, & \int_\Omega P(x) = 1. \end{cases} \tag{1.10}$$

Note that both P and W must be nonnegative. From the equation for P in (1.10) and the condition that $m = 1$, we get

$$P(x) = \frac{1}{\int_\Omega W^p} W^p(x). \tag{1.11}$$

Defining the new function $\hat{W}$ by

$$W(x) = \frac{1}{\gamma \int_\Omega \hat{W}^p} \hat{W} \tag{1.12}$$

and substituting (1.11) and (1.12) into (1.10), we obtain an equation for $\hat{W}$:

(1.13)
$$\epsilon^2\Delta\hat{W} - \hat{W} + \frac{\hat{W}^{p+1}}{\int_\Omega \hat{W}^p + \hat{W}} = 0 \quad \text{in } \Omega, \quad \hat{W} > 0 \quad \text{in } \Omega, \quad \frac{\partial \hat{W}}{\partial \nu} = 0 \quad \text{on } \partial\Omega.$$

Equation (1.13) without the nonlocal term $\int_\Omega \hat{W}^p$ has a variational structure and has been studied by numerous authors. For results on the existence of boundary spike solutions, see [2], [27], [28], [40], [43], and the references therein. Results for the existence of interior spike solutions are given in [11], [38], [39], and the references therein. A survey of some of these previous results is given in [26].

Throughout the paper, $C > 0$ is a generic constant, which is independent of ϵ, that may change from line to line. The notation $O(A), o(A)$ means that $|O(A)| \le C|A|$, $\lim_{\epsilon\to 0} \frac{o(A)}{|A|} = 0$.

The organization of the paper is as follows. In section 2, we state our main results. In section 3, we construct both single boundary and single interior spikes. In sections 4–6, we analyze the spectrum of the linearized problem. In the spectrum there are eigenvalues that are $O(1)$ as $\epsilon \to 0$, called the large eigenvalues, and eigenvalues that tend to zero as $\epsilon \to 0$, called the small eigenvalues. In section 4, we study the linearized eigenvalue problem and reduce the study of the large eigenvalues to a nonlocal eigenvalue problem. In section 5, we analyze this nonlocal eigenvalue problem. In section 6, we analyze the small eigenvalues. In section 7, we derive the dynamical law for the motion of an interior spike and present some numerical results. Finally, a brief discussion in given in section 8.

2. Statements of main results. We first state our main results on the existence of steady-state solutions.

THEOREM 2.1. *Assume that*

$$1 < p < +\infty \quad \text{if } N = 1, 2; \qquad 1 < p < 5, \quad \text{if } N = 3. \tag{2.1}$$

Then, for $\epsilon \ll 1$, there exists a steady-state solution for (1.10) *of the following form:*

$$(P_\epsilon, W_\epsilon) = \left(\frac{1}{\int_\Omega \hat{W}_\epsilon^p}\hat{W}_\epsilon^p, \frac{\hat{W}_\epsilon}{\gamma\int_\Omega \hat{W}_\epsilon^p}\right), \quad \text{where} \quad \hat{W}_\epsilon = w\left(\frac{x - Q_\epsilon}{\epsilon}\right) + O(\epsilon). \tag{2.2}$$

Here $w(y)$ is the unique solution of

$$\Delta w - w + w^p = 0, \quad w > 0 \quad \text{in } \mathbb{R}^N, \quad w(0) = \max_{y\in\mathbb{R}^N} w(y), \quad w(y) \to 0 \quad \text{as } |y| \to +\infty. \tag{2.3}$$

The point Q_ϵ is classified either by

(a) *(single boundary spike) $Q_\epsilon \in \partial\Omega$, $H(Q_\epsilon) \to \max_{Q\in\partial\Omega} H(Q)$, where $H(Q)$ is the mean curvature function at $Q \in \partial\Omega$, or*

(b) *(single interior spike) $Q_\epsilon \in \Omega$, $d(Q_\epsilon, \partial\Omega) \to \max_{Q\in\Omega} d(Q, \partial\Omega)$, where $d(Q, \partial\Omega)$ is the distance function at $Q \in \Omega$.*

Next, we study the linearized stability of the solutions constructed in Theorem 2.1. To this end, we linearize (1.8) around (P_ϵ, W_ϵ), as given in Theorem 2.1, to obtain

the following linearized eigenvalue problem:

$$\nabla \cdot \left(\psi_\epsilon \nabla \log \left(\frac{P_\epsilon}{W_\epsilon^p} \right) \right) + \nabla \cdot \left(P_\epsilon \nabla \left(\frac{\psi_\epsilon}{P_\epsilon} - p \frac{\phi_\epsilon}{W_\epsilon} \right) \right) = \lambda_\epsilon \psi_\epsilon \quad \text{in } \Omega, \tag{2.4}$$

$$\epsilon^2 \Delta \phi_\epsilon - \phi_\epsilon + \frac{P_\epsilon}{(1+\gamma W_\epsilon)^2} \phi_\epsilon + \frac{W_\epsilon}{1+\gamma W_\epsilon} \psi_\epsilon = \lambda_\epsilon \phi_\epsilon \quad \text{in } \Omega, \tag{2.5}$$

$$\frac{\partial \phi_\epsilon}{\partial \nu} = \frac{\partial \psi_\epsilon}{\partial \nu} = 0 \quad \text{on } \partial\Omega, \tag{2.6}$$

where $\lambda_\epsilon \in \mathcal{C}$—the set of complex numbers.

Note that (2.4)–(2.6) is *not self-adjoint*, and so complex eigenvalues are expected. We say that (P_ϵ, W_ϵ) is *linearly stable* if for all eigenvalues λ_ϵ of (2.4)–(2.6) we have $Re(\lambda_\epsilon) < 0$. We say that (P_ϵ, W_ϵ) is *linearly unstable* if there exists an eigenvalue λ_ϵ of (2.4)–(2.6) such that $Re(\lambda_\epsilon) > 0$. We say that (P_ϵ, W_ϵ) is *metastable* if for all eigenvalues λ_ϵ of (2.4)–(2.6) we have either $Re(\lambda_\epsilon) < 0$ or $|\lambda_\epsilon| = O(e^{-d/\epsilon})$ for some $d > 0$ independent of $\epsilon > 0$. With these definitions, we now give our main results classifying the stability of (P_ϵ, W_ϵ).

THEOREM 2.2. *Assume that*

$$1 < p < +\infty \quad \text{if } N = 1; \qquad 2 \le p \le 5 \quad \text{if } N = 2; \qquad 2 \le p \le 3 \quad \text{if } N = 3. \tag{2.7}$$

Let (P_ϵ, W_ϵ) be the solution given in Theorem 2.1.

(a) (metastability) *The single interior spike is metastable.*

(b) (stability) *If $N = 1$, then the single boundary spike is linearly stable.*

(c) (stability) *If $\Omega = B_R(0) = \{x \mid |x| < R\}$ and $(P(x,t), W(x,t)) = (P(|x|,t), W(|x|,t))$, then the single interior spike is linearly stable.*

(d) (stability) *If $N = 2, 3$ and Q_0 is a nondegenerate global maximum point of $H(P)$, where $Q_\epsilon \to Q_0$, then the single boundary spike is linearly stable.*

Remark 2.3. The condition on the exponent p given in (2.7) is needed for the analysis in section 5 of a nonlocal eigenvalue problem. Certainly it is not optimal. We conjecture that the same conclusion holds if p satisfies (2.1) only.

Remark 2.4. As $\epsilon \to 0$, we have $\int_\Omega \hat{W}_\epsilon^p \sim \epsilon^N$. Therefore, we see from (2.2) that $P_\epsilon(Q_\epsilon) \sim \epsilon^{-N}$, $W_\epsilon(Q_\epsilon) \sim \epsilon^{-N}$, and $P_\epsilon(x), W_\epsilon(x) \to 0$ for all $x \in \Omega$ with $|x - Q_\epsilon| \ge \delta > 0$.

Remark 2.5. Theorems 2.1 and 2.2 remain true for the following Keller–Segel model with logarithmic growth ([17], [23], [24]):

$$\begin{cases} P_t = \nabla \cdot \left(P \nabla \left(\log \frac{P}{W^p} \right) \right), \quad W_t = \epsilon^2 \Delta W - W + P \quad \text{in } \Omega \times (0, +\infty), \\ \frac{\partial P}{\partial \nu} = \frac{\partial W}{\partial \nu} = 0 \quad \text{on } \partial\Omega \times (0, +\infty), \quad P(x,0) = P_0(x) \ge 0, \quad W(x,0) = W_0(x) \ge 0. \end{cases} \tag{2.8}$$

Remark 2.6. In Theorems 2.1 and 2.2, we have assumed that $D_1 = 1$, where D_1 is the diffusion coefficient of P. Theorem 2.1 holds true for any $D_1 > 0$. It is not difficult to see that Theorem 2.2 also holds, provided that

$$\frac{\epsilon^2}{D_1} \ll 1. \tag{2.9}$$

Biologically, this means that if the active agent W diffuses more slowly than the species P, the species will move toward the boundary and form nontrivial stable spiky patterns. It is unclear what happens if $\frac{\epsilon^2}{D_1} \sim 1$.

Remark 2.7. There may be solutions with multiple spikes. We will not discuss this case here, as most likely multiple spike solutions are unstable.

The existence of spiky patterns for the steady states of Keller–Segel model (2.8) has been established in [23], [27], [28]. Theorem 2.1 establishes the existence of spiky patterns for the more general case (1.8). As far as the authors know, Theorem 2.2 is the first rigorous result on the stability of spiky patterns for a chemotaxis system.

3. Construction of the steady state: Proof of Theorem 2.1. In this section we construct steady-state solutions for (1.8) and prove Theorem 2.1. By the transformation leading to (1.13), we need to find a $\hat{W}$ satisfying (1.13). We do this in two steps.

In the first step, we fix δ small and solve the following problem:

$$\epsilon^2 \Delta \hat{W} - \hat{W} + \frac{\hat{W}^{p+1}}{\delta + \hat{W}} = 0, \quad \hat{W} > 0 \quad \text{in } \Omega, \qquad \frac{\partial \hat{W}}{\partial \nu} = 0 \quad \text{on } \partial\Omega. \tag{3.1}$$

This yields a solution $\hat{W}_{\epsilon,\delta}$. In the second step, we solve the algebraic equation

$$\delta = \int_\Omega \hat{W}^p_{\epsilon,\delta}. \tag{3.2}$$

The first step is more or less standard, but we have to treat the dependence of $\hat{W}$ on δ. In the second step we have to make sure that the function on the right-hand side of (3.2) is continuous in δ. We begin with the following simple but important observation.

LEMMA 3.1. *There exists a unique solution to*

$$\begin{aligned} &\Delta w - w + \frac{w^{p+1}}{\delta + w} = 0, \quad w > 0 \quad \text{in } \mathbb{R}^N, \quad w(0) = \max_{y \in \mathbb{R}^N} w(y), \\ &w(y) \to 0 \quad \text{as } |y| \to +\infty. \end{aligned} \tag{3.3}$$

We call such a solution $w_\delta(y)$. As $\delta \to 0$, we have

$$|w_\delta(y) - w(y)| \le C\delta e^{-\min(1,p-1)|y|}, \tag{3.4}$$

where C is independent of $\delta > 0$ and w is the unique solution of (2.3).

Proof. By the well-known Gidas–Ni–Nirenberg theorem, all solutions to (3.3) are radially symmetric. Let $f_\delta(u) = \frac{u^{p+1}}{\delta+u}$. Then we have $\left(\frac{f_\delta(u)}{u}\right)' \ge 0$. By [18], there exists a unique solution, called $w_\delta(|y|)$, to (3.3). Since p is subcritical and $f_\delta(u) \le u^p$, we see that w_δ is uniformly bounded in δ. By compactness and the uniqueness of w_δ, it follows that as $\delta \to 0$, $w_\delta \to w(y)$, where $w(y)$ is the unique solution of (2.3). This implies that

$$w_\delta(y) < Ce^{-|y|}, \tag{3.5}$$

where C is independent of $\delta > 0$. Next we consider $w_\delta = w + \delta\hat{w}_\delta$. It is easy to see that $\hat{w}_\delta$ satisfies

$$\Delta_y \hat{w}_\delta - \hat{w}_\delta + pw^{p-1}\hat{w}_\delta + \delta^{-1}\left(\frac{(w+\delta\hat{w}_\delta)^{p+1}}{\delta + w_\delta} - w^p - p\delta w^{p-1}\hat{w}_\delta\right) = 0, \tag{3.6}$$

where, by (3.5),

$$\left|\delta^{-1}\left(\frac{(w+\delta\hat{w}_\delta)^{p+1}}{\delta+w_\delta}-w^p-p\delta w^{p-1}\hat{w}_\delta\right)\right|\le Cw_\delta^{p-1}\le Ce^{-(p-1)|y|}. \tag{3.7}$$

Since the operator $L_0:=\Delta-1+pw^{p-1}$ is invertible from $H_r^2(\mathbb{R}^N)=H^2(\mathbb{R}^N)\cap\{u(y)=u(|y|)\}$ to $L_r^2(\mathbb{R}^N)=L^2(\mathbb{R}^N)\cap\{u(y)=u(|y|)\}$ (see Lemma 4 of [45]), we see from (3.6) and (3.7) that

$$\|\hat{w}_\delta\|_{H^2(\mathbb{R}^N)}\le C \quad\text{and}\quad |\hat{w}_\delta|\le Ce^{-\min(1,p-1)|y|}. \qquad \square$$

To analyze single boundary spikes we proceed as follows. For each $\delta>0$ small, we define

$$J_{\epsilon,\delta}[u]=\frac{\epsilon^2}{2}\int_\Omega|\nabla u|^2+\frac{1}{2}\int_\Omega u^2-\int_\Omega F_\delta(u)\qquad\text{for } u\in H^1(\Omega), \tag{3.8}$$

where $F_\delta(u)=\int_0^u\frac{s^{p+1}}{s+\delta}ds$. By taking a function $e(x)\equiv k$ for some constant k in Ω and by choosing k large enough, we have $J_{\epsilon,\delta}(e)<0$ for all $\epsilon\in(0,1)$ and $\delta\in(0,1)$. Then, for each $\epsilon\in(0,1)$ and $\delta\in(0,1)$, we can define the so-called mountain-pass value

$$c_{\epsilon,\delta}=\inf_{h\in\Gamma}\max_{0\le t\le1}J_{\epsilon,\delta}[h(t)], \tag{3.9}$$

where $\Gamma=\{h:[0,1]\to H^1(\Omega)|h(t)\text{ is continuous, }h(0)=0,\,h(1)=u_0\}$.

Since p satisfies (2.1), p is subcritical. Furthermore, $\left(\frac{f_\delta(u)}{u}\right)'\ge0$. Thus f_δ satisfies all the assumptions in [27]. Similar to the analysis in section 2 of [27], $c_{\epsilon,\delta}$ is attained by some function $\hat{W}_{\epsilon,\delta}$, which satisfies (3.1), and $c_{\epsilon,\delta}$ is the least among all nonzero critical values of $J_{\epsilon,\delta}$. Furthermore, the analysis in section 3 of [27] shows that for ϵ sufficiently small, and uniformly in δ, $\hat{W}_{\epsilon,\delta}$ has a unique maximum point $Q_{\epsilon,\delta}$, with $Q_{\epsilon,\delta}\in\partial\Omega$ and $H(Q_{\epsilon,\delta})\to\max_{P\in\partial\Omega}H(P)$ as $\epsilon\to0$. This completes the first step in the proof.

Next we define the following set:

$$\mathcal{S}_{\epsilon,\delta}=\{W\mid W\text{ satisfies (3.1) and }\ J_{\epsilon,\delta}[W]=c_{\epsilon,\delta}\}. \tag{3.10}$$

In other words, $\mathcal{S}_{\epsilon,\delta}$ contains the set of all least energy solutions of (3.1). By our first step above, $\mathcal{S}_{\epsilon,\delta}$ is not empty. Moreover, $\mathcal{S}$ is a compact set (uniformly in δ and ϵ small) since

$$\sup_{W\in\mathcal{S}_{\epsilon,\delta}}\|W\|_\epsilon\le C, \tag{3.11}$$

where C is independent of ϵ and δ and

$$\|W\|_\epsilon^2:=\epsilon^{-N}\left(\epsilon^2\int_\Omega|\nabla W|^2+\int_\Omega W^2\right). \tag{3.12}$$

(In fact, by Lemma 3.1 and by using a test function, we have $c_{\epsilon,\delta}\le C\epsilon^N$, where C is independent of ϵ and δ. Integrating the equation (3.1) gives (3.11).)

We consider the algebraic equation

$$\beta(\delta)=\delta-\rho(\delta)=0,\qquad\text{where}\quad\rho(\delta):=\inf_{W\in\mathcal{S}_{\epsilon,\delta}}\int_\Omega W^p. \tag{3.13}$$

Note that for any $W \in \mathcal{S}_{\epsilon,\delta}$, the same asymptotic analysis holds for mountain-pass solutions (since they have the energy level). Thus we have

$$\int_\Omega W^p = \epsilon^N \left(\frac{1}{2} \int_{\mathbb{R}^N} w_\delta^p + o(1) \right), \tag{3.14}$$

where $o(1) \to 0$ as $\epsilon \to 0$ uniformly in δ. We also remark that, by the compactness of the set $\mathcal{S}_{\epsilon,\delta}$, $\rho(\delta)$ is attained and is a continuous function in δ.

Note that $\beta(0) < 0$ and $\beta(\epsilon^N \int_{\mathbb{R}^N} w^p) > 0$. Therefore, by the mean-value theorem, there exists a $\delta_\epsilon \in (0, \epsilon^N \int_{\mathbb{R}^N} w^p)$ such that $\beta(\delta_\epsilon) = 0$. That is, there exists a $\hat{W}_{\epsilon,\delta_\epsilon} \in \mathcal{S}_{\epsilon,\delta_\epsilon}$ such that $\delta_\epsilon = \int_\Omega \hat{W}^p_{\epsilon,\delta_\epsilon}$.

Let $\hat{W}_\epsilon = \hat{W}_{\epsilon,\delta_\epsilon}$ and $Q_\epsilon = Q_{\epsilon,\delta_\epsilon}$. Then, $\hat{W}_\epsilon$ is a single boundary spike and satisfies the properties stated in Theorem 2.1. This completes our second step for single boundary spikes.

Finally, we use a similar method to discuss the case of single interior spikes. We follow the analysis in [11]. By [11], there exists solution $\hat{W}_{\epsilon,\delta}$ to (3.1), with a single interior spike for ϵ small (uniformly for δ small). Moreover, $\hat{W}_{\epsilon,\delta}$ has a unique local maximum point $Q_{\epsilon,\delta}$ such that $d(Q_{\epsilon,\delta}, \partial\Omega) \to \max_{Q\in\Omega} d(Q, \partial\Omega)$. Now we fix one such solution $\bar{W}_{\epsilon,\delta}$, and consider the following set:

$$\mathcal{S}'_{\epsilon,\delta} = \{u | u \text{ satisfies (3.1) and } \|u - \bar{W}_{\epsilon,\delta}\|_\epsilon \le \epsilon\}. \tag{3.15}$$

Similarly $\mathcal{S}'_{\epsilon,\delta}$ is a nonempty compact set, and the following problem has a solution δ_ϵ:

$$\beta'(\delta) = \delta - \rho'(\delta) = 0, \qquad \text{where} \qquad \rho'(\delta) := \inf_{\hat{W}\in\mathcal{S}'_{\epsilon,\delta}} \int_\Omega \hat{W}^p. \tag{3.16}$$

Let $\hat{W}_\epsilon = \hat{W}_{\epsilon,\delta_\epsilon}$ and $Q_\epsilon = Q_{\epsilon,\delta_\epsilon}$. Then, $\hat{W}_\epsilon$ is a single interior spike solution and satisfies the properties stated in Theorem 2.1. □

Remark 3.2. If $N = 1$, both the single boundary spike solution and the single interior spike solution are unique.

Remark 3.3. If $\Omega = B_R(0)$, (P_ϵ, W_ϵ) can be chosen to be radially symmetric if we restrict our analysis to the class of radially symmetric functions.

We list several properties of $\hat{W}_\epsilon$ for later use. Their proofs can be found in [27], [28], and [11].

LEMMA 3.4. *Let $\hat{W}_\epsilon$ be given in Theorem* 2.1. *Then, we have*

(1)

$$\delta_\epsilon = \int_\Omega \hat{W}^p_\epsilon = \begin{cases} \epsilon^N \left(\displaystyle\int_{\mathbb{R}^N} w^p + o(1) \right) & \text{for } Q_\epsilon \in \Omega, \\ \epsilon^N \left(\dfrac{1}{2} \displaystyle\int_{\mathbb{R}^N} w^p + o(1) \right) & \text{for } Q_\epsilon \in \partial\Omega. \end{cases}$$

(2) $\hat{W}_\epsilon(x) \le Ce^{-c|x-Q_\epsilon|/\epsilon}$ *for some constants* $C, c > 0$.

(3) $\epsilon \frac{|\nabla_x \hat{W}_\epsilon(x)|}{\hat{W}_\epsilon(x)} \ge \sqrt{1-\eta}$ *for* $|x - Q_\epsilon| > \epsilon R$, *where* $0 < \eta < 1$ *is a fixed constant,* R *is large, and* ϵ *is sufficiently small.*

(4)

$$\hat{W}_\epsilon = w_{\delta_\epsilon}\left(\frac{x - Q_\epsilon}{\epsilon} \right) + \begin{cases} O(e^{-d/\epsilon}) & \text{for } Q_\epsilon \in \Omega, \\ O(\epsilon) & \text{for } Q_\epsilon \in \partial\Omega. \end{cases}$$

Here w_{δ_ϵ} is the unique solution of (3.3)*, and $d > 0$ is some constant (independent of ϵ).*

4. Study of the linearized eigenvalue problem. In this section, we begin to study the stability of (P_ϵ, W_ϵ). We consider the interior spike case first. The boundary spike case will be treated later.

We introduce a perturbation around (P_ϵ, W_ϵ) of the following:

$$P(x,t) = P_\epsilon(x) + \eta e^{\lambda_\epsilon t}\psi_\epsilon, \qquad W(x,t) = W_\epsilon(x) + \eta e^{\lambda_\epsilon}\phi_\epsilon. \tag{4.1}$$

Substituting (4.1) into (1.8) and discarding higher order terms, we obtain the following linearized eigenvalue problem:

$$\nabla \cdot \left(P_\epsilon \nabla \left(\frac{\psi_\epsilon}{P_\epsilon} - p\frac{\phi_\epsilon}{W_\epsilon} \right) \right) = \lambda_\epsilon \psi_\epsilon \qquad \text{in } \ \Omega, \tag{4.2}$$

$$\epsilon^2 \Delta\phi_\epsilon - \phi_\epsilon + \frac{P_\epsilon}{(1+\gamma W_\epsilon)^2}\phi_\epsilon + \frac{W_\epsilon}{1+\gamma W_\epsilon}\psi_\epsilon = \lambda_\epsilon \phi_\epsilon \qquad \text{in } \ \Omega, \tag{4.3}$$

$$\frac{\partial \phi_\epsilon}{\partial \nu} = \frac{\partial \psi_\epsilon}{\partial \nu} = 0 \qquad \text{on } \ \partial\Omega, \tag{4.4}$$

where $\lambda_\epsilon \in \mathcal{C}$. Note that the conservation of mass (1.9) requires that $\int_\Omega \psi_\epsilon = 0$.

Recall from (2.2) that

$$P_\epsilon = \frac{1}{\int_\Omega W_\epsilon^p} W_\epsilon^p = \frac{1}{\int_\Omega \hat{W}_\epsilon^p}\hat{W}_\epsilon^p, \qquad W_\epsilon = \frac{1}{\gamma \int_\Omega \hat{W}_\epsilon^p}\hat{W}_\epsilon, \tag{4.5}$$

where $\hat{W}_\epsilon$ satisfies (1.13) and has all the properties listed in Lemma 3.4.

We begin by simplifying (4.2) and (4.3). We introduce $\tilde{\psi}_\epsilon$ by

$$\psi_\epsilon = p\frac{P_\epsilon}{W_\epsilon}\phi_\epsilon - \eta_\epsilon P_\epsilon + \tilde{\psi}_\epsilon, \tag{4.6}$$

where η_ϵ is a constant and $\tilde{\psi}_\epsilon$ satisfies

$$\int_\Omega \tilde{\psi}_\epsilon = 0. \tag{4.7}$$

Since $\int_\Omega \psi_\epsilon = 0$, from (4.6), we obtain that $\eta_\epsilon = (\int_\Omega P_\epsilon)^{-1} p \int_\Omega \frac{P_\epsilon}{W_\epsilon}\phi_\epsilon$. Therefore, using (4.5), we get

$$\psi_\epsilon = p\gamma \hat{W}_\epsilon^{p-1}\phi_\epsilon - p\gamma \frac{\int_\Omega \hat{W}_\epsilon^{p-1}\phi_\epsilon}{\int_\Omega \hat{W}_\epsilon^p}\hat{W}_\epsilon^p + \tilde{\psi}_\epsilon. \tag{4.8}$$

Substituting (4.5) and (4.8) into (4.2), we obtain that

$$\nabla \cdot \left(P_\epsilon \nabla \left(\frac{\tilde{\psi}_\epsilon}{P_\epsilon} \right) \right) = \lambda_\epsilon \left(p\gamma \hat{W}_\epsilon^{p-1}\phi_\epsilon - p\gamma \frac{\int_\Omega \hat{W}_\epsilon^{p-1}\phi_\epsilon}{\int_\Omega \hat{W}_\epsilon^p}\hat{W}_\epsilon^p + \tilde{\psi}_\epsilon \right). \tag{4.9}$$

We introduce local coordinates y and $\hat{\psi}_\epsilon$ by

$$x = Q_\epsilon + \epsilon y, \qquad y \in \Omega_\epsilon := \{y | \epsilon y + Q_\epsilon \in \Omega_\epsilon\}, \qquad \tilde{\psi}_\epsilon(x) = \epsilon^2 \lambda_\epsilon \gamma \hat{W}_\epsilon^{p/2} \hat{\psi}_\epsilon(y), \tag{4.10}$$

where Q_ϵ is the unique maximum point of $\hat{W}_\epsilon$. We still use $\hat{W}_\epsilon, \phi_\epsilon$, etc. to denote the functions $\hat{W}_\epsilon, \phi_\epsilon$, etc. under the new coordinate y.

A simple computation shows that (4.7) and (4.9) become

$$\int_{\Omega_\epsilon} \hat{W}_\epsilon^{\frac{p}{2}} \hat{\psi}_\epsilon(y) = 0, \tag{4.11}$$

$$\Delta_y \hat{\psi}_\epsilon - h(\hat{W}_\epsilon)\hat{\psi}_\epsilon - \epsilon^2 \lambda_\epsilon \hat{\psi}_\epsilon = p \hat{W}_\epsilon^{\frac{p}{2}-1} \phi_\epsilon - p \frac{\int_\Omega \hat{W}_\epsilon^{p-1} \phi_\epsilon}{\int_\Omega \hat{W}_\epsilon^p} \hat{W}_\epsilon^{\frac{p}{2}}, \qquad y \in \Omega_\epsilon, \tag{4.12}$$

where $h(\hat{W}_\epsilon) = \frac{\Delta_y \hat{W}_\epsilon^{p/2}}{\hat{W}_\epsilon^{p/2}}$. Substituting (4.5) and (4.8) into (4.3), we obtain that ϕ_ϵ satisfies

$$\Delta_y \phi_\epsilon - \phi_\epsilon + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\phi_\epsilon - p \frac{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} \phi_\epsilon}{\int_{\Omega_\epsilon} \hat{W}_\epsilon^p} \frac{\hat{W}_\epsilon^{p+1}}{\delta_\epsilon + \hat{W}_\epsilon} = \lambda_\epsilon \left(\phi_\epsilon - \frac{\epsilon^2 \hat{W}_\epsilon^{1+p/2} \hat{\psi}_\epsilon}{\delta_\epsilon + \hat{W}_\epsilon} \right), \quad y \in \Omega_\epsilon, \tag{4.13}$$

where $f'_{\delta_\epsilon}(\hat{W}_\epsilon)$ is defined by

$$f'_{\delta_\epsilon}(\hat{W}_\epsilon) = \frac{p \hat{W}_\epsilon^p}{\delta_\epsilon + \hat{W}_\epsilon} + \frac{\delta_\epsilon \hat{W}_\epsilon^p}{(\delta_\epsilon + \hat{W}_\epsilon)^2}. \tag{4.14}$$

The boundary condition (4.4) becomes

$$\frac{\partial \phi_\epsilon}{\partial \nu_\epsilon} = \frac{\partial \hat{\psi}_\epsilon}{\partial \nu_\epsilon} = 0 \qquad \text{on } \partial\Omega_\epsilon, \tag{4.15}$$

where ν_ϵ is the unit normal derivative of $\partial\Omega_\epsilon$ at y.

We now need to solve the reformulated eigenvalue problem (4.12) and (4.13), subject to (4.11) and (4.15). We begin with the following simple observation.

LEMMA 4.1. *There exists a constant $C > 0$ such that for ϵ sufficiently small we have*

$$\int_{\Omega_\epsilon} (|\nabla \psi|^2 + h(\hat{W}_\epsilon)\psi^2) \geq C \int_{\Omega_\epsilon} \psi^2 \quad \forall \psi \in H^1(\Omega_\epsilon) \quad \textit{such that} \quad \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p/2} \psi = 0. \tag{4.16}$$

Proof. We just need to show that the principal eigenvalue ν_1^ϵ of

$$\Delta_y \psi^\epsilon - h(\hat{W}_\epsilon)\psi^\epsilon = \nu_1^\epsilon \psi^\epsilon \quad \text{in } \Omega_\epsilon, \quad \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p/2} \psi^\epsilon = 0, \quad \frac{\partial \psi^\epsilon}{\partial \nu_\epsilon} = 0 \quad \text{on } \partial\Omega_\epsilon \tag{4.17}$$

satisfies $\nu_1^\epsilon < -C < 0$. Suppose not. Multiplying (4.17) by ψ_ϵ and integrating over Ω_ϵ, we obtain

$$\nu_1^\epsilon \int_{\Omega_\epsilon} (\psi^\epsilon)^2 = \int_{\Omega_\epsilon} \left(\nabla \cdot \left(P_\epsilon \nabla \left(\frac{\psi^\epsilon}{\sqrt{P_\epsilon}} \right) \right) \right) \frac{\psi^\epsilon}{\sqrt{P_\epsilon}} = - \int_{\Omega_\epsilon} P_\epsilon \left| \nabla \cdot \left(\frac{\psi^\epsilon}{\sqrt{P_\epsilon}} \right) \right|^2. \tag{4.18}$$

Hence $\nu_1^\epsilon \le 0$ and $\nu_1^\epsilon = 0$ if and only if $\frac{\psi^\epsilon}{\sqrt{P_\epsilon}}$ is identically a constant. Since $\int_{\Omega_\epsilon} \psi^\epsilon \sqrt{P_\epsilon} = 0$, we see that $\nu_1^\epsilon < 0$. Suppose now that as $\epsilon \to 0$ we have $\nu_1^\epsilon < 0$ with $\nu_1^\epsilon \to 0$. We proceed to derive a contradiction.

We calculate

$$h(\hat{W}_\epsilon) = \frac{p}{2}\left(\frac{p}{2} - 1\right)\frac{|\nabla \hat{W}_\epsilon|^2}{\hat{W}_\epsilon^2} + \frac{p}{2} - \frac{p}{2}\frac{\hat{W}_\epsilon^p}{\delta_\epsilon + \hat{W}_\epsilon}. \tag{4.19}$$

By Lemma 3.4 we see that, for ϵ sufficiently small, the inequalities

$$\frac{|\nabla \hat{W}_\epsilon|}{\hat{W}_\epsilon} \ge \sqrt{1-\eta}, \qquad \frac{\hat{W}_\epsilon^p}{\delta_\epsilon + \hat{W}_\epsilon} < \eta \tag{4.20}$$

hold for any η small and $|y|$ large. Hence, for $|y|$ large, we have

$$h(\hat{W}_\epsilon) \ge \frac{p}{2}\left(\frac{p}{2} - 1\right)(1-\eta) + \frac{p}{2} - \frac{p}{2}\eta = \frac{p^2}{4}(1-\eta).$$

Therefore, by the maximum principle, we get

$$|\psi^\epsilon(y)| \le C\|\psi^\epsilon\|_{H^1(\Omega_\epsilon)} e^{-\delta|y|}, \tag{4.21}$$

where $\delta = \frac{p^2}{8}(1-\eta)$. By (4.21) and a compactness argument we can now take a subsequence $\epsilon \to 0$ such that $\psi^\epsilon \to \psi^0$ in $H^1(\Omega_\epsilon)$, and ψ^0 satisfies

$$\Delta_y \psi^0 - h(w^{p/2})\psi^0 = 0, \qquad \psi^0 \in H^1(\mathbb{R}^N), \qquad \int_{\mathbb{R}^N} w^{p/2}\psi^0 = 0.$$

This is impossible by the same reasoning leading to (4.18). (Note that $\psi^0 \in H^1(\mathbb{R}^N)$ and w decays exponentially fast.) □

From Lemma 4.1, we have the following result.

LEMMA 4.2. *Let λ_ϵ be such that $\mathrm{Re}(\lambda_\epsilon) \ge 0$. Then, there exists a constant $C > 0$ such that $|\lambda_\epsilon| \le C$, uniformly for ϵ small.*

Proof. Multiplying (4.12) by the conjugate function of $\hat{\psi}_\epsilon$, labeled by $\overline{\hat{\psi}_\epsilon}$, and integrating over Ω_ϵ, we obtain

$$\begin{aligned}&\left|\int_{\Omega_\epsilon}(|\nabla\hat{\psi}_\epsilon|^2 + h(\hat{W}_\epsilon)|\hat{\psi}_\epsilon|^2 + \epsilon^2\lambda_\epsilon|\hat{\psi}_\epsilon|^2)\right| \\ &= \left|p\int_{\Omega_\epsilon}\hat{W}_\epsilon^{p/2-1}\phi_\epsilon\overline{\hat{\psi}_\epsilon} - p\frac{\int_{\Omega_\epsilon}\hat{W}_\epsilon^{p-1}\phi_\epsilon}{\int_{\Omega_\epsilon}\hat{W}_\epsilon^p}\int_{\Omega_\epsilon}\hat{W}_\epsilon^{p/2}\overline{\hat{\psi}_\epsilon}\right| \le C\|\hat{\psi}_\epsilon\|_{L^2(\Omega_\epsilon)}\|\phi_\epsilon\|_{L^2(\Omega_\epsilon)}.\end{aligned} \tag{4.22}$$

Now applying Lemma 4.1 and the fact that $\mathrm{Re}(\lambda_\epsilon) \ge 0$, we arrive at

$$\|\hat{\psi}_\epsilon\|_{H^1(\Omega_\epsilon)} \le C\|\phi_\epsilon\|_{L^2(\Omega_\epsilon)}. \tag{4.23}$$

Multiplying (4.13) by $\bar{\phi}_\epsilon$, the conjugate function of ϕ_ϵ, and integrating over Ω_ϵ, we get

$$\left|\int_{\Omega_\epsilon}(|\nabla\phi_\epsilon|^2 + |\phi_\epsilon|^2 + \lambda_\epsilon|\phi_\epsilon|^2)\right| \le C\left(\int_{\Omega_\epsilon}|\phi_\epsilon|^2 + \epsilon^2|\lambda_\epsilon|\int_{\Omega_\epsilon}|\phi_\epsilon||\hat{\psi}_\epsilon|\right). \tag{4.24}$$

This yields that $|\lambda_\epsilon| \le C$, using (4.23). ∎

A corollary of Lemma 4.2 is the following.

COROLLARY 4.3. *Let λ_ϵ be such that* $\mathrm{Re}(\lambda_\epsilon) \ge 0$. *Assume that for a subsequence $\epsilon \to 0$, $\lambda_\epsilon \to \lambda_0$. Then λ_0 is an eigenvalue of the nonlocal eigenvalue problem*

$$\Delta_y \phi_0 - \phi_0 + p w^{p-1}\phi_0 - p\frac{\int_{\mathbb{R}^N} w^{p-1}\phi_0}{\int_{\mathbb{R}^N} w^p} w^p = \lambda_0 \phi_0, \quad \phi_0 \in H^1(\mathbb{R}^N), \tag{4.25}$$
$$\lambda_0 \in \mathcal{C}, \qquad \mathrm{Re}(\lambda_0) \ge 0.$$

Proof. By Lemma 4.2, we have $|\lambda_\epsilon| \le C$. We may assume that for a subsequence $\epsilon \to 0$, $\lambda_\epsilon \to \lambda_0$. Assume that $\|\phi_\epsilon\|_{H^1(\Omega_\epsilon)} = 1$. Then, from Lemma 4.1, we have

$$\|\hat{\psi}_\epsilon\|_{H^1(\Omega_\epsilon)} \le C, \qquad \|\hat{\psi}_\epsilon\|_{L^\infty(\Omega_\epsilon)} \le C.$$

By taking a limit in (4.13), we see that $\phi_\epsilon \to \phi_0$ in $H^1(\Omega_\epsilon)$ and $\lambda_\epsilon \to \lambda_0$, where (λ_0, ϕ_0) satisfies (4.25). ∎

Finally we discuss the boundary spike case. Let $Q_\epsilon \in \partial\Omega$ be the global maximum point $\hat{W}_\epsilon$. Without loss of generality we may assume from now on that $Q_\epsilon = 0$ and that the normal derivative at Q_ϵ is $\nu(Q_\epsilon) = (0, \dots, -1)$. Similarly as in the interior spike case, we have the following conclusion.

COROLLARY 4.4. *Let (P_ϵ, W_ϵ) be a single boundary spike at Q_ϵ. Let λ_ϵ be such that $Re(\lambda_\epsilon) \ge 0$. Assume that for a subsequence $\epsilon \to 0$, $\lambda_\epsilon \to \lambda_0$. Then, λ_0 is an eigenvalue of the nonlocal eigenvalue problem*

$$\Delta_y \phi_0 - \phi_0 + p w^{p-1}\phi_0 - p\frac{\int_{\mathbb{R}^N_+} w^{p-1}\phi_0}{\int_{\mathbb{R}^N_+} w^p} w^p = \lambda_0 \phi_0 \quad \text{in } \mathbb{R}^N_+, \tag{4.26}$$
$$\frac{\partial \phi_0}{\partial y_N} = 0 \quad \text{on } \partial\mathbb{R}^N_+, \quad \phi_0 \in H^1(\mathbb{R}^N_+),$$

with $Re(\lambda_0) \ge 0$, where $\mathbb{R}^N_+ = \{(y', y_N) \in \mathbb{R}^N | y_N > 0\}$.

Let ϕ_0 be a solution of (4.26) on $\mathbb{R}^N_+$. By an even extension of ϕ_0 to $\mathbb{R}^N$, it is easy to see that the new function, denoted by $\tilde{\phi}_0$, satisfies (4.25).

5. Study of a nonlocal eigenvalue problem. In this section, we study the following nonlocal eigenvalue problem derived in Corollary 4.3:

(5.1)
$$L\phi := \Delta_y \phi - \phi + p w^{p-1}\phi - p\frac{\int_{\mathbb{R}^N} w^{p-1}\phi}{\int_{\mathbb{R}^N} w^p} w^p = \lambda_0 \phi, \qquad \phi \in H^1(\mathbb{R}^N),\ Re(\lambda_0) \ge 0,$$

where w is the unique solution of (2.3) and $\lambda_0 \in \mathcal{C}$ is the set of complex numbers. Nonlocal eigenvalues of this type have been studied in several papers. For the case of $N = 1$, we refer to [7] and [41]. For the case of $p = 2$, we refer to [5] and [41]. In the general (p, N) case, we follow an approach in [45].

We first characterize the kernel of L as follows.

LEMMA 5.1. *We have*

$$\{\phi \in H^1(\mathbb{R}^N) | L\phi = 0\} = K_0 := span\ \left\{ \frac{\partial w}{\partial y_j}, j = 1, \dots, N \right\},$$

$$\left\{\phi \in H^1(\mathbb{R}^N_+) | L\phi = 0,\ \frac{\partial \phi}{\partial y_N} = 0 \text{ on } \partial\mathbb{R}^N_+\right\} = \text{ span } \left\{\frac{\partial w}{\partial y_j}, j = 1, \ldots, N-1\right\}.$$

Proof. The proof is similar to that of Lemma 5.1 of [41]. We omit the details here. ∎

From Lemma 5.1, we may assume that $\lambda_0 \neq 0$. The following result was proved in [44].

LEMMA 5.2. *Assume that $N = 1$ and $1 < p < +\infty$. Then, for any nonzero eigenvalue λ_0 of (5.1), we have $Re(\lambda_0) \leq -C < 0$ for some constant $C > 0$.*

We are left with the case of $N = 2, 3$. We now use a continuation argument, similar to [45], where p is a continuation parameter. For $p = 2$, (5.1) was studied in [41]. Applying Theorem 1 of [45], we have the next result.

THEOREM 5.3. *Suppose that p satisfies (2.7) in Theorem 2.2. Then, for any nonzero eigenvalue λ_0 of (5.1), we have $\mathrm{Re}(\lambda_0) \leq -C < 0$ for some constant $C > 0$.*

Proof. Let $r = p$ and $\gamma = \frac{p}{p-1}$. Using (2.7), it is easy to see that $F(p) = 1 - \frac{p-1}{2p}N \geq 0$. Applying Theorem 1 of [45], we just need to check that

$$F(p) \geq \frac{\gamma - 2}{\gamma} F(p+1) + \frac{|\gamma - 2|}{\gamma}\sqrt{F(p+1)(F(p+1) - F(2))}, \tag{5.2}$$

where $F(r) = 1 - \frac{p-1}{2r}N$. Note that for $2 \leq p$, we have $\frac{\gamma-2}{\gamma} = \frac{2-p}{p} \leq 0$.

If $N = 2$, we have $F(p) = \frac{1}{p}, F(p+1) = \frac{2}{p+1}, F(2) = \frac{3-p}{2}$. By simple computations, (5.2) is equivalent to $p^2 - 6p + 5 \leq 0$, which holds if $2 \leq p \leq 5$.

If $N = 3$, we have $F(p) = \frac{3-p}{2p}, F(p+1) = \frac{5-p}{2(p+1)}, F(2) = \frac{7-3p}{4}$. By simple computations, $\frac{\gamma-2}{\gamma}F(p+1) + \frac{|\gamma-2|}{\gamma}\sqrt{F(p+1)(F(p+1) - F(2))} \leq 0 \leq F(p)$ if $2 \leq p \leq 3$. ∎

6. Study of the small eigenvalues: Proof of Theorem 2.2. In this section, we study the asymptotic behavior of the small eigenvalues that tend to zero as $\epsilon \to 0$. We also prove Theorem 2.2.

Suppose that p satisfies (2.7) and that λ_ϵ is an eigenvalue with $\mathrm{Re}(\lambda_\epsilon) \geq 0$. Then, by Corollaries 4.3 and 4.4, Lemma 5.1, and Theorem 5.3, we must have that $\lim_{\epsilon\to 0}\lambda_\epsilon = \lambda_0 = 0$. Namely, if $\mathrm{Re}(\lambda_\epsilon) \geq 0$, then necessarily $\lambda_\epsilon \to 0$. By Lemma 5.1, we have $\phi_0 \in \text{span}\,\{\frac{\partial w}{\partial y_j}, j = 1, \ldots, N\}$ for $Q_\epsilon \in \Omega$, and $\phi_0 \in \text{span}\,\{\frac{\partial w}{\partial y_j}, j = 1, \ldots, N-1\}$ for $Q_\epsilon \in \partial\Omega$. This result is summarized as follows.

LEMMA 6.1. *Suppose that p satisfies (2.7). Let λ_ϵ be an eigenvalue of (4.2) and (4.3) with $\mathrm{Re}(\lambda_\epsilon) \geq 0$. Then, for $\epsilon \to 0$ and $y \in \Omega_\epsilon$, we must have*

$$\phi_\epsilon = \begin{cases} \sum_{j=1}^N a_j^\epsilon \frac{\partial w}{\partial y_j}(y) + o(1) & \text{if} \quad Q_\epsilon \in \Omega, \\ \sum_{j=1}^{N-1} a_j^\epsilon \frac{\partial w}{\partial y_j}(y) + o(1) & \text{if} \quad Q_\epsilon \in \partial\Omega. \end{cases} \tag{6.1}$$

Lemma 6.1 immediately implies that for $N = 1$ the single boundary spike is linearly stable. Next, consider the radially symmetric case where $(P(x,t), W(x,t)) = (P(|x|,t), W(|x|,t))$. Then $\phi_0(y) = \phi(|y|)$, and by Lemma 6.1 we conclude that $\phi_0 = 0$. Hence, there are no small eigenvalues. Moreover, if p satisfies (2.7), then $\mathrm{Re}(\lambda_0) < 0$ for $\lim_{\epsilon\to 0}\lambda_\epsilon = \lambda_0 \neq 0$. Therefore, we conclude that in the radially symmetric case (P_ϵ, W_ϵ) is linearly stable. This proves (b) and (c) of Theorem 2.2.

Now we prove (a) of Theorem 2.2. Let (P_ϵ, W_ϵ) be a single interior spike solution. We now show that (P_ϵ, W_ϵ) is metastable. Namely, we need to show that for $\mathrm{Re}(\lambda_\epsilon) \geq 0$ we must have $|\lambda_\epsilon| = O(e^{-d/\epsilon})$.

Suppose now that $\mathrm{Re}(\lambda_\epsilon) \geq 0$. From (4.13), the equation for ϕ_ϵ becomes

(6.2)
$$\Delta_y \phi_\epsilon - \phi_\epsilon + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\phi_\epsilon - p\frac{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1}\phi_\epsilon}{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p}} \frac{\hat{W}_\epsilon^{p+1}}{\delta_\epsilon + \hat{W}_\epsilon} = \lambda_\epsilon \left(\phi_\epsilon - \epsilon^2 \frac{\hat{W}_\epsilon^{1+p/2}}{\delta_\epsilon + \hat{W}_\epsilon}\hat{\psi}_\epsilon \right), \quad y \in \Omega_\epsilon.$$

We introduce the new function $\hat{\phi}_\epsilon$ by

$$\phi_\epsilon = \hat{\phi}_\epsilon + c_\epsilon \hat{W}_\epsilon, \qquad \text{where} \qquad c_\epsilon = -p\frac{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1}\hat{\phi}_\epsilon}{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p}}. \tag{6.3}$$

Then, it is easy to see that $\hat{\phi}_\epsilon$ satisfies

$$\Delta_y \hat{\phi}_\epsilon - \hat{\phi}_\epsilon + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\hat{\phi}_\epsilon + c_\epsilon \frac{\delta_\epsilon \hat{W}_\epsilon^{p+1}}{(\delta_\epsilon + \hat{W}_\epsilon)^2} = \lambda_\epsilon \left(\hat{\phi}_\epsilon + c_\epsilon \hat{W}_\epsilon - \epsilon^2 \frac{\hat{W}_\epsilon^{1+p/2}}{\delta_\epsilon + \hat{W}_\epsilon}\hat{\psi}_\epsilon \right). \tag{6.4}$$

Let $\eta(x)$ be a smooth cut-off function such that $\eta(x) = 1$ for $|x| \leq 1$, and $\eta(x) = 0$ for $|x| > 2$. Set $r = \frac{1}{4}d(Q_\epsilon, \partial\Omega)$. Consider the following functions:

$$\phi_{\epsilon,j}(y) = \frac{\partial w_{\delta_\epsilon}}{\partial y_j}(y)\eta\left(\frac{\epsilon y}{r}\right), \qquad j = 1, \ldots, N, \qquad y \in \Omega_\epsilon. \tag{6.5}$$

Then, by Lemma 3.4, we have

(6.6)
$$\Delta_y \phi_{\epsilon,j} - \phi_{\epsilon,j} + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\phi_{\epsilon,j} = O(e^{-d/\epsilon}), \quad \int_{\Omega_\epsilon} \phi_{\epsilon,j}\phi_{\epsilon,k} = O(e^{-d/\epsilon}) \qquad \text{for } \ j \neq k.$$

Next, we decompose $\hat{\phi}_\epsilon$ as follows:

$$\hat{\phi}_\epsilon = \sum_{j=1}^{N} c_j^\epsilon \phi_{\epsilon,j} + \hat{\phi}_\epsilon^\perp,$$

where $\hat{\phi}_\epsilon^\perp \perp \phi_{\epsilon,j}$ for $j = 1, \ldots, N$ and $\sum_{j=1}^N |c_j^\epsilon|^2 = 1$. Lemma 6.1 implies $\|\hat{\phi}_\epsilon^\perp\|_\epsilon \to 0$ as $\epsilon \to 0$.

Note that from Lemma 3.4 we have

$$\left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1}\phi_{\epsilon,j} \right| + \left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p}\phi_{\epsilon,j} \right| = O(e^{-d/\epsilon}), \quad j = 1, \ldots, N. \tag{6.7}$$

The proof of part (a) of Theorem 2.2 proceeds in two steps. First, we obtain the estimates for $\hat{\phi}_\epsilon^\perp$. Then, we deduce the equation for λ_ϵ. Similar arguments have been used in section 4 of [41].

It is easy to see that $\hat{\phi}_\epsilon^\perp$ satisfies

$$\Delta_y \hat{\phi}_\epsilon^\perp - \hat{\phi}_\epsilon^\perp + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\hat{\phi}_\epsilon^\perp = -c_\epsilon \frac{\delta_\epsilon \hat{W}_\epsilon^{p+1}}{(\delta_\epsilon + \hat{W}_\epsilon)^2} \tag{6.8}$$

$$+\sum_{j=1}^{N} c_j^\epsilon O(e^{-d/\epsilon}) + \lambda_\epsilon \left(\hat{\phi}_\epsilon + \sum_{j=1}^{N} c_j^\epsilon \phi_{\epsilon,j} + c_\epsilon \hat{W}_\epsilon - \epsilon^2 \frac{\hat{W}_\epsilon^{1+p/2}}{\delta_\epsilon + \hat{W}_\epsilon} \hat{\psi}_\epsilon \right).$$

Note that from the definition of c_ϵ, we have that

$$c_\epsilon = -p \frac{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} (\sum_{j=1}^{N} c_j^\epsilon \phi_{\epsilon,j} + \hat{\phi}_\epsilon^\perp)}{\int_{\Omega_\epsilon} \hat{W}_\epsilon^p} = O\left(e^{-d/\epsilon} + \left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} \hat{\phi}_\epsilon^\perp \right| \right). \tag{6.9}$$

Let us define

(6.10)
$$\mathcal{K}_\epsilon = \text{span}\,\{\phi_{\epsilon,j}, j = 1, \ldots, N\} \subset H^2_{\nu_\epsilon}(\Omega_\epsilon), \quad \mathcal{C}_\epsilon = \text{span}\,\{\phi_{\epsilon,j}, j = 1, \ldots, N\} \subset L^2(\Omega_\epsilon),$$

where $H^2_{\nu_\epsilon}(\Omega_\epsilon) = H^2(\Omega_\epsilon) \cap \{\frac{\partial u}{\partial \nu_\epsilon} = 0 \text{ on } \partial\Omega_\epsilon\}$. Let $\mathcal{K}_\epsilon^\perp$ and $\mathcal{C}_\epsilon^\perp$ be the orthogonal space of $\mathcal{K}_\epsilon$ and $\mathcal{C}_\epsilon$, respectively, under the $L^2(\Omega_\epsilon)$ inner product. Set

$$L_\epsilon := \Delta_y \phi - \phi + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\phi : \qquad H^2_{\nu_\epsilon}(\Omega_\epsilon) \to L^2(\Omega_\epsilon). \tag{6.11}$$

Then, as in Lemma 2.3 of [41], we have that the map $\mathcal{L}_\epsilon = \pi_\epsilon \circ L_\epsilon : \mathcal{K}_\epsilon^\perp \to \mathcal{C}_\epsilon^\perp$ is invertible and the inverse is bounded uniformly in ϵ. Here π_ϵ is the projection from $L^2(\Omega_\epsilon)$ into $\mathcal{C}_\epsilon^\perp$.

From (6.8) and (4.23) we obtain

$$\|\hat{\phi}_\epsilon^\perp\|_{H^2(\Omega_\epsilon)} \le C \left(|c_\epsilon|\delta_\epsilon + |c_\epsilon||\lambda_\epsilon| + e^{-d/\epsilon} + \epsilon^2 |\lambda_\epsilon| \right).$$

From (6.9), this implies that

$$\|\hat{\phi}_\epsilon^\perp\|_{H^2(\Omega_\epsilon)} \le C(e^{-d/\epsilon} + \epsilon^2 |\lambda_\epsilon|). \tag{6.12}$$

Multiplying (6.8) by $\phi_{\epsilon,k}$ and integrating over Ω_ϵ, we obtain

(6.13)
$$\begin{aligned} \lambda_\epsilon \left(\sum_{j=1}^{N} c_j^\epsilon \int_{\Omega_\epsilon} \phi_{\epsilon,j}\phi_{\epsilon,k} + O(\epsilon^2) \right) &= O(e^{-d/\epsilon}) + \int_{\Omega_\epsilon} \phi_{\epsilon,k} \left(\Delta \hat{\phi}_\epsilon^\perp - \hat{\phi}_\epsilon^\perp + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\hat{\phi}_\epsilon^\perp \right) \\ &= O(e^{-d/\epsilon}). \end{aligned}$$

This shows that $|\lambda_\epsilon| = O(e^{-d/\epsilon})$, which proves part (a) of Theorem 2.2.

Finally, we prove (d) of Theorem 2.2. Let us assume that $Q_\epsilon \to Q_0$, where Q_0 is a nondegenerate global maximum point of $H(P)$. For single boundary spikes, we have from Theorem 1.3 of [42] or Theorem 2.2 of [3] that the eigenvalue problem

$$\Delta_y \phi - \phi + f'_{\delta_\epsilon}(\hat{W}_\epsilon)\phi = \tau_\epsilon \phi \quad \text{in } \Omega_\epsilon, \qquad \frac{\partial \phi}{\partial \nu_\epsilon} = 0 \quad \text{on } \partial\Omega_\epsilon, \tag{6.14}$$

has $N-1$ normalized eigenfunctions $\{\phi_{\epsilon,j}, j = 1, \ldots, N-1\}$ with N eigenvalues (multiplicity is allowed)

$$\tau_1^\epsilon \le \cdots \le \tau_{N-1}^\epsilon, \qquad \tau_j^\epsilon = c_0 \epsilon^2 \lambda_j + o(\epsilon^2). \tag{6.15}$$

Here λ_j is the eigenvalue of the matrix $(\nabla^2 H(Q_0))$, and $c_0 > 0$ is a generic constant. Moreover, we have

$$\int_{\Omega_\epsilon} \phi_{\epsilon,j}^2 = 1, \qquad \int_{\Omega_\epsilon} \phi_{\epsilon,j}\phi_{\epsilon,k} = 0, \quad \text{for } j \neq k, \tag{6.16}$$
$$\phi_{\epsilon,j}(y) = \sum_{k=1}^{N-1} a_{jk} \frac{\partial w}{\partial y_k} + O(\epsilon), \qquad j = 1, \dots, N-1,$$

for some constants a_{jk}.

Similar to the analysis above, we now have from Lemma 3.4 that

$$\hat{W}_\epsilon(y) = w_{\delta_\epsilon}(y) + O(\epsilon), \quad \left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} \phi_{\epsilon,j} \right| + \left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p} \phi_{\epsilon,j} \right| = O(\epsilon), \quad j = 1, \dots, N-1. \tag{6.17}$$

We decompose

$$\hat{\phi}_\epsilon = \sum_{j=1}^{N-1} c_j^\epsilon \phi_{\epsilon,j} + \hat{\phi}_\epsilon^\perp, \qquad \hat{\phi}_\epsilon^\perp \perp \phi_{\epsilon,j}, \quad j = 1, \dots, N-1.$$

Hence, we have

$$c_\epsilon = -p \frac{\int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} (\sum_{j=1}^N c_j^\epsilon \phi_{\epsilon,j} + \hat{\phi}_\epsilon^\perp)}{\int_{\Omega_\epsilon} \hat{W}_\epsilon^p} = O\left(\epsilon + \left| \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} \hat{\phi}_\epsilon^\perp \right| \right). \tag{6.18}$$

From (6.8) we obtain that

$$\begin{aligned} \Delta_y \hat{\phi}_\epsilon^\perp - \hat{\phi}_\epsilon^\perp + f_\delta'(\hat{W}_\epsilon)\hat{\phi}_\epsilon^\perp &= O\left(\epsilon\delta_\epsilon + \delta_\epsilon \int_{\Omega_\epsilon} \hat{W}_\epsilon^{p-1} |\hat{\phi}_\epsilon^\perp| \right) \\ &\quad - \sum_{j=1}^{N-1} c_j^\epsilon \tau_j^\epsilon \phi_{\epsilon,j} + \lambda_\epsilon \left(\sum_{j=1}^{N-1} c_j^\epsilon \phi_{\epsilon,j} + \hat{\phi}_\epsilon^\perp + c_\epsilon \hat{W}_\epsilon - \epsilon^2 \frac{\hat{W}_\epsilon^{1+p/2}}{\delta_\epsilon + \hat{W}_\epsilon} \hat{\psi}_\epsilon \right). \end{aligned} \tag{6.19}$$

Similar arguments leading to (6.12) imply that

$$\|\hat{\phi}_\epsilon^\perp\|_{H^2(\Omega_\epsilon)} \leq C \left(\epsilon\delta_\epsilon + \epsilon^2 |\lambda_\epsilon| + |c_\epsilon||\lambda_\epsilon| \right). \tag{6.20}$$

Multiplying (6.19) by $\phi_{\epsilon,k}$ and integrating over Ω_ϵ, we obtain

$$\lambda_\epsilon \left(\sum_{j=1}^{N-1} c_j^\epsilon \int_{\Omega_\epsilon} \phi_{\epsilon,j}\phi_{\epsilon,k} + O(\epsilon^2) \right) = O(\epsilon\delta_\epsilon) + \sum_{j=1}^{N-1} c_j^\epsilon \tau_j^\epsilon \int_{\Omega_\epsilon} \phi_{\epsilon,j}\phi_{\epsilon,k}. \tag{6.21}$$

Therefore,

$$\lambda_\epsilon (c_k^\epsilon + O(\epsilon^2)) = O(\epsilon^{N+1}) + c_k^\epsilon \tau_k^\epsilon. \tag{6.22}$$

Since $\sum_{k=1}^N |c_k^\epsilon|^2 = 1$, we see that there exists some k such that $\lambda_\epsilon = \tau_k^\epsilon + o(\epsilon^2)$. Since $\tau_k^\epsilon < 0$, we see that $\mathrm{Re}(\lambda_\epsilon) \leq -c_1\epsilon^2 < 0$, where $c_1 > 0$ is a generic constant. This finishes the proof of part (d) of Theorem 2.2. ∎

7. Metastable dynamics and numerical results. In this section, we assume that p satisfies the conditions (2.7) under Theorem 5.3. We then use a formal asymptotic analysis to characterize the metastable dynamics of an interior spike solution for (1.8). The metastability analysis is similar to that given in [16] for an interior spike solution to the Gierer–Meinhardt model of [10]. We look for a solution to (1.8) in the form

(7.1)
$$W(x,t) = W_\epsilon\left(\epsilon^{-1}|x-x_0|\right) + R(x,t), \qquad P(x,t) = P_\epsilon\left(\epsilon^{-1}|x-x_0|\right) + H(x,t).$$

Here (W_ϵ, P_ϵ) satisfy the PDEs of (1.10), and the error terms R and W are such that $R \ll W_\epsilon$ and $H \ll P_\epsilon$. In (7.1), $x_0 = x_0(t) \in \Omega$ is the unknown location of the center of the spike. Our goal is to derive an equation of motion for $x_0(t)$. We will only consider the long-time evolution of the spike, and do not discuss the transient process by which a spike forms from initial data. Therefore, we assume that at $t = 0$ we have $x_0(0) = x_0^0 \in \Omega$ and $R(x,0) = H(x,0) = 0$. Since the linearized problem has an exponentially small principal eigenvalue, we expect that the speed $x_0^{'}$ is exponentially small as $\epsilon \to 0$.

Substituting (7.1) into (1.8) and linearizing the resulting system, we obtain

(7.2a)
$$\nabla\cdot\left(P_\epsilon\nabla\left(\frac{H}{P_\epsilon} - \frac{pR}{W_\epsilon}\right)\right) = \partial_t P_\epsilon + \partial_t H \quad \text{in } \Omega; \qquad \frac{\partial R}{\partial \nu} = -\frac{\partial W_\epsilon}{\partial \nu} \quad \text{on } \Omega,$$

(7.2b)
$$\epsilon^2\Delta R - R + \frac{P_\epsilon}{(1+\gamma W_\epsilon)^2}R + \frac{W_\epsilon}{1+\gamma W_\epsilon}H = \partial_t W_\epsilon + \partial_t R; \qquad \frac{\partial H}{\partial \nu} = -\frac{\partial P_\epsilon}{\partial \nu} \quad \text{on } \partial\Omega.$$

Since both $\partial H/\partial\nu$ on $\partial\Omega$ and the right-hand side of the PDE in (7.2a) are small, we can asymptotically solve (7.2a) for H to get

(7.3)
$$H \sim \left(\frac{pP_\epsilon}{W_\epsilon}\right)R - pP_\epsilon\int_\Omega \frac{P_\epsilon R}{W_\epsilon}.$$

Substituting (7.3) into (7.2b), we obtain

(7.4)
$$\epsilon^2\Delta R - R + f^{'}(W_\epsilon)R - \frac{pW_\epsilon P_\epsilon}{1+\gamma W_\epsilon}\int_\Omega \frac{P_\epsilon R}{W_\epsilon} = \partial_t W_\epsilon + \partial_t R \quad \text{in } \Omega,$$
$$\frac{\partial R}{\partial \nu} = -\frac{\partial W_\epsilon}{\partial \nu} \quad \text{on } \partial\Omega.$$

Here $f^{'}(W_\epsilon)$ is defined by

(7.5)
$$f^{'}(W_\epsilon) = \frac{P_\epsilon}{(1+\gamma W_\epsilon)^2} + \frac{pP_\epsilon}{1+\gamma W_\epsilon}.$$

Next, we use (2.2) to write (7.4) as

(7.6a)
$$\mathcal{L}_\epsilon R \equiv \epsilon^2\Delta R - R + f^{'}_{\delta_\epsilon}(\hat{W}_\epsilon)R - \frac{p\hat{W}_\epsilon^{p+1}}{\delta_\epsilon + \hat{W}_\epsilon}\frac{\int_\Omega \hat{W}_\epsilon^{p-1}R}{\int_\Omega \hat{W}_\epsilon^{p}} = \partial_t W_\epsilon + \partial_t R \quad \text{in } \Omega,$$

(7.6b)
$$\frac{\partial R}{\partial \nu} = -\frac{\partial W_\epsilon}{\partial \nu} \quad \text{on } \partial\Omega.$$

Here δ_ϵ and $f'_{\delta_\epsilon}(\hat{W}_\epsilon)$ are defined in Lemmas 3.4 and 4.14, respectively, and $\hat{W}_\epsilon$ satisfies (1.13).

We define the local operator in (7.6) as

$$L_\epsilon R \equiv \epsilon^2 \Delta R - R + f'_{\delta_\epsilon}(\hat{W}_\epsilon) R. \tag{7.7}$$

By translation invariance, we find upon differentiating (1.13) that

$$L_\epsilon \left(\partial_{x_j} \hat{W}_\epsilon \right) = 0, \qquad j = 1, \ldots, N. \tag{7.8}$$

In addition, since $x_0 \in \Omega$ and $\hat{W}_\epsilon$ is locally radially symmetric near x_0, then $\mathcal{L}_\epsilon(\partial_{x_j} \hat{W}_\epsilon)$ is exponentially small as $\epsilon \to 0$. Moreover, $\partial_{x_j} \hat{W}_\epsilon$ is exponentially small on $\partial\Omega$ for $j = 1, \ldots, N$.

From part 4 of Lemma 3.4, we recall that

$$\hat{W}_\epsilon = w_{\delta_\epsilon}\left[\epsilon^{-1}|x - x_0|\right] + O(e^{-d/\epsilon}), \tag{7.9}$$

where $d > 0$ is some constant independent of ϵ. Here w_{δ_ϵ} satisfies (3.3), with $\delta_\epsilon = \int_\Omega \hat{W}_\epsilon^p = O(\epsilon^N)$. The far-field behavior of the solution, valid for $|x - x_0| \gg O(\epsilon)$, is

$$\hat{W}_\epsilon \sim a \left(\frac{|x - x_0|}{\epsilon} \right)^{(1-N)/2} e^{-|x-x_0|/\epsilon}. \tag{7.10}$$

Here a is a positive constant that depends on N, p, and ϵ. However, as $\epsilon \to 0$ we have $a \to a_0 > 0$, where a_0 is determined from the far-field behavior of (2.3), which corresponds to setting $\delta = 0$ in (3.3). In section 7.1 we derive an ODE for $x_0(t)$ for the multidimensional case where $N \geq 2$. The one-dimensional case is studied in section 7.2.

7.1. The multidimensional case. To derive an equation of motion for $x_0(t)$, we first must determine the eigenfunctions of $\mathcal{L}_\epsilon$ in (7.6) corresponding to the exponentially small eigenvalues. Let $(\lambda_{0j}, \phi_{0j})$, for $j = 1, \ldots, N$, be the eigenpairs of $\mathcal{L}_\epsilon \phi_0 = \lambda_0 \phi_0$, where λ_{0j} is exponentially small as $\epsilon \to 0$. From (7.8), we note that these eigenfunctions are given asymptotically, in the interior of the domain, by $\phi_{0j} \sim \partial_{x_j} \hat{W}_\epsilon$ for $j = 1, \ldots, N$. However, as in [16], we must insert a boundary layer correction term near Ω to ensure that ϕ_{0j} satisfies the homogeneous boundary condition $\partial\phi_{0j}/\partial\nu = 0$ on $\partial\Omega$. In order to resolve the boundary layer, we define a local coordinate system. Let $\hat{\eta}$ represent the distance from a point in Ω to $\partial\Omega$, where $\hat{\eta} < 0$ corresponds to the interior of Ω. Let s correspond to the other $N - 1$ orthogonal coordinates. To localize the region near $\partial\Omega$, we let $\eta = \epsilon^{-1}\hat{\eta}$. The eigenfunction is then approximated by

$$\phi_{0j} \sim \partial_{x_j} \hat{W}_\epsilon + \hat{\phi}_j, \qquad j = 1, \ldots, N. \tag{7.11}$$

Substituting (7.11) into (7.6a), we obtain that $\hat{\phi}_j$ satisfies

$$\partial_{\eta\eta}\hat{\phi}_j - \phi_j = 0, \quad \eta < 0, \qquad \partial_\eta \hat{\phi}_j = -\epsilon \partial_{\hat{\eta}}(\partial_{x_j} \hat{W}_\epsilon)|_{\eta=0} \quad \text{on} \quad \eta = 0, \tag{7.12}$$

with $\hat{\phi}_j \to 0$ as $\eta \to -\infty$. Below, we require a formula for ϕ_{0j} on $\partial\Omega$. Solving (7.12) and using the far-field form (7.10), we substitute the resulting expression into (7.11) to get for $j = 1, \ldots, N$ that

$$\phi_{0j} \sim -a\epsilon^{(N-3)/2} r^{-(1+N)/2} (x_j - x_{0j})\, e^{-r/\epsilon} (1 + \hat{r} \cdot \hat{n}) \qquad \text{on} \quad \Omega. \tag{7.13}$$

Here x_j denotes the jth coordinate of x, $r \equiv |x - x_0|$, $\hat{r} = (x - x_0)/r$, and $\hat{n}$ is the unit outward normal to $\partial\Omega$. A similar calculation was done in [16] with regards to metastable behavior in the Gierer–Meinhardt model [10]. For further details of the calculation leading to (7.13), see [16].

Next, we multiply (7.6a) by ϕ_{0j} and integrate over Ω. Integrating the resulting equation by parts over Ω and assuming that $\partial_t R$ is asymptotically small, we obtain

$$(\partial_t W_\epsilon, \phi_{0j}) = -\epsilon^2 \int_{\partial\Omega} \phi_{0j}\, \partial_\nu \hat{W}_\epsilon \, dS + (R, \mathcal{L}_\epsilon{}^* \phi_{0j})\,. \tag{7.14}$$

We now evaluate the terms in (7.14) using $W_\epsilon = C\hat{W}_\epsilon$, for some constant C. The dominant contribution to the integral on the left-hand side of (7.14) arises from the region near $x = x_0$. Using $\phi_{0j} \sim \partial_{x_j}\hat{W}_\epsilon$, $W_\epsilon = C\hat{W}_\epsilon$, and (7.9) for $\hat{W}_\epsilon$, we calculate for $j = 1, \ldots, N$ that

$$(\partial_t W_\epsilon, \phi_{0j}) \sim -C\epsilon^{N-2} x_{0j}^{'} \left(\frac{\omega_N \beta_N}{N}\right), \qquad \beta_N \equiv \int_0^\infty \rho^{N-1} \left[w_{\delta_\epsilon}^{'}(\rho)\right]^2 \, d\rho. \tag{7.15}$$

Here $(u, v) \equiv \int_\Omega uv$, $x_{0j}^{'} \equiv dx_{0j}/dt$, $w_{\delta_\epsilon}(\rho)$ is the radially symmetric solution to (3.3), and ω_N is the surface area of the unit N-sphere. Next, we use (7.10) and (7.13) to estimate the boundary integral term in (7.14) as

$$-\epsilon^2 \int_{\partial\Omega} \phi_{0j}\, \partial_\nu \hat{W}_\epsilon \, dS \sim -Ca^2\epsilon^{N-1} \int_{\partial\Omega} r^{1-N} e^{-2r/\epsilon} \frac{(x_j - x_{0j})}{r} \hat{r}\cdot\hat{n}\,(1 + \hat{r}\cdot\hat{n})\; dS. \tag{7.16}$$

This expression shows that the boundary integral term in (7.14) is $O(\epsilon^q e^{-2r_0/\epsilon})$, where q is some constant, and $r_0 = \operatorname{dist}(x_0, \partial\Omega)$.

We now show that the inner product term on the right-hand side of (7.14) is asymptotically negligible in comparison with (7.16). We calculate, using $\delta_\epsilon = O(\epsilon^N)$ and symmetry, that

$$\mathcal{L}_\epsilon{}^* \phi_{0j} \sim -\frac{p\hat{W}_\epsilon^{p-1}}{\int_\Omega \hat{W}_\epsilon^p} \int_\Omega \frac{\hat{W}_\epsilon^{p+1}}{\delta_\epsilon + \hat{W}_\epsilon} \partial_{x_j}\hat{W}_\epsilon \sim -\frac{p\hat{W}_\epsilon^{p-1}}{N\,(p+1)\int_\Omega \hat{W}_\epsilon^p} \int_\Omega \nabla\cdot\hat{W}_\epsilon^{p+1}. \tag{7.17}$$

Then, using the divergence theorem and the far-field behavior (7.10), we obtain

$$\mathcal{L}_\epsilon{}^* \phi_{0j} \sim -\frac{p\hat{W}_\epsilon^{p-1}}{N\int_\Omega \hat{W}_\epsilon^p} \int_{\partial\Omega} \frac{\hat{W}_\epsilon^{p+1}}{p+1} = \hat{W}_\epsilon^{p-1}\, O\left(\epsilon^q e^{-(p+1)r_0/\epsilon}\right). \tag{7.18}$$

Here q is a constant, and $r_0 = \operatorname{dist}(x_0, \partial\Omega)$. Since $R \ll 1$ and $p > 1$, it follows that the exponentially small term $(R, \mathcal{L}_\epsilon{}^* \phi_{0j})$ is asymptotically negligible in comparison with the boundary integral term in (7.16).

Therefore, substituting (7.15) and (7.16) into (7.14) and neglecting $(R, \mathcal{L}_\epsilon{}^* \phi_{0j})$ in (7.14), we obtain

$$\frac{dx_0}{dt} \sim \frac{a^2 N\epsilon}{\beta_N \omega_N} \int_{\partial\Omega} r^{1-N} e^{-2r/\epsilon}\, \hat{r}\; (1 + \hat{r}\cdot\hat{n})\; \hat{r}\cdot\hat{n}\, dS. \tag{7.19}$$

Assuming that there is a unique point $x_m \in \partial\Omega$ closest to the initial center $x_0(0)$ of the spike, we can evaluate the surface integral in (7.19) using Laplace's method. This leads to the following explicit result.

PROPOSITION 7.1. *For $\epsilon \ll 1$, a metastable spike solution for* (1.8) *is given by*

$$W_\epsilon \sim \frac{w_{\delta_\epsilon}\left[\epsilon^{-1}(x-x_0)\right]}{\gamma\epsilon^N \int_{\mathbb{R}^N}[w_{\delta_\epsilon}(y)]^p\, dy}, \qquad P_\epsilon \sim \frac{\left(w_{\delta_\epsilon}\left[\epsilon^{-1}(x-x_0)\right]\right)^p}{\epsilon^N \int_{\mathbb{R}^N}[w_{\delta_\epsilon}(y)]^p\, dy}. \tag{7.20a}$$

Here w_{δ_ϵ} satisfies (3.3). *Let x_m be the point on $\partial\Omega$ closest to $x_0(0)$. Then, for $t > 0$, the spike moves in the direction of x_m, and the distance $r_m(t) = |x_m - x_0(t)|$ satisfies the first order nonlinear differential equation*

$$\frac{dr_m}{dt} \sim -\xi r_m \left(\frac{\epsilon}{r_m}\right)^{(N+1)/2} K(r_m) e^{-2r_m/\epsilon}, \tag{7.20b}$$

where $\xi > 0$ and the functions $K(r_m)$ are defined by

$$\xi \equiv \frac{2Na^2}{\omega_N \beta_N}\pi^{(N-1)/2}, \qquad K(r_m) \equiv \left(1-\frac{r_m}{R_1}\right)^{-1/2}\left(1-\frac{r_m}{R_2}\right)^{-1/2}\cdots\left(1-\frac{r_m}{R_{N-1}}\right)^{-1/2}. \tag{7.20c}$$

Here $R_j > 0$, for $j = 1, \ldots, N-1$, are the principal radii of curvature of $\partial\Omega$ at x_m, ω_N is the surface area of the unit N-sphere, and a and β_N were defined in (7.10) *and* (7.15), *respectively.*

This result is valid up until the time when the spike approaches to within an $O(\epsilon)$ distance of x_m. If the initial condition for (7.20b) is $r_m(0) = r_0$, then the time T needed for $r_m(T) = 0$, is readily found to be

$$T \sim \frac{\epsilon^{(1-N)/2} r_0^{(N-1)/2}}{2K(r_0)\xi} e^{2r_0/\epsilon}. \tag{7.21}$$

7.2. The one-dimensional case. Let (λ_0, ϕ_0) be the principal eigenpair of $\mathcal{L}_\epsilon\phi_0 = \lambda_0\phi_0$ with $\phi_0'(\pm 1) = 0$. Here $\mathcal{L}_\epsilon$ is defined in (7.6), and λ_0 is exponentially small. Similar to the analysis for the multidimensional case, ϕ_0 has the boundary layer form

$$\phi_0 \sim \partial_x \hat{W}_\epsilon + \phi_l\left[\epsilon^{-1}(1+x)\right] + \phi_r\left[\epsilon^{-1}(1-x)\right]. \tag{7.22}$$

Substituting (7.22) into (7.6), we obtain that the boundary layer correction terms $\phi_l(\eta)$ and $\phi_r(\eta)$ satisfy $v'' - v = 0$. Imposing that $\phi_0'(\pm 1) = 0$, and using the far-field behavior (7.10) with $N = 1$, we get

$$\phi_l(\eta) = a\epsilon^{-1}e^{-(1+x_0)/\epsilon}e^{-\eta}, \qquad \phi_r(\eta) = -a\epsilon^{-1}e^{-(1-x_0)/\epsilon}e^{-\eta}. \tag{7.23}$$

Combining (7.10), (7.22), and (7.23), and where a is defined in (7.10), we calculate

$$\phi_0(-1) \sim 2\epsilon^{-1}ae^{-(1+x_0)/\epsilon}, \qquad \phi_0(+1) \sim -2\epsilon^{-1}ae^{-(1-x_0)/\epsilon}. \tag{7.24}$$

To derive a differential equation for x_0, we proceed as in the multidimensional case. We multiply both sides of (7.6) by ϕ_0 and integrate over the domain. Assuming that $\partial_t R$ on the right-hand side of (7.6) is asymptotically small, we integrate the resulting expression by parts, and then use the boundary condition (7.6b), to obtain

$$(\phi_0, \partial_t W_\epsilon) = -\epsilon^2\phi_0\partial_x W_e|_{-1}^1 + (R, \mathcal{L}_\epsilon{}^*\phi_0). \tag{7.25}$$

Here $\mathcal{L}_\epsilon{}^*$ denotes the adjoint operator of $\mathcal{L}_\epsilon$. As in the multidimensional case, the second term on the right-hand side of (7.25) is asymptotically negligible in comparison to the other two terms in (7.25). Then, since $W_\epsilon = C\hat{W}_\epsilon$ for some constant C, (7.25) reduces to

$$\left(\phi_0, \partial_t \hat{W}_\epsilon\right) \sim -\epsilon^2 \phi_0 \hat{W}_{\epsilon x}|_{-1}^{1}. \tag{7.26}$$

Using (7.9), (7.10), (7.22), and (7.24), we calculate

$$\left(\phi_0, \partial_t \hat{W}_\epsilon\right) \sim -\epsilon^{-1} x_0^{'} \int_{-\infty}^{\infty} \left[\hat{W}_\epsilon^{'}(y)\right]^2 dy, \tag{7.27}$$

$$\epsilon^2 \phi_0 \hat{W}_{\epsilon x}|_{-1}^{1} \sim 2a^2 \left(e^{-2(1-x_0)/\epsilon} - e^{-2(1+x_0)/\epsilon}\right).$$

Substituting (7.28) into (7.26), we obtain the ODE for the spike location. The corresponding asymptotic solution is obtained by combining (2.2) and part 4 of Lemma 3.4. We summarize the result as follows.

PROPOSITION 7.2. *For $\epsilon \ll 1$, a metastable spike solution for* (1.8) *is given by*

$$W_\epsilon \sim \frac{w_{\delta_\epsilon}\left[\epsilon^{-1}(x-x_0)\right]}{\gamma\epsilon \int_{-\infty}^{\infty} \left[w_{\delta_\epsilon}(y)\right]^p \, dy}, \qquad P_\epsilon \sim \frac{\left(w_{\delta_\epsilon}\left[\epsilon^{-1}(x-x_0)\right]\right)^p}{\epsilon \int_{-\infty}^{\infty} \left[w_{\delta_\epsilon}(y)\right]^p \, dy}. \tag{7.28a}$$

Here w_{δ_ϵ} satisfies (3.3), *and the spike location $x_0(t)$ satisfies the differential equation*

$$\frac{dx_0}{dt} \sim \frac{2a^2\epsilon}{\beta}\left(e^{-2(1-x_0)/\epsilon} - e^{-2(1+x_0)/\epsilon}\right), \quad x_0(0) = x_0^0, \qquad \beta \equiv \int_{-\infty}^{\infty} \left[w_{\delta_\epsilon}^{'}(y)\right]^2 dy. \tag{7.28b}$$

The constant $a > 0$ is defined in (7.10).

Following ideas in [37], the homoclinic orbit constants a, β, and δ_ϵ can be computed numerically in terms of the nonlinearity of (3.3). In this way, we obtain the explicit formulae for a and β:

$$\log a \equiv \log w_m + \int_0^{w_m} \left(\frac{1}{\left[\eta^2 - 2Q(\eta)\right]^{1/2}} - \frac{1}{\eta}\right) d\eta, \quad \beta = 2\int_0^{w_m} \left[\eta^2 - 2Q(\eta)\right]^{1/2} d\eta. \tag{7.29a}$$

Here $w_m = w_{\delta_\epsilon}(0)$, which denotes the maximum of $w_{\delta_\epsilon}(y)$ on $y \geq 0$, satisfies the transcendental equation

$$w_m^2 = 2Q(w_m), \qquad \text{where} \qquad Q(w) = \int_0^w \frac{y^{p+1}}{\delta_\epsilon + y}\, dy. \tag{7.29b}$$

The nonlocal term δ_ϵ, defined in Lemma 3.4, can be rewritten by determining a formula for $w_{\delta_\epsilon}^{'}$ in terms of w_{δ_ϵ} for $y \geq 0$. In this way, we get

$$\delta_\epsilon = 2\epsilon \int_0^{w_m} \frac{w^p}{\sqrt{w^2 - 2Q(w)}}\, dw. \tag{7.29c}$$

We use Newton's method to solve the coupled system (7.29b) and (7.29c) for w_m and δ_ϵ for various values of ϵ. In terms of these values, we then calculate a and β from

TABLE 1
Numerical values for the homoclinic orbit constants at different values of ϵ when $p = 2$.

ϵ	w_m	δ_ϵ	a	β
0.01	1.587	0.0625	5.34	1.38
0.02	1.679	0.137	5.27	1.57

0.10	2.741	1.627	6.51	4.60

TABLE 2
Numerical values for the homoclinic orbit constants for different values of p when $\epsilon = 0.06$.

p	w_m	w_{m0}	δ_ϵ	δ_0	a	β
2	2.115	1.500	0.610	0.360	5.59	2.64
3	1.604	1.414	0.351	0.267	2.85	1.77
4	1.456	1.357	0.276	0.228	2.17	1.59
5	1.379	1.316	0.240	0.207	1.89	1.51

(7.29a). An important feature of these formulae is that they do not require an explicit pointwise expression for the solution $w_{\delta_\epsilon}(y)$ to (3.3).

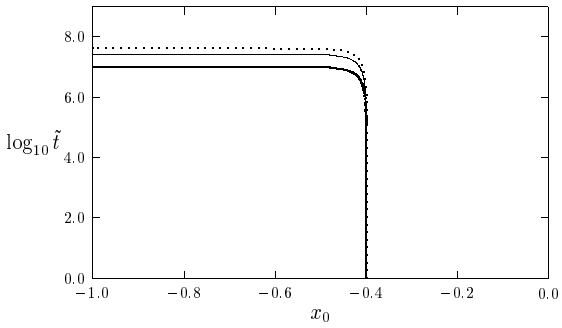
When $\epsilon \to 0$, then $\delta_\epsilon \to 0$. Consequently, in this limit, the solution to (3.3) is given to leading order by the solution to (2.3), which is given explicitly by

$$w(y) = \left(\frac{p+1}{2}\right)^{1/(p-1)} \left(\cosh\left[\frac{(p-1)y}{2}\right]\right)^{-2/(p-1)}. \tag{7.30}$$

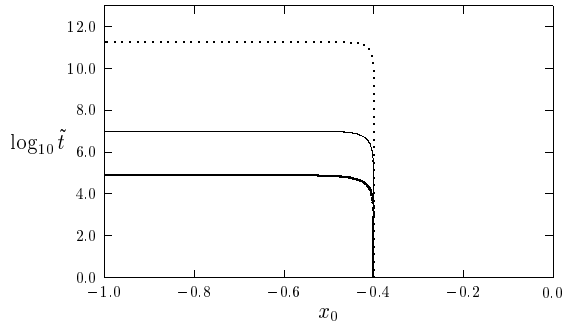
Therefore, as $\epsilon \to 0$, we have for $p = 2$ that $w_m \to w_{m0} = 1.5$, $\delta_\epsilon \to \delta_0 = \epsilon \int_{-\infty}^{\infty} w^2\, dy = 6\epsilon$, $a \to a_0 = 6$, and $\beta \to \beta_0 = 6/5$. In Table 1 we give numerical values for the homoclinic orbit constants for different values of ϵ when $p = 2$. In Table 2 numerical values are given for these constants for different values of p when $\epsilon = 0.06$. In the latter table we compare the numerical values for w_m and δ_ϵ with the numerical values for the corresponding leading order approximations w_{m0} and δ_0 at different values of p. These values show that the nonlocal term δ_ϵ is significant at this value of ϵ.

The ODE (7.28b) shows that the spike moves exponentially slowly towards the right or the left boundary when $x_0(0) > 0$ or $x_0(0) < 0$, respectively. In Figure 1(a) we plot the numerical solution to (7.28b) in the form $\log_{10}(1 + t)$ versus x_0 when $\epsilon = 0.06$ for $p = 2$, $p = 3$, and $p = 4$. The homoclinic orbit constants needed in (7.28b) are given in Table 2. The initial value for (7.28b) is $x_0(0) = -0.4$. The spike motion is found to be slower for larger values of p. For $p = 2$ and the initial value $x_0(0) = -0.4$, in Figure 1(b) we plot $\log_{10}(1 + t)$ versus x_0 for $\epsilon = 0.04$, $\epsilon = 0.06$, and $\epsilon = 0.08$. Notice the dramatic change in the time-scale of the metastability for a small change in ϵ. For $p = 2$ and $\epsilon = 0.06$, in Figure 2(a) and (b) we plot the leading order solutions for W_ϵ and P_ϵ, respectively, at different times. These leading order solutions are obtained by replacing w_{δ_ϵ} in (7.28a) by w as given in (7.30).

Finally, we compare full numerical results for the evolution of an interior spike for (1.8) with the asymptotic dynamical behavior given in (7.28). The routine D03PCF of the NAG library [25] is used to compute the numerical solution to (1.8). The initial



(a) $\log_{10}\tilde{t}$ versus x_0: $\tilde{t} = 1 + t$.



(b) $\log_{10}\tilde{t}$ versus x_0: $\tilde{t} = 1 + t$.

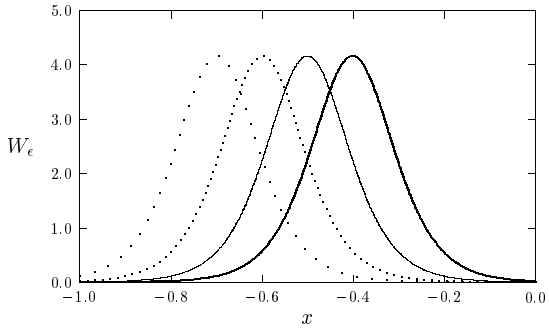
FIG. 1. (a): *Plot of asymptotic spike location computed from* (7.28*b*) *when* $\epsilon = 0.06$*, for* $p = 2$ *(heavy solid curve),* $p = 3$ *(solid curve), and* $p = 4$ *(dashed curve).* (b): *Similar plot when* $p = 2$*, for* $\epsilon = 0.08$ *(heavy solid curve),* $\epsilon = 0.06$ *(solid curve), and* $\epsilon = 0.04$ *(dashed curve).*

condition for the numerical solution to (1.8) is

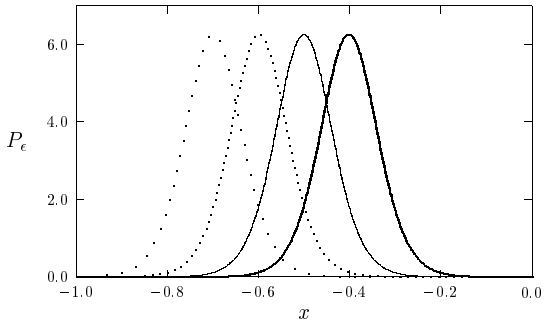
$$W(x,0) = \frac{w\left[\epsilon^{-1}(x - x_0^0)\right]}{\gamma\epsilon\int_{-\infty}^{\infty}[w(y)]^p\,dy}, \qquad P(x,0) = \frac{\left(w\left[\epsilon^{-1}(x - x_0^0)\right]\right)^p}{\epsilon\int_{-\infty}^{\infty}[w(y)]^p\,dy}, \tag{7.31}$$

where w is given in (7.30). In the computations, we choose $p = 2$, $\gamma = 1$, $\epsilon = 0.06$, and $x_0^0 = -0.4$. The spike location is determined numerically from the maximum of the numerical solution for W. In Figure 3, we show a favorable comparison between the asymptotic and numerical results for x_0. For this value of ϵ, the relative error between the asymptotic and numerical predictions for the time at which the spike hits the boundary at $x = -1$ is about 3%.

8. Concluding remarks. Motivated by the general system (1.1), (1.2) in which we have a single equation governing the population density P coupled with a system governing several substrates or nutrients, we have focussed on the simpler system (1.5) in which the transition probability function is represented by a power law.



(a) W_ϵ versus x.



(b) P_ϵ versus x.

FIG. 2. *Plot of the leading order solutions for W_ϵ and P_ϵ at four different times when $p = 2$, $\gamma = 1$, and $\epsilon = 0.06$. The heavy solid curve is for $t = 0$, the solid curve is for $t = 4.01 \times 10^5$, the dashed curve is for $t = 1.0214 \times 10^7$, and the widely spaced dots are for $t = 1.0227 \times 10^7$.*

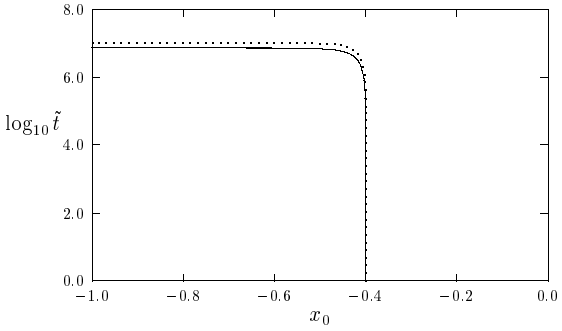


FIG. 3. *Comparison of numerical and asymptotic results for $\log_{10} \tilde{t}$, where $\tilde{t} = 1 + t$, versus x_0 when $p = 2$, $\gamma = 1$, $x_0^0 = -0.4$, and $\epsilon = 0.06$. The solid curve is the full numerical result computed from* (1.8). *The dashed curve is the asymptotic result computed from the ODE* (7.28b).

Under weak diffusion of the substrate, we have established the existence of spike solutions and investigated their stability. Of particular interest is the existence of metastable spikes. With regards to the modeling of the movement of myxobacteria our results suggest that bacteria which aggregate when diffusion of the substrate is neglected are, in fact, metastable spikes under weak diffusion. A similar observation can be made regarding the initiation of capillary sprouts in tumor angiogenesis under the simple model indicated in section 1. Furthermore, it is an important problem to investigate whether spike behavior can account for the observed vigorous angiogenesis in a vascularised tumor.

The investigations of this paper suggest a number of open problems. For example, it is of interest to investigate whether spikes arise for more a general transition probability function Φ. In addition, we may ask whether spike patterns exist for systems of the form (1.1) in which there are several substrates or nutrients.

Acknowledgments. We would like to thank the referees for their careful reading of the manuscript.

FAST INVERSION OF THE RADON TRANSFORM USING LOG-POLAR COORDINATES AND PARTIAL BACK-PROJECTIONS*

FREDRIK ANDERSSON†

Abstract. In this paper a novel filtered back-projection algorithm for inversion of a discretized Radon transform is presented. It makes use of invariance properties possessed by both the Radon transform and its dual. By switching to log-polar coordinates, both operators can be expressed in a displacement invariant manner. Explicit expressions for the corresponding transfer functions are calculated. Furthermore, by dividing the back-projection into several partial back-projections, inversion can be performed by means of finite convolutions and hence implemented by an FFT-algorithm. In this way, a fast and accurate reconstruction method is obtained.

Key words. Radon transform, filtered back-projection

1. Introduction.

Computerized tomography, CT, is a well established image acquisition technique with a growing range and diversity of applications. The most common algorithm used in X-ray CT, SPECT, and many other image modalities is called filtered back-projection. It consists of two steps: a one-dimensional filtering of the data followed by a back-projection step, where the filtered data values are distributed along the lines of measurement. In standard implementations of filtered back-projection algorithms, the latter part is by far the most time-consuming. Doubling the image resolution requires four times the amount of measurement data, while the computational cost in the back-projection step increases by a factor of eight. For the reconstruction of an image with resolution $q \times q$, the number of computations needed in the back-projection part is $\mathcal{O}(q^3)$.

The principle of CT is mathematically described by the *Radon transform*. The two-dimensional Radon transform is the mapping of a function in $\mathbb{R}^2$ to its line integral values, and the reconstruction problem of CT lies in inverting this mapping. The back-projection mentioned above is mathematically described by the dual Radon transform which integrates over all lines passing through a point.

Several suggestions on how to invert the Radon transform in $\mathcal{O}(q^2 \log q)$ time have appeared in the literature during the years. Most common are Fourier-based methods. Using such an approach results in data of the two-dimensional Fourier transform of the sought function on a nonuniform grid. Direct interpolation to a rectangular grid followed by FFT inversion results in $\mathcal{O}(q^2 \log q)$ complexity but gives rise to unacceptable artifacts. To cope with this one can, e.g., use over-sampling combined with more sophisticated interpolation, as suggested in [14], or use fast Fourier algorithms for unequally spaced data; cf. [2], [16], [8].

For issues of quality, the algorithms of filtered back-projection type have traditionally been preferred among the manufacturers of CT machines. Fast techniques for filtered back-projection algorithms are presented in [15], [6], [3], [4], where the back-projection is calculated recursively in $\mathcal{O}(q^2 \log q)$ time.

In this paper we exploit the fact that both the Radon transform and its dual possess similar invariance properties. By a change of coordinates to log-polar coordinates, the operators can be expressed as convolutions. In particular, by introducing an appropriate Fourier transform, it is possible to compute parts of the back-projection in a fast manner by means of the FFT. In this way a filtered back-projection algorithm is constructed which works in $\mathcal{O}(q^2 \log q)$ time.

A log-polar grid is hence introduced for treating the back-projection part in a fast manner. Log-polar grids have previously been used in an ART fashion; cf. [7]. However, according to [7], this approach was not successful in competition with the standard filtered back-projection algorithm, in either speed or quality.

The methods developed in this paper may also be used in fast calculation of the (forward) Radon transform, although the focus of the paper lies on the inverse problem. Fast computation of the forward problem has also appeared in, e.g., [9], [3]. Besides simulation possibilities, this is, e.g., useful in fast computation of the Hough transform, a tool used in image analysis and pattern recognition for finding lines.

The paper begins with a brief review of the Radon transform and its inversion. In section 3.1 follows a discussion on the invariance properties possessed by the Radon transform and its dual. We show that when expressed by log-polar coordinates, both can be written in terms of convolutions. Explicit expressions for the corresponding kernels are given in section 3.2. However, the geometry of log-polar grids makes it impractical to use the convolutional structure directly. In section 3.3 the concept of partial back-projections is introduced to deal with this problem. The discrete setting is dealt with in section 4, where implementation techniques are discussed and numerical experiments displayed.

2. Preliminaries. The two-dimensional Radon transform is the mapping from (sufficiently regular) functions on $\mathbb{R}^2$ to line integrals in $\mathbb{R}^2$,

$$\mathcal{R}f(\theta, s) = \int_{x\cdot\theta=s} f(x)\, dx, \tag{2.1}$$

i.e., the integral of f over the line with normal direction θ and (signed) distance s to the origin. When defined on the unit cylinder $\mathbb{S} = S^1 \times \mathbb{R}$, the two-dimensional Radon transform (defined by (2.1)) is even, i.e., $\mathcal{R}f(-\theta, -s) = \mathcal{R}f(\theta, s)$, since each line can be parameterized in two ways. Here S^1 denotes the unit circle, parameterized by $[-\pi, \pi)$. When describing an element of S^1, it is sometimes advantageous to describe it via a unit vector and sometimes with the corresponding angle in a polar representation. To avoid cumbersome notation, it is customary to use the same symbol in both cases, and we will follow this tradition. Sometimes it is convenient to work on $\mathbb{S}_+ = S^1 \times \mathbb{R}_+$ or $\mathbb{S}_{1/2} = [-\pi/2, \pi/2) \times \mathbb{R}$ instead of $\mathbb{S}$, both able to describe all lines in the plane.

It is well known that the Radon transform as a mapping $\mathcal{S}(\mathbb{R}^2) \to \mathcal{S}(\mathbb{S})$ is injective, where $\mathcal{S}$ denotes the Schwartz space. In this paper we are especially interested in the Radon transform of compactly supported functions, and inversion techniques for such. The Radon transform can then (possibly combined with a suitable preceding translation) be viewed as an injective mapping $\mathcal{C}_0^\infty(\mathbb{S}_+) \to \mathcal{C}_0^\infty(\mathbb{S}_+)$.

The dual Radon transform $\mathcal{R}^\#$ integrates functions defined on $\mathbb{S}$ over subsets of $\mathbb{S}$ corresponding to lines passing through a point $x \in \mathbb{R}^2$,

$$\mathcal{R}^\# g(x) = \int_{S^1} g(\theta, x\cdot\theta)\, d\theta. \tag{2.2}$$

It is dual in the sense that

$$\int_{\mathbb{S}} (\mathcal{R}f)(\theta,s)g(\theta,s)\; ds d\theta = \int_{\mathbb{R}^2} f(x)(\mathcal{R}^{\#}g)(x)\; dx,$$

and in the literature is commonly referred to as the *back-projection operator*.

In order to write the inversion formula for the Radon transform in a simple form, we introduce the operator $\mathcal{J}$ acting on (sufficiently regular) functions on $\mathbb{S}$, defined by

$$\mathcal{J} = \frac{\partial}{\partial s}\mathcal{H},$$

where $\mathcal{H}$ is the Hilbert transform operator, applied to the second variable in $\mathbb{S}$. Here, the Hilbert transform is defined by

$$\mathcal{H}f(x) = \frac{1}{\pi}\int_{\mathbb{R}} \frac{1}{x-y} f(y)\, dy,$$

where the integral is interpreted as a principal value.

An inversion formula then reads as

$$f = \frac{1}{4\pi}\mathcal{R}^{\#}\mathcal{J}\mathcal{R}f. \tag{2.3}$$

For more details, see [14]. A factor of $1/2$ on the right-hand side is due to the fact that, in the interpretation of $\mathcal{R}^{\#}$, each line is taken into account twice. Using instead $\mathbb{S}_+$ or $\mathbb{S}_{1/2}$, the factor $1/4\pi$ is replaced by $1/2\pi$. The operator $\mathcal{J}$ cannot be defined directly on $\mathbb{S}_+$, and hence instead it is defined as the restriction of the action on $\mathbb{S}$ to $\mathbb{S}_+$.

In practice, where Radon data are given on a discrete sampling grid, the operator $\mathcal{J}$ is usually implemented by a discrete convolution in the s-variable with a band-limited filter. More specifically, one makes use of the formula

$$W * f = \mathcal{R}^{\#}(w \overset{s}{*} \mathcal{R}f), \tag{2.4}$$

where $\overset{s}{*}$ denotes one-dimensional convolution with respect to the second variable, s, in $\mathbb{S}$, and where W and w are related by $W = \mathcal{R}^{\#}w$; cf. [14]. By choosing W to approximate a δ-distribution, an approximate reconstruction is obtained. More specifically, one usually chooses $W = W_b$ to be radially symmetric and band-limited with some cut-off frequency b. When chosen in this way, $w = w_b$ depends only on the s-variable, in which it is band-limited by b; cf. [14].

Let us consider the problem of making reconstructions on a rectangular grid of size $q \times q$. To do that, the number of needed parallel lines and directions in data measurements are both of order q; cf. [14]. By approximating the continuous convolution in (2.4) by a discrete one, the filtering step $w \overset{s}{*} \mathcal{R}f$ can be accomplished, by use of FFT, with a time complexity $\mathcal{O}(q^2 \log q)$. A more time-consuming step is the computation of the back-projection. The straightforward numerical implementation of $\mathcal{R}^{\#}$ uses, for each discrete direction sample point θ_j, some kind of interpolation in the s-variable to approximate $g(\theta_j, x\cdot\theta_j)$ in (2.2), in combination with some quadrature rule on S^1:

$$\mathcal{R}_d^{\#}g(x) = \sum_j \alpha_j g(\theta_j, x\cdot\theta_j).$$

Hence, roughly q values are summed up at each reconstruction point, giving a time complexity of order $\mathcal{O}(q^3)$ for q^2 reconstruction points. Reconstruction methods which are based on (2.3) are referred to as *filtered back-projection algorithms*.

Next, we present a discussion about some properties of the continuous Radon transformation and its dual, which are both of interest on their own and useful for the discrete approximative inversion presented below. A somewhat reminiscent discussion is given in [1], where some closed-form formulas, involving Chebyshev polynomials, are given starting from a polar representation. A numerical implementation is presented in [1], but the number of computations needed is of order $\mathcal{O}(q^3)$.

3. Properties of the continuous Radon transform and its dual.

3.1. Convolution operators. Consider the cylinder $\mathbb{S}_+ = S^1 \times \mathbb{R}_+$ as a group, provided with the algebraic structure inherited from its components, i.e., the additive group $S^1 = \mathbb{R}/2\pi\mathbb{Z}$ (addition modulo 2π) and the multiplicative group $\mathbb{R}_+$ (positive real numbers).

Let $z = (\theta, s) \in \mathbb{S}_+$. The group operation on $\mathbb{S}_+$, written multiplicatively, is

$$(\theta_1, s_1)(\theta_2, s_2) = ((\theta_1 + \theta_2) \bmod 2\pi, s_1 s_2).$$

The Haar measure on $\mathbb{S}_+ = S^1 \times \mathbb{R}_+$ is inherited from the components and can be written $dh(z) = d\theta\, ds/s$. Hence

$$\int_{\mathbb{S}_+} f(z)\, dh(z) = \int_0^{2\pi} \int_0^{\infty} f(\theta, s)\, d\theta\, \frac{ds}{s} \quad \text{for} \quad f \in \dot{\mathcal{C}}_0^{\infty}(\mathbb{S}_+),$$

where $\dot{\mathcal{C}}_0^{\infty}(\mathbb{S}_+)$ is the $\mathcal{C}_0^{\infty}$ class on $\mathbb{S}_+$, with support outside the origin $S^1 \times \{0\}$. The Haar property means that

$$\int_{\mathbb{S}_+} f(wz)\, dh(z) = \int_{\mathbb{S}_+} f(z)\, dh(z) \quad \text{for} \quad w \in \mathbb{S}_+,\ f \in \dot{\mathcal{C}}_0^{\infty}(\mathbb{S}_+).$$

There exists a natural isomorphism between $\mathbb{S}_+$ and the punctured complex plane $\dot{\mathbb{C}} = \mathbb{C} \setminus \{0\}$ considered multiplicatively, parameterized by $(\theta, s) \longleftrightarrow s e^{i\theta}$. Using the Cartesian representation $z = x + iy$ for $\dot{\mathbb{C}}$, the Haar measure on $\mathbb{S}_+$ can be written

$$dh(z) = d\theta\, \frac{ds}{s} = \frac{dx\, dy}{x^2 + y^2}.$$

If $\dot{\mathbb{C}}$ is represented instead by coordinates

$$s e^{i\theta} = e^{\rho} e^{i\theta}, \quad \rho \in \mathbb{R}, \tag{3.1}$$

which we will refer to as *log-polar coordinates*, then the Haar measure on $\mathbb{S}_+$ becomes

$$dh(z) = d\theta\, d\rho.$$

Let λ be the distribution that represents integration over the line $x = 1$ in $\dot{\mathbb{C}}$,

$$\lambda : f \longmapsto \int_{-\infty}^{\infty} f(1, y)\, dy = \int_{\dot{\mathbb{C}}} f(x, y) \delta(x - 1)\, dx\, dy, \quad f \in \mathcal{S}(\mathbb{S}_+).$$

In the $(\theta, s) = z$ representation, it can be written

$$\lambda : f \longmapsto \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} f\left(\theta, \frac{1}{\cos\theta}\right) \frac{1}{\cos^2\theta}\, d\theta = \int_{\mathbb{S}_+} f(\theta, s)\delta(s\cos\theta - 1) s\, ds\, d\theta$$
$$= \int_{\mathbb{S}_+} f(z)\lambda(z)\, dh(z), \quad \text{with} \quad \lambda(z) = s^2\delta(s\cos\theta - 1).$$

Let lines in $\dot{\mathbb{C}}$ be denoted L_ξ, where ξ is the footprint of the normal of the line through the origin. The Radon transform (2.1) can be expressed as

$$g(\xi) = Rf(\xi) = |\xi| \int_{\mathbb{S}_+} f(z\xi)\lambda(z)\, dh(z). \tag{3.2}$$

This follows from the fact that, in the last integral, the distribution λ is applied to a function that is obtained from f by a similarity transformation of the coordinate plane, such that the line L_ξ is transferred to L_1, which is the support of λ. Using $|\xi|$ to compensate for the change in scale, we obtain the Radon transform.

The duality between points on a line in $\dot{\mathbb{C}}$ and lines through a point in $\dot{\mathbb{C}}$ motivates interest in the distribution

$$\lambda^\# : f \longmapsto \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} f(\theta, \cos\theta)\, d\theta = \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \int_{\mathbb{R}_+} f(\theta, s)\delta(\cos\theta - s)\, ds\, d\theta$$
$$= \int_{\mathbb{S}_+} f(z)\lambda^\#(z)\, dh(z), \quad \text{with} \quad \lambda^\#(z) = s\delta(\cos\theta - s).$$

If f is interpreted as a function on lines in $\dot{\mathbb{C}}$, then this represents the integral of f over all lines through the point $1 \in \dot{\mathbb{C}}$. Also note that

$$\int_\alpha^\beta \int_{\mathbb{R}_+} f(s, \theta)\lambda^\#(s, \theta)\, ds\, d\theta \tag{3.3}$$

is the integral over all lines through the point $1 \in \dot{\mathbb{C}}$ with normal direction in the interval $[\alpha, \beta]$.

The distributions $\zeta(z) = \lambda(1/z)$ and $\zeta^\#(z) = \lambda^\#(1/z)$, formally defined by

$$\zeta : f \longmapsto \int_{\mathbb{S}_+} f\left(\frac{1}{z}\right) \lambda(z)\, dh(z),$$
$$\zeta^\# : f \longmapsto \int_{\mathbb{S}_+} f\left(\frac{1}{z}\right) \lambda^\#(z)\, dh(z), \quad f \in \dot{\mathcal{C}}_0^\infty(\mathbb{S}_+),$$

will be crucial in what follows. In the $(\theta, s) = z$ representation, these can explicitly be written

$$\zeta(z) = s^{-2}\delta(s^{-1}\cos\theta - 1),$$
$$\zeta^\#(z) = \delta(s\cos\theta - 1).$$

Using the Haar property on the integral, the formula (3.2) can also be written

$$\mathcal{Z}f(\xi) = \frac{\mathcal{R}f(\xi)}{|\xi|} = \int f(z)\zeta\left(\frac{\xi}{z}\right)\, dh(z). \tag{3.4}$$

Apart from the scaling factor $|\xi|$, the Radon transform can thus be expressed as a convolution on $\mathbb{S}_+$.

For the back-projecting operator (2.2), note that if $\xi \in \dot{\mathbb{C}}$ and if $g \in \dot{\mathcal{C}}_0^\infty(\mathbb{S}_+)$ is interpreted as a function on lines in $\dot{\mathbb{C}}$, then

$$\mathcal{R}^\# g(\xi) = \int_{\mathbb{S}_+} g(\xi z)\lambda^\#(z)\, dh(z)$$

is the integral of g over all lines that pass through ξ. Hence, again by using the Haar property,

$$\mathcal{R}^\# g(\xi) = \int_{\mathbb{S}_+} g(z)\zeta^\#\left(\frac{\xi}{z}\right) dh(z), \tag{3.5}$$

which in the log-polar representation can be expressed by the following convolution:

$$\mathcal{R}^\# g(\rho,\theta) = \int_{\mathbb{S}_+} g(\rho',\theta')\zeta^\#(\rho-\rho',\theta-\theta')\, d\rho'\, d\theta'. \tag{3.6}$$

This fact opens the possibility of performing the inversion in (2.3) by means of an appropriate Fourier transform.

Note also that by using (3.3) and the same arguments as above, it follows that the back-projection restricted to lines with normal directions in the interval $[\alpha,\beta]$ can be written

$$\mathcal{R}^\#_{[\alpha,\beta]} g(\rho,\theta) = \int_\alpha^\beta \int_{\mathbb{R}_+} g(\rho',\theta')\zeta^\#(\rho-\rho',\theta-\theta')\, d\rho'\, d\theta'. \tag{3.7}$$

3.2. Fourier analysis. The Fourier transform $\mathcal{F}_{\mathbb{S}_+} = \mathcal{F}$ on $\mathbb{S}_+$ is a compound of the Fourier series transform on S^1 and the Mellin transform on $\mathbb{R}_+$:

$$\mathcal{F} : f(\theta,s) \longmapsto g(\mu,\sigma) = \int_0^{2\pi}\int_0^\infty e^{-i\mu\theta} s^{-\sigma} f(\theta,r)\, \frac{ds}{s}\, d\theta, \quad \mu \in \mathbb{Z},\ \sigma \in \mathbb{C}.$$

In a log-polar representation, (3.1), the Fourier transform instead becomes a compound of the Fourier series transform and the Laplace transform on $\mathbb{R}$,

$$\mathcal{F} : f(\theta,\rho) \longmapsto g(\mu,\sigma) = \int_0^{2\pi}\int_{-\infty}^\infty e^{-i\mu\theta} e^{-\sigma\rho} f(\theta,r)\, d\rho\, d\theta, \quad \mu \in \mathbb{Z},\ \sigma \in \mathbb{C}.$$

As the operators $\mathcal{Z}$ in (3.4) and $\mathcal{R}^\#$ in (3.5) can be expressed as convolutions on $\mathbb{S}_+$, it suffices to calculate the corresponding transfer functions for determination of $\mathcal{F}\zeta$ and $\mathcal{F}\zeta^\#$.

It is readily verified using (3.2) that, for $\xi = re^{i\psi}$,

$$\mathcal{Z}f(\xi) = \int_{\mathbb{S}_+} f(\theta+\psi, rs)\delta(s\cos\theta - 1)s\, ds\, d\theta = \int_{-\pi/2}^{\pi/2} f\left(\theta+\psi, \frac{r}{\cos\theta}\right)\frac{1}{\cos^2\theta}\, d\theta.$$

Let $f(\theta,s) = s^\sigma e^{i\mu\theta}$. Then the transfer function for $\mathcal{Z}$ is obtained by

$$\begin{aligned}\mathcal{Z}f(\xi) &= \int_{-\pi/2}^{\pi/2} e^{i\mu(\theta+\psi)}\left(\frac{r}{\cos\theta}\right)^\sigma \frac{1}{\cos^2\theta}\, d\theta = r^\sigma e^{i\mu\psi}\int_{-\pi/2}^{\pi/2} e^{i\mu\theta}\big(\cos\theta\big)^{-\sigma-2}\, d\theta \\ &= f(\xi)\mathcal{F}\zeta(\mu,\sigma).\end{aligned}$$

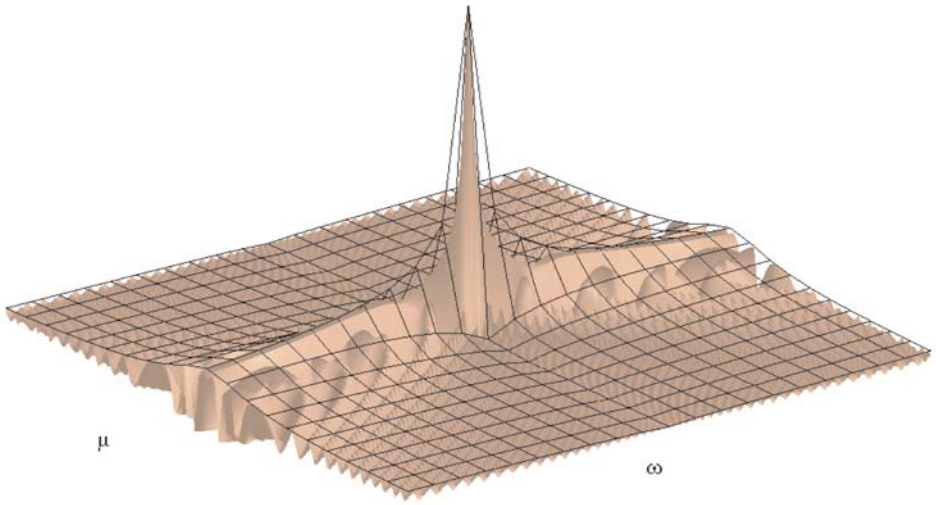

FIG. 3.1. *The absolute value and real part of* $\mathcal{F}\zeta^{\#}(\mu, i\omega)$.

Here, $\mathcal{F}\zeta(\mu,\sigma)$ converges in the classical sense for $\operatorname{Re}\sigma < -1$, where it defines an analytic function.

Similarly, the transfer function for the back-projecting operator $\mathcal{R}^{\#}$ is obtained by

$$\begin{aligned}\mathcal{R}^{\#}f(\xi) &= \int_{-\pi/2}^{\pi/2} e^{i\mu\theta}(r\cos(\theta-\psi))^{\sigma}\,d\theta = \int_{-\pi/2}^{\pi/2} e^{i\mu(\theta+\psi)}(r\cos\theta)^{\sigma}\,d\theta \\ &= r^{\sigma}e^{i\mu\psi}\int_{-\pi/2}^{\pi/2} e^{i\mu\theta}(\cos\theta)^{\sigma}\,d\theta = f(\xi)\mathcal{F}\zeta^{\#}(\mu,\sigma),\end{aligned}$$

where $\mathcal{F}\zeta^{\#}(\mu,\sigma)$ converges in the classical sense for $\operatorname{Re}\sigma > -1$.

Note that $\mathcal{F}\zeta(\mu,\sigma)$ and $\mathcal{F}\zeta^{\#}(\mu,\sigma)$ are not simultaneously (classically) well defined, and note further the resemblance between the two Fourier transforms:

$$\mathcal{F}\zeta(\mu,\sigma) = \mathcal{F}\zeta^{\#}(\mu,-\sigma-2).$$

An analogue to the following formula can be found in [10, p. 372].

$$\int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} e^{i\mu\theta}\cos^{\sigma}(\theta)\,d\theta = \frac{\pi\Gamma(\sigma+1)}{2^{\sigma}\Gamma(\frac{\sigma+\mu}{2}+1)\Gamma(\frac{\sigma-\mu}{2}+1)}, \qquad \operatorname{Re}\sigma > -1.$$

Hence we conclude that

$$\begin{aligned}\mathcal{F}\zeta(\mu,\sigma) &= \frac{\pi\Gamma(-\sigma-1)}{2^{-\sigma-2}\Gamma(\frac{-\sigma+\mu}{2})\Gamma(\frac{-\sigma-\mu}{2})}, \quad \operatorname{Re}\sigma < -1, \\ \mathcal{F}\zeta^{\#}(\mu,\sigma) &= \frac{\pi\Gamma(\sigma+1)}{2^{\sigma}\Gamma(\frac{\sigma+\mu}{2}+1)\Gamma(\frac{\sigma-\mu}{2}+1)}, \quad \operatorname{Re}\sigma > -1. \end{aligned} \tag{3.8}$$

Figure 3.1 illustrates the function $\mathcal{F}\zeta^{\#}(\mu, iw)$. The real part is displayed in the form of a surface plot, and the absolute value is shown on a coarser grid in a mesh

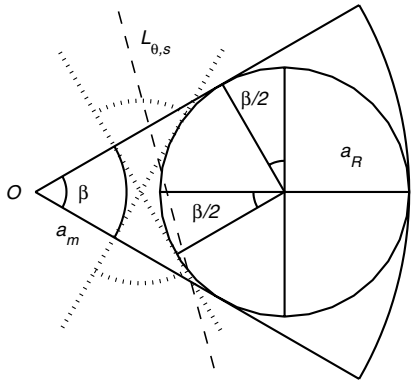

FIG. 3.2. *Lines with directions* $\theta \in [-\frac{\beta}{2}, \frac{\beta}{2}]$, *passing through a circle inscribed in a segment.*

plot. Its energy content is mainly contained in a neighborhood of the origin and along the line $\mu = 0$. Note that, although its absolute value is rather smooth, the real and imaginary parts are strongly oscillating.

3.3. Partial back-projection. Our aim is to present a fast procedure for computing the back-projection as a discrete convolution on a uniformly sampled grid in log-polar coordinates. However, the counterpart in polar coordinates will be nonuniform, corresponding to a dense assembling of grid points close to the origin in $\mathbb{C}$. This assembling causes large variation in the density of both reconstruction grid points and data sample points. By moving the origin it is possible to obtain a more uniform structure within the grid points of the reconstruction region, but this does not simplify the treatment of the data sample points. The difficulty here is the need to deal with lines with various distances to the origin, and this problem exists no matter where the origin is situated, if lines with all directions must be considered.

To cope with this, we divide the measurement data into $m \geq 3$ (disjoint) sets, each containing lines with directions in an interval of length $\frac{\pi}{m}$. Corresponding to each such set, we choose an origin outside the region of interest, in such a way that the back-projection from lines with directions within each interval (cf. (3.3)) can be calculated by means of finite integrals. We refer to this procedure as *partial back-projection*. By putting these partial back-projections together, it is possible to obtain a total back-projection. To begin with, we consider one special case.

Let $\beta = \frac{\pi}{m}$ for some positive integer $m \geq 3$, and let a_R denote the radius of the largest circle inscribed in a sector with unit radius and central angle β; cf. Figure 3.2. It is straightforward to show that

$$a_R = \frac{\sin(\frac{\beta}{2})}{1 + \sin(\frac{\beta}{2})}. \tag{3.9}$$

Consider the set of all lines $L_{\theta,s}$, with normal directions $|\theta| \leq \frac{\beta}{2}$ with respect to the symmetry axis of the sector, passing through the inscribed circle; cf. Figure 3.2. It is clear that the normal distances to the origin, s, of these lines will be in the interval $(a_m, 1)$, where

$$a_m + a_R = (1 - a_R) \cos\left(\frac{\beta}{2}\right), \tag{3.10}$$

or, by using (3.9),

$$a_m = \frac{\cos(\frac{\beta}{2}) - \sin(\frac{\beta}{2})}{1 + \sin(\frac{\beta}{2})}. \tag{3.11}$$

Suppose that $f \in \mathcal{C}_0^\infty$ has its support inside the inscribed circle, and that $\mathcal{R}f(\theta, s)$ is known. Let

$$h^0(\theta, s) = \chi_\beta \mathcal{J}\mathcal{R}f(\theta, s),$$

where χ_β is the characteristic function of the set

$$\left\{\theta : -\frac{\beta}{2} \le \theta < \frac{\beta}{2}\right\}.$$

The contribution

$$f_0(x) = \int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} \mathcal{J}\mathcal{R}f(\theta, \theta \cdot x)\, d\theta$$

from the back-projection of lines with directions in the interval $(-\frac{\beta}{2}, \frac{\beta}{2})$ in log-polar coordinates, for x inside the inscribed circle, may be written as (by using (3.7))

$$f_0(\theta, \rho) = \int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} \int_{\ln(a_m)}^{0} h^0(\theta', \rho')\zeta^{\#}(\theta - \theta', \rho - \rho')\, d\rho' d\theta'.$$

Furthermore, if $\zeta_p^{\#}(\theta, \rho)$ is defined as the periodic extension of $\zeta^{\#}(\theta, \rho)$ for $\theta \in [\beta, \beta]$ and $\rho \in [\ln(a_m), 0]$, then

$$f_0(\theta, \rho) = \int_{-\beta}^{\beta} \int_{\ln(a_m)}^{0} h^0(\theta', \rho')\zeta_p^{\#}(\theta - \theta', \rho - \rho')\, d\rho' d\theta', \tag{3.12}$$

when $\theta \in [-\frac{\beta}{2}, \frac{\beta}{2}]$ and $\rho \in [1 - 2a_R, 1]$. This is due to the fact that the interval length in the θ'-direction is twice the θ'-support of $h^0(\theta', \rho')$, and to the fact that the values of $h^0(\theta', \rho')$ for ρ' outside $[\ln(a_m), 0]$ are of no importance in (partial) back-projecting for $x = (\theta, \rho)$ inside the inscribed circle. Thus, replacing $h^0(\theta', \rho')$ with a periodical extension of $h^0(\theta', \rho')$ as above (which is equivalent to extending $\zeta^{\#}$) does not influence the result. Hence, the partial back-projection at points of interest can be calculated as a periodic convolution.

Now, let $f \in \mathcal{C}_0^\infty(\Omega^2)$, where Ω^2 denotes the unit disc in $\mathbb{R}^2$, and suppose that $\mathcal{R}f(\theta, s)$ is known. By dividing the data into m different parts, each spanning an angle interval of length β, and making a suitable change of coordinates to each such set, one transforms the full back-projection problem into m subproblems of the form above. An illustration of the procedure, for $m = 3$, is given in Figure 3.3. The coordinate transformation $x \to x_\nu$ consists of, after a rescaling with a_R, a rotation by the angle β followed by a translation of the origin O to O_ν. Each part is then of the form discussed above. Adding the respective partial back-projections gives the total back-projection, since each partial back-projection integrates over disjunct intervals $(-\beta/2 + \nu\beta, \beta/2 + \nu\beta)$, which together covers an interval length of $m\beta = \pi$. For the sake of completeness, we include the details.

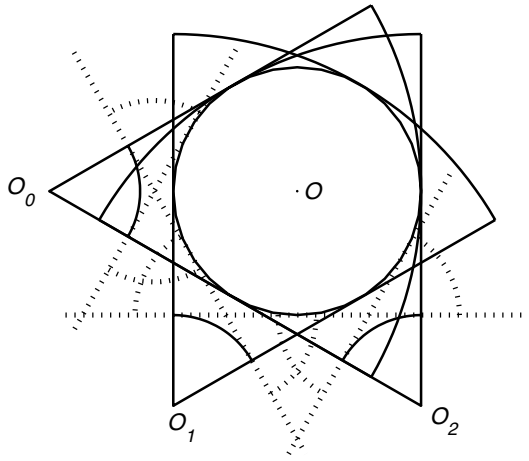

FIG. 3.3. *Reconstruction from three views.*

Let $\nu = 0, \ldots, m-1$; introduce for each ν new coordinates

$$x_\nu = a_R \begin{pmatrix} \cos(\nu\beta) & \sin(\nu\beta) \\ -\sin(\nu\beta) & \cos(\nu\beta) \end{pmatrix} x + \begin{pmatrix} 1 - a_R \\ 0 \end{pmatrix};$$

and let $f^\nu(x_\nu) = f(x)$. Each f^ν then has its support inside a circle inscribed in a sector with unit radius and central angle β, as in Figure 3.2. Let $h^\nu = \chi_\beta \mathcal{J}\mathcal{R} f^\nu$. The following relation, easily verified,

$$x_\nu \cdot \theta = x \cdot a_R(\theta + \nu\beta) + (1 - a_R)\cos(\theta), \tag{3.13}$$

will be useful. Any line in the x-coordinate system may be written

$$L_{\theta+\nu\beta,s} = \{x | x \cdot (\theta + \nu\beta) = s\},$$

for some $\nu \in \{0, \ldots, m-1\}$ and $-\frac{\beta}{2} \le \theta < \frac{\beta}{2}$. In the x_ν-coordinate system the corresponding line may then, by using (3.13), be written

$$L^\nu_{\theta, a_R s + (1-a_R)\cos(\theta)} = \{x_\nu | x_\nu \cdot \theta = a_R s + (1 - a_R)\cos(\theta)\},$$

and hence,

$$h^\nu(\theta, s) = \chi_\beta \mathcal{J}\mathcal{R} f \left(\theta + \nu\beta, \frac{s - (1 - a_R)\cos(\theta)}{a_R} \right). \tag{3.14}$$

The total back-projection for some point x inside the support of f can now, again by using (3.13), be written as

$$\begin{aligned} \mathcal{R}^\# \mathcal{J}\mathcal{R} f(x) &= \int_{S^1} \mathcal{J}\mathcal{R} f(\theta, x \cdot \theta)\, d\theta \\ &= 2 \sum_{\nu=0}^{m-1} \int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} \mathcal{J}\mathcal{R} f(\theta + \nu\beta, (\theta + \nu\beta) \cdot x)\, d\theta \\ &= 2 \sum_{\nu=0}^{m-1} \int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} h^\nu(\theta, a_R(\theta + \nu\beta) \cdot x + (1 - a_R)\cos(\theta))\, d\theta \\ &= 2 \sum_{\nu=0}^{m-1} \int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} h^\nu(\theta, x_\nu \cdot \theta)\, d\theta, \end{aligned}$$

where the factor 2 in the last expression is due to the fact that the total integration is performed on only half of S^1.

We now have reduced the full back-projection problem to m partial reconstructions of the form discussed above. For future reference, let us introduce

$$f_r^\nu(x_\nu) = \frac{1}{2\pi}\int_{-\frac{\beta}{2}}^{\frac{\beta}{2}} h^\nu(\theta, x_\nu\cdot\theta)\,d\theta. \tag{3.15}$$

The inversion formula (2.3) then allows us to write

$$f(x) = \sum_{\nu=0}^{m-1} f_r^\nu(x_\nu). \tag{3.16}$$

We have deduced that it is possible to compute the total back-projection as a sum of partial back-projection. The sharp cutoff caused by χ_β will, however, in practice give rise to artifacts in the form of sharp lines with normal directions corresponding to the cutoff angles. Therefore it is desirable to make a smoother cutoff. This requires that the supports in the θ-direction for the respective h^ν overlap. The angle β is then not equal to $\frac{\pi}{m}$ (where m is the number of partial back-projections to be used) but larger. Suppose $\frac{\pi}{m} \le \beta \le \frac{2\pi}{m}$. By letting

$$\eta(t) = \begin{cases} e^{\frac{-\beta^2}{\beta^2-4t^2}} & \text{if } |t| < \frac{\beta}{2}, \\ 0 & \text{otherwise,} \end{cases}$$

a smooth cutoff function

$$\chi_{\beta,m}(\theta) = \frac{\eta(\theta)}{\eta(\theta)+\eta(\frac{\pi}{m}-\arccos(\cos\theta))}, \tag{3.17}$$

with support in $[-\frac{\beta}{2}, \frac{\beta}{2}]$, can be formed. Since

$$\sum_{k=-\infty}^{\infty} \chi_{\beta,m}\left(\theta + k\frac{\pi}{m}\right) \equiv 1,$$

it follows that the reconstruction (3.16) is still valid if χ_β in (3.14) is replaced by $\chi_{\beta,m}$.

4. Discrete log-polar reconstruction.

4.1. Principles. In this section we describe how to use the method of section 3.3 to make reconstructions from discrete measurements. For simplicity, in this paper we deal with the case of parallel beam data. Let $f \in \mathcal{C}_0^\infty(\Omega^2)$; let $g = \mathcal{R}f$ be sampled at (θ_j, s_l), $j = 0,\dots,p-1$, $l = 0,\dots,q-1$ (parallel beam geometry), where $\theta_j \in S^1$ and $s_l = \frac{2l}{q} - 1$; and let $h = w_b \overset{s}{*} g$, in accordance with (2.4). The latter quantity is approximated by the discrete convolution

$$w_b \overset{d}{*} g(\theta_j, s) = \frac{1}{q}\sum_{l=-q}^{q} w_b(s-s_l)g(\theta_j, s_l). \tag{4.1}$$

What now remains for reconstruction is the back-projection. To this end, let the integer m be the number of partial reconstructions to be used, let $\beta = \pi/m_\beta$, suppose that m and m_β are divisors of p, and let $\theta_j = -\frac{\beta}{2} + \frac{j\pi}{p}$.

For the construction of the discrete back-projecting operator we will make use of the interpolation results discussed in section A. To begin with, suppose $h(\theta, s)$ is known, and make a uniform sampling of h^ν defined in (3.14), with χ_β replaced by $\chi_{\beta,m}$ from (3.17), in a log-polar representation (θ_j, ρ_i) covering $(-\frac{\beta}{2}, \frac{\beta}{2}) \times (-\ln(a_m), 0)$. Let $I_{\Delta_2} = I_{(\Delta\theta,\Delta\rho)}$ be a quasi-interpolator of order o_2, with kernel $\varphi(\theta, \rho) = \varphi_\theta(\theta)\varphi_\rho(\rho)$, where $\Delta\theta$ and $\Delta\rho$ is the grid spacing of (θ_j, ρ_i).

Construct

$$h_*^\nu(\theta, \rho) = \sum_j \sum_i h^\nu[j, i]\varphi\left(\frac{\theta - \theta_j}{\Delta\theta}, \frac{\rho - \rho_i}{\Delta\rho}\right),$$

as an approximation of h^ν. Now the back-projection of h_*^ν, for x_ν represented by $\theta \in [-\frac{\beta}{2}, \frac{\beta}{2}]$ and $\rho \in [1 - 2a_R, 1]$, can be written

$$\begin{aligned}
\mathcal{R}^\# h_*^\nu(\theta, \rho) &= \int_{-\beta}^{\beta} \int_{\ln(a_m)}^{0} h_*^\nu(\theta - \theta', \rho - \rho')\zeta^\#(\theta', \rho')\, d\rho'\, d\theta' \\
&= \int_{-\beta}^{\beta} \int_{\ln(a_m)}^{0} \left(\sum_j \sum_i h^\nu[j, i]\varphi\left(\frac{\theta - \theta' - \theta_j}{\Delta\theta}, \frac{\rho - \rho' - \rho_i}{\Delta\rho}\right)\right)\zeta^\#(\theta', \rho')\, d\rho'\, d\theta' \\
&= \sum_j \sum_i h^\nu[j, i]Z(\theta - \theta_j, \rho - \rho_i), \qquad (4.2)
\end{aligned}$$

where

$$Z(\theta, \rho) = \int_{-\beta}^{\beta} \int_{\ln(a_m)}^{0} \varphi\left(\frac{\theta - \theta'}{\Delta\theta}, \frac{\rho - \rho'}{\Delta\rho}\right) \zeta^\#(\theta', \rho')\, d\theta' d\rho'. \qquad (4.3)$$

This follows by exchanging the order between sums and integrals. Note that Z is independent of the Radon data.

Due to this structure, it is particularly convenient to make reconstructions on some uniformly sampled (θ, ρ)-grids, e.g., the same upon which h^ν was resampled, as this enables computation of the discrete convolutions by means of two-dimensional FFT (after appropriate zero padding). Once the partial back-projections f_r^ν are computed on the (θ_j, ρ_i)-grid, it remains only to interpolate them onto a Cartesian representation and sum up the results to obtain a reconstruction f. A survey of relevant interpolation methods is given in the appendix.

The procedure discussed above involves three quasi interpolators. The first one (not discussed above) is needed in the resampling onto the uniform (θ_j, ρ_i)-grid; let it be denoted by $I_{\Delta_1} = I_{\frac{2}{q}}$, and its interpolating order by o_1. Hence, $h[j, i]$ above should be replaced by $(I_{\Delta_1} h)[j, i]$. The second quasi interpolator, represented by I_{Δ_2} above, is naturally incorporated into $Z(\theta, \rho)$ as described by (4.3), and the third, I_{Δ_3} of interpolating order o_3, is needed when adding up the parts. In short, a pseudocode for the reconstruction is presented below.

ALGORITHM 4.1.

```
function f=iradonlp(g,m,mbeta);
    [p,q]=size(g);
    h=wfilter(g);
    FZ=fft2(get_Z(p,q,mbeta));
    chi=get_chi(m,mbeta,q);
    f=0;
```

```
    for nu=0:m-1,
        hlp=interp_pol2lp(chi.*h(nu*p/m+(0:p/mbeta-1),:));
        hlp=[hlp;zeros(size(hlp))];
        flp=ifft2(FZ*fft2(hlp));
        f=f+interp_lp2cart(flp);
    end;
end;
```

Let us discuss the first interpolation step in slightly more detail. Since, for each fixed θ, $h(\theta, s)$ is band-limited by b, the first interpolation step can actually be computed exactly from $h(\theta_j, s_l)$ by (A.1), as long as the Nyquist condition $b < \frac{\pi q}{2}$ is satisfied. However, this is quite time-consuming and ruins the time gain achieved by using log-polar coordinates in the back-projection.

The nonuniformity between data in polar and log-polar representation requires use of more sample points in the log-polar representation in order to avoid too much loss of information. Suppose $\Delta\rho = \frac{-\ln(a_m)}{q'-1}$ and $\rho_i = 1 - i\Delta\rho$, $i = 0, \ldots, q'-1$, where $q' = \kappa q$ for some oversample factor κ. If the filter bandwidth of (4.1) is given by $b = \frac{\pi q}{2}$, then by choosing

$$\kappa > -\frac{\ln(a_m)}{2a_R},$$

the knowledge of $h(\theta, \rho_i)$ at all grid points suffices to reconstruct $h(\theta, \rho_i)$; cf. Theorem 3.1 in [22]. A typical choice here is $\kappa = 2$.

Remark. The combination of uniformly spaced FFT and the interpolation scheme described above is in principle the same as in the procedures used in fast Fourier transforms for unequally spaced data; cf. [2]. Usage of the fast implementations available for such routines allows simple and fast implementation of the algorithm described above. It should be stressed that, although the tools used are the same as in, e.g., [16], the underlying method is quite different; the approach of this paper is based on the filtered back-projection technique, whereas the others have been based on the Fourier slice theorem.

4.2. Error analysis. In the algorithm described above, errors are introduced at several places. The first one is in the filtering step, caused by the discrete convolution (4.1). This is common for algorithms of filtered back-projection type, and estimated in [14] by

$$|w_b \overset{d}{*} g - w_b \overset{s}{*} g|(\theta, s) \leq \frac{1}{2} \int_{\sigma \geq b} |\sigma|^{n-1} \hat{f}(\sigma\theta)\, d\sigma = e_1. \tag{4.4}$$

To describe the errors caused by interpolation we need to introduce modified Sobolev norms for polar and log-polar coordinates. The main reason for not using the natural definitions is that each filtering h of Radon data of some compactly supported function is not compactly supported. In particular, since the filtering does not vanish in a neighborhood of $s = 0$, the natural Sobolev norm in log-polar coordinates of h is in general, if it exists, infinite.

As in the definition (A.4), let

$$||f||_{H^\gamma_{\mathrm{pol}}} = \sum_{|\alpha| \leq \gamma} \int\int |D^\alpha_{\theta,s} f(\theta, s)|^2 \chi_{\mathrm{pol}}(\theta, \rho)\, d\theta\, ds$$

and

$$||f||_{H^\gamma_{\rm lp}} = \sum_{|\alpha|\le\gamma} \int\int |D^\alpha_{\theta,\rho} f(\theta,\rho)|^2 \chi_{\rm lp}(\theta,\rho)\, d\theta\, d\rho$$

be polar and log-polar Sobolev norms, respectively. Here $f(\theta,s)$ and $f(\theta,\rho)$ are connected through the change of variables

$$\rho = \ln\left(\frac{s-(1-a_R)\cos(\theta)}{a_R}\right), \tag{4.5}$$

$\chi_{\rm pol}$ is a smooth cutoff function equal to one on $(-\frac{\beta}{2},\frac{\beta}{2})\times(-1,1)$, and similarly $\chi_{\rm lp}$ equal to one on $(-\frac{\beta}{2},\frac{\beta}{2})\times(-\ln(a_m),0)$. Since the function defined by (4.5) is $\mathcal{C}^\infty$ for $s\in[-1,1]$, and correspondingly $\rho\in[-\ln(a_m),0]$, it is possible to choose $\chi_{\rm pol}$ and $\chi_{\rm lp}$ such that the two norms above are equivalent. It is clear that the results in the appendix are also valid with the norms above. By abuse of notation, we will denote all constants in the remainder of this section by C.

The error introduced in the first interpolation step can now be expressed as

$$||I_{\Delta_1} h^\nu - h^\nu||_{H^0_{\rm pol}} \le C|\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm pol}}, \tag{4.6}$$

by using (A.5) of Theorem A.1. Because of the norm equivalence between $||\cdot||_{H^\gamma_{\rm pol}}$ and $||\cdot||_{H^\gamma_{\rm lp}}$, the analogous estimate of (4.6) holds for $||\cdot||_{H^\gamma_{\rm lp}}$. This, in combination with the triangle inequality, implies that

$$\begin{aligned}||h^\nu_* - h^\nu||_{H^0_{\rm lp}} &= ||I_{\Delta_2} I_{\Delta_1} h^\nu - h^\nu||_{H^0_{\rm lp}} \le ||I_{\Delta_2} I_{\Delta_1} h^\nu - I_{\Delta_1} h^\nu||_{H^0_{\rm lp}} + ||I_{\Delta_1} h^\nu - h^\nu||_{H^0_{\rm lp}} \\ &\le C|\Delta_2|^{o_2}||I_{\Delta_1} h^\nu||_{H^{o_2}_{\rm lp}} + C|\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm lp}}.\end{aligned}$$

Since I_{Δ_1} is bounded, it follows that

$$||h^\nu_* - h^\nu||_{H^0_{\rm lp}} \le C(|\Delta_2|^{o_2}||h^\nu||_{H^{o_2}_{\rm lp}} + |\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm lp}}).$$

Hence, for the partial back-projection

$$||\mathcal{R}^\#(h^\nu_* - h^\nu)||_{H^0_{\rm lp}} \le \beta C(|\Delta_2|^{o_2}||h^\nu||_{H^{o_2}_{\rm lp}} + |\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm lp}}),$$

since both h^ν and h^ν_* are zero outside a θ-interval of length β. The total error from one partial back-projection is then bounded by

$$\begin{aligned}||I^3\mathcal{R}^\# h^\nu_* - \mathcal{R}^\# h^\nu)||_{H^0_{\rm lp}} &\le ||I^3\mathcal{R}^\# h^\nu_* - \mathcal{R}^\# h^\nu_*)||_{H^0_{\rm lp}} + ||\mathcal{R}^\# h^\nu_* - h^\nu)||_{H^0_{\rm lp}} \\ &\le C|\Delta_3|^{o_3}||\mathcal{R}^\# I_{\Delta_2} I_{\Delta_1} h^\nu||_{H^{o_3}_{\rm lp}} + \beta C(|\Delta_2|^{o_2}||h^\nu||_{H^{o_2}_{\rm lp}} + |\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm lp}}) \\ &\le C(|\Delta_3|^{o_3}||h^\nu||_{H^{o_3}_{\rm lp}} + |\Delta_2|^{o_2}||h^\nu||_{H^{o_2}_{\rm lp}} + |\Delta_1|^{o_1}||h^\nu||_{H^{o_1}_{\rm lp}}),\end{aligned}$$

and hence also the total back-projection. We summarize the analysis above in the following theorem.

THEOREM 4.1. *The reconstruction error made in the back-projection step of Algorithm* 4.1 *satisfies*

$$||(\mathcal{R}^\#_{\rm lp} - \mathcal{R}^\#)h||_{H^0_{\rm lp}} \le C(|\Delta_3|^{o_3}||h||_{H^{o_3}_{\rm lp}} + |\Delta_2|^{o_2}||h||_{H^{o_2}_{\rm lp}} + |\Delta_1|^{o_1}||h||_{H^{o_1}_{\rm lp}}).$$

We end with a quantitative remark on the estimates above. The frequency content of quasi interpolators is, generally speaking, one at a neighborhood of zero and dies out for higher frequencies; cf. [21]. In principle they mimic sinc-interpolation, where the frequency content of the kernel is a box function centered at the origin. Thus, the error introduced by replacing the operator $\mathcal{R}^{\#}$ with $I_{\Delta_3}\mathcal{R}^{\#}I_{\Delta_2}$ is mainly due to what happens with Radon data far away from the origin. Now, consider the back-projection kernel of Figure 3.1. Apart from along the line $\mu = 0$, most of its energy lies in a neighborhood of the origin. As pointed out above, if data (limited to $s \in [\ln(a_m), 1]$) is smooth when represented in polar coordinates, it is smooth also in the log-polar representation. The fact that data is band-limited with respect to s in combination with the fast decay in the ω-direction should therefore keep the errors relatively small in practice.

4.3. Time complexity and implementation. Let us analyze Algorithm 4.1 in slightly more detail. The first filtering step is the same as in other filtered back-projection algorithms and can be implemented by p FFT operations of length $2q$ in time $\mathcal{O}(pq\log(q))$. At the first interpolation step, each interpolation $(I_{\Delta_1}h^{\nu})(\theta_j, \rho_i)$ consists of a weighted sum of $h(\theta_j, s_l)$ at points where s_l is within a kernel length distance from ρ_i. Hence this step is $\mathcal{O}(d_1pq') = \mathcal{O}(d_1p\kappa q)$, with d_1 the kernel length of I_{Δ_1}. Similarly, each interpolation from log-polar coordinates to a Cartesian $q \times q$-grid is made by a weighted sum, in both θ and ρ directions, giving a time complexity of $\mathcal{O}(d_3q^2)$, where d_3 is the kernel area of I_{Δ_3}. Assuming both d_1 and d_3 to be relatively small, and using the optimal relation between p and q in parallel beam geometry, $p = \frac{\pi q}{2}$ (cf. [14]), we arrive at a time complexity of $\mathcal{O}(q^2)$ for both interpolation steps.

Note that both for the interpolation weights above as well as for the computation of the kernel Z defined in (4.3), only geometry matters; i.e., these can be precomputed to save time. What remains are then the two-dimensional FFT steps. Taking into account the needed zero-padding, $2m$ two-dimensional FFT operations of size $(\frac{2p}{m} \times q')$ are required. This is performed in time $\mathcal{O}(pq\log(pq)) = \mathcal{O}(q^2\log(q))$, i.e. at the same complexity as other fast reconstruction methods. However, in comparison to, e.g., Fourier slice-reconstruction on a $q \times q$ grid, the constant of the leading term is worse. In principle this is due to oversampling factors of κ and 2 in the s and θ directions, respectively, and to the fact that both transformation and inversion are used. Together, this causes a worsening by a factor of about ten. However, that is in comparison with the most simple Fourier slice-reconstruction, with its well-known severe drawbacks in quality and without the effort of speeding up our proposed method (it is possible to use the zero-padded structure to decrease needed calculations). It should be added that more sophisticated slice-reconstruction schemes also require oversampling for accurate results.

Throughout section 4.1 we worked with quasi interpolators. The structure of Algorithm 4.1 easily incorporates usage of the prefiltering required by, e.g., spline interpolators discussed in section A. Required prefiltering for I_{Δ_1} can thus be included in w_b of (4.1), and prefiltering needed for I_{Δ_2} and I_{Δ_3} can be included in Z, defined by (4.3). This allows the usage of spline interpolators without increasing the computational cost, and thus allows higher interpolation orders than the ones achieved by interpolators of the same kernel length.

4.4. Simulations. Finally, let us look at some numerical results. In these simulations we have used cubic spline interpolators for I_{Δ_1}, I_{Δ_2}, and I_{Δ_3}; $m = 4$ partial reconstructions; $m_\beta = 3$; and $\kappa = 2$. The number of parallels and directions

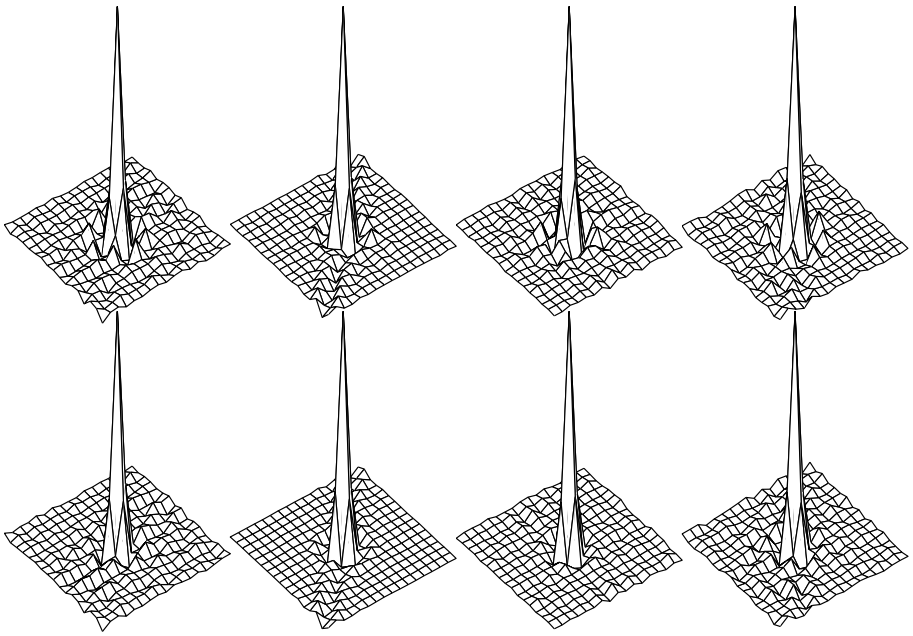

FIG. 4.1. *Impulse responses for log-polar (above) versus classical (below) back-projection at points* $(0.1233, 0.3816)$, $(0.0998, 0.0998)$, $(0.8004, -0.0020)$ *and* $(-0.3229, -0.2368)$, *respectively, from left to right.*

are $q = 512$ and $p = 768$, respectively. Furthermore, to limit the regularization impact from the choice of filter in the filtering step, the *Ram–Lak* filter suggested by Ramachandran and Lakshminarayanan in [17] is used. One of the most commonly used filters in CT is the *Shepp–Logan* filter. For purposes of noise-reduction, high frequency content is suppressed when using this filter, and the reconstructions obtained are somewhat smoothed. In the simulations presented below there is no noise present. We want to compare our proposed reconstruction method with the standard one, and the most honest way of doing this is without any smoothing present. The tests performed with the Ram–Lak filter are thus more unmasking than tests with the Shepp–Logan filter.

In, e.g., [11], analytic expressions are derived for the Radon transform of functions being characteristic functions of elliptical discs. We use such functions as reconstructions objects, since they allow us to sample the Radon data exactly.

To test the performance of our proposed method, we consider two types of test objects. First we use the characteristic function of small circles as approximations of delta functions, and then apply the *Shepp–Logan* phantom, described in [11], to analyze an artificial slice of a head built up by characteristic functions of ellipses.

In Figure 4.1 are shown impulse responses at four different points for log-polar and classically computed back-projection. The reconstructions show quite high resemblance to one another. Reconstruction on a Cartesian grid makes the impulse response vary slightly, depending on the placement of the impulse. Recall that the responses usually are wider and smoother when the ordinary filters (such as the Shepp–Logan filter) of the filtering step are used.

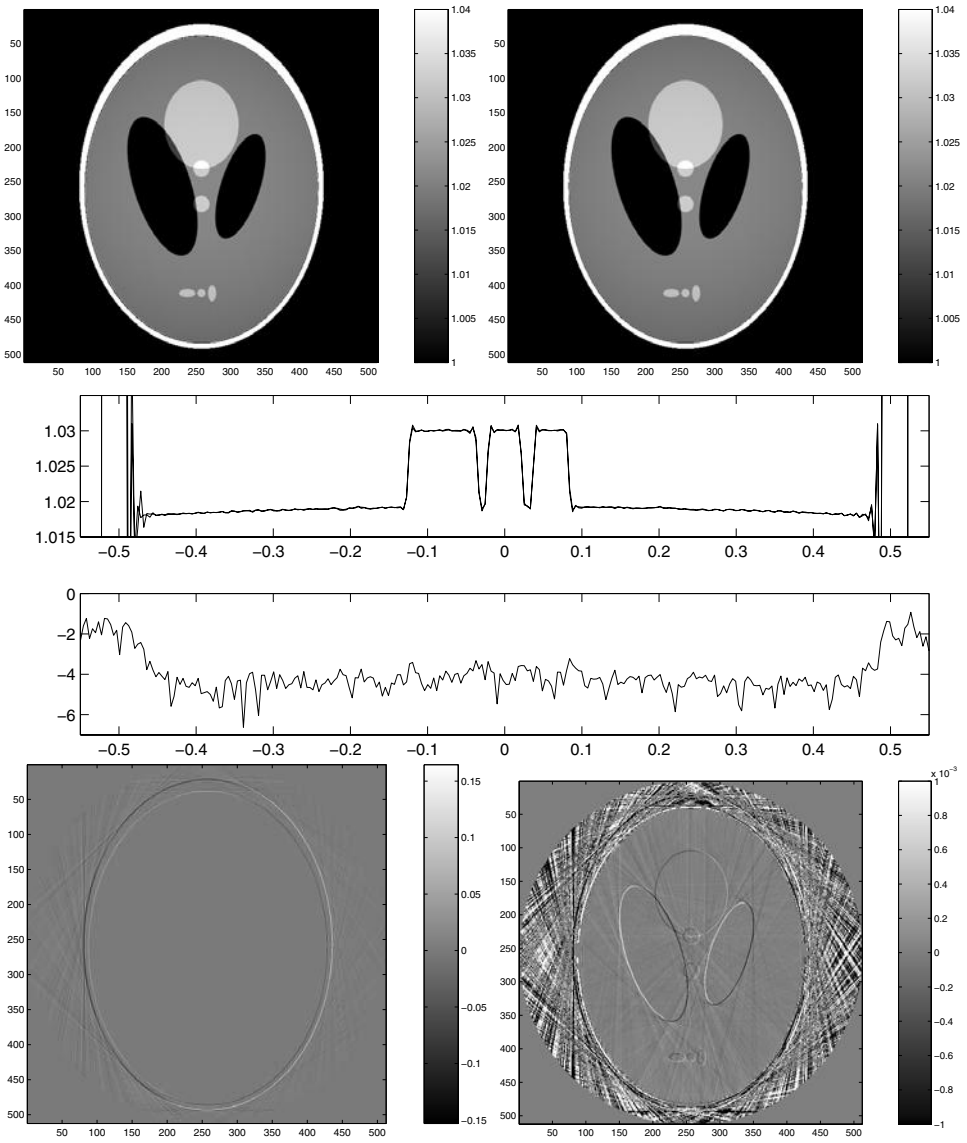

FIG. 4.2. *Upper left shows reconstruction using log-polar coordinates, upper right classical reconstruction. The two plots at center show comparisons between the two reconstructions along a horizontal line, where the upper one show their values, and the lower one their difference in* $\log_{10}$*-scale. The two lower images show the difference between the two reconstructions at different scales.*

Next we turn our attention to the Shepp–Logan phantom; cf. Figure 4.2. The true head phantom carries an intensity of 1.02 at its inner part, a border of intensity 2.0, "eyes" at 1.0, and additional ellipses at 1.03 (except at intersections). The two top images of Figure 4.2 show reconstruction by log-polar (right) and traditional (left) back-projection. Visually they appear to be identical, and it is hard to draw further conclusions. For a better perspective, we have chosen to plot the two reconstructions along a horizontal line through the "mouth" part of the phantom. This is shown

in the upper plot of Figure 4.2. More precisely the values of the two reconstructions along row 410 have been plotted. Except for minor disparities at the points of discontinuity, visually the two reconstructions agree completely. The (absolute) difference between the two reconstructions has therefore been plotted in $\log_{10}$-scale in the lower of the plots in Figure 4.2. This illustrates the high accuracy of our proposed method, compared to standard methods of higher complexity. For comparison, similar plots of the "mouth" part are made in [6], but there, differences between the different reconstruction methods investigated can be seen in the (linear scaled) plots.

For further comparison, the differences between the two reconstructions are shown as images below in Figure 4.2, with different intensity scales. The left panel displays differences in the reconstruction of the high intensity border around the skull. At right we can also see differences at the other discontinuity parts, but note the low intensity span. This image also clearly shows a slightly inhomogeneous assembling of lines outside the head, an effect of the different techniques used.

5. Conclusion. In this paper we have made use of the invariance properties of the Radon transform and its dual to construct a method of inversion based on log-polar representations. An analysis of the continuous case as well as analytical expressions for the kernels have been presented. To deal with the nonuniformity of the discrete case, the concept of partial reconstructions was introduced. The nonuniformity also enforces the discrete reconstruction developed to rely on interpolation. Fortunately, these can be invoked in the reconstruction procedure, for construction of a fast and accurate back-projection algorithm, based on use of the (uniform) two-dimensional FFT. The algorithm presented has a time complexity of $\mathcal{O}(q^2 \log(q))$, the same as those of other fast reconstruction algorithms. From the tests presented in this paper, the accuracy of the method seems to be of the same order as the traditional back-projection algorithms, having time complexity $\mathcal{O}(q^3)$.

Appendix. Some properties of convolution interpolators. According to the Whittaker–Shannon sampling theorem, for any b-band-limited function f, i.e., a function with a Fourier transform $\hat{f}(\xi)$ vanishing for $|\xi| > b$, it is possible to reconstruct f given the uniformly sampled values of f at $x_k = kT$, where $T = \pi/b$, $k \in \mathbb{Z}$. The reconstruction formula reads as

$$f(x) = \sum_{k\in\mathbb{Z}} f(x_k)\mathrm{sinc}(x - x_k). \tag{A.1}$$

A drawback of this *sinc*-based interpolation is the slow decay of the sinc-function. The sinc-interpolation is an example of convolution-based interpolation for uniformly sampled data:

$$I_T f(x) = \sum_{j\in\mathbb{Z}} c_j[f]\varphi\left(\frac{x}{T} - j\right), \tag{A.2}$$

a semidiscrete convolution of a set of coefficients and an interpolation kernel φ. The coefficients $c_j[f]$ are generally obtained from

$$c_j^T[f] = \mu\left(f\left(\frac{\cdot + j}{T}\right)\right), \tag{A.3}$$

where μ is a linear functional. For an overview of convolution-based interpolation, see [13]. The operator I_T is said to be an *interpolator* (sometimes referred to as cardinal interpolator) if $I_T f$ coincides with f at the sample points.

In some cases it is of more interest if I_T manages to reconstruct polynomials of a certain order correctly. To this end, I_T is said to be a *quasi interpolator* of order p if it successfully interpolates all polynomials of degree $p-1$. In order to construct a quasi interpolator of order p from an interpolation kernel φ, φ must satisfy the *Strang–Fix Conditions*; cf. [20]. Of course, there are additional requirements on the coefficients $c_j[f]$.

In this paper, the error estimates in approximating a function by (A.2) are carried out in Sobolev-norms, where $H^\gamma(\mathbb{R}^n)$ or H^γ of real order γ consists of the functions f such that

$$||f||_{H^\gamma}^2 = \sum_{|\alpha|\leq\gamma} ||D^\alpha f||_{L_2(\mathbb{R}^n)}^2 \quad \text{is finite,} \tag{A.4}$$

where

$$D^\alpha f = \left(\frac{\partial}{\partial x_1}\right)^{\alpha_1} \cdots \left(\frac{\partial}{\partial x_n}\right)^{\alpha_n}, \quad \alpha = (\alpha_1, \ldots, \alpha_n).$$

The following theorem is a somewhat weaker version of Theorem 2.2 in [5].

THEOREM A.1. *Let I_T be a quasi interpolator of order p, defined by (A.2), where φ satisfies the Strang–Fix conditions and, in addition, φ and μ of (A.3) satisfy the conditions given in Theorem* 2.1 *in* [5]. *Then for $f \in H^p$ the following estimate holds:*

$$||f - I_T f||_{H^0} \leq C|T|^p ||f||_{H^p}. \tag{A.5}$$

An important type of interpolators are the spline interpolators [18], [19]. The B-spline kernel of order m is defined by

$$\varphi_{B^m} = \left(\frac{1}{2}\chi_{[-\frac{1}{2},\frac{1}{2}]} + \frac{1}{2}\chi_{(-\frac{1}{2},\frac{1}{2})}\right) * \cdots * \left(\frac{1}{2}\chi_{[-\frac{1}{2},\frac{1}{2}]} + \frac{1}{2}\chi_{(-\frac{1}{2},\frac{1}{2})}\right) \quad (m+1 \text{ factors}).$$

It is readily verified that φ_{B^m} consists of piecewise polynomials of degree m, and that it is supported in $(-\frac{m+1}{2}, \frac{m+1}{2})$.

A quasi interpolator of order m can be constructed with φ_{B^m} as interpolation kernel, and with

$$c_k[f] = \sum_{j\in\mathbb{Z}} b_k f(x_{j-k}), \tag{A.6}$$

where

$$\sum_{k\in\mathbb{Z}} b_k e^{-i\xi k} = \frac{1}{\sum_{k\in\mathbb{Z}} \varphi_{B^m}(k) e^{-i\xi k}}, \quad \xi \in \mathbb{R}.$$

This follows, e.g., from [12], [21]. The construction of the coefficients $c_k[f]$ in (A.6) can be interpreted as a prefiltering step, which preferably is computed by means of FFT. Note that since the support of the B-spline kernel is relatively short, the number of terms needed in (A.2) are relatively few. Hence, an accurate interpolation procedure can be constructed which, in contrast to the sinc-interpolation of (A.1), requires data in only a small neighborhood around the point of evaluation.

ON THE DESIGN AND ANALYSIS OF INFLATED MEMBRANES: NATURAL AND PUMPKIN SHAPED BALLOONS*

FRANK BAGINSKI†

Abstract. Large scientific balloons are used by NASA and the space agencies of many countries to carry out research in the upper stratosphere. Such a balloon typically consists of a thin plastic shell with several external caps. Load tendons run the length of the balloon from top fitting to bottom fitting, dividing the balloon into identical regions called gores. The gores are made from flat panels of 20–30 μm polyethylene film that are sealed edge-to-edge to form the complete shape. A typical fully inflated shape can be over 120 meters in diameter and over 1 million cubic meters in volume. To date, the workhorse of NASA's balloon program has been the zero-pressure natural shape balloon, an axisymmetric onion-like design that dates back to the 1950s. The equilibrium equations at float for a natural shape balloon lead to a nonlinear boundary value problem that can be solved to determine the design shape. In recent years, demand for long duration midlatitude balloon flights has led to a design concept known as the pumpkin balloon. A number of ad hoc approaches based on crude approximations of equilibrium have been put forth that lead to pumpkin-like balloon shapes. In this paper, we derive equilibrium equations for a pumpkin balloon. We also present a brief review of balloon models that follow from the axisymmetric membrane theory. Numerical solutions are included.

Key words. high altitude balloons, inflated membranes

1. Introduction.

Balloons play an important role in NASA's current scientific investigations, including upper atmosphere research, high energy astrophysics, stratospheric composition, meteorology, and astronomy. With the development of the ultra long duration balloon and the possible uses of balloons in the exploration of planets in our solar system, balloons will play an important role in NASA's future scientific endeavors.

A high altitude large scientific balloon is normally designed to carry a payload of instruments to a certain altitude and then to maintain constant altitude while the science is carried out. The theoretical shape of a fully inflated high altitude balloon at float altitude is called the design shape. The design shape is normally modeled as an inextensible membrane. Quantities such as film weight density w_f, payload L, specific buoyancy of lifting gas b, circumferential stress σ_c, and differential pressure at the base of the balloon p_0 are parameters that affect the final shape. An axisymmetric model commonly used for applications to large scientific balloons is the *natural shape* model, which assumes that $\sigma_c = 0$, i.e., that all tension is meridional. When $p_0 = 0$ in the natural shape model, we have the so called *zero-pressure natural shape* (ZPNS) balloon (see Figure 1.1(a)), a design that NASA flies regularly in its scientific balloon program. Venting ducts open to the atmosphere are located at the base of a ZPNS balloon. During daylight, when the balloon envelope and lifting gas are heated, excess gas is vented through these ducts. At night, when the gas cools and the volume

(a) Zero-pressure natural shape (b) Pumpkin shape

FIG. 1.1. *A* 20*-gore zero-pressure natural (onion-)shape balloon and a* 20*-gore pumpkin balloon.*

of the balloon decreases, ballast is dropped to maintain altitude. The number of diurnal cycles limits ZPNS balloons to midlatitude flights of a few days due to ballast limitations. ZPNS flights of several weeks have been achieved in Antarctica where day/night diurnal cycles can be avoided during certain times of the year. One way to avoid carrying significant ballast is to design a balloon that can hold enough gas to maintain a positive differential pressure during the night and is strong enough to hold the overpressure caused by solar heating during the day. Thus, by reducing the volume variation over diurnal cycles, altitude excursions will be reduced and less ballast will be required during the life of the mission. This approach led to a design that has come to be known as the *pumpkin balloon* (see Figure 1.1(b)), a concept that goes back to the 1970s. While there have been a number of pumpkin-like balloon models proposed, many are based on ad hoc analysis and approximate equilibrium conditions. In this paper, we develop equilibrium equations for a pumpkin balloon based on a simplification of a *unishell* theory. As defined by Libai and Simmonds [17, p. 343], a unishell is a shell in which there is a system of coordinates (σ, τ) on the reference surface in which the components of the deformed metric and curvature tensors are independent of τ. In the case of a pumpkin balloon, we will develop a system of equilibrium equations that depend only on the arc-length of the generating curve for a tubular surface corresponding to one lobe of the pumpkin shape. We formulate the equilibrium equations for a pumpkin balloon in the deformed configuration and derive a set of nonlinear ordinary differential equations (ODEs). The ODEs can be solved to determine the generating curve for the tubular surface defining the pumpkin balloon.

The original work on high altitude plastic balloons was carried out in the 1950s at the University of Minnesota, where the term natural shape balloon emerged (see [1]). In the 1960–70s, Justin Smalley did extensive work on axisymmetric balloon shapes (see e.g., [22], [23], [24]). He extended the natural shape model to handle a number of related axisymmetric cases, and implemented these mathematical models on a digital computer. Even though many axisymmetric balloon models are discussed in the literature, most follow from the natural shape equations. For the convenience of the reader, we will present a brief review of axisymmetric membrane models. By choosing parameters in the axisymmetric model in a certain way, we are led to various balloon models, including the ZPNS balloon, the super-pressure natural shape balloon, the Σ-shape, the Euler-elastica, and others. For an axisymmetric shape with $\sigma_c \neq 0$, we present one model whose solutions give rise to Delaunay surfaces (the spherical balloon is a special case).

The idea behind the pumpkin balloon is to use a light film as a gas barrier together with strong reinforcing tendons for both pressure confinement and to carry the weight of the balloon system. Roughly speaking, the shape of the pumpkin gore transfers much of the film stress to the load tendons. The term pumpkin balloon was coined by Smalley in his original work on the *e-balloon* (a model whose governing equations are the same as those for the Euler–Bernoulli elastica; "e" is for Euler). Smalley's original idea was to use the straining in an inflated gore to form a doubly curved surface. When fully pressurized, the balloon would take on the appearance of a pumpkin-like shape (see [25]). Shortly after Smalley's work on the e-balloon, the French carried out work on pumpkin balloons (see, e.g., [20]). There have been many variants on the pumpkin design. One notable effort in the 1980s was the *Endeavour* of Julian Nott in the race for the first circumnavigation of the globe. The *Endeavour* was a 64 gore *constant bulge shape design*; i.e., the angular width of the circular arc of a lobe was constant. There were some deployment problems related to this design (see section 3 for further details). The Japanese have studied pumpkin balloons (see, e.g., [26]), introducing cinching techniques in sewing to achieve a pressurized pumpkin shape. Using a *constant bulge radius design* and a tendon-based theory, Schur was the first to give a more analytical treatment of the pumpkin balloon (see [21]).

In ad hoc approaches to pumpkin balloons, it is usual to assume that the tendon profiles are known a priori from axisymmetric models (like those discussed in section 2). While this may be adequate as a rough first approximation, it is straightforward to model the pumpkin gore as a tubular surface and derive the generating curve for the pumpkin gore as the solution of a set of equilibrium equations. The formulation of a membrane model for a pumpkin gore is presented in section 3. Our formulation introduces the number of gores n_g and the bulge radius r_B as additional design parameters in the model equations.

It should be noted that a number of underlying assumptions made to determine shapes are sometimes violated in the real balloon. For example, the assumption of zero circumferential stress cannot hold in a real ZPNS balloon that is elastic: once it is pressurized, the hoop and meridional stresses will be nonzero and roughly the same order of magnitude in the upper portion of the balloon. Moreover, the ZPNS model assumes an axisymmetric surface of revolution, while the real balloon is constructed from long flat panels of film. This is not a problem, due in part to the compliant nature of polyethylene. Decades of successful ZPNS flights demonstrate the effectiveness of the ZPNS balloon.

The real ZPNS balloon has a curved unstrained reference configuration (bend a flat panel so that a developable surface spans the region between adjacent tendons). There is no such analogous unstrained/unwrinkled state of a three dimensional pumpkin balloon that is constructed from flat panels of film. This poses some complications in the construction process and is discussed in section 3. In this paper, our analysis assumes that the material is inextensible. However, we refer the reader to the literature for more on the subject of strained elastic balloons (see, [3], [6], [9], and the references therein).

The remainder of this paper is divided into four sections. In section 2, we provide some historical background on models that have been used in the design of scientific balloons. The most common models are derived from the equations for an axisymmetric membrane, and we establish connections between a number of special models. In section 3, we propose a model for a pumpkin balloon that reduces to a system of ODEs. In section 4, we present numerical solutions and also discuss some aspects of

TABLE 1.1
Design parameters.

Description	Variable	Value
Bulge radius (pumpkin only)	r_B	0.1066 m
Weight of top fitting	L_1	8.45 N
Radius of top/bot fittings	r_1	0.10 m
Number of gores	n_g	96
Tendon weight density	w_t	0.03 N/m
Film weight density	w_f	0.344 N/m^2
Payload	L_0	283 N
Buoyancy at design altitude	b_d	3.441 N/m^3
Buoyancy at sea level	b_0	10.258 N/m^3

the various balloon shape models. Table 1.1 contains design parameters that were used to generate shapes presented in this paper.

2. Axisymmetric membrane models for a balloon. First, it is instructive to consider the problem of "designing" an inextensible spherical balloon. Suppose that we wish to determine the radius R of a spherical balloon that must carry a weight L_0 at a constant design altitude. The density of the lifting gas ρ_g and the density of the atmosphere ρ_a are assumed to be known at the design altitude. Archimedes' Principle states that a balloon enclosing a gas volume V of density ρ_g will exert a net upward force (lift) that is equal in magnitude to the difference between the weight of the displaced air and the weight of the lifting gas, i.e.,

$$\text{Lift} = g\rho_a V - g\rho_g V.$$

The specific buoyancy of the lifting gas is $b = \frac{\text{Lift}}{V} = g(\rho_a - \rho_g)$, where b has the dimensions of force per volume. In our example, the balloon is assumed to be made of a single layer of film with weight density w_f. We assume that n load tendons of weight density w_t run from top to bottom of the balloon. From Archimedes' Principle, we know that a spherical balloon of radius R in equilibrium must satisfy

$$\frac{4}{3}b\pi R^3 = 4w_f\pi R^2 + nw_t\pi R + L_0. \tag{2.1}$$

Solving for R, we find the spherical design shape. It is not difficult to show that there is exactly one solution of (2.1) with $R > 0$ (see [7]). Finding the natural shape or a pumpkin shape is more involved. From force balance equations at float, a system of ODEs can be derived. Solving the ODEs yields the design shape.

2.1. Equilibrium equations for an axisymmetric membrane. The equations for a natural balloon shape were first derived by researchers at the University of Minnesota (see [1]). These equations and other related models are presented in [15, section V]. In [8], design and ascent shapes for axisymmetric membranes are considered for constant film weight density (i.e., the Σ-shape equations). In [7], the film weight density included contributions from external reinforcing caps and load tapes. For convenience, we present a synopsis of the equilibrium equations for an axisymmetric membrane. We choose a coordinate system such that the nadir of the balloon is located at the origin.

Since we seek axisymmetric solutions, we need to find a generating curve $s \to (z(s), r(s))$, where s is the arc-length. Let ℓ_d be the total length of the generating curve. The surface of the balloon $\mathcal{S}$ can be parametrized by $\mathbf{x}(s,\phi)$, where

$$\begin{aligned} \mathbf{x}(s,\phi) &= r(s)\mathbf{e}_1(\phi) + z(s)\mathbf{k}, \quad 0 < s < \ell_d, 0 \le \phi < 2\pi, \\ \mathbf{e}_1(\phi) &= \cos\phi\mathbf{i} + \sin\phi\mathbf{j}, \quad 0 \le \phi \le 2\pi. \end{aligned} \tag{2.2}$$

The set $\{\mathbf{e}_1(\phi), \mathbf{e}_2(\phi), \mathbf{k}\}$ is an orthonormal basis for $\mathbb{R}^3$, where $\mathbf{e}_2(\phi) = \mathbf{k} \times \mathbf{e}_1(\phi) = -\sin\phi\mathbf{i} + \cos\phi\mathbf{j}$. The balloon's shape is defined by $\mathcal{S} = \{\mathbf{x}(s,\phi) \mid s \in [0,\ell_d], \phi \in [0,2\pi]\}$. At each point along the curve, $s \to \mathbf{x}(s,\phi)$, the tangent vector is given by

$$\mathbf{t}(s,\phi) = \frac{\partial \mathbf{x}}{\partial s}(s,\phi) = \sin\theta(s)\mathbf{e}_1(\phi) + \cos\theta(s)\mathbf{k},$$

where $\theta(s)$ is the angle between $\mathbf{t}$ and $\mathbf{k}$, $z'(s) = \cos\theta(s)$, and $r'(s) = \sin\theta(s)$. The inward normal is $\mathbf{b}(s,\phi) = \mathbf{t} \times \mathbf{e}_2(\phi) = -\cos\theta\mathbf{e}_1(\phi) + \sin\theta\mathbf{k}$. Because the balloon is modeled as a membrane, we can ignore all stress couples. Under the assumption of axisymmetry, we can write the contact forces as

$$\begin{aligned} \mathbf{n}_1(s,\phi) &= \sigma_m(s)\mathbf{t}(s,\phi), \\ \mathbf{n}_2(s,\phi) &= \sigma_c(s)\mathbf{e}_2(\phi), \end{aligned}$$

where σ_m is the meridional stress resultant and σ_c the circumferential stress resultant. The forces acting on a curvilinear patch $\mathcal{A} \subset \mathcal{S}$ are the internal forces, $\mathbf{n}_1(s,\phi)$ and $\mathbf{n}_2(s,\phi)$, and the external forces,

$$\mathbf{f}(s,\phi) = -p(s)\mathbf{b}(s,\phi) - w(s)\mathbf{k},$$

where p is hydrostatic differential pressure and w is the balloon film weight density. All external forces are measured per unit area in the deformed configuration. Balancing the forces that act on $\mathcal{A}$, we are led to the following equilibrium equations (see [7]):

$$\frac{\partial}{\partial s}(r\sigma_m\mathbf{t}) - \sigma_c\mathbf{e}_1(\phi) + r\mathbf{f} = \mathbf{0}. \tag{2.3}$$

If we carry out the differentiation in (2.3) and project the result onto $\mathbf{t}$ and $\mathbf{b}$, we obtain

$$(r\sigma_m)\frac{d\theta}{ds} = \sigma_c\cos\theta - rw\sin\theta - rp, \tag{2.4}$$

$$\frac{d}{ds}(r\sigma_m) = \sigma_c\sin\theta + rw\cos\theta, \tag{2.5}$$

respectively. Equations (2.4)–(2.5) are in agreement with those in [1, Vol. I, p. 3-2, (6)–(7)].

The hydrostatic pressure can be written as $p = bz + p_0$, where p_0 is the pressure at the base of the balloon ($z = 0$) and $b = g(\rho_a - \rho_g)$. While b is assumed to be known as a function of altitude, it depends on a number of other parameters such as air and gas temperatures. A natural shape balloon derived under the assumption $p_0 = 0$ is called a *ZPNS* balloon. If $p_0 > 0$, we refer to the corresponding shape as a

superpressure natural shape balloon (SPNS balloon). At the bottom of a zero-pressure balloon are venting ducts which are open to the atmosphere. A superpressure balloon is sealed.

2.2. The natural shape model equations ($\sigma_c = 0$). In this section, we formulate the natural shape model (i.e., $\sigma_c = 0$). It is convenient to define the total film load T in the meridional direction, i.e., $T = 2\pi r\sigma_m$. Multiplying (2.4)–(2.5) by 2π, substituting T for $2\pi r\sigma_m$, and setting $\sigma_c = 0$, we have

$$\begin{aligned}\theta'(s) &= \frac{-2\pi r\,(w\sin\theta + p)}{T},\\ T'(s) &= 2\pi r w\cos\theta.\end{aligned}$$

For applications considered here, we will assume that a load L_0 is suspended from the base of the balloon. In addition, we assume that the balloon is attached to a circular disk of radius r_0 at the bottom and disk of radius r_1 at the top. In a superpressure balloon, a force of magnitude $p_0\pi r_0^2$ acts on the bottom end-cap. Thus,

$$\cos\theta_0 T(0) = L_0 + p_0\pi r_0^2, \tag{2.6}$$

where $p_0 \geq 0$, $\theta(0) = \theta_0$, and θ_0 is one-half the "cone-angle" at the base of the balloon. Note that θ_0 is not known a priori and must be computed based on certain parameter values and boundary conditions.

The governing differential equations for a natural shape balloon in terms of T are

$$\theta'(s) = \frac{-2\pi r(w\sin\theta + p)}{T}, \tag{2.7}$$

$$T'(s) = 2\pi r w\cos\theta, \tag{2.8}$$

$$z'(s) = \cos\theta, \tag{2.9}$$

$$r'(s) = \sin\theta. \tag{2.10}$$

The initial conditions for (2.7)–(2.10) are

$$\begin{aligned}\theta(0) &= \theta_0,\\ T(0) &= \frac{(L_0 + \pi r_0^2 p_0)}{\cos\theta_0},\\ z(0) &= 0,\\ r(0) &= r_0.\end{aligned} \tag{2.11}$$

For a given pair (θ_0, ℓ), (2.7)–(2.10) can be integrated over the interval $0 < s < \ell$ beginning with the initial conditions in (2.11). Using a shooting method, one determines $(\theta_0, \ell) = (\theta_d, \ell_d)$ and the functions $\theta(s;\theta_d,\ell_d)$, $T(s;\theta_d,\ell_d)$, $z(s;\theta_d,\ell_d)$, and $r(s;\theta_d,\ell_d)$ that satisfy (2.7)–(2.10), and

$$\begin{aligned}\cos\theta_1 T(\ell_d;\theta_d,\ell_d) &= -L_1 + \pi r_1^2 p_1,\\ r(\ell_d;\theta_d,\ell_d) &= r_1,\end{aligned} \tag{2.12}$$

where L_1 is the weight of the top fitting, $\theta_1 = \theta(\ell_d;\theta_d,\ell_d)$, $z_1 = z(\ell_d;\theta_d,\ell_d)$, and $p_1 = bz_1 + p_0$. Note that when $L_1 > 0$, we expect $-\pi < \theta_1 < -\frac{1}{2}\pi$. With $p(z) = bz + p_0$, such a solution automatically satisfies Archimedes Principle. If we project (2.3) onto the **k** direction, multiply by 2π, integrate from $s = 0$ to $s = \ell_d$, and use the identity

$$r(bz + p_0)\frac{dr}{ds} = \frac{1}{2}\frac{d}{ds}\left(r^2(bz + p_0)\right) - \frac{1}{2}br^2\frac{dz}{ds},$$

we obtain $T(\ell_d)\cos\theta_1 - T(0)\cos\theta_0 = 2\pi\int_0^{\ell_d} wrds - b\mathcal{V}$. After rearranging terms and using (2.11) and (2.12), we observe that Archimedes Principle is satisfied; i.e.,

$$L_1 + L_0 + \pi(p_1 r_1^2 - p_0 r_0^2) + W_B = b\mathcal{V}, \tag{2.13}$$

where W_B is the total weight of the balloon system (balloon shell, caps, and load tapes).

In the natural shape model presented in [8], the weight of the caps and load tapes were added to the payload. The model presented here follows the approach in [7], where a variable film thickness and tendons are introduced. Here, we assume that the balloon system includes one cap that is modeled as an added thickness. The length of the cap is denoted by c_1 and is assumed to be known. For a given ℓ, let $s_1 = \ell - c_1$. This means that $w(s_1+0) \neq w(s_1-0)$ and $d\theta/ds$ and dT/ds are discontinuous at s_1. The number of gores in a complete shape is n_g.

For shape determination, we assume that the tendon weight is distributed uniformly over the circumference of the balloon and is incorporated by modifying w appropriately. We divide $n_g w_t$ by $2\pi r(s)$ for $0 < s < \ell$ to get the average weight density of load tape (tendon) with respect to area. We define the *effective film weight density*,

$$w(s) = w_f(s) + w_t(s), \quad 0 < s < \ell, \tag{2.14}$$

where $w_t(s) = n_g w_{tape}/(2\pi r(s))$, $0 < s < \ell$,

$$w_f(s) = \begin{cases} w_s, & 0 \le s \le s_1, \\ w_s + w_c, & s_1 < s \le \ell, \end{cases}$$

w_s is the weight density of a single layer of balloon film, and w_{tape} is the load tape weight density. Additional caps with different weight densities can be incorporated easily. As a structural element, a load tendon and load tape behave very differently. However, for a statically determinate balloon, weight is the only consideration that is relevant.

In previous work (see, e.g., [7]), we handled the discontinuity in the effective film weight density by using a parallel shooting method to break the integration of (2.7)–(2.10) into subintervals. Doing so, we see that all functions are continuously differentiable on each subinterval. Existence of solutions obtained by the shooting method follows from standard arguments (see, e.g., [14]).

2.3. Axisymmetric balloon models related to the natural shape. In the following subsections we present a number of balloon models that are based on the natural shape equations (2.7)–(2.10). See [4] for further discussions on balloon models.

2.3.1. ZPNS balloons.

Constant film weight density (Σ-shapes). In the early days of scientific ballooning and before digital computers were readily available, balloon designers relied on the Σ-shape model. Assuming $p_0 = 0$ and $w(s) = w_s$ in (2.7)–(2.10), one finds that the resulting equations can be rescaled in a convenient way using parameters λ and Σ (see [15, p. V-8]), where $\lambda^3 = L_0/b$, $\Sigma = (2\pi/L_0)^{1/3}(\mathcal{V}_d/G)^{2/3} w_s$, G is the gross weight of the system, and $\mathcal{V}_d$ is the volume of the balloon at float. For this reason, the resulting shapes were called Σ-shapes. See [8] for a discussion on Σ-shapes and related axisymmetric ascent shapes for which the volume $\mathcal{V} \le \mathcal{V}_d$. See [1] and [15] for more on Σ-shapes. The Σ-shape equations were first solved using an analog

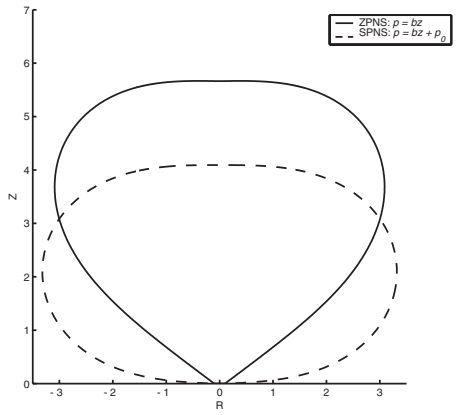

FIG. 2.1. *Comparison of ZPNS and SPNS balloon profiles.*

computer (see [1]). Using a set of tables with various values of λ and Σ, the balloon designer could look up the appropriate value of θ_0 and determine the gore length in terms of λ.

Nonconstant film weight density. When $w(s) = w_f(s) + w_t(s)$ is the effective film weight density, this model will yield a shape that, in general, is slightly shorter and fatter than the one determined by the Σ-shape model (see [7]). When $w(s)$ is not constant, then the basic equations cannot be rescaled as was done for the Σ-shapes. Smalley was the first to use a digital computer in the analysis of balloon shapes, and carried out extensive research and development of other related models (see, e.g., [22], [23], [24], [25]). Variants of this model are used in the design and manufacture of high altitude zero-pressure balloons.

2.3.2. Superpressure balloons. High altitude balloons are very sensitive to temperature changes that are experienced during a day/night cycle. A ZPNS balloon will lose significant altitude during the evening when the lifting gas cools and its volume contracts. On the other hand, the lifting gas will expand during the day when the balloon is heated by the sun. To reduce volume fluctuations, one idea is to overpressurize the balloon in such a way that the differential pressure at the nadir is positive for all conditions (day/night, clear/cloudy, etc.). While the axisymmetric inextensible membrane theory suggests that a SPNS balloon might work, a stress analysis of an elastic SPNS balloon shows that when p_0 is too large, the corresponding stress resultants for currently available films would be outside the safe operating range (see [3]). In some ad hoc approaches to the pumpkin balloon, the tendons are assumed to lie along the trace of the generating curve of a SPNS balloon, and so for completeness we include results on SPNS balloons.

SPNS balloons. In a superpressurized natural shape balloon, we include $p_0 > 0$ as an additional design parameter and solve (2.7)–(2.10) to compute the balloon shape. Compared to the zero-pressure design, the superpressure natural shape balloon is, in general, shorter and wider (see Figure 2.1).

Euler elastica and the e-balloon. In this model, it is supposed that $bz_1 \ll p_0$ near float. We neglect film and load tape weight contributions in the ODEs, and set $p = p_0$ for shape determination. Weight contributions due to the load tapes, film, and caps are added to the payload. The length of the generating curve must be chosen so

that $b\mathcal{V}$ is equal to the weight of the balloon system. In particular, setting $b = 0$ and $w = 0$ in (2.7)–(2.10), we find that T must be constant and $\theta'(s) = -2\pi r p_0/T$. Setting $T = T_0$ and differentiating this result, we find $\theta''(s) = -2\pi p_0 r'(s)/T_0$ and

$$\theta'' + 2\tau \sin\theta = 0, \tag{2.15}$$

where $\tau = \pi p_0/T_0$. In this model, T_0 is the total tension. Typical boundary conditions that are used in conjunction with (2.15) are

$$\theta'(0) = \theta'(\ell) = 0. \tag{2.16}$$

For each ℓ, there is a one parameter family of shapes parametrized by θ_0. Equation (2.15) can be solved explicitly in terms of elliptic functions. Following Smalley's discussion in [25], we note that the radial component of the generating curve for the e-balloon is

$$r^2(\theta) = \tau^{-1} \sin\left(\frac{1}{2}\pi - \theta\right). \tag{2.17}$$

An expression for z can be found by integrating the appropriate differential equation or by using elliptic functions (see [16]). In [18], the problem of constructing a mylar balloon from two circular disks is considered. While this approach is not practical for large balloons, the shapes of [18] are not unrelated to the Euler-elastica balloon discussed here and the Delaunay surfaces discussed in the following section.

In Figure 2.1, we present axisymmetric balloon designs based on the ZPNS and the SPNS models. Design parameters and related quantities are presented in Tables 1.1 and 2.1. Numerical results will be discussed in more detail in section 4.

TABLE 2.1
Design values.

(a) Axisymmetric shapes

Description	ZPNS	SPNS	Elastica
Nadir pressure (Pa)	0	200	200
Base angle (deg)	53.21	87.74	87.23
Height (m)	5.664	4.091	4.153
Diameter (m)	6.178	6.638	6.690
Tendon length (m)	8.988	8.547	8.628
Volume (m^3)	102.07	101.91	104.73
Surface area (m^2)	107.39	109.40	111.32
Skin weight (N)	36.91	37.60	0
Tape weight (N)	25.89	24.62	0
Load (N)	280	280	353

(b) Pumpkin shape: $r_B = 0.1066$ m and $p_0 = 200$ Pa

Description	$\sigma_c = 0$ N/m	$\sigma_c = 10$ N/m
Base angle (deg)	87.75	85.94
Height (m)	4.178	4.234
Diameter (m)	6.691	6.694
Volume (m^3)	104.15	104.46
Surface area (m^2)	133.50	133.7
Skin weight (N)	45.89	45.96
Tendon weight (N)	24.48	24.52
Tendon length (m)	8.501	8.513
Flat Tendon length (m)	8.662	8.674
Mid gore length (m)	8.659	8.668

2.4. Axisymmetric balloons with $\sigma_c \neq 0$. Smalley considered balloons with nonzero circumferential stress in [23]. A spherical balloon under a buoyant load is treated in [15, pp. V-19–V-21]. Balloons of this type have not been used as extensively as the natural shape for high altitude balloons.

If we eliminate s in the problem formulation and use z to parametrize the generating curve (i.e., $(r, z) = (r(z), z)$), we find that the curvature $\theta'(s)$ can be expressed as $r''/(\sqrt{1+r'^2})^3$, and we can replace (2.4)–(2.5) by the following:

$$\frac{rr''\sigma_m}{(\sqrt{1+r'^2})^3} = \frac{\sigma_c - wrr'}{\sqrt{1+r'^2}} - pr, \tag{2.18}$$

$$\frac{d}{dz}(r\sigma_m) = \sigma_c r'(z) + wr,$$

where $r'(z) = dr/dz$ (see [1, Vol. I, p. 3-2]). If the weight of the film and buoyancy are negligible (i.e., $w = 0$ and $b = 0$), and we set $p = p_0$, with σ_m and σ_c constant, then (2.19) is satisfied when $\sigma_c = \sigma_m$. Thus, if we let σ_f denote the common film stress resultant, we find that (2.19) can be expressed as

$$2\mathcal{H}r(\sqrt{1+r'^2})^3 = -rr'' + 1 + r'^2. \tag{2.19}$$

Equation (2.19) is the equation for a Delaunay surface with $\mathcal{H} = p_0/(2\sigma_f)$ (see [13, p. 107]). A Delaunay surface (see [10]) is a surface of revolution with constant mean curvature $\mathcal{H}$. Thus (2.19) should not have been a complete surprise. Any soap bubble, axisymmetric or otherwise, displays equal tension in all directions, and so the equation of normal equilibrium immediately leads to the condition that the mean curvature must be constant. For a sphere of radius R with constant pressure p_0, we find $\sigma_f = \frac{1}{2}p_0R$. If we set $w = 0$ and $\sigma_f = \frac{1}{2}Rp_0$, then we see $\theta(s) = \frac{1}{2}\pi - s/R, r(s) = R\cos\theta, z(s) = R - R\sin\theta$ satisfy (2.7)–(2.10), defining a sphere of radius R. A thorough discussion of Delaunay's surfaces can be found in [19, p. 115]. A number of interesting geometrical characterizations of Delaunay surfaces can be found in [12]. See also [18] for a related discussion on small mylar balloons.

3. Pumpkin shape.

3.1. Background. As a first approximation to a pumpkin-like shape, it is not uncommon to make ad hoc assumptions to simplify finding the shape (see, e.g., [25], [26]). For example, in a constant bulge radius approach the author in [21] assumes that a tendon follows the trace of the generating curve for a related SPNS balloon. If the number of gores is sufficiently high and the bulge radius is chosen appropriately, it is not unreasonable to suppose that the region between adjacent load tendons is spanned by circular arcs, forming a pumpkin-like balloon. In the constant bulge radius approach, one assumes that the tendon profiles are known. The tangent to the tendon profile is orthogonal to a plane containing a circle of radius r_B. The angular width of the circular arc is then determined. In the constant bulge shape approach, the angular width is assumed to be a constant value independent of s. Since it is straightforward to formulate the equations for a pumpkin gore, assuming a tubular surface geometry, we can avoid these ad hoc assumptions and obtain a model that is a better representation of the three dimensional pumpkin gore. We will discuss the merits and flaws of these various designs in section 2.3.1, but first we derive the ODEs for a pumpkin balloon.

3.2. Equilibrium equations for a pumpkin balloon. In this section, we derive the equilibrium equations for a pumpkin shape balloon as a membrane with the geometry of a tubular surface (see [17, Chapter VI] for a related discussion on unishells). While tubular surfaces with boundary are considered in other works (see, e.g., [2]), the balloon problem is somewhat simpler because we can ignore bending moments. We will assume that the pumpkin shape is made up of n_g symmetric pumpkin gores.

We begin with a curve, $\boldsymbol{\Upsilon}(s) = R(s)\mathbf{i} + Z(s)\mathbf{k} \in \mathbb{R}^3$, that we call the generator of the pumpkin gore. A priori, $\boldsymbol{\Upsilon} \in \mathbb{R}^3$ is unknown and must be derived from equilibrium conditions. The generator is parametrized by arc length s, i.e., $R'(s)^2 + Z'(s)^2 = 1$. Let $\mathbf{t}$ denote the unit tangent of $\boldsymbol{\Upsilon}$, $\mathbf{b}$ its inward unit normal ($\mathbf{j} = \mathbf{t} \times \mathbf{b}$), $\theta = \theta(s)$ is the angle between $\mathbf{t}$ and $\mathbf{k}$, and

$$\begin{aligned} \mathbf{t}(s) &= \sin\theta\mathbf{i} + \cos\theta\mathbf{k}, \\ \mathbf{b}(s) &= -\cos\theta\mathbf{i} + \sin\theta\mathbf{k}. \end{aligned}$$

Typically, $\theta(s)$ is decreasing in superpressure applications. The set $\{\mathbf{b}, \mathbf{t}, \mathbf{j}\}$ gives a right-hand curvilinear basis for $\mathbb{R}^3$. Since $\boldsymbol{\Upsilon}$ is a plane curve, its torsion is zero, and the Frenet equations reduce to

$$\begin{aligned} \mathbf{t}'(s) &= \kappa(s)\mathbf{b}(s), \\ \mathbf{b}'(s) &= -\kappa(s)\mathbf{t}(s), \end{aligned}$$

where κ is the curvature of $\boldsymbol{\Upsilon}$ (see [11, section 1.5]). We define a tubular surface in the following manner. Let

$$\mathbf{x}(s,v) = \boldsymbol{\Upsilon}(s) + r_B\left(-\mathbf{b}(s)\cos v + \mathbf{j}\sin v\right), \quad -\pi < v < \pi, \quad 0 < s < L_d, \tag{3.1}$$

and $x(s,v) = \mathbf{x}(s,v)\cdot\mathbf{i}$, $y(s,v) = \mathbf{x}(s,v)\cdot\mathbf{j}$, and $z(s,v) = \mathbf{x}(x,v)\cdot\mathbf{k}$.

In the following, we denote partial differentiation using subscript notation, e.g., $\mathbf{x}_s = \partial\mathbf{x}/\partial s$. By direct calculation, we have

$$\begin{aligned} \mathbf{x}_s(s,v) &= (1 + r_B\kappa(s)\cos v)\mathbf{t}(s), \\ \mathbf{x}_v(s,v) &= r_B\left(\mathbf{b}(s)\sin v + \mathbf{j}\cos v\right), \\ \mathbf{x}_s \times \mathbf{x}_v &= r_B(1 + r_B\kappa(s)\cos v)\left(\mathbf{b}(s)\cos v - \mathbf{j}\sin v\right), \end{aligned}$$

and $dA = r_B(1 + r_B\kappa\cos v)dsdv$. A unit vector normal to the tubular surface is

$$\mathbf{N}(s,v) = \frac{\mathbf{x}_s \times \mathbf{x}_v}{|\mathbf{x}_s \times \mathbf{x}_v|} = \mathbf{b}(s)\cos v - \mathbf{j}\sin v,$$

and the triple $\{\mathbf{x}_s, \mathbf{x}_v, \mathbf{N}\}$ gives a right-hand basis for $\mathbb{R}^3$.

By direct calculation, we have $\mathbf{N}_s(s,v) = -\kappa(s)\mathbf{t}(s)\cos v$ and $\mathbf{N}_v(s,v) = -\mathbf{b}(s)\sin v + \mathbf{j}\cos v$. The principal curvatures of the tubular surface are

$$\begin{aligned} \kappa_1(s,v) &= -\frac{\mathbf{N}_s\cdot\mathbf{x}_s}{\mathbf{x}_s\cdot\mathbf{x}_s} = \frac{\kappa\cos v}{1 + r_B\kappa\cos v}, \\ \kappa_2(s,v) &= -\frac{\mathbf{N}_v\cdot\mathbf{x}_v}{\mathbf{x}_v\cdot\mathbf{x}_v} = \frac{1}{r_B}. \end{aligned}$$

The tubular surface is sufficiently smooth if we assume (see [11, p. 399])

$$r_B\kappa_0 < 1, \quad \text{where} \quad \kappa_0 < \max_{0\le s\le L_d} |\kappa(s)|. \tag{3.2}$$

We find that the condition in (3.2) is met for our work on pumpkin balloons.

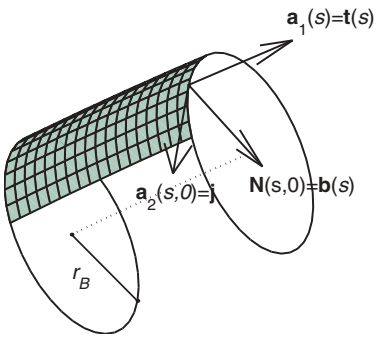

FIG. 3.1. *A patch of a pumpkin gore with* $\mathbf{a}_1, \mathbf{a}_2, \mathbf{N}$.

For the problems considered here, (3.2) is satisfied. A unit tangent to the curve $s \to \mathbf{x}(s, v)$ is

$$\mathbf{a}_1(s, v) = \frac{\mathbf{x}_s(s, v)}{|\mathbf{x}_s(x, v)|} = \mathbf{t}(s),$$

and a unit tangent to the curve $v \to \mathbf{x}(s, v)$ is

$$\mathbf{a}_2(s, v) = \frac{\mathbf{x}_v(s, v)}{|\mathbf{x}_v(s, v)|} = \mathbf{b}(s) \sin v + \mathbf{j} \cos v.$$

Note that $\partial \mathbf{a}_2 / \partial v = \mathbf{b}(s) \cos v - \mathbf{j} \sin v = \mathbf{N}$. In Figure 3.1, the geometry of a pumpkin gore patch is illustrated with the vectors $\{\mathbf{a}_1, \mathbf{a}_2, \mathbf{N}\}$ when $v = 0$. Arc length in the tubular surface along a curve parallel to the generator $s \to \mathbf{x}(s, v)$ is $\bar{s}$, where $d\bar{s} = (1 + r_B \kappa(s) \cos v) ds$. We formulate the equilibrium equations for the tubular surface using (s, v) as parameters. We assume the meridional stress resultant is independent of v; i.e., $\sigma_m(\bar{s}(s), v) = \sigma_m(s)$ and the circumferential stress resultant is $\sigma_c(\bar{s}(s), v) = \sigma_c(s)$. The quantities $\sigma_m(s)$ and $\sigma_c(s, v)$ are measured per unit length in the tubular surface. We define

$$\mathbf{n}_1(s, v) = \sigma_m(s) \mathbf{a}_1(s),$$
$$\mathbf{n}_2(s, v) = \sigma_c(s) \mathbf{a}_2(s, v).$$

A pumpkin gore will be a subset of a tubular surface. We assume that the pumpkin gore is situated symmetrically with respect to the xz plane and interior to the wedge defined by the half-planes $y = \pm \tan(\pi / n_g) x$ with $x \geq 0$. We will refer to r_B as the *bulge radius* of the pumpkin gore. The curve traced by $v \to \boldsymbol{\Upsilon}(s) + r_B(-\mathbf{b}(s) \cos v + \mathbf{j} \sin v)$ is a circle lying in the plane with normal $\mathbf{t}(s)$. To find the length of the segment of the circle that forms a circumferential arc of the pumpkin gore, we need to find the values of v where this arc intersects the planes $y = \pm \tan(\pi / n_g) x$. For fixed s, we find that v must satisfy the condition

$$y(s, v) = \tan\left(\frac{\pi}{n_g}\right) \; x(s, v).$$

This leads us to the equation

$$A(s) + B(s) \cos v + C \sin v = 0, \tag{3.3}$$

where $A(s) = -R(s)\tan(\pi/n_g)$, $B(s) = -r_B\cos\theta(s)\tan(\pi/n_g)$, $C = r_B$. Now (3.3) can be solved for v, yielding

$$v = v_B = \arccos\left(\frac{-AB + C\sqrt{C^2 + B^2 - A^2}}{B^2 + C^2}\right).$$

Since A and B are functions of s and other parameters, so is $v_B = v_B(s, n_g, R(s), \theta(s))$. The parameter dependence will be clear from context, and so we write v_B or $v_B(s)$ for convenience. By symmetry, the solution corresponding to the plane $y = -\tan(\pi/n_g)x$ is $v = -v_B$. We define the theoretical three dimensional pumpkin gore $\mathcal{G}$ to be the set

$$\mathcal{G} = \{\mathbf{x}(s, v), \quad -v_B(s) < v < v_B(s), \quad 0 < s < L_d\}.$$

A complete shape $\mathcal{S}$ has cyclic symmetry and is made up of n_g copies of $\mathcal{G}$. Although $\mathcal{G}$ is not axisymmetric, in practice n_g is large, and so we ignore shear stress resultants in our formulation. A priori, the generating curve $\boldsymbol{\Upsilon}(s)$ for the pumpkin gore is unknown. To determine $\boldsymbol{\Upsilon}(s)$, we must first consider the equilibrium equations for an arbitrary patch on the tubular surface. From these, we are led to a system of ODEs that can be solved to determine $\boldsymbol{\Upsilon}$ and then $\mathcal{G}$.

We begin by deriving equilibrium equations for a patch, $\mathcal{A} = \{\mathbf{x}(\xi, v) \mid s_0 < \xi < s, v_0 < v < v_1\}$, where $-v_B(\xi) < v_0 < v < v_1 < v_B(\xi)$ for $s_0 < \xi < s$. Balancing forces acting on $\mathcal{A}$, we find

$$\begin{aligned}\vec{0} = &\int_{v_0}^{v_1} \sigma_m(s)\mathbf{a}_1(s) r_B\, dv - \int_{v_0}^{v_1} \sigma_m(s_0)\mathbf{a}_1(s_0) r_B\, dv \\ &+ \int_{s_0}^{s} \sigma_c(\xi)\mathbf{a}_2(s, v_1)(1 + r_B\kappa\cos v_1)\, d\xi - \int_{s_0}^{s} \sigma_c(\xi)\mathbf{a}_2(s, v_0)(1 + r_B\kappa\cos(v_0))\, d\xi \\ &+ \int_{\mathcal{A}} \mathbf{f}(\xi, \psi) r_B(1 + r_B\kappa(\xi)\cos\psi)\, d\psi\, d\xi, \end{aligned} \tag{3.4}$$

where $\mathbf{f}$ is the external force. Thus, we can rewrite (3.4) in the form

$$\begin{aligned}\vec{0} = \int_{s_0}^{s}\int_{v_0}^{v_1} \Big\{ &\frac{\partial}{\partial s}\left[\sigma_m(\xi)\mathbf{a}_1(\xi) r_B\right] + \frac{\partial}{\partial \psi}\left[\sigma_c(\xi)\mathbf{a}_2(\xi, \psi)(1 + r_B\kappa(\xi)\cos\psi)\right] \\ &+ \mathbf{f}(\xi, \psi) r_B(1 + r_B\kappa(\xi)\cos\psi)\Big\} d\psi\, d\xi, \end{aligned} \tag{3.5}$$

where

$$\begin{aligned}&\mathbf{f}(s, v) = -p(z(s, v))\mathbf{N}(s, v) - w(s)\mathbf{k}, \\ &z(s, v) = Z(s) - r_B\sin\theta\cos v.\end{aligned}$$

By differentiating (3.5), one is led to a system of partial differential equations that determines the pumpkin gore. This system is complicated, and since n_g is typically large, it is tempting to use a small angle approximation to justify dropping terms involving $2\pi/n_g$ to obtain a simpler system. However, we can eliminate the dependence on v by integrating and retain terms that influence the design profile. In particular, if we set $v_0 = -v_B(s)$ and $v_1 = v_B(s)$ in (3.5) and integrate with respect to ψ,

we obtain

$$\begin{aligned}\vec{0} = \int_{s_0}^{s} \Bigg\{ & \frac{\partial}{\partial s}\left(\sigma_m(\xi)\mathbf{a}_1(\xi)2r_B v_B(\xi)\right) \\ & + \sigma_c(\xi)\left(\mathbf{a}_2(\xi, v_B(\xi)) - \mathbf{a}_2(\xi, -v_B(\xi))\right)\left(1 + r_B\kappa(\xi)\cos v_B\right) \\ & + \int_{-v_B(\xi)}^{v_B(\xi)} \left(-p(z(\xi,\psi))\mathbf{N}(\xi,\psi) - w(\xi)\mathbf{k}\right) r_B(1 + r_B\kappa(\xi)\cos\psi)d\psi \Bigg\} d\xi. \end{aligned} \tag{3.6}$$

To add the tendon weight density to (3.6), we note that $d\bar{s} = (1+r_B\kappa\cos v_B(s))ds$ is an arc-length measure along the tendon. The weight of a segment $d\bar{s}$ is $w_t d\bar{s}$, and (3.6) becomes

$$\begin{aligned}\vec{0} = \int_{s_0}^{s} \Bigg\{ & \frac{\partial}{\partial s}\left(\sigma_m(\xi)\mathbf{a}_1(\xi)2r_B v_B(\xi)\right) \\ & + \sigma_c(\xi)\left(\mathbf{a}_2(\xi, v_B(\xi)) - \mathbf{a}_2(\xi, -v_B(\xi))\right)\left(1 + r_B\kappa(\xi)\cos v_B(\xi)\right) \\ & - w_t\mathbf{k}(1 + r_B\kappa(\xi)\cos v_B(\xi)) \\ & + \int_{-v_B(\xi)}^{v_B(\xi)} \left(-p(z(\xi,\psi))\mathbf{N}(\xi,\psi) - w(\xi)\mathbf{k}\right) r_B(1 + r_B\kappa(\xi)\cos\psi)d\psi \Bigg\} d\xi. \end{aligned} \tag{3.7}$$

In balloon design, it is not uncommon to make some simplifying assumptions about the form of σ_c. In the axisymmetric natural shape models, one assumes that $\sigma_c = 0$. In the Delaunay surfaces, one assumes that $\sigma_c = \sigma_m$ is constant. The assumption $\sigma_c(\xi) = \sigma_m(\xi)$ could be handled without difficulty, but for convenience of exposition we will assume that σ_c is a nonnegative constant. Using the properties of $\mathbf{a}_2$ and assuming $\sigma_c(\xi, v) = \sigma_c$, we find $\mathbf{a}_2(\xi, v) - \mathbf{a}_2(\xi, -v) = 2\mathbf{b}(\xi)\sin v$ and

$$\sigma_c(\xi)(\mathbf{a}_2(\xi, v_B(\xi)) - \mathbf{a}_2(\xi, -v_B(\xi))) = 2\sigma_c\mathbf{b}(\xi)\sin v_B(\xi). \tag{3.8}$$

Using (3.7) and (3.8), we obtain the following:

$$\begin{aligned}\vec{0} = \int_{s_0}^{s} \Bigg\{ & \frac{\partial}{\partial s}\left(\sigma_m(\xi)\mathbf{a}_1(\xi)2r_B v_B(\xi)\right) \\ & + \left[2\sigma_c\mathbf{b}(\xi)\sin v_B(\xi) - w_t\mathbf{k}\right]\left(1 + r_B\kappa(\xi)\cos v_B(\xi)\right) \\ & + \int_{-v_B(\xi)}^{v_B(\xi)} \left(-p(z(\xi,\psi))\mathbf{N}(\xi,\psi) - w(\xi)\mathbf{k}\right) r_B(1 + r_B\kappa(\xi)\cos\psi)d\psi \Bigg\} d\xi. \end{aligned} \tag{3.9}$$

From the last term in (3.9), we find

$$-\int_{-v_B(\xi)}^{v_B(\xi)} p\mathbf{N}(\xi,\psi)\; r_B(1 + r_B\kappa\cos\psi)d\psi = -\mathbf{b}(\xi)\left(\kappa Q_1 + Q_0\right),$$

where

$$\begin{aligned} Q_1(b, p_0, r_B, v_B, Z, \theta) = {} & \frac{1}{12}r_B^2\big(12p_0 v_B + 12bv_B Z - br_B\cos(\theta - 3v_B) \\ & - 9br_B\cos(\theta - v_B) + 9br_B\cos(\theta + v_B) + br_B\cos(\theta + 3v_B) \\ & + 6p_0\sin(2v_B) + 6bZ\sin(2v_B)\big), \\ Q_0(b, p_0, r_B, v_B, Z, \theta) = {} & \frac{1}{4}r_B\big(-br_B\cos(\theta - 2v_B) + br_B\cos(\theta + 2v_B) \\ & - 4br_B v_B\sin\theta + 8p_0\sin v_B + 8bZ\sin v_B\big). \end{aligned}$$

Equation (3.9) can be expressed in the form

$$\begin{aligned}\vec{0} = \int_{s_0}^{s} \Big\{ & \frac{\partial}{\partial \xi} \left(2 v_B(\xi) r_B \sigma_m(\xi) \mathbf{t}(\xi)\right) \\ & + \mathbf{b}(\xi) \left\{2\sigma_c \sin v_B (1 + \kappa r_B \cos v_B) - \kappa Q_1 - Q_0\right\} \\ & - 2\mathbf{k} r_B w_f \left\{v_B + r_B \kappa \sin v_B\right\} - \mathbf{k} w_t (1 + r_B \kappa \cos v_B) \Big\} \, d\xi. \end{aligned} \tag{3.10}$$

Differentiating (3.10) with respect to s and simplifying, we obtain

$$\begin{aligned}\vec{0} = & \left(\sigma_m(s) 2 r_B v_B(s)\right)' \mathbf{t}(s) + \left(\sigma_m(s) 2 r_B v_B(s)\right) \left(-\theta'(s)\right) \mathbf{b}(s) \\ & + \mathbf{b}(s) \left\{2\sigma_c \sin v_B (1 + \kappa r_B \cos v_B) - \kappa Q_1 - Q_0\right\} \\ & - 2\mathbf{k} r_B w_f \left\{v_B + r_B \kappa \sin v_B\right\} - \mathbf{k} w_t (1 + r_B \kappa \cos v_B). \end{aligned} \tag{3.11}$$

The inner product of (3.11) with $\mathbf{j}$ is zero. Taking the inner product of (3.11) with $\mathbf{t}$ and $\mathbf{b}$, we obtain the respective equations

$$\left(\sigma_m(s) 2 r_B v_B(s)\right)' = 2 r_B w_f \left(v_B + r_B \kappa \sin v_B\right) \cos\theta + w_t (1 + r_B \kappa \cos v_B) \cos\theta$$

and

$$\begin{aligned} 0 = & -\sigma_m 2 r_B v_B \theta'(s) + 2\sigma_c \sin v_B (1 + \kappa r_B \cos v_B) - \kappa Q_1 - Q_0 \\ & - 2 r_B w_f \left(v_B + r_B \kappa \sin v_B\right) \sin\theta - w_t (1 + r_B \kappa \cos v_B) \sin\theta. \end{aligned}$$

Using the definition $\kappa = -\theta'(s)$, we find

$$\begin{aligned} 0 = \theta'(s) & \left\{-\sigma_m 2 r_B v_B + Q_1 + 2 r_B^2 w_f \sin v_B \sin\theta - \sigma_c r_B \sin(2 v_B) + w_t r_B \cos v_B \sin\theta\right\} \\ & + 2\sigma_c \sin v_B - Q_0 - 2 r_B w_f v_B \sin\theta - w_t \sin\theta. \end{aligned}$$

Defining the total meridional tension per gore,

$$T_m(s) = 2 r_B v_B(s) \sigma_m(s),$$

and replacing κ with $-\theta'(s)$, we find

$$\cos\theta \left(2 r_B^2 w_f \sin v_B + w_t r_B \cos v_B\right) \theta'(s) + T_m'(s) = 2 r_B v_B w_f \cos\theta + w_t \cos\theta,$$

$$\begin{aligned} & \left(T_m(s) - Q_1 - 2 r_B^2 w_f \sin v_B \sin\theta - w_t r_B \cos v_B \sin\theta + \sigma_c r_B \sin(2 v_B)\right) \theta'(s) \\ & \qquad = 2(\sigma_c \sin v_B - \tfrac{1}{2} Q_0 - r_B w_f v_B \sin\theta) - w_t \sin\theta. \end{aligned}$$

We are finally led to a system of ODEs in s that the generating curve for the pumpkin gore must satisfy. Setting $w^*(s) = 2 r_B v_B(s) w_f$ and

$$\hat{\kappa}(\theta, T_m, Z, Q_0, Q_1, r_B, v_B, \sigma_c, w^*, w_t)$$

$$= -\frac{2\sigma_c \sin v_B - Q_0 - (w^* + w_t) \sin\theta}{T_m - Q_1 - r_B (w^* \sin v_B / v_B + w_t \cos v_B) \sin\theta + \sigma_c r_B \sin(2 v_B)},$$

we obtain

$$\theta'(s) = -\hat{\kappa}(\theta, T_m, Z, Q_0, Q_1, r_B, v_B, \sigma_c, w^*, w_t), \tag{3.12}$$

$$T_m'(s) = \left(w^* \left(1 + \frac{r_B \hat{\kappa} \sin v_B}{v_B}\right) + w_t (1 + r_B \hat{\kappa} \cos v_B)\right) \cos\theta, \tag{3.13}$$

$$R'(s) = \sin\theta, \tag{3.14}$$

$$Z'(s) = \cos\theta. \tag{3.15}$$

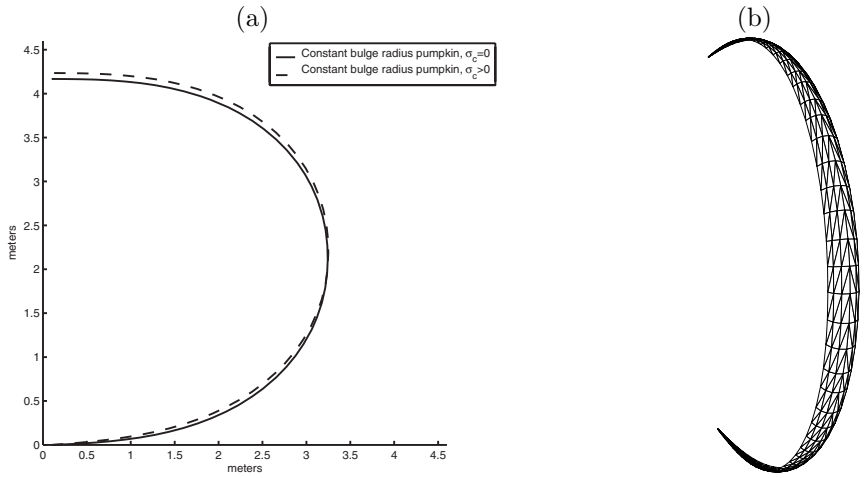

FIG. 3.2. (a) *Tendon profiles for pumpkin balloon models* $\sigma_c = 0$ *N/m and* $\sigma_c = 10$ *N/m;* $p_0 = 200$ *Pa and* $r_B = 0.1066$ *m.* (b) *Three dimensional pumpkin gore.*

The ODEs (3.12)–(3.15) are supplemented by initial conditions

$$\begin{aligned} \theta(0) &= \theta_0, \\ T_m(0) &= \frac{(L_0 + \pi R_0^2 p_0)}{(n_g \cos\theta_0)}, \\ R(0) + r_B \cos\theta(0) &= R_0, \\ z(0) &= Z_0, \end{aligned} \tag{3.16}$$

and auxiliary equations

$$\begin{aligned} n_g \cos\theta_1 T_m(\ell) &= L_1 - \pi R_1^2 p_1, \\ R(\ell) + r_B \cos\theta(\ell) &= R_1. \end{aligned} \tag{3.17}$$

Equations (3.12)–(3.17) are solved via a shooting method, and the generating curve $\boldsymbol{\Upsilon}$ is determined. In Figure 3.2(a), we present the tendon profiles for pumpkin balloons with $\sigma_c = 0$ and $\sigma_c > 0$. The models will be discussed in more detail in the next section. In Figure 3.2(b), we present a discretization of the theoretical pumpkin gore.

As a check that Archimedes' Principle is satisfied at float, we take the dot product of (3.9) with $\mathbf{k}$, multiply by n_g, and integrate from $s = 0$ to $s = L_d$; after simplifying the result and using

$$2n_g r_B v_B(L_d)\sigma_m(L_d)\cos\theta(L_d) - 2n_g r_B v_B(0)\sigma_m(0)\cos\theta_d + W_c + W_{tapes} + W_{film} - b\mathcal{V} = 0,$$

$$W_c = 2\int_0^{L_d} \sigma_c(\xi)\mathbf{b}(\xi)\cdot\mathbf{k}\sin v_B(\xi)(1+\kappa(\xi)\cos v_B(\xi))d\xi,$$

we find

$$L_0 + L_1 - \pi(p_1 R_1^2 - p_0 R_0^2) + W_{tapes} + W_c + W_{film} = bV. \tag{3.18}$$

Note, if $\sigma_c \neq 0$, that the boundary conditions along the edge of the gore contribute a net force W_c in the $\mathbf{k}$ direction, which is reflected in (3.18). For the case considered in Table 2.1(b), we find that W_c is approximately 2 N.

4. Numerical results. In this section, we present numerical results for solutions of the respective shape-finding problems for balloon models discussed in previous sections. The design parameters used in our demonstration cases are those given in Table 1.1. For each balloon type, we calculated the corresponding shape (ZPNS, SPNS, and pumpkin) that would maintain a payload of 280 N at an altitude of 10 km. Each balloon was constructed with 96 gores and no caps. We use a 1.5 mil polyethylene skin for our designs. Relevant values (height, diameter, volume, etc.) of the specific designs are presented in Table 2.1(a) for axisymmetric shapes and in Table 2.1(b) for pumpkin shapes.

Normally, load tapes are used in the construction of natural shape balloons, and (heavier) load tendons are used in the construction of pumpkin balloons. This distinction is important to the balloon designer. For example, since a load tape can contain as much as 3% slackness and is less stiff than a load tendon, the balloon film will bear a significant portion the weight of the balloon system in certain regions. In a pumpkin balloon, the balloon film functions primarily as a gas barrier, locally transmitting loads to the tendons. Because we are not concerned with straining of the balloon film here, we use the same weight densities for tendons and load tapes.

While the Euler-elastica model utilizes some crude assumptions, it does have the advantage of a closed form solution. We note that the maximum radius for an Euler elastica profile is given by $1/\sqrt{\tau}$ (see (2.17)). For the Euler-elastica shape related to the designs presented in Figure 3.2(a) with $p_0 = 200$ Pa, we find $T_0 = (274\text{ N})/\cos(1.526) = 6.134$ kN and $\tau = \pi p_0/T_0 = 0.1024\text{ m}^{-2}$, and the maximum radius is $\sqrt{1/\tau} = 3.1246$ m. The maximal radius in the SPNS model is 3.0267 m. The elastica model gives a 3.0% relative error.

It is important to keep in mind that in reality, the shape-finding process as described in sections 2–3 is only one part of the process in the construction of a balloon. In a ZPNS, once (θ_d, ℓ_d) are determined and $r(s)$ and $z(s)$ are known, the theoretical natural shape gore is given by

$$\mathcal{N} = \{(x, y, z) = \mathbf{x}(s, \phi), 0 < s < \ell_d, -\pi/n_g < \phi < \pi/n_g\}.$$

In reality, the true gore $\mathcal{N}$ is approximated by a developable surface,

$$\hat{\mathcal{N}} = \left\{(x, y, z) = (r(s), y, z(s)), 0 < s < \ell_d, -r(s)\tan\left(\frac{\pi}{n_g}\right) < y < r(s)\tan\left(\frac{\pi}{n_g}\right)\right\}.$$

The developable surface $\hat{\mathcal{N}}$ can be rolled into a plane without straining, thus defining the lay-flat gore pattern to be cut. The complete balloon is then constructed by seaming together n_g individual gores. While a circumferential fiber in $\mathcal{N}$ has a length of $2\pi r(s)/n_g$, when n_g is large $\tan(\pi/n_g) \approx \pi/n_g$ and we see that $\hat{\mathcal{N}}$ is a good approximation of $\mathcal{N}$. For a large balloon, r is comparatively large (away from the end-caps), and we see that the curvature κ of the curve $s \to (r(s), 0, z(s))$ is small. The other principal curvature is $-\cos\theta(s)/r(s)$, and so, away from the end-caps, it is also small because r is large. For superpressure balloons, θ is near $\pm\pi/2$ in the vicinity of the end-caps. ZPNS balloons flown by NASA typically have between 100 and 200 gores. When a real ZPNS balloon is fully pressurized, the balloon will assume a shape that is very nearly a surface of revolution.

The curvature of the pumpkin gore generator $\boldsymbol{\Upsilon}$ is of the same order of magnitude as the curvature of the generator of the corresponding SPNS. However, the curvature in the hoop direction is r_B^{-1} and in general is not small. If s_c is arc-length measured

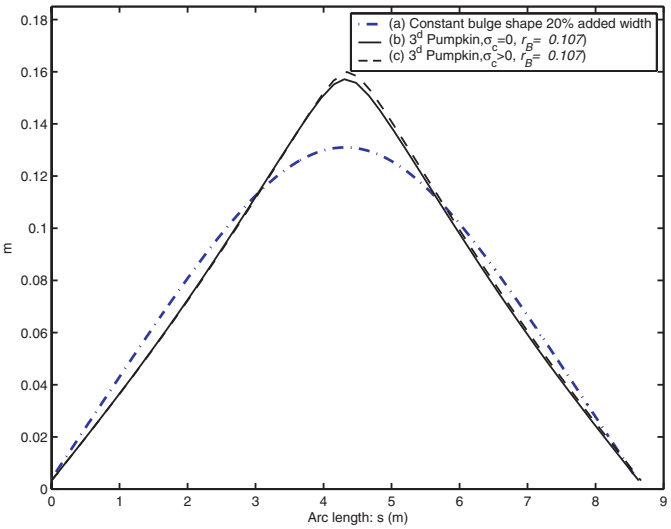

FIG. 4.1. *Normalized flat half-gore patterns.*

down the center of the pumpkin gore, then $ds_c = (1 + r_B\kappa(s))ds$, and we define

$$\tilde{\mathcal{G}} = \{(u,t) \mid t = s_c(s), -r_B v_B(s) < u < r_B v_B(s), 0 < s < L_d\}.$$

While $\tilde{\mathcal{G}}$ can be thought of as a flat panel approximation to $\mathcal{G}$, even when fully pressurized, the balloon will have difficulty achieving the desired doubly curved shape. The length of an edge of $\tilde{\mathcal{G}}$ is much longer than the length of the corresponding theoretical gore $\mathcal{G}$. To achieve the desired shape in a real balloon, the material along the edge of $\tilde{\mathcal{G}}$ is gathered, and a tendon of length $L_t = \int_0^{L_d} ds_t$ is attached. Note that the gathering is nonuniform. (It is maximal near the equatorial latitudes and decreases as one approaches the end-caps.) In any case, there will be wrinkling in the inflated pumpkin balloon. If flat warped panels of film are used in the construction of a pumpkin gore, the amount of excess material and wrinkling can be reduced (see [5]).

In Figure 4.1, we present three flat gore patterns: a constant bulge shape design, a constant bulge radius design with $\sigma_c = 0$, and a constant bulge radius design with $\sigma_c = 10$ N/m. The first design is based on the constant bulge shape approach, as was utilized in the *Endeavour* design. In the constant bulge shape approach, it is assumed that the load tendons followed the trace of the Euler-elastica curve and the region between tendons is spanned by circular arcs, assuming a constant angular width. In this approach, a node on the tendon in the $\phi = -\pi/n_g$ plane is identified with the corresponding node in the $\phi = \pi/n_g$ plane. The chord length $2y(s)$ is replaced by a circular arc of length $1.2 \times 2y(s)$ (20% "added width"). It is clear from Figure 4.1 that the constant bulge shape approach has significantly more material away from the equatorial region than $\tilde{\mathcal{G}}$ for a comparable pumpkin gore. The *Endeavor* was built with 64 constant bulge shape gores and, when fully pressurized, it assumed a severely distorted configuration that did not resemble a pumpkin shape. In hindsight, this should not have been a complete surprise, since the *Endeavor* gore pattern did not follow from equilibrium equations of the fully inflated shape. Only when four gores were removed was the *Endeavor* able to deploy into a shape one might characterize

as pumpkin-like (see [16]).

5. Concluding remarks. In this paper, we reviewed a number of axisymmetric balloon models including the zero-pressure natural shape balloon, the superpressure natural shape balloon, the Euler-elastica, and the sphere. Based on a tubular surface membrane theory, we developed a model for a three dimensional pumpkin gore. The pumpkin model that we present is an improvement over previous models in that it introduces a circumferential stress parameter into the model and leads to a more accurate representation of the three dimensional gore. We also discussed some of the practical issues that the manufacturer must deal with when trying to construct large doubly curved gores from flat sheets of balloon film.

Acknowledgment. The author would like to thank the referees for their comments.

MODELING AND DESIGN OF COATED STENTS TO OPTIMIZE THE EFFECT OF THE DOSE*

MICHEL C. DELFOUR†, ANDRÉ GARON‡, AND VITO LONGO§

Abstract. Stents are used in interventional cardiology to keep a diseased vessel open. New stents are coated with a medicinal agent to prevent early reclosure due to the proliferation of smooth muscle cells. It is recognized that it is the dose of the agent that effectively controls the cells in the wall of the vessel. This paper focuses on the effect of the number of struts and the ratio between the coated area of the struts and the targeted area of the vessel on the design problem under set therapeutic bounds on the dose. It introduces mathematical models of the dose for a zero-thickness periodic stent and an asymptotic stent that will play a central role in our analysis. Theoretical and numerical results are presented along with their impact on the design process.

Key words. stenosis, restenosis, atherosclerosis, bioactive material, dose, modeling, design, numerical simulation, coated stent, interventional cardiology, medical applications, asymptotic behavior of solutions, Neumann sieve, shape optimization, sensitivity analysis

1. Introduction.

The use of stents (see Figure 1.1) in *interventional cardiology* is fairly recent.[1]

> An electrical engineer, Wiktor underwent open heart surgery to correct an aortic dissection in 1984. Following the procedure, he wondered why such a vascular repair couldn't be done with less surgical trauma, and began to read about angioplasty. He came up with a variety of stent designs and signed a consulting agreement with Medtronic in 1988.
>
> The "Wiktor Stent," an intravascular stent (U.S. patent No. 4,886,062) provides an important solution to coronary artery reconstruction and recanalization. The stent keeps a diseased vessel open and prevents reclosure. Made of tantalum, a noncorrosive and malleable metal which is easily seen by the cardiologist during fluoroscopy, the stent is extremely easy to handle, deliver and deploy, which is of the utmost importance in emergency and routine situations.
>
> In the case of the Wiktor Stent, the delivering catheter is inflated to expand and deploy the stent to maintain the opening. The balloon is then deflated and the catheter removed. Within a month, the stent becomes incorporated into the artery wall. Today, Medtronics' Wiktor stent has a 20 percent market share in Europe.

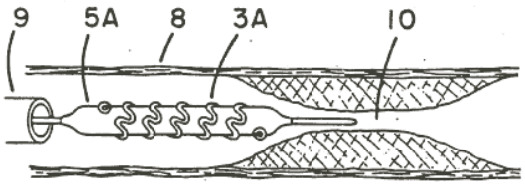

FIG. 1.1. *Wiktor stent as drawn in U.S. patent No.* 4,886,062.

More than 40 percent of patients treated for atherosclerosis present restenosis within six months of the operation. Indeed, implanting a stent generally leads to complications, thrombosis and proliferation of smooth-muscle cells being the root causes of restenosis. It is important to understand that stenosis and restenosis develop by different mechanisms and over very different time scales: 30 years for stenosis, 6 months for restenosis. A great deal of research has been conducted on medicinal agents designed to have an antithrombotic effect or to limit the proliferation of smooth-muscle cells. This type of medication can be delivered in two ways: systematically or locally. The primary disadvantage of systemic delivery is generally its greater toxicity in the body, since, to be effective, a much higher level of the medication is a priori required than for local delivery. For this reason, the local solution is the preferred choice. For instance, a typical system consists of a stent coated with a thin layer of polymer which has been impregnated with a molecule that has an effect on the proliferation of smooth muscle cells [1, 9, 10].

Modern stents are designed to be less invasive from the hemodynamic point of view. Engineers are introducing new shapes with minimal strut diameters to minimize induced perturbations that would theoretically increase stresses on the fluid and recirculation. Yet it is recognized that this strategy alone cannot prevent restenosis and considerable efforts are currently aimed at developing new stent coating to reduce or stop the proliferation of smooth muscle cells. However, to the authors' knowledge, the distribution of the coating (mass and contact surface) are not part of the design and the optimal selection of the shape parameters of the stent (coating is added to an already mechanically designed stent). An optimal coated stent (that would produce minimal restenosis) would be the result of a shape optimization that would simultaneously account for the hemodynamic and mass transfer processes.

It is the purpose of this paper to broaden the knowledge and improve the craft of the stent designer by providing new mathematical and numerical tools to help in the preliminary shape selection of stents. Mechanically the stent has to be strong enough to exert pressure on the wall of the vessel sufficient to keep it open and to restore a normal flow of blood. Once the purely mechanical parameters are set (choice of the material, contact surface, and thickness of the struts), there are a number of parameters left to control the delivery of the molecule to the wall: the total mass of the molecule and the distribution of the contact surface.

It is generally accepted that it is the effect of the concentration of the molecule over time that effectively controls the proliferation of the smooth muscle cells (cf. [2, 9, 10]). This naturally leads to the notion of a *dose* in each point of the artery. Mathematically the dose is defined as the integral of the concentration over all times ranging from 0 to ∞. The first key finding of this paper is the high sensitivity of the dose to the geometric distribution of the contact surface. This leads to the introduction of an *asymptotic stent* that describes the limit behavior of a family of

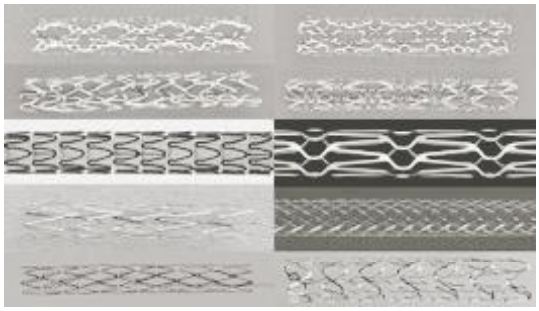

FIG. 1.2. *Typical patterns of stents.*

periodic stents as the number of struts increases, while maintaining a constant contact surface (and hence a constant distributed force on the wall to keep the vessel open). Given a bioactive material or molecule and the appropriate therapeutic bounds on the dose (a lower one to control the smooth muscle cells and an upper one to limit the toxicity of the molecule), the asymptotic stent provides a first estimate of the minimum total amount of bioactive material required. The second key finding is the behavior of the dose as the number of struts increases: It is almost periodic, and its amplitude decreases as the number of struts increases. It is then possible to select a realistic number of struts to achieve the design objectives and deliver the proper amount of bioactive material to the wall while respecting the upper therapeutic bound. Obviously this design would be followed by three-dimensional simulations to confirm the complete behavior of the device.

In this paper we have limited our investigation to the first two issues since they steer the overall process and contribute to limiting the number of three-dimensional simulations, thus reducing the cost of the design. For that purpose, we use a crude yet operational model of the lumen and the wall of the vessel: two concentric cylinders long enough not to affect the design in the *target area* where the stent will be deployed. For simplicity, the stent is chosen to be periodic and made up of a finite number of rings of radius R with no thickness and uniform width. However, our modeling and our analysis (in sections 4 and 5) and their consequences readily extend to more complex periodic stent structures (in section 5.3) of the type shown in Figure 1.2. In its undeployed state we assume that all the struts of the stent are side by side without space between them. When the stent is deployed to fill the target area, space is created between the struts. We call ρ the ratio between the contact surface occupied by the struts and the surface of the target area; it is a number between 0 and 1. When the struts are periodically spaced, $1 - \rho$ is a measure of the percentage of the area of the interface lumen/wall in the target area which is open to chemical/biological exchanges. The impact of such exchanges on the stent has not yet been fully investigated in the literature.

In our analysis we assume that the mass per unit area of the molecule impregnated in the thin layer on the stent is constant. We study the distribution of the dose in the artery with respect to the number of struts and the ratio ρ while keeping the surface of the target area constant. For a fixed ρ, as the number of struts increases, their width and the space between two adjacent struts decrease. So we are naturally led to introduce the notion of an *asymptotic stent*. We obtain the equations for the dose of the *asymptotic stent* and study the distribution of the dose in the wall of

the artery. One of the technical difficulties is to determine the right *transmission conditions* at the wall/lumen interface in the target area. This naturally comes out of our mathematical analysis without any ad hoc arguments: a variational formulation for the zero-thickness periodic stent leading to the identification of the variational equation of the asymptotic stent and a complete constructive proof of convergence of the dose. The constructive analysis is certainly one of the main contributions of this paper, since it clarifies and justifies the general mathematical modeling of the biophysical process at hand.

Section 2 presents the time-space diffusion-transport equations for the concentration of the product using appropriate conditions on the flow at both ends of the artery. Section 3 gives the equations for the *dose* and the variational model. Since the thickness of the layer of polymer is small compared to the other geometric parameters, we let the thickness of the layer go to zero in the variational model and obtain in section 4 a new variational model for the dose which is a reasonable approximation. The construction of the asymptotic stent[2] and the corresponding variational equation for the dose are given in section 5. The generalization to stents of arbitrary geometry via an arbitrary characteristic function is developed in section 5.3. The asymptotic model is related to the *Neumann sieve* studied in [13, 5, 7], where the plane surface is replaced by the interface lumen/wall in the lateral boundary of a cylinder and the possible apparition of a jump across the interface and a "strange term coming from nowhere," as in [3, 4, 12]. However, in our limiting process the surface of the holes does not go to zero, and we do not get a jump in the dose across the interface lumen/wall in the target area. Section 6 presents selected numerical simulations for a stent with 1, 6, 12, 24, 48, 96, 192, and 384 struts, and the asymptotic case for ρ equal to 0.1, 0.2, 0.5, and 0.9. A table of the integral of the dose in the wall of the artery is presented as a function of the ratio ρ and the number of struts N. Complete results and details on the numerical implementation will be available in a more specialized paper. This paper concentrates on the theory and the discussion of the numerical simulation. Section 7 is a concluding section that reviews the theoretical and numerical results and their impact on the design process and objectives.

2. Equations for the concentration of product. Consider a section of cylindric artery of length H where the stent will be deployed (cf. Figure 2.1). For simplicity assume that the artery is made up of two homogeneous regions: the *lumen* and the *wall*. More realistic multilayer models of the wall can be considered [11], but this will be sufficient for our purposes. Before the insertion of the stent, the lumen is assumed to be the open cylinder

$$C_R \stackrel{\text{def}}{=} \left\{(x_1, x_2, z) \,:\, x_1^2 + x_2^2 < R^2, \quad 0 < z < H\right\} \tag{2.1}$$

of radius R and length H. The wall is the open domain $C_{R+E}\backslash\overline{C}_R$ between the closed cylinder $\overline{C}_R$ and the open cylinder

$$C_{R+E} \stackrel{\text{def}}{=} \left\{(x_1, x_2, z) \,:\, x_1^2 + x_2^2 < (R+E)^2, \quad 0 < z < H\right\} \tag{2.2}$$

of radius $R + E$ and length H, where E is the radial thickness of the wall.

A stent of zero thickness will be deployed in the *target area*

$$\tilde{\Sigma} \stackrel{\text{def}}{=} \left\{(x_1, x_2, z) \,:\, x_1^2 + x_2^2 = R^2, \quad \frac{H - L_s}{2} \le z \le \frac{H + L_s}{2}\right\} \tag{2.3}$$

[2]When the number of struts goes to infinity and the width of each strut goes to zero, while the surface of the target area, the ratio ρ, and the mass per unit area of product are kept fixed.

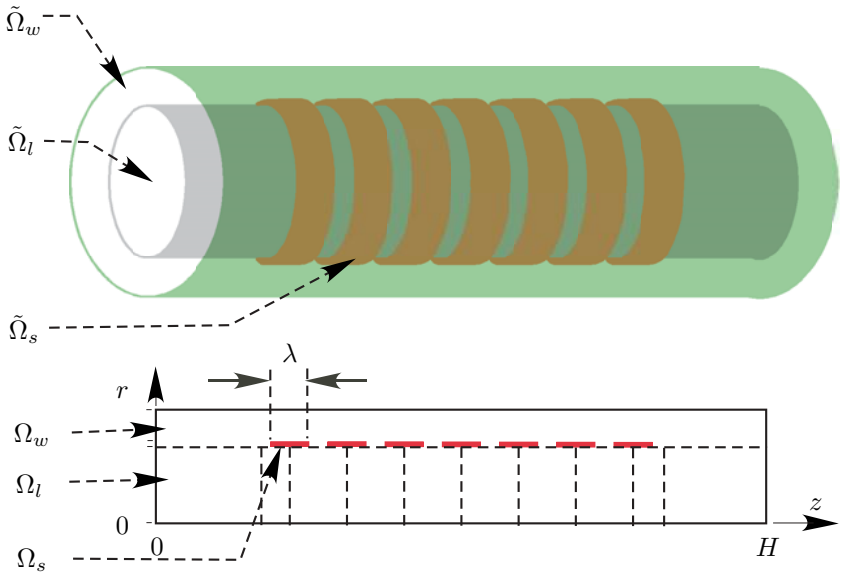

FIG. 2.1. *The lumen $\tilde{\Omega}_l$, the stent $\tilde{\Omega}_s$, and the wall $\tilde{\Omega}_w$ in $\mathbf{R}^3$ and the associated two-dimensional generating surfaces Ω_l for the lumen, Ω_s for the stent, and Ω_w for the wall.*

of the interface between the lumen and the wall. The length of the target region is $L_s < H$. The *actual stent* will be characterized by a closed subset $\tilde{\Sigma}_s$ of the surface $\tilde{\Sigma}$ (cf., for instance, one of the periodic patterns in Figure 1.2). By construction, the region $\tilde{\Sigma}$ is centered in $H/2$ at equal distance

$$z_0 \stackrel{\text{def}}{=} \frac{H - L_s}{2} > 0 \tag{2.4}$$

from the boundaries of C_{R+E} in $z = 0$ and $z = H$, which are *artificial boundaries* introduced for the analysis of the problem. The length H of the section of the artery is assumed to be enough longer than L_s that the effect of introducing an artificial boundary in $z = 0$ and $z = H$ is negligible. It also means that the region $\tilde{\Sigma}$ does not touch the boundaries of the cylinder C_{R+E} in $z = 0$ and $z = H$.

The zero-thickness stent is coated with a polymer. Coating can exist on both sides of the stent. The regions occupied by the polymer are denoted

$$\tilde{\Omega}_s^+ \stackrel{\text{def}}{=} \left\{ (x_1, x_2, z) \,:\, \left(R\frac{(x_1, x_2)}{\sqrt{x_1^2 + x_2^2}}, z \right) \in \tilde{\Sigma}_s \text{ and } R < \sqrt{x_1^2 + x_2^2} < R + e^+ \right\},$$

$$\tilde{\Omega}_s^- \stackrel{\text{def}}{=} \left\{ (x_1, x_2, z) \,:\, \left(R\frac{(x_1, x_2)}{\sqrt{x_1^2 + x_2^2}}, z \right) \in \tilde{\Sigma}_s \text{ and } R - e^- < \sqrt{x_1^2 + x_2^2} < R \right\},$$

$$\tilde{\Omega}_s \stackrel{\text{def}}{=} \tilde{\Omega}_s^+ \cup \tilde{\Omega}_s^-,$$

where e^+ and e^- are the respective thicknesses of the *coating* on the upper and lower surfaces of $\tilde{\Sigma}_s$. Once the stent is deployed, the open regions $\tilde{\Omega}_l$ and $\tilde{\Omega}_w$ occupied by the lumen and the wall are

$$\tilde{\Omega}_l \stackrel{\text{def}}{=} C_R \backslash \overline{\tilde{\Omega}_s^-} \quad \text{and} \quad \tilde{\Omega}_w \stackrel{\text{def}}{=} C_{R+E} \backslash \overline{\tilde{\Omega}_s^+ \cup C_R}. \tag{2.5}$$

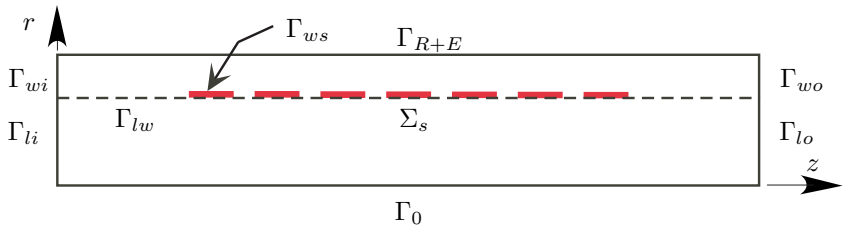

FIG. 2.2. *The two-dimensional boundaries and interfaces.*

Mathematically, $\tilde{\Omega}_l$, $\tilde{\Omega}_w$, and $\tilde{\Omega}_s^{\pm}$ are open domains in $\mathbf{R}^3$.

It is the design of the set $\tilde{\Sigma}_s$ which is the ultimate objective of the analysis. There are several aspects to this design. For instance, the stent has to be mechanically strong enough to keep the lumen open. In this paper we neglect this aspect and concentrate on the delivery of the product to the wall. For simplicity we start with a periodic stent (in the z-direction) with cylindric symmetry. Further assume that it is coated only on its upper surface, that is, $e^- = 0$, $\tilde{\Omega}_s^- = \varnothing$, and $\tilde{\Omega}_s = \tilde{\Omega}_s^+$ (cf. Figure 2.1). In addition, the stent is assumed to be a set of N equally spaced rings of width λ and zero thickness with coating of thickness $e = e^+$, that is, the region between the radius R and the radius $R + e$. The centerlines of the rings are located at coordinates

$$\{z_i \,:\, 1 \le i \le N\}, \quad z_0 < z_1 < z_2 < \cdots < z_N < z_0 + L_s, \tag{2.6}$$

along the z-axis as shown in the lower part of Figure 2.1 with $z_i + \lambda < z_{i+1}$. Thus all the rings are contained in the target region $\tilde{\Sigma}$. The domains $\tilde{\Omega}_l$, $\tilde{\Omega}_w$, and $\tilde{\Omega}_s$ and the interfaces $\tilde{\Sigma}$ and $\tilde{\Sigma}_s$ are generated by rotation of the two-dimensional open domains Ω_l, Ω_w, and Ω_s and the interfaces Σ and Σ_s (cf. Figure 2.1) around the axis Γ_0. In what follows, the tilded domains, boundaries, and interfaces will always denote the three-dimensional object generated by rotation around the axis Γ_0.

The boundary $\tilde{\Gamma}_l = \partial\tilde{\Omega}_l$ of the lumen $\tilde{\Omega}_l$ is made up of four parts:

- $\tilde{\Sigma}_s$, the interface between $\tilde{\Omega}_l$ and the region $\tilde{\Omega}_s$ occupied by the polymer;
- $\tilde{\Gamma}_{lw}$, the interface between $\tilde{\Omega}_l$ and the region $\tilde{\Omega}_w$ occupied by the wall;
- $\tilde{\Gamma}_{li}$, the part of the boundary of $\tilde{\Omega}_l$ where the blood flows in;
- $\tilde{\Gamma}_{lo}$, the part of the boundary of $\tilde{\Omega}_l$ where the blood flows out.

The corresponding parts of the generating surface are Σ_s, Γ_{lw}, Γ_{li}, Γ_{lo}, and the centerline or axis Γ_0 of the cylinders (cf. Figure 2.2).

The boundary $\tilde{\Gamma}_w = \partial\tilde{\Omega}_w$ of the wall $\tilde{\Omega}_w$ is made up of five parts:

- $\tilde{\Gamma}_{lw}$, the interface between $\tilde{\Omega}_w$ and the region $\tilde{\Omega}_l$ occupied by the lumen;
- $\tilde{\Gamma}_{ws}$, the interface between $\tilde{\Omega}_w$ and the region $\tilde{\Omega}_s$ occupied by the polymer;
- $\tilde{\Gamma}_{wi}$, the part of the boundary of $\tilde{\Omega}_w$ where $z = 0$;
- $\tilde{\Gamma}_{wo}$, the part of the boundary of $\tilde{\Omega}_w$, where $z = H$;
- $\tilde{\Gamma}_{R+E}$, the outer lateral boundary of the cylinder of radius $R + E$.

The corresponding parts of the generating surface are Γ_{lw}, Γ_{ws}, Γ_{wi}, Γ_{wo}, and the upper boundary Γ_{R+E} at $r = R + E$ (cf. Figure 2.2).

The boundary $\tilde{\Gamma}_s = \partial\tilde{\Omega}_s$ of the polymer $\tilde{\Omega}_s$ is made up of two parts:

- $\tilde{\Sigma}_s$, the interface between $\tilde{\Omega}_s$ and the region $\tilde{\Omega}_l$ occupied by the lumen;
- $\tilde{\Gamma}_{ws}$, the interface between $\tilde{\Omega}_s$ and the region $\tilde{\Omega}_w$ occupied by the wall.

The corresponding parts of the generating surface are Σ_s and Γ_{ws} (cf. Figure 2.2).

The fluid (here, the blood) in the lumen is assumed to be incompressible,

$$\operatorname{div} u = 0 \quad \text{in } \tilde{\Omega}_l, \tag{2.7}$$

where u is the *velocity of the fluid*. Further assume that

$$u \cdot n_l \le 0 \text{ on } \tilde{\Gamma}_{li} \quad \text{and} \quad u \cdot n_l \ge 0 \text{ on } \tilde{\Gamma}_{lo}, \tag{2.8}$$

$$u \cdot n_l = 0 \quad \text{or} \quad u = 0 \text{ on } \tilde{\Sigma}_s \cup \tilde{\Gamma}_{lw}. \tag{2.9}$$

Condition (2.8)–(2.9) means that the blood is coming *in* through the cross section $\tilde{\Gamma}_{li}$ and going *out* through the cross section $\tilde{\Gamma}_{lo}$. The velocity u and the pressure p will also verify the Navier–Stokes equation with the condition $u = 0$ on $\tilde{\Sigma}_s \cup \tilde{\Gamma}_{lw}$. Yet the diffusion-transport equations will still make sense under the weaker condition $u \cdot n_l = 0$ on $\tilde{\Sigma}_s \cup \tilde{\Gamma}_{lw}$. This would correspond to a non-Newtonian viscosity model, which is not the purpose of this paper. For instance, experimental data show the existence of a near-wall plasma layer that separates the blood corpuscles from the wall. The effect of this small layer is to account for a *slipping* of the flow over the wall.

Assume that the concentration $c(x,t)$ of product is given by the diffusion-transport equation (lumen) and diffusion equations (wall and the polymer):

$$\frac{\partial c}{\partial t} = \begin{cases} \operatorname{div}(D_w \nabla c) & \text{in } \tilde{\Omega}_w, \\ \operatorname{div}(D_s \nabla c) & \text{in } \tilde{\Omega}_s, \end{cases} \tag{2.10}$$

$$\frac{\partial c}{\partial t} + u \cdot \nabla c = \operatorname{div}(D_l \nabla c) \quad \text{in } \tilde{\Omega}_l, \tag{2.11}$$

where D_w, D_s, and D_l are the respective diffusion constants in the wall, the polymer, and the lumen. The *inner product* of two vectors $u = (u_1, u_2, u_3)$ and $v = (v_1, v_2, v_3)$ in $\mathbf{R}^3$ is denoted by

$$u \cdot v \stackrel{\text{def}}{=} \sum_{i=1}^{3} u_i \, v_i.$$

In view of the incompressibility condition (2.7), equation (2.11) can be rewritten

$$\frac{\partial c}{\partial t} = \operatorname{div}(D_l \nabla c - cu) \quad \text{in } \tilde{\Omega}_l, \tag{2.12}$$

since $\operatorname{div} u = 0$ implies $\operatorname{div}(cu) = \nabla c \cdot u + c \operatorname{div} u = \nabla c \cdot u$.

The boundary conditions on c are

$$\begin{aligned} &\text{wall} && \left[\frac{\partial c}{\partial n_w} = 0 \quad \text{on } \tilde{\Gamma}_{wi} \cup \tilde{\Gamma}_{wo} \cup \tilde{\Gamma}_{R+E}, \right. \\ &\text{lumen} && \left[\begin{array}{l} D_l \dfrac{\partial c}{\partial n_l} - u \cdot n_l \, c = 0 \quad \text{or} \quad c = 0 \text{ on } \tilde{\Gamma}_{li}, \\ \dfrac{\partial c}{\partial n_l} = 0 \text{ on } \tilde{\Gamma}_{lo}, \end{array} \right. \end{aligned} \tag{2.13}$$

where n_w, n_l, and n_s are the respective unit outward normals to $\tilde{\Omega}_w$, $\tilde{\Omega}_l$, and $\tilde{\Omega}_s$. The first boundary condition involving u at the entry $\tilde{\Gamma}_{li}$ of the lumen is a *transparent condition* similar to those used in [2]. It allows for some backward diffusion at the interface $\tilde{\Gamma}_{li}$. In that case the first condition (2.8) has to be strengthened to

$$\exists \beta > 0 \text{ such that } -u \cdot n_l \ge \begin{cases} 0 & \text{on } \tilde{\Gamma}_{li} \backslash \tilde{\gamma}_{li}, \\ \beta & \text{on } \tilde{\gamma}_{li} \subset \tilde{\Gamma}_{li}, \end{cases} \quad \text{and} \quad u \cdot n_l \ge 0 \text{ on } \tilde{\Gamma}_{lo}, \tag{2.14}$$

where $\tilde{\gamma}_{li}$ is some fixed subarea of the cross section $\tilde{\Gamma}_{li}$ around its center. The second case with $c = 0$ on $\tilde{\Gamma}_{li}$ corresponds to the assumption that $\tilde{\Gamma}_{li}$ is chosen sufficiently far from the region of the stent $\tilde{\Sigma}_s$ that the concentration c on $\tilde{\Gamma}_{li}$ can be taken as zero.

The conditions on c at the interfaces are

$$\begin{aligned} &\text{wall/polymer} && D_w \frac{\partial c}{\partial n_w} + D_s \frac{\partial c}{\partial n_s} = 0 \quad \text{on } \tilde{\Gamma}_{ws}, \\ &\text{wall/lumen} && D_w \frac{\partial c}{\partial n_w} + D_l \frac{\partial c}{\partial n_l} = 0 \quad \text{on } \tilde{\Gamma}_{lw}, \\ &\text{polymer/lumen} && \frac{\partial c^+}{\partial n_s} = 0 \quad \text{and} \quad \frac{\partial c^-}{\partial n_l} = 0 \quad \text{on } \tilde{\Sigma}_s. \end{aligned} \tag{2.15}$$

Recall that the lumen is isolated from the polymer and that there is an upper trace c^+ and a lower trace c^- of the concentration on the two sides of the interface $\tilde{\Sigma}_s$. $\tilde{\Sigma}_s$ is made up of the N ring-shaped cracks in the three-dimensional domain, and different boundary conditions are specified on each side.

The initial condition is

$$c(0,x) = \begin{cases} c_0(x) & \text{in } \tilde{\Omega}_s, \\ 0 & \text{in } \tilde{\Omega}_w \cup \tilde{\Omega}_l, \end{cases} \tag{2.16}$$

for some positive function $c_0(x) \geq 0$ representing the initial concentration of the product at time 0 in the polymer.

3. Mathematical models for the dose. The *dose* is the cumulative concentration integrated over time from 0 to infinity in a given position x, that is,

$$q(x) \stackrel{\text{def}}{=} \int_0^\infty c(t,x)\, dt. \tag{3.1}$$

3.1. Equations for the dose. Since all our equations are linear, the equations, boundary conditions, and interface conditions for q are readily obtained from those for c. The equations for the dose $q(x)$ are

$$\operatorname{div}(D_w \nabla q) = 0 \quad \text{in } \tilde{\Omega}_w, \tag{3.2}$$

$$\operatorname{div}(D_s \nabla q) = -c_0 \quad \text{in } \tilde{\Omega}_s, \tag{3.3}$$

$$\operatorname{div}(D_l \nabla q - qu) = 0 \quad \text{in } \tilde{\Omega}_l. \tag{3.4}$$

The boundary conditions are

$$\begin{aligned} &\text{wall} && \left[\frac{\partial q}{\partial n_w} = 0 \quad \text{on } \tilde{\Gamma}_{wi} \cup \tilde{\Gamma}_{wo} \cup \tilde{\Gamma}_{R+E}, \right. \\ &\text{lumen} && \left[\begin{aligned} &D_l \frac{\partial q}{\partial n_l} - u \cdot n_l\, q = 0 \quad \text{or} \quad q = 0 \text{ on } \tilde{\Gamma}_{li}, \\ &\frac{\partial q}{\partial n_l} = 0 \quad \text{on } \tilde{\Gamma}_{lo}. \end{aligned} \right. \end{aligned} \tag{3.5}$$

Again the choice of the first transparent condition on $\tilde{\Gamma}_{li}$ requires the stronger condi-

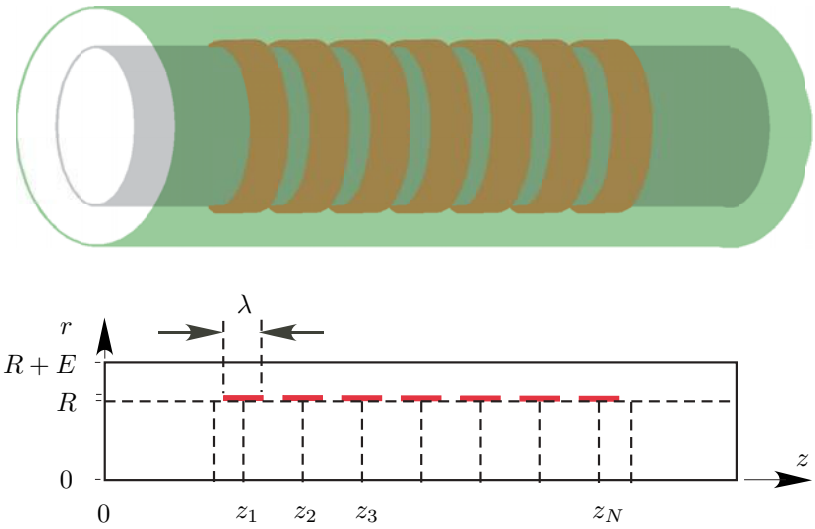

FIG. 3.1. *Schematic representation of the lumen, the polymer, and the wall (upper panel) and its* 2*-dimensional generating surface (lower panel).*

tion (2.14) on u. The conditions at the interfaces are

$$\begin{aligned}
&\text{wall/polymer} && D_w \frac{\partial q}{\partial n_w} + D_s \frac{\partial q}{\partial n_s} = 0 \quad \text{on } \tilde{\Gamma}_{ws},\\
&\text{wall/lumen} && D_w \frac{\partial q}{\partial n_w} + D_l \frac{\partial q}{\partial n_l} = 0 \quad \text{on } \tilde{\Gamma}_{lw},\\
&\text{polymer/lumen} && \frac{\partial q^+}{\partial n_s} = 0 \quad \text{and} \quad \frac{\partial q^-}{\partial n_l} = 0 \quad \text{on } \tilde{\Sigma}_s.
\end{aligned} \tag{3.6}$$

3.2. Variational equation for the dose. In this section we construct a variational formulation of the equations of the dose over the domain (cf. Figure 3.1)

$$\tilde{\Omega} \stackrel{\text{def}}{=} \left\{(x_1, x_2, z) \,:\, |x_1|^2 + |x_2|^2 < (R+E)^2,\, 0 < z < H\right\} \setminus \tilde{\Sigma}_s, \tag{3.7}$$

that is, $C_{R+E} \setminus \tilde{\Sigma}_s$. It is a bounded connected open domain with *two-dimensional cracks* along the polymer/lumen interfaces $\tilde{\Sigma}_s$. *This is not a Lipschitzian domain.* The associated space of solution is

$$V(\tilde{\Omega}) \stackrel{\text{def}}{=} \begin{cases} H^1(\tilde{\Omega}) & \text{with condition (2.14)–(2.9) on } u,\\ \{v \in H^1(\tilde{\Omega}) \,:\, v|_{\tilde{\Gamma}_{li}} = 0\} & \text{with condition (2.8)–(2.9) on } u. \end{cases} \tag{3.8}$$

We introduce the following bilinear form:

$$\begin{aligned} a(q,v) \stackrel{\text{def}}{=} &\int_{\tilde{\Omega}_w} D_w \nabla q \cdot \nabla v \, dx + \int_{\tilde{\Omega}_s} D_s \nabla q \cdot \nabla v \, dx\\ &+ \int_{\tilde{\Omega}_l} (D_l \nabla q - q u) \cdot \nabla v \, dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l \, q \, v \, d\Gamma. \end{aligned}$$

Then $q \in V(\tilde{\Omega})$ must verify the variational equation

$$\boxed{\forall v \in V(\tilde{\Omega}), \quad a(q,v) = \int_{\tilde{\Omega}_s} c_0 \, v \, dx.} \tag{3.9}$$

The bilinear form can be rewritten as

$$a(q,v) = \int_{\tilde{\Omega}} D\,\nabla q \cdot \nabla v\,dx - \int_{\tilde{\Omega}_l} q\,u \cdot \nabla v\,dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l\,q\,v\,d\Gamma,$$

by introducing the space-dependent diffusion defined almost everywhere on $\tilde{\Omega}$:

$$D(x) \stackrel{\text{def}}{=} \begin{cases} D_w & \text{if } x \in \tilde{\Omega}_w, \\ D_s & \text{if } x \in \tilde{\Omega}_s, \\ D_l & \text{if } x \in \tilde{\Omega}_l. \end{cases}$$

The bilinear form a is not symmetrical, but it is coercive on $V(\tilde{\Omega})$ under the two boundary conditions (2.8) and (2.9) on the velocity field u and $q = 0$ on $\tilde{\Gamma}_{li}$ and under the two boundary conditions (2.14) and (2.9) on the velocity field u for the transparent condition on q. Indeed, let $\alpha > 0$ be the minimum of D_w, D_s, and D_l. Then, using the fact that $\operatorname{div} u = 0$ and condition (2.9) and (2.8), we get

$$a(q,q) \geq \alpha \int_{\tilde{\Omega}} |\nabla q|^2\,dx - \frac{1}{2}\int_{\tilde{\Gamma}_{li}} u \cdot n_l\,|q|^2\,d\Gamma + \frac{1}{2}\int_{\tilde{\Gamma}_{lo}} u \cdot n_l\,|q|^2\,d\Gamma \geq \alpha \int_{\tilde{\Omega}} |\nabla q|^2\,dx.$$

Using condition (2.9) and (2.14), we get

$$\begin{aligned} a(q,q) &\geq \alpha \int_{\tilde{\Omega}} |\nabla q|^2\,dx - \frac{1}{2}\int_{\tilde{\Gamma}_{li}} u \cdot n_l\,|q|^2\,d\Gamma + \frac{1}{2}\int_{\tilde{\Gamma}_{lo}} u \cdot n_l\,|q|^2\,d\Gamma \\ &\geq \alpha \int_{\tilde{\Omega}} |\nabla q|^2\,dx + \frac{\beta}{2}\int_{\tilde{\gamma}_{li}} q^2\,d\tilde{\Sigma} \geq \min\left\{\alpha, \frac{\beta}{2}\right\}\left\{\int_{\tilde{\Omega}} |\nabla q|^2\,dx + \int_{\tilde{\gamma}_{li}} q^2\,d\tilde{\Sigma}\right\}. \end{aligned}$$

However, the last term on the right-hand side is an equivalent norm on $H^1(\tilde{\Omega})$ and a is coercive on it. Therefore, by the Lax–Milgram theorem (cf. [8]), there exists a unique $q \in V(\tilde{\Omega})$ solution of the variational equation (3.9).

4. Equations for the dose as the thickness of the polymer goes to zero. In this section we construct new equations for the dose as the thickness of the polymer goes to zero, while keeping the total mass of product constant in the polymer. They are obtained from the stent made up of N identical equally spaced flat rings, with $L > 0$ the distance between the center of two consecutive struts; λ, $0 < \lambda < L$, the width of the rings; and $e > 0$ the thickness of the polymer.

4.1. Parametrization of the thickness. Start from the zero-thickness stent

$$\tilde{\Sigma}_s \stackrel{\text{def}}{=} \bigcup_{i=1}^{N} \left\{ (x_1,x_2,z) \,:\, \begin{array}{l} |x_1|^2 + |x_2|^2 = R^2 \\ 0 < z < H \text{ and } |z - z_i| \leq \lambda/2 \end{array} \right\} \tag{4.1}$$

made up of N identical equally spaced flat rings, with $L > 0$ the distance between the centerlines of two consecutive struts and λ, $0 < \lambda < L$, the width of the rings (cf. Figure 3.1). Let ε, $0 < \varepsilon \leq e$, be the variable thickness of the polymer, and define the new domain occupied by the polymer as

$$\tilde{\Omega}_s^{\varepsilon} \stackrel{\text{def}}{=} \bigcup_{i=1}^{N} \left\{ (x_1,x_2,z) \,:\, \begin{array}{l} R^2 < |x_1|^2 + |x_2|^2 < (R+\varepsilon)^2 \\ 0 < z < H \text{ and } |z - z_i| < \lambda/2 \end{array} \right\},$$

where z_i is the position of the ith strut along the z-axis. This induces a new domain for the wall

$$\tilde{\Omega}_w^\varepsilon \stackrel{\text{def}}{=} \left\{(x_1,x_2,z) \,:\, \begin{array}{l} R^2 < |x_1|^2+|x_2|^2 < (R+E)^2 \\ 0<z<H \end{array}\right\} \setminus \bigcup_{i=1}^N \left\{(x_1,x_2,z) \,:\, \begin{array}{l} R^2 \le |x_1|^2+|x_2|^2 \le (R+\varepsilon)^2 \\ 0<z<H \text{ and } |z-z_i| \le \lambda/2 \end{array}\right\}.$$

For $\varepsilon = 0$, $\tilde{\Omega}_s^0 = \varnothing$ and

$$\tilde{\Omega}_w^0 = \left\{(x_1,x_2,z) \,:\, R^2 < |x_1|^2+|x_2|^2 < (R+E)^2 \text{ and } 0<z<H\right\} = C_{R+E}\backslash\overline{C_R}.$$

Since, up to a set of zero measure, $\tilde{\Omega}_w^\varepsilon \cup \tilde{\Omega}_s^\varepsilon = \tilde{\Omega}_w^0$ and $\tilde{\Omega} = \tilde{\Omega}_w^\varepsilon \cup \tilde{\Omega}_s^\varepsilon \cup \tilde{\Omega}_l = \tilde{\Omega}_w^0 \cup \tilde{\Omega}_l$, it will be convenient to define the new space-dependent diffusion D^ε almost everywhere on $\tilde{\Omega}$ as

$$\boxed{D^\varepsilon(x) \stackrel{\text{def}}{=} \begin{cases} D_w & \text{if } x \in \tilde{\Omega}_w^\varepsilon, \\ D_s & \text{if } x \in \tilde{\Omega}_s^\varepsilon, \\ D_l & \text{if } x \in \tilde{\Omega}_l, \end{cases}}$$

and the new bilinear form

$$\boxed{a^\varepsilon(q,v) \stackrel{\text{def}}{=} \int_{\tilde{\Omega}} D^\varepsilon \,\nabla q \cdot \nabla v \, dx - \int_{\tilde{\Omega}_l} q\, u \cdot \nabla v \, dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l \, q \, v \, d\Gamma,}$$

which turns out to be coercive with the same constant (independent of ε) as for the bilinear form $a(q,v)$ on $V(\tilde{\Omega})$. Here, to make the connection with the notation of the previous sections, the bilinear form $a(q,v)$ is now equal to $a^e(q,v)$. Note that the parameter ε occurs only in the definition of the diffusion coefficient D^ε and not in the domains over which the integrals are defined.

The initial linear right-hand side

$$\ell(v) \stackrel{\text{def}}{=} \int_{\tilde{\Omega}_s} c_0 \, v \, dx \tag{4.2}$$

(for the thickness e) has to be adjusted in order to deliver the same mass of product for a thickness ε. Assume that the initial concentration c_0 is constant in $\tilde{\Omega}_s$; that is, the total mass of product in the polymer is

$$\begin{aligned} m &\stackrel{\text{def}}{=} c_0 \int_{\tilde{\Omega}_s} dx = c_0 \sum_{i=1}^N \int_{z_i-\lambda/2}^{z_i+\lambda/2} dz \int_R^{R+e} 2\pi\, r \, dr \\ &= c_0 \, N \, \lambda\pi \, \left[(R+e)^2 - R^2\right] = \boxed{c_0 \, N \, \lambda\pi \, e \, (2R+e).} \end{aligned}$$

Define the new concentration c_0^ε such that the total mass remains m over the new domain $\tilde{\Omega}_s^\varepsilon$; that is,

$$\begin{aligned} m &= \int_{\tilde{\Omega}_s^\varepsilon} c_0^\varepsilon \, dx = \sum_{i=1}^N \int_{z_i-\lambda/2}^{z_i+\lambda/2} dz \int_R^{R+\varepsilon} c_0^\varepsilon \, 2\pi \, r \, dr \\ &= c_0^\varepsilon \, N \, \lambda\pi \, \left[(R+\varepsilon)^2 - R^2\right] = \boxed{c_0^\varepsilon \, N \, \lambda \, \pi \, \varepsilon \, (2R+\varepsilon).} \end{aligned}$$

In the domain $\tilde{\Omega}_s^\varepsilon$ occupied by the polymer, choose the new concentration

$$\boxed{c_0^\varepsilon \stackrel{\text{def}}{=} \frac{1}{\varepsilon}\left(\frac{1}{\lambda\,(2R+\varepsilon)\,\pi}\right)\frac{m}{N}}$$

and the corresponding linear right-hand side

$$\boxed{\ell^\varepsilon(v) \stackrel{\text{def}}{=} \int_{\tilde{\Omega}_s^\varepsilon} c_0^\varepsilon\, v\, dx.} \tag{4.3}$$

The new variational problems indexed by ε, $0 < \varepsilon \le e$, are

$$\boxed{\exists q^\varepsilon \in V(\tilde{\Omega}) \quad \text{such that } \forall v \in V(\tilde{\Omega}), \quad a^\varepsilon(q^\varepsilon, v) = \ell^\varepsilon(v),} \tag{4.4}$$

where $\tilde{\Omega}$ is the open cylinder C_{R+E} minus the stent $\tilde{\Sigma}_s$, as defined in (3.7).

4.2. Limiting process. The next step is to determine the limit q^0 of the dose q^ε as ε goes to zero, and to show that it is a solution of a new variational equation.

THEOREM 4.1. *As $\varepsilon > 0$ goes to zero, the solution $q_\varepsilon \in V(\tilde{\Omega})$ of (4.4) weakly converges to the solution $q^0 \in V(\tilde{\Omega})$ of the variational equation*

$$\boxed{\forall v \in V(\tilde{\Omega}), \quad a^0(q^0, v) = \ell^0(v),} \tag{4.5}$$

where

$$\boxed{\ell^0(v) \stackrel{\text{def}}{=} \int_{\tilde{\Sigma}_s} c_s\, v^+\, dx, \qquad c_s \stackrel{\text{def}}{=} \frac{1}{\lambda\, 2R\,\pi}\frac{m}{N},} \tag{4.6}$$

$$\boxed{a^0(q^0, v) \stackrel{\text{def}}{=} \int_{\tilde{\Omega}} \nabla q^0 \cdot D^0\, \nabla v\, dx - \int_{\tilde{\Omega}_l} q^0\, u \cdot \nabla v\, dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l\, q^0\, v\, d\Gamma} \tag{4.7}$$

are the respective continuous linear and bilinear forms on $V(\tilde{\Omega})$, c_s is the surface density of the product *in kg/m^2, v^+ is the trace of v on the upper side of $\tilde{\Sigma}_s$, and D^0 is the diffusion defined almost everywhere in $\tilde{\Omega}$:*

$$\boxed{D^0(x) \stackrel{\text{def}}{=} \begin{cases} D_w & \text{if } x \in \tilde{\Omega}_w^0, \\ D_l & \text{if } x \in \tilde{\Omega}_l. \end{cases}} \tag{4.8}$$

Proof. The proof follows by standard arguments. ∎

4.3. Equations for q^0. From the variational equation (4.5) for q^0 we get the following set of equations for the dose $q^0(x,t)$:

$$\operatorname{div}(D_w \nabla q^0) = 0 \quad \text{in } \tilde{\Omega}_w^0, \tag{4.9}$$

$$\operatorname{div}(D_l \nabla q^0 - q^0 u) = 0 \quad \text{in } \tilde{\Omega}_l. \tag{4.10}$$

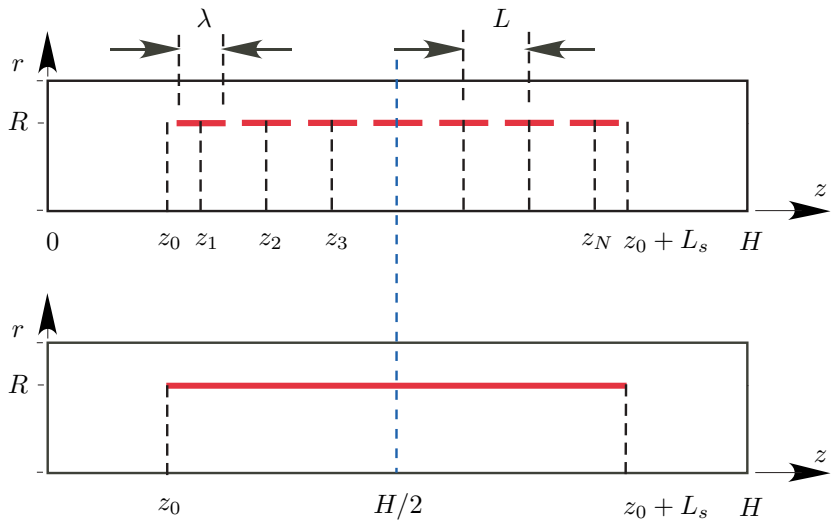

FIG. 5.1. *Stent/lumen and stent/wall interfaces for N struts (upper panel) and as N goes to infinity (lower figure).*

The boundary conditions are

$$
\text{(4.11)}\qquad
\begin{aligned}
&\text{wall} \quad \begin{cases} \dfrac{\partial q^0}{\partial n_w} = 0 & \text{on } \tilde{\Gamma}_{wi} \cup \tilde{\Gamma}_{wo} \cup \tilde{\Gamma}_{R+E}, \\ D_w \dfrac{\partial q^{0+}}{\partial n_w} = c_s & \text{on } \tilde{\Sigma}_s, \end{cases} \\
&\text{lumen} \quad \begin{cases} D_l \dfrac{\partial q^0}{\partial n_l} - u \cdot n_l \, q^0 = 0 \quad \text{or} \quad q^0 = 0 & \text{on } \tilde{\Gamma}_{li}, \\ \dfrac{\partial q^0}{\partial n_l} = 0 & \text{on } \tilde{\Gamma}_{lo}, \\ \dfrac{\partial q^{0-}}{\partial n_l} = 0 & \text{on } \tilde{\Sigma}_s. \end{cases}
\end{aligned}
$$

The condition at the interface is

$$
\text{(4.12)}\qquad \text{wall/lumen} \quad D_w \frac{\partial q^0}{\partial n_w} + D_l \frac{\partial q^0}{\partial n_l} = 0 \quad \text{on } \tilde{\Gamma}_{lw}.
$$

5. Asymptotic stent. In the design of the stent, we are left with several parameters: the surface density of product $c_s = m/(2\pi RN\lambda)$, the total length of the space occupied by the stent $L_s = NL$, the ratio $\rho = N\lambda/NL = \lambda/L$ between the width of a strut λ and the distance L between two successive struts, and the total number N of struts. Recall that the stent (see Figure 5.1) is specified by the set

$$
\tilde{\Sigma}_s^N \overset{\text{def}}{=} \bigcup_{i=1}^{N} \left\{ (x_1, x_2, z) : \begin{array}{l} x_1^2 + x_2^2 = R^2 \\ z_i - \dfrac{\lambda}{2} \le z \le z_i + \dfrac{\lambda}{2} \end{array} \right\}, \quad z_i = z_0 + \left(i - \frac{1}{2} \right) L, \ 1 \le i \le N,
$$

where the superscript emphasizes the dependence on N. Recall that

$$
z_0 = \frac{H - L_s}{2} > 0.
$$

Therefore the N-strut stent and the asymptotic stent will be centered in $[0, H]$:

$$[z_0, z_0 + L_s] = [z_0, z_0 + NL] \subset]0, H[\quad \text{and} \quad z_0 + \frac{NL}{2} = \frac{H}{2}.$$

In this section we construct an asymptotic model for the dose $q_N^0 = q^0$ as the number of struts goes to infinity, while keeping constant the length L_s, the ratio ρ, and the surface density of the product c_s. Again the superscript on q_N^0 emphasizes the dependence of q^0 on N. The main technical difference between this and the asymptotic analysis in the previous section is that the space of the solution will also depend on N. In general, even if we can find a uniform bound in a large enough function space independent of N, we will not be able to use test functions in the fixed larger space unless the projection onto the N-dependent solution spaces is strongly continuous. This asymptotic problem is very similar to the *Neumann sieve* studied by [13, 5, 7], where the plane surface is replaced by the lateral boundary of the cylinder of radius R. Fortunately here the total surface of the *holes* is constant and different from zero in the limiting process, and there will be no discontinuity of the trace of the asymptotic solution. The proof will use the weak convergence of a sequence of characteristic functions associated with the N-stent strut as in [6].

5.1. Construction of the asymptotic problem. Recall that for fixed N the dose q_N^0 is the solution in the space

$$V(\tilde{\Omega}^N) \stackrel{\text{def}}{=} \begin{cases} H^1(\tilde{\Omega}^N), & \text{condition (2.14)–(2.9) on } u, \\ \{v \in H^1(\tilde{\Omega}^N) \,:\, v|_{\tilde{\Gamma}_{li}} = 0\}, & \text{condition (2.8)–(2.9) on } u, \end{cases} \tag{5.1}$$

$$\tilde{\Omega}^N \stackrel{\text{def}}{=} \{(x_1, x_2, z) \,:\, |x_1|^2 + |x_2|^2 < (R+E)^2,\, 0 < z < H\} \backslash \tilde{\Sigma}_s^N \tag{5.2}$$

of the variational equation

$$\forall v \in V_N, \quad a^0(q_N^0, v) = \ell_N^0(v). \tag{5.3}$$

The linear form can now be rewritten in terms of the following characteristic function on $[0, H]$,

$$\chi_N(z) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } z \in \displaystyle\bigcup_{i=1}^{N} \left[z_i - \frac{\lambda}{2}, z_i + \frac{\lambda}{2} \right], \\ 0 & \text{otherwise,} \end{cases} \tag{5.4}$$

$$\begin{aligned} \ell_N^0(v) = \int_{\tilde{\Sigma}_s^N} c_s\, v^+\, dx &= \sum_{i=1}^{N} \int_{z_i - \frac{\lambda}{2}}^{z_i + \frac{\lambda}{2}} dz\, R \int_0^{2\pi} d\theta\, c_s\, v(R^+, \theta, z) \\ &= c_s \int_0^H dz\, \chi_N(z)\, R \int_0^{2\pi} d\theta\, v(R^+, \theta, z), \end{aligned} \tag{5.5}$$

or in terms of the characteristic function $\chi_{\tilde{\Sigma}_s^N}$, defined on the target area $\tilde{\Sigma}$ in the lateral boundary of the cylinder C_R,

$$\ell_N^0(v) = \int_{\tilde{\Sigma}} c_s \chi_{\tilde{\Sigma}_s^N}\, v^+\, d\tilde{\Sigma}, \quad \chi_{\tilde{\Sigma}_s^N}(x) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } x \in \tilde{\Sigma}_s^N, \\ 0 & \text{otherwise.} \end{cases}$$

The bilinear form

$$\boxed{a^0(w,v) = \int_{\tilde{\Omega}^0_w} D_w\, \nabla w \cdot \nabla v\, dx + \int_{\tilde{\Omega}_l} (D_l\, \nabla w - w\, u) \cdot \nabla v\, dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l\, w\, v\, d\Gamma} \tag{5.6}$$

is independent of N. Assuming that there exist constants L_s, $0 < L_s < H$, and ρ, $0 < \rho < 1$, such that, as N goes to infinity, $LN = L_s$ and $\lambda N = \rho L_s$, it is readily seen that the sequence $\{\chi_N\}$ is uniformly bounded in $L^2(0,H)$ and weakly convergent:

$$\begin{aligned} \forall p \geq 1, \quad & \int_0^H (\chi_N)^p\, dz = \int_0^H \chi_N\, dz = N\lambda = \rho\, L_s = \text{constant} \\ & \Rightarrow \chi_N \rightharpoonup \rho\, \chi_{[z_0, z_0+L_s]} \quad L^2(0,H)\text{-weak}, \\ \forall \varphi \in L^2(0,H), \quad & \int_0^H \chi_N\, \varphi\, dz \to \rho \int_{z_0}^{z_0+L_s} \varphi\, dz, \end{aligned}$$

where

$$\chi_{[z_0,z_0+L_s]}(z) \stackrel{\text{def}}{=} \begin{cases} 1, & z \in [z_0, z_0+L_s], \\ 0 & \text{otherwise.} \end{cases} \tag{5.7}$$

Equivalently,

$$\chi_{\tilde{\Sigma}^N_s} \rightharpoonup \rho\, \chi_{\tilde{\Sigma}} \quad L^2(\tilde{\Sigma})\text{-weakly} \quad \text{and} \quad \forall \varphi \in L^2(\tilde{\Sigma}), \quad \int_{\tilde{\Sigma}} \chi_{\tilde{\Sigma}^N_s}\, \varphi\, d\Sigma \to \rho \int_{\tilde{\Sigma}} \varphi\, d\Sigma,$$

where $\tilde{\Sigma}$ is the target area as defined in (2.3).

Since $L_s = NL$, $\lambda N = \rho L_s$, and $\rho = \lambda / L$ are constant in the limiting process, we get for all v in $L^2(\tilde{\Sigma})$

$$\begin{aligned} \ell^0_N(v) &= c_s \int_{\tilde{\Sigma}} \chi_{\tilde{\Sigma}^N_s}\, v\, d\Sigma = c_s \int_0^H dz\, \chi_N(z)\, R \int_0^{2\pi} d\theta\, v(R^+, \theta, z) \\ &\to \ell^0_\infty(v) \stackrel{\text{def}}{=} c_s\, \rho \int_{z_0}^{z_0+L_s} dz\, R \int_0^{2\pi} d\theta\, v(R^+, \theta, z) = c_s\, \rho \int_{\tilde{\Sigma}} v^+\, d\Gamma. \end{aligned}$$

This suggests introducing the new domain $\tilde{\Omega}^\infty$,

$$\tilde{\Omega}^\infty \stackrel{\text{def}}{=} \tilde{\Omega}^0 \backslash \tilde{\Sigma}, \tag{5.8}$$

in the open cylinder C_{R+E},

$$\tilde{\Omega}^0 \stackrel{\text{def}}{=} C_{R+E} = \left\{(x_1, x_2, z) \,:\, |x_1|^2 + |x_2|^2 < (R+E)^2,\, 0 < z < H\right\}, \tag{5.9}$$

along with the new larger space of solution

$$\boxed{V(\tilde{\Omega}^\infty) \stackrel{\text{def}}{=} \begin{cases} H^1(\tilde{\Omega}^\infty), & \text{condition (2.14)–(2.9) on } u, \\ \left\{v \in H^1(\tilde{\Omega}^\infty) \,:\, v|_{\tilde{\Gamma}_{li}} = 0\right\}, & \text{condition (2.8)–(2.9) on } u, \end{cases}} \tag{5.10}$$

and the smaller space

$$\boxed{V(\tilde{\Omega}^0) \stackrel{\text{def}}{=} \begin{cases} H^1(\tilde{\Omega}^0), & \text{condition (2.14)–(2.9) on } u, \\ \left\{v \in H^1(\tilde{\Omega}^0) \,:\, v|_{\tilde{\Gamma}_{li}} = 0\right\}, & \text{condition (2.8)–(2.9) on } u. \end{cases}} \tag{5.11}$$

Observe that for all $N \geq 1$, $V(\tilde{\Omega}^0) \subset V(\tilde{\Omega}^N) \subset V(\tilde{\Omega}^\infty)$, and recall that the linear term acts only on the upper part of the new crack $\tilde{\Sigma}$, that is,

$$\boxed{\ell^0_\infty(v) \stackrel{\text{def}}{=} \int_{\tilde{\Sigma}} \rho\, c_s\, v^+\, d\Gamma.} \tag{5.12}$$

It is easy to show that the solutions q^0_N are uniformly bounded in the norm of $V(\tilde{\Omega}^\infty)$, that there is a subsequence which weakly converges to some $q^0_\infty \in V(\tilde{\Omega}^\infty)$, and that q^0_∞ is a solution of the variational equation

$$\boxed{\forall v \in V(\tilde{\Omega}^0), \quad a^0(q^0_\infty, v) = \ell^0_\infty(v).} \tag{5.13}$$

However this equation is incomplete since the test function belongs to the smaller space $H^1(\tilde{\Omega}^0)$ which does not see the crack $\tilde{\Sigma}$.

THEOREM 5.1. *Assume that there exist constants L_s, $0 < L_s < H$, and ρ, $0 < \rho < 1$, such that, as N goes to infinity,*[3] *$LN = L_s$ and $\lambda N = \rho L_s$. The sequence of solutions $q^0_N \in V(\tilde{\Omega}^N)$ converges $V(\tilde{\Omega}^\infty)$-weakly to q^0_∞, which is the solution in $V(\tilde{\Omega}^0)$ of the variational equation*

$$\boxed{\exists q^0_\infty \in V(\tilde{\Omega}^0) \quad \textit{such that}\, \forall v \in V(\tilde{\Omega}^0), \quad a^0(q^0_\infty, v) = \ell^0_\infty(v),} \tag{5.14}$$

where the continuous bilinear and the linear forms a^0 and ℓ^0_∞ are given by the expressions (5.6) *and* (5.12).

Remark 5.1. When the product is applied on the inner and outer surfaces of the stent, the asymptotic model predicts that the two sides contribute to increasing the total dose in the wall.

Proof. By the weak convergence of $\{q^0_N\}$ in $V(\tilde{\Omega}^\infty)$, the *jump* $[q^0_N] \stackrel{\text{def}}{=} \left(q^{0+}_N - q^{0-}_N\right)\big|_{\tilde{\Sigma}}$ of q^0_N across $\tilde{\Sigma}$ strongly converges:

$$\left[q^0_N\right] \to \left[q^0_\infty\right] \quad L^2(\tilde{\Sigma})\text{-strongly.}$$

By continuity of the trace of q^0_N across the region of the holes $\tilde{\Sigma} \backslash \tilde{\Sigma}^N_s$,

$$\forall \varphi \in L^2(\tilde{\Sigma}), \quad \int_{\tilde{\Sigma} \backslash \tilde{\Sigma}^N_s} [q^0_N]\, \varphi\, d\Gamma = 0.$$

Since we already have

$$\chi_N \rightharpoonup \rho\, \chi_{[z_0, z_0 + L_s]} \quad L^2(0,H)\text{-weakly} \quad \text{and} \quad \chi_{\tilde{\Sigma}^N_s} \rightharpoonup \rho\, \chi_{\tilde{\Sigma}} \quad L^2(\tilde{\Sigma})\text{-weakly,}$$

then for all $\varphi \in L^2(\tilde{\Sigma})$

$$\begin{aligned} 0 = \int_{\tilde{\Sigma} \backslash \tilde{\Sigma}^N_s} [q^0_N]\, \varphi\, d\Gamma &= \int_{\tilde{\Sigma}} \left(1 - \chi_{\tilde{\Sigma}^N_s}\right)\, [q^0_N]\, \varphi\, d\Gamma \\ &\to \int_{\tilde{\Sigma}} (1 - \rho\, \chi_{\tilde{\Sigma}})\, [q^0_\infty]\, \varphi\, d\Gamma = (1-\rho) \int_{\tilde{\Sigma}} [q^0_\infty]\, \varphi\, d\Gamma \\ &\Rightarrow\ \forall \varphi \in L^2(\tilde{\Sigma}), \quad (1-\rho) \int_{\tilde{\Sigma}} [q^0_\infty]\, \varphi\, d\Gamma = 0. \end{aligned}$$

Hence for $0 \leq \rho < 1$

$$[q^0_\infty] = 0 \text{ along } \tilde{\Sigma} \quad \Rightarrow\ q^0_\infty \in H^1(\tilde{\Omega}^0) \quad \Rightarrow\ q^0_\infty \in V(\tilde{\Omega}^0).$$

Combining $q^0_\infty \in V(\tilde{\Omega}^0)$ with (5.13) and the fact that a^0 is coercive on $V(\tilde{\Omega}^0)$, we conclude that q^0_∞ is the unique solution of the variational equation (5.14). ∎

[3] $L = L_s/N$ and $\lambda = \rho L_s/N$ both depend on N and go to zero as N goes to infinity.

5.2. Equations for the dose of the asymptotic stent. From the variational equation (5.14) for q^0_∞ we get the following set of equations for the dose $q^0_\infty(x,t)$:

$$\operatorname{div}(D_w \nabla q^0_\infty) = 0 \quad \text{in } \tilde{\Omega}^0_w, \tag{5.15}$$

$$\operatorname{div}(D_l \nabla q^0_\infty - q^0_\infty u) = 0 \quad \text{in } \tilde{\Omega}_l. \tag{5.16}$$

The boundary conditions are

$$\begin{aligned} &\text{wall} && \begin{cases} \dfrac{\partial q^0_\infty}{\partial n_w} = 0 & \text{on } \tilde{\Gamma}_{wi} \cup \tilde{\Gamma}_{wo} \cup \tilde{\Gamma}_{R+E}, \end{cases} \\ &\text{lumen} && \begin{cases} D_l \dfrac{\partial q^0_\infty}{\partial n_l} - u \cdot n_l \, q^0_\infty = 0 \text{ or } q^0_\infty = 0 & \text{on } \tilde{\Gamma}_{li}, \\ \dfrac{\partial q^0_\infty}{\partial n_l} = 0 & \text{on } \tilde{\Gamma}_{lo}. \end{cases} \end{aligned} \tag{5.17}$$

The condition at the interface is

$$\text{wall/lumen} \quad D_w \frac{\partial q^0_\infty}{\partial n_w} + D_l \frac{\partial q^0_\infty}{\partial n_l} = \begin{cases} 0 & \text{on } \tilde{\Gamma}^\infty_{lw}, \\ \rho \, c_s & \text{on } \tilde{\Sigma}, \end{cases} \tag{5.18}$$

where

$$\tilde{\Gamma}^\infty_{lw} = \left\{ (x_1, x_2, z) \,:\, x_1^2 + x_2^2 + z^2 = R^2 \text{ and } z \in]0, H[\setminus [z_0, z_0 + L_s] \right\}. \tag{5.19}$$

5.3. Extension to general periodic stents. The previous modeling and asymptotic analysis rests on the introduction of a periodic characteristic function (only a function of the axial variable z). Yet the modeling and the variational equations of section 4 remain true for an arbitrary characteristic function $\chi(z,\theta)$ of the axial variable z and the angular variable θ in cylindrical coordinates. Stents with a periodicity in a transverse direction (e.g., a spiral or helical shape) can now be considered and, once the pattern (cf. Figure 1.2) of the periodic stent has been selected, an asymptotic analysis similar to that of the previous subsections can be carried out.

Given an arbitrary characteristic function χ defined in the target area $\tilde{\Sigma}$,

$$\chi \in X(\tilde{\Sigma}) \stackrel{\text{def}}{=} \{\chi \in L^2(\tilde{\Sigma}) \,:\, (1-\chi)\chi = 0 \text{ a.e. in } \tilde{\Sigma}\}, \tag{5.20}$$

the zero-thickness stent is completely specified by

$$\tilde{\Sigma}_s(\chi) \stackrel{\text{def}}{=} \{x \in \tilde{\Sigma} \,:\, \chi(x) = 1\}, \tag{5.21}$$

the cracked open domain by

$$\tilde{\Omega}(\chi) \stackrel{\text{def}}{=} \{(x_1, x_2, z) \,:\, x_1^2 + x_2^2 < (R+E)^2 \text{ and } 0 < z < H\} \setminus \tilde{\Sigma}_s(\chi), \tag{5.22}$$

and the space of solutions by

$$V(\chi) = V(\tilde{\Omega}(\chi)) \stackrel{\text{def}}{=} \{v \in V(\tilde{\Omega}) \,:\, (1-\chi)\,[v] = 0 \text{ on } \tilde{\Sigma}\}, \tag{5.23}$$

where $[v]$ denotes the jump of v across the target surface $\tilde{\Sigma}$. The dose $q = q(\chi)$ is the solution of the variational equation

$$\boxed{\exists q \in V(\chi) \quad \text{such that } \forall v \in V(\chi), \quad a^0(q,v) = \ell^0(\chi; v),} \tag{5.24}$$

TABLE 6.1
Parameters.

	Artery and Blood		
Notation	Description	mm	a-dimensional
R	Radius of the lumen	1.5	0.5

c_s	Surface density of product		10^{-8}

where

$$a^0(w,v) \stackrel{\text{def}}{=} \int_{\tilde{\Omega}_p^0} D_w\, \nabla w \cdot \nabla v\, dx + \int_{\tilde{\Omega}_l} (D_l\, \nabla w - w\, u) \cdot \nabla v\, dx + \int_{\tilde{\Gamma}_{lo}} u \cdot n_l\, w\, v\, d\Gamma, \tag{5.25}$$

$$\ell^0(\chi; v) \stackrel{\text{def}}{=} \int_{\tilde{\Sigma}} c_s\, \chi\, v\, d\tilde{\Sigma}. \tag{5.26}$$

The notation emphasizes the fact that ℓ^0 and V both depend on χ. This generalizes the equation of the dose to a stent of arbitrary geometry.

6. Numerical experimentation. In this section we complete the theoretical results by extensive numerical simulations in order to get a feeling for the kind of phenomena involved. The velocity profile u of the flow in the lumen has been obtained by solving the incompressible Navier–Stokes equations (269,000 unknowns). The geometry and the equation of the dose have been scaled in order to work with dimensionless variables. The geometry of the artery, the parameters of the incompressible Navier–Stokes equation, and the characteristics of the diffusion-transport equation are given in Table 6.1 with the condition $q = 0$ on $\tilde{\Sigma}_{li}$. As a point of comparison, the parameters of the Wiktor stent were approximatively $L = 0.7$ mm for the distance between the centers of two struts, $\lambda = 0.15$ mm for the width, and 3–4 mm for the diameter. The number of struts was $N = 24$, which gives a target area of length $L_s = 16.8$ mm and a ratio $\rho = 0.15/0.7 \simeq 0.214$.

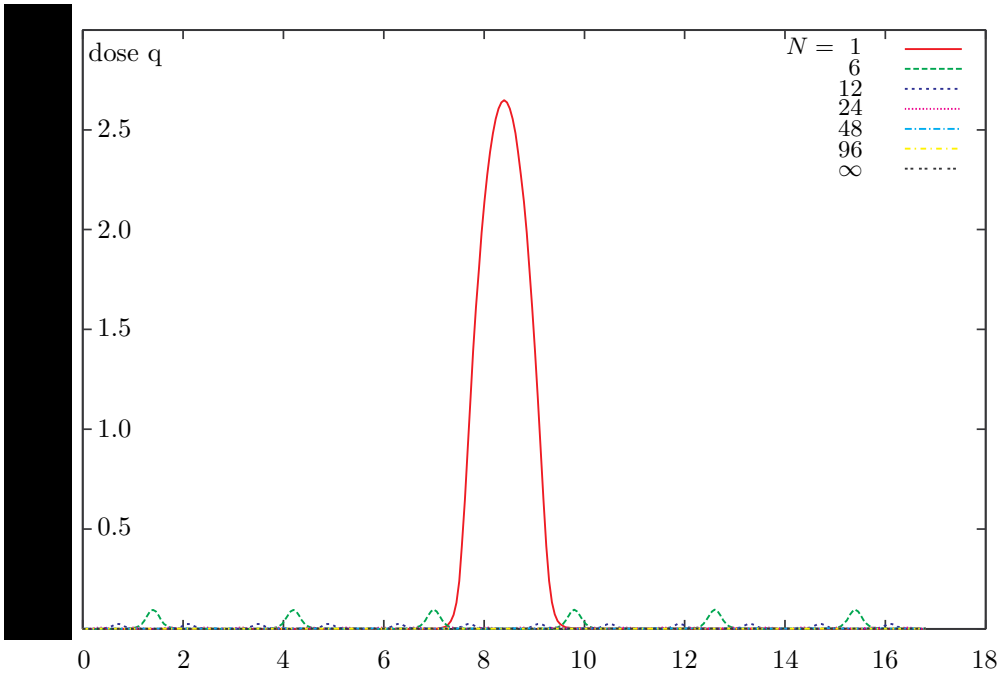

FIG. 6.1. *Dose versus the position z along the axis at the exterior radius $R+E=0.6333$ of the artery as a function of the number of struts N for $\rho=0.1$.*

We have made the computations for $\rho=0.1$, 0.2, 0.5, and 0.9 and for N from 1 to 382. We have chosen to display the dose at the outer radius $R+E$ of the artery for the case $\rho=0.1$ in order to avoid the large fluctuations at the lumen/wall interface. The graphs of the dose start at $z_0=6$ and extend to z_0+18, which goes slightly beyond the target region of length $L_s=16.8$ with the variable $z-z_0$ in abscissa. They are displayed for different values of the number of struts N. Because of the broad range of numerical values of the dose, three sets of graphs are used. Figure 6.1 is in the range of 0 to 2.7 for $N=1$, 6, 12, 24, 48, 96, ∞. At that scale, only the cases $N=1$, 6, and 12 are visible. Figure 6.2 has two sets of graphs: the first one in the range of 0 to 0.0065 for $N=24$, 48, 96, 192, 384, and $N=\infty$, and the second one in the range of 0 to 0.0020 for $N=48$, 96, 192, 384, and $N=\infty$.

As an indication of the highly irregular behavior of the dose in the vicinity of the stent, two figures give an (r,z)-plot of the dose at the upstream end of the target region occupied by the stent. For $\rho=0.1$, Figure 6.3 corresponds to $N=382$ struts and Figure 6.4 to the asymptotic stent. Notice the sharp spikes in the area of the struts and the sharp drop between two struts. It is also interesting that, even if the asymptotic theory predicts that the dose is continuous across the wall/lumen interface, a sharp drop is observed in the dose near the target area $\tilde{\Sigma}$ of the wall/lumen interface due to the high level of convection in the lumen. To get sharp and stable results, a very large number of variables was used in the numerical computations. Complete numerical tests and a description of the numerical method used will be reported in a subsequent paper. Finally, Table 6.2 gives the integral of the dose as a function of the number of struts N and the ratio ρ.

7. Concluding remarks.

7.1. The onchocerciasis control problem. A problem closely related to the coating of stents is the onchocerciasis control program [2]. Black flies are known not only as a nuisance, causing economic losses in different areas of human activities, but also as transmitters of pathogens and parasites to man and animals. In some areas, black flies are vectors of a filarial worm (Onchocerca volvulus) which causes a serious endemic disease whose final stage is known as river blindness. The strategy chosen to combat this parasite was to break the chain of transmission by destroying the vector at its most vulnerable state, that is, the larval state. To control black fly larvae in running waters, special products have been developed with targeted toxic effects. Helicopters are used to periodically spray the rivers at prescribed sites over very large geographical areas. The objective was to minimize the total amount of larvicide used to treat a segment of river while maintaining a mortality rate P of the larvae at each point in the river. The control parameters were the number of injections, the amount injected, and the location of the injections. It turned out that the minimum total weight corresponds to an infinity of uniformly distributed injection points. Of course, this asymptotic solution is not practically implementable when the injections are made by helicopters crossing the river. In practice, with real parameters, there was a significant drop in the minimal weights going from 1 (166.9kg) to 2 (22.97kg) to 3 (13.12kg) injections, and 20 (5.9kg) injections gave a total weight close to the asymptotic solution (5.34kg). Experiments and measurements were possible in the laboratory, and a reliable relation between the mortality rate P of the larvae and the required dose was established.

N	1	6	24	48	96	192	384	asympt.
Dose	2.6000	0.1000	0.0068	0.0020	0.0010	0.00075	0.00065	0.00065

7.2. Analogies between the two problems. The injection points on the river correspond to the positions of our struts. What is required is a relatively uniform dose in the wall along the target area in the vicinity of the lumen. In Figure 6.1 the case $N = 1$ gives a peak of 2.6 concentrated at the center of the stent for $N = 1$. Figure 6.2 goes to smaller scales. Starting with $N = 6$, the dose is roughly periodic in the target area and its amplitude decreases as N increases, as shown in Table 7.1. As in the onchocerciasis control problem and with realistic parameters, we observe a very high sensitivity of the amplitude of the dose for N small, but after $N = 24$ we have

practically reached the asymptotic level. Recall that the original Wiktor stent had $N = 24$ struts. If the mass surface density c_s becomes a design parameter, we could require a minimum therapeutic dose q_{min} on the upper side of the target area $\tilde{\Sigma}$ or in a small region S' above $\tilde{\Sigma}$,

$$q(\chi)^+ \geq q_{min} \text{ on } \tilde{\Sigma} \quad \text{or} \quad q(\chi)^+ \geq q_{min} \text{ on } S', \tag{7.1}$$

$$S' \stackrel{\text{def}}{=} \left\{ (x_1, x_2, z) \,:\, \begin{array}{l} R^2 < x_1^2 + x_2^2 < (R + e')^2 \\ z_0 < z < z_0 + L_s \end{array} \right\}, \quad 0 < e' < E, \tag{7.2}$$

while minimizing c_s.

This strategy is probably not far from what is required for the design. Yet the wall of the artery is quite different from a river. In the wall there are biochemical effects and dynamics that are not fully understood or, more importantly, quantified. Following the implant of a stent, the endothelial wall is seriously damaged. It is necessary to delay the growth of smooth muscle cells to give time for the arterial wall to be recolonized by endothelial cells that contain chemical mediators responsible for orderly control of the growth process. Without such cells the growth process goes incorrectly. What is required is a relationship between the rate of growth of the smooth muscle cells (analgous to the larval mortality rate in [2]) and the dose in the vicinity of the wall/lumen interface. This could be obtained by ex vivo experiments and measurements to relate the rate of growth of the smooth muscle cells to the therapeutic dose.

As a side remark, clinical observations indicate that restenosis often takes place at the ends of the stent. This is corroborated by the fact that the dose sharply drops at both ends of the stent, as predicted in Figures 6.2, 6.3, and 6.4.

7.3. Impact on the design process. Using real parameters, our numerical simulations have revealed the high sensitivity of the dose to the number of struts N of a periodic stent. The space distribution of the dose is almost periodic in the target area: It is maximal at the strut and decreases to a minimal value between two adjacent struts. The results also show that the design parameter N effectively controls the amplitude and the uniformity of the dose in the target area and that the dose is always above the dose of the asymptotic stent (cf. Figure 6.2). Furthermore, the amplitude of the dose diminishes as the number of struts is increased.

As the *quantitative discussion* of section 7.2 indicates, even if an asymptotic stent cannot be constructed, a periodic stent (with a sufficiently large number of struts) can be designed to produce a distribution of the dose that is very close to that of the asymptotic stent. In view of this analysis, the design of a stent should start from the asymptotic analysis described in section 5. From a numerical point of view, this is simple and requires only two-dimensional simulations. Given a bioactive material, the *lower therapeutic bound* on the dose, a fixed target area, and a deployment ratio ρ, the asymptotic stent would yield an estimate of the minimum value of the required mass surface density c_s (that is, a minimum total mass of bioactive material). The coating thickness of this material is easily obtained from the required total mass and the area of the target surface. Using the parameters obtained from the asymptotic design, the next step is to choose the number of struts N of the periodic stent of section 4. The numerical experiments of Figure 6.2 show that, for the same mass surface density c_s and ratio ρ, the dose of the periodic stent with a finite number of struts always lies above the dose for the asymptotic stent. Hence the same c_s can be used for an N-strut stent to achieve the same lower therapeutic bound. Then the

designer can adjust the number of struts and possibly reduce c_s in order to keep the dose under the upper therapeutic bound. This problem is two-dimensional and shares with the asymptotic stent the same geometrical simplicity.

As is often the case in design problems associated with complex systems, a simple operational model incorporating sensitive design parameters and retaining the essential features of the system can be extremely useful in quickly and economically identifying a good *suboptimal design*. Our analysis and design approach fall into that category and readily extend to more complex periodic stents (cf. section 5.3). As a better understanding of the biochemical and biophysical mechanisms in the wall becomes available, it will be incorporated into the model and the formulation of the design objectives in order to sharpen our results and improve the design process.

A MODEL OF CONTINUOUS SEDIMENTATION OF FLOCCULATED SUSPENSIONS IN CLARIFIER-THICKENER UNITS*

RAIMUND BÜRGER†, KENNETH H. KARLSEN‡, AND JOHN D. TOWERS§

Abstract. The chief purpose of this paper is to formulate and partly analyze a new mathematical model for continuous sedimentation-consolidation processes of flocculated suspensions in clarifier-thickener units. This model appears in two variants for cylindrical and variable cross-sectional area units, respectively (Models 1 and 2). In both cases, the governing equation is a scalar, strongly degenerate parabolic equation in which both the convective and diffusion fluxes depend on parameters that are discontinuous functions of the depth variable. The initial value problem for this equation is analyzed for Model 1. We introduce a simple finite difference scheme and prove its convergence to a weak solution that satisfies an entropy condition. A limited analysis of steady states as desired stationary modes of operation is performed. Numerical examples illustrate that the model realistically describes the dynamics of flocculated suspensions in clarifier-thickeners.

Key words. clarifier-thickener units, discontinuous flux, degenerate diffusion, uniqueness, stationary solutions, finite difference scheme, numerical simulation

1. Introduction.

Continuously operated clarifier-thickener units for the solid-liquid separation of suspensions are widely used in chemical engineering, mineral processing, the pulp-and-paper and food industries, and wastewater treatment. For many purposes, spatially one-dimensional mathematical models of these units are sufficient. They are usually based on the kinematic sedimentation theory by Kynch [62], which describes the batch settling of a so-called ideal suspension of small, equal-sized rigid spheres in a viscous fluid by the conservation law $u_t + b(u)_x = 0$ for the solids volume fraction u as a function of depth x and time t. The material-specific properties of the suspension are described by the Kynch batch flux density function $b(u)$. If a global conservation of mass principle is taken into account, then the extension of this theory to clarifier-thickener units leads to a conservation law with a flux that depends discontinuously on x, since the suspension feed flow is split into upwards- and downwards-directed bulk flows into the clarification and thickening zones, respectively. The discontinuous flux makes the well-posedness analysis and numerical simulation of the clarifier-thickener model difficult.

As is well known, the solution of the conservation law arising from the kinematic theory propagates along characteristics, which are straight lines in cylindrical vessels. However, most suspensions are not ideal; rather, they consist of small flocs, or as we

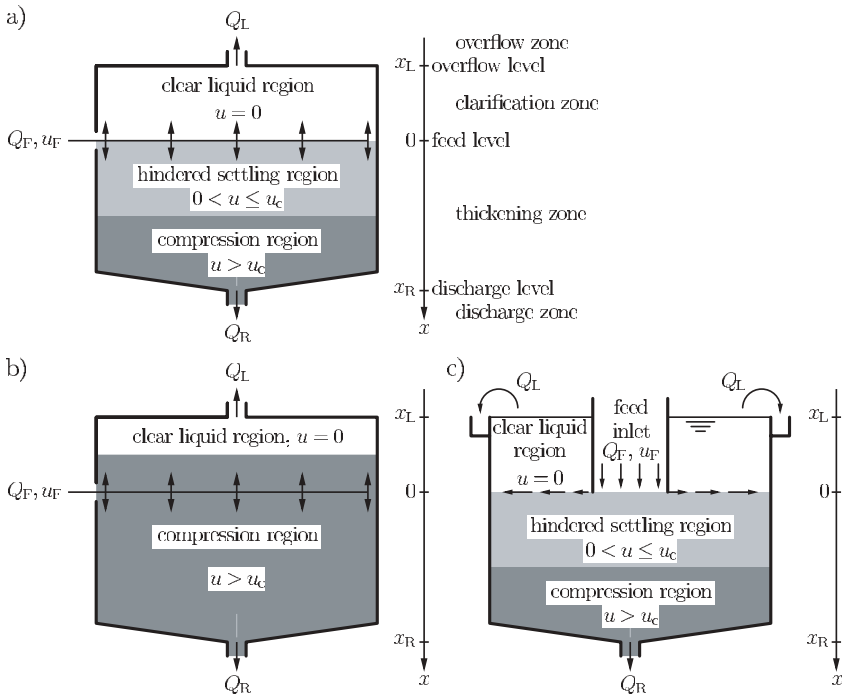

FIG. 1.1. *Clarifier-thickener units treating a flocculated suspension:* (a) *steady-state operation in conventional mode,* (b) *steady-state operation in high-rate mode,* (c) *a variant of the clarifier-thickener setup with a vertical feed inlet.*

say, they are *flocculated*. These mixtures include inorganic slurries such as tailings from mineral processing, which are flocculated artificially in order to enhance settling rates, as well as biological sludges in wastewater treatment. They form compressible sediment layers, which are characterized by curved isoconcentration lines in settling columns, and can therefore not be predicted by the kinematic theory. Instead, an extended dynamic model including pore pressure and effective solids stress has to be used. Such a model is provided by a theory of sedimentation-consolidation processes [10, 27], whose governing equation (if the model is reduced to one space dimension) is a quasi-linear degenerate parabolic equation, which degenerates into the equation of first-order hyperbolic type of the kinematic sedimentation model when $u \le u_c$, where u_c is a material-dependent *critical concentration* or *gel point* at which the solid flocs start to touch each other.

It is the purpose of this paper to present and analyze a clarifier-thickener model for flocculated suspensions as a combination of the first-order models for ideal suspensions with the sedimentation-consolidation theory, which contributes a strongly degenerate diffusion term. The proposed model consists of an initial value problem for a strongly degenerate parabolic PDE, in which both the convective flux and the diffusion flux depend discontinuously on the spatial variable x.

To be more precise, we consider a continuously operated axisymmetric clarifier-thickener vessel as drawn in two variants in Figures 1.1(a) and (b) and Figure 1.1(c), respectively. Throughout this paper, we assume that all flow variables depend on depth x and time t only. This means in particular that u is assumed to be constant across each horizontal cross section. We subdivide the vessel into four different zones:

the thickening zone ($0 < x < x_{\mathrm{R}}$), which is usually the unique zone considered in conventional analyses of continuous sedimentation, the clarification zone ($x_{\mathrm{L}} < x < 0$) located above, the underflow zone ($x > x_{\mathrm{R}}$), and the overflow zone ($x < x_{\mathrm{L}}$). The vessel is continuously fed at depth $x = 0$, the feed level, with fresh feed suspension at a volume feed rate $Q_{\mathrm{F}}(t) \geq 0$. The concentration of the feed suspension is $u_{\mathrm{F}}(t)$. The prescribed volume underflow rate, at which the thickened sediment is removed from the unit, is $Q_{\mathrm{R}}(t) \geq 0$. Consequently, the overflow rate is $Q_{\mathrm{L}}(t) = Q_{\mathrm{R}}(t) - Q_{\mathrm{F}}(t)$, where we assume that the two control functions $Q_{\mathrm{F}}(t)$ and $Q_{\mathrm{R}}(t)$ are chosen such that $Q_{\mathrm{L}}(t) \leq 0$. Of course, the solids concentrations in the underflow and overflow cannot be prescribed and are part of the solution. Furthermore, we distinguish between the four abovementioned *zones* in the clarifier-thickener, which are a property of the equipment modeled, and the clear liquid, hindered settling, and compression regions, in which a suspension at a given point of time has the concentrations zero, $0 < u \leq u_{\mathrm{c}}$, and $u > u_{\mathrm{c}}$, respectively. Thus, the time-dependent location of the regions is a property of a particular flow, that is, of the solution to the problem. Finally, let us mention that the hypothetical assumption $Q_{\mathrm{F}} < 0$ would mean that material is suctioned from rather than injected into the unit (as corresponding to our assumption $Q_{\mathrm{F}} \geq 0$). This case is not included in the present analysis.

The model includes two different stationary modes of operation that are usually distinguished in the applicative literature [34]: *conventional operation*, as shown in Figure 1.1(a), when the sediment level (where $u = u_{\mathrm{c}}$) is located below the feed level, and *high-rate* (also known as *high-capacity*) operation (Figure 1.1(b)), when one lets the sediment level (and thus the compression region) rise into the clarification zone. In the latter mode of operation, practitioners observe that the concentration above the compression region usually is zero. These distinctions are made in engineering applications, and we will show that both modes are captured by the model which we analyze in this paper. Figure 1.1(c) shows a variant of the clarifier-thickener setup of Figures 1.1(a) and (b), in which the feed flow enters the vessel from above through a feed inlet. Note that the feed inlet will usually occupy some of the cross-sectional area of the vessel. We assume that the vessel drawn in Figure 1.1(c) is controlled by regulating the feed flow Q_{F} and the discharge flow Q_{R}, such that no active control of the overflow rate Q_{L} is necessary. In any circumstance we consider a submerged feed source at a fixed vertical location. The notion "high rate" stems from the observation that this mode of operation usually permits higher solids throughput than the conventional mode, since the clarification zone can handle part of the solids feed flux. Capacity and design calculations based on the new model are, however, outside the scope of this paper. For the sake of simplicity, we also neglect the action of the rake provided in most industrial thickeners, which rotates above the gently sloped floor of the thickener to move the concentrated sediment towards the discharge opening.

Similar clarifier-thickener models were proposed by several authors including Barton, Li, and Spencer [6], Chancelier, Cohen de Lara, and Pacard [30], and Lev, Rubin, and Sheintuch [64]. All available treatments are, however, limited to the case of an ideal (nonflocculated) suspension, which is included as a special case in our analysis. In addition, we point out that in [30] the problem of flux discontinuities is circumvented by smoothing out the flux in small ε-neighborhoods of the flux around the levels zero and x_{R} (in our notation). However, uniqueness for $\varepsilon \to 0$ is proved in [30] for steady-state solutions only. Important contributions to the analysis and the determination of solutions to clarifier-thickener models for ideal suspensions have been made by Diehl [39, 40, 41, 42, 43], in which local-in-time existence and uniqueness

results for problems with piecewise constant initial data are obtained [39, 40, 41] and stationary solutions are completely classified [41, 43]. Numerical simulations using a Godunov-type scheme are presented in [40, 41, 42]. The paper [34] presents a limited discussion of a steady-state clarifier-thickener model for flocculated suspensions that has many features in common with the one presented here but is incomplete in that boundary conditions or flux transitions at the discharge level are lacking.

In a recent series of papers [19, 21, 23, 25] the authors with collaborators have initiated an activity aiming at providing a firm rigorous ground of mathematical (existence and uniqueness) and numerical analysis for the first-order clarifier-thickener models. Roughly speaking, the main ingredient in these clarifier-thickener models is a first-order scalar conservation law of the type

$$u_t + f\big(\boldsymbol{\gamma}(x), u\big)_x = 0, \tag{1.1}$$

where the (with respect to u, nonconvex) flux f and the discontinuous vector-valued coefficient $\boldsymbol{\gamma} = (\gamma_1, \gamma_2)$ are given functions. As is well known, independently of the smoothness of $\boldsymbol{\gamma}(x)$, solutions to (1.1) are in general not smooth, and weak solutions must be sought. Moreover, discontinuous weak solutions are in general not uniquely determined by their initial data. Consequently, an entropy condition must be imposed to single out the physically correct solution. These "physically relevant" solutions are called entropy weak solutions. When $\boldsymbol{\gamma}$ is smooth, Kružkov's theory [61] ensures the existence of a unique and stable entropy weak solution to (1.1). Kružkov's theory does not apply when $\boldsymbol{\gamma}$ is discontinuous. In our previous work cited above, which culminated in [25], we suggested using a variant of Kružkov's notion of entropy weak solution for (1.1) that accounts for the discontinuities in $\boldsymbol{\gamma}$. Moreover, we proved existence and uniqueness (stability) of such entropy weak solutions in a certain functional class. The existence of such solutions was a consequence of convergence results for various numerical schemes such as front tracking [19], a relaxation scheme [21], and upwind difference schemes [23, 25].

The papers [19, 21, 23, 25] were inspired by previous work in the area of conservation laws with discontinuous fluxes. Due to their many applications, this is an area that has enjoyed a lot of interest in recent years [2, 5, 9, 12, 39, 40, 48, 49, 50, 51, 52, 57, 59, 60, 65, 66, 67, 70, 72, 73, 75, 76, 77, 78]. (This list is not complete.) Without entering into too many details, let us just mention that the usual way to cope with the discontinuous parameter $\boldsymbol{\gamma}(x)$ is to express it as an additional conservation law $\boldsymbol{\gamma}_t = 0$, which yields a system of conservations laws for the "unknowns" $(\boldsymbol{\gamma}, u)$. The equation $\boldsymbol{\gamma}_t = 0$ introduces linearly degenerate fields in this system with eigenvalues that are zero. Consequently, if f_u is zero at some points $(\boldsymbol{\gamma}, u)$, then the system is nonstrictly hyperbolic and it experiences so-called nonlinear resonant behavior, which means more complicated wave interactions than in strictly hyperbolic systems. Indeed, one cannot in general expect to bound the total variation of the conserved quantities directly but only when measured under a certain singular mapping, as was done first in [76] for a related system. An alternative "scalar" approach in which $\boldsymbol{\gamma}$ is not treated as a separate unknown is presented in [52, 54, 55, 57, 77, 78] and further developed in [21, 23, 25] in the context of the first-order clarifier-thickener models. If we took the model studied herein and discretized the discontinuity vector $\boldsymbol{\gamma}(x)$ as an additional conservation law $\boldsymbol{\gamma}_t = 0$, then we should expect similar nonlinear resonance phenomena as known for first-order systems, since our model degenerates to first-order type on a solution value interval (u-interval) of positive length.

The main ingredient in the models suggested herein, which accounts for compression effects, is not a first-order equation like (1.1) but rather a second-order strongly

degenerate parabolic (or mixed hyperbolic-parabolic) equation of the type

$$u_t + f\big(\boldsymbol{\gamma}(x), u\big)_x = (\gamma_1(x)A(u)_x)_x, \tag{1.2}$$

where $A(\cdot)$ is nondecreasing with $A(0) = 0$. Note that $A(\cdot)$ can have "flat" regions, and thus (1.2) is strongly degenerate. As a consequence, independently of the smoothness of $\boldsymbol{\gamma} = (\gamma_1, \gamma_2)$, solutions to (1.2) will in general be discontinuous, and it becomes necessary to work within a framework of entropy weak solutions also for (1.2). In the case of smooth coefficients, the general mathematical theory of hyperbolic conservation laws was developed more than 30 years ago. On the other hand, the mathematical theory for strongly degenerate parabolic equations (with smooth coefficients) has advanced significantly only in the last few years [7, 8, 28, 31, 32, 53, 68, 69, 82, 83, 84]. (This list is not complete either.) Although conservation laws with discontinuous fluxes are well studied by now, strongly degenerate parabolic equations with discontinuous fluxes are much less studied. In fact, the only papers that we are aware of are [54, 55, 56], among which the latter two are of importance for the present paper. In [55] equations like (1.2) are studied with a concave convective flux $u \mapsto f(\boldsymbol{\gamma}(x), u)$ and with $(\gamma_1(x)A(u)_x)_x$ replaced by $A(u)_{xx}$. Existence of an entropy weak solution is established by proving convergence of a difference scheme of the type discussed in this paper. Uniqueness and stability issues for entropy weak solutions are studied in [56] for a particular class of equations.

Herein we develop further the methods used in [25, 55, 56] in order to apply them to our new mathematical model for the dynamics of flocculated suspensions in clarifier-thickener units. The new results of this paper can be summarized as follows. First, we introduce a suitable definition of entropy weak solutions for the model variant with constant cross-sectional area (to which the mathematical and numerical analysis is limited). We argue that the x-discontinuity of the diffusion term $(\gamma_1(x)A(u)_x)_x$ requires an additional condition in this definition, which states that $A(u)$ is continuous across the jumps of γ_1 (in our model γ_1 is the characteristic function on an interval $(x_{\mathrm{L}}, x_{\mathrm{R}})$). Support for the necessity to state this condition comes from analyses of similar equations for two-phase flow in heterogeneous porous media, in which a similar condition is stated, and from the uniqueness analysis of our problem, which is the second novel point and in particular relies on this condition. Third, we formulate a simple finite difference scheme for the clarifier-thickener and prove its convergence by a compactness analysis. A feature of the compactness analysis is that the discontinuities in the fluxes make it hard to bound the total variation of the conserved variable. Instead, we introduce a particular nonlinear functional under which we are able to bound the total variation. We show that the limit element satisfies all parts of the definition of entropy weak solutions, except for the continuity of $A(u)$. This issue is left as an open problem. Fourth, we present an analysis of admissible stationary solutions based on the discussion of entropy weak solutions of the stationary ODE variant of the governing PDE of the transient model and, finally, a limited selection of numerical examples illustrating the clarifier-thickener model. Both the steady-state analysis and the numerical simulations support the view that it is reasonable to require $A(u)$ to be continuous.

Before outlining the remainder of this paper, let us briefly mention that we do not explicitly include the effect of hydrodynamic diffusion. This effect is also omitted in the majority of clarifier-thickener papers by other authors [6, 30, 34, 39, 40, 41, 42, 43] but is included in the analyses by Lev, Rubin, and Sheintuch [64] and Verdickt et al. [81]. A profound justification of the omission of hydrodynamic diffusion is

beyond the scope of this paper but is provided in section 7.4 of [10] on the basis of practical limitations, theoretical considerations, computational comparisons, and experimental results. If we had decided to include hydrodynamic diffusion by adding a term, say μu_{xx}, with $\mu > 0$ to the right-hand side of (1.2), then the resulting governing PDE would possess smooth solutions and allow for a simpler analytical and numerical treatment than the one advanced in this work. In essence, the discontinuities appearing in transient solutions would be blurred, and in Remark 5.4 we discuss how hydrodynamic diffusion affects steady states for the clarifier-thickener problem. Finally, let us mention that hydrodynamic diffusion is not explicitly modeled but is in a sense implicitly present in our model, since our concept of Kružkov entropy weak solution is equivalent to stating that our solution is obtained in the limit $\mu \to 0$ of smooth solutions of strictly parabolic equations with regularizing (hydrodynamic) diffusion term μu_{xx}. See section 4.3.

The remainder of this paper is organized as follows. In section 2, the clarifier-thickener model is derived. We consider two variants for units with constant and variable interior cross-sectional area, respectively (Models 1 and 2). In particular, we incorporate the governing equation of the sedimentation-consolidation theory developed in full detail in [10]. We describe in section 3 the finite difference scheme for the simulation of both models. The scheme appears in two variants, an explicit one which also is analyzed, and a semi-implicit one for which a less restrictive condition for the time step size is valid, and which therefore is suitable for large-time simulations. In section 4 we analyze the initial value problem for Model 1, relying on our previous efforts [25, 55, 56]. A definition of entropy weak solutions is given (and discussed extensively), jump and entropy jump conditions are derived, and uniqueness of entropy weak solutions is proved. We study the explicit difference scheme described in section 3 and prove compactness of a family of approximate solutions generated by this difference scheme. We prove that the limit function u is a weak solution of Model 1 that satisfies the entropy condition. The question of whether $A(u)$ is continuous for this limit function is left open. An important problem for practitioners are steady-state solutions, which correspond to the normal operation of a clarifier-thickener unit for constant feed and discharge control parameters. In section 5, we construct steady-state solutions to Model 1 as piecewise continuous solutions to a time-independent ODE version of the transient Model 1. These solutions are again based on the continuity of $A(u)$, but this time this property *follows* from the ODE formulation. Finally, section 6 presents a limited choice of numerical examples illustrating Models 1 and 2.

2. Mathematical model.

2.1. Balance equations. Consider a vessel with a variable cross-sectional area $S(x)$. Since we assume $u = u(x,t)$, the continuity equations for the solids and the fluid are given by

$$S(x)u_t + \big(S(x)uv_{\mathrm{s}}\big)_x = 0, \tag{2.1}$$

$$-S(x)u_t + \big(S(x)(1-u)v_{\mathrm{f}}\big)_x = 0, \tag{2.2}$$

where v_{s} and v_{f} are the solids and the fluid phase velocity, respectively. The mixture flux, that is, the volume average flow velocity weighted with the cross-sectional area at height x, is given by $Q(x,t) := S(x)(uv_{\mathrm{s}} + (1-u)v_{\mathrm{f}})$. The sum of (2.1) and (2.2) produces the continuity equation of the mixture, $Q_x(x,t) = 0$, which implies that $Q(\cdot,t)$ is constant as a function of x. When Q suffers no jumps with respect to x, we obtain $Q(x,t) = Q(x_{\mathrm{R}},t) = Q(t)$. This equation is equivalent to one of the mass

balance equations. We let it replace (2.2) and rewrite (2.1) in terms of the flow rate $Q(t)$ and the solid-fluid relative velocity or slip velocity $v_{\mathrm{r}} := v_{\mathrm{s}} - v_{\mathrm{f}}$, for which a constitutive equation will be formulated. Observing that

$$\begin{aligned} S(x)uv_{\mathrm{s}} &= S(x)\big[\big(uv_{\mathrm{s}} + (1-u)v_{\mathrm{f}}\big)u + u(1-u)(v_{\mathrm{s}} - v_{\mathrm{f}})\big] \\ &= Q(t)u + S(x)u(1-u)v_{\mathrm{r}}, \end{aligned} \tag{2.3}$$

we obtain from (2.1) the equation

$$S(x)u_t + \big(Q(t)u + S(x)u(1-u)v_{\mathrm{r}}\big)_x = 0. \tag{2.4}$$

The kinematic sedimentation theory [62] is based on the assumption that v_{r} is a function of u only, $v_{\mathrm{r}} = v_{\mathrm{r}}(u)$. However, the slip velocity is usually expressed in terms of the Kynch batch flux density function $b(u)$, such that $v_{\mathrm{r}}(u) = b(u)/(u(1-u))$ and (2.4) takes the form

$$S(x)u_t + \big(Q(t)u + S(x)b(u)\big)_x = 0. \tag{2.5}$$

The function b is usually assumed to be piecewise differentiable with $b(u) = 0$ for $u \le 0$ or $u \ge u_{\max}$, where $u_{\max}$ is the maximum solids concentration, $b(u) > 0$ for $0 < u < u_{\max}$, $b'(0) > 0$, and $b'(u_{\max}) \le 0$. A typical example is [74]

$$b(u) = v_\infty u(1-u)^C \quad \text{if } 0 < u < u_{\max}, \quad b(u) = 0 \quad \text{otherwise}, \tag{2.6}$$

where $C \ge 1$ and $v_\infty > 0$ is the settling velocity of a single floc in pure fluid. It should be pointed out that in the presence of diffusion terms modeling compression effects, to be introduced later, the maximum concentration attained in a settling system depends on the balance between convection and diffusion terms but not critically on the choice of $u_{\max}$. In order to facilitate the analysis, we assume in this paper that $u_{\max} = 1$ and that $b(u)$ is smooth on $[0,1]$.

We now apply the sedimentation-consolidation theory outlined in [10, 27] to include the sediment compressibility. By constitutive assumptions, a dimensional analysis, and considering one space dimension only, this theory leads to the following equation for the relative velocity v_{r}, which plays the role of one of the linear momentum balances:

$$v_{\mathrm{r}} = v_{\mathrm{r}}(u, u_x) = \frac{b(u)}{u(1-u)}\left(1 - \frac{\sigma_{\mathrm{e}}'(u)}{\Delta\varrho g u}u_x\right), \tag{2.7}$$

where $\Delta\varrho > 0$ denotes the solid-fluid density difference, g the acceleration of gravity, and $\sigma_{\mathrm{e}}(u)$ is the effective solid stress function, which is now the second constitutive function (besides b) characterizing the suspension. This function is assumed to satisfy $\sigma_{\mathrm{e}}(u) \ge 0$ for all u and

$$\sigma_{\mathrm{e}}'(u) := \frac{d\sigma_{\mathrm{e}}(u)}{du}\begin{cases} = 0 & \text{for } u \le u_{\mathrm{c}}, \\ > 0 & \text{for } u > u_{\mathrm{c}}. \end{cases} \tag{2.8}$$

A commonly used semiempirical effective stress formula is the power law

$$\sigma_{\mathrm{e}}(u) = 0 \quad \text{for } u \le u_{\mathrm{c}}; \quad \sigma_{\mathrm{e}}(u) = \sigma_0\big((u/u_{\mathrm{c}})^k - 1\big) \quad \text{for } u > u_{\mathrm{c}}, \tag{2.9}$$

with parameters $\sigma_0 > 0$ and $k > 1$. Note that the derivative $\sigma_e'(u)$ of the function defined in (2.9) is in general discontinuous at $u = u_c$. Inserting (2.7) into (2.4) and defining

$$a(u) := \frac{b(u)\sigma_e'(u)}{\Delta\varrho g u}, \quad A(u) := \int_0^u a(s)\,ds, \tag{2.10}$$

we obtain the governing equation

$$\big(S(x)u\big)_t + \big(Q(t)u + S(x)b(u)\big)_x = \big(S(x)A(u)_x\big)_x. \tag{2.11}$$

Since $a(u) = 0$ for $u \le u_c$ and $u = u_{\max}$ and $a(u) > 0$ otherwise, (2.11) is first-order hyperbolic for $u \le u_c$ and second-order parabolic for $u > u_c$. Since (2.11) degenerates into hyperbolic type on a solution value interval of positive length, (2.11) is called strongly degenerate parabolic. The location of the type-change interface $u = u_c$ (the sediment level) is in general unknown beforehand.

For the determination of appropriate functions b and σ_e for real materials, see [15, 16, 45]. Moreover, the sedimentation-consolidation model is equivalent to the suspension dewatering theory employed in [4, 38, 63, 79] and other works by the same group of authors.

2.2. The clarifier-thickener model. In the present model, the volume bulk flows are $Q(x,t) = Q_R(t)$ for $x > 0$ and $Q(x,t) = Q_L(t)$ for $x < 0$. This suggests employing (2.11) with $Q(t) = Q_R(t)$ for $0 < x < x_R$ and $Q(t) = Q_L(t)$ for $x_L < x < 0$. Furthermore, we assume that in the overflow and underflow zones, the solid material is transported with the same velocity as the liquid. This means that the solid-fluid relative velocity vanishes, $v_r = 0$. Moreover, the cross-sectional area $S(x)$ needs to be positive outside the interval $[x_L, x_R]$. We assume that $S(x) = S_0$ for $x < x_L$ and $x > x_R$, where $S_0 > 0$ is a small but positive pipe diameter. From (2.3) we now read off that

$$S(x)uv_s|_{x\notin[x_L,x_R]} = S_0 u v_s = \begin{cases} Q_L(t)u & \text{for } x < x_L, \\ Q_R(t)u & \text{for } x > x_R. \end{cases} \tag{2.12}$$

The feed mechanism is introduced by adding a singular source term to the right-hand side of the solids continuity equation (2.1). If we prescribe an initial concentration u_0 in the vessel, we can summarize the resulting dynamic model as

$$S(x)u_t + \tilde{G}(x,t,u)_x = \big(\gamma_1(x)A(u)_x\big)_x + Q_F(t)u_F(t)\delta(x), \quad x \in \mathbb{R}, \quad t > 0, \tag{2.13}$$

$$u(x,0) = u_0(x), \quad x \in \mathbb{R}, \quad u_0(x) \in [0, u_{\max}], \tag{2.14}$$

$$\tilde{G}(x,t,u) = S(x)uv_s = \begin{cases} Q_L(t)u & \text{for } x < x_L, \\ Q_L(t)u + S(x)b(u) & \text{for } x_L < x < 0, \\ Q_R(t)u + S(x)b(u) & \text{for } 0 < x < x_R, \\ Q_R(t)u & \text{for } x > x_R, \end{cases} \tag{2.15}$$

$$\gamma_1(x) := \begin{cases} S(x) & \text{if } x_L \le x \le x_R, \\ 0 & \text{otherwise.} \end{cases}$$

For the mathematical analysis we assume that the control functions Q_L, Q_R, and u_F are constant. Finally, we may express the singular source term in (2.13) in terms of the derivative of the Heaviside function. Adding the term $-H(x)Q_F u_F$ to $\tilde{G}(x,u)$

and subtracting the term $Q_{\mathrm{L}}u_{\mathrm{F}}$, which is constant with respect to x, we obtain the strongly degenerate convection-diffusion problem

$$S(x)u_t + G(x,u)_x = \big(\gamma_1(x)A(u)_x\big)_x, \quad x \in \mathbb{R}, \quad t > 0, \tag{2.16}$$

$$u(x,0) = u_0(x), \quad x \in \mathbb{R}, \quad u_0(x) \in [0, u_{\max}], \tag{2.17}$$

$$G(x,u) = \begin{cases} Q_{\mathrm{L}}(u-u_{\mathrm{F}}) & \text{for } x < x_{\mathrm{L}}, \\ Q_{\mathrm{L}}(u-u_{\mathrm{F}}) + S(x)b(u) & \text{for } x_{\mathrm{L}} < x < 0, \\ Q_{\mathrm{R}}(u-u_{\mathrm{F}}) + S(x)b(u) & \text{for } 0 < x < x_{\mathrm{R}}, \\ Q_{\mathrm{R}}(u-u_{\mathrm{F}}) & \text{for } x > x_{\mathrm{R}}. \end{cases} \tag{2.18}$$

2.3. Model 1 (constant interior cross-sectional area). A simple but important subcase is a vessel whose cross-sectional area is constant in the interior; i.e., we consider

$$S(x) = \begin{cases} S_0 & \text{for } x < x_{\mathrm{L}} \text{ and } x > x_{\mathrm{R}}, \\ S_{\mathrm{int}} & \text{for } x_{\mathrm{L}} \le x \le x_{\mathrm{R}}. \end{cases} \tag{2.19}$$

In this case, the solution of (2.16)–(2.18) does not depend on the value of S_0. To see this, we introduce the new space variable $w = w(x)$ defined by the bijective mapping $\mathbb{R} \ni x \mapsto w \in \mathbb{R}$,

$$w(x) := \begin{cases} (S_0/S_{\mathrm{int}})(x - x_{\mathrm{L}}) + x_{\mathrm{L}} & \text{for } x < x_{\mathrm{L}}, \\ x & \text{for } x_{\mathrm{L}} \le x \le x_{\mathrm{R}}, \\ (S_0/S_{\mathrm{int}})(x - x_{\mathrm{R}}) + x_{\mathrm{R}} & \text{for } x > x_{\mathrm{R}}, \end{cases} \tag{2.20}$$

and from (2.16) we infer that the function v defined by $v(w(x),t) = u(x,t)$ satisfies the following initial value problem, where we define the velocities $q_{\mathrm{R}} := Q_{\mathrm{R}}/S_{\mathrm{int}}$, $q_{\mathrm{L}} := Q_{\mathrm{L}}/S_{\mathrm{int}}$ and the diffusion functions $\tilde{a}(\cdot) := a(\cdot)/S_{\mathrm{int}}$, $\mathcal{A}(\cdot) := A(\cdot)/S_{\mathrm{int}}$:

$$v_t + g(w,v)_w = \big(\gamma_1(w)\mathcal{A}(v)_w\big)_w, \quad w \in \mathbb{R}, \quad t > 0, \tag{2.21}$$

$$v(w,0) = u_0\big(w(x)\big), \quad x \in \mathbb{R}, \tag{2.22}$$

$$g(w,v) := \begin{cases} q_{\mathrm{L}}(v-u_{\mathrm{F}}) & \text{for } w < x_{\mathrm{L}}, \\ q_{\mathrm{L}}(v-u_{\mathrm{F}}) + b(v) & \text{for } x_{\mathrm{L}} < w < 0, \\ q_{\mathrm{R}}(v-u_{\mathrm{F}}) + b(v) & \text{for } 0 < w < x_{\mathrm{R}}, \\ q_{\mathrm{R}}(v-u_{\mathrm{F}}) & \text{for } w > x_{\mathrm{R}}. \end{cases} \tag{2.23}$$

We refer to (2.21)–(2.23) as *Model* 1. Since the variation of $S(x)$ at $x = x_{\mathrm{L}}$ and $x = x_{\mathrm{R}}$ no longer appears in (2.21), Model 1 is formally attained by setting $S \equiv 1$ in (2.18) for all $x \in \mathbb{R}$. This significantly facilitates the analysis. Finally, we define the vector of discontinuity parameters

$$\boldsymbol{\gamma} := (\gamma_1, \gamma_2), \quad \gamma_1(w) := \begin{cases} 1 & \text{for } w \in (x_{\mathrm{L}}, x_{\mathrm{R}}), \\ 0 & \text{for } w \notin (x_{\mathrm{L}}, x_{\mathrm{R}}), \end{cases} \qquad \gamma_2(w) := \begin{cases} q_{\mathrm{L}} & \text{for } w < 0, \\ q_{\mathrm{R}} & \text{for } w > 0 \end{cases}$$

and the flux function

$$f\big(\boldsymbol{\gamma}(w), u\big) := g(x,u) = \gamma_1(x)b(u) + \gamma_2(x)(u - u_{\mathrm{F}}). \tag{2.24}$$

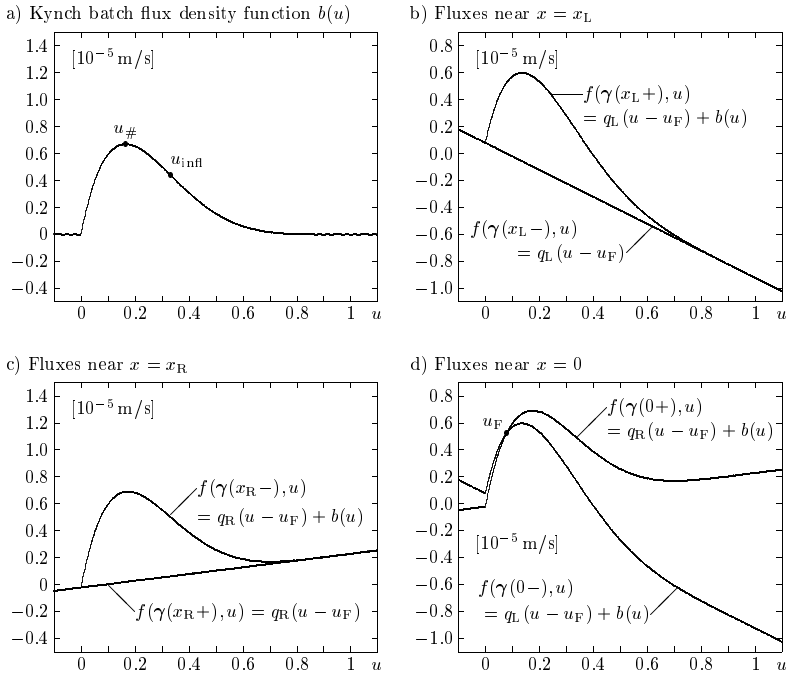

FIG. 2.1. (a) *The Kynch batch flux density function* $b(u)$ *and the fluxes adjacent to* (b) $x = x_{\mathrm{L}}$, (c) $x = x_{\mathrm{R}}$, *and* (d) $x = 0$.

REMARK 2.1. *Consider a nonflocculated ideal suspension for which* $A \equiv 0$. *Then Model* 1 *recovers the clarifier-thickener model with* $S \equiv 1$ *and* $x_{\mathrm{L}} = -x_{\mathrm{R}}$ *we analyzed previously* [19, 21, 22, 25]. *Our derivation now clearly shows that these analyses (including well-posedness and convergence of numerical schemes) are in fact not restricted to the assumption of transport pipes (leading away from the unit for* $x < x_{\mathrm{L}}$ *and* $x > x_{\mathrm{R}}$*) that have the same diameter as the thickening vessel. Rather, by application of the inverse of* (2.20)*, they are also valid for vessels with cylindrical interior and transport pipes of arbitrarily small (but positive) pipe diameter* S_0.

For the function $b(u)$ given by (2.6) with $v_\infty = 10^{-4}\,\mathrm{m/s}$, $C = 5$, the velocities $q_{\mathrm{L}} = -10^{-5}\,\mathrm{m/s}$ and $q_{\mathrm{R}} = 2.5 \times 10^{-6}\,\mathrm{m/s}$, and $u_{\mathrm{F}} = 0.08$, the flux functions $b(u)$ and the fluxes adjacent to the discontinuities of $\boldsymbol{\gamma}$ near $x = x_{\mathrm{L}}$, $x = 0$, and $x = x_{\mathrm{R}}$ are plotted in Figure 2.1. These parameters will also be utilized in sections 5 and 6.

2.4. Model 2 (variable interior cross-sectional area). In the case that $S(x)$ is variable on $(x_{\mathrm{L}}, x_{\mathrm{R}})$, we refer to (2.16)–(2.18) as *Model* 2. It is convenient to rewrite (2.16) as

$$S(x)u_t + F(\boldsymbol{\gamma}(x), u)_x = (\gamma_1(x)A(u)_x)_x$$

and rewrite the flux function $G(x, u)$ as

$$F(\boldsymbol{\gamma}(x), u) := G(x, u) = \gamma_1(x)b(u) + \gamma_2(x)(u - u_{\mathrm{F}}),$$

where

$$\gamma_1(w) := \begin{cases} S(x) & \text{for } x \in (x_{\mathrm{L}}, x_{\mathrm{R}}), \\ 0 & \text{for } x \notin (x_{\mathrm{L}}, x_{\mathrm{R}}), \end{cases} \qquad \gamma_2(w) := \begin{cases} Q_{\mathrm{L}} & \text{for } x < 0, \\ Q_{\mathrm{R}} & \text{for } x > 0. \end{cases}$$

3. Numerical scheme. The numerical scheme for the solution of (2.16)–(2.18) is a straightforward extension of that used in [23] for the first-order variant of (2.16). To define it, choose $\Delta x > 0$, set $x_j := j\Delta x$, and discretize the parameter vector $\boldsymbol{\gamma}$, the initial data, and the cross-sectional area by

$$\boldsymbol{\gamma}_{j+1/2} := \boldsymbol{\gamma}(x_{j+1/2}), \quad U_j^0 := u_0(x_j), \quad S_j := \frac{1}{\Delta x}\int_{x_{j-1/2}}^{x_{j+1/2}} S(x)\,dx.$$

Here $x_{j+1/2} := x_j + \Delta x/2$, i.e., the midpoint in the interval $[x_j, x_{j+1})$. In contrast to [25], we discretize u_0 and $\boldsymbol{\gamma}$ in a pointwise manner, rather than via cell averages. The discretization of u_0 circumvents some analytical difficulties that would otherwise turn up in the proof of Lemma 4.18 and is not unreasonable from a computational point of view. For $n > 0$ we define the approximations according to the explicit marching formula

$$U_j^{n+1} = U_j^n - \lambda_j \Delta_- h\big(\boldsymbol{\gamma}_{j+1/2}, U_{j+1}^n, U_j^n\big) + \frac{\lambda_j}{\Delta x}\Delta_-\big(\gamma_{1,j+1/2}\Delta_+ A(U_j^n)\big), \tag{3.1}$$

where $\lambda_j := \Delta t/(S_j\Delta x)$, $\Delta_- V_j := V_j - V_{j-1}$, $\Delta_+ V_j := V_{j+1} - V_j$, and

$$h(\boldsymbol{\gamma}, v, u) := \frac{1}{2}\left[f(\boldsymbol{\gamma}, u) + f(\boldsymbol{\gamma}, v) - \int_u^v \big|f_u(\boldsymbol{\gamma}, w)\big|dw\right] \tag{3.2}$$

is the Engquist–Osher flux [44]. Let $t_n := n\Delta t$, and let χ^n, χ_j, and $\chi_{j+1/2}$ denote the characteristic functions of the intervals $[t_n, t_{n+1})$, $[x_{j-1/2}, x_{j+1/2})$, and $[x_j, x_{j+1})$, respectively. We then define

$$u^\Delta(x,t) := \sum_{n\ge 0}\sum_{j\in\mathbb{Z}} U_j^n \chi_j(x)\chi^n(t), \quad \boldsymbol{\gamma}^\Delta(x) := \sum_{j\in\mathbb{Z}} \boldsymbol{\gamma}_{j+1/2}\chi_{j+1/2}(x). \tag{3.3}$$

Note that the discontinuity vector $\boldsymbol{\gamma}$ is discretized on a spatial mesh which is staggered (i.e., shifted by $\Delta x/2$) with respect to that of the conserved quantity u. This makes it possible to use the scalar Engquist–Osher function (3.2) for the convective part of the problem. A natural alternative would be to align the two discretizations. However, in that case one would have to solve (exactly or approximately) a Riemann problem for a system of two equations in two variables (namely, for u and the volume average velocity q) at each cell boundary, which makes the resulting numerical method rather complicated; see [48, 59, 60, 65, 66]. In particular, our treatment of the convective part is simpler than the complicated (but accurate) front tracking algorithm used in [19]. Staggering the discretizations also simplifies the analysis, making it possible to apply, with some allowances for the parabolic terms, some of the analytical techniques developed for monotone schemes for purely hyperbolic problems.

Let us recall that the scheme stated here comprises both Model 1 and Model 2 and is employed for numerical examples for both models in section 6. The analysis of the scheme is, however, limited to Model 1 (with $S \equiv 1$).

In section 6 we also use the following semi-implicit variant of (3.1) for large-time computations:

$$U_j^{n+1} = U_j^n - \lambda_j \Delta_- h\big(\boldsymbol{\gamma}_{j+1/2}, U_{j+1}^n, U_j^n\big) + \frac{\lambda_j}{\Delta x}\Delta_-\big(\gamma_{1,j+1/2}\Delta_+ A(U_j^{n+1})\big). \tag{3.4}$$

The scheme (3.4) requires the solution of a system of nonlinear equations in each time step by the Newton–Raphson method. This can be done efficiently by Thomas's algorithm, since the coefficient matrix is tridiagonal. The advantage of using (3.4) lies in the fact that we need only to satisfy a CFL condition requiring that $\Delta t/\Delta x$ is bounded; while (3.1) enforces that $\Delta t/(\Delta x)^2$ be bounded; see Lemmas 4.16 and 4.17.

4. Mathematical analysis. In several instances we will not repeat arguments that are only minor modifications of proofs that have already appeared in [25], [55], or [56]. In various bounds, C denotes a universal constant.

4.1. The initial value problem. For the sake of consistency with our previous papers, we will abuse the notation slightly by replacing the transformed spatial variable w by x, and the transformed functions v and $\mathcal{A}$ by u and A, respectively. The Cauchy problem of interest is then

$$\begin{aligned} &u_t + f(\boldsymbol{\gamma}(x), u)_x = (\gamma_1(x) A(u)_x)_x, \ (x,t) \in \Pi_T := \mathbb{R} \times (0,T); \\ &u(x,0) = u_0(x), \ x \in \mathbb{R}, \end{aligned} \tag{4.1}$$

where $f(\boldsymbol{\gamma}, u) = \gamma_1 b(u) + \gamma_2 (u - u_{\mathrm{F}})$. The parameter vector for this problem is $\boldsymbol{\gamma} := (\gamma_1, \gamma_2)$, where

$$\gamma_1(x) := \begin{cases} 1 & \text{for } x \in (x_{\mathrm{L}}, x_{\mathrm{R}}), \\ 0 & \text{for } x \notin (x_{\mathrm{L}}, x_{\mathrm{R}}), \end{cases} \qquad \gamma_2(x) := \begin{cases} q_{\mathrm{L}} & \text{for } x \le 0, \\ q_{\mathrm{R}} & \text{for } x > 0. \end{cases}$$

We assume that $q_{\mathrm{L}} < 0$ and $q_{\mathrm{R}} > 0$. This rules out the case of batch settling ($q_{\mathrm{L}} = 0$, $q_{\mathrm{R}} = 0$). However, once our analysis is complete, it will be clear that one can accommodate batch processing as a separate case where one restricts the analysis to the interval $[x_{\mathrm{L}}, x_{\mathrm{R}}]$. We assume that $b \in C^2([0,1])$, and $b(0) = b(1) = 0$. Furthermore, we assume that b' vanishes at exactly one location $u_{\#} \in (0,1)$, where the function has a maximum, and that b'' vanishes at no more than one inflection point in $u_{\mathrm{infl}} \in (0,1)$; if such a point is present, we assume that $u_{\mathrm{infl}} \in (u_{\#}, 1)$. For example, $b(u)$ may be given by (2.6). In accordance with (2.9), (2.10), we will assume that $A \in \mathrm{Lip}([0,1])$, $A'(u) = 0$ for $u < u_{\mathrm{c}}$ and that $A'(u) > 0$ for $u \in (u_{\mathrm{c}}, 1)$.

For the initial data, we assume that u_0 satisfies

$$\begin{cases} u_0 \in L^1(\mathbb{R}) \cap BV(\mathbb{R}); \ \ u_0(x) \in [0,1] \ \forall x \in \mathbb{R}; \\ A(u_0) \text{ is absolutely continuous on } [x_{\mathrm{L}}, x_{\mathrm{R}}]; \ \ \gamma_1 A(u_0)_x \in BV(\mathbb{R}). \end{cases} \tag{4.2}$$

In this paper, $\boldsymbol{\gamma}$ is allowed to take values in $\mathcal{G} := \{(q_{\mathrm{L}}, 0), (q_{\mathrm{L}}, 1), (q_{\mathrm{R}}, 0), (q_{\mathrm{R}}, 1)\}$ only. This simplifies matters somewhat compared to our previous paper [25], where the cell average discretization of $\boldsymbol{\gamma}$ required us to consider several lateral sides of the rectangle marked by the vertices in $\mathcal{G}$.

4.2. Definition of entropy weak solution. If (4.1) is allowed to degenerate at certain points, that is, $A'(s) = 0$ for some values of s, solutions are not necessarily smooth, and weak solutions must be sought. This property is independent of the smoothness of $\boldsymbol{\gamma}$. Moreover, weak solutions are not necessarily unique, requiring some additional condition, a so-called entropy condition, to single out the physically meaningful solution.

As in [25], the function space $BV_t(\Pi_T)$ plays an important role in our definition of entropy weak solution. We denote by $\mathcal{M}(\Pi_T)$ the locally finite Radon (signed) measures on Π_T. The space $BV_t(\Pi_T)$ consists of locally integrable functions $W : \Pi_T \to \mathbb{R}$ for which $\partial_t W \in \mathcal{M}(\Pi_T)$.

Let $\mathcal{J} := \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$ denote the set of points where $\boldsymbol{\gamma}$ is discontinuous. For a point $m \in \mathcal{J}$, we use the notation $\boldsymbol{\gamma}(m-)$ and $\boldsymbol{\gamma}(m+)$ for the one-sided limits at the point m:

$$\boldsymbol{\gamma}(m-) := \lim_{x \uparrow m} \boldsymbol{\gamma}(x), \quad \boldsymbol{\gamma}(m+) := \lim_{x \downarrow m} \boldsymbol{\gamma}(x).$$

The following definition is motivated by [25, 55, 56].

DEFINITION 4.1 (BV_t entropy weak solution). *A measurable function $u : \Pi_T \to R$ is a BV_t entropy weak solution of the initial value problem* (4.1) *if it satisfies the following conditions:*

(D.1) $u \in L^1(\Pi_T) \cap BV_t(\Pi_T)$, $u \in [0,1]$ *a.e. in* Π_T, *and* $A(u)_x \in L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0,T))$.

(D.2) *For all test functions* $\phi \in \mathcal{D}(\Pi_T)$

$$\iint_{\Pi_T} \Big(u\phi_t + \big[f\big(\boldsymbol{\gamma}(x), u\big) - \gamma_1(x) A(u)_x \big] \phi_x \Big)\, dx\, dt = 0. \tag{4.3}$$

(D.3) *The initial condition is satisfied in the following strong* L^1 *sense:*

$$\operatorname*{ess\,lim}_{t \downarrow 0} \int_{\mathbb{R}} \big| u(x,t) - u_0(x) \big|\, dx = 0. \tag{4.4}$$

(D.4) *For a.e.* $t \in [0,T]$, $x \mapsto A(u(x,t))$ *is continuous at* $x = x_{\mathrm{L}}$ *and* $x = x_{\mathrm{R}}$.

(D.5) *The following Kružkov-type entropy inequality holds for all* $c \in \mathbb{R}$ *and all test functions* $0 \le \phi \in \mathcal{D}(\Pi_T)$*:*

$$\begin{aligned} \iint_{\Pi_T} \Big(& |u-c| \phi_t + \operatorname{sgn}(u-c) \big[f\big(\boldsymbol{\gamma}(x), u\big) - f\big(\boldsymbol{\gamma}(x), c\big) \big] \phi_x \\ & - \gamma_1(x) \big| A(u) - A(c) \big|_x \phi_x \Big)\, dx\, dt \\ & + \int_0^T \sum_{m \in \mathcal{J}} \big| f\big(\boldsymbol{\gamma}(m+), c\big) - f\big(\boldsymbol{\gamma}(m-), c\big) \big| \phi(m,t)\, dt \ge 0. \end{aligned} \tag{4.5}$$

A function $u : \Pi_T \to \mathbb{R}$ satisfying conditions (D.1), (D.2), *and* (D.3) *is called a BV_t weak solution of the initial value problem* (4.1).

4.3. Comments on the entropy weak solution concept.

4.3.1. Motivation of the entropy condition (4.5). It is possible to motivate the entropy condition (4.5) by the fact that limit functions constructed by the method of vanishing viscosity, in combination with smoothing of the coefficients, satisfy this condition. To this end, let $\boldsymbol{\gamma}_\varepsilon(x) := (\gamma_{1,\varepsilon}, \gamma_{2,\varepsilon})$ be a C^∞ approximation of $\boldsymbol{\gamma}$, such that $\boldsymbol{\gamma}_\varepsilon$ equals $\boldsymbol{\gamma}$ everywhere except on $(m-\varepsilon, m+\varepsilon)$ for $m \in \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$, and such that the sign of $\boldsymbol{\gamma}_\varepsilon'$ is constant on $(m-\varepsilon, m+\varepsilon)$ for $m \in \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$. Since $\boldsymbol{\gamma} \mapsto f(\boldsymbol{\gamma}, c)$ is linear, $f_{\boldsymbol{\gamma}}(\boldsymbol{\gamma}, c)$ does not depend on x. For each $\mu, \varepsilon > 0$, let $u^{\mu,\varepsilon}$ be a classical solution to the uniformly parabolic equation

$$u_t^{\mu,\varepsilon} + f\big(\boldsymbol{\gamma}_\varepsilon(x), u^{\mu,\varepsilon}\big)_x = \big(\gamma_{1,\varepsilon}(x) A(u^{\mu,\varepsilon})_x\big)_x + \mu u_{xx}^{\mu,\varepsilon}. \tag{4.6}$$

Let us suppose that $u^{\mu,\varepsilon} \to u$ in L^p_{loc} for any $1 \le p < \infty$. The rest of this remark is devoted to proving that the limit u satisfies the entropy condition (4.5).

Since $\boldsymbol{\gamma}_\varepsilon$ is smooth, the chain rule and the convexity of η imply that $u^{\mu,\varepsilon}$ satisfies the following entropy condition for all convex C^2 functions $\eta : \mathbb{R} \to \mathbb{R}$:

$$\begin{aligned} & \eta(u^{\mu,\varepsilon})_t + q\big(\boldsymbol{\gamma}_\varepsilon(x), u^{\mu,\varepsilon}\big)_x - \big(\gamma_{1,\varepsilon}(x) r(u^{\mu,\varepsilon})_x\big)_x - \mu \eta(u^{\mu,\varepsilon})_{xx} \\ & \qquad + \boldsymbol{\gamma}_\varepsilon'(x) \cdot \big(\eta'(u^{\mu,\varepsilon}) f_{\boldsymbol{\gamma}}(\boldsymbol{\gamma}_\varepsilon(x), u^{\mu,\varepsilon}) - q_{\boldsymbol{\gamma}}(\boldsymbol{\gamma}_\varepsilon(x), u^{\mu,\varepsilon}) \big) \le 0 \quad \text{in } \mathcal{D}'(\Pi_T), \end{aligned} \tag{4.7}$$

where $q : \mathbb{R}^2 \times \mathbb{R} \to \mathbb{R}$ and $r : \mathbb{R} \to \mathbb{R}$ are defined, respectively, by

$$q_u(\boldsymbol{\gamma}, u) = \eta'(u) f_u(\boldsymbol{\gamma}, u), \qquad r'(u) = \eta'(u) A'(u).$$

By a standard approximation argument, (4.7) implies that the following Kružkov-type entropy condition holds for any constant $c \in \mathbb{R}$:

$$
\begin{aligned}
&|u^{\mu,\varepsilon}-c|_t + \big[\operatorname{sgn}(u^{\mu,\varepsilon}-c)\big(f(\boldsymbol{\gamma}_\varepsilon(x),u^{\mu,\varepsilon})-f(\boldsymbol{\gamma}_\varepsilon(x),c)\big)\big]_x \\
&\qquad - \big(\gamma_{1,\varepsilon}\big|A(u^{\mu,\varepsilon})-A(c)\big|_x\big)_x \\
&\qquad - \mu|u^{\mu,\varepsilon}-c|_x + \operatorname{sgn}(u^{\mu,\varepsilon}-c) f\big(\boldsymbol{\gamma}_\varepsilon(x),c\big)_x \le 0 \quad \text{in } \mathcal{D}'(\Pi_T),
\end{aligned} \tag{4.8}
$$

where

$$
f(\boldsymbol{\gamma}_\varepsilon(x),c)_x = \boldsymbol{\gamma}_\varepsilon'(x)\cdot f_{\boldsymbol{\gamma}}(\boldsymbol{\gamma}_\varepsilon(x),c) = \gamma_{1,\varepsilon}'(x) f_{\gamma_{1,\varepsilon}}(\boldsymbol{\gamma}_\varepsilon(x),c) + \gamma_{2,\varepsilon}'(x) f_{\gamma_{2,\varepsilon}}(\boldsymbol{\gamma}_\varepsilon(x),c).
$$

From (4.8) it is clear that the following "less precise" inequality holds:

$$
\begin{aligned}
&|u^{\mu,\varepsilon}-c|_t + \big[\operatorname{sgn}(u^{\mu,\varepsilon}-c)\big(f(\boldsymbol{\gamma}_\varepsilon(x),u^{\mu,\varepsilon})-f(\boldsymbol{\gamma}_\varepsilon(x),c)\big)\big]_x \\
&- \big(\gamma_{1,\varepsilon}\big|A(u^{\mu,\varepsilon})-A(c)\big|_x\big)_x - \mu|u^{\mu,\varepsilon}-c|_{xx} - \big|f\big(\boldsymbol{\gamma}_\varepsilon(x),c\big)_x\big| \le 0 \quad \text{in } \mathcal{D}'(\Pi_T);
\end{aligned} \tag{4.9}
$$

that is, for any $0 \le \phi \in \mathcal{D}'(\Pi_T)$,

$$
\begin{aligned}
&\iint_{\Pi_T} \Big(|u^{\mu,\varepsilon}-c|\phi_t + \operatorname{sgn}(u^{\mu,\varepsilon}-c)\big(f(\boldsymbol{\gamma}_\varepsilon(x),u^{\mu,\varepsilon})-f(\boldsymbol{\gamma}_\varepsilon(x),c)\big)\phi_x \\
&\qquad - \gamma_{1,\varepsilon}\big|A(u^{\mu,\varepsilon})-A(c)\big|_x\phi_x + \mu|u^{\mu,\varepsilon}-c|\phi_{xx}\Big)\,dx\,dt \\
&\quad + \iint_{\Pi_T} \big|f(\boldsymbol{\gamma}_\varepsilon(x),c)_x\big|\phi\,dx\,dt \ge 0.
\end{aligned} \tag{4.10}
$$

Using the properties of $\boldsymbol{\gamma}$ and $\boldsymbol{\gamma}_\varepsilon$, we can write (notice the signs)

$$
\begin{aligned}
\iint_{\Pi_T} \big|f(\boldsymbol{\gamma}_\varepsilon(x),c)_x\big|\phi\,dx\,dt &= \int_0^T \int_{x_{\mathrm{L}}-\varepsilon}^{x_{\mathrm{L}}+\varepsilon} \gamma_{1,\varepsilon}'(x)|b(c)|\phi(x,t)\,dx\,dt \\
&\quad - \int_0^T \int_{x_{\mathrm{R}}-\varepsilon}^{x_{\mathrm{R}}+\varepsilon} \gamma_{1,\varepsilon}'(x)|b(c)|\phi(x,t)\,dx\,dt + \int_0^T \int_{-\varepsilon}^{\varepsilon} \gamma_{2,\varepsilon}'(x)|c-u_{\mathrm{F}}|\phi(x,t)\,dx\,dt.
\end{aligned}
$$

After three integrations by parts and subsequently sending ε to zero, we obtain

$$
\begin{aligned}
\lim_{\varepsilon\to 0}\iint_{\Pi_T} \big|f(\boldsymbol{\gamma}_\varepsilon(x),c)_x\big|\phi\,dx\,dt &= \int_0^T \big(\gamma_1(x_{\mathrm{L}}+)-\gamma_1(x_{\mathrm{L}}-)\big)\,|b(c)|\phi(x_{\mathrm{L}},t)\,dt \\
&\quad - \int_0^T \big(\gamma_1(x_{\mathrm{R}}+)-\gamma_1(x_{\mathrm{R}}-)\big)\,|b(c)|\phi(x_{\mathrm{R}},t)\,dt \\
&\quad + \int_0^T \big(\gamma_2(0+)-\gamma_2(0-)\big)\,|c-u_{\mathrm{F}}|\phi(0,t)\,dt. \\
&= \int_0^T \sum_{m\in\mathcal{J}} \big|f\big(\boldsymbol{\gamma}(m+),c\big)-f\big(\boldsymbol{\gamma}(m-),c\big)\big|\phi(m,t)\,dt.
\end{aligned}
$$

In view of the previous calculations, we can send $\mu,\varepsilon \to 0$ in (4.10) to conclude that the limit function u satisfies the entropy condition (4.5).

4.3.2. Status of the weak formulation (4.3). We point out that the entropy inequality (4.5) does not imply the weak formulation (4.3). In fact, the usual procedure to derive the weak formulation from the Kružkov entropy inequality consists

in taking first $c > \|u\|_\infty$ and then $c < -\|u\|_\infty$, and then combining the resulting inequalities. This does not work here, since the term $|f(\boldsymbol{\gamma}(m+), c) - f(\boldsymbol{\gamma}(m-), c)|$ does not have compact support with respect to c, and therefore the sum over $m \in \mathcal{J}$ in (4.5) will not disappear for these values of c. Consequently, we state the weak formulation (4.3) and the entropy inequality (4.5) as independent ingredients of the solution concept.

4.3.3. Alternative entropy weak solution concepts. Section 4.3.1 shows that the (Kružkov) entropy formulation (4.5) for the clarifier-thickener model can be derived from the parabolic regularization (4.6) when the regularization parameter μ and the parameter ε that smoothes the flux discontinuities tend to zero. In section 1 we mentioned that the term μu_{xx} corresponds to hydrodynamic diffusion. Consequently, the entropy formulation (4.5), which eventually leads to uniqueness, encodes that our "physically relevant" solutions are those obtained in the limit of vanishing hydrodynamic diffusion.

Alternative entropy concepts for conservation laws with discontinuous flux, which equally lead to unique solutions (that are, however, different from the ones constructed here), are possible. For example, a mathematical model for two-phase flow in a one-dimensional porous medium that changes its type at $x = 0$ can be written as the conservation law with discontinuous flux

$$u_t + \big(H(x)f(u) + (1 - H(x))g(u)\big)_x = 0, \tag{4.11}$$

where u is the saturation of one of the phases, the functions $f(u)$ and $g(u)$ are the rock-type dependent Darcy velocities for $x > 0$ and $x < 0$, respectively, and $H(x)$ is the Heaviside function. These models are usually based on the assumption that the capillary pressure is continuous across heterogeneities of the porous medium. Consequently, the appropriate viscous regularization term of (4.11) for this model is not given by μu^ε_{xx} but by $\mu(\lambda_c(u^\varepsilon)p_c(u^\varepsilon)_x)_x$, where λ_c and p_c are the mobility and capillary pressure functions for the phase considered and $x < 0$ ($c = \mathrm{L}$) and $x > 0$ ($c = \mathrm{R}$), respectively [51, 71]. Analyzing the limit $\varepsilon \to 0$ for this regularization term, Kaasschieter [51] shows that the corresponding viscosity limit produces an entropy condition for the limiting equation (4.11) that excludes that characteristics leave the discontinuity at $x = 0$ from both sides. In other words, the capillary pressure characterization does not allow undercompressive shocks emerging from $x = 0$. This contrasts with the role of the flux discontinuity at $x = 0$ in the clarifier-thickener model, in which material is injected at $x = 0$ and transported from both sides of that source term location, which allows characteristics to emerge to both sides of $x = 0$.

Based on the properties of this two-phase flow in heterogeneous porous media model, Adimurthi, Jaffré, and Veerappa Gowda propose in [1] an entropy formulation alternative to ours, which is essentially based on the usual Kružkov entropy characterization away from flux discontinuities, supplemented by an additional entropy jump condition that rules out undercompressive shocks. In [1] it is shown that regular solutions satisfying these conditions are unique, and convergence of a Godunov-type scheme to weak solutions of this type is proved. The entropy concepts of [1] and [25] (to which the present treatment reduces for $A \equiv 0$) coincide if the "left" and "right" fluxes $f(u)$ and $g(u)$ do *not* intersect and in general yield different results if these fluxes intersect in an "undercompressive" way. This means that if we suppose, for simplicity, that the functions $f(u)$ and $g(u)$ intersect at only one point, called u_χ here, then in the vicinity of u_χ we have $g'(u) < 0$ for $u \le u_\chi$ and $f'(u) > 0$ for $u \ge u_\chi$. Such a situation frequently occurs in the two-phase flow in porous media model and

is also possible in the clarifier-thickener model. For example, consider the situation near the feed level $x = 0$, and assume that we take the parameters q_{L} and q_{R} as used in Figure 2.1 but set $u_{\mathrm{F}} = 0.8$. Graphically, this situation corresponds to moving the two curves in Figure 2.1(d) further apart until they intersect at $u_\chi = u_{\mathrm{F}} = 0.8$. From the shape of these curves it becomes clear that this is indeed a case of an "undercompressive" intersection, where $f(u) = q_{\mathrm{R}}(u - u_{\mathrm{F}}) + b(u)$ and $g(u) = q_{\mathrm{L}}(u - u_{\mathrm{F}}) + b(u)$. Furthermore, if we assume that the clarifier-thickener is initially filled with suspension of that same concentration $u_0 = u_{\mathrm{F}}$, we expect that filling up the vessel with (strongly concentrated) suspension of concentration $u = u_{\mathrm{F}}$ produces a solution that is constant near $x = 0$ (for small times at least, until waves coming from x_{L} or x_{R} start to interfere). In this scenario, however, the theory of [1], which excludes undercompressive shocks, leads to a different solution, which includes one stationary oscillation between solution values θ_f and θ_g such that $f'(\theta_f) \le 0$ or $g'(\theta_g) \ge 0$; i.e., the resulting stationary discontinuity is not undercompressive. In [20] we also present a numerical example for a similar case showing that both entropy theories, along with the convergence of the respective associated schemes, lead to different admissible solutions. Of course, these alternative theories mirror the different physics involved, as the different viscous regularizations of the clarifier-thickener model and of the two-phase flow in porous media model show. Finally, let us clarify that the problem of whether the fluxes $f(u)$ and $g(u)$ intersect in an "undercompressive way" is *not* equivalent to the satisfaction of the so-called crossing condition, to which we appeal in section 4.5 for the uniqueness proof. See the comment following Lemma 4.14 for a discussion of this point in the context of the clarifier-thickener model.

4.3.4. Motivation of condition (D.4). One consequence of this definition is that for a.e. $t \in [0, T]$, $A(u(x,t))$ is absolutely continuous as a function of x on $[x_{\mathrm{L}}, x_{\mathrm{R}}]$ and that $A(u)_x$ exists a.e. in $[x_{\mathrm{L}}, x_{\mathrm{R}}]$. The point that deserves to be discussed extensively is, however, our explicit requirement that $A(u)$ be continuous across $x = x_{\mathrm{L}}$ and $x = x_{\mathrm{R}}$. To justify this assumption, we follow the analysis of van Duijn, de Neef, and Molenaar [80] and Molenaar [71]. We consider the situation near x_{R}. (The jump across x_{L} is handled in the same way.) We approximate the discontinuous coefficient $\gamma_1(x)$ by a smooth function $\gamma_1^\varepsilon(x)$, where $\varepsilon > 0$ is a small smoothing parameter and $\gamma_1^\varepsilon(x) = \gamma_1(x)$ outside $(x_{\mathrm{R}} - \varepsilon, x_{\mathrm{R}} + \varepsilon)$. The differential equation that should be satisfied by the limit function in this interval for $\varepsilon \to 0$ provides an additional interface condition. We assume that v^ε is the solution of Model 1 with $\gamma_1(x)$ replaced by γ_1^ε and introduce the rescaled space variable $y := (x - x_{\mathrm{R}})/\varepsilon$. Inside $(x_{\mathrm{R}} - \varepsilon, x_{\mathrm{R}} + \varepsilon)$, our equation can be written as $\varepsilon v_t^\varepsilon + (f^\varepsilon(y, v^\varepsilon))_y = 0$ with

$$f^\varepsilon(y, v^\varepsilon) = q_{\mathrm{R}}(v^\varepsilon - u_{\mathrm{F}}) + \gamma_1^\varepsilon b(v^\varepsilon) - \gamma_1^\varepsilon \frac{1}{\varepsilon} A(v^\varepsilon)_y.$$

We assume that v^ε with $0 \le v^\varepsilon \le 1$ converges to a function v as $\varepsilon \to 0$ and that the total flux f^ε remains bounded uniformly in ε as $\varepsilon \to 0$. Then the limit function v should satisfy $A(v)_y = 0$ for $-1 < y < 1$. Integrating this equation yields the following relation between $v(-1,t)$ and $v(1,t)$, which are identified with the limits of u to the left and to right of $x = x_{\mathrm{R}}$, $u(x_{\mathrm{R}}-,t)$, and $u(x_{\mathrm{R}}+,t)$:

$$A\big(u(x_{\mathrm{R}}+,t)\big) - A\big(u(x_{\mathrm{R}}-,t)\big) = A\big(v(1,t)\big) - A\big(v(-1,t)\big) = \int_{-1}^{1} A(v)_y \, dy = 0,$$

which motivates our condition (D.4).

To highlight the status of condition (D.4), we first mention that (D.4) is the analogue of the "extended pressure condition" postulated in problems of multiphase flow in heterogeneous porous media [71, 80, 85]. These problems lead to equations with discontinuous flux and discontinuous (with respect to the space variable) diffusion, which require an additional jump condition across jumps of the diffusion coefficient (apart from the appropriate Rankine–Hugoniot condition) to ensure uniqueness. This analogy and the observation that in our case the diffusion terms are not present at all for $x < x_{\mathrm{L}}$ and $x > x_{\mathrm{R}}$ and it is therefore unlikely to obtain control on the limits of $A(u)_x$ for $x \downarrow x_{\mathrm{L}}$ and $x \uparrow x_{\mathrm{R}}$ strongly support the necessity to postulate (D.4) as a separate ingredient of the definition of an entropy weak solution. This view is also supported by the fact that our uniqueness proof relies on (D.4). In other words, (D.4) is necessary to ensure uniqueness.

It should be mentioned, however, that it is currently unclear how to prove that the numerical scheme converges to a solution that satisfies (D.4). In fact, we will prove that the scheme converges to a limit u that satisfies all components of Definition 4.1 except (D.4). However, our numerical results support that $A(u)$ is continuous across $x = x_{\mathrm{L}}$ and $x = x_{\mathrm{R}}$. In particular, transient numerical simulations converge (for large times) to steady-state solutions. These are x-dependent piecewise continuous functions that are defined by a time-independent version of Definition 4.1 which does *not* include a postulate of continuity of $A(u)$, since satisfaction of this condition can be derived in the ODE context.

4.4. Existence of traces. In what follows, we often use the notation

$$F(\boldsymbol{\gamma}, u, c) := \operatorname{sgn}(u - c)\big(f(\boldsymbol{\gamma}, u) - f(\boldsymbol{\gamma}, c)\big) \tag{4.12}$$

for the Kružkov entropy flux appearing in (4.5). Here, the sign function is defined by $\operatorname{sgn}(w) := w/|w|$ for $w \neq 0$ and $\operatorname{sgn}(0) := 0$. It is sometimes convenient to work with the function $\hat{f}(\boldsymbol{\gamma}, u) := f(\boldsymbol{\gamma}, u) + \gamma_2 u_{\mathrm{F}}$ and to use the identity $F(\boldsymbol{\gamma}, u, c) = \operatorname{sgn}(u - c)(\hat{f}(\boldsymbol{\gamma}, u) - \hat{f}(\boldsymbol{\gamma}, c))$. We will also find the following notation useful: $a \vee b := \max\{a, b\}$, $a \wedge b := \min\{a, b\}$, $a_+ := a \vee 0$, and $a_- := a \wedge 0$.

Our analysis makes use of certain jump conditions that relate limits from the right and left of the entropy weak solution u at jumps in the spatially varying coefficient $\boldsymbol{\gamma}(x)$. Thus, we need a notion of one-sided limits (from both the right and left) at the points $x \in \mathcal{J}$.

Definition 4.2 (traces). *Let $W \in L^\infty(\Pi_T)$ be a real function. By the right and left traces of $W(\cdot, t)$ at a point $x = x_0 \in \mathbb{R}$ we understand functions $t \mapsto W(x_0\pm, t) \in L^\infty(0, T)$ that satisfy*

$$\operatorname*{ess\,lim}_{x \downarrow x_0} \big|W(x, t) - W(x_0+, t)\big| = 0 \quad \textit{for a.e. } t \in (0, T),$$
$$\operatorname*{ess\,lim}_{x \uparrow x_0} \big|W(x, t) - W(x_0-, t)\big| = 0 \quad \textit{for a.e. } t \in (0, T).$$

As in [25, 56], we now derive the existence of the required traces from our definition of BV_t entropy weak solution. To this end, we introduce the so-called singular mapping. Let $\mathcal{S}(w)$ denote the characteristic function of the interval $[0, u_{\mathrm{c}}]$, where $A'(u) = 0$, and recall that

$$f\big(\boldsymbol{\gamma}(w), u\big) = \gamma_1(x) b(u) + \gamma_2(x)(u - u_{\mathrm{F}}).$$

The singular mapping is defined by

(4.13)
$$\Psi(\boldsymbol{\gamma},u) := \mathcal{F}(\boldsymbol{\gamma},u) + \gamma_1 A(u), \quad \mathcal{F}(\boldsymbol{\gamma},u) := \int_0^u \big(\gamma_1 \mathcal{S}(w) + 1 - \gamma_1\big)\big|f_u(\boldsymbol{\gamma},w)\big|\,dw.$$

Following [55], we have broken the singular mapping into two parts: $\mathcal{F}$ for the hyperbolic spatial operator and $\gamma_1 A$ for the parabolic operator. Note that if $\gamma_1 = 0$, which means that $x \notin [x_{\mathrm{L}}, x_{\mathrm{R}}]$, the parabolic term will not be present, and the singular mapping simplifies to $\Psi(\boldsymbol{\gamma},u) = \mathcal{F}(\boldsymbol{\gamma},u) = \int_0^u |f_u(\boldsymbol{\gamma},w)|\,dw$. If $x \in (x_{\mathrm{L}}, x_{\mathrm{R}})$, then $\gamma_1 = 1$, and

$$\Psi(\boldsymbol{\gamma},u) = \mathcal{F}(\boldsymbol{\gamma},u) + A(u), \quad \mathcal{F}(\boldsymbol{\gamma},u) = \int_0^u \mathcal{S}(w)|f_u(\boldsymbol{\gamma},w)|\,dw.$$

Thus, for $x \in (x_{\mathrm{L}}, x_{\mathrm{R}})$,

$$\partial_u \Psi(\boldsymbol{\gamma},u) = \begin{cases} |f_u(\boldsymbol{\gamma},u)| & \text{for } u \le u_{\mathrm{c}}, \\ A'(u) & \text{for } u > u_{\mathrm{c}}. \end{cases}$$

Thus, we see that for any fixed value of x (and hence $\boldsymbol{\gamma}$) and u, exactly one of the mappings $u \mapsto \mathcal{F}(\boldsymbol{\gamma},u)$, $u \mapsto \gamma_1 A(u)$ is increasing, and the other is constant. This allows us to separate the hyperbolic and parabolic terms somewhat in our analysis and is the motivation behind the particular form of the singular mapping given by (4.13).

The following lemma records some easily verified properties of Ψ. We omit the elementary proofs.

LEMMA 4.3. *The mapping $u \mapsto \Psi(\boldsymbol{\gamma},u)$ is Lipschitz continuous on $[0,1]$, uniformly for $\gamma \in \mathcal{G}$. In addition, $u \mapsto \Psi(\boldsymbol{\gamma},u)$ is strictly increasing on $[0,1]$ for each fixed vector $\boldsymbol{\gamma} \in \mathcal{G}$.*

The proof of the following lemma is easily adapted to the present situation from that of Lemma 3.1 of [56]. The key ingredients are (4.3), (4.5), and the fact that $u_t \in \mathcal{M}(\Pi_T)$.

LEMMA 4.4. *Suppose u is a BV_t entropy weak solution. Then, for any $c \in \mathbb{R}$,*

$$\Big(f\big(\boldsymbol{\gamma}(x),u\big) - f\big(\boldsymbol{\gamma}(x),c\big) - \gamma_1(x)\big(A(u) - A(c)\big)_x\Big)_x \in \mathcal{M}(\Pi_T), \tag{4.14}$$

$$\Big(\operatorname{sgn}(u-c)\big[f\big(\boldsymbol{\gamma}(x),u\big) - f\big(\boldsymbol{\gamma}(x),c\big)\big] - \gamma_1(x)\big|A(u) - A(c)\big|_x\Big)_x \in \mathcal{M}(\Pi_T). \tag{4.15}$$

LEMMA 4.5. *Let u be a BV_t entropy weak solution of (4.1), and consider the transformed function $z(x,t) := \Psi(\boldsymbol{\gamma}(x), u(x,t))$. Then $\int_0^T \mathrm{TV}(z(\cdot,t))\,dt < C$ for some finite constant $C > 0$. In other words, $z_x \in \mathcal{M}(\Pi_T)$.*

Proof. For $A \equiv 0$, the proof of Lemma 2.2 of [25] applies unchanged up to minor differences in notation. Here we modify that proof to account for the presence of $A(u)$. Let $\mathrm{TV}(z(\cdot,t)|_{\mathcal{I}})$ denote the spatial variation of $z(\cdot,t)$ measured over the interval $\mathcal{I}$. Then it suffices to show that $\int_0^T \mathrm{TV}(z(\cdot,t)|_{\mathcal{I}})\,dt$ is bounded for each of the open intervals $\mathcal{I} = (-\infty, x_{\mathrm{L}})$, $(x_{\mathrm{L}}, 0)$, $(0, x_{\mathrm{R}})$, and (x_{R}, ∞). Due to the factor $\gamma_1(x)$, the singular mapping Ψ simplifies to $\Psi(\boldsymbol{\gamma},u) = \int_0^u |f_u(\boldsymbol{\gamma},w)|\,dw$ when $\mathcal{I} = (-\infty, x_{\mathrm{L}})$ or $\mathcal{I} = (x_{\mathrm{R}}, \infty)$, and so the proof of Lemma 2.2 of [25] applies to those intervals

without any modifications. We will focus on the interval $\mathcal{I} = (0, x_{\mathrm{R}})$ and omit the proof for $(x_{\mathrm{L}}, 0)$ since it is similar. Thus, we now set out to show that

$$\int_0^T \mathrm{TV}\big(z(\cdot,t)|_{\{x|\,0<x<x_{\mathrm{R}}\}}\big)\,dt < \infty. \tag{4.16}$$

To this end, recall that for $x \in (0, x_{\mathrm{R}})$, we have $\boldsymbol{\gamma} = (1, q_{\mathrm{R}})$, and

$$\begin{aligned}
f(\boldsymbol{\gamma}, u) &= q_{\mathrm{R}} u + b(u) - q_{\mathrm{R}} u_{\mathrm{F}} = \hat{f}(\boldsymbol{\gamma}, u) - q_{\mathrm{R}} u_{\mathrm{F}},\\
\Psi(\boldsymbol{\gamma}, u) &= \int_0^u \mathcal{S}(w)\big|\hat{f}_u(\boldsymbol{\gamma}, w)\big|\,dw + A(u) = \int_0^u \mathcal{S}(w)\big|q_{\mathrm{R}} + b'(w)\big|\,dw + A(u),\\
F(\boldsymbol{\gamma}, u, c) &= \operatorname{sgn}(u-c)\big(f(\boldsymbol{\gamma}, u) - f(\boldsymbol{\gamma}, c)\big) = \operatorname{sgn}(u-c)\big(\hat{f}(\boldsymbol{\gamma}, u) - \hat{f}(\boldsymbol{\gamma}, c)\big).
\end{aligned}$$

Let $\Pi_T^{\mathrm{R}} := (0, x_{\mathrm{R}}) \times (0, T) \subset \Pi_T$. Since $A(u)_x \in L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0,T))$, we have

$$A(u)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}}), \quad \big(A(u) - A(c)\big)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}}), \quad \big|A(u) - A(c)\big|_x \in \mathcal{M}(\Pi_T^{\mathrm{R}}).$$

Thus, it suffices to show that $\mathcal{F}(\boldsymbol{\gamma}, u)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}})$. Note that

$$\mathcal{F}\big(\boldsymbol{\gamma}(x), u(x,t)\big) = \int_0^{u(x,t)} \mathcal{S}(w)\big|\hat{f}_u(\boldsymbol{\gamma}, w)\big|\,dw \quad \text{for } (x,t) \in \Pi_T^{\mathrm{R}}.$$

Due to the assumptions on q_{R} and $b(u)$, the function $\hat{f}$ has at most two extrema for $u \in (0,1)$. We assume that q_{R} is chosen such that there are exactly two extrema $u_1^* < u_2^*$. The cases with one or no extremum will be omitted; they are handled in a similar manner. It is clear that $u \mapsto \hat{f}(\boldsymbol{\gamma}, u)$ is strictly monotone on intervals not containing extrema. We need the following fact, which follows by subtracting (4.14) from (4.15) and then dividing by 2:

$$\Big(\chi_l(w;c)\big(f(\boldsymbol{\gamma}_{\mathrm{R}}, u) - f(\boldsymbol{\gamma}_{\mathrm{R}}, c)\big) - \gamma_1(x)\big((A(u) - A(c))_-\big)_x\Big)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}}) \quad \forall c \in \mathbb{R}. \tag{4.17}$$

Here $\chi_l(w;c)$ is the characteristic function for $[0,c]$, and we have restricted our attention to the smaller domain Π_T^{R}. Finally, we have used the fact that $\boldsymbol{\gamma}(x) \equiv \boldsymbol{\gamma}_{\mathrm{R}}$ for $x \in (0, x_{\mathrm{R}})$.

Next, note that for $c \le u_{\mathrm{c}}$ in (4.17), the term $(A(u) - A(c))_-$ vanishes. This is easy to see by considering the two possible cases $u > c$ and $u \le c$. In the first case, $A(u) - A(c) \ge 0$, since $A(\cdot)$ is nondecreasing, and in the second case $A(u) - A(c) = 0$, since $A(\cdot)$ is constant on $[0, u_{\mathrm{c}}]$. Also, $\hat{f}(\boldsymbol{\gamma}, u) - \hat{f}(\boldsymbol{\gamma}, c) = f(\boldsymbol{\gamma}, u) - f(\boldsymbol{\gamma}, c)$. Thus, we conclude from (4.17) that

$$\Big(\chi_l(w;c)\big(\hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, u) - \hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, c)\big)\Big)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}}) \quad \text{for } c \le u_{\mathrm{c}}. \tag{4.18}$$

In (4.18), we now take $c_1 := u_1^* \wedge u_{\mathrm{c}}$, $c_2 := u_2^* \wedge u_{\mathrm{c}}$, and $c_3 := 1 \wedge u_{\mathrm{c}}$, and letting

$$P_i(\boldsymbol{\gamma}_{\mathrm{R}}, u) := \chi_l(w; c_i)\big(\hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, u) - \hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, c_i)\big), \quad i = 1,2,3,$$

we have $\partial_x P_i \in \mathcal{M}(\Pi_T^{\mathrm{R}})$. It is a straightforward exercise to verify that

$$\begin{aligned}
\mathcal{F}(\boldsymbol{\gamma}, u) = {} & P_3(\boldsymbol{\gamma}_{\mathrm{R}}, u) - 2P_2(\boldsymbol{\gamma}_{\mathrm{R}}, u) + 2P_1(\boldsymbol{\gamma}_{\mathrm{R}}, u)\\
& + \hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, c_3) - 2\hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, c_2) + 2\hat{f}(\boldsymbol{\gamma}_{\mathrm{R}}, c_1),
\end{aligned} \tag{4.19}$$

from which it follows immediately that $\mathcal{F}(\boldsymbol{\gamma}, u)_x \in \mathcal{M}(\Pi_T^{\mathrm{R}})$. ∎

The proof of the following lemma is a direct application of Lemma 4.5. Its proof follows from the proofs of Lemmas 3.3 and 3.4 of [56].

LEMMA 4.6. *A BV_t entropy solution u and the quantities $\gamma_1 A(u)$, $\gamma_1 A(u)_x$, and $\gamma_1|A(u)-A(c)|_x$ admit right and left traces at each jump in $\boldsymbol{\gamma}$.*

4.5. Entropy jump conditions and uniqueness of entropy solutions. Our objective in this section is to prove the L^1 stability of entropy weak solutions, which is stated in Theorem 4.15. If we had in our problem (4.1) the parabolic term $A(u)_{xx}$ instead of $(\gamma_1(x)A(u)_x)_x$, i.e., if $\gamma_1 \equiv 1$, section 2 of [56] would apply verbatim, and we could simply appeal to Theorem 2.1 of that paper. Thus we will follow closely section 2 of [56]. Since the spatially varying parameter γ_1 plays a key role here, we remind the reader that γ_1 is simply the characteristic function for the interval $(x_{\mathrm{L}}, x_{\mathrm{R}})$.

As in [56], it is convenient, and sufficient, to work with limits in the sense of Lebesgue. Specifically, let $W = W(x)$ be any function on $\mathbb{R}$, and fix a point $x_0 \in \mathbb{R}$. We define Lebesgue-type one-sided limits as follows:

$$\operatorname*{L\,lim}_{x\downarrow x_0} W(x) := \lim_{\epsilon\downarrow 0} \frac{1}{\epsilon}\int_{x_0}^{x_0+\epsilon} W(x)\,dx, \quad \operatorname*{L\,lim}_{x\uparrow x_0} W(x) := \lim_{\epsilon\downarrow 0} \frac{1}{\epsilon}\int_{x_0-\epsilon}^{x_0} W(x)\,dx.$$

The key fact here (see Lemma 2.1 of [56]) is the following.

LEMMA 4.7. *Let $W \in L^\infty(\Pi_T)$, and fix a point $x_0 \in \mathbb{R}$. If the right and left traces $t \mapsto W(x_0\pm, t)$ exist in the sense of Definition 4.2, then for a.e. $t \in (0,T)$ they also exist as right and left traces in the sense of Lebesgue points in L^1:*

$$\operatorname*{L\,lim}_{x\downarrow x_0} W(x,t) = W(x_0+,t), \qquad \operatorname*{L\,lim}_{x\uparrow x_0} W(x,t) = W(x_0-,t).$$

Next, we record the versions of Lemmas 2.2 and 2.3 of [56] that account for the coefficient $\gamma_1(x)$ multiplying $A(u)_x$. The proofs in [56] are easily modified to deal with γ_1 and are omitted here.

LEMMA 4.8. *Let u and v be a pair of BV_t entropy weak solutions. Let F be the Kružkov entropy flux defined in* (4.12). *Fix one of the jumps in $\boldsymbol{\gamma}$ located at $m \in \mathcal{J}$. Then for a.e. $t \in (0,T)$*

$$\begin{aligned} &\operatorname*{L\,lim}_{x\downarrow m} F\big(\boldsymbol{\gamma}(x), u(x,t), v(x,t)\big) = F\big(\boldsymbol{\gamma}(m+), u(m+,t), v(m+,t)\big),\\ &\operatorname*{L\,lim}_{x\uparrow m} F\big(\boldsymbol{\gamma}(x), u(x,t), v(x,t)\big) = F\big(\boldsymbol{\gamma}(m-), u(m-,t), v(m-,t)\big), \end{aligned} \tag{4.20}$$

$$\operatorname*{L\,lim}_{x\downarrow m}\big(\gamma_1(x)\big|A(u)-A(v)\big|_x\big)(x,t)$$

$$= \begin{cases} \gamma_1(m+)\sigma(m+,t)\big(A(u)_x(m+,t) - A(v)_x(m+,t)\big) & \text{if } A(u(m+,t)) \\ & \neq A(v(m+,t)), \\ \gamma_1(m+)\big|A(u)_x(m+,t) - A(v)_x(m+,t)\big| & \text{otherwise}, \end{cases} \tag{4.21}$$

$$\operatorname*{L\,lim}_{x\uparrow m}\big(\gamma_1(x)\big|A(u)-A(v)\big|_x\big)(x,t)$$

$$= \begin{cases} \gamma_1(m-)\sigma(m-,t)\big(A(u)_x(m-,t) - A(v)_x(m-,t)\big) & \text{if } A(u(m-,t)) \\ & \neq A(v(m-,t)), \\ -\gamma_1(m-)\big|A(u)_x(m-,t) - A(v)_x(m-,t)\big| & \text{otherwise}, \end{cases} \tag{4.22}$$

where $\sigma(m+,t) := \operatorname{sgn}(u(m+,t)-v(m+,t))$ and $\sigma(m-,t) := \operatorname{sgn}(u(m-,t)-v(m-,t))$.

LEMMA 4.9. *Let u be a BV_t entropy weak solution. Let F be the Kružkov entropy flux defined in* (4.12)*. Fix one of the jumps in $\boldsymbol{\gamma}$ located at $m \in \mathcal{J}$. For any $c \in \mathbb{R}$, we have for a.e. $t \in (0,T)$*

$$\begin{aligned} \operatorname*{L\,lim}_{x \downarrow m} F\big(\boldsymbol{\gamma}(x), u(x,t), c\big) &= F\big(\boldsymbol{\gamma}(m+), u(m+,t), c\big), \\ \operatorname*{L\,lim}_{x \uparrow m} F\big(\boldsymbol{\gamma}(x), u(x,t), c\big) &= F\big(\boldsymbol{\gamma}(m-), u(m-,t), c\big), \end{aligned} \tag{4.23}$$

$$\begin{aligned} &\operatorname*{L\,lim}_{x \downarrow m} \big(\gamma_1(x) \big| A(u) - A(c) \big|_x\big)(x,t) \\ &= \begin{cases} \gamma_1(m+)\sigma(m+,t) A(u)_x(m+,t) & \text{if } u(m+,t) \neq c, \\ \gamma_1(m+) \big| A(u)_x(m+,t) \big| & \text{if } u(m+,t) = c, \end{cases} \end{aligned} \tag{4.24}$$

$$\begin{aligned} &\operatorname*{L\,lim}_{x \uparrow m} \big(\gamma_1(x) \big| A(u) - A(c) \big|_x\big)(x,t) \\ &= \begin{cases} \gamma_1(m-)\sigma(m-,t) A(u)_x(m-,t) & \text{if } u(m-,t) \neq c, \\ -\gamma_1(m-) \big| A(u)_x(m-,t) \big| & \text{if } u(m-,t) = c, \end{cases} \end{aligned} \tag{4.25}$$

where $\sigma(m-,t) := \operatorname{sgn}(u(m-,t) - c)$ and $\sigma(m+,t) := \operatorname{sgn}(u(m+,t) - c)$.

Before continuing, we introduce a notational convention that we hope will simplify the appearance of the formulas that follow. Whenever we are discussing a fixed element $m \in \mathcal{J}$, and the time is fixed at $t \in [0,T]$ where all of the relevant right and left limits exist, we use the notation $u_\pm = u_\pm(t) = u(m\pm,t)$, $\boldsymbol{\gamma}_\pm = \boldsymbol{\gamma}(m\pm)$, and $(\gamma_1 A(u_x))_\pm = (\gamma_1 A(u)_x)(m\pm,t)$.

We collect in the following lemma several properties of a BV_t entropy weak solution near a jump in $\boldsymbol{\gamma}$. The relationship (4.26) is the Rankine–Hugoniot condition for this problem, while (4.28) is an entropy condition. The relationship (4.27) restricts the sign of $A(u)_x$ at a jump in $\boldsymbol{\gamma}$.

REMARK 4.1. *To highlight once again the significance of assumption* (D.4)*, we mention that the proof of* (4.27) *requires the hypothesis that $A(u)$ is continuous across the jumps in $\boldsymbol{\gamma}$ at x_{L} and x_{R}. Thus,* (D.4) *is crucial for the uniqueness of entropy weak solutions of Model* 1*.*

LEMMA 4.10. *Let u be a BV_t entropy weak solution. Fix one of the jumps in $m \in \mathcal{J}$. Then the following relationships hold across the jump for a.e. $t \in (0,T)$:*

$$f\big(\boldsymbol{\gamma}_+, u_+\big) - (\gamma_1 A(u)_x)_+ = f\big(\boldsymbol{\gamma}_-, u_-\big) - (\gamma_1 A(u)_x)_-, \tag{4.26}$$

$$\operatorname{sgn}(u_+ - u_-) \operatorname{sgn}\big((A(u)_x)_+\big) \geq 0, \quad \operatorname{sgn}(u_+ - u_-) \operatorname{sgn}\big((A(u)_x)_-\big) \geq 0. \tag{4.27}$$

And for $u_-(t) \neq u_+(t)$,

$$\begin{aligned} &\big[F\big(\boldsymbol{\gamma}_+, u_+, c\big) - \operatorname{sgn}(u_+ - c)\,(\gamma_1 A(u)_x)_+\big] \\ &- \big[F\big(\boldsymbol{\gamma}_-, u_-, c\big) - \operatorname{sgn}(u_- - c)\,(\gamma_1 A(u)_x)_-\big] \\ &\qquad \leq \big|f(\boldsymbol{\gamma}_+, c) - f(\boldsymbol{\gamma}_-, c)\big| \qquad \forall c \in \mathbb{R}, \end{aligned} \tag{4.28}$$

where F is the Kružkov entropy flux function defined in (4.12)*. In addition, the appropriate inequality in Table* 4.1 *holds for all c between u_- and u_+.*

Proof. The proofs of these assertions are similar to the proofs of Lemmas 2.4, 2.5, 2.6, and 2.7 of [56]. Since the proof of (4.27) relies on the assumption (D.4), we will review its proof but will not repeat the proofs of the other assertions. We start by fixing a time $t \in (0,T)$ where all of the relevant right and left spatial (essential)

TABLE 4.1
Entropy jump conditions.

	$f(\boldsymbol{\gamma}_-, c) \le f(\boldsymbol{\gamma}_+, c)$	$f(\boldsymbol{\gamma}_-, c) \ge f(\boldsymbol{\gamma}_+, c)$
$u_- \le c \le u_+$	$f(\boldsymbol{\gamma}_+, u_+) - (\gamma_1 A(u)_x)_+$ $\le f(\boldsymbol{\gamma}_+, c)$	$f(\boldsymbol{\gamma}_-, u_-) - (\gamma_1 A(u)_x)_-$ $\le f(\boldsymbol{\gamma}_-, c)$
$u_+ \le c \le u_-$	$f(\boldsymbol{\gamma}_-, u_-) - (\gamma_1 A(u)_x)_-$ $\ge f(\boldsymbol{\gamma}_-, c)$	$f(\boldsymbol{\gamma}_+, u_+) - (\gamma_1 A(u)_x)_+$ $\ge f(\boldsymbol{\gamma}_+, c)$

limits exist at $x = m$. We prove only the first inequality in (4.27); the proof of the other inequality is similar. Let us suppress the dependence on t for the remainder of the proof. If $u_+ = u_-$, the inequality is obvious, so assume that $u_+ > u_-$. We must show that $(A(u)_x)_+ \ge 0$. From

$$\operatorname*{ess\,lim}_{\varepsilon \downarrow 0} u(m+\varepsilon) =: u_+ > u_-,$$

it is clear that $u(m+\varepsilon) > u_-$ for a.e. sufficiently small $\varepsilon > 0$. Next, we apply A to both sides of $u(m+\varepsilon) > u_-$. Since A is nondecreasing, we obtain $A(u(m+\varepsilon)) \ge A(u_-)$ for a.e. sufficiently small $\varepsilon > 0$. If the jump point is at the origin, i.e., $m = 0$, then continuity of $A(u)$ follows from assumption (D.1). If $m = x_{\mathrm{L}}$ or $m = x_{\mathrm{R}}$, then assumption (D.4) gives us continuity of $A(u)$. In either case, we have $A(u_-) = A(u_+)$. Thus,

$$\frac{1}{\varepsilon} \int_m^{m+\varepsilon} A(u)_x \, dx = \frac{1}{\varepsilon} \left(A(u(m+\varepsilon)) - A(u_+) \right) \ge 0 \tag{4.29}$$

for a.e. sufficiently small $\varepsilon > 0$. Letting $\varepsilon \downarrow 0$ (along a subsequence for which (4.29) holds) yields $(A(u)_x)_+ \ge 0$. The proof is completed by showing via a similar argument that if $u_+ < u_-$, then $(A(u)_x)_+ \le 0$. ∎

REMARK 4.2. *Since A is nondecreasing, we can write the entropy condition* (4.28) *in the alternative form*

$$\Phi(\boldsymbol{\gamma}, u, c)_+ - \Phi(\boldsymbol{\gamma}, u, c)_- \le \left| f(\boldsymbol{\gamma}_+, c) - f(\boldsymbol{\gamma}_-, c) \right| \quad \forall c \in \mathbb{R}, \tag{4.30}$$

where $\Phi(\boldsymbol{\gamma}, u, c) := F(\boldsymbol{\gamma}, u, c) - \gamma_1 |A(u) - A(c)|_x$. Note that the entropy jump condition (4.28) *is the same as the one stated in Lemma* 2.6 *of* [56]*, with the exception that $\gamma_1 = \gamma_1(x)$ is not present in* [56]*. Similarly, this is the only difference between Table* 1 *of* [56] *and our Table* 4.1.

The next lemma is basically Lemma 2.8 of [56], adapted to the present setup.

LEMMA 4.11. *Let u be a BV_t entropy weak solution. Fix the jump in $\boldsymbol{\gamma}$ located at $m = 0$ and a time $t \in [0, T]$ where all of the relevant right and left limits exist. If $u_- \ne u_+$, then $A'(w) = 0$ for w between u_- and u_+, and thus $A(\cdot)$ is constant on the interval connecting u_- to u_+; that is,*

$$A(w) = A(u_-) = A(u_+) \quad \text{for } w \text{ between } u_- \text{ and } u_+. \tag{4.31}$$

Taken together, Lemma 4.11 and assumption (D.4) guarantee continuity of $x \mapsto A(u(x,t))$ for a.e. $t \in [0, T]$ at each of the jumps $m \in \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$. Using this fact, along with the relationships in Table 4.1, it is possible to prove the following lemma, whose proof we omit, since it is essentially the same as the proof of Lemma 2.9 of [56].

LEMMA 4.12. *Let u and v be a pair of BV_t entropy weak solutions. Fix a jump in $\boldsymbol{\gamma}$ located at $m \in \mathcal{J}$ and a time $t \in (0,T)$ where all of the relevant right and left traces exist. Assume that $u_- > v_-$, $u_+ < v_+$. If $u_+ \le u_-$, then*

$$\begin{aligned} &v_- \in [u_+, u_-), \;\; f(\boldsymbol{\gamma}_+, v_-) \ge f(\boldsymbol{\gamma}_-, v_-) \\ &\qquad \Longrightarrow f(\boldsymbol{\gamma}_-, v_-) - \big(\gamma_1 A(v)_x\big)_- \le f(\boldsymbol{\gamma}_-, u_-) - \big(\gamma_1 A(u)_x\big)_-, \\ &v_+ \in (u_+, u_-], \;\; f(\boldsymbol{\gamma}_-, v_+) \ge f(\boldsymbol{\gamma}_+, v_+) \\ &\qquad \Longrightarrow f(\boldsymbol{\gamma}_+, v_+) - \big(\gamma_1 A(v)_x\big)_+ \le f(\boldsymbol{\gamma}_+, u_+) - \big(\gamma_1 A(u)_x\big)_+. \end{aligned} \tag{4.32}$$

If $v_- \le v_+$, then

$$\begin{aligned} &u_- \in (v_-, v_+], \;\; f(\boldsymbol{\gamma}_+, u_-) \le f(\boldsymbol{\gamma}_-, u_-) \\ &\qquad \Longrightarrow f(\boldsymbol{\gamma}_-, v_-) - \big(\gamma_1 A(v)_x\big)_- \le f(\boldsymbol{\gamma}_-, u_-) - \big(\gamma_1 A(u)_x\big)_-, \\ &u_+ \in [v_-, v_+), \;\; f(\boldsymbol{\gamma}_+, u_+) \ge f(\boldsymbol{\gamma}_-, u_+) \\ &\qquad \Longrightarrow f(\boldsymbol{\gamma}_+, v_+) - \big(\gamma_1 A(v)_x\big)_+ \le f(\boldsymbol{\gamma}_+, u_+) - \big(\gamma_1 A(u)_x\big)_+. \end{aligned} \tag{4.33}$$

Before proceeding to our main uniqueness theorem, let us recall the so-called crossing condition that we introduced in [56].

DEFINITION 4.13 (crossing condition). *For any jump in $\boldsymbol{\gamma}$ with associated left and right limits $(\boldsymbol{\gamma}_-, \boldsymbol{\gamma}_+)$, we say that the crossing condition holds if, for any states u and v,*

$$f(\boldsymbol{\gamma}_+, u) - f(\boldsymbol{\gamma}_-, u) < 0 < f(\boldsymbol{\gamma}_+, v) - f(\boldsymbol{\gamma}_-, v) \text{ implies } u < v. \tag{4.34}$$

The geometric interpretation of this condition is that if the graphs of $u \mapsto f(\boldsymbol{\gamma}_-, u)$ and $u \mapsto f(\boldsymbol{\gamma}_+, u)$ cross, then there can be at most one crossing, say at $u = u_\chi$, and in this case the graph of $f(\boldsymbol{\gamma}_-, u)$ lies above (below) the graph of $f(\boldsymbol{\gamma}_+, u)$ for $u < u_\chi$ ($u > u_\chi$). The crossing condition is satisfied automatically if there is no crossing. Figure 2.1(d) shows an example of a flux crossing that satisfies the crossing condition, with crossing point $u_\chi = u_{\mathrm{F}}$. A motivation for the crossing condition in the present context is given by the following lemma, whose elementary proof is provided in [25]. See also Figure 2.1.

LEMMA 4.14. *With our assumptions on b, q_{L}, and q_{R}, the crossing condition is satisfied at each jump $m \in \mathcal{J}$. Specifically, there are no flux crossings associated with the jumps $x = x_{\mathrm{L}}$, $x = x_{\mathrm{R}}$. There may be a single crossing at the jump $x = 0$, but it satisfies the crossing condition.*

Satisfaction of the crossing condition at the nontrivial crossing at $x = 0$ may be traced to the fact that a source is located there, and thus the flow diverges from the origin. This is most easily understood by ignoring for a moment the batch flux $b(u)$ and the parabolic term. It is easy to check that these terms do not affect the crossing relationship at $x = 0$. Then, if we use $\delta(x)$ to denote the delta function, our model simplifies to

$$u_t + q(x) u_x = (q_{\mathrm{R}} - q_{\mathrm{L}}) u_{\mathrm{F}}\, \delta(x), \quad q(x) = \begin{cases} q_{\mathrm{L}} & \text{for } x < 0, \\ q_{\mathrm{R}} & \text{for } x > 0. \end{cases}$$

Since $q_{\mathrm{L}} < 0 < q_{\mathrm{R}}$, we have diverging flows, balanced by a source term on the right-hand side. Notice that in this case the flux curves are the straight lines $u \mapsto q_{\mathrm{L}}(u - u_{\mathrm{F}})$ and $u \mapsto q_{\mathrm{R}}(u - u_{\mathrm{F}})$, and the crossing condition is satisfied. On the other hand, if we

had $q_{\mathrm{L}} > 0 > q_{\mathrm{R}}$, then our simplified model would result in converging flows, balanced by a sink term, and the crossing condition would be violated. Thus, from a physical point of view, our assumption that the crossing condition is satisfied is a natural one and follows directly from the fact that the clarifier-thickener model has a source term (as opposed to a sink term).

If any of the jumps in $\boldsymbol{\gamma}$ violated the crossing condition, our definition of entropy solution would not be strong enough to rule out so-called expansion shocks (see [56] for a detailed explanation), and our uniqueness theory would break down. It turns out that additional entropy conditions are required when the crossing condition is not satisfied; we defer further discussion of this issue to a future paper since the crossing condition is satisfied in the present context.

We are finally able to prove our main uniqueness theorem.

THEOREM 4.15 (L^1 stability and uniqueness). *Let v and u be two BV_t entropy weak solutions to the initial value problem* (4.1). *For a.e. $t \in (0,T)$,*

$$\big\|v(\cdot,t) - u(\cdot,t)\big\|_{L^1(\mathbb{R})} \le \|v_0 - u_0\|_{L^1(\mathbb{R})}. \tag{4.35}$$

Proof. For BV_t entropy weak solutions u and v, a "doubling of variables" argument appearing in Appendix A of [56] yields

$$-\iint_{\Pi_T} \Big(|v-u|\varphi_t + F(\boldsymbol{\gamma}(x),v,u)\varphi_x + \big|\gamma_1 A(v) - \gamma_1 A(u)\big|\varphi_{xx} \Big)\, dt\, dx \le 0 \tag{4.36}$$

for any $0 \le \varphi \in \mathcal{D}(\Pi_T \setminus \mathcal{J})$. Next, via a limiting argument (see the proof of Theorem 2.1 of [56]) we extend this inequality to the larger class of test functions which do not vanish near $x \in \mathcal{J}$. Specifically, we obtain for any $0 \le \phi \in \mathcal{D}(\Pi_T)$

$$\begin{aligned} &-\iint_{\Pi_T} \Big(|v-u|\phi_t + F(\boldsymbol{\gamma}(x),v,u)\phi_x - \big|\gamma_1 A(v) - \gamma_1 A(u)\big|\phi_{xx} \Big)\, dt\, dx \\ &\quad \le \sum_{m \in \mathcal{J}} \int_0^T \Big[F(\gamma(x),v,u) - \big|\gamma_1 A(v) - \gamma_1 A(u)\big|_x \Big]_{x=m-}^{x=m+} \phi(m,t)\, dt, \end{aligned} \tag{4.37}$$

where the notation indicates limits from the right and left at $x = m$.

We wish to show that each term in the sum on the right-hand side of (4.37) is nonpositive. If we fix a jump point $m \in \mathcal{J}$, then the contribution to this sum from the jump point m is given by

$$R := \Phi\big(\boldsymbol{\gamma}(m+), v(m+,t), u(m+,t)\big) - \Phi\big(\boldsymbol{\gamma}(m-), v(m-,t), u(m-,t)\big). \tag{4.38}$$

Here Φ is defined in Remark 4.2 and appears in the entropy condition (4.30). Our goal is now to show that R is nonpositive. Let us fix a time $t \in (0,T)$ where all of the relevant essential right and left limits exist. If $m = 0$, then since $\gamma_1 = 1$ on the interval $(x_{\mathrm{L}}, x_{\mathrm{R}})$ containing $x = 0$, $R \le 0$ is immediate by repeating the relevant portion (the seven cases) of the proof of Theorem 2.1 of [56]. (Note that in [56] we used the symbol S for the quantity known here as R.) We will not reproduce that proof here, but we emphasize that this ($m = 0$) is the only case where a nontrivial flux crossing occurs, and thus we rely on the fact that the crossing condition is satisfied.

If $x = x_{\mathrm{L}}$ or $x = x_{\mathrm{R}}$, then because of the jump in γ_1, we cannot appeal directly to [56], which did not address the case of a spatially varying parabolic term. We will focus on the case $x = x_{\mathrm{R}}$ and omit the similar case $x = x_{\mathrm{L}}$. The approach is to verify that $R \le 0$ in each of the seven cases identified in [56]. The assumptions on $b(u)$

ensure that at $x = x_{\mathrm{R}}$, we will always have $f(\boldsymbol{\gamma}_-, u) \geq f(\boldsymbol{\gamma}_+, u)$. In particular, there are no flux crossings, which simplifies the proofs of Cases 6 and 7.

Case 1 ($v_- = u_-$, $v_+ = u_+$). Then $F(\boldsymbol{\gamma}_+, v_+, u_+) = 0$ and $F(\boldsymbol{\gamma}_-, v_-, u_-) = 0$, and by Lemma 4.8 and the fact that $\gamma_1(x_{\mathrm{R}}+) = 0$, R reduces to

$$R = -\big|\big(\gamma_1 A(u)_x\big)_- - \big(\gamma_1 A(v)_x\big)_-\big| \leq 0.$$

Case 2 ($v_- = u_-$, $u_+ \neq v_+$). Assume that $v_+ > u_+$. In this case

$$\begin{aligned} R = {} & f(\boldsymbol{\gamma}_+, v_+) - f(\boldsymbol{\gamma}_+, u_+) - \big(\gamma_1 A(v)_x\big)_+ + \big(\gamma_1 A(u)_x\big)_+ \\ & - \big|\big(\gamma_1 A(v)_x\big)_- - \big(\gamma_1 A(u)_x\big)_-\big|, \end{aligned} \tag{4.39}$$

where we have used the equality $f(\boldsymbol{\gamma}_-, v_-) = f(\boldsymbol{\gamma}_-, u_-)$. Via the Rankine–Hugoniot condition and another application of $f(\boldsymbol{\gamma}_-, u_-) = f(\boldsymbol{\gamma}_-, v_-)$, we get

$$f(\boldsymbol{\gamma}_+, v_+) - f(\boldsymbol{\gamma}_+, u_+) = -\big(\gamma_1 A(v)_x\big)_- + \big(\gamma_1 A(u)_x\big)_-.$$

We have again used the fact that $\gamma_1(x_{\mathrm{R}}+) = 0$. Substituting this into (4.39) gives

$$R = -\big|\big(\gamma_1 A(v)_x\big)_- - \big(\gamma_1 A(u)_x\big)_-\big| \leq 0.$$

The situation where $v_+ < u_+$ is handled similarly.

Case 3 ($v_+ = u_+$, $u_- \neq v_-$). The proof of this case is similar to that of Case 2 and is therefore omitted.

Case 4 ($u_- < v_-$, $u_+ < v_+$). In this case, using $\gamma_1(x_{\mathrm{R}}+) = 0$, we obtain from (4.38)

$$\begin{aligned} R = {} & \big(f(\boldsymbol{\gamma}_+, v_+) - f(\boldsymbol{\gamma}_+, u_+)\big) \\ & - \big[f(\boldsymbol{\gamma}_-, v_-) - f(\boldsymbol{\gamma}_+, u_+) - \big(\gamma_1 A(v)_x\big)_- + \big(\gamma_1 A(u)_x\big)_-\big], \end{aligned} \tag{4.40}$$

which equals zero, by the Rankine–Hugoniot condition (4.26).

Case 5 ($u_- > v_-$, $u_+ > v_+$). As in the preceding case, $R = 0$ due to a similar calculation.

Case 6 ($u_- > v_-$, $u_+ < v_+$). In this case, (4.38) becomes

$$R = f(\boldsymbol{\gamma}_-, v_-) + f(\boldsymbol{\gamma}_+, v_+) - f(\boldsymbol{\gamma}_-, u_-) - f(\boldsymbol{\gamma}_+, u_+) - \big(\gamma_1 A(v)_x\big)_- + \big(\gamma_1 A(u)_x\big)_- \tag{4.41}$$

$$= 2f(\boldsymbol{\gamma}_+, v_+) - 2f(\boldsymbol{\gamma}_+, u_+) \tag{4.42}$$

$$= 2\big[f(\boldsymbol{\gamma}_-, v_-) - \big(\gamma_1 A(v)_x\big)_-\big] - 2\big[f(\boldsymbol{\gamma}_-, u_-) - \big(\gamma_1 A(u)_x\big)_-\big],$$

where (4.41) and (4.42) follow from the Rankine–Hugoniot condition (4.26). In (4.41) we have used again the fact that $\gamma_1(x_{\mathrm{R}}+) = 0$. It follows from the assumption $u_- > v_-$, $u_+ < v_+$ that $u_+ < v_+ \leq u_-$ or $v_- < u_- \leq v_+$ must hold. Take the case where $u_+ < v_+ \leq u_-$. Recalling that at $m = x_{\mathrm{R}}$ we always have $f(\boldsymbol{\gamma}_-, \cdot) \geq f(\boldsymbol{\gamma}_+, \cdot)$, we can apply (4.32) of Lemma 4.12, giving us $f(\boldsymbol{\gamma}_+, v_+) \leq f(\boldsymbol{\gamma}_+, u_+)$. With (4.41) in mind, we see that $R \leq 0$. In the case where $v_- < u_- \leq v_+$, (4.33) of Lemma 4.12 yields $f(\boldsymbol{\gamma}_-, v_-) - (\gamma_1 A(v)_x)_- \leq f(\boldsymbol{\gamma}_-, u_-) - (\gamma_1 A(u)_x)_-$, again implying that $R \leq 0$, this time using (4.42).

Case 7 ($u_- < v_-$, $u_+ > v_+$). The proof is identical to that of Case 6; we switch the roles of u and v and use the version of Lemma 4.12 that results by also switching the roles of u and v.

We have established that for any $0 \le \phi \in \mathcal{D}(\Pi_T)$

$$-\iint_{\Pi_T} \Big(|v-u|\phi_t + F(\boldsymbol{\gamma}(x), v, u)\phi_x - \big|\gamma_1 A(v) - \gamma_1 A(u)\big|\phi_{xx} \Big)\, dt\, dx \le 0. \tag{4.43}$$

The proof is concluded via a standard test function argument which is outlined in the proof of Theorem 2.1 of [56]. ∎

4.6. Convergence of the numerical approximations. In what follows, let us denote by Δ the pair $\Delta := (\Delta t, \Delta x)$. Our purpose in this section is to prove convergence (along a subsequence) of the numerical approximations as $\Delta \downarrow 0$, i.e., as $\Delta t, \Delta x \to 0$ with $\Delta t, \Delta x > 0$. For the sake of simplicity, we will concentrate on the explicit version of the algorithm.

Let $(\boldsymbol{\gamma}^\Delta, u^\Delta)$ be the finite difference approximation defined in (3.3). A significant part of the convergence analysis consists of establishing a spatial total variation estimate for the approximate solution u^Δ, measured with respect to a particular transformed variable. More precisely, we prove that u^Δ converges (along a subsequence) to a weak solution by introducing a singular mapping $\Psi : (\boldsymbol{\gamma}, u) \mapsto (\boldsymbol{\gamma}, z)$ such that strong compactness of $z^\Delta = \Psi(\boldsymbol{\gamma}^\Delta, u^\Delta)$ can be obtained. As always in problems involving resonance phenomena, one should measure the space translates with respect to a nonlinear transformation; as already mentioned in the introduction, there is generally no spatial total variation bound for the conserved variable u itself. The singular mapping approach has been used for many years in the purely hyperbolic setting, starting with the paper [76].

On the other hand, the construction of a suitable singular mapping Ψ for second-order equations is more recent and was done first in [55]. The idea is to construct a singular mapping that includes a contribution from both the convective flux and the diffusion function. We first prove compactness for the two parts of the singular mapping separately. We then combine the two portions to recover the original singular mapping and conclude that since the mapping is strictly increasing as a function of the conserved variable u, convergence of the transformed variable implies convergence of u.

Since we are applying the scheme described in section 3 to Model 1 (constant cross section), we can simplify the analysis by taking $S_j \equiv 1$, and then $\lambda_j =: \lambda = \Delta t/\Delta x$. To simplify the notation a little further, let $\mu = \lambda/\Delta x$, $h^n_{j+1/2} = h(\gamma_{j+1/2}, U^n_{j+1}, U^n_j)$, ${\gamma_1}_{j+1/2} = s_{j+1/2}$, and $A^n_j = A(U^n_j)$. The marching formula (3.1) then takes the form

$$U^{n+1}_j = U^n_j - \lambda \Delta_+ h^n_{j-1/2} + \mu \Delta_+ \left(s_{j-1/2} \Delta_- A^n_j \right). \tag{4.44}$$

The Engquist–Osher numerical flux is consistent with the actual flux, i.e., $h(\boldsymbol{\gamma}, u, u) = f(\boldsymbol{\gamma}, u)$. In addition, for fixed $\boldsymbol{\gamma}$, $h(\boldsymbol{\gamma}, v, u)$ is a two-point monotone flux, meaning that it is nonincreasing with respect to v and nondecreasing with respect to u. Due to the regularity assumptions on f, the numerical flux h is Lipschitz continuous with respect to each of its arguments and in fact satisfies

$$f^-_u(\boldsymbol{\gamma}, v) = h_v(\boldsymbol{\gamma}, v, u) \le 0 \le h_u(\boldsymbol{\gamma}, v, u) = f^+_u(\boldsymbol{\gamma}, u), \tag{4.45}$$

where $f^-_u(\boldsymbol{\gamma}, u) := \min\{0, f_u(\boldsymbol{\gamma}, u)\}$ and $f^+_u(\boldsymbol{\gamma}, u) := \max\{0, f_u(\boldsymbol{\gamma}, u)\}$ denote the negative and positive parts of f_u. Thus, whenever the flux $u \mapsto f(\boldsymbol{\gamma}, u)$ is C^1, the

numerical flux is also C^1 as a function of the conserved variables u and v. The following bound is easily checked:

$$\|h\| := \max\Big\{ \big|h(\boldsymbol{\gamma}, v, u)\big| \;\Big|\; \boldsymbol{\gamma} \in \mathcal{G},\ v, u \in [0,1] \Big\} \le \|f\| + \frac{1}{2}\|f_u\|.$$

From formula (4.45) it is clear that $\|f_u\|$ is a Lipschitz constant for the numerical flux h with respect to the conserved variables u and v.

We assume that the discretization parameters $(\Delta x, \Delta t)$ are chosen so that the following Courant–Friedrichs–Lewy (CFL) [35] condition holds:

$$\lambda\Big(\max\{-q_{\mathrm{L}}, q_{\mathrm{R}}\} + \max_{u\in[0,1]} |b'(u)|\Big) + \mu \max_{u\in[0,1]} A'(u) \le 1/2. \tag{4.46}$$

In our case, the stability analysis relies very much on the monotonicity property of the scheme, where we recall that a finite difference scheme such as (4.44) is monotone [36] if

$$U_j^n \le V_j^n \quad \forall j \quad \Longrightarrow \quad U_j^{n+1} \le V_j^{n+1} \quad \forall j. \tag{4.47}$$

The following lemma and its proof illustrate how the CFL condition (4.46) is derived from the requirement that our scheme (4.44) be monotone.

LEMMA 4.16. *If the initial data $\{U_j^0\}_{j\in\mathbb{Z}}$ lies in the interval $[0,1]$ and the CFL condition* (4.46) *is satisfied, then the solution $\{U_j^n\}_{j\in\mathbb{Z}}$ computed by the explicit scheme* (4.44) *also belongs to the interval $[0,1]$ for each $n \ge 0$. Moreover, the difference scheme* (4.44) *remains monotone at each time level $n \ge 0$.*

Proof. Let us first rewrite (4.44) as $U_j^{n+1} = G_j(U_{j+1}^n, U_j^n, U_{j-1}^n, \gamma_{j+1/2}, \gamma_{j-1/2})$ for $j \in \mathbb{Z}$. Then the scheme is monotone, i.e., satisfies (4.47), if

$$\partial U_j^{n+1}/\partial U_{j+1}^n \ge 0, \quad \partial U_j^{n+1}/\partial U_j^n \ge 0, \quad \partial U_j^{n+1}/\partial U_{j-1}^n \ge 0, \quad j \in \mathbb{Z}. \tag{4.48}$$

However, in our case we have for $j \in \mathbb{Z}$

$$\partial U_j^{n+1}/\partial U_{j+1}^n = -\lambda f_u^-\big(\boldsymbol{\gamma}_{j+1/2}, U_{j+1}^n\big) + \mu\gamma_{1\,j+1/2} A'\big(U_{j+1}^n\big), \tag{4.49}$$

$$\partial U_j^{n+1}/\partial U_{j-1}^n = \lambda f_u^+\big(\boldsymbol{\gamma}_{j-1/2}, U_{j-1}^n\big) + \mu\gamma_{1\,j-1/2} A'\big(U_{j-1}^n\big), \tag{4.50}$$

$$\begin{aligned} \partial U_j^{n+1}/\partial U_j^n = {} & 1 + \lambda f_u^-\big(\boldsymbol{\gamma}_{j+1/2}, U_j^n\big) - \lambda f_u^+\big(\boldsymbol{\gamma}_{j-1/2}, U_j^n\big) \\ & - \mu\big(\gamma_{1\,j-1/2} + \gamma_{1\,j+1/2}\big) A'\big(U_j^n\big). \end{aligned} \tag{4.51}$$

Since $f_u^- \le 0$, $f_u^+ \ge 0$, and $A'(u) \ge 0$ by definition, we see that the right-hand sides of (4.49) and (4.50) are always nonnegative. If $U_j^n \in [0,1]$, then it is easy to deduce from (4.51) and from $\gamma_1 \in [0,1]$ that also $\partial U_j^{n+1}/\partial U_j^n \ge 0$ if the CFL condition (4.46) is satisfied. Precisely speaking, $U_j^n \in [0,1]$ and the CFL condition (4.46) ensure that the scheme is monotone *at time* t_n.

It remains to prove that if we have $U_j^n \in [0,1]$, then the quantities U_j^{n+1} calculated by the scheme also satisfy $U_j^{n+1} \in [0,1]$ for $j \in \mathbb{Z}$. To this end, we now apply the scheme (4.44) to the initial data $V_j^0 \equiv 0$. The parabolic terms vanish, since the data is constant, and at time level 1 we get $V_j^1 = V_j^0 - \lambda\Delta_- h(\gamma_{j+1/2}, V_{j+1}^0, V_j^0)$. Since $b(u) = 0$ for $u = 0$ and $u = 1$, it is easy to check that $V_0^1 = \lambda(q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}}$ and $V_j^1 = 0$ for $j \ne 0$. The CFL condition implies that $0 \le \lambda(-q_{\mathrm{L}}) \le 1/2$ and $0 \le \lambda q_{\mathrm{R}} \le 1/2$, which yields $0 \le \lambda(q_{\mathrm{R}} - q_{\mathrm{L}}) \le 1$, and thus $V_j^1 \in [0,1]$.

Next, we apply the scheme (4.44) to the initial data $W_j^0 \equiv 1$, yielding at time level 1 $W_j^1 = W_j^0 - \lambda\Delta_- h(\gamma_{j+1/2}, W_{j+1}^0, W_j^0)$. This time we find that $W_0^1 = 1 - \lambda(q_{\mathrm{R}} - q_{\mathrm{L}})(1 - u_{\mathrm{F}})$ and $W_j^1 = 1$ for $j \neq 0$. The CFL condition again guarantees that $W_j^1 \in [0,1]$. Thus, $0 \leq V_j^1, W_j^1 \leq 1$, the CFL condition remains valid for $\{V_j^1\}_{j\in\mathbb{Z}}$ and $\{W_j^1\}_{j\in\mathbb{Z}}$, and monotonicity implies that $V_j^1 \leq U_j^1 \leq W_j^1$. Continuing inductively, we see that $0 \leq V_j^n \leq U_j^n \leq W_j^n \leq 1$, the CFL condition remains satisfied at each successive time step, and we continue to have monotonicity for each $n \geq 0$. ∎

When sending $\Delta \downarrow 0$, as we will do in the analysis of the explicit scheme (3.1), the ratio $\mu = \lambda/\Delta x = \Delta t/\Delta x^2$ will be kept constant, which means that $\lambda = \mu\Delta x$ is variable with $\lambda \to 0$ as $\Delta \downarrow 0$.

The CFL condition for the semi-implicit scheme (3.4), which we do not analyze here but use for some of the numerical examples, is

$$\lambda\Big(\max\{-q_{\mathrm{L}}, q_{\mathrm{R}}\} + \max_{u\in[0,1]} |b'(u)|\Big) \leq 1/2. \tag{4.52}$$

Consequently, the semi-implicit scheme behaves stably for $\Delta \downarrow 0$ if we fix $\lambda = \Delta t/\Delta x$ such that (4.52) is satisfied. The semi-implicit scheme (3.4) allows a faster computation than the explicit scheme (3.1), since Δt needs to be chosen proportional to Δx, not Δx^2 (as for the explicit scheme). Again, the CFL condition (4.52) accrues from the requirement that the scheme be monotone, as we shall see in the following version of Lemma 4.16 for the semi-implicit scheme (3.4). This lemma can be considered as a motivation for the CFL condition (4.52).

LEMMA 4.17. *If the initial data $\{U_j^0\}_{j\in\mathbb{Z}}$ lies in the interval $[0,1]$ and the CFL condition* (4.52) *is satisfied, then the solution $\{U_j^n\}_{j\in\mathbb{Z}}$ computed by the semi-implicit scheme* (3.4) *also belongs to the interval $[0,1]$ for each $n \geq 0$. Moreover, the difference scheme* (3.4) *remains monotone at each time level $n \geq 0$.*

Proof. Let $V^n := \{V_j^n\}_{j\in\mathbb{Z}}$ and $W^n := \{W_j^n\}_{j\in\mathbb{Z}}$ satisfy $V_j^n, W_j^n \in [0,1]$ for all $j \in \mathbb{Z}$. If we compute V^{n+1} and W^{n+1} using the implicit scheme, then with the help of (4.45) we can write their difference as

$$\begin{aligned} W_j^{n+1} - V_j^{n+1} = {} & W_j^n - V_j^n + \alpha_{j+1/2}\left(W_{j+1}^n - V_{j+1}^n\right) - \beta_{j+1/2}\left(W_j^n - V_j^n\right) \\ & - \alpha_{j-1/2}\left(W_j^n - V_j^n\right) + \beta_{j-1/2}\left(W_{j-1}^n - V_{j-1}^n\right) \\ & + s_{j+1/2}\theta_{j+1}\left(W_{j+1}^{n+1} - V_{j+1}^{n+1}\right) \\ & - (s_{j+1/2} + s_{j-1/2})\theta_j\left(W_j^{n+1} - V_j^{n+1}\right) \\ & + s_{j-1/2}\theta_{j-1}\left(W_{j-1}^{n+1} - V_{j-1}^{n+1}\right), \end{aligned} \tag{4.53}$$

where we define for $j \in \mathbb{Z}$

$$\begin{aligned} \alpha_{j+1/2} &:= -\lambda \int_0^1 f_u^-\left(\boldsymbol{\gamma}_{j+1/2}, V_{j+1}^n + \phi(W_{j+1}^n - V_{j+1}^n)\right) d\phi \geq 0, \\ \beta_{j+1/2} &:= \lambda \int_0^1 f_u^+\left(\boldsymbol{\gamma}_{j+1/2}, V_j^n + \phi(W_j^n - V_j^n)\right) d\phi \geq 0, \end{aligned} \tag{4.54}$$

and

$$\theta_j := \mu \frac{A(W_j^{n+1}) - A(V_j^{n+1})}{W_j^{n+1} - V_j^{n+1}} \geq 0. \tag{4.55}$$

Let us abbreviate $D_j^n := W_j^n - V_j^n$ and rearrange (4.53) into the form

$$\begin{aligned}\big(1+(s_{j+1/2}+s_{j-1/2})\theta_j\big)D_j^{n+1} &= (1-\beta_{j+1/2}-\alpha_{j-1/2})D_j^n + \alpha_{j+1/2}D_{j+1}^n \\ &\quad + \beta_{j-1/2}D_{j-1}^n + s_{j+1/2}\theta_{j+1}D_{j+1}^{n+1} \\ &\quad + s_{j-1/2}\theta_{j-1}D_{j-1}^{n+1}.\end{aligned} \tag{4.56}$$

Thanks to the CFL condition (4.52), we have $1-\beta_{j+1/2}-\alpha_{j-1/2}\geq 0$. Thus all of the coefficients appearing in (4.56) are nonnegative, and taking absolute values results in

$$\begin{aligned}\big(1+(s_{j+1/2}+s_{j-1/2})\theta_j\big)\big|D_j^{n+1}\big| &\leq (1-\beta_{j+1/2}-\alpha_{j-1/2})\big|D_j^n\big| \\ &\quad + \alpha_{j+1/2}\big|D_{j+1}^n\big| + \beta_{j-1/2}\big|D_{j-1}^n\big| \\ &\quad + s_{j+1/2}\theta_{j+1}\big|D_{j+1}^{n+1}\big| + s_{j-1/2}\theta_{j-1}\big|D_{j-1}^{n+1}\big|.\end{aligned} \tag{4.57}$$

Summing (4.57) over $j\in\mathbb{Z}$, canceling wherever possible, and recalling the definition of D_j^n, we find that

$$\sum_{j\in\mathbb{Z}}\big|W_j^{n+1}-V_j^{n+1}\big| \leq \sum_{j\in\mathbb{Z}}\big|W_j^n-V_j^n\big|, \tag{4.58}$$

indicating that the semi-implicit scheme is L^1-contractive on data that is constrained to the interval $[0,1]$. It now follows from the Crandall–Tartar lemma [37] that the scheme is also monotone (on data that is constrained to the interval $[0,1]$).

We still must show that the solution remains in $[0,1]$. First, observe that the L^1-contraction property (4.58) implies that the solution to the implicit scheme is unique. Referring back to the portion of the proof of Lemma 4.16 where we used the specific data $V_j^0\equiv 0$, and $W_j^0\equiv 1$, we see that the solutions V_j^1 and W_j^1 are also (the unique) solutions to the implicit scheme at time level 1. With these observations in mind, it is clear that the relevant portion of the proof of Lemma 4.16 also shows invariance of the interval $[0,1]$ for the semi-implicit scheme. ∎

We now continue our analysis of the explicit scheme (3.1).

LEMMA 4.18. *Our numerical approximation satisfies the following discrete time continuity estimate (which is uniform in n and Δ):*

$$\Delta x\sum_{j\in\mathbb{Z}}\big|U_j^{n+1}-U_j^n\big| \leq \Delta x\sum_{j\in\mathbb{Z}}\big|U_j^1-U_j^0\big| \leq C\Delta t. \tag{4.59}$$

It also satisfies a uniform (in n and Δ) L^1 bound:

$$\|u^\Delta(\cdot,t^n)\|_{L^1(\mathbb{R})} \leq CT. \tag{4.60}$$

Proof. The proof of Lemma 3.3 of [55] is almost entirely applicable to (4.59), the only possible complication arising when we have to bound the quantity

$$\sum_{j\in\mathbb{Z}}\left|\Delta_-\frac{1}{\Delta x}s_{j+1/2}\Delta_+A(U_j^0)\right|.$$

One finds that the proof of the analogous bound in [55] can be modified to accommodate the present situation. The key ingredients are the assumption that $\gamma_1 A(u_0)_x\in BV(\mathbb{R})$, along with the pointwise discretization of u_0. For the proof of (4.60), see Lemma 3.4 of [55]. ∎

In what follows, it will be convenient to have available the notation $\mathcal{O}(1)$ to denote a quantity that is bounded uniformly in n and Δ.

LEMMA 4.19. *The following bound holds independently of Δ and the time level n:*

$$\sum_{j\in\mathbb{Z}} s_{j-1/2}\big|\Delta_- A_j^n\big| \le C. \tag{4.61}$$

Proof. Let $\rho_{j-1/2}^n := h_{j-1/2}^n - s_{j-1/2}\Delta_- A_j^n/\Delta x$. By substituting $U_j^{n+1} - U_j^n = -\lambda\Delta_+\rho_{j-1/2}^n$ into (4.59) we find that

$$\sum_{j\in\mathbb{Z}} \big|\Delta_+\rho_{j-1/2}^n\big| = \mathcal{O}(1). \tag{4.62}$$

At the same time, if j is so large that $x_j > x_{\mathrm{R}} + 2\Delta x$, then $\rho_{j-1/2}^n = q_{\mathrm{R}}U_j^n$. From Lemma 4.16, we get that $|\rho_{j-1/2}^n| \le q_{\mathrm{R}}$. This bound, together with the bound (4.62), implies a uniform bound of the form $|\rho_{j-1/2}^n| = \mathcal{O}(1)$. Since the convective numerical flux $h(\gamma, v, u)$ is continuous, the quantity $h_{j-1/2}^n$ is also uniformly bounded, and so we have the bound $s_{j-1/2}|\Delta_- A_j^n|/\Delta x = \mathcal{O}(1)$. The proof is completed by multiplying both sides of this relationship by Δx, summing over j, and recalling that $s_{j-1/2}$ vanishes for x_j outside of the interval $[x_{\mathrm{L}} - \Delta x, x_{\mathrm{R}}]$. ∎

Let $z^\Delta(x,t) := \Psi(\boldsymbol{\gamma}(x), u^\Delta(x,t))$. Defining (see (4.13) for the definition of $\mathcal{F}$)

$$\mathcal{F}^\Delta(x,t) := \mathcal{F}(\boldsymbol{\gamma}(x), u^\Delta(x,t)), \quad A^\Delta(x,t) := A(u^\Delta(x,t)),$$

we can separate z^Δ into its hyperbolic and parabolic contributions:

$$z^\Delta(x,t) = \mathcal{F}^\Delta(x,t) + \gamma_1(x)A^\Delta(x,t). \tag{4.63}$$

To prove that the difference scheme converges, we follow [25] and first prove compactness for the transformed quantity z^Δ. We establish spatial variation bounds separately for each of the intervals $(-\infty, x_{\mathrm{L}})$, $(x_{\mathrm{L}}, 0)$, $(0, x_{\mathrm{R}})$, (x_{R}, ∞). The jumps in z^Δ where these intervals meet are bounded, and so we can ignore them. Indeed consider the jump in $z^\Delta(x, t^n)$ that occurs at $x = m \in \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$, which is given by

$$z^\Delta(m+, t^n) - z^\Delta(m-, t^n) = \Psi\big(\boldsymbol{\gamma}+, u^\Delta(m+, t^n)\big) - \Psi\big(\boldsymbol{\gamma}-, u^\Delta(m-, t^n)\big).$$

Since u^Δ is bounded uniformly (by Lemma 4.16), $\boldsymbol{\gamma}$ is bounded by assumption, and the transformation Ψ is Lipschitz continuous with respect to all variables, it is clear that the magnitude of this jump is uniformly bounded also.

In the intervals $(-\infty, x_{\mathrm{L}})$ and (x_{R}, ∞), the parabolic term is not present, and (4.63) simplifies to $z^\Delta(x,t) = \gamma_2 u^\Delta(x,t)$. This makes it clear that the proof of the variation bound for these intervals is the same as the proof of Lemma 3.5 of [25]. We record this fact in the following lemma.

LEMMA 4.20. *We have the following bounds, which are independent of Δ and n:*

$$\mathrm{TV}\big(z^\Delta(\cdot, t^n)|_{\{x|x<x_{\mathrm{L}}\}}\big) \le C, \qquad \mathrm{TV}\big(z^\Delta(\cdot, t^n)|_{\{x|x>x_{\mathrm{R}}\}}\big) \le C. \tag{4.64}$$

We now address the variation bound for the remaining intervals, $(x_{\mathrm{L}}, 0)$ and $(0, x_{\mathrm{R}})$. As in [25], we will focus on $(0, x_{\mathrm{R}})$, omitting the proof for the other interval, since it is similar. Let $\boldsymbol{\gamma}_{\mathrm{R}} := (q_{\mathrm{R}}, 1)$; i.e., let $\boldsymbol{\gamma}_{\mathrm{R}}$ denote the value that $\boldsymbol{\gamma}$ takes on

$(0, x_{\mathrm{R}})$. Recalling the definition (4.13), we see that $\gamma_1 = 1$ for $x \in (0, x_{\mathrm{R}})$, and so Ψ simplifies to

$$\Psi(\boldsymbol{\gamma}, u) = \mathcal{F}(\boldsymbol{\gamma}_{\mathrm{R}}, u) + A(u), \quad \mathcal{F}(\boldsymbol{\gamma}_{\mathrm{R}}, u) = \int_0^u \mathcal{S}(w) |f_u(\boldsymbol{\gamma}_{\mathrm{R}}, w)| \, dw. \tag{4.65}$$

Let J^- be the largest index j such that $x_j - \Delta x/2 \le 0$, and let J^+ be the smallest index j such that $x_j + \Delta x/2 \ge x_{\mathrm{R}}$. Thus $0 \in I_{J^-}$, $x_{\mathrm{R}} \in I_{J^+}$, and $[0, x_{\mathrm{R}}] \subseteq [x_{J^-} - \Delta x/2, x_{J^+} + \Delta x/2]$.

The following lemma records a discrete entropy inequality. It can be proved via a slight modification (to account for $s_{j-1/2}$) of the proof of Lemma 4.1 of [56].

LEMMA 4.21. *For any $c \in \mathbb{R}$, the following cell entropy inequality is satisfied by approximate solutions U_j^n generated by the scheme* (4.44)*:*

$$\begin{aligned} \left|U_j^{n+1} - c\right| \le \left|U_j^n - c\right| &- \lambda \Delta_- H_{j+1/2}^n + \mu \Delta_+ \left(s_{j-1/2} \Delta_- \left| A\left(U_j^n\right) - A(c) \right| \right) \\ &- \lambda \operatorname{sgn}\left(U_j^{n+1} - c\right) \Delta_+ f\left(\gamma_{j-1/2}, c\right), \end{aligned} \tag{4.66}$$

where the numerical entropy flux $H_{j+1/2}$ is defined by

$$H_{j+1/2}^n := h\left(\gamma_{j+1/2}, U_{j+1}^n \vee c, U_j^n \vee c\right) - h\left(\gamma_{j+1/2}, U_{j+1}^n \wedge c, U_j^n \wedge c\right). \tag{4.67}$$

Formally, the cell entropy inequality (4.66) can be motivated by assuming that the function u in the integrand of (4.5) is piecewise constant on the rectangle $R_j^n := (x_{j-1/2}, x_{j+1/2}) \times (t_n, t_{n+1})$ and by choosing a sequence of test functions ϕ with support on R_j^n that approximate the characteristic function χ_j^n of R_j^n. Moreover, the exact entropy flux defined in (4.12) is replaced by the numerical entropy flux (4.67). In this sense, the discrete entropy inequality (4.66) is consistent with the entropy inequality (4.5) for the exact solution, but observe that the term in the second line of (4.66), which mirrors the sum over $m \in \mathcal{J}$ in (4.5), is evaluated at time level t_{n+1}.

Let $\chi_l(w; c) := H(c - w)$, where $H(\cdot)$ is the Heaviside function, and $\chi_r(w; c) := 1 - \chi_l(w; c)$. The following lemma is easily established using the calculations used in Lemma 3.9 of [25], adapted to the cell entropy inequality (4.66) appearing in Lemma 4.21.

LEMMA 4.22. *Fix $c \in \mathbb{R}$ and $\boldsymbol{\gamma} \in \mathcal{G}$. The following inequalities are valid for $J^- \le j \le J^+$:*

$$\begin{aligned} &- \int_{U_j^n}^{U_{j+1}^n} \chi_l(w; c) f_u^-(\boldsymbol{\gamma}, w) \, dw - \int_{U_{j-1}^n}^{U_j^n} \chi_l(w; c) f_u^+(\boldsymbol{\gamma}, w) \, dw \\ &\le \frac{-1}{\lambda} \left(U_j^n - U_j^{n+1}\right)_- - \frac{1}{\Delta x} \Delta_+ \left(s_{j-1/2} \Delta_- (A(U_j^{n+1}) - A(c))_- \right) + \alpha_j^n, \end{aligned} \tag{4.68}$$

$$\begin{aligned} &\int_{U_j^n}^{U_{j+1}^n} \chi_r(w; c) f_u^-(\boldsymbol{\gamma}, w) \, dw + \int_{U_{j-1}^n}^{U_j^n} \chi_r(w; c) f_u^+(\boldsymbol{\gamma}, w) \, dw \\ &\le \frac{1}{\lambda} \left(U_j^n - U_j^{n+1}\right)_+ - \frac{1}{\Delta x} \Delta_+ \left(s_{j-1/2} \Delta_- (A(U_j^{n+1}) - A(c))_+ \right) + \beta_j^n. \end{aligned} \tag{4.69}$$

The quantities α_j^n and β_j^n are bounded independently of n and Δ. In fact, $\alpha_j^n = \beta_j^n = 0$ for $J^- + 2 \le j \le J^+ - 2$.

With the help of these entropy inequalities, we can prove the following lemma.

LEMMA 4.23. *The following spatial variation bounds are satisfied, independent of* Δ *and* n*:*

$$\mathrm{TV}\big(\mathcal{F}^{\Delta}(\cdot,t^n)|_{\{x|x_{\mathrm{L}}<x<0\}}\big)\le C,\qquad \mathrm{TV}\big(\mathcal{F}^{\Delta}(\cdot,t^n)|_{\{x|0<x<x_{\mathrm{R}}\}}\big)\le C.$$

Proof. We prove only the second assertion; the proof of the first is similar. We follow closely the proof of Lemma 3.10 of [25]. First, observe that if the term

$$\frac{1}{\Delta x}\Delta_-\big(\Delta_+ s_{j-1/2}(A(U_j^n)-A(c))_-\big)$$

was not present in (4.68), the proof of Lemma 3.10 of [25] would apply verbatim. Next, recall from the proof of Lemma 4.5 that if $c\le u_{\mathrm{c}}$, then $(A(U_j^n)-A(c))_-=0$. Thus, when $c\le u_{\mathrm{c}}$, the parabolic term in (4.68) disappears, giving us

(4.70)
$$-\int_{U_j^n}^{U_{j+1}^n}\chi_l(w;c)f_u^-(\boldsymbol{\gamma},w)\,dw-\int_{U_{j-1}^n}^{U_j^n}\chi_l(w;c)f_u^+(\boldsymbol{\gamma},w)\,dw\le\frac{-1}{\lambda}\big(U_j^n-U_j^{n+1}\big)_-+\alpha_j^n.$$

When $x\in(0,x_{\mathrm{R}})$, $(\gamma_1(x),\gamma_2(x))=(q_{\mathrm{R}},1)\equiv\boldsymbol{\gamma}_{\mathrm{R}}$, and by the assumptions on b and q_{R}, $u\mapsto f(\boldsymbol{\gamma}_{\mathrm{R}},u)$ has at most two extrema for $u\in(0,1)$. For the sake of argument, we assume that there are exactly two extrema. It will become clear that a simplified version of the following proof will suffice if there are fewer than two. So assume that there is one maximum located at $u_1^*\in(0,1)$ and one minimum located at $u_2^*\in(0,1)$, with $u_1^*<u_2^*$. The flux $u\mapsto f(\boldsymbol{\gamma}_{\mathrm{R}},u)$ is strictly monotone away from these critical points. Let $u_0^*:=0$ and $u_3^*:=1$, and for $\nu=0,1,2$, let $\chi^\nu(u)$ be the characteristic function of the interval $[\min\{u_\nu^*,u_{\mathrm{c}}\},\min\{u_{\nu+1}^*,u_{\mathrm{c}}\})$. Each of the intervals $[\min\{u_\nu^*,u_{\mathrm{c}}\},\min\{u_{\nu+1}^*,u_{\mathrm{c}}\})$ either is empty (if the left endpoint happens to equal u_{c}) or $f(\gamma_{\mathrm{R}},u)$ is strictly monotone in its interior. Define

$$\phi^\nu(\boldsymbol{\gamma}_{\mathrm{R}},u):=\int_0^u\chi^\nu(w)\big|f_u(\boldsymbol{\gamma}_{\mathrm{R}},w)\big|\,dw,\qquad\nu=0,1,2.$$

Clearly, $\mathcal{S}(u)=\chi^0(u)+\chi^1(u)+\chi^2(u)$, so that $\mathcal{F}(\boldsymbol{\gamma}_{\mathrm{R}},\cdot)$ has the decomposition

$$\mathcal{F}(\boldsymbol{\gamma}_{\mathrm{R}},u)=\phi^0(\boldsymbol{\gamma}_{\mathrm{R}},u)+\phi^1(\boldsymbol{\gamma}_{\mathrm{R}},u)+\phi^2(\boldsymbol{\gamma}_{\mathrm{R}},u).\tag{4.71}$$

We now use the entropy inequality (4.70) three times, just as in the proof of Lemma 3.10 of [25], except that now instead of $c=u_\nu$, $\nu=1,2,3$, we take $c=\min\{u_\nu^*,u_{\mathrm{c}}\}$, $\nu=1,2,3$. In order to keep the analysis somewhat self-contained, let us review the calculation appearing in [25] when $c=u_1^*$. We start by setting $c=u_1^*$ in inequality (4.70) and observe that $u\mapsto f(\boldsymbol{\gamma}_{\mathrm{R}},u)$ is strictly increasing on $(0,u_1^*)$. Then (4.70) simplifies to

$$-\int_{U_{j-1}^n}^{U_j^n}\chi_l(w;u_1^*)f_u^+(\boldsymbol{\gamma}_{\mathrm{R}},w)\,dw\le\frac{-1}{\lambda}\big(U_j^n-U_j^{n+1}\big)_-+\alpha_j^n.\tag{4.72}$$

Since $f_u^+(\boldsymbol{\gamma}_{\mathrm{R}},u)=|f_u(\boldsymbol{\gamma}_{\mathrm{R}},u)|$ for $u\in(0,u_1^*)$, we find that

$$\begin{aligned}\int_{U_{j-1}^n}^{U_j^n}\chi_l(w;u_1^*)f_u^+(\boldsymbol{\gamma}_{\mathrm{R}},w)\,dw&=\int_{U_{j-1}^n}^{U_j^n}\chi^0(w)\big|f_u(\boldsymbol{\gamma}_{\mathrm{R}},w)\big|dw\\&=\phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}},U_j^n\big)-\phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}},U_{j-1}^n\big).\end{aligned}$$

Combining this last relationship with (4.72), we have the inequality

$$\phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_{j-1}^n\big) - \phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_j^n\big) \le \frac{1}{\lambda}\big|U_j^{n+1} - U_j^n\big| + \alpha_j^n,$$

and, since the right-hand side of this inequality is nonnegative, we also have

$$-\Big(\phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_j^n\big) - \phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_{j-1}^n\big)\Big)_- \le \frac{1}{\lambda}\big|U_j^{n+1} - U_j^n\big| + \alpha_j^n. \tag{4.73}$$

Next, we sum (4.73) over j and invoke Lemmas 4.22 and 4.18 to obtain

$$\begin{aligned}
&-\sum_{j=J^-}^{J^+}\Big(\phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_j^n\big) - \phi^0\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_{j-1}^n\big)\Big)_- \le \sum_{j=J^-}^{J^+}\left(\frac{1}{\lambda}\big|U_j^{n+1} - U_j^n\big| + \big|\alpha_j^n\big|\right)\\
&\le \sum_{j\in\mathbb{Z}}\frac{1}{\lambda}\big|U_j^{n+1} - U_j^n\big| + \big|\alpha_{J^+}^n\big| + \big|\alpha_{J^+-1}^n\big| + \big|\alpha_{J^-}^n\big| + \big|\alpha_{J^-+1}^n\big| = \mathcal{O}(1).
\end{aligned}$$

Finally, we observe that since ϕ^0 is bounded uniformly in Δ and n, it follows from this bound on the negative variation that ϕ^0 also has uniformly bounded *total* variation. Similar calculations (see [25]) result in uniform bounds on the total variation of ϕ^1 and ϕ^2; i.e., we have

$$\sum_{j=J^-}^{J^+}\Big|\phi^\nu\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_j^n\big) - \phi^\nu\big(\boldsymbol{\gamma}_{\mathrm{R}}, U_{j-1}^n\big)\Big| = \mathcal{O}(1), \quad \nu = 0, 1, 2.$$

In view of (4.71), the proof is completed by combining these three bounds. ∎

With this spatial variation bound established, we can prove the following lemma. We omit the proof, which is not essentially different from the proof of Lemma 3.8 of [55].

LEMMA 4.24. *There exists a subsequence of $\{\mathcal{F}^\Delta\}$, also denoted by $\{\mathcal{F}^\Delta\}$, and a function $\overline{\mathcal{F}} \in L^1(\Pi_T) \cap L^\infty(\Pi_T)$ such that $\mathcal{F}^\Delta \to \overline{\mathcal{F}}$ in $L^1_{\mathrm{loc}}(\Pi_T)$ and a.e. in Π_T. Furthermore, $\overline{\mathcal{F}}(\cdot, t) \in L^1(\mathbb{R})$ for all $t \in [0, T]$.*

The following lemma establishes convergence (along a subsequence) of the discrete diffusion term A^Δ. The proof is similar to the proofs of Lemmas 3.9, 3.10, 3.11, and 3.12 of [55].

LEMMA 4.25. *The following bounds are satisfied, independent of n and Δ:*

$$\left\{\Delta t\,\Delta x\sum_{n\ge 0}\sum_{j\in\mathbb{Z}} s_{j+1/2}\big(\Delta_+ A(U_j^n)\big)^2\right\}^{1/2} \le C\Delta x, \tag{4.74}$$

$$\big\|A\big(u^\Delta(\cdot + y, \cdot)\big) - A\big(u^\Delta(\cdot, \cdot)\big)\big\|_{L^2(\Omega_y)} \le C\sqrt{|y|(|y| + \Delta x)} \qquad \forall y \in (x_{\mathrm{L}}, x_{\mathrm{R}}),$$

$$\big\|A\big(u^\Delta(\cdot, \cdot + \tau)\big) - A\big(u^\Delta(\cdot, \cdot)\big)\big\|_{L^2(\Omega_\tau)} \le C\sqrt{\tau + \Delta t} \qquad \forall \tau \in (0, T), \tag{4.75}$$

where Ω_y consists of all $(x, t) \in \Pi_T$ such that x and $x + y$ belong to $(x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T)$ and $\Omega_\tau := (x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T - \tau))$. Finally, we have that there exists a subsequence of $\{A^\Delta\}$, also denoted by $\{A^\Delta\}$, and a function $\overline{A} \in L^2(0, T; H^1(x_{\mathrm{L}}, x_{\mathrm{R}}))$ such that $A^\Delta \to \overline{A}$ in $L^2((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T)$ and boundedly a.e. in $(x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T)$. Furthermore, $\overline{A} = A(u)$ a.e. in $(x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T)$, where u denotes the L^∞ weak-$*$ limit of u^Δ.

It is possible to establish more regularity of the diffusion function than displayed in Lemma 4.25. This additional regularity, which is stated in the lemma below, will be used later in the proof of Theorem 4.27.

LEMMA 4.26. *There exists a constant C, independent of Δ, such that*

$$\big|A(U_j^n) - A(U_i^n)\big| \le C|j-i|\Delta x, \quad \big|A(U_j^n) - A(U_j^m)\big| \le C\sqrt{|n-m|\Delta t}$$

for all i, j, n, m such that (x_i, t_n), (x_j, t_n), and (x_j, t_m) belong to $(x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0, T)$.

Define $\tilde{A}^n(x)$ as

$$\tilde{A}^n(x) = \frac{1}{\Delta x}\Big((x - x_{j-1})\, A(U_j^n) + (x_j - x)\, A(U_{j-1}^n)\Big), \qquad x \in [x_{j-1}, x_j].$$

Then define

$$\tilde{A}^\Delta(x,t) = \frac{1}{\Delta t}\Big((t - t_n)\, \tilde{A}^{n+1}(x) + (t_{n+1} - t)\, \tilde{A}^n(x)\Big), \qquad t \in [t_n, t_{n+1}].$$

Then there exists a subsequence of $\tilde{A}^\Delta$, also denoted by $\tilde{A}^\Delta$, and a function

$$\tilde{A} \in C^{1,1/2}\big((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0,T)\big)$$

such that $\tilde{A}^\Delta \to \bar{A}$ in $L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0,T))$. Moreover, there holds $(\tilde{A}^\Delta)_x \overset{\star}{\rightharpoonup} \tilde{A}_x$ in $L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}}) \times (0,T))$.

This lemma can be proved by a straightforward adaptation of the proofs of Lemmas 4.1 and 4.2 and Theorem 4.1 in [55].

We can now prove our main convergence theorem.

THEOREM 4.27. *Assume that the hypotheses concerning the data stated in section* 4.1 *are satisfied. Then there exists a BV_t weak solution of the initial value problem* (4.1) *that satisfies the entropy condition* (D.5). *Let u^Δ be defined by* (3.3) *and the scheme* (4.44), *with the parameters Δx and Δt chosen so that the CFL condition* (4.46) *holds. Then, along a subsequence, $u^\Delta \to u$ in $L^1_{\mathrm{loc}}(\Pi_T)$ and a.e. in Π_T, where u is a BV_t weak solution.*

Proof. The proof of convergence (along a subsequence) to a function $u : \Pi_T \to \mathbb{R}$ is essentially the same as the proof of Theorem 3.1 of [55]. The main idea is to observe that $z^\Delta = \Psi(\boldsymbol{\gamma}^\Delta, u^\Delta) = \mathcal{F}^\Delta + \gamma_1 A^\Delta$. Convergence (along a subsequence) of $\{z^\Delta\}$ then follows from compactness for the sequences $\mathcal{F}^\Delta$ and $\gamma_1 A^\Delta$ (Lemmas 4.24 and 4.25). Letting $z(x,t)$ denote $\lim_{\Delta \to 0} z^\Delta(x,t)$, one then recovers the conserved quantity u via $u(x,t) = \Psi^{-1}(\boldsymbol{\gamma}(x), z(x,t))$. The arguments in [55] also (with some slight modifications to account for γ_1 multiplying $A(u)_x$) show that $u \in L^1(\Pi_T) \cap L^\infty(\Pi_T) \cap C(0,T; L^1(\mathbb{R}))$ and $A(u) \in L^2(0,T; H^1(x_{\mathrm{L}}, x_{\mathrm{R}}))$. It follows readily from the discrete time continuity estimate (4.59) that $u \in BV_t(\Pi_T)$ (see the proof of Theorem 3.1 of [25]) and that the initial data is assumed in the strong L^1 sense; i.e, (4.4) is satisfied.

To show that the limit u is a BV_t weak solution, it remains to verify that the weak formulation (4.3) is satisfied, for which a a Lax–Wendroff-type calculation is required. The proof of Theorem 3.1 of [55] applies in the present situation, with the exception that the spatially varying coefficient $s_{j-1/2}$ multiplying the parabolic term causes some new complications. We can lay this matter to rest if we can show that for $\phi \in \mathcal{D}(\Pi_T)$, and with $\phi_j^n := \phi(x_j, t_n)$,

$$\Delta x \Delta t \sum_{n \ge 0} \sum_{j \in \mathbb{Z}} \frac{1}{\Delta x^2} \Delta_+ \left(s_{j-1/2} \Delta_- A_j^n\right) \phi_j^n \to - \iint_{\Pi_T} \gamma_1(x) A(u)_x \phi_x \, dx \, dt. \tag{4.76}$$

Summing by parts, we get the following expression for the left-hand side of (4.76):

$$-\Delta x\Delta t\sum_{n\geq 0}\sum_{j\in\mathbb{Z}}\frac{1}{\Delta x}\left(s_{j-1/2}\Delta_- A_j^n\right)\left(\Delta_-\phi_j^n/\Delta x\right). \tag{4.77}$$

Let $\tilde{A}^\Delta$ be the interpolant defined in Lemma 4.26. Observe that $(\tilde{A}^\Delta)_x = \Delta_+ A(U_j^n)$ on the parallelogram P_j^n with vertices (x_j, t^{n-1}), (x_j, t^n), (x_{j+1}, t^n), and (x_{j+1}, t^{n+1}).

We now have

$$\begin{aligned}
&-\Delta x\Delta t\sum_{n\geq 0}\sum_{j\in\mathbb{Z}}\frac{1}{\Delta x}\left(s_{j-1/2}\Delta_- A_j^n\right)\left(\Delta_-\phi_j^n/\Delta x\right)\\
&=\sum_{n\geq 0}\sum_{j\in\mathbb{Z}}\iint_{P_j^{n+1}}\gamma_1(x)(\tilde{A}^\Delta)_x\phi_x\,dx\,dt+\mathcal{O}(\Delta x+\Delta t)\\
&=\iint_{\Pi_T}\gamma_1(x)(\tilde{A}^\Delta)_x\phi_x\,dx\,dt+\mathcal{O}(\Delta x+\Delta t).
\end{aligned} \tag{4.78}$$

According to Lemma 4.26 we can assume that $\tilde{A}^\Delta \to \bar{A}$ in $L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}})\times(0,T))$. Since $u^\Delta \to u$ a.e. in Π_T, we can repeat the proof of Theorem 4.1 in [55] to show that $\tilde{A} = A(u)$ a.e. in $(x_{\mathrm{L}}, x_{\mathrm{R}})\times(0,T)$. Recall that the parameter $\gamma_1(x)$ takes the value 1 for $x \in (x_{\mathrm{L}}, x_{\mathrm{R}})$ and is zero elsewhere. Using this and the convergence $(\tilde{A}^\Delta)_x \overset{\star}{\rightharpoonup} A(u)_x$ in $L^\infty((x_{\mathrm{L}}, x_{\mathrm{R}})\times(0,T))$ when sending $\Delta \to 0$ in (4.78), we get (4.76).

The proof that u satisfies the entropy inequality (4.5) requires another Lax–Wendroff-type calculation, this time based on the cell entropy inequality (4.66). The proof of Theorem 5.1 of [55], or Lemma 4.1 of [56], suffices for the situation at hand, again with the exception of the parabolic terms, due to the presence of $s_{j-1/2}$. It is possible to resolve this matter by an argument (which we omit) similar to the one above. ∎

REMARK 4.3. *In this proof, we have verified all but condition* (D.4) *of Definition* 4.1. *Thus, if we were able to prove that* (D.4) *is satisfied, then the limit* u *of Theorem* 4.27 *would be the* BV_t *entropy solution whose uniqueness is guaranteed by Theorem* 4.15. *Although our numerical results suggest that this condition is satisfied by the limit of the sequence of approximate solutions, a rigorous proof of this property is still left as an open problem.*

5. Steady-state solutions. The construction of steady states is based on the stationary version of (2.16) or (2.21). We do not present here a thorough analysis of all steady states but identify some stationary solutions in order to motivate the choices of the control parameters for the transient simulations. Our construction of steady states will follow a procedure similar to that of the simpler continuous thickening models treated in [16, 17]. Specifically, we fix the material model and the vessel geometry and assume that the clarifier-thickener is to be operated at given values of Q_{L}, Q_{F}, and u_{F} and is supposed to produce a thickened sediment of a discharge concentration $u_{\mathrm{D}} > u_{\mathrm{c}}$. Although the construction given below can be extended in a straightforward manner to vessels with varying cross-sectional area, there are some subtle details that require us to restrict the rigorous discussion to vessels with constant cross-sectional interior area, so that we limit the discussion to Model 1.

Our notation is consistent with section 4; i.e., we refer to the space variable by x (instead of w), to the solution by u (instead of v), and to the integrated diffusion coefficient by A (instead of $\mathcal{A}$).

DEFINITION 5.1. *A piecewise twice differentiable function* $u : \mathbb{R} \to [0, u_{\max}]$ *is a* steady-state entropy weak solution *of Model* 1 *if the following conditions are satisfied:* (a) *the function* $\gamma_1(x)A(u)'$ *is bounded, where* $' = d/dx$*;* (b) *the function* u *is a weak solution to the following ODE that arises from* (2.21) *and where* $g(x,u)$ *is given by* (2.23)*:*

$$g(x,u)' = \big(\gamma_1(x)A(u)'\big)'; \tag{5.1}$$

i.e., for every test function $\phi \in C_0^2(\mathbb{R})$ *with compact support we have*

$$\int_{\mathbb{R}} \Big(f\big(\boldsymbol{\gamma}(x), u(x)\big) - \gamma_1(x) A\big(u(x)\big)' \Big) \phi'(x)\, dx = 0; \tag{5.2}$$

and (c) *the following entropy inequality holds for all test functions* $\phi \in C_0^2(\mathbb{R})$, $\phi \geq 0$, *and* $k \in \mathbb{R}$*:*

$$\begin{aligned} &\int_{\mathbb{R}} \Big(\operatorname{sgn}\big(u(\xi)-k\big)\big(f(\boldsymbol{\gamma}(\xi),u(\xi)) - f(\boldsymbol{\gamma}(\xi),k)\big) - \gamma_1(\xi)A(u)' \Big)\phi'(\xi) d\xi \\ &+ \sum_{m\in\mathcal{J}} \big| f\big(\boldsymbol{\gamma}(m^+),k\big) - f\big(\boldsymbol{\gamma}(m^-),k\big)\big| \phi(m) \geq 0. \end{aligned} \tag{5.3}$$

It is standard to conclude from (5.2) that the following jump condition has to be satisfied across any discontinuity of the steady-state solution, where $u(x^+)$ and $u(x^-)$ refer to limits of $u(\xi)$ taken for $\xi \to x$ with $\xi > x$ and $\xi < x$, respectively:

$$f\big(\boldsymbol{\gamma}(x^-),u(x^-)\big) - \gamma_1(x^-)A'(u)|_{x=x^-} = f\big(\boldsymbol{\gamma}(x^+),u(x^+)\big) - \gamma_1(x^+)A'(u)|_{x=x^+}. \tag{5.4}$$

It is easy to see that this condition implies that steady-state solutions are constant for $x < x_{\mathrm{L}}$ and $x > x_{\mathrm{R}}$.

LEMMA 5.2. *Inequality* (5.3) *implies the following entropy jump condition:*

$$\begin{aligned} &\operatorname{sgn}\big(u(x^+)-k\big)\big[f\big(\boldsymbol{\gamma}(x^+),u(x^+)\big) - f\big(\boldsymbol{\gamma}(x^+),k\big) - \gamma_1(x^+)A'(u)|_{x=x^+}\big] \\ &- \operatorname{sgn}\big(u(x^-)-k\big)\big[f\big(\boldsymbol{\gamma}(x^-),u(x^-)\big) - f\big(\boldsymbol{\gamma}(x^-),k\big) - \gamma_1(x^-)A'(u)|_{x=x^-}\big] \\ &\leq \big| f\big(\boldsymbol{\gamma}(x^+),k\big) - f\big(\boldsymbol{\gamma}(x^-),k\big)\big| \quad \forall k \in \mathbb{R}. \end{aligned} \tag{5.5}$$

(Note that the right-hand side of (5.5) *is zero for* $x \notin \mathcal{J}$*.)*

Proof. The proof is a simpler variant of the proof of Lemma 2.6 of [56]. To outline it, let us fix $m \in \mathcal{J} = \{x_{\mathrm{L}}, 0, x_{\mathrm{R}}\}$, and define the function

$$\theta_\varepsilon(x) := \begin{cases} (\varepsilon + x)/\varepsilon & \text{if } x \in [-\varepsilon, 0], \\ (\varepsilon - x)/\varepsilon & \text{if } x \in [0, \varepsilon], \\ 0 & \text{otherwise} \end{cases}$$

with a parameter $\varepsilon > 0$. A density argument will reveal that we may choose the compactly supported Lipschitz continuous function $\theta_\varepsilon(x-m)$ as a test function in (5.3). This yields

$$\begin{aligned} &\frac{1}{\varepsilon}\int_{m-\varepsilon}^{m} \Big(F\big(\boldsymbol{\gamma}(\xi),u(\xi),k\big) - \gamma_1(x)\big|A(u)-A(k)\big|' \Big)\, dx \\ &- \frac{1}{\varepsilon}\int_{m}^{m+\varepsilon} \Big(F\big(\boldsymbol{\gamma}(\xi),u(\xi),k\big) - \gamma_1(x)\big|A(u)-A(k)\big|' \Big)\, dx \\ &\qquad + \big| f\big(\boldsymbol{\gamma}(m^+),k\big) - f\big(\boldsymbol{\gamma}(m^-),k\big)\big| \geq 0, \end{aligned} \tag{5.6}$$

where we recall the notation (4.12). Since the solution $u(x)$ is piecewise smooth, we may apply a time-independent version of Lemma 4.9 to conclude that for $\varepsilon \to 0$, we obtain from (5.6)

$$\begin{aligned} &F\big(\boldsymbol{\gamma}(m^+), u(m^+), k\big) - \mathrm{L}\lim_{\xi \downarrow m}\big(\gamma_1(\xi)\big|A(u) - A(k)\big|'\big) \\ &- F\big(\boldsymbol{\gamma}(m^-), u(m^-), k\big) + \mathrm{L}\lim_{\xi \uparrow m}\big(\gamma_1(\xi)\big|A(u) - A(k)\big|'\big) \\ &\le \big|f\big(\boldsymbol{\gamma}(m^+), k\big) - f\big(\boldsymbol{\gamma}(m^-), k\big)\big|. \end{aligned} \tag{5.7}$$

Assume for the moment that $u(m^+) \neq k$ and $u(m^-) \neq k$. Then Lemma 4.9 implies that

$$\begin{aligned} \mathrm{L}\lim_{\xi \downarrow m}\big(\gamma_1(\xi)\big|A(u) - A(k)\big|'\big) &= \operatorname{sgn}\big(u(m^+) - k\big)\gamma_1(m^+)A'(u)|_{x=m^+}, \\ \mathrm{L}\lim_{\xi \uparrow m}\big(\gamma_1(\xi)\big|A(u) - A(k)\big|'\big) &= \operatorname{sgn}\big(u(m^-) - k\big)\gamma_1(m^-)A'(u)|_{x=m^-}, \end{aligned}$$

such that (5.7) already implies (5.5). To remove this restriction, assume that $k = u(m^-)$. (The other case is similar.) Then the left-hand side of (5.5) is just

$$\begin{aligned} L := \operatorname{sgn}\big(u(m^+) - u(m^-)\big)\big[&f\big(\boldsymbol{\gamma}(m^+), u(m^+)\big) \\ &- f\big(\boldsymbol{\gamma}(m^+), u(m^-)\big) - \gamma_1(m^+)A'(u)\big|_{x=m^+}\big]. \end{aligned}$$

Using the jump condition (5.4), we obtain

$$\begin{aligned} L &= \operatorname{sgn}\big(u(m^+) - u(m^-)\big)\big[f\big(\boldsymbol{\gamma}(m^-), u(m^-)\big) \\ &\qquad - f\big(\boldsymbol{\gamma}(m^+), u(m^-)\big) - \gamma_1(m^-)A'(u)\big|_{x=m^-}\big] \\ &\le \big|f\big(\boldsymbol{\gamma}(m^-), u(m^-)\big) - f\big(\boldsymbol{\gamma}(m^+), u(m^-)\big)\big| \\ &\qquad - \operatorname{sgn}\big(u(m^+) - u(m^-)\big)\gamma_1(m^-)A'(u)\big|_{x=m^-}, \end{aligned}$$

and applying a steady-state variant of the right inequality of (4.27) in Lemma 4.10, we finally get

$$L \le \big|f\big(\boldsymbol{\gamma}(m^-), u(m^-)\big) - f\big(\boldsymbol{\gamma}(m^+), u(m^-)\big)\big|,$$

which is the inequality (5.5). Finally, since we are dealing with time-independent solutions, inequality (5.6) and the remaining discussion remain valid if we replace $m \in \mathcal{J}$ by $x \in \mathbb{R}$. □

The following lemma states a useful continuity result.

LEMMA 5.3. *Let $u(x)$ be a piecewise differentiable steady-state entropy weak solution of Model 1. Then $A(u(x^+)) = A(u(x^-))$ for all $x \in \mathbb{R}$.*

Proof. We consider first a point $x \in (x_\mathrm{L}, x_\mathrm{R})$, at which γ_1 is continuous. Then the boundedness of $\gamma_1(x)A(u)'$ implies that

$$0 = \lim_{\varepsilon \to 0}\int_{x-\varepsilon}^{x+\varepsilon} \gamma_1(\xi)A\big(u(\xi)\big)'d\xi = \lim_{\varepsilon \to 0}\int_{x-\varepsilon}^{x+\varepsilon} A\big(u(\xi)\big)'d\xi = A\big(u(x^+)\big) - A\big(u(x^-)\big).$$

Furthermore, consider that boundedness of $\gamma_1(x)A(u)'$ implies that $A(u)'$ is uniformly bounded on $[x_\mathrm{L}, x_\mathrm{R}]$. On the other hand, for $x < x_\mathrm{L}$ and $x > x_\mathrm{R}$, the jump condition (5.4) reduces to $q_\mathrm{L}u(x^-) = q_\mathrm{L}(x^+)$ and $q_\mathrm{R}u(x^+) = q_\mathrm{R}u(x^+)$, respectively, which

implies that $u(x^-) = u(x^+)$ and therefore no jumps are possible for $x < x_L$ and $x > x_R$. We conclude that piecewise smooth steady-state solutions are constant on $(-\infty, x_L)$ and (x_R, ∞), and therefore we have $A(u)' = 0$ on $(-\infty, x_L) \cup (x_R, \infty)$. Thus $A(u)'$ is uniformly bounded, and therefore has a continuous primitive $A(u)$, which implies that $A(u(x^+)) = A(u(x^-))$ for all $x \in \mathbb{R}$. ∎

REMARK 5.1. *We point out that the continuity property established by Lemma* 5.3 *includes the steady-state analogue of condition* (D.4) *stated for the time-dependent Model* 1. *However, we see that for our class of steady-state solutions, the continuity of* $A(u)$ *across* $x = x_L$ *and* $x = x_R$ *is a result of a more general regularity property and need not be postulated separately.*

Constructively, we select the discharge concentration $u_D = u(x)|_{x>x_R}$ and then integrate the ODE arising from the steady-state version of Model 1 upwards by obeying jump conditions wherever necessary. In doing so, we shall establish the limitations the entropy condition imposes on the choice of control parameters. Thus, the one-sided boundary condition is

$$u(x_R^-) = u_D > u_c. \tag{5.8}$$

The discussion will be limited to those cases where the compression zone does not reach the overflow level. In addition, to further simplify the discussion, we assume that the functions $g_L(u) := q_L u + b(u)$ and $g_R(u) := q_R u + b(u)$ are monotone on the interval $[0, u_c]$; i.e.,

$$q_L + b'(u) > 0, \quad q_R + b'(u) > 0 \quad \text{for } u \in [0, u_c]. \tag{5.9}$$

Moreover, we limit ourselves to steady-state solutions for which the overflow or effluent concentration $u_E := u(x)|_{x<x_L}$ is zero; that is, we choose the parameters u_D and u_F such that

$$Q_F u_F = (Q_R - Q_L)u_F = Q_R u_D - Q_L u_E \tag{5.10}$$

is satisfied with $u_E = 0$, or, equivalently, and since we consider Model 1 only,

$$u_F(q_R - q_L)/q_R = u_D. \tag{5.11}$$

These steady states represent either the conventional or the high-rate mode of continuous operation shown in Figure 1.1(a) and Figure 1.1(b), respectively.

At this point it should be emphasized that our steady-state problem is in general overdetermined. In fact, fixing u_D and integrating (5.1) upwards and obeying entropy and jump conditions, we will in general not achieve a solution with $u|_{x<x_L} = u_E = 0$. All profiles with $u|_{w<x_L} \neq u_E = 0$ have to be rejected as candidates for steady-state entropy solutions, since the global mass balance (5.10) is a consequence of the weak formulation (5.2). To make the analysis transparent, we will in some instances write out the symbol u_E in manipulations before setting it to zero. One result of this procedure is that under our model assumptions, no steady states with the compression region completely contained in the thickening zone but with a nonzero effluent concentration exist.

To determine a steady-state entropy weak solution that satisfies the global mass balance, it is in general necessary, say, to fix u_F, to choose u_D, to solve (5.1), to verify whether (5.10) is satisfied with u_E replaced by $u(x_L^-)$, and to iterate this solution procedure (for example, by varying u_D) until the global mass balance (5.10) is attained. However, under the simplifying assumption (5.9), it turns out that solutions

with $u_{\mathrm{E}} = 0$ can easily be characterized: these are those steady-state entropy weak solutions for which the compression region is strictly contained in the container, i.e., for which $\inf\{x \in \mathbb{R} : u(x) > u_{\mathrm{c}}\} > x_{\mathrm{L}}$. This is the most important subclass of steady states, since they are the most desired mode of operation (see Figure 1.1). Moreover, it turns out that these steady-state entropy weak solutions are strictly increasing.

5.1. Steady-state solution in the discharge zone. Before proceeding to integrate the ODE (5.1) upwards from $x = x_{\mathrm{R}}$, we consider the discharge zone $x > x_{\mathrm{R}}$. Since we are seeking solutions for which $A(v)$ is continuous, we conclude that $A(u(x_{\mathrm{R}}^+)) = A(u(x_{\mathrm{R}}^-)) = A(u_{\mathrm{D}})$, and therefore $u(x_{\mathrm{R}}^+) = u_{\mathrm{D}}$. On the other hand, from (5.1) we infer that the steady-state solution must be constant for $x > x_{\mathrm{R}}$. We conclude that $u(x) = u_{\mathrm{D}}$ for $x > x_{\mathrm{R}}$.

5.2. Steady-state solution in the thickening zone. Now that the steady-state solution has been determined in the interval (x_{R}, ∞), we determine the solution in the interval $(0, x_{\mathrm{R}})$. To this end, note first that as a consequence of the jump condition (5.4), the steady-state solution must satisfy the condition $q_{\mathrm{R}} u_{\mathrm{D}} + b(u_{\mathrm{D}}) - A(u)'|_{x=x_{\mathrm{R}}^+} = q_{\mathrm{R}} u_{\mathrm{D}}$, which means

$$b(u_{\mathrm{D}}) - A(u)'|_{x=x_{\mathrm{R}}^+} = 0. \tag{5.12}$$

Assume now that $v(x)$ is a continuously differentiable solution of the following one-sided boundary value problem, which is the subcase of (5.1) occurring for the interval $(0, x_{\mathrm{R}}]$:

$$q_{\mathrm{R}}(u - u_{\mathrm{D}}) + b(u) - A(u)' = 0 \quad \text{for } x < x_{\mathrm{R}}, \quad u(x_{\mathrm{R}}) = u_{\mathrm{D}}. \tag{5.13}$$

Note that we have used (5.12) to reduce the second-order ODE (5.1) to the first-order ODE (5.13). We consider the solution of (5.13) on the interval $[x_{\mathrm{c}}, x_{\mathrm{R}}]$, where

$$x_{\mathrm{c}} := \inf\big\{x \in (0, x_{\mathrm{R}}] \;\big|\; u(x) \text{ is the solution of (5.13) and } u(x) > u_{\mathrm{c}}\big\}. \tag{5.14}$$

However, not every solution of (5.13) is an acceptable steady-state solution. Rather, the following lemma shows that the entropy condition (5.3) imposes an additional admissibility condition. This condition imposes a restriction on the choice of q_{R} and u_{D} for a given flux density function $b(u)$.

LEMMA 5.4. *Any steady-state entropy solution $u(x)$ of the one-sided boundary value problem* (5.13) *on the interval $(x_{\mathrm{c}}, x_{\mathrm{R}})$ is monotonically increasing; i.e., $u'(x) \geq 0$ for $x \in [x_{\mathrm{c}}, x_{\mathrm{R}}]$. This statement is equivalent to the requirement*

$$q_{\mathrm{R}} u_{\mathrm{D}} \leq q_{\mathrm{R}} k + b(k) \quad \forall k \text{ between } u(x) \text{ and } u_{\mathrm{D}} \text{ for } x \in [x_{\mathrm{c}}, x_{\mathrm{R}}]. \tag{5.15}$$

Proof. In view of (5.12), we obtain from (5.5) the inequality

$$\begin{aligned} \forall k \in \mathbb{R} :\ \forall x \in (x_{\mathrm{c}}, x_{\mathrm{R}}) :\quad & \operatorname{sgn}(u_{\mathrm{D}} - k)\big(q_{\mathrm{R}}(u_{\mathrm{D}} - k) - b(k)\big) \\ & - \operatorname{sgn}\big(u(x) - k\big)\big[q_{\mathrm{R}}\big(u(x) - k\big) + b\big(u(x)\big) - b(k) - A(u)'\big] \leq 0. \end{aligned} \tag{5.16}$$

We now fix $x \in (x_{\mathrm{c}}, x_{\mathrm{R}})$ and evaluate (5.16) for different values of k. Setting $k < \min\{u(x), u_{\mathrm{D}}\}$ and $k > \max\{u(x), u_{\mathrm{D}}\}$, we obtain $\pm[q_{\mathrm{D}} u_{\mathrm{D}} - q_{\mathrm{R}} u - b(u) + A(u)'] \leq 0$, which in view of (5.13) is no new information. The choices $k = u(x)$ and $k = u_{\mathrm{D}}$ are covered as limiting cases in the subsequent discussion of the two alternatives in which k is located strictly between $u(x)$ and u_{D}.

Assume first that $u_{\mathrm{D}} < k < u(x)$. Then (5.16) leads to the inequality

$$2\big(q_{\mathrm{R}}k + b(k)\big) - q_{\mathrm{R}}u_{\mathrm{D}} - q_{\mathrm{R}}u(x) - b\big(u(x)\big) + A(u)' \le 0 \quad \forall k \in (u_{\mathrm{D}}, u(x)). \tag{5.17}$$

Using that $-q_{\mathrm{R}}u(x) - b(u(x)) + A(u)' = -q_{\mathrm{R}}u_{\mathrm{D}}$, we obtain from (5.17)

$$q_{\mathrm{R}}(k - u_{\mathrm{D}}) + b(k) \le 0 \quad \forall k \in (u_{\mathrm{D}}, u(x)). \tag{5.18}$$

However, (5.18) can never be satisfied, since $q_{\mathrm{R}} > 0$, $k > u_{\mathrm{D}}$, and we assume $b \ge 0$.

The remaining case is the assumption $u(x) < k < u_{\mathrm{D}}$, which leads to the inequality

$$-2\big(q_{\mathrm{R}}k + b(k)\big) + q_{\mathrm{R}}u_{\mathrm{D}} + q_{\mathrm{R}}u(x) + b\big(u(x)\big) - A(u)' \le 0 \quad \forall k \in (u(x), u_{\mathrm{D}}). \tag{5.19}$$

Using that $q_{\mathrm{R}}u(x) + b(u(x)) - A(u)' = q_{\mathrm{R}}u_{\mathrm{D}}$ and that $b(u_{\mathrm{D}}) > 0$, we obtain from (5.19)

$$q_{\mathrm{R}}u_{\mathrm{D}} \le q_{\mathrm{R}}k + b(k) \quad \forall k \in [u(x), u_{\mathrm{D}}]. \tag{5.20}$$

Since (5.13) can be rearranged to give

$$u'(x) = \frac{q_{\mathrm{R}}(u(x) - u_{\mathrm{D}}) + b(u(x))}{a(u(x))}, \tag{5.21}$$

we see that (5.20) implies that $u'(x) \ge 0$ for $x \in [x_{\mathrm{c}}, x_{\mathrm{R}}]$. □

REMARK 5.2. *Note that* (5.20) *has a useful graphical interpretation: namely, the graph of* $g_{\mathrm{R}}(u) = q_{\mathrm{R}}u + b(u)$ *must lie above the horizontal line* $f = q_{\mathrm{R}}u_{\mathrm{D}}$ *fixed by the desired operation data. This condition implies a limitation of the attainable solids throughput for the given material and vessel.*

To proceed with the discussion, we distinguish between three cases: $x_{\mathrm{c}} > 0$ (Case 1), $x_{\mathrm{c}} = 0$ and $u(0^+) > u_{\mathrm{c}}$ (Case 2), and $x_{\mathrm{c}} = 0$ and $u(0^+) = u_{\mathrm{c}}$ (Case 3).

Case 1 ($x_{\mathrm{c}} > 0$). The Rankine–Hugoniot and entropy jump conditions across $x = x_{\mathrm{c}}$ are

$$q_{\mathrm{R}}u(x_{\mathrm{c}}^-) + b\big(u(x_{\mathrm{c}}^-)\big) - A(u)'|_{x=x_{\mathrm{c}}^-} = q_{\mathrm{R}}u(x_{\mathrm{c}}^+) + b\big(u(x_{\mathrm{c}}^+)\big) - A(u)'|_{x=x_{\mathrm{c}}^+}, \tag{5.22}$$

$$\begin{aligned}\forall k \in \mathbb{R}: \quad & \operatorname{sgn}\big(u(x_{\mathrm{c}}^+) - k\big)\big[q_{\mathrm{R}}\big(u(x_{\mathrm{c}}^+) - k\big) + b\big(u(x_{\mathrm{c}}^+)\big) - b(k) - A(u)'|_{x=x_{\mathrm{c}}^+}\big] \\ & - \operatorname{sgn}\big(u(x_{\mathrm{c}}^-) - k\big)\big[q_{\mathrm{R}}\big(u(x_{\mathrm{c}}^-) - k\big) + b\big(u(x_{\mathrm{c}}^-)\big) - b(k) - A(u)'|_{x=x_{\mathrm{c}}^-}\big] \le 0,\end{aligned} \tag{5.23}$$

respectively. Moreover, from Lemma 5.3 it follows that $A(u(x_{\mathrm{c}}^-)) = A(u(x_{\mathrm{c}}^+)) = A(u_{\mathrm{c}}) = 0$, so that $0 \le u(x_{\mathrm{c}}^-) \le u_{\mathrm{c}}$. From (5.13) and the definition of x_{c} it follows that $q_{\mathrm{R}}u(x_{\mathrm{c}}^+) + b(u(x_{\mathrm{c}}^+)) - A(u)'|_{x=x_{\mathrm{c}}^+} = q_{\mathrm{R}}u_{\mathrm{D}}$. Inserting this into (5.22), we get

$$q_{\mathrm{R}}u(x_{\mathrm{c}}^-) + b\big(u(x_{\mathrm{c}}^-)\big) - A(u)'|_{x=x_{\mathrm{c}}^-} = q_{\mathrm{R}}u_{\mathrm{D}}. \tag{5.24}$$

Inserting (5.13), (5.24), and $u(x_{\mathrm{c}}^+) = u_{\mathrm{c}}$ into (5.23) yields

$$\begin{aligned}\forall k \in \mathbb{R}: \quad & \operatorname{sgn}(u_{\mathrm{c}} - k)\big(q_{\mathrm{R}}u_{\mathrm{D}} - q_{\mathrm{R}}k - b(k)\big) \\ & - \operatorname{sgn}\big(u(x_{\mathrm{c}}^-) - k\big)\big(q_{\mathrm{R}}u_{\mathrm{D}} - q_{\mathrm{R}}k - b(k)\big) \le 0.\end{aligned}$$

Obviously, the unique nontrivial case that needs to be discussed here is $u(x_{\mathrm{c}}^-) < k < u_{\mathrm{c}}$. Then we have $\operatorname{sgn}(u_{\mathrm{c}} - k) = 1$, $\operatorname{sgn}(u(x_{\mathrm{c}}^-) - k) = -1$, and the inequality is reduced to

$$q_{\mathrm{R}}u_{\mathrm{D}} \le g_{\mathrm{R}}(k) = q_{\mathrm{R}}k + b(k) \quad \forall k \in (u(x_{\mathrm{c}}^-), u_{\mathrm{c}}). \tag{5.25}$$

On the other hand, from (5.15) we infer that $q_{\mathrm{R}}u_{\mathrm{D}} \le q_{\mathrm{R}}u_{\mathrm{c}} + b(u_{\mathrm{c}})$. This means that at $u = u_{\mathrm{c}}$, the graph of $g_{\mathrm{R}}(u)$ lies above or intersects the horizontal line $f = q_{\mathrm{R}}u_{\mathrm{D}}$. Consequently, $u(x_{\mathrm{c}}^-)$ is the largest intersection of $g_{\mathrm{R}}(u)$ with the horizontal line $f = q_{\mathrm{R}}u_{\mathrm{D}}$ that is smaller than or equal to u_{c}:

$$u(x_{\mathrm{c}}^-) = \inf\big\{u \in [0, u_{\mathrm{c}}] \;\big|\; \forall \xi \in [u, u_{\mathrm{c}}] : g_{\mathrm{R}}(\xi) = q_{\mathrm{R}}\xi + b(\xi) \ge q_{\mathrm{R}}u_{\mathrm{D}}\big\}.$$

Since $g_{\mathrm{R}}(0) = 0 < q_{\mathrm{R}}u_{\mathrm{D}}$ and $g_{\mathrm{R}}(u_{\mathrm{c}}) > q_{\mathrm{R}}u_{\mathrm{D}}$ by assumption, it is ensured that the curve $u \mapsto g_{\mathrm{R}}(u)$ and the horizontal line $u \mapsto q_{\mathrm{R}}u_{\mathrm{D}}$ always intersect on $[0, u_{\mathrm{c}}]$, and thus $u(x_{\mathrm{c}}^-)$ is well defined. Note that for a function $b(u)$ with exactly one inflection point, the infimum is taken over at most three solutions of the equation $q_{\mathrm{R}}u + b(u) = q_{\mathrm{R}}u_{\mathrm{D}}$. It is not difficult to see that the steady-state solution in the interval $(x_{\mathrm{c}}, 0)$ is given by the constant $u(x_{\mathrm{c}}^-)$, which is uniquely constructed here.

It is at this point that assumption (5.9) turns out to be convenient in order to reduce the number of possible cases occurring in the continuation of the solution into the clarification zone. There would be no difficulty associated with relaxing this assumption.

Cases 2 *and* 3 ($x_{\mathrm{c}} = 0$, $v(0^+) \ge u_{\mathrm{c}}$). The construction of the steady-state solution in the thickening zone $(0, x_{\mathrm{R}}]$ is completed. The differentiable solution profile is given by the solution of the one-sided boundary value problem (5.13).

5.3. Steady-state solution in the clarification zone.

Case 1 ($x_{\mathrm{c}} > 0$). At $x = 0$, the next flux discontinuity has to be dealt with. However, since the solution for $x > 0$ is a constant not exceeding u_{c} and since $A(u)$ is continuous across $x = 0$, we have to treat a transition between two fluxes of a hyperbolic conservation law. The entropy weak solution to this problem has been determined in several papers [19, 39, 40, 41, 46, 47, 48, 58, 75]. The basic complication is that if the fluxes adjacent to $x = 0$ are nonmonotone, then there might be several possibilities to satisfy the Rankine–Hugoniot condition if $u(0^+)$ is given, and an entropy condition is necessary to single out the unique entropy-satisfying solution. This will in general generate a multitude of cases here, depending on the flux parameters and properties of the function b and on which solution of the equation $q_{\mathrm{R}}u + b(u) = q_{\mathrm{D}}u_{\mathrm{D}}$ yields the relevant state $u(0^+)$.

All these cases can be handled by the recent theory of conservation laws with discontinuous flux. However, assumption (5.9) helps to avoid this complication since it ensures that to a given value $u(0^+)$ there corresponds a *unique* value $u(0^-)$ such that the jump condition across $x = 0$,

$$q_{\mathrm{R}}(u(0^+) - u_{\mathrm{F}}) + b\big(u(0^+)\big) = q_{\mathrm{L}}(u(0^-) - u_{\mathrm{F}}) + b\big(u(0^-)\big), \tag{5.26}$$

is satisfied. To see this, recall that the constancy of u on $(0, x_{\mathrm{c}})$ and (5.24) imply that $q_{\mathrm{R}}u(0^+) + b(u(0^+)) = q_{\mathrm{R}}u_{\mathrm{D}}$. Inserting this into (5.26), we get

$$-(q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}} + q_{\mathrm{R}}u_{\mathrm{D}} = q_{\mathrm{L}}u(0^-) + b\big(u(0^-)\big). \tag{5.27}$$

However, the left-hand side of (5.27) is just $q_{\mathrm{L}}u_{\mathrm{E}} \le 0$. On the other hand, due to (5.9) and since we seek a solution $0 \le u(0^-) \le u_{\mathrm{c}}$, the right-hand side of (5.27) is nonnegative and is zero only for $u(0^-) = 0$. Thus, the only solution is $u_{\mathrm{E}} = 0$, $u(0^-) = 0$, which implies that $u(x) = 0$ for all $x \le 0$.

Consequently, under the assumption (5.9) the only steady-state entropy weak solutions for which the sediment level $x = x_{\mathrm{c}}$ is located strictly below the feed level $x = 0$ are solutions for which there is only clear liquid in the clarification and overflow

zones ($x \geq 0$). For these solutions, the feed and discharge concentrations u_{F} and u_{D} are linked by $(q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}} = q_{\mathrm{R}}u_{\mathrm{D}}$.

Case 2 ($x_{\mathrm{c}} = 0$, $u(0^+) > u_{\mathrm{c}}$). Lemma 5.3 implies that $u(0^-) = u(0^+)$ if $u^+ > u_{\mathrm{c}}$. Thus, we can continue to solve (5.1) in the clarification zone $x \in (x_{\mathrm{L}}, 0)$. Integrating this ODE over the interval $(x, 0)$, we obtain the following one-sided boundary value problem for a first-order ODE:

(5.28)
$$q_{\mathrm{L}}\big(u(x) - u(0^-)\big) + b(u) - b\big(u(0^-)\big) - A(u)'|_{x=0^-} = 0 \quad \text{for } x < 0, \quad u(0) = u(0^-).$$

To determine $u'(0^-)$, we use the Rankine–Hugoniot condition (5.4) across $x = 0$,

$$\begin{aligned} &q_{\mathrm{L}}\big(u(0^-) - u_{\mathrm{F}}\big) + b\big(u(0^-)\big) - A(u)'|_{x=0^-} \\ &= q_{\mathrm{R}}\big(u(0^+) - u_{\mathrm{F}}\big) + b\big(u(0^+)\big) - A(u)'|_{x=0^+}. \end{aligned} \tag{5.29}$$

Recalling that we already know that $u(0^-) = u(0^+)$, we get

$$A(u)'|_{x=0^-} = (q_{\mathrm{L}} - q_{\mathrm{R}})\big(u(0^-) - u_{\mathrm{F}}\big) + A(u)'|_{x=0^+}. \tag{5.30}$$

On the other hand, in the present case we know that $A(u)'|_{x=0^+} = q_{\mathrm{R}}(u(0^+) - u_{\mathrm{D}}) + b(u(0^+))$. Inserting this into (5.30) and replacing $u(0^+)$ by $u(0^-)$, we get

$$A(u)'|_{x=0^-} = q_{\mathrm{L}}u(0^-) - q_{\mathrm{R}}u_{\mathrm{D}} - (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} + b\big(u(0^-)\big). \tag{5.31}$$

Finally, we insert (5.31) into (5.28) and obtain the one-sided boundary value problem

$$q_{\mathrm{L}}u(x) + b(u) - A(u)' - q_{\mathrm{R}}u_{\mathrm{D}} - (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} = 0, \quad x < 0; \quad v(0) = v(0^-). \tag{5.32}$$

We now define

$$\tilde{x}_{\mathrm{c}} := \inf\big\{x \in [x_{\mathrm{L}}, 0) \;\big|\; u(x) \text{ is the solution of (5.28) and } u_{\max} \geq u(x) > u_{\mathrm{c}}\big\} \tag{5.33}$$

and recall from (5.32) and (5.31) that we have

$$b\big(u(x)\big) - A(u)' = -q_{\mathrm{L}}u(x) + q_{\mathrm{R}}u_{\mathrm{D}} + (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} \quad \text{for } x \in (\tilde{x}_{\mathrm{c}}, 0],$$

as well as that we obtain from (5.5) the inequality

$$\begin{aligned} &\big[\operatorname{sgn}\big(u(0^-) - k\big) - \operatorname{sgn}\big(u(x) - k\big)\big]\big(-q_{\mathrm{L}}k - b(k) + q_{\mathrm{R}}u_{\mathrm{D}} + (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}}\big) \leq 0 \\ &\forall x \in (\tilde{x}_{\mathrm{c}}, 0) \text{ and } \forall k \in \mathbb{R}. \end{aligned} \tag{5.34}$$

We observe that $q_{\mathrm{R}}u_{\mathrm{D}} + (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} = q_{\mathrm{L}}u_{\mathrm{E}}$. Then, the solution in the interval $(\tilde{x}_{\mathrm{c}}, 0)$ is given by the solution of the one-sided boundary problem (which is a slight rearrangement of (5.32))

$$u'(x) = \frac{q_{\mathrm{L}}u(x) + b(u(x)) - q_{\mathrm{L}}u_{\mathrm{E}}}{a(u(x))}, \quad x < 0, \quad u(0) = u(0^-). \tag{5.35}$$

Due to our assumption (5.9), since $g_{\mathrm{L}}(0) = 0$, and $b(u)$ and therefore $g_{\mathrm{L}}(u)$ has exactly one inflection point, we know that $g_{\mathrm{L}}(u)$ has exactly one positive maximum $u_{\mathrm{M}} > u_{\mathrm{c}}$ and that $g_{\mathrm{L}}(u)$ is monotonically decreasing between u_{M} and $u_{\max} = 1$ with $g_{\mathrm{L}}(u_{\max}) = q_{\mathrm{L}}u_{\max} < 0$. Consequently, there exists exactly one point u^* with

$u_c < u^* < u_{\max}$ such that $q_L u^* + b(u^*) = q_L u_E$. Since the maximum of g_L is positive but $q_L u_E \le 0$, we know that $u^* > u_M$, and therefore

$$g_L(u) < g_L(u^*) \quad \text{for } u > u^*,\ u \le u_{\max}. \tag{5.36}$$

We first assume that $u(0^+) = u(0^-) > u^*$. Our immediate goal is to show that $u(0^-) > u^*$ does not lead to an admissible steady-state solution. Note that by the discussion of the solution in the thickening zone, we know that $u(0^-) < u_D$.

By the definition of u^*, we may rewrite the ODE (5.35) as

$$u'(x) = \frac{g_L(u(x)) - g_L(u^*)}{a(u(x))}, \quad x < 0, \quad u(0) = u(0^-).$$

In light of (5.36), we see that inserting $u(0^-) > u^*$ will cause the right-hand side of the ODE in (5.35) to be negative at $x = 0$, and this right-hand side remains negative if we proceed with the integration of (5.35), since we produce a solution that is monotonically decreasing (increasing upwards). This integration may be continued upwards until either $u = u_{\max} = 1$ is attained or $x = x_L$ is reached. In the first case, however, there is no valid way to continue the solution to the remaining interval $(x_L, \tilde{x}_c)$ other than setting $u = u_{\max} = 1$ for $x \in (x_L, \tilde{x}_c)$. This means that at $x = x_L$, the jump condition implies that $q_L u_{\max} = q u_E$, that is, $u_E = u_{\max}$, in contradiction with the assumption $u_E < u_{\max}$. In the other case, in which $x = x_L$ is reached by integrating (5.35), we have the following Rankine–Hugoniot condition across $x = x_L$:

$$q_L u(x_L^+) + b\big(u(x_L^+)\big) - A(u)'\big|_{w=x_L^+} = q_L u(x_L^-). \tag{5.37}$$

On the other hand, since $u(x_L^+) \ge u(0^-) > u_c$, we have $A(u(x_L^+)) > 0$, and thus, due to Lemma 5.3, $u(x_L^+) = u(x_L^-)$, and therefore (5.37) reduces to $b(u(x_L^+)) = A(u)'|_{x=x_L^+}$. However, since by assumption $u'(x_L^+) < 0$, we have that $A'(u)|_{x=x_L^+} < 0$, which in turn implies that $b(u(x_L^+)) < 0$. This is a contradiction to the nonnegativity of b. Thus, no admissible steady-state solution can be constructed if $u(0^-) > u^*$.

The case $u(0^-) = u^*$ equally leads to an inadmissible solution, since integrating (5.35) leads to the constant solution $u \equiv u^*$ on $(x_L, 0)$. Similarly to the discussion of the previous case, the jump condition (5.37) and Lemma 5.3 imply that $b(u^*) = A(u)'|_{x=x_L^+}$. However, the constancy of u along $x \in (x_L, 0)$ implies that $A(u)'|_{x=x_L^+} = 0$, and therefore $b(u^*) = 0$, in contradiction with the assumed properties of b. Another reason to reject the profiles with $u(0^-) \ge u^*$ as candidates for steady-state entropy weak solutions is the violation of the global conservation principle (5.10), since we have chosen u_D and u_F such that $u_E = 0$, but in these cases our integration yields positive values of $u(x_L^-)$, which should equal u_E.

We now look at the remaining case $u(0^-) < u^*$. Then the right-hand side of the ODE in (5.35) is always positive, which implies a monotonically increasing (decreasing upwards) solution $u(x)$ until $x = \tilde{x}_c$ is reached. This solution also satisfies the entropy condition. In fact, for any $x \in (\tilde{x}_c, 0)$ with $u(x) < u(0^-)$ and for all $k \in (u(x), u(0^-))$, condition (5.34) (which is void for all other values of k and for $u(x) = u(0^-)$) implies that $2(-q_L k - b(k) + q_L u_E) \le 0$, i.e.,

$$q_L k + b(k) - q_L u_E \ge 0 \quad \forall k \in (u(x), u(0^-)), \tag{5.38}$$

which in view of (5.35) is satisfied if $u(x)$ is a monotonically increasing solution on $(\tilde{x}_c, 0)$.

We summarize our discussion of Case 2 in the clarification zone by the following lemma.

LEMMA 5.5. *Any admissible steady-state entropy solution $u = u(x)$ of Model 1 with $u(0^-) = u(0^+) > u_c$ must satisfy $u(0^-) < u^*$, where u^* is the unique point in (u_c, u_{max}) satisfying $g_L(u^*) \equiv q_L u^* + b(u^*) = q_L u_E$. This solution is monotonically increasing on the interval $(\tilde{x}_c, 0)$, where $\tilde{x}_c$ is defined by (5.33).*

REMARK 5.3. *The statement of Lemma 5.5 also has an obvious graphical interpretation. However, this condition requires knowledge of the value $u(0^+) = u(0^-)$. Thus, it can be evaluated only after the solution in the thickening zone has been determined. Furthermore, combining this finding with Lemma 5.4 for the thickening zone, we see that in any of the Cases 1, 2, or 3, the entropy condition and jump conditions enforce that $u'(x) \geq 0$ in the compression region.*

With the present discussion, we have constructed a steady-state solution up to $\tilde{x}_c$, provided that $u(x) > u_c$ in the thickening zone $x \in (0, x_R)$. To finish the steady-state construction, let us first recall that for sake of brevity and being well aware of the incompleteness of the treatment in the present paper, we limit the discussion to those steady states for which $\tilde{x}_c > x_L$. In this case, there is a jump located at $x = \tilde{x}_c$. We now seek the constant solution value $u = u(\tilde{x}_c^-)$ in the interval $(x_L, \tilde{x}_c)$. This value must satisfy $0 \leq u(\tilde{x}_c^-) \leq u_c$. From the Rankine–Hugoniot condition that follows from (5.4), $q_L u(\tilde{x}_c^-) + b(\tilde{x}_c^-) = q_L u_c + b(u_c) - A(u)'|_{x=\tilde{x}_c^+}$, we see that the constant $u(\tilde{x}_c^-) = u_c$ is not a solution. Consequently, we look for a constant $0 \leq u(\tilde{x}_c^-) < u_c$. To this end, note that the steady-state jump condition at $x = x_L$ is $g_L(u(x_L^+)) = q_L u(x_L^+) + b(u(x_L^+)) = q_L u(x_L^-) = q_L u_E$. Taking into account that $g_L(u)$ is a nonnegative monotonically increasing function on $[0, u_c]$, while the right-hand side is a nonpositive constant, we conclude (similar as in the discussion of Case 1) that $u_E = 0$ and $u(\tilde{x}_c^-) = 0$; i.e., the solution is zero on $(x_L, \tilde{x}_c)$.

REMARK 5.4. *The last result means that the mathematical model correctly describes the elimination of the hindered settling region in steady-state operation when the sediment level (where $u = u_c$) is allowed to rise above the feed level, as drawn in Figure 1.1(b). No particles are elutriated from the compression region into the overflow. This supports the physical explanation that above the feed level, the sediment bed acts as a filter medium for the portion of the feed flow that is directed into the clarification zone.*

If we added a small amount of hydrodynamic diffusion and used a strictly positive diffusion coefficient $a(u)$ such that the resulting model were strictly parabolic, then there would be no upper limit for the integration of ODEs like (5.28), and under the preconditions of Case 2 discussed here, the quantity $\tilde{x}_c$ defined by (5.33) would always assume the value x_L (corresponding to the overflow level) with $u(x_L^+) > 0$. In other words, there would be a small but positive volume fraction of solids in the overflow. Steady-state concentration profiles for a clarifier-thickener model with a strictly positive diffusion coefficient that illustrate this situation are plotted, for example, in [81].

Finally, we mention that Lev, Rubin, and Sheintuch [64] *use a steady-state clarifier-thickener model without compression effects but with a hydrodynamic diffusion term instead. A discussion of possible concentration extrema at steady state leads them to the conclusion that the concentration must increase downwards. Our analysis shows that by applying the entropy concept to the steady-state ODE, this characterization remains valid even when hydrodynamic diffusion vanishes.*

Case 3 ($x_c = 0$, $u(0^+) = u_c$). In this case, we have $A(u(0^+)) = 0$ and due to the continuity of $A(u)$ across $x = 0$, $A(u(0^-)) = 0$, which means $u(0^-) \in [0, u_c]$. Since, in the present case, it has been possible to integrate (5.13) up to $x = 0^+$, we can

replace the Rankine–Hugoniot condition across $x = 0$, (5.29), by $q_{\mathrm{L}}u(0^-)+b(u(0^-))-A(u)'|_{x=0^-} = (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} + q_{\mathrm{R}}u_{\mathrm{D}}$. On the other hand, the following entropy jump condition follows by evaluating (5.5) for $x = 0$:

$$\begin{aligned} &\operatorname{sgn}\big(u(0^+) - k\big)\big[q_{\mathrm{R}}\big(u(0^+) - k\big) + b\big(u(0^+)\big) - b(k) - A(u)'|_{x=0^+}\big] \\ &- \operatorname{sgn}\big(u(0^-) - k\big)\big[q_{\mathrm{L}}\big(u(0^-) - k\big) + b\big(u(0^-)\big) - b(k) - A(u)'|_{x=0^-}\big] \\ &\le \big|q_{\mathrm{R}}(k - u_{\mathrm{F}}) - q_{\mathrm{L}}(k - u_{\mathrm{F}})\big| \quad \forall k \in \mathbb{R}. \end{aligned} \tag{5.39}$$

Inserting (5.29), using once again (5.13) and that $u(0^+) = u_{\mathrm{c}}$, we get

$$\begin{aligned} &\operatorname{sgn}\big(u_{\mathrm{c}} - k\big)\big(-q_{\mathrm{R}}k - b(k) + q_{\mathrm{R}}u_{\mathrm{D}}\big) \\ &- \operatorname{sgn}\big(u(0^-) - k\big)\big(-q_{\mathrm{L}}k - b(k) + (q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} + q_{\mathrm{R}}u_{\mathrm{D}}\big) \\ &\le \big|(q_{\mathrm{R}} - q_{\mathrm{L}})(k - u_{\mathrm{F}})\big| \quad \forall k \in \mathbb{R}. \end{aligned}$$

Choosing $k = 0$ and exploiting that $b(k) = 0$, we get

$$\operatorname{sgn}(u_{\mathrm{c}})q_{\mathrm{R}}u_{\mathrm{D}} - \operatorname{sgn}\big(u(0^-)\big)\big((q_{\mathrm{L}} - q_{\mathrm{R}})u_{\mathrm{F}} + q_{\mathrm{R}}u_{\mathrm{D}}\big) \le \big|(q_{\mathrm{R}} - q_{\mathrm{L}})(-u_{\mathrm{F}})\big|, \tag{5.40}$$

which in view of $u_{\mathrm{c}} > 0$, $u_{\mathrm{F}} > 0$, and $q_{\mathrm{R}} - q_{\mathrm{L}} \ge 0$ implies that

$$q_{\mathrm{R}}u_{\mathrm{D}} + \operatorname{sgn}\big(u(0^-)\big)(q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}} + \operatorname{sgn}\big(v(0^-)\big)q_{\mathrm{R}}u_{\mathrm{D}} \le (q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}}. \tag{5.41}$$

If $\operatorname{sgn}(u(0^-)) = 1$, then the left-hand side of (5.41) equals $2q_{\mathrm{R}}u_{\mathrm{D}} + (q_{\mathrm{R}} - q_{\mathrm{L}})u_{\mathrm{F}}$. Thus, inequality (5.41) cannot be satisfied. The unique remaining option is $\operatorname{sgn}(u(0^-)) = 0$, i.e., $u(0^-) = 0$. It is then easily seen that the solution for $x < 0$, including also the section $x < x_{\mathrm{L}}$, vanishes identically. Thus, the solution of Case 3 is the limiting case of Cases 1 and 2 for $u(0^+) \to u_{\mathrm{c}}$.

REMARK 5.5. *The condition $u'(x) \ge 0$ is in full agreement with engineering intuition, since one expects that in a clarifier-thickener operating properly at steady state, the concentration increases downwards. In fact, in several previous papers dealing with a simpler model of an ideal continuous thickener* [13, 16]*, which basically consists only of the thickening zone of the model discussed here, the condition $u'(x) \ge 0$ was* postulated *as a separate* requirement *for the determination of admissible steady states following just from this intuition, and the graphical condition* (5.20) *was derived by using this assumption in* (5.21)*. We now clearly see that the natural requirement that a steady state should be an entropy weak solution* implies *this monotonicity property in the thickening zone, and it is therefore* unnecessary *to introduce it as an additional condition.*

Observe that in contrast to our analysis of the thickening zone, we do not apply the entropy condition to construct the restrictions on the parameters (expressed by Lemma 5.5*) in the clarification and overflow zones; rather, we exploit the jump conditions to establish these restrictions and then check that the admissible solution satisfies the entropy condition.*

5.4. Examples of steady states. Here and in the numerical examples, the flocculated suspension is characterized by the functions $b(u)$ and $\sigma_{\mathrm{e}}(u)$ given by (2.6) and (2.9), respectively, with $v_\infty = 10^{-4}\,\mathrm{m/s}$, $C = 5$, $\sigma_0 = 1.0\,\mathrm{Pa}$, $u_{\mathrm{c}} = 0.1$, and $k = 6$. The remaining parameters are $\Delta\varrho = 1500\,\mathrm{kg/m^3}$ and $g = 9.81\,\mathrm{m/s^2}$. These values are fairly realistic and are also used in [14, 16].

Moreover, we assume the bulk velocities $q_{\mathrm{R}} = 2.5 \times 10^{-6}\,\mathrm{m/s}$ and $q_{\mathrm{L}} = -1.0 \times 10^{-5}\,\mathrm{m/s}$. Thus, we are interested in steady states for which $u_{\mathrm{D}} = u_{\mathrm{F}}(q_{\mathrm{R}} - q_{\mathrm{L}})/q_{\mathrm{R}} =$

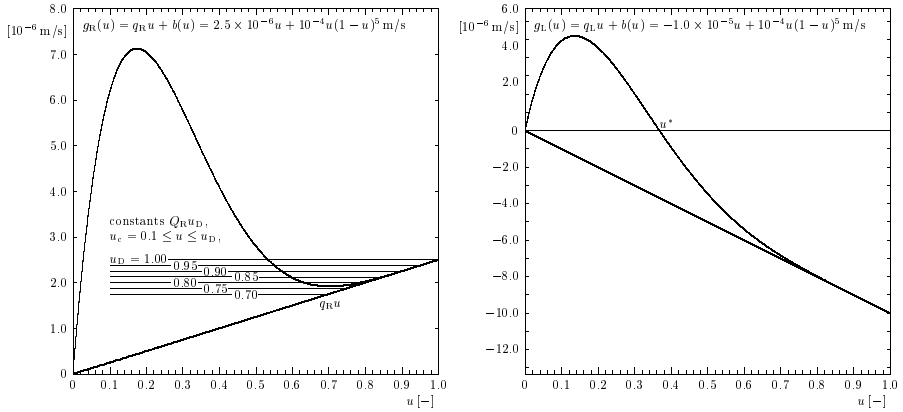

FIG. 5.1. *The flux functions $q_R u + b(u)$ (left) and $q_L + b(u)$ (right). The left diagram also shows the constant lines $q_R u_D$ for some values of u_D.*

$5u_F$, and these parameters have been chosen so that assumption (5.9) is satisfied. The relevant flux functions for the thickening and clarification zone, $g_R(u)$ and $g_L(u)$, are plotted in Figure 5.1.

We start the steady-state construction by fixing values of u_D and determining the corresponding value x_c. We limit ourselves to those values u_D that ensure that the entropy condition (5.15) is satisfied. To this end, we consider the plot of $g_R(u)$ and draw horizontal line segments $f = q_R u_D$ for a selection of values of u_D and for $u_c \le u \le u_D$, as has been done in the left plot of Figure 5.1. We see that these lines remain strictly below the graph of $g_R(u)$ for those values of u_D for which

$$q_R u_D < \min_{u_c \le u \le 1} g_R(u) = g_R(0.703) \approx 1.92 \times 10^{-6}\,\mathrm{m/s}.$$

This implies that the entropy condition (5.15) is satisfied a priori (i.e., independently of the depth of the thickening zone x_R) for all u_D with

$$u_c \le u_D < u_{D\max} := \frac{1}{q_R} \min_{u_c \le u \le 1} g_R(u) = \frac{1.92 \times 10^{-6}\,\mathrm{m/s}}{2.5 \times 10^{-6}\,\mathrm{m/s}} = 0.768.$$

For all other values of u_D, it would be necessary to determine a solution to (5.13) and to check whether this is monotone on $[x_c, x_R]$. We will not pursue this here.

Given this limitation on u_D, we choose the profiles for $u_D = 0.3, 0.35, 0.4, 0.405, 0.41, \ldots, 0.455$ for closer inspection. Solving (5.13) with a standard numerical ODE method, we obtain that for $u_D \le 0.41$, we have $x_c > 0$ and therefore steady states of Case 1, while all other values lead to candidates for Case 2. Solving the equation $q_R u(x_c^-) + b(u(x_c^-)) = q_R u_D$ numerically yields the following values of $u(x_c^-)$, which are the constant values each entropy weak solution assumes on $[0, x_c]$:

u_D	0.3	0.35	0.4	0.405	0.41
$u(x_c^-)$	0.00759	0.00892	0.01026	0.01039	0.01053

For these values of u_D, the steady-state entropy weak solution in the clarification and overflow zones is zero. Figure 5.2 includes plots of these profiles.

It remains to deal with $u_D = 0.415, 0.42, \ldots, 0.455$, the candidates for Case 2, for which the clarification zone has to be examined. We have just found out that

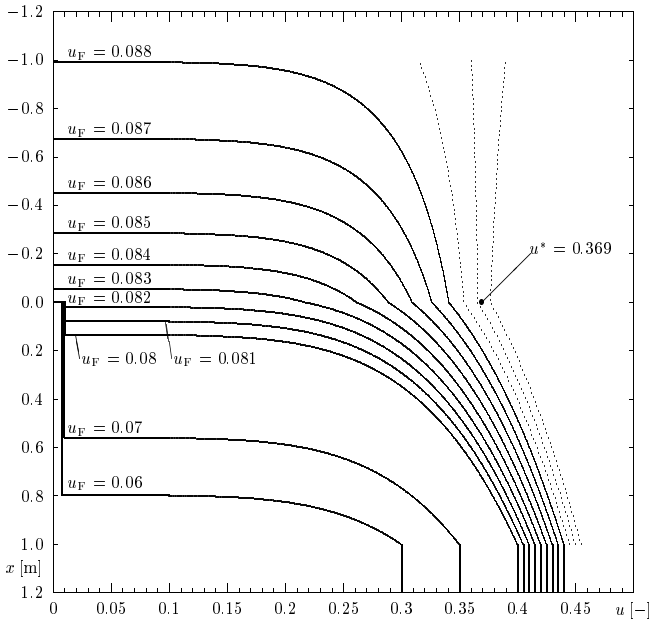

FIG. 5.2. *Steady-state concentration profiles in Vessel* 1. *The dotted curves show solutions of* (5.13) *and* (5.28) *that do not lead to admissible steady states with zero overflow concentration.*

all of these concentration values admit an entropy-satisfying steady-state solution in the thickening zone. However, with the present parameters we have $u_E = 0$, which implies that $u^* = 0.369$. This point is marked in Figures 5.1 and 5.2. We see that integrating (5.13) from $u_D = 0.455$ leads to a profile with $u(0^+) > u^*$, which does not lead to an admissible solution in the clarification zone. The tentative profile for this case is the rightmost dotted profile in Figure 5.2. For $u_D = 0.445$ and $u_D = 0.45$, we obtain admissible profiles in the clarification zone, which, however, reach the overflow level $x = x_L$ and will produce an effluent with $u_E > 0$. These profiles are no admissible entropy steady-state solutions since the global conservation principle is violated. The values $u_D = 0.415, 0.42, \ldots, 0.435$ lead to admissible steady-state profiles with $\tilde{x}_c > x_L$, and, as a consequence of our analysis, $u_E = 0$.

6. Numerical examples.

6.1. Preliminary remarks. Note that for $k \in \mathbb{N}$, as chosen here, standard calculus yields that the function $A(u)$ has the explicit representation $A(u) = \mathsf{A}(u) - \mathsf{A}(u_c)$ for $u > u_c$ with

$$\mathsf{A}(u) := -\frac{v_\infty \sigma_0}{\Delta \varrho g u_c^k}(1-u)^C u^k \sum_{j=1}^{k} c_j \left(\frac{1}{u} - 1\right)^j, \quad c_j = \prod_{l=1}^{j} \frac{k+1-l}{C+l}, \quad j = 1, \ldots, k;$$

it is straightforward to verify by differentiating $\mathsf{A}(u)$ that

$$\frac{d\mathsf{A}(u)}{du} = v_\infty u(1-u)^C \cdot \frac{1}{\Delta \varrho g u} \cdot \frac{d}{du}\big(\sigma_0\big((u/u_c)^k - 1\big)\big) = \frac{v_\infty \sigma_0}{\Delta \varrho g u_c^k}(1-u)^C k u^{k-1},$$

so that the function $A(u)$ defined here indeed satisfies (2.10).

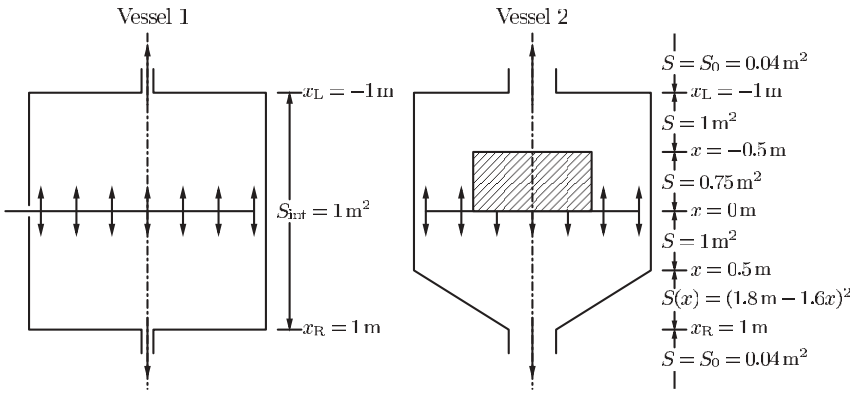

FIG. 6.1. *The cylindrical clarifier-thickener (left) and the unit with discontinuously varying cross-sectional area (right) used for numerical simulations.*

We consider two units, a cylindrical one (Vessel 1) and one with discontinuously varying cross-sectional area (Vessel 2); see Figure 6.1. The interior of Vessel 1 is $S_{\text{int}} = 1\,\text{m}^2$. (Recall that the outer pipe diameter S_0 can always be transformed away.) The piecewise constant cross-sectional area function $S(x)$ of the noncylindrical one, Vessel 2, is defined in Figure 6.1.

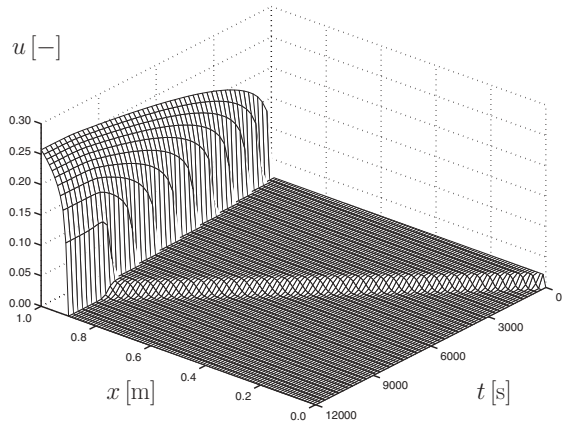
The motivation of the choice of $S(x)$ for Vessel 2 is that most clarifier-thickeners have a conically shaped bottom to facilitate transport of material to the discharge outlet and that we assume that one-quarter of the cross-sectional area in the clarification zone is occupied by installations related to the feed mechanisms. Observe that in the second case, both parameters γ_1 and γ_2 accounting for the cross-sectional area and the bulk flow, respectively, have a discontinuity at $x = 0$.

6.2. Example 1: Batch settling. To illustrate the material behavior of the suspension, we present in Figure 6.2 three simulations of the settling of an initially homogeneous suspension at initial concentrations $u_0 = 0.02$, 0.08, and 0.2 in a closed column (for which all Q's and q's vanish) of height $L = 1\,\text{m}$. We employ the explicit numerical method (3.1), $\Delta x = L/500$, and $\lambda = 20\,\text{s/m}$. In the first two cases, we have $a(u_0) = 0$, and the suspension-clear liquid interface propagates as a sharp shock and the transition between the region of initial concentration and the sediment rising from below is sharp, while in the third case transitions are continuous. In all three cases, a stationary sediment is forming. In Figure 6.2 and all subsequent three-dimensional plots, the visual grid used to represent the solution is much coarser than the computational.

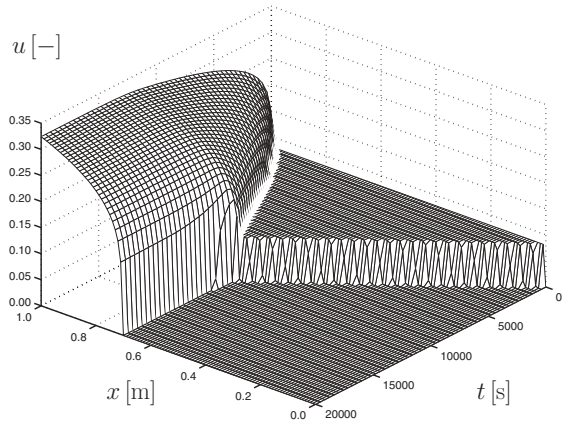
6.3. Numerical simulations of Model 1.

6.3.1. Example 2: Variation of discharge and overflow rates. The four simulations shown in Figure 6.3 have been computed using the unique feed flux $q_F u_F = (q_R - q_L)u_F$ with $q_F = 1.25 \times 10^{-5}\,\text{m/s}$ and $u_F = 0.08$ but by using four different "splits" of the feed rate into the discharge and overflow rates attained by varying the parameter $\nu \in [0, 1]$ in $q_R = \nu q_F$ and $q_L = -(1-\nu)q_F$. In all four simulations, solving the transient equations for sufficiently large times apparently leads to a stationary solution. The numerical scheme is the explicit one (3.1) with $\lambda = 40\,\text{s/m}$, and for this and all other numerical simulations of Model 1, we choose $\Delta x = 1/300\,\text{m}$.

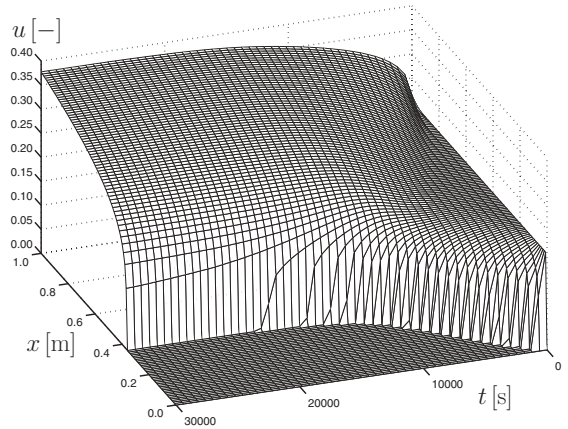
In Figure 6.3(a), we set $\nu = 1$; i.e., the vessel is closed at the top and opened



(a)



(b)



(c)

FIG. 6.2. *Example* 1: *Simulation of batch settling of an initially homogeneous suspension with* $u_0 = 0.02$ (a), $u_0 = 0.08$ (b), *and* $u_0 = 0.20$ (c).

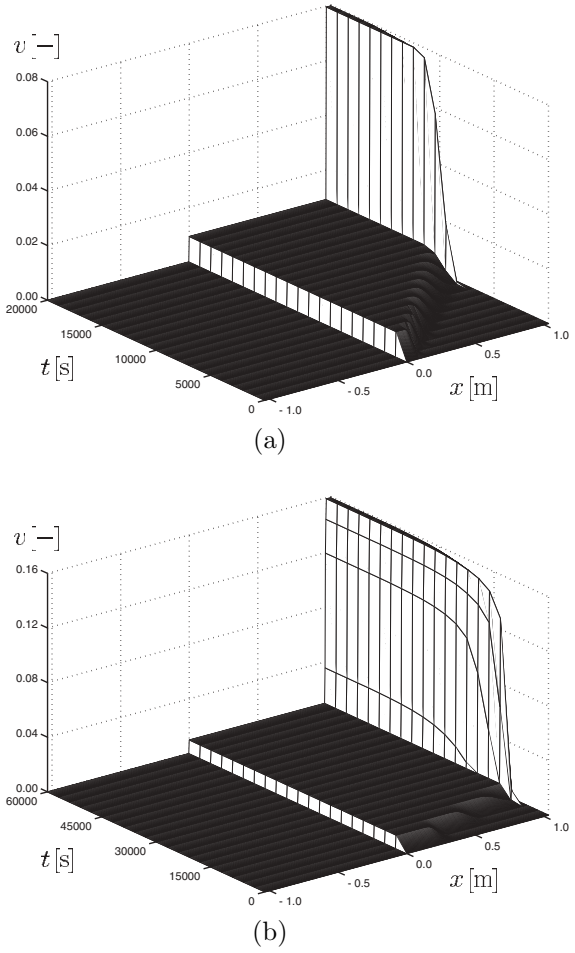


FIG. 6.3. *Example* 2: *Simulation of filling up a cylindrical clarifier-thickener with* $u_{\mathrm{F}} = 0.08$, $q_{\mathrm{F}} = 1.25 \times 10^{-5}\mathrm{m/s}$, $q_{\mathrm{R}} = \nu q_{\mathrm{F}}$, *and* $q_{\mathrm{L}} = -(1-\nu)q_{\mathrm{F}}$ *for* $\nu = 1$ (a) *and* $\nu = 0.5$ (b).

at the bottom, with the volume feed rate equaling the discharge rate. We see that the feed suspension is immediately diluted upon entering the vessel but attains its original concentration, 0.08, again when passing the discharge level. No compression region occurs.

For $\nu = 0.5$ (Figure 6.3(b)), we obtain a very thin sediment layer at the bottom, and the discharge concentration is 0.16, twice the feed concentration. The solution qualitatively agrees with that for $\nu = 0.25$ (Figure 6.3(c)). However, for $\nu = 0.25$ the final discharge concentration is $0.32 = 4u_{\mathrm{F}}$, and the sediment layer is appreciable. The stationary solutions attained in these cases correspond to steady-state solutions of Case 1 (conventional operation).

Finally, we take $\nu = 0$; i.e., the vessel is closed at its bottom. The corresponding solution is shown in Figure 6.3(d). We observe that the feed suspension is at first immediately diluted upon entering the thickening zone. The material forms a compressible sediment layer at the bottom. This layer rises at nearly constant speed, breaks into the clarification zone, and, finally, produces an overflow at constant

FIG. 6.3 (CONT'D.). *Example* 2: *Simulation of filling up a cylindrical clarifier-thickener with* $u_{\mathrm{F}} = 0.08$, $q_{\mathrm{F}} = 1.25 \times 10^{-5}\mathrm{m/s}$, $q_{\mathrm{R}} = \nu q_{\mathrm{F}}$, *and* $q_{\mathrm{L}} = -(1-\nu)q_{\mathrm{F}}$ *for* $\nu = 0.25$ (c) *and* $\nu = 0$ (d).

concentration 0.08, which is just the feed concentration. (Note that this kind of steady state is not included in the analysis of section 5.)

6.3.2. Example 3: Transitions between approximate steady states. We now utilize the examples of section 5.4 to design a long-time numerical example in which the parameters for the time-dependent Model 1 are chosen in such a way that the predetermined steady states may be attained. This example and Example 4 (for Model 2) are solved by the semi-implicit method (3.4) with $\lambda = 4000\,\mathrm{s/m}$. We consider the constant flow velocities $q_{\mathrm{R}} = 2.5 \times 10^{-6}\,\mathrm{m/s}$ and $q_{\mathrm{L}} = -1.0 \times 10^{-5}\,\mathrm{m/s}$. The feed concentration u_{F} is varied in a stepwise fashion as follows:

$$u_{\mathrm{F}}(t) = \begin{cases} 0.086 & \text{for } 0 \le t \le t_1 := 4.0 \times 10^7\,\mathrm{s}, \\ 0.08 & \text{for } t_1 < t \le t_2 := 6.0 \times 10^7\,\mathrm{s}, \\ 0.088 & \text{for } t_2 < t \le t_3 := 9.5 \times 10^7\,\mathrm{s}, \\ 0 & \text{for } t > t_3. \end{cases} \tag{6.1}$$

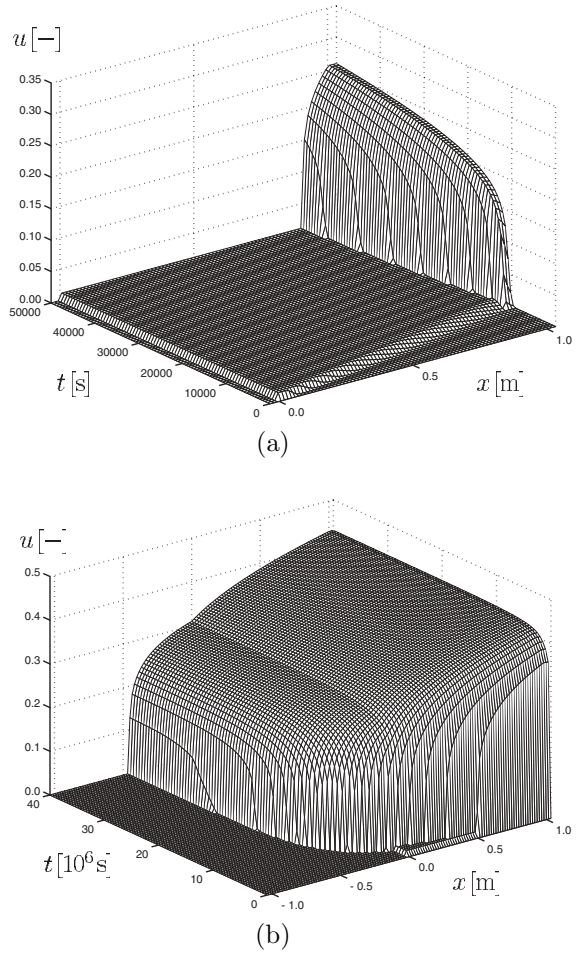

FIG. 6.4. *Example* 3: *Simulations of the fill-up and transitions between steady states in a cylindrical clarifier-thickener (Vessel* 1*): filling up a cylindrical clarifier-thickener up to steady state with* $u_{\mathrm{F}} = 0.086$ *(initial stages:* (a)*, complete process:* (b)*).*

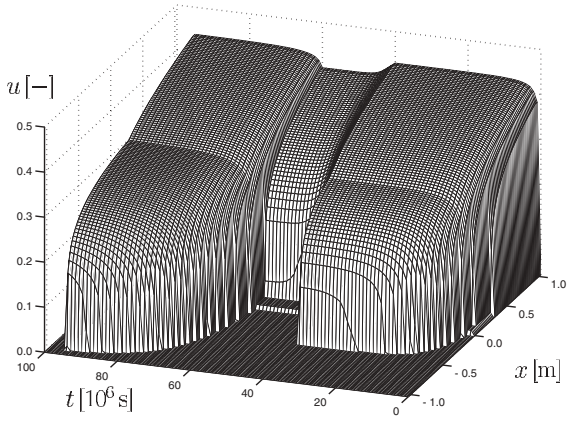
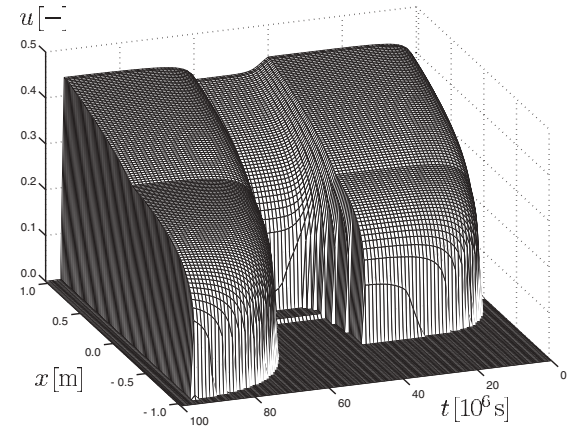
The initial stage of the fill-up process is shown in Figure 6.4(a), while the complete solution for the first time interval $[0, t_1]$ is plotted in Figure 6.4(b). We observe that the feed propagates as a rarefaction wave into the thickening zone and that a sediment layer is built up, which rises above the feed level. The interesting point is that the numerical solution becomes stationary after the very long simulated time of about 3.0×10^7 s, which corresponds to roughly one year, and the stationary solution closely approximates the steady-state profile corresponding to the same values of q_{L}, q_{R}, and u_{F} plotted in Figure 5.2. In particular, the numerical value of the overflow concentration remains zero, and the solution value assumed at $w = x_{\mathrm{R}}$ equals 0.42997. Thus, we have reason to believe that this steady-state solution is indeed the limit attained by the entropy weak solution for these parameters, at least for $t \to \infty$; whether the steady state is reached even in finite time would be a further question.

At the simulated time $t = t_1$, we reduce u_{F} to a value that in combination with those of q_{L} and q_{R} once again corresponds to a steady state plotted in Figure 5.2 but



(c)



(d)

FIG. 6.4 (CONT'D.). *Example* 3: *Simulations of the fill-up and transitions between steady states in a cylindrical clarifier-thickener (Vessel* 1*): two different views of the complete simulation with successive changes of* u_{F} *from* 0.086 *to* 0.08, 0.088, *and* 0 *(*(c) *and* (d)*).*

this time to one of conventional operation. Figures 6.4(c) and (d) indicate that also this steady state seems to be attained by the transient solution. In particular, the hindered settling region becomes visible again. Shortly before $t = t_2$, the numerical solution value at $x = x_{\mathrm{R}}$ equals 0.40001.

At $t = t_2$, we increase u_{F} to 0.088, and we observe that the simulation converges again to the corresponding steady state of Figure 5.2. Shortly before the solution becomes stationary, at $t = t_3$, we switch off the feed by setting $u_{\mathrm{F}} = 0$, and the clarifier-thickener unit empties rapidly.

Although the operations involved in this run—filling up, transitions between steady states, and emptying of a clarifier-thickener—are typical control actions, practitioners would, of course, accelerate the fill-up by closing the unit [15, 16]. The main intention behind our example is, however, to illustrate that the model apparently converges to steady-state solutions.

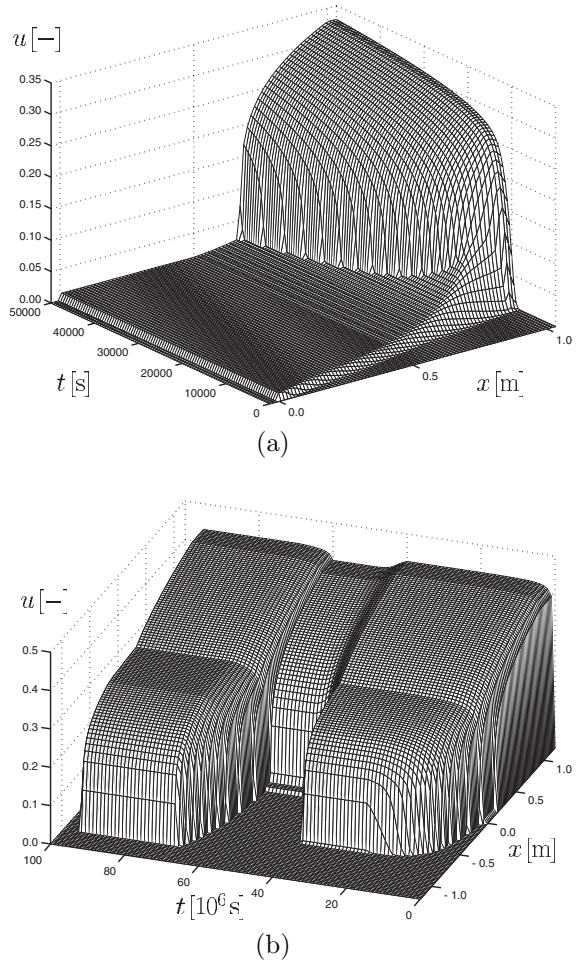


FIG. 6.5. *Example* 4: *Simulation of transitions between steady states in Vessel* 2*: plot of the initial fill-up stage* (a) *and long-time simulation* (b).

6.4. Example 4: Numerical simulation of Model 2. Finally, we repeat the simulation of Example 3; that is, we use again the function $u_{\mathrm{F}}(t)$ defined by (6.1), but now we consider Model 2, Vessel 2 drawn in Figure 6.1, and select $Q_{\mathrm{L}} = -1.0 \times 10^{-5}\mathrm{m}^3/\mathrm{s}$ and $Q_{\mathrm{R}} = 2.5 \times 10^{-6}\mathrm{m}^3/\mathrm{s}$. Model 2 enforces a CFL condition involving a factor $\max S(x)/\min S(x)$, which equals 25 here, so we have to decrease accuracy to maintain acceptable computation time. We here choose $\lambda = 100\,\mathrm{s/m}$ and $\Delta x = 1/50\,\mathrm{m}$ for the long-time run shown in Figure 6.5(b) but $\Delta x = 1/300\,\mathrm{m}$ for the short simulated period in Figure 6.5(a).

We observe that the concentration profiles slightly reflects the thickener geometry, although due to the diffusion term, this effect is less pronounced than for the same model without compression (i.e., for $A \equiv 0$); see [23, 24]. First, observe the difference between Figure 6.5(a) and the corresponding simulation for Model 1 and Vessel 1 in Figure 6.4(a). The conical cross-section of the lower part of the thickening zone causes a continuous variation of the concentration in the initial hindered settling region and

TABLE 6.1
Approximate L^1 errors for the numerical solution of Example 3.

	$t = 200000\,\mathrm{s}$		$t = 1000000\,\mathrm{s}$		$t = 2000000\,\mathrm{s}$	
$J = \frac{1\,\mathrm{m}}{\Delta x}$	L^1 error	conv. rate	L^1 error	conv. rate	L^1 error	conv. rate
10	1.429e−2		2.301e−2		2.857e−2	
20	7.092e−3	1.010	1.115e−2	1.004	1.424e−2	1.005
40	3.475e−3	1.029	5.666e−3	1.017	7.026e−3	1.019
80	1.691e−3	1.039	2.758e−3	1.038	3.425e−3	1.037
100	1.338e−3	1.048	2.176e−3	1.063	2.704e−3	1.059
160	8.004e−4	1.094	1.306e−3	1.087	1.623e−3	1.085
200	6.225e−4	1.126	1.015e−3	1.129	1.263e−3	1.124

accelerates the fill-up process.

Of course, a variable cross-sectional area $S(x)$ complicates the discussion of steady states but also offers new design opportunities [16]. Here, Vessel 2 no longer admits a steady state for $u_\mathrm{F} = 0.088$ with $u_\mathrm{E} = 0$. In fact, we observe in Figure 6.5(b) that a stationary profile is attained with nonzero overflow concentration. Rather, the numerical values attained are overflow and underflow concentrations $u(x_\mathrm{L}^-) = 0.00121$ and $u(x_\mathrm{R}^+) = 0.43293$. The stationary profile is probably a steady state with nonzero effluent concentration (which is not included in the analysis of section 5, as are not any other steady states for Model 2).

6.5. Comments on the numerical results. First of all, we mention that our numerical results, including test runs with coarser discretizations (not shown here), suggest that the scheme indeed converges to solutions for which $A(u)$ is continuous across x_L and x_R, as required by condition (D.4). However, it should be emphasized that our scheme does not possess a built-in mechanism to enforce this property. As emphasized before, a rigorous proof for the convergence of the scheme towards a solution satisfying (D.4) is still an open problem, and it might be that one even has to modify the scheme to ensure this property. This requires a deeper numerical analysis, which we defer to another paper.

Furthermore, the accuracy and convergence rate of the numerical scheme used herein may be of interest. To this end, we measured approximate L^1 errors for the simulation of Example 3 by measuring the difference $\|u^\Delta(\cdot,t) - u^\mathrm{ref}(\cdot,t)\|_{L^1(-1.1\,\mathrm{m},1.1\,\mathrm{m})}$ for a number of discretizations $(\Delta x, \Delta t = \lambda \Delta x)$ at $t = 200000\,\mathrm{s}$, $t = 1000000\,\mathrm{s}$, and $t = 2000000\,\mathrm{s}$, where u^Δ is the numerical solution obtained with $\Delta x = 1\,\mathrm{m}/J$, $J = 10, 20, 40, 80, 100, 160, 200$, and u^ref is a high-accuracy reference solution with $J = 1600$; see Table 6.1. In all cases, the semi-implicit scheme (3.4) with the parameter $\lambda = 4000\,\mathrm{s/m}$ was used.

We observe that the approximate L^1 convergence rates are slightly larger than but close to 1. This is consistent with the formal first-order accuracy of the time discretization and of the discretization of the convective fluxes. Similar approximately linear convergence has been observed for the explicit version (3.1) of the scheme applied to a slightly simpler equation that does not involve a discontinuous parameter in the diffusion term in [55], and for the application of the explicit scheme to the initial-boundary value problem of batch settling of a flocculated suspension in [18], which does not involve a discontinuous parameter at all. It should be pointed out that observed convergence rates substantially depend on the parameters and numerical examples chosen. For example, similar approximate L^1 tables for the explicit scheme (3.1) applied to the first-order clarifier-thickener model (obtained by setting $A \equiv 0$) are presented in [25]. It turns out that when approximate L^1 errors are measured at

times when the solution includes nonstationary "hyperbolic" discontinuities (shocks), then the observed L^1 convergence rate measured on a succession of grids may fall substantially below 1.

To put these observations into the proper perspective, let us mention that a theoretical estimate of the rate of convergence of the numerical scheme presented herein is outside current theory, even in the case of smooth coefficients. However, our prime motivation behind advancing the scheme (3.1) (and its semi-implicit variant (3.4)) was to use it as a constructive tool for the well-posedness analysis and to employ it for simulations to illustrate the mathematical analysis. Clearly, we do not propose (3.1) or (3.4) as the optimal scheme for simulations in practice. For that purpose the scheme should be upgraded to formal second order both in time and in space accuracy, which can be attained, for example, by combining flux correction and Strang-type operator splitting between the hyperbolic and parabolic portions of the problem. We pursue this further in [26].

Finally, there are conceivable alternative schemes for the clarifier-thickener model that seem worth exploring. For example, one could combine the very efficient front tracking method introduced in [19] for the hyperbolic portion and combine it with finite differencing of the diffusion term in an operator splitting procedure. Alternatively, the relaxation scheme used in [21] for the simulation of the first-order clarifier-thickener model could be extended to handle the second-order degenerate diffusion term accounting for sediment compressibility (as in [29]). Recent numerical schemes for strongly degenerate parabolic equations that can possibly be extended to the clarifier-thickener model also include the local discontinuous Galerkin method [33] and diffusive kinetic BGK approximations [3, 11].

Acknowledgment. We are grateful to the referees for valuable comments that resulted in a number of improvements in this paper.

EXACT SOLUTIONS FOR THE EVOLUTION OF A BUBBLE IN STOKES FLOW: A CAUCHY TRANSFORM APPROACH*

DARREN CROWDY† AND MICHAEL SIEGEL‡

Abstract. A Cauchy transform approach to the problem of determining the free surface evolution of a single bubble in Stokes flow is developed. A number of exact solutions to a class of problems have been derived in the literature using conformal mapping theory, and these solutions are retrieved and further generalized using the new formulation. Certain quantities which are conserved by the dynamics are also identified, the existence of which had not previously been pointed out. A principal purpose of this paper is to use the new formulation to understand when it is possible to externally specify the evolution of the bubble area in such classes of exact solution. It is found to be possible only for certain types of far-field boundary conditions.

Key words. bubble, Stokes flow, complex variables, Cauchy transform

DOI. 10.1137/S0036139903430847

1. Introduction.

It is a well-known yet remarkable fact that large classes of exact solutions can be found for unsteady two-dimensional (2-D) Stokes flow with a free surface, both with and without surface tension. The solutions follow from the application of powerful complex variable methods; most often these methods involve the use of a conformal mapping $z(\zeta, t)$ to reformulate the free boundary problem as a boundary value problem on a fixed domain in the ζ-plane (assumed in this paper to be a unit disk). The free boundary evolution is then conveniently described by the functional form of the map $z(\zeta, t)$.

Among the first results from the application of complex variable methods to free boundary problems for 2-D Stokes bubbles are the steady bubble solutions of Richardson [18, 19]. Antanovskii [2] later constructed exact unsteady solutions in the case when the asymptotic form of the far-field flow is given by an mth order irrotational straining flow. Independently, Tanveer and Vasconcelos [23] derived explicit unsteady solutions in the form of polynomial mappings in the case when the far-field flow is purely linear, e.g., pure straining flow or simple shear flow with $m = 1$. They also constructed new exact solutions for an expanding/contracting bubble in a quiescent flow. Antanovskii [3] also constructed explicit steady solutions in the case of nonlinear[1] and rotational far-field conditions. The latter solutions were applied as a simple 2-D model for flow in Taylor's four roller mill. Siegel [22] later generalized these results to include explicit unsteady solutions for certain nonlinear rotational far-field conditions, including the time-dependent evolution of the solutions in [3]. Additionally, there is a large amount of literature describing related developments for the evolution of viscous blobs in 2-D Stokes flow (see, e.g., Howison and Richardson [14] and the

[1] A precise definition of the term "nonlinear" in this context is given in section 3.3.1.

references therein). Complex variable methods have also been applied to study the evolution of bubbles in Hele–Shaw flow. Cummings, Howison, and King [10] provide a comparison of the developments in Hele–Shaw flow and 2-D Stokes flows. Aside from their intrinsic mathematical interest, these investigations have led to improved understanding of the formation of cusp singularities in free surface flow. The exact 2-D solutions are also useful as an important component of the leading-order solution to three-dimensional flow in slender geometries [9].

The aforementioned exact solutions for 2-D Stokes flow and Hele–Shaw flow all take the form of rational conformal mappings which may be written as

$$z(\zeta,t)=\frac{a_0(t)+a_1(t)\zeta+\cdots+a_N(t)\zeta^N}{\zeta(1+b_1(t)\zeta+\cdots+b_M(t)\zeta^M)}. \tag{1}$$

For convenience we have chosen $b_0(t)=1$ (this is always possible through a redefinition of the other coefficients); if $b_i(t)\equiv 0$, then the mapping reduces to a simpler polynomial form. Note that the extra ζ term in the denominator of (1) is due to the mapping of the inside of the unit disk to the exterior of the bubble. When the dynamics preserves the form (1), the free boundary evolution reduces from an infinite-dimensional dynamical system (namely, the original governing PDEs) to a finite system of ODEs from which one can compute the $N+M+1$ parameters of the conformal mapping from given initial data and external flow.[2]

In essence, demonstration of the existence of a solution of the form (1) for a given free boundary problem involves two key steps. First, it must be shown that the form (1) is preserved in time; i.e., if $z(\zeta,0)$ is a rational function of the form (1) for some M,N, then, as long as the solution exists, $z(\zeta,t)$ remains a rational function with the same M,N. In this paper we shall refer to this requirement as the closure condition. In particular, this implies that the number and type of (pole) singularities in the complex plane (i.e., $|\zeta|>1$) is invariant with time. Second, it is generally required that solutions $z(\zeta,t)$ do not generate any flow singularities (i.e., sources or sinks) in the *finite* fluid domain, although we do allow sources or sinks at infinity, corresponding to expanding/contracting bubble area.

For the solutions described in [2, 23] the closure condition is automatically satisfied, i.e., without any restrictions on the map coefficients $a_i,\ b_i$. The governing ODEs for the coefficients $a_i,\ b_i$ therefore come strictly from the second requirement, which gives $N+M$ conditions for $N+M+1$ unknowns. As a final condition, one is free to specify the time rate of change of the bubble area or, in other words, to specify the existence of a time-dependent source or sink fixed at infinity.

In contrast, for the solutions derived in [22] the closure condition imposes a constraint on the map coefficients $a_i,\ b_i$, in addition to the $N+M$ constraints supplied by the second condition above. Thus, seemingly, one is not free to arbitrarily specify the bubble area. It therefore seems rather fortuitous that the constant area condition employed in [22] is correct, i.e., that the dynamics actually preserves bubble area. However, it is not at all clear from the discussion there how to ascertain if or when this is the case.

In this paper, we provide a general discussion of when it is possible to obtain exact solutions to a very broad class of problems which encompasses and expands the class investigated in [2, 22, 23]. Additionally, we specify precisely when it is possible to externally control the bubble area and, in cases for which the area is not controllable,

[2]Solutions to such a system of ODEs are commonly referred to as exact solutions.

provide a simple means of ascertaining its time dependence. Our analysis involves a different approach from the one given in [2, 22, 23], namely, that emphasis is placed on consideration of the Cauchy transform which we define here as

$$\frac{1}{2\pi i}\oint_{\partial D(t)} \frac{\bar{z}'}{z'-z}dz', \tag{2}$$

where $\partial D(t)$ denotes the boundary of the fluid domain $D(t)$. When z is inside the bubble, the line integral (2) defines an analytic function, say $C(z,t)$. The analytic continuation of $C(z,t)$ outside the bubble (and into the fluid region $D(t)$) contains a great deal of information about the bubble shape. In many respects, $C(z,t)$ is a more natural mathematical object to consider; indeed, given the functional form of $C(z,t)$ at each instant it is possible to reconstruct the relevant conformal mapping. The evolution equation for $C(z,t)$ also has a convenient mathematical form which is easy to analyze. In particular, using the new formulation presented here it is possible to resolve such issues as the question of bubble area evolution, a question which often involves formidable calculation in the usual conformal map approach. It is appropriate to mention that the Cauchy transform has been used to great effect by many previous authors in the study of Hele–Shaw free boundary problems [12, 20, 21, 24].

The rest of this paper is organized as follows. In section 2 we introduce the Cauchy transform formulation for the problem of Stokes flow for a single bubble and prove its equivalence to the usual Stokes flow formulation. We also demonstrate the existence of certain conserved quantities which are useful in constructing exact solutions. In section 3 we use the new formulation to retrieve the exact solutions which have been previously presented in the literature and show how new classes of solutions may be derived. In particular, with the new approach the closure condition is easily verified, in contrast to the much more involved calculations that are necessary using the conformal map approach. More importantly, we use our formulation to investigate when it is possible to externally specify the evolution of bubble area. Some concluding remarks are presented in section 4.

2. Mathematical formulation.

2.1. Stokes flow problem. Consider the quasi-steady evolution of a single bubble in an ambient Stokes flow. The fluid inside the bubble is assumed to have zero viscosity, implying that it is a passive fluid with spatially constant pressure, which for convenience is set to zero. We denote the fluid region exterior to the bubble by $D(t)$, and the bubble is denoted by $D_c(t)$. The flow is allowed to be singular at infinity, although we do not consider any flow singularities (such as sources or sinks) in the finite flow domain. Figure 1 gives a schematic. In view of the incompressibility of the flow, it is convenient to introduce a streamfunction $\psi(x,y)$ which satisfies

$$\mathbf{u} = \nabla^{\perp}\psi. \tag{3}$$

It is easily seen that

$$\nabla^4\psi = 0 \quad \text{in } D(t). \tag{4}$$

We assume that surface tension acts on the bubble boundary so that the stress condition is

$$-pn_j + 2e_{jk}n_k = \kappa n_j, \tag{5}$$

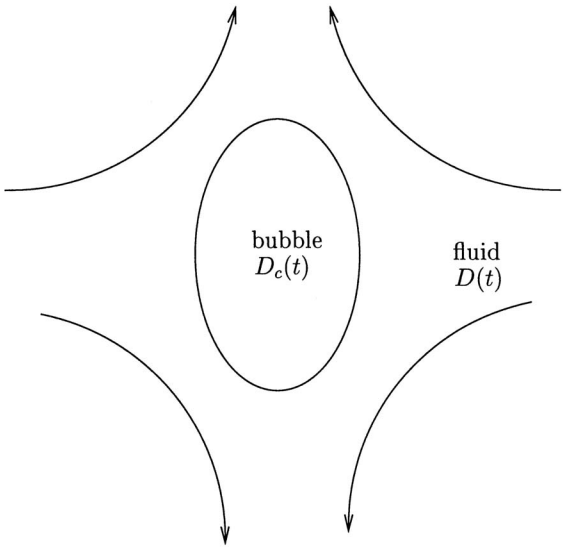

FIG. 1. *Schematic illustrating the bubble region $D_c(t)$ and the fluid region $D(t)$. There is a singular flow field at infinity.*

where κ is the surface curvature (assumed positive for a convex surface), p is the pressure exterior to the bubble, $\mathbf{n}$ is a unit normal pointing outward from the bubble, and

$$e_{jk} = \frac{1}{2}\left(\frac{\partial u_j}{\partial x_k} + \frac{\partial u_k}{\partial x_j}\right)$$

is the rate of strain tensor. In (5) we have assumed that velocities are nondimensionalized by σ/μ, where σ is the surface tension, lengths are nondimensionalized by R, the undeformed bubble radius, and p is nondimensionalized by σ/R. Additionally, time is nondimensionalized by $R\mu/\sigma$. The kinematic condition is that

$$\mathbf{u}\cdot\mathbf{n} = V_n \tag{6}$$

at each point on the interface.

The problem is now reformulated as a problem in analytic function theory following the formulation of Tanveer and Vasconcelos [23]. The general solution of (4) at each instant has the form

$$\psi = \mathrm{Im}[\bar{z}f(z,t) + g(z,t)], \tag{7}$$

where $z = x + iy$ and the overbar denotes complex conjugate. Here $f(z,t)$ and $g(z,t)$ are the *Goursat functions* which are analytic everywhere in the fluid region $D(t)$. In terms of the Goursat functions, the following relations can easily be established:

$$\begin{aligned} p - i\omega &= 4f'(z,t), \\ u + iv &= -f(z,t) + z\overline{f'(z,t)} + \overline{g'(z,t)}, \\ e_{11} + ie_{12} &= z\overline{f''(z,t)} + \overline{g''(z,t)}, \end{aligned} \tag{8}$$

where ω is the vorticity and u, v are the x- and y-components of velocity. Defining s to be the arclength traversed in a counterclockwise direction around the bubble boundary $z(s,t)$, the stress boundary condition can be written in the form

$$f(z,t) + z\overline{f'(z,t)} + \overline{g'(z,t)} = -i\frac{z_s}{2} \quad \text{on } \partial D(t). \tag{9}$$

Using the second equation of (8) and (9), the kinematic condition can be written as

$$\operatorname{Im}\left[(z_t + 2f)\,\bar{z}_s\right] = -\frac{1}{2} \quad \text{on } \partial D(t). \tag{10}$$

Equations (9) and (10) are supplemented by boundary conditions on $f(z,t)$ and $g'(z,t)$ at infinity. In this paper we consider far-field conditions of the form

$$f(z,t) = f_n z^n + \cdots + f_0 + O\left(\frac{1}{z}\right), \tag{11}$$

$$g'(z,t) = g_m z^m + \cdots + g_0 + O\left(\frac{1}{z}\right). \tag{12}$$

2.2. Evolution of the Cauchy transform. Given the above formulation, it is instructive to consider the evolution of the Cauchy transform $C(z,t)$ introduced in (2). The following result is central to the subsequent developments in this paper.

THEOREM 2.1 (evolution of the Cauchy transform). *The Stokes flow problem described in section* 2.1 *is equivalent to the equation*

$$\frac{\partial C(z,t)}{\partial t} + \frac{\partial I(z,t)}{\partial z} = R(z,t) \tag{13}$$

together with (10) *and boundary condition* (11). *Here* $C(z,t)$ *and* $I(z,t)$ *are defined for* $z \in D_c(t)$ *(i.e., inside the bubble) by*

$$\begin{aligned} C(z,t) &= \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{\bar{z}'}{z'-z}dz', \\ I(z,t) &= \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{-2f(z',t)\bar{z}'}{z'-z}dz' \end{aligned} \tag{14}$$

and where the forcing term $R(z,t)$ *is given by*

$$R(z,t) = 2\left(g_m z^m + g_{m-1}z^{m-1} + \cdots + g_0\right). \tag{15}$$

Remark. The viscous sintering problem, which involves the evolution of fluid drops (rather than bubbles), has been investigated using the Cauchy transform approach by Crowdy [5]. There, the Cauchy transform of the domain was defined by the area integral

$$C(z,t) \equiv \frac{1}{\pi}\int\int_{D(t)} \frac{dx'dy'}{z'-z}. \tag{16}$$

In the case of a bounded fluid region, (16) is equivalent to our current definition (2), by the complex form of Green's theorem [1]. Note also that, in the viscous sintering problem, the inhomogeneous term $R(z,t)$ is absent since there are no singularities present to drive the flow; i.e., the flow is driven purely by surface tension. For the

Stokes bubbles considered here, the term $R(z,t)$ represents the forcing due to the singular behavior of the flow at infinity.

Remark. In the viscous sintering problem, [5] provides a proof of the forward result for Theorem 2.1, i.e., that a solution to the Stokes flow problem satisfies (13) (with $R(z,t)=0$). This paper provides the first proof of the "backward" result, and hence the equivalence of the two formulations. Although the proof here is for bubbles, it may easily be modified to the case of fluid drops.

Proof of Theorem 2.1. We first prove the "backward" result; i.e., we assume the existence of a solution $C(z,t)$, $f(z,t)$ to (10), (13) (with $f(z,t)$ analytic in $D(t)$ and having far-field behavior (11)) and show that (9) is satisfied for an appropriately defined $g'(z,t)$ that is analytic in the fluid domain $D(t)$ and satisfies (12). By direct differentiation we have

$$\frac{\partial C(z,t)}{\partial t} = -\frac{1}{2\pi i}\oint_{\partial D(t)} \frac{z_t' \bar{z}' dz'}{(z'-z)^2} + \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{(\bar{z}' dz')_t}{z'-z}. \tag{17}$$

Next, the kinematic condition (10) is rewritten in the form

$$(\bar{z}dz)_t = z_t d\bar{z} + \bar{z}(dz_t) + 2f d\bar{z} - 2\bar{f}dz + ids. \tag{18}$$

Substituting (18) into (17) gives the equation

$$\begin{aligned}\frac{\partial C(z,t)}{\partial t} &= \frac{1}{2\pi i}\oint_{\partial D(t)} \left[\frac{-z_t' \bar{z}' dz'}{(z'-z)^2} + \frac{{z'}_t d\bar{z}' + \bar{z}'(dz')_t}{z'-z}\right] \\ &\quad + \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2f(z',t)d\bar{z}' - 2\overline{f}(z',t)dz' + ids}{z'-z}.\end{aligned} \tag{19}$$

The terms in square brackets represent a total (spatial) differential of ${z'}_t\bar{z}'/(z'-z)$ which is assumed to be single-valued. Therefore the first integral term is zero. After replacing $\partial C/\partial t$ using (13), we obtain

$$\begin{aligned}R(z,t) &+ \frac{1}{2\pi i}\frac{\partial}{\partial z}\oint_{\partial D(t)} \frac{2f(z',t)\bar{z}'}{z'-z}\, dz' \\ &- \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2f(z',t)d\bar{z}' - 2\overline{f}(z',t)dz' + ids}{z'-z} = 0.\end{aligned} \tag{20}$$

But

$$\begin{aligned}\frac{1}{2\pi i}\frac{\partial}{\partial z}\oint_{\partial D(t)} \frac{f(z',t)\bar{z}'}{z'-z}\, dz' &= \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{f(z',t)\bar{z}'}{(z'-z)^2}\, dz' \\ &= \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{f_{z'}(z',t)\bar{z}' + f(z',t)\bar{z}'_{z'}}{z'-z}\, dz',\end{aligned} \tag{21}$$

where the subscript z' denotes partial differentiation, and the latter equality follows after integration by parts. Substituting (21) into (20) then yields

$$R(z,t) + \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{\left(2f_{z'}(z',t)\bar{z}' + 2\overline{f}(z',t)\right) - ids}{z'-z} = 0. \tag{22}$$

It is convenient to introduce the notation

$$\tilde{f}(z,t) = f(z,t) - (f_n z^n + \cdots + f_0)$$

so that $\tilde{f}(z,t)$ represents the component of $f(z,t)$ that decays to zero as $z \to \infty$. By the well-known properties of Cauchy integrals, we have for $z \in D_c(t)$

$$\frac{1}{2\pi i} \oint_{\partial D(t)} \frac{\tilde{f}(z',t)}{z'-z}\, dz' = 0, \tag{23}$$

$$\frac{1}{2\pi i} \frac{\partial}{\partial z} \oint_{\partial D(t)} \frac{\tilde{f}(z',t)}{z'-z}\, dz' = 0, \tag{24}$$

$$\frac{1}{2\pi i} \oint_{\partial D(t)} \frac{R(z',t)}{z'-z}\, dz' = R(z,t). \tag{25}$$

Equation (22) is now modified by adding twice the conjugate of (23) and the product of $2\bar{z}$ with (24) to it. After employing (25), the modified equation is written as

$$\overline{\Phi}(z,t) + \bar{z}\Phi'(z,t) + \Psi(z,t) = 0 \tag{26}$$

for $z \in D_c(t)$, where

$$\Phi(z,t) = \frac{1}{2\pi i} \oint_{\partial D(t)} \frac{2\tilde{f}(z',t)}{z'-z}\, dz', \tag{27}$$

$$\Psi(z,t) = \frac{1}{2\pi i} \oint_{\partial D(t)} \frac{R(z',t) + 2f_{z'}(z',t)\bar{z}' + 2\overline{f}(z',t)}{z'-z}\, dz',$$

$$- \frac{1}{2\pi i} \oint_{\partial D(t)} \frac{ids}{z'-z}. \tag{28}$$

Additionally, upon taking the limit of (26) as $z \to \tau$, a point on the boundary of $D_c(t)$, we obtain the relation

$$\overline{\Phi}(\tau,t) + \bar{\tau}\Phi'(\tau,t) + \Psi(\tau,t) = 0. \tag{29}$$

The functions $\Phi(z,t)$ and $\Psi(z,t)$ are analytic in $D_c(t)$, and the boundary condition (29) is identical to the one satisfied by the Goursat functions in the plane problem of the theory of elasticity for the region $D_c(t)$, under the assumption that the boundary of the region is free from the action of external forces. It follows from the theorem of uniqueness [15] of the solution to the plane problem of elasticity that

$$\Phi(z,t) = i\alpha z + \beta,$$
$$\Psi(z,t) = -\bar{\beta},$$

where α is a real and β is a complex constant. But from (23), $\Phi(z) = 0$ in $D_c(t)$, implying that $\alpha = \beta = 0$. Hence

$$\Phi(z,t) = 0, \qquad \Psi(z,t) = 0. \tag{30}$$

From the second identity of (30) it is concluded that the following function may be analytically continued to $D(t)$:

$$\chi(z,t) = g_m z^m + \cdots + g_0 + \overline{f}(z,t) + \bar{z}f'(z,t) - \frac{i}{2z_s}.$$

Upon associating $g'(z,t)$ with $g_m z^m + \cdots + g_0 - \chi(z,t)$, it is concluded that (10)–(13) determine $f(z,t)$ and $g'(z,t)$ as analytic functions in $D(t)$ that satisfy the boundary condition (9) and far-field condition (12). This proves the "backward" result.

We next consider the "forward" problem; i.e., we show that the Stokes problem (9)–(12) implies (13). First, take the conjugate of (9) and use the fact that $z_s\bar{z}_s = 1$ to write the stress condition in the form

$$2\bar{f}dz + 2\bar{z}df + 2dg = ids.$$

This equation is combined with the kinematic condition (10) to give

$$(\bar{z}dz)_t = 2dg + 2d(\bar{z}f) + \bar{z}dz_t + z_t d\bar{z}. \tag{31}$$

Substituting (31) into (17) then yields the equation

$$\frac{\partial C(z,t)}{\partial t} = \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2g'(z',t)dz'}{z'-z} + \frac{2d(\bar{z}'f)}{z'-z} + \left[-\frac{z_t'\bar{z}'dz'}{(z'-z)^2} + \frac{\bar{z}'(dz')_t}{z'-z} + \frac{z_t'd\bar{z}'}{z'-z}\right].$$

The terms in square brackets represent a total (spatial) differential and therefore give zero total contribution to the integral. The first integral term on the right-hand side is rewritten using

$$\frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2g'(z',t)}{z'-z}\,dz' = 2(g_m z^m + \cdots + g_0) = R(z,t).$$

Finally, using integration by parts on the second integral term and rearranging, we obtain (13), which completes the proof. □

2.3. Analytic continuation inside the fluid region. The functions $C(z,t)$, $I(z,t)$, and $R(z,t)$ defined by the integrals (14) and (15) are all analytic inside the bubble. We now consider the analytic continuations of these functions inside the fluid domain $D(t)$, i.e., exterior to the bubble. By the continuation principle, (13) is also the equation relating these (analytically continued) functions inside $D(t)$.

It is assumed that the bubble boundary $\partial D(t)$ is an analytic curve. This implies that there exists a (unique) function (known as the *Schwarz function* of the curve [11]) analytic inside an annular domain containing the curve $\partial D(t)$ which satisfies the equation

$$\bar{z} = S(z,t) \tag{32}$$

everywhere on the curve $\partial D(t)$. But, by the Plemelj formulae,

$$S(z,t) = C(z,t) - C_i(z,t), \tag{33}$$

$$-2f(z,t)S(z,t) = I(z,t) - I_i(z,t), \tag{34}$$

$$2g'(z,t) = R(z,t) - R_i(z,t), \tag{35}$$

where, for $z \in D(t)$, the functions $C_i(z,t)$, $I_i(z,t)$, and $R_i(z,t)$ are given by the integrals

$$C_i(z,t) = \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{\bar{z}'}{z'-z}dz', \tag{36}$$

$$I_i(z,t) = \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{-2f(z',t)\bar{z}'}{z'-z}dz', \tag{37}$$

$$R_i(z,t) = \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2g'(z',t)}{z'-z}dz'. \tag{38}$$

The formulae (33)–(35) provide expressions for the analytic continuations of $C(z,t)$, $I(z,t)$, and $R(z,t)$ into the fluid domain $D(t)$.

2.4. Conservation of finite poles of $C(z,t)$. The following result will be useful in constructing exact solutions to the Stokes flow problem (10)–(13).

Let $C(z,t)$, $f(z,t)$ be solutions to (10)–(13). If $C(z,0)$ initially has a pole at a finite point $z_j(0)$ inside the fluid domain, then (provided the solution exists) $C(z,t)$ continues to have a pole at the point $z_j(t)$, where $z_j(t)$ satisfies the ODE

$$\dot{z}_j(t) = -2f(z_j(t),t). \tag{39}$$

To derive the result, first note that the complex form of Green's theorem [1] can be used to write $I(z,t)$ in the form

$$I(z,t) = -\frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2f(z',t)-2f(z,t)}{z'-z}\ \bar{z}'dz' - 2f(z,t)C(z,t). \tag{40}$$

Define the function $\Sigma(z,t)$ as

$$\Sigma(z,t) = -\frac{1}{2\pi i}\oint_{\partial D(t)} \frac{2f(z',t)-2f(z,t)}{z'-z}\ \bar{z}'dz'. \tag{41}$$

The singularity of the integrand in (41) is removable, and $\Sigma(z,t)$ is therefore analytic in $D(t)$. Thus,

$$I(z,t) = \Sigma(z,t) - 2f(z,t)C(z,t), \tag{42}$$

which, when substituted into (13), yields the following PDE for the Cauchy transform:

$$\frac{\partial C}{\partial t} - 2f(z,t)\frac{\partial C}{\partial z} - 2\frac{\partial f(z,t)}{\partial z}C(z,t) + \frac{\partial \Sigma}{\partial z}(z,t) = R(z,t). \tag{43}$$

This equation also governs the analytic continuation of $C(z,t)$ inside $D(t)$. But inside $D(t)$, (43) has the form of a first-order linear equation for $C(z,t)$ with coefficients that are known a priori to be analytic in $D(t)$. Thus, provided they exist, solutions for $C(z,t)$ will have the same analytic structure inside $D(t)$ as solutions of a first-order linear PDE with analytic coefficients. Using the well-known theory of such equations, it is deduced that the pole singularities are preserved and move on characteristics. In this case,

$$-\dot{z}_j(t) - 2f(z_j(t),t) = 0, \tag{44}$$

and the result is demonstrated.

Remark. Note that the above result says nothing about any singularities of $C(z,t)$ at infinity. In the present application, the coefficient function $f(z,t)$ is singular at infinity (and, in the language of ODEs [13], is therefore a *fixed singularity* of (43)).

Moreover, depending on the far-field flow, $R(z,t)$ may also be singular at infinity. The behavior of $C(z,t)$ at $z \to \infty$ must be examined by a local analysis of (13) in each case. Such an analysis will be seen to be crucial in determining whether $C(z,t)$ can consistently preserve a rational function form under evolution, i.e., satisfy the closure condition. When this is the case, the pole at infinity does not move into the finite complex plane. These issues are discussed further in section 3.

Remark. The results of this section are closely related to the results of section 4.5 of Cummings, Howison, and King [10], where rather different arguments are used.

2.5. Circulation theorem and conserved quantities. In the context of the viscous sintering problem, Crowdy [5] derived a circulation theorem which provides the existence of conserved quantities associated with certain choices of initial conditions. This theorem can be extended to the case of a bubble in an infinite flow.

Let the curve γ_j be a *fixed* closed curve surrounding the isolated pole singularity $z_j(t) \in D(t)$. Because $z_j(t)$ moves at finite speed (see (39)), γ_j can always be chosen so that it continues to enclose the (moving) singularity $z_j(t)$, at least for sufficiently short times. Consider the circulation-type quantity

$$\oint_{\gamma_j} C(z,t)dz. \tag{45}$$

Because γ_j is assumed fixed, we have

$$\frac{d}{dt}\oint_{\gamma_j} C(z,t)dz = \oint_{\gamma_j} \frac{\partial C(z,t)}{\partial t}dz = \oint_{\gamma_j} \left(-\frac{\partial I(z,t)}{\partial z} + 2g'(z,t) + R_i(z,t)\right) dz. \tag{46}$$

But $R_i(z,t)$ is analytic everywhere inside γ_j, as is $g'(z,t)$ if the flow has no singularities in the finite plane. Use of Cauchy's theorem then implies that

$$\frac{d}{dt}\oint_{\gamma_j} C(z,t)dz = -\left[I(z,t)\right]_{\gamma_j}, \tag{47}$$

where the square bracket denotes the change in $I(z,t)$ around the contour γ_j. But, by (33) and (34), while $I(z,t)$ has a simple pole at $z_j(t)$, it is single-valued so that the right-hand side of (47) vanishes. This implies that

$$\oint_{\gamma_j} C(z,t)dz = A_j(t), \qquad j = 1, \ldots, N, \tag{48}$$

are constants of the motion, i.e.,

$$A_j(t) = A_j(0). \tag{49}$$

Note that in (48) we have used the fact that the simple pole of $C(z,t)$ at $z_j(t)$ is preserved in time.

The existence of the above conserved quantities has not been pointed out in any previous studies of bubbles in ambient Stokes flows. It is, however, closely related to a similar result that has been observed in the context of evolving viscous blobs [5, 17, 6].

3. Exact solutions. The advantage of considering the Cauchy transform $C(z,t)$ is that its evolution equation is particularly simple. In certain situations, it will be seen that $C(z,t)$ can retain a rational function form under evolution. In this case, the corresponding solutions will be called *exact* in the sense that the evolution depends on just a *finite set* of time-evolving parameters. As an example of the simplicity of the evolution equations, suppose $C(z,0)$ is rational with a finite distribution of simple pole singularities. Suppose too that it is known that $C(z,t)$ preserves this functional form under evolution. Then, if $C(z,0)$ has the form

$$C(z,0) = \sum_{j=1}^{N} \frac{A_j(0)}{z - z_j(0)}, \tag{50}$$

then, by the results above, $C(z,t)$ has the form

$$C(z,t) = \sum_{j=1}^{N} \frac{A_j(0)}{z - z_j(t)}, \tag{51}$$

where

$$\dot{z}_j(t) = -2f(z_j(t),t), \qquad j = 1,\dots,N. \tag{52}$$

With the singularities under control at all regular points of the evolution equation (13), the question of whether $C(z,t)$ can consistently preserve a given rational function form must be determined by a local analysis of (13) at the fixed singularity at infinity. This will be illustrated in the context of the examples considered in section 3.1.

Even supposing that $C(z,t)$ indeed evolves as a rational function, it still remains to reconstruct the corresponding time-evolving domain from knowledge of the Cauchy transform. This can be done using conformal maps, but it is important to observe that in the case of unbounded domains such as here, knowledge of the Cauchy transform does not uniquely determine the unbounded domain. Rather, it determines it only up to a real degree of freedom which can be associated with the freedom to specify the bubble area. The appendix provides a discussion of this point in terms of the inverse problem of 2-D potential theory.

None of the authors Antanovskii [2], Siegel [22], or Tanveer and Vasconcelos [23] use the above formulation but instead make direct use of a conformal map formulation in a parametric ζ-plane. It is instructive to retrieve the conformal mapping solutions of [2, 22, 23] using the above perspective. In this way, certain advantages of the Cauchy transform formulation will become apparent. In particular, we gain important insight into the bubble area evolution in each case and see exactly when it is possible to specify it externally.

We note that, in the process of retrieving the conformal mapping solutions of [2, 22, 23], the values of $f(z_j(t),t)$ are computed with the aid of the conformal map. One can bypass the introduction of a conformal map and compute f from the kinematic condition (10) by using an alternative representation of the boundary (e.g., algebraic curves; see [8]). Although this may require the use of a boundary integral numerical calculation, one still has the advantage of a finite/exact representation of the interface, since the preserved rational function form of the Cauchy transform implies that the shape can be described by a small finite number of parameters.

3.1. Exact solutions of Tanveer and Vasconcelos [23].

3.1.1. The Cauchy transform. Tanveer and Vasconcelos assume that the far-field form of $f(z,t)$ and $g'(z,t)$ are of the form

$$f(z,t) \sim f_1 z + \mathcal{O}(1), \tag{53}$$

$$g'(z,t) \sim g_1 z + \mathcal{O}(1). \tag{54}$$

Specifically, in the notation of Tanveer and Vasconcelos [23],

$$f_1 = \frac{1}{4}\left(\frac{p_\infty(t)}{\mu} - i\omega_0\right) \tag{55}$$

and

$$g_1 = \frac{1}{2}\left(\alpha_0 - i\beta_0\right). \tag{56}$$

$p_\infty(t)$ and ω_0 are the fluid pressure and vorticity in the far-field, respectively, while α_0 and β_0 characterize the strain rates of a linear straining flow at infinity.

As an illustrative example, we take the first case considered by Tanveer and Vasconcelos [23], that is, a bubble in a shear flow of the form

$$\mathbf{u} = (\Gamma y, 0). \tag{57}$$

This corresponds to the far-field values $\alpha_0 = 0$ and $\beta_0 = -\omega_0 = \Gamma$ in the notation of (55) and (56), or equivalently

$$f_1 = \frac{i\Gamma}{4}, \qquad g_1 = -\frac{i\Gamma}{2} \tag{58}$$

in the notation of (53) and (54).

Tanveer and Vasconcelos [23] show the existence of exact solutions that are polynomial maps, i.e., of the form (1) with $b_i = 0$. To retrieve these, let us seek solutions in which $C(z,t)$ has the rational function form

$$C(z,t) = A(t)z; \tag{59}$$

that is, the only singularity of $C(z,t)$ in the fluid region is a single simple pole singularity at infinity. It is necessary to check that this is a consistent solution of (13). To do this, we analyze (13) in the neighborhood of infinity and find that we require

$$\frac{\partial}{\partial t}\left(A(t)z\right) + \frac{\partial}{\partial z}\left(-2f_1 z(A(t)z)\right) + o(z) = 2g_1 z + o(z). \tag{60}$$

This is consistent, provided $A(t)$ satisfies

$$\dot{A}(t) - 4f_1 A(t) = 2g_1, \tag{61}$$

where this equation comes from equating coefficients of z in (60).

3.1.2. Conformal mapping. We now consider the conformal maps for which the corresponding Cauchy transform $C(z,t)$ has the form (16). Consider, for example, the mapping from the unit ζ-disc given by

$$z(\zeta,t) = \frac{a}{\zeta} + b\zeta, \tag{62}$$

where a and b are functions of time and where a can be assumed real (using a rotational degree of freedom of the Riemann mapping theorem). Note that, on the unit ζ-circle,

$$\bar{z} = a\zeta + \frac{\bar{b}}{\zeta}. \tag{63}$$

From (62) we have that

$$\frac{1}{\zeta} = \frac{z}{a} - \frac{b}{a}\zeta. \tag{64}$$

Using (64) in (63) we obtain

$$\bar{z} = \frac{\bar{b}}{a}z + \left(a - \frac{|b|^2}{a}\right)\zeta, \tag{65}$$

which is valid on the unit ζ-circle. By comparison with (33) we make the identifications

$$C(z,t) = \frac{\bar{b}}{a}z, \qquad C_i(z,t) = -\left(a - \frac{|b|^2}{a}\right)\zeta(z,t), \tag{66}$$

where we have also used the fact that $C_i(z,t)$ decays at infinity. This shows that all conformal maps of the form (62) have corresponding Cauchy transforms of the form (16) with

$$A = \frac{\bar{b}}{a}. \tag{67}$$

Note that a and b can be multiplied by any real constant (corresponding to changing the area of the elliptical bubble) and the Cauchy transform (16) remains unchanged. A degree of freedom is therefore available, and this is used up, following Tanveer and Vasconcelos [23], by specifying the area of the bubble to be fixed in time, i.e.,

$$a^2 - |b|^2 = R^2, \tag{68}$$

where R is constant. (Alternatively, one can specify the bubble area to be an arbitrary function of time, corresponding to the presence of a source or sink at infinity.) This gives one equation relating a and b as derived by Tanveer and Vasconcelos [23]. The second equation obtained by them is

$$\frac{d(ab)}{dt} = -(2I_0 + i\Gamma)ab + i\Gamma a^2, \tag{69}$$

where $I_0 = I(0,t)$ and

$$I(\zeta,t) = \frac{1}{4\pi i}\oint_{|\zeta'|=1} \frac{d\zeta'}{\zeta'}\left[\frac{\zeta+\zeta'}{\zeta'-\zeta}\right]\frac{1}{|z_\zeta(\zeta',t)|}. \tag{70}$$

This equation must, of course, be equivalent to (61). To see this, note that upon applying the Poisson integral formula [1] to the kinematic condition it can be shown that

$$z_t(\zeta,t) + 2f(z(\zeta,t),t) = \zeta\left[I(\zeta,t) + \frac{i\omega_0}{2}\right] z_\zeta(\zeta,t) \tag{71}$$

(see Tanveer and Vasconcelos [23]). Substituting the conformal map (62) into this equation and equating powers of ζ^{-1} provides

$$\dot{a} + 2f_1 a = -a\left(I_0 + \frac{i\omega_0}{2}\right). \tag{72}$$

Eliminating f_1 in (61) using (72), as well as using (67) and (58), gives the required (69).

3.2. Exact solutions of Antanovskii [2]. Antanovskii [2] assumes the far-field asymptotic form of $f(z,t)$ and $g'(z,t)$ to be

$$f(z,t) \sim f_1 z + \mathcal{O}(1/z), \tag{73}$$

$$g'(z,t) \sim g_m z^m + \mathcal{O}(1/z), \tag{74}$$

where $m \geq 1$ is some positive integer and f_1 is some real time-dependent function that is independent of z. This gives rise to a situation in which the far-field flow is irrotational and given by an mth order straining flow.

Anticipating the form of the singularity in $C(z,t)$ at infinity in order to satisfy the closure condition, we seek solutions in which $C(z,t)$ is an mth order polynomial, i.e.,

$$C(z,t) = A_m z^m + A_{m-1} z^{m-1} + \cdots + A_1 z. \tag{75}$$

Analyzing the singularity of (13) at infinity gives the equations

$$\begin{aligned}
\dot{A}_m - 2(m+1)f_1 A_m &= 2g_m,\\
\dot{A}_{m-1} - 2m f_1 A_{m-1} &= 0,\\
\dot{A}_{m-2} - 2(m-1)f_1 A_{m-2} &= 0,\\
&\cdots\\
\dot{A}_1 - 2f_1 A_1 &= 0.
\end{aligned} \tag{76}$$

First, it is immediately clear that if $A_{m-1}(0) = A_{m-2}(0) = \cdots = A_1(0) = 0$, then $A_{m-1}(t) = A_{m-2}(t) = \cdots = A_1(t) = 0$. It therefore remains only to satisfy the equation for A_m, viz.,

$$\dot{A}_m - 2(m+1)f_1 A_m = 2g_m. \tag{77}$$

3.2.1. Conformal mapping. Now consider the class of conformal maps given by

$$z(\zeta,t) = \frac{a}{\zeta} + b\zeta^m, \tag{78}$$

where a is again assumed to be real. On the unit ζ-circle we have

$$\overline{z}(\zeta^{-1},t) = a\zeta + \frac{\overline{b}}{\zeta^m}. \tag{79}$$

But from (78),

$$\frac{1}{\zeta} = \frac{z}{a} - \frac{b}{a}\zeta^m, \tag{80}$$

which, when substituted into (79), gives

$$S(z(\zeta)) = \overline{z}(\zeta^{-1},t) = a\zeta + \overline{b}\left(\frac{z}{a} - \frac{b}{a}\zeta^m\right)^m \tag{81}$$

from which, by comparison with (33), we deduce that

$$C(z,t) = \frac{\overline{b}}{a^m} z^m. \tag{82}$$

Thus, all maps of the form (78) yield Cauchy transforms of the form $C(z,t) = A_m z^m$ with

$$A_m = \frac{\overline{b}}{a^m}. \tag{83}$$

Note again that b and a can be multiplied by a real number without changing $C(z,t)$, while the only equation to be satisfied is (77). Thus, the relevant evolution equations for the two parameters a and b are (77) along with an area evolution equation which may be arbitrarily specified. These can be shown to be equivalent to those given in equation (37) of Antanovskii [2].

3.3. Exact solutions of Siegel [22].

3.3.1. The Cauchy transform. Siegel [22] assumes the far-field asymptotic form of $f(z,t)$ and $g'(z,t)$ to be

$$f(z,t) \sim f_3 z^3 + f_1 z + \mathcal{O}(1/z), \tag{84}$$

$$g'(z,t) \sim g_1 z + \mathcal{O}(1/z). \tag{85}$$

f_3 and g_1 are externally specifiable and will be taken to be constant in time (g_1 gives a measure of an imposed irrotational straining flow at infinity, while f_3 produces a rotational far-field component). Such boundary conditions in which $f(z)$ is a nonlinear function of z in the far field will be referred to as *nonlinear* far field conditions. Siegel [22] makes the choices

$$g_1 = 1, \qquad f_3 = \frac{\epsilon}{2}. \tag{86}$$

Antanovskii [3] derived exact *steady* solution for the bubble shape subject to the above far-field conditions. The analysis of Siegel [22] essentially generalizes the results of Antanovskii [3] to the case where the bubble evolves in a quasi-steady, time-dependent manner.

Suppose we seek solutions to (13) in which $C(z,t)$ evolves as

$$C(z,t) = \sum_{j=1}^{N} \frac{A_j(t)}{z - z_j(t)} \tag{87}$$

for all times. It is clear that

$$C(z,t) \sim \frac{B(t)}{z} \quad \text{as } z \to \infty, \tag{88}$$

where

$$B(t) = \sum_{j=1}^{N} A_j(t). \tag{89}$$

By the circulation theorem, all the quantities $\{A_j(t)\}$ are constants of the motion. This implies, by (89), that $B(t)$ is also a constant of the motion. Moreover, all the poles $\{z_j(t)\}$ move according to (52). The Cauchy transform is determined at each instant by these equations.

As mentioned earlier, it is important to verify that the solution (87) is a consistent solution of (13) at the fixed singularity at the point at infinity. To see this, note from (36) that

$$C_i(z,t) \sim -\frac{1}{2\pi i}\left(\oint_{\partial D(t)} \bar{z}' dz'\right)\frac{1}{z} + \mathcal{O}(1/z^2), \tag{90}$$

while, from (37),

$$I_i(z,t) \sim \mathcal{O}\left(\frac{1}{z}\right) \tag{91}$$

as $z \to \infty$. But the area of the bubble (denoted $\mathcal{A}$) is precisely

$$\mathcal{A} = \frac{1}{2i}\oint_{\partial D(t)} \bar{z}' dz'. \tag{92}$$

Therefore, using (33) and (88),

$$S(z) = \frac{B(t) + \mathcal{A}/\pi}{z} + \mathcal{O}\left(\frac{1}{z^2}\right) \tag{93}$$

as $z \to \infty$. Inside the fluid domain $D(t)$, (13) takes the form

$$\frac{\partial C(z,t)}{\partial t} + \frac{\partial}{\partial z}\left[-2f(z,t)S(z,t) + I_i(z,t)\right] = 2g'(z,t) + R_i(z,t). \tag{94}$$

A local analysis of this equation as $z \to \infty$ therefore implies that

$$\frac{\partial}{\partial z}\left(-2f_3 z^3\left(\frac{B}{z} + \frac{\mathcal{A}/\pi}{z}\right)\right) + \mathcal{O}(1/z) = 2g_1 z + \mathcal{O}(1/z) \tag{95}$$

so that, equating coefficients of the singularity at $\mathcal{O}(z)$, we have

$$-2(\mathcal{A}/\pi + B)f_3 = g_1. \tag{96}$$

This is a necessary condition if the solution (87) is to be a consistent solution of (13).

It is crucial to note that if $C(z,t)$ is determined at each instant, then, in contrast to the previous examples of Tanveer and Vasconcelos [23] and Antanovskii [2], (96) represents an *additional* constraint on the free boundary evolution. In this case, there is no freedom to externally specify the bubble area evolution. Rather, it is determined implicitly by the exact solution itself. Since A has been shown to be a constant of the motion, (96) implies that, for solutions of the form (87), the area $\mathcal{A}$ of the bubble is necessarily fixed in time if f_3 and g_1 are constant (independent of time), which has been assumed to be the case, i.e.,

$$\mathcal{A} = -\pi \left(B + \frac{g_1}{2f_3} \right). \tag{97}$$

The initial area of the bubble therefore dictates the value of B.

In summary, solutions of (13) in which $C(z,t)$ is rational with a finite set of simple pole singularities (and for which $f(z,t)$ and $g'(z,t)$ have the far-field form (53) and (54)) are admitted, and, in these solutions, the bubble area remains constant. If we seek solutions in which the bubble area is not fixed in time (but varies, for example, at some externally specified rate Q), the solutions will not be such that the Cauchy transform has the far-field behavior (88) for all times $t > 0$. In that case, the functional form of the Cauchy transform will not be of the proposed simple rational character and will not lend itself to exact solutions.

3.3.2. Conformal maps. The corresponding conformal maps from a unit ζ-disk to fluid domains whose Cauchy transforms have a finite distribution of simple pole singularities with the far-field behavior (88) are given by rational functions of the form

$$z(\zeta,t) = \frac{C}{\zeta} \left(\frac{\prod_{j=1}^{N} (\zeta - \eta_j(t))}{\prod_{j=1}^{N} (\zeta - \zeta_j(t))} \right), \tag{98}$$

where C can be assumed real (to use up the rotational degree of freedom in the Riemann mapping theorem). It follows that

$$\overline{z}(\zeta^{-1},t) = C\zeta \left(\frac{\prod_{j=1}^{N} (1 - \zeta\bar{\eta}_j(t))}{\prod_{j=1}^{N} (1 - \zeta\bar{\zeta}_j(t))} \right). \tag{99}$$

It is clear that because $S(z,t) = \bar{z}$, this class of domains is such that the far-field asymptotic form of $C(z,t)$ is of the form in (88). It is also clear that

$$z_j(t) = \overline{z(\zeta_j,t)} \tag{100}$$

so that the N equations (39) can be viewed as providing evolution equations for the parameters $\{\zeta_j(t) | j = 1,\ldots,N\}$. The N constants of motion derived from the circulation theorem (by taking a contour γ_j around each distinct pole $z_j(t)$) provide N additional equations for the parameters $\{\eta_j(t) | j = 1,\ldots,N\}$. Finally, the parameter C is determined by condition (96). Equivalently, one could determine C by ensuring that the bubble area is conserved under evolution.

Siegel [22] considers one of the above solutions in detail. This solution has a mapping given by the special choice

$$z(\zeta,t) = \frac{1}{\zeta} \frac{\gamma_0 + \gamma_1\zeta^2}{1 - \gamma_2\zeta^2}. \tag{101}$$

It is straightforward to see that this map corresponds to domains with the Cauchy transform

$$C(z,t) = \frac{E(t)}{z - z_0(t)} + \frac{E(t)}{z + z_0(t)}, \tag{102}$$

where

$$z_0(t) = z(\sqrt{\gamma_2}, t). \tag{103}$$

In this case,

$$C(z,t) \sim \frac{2E(t)}{z} \quad \text{as } z \to \infty. \tag{104}$$

The relevant equations of motion for this solution are

$$\dot{z}_0(t) = -2f(z_0(t), t), \tag{105}$$

$$E(t) = E(0), \tag{106}$$

$$-\left(\frac{\mathcal{A}}{\pi} + 2E\right) = \frac{g_1}{2f_3}, \tag{107}$$

where the last equation is just (96). Equations (105) and (106) determine $C(z,t)$ at each instant, while (107) additionally constrains the bubble area to be fixed in time. This additional constraint is absent in the solutions of [23] and [2].

The three equations obtained by Siegel [22] are

$$\dot{\gamma}_2 = -2\gamma_2 \left[I(\sqrt{\gamma_2}, t) - \epsilon \frac{\gamma_0^2}{\gamma_2} \right], \tag{108}$$

$$\gamma_1 = \frac{\gamma_2}{\epsilon \gamma_0}, \tag{109}$$

$$\gamma_0 = \left[\frac{2(1+\gamma_1^2)}{c_1 + (c_1^2 - c_2)^{1/2}} \right]^{1/2}, \tag{110}$$

where condition (110) derives from the fact that the bubble area is taken to be constant and equal to π. c_1 and c_2 are defined as

$$c_1 = 1 - \epsilon\gamma_1^2 \left(2(1-\epsilon) + \epsilon\gamma_1^2\right) \quad \text{and} \quad c_2 = 4\epsilon^2\gamma_1^2(1+\gamma_1^2)\left[3 + \epsilon(2+\epsilon)\gamma_1^2\right], \tag{111}$$

while

$$I(\zeta, t) = \frac{1}{2\pi i} \oint_{|\zeta'|=1} \frac{d\zeta'}{\zeta'} \left[\frac{\zeta' + \zeta}{\zeta' - \zeta}\right] \left\{ \frac{1}{|z_\zeta|} + \mathrm{Re}\left[\frac{\epsilon\gamma_0^2}{\zeta^2}\right] \right\}. \tag{112}$$

We now indicate how (105)–(107) are equivalent to (108)–(110). First we use the fact, as derived by Siegel [22], that

$$z_t(\zeta, t) + 2f(z(\zeta,t),t) = \zeta z_\zeta(\zeta,t)\left(-\frac{\epsilon\gamma_0^2}{\zeta^2} + I(\zeta,t)\right) \tag{113}$$

to eliminate $f(z_0(t),t)$ from (105). This reproduces exactly (108). Next recall from (93) that as $z \to \infty$,

$$S(z) \sim \left(2E + \frac{\mathcal{A}}{\pi}\right)\frac{1}{z}. \tag{114}$$

But

$$\begin{aligned} S(z(\zeta,t)) = \overline{z(\zeta,t)} = &= \zeta\left(\frac{\gamma_0\zeta^2+\gamma_1}{\zeta^2-\gamma_2}\right) \\ &\sim -\frac{\gamma_1}{\gamma_2}\zeta \quad \text{as} \quad \zeta \to 0 \\ &\sim -\left(\frac{\gamma_1\gamma_0}{\gamma_2}\right)\frac{1}{z} \quad \text{as} \quad z \to \infty, \end{aligned} \tag{115}$$

where we have used that fact that $\zeta \sim \frac{\gamma_0}{z}$ as $z \to \infty$. Together, (114), (115), (86), and (107) yield Siegel's second equation (109). Finally, the equation for $S(z(\zeta,t),t)$ in (115) also yields the following equation for $E(t)$ in terms of the conformal mapping parameters, viz.,

$$E(t) = \frac{\gamma_0\gamma_2+\gamma_1}{2} z_\zeta(\sqrt{\gamma_2},t) = \frac{\gamma_0\gamma_2+\gamma_1}{2\gamma_2(1-\gamma_2^2)^2}\left(\gamma_1\gamma_2+\gamma_1\gamma_2^3-\gamma_0+3\gamma_0\gamma_2^2\right). \tag{116}$$

Using (116), (86), and the fact that $\mathcal{A} = \pi$ in (107) combine, after some further algebra, to retrieve Siegel's final equation (110).

Remark. The Cauchy transform formulation is crucial in proving that the bubble area is conserved for all maps of the form (98). This is because the bubble area $\mathcal{A}$ appears explicitly in the form of the far-field asymptotics of $C(z,t)$. To establish this general result using the direct conformal mapping approach of [23, 22] would be exceedingly difficult.

Remark. If the conformal map $z(\zeta,t)$ of the form (98) has N poles, the Cauchy transform formulation also immediately implies the existence of precisely N conserved quantities, one associated with each of the N poles.

3.4. A final example. We now give an example to show that the previous result is rather special and that, for general nonlinear flow conditions at infinity, while exact solutions to the problem exist, it is not generally possible to externally specify the bubble area evolution in these solutions.

A natural generalization of the far-field conditions considered in the previous three subsections is

$$f(z,t) \sim f_3 z^3 + f_1 z + \mathcal{O}(z^{-1}), \tag{117}$$

$$g'(z,t) \sim g_3 z^3 + g_1 z + \mathcal{O}(z^{-1}). \tag{118}$$

These far-field conditions are again nonlinear and are exactly those considered by Antanovskii [4] in his studies of the formation of cusped bubbles, although his analysis is restricted to the derivation of classes of exact *steady* solutions. The special case $g_3 = 0$ reduces to the far-field conditions considered in Antanovskii [3] and Siegel [22] (as well as in section 3.3). For this reason, one might expect the bubble area to again be constant under evolution. However, this is not the case, as will now be shown.

Suppose that we seek exact solutions in which $C(z,t)$ has the rational function form

$$C(z,t) = A_0(t)z + \sum_{k=1}^{N} \frac{A_k(t)}{z - z_k(t)} \tag{119}$$

for all times. As $z \to \infty$,

$$C(z,t) \sim A_0(t)z + \left(\sum_{k=1}^{N} A_k(t)\right) \frac{1}{z} + \ldots, \tag{120}$$

and this far-field form is forced by (13), as will be shown. First, it is known immediately that the points $\{z_k(t)|k = 1, 2, \ldots, N\}$ must satisfy

$$\dot{z}_k(t) = -2f(z_k(t), t), \qquad k = 1, \ldots, N, \tag{121}$$

while the circulation theorem implies that

$$A_k(t) = A_k(0), \qquad k = 1, \ldots, N. \tag{122}$$

It remains to determine the evolution of $A_0(t)$, as well as to ensure that (119) is a consistent solution of (13) at $z \to \infty$. Analyzing (13) as $z \to \infty$, at $\mathcal{O}(z^3)$ we get

$$-8f_3 A_0(t) = 2g_3, \tag{123}$$

which implies that $A_0(t)$ must also be constant. $C(z,t)$ is now completely determined, but we expect to be able to specify another degree of freedom associated with the bubble area $\mathcal{A}$. But at $\mathcal{O}(z)$, we get another equation having the form

$$-4\left(f_1 A_0 + f_3 \mathcal{A}\right) = 2g_1. \tag{124}$$

Equation (124) is a further constraint on the solution and can be thought of as an equation governing the bubble area $\mathcal{A}$. It is clear from (124) that the bubble area is not constant this time. Rather, how the bubble area evolves is governed by the exact solution itself. To see this, recall that f_1 (which is related to the far-field pressure evaluated in the near field of the bubble) is a time-evolving quantity whose evolution is governed by (113) and is not externally controllable.

Note that if g_3 is taken equal to zero (so that the far-field conditions of Siegel [22] are retrieved), then necessarily $A_0(t) = 0$ (by (123)), and then $\mathcal{A}$ turns out to be constant (by (124)).

4. Conclusion. We have introduced a Cauchy transform formulation of the problem of Stokes flow for a single bubble and proven its equivalence to the usual formulation of free surface Stokes flow. The new formulation has been used to derive a very broad class of exact solutions (namely, the class for which the Cauchy transform takes the form of a rational function), generalizing the set of solutions which have heretofore appeared in the literature. Indeed, it is surmised that the class of solutions discussed here is maximal, i.e., that it includes all cases for which the evolution is reducible to a finite-dimensional system of ODEs. We use our formulation to investigate when it is possible to externally specify the evolution of bubble area. This issue is extremely difficult to address using other approaches. In general, it is found that when the Goursat function $f(z)$ has a nonlinear far-field

behavior it is *not* possible to find exact solutions *and* specify the bubble area evolution. Instead the bubble area in such cases is determined by the exact solution. In the case of pure linear strain (so that $g'(z) \sim g_1 z$ as $z \to \infty$) it happens that the bubble area is constant, and this situation corresponds to a physically interesting case. However, this occurrence is somewhat coincidental.

Concerning generalizations, it is possible to extend the present formulation to the case of a more general compressible bubble with an externally specified equation of state relating its internal pressure (say, $p_B(t)$) to its area. Pozrikidis [16] has considered such problems using numerical boundary integral methods, while Crowdy [7] has generalized the solutions of Tanveer and Vasconcelos [23] to this case.

Appendix. Inverse problem of potential theory. In this appendix we explain why, in the case of a simply connected unbounded domain, knowledge of $C(z,t)$ determines the domain $D(t)$ up to a single real degree of freedom associated with specification of the bubble area.

Consider a smooth family of bounded, time-evolving, simply connected planar domains $D(t)$ in some time interval $t \in [0,T)$. Define the harmonic moments of these domains to be the integrals of a basis of all functions harmonic in $D(t)$ at time t. Suppose all the moments of $D(t)$ for $t \in [0,T)$ are known. It is a well-known result of the inverse problem of 2-D potential theory that the domains $D(t)$ can be uniquely reconstructed from knowledge of all these harmonic moments. Varchenko and Etingof [24] discuss this result in detail. For a bounded domain, if the Cauchy transform is defined as

$$C(z,t) = \frac{1}{\pi}\int\int_{D(t)} \frac{dx'dy'}{z'-z} = \frac{1}{2\pi i}\oint_{\partial D(t)} \frac{\bar{z}'dz'}{z'-z}, \tag{125}$$

then it is a generating function for the harmonic moments because, Laurent expanding for large $|z|$,

$$C(z,t) = \sum_{n=0}^{\infty} \frac{M_n}{z^{n+1}}, \tag{126}$$

where

$$M_n = \frac{1}{\pi}\int\int_{D(t)} z'^n dx'dy'. \tag{127}$$

The harmonic functions

$$\left\{ \mathrm{Re}\left[z^n\right],\ \mathrm{Im}\left[z^n\right] \middle| n = 0,1,2,\dots \right\} \tag{128}$$

span the space of functions harmonic in $D(t)$. The real and imaginary parts of the set of complex moments (127) generate all the harmonic moments of $D(t)$.

Exactly the same result pertains to the case of unbounded domains $D(t)$, except that if the moments are defined in terms of area integrals over $D(t)$, some of them do not exist, owing to the unboundedness of the domain. This is the reason for our choice of defining the Cauchy transform, from the outset, as the line integral

$$\frac{1}{2\pi i}\oint_{\partial D} \frac{\bar{z}'dz'}{z'-z}. \tag{129}$$

If $z \in D_c$, the Cauchy transform defines an analytic function $C(z,t)$, say. Assume D_c contains the origin. Then $C(z,t)$ has a Taylor expansion

$$C(z,t) = \sum_{n=0}^{\infty} M_n z^n, \tag{130}$$

where

$$M_n = \frac{1}{2\pi i} \oint_{\partial D} \frac{\bar{z}' dz'}{z'^{n+1}}. \tag{131}$$

Suppose now that $C(z,t)$ is known. This is equivalent to knowledge of the moments $M_n, n = 0, 1, \ldots$, from which it is possible to infer the values of the harmonic moments associated with the set of functions

$$\left\{ \mathrm{Re}\left[\frac{1}{z^{n+1}}\right],\ \mathrm{Im}\left[\frac{1}{z^{n+1}}\right] \middle| n = 0, 1, , \ldots \right\}. \tag{132}$$

This is a subspace of codimension one in the space of functions harmonic in $D(t)$ because it excludes the constant function 1, which is also harmonic in $D(t)$. Thus, knowledge of $C(z,t)$ is not quite enough to determine all harmonic moments—just one more moment is needed. Generalizing the set (131), the "moment" corresponding to the constant function 1 is

$$\frac{1}{2\pi i} \oint_{\partial D} \bar{z}' dz', \tag{133}$$

which is proportional to the area of the bubble. Thus, in the case of an unbounded simply connected domain $D(t)$, the Cauchy transform $C(z,t)$ determines the domain up to a single real degree of freedom associated with the area of the complement of $D(t)$ (here, the area of the bubble).

Acknowledgments. The authors wish to thank B. Gustafsson and S. Tanveer for useful discussions.

DYNAMICS OF TWO-STRAIN INFLUENZA WITH ISOLATION AND PARTIAL CROSS-IMMUNITY*

M. NUÑO†, Z. FENG‡, M. MARTCHEVA§, AND C. CASTILLO-CHAVEZ¶

Abstract. The time evolution of the influenza A virus is linked to a nonfixed landscape driven by interactions between hosts and competing influenza strains. Herd-immunity, cross-immunity, and age-structure are among the factors that have been shown to support strain coexistence and/or disease oscillations. In this study, we put two influenza strains under various levels of (interference) competition. We establish that cross-immunity and host isolation lead to periodic epidemic outbreaks (sustained oscillations) in this multistrain system. We compute the isolation reproductive number for each strain ($\Re_i$) independently, as well as for the full system ($\Re_q$), and show that when $\Re_q < 1$, both strains die out. Subthreshold coexistence driven by cross-immunity is possible even when the isolation reproductive number of one strain is below 1. Conditions that guarantee a winning type or coexistence are established in general. Oscillatory coexistence is established via Hopf bifurcation theory and confirmed via numerical simulations.

Key words. influenza, multiple strains, cross-immunity, isolation, stability, bifurcation, oscillations, coexistence

1. Introduction.

Several studies have focused on the identification of mechanisms capable of supporting multiple-strain coexistence for diseases that provide permanent or temporary immunity [19, 18]. Although there is still limited understanding on the role of cross-immunity (form of interference competition) between strains of a given virus, host variability (behavioral and immunological) is known to play a key role in maintaining virus diversity. Influenza epidemics and pandemics are closely linked to two types of mechanisms that maintain viral genetic diversity: antigenic "drift," the driver of strain heterogeneity, and antigenic "shift," the generator of subtype variability [28].

In 1918, the "Spanish Flu" pandemic caused the largest number of flu-related deaths worldwide in a single season [28]. More than 500,000 people died in the United States with 20–50 millions deaths worldwide. The "Asian Flu," a result of an antigenic shift in the hemmaglutinin and neuraminidase surface proteins, was responsible for about 70,000 deaths in the United States in 1969 [9]. The most recent and least lethal "pandemic," the "Hong Kong" pandemic, is attributed to the appearance of the H3N2 subtype [9].

The main focus of this paper is on the identification of competitive outcomes (mediated by cross-immunity) that result from the interactions between two strains of influenza A in a population where sick individuals may be isolated. Single-strain susceptible-infected-quarantined-recovered (SIQR) models with vital dynamics can generate sustained oscillations [15, 20]. The introduction of a second strain increases the competition for susceptibles, a process mediated by cross-immunity in our setting. Will such competition preclude the possibility of sustained multistrain oscillations? We show that coexistence of both strains in the oscillatory regime is not uncommon and that oscillatory dynamics are possible for reasonable values of influenza parameters [17, 11, 28].

Our paper is structured as follows. Section 2 introduces the general two-strain model; section 3 carries out the local stability analysis of the disease-free state; section 4 shows that periodic solutions can arise via a Hopf bifurcation; section 5 illustrates our theoretical results; section 6 summarizes our findings and collects some conclusions and thoughts.

2. Two-strain model. Theoretical work on two-strain models that incorporate the effects of interference competition in the context of communicable diseases goes back (at least) to the work of Dietz [13]. His work has been extended in the context of influenza [5, 1, 6]. None of these extensions considered the role of isolation. The study of mechanisms capable of generating sustained oscillations in single-strain epidemic models has received some attention in the last decades [19, 18]. Feng [14] and Feng and Thieme [15] showed that the introduction of an isolation class, in an otherwise standard SIR epidemiological model, is enough to generate sustained oscillations in single-strain models, but the region of parameter space where such oscillations are possible is unrealistic. Castillo-Chavez et al. [5, 6] provide support for the hypothesis that age-structure (age-dependent survival) and cross-immunity are enough to generate multistrain sustained oscillations in two-strain models without isolation. Here we show that cross-immunity in a two-strain system with isolation classes generate sustained oscillations within a region of parameter space that is consistent with the "flu" [11, 29, 24]. Furthermore, we identify the dependence of these regions on cross-immunity levels. The description of the two-strain model requires the division of the population into ten different classes: susceptibles (S), infected with strain i (I_i, primary infection), isolated with strain i (Q_i), recovered from strain i (R_i, as a result of primary infection), infected with strain i (V_i, secondary infection), given that the population had recovered from strains $j \neq i$, and recovered from both strains (W). The population is assumed to mix randomly, except that the mixing is impacted by the process of quarantine/isolation [14, 15, 20, 8]. Using the flow diagram in Figure 1, we arrive at the model

$$
\begin{aligned}
\frac{dS}{dt} &= \Lambda - \sum_{i=1}^{2} \beta_i S \frac{(I_i + V_i)}{A} - \mu S, \\
\frac{dI_i}{dt} &= \beta_i S \frac{(I_i + V_i)}{A} - (\mu + \gamma_i + \delta_i) I_i, \\
\frac{dQ_i}{dt} &= \delta_i I_i - (\mu + \alpha_i) Q_i, \\
\frac{dR_i}{dt} &= \gamma_i I_i + \alpha_i Q_i - \beta_j \sigma_{ij} R_i \frac{(I_j + V_j)}{A} - \mu R_i, \qquad j \neq i,
\end{aligned} \tag{1}
$$

$$\frac{dV_i}{dt} = \beta_i \sigma_{ij} R_j \frac{(I_i + V_i)}{A} - (\mu + \gamma_i) V_i, \qquad j \neq i$$

$$\frac{dW}{dt} = \sum_{i=1}^{2} \gamma_i V_i - \mu W,$$

$$A = S + W + \sum_{i=1}^{2} (I_i + V_i + R_i),$$

where A denotes the population of nonisolated individuals and $\frac{\beta_i S(I_i+V_i)}{A}$ models the rate at which susceptibles become infected with strain i. That is, the ith $(i \neq j)$ incidence rate is assumed to be proportional to both the number of susceptibles and the available proportion of i-infectious individuals, $\frac{(I_i+V_i)}{A}$. The parameter σ_{ij} is a measure of the cross-immunity provided by a prior infection with strain i to exposure with strain j $(i \neq j)$. Data from epidemiological studies conducted in Houston and Seattle [27, 17] generate rough measures of cross-immunity. From these studies it is clear that $\sigma_{ij} \in [0, 1]$. Model (1) includes the models in [5, 6]. The absence of the Q classes in earlier work precludes the possibility of sustained oscillations (see [5, 6]). Isolation classes are not introduced after the V-classes to simplify the analysis and because often symptoms are less severe in these classes.

3. Disease invasion and stability. System (1) can support four equilibria. Analysis of the local stability of the trivial equilibrium (absence of disease) helps identify conditions under which the "flu" can invade. We assume (sections 3 and 4)

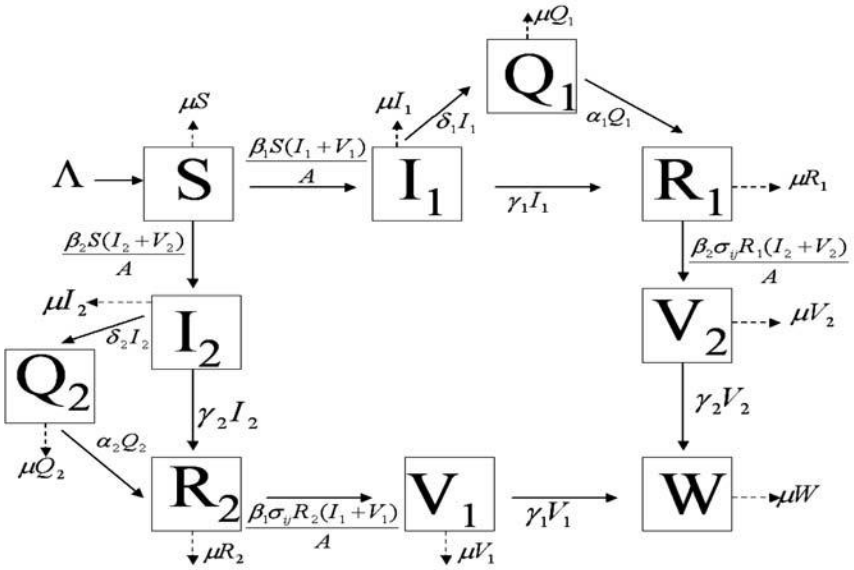

FIG. 1. *Schematic diagram of disease dynamics when the host is exposed to two cocirculating strains.* Λ *is the rate at which individuals are born into the population,* β_i *denotes the transmission coefficient for strain* i, μ *is the per capita mortality rate,* δ_i *is the per capita isolation rate for strain* i, γ_i *denotes the per capita recovery rate from strain* i, α_i *is the per capita rate at which individuals leave the isolated class as a result of infection with strain* i, *and* σ_{ij} *is the relative susceptibility to strain* j *for an individual previously infected with and recovered from strain* i $(i \neq j)$. $\sigma_{ij} = 0$ *corresponds to total cross-immunity, while* $\sigma_{ij} = 1$ *indicates no cross-immunity.*

that $\sigma_{12} = \sigma_{21} = \sigma$ (as it was done in [5, 6]). This approach strongly limits the generality of our analysis, but the general case has turned out to be too difficult. The case where $|\sigma_{12} - \sigma_{21}| = \varepsilon$ (a small positive number) is explored numerically. Quantitative results do not seem to change when ε is small enough. Flu-related mortality is low, and hence it is ignored. This is not a limiting factor over appropriate time scales. From our model (time scale for which demographic factors can be ignored)

$$\frac{d}{dt}N = \Lambda - \mu N,$$

where $N = S + W + \sum_{i=1}^{2}(I_i + V_i + Q_i + R_i)$. Hence, $N(t) \to \frac{\Lambda}{\mu}$ as $t \to \infty$, and the results in [7] allow us to assume, without loss of generality, that $N(0) = \frac{\Lambda}{\mu}$. Hence, we set

$$N(t) \equiv \frac{\Lambda}{\mu} \equiv S + W + \sum_{i=1}^{2}(I_i + V_i + Q_i + R_i) = A + Q \qquad \text{for all } t,$$

where $Q = Q_1 + Q_2$ and $A = N - Q$.

The *isolation* reproductive number $\Re_q$, the average number of secondary infections generated by the simultaneous introduction of both strains in a fully susceptible population, is a function of the independent capacity of each strain to invade. Hence, $\Re_q = \max\{\Re_1, \Re_2\}$, where

$$\Re_i = \frac{\beta_i}{\mu + \gamma_i + \delta_i}.$$

Here, β_i is the maximal effective transmission rate and $(\mu + \gamma_i + \delta_i)^{-1}$ is the average window of opportunity (effective infectious period) for transmission. It follows that E_0, the disease-free state, is locally asymptotically stable when $\Re_q < 1$ and an unstable (saddle) whenever $\Re_i > 1$ for either $i = 1$ or $i = 2$ (for details see Appendix A).

4. Nontrivial equilibria and sustained oscillations. Hethcote and Levin's 1989 survey of mathematical models [18], Feng [14], Feng and Thieme [15], Hethcote [19], and the recent comprehensive literature review of Hethcote and Levin [18] provide a solid perspective on what is known about the mechanisms that are capable of supporting sustained oscillations in epidemic models. Nonstructured two-strain SIR models with cross-immunity appear to be incapable of supporting them [1], but the addition of a third strain reverses the situation [26].

Here we focus on the role of isolation, a mechanism capable of generating sustained oscillations even in a single-strain model. The "flu" may survive in three states: either strain 1 or 2 survives or both strains coexist. Here, we carry only out the analysis in the symmetric cross-immunity case ($\sigma_{12} = \sigma_{21} = \sigma$). We let $U = (S, I_1, Q_1, R_1, V_1, I_2, Q_2, R_2, V_2, W)$ denote the state variables and focus on the analysis of the stability of the boundary equilibria, namely $E_1 = (\tilde{S}, \tilde{I}_1, \tilde{Q}_1, \tilde{R}_1, 0, 0, 0, 0, 0, 0)$. Setting $V_1 = I_2 = Q_2 = R_2 = V_2 = W = 0$ in (1) leads to the following relationships:

$$\begin{aligned} &\frac{\tilde{S}}{\tilde{A}} = \frac{1}{\Re_1}, \qquad &&\frac{\tilde{I}_1}{\tilde{A}} = \mu(\mu + \alpha_1)\phi, \\ &\frac{\tilde{Q}_1}{\tilde{A}} = \mu\delta_1\phi, \qquad &&\frac{\tilde{R}_1}{\tilde{A}} = (\gamma_1(\mu + \alpha_1) + \alpha_1\delta_1)\,\phi, \end{aligned} \tag{2}$$

where

$$\phi = \frac{(1 - \frac{1}{\Re_1})}{(\mu + \gamma_1)(\mu + \alpha_1) + \alpha_1 \delta_1} \tag{3}$$

and

$$\tilde{A} = \frac{1}{\mu(1 + \mu \delta_1 \phi)}.$$

E_1 exists (entries are positive) and is unique if and only if $\Re_1 > 1$. Letting $A = N - Q$ and $S = A - \sum_{i=1}^{2}(I_i + V_i + R_i) - W$ allows the elimination of the S equation. The I_i equations become

$$\frac{dI_i}{dt} = \beta_i \left(1 - \frac{W + \sum_{i=1}^{2}(I_i + R_i + V_i)}{A}\right)(I_i + V_i) - (\mu + \gamma_i + \delta_i) I_i.$$

The Jacobian at E_1, $\tilde{J}$, is given by the 9×9 (without S) matrix

$$\tilde{J} = \begin{pmatrix} G_1 & * & * & * \\ 0 & -(\mu + \gamma_1) & * & 0 \\ 0 & 0 & G_2 & 0 \\ 0 & * & * & -\mu \end{pmatrix},$$

where

$$G_1 = \begin{pmatrix} -\beta_1 \frac{\tilde{I}_1}{\tilde{A}} & -\beta_1 \frac{\tilde{I}_1}{\tilde{A}}(1 - \frac{1}{\Re_1}) & -\beta_1 \frac{\tilde{I}_1}{\tilde{A}} \\ \delta_1 & -(\mu + \alpha_1) & 0 \\ \gamma_1 & \alpha_1 & -\mu \end{pmatrix},$$

and

$$G_2 = \begin{pmatrix} \beta_2 \frac{\tilde{S}}{\tilde{A}} - (\mu + \gamma_2 + \delta_2) & 0 & 0 & \beta_2 \frac{\tilde{S}}{\tilde{A}} \\ \delta_2 & -(\mu + \alpha_2) & 0 & 0 \\ \gamma_2 & \alpha_2 & -\mu - \beta_1 \sigma \frac{\tilde{I}_1}{\tilde{A}} & 0 \\ \beta_2 \sigma \frac{\tilde{R}_1}{\tilde{A}} & 0 & 0 & \beta_2 \sigma \frac{\tilde{R}_1}{\tilde{A}} - (\mu + \gamma_2) \end{pmatrix}.$$

"*" represents a nonzero block matrix.

G_2 has two negative eigenvalues, plus the roots of the equation

$$\lambda^2 - c_1 \lambda + c_2 = 0, \tag{4}$$

where

$$\begin{aligned} c_1 &= (\mu + \gamma_2 + \delta_2)\left(\frac{\Re_2 - \Re_1}{\Re_1}\right) + \beta_2 \sigma \frac{\tilde{R}_1}{\tilde{A}} - (\mu + \gamma_2), \\ c_2 &= -(\mu + \gamma_2 + \delta_2)\left[\beta_2 \sigma \frac{\tilde{R}_1}{\tilde{A}} + (\mu + \gamma_2)\left(\frac{\Re_2 - \Re_1}{\Re_1}\right)\right]. \end{aligned} \tag{5}$$

Hence $c_1 < 0$ and $c_2 > 0$ guarantee the local asymptotic stability (l.a.s.) of E_1.

$$c_1 < 0 \Longleftrightarrow F_1(\Re_1, \Re_2) := (\mu + \gamma_2 + \delta_2)\left(\frac{\Re_2}{\Re_1} - 1 + \sigma \Re_2 \frac{\tilde{R}_1}{\tilde{A}}\right) - (\mu + \gamma_2) < 0, \tag{6}$$

$$c_2 > 0 \Longleftrightarrow F_2(\Re_1, \Re_2) := \sigma(\mu + \gamma_2 + \delta_2)\Re_2 \frac{\tilde{R}_1}{\tilde{A}} + (\mu + \gamma_2)\left(\frac{\Re_2}{\Re_1} - 1\right) < 0, \tag{7}$$

where $\tilde{R}_1/\tilde{A}$ is given in (2). In the case of full immunity ($\sigma = 0$), the conditions in (6) and (7) hold if and only if $\Re_2 < \Re_1$. That is, when $\sigma = 0$, E_1 has l.a.s., as long as $\Re_1 > 1$ and $\frac{\Re_1}{\Re_2} > 1$ and E_1 is unstable ($\sigma = 0$) when $\frac{\Re_2}{\Re_1} > 1$. As cross-immunity between strains diminishes ($0 < \sigma \uparrow 1$), alternative conditions are needed to ensure that (6) and (7) hold. To find these conditions we rewrite F_1 in terms of F_2,

$$F_1(\Re_1, \Re_2) = F_2(\Re_1, \Re_2) + \delta_2\left(\frac{\Re_2}{\Re_1} - 1\right) - (\mu + \gamma_2),$$

and observe that $F_1 \leq F_2$ when $\Re_2 < \Re_1$. Alternatively, the introduction of

$$f(\Re_1) \equiv \frac{\Re_1}{1 + \sigma(\Re_1 - 1)\left(1 + \frac{\delta_2}{\mu+\gamma_2}\right)\left(1 - \frac{\mu(\mu+\alpha_1)}{(\mu+\gamma_1)(\mu+\alpha_1)+\alpha_1\delta_1}\right)} \tag{8}$$

implies that $F_2 < 0$ if and only if $\Re_2 < f(\Re_1)$ ($0 < f(\Re_1) < \Re_1$). Therefore, $\Re_2 < f(\Re_1)$ implies that $F_1 \leq F_2 < 0$. Hence, all eigenvalues of G_2 have negative real part when $\frac{\Re_2}{f(\Re_1)} < 1$, and E_1 is unstable when $\frac{\Re_2}{f(\Re_1)} > 1$. Similarly, the use of

$$g(\Re_2) \equiv \frac{\Re_2}{1 + \sigma(\Re_2 - 1)\left(1 + \frac{\delta_1}{\mu+\gamma_1}\right)\left(1 - \frac{\mu(\mu+\alpha_2)}{(\mu+\gamma_2)(\mu+\alpha_2)+\alpha_2\delta_2}\right)} \tag{9}$$

implies that the eigenvalues corresponding to the system when strain 2 has become established are all negative whenever $\Re_1 < g(\Re_2)$. The boundary endemic equilibria for strain 2 (E_2) are stable when $\frac{\Re_1}{g(\Re_2)} < 1$ and unstable when $\frac{\Re_1}{g(\Re_2)} > 1$.

Conditions that guarantee "coexistence" equilibria are formulated in terms of the (conditional) "invasion" reproductive numbers for strains 2 and 1 ($\Re_2^1$ and $\Re_1^2$). $\Re_2^1$ is defined as the number of secondary infections generated by a "typical" strain-2-infected individual in a population where strain 1 is endemic (E_1). From conditions (6) and (7) (which ensure the stability of E_1) we find that

$$\Re_2^1 = \frac{\beta_2}{\mu + \gamma_2 + \delta_2}\frac{\tilde{S}}{\tilde{A}} + \frac{\beta_2\sigma}{\mu + \gamma_2}\frac{\tilde{R}_1}{\tilde{A}}.$$

Similarly, the (conditional) invasion reproductive number of strain 1 under the assumption that strain 2 is endemic is given by

$$\Re_1^2 = \frac{\beta_1}{\mu + \gamma_1 + \delta_1}\frac{\tilde{S}}{\tilde{A}} + \frac{\beta_1\sigma}{\mu + \gamma_1}\frac{\tilde{R}_2}{\tilde{A}}.$$

The condition $\Re_2 < f(\Re_1)$ is equivalent to the condition $\Re_2^1 < 1$, while the condition $\Re_1 < g(\Re_2)$ is equivalent to the condition $\Re_1^2 < 1$. $\Re_i^j$ $(i, j = 1, 2\ i \neq j)$ is in fact the result of two additive contributions: $\beta_i/(\mu + \gamma_i + \delta_i)$ gives the number of secondary cases that a "typical" strain-i-infected individual will generate in the fully susceptible proportion of the population $\tilde{S}/\tilde{A}$, while $\beta_i\sigma/(\mu + \gamma_i)$ is the number of secondary cases that a "typical" strain-i-infected individual will generate in the "cross-immune" proportion of the susceptible population $\tilde{R}_i/\tilde{A}$. Note that whenever $\Re_i > 1$ and $\Re_j^i < 1$, the boundary equilibrium E_i is locally stable.

4.1. Multiple and subthreshold coexistence. Both strains coexist if their basic reproductive numbers are above 1 (see Figures 2(a), (b), (d)), but subthreshold coexistence is possible (see Figure 2(c)). In order to see this (in system (1)) let $S/A = s$, $I_i/A = i_i$, $Q_i/A = q_i$, $R_i/A = r_i$, $V_i/A = v_i$, $W/A = w$, and $n = \frac{N}{A}$ with $\sigma_{12} = \sigma_{21} = \sigma$. The equilibrium conditions for the rescaled system are

$$\beta_1 s(i_1 + v_1) + \beta_2 s \frac{\Re_1}{\Re_2} \frac{i_2}{i_1}(i_1 + v_1) + \mu s = \mu(1 + \eta_1 i_1 + \eta_2 i_2), \tag{10}$$

$$\beta_1 s(i_1 + v_1) = (\mu + \gamma_1 + \delta_1) i_1, \tag{11}$$

$$\frac{(i_1 + v_1)}{(i_2 + v_2)} = \frac{\Re_2}{\Re_1} \frac{i_1}{i_2}, \tag{12}$$

$$\beta_2 \sigma r_1 \frac{\Re_1}{\Re_2} \frac{i_2}{i_1}(i_1 + v_1) + \mu r_1 = (\gamma_1 + \kappa_1) i_1, \tag{13}$$

$$\beta_1 \sigma r_2 (i_1 + v_1) = (\mu + \gamma_1) v_1, \tag{14}$$

$$\beta_1 \sigma r_2 (i_1 + v_1) + \mu r_2 = (\gamma_2 + \kappa_2) i_2, \tag{15}$$

$$\beta_2 \sigma r_1 \frac{\Re_1}{\Re_2} \frac{i_2}{i_1}(i_1 + v_1) + (\mu + \gamma_2) i_2 = (\mu + \gamma_2)(i_2 + v_2), \tag{16}$$

where

$$\kappa_i = \frac{\alpha_i \delta_i}{\mu + \alpha_i},$$

$$\eta_i = \frac{\delta_i}{\mu + \alpha_i}.$$

Expressions (10) and (11) can be solved for s, that is,

$$s = \frac{\mu(1 + \eta_1 i_1 + \eta_2 i_2)}{\beta_1(i_1 + v_1) + \beta_2(i_2 + v_2) + \mu} = \frac{(\mu + \gamma_1 + \delta_1) i_1}{\beta_1(i_1 + v_1)}. \tag{17}$$

From (17) it follows that

$$\frac{\mu \beta_1 (i_1 + v_1)(1 + \eta_1 i_1 + \eta_2 i_2)}{\beta_1(i_1 + v_1) + \beta_2(i_2 + v_2) + \mu} = (\mu + \gamma_1 + \delta_1) i_1. \tag{18}$$

Equation (14) and its symmetric analogue are solved for r_1 and r_2. In fact,

$$r_1 = \frac{(\mu + \gamma_2) v_2}{\beta_2 \sigma (i_2 + v_2)}$$

and

$$r_2 = \frac{(\mu + \gamma_1) v_1}{\beta_1 \sigma (i_1 + v_1)}.$$

From (13) and the relationship $\beta_2 \sigma (i_2 + v_2) r_1 = (\mu + \gamma_2) v_2$ we have that

$$(\gamma_1 + \kappa_1) i_1 - (\mu + \gamma_2) v_2 = \mu r_1.$$

Using (12) and substituting the above expression for r_1 helps rewrite (13) as

$$(\gamma_1 + \kappa_1) i_1 - (\mu + \gamma_2) \frac{\Re_1 i_2 (i_1 + v_1)}{\Re_2 i_1} + (\mu + \gamma_2) i_2 = \frac{\mu(\mu + \gamma_2)}{\beta_2 \sigma} - \frac{\mu(\mu + \gamma_2) i_2}{\beta_2 \sigma (i_2 + v_2)}. \tag{19}$$

Solving for $(i_2 + v_2)$ in (13) and using (19) leads to

(20)
$$(\gamma_1 + \kappa_1)i_1 - (\mu + \gamma_2)\frac{\Re_1 i_2(i_1 + v_1)}{\Re_2 i_1} + (\mu + \gamma_2)i_2 = \frac{\mu(\mu + \gamma_2)}{\beta_2\sigma}\left(1 - \frac{\Re_2 i_1}{\Re_1(i_1 + v_1)}\right).$$

In a similar manner, using r_2 and the expression $\beta_1\sigma r_2(i_1 + v_1) = (\mu + \gamma_1)v_1$ leads to the reduced system

$$\frac{\mu\beta_1(1 + \eta_1 i_1 + \eta_2 i_2)(i_1 + v_1)}{\beta_1(i_1 + v_1) + \frac{\beta_2\Re_1(i_1+v_1)i_2}{\Re_2 i_1} + \mu} = (\mu + \gamma_1 + \delta_1)i_1,$$

$$(\gamma_1 + \kappa_1)i_1 - (\mu + \gamma_2)i_2\left(\frac{\Re_1(i_1 + v_1)}{\Re_2 i_1} - 1\right) = \frac{\mu(\mu + \gamma_2)}{\beta_2\sigma}\left(1 - \frac{\Re_2 i_1}{\Re_1(i_1 + v_1)}\right), \tag{21}$$

$$(\gamma_2 + \kappa_2)i_2 - (\mu + \gamma_1)v_1 = \frac{\mu(\mu + \gamma_1)v_1}{\beta_1\sigma(i_1 + v_1)}.$$

From the first equation in (17) we get that

$$\begin{aligned}(i_1 + v_1) &= \frac{\mu(\mu + \gamma_1 + \delta_1)i_1}{\beta_1[\mu(1 + \eta_1 i_1 + \eta_2 i_2) - i_1(\mu + \gamma_1 + \delta_1) - i_2(\mu + \gamma_2 + \delta_2)]},\\ &= \frac{\mu(\mu + \gamma_1 + \delta_1)i_1}{\beta_1[\triangle(i_1, i_2)]},\end{aligned} \tag{22}$$

where

$$\triangle(i_1, i_2) = \mu(1 + \eta_1 i_1 + \eta_2 i_2) - i_1(\mu + \gamma_1 + \delta_1) - i_2(\mu + \gamma_2 + \delta_2).$$

The substitution of (22) into the second equation in (21) and the use of its symmetric analogue gives a system of equations (in terms of i_1 and i_2 only). The system is

$$\begin{aligned}&\big(\triangle(i_1, i_2)\big)^2\frac{(\mu + \gamma_2)\Re_2}{\beta_2\sigma} + \triangle(i_1, i_2)\left[(\gamma_1 + \kappa_1)i_1 + (\mu + \gamma_2)i_2 - \frac{\mu(\mu + \gamma_2)}{\beta_2\sigma}\right]\\ &\quad - \frac{\mu(\mu + \gamma_2)i_2}{\Re_2} = 0,\\ &\big(\triangle(i_1, i_2)\big)^2\frac{(\mu + \gamma_1)\Re_1}{\beta_1\sigma} + \triangle(i_1, i_2)\left[(\gamma_2 + \kappa_2)i_2 + (\mu + \gamma_1)i_1 - \frac{\mu(\mu + \gamma_1)}{\beta_1\sigma}\right]\\ &\quad - \frac{\mu(\mu + \gamma_1)i_1}{\Re_1} = 0.\end{aligned} \tag{23}$$

Positive solutions of (23) are only candidates for coexistence equilibria, as we must check that the corresponding values (s, q_i, r_i, v_i, and w) are positive. Numerical simulations show that such solutions exist in the ranges $0 \le i_1 \le 1$ and $0 \le i_2 \le 1$ for parameter values that are reasonable for the "flu." Figure 2(a) ($\Re_1 > 1$ and $\Re_2 > 1$) shows one such intersection in the positive quadrant. Subthreshold coexistence equilibrium is also possible for $\Re_1 < 1$ and $\Re_2 > 1$ (see Figure 2(c)). As we increase the basic reproductive number of both strains and allow varying levels of cross-immunity ($\sigma = 0.5$ and $\sigma = 0.6$), Figures 2(b) and 2(d) show that two intersections (in the positive quadrant) are possible. That is, multiple coexistence equilibria exist (it was verified that all classes are positive). This possibility is absent from prior influenza models. For the parameter values in Table 1, only a single coexistence equilibrium is biologically reasonable. Figures 2(a), (c) provide additional examples where coexistence and subthreshold coexistence are possible.

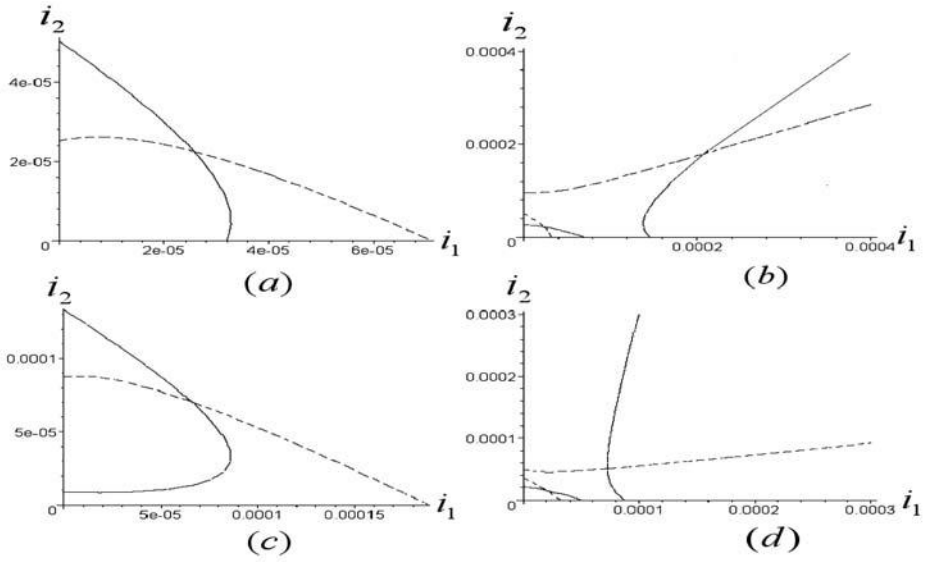

FIG. 2. *Positive solutions of* (23) *are provided to illustrate the existence of multiple endemic states and subthreshold coexistence (section* 4.1*). The horizontal axis is the fraction* ($i_1 = I_1/A$) *of individuals infected with strain* 1*, and the vertical axis depicts the fraction* ($i_2 = I_2/A$) *of individuals infected with strain* 2. (a) $\Re_1 = 2, \Re_2 = 1.99$*, and* $\sigma = 0.9$. (b) $\Re_1 = 2, \Re_2 = 1.99$*, and* $\sigma = 0.5$. (c) $\Re_1 = 0.75, \Re_2 = 2.9$*, and* $\sigma = 0.9$. (d) $\Re_1 = 2.83, \Re_2 = 2.93$*, and* $\sigma = 0.6$.

TABLE 1

The parameter values used for the numerical simulations are provided here. The initial conditions are given by $s(0) = 0.4$, $i_1(0) = 0.199$, $r_1(0) = r_2(0) = 0.2$, *and* $i_2(0) = q_1(0) = q_2 = w(0) = 0$ *(only one strain present initially) and* $s(0) = 0.4$, $i_1(0) = 0.199$, $q_1(0) = 0.1$, $r_1(0) = r_2(0) = 0.2$, $i_2(0) = 0.001$, *and* $q_1(0) = q_2(0) = w(0) = 0$ *(both strains present initially).*

Parameters	Definition	Values
$\Re_i$	Number of secondary cases generated by a primary case infected with strain i	(0.75, 4.5)
σ_{ij}	Cross-immunity against strain j following an infection with strain i	(0.008, 0.8)
Λ	Rate at which individuals are born into the population	0.00004
α_i	Rate at which individuals leave isolation ($1/\alpha_i$ = days)	(1, 15)
δ_i	Rate of isolation with strain i, $i = 1, 2$ ($1/\delta_i$ = days)	(1, 6)
γ_i	Recovery rate from strain i, $i = 1, 2$ ($1/\gamma_i$ = days)	(5, 7)
β_i	Transmission coefficient for strain i, $i = 1, 2$	(0.4, 2.2)
μ	Mortality rate	0.00004

4.2. Sustained oscillations. A detailed study of the nature of the eigenvalues of matrix G_1 makes use of the identity

$$\beta_1 \frac{\tilde{S}}{\tilde{A}} - (\mu + \gamma_1 + \alpha_1) = -\beta_1 \frac{\tilde{I}_1}{\tilde{A}}$$

and the fact that $\Re_1$ does not depend on α_1. The dependence of f on α_1 is in the order of μ, and this observation is used in the study of the characteristic equation associated with G_1 as we search for the possibility of sustained oscillations. The characteristic

equation is

$$\omega^3 + a_1\omega^2 + a_2\omega + a_3 = 0, \tag{24}$$

where

$$\begin{aligned}
a_1 &= 2\mu + \alpha_1 + \Re_1(\mu + \gamma_1 + \delta_1)\mu(\mu + \alpha_1)\phi,\\
a_2 &= \mu(\mu + \alpha_1)\left[1 + \Re_1(\mu + \gamma_1 + \delta_1)\left(2\mu + \alpha_1 + \gamma_1 + \delta_1\left(1 - \frac{1}{\Re_1}\right)\right)\phi\right],\\
a_3 &= \left[\mu^2 + \alpha_1\mu + \delta_1\alpha_1 + \gamma_1\mu + \gamma_1\alpha_1 + \delta_1\mu\left(1 - \frac{1}{\Re_1}\right)\right]\Re_1(\mu + \gamma_1 + \delta_1)\mu(\mu + \alpha_1)\phi.
\end{aligned} \tag{25}$$

Since a_1, a_2, and a_3 are all positive ($\Re_1 > 1$), then the cubic equation in (24) has either three negative or one negative root and possibly two complex conjugate roots. Differences in epidemiological and demographic time scales are used to tease out the nature of the roots of (24). The average life expectancy ($1/\mu$) is in the order of decades, while the infective ($1/\delta_i$ or $1/\gamma_i$) and isolation periods ($1/\alpha_i$) are just a few days. That is, μ is much smaller than δ_i, γ_i, and α_i. Following early approaches [14, 15, 23], we carry out an asymptotic expansion on the coefficients of (24) using μ. From (25), it is clear that a_i are analytic functions of $\mu > -\varepsilon$ for some $\varepsilon > 0$. Hence,

$$\begin{aligned}
a_1 &= \alpha_1 + (\Re_1^* + 1)\mu + O(\mu^2),\\
a_2 &= \left[(\alpha_1 + \gamma_1)\Re_1^* - \gamma_1 + \frac{\delta_1(\Re_1^* - 1)^2}{\Re_1^*}\right]\mu + O(\mu^2),\\
a_3 &= \alpha_1(\delta_1 + \gamma_1)(\Re_1^* - 1)\mu + O(\mu^2),
\end{aligned} \tag{26}$$

where $\Re_1^*$ denotes $\Re_1(\mu)$ evaluated at $\mu = 0$, that is, $\Re_1^* = \Re_1(0)$. The continuous dependence of the roots on μ is acknowledged by letting $\omega_i = \omega_i(\mu)$ ($i = 1, 2, 3$) denote the roots of (24) (for a fixed value of μ). In the limiting case, $\mu = 0$, a_2 and a_3 are zero, while $a_1 = \alpha_1$ (from (26)). The characteristic polynomial in this limiting case is simply

$$\omega^3 + \alpha_1\omega^2 = 0,$$

which has the roots $\omega_1(0) = -\alpha_1$ and $\omega_2(0) = \omega_3(0) = 0$. Hence, by continuity, $\omega_1(\mu) = -\alpha_1 + O(\mu)$ is a negative real root of (24) for small $\mu > 0$. In order to use arguments similar to those found in [14, 15, 23] or in Kato [23, II, §1, section 2], it is assumed that the roots $\omega_2(\mu)$ and $\omega_3(\mu)$ have expansions of the form

$$\omega(\mu) = \sum_{j=1}^{\infty} \xi_j \nu^j, \qquad \nu = \mu^{\frac{1}{2}}. \tag{27}$$

The formal substitution of (27) into (24) (neglecting higher-order terms in ν) yields

$$\begin{aligned}
&\left[\xi_1^2\alpha_1 + \alpha_1(\delta_1 + \gamma_1)(\Re_1^* - 1)\right]\nu^2\\
&\quad + \left[\xi_1^3 + 2\xi_1\xi_2\alpha_1 + \left((\gamma_1 + \alpha_1)\Re_1^* - \gamma_1 + \frac{\delta_1(\Re_1^* - 1)^2}{\Re_1^*}\right)\xi_1\right]\nu^3 + O(\nu^4) = 0.
\end{aligned}$$

Hence,

$$\xi_1^2 = -(\gamma_1 + \delta_1)(\Re_1^* - 1) \quad \text{and} \quad \xi_2 = -\frac{1}{2\alpha_1}\left(\xi_1^2 - \gamma_1 + (\gamma_1 + \alpha_1)\Re_1^* + \frac{\delta_1(\Re_1^* - 1)^2}{\Re_1^*}\right).$$

From the fact that $\Re_1^* > 1$ we have that

$$\xi_1 = \pm i\sqrt{(\gamma_1+\delta_1)\left(\Re_1^*-1\right)} \quad \text{and} \quad \xi_2 = -\frac{1}{2\alpha_1}\left(\alpha_1\Re_1^* + \delta_1\left(\frac{1}{\Re_1^*}-1\right)\right). \tag{28}$$

That is, the three roots of (24) have expressions of the form

$$\omega_1(\nu) = -\alpha_1 + O(\nu^2) \tag{29}$$

and

$$\omega_{2,3}(\nu) = \pm i\left((\gamma_1+\delta_1)\left(\Re_1^*-1\right)\right)^{\frac{1}{2}}\nu - \frac{1}{2\alpha_1}\left(\alpha_1\Re_1^* + \delta_1\left(\frac{1}{\Re_1^*}-1\right)\right)\nu^2 + O(\nu^3). \tag{30}$$

We select α_1 as our implicit bifurcation parameter ($1/\alpha_1$ is the isolation period for strain 1). We observe that $\alpha_1 = \alpha_1(\nu)$ is a function of ν that satisfies the equation $\xi_2(\alpha_1(0)) = 0$. Hence

$$\alpha_1(0) = \frac{\delta_1}{\Re_1^*}\left(1 - \frac{1}{\Re_1^*}\right).$$

The use of functions $\omega_{2,3} = \omega_{2,3}(\alpha_1,\nu)$ and $H(\alpha_1,\nu) = \frac{1}{\nu^2}\,\mathbb{R}\,\omega_{2,3}(\alpha_1,\nu)$ (where $\mathbb{R}\omega_{2,3}(\alpha_1,\nu)$ denotes the real part of the roots of (24) as given in (30)) imply that $H(\alpha_1(0),0) = \xi_2(\alpha_1(0)) = 0$. The implicit function theorem guarantees the existence of a critical function $\alpha_c(\nu) = \frac{\delta_1}{\Re_1^*}(1-\frac{1}{\Re_1^*}) + O(\nu)$, such that $H(\alpha_c(\nu),\nu) = 0$ for small ν. Clearly, $\alpha_c(\nu) > 0$, as long as $\Re_1^* > 1$. Furthermore, since

$$\frac{\partial H}{\partial \alpha_1}(0) = -\frac{1}{2\delta_1}\frac{{\Re_1^*}^3}{(\Re_1^*-1)} < 0,$$

nonresonance holds [21], that is, as the frequency of strain 1 approaches that of strain 2 (or vice versa). Solutions remain bounded. The use of α_1 as a bifurcation parameter shows that the roots $\omega_{2,3}$ cross the imaginary axis from left to right whenever α_1 crosses α_c from right to left. That is, the crossing is transversal. Hence, a Hopf bifurcation occurs near the critical point $\alpha_c = \delta_1(\Re_1^*-1)/(\Re_1^*)^2$. We collect these results in the following theorem.

THEOREM 1. *There are two functions: $f(\Re_1)$ as defined in* (8), *and $\alpha_c(\mu)$ defined for small $\mu > 0$ by*

$$\alpha_c(\mu) = \frac{\delta_1}{\Re_1^*}\left(1 - \frac{1}{\Re_1^*}\right) + O\left(\mu^{\frac{1}{2}}\right),$$

with the following properties: (i) *The boundary endemic equilibrium E_1 is locally asymptotically stable if $\Re_2 < f(\Re_1)$ and $\alpha_1 < \alpha_c(\mu)$, and unstable if $\Re_2 > f(\Re_1)$ or $\alpha_1 > \alpha_c(\mu)$.* (ii) *When $\Re_2 < f(\Re_1)$, periodic solutions arise at $\alpha_1 = \alpha_c(\mu)$ via Hopf bifurcation for small enough $\mu > 0$. The period can be approximated by*

$$T = \frac{2\pi}{|\Im\omega_{2,3}|} \approx \frac{2\pi}{((\gamma_1+\delta_1)(\Re_1^*-1))^{\frac{1}{2}}\,\mu^{\frac{1}{2}}}$$

or (using (2)*) by*

$$T \approx \frac{2\pi}{(\gamma_1+\delta_1)^{\frac{1}{2}}\left(\frac{\hat{I}_1}{\hat{A}}\right)^{\frac{1}{2}}\mu^{\frac{1}{2}}},$$

where $\hat{I}_1/\hat{A}$ *denotes* $\beta_1\tilde{I}_1/\mu\tilde{A}$ *evaluated at* $\mu = 0$ *and* $|\Im\omega_{2,3}|$ *refers to the imaginary roots calculated in* (30).

The latter expression for T allows one to compare the period of this model with the quasi periods obtained from models which do not include an isolation class [5, 6]. Since we have focused on the symmetric case, an analogous result for the second boundary equilibrium E_2 can be stated immediately. That is, the boundary endemic equilibrium E_2 is locally asymptotically stable if $\Re_1 < g(\Re_2)$ and $\alpha_2 < \alpha_c(\mu)$. It becomes unstable if $\Re_1 > g(\Re_2)$ or $\alpha_2 > \alpha_c(\mu)$. A summary of the stability results as presented in Theorem 1 for strain 1 is obtained for strain 2 by replacing the parameter indices 1's with 2's and replacing $f(\Re_1)$ with $g(\Re_2)$. Functions $f(\Re_1)$ and $g(\Re_2)$ help in the characterization of the stability and coexistence regions for strains 1 and 2. Changes in the regions of stability for either a single or for both strains can be illustrated as the coefficients of cross-immunity are varied. For instance, from (8) we can compute the value of σ at which

$$f'(\Re_1) \equiv \frac{\partial f(\Re_1, \sigma)}{\partial \Re_1}\Big|_{\sigma_1^*} = 0, \tag{31}$$

namely

$$\sigma_1^* = \frac{1}{\left(1 + \frac{\delta_2}{\mu+\gamma_2}\right)\left(1 - \frac{\mu(\mu+\alpha_1)}{(\mu+\gamma_1)(\mu+\alpha_1)+\alpha_1\delta_1}\right)}.$$

Hence, for all $\Re_1 > 1$,

$$f'(\Re_1) > (<, =)\ 0, \qquad f(\Re_1) > (<, =)\ 1 \qquad \text{if } \sigma < (>, =)\ \sigma_1^*.$$

These properties are easily verified, since (from (8))

$$f(\Re_1) = \frac{\Re_1}{1 + \frac{\sigma}{\sigma_1^*}(\Re_1 - 1)} \quad \text{and} \quad f'(\Re_1) = \frac{1 - \frac{\sigma}{\sigma_1^*}}{\left(1 + \frac{\sigma}{\sigma_1^*}(\Re_1 - 1)\right)^2}.$$

From the facts that $f(\Re_1) < \Re_1$ and $f(1) = 1$ we see that Figure 3 captures the properties of the curve $\Re_2 = f(\Re_1)$. Similar curve "boundary" features can be studied using threshold value σ_2^* (interchanging the subscripts 1 and 2 in the expression of σ_1^*) and the function $\Re_1 = g(\Re_2)$ (also shown in Figure 3). The special case when both strains are identical, $\sigma_1^* = \sigma_2^* = \sigma^*$, is implicit in Figure 3. $\Re_2 < f(\Re_1)$ is a necessary condition for the stability of strain 1 (either a stable boundary endemic equilibrium E_1 or the equilibrium associated with strain-1 oscillations). Hence, E_1 is unstable when $\Re_2 > f(\Re_1)$. Similarly, E_2 is unstable when $\Re_1 > g(\Re_2)$. Hence, coexistence is expected when $\Re_2 > f(\Re_1)$ and $\Re_1 > g(\Re_2)$.

Next, the cases $\sigma_2^* < \sigma < \sigma_1^*$ and $\sigma_1^* < \sigma < \sigma_2^*$ are considered. $f(\Re_1)$ and $g(\Re_2)$ are increasing and decreasing functions of σ correspondingly for $\sigma_2^* < \sigma < \sigma_1^*$ and decreasing and increasing (respectively) for $\sigma_1^* < \sigma < \sigma_2^*$ (Figure 4(b)). Hence, the stability region for strain 1 (Figure 4(a), region I) may be significantly larger than that of strain 2 (Figure 4(a), region II) for $\sigma_2^* < \sigma < \sigma_1^*$. For $\sigma_1^* < \sigma < \sigma_2^*$, the stability region of strain 1 may be noticeably smaller than that of strain 2. The changes in the relative sizes of these stability regions seem to cause strong cross-immunity when it is conferred by strain i ($\sigma_i \downarrow 0$) against an infection with strain j (largely reduced susceptibility to alternative strain infections). The possibility that strain j

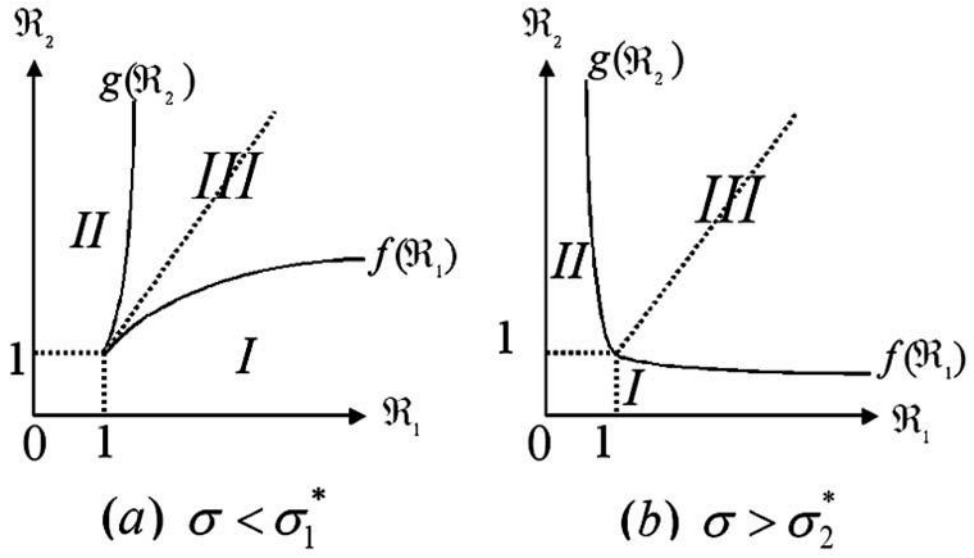

FIG. 3. *Bifurcation diagram in the* $(\Re_1, \Re_2)$*-plane. The curves* $\Re_2 = f(\Re_1)$ *(for* $\Re_1 > 1$*) and* $\Re_1 = g(\Re_2)$ *(for* $\Re_2 > 1$*) divide the region* $\mathbf{R}^2_+ - \{(\Re_1, \Re_2) \mid \Re_1 < 1$ *and* $\Re_2 < 1\}$ *into three subregions:* I, II, III*. When the parameters are in region* I *(*II*), only strain* 1 *(strain* 2*) will be maintained (a stable boundary equilibrium or sustained oscillations of a single strain). In region* III*, both strains will be maintained (a stable boundary equilibrium or sustained oscillations of both strains).*

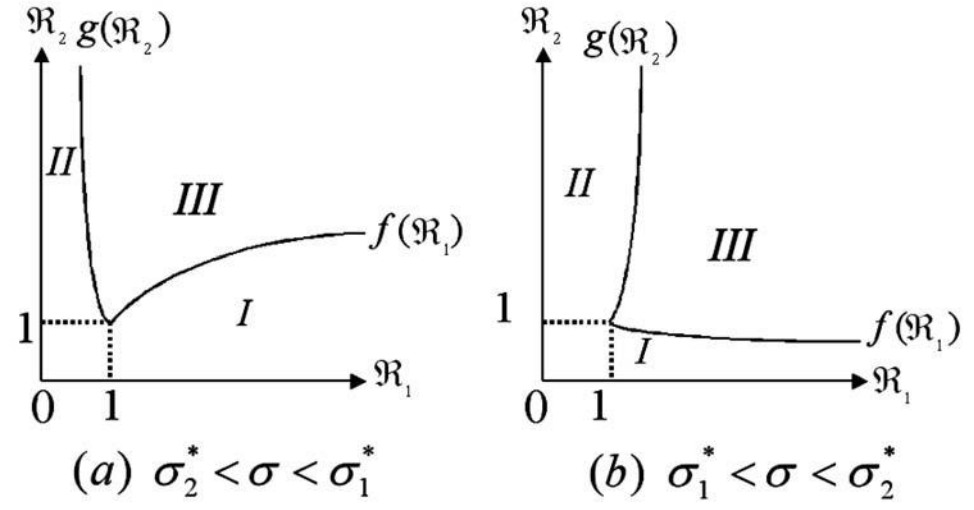

FIG. 4. *Bifurcation diagram in the* $(\Re_1, \Re_2)$*-plane for the case when* $\sigma_1^* \neq \sigma_2^*$*. The curves* $\Re_2 = f(\Re_1)$ *(for* $\Re_1 > 1$*) and* $\Re_1 = g(\Re_2)$ *(for* $\Re_2 > 1$*) divide the region* $\mathbf{R}^2_+ - \{(\Re_1, \Re_2) \mid \Re_1 < 1$ *and* $\Re_2 < 1\}$ *into three subregions:* I, II, III*. The meanings of these regions are the same as those in Figure* 3*.*

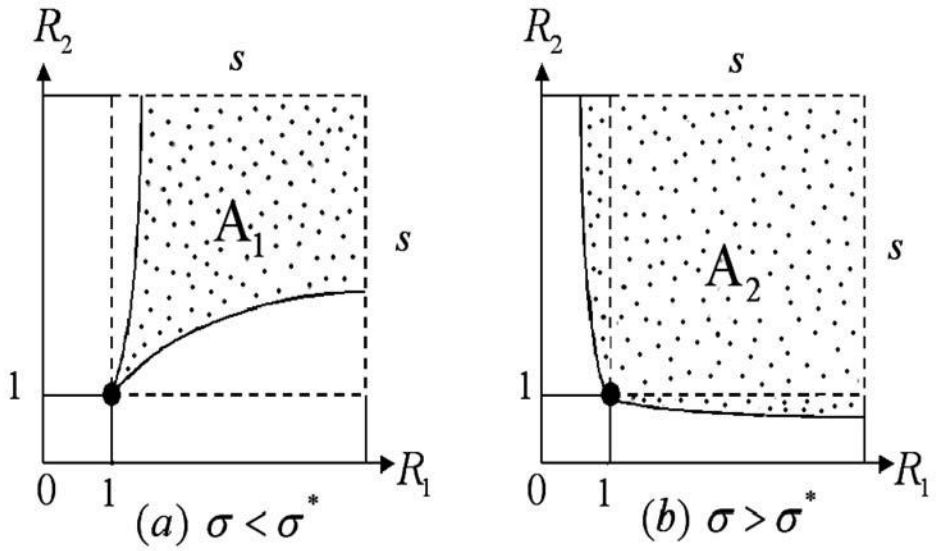

FIG. 5. *A_1 and A_2 are the regions used to approximate the areas pertaining to section III in Figures 2(a)–(b). In order to approximate these areas we enclose regions A_1 and A_2 with a square with dimensions s and corresponding area s^2 (dashed region); s is chosen so that $1 + s = \Re_1$ (and $\Re_2 \approx \Re_1$) using the parameters in Table 1 and two values of σ^* (see the text).*

may become established under these conditions can be small. Likewise, weaker levels of cross-immunity to strain j after an infection with strain i ($\sigma_i \uparrow 1$) will support relatively larger regions of stability for strain j.

The stability regions for strain 1 (I) and strain 2 (II) in the $(\Re_1, \Re_2)$-plane ($\sigma < \sigma_1^*$ and $\sigma > \sigma_2^*$, $\sigma_1^* = \sigma_2^* = \sigma^*$) are illustrated in Figures 3(a)–(b). We show that as the levels of cross-immunity decrease, that is, as the values of σ get closer to 1 (from Figure 3(a) to Figure 3(b)), the region of stability corresponding to each individual strain is reduced significantly (regions I and II). Simultaneously, an increase in the region of multiple strain coexistence (III) can be observed as cross-immunity is weakened. It seems that as strains become antigenically distinct; that is, when cross-immunity against each other is weak, coexistence is more likely. Strong levels of cross-immunity ($\sigma \downarrow 0$) support the survival of a single strain; that is, in this case competition for susceptibles between strains is "fierce" ("competitive exclusion"). The strain with the highest ability to invade the host (largest $\Re_q$) is the most likely to become established (driving the other strain to extinction [4]).

Using Figures 5(a)–(b), a rough estimate for the "probability" of multiple strain coexistence is computed as a function of cross-immunity. The areas of both regions A_1 and A_2 (previously depicted by region III) by delineating the regions of interest with functions $f(\Re_1)$ and $g(\Re_2)$ are "approximately" computed. The area of A_1 in Figure 5(a) is enclosed by a square region with dimensions s, where $1+s=\Re_1$ and $\Re_2 \approx \Re_1$. Similarly, the area A_2 in Figure 5(b) is estimated. The selected value of σ^* ($\sigma^* = 0.33$) used corresponds to the one derived using the parameters provided in Table 1. A value of $\sigma = 0.0008$ is used in Figure 5(a) and $\sigma = 0.8$ in Figure 5(b). Letting A_1 ($\sigma = 0.0008$) and A_2 ($\sigma = 0.8$) in Figures 5(a)–(b) be the calculated areas corresponding to region III, we find that the quotient A_1/A_2 is small (0.0055562).

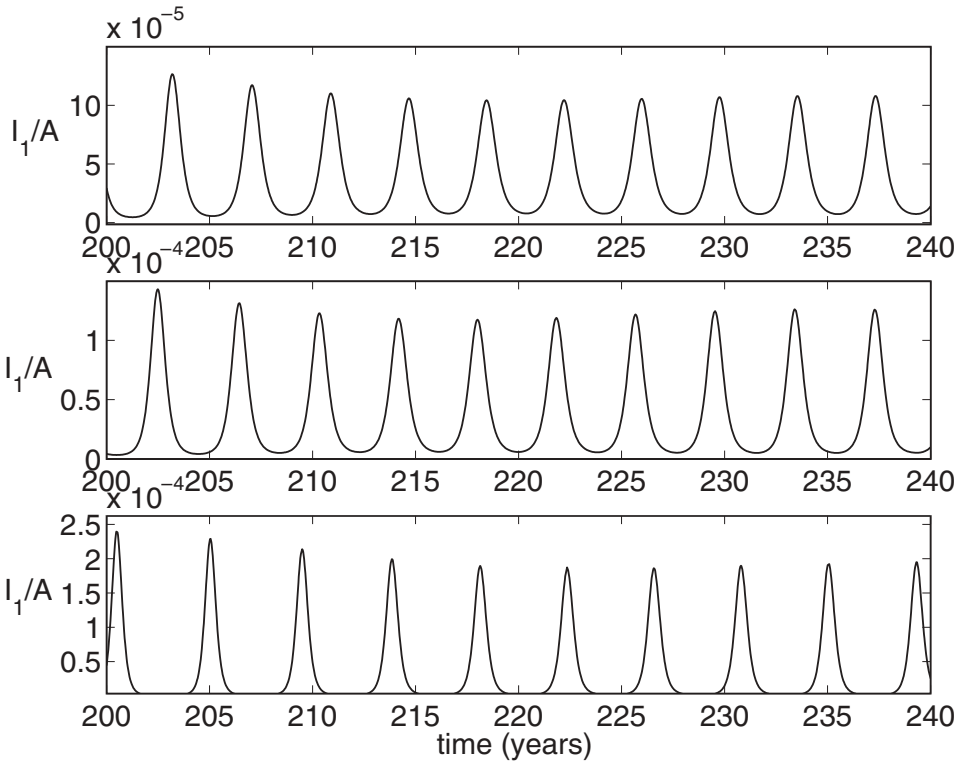

FIG. 6. *Numerical integration of the model equations. The fraction of the infective individuals (nonisolated) with strain* 1 (I_1/N) *is shown for increasing periods of isolation. The length of the isolation period has been chosen (from top to bottom) to be* 3 *days,* 7 *days, and* 15 *days. Cross-immunity between strains is intermediate* ($\sigma = 0.5$).

Hence, the coexistence of antigenically similar strains (sharing strong levels of cross-immunity) seems less likely than when cross-immunity is weak.

5. Numerical results. In this section we explore the model equations numerically as the levels of cross-immunity and isolation are varied. In the first set of simulations, we study the symmetric case ($\sigma_{12} = \sigma_{21} = \sigma$). We explore the role of cross-immunity and host isolation in supporting sustained oscillations for a single and/or both strains where $\sigma \in (0.01, 0.8)$ and $\frac{1}{\alpha}$ is either 1 day, 3 days, or 15 days. In the second set of simulations, we explore the case where $\sigma_{12} \neq \sigma_{21}$. Average life expectancy is fixed at 70 years; infected individuals recover from infection in 5–7 days; individuals are isolated for 1–15 days. The parameters used in simulations are listed in Table 1.

Case 1. $\sigma_{12} = \sigma_{21} = \sigma$. The robustness of multiple strain coexistence begins from the assumption that both strains are present in the population ($s(0) = 0.4$, $i_1(0) = 0.199$, $r_1(0) = r_2(0) = 0.2$, $i_2(0) = 0.001$, and $q_1(0) = q_2(0) = w(0) = 0$). Simulations are conducted using varying levels of cross-immunity ($\sigma = 0.01$, 0.33, 0.5, and 0.8) and isolation periods (1 day, 3 days, and 15 days). Figure 6 shows that for intermediate cross-immunity ($\sigma = 0.5$) the periods between outbreaks is approximately 4 years with an amplitude ranging from 1.1×10^{-4} to 1.5×10^{-4}. Figure 7 shows that strong cross-immunity gives periods of approximately 3 years and amplitude of 2×10^{-4}. As the levels of cross-immunity range from intermediate

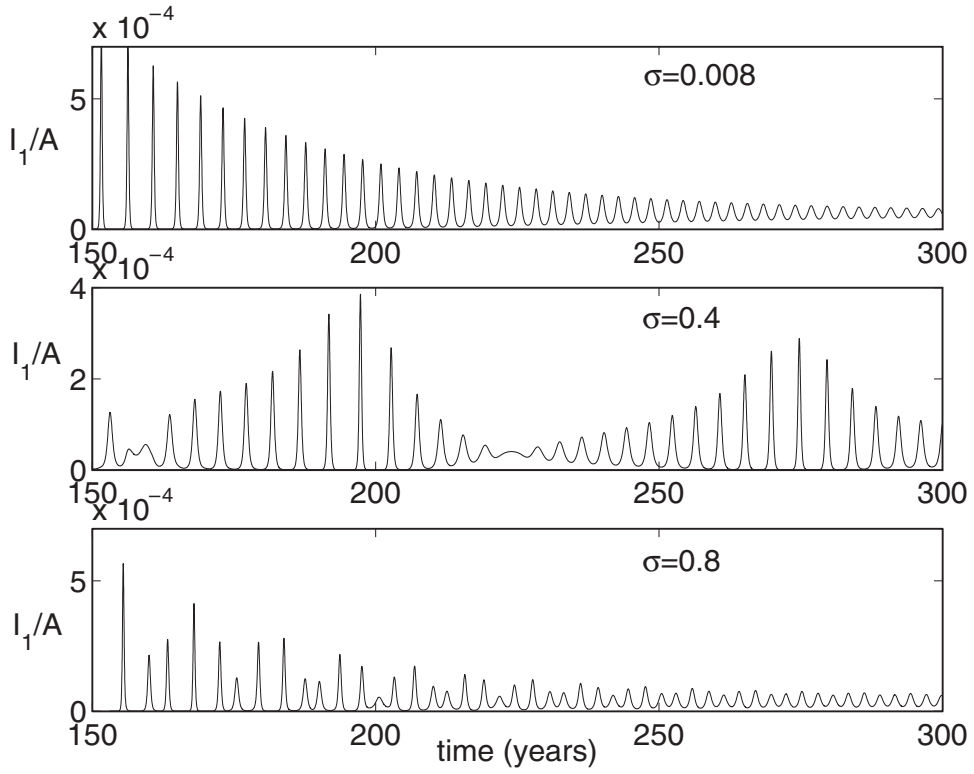

FIG. 7. *Numerical integration of the model equations. The fraction of the infective individuals (nonisolated) with strain* 1 (I_1/N) *is shown. The isolation period is fixed at* 3 *days, while cross-immunity levels are varied (from top to bottom:* 0.008 *(strong),* 0.4 *(intermediate), and* 0.8 *(weak).*

to weak, the periods become more irregular, and the amplitude ranges vary (4×10^{-5} to 4×10^{-4}, $\sigma = 0.4$ and 1–5.5×10^{-4}, $\sigma = 0.8$).

Case 2. $\sigma_{12} \neq \sigma_{21}$. Briefly, we study the effect of isolation for asymmetric cross-immunity by allowing strains to become antigenically distinct with increasing ε (that is, $|\sigma_{12} - \sigma_{21}| = \varepsilon$) (see also [12]). We assume a 3-day isolation period. Figure 8 illustrates the interactions that arise between nonsymmetric strains as their difference in cross-immunity increases, $\varepsilon \in (0.01, 0.03)$. The periods between oscillations for strain 1 (solid) vary from 10–11 years with increasing ε and decreasing levels of cross-immunity. Similarly, the periods between oscillations corresponding to strain 2 (dashed) vary from 10–13 years. The amplitude with highest peak for strain 1 (3.8×10^{-4}) is attained at $\varepsilon = 0.02$, whereas that of strain 2 is observed at $\varepsilon = 0.02$ and $\varepsilon = 0.03$ (3×10^{-4}). Figure 8 shows that for intermediate coupled strains ($\sigma_{ij} \approx 0.33$), the system goes through cycles with approximate periods of 10–13 years, where each cycle may contain minor outbreaks followed by a period with very low disease levels (1–2 $\times 10^{-5}$).

6. Discussion. "Flu" epidemic patterns include yearly outbreaks (antigenic drift), the explosive onset of outbreaks, the rapid termination of local epidemics (despite an "abundance" of susceptible individuals), and potentially major pandemics (antigenic shift). The continuous generation (most likely from random mutations in the NS gene) of new "flu" strains ("minor" genetic changes) and the sudden generation of subtypes (radical genetic changes) and their impact on the history of

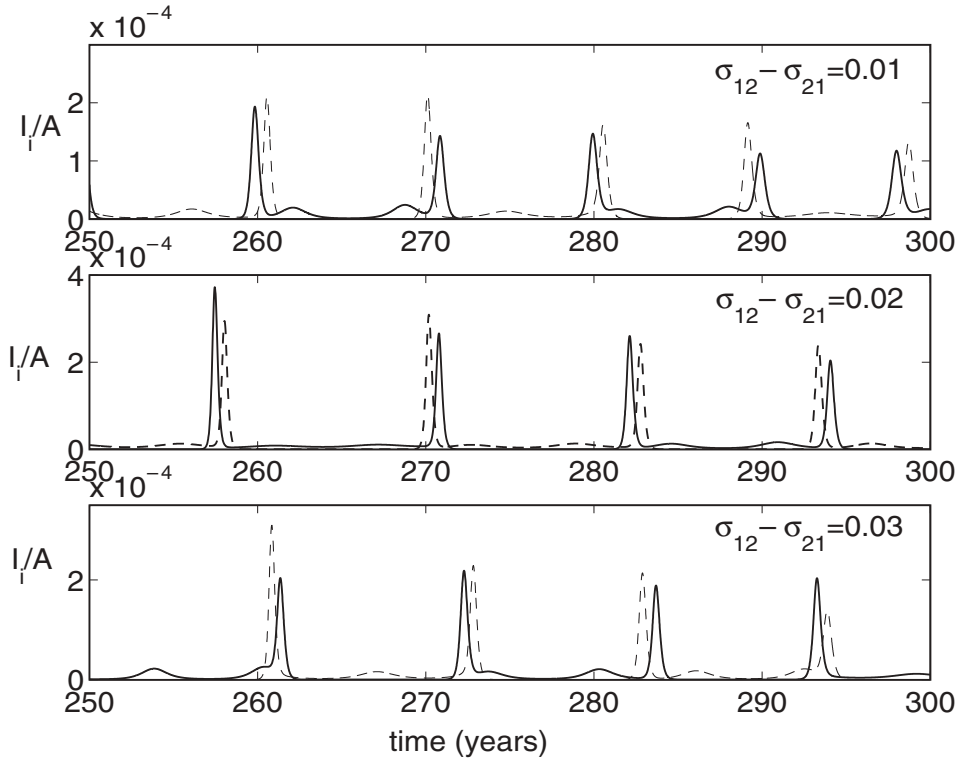

FIG. 8. *Numerical integration of the model equations. The fraction of the infective individuals (nonisolated) with strain* 1 *(solid) and strain* 2 *(dashed) is shown. Differences in cross-immunity levels between strains* 1 *and* 2 $(\sigma_{12} - \sigma_{21})$ *increase (from top to bottom):* 0.01, 0.02, *and* 0.03. *For example, cross-immunity for strains* 1 *and* 2 *correspondingly are given by* $\sigma_{12} = 0.36$ *and* $\sigma_{21} = 0.33$ *(bottom panel).*

acquired (age-dependent) immunity of host populations make the study of influenza dynamics and its control challenging and fascinating [2, 16].

The focus of this article is on the time evolution of influenza A in a nonfixed landscape driven by tight coevolutionary interactions (that is, interactions where the fate of the host and the parasite are intimately connected; see [25]) between human hosts and competing strains. The process is mediated by intervention (behavioral changes) and cross-immunity. In other words, the nature of the invading landscape (susceptible host) changes dynamically from behavioral changes (isolation, short time scale) and past immunological experience (cross-immunity, long time scale).

The "partial" herd-immunity generated by past history of invasions on the host population can have a huge impact on the quantitative dynamics of the "flu" at the population level. The assumption that $\sigma_{12} = \sigma_{21} = \sigma$ for $i \neq j$ naturally results in a dynamic landscape that is not too different (in the oscillatory regime) than the one observed on single-strain models with isolation [15, 20]. That is, a lack of heterogeneity in cross-immunity results in a system "more or less" driven (in the oscillatory regime) by the process of isolation. However, small variations in isolation (Figure 6) leads to radically quantitatively distinct epidemics in the oscillatory regime. This modeling framework (see also [5, 6]) can "asses" the impact of antigenically similar ($|\sigma_{ij} - \sigma_{ji}| \to 0$) and antigenically distinct strains ($|\sigma_{ij} - \sigma_{ji}| > \epsilon$).

In all cases, sustained oscillations with periods that are consistent with influenza epidemics/pandemics are possible [11, 28]. These results are consistent with those obtained in single-strain models [14] (i.e., sustained oscillations are preserved), except that the oscillations are now possible for "realistic" isolation periods. The introduction of a second strain enhances the possibilities. Numerical simulations illustrate various outcomes, including competitive exclusion, coexistence, and subthreshold coexistence. The interepidemic periods range from 2 to 10–13 years, depending on the levels of cross-immunity. Strong intermediate asymmetric cross-immunity leads to interepidemic periods in the range of 10–13 years. Symmetric cross-immunity reduces the range to 1–3 years. The results of intermediate (symmetric) cross-immunity are consistent with those found in [5, 6]. Documented evidence on the cocirculation of strains belonging to the same subtype [11, 28] appears to be consistent with these results.

Our results show that multiple strain coexistence is highly likely for antigenically distinct (weak cross-immunity) strains and not for antigenically similar under symmetric cross-immunity ("competitive exclusion" principle [4]). As the levels of cross-immunity weaken, the likelihood of subthreshold coexistence ($\Re_i^j < 1$) increases. However, "full" understanding of the evolutionary implications that result from human host and influenza virus interactions may require the study of systems that incorporate additional mechanisms such as seasonality in transmission rates, age-structure, individual differences in susceptibility or infectiousness, and the possibility of coinfections. Thacker [28] notes that the observed seasonality of influenza in temperate zones may be the key to observed patterns of recurrent epidemics. Superinfection may also be a mechanism worth consideration, even though studies in [22] show that it is only moderately possible for young individuals to become infected with two different strains in one "flu" season.

The recent flu epidemic [3] which has invaded all 50 states (2003–2004) and our experiences with the recent SARS epidemic [10] are a source of concern. While isolation and quarantine [8] seem effective [10], they can "destabilize" "flu" dynamics (oscillations) and generate some level of uncertainty. The results in this paper suggest the need to explore the long-term impact of current U.S. vaccination policies on the levels of cross-immunity generated by herd-immunity in the case of the flu. Whether or not they increase or reduce the likelihood of a future major outbreak is a question worth considering.

Appendix A. The local stability of the disease-free state follows from the study of the eigenvalues of the Jacobian matrix J of system (1) at E_0. The 10×10 Jacobian matrix J is partitioned after arranging the variables, that is, after rewriting system (1) as $dM/dt = F(M)$, where $M = (S, I_1, I_2, Q_1, Q_2, R_1, R_2, V_1, V_2, W)$. The corresponding eigenvalues are given by $\lambda_i = -\mu$ for $i = 1, 2, 3, 4$; $\lambda_i = \beta_i - (\mu + \gamma_i + \delta_i)$ for $i = 1, 2$; $\lambda_i = -(\mu + \alpha_i)$ for $i = 1, 2$; $\lambda_i = (\mu + \gamma_i)$.

Acknowledgments. The authors are sincerely grateful to Gerardo Chowell, Laura Jones, Prasith Baccam, Catherine Macken, and Christopher Kribs for their beneficial comments and suggestions. The authors would also like to thank LANL (Center for Nonlinear Studies) for their support during the visit of Dr. Castillo-Chavez as a Ulam Scholar.

HOMOGENIZATION OF INTERFACES BETWEEN RAPIDLY OSCILLATING FINE ELASTIC STRUCTURES AND FLUIDS*

K.-H. HOFFMANN†, N. D. BOTKIN†, AND V. N. STAROVOITOV‡

Abstract. The paper studies the interaction of a periodic solid bristle structure with a fluid. Such problems arise, for example, when modelling biotechnological devices operating in liquids or when simulating epithelium surfaces of blood vessels. The fluid is described by the linearized Navier–Stokes equation whereas the solid part is governed by equations of linear elasticity. The interface conditions are accounted. A homogenized model of the structure is derived by employing the two-scale convergence technique. The model describes a new material which possesses some interesting properties.

Key words. homogenization, fluid-solid interface, biosensor, multi-layered structure

1. Introduction. We study a mechanical system consisting of a fluid and a rapidly oscillating elastic fine structure interacting with the fluid. The goal is to obtain averaged equations which effectively describe the behavior of the system.

This investigation is motivated by modelling a surface acoustic wave sensor based on the generation and detection of horizontally polarized shear waves (see [3]). Acoustic shear waves are excited through an alternate voltage applied to electrodes deposited on a quartz crystal substrate. The waves are transmitted into a thin isotropic guiding layer covered by a thin gold film that contacts a liquid containing a protein to be detected. The protein adheres to a specific receptor (aptamer) placed on the surface of the gold film. The arising mass loading causes a phase shift in the electric signal to be measured by an electronic circuit.

One can impress the aptamer-protein layer as a periodic bristle or pin structure on the top of the gold film contacting with the liquid (see Figure 1). The thickness of the aptamer-protein layer is about 4 nm, and the number of bristles per surface unit is enormous large. Therefore, the direct numerical modelling of such a structure using fluid-solid interface conditions is impossible. Proper models can be derived using the homogenization technique from [12], [11], [1], [7], [8], and [5] along with the strict treatment of the solid-fluid interface (see, e.g., [6]).

Problems that are close to ours were studied in [13] and [2]. L. Baffico and C. Conca [2] considered the same geometry but the equations differ from ours. J. Sanchez-Hubert [13] investigated almost the same problem. She used techniques based on the Laplace transformation whereas we apply another approach which makes it possible to obtain an explicit representation of solutions to the cell equation, which allows us to investigate the limiting equations and to develop numerical algorithms.

2. Mathematical model. The coupled mechanical system under consideration is shown in Figure 1. The solid part consists of a substrate and pins located on its top.

‡Lavrentyev Institute of Hydrodynamics, 630090 Novosibirsk, Russia, Center of Advanced European Studies and Research, Ludwig-Erhard-Allee 2, 53175 Bonn, Germany (starovoitov@caesar.de).

The pin structure is assumed to be periodic in the plane (x_1, x_2) and independent of x_3. The domain of the coupled system is denoted by $\Omega \subset \mathbb{R}^3$. For simplicity, we suppose that Ω is the cube $\{\boldsymbol{x} \in \mathbb{R}^3 \,|\, x_k \in (-1;+1),\ k = 1,2,3\}$. The domains occupied by the fluid and elastic continua are denoted by $\Omega_{_F}$ and $\Omega_{_S}$, respectively; the boundary separating the continua by Γ. Thus, $\Omega = \Omega_{_F} \cup \Gamma \cup \Omega_{_S}$. Let $(\partial\Omega)_{_F} = \partial\Omega \cap \overline{\Omega}_{_F}$ and $(\partial\Omega)_{_S} = \partial\Omega \cap \overline{\Omega}_{_S}$. Then the sets $\Gamma \cup (\partial\Omega)_{_F}$ and $\Gamma \cup (\partial\Omega)_{_S}$ are the boundaries of the domains $\Omega_{_F}$ and $\Omega_{_S}$, respectively.

2.1. Governing equations. We assume that the fluid is weakly compressible, which is physically correct because the operation frequency of the coupled structure lies in the acoustic range and the displacements of the fluid particles are small. This is a typical acoustic approximation which additionally utilizes linearized Navier–Stokes equations (see [9]).

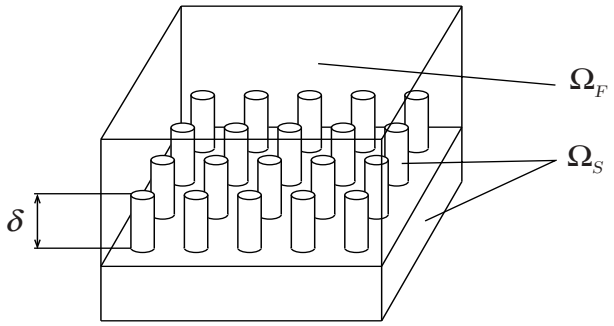

FIG. 1. *Coupled system:* $\Omega = \Omega_{_F} \cup \Gamma \cup \Omega_{_S}$

The solid part of the system will be described using the linear elasticity approach. This linear setting is supplemented by the assumption that the domains $\Omega_{_F}$ and $\Omega_{_S}$ remain unchangeable. Therefore, the coupled mechanical system is described by the following equations:

$$\rho_{_F}\boldsymbol{u}_t = -\nabla p + \operatorname{div} P\boldsymbol{u}_{\boldsymbol{x}} + \rho_{_F}\boldsymbol{f} \quad \text{in} \quad \Omega_{_F}, \tag{2.1}$$

$$\gamma p_t = -\operatorname{div}\boldsymbol{u} \quad \text{in} \quad \Omega_{_F}, \tag{2.2}$$

$$\rho_{_S}\boldsymbol{v}_{tt} = \operatorname{div} G\boldsymbol{v}_{\boldsymbol{x}} + \rho_{_S}\boldsymbol{f} \quad \text{in} \quad \Omega_{_S}. \tag{2.3}$$

Let $\boldsymbol{n}$ be the normal vector to the fluid-solid interface Γ. The no-slip and stress equilibrium conditions on Γ read

$$\boldsymbol{v}_t = \boldsymbol{u} \quad \text{on} \quad \Gamma, \tag{2.4}$$

$$G\boldsymbol{v}_{\boldsymbol{x}} \cdot \boldsymbol{n} = \big(-p\mathcal{I} + P\boldsymbol{u}_{\boldsymbol{x}} \big) \cdot \boldsymbol{n} \quad \text{on} \quad \Gamma. \tag{2.5}$$

The boundary and initial conditions are prescribed:

$$\boldsymbol{u} = 0 \quad \text{on} \quad (\partial\Omega)_{_F}, \tag{2.6}$$

$$\boldsymbol{v} = 0 \quad \text{on} \quad (\partial\Omega)_{_S}, \tag{2.7}$$

$$\boldsymbol{u}|_{t=0} = \boldsymbol{u}^0,\ p|_{t=0} = p^0 \quad \text{in} \quad \Omega_{_F}, \tag{2.8}$$

$$\boldsymbol{v}|_{t=0} = \boldsymbol{v}^0,\ \boldsymbol{v}_t|_{t=0} = \boldsymbol{v}'^0 \quad \text{in} \quad \Omega_{_S}. \tag{2.9}$$

Here, $\rho_{_F}$ and $\rho_{_S}$ are the constant densities of the fluid and of the solid parts, respectively; $\boldsymbol{u}$ is the velocity field of the fluid, p is the pressure in the fluid, $\boldsymbol{v}$ is the displacement field of the solid part, and $\boldsymbol{f}$ is an external force like the gravity. The coefficient γ characterizes the compressibility of the fluid. The fourth-rank tensor $P = \{P_{ijkl}\}$ is defined through the relation

$$P\boldsymbol{u}_{\boldsymbol{x}} = \lambda\,\mathcal{I}\,\mathrm{div}\,\boldsymbol{u} + 2\mu\,\mathcal{D}(\boldsymbol{u}). \tag{2.10}$$

The unit tensor $\mathcal{I}$ has the components $\mathcal{I}_{ij} = \delta_{ij}$, where δ_{ij} is the Kronecker symbol. The strain velocity tensor $\mathcal{D}(\boldsymbol{u})$ has, as is usual, the components $\mathcal{D}_{ij}(\boldsymbol{u}) = 1/2\,(\partial u_i/\partial x_j + \partial u_j/\partial x_i)$. The symbols λ and μ denote positive balk and dynamic viscosity coefficients of the fluid, respectively. As is usual, the summation over repeating indices is assumed. The components G_{ijkl} of the elastic stiffness tensor G can be arbitrary up to base restrictions so that arbitrary *anisotropic solids* can be considered.

The model (2.1)–(2.9) was investigated in [10] where it was supposed to use the velocity instead of the displacement in (2.3). Following this approach, we introduce the integral operator

$$\mathcal{J}_t\boldsymbol{w} = \int_0^t \boldsymbol{w}(s)ds$$

that enables us to rewrite (2.3) in the form

$$\rho_{_S}\boldsymbol{u}_t = \mathrm{div}\big(G\mathcal{J}_t\boldsymbol{u}_{\boldsymbol{x}}\big) + \mathrm{div}\,\mathcal{G}^0 + \rho_{_S}\boldsymbol{f}, \tag{2.11}$$

where $\boldsymbol{u} = \boldsymbol{v}_t$, $\mathcal{G}^0 = G\boldsymbol{v}^0_{\boldsymbol{x}}$ in $\Omega_{_S}$. Similarly, the pressure p can be expressed from (2.3) as follows:

$$p = -\gamma^{-1}\mathrm{div}\,\mathcal{J}_t\boldsymbol{u} + p^0 \quad \text{in} \quad \Omega_{_F}. \tag{2.12}$$

Let χ be the characteristic function of the domain $\Omega_{_F}$. Then (2.1), (2.2), and (2.3) can be written in the whole domain Ω as one equation with discontinuous coefficients

$$\rho\,\boldsymbol{u}_t = \mathrm{div}\big(\boldsymbol{M}^t\boldsymbol{u}_x\big) + \mathrm{div}\,\mathcal{N}^0 + \rho\boldsymbol{f}, \tag{2.13}$$

where

$$\boldsymbol{M}^t = \chi P + \big(\chi\gamma^{-1}\mathcal{I}\otimes\mathcal{I} + (1-\chi)G\big)\,\mathcal{J}_t,$$

$$\rho = \rho_{_F}\chi + \rho_{_S}(1-\chi), \quad \mathcal{N}^0 = -\chi p^0\mathcal{I} + (1-\chi)\mathcal{G}^0.$$

The interface condition (2.4) is equivalent to the "continuity" of $\boldsymbol{u}$ on Γ but the condition (2.5) now assumes the form

$$\big(G\mathcal{J}_t\boldsymbol{u}_{\boldsymbol{x}} + \mathcal{G}^0\big)\cdot\boldsymbol{n} = \big(\gamma^{-1}\mathrm{div}\mathcal{J}_t\,\boldsymbol{u}I - p^0I + P\boldsymbol{u}_{\boldsymbol{x}}\big)\cdot\boldsymbol{n} \quad \text{on} \quad \Gamma \tag{2.14}$$

accounting (2.12). The boundary and initial data are

$$\boldsymbol{u} = 0 \qquad \text{on} \quad (\partial\Omega)_{_F}, \tag{2.15}$$

$$\boldsymbol{u}|_{t=0} = \boldsymbol{u}^0 \qquad \text{in} \quad \Omega, \tag{2.16}$$

where the fluid initial condition $\boldsymbol{u}^0$ is extended to Ω_S by setting $\boldsymbol{u}^0(\boldsymbol{x}) = \boldsymbol{v}'^0(\boldsymbol{x})$ for $\boldsymbol{x} \in \Omega_S$.

Remark 2.1. One can forget the initial distribution $\boldsymbol{v}^0$ of the displacement when considering (2.13). It is sufficient to prescribe the initial velocity field $\boldsymbol{u}^0$ in Ω, the initial stress $\mathcal{G}^0$ in Ω_S (this replaces the information about $\boldsymbol{v}^0$), and initial pressure p^0 in Ω_F. The functions $\mathcal{G}^0$ and p^0 yield the function $\mathcal{N}^0$ involved in (2.13).

Remark 2.2. For mechanical reasons, the tensors P_{ijkl} and G_{ijkl} have the following properties:

$$Z_{ijkl} = Z_{ijlk} = Z_{klij} = Z_{jikl}, \quad Z_{ijkl}\mathcal{V}_{ij}\mathcal{V}_{kl} \geqslant 0,$$

$$Z_{ijkl}\mathcal{V}_{ij}\mathcal{V}_{kl} = 0 \quad \text{if and only if} \quad \mathcal{V}_{kl} + \mathcal{V}_{lk} = 0 \quad \text{for all} \quad k, l = 1, 2, 3.$$

Here, Z_{ijkl} stands for P_{ijkl} or G_{ijkl}.

2.2. Refinement of the structure. Let us define the structure of the regions Ω, Ω_F, and Ω_S more precisely. The pin structure (see Figure 1) is supposed to be (x_1, x_2)-periodic. Without loss of generality, we assume that the periodicity cell is a square with the side length equal to ε, where ε is a positive number. After scaling with the factor $1/\varepsilon$, the cell becomes the unit square $\Sigma = [0, 1] \times [0, 1]$. Let Σ_S be the $1/\varepsilon$-scaled projection of a solid pin to the (x_1, x_2)-plane. It is assumed to be a smooth, simply connected domain in Σ such that its boundary $\partial\Sigma_S$ does not meet $\partial\Sigma$. Denote by Σ_F the domain $\Sigma \setminus \overline{\Sigma}_S$ (see Figure 2).

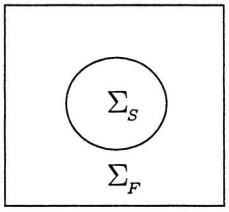

FIG. 2. *Structural cell* $\Sigma = [0, 1] \times [0, 1]$.

Let $\hat{\boldsymbol{x}} = (x_1, x_2)$ and $\hat{\chi}(\hat{\boldsymbol{x}})$ be the Σ-periodic extension of the characteristic function of the domain Σ_F to all $\mathbb{R}^2$. Then the function χ introduced in the previous subsection can be represented as follows:

$$\chi(\boldsymbol{x}) = \chi(\hat{\boldsymbol{x}}, x_3) = \begin{cases} 1, & x_3 > \delta, \\ \hat{\chi}(\frac{\hat{\boldsymbol{x}}}{\varepsilon}), & 0 \leqslant x_3 \leqslant \delta, \\ 0, & x_3 < 0. \end{cases} \tag{2.17}$$

Remember that δ is the thickness of the pin layer. If $\varepsilon \to 0$, the pin structure becomes finer in the (x_1, x_2)-plane, whereas its height remains constant. Thus, the problem (2.13)–(2.16) depends in fact on ε. For this reason, we call it *Problem* S_ε.

DEFINITION 2.3. *A function* $\boldsymbol{u}$ *is called a weak solution to Problem* S_ε *if*

$$\boldsymbol{u} \in L^\infty(0, T; L^2(\Omega)) \cap L^2(0, T; H^1(\Omega_F)), \quad \mathcal{J}_t\boldsymbol{u} \in L^\infty(0, T; H_0^1(\Omega)) \tag{2.18}$$

and the integral identity

$$\int_0^T \int_\Omega \Big(-\rho \boldsymbol{u}\cdot\boldsymbol{\varphi}_t + \boldsymbol{M}^t \boldsymbol{u}_x : \boldsymbol{\varphi}_x + \mathcal{N}^0 : \boldsymbol{\varphi}_x - \rho \boldsymbol{f}\cdot\boldsymbol{\varphi}\Big) d\boldsymbol{x}dt = \int_\Omega \rho \boldsymbol{u}^0\cdot\boldsymbol{\varphi}^0 d\boldsymbol{x} \tag{2.19}$$

holds for every smooth function $\boldsymbol{\varphi}$ *such that* $\boldsymbol{\varphi}|_{t=T} = \boldsymbol{\varphi}|_{\partial\Omega} = 0$.

In this definition and further, T is an arbitrary positive number; the colon denotes the convolution of tensors so that $\mathcal{U} : \mathcal{V} = \mathcal{U}_{ij}\mathcal{V}_{ij}$ for all second-rank tensors $\mathcal{U}$ and $\mathcal{V}$; and the notation f^0 means $f|_{t=0}$. Remark that the second inclusion of (2.18) prevents jumps of $\boldsymbol{u}$ on Γ.

2.3. Solvability of Problem S_ε. It is not difficult to prove existence of a weak solution to Problem S_ε. This question was investigated in [10, section 9.1], and the following result was established.

THEOREM 2.4. *Let* $\boldsymbol{u}^0 \in L^2(\Omega)$, $\mathcal{N}^0 \in L^2(\Omega)$, *and* $\boldsymbol{f} \in L^2([0,T]\times\Omega)$. *Then there exists a unique weak solution to Problem* S_ε, *and the following energy estimate holds:*

$$\operatorname{ess\,sup}_{t\in(0,T)} \Big(\|\boldsymbol{u}(t)\|^2_{L^2(\Omega)} + \|\mathcal{D}\big(\mathcal{J}_t\boldsymbol{u}\big)\|^2_{L^2(\Omega_S)} \Big) + \int_0^T \|\mathcal{D}(\boldsymbol{u}(t))\|^2_{L^2(\Omega_F)}\, dt \leqslant C, \tag{2.20}$$

where C *is a constant which depends on* $\|\boldsymbol{u}^0\|_{L^2(\Omega)}$, $\|\mathcal{N}^0\|_{L^2(\Omega)}$, *and* $\|\boldsymbol{f}\|_{L^2([0,T]\times\Omega)}$ *but does not depend on* ε.

COROLLARY 2.5. *Under the conditions of Theorem* 2.4, *there exists an independent of* ε *constant* C *such that*

$$\operatorname{ess\,sup}_{t\in(0,T)} \|\mathcal{J}_t\boldsymbol{u}(t)\|_{H^1(\Omega)} \leqslant C. \tag{2.21}$$

Generally speaking, the estimates (2.20) and (2.21) are sufficient to fulfill the homogenization of Problem S_ε due to Proposition 3.9 which will be given below. However, some technical difficulties must be overcome in this case. To avoid that, a stronger estimate for $\boldsymbol{u}$ will be obtained under some compatibility conditions. The next theorem states such a result.

THEOREM 2.6. *Let* $\boldsymbol{u}^0 \in H^1(\Omega)$, $\mathcal{N}^0 \in L^2(\Omega)$, $\boldsymbol{f}, \boldsymbol{f}_t \in L^2([0,T]\times\Omega)$, *and*

$$\operatorname{div}\big(\chi P\boldsymbol{u}^0_{\boldsymbol{x}} + \mathcal{N}^0\big) \in L^2(\Omega). \tag{2.22}$$

Then the weak solution to Problem S_ε *satisfies the estimate*

$$\operatorname{ess\,sup}_{t\in(0,T)} \big(\|\boldsymbol{u}_t(t)\|_{L^2(\Omega)} + \|\boldsymbol{u}_x(t)\|_{L^2(\Omega)} \big) \leqslant C, \tag{2.23}$$

where C *is an independent of* ε *constant.*

Proof. Let us introduce a function $\boldsymbol{w}$ as a solution of the problem

$$\begin{aligned} &\rho\,\boldsymbol{w}_t = \operatorname{div}\big(\boldsymbol{M}^t\boldsymbol{w}_x\big) + \operatorname{div}\big(\chi\gamma^{-1}I\operatorname{div}\boldsymbol{u}^0 + (1-\chi)G\boldsymbol{u}^0_{\boldsymbol{x}}\big) + \rho\boldsymbol{f}_t,\\ &\rho\,\boldsymbol{w}\big|_{t=0} = \rho\,\boldsymbol{w}_0 = \operatorname{div}\big(Pu^0_{\boldsymbol{x}} + \mathcal{N}^0\big) + \rho\boldsymbol{f}^0,\\ &\boldsymbol{w}\big|_{\partial\Omega} = 0. \end{aligned}$$

The energy estimate for this problem appears as follows:

$$\operatorname{ess\,sup}_{t\in(0,T)} \Big(\|\boldsymbol{w}(t)\|^2_{L^2(\Omega)} + \|\mathcal{D}\big(\mathcal{J}_t\boldsymbol{w}\big)\|^2_{L^2(\Omega_S)} \Big) + \int_0^T \|\mathcal{D}(\boldsymbol{w}(t))\|^2_{L^2(\Omega_F)}\, dt \leqslant C, \tag{2.24}$$

which yields

$$\operatorname{ess\,sup}_{t\in(0,T)}\|\mathcal{J}_t\boldsymbol{w}\|_{H^1(\Omega)} \leqslant C.$$

The assertion of the theorem is an immediate consequence of the last estimates because the function defined as

$$\boldsymbol{u}(\boldsymbol{x},t) = \int_0^t \boldsymbol{w}(\boldsymbol{x},s)\,ds + \boldsymbol{u}^0(\boldsymbol{x}) = \mathcal{J}_t\boldsymbol{w}(\boldsymbol{x},t) + \boldsymbol{u}^0(\boldsymbol{x})$$

is the solution of Problem S_ε, and $\boldsymbol{u}_t = \boldsymbol{w}$. ∎

According to the definition of $\boldsymbol{u}^0$, the requirement $\boldsymbol{u}^0 \in H^1(\Omega)$ expresses the no-slip condition on Γ at the initial time instant $t = 0$. The requirement (2.22) expresses the stress equilibrium condition on Γ at $t = 0$. From the mechanical point of view, such conditions hold for any time instant including the initial one. Therefore, the requirements of the theorem are feasible.

3. Homogenization of the structure.

3.1. Two-scale convergence. Let us denote by $\boldsymbol{u}_\varepsilon$ the solution of Problem S_ε. In order to emphasize the dependence of χ on ε, we denote it by χ^ε. Our goal is to perform the passage to the limit in Problem S_ε as $\varepsilon \to 0$. To do this, we use the two-scale convergence method introduced by G. Nguetseng and developed by other mathematicians (see [12], [11], [1], [7]). Let us formulate the main results of this approach adapted to our situation.

THEOREM 3.7. *Let $\boldsymbol{w}_\varepsilon$ be a bounded sequence in $L^2\big([0,T]\times\Omega\big)$. There exists a subsequence, still denoted by $\boldsymbol{w}_\varepsilon$, and a function $\overline{\boldsymbol{w}}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}}) \in L^2\big([0,T]\times\Omega\times\Sigma\big)$ such that*

$$\lim_{\varepsilon\to 0}\int_0^T\int_\Omega \boldsymbol{w}_\varepsilon(t,\boldsymbol{x})\boldsymbol{\phi}\left(t,\boldsymbol{x},\frac{\hat{\boldsymbol{x}}}{\varepsilon}\right)d\boldsymbol{x} = \int_0^T\int_\Omega\int_\Sigma \overline{\boldsymbol{w}}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})\boldsymbol{\phi}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})\,d\hat{\boldsymbol{\xi}}d\boldsymbol{x}dt$$

for every smooth function $\boldsymbol{\phi}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})$ which is Σ-periodic in $\hat{\boldsymbol{\xi}}$. Such a sequence $\boldsymbol{w}_\varepsilon$ is said to be two-scale convergent to $\overline{\boldsymbol{w}}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})$.

Recall the notation $\hat{\boldsymbol{x}} = (x_1, x_2)$ and $\hat{\boldsymbol{\xi}} = (\xi_1, \xi_2)$.

THEOREM 3.8. *Let a sequence $\boldsymbol{w}_\varepsilon$ converge weakly to $\boldsymbol{w}$ in $L^2\big(0,T;H^1(\Omega)\big)$. Then $\boldsymbol{w}_\varepsilon$ two-scale converges to $\boldsymbol{w}$ and there exists a function $\overline{\boldsymbol{w}}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})$ in $L^2\big([0,T]\times\Omega;H^1_\#(\Sigma)/\mathbb{R}\big)$ such that $\nabla\boldsymbol{w}_\varepsilon$ two-scale converges to $\nabla_x\boldsymbol{w}(t,\boldsymbol{x}) + \nabla_\xi\overline{\boldsymbol{w}}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})$ up to a subsequence.*

Here $H^1_\#(\Sigma)$ is the space of Σ–periodic functions which belong to the space $H^1(\Sigma)$. Since all functions under consideration do not depend on ξ_3, the notation $\nabla_\xi = (\partial_{\xi_1}, \partial_{\xi_2}, 0)^\top$ is used below.

As a simple application of the theorems stated above, we formulate (without proof) the following result concerning the convergence of solutions of Problem S_ε.

PROPOSITION 3.9. *Let $\boldsymbol{u}_\varepsilon$ be the sequence of solutions to Problem S_ε. Then there exist a subsequence (still denoted by $\boldsymbol{u}_\varepsilon$) and a function $\boldsymbol{u}(t,\boldsymbol{x})$ such that*

1. *$\boldsymbol{u}_\varepsilon$ two-scale converges to $\boldsymbol{u}$, and $\boldsymbol{u}_\varepsilon \to \boldsymbol{u}$ weakly in $L^2\big([0,T]\times\Omega\big)$;*
2. *$\mathcal{J}_t\boldsymbol{u}_\varepsilon$ two-scale converges to $\mathcal{J}_t\boldsymbol{u}$, and $\mathcal{J}_t\boldsymbol{u}_\varepsilon \to \mathcal{J}_t\boldsymbol{u}$ in $L^2\big([0,T]\times\Omega\big)$;*
3. *$\nabla\mathcal{J}_t\boldsymbol{u}_\varepsilon$ two-scale converges to $\nabla_x\mathcal{J}_t\boldsymbol{u} + \nabla_\xi\boldsymbol{\zeta}$, where $\boldsymbol{\zeta}(t,\boldsymbol{x},\hat{\boldsymbol{\xi}})$ is a function from $L^2\big([0,T]\times\Omega;H^1_\#(\Sigma)/\mathbb{R}\big)$.*

3.2. Passage to the limit in Problem S_ε. Let the initial data of Problem S_ε satisfy the conditions of Theorem 2.6. A solution $\boldsymbol{u}_\varepsilon$ of Problem S_ε satisfies the following integral identity,

(3.1)
$$\int_0^T \int_\Omega \Big(-\rho^\varepsilon \boldsymbol{u}_\varepsilon \cdot \boldsymbol{\varphi}_t + \boldsymbol{M}^{\varepsilon t} \boldsymbol{u}_{\varepsilon x} : \boldsymbol{\varphi}_x + \mathcal{N}^{\varepsilon 0} : \boldsymbol{\varphi}_x - \rho^\varepsilon \boldsymbol{f} \cdot \boldsymbol{\varphi} \Big) d\boldsymbol{x} dt = \int_\Omega \rho^\varepsilon \boldsymbol{u}^0 \cdot \boldsymbol{\varphi}^0 d\boldsymbol{x},$$

where ρ^ε, $\boldsymbol{M}^{\varepsilon t}$, and $\mathcal{N}^{\varepsilon 0}$ are defined as in (2.13) but with χ replaced by χ^ε. Let us take

$$\boldsymbol{\varphi}(t, \boldsymbol{x}) = \boldsymbol{\phi}(t, \boldsymbol{x}) + \varepsilon \, \overline{\boldsymbol{\phi}}\Big(t, \boldsymbol{x}, \frac{\hat{\boldsymbol{x}}}{\varepsilon}\Big),$$

where $\boldsymbol{\phi}$ and $\overline{\boldsymbol{\phi}}$ are arbitrary functions that vanish for $\boldsymbol{x} \in \partial\Omega$ and at $t = T$. Theorem 3.8 enables the passage to the limit in (3.1) as $\varepsilon \to 0$. The limiting equations look as follows:

(3.2)
$$\int_0^T \int_\Omega \int_\Sigma \Big(-\rho \boldsymbol{u} \cdot \boldsymbol{\phi}_t + \boldsymbol{M}^t (\boldsymbol{u}_x + \overline{\boldsymbol{u}}_\xi) : \boldsymbol{\phi}_x + \mathcal{N}^0 : \boldsymbol{\phi}_x - \rho \boldsymbol{f} \cdot \boldsymbol{\phi} \Big) \, d\hat{\boldsymbol{\xi}} \, d\boldsymbol{x} dt = \int_\Omega \int_\Sigma \rho \boldsymbol{u}^0 \cdot \boldsymbol{\phi}^0 \, d\hat{\boldsymbol{\xi}} \, d\boldsymbol{x},$$

(3.3)
$$\int_\Sigma \Big(\boldsymbol{M}^t (\boldsymbol{u}_x + \overline{\boldsymbol{u}}_\xi) : \overline{\boldsymbol{\phi}}_\xi + \mathcal{N}^0 : \overline{\boldsymbol{\phi}}_\xi \Big) \, d\hat{\boldsymbol{\xi}} = 0 \quad \text{in} \quad L^2\big([0,T] \times \Omega\big).$$

These equations hold for all functions $\boldsymbol{\phi} \in H^1([0,T] \times \Omega)$ and $\overline{\boldsymbol{\phi}} \in H^1_\#(\Sigma)$ such that $\boldsymbol{\phi}$ vanish on $\partial\Omega$ and at $t = T$. The coefficients ρ, $\boldsymbol{M}^t$, and $\mathcal{N}^0$ are defined as in (2.13) with $\chi(\boldsymbol{x})$ replaced by $\chi(\boldsymbol{x}, \hat{\boldsymbol{\xi}})$. The function $\chi(\boldsymbol{x}, \hat{\boldsymbol{\xi}})$ is defined as in subsection 2.2:

$$\chi(\boldsymbol{x}, \hat{\boldsymbol{\xi}}) = \begin{cases} 1, & x_3 > \delta, \\ \hat{\chi}(\hat{\boldsymbol{\xi}}), & 0 \leqslant x_3 \leqslant \delta, \\ 0, & x_3 < 0. \end{cases}$$

Equation (3.3) is called a *cell equation*.

Equations (3.2) and (3.3) are coupled through the auxiliary function $\overline{\boldsymbol{u}}$. The next step consists of finding $\overline{\boldsymbol{u}}$ from the cell equation (3.3) and substituting the obtained expression into (3.2).

4. Explicit solving of the cell equation.

4.1. Operator form of the cell equation in a Hilbert space. It is appropriate to rewrite (3.3) as an equation in the Hilbert space $H = H^1_\#(\Sigma)/\mathbb{R}$ with the inner product

$$\langle \boldsymbol{u}, \boldsymbol{v} \rangle = \int_\Sigma \frac{\partial u_i}{\partial \xi_j} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}}.$$

The norm in H is denoted by $\| \cdot \|$. Let us define operators $\mathcal{A}$ and $\mathcal{B}$ as follows:

$$\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{v} \rangle = \int_\Sigma \chi P_{ijkl} \frac{\partial u_k}{\partial \xi_l} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}}, \quad \langle \mathcal{B}\boldsymbol{u}, \boldsymbol{v} \rangle = \int_\Sigma \Big(\chi \gamma^{-1} \delta_{ij} \delta_{kl} + (1 - \chi) \, G_{ijkl} \Big) \frac{\partial u_k}{\partial \xi_l} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}}$$

for all functions $\boldsymbol{u}, \boldsymbol{v} \in H$. Due to the Riesz representation theorem, there exist $\boldsymbol{n}_0$, $\boldsymbol{a}_{kl}$, and $\boldsymbol{b}_{kl}$, $k, l = 1, 2, 3$, such that

$$\langle \boldsymbol{n}_0, \boldsymbol{v} \rangle = \int_\Sigma \mathcal{N}^0 : \boldsymbol{v}_\xi \, d\hat{\boldsymbol{\xi}}, \qquad \langle \boldsymbol{a}_{kl}, \boldsymbol{v} \rangle = \int_\Sigma \chi P_{ijkl} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}},$$

$$\langle \boldsymbol{b}_{kl}, \boldsymbol{v} \rangle = \int_\Sigma \left(\chi \gamma^{-1} \delta_{ij} \delta_{kl} + (1 - \chi) \, G_{ijkl} \right) \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}}$$

for all $\boldsymbol{v} \in H$. Remark that $\mathcal{A}$, $\mathcal{B}$, $\boldsymbol{a}$, $\boldsymbol{b}$, and $\boldsymbol{n}_0$ do not depend on t and depend on the variable $\boldsymbol{x}$ just in the same way as the function $\chi(\boldsymbol{x}, \hat{\boldsymbol{\xi}})$. So we can consider $\boldsymbol{x}$ and t in (3.3) as parameters.

Now, the problem (3.3) transforms to the following equation in the space H:

$$\mathcal{A}\overline{\boldsymbol{u}} + \mathcal{B}\mathcal{J}_t \overline{\boldsymbol{u}} = \boldsymbol{g}, \tag{4.1}$$

where

$$\boldsymbol{g} = -\big(\boldsymbol{a}_{kl} + \boldsymbol{b}_{kl} \mathcal{J}_t \big) \frac{\partial u_k}{\partial x_l} - \boldsymbol{n}_0$$

and $\boldsymbol{u}(\boldsymbol{x}, t)$ is from (3.2) and (3.3).

Since the operators $\mathcal{A}$ and $\mathcal{B}$ are trivial whenever $x_3 \notin [0, \delta]$, we consider (4.1) for $x_3 \in [0, \delta]$, which corresponds to the treatment of the pin layer. In this case, the operators $\mathcal{A}$ and $\mathcal{B}$ are degenerated. Therefore, some difficulties appear when solving (4.1).

The next section is devoted to the study of the data of (4.1) to prepare tools for its explicit solving.

4.2. Properties of $\mathcal{A}$, $\mathcal{B}$, and $\boldsymbol{g}$.

PROPOSITION 4.10. *The operator $\mathcal{A}$ has the following properties:*

1. *$\mathcal{A}$ is a bounded self-adjoint operator on H.*
2. *$\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u} \rangle \geqslant 0$ for all $\boldsymbol{u} \in H$.*
3. *The null-space $N(\mathcal{A}) = \{ \boldsymbol{u} \in H : \ \boldsymbol{u}$ is constant in $\Sigma_F \}$, and $N(\mathcal{A})^\perp \subset \{ \boldsymbol{u} \in H : \ \Delta \boldsymbol{u} = 0$ in $\Sigma_S \}$.*
4. *There exist positive constants c and C such that*

$$c \, \|\boldsymbol{u}\|^2 \leqslant \langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u} \rangle \leqslant C \, \|\boldsymbol{u}\|^2 \tag{4.2}$$

for all $\boldsymbol{u} \in N(\mathcal{A})^\perp$.

5. *The range $R(\mathcal{A})$ is closed in H, $R(\mathcal{A}) = N(\mathcal{A})^\perp$, and $\mathcal{A}^{-1}$ is defined and bounded as an operator on $R(\mathcal{A})$.*

Proof. Assertions 1 and 2 are obvious (see Remark 2.2). The third assertion consists of two parts. In order to prove the first one we have only to establish that

$$N(\mathcal{A}) \subset \{ \boldsymbol{u} \in H : \ \boldsymbol{u} \text{ is constant on } \Sigma_F \}$$

because the opposite inclusion is clearly true. Due to the positiveness of the operator $\mathcal{A}$, its null-space consists of functions $\boldsymbol{u}$ which satisfy the condition $\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u} \rangle = 0$. Thus, $\boldsymbol{u} \in N(\mathcal{A})$ implies

$$\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u} \rangle = \int_\Sigma \chi P_{ijkl} \frac{\partial u_k}{\partial \xi_l} \frac{\partial u_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}} = 0.$$

Consequently, $\mathcal{D}(\boldsymbol{u}) = 0$ in Σ_F, and, hence, $\boldsymbol{u}$ is constant in Σ_F because of its periodicity.

Let $\boldsymbol{u} \in N(\mathcal{A})^\perp$. By definition, this means that

$$\int_\Sigma \frac{\partial u_k}{\partial \xi_l}\frac{\partial v_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}} = \int_{\Sigma_S} \frac{\partial u_k}{\partial \xi_l}\frac{\partial v_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}} = 0$$

for any function $\boldsymbol{v} \in C^\infty(\Sigma)$ such that $\boldsymbol{v}$ is constant on $\overline{\Sigma}_F$. Consequently, $\boldsymbol{u}$ is harmonic in Σ_S, which proves the third assertion.

To validate assertion 3, we need only to prove the left inequality since the right one is obvious. Due to the Korn inequality (see, e.g., [14]), there exists a positive constant c_1 such that

$$\int_{\Sigma_F} |\boldsymbol{u}_\xi|^2\,d\hat{\boldsymbol{\xi}} \leqslant c_1\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u}\rangle$$

for every $\boldsymbol{u} \in H$. If $\boldsymbol{u} \in N(\mathcal{A})^\perp$, then $\boldsymbol{u}$ is harmonic in Σ_S and there exist positive constants c_2 and c_3 such that

$$c_2\int_{\Sigma_S} |\boldsymbol{u}_\xi|^2\,d\hat{\boldsymbol{\xi}} \leqslant \|\boldsymbol{u}\|_{H^{1/2}(\partial\Sigma_S)} \leqslant c_3\int_{\Sigma_F} |\boldsymbol{u}_\xi|^2\,d\hat{\boldsymbol{\xi}}.$$

That is, $\langle \mathcal{A}\boldsymbol{u}, \boldsymbol{u}\rangle \geqslant c\,\|\boldsymbol{u}\|^2$ for some constant c.

When proving assertion 5, denote by $\mathcal{A}_R$ the restriction of $\mathcal{A}$ to $N(\mathcal{A})^\perp$. Due to the estimate (4.2), $R(\mathcal{A}_R)$ is closed in H. Since $R(\mathcal{A}) = R(\mathcal{A}_R)$, we conclude that $R(\mathcal{A})$ is also a closed subspace of H. This implies that $N(\mathcal{A})^\perp = \overline{R(\mathcal{A})} = R(\mathcal{A})$, and (4.2) is true for $\boldsymbol{u} \in R(\mathcal{A})$. Thus, $\mathcal{A}^{-1}$ exists and is bounded if $\mathcal{A}$ is considered being restricted to $R(\mathcal{A})$. The proposition is proved. □

PROPOSITION 4.11. *The operator $\mathcal{B}$ has the following properties:*

1. *$\mathcal{B}$ is a bounded self-adjoint operator on H.*

2. *$\langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u}\rangle \geqslant 0$ for all $\boldsymbol{u} \in H$.*

3. *The null-space $N(\mathcal{B}) = \{\boldsymbol{u} \in H :\ \mathcal{D}(\boldsymbol{u}) = 0$ in Σ_S and $\operatorname{div}\boldsymbol{u} = 0$ in $\Sigma_F\}$, and $N(\mathcal{B})^\perp \subset \{\boldsymbol{u} \in H :\ \Delta\boldsymbol{u} = \nabla q$ in Σ_F for some $q \in L^2(\Sigma)\}$.*

4. *There exist positive constants c and C such that*

$$c\,\|\boldsymbol{u}\|^2 \leqslant \langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u}\rangle \leqslant C\,\|\boldsymbol{u}\|^2 \tag{4.3}$$

for all $\boldsymbol{u} \in N(\mathcal{B})^\perp$.

5. *The range $R(\mathcal{B})$ is closed in H, $R(\mathcal{B}) = N(\mathcal{B})^\perp$, and $\mathcal{B}^{-1}$ is defined and bounded as an operator on $R(\mathcal{B})$.*

Proof. The first two assertions are obvious. To prove the third one, note that

$$\begin{aligned}\langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u}\rangle &= \int_\Sigma \left(\chi\gamma^{-1}\delta_{ij}\delta_{kl} + (1-\chi)G_{ijkl}\right)\frac{\partial u_i}{\partial \xi_j}\frac{\partial u_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}}\\ &= \gamma^{-1}\int_{\Sigma_F} (\operatorname{div}\boldsymbol{u})^2\,d\hat{\boldsymbol{\xi}} + \int_{\Sigma_S} G_{ijkl}\frac{\partial u_i}{\partial \xi_j}\frac{\partial u_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}}\end{aligned}$$

for every $\boldsymbol{u} \in H$. Therefore, $\langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u}\rangle = 0$ if and only if $\operatorname{div}\boldsymbol{u} = 0$ in Σ_F and $\mathcal{D}(\boldsymbol{u}) = 0$ in Σ_S.

If $\boldsymbol{u} \in N(\mathcal{B})^{\perp}$, then the equalities

$$0 = \langle \boldsymbol{u}, \boldsymbol{v} \rangle = \int_{\Sigma} \boldsymbol{u}_{\xi} \boldsymbol{v}_{\xi} \, d\hat{\boldsymbol{\xi}} = \int_{\Sigma} \mathcal{D}(\boldsymbol{u}) : \mathcal{D}(\boldsymbol{v}) \, d\hat{\boldsymbol{\xi}} = \int_{\Sigma_F} \mathcal{D}(\boldsymbol{u}) : \mathcal{D}(\boldsymbol{v}) \, d\hat{\boldsymbol{\xi}} \tag{4.4}$$

hold for every $\boldsymbol{v} \in N(\mathcal{B})$. Let $\boldsymbol{u}^k \in N(\mathcal{B})^{\perp}$ be a sequence of smooth functions that converges to $\boldsymbol{u}$ in H. Such a sequence exists because $C^{\infty}(\Sigma)$ is dense in $N(\mathcal{B})^{\perp}$. Relation (4.4) is also valid for all $\boldsymbol{u}^k$. If $\boldsymbol{v}$ is an arbitrary smooth function such that $\operatorname{div} \boldsymbol{v} = 0$ and $\operatorname{supp} \boldsymbol{v} \subset \Sigma_F$, then $\boldsymbol{v} \in N(\mathcal{B})$, and

$$0 = \int_{\Sigma_F} \mathcal{D}(\boldsymbol{u}^k) : \mathcal{D}(\boldsymbol{v}) \, d\hat{\boldsymbol{\xi}} = - \int_{\Sigma_F} \operatorname{div}\big(\mathcal{D}(\boldsymbol{u}^k)\big) \cdot \boldsymbol{v} \, d\hat{\boldsymbol{\xi}}.$$

Consequently, there exist functions $\tilde{q}^k \in L^2(\Sigma)$ such that $\operatorname{div}\mathcal{D}(\boldsymbol{u}^k) = \nabla \tilde{q}^k$ for all k. Passing to the limit yields $\operatorname{div}\mathcal{D}(\boldsymbol{u}) = \nabla \tilde{q}$. That is, $\Delta \boldsymbol{u} = \nabla q$, where $q = \tilde{q} - \operatorname{div}\boldsymbol{u}$. This proves the third assertion.

The right inequality of the fourth assertion is obvious. Let us prove the left one. According to the classical theory of the Stokes equations (see [4, Chap. 4]), the following estimate holds for all $\boldsymbol{u} \in N(\mathcal{B})^{\perp}$:

$$\int_{\Sigma_F} |\boldsymbol{u}_{\xi}|^2 \, d\hat{\boldsymbol{\xi}} \leqslant c_1 \big(\|\operatorname{div} \boldsymbol{u}\|^2_{L_2(\Sigma_F)} + \|\boldsymbol{u}_{\Gamma}\|^2_{H^{1/2}(\partial\Sigma_S)/\mathbb{R}} \big),$$

where $\boldsymbol{u}_{\Gamma}$ is the trace of $\boldsymbol{u}$ on $\partial\Sigma_S$. On the other hand,

$$\|\boldsymbol{u}_{\Gamma}\|^2_{H^{1/2}(\partial\Sigma_S)/\mathbb{R}} \leqslant c_2 \int_{\Sigma_S} |\boldsymbol{u}_{\xi}|^2 \, d\hat{\boldsymbol{\xi}}.$$

Thus, there exists a positive constant c_3 such that

$$\|\boldsymbol{u}\|^2 \leqslant c_3 \left(\int_{\Sigma_S} |\boldsymbol{u}_{\xi}|^2 \, d\hat{\boldsymbol{\xi}} + \|\operatorname{div} \boldsymbol{u}\|^2_{L_2(\Sigma_F)} \right) \tag{4.5}$$

for every $\boldsymbol{u} \in N(\mathcal{B})^{\perp}$. In order to obtain (4.3), it is sufficient to prove that there exists a positive constant c_4 such that

$$\int_{\Sigma_S} |\boldsymbol{u}_{\xi}|^2 \, d\hat{\boldsymbol{\xi}} \leqslant c_4 \langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u} \rangle \tag{4.6}$$

for $\boldsymbol{u} \in N(\mathcal{B})^{\perp}$. This can be done using standard contradiction arguments. Assume the converse, i.e., there exists a sequence $\boldsymbol{u}^n \in N(\mathcal{B})^{\perp}$, $n \in \mathbb{N}$, such that $\int_{\Sigma_S} |\boldsymbol{u}^n_{\xi}|^2 \, d\hat{\boldsymbol{\xi}} = 1$ and $\langle \mathcal{B}\boldsymbol{u}^n, \boldsymbol{u}^n \rangle \to 0$ as $n \to 0$. The estimate (4.5) implies that the sequence $\{\boldsymbol{u}^n\}$ is bounded in H too. Thus, there exists its subsequence (still denoted by $\{\boldsymbol{u}^n\}$) that converges weakly in H and $H^1(\Sigma_S)/\mathbb{R}$ but strongly in $L^2(\Sigma)$ to a function $\boldsymbol{u}$. Note that $\boldsymbol{u} \in N(\mathcal{B})^{\perp}$ since $N(\mathcal{B})^{\perp}$ is weakly closed in H. Using the Korn inequality yields

$$\int_{\Sigma_S} |\boldsymbol{u}^n_{\xi} - \boldsymbol{u}_{\xi}|^2 \, d\hat{\boldsymbol{\xi}} \leqslant C \left(\langle \mathcal{B}(\boldsymbol{u}^n - \boldsymbol{u}), \boldsymbol{u}^n - \boldsymbol{u} \rangle + \|\boldsymbol{u}^n - \boldsymbol{u}\|^2_{L^2(\Sigma)} \right).$$

The passage to the limit in this inequality implies that $\langle \mathcal{B}\boldsymbol{u}, \boldsymbol{u} \rangle = 0$ and $\boldsymbol{u}^n \to \boldsymbol{u}$ in H. This means that $\boldsymbol{u} \in N(\mathcal{B})^{\perp} \cap N(\mathcal{B})$ and $\boldsymbol{u} = 0$ in H. On the other

hand, $\int_{\Sigma_S} |\boldsymbol{u}_\xi|^2 \, d\hat{\boldsymbol{\xi}} = \lim_{n\to\infty} \int_{\Sigma_S} |\boldsymbol{u}_\xi^n|^2 \, d\hat{\boldsymbol{\xi}} = 1$. This contradiction proves (4.6) and, consequently, (4.3).

The proof of the fifth assertion is the same as for the operator $\mathcal{A}$ in Proposition 4.10. ∎

PROPOSITION 4.12. *The following is true:*

$$\boldsymbol{a}_{kl}, \boldsymbol{b}_{kl}, \boldsymbol{n}_0 \in R(\mathcal{A}) \cap R(\mathcal{B}), \quad k,l = 1,2,3.$$

Consequently, $\boldsymbol{g} \in R(\mathcal{A}) \cap R(\mathcal{B})$ *for almost all* t *and* $\boldsymbol{x}$*, where* $\boldsymbol{g}$ *is the right-hand side of the cell equation* (4.1).

Proof. Due to Propositions 4.10 and 4.11, $\boldsymbol{w} \in R(\mathcal{A}) \cap R(\mathcal{B})$ if and only if $\langle \boldsymbol{w}, \boldsymbol{v} \rangle = 0$ for all $\boldsymbol{v} \in N(\mathcal{A}) \cup N(\mathcal{B})$. Let us verify this condition for $\boldsymbol{a}_{kl}$. The functions $\boldsymbol{b}_{kl}$ and $\boldsymbol{n}_0$ can be treated in the same way. Let $\boldsymbol{v}$ be an arbitrary function from $N(\mathcal{A})$. That is, $\boldsymbol{v}$ is a constant in Σ_F because of Proposition 4.10. Thus,

$$\langle \boldsymbol{a}_{kl}, \boldsymbol{v} \rangle = \int_{\Sigma_F} P_{ijkl} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}} = 0.$$

If $\boldsymbol{v} \in N(\mathcal{B})$ then $\mathcal{D}(\boldsymbol{v}) = 0$ in Σ_S according to Proposition 4.11, and

$$\begin{aligned} \langle \boldsymbol{a}_{kl}, \boldsymbol{v} \rangle &= \int_{\Sigma_F} P_{ijkl} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}} = \int_{\Sigma} P_{ijkl} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}} - \int_{\Sigma_S} P_{ijkl} \frac{\partial v_i}{\partial \xi_j} \, d\hat{\boldsymbol{\xi}} \\ &= \int_{\Sigma_S} P_{ijkl} \mathcal{D}_{ij}(\boldsymbol{v}) \, d\hat{\boldsymbol{\xi}} = 0. \end{aligned}$$

Here, we used the periodicity of $\boldsymbol{v}$ in Σ and the symmetry of the tensor P (see Remark 2.2). This proves the proposition. ∎

PROPOSITION 4.13.

$$N(\mathcal{A}) \cap N(\mathcal{B}) = \{0\}.$$

Proof. If $\boldsymbol{u} \in N(\mathcal{A}) \cap N(\mathcal{B})$, then $\mathcal{D}(\boldsymbol{u}) = 0$ in Σ due to Propositions 4.10 and 4.11. That is, $\boldsymbol{u}$ is constant in Σ because of its periodicity. This means that $\boldsymbol{u} = 0$ in H. ∎

The result of Proposition 4.13 implies that the operator $\lambda\mathcal{A} + \mathcal{B}$ is invertible for every $\lambda > 0$. Besides that, it is not difficult to see that the operator $(\lambda\mathcal{A} + \mathcal{B})^{-1}$ is bounded in H: Let us introduce the following closed subspaces of H:

$$\begin{aligned} &E_A = (\lambda\mathcal{A} + \mathcal{B})^{-1} R(\mathcal{A}), \\ &E_B = (\lambda\mathcal{A} + \mathcal{B})^{-1} R(\mathcal{B}), \\ &E = E_A \cap E_B = (\lambda\mathcal{A} + \mathcal{B})^{-1} \big(R(\mathcal{A}) \cap R(\mathcal{B}) \big). \end{aligned}$$

Note that the spaces E, E_A, and E_B do not depend on λ. More precisely, if $E_A^\lambda = (\lambda\mathcal{A} + \mathcal{B})^{-1} R(\mathcal{A})$ then $E_A^\lambda = E_A^\mu$ for all $\lambda > 0$ and $\mu > 0$. This follows from simple arguments like those. If $\boldsymbol{x} \in E_A^\lambda$, then $(\lambda\mathcal{A} + \mathcal{B})\boldsymbol{x} \in R(\mathcal{A})$ and $\mathcal{B}\boldsymbol{x} \in R(\mathcal{A})$. Consequently, $(\mu\mathcal{A} + \mathcal{B})\boldsymbol{x} \in R(\mathcal{A})$ and $\boldsymbol{x} \in E_A^\mu$. That is, $E_A^\lambda \subset E_A^\mu$. In the same way we can obtain that $E_A^\mu \subset E_A^\lambda$.

LEMMA 4.14. *The operator* $\mathcal{A}$ *maps the space* E_B *into* $R(\mathcal{B})$*, and the operator* $\mathcal{B}$ *maps the space* E_A *into* $R(\mathcal{A})$.

Proof. The first part is true due to the following implications:

$$\boldsymbol{x} \in E_{\mathcal{B}} \Longrightarrow (\lambda\mathcal{A}+\mathcal{B})\boldsymbol{x} \in R(\mathcal{B}) \Longrightarrow \mathcal{A}\boldsymbol{x} \in R(\mathcal{B}).$$

The second part is being proved analogously. ∎

LEMMA 4.15. *If X is a closed subspace of H then $\mathcal{A}(X)$ and $\mathcal{B}(X)$ are closed in H.*

Proof. Let us verify this assertion for the operator $\mathcal{A}$ by taking an arbitrary sequence $\boldsymbol{u}_n \in \mathcal{A}(X)$ which converges to a function $\boldsymbol{u}$ in H. There exists a corresponding sequence $\boldsymbol{v}_n \in R(\mathcal{A}) \cap X$ such that $\boldsymbol{u}_n = \mathcal{A}(\boldsymbol{v}_n)$. Due to Proposition 4.10, the operator $\mathcal{A}^{-1}$ is bounded on $R(\mathcal{A})$. This implies that the sequence $\{\boldsymbol{v}_n\}$ converges in H to a function $\boldsymbol{v}$ which is in X because X is closed. In the limit, we have $\boldsymbol{u} = \mathcal{A}(\boldsymbol{v})$. That is, $\boldsymbol{u} \in \mathcal{A}(X)$, which proves the lemma. ∎

PROPOSITION 4.16.

$$\mathcal{B}E_{\mathcal{A}} = \mathcal{A}E_{\mathcal{B}} = R(\mathcal{A}) \cap R(\mathcal{B}).$$

That is, for every $\boldsymbol{\psi} \in R(\mathcal{A}) \cap R(\mathcal{B})$, there exist $\boldsymbol{\psi}_{\mathcal{B}} \in E_{\mathcal{B}}$ and $\boldsymbol{\psi}_{\mathcal{A}} \in E_{\mathcal{A}}$ such that $\boldsymbol{\psi} = \mathcal{A}\boldsymbol{\psi}_{\mathcal{B}} = \mathcal{B}\boldsymbol{\psi}_{\mathcal{A}}$.

Proof. Let us prove the first claim. Due to Lemma 4.14, $\mathcal{B}E_{\mathcal{A}} \subset R(\mathcal{A}) \cap R(\mathcal{B})$. Besides that, Lemma 4.15 implies that $\mathcal{B}E_{\mathcal{A}}$ is a closed subspace in H. Suppose that $\mathcal{B}E_{\mathcal{A}} \neq R(\mathcal{A}) \cap R(\mathcal{B})$. Then there exists $\boldsymbol{x} \in R(\mathcal{A}) \cap R(\mathcal{B})$ such that $\langle \boldsymbol{x}, \boldsymbol{y}\rangle = 0$ for every $\boldsymbol{y} \in \mathcal{B}E_{\mathcal{A}}$. That is, $\langle \boldsymbol{x}, \mathcal{B}(\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{z}\rangle = 0$ for all $\boldsymbol{z} \in H$, and

$$\langle \mathcal{A}(\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{B}\boldsymbol{x}, \boldsymbol{z}\rangle = 0 \quad \text{for all} \quad \boldsymbol{z} \in H.$$

Consequently, $(\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{B}\boldsymbol{x} \in N(\mathcal{A})$ and, hence, $\mathcal{B}\boldsymbol{x} \in (\lambda\mathcal{A}+\mathcal{B})N(\mathcal{A}) = \mathcal{B}N(\mathcal{A})$. That is, there exists $\boldsymbol{y} \in N(\mathcal{A})$ such that $\mathcal{B}\boldsymbol{x} = \mathcal{B}\boldsymbol{y}$ and, therefore, $\mathcal{B}(\boldsymbol{x}-\boldsymbol{y}) = 0$. This implies that $\boldsymbol{w} = \boldsymbol{x}-\boldsymbol{y} \in N(\mathcal{B})$. Thus, $\boldsymbol{x} = \boldsymbol{y}+\boldsymbol{w}$, where $\boldsymbol{y} \in N(\mathcal{A})$, and $\boldsymbol{w} \in N(\mathcal{B})$. That is, $\boldsymbol{x} \in N(\mathcal{A}) \oplus N(\mathcal{B})$. Consequently, $\boldsymbol{x} = 0$ because $\big(N(\mathcal{A}) \oplus N(\mathcal{B})\big) \cap \big(R(\mathcal{A}) \cap R(\mathcal{B})\big) = \{0\}$. The proposition is proved. ∎

Let us introduce the restrictions $\mathcal{A}_{\mathcal{E}}$ and $\mathcal{B}_{\mathcal{E}}$ of the operators $\mathcal{A}$ and $\mathcal{B}$ to the space E.

THEOREM 4.17.

1. *The operators $\mathcal{A}_{\mathcal{E}}$ and $\mathcal{B}_{\mathcal{E}}$ map E onto $R(\mathcal{A}) \cap R(\mathcal{B})$.*
2. *The operators $\mathcal{A}_{\mathcal{E}}$, $\mathcal{B}_{\mathcal{E}} : E \to R(\mathcal{A}) \cap R(\mathcal{B})$ are one to one.*
3. *There exist bounded operators $\mathcal{A}_{\mathcal{E}}^{-1}$, $\mathcal{B}_{\mathcal{E}}^{-1} : R(\mathcal{A}) \cap R(\mathcal{B}) \to E$.*

Proof. Let us prove these assertions for the operator $\mathcal{A}_{\mathcal{E}}$ only. The operator $\mathcal{B}_{\mathcal{E}}$ can be treated in the same way.

1. Since $E \subset E_{\mathcal{B}}$, Proposition 4.16 and Lemma 4.15 imply that $\mathcal{A}E \subset R(\mathcal{A}) \cap R(\mathcal{B})$, and $\mathcal{A}E$ is a closed subspace in H. Suppose that $\mathcal{A}E \neq R(\mathcal{A}) \cap R(\mathcal{B})$. This means that there exists $\boldsymbol{x} \in R(\mathcal{A}) \cap R(\mathcal{B})$ such that $\langle \boldsymbol{x}, \boldsymbol{y}\rangle = 0$ for every $\boldsymbol{y} \in \mathcal{A}E$. That is,

$$\langle (\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{x}, \boldsymbol{z}\rangle = \langle \boldsymbol{x}, \mathcal{A}(\lambda\mathcal{A}+\mathcal{B})^{-1}\boldsymbol{z}\rangle = 0$$

for all $\boldsymbol{z} \in R(\mathcal{A}) \cap R(\mathcal{B})$. Thus, due to Proposition 4.16,

$$\langle (\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{x}, \mathcal{B}\boldsymbol{z}\rangle = 0 \quad \text{for all } \boldsymbol{z} \in E_{\mathcal{A}}. \tag{4.7}$$

Since $(\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{x} \in E_{\mathcal{A}}$, we can take $\boldsymbol{z} = (\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{x}$. Then the relation (4.7) implies that $(\lambda\mathcal{A}+\mathcal{B})^{-1}\mathcal{A}\boldsymbol{x} \in N(\mathcal{B})$, that is, $\mathcal{A}\boldsymbol{x} \in \mathcal{A}N(\mathcal{B})$. Consequently (see the

end of the proof of Proposition 4.16), $\boldsymbol{x} = 0$, which proves the first assertion of the theorem.

2. We have to prove that $N(\mathcal{A}) \cap E = \{0\}$. Let $\boldsymbol{x} \in E$ and $\mathcal{A}\boldsymbol{x} = 0$. Then $\mathcal{B}\boldsymbol{x} = (\lambda\mathcal{A} + \mathcal{B})\boldsymbol{x} \in R(\mathcal{A}) \cap R(\mathcal{B})$, that is, $\mathcal{B}\boldsymbol{x} \in R(\mathcal{A})$. But $\boldsymbol{x} \in N(\mathcal{A}) = R(\mathcal{A})^{\perp}$ and, consequently, $\langle \mathcal{B}\boldsymbol{x}, \boldsymbol{x}\rangle = 0$. Since $\mathcal{B}$ is a positive operator, the last relation implies that $\boldsymbol{x} \in N(\mathcal{B})$. Thus, $\boldsymbol{x} \in N(\mathcal{A}) \cap N(\mathcal{B}) = \{0\}$, which proves the second assertion of the theorem.

3. This assertion is the consequence of parts 1 and 2. The theorem is proved. □

4.3. Solving the cell equation. Now we are in position to find an explicit representation of solutions to the cell equation (4.1). With a new unknown function $\overline{\boldsymbol{\zeta}} = \mathcal{J}_t\overline{\boldsymbol{u}}$, the problem (4.1) assumes the form

$$\mathcal{A}\overline{\boldsymbol{\zeta}}_t + \mathcal{B}\overline{\boldsymbol{\zeta}} = \boldsymbol{g}, \qquad \overline{\boldsymbol{\zeta}}(0) = 0. \tag{4.8}$$

As it follows from Theorem 4.17, the operator $\mathcal{A}_{_E}$ ($\mathcal{A}$ restricted to E) is invertible, the operator $\mathcal{A}_{_E}^{-1}\mathcal{B}_{_E}$ bounded, and $\mathcal{A}_{_E}^{-1}\boldsymbol{g} \in E$. Therefore, the problem

$$\overline{\boldsymbol{\zeta}}_t + \mathcal{A}_{_E}^{-1}\mathcal{B}_{_E}\overline{\boldsymbol{\zeta}} = \mathcal{A}_{_E}^{-1}\boldsymbol{g}, \qquad \overline{\boldsymbol{\zeta}}(0) = 0 \tag{4.9}$$

is uniquely solvable on the subspace E, and the solution is of the form

$$\overline{\boldsymbol{\zeta}}(t) = \int_0^t e^{-(t-s)\mathcal{A}_{_E}^{-1}\mathcal{B}_{_E}}\mathcal{A}_{_E}^{-1}\boldsymbol{g}(s)\,ds. \tag{4.10}$$

THEOREM 4.18. *Equations* (4.8) *and* (4.9) *are equivalent.*

Proof. Obviously, if $\overline{\boldsymbol{\zeta}}$ is a solution to (4.9), then $\overline{\boldsymbol{\zeta}}$ satisfies (4.8). If $\overline{\boldsymbol{\zeta}}$ is a solution to (4.8), then the function $\overline{\boldsymbol{\eta}} = e^{-\lambda t}\overline{\boldsymbol{\zeta}}$ solves the problem

$$\mathcal{A}\overline{\boldsymbol{\eta}}_t + (\lambda\mathcal{A} + \mathcal{B})\overline{\boldsymbol{\eta}} = e^{-\lambda t}\boldsymbol{g}, \qquad \overline{\boldsymbol{\eta}}(0) = 0. \tag{4.11}$$

Since the operator $\lambda\mathcal{A} + \mathcal{B}$ is nondegenerate for any $\lambda > 0$, we can rewrite (4.11) as follows:

$$(\lambda\mathcal{A} + \mathcal{B})^{-1}\mathcal{A}\overline{\boldsymbol{\eta}}_t + \overline{\boldsymbol{\eta}} = e^{-\lambda t}(\lambda\mathcal{A} + \mathcal{B})^{-1}\boldsymbol{g}, \qquad \overline{\boldsymbol{\eta}}(0) = 0. \tag{4.12}$$

Due to Proposition 4.12, $\boldsymbol{g} \in R(\mathcal{A})$, and, hence $\overline{\boldsymbol{\eta}}(t)$ must belong to $E_{_A}$ for all t. Therefore, $\overline{\boldsymbol{\zeta}}(t) \in E_{_A}$ for all t. On the other hand, (4.8) can be rewritten as follows:

$$(\lambda\mathcal{A} + \mathcal{B})\overline{\boldsymbol{\zeta}}_t - \mathcal{B}\overline{\boldsymbol{\zeta}}_t + \lambda\mathcal{B}\overline{\boldsymbol{\zeta}} = \lambda\boldsymbol{g}.$$

That is,

$$\overline{\boldsymbol{\zeta}}_t = (\lambda\mathcal{A} + \mathcal{B})^{-1}\mathcal{B}(\overline{\boldsymbol{\zeta}}_t - \lambda\overline{\boldsymbol{\zeta}}) + \lambda(\lambda\mathcal{A} + \mathcal{B})^{-1}\boldsymbol{g}.$$

Taking into account that $\overline{\boldsymbol{\zeta}}(t)$ and $\overline{\boldsymbol{\zeta}}_t(t) \in E_{_A}$ for all t, we establish, using Proposition 4.16, that $\overline{\boldsymbol{\zeta}}_t(t) \in E$ for all t. Since $\overline{\boldsymbol{\zeta}}(0) = 0$, we conclude that $\overline{\boldsymbol{\zeta}}(t) \in E$ for all t. Therefore, $\overline{\boldsymbol{\zeta}}$ is a solution of (4.9). The theorem is proved. □

Thus, the unique solution of the problem (4.8) is given by (4.10) and the unique solution $\overline{\boldsymbol{u}}$ of the problem (4.1) reads as

$$\overline{\boldsymbol{u}}(t) = \overline{\boldsymbol{\zeta}}_t(t) = \mathcal{A}_{_E}^{-1}\boldsymbol{g}(t) - \mathcal{A}_{_E}^{-1}\mathcal{B}_{_E}\int_0^t e^{-(t-s)\mathcal{A}_{_E}^{-1}\mathcal{B}_{_E}}\mathcal{A}_{_E}^{-1}\boldsymbol{g}(s)\,ds. \tag{4.13}$$

5. Homogenized structure.

5.1. Limiting equations. Substitution of the expression for $\boldsymbol{g}$ into (4.13) gives

(5.1)
$$\overline{\boldsymbol{u}}(t) = -e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\mathcal{A}_{E}^{-1}\boldsymbol{n}_0 - \mathcal{A}_{E}^{-1}\boldsymbol{a}_{kl}\,\frac{\partial u_k(t)}{\partial x_l} - \int_0^t \boldsymbol{m}_{kl}(t-s)\,\frac{\partial u_k(s)}{\partial x_l}\,ds,$$

(5.2)
$$\mathcal{J}_t\overline{\boldsymbol{u}}(t) = \big(e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}} - \mathcal{I}\big)\mathcal{B}_{E}^{-1}\boldsymbol{n}_0 - \mathcal{B}_{E}^{-1}\boldsymbol{b}_{kl}\int_0^t \frac{\partial u_k(s)}{\partial x_l}\,ds - \int_0^t \widetilde{\boldsymbol{m}}_{kl}(t-s)\frac{\partial u_k(s)}{\partial x_l}\,ds,$$

where

$$\boldsymbol{m}_{kl}(t) = -\mathcal{A}_{E}^{-1}\mathcal{B}_{E}e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\big(\mathcal{A}_{E}^{-1}\boldsymbol{a}_{kl} - \mathcal{B}_{E}^{-1}\boldsymbol{b}_{kl}\big) \in E,$$

$$\widetilde{\boldsymbol{m}}_{kl}(t) = e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\big(\mathcal{A}_{E}^{-1}\boldsymbol{a}_{kl} - \mathcal{B}_{E}^{-1}\boldsymbol{b}_{kl}\big) \in E.$$

The integration by parts and the formula

$$\frac{d}{ds}e^{-(t-s)\mathcal{A}_{E}^{-1}\mathcal{B}_{E}} = \mathcal{A}_{E}^{-1}\mathcal{B}_{E}e^{-(t-s)\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}$$

are applied when deriving (5.1) and (5.2). Now we are in position to compute the principal term

$$\int_\Sigma M_{ijkl}^t\frac{\partial\overline{u}_k}{\partial\xi_l}\,d\hat{\boldsymbol{\xi}} = \langle\boldsymbol{a}_{ij},\overline{\boldsymbol{u}}\rangle + \langle\boldsymbol{b}_{ij},\mathcal{J}_t\overline{\boldsymbol{u}}\rangle$$

appearing in the limiting (homogenized) equation (3.2). Utilizing (5.1) and (5.2) and computing other terms in (3.2), we obtain the following limiting equation:

(5.3)
$$\begin{aligned}&\int_0^T\int_\Omega\Big(-\rho_\theta u_i\,\frac{\partial\phi_i}{\partial t} + \big(\theta P_{ijkl} - \alpha_{ijkl}\big)\frac{\partial u_k}{\partial x_l}\,\frac{\partial\phi_i}{\partial x_j}\\ &\quad+\int_0^t\Big(\theta\gamma^{-1}\delta_{ij}\delta_{kl} + (1-\theta)G_{ijkl} - \beta_{ijkl} + \omega_{ijkl}(t-s)\Big)\frac{\partial u_k}{\partial x_l}\,ds\,\frac{\partial\phi_i}{\partial x_j}\Big)\,d\boldsymbol{x}dt\\ &\quad=\int_0^T\int_\Omega\Big(\rho_\theta f_i\phi_i - \big(\nu_{ij} - \theta p^0\delta_{ij} + (1-\theta)\mathcal{G}_{ij}^0\big)\,\frac{\partial\phi_i}{\partial x_j}\Big)\,d\boldsymbol{x}dt + \int_\Omega\rho_\theta\boldsymbol{u}^0\cdot\boldsymbol{\phi}^0\,d\boldsymbol{x},\end{aligned}$$

where

$$\theta(\boldsymbol{x}) = \int_\Sigma\chi\,d\hat{\boldsymbol{\xi}}, \qquad \rho_\theta = \theta\rho_{{}_F} + (1-\theta)\,\rho_{{}_S},$$

$$\begin{aligned}&\nu_{ij} = -\langle\boldsymbol{a}_{ij},e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\mathcal{A}_{E}^{-1}\boldsymbol{n}_0\rangle + \langle\boldsymbol{b}_{ij},\big(e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}} - \mathcal{I}\big)\mathcal{B}_{E}^{-1}\boldsymbol{n}_0\rangle,\\ &\alpha_{ijkl} = \langle\boldsymbol{a}_{ij},\mathcal{A}_{E}^{-1}\boldsymbol{a}_{kl}\rangle,\\ &\beta_{ijkl} = \langle\boldsymbol{b}_{ij},\mathcal{B}_{E}^{-1}\boldsymbol{b}_{kl}\rangle,\\ &\omega_{ijkl}(t) = -\langle\boldsymbol{a}_{ij},\boldsymbol{m}_{kl}\rangle - \langle\boldsymbol{b}_{ij},\widetilde{\boldsymbol{m}}_{kl}\rangle.\end{aligned}$$

Let us denote by $\overline{P}$, $\overline{G}$, and $\mathcal{S}^0$ the tensors with components

$$\overline{P}_{ijkl} = \theta P_{ijkl} - \alpha_{ijkl}, \quad \overline{G}_{ijkl} = \theta\gamma^{-1}\delta_{ij}\delta_{kl} + (1-\theta)G_{ijkl} - \beta_{ijkl},$$

$$\mathcal{S}^0_{ij} = \nu_{ij} - \theta p^0\delta_{ij} + (1-\theta)\mathcal{G}^0_{ij}.$$

Let us divide the domain Ω into three parts:

$$\Omega^f = \{\boldsymbol{x} \in \Omega \,|\, x_3 > \delta\}, \quad \Omega^s = \{\boldsymbol{x} \in \Omega \,|\, x_3 < 0\}, \quad \Omega^h = \{\boldsymbol{x} \in \Omega \,|\, 0 < x_3 < \delta\}.$$

Let Γ^+_δ be the boundary between Ω^f and Ω^h, Γ^-_δ the boundary between Ω^s and Ω^h. That is, $\Omega = \Omega^f \cup \Gamma^+_\delta \cup \Omega^h \cup \Gamma^-_\delta \cup \Omega^s$. Note that $\theta(\boldsymbol{x}) = 1$ if $\boldsymbol{x} \in \Omega^f$, $\theta(\boldsymbol{x}) = 0$ if $\boldsymbol{x} \in \Omega^s$, and θ is a constant from the interval $(0,1)$ for $\boldsymbol{x} \in \Omega^h$. As for α_{ijkl}, β_{ijkl}, ν_{ij}, and ω_{ijkl}, they are constants for $\boldsymbol{x} \in \Omega^h$ and equal to zero if $\boldsymbol{x} \in \Omega^f \cup \Omega^s$, so that the integral identity (5.3) delivers the following equations which should be understood in the distributional sense:

(5.4)
$$\rho_{_F}\boldsymbol{u}_t - \operatorname{div} P\boldsymbol{u}_x - \gamma^{-1}\nabla\operatorname{div}\mathcal{J}_t\boldsymbol{u} = -\nabla p^0 + \rho_{_F}\boldsymbol{f}, \qquad \boldsymbol{x} \in \Omega^f,$$

(5.5)
$$\rho_{_S}\boldsymbol{u}_t - \operatorname{div}\mathcal{J}_t G\boldsymbol{u}_x = \operatorname{div}\mathcal{G}^0 + \rho_{_S}\boldsymbol{f}, \qquad \boldsymbol{x} \in \Omega^s,$$

(5.6)
$$\rho_\theta\boldsymbol{u}_t - \operatorname{div}\overline{P}\boldsymbol{u}_x - \operatorname{div}\mathcal{J}_t\overline{G}\boldsymbol{u}_x - \operatorname{div}\int_0^t \omega(t-s)\boldsymbol{u}_x(s)\,ds + \operatorname{div}\mathcal{S}^0 = \rho_\theta\boldsymbol{f}, \quad \boldsymbol{x} \in \Omega^h.$$

The natural interfacial boundary conditions at Γ^+_δ and Γ^-_δ can be derived from the integral identity (5.3). Equations (5.4) and (5.5) coincide with (2.1) and (2.11), respectively. That is, the governing equations for the pure fractions do not change after the homogenization, which have been expected. What is new is an integral-differential equation (5.6) which cannot be reduced to a pure differential equation by differentiating or by a substitution like $\boldsymbol{w} = \mathcal{J}_t\boldsymbol{u}$. The operators involved in the equation have to be investigated to confirm the parabolic type of its principal part.

5.2. Investigation of $\overline{P}$ and $\overline{G}$. It is not difficult to verify that the tensors $\overline{P}$ and $\overline{G}$ have the symmetry properties mentioned in Remark 2.2. Therefore, $\overline{P}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = 0$ and $\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = 0$ for every skew symmetric matrix $\mathcal{Z}$. The main objective of this subsection is to prove the strong positiveness of the tensor $\overline{P}$ and the nonnegativeness of $\overline{G}$ on the space of symmetric matrices. The null-space of $\overline{G}$ will be also described.

PROPOSITION 5.19. *For every second-rank tensor $\mathcal{Z}$, the following is valid:*

$$\overline{P}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} \geqslant 0, \qquad \overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} \geqslant 0.$$

Proof. Let us prove the assertion for $\overline{P}$. Denote $\boldsymbol{z} = \boldsymbol{a}_{ij}\mathcal{Z}_{ij}$. Due to Proposition 4.12, $\boldsymbol{z} \in R(\mathcal{A}) \cap R(\mathcal{B})$ and, as it follows from Theorem 4.17, there exists a unique $\boldsymbol{y} \in E$ such that $\mathcal{A}_{_E}\boldsymbol{y} = \boldsymbol{z}$. This means that

$$\int_\Sigma \chi P_{ijkl}\frac{\partial y_i}{\partial\xi_j}\frac{\partial v_k}{\partial\xi_l}\,d\hat{\boldsymbol{\xi}} = \langle\boldsymbol{z},\boldsymbol{v}\rangle = \int_\Sigma \chi P_{ijkl}\mathcal{Z}_{ij}\frac{\partial v_k}{\partial\xi_l}\,d\hat{\boldsymbol{\xi}} \tag{5.7}$$

for all $\boldsymbol{v} \in H$. On the other hand, the definition yields

$$\alpha_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = \langle\boldsymbol{a}_{ij}\mathcal{Z}_{ij}, \mathcal{A}_{_E}^{-1}\boldsymbol{a}_{kl}\mathcal{Z}_{kl}\rangle = \langle\boldsymbol{z}, \mathcal{A}_{_E}^{-1}\boldsymbol{z}\rangle = \langle\mathcal{A}_{_E}\boldsymbol{y},\boldsymbol{y}\rangle.$$

From the last relation and (5.7) with $\boldsymbol{v} = \boldsymbol{y}$, we obtain

(5.8)
$$\overline{P}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = \theta\, P_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} - \langle \mathcal{A}_{E}\boldsymbol{y}, \boldsymbol{y}\rangle = \int_{\Sigma}\Big(\chi P_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} - \chi P_{ijkl}\frac{\partial y_i}{\partial \xi_j}\frac{\partial y_k}{\partial \xi_l}\Big)\, d\hat{\boldsymbol{\xi}}$$
$$= \int_{\Sigma}\chi P_{ijkl}\Big(\mathcal{Z}_{ij} - \frac{\partial y_i}{\partial \xi_j}\Big)\Big(\mathcal{Z}_{kl} - \frac{\partial y_k}{\partial \xi_l}\Big)\, d\hat{\boldsymbol{\xi}}.$$

The right-hand side of the last relation is clearly positive and the required assertion is proved for the tensor $\overline{P}$. Positiveness of the tensor $\overline{G}$ can be verified in the same way. ∎

The next theorem states the strong positiveness of the tensor $\overline{P}$.

THEOREM 5.20. *There exists a positive constant C such that*

$$\overline{P}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} \geqslant C\,|\mathcal{Z}|^2$$

for every symmetric second-rank tensor $\mathcal{Z}$. Here, $|\mathcal{Z}|^2 = \mathcal{Z}_{ij}\mathcal{Z}_{ij}$.

Proof. Assume that the assertion of the theorem is false. Then there exists a sequence $\{\mathcal{Z}^n\}$ such that $|\mathcal{Z}^n| = 1$ and $\overline{P}_{ijkl}\mathcal{Z}^n_{ij}\mathcal{Z}^n_{kl} \to 0$ as $n \to \infty$. The sequence $\{\mathcal{Z}^n\}$ is compact in $\mathbb{R}^3 \times \mathbb{R}^3$ and, therefore, it has a subsequence denoted again by $\{\mathcal{Z}^n\}$, which converges to a matrix $\mathcal{Z}^0$ such that $|\mathcal{Z}^0| = 1$. This means that the corresponding sequences $\boldsymbol{z}^n$ and $\boldsymbol{y}^n$, defined as $\boldsymbol{z}^n = \boldsymbol{a}_{ij}\mathcal{Z}^n_{ij}$ and $\boldsymbol{y}^n = \mathcal{A}_{E}^{-1}\boldsymbol{z}^n$, converge in H to $\boldsymbol{z}^0$ and $\boldsymbol{y}^0$, respectively. We use here the notations introduced in the proof of the previous proposition. Thus, the relation

$$\overline{P}_{ijkl}\mathcal{Z}^0_{ij}\mathcal{Z}^0_{kl} = \theta\, P_{ijkl}\mathcal{Z}^0_{ij}\mathcal{Z}^0_{kl} - \langle \mathcal{A}_{E}\boldsymbol{y}^0, \boldsymbol{y}^0\rangle = \int_{\Sigma}\chi P_{ijkl}\Big(\mathcal{Z}^0_{ij} - \frac{\partial y^0_i}{\partial \xi_j}\Big)\Big(\mathcal{Z}^0_{kl} - \frac{\partial y^0_k}{\partial \xi_l}\Big)\, d\hat{\boldsymbol{\xi}} = 0.$$

holds due to (5.8). That is,

$$\chi P_{ijkl}\Big(\mathcal{Z}^0_{ij} - \frac{\partial y^0_i}{\partial \xi_j}\Big)\Big(\mathcal{Z}^0_{kl} - \frac{\partial y^0_k}{\partial \xi_l}\Big) = 0 \qquad \text{in} \quad \Sigma,$$

and, consequently, $\mathcal{D}(\boldsymbol{y}^0) = \mathcal{Z}^0$ in Σ_{F}. This implies that $\mathcal{D}(\boldsymbol{y}^0 - \mathcal{Z}^0\boldsymbol{\xi}) = 0$ in Σ_{F}. Therefore, $\boldsymbol{y}^0(\boldsymbol{\xi})$ is a linear function of $\boldsymbol{\xi}$ for $\boldsymbol{\xi} \in \Sigma_{F}$. The only linear function satisfying the periodicity boundary conditions on $\partial\Sigma$ is a constant, which implies that $\mathcal{Z}^0 = 0$. This is impossible because $|\mathcal{Z}^0| = 1$. This contradiction proves the theorem. ∎

Remark that the arguments like those in the proof of Theorem 5.20 do not lead to a contradiction in the case of the tensor $\overline{G}$. The next theorem shows that the tensor $\overline{G}$ is degenerated and describes its null-space.

THEOREM 5.21. *The tensor $\overline{G}$ is degenerate, and $\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = 0$ for a symmetric matrix $\mathcal{Z}$ if and only if $\mathcal{Z}_{11} + \mathcal{Z}_{22} = 0$ and $\mathcal{Z}_{33} = 0$.*

Proof. Let us denote $\boldsymbol{z} = \boldsymbol{b}_{ij}\mathcal{Z}_{ij}$. Due to Proposition 4.12 and Theorem 4.17, $\boldsymbol{z} \in R(\mathcal{A}) \cap R(\mathcal{B})$, and there exist unique elements $\boldsymbol{y}^{E} \in E$ and $\boldsymbol{y}^{R} \in R(\mathcal{B})$ such that

$$\mathcal{B}\boldsymbol{y}^{E} = \boldsymbol{z}, \qquad \mathcal{B}\boldsymbol{y}^{R} = \boldsymbol{z}. \tag{5.9}$$

It follows that $\boldsymbol{y}^{N} = \boldsymbol{y}^{E} - \boldsymbol{y}^{R} \in N(\mathcal{B})$. Besides that, $\mathcal{B}_{E}^{-1}\mathcal{B}\boldsymbol{y}^{E} = \boldsymbol{y}^{E}$. Therefore,

$$\langle \boldsymbol{z}, \mathcal{B}_{E}^{-1}\boldsymbol{z}\rangle = \langle \mathcal{B}\boldsymbol{y}^{E}, \boldsymbol{y}^{E}\rangle = \langle \mathcal{B}\boldsymbol{y}^{R}, \boldsymbol{y}^{R} + \boldsymbol{y}^{N}\rangle = \langle \mathcal{B}\boldsymbol{y}^{R}, \boldsymbol{y}^{R}\rangle.$$

The second equation in (5.9) implies that

$$\int_\Sigma K_{ijkl}(\chi)\frac{\partial y_i^R}{\partial \xi_j}\frac{\partial v_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}} = \int_\Sigma K_{ijkl}(\chi)\mathcal{Z}_{ij}\frac{\partial v_k}{\partial \xi_l}\,d\hat{\boldsymbol{\xi}}, \tag{5.10}$$

for all $\boldsymbol{v} \in H$, where

$$K_{ijkl}(\chi) = \chi\gamma^{-1}\delta_{ij}\delta_{kl} + (1-\chi)G_{ijkl}.$$

As a consequence of this equation, we find

$$\begin{aligned}\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} &= K_{ijkl}(\theta)\mathcal{Z}_{ij}\mathcal{Z}_{kl} - \langle \boldsymbol{z}, \mathcal{B}_E^{-1}\boldsymbol{z}\rangle = K_{ijkl}(\theta)\mathcal{Z}_{ij}\mathcal{Z}_{kl} - \langle \mathcal{B}\boldsymbol{y}^R, \boldsymbol{y}^R\rangle \\ &= \int_\Sigma K_{ijkl}(\chi)\Big(\mathcal{Z}_{ij} - \frac{\partial y_i^R}{\partial \xi_j}\Big)\Big(\mathcal{Z}_{kl} - \frac{\partial y_k^R}{\partial \xi_l}\Big)\,d\hat{\boldsymbol{\xi}} \\ &= \int_{\Sigma_F}\gamma^{-1}(\operatorname{tr}\mathcal{Z} - \operatorname{div}\boldsymbol{y}^R)^2\,d\hat{\boldsymbol{\xi}} + \int_{\Sigma_S} G_{ijkl}\big(\mathcal{Z}_{ij} - \mathcal{D}_{ij}(\boldsymbol{y}^R)\big)\big(\mathcal{Z}_{kl} - \mathcal{D}_{kl}(\boldsymbol{y}^R)\big)\,d\hat{\boldsymbol{\xi}}.\end{aligned}$$

Notice that (5.10) is the Euler–Lagrange equation for the functional

$$F_z(\boldsymbol{y}) = \int_\Sigma K_{ijkl}(\chi)\Big(\mathcal{Z}_{ij} - \frac{\partial y_i}{\partial \xi_j}\Big)\Big(\mathcal{Z}_{kl} - \frac{\partial y_k}{\partial \xi_l}\Big)\,d\hat{\boldsymbol{\xi}}.$$

Due to Proposition 4.11 (assertion 4), this functional is strictly convex on $R(\mathcal{B})$ and $\boldsymbol{y}^R$ is its unique minimizer there. That is,

$$\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = F_z(\boldsymbol{y}^R) = \min_{\boldsymbol{y}\in R(\mathcal{B})} F_z(\boldsymbol{y}).$$

Thus, $\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = 0$ if and only if there exists $\boldsymbol{y}^R \in R(\mathcal{B})$ such that $F_z(\boldsymbol{y}^R) = 0$. It is not difficult to see that $F_z(\boldsymbol{y}) = F_z(\boldsymbol{y}+\boldsymbol{w})$ for every $\boldsymbol{w} \in N(\mathcal{B})$. Since $R(\mathcal{B}) \oplus N(\mathcal{B}) = H$, the existence of $\boldsymbol{y}^R \in R(\mathcal{B})$ with $F_z(\boldsymbol{y}^R) = 0$ is equivalent to the existence of a function $\boldsymbol{y} \in H$ which satisfies the condition $F_z(\boldsymbol{y}) = 0$. Due to the positiveness of the functional F_z, we can conclude that $\overline{G}_{ijkl}\mathcal{Z}_{ij}\mathcal{Z}_{kl} = 0$ if and only if there exists $\boldsymbol{y} \in H$ such that

$$\operatorname{div}\boldsymbol{y} = \operatorname{tr}\mathcal{Z} \quad \text{as} \quad \hat{\boldsymbol{\xi}} \in \Sigma_F, \tag{5.11}$$

$$\mathcal{D}(\boldsymbol{y}) = \mathcal{Z} \qquad \text{as} \quad \hat{\boldsymbol{\xi}} \in \Sigma_S. \tag{5.12}$$

Suppose that both of the last conditions are satisfied. Since functions from H do not depend on ξ_3, (5.12) implies that $\mathcal{Z}_{33} = 0$. Moreover, due to (5.12), $\operatorname{div}\boldsymbol{y} = \operatorname{tr}\mathcal{Z}$ in Σ_S. That is, $\operatorname{div}\boldsymbol{y} = \operatorname{tr}\mathcal{Z}$ in Σ. Integrating this equality over Σ we find that $\operatorname{tr}\mathcal{Z} = 0$ because $\boldsymbol{y}$ is periodic. Thus, we have proved the assertion of the theorem in one direction (the necessity).

Let us suppose that $\mathcal{Z}_{11} + \mathcal{Z}_{22} = 0$ and $\mathcal{Z}_{33} = 0$. In order to complete the proof of the theorem, we have to prove that there exists a function $\boldsymbol{y} \in H$ satisfying (5.11) and (5.12). Equation (5.12) is easy to solve. Namely, its solution appears as follows:

$$\boldsymbol{y}(\boldsymbol{\xi}) = \mathcal{Z}\boldsymbol{\xi} + \mathcal{Q}\boldsymbol{\xi} + \boldsymbol{y}_0, \qquad \hat{\boldsymbol{\xi}} \in \Sigma_S,$$

where $\mathcal{Q}$ is a skew-symmetric matrix and $\boldsymbol{y}_0$ is a constant which can be dropped because functions from the space H are defined up to a constant. Let us denote $\mathcal{T} =$

$\mathcal{Z} + \mathcal{Q}$. Since functions from H do not depend on ξ_3, we find that $\mathcal{T}_{i3} = 0\,(i = 1, 2, 3)$ and $y_3 = \mathcal{T}_{31}\xi_1 + \mathcal{T}_{32}\xi_2$ for $\hat{\boldsymbol{\xi}} \in \Sigma_{\scriptscriptstyle S}$. We extend y_3 to the whole domain Σ in such a way that it would be a periodic function (assuming equal values on the opposite edges of Σ).

In order to determine y_1 and y_2 in $\Sigma_{\scriptscriptstyle F}$, we have to solve the problem

$$\begin{aligned} &\frac{\partial y_1}{\partial \xi_1} + \frac{\partial y_2}{\partial \xi_2} = 0, && \hat{\boldsymbol{\xi}} \in \Sigma_{\scriptscriptstyle F}, \\ &\boldsymbol{y}(\hat{\boldsymbol{\xi}}) = \mathcal{T}\boldsymbol{\xi}, && \hat{\boldsymbol{\xi}} \in \partial\Sigma_{\scriptscriptstyle S}, \\ &y_1 \quad \text{and} \quad y_2 \quad \text{are} \quad \text{periodic} \quad \text{in} \quad \Sigma. \end{aligned}$$

This problem is clearly solvable, and the theorem is completely proved. □

As one can see from (5.6), the tensor $\overline{G}$ describes elastic stresses in the homogenized continuum. Theorem 5.21 says that the homogenized material has rather strange properties. Namely, it does not resist to the deformation, if the first invariant and the component (3,3) of the corresponding strain tensor are equal to zero. In other words, such deformations do not produce any stresses. The described class of deformations is sufficiently large. It contains all deformations which do not change volume. The following assertion is a simple consequence of Theorem 5.21.

COROLLARY 5.22. *If $i \neq j$ and $k \neq l$, then $\overline{G}_{ijkl} = 0$.*

This property of the tensor $\overline{G}$ yields an interesting conclusion about the passage to the limit as $\theta \to 0$. If we set $\theta = 0$ formally, the elastic structure will occupy the whole layer Ω^h. Therefore, it can seem that the limiting material must be the same as the original elastic one so that $\lim_{\theta\to 0} \overline{G} = G$. Nevertheless, it is wrong in general because the properties of the tensor $\overline{G}$ stated in Theorem 5.21 and in Corollary 5.22 do not depend on θ. Thus, if, for instance, the tensor G is not degenerate or $G_{1212} \neq 0$, then $\lim_{\theta\to 0} \overline{G} \neq G$. The physical reason is that the elastic structure consists of separate bristles for each $\theta > 0$, which differs from the bulk material corresponding to $\theta = 0$.

6. Numerical procedures. The formulas for the coefficients $\overline{P}$, $\overline{G}$, and ω contain the functions $\boldsymbol{a}_{kl}$, $\boldsymbol{b}_{kl}$, $\boldsymbol{n}_0$, the operators $\mathcal{A}_{\scriptscriptstyle E}$, $\mathcal{B}_{\scriptscriptstyle E}$, and their inverse defined in $H = H^1_{\#}(\Sigma)/\mathbb{R}$. From the mathematical point of view, all these functions and operators are well defined and completely described. However, numerical implementation of these formulas requires some effort. The computation of the functions $\boldsymbol{a}_{kl}$, $\boldsymbol{b}_{kl}$, and $\boldsymbol{n}_0$ is not difficult if one uses the finite element method. The situation with the operators $\mathcal{A}$, $\mathcal{B}$ is not so trivial, because they must be restricted to the subspace E, which creates additional problems when using finite elements. Below, we propose numerical procedures that can be implemented using conventional finite element software.

6.1. Calculation of $\boldsymbol{a_{kl}}$, $\boldsymbol{b_{kl}}$, and $\boldsymbol{n_0}$. Let us introduce functions $\sigma_k \in H$, $k = 1, 2, 3$, as solutions of the following problems:

$$\int_\Sigma \frac{\partial \sigma_k}{\partial \xi_i} \frac{\partial v}{\partial \xi_i}\, d\hat{\boldsymbol{\xi}} = \int_\Sigma \chi\, \frac{\partial v}{\partial \xi_k}\, d\hat{\boldsymbol{\xi}} \qquad \text{for all} \quad v \in H.$$

These problems can be easily solved applying the finite element method. Note that $\sigma_3 = 0$ because functions from the space H do not depend on ξ_3. It is not difficult to see that

$$\begin{aligned} a^i_{kl} &= P_{kli1}\sigma_1 + P_{kli2}\sigma_2, \\ b^i_{kl} &= \gamma^{-1}\delta_{kl}\sigma_i - G_{kli1}\sigma_1 - G_{kli2}\sigma_2, \\ n^i_0 &= -p^0\sigma_i - \mathcal{G}^0_{i1}\sigma_1 - \mathcal{G}^0_{i2}\sigma_2 \end{aligned}$$

for $i,k,l \in \{1,2,3\}$. Here, the superscript i denotes the components of the vectors $\boldsymbol{a}_{kl}$, $\boldsymbol{b}_{kl}$, and $\boldsymbol{n}_0$.

6.2. Calculation of $\mathcal{A}_{E}^{-1}$ and $\mathcal{B}_{E}^{-1}$. The problem can be formulated as follows: *for every* $\boldsymbol{w} \in R(\mathcal{A}) \cap R(\mathcal{B})$, *find* $\boldsymbol{u}, \boldsymbol{v} \in E$ *such that* $\mathcal{A}\boldsymbol{u} = \boldsymbol{w}$ *and* $\mathcal{B}\boldsymbol{v} = \boldsymbol{w}$. It is enough to solve this problem for the operator $\mathcal{A}$. The operator $\mathcal{B}$ can be treated similarly. Let us consider the equation

$$(\mathcal{A} + \varepsilon\mathcal{B})\,\boldsymbol{u}_\varepsilon = \boldsymbol{w}. \tag{6.1}$$

As follows from Proposition 4.13, the operator $\mathcal{A} + \varepsilon\mathcal{B}$ is invertible in H for every $\varepsilon > 0$. Thus, there exists a unique $\boldsymbol{u}_\varepsilon \in H$ that satisfies (6.1). Moreover, $\boldsymbol{u}_\varepsilon \in E$ for every $\varepsilon > 0$ by definition of the subspace E. Equation (6.1) can be easily solved numerically with finite elements. Let us show that $\boldsymbol{u}_\varepsilon$ is an approximation of a function $\boldsymbol{u} \in E$ that satisfies the equation $\mathcal{A}\boldsymbol{u} = \boldsymbol{w}$. Since $\boldsymbol{u}_\varepsilon \in E$, we can rewrite (6.1) as $(\mathcal{A}_{E} + \varepsilon\mathcal{B}_{E})\,\boldsymbol{u}_\varepsilon = \boldsymbol{w}$. Consequently,

$$\boldsymbol{u}_\varepsilon = \mathcal{A}_{E}^{-1}(\boldsymbol{w} - \varepsilon\mathcal{B}_{E}\boldsymbol{u}_\varepsilon). \tag{6.2}$$

Due to Theorem 4.17, the operator $\mathcal{A}_{E}^{-1} : R(\mathcal{A}) \cap R(\mathcal{B}) \to E$ is bounded. Therefore, there exists an independent of ε constant C such that

$$\|\boldsymbol{u}_\varepsilon\| \leqslant C(1 + \varepsilon\|\boldsymbol{u}_\varepsilon\|).$$

This means that the sequence $\{\boldsymbol{u}_\varepsilon\}_\varepsilon$ is weakly compact in H. That is, there exist $\boldsymbol{u} \in H$ and a subsequence $\{\boldsymbol{u}_\varepsilon\}_\varepsilon$ such that $\boldsymbol{u}_\varepsilon \to \boldsymbol{u}$ weakly in H as $\varepsilon \to 0$. Since E is weakly closed, $\boldsymbol{u} \in E$. The passage to the limit in (6.1) yields the desired relation $\mathcal{A}\boldsymbol{u} = \boldsymbol{w}$. Moreover, the whole sequence $\{\boldsymbol{u}_\varepsilon\}_\varepsilon$ converges to $\boldsymbol{u}$ in H. In reality, $\boldsymbol{u}_\varepsilon - \boldsymbol{u} = -\varepsilon\mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{u}_\varepsilon$, which implies

$$\|\boldsymbol{u}_\varepsilon - \boldsymbol{u}\| \leqslant C\varepsilon. \tag{6.3}$$

Thus, the order of the approximation is obtained.

6.3. Calculation of $e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\mathcal{A}_{E}^{-1}\mathcal{B}_{E}$. Problem: *For every* $\boldsymbol{w} \in E$ *and all* $t > 0$, *find* $\boldsymbol{u}(t) = e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{w}$. Let us consider the following equation:

$$\boldsymbol{u}_t + \mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{u} = 0, \qquad \boldsymbol{u}(0) = \mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{w}. \tag{6.4}$$

It is obvious that $\boldsymbol{u}(t) = e^{-t\mathcal{A}_{E}^{-1}\mathcal{B}_{E}}\mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{w} \in E$ is a unique solution of this equation (see section 4.3). Let us construct an approximate solution to problem (6.4) using the semidiscretization method. Fix t and introduce $\tau = t/N$, $N \in \mathbb{N}$. Define functions $\boldsymbol{u}_n$, $n = 1, 2, \ldots, N$, as solutions of the following problem:

$$(\mathcal{A} + \tau\,\mathcal{B})\boldsymbol{u}_n = \mathcal{A}\boldsymbol{u}_{n-1}, \qquad \boldsymbol{u}_0 = \mathcal{A}_{E}^{-1}\mathcal{B}_{E}\boldsymbol{w}. \tag{6.5}$$

That is,

$$\boldsymbol{u}_n = (\mathcal{A} + \tau\,\mathcal{B})^{-1}\mathcal{A}\boldsymbol{u}_{n-1}.$$

Note that $\boldsymbol{u}_n \in E$ for all $n \geq 0$ because $\boldsymbol{u}_0 \in E$ and $\boldsymbol{u}_{n-1} \in E$ implies $\boldsymbol{u}_n \in E$ for any $n > 0$. Therefore, the operators $\mathcal{A}$ and $\mathcal{B}$ can be replaced by $\mathcal{A}_{E}$ and $\mathcal{B}_{E}$ in (6.5).

To estimate $\boldsymbol{u}_N - \boldsymbol{u}(t)$ we prove first that there exists a constant C such that $\|\boldsymbol{u}_n\| \leqslant C$ for all n. Indeed,

$$\boldsymbol{u}_n = \boldsymbol{u}_0 - \tau \mathcal{A}_{E}^{-1} \mathcal{B}_{E} \sum_{k=1}^{n} \boldsymbol{u}_k,$$

which implies due to the boundness of $\mathcal{A}_{E}^{-1}$ and $\mathcal{B}_{E}^{-1}$ (see Theorem 4.17), the existence of a constant C such that

$$\|\boldsymbol{u}_n\| \leqslant \|\boldsymbol{u}_0\| + C\,\tau \sum_{k=1}^{n} \|\boldsymbol{u}_k\|.$$

The Gronwall inequality now implies the required estimate. The boundness of $\|\boldsymbol{u}_n\|$ and (6.5) provide the following estimate:

$$\|\boldsymbol{u}_n - \boldsymbol{u}_{n-1}\| \leqslant C\tau\, \|\mathcal{A}_{E}^{-1}\mathcal{B}_{E}\| \|\boldsymbol{u}_n\| \leqslant C\tau. \tag{6.6}$$

Let us introduce two time interpolations of $\{u_n\}$,

$$\hat{\boldsymbol{u}}^{\tau}(s) = \boldsymbol{u}_n\Big(1 - n + \frac{s}{\tau}\Big) + \boldsymbol{u}_{n-1}\Big(n - \frac{s}{\tau}\Big) \qquad \text{as} \quad s \in [(n-1)\tau, n\tau],$$
$$\bar{\boldsymbol{u}}^{\tau}(s) = \boldsymbol{u}_n \qquad \text{as} \quad s \in ((n-1)\tau, n\tau].$$

Due to (6.6),

$$\int_0^t \|\hat{\boldsymbol{u}}^{\tau}(s) - \bar{\boldsymbol{u}}^{\tau}(s)\|\, ds = \sum_{n=1}^{N} \|\boldsymbol{u}_n - \boldsymbol{u}_{n-1}\| \int_{(n-1)\tau}^{n\tau} \Big(n - \frac{s}{\tau}\Big)\, ds$$
$$= \frac{\tau}{2} \sum_{n=1}^{N} \|\boldsymbol{u}_n - \boldsymbol{u}_{n-1}\| \leqslant C\tau.$$

Moreover, we have

$$\frac{\partial \hat{\boldsymbol{u}}^{\tau}}{\partial t} + \mathcal{A}_{E}^{-1}\mathcal{B}_{E}\bar{\boldsymbol{u}}^{\tau} = 0.$$

Therefore,

$$\|\boldsymbol{u}_N - \boldsymbol{u}(t)\| = \|\hat{\boldsymbol{u}}^{\tau}(t) - \boldsymbol{u}(t)\| \leqslant \|\mathcal{A}_{E}^{-1}\mathcal{B}_{E}\| \int_0^t \|\bar{\boldsymbol{u}}^{\tau}(s) - \boldsymbol{u}(s)\|\, ds$$
$$\leqslant C \int_0^t \big(\|\hat{\boldsymbol{u}}^{\tau}(s) - \boldsymbol{u}(s)\| + \|\hat{\boldsymbol{u}}^{\tau}(s) - \bar{\boldsymbol{u}}^{\tau}(s)\|\big)\, ds \leqslant C\Big(\tau + \int_0^t \|\hat{\boldsymbol{u}}^{\tau}(s) - \boldsymbol{u}(s)\|\, ds\Big).$$

Finally, the Gronwall inequality yields

$$\|\boldsymbol{u}_N - \boldsymbol{u}(t)\| \leqslant C\tau.$$

6.4. Numerics. In this section we give some examples which demonstrate properties of the homogenized continuum for various values of θ. We consider the system consisting of the water and an isotropic elastic material (polymer) with the following properties:

$$P\boldsymbol{u}_{\boldsymbol{x}} = \lambda_f\, \mathcal{I}\, \mathrm{div}\, \boldsymbol{u} + 2\,\mu_f\, \mathcal{D}(\boldsymbol{u}), \qquad G\boldsymbol{u}_{\boldsymbol{x}} = \lambda_s\, \mathcal{I}\, \mathrm{div}\, \boldsymbol{u} + 2\,\mu_s\, \mathcal{D}(\boldsymbol{u}),$$
$$\lambda_f = 1.\mathsf{e}{-3}, \quad \mu_f = 1.\mathsf{e}{-3},$$
$$\lambda_s = 2.777778\mathsf{e}+9, \quad \mu_s = 4.166667\mathsf{e}+9.$$

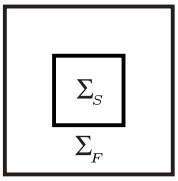

FIG. 3. *Structural cell* $\Sigma = [0,1] \times [0,1]$.

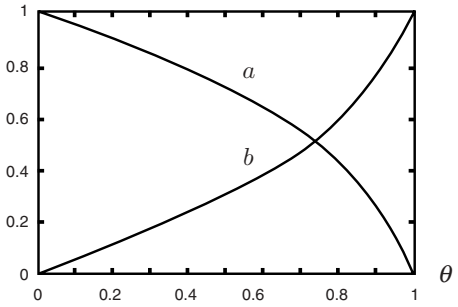

FIG. 4. *Dependence of* $|P - \overline{P}|/|P|$ *(curve a) and* $|\overline{P}|/|P|$ *(curve b) on* θ.

The constant which characterizes compressibility of the water is $\gamma = 4.597696\mathrm{e} - 10$. We take the structural cell of the form shown in Figure 3.

First, we investigate properties of the tensor $\overline{P}$. The graphics in Figure 4 present the dependence of $|P - \overline{P}|/|P|$ and $|\overline{P}|/|P|$ on θ, where $|P| = \left(\sum_{ijkl} P_{ijkl} P_{ijkl}\right)^{1/2}$. As one can see, $\lim_{\theta \to 1} \overline{P} = P$ and $\lim_{\theta \to 0} \overline{P} = 0$.

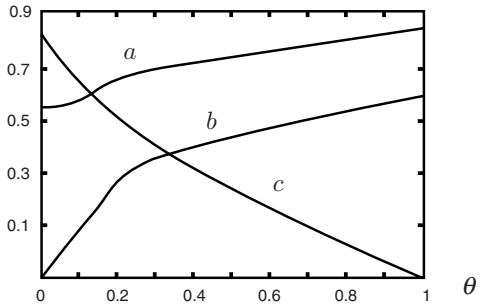

FIG. 5. *Dependence of* $|\overline{G} - G|/|G|$ *(curve a),* $|\overline{G} - Q|/|G|$ *(curve b), and* $|\overline{G} - \theta R|/|G|$ *(curve c) on* θ.

The dependence of the tensor $\overline{G}$ on θ is more complex. Let us introduce two tensors R and Q having the following components:

$$R_{ijkl} = \gamma^{-1} \delta_{ij} \delta_{kl}, \qquad Q_{ijkl} = \begin{cases} G_{ijkl} & \text{if} \quad i = j \quad \text{and} \quad k = l, \\ 0 & \text{otherwise.} \end{cases}$$

The curves in Figure 5 show the dependence of $|\overline{G} - G|/|G|$, $|\overline{G} - \theta R|/|G|$ and $|\overline{G} - Q|/|G|$ on θ. One can see that $\overline{G}$ does not tend to G as $\theta \to 0$ (see curve a). This fact was already noted in section 5.2 after Corollary 5.22. It is not surprising that

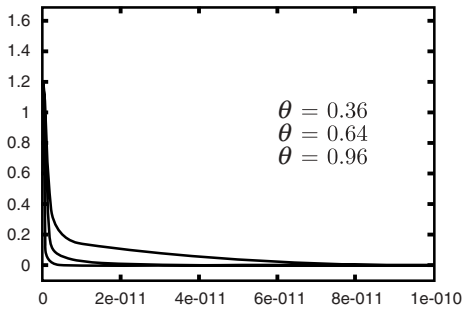

FIG. 6. *Graphics of the function* $|\omega(t)|/|\overline{G}|$ *for various values of* θ. *The time unit is* 1 *second.*

$\lim_{\theta\to 1}\overline{G}\neq 0$. It can be explained by the presence of the tensor R in the definition of $\overline{G}$. Really, curve c in Figure 5 shows that $\lim_{\theta\to 1}(\overline{G}-R)=0$. Curve b shows that $\lim_{\theta\to 0}\overline{G}=Q$. This means that, in the limit case as $\theta\to 0$ (the elastic continuum occupies the whole domain Ω^h), the tensor $\overline{G}$ can be obtained from the tensor G by vanishing all of the "nondiagonal" components.

Thus, the limits of (5.6) as $\theta\to 0$ and $\theta\to 1$ look as follows:

$$\rho_{\scriptscriptstyle S}\boldsymbol{u}_t-\operatorname{div}\mathcal{J}_tQ\boldsymbol{u}_x-\operatorname{div}\int_0^t\omega(t-s)\boldsymbol{u}_x(s)\,ds=\rho_{\scriptscriptstyle S}\boldsymbol{f},\qquad(\theta\to 0),\tag{6.7}$$

$$\rho_{\scriptscriptstyle F}\boldsymbol{u}_t-\operatorname{div}P\boldsymbol{u}_x-\gamma^{-1}\nabla\operatorname{div}\boldsymbol{u}-\operatorname{div}\int_0^t\omega(t-s)\boldsymbol{u}_x(s)\,ds=\rho_{\scriptscriptstyle F}\boldsymbol{f},\quad(\theta\to 1).\tag{6.8}$$

We take here the initial data being equal to zero.

In Figure 6, the graphs of the function $|\omega(t)|/|\overline{G}|$ are presented for several values of θ. The function $|\omega(t)|$ decreases very rapidly. In fact, $|\omega(t)|/|\overline{G}|$ vanishes practically at the time $t\sim 10^{-10}\,s$. Thus, the memory term in (5.6) is very small and can be dropped in applications, if high frequency oscillations are not present.

7. Conclusions. Homogenization of a fine elastic structure immersed in a viscous weakly compressible fluid yields a continuum that possesses very interesting and rather unexpected properties. Equation (5.6) describing the behavior of the resulting continuum includes three basic terms. Two of them containing the tensors $\overline{P}$ and $\overline{G}$ are related to stresses. The third integral-term represents a memory effect that is responsible for viscoelastic properties of the resulting material. The presence of such a memory is not surprising because similar results were already obtained by other authors (see, for instance, [13]). More interesting from the mathematical and mechanical viewpoints is the investigation of the above mentioned stress terms. The term containing the tensor $\overline{P}$ describes a viscous damping and originates from the fluid part of the structure. Theorem 5.20 states the strict positiveness of $\overline{P}$, which implies the ellipticity of the corresponding differential operator. The term containing the tensor $\overline{G}$ represents elastic stresses. The tensor $\overline{G}$ is degenerate, its kernel is described in Theorem 5.21. The theorem implies that volume conserving deformations (shear deformations in particular) do not produce elastic stresses.

All of the coefficients involved in the homogenized equation are found in an explicit form. Although expressions representing them are rather complex, the coefficients can be computed numerically using the algorithms given in section 6. The numerical treatment delivers another interesting properties of the homogenized model. It is stated

numerically that the memory effect is very weak. The system "forgets" the current history in a very short time. Therefore, the memory term can be dropped in most of the applications. Another interesting question is the dependence of properties of the homogenized continuum on the parameter θ which represents the volume fracture of the fluid so that the pure fluid corresponds to $\theta = 1$. As was expected, the homogenized equations coincide in the limit ($\theta \to 1$) with the ones being used for the description of the original fluid. In the opposite limiting case ($\theta \to 0$) the homogenized equations differ from the model of the original elastic continuum. In particular, the limiting elastic continuum can be nonisotropic even though the original material is isotropic. Thus, the limiting continuum inherits certain geometric properties of the fine elastic structure even if the fluid vanishes and the solid occupies the whole volume.

MODELING CALCIUM DYNAMICS IN DENDRITIC SPINES*

D. HOLCMAN†‡ AND Z. SCHUSS§

Abstract. Dendritic spines are microstructures located on dendrites of neurons, where calcium can be compartmentalized. They are usually the postsynaptic parts of synapses and may contain anywhere from a few up to thousands of calcium ions at a time. Initiated by an action potential, a back-propagating action potential, or a synaptic stimulation, calcium ions enter spines and are known to bring about their fast contractions (twitching), which in turn affect calcium dynamics. In this paper, we propose a coarse-grained reaction-diffusion (RD) model of a Langevin simulation of calcium dynamics with twitching and relate the biochemical changes induced by calcium to structural changes occurring at the spine level. The RD equations model the contraction of proteins as chemical events and serve to describe how changes in spine structure affect calcium signaling. Calcium ions induce contraction of actin-myosin-type proteins and produce a flow of the cytoplasmic fluid in the direction of the dendritic shaft, thus speeding up the time course of calcium dynamics in the spine, relative to pure diffusion. Experimental and simulation results reveal two time periods in spine calcium dynamics. Simulations [D. Holcman, Z. Schuss, and E. Korkotian, *Biophysical Journal*, 87 (2004), pp. 81–91] show that in the first period, calcium motion is mainly driven by the hydrodynamics, while in the second period it is diffusion. The coarse-grained RD model also gives this result, and the analysis reveals how the two time constants depend on spine geometry. The model's prediction, that there are not two time periods in the diffusion of inert molecules in the spine, has been verified experimentally.

1. Dendritic spines and their function.

Dendritic spines are microstructures, about 1 μm across, made of a head and connected by a cylindrical neck to the dendrite. Although discovered more than 100 years ago by Ramón y Cajal [1] on dendrites of most neurons, including cortical pyramidal neurons and cerebellar Purkinje cells [2], their function is still unclear. The current consensus is that the main function of dendritic spines is to compartmentalize calcium [3]. Regulated by synaptic activity, spines are constantly moving and changing shape [4]. The 100,000 to 300,000 spines on a single spiny neuron drastically increase the active surface of a dendrite [5], [6], and more than 90% of excitatory synapses terminate on dendritic spines. Spines are considered to be basic units of dendritic integration [7], [8], though their role and function are still unclear. There is evidence that morphological changes in spines are associated with synaptic plasticity [4], that is, with the structural and biochemical changes in spines, dendrites, and neuronal synapses.

A debate is still raging about the specific function of dendritic spines. In particular, two main views prevail [9], [10]. The first maintains that a dendritic spine constitutes a privileged location for calcium restriction, and consequently, it is a place where synaptic plasticity can be induced. Calcium in dendritic spines triggers changes, such as long-term potentiation (LTP) and long-term depression (LTD) [11], which result in a permanent modification of the synaptic weight. Indeed, calcium dynamics, defined as the rise and duration of concentration inside a dendritic spine, is believed to be determinant for the nature of spine synaptic plasticity. These processes constitute the implementation of some of the memory in the brain at the cellular and subcellular levels. The second view maintains that by changing the shape of the spine, the electrical characteristics of the spine change, thereby modulating the voltage and the depolarization of the dendrite. This way the spines participate in the dendritic computation process.

Recently, it has been observed [12] that after calcium ions flow in, a dendritic spine can change shape in a few hundreds milliseconds. This fast change of shape decreases the volume of the spine head. Spine motility was proposed by Blomberg, Cohen, and Siekevitz [13] and the fast twitching movement of the spine was anticipated by Crick in [14], where questions were asked about the rules "governing the change of shape of the spine and, in particular, the neck of the spine" and also on "how these rules are implemented in molecular terms." Many models of calcium dynamics in dendritic spines have been proposed in the literature [5], [7], [15], [16], [17], [18], [19]; however, calcium dynamics was not considered in conjunction with Crick's questions and with the observations of [12].

When the spine shape is described by a spherical head connected to a cylindrical neck, several classes of shapes can be distinguished, according to three independent geometrical parameters (see Figure 1). According to this representation, the three parameters are the radius of the head (R), the length of the neck (l), and its diameter (d). There are at most eight possible classes of spines, according to the relative sizes (large or small) of the three parameters. It is not clear yet what are the rules, if any, of the distribution of the different classes in a given neuron. Spines may appear isolated or in clusters on a dendrite [4]. The number of spines and their distribution are regulated by neuronal activity, because increased activity tends to increase the production of spines, whereas light deprivation tends to reduce the number of spines. However, the details remain unclear.

Dendritic spines can change shape on various time scales. On the time scale of minutes, synaptic stimulation can generate new spines. LTP experiments in the dentate gyrus are correlated with a change in the diameter of the spine neck. A single spine can split into two, and transitions between filopodia (spines with no head) and the standard form have been observed experimentally [4]. Modulation of sensory inputs, such as monocular deprivation in specific periods of development, modulates spine motility [20], [21]. Spines are less motile in adult neurons than in neurons of juvenile animals. Changes of shape on the time scale of minutes are due to actin (de-)polymerization and can be induced by a variation in the concentration of a neurotransmitter, such as glutamate [12], [23]. Dendritic spines have been observed to move on a very short time scale. For example, vibrations along the spine axis, which are independent of the calcium concentration, occur on the time scale of tens of milliseconds [12].

Spine movements on the time scale of seconds have been observed directly by recent imaging techniques, such as confocal microscopy or two-photon microscopy. It was reported that spines are constantly changing shape [18], [24]. This motility is also

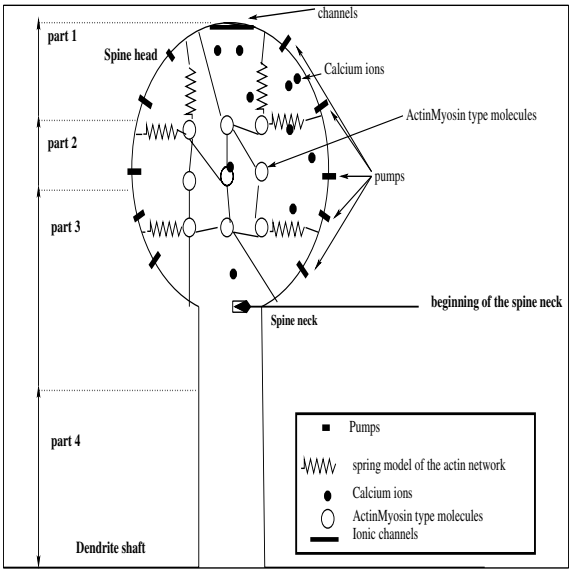

FIG. 1. *Schematic description of a dendritic spine. A dendritic spine is modelled as a spherical head connected to the dendrite by a cylindrical neck. The surface of the head contains a postsynaptic density, where various types of protein channels, such as the glutamate receptors NMDA and AMPA, are anchored and conduct ions into the spine when opened. A spine contains signalling molecules, such as calmodulin; cytoskeletal proteins, such as actin-myosin; and organelles, such as smooth endoplasmic reticulum. Pumps are located on the side and channels at the top of the spine head. Actin-myosin sites are represented schematically, attached to the actin network, so that a contraction of a single protein affects the entire spine. (Figure reprinted from* [D. Holcman, Z. Schuss, and E. Korkotion, *Calcium dynamics in dendritic spines and spine motility,* Biophysical Journal, 87 (2004), pp. 81–91] *with permission.*

an actin-dependent process. The postsynaptic current can be modified by affecting the spine geometry, thus modulating the synapse. Changes in spine shape can then affect the efficacy of calcium dynamics. Specifically, it was reported in [18] that changing the spine neck affects the time course of calcium dynamics: High calcium concentration is maintained for a shorter period of time when the neck is shorter. Thus dendritic spines with shorter necks are less efficient in compartmentalizing calcium. In summary, spines undergo a constant readjustment, which can be viewed as an intrinsic spine property [20], and motility possibly contributes to synaptic plasticity.

It has recently been observed [12] that a dendritic spine can change shape quickly, on the scale of a few hundreds of milliseconds, after calcium ions flow into the spine. Transient calcium causes the spine to twitch (see [12]). This quick change of shape consists in head contractions oriented on the average in the direction of the dendritic shaft. This contraction can be induced by agonists, such as a neurotransmitter, or by a back-propagating action potential.

Evidence of high concentration of actin and myosin in spines was reported in [25], where proteins were observed to form clusters inside the spine head, near the channels. These clusters are called the *postsynaptic density* (PSD). More uniform distributions of clusters of myosin molecules were also observed. As in muscle cells, high concentrations of actin molecules indicate that rapid movement can be ascribed to the contraction of these molecules, because blocking them prevents all shape fluctuations [12].

It is remarkable that the description of the diffusive motion of ions in spines can be considered in the intermediate regime between continuum and discrete. Due to its specific geometry, the dendritic spine can be studied as a separate unit from the remaining part of the dendrite. Chemical reactions in the spine involve only a small number of molecules (hundreds), which explains the relatively large fluctuations in the reactions. These may lead to synaptic plasticity. This fact also reinforces the idea that the spine has a major role in converting a random signal, carried by the motion of ions or secondary messengers, into a more deterministic, less fluctuating, and more stable variable, represented by the synaptic weight.

2. Introduction. Despite the rapid development of high-quality technology, today's biophysical analysis of calcium in dendritic spines is limited by the resolution of the instruments. Thus models become useful tools for the analysis and prediction of spine activity, based on the evidence of molecular chemical reactions.

2.1. Modeling the dendritic spine dynamics. We propose here an answer to Crick's question about the cause and effect of the twitching and its role in the functioning of the spine as a conductor of calcium. Specifically, we attribute the twitching motion to the contraction of actin-myosin-type proteins, denoted AM, when they bind calcium, and include its effect on the dynamics of the calcium ions in the spine. This is the first quantitative theoretical and mathematical treatment of the twitching and its role in calcium dynamics in the spine. In [26] we constructed a Langevin dynamics simulation of calcium dynamics in the spine, and here we propose a continuum model of the same.

The calmodulin proteins (CaM) can bind up to four calcium ions to form the complex $CaMCa_4$. This complex starts other important chemical reactions, involving, for example, calmodulin-protein kinase-II. This kinase plays a crucial role in LTP induction [16]. When a sufficiently large number of $CaMCa_4$ complexes are formed, it produces LTP changes and/or induces dephosphorylation and (de-)polymerizations. It can also affect certain biophysical properties of certain channels, such as N-methyl-D-aspartale (NMDA) receptors. More generally, this type of reaction is known to induce modifications in the spine shape and biophysical changes at various levels, such as synaptic modifications, and changes in the number of channels (see [17]): When channel subunits are modified, the selectivity and/or ionic conductivity is changed, affecting the number of ions that enter the spine. When the number of receptors increases, e.g., of AMPA receptors, the spine's depolarization increases, resulting in a higher probability of opening of NMDA receptors and thus increasing the total number of calcium ions entering the spine.

We model the spine as a machine powered by the calcium it conducts, and we describe here the induced movement. Proteins involved in the calcium conduction process are found inside the dendritic spine. Their spatial distribution was reported in [25]. As mentioned above, relevant proteins involved in spine motility include actin, which has been shown in [12], [20], [24] to be directly involved in the biophysical process underlying fast spine motility. We maintain here that AM sites are driving the motility events. It was shown in [25] that dendritic spines contain a network of myosin molecules. The spatial distribution of myosin molecule in the spine has been observed to be uniform and to be sparse inside the PSD.

From a biological point of view, it is of primary interest to answer two related questions about calcium dynamics in dendritic spines, after their channels open: (1) How much calcium is there inside the spine? (2) How long does a given quantity of calcium stay inside the spine? Obviously, the answers depend on the geometry of the

cell. In this context, the aim of our model is to reproduce the time course of events, such as calcium dynamics, which determine the transition between depression and facilitation, or long- and short-term depression (see [28]). We propose that calcium ions set the machine in motion by initiating the contraction of AM as they bind at active sites [26]. We elucidate the cause and effect of twitching in the functioning of the spine by adding up the local contractions of the separate calcium-saturated proteins to achieve a global contraction effect. The contraction of the spine head induces a flow field of the cytoplasmic fluid, which in turn pushes the ions, thus speeding up their movement in the spine.

2.2. Biological consequences. We reported and discussed the biological consequences of a Langevin simulation, designed at a molecular level, in our first paper [26]. The purpose of the simulation was to investigate at a molecular level biochemical events induced by calcium and thus to explain structural changes occurring at the spine level. The main biological conclusion of [26] concerns the quantification of the effect of the hydrodynamical push on calcium dynamics in the spine. In particular, we showed not only that the push effect is created by the calcium ions, but that the push targets the same calcium ions towards the dendrite and in the direction of the center of the spine, where the spine apparatus and other relevant proteins are located. The flow due to the push does not allow the calcium ions to stay inside the spine head and to return to the head once they are inside the neck. The drift increases the efficiency of calcium conduction from the synapse to the dendrite and speeds up the calcium clearance of the spine. The simulations of [26] show that in the absence of the drift effect, the proportion of calcium ions conducted to the dendrite is two to three times smaller than in its presence. This led to the prediction that there are not two time periods in the diffusion of inert dye molecules in the spine, as has been recently verified experimentally [27].

We propose here a coarse-grained description of the coupling between changes in spine structure and calcium dynamics. A set of nonlinear reaction-diffusion equations is derived from the Langevin description. The analysis of the model reveals the time scale of the hydrodynamical effect and leads to the calculation of the time constant of the first concentration decay period. Consequently the push effect offers a possible reinterpretation of the results of [19], about the double exponential decay of the calcium concentration inside the spine. The first decay period was reported in [19] to be the consequence of buffered calcium diffusion from spine to dendrite and the effect of calcium pumps in the spine head. According to [19], the second period starts when near equilibrium is achieved between the spine's and the dendrite's calcium concentrations. We show in this paper that the two time periods of calcium concentration decay are recovered, under specific conditions, when the hydrodynamical push effect is included. We observe that the decay, corresponding to a predominantly hydrodynamical effect, starts immediately after the ions enter the spine head. This decay is rapid and its duration is random. It ends when hardly any saturated contractive molecules are left. The ionic motion in the second period is mainly pure diffusion and pump extrusion. An analytic expression for the fast decay rate is derived from the model in terms of the average hydrodynamical flow velocity. The main biological result of our model is that the rapid spine movement produces fast clearance of calcium from the dendritic spine and directs calcium ions to a specific location between the neck and the dendritic shaft, preventing the pumping out of the majority of ions. As mentioned above, the model also predicts that there are not two time periods in the diffusion of inert dye molecules in the spine, which means that diffusion alone cannot

be responsible for the double exponential decay.

2.3. The need of a molecular approach. The models of calcium diffusion in dendritic spines used, e.g., in [5], [6], [7], [15], [16], [17], [18], [19], [22] are based on a phenomenological approach that uses the coupling between the diffusion equation and the ambient chemical reactions. They are based on compartmentalization of the spine into several subunits, where the calcium diffusion process is discretized, while ordinary differential equations describe the chemical bonding of calcium to buffer protein molecules.

In this paper, we present a mathematical model of calcium dynamics in dendritic spines, based on molecular-level considerations. Actually, we propose a unified approach to modeling calcium dynamics inside microstructures, including dendritic spines, that postulates Brownian motion of the calcium ions in the cell. The randomness of the ionic motion becomes significant when the number of ions in the cell is small. At the molecular level, all phenomena, beginning with the motion of a single ion and up to the dynamics of the entire ionic population, are stochastic processes. These include the random walk of an ion, forming or breaking bonds with proteins by an individual ion. On the entire calcium population level, they include the dynamics of the number of bound proteins, which depends on the trajectory of each ion, and the distribution of the protein molecules.

Our model begins with the description of the dynamics of individual calcium ions in terms of a system of Langevin equations. The collective effect inside the spine of the entire calcium population, due to the interaction between the calcium and the proteins, is captured in our model by a nonlinear drift term that couples the hydrodynamical flow field to the number of ions bound to certain proteins. This produces a new effect that has to be included in the diffusion equation. The distribution of proteins inside the cell becomes an important part of the model.

2.4. Biological simplifications of the model. We make several simplifications in constructing the model of the spine. Thus, we neglect other types of organelles that are also involved in calcium dynamics: the spine apparatus, mitochondria, and other types of proteins. We have included a low concentration (.5–1 μM) of binding molecules such as calcineurin. However, at this concentration these molecules cannot capture fully the role played by the buffer activity. The present model ignores the effect of a large buffer regulation, but we keep in mind that it can affect the calcium dynamics.

Furthermore, it is known that calcium stores in the spine release calcium ions when prompted by external calcium ions, under specific conditions. We neglect this effect here to avoid complicating our model. We also restrict the biochemical structure of the spine by singling out the CaM, AM, calcineurin, and one type of calcium pump. All these proteins constrain calcium flow in the dendritic spine by binding calcium ions for random periods of time. The technical assumption in our model is that the AM proteins contract at a fixed rate as long as they keep four calcium ions bound. Thus contraction begins and ends at random times. Since we are interested in the dynamics of calcium, when the ions are already inside the spine, we avoid the computation of the transient time starting from the action potential and the opening of the voltage-sensitive calcium channels.

The specific geometry of the spine needs to be considered in order to evaluate the time evolution of calcium concentration in the spine. In the present simplified model, the spine geometry has been described by three parameters: the length and diameter

of the spine neck and the radius of the spine head (see Figure 1), smoothing out the local irregularities of the boundary.

Another geometric feature is the distribution $S_0(\boldsymbol{x})$ of calcium-dependent molecules that contract when they bind enough calcium. Two extreme possible distributions of proteins have been considered in the simulation, reported in [26]: a uniform distribution inside the head or an accumulation at the PSD area and the simulations show that the calcium dynamics depend on the distributions of the proteins. In reality, a mixture of the two distributions is observed in [26], but we will ignore it in the derivation of the decay rate.

3. A simplified physical model of the spine. The two main components of the dendritic spine in our model are a spherical head and a cylindrical neck, which connects it to the dendritic shaft. On top of the spine head, opposite the neck, there are protein channels that conduct calcium into the spine head. These channels can be of two types: NMDA channels (opened by the glutamate neurotransmitter) and calcium channels, which are voltage sensitive. There are only 2–5 NMDA channels open at a time. For the purpose of this model, we use only the location of these channels as the initial positions for the ions. Our model concerns times after the calcium ions have entered the spine head. A schematic figure of the spine is presented in Figure 1. Active pumps are located on the lower half of the spine head. Their role is to conduct calcium out of the spine head. Pumping is an active process that requires energy, provided by the adenosine tri phosphate (ATP) molecules, whereas when calcium enters through the channels, no extra molecular energy is needed. We assume that there is only one ion at a time inside a pump and, due to the active structure, it requires a certain time to be pumped out. This time can be assumed random or deterministic. The latter case is valid when the exit time distribution is concentrated around the mean value. In a coarse-grained continuum model the pumping time is neglected, so the part of the boundary occupied by pumps becomes an absorbing boundary.

The many organelles inside the spine head do not affect the nature of the random motion of ions, mainly due to their large size relative to that of ions. They only restrict the volume available for free diffusion of calcium. Neglecting their presence effectively frees the interior of the spine head from obstacles to ionic movement. This can be compensated for by decreasing the radius of the head. The incompressible cytoplasmic fluid that fills out the spine and its flow are a part of our model.

3.1. A schematic model of spine twitching. Once calcium ions enter the spine they reach AM binding sites by diffusion and can bind there. When four calcium ions bind to a single AM protein, a local contraction of the protein occurs. All the local contractions at a given time produce a global contraction and induce a hydrodynamical movement of the cytoplasmic fluid. Calcium ions can reach the dendritic shaft through the spine neck and be totally absorbed there, or they can be pumped out of the spine by active pumps. Our model allows us to calculate the fraction of ions that are pumped out, relative to those that reach the dendrite. At a molecular level, in a phenomenological approach, a contraction produced by AM occurs with a characteristic time $t_c = 1$ ms, say, and the length fluctuates about $l_c = 0.02$ μm [2, p. 681], depending only on the type of protein. In a homogenization approximation of the spine head, the result of this local contraction produces a fixed average velocity of the cytoplasmic fluid of the order $v_Q = l_c/t_c = 0.02$ μm/ms.

Since it is known that there are only a few AM binding sites (less than a hundred [25]), each binding event can modify the dynamics significantly. It is important

therefore to keep track of the number of bound ions at any given time. Both the distribution of AM binding sites and the binding times are random. Consequently, the twitching of the spine head is also random. This, in turn, implies that the evolution of calcium concentration inside the spine is random. In a continuum description of this process, only average motion is observed, so the random realizations that can be observed in molecular simulations are smoothed out.

3.2. Final model simplifications. We simplify the model further by neglecting the long range ion-ion electrostatic interactions, as well as the ion-protein interactions. At a molecular level, when 500 calcium ions enter the dendritic spine, they create a difference of potential of about 16 mV (compared to -70 mV of the cell potential), so there are enough negative ions inside the spine to electrostatically neutralize the calcium ions. Specifically, the cooperative effect of the ions creates dipoles that screen the long-range interaction forces (r^{-2}) to short-range interactions. The shield around each ion is a basis for an approximation that neglects the electrostatic forces in order to study the dynamics of calcium ions inside the spine. In this approximation the trajectories of the calcium ions are independent. The ion-water interaction is simplified into hydrodynamical drag and a zero mean fluctuating force that describes the randomness of the water-ion collisions [29]. The ion-protein interaction near a binding site, where a high electrical field targets the ions toward the active center of a binding site, is represented by a short range parabolic potential well. This allows us to include the backward binding reaction constant in the model. The effect of the forward constant is discussed below.

Each time an ion nears an active neighborhood of a protein, we assume that the electrostatic forces direct the ion so that a bond is formed with a given probability, depending on the forward rate constant. The backward reaction rate is the reciprocal of the mean time an ion stays bound. A binding site that holds an ion cannot bind additional ions before the bound ion escapes. We say that a protein is saturated if each of the four binding sites contains a calcium ion at the same time.

The chemical kinetics of the binding and unbinding of calcium to and from the substrate proteins (CaM, AM, calcineurin) in the spine cannot be described by the usual Arrhenius kinetics because of the small number of the reactant particles, the large fluctuations in the number of bound ions, and the hydrodynamic effect on the binding and unbinding reactions. We describe the forward and backward reactions on a molecular level in section 5 and then coarse-grain the equations in section 6. We consider in our model only two classes of binding proteins: one that includes CaM and AM (that is, proteins that can bind 4 calcium ions) and a second that includes calcineurin, which can bind only one calcium ion at a time. The simplified model described above was used for a molecular simulation of calcium dynamics in a dendritic spine in [26].

4. The mathematical model. The mathematical model of the simplified physical model of the dendritic spine has several components. First, the domain Ω_t, available for the motion of an ion at time t, has quite a complicated geometry, due to the presence of many obstacles, as mentioned in section 3, and it may change in time. Actually, this change is one of the main phenomena captured by our model. Second, when Ω_t changes, a flow of the cytoplasmic fluid in the dendritic spine ensues, which in turn gives rise to an hydrodynamical drag force on the ions inside the dendritic spine. This drag is a frictional force proportional to the relative velocity between the ions and the fluid. This force is not neglected in our simplified model. Third, the mathematical expression of these assumptions is a Langevin model of the ionic

motion. That is, the motion is described by a system of identical uncoupled Langevin equations driven by independent Brownian motions.

4.1. Mathematical simplifications. To simplify the analysis and simulation of the spine, we make several drastic simplifications. The quality of the simplified model is evaluated by its ability to capture the main phenomenology observed in experiment and by its ability to predict the fluid flow and the time dependence of the measured calcium concentration inside the dendritic spine.

The first simplification is that we consider the ions to be point charges, that is, we neglect Lennard–Jones repulsion. The second simplification is that we neglect electrostatic ion-ion interactions. This means that we can neglect all ionic species except the calcium, whose concentration needs to be predicted. We replace electrostatic interactions by interactions with a fixed mean field (that is, with a field not computed from Poisson's equation). Thus, we assume that the calcium ions move in an effective electrostatic field created by their interactions with each other and with other ions and by the permanent charge distribution on the CaM, calcineurin proteins, and AM complex. The behavior of this potential is assumed, rather than computed. We also neglect the change in the shape of the potential when a calcium ion binds to a protein molecule. The third simplification is that we neglect the impenetrable obstacles to the ionic motion posed by the presence of the proteins. Thus, we assume that the ionic motion inside the dendritic spine is geometrically unrestricted. Therefore, the domain Ω_t is the interior of the dendritic spine.

4.2. The Langevin equations. For a dendritic spine containing N ions of different species (e.g., Ca^{++}, Na^{+}, Cl^{-}, and so on), $\boldsymbol{x}_i(t)$ is the displacement vector of the ith ion, m_i is its mass, and z_i is its valence. $\tilde{\boldsymbol{x}} = (\boldsymbol{x}_1, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_N)$ is the coordinate of the N ions in configuration space. We assume that a flow field $\boldsymbol{V}(\boldsymbol{x}, t)$ is given (see description below) and that ions interact with a fixed potential of the charges on the proteins, $U_0(\boldsymbol{x})$, and with the variable potential of all other ions. The variable potential consists of both the electrostatic ion-ion interaction potential, $U_{\mathrm{ii}}(\tilde{\boldsymbol{x}})$, and the potential of Lennard–Jones-type repulsions, $U_{\mathrm{LJ}}(\tilde{\boldsymbol{x}})$ (that represents the finite size of the ions). The force per unit mass on the ith ion is

$$\boldsymbol{F}_i(\tilde{\boldsymbol{x}}) = -z_i e \nabla_{\boldsymbol{x}_i} \left[U_0(\boldsymbol{x}_i) + U_{\mathrm{ii}}(\tilde{\boldsymbol{x}}) \right] - \nabla_{\boldsymbol{x}_i} U_{\mathrm{LJ}}(\tilde{\boldsymbol{x}}).$$

The dynamics of the ith ion is given by the Langevin equation

$$\ddot{\boldsymbol{x}}_i + \gamma_i \left[\dot{\boldsymbol{x}}_i - \boldsymbol{V}(\boldsymbol{x}_i, t) \right] + \boldsymbol{F}_i(\tilde{\boldsymbol{x}}) = \sqrt{2\epsilon_i \gamma_i}\ \dot{\boldsymbol{w}}_i, \tag{4.1}$$

where e is the electronic charge. Here $\epsilon_i = k_B T / m_i$, T is the temperature, k_B is the Boltzmann constant, $\gamma_i = 6\pi a_i \eta_i$ is the dynamical viscosity (where η_i is the viscosity coefficient per unit mass), and a_i is the radius of the ion. The frictional drag force, $-\gamma \left[\dot{\boldsymbol{x}}_i - \boldsymbol{V}(\boldsymbol{x}_i, t) \right]$, is proportional to the relative velocity of the ion and the cytoplasmic fluid. The accelerations $\dot{\boldsymbol{w}}_i$ represent the thermal fluctuations of the fluid. The relation between the velocity diffusion constant and the friction coefficient,

$$D_i = \frac{k_B T}{m_i \gamma_i},$$

is Einstein's fluctuation-dissipation principle [30].

In the Smoluchowski limit of large damping [30], the Langevin equation (4.1) reduces to

$$\gamma_i \left[\dot{\boldsymbol{x}}_i - \boldsymbol{V}(\boldsymbol{x}_i, t) \right] + \boldsymbol{F}_i(\tilde{\boldsymbol{x}}) = \sqrt{2\epsilon_i \gamma_i}\ \dot{\boldsymbol{w}}_i. \tag{4.2}$$

In this paper, we neglect the ion-ion interactions; that is, we set $U_{\mathrm{LJ}}(\tilde{\boldsymbol{x}}) = U_{\mathrm{ii}}(\tilde{\boldsymbol{x}}) = 0$ so that (4.2) becomes

$$\gamma_i \left[\dot{\boldsymbol{x}}_i - \boldsymbol{V}(\boldsymbol{x}_i, t)\right] + \boldsymbol{F}(\boldsymbol{x}_i) = \sqrt{2\epsilon_i \gamma_i}\ \dot{\boldsymbol{w}}_i, \tag{4.3}$$

where

$$\boldsymbol{F}(\boldsymbol{x}_i) = -z_i e \nabla_{\boldsymbol{x}_i} U_0(\boldsymbol{x}_i).$$

Since we are interested in tracing only one species in the spine, namely, the concentration of calcium, we assume that $\gamma_i = \gamma_{_{Ca}++},\ m_i = m_{_{Ca}++},\ z_i = z = 2$.

Under these assumptions, equations (4.3) are independent and identical, so that their transition probability densities are identical. We denote the transition probability density function (pdf) of each ion by $p(\boldsymbol{x}, t \,|\, \boldsymbol{x}_0, t_0)$ so that the calcium concentration is

$$c(\boldsymbol{x}, t) = \int_{\Omega_t} p(\boldsymbol{x}, t \,|\, \boldsymbol{x}_0, t_0) c_0(\boldsymbol{x}_0)\, d\boldsymbol{x}_0,$$

where $c_0(\boldsymbol{x}_0)$ is the initial calcium density.

4.3. Reaction-diffusion description of the binding and unbinding reactions. We derive a reaction-diffusion system of equations in a slightly more general setting. We consider a single reactant M (e.g., calcium), whose density, $c_M(\boldsymbol{x}, t)$, satisfies the Nernst–Planck (or Smoluchowski) equation corresponding to the Langevin dynamics (4.2) [30],

$$\frac{\partial c_M(\boldsymbol{x}, t)}{\partial t} = -\nabla \cdot \boldsymbol{J}(\boldsymbol{x}, t), \tag{4.4}$$

where the flux $\boldsymbol{J}(\boldsymbol{x}, t)$ is defined as

$$\boldsymbol{J}(\boldsymbol{x}, t) = \left[\boldsymbol{V}(\boldsymbol{x}, t) - \frac{\boldsymbol{F}(\boldsymbol{x}, t)}{\gamma}\right] c_M(\boldsymbol{x}, t) - D \nabla c_M(\boldsymbol{x}, t). \tag{4.5}$$

The immobile substrate protein S is represented in this model by the potential $U_0(\boldsymbol{x}, t)$ of the electrostatic force $\boldsymbol{F}(\boldsymbol{x}, t)$. This force varies in time as reactant ions bind to or unbind from the substrate, thus changing the net electrostatic charge on the substrate. Instead of following the details of the binding and unbinding process and the fluctuations in the force $\boldsymbol{F}(\boldsymbol{x}, t)$, we coarse grain the Nernst–Planck equation (4.4) by replacing it with reaction-diffusion equations.

To formulate our problem in terms of reaction-diffusion equations, we partition the boundary of the domain Ω into three parts: the pumps and the bottom of the neck, denoted $\partial\Omega_a(t)$, which absorb calcium ions; the remaining surface of the head, denoted $\Sigma_H(t)$; and the surface of the neck, denoted $\partial\Omega_N$, where the normal flux equals the velocity of the boundary at each point. We introduce the variables $S^{(j)}(\boldsymbol{x}, t)$, $(0 \le j \le 4)$, that represent the number of proteins in a test volume about $\boldsymbol{x}$ that contains j bound M ions at time t. Then the number of occupied binding sites on these proteins is $jS^{(j)}(\boldsymbol{x}, t)$, and the number of free binding sites on these proteins is $(4-j)S^{(j)}(\boldsymbol{x}, t)$. Obviously, at all times

$$\sum_{j=0}^{4} S^{(j)}(\boldsymbol{x}, t) = S_0(\boldsymbol{x}),$$

where $S_0(\boldsymbol{x})$ is the number of proteins in the volume element.

We assume that the forward and backward reaction rates, k_1 and k_{-1}, respectively, are constant and independent of the densities (see discussion in section 8 below). It follows that the reaction-diffusion equations for the number of free calcium ions, $M(\boldsymbol{x},t)$, and $S^{(j)}(\boldsymbol{x},t)$ are

$$\frac{\partial M(\boldsymbol{x},t)}{\partial t} = -\nabla\cdot\boldsymbol{J}_M(\boldsymbol{x},t) - k_1 M(\boldsymbol{x},t)\sum_{j=0}^{4}(4-j)S^{(j)}(\boldsymbol{x},t)$$

$$+k_{-1}\sum_{j=0}^{4} jS^{(j)}(\boldsymbol{x},t), \tag{4.6}$$

$$\frac{\partial S^{(j)}(\boldsymbol{x},t)}{\partial t} = k_1 M(\boldsymbol{x},t)\left[(5-j)S^{(j-1)}(\boldsymbol{x},t) - (4-j)S^{(j)}(\boldsymbol{x},t)\right]$$

$$-k_{-1}\left[jS^{(j)}(\boldsymbol{x},t) - (j+1)S^{(j+1)}(\boldsymbol{x},t)\right], \tag{4.7}$$

where the flux is defined by

$$\boldsymbol{J}_M(\boldsymbol{x},t) = -D\nabla M(\boldsymbol{x},t) + \boldsymbol{V}(\boldsymbol{x},t)M(\boldsymbol{x},t), \tag{4.8}$$

and $S^{(-1)}(\boldsymbol{x},t) = S^{(5)}(\boldsymbol{x},t) = 0$. The initial conditions are

$$S^{(0)}(\boldsymbol{x},0) = S_0(\boldsymbol{x}), \quad S^{(j)}(\boldsymbol{x},0) = 0 \quad \text{for } 1\le j\le 4. \tag{4.9}$$

The system (4.6), (4.7) is a coarse-grained reaction-diffusion model of the transient chemical reaction in $\Omega(t)$. Renormalizing the numbers of the different species per unit test volume converts them into densities. Obviously, the forward rate constant k_1 has to be changed accordingly. The initial and boundary conditions for $M(\boldsymbol{x},t)$ are the initial reactant density, absorption at the absorbing boundary, and flux given by the motion of the reflective boundary,

$$M(\boldsymbol{x},0) = c_0(\boldsymbol{x}) \quad \text{for } \boldsymbol{x}\in\Omega(t),$$

$$M(\boldsymbol{x},t) = 0 \quad \text{for } \boldsymbol{x}\in\partial\Omega_a(t), \tag{4.10}$$

$$\boldsymbol{J}_M(\boldsymbol{x},t)\cdot\boldsymbol{\nu}(\boldsymbol{x}) = 0 \quad \text{for } \boldsymbol{x}\in\partial\Omega_N,$$

$$\frac{\partial M(\boldsymbol{x},t)}{\partial n(\boldsymbol{x})} = 0 \quad \text{for } \boldsymbol{x}\in\Sigma_H(t). \tag{4.11}$$

The boundary condition (4.11) means that the boundary flux $\boldsymbol{J}_M(\boldsymbol{x},t)\cdot\boldsymbol{\nu}(\boldsymbol{x})$ (see (4.8)) is actually the flux of the particles carried by the moving boundary. Note that $\boldsymbol{V}(\boldsymbol{x},t)\cdot\boldsymbol{\nu}(\boldsymbol{x}) = 0$ on $\partial\Omega_N$. The geometrical effect of substrate distribution is expressed in $S_0(\boldsymbol{x})$. There are no moving internal boundaries, because the support of $S^{(j)}(\boldsymbol{x},t)$ at all times is that of $S_0(\boldsymbol{x})$.

4.4. Specification of the hydrodynamical flow. The flow of the incompressible cytoplasmic fluid, as explained above, is due to the local contraction of the saturated AM complexes. We assume that the flow field is derived from a potential $\phi(\boldsymbol{x},t)$

(see, e.g., [31]),

$$\boldsymbol{V}(\boldsymbol{x},t) = \nabla\phi(\boldsymbol{x},t). \tag{4.12}$$

The incompressibility condition, $\nabla\cdot\boldsymbol{V}(\boldsymbol{x},t) = 0$, reduces to the Laplace equation in the head $\Omega_H(t)$ of the spine at time t. The surface of the head, $\Sigma(t)$, is partitioned into the surface $\Sigma_H(t)$ of the spine head that does include the surface common with the neck and the cap $\Sigma_N(t)$ of the surface of the head inside the neck, $\Sigma(t) = \Sigma_H(t) \cup \Sigma_N(t)$.

The Laplace equation in $\Omega_H(t)$ is

$$\Delta_{\boldsymbol{y}}\phi(\boldsymbol{y},t) = 0 \quad \text{for } \boldsymbol{y} \in \Omega_H(t),\ t > 0\ , \tag{4.13}$$

with the boundary conditions

$$\left.\frac{\partial\phi(\boldsymbol{y},t)}{\partial n}\right|_{\boldsymbol{y}\in\Sigma_H(t)} = -V(t), \quad \left.\frac{\partial\phi(\boldsymbol{y},t)}{\partial n}\right|_{\boldsymbol{y}\in\Sigma_N(t)} = F(V(t)), \tag{4.14}$$

where $V(t)$ is the average velocity induced by the deformation of the head (see (4.17) below and the appendix), due to the sum of all the local contractions, and $F(V(t))$ is the induced field velocity at the top of the neck $\Sigma_N(t)$. The function $F(V)$ is described in the appendix. The quantities $V(t)$ and $F(V(t))$ are stochastic processes that are proportional to the number of saturated proteins at any given time t.

The flow field can be expressed explicitly in terms of the functions $V(t)$ and $F(V(t))$ by Green's function for the Neumann problem for Poisson's equation in a sphere (or a disk) through Stokes's formula. Green's function $G(\boldsymbol{x},\boldsymbol{y},t)$ is the solution (defined up to a constant) of the equation

$$\begin{aligned} -\Delta_{\boldsymbol{y}}G(\boldsymbol{x},\boldsymbol{y},t) &= \delta(\boldsymbol{x}-\boldsymbol{y}) - \frac{1}{|\Omega_t|} \quad \text{for } \boldsymbol{x},\boldsymbol{y} \in \Omega_H(t), \\ \frac{\partial G(\boldsymbol{x},\boldsymbol{y},t)}{\partial\boldsymbol{\nu}(\boldsymbol{y})} &= 0 \quad \text{for } \boldsymbol{x} \in \Omega_H(t),\ \boldsymbol{y} \in \Sigma(t). \end{aligned} \tag{4.15}$$

Multiplying (4.13) by $G(\boldsymbol{x},\boldsymbol{y},t)$ and (4.15) by $\phi(\boldsymbol{y},t)$ and integrating with respect to $\boldsymbol{y}$ over the domain, using Stokes's theorem and the boundary condition (4.14), we get

$$\begin{aligned} \phi(\boldsymbol{x},t) &= \int_{\boldsymbol{y}\in\Sigma(t)} \frac{\partial\phi(\boldsymbol{y},t)}{\partial n} G(\boldsymbol{x},\boldsymbol{y},t)\, dS_{\boldsymbol{y}} - \int_{\boldsymbol{y}\in\Sigma(t)} \frac{\partial G(\boldsymbol{x},\boldsymbol{y},t)}{\partial n}\phi(\boldsymbol{y},t)\, dS_{\boldsymbol{y}} \\ &\quad + \frac{1}{V_H}\int_{\Omega_H(t)} \phi(\boldsymbol{y},t) d\boldsymbol{y} \\ &= \int_{\boldsymbol{y}\in\Sigma(t)} \frac{\partial\phi(\boldsymbol{y},t)}{\partial n} G(\boldsymbol{x},\boldsymbol{y},t)\, dS_{\boldsymbol{y}} + \frac{1}{V_H}\int_{\Omega_H(t)} \phi(\boldsymbol{y},t) d\boldsymbol{y} \\ &= -\int_{\Sigma_H(t)} V(t) G(\boldsymbol{x},\boldsymbol{y},t)\, dS_{\boldsymbol{y}} + \int_{\Sigma_N(t)} F(V(t)) G(\boldsymbol{x}\, y,t)\, S_{dy} \\ &\quad + \frac{1}{V_H}\int_{\Omega_H(t)} \phi(\boldsymbol{y},t) d\boldsymbol{y} \\ &= -V(t)\int_{\Sigma_H(t)} G(\boldsymbol{x},\boldsymbol{y},t)\, dS_{\boldsymbol{y}} + F(V(t))\int_{\Sigma_N(t)} G(\boldsymbol{x},\boldsymbol{y},t)\, dS_{\boldsymbol{y}} \\ &\quad + \frac{1}{V_H}\int_{\Omega_H(t)} \phi(\boldsymbol{y},t) d\boldsymbol{y}. \end{aligned}$$

The flow field is given by

$$\nabla\phi(\boldsymbol{x},t) = -V(t)\int_{\Sigma_H} \nabla_{\boldsymbol{x}} G(\boldsymbol{x},\boldsymbol{y})\, dS_{\boldsymbol{y}} + F(V(t))\int_{\Sigma_N} \nabla_{\boldsymbol{x}} G(\boldsymbol{x},\boldsymbol{y})\, dS_{\boldsymbol{y}}.$$

In the neck, due to the symmetries and the uniform initial conditions, we simplify the flow field by assuming its velocity is parallel to the axis of the neck. It is given by

$$\nabla\phi(\boldsymbol{x},t) = \boldsymbol{V}(\boldsymbol{x},t) = F(V(t))\boldsymbol{k},$$

where $\boldsymbol{k}$ is a unit vector along the axis of the neck.

In order to close the equations, we recall that the velocity of the boundary $V(t)$ is a function of the number of proteins

$$S^{(4)}(t) = \int_\Omega S^{(4)}(\boldsymbol{x},t)\, d\boldsymbol{x} \tag{4.16}$$

that are saturated at time t. Thus

$$\begin{aligned} V(t) &= v_Q S^{(4)}(t), \\ F(V(t)) &= K v_Q S^{(4)}(t), \end{aligned} \tag{4.17}$$

where v_Q is a constant velocity, depending on the nature of the contractile protein, and K is a constant that depends on the geometry of the spine and the dimension (here 2 or 3). We note that, according to (4.17), as the number of saturated proteins increases the hydrodynamical flow begins to dominate the diffusion.

5. The chemical kinetics of the binding and unbinding reactions. The forward binding reaction of M to S, $M + S \xrightarrow{k_1} MS$, is governed by a forward rate constant k_1, because the process of binding consists of an ion falling into a potential well. The survival probability of a single ion inside the spine head, in the presence of potential traps, decays exponentially fast, so that the rate constant for binding is the exponential decay rate. If the binding process involves many ions, the binding rate is the total absorption flux on the boundaries of the potential wells [32].

More precisely, the instantaneous binding rate is

$$k_1(t) = \oint_{\partial\Omega_{S(t)}} \boldsymbol{J}(\boldsymbol{x},t)\cdot\boldsymbol{\nu}(\boldsymbol{x})\, dS_{\boldsymbol{x}}, \tag{5.1}$$

where $\partial\Omega_{S(t)}$ is the boundary of the free binding sites on the substrate at time t. An approximation to $k_1(t)$ can be obtained by replacing the flux density $\boldsymbol{J}(\boldsymbol{x},t)\cdot\boldsymbol{\nu}(\boldsymbol{x})$ with its instantaneous average over the entire boundary $\partial\Omega_{S(t)}$. Then the local instantaneous binding rate of calcium near $\boldsymbol{x}$ is

$$k_1(t) = k_1\sum_{j=0}^{4}(4-j)S^{(j)}(\boldsymbol{x},t), \tag{5.2}$$

where k_1 is the forward binding rate per ion per protein and $S^{(j)}(\boldsymbol{x},t)$ is the number of proteins with j attached calcium ions. When the radius of a potential well with circular cross-section is R_p, the forward binding rate constant k_1 is given by Smoluchowski's formula

$$k_1 = 2\pi R_p D_M, \tag{5.3}$$

where D_M is the diffusion constant of M-ions [32], [33]. This determination is done for a separate reaction, not necessarily in the domain Ω. The forward rate constant k_1 is an input parameter into the model, e.g., from a molecular dynamics simulation or from direct measurement in a separate chemical reaction [26]. Note that the forward binding rate depends on the radius of the potential well, but not on its depth.

The backward binding rate, k_{-1}, is the rate at which ions escape the potential well. According to Kramers's theory [30], [34] such a dissociation is due to thermal activation of the ions inside the potential well, and its rate is given by the Arrhenius law with a given activation energy. We recall that in Kramers's theory of thermal activation over a smooth (parabolic) potential barrier, the dissociation rate is one-half the reciprocal of the mean first passage time (MFPT) of an ion, initially inside the well, to its boundary [30], [34], [35]. This constant is also an input parameter. Given k_1, k_{-1}, both the depth and the radius of a binding site can be selected by calibration according to (5.3) and Kramers's formulas. Explicit calculations are given in [36].

6. Simulation of calcium kinetics in dendritic spines. When channels open, the maximal number of calcium ions that flow into the dendritic spine is of the order of a few hundred [19], which is also the order of magnitude of the number of calmodulin or myosin molecules inside the spine head. A Brownian simulation gives a description of calcium dynamics over a wide range of parameters, starting with only one ion in the spine and up to a number, where a continuum approximation is valid. In such a simulation the number of bonds formed by each calcium ion can be monitored over time. The number of bound proteins at a given time is a random process, because the forward and backward binding processes occur at random times and at random places. Consequently, the twitching movement of the dendritic spine is a random process as well.

Simulations of our model give the probability that an ion forms a bond, given the protein distribution. They also demonstrate the role of the drift in modifying the recurrent bindings and unbindings of the Brownian particles to given proteins.

6.1. A Langevin (Brownian) dynamics simulation. The binding (unbinding) of Ca^{++} ions to (from) a fixed substrate S (e.g., CaM, AM, etc.) can be described in a Langevin simulation at various degrees of molecular resolution. The simplest way is to describe the binding sites as appropriately calibrated potential wells and count the number of occupied wells as a function of time. A trajectory that hits a free pump on the boundary of the spine head or reaches the dendritic shaft at the bottom of the spine neck is terminated there. The remaining part of the boundary is reflecting to trajectories. This is essentially the simplified molecular dynamics simulation described above. A coarse-grained description of the reaction of binding and unbinding of the diffusing ions with the immobile substrate is given by the reaction-diffusion equations (4.6)–(4.10). A numerical study of this system will be presented in a separate paper.

The results of a full Langevin simulation based on our simplified physical and mathematical model are summarized below (see [26] for details). These results can be used as benchmarks for the results of the coarse-grained model described above.

Figure 2 shows the results of a simulation with $N_{init} = 100$, $k_{-1} = K_{\text{back}}^{\text{AM}} = 1\,\text{kHz}$, $k_1 = K_{\text{back}}^{\text{cal}} = 5\,\text{Hz/M}$, $R = 0.5\ \mu\text{m}$, $l = 0.2\ \mu\text{m}$, $d/2 = \mu\text{m}$, $N_{\text{pumps}} = 10$, and the protein molecules (about 50 of AM type and 10 of the other type) distributed in the PSD.

Two types of decay can be discerned in the first graph of calcium concentration vs. time in Figure 2: quick decay, starting at the beginning of the simulation and ending at about 250 msec, is followed by a slower decay that continues to the end of

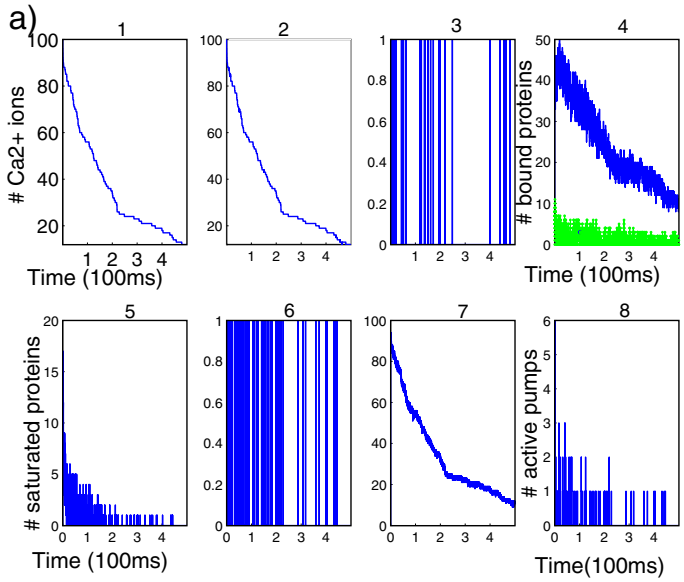

FIG. 2. *Dynamics of* 100 *calcium ions in dendritic spine. Time evolution of the concentration and binding. the simulation. The first period is the decay curve of the saturation of type 1 proteins. When a simulation starts with 100 ions, only 10 proteins get saturated; that is, only about 40 ions are captured at the beginning and the number of saturated proteins continues to decay in time. To have a rough idea of the effect of the hydrodynamical push, we can approximate the push by its average of 2.5 proteins saturated for the first 250 msec, where each protein contributes to the speed a total of 50 nm/msec. The total speed of the push is $0.5\,\mu$m/ms. The push speeds up the arrival of ions at the lower part of the spine head, where the pumps are located, relative to arrivals by pure diffusion. Since the sojourn time of ions in the pumps is chosen to be short, the ions leave mainly through the head. At 500 msec into the simulation only about 20% of initial ions are still in the spine. In this simulation the effect of the push is not sufficiently strong to direct all the ions toward the neck. The 1:4 ratio of the efflux through the pumps, compared to that through the dendrite, may be due to the large number of fast pumps. These results are in agreement with the experimental results of [19].

In Figure 3 the results of simulations with and without the hydrodynamical push are shown: blue curves correspond to a simulation without the push effect, while magenta curves correspond to simulations with it. The characteristic parameters of the simulation are $N_{init} = 200$, $k_{-1} = K^{\rm AM}_{\rm back} = 10\,$kHz, $k_1 = K^{\rm cal}_{\rm back} = 0.5\,$kHz/M, $R = 1\,\mu$m, $l = 0.3\,\mu$m, and $d/2 = 0.3\,\mu$m. There are 4 pumps, 60 AM proteins, and 10 calcineurin proteins [15]. Results similar to those predicted in Figure 3 were

obtained recently with calcium replaced by an inert dye that does not bind to proteins [27].

7. An estimate of a decay rate. In the absence of the flow field $\boldsymbol{V}(\boldsymbol{x},t)$, the decay of $M(\boldsymbol{x},t)$ is governed by the first eigenvalue of the Laplace operator in the head with the mixed reflecting and absorbing boundary conditions. In the presence of $\boldsymbol{V}(\boldsymbol{x},t)$, the decay rate can be estimated as follows (see also [37] for another estimate of the fast rate constant, using internal buffer kinetics).

Consider the dynamics

$$\dot{x} = v(t) + \sqrt{2D}\,\dot{w}_x,$$

$$\dot{y} = \sqrt{2D}\,\dot{w}_y, \quad \dot{z} = \sqrt{2D}\,\dot{w}_z$$

in the neck, where w_x, w_y, and w_z are independent Brownian motions. The solution is

$$x(t) = x_0 + \int_0^t v(s)\,ds + \sqrt{2D}\,w_x(t),$$

$$y = y_0 + \sqrt{2D}\,w_y(t), \quad z = z_0 + \sqrt{2D}\,w_z(t).$$

This means that the solution to the Nernst–Planck equation (4.4) in the neck,

$$c_t = D\Delta c - v(t)c_x,$$

is given by

$$c(x,y,z,t) = \int\int_{\text{neck}} \int G(y,z,t \,|\, y_0,z_0) \times \exp\left\{ -\frac{\left(x - x_0 - \int_0^t v(s)\,ds\right)^2}{4Dt} \right\} f(x_0,y_0,z_0)\,dx_0\,dy_0\,dz_0,$$

where $f(x_0,y_0,z_0)$ is the initial ionic density in an infinite neck and $G(y,z,t \,|\, y_0,z_0)$ is Green's function for the diffusion equation in the cross-section of the neck, with reflecting boundary conditions.

We consider the initial decay law, when the decay is due primarily to the hydrodynamical effect, because it is faster than that due to diffusion. Suppose that the ions are concentrated near a single point (x_0',y_0',z_0'); that is, $f(x_0,y_0,z_0) = \delta(x_0 - x_0', y_0 - y_0', z_0 - z_0')$. In the initial tenths of a second, the decay of the concentration in the neck is due to the large hydrodynamical effect. The velocity $v(t)$ is maximal when all proteins are saturated. We write

$$c(x,y,z,t) = G(y,z,t \,|\, y_0',z_0') \exp\left\{ -\frac{\left(x - x_0' - \int_0^t v(s)\,ds\right)^2}{2Dt} \right\}$$

and

$$\frac{\left(x - x_0' - \int_0^t v(s)\,ds\right)^2}{2Dt} = \frac{(x-x_0)^2}{2Dt} - \frac{(x-x_0)}{D}\bar{v}(t) + \frac{\bar{v}^2(t)}{2D}t, \tag{7.1}$$

where

$$\bar{v}(t) = \frac{1}{t}\int_0^t v(s)\,ds \approx \text{const} \equiv \bar{v}_0.$$

Set

$$u_d(x,y,z,t) = G(y,z,t \,|\, y_0',z_0') \exp\left\{ -\frac{(x-x_0)^2}{4Dt} \right\}$$

to represent the diffusion term. We can write in (7.1)

$$-\frac{(x-x_0)\bar{v}(t)}{2D} \approx -\frac{(x-x_0)\bar{v}_0}{2D},$$

so this term does not contribute to the time decay of the concentration $c(x,y,z,t)$ in the initial period. The last term in the exponent (7.1) is approximately $\frac{\bar{v}_0^2}{4D}t$, so in the limit of fast binding, which lasts a few hundreds of milliseconds, we can write

$$c(x,y,z,t) = C u_d(x,y,z,t) \exp\left\{ -\frac{\bar{v}_0^2}{4D}t \right\}.$$

This gives the decay time

$$\tau = \frac{4D}{\bar{v}_0^2}. \tag{7.2}$$

The initial average velocity $\bar{v}_0$ can be estimated, if we assume that all proteins are distributed along the surface of the head and are saturated at the same time. In this case the membrane shrinks on the time scale of a single protein contraction time and of length equal to the number of proteins, $N_p = \int_\Omega S_0(\boldsymbol{x})\, d\boldsymbol{x}$, times the contraction length of a single protein. We consider two models of saturation. First, if the proteins are located on the membrane, we can say that the lengths do not sum, but act in parallel to contract the head. This yields a contraction length of order l_c, the length of contraction of one protein, independently of the number of proteins distributed on the surface. Knowing the size of the myosin protein and the size of the head (e.g., radius of $1\,\mu$m), the maximal number of proteins packed on the membrane surface is $1\,\mathrm{mM}(= 600$ proteins).

Second, if there are different layers of contractile proteins, then all contractions add together, if they occur simultaneously. In that case the length of the contraction equals $N_p l_c$.

We have (see the appendix)

$$\bar{v}_0 = \bar{F}(V(0)) = \begin{cases} \dfrac{4\pi R_0^2 \bar{V}_0}{|\Sigma_N|} & \text{in dimension 3,} \\[2ex] \dfrac{2\pi R_0 \bar{V}_0}{|\Sigma_N|} & \text{in dimension 2,} \end{cases}$$

where $\bar{V}_0 = v_Q N_p$ is the average initial velocity of the surface of the spine head, as given by (4.17) with $S^{(4)}(0) = N_p$ (by assumption); R_0 is the initial radius of the spine head; and $|\Sigma_N|$ is the surface area of the cross-section of the neck.

The value $v_Q = 0.02\,\mu m/\mathrm{ms}$ is given in [2], so that $\bar{v}_0 = 0.1\,\mu m/\mathrm{ms}$; hence

$$\bar{v}_0 = \bar{F}(V(0)) = \begin{cases} \dfrac{0.4\pi R_0^2}{|\Sigma_N|} & \text{in dimension 3,} \\[2ex] \dfrac{0.2\pi R_0}{|\Sigma_N|} & \text{in dimension 2.} \end{cases}$$

Now, (7.2) gives $\tau = 160\,\mathrm{msec}$, which is comparable to the experimental result given in [19].

This result can be obtained also from the following calculations. First, using the assumption that each protein contributes additively to the total contraction in the simulation of [26], we see that during the hydrodynamical push period about 5 contractile proteins are saturated on the average, so the average velocity of the head is $\bar{V}_0 = 0.02 \times 5 = 0.1\,\mu/\mathrm{ms}$. Second, if in our model all proteins are distributed in a single layer and are instantaneously saturated, they produce a contraction of $0.02\,\mu\mathrm{m/sec}$. In this case, when the ratio of surface areas of the head and the neck $(|\Sigma_H| + |\Sigma_N|)/|\Sigma_N| = 5$, the average velocity of the head is $\bar{v}_0$.

8. Discussion and conclusions. We have introduced a Brownian dynamics simulation of calcium dynamics in a dendritic spine and its coarse-grained continuum

description by partial differential equations. The equations couple the hydrodynamical flow, caused by spine motility, to the chemical reaction between the diffusing calcium and the immobile substrate. We have identified the dominant molecular mechanism of the fast macroscopic twitching as the contraction of the calcium saturated AM proteins. This contraction produces a hydrodynamical flow, which causes the fast decay of calcium. The decay rate has been derived theoretically, and the reaction-diffusion equations described here are the coarse-grained version of the Langevin simulation of [26]. They provide a mathematical description of the molecular events during the fast motility of the spine.

The main goal of the coarse-graining is to capture the features of calcium dynamics with a small number of equations, ideally with a single ordinary differential equation, so that a comprehensive model of calcium dynamics in a spiny dendrite can be derived and the effect of hundreds of thousands of spines can be integrated and coupled to an action potential. In this context the dynamics of calcium can possibly be linked to the induction of synaptic plasticity.

An important feature of the Langevin simulation is that the number of bonds per protein, as a function of time, can be followed and compared to the initial calcium concentration. The coarse-grained reaction-diffusion description of the Langevin simulation should be helpful in relating the threshold of initiation of synaptic plasticity, such as LTP, to the initial calcium concentration.

One of the most significant results of this paper is the derivation of the decay rate from the fast motility of the spine. This result should be compared to the calcium extrusion rate in spines, as presented in [19]. The two very distinct decay rates suggest that the fast extrusion period can also be due to the spine fast motility. This phenomenon was ascribed in [19], [37] to the fast pumping of calcium ions into stores. Indeed, in the present paper we have neglected calcium stores and high concentration of buffers, which may impose a decay rate faster than diffusion. An improved model that includes a large number of buffers should reveal the precise contribution of buffers to the calcium fast decay rate, as compared to the rate imposed by the spine contraction. Such a model has to be based on the mechanism of interactions between diffusing calcium and the buffers.

We conclude, on the basis of the present model and of the Langevin simulation of [26], that one of the possible roles in calcium dynamics of the spine's fast motility is to increase significantly the fraction of ions that are directed toward the dendrite and the organelles, compared to the ions that are pumped out.

Appendix. The velocities $V(t)$ and $F(V(t))$. In this section, we compute the velocity $V(t)$ of the spine head surface, given by (4.17), and the velocity $F(V(t))$, used in the boundary condition (4.14). While $V(t)$ is given in (4.17), the velocity in the neck, $F(V(t))$, has to be calculated.

To calculate the cytoplasmic fluid velocity $F(V(t))$ at the surface of the sphere inside the neck, we make the following simplifying assumptions that lead to an explicit expression for the velocity of the efflux. The entire fluid displaced by the contraction of the spine head flows into the spine neck with a uniform velocity $v(t)$ in a direction normal to the sphere. We also assume that the neck is sufficiently narrow so that all normals to the spherical surface inside the neck, Σ_N, are parallel to the axis of the neck.

Under these assumptions the volume displaced per unit time is $4\pi R^2(t)V(t)$ in dimension 3 and $2\pi R(t)V(t)$, where $R(t)$ is the instantaneous radius of the head and

$\dot{R}(t) = -V(t)$. The flux through Σ_N is $|\Sigma_N|v(t)$; hence

$$v(t) = F(V(t)) = \begin{cases} \dfrac{4\pi R^2(t)V(t)}{|\Sigma_N|} & \text{in dimension 3,} \\ \dfrac{2\pi R(t)V(t)}{|\Sigma_N|} & \text{in dimension 2.} \end{cases}$$

EXPLOITING SYMMETRY IN FAN BEAM CT: OVERCOMING THIRD GENERATION UNDERSAMPLING*

STEVEN H. IZEN†, DAVID P. ROHLER‡, AND SASTRY K.L.A.‡

Abstract. A new reconstruction algorithm is presented for tomographic reconstruction from fan beam data acquired with a quarter detector shift. This algorithm exploits the reflection property of the divergent beam transform by representing the sample and reflected points as a discrete, multichannel sample set. A doubling of the reconstruction resolution is achieved by increasing the number of source locations without changing the detector sample density. The algorithm can be used to reconstruct images from a third generation CT scanner at the maximum resolution consistent with the frequency characteristics of the detector.

Key words. tomography, divergent beam transform, Radon transform, multichannel sampling theorem

1. Introduction.

A CT scanner provides two-dimensional images of a cross section of an object by measuring integrals of the object's x-ray attenuation through the cross section. The attenuation data can be modeled as giving the Radon transform of x-ray attenuation. The Radon transform of a function f in $\mathbb{R}^2$ is

$$Rf(\phi, p) = \int_{x\Phi=p} f(x)dx, \tag{1.1}$$

where $\Phi = (\cos\phi, \sin\phi)^T \in S^1$ is normal to the line of integration and $p\Phi$ locates the closest point to the origin on the line. The parameterization (ϕ, p) of lines in $\mathbb{R}^2$ is called the parallel beam geometry, as fixing ϕ results in a family of parallel lines.

The divergent beam (or fan beam) parameterization for lines in $\mathbb{R}^2$ is appropriate to use when modeling scanners in which the x-ray source moves on a circle (the source circle) of radius r exterior to a circle (scan circle) of radius ρ containing the object being imaged. The source angle β measures the position of the x-ray source with respect to x axis. The fan angle α measures the detector position with respect to the central ray of the fan, the ray from the source through the origin. By convention, α is positive if, viewed from the source, the detector position is to the left of the central ray. See Figure 1. The parallel beam and fan beam parameterizations are related by

$$p = r\sin\alpha, \qquad \phi = \beta + \alpha - \pi/2, \tag{1.2}$$

where r is the radius of the source circle. The reparameterization gives rise to the divergent beam transform

$$Df(\beta, \alpha) = Rf(\beta + \alpha - \pi/2, r\sin\alpha). \tag{1.3}$$

In a real measurement system, only a finite set of data is available. The goal in fan beam tomography is to reconstruct f within $|x| \leq \rho$ with as much resolution as possible from discrete samples of Df.

In a third generation CT scanner, there is a detector bank which is physically connected to an x-ray source located on the opposite side of the object being imaged. The entire source-detector assembly is rotated around the object. At a discrete set of positions, the detector apparatus reads out, and an entire fan of data is acquired. In order to attain maximum use of the available photons, it is normal to have each detector element abut its neighbors. While this geometry is efficient in collecting all the available photons, it effectively bandlimits the measured signal. Were the standard fan-beam sampling scheme and reconstruction algorithm (Algorithm 5.3 in [13]) to be used to attain the resolution corresponding to the detector bandwidth, the detector sample density needed would be twice that which is available. In other words, the measurement would be undersampled by a factor of two. This so-called third generation undersampling is explained in section 3.1.

In this paper, we present an algorithm which can be used with third generation CT scanners to attain reconstructions at a resolution limited only by the bandwidth of the detector elements.

The divergent beam transform has a twofold symmetry which can be exploited to compensate for the third generation undersampling. Placing a detector bank off center by one quarter of the width of a detector element breaks the acquisition symmetry, effectively doubling the sample density. A similar detector shift was suggested for the third generation problem in the parallel beam geometry by Cormack [2].

For the parallel beam geometry, the sample points obtained by introducing a detector shift can be reorganized as a lattice with twice the density along the detector direction. When a bandlimited function is sampled on a suitably dense lattice, its integral can be replaced by a discrete sum without error. Applying this to continuous inversion formulas is the foundation for both the standard and interlaced parallel beam reconstruction algorithms (Algorithms 5.1 and 5.2 in [13]).

For the divergent beam geometry, the fortuitous realignment of the original and reflected sample points into a single lattice does not occur, so the standard multidimensional sampling theory cannot be applied. Instead, multichannel sampling theory

[1, 16] in a lattice context [3, 6, 7, 8, 9] must be used. In this paper, it is shown that the original and reflected sample points can be reorganized as a union of identical rectangular lattices. The samples on each rectangular lattice become a channel of a multichannel lattice sample scheme. For appropriate scanner geometries, the Parseval-like result of [9] for sampling on unions of lattices can be used to justify the replacement of the continuous inversion integral by the discrete analog. This leads to a new fan beam algorithm which can reconstruct at the maximum resolution consistent with the detector-limited bandwidth. An alternate approach [6, 7] can also be applied. However, that method is more complex than our method, as it requires the multichannel lattice data to be interpolated to a sufficiently dense single lattice.

The remainder of this paper is organized as follows. In section 2.1, a brief review of lattice sampling theory and multichannel sampling for lattices is presented. In section 2.2, the sampling requirements for the divergent beam transform are reviewed. The third generation detector model is described in section 3.1. It is shown how to apply multichannel sampling theory in this context in section 3.2. The new divergent beam reconstruction algorithm appears in section 3.2.2. Finally, a numerical implementation which validates the algorithm is exhibited in section 4.

2. Sampling in tomography. In order to achieve a desired resolution in the reconstructed image, the divergent beam transform must be sampled at an appropriate density. A framework for studying reconstruction resolution in terms of spatial frequency content was presented by Natterer in [10]. A function f is Ω-bandlimited if its Fourier transform,

$$\hat{f}(\xi) = (2\pi)^{-n/2} \int_{\mathbb{R}^n} f(x) e^{-ix\xi} dx, \tag{2.1}$$

satisfies $\hat{f}(\xi) = 0$ for $|\xi| > \Omega$. Such functions can represent details no smaller than π/Ω. In practice, as the reconstruction region will have compact support, the functions to be recovered cannot be bandlimited. As a result, one works with essentially bandlimited functions. A function f on $\mathbb{R}^n$ is essentially Ω-bandlimited if $\hat{f}(\xi)$ is small for $\xi > \Omega$. More precisely, it is assumed that $\varepsilon_0(f, \Omega) = \int_{|\xi|>\Omega} |\hat{f}(\xi)| d\xi$ is negligible. Refer to [10] for a thorough treatment of this notion in the context of sampling theory.

The sample density needed to reconstruct a bandlimited function f can be determined by examining the bandregion $K = \operatorname{supp} \hat{f}$. Roughly speaking, a sampled function has as its spectrum sums of translates of the spectrum of the unsampled function. The translation distance is inversely proportional to the sample density. To reconstruct accurately, it is necessary to ensure that translates of K are mutually disjoint.

The Radon transform and divergent beam transforms possess symmetries in both the Fourier domain and the sample domain. The essential support of the divergent beam transform of a bandlimited function has the shape [11, 15] shown in Figure 2. Selecting nonoverlapping translates parallel to the coordinate axes lead to the standard fan beam reconstruction algorithm (Algorithm 5.3 in [13]). Much of Fourier space remains uncovered. A completely efficient tiling of Fourier space is possible [11]. The corresponding sampling scheme requires a complex dynamic detector shift, the periodicity of which depends on the ratio of the source and scan radii. This acquisition is difficult to implement in hardware.

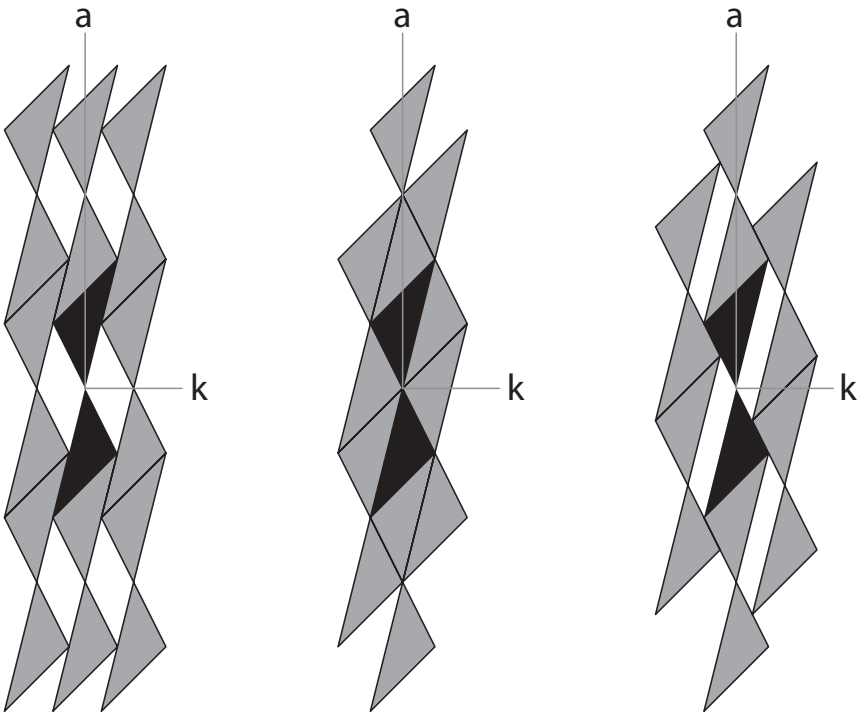

FIG. 2. *The solid region shows the essential support K when $\rho/r = 1/3$ of the Fourier transform of the divergent beam transform of an essentially Ω-bandlimited function. K scales linearly with Ω along each axis and is symmetric with respect to the origin. The coordinates of the upper and lower right corners of K are, respectively, $(r\Omega, (\rho + r)\Omega)$ and $(r\Omega, (\rho - r)\Omega)$. In the leftmost figure, the gray areas are translates of K parallel to the coordinate axes by the minimal distance required to avoid overlaps. The corresponding sampling scheme is the standard fan beam sampling. In the middle figure, the gray areas are translates of K which are optimally packed. The corresponding sampling scheme is the efficient fan beam sampling. To acquire data for the efficient sampling scheme requires a dynamic detector shift. In the rightmost figure, the gray areas are the translates of K which correspond to sampling the divergent beam transform at points which are reflections of the points in the standard sampling scheme. Since there is no overlap, this sample set can be used to reconstruct at the same resolution as the standard fan beam sampling.*

Alternatively, symmetry can be seen directly in the sample domain via the reflection property, which for the Radon transform reads

$$Rf(\phi, p) = Rf(\phi + \pi, -p), \tag{2.2}$$

and for the divergent beam transform reads

$$Df(\beta, \alpha) = Df(\beta + \pi + 2\alpha, -\alpha). \tag{2.3}$$

That is, any sample can be used twice, once at the actual sample point and again at the reflected point. By carefully choosing the sample points to avoid duplication as the source is rotated through a full 2π on the source circle, the sample density is effectively doubled, which, in principle, can compensate for undersampling. A shift of a quarter detector width in the placement of the origin of the detector bank avoids duplication and interlaces the reflected sample points as evenly as possible [12].

In order to directly apply the standard reconstruction algorithms, the original and reflected sample points must line up on a suitable rectangular grid. This scenario

occurs for the parallel beam geometry. In fact, it can be shown that the result of the standard parallel beam reconstruction algorithm (Algorithm 5.1 in [13]) applied to a 2π scan ($0 \le \phi \le 2\pi$) with a 1/4 detector shift is numerically identical to the result when the same algorithm is applied to a π scan ($0 \le \phi \le \pi$) with a 1/2 detector shift with samples spaced at a (nonphysical) half detector width.

For the divergent beam geometry, the reflected sample points do not line up in a rectangular grid. Although the sample positions will be regular in the coordinate tracking detector position, the reflection geometry induces a shift in the coordinate tracking the source position. This shift is periodic, with the periodicity depending on the choice of sampling density. In this paper, a new divergent beam reconstruction algorithm is constructed which properly accounts for these shifts. The key idea is that the sampling pattern resulting from the union of the original and reflected sample points can be viewed as a multichannel sample scheme for the divergent beam transform. This construction answers the question posed in [12] about how to effectively exploit the symmetry in the divergent beam transform.

2.1. Sampling on lattices. To analyze sampling in tomography [4, 6, 10, 11, 13], it is necessary to invoke the Petersen–Middleton sampling theory on lattices [17]. For the analysis of the divergent beam geometry, it is necessary to use an extension of lattice sampling theory to a multichannel setting. This can be done with the theory developed in [6, 7, 8], or, as in this paper, the theory developed in [9].

In this subsection, notation will be introduced, and the relevant results will be quoted.

Given n linearly independent vectors $w_i \in \mathbb{R}^n$, denote by W the invertible matrix with columns w_i. The lattice L_W is defined by

$$L_W = \{Wz \mid z \in \mathbb{Z}^n\} = W\mathbb{Z}^n. \tag{2.4}$$

Although the lattice L_W does not uniquely determine the generating matrix W, $|\det W|$ is independent of the choice of the generating matrix for the lattice.

The dual lattice $L_W^\perp$ is defined to be $L_{W^\perp}$, where $W^\perp = 2\pi W^{-T}$. Any nonsingular $n \times n$ matrix M with integer entries defines a sublattice $L_P \subseteq L_W$, where $P = WM$. If $L_P \subseteq L_W$, then $L_P^\perp \supseteq L_W^\perp$, and $|\frac{\det P}{\det W}| = |\frac{\det W^\perp}{\det P^\perp}| = |\det M|$.

A fundamental region of a lattice L_P is a subset $F_P \subseteq \mathbb{R}^n$ such that each $x' \in F_P$ uniquely defines an equivalence class $x' + L_P \in \mathbb{R}^n/L_P$, and every $x \in \mathbb{R}^n/L_P$ can be written as $x = x' + L_P$ for some $x' \in F_P$. A fundamental region of L_P can be identified with $\mathbb{R}^n/L_P$. With $[0,1)^n$ denoting the n-fold Cartesian product of $[0,1)$, the set $P[0,1)^n = \{Px \mid x \in [0,1)^n\}$ is the canonical example of a fundamental region for the lattice L_P. From [9, Theorem 1], we have the following.

THEOREM 2.1. *Let $L_P \subseteq L_W$. When $\mathbb{R}^n/L_W$ is identified with $W[0,1)^n$, the set $\mathbb{R}^n/L_P$ can be identified with the direct sum $\mathbb{R}^n/L_W \oplus L_W/L_P$.*

DEFINITION 2.2. *A function f on $\mathbb{R}^n$ is said to be W-bandlimited with bandregion K if $\hat{f} = 0$ outside some compact set $K \in \mathbb{R}^n$, and $(K^\circ + \xi) \cap (K^\circ + \xi') = \emptyset$ for $\xi, \xi' \in L_W^\perp$, and $\xi \neq \xi'$. K° denotes the interior of K.*

A square integrable, continuous, W-bandlimited function can be reconstructed from its samples on L_W. In particular, Parseval's formula holds.

THEOREM 2.3. *Let $f_1, f_2 \in L^2(\mathbb{R}^n)$ be W-bandlimited and continuous, both with the same bandregion K. Then*

$$\int_{\mathbb{R}^n} f_1(x)\overline{f_2(x)}dx = |\det W| \sum_{x \in L_W} f_1(x)\overline{f_2(x)}. \tag{2.5}$$

DEFINITION 2.4. *A function on $\mathbb{R}^n$ is periodic with respect to the lattice L_Q (or alternatively Q-periodic) if, for all $x \in L_Q$ and $y \in \mathbb{R}^n$, $f(y+x) = f(y)$.*

A Q-periodic function f can be sampled on a lattice L_W if and only if $L_Q \subseteq L_W$. The sample points can be treated as elements of L_W/L_Q. The Fourier and inverse Fourier transforms in the periodic setting are

$$\hat{f}(\eta) = \frac{1}{|\det Q|} \int_{\mathbb{R}^n/L_Q} f(x) e^{-ix\eta} dx, \quad \eta \in L_Q^\perp, \tag{2.6}$$

$$f(x) = \sum_{\eta \in L_Q^\perp} \hat{f}(\eta) e^{ix\eta}. \tag{2.7}$$

The definition of bandlimited functions in the periodic setting requires the use of the discrete topology. In this case, one cannot ignore the boundary of K when considering shifts.

DEFINITION 2.5. *Let $L_Q \subseteq L_W$, and $f \in L_2(\mathbb{R}^n/L_Q)$. f is W-bandlimited if $\hat{f} = 0$ outside some compact set $K \subseteq L_Q^\perp$, and $(K+\xi) \cap (K+\xi') = \emptyset$ for $\xi, \xi' \in L_W^\perp$, and $\xi \neq \xi'$.*

Parseval's formula in the periodic setting is the following.

THEOREM 2.6. *Let $f_1, f_2 \in L^2(\mathbb{R}^n/L_Q)$ be W-bandlimited and continuous, both with the same bandregion K. Then*

$$\int_{L^2(\mathbb{R}^n/L_Q)} f_1(x)\overline{f_2(x)} dx = |\det W| \sum_{x \in L_W/L_Q} f_1(x)\overline{f_2(x)}. \tag{2.8}$$

Let the lattice L_P satisfy $L_Q \subseteq L_P \subseteq L_W$, with $r = \frac{|\det P|}{|\det W|}$. Under suitable conditions, a Q-periodic, W-bandlimited function with bandregion K can be recovered from samples on L_P/L_Q of r filtered versions of f (channels) [7, 9]. Following [7], when each channel g_k is of the form $g_k = f * \delta(x - \gamma_k)$ for independent translations $\gamma_k \in \mathbb{R}^n/L_Q$, L_2 inner products of two such functions can be computed using Theorem 2.6 after upsampling by interpolation from L_P to L_W. Alternatively, following [9], if the lattice L_P undersamples along one generator of L_W, and if K is shift-convex with respect to $W^\perp$ and $P^\perp$, a Parseval-like result will hold. The definitions for shift-convexity and independent translations follow.

Let $\mathbf{i} \in \mathbb{Z}^n$ denote the multi-index $\mathbf{i} = (i_1, \ldots, i_n)^T$.

DEFINITION 2.7. *Let $L_Q \subseteq L_P \subseteq L_W$. Suppose that K is the bandregion for a W-bandlimited Q-periodic function, and that $P = WM$, where M is a diagonal matrix with positive integer entries, $M = \mathrm{diag}(r_1, \ldots, r_n)$. K is said to be shift-convex with respect to $W^\perp$ and $P^\perp$ if $K \cap (K + P^\perp \mathbf{i}) = \emptyset$ for all $\mathbf{i}$ such that $-(\mathbf{r}-1) \leq \mathbf{i} \leq \mathbf{r}-1$ does not hold.*

The idea of shift-convexity is to eliminate the pathological cases where a suitably sampled function becomes undersampled when the sample density increases. W-bandlimiting implies that shifts of K by nonzero elements of $L_W^\perp$ do not overlap K. Roughly speaking, any additional shifts of the bandregion K by elements of $L_P^\perp$ do not re-introduce overlap with K. For two examples, see section 3.2.3.

Now consider $L_Q \subseteq L_P \subseteq L_W$. Fix K, the bandregion for a W-bandlimited Q-periodic function. Since each coset $\xi \in L_Q^\perp/L_W^\perp$ intersects K in at most one point, when $K \cap \xi \neq \emptyset$, the point of intersection is a canonical representative $\xi' \in L_Q^\perp$ for $\xi = \xi' + L_W^\perp \in L_Q^\perp/L_W^\perp$. When $K \cap \xi$ is empty, the fixed representative ξ' can be chosen arbitrarily. As $L_P^\perp/L_W^\perp \subseteq L_Q^\perp/L_W^\perp$, the same construction provides a canonical representative $\zeta' \in L_P^\perp$ for each coset $\zeta = \zeta' + L_W^\perp \in L_P^\perp/L_W^\perp$.

DEFINITION 2.8. *Let ζ_j, $j = 0, \ldots, r-1$, be the r distinct equivalence classes in $L_P^\perp / L_W^\perp$. Let $\zeta_0 = L_W^\perp$, and ζ_j' be the canonical representative for ζ_j. The translations $\gamma_k \in \mathbb{R}^n / L_Q$, $k = 0, \ldots, r-1$, are independent if the matrix $\mathbf{H}$, with k, jth entry $\mathbf{H}_{k,j} = e^{-i\zeta_j' \gamma_k}$, is invertible. Let $\lambda_{k,j}$ denote the k, jth entry of $\mathbf{H}^{-T}$.*

Since $\zeta_j' \in L_P^\perp \subseteq L_Q^\perp$, $\mathbf{H}_{k,j}$ is independent of the representative chosen for $\gamma_k \in \mathbb{R}^n / L_Q$, and thus is well defined.

THEOREM 2.9. *Let $f_1, f_2 \in L_2(\mathbb{R}^n / L_Q)$ be W-bandlimited and continuous, both with bandregion K, and with $f_1 \overline{f_2}$ real. Let $L_Q \subseteq L_P \subseteq L_W$, with r equivalence classes in $L_P^\perp / L_W^\perp$. Moreover, suppose that K is shift-convex with respect to $W^\perp$ and $P^\perp$. Let the r filters h_r, $k = 0, \ldots, r-1$, implement independent translations $\gamma_k \in \mathbb{R}^n / L_Q$ such that λ_{k0}, $k = 0, \ldots, r-1$, are all real. Then,*

$$\int_{\mathbb{R}^n / L_Q} f_1(x) \overline{f_2}(x) dx = |\det P| \sum_{k=0}^{r-1} \lambda_{k0} \sum_{y \in L_P / L_Q} f_1(y - \gamma_k) \overline{f_2}(y - \gamma_k). \tag{2.9}$$

Proof. This is Theorem 10 in [9]. □

We remark that another method [6, 7] is available for computing the L_2 inner product of W-bandlimited functions from samples on L_P. That method does not require the restrictive hypotheses of shift-convexity, one generator subsampling, or the reality conditions of Theorem 2.9. In that approach, the missing samples of f_1 and f_2 on L_W needed for the application of Theorem 2.6 are obtained by interpolation. The interpolation is accomplished with a generalized sampling expansion. On the other hand, when Theorem 2.9 can be used, the computation is simpler and more direct, as no interpolation is required.

2.2. Divergent beam geometry. In [11], the sampling criteria for a standard fan beam reconstruction of an essentially Ω-bandlimited function were derived. The divergent beam transform is periodic in both arguments, so for $(k, a) \in \mathbb{Z} \times 2\mathbb{Z}$, the Fourier transform of Df is

$$\widehat{Df}(k, a) = \frac{1}{4\pi^2} \int_0^{2\pi} \int_0^{\pi} Df(\beta, \alpha) e^{-i(k\beta + a\alpha)} d\alpha d\beta. \tag{2.10}$$

THEOREM 2.10. *Let $f \in \mathcal{S}(\mathbb{R}^2)$ have support $|x| \leq \rho$ and be essentially Ω-bandlimited. Then the essential support of $\widehat{Df}(k, a)$ is the set*

$$K = \left\{ (k, a) \in \mathbb{Z} \times 2\mathbb{Z} \,\middle|\, |k - a| \leq \Omega r, |k| r \leq |k - a| \rho \right\}. \tag{2.11}$$

An essentially Ω-bandlimited reconstruction of f from fan beam data is achieved by converting the parallel beam reconstruction, equation (5.22) in [13], to fan beam coordinates:

$$V_\Omega * f(x) = r \int_0^{2\pi} \int_{-\pi/2}^{\pi/2} v_\Omega(x\Phi - r \sin\alpha) Df(\beta, \alpha) \cos\alpha d\alpha d\beta, \tag{2.12}$$

where Φ is the unit vector associated with the angle $\phi = \beta + \alpha - \pi/2$, v_Ω is an Ω-bandlimited approximation to the ramp filter, and V_Ω is the corresponding Ω-bandlimited approximate δ function. That is, for a filter $\hat{\psi}(\sigma)$ which is supported on $|\sigma| \leq 1$, and which is approximately unity on its support,

$$\begin{aligned} \hat{V}_\Omega(\xi) &= (2\pi)^{-1} \hat{\psi}(|\xi| / \Omega), \\ \hat{v}_\Omega(\sigma) &= \frac{(2\pi)^{-3/2}}{2} |\sigma| \hat{\psi}(\sigma / \Omega). \end{aligned} \tag{2.13}$$

In order to accurately compute (2.12) by a discrete sum, Df must be suitably sampled.

2.2.1. Standard divergent beam geometry. Sampling density criteria for the standard fan beam reconstruction (Algorithm 5.3 in [13]) result when translates of K parallel to the coordinate axes are packed as densely as possible. See Figure 2. For

$$W = \begin{pmatrix} \Delta\beta & 0 \\ 0 & \Delta\alpha \end{pmatrix}, \qquad \Delta\beta \leq \frac{r+\rho}{r}\frac{\pi}{\rho\Omega}, \qquad \Delta\alpha \leq \frac{\pi}{r\Omega}, \tag{2.14}$$

the translates of K by $L_W^{\perp}$ do not overlap [11, 15]. Since the lattice L_W must be a sublattice of $2\pi\mathbb{Z} \times \pi\mathbb{Z}$, when (2.14) holds with equality, both $r\Omega$ and $\frac{r+\rho}{2r\rho\Omega}$ are required to be integral. The sample points are (β_j, α_ℓ), with

$$\beta_j = j\Delta\beta, \qquad \alpha_\ell = (\ell + \delta)\Delta\alpha. \tag{2.15}$$

The parameter δ is the detector shift. This parameter indicates the alignment of the elements in the detector assembly with respect to the central ray. That is, the center of each detector element will be shifted by $\delta\Delta\alpha$ with respect to the lattice $\Delta\alpha\mathbb{Z}$. We remark that, as with the standard parallel beam sample lattice, the standard fan beam sample lattice is sufficiently dense along the detector direction to allow the inner integral in the reconstruction formula (2.12) to be replaced by a sum of discrete samples. Also, the translations of K do not completely fill $\mathbb{R}^2$ so this sampling scheme is not efficient.

2.2.2. Efficient geometry. An efficient sample scheme can be obtained by tiling $\mathbb{R}^2$ with translations of K. Translates by $L_W^{\perp}$ will tile the plane if the lattice L_W is generated by

$$W = \begin{pmatrix} \Delta\beta & \dfrac{r-\rho}{2r}\Delta\beta \\ 0 & \Delta\alpha \end{pmatrix}, \qquad \Delta\beta = \frac{2\pi}{\rho\Omega}, \qquad \Delta\alpha = \frac{\pi}{r\Omega}. \tag{2.16}$$

See Figure 2. Here, both $r\Omega$ and $\rho\Omega$ are required to be integral. To acquire data for this efficient sampling, a dynamic detector shift is required. An implementation of such an acquisition system presents many technical difficulties. See [11] for a detailed treatment of the efficient geometry.

2.2.3. Reflected geometry. Another option for a fan-beam acquisition is to use only the reflections of the sample points. This corresponds to choosing for W,

$$W = \begin{pmatrix} \Delta\beta & 2\Delta\alpha \\ 0 & -\Delta\alpha \end{pmatrix}, \tag{2.17}$$

with $\Delta\beta$ and $\Delta\alpha$ the same as in (2.14). The translates of K by $L_W^{\perp}$ are shown in Figure 2. When the original sample points are given by (2.15) and $\lambda = \Delta\beta/\Delta\alpha$, the reflected samples $(\beta'_{j,\ell}, \alpha'_\ell)$ are

$$\beta'_{j,\ell} = (J/2 + j + 2(\ell + \delta)/\lambda)\Delta\beta, \qquad \alpha'_\ell = -(\ell + \delta)\Delta\alpha, \tag{2.18}$$

where $J = 2\pi/\Delta\beta$. Because L_W must be 2π-periodic in β and π-periodic in α, λ is rational, so the reflected geometry has an interpretation as a dynamic detector shift with the periodicity determined by the denominator after $2/\lambda$ is reduced to lowest terms. A reconstruction algorithm similar to that in section 3.2 can be given for this geometry. However, as this algorithm will be significantly more time consuming than the standard fan beam algorithm, there is no practical incentive to use it.

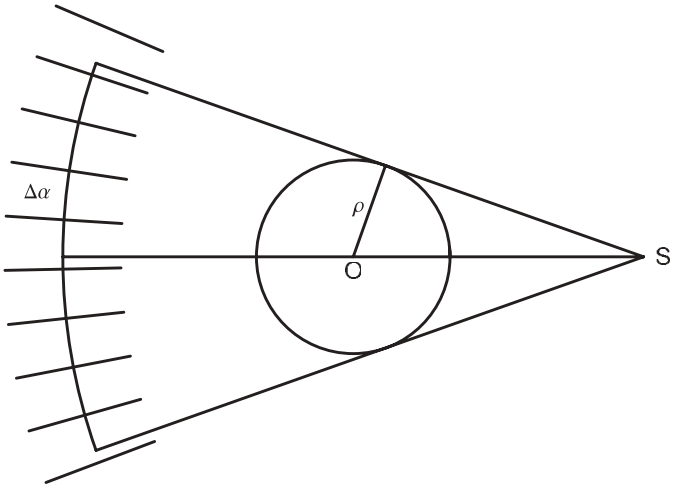

FIG. 3. *A model of the source-detector assembly is shown. All the photons arriving at an interval of width $\Delta\alpha$ between the ticks contribute to the measurement sample located at the center of that interval. The central ray of the fan intersects the central interval of the detector at $\delta\Delta\alpha$ from the center of the interval.*

3. The third generation problem and the quarter detector shift. For a typical third generation CT scanner, the spacing between detector pixels is the limiting factor determining the maximum attainable resolution in reconstructed images. That is, the size of the smallest reconstructible detail, π/Ω, is determined by the detector spacing, $\Delta\alpha$. This in turn determines the source sampling interval, $\Delta\beta$, needed to achieve the π/Ω resolution.

3.1. The detector model. The detector assembly for a third generation CT scanner can be modeled as a contiguous collection of detector elements, each of width $\Delta\alpha$. See Figure 3. For simplicity, it is assumed that each detector element will respond uniformly to all photons arriving within $\Delta\alpha/2$ of the element center. Other models could be considered. Accordingly, the measured data $D'f(\beta,\alpha)$ is a convolution of Df with the detector element response function $(\Delta\alpha)^{-1}\chi_{[-\Delta\alpha/2,\Delta\alpha/2]}$, where χ_I denotes the characteristic function for the interval I:

(3.1)
$$D'f(\beta,\alpha) = (\Delta\alpha)^{-1}\int_{-\Delta\alpha/2}^{\Delta\alpha/2} Df(\beta,\alpha-t)dt = (\Delta\alpha)^{-1} Df * \chi_{[-\Delta\alpha/2,\Delta\alpha/2]}(\beta,\alpha).$$

The Fourier transform of $(\Delta\alpha)^{-1}\chi_{[-\Delta\alpha/2,\Delta\alpha/2]}$ is

(3.2)
$$\hat{\chi}_{[-\Delta\alpha/2,\Delta\alpha/2]}(\xi) = (2\pi)^{-1/2}\mathrm{sinc}(\xi\Delta\alpha/2)/2.$$

Ignoring the contribution from the side lobes of the sinc function allows the finite width detector to be treated as a low-pass filter, effectively making the measured data $2\pi/\Delta\alpha$-bandlimited in the α direction. This hardware-determined bandwidth sets an intrinsic resolution limit for reconstructions from data measured by this acquisition system. On the other hand, a separation of $\Delta\alpha$ between samples implies a maximum sampling-determined bandwidth of $\pi/\Delta\alpha$ in the α direction, which by (2.14), implies a maximum reconstruction resolution of $\pi/\Omega = r\Delta\alpha$, where $\Omega = \pi/(r\Delta\alpha)$. As the

bandwidth in the measured data is twice that which can be exploited by the standard sample scheme, it is natural to ask whether it is possible to reconstruct at the doubled resolution corresponding to the higher data bandwidth. Since this is a two-dimensional reconstruction, doubling the resolution requires a fourfold increase in the number of samples. In the source direction, β, a density doubling can be achieved by finer sampling. An increase in the sample density in the detector direction will be achieved by the judicious use of the reflected sample points.

As previously mentioned, for the parallel beam geometry, the reflected sample points mesh well with the original sample points, resulting in a relatively straight forward algorithm to reconstruct at the hardware-limited resolution. The divergent beam geometry requires a more delicate analysis.

3.2. Symmetry in the divergent beam transform. Following the success in the parallel beam context of using reflected sample points to reconstruct at the hardware-limited resolution, it is natural to ask how to perform the analogous computation for the divergent beam geometry. Unfortunately, with the divergent beam transform and a 1/4 detector shift, the reflected sample points do not align in a rectangular grid, so the straightforward application of the standard divergent beam (Algorithm 5.3 in [13]) can only be viewed, at best, as an approximation. A reconstruction at the hardware-limited resolution can be obtained if the combined original and reflected sets are together viewed as samples on multiple channels for a suitably chosen undersampled lattice. In the language of signal processing, the combined lattices are a periodic, nonuniform sampling set. The undersampled lattice and the number of channels needed depend on the ratio $\theta = \rho/r$.

It is now assumed that $D'f$ is available on the original lattice L_O,

$$L_O = \{(\beta_j, \alpha_\ell) \mid j \in \mathbb{Z}, \ell \in \mathbb{Z}\}, \qquad \beta_j = j\Delta\beta, \quad \alpha_\ell = (\ell + \delta)\Delta\alpha. \tag{3.3}$$

Since L_O must be a sublattice of $2\pi\mathbb{Z} \times \pi\mathbb{Z}$, both of

$$\frac{\pi}{\Delta\alpha} = n \quad \text{and} \quad \frac{2\pi}{\Delta\beta} = m, \tag{3.4}$$

are integral.

Here $\Delta\alpha$ is the detector pixel width and $\Delta\beta$ is the angular sampling interval to be specified shortly. In practice, only $j = 0, \ldots, m-1$ and $\ell = -L, \ldots, L$ for $L > \frac{\sin^{-1}\rho/r}{\Delta\alpha}$ are needed as $D'f$ either is 0 or can be computed by periodicity from the other points.

The resolution implied by the detector sample density is π/Ω, where

$$\Omega \leq \frac{\pi}{r\Delta\alpha}. \tag{3.5}$$

The hardware-limited bandwidth of the data from the third generation detector is 2Ω. A reconstruction at the corresponding resolution will require that $\Delta\beta$ be chosen appropriately. That is,

$$\Delta\beta \leq \frac{r+\rho}{r\rho}\frac{\pi}{2\Omega}. \tag{3.6}$$

The divergent beam reflection property (2.3) is applied to the sample lattice L_O with $\Delta\alpha$ and $\Delta\beta$ given by (3.5) and (3.6), respectively. The reflected sample points are

$$L_R = \left\{(\beta'_{j,\ell}, \alpha'_\ell) \mid j \in \mathbb{Z}, \ell \in \mathbb{Z}\right\}, \tag{3.7}$$

where

$$\beta'_{j,\ell} = \pi + j\Delta\beta + 2(\ell+\delta)\Delta\alpha, \qquad \alpha'_\ell = -(\ell+\delta)\Delta\alpha. \tag{3.8}$$

If $\delta = 0$, then $\beta'_{j,\ell} = \pi + j\Delta\beta + 2\ell\Delta\alpha$ and $\alpha'_\ell = -\ell\Delta\alpha$. Regardless of the possibly increased sample density in the β direction, the α coordinates of the sample points in L_O match those of L_R. As a result, the translates of K in the direction dual to α still overlap, and the data remain insufficient to reconstruct at the higher resolution $\pi/(2\Omega)$. The same occurs for $\delta = \pm 1/2$.

Duplication is avoided and the α coordinates of the reflected points interlace perfectly with the α coordinates of the original samples when $\delta = 1/4$. With $\delta = 1/4$, (3.8) becomes

$$\beta'_{j,\ell} = \pi + j\Delta\beta + (2\ell + 1/2)\Delta\alpha, \qquad \alpha'_\ell = -(\ell + 1/4)\Delta\alpha. \tag{3.9}$$

From (3.4), $\Delta\alpha = \frac{m}{2n}\Delta\beta$ and

$$\beta'_{j,\ell} = \pi + \left(j + \frac{(4\ell+1)m}{4n}\right)\Delta\beta. \tag{3.10}$$

The reflected sample set L_R has a static shift in β of $\pi + \frac{m}{4n}\Delta\beta$ in addition to a dynamic shift of $m\Delta\beta/n$, which is periodic in ℓ. This is illustrated in Figure 4.

To work with this sample set, the union of the original and the reflected sample points is recast as a union of identical rectangular lattices, each shifted by a static distance from the origin. The β separation between lattice points of these rectangular lattices will be $\Delta\beta$, and the α separation will be a multiple of $\Delta\alpha$. Each rectangular lattice provides one channel of a multichannel sampling. Within this framework, Theorem 2.9 can be applied to accurately compute (2.12) as a discrete sum of the sampled divergent beam transform data.

3.2.1. Sample points as a union of rectangular lattices. In this subsection we show that the original sample points together with the reflected points can be reorganized as multiple shifted copies of a rectangular lattice. Thus, sampling on $L_O \cup L_R$ defines a periodic, nonuniform sampling set.

THEOREM 3.1. *Let L_O be the sample lattice arising from a quarter detector shift with a source sampling at twice the standard density, and let L_R be the corresponding reflected lattice. Then, the union, $L_O \cup L_R$, is a disjoint union of $2n'$ translates of the lattice L_P,*

$$L_P = \begin{pmatrix} \Delta\beta & 0 \\ 0 & n'\Delta\alpha \end{pmatrix} \mathbb{Z}^2, \tag{3.11}$$

where n' is the denominator when m/n is reduced to lowest terms.

Proof. The lattices L_O and L_R are given by (3.3), (3.4), (3.7), and (3.10).

Since L_O must be a sublattice of $2\pi\mathbb{Z} \times \pi\mathbb{Z}$, both of

$$n = \frac{\pi}{\Delta\alpha} \geq r\Omega \tag{3.12}$$

and

$$m = \frac{2\pi}{\Delta\beta} \geq \frac{4r\rho\Omega}{r+\rho} \tag{3.13}$$

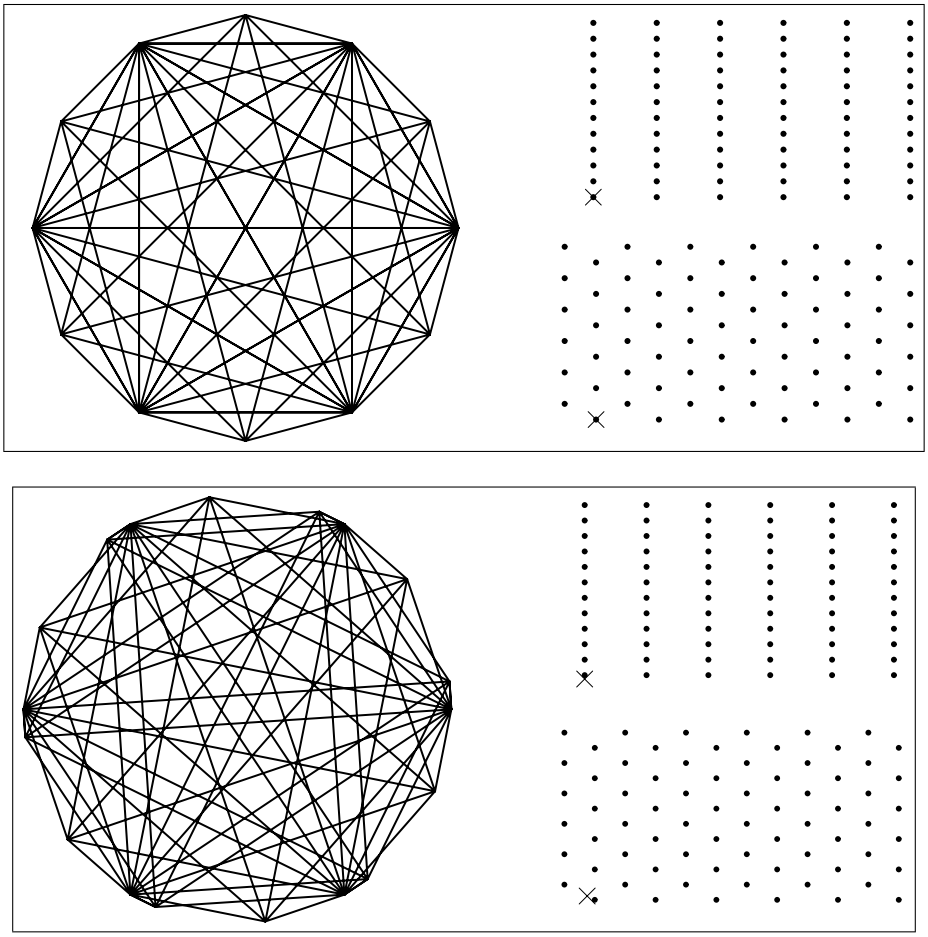

FIG. 4. *For a divergent beam scanner with $\rho/r = 1/3$, the doilygram (the set of lines on which line integrals are available), the standard sample lattice L_O (upper right), and the reflected sample lattice L_R (lower right) are shown for a detector shift of $\delta = 0$ (top) and $\delta = 1/4$ (bottom). On the lattices, the source position (β) is the horizontal coordinate and position along the detector (α) is the vertical coordinate. The origin is marked with $\times$. The doilygram for $\delta = 1/4$ appears denser than $\delta = 0$ because each point in the sample lattice corresponds to a unique line in the doilygram. For $\delta = 0$, some lines are generated by two points in the lattice. Samples of Df on any of the lattices shown can be used to reconstruct an essentially Ω-bandlimited function from its divergent beam transform. The lattices are shown for $\Omega = 8$.*

are integral. Let m/n be expressed in lowest terms as m'/n'. That is,

$$m' = \frac{m}{\gcd(m,n)}, \qquad n' = \frac{n}{\gcd(m,n)}. \tag{3.14}$$

As ℓ varies, a shift $\frac{m'}{n'}\Delta\beta$ is induced in $\beta'_{j,\ell}$. This shift is a rational multiple of the sample interval $\Delta\beta$. From (3.10) and (3.14),

$$\beta'_{j,\ell} = \pi + \beta_{j+\frac{m'}{n'}(\ell+1/4)}, \tag{3.15}$$

and for any j_1, j_2, ℓ_1, ℓ_2,

$$\beta'_{j_1,\ell_1} - \beta'_{j_2,\ell_2} = \left(j_1 - j_2 + \frac{(\ell_1 - \ell_2)m'}{n'} \right) \Delta\beta, \tag{3.16}$$

which is an integral multiple of $\Delta\beta$ if and only if $\ell_1 \equiv \ell_2 \mod n'$. Hence, for each $\ell_0 \in \mathbb{Z}$, the set $L_{\ell_0 R} = \{(b'_{j,\ell}, \alpha'_\ell) \mid \ell \equiv \ell_0 \mod n', j \in \mathbb{Z}\}$ is a shifted copy of the rectangular lattice L_P,

$$L_{\ell_0 R} = \begin{pmatrix} \pi + \left(\frac{(\ell_0 + 1/4)m'}{n'}\right)\Delta\beta \\ (-1/4 - \ell_0)\Delta\alpha \end{pmatrix} + L_P. \tag{3.17}$$

In view of (3.16), a distinct lattice is obtained for each equivalence class in $\mathbb{Z}/(n'\mathbb{Z})$. Therefore, the reflected sample set L_R is the disjoint union of the distinct lattices,

$$L_R = \bigcup_{[\ell_0] \in \mathbb{Z}/(n'\mathbb{Z})} L_{\ell_0 R}. \tag{3.18}$$

The original sample set L_O can easily be represented as a disjoint union of n' shifted copies of the lattice L_P,

$$L_O = \bigcup_{[\ell_0] \in \mathbb{Z}/(n'\mathbb{Z})} \begin{pmatrix} 0 \\ (\ell_0 + 1/4)\Delta\alpha \end{pmatrix} + L_P. \tag{3.19}$$

Combining (3.18) and (3.19) completes the proof. □

Three examples are shown in Figure 5.

3.2.2. The divergent beam multichannel sampling algorithm. Equation (2.12) with Ω replaced by 2Ω is used to reconstruct a bandlimited approximation to f from Divergent beam transform data. To properly compute the continuous integral from discrete data, Theorem 2.9 must be applied.

First, the relevant lattices are identified. $D'f$ is Q-periodic with

$$L_Q = 2\pi\mathbb{Z} \times \pi\mathbb{Z}, \qquad L_Q^\perp = \mathbb{Z} \times 2\mathbb{Z}. \tag{3.20}$$

As $D'f$ is essentially W-bandlimited with K as in (2.11) when Ω is replaced by 2Ω, a reconstruction at the hardware-limited resolution is possible when samples of $D'f$ are available on L_W/L_Q, where, with m and n as in (3.12) and (3.13),

$$L_W = \left(\frac{2\pi}{m}\right)\mathbb{Z} \times \left(\frac{\pi}{2n}\right)\mathbb{Z}, \qquad L_W^\perp = m\mathbb{Z} \times 4n\mathbb{Z}. \tag{3.21}$$

With $\beta_s = s\Delta\beta$ and $\alpha_\ell = \ell\Delta\alpha$, we make the identification

$$L_W/L_Q = \left\{ (\beta_s, \alpha_\ell) \mid s = 0, \ldots, m-1, \ell = \frac{-n}{2}, \frac{-n+1}{2}, \ldots, \frac{n-2}{2}, \frac{n-1}{2} \right\}. \tag{3.22}$$

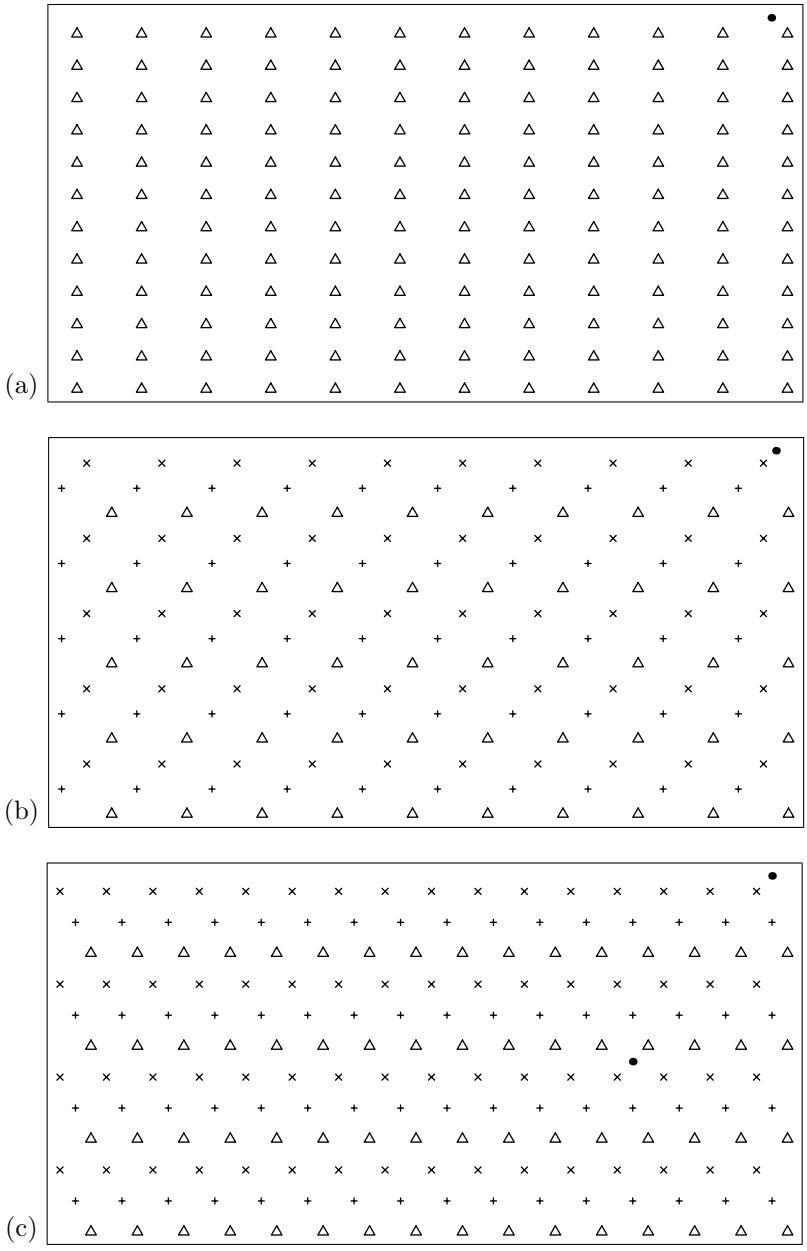

FIG. 5. *Lattices are shown for $\theta = 1/3, 1/5, 1/2$, respectively. For each case, the original lattice L_O is shown by dots. For* (a), *$n' = 1$. The reflected lattice L_R is rectangular and is shown by triangles. For both* (b) *and* (c), *L_R is a union of $n' = 3$ rectangular lattices, shown by the triangles, $+$, and $\times$. For each case, the horizontal spacing of all the rectangular lattices is the same, and the vertical spacing of the rectangular lattices making up L_R is n' times that of L_O.*

By Theorem 3.1, the original and reflected lattices together can be realized as a union of $2n'$ copies of the lattice L_P,

$$L_P = \left(\frac{2\pi}{m}\right)\mathbb{Z} \times \left(\frac{n'\pi}{n}\right)\mathbb{Z}, \qquad L_P^{\perp} = m\mathbb{Z} \times \left(\frac{2n}{n'}\right)\mathbb{Z}, \tag{3.23}$$

the kth copy of L_P being shifted by γ_k. For $k = 0, \ldots, n' - 1$,

$$\gamma_k = \begin{pmatrix} 0 \\ (k+1/4)\frac{\pi}{n} \end{pmatrix}, \qquad \gamma_{k+n'} = \begin{pmatrix} \pi + (k+1/4)\frac{2\pi}{n} \\ -(k+1/4)\frac{\pi}{n} \end{pmatrix}. \tag{3.24}$$

For $\zeta \in L_P^\perp / L_W^\perp$, $\zeta = (u, 2v)^T$, with $u \in m\mathbb{Z}/m\mathbb{Z}$ and $2v \in \frac{2n}{n'}\mathbb{Z}/4n\mathbb{Z}$. To find a representative $\zeta' = (u', v')$ for ζ, observe that if $u' = mt$, with $0 \neq t \in \mathbb{Z}$, then $|u'| \geq |t|\frac{4\pi\rho\Omega}{r+\rho}$ which implies $(mt, v') \notin K$. Hence, $\zeta' = (0, 2v')$. Next, by (2.11), $|2v'| < 2\Omega r$. Any other representative for ζ is of the form $\zeta' = (0, 2v + 4n\tau)$ with $0 \neq \tau \in \mathbb{Z}$. However, $|2v + 4n\tau| \geq |4n\tau| - |2v| > 4n - 2r\Omega \geq 2r\Omega$. Hence, $\zeta' = (0, 2v + 4n\tau) \notin K$. Accordingly, we may take $\zeta' = (0, 2jn/n')$ for $j = -n', \ldots, n' - 1$. Note that the symmetry of K allows an equivalent choice of $j = -n' + 1, \ldots, n'$, and that $\zeta_j \cap K = \emptyset$ for either indexing scheme.

The samples of $D'f$ on each $\gamma_k + L_P$ are samples of the measurement channel, $g_k = h_k * f$, where $h_k(x) = \delta(x - \gamma_k)$. For $\eta \in L_Q^\perp / L_P^\perp$, $\eta = (u, 2v)^T$, with $u \in \mathbb{Z}/m\mathbb{Z}$ and $2v \in (2\mathbb{Z})/(\frac{2n}{n'}\mathbb{Z})$. The k, j element of $\mathbf{H}$ in Definition 2.8 is given by

$$\mathbf{H}_{k,j} = e^{-i\zeta_j' \gamma_k} = e^{-i(0, 2jn/n')\gamma_k}. \tag{3.25}$$

So, for $k = 0, \ldots, n' - 1$,

$$\mathbf{H}_{k,j} = e^{-i(2jn/n')(k+1/4)\pi/n} = e^{-i(k+1/4)2\pi j/n'}, \tag{3.26}$$

$$\mathbf{H}_{k+n',j} = e^{i(2jn/n')(k+1/4)\pi/n} = e^{i(k+1/4)2\pi j/n'}. \tag{3.27}$$

Since

$$\sum_{j=-n'}^{n'-1} (\mathbf{H})_{k_1,j} (\overline{\mathbf{H}})_{k_2,j} = 2n' \delta_{k_1,k_2}, \tag{3.28}$$

$\mathbf{H}^{-T}$ is explicitly computed as $\mathbf{H}^{-T} = \frac{1}{2n'}\overline{\mathbf{H}}$, and therefore, $\lambda_{k,0} = \frac{1}{2n'}$, which is real.

To apply Theorem 2.9, the essential bandregion K, given by (2.11) with Ω replaced by 2Ω, must be shift-convex with respect to $W^\perp$ and $P^\perp$. The discussion of the circumstances under which K is shift-convex will be postponed to section 3.2.3. For now, we proceed under the assumption that K is indeed shift-convex.

In the present setting, Theorem 2.9 reads

$$\begin{aligned} &\int_0^{2\pi} \int_{-\pi/2}^{\pi/2} f_1(\beta, \alpha) f_2(\beta, \alpha) d\alpha d\beta \\ &\quad = \frac{2\pi^2 n'}{mn} \sum_{k=0}^{2n'-1} \frac{1}{2n'} \sum_{(\beta,\alpha) \in \frac{(2\pi/m)\mathbb{Z}}{2\pi\mathbb{Z}} \times \frac{(n'/n)\mathbb{Z}}{\pi\mathbb{Z}}} f_1((\beta, \alpha) - \gamma_k) f_2((\beta, \alpha) - \gamma_k) \\ &\quad = \frac{\pi^2}{mn} \sum_{(\beta,\alpha) \in \frac{L_Q \cup L_R}{2\pi\mathbb{Z} \times \pi\mathbb{Z}}} f_1(\beta, \alpha) f_2(\beta, \alpha). \end{aligned} \tag{3.29}$$

Applying (3.29) to (2.12) with $f_1(\beta, \alpha) = v_{2\Omega}(x\Phi - r \sin\alpha)\cos\alpha$ and $f_2(\beta, \alpha) = Df(\beta, \alpha)$ allows the recovery of the 2Ω bandlimited version of f by a discrete sum of

samples of the hardware-limited $D'f$,

$$
\begin{aligned}
V_{2\Omega} * f(x) &= \frac{r\pi^2}{mn} \sum_{(\beta,\alpha)\in \frac{(2\pi/m)\mathbb{Z}}{2\pi\mathbb{Z}} \times \frac{(n'/n)\mathbb{Z}}{\pi\mathbb{Z}}} v_{2\Omega}(x\Phi - r\sin\alpha) D'f(\beta,\alpha)\cos\alpha \\
&= \frac{r\pi^2}{mn} \sum_{s=0}^{m-1} \sum_{\ell=-n}^{n-1} \Big(v_{2\Omega}(x\Phi_{s,\ell} - r\sin\alpha_\ell) D'f(\beta_s,\alpha_\ell)\cos\alpha_\ell \\
&\qquad + \; v_{2\Omega}(x\Phi'_{s,\ell} - r\sin\alpha'_\ell) D'f(\beta'_{s,\ell},\alpha'_\ell)\cos\alpha'_\ell \Big) \qquad (3.30) \\
&= \frac{r\pi^2}{mn} \sum_{s=0}^{m-1} \sum_{\ell=-n}^{n-1} \Big(v_{2\Omega}(x\Phi_{s,\ell} - r\sin\alpha_\ell)\cos\alpha_\ell \\
&\qquad + \; v_{2\Omega}(x\Phi'_{s,\ell} - r\sin\alpha'_\ell)\cos\alpha'_\ell \Big) D'f(\beta_s,\alpha_\ell),
\end{aligned}
$$

where $\Phi_{s,\ell}$ and $\Phi'_{s,\ell}$ are the unit vectors associated with $\phi_{s,\ell} = \beta_s + \alpha_\ell - \pi/2$ and $\phi'_{s,\ell} = \beta'_{s,\ell} + \alpha'_\ell - \pi/2$, respectively.

The reconstruction exhibited in (3.30) has a computational complexity of $O(\Omega^4)$. Following [13], to develop an algorithm with a more tractable complexity of $O(\Omega^3)$, it is necessary to replace (2.12) by the approximation, valid when both $|x| \ll r$ and $V_{2\Omega}(k)$ is close to zero for $|k|$ near 2Ω [14],

$$
V_{2\Omega} * f(x) = r \int_0^{2\pi} |b-x|^{-2} \int_{-\pi/2}^{\pi/2} v_{2\Omega r}(\sin(\nu(b,x)-\alpha))\cos\alpha D'f(\beta,\alpha)\, d\alpha d\beta. \qquad (3.31)
$$

Here, $b = (r\cos\beta, r\sin\beta)^T$, $b_\perp = (r\cos(\beta+\pi/2), r\sin(\beta+\pi/2))^T$, and

$$
\cos\nu(b,x) = \frac{(b-x)b}{|b-x||b|}, \quad \nu(b,x) \lesseqgtr 0 \quad \text{when } xb_\perp \gtreqless 0. \qquad (3.32)
$$

By Theorem 2.9 and (3.29), the double integral can be computed as a discrete sum. For $|x| < \rho$,

$$
\begin{aligned}
V_{2\Omega} * f(x) &= \frac{r\pi^2}{mn} \sum_{s=0}^{m-1} |b_s - x|^{-2} \sum_{\ell=-n}^{n-1} v_{2\Omega r}(\sin(\nu(b_s,x)-\alpha_\ell))\cos\alpha_\ell D'f(\beta_s,\alpha_\ell) \\
&\quad + \frac{r\pi^2}{mn} \sum_{s=0}^{m-1} \sum_{\ell=-n}^{n-1} |b'_{s,\ell} - x|^{-2} v_{2\Omega r}(\sin(\nu(b'_{s,\ell},x)-\alpha'_\ell))\cos\alpha'_\ell D'f(\beta_s,\alpha_\ell) \\
&= T_1(x) + T_2(x).
\end{aligned} \qquad (3.33)
$$

The first term on the right-hand side, T_1, in (3.33) can be computed by adapting the method to interpolate convolutions suggested in [5] to the divergent beam geometry. As the inner sum is not sufficiently sampled to be a valid approximation to the corresponding integral, artifacts are introduced in the interpolation step. To avoid the artifacts, instead of interpolation with a step size of $\Delta\alpha$, the interpolation is done with a finer step size of $\Delta\alpha/M$ for a sufficiently large M.

As written, the discrete convolution argument cannot be applied to the second term T_2 in (3.33) because $b'_{s,\ell}$ depends on ℓ. To restore a convolution structure, the

sample points are reorganized as a union of n' lattices as in (3.18). After a reindexing, the discrete convolution argument can be applied to each lattice independently, and T_2 is obtained by summing the result,

(3.34)
$$T_2(x) = \frac{r\pi^2}{mn} \sum_{k=0}^{n'-1} \sum_{s=0}^{m-1} \sum_{\ell=-n/n'}^{n/n'-1} |b'_{s,n'\ell+k} - x|^{-2} v_{2\Omega r}(\sin(\nu(b'_{s,n'\ell+k}, x) - \alpha'_{n'\ell+k})) \times \cos\alpha'_{n'\ell+k} D'f(\beta_s, \alpha_{n'\ell+k}).$$

From (3.15), $b'_{s,n'\ell+k} = -b_{s+m'(\ell+(k+1/4)/n')}$ and

(3.35)
$$\begin{aligned} \cos\nu(b'_{s,n'\ell+k}, x) &= \frac{(b'_{s,n'\ell+k} - x)b'_{s,n'\ell+k}}{|b'_{s,n'\ell+k} - x||b'_{s,n'\ell+k}|} \\ &= \frac{(b_{s+m'(\ell+(k+1/4)/n')} + x)b_{s+m'(\ell+(k+1/4)/n')}}{|b_{s+m'(\ell+(k+1/4)/n')} + x||b_{s+m'(\ell+(k+1/4)/n')}|} \\ &= \cos\nu(b_{s+m'(\ell+(k+1/4)/n')}, -x). \end{aligned}$$

Also, the sign of $\nu(b'_{s,n'\ell+k}, x)$ is the same as that of $\nu(b_{s+m'(\ell+(k+1/4)/n')}, -x)$. Hence,

(3.36)
$$\nu(b'_{s,n'\ell+k}, x) = \nu(b_{s+m'(\ell+(k+1/4)/n')}, -x).$$

Of course, it is understood that the arithmetic in the subscripts of β_s and b_s is in $\mathbb{R}/m\mathbb{Z}$,

(3.37)
$$T_2(x) = \frac{r\pi^2}{mn} \sum_{k=0}^{n'-1} \sum_{s=0}^{m-1} \sum_{\ell=-n/n'}^{n/n'-1} |b_{s+m'(\ell+(k+1/4)/n')} + x|^{-2} \times v_{2\Omega r}(\sin(\nu(b_{s+m'(\ell+(k+1/4)/n')}, -x) - \alpha'_{n'\ell+k})) \cos\alpha'_{n'\ell+k} D'f(\beta_s, \alpha_{n'\ell+k}).$$

Reindex the sums over s and ℓ as sums over $t = s + m'\ell$ and ℓ,

(3.38)
$$\begin{aligned} T_2(x) = \frac{r\pi^2}{mn} \sum_{k=0}^{n'-1} \Bigg(& \sum_{t=0}^{m-1} |b_{t+(k+1/4)m'/n'} + x|^{-2} \\ & \times \sum_{\ell=-n/n'}^{n/n'-1} v_{2\Omega r}(\sin(\nu(b_{t+(k+1/4)m'/n'}, -x) - \alpha'_{n'\ell+k})) \\ & \times \cos\alpha'_{n'\ell+k} D'f(\beta_{t-m'\ell}, \alpha_{n'\ell+k}) \Bigg). \end{aligned}$$

For each k, the innermost sum of (3.38) is a discrete convolution with separation $n'\Delta\alpha$. To achieve $O(\Omega^3)$ computation, the convolution at $\nu(b_{t+(k+1/4)m'/n'}, -x)$ is obtained by interpolation from the convolution evaluated at a discrete set of values. As this discrete convolution is $2n'$ times undersampled with respect to the corresponding continuous integral in α, Theorem 2.6 cannot be applied. To avoid the introduction of artifacts, it is again necessary to compute the convolution on an extra fine grid. Introduce a multiplier M^R, and compute the convolution on a grid with a separation of $n'\Delta\alpha/M^R$ between grid points. The algorithm for reconstruction can now be presented.

ALGORITHM 3.2 (divergent beam reconstruction at hardware resolution).

1. *Choose an integer multiplier* M^O. *Typically,* $M^O = 8$ *is large enough. For* $s = 0, \ldots, m-1$ *and* $\ell = -nM^O, \ldots, (n-1)M^O$, *compute the discrete convolutions*

$$h^O_{s,\ell} = \sum_{\mu=-n}^{n-1} v_{2\Omega r}(\sin(\alpha_{\ell/M^O} - \alpha_\mu)) \cos\alpha_\mu D'f(\beta_s, \alpha_\mu). \tag{3.39}$$

2. *Choose an integer multiplier* M^R. *Typically,* $M^R = 8n'$ *should be large enough. For* $k = 0, \ldots, n'-1$ *and* $t = 0, \ldots, m-1$, *compute the discrete convolutions at* $\ell = -nM^R, \ldots, (n-1)M^R$

$$h^R_{k,t,\ell} = \sum_{\mu=-n/n'}^{n/n'-1} \Big(v_{2\Omega r}(\sin(\alpha_{\ell/M^R} - \alpha'_{n'\mu+k})) \cos\alpha_\mu D'f(\beta_{t+m'\mu}, \alpha_{n'\mu+k}) \Big). \tag{3.40}$$

3. *For each* x *at which the reconstruction is needed, evaluate the interpolated discrete backprojection*

$$f_O(x) = \frac{r\pi^2}{mn} \sum_{s=0}^{m-1} |b_s - x|^{-2} \Big((1-\vartheta_s) h^O_{s,\ell_s} + \vartheta_s h^O_{s,\ell_s+1} \Big), \tag{3.41}$$

where

$$\tau_s = \frac{M^O \nu_s(x)}{\Delta\alpha}, \quad \ell_s = \lfloor \tau_s - 1/4 \rfloor, \quad \vartheta_s = \tau_s - (\ell_s + 1/4). \tag{3.42}$$

4. *For each* x *at which the reconstruction is needed, and for each* $k = 0, \ldots, n'-1$, *evaluate the interpolated discrete backprojection*

$$f_{R,k}(x) = \frac{r\pi^2}{mn} \sum_{t=0}^{m-1} |b_{t+(k+1/4)m'/n'} + x|^{-2} \Big((1-\vartheta_t) h^R_{k,t,\ell_t} + \vartheta_t h^R_{k,t,\ell_t+1} \Big), \tag{3.43}$$

where

$$\tau_t = \frac{M^R \nu(b_{t+(k+1/4)m'/n'}, -x)}{\Delta\alpha}, \quad \ell_t = \lfloor \tau_t - 1/4 \rfloor, \quad \vartheta_t = \tau_t - (\ell_t + 1/4). \tag{3.44}$$

5. *The approximation* $f_{2\Omega}(x)$ *to* $V_{2\Omega} * f(x)$ *is given by*

$$f_{2\Omega}(x) = f_O(x) + \sum_{k=0}^{n'-1} f_{R,k}(x). \tag{3.45}$$

The errors in this approximation can arise from a number of sources.

1. The aliasing from the side lobes in the measurement system response function was ignored. One way to reduce this effect is to custom design a detector to minimize the size of the side lobes.

2. The divergent beam transform of a function is not bandlimited, but essentially bandlimited. Reconstructing at a slightly reduced bandwidth from the optimal bandwidth will reduce the aliasing due to the Fourier transform not truly vanishing outside the nominal support region K. Estimates for this type of error are available. See [6, 10], for example.

3. In the derivation of (3.31), the correct kernel $V_{2\Omega|b-x|}$ was replaced by the kernel $V_{2\Omega r}$. This approximation will break down when x gets close to r. Thus, it is necessary to keep $\rho \ll r$.

4. While $Df(\beta_s, \alpha_\ell) = Df(\beta'_{s,\ell}, \alpha'_\ell)$, it is not strictly true that $D'f(\beta_s, \alpha_\ell) = D'f(\beta'_{s,\ell}, \alpha'_\ell)$ as the two are averaged over slightly different sets of lines. Incorporating a source width into the model mitigates the effect of this approximation.

5. If either M^O or M^R is not large enough, the linear interpolation in step 3 or step 4 will effectively further bandlimit the reconstruction, causing artifacts in the reconstructed image.

3.2.3. Shift-convexity of K. In order to apply Algorithm 3.2, the bandregion K must be shift-convex with respect to $W^\perp$ and $P^\perp$. The shape of K is determined by $\theta = \rho/r$, and the scaling of K is determined by the product $r\Omega$. From these parameters, it is not immediately obvious whether K is shift-convex with respect to the sampling lattices. In this section, it will be shown how to choose the parameters m and n to guarantee shift-convexity of K, so Algorithm 3.2 can be applied to recover f at the maximum resolution consistent with the detector hardware.

First, to illustrate the problem which can arise, consider equality in (3.12) and (3.13) with the two examples $\theta = 1/2$ and $\theta = 1/3$. Shift-convexity with respect to $W^\perp$ and $P^\perp$ requires that once K has been shifted by an element of $L_W^\perp$, further shifting away from the origin by elements of $L_P^\perp$ does not reintroduce overlap. The smallest generators for $L_W^\perp$ consistent with (3.12) and (3.13) are $w_1 = (0, 4r\Omega)^T$ and $w_2 = (\frac{\rho}{r+\rho} 4r\Omega, 0)^T$. w_2 has been chosen to be the minimal horizontal shift necessary to ensure $K \cap (K + w_2) = \emptyset$. With equality in (3.12) and (3.13), $m/n = \frac{4\rho}{r+\rho} = \frac{4\theta}{1+\theta}$. For $\theta = 1/2$, $m/n = 8/3$, so $n' = 3$. Hence, $p_1 = w_1/6 = (0, 2r\Omega/3)^T$. As illustrated in Figure 6, further shifting of $K + w_2$ by several multiples of p_1 reintroduces overlap, so K is not shift-convex. On the other hand, for $\theta = 1/3$, $m/n = 1$, so $n' = 1$. Here, $p_1 = w_1/2 = (0, 2r\Omega)$. In this case, $K + w_2 + P_1$ interlaces with K, so no overlap is introduced and K is shift-convex. As θ controls the shape of K, whether this interlacing occurs depends on θ, and also on the size of the vertical shift p_1, which depends on n'.

From the above examples, it can be seen that absent an interlacing of the type seen for $\theta = 1/3$, vertical shifts of $K + w_2$ by multiples of p_1 can reintroduce overlap when the left side of a shifted K covers the upper right side of K. To avoid such overlapping, two approaches are suggested. Each requires an oversampling in β, the amount depending on θ. Oversampling is measured with respect to the optimal sampling density, given by equality in (3.13).

Method 1. Extend w_2 to be the smallest length such that all vertical translations of $K + w_2$ do not overlap K. That is, the inequality of (3.13) is replaced by

$$m = \frac{2\pi}{\Delta\beta} \geq 4\rho\Omega. \tag{3.46}$$

By construction, K is automatically shift-convex, independently of any choice of m and n consistent with (3.12) and (3.46). The shift-convexity comes at the expense of an oversampling in β by a factor of $4\rho\Omega / \frac{4r\rho\Omega}{r+\rho} = 1 + \theta$ with respect to the optimal sampling density.

Since the possibility that K may interlace with its shifts has not been utilized, for some parameter values (such as $\theta = 1/3$), shift-convexity can be achieved with a sparser sampling than this method constructs.

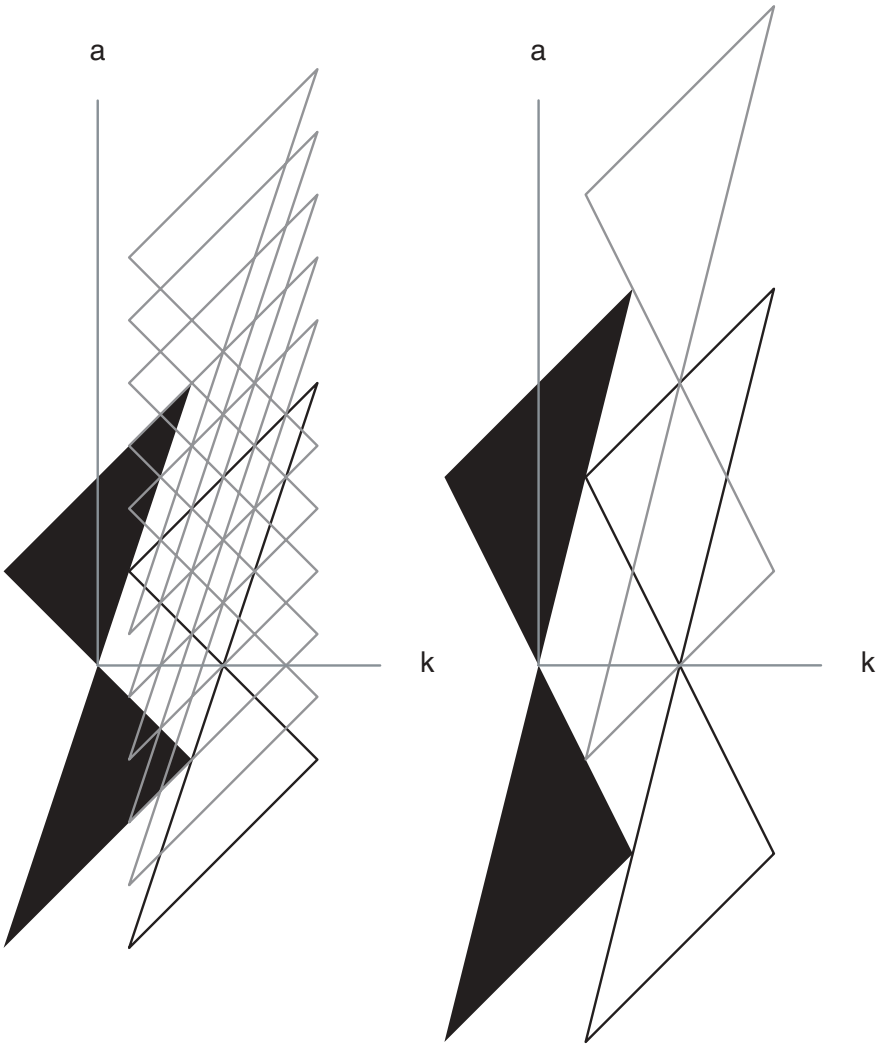

FIG. 6. *The essential bandregion K for the divergent beam transform is shown along with some of its translates. K is solid, $K + w_2$ is outlined in black, and $K + w_2 + jp_1$ with $j \neq 0$ is shown in gray. The left figure was drawn with equality in* (3.12) *and* (3.13) *and with $\theta = 1/2$. Here $n' = 3$. Although $K \cap (K + w_2) = \emptyset$, there is overlap between K and $K + w_2 + jp_1$ for $j = 1, 2, 3$. Hence K is not shift-convex with respect to the corresponding $W^{\perp}$ and $P^{\perp}$. The right figure was drawn with equality in* (3.12) *and* (3.13) *and with $\theta = 1/3$. In this case $n' = 1$, and both $K \cap (K + w_2) = \emptyset$ and $K \cap (K + w_2 + p_1) = \emptyset$. K is shift-convex with respect to the corresponding $W^{\perp}$ and $P^{\perp}$.*

Method 2. The physical detector geometry determines r and $\Delta\alpha$. Accordingly, n is fixed. Since maximizing reconstruction resolution is the objective, Ω is determined by equality in (3.12). $m \in \mathbb{Z}$ can be chosen freely as long as the inequality of (3.13) is satisfied and K is shift-convex.

Algorithm 3.2 is simplest, easiest to implement, and quickest when $n' = 1$. In what follows, it is shown how to choose m so that $n' = 1$ simultaneously with K being shift-convex.

When $n' = 1$, $L_P^{\perp}$ undersamples by a factor of 2, so $p_1 = (0, 2r\Omega)^T$. It is necessary to select $v > 0$ to locate the minimal shift $w_2 = (2vr\Omega, 0)^T$ such that both $K \cap (K +$

$w_2) = \emptyset$ and $K \cap (K + w_2 + p_1) = \emptyset$. The latter holds when either the upper left corner of $K + w_2 + p_1$ is to the right of the line $a = (1 + 1/\theta)k$, or the upper right corner of K is to the left of the line connecting the center of $K + w_2 + p_1$ to the upper left corner of $K + w_2 + p_1$. The coordinates of the upper left and right corners of K are, respectively, $(-2\rho\Omega, 2(r-\rho)\Omega)^T$ and $(2\rho\Omega, 2(r+\rho)\Omega)^T$, and the coordinates of the center and upper left corners of $K + w_2 + p_1$ are, respectively, $(2\upsilon r\Omega, 2r\Omega)^T$ and $(2(\upsilon r - \rho)\Omega, 2(2r-\rho)\Omega)^T$. The first condition becomes (assuming $\upsilon > 0$), $\frac{2(2r-\rho)\Omega}{2(\upsilon r-\rho)\Omega} \leq (1 + 1/\theta)$, or equivalently, since $K \cap (K + w_2) = \emptyset$ implies $\upsilon r > \rho$,

$$\upsilon \geq \frac{3\theta}{1+\theta}. \tag{3.47}$$

The second condition is satisfied when $(2\rho\Omega, 2(r+\rho)\Omega)^T$ is to the left of the line of slope $1 - 1/\theta$ through $(2\upsilon r\Omega, 2r\Omega)^T$. That is, $\frac{2\rho\Omega}{2(\rho-\upsilon r)\Omega} \geq \frac{\theta-1}{\theta}$, or equivalently,

$$\upsilon \geq \frac{\theta}{1-\theta}. \tag{3.48}$$

Thus, for K to be shift-convex with $n' = 1$, (3.13), (3.47), and (3.48) together require m/n to be integral and

$$m \geq 2r\Omega \max\left(\frac{2\theta}{1+\theta}, \min\left(\frac{3\theta}{1+\theta}, \frac{\theta}{1-\theta}\right)\right). \tag{3.49}$$

Inequality (3.49) can be expressed as

$$m \geq n \begin{cases} \frac{4\theta}{1+\theta} & \theta \in (0, 1/3], \\ \frac{2\theta}{1-\theta} & \theta \in (1/3, 1/2], \\ \frac{6\theta}{1+\theta} & \theta \in (1/2, 1). \end{cases} \tag{3.50}$$

For $\theta \leq 1/3$, $\frac{4\theta}{1+\theta} \leq 1$, so $m = n$ satisfies both requirements, for an effective oversampling in β of $\frac{1+\theta}{4\theta}$. For $\theta \in (1/3, 1/2]$, $1 < \frac{2\theta}{1-\theta} \leq 2$, so $m = 2n = 2r\Omega$. This gives an effective oversampling of $\frac{1+\theta}{2\theta}$. For $\theta \in (1/2, 1)$, $2 < \frac{6\theta}{1+\theta} < 3$, so $m = 3n = 3r\Omega$. This gives an effective oversampling of $\frac{3(1+\theta)}{4\theta}$.

Inequality (3.50) governs the additional sampling density beyond that of (3.13) which is needed to avoid overlap. A component of the inefficiency (which, for small θ, is unacceptably large) arises from the requirement that m/n be integral. Which of the two methods is preferable can be ascertained by examining Figure 7 in which the oversampling required for each method is plotted as a function of θ. The maximum oversampling of 1.75 occurs for $\theta = 3/4$. We note that for modern medical CT scanners, typically $\theta \leq 1/3$, and $\theta \leq 1/2$ almost always.

No oversampling occurs when $\theta = 1/3$. As θ increases beyond $1/3$, the oversampling jumps abruptly to $4/3$ because (3.46) requires $m = 2n$ when the right-hand side is slightly larger than 1. In a configuration with θ slightly larger than $1/3$, practically speaking, the relatively large ρ precludes visualization of the full 2Ω bandwidth. Therefore, it is common practice to filter the acquired data to perform a reduced resolution reconstruction. With Ω slightly reduced from the optimal value given by (3.12), $m = n$ can be used. This gain in reconstruction efficiency comes at the cost of a slight loss in reconstruction resolution.

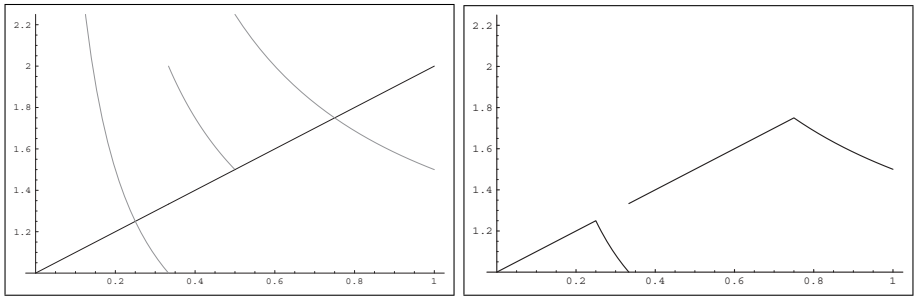

FIG. 7. *The left figure shows the oversampling required in the β direction to ensure the shift-convexity of K is plotted against θ. The oversampling required for Methods* 1 *and* 2 *are shown in black and gray, respectively. The right figure shows the oversampling required when the most efficient method is selected.*

Reduction of the reconstruction bandwidth Ω to reduce oversampling can be interpreted as yet a third method available to guarantee shift-convexity. The specific application requirements will determine what levels of oversampling versus resolution reduction are acceptable.

We close this section by remarking that the increased source density from shift-convexity induced oversampling impacts reconstruction time. The data from each source point must be backprojected. Since the bulk of the processing time is in the backprojection phase, computation time is increased by a factor matching that of the oversampling. Future studies will assess the practical significance of this increased execution time.

4. Numerical experiments. To validate the performance of the divergent beam multichannel sampling algorithm, Algorithm 3.2, third generation projection data from a simulated phantom was reconstructed both with Algorithm 3.2 and with the standard algorithm (Algorithm 5.3 in [13]).

The phantom used was an off-center disk modeling water with two pins of bone. This phantom, shown in Figure 8, was selected to test the recovery of details near the edge of the scan circle, a region in which any lack of conformance to (3.6) will produce artifacts. Also, in this region the approximation of (3.31) incurs the largest error. The scan radius for the phantom is $\rho = 20$. The circle which modeled water had a radius of 6.27208, was centered at $(-9, 9)$, and had attenuation coefficient in CT numbers of 1000. The pins modeling bone had a radius of 0.2, attenuation coefficient 2000, and were centered at $(14.3313, 9)$ and $(-9, 14.3313)$.

The simulated data from a third generation detector were generated with a source radius of $r = 60$. Thus, $\rho/r = 1/3$, which, with equality in (3.12) and (3.13), implies $n' = 1$. Figure 5(a) shows the interlacing of the original and reflected lattices for this geometry. The reconstruction bandwidth for the standard algorithm is $\Omega = 31.59$ corresponding to a resolution of 0.1 in the reconstructed image. The simulated hardware-limited bandwidth was 2Ω for an effective reconstruction resolution of 0.05.

Four reconstructions were performed, all using the cosine filter with a minor correction to reduce ringing. That is, ψ in (2.13) is taken to be $\hat{\psi}(\sigma) = \chi_{[-1,1]}(\sigma) \cos \sigma\pi/2$.

In Figure 9, the reconstruction at bandwidth 2Ω using the divergent beam multichannel sampling algorithm with $M_O = M_R = 8$ is shown. The data set consisted of 410 samples in α and 1884 samples in β. The top two images show the intermediate reconstructions f_O and f_R obtained by using only the original or reflected sample

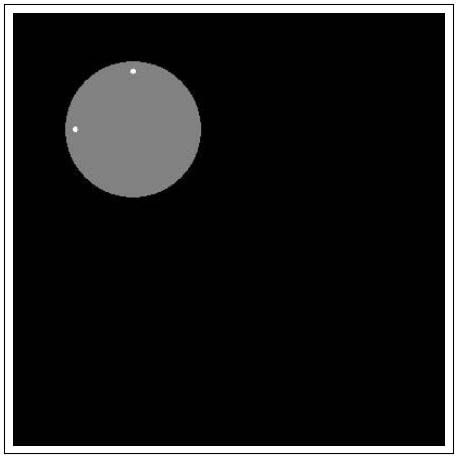

FIG. 8. *The phantom used for numerical experiments is shown. The scan radius for the phantom is* $\rho = 20$. *Data were collected using a source radius of* $r = 60$. *The larger circle modeling water has radius* 6.27208, *is centered at* $(-9, 9)$ *and has attenuation coefficient* 1000. *The pins modeling bone have radius* 0.2, *attenuation* 2000, *and are centered at* $(14.3313, 9)$ *and* $(-9, 14.3313)$. *This phantom was chosen to test the reconstruction algorithms' ability to recover details near the edge of the scan circle, a region in which any lack of conformance to* (3.6) *will produce artifacts. points. Observe that each of the intermediate images exhibits undersampling artifacts which disappear in the final reconstructed image. The reconstructions in this figure and the following one are all displayed with a window of 5 units centered on 1000.

A comparison between the divergent beam multichannel reconstruction and the standard algorithm appears in Figure 10. In Figure 10(a), the 2Ω reconstruction from the divergent beam multichannel sampling algorithm with 410 α samples and 1884 β samples is copied from Figure 9.

Figure 10(b) shows the standard divergent beam reconstruction at bandwidth Ω from 942 β samples and 410 α samples. It was sampled with the minimum density sufficient for applying the standard divergent beam reconstruction at a bandwidth of Ω. It shows a swirl artifact which is probably from a slight undersampling in β. The reconstructed diameter of the two pins is significantly larger than that of the phantom or that of the multichannel sampling reconstruction. This is due to the lower bandwidth, and hence, inferior resolution.

Figure 10(c) shows the reconstruction obtained when the standard divergent beam algorithm at bandwidth Ω is applied to the same data set used in generating Figure 10(a). This reconstruction is two-times oversampled in β and at the minimum sample density in α. The oversampling in β clears the swirl artifact, but as this reconstruction is still at bandwidth Ω, the smearing artifact does not improve.

Figure 10(d) shows the standard divergent beam algorithm applied at bandwidth 2Ω to data with 818 α and 1884 β samples. In this simulation the 818 α samples were "acquired" with detector elements half the size of those in Figures 10(a), 10(c), and 10(d). This data set is at the minimal density for a 2Ω application of the standard algorithm. As the bandwidth is 2Ω, the pins do not show the smearing artifact.

Comparing Figures 10(a) and 10(d), it can be seen that the multichannel algorithm does effectively reconstruct at a 2Ω bandwidth.

Finally, it has been observed that the residual artifact between the pins is not

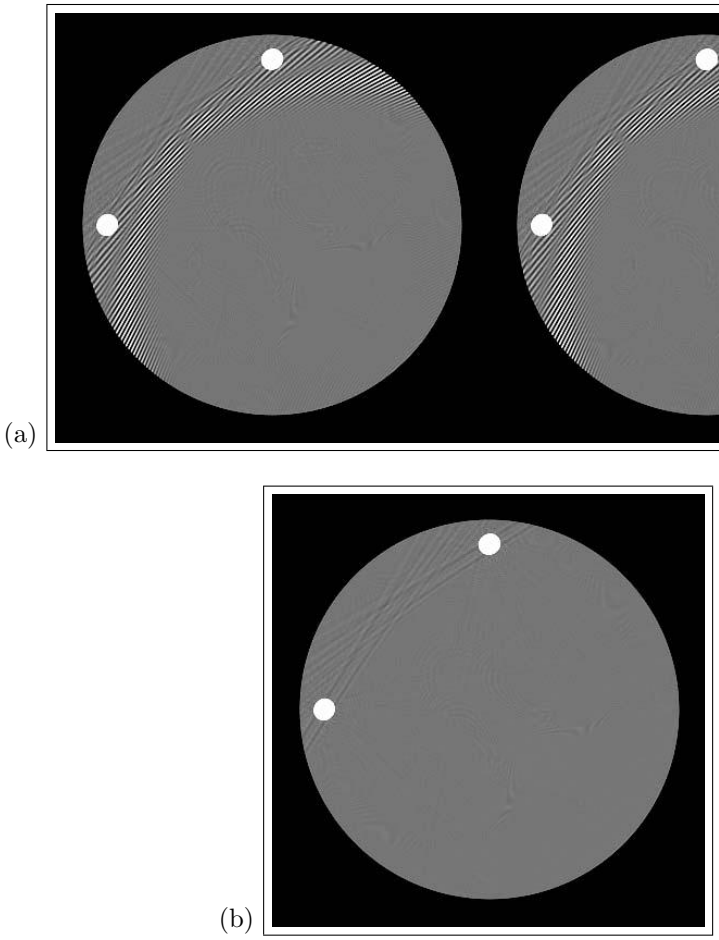

FIG. 9. *The reconstruction of the phantom from simulated third generation divergent beam projection data is shown with a window of* 5 *CT units centered about* 1000 *(water). a function of the reconstruction algorithm. It is an artifact of the fine sampling incorporated into the third generation projection simulator. Increasing the fine sampling reduces this artifact. Due to the smaller detector element, the data set for Figure 10(d) has an effective fine sampling double that of the other data sets. As a result, the amplitude of the artifact is reduced.

5. Conclusions. A multichannel sampling reconstruction algorithm has been presented to reconstruct data from a third generation CT scanner at the resolution limit of hardware detector. Initial reconstructions have validated the algorithm. Further testing is underway to evaluate the speed and image quality of this algorithm. It is expected that similar techniques can be applied to handle the flying focal spot capability of some modern scanners.

PERIODICALLY GENERATED PROPAGATING PULSES*

L. L. BONILLA†, M. KINDELAN†, AND J. B. KELLER‡

Abstract. Certain equations with integral constraints have as solutions time-periodic pulses of a fieldlike unknown while a currentlike unknown oscillates periodically with time. A general asymptotic theory of this phenomenon, the generalized Gunn effect, has been found recently. Here we extend this theory to the case of nonlinearities having only one stable zero, which is the case for the usual Gunn effect in n-GaAs. Our ideas are presented in the context of a simple scalar model where the waves can be constructed analytically and explicit expressions for asymptotic approximations can be found.

Key words. reaction-diffusion-convection equations, propagation of pulses and wavefronts, piecewise linear model, Gunn effect

AMS subject classifications. 34E15, 92C30

DOI. 10.1137/S0036139903434948

1. Introduction.

The Gunn effect is the periodic oscillation of the current in a passive external circuit attached to a dc-voltage biased semiconductor whose electron drift velocity has a single maximum as a function of the electric field (and therefore the curve of electron velocity versus electric field has negative slope for field values on a certain interval, a fact called *negative differential mobility*) [22, 25]. During each period of the oscillation, a pulse of the electric field is created at the injecting contact, moves through the semiconductor, and is annihilated at the receiving contact. While originally observed in bulk n-GaAs samples, similar current oscillations, mediated by pulse dynamics in dc-voltage biased semiconductors, have been found in many materials, several of which lack negative differential mobility [1]. Instead, other processes (impact ionization at impurities [24], nonlinear capture coefficients [21], nonlinear recombination processes, etc.) may be responsible for a current vs. local electric field characteristic curve displaying a local maximum followed by a region of negative slope (negative differential conductivity).

Propagation of pulses occurs in many systems of interest in biology, physics, and so on: morphogen pulses or spikes in activator-inhibitor reaction-diffusion systems modeling cell development or chemical reactors [16, 12, 13, 23], propagation of nerve impulses along myelinated or unmyelinated fibers [18, 20, 17], pulse propagation through cardiac cells [18], calcium release waves in living cells [9], semiconductor superlattices [8, 26], and oscillatory instabilities of the current in bulk semiconductors with an N-shaped current-field characteristic [1, 22, 25]. These distributed systems can be spatially discrete or continuous and can be described by a variety of model equations. Sometimes a pulse is created from an appropriate initial condition and reaches a stable shape, moving uniformly until it arrives at a boundary. Sometimes understanding pulse dynamics is the key to describing a more complicated evolution of the system. A good example is the Gunn effect in bulk semiconductors.

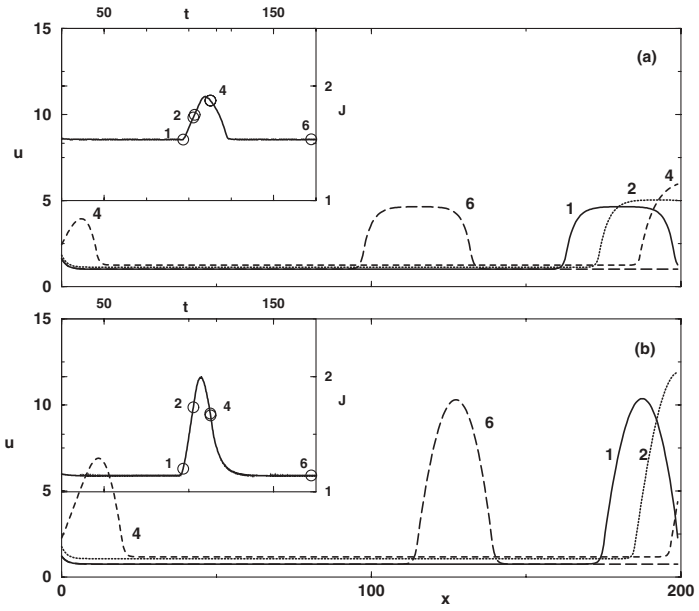

FIG. 1. *Self-sustained oscillations of the "current" $J(t)$ (see inset, which shows one period of $J(t)$) mediated by pulses of the "field" $u(x,t)$, which are solutions of the model described in section* 2. *The pulse profiles correspond to the times marked in the inset. Case* (a): *bistable source. Case* (b): *source with a single stable zero.*

While Gunn-like instabilities have been known for a long time, only recently have pulse annihilation and creation at boundaries been studied by asymptotic methods [14, 5, 6]. These theories treated the case in which the relevant nonlinear source term has two stable zeros. Then there are stable wavefronts joining these two zeros, and a moving pulse is a flat region of high field bounded by two wavefronts. The pulse changes its size if its leading and trailing wavefronts move at different speeds. Figure 1 shows the time-periodic oscillation of a "current" $J(t)$ accompanied by the repeated generation and motion of flat-top pulses of an "electric field" $u(x,t)$, which are solutions of model equations described in section 2. Figure 1(a) corresponds to the case of a bistable nonlinear source. The asymptotic analysis of the Gunn effect is based on the dynamics of such pulses [5]. However, the source term (velocity-field characteristic curve) in very relevant materials, such as bulk n-GaAs [22], wide-miniband GaAs/AlAs superlattices [11, 15], and semi-insulating GaAs [21], does not have two stable zeros. Instead, the nonlinearity has a single stable zero, so the previous theories, based on two moving wavefronts, are not valid. Figure 1(b) shows the self-sustained oscillations corresponding to this case. Can we find an asymptotic theory of pulse mediated oscillations in this case? The answer is yes, as we show in this paper.

To emphasize that our analysis applies to a class of models, we shall analyze a simpler problem than that of the Gunn effect. We will study a nonlinear reaction-diffusion-convection equation with an integral constraint [6] and a piecewise linear source term. Then the pulses can be constructed analytically, their size can change as they move, and explicit expressions for the asymptotic approximations can be found. Such a construction was used by Rinzel and Keller for the FitzHugh–Nagumo equation [20]. For Kroemer's model, a piecewise linear electron velocity was used to calculate the exact form and speed of a steadily propagating pulse [10].

The outline of the paper is as follows. Section 2 presents our simplified model. It also reviews the key ideas of previous asymptotic theories, valid for an N-shaped nonlinearity with two stable zeros. Section 3 discusses the construction of stationary solutions, and the kinematics of wave fronts, in the limit of long samples. When the nonlinearity is piecewise linear, the pulses can be found analytically. Section 4 discusses the dynamics of a single pulse moving from the injecting to the receiving boundary. We show that the pulse changes form and speed adiabatically, following the instantaneous value of the current. In section 5, we complete our description of the oscillations by explaining what happens when the pulse reaches the receiving boundary and how a new pulse is created at the injecting boundary. Section 6 contains our conclusions. The appendices are devoted to technical matters.

2. Simple scalar model. The model consists of a one-dimensional nonlinear parabolic equation for $u(x,t)$ (the "electric field") with an unknown forcing term $J(t)$ (the "current"). There is also an integral constraint (the "voltage bias condition"), as well as boundary and initial conditions,

$$\frac{\partial u}{\partial t} + K\,\frac{\partial u}{\partial x} = \frac{\partial^2 u}{\partial x^2} + J - g(u), \quad 0 < x < L, \tag{2.1}$$

$$\frac{1}{L}\int_0^L u(x,t)\,dx = \phi, \tag{2.2}$$

$$u(0,t) = \rho\,J(t), \qquad \rho > 0, \qquad \frac{\partial u}{\partial x}(L,t) = 0, \tag{2.3}$$

$$u(x,0) = f(x) \geq 0, \qquad 0 < x < L. \tag{2.4}$$

Here K, ρ, and ϕ are positive constants.

This model becomes the Kroemer model of the Gunn effect if the advection constant K in (2.1) is replaced by $g(u)$ [2, 3, 4, 14, 22, 25]. For the Kroemer model, existence and uniqueness of solutions have been studied by Liang [19]. Furthermore, linear stability of the stationary and moving pulse solutions has been analyzed in [3]; see also [22, 25]. A bifurcation analysis of the self-sustained oscillations due to pulse dynamics near critical values of ϕ can be found in [4]. Asymptotic analyses of the Gunn effect for the Kroemer model with a bistable $g(u)$ can be found in [14, 5].

2.1. Bistable source $g(u)$. The simplest case to consider is that of an N-shaped nonlinearity $g(u)$ (the "velocity-field characteristic") for $u \geq 0$, with a local maximum $g_M = g(u_M)$, $u_M > 0$, followed by a local minimum $g_m = g(u_m) > 0$, $u_m > u_M$. Then $J - g(u)$ may have up to three positive zeros for $J > 0$, namely, $u_1(J) < u_2(J) < u_3(J)$. For large enough L and K, $g_M/u_M < \rho < g_m/u_m$, and for ϕ in a certain subinterval of $(u_M, u_3(g_M))$, there are stable time periodic solutions of (2.1)–(2.3) of Gunn type. As shown in Figure 1(a), while $J(t)$ oscillates periodically, pulses of $u(x,t)$ are created at $x = 0$, move towards $x = L$, and disappear there.

The analysis of the model is simple in the asymptotic limit

$$0 < \epsilon \equiv \frac{1}{L} \ll 1. \tag{2.5}$$

In this limit (2.1)–(2.2) may be written as

$$\frac{\partial u}{\partial s} + K\,\frac{\partial u}{\partial y} = \epsilon \frac{\partial^2 u}{\partial y^2} + \frac{J - g(u)}{\epsilon}, \tag{2.6}$$

$$\int_0^1 u(y,s)\,dy = \phi, \tag{2.7}$$

where

$$y = \epsilon x, \quad s = \epsilon t. \tag{2.8}$$

Equation (2.6) is a parabolic equation with fast reaction and slow diffusion terms. As $\epsilon \to 0+$, $u(y,s)$ is typically a piecewise constant function taking on the *order* 1 *values* $u_1(J)$ or $u_3(J)$ in intervals of length $y = O(1)$. The extrema of these intervals are typically moving internal layers. These layers are important because they bound pulses, and the self-sustained oscillation we want to describe is due to recycling and motion of pulses at the boundaries. A pulse is a region where u is $u_3(J)$, separated by moving wavefronts from two other regions where u is $u_1(J)$. There are two wavefronts bounding the pulse. In the backfront, u increases from $u_1(J)$ to $u_3(J)$; this front moves with a speed $c_+(J)$. The forefront moves at speed $c_-(J)$, and in it u decreases from $u_3(J)$ to $u_1(J)$. Forefront and backfront are heteroclinic trajectories connecting the two saddles $(u_1(J), 0)$ and $(u_3(J), 0)$ in an appropriate phase plane $(u, du/d\chi)$, where $\chi = [y - Y(s)]/\epsilon$ is a moving coordinate ($\chi = 0$ at the wavefront and $dY/ds = c_\pm(J)$). The instantaneous value of $J(s)$ is determined by using the integral condition (2.7). Typically J obeys the simple equation

$$\frac{dJ}{ds} = A(J)\,[n_+ c_+(J) - n_- c_-(J)], \tag{2.9}$$

where $A(J) > 0$ is a known function of J, and n_+ and n_- are the numbers of wavefronts with increasing and decreasing u profiles, respectively. For high-field domains, $n_+ - n_- = 0, 1$ [6, 5]. The fixed points of (2.9) correspond to the equal area rule

$$\int_{u_1}^{u_3} [g(u) - c]\,du = 0 \tag{2.10}$$

if $n_+ = n_-$, or to possible plateaus in the shape of $J(s)$ otherwise. Many questions on the stability of the pulses and their evolution can be simply answered by analyzing (2.9) and using the asymptotic procedure explained in [6, 5]. The description of pulse creation and annihilation at the boundaries requires a finer analysis, as explained in [6, 5].

2.2. Saturating source. If $g(u)$ saturates, i.e., $g(u) \to$ constant as $u \to \infty$, no $u_3(J)$ exists and the previous construction is no longer possible. What is the correct asymptotic description of a pulse in this case? Let us anticipate the answer here. As Figure 1(b) shows, a pulse is a traveling wave whose profile has a single maximum, and tends to $u = u_1(J)$ as $x \to \pm\infty$. The pulse is bounded by a leading front (forefront, moving at speed c_-) and a trailing front (backfront, moving at speed c_+). Two parameters uniquely determine the pulse: its maximum height, u_m, and the instantaneous value of J. Given u_m and J, we can find the wavefronts enclosing the pulse by simple phase plane constructions. Consider the phase plane $(u, du/d\chi)$,

$\chi = x - X(t)$, where $X(t)$ is the instantaneous position of a wavefront and dX/dt its speed. There is a unique speed $c_+ = c_+(J, u_m)$ for which a separatrix issuing from the saddle $(u_1(J), 0)$ on the upper half plane reaches the u axis at $(u_m, 0)$. This separatrix constitutes the backfront of the pulse, and a similar construction supplies its forefront moving at speed $c_-(J, u_m)$. In general, $c_+ \neq c_-$, which implies that our pulse changes its size as it moves. How do we characterize the dynamics of pulses?

Suppose that there is a single pulse moving in the sample. We need to determine the instantaneous values of J and u_m, for they characterize the pulse completely . The pulse width, l, changes as $dl/dt = c_- - c_+$. On the other hand, l may be determined by a line integral on the corresponding phase plane trajectories which form the pulse. Then $l = l(J, u_m)$. The dc bias condition yields a connection between u_m and J, $u_m = U(J)$. Then the pulse width is a function of J only, $\varphi(J) = l(J, U(J))$. Therefore, since $dl/ds = \varphi'(J)\, dJ/ds = c_- - c_+$, we get

$$\frac{dJ}{ds} = \frac{c_+(J, U(J)) - c_-(J, U(J))}{-\varphi'(J)}. \tag{2.11}$$

Typically the fixed point of this equation, $J = J^*$, is such that $c_+ = c_-$ is a globally stable solution, so that J tends exponentially fast to J^*. The corresponding pulse moves steadily without changing its size. This pulse is the homoclinic orbit in the phase plane, usually given by an equal-area rule, and has been exhaustively studied by previous authors. Notice that the present construction explains why this steadily moving pulse is stable, thereby clarifying an old issue at the heart of the Gunn effect [25, 2]. When the pulse reaches the receiving contact, a different stage of the Gunn oscillation begins. This stage and others needed to fully describe the Gunn oscillation will be explained later.

A subtle point follows. Due to the integral condition (2.2), the pulse height and width (in the (y, s) scales) are $O(\epsilon^{-\frac{1}{2}}) \gg 1$ and $O(\epsilon^{\frac{1}{2}})$, respectively, while outside the pulse, $u = u_1 = O(1)$ and $J = O(1)$. Thus our leading order approximation for $u(y, s)$ is not uniformly of the same order in space. Successive approximations of a single pulse lead to the following ansatz for u:

$$u(y, s; \epsilon) \sim u^{(0)}(y, s; \epsilon) + \epsilon\, u^{(1)}(y, s; \epsilon).$$

Here each $u^{(j)}(y, s; \epsilon)$ may be of different order in ϵ for different values of the space and time variables. However, we shall impose that

$$\frac{u^{(1)}}{u^{(0)}} = O(1)$$

uniformly in y and s as $\epsilon \to 0+$. This situation results in a changing (self-adjusting) time scale for the evolution of J described by (2.11). See [7] for the description of a similar situation in combustion theory.

3. Boundary layers and wavefronts. The model (2.1)–(2.4) was introduced in order to argue that the asymptotics of the Gunn effect is universal within a class of models [6]. The nonlinearity $g(u)$ was originally N-shaped: it had three branches for $u > 0$ (with a maximum at $u_M > 0$ and a minimum at $u_{\min} > u_M$ such that $g(u_M) > g(u_{\min}) > 0$, with $g(u) \to \infty$ as $u \to \infty$). In the present paper, we shall assume that $g(u)$ is a smooth function having a single maximum at $u_M > 0$, $g(u_M) = g_M > 0$, such that $g'(0) = \beta > 0$, and $\lim_{u\to\infty} g(u) = \alpha \in (0, g_M)$. To

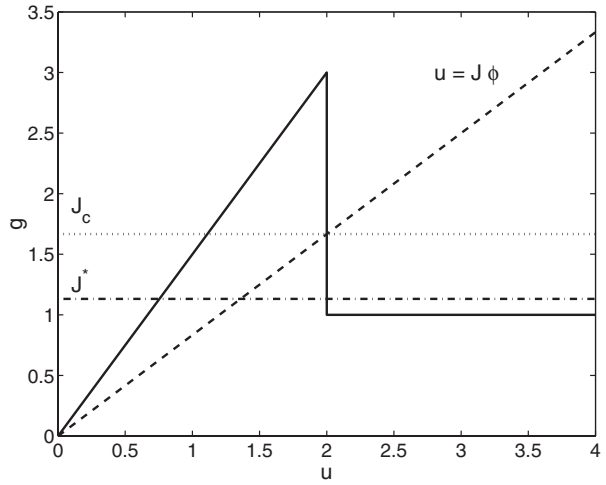

FIG. 2. *The nonlinearity function $g(u)$ (solid) and the curve corresponding to the boundary conditions $J = u/\rho$ (dashed). The parameter values are $\phi = 1.6$, $L = 200$, $K = 2.0$, $u_M = 2.0$, $\beta = 1.5$, $\alpha = 1.0$, $\rho = 1.2$.*

obtain explicit analytic expressions, we shall use a piecewise linear version of $g(u)$,

$$g(u) = \beta u\,\theta(u_M - u) + \alpha\,\theta(u - u_M), \tag{3.1}$$

where $\theta(x)$ is the Heaviside unit step function. See Figure 2, where we have also shown a typical straight line $J = u/\rho$ which gives the value of u at the left boundary. Notice that the straight line intersects $g(u)$ at $(u_M, \rho u_M)$, with $\alpha < \rho u_M < g_M$. We want to find stable solutions $(u(x,t), J(t))$ of (2.1) and (2.2) under the boundary conditions (2.3) and the initial condition (2.4) for appropriate positive values of the bias ϕ in the asymptotic limit $L \to \infty$.

3.1. Outer limit and boundary layers. If $0 < \phi < u_M$, there is a single stationary solution of (2.1)–(2.3) which is easily constructed. Let $y = x/L \equiv \epsilon x$, $0 < \epsilon \ll 1$. Introducing this scaling in (2.1) yields the leading order equation

$$J - g(u) = 0 \tag{3.2}$$

outside the boundary layers at $y = 0, 1$. For $0 < J < g_M$ and $0 < y < 1$, (3.2) has the solutions $u_1(J) < u_2(J)$. Of these we may choose $u = u_1(J)$, $0 < y < 1$, as the outer limit. Inserting it into (2.2), we find $u_1(J) + O(\epsilon) = \phi$ and then (3.2) yields

$$J = g(\phi). \tag{3.3}$$

For the piecewise linear $g(u)$, $J = \beta\,\phi$, and $u_1(J) = J/\beta$.

The boundary layers at $y = 0, 1$ are solutions of the problems

$$\frac{\partial^2 U}{\partial \xi^2} \mp K\frac{\partial U}{\partial \xi} + J - g(U) = 0, \quad 0 < \xi < \infty, \tag{3.4}$$

$$U(0) = \rho J, \quad U(\infty) = u_1(J). \tag{3.5}$$

Here $\xi = x = y/\epsilon$ for the injecting boundary layer at $y = 0$, and $\xi = L - x = (1-y)/\epsilon$ for the receiving boundary layer at $y = 1$. The minus (resp., plus) sign in (3.4)

corresponds to the injecting (resp., receiving) boundary. Clearly, the shape of the unique solution of (3.4) and (3.5) (for $\xi = x$) depends on whether J is smaller or larger than $J = J_c = u_M/\rho$. When $0 < J < J_c$, the boundary layer profile monotonically decreases from $u = \rho J$ to $u_1 = J/\beta$. For the piecewise linear $g(u)$, we have

$$U(\xi) = \frac{J}{\beta} + \left(\rho J - \frac{J}{\beta}\right) \exp\left(-\frac{\sqrt{K^2 + 4\beta} \mp K}{2}\,\xi\right), \tag{3.6}$$

$$\int_0^\infty (U - u_1)\, d\xi = \frac{2\left(\rho J - \frac{J}{\beta}\right)}{\sqrt{K^2 + 4\beta} \mp K}. \tag{3.7}$$

However, if $J > J_c$, the boundary layer profile reaches a maximum before decreasing to $u_1 = J/\beta$. Numerical simulations show that in this case, the stationary solution of the model becomes unstable to Gunn-type oscillations. Given (3.3), this occurs for $\phi > u_1(J_c)$.

3.2. Wavefronts.

3.2.1. Bistable source. Let us first review how to compute the wavefronts when $g(u)$ is N-shaped. Then (3.2) has three solutions $u_1(J) < u_2(J) < u_3(J)$ for $g(u_m) < J < g(u_M)$. As explained in [6], the building blocks of the Gunn-oscillation asymptotics are wavefronts connecting $u_1(J)$ and $u_3(J)$. These wavefronts adjust themselves instantaneously to the value of J, as this unknown evolves on a slower time scale (see below). A wavefront centered at $x = X_\pm(t)$ is a monotone function of $\chi = x - X_\pm(t)$ such that

$$u(-\infty; c_+) = u_1(J), \quad u(+\infty; c_+) = u_3(J) \quad \text{and}$$
$$u(-\infty; c_-) = u_3(J), \quad u(+\infty; c_-) = u_1(J).$$

For the simple model used here, there is a relation between the wavefronts $u(\chi; c_+)$ and $u(\chi; c_-)$.

THEOREM 1. *Let $u(\chi; c_\pm)$ be the wavefront satisfying*

$$\frac{d^2u}{d\chi^2} - (K - c_\pm)\frac{du}{d\chi} + J - g(u) = 0, \tag{3.8}$$

$$u(-\infty; c_+) = u_1(J), \qquad u(+\infty; c_+) = u_3(J), \tag{3.9}$$

$$u(-\infty; c_-) = u_3(J), \qquad u(+\infty; c_-) = u_1(J), \tag{3.10}$$

where $\chi = x - X_\pm(t)$ ($X_\pm$ is the position of the front at time t, determined by imposing $u(0) = u^0$. $dX_\pm/dt = c_\pm$). Then we have

$$u(\chi; c_-) = u(-\chi; c_+), \qquad c_+ + c_- = 2K. \tag{3.11}$$

The proof is evident. This theorem shows that we only need to construct $u(\chi; c_+)$ and find c_+ in order to have $u(\chi; c_-)$ and c_-.

3.2.2. Saturating source. Now let $g(u)$ be a function with only two branches such as (3.1). A wavefront is the only monotone trajectory connecting $(u_1(J), 0)$ and a given point on the u axis $(u_m, 0)$. There is again a symmetry result for these wavefronts.

THEOREM 2. *Let $u(\chi;c_+)$ be the wavefront satisfying* (3.8), *$\partial u/\partial\chi > 0$ for $-\infty < \chi \equiv x - X_+(t) < \chi_m$, and*

$$\begin{aligned} u(-\infty;c_+) &= u_1(J), \qquad u(0;c_+) = u^0, \\ u(\chi_m;c_+) &= u_m, \qquad \frac{\partial u}{\partial\chi}(\chi_m;c_+) = 0. \end{aligned} \tag{3.12}$$

Here $dX_+/dt = c_+$, and $2\chi_m = l(J,u_m) > 0$ is a function of J and u_m. Then the wavefront satisfying (3.8), *$\partial u/\partial\chi < 0$ for $-\chi_m < \chi \equiv x - X_-(t) < \infty$, $c_- = dX_-/dt$, and*

$$\begin{aligned} u(-\chi_m;c_-) &= u_m, \qquad \frac{\partial u}{\partial\chi}(-\chi_m;c_-) = 0, \\ u(0;c_-) &= u^0, \qquad u(+\infty;c_-) = u_1(J), \end{aligned} \tag{3.13}$$

is such that (3.11) *holds.*

Again the proof is immediate.

Let us now choose a certain $u_m = U(J)$ for each $\phi > u_M$ so that the bias condition (2.2) holds for a pulse made out of the following:

- a backfront $u(\chi;c_+)$ at $x = X_+(t)$, $\chi = x - X_+(t)$; and
- a forefront $u(-\chi;c_+)$ at $X_- = X_+ + 2\chi_m$.

Now $\chi = x - X_-(t)$. The pulse $u(\chi;c_+)$ can be constructed explicitly for the piecewise linear $g(u)$ of (3.1). If we choose $u^0 = u_M$, the solution of (3.8) and (3.9) which is continuous and has a continuous first derivative at $\chi = 0$ is

$$u(\chi;c_+) = u_1(J) + [u_M - u_1(J)]\, e^{\lambda_+\chi}, \quad \chi < 0, \tag{3.14}$$

$$u(\chi;c_+) = u_M + \frac{J-\alpha}{K-c_+}\,\chi + B_+\left[e^{(K-c_+)\chi} - 1\right], \quad \chi > 0. \tag{3.15}$$

Here $u_1(J) = J/\beta$, and

$$\lambda_+ = \frac{K-c_+}{2} + \sqrt{\left(\frac{K-c_+}{2}\right)^2 + \beta}, \tag{3.16}$$

$$B_+ = \frac{1}{K-c_+}\left[\lambda_+[u_M - u_1(J)] - \frac{J-\alpha}{K-c_+}\right], \tag{3.17}$$

$$\begin{aligned} \chi_m &= \frac{1}{K-c_+}\,\ln\left[-\frac{J-\alpha}{(K-c_+)^2\,B_+}\right] \\ &= -\frac{1}{K-c_+}\,\ln\left[1 - \frac{\lambda_+(u_M-u_1)(K-c_+)}{J-\alpha}\right], \end{aligned} \tag{3.18}$$

$$u_m = u_M + \frac{J-\alpha}{K-c_+}\,\chi_m + B_+\left[e^{(K-c_+)\chi_m} - 1\right]. \tag{3.19}$$

If these expressions are inserted in the bias condition (2.2), c_+, χ_m, and u_m may be determined as functions of J for a fixed ϕ. Figures 3 and 4 show the phase planes and the trajectories corresponding to $u(\chi;c_+)$ and $u(\chi;c_-)$, respectively, for a given value of $J = 1.3$. Figure 5 shows χ_m and u_m as functions of J.

There are two important approximations to the wavefronts of Theorem 2, which yield either approximately triangular pulses ($c_+ \neq c_-$, $u_m \gg 1$) or the homoclinic pulse ($c_+ = c_- = K$). These two limiting cases are described in detail in Appendix A.

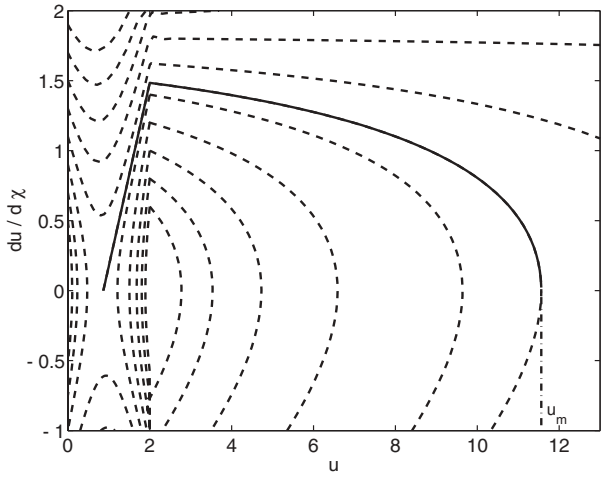

FIG. 3. *Phase plane* $(u, du/d\chi)$ *and trajectory corresponding to* $u(\chi; c_+)$ *for* $J = 1.3$, $c_+ = 1.8359$. *Other parameter values are as in Figure* 2.

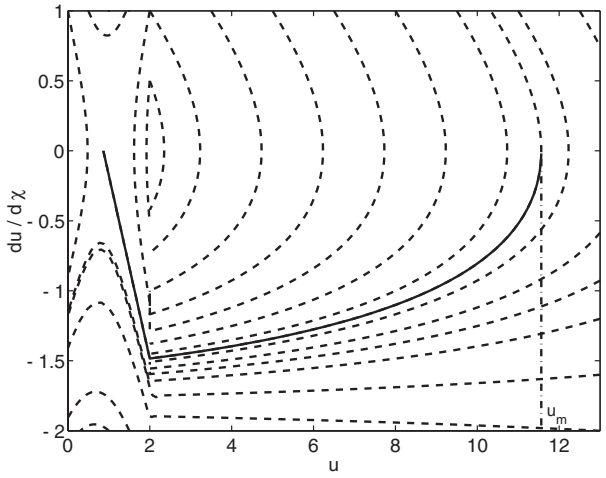

FIG. 4. *Phase plane* $(u, du/d\chi)$ *and trajectory corresponding to* $u(\chi; c_-)$ *for* $J = 1.3$, $c_- = 2.1641$. *Other parameter values are as in Figure* 2.

4. Pulse dynamics.

4.1. One pulse far from the boundaries. Let us consider a single pulse moving far from the boundaries, as described in the previous section. Its height and width are established by imposing the integral condition (2.2). The result will show that the pulse is a tall and narrow moving layer which changes size as it moves. At certain stages of the periodic Gunn oscillation (see below), the pulse height is $u = O(\epsilon^{-\frac{1}{2}})$ and its width is $\Delta y = O(\epsilon^{\frac{1}{2}})$, so that the pulse excess area (in y space units) is $O(1)$. The inner core of the pulse contributes an order 1 amount to the bias whereas its exponential tails approaching $u_1(J)$ yield an $O(\epsilon)$ correction to its excess area. Thus we suggest a decomposition of the solution u into an outer solution valid outside the pulse and boundary layers, and inner solutions comprising the front(s)

and boundary layers. In this section, we shall calculate the leading order term in each asymptotic expansion explicitly. The first correction to these results can be found in Appendix B.

4.1.1. Outer solution. The outer solution is

$$u^{outer} = u^{(0)}(y,s) + \epsilon\, u^{(1)}(y,s) + O(\epsilon^2), \tag{4.1}$$

$$J = J^{(0)}(s) + \epsilon\, J^{(1)}(s) + O(\epsilon^2). \tag{4.2}$$

Here $u^{(0)} = O(1)$ yields an order 1 contribution to the integral condition (2.2), of the same order as that provided by integration of the excess area of the pulse inner core. $\epsilon\, u^{(1)}$ yields an order ϵ contribution to (2.2), of the same order as that provided by integration of the excess area of the pulse tails. Inserting this ansatz into (2.6), we obtain

$$J^{(0)} - g(u^{(0)}) = 0, \tag{4.3}$$

$$J^{(1)} - g'(u^{(0)})\, u^{(1)} = \frac{\partial u^{(0)}}{\partial s} + K\, \frac{\partial u^{(0)}}{\partial y}. \tag{4.4}$$

Solving (4.3) and (4.4) yields

$$u^{(0)} = u_1(J^{(0)}) = \frac{J^{(0)}}{\beta}, \tag{4.5}$$

$$u^{(1)} = \frac{J^{(1)} - \frac{1}{g_1'}\frac{dJ^{(0)}}{ds}}{g_1'} = \frac{1}{\beta}\left(J^{(1)} - \frac{1}{\beta}\,\frac{dJ^{(0)}}{ds}\right). \tag{4.6}$$

$J^{(0)}$ and $J^{(1)}$ will be found later from the integral constraint.

4.1.2. Two-term description of the pulse. The pulse described in the previous section may be considered a moving inner layer solution. Its height is much larger than 1 and its width much smaller than 1 (the precise orders will be determined later). We shall assume

$$u^{inner} \sim P^{(0)}(y,s;\epsilon) + \epsilon\, P^{(1)}(y,s;\epsilon), \tag{4.7}$$

where $P^{(0)}$ is the pulse solution of (3.8) described in Theorem 2:

$$\begin{aligned} P^{(0)}(y,s;\epsilon) &= u(x - X_+; c_+)\,\theta[\chi_m - (x - X_+)] \\ &\quad + u(X_+ + 2\chi_m - x; c_+)\,\theta[x - X_+ - \chi_m]. \end{aligned} \tag{4.8}$$

$P^{(0)}(y,s;\epsilon)$ and $P^{(1)}(y,s;\epsilon)$ depend on ϵ in such a way that

$$\frac{P^{(1)}(y,s;\epsilon)}{P^{(0)}(y,s;\epsilon)} = O(1) \quad \text{as} \qquad \epsilon \to 0+$$

uniformly in y, s. The inner expansion (4.7) is chosen so that the pulse inner core in $P^{(0)}$ yields an order 1 contribution to the bias condition, whereas its tails together with the inner core of $\epsilon P^{(1)}$ yield an $O(\epsilon)$ contribution. The latter is of the same order as the contribution of the outer solution, $\epsilon u^{(1)}$, to the bias.

In (4.8), the location of the fronts and their velocities are

$$X_+ \sim X_+^{(0)}(t) + \epsilon X_+^{(1)}(t),$$
$$c_+ \sim c_+^{(0)} + \epsilon c_+^{(1)}, \tag{4.9}$$

and similarly for X_- and c_-. Inserting (4.2) and (4.7)–(4.9) in (2.1) and (3.9), we obtain for the trailing front

$$\frac{\partial^2 P^{(0)}}{\partial \chi^2} - (K - c_\pm^{(0)}) \frac{\partial P^{(0)}}{\partial \chi} + J^{(0)} - g(P^{(0)}) = 0, \tag{4.10}$$
$$P^{(0)}(-\infty; c_+^{(0)}) = u^{(0)} = u_1, \quad P^{(0)}(0; c_+^{(0)}) = u_M,$$

$$P^{(0)}(\chi_m; c_+^{(0)}) = u_m, \qquad \frac{\partial P^{(0)}}{\partial \chi}(\chi_m; c_+^{(0)}) = 0, \tag{4.11}$$

whose solution is (4.8), and

$$\frac{\partial^2 P^{(1)}}{\partial \chi^2} - (K - c_\pm^{(0)}) \frac{\partial P^{(1)}}{\partial \chi} - g'(P^{(0)}) P^{(1)} = \frac{\partial P^{(0)}}{\partial s} - J^{(1)} - c_\pm^{(1)} \frac{\partial P^{(0)}}{\partial \chi}, \tag{4.12}$$

$$P^{(1)}(-\infty; c_+^{(0)}) = u^{(1)}, \qquad \frac{\partial P^{(1)}}{\partial \chi}(\chi_m; c_+^{(0)}) = 0. \tag{4.13}$$

The leading front of the pulse obeys similar expressions. The correction $P^{(1)}$ is calculated in Appendix B, in which explicit formulas for piecewise linear $g(u)$ are given.

4.2. General equation for $J^{(0)}$. Using Theorem 2, we can calculate the bias condition for a single pulse moving far from the boundaries as

$$\begin{aligned}\phi = {} & u_1(J^{(0)}) + 2\epsilon \int_0^{\chi_m} (P^{(0)} - u_1)\, d\chi \\ & + 2\epsilon \int_{-\infty}^{0} (P^{(0)} - u_1)\, d\chi + \epsilon \frac{J^{(1)} - g_1' J_s^{(0)}}{{g_1'}^2} \\ & + 2\epsilon^2 \int_0^{\chi_m} \left(P^{(1)} - \frac{J^{(1)} - g_1' J_s^{(0)}}{{g_1'}^2} \right) d\chi \\ & + \epsilon \int_0^{\infty} [U_L(\xi) - u_1]\, d\xi \\ & + \epsilon \int_0^{\infty} [U_R(\xi) - u_1]\, d\xi + O(\epsilon^2).\end{aligned} \tag{4.14}$$

Here the bias is the sum of the areas of the regions inside and outside the moving pulse. The leading order contributions to these areas are the first two terms on the right-hand side, which are of order 1. They are (i) the leading order contribution of the outer solution and (ii) the leading order contribution of the inner core of the pulse. The other terms are $O(\epsilon)$ and correspond to the following:

(i) the tails of the pulse to leading order,

$$2\epsilon \int_{-\infty}^{0} (P^{(0)} - u_1)\, d\chi = \frac{2\epsilon(u_M - u_1)}{\lambda_+},$$

(ii) the second order contribution to the outer solution,

(iii) the second order contribution to the area of the inner core of the pulse,

$2\epsilon^2 \int_0^{\chi_m} P^{(1)}\, d\chi = O(\epsilon)$ (we have ignored a much smaller term of order $\epsilon^2\chi_m$), (iv) the layer at the left boundary, (3.6) and (3.7):

$$\epsilon \int_0^{\infty} (U_L - u_1)\, d\xi = \frac{2\epsilon\,(\rho - \beta^{-1})\, J^{(0)}}{\sqrt{K^2 + 4\beta} - K}.$$

The area of the injecting (left) boundary layer becomes of order 1 when a new pulse is being shed; otherwise it is of order ϵ, as indicated above.

If the pulse is far from the boundaries, only the first two terms are of order 1, and we have

$$\begin{aligned}\phi &= u_1(J^{(0)}) + 2\epsilon \left[\chi_m(u_M - u_1 - B_+)\right. \\ &\qquad \left. + \frac{(J^{(0)} - \alpha)\chi_m^2}{2(K - c_+^{(0)})} + \frac{B_+ \left(e^{(K - c_+^{(0)})\chi_m} - 1\right)}{K - c_+^{(0)}}\right] + O(\epsilon) \\ &= u_1 + 2\epsilon \left[\chi_m(u_M - u_1 - B_+) + \frac{(J^{(0)} - \alpha)\chi_m^2}{2(K - c_+^{(0)})}\right. \\ &\qquad \left. + \frac{B_+\lambda_+(u_M - u_1)}{J^{(0)} - \alpha}\right] + O(\epsilon). \qquad (4.15)\end{aligned}$$

Now we can proceed as sketched in section 2. Equation (3.18) allows us to obtain $c_+^{(0)}$ as a function of $J^{(0)}$ and χ_m,

$$c_+^{(0)} = \Xi(J^{(0)}, \chi_m), \qquad (4.16)$$

for a fixed value of ϕ. Inserting this function in (4.15), we can determine χ_m as a function of $J^{(0)}$. Then (3.19) yields u_m as a function of $J^{(0)}$. The results are certain functions

$$\chi_m = \frac{\varphi(J^{(0)})}{2}, \quad u_m = U(J^{(0)}) \qquad (4.17)$$

that have been depicted in Figure 5. Time differentiation of $2\chi_m = \varphi(J^{(0)})$ yields (2.11)

$$\frac{dJ^{(0)}}{ds} = 2\frac{c_+^{(0)}(J^{(0)}, U(J^{(0)})) - K}{-\varphi'(J^{(0)})}, \qquad (4.18)$$

which describes the time evolution of $J^{(0)}$. Provided that $J^{(0)}(0) > J^*$, $J^{(0)}$ decreases exponentially fast to J^* such that $c_+^{(0)} = c_-^{(0)} = K$. The pulse then moves at constant $J^{(0)} = J^*$ and speed K, and it is a homoclinic orbit of the phase plane (3.8) with $c = K$, as shown in Figure 6.

Figure 7 compares the leading order asymptotic solution with the numerical solution. The upper part shows the time evolution of $J(t)$ and the lower part $u(x,t)$ at the times marked in the upper figure. Notice that initially $J(t)$ decreases exponentially fast to J^*. Consider an instant (point 6) at which the wave is fully developed and far from the boundaries. We observe that the profile of the asymptotic solution

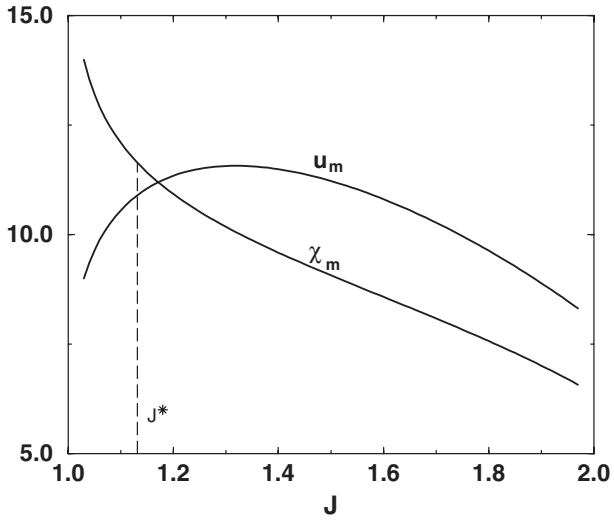

FIG. 5. *Half-width χ_m and maximum height u_m of the single pulse as a function of J for the same parameter values as in Figures 2–4.*

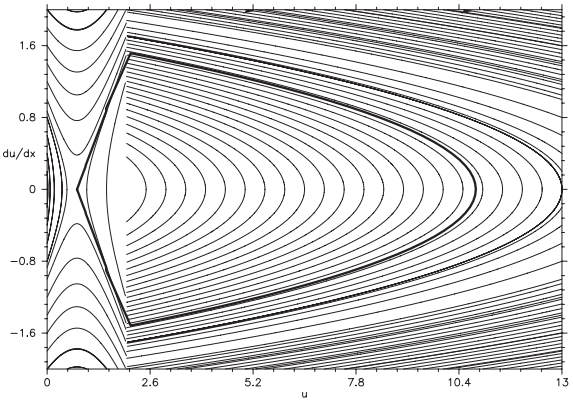

FIG. 6. *Phase plane $(u, du/d\chi)$ and homoclinic orbit for $J^* = 1.13182$, $c = 2$. Other parameter values are as in Figure 2.*

has a larger height and is slightly thinner than the numerical solution. Why? We have neglected $O(\epsilon)$ terms (boundary layers, wave tails, etc.) when calculating the integral condition with the leading order asymptotic solution. Then $J^{(0)}(t)$ is slightly larger than the numerically calculated $J(t)$. The asymptotic profile fully agrees with the homoclinic solution described in Appendix A by (A.10), (A.11), and (A.12) (also calculated excluding order ϵ effects).

The previous ideas are correct if we can show that $J^{(0)}$ evolves on a slow time scale, say $\sigma = \sqrt{\epsilon}(t - t_0)$ or $\tau = \epsilon(t - t_0)$. To see this we should analyze (4.15) and the previous equations with a little more care. We shall show that there are two limiting cases for which the pulse can be easily calculated and (2.11) explicitly obtained to leading order:

- $J^{(0)} - J^* = O(1)$, $K - c_+^{(0)} = O(1)$, and $(J^{(0)} - \alpha)\chi_m \gg 1$. The limiting pulse is a triangular wave formed by pieces of phase plane trajectories which

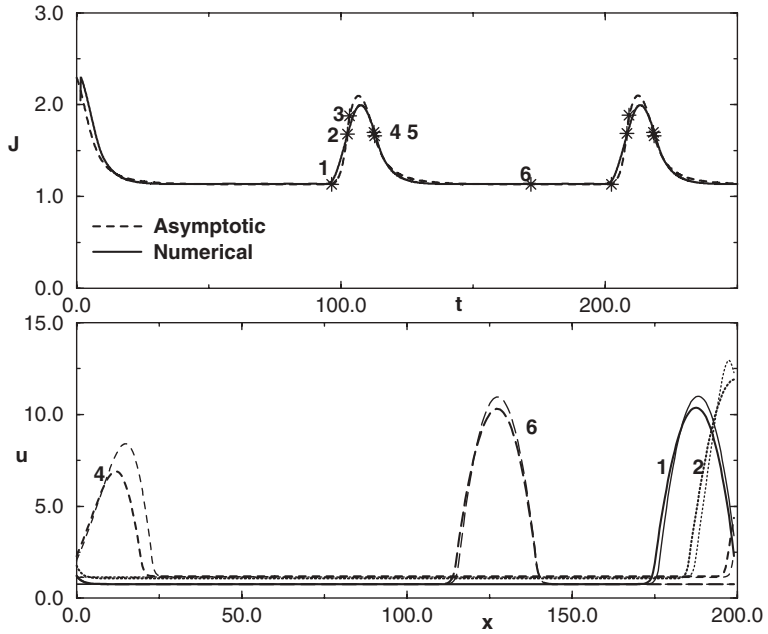

FIG. 7. *Upper: Time evolution of J. Times marked correspond to the following:* (1) *wave reaches receiving contact,* (2) *J reaches J_c,* (3) *$\chi_m < \chi_L$,* (4) *wave completely exits,* (5) *$J < J_c$,* (6) *fully developed wave. Lower: Profiles of $u(x,t)$ at the times marked in the upper figure.*

do not tend exponentially to infinity as $\chi \to \pm\infty$.

- $(K - c_+^{(0)}) \ll (J^{(0)} - \alpha) \ll 1$, $\chi_m \gg 1$. The limiting pulse is the homoclinic trajectory with $c = K$.

In the first case, $J^{(0)}$ evolves on the slow time scale $\sigma = \sqrt{\epsilon}(t - t_0)$. In the second case, the time over which $J^{(0)}$ varies appreciably is $o(\epsilon^{-1})$. One period of the Gunn oscillation contains stages during which these limiting cases are good approximations to (2.11). In fact the Gunn oscillation may be considered as transitions from one limiting case to the other depending on the number of pulses existing at the time. Then $J^{(0)}$ changes slowly with time, which justifies our wavefront constructions.

Appendix C analyzes the dynamics of pulses corresponding to the two limiting cases of triangular and homoclinic pulses. At this point, we call attention to two peculiar features of our results:

1. Our leading order approximation for the solution is of order one outside a pulse, but it is much larger inside it: of order $\epsilon^{-\frac{1}{2}}$.
2. The proper time scale for the variation of J is $\epsilon^{\frac{1}{2}}t$ if the pulse may be approximated by a triangular wave. It is slower as the pulse approaches a homoclinic pulse. Both approximations are limits of the same equation, (2.11). Thus this equation contains more than one asymptotic limit and its time scale is changing as time changes.

5. Pulse dynamics near the boundaries. In the previous section, we described the dynamics of a single pulse far from the boundaries. Basically the pulse approaches the homoclinic pulse on a slow time scale: at each time on the scale t the pulse follows adiabatically the instantaneous value of J. J changes on the scale $\sigma = \sqrt{\epsilon}t$ or even more slowly as described by (2.11), where φ is a function of J and ϵ

($\varphi(J)$ is of order $\epsilon^{-\frac{1}{2}}$ or larger). In this section we shall describe what occurs when the pulse reaches the receiving boundary at $x = L$ and beyond, until a period of the Gunn oscillation is completed.

5.1. Pulse disappearing through the receiving boundary. Let us assume that a single pulse has reached its asymptotic shape ($J^{(0)} = J^*$) and advances with speed K until its forefront reaches $X_- = L$ at time t_1. Afterwards, it begins leaving the sample. As time elapses the wave *exits* through the receiving boundary, and therefore the area under the wave decreases. Since the total area has to satisfy the bias condition, this loss of area has to be compensated by a corresponding increase in u_1 so that (2.2) still holds.

Let us denote by u_L the value of the pulse inner solution $P^{(0)}(y, s)$ at the receiving boundary. u_L is obtained from (3.15) for $u(x - X_-^{(0)}; c_-^{(0)}) = u(X_-^{(0)} - x; c_+^{(0)}) = u(2\chi_m - \chi; c_+^{(0)})$ when $\chi - 2\chi_m = L - X_-^{(0)}$. The corresponding argument of $u(X_-^{(0)} - x; c_+^{(0)})$ is $\chi_L = X_-^{(0)} - L > 0$. When $0 < \chi_L < \chi_m$, the bias condition (2.2) yields

$$\phi = u_1 + \Phi^{(0)}(J, c_+^{(0)}, \chi_m, \chi_L) + \epsilon\, \Phi^{(1)}(J, c_+^{(0)}, \chi_m, \chi_L, J^{(1)}) + O(\epsilon^2), \tag{5.1}$$

$$\begin{aligned}\frac{\Phi^{(0)}(J, c_+^{(0)}, \chi_m, \chi_L)}{\epsilon} &= 2\int_0^{\chi_m} [u(\chi; c_+^{(0)}) - u_1]\, d\chi - \int_0^{\chi_L} [u(\chi; c_+^{(0)}) - u_1]\, d\chi \\ &= (2\chi_m - \chi_L)\,(u_M - u_1 - B_+) + \frac{(J - \alpha)}{(K - c_+^{(0)})}\left(\chi_m^2 - \frac{\chi_L^2}{2}\right) \\ &\quad + \frac{B_+\left(2e^{(K - c_+^{(0)})\chi_m} - e^{(K - c_+^{(0)})\chi_L} - 1\right)}{K - c_+^{(0)}},\end{aligned} \tag{5.2}$$

$$\begin{aligned}\Phi^{(1)}(J, c_+^{(0)}, \chi_m, \chi_L, J^{(1)}) &= \int_{-\infty}^{0} (P^{(0)} - u_1)\, d\chi + \frac{J^{(1)} - g_1' J_s^{(0)}}{{g_1'}^2} \\ &\quad + 2\epsilon\int_0^{\chi_m} P^{(1)}\, d\chi - \epsilon\int_0^{\chi_L} P^{(1)}\, d\chi + \epsilon\int_0^{\infty} [U_L(\xi) - u_1]\, d\xi\end{aligned} \tag{5.3}$$

instead of (4.14). In this equation, $\Phi^{(0)}$ and $\Phi^{(1)}$ are of order 1 because the integrations of $P^{(0)}$ and $P^{(1)}$ over the inner core of the pulse are of order ϵ^{-1}. Equation (5.1) yields

$$\phi = u_1 + \Phi^{(0)}(J^{(0)}, c_+^{(0)}, \chi_m, \chi_L), \tag{5.4}$$

$$\Phi^{(1)}(J^{(0)}, c_+^{(0)}, \chi_L, \chi_m, J^{(1)}) = 0. \tag{5.5}$$

We shall now find the evolution equation for $J^{(0)}$ by a procedure similar to that used to find (4.18). The right-hand side of (5.4) depends on $J^{(0)}$, $c_+^{(0)}$, χ_m, and χ_L. χ_m is a function of $J^{(0)}$ and $c_+^{(0)}$ given by (3.18). As wavefront velocity $c_+^{(0)}$, we shall use the function of $J^{(0)}$ (for a fixed value of ϕ) that was determined at the end of section 3. Then the right-hand side of (5.4) is a function of $J^{(0)}$ and χ_L only (for fixed ϕ):

$$\phi = \mathcal{B}(J^{(0)}, \chi_L) \equiv u_1(J^{(0)}) \quad + \Phi^{(0)}(J^{(0)}, c_+^{(0)}(J^{(0)}), \chi_m(J^{(0)}, c_+^{(0)}(J^{(0)})), \chi_L). \tag{5.6}$$

χ_L can be explicitly calculated from

$$\frac{d\chi_L}{dt} = c_-^{(0)} = 2K - c_+^{(0)}, \quad \chi_L(t_1) = 0, \tag{5.7}$$

where $c_+^{(0)}$ is our known function of $J^{(0)}$. We can obtain a closed system of equations for χ_L and $J^{(0)}$ by differentiating (5.6) with respect to time and then using (5.7). The result is

$$\frac{\partial \mathcal{B}}{\partial J^{(0)}}\,\frac{dJ^{(0)}}{dt} \sim \epsilon\,(u_L - u_1)\,(2K - c_+^{(0)}). \tag{5.8}$$

Here we have used that (5.2) and (5.6) imply $\partial\mathcal{B}/\partial\chi_L = -(u_L - u_1)$.

The time evolution of $J^{(0)}$ is found by solving this equation while the wave disappears through the receiving contact. Having found the solution to leading order, (5.5) yields the correction $J^{(1)}$. Numerical solution of (5.1)–(5.8) shows that $J^{(0)}$ increases with time, as shown in the region between times 1 and 2 in Figure 7. Notice that this increase agrees with the numerical solution of (2.1)–(2.4).

Depending on the bias ϕ, one of the following two events may happen first:

(i)$J^{(0)}$ reaches J_c, or

(ii)$\chi_L = \chi_m$.

In both cases the stage described by the previous equations ends. In case (i), a new wave is created at $x = 0$, whereas in case (ii) (5.1) should be changed to

$$\phi = u_1 + \Psi^{(0)}(J^{(0)}, c_+^{(0)}, \chi_L) + \epsilon\,\Psi^{(1)}(J^{(0)}, c_+^{(0)}, \chi_L, J^{(1)}) + O(\epsilon^2), \tag{5.9}$$

$$\Psi^{(0)}(J^{(0)}, c_+^{(0)}, \chi_L) = \epsilon \int_0^{\chi_L} [u(\chi; c_+^{(0)}) - u_1]\,d\chi$$

$$= \epsilon \left[\frac{(J^{(0)} - \alpha)\chi_L^2}{2(K - c_+^{(0)})} + \chi_L(u_M - u_1 - B_+) + \frac{B_+ \left(e^{(K - c_+^{(0)})\chi_L} - 1\right)}{K - c_+^{(0)}} \right], \tag{5.10}$$

$$\Psi^{(1)}(J, c_+^{(0)}, \chi_L, J^{(1)}) = \int_{-\infty}^{0} [u(\chi; c_+^{(0)}) - u_1]\,d\chi + \frac{J^{(1)} - g_1' J_s^{(0)}}{{g_1'}^2}$$

$$+ \epsilon \int_0^{\chi_L} P^{(1)}\,d\chi + \epsilon \int_0^{\infty} [U_L(\xi) - u_1]\,d\xi, \tag{5.11}$$

where now $\chi_L = L - X_+^{(0)} > 0$ and

$$\frac{d\chi_L}{dt} = -c_+^{(0)}, \quad \chi_L(t_2) = \chi_m(t_2). \tag{5.12}$$

Here t_2 is the time at which the maximum of the pulse reaches $x = L$ (equivalently $\chi_L = \chi_m$ in the previous stage). Arguments similar to those used in the previous stage lead to

$$\left(\frac{1}{\beta} + \frac{\partial \tilde{\Psi}^{(0)}}{\partial J^{(0)}}\right) \frac{dJ^{(0)}}{dt} \sim \epsilon\,(u_L - u_1)\,c_+^{(0)}, \tag{5.13}$$

where $\tilde{\Psi}^{(0)}(J^{(0)}, \chi_L) = \Psi^{(0)}(J^{(0)}, c_+^{(0)}(J^{(0)}), \chi_L)$.

This stage lasts until $J^{(0)}$ reaches J_c and a new pulse is shed. If the bias is small enough, the solution of these equations may be such that $J^{(0)}$ never reaches J_c and it eventually decreases with time. In such case, the pulse exits and leaves a stable stationary state in its wake after $\chi_L = 0$. Notice that setting $\chi_L = \chi_m = 0$ in (3.18) implies a front velocity (A.7). Thus the velocity of the disappearing wavefront approaches that of the triangular wave, although the shapes of the respective wavefronts may differ greatly. As in the previous stage, we find $J^{(1)}$ by solving the equation $\Psi^{(1)}(J^{(0)}, c_+^{(0)}, \chi_L, J^{(1)}) = 0$.

5.2. Pulse shedding at the injecting boundary. If $J(t)$ reaches J_c at $t = t_2$, the boundary layer becomes unstable and a new pulse starts being shed at the injecting boundary. The boundary layer profile, $U(x,t)$, solves the following semi-infinite integrodifferential problem:

$$\frac{\partial U}{\partial \sigma} + K\frac{\partial U}{\partial x} - \frac{\partial^2 U}{\partial x^2} + g(U) = J(\sigma), \tag{5.14}$$

$$U(0,\sigma) = \rho\, J, \tag{5.15}$$

whose solution exhibits an explosion-type behavior and a rapid growth of the area enclosed by the boundary layer which can no longer be neglected. This increase in area is to be compared with the area released by the disappearing pulse at $x = L$. Initially, the area released is larger, and this net area loss has to be compensated by an equal increase in the area of the outer solution, so that J continues to increase, although at a slower rate. After a short time, the growth of the boundary layer is larger than the area released, so that J reaches a maximum and starts decreasing.

The structure of the injecting boundary layer when $J > J_c$ is as follows:

1. $u = u(x; J, U_m)$ is quasi-stationary for $0 < x < X_m$ such that (3.4) holds with $u(0; J, U_m) = \rho J$, $u(X_m; J, U_m) = U_m$, with $\partial u(X_m; J, U_m)/\partial x = 0$. The boundary layer solution is the trajectory of the phase plane corresponding to (3.4) which leaves the vertical line $u = \rho J$ at $x = 0$ and intersects the u axis at $u = U_m$. Notice that this trajectory is uniquely determined by giving J and U_m.
2. For $x > X_m$, the boundary layer is a wavefront of type $u(\chi; c_-)$ moving at speed C_-. This speed and the forefront are uniquely determined by J and U_m: $u = u(\xi; C_+)$, $\xi = Xn_- - x$, with $C_+ = 2K - C_-$, $u(-\infty; C_+) = u_1(J)$, $u(0; C_+) = u_M$, $u(\xi_m; C_+) = U_m$, $\partial u(\xi_m; C_+)/\partial \xi = 0$.

The bias condition (including the injecting boundary layer) is

$$\phi = u_1 + \tilde{\Psi}^{(0)}(J, \chi_m, \chi_L) + \epsilon\, A^{(0)}(t) + O(\epsilon), \tag{5.16}$$

$$A^{(0)} = \int_0^\infty [U(\xi) - U_\infty]\, d\xi, \tag{5.17}$$

provided that the maximum of the old pulse has left the sample. Time differentiation of (5.16) yields

$$\left(\frac{1}{\beta} + \frac{\partial \tilde{\Psi}^{(0)}}{\partial J^{(0)}}\right) \frac{dJ^{(0)}}{dt} \sim -\epsilon \frac{dA^{(0)}}{dt} + \epsilon\,(u_L - u_1)\, c_+^{(0)}. \tag{5.18}$$

Equations (5.12), (5.16), and (5.18), together with (5.2), (5.10), and (4.17), constitute a closed system of equations for the unknowns J, χ_L, and χ_m. During this stage, J initially increases and then decreases until either it again reaches J_c or the old wave completely disappears. In the latter case, the evolution of $J(t)$ is still given by (5.18) without the last term which represents the area lost by the disappearing wave. The evolution during this stage can be observed between points 3 and 4 in Figure 7.

Also, Figure 8 shows in detail the evolution of the boundary layer profile from the time that $J > J_c$. Initially, u grows at the injecting boundary because J increases. Furthermore, the slope $\partial u(0,t)/\partial x$ increases and becomes positive at a certain time. Then a wavelike structure is created. The leading front of this wave moves away from the boundary while the backfront is attached to it. The wave continues its growth

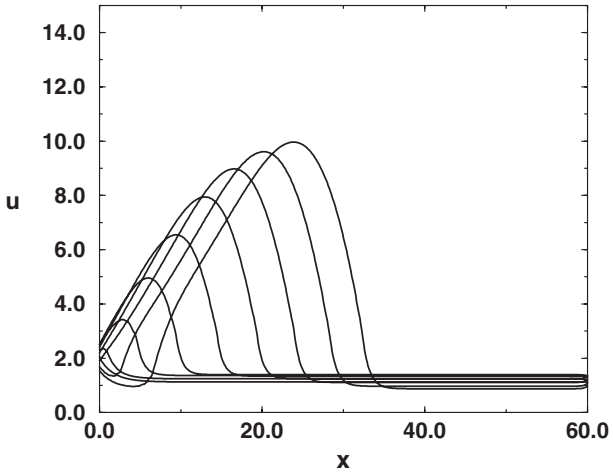

FIG. 8. *Boundary layer profile evolution during the shedding stage.*

until the time when J becomes again smaller than J_c. Then, the slope at the boundary becomes negative, and the wave detaches and moves away from the boundary as a solitary wave. At that time, the quasi-stationary part of the boundary layer which joins $x = 0$ to the maximum at $x = X_m$ becomes the backfront of a detached pulse. Then, we again have the same equation, (2.11), describing the first stage, and a cycle of the Gunn oscillation has been completed. The time evolution during this stage can be observed in Figure 7 for times larger than t_5.

6. Conclusions. In this paper we have asymptotically described one period of a Gunn-type oscillation in a simple model. The nonlinearity of the model is such that at most two constant solutions are possible for each value of J (the currentlike unknown). The model consists of a parabolic equation for the fieldlike unknown, $u(x,t)$, and an integral constraint (bias condition) which determines $J(t)$. Appropriate boundary and initial conditions are imposed. The key new idea of our analysis is that a pulse that changes shape as it advances may be constructed by fixing only two parameters: J and the pulse maximum, u_m. If the pulse width is small compared to the sample length, then L, J, and u_m change on a slow time scale. The trailing front of the pulse is part of a separatrix joining a saddle point to $(u_m, 0)$ with $du/d\chi > 0$ on the $(u, du/d\chi)$ phase plane. The initial and final points determine the backfront speed c_+ as a function of J and u_m. Similarly the forefront of a pulse is constructed and its speed c_- determined. Then equations for J and u_m are obtained by time-differentiation of the bias condition and of the pulse width. The time derivative of the latter is $c_- - c_+$ and J tends toward a fixed value corresponding to a rigidly moving pulse with $c_- = c_+$. Other stages of a Gunn oscillation, including wave creation and annihilation at the boundaries, are analyzed by similar methods. Our theory compares well with direct numerical simulations.

We have found an asymptotic theory of the "Gunn effect" in a simple piecewise linear model, whose main step is a construction of pulses and a derivation of an equation for the "current." An analysis of the stability of these solutions is an open problem, although there is some work on this problem in the related Kroemer model [3, 25]. That the profile of pulses can become oscillatory for appropriate parameter values has been shown by Sun et al. for some reaction-diffusion models [23]. We expect

that the present method yield results independent of the model equations within a class thereof displaying the Gunn instability [6, 21, 22, 25, 26]. Studies of other systems that can be understood by the dynamics of pulses are in progress.

Appendix A. Limiting cases.

A.1. Triangular pulses. The bias condition (2.2) determines the orders of magnitude of χ_m and u_m in terms of the small parameter ϵ. Let us assume that $(K - c_+)$ and $(J - \alpha)$ are $O(1)$, whereas $\chi_m \gg 1$. Then (3.17), (3.18), and (3.19) imply that

$$\begin{aligned} u_m &= u_M + \frac{J-\alpha}{K-c_+}\,\chi_m - \frac{\lambda_+(u_M-u_1)}{K-c_+} \\ &\sim \frac{J-\alpha}{K-c_+}\,\chi_m. \end{aligned} \tag{A.1}$$

The wavefront $u(\chi; c_+)$ is given by (3.14) for $\chi < 0$ and

$$u = u_m + \frac{J-\alpha}{K-c_+}\,(\chi - \chi_m) + B_+\left[e^{(K-c_+)\chi} - e^{(K-c_+)\chi_m}\right] \tag{A.2}$$

$$\sim \frac{J-\alpha}{K-c_+}\,\chi \tag{A.3}$$

for $\chi > 0$, where (A.1) has been used. The bias condition (2.2) then yields

$$\frac{\phi - u_1}{\epsilon} \sim \frac{J-\alpha}{K-c_+}\,\chi_m^2, \tag{A.4}$$

$$\chi_m \sim \sqrt{\frac{(\phi-u_1)\,(K-c_+)}{\epsilon\,(J-\alpha)}}. \tag{A.5}$$

These equations imply that χ_m and u_m are $O(\epsilon^{-\frac{1}{2}})$, while the proper time scale over which J varies is $t = O(\epsilon^{-\frac{1}{2}})$.

We can obtain (A.1)–(A.5) directly from (3.8) and the bias condition. If $\chi_m \gg 1$, so is u_m. Then we shall select uniquely the wavefront solution of (3.8), $u(\chi; c_+)$, so that it satisfies $u(-\infty; c_+) = u_1(J)$ and does not grow exponentially as $\chi \to +\infty$. Similarly, $u(\chi; c_-) = u(-\chi; c_+)$ does not grow exponentially as $\chi \to -\infty$ and satisfies $u(+\infty; c_-) = u_1(J)$. As in Theorem 1, we still have $c_+ + c_- = 2K$.

$u(\chi; c_+)$ satisfies (3.14) and

$$u(\chi; c_+) = u_M + \frac{J-\alpha}{K-c_+}\,\chi \quad \text{if} \quad \chi > 0. \tag{A.6}$$

Continuity of $du/d\chi$ at $\chi = 0$ directly yields

$$\left(u_M - \frac{J}{\beta}\right)\lambda_+ = \frac{J-\alpha}{K-c_+},$$

which in turn implies

$$c_+ = K - \frac{J-\alpha}{\sqrt{\beta\,(u_M-u_1)\,\left(u_M - \frac{\alpha}{\beta}\right)}} > 0. \tag{A.7}$$

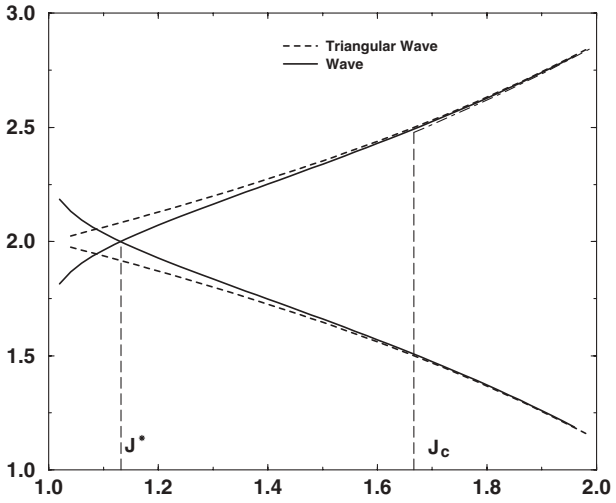

FIG. 9. *Velocities of the backfront, c_+, and of the forefront, c_-, as functions of J for $\phi = 1.6$ and the same parameter values as in Figure 2. We have also shown the corresponding approximate values $c_\pm$ obtained for the triangular pulse described in the text.*

Figure 9 compares the actual values of $c_\pm$ with the approximation (A.7). Notice that both lines are reasonably close for J sufficiently higher than J^*.

We can now form a pulse by joining the backfront $u(\chi; c_+)$, $\chi = x - X_+ < \chi_m$ to the forefront $u(2\chi_m - \chi; c_+)$. This pulse asymptotically approaches an isosceles triangle of basis $(X_- - X_+) = 2\chi_m$ and height approximately given by

$$u_m = u(\chi_m; c_+) = u\left(\frac{X_- - X_+}{2}; c_+\right) \sim \frac{(J-\alpha)\,(X_- - X_+)}{2(K - c_+)}. \tag{A.8}$$

See Figure 10, which compares the triangular pulse to the real pulse and the homoclinic pulse for the same values of J and ϕ. Here we have used (A.6) and assumed that χ_m (the location of the maximum, equal to the pulse half-width) is very large. To be precise, we assume that $(K - c_+) = O(1)$ and that $(J - \alpha)\,\chi_m \gg 1$.

Notice that the way we have constructed $u(\chi; c_+)$ is immediately applicable to a general smooth nonlinearity $g(u)$ of the same type. We have thus the following result.

RESULT. *Let the characteristic curve $g(u)$ be an odd function of u with a positive local maximum after which it monotonically decays to a positive constant as $u \to +\infty$. The approximate backfront $u(\chi; c_+)$ is the unique solution of (3.8) which, for an appropriate choice of the velocity c_+, satisfies $u(-\infty; c_+) = u_1(J)$ and does not grow exponentially as $\chi \to +\infty$.*

A.2. The homoclinic pulse. If $c_+ = c_- = K$, the pulse is a homoclinic orbit of the phase plane (3.8),

$$\frac{\partial^2 u}{\partial \zeta^2} + J - g(u) = 0, \tag{A.9}$$

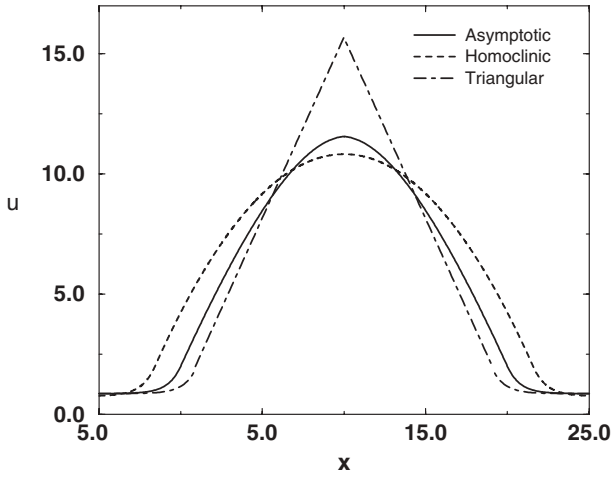

FIG. 10. *Shape of the pulse for $J = 1.3$ and the parameter values of Figure 2. Also shown are the corresponding triangular and homoclinic pulses.*

with $u(\pm\infty) = u_1(J) = J/\beta$ (see Figure 6). Here $\zeta \equiv x - X_0$, and $X_0 = (X_+ + X_-)/2$ is the location of the maximum of the pulse, u_m. The solution is

$$u(\zeta) = \frac{J}{\beta} + \left(u_M - \frac{J}{\beta}\right) e^{-\sqrt{\beta}(|\zeta| - \zeta_0)} \quad \text{for} \quad |\zeta| > \zeta_0, \tag{A.10}$$

$$u(\zeta) = u_m - \frac{J-\alpha}{2}\,\zeta^2 \quad \text{for} \quad |\zeta| < \zeta_0, \tag{A.11}$$

$$u_m = u_M + \frac{J-\alpha}{2}\,\zeta_0^2. \tag{A.12}$$

ζ_0 is determined by imposing continuity of $du/d\zeta$ at $\zeta = \pm\zeta_0$:

$$\zeta_0 = \frac{\sqrt{\beta}\left(u_M - \frac{J}{\beta}\right)}{J-\alpha}. \tag{A.13}$$

Now we may find $J = J^*$ from the bias condition. The result is

$$J^* = \alpha + \beta^{\frac{3}{4}} \sqrt{\frac{2\epsilon\left(u_M - \frac{\alpha}{\beta}\right)^3}{3\left(\phi - \frac{\alpha}{\beta}\right)}} + O(\epsilon), \tag{A.14}$$

$$\zeta_0 = \beta^{-\frac{1}{4}} \sqrt{\frac{3\left(\phi - \frac{\alpha}{\beta}\right)}{2\epsilon\left(u_M - \frac{\alpha}{\beta}\right)}} + O(1), \tag{A.15}$$

$$u_m = \frac{\beta^{\frac{1}{4}}}{2} \sqrt{\frac{3}{2\epsilon}\left(\phi - \frac{\alpha}{\beta}\right)\left(u_M - \frac{\alpha}{\beta}\right)} + O(1). \tag{A.16}$$

Figure 11 compares J^* to the approximation (A.14). Notice that a simple phase plane

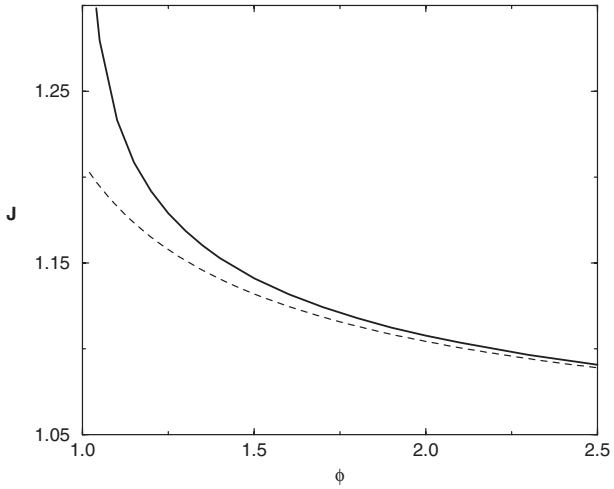

FIG. 11. *Value $J = J^*$ for the homoclinic pulse as a function of the bias ϕ. The dashed curve corresponds to the approximation* (A.14).

argument indicates that J^* obeys the following equal-area rule:

$$J^* = \frac{1}{u_m - u_1} \int_{u_1}^{u_m} g(u)\, du, \tag{A.17}$$

where u_m is given by (A.16). Figure 10 compares the actual pulse, the homoclinic pulse with $c = K$ and the triangular wave for the same values of J and ϕ.

Appendix B. Explicit calculation of $P^{(1)}$ and $c_+^{(1)}$. First of all, $P^{(1)} = P_\chi^{(0)} \equiv \partial P^{(0)}/\partial\chi$ is a solution of the homogeneous problem (4.12) (with zero right-hand side) and (4.13). The solvability conditions for the nonhomogeneous problem yield

$$\left[P_\chi^{(0)}\, P_\chi^{(1)} - P_{\chi\chi}^{(0)}\, P^{(1)}\right]_{\chi=\chi_m} e^{-(K-c_+^{(0)})\chi_m}$$

$$= \int_{-\infty}^{\chi_m} P_\chi^{(0)} \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)}\right] e^{-(K-c_+^{(0)})\chi} d\chi, \tag{B.1}$$

$$c_+^{(1)} + c_-^{(1)} = 0. \tag{B.2}$$

Let us define

$$P^{(1)} \equiv p(\chi; c_+^{(0)})\, \frac{\partial P^{(0)}}{\partial \chi}. \tag{B.3}$$

Inserting (B.3) in (4.12), we obtain an equation which can be solved by two quadratures. We find

$$\frac{\partial p}{\partial \chi} = \frac{e^{(K-c_+^{(0)})\,\chi}}{P_\chi^{(0)\,2}} \int_{-\infty}^{\chi} e^{-(K-c_+^{(0)})\,\chi} P_\chi^{(0)} \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)}\right] d\chi. \tag{B.4}$$

Here subscripts indicate partial derivatives with respect to the corresponding variable. It is easy to check that this expression satisfies (B.1). Further integration yields

(for $\chi < 0$)

$$p = \frac{(\beta J^{(1)} - J_s^{(0)})\, e^{-\lambda_+ \chi}}{\beta^2 \lambda_+ (u_M - u_1)} + \frac{\lambda_{+s} \chi^2}{2\lambda_+ \sqrt{(K - c_+^{(0)})^2 + 4\beta}}$$

$$- \frac{\chi}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}} \left[\frac{J_s^{(0)}}{\beta \lambda_+ (u_M - u_1)} + \frac{\lambda_{+s}}{\lambda_+ \sqrt{(K - c_+^{(0)})^2 + 4\beta}} + c_+^{(1)} \right] + q, \tag{B.5}$$

where q is a constant. For $\chi > 0$, $P_{\chi\chi}^{(0)} = B_+ (K - c_+^{(0)})^2 e^{(K - c_+^{(0)})\chi}$, and we can simplify the expression for p by integrating by parts. The result is

$$p = \frac{1}{B_+ (K - c_+^{(0)})^2 P_\chi^{(0)}} \left\{ P_\chi^{(0)} \int_0^\chi e^{-(K - c_+^{(0)})\chi} \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)} \right] d\chi - \int_{-\infty}^\chi e^{-(K - c_+^{(0)})\chi} P_\chi^{(0)} \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)} \right] d\chi \right\} + Q. \tag{B.6}$$

Continuity of p at $\chi = 0$ yields

$$q = Q - \frac{J^{(1)} - \frac{J_s^{(0)}}{\beta} + \frac{\beta I_0}{B_+ (K - c_+^{(0)})^2}}{\lambda_+ \beta (u_M - u_1)}, \tag{B.7}$$

where I_0 is the following integral:

$$I_0 \equiv \int_{-\infty}^0 e^{-(K - c_+^{(0)})\chi} P_\chi^{(0)} \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)} \right] d\chi$$

whose value can be computed as

$$I_0 \;=\; I_{00} \;+\; I_{0J}\, J^{(1)} \;+\; I_{0c}\, c_+^{(1)}, \tag{B.8}$$

where

$$I_{00} = \frac{\lambda_+^2 (u_M - u_1)}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}} \left[\frac{\lambda_+ J_s^{(0)}}{\beta^2} + \frac{(u_M - u_1)\, c_{+s}}{(K - c_+^{(0)})^2 + 4\beta} \right],$$

$$I_{0J} = -\frac{\lambda_+^2 (u_M - u_1)}{\beta},$$

$$I_{0c} = -\frac{\lambda_+^2 (u_M - u_1)^2}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}}.$$

Continuity of $P_\chi^{(1)}$ at $\chi = 0$ implies

$$P_\chi^{(0)}(0)\, [p_\chi(0+) - p_\chi(0-)] = \qquad -p(0) \left[P_{\chi\chi}^{(0)}(0+) - P_{\chi\chi}^{(0)}(0-) \right]. \tag{B.9}$$

The second argument $c_+^{(0)}$ has been omitted in all the functions in this formula. The jump discontinuity of the second derivative $P_{\chi\chi}^{(0)}$ at $\chi = 0$ implies that p_χ also has a jump discontinuity at $\chi = 0$. Substituting (B.5) and (B.6) in (B.9), we obtain

$$QB_+(K - c_+^{(0)})^2 = q\lambda_+^2(u_M - u_1) - \frac{1}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}} \times \left[\frac{J_s^{(0)}}{\beta} + (u_M - u_1)\lambda_+ c_+^{(1)} + \frac{\lambda_{+\,s}(u_M - u_1)}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}}\right]. \tag{B.10}$$

We can obtain Q from (B.7), (B.8), and (B.10). After some algebra, the result is

$$Q \,=\, Q_0 \,+\, Q_J\, J^{(1)} \,+\, Q_c\, c_+^{(1)} \tag{B.11}$$

with

$$\upsilon\, Q_0 \,=\, \frac{J_s^{(0)}}{\beta}\left[\frac{1}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}} \,-\, \frac{\lambda_+}{\beta}\right] + \frac{\lambda_+\, I_{00}}{B_+(K - c_+^{(0)})^2} \,-\, \frac{\lambda_+\,(u_M - u_1)\, c_{+\,s}^{(0)}}{[(K - c_+^{(0)})^2 + 4\beta]^{\frac{3}{2}}},$$

$$\upsilon\, Q_J \,=\, \frac{\lambda_+\, I_{0J}}{B_+(K - c_+^{(0)})^2} \,+\, \frac{\lambda_+}{\beta},$$

$$\upsilon\, Q_c \,=\, \frac{\lambda_+\, I_{0c}}{B_+(K - c_+^{(0)})^2} \,+\, \frac{\lambda_+\,(u_M - u_1)}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}},$$

$$\upsilon \,=\, \lambda_+^2\,(u_M - u_1) \,-\, B_+(K - c_+^{(0)})^2.$$

The velocity correction $c_+^{(1)}$ can be obtained from the condition $\partial P^{(1)}/\partial\chi = 0$ at $\chi = \chi_m$. Thus

$$Q + \frac{1}{B_+(K - c_+^{(0)})^2}\int_0^{\chi_m} e^{-(K - c_+^{(0)})\,\chi} P_\chi^{(0)} \times \left[P_s^{(0)} - J^{(1)} - c_+^{(1)} P_\chi^{(0)}\right] d\chi = 0. \tag{B.12}$$

Inserting (B.11) in this equation, we get $c_+^{(1)}$. After simplification, the result is

$$\gamma\, c_+^{(1)} \,=\, c_{+0} \,+\, c_{+J}\, J_c^{(1)} \tag{B.13}$$

with

$$c_{+0} = \frac{J_s^{(0)}}{K - c_+^{(0)}} \left[z_1 + \frac{z_2}{K - c_+^{(0)}} + (\chi_m + z_2) \left(\frac{\lambda_+}{\beta} + \frac{1}{K - c_+^{(0)}} \right) \right]$$
$$+ \frac{c_{+\,s}^{(0)}}{(K - c_+^{(0)})^2} \left[2(\chi_m + z_2) \left(\frac{J^{(0)} - \alpha}{K - c_+^{(0)}} - \frac{\beta(u_M - u_1)}{\sqrt{(K - c_+^{(0)})^2 + 4\beta}} \right) \right.$$
$$\left. + (J^{(0)} - \alpha) \left(z_1 + \frac{z_2}{K - c_+^{(0)}} \right) - \frac{B_+}{2} (K - c_+^{(0)})^2 \chi_m^2 \right]$$
$$- B_+ Q_0 (K - c_+^{(0)})^2,$$
$$c_{+J} = -z_2 - B_+ Q_J (K - c_+^{(0)})^2,$$
$$\gamma = \frac{J^{(0)} - \alpha}{K - c_+^{(0)}} z_2 - B_+ (K - c_+^{(0)}) \chi_m + B_+ Q_c (K - c_+^{(0)})^2,$$
$$z_1 \equiv \frac{\chi_m \exp[(K - c_+^{(0)})\chi_m]}{(K - c_+^{(0)})} = -\frac{\chi_m B_+ (K - c_+^{(0)})}{J^{(0)} - \alpha},$$
$$z_2 \equiv \frac{\exp[(K - c_+^{(0)})\chi_m] - 1}{(K - c_+^{(0)})} = -\frac{\lambda_+ (u_M - u_1)}{J^{(0)} - \alpha}.$$

Here we have used (3.16)–(3.18) to simplify the result. $J^{(1)}$ is found from the equation

$$0 = 2 \int_{-\infty}^{0} (P^{(0)} - u_1)\, d\chi + \frac{J^{(1)} - g_1' J_s^{(0)}}{{g_1'}^2}$$
$$+ 2\epsilon \int_0^{\chi_m} P^{(1)}\, d\chi + \int_0^{\infty} (U_L(\xi) - u_1)\, d\xi + \int_0^{\infty} (U_R(\xi) - u_1)\, d\xi \tag{B.14}$$

after substitution of (4.14), (4.15), and (B.13).

Appendix C. Pulse dynamics: Limiting cases.

C.1. Triangular pulse. If the limiting pulse is triangular, the approximate evolution equation for J may be obtained by time-differentiating (A.5) and using (A.7):

$$\frac{dJ}{dt} = -\sqrt{\epsilon}\, B(J)\, [K - c_+(J)], \tag{C.1}$$

$$B(J) = \frac{4\beta(\beta u_M - \alpha)^{\frac{1}{4}} (\phi - u_1)^{\frac{1}{2}} (u_M - u_1)^{\frac{5}{4}}}{2u_M - \phi - u_1}. \tag{C.2}$$

For typical values of the parameters such as those in Figure 2, $B(J) > 0$, so that J tends to the solution of $c_+(J) = K$. Triangular pulses are good approximations for J sufficiently large, which means that the solution of (C.1) decreases towards $J = \alpha$ according to (A.7). Of course, before this value can be reached, (C.1) ceases to be valid and we revert to the general equation for J, (2.11), whose fixed point is J^*.

C.2. Homoclinic pulse. Let us now assume that $(K - c_+) \ll (J - \alpha) \ll 1$, whereas $\chi_m \gg 1$. Then (3.17) and (3.18) imply that

$$\chi_m \sim \frac{\lambda_+ (u_M - u_1)}{J - \alpha} + \frac{\lambda_+^2 (u_M - u_1)^2 (K - c_+)}{2(J - \alpha)^2}. \tag{C.3}$$

Here $\lambda_+ \sim \sqrt{\beta}$. Notice that (C.3) becomes (A.13) as $(K - c_+) \to 0$. We now insert this approximation in (3.19) after (3.17) has been substituted. The result is

$$u_m \sim u_M + \frac{\lambda_+^2 (u_M - u_1)^2}{2(J - \alpha)} \sim \frac{1}{2}(J - \alpha)\chi_m^2. \tag{C.4}$$

The bias condition (4.15) may now be approximated by using (C.3) and (C.4) to obtain

$$\frac{\phi - u_1}{\epsilon} \sim \frac{2\beta^{\frac{3}{2}} (u_M - u_1)^3}{3(J - \alpha)^2}.$$

Then

$$\begin{aligned} (J - \alpha) &\sim \beta^{\frac{3}{4}} \sqrt{\frac{2\epsilon (u_M - u_1)^3}{3(\phi - u_1)}} \\ &\sim \beta^{\frac{3}{4}} \sqrt{\frac{2\epsilon \left(u_M - \frac{\alpha}{\beta}\right)^3}{3\left(\phi - \frac{\alpha}{\beta}\right)}}. \end{aligned} \tag{C.5}$$

Inserting (C.5) in (C.3) and (C.4), we obtain

$$\chi_m \sim \beta^{-\frac{1}{4}} \sqrt{\frac{3(\phi - u_1)}{2\epsilon\,(u_M - u_1)}}, \tag{C.6}$$

$$u_m \sim \frac{\beta^{\frac{1}{4}}}{2} \sqrt{\frac{3}{2\epsilon}\,(\phi - u_1)\,(u_M - u_1)}. \tag{C.7}$$

Equations (C.5)–(C.7) are the same as (A.14)–(A.16) for the homoclinic pulse.

As explained before, $d\chi_m/dt = (c_- - c_+)/2 = K - c_+$. Therefore, the derivative of (C.6) with respect to time yields

$$\frac{dJ}{dt} \sim -\sqrt{\frac{8\epsilon}{3}}\, \frac{\beta^{\frac{5}{4}}\, (\phi - u_1)^{\frac{1}{2}} (u_M - u_1)^{\frac{3}{2}}}{u_M - \phi}\, (K - c_+). \tag{C.8}$$

This equation has the same form as (2.11), and shows that the unknown $J(t)$ varies on a slow time scale $t = O(1/\sqrt{\epsilon(K - c_+)})$. In the present limit, $(K - c_+) \ll (J - \alpha) = O(\sqrt{\epsilon})$, so that the corresponding time scale is slower than $\tau = \epsilon t$.

A glance to (C.8) shows that J decreases exponentially fast to J^* such that $c_+ = c_- = K$. The resulting pulse is the homoclinic orbit of the phase plane (3.8) with $c = K$ described in the previous section.

GENERALIZED AZIMUTHAL SHEAR DEFORMATIONS IN COMPRESSIBLE ISOTROPIC ELASTIC MATERIALS*

ELEFTHERIOS KIRKINIS† AND HUNGYU TSAI‡

Abstract. In this article we study the azimuthal shear deformations in a compressible isotropic elastic material. This class of deformations involves an azimuthal displacement as a function of the radial and axial coordinates. The equilibrium equations are formulated in terms of the Cauchy–Green strain tensors, which form an overdetermined system of partial differential equations for which solutions do not exist in general. By means of a Legendre transformation, necessary and sufficient conditions for the material to support this deformation are obtained explicitly, in the sense that every solution to the azimuthal equilibrium equation will satisfy the remaining two equations. Additionally, we show how these conditions are sufficient to support *all* currently known deformations that locally reduce to simple shear. These conditions are then expressed both in terms of the invariants of the Cauchy–Green strain and stretch tensors. Several classes of strain energy functions for which this deformation can be supported are studied. For certain boundary conditions, exact solutions to the equilibrium equations are obtained.

Key words. nonlinear elasticity, Legendre transforms, constitutive laws, azimuthal shear, quasi-linear partial differential equations

1. Introduction.

It is well known [8] that the only deformations possible in all isotropic *compressible* elastic materials are homogeneous. Therefore, the analysis of nonhomogeneous deformations can only be accomplished if one concentrates on specific classes of strain energy functions. A growing body of literature that addresses these issues has been developed in recent years. The reader is referred to [12] for a review and relevant references.

One important nonhomogeneous deformation that attracts our attention is the *generalized azimuthal shear* deformation. Its perceived importance stems from the fact that it presents an analogous (but more complicated) kinematic structure to that of the *antiplane shear* deformation; hence, it may emerge as the impetus of developments and analysis on issues such as loss of ellipticity, crack problems cavitation, and phase transitions. The generalized azimuthal shear is an *isochoric* deformation of the form

$$r = R, \quad \theta = \Theta + g(R, Z), \quad z = Z, \tag{1.1}$$

with (R, Θ, Z) and (r, θ, z) being the cylindrical polar coordinates in the unstressed natural configuration and the deformed configuration, respectively. This deformation (or its Z-independent specialization) may also appear under the names of *circular* or *rotational* shear. The function $g(R, Z)$ has to be determined by the equilibrium equations and it depends on the form of strain energy function employed. This deformation belongs to a class of isochoric deformations that locally reduce to simple shear;

the other well-known deformations in this class are the *helical shear* deformation [3] and the *antiplane shear* deformation [10, 17].

Research in this area was initiated by Knowles [17], in his study of antiplane shear, who recognized that compressible materials can undergo isochoric deformations (which locally reduce to simple shear) only if the strain energy function is consistent with certain restrictive conditions.

A special case of the deformation under study is the *pure azimuthal* shear deformation ($g = g(R)$), for which conditions on the strain energy function were derived by Polignone and Horgan [20] and explicit necessary and sufficient conditions were found by Beatty and Jiang [2]. More recently, Horgan and Saccomandi [13], gave a detailed theoretical analysis and computed all mechanical quantities of interest for the pure azimuthal shear deformation in the case of incompressible materials exhibiting limiting chain extensibility.

A second special case of the deformation under consideration is the *pure torsion* deformation ($g = \tau Z$), investigated by Beatty and Jiang [2], who also derived several constitutive assumptions to support this special deformation. For the same problem, explicit necessary and sufficient conditions on the strain energy function were derived by Polignone and Horgan [18]. Throughout the present study appropriate comparisons with the deformations of *helical shear* and *antiplane shear* will also be made.

Closed form and approximate solutions for special forms of the azimuthal displacement $g = g(R, Z)$, namely pure azimuthal shear and combined pure azimuthal shear/pure torsion, were considered by Tao, Rajagopal, and Wineman [22]. They considered a generalized power law neo-Hookean material in the framework of the incompressible theory, without reference, however, to the locally simple shear character of the deformation as well as the need for discussion of necessary and sufficient conditions on the form of the strain energy function.

In this paper we present the first result available in the literature for the deformation (1.1), in the context of the finite theory of elasticity. Section 2 describes the kinematics, stress, and equilibrium associated with the deformation (1.1). The equilibrium equations are expressed in terms of the Cauchy stress tensor $\boldsymbol{\sigma}$. New universal relations are derived, and a discussion of uniqueness of solution and ellipticity of the governing displacement equations is included. Section 3 describes the transformation method of the equilibrium equations from the reference configuration space to the reference strain space. The equilibrium equations then are obtained in strain space coordinates and their form is used in section 4 to derive necessary and sufficient conditions for the strain energy function to admit the generalized azimuthal shear deformation. In the same section, a straightforward comparison with results from the current literature shows that the above conditions are clearly sufficient to support all currently known isochoric deformations that locally reduce to simple shear, though there might be others whose structure has not been examined yet. These results are then utilized to obtain conditions in terms of the principal invariants of the Cauchy–Green and stretch tensors, in a fashion similar to the discussion of helical shear in [15]. These simple restrictions are then combined, first to determine classes of strain energy functions for which generalized azimuthal shear deformations are possible and second, in section 5, to obtain closed form solutions of $g(R, Z)$ for particular members of these classes. The solutions are subjected to some physically realistic boundary conditions which give further insight into this newly studied deformation. Further, the solutions are compared with the special forms of pure azimuthal shear and pure torsion, analyzed in the literature recently, and some Riemann type similarity solu-

tions are obtained that serve as a test for the validity of the necessary and sufficient conditions we derived earlier. Finally, in this section the effect of torsion on the form of the pure azimuthal displacement is examined for two members of the previously determined energy classes and comparison with previous results of the pure azimuthal shear deformation is made, in the spirit of the work by Tao, Rajagopal, and Wineman [22]. Finally, in section 6 we close with some concluding remarks and compare further the conditions on the strain energy for the generalized azimuthal shear problem with its counterparts, e.g., the antiplane and helical shear deformations. Throughout this article, the notation used closely follows the one adopted by Tsai and Fan [23].

2. Kinematics, strain energy, stress, and equilibrium. We consider a body composed of a compressible, nonlinearly elastic material, occupying the following cylindrical region in its natural (unstressed) configuration:

$$A \le R \le B, \quad 0 \le \Theta \le 2\pi, \quad 0 \le Z \le L, \tag{2.1}$$

where R, Θ, Z are the cylindrical coordinates associated with the reference configuration denoted by $\mathcal{B}_o$. The general azimuthal shear deformation is defined by

$$r = R, \quad \theta = \Theta + g(R, Z), \quad z = Z, \tag{2.2}$$

where r, θ, z are the cylindrical coordinates of a material point in the current configuration denoted by $\mathcal{B}$. In vector notation, the reference and current configurations of the body are related through a mapping $\boldsymbol{\chi}$,

$$\boldsymbol{\chi} : \mathcal{B}_o \to \mathcal{B}, \quad \text{such that} \quad \boldsymbol{x} = \boldsymbol{\chi}(\boldsymbol{X}), \tag{2.3}$$

where $\boldsymbol{x} = r\boldsymbol{e}_r + z\boldsymbol{e}_z$ and $\boldsymbol{X} = R\boldsymbol{E}_R + Z\boldsymbol{E}_Z$ are the position vectors of a particle in the current and reference configurations, respectively, while $\boldsymbol{e}_r, \boldsymbol{e}_z, \boldsymbol{E}_R, \boldsymbol{E}_Z$ are the corresponding radial and axial unit cylindrical polar vectors. The mapping $\boldsymbol{\chi}$ is assumed to be at least twice continuously differentiable. The deformation gradient associated with the generalized azimuthal shear deformation (1.1) obtains the form

$$\boldsymbol{F} = \boldsymbol{Q} + \mathbf{e}_\theta \otimes (R\, g_{,R}\mathbf{E}_R + R\, g_{,Z}\mathbf{E}_Z), \tag{2.4}$$

where

$$\boldsymbol{Q} = \mathbf{e}_r \otimes \mathbf{E}_R + \mathbf{e}_\theta \otimes \mathbf{E}_\Theta + \mathbf{e}_z \otimes \mathbf{E}_Z \tag{2.5}$$

is a local rotation of angle $g(R, Z)$ about Z-axis, mapping the cylindrical axes from the referential basis $\{\mathbf{E}_R, \mathbf{E}_\Theta, \mathbf{E}_Z\}$ to the current basis $\{\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z\}$. With the notation

$$\omega_r = R\, g_{,R}, \quad \omega_z = R\, g_{,Z}, \tag{2.6}$$

we introduce the *shear strain vectors*, $\boldsymbol{\Omega}$ and $\boldsymbol{\omega}$, associated with the reference and current configurations, respectively, given by

$$\boldsymbol{\Omega} = \omega_r\mathbf{E}_R + \omega_z\mathbf{E}_Z, \quad \boldsymbol{\omega} = \omega_r\mathbf{e}_r + \omega_z\mathbf{e}_z = \boldsymbol{Q}\boldsymbol{\Omega}. \tag{2.7}$$

It then follows that the deformation gradient can be written as

$$\boldsymbol{F} = (\boldsymbol{I} + \mathbf{e}_\theta \otimes \boldsymbol{\omega})\boldsymbol{Q} = \boldsymbol{Q}(\boldsymbol{I} + \mathbf{E}_\Theta \otimes \boldsymbol{\Omega}). \tag{2.8}$$

Clearly, the deformation is isochoric. It consists of the rotation $\boldsymbol{Q}$ followed by a simple shear, with the amount of shear $\omega \equiv |\boldsymbol{\omega}|$,

$$\omega = (\omega_r^2 + \omega_z^2)^{1/2} = R(g_{,R}^2 + g_{,Z}^2)^{1/2}, \tag{2.9}$$

along the $\mathbf{e}_\theta$ direction. Or equivalently, the deformation consists of a simple shear of amount $\Omega \equiv |\boldsymbol{\Omega}|$, along the direction of $\mathbf{E}_\theta$, followed by the rotation $\boldsymbol{Q}$. Notice that both representations correspond to the same amount of shear $\omega = \Omega$, with glide planes normal to $\boldsymbol{\omega}$ and $\boldsymbol{\Omega}$, respectively. The notation ω and Ω for the amount of shear will be employed interchangeably when need arises.

For the generalized azimuthal deformation (2.2), the left Cauchy–Green strain tensor $\boldsymbol{B} = \boldsymbol{F}\boldsymbol{F}^T$ can be written in terms of the current basis $\{\mathbf{e}_r, \mathbf{e}_\theta, \mathbf{e}_z\}$ as

$$\boldsymbol{B} = \boldsymbol{I} + \boldsymbol{\omega} \otimes \mathbf{e}_\theta + \mathbf{e}_\theta \otimes \boldsymbol{\omega} + \omega^2 \mathbf{e}_\theta \otimes \mathbf{e}_\theta. \tag{2.10}$$

Its invariants are simply

$$I_1 = I_2 = I = \omega_r^2 + \omega_z^2 + 3 = \omega^2 + 3, \quad I_3 = 1. \tag{2.11}$$

Assume the hyperelastic material is homogeneous and isotropic, so its strain energy function Wcan be expressed in terms of the invariants as

$$W = \bar{W}(I_1, I_2, I_3). \tag{2.12}$$

For compatibility with the infinitesimal theory, the strain energy function must satisfy the following restrictions at $I_1 = I_2 = 3$ and $I_3 = 1$,

$$\bar{W}(3,3,1) = 0, \quad \bar{W}_1 + \bar{W}_2 = -(\bar{W}_2 + \bar{W}_3) = \frac{\mu}{2}, \tag{2.13}$$

$$\bar{W}_{11} + 4\bar{W}_{12} + 4\bar{W}_{22} + 2\bar{W}_{13} + 4\bar{W}_{23} + \bar{W}_{33} = \frac{\kappa}{4} + \frac{\mu}{3}, \tag{2.14}$$

where $\bar{W}_i = \partial \bar{W}/\partial I_i$ and $\bar{W}_{ij} = \partial^2 \bar{W}/\partial I_i \partial I_j$; κ and μ are the bulk and shear moduli, respectively.

For the generalized azimuthal deformation (2.2), the Cauchy stress tensor

$$\boldsymbol{\sigma} = 2\bar{W}_1 \boldsymbol{B} + 2\bar{W}_2(I_1 \boldsymbol{B} - \boldsymbol{B}^2) + 2\bar{W}_3 \boldsymbol{I} \tag{2.15}$$

can obtain the alternative representation

$$\boldsymbol{\sigma} = \hat{\sigma}\boldsymbol{I} + \hat{\mu}(\boldsymbol{\omega} \otimes \mathbf{e}_\theta + \mathbf{e}_\theta \otimes \boldsymbol{\omega}) + (\hat{\mu} - \hat{\beta})\omega^2 \mathbf{e}_\theta \otimes \mathbf{e}_\theta - \hat{\beta}\boldsymbol{\omega} \otimes \boldsymbol{\omega}, \tag{2.16}$$

in terms of the material response functions

$$\hat{\sigma}(\omega) = 2[\bar{W}_1 + (I-1)\bar{W}_2 + W_3]\Big|_{I_1 = I_2 = I = 3+\omega^2, I_3 = 1}, \tag{2.17}$$

$$\hat{\mu}(\omega) = 2(\bar{W}_1 + \bar{W}_2)\Big|_{I_1 = I_2 = I = 3+\omega^2, I_3 = 1}, \tag{2.18}$$

$$\hat{\beta}(\omega) = 2\bar{W}_2\Big|_{I_1 = I_2 = I = 3+\omega^2, I_3 = 1} \tag{2.19}$$

by use of relation (2.10). The components of the Cauchy stress in cylindrical coordinates now take the form

$$\sigma_{rr} = \hat{\sigma} - \hat{\beta}\omega_r^2, \quad \sigma_{\theta\theta} = \hat{\sigma} + (\hat{\mu} - \hat{\beta})\omega^2, \quad \sigma_{zz} = \hat{\sigma} - \hat{\beta}\omega_z^2 \tag{2.20}$$

and

$$\sigma_{r\theta} = \hat{\mu}\omega_r, \quad \sigma_{z\theta} = \hat{\mu}\omega_z, \quad \sigma_{rz} = -\hat{\beta}\omega_r\omega_z. \tag{2.21}$$

It will be convenient in what follows to introduce the notation

$$\hat{W}(\omega) = \bar{W}(3 + \omega^2, 3 + \omega^2, 1). \tag{2.22}$$

The material's shear stress response $\hat{\tau}(\omega)$ with respect to simple shear is then given by

$$\hat{\tau}(\omega) = \hat{W}'(\omega) = 2\omega(\bar{W}_1 + \bar{W}_2)\Big|_{I_1=I_2=3+\omega^2, I_3=1}. \tag{2.23}$$

The response function $\hat{\mu}$ defined above is then the secant modulus with respect to simple shear

$$\hat{\mu} = \hat{\tau}(\omega)/\omega = \hat{W}'(\omega)/\omega. \tag{2.24}$$

One can readily show that for the deformation at hand, $\hat{\tau} = \sqrt{\sigma_{r\theta}^2 + \sigma_{z\theta}^2} = \hat{\mu}\omega$ is the resolved shear stress. Note that as $\omega \to 0$, the secant modulus recovers the shear modulus of the infinitesimal theory, $\hat{\mu}(0) = \mu$. Also note that, for consistency with (2.13) and (2.14), $\hat{W}(\omega)$ must satisfy

$$\hat{W}(0) = 0, \quad \hat{W}'(0) = 0, \quad \hat{W}''(0) = \mu > 0. \tag{2.25}$$

Further, we assume $\hat{W}$ satisfies the following condition:

$$\hat{W}'(\omega) > 0 \quad \text{for } \omega > 0. \tag{2.26}$$

This can be viewed as a specialization to simple shear of the Baker–Ericksen inequality. We may also assume that $\hat{W}''(\omega) > 0$ so that $\hat{\tau}$ is a monotonic increasing function of ω; hence increasing shear corresponds to increasing stress, although this restriction can be relaxed if need be.

In view of (2.11) and (2.12), the stress components (2.20)–(2.21) depend on ω and in turn depend on R and Z, and equivalently on r and z by (2.2). The equilibrium equations $\operatorname{div}\boldsymbol{\sigma} = \mathbf{0}$ specialize to

$$\frac{\partial\sigma_{rr}}{\partial r} + \frac{\partial\sigma_{rz}}{\partial z} + \frac{1}{r}(\sigma_{rr} - \sigma_{\theta\theta}) = 0, \tag{2.27}$$

$$\frac{\partial\sigma_{r\theta}}{\partial r} + \frac{\partial\sigma_{\theta z}}{\partial z} + \frac{2}{r}\sigma_{r\theta} = 0, \tag{2.28}$$

$$\frac{\partial\sigma_{rz}}{\partial r} + \frac{\partial\sigma_{zz}}{\partial z} + \frac{1}{r}\sigma_{rz} = 0. \tag{2.29}$$

Using the notation in (2.21), it can be shown that the azimuthal equation (2.28) can be written as

$$\frac{\partial}{\partial R}\Big(R^3\hat{\mu}\Big(R\sqrt{g_{,R}^2 + g_{,Z}^2}\Big)g_{,R}\Big) + \frac{\partial}{\partial Z}\Big(R^3\hat{\mu}\Big(R\sqrt{g_{,R}^2 + g_{,Z}^2}\Big)g_{,Z}\Big) = 0, \tag{2.30}$$

where we have recognized the fact that $r = R$ and $z = Z$ from (2.2). A more compact expression takes the following form:

$$\nabla \cdot (R^3 \hat{\mu}(R|\nabla g|)\nabla g) = 0, \tag{2.31}$$

where ∇ should be interpreted as the gradient operator in the two-dimensional (R, Z)–space.

Throughout the rest of this article we will assume that the equation governing the form of the azimuthal displacement is locally elliptic at a solution g at the reference point $\mathbf{X}$ [7]. It is not difficult to show that this requirement is equivalent to the two inequalities

$$\hat{W}''(\omega) > 0, \quad \hat{W}'(\omega)/\omega > 0 \tag{2.32}$$

for all $\omega > 0$, which we have already adopted. These two inequalities coincide with those imposed by Knowles [17] for the antiplane shear problem to ensure the ellipticity of the governing axial equation and the conditions imposed in [15] for the problem of helical shear, to ensure uniqueness of solution for moderate values of the applied loading. Furthermore, a concise expression adopted in [23], incorporating both relations in (2.32), can be written in the form

$$\hat{\mu}(\hat{\mu}\omega)' > 0, \tag{2.33}$$

where the prime signifies differentiation with respect to the shear ω.

It would be beneficial to consider the equations of equilibrium in an alternative form for reference in the discussion of boundary value problems for the generalized azimuthal shear problem in section 5. In terms of the nominal stress tensor $\boldsymbol{S} = \boldsymbol{F}^{-1}\boldsymbol{\sigma}$, the equilibrium equations $\mathrm{Div}\boldsymbol{S} = \mathbf{0}$ obtain the form

$$\frac{\partial S_{Rr}}{\partial R} + \frac{\partial S_{Zr}}{\partial Z} - g_{,R}S_{R\theta} - g_{,Z}S_{Z\theta} + \frac{1}{R}(S_{Rr} - S_{\Theta\theta}) = 0, \tag{2.34}$$

$$\frac{\partial S_{R\theta}}{\partial R} + \frac{\partial S_{Z\theta}}{\partial Z} + g_{,R}S_{Rr} + g_{,Z}S_{Zr} + \frac{1}{R}(S_{R\theta} + S_{\Theta r}) = 0, \tag{2.35}$$

$$\frac{\partial S_{Rz}}{\partial R} + \frac{\partial S_{Zz}}{\partial Z} + \frac{1}{R}S_{Rz} = 0, \tag{2.36}$$

where the components of the nominal stress tensor $\boldsymbol{S}$ are given by

$$S_{Rr} = 2\bar{W}_1 + 2\bar{W}_2(2 + \omega_z^2) + 2\bar{W}_3, \quad S_{R\theta} = 2\omega_r\left(\bar{W}_1 + \bar{W}_2\right), \tag{2.37}$$

$$S_{Rz} = S_{Zr} = -2\omega_z\omega_r\bar{W}_2, \quad S_{Z\theta} = 2\omega_z\left(\bar{W}_1 + \bar{W}_2\right), \tag{2.38}$$

$$S_{\Theta r} = -2(\bar{W}_2 + \bar{W}_3)\omega_r, \quad S_{\Theta z} = -2(\bar{W}_2 + \bar{W}_3)\omega_z, \tag{2.39}$$

$$S_{\Theta\theta} = 2(I - 2)\bar{W}_1 + 2(I - 1)\bar{W}_2 + 2\bar{W}_3, \tag{2.40}$$

$$S_{Zz} = 2\bar{W}_1 + 2(2 + \omega_r^2)\bar{W}_2 + 2\bar{W}_3, \tag{2.41}$$

evaluated for $I_1 = I_2 = I = 3 + \omega_r^2 + \omega_z^2 = 3 + \omega^2, I_3 = 1$. For nominal stress, we have $S_{R\theta} = \hat{\mu}\omega_r$ and $S_{Z\theta} = \hat{\mu}\omega_r$. From (2.21) and (2.38), it is clear that $\sigma_{r\theta} = S_{r\theta}$ and

$\sigma_{z\theta} = S_{Z\theta}$. It should be noted here that (2.34)–(2.36) can be recovered as a special case of the more general form of the equilibrium equations (2.14a)–(2.14c) of reference [21] associated with the more general form of the deformation field

$$r = r(R, \Theta, Z), \quad \theta = \theta(R, \Theta, Z), \quad z = z(R, \Theta, Z). \tag{2.42}$$

In [21] the authors emphasize the nominal stress (material) formulation of the equilibrium equations in contrast to a Cauchy stress (spatial) formulation and describe why the former representation is more advantageous in specific cases.

3. Transformation of the equations of equilibrium. In general, the equations of equilibrium (2.27)–(2.29) form an overdetermined system for the azimuthal displacement $g(R, Z)$. Specifically, for a suitable secant modulus, the azimuthal equation (2.30) determines a unique g. This solution does not always satisfy the other two equations unless additional restrictions are imposed on the form of the strain energy function W. When these conditions are met, every solution of the azimuthal equation (2.28) will automatically satisfy the other two equations of equilibrium. Then, the system (2.27)–(2.29) reduces to a single quasi-linear partial differential equation for one unknown function g involving only a single constitutive function—the secant shear modulus $\hat{\mu}$. This is exactly the motivation behind the consideration of such specialized deformation classes: to have a single, well-behaved equation for the displacement. The other two equilibrium equations can be ignored, since they are satisfied automatically. Restrictions on the stored energy function always ensure this to be the case.

In what follows we follow the approach by Knowles [16] and Tsai and Fan [23] and implement one-to-one and smooth mappings from the configuration space to a region in the shear strain space. However, in contrast to the problem of antiplane shear, here the basis vectors in the deformed configuration depend nonlinearly on the reference coordinates R and Z, through their dependence on the unknown function $g(R, Z)$, and this nonlinearity carries over to their counterparts in the strain space.

Let $\mathcal{S}_o$ and $\mathcal{S}$ denote the reference and current strain spaces, respectively. We introduce the *reduced shear* vectors, $\boldsymbol{\Gamma} \in \mathcal{S}_o$ and $\boldsymbol{\gamma} \in \mathcal{S}$, associated with the reference and current configurations, respectively, which are defined by

$$\boldsymbol{\Gamma} = \nabla_X g = g_{,R}\mathbf{E}_R + g_{,Z}\mathbf{E}_Z = \boldsymbol{\Omega}/R, \tag{3.1}$$

$$\boldsymbol{\gamma} = \nabla_x g = g_{,R}\mathbf{e}_r + g_{,Z}\mathbf{e}_z = \boldsymbol{\omega}/R = \boldsymbol{Q}\boldsymbol{\Gamma}. \tag{3.2}$$

Note that g will be considered as a scalar function of $\mathbf{X} \in \mathcal{B}_o$ (the reference configuration space) when associated with $\boldsymbol{\Gamma}$, while it will be considered as a scalar function of $\mathbf{x} \in \mathcal{B}$ (the current configuration) when associated with $\boldsymbol{\gamma}$. For simplicity, we use the same notation for various functional representations of the same quantity unless otherwise indicated, so that, for example, $g(\mathbf{X}) = g(\mathbf{x}) = g(R, Z)$. We can consider the two strain vectors as being related by a mapping $\boldsymbol{\psi}$,

$$\boldsymbol{\psi} : \mathcal{S}_o \to \mathcal{S}, \quad \text{such that} \quad \boldsymbol{\gamma} = \boldsymbol{\psi}(\boldsymbol{\Gamma}) \tag{3.3}$$

and $\boldsymbol{\psi}(\boldsymbol{\Gamma}) = \boldsymbol{Q}\boldsymbol{\Gamma}$. Comparing the mappings in (2.3) and (3.3) we notice that the effect of using variables in the strain space has led to a linear relation $\boldsymbol{\gamma} = \boldsymbol{Q}\boldsymbol{\Gamma}$ between the vectors that define deformation in this space. We continue this analysis by constructing a new spherical coordinate system in the shear strain space $\mathcal{S}_o$ with coordinates (Γ, Φ, Θ) in the reference strain space whose radial unit vector points to the direction of the reduced strain vector $\boldsymbol{\Gamma}$. Therefore, we have

$$\Gamma = |\boldsymbol{\Gamma}|, \qquad \Phi = \arctan\frac{\omega_r}{\omega_z} \tag{3.4}$$

and Θ is the same as in $\mathcal{B}_o$. The associated unit vectors in $\mathcal{S}_o$ can be expressed in terms of their cylindrical counterparts in $\mathcal{B}_o$,

$$\mathbf{E}_\Gamma = \sin\Phi\mathbf{E}_R + \cos\Phi\mathbf{E}_Z, \tag{3.5}$$

$$\mathbf{E}_\Phi = \cos\Phi\mathbf{E}_R + \sin\Phi\mathbf{E}_Z, \tag{3.6}$$

with the azimuthal unit vector $\mathbf{E}_\Theta$ the same as the one in the configuration space. Therefore, in the discussion above we introduced a transformation from the reference configuration space to the reference strain space, characterized by the mapping $\hat{\boldsymbol{\Xi}}$,

$$\hat{\boldsymbol{\Xi}} : \mathcal{B}_o \to \mathcal{S}_o \quad \text{such that} \quad \hat{\boldsymbol{\Xi}}(\mathbf{X}) = \boldsymbol{\Gamma} = \Gamma\mathbf{E}_\Gamma. \tag{3.7}$$

The inverse mapping is denoted by $\hat{\mathbf{X}} : \mathcal{S}_o, \to \mathcal{B}_o$ so that

$$\hat{\mathbf{X}}(\hat{\boldsymbol{\Xi}}(\mathbf{X})) = \mathbf{X} \qquad \text{and} \qquad \hat{\boldsymbol{\Xi}}(\hat{\mathbf{X}}(\boldsymbol{\Gamma})) = \boldsymbol{\Gamma}. \tag{3.8}$$

The maps defined above are summarized on the following diagram:

$$\begin{array}{ccc} \mathcal{B}_o & \xrightarrow{\boldsymbol{\chi}} & \mathcal{B} \\ \hat{\boldsymbol{X}} \uparrow \downarrow \hat{\boldsymbol{\Xi}} & & \downarrow \\ \mathcal{S}_o & \xrightarrow[\boldsymbol{\psi}]{} & \mathcal{S} \end{array}.$$

The analysis above has prepared the grounds for the introduction of the Legendre transformation of the function $g : \mathcal{B}_o \to \mathbb{R}$, given by the conjugate function $G : \mathcal{S}_o \to \mathbb{R}$,

$$G(\Gamma, \Phi) = \mathbf{X} \cdot \boldsymbol{\Gamma} - g(R, Z). \tag{3.9}$$

From this expression, the following connections can be derived:

$$R\mathbf{E}_R + Z\mathbf{E}_Z = \mathbf{X} = \nabla_\Gamma G = G_{,\Gamma}\mathbf{E}_\Gamma + \frac{1}{\Gamma}G_{,\Phi}\mathbf{E}_\Phi, \tag{3.10}$$

and hence R and Z can be expressed in terms of Γ and Φ:

$$R = R(\Gamma, \Phi) = \sin\Phi G_{,\Gamma} + \frac{1}{\Gamma}\cos\Phi G_{,\Phi}, \tag{3.11}$$

$$Z = Z(\Gamma, \Phi) = \cos\Phi G_{,\Gamma} - \frac{1}{\Gamma}\sin\Phi G_{,\Phi}. \tag{3.12}$$

We denote the gradient of the mapping $\hat{\boldsymbol{\Xi}}$ in (3.7) by

$$\boldsymbol{H}(\mathbf{X}) = \nabla_X \hat{\boldsymbol{\Xi}}(\mathbf{X}), \quad \forall\, \mathbf{X} \in \mathcal{B}_o. \tag{3.13}$$

The assumption that the mapping be smoothly invertible requires that the Jacobian $\det \boldsymbol{H} \neq 0$; this is exactly the necessary and sufficient condition for the existence of the Legendre transformation (3.9). It follows from (3.8) that the gradient of the inverse mapping is

$$\nabla_\Xi \hat{\mathbf{X}}(\boldsymbol{\Gamma}) = \boldsymbol{H}^{-1}(\mathbf{X}) \text{ evaluated at } \mathbf{X} = \hat{\mathbf{X}}(\boldsymbol{\Gamma}). \tag{3.14}$$

Using this mapping we can now calculate the components of the gradient of the vector $\mathbf{X}$ in the reference strain basis as

$$\boldsymbol{H}^{-1} = \begin{pmatrix} G_{,\Gamma\Gamma} & \left(\frac{1}{\Gamma}G_{,\Phi}\right)_{,\Gamma} & 0 \\ \left(\frac{1}{\Gamma}G_{,\Phi}\right)_{,\Gamma} & \frac{1}{\Gamma}\left(\frac{1}{\Gamma}G_{,\Phi\Phi}+G_{,\Gamma}\right) & 0 \\ 0 & 0 & \frac{R(\Gamma,\Phi)}{\Gamma\sin\Phi} \end{pmatrix}, \tag{3.15}$$

where $R(\Gamma,\Phi)$ is given by (3.11). For the calculation of the equilibrium equations we will also need the inverse of the gradient of $\hat{\mathbf{X}}$ given by

$$\boldsymbol{H} = \frac{1}{\bar{D}}\begin{pmatrix} \frac{1}{\Gamma}\left(\frac{1}{\Gamma}G_{,\Phi\Phi}+G_{,\Gamma}\right) & -\left(\frac{1}{\Gamma}G_{,\Phi}\right)_{,\Gamma} & 0 \\ -\left(\frac{1}{\Gamma}G_{,\Phi}\right)_{,\Gamma} & G_{,\Gamma\Gamma} & 0 \\ 0 & 0 & \frac{\Gamma\sin\Phi}{R(\Gamma,\Phi)}\bar{D} \end{pmatrix}, \tag{3.16}$$

where $\bar{D} = \bar{D}(\Gamma,\Phi)$ is the determinant of the upper-left two-by-two submatrix of $\boldsymbol{H}^{-1}$, i.e.,

$$\bar{D}(\Gamma,\Phi) = \frac{1}{\Gamma}G_{,\Gamma\Gamma}\Big(\frac{1}{\Gamma}G_{,\Phi\Phi}+G_{,\Gamma}\Big) - \left[\Big(\frac{1}{\Gamma}G_{,\Phi}\Big)_{,\Gamma}\right]^2. \tag{3.17}$$

The nominal stress tensor in the strain space coordinates, $\boldsymbol{S}^*(\boldsymbol{\Gamma}) = \boldsymbol{S}(\hat{\mathbf{X}}(\boldsymbol{\Gamma}))$ can be written as

$$\begin{aligned} \boldsymbol{S}^* &= (\hat{\sigma}-\hat{\beta}R^2\Gamma^2)\mathbf{E}_\Gamma\otimes\mathbf{e}_\gamma + \hat{\sigma}\mathbf{E}_\Phi\otimes\mathbf{e}_\phi + (\hat{\sigma}-\hat{\beta}R^2\Gamma^2)\mathbf{E}_\Theta\otimes\mathbf{e}_\theta \\ &+\hat{\mu}R\Gamma\mathbf{E}_\Gamma\otimes\mathbf{e}_\theta + (\hat{\mu}-\hat{\sigma}+\hat{\beta}R^2\Gamma^2)R\Gamma\mathbf{E}_\Theta\otimes\mathbf{e}_\gamma, \end{aligned} \tag{3.18}$$

where the response functions $\hat{\beta}$, $\hat{\sigma}$, and $\hat{\mu}$ are evaluated at $\omega = R\Gamma$. The radial, polar, and azimuthal components of the equilibrium equations, $\nabla_\Xi[\boldsymbol{S}^*]\cdot\boldsymbol{H} = \mathbf{0}$, in the *current* strain space, respectively, obtain the form

$$(\hat{\sigma}-\hat{\beta}R^2\Gamma^2)_{,\Gamma}\bar{E} - (\hat{\sigma}-\hat{\beta}R^2\Gamma^2)_{,\Phi}\bar{B} - \hat{\beta}\Gamma^2R^2\bar{A} - \bar{D}\hat{\mu}\Gamma^2R\sin\Phi = 0, \tag{3.19}$$

$$(-\hat{\sigma}_{,\Gamma}+\hat{\beta}R^2\Gamma)\Gamma\bar{B} + \bar{A}\hat{\sigma}_{,\Phi} + \bar{D}(\hat{\beta}-\hat{\mu})\Gamma^2R\cos\Phi = 0, \tag{3.20}$$

$$(\hat{\mu}R\Gamma)_{,\Gamma}\bar{E} + \hat{\mu}R\Gamma\bar{A} - (\hat{\mu}R\Gamma)_{,\Phi}\bar{B} + 2\bar{D}\hat{\mu}\Gamma\sin\Phi = 0, \tag{3.21}$$

where $\bar{A},\bar{B},\bar{E},\bar{D}$ are functions of Γ,Φ defined as follows: $\bar{A}(\Gamma,\Phi) = \frac{1}{\Gamma}G_{,\Gamma\Gamma}$, $\bar{B}(\Gamma,\Phi) = \frac{1}{\Gamma}\left(\frac{1}{\Gamma}G_{,\Phi}\right)_{,\Gamma}$, $\bar{E}(\Gamma,\Phi) = \frac{1}{\Gamma}\left(\frac{1}{\Gamma}G_{,\Phi\Phi}+G_{,\Gamma}\right)$, and $\bar{D}$ is defined in (3.17). In addition, use has been made of Eulerian strain space quantities and their derivatives with respect to Lagrangian strain space variables, which appear in the appendix. We now consider the real amount of shear $\Omega = R\Gamma$, where the upper case notation is kept throughout this section to emphasize use of quantities in the reference configuration. Using this notation, the equilibrium equations can be transformed into the following equivalent set:

$$\bar{D}\Gamma\sin\Phi\left[(\hat{\sigma}-\hat{\beta}\Omega^2)_{,\Omega}-\hat{\mu}\Omega\right] - \hat{\beta}\Omega^2\bar{A} + \bar{E}R[\hat{\sigma}-\hat{\beta}\Omega^2]_{,\Omega} = 0, \tag{3.22}$$

$$\bar{D}\Gamma\cos\Phi\left[\hat{\sigma}_{,\Omega}+\Omega(\hat{\beta}-\hat{\mu})\right] + R\Gamma\bar{B}[-\hat{\sigma}_{,\Omega}+\hat{\beta}\Omega] = 0, \tag{3.23}$$

$$\bar{D}\Gamma\sin\Phi\left[(\hat{\mu}\Omega)_{,\Omega}+2\hat{\mu}\right] + \hat{\mu}\Omega\bar{A} + \bar{E}R[\hat{\mu}\Omega]_{,\Omega} = 0. \tag{3.24}$$

In the next section, we derive the necessary and sufficient conditions satisfied by the constitutive functions $\hat{\mu}, \hat{\beta}, \hat{\sigma}$ such that the above system collapses into a single equation. Materials that satisfy these conditions are referred to as being able to support a state of generalized azimuthal shear.

4. Necessary and sufficient conditions for materials to support generalized azimuthal shear. In what follows we establish necessary and sufficient conditions on the strain energy function of an isotropic material to support a state of generalized azimuthal shear (1.1) in the sense that every solution to the azimuthal equation of equilibrium will satisfy the remaining two equations. The derivation here differs from those by Knowles [16] and Tsai and Fan [23] in that we do not seek to satisfy a solution of a special form for the azimuthal equation, but we essentially look at a superset of conditions whose combination will provide the required results. Our main result in this section is as follows.

THEOREM 4.1. *A homogeneous, compressible isotropic hyperelastic material with stored-energy function characterized by* (2.12)*, can support a state of generalized azimuthal shear* (1.1) *if and only if the constitutive functions* $\hat{\sigma}$*,* $\hat{\beta}$*, and* $\hat{\mu}$ *characterized by* (2.17), (2.18)*, and* (2.19) *satisfy*

$$\hat{\sigma}_{,\Omega} = \hat{\beta}\Omega, \quad \hat{\beta} = \frac{\hat{\mu}}{2}. \tag{4.1}$$

Proof. To prove sufficiency, we first consider a material that satisfies conditions (4.1). Then the polar component of the equilibrium equations (3.23) is automatically satisfied. Also from the relations (4.1), it follows that

$$\frac{1}{\Omega}(\hat{\sigma} - \hat{\beta}\Omega^2)_{,\Omega} = -(\hat{\beta}\Omega)_{,\Omega} = -\frac{1}{2}(\hat{\mu}\Omega)_{,\Omega} \quad \text{and} \quad \hat{\beta}\Omega = \frac{1}{2}(\hat{\mu}\Omega). \tag{4.2}$$

It then follows that the radial equation (3.22) is equivalent to the azimuthal equation (3.24). Thus, any solution to the azimuthal equation (3.24) satisfies (3.22) and (3.23).

To prove necessity, we consider the necessary and sufficient conditions derived from the literature for pure torsion [18] and pure azimuthal shear [2], which, in our notation, can be rewritten respectively in the form

$$\hat{\sigma}_{,\Omega} = \Omega(\hat{\mu} - \hat{\beta}), \tag{4.3}$$

$$\hat{\sigma}_{,\Omega} = -\frac{1}{2}\left(\Omega(\hat{\mu} - 4\hat{\beta}) + \Omega^2(\hat{\mu} - 2\hat{\beta})_{,\Omega}\right). \tag{4.4}$$

We now assume that a strain energy function supports a state of generalized azimuthal shear (1.1); it follows that it will support *both* a state of pure torsion (and therefore satisfy (4.3)) *and* a state of pure azimuthal shear (and therefore will satisfy (4.4)). Combining the two expressions (4.3) and (4.4) we arrive at the equivalent system

$$3\hat{\mu} + \Omega\hat{\mu}_{,\Omega} = 6\hat{\beta} + 2\Omega\hat{\beta}_{,\Omega}. \tag{4.5}$$

Multiply both sides by Ω^2 and integrate to find

$$\hat{\beta} = \frac{1}{2}\hat{\mu}, \tag{4.6}$$

where the integration constant is taken to be zero for $\Omega \to 0$. Substitute from the above into (4.3) to recover $(4.1)_1$. This concludes the proof of necessity. ∎

4.1. Sufficient conditions on W to support deformations that locally reduce to simple shear. We have already recorded the necessary and sufficient conditions on the strain energy function to support a state of pure torsion in (4.3) (cf. [18]) and a state of pure azimuthal shear in (4.4) (cf. [2, 20]). We augment this set by the necessary and sufficient conditions to support a state of axisymmetric antiplane shear [14, 19] and a state of antiplane shear [17], which, in our notation, can be written, respectively, in the form

$$\hat{\mu}(\hat{\sigma}_{,\Omega} - \hat{\beta}\Omega) = (\hat{\mu}\hat{\beta}_{,\Omega} - \hat{\beta}\hat{\mu}_{,\Omega})\Omega \tag{4.7}$$

and

$$\hat{\sigma}_{,\Omega} = \hat{\beta}\Omega, \quad \hat{\beta} = b\hat{\mu}, \tag{4.8}$$

where b is a constant. It is a straightforward task to deduce then that the conditions (4.1) that support a state of generalized azimuthal shear are *sufficient* to support all deformations above. Therefore, strain energy functions that satisfy conditions (4.1) form a distinctive class of materials to which more attention is devoted in the following two paragraphs.

4.2. Strain energies and necessary and sufficient conditions in terms of I_1, I_2, I_3. In terms of the principal invariants of the left (or right) Cauchy–Green strain tensors the conditions (4.1) take the form

$$\bar{W}_1 = \bar{W}_2, \tag{4.9}$$

$$\bar{W}_1 + 2I(\bar{W}_{11} + \bar{W}_{12}) + 2\bar{W}_{13} + 2\bar{W}_{23} = 0 \tag{4.10}$$

for $I_1 = I_2 = I, I_3 = 1$. The second of these conditions involve second derivatives of the strain energy with respect to the principal invariants. However, it was shown in [15] that the second of these conditions is equivalent to

$$4I\bar{W}_1 + 4\bar{W}_3 - \bar{W} = 0. \tag{4.11}$$

In summary, the following two equations:

$$\bar{W}_1(I, I, 1) = \bar{W}_2(I, I, 1), \quad 4I\bar{W}_1(I, I, 1) + 4\bar{W}_3(I, I, 1) - \bar{W}(I, I, 1) = 0 \tag{4.12}$$

constitute the necessary and sufficient conditions for the strain energy function to admit a state of general azimuthal shear, in terms of the principal invariants of the Cauchy–Green strain tensors.

We may now attempt to derive some possible forms of strain energy functions that satisfy the conditions (4.12) and ideally support a generalized azimuthal shear deformation (1.1). We begin by considering a strain energy function in the form

$$\bar{W}(I_1, I_2, I_3) = f_1(I_1)h_1(I_3) + f_2(I_2)h_2(I_3) + h_3(I_3), \tag{4.13}$$

where f_1 and f_2 are functions to be determined, while h_1, h_2, h_3 have to be compatible with (2.13) and (2.14). Without loss of generality we may set

$$h_1(1) = h_2(1) = 1. \tag{4.14}$$

It was shown in [15], that a strain energy function of the form (4.13) that satisfies the necessary and sufficient conditions (4.12), necessarily has the form

$$\bar{W}(I_1, I_2, I_3) = \frac{3\mu}{4k3^k}\left[I_1^k h_1(I_3) + I_2^k h_2(I_3)\right] + h_3(I_3) \tag{4.15}$$

for $k \neq 0$ and

$$\bar{W}(I_1, I_2, I_3) = \frac{3\mu}{4}\left[\log I_1 h_1(I_3) + \log I_2 h_2(I_3)\right] + h_3(I_3) \tag{4.16}$$

for $k = 0$. A widely used constitutive assumption, being a special case of (4.15) for the value of the constant $k = 1$, is the generalized Hadamard material [1, 14, 18, 19, 20]. Further discussion of this material in the context of the solution of boundary value problems is included in section 5.

4.3. Strain energies and necessary and sufficient conditions in terms of i_1, i_2, i_3. In this subsection we recast the conditions (4.12) as equivalent conditions in terms of the principal invariants of the stretch tensor $\boldsymbol{U}$ arising in the polar decomposition $\boldsymbol{F} = \boldsymbol{RU}$ of the deformation gradient. These are related to the invariants of the left Cauchy–Green strain tensor through

$$I_1 = i_1^2 - 2i_2, \quad I_2 = i_2^2 - 2i_1 i_3, \quad I_3 = i_3^2 \tag{4.17}$$

and are expressed in terms of the principal stretches as

$$i_1 = \lambda_1 + \lambda_2 + \lambda_3, \quad i_2 = \lambda_1\lambda_2 + \lambda_2\lambda_3 + \lambda_1\lambda_3, \quad i_3 = \lambda_1\lambda_2\lambda_3. \tag{4.18}$$

Then, by using the notation $\tilde{W}(i_1, i_2, i_3)$ to represent the strain energy when regarded as a function of i_1, i_2, i_3, it is straightforward to show that (4.12) are re-expressed as

$$\tilde{W}_1(i, i, 1) = \tilde{W}_2(i, i, 1), \quad 2i\tilde{W}_1(i, i, 1) + 2\tilde{W}_3(i, i, 1) - \tilde{W}(i, i, 1) = 0, \tag{4.19}$$

where the subscripts denote partial derivatives with respect to i_1, i_2, i_3 and we have considered the first two principal directions to lie on the plane of shear. We consider the strain energy function

$$\tilde{W}(i_1, i_2, i_3) = f(i_1)h_1(i_3) + f(i_2)h_2(i_3) + h_3(i_3), \tag{4.20}$$

which is the counterpart of (4.13), so that $(4.19)_1$ is satisfied provided $h_1(1) = h_2(1)$. We therefore set

$$h_1(1) = h_2(1) = 1. \tag{4.21}$$

Equation $(4.19)_2$ then leads to

$$\tilde{W}(i_1, i_2, i_3) = \frac{3\mu}{k3^k}\left[i_1^k h_1(i_3) + i_2^k h_2(i_3)\right] + h_3(i_3), \tag{4.22}$$

where, in addition to (4.21),

$$h_1'(1) + h_2'(1) = 1 - k, \quad h_3(1) = -\frac{6\mu}{k}, \quad h_3'(1) = -\frac{3\mu}{k} \tag{4.23}$$

for all nonzero values of k, in a manner analogous to [15]. For $k = 1$, the strain energy function has the form

$$\tilde{W}(i_1, i_2, i_3) = \mu\left[i_1 h_1(i_3) + i_2 h_2(i_3)\right] + h_3(i_3). \tag{4.24}$$

For the special case $h_1'(i_3) = h_2'(i_3) \equiv 0$ this energy function reduces to a (compressible) Varga material that was introduced by Carroll [6] (cf. [12]).

4.4. Strain energies and necessary and sufficient conditions in terms of the principal stretches, $\boldsymbol{\lambda_1, \lambda_2, \lambda_3}$. Since the conditions (4.12) are also necessary and sufficient to support a state of helical shear, they can be described in terms of the principal stretches, with $W = W(\lambda_1, \lambda_2, \lambda_3)$, in the form

$$\lambda W_1 + \lambda^{-1} W_2 - W = 0, \quad \lambda W_1 + \lambda^{-1} W_2 - 2W_3 = 0, \tag{4.25}$$

where subscripts denote differentiation with respect to the principal stretches and the strain energy is evaluated at $\lambda_1 = \lambda, \lambda_2 = \lambda^{-1}, \lambda_3 = 1$. The reader is referred to [15] for the details of this derivation. Furthermore, it was shown in [15] that the strain energy function

$$W = f(I_{(\alpha)})h_1(J) + f(I_{(-\alpha)})h_2(J) + h_3(J), \tag{4.26}$$

with $I_{(\alpha)} = \lambda^\alpha + \lambda^{-\alpha} + 1$ and $J = \lambda_1 + \lambda_2 + \lambda_3$, satisfies the conditions (4.25), for any function f and $\alpha \neq 0$, subject to some conditions on the functions h_1, h_2, h_3, which for brevity are not included here.

5. Boundary value problems for generalized azimuthal shear deformations. In this section we intend to investigate specific solutions of the equilibrium equations for materials undergoing generalized azimuthal deformations. To find the general solutions to the equilibrium equations, we could have started, in principle, from the equilibrium equations (3.22)–(3.24) in the strain space and calculated the desired unknown displacement function. This would be lengthy though, if feasible at all, since the transformed equilibrium equations are not linear as was the case for the corresponding equations formulated in strain space coordinates for the antiplane shear deformations [23]. Instead, we concentrate on the equilibrium equations in their configuration space form (2.34)–(2.36). To this end, we substitute the first of the necessary and sufficient conditions,

$$\bar{W}_1 = \bar{W}_2, \tag{5.1}$$

into the equilibrium equations (2.34)–(2.36), which reduce to

$$\frac{\partial}{\partial R}\left((\omega_z^2 + 3)\bar{W}_1 + \bar{W}_3\right) + \frac{\partial}{\partial Z}\left(-\bar{W}_1\omega_r\omega_z\right) + \frac{1}{R}\left(\bar{W}_1(\omega_z^2 - 2I + 6)\right) = 0, \tag{5.2}$$

$$\frac{\partial}{\partial R}\left(\omega_r\bar{W}_1\right) + \frac{\partial}{\partial Z}\left(\bar{W}_1\omega_z\right) + \frac{2}{R}\left(\omega_r\bar{W}_1\right) = 0, \tag{5.3}$$

$$\frac{\partial}{\partial R}\left(-\bar{W}_1\omega_r\omega_z\right) + \frac{\partial}{\partial Z}\left((\omega_r^2 + 3)\bar{W}_1 + \bar{W}_3\right) + \frac{1}{R}\left(-\bar{W}_1\omega_z\omega_r\right) = 0. \tag{5.4}$$

After some lengthy but straightforward calculations, taking into account the identity $\omega_{z,R} - \omega_{r,Z} - \omega_z/R = 0$ and relation (5.1), equations (5.2), (5.3), and (5.4) reduce to

$$\bar{W}_1 + 2I(\bar{W}_{11} + \bar{W}_{12}) + 2\bar{W}_{13} + 2\bar{W}_{23} = 0 \tag{5.5}$$

and

$$\frac{\partial}{\partial R}\left(R^2\gamma_r\bar{W}_1\right) + \frac{\partial}{\partial Z}\left(R^2\gamma_z\bar{W}_1\right) = 0. \tag{5.6}$$

The first of these relations corresponds to the second order necessary and sufficient condition (4.10) required to support a state of generalized azimuthal shear which, furthermore, is equivalent to its first order counterpart

$$4I\bar{W}_1 + 4\bar{W}_3 - \bar{W} = 0. \tag{5.7}$$

Equation (5.6), which equivalently can be rewritten as

$$\nabla \cdot \left(R^3 \bar{W}_1 \nabla g\right) = 0, \tag{5.8}$$

will provide the form of the azimuthal displacement $g(R, Z)$ given a specific form of the strain energy function $\bar{W}$ (that satisfies the conditions (4.12)). Note that the above discussion constitutes an alternative way to show that conditions (4.1) indeed form a set of *sufficient* expressions a strain energy has to satisfy in order to support a state of generalized azimuthal shear (1.1). For the strain energy (4.15) we obtain

$$\hat{W}(\omega) = \frac{3\mu}{2k3^k}(3 + \omega^2)^k - \frac{3\mu}{2k}, \tag{5.9}$$

and hence

$$\hat{W}'(\omega) = \frac{\mu\omega}{3^{k-1}}(3 + \omega^2)^{k-1}, \tag{5.10}$$

from which the inequality $(2.32)_2$ follows. It is then easy to show that $(2.32)_1$ holds for all $\gamma \geq 0$ if and only if

$$k \geq \frac{1}{2}. \tag{5.11}$$

Henceforth, we consider only members of the class (4.15) for which (5.11) holds, and we note that (4.16) is therefore ruled out.

Substitution of (4.15) into the governing equation (5.8) leads to a quasi-linear PDE for $g(R, Z)$ in general. A special form of (4.15) with $k = 1$, the (general) Hadamard material, has been used widely in the literature [1, 11, 14, 18]. It is given by the expression

$$\bar{W}(I_1, I_2, I_3) = \frac{\mu}{4}\left[I_1 h_1(I_3) + I_2 h_2(I_3)\right] + h_3(I_3), \tag{5.12}$$

where

$$h_3(1) = -\frac{3\mu}{2}, \quad h_3'(1) = -\frac{3\mu}{8}, \tag{5.13}$$

while (5.8) reduces to the following linear (and elliptic) equation:

$$g_{,RR} + g_{,ZZ} + \frac{3}{R} g_{,R} = 0. \tag{5.14}$$

The form of the solution will be determined by the boundary conditions. This issue is dealt within the following paragraphs.

5.1. Boundary value problems involving the general solutions.

5.1.1. Example 1. First, the inner surface of the tube at $r = A$ is held fixed, bonded on a rigid cylinder, while the outer surface at $r = B$ is subjected to a given azimuthal displacement $\varphi(Z)$,

$$g(A, Z) = 0, \quad g(B, Z) = \varphi(Z). \tag{5.15}$$

Furthermore, we consider the following additional conditions on the boundary $g(R, 0) = g(R, L) = 0$, $\varphi(0) = \varphi(L) = 0$. We seek separable solutions for the azimuthal displacement of the form

$$g(R, Z) = f_1(R) f_2(Z). \tag{5.16}$$

On substitution of this separable form into (5.14), the boundary conditions are satisfied given the separation constant is chosen to be positive as l^2, i.e., the axial dependence is taken to vary sinusoidally. With the transformation $f_1(R) = x^{-1}y(x)$, $x = lR$, the ODE involving the radial coordinate reduces to the modified Bessel equation for y of order one. Since the configuration involves a tube of finite radius, both solutions of this equation, the modified Bessel functions of the first kind (I_1) and second kind (K_1) are involved. The final result for the l-mode of $g(R, Z)$, g_l is now given by

$$g_l(R, Z) = \frac{1}{lR} \left[C_l I_1(lR) + D_l K_1(lR) \right] \left[A_l \cos lZ + B_l \sin lZ \right], \tag{5.17}$$

where A_l, B_l, C_l, D_l are constants to be determined by the boundary conditions. Employing the boundary conditions (5.15), the azimuthal displacement can now be written as

$$g(R, Z) = \sum_{n=1}^{\infty} \frac{1}{l_n R} \left[I_1(l_n R) K_1(l_n A) - K_1(l_n R) I_1(l_n A) \right] C_n \sin l_n Z, \tag{5.18}$$

where $l_n = \pi n / L$, for some positive integer n, and

$$C_n = \frac{2}{L E_n} \int_0^L \varphi(Z) \sin l_n Z dZ, \qquad n = 1, \ldots, \infty, \tag{5.19}$$

$$E_n = \frac{1}{l_n B} \left[I_1(l_n B) K_1(l_n A) - K_1(l_n B) I_1(l_n A) \right], \qquad n = 1, \ldots, \infty. \tag{5.20}$$

5.1.2. Example 2. The second set of boundary conditions involves our elastic tube bonded between two concentric solid cylinders which do not rotate relative to each other, the lower end of the elastic tube is kept undeformed. These conditions are given by

$$g(A, Z) = 0, \quad g(B, Z) = 0, \quad g(R, 0) = 0. \tag{5.21}$$

In order to maintain the deformation (1.1), an axial load is required on the end of the tube together with a torsional couple, but these expressions will not be needed here. Seeking separable solutions of the governing equation (5.14), the boundary conditions are satisfied with a negative separation constant, $-l^2$, i.e., the axial dependence is taken to vary exponentially. With the same transformation as before, the ODE involving the radial independent variable reduces to the Bessel equation of order one.

Since the configuration here is that of a tube with a finite radius, both solutions of this equation, the Bessel functions of the first kind (J_1) and second kind (Y_1) are involved. The l-mode solution for this problem is now given by

$$g_l(R,Z) = \frac{1}{lR}\left[C_l J_1(lR) + D_l Y_1(lR)\right]\left[A_l e^{lZ} + B_l e^{-lZ}\right], \tag{5.22}$$

where A_l, B_l, C_l, D_l are constants to be determined by the boundary conditions. We note that, for the boundary conditions (5.21), the permissible values of l are to be determined by the Bessel equation as solutions of an eigenvalue problem. The solution of the problem is now given by

$$g(R,Z) = \sum_{n=1}^{\infty} \frac{1}{l_n R}\left[J_1(l_n R)Y_1(l_n A) - Y_1(l_n R)J_1(l_n A)\right]\sinh l_n Z, \tag{5.23}$$

where the l_n are the (positive) roots of the transcendental equation [5]

$$J_1(l_n A)Y_1(l_n B) = J_1(l_n B)Y_1(l_n A). \tag{5.24}$$

5.2. Some further solutions for the generalized azimuthal displacement. In this subsection it would be desirable to compare the form of the general deformation component $g = g(R,Z)$ with the special cases of pure azimuthal shear ($g = g(R)$) and pure torsion ($g = \tau Z$, τ = constant) that have been investigated in the current literature without referring to any choice of boundary conditions. Furthermore, we wish to derive some Riemann type similarity solutions to the governing differential equation (5.14), whose simple form can be used to verify the validity of the necessary and sufficient conditions (4.9) and (4.10). To this end, for the generalized Hadamard material (5.12), we examine the following three cases.

(i) We seek an additively separable solution of (5.14) of the form

$$g(R,Z) = f_1(R) + f_2(Z). \tag{5.25}$$

Substituting this relation into the governing differential equation (5.14), we obtain

$$g(R,Z) = -\frac{2C_1}{R^2} + \frac{lR^2}{8} - \frac{lZ^2}{2} + C_2 Z, \tag{5.26}$$

where C_1, C_2 are integration constants and l is a separation constant. We immediately see that the first term on the left-hand side is a solution of the *pure azimuthal shear* problem for a related material, obtained by Beatty and Jiang [2]. The last term on the right-hand side of the same formula is a deformation known as *pure torsion*, where C_2 is the angle of twist per unit undeformed length. It was shown by Polignone and Horgan [18] that pure torsion is supported for the general Hadamard materials. The simultaneous dependence of the azimuthal displacement on the radial and axial coordinate introduces the coupling constant l and generalizes the previously mentioned individual deformations.

(ii) We seek a Riemann type similarity solution of the form

$$g(R,Z) = f(\xi), \quad \xi = R^n Z^m,\ n, m \text{ being integers.} \tag{5.27}$$

Substitution of this form into (5.14) leads to the values $n = 2, m = -2$ for the two integer powers. Solving the corresponding ODE, the azimuthal displacement obtains the form

$$g(R,Z) = C_1\left(\frac{\sqrt{\xi+1}}{\xi} + \log\frac{1+\sqrt{\xi+1}}{\sqrt{\xi}}\right), \quad \xi = \frac{R^2}{Z^2}, \tag{5.28}$$

where C_1 is an integration constant. Therefore, if suitable boundary conditions can be chosen, the displacement profile will remain constant on the cones $R/Z = \text{constant}$.

(iii) The paragraph above suggests the existence of solutions in the form

$$g(R, Z) = f(\zeta), \quad \zeta = \alpha R^2 + \beta Z^2, \ \alpha, \beta \text{ are constants.} \tag{5.29}$$

Substitution into (5.14) leads to $\alpha = \beta = 1$. The corresponding solution for the azimuthal displacement is then given in the form

$$g(R, Z) = C_1 \zeta^{-\frac{3}{2}}, \quad \zeta = R^2 + Z^2, \tag{5.30}$$

where C_1 is an integration constant. Again, if suitable boundary conditions can be employed, the azimuthal profile remains constant along the spherical surfaces of revolution $R^2 + Z^2 = \text{constant}$. The simple form of this solution can be used to verify the validity of the necessary and sufficient conditions in a straightforward manner. It should be noted here that Hill [9] has provided examples of similarity solutions to a variety of deformations for incompressible elastic materials, a subject closely related to the paragraphs (ii) and (iii) above.

5.3. The effect of torsion on the pure azimuthal shear. In this section we consider the azimuthal displacement with the predetermined form

$$g(R, Z) = \rho(R) + \tau Z, \quad \tau = \text{constant}, \tag{5.31}$$

which will account for the simultaneous azimuthal shearing and torsion and will enable us to compare the unknown function $\rho(R)$, with results from the pure azimuthal deformation $g = g(R)$ in [20, 2]. We start by noting that the strain invariants depend only on R,

$$I = I_1 = I_2 = (R\rho'(R))^2 + (R\tau)^2 + 3; \tag{5.32}$$

hence the azimuthal equilibrium equation (5.3) can be integrated once to

$$4R^3 \rho'(R) \bar{W}_1 = B^2 \bar{\sigma}_\theta, \tag{5.33}$$

where the constant $\bar{\sigma}_\theta$ is the value of the azimuthal shear stress $\sigma_{r\theta}$ on the outer boundary of the cylinder $R = B$. Expression (5.33) is valid for both pure shear and azimuthal shear combined with pure torsion. However, in the case of pure shear, the strain invariants are given by

$$I = I_1 = I_2 = (R\rho'(R))^2 + 3. \tag{5.34}$$

We now consider the following special case of the material (4.15).

(i) $k = 1$. The strain energy function in this case is the generalized Hadamard material (5.12). For the deformation of shear coupled with torsion (5.33) can be integrated once to give

$$\rho(R) = -\frac{B^2 \bar{\sigma}_\theta}{2\mu} \frac{1}{R^2} + C, \tag{5.35}$$

where C is an integration constant and we note that this solution can be obtained directly from the results of the previous section with the value of the separation constant set equal to zero. It can be shown that this is the solution of the pure

azimuthal shear problem for the Hadamard material (5.12) in accordance with the work of Beatty and Jiang [2]. As in the incompressible case [22] for the neo-Hookean material, we deduce that torsion does not affect the shearing for the material under study.

(ii) $k = 1/2$. In this case the strain energy function obtains the form

$$\bar{W}(I_1, I_2, I_3) = \frac{\sqrt{3}\mu}{2}\left[\sqrt{I_1}h_1(I_3) + \sqrt{I_2}h_2(I_3)\right] + h_3(I_3), \tag{5.36}$$

where

$$h_3(1) = -3\mu, \quad h_3'(1) = -\frac{3\mu}{4}. \tag{5.37}$$

Because of the inclusion of the square root of the first principal invariant, this model is reminiscent of the recently introduced strain energy by Bischoff, Arruda, and Grosh [4] for the accurate description of the nonlinear pressure-volume response of rubber-like solids in hydrostatic compression. For shear with torsion substituting (5.36) into (5.33) and considering the invariants (5.32), the function $\rho(R)$ is given in terms of elliptic function in principle. However, requiring the stress value σ_θ and the twist τ to satisfy the relation

$$\frac{\sqrt{3}\mu}{B^2\bar{\sigma}_\theta} = \frac{\tau^2}{3}, \tag{5.38}$$

we obtain the following form for the azimuthal function:

$$\rho(R) = -\sqrt{3}\arcsin\left(\frac{\sqrt{3}}{R\tau}\right) + C, \tag{5.39}$$

where C is an integration constant and $R\tau \geq \sqrt{3}$.

For pure azimuthal shear, substituting (5.36) into (5.33) and taking into account the invariants (5.34), we obtain the solution (ρ_p for pure azimuthal shear),

$$\rho_p(R) = \frac{\sqrt{3}}{2}\arcsin\left(\frac{B^2\bar{\sigma}_\theta}{\sqrt{3}\mu R^2}\right) + C. \tag{5.40}$$

We notice that the different structure between (5.39) and (5.40) is due to the presence of the pure torsion term and is quite profound even for the special case under consideration. Similar conclusions were drawn in [22], for the power neo-Hookean material and the value of the power $n = 1/2$.

6. Concluding remarks. In this article we derived a set of necessary and sufficient conditions (4.1), a compressible and isotropic strain energy has to satisfy, in order to support the generalized azimuthal deformation (1.1). This is a deformation that locally reduces to simple shear. The same conditions remain sufficient for a strain energy to support the special cases of pure azimuthal shear and pure torsion. However, a close examination of the current literature reveals that the same conditions are also sufficient for a strain energy to support antiplane shear deformations [17], helical shear deformations [15], and, of course, their special cases such as axisymmetric antiplane shear. Therefore, if a strain energy function satisfies these conditions, the material is able to support a large class of deformations that locally reduce to simple

shear. It remains open whether such materials will support *all* isochoric deformations that locally reduce to simple shear.

Appendix. Derivatives of Eulerian strain-space quantities. Derivatives of the Eulerian strain-space coordinates and basis vectors in terms of Lagrangian strain-space coordinates are as follows:

$$\frac{\partial\theta}{\partial\Gamma} = \Gamma G_{,\Gamma\Gamma} \equiv \tilde{A}, \quad \frac{\partial\theta}{\partial\Phi} = \Gamma^2 \left(\frac{1}{\Gamma} G_{\Phi}\right)_{,\Gamma} \equiv \tilde{B}, \tag{A.1}$$

$$\frac{\partial \boldsymbol{e}_r}{\partial\Gamma} = \tilde{A}\boldsymbol{e}_\theta, \quad \frac{\partial \boldsymbol{e}_r}{\partial\Phi} = \tilde{B}\boldsymbol{e}_\theta, \tag{A.2}$$

$$\frac{\partial \boldsymbol{e}_\theta}{\partial\Gamma} = -\tilde{A}\boldsymbol{e}_r, \quad \frac{\partial \boldsymbol{e}_\theta}{\partial\Phi} = -\tilde{B}\boldsymbol{e}_r, \tag{A.3}$$

$$\frac{\partial \boldsymbol{e}_\gamma}{\partial\Gamma} = \sin\Phi\tilde{A}\boldsymbol{e}_\theta, \quad \frac{\partial \boldsymbol{e}_\gamma}{\partial\Phi} = \sin\Phi\tilde{B}\boldsymbol{e}_\theta + \boldsymbol{e}_\phi, \tag{A.4}$$

$$\frac{\partial \boldsymbol{e}_\phi}{\partial\Gamma} = \cos\Phi\tilde{A}\boldsymbol{e}_\theta, \quad \frac{\partial \boldsymbol{e}_\phi}{\partial\Phi} = \cos\Phi\tilde{B}\boldsymbol{e}_\theta - \boldsymbol{e}_\gamma. \tag{A.5}$$

Acknowledgments. The authors would like to thank the reviewers for their valuable comments. In addition, the authors are grateful to Professor T. J. Pence at Michigan State University, who invited the first author and provided the facilities during his visit that made this collaboration possible.

MODELING OF WAVE RESONANCES IN LOW-CONTRAST PHOTONIC CRYSTALS*

DMITRI AGUEEV† AND DMITRY PELINOVSKY†

Abstract. Coupled-mode equations are derived from Maxwell equations for modeling of low-contrast cubic-lattice photonic crystals in three spatial dimensions. Coupled-mode equations describe resonantly interacting Bloch waves in stop bands of the photonic crystal. We study the linear boundary-value problem for stationary transmission of four counter-propagating and two oblique waves on the plane. Well-posedness of the boundary-value problem is proved by using the method of separation of variables and generalized Fourier series. For applications in photonic optics, we compute integral invariants for transmission, reflection, and diffraction of resonant waves.

Key words. photonic crystals, coupled-mode equations, wave resonances, stationary transmission boundary-value problems

1. Introduction.

Photonic band-gap crystals are periodic optical materials, the spectrum of which consists of bands separated by band gaps [13]. Linear periodic properties of the isotropic photonic crystals are modeled with the Maxwell equations

$$\nabla^2 \mathbf{E} - \frac{n^2}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} = \nabla(\nabla \cdot \mathbf{E}), \qquad \nabla \cdot \left(n^2 \mathbf{E}\right) = 0, \tag{1.1}$$

where $n = n(\mathbf{x})$ is the periodic refractive index, $\mathbf{E} = (E_x, E_y, E_z)$ is the electric field vector, $\mathbf{x} = (x, y, z)$ is the physical space, t is the time variable, $\nabla = (\partial_x, \partial_y, \partial_z)$ is the gradient vector, and c is the speed of light. Components of the magnetic field vector are eliminated from the Maxwell equations (1.1) [13].

The Maxwell equations (1.1) in one dimension can be simplified for a linearly polarized light, such that $\mathbf{E} = (E, 0, 0)$, where $E = E(z, t)$ and $n = n(z)$. The scalar component $E(z, t)$ solves the wave equation with the periodic speed variations

$$\frac{\partial^2 E}{\partial z^2} - \frac{n^2(z)}{c^2}\frac{\partial^2 E}{\partial t^2} = 0. \tag{1.2}$$

If the refractive index $n(z)$ is a periodic function with period z_0, the linear spectrum of the wave equation (1.2) reduces to the Mathieu equation for $E(z, t) = \psi(z)e^{-i\omega t}$, where ω is the eigenvalue and $\psi(z)$ is the eigenfunction of the spectral problem

$$\psi'' + \frac{\omega^2}{c^2} n^2(z)\psi = 0. \tag{1.3}$$

According to the Floquet theory [12], solutions of the Mathieu equation (1.3) take the form $\psi(z) = \Psi(z)e^{ik(\omega)z}$, where $\Psi(z + z_0) = \Psi(z)$ and $k = k(\omega)$ is the propagation constant. For a general class of periodic potentials $n^2(z)$, there exist infinitely many

intervals of ω, called *band gaps*, where the propagation constant $k(\omega)$ is purely imaginary and the Bloch function $\psi(z)$ is unbounded in z. The band gaps are supported by the low-contrast photonic crystal with the refractive index $n(z) = n_0 + \epsilon n_1(z)$, where n_0 is constant and ϵ is small parameter.

The linear Maxwell equations (1.1) in two and three dimensions can also be reduced to a spectral problem for $\mathbf{E}(\mathbf{x}, t) = \boldsymbol{\psi}(\mathbf{x})e^{-i\omega t}$, where ω is the eigenvalue and $\boldsymbol{\psi}(\mathbf{x})$ is the eigenvector. When $n(\mathbf{x})$ is a periodic function in x, y, z with periods x_0, y_0, z_0, respectively, the eigenvector $\boldsymbol{\psi}(\mathbf{x})$ satisfies the Floquet theorem [12] and has the form of the Bloch wave: $\boldsymbol{\psi}(\mathbf{x}) = \boldsymbol{\Psi}(\mathbf{x})e^{i(k_x x + k_y y + k_z z)}$, where $\boldsymbol{\Psi}(\mathbf{x})$ is periodic in x, y, and z with periods x_0, y_0, and z_0, and $\omega = \omega(k_x, k_y, k_z)$. No band gaps exist in the linear spectrum for low-contrast photonic crystals. As a result, the bounded Bloch functions $\boldsymbol{\psi}(\mathbf{x})$ may exist for any value of $\omega \in \mathbb{R}$. High-contrast photonic crystals may, however, exhibit band gaps for some configurations of the refractive index $n(\mathbf{x})$ [13].

Modeling of time-dependent responses of photonic crystals in three spatial dimensions can be computationally difficult in the framework of the Maxwell equations, especially if the nonlinear and nonlocal dispersive terms are taken into account. A more efficient method is based on reduction of Maxwell equations (1.1) to the coupled-mode equations [23]. For instance, shock wave singularities may occur in the nonlinear Maxwell equations but they do not occur in the nonlinear coupled-mode equations [8]. Coupled-mode equations are typically derived in the first band gap of the Bragg resonance between two counter-propagating waves in one spatial dimension [20, 21]. More complicated coupled-mode equations are considered for three-dimensional nonlinear photonic crystals [1, 2, 3, 6]. Recent reviews [4, 5] also include classification of different resonances of Bloch waves in photonic crystals with quadratic nonlinearities.

In this paper, we classify wave resonances and coupled-mode equations for low-contrast cubic-lattice photonic crystals in three spatial dimensions. Since low-contrast crystals do not support band gaps beyond one dimension [12, 13], resonances are considered in stop bands of the linear spectrum [10]. Stop bands occur between resonant counter-propagating waves, which could be coupled resonantly with other oblique Bloch waves. The number of resonant Bloch waves depends on the geometric configuration of the incident wave with respect to the cubic lattice. When the Maxwell equations are truncated with the perturbation series expansions, coupled-mode equations for the lowest-order Bragg resonances are derived and studied in bounded domains, subject to the radiation boundary conditions. The radiation boundary conditions describe transmission of the incident Bloch waves which generate resonantly reflected and diffracted Bloch waves in the photonic crystals.

We study here the linear coupled-mode equations for four counter-propagating and two oblique Bloch waves on the plane. It is not a priori clear why the stationary boundary-value problem with radiation boundary conditions is well posed, since it is specified by non–self-adjoint operators on the bounded domains. We prove, however, the well-posedness of the linear stationary problem by using separation of variables and generalized Fourier series [24]. Eigenfunction expansions and convergence of generalized Fourier series follow from the general theory [7]. As a result, we construct explicit analytical expressions for stationary transmission, reflection, and diffraction of resonant Bloch waves, which are used in modeling of the low-contrast photonic crystals.

Other applications of optical photonic structures include nonlinear phenomena, such as bistable stationary transmission and gap soliton propagation [6, 14, 15, 22]. Very little is known about the persistence of such phenomena in two and three spatial

dimensions, especially given that no band gap exists in low-contrast three-dimensional photonic structures. The coupled-mode equations can be generalized to include the weakly nonlinear (cubic) terms and to extend the time-dependent problems to the nonlinear coupled-mode equations [18, 19]. Well-posedness of the nonlinear stationary problems is beyond the scope of this manuscript, which only presents solutions of the linear stationary problems. Nevertheless, linear analysis opens the road to nonlinear analysis of the corresponding boundary-value problems.

The paper is organized as follows. Classification of resonances in low-contrast cubic-lattice crystals is given in section 2. Derivation of coupled-mode equations for lowest-order resonances is described in section 3. The linear stationary boundary-value problems for four counter-propagating and two oblique resonant Bloch waves are analyzed in section 4. Section 5 concludes the paper. Appendix A gives derivation and explicit forms of the nonlinear coupled-mode equations with cubic (Kerr) nonlinearities.

2. Classification of resonances. When the optical material is homogeneous, such that $n(\mathbf{x}) = n_0$ is constant, the linear spectrum of the Maxwell equations (1.1) is defined by the free transverse waves,

$$\mathbf{E}(\mathbf{x}, t) = \mathbf{e}_{\mathbf{k}} e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)}, \tag{2.1}$$

where $\mathbf{e}_{\mathbf{k}}$ is the polarization vector, $\mathbf{k} = (k_x, k_y, k_z)$ is the wave vector, and $\omega = \omega(\mathbf{k})$ is the wave frequency. It follows from system (1.1) that

$$\mathbf{k} \cdot \mathbf{e}_{\mathbf{k}} = 0, \qquad \omega^2 = \frac{c^2}{n_0^2}(k_x^2 + k_y^2 + k_z^2). \tag{2.2}$$

For each wave vector $\mathbf{k}$ there exist two independent polarizations $\mathbf{e}_{\mathbf{k}}^{(1)}$ and $\mathbf{e}_{\mathbf{k}}^{(2)}$ such that $\mathbf{e}_{\mathbf{k}}^{(1)} \cdot \mathbf{e}_{\mathbf{k}}^{(2)} = 0$. This degeneracy in the polarization vector is neglected here by the assumption that the incident wave is linearly polarized.

When the optical material is periodic such that $n(\mathbf{x} + \mathbf{x}_0) = n(\mathbf{x}_0)$, the linear spectrum of the Maxwell equations (1.1) is defined by the Bloch waves:

$$\mathbf{E}(\mathbf{x}, t) = \mathbf{\Psi}(\mathbf{x}) e^{i(\mathbf{k}\cdot\mathbf{x} - \omega t)}, \tag{2.3}$$

where $\mathbf{\Psi}(\mathbf{x} + \mathbf{x}_0) = \mathbf{\Psi}(\mathbf{x})$ is the periodic envelope, $\mathbf{k} = (k_x, k_y, k_z)$ is the wave vector, and $\omega = \omega(\mathbf{k})$ is the wave frequency. Existence of the Bloch waves (2.3) for the Maxwell equations (1.1) is proved in [12]. The geometric configuration of the photonic crystal is defined by the fundamental (linearly independent) lattice vectors $\mathbf{x}_{1,2,3}$ and fundamental reciprocal lattice vectors $\mathbf{k}_{1,2,3}$ such that $\mathbf{k}_i \cdot \mathbf{x}_j = 2\pi\delta_{i,j}$, where $1 \le i, j \le 3$ (see [10]). Therefore, the linear refractive index $n(\mathbf{x})$ can be expanded into a triple Fourier series:

$$n(\mathbf{x}) = n_0 \sum_{(n,m,l)\in\mathbb{Z}^3} \alpha_{n,m,l} e^{i(n\mathbf{k}_1 + m\mathbf{k}_2 + l\mathbf{k}_3)\cdot\mathbf{x}}, \tag{2.4}$$

where the factor n_0 is included for convenience. If n_0 is the mean value of $n(\mathbf{x})$, then $\alpha_{0,0,0} = 1$. Let the wave vector $\mathbf{k}$ in the incident Bloch wave (2.3) be chosen as $\mathbf{k} = \mathbf{k}_{\text{in}}$. The incident wave vector $\mathbf{k}_{\text{in}}$ is expanded in terms of the lattice vectors:

$$\mathbf{k}_{\text{in}} = \frac{1}{2}(p\mathbf{k}_1 + q\mathbf{k}_2 + r\mathbf{k}_3), \tag{2.5}$$

where $(p,q,r) \in \mathbb{R}^3$ are parameters. The Bloch wave (2.3) is represented by triple Fourier series for $\mathbf{\Psi}(\mathbf{x})$, such that $\mathbf{E}(\mathbf{x},t)$ consists of an infinite superposition of free transverse waves with the wave vectors $\mathbf{k}_{\rm out}^{(n,m,l)}$:

$$\mathbf{k}_{\rm out}^{(n,m,l)} = \mathbf{k}_{\rm in} + n\mathbf{k}_1 + m\mathbf{k}_2 + l\mathbf{k}_3, \quad (n,m,l) \in \mathbb{Z}^3. \tag{2.6}$$

The wave vector $\mathbf{k}_{\rm out}^{(n,m,l)}$ with a nonempty triple (n,m,l) is said to be *resonant* with the wave vector $\mathbf{k}_{\rm in}$ if $|\mathbf{k}_{\rm out}^{(n,m,l)}| = |\mathbf{k}_{\rm in}|$ such that $|\omega(\mathbf{k}_{\rm out}^{(n,m,l)})| = |\omega(\mathbf{k}_{\rm in})|$.

We consider here a simple cubic crystal, where the fundamental lattice vectors and reciprocal lattice vectors are all orthogonal [10]:

$$\mathbf{x}_{1,2,3} = a\mathbf{e}_{1,2,3}, \qquad \mathbf{k}_{1,2,3} = k_0\mathbf{e}_{1,2,3}, \quad k_0 = \frac{2\pi}{a}, \tag{2.7}$$

where $\mathbf{e}_{1,2,3}$ are unit vectors in $\mathbb{R}^3$. The coordinate axes (x,y,z) are oriented along the axes of the simple cubic crystal, while the incident wave vector $\mathbf{k}_{\rm in}$ is directed according to the spherical angles (θ,φ) as follows:

$$\mathbf{k}_{\rm in} = k(\sin\theta\cos\varphi, \sin\theta\sin\varphi, \cos\theta), \quad k \in \mathbb{R},\ 0 \le \theta \le \pi,\ 0 \le \varphi \le 2\pi, \tag{2.8}$$

where $k = |\mathbf{k}_{\rm in}|$. When $\theta = 0$, the wave vector $\mathbf{k}_{\rm in}$ is perpendicular to the (x,y) crystal plane. For the simple cubic crystal, the set of resonant Bloch waves is given by the set of triples

$$\mathcal{S} = \{(n,m,l) \in \mathbb{Z}^3 : n(n+p) + m(m+q) + l(l+r) = 0\}, \tag{2.9}$$

where

$$p = \frac{2k}{k_0}\sin\theta\cos\varphi, \qquad q = \frac{2k}{k_0}\sin\theta\sin\varphi, \qquad r = \frac{2k}{k_0}\cos\theta. \tag{2.10}$$

The set $\mathcal{S}$ always has a zero solution: $(n,m,l) = (0,0,0)$. When $(p,q,r) \in \mathbb{Z}^3$ and $|p|+|q|+|r| \neq 0$, the set $\mathcal{S}$ has at least one nonzero solution: $(n,m,l) = (-p,-q,-r)$. The set $\mathcal{S}$ is also bounded, since (n,m,l) are integer solutions inside the sphere:

$$\left(n + \frac{p}{2}\right)^2 + \left(m + \frac{q}{2}\right)^2 + \left(l + \frac{r}{2}\right)^2 = \left(\frac{k}{k_0}\right)^2 < \infty. \tag{2.11}$$

When $(p,q,r) \in \mathbb{Z}^3$, resonant triples (n,m,l) can all be classified analytically. However, when $(p,q,r) \notin \mathbb{Z}^3$, additional resonant triples may also exist. In solid state physics [10], a geometric solution for the resonant triples (n,m,l) is constructed from the condition that the vector $\mathbf{G}^{(n,m,l)} = \mathbf{k}_{\rm out}^{(n,m,l)} - \mathbf{k}_{\rm in}$ lies on the edge of sectors of the reciprocal lattice. Here we review particular resonant sets $\mathcal{S}$ for integer and noninteger values of (p,q,r).

2.1. A family of one-dimensional resonances. The one-dimensional Bragg resonance occurs when the incident wave is coupled with the counter-propagating reflected wave such that the set $\mathcal{S}$ has at least one nonzero solution: $(n,m,l) = (0,0,-r)$, where $r \in \mathbb{Z}_+$. The values of p and q are not defined for the Bragg resonance when $n = m = 0$. As a result, spherical angles θ and φ in the parametrization (2.8) are arbitrary, while the wave number k satisfies the Bragg resonance condition [10]:

$$rk_0 = 2k\cos\theta \tag{2.12}$$

such that $r\lambda = 2a\cos\theta$, where λ is the wavelength. The one-dimensional Bragg resonance is generalized in three dimensions for $p = q = 0$ and $r \in \mathbb{Z}_+$, when the geometric configuration for the Bragg resonance (2.12) is fixed at the specific value $\theta = 0$, and

$$\mathbf{k}_{\text{in}} = \frac{\pi}{a}(0,0,r), \qquad \mathbf{k}_{\text{out}}^{(0,0,-r)} = \frac{\pi}{a}(0,0,-r). \tag{2.13}$$

The incident wave is directed to the z-axis of the cubic lattice crystal, and the wavelength is $\lambda = 2a/r$. The family of Bragg resonances with $p = q = 0$ and $r \in \mathbb{Z}_+$ may include not only the two counter-propagating waves (2.13) but also other Bloch waves in three-dimensional photonic crystals. The lowest-order resonant sets $\mathcal{S}$ for $p = q = 0$ and $r \in \mathbb{Z}_+$ are listed below:

$$\begin{aligned}
&r = 1 : \mathcal{S} = \{(0,0,0),(0,0,-1)\},\\
&r = 2 : \mathcal{S} = \{(0,0,0),(1,0,-1),(-1,0,-1),(0,1,-1),(0,-1,-1),(0,0,-2)\},\\
&r = 3 : \mathcal{S} = \{(0,0,0),(1,1,-1),(-1,1,-1),(1,-1,-1),(-1,-1,-1),\\
&\qquad\qquad (1,1,-2),(-1,1,-2),(1,-1,-2),(-1,-1,-2),(0,0,-3)\}.
\end{aligned}$$

The dimension of $\mathcal{S}$ depends on the total number of all possible integer solutions for (n,m,l). The sets $\mathcal{S}$ for higher-order resonances with $r \in \mathbb{Z}_+$ can be found algorithmically, with symbolic computing software.

2.2. A family of two-dimensional resonances. Two-dimensional Bragg resonances occur when the incident wave vector $\mathbf{k}_{\text{in}}$ is resonant to the counter-propagating reflected wave vector $\mathbf{k}_{\text{out}}^{(-p,-q,0)}$, as well as to two other diffracted wave vectors $\mathbf{k}_{\text{out}}^{(0,-q,0)}$ and $\mathbf{k}_{\text{out}}^{(-p,0,0)}$, where $(p,q) \in \mathbb{Z}_+^2$. The value of r is not defined for the two-dimensional resonance, such that the angle θ in the parametrization (2.8) is arbitrary, while k and φ satisfy the resonance conditions

$$\varphi = \arctan\left(\frac{q}{p}\right), \qquad \sqrt{p^2+q^2}k_0 = 2k\sin\theta. \tag{2.14}$$

The two-dimensional Bragg resonances are generalized in three dimensions for $(p,q) \in \mathbb{Z}_+^2$ and $r = 0$, when the geometric configuration for the Bragg resonance (2.14) is fixed at the specific value $\theta = \frac{\pi}{2}$, and

$$\begin{aligned}
\mathbf{k}_{\text{in}} &= \frac{\pi}{a}(p,q,0), \qquad \mathbf{k}_{\text{out}}^{(-p,-q,0)} = \frac{\pi}{a}(-p,-q,0),\\
\mathbf{k}_{\text{out}}^{(0,-q,0)} &= \frac{\pi}{a}(p,-q,0), \qquad \mathbf{k}_{\text{out}}^{(-p,0,0)} = \frac{\pi}{a}(-p,q,0).
\end{aligned} \tag{2.15}$$

The incident wave $\mathbf{k}_{\text{in}}$ is directed along the diagonal of the (px,qy)-cell of the cubic lattice crystal, and the wavelength is $\lambda = 2a/\sqrt{p^2+q^2}$.

The families of Bragg resonances with $(p,q) \in \mathbb{Z}_+^2$ and $r = 0$ may include not only the four resonant waves (2.15) but also other Bloch waves in three-dimensional photonic crystals. The lowest-order resonant sets $\mathcal{S}$ for $(p,q) \in \mathbb{Z}_+^2$ and $r = 0$ are listed below:

$$\begin{aligned}
&p{=}1,\ q{=}1 : \mathcal{S} = \{(0,0,0),(-1,0,0),(0,-1,0),(-1,-1,0)\},\\
&p{=}2,\ q{=}1 : \mathcal{S} = \{(0,0,0),(0,-1,0),(-1,0,1),(-1,0,-1),(-1,-1,1),(-1,-1,-1),\\
&\qquad\qquad (-2,0,0),(-2,-1,0)\},
\end{aligned}$$

$$p=2,\ q=2 : \mathcal{S} = \{(0,0,0),(0,-1,1),(0,-1,-1),(0,-2,0),(-1,0,1),(-1,0,-1),$$
$$(-1,-2,1),(-1,-2,-1),(-2,0,0),(-2,-1,1),(-2,-1,-1),$$
$$(-2,-2,0)\}.$$

2.3. Two-dimensional resonances of oblique waves. The resonant set $\mathcal{S}$ can be nonempty for $(p,q,r) \notin \mathbb{Z}^3$, which correspond to oblique Bloch waves. For instance, two oblique waves can be resonant on the (x,y)-plane if

$$\mathbf{k}_{\rm in} = \frac{\pi}{a}(p,q,0), \qquad \mathbf{k}_{\rm out}^{(n,m,0)} = \frac{\pi}{a}(p+2n, q+2m, 0), \tag{2.16}$$

where $(n,m) \in \mathbb{Z}^2$ are arbitrary and $(p,q) \in \mathbb{R}^2$ are taken on the straight line:

$$np + mq = -(n^2+m^2). \tag{2.17}$$

Similarly, three oblique waves can be resonant on the (x,y)-plane if

$$\begin{aligned} \mathbf{k}_{\rm in} &= \frac{\pi}{a}(p,q,0), \\ \mathbf{k}_{\rm out}^{(n_1,m_1,0)} &= \frac{\pi}{a}(p+2n_1, q+2m_1, 0), \\ \mathbf{k}_{\rm out}^{(n_2,m_2,0)} &= \frac{\pi}{a}(p+2n_2, q+2m_2, 0), \end{aligned} \tag{2.18}$$

where $(n_1,m_1) \in \mathbb{Z}^2$ and $(n_2,m_2) \in \mathbb{Z}^2$ are arbitrary subject to the constraint $m_1 n_2 \neq m_2 n_1$, while (p,q) take rational values

$$p = \frac{m_1(n_2^2+m_2^2) - m_2(n_1^2+m_1^2)}{m_2 n_1 - m_1 n_2}, \qquad q = \frac{n_1(n_2^2+m_2^2) - n_2(n_1^2+m_1^2)}{n_2 m_1 - n_1 m_2}. \tag{2.19}$$

In the general case, two oblique waves (2.16) or three oblique waves (2.18) may have resonances with other Bloch waves in three-dimensional photonic crystals.

2.4. A family of three-dimensional resonances. When $(p,q,r) \in \mathbb{Z}_+^3$, the resonant sets $\mathcal{S}$ include eight coupled waves for fully three-dimensional Bragg resonance:

$$\begin{aligned} \mathbf{k}_{\rm in} &= \frac{\pi}{a}(p,q,r), \qquad \mathbf{k}_{\rm out}^{(-p,-q,-r)} = \frac{\pi}{a}(-p,-q,-r), \\ \mathbf{k}_{\rm out}^{(-p,0,0)} &= \frac{\pi}{a}(-p,q,r), \qquad \mathbf{k}_{\rm out}^{(0,-q,0)} = \frac{\pi}{a}(p,-q,r), \\ \mathbf{k}_{\rm out}^{(0,0,-r)} &= \frac{\pi}{a}(p,q,-r), \qquad \mathbf{k}_{\rm out}^{(-p,-q,0)} = \frac{\pi}{a}(-p,-q,r), \\ \mathbf{k}_{\rm out}^{(-p,0,-r)} &= \frac{\pi}{a}(-p,q,-r), \qquad \mathbf{k}_{\rm out}^{(0,-q,-r)} = \frac{\pi}{a}(p,-q,-r). \end{aligned} \tag{2.20}$$

The resonance condition for the three-dimensional Bragg resonance takes the form

$$\varphi = \arctan\left(\frac{q}{p}\right), \qquad \theta = \arctan\left(\frac{\sqrt{p^2+q^2}}{r}\right), \qquad \sqrt{p^2+q^2+r^2}k_0 = 2k. \tag{2.21}$$

The incident wave $\mathbf{k}_{\rm in}$ is directed along the diagonal of the (px, qy, rz)-cell of the cubic lattice crystal, and the wavelength is $\lambda = 2a/\sqrt{p^2+q^2+r^2}$. The eight waves (2.20) can be coupled with some other resonant waves such that $\dim(\mathcal{S}) \geq 8$ for $(p,q,r) \in \mathbb{Z}_+^3$. For instance, $\dim(\mathcal{S}) = 8$ for $(p,q,r) = (1,1,1)$ and $(p,q,r) = (2,1,1)$, but $\dim(\mathcal{S}) = 10$ for $(p,q,r) = (2,2,1)$ and $\dim(\mathcal{S}) = 16$ for $(p,q,r) = (3,2,1)$.

3. Derivation of coupled-mode equations. The dispersion surface $\omega = \omega(\mathbf{k})$ for the Bloch waves (2.3) in the periodic photonic crystal is defined by the profile of the refractive index $n(\mathbf{x})$. We shall consider the asymptotic approximation of the dispersion surface $\omega = \omega(\mathbf{k})$ in the limit when the photonic crystal is low-contrast, such that the refractive index $n(\mathbf{x})$ is given by

$$n(\mathbf{x}) = n_0 + \epsilon n_1(\mathbf{x}), \tag{3.1}$$

where n_0 is a constant and ϵ is small parameter. It is proved in [12] that the Bloch waves (2.3) are smooth functions of ϵ, such that the asymptotic solution of the Maxwell equations (1.1) as $\epsilon \to 0$ takes the form of the perturbation series expansions:

$$\mathbf{E}(\mathbf{x}, t) = \mathbf{E}_0(\mathbf{x}, t) + \epsilon \mathbf{E}_1(\mathbf{x}, t) + \mathrm{O}(\epsilon^2). \tag{3.2}$$

The leading-order term $\mathbf{E}_0(\mathbf{x}, t)$ consists of free transverse waves (2.1) with wave vectors $\mathbf{k}_{\text{out}}^{(n,m,l)}$, given by (2.6), such that the asymptotic form (3.2) represents the Bloch wave (2.3) as $\epsilon \neq 0$.

Coupled-mode equations are derived by separating resonant free waves from nonresonant free waves in the Bloch wave (2.3), where the resonant set $\mathcal{S}$ with $N = \dim(\mathcal{S}) < \infty$ is defined by (2.9). Let $\mathbf{E}_0(\mathbf{x}, t)$ be a linear superposition of N resonant waves with wave vectors $\mathbf{k}_j$ at the same frequency ω:

$$\mathbf{E}_0(\mathbf{x}, t) = \sum_{j=1}^{N} A_j(\mathbf{X}, T) \mathbf{e}_{\mathbf{k}_j} e^{i(\mathbf{k}_j \mathbf{x} - \omega t)}, \quad \mathbf{X} = \frac{\epsilon \mathbf{x}}{k}, \; T = \frac{\epsilon t}{\omega}, \tag{3.3}$$

where ω and $\mathbf{k}_j$ are related by the same dispersion equation (2.2), $A_j(\mathbf{X}, T)$ is the envelope amplitude of the jth resonant wave (2.1), and $(\mathbf{X}, T)$ are slow variables. The slow variables represent a deformation of the dispersion surface $\omega = \omega(\mathbf{k}_j)$ due to the low-contrast periodic photonic crystal. The degeneracy in the polarization vector is neglected by the assumption that the incident wave is linearly polarized with the polarization vector $\mathbf{e}_{\text{in}} = \mathbf{e}_{\mathbf{k}_{\text{in}}}$. The triple Fourier series (2.4) for the cubic-lattice crystal (2.7) is simplified as follows:

$$n_1(\mathbf{x}) = n_0 \sum_{(n,m,l) \in \mathbb{Z}^3} \alpha_{n,m,l} e^{ik_0(nx+my+lz)}, \tag{3.4}$$

where $\alpha_{0,0,0} = 0$. The Fourier coefficients $\alpha_{n,m,l}$ satisfy the constraints

$$\alpha_{n,m,l} = \bar{\alpha}_{-n,-m,-l}, \tag{3.5}$$

due to the reality of $n_1(\mathbf{x})$;

$$\alpha_{n,m,l} = \alpha_{m,n,l} = \alpha_{n,l,m} = \alpha_{l,m,n}, \tag{3.6}$$

due to the crystal isotropy in the directions of x, y, z-axes; and

$$\alpha_{-n,m,l} = \alpha_{n,m,l}, \quad \alpha_{n,-m,l} = \alpha_{n,m,l}, \quad \alpha_{n,m,-l} = \alpha_{n,m,l}, \tag{3.7}$$

due to the crystal symmetry with respect to the origin $(0, 0, 0)$. (The latter property can be achieved by a simple shift of (x, y, z).) It follows from constraints (3.5) and (3.7) that all coefficients $\alpha_{n,m,l}$ for $(n, m, l) \in \mathbb{Z}^3$ are real-valued.

It follows from (1.1), (3.1), and (3.2) that the first-order correction term $\mathbf{E}_1(\mathbf{x},t)$ solves the nonhomogeneous linear problem

$$\begin{aligned}\nabla^2\mathbf{E}_1 - \frac{n_0^2}{c^2}\frac{\partial^2\mathbf{E}_1}{\partial t^2} &= 2\frac{n_0^2\omega}{c^2}\frac{\partial^2\mathbf{E}_0}{\partial T\partial t} - 2k\left(\nabla\cdot\nabla_X\right)\mathbf{E}_0 \\ &\quad + \frac{2n_0n_1(\mathbf{x})}{c^2}\frac{\partial^2\mathbf{E}_0}{\partial t^2} + \frac{2}{n_0}\nabla(\nabla n_1\cdot\mathbf{E}_0),\end{aligned} \tag{3.8}$$

where $\nabla_X = (\partial_X,\partial_Y,\partial_Z)$ and the second equation of (1.1) has been used. The right-hand side of the nonhomogeneous equation (3.8) has resonant terms, which are parallel to the free-wave resonant solutions of the homogeneous problem. The resonant terms lead to the secular growth of $\mathbf{E}_1(\mathbf{x},t)$ in t unless they are identically zero. The latter conditions define the coupled-mode equations for amplitudes $A_j(\mathbf{X},T)$, $j=1,\ldots,N$, in the general form

$$i\left(\frac{\partial A_j}{\partial T} + \left(\frac{\mathbf{k}_j}{k}\cdot\nabla_X\right)A_j\right) + \sum_{k\neq j}\hat{\alpha}_{j,k}A_k = 0, \quad j=1,\ldots,N, \tag{3.9}$$

where the elements $\{\hat{\alpha}_{j,k}\}_{1\leq j,k\leq N}$ are related to the Fourier coefficients of the resonant waves $\{\alpha_{n,m,l}\}_{(n,m,l)\in\mathcal{S}}$. The explicit forms of the coupled-mode equations (3.9) are given for two and four counter-propagating and two oblique resonant Bloch waves.

3.1. Coupled-mode equations for two counter-propagating waves. The lowest-order Bragg resonance for two counter-propagating waves (2.13) occurs for $r=1$, when

$$\mathbf{k}_1 = \frac{\pi}{a}(0,0,1), \qquad \mathbf{k}_2 = \frac{\pi}{a}(0,0,-1). \tag{3.10}$$

Let $A_1 = A_+(Z,T)$ and $A_2 = A_-(Z,T)$ be the amplitudes of the right (forward) and left (backward) propagating waves, respectively. The envelope amplitudes are not modulated across the (X,Y)-plane, since the coupled-mode equations for $A_\pm$ are essentially one-dimensional. The polarization vectors are chosen in the x-direction such that $\mathbf{e}_{\mathbf{k}_1} = \mathbf{e}_{\mathbf{k}_2} = (1,0,0)$ and $\mathbf{E}_0 = (E_{0,x}(z,Z,T)e^{-i\omega t},0,0)$. The nonhomogeneous equation (3.8) at the x-component of the solution $\mathbf{E}_1$ at $e^{-i\omega t}$ takes the form

$$\begin{aligned}\nabla^2E_{1,x} + k^2E_{1,x} &= -2ik^2\frac{\partial}{\partial T}E_{0,x} - 2k\frac{\partial^2}{\partial Z\partial z}E_{0,x} \\ &\quad - \frac{2k^2n_1(\mathbf{x})}{n_0}E_{0,x} + \frac{2}{n_0}\frac{\partial^2n_1(\mathbf{x})}{\partial x^2}E_{0,x}.\end{aligned} \tag{3.11}$$

By removing the resonant terms at $e^{\pm ikz}$, the coupled-mode equations for amplitudes $A_\pm(Z,T)$ take the form

$$i\left(\frac{\partial A_+}{\partial T} + \frac{\partial A_+}{\partial Z}\right) + \alpha A_- = 0, \tag{3.12}$$

$$i\left(\frac{\partial A_-}{\partial T} - \frac{\partial A_-}{\partial Z}\right) + \alpha A_+ = 0, \tag{3.13}$$

where $\alpha = \alpha_{0,0,1} = \alpha_{0,0,-1}$. The coupled-mode equations (3.12)–(3.13) can be defined on the interval $0\leq Z\leq L_z$ for $T\geq 0$, where the end points at $Z=0$ and $Z=L_z$ are the left and right (x,y)-planes, which cut a slice of the photonic crystal. The linear system (3.12)–(3.13) is reviewed in [23]. The nonlinear coupled-mode equations are derived in [6, 22] and analyzed recently in [8, 14, 15].

3.2. Coupled-mode equations for four counter-propagating waves. The lowest-order resonance for four counter-propagating waves (2.15) occurs for $p = q = 1$, when

$$\mathbf{k}_1 = \frac{\pi}{a}(1,1,0), \quad \mathbf{k}_2 = \frac{\pi}{a}(1,-1,0), \quad \mathbf{k}_3 = \frac{\pi}{a}(-1,1,0), \quad \mathbf{k}_4 = \frac{\pi}{a}(-1,-1,0). \tag{3.14}$$

Let $A_1 = A_+(X,Y,T)$ and $A_4 = A_-(X,Y,T)$ be the amplitudes of the counter-propagating waves along the main diagonal of the (x,y) plane, while $A_2 = B_+(X,Y,T)$ and $A_3 = B_-(X,Y,T)$ are the amplitudes of the counter-propagating waves along the antidiagonal of the (x,y)-plane. The envelope amplitudes are not modulated in the Z-direction, since the coupled-mode equations for $A_\pm$ and $B_\pm$ are essentially two-dimensional. The polarization vectors are chosen in the z-direction such that $\mathbf{e}_{\mathbf{k}_j} = (0,0,1)$, $1 \le j \le 4$, and $\mathbf{E}_0 = (0,0,E_{0,z}(x,y,X,Y,T)e^{-i\omega t})$. The nonhomogeneous equation (3.8) at the z-component of the solution $\mathbf{E}_1$ at $e^{-i\omega t}$ takes the form

$$\begin{aligned}\nabla^2 E_{1,z} + k^2 E_{1,z} = &-2ik^2 \frac{\partial}{\partial T} E_{0,z} - 2k \frac{\partial^2}{\partial X \partial x} E_{0,z} - 2k \frac{\partial^2}{\partial Y \partial y} E_{0,z} \\ &- \frac{2k^2 n_1(\mathbf{x})}{n_0} E_{0,z} + \frac{2}{n_0} \frac{\partial^2 n_1(\mathbf{x})}{\partial z^2} E_{0,z}.\end{aligned} \tag{3.15}$$

By removing the resonant terms at $e^{\frac{i}{\sqrt{2}}(\pm kx \pm ky)}$, the coupled-mode equations for amplitudes $A_\pm(X,Y,T)$ and $B_\pm(X,Y,T)$ take the form

$$i\left(\frac{\partial A_+}{\partial T} + \frac{\partial A_+}{\partial X} + \frac{\partial A_+}{\partial Y}\right) + \alpha A_- + \beta\,(B_+ + B_-) = 0, \tag{3.16}$$

$$i\left(\frac{\partial A_-}{\partial T} - \frac{\partial A_-}{\partial X} - \frac{\partial A_-}{\partial Y}\right) + \alpha A_+ + \beta\,(B_+ + B_-) = 0, \tag{3.17}$$

$$i\left(\frac{\partial B_+}{\partial T} + \frac{\partial B_+}{\partial X} - \frac{\partial B_+}{\partial Y}\right) + \beta\,(A_+ + A_-) + \alpha B_- = 0, \tag{3.18}$$

$$i\left(\frac{\partial B_-}{\partial T} - \frac{\partial B_-}{\partial X} + \frac{\partial B_-}{\partial Y}\right) + \beta\,(A_+ + A_-) + \alpha B_+ = 0, \tag{3.19}$$

where $\alpha = \alpha_{1,1,0} = \alpha_{-1,-1,0} = \alpha_{1,-1,0} = \alpha_{-1,1,0}$ and $\beta = \alpha_{0,1,0} = \alpha_{1,0,0} = \alpha_{0,-1,0} = \alpha_{-1,0,0}$. The coupled-mode equations (3.16)–(3.19) can be defined in the domain $(X,Y) \in \mathcal{D}$ and $T \ge 0$, where $\mathcal{D}$ is a domain on the (x,y)-plane of the photonic crystal. The system has not been previously studied in literature, to the best of our knowledge.

3.3. Coupled-mode equations for two oblique waves. Two oblique resonant waves on the (x,y)-plane are defined by the resonant wave vectors (2.16) under the constraint (2.17). Assuming that $\mathbf{e}_1 = \mathbf{e}_2 = (0,0,1)$, the Maxwell equations can be reduced to the same form (3.15), where the resonant terms are eliminated at the wave vectors $\mathbf{k}_1 = \mathbf{k}_{\text{in}}$ and $\mathbf{k}_2 = \mathbf{k}_{\text{out}}^{(n,m,0)}$. The coupled-mode equations for amplitudes $A_{1,2}(X,Y,T)$ take the form

$$i\left(\frac{\partial A_1}{\partial T} + \frac{p}{\sqrt{p^2+q^2}}\frac{\partial A_1}{\partial X} + \frac{q}{\sqrt{p^2+q^2}}\frac{\partial A_1}{\partial Y}\right) + \alpha A_2 = 0, \tag{3.20}$$

$$i\left(\frac{\partial A_2}{\partial T} + \frac{p+2n}{\sqrt{p^2+q^2}}\frac{\partial A_2}{\partial X} + \frac{q+2m}{\sqrt{p^2+q^2}}\frac{\partial A_2}{\partial Y}\right) + \alpha A_1 = 0, \tag{3.21}$$

where $\alpha = \alpha_{n,m,0} = \alpha_{-n,-m,0}$. Coupled-mode equations (3.20)–(3.21) for two oblique waves cannot be reduced to the one-dimensional system (3.12)–(3.13), since the characteristics in the system (3.20)–(3.21) are no longer parallel.

The coupled-mode equations for three oblique resonant waves (2.18) can be derived similarly, subject to the resonance condition (2.19). Three characteristics along the wave vectors $\mathbf{k}_1 = \mathbf{k}_{\rm in}$, $\mathbf{k}_2 = \mathbf{k}_{\rm out}^{(n_1,m_1,0)}$, and $\mathbf{k}_3 = \mathbf{k}_{\rm out}^{(n_2,m_2,0)}$ belong to the same (X,Y)-plane. The stationary transmission problem for the three oblique waves is hence a boundary-value problem on the (X,Y)-plane with three (linearly dependent) characteristic coordinates. Oblique interaction of three oblique resonant Bloch waves in a hexagonal crystal was considered numerically in [18].

4. Analysis of stationary transmission. The stationary transmission problem follows from separation of variables in the coupled-mode equations (3.9):

$$A_j(\mathbf{X},T) = a_j(\mathbf{X})e^{-i\Omega T}, \quad j = 1,\ldots,N, \tag{4.1}$$

where Ω is the detuning frequency. When the boundary-value problem for $a_j(\mathbf{X})$ is well posed in a bounded domain, analytical solutions for the linear stationary coupled-mode equations can be derived by using separation of variables and generalized Fourier series [24]. Exploiting these analytical solutions, integral invariants of the stationary transmission, reflection, and diffraction of the resonant Bloch waves can be computed explicitly. We analyze here the stationary coupled-mode equations for two and four counter-propagating and two oblique resonant Bloch waves.

4.1. Transmission of two counter-propagating waves. After separation of variables (4.1), the linear coupled-mode equations (3.12)–(3.13) reduce to the following ODE system:

$$i\frac{da_+}{dZ} + \Omega a_+ + \alpha a_- = 0, \tag{4.2}$$

$$-i\frac{da_-}{dZ} + \alpha a_+ + \Omega a_- = 0. \tag{4.3}$$

The problem (4.2)–(4.3) is defined on the interval $0 \le Z \le L_Z$. When the incident wave strikes the photonic crystal from the left, the linear system (4.2)–(4.3) is completed by the boundary conditions

$$a_+(0) = \alpha_+, \qquad a_-(L_Z) = 0, \tag{4.4}$$

where α_+ is the given amplitude of the incident wave at the left (x,y)-plane of the crystal. The general solution of the ODE system (4.2)–(4.3) is given explicitly as follows:

$$\begin{pmatrix} a_+ \\ a_- \end{pmatrix} = c_+ \begin{pmatrix} \alpha \\ \Omega + i\kappa \end{pmatrix} e^{\kappa Z} + c_- \begin{pmatrix} \alpha \\ \Omega - i\kappa \end{pmatrix} e^{-\kappa Z}, \tag{4.5}$$

where $c_\pm \in \mathbb{C}$ are arbitrary and $\kappa \in \mathbb{C}$ is the root of the determinant equation

$$\kappa = \sqrt{\alpha^2 - \Omega^2}. \tag{4.6}$$

When $\kappa = iK$, $K \in \mathbb{R}$, the linear dispersion relation $\Omega = \Omega(K)$ follows from the quadratic equation

$$\Omega^2 = \alpha^2 + K^2. \tag{4.7}$$

The two branches of the dispersion relation (4.7) correspond to the two counter-propagating resonant waves. Their resonance leads to the photonic stop band, which is located in the interval $|\Omega| < |\alpha|$. Let $\Omega = 0$ for simplicity; i.e., the detuning frequency is fixed in the middle of the stop band. The unique solution of the boundary-value problem (4.2)–(4.4) follows from the general solution (4.5):

$$\begin{pmatrix} a_+ \\ a_- \end{pmatrix} = \frac{\alpha_+}{\cosh \alpha L_Z} \begin{pmatrix} \cosh \alpha (L_Z - Z) \\ -i \sinh \alpha (L_Z - Z) \end{pmatrix}. \tag{4.8}$$

The transmittance T and reflectance R are defined from the other boundary values of the solution (4.8),

$$T = \left| \frac{a_+(L_Z)}{a_+(0)} \right|^2 = \frac{1}{\cosh^2 \alpha L_Z}, \qquad R = \left| \frac{a_-(0)}{a_+(0)} \right|^2 = \frac{\sinh^2 \alpha L_Z}{\cosh^2 \alpha L_Z}, \tag{4.9}$$

such that the balance identity $T + R = 1$ is satisfied. The analytical solution (4.8) for the two counter-propagating waves is well known [23] and is reproduced here for comparison with the case of four counter-propagating and two oblique waves on the plane.

4.2. Transmission of four counter-propagating waves. The stationary transmission of four counter-propagating waves in the coupled-mode equations (3.16)–(3.19) is studied in the characteristic coordinates (ξ, η):

$$\xi = \frac{X + Y}{2}, \qquad \eta = \frac{X - Y}{2}. \tag{4.10}$$

After the separation of variables (4.1), the linear coupled-mode equations (3.16)–(3.19) reduce to the PDE system

$$i \frac{\partial a_+}{\partial \xi} + \Omega a_+ + \alpha a_- + \beta (b_+ + b_-) = 0, \tag{4.11}$$

$$-i \frac{\partial a_-}{\partial \xi} + \alpha a_+ + \Omega a_- + \beta (b_+ + b_-) = 0, \tag{4.12}$$

$$i \frac{\partial b_+}{\partial \eta} + \beta (a_+ + a_-) + \Omega b_+ + \alpha b_- = 0, \tag{4.13}$$

$$-i \frac{\partial b_-}{\partial \eta} + \beta (a_+ + a_-) + \alpha b_+ + \Omega b_- = 0. \tag{4.14}$$

The problem (4.11)–(4.14) is defined in a bounded domain on the plane (ξ, η). We consider the rectangle

$$\mathcal{D} = \{(\xi, \eta) : 0 \le \xi \le L_\xi,\ 0 \le \eta \le L_\eta\}, \tag{4.15}$$

which corresponds to a rectangle in physical coordinates (X, Y), rotated at 45° in characteristic coordinates (ξ, η). When the incident wave moves along the main diagonal in the (X, Y)-plane of the photonic crystal, the linear system (4.11)–(4.14) is completed by the boundary conditions

$$a_+(0, \eta) = \alpha_+(\eta), \qquad a_-(L_\xi, \eta) = 0, \qquad b_+(\xi, 0) = 0, \qquad b_-(\xi, L_\eta) = 0, \tag{4.16}$$

where $\alpha_+(\eta)$ is the given amplitude of the incident wave at the left boundary of the crystal. The linear dispersion relation $\Omega = \Omega(K_\xi, K_\eta)$, where (K_ξ, K_η) are Fourier

wave numbers, follows from the determinant equation of the linear PDE system (4.11)–(4.14).

LEMMA 4.1. *The linear dispersion relation $\Omega = \Omega(K_\xi, K_\eta)$ is defined by the roots of $D(\Omega, K_\xi, K_\eta)$, where*

$$D(\Omega, K_\xi, K_\eta) = (\Omega^2 - \alpha^2 - K_\xi^2)(\Omega^2 - \alpha^2 - K_\eta^2) - 4\beta^2(\Omega - \alpha)^2. \tag{4.17}$$

There exist real-valued roots of $D(0, K_\xi, K_\eta) = 0$ for $\alpha^2 \leq 4\beta^2$, while no real-valued roots exist for $\alpha^2 > 4\beta^2$.

Proof. The determinant equation follows from the PDE system (4.11)–(4.14) for the Fourier modes $e^{i(K_\xi \xi + K_\eta \eta)}$ in the explicit form

$$D(\Omega, K_\xi, K_\eta) = \begin{vmatrix} \Omega - K_\xi & \alpha & \beta & \beta \\ \alpha & \Omega + K_\xi & \beta & \beta \\ \beta & \beta & \Omega - K_\eta & \alpha \\ \beta & \beta & \alpha & \Omega + K_\eta \end{vmatrix}. \tag{4.18}$$

Although the straightforward computations of $D(\Omega, K_\xi, K_\eta)$ are involved technically, it is easy to compute that

$$\frac{\partial D}{\partial \Omega} = 2\Omega(\Omega^2 - \alpha^2 - K_\xi^2) + 2\Omega(\Omega^2 - \alpha^2 - K_\eta^2) - 8\beta^2\Omega + 8\alpha\beta^2 \tag{4.19}$$

and

$$D(0, K_\xi, K_\eta) = (\alpha^2 + K_\xi^2)(\alpha^2 + K_\eta^2) - 4\alpha^2\beta^2. \tag{4.20}$$

Integrating (4.19)–(4.20), we find that $D(\Omega, K_\xi, K_\eta)$ is given by (4.17). When $\alpha^2 > 4\beta^2$, the function $D(0, K_\xi, K_\eta)$ is positive definite on $(K_\xi, K_\eta) \in \mathbb{R}^2$ such that no real-valued roots (K_ξ, K_η) exist for $\Omega = 0$. When $\alpha^2 \leq 4\beta^2$, there exist two curves on the (K_ξ, K_η)-plane, which correspond to the real-valued roots of $D(0, K_\xi, K_\eta)$. ∎

There are four surfaces of the dispersion relations $\Omega = \Omega(K_\xi, K_\eta)$, which correspond to the four resonant counter-propagating Bloch waves. When $\alpha^2 > 4\beta^2$, the interaction of four resonant waves leads to a stop band near the zero detuning frequency $\Omega = 0$. When $\alpha^2 \leq 4\beta^2$, no stop bands occur in the interaction of the four resonant waves. We consider solutions of the system (4.11)–(4.14) at $\Omega = 0$. By separating variables [24], we reduce the PDE problem to two ODE problems as follows:

$$a_+(\xi, \eta) = u_+(\xi) w_a(\eta), \qquad a_-(\xi, \eta) = u_-(\xi) w_a(\eta), \tag{4.21}$$

$$b_+(\xi, \eta) = w_b(\xi) v_+(\eta), \qquad b_-(\xi, \eta) = w_b(\xi) v_-(\eta), \tag{4.22}$$

where

$$v_+(\eta) + v_-(\eta) = \mu w_a(\eta), \qquad u_+(\xi) + u_-(\xi) = -\lambda w_b(\xi), \tag{4.23}$$

parameters (λ, μ) are arbitrary, and vectors $(u_+, u_-)^T$ and $(v_+, v_-)^T$ solve the two uncoupled ODE systems

$$\begin{pmatrix} i\partial_\xi & \alpha \\ \alpha & -i\partial_\xi \end{pmatrix} \begin{pmatrix} u_+ \\ u_- \end{pmatrix} = \beta \Gamma^{-1} \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} u_+ \\ u_- \end{pmatrix} \tag{4.24}$$

and

$$\begin{pmatrix} i\partial_\eta & \alpha \\ \alpha & -i\partial_\eta \end{pmatrix} \begin{pmatrix} v_+ \\ v_- \end{pmatrix} = \beta \Gamma \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} \begin{pmatrix} v_+ \\ v_- \end{pmatrix}, \tag{4.25}$$

where $\Gamma = \lambda/\mu$. The boundary conditions for (4.24)–(4.25) follow from (4.16) as follows:

$$u_+(0) = 1, \qquad u_-(L_\xi) = 0 \tag{4.26}$$

and

$$v_+(0) = v_-(L_\eta) = 0. \tag{4.27}$$

The homogeneous problem (4.25) and (4.27) defines the spectrum of Γ, while the inhomogeneous problem (4.24) and (4.26) defines a particular solution (4.21)–(4.22). The general solution of the problem (4.11)–(4.14) with the boundary values (4.16) is thought to be a linear superposition of infinitely many particular solutions, if the convergence and completeness of the decomposition formulas can be proved [24]. We first give solutions of the two problems above and then consider the orthogonality and completeness of the generalized Fourier series.

LEMMA 4.2. *All eigenvalues* Γ *of the homogeneous problem* (4.25) *and* (4.27) *are given by nonzero roots of the characteristic equation*

$$\mathcal{R} = \left\{ k \in \mathbb{C} : \left(\frac{k-\alpha}{k+\alpha} \right)^2 e^{-2ikL_\eta} = 1, \ \mathrm{Re}(k) \geq 0, \ k \neq 0 \right\} \tag{4.28}$$

such that

$$\Gamma = \frac{\alpha^2 + k^2}{2\alpha\beta}. \tag{4.29}$$

Let $\alpha > 0$. *Then the roots* $k \in \mathcal{R}$ *are all located in the first open quadrant of* $k \in \mathbb{C}$. *Moreover, all roots are simple, and there exist* $C > 0$ *and* $N \in \mathbb{Z}_+$ *such that only one root* $k \in \mathcal{R}$ *is located in each rectangle:*

$$\mathcal{D}_n^+ = \left\{ k \in \mathbb{C} : \frac{\pi(4n-1)}{2L_\eta} < k < \frac{\pi(4n+1)}{2L_\eta}, \ 0 < \mathrm{Im}(k) < C \right\}, \quad n \geq N, \tag{4.30}$$

and

$$\mathcal{D}_n^- = \left\{ k \in \mathbb{C} : \frac{\pi(4n+1)}{2L_\eta} < k < \frac{\pi(4n+3)}{2L_\eta}, \ 0 < \mathrm{Im}(k) < C \right\}, \quad n \geq N. \tag{4.31}$$

Proof. The general solution of the ODE system (4.25) with the use of (4.29) is found explicitly as follows:

$$\begin{pmatrix} v_+ \\ v_- \end{pmatrix} = c_k \begin{pmatrix} \alpha - k \\ \alpha + k \end{pmatrix} e^{ik\eta} + c_{-k} \begin{pmatrix} \alpha + k \\ \alpha - k \end{pmatrix} e^{-ik\eta}. \tag{4.32}$$

The coefficients c_k and c_{-k} satisfy the relations due to the boundary conditions (4.27):

$$\frac{c_k}{c_{-k}} = \frac{k+\alpha}{k-\alpha} = \frac{k-\alpha}{k+\alpha} e^{-2ikL_\eta}, \tag{4.33}$$

from which the characteristic equation (4.28) for roots $k \in \mathbb{C}$ follows. The symmetric roots k and $(-k)$ correspond to the same Γ and $v_\pm(\eta)$. The root $k = 0$ corresponds to the zero solution for $v_\pm(\eta)$. Therefore, the roots $k = 0$ and $\mathrm{Re}(k) < 0$ are excluded

from the definition of $\mathcal{R}$. The characteristic equation (4.28) results in the modulus equation

$$\frac{|k-\alpha|}{|k+\alpha|} = |e^{ikL_\eta}|.$$

When $\alpha > 0$, the left-hand side equals 1 at $\mathrm{Re}(k) = 0$ and is smaller than 1 for $\mathrm{Re}(k) > 0$. The right-hand side equals 1 at $\mathrm{Im}(k) = 0$ and is larger than 1 for $\mathrm{Im}(k) < 0$. Therefore, roots $k \in \mathcal{R}$ may occur only in the first open quadrant of $k \in \mathbb{C}$.

Let the roots $k \in \mathcal{R}$ be defined by the function $f(k) = (k-\alpha)^2 e^{-2ikL_\eta} - (k+\alpha)^2 = 0$. Then,

$$f'(k) = -\frac{2i(k+\alpha)}{(k-\alpha)}[(k^2-\alpha^2)L_\eta + 2i\alpha]. \tag{4.34}$$

Since the values of $k^2-\alpha^2$ for $k \in \mathcal{R}$ are located in the upper half-plane of the complex plane, $f'(k) \neq 0$ for $\alpha > 0$ such that all roots of $k \in \mathcal{R}$ are simple.

The characteristic equation (4.28) splits into two sets of roots $\mathcal{R}_+$ and $\mathcal{R}_-$ such that $\mathcal{R}_+ \cup \mathcal{R}_- = \mathcal{R}$, where

$$\mathcal{R}_\pm = \left\{ k \in \mathbb{C} : \frac{k-\alpha}{k+\alpha}\, e^{-ikL_\eta} = \pm 1,\ \mathrm{Re}(k) > 0 \right\}. \tag{4.35}$$

We consider the set $k \in \mathcal{R}_+$ and rewrite it in the form $f(k) + g(k) = 0$, where

$$f(k) = e^{ikL_\eta} - 1, \qquad g(k) = \frac{2\alpha}{k+\alpha}.$$

The function $f(k)$ has a zero at

$$k = k_n = \frac{2\pi n}{L_\eta}, \quad n \geq 1.$$

Let us consider the domain $\tilde{\mathcal{D}}_n^+$:

$$\tilde{\mathcal{D}}_n^+ = \left\{ k \in \mathbb{C} : \frac{\pi(4n-1)}{2L_\eta} < k < \frac{\pi(4n+1)}{2L_\eta},\ -C < \mathrm{Im}(k) < C \right\}, \quad n \geq N,$$

for some large $C > 0$ and $N \geq 1$, such that $\frac{\pi(4n-1)}{2L_\eta} > \alpha$. The domain $\tilde{\mathcal{D}}_n^+$ surrounds a simple zero of $f(k)$ at $k = k_n$ such that $|f(k)| > |g(k)|$ on the boundary of $\tilde{\mathcal{D}}_n^+$. By Rouche's theorem, the function $f(k) + g(k)$ has the same number of zeros inside $\tilde{\mathcal{D}}_n^+$ as $f(k)$ does, i.e., only one zero. Since the roots are located in the first open quadrant of $k \in \mathbb{C}$, the root in $\tilde{\mathcal{D}}_n^+$ is located in $\mathcal{D}_n^+$. The same analysis applies to the second set $k \in \mathcal{R}_-$ in the domain $\mathcal{D}_n^-$. □

Roots $k \in \mathcal{R}$ and $(-k) \in \mathcal{R}$ are shown in Figure 1 from the numerical solution of the characteristic equation (4.28) for $\alpha = 1$ and $L_\eta = 20$. In agreement with Lemma 4.2, all roots $k \in \mathcal{R}$ are isolated points in the first open quadrant, which accumulate to the real axis of k at infinity. The standard analysis of analytic functions at infinity leads to the asymptotic formula for distribution of large roots k in the domain $|k| > k_0 \gg 1$:

$$k_n^+ = \frac{2\pi n}{L_\eta} + \frac{i\alpha}{\pi n} + \mathrm{O}\left(\frac{1}{n^2}\right), \qquad k_n^- = \frac{\pi(1+2n)}{L_\eta} + \frac{2i\alpha}{\pi(1+2n)} + \mathrm{O}\left(\frac{1}{n^2}\right), \tag{4.36}$$

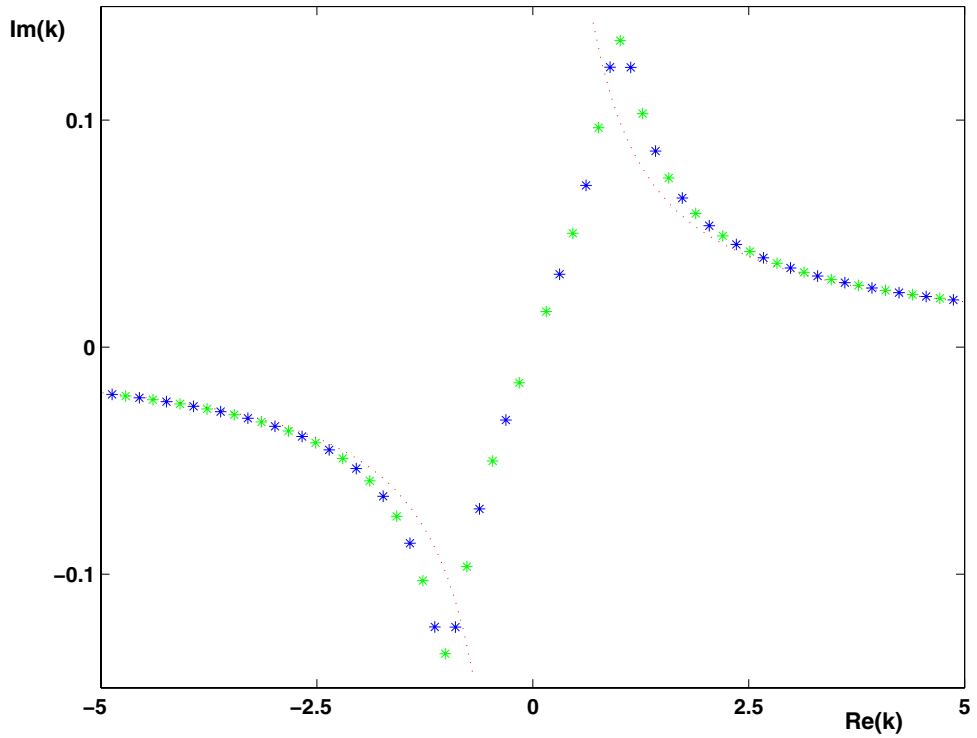

FIG. 1. *Roots $k \in \mathcal{R}$ and $(-k) \in \mathcal{R}$ of the characteristic equation* (4.28) *for $\alpha = 1$ and $L_\eta = 20$. Dark dots show roots of $\mathcal{R}_+$, and bright dots show roots of $\mathcal{R}_-$. The dotted curves show the leading-order asymptotic approximation* (4.36).

where n is a large positive integer. The leading order of the asymptotic approximation (4.36) is also shown in Figure 1 by dotted curves. The two sets in (4.36) correspond to the splitting $k \in \mathcal{R}_\pm$ in (4.35). The eigenfunction $v(\eta) = v_+(\eta) + v_-(\eta)$ is symmetric (antisymmetric) with respect to $\eta = L_\eta/2$ for $k \in \mathcal{R}_+$ ($k \in \mathcal{R}_-$). Moreover, explicit formulas for $v(\eta)$ follow from (4.32) and (4.33):

$$k \in \mathcal{R}_+ : v(\eta) = c_+ \cos k \left(\frac{L_\eta}{2} - \eta \right), \tag{4.37}$$

$$k \in \mathcal{R}_- : v(\eta) = c_- \sin k \left(\frac{L_\eta}{2} - \eta \right), \tag{4.38}$$

where (c_+, c_-) are normalization constants. Asymptotic solutions (4.36) correspond to two sets of eigenfunctions

$$\left\{ \cos(\pi n \tilde{\eta}),\ \sin\left(\frac{\pi(2n+1)\tilde{\eta}}{2} \right) \right\}, \quad \tilde{\eta} = \frac{2\eta}{L_\eta} - 1, \tag{4.39}$$

which solve the homogeneous Neumann problem on the normalized interval $-1 \le \tilde{\eta} \le 1$.

LEMMA 4.3. *Let Γ be an eigenvalue of the problem* (4.25) *and* (4.27). *There exists a unique solution of the nonhomogeneous problem* (4.24) *and* (4.26) *for this Γ.*

Proof. A general solution of the ODE system (4.24) is found explicitly as follows:

$$\begin{pmatrix} u_+ \\ u_- \end{pmatrix} = d_k \begin{pmatrix} \alpha^2+k^2-2\beta^2 \\ \lambda_k(\alpha^2+k^2)+2\beta^2 \end{pmatrix} e^{i\alpha\lambda_k\eta} + d_{-k} \begin{pmatrix} \alpha^2+k^2-2\beta^2 \\ -\lambda_k(\alpha^2+k^2)+2\beta^2 \end{pmatrix} e^{-i\alpha\lambda_k\eta}, \tag{4.40}$$

where

$$\lambda_k = \sqrt{\frac{4\beta^2}{\alpha^2+k^2} - 1}. \tag{4.41}$$

The relation (4.41) satisfies the determinant equation (4.17) such that $D(0, \alpha\lambda_k, k) = 0$. Using the boundary conditions (4.26), coefficients d_k and d_{-k} are found uniquely, under the constraint

$$u_0 = \lambda_k(\alpha^2+k^2)\cos\alpha\lambda_k L_\xi + 2i\beta^2 \sin\alpha\lambda_k L_\xi \neq 0. \tag{4.42}$$

We show that $u_0 \neq 0$. The equation $u_0 = 0$ can be rewritten in the form

$$\frac{(\lambda_k-1)^2}{(\lambda_k+1)^2} = e^{2i\alpha\lambda_k L_\xi}. \tag{4.43}$$

By analysis of Lemma 4.2, it is clear that nonzero roots of the characteristic equation (4.43) may exist only in the first and third open quadrants of $\lambda_k \in \mathbb{C}$ for $\alpha > 0$, such that the values of $\lambda_k^2 + 1$ are located in the upper half-plane of the complex plane. The zero root $\lambda_k = 0$ is located on the real axis for $\lambda_k^2 + 1$. On the other hand, the values of $4\beta^2/(\alpha^2+k^2)$ for $k \in \mathcal{R}$ are located in the lower half-plane. Therefore, the relation (4.41) leads to a contradiction, which proves that $u_0 \neq 0$. ∎

Solutions of the nonhomogeneous problem (4.24) and (4.26) with the normalization $u_+(0) = u_0 \neq 0$ can be written explicitly by eliminating d_k and d_{-k} from the implicit form (4.40):

$$\begin{pmatrix} u_+ \\ u_- \end{pmatrix} = \lambda_k(\alpha^2+k^2) \begin{pmatrix} 1 \\ 0 \end{pmatrix} \cos\alpha\lambda_k(L_\xi - \xi) + i \begin{pmatrix} 2\beta^2 \\ \alpha^2+k^2-2\beta^2 \end{pmatrix} \sin\alpha\lambda_k(L_\xi - \xi). \tag{4.44}$$

When the representation (4.21) is used for $\alpha_+(\eta) = a_+(0,\eta)$, the function $\alpha_+(\eta)$ is expanded as a series of scalar eigenfunctions $v(\eta) = v_+(\eta) + v_-(\eta)$, defined for roots $k \in \mathcal{R}$. This decomposition is possible only if the set of eigenfunctions $v(\eta)$ is orthogonal and complete.

LEMMA 4.4. *There exists a set of normalized and orthogonal eigenfunctions $v_j(\eta)$ for distinct roots $k = k_j \in \mathcal{R}$, according to the inner product*

$$\int_0^{L_\eta} v_i(\eta) v_j(\eta) d\eta = \delta_{i,j}. \tag{4.45}$$

Proof. The set of adjoint eigenvectors to the problem (4.25) and (4.27) with respect to the standard inner product in $L^2([0, L_\eta])$ is given by the vectors $(\bar{v}_-, \bar{v}_+)^T$. As a result, the scalar eigenfunctions $v_j(\eta)$ for distinct roots $k = k_j$ satisfy the orthogonality relations (4.45) with $i \neq j$. The scalar eigenfunction $v(\eta)$ is found from (4.32) and (4.33) in the explicit form

$$v(\eta) = c_0(k\cos k\eta + i\alpha \sin k\eta), \tag{4.46}$$

where c_0 is a normalization constant. Integrating $v^2(\eta)$ on $\eta \in [0, L_\eta]$, we confirm that the eigenfunctions $v_j(\eta)$ can be normalized by the inner product (4.45) with $i = j$, under the constraint

$$(k^2 - \alpha^2)L_\eta + 2i\alpha \neq 0. \tag{4.47}$$

Since the roots $k \in \mathcal{R}$ are all simple, such that $f'(k) \neq 0$ in (4.34), the constraint (4.47) is met. □

PROPOSITION 4.5. *Any continuously differentiable complex-valued function $f(\eta)$ on $0 \leq \eta \leq L_\eta$ is uniquely represented by the series of eigenfunctions*

$$f(\eta) = \sum_{\text{all } k_j \in \mathcal{R}} c_j v_j(\eta), \quad c_j = \int_0^{L_\eta} f(\eta) v_j(\eta) d\eta, \tag{4.48}$$

and the series converges to $f(\eta)$ uniformly on $0 \leq \eta \leq L_\eta$.

Proof. It follows from (4.25) and (4.27) that the scalar eigenfunction $v(\eta)$ solves the second-order boundary-value problem

$$v'' + k^2 v = 0 \tag{4.49}$$

such that

$$iv'(0) + \alpha v(0) = 0, \qquad -iv'(L_\eta) + \alpha v(L_\eta) = 0. \tag{4.50}$$

The Sommerfeld radiation boundary conditions (4.50) explain why the spectrum of the formally self-adjoint operator (4.49) is complex-valued. The statement of the proposition follows from the expansion theorem [7, p. 303], since the theorem's condition is satisfied: $A_{2,4} = 1$, where $A_{2,4}$ is the determinant of the second and fourth columns of the matrix A, associated with the boundary conditions

$$A = \begin{pmatrix} \alpha & i & 0 & 0 \\ 0 & 0 & \alpha & -i \end{pmatrix}.$$

As a result, the Fourier series of asymptotic eigenfunctions (4.39) approximates the series expansion (4.48) for large roots $k = k_n^{\pm}$ uniformly on $\eta \in [0, L_\eta]$. The uniform convergence of (4.48) follows from that of the Fourier series [24]. □

Using separation of variables and convergence of series of eigenfunctions, we summarize the existence and uniqueness results on the generalized Fourier series solutions of the linear boundary-value problem (4.11)–(4.14) and (4.16) with $\Omega = 0$.

PROPOSITION 4.6. *Let the set $\{c_j\}$ be uniquely defined by the series* (4.48) *for $f(\eta) = \alpha_+(\eta)$. There exists a unique solution of the boundary-value problem* (4.11)–(4.14) *and* (4.16) *with $\Omega = 0$ in the domain* (4.15):

$$a_+(\xi, \eta) = \sum_{\text{all } k_j \in \mathcal{R}} c_j \frac{u_{+j}(\xi)}{u_{+j}(0)} (v_{+j}(\eta) + v_{-j}(\eta)), \tag{4.51}$$

$$a_-(\xi, \eta) = \sum_{\text{all } k_j \in \mathcal{R}} c_j \frac{u_{-j}(\xi)}{u_{+j}(0)} (v_{+j}(\eta) + v_{-j}(\eta)), \tag{4.52}$$

$$b_+(\xi, \eta) = -\sum_{\text{all } k_j \in \mathcal{R}} c_j \frac{u_{+j}(\xi) + u_{-j}(\xi)}{\Gamma_j u_{+j}(0)} v_{+j}(\eta), \tag{4.53}$$

$$b_-(\xi, \eta) = -\sum_{\text{all } k_j \in \mathcal{R}} c_j \frac{u_{+j}(\xi) + u_{-j}(\xi)}{\Gamma_j u_{+j}(0)} v_{-j}(\eta). \tag{4.54}$$

We illustrate the generalized Fourier series solutions (4.51)–(4.54) with two examples: (i) a single term of the generalized Fourier series and (ii) a constant input function $\alpha_+(\eta) = \alpha_+$. For both examples, we compute the integral invariants for the incident ($\mathcal{I}_{\rm in}$), transmitted ($\mathcal{I}_{\rm out}$), reflected ($\mathcal{I}_{\rm ref}$), and diffracted ($\mathcal{I}_{\rm dif}$) waves from their definitions:

$$\mathcal{I}_{\rm in} = \int_0^{L_\eta} |a_+(0,\eta)|^2 d\eta, \qquad \mathcal{I}_{\rm out} = \int_0^{L_\eta} |a_+(L_\xi,\eta)|^2 d\eta, \tag{4.55}$$

$$\mathcal{I}_{\rm ref} = \int_0^{L_\eta} |a_-(0,\eta)|^2 d\eta, \qquad \mathcal{I}_{\rm dif} = \int_0^{L_\xi} (|b_+(\xi,L_\eta)|^2 + |b_-(\xi,0)|^2) d\xi. \tag{4.56}$$

Let the transmittance T, reflectance R, and diffractance D be defined from the relations

$$T = \frac{\mathcal{I}_{\rm out}}{\mathcal{I}_{\rm in}}, \qquad R = \frac{\mathcal{I}_{\rm ref}}{\mathcal{I}_{\rm in}}, \qquad D = \frac{\mathcal{I}_{\rm dif}}{\mathcal{I}_{\rm in}}. \tag{4.57}$$

The integral invariants satisfy the balance identity

$$R + T + D = 1, \tag{4.58}$$

which follows from integration of the balance equation

$$\frac{\partial}{\partial \xi}(|a_+|^2 - |a_-|^2) + \frac{\partial}{\partial \eta}(|b_+|^2 - |b_-|^2) = 0. \tag{4.59}$$

First, we consider a single term of the Fourier series solutions (4.51)–(4.54). The transmittance and reflectance for $k \in \mathcal{R}$ are found from (4.44) in the explicit form

$$T_k = \left| \frac{\lambda_k(\alpha^2 + k^2)}{\lambda_k(\alpha^2 + k^2)\cos \alpha\lambda_k L_\xi + 2i\beta^2 \sin \alpha\lambda_k L_\xi} \right|^2, \tag{4.60}$$

$$R_k = \left| \frac{(\alpha^2 + k^2 - 2\beta^2)\sin \alpha\lambda_k L_\xi}{\lambda_k(\alpha^2 + k^2)\cos \alpha\lambda_k L_\xi + 2i\beta^2 \sin \alpha\lambda_k L_\xi} \right|^2, \tag{4.61}$$

while the diffractance is found from the balance identity as $D_k = 1 - T_k - R_k$. These integral invariants of the stationary transmission for $\alpha = 1$ and $L_\xi = L_\eta = 20$ are shown in Figure 2 for $\beta = 0.25$ and in Figure 3 for $\beta = 0.75$. In the first case, when $\alpha^2 > 4\beta^2$, there is a stop band at $\Omega = 0$, such that all modes are fully reflected except for small losses due to diffraction. In the second case, when $\alpha^2 < 4\beta^2$, there is no stop band at $\Omega = 0$, such that transmittance and diffractance are large for smaller values of $|k|$ and become negligible for larger values of $|k|$.

Next, we consider a constant input function:

$$\alpha_+(\eta) = \alpha_+, \quad \eta \in [0, L_\eta], \tag{4.62}$$

when c_j can be found from (4.48),

$$c_j = \frac{4i\alpha\alpha_+}{k_j[L(k_j^2 - \alpha^2) + 2i\alpha]}, \quad k_j \in \mathcal{R}_+, \tag{4.63}$$

and $c_j = 0$ for $k_j \in \mathcal{R}_-$. The solution surfaces $|a_\pm(\xi,\eta)|^2$ and $|b_\pm(\xi,\eta)|^2$ in the domain (4.15) are shown for $\alpha = 1$, $L_\xi = L_\eta = 20$, and $\alpha_+ = 1$ in Figure 4 for $\beta = 0.25$ and

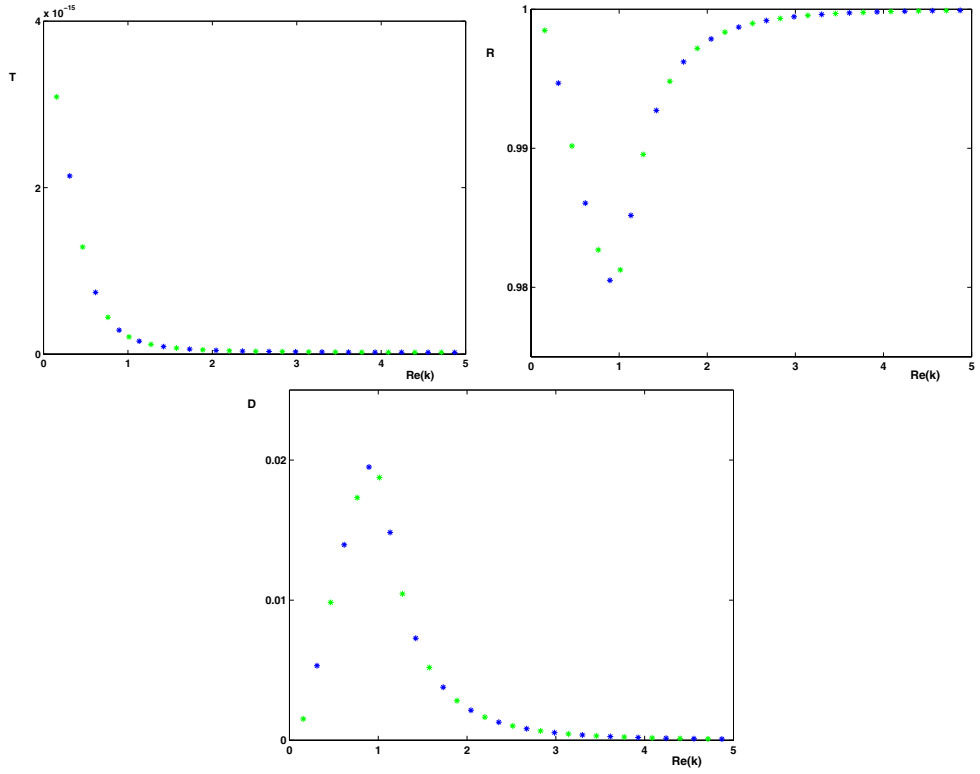

FIG. 2. *Transmittance* (T_k)*, reflectance* (R_k)*, and diffractance* (D_k) *versus* $\mathrm{Re}(k)$ *for the roots* $k \in \mathcal{R}$ *when* $\alpha = 1$*,* $\beta = 0.25$*, and* $L_\xi = L_\eta = 20$*.*

in Figure 5 for $\beta = 0.75$. We can see from the figures that the boundary conditions (4.16) are satisfied by the truncated generalized Fourier series (4.51)–(4.54) with only 30 first terms.

The Parseval identity cannot be applied to eigenfunctions $v_j(\eta)$, because the inner product (4.45) is not the standard inner product in $L^2([0, L_\eta])$. As a result, the energy spectrum of $I_{\rm out}$, $I_{\rm ref}$, and $I_{\rm dif}$ cannot be decomposed into a superposition of the squared amplitudes $|c_j|^2$. Nevertheless, the numerical values for T, R, and D can be found from numerical integration of the solution surfaces (4.55)–(4.56). The numerical values are

$$\begin{aligned} &\beta = 0.25 : T \approx 3 \times 10^{-15}, \quad R \approx 0.9853, \quad D \approx 0.0147, \\ &\beta = 0.75 : T \approx 0.7394, \quad R \approx 0.0133, \quad D \approx 0.2473, \end{aligned}$$

such that $T + R + D \approx 1$. When $\alpha^2 > 4\beta^2$, there exists a stop band at $\Omega = 0$, and the incident wave is reflected from the photonic crystal with energy loss of 1.5% due to diffraction. When $\alpha^2 < 4\beta^2$, there is no stop band at $\Omega = 0$, and the incident wave is transmitted along the photonic crystal with energy loss of 26% due to reflection and diffraction.

4.3. Transmission of two oblique waves. The stationary transmission of two oblique waves in the coupled-mode equations (3.20)–(3.21) becomes diagonal in the

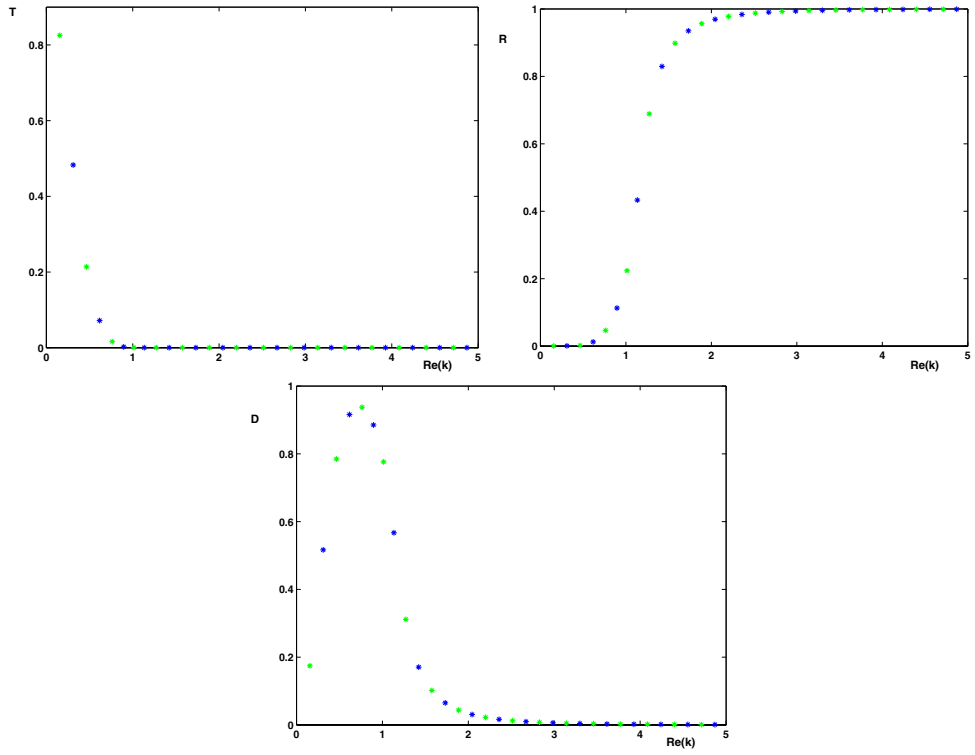

FIG. 3. *Transmittance* (T_k)*, reflectance* (R_k)*, and diffractance* (D_k) *versus* $\mathrm{Re}(k)$ *for the roots* $k \in \mathcal{R}$ *when* $\alpha = 1$*,* $\beta = 0.75$*, and* $L_\xi = L_\eta = 20$*.*

characteristic coordinates (ξ, η):

$$X = \frac{p\xi + (p+2n)\eta}{\sqrt{p^2+q^2}}, \qquad Y = \frac{q\xi + (q+2m)\eta}{\sqrt{p^2+q^2}}. \tag{4.64}$$

After the separation of variables (4.1), the linear coupled-mode equations (3.20)–(3.21) reduce to the PDE system

$$i\frac{\partial a_1}{\partial \xi} + \Omega a_1 + \alpha a_2 = 0, \tag{4.65}$$

$$i\frac{\partial a_2}{\partial \eta} + \alpha a_1 + \Omega a_2 = 0. \tag{4.66}$$

Coordinate axes (ξ, η) are parallel to the wave vectors $\mathbf{k}_1 = \mathbf{k}_{\rm in}$ and $\mathbf{k}_2 = \mathbf{k}_{\rm out}^{(n,m,0)}$, but they are no longer orthogonal. The problem (4.65)–(4.66) is defined in a bounded domain on the plane (ξ, η). We consider the same rectangle $\mathcal{D}$, defined by (4.15). When the incident wave is illuminated in the direction of the wave vector $\mathbf{k}_1$ but not in the direction of the wave vector $\mathbf{k}_2$, the linear system (4.65)–(4.66) is completed by the boundary conditions

$$a_1(0,\eta) = \alpha_1(\eta), \qquad a_2(\xi, 0) = 0. \tag{4.67}$$

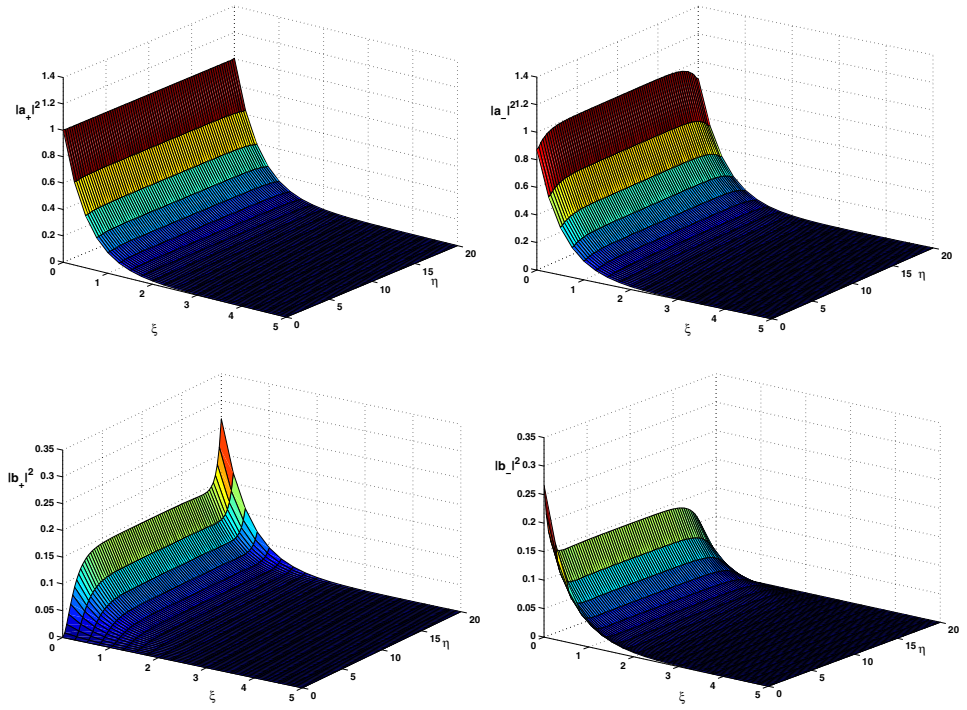

FIG. 4. *Solution surfaces* $|a_\pm|^2(\xi,\eta)$ *and* $|b_\pm|^2(\xi,\eta)$ *on the domain* (4.15) *for* $\alpha = 1$, $\beta = 0.25$, $L_\xi = L_\eta = 20$, *and* $\alpha_+ = 1$.

The linear dispersion relation $\Omega = \Omega(K_\xi, K_\eta)$, where (K_ξ, K_η) are Fourier wave numbers, is given explicitly as

$$\left(\Omega - \frac{K_\xi + K_\eta}{2}\right)^2 = \alpha^2 + \left(\frac{K_\xi - K_\eta}{2}\right)^2. \tag{4.68}$$

Two surfaces of the dispersion relation (4.68) correspond to the two oblique resonant waves. In a moving reference frame on the plane (ξ,η) there exists a stop band in the dispersion relation (4.68). We consider solutions of the system (4.65)–(4.66) at $\Omega = 0$ by using the Fourier transform

$$a_1(\xi,\eta) = \int_{-\infty}^{\infty} kc(k) e^{i\alpha(k^{-1}\xi + k\eta)} dk, \tag{4.69}$$

$$a_2(\xi,\eta) = \int_{-\infty}^{\infty} c(k) e^{i\alpha(k^{-1}\xi + k\eta)} dk. \tag{4.70}$$

It follows from the boundary conditions (4.67) that

$$kc(k) = \frac{\alpha}{2\pi} \int_0^{L_\eta} \alpha_1(\eta) e^{-i\alpha k\eta} d\eta, \quad k \in \mathbb{R}, \tag{4.71}$$

and

$$0 = \int_{-\infty}^{\infty} c(k) e^{i\alpha k^{-1}\xi} dk, \quad 0 \le \xi \le L_\xi. \tag{4.72}$$

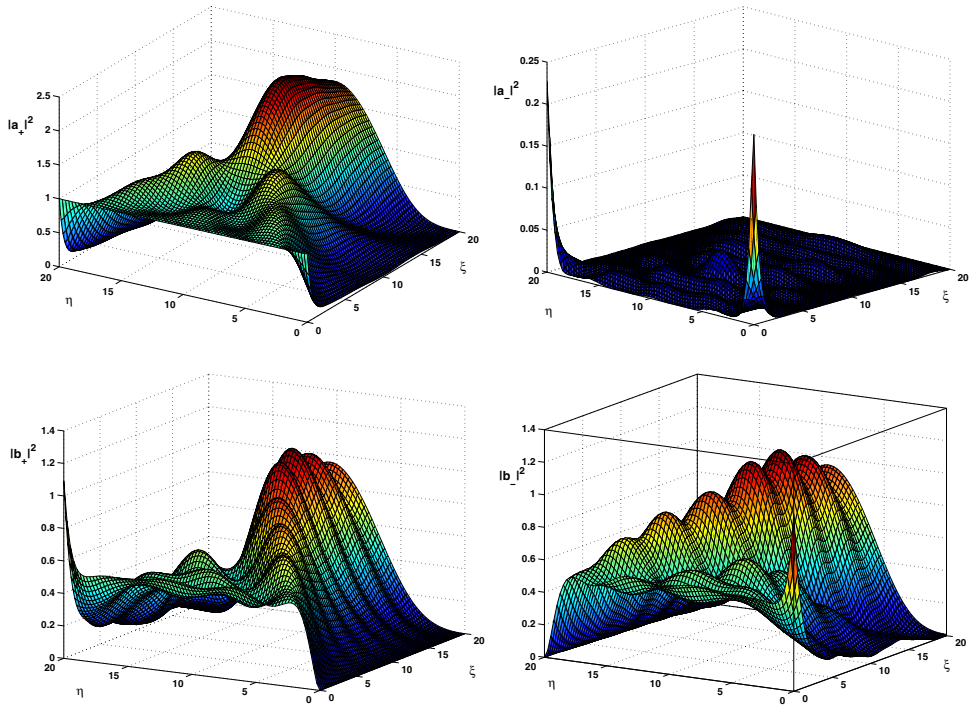

FIG. 5. *Solution surfaces* $|a_\pm|^2(\xi,\eta)$ *and* $|b_\pm|^2(\xi,\eta)$ *on the domain* (4.15) *for* $\alpha = 1$, $\beta = 0.75$, $L_\xi = L_\eta = 20$, *and* $\alpha_+ = 1$.

Interchanging integrals, we reduce the constraint (4.72) to the form

$$0 = \frac{\alpha}{2\pi i} \int_0^{L_\eta} \alpha_1(\eta) \left(\int_{-\infty}^{\infty} \frac{\sin \alpha(k\eta - k^{-1}\xi)}{k} dk \right) d\eta, \quad 0 \leq \xi \leq L_\xi. \tag{4.73}$$

The inner integral is zero for $\xi > 0$ and $\eta > 0$, due to the table integral 3.871 on p. 474 of [9]. Therefore, the constraint (4.72) is satisfied, and a unique solution of the problem (4.65)–(4.67) exists in the form (4.69)–(4.71).

We illustrate the Fourier transform solution (4.69)–(4.70) with the constant input function

$$\alpha_1(\eta) = \alpha_1, \quad \eta \in [0, L_\eta], \tag{4.74}$$

when $c(k)$ can be found from (4.71):

$$c(k) = \frac{\alpha_1}{2\pi i} \frac{1 - e^{-i\alpha k L_\eta}}{k^2}, \quad k \in \mathbb{R}. \tag{4.75}$$

Evaluating Fourier integrals (4.69)–(4.70) with the help of the table integral 3.871 on p. 474 of [9], we find the explicit solution of the stationary problem:

$$a_1(\xi,\eta) = \alpha_1 J_0(2\alpha\sqrt{\xi\eta}), \qquad a_2(\xi,\eta) = \frac{i\alpha_1\sqrt{\eta}}{\sqrt{\xi}} J_1(2\alpha\sqrt{\xi\eta}), \tag{4.76}$$

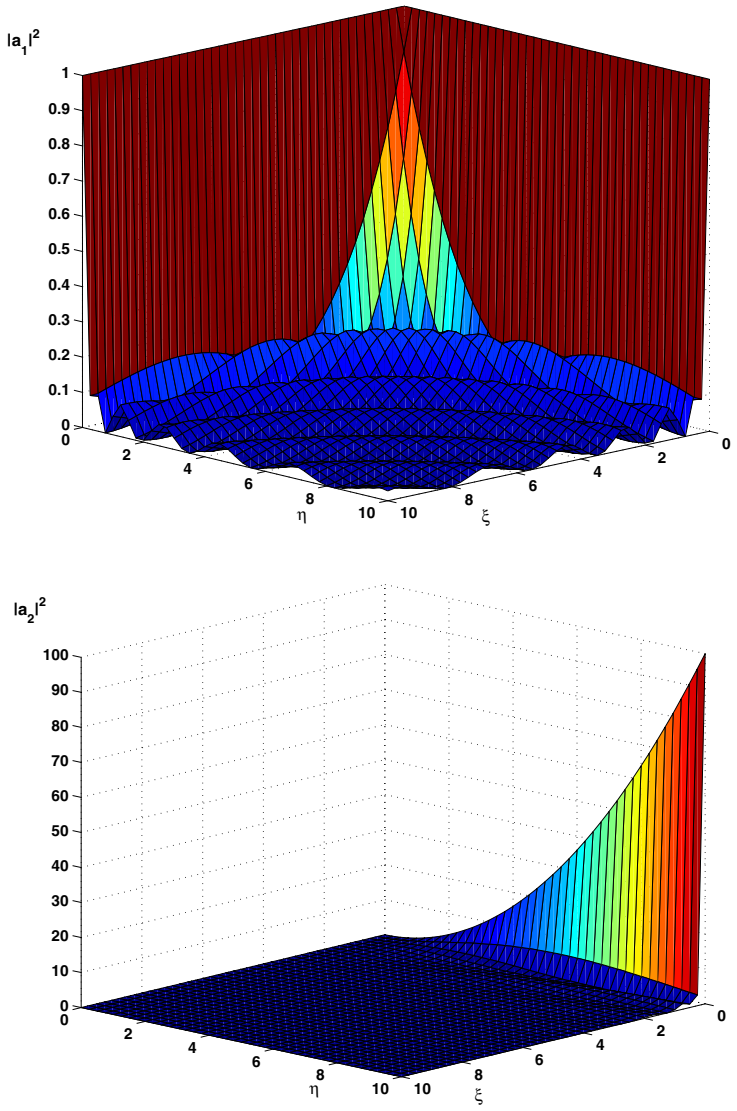

FIG. 6. *Solution surfaces* $|a_1|^2(\xi,\eta)$ *and* $|a_2|^2(\xi,\eta)$ *on the domain* (4.15) *for* $\alpha = 1$, $L_\xi = L_\eta = 10$, *and* $\alpha_1 = 1$.

where $J_{0,1}(z)$ are Bessel functions [9]. Figure 6 shows the solution surfaces $|a_1(\xi,\eta)|^2$ and $|a_2(\xi,\eta)|^2$ in the domain (4.15) for $\alpha = 1$, $L_\xi = L_\eta = 10$, and $\alpha_1 = 1$. The integral invariants for the stationary transmission follow from integration of the balance equation:

$$\frac{\partial}{\partial\xi}|a_1|^2 + \frac{\partial}{\partial\eta}|a_2|^2 = 0. \tag{4.77}$$

We define the incident ($\mathcal{I}_{\rm in}$), transmitted ($\mathcal{I}_{\rm out}$), and diffracted ($\mathcal{I}_{\rm dif}$) intensities by

$$\mathcal{I}_{\rm in} = \int_0^{L_\eta} |a_1(0,\eta)|^2 d\eta, \quad \mathcal{I}_{\rm out} = \int_0^{L_\eta} |a_1(L_\xi,\eta)|^2 d\eta, \quad \mathcal{I}_{\rm dif} = \int_0^{L_\xi} |a_2(\xi,L_\eta)|^2 d\xi. \tag{4.78}$$

The transmittance (T) and diffractance (D) are defined by the same relations (4.57), and the balance identity $T + D = 1$ follows from integration of the balance equation (4.77). The numerical values for T and D are found from numerical integration of the solution surfaces (4.78) as follows:

$$T \approx 0.032, \qquad D \approx 0.968,$$

such that $T + D \approx 1$. These values show that the incident wave is diffracted to the oblique resonance wave such that only 3.2% of the wave energy remains in the transmitted wave.

4.4. General transmission problems. A general system of coupled-mode equations (3.9) can be diagonalized in characteristic coordinates, similarly to the case of four counter-propagating and two oblique resonant waves. The characteristic coordinates are introduced from the set of resonant wave vectors as follows:

$$\frac{\partial}{\partial \xi_j} = \frac{\mathbf{k}_{j,x}}{k}\frac{\partial}{\partial X} + \frac{\mathbf{k}_{j,y}}{k}\frac{\partial}{\partial Y} + \frac{\mathbf{k}_{j,z}}{k}\frac{\partial}{\partial Z}, \quad j = 1, \dots, N, \tag{4.79}$$

such that the characteristic coordinate ξ_j extends in the direction of the wave vector $\mathbf{k}_j$. The characteristic coordinates $(\xi_1, \dots, \xi_N) \in \mathbb{R}^N$ are related to the physical coordinates $(X, Y, Z) \in \mathbb{R}^3$ as follows:

$$\mathbf{X} = \mathbf{X}_0 + \sum_{j=1}^N \xi_j \frac{\mathbf{k}_j}{k}, \tag{4.80}$$

where $\mathbf{X}_0 \in \mathbb{R}^3$ is an arbitrary point. The boundary-value problem for the linear stationary transmission with $\Omega = 0$ can be rewritten in the form

$$i\frac{\partial a_j}{\partial \xi_j} + \sum_{k \neq j} \hat{\alpha}_{j,k} a_k = 0, \quad j = 1, \dots, N. \tag{4.81}$$

We consider the domain of definition in the cone $(\xi_1, \dots, \xi_N) \in \mathbb{R}^N_+$, subject to the Goursat boundary values

$$a_j(\xi_1, \dots, \xi_{j-1}, 0, \xi_{j+1}, \dots, \xi_N) = \alpha_j(\xi_1, \dots, \xi_{j-1}, \xi_{j+1}, \dots, \xi_N), \quad j = 1, \dots, N. \tag{4.82}$$

The Goursat boundary-value problem (4.81)–(4.82) can be rewritten as the Volterra integral equations:

$$a_j(\xi_j) = \alpha_j + i\int_0^{\xi_j} \sum_{k \neq j} \hat{\alpha}_{j,k} a_k(\xi_j') d\xi_j'. \tag{4.83}$$

By the contraction mapping principle [11], there exists a unique solution of the Volterra equations (4.83) in the cone $(\xi_1, \dots, \xi_N) \in \mathbb{R}^N_+$, such that we have the following result.

THEOREM 4.7. *Let $\mathcal{D}$ be a convex domain in $\mathbb{R}^3$, which is cut by the characteristic coordinate projections $\xi_j = 0$, $j = 1, \ldots, N$. There exists a unique solution $a_j = a_j(\xi_1, \ldots, \xi_N)$, which corresponds to the boundary-value problem* (4.81)–(4.82) *and depends smoothly on the boundary values α_j, $j = 1, \ldots, N$.*

If $N = \text{rank}(\mathbf{k}_1, \ldots, \mathbf{k}_N)$, there exists only one domain $\mathcal{D} \subset \mathbb{R}^N$, which corresponds to the cone $\xi_j \geq 0$, $j = 1, \ldots, N$. The case of two oblique waves on the plane (X, Y) gives an example of this situation for $N = 2$. The Goursat problem (4.81)–(4.82) is rewritten as the PDE problem (4.65)–(4.66) with the boundary values (4.67), which is solved with the explicit Fourier transform solutions (4.69)–(4.71).

If $N > \text{rank}(\mathbf{k}_1, \ldots, \mathbf{k}_N)$, the characteristic coordinates $(\xi_1, \ldots, \xi_N)$ are linearly dependent such that there exist multiple ways to choose a convex domain $\mathcal{D} \subset \mathbb{R}^3$ that corresponds to the cone $\xi_j \geq 0$, $j = 1, \ldots, N$. The case of four counter-propagating waves on the plane (X, Y) gives an example of this situation for $N = 4$ and $\text{rank}(\mathbf{k}_1, \ldots, \mathbf{k}_N) = 2$. In this case, we have chosen that $\xi_1 = \xi$, $\xi_2 = \eta$, $\xi_3 = L_\eta - \eta$, and $\xi_4 = L_\xi - \xi$, such that $0 \leq \xi \leq L_\xi$ and $0 \leq \eta \leq L_\eta$. As a result, the Goursat problem (4.81)–(4.82) is rewritten as the PDE problem (4.11)–(4.14) with the boundary values (4.16). Theorem 4.7 does not guarantee well-posedness of (4.11)–(4.14), while explicit Fourier series solutions (4.51)–(4.54) do (see Proposition 4.6).

5. Summary and open problems. We have shown that the coupled-mode equations can be used for analysis and modeling of resonant interaction of Bloch waves in low-contrast cubic-lattice three-dimensional photonic crystals. The analytical solutions for the linear stationary transmission problem are found by using separation of variables and generalized Fourier series. We have proved that the linear stationary boundary-value problem is well-posed in the context of four counter-propagating and two oblique waves on the plane. We have also given general results on well-posedness of the general linear stationary transmission problem.

It remains an open problem to prove well-posedness of the nonlinear stationary boundary-value problem for small-norm and finite-norm solutions. Nonstationary transmission problems are also of interest, and very few analytical results are available on local and global well-posedness of the nonstationary nonlinear coupled-mode equations. Finally, numerical approximations of the stationary and nonstationary, fully nonlinear coupled-mode equations can be constructed in bounded domains with the method of orthogonal polynomials [17]. All these problems are beyond the scope of the present work.

Appendix A. Nonlinear coupled-mode equations with cubic nonlinearities. Modeling of nonlinear photonic band-gap crystals with cubic (Kerr) nonlinearities is based on the Maxwell equations, where the polarization vector depends nonlinearly on the electric field vector $\mathbf{E}$ (see [13]). When the nonlinearity terms are small, nonlocal (dispersive) terms in the polarization vector can be neglected, and the low-contrast weakly nonlinear photonic crystals can be modeled with the Maxwell equations (1.1), where the refractive index $n = n(\mathbf{x}, |\mathbf{E}|^2)$ is decomposed into the linear and nonlinear parts [23]:

$$n(\mathbf{x}, |\mathbf{E}|^2) = n_0 + \epsilon n_1(\mathbf{x}) + \epsilon n_2(\mathbf{x})|\mathbf{E}|^2, \tag{A.1}$$

where n_0 is constant and ϵ is of small parameter. When the photonic crystal has cubic-lattice structure, the periodic functions $n_1(\mathbf{x})$ and $n_2(\mathbf{x})$ are expanded into the

triple Fourier series (3.4) and

$$n_2(\mathbf{x}) = n_0 \sum_{(n,m,l)\in\mathbb{Z}^3} \beta_{n,m,l} e^{ik_0(nx+my+lz)}, \quad \beta_{n,m,l} = \bar{\beta}_{-n,-m,-l}, \tag{A.2}$$

where the factor n_0 is included for convenience. Derivation of the nonlinear coupled-mode equations is based on rigorous methods of Lyapunov–Schmidt reductions [16]. Equivalently, the formal derivation can be recovered with perturbation series expansions [19], which follows the formalism (3.2) and (3.3) outlined in section 3. The first-order correction term $\mathbf{E}_1(\mathbf{x},t)$ solves the nonhomogeneous problem (3.8) with additional nonlinear terms:

$$\begin{aligned} \nabla^2\mathbf{E}_1 - \frac{n_0^2}{c^2}\frac{\partial^2\mathbf{E}_1}{\partial t^2} &= 2\frac{n_0^2\omega}{c^2}\frac{\partial^2\mathbf{E}_0}{\partial T\partial t} - 2k\left(\nabla\cdot\nabla_X\right)\mathbf{E}_0 \\ &\quad + \frac{2n_0n_1(\mathbf{x})}{c^2}\frac{\partial^2\mathbf{E}_0}{\partial t^2} + \frac{2}{n_0}\nabla\left(\nabla n_1\cdot\mathbf{E}_0\right) \\ &\quad + \frac{2n_0n_2(\mathbf{x})}{c^2}|\mathbf{E}_0|^2\frac{\partial^2\mathbf{E}_0}{\partial t^2} + \frac{2}{n_0}\nabla\left(\nabla n_2|\mathbf{E}_0|^2\cdot\mathbf{E}_0\right). \end{aligned} \tag{A.3}$$

The cubic nonlinear terms generate N^3 terms from the leading-order solution (3.3), which all give resonant terms by means of the triple series (A.2). By removing the resonant terms, the nonlinear coupled-mode equations for $A_j(\mathbf{X},T)$, $j=1,\ldots,N$, are derived in the general form:

$$i\left(\frac{\partial A_j}{\partial T} + \left(\frac{\mathbf{k}_j}{k}\cdot\nabla_X\right)A_j\right) + \sum_{k\neq j}\hat{\alpha}_{j,k}A_k + \sum_{1\leq k_1,k_2,k_3\leq N}\hat{\beta}_{j,k_1,k_2,k_3}A_{k_1}A_{k_2}\bar{A}_{k_3} = 0, \tag{A.4}$$

where the elements $\{\hat{\beta}_{j,k_1,k_2,k_3}\}_{1\leq j,k_1,k_2,k_3\leq N}$ are related to the Fourier coefficients of the resonant waves $\{\beta_{n,m,l}\}_{(n,m,l)\in\mathcal{S}}$. The explicit forms of the nonlinear coupled-mode equations are given below for two and four counter-propagating and two oblique resonant Bloch waves.

The nonlinear coupled-mode equations for two counter-propagating waves (3.10) generalize the linear equations (3.12)–(3.13) as follows:

$$\begin{aligned} &i\left(\frac{\partial A_+}{\partial T} + \frac{\partial A_+}{\partial Z}\right) + \alpha A_- + \beta_{0,0,0}(|A_+|^2 + 2|A_-|^2)A_+ \\ &\quad + \beta_{0,0,1}(2|A_+|^2 + |A_-|^2)A_- + \beta_{0,0,-1}A_+^2\bar{A}_- + \beta_{0,0,2}\bar{A}_+A_-^2 = 0, \end{aligned} \tag{A.5}$$

$$\begin{aligned} &i\left(\frac{\partial A_-}{\partial T} - \frac{\partial A_-}{\partial Z}\right) + \alpha A_+ + \beta_{0,0,0}(2|A_+|^2 + |A_-|^2)A_- \\ &\quad + \beta_{0,0,-1}(|A_+|^2 + 2|A_-|^2)A_+ + \beta_{0,0,1}\bar{A}_+A_-^2 + \beta_{0,0,-2}A_+^2\bar{A}_- = 0. \end{aligned} \tag{A.6}$$

The system (A.5)–(A.6) is reviewed in [8, 23] for $\beta_{0,0,1} = \beta_{0,0,2} = 0$ and analyzed in [14, 15] for $\beta_{0,0,1} \neq 0$ and $\beta_{0,0,2} = 0$. When $\beta_{0,0,1}, \beta_{0,0,2} \neq 0$, the system (3.12)–(3.13) is the most general coupled-mode system for Bragg resonance of two counter-propagating waves [6, 22].

The nonlinear coupled-mode equations for four counter-propagating waves (3.14) generalize the linear equations (3.16)–(3.19) as follows:

$$i\left(\frac{\partial A_+}{\partial T} + \frac{\partial A_+}{\partial X} + \frac{\partial A_+}{\partial Y}\right) + \alpha A_- + \beta\left(B_+ + B_-\right) + F_+(A_+, A_-, B_+, B_-) = 0, \tag{A.7}$$

$$i\left(\frac{\partial A_-}{\partial T}-\frac{\partial A_-}{\partial X}-\frac{\partial A_-}{\partial Y}\right)+\alpha A_+ +\beta\,(B_+ + B_-)+F_-(A_+,A_-,B_+,B_-)=0, \tag{A.8}$$

$$i\left(\frac{\partial B_+}{\partial T}+\frac{\partial B_+}{\partial X}-\frac{\partial B_+}{\partial Y}\right)+\beta\,(A_+ + A_-)+\alpha B_- +G_+(A_+,A_-,B_+,B_-)=0, \tag{A.9}$$

$$i\left(\frac{\partial B_-}{\partial T}-\frac{\partial B_-}{\partial X}+\frac{\partial B_-}{\partial Y}\right)+\beta\,(A_+ + A_-)+\alpha B_+ +G_-(A_+,A_-,B_+,B_-)=0, \tag{A.10}$$

where the cubic nonlinear functions are given by

$$\begin{aligned}
F_+ =\ & \beta_{0,0,0}((|A_+|^2+2|A_-|^2+2|B_+|^2+2|B_-|^2)A_+ + 2\bar{A}_-B_+B_-)\\
&+\beta_{0,-1,0}(A_+^2\bar{B}_+ + 2A_+\bar{A}_-B_-)+\beta_{-1,0,0}(A_+^2\bar{B}_- + 2A_+\bar{A}_-B_+)\\
&+\beta_{1,1,0}((2|A_+|^2+|A_-|^2+2|B_+|^2+2|B_-|^2)A_- + 2\bar{A}_+B_+B_-)\\
&+\beta_{0,1,0}((2|A_+|^2+2|A_-|^2+|B_+|^2+2|B_-|^2)B_+ + 2A_+A_-\bar{B}_-)\\
&+\beta_{-1,1,0}(2A_+B_+\bar{B}_- + \bar{A}_-B_+^2)+\beta_{1,-1,0}(2A_+\bar{B}_+B_- + \bar{A}_-B_-^2)\\
&+\beta_{1,0,0}((2|A_+|^2+2|A_-|^2+2|B_+|^2+|B_-|^2)B_- + 2A_+A_-\bar{B}_+)\\
&+\beta_{2,0,0}(\bar{A}_+B_-^2 + 2A_-\bar{B}_+B_-)+\beta_{2,1,0}(2\bar{A}_+A_-B_- + A_-^2\bar{B}_+)\\
&+\beta_{1,2,0}(A_-^2\bar{B}_- + 2\bar{A}_+A_-B_+)+\beta_{2,-1,0}\bar{B}_+B_-^2+\beta_{-1,2,0}B_+^2\bar{B}_-\\
&+\beta_{0,2,0}(\bar{A}_+B_+^2 + 2A_-B_+\bar{B}_-)+\beta_{-1,-1,0}A_+^2\bar{A}_- + \beta_{2,2,0}\bar{A}_+A_-^2,\\
F_- =\ & \beta_{-1,-1,0}((|A_+|^2+2|A_-|^2+2|B_+|^2+2|B_-|^2)A_+ + 2\bar{A}_-B_+B_-)\\
&+\beta_{-1,-2,0}(A_+^2\bar{B}_+ + 2A_+\bar{A}_-B_-)+\beta_{-2,-1,0}(A_+^2\bar{B}_- + 2A_+\bar{A}_-B_+)\\
&+\beta_{0,0,0}((2|A_+|^2+|A_-|^2+2|B_+|^2+2|B_-|^2)A_- + 2\bar{A}_+B_+B_-)\\
&+\beta_{-1,0,0}((2|A_+|^2+2|A_-|^2+|B_+|^2+2|B_-|^2)B_+ + 2A_+A_-\bar{B}_-)\\

$$+\beta_{-1,2,0}(\bar{A}_+B_+^2+2A_-B_+\bar{B}_-)+\beta_{-2,-1,0}A_+^2\bar{A}_-+\beta_{1,2,0}\bar{A}_+A_-^2.$$

The nonlinear coupled-mode equations for two oblique waves (2.16) generalize the linear equations (3.20)–(3.21) as follows:

$$i\left(\frac{\partial A_1}{\partial T}+\frac{p}{\sqrt{p^2+q^2}}\frac{\partial A_1}{\partial X}+\frac{q}{\sqrt{p^2+q^2}}\frac{\partial A_1}{\partial Y}\right)+\alpha A_2+\beta_{0,0,0}(|A_1|^2+2|A_2|^2)A_1$$
$$+\beta_{-n,-m,0}(2|A_1|^2+|A_2|^2)A_2+\beta_{n,m,0}A_1^2\bar{A}_2+\beta_{-2n,-2m,0}\bar{A}_1A_2^2=0, \tag{A.11}$$

$$i\left(\frac{\partial A_2}{\partial T}+\frac{p+2n}{\sqrt{p^2+q^2}}\frac{\partial A_2}{\partial X}+\frac{q+2m}{\sqrt{p^2+q^2}}\frac{\partial A_2}{\partial Y}\right)+\alpha A_1+\beta_{0,0,0}(2|A_1|^2+|A_2|^2)A_1$$
$$+\beta_{n,m,0}(|A_1|^2+2|A_2|^2)A_1+\beta_{-n,-m,0}\bar{A}_1A_2^2+\beta_{2n,2m,0}A_1^2\bar{A}_2=0. \tag{A.12}$$

The system (A.11)–(A.12) and its generalization to three oblique resonant waves are reviewed in [18, 19].

A UNIVERSAL PROCEDURE FOR NORMALIZING n-DEGREE-OF-FREEDOM POLYNOMIAL HAMILTONIAN SYSTEMS*

SUSANA GUTIÉRREZ-ROMERO†, JESÚS F. PALACIÁN†, AND PATRICIA YANGUAS†

Abstract. We depart from an n-degree-of-freedom Hamiltonian formed by the sum of homogeneous polynomials in n coordinates and n momenta with arbitrary coefficients. By extending formally an integral of the principal part of the system to the full Hamiltonian and truncating higher-order terms, we obtain a simplified Hamiltonian. This "normalization" procedure can be used to extract qualitative features of the departure system. In this paper we present the symbolic routines needed to achieve the normalization. The power and generality of the algorithm are exhibited through two examples.

Key words. polynomial Hamiltonians, generalized normal forms, formal integrals, reduction and simplification, monodromy, invariants

1. Introduction.

This work is devoted to the algorithmic implementation of the theory developed in [25, 26, 27] dealing with "normalization" of polynomial Hamiltonian systems in n degrees of freedom (n DOFs). We are interested in the actual construction of "normal form" Hamiltonians, as well as their associated changes of coordinates and formal integrals. The motivation for this series of works is the wide rank of applications of normal form theory in the last 30 years in various fields, such as classical mechanics, astrodynamics, qualitative theory of ordinary differential equations, or molecular physics.

We consider Hamilton functions of the form

$$\mathcal{H}(\boldsymbol{x};\varepsilon) = \sum_{i\geq 0} \frac{\varepsilon^i}{i!}\,\mathcal{H}_i(\boldsymbol{x}), \tag{1.1}$$

where $\boldsymbol{x} = (x_1,\ldots,x_n,X_1,\ldots,X_n)$ is a $(2n)$-dimensional vector in the coordinates $x_1,\ldots,x_n$ and corresponding momenta $X_1,\ldots,X_n$. Moreover, each $\mathcal{H}_i$ is an arbitrary homogeneous polynomial in $\boldsymbol{x}$ of degree $i+p+2$ for some fixed integer $p \geq -1$. Note that with this choice of p we can deal with polynomial Hamiltonians starting at degree one and therefore we do not restrict ourselves to local analysis around equilibria points. Indeed if our starting Hamiltonian function is a polynomial our approach is of global nature; however, if we are interested in the neighborhood of a critical point, then p should be 0. Thus, we consider the most generic class of Hamiltonians in the polynomial context.

Our purpose is to simplify system (1.1) by introducing a constant of motion independent of $\mathcal{H}$, up to a certain degree. The tool for carrying out our normalizing procedures are the well-known Lie transformations for canonical systems [6]. From the practical point of view the normalization up to any order becomes a cumbersome task due to two drawbacks principally. (1) The form of the principal term $\mathcal{H}_0$ dictates the form acquired by the homological equation, which is the one needed to be solved at each order to calculate the "normal form." Thus, for certain types of $\mathcal{H}_0$ the procedure should be stopped at a certain order and should not be extended up to any order. (2) The computational trouble caused by the huge amount of terms in those cases where the calculations are carried out to very high degrees or when the number of DOFs is big, let us say, greater than four.

From our side we have adopted the compromise of building an algorithm being as generic as possible, sacrificing on some occasions the possibility of writing an optimal set of routines for some types of $\mathcal{H}_0$. The reason for this choice lies on the fact that we intend to present a universal procedure. Thus, we have designed our algorithm by following three criteria: (i) $\mathcal{H}_0$ can be any homogenous polynomial of degree $p+2$ in $\boldsymbol{x}$ with real or complex coefficients, $p \geq -1$ being an integer. Indeed, it is not necessary to bring $\mathcal{H}_0$ to a prescribed form to resolve the corresponding homological equations. (ii) The classical techniques of normal forms for Hamiltonians [20] (see also the general case in [18, 3, 19, 22]) are enlarged, as we make use of the concept of generalized normal forms [25, 26]. This allows us either to execute the usual approach of normalization or to extend other integrals of $\mathcal{H}_0$ up to a certain order. (iii) Our algorithm is based on the routines we have prepared with MATHEMATICA, but it can be programmed in other similar algebraic manipulators, such as MAPLE or MACSYMA.

Poincaré [30] is considered a pioneer in the simplification of systems of differential equations, as he developed a method applicable to systems of not necessarily Hamiltonian nature. Birkhoff [1] considered the Hamiltonian version thereafter. The normalization of semisimple systems in equilibrium at the origin was carried out for the planar case by Whittaker [34]. Moser [24] extended the work of Birkhoff to resonant Hamiltonians in $2n$ dimensions. Thereafter there appeared a generalization by Meyer [20], who presented the general solution for a Hamiltonian system whose corresponding matrix related to the linear part was semisimple. Normal forms for nonsemisimple matrices have been studied by Meyer and Schmidt [23], Sokol'skij [32], and van der Meer [18], for instance. Furthermore, Meyer [21] established the normal form theorem for any type of equilibrium point in systems of ordinary differential equations whose main part is linear. The Hamiltonian case appears in Meyer and Hall [22].

In the classical theory of normal forms the dominant term $\mathcal{H}_0$ is a homogeneous polynomial of degree two (so $p=0$). Associated with it is a linear differential system of equations. When the matrix defining the linear system has a nonnull semisimple part, the normal form theorem for the general equilibrium [22] is the best choice for reducing the number of degrees of freedom of the original system, provided that the reduced system would not have a trivial flow. However, if the matrix is nilpotent or if the reduced flow is trivial, we should resort to the extended normal form approach proposed in [25, 26].

This article is divided into five sections. Section 2 revises the basic theory on the subject of transformations bringing a system to a generalized normal form. In section 3 we offer a detailed description of the routines included in our algorithms. In section 4 we give two examples where the advantages of the exposed algorithm with respect to other current theories are shown. The first example consists in a 1-DOF

Hamiltonian vector field whose dominant part is a homogenous polynomial of degree 3. We show that under certain conditions on the coefficients of the Hamiltonian it is possible to introduce a polynomial formal integral. This allows the reduction of the system to another of 0 DOF. The motivation for the second example is the occurrence of Hamiltonian–Hopf bifurcations and monodromy in a swing spring. Finally, in section 5 we outline the conclusions of the paper.

2. Generalized normal forms and formal integrals. In this section we broach the normalization of Hamiltonian systems through the construction of formal integrals. First, we recall the normal form theorem [21, 22]. (See also the previous contributions by van der Meer [18, 19], Cushman, Deprit, and Mosak [3], and Churchill, Kummer, and Rod [2].) Thereafter we continue with the concept of generalized normal forms.

2.1. Normal form theorem. Let us recall this standard result, which combines results by van der Meer and Meyer.

THEOREM 2.1. *Let*

$$\mathcal{H}(\boldsymbol{x};\varepsilon) = \sum_{i\geq 0} \frac{\varepsilon^i}{i!}\,\mathcal{H}_i(\boldsymbol{x}) \tag{2.1}$$

be a Hamilton function such that each $\mathcal{H}_i(\boldsymbol{x})$ is a homogeneous polynomial of degree $i+2$ in $\boldsymbol{x}\in\boldsymbol{R}^{2n}$. It defines a differential system of n DOFs whose quadratic part is $\mathcal{H}_0(\boldsymbol{x}) = \frac{1}{2}\,\boldsymbol{x}^t\,B\,\boldsymbol{x}$, where B is a symmetric $(2n\times 2n)$-matrix. Let $\mathcal{J}$ be the standard skew-symmetric matrix of order $2n$

$$\mathcal{J} = \begin{pmatrix} 0 & I_n \\ -I_n & 0 \end{pmatrix}$$

(I_n stands for the identity matrix of order n), and let $A = \mathcal{J}\,B$ be the matrix associated with the linear system of differential equations defined by $\mathcal{H}_0$. Let $\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{y};\varepsilon) = \boldsymbol{y} + \cdots$ be the symplectic change of coordinates that transforms $\mathcal{H}$ into its normal form (up to an order $L\geq 1$), the convergent Hamiltonian $\mathcal{K}(\boldsymbol{y}) = \mathcal{K}_0(\boldsymbol{y}) + \mathcal{K}_1(\boldsymbol{y}) + \cdots + \mathcal{K}_L(\boldsymbol{y}) + \mathcal{O}(\varepsilon^{L+1})$. Let $A = S + N$ represent the Jordan decomposition of A into its semisimple (S) plus nilpotent (N) parts. Then, the quadratic polynomial $\mathcal{I}_S(\boldsymbol{y}) = \mathcal{I}_S(\boldsymbol{x}) = -\frac{1}{2}\,\boldsymbol{x}^t\,\mathcal{J}\,S\,\boldsymbol{x}$ is an integral of $\mathcal{H}_0$, provided that $S\neq 0$. Moreover, by means of the normal form transformation, $\mathcal{I}_S(\boldsymbol{y})$ becomes an integral (formal integral) of $\mathcal{K}$ independent of it and the number of DOFs of the system related to $\mathcal{K}$, after truncation, is at most $n-1$.

Proof. See the papers by van der Meer [19] and Meyer [21] and the book by Meyer and Hall [22]. □

First, if we define $\mathcal{K}_0^t = \frac{1}{2}\boldsymbol{y}^t R\boldsymbol{y}$ with $R = \mathcal{J}B\mathcal{J} = -\mathcal{J}A^t$, when applying the normal form theorem, Theorem 2.1, the terms $\mathcal{K}_i$ for $i\geq 1$ are built so that they satisfy $\{\mathcal{K}_i, \mathcal{K}_0^t\} = 0$. That is, the terms of the normal form are invariant under the flow defined by $\exp(A^t s)$. In this respect one can understand that the normal form Hamiltonian is simpler than the original Hamiltonian.

As is well known, normal forms are in general divergent; see, for instance, [29]. Indeed the transformation proposed in Theorem 2.1 does not converge in general. However, we can say that $\mathcal{K}$ is convergent as we are including the tail $\mathcal{O}(\varepsilon^{L+1})$ in its definition.

When $S\neq 0$ one can build a formal integral of $\mathcal{H}$ up to a certain order of approximation, as we shall detail later on. Therefore, the initial system is reduced by

the calculation of a formal integral. Nevertheless, when $S = 0$ we cannot construct a new formal integral by the application of the normal form theorem. In such a situation we resort to another strategy to reduce the number of DOFs of $\mathcal{H}$.

The number of DOFs defined by $\mathcal{K}$ is $n - 1$ at most. It is smaller when the semisimple component of $\mathcal{H}_0$ is composed by the sum of semisimple terms such that there is no resonance among all of them. In these situations the reduction procedure could be too drastic in the sense that one would not obtain enough information from the reduced system [28]. A way to overcome this problem would be to take another integral of $\mathcal{H}_0$ to be extended to the whole system. This is the subject of the following subsections.

2.2. Extension of an integral of the principal part to the full system. We provide a result which can be used to enlarge the applicability of the normal form theorem. We start with some useful definitions.

DEFINITION 2.2. *Given two scalar fields $\mathcal{P}$ and $\mathcal{Q}$ defined over an open domain of $\boldsymbol{R}^{2n}$, the Poisson bracket of $\mathcal{P}$ and $\mathcal{Q}$ is given by the relation*

$$\{\mathcal{P}, \mathcal{Q}\} = \sum_{i=1}^{n} \left(\frac{\partial \mathcal{P}}{\partial x_i} \frac{\partial \mathcal{Q}}{\partial X_i} - \frac{\partial \mathcal{P}}{\partial X_i} \frac{\partial \mathcal{Q}}{\partial x_i} \right).$$

DEFINITION 2.3. *Given two scalar fields $\mathcal{P}$ and $\mathcal{Q}$, the Lie operator associated with $\mathcal{Q}$ is given by means of the Poisson bracket $\mathcal{L}_{\mathcal{Q}}(\mathcal{P}) = \{\mathcal{P}, \mathcal{Q}\}$.*

THEOREM 2.4. *Let the integers $L \geq 1$ and $p \geq -1$ be given. Let Hamiltonian* (1.1) *be given. Let $\{\mathcal{P}_i\}_{i=0}^{L}$ be the sequence of the linear spaces of all homogeneous polynomials of degree $i + p + 2$ in $\boldsymbol{x} \in \boldsymbol{R}^{2n}$. Let $\{\mathcal{Q}_i\}_{i=1}^{L}$ be the sequence of some subsets of the sets $\mathcal{P}_i$ and let $\{\mathcal{R}_i\}_{i=1}^{L}$ be the sequence of some linear spaces of $\mathcal{C}^k$-functions ($k \geq 0$) for $i = 1, \ldots, L$. Let $\mathcal{G}$ be a polynomial in $\mathcal{P}_j$ for some $j \in \{0, \ldots, L\}$. Let $\Omega \subseteq \boldsymbol{R}^{2n}$ be the common domain where the sequences $\{\mathcal{P}_i\}_{i=0}^{L}$, $\{\mathcal{Q}_i\}_{i=1}^{L}$, and $\{\mathcal{R}_i\}_{i=1}^{L}$ are defined. Moreover, suppose that the following properties are satisfied:*

(i) $\mathcal{H}_i \in \mathcal{P}_i$, $i = 0, 1, \ldots, L$;
(ii) $\{\mathcal{P}_i, \mathcal{R}_j\} \subseteq \mathcal{P}_{i+j}$, $i + j = 1, \ldots, L$;
(iii) *for any $D \in \mathcal{P}_i$, $i = 1, \ldots, L$, there exist $E \in \mathcal{Q}_i$ and $F \in \mathcal{R}_i$ such that*

$$E = D + \{\mathcal{H}_0, F\} \quad \text{and} \quad \{\mathcal{G}, E\} = 0.$$

Then, there exists a $\mathcal{C}^k$-function

$$\mathcal{W}(\boldsymbol{x}; \varepsilon) = \sum_{i=0}^{L-1} \frac{\varepsilon^i}{i!} \mathcal{W}_{i+1}(\boldsymbol{x})$$

with $\mathcal{W}_i \in \mathcal{R}_i$, $i = 1, \ldots, L$, such that the change of coordinates $\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{y}; \varepsilon)$ is the general solution of the initial value problem

$$\begin{aligned} \frac{d\,\boldsymbol{x}}{d\,\varepsilon} &= \mathcal{J} \frac{\partial \mathcal{W}}{\partial \boldsymbol{x}}(\boldsymbol{x}; \varepsilon), \\ \boldsymbol{x}(0) &= \boldsymbol{y}, \end{aligned}$$

and transforms the convergent Hamiltonian (1.1) *into the convergent Hamiltonian*

$$\mathcal{K}(\boldsymbol{y}; \varepsilon) = \sum_{i=0}^{L} \frac{\varepsilon^i}{i!} \mathcal{K}_i(\boldsymbol{y}) + \mathcal{O}(\varepsilon^{L+1})$$

with $\mathcal{K}_i \in \mathcal{Q}_i$, $i = 1, \ldots, L$, *such that each* $\mathcal{K}_i$ *is a polynomial in* $\boldsymbol{y}$ *of degree* $i + p + 2$ *with* $\{\mathcal{K}_i, \mathcal{G}\} = 0$ *for* $i = 1, \ldots, L$.

Additionally, if $\{\mathcal{H}_0, \mathcal{G}\} = 0$, *then* $\mathcal{G}$ *is an integral of* $\mathcal{K}$.

Proof. See [26]. □

The smoothness of the spaces $\mathcal{R}_i$ and of $\mathcal{W}$ depends on the possible appearance of nonpolynomial terms at some order i. For instance, in the example of section 4.1, $\mathcal{W}$ is $\mathcal{C}^2$, while in section 4.2 it is analytic.

As in the standard approach, the application of Theorem 2.4 does not produce generally a convergent normal form Hamiltonian. Nevertheless, the reader should notice that in the definition of $\mathcal{K}$ we are putting higher-order terms inside the error $\mathcal{O}(\varepsilon^{L+1})$.

The reader should notice that whenever $\mathcal{G}$ is an integral of $\mathcal{H}_0$, the effect of constructing $\mathcal{K}$, where $\mathcal{K}_i \in \ker(\mathcal{L}_\mathcal{G})$ (i.e., the Poisson bracket $\{\mathcal{K}_i, \mathcal{G}\}$ vanishes) for $i = 1, \ldots, L$, is to extend formally the integral of the unperturbed system, $\mathcal{G}$, to the whole Hamiltonian $\mathcal{K}$ after truncating it at order L.

We stress that the integral $\mathcal{G}$ of $\mathcal{H}_0$ must be chosen a priori and it can be other than the part of $\mathcal{H}_0$ whose associated matrix is semisimple. This is the main difference with respect to the usual treatment of normal forms, although Theorem 2.4 can be interpreted as a generalization of the standard approach. In fact, under further hypotheses, if $\mathcal{G}$ corresponds to the semisimple part of $\mathcal{H}_0$, both normal form transformations yield the same results; see the details in [26, 28]. Our way of computing formal integrals extends the classical approaches of Whittaker [33, 34], Gustavson [13], and Giorgilli [12] as we can obtain approximate integrals of polynomial Hamiltonians in n DOFs, with $\mathcal{H}_0$ being any homogeneous (not necessarily quadratic) polynomial.

Theorem 2.4 can be applied to calculate formal integrals of polynomial Hamiltonians whose dominant parts are related to nilpotent matrices A. Furthermore, this approach can be used to calculate different normalized Hamiltonians whose flows lie on different reduced phase spaces. Thus, performing several reductions allows us to analyze the original Hamiltonian from different points of view. The theorem also can be applied to lower the number of DOFs by two or more units. Indeed, the number of DOFs of the resulting Hamiltonian system depends on the type of integral introduced through the reduction. Nevertheless, this needs a careful analysis based on Lie groups and invariant theory; see [28] for details.

The drawback of this generalized method is that at each step $i \geq 1$, $\mathcal{W}_i$ is not necessarily a polynomial function, as is always the case with the application of the normal form theorem. Indeed, the occurrence of polynomial generating functions in a specific normal form computation can be known in advance by analyzing the dimensions of the kernels of various linear spaces of homogeneous polynomials. Thus, depending on the choice of $\mathcal{G}$, as well as on $\mathcal{H}_0$ and the type of terms in the perturbation, $\mathcal{W}$ could be a polynomial of degree $i + 2$. (In this optimal case the linear spaces $\mathcal{R}_i$ correspond to the spaces of homogeneous polynomials of degree $i + 2$ in $\boldsymbol{x} \in \boldsymbol{R}^{2n}$.) For more information, see [26, 28]. Nevertheless, in the design of the algorithm we do not perform this algebraic analysis prior to the computation of the normal form. Instead, we prefer to try first to solve the homological equation with a homogeneous polynomial. When it is not possible we resort to finding the solution of the usual partial differential equation (PDE). This will be a fundamental step in the design of the algorithms presented in the next section.

2.3. Types of normalization according to $\mathcal{H}_0$. The cases where $\mathcal{H}_0$ is not a quadratic polynomial cannot be treated by the normal form theorem and we have to

resort to Theorem 2.4 for its reduction. The choice of the integral $\mathcal{G}$ to be extended depends on each problem and can be, for instance, $\mathcal{H}_0$, as we will see in section 4.1.

If $\mathcal{H}_0$ is a quadratic homogeneous polynomial we perform the following classification according to the type of the associated matrix A:

(a) semisimple case: $A = S$;
(b) semisimple plus nilpotent case: $A = S + N$, with $S, N \neq 0$;
(c) nilpotent case: $A = N$.

In cases (a) and (b), as the semisimple part is not zero, both Theorem 2.1 and Theorem 2.4 apply. Let us see when one should apply the first and when the second.

On the one hand, by applying the normal form theorem, $\mathcal{I}_S$ (the semisimple part of $\mathcal{H}_0$) becomes a formal integral of the reduced system. This would be equivalent to choosing $\mathcal{G} = \mathcal{I}_S$ and applying Theorem 2.4. Nevertheless, the reduced Hamiltonians in both cases may not be the same [26]. In this situation the application of the normal form theorem would be preferable because the generating function is polynomial and may not be polynomial with Theorem 2.4.

On the other hand, when the application of the normal form theorem leads to $\mathcal{K}$ defining a system of 0 DOFs ($n > 1$), the reduction does not allow one to extract information from the flow of the reduced system. Then, the application of the generalized normal form theorem by choosing $\mathcal{G}$ an integral of $\mathcal{H}_0$ different from $\mathcal{I}_S$ is recommended.

Moreover, in both situations, when one intends to obtain information about the original system from different reduced Hamiltonians, one should resort to Theorem 2.4, as the normal form theorem allows only one reduction.

In case (c), as the semisimple part is zero the application of the normal form theorem does not lead to a reduction in the number of DOFs. Thus, for this purpose we use the generalized method by taking $\mathcal{G} = \mathcal{H}_0$, for instance. Obviously, other integrals could be chosen depending on the system. Besides, if $\mathcal{H}_0 = 0$, we could even select $\mathcal{G}$ among the integrals of $\mathcal{H}_k$, provided that $\mathcal{H}_i = 0$ for $i = 0, \ldots, k-1$, with $k \geq 1$.

Once we have made the choice of $\mathcal{G}$ the next step consists in performing the normal form transformation, i.e., in calculating $\mathcal{K}$ and $\mathcal{W}$ up to order L of the process. This is done through Lie transformations and will be treated algorithmically in section 3.

Next we calculate the direct and inverse changes of coordinates related to the generalized normal form transformation. This is useful when going back to the original Hamiltonian. For example, one can think of a qualitative study of a certain Hamilton vector field based on the calculation of normal forms. In this situation it is usually convenient to get the expressions in the original coordinates of the invariant objects of the original system obtained from the ones in the normal form Hamiltonians.

Finally, it is possible to determine a formal integral of the Hamiltonian $\mathcal{H}$ using $\mathcal{G}$, that is, the function extended to become an integral of $\mathcal{K}$, and the generating function related to the normal form construction. Specifically, if $\mathcal{G}$ commutes with $\mathcal{K}$, the result of applying the inverse change of coordinates to $\mathcal{G}$, which we denote by $\mathcal{I}_{\mathcal{G}}(\boldsymbol{x}; \varepsilon)$, is a formal symmetry of $\mathcal{H}$, i.e., $\{\mathcal{H}, \mathcal{I}_{\mathcal{G}}\} = \mathcal{O}(\varepsilon^{L+1})$. Note that if $\mathcal{W}$ is of polynomial nature, $\mathcal{I}_{\mathcal{G}}$ is also a polynomial. However, when $\mathcal{W}$ contains nonpolynomial terms, $\mathcal{I}_{\mathcal{G}}$ will be in general nonpolynomial.

The direct and inverse changes of coordinates will be explained in section 3.4 from the point of view of the computations which are needed.

For a complete description of the methodology and some examples, see [25, 26, 27] and references therein.

3. The algorithms. This section shows the main features of the routines we have developed so as to apply the reduction process to an arbitrary n-DOF polynomial Hamiltonian of the type (1.1) up to a certain order of approximation. We used MATHEMATICA to write the routines, but other symbolic processors, such as MAPLE or MACSYMA, would be also adequate. We present the entire collection of routines to give a full description of the normal form procedure for polynomial Hamiltonians, emphasizing the main features of the implementation. In addition, our exposition provides the computational cost of all steps and, to our knowledge, it is the first time all these issues appear together in one paper.

3.1. Choice of the integral $\mathcal{G}$. According to $\mathcal{H}_0$ and our purposes we start by choosing the type of normal form we are going to calculate. If $\mathcal{H}_0$ is quadratic we implement an auxiliary procedure to split this Hamilton function into its semisimple and nilpotent parts. The so-called Jordan decomposition of the associated Hamiltonian matrix A is the algebraic tool which provides us with this result.

ALGORITHM 1 (choice of the integral to be extended).

INPUT:

↪ $\mathcal{H}_0$ *and* p*: the main (or unperturbed) part of* $\mathcal{H}$ *and the degree of* $\mathcal{H}_0$ *minus two, respectively;*

↪ n*: number of DOFs of the system;*

↪ `option` $\in \{\{\texttt{no}\}, \{\texttt{yes}, \mathcal{G}\}\}$*: chance of either allowing the program to choose the integral to be extended or the user to choose a formal integral* $\mathcal{G}$ *of* $\mathcal{H}_0$*, resp. In case* $\mathcal{H}_0$ *is not quadratic the user should choose* $\mathcal{G}$*;*

↪ `ForceNFT`*: Boolean variable which indicates whether the user wants to apply the normal form theorem.*

OUTPUT:

↩ $\mathcal{I}_S, \mathcal{I}_N$*: decomposition of* $\mathcal{H}_0$ *into its semisimple and nilpotent parts, resp. (when* $\mathcal{H}_0$ *is quadratic, otherwise both are taken to be zero);*

↩ $\mathcal{G}$*: integral of* $\mathcal{H}_0$ *to be extended to higher orders;*

↩ `NFT`*: it takes the value* `True` *if the normal form theorem is going to be used or* `False` *otherwise.*

CODE:

`NFT` = `False`;
If ($p = 0$) *then*
  Compute the Jordan decomposition of the Hamiltonian matrix A *associated with* $\mathcal{H}_0$*, that is,* $A = S + N$*;*
  Construct $\mathcal{I}_S, \mathcal{I}_N$ *from the preceding step;*
  If (`ForceNFT` = `True`) *then*
    If ($\mathcal{I}_S = 0$) *show the message "After the normalization,* $\mathcal{K}$ *will define a system with the same number of DOFs as* $\mathcal{H}$*";*
    Calculate $\mathcal{G}$ *as in the normal form theorem (*$\mathcal{G} = \mathcal{K}_0^t$*);*
    `NFT` = `True`;
  Else
    If (`option` = `no`) *then*
      Compute $\mathcal{G}$ *following the guidelines of section* 2.3.
    Else
      Check if $\mathcal{G}$ *is an integral of* $\mathcal{H}_0$*. When* $\mathcal{G}$ *does not commute with* $\mathcal{H}_0$ *(i.e.,* $\{\mathcal{G}, \mathcal{H}_0\} \neq 0$*), a warning message is displayed saying that no integral will be introduced through the transformation;*
Else

Set $\mathcal{I}_S = \mathcal{I}_N = 0$*;*
Define $\mathcal{G}$ *as the second component of* $\{\texttt{yes}, \mathcal{G}\}$.

Remark 3.1. The algorithm allows the user to normalize Hamiltonians satisfying $\mathcal{H}_i = 0$, for $i = 1, \ldots, k-1$ and $\mathcal{H}_k \neq 0$; the input variable `option` brings such possibility by means of giving it the value $\{\texttt{yes}, \mathcal{G}\}$ and introducing any homogeneous polynomial which commutes with $\mathcal{H}_k$ as the second component, $\mathcal{G}$.

3.2. Resolution of the homological equation. The construction of the transformed Hamiltonian $\mathcal{K}$ is done order by order, i.e., one has to proceed in an ascendant way from $i = 1$ to $i = L$ so as to determine each $\mathcal{K}_i$. For that, the homological equation

$$\mathcal{L}_{\mathcal{H}_0}(\mathcal{W}_i) + \mathcal{K}_i = \bar{\mathcal{H}}_i \tag{3.1}$$

has to be solved, with the extra condition $\{\mathcal{K}_i, \mathcal{G}\} = 0$ for $i = 1, \ldots, L$. Note that the terms $\bar{\mathcal{H}}_i$ are the ones known from the previous orders through the Poisson bracket calculations. The solution of (3.1) is the pair $(\mathcal{W}_i, \mathcal{K}_i)$, where $\mathcal{W}_i$ denotes the generating function at order i.

To actually solve (3.1) we split $\bar{\mathcal{H}}_i$ as $\bar{\mathcal{H}}_i = \bar{\mathcal{H}}_i^* + \bar{\mathcal{H}}_i^{\#}$, where $\bar{\mathcal{H}}_i^* \in \ker(\mathcal{L}_{\mathcal{G}})$ and $\bar{\mathcal{H}}_i^{\#} = \bar{\mathcal{H}}_i - \bar{\mathcal{H}}_i^*$, for each $i = 1, \ldots, L$. In this way, we choose $\mathcal{K}_i = \bar{\mathcal{H}}_i^*$ and $\mathcal{W}_i$ as a solution of

$$\mathcal{L}_{\mathcal{H}_0}(\mathcal{W}_i) = \bar{\mathcal{H}}_i^{\#}. \tag{3.2}$$

When Theorem 2.4 is applied, for the general case nonpolynomial terms appear in $\bar{\mathcal{H}}_i$ at a certain order i. To solve (3.1) these terms are always considered to belong to $\bar{\mathcal{H}}_i^{\#}$. Thus, in the program we introduce a simple algorithm to separate the polynomial terms of $\bar{\mathcal{H}}_i$ from the nonpolynomial ones.

ALGORITHM 2 (splitting in polynomial and nonpolynomial terms).
INPUT:
↪ `Expr`*: a function in the coordinates and respective momenta;*
↪ *n: number of DOFs of the system.*
OUTPUT:
↩ `Pol` *and* `NoPol`*:* `Pol` *collects the polynomial terms of* `Expr` *while* `NoPol` *collects the nonpolynomial ones.*

Remark 3.2. (i) The only nonpolynomial terms are rational, logarithmic, arctangent functions and combinations of them. They appear in the generating function at a certain order as the solution of (3.2) and are propagated through the intermediate Hamiltonians needed to proceed to higher orders (see also section 3.3).

(ii) Every symbolic processor has its own functions to distinguish between polynomial and nonpolynomial terms. For example, MATHEMATICA makes use of the Boolean built-in function `PolynomialQ` which recognizes whether a single term is polynomial in a given set of variables. Thus, the issue of splitting the polynomial terms from the others becomes a simple matter.

Now, we describe the main algorithm of this section—the one for the resolution of (3.1). We suppose that Algorithm 1 has been already applied.

ALGORITHM 3 (resolution of the homological equation).
INPUT:
↪ *i: step in the normalizing procedure;*
↪ $\bar{\mathcal{H}}_i$*: terms computed in order* $i-1$ *through the Lie transformation;*
↪ $\mathcal{G}$, `NFT`, *and s: the latter denoting the degree of* $\mathcal{G}$*;*

OUTPUT:
↩ *The pair* $(\mathcal{K}_i, \mathcal{W}_i)$*: solution of* (3.1)*;*
↩ `resolved`*: it takes the value* `True` *if* (3.1) *has been solved successfully.*
CODE:
Split $\bar{\mathcal{H}}_i$ *into its polynomial* (`Pol`) *and nonpolynomial* (`NoPol`) *components by making use of Algorithm 2;*
Redefine $\bar{\mathcal{H}}_i = \mathtt{Pol}$*;*
Define $\mathtt{arb}_1$*, an arbitrary polynomial of degree* $i+p+2$ *in* $\boldsymbol{x}$*, and solve the equation* $\mathcal{L}_{\mathcal{G}}(\mathtt{arb}_1) = 0$ *in the coefficients of* $\mathtt{arb}_1$*; store the resulting conditions for the coefficients of* $\mathtt{arb}_1$ *in a new variable called* $\mathtt{sol}_\mathtt{p}$*;*
Define $\mathtt{arb}_2$*, a homogeneous polynomial of degree* $i+2$ *in* $\boldsymbol{x}$*;*
If ($\mathtt{NoPol} = 0$) *then*
    Try to solve $\{\mathcal{H}_0, \mathtt{arb}_2\} + \mathtt{arb}_1 = \bar{\mathcal{H}}_i$ *in the coefficients of* $\mathtt{arb}_1$ *and* $\mathtt{arb}_2$*, including the restrictions given by* $\mathtt{sol}_\mathtt{p}$*. The solution, if any, is stored in* $\mathtt{sol} = (\mathtt{arb}_1, \mathtt{arb}_2)$*;*
Else
    $\mathtt{sol} = \emptyset$*;*
If ($\mathtt{sol} \neq \emptyset$) *then*
    Set $(\mathcal{K}_i, \mathcal{W}_i) = \mathtt{sol}$ *and* $\mathtt{resolved} = \mathtt{True}$*;*
Else
    Define $\mathcal{K}_i$ *as the terms of* $\bar{\mathcal{H}}_i$ *that are in* $\ker(\mathcal{L}_{\mathcal{G}})$*;*
    Try to solve the PDE $\{\mathcal{H}_0, \mathcal{W}_i\} + \mathcal{K}_i = \bar{\mathcal{H}}_i + \mathtt{NoPol}$ *in the unique unknown* $\mathcal{W}_i$*. We call the solution, if any,* `Dsol`*;*
    If (`Dsol` *is computed properly*) *then*
        $\mathtt{resolved} = \mathtt{True}$*;*
    Else
        An error message telling that $\mathcal{W}_i$ *cannot be obtained is displayed; in addtion* $\mathtt{resolved} = \mathtt{False}$ *and the algorithm is aborted.*

Remark 3.3. (i) If the number of DOFs of our problem is n and we are at order i, then the number of different coefficients of $\mathtt{arb}_1$ is $\binom{2n+i+p+1}{i+p+2}$. Besides, since the degrees of $\mathcal{G}$ and $\mathtt{arb}_1$ are, respectively, s and $i+p+2$, then $\mathcal{L}_{\mathcal{G}}(\mathtt{arb}_1)$ is a homogeneous polynomial of degree $i+p+s$ in $\boldsymbol{x}$. Hence, the solution of $\mathcal{L}_{\mathcal{G}}(\mathtt{arb}_1) = 0$ is obtained by matching the coefficients of $\mathtt{arb}_1$ so that the latter expression becomes identically zero. Therefore, one needs to solve a system of $\binom{2n+i+p+1}{i+p+2}$ linear homogeneous equations with $\binom{2n+s-1}{s}$ unknowns. This system always has an infinite number of nontrivial solutions provided that the number of unknowns is smaller than or equal to the number of linear equations; this is satisfied whenever $s \leq i+p+2$. The solution is the one denoted by $\mathtt{sol}_\mathtt{p}$.

(ii) When $\mathtt{NoPol} = 0$ we try to resolve the PDE: $\mathcal{L}_{\mathcal{H}_0}(\mathtt{arb}_2) = \bar{\mathcal{H}}_i - \mathtt{arb}_1$ for $\mathtt{arb}_2$ (once the conditions for $\mathtt{arb}_1$ are imposed) by matching the coefficients of $\mathtt{arb}_2$. Since we try to get $\mathtt{arb}_2$ as a polynomial in $\boldsymbol{x}$, $\bar{\mathcal{H}}_i$ and $\mathtt{arb}_1$ are homogeneous polynomials of degree $i+p+2$ and the degree of $\mathcal{H}_0$ is $p+2$, the degree of $\mathtt{arb}_2$ should be $i+2$, and hence, the number of different coefficients for $\mathtt{arb}_2$ is $\binom{2n+i+1}{i+2}$. Now, the solution of the PDE is achieved by solving a system of $\binom{2n+i+p+1}{i+p+2}$ linear equations with $\binom{2n+i+1}{i+2}$ unknowns. We store the solution on the variable `sol`. Unlike what occurs in Remark 3.3(i), this system does not always have a solution for $\mathtt{arb}_2$. In this case $\mathtt{sol} = \emptyset$ (we are taking $\emptyset$ as the empty subset) and the algorithm tries to solve $\mathcal{L}_{\mathcal{H}_0}(\mathcal{W}_i) = \bar{\mathcal{H}}_i{}^{\#}$ as a PDE to determine $\mathcal{W}_i$. For that we make use of the MATHEMATICA function `DSolve`. This second situation is worse than the first in terms of computational cost.

Indeed, there are a few examples where even the command `DSolve` does not return the desired result. In these cases, a suitable change of coordinates could sort out the trouble.

(iii) If $\mathcal{W}_i$ admits a polynomial expression, that is, when $\texttt{sol} \neq \emptyset$, the undetermined coefficients of $\texttt{arb}_1$ and $\texttt{arb}_2$ are settled to zero, so as to avoid an increase of unnecessary monomials in $\mathcal{K}_i$ and $\mathcal{W}_i$.

(iv) During the process we express $\mathcal{K}_i$ in Cartesian coordinates. However, for some systems, from a computational point of view, it is usually convenient to use an adequate set of symplectic variables such that the homological equation presents a "nicer" aspect, for example, spherical or complex variables. Sometimes it is better to use a combination of them. See examples of this in [27].

(v) Every time Algorithm 3 is applied, a message showing us if the homological equation is solved correctly at order i is displayed. Additionally, we are informed whether the generating function is a polynomial.

(vi) Taking $i = 0$ at all steps and considering also that $p = 0$, the algorithm computes versal deformations of linear Hamiltonian vector fields; see, for instance, [11]. This feature is included in the next subsection.

(vii) A little algorithm to compute Poisson brackets should be added to Algorithm 3. In MATHEMATICA it is a simple matter to compute the Poisson bracket of two scalar functions $\mathcal{P}, \mathcal{Q} : \Omega \subseteq \boldsymbol{R}^{2n} \to \boldsymbol{R}$ by using the built-in function for derivatives `D`.

(viii) Tests to check if the algorithm works properly are introduced at several steps in the procedure. For instance, when redefining $\bar{\mathcal{H}}_i$ as a polynomial we introduce a line in the code to check if $\bar{\mathcal{H}}_i$ is in fact a homogeneous polynomial in $\boldsymbol{x} = (x_1, \ldots, x_n, X_1, \ldots, X_n)$. If it is not, the algorithm is aborted and an error message is shown.

3.3. Lie–Deprit method. Once the order we want to reach in the transformation, say L, is fixed, we are ready to proceed to the construction of both $\mathcal{K}$ and $\mathcal{W}$. The way to obtain them is by going ascendantly order by order from $i = 1$ to $i = L$. Notice that we need to calculate $\mathcal{K}_i$ for $i = 1, \ldots, L$, such that

$$\mathcal{K}(\boldsymbol{y}; \varepsilon) \,=\, \sum_{i=0}^{L} \frac{\varepsilon^i}{i!}\, \mathcal{K}_i(\boldsymbol{y}),$$

where each $\mathcal{K}_i$ is a polynomial in $\boldsymbol{y}$ of degree $i+p+2$ and $\{\mathcal{K}_i, \mathcal{G}\} = 0$ for $i = 1, \ldots, L$. Besides, we need to obtain

$$\mathcal{W}(\boldsymbol{x}; \varepsilon) \,=\, \sum_{i=0}^{L-1} \frac{\varepsilon^i}{i!}\, \mathcal{W}_{i+1}(\boldsymbol{x}),$$

and at each order i we will make use of Algorithm 3 to get $\mathcal{K}_i$ and $\mathcal{W}_i$. Indeed, the advance from one order to the other is done through the recursion formula

$$\mathcal{H}_{j,k} \,=\, \mathcal{H}_{j+1,k-1} + \sum_{\ell=0}^{j} \binom{j}{\ell} \{\mathcal{H}_{j-\ell,k-1}, \mathcal{W}_{\ell+1}\} \tag{3.3}$$

for $j \geq 0$ and $k \geq 1$. Here it is assumed that $\mathcal{H}_{i,0} = \mathcal{H}_i$ and $\mathcal{H}_{0,i} = \mathcal{K}_i$ for all $i \geq 0$. At the end of the process one has computed the Hamiltonians $\mathcal{H}_{j,k}$ with $0 \leq j \leq L$, $1 \leq k \leq L$, and $j + k \leq L$. Hence, the intermediate Hamiltonians form the so-called

Lie–Deprit triangle. See Deprit [6] for the original version of the method and for different applications [2, 22, 5, 26, 27, 10].

ALGORITHM 4 (Lie–Deprit method).

INPUT:

↪ *L: number of steps to be performed in the Lie–Deprit process;*
↪ *n: number of DOFs of the vector field related to $\mathcal{H}$;*
↪ *$\mathcal{H}_0, \ldots, \mathcal{H}_L$: the first, second, $\ldots, L+1$th terms of the Hamiltonian $\mathcal{H}$;*
↪ `VDef`*: Boolean variable which offers the user the possibility of carrying out a transformation within linear versal deformations.*

OUTPUT:

↩ *$(\mathcal{K}_i, \mathcal{W}_i)$: for $i = 1, \ldots, L$.*

CODE:

If (`VDef`) *then*
  Set the auxiliary variable $d_{\mathtt{aux}} = 0$*;*
Else
  Set $d_{\mathtt{aux}} = 1$*;*
For d from 1 to L do
  Define $\mathcal{H}_{d,0} = \mathtt{aux}_1 = \mathcal{H}_d$*;*
  Set $g_d = 0$*;*
  For j from $d-1$ to 0 do

$$\textit{Compute } \mathcal{H}_{j,d-j} = \mathtt{aux}_1 = \mathtt{aux}_1 + \sum_{\ell=0}^{j} \binom{j}{\ell} \{\mathcal{H}_{j-\ell,d-j-1}, g_{\ell+1}\};$$

  $(\mathcal{H}_{0,d}, \mathtt{aux}_2)$ *= solution of applying Algorithm 3 to* $\mathtt{aux}_1$ *(with index* $i = d \cdot d_{\mathtt{aux}}$*);*
  Set $g_d = -\mathtt{aux}_2$*;*
  Or
    $d = 1$*;*
    $\mathtt{aux}_2 = \mathcal{H}_{0,d} - \mathtt{aux}_1$*;*
    For j from $d-1$ to 1 do
      $\mathcal{H}_{d-j,j} = \mathcal{H}_{d-j,j} + \mathtt{aux}_2$*;*
Set $\mathcal{K}_i = \mathcal{H}_{0,i}$*, for* $i = 0, \ldots, L$ *and* $\mathcal{W}_i = g_i$ *for* $i = 1, \ldots, L$.

Remark 3.4. (i) The number of Poisson brackets needed to achieve the Lie–Deprit method is $\binom{L+2}{3}$.

(ii) Since at each order i, according to Remark 3.2(i) and (ii), one must solve a system of linear equations with $\binom{2n+s-1}{s}$ variables plus another system with $\binom{2n+i+1}{i+2}$ variables, after completing the entire process of the Lie transformation, one has solved $2\,L$ systems of linear equations. The total number of unknowns which have been determined is $\binom{2n+L+1}{L+2} + L\binom{2n+s-1}{s} - (2n+1)(n+1)$.

3.4. The algorithm of the inverse for Lie transformations. Once the normal form transformation has been obtained, a further step consists in calculating the explicit expressions of the changes of variables relating the original coordinates $\boldsymbol{x}$ with the transformed $\boldsymbol{y}$. In other words, if the direct change, called $\boldsymbol{x} = \boldsymbol{X}(\boldsymbol{y}; \varepsilon)$, is responsible for writing the "old" coordinates $\boldsymbol{x}$ in terms of the "new" $\boldsymbol{y}$, we need to find an expression for $\boldsymbol{X}$. Equivalently, if the inverse change puts the new coordinates $\boldsymbol{y}$ in terms of the old $\boldsymbol{x}$ and this change is denoted by $\boldsymbol{y} = \boldsymbol{Y}(\boldsymbol{x}; \varepsilon)$, we have to look for an expression of $\boldsymbol{Y}$.

For this purpose we have designed Algorithms 5 and 6. In particular, the corresponding codes have been developed according to the algorithm of the inverse for Lie

transformations due to Henrard [16]. The method proposed in that paper reduces the amount of computations compared with the usual method for the direct and inverse changes proposed by Deprit [6]. For example, in the Lie transformations utilized in the analytical lunar theory [7, 8], the number of Poisson brackets evaluated was reduced by a factor of three.

We give a brief description of Henrard's method [16]. Notice that its purpose is a bit wider than the matter of constructing the direct and inverse changes of coordinates. For instance, we can use the method proposed by Henrard to write any function expressed in terms of the variables $\boldsymbol{x}$ as a function of the variables $\boldsymbol{y}$ and vice versa, provided only that we know the generating function $\mathcal{W}$.

The coefficients of the transformed function

$$g(\boldsymbol{y};\varepsilon) \,=\, \sum_{i\geq 0} \frac{\varepsilon^i}{i!}\, g_i(\boldsymbol{y}),$$

corresponding to a certain smooth function

$$f(\boldsymbol{x};\varepsilon) \,=\, \sum_{i\geq 0} \frac{\varepsilon^i}{i!}\, f_i(\boldsymbol{x}),$$

under the inverse of the transformation generated by the smooth function

$$\mathcal{V}(\boldsymbol{x};\varepsilon) \,=\, \sum_{i\geq 0} \frac{\varepsilon^i}{i!}\, \mathcal{V}_{i+1}(\boldsymbol{x}),$$

are computed recursively by the formula

$$g_i \,=\, \sum_{j=0}^{i} \binom{i}{j} f_{j,i-j}. \tag{3.4}$$

The intermediate terms $f_{j,k}$ are calculated taking into account that

$$f_{0,k} \,=\, f_k, \qquad f_{j,k} \,=\, -\sum_{\ell=1}^{j} \binom{j-1}{\ell-1} \{f_{j-\ell,k}, \mathcal{V}_\ell\} \quad \text{for} \quad j>0.$$

Now we can use the above to calculate the direct and inverse changes as follows.

ALGORITHM 5 (direct change).

INPUT:

↪ *L: number of steps of the transformation process;*

↪ *n: number of DOFs of the system;*

↪ *$f_0, \ldots, f_L$: the first, second, $\ldots$, $L+1$th terms of a function f of $\boldsymbol{x}$;*

↪ *$\mathcal{W}_1, \ldots, \mathcal{W}_L$: the first, second, $\ldots$, Lth terms of the generating function $\mathcal{W}$.*

OUTPUT:

↩ *g: the expression of f as a function of $\boldsymbol{y}$ up to an approximation of order $\mathcal{O}(\varepsilon^{L+1})$.*

CODE:

Define $g_0 = g_{0,0} = f_0$*;*

For d *from* 0 *to* $L-1$ *do*

For j *from* 1 *to* $L-d$ *do*

$$g_{j,d} \,=\, -\sum_{k=1}^{j} \binom{j-1}{k-1} \{g_{j-k,d}, \mathcal{W}_k\};$$

$$g_{d+1} = f_{d+1} - \sum_{\ell=1}^{d+1} \binom{d+1}{\ell} g_{\ell,d+1-\ell};$$

Compute $g = \sum_{i=0}^{L} \frac{\varepsilon^i}{i!} g_i$.

Remark 3.5. (i) For the direct change of coordinates we need to apply Algorithm 5, replacing f_0 by each component of $\boldsymbol{x}$ and putting $f_i = 0$ for $1 \leq i \leq L$.

(ii) To put a function g in terms of another function f one needs to calculate $\binom{L+2}{3}$ Poisson brackets.

The advantage of the algorithm of the inverse is that it can be used backward as well as forward. More precisely, using (3.4) one can express the terms f_i as functions of the g_j as follows:

$$f_i = g_i - \sum_{j=1}^{i} \binom{i}{j} f_{j,i-j}. \tag{3.5}$$

Thus, we modify Algorithm 5 accordingly.

ALGORITHM 6 (inverse change).

INPUT:

↪ *L: the number of steps of the transformation process;*

↪ *n: number of DOFs of the system;*

↪ *$g_0, \ldots, g_L$: the first, second, $\ldots, L+1$th terms of a function g of $\boldsymbol{y}$;*

↪ *$\mathcal{W}_1, \ldots, \mathcal{W}_L$: the first, second, $\ldots, L$th terms of the generating function $\mathcal{W}$.*

OUTPUT:

↩ *f: the expression of g as a function of $\boldsymbol{x}$ up to an approximation of order $\mathcal{O}(\varepsilon^{L+1})$.*

CODE:

For d from 0 to L do

Define $g_{0,d} = g_d$;

If $g_d \neq 0$ then

For ℓ from 1 to $L - d$ do

$$g_{\ell,d} = -\sum_{k=1}^{\ell} \binom{\ell-1}{k-1} \{g_{\ell-k,d}, \mathcal{W}_k\};$$

Else

$g_{\ell,d} = 0$ *for* $\ell = 1, \ldots, L-d$;

$$f_d = \sum_{\ell=0}^{d} \binom{d}{\ell} g_{\ell,d-\ell};$$

Compute $f = \sum_{i=0}^{L} \frac{\varepsilon^i}{i!} f_i$.

Remark 3.6. (i) The inverse change of coordinates is obtained after application of Algorithm 6 substituting g_0 by each component of $\boldsymbol{y}$ and setting $g_i = 0$ for $1 \leq i \leq L$.

(ii) The first "if" command of Algorithm 6 is due to the advantageous fact that each column of $g_{i,d}$ for $i = 0, \ldots, L-d$ is independent from the others and it is computed recursively from the first to the last element. Hence, if the first element of any column vanishes, the entire column vanishes as well. Thereby, in some particular but typical situations, only some of these columns have to be computed. Consequently, the number of operations is reduced drastically.

(iii) Given a Hamilton function $\mathcal{H}$ together with its normal form Hamiltonian $\mathcal{K}$ and the generating function $\mathcal{W}$ constructed such that $\mathcal{K}_i$ commutes with $\mathcal{G}$ for

$i \in \{0, \ldots, L\}$, a formal integral of $\mathcal{H}$ can be built up with the use of Algorithm 6, after replacing $\mathcal{G}$ by g_0 and setting $g_i = 0$ for $1 \le i \le L$. Thus, the formal integral $\mathcal{I}_{\mathcal{G}}$ will be the output function f.

(iv) The number of Poisson brackets used in the computation of a function g as a function of f is $\binom{L+2}{3}$. However, if g is such that $g_i = 0$ for $1 \le i \le L$, as it occurs for situations (i) and (iii), the number of Poisson brackets to be evaluated gets reduced to $\binom{L+1}{2}$, due to the consideration explained in (ii).

4. Applications. This section displays the features of the algorithm exposed in the preceding paragraphs through two examples.

4.1. Normalization of a Hamiltonian with null quadratic terms. First we have chosen a polynomial Hamiltonian where the first nonnull term is a homogeneous polynomial of degree 3.

In this application we assume that the vector $\boldsymbol{x}$ is two-dimensional, i.e., $\boldsymbol{x} = (x, X)$; the lowercase x stands for the position, whereas the uppercase X refers to its associated momentum.

We start by defining the Hamilton function through

$$\mathcal{H}(\boldsymbol{x}) = \sum_{i=0}^{\infty} \frac{1}{i!}\, \mathcal{H}_i(\boldsymbol{x}), \tag{4.1}$$

where

$$\begin{aligned} \mathcal{H}_0(\boldsymbol{x}) &= x^2 X, \\ \mathcal{H}_i(\boldsymbol{x}) &= x^2 \sum_{j=1}^{i+2} h_{i,j}\, x^{i+2-j} X^{j-1}, \qquad i = 1, \ldots, \infty, \end{aligned} \tag{4.2}$$

and $h_{i,j} \in \boldsymbol{R}$. Note that the vector field associated with $\mathcal{H}$ is a 1-DOF system. With the notation introduced in section 2 we have that $A = (0)$, that is, the square matrix of order two whose entries are all zero. In this situation, it is clear that the normal form theorem, Theorem 2.1, does not produce any change in $\mathcal{H}$ because the quadratic part is zero. As a consequence, if we want to simplify (4.1) we need to change to the setting of generalized normal forms.

RESULT 4.1. *We select $\mathcal{G}(\boldsymbol{x}) = \mathcal{H}_0(\boldsymbol{x})$ and apply Theorem 2.4 to Hamiltonian (4.1). Note that s, the degree of $\mathcal{G}$, is 3, whereas $p = 1$. Thus, each $\mathcal{H}_i$ is a homogenous polynomial of degree $i+3$. For all $i \ge 1$ the ith term of the generating function $\mathcal{W}(\boldsymbol{x})$ of the transformation has the form $\mathcal{W}_i(\boldsymbol{x}) = x\, p_{i+1} + x^2 \log|x|\, q_i$, with p_{i+1} and q_i homogeneous polynomials in $\boldsymbol{x}$ of degrees $i+1$ and i, respectively. Furthermore, if the new variables are called $\boldsymbol{y} = (y, Y)$, the new Hamiltonian will be a polynomial $\mathcal{K}$ composed of homogeneous polynomials $\mathcal{K}_i$. More precisely, for all $i \ge 0$ we have that $\mathcal{K}_{3\,i} = \bar{h}_i\, (y^2\, Y)^{i+1}$ (with $\bar{h}_i$ a constant polynomial in the coefficients $h_{i\,j}$), whereas $\mathcal{K}_{3\,i+1} = \mathcal{K}_{3\,i+2} = 0$.*

Proof. We make a single-induction process over i, the order of the Lie transformation. We have the following.

Step 1. *First-order normalization.* Applying the algorithms of section 3 at order $i = 1$ we get

$$\begin{aligned} \mathcal{K}_1 &= 0, \\ \mathcal{W}_1 &= \frac{x}{3}\left(h_{1,1}\, x^2 - h_{1,3}\, X^2\right) + x^2 \log|x|\, h_{1,2}\, X. \end{aligned}$$

This is straightforward, noting that the induction hypothesis is true for $i = 1$.

Step 2. *Higher-order terms.* Suppose now that the assertion is true up to order $i-1$. Thus we have that $\mathcal{K}_{i-1}$ will be zero when $i-1$ does not divide 3 or $\bar{h}_{(i-1)/3}\,(y^2\,Y)^{(i+2)/3}$ otherwise. Besides, $\mathcal{W}_{i-1} = x\,p_i + x^2\,\log|x|\,q_{i-1}$ with p_i and q_{i-1} homogeneous polynomials in $\boldsymbol{x}$ of degrees i and $i-1$, respectively. In addition, since $\mathcal{W}_{i-1}$ satisfies the identity $\mathcal{L}_{\mathcal{H}_0}(\mathcal{W}_{i-1}) + \mathcal{K}_{i-1} = \bar{\mathcal{H}}_{i-1}$, we can put $\bar{\mathcal{H}}_{i-1} = x^2\,\bar{p}_i + x^3\,\log|x|\,\bar{q}_{i-1}$ with $\bar{p}_i$ and $\bar{q}_{i-1}$ homogeneous polynomials in $\boldsymbol{x}$ of degrees i and $i-1$, respectively. Therefore, using the properties of the Poisson brackets we know that all intermediate Hamiltonians $\mathcal{H}_{j,k}$, with $j+k=i-1$, are of the form $x^2\,\bar{p}_i^{(j,k)} + x^3\,\log|x|\,\bar{q}_{i-1}^{(j,k)}$ for some polynomials $\bar{p}_i^{(j,k)}$ and $\bar{q}_{i-1}^{(j,k)}$ of respective degrees i and $i-1$.

We need to conclude that it remains true at order i. Notice that now we have to calculate the diagonal $\mathcal{H}_{j,k}$ for $j+k=i$ starting at $\mathcal{H}_{i-1,1}$ and ending at $\mathcal{H}_{0,i}$ using Algorithm 4. Specifically, we set $\mathcal{W}_i = 0$ and compute

$$\mathcal{H}_{i-1,1} \;=\; \mathcal{H}_i + \sum_{\ell=0}^{i-1} \binom{i-1}{\ell} \{\mathcal{H}_{i-1-\ell,0}, \mathcal{W}_{\ell+1}\}.$$

Taking into account the forms of $\mathcal{W}_j$ for each $j < i$ and of $\mathcal{H}_k$ for $k \le i$, it is not hard to observe that all Poisson brackets $\{\mathcal{H}_{i-1-\ell,0}, \mathcal{W}_{\ell+1}\}$ produce terms like $x^2\,\bar{p}_{i+1}^{(\ell)} + x^3\,\log|x|\,\bar{q}_i^{(\ell)}$ with $\bar{p}_{i+1}^{(\ell)}$ and $\bar{q}_i^{(\ell)}$ homogeneous polynomials of degrees $i+1$ and i. Using the recurrence (3.3) we obtain that all Hamiltonians $\mathcal{H}_{j,k}$ with $j+k=i$ are written as $x^2\,\bar{p}_{i+1}^{(j,k)} + x^3\,\log|x|\,\bar{q}_i^{(j,k)}$, where $\bar{p}_{i+1}^{(j,k)}$ and $\bar{q}_i^{(j,k)}$ are polynomials of degrees $i+1$ and i; the same holds for $\bar{\mathcal{H}}_i$. Thus we can write $\bar{\mathcal{H}}_i = x^2\,\bar{p}_{i+1} + x^3\,\log|x|\,\bar{q}_i$. Next we need to extract $\mathcal{K}_i$ from $x^2\,\bar{p}_{i+1}$ (expressing it first in terms of $\boldsymbol{y}$). Note that $\mathcal{K}_i$ must belong to $\ker(\mathcal{L}_{\mathcal{G}})$ and this kernel is spanned by integer powers of $y^2\,Y$; thus $\mathcal{K}_i$ is zero when i is not a multiple of 3 or $\mathcal{K}_i = \bar{h}_{i/3}\,(y^2\,Y)^{(i+3)/3}$ otherwise. Finally we solve the PDE $\mathcal{L}_{\mathcal{H}_0}(\mathcal{W}_i) = \bar{\mathcal{H}}_i - \mathcal{K}_i$, but it is satisfied whenever $\mathcal{W}_i$ is of the form demanded in the induction hypothesis. Therefore, all assertions turn out to be true and Result 4.1 is obtained. □

The generating function $\mathcal{W}(\boldsymbol{x})$ contains polynomial and logarithmic terms. However, it satisfies $\mathcal{W}(\boldsymbol{x}) \to 0$ as $\boldsymbol{x} \to \boldsymbol{0}$. Besides, the normalization process will map the coordinates $\boldsymbol{x} = (x, X)$ into the new coordinates $\boldsymbol{y} = (y, Y)$ and vice versa. By construction (using Algorithms 5 and 6) both maps are $\mathcal{C}^2$ in $\boldsymbol{R}^2$. Note also that $\mathcal{W}$ is $\mathcal{C}^\infty$ in $\boldsymbol{R}^2 \setminus \{x=0\}$ and therefore this treatment could be used to analyze a piece of the phase space, excluding the ray $x=0$, whenever the Hamiltonian $\mathcal{H}$ does not come from an expansion around the origin of $\boldsymbol{R}^2$.

One should observe that when trying to solve the homological equation (3.1) at any order i, the Hamiltonians $\mathcal{H}_i$ need to be of the type (4.2), as the corresponding generating function can be obtained as $\mathcal{W}_i = p_i + \log|x|\,q_i$. This is requested to overcome the problem of dropping significant terms when truncating the system at order $L \ge 1$.

Remark 4.1. It is clear that after the normalizing process, we arrive at a system of 0 DOFs. We could extend this result for n-DOF Hamiltonians with $n > 1$ and $\mathcal{H}_0 = x^2\,X$. Similar conclusions would be drawn and the method would lead to an $(n-1)$-DOF Hamiltonian vector field through $\mathcal{C}^2$-maps. Note in addition that a formal integral of $\mathcal{H}$ can be calculated through Algorithm 6 using $\mathcal{W}$ and $\mathcal{G}$.

4.2. The swing spring. Our aim is to show the occurrence of Hamiltonian–Hopf bifurcations in the swing spring (also called elastic or spring pendulum) through

the use of generalized normal forms and the algorithms developed in section 3. Furthermore, we also will show that the dynamical system of the swing spring has monodromy.

4.2.1. Description of the system. The spring pendulum is a mechanical system that exemplifies the motion of a point particle attached to a spring under a constant vertical gravitation field. The position of the particle is denoted by $\boldsymbol{r} = (x_1, x_2, x_3)$, whereas the velocity $\dot{\boldsymbol{r}}$ is the vector (X_1, X_2, X_3). This dynamical system is represented through the Hamilton function

$$\mathcal{H}(\boldsymbol{x}) = \frac{1}{2}(X_1^2 + X_2^2 + X_3^2) + U(\boldsymbol{r}), \tag{4.3}$$

where the potential U is written as

$$U(\boldsymbol{r}) \;=\; x_3 + \frac{1}{2}\nu^2 \left(1 - \frac{1}{\nu^2} - \sqrt{x_1^2 + x_2^2 + x_3^2}\right)^2. \tag{4.4}$$

The parameter ν is related to the equilibrium and unstretched lengths of the spring, respectively, l and l_0, by $\nu = \sqrt{l/(l - l_0)}$. Thus, $\nu > 1$ since the frequency of the spring oscillation is bigger than the frequency of the small amplitude pendulum oscillations, that is, $l \geq l_0$.

The potential has an equilibrium point when the forces of gravity and the spring balance. It corresponds to $\boldsymbol{r}_0 = (0, 0, -1)$ and is linearly stable. We will carry out four steps of the Lie–Deprit process so as to make a proper analysis that we will explain later on. As a consequence, we expand the potential $U(\boldsymbol{r})$ around $(0, 0, -1)$ up to terms of degree 6. Hence, we calculate the Hamiltonian approximated up to degree 6 with the equilibrium shifted to the origin

$$\mathcal{H}(\boldsymbol{x}) \;=\; \mathcal{H}_0 + \sum_{i=1}^{4} \mathcal{H}_i(\boldsymbol{x}), \tag{4.5}$$

where

$$\mathcal{H}_0 \;=\; \frac{1}{2}(X_1^2 + X_2^2 + X_3^2) + \frac{1}{2}(x_1^2 + x_2^2 + \nu^2 x_3^2)$$

and each $\mathcal{H}_i$ is a homogeneous polynomial in $\boldsymbol{x}$ of degree $i+2$ for $i \in \{1, \ldots, 4\}$. Note that x_3 accounts for the displacement from -1. Note also that the coefficients of $\mathcal{H}_i$ depend on ν. We could introduce a small parameter by stretching the coordinates $\boldsymbol{x} = \varepsilon\, \boldsymbol{x}'$ and scaling time. However, we prefer to set $\varepsilon = 1$ and use the theory of section 2 and algorithms of section 3, proceeding straightforwardly.

We easily see that the system is a $1:1:\nu$ resonant Hamiltonian. The $1:1:2$ case has already been analyzed by Dullin, Giacobbe, and Cushman [9]. In our treatment, we broach the nonresonant case; equivalently, we take $\nu \in \boldsymbol{R} \setminus \mathbf{Q}$ together with $\nu > 1$.

4.2.2. Integrable approximation. First, it is straightforward to note that the system is symmetric with respect to the z-axis. Equivalently, Hamiltonian (4.5) is invariant under the flow defined by the field associated with the third component of the angular momentum $L_3 = x_1 X_2 - x_2 X_1$. Therefore, the departure (i.e., the original) Hamiltonian defines, in fact, a 2-DOF system.

The next step is the introduction of a new (formal) symmetry in the system to achieve an integrable approximation. Now it should be clear that the application

of the normal form theorem would lead to a 0-DOF Hamiltonian dynamical system. The reason for this is the following. After the normalization procedure (i.e., after applying Theorem 2.1 and truncating higher-order terms), one introduces in principle one (formal) integral, which in this case, due to the semisimple character of $\mathcal{H}_0$, is precisely $\mathcal{H}_0$. However the number of independent integrals introduced in the process is two—$I_1 = (X_1^2 + x_1^2)/2 + (X_2^2 + x_2^2)/2$ and $I_2 = (X_3^2 + \nu^2 x_3^2)/2$—due to the absence of resonant terms involving x_3 and X_3 with x_1, x_2, X_1, or X_2. Now, one still has to take into account the occurrence of the (exact) integral L_3 yielding three independent integrals. As a result, the reduction process using invariant theory leads to the so-called fully reduced normalized system, which is indeed a trivial integrable Hamiltonian system. In this sense this normalization would be too drastic. Thence, we have to make use of the generalized method for constructing normal forms as stated in Theorem 2.4.

First reduction. We choose $\mathcal{G}(\boldsymbol{x}) = \nu^2 x_3^2 + X_3^2$. At this point, we make use of Algorithms 3 and 4 presented in section 3 to compute the generalized normal form with the aim of extending the integral $\mathcal{G}$ up to some degree. The normalized and truncated Hamiltonian up to order 4 (that is, $L = 4$ and the polynomials are of degree 6) is denoted by $\mathcal{K}$, thus $\{\mathcal{K}, \mathcal{G}\} = 0$. The reason for going to order 6 is motivated by the fact that odd orders give 0 and at order 2 the system has nonisolated equilibria and thus is not structurally stable.

The reduction is regular. Moreover, the corresponding homological equations give polynomial results in all orders $i \in \{1, \ldots, 4\}$. Henceforth the generating function of the transformation $\mathcal{W}$ is a polynomial of degree 6 and always would be a polynomial if we would push the calculations up to any order. This is due to the nonresonant situation existing between $\mathcal{G}$ and $\frac{1}{2}(x_1^2 + X_1^2) + \frac{1}{2}(x_2^2 + X_2^2)$. An asymptotic integral of $\mathcal{H}$ could be found by means of Algorithm 6 applied to $\mathcal{G}$ with the aid of $\mathcal{W}$. The result would be $\mathcal{I}_\mathcal{G}$, a polynomial in $\boldsymbol{x}$ of degree 6 such that $\{\mathcal{H}, \mathcal{I}_\mathcal{G}\} = p_7(\boldsymbol{x})$, where p_7 is a polynomial whose lowest degree is 7.

The invariants associated with this reduction are

$$i_1 = x_1, \quad i_2 = X_1, \quad i_3 = x_2, \quad i_4 = X_2, \quad i_5 = \nu^2 x_3^2 + X_3^2.$$

Then, we fix a value for the integral, i.e., we set $\mathcal{G} = i_5 = j_1 \geq 0$. Next, the reduced phase space is the hyperplane $i_5 = j_1$ defined in the four-dimensional space determined by $i_1, \ldots, i_4$ that we call P_{j_1}. In this way the transformed Hamiltonian $\mathcal{K}$ in that hyperplane can be expressed as $\mathcal{K}(i_1, i_2, i_3, i_4; j_1)$.

Second reduction. As we have stressed previously, the system is axially symmetric with the third component of the angular momentum L_3 an integral of motion. Thus, a second (and exact) reduction can be performed straightforwardly.

The invariants associated with this second reduction are

$$\varphi_1 = i_1^2 + i_3^2 = x_1^2 + x_2^2, \qquad \varphi_2 = i_2^2 + i_4^2 = X_1^2 + X_2^2,$$
$$\varphi_3 = i_1 i_2 + i_3 i_4 = x_1 X_1 + x_2 X_2, \qquad \varphi_4 = i_1 i_4 - i_2 i_3 = x_1 X_2 - x_2 X_1.$$

Again, we fix a value for the integral L_3; i.e., we let $\varphi_4 = j_2$ for some constant $j_2 \in \boldsymbol{R}$. Now, the twice-reduced phase space is the two-dimensional hyperbolic paraboloid defined by

$$V_{j_2} = \{\varphi \in \boldsymbol{R}^3 \mid R_{j_2}(\varphi) = 0\},$$

where $R_{j_2}(\varphi) = \varphi_1 \varphi_2 - \varphi_3^2 + j_2^2$. Depending on the value of j_2 there are two cases; see Figure 4.1. If $j_2 \neq 0$, the reduction is regular, whereas if $j_2 = 0$, the reduction is singular with the origin of the frame $0, \varphi_1, \varphi_2, \varphi_3$ being a singular point.

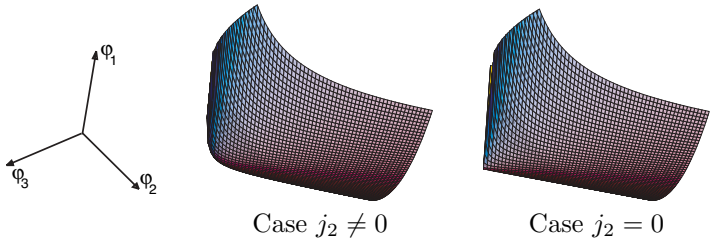

FIG. 4.1. *Twice-reduced phase space.*

Then, putting the twice-reduced Hamiltonian as a function of these invariants, we arrive at

$$\begin{aligned}\mathcal{S}^{\nu}(\varphi_1,\varphi_2,\varphi_3;j_1,j_2) \;=\; & \frac{1}{768\,\nu^6\,(\nu^2-4)^4\,(64-148\,\nu^2+9\,\nu^4)}\\ & \times [c_1\,\varphi_1^3 + c_2\,\varphi_2^3 + c_3\,\varphi_1\,\varphi_2^2 + c_4\,\varphi_1^2\\ & \quad + c_5\,\varphi_2^2 + c_6\,\varphi_1\,\varphi_2 + c_7\,\varphi_1 + c_8\varphi_2 + c_9],\end{aligned} \tag{4.6}$$

where all the c_i are polynomials in ν, j_1, and j_2 having integer coefficients. In the remainder, we will denote this twice-reduced Hamilton function as $\mathcal{S}^{\nu}$.

4.2.3. Hamiltonian–Hopf bifurcations at the origin. We have to look at the points on the twice-reduced phase space V_{j_2} where the gradient $\nabla\mathcal{S}^{\nu}$ is parallel to the gradient ∇R_{j_2} to get the equilibria of the system defined by $\mathcal{S}^{\nu}$. Equivalently, this can be interpreted geometrically as seeking whether the level set $\{\mathcal{S}^{\nu}(\varphi) = h\}$ is tangent to V_{j_2}, which always occurs at the singular point of V_{j_2}.

Now, we restrict ourselves to the singular case $j_2 = 0$. In this situation the reduced phase space is singular at the origin, which is always an equilibrium point of this space. This singularity reflects the fact that the S^1-action defined by the axial symmetry is not free.

Next we study the stability of the origin, which we denote by φ^0 (so, this equilibrium point satisfies $\varphi_i = 0$ for $i \in \{1,2,3,4\}$). We need to calculate the Poisson brackets of the φ_i. We do that with the aim of using the symplectic structure on the reduced phase space. The matrix containing all brackets appears in Table 4.1.

TABLE 4.1
The Poisson bracket relations $\{\varphi_i,\varphi_j\}$ *for* $i,j = 1,\ldots,4$.

$\{\ ,\ \}$	φ_1	φ_2	φ_3	φ_4
φ_1	0	$4\varphi_3$	$2\varphi_1$	0
φ_2	$-4\varphi_3$	0	$-2\varphi_2$	0
φ_3	$-2\varphi_1$	$2\varphi_2$	0	0
φ_4	0	0	0	0

Now we can obtain the Hamiltonian vector field $X_{\mathcal{S}^{\nu}}$ associated with the Hamiltonian $\mathcal{S}^{\nu}(\varphi_1,\varphi_2,\varphi_3;j_1,j_2)$ and, after that, we set $j_2 = 0$ to analyze whether that system undergoes a Hamiltonian–Hopf bifurcation.

The Hessian matrix obtained from its linearization evaluated at the origin turns out to be

$$DX_{\mathcal{S}_0^\nu}(\varphi^0) = \begin{pmatrix} 0 & 0 & \frac{\lambda_{\nu j_1}}{128\,\nu^4\,(\nu^2-4)^3} \\ 0 & 0 & \frac{-2\,j_1+(32+5\,j_1)\,\nu^2-8\,\nu^4}{8\,\nu^2\,(\nu^2-4)} \\ \frac{-2\,j_1+(32+5\,j_1)\,\nu^2-8\,\nu^4}{4\,\nu^2\,(\nu^2-4)} & \frac{\lambda_{\nu j_1}}{64\,\nu^4\,(\nu^2-4)^3} & 0 \end{pmatrix},$$

where we have defined

$$\begin{aligned}\lambda_{\nu j_1} &= 128\,\nu^4\,(\nu^2-4)^3 + 16\,j_1\,\nu^2\,(\nu^2-4)^2(-6+7\,\nu^2+2\,\nu^4) \\ &\quad + j_1^2\,(-144+436\,\nu^2-300\,\nu^4-105\,\nu^6+59\,\nu^8).\end{aligned}$$

The eigenvalues of $DX_{\mathcal{S}_0^\nu}(\varphi^0)$ vanish if and only if j_1 takes the values

$$\begin{aligned} j_{11} &= \tfrac{8\,\nu^2\,(\nu^2-4)}{5\,\nu^2-2}, \\ j_{12} &= -\frac{16\,\nu^2\,(\nu^2-4)^{3/2}}{\sqrt{\nu^2-4}\,(2\,\nu^4+7\,\nu^2-6)-\sqrt{(\nu^2+2)\,(72-286\,\nu^2+351\,\nu^4-114\,\nu^6+4\,\nu^8)}}, \\ j_{13} &= -\frac{16\,\nu^2\,(\nu^2-4)^{3/2}}{\sqrt{\nu^2-4}\,(2\,\nu^4+7\,\nu^2-6)+\sqrt{(\nu^2+2)\,(72-286\,\nu^2+351\,\nu^4-114\,\nu^6+4\,\nu^8)}}. \end{aligned}$$

For irrational values of $\nu > 1$, the denominators of j_{11} and j_{13} do not vanish, whereas the denominator of j_{12} is zero provided that $\nu = 1.6635156185484876$. (As the infinite-precision expressions are very involved, we use floating-point arithmetic.) Thus, for this particular value of ν, the values of j_1 for which $DX_{\mathcal{S}^{1.66\ldots}}(\varphi^0)$ has three null eigenvalues get reduced to $j_{11} = 0.9513184442193461$.

Now, if we vary j_1 and make it pass through j_{11}, j_{12}, or j_{13}, we find that the origin changes its stability from elliptic to hyperbolic point or vice versa. In fact, one of the eigenvalues of $DX_{\mathcal{S}_0^\nu}(\varphi^0)$ is always zero as the system is 1-DOF, and we are using a three-dimensional frame with the constraint given through R_{j_2}. Besides, the other two eigenvalues are either pure imaginary (elliptic point, also called center) or real ones with different sign (hyperbolic point, also called saddle). More concretely, depending on the value of the external parameter ν, we have three cases. We have

(1) for $\nu \in (1, 1.5117504938658013)$: *elliptic*;
(2) for $\nu \in (1.5117504938658013, 1.6635156185484876)$: *hyperbolic* if ($j_1 < j_{13}$ or $j_1 > j_{12}$) and *elliptic* for $j_1 \in (j_{13}, j_{12})$;
(3) for $\nu \in (1.6635156185484876, 2)$: *elliptic* for $j_1 < j_{13}$ and *hyperbolic* for $j_1 > j_{13}$;
(4) for $\nu > 2$: *elliptic* for $j_1 < j_{11}$ and *hyperbolic* for $j_1 > j_{11}$.

Recall that the origin φ^0 is an isolated equilibrium point in all the cases since we have pushed the calculations to degree 6. (At degree 4 the origin was not an isolated critical point.) Note as well that the twice-reduced Hamiltonian is a family of Hamiltonians depending on two parameters (ν and j_1). However, ν is an external parameter while j_2 is an internal or distinguished one.

Next we perform a suitable change of coordinates so that $\mathcal{S}^\nu$ acts as a Morse function on V_{j_2}. This is achieved through two successive changes of coordinates. We define

$$\sigma_1 : \boldsymbol{R}^3 \to \boldsymbol{R}^3 : (\varphi_1, \varphi_2, \varphi_3) \mapsto (\varsigma_1 + \varsigma_2, \varsigma_1 - \varsigma_2, \varsigma_3)$$

and

$$\sigma_2 : \boldsymbol{R}^3 \to \boldsymbol{R}^3 : (\varsigma_1, \varsigma_2, \varsigma_3) \mapsto \left(\tfrac{1}{4}(\tau_1^2 - \tau_2^2), \tfrac{1}{2}\,\tau_1\tau_2, \tfrac{1}{4}\,\tau_3\right).$$

By doing so we transform $R_{j_2}(\varphi)$ into $R_{j_2}(\tau) = \frac{1}{16}(\tau_3^2 - \tau_1^4 - 2\tau_1^2\tau_2^2 - \tau_2^4) - j_2^2$. Consequently, $R_0(\tau) = \frac{1}{16}(\tau_3^2-\tau_1^4-2\tau_1^2\tau_2^2-\tau_2^4)-j_2^2$, and $R_0(\tau) = 0$ defines a parabolic surface. Thus, through the changes σ_1 and σ_2 we have removed the singularity from the twice-reduced phase space V_{j_2}.

As the next step we determine the 2-jet related to $\mathcal{S}^{\nu}_{j_2=0}$. It leads to the expression

(4.7)
$$\begin{aligned}\mathcal{S}^{2\text{-jet}}_{j_2=0}&(\tau_1,\tau_2)\\ &= \tfrac{2j_1-(32+5j_1)\nu^2+8\nu^4}{32\nu^2(\nu^2-4)}\,\tau_2^2\\ &\quad+\tfrac{128\nu^4(\nu^2-4)^3+16j_1\nu^2(\nu^2-4)^2(2\nu^4+7\nu^2-6)+j_1^2(59\nu^8-105\nu^6-300\nu^4+436\nu^2-144)}{512\nu^4(\nu^2-4)^3}\,\tau_1^2.\end{aligned}$$

Note that the composition $\sigma_2 \circ \sigma_1$ maps the origin φ^0 to the origin τ^0 in the new variables.

The 2-jet plays the role of a Morse function. As a consequence, given a fixed value of $\nu > 1$, the analysis is carried out by replacing j_1 by its value before the bifurcations, after the bifurcations, and in the bifurcations value itself. From the expression (4.7) it is easy to deduce that when ν and j_1 are taken so that the stability at the origin is of elliptic type, the 2-jet takes the form

$$\mathcal{S}^{2\text{-jet}}_{j_2=0}(\tau_1,\tau_2) \;=\; a_1\,\tau_1^2 + a_2\,\tau_2^2,$$

while when we select ν and j_1 such that the origin τ^0 is of hyperbolic character, we have

$$\mathcal{S}^{2\text{-jet}}_{j_2=0}(\tau_1,\tau_2) \;=\; a_1\,\tau_1^2 - a_2\,\tau_2^2,$$

where a_1, a_2 are nonnull constants such that they satisfy $a_1\,a_2 > 0$. Therefore, the origin will be stable in the first case and unstable in the second. Besides, in the bifurcation values, the 2-jet shows an unstable behavior of τ^0.

The above paragraphs enable us to conclude that indeed a Hamiltonian–Hopf bifurcation takes place whenever one of these situations occurs (see also the different regions and bifurcation lines in Figure 4.2):

(1) for $\nu \in (1.5117504938658013, 1.6635156185484876)$ and $j_1 = j_{12}$,
(2) for $\nu \in (1.5117504938658013, 2)$ and $j_1 = j_{13}$,
(3) for $\nu > 2$ and $j_1 = j_{11}$.

A very detailed description of Hamiltonian–Hopf bifurcations is available in [14].

4.2.4. Monodromy. We end our example with an analysis of the occurrence of monodromy in the Liouville-integrable system $(\mathcal{K}, \mathcal{G}, L_3, \boldsymbol{R}^6, \omega)$, with $\omega = dx_1 \wedge dX_1 + dx_2 \wedge dX_2 + dx_3 \wedge dX_3$. Nontrivial monodromy describes the global twisting of a family of invariant two-dimensional tori parameterized by a circle of regular values of the energy-momentum map of a certain integrable system. Its presence is determined by the existence of a singular fiber of the energy-momentum map, topologically a torus with one or two pinched points. If an integrable system has monodromy, then one cannot label the tori in a unique way by values of the actions [5]. To unveil the monodromy feature of our departure Hamiltonian we start by studying the 2-DOF integrable system $(\mathcal{K}(i_1, i_2, i_3, i_4; j_1), L_3, P_{j_1}, \{\ ,\ \})$, where $\mathcal{K}$ represents the normal form Hamiltonian expressed in the invariants associated with the first reduction and in P_{j_1} we take $j_1 > 0$. We note that $\mathcal{K}$ and L_3 commute, which is an essential hypothesis for proving monodromy. In the case where we have a hyperbolic behavior of the origin φ^0, that is, whenever

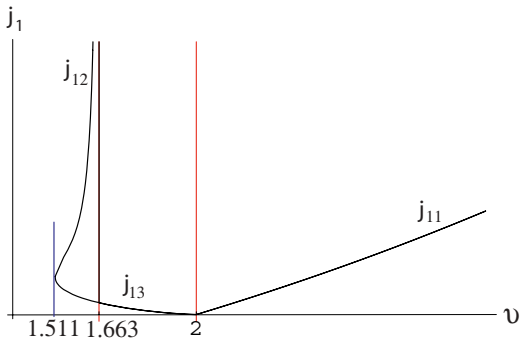

FIG. 4.2. *The bifurcation lines in the plane defined by the external parameter ν and the internal one j_1 are shown. In the ν-axis we are taking into account only the irrational values. The origin of the coordinates in the picture is the point* ($\nu = 1.5117504938658013$, $j_1 = 0$).

(1) $\nu \in (1.5117504938658013, 1.6635156185484876)$ and $j_1 < j_{13}$ or $j_1 > j_{12}$,
(2) $\nu \in (1.6635156185484876, 2)$ and $j_1 > j_{13}$,
(3) $\nu > 2$ and $j_1 > j_{11}$,

we see that the system satisfies the hypotheses of the monodromy theorem for Hamiltonian systems as stated in Matveev [17] and Zung [35]; see also a similar case in [5] and the non-Hamiltonian situation in [4].

Looking at the energy momentum mapping

$$\mathcal{EM}_{j_1} : P_{j_1} \subseteq \boldsymbol{R}^4 \to \boldsymbol{R}^2 : (i_1, i_2, i_3, i_4) \mapsto (\mathcal{K}_{j_1}(i_1, i_2, i_3, i_4), L_3(i_1, i_2, i_3, i_4)), \tag{4.8}$$

fixing values for the energy, h, and for the third component of the angular momentum, j_2, it is straightforward to observe that the fiber $\mathcal{EM}_{j_1}^{-1}(h, j_2)$ is compact and connected by simply inverting $\mathcal{EM}_{j_1}$ and putting the invariants i_j in terms of j_2 and h. So at the critical value $(j_1/2, 0)$ of $\mathcal{EM}_{j_1}$ we have a once-pinched 2-torus. Therefore, applying the monodromy theorem, if Γ represents a closed curve around the critical value $(j_1/2, 0)$ we have that the 2-torus bundle $\mathcal{EM}_{j_1}(\Gamma)$ has a monodromy linear mapping whose matrix is

$$\begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}.$$

This implies, following reasoning due to Rink [31], that the system defined through the system (4.3) also has monodromy. The analysis of the Hamiltonian–Hopf bifurcations in the original system could be done by reconstructing the flow near φ^0, using the direct change of coordinates, that is, by making use of Algorithm 5. The analysis of monodromy for the spring pendulum when $\nu = 2$ can be found in the work by Dullin, Giacobbe, and Cushman [9].

5. Conclusions. We present a set of algorithms to deal with generalized normal forms for polynomial Hamiltonians. Our initial Hamiltonian $\mathcal{H}$ is a Hamiltonian vector field with n DOFs that can be written as a sum of homogeneous polynomial Hamiltonians, $\mathcal{H}_i$, starting at degree $p + 2$ (with $p \geq -1$ a fixed integer) up to a certain degree. The coefficients of the polynomials $\mathcal{H}_i$ are arbitrary and can be real or complex. Given a polynomial $\mathcal{G}$ of degree $s \geq 1$ our aim is to construct a polynomial Hamiltonian $\mathcal{K}$ up to a certain degree $L + p + 2$ and a generating function $\mathcal{W}$ (sometimes also a polynomial of degree $L+p+2$ and generically a smooth function in some domain) such that the Poisson brackets $\{\mathcal{K}_i, \mathcal{G}\}$ vanish for all $i \in \{1, \ldots, L\}$.

So, if $\mathcal{H}_0$ commutes with $\mathcal{G}$, then $\mathcal{G}$ becomes an integral of $\mathcal{K}$, after truncation of higher-order terms.

One of our algorithms looks for a polynomial generating function when possible. If at an order i there is not a solution of a certain linear system, it tries to solve a PDE corresponding to the homological equation with the aim of determining a smooth generating function $\mathcal{W}_i$. We have included within our approach the case of the normal form theorem, selecting $\mathcal{G}$ adequately to yield the same result.

The resolution of the homological equation is not optimal from the computational point of view as the algorithm we use requires handling, at least, two systems of linear equations. However, it can be applied to a large class of Hamilton functions in n DOFs. Besides, one does not need to write the unperturbed part of the Hamiltonian, that is, $\mathcal{H}_0$, in normal form. Moreover, the computation of the direct and inverse changes of variables is optimized as much as possible since we use the algorithm of the inverse introduced by Henrard [16].

We apply the theory of generalized normal forms together with the algorithms developed in section 3 to deal with two applications that could not be studied with the current techniques of the standard approaches based on normal forms.

Acknowledgments. We thank the anonymous referees for remarks that helped to improve a previous version of the paper.

SPATIALLY DISCRETE FITZHUGH–NAGUMO EQUATIONS*

CHRISTOPHER E. ELMER† AND ERIK S. VAN VLECK‡

Abstract. We consider pulse and front solutions to a spatially discrete FitzHugh–Nagumo equation that contains terms to represent both depolarization and hyperpolarization of the nerve axon. We demonstrate a technique for deriving candidate solutions for the McKean nonlinearity and present and apply solvability conditions necessary for existence. Our equation contains both spatially continuous and discrete diffusion terms.

Key words. traveling fronts and pulses, discrete diffusion

1. Introduction. By considering an electrical circuit model with a complicated nonlinear resistor, Hodgkin and Huxley (along with Katz) modeled the ionic conductances that generate the action potential of nerve fibers. To develop their model they performed voltage and space clamping experiments on the giant axon of squids, axons which were *relatively* easy to work with because of their size. The Hodgkin–Huxley equations are a four-variable model which may be reduced to a two-variable model (the FitzHugh–Nagumo (FH-N) ODE model) which preserves much of the dynamics of the Hodgkin–Huxley system by considering fast and slow variables and slaving the other variables. When considering a chain of electrical circuits, diffusion is added as a means of propagation in the spatial variable, thus obtaining the FH-N PDE model. Since the seminal work of Hodgkin, Huxley, and Katz, similar experiments have been performed on nerve axons of vertebrates and its been discovered that, electrically, nerve fibers behave as spatially discrete periodic structures in vertebrates. This is due to the periodically spaced active channels (nodes of Ranvier) in the myelin insulation (in the coating by Schwann cells or oligodendrocytes). Thus it is not only appropriate but correct to model motor nerves in vertebrates with equations which also have a spatially discrete periodic structure, to model with nonlinear differential-difference equations (DDEs), in particular an FH-N DDE model.

Our contribution in this paper is to consider front and pulse solutions for a FitzHugh–Nagumo system with both continuous and discrete diffusion, thus allowing one to compare and contrast the dynamics generated by spatially continuous and spatially discrete models of action potential propagation. By employing a piecewise linear bistable nonlinearity we reduce the problem to a linear inhomogeneous equation, for which candidate solutions can be derived using transform methods. The candidate solutions are then shown to be consistent with our ansatz of a front or pulse solution, a necessary condition for existence. We focus on one-front and one-pulse solutions and prove their existence using two approaches: (1) we show that consistency of the

infinite interval solution may be reduced to showing consistency on a finite interval, and (2) we use the implicit function theorem, thus showing that consistency can be obtained with a perturbation argument. Once we have derived the exact solutions and verified their existence, we investigate the solution behavior as a function of the problem parameters.

Mathematical models of the electrical behavior of axons often come from postulating an equivalent electrical circuit model (leaky underwater cable theory) of the excitable axonal membrane. Consider a single nerve fiber (axon) coated with a lipid material called myelin with periodically spaced gaps (which are commonly call nodes). Assuming the axial currents are constant, the intracellular, I_i, and the extracellular, I_e, currents between two consecutive nodes are (by Ohm's law)

$$Lr_iI_{i,n} = -(v_{i,n+1} - v_{i,n}) \qquad \text{and} \qquad Lr_eI_{e,n} = -(v_{e,n+1} - v_{e,n}),$$

where L is the length of the myelin sheath between the nodes, r_i and r_e are the intracellular and extracellular resistances per unit length of material, and $v_{i,n}$ and $v_{e,n}$ are the intracellular and extracellular voltages in the nth node. Using Kirchoff's laws, one obtains

$$I_{i,n-1} - I_{i,n} = I_{e,n} - I_{e,n-1} = \mu p\left(C\frac{\partial v_n}{\partial t} + I_{ion,n}\right),$$

where the quantities in the parentheses are the capacitive current and the ionic current flowing through the nth node from inside to outside, $v_n = v_{i,n} - v_{e,n}$, μ is the length of each node (here they will all be assumed to be the same), p is the perimeter length of the axon (assumed to be constant), C is the capacitance, and $I_{ion,n}$ is the ionic current at each node. The total transmembrane current at a node n is thus given by

$$p\left(C\frac{\partial v_n}{\partial t} + I_{ion,n}\right) = \frac{1}{\mu L(r_e + r_i)}(v_{n+1} - v_n + v_{n-1} - v_n). \tag{1.1}$$

The change of variables $\tau = t/(CR)$ nondimensionalizes time (where R has units $\Omega\, cm^2$) and (1.1) becomes

$$\frac{dv_n}{d\tau} = \rho(v_{n+1} - 2v_n + v_{n-1}) - RI_{ion,n},$$

where $\rho = R/(\mu Lp(r_i + r_e))$. We want the transmembrane ionic current at each node to possess both a sodium and a potassium component (like an actual nerve we want both a "front" and "back" to our traveling waves), thus we use the analytically simple $RI_{ion,n} = f(v_n) + w_n$, where $f(v_n)$ represents the sodium ion current component and w_n represents the potassium ion current contribution, and we add the governing equation

$$\frac{\partial w_n}{\partial t} = b(v_n - rw_n)$$

for our potassium recovery variable w_n. Note that by setting $b = 0$, one can assume that the behavior is dominated by the leading edge behavior and that recovery is so slow that it can be treated as constant.

Related to our work on the discrete FitzHugh–Nagumo equation is the work of Anderson and Sleeman [1] on the existence and stability of equilibrium solutions, the work of Binczak, Eilbeck, and Scott [9] on ephaptic coupling in systems related to

systems of discrete FitzHugh–Nagumo equations, the work of Tonnelier [38, 39, 40], the work of Carpio and Bonilla [8], as well as the enlightening books of Keener and Sneyd [28] and Scott [36]. Work on the discrete Nagumo equation includes the work of Bell and Cosner [4], Keener [26, 27], and Zinner [44, 45] on existence, stability, and propagation failure, and the work of Mallet-Paret [31, 32] establishing a Fredholm theory for linear mixed type delay equations. Other works on discrete Nagumo type equations include [3, 5, 6, 7, 11, 12, 13, 14, 19, 23, 24]. Notable work on the existence and stability on monotone traveling fronts for the Nagumo PDE include that of Aronson and Weinberger [2] and Fife and McLeod [21] and the original work of Nagumo, Arimoto, and Yoshizawa [34]. Existence and stability of fronts and pulses for the FitzHugh–Nagumo PDE begins from the work of FitzHugh [22] (see also [34]) and includes the work on stability of Jones [25], Maginu [30], and Yanagida [43] (see also [29]), the work on existence of Deng [10] and existence and stability results of Evans [15, 16, 17, 18], Feroe [20], Wang [41, 42], Rinzel and Keller [35], and McKean [33] for the piecewise linear nonlinearity considered here.

This paper is organized as follows. In section 2 we present the model equations to be considered, including the nonlinearity, and derive traveling wave equations. In section 3, using transform techniques, we derive the general form for candidate front and pulse solutions. We consider one-front solutions in section 4 and show similarities with monotone one-front solutions of Nagumo type equations. In sections 5 and 6, using the form of the candidate solutions found in section 3, we derive conditions for the existence of one-pulse solutions. Two approaches are considered: one is perturbative in that it shows under certain conditions the existence of one-pulse solutions in a neighborhood of an existing one-pulse solution, while the other shows the existence of a one-pulse solution more directly, but with assumptions that are more difficult to verify. We present plots of the relationship between the driving force and the speed of wave propagation, and we present waveforms obtained numerically, in section 7.

2. Models. The continuous FitzHugh–Nagumo equations (the FH-N PDEs) can be derived as above by considering a smooth spatial domain (or a spatial scale where the local behavior appears homogenous) and thus allowing the spatial difference terms to go zero. This gives the model

$$\begin{cases} v_t = v_{xx} - f(v) - w, & x \in \mathbb{R}^N,\ t > 0, \\ w_t = b(v - rw), \end{cases} \tag{2.1}$$

where $b > 0$ relates the time scales of the pulse front and the recovery, the pulse's tail, and $r \geq 0$ indicates the strength of recovery.

In this paper we consider a differential-difference equation of FitzHugh–Nagumo type which contains both the diffusion term derived by considering periodically nodes, as in the introduction, and the diffusion term obtained by allowing the spatial domain to be uniform. While this may not be a valid first principle derivation, it does allow us to compare and contrast propagation of action potential in the two perspectives (allowing for different length scale assumptions). The equations of interest are

$$\begin{cases} \dot{v}(\eta,t) = \displaystyle\sum_{i=1}^{N} d_i L_i v(\eta,t) + \sum_{i=1}^{N} \gamma_i \frac{\partial^2 v}{\partial \eta_i^2}(\eta,t) - f(v(\eta,t)) - w(\eta,t), \\ \dot{w}(\eta,t) = b[v(\eta,t) - rw(\eta,t)], \end{cases} \tag{2.2}$$

for

- $\eta \in \mathbb{R}^N$, $t \in \mathbb{R}^+$, and η_i is the ith element of η,
- "$\dot{}$" denotes differentiation with respect to t,
- $d_i \geq 0$, $\gamma_i \geq 0$, $i = 1, \ldots, N$, $b > 0$, and $r \geq 0$ are parameters,
- $L_i v(\eta, t) = v(\eta + e_i, t) - 2v(\eta, t) + v(\eta - e_i, t)$, where e_i is the unit vector with 1 in the ith element, and
- in general, f is a function of "cubic" shape, but for our investigations, we employ the piecewise linear f (as was done in [33, 35, 20, 41, 42, 19, 7, 12, 13, 38, 39, 40]),

$$f(v) \equiv v - h(v-a), \quad \text{where} \quad h(v-a) \equiv \begin{cases} 0, & v < a, \\ [0,1], & v = a, \\ 1, & v > a, \end{cases} \tag{2.3}$$

  where $a \in (0,1)$ is a "detuning" parameter allowing for tuning the behavior based on the behavior of the sodium channels.

While we have discussed only the derivation of the one-dimensional model of propagation along a single nerve axon, the equations presented in (2.2) are three-dimensional. This is simply a generalization we choose to explore and it may (or may not) be used to gain insight into three-dimensional biological domains such as cardiac tissue. We intend to study traveling waves (plane waves), and thus we now specify a direction of propagation with the direction normal $\sigma = \{\sigma_1, \ldots, \sigma_N\}^T \in \mathbb{R}^N$, with $\sum_{i=1}^N \sigma_i^2 = 1$, and apply the classic traveling wave ansatz $\phi(\eta \cdot \sigma - ct) = v(\eta, t)$ and $\psi(\eta \cdot \sigma - ct) = w(\eta, t)$ to (2.2) to obtain the system of differential-difference equations:

$$\begin{cases} -c\phi'(\xi) = \displaystyle\sum_{i=1}^N d_i[\phi(\xi + \sigma_i) - 2\phi(\xi) + \phi(\xi - \sigma_i)] + \gamma\phi''(\xi) - f(\phi(\xi)) - \psi(\xi), \\ -c\psi'(\xi) = b[\phi(\xi) - r\psi(\xi)], \end{cases} \tag{2.4}$$

where $\gamma := \sum_{i=1}^N \gamma_i \sigma_i^2$ and c is the unknown wave speed.

3. Multiple pulse and front solutions. Although our interest in this paper is in one-pulse and one-front solutions, in this section we construct candidate solutions with any number of pulses or fronts, i.e., for $m \in \mathbb{Z}^+$ we construct

- m-pulse solutions where $\phi(-\infty) = \phi(+\infty) = 0$ and $\psi(-\infty) = \psi(+\infty) = 0$, homoclinic connections between constant stable equilibrium solution 0 of (2.4), and
- m-front solutions for $r > 0$ such that $\phi(-\infty) = 0$, $\phi(+\infty) = \frac{r}{1+r}$, and $\psi(-\infty) = 0$, $\psi(+\infty) = \frac{1}{1+r}$, heteroclinic connections between constant stable equilibrium solutions of (2.4) for $0 < a < \frac{r}{1+r}$.

Before we begin construction, using linear transforms, we now take a close look at the piecewise linear nonlinearity f and its effects and a close look at the characteristic equation of (2.4).

3.1. The nonlinearity. Because we intend to apply linear transforms to (2.4) we rewrite the piecewise linear nonlinearity as

$$f(\phi(\xi)) = \phi(\xi) - h(\phi(\xi) - a) = \phi(\xi) - \sum_{k=0}^{n} (-1)^k h(\xi - \xi_k), \tag{3.1}$$

where the ξ_k are the unknown values of ξ, where $\phi = a$, $\phi' \neq 0$, $n = 2m - 1$ for pulse solutions and $n = 2m - 2$ for front solutions. This implies that when finding an

m-pulse solution, one also needs to seek the values $\xi_0 < \xi_1 < \cdots < \xi_{2m-1}$ such that $\phi(\xi_k) = a$ for $k = 0, 1, \ldots, 2m-1$ with

- $\phi(\xi) < a$ for $\xi < \xi_0$, for $\xi_k < \xi < \xi_{k+1}$ with k odd, and for $\xi > \xi_{2m-1}$; and
- $\phi(\xi) > a$ for $\xi_k < \xi < \xi_{k+1}$ with k even.

Similarly, for an m-front solution one also needs to seek $0 = \xi_0 < \xi_1 < \cdots < \xi_{2m-2}$ where $\phi(\xi_k) = a$ for $k = 0, 1, \ldots, 2m-2$ with

- $\phi(\xi) < a$ for $\xi < \xi_0$ and for $\xi_k < \xi < \xi_{k+1}$ with k odd; and
- $\phi(\xi) > a$ for $\xi > \xi_{2m-2}$ and for $\xi_k < \xi < \xi_{k+1}$ with k even.

Because the solutions we seek are translationally invariant we pin down the solution by choosing $\xi_0 = 0$.

Remark 3.1. Due to the set-valued nature of the nonlinearity (2.3) and the corresponding Heaviside functions in (3.1) we have that from (2.4)

$$\lim_{\xi \to \xi_k -} c\phi'(\xi) + \gamma\phi''(\xi) \neq \lim_{\xi \to \xi_k +} c\phi'(\xi) + \gamma\phi''(\xi)$$

and

$$\begin{cases} -c\phi'(\xi_k) - \gamma\phi''(\xi_k) \in \displaystyle\sum_{i=1}^{N} d_i(\phi(\xi_k + \sigma_i) - 2\phi(\xi_k) + \phi(\xi_k - \sigma_i)) - f(\phi(\xi_k)) - \psi(\xi_k), \\ -c\psi'(\xi_k) = b(\phi(\xi_k) - r\psi(\xi_k)) \end{cases}$$

for $k = 0, 1, \ldots, n$.

3.2. The characteristic equation. We consider connecting orbits, homoclinic and heteroclinic connections, between homogeneous equilibria. A central aspect is the eigenstructure of the linearization about these equilibrium solutions. In contrast with the case of continuous diffusion in which the characteristic equation is written in terms of a polynomial, in the case of discrete diffusion the characteristic equation is a transcendental equation with an infinite number of solutions. Three aspects are especially important:

(i) that the equilibria are hyperbolic in the sense that there are not purely imaginary solutions to the characteristic equation;
(ii) that the dominant eigenvalues, those with smallest real part among those with positive real part and those with largest real part among those with negative real part, possess a gap (up to complex conjugates in the case of dominant complex eigenvalue) in their real parts with respect to other eigenvalues; and
(iii) whether the dominant eigenvalues are real or a complex conjugate pair.

To study the characteristic equation of (2.4) we begin by linearizing around a constant equilibrium solution such that $f(\phi) \neq a$ to obtain the following linear differential equation:

$$\begin{cases} -cx'(\xi) = \displaystyle\sum_{i=1}^{N} d_i(x(\xi + \sigma_i) - 2x(\xi) + x(\xi - \sigma_i)) + \gamma x''(\xi) - x(\xi) - y(\xi), \\ -cy'(\xi) = b(x(\xi) - ry(\xi)). \end{cases}$$

On substituting $x(\xi) = \kappa_1 \exp(\lambda\xi)$ and $y(\xi) = \kappa_2 \exp(\lambda\xi)$ we obtain

$$\begin{cases} -c\lambda x(\xi) = \displaystyle\sum_{i=1}^{N} d_i(\exp(\lambda\sigma_i) - 2 + \exp(-\lambda\sigma_i))x(\xi) + \gamma\lambda^2 x(\xi) - x(\xi) - y(\xi), \\ -c\lambda y(\xi) = b(x(\xi) - ry(\xi)). \end{cases} \tag{3.2}$$

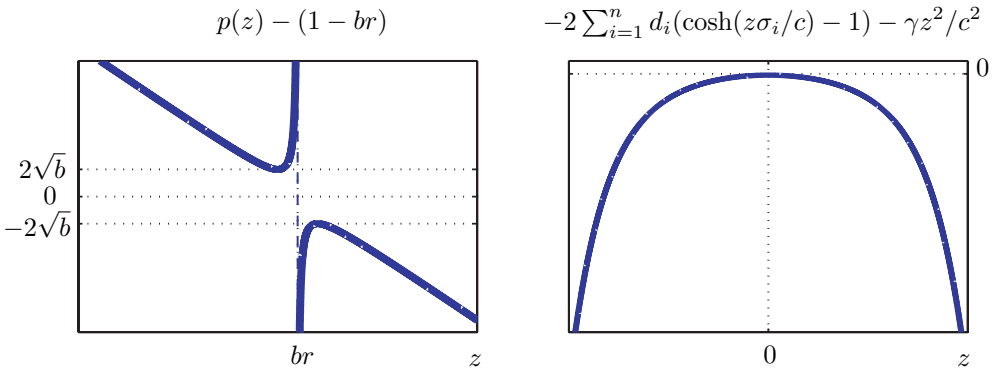

FIG. 3.1. *On the left is a plot of the function* $p(z)-(1-br)$. *To find the real roots of* $p(z)$ *one only needs to plot the constant valued function* $br-1$. *On the right is a plot of* $-2\sum_{i=1}^{n} d_i(\cosh(z\sigma_i/c)-1) - \gamma z^2/c^2$ *when* c *is finite.*

When $br \neq c\lambda$ the second equation of (3.2) is $y(\xi) = bx(\xi)/(br - c\lambda)$, which on substitution into the first equation of (3.2) yields the characteristic equation

$$\Delta(\lambda) := 1 - 2\sum_{i=1}^{n} d_i(\cosh(\lambda\sigma_i) - 1) - \gamma\lambda^2 + \frac{b}{(br - c\lambda)} - c\lambda = 0. \tag{3.3}$$

Consider the change of variables $z = \lambda c$ and let $|c| \to \infty$. Then we have

$$p(z) = 0, \quad \text{where} \quad p(z) \equiv \lim_{|c|\to\infty} \Delta(z/c) = 1 + \frac{b}{(br - z)} - z.$$

For the following it may be illustrative to refer to Figure 3.1. Thus $p'(z) = b/(br-z)^2 - 1$, which equals zero when $z_\pm = br \pm \sqrt{b}$, one value on each side of the vertical asymptote $z = br$. The function p has a maximum of $p(z_+) = 1 - 2\sqrt{b} - br$ at $z_+ = br+\sqrt{b}$ and a minimum of $p(z_-) = 1+2\sqrt{b}-br$ at $z_- = br-\sqrt{b}$. Therefore, in the limit as $|c| \to \infty$, there are two positive real roots (greater than br) to the characteristic equation $\Delta(z/c)$ if $p(z_+) > 0$, i.e., if $r < (1 - 2\sqrt{b})/b$, and two positive real roots (less than br) in the limit if $p(z_-) < 0$, i.e., if $r > (1 + 2\sqrt{b})/b$. If $(1 - 2\sqrt{b})/b < r < (1 + 2\sqrt{b})/b$, then the roots in the limit are complex.

For c finite, the characteristic equation $\Delta(z/c) = p(z) - 2\sum_{i=1}^{n} d_i(\cosh(z\sigma_i/c) - 1) - \gamma z^2/c^2$ always has one negative real root. If the roots in the limit are complex with positive real part, then for all finite c there will not be real positive roots to the characteristic equation. We are interested in cases where the characteristic equation does not admit purely imaginary or zero solutions. In this case the following lemma provides justification for our calculations.

LEMMA 3.1. *Let* (ϕ, ψ) *be a solution of* (2.3), (2.4) *for some* $c \neq 0$. *Then there exists* $\delta_0 > 0$ *such that for some* $K > 0$,

$$|\phi(\xi)| \leq Ke^{\delta_0\xi}, \ |\psi(\xi)| \leq Ke^{\delta_0\xi}, \text{ for } \xi \leq 0.$$

Proof. The proof follows the proof of Lemma 4.1 of [7]; see also the proof of Lemma 3.1 of [13] and the proof of Lemma 2.1 of [12]. ∎

3.3. Construction of candidate solutions. We are now ready to construct candidate solutions by employing the Fourier transform

$$\hat{\phi}_\delta(s) = \int_{-\infty}^{+\infty} e^{-is\xi}\phi_\delta(\xi)d\xi \quad \text{with} \quad \phi_\delta(\xi) = e^{-\delta\xi}\phi(\xi)$$

(and similarly for ψ) and $\delta > 0$ is sufficiently small. Convergence of the integral is guaranteed by Lemma 3.1, which implies that $\phi_\delta(\xi) \to 0$ and $\psi_\delta(\xi) \to 0$ exponentially fast, both as $\xi \to -\infty$ and $\xi \to +\infty$ for $0 < \delta < \delta_0$. Using (2.4) and (3.1) we have that $(\phi_\delta, \psi_\delta)$ satisfy

(3.4)
$$\begin{cases} (-c - 2\gamma\delta)\phi_\delta'(\xi) = \displaystyle\sum_{i=1}^{N} d_i[e^{\delta\sigma_i}\phi_\delta(\xi+\sigma_i) - 2\phi_\delta(\xi) + e^{-\delta\sigma_i}\phi_\delta(\xi-\sigma_i)] + \gamma\ddot{\phi}_\delta(\xi) \\ \qquad\qquad - (1 - c\delta - \gamma\delta^2)\phi_\delta(\xi) + e^{-\delta\xi}\displaystyle\sum_{k=0}^{n}(-1)^k h(\xi - \xi_k) - \psi_\delta(\xi), \\ -c\psi_\delta'(\xi) = b\phi_\delta(\xi) - [br - c\delta]\psi_\delta(\xi). \end{cases}$$

By applying the Fourier transform to (3.4) we obtain the following matrix equation:

$$M(s - i\delta)\begin{pmatrix} \hat{\phi}_\delta(\xi) \\ \hat{\psi}_\delta(\xi) \end{pmatrix} = \frac{1}{is+\delta}\begin{pmatrix} \sum_{k=0}^{n}(-1)^k e^{-is\xi_k} \\ 0 \end{pmatrix} \quad \text{with} \quad M(s) := \begin{pmatrix} R(s) & 1 \\ -b & B(s) \end{pmatrix},$$

where

(3.5)
$$R(s) = -cis + A(s), \quad A(s) = 1 + \gamma s^2 + 2\sum_{i=1}^{N} d_i(1 - \cos(\sigma_i s)), \quad \text{and } B(s) = -cis + br.$$

The matrix function $M(s)$ is invertible near the real axis. To see this note that we have $\det(M(s)) = R(s)B(s) + b$, and the imaginary part of the determinant is bounded away from zero for $s \neq 0$ near the real axis, while for $s = 0$ the real part of the determinant is bounded away from zero since $b > 0$ and $r \geq 0$.

Solving we obtain

$$\hat{\phi}_\delta(s) = \frac{B(s - i\delta)}{(is+\delta)[R(s-i\delta)B(s-i\delta) + b]}\sum_{k=0}^{n}(-1)^k e^{-is\xi_k}$$

and

$$\hat{\psi}_\delta(s) = \frac{b}{(is+\delta)[R(s-i\delta)B(s-i\delta) + b]}\sum_{k=0}^{n}(-1)^k e^{-is\xi_k},$$

and on applying the Fourier inversion theorem we obtain

$$\begin{aligned} \phi(\xi) = e^{\delta\xi}\phi_\delta(\xi) &= \frac{1}{2\pi}\int_{-\infty}^{+\infty}\hat{\phi}_\delta(s)e^{(is+\delta)\xi}ds \\ &= \frac{1}{2\pi i}\int_{-i\delta-\infty}^{-i\delta+\infty}\frac{B(s)}{s(R(s)B(s)+b)}\sum_{k=0}^{n}(-1)^k e^{is(\xi-\xi_k)} \\ &= \frac{1}{2\pi i}\left(\int_{C_\delta} + \int_{S_\delta}\right)\frac{B(s)}{s(R(s)B(s)+b)}\sum_{k=0}^{n}(-1)^k e^{is(\xi-\xi_k)}ds \end{aligned} \tag{3.6}$$

and

$$\psi(\xi) = e^{\delta\xi}\psi_\delta(\xi) = \frac{1}{2\pi i}\left(\int_{C_\delta} + \int_{S_\delta}\right)\frac{b}{s(R(s)B(s)+b)}\sum_{k=0}^{n}(-1)^k e^{is(\xi-\xi_k)}ds, \tag{3.7}$$

where C_δ denotes the two half-lines $(-\infty, -\delta]$ and $[\delta, \infty)$, and S_δ is the half-circle $t \to \delta e^{it}$ for $-\pi \le t \le 0$. Upon simplification, and taking $\delta \to 0$ we next obtain

$$\begin{aligned}\phi(\xi) = \left(\frac{1+(-1)^n}{4}\right)\left(\frac{r}{1+r}\right) &+ \int_0^\infty W(s)\sum_{k=0}^{n}(-1)^k \sin(s(\xi-\xi_k))ds \\ &+ \int_0^\infty X(s)\sum_{k=0}^{n}(-1)^k \cos(s(\xi-\xi_k))ds \quad \text{and} \\ \psi(\xi) = \left(\frac{1+(-1)^n}{4}\right)\left(\frac{1}{1+r}\right) &+ \int_0^\infty Y(s)\sum_{k=0}^{n}(-1)^k \sin(s(\xi-\xi_k))ds \\ &+ \int_0^\infty Z(s)\sum_{k=0}^{n}(-1)^k \cos(s(\xi-\xi_k))ds,\end{aligned} \tag{3.8}$$

where

$$W(s) = \frac{1}{\pi}\left[\frac{b^2 r + C(s)A(s)}{sD(s)}\right], \qquad X(s) = \frac{c}{\pi}\left[\frac{-b+C(s)}{D(s)}\right], \tag{3.9}$$

$$Y(s) = \frac{b}{\pi}\left[\frac{brA(s)+b-c^2s^2}{sD(s)}\right], \quad \text{and} \quad Z(s) = \frac{bc}{\pi}\left[\frac{A(s)+br}{D(s)}\right], \tag{3.10}$$

with $C(s) := b^2r^2 + c^2s^2$ and

$$D(s) := (R(s)B(s)+b)(R(-s)B(-s)+b) = c^2s^2(A(s)+br)^2 + (brA(s) - c^2s^2 + b)^2.$$

Remark 3.2. The construction of candidate solutions is also applicable to more general diffusive operators. For example, consider for $N = 1$, the term (see also [3]) $\sum_{i=1}^{N} d_i(v(\eta+e_i,t) - 2v(\eta,t) + v(\eta-e_i,t)) + \sum_{i=1}^{N}\gamma_i \frac{\partial^2 v}{\partial \eta_i^2}(\eta,t)$ in (2.2) replaced by

$$d\left(-2v(\eta,t) + \sum_{j=1}^{\infty}\alpha_j\{v(\eta+j,t)+v(\eta-j,t)\}\right) + \gamma\frac{\partial^2 v}{\partial \eta_i^2}(\eta,t), \quad \sum_{j=1}^{\infty}\alpha_j = 1.$$

The main change to the derivation is that $A(s)$ in (3.5) becomes

$$A(s) = 1 + \gamma s^2 + 2d\sum_{j=1}^{\infty}\alpha_j(1-\cos(js)).$$

4. Further discussion of one-front candidate solutions. The potential solutions derived in (3.8)–(3.10) are one-front solutions when $n = 0$. Notice that to satisfy the boundary conditions, the detuning parameter a must be restricted so that $a \in [0, r/(1+r)]$. From (3.8)–(3.10) we have the following symmetry property:

$$\phi(\xi, c) = \frac{r}{1+r} - \phi(-\xi, -c) \quad \text{and} \quad \psi(\xi, c) = \frac{1}{1+r} - \psi(-\xi, -c). \tag{4.1}$$

By (3.6) we have that $|\phi(\xi)| = O(e^{\delta\xi})$ as $\xi \to -\infty$, so the boundary condition $\phi(-\infty) = 0$ holds. By (4.1), $\phi(+\infty) = \frac{r}{1+r}$ and the boundary conditions for ψ are satisfied similarly using (3.7) and (4.1).

In certain limits the existence of one-front solutions is known. For instance, if we let $b = \epsilon$ in (2.4), then in the limit as $\epsilon \to 0$, $\psi(\xi) = \psi_0$, a constant, and we can then consider the Nagumo equation with nonlinearity $\tilde{f}(\phi) = f(\phi) - \psi_0$ provided $1 - a < \psi_0 < a$, in which case we seek a one-front solution such that $\phi(-\infty) = \psi_0$ and $\phi(+\infty) = 1 + \psi_0$. In this case previous results (see, e.g., [7]) concerning one-front solutions scaled so that $\tilde{\phi}(-\infty) = 0$ and $\tilde{\phi}(+\infty) = 1$ are applicable by considering a fixed ψ_0 and considering the correspondence $\phi(\xi) = \tilde{\phi}(\xi) + \psi_0$.

Similarly, if we let $r = 1/\epsilon$ and let $\epsilon \to 0$, then $\psi_0 = 0$ and results in [7] on propagation failure, monotonicity of one-front solutions, and monotonicity of the (a, c) relationship are directly applicable. Furthermore, we expect these behaviors to persist in a neighborhood of the limiting parameter value.

4.1. Verification of candidate one-front solution. First, we have assumed $\phi(0) = a$, so by (3.8),

$$a = \frac{1}{2}\left(\frac{r}{1+r}\right) + \int_0^\infty X(s)ds. \tag{4.2}$$

The candidate solution found in (3.8)–(3.10) is consistent with our ansatz of (3.1) with $n = 0$ provided $\phi(\xi) > a$ for $\xi > 0$ and $\phi(\xi) < a$ for $\xi < 0$, where ϕ is defined by (3.8) and a is defined in (4.2). Since the boundary conditions are satisfied, if the roots of the corresponding characteristic equation (3.3) do not lie on the imaginary axis, then for $|\xi|$ large enough the solution ϕ in (3.8) is bounded away from a. Thus it is enough to check $\phi(\xi) > a$ for $\xi > 0$ and $\phi(\xi) < a$ for $\xi < 0$ over a finite interval of values ξ. Clearly, we expect to have one-front solutions for $b \approx 0$ and for r large enough.

5. Further discussion of one-pulse candidate solutions. The derivation in section 3 relied on the assumption that there exists an m-pulse solution (or a front solution). This allowed us to write the nonlinear term as a linear term and a sum of Heaviside functions. In this section we give conditions under which these assumptions may be verified for one-pulse solutions.

Existence of ξ_1. Our assumption for one-pulse solutions was that $\phi(0) = a$ and $\phi(\xi_1) = a$ for some $\xi_1 > 0$ and $\phi(\xi) < a$ for $\xi < 0$ and for $\xi > \xi_1$ with $\phi(\xi) > a$ for $0 < \xi < \xi_1$. Using the form of the candidate solutions (3.8), (3.9), and (3.10), to have $\phi(0) = \phi(\xi_1) = a$, there must be $\xi_1 > 0$ such that $g(\xi_1) = 0$, where

$$\int_0^\infty X(s)(2 - 2\cos(s\xi))ds = \frac{2c}{\pi}\int_0^\infty \frac{-b + C(s)}{D(s)}(1 - \cos(s\xi_1))ds \equiv \frac{2c}{\pi}g(\xi).$$

The existence of such a $\xi_1 > 0$ that satisfies $g(\xi_1) = 0$ for $c \neq 0$ is a *necessary* condition for the existence a one-pulse solution to (2.3) and (2.4). Let

$$Q(s) = -b + C(s),$$

so we can write

$$g(\xi_1) = \int_0^\infty \frac{Q(s)}{D(s)}(1 - \cos(s\xi_1))ds. \tag{5.1}$$

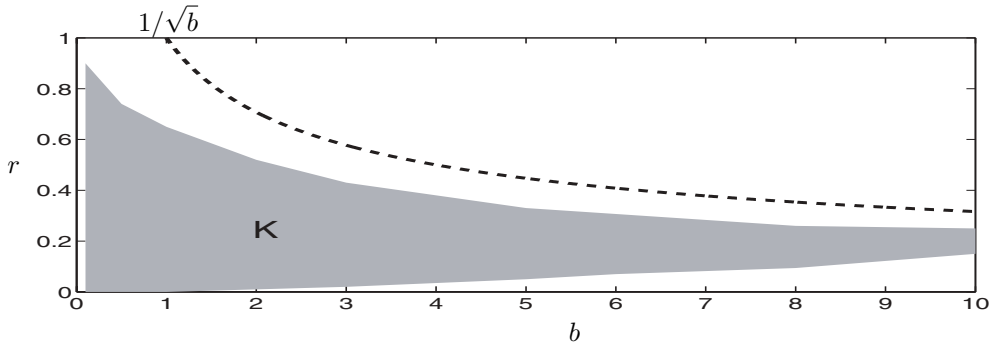

FIG. 5.1. *In this example, the shaded area K indicates values of* (b, r) *which satisfy the conditions of Theorem* 5.1. *The dashed line is* $br^2 = 1$. $N = \gamma = d_1 = c = 1$.

Remark 5.1. This same type of idea could be applied to verifying the existence of general m-pulse solutions. However, in that case, the existence of a zero for a system of $2m - 1$ equations in $2m - 1$ unknowns must be verified.

The idea behind the following theorem is to show that for $\xi_1 > 0$ g is positive for ξ_1 small and g is negative for ξ_1 large. It is motivated by the situation for the spatially continuous problem (2.1) with the piecewise linear nonlinearity (2.3). In the spatially continuous diffusion operator case, $D(s)$ is proportional to s^6 as $s \to \infty$ so that g, g', and g'' are defined by absolutely convergent integrals.

THEOREM 5.1. *There exists a positive zero of* g *defined in* (5.1) *for wave speed* $c \neq 0$ *provided* $br^2 < 1$,

$$\int_0^\infty \frac{Q(s)}{D(s)} ds < 0, \tag{5.2}$$

and for all $\nu > 0$ *sufficiently small*

$$-\int_0^{s^*} s^2 \frac{Q(s)}{D(s)} ds < \int_{s^*}^\infty s^2 \frac{Q(s)}{D(s) + \nu s^6} ds, \tag{5.3}$$

where $s^* = \sqrt{\frac{b(1-br^2)}{c^2}}$.

The shaded region of Figure 5.1 illustrates values of (b, r) which satisfy the conditions of this theorem, for $N = \gamma = d_1 = c = 1$. They were verified by comparison, bounding $D(s)$ with functions of the form $c_1 s^6 + c_2 s^3 + c_3$.

Proof. We have $D(s) > 0$ for $s \geq 0$ and since $br^2 < 1$, $Q(s^*) = 0$, $Q(s) < 0$ for $s < s^*$, and $Q(s) > 0$ for $s > s^*$. We want to show that $g(\xi_1) > 0$ for $\xi_1 > 0$ sufficiently small and $g(\xi_1) < 0$ for $\xi_1 > 0$ sufficiently large.

To this end note that for any bounded continuous function κ defined for $s \geq 0$, for $x > 0$

$$\int_0^\infty \kappa(s) \cos(sx) ds = \int_0^\infty \frac{1}{x} \kappa(u/x) \cos(u) du \to 0 \quad \text{as } x \to \infty.$$

Thus, $g(\xi_1) < 0$ for $\xi_1 > 0$ sufficiently large follows from (5.2).

Next observe that $g(0) = 0$ and define

$$h(\xi_1) = \int_0^{s^*} \frac{Q(s)}{D(s)} (1 - \cos(s\xi_1)) ds + \int_{s^*}^\infty \frac{Q(s)}{D(s) + \nu s^6} (1 - \cos(s\xi_1)) ds.$$

Then

$$h'(\xi_1) = \int_0^{s^*} s\frac{Q(s)}{D(s)}\sin(s\xi_1)ds + \int_{s^*}^{\infty} s\frac{Q(s)}{D(s)+\nu s^6}\sin(s\xi_1)ds,$$

and so $h'(0) = 0$. Similarly,

$$h''(\xi_1) = \int_0^{s^*} s^2\frac{Q(s)}{D(s)}\cos(s\xi_1)ds + \int_{s^*}^{\infty} s^2\frac{Q(s)}{D(s)+\nu s^6}\cos(s\xi_1)ds,$$

and since for $s \geq s^*$, $Q(s) \geq 0$ and $(D(s)+\nu s^6)^{-1} < (D(s))^{-1}$, (5.3) implies that g is increasing for $\xi_1 = 0$, so that $g(\xi_1) > 0$ for $\xi_1 > 0$ sufficiently small. Thus, since g is continuous and changes sign at least once, there exists a $\xi_1 > 0$ such that $g(\xi_1) = 0$. □

COROLLARY 5.1. *There exists a positive zero of g defined in* (5.1) *for wave speed $c \neq 0$ provided $br^2 < 1$ and either*

(i) *for $d_1 = \cdots = d_N = 0$ and $\gamma > 0$,* (5.2) *holds and* (5.3) *holds with $\nu = 0$, or*

(ii) *for $d_j \geq 0$, with at least one $d_j > 0$, $j = 1, \ldots, N$, and $\gamma = 0$,* (5.2) *holds.*

Proof. When $d_1 = \cdots = d_N = 0$ and $\gamma > 0$, then the integral on the right-hand side of (5.3) is absolutely convergent with $\nu = 0$. However, for $d_j \geq 0$, with at least one $d_j > 0$, and $\gamma = 0$, the right-hand side of (5.3) approaches $+\infty$ as $\nu \to 0$, and so in this case (5.3) is always satisfied. □

6. Existence of solutions. An important aspect of employing the McKean nonlinearity (2.3) is that (3.8)–(3.10) provide an explicit form (up to quadrature) for candidate solutions. This explicit form is useful in determining $\{\xi_k\}_k^n$ since for $\xi_0 = 0$ and $n \geq 1$, $\{\xi_k\}_k^n$ satisfies the system of nonlinear equations

$$\phi(0) - \phi(\xi_k) = 0, \quad k = 1, \ldots, n, \tag{6.1}$$

and in subsequently verifying

$$(-1)^k(\phi(0) - \phi(\xi)) > 0, \quad \xi \in (\xi_{k-1}, \xi_k), \quad k = 0, \ldots, n, \tag{6.2}$$

where we have set $\xi_{-1} = -\infty$ and $\xi_{n+1} = +\infty$. A necessary condition for (6.2) is that

$$(-1)^k \lim_{\xi \to \xi_k \pm} \phi'(\xi) > 0, \tag{6.3}$$

which for $c > 0$ involves only a one-sided limit since

$$(-1)^k \lim_{\xi \to \xi_k -} \phi'(\xi) > (-1)^k \lim_{\xi \to \xi_k +} \phi'(\xi). \tag{6.4}$$

One needs only to determine if the inequalities (6.2) are satisfied outside a neighborhood of $\{\xi_k\}_{k=1}^n$ if (6.3) holds.

The existence of $\{\xi_k\}_{k=0}^n$ is trivial for one-front solutions, $n = 0$, since we may choose $\xi_0 = 0$ by translation invariance, while for one-pulse solutions, $n = 1$, Theorem 5.1 and Corollary 5.1 provide criteria for the existence of $\xi_1 > 0$. In general for $n \geq 2$ establishing the existence of $\{\xi_k\}_k^n$ such that (6.1) holds is more difficult since this results in a nonlinear system of $n \geq 2$ equations in n unknowns. In the case of $n \geq 2$ perturbation/continuation techniques are more promising. One-front ($n = 0$) and one-pulse ($n = 1$) solutions provide building blocks for more general $n \geq 2$ solutions.

We are interested in connecting orbits between hyperbolic equilibria in which there is gap between

(1) the dominant solution(s) to the characteristic equation
(2) and the rest of the solutions to the characteristic equation.

The following lemmas show that for the characteristic equation (3.3) of (2.4) with (2.3) with $N = 1$, $d_1 = d > 0$, and $\gamma = 0$

- there are no purely imaginary solutions
- and if $\sinh((1 + 2d - \sqrt{4d^2 + c^2})/c) \neq -c/(2d)$, then all the solutions are simple.

LEMMA 6.1. *Let λ_1, λ_2 denote two solutions to the characteristic equation* (3.3). *Write $\lambda_j = a_j + ib_j$ for $j = 1, 2$ and let $c > 0$ be given. If $(br - ca_1)^2 + (cb_j)^2 > 0$ for $j = 1, 2$, then $a_1 = a_2$ implies $b_1 = \pm b_2$.*

Proof. We have that λ_j is a solution of the characteristic equation provided

$$\begin{aligned} &(br - ca_j)R_j + cb_jI_j = 0, && R_j = 1 - 2d(\mathrm{Re}(\cosh(\lambda_j)) - 1) - ca_j, \\ &\qquad\qquad \text{where} \\ &-cb_jR_j + (br - ca_j)I_j = 0, && I_j = -2d(\mathrm{Im}(\cosh(\lambda_j))) - cb_j, \end{aligned}$$

for $j = 1, 2$. Thus, if $a_1 = a_2$ and $(br - ca_1)^2 + (cb_j)^2 > 0$, then $R_j = 0$ and $I_j = 0$ for $j = 1, 2$, and so

$$1 - 2d(\cos(b_j)\cosh(a_j) - 1) - ca_j = 0, \quad -2d\sin(b_j)\sinh(a_j) - cb_j = 0 \tag{6.5}$$

for $j = 1, 2$. Using the first equation in (6.5), if $a_1 = a_2$, then $\cos(b_1) = \cos(b_2)$, and so $\sin(b_1) = \pm\sin(b_2)$. If $\sin(b_1) = \sin(b_2)$, then the second equation in (6.5) implies that $c(b_1 - b_2) = 0$, and if $\sin(b_1) = -\sin(b_2)$, then the second equation in (6.5) gives $c(b_1 + b_2) = 0$. ∎

LEMMA 6.2. *If $c > 0$, $b > 0$, $r \geq 0$, and $d > 0$, then any root $\lambda = x + iy$ of* (3.3) *has $x \neq 0$.*

Proof. If we write $\Delta(\lambda) = 0$ as $N(\lambda) + b/(br - c\lambda) = 0$, then $r = 0$ implies $\lambda \neq 0$. If $r > 0$ and $\lambda = 0$ is a solution, then $N(0) + 1/r = 0$, so $1 - 2d(\cos(0) - 1) + 1/r = 0$, which cannot occur for $r > 0$. If $x = 0$, but $y \neq 0$, then by the argument in the proof of Lemma 6.1, $\mathrm{Re}(N(\lambda)) = 0$ and $\mathrm{Im}(N(\lambda)) = 0$, so we have $1 + 2d - \cos(y) = 0$ and $-cy = 0$, which cannot both be simultaneously satisfied. ∎

LEMMA 6.3. *If for $c > 0$ and $d > 0$ one has $\sinh((1 + 2d - \sqrt{4d^2 + c^2})/c) \neq -c/(2d)$, then there does not exist a double root to* (3.3) *for λ not purely imaginary.*

Proof. If there is a double root, λ, then $\Delta(\lambda) = 0$ and $\Delta'(\lambda) = 0$. Write $\Delta(\lambda)$ as $N(\lambda) + b/(br - c\lambda)$, so $\Delta'(\lambda) = N'(\lambda) + cb/(br - c\lambda)^2$. Thus, $\Delta'(\lambda) = N'(\lambda) + \frac{c}{b}N^2(\lambda)$, so by the argument in the proof of Lemma 6.1, $\mathrm{Re}(N(\lambda)) = 0$ and $\mathrm{Im}(N(\lambda)) = 0$, and if there is a double root, then $\Delta'(\lambda) = N'(\lambda) = 0$. Then for $\lambda = x + iy$, $-2d\cos(y)\sinh(x) - c = 0$ and $-2d\sin(y)\cosh(x) = 0$, we have $\sin(y) = 0$, and since $\mathrm{Im}(N(\lambda)) = 0$, we have $-2d\sin(y)\sinh(x) - cy = 0$, so $y = 0$. Thus, $-2d\sinh(x) - c = 0$, which implies $\sinh(x) = -c/(2d)$ and $\cosh(x) = \sqrt{4d^2 + c^2}/(2d)$. Hence, the only way for $\mathrm{Re}(N(\lambda)) = 0$ is if $x = (1 + 2d - \sqrt{4d^2 + c^2})/c$. ∎

6.1. Existence of one-pulse solutions. Given existence of $\xi_1 > 0$ such that $g(\xi_1) = 0$ for g in (5.1), we now turn our attention to showing existence of one-pulse solutions. We proceed in two ways: in the first we assume the existence at a particular value of the wave speed c and then show existence (under certain conditions) in a neighborhood (Theorem 6.4); in the second we verify that $\phi(\xi) < a$ only when $\xi < 0$ and $\xi > \xi_1$ ($\phi(\xi) > a$ for $\xi \in (0, \xi_1)$) and then show that this condition can in certain cases be reduced to checking on finite intervals (Theorems 6.5 and 6.6).

THEOREM 6.4. *Suppose for fixed values of the parameters and* $(a, c) = (a^*, c^*)$ *with* $c^* > 0$ *we have a one-pulse solution defined for* $\xi_1 > 0$ *such that*

$$\text{for } \xi \in (0, \xi_1),\ \phi(\xi) - \phi(0) > 0, \quad \text{for } \xi < 0 \text{ and } \xi > \xi_1,\ \phi(\xi) - \phi(0) < 0, \tag{6.6}$$

$$\lim_{\xi \to 0^{\pm}} \phi'(\xi) > 0 \text{ and } \lim_{\xi \to \xi_1^{\pm}} \phi'(\xi) < 0, \tag{6.7}$$

and

$$0 < \left| \int_0^{\infty} \frac{sQ(s)}{D(s)} \sin(s\xi_1) ds \right| < \infty. \tag{6.8}$$

Then for all c *in a neighborhood of* c^* *there exist one-pulse solutions to* (2.3), (2.4).

Proof. We argue by the implicit function theorem. We need to show that ξ_1 depends smoothly on c. This follows from (6.8) since by direct calculation

$$\xi_1'(c) = -\frac{\int_0^{\infty} \frac{Q_1(s)}{D^2(s)}(1 - \cos(s\xi_1)) ds}{\int_0^{\infty} \frac{sQ(s)}{D(s)} \sin(s\xi_1) ds}, \tag{6.9}$$

where $Q_1(s) = Q_c(s)D(s) - Q(s)D_c(s)$ and Q_c and D_c are the derivatives of Q and D with respect to c, respectively. Now by the implicit function theorem, (6.6) and (6.7) hold in a neighborhood of c^* since the derived solution (3.8)–(3.10) and the one-sided derivatives at $\xi = 0$ and $\xi = \xi_1$ depend smoothly on ξ_1 and c. ∎

Inequalities (6.2), when satisfied over the entire real line, imply existence; see Theorem 6.5. Lemmas 6.1–6.3 that show the hyperbolicity of the equilibria and the gap condition are used to show that is sufficient to check these inequalities over a certain finite interval; see Theorem 6.6.

THEOREM 6.5. *If* $g(\xi_1) = 0$ *for* $\xi_1 > 0$ *and*

$$\int_0^{\infty} W(s)[\sin(s(\xi_1 + \delta)) - \sin(s\delta) - \sin(s\xi_1)] ds < \left| \int_0^{\infty} X(s)[\cos(s(\xi_1 + \delta)) - \cos(s\delta)] ds \right|, \tag{6.10}$$

if $\delta > 0$,

$$-\int_0^{\infty} W(s)[\sin(s(\xi_1 + \delta)) - \sin(s\delta) - \sin(s\xi_1)] ds < \int_0^{\infty} X(s)[\cos(s(\xi_1 + \delta)) - \cos(s\delta)] ds, \tag{6.11}$$

if $-\xi_1 < \delta < 0$, *then there exists a one-pulse solution to* (2.3), (2.4).

Proof. We assume there exists a positive zero, ξ_1, of g. Then for this $\xi_1 > 0$ we have $\phi(0) = a$ and $\phi(\xi_1) = a$. We show that (6.10) implies that $\phi(\xi) < a$ for $\xi < 0$ and $\xi > \xi_1$ and (6.11) implies $\phi(\xi) > a$ for $0 < \xi < \xi_1$. Recalling that $g(\xi_1) = 0$ implies $\int_0^{\infty} X(s)(1 - \cos(s\xi_1))\, ds = 0$ along with the solution equalities (3.8)–(3.10), (6.10) can be rewritten as

$$-\phi(0) < -\phi(-\delta) \qquad \text{and} \qquad -\phi(0) < -\phi(\delta + \xi_1), \qquad \delta > 0,$$

which implies $\phi(\xi) < a \equiv \phi(0)$ for $\xi < 0$ and for $\xi > \xi_1$. Similarly (6.11) can be rewritten as

$$\phi(0) < \phi(\delta + \xi_1), \qquad -\xi_1 < \delta < 0,$$

which implies $\phi(\xi) > a \equiv \phi(0)$ for $0 < \xi < \xi_1$. ∎

THEOREM 6.6. *Suppose for some value $c > 0$ and all other parameter values fixed there exists $\xi_1 > 0$ such that $g(\xi_1) = 0$. Suppose that the characteristic equation (3.3) has no solutions on the imaginary axis and order the solutions with positive real parts by the real parts: $\mathrm{Re}(\lambda_1^+) \le \mathrm{Re}(\lambda_2^+) \le \mathrm{Re}(\lambda_3^+) \le \cdots$ and similarly for the solutions with negative real parts as: $\mathrm{Re}(\lambda_1^-) \ge \mathrm{Re}(\lambda_2^+) \ge \mathrm{Re}(\lambda_3^+) \ge \cdots$. If $\lambda_1^+ = \bar{\lambda}_2^+$ assume $\epsilon_0^+ := \mathrm{Re}(\lambda_3^+) - \mathrm{Re}(\lambda_2^+) > 0$. If $\lambda_1^+ \neq \bar{\lambda}_2^+$ assume $\epsilon_0^+ := \mathrm{Re}(\lambda_2^+) - \mathrm{Re}(\lambda_1^+) > 0$. Similarly, assume $\epsilon_0^- > 0$ for the solutions with negative real parts. Then there exist $T^+ > 0$ and $T^- < 0$ such that (6.10) and (6.11) need only be checked on $(0, T^+)$ and $(0, -T^-)$, respectively.*

Proof. Consider (3.6) and observe that if $\lambda \in \mathbb{C}$ is a solution of the characteristic equation (3.3), then $-i\lambda$ is a zero of $R(s) + b/B(s)$ in (3.6). First assume that $0 < \epsilon^+ < \epsilon_0^+$ and shift the contour in (3.6) from $\mathrm{Im}\, s = -\delta$ to $\mathrm{Im}\, s = -(\mathrm{Re}(\lambda_1^+) + \epsilon^+)$. Then there are two cases: $\lambda_1^+ = \bar{\lambda}_2^+$ and $\lambda_1^+ \neq \bar{\lambda}_2^+$. If $\lambda_1^+ = \bar{\lambda}_2^+$, then we obtain

$$\begin{aligned}\phi(\xi) &= -\frac{B(s)\{e^{is\xi} - e^{is(\xi-\xi_1)}\}}{s(R'(s)B(s) + R(s)B'(s))}\bigg|_{s=-i\lambda_1^+} - \frac{B(s)\{e^{is\xi} - e^{is(\xi-\xi_1)}\}}{s(R'(s)B(s) + R(s)B'(s))}\bigg|_{s=-i\lambda_2^+} \\ &\quad + \frac{1}{2\pi i}\int_{-i(\mathrm{Re}(\lambda_1^+)+\epsilon^+)-\infty}^{-i(\mathrm{Re}(\lambda_1^+)+\epsilon^+)+\infty} \frac{B(s)\{e^{is\xi} - e^{is(\xi-\xi_1)}\}}{s(R(s)B(s) + b)} ds \\ &= C^+\{e^{\lambda_1^+\xi} - e^{\lambda_1^+(\xi-\xi_1)}\} + O(e^{(\lambda_1^+ + \epsilon^+)\xi})\end{aligned}$$

as $\xi \to -\infty$. Observe that

$$C^+ = -\frac{B(s)}{s(R'(s)B(s) + R(s)B'(s))}\bigg|_{s=-i\lambda_1^+} - \frac{B(s)}{s(R'(s)B(s) + R(s)B'(s))}\bigg|_{s=-i\lambda_2^+}.$$

If $\lambda_1^+ \neq \bar{\lambda}_2^+$ (and λ_1^+, λ_2^+ real), then we obtain

$$\begin{aligned}\phi(\xi) &= -\frac{B(s)\{e^{is\xi} - e^{is(\xi-\xi_1)}\}}{s(R'(s)B(s) + R(s)B'(s))}\bigg|_{s=-i\lambda_1^+} \\ &\quad + \frac{1}{2\pi i}\int_{-i(\lambda_1^+ + \epsilon^+)-\infty}^{-i(\lambda_1^+ + \epsilon^+)+\infty} \frac{B(s)\{e^{is\xi} - e^{is(\xi-\xi_1)}\}}{s(R(s)B(s) + b)} ds \\ &= C^+\{e^{\lambda_1^+\xi} - e^{\lambda_1^+(\xi-\xi_1)}\} + O(e^{(\lambda_1^+ + \epsilon^+)\xi})\end{aligned}$$

as $\xi \to -\infty$, where $C^+ = -\frac{B(s)}{s(R'(s)B(s)+R(s)B'(s))}|_{s=-i\lambda_1^+}$. Thus, there exists $T^- < 0$ such that $\phi(\xi) < \phi(0) =: a$ for $\xi \le T^-$.

The argument for solutions to the characteristic equation (3.3) with negative real parts is treated similarly by moving the contour up. ∎

7. Numerical results. In this section we present numerical results obtained by numerical integration of (3.8)–(3.10) and for one-pulse solutions by determining the positive zeros of (5.1). We approximate the integrals using the adaptive Gaussian quadrature code `adapt` of [37] after truncation to the interval $[0, 10^6]$. To find zeros of g we use the combined secant/bisection code `zero` of [37]. We focus on one-front, one-pulse, and two-pulse solutions, exhibit (a, c) curves, and waveforms of (3.8)–(3.10) with both continuous and discrete diffusion.

7.1. (a, c) curves. In Figure 7.1 we plot (a, c) curves for one-front solutions by approximating (4.2). We set $N = d_1 = d = 1$ and $\gamma = 0$ and vary b and r.

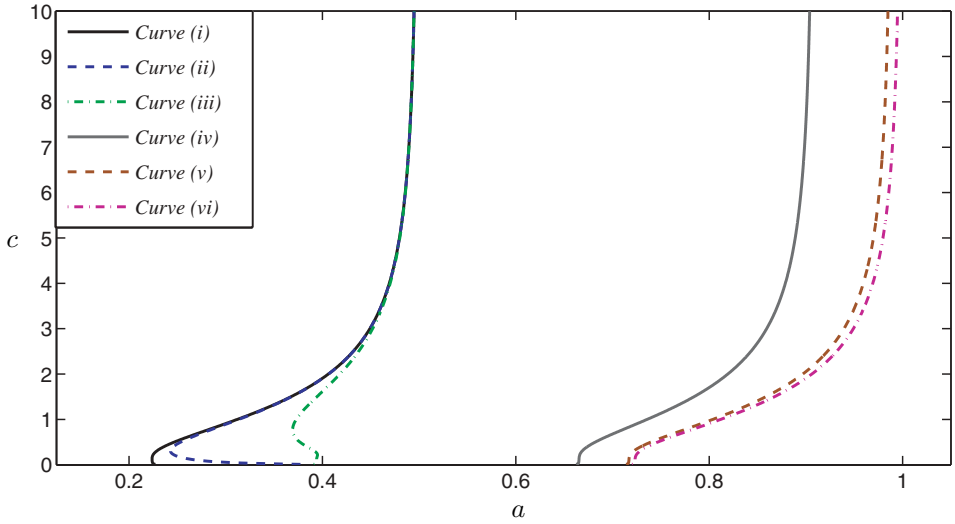

FIG. 7.1. *Plot of* (a, c) *curves (moving from left to right) for* (i) $(d, \gamma, b, r) = (1, 0, 10^{-4}, 1)$, (ii) $(d, \gamma, b, r) = (1, 0, 10^{-2}, 1)$, (iii) $(d, \gamma, b, r) = (1, 0, 1, 1)$, (iv) $(d, \gamma, b, r) = (1, 0, 1, 10^{1})$, (v) $(d, \gamma, b, r) = (1, 0, 1, 10^{2})$, *and* (vi) $(d, \gamma, b, r) = (1, 0, 0, 0)$, *the discrete Nagumo equation.*

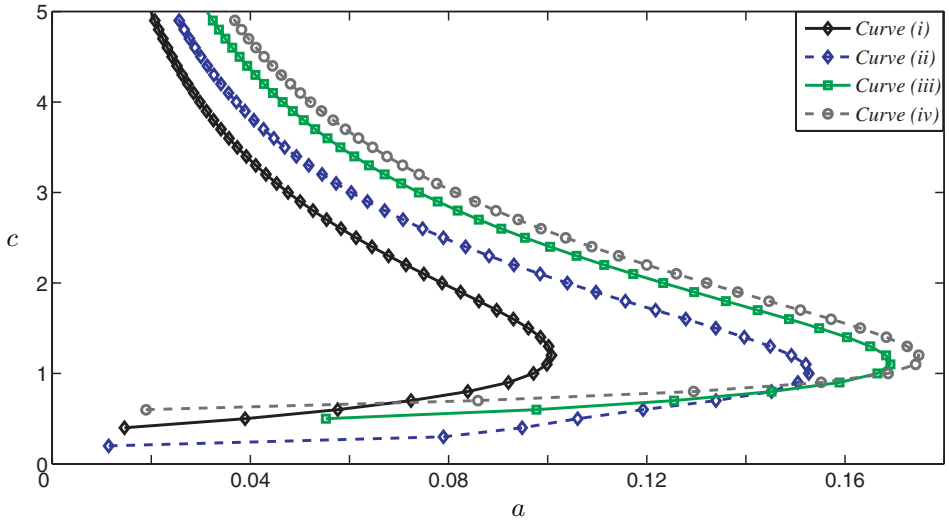

FIG. 7.2. *Plot of* (a, c) *curves (moving from left to right) for* (i) $(d, \gamma, b, r) = (1, 0, 1, 0)$, (ii) $(d, \gamma, b, r) = (0.8, 0.2, 1, 0)$, (iii) $(d, \gamma, b, r) = (0.4, 0.6, 1, 0)$, *and* (iv) $(d, \gamma, b, r) = (0, 1, 1, 0)$.

Notice the nonuniqueness suggested for $(b, r) = (10^{-2}, 1)$ and $(b, r) = (1, 1)$. The curves limit to $r/(r + 1)$ as $c \to \infty$. In Figure 7.2 we plot (a, c) curves for one-pulse solutions (these are actually (a, c) curves obtained when there exists $\xi_1 > 0$ such that $g(\xi_1) = 0$) for various values of the parameters d, γ, b, r. The plot illustrates the difference between the behavior with continuous and discrete diffusion. In the case of continuous diffusion it is known that the fast waves, i.e., those above the tip on the (a, c) curve, are stable (see [43, 30, 25, 29]), while the slow waves (those below the tip)

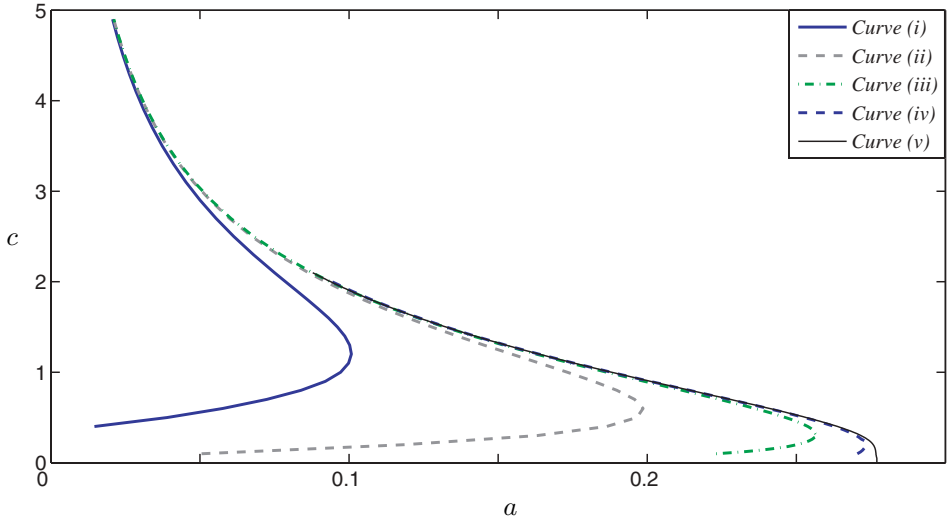

FIG. 7.3. *Plot of* (a, c) *curves (moving from left to right) for* (i) $(d, \gamma, b, r) = (1, 0, 1, 0)$, (ii) $(d, \gamma, b, r) = (1, 0, 10^{-1}, 0)$, (iii) $(d, \gamma, b, r) = (1, 0, 10^{-2}, 0)$, (iv) $(d, \gamma, b, r) = (1, 0, 10^{-3}, 0)$, *and the limiting* (a, c) *curve obtained from the discrete Nagumo equation.*

are unstable. In Figure 7.3 we highlight the dependence of the (a, c) relationship on the parameter $b > 0$ and compare it with the limiting (a, c) curve obtained from the discrete Nagumo equation, i.e., $b = 0$. Notice how the range of propagation failure in the discrete Nagumo equation limits tip of the (a, c) curve. The range of propagation failure limits the size of a for which there are one pulse solutions. Observe the larger values of a that are possible when b is small and the larger values of a obtained for the plot of the continuous (a, c) curve with $\gamma = 1$ as compared to the discrete for $d = 1$. In Figure 7.4 we vary the parameter $r > 0$. We set $b = 1$ and then have the requirement from Theorem 5.1 that $r^2 < 1$. In the plot for $r > 0$ there is an upper bound in c as well as a lower bound in c on the (a, c) curve.

7.2. Waveforms. In Figure 7.5 we plot one-front waveforms $\phi(\xi)$ and $\psi(\xi)$ fixing $(d, c, \gamma) = (1, 1, 0)$ and varying (b, r). In Figure 7.6 we plot one-pulse waveforms $\phi(\xi)$ and $\psi(\xi)$ fixing $(b, r) = (1, 0)$, setting $(d, \gamma) = (1, 0)$, and varying the wavespeed c. Refer to Figure 7.2 for the parameter values in the (a, c) curve. The plot for $c = 0.6$ does not satisfy our assumption of a one-pulse solution since it violates $\phi(\xi) < a$ for $\xi > \xi_1$. Note, however, that $c = 0.6$ is one of the smaller values of c obtained in the (a, c) curve in Figure 7.2. In Figure 7.7 we plot waveforms $\phi(\xi)$ and $\psi(\xi)$ fixing $(b, r) = (1, 0)$, setting $(d, \gamma) = (0, 1)$, and varying the wavespeed c. The waveforms for the continuous operator are smooth compared to the waveforms for the discrete operator especially for small wavespeeds. The two-pulse solution in Figure 7.8 is obtained by superimposing two identical one-pulse solutions, using the superimposed one-pulse solutions as an initial guess and then applying Newton's method. The one-pulse solution is obtained from $(d, \gamma, c, b, r) = (1, 0, 1, 1, 0)$ and the pulses are put at a distance (in ξ) of 40 units apart. The value of a is slightly perturbed from the value of a for the one-pulse as one might expect (see [41]). In Figure 7.9 we plot the dependence of the parameter a on the distance between the pulses, $\xi_2 - \xi_1$, and compare with the value of a obtained for the one-pulse solution.

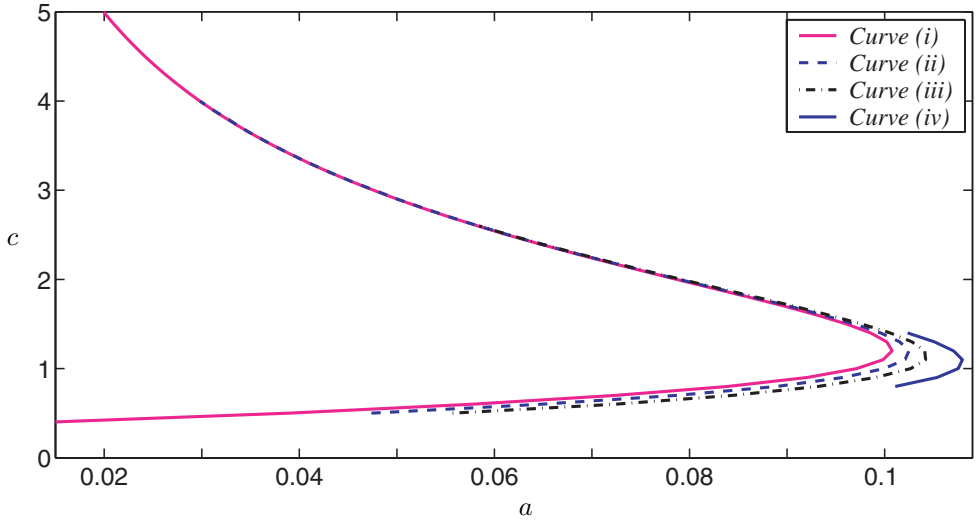

FIG. 7.4. *Plot of* (a, c) *curves (moving from left to right) for* (i) $(d, \gamma, b, r) = (1, 0, 1, 0)$, (ii) $(d, \gamma, b, r) = (1, 0, 1, 1/16)$, (iii) $(d, \gamma, b, r) = (1, 0, 1, 1/8)$, *and* (iv) $(d, \gamma, b, r) = (1, 0, 1, 1/4)$.

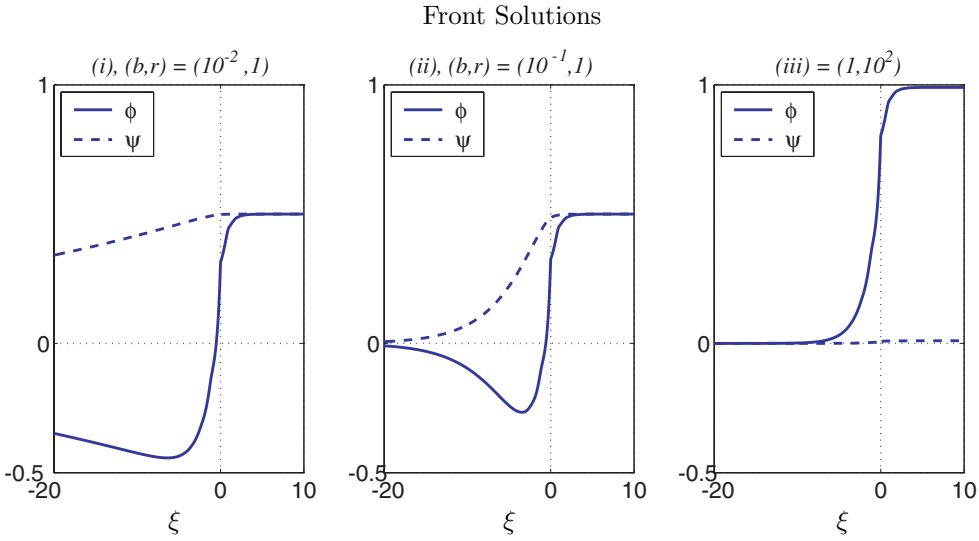

FIG. 7.5. *Plot of one-front waveforms* $\phi(\xi)$ *and* $\psi(\xi)$ *for fixed* $(d, c, \gamma) = (1, 1, 0)$, *and* (i) $(b, r) = (10^{-2}, 1)$, (ii) $(b, r) = (10^{-1}, 1)$, *and* (iii) $(b, r) = (1, 10^2)$.

7.3. Mixed continuous/discrete model. As an example of a model with continuous diffusion in one direction and discrete diffusion in the other coordinate direction we consider (2.2) with $N = 2$, $d_1 = d$, $d_2 = 0$, and $\gamma_1 = 0$, $\gamma_2 = \gamma$. Consider the direction of propagation $\sigma \in \mathbb{R}^2$ such that $||\sigma||_2 = 1$, and apply the traveling wave ansatz $u(\eta, t) = \phi(\eta \cdot \sigma - ct)$ and $w(\eta, t) = \psi(\eta \cdot \sigma - ct)$ to obtain (see (2.4))

$$(7.1)\quad \begin{cases} -c\phi'(\xi) = d(\phi(\xi + \sigma_1) - 2\phi(\xi) + \phi(\xi - \sigma_1)) + \gamma\sigma_2^2\phi''(\xi) - f(\phi(\xi)) - \psi(\xi), \\ -c\psi'(\xi) = b(\phi(\xi) - r\psi(\xi)). \end{cases}$$

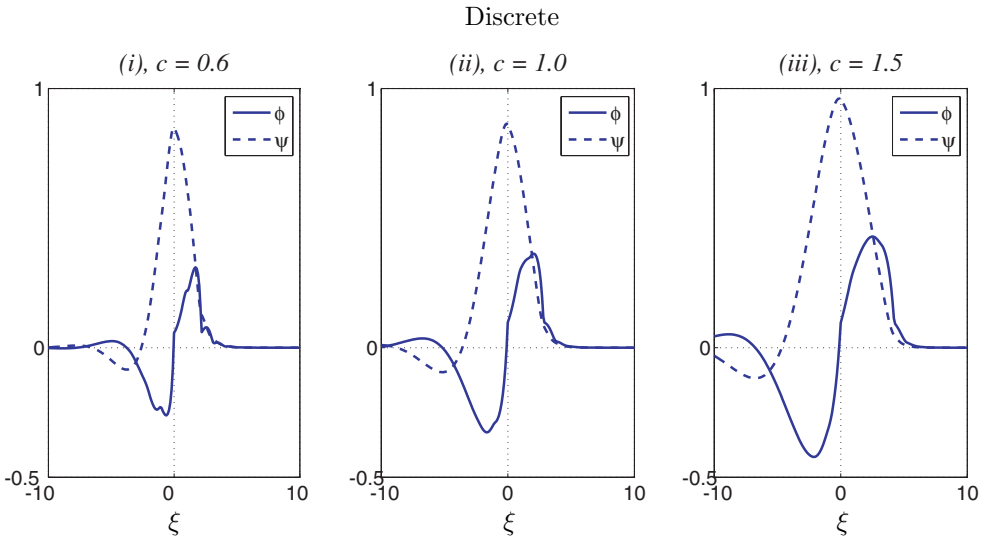

FIG. 7.6. *Discrete. Plot of waveforms for fixed* $(b, r) = (1, 0)$*, and* (i) $(d, \gamma, c) = (1, 0, 0.6)$, (ii) $(d, \gamma, c) = (1, 0, 1)$, (iii) $(d, \gamma, c) = (1, 0, 1.5)$.

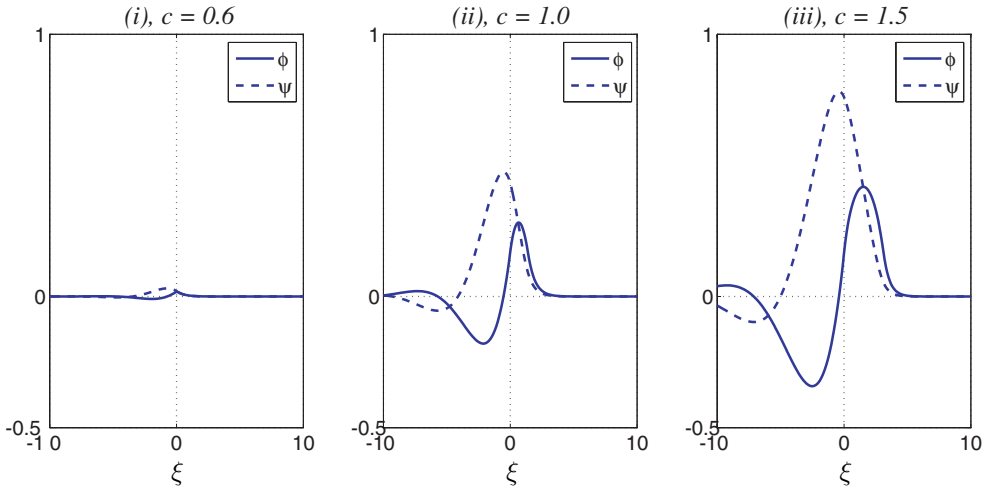

FIG. 7.7. *Continuous. Plot of waveforms for fixed* $(b, r) = (1, 0)$*, and* (i) $(d, \gamma, c) = (0, 1, 0.6)$, (ii) $(d, \gamma, c) = (0, 1, 1)$, (iii) $(d, \gamma, c) = (0, 1, 1.5)$.

If we rescale variables $x = \xi/\sigma_1$ and $\tilde{c} = c/\sigma_1$, then (7.1) becomes

$$\begin{cases} -\tilde{c}\phi'(x) = d(L\phi)(x) + g\phi''(x) - f(\phi(x)) - \psi(x), \\ -\tilde{c}\psi'(x) = b(\phi(x) - r\psi(x)), \end{cases} \tag{7.2}$$

where $g = \gamma\frac{\sigma_2^2}{\sigma_1^2}$ for $\sigma_1 \neq 0$ and $(L\phi)(x) = \phi(x+1) - 2\phi(x) + \phi(x-1)$.

In Figure 7.10 we set $(d, \gamma, b, r) = (1, 1, 1, 0)$ and $(d, \gamma, b, r) = (1, 0, 1, 0)$, set $c = 1$ and $c = 2$, let $\sigma_1 = \cos(\theta)$ and $\sigma_2 = \sin(\theta)$ for $0 \leq \theta \leq 2\pi$. The plot in Figure 7.10(i)

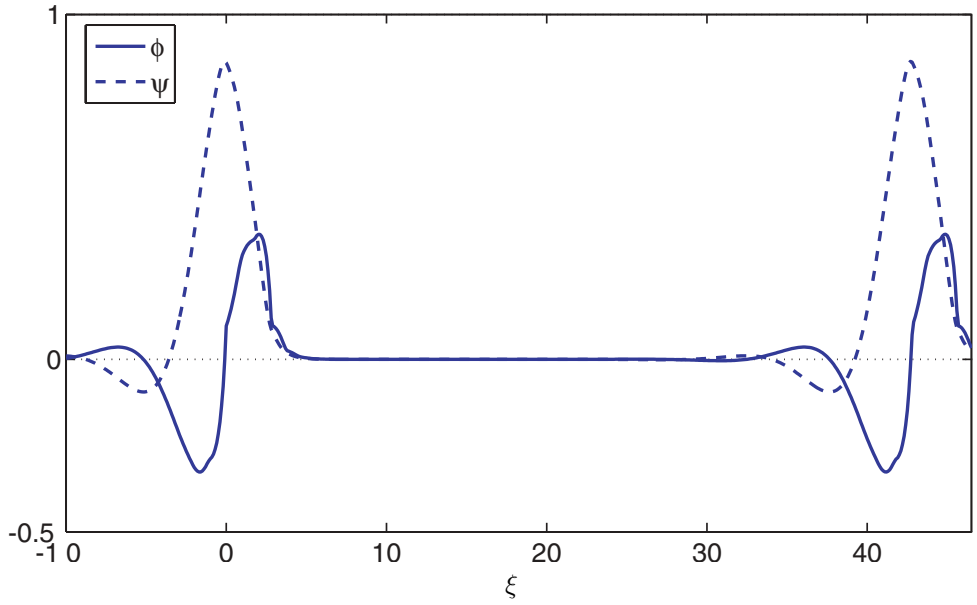

FIG. 7.8. *Plot of two-pulse waveforms for* $(d, c, \gamma, b, r) = (1, 1, 0, 1, 0)$ *obtained as a perturbation of a superposition of two identical one-pulse solutions.*

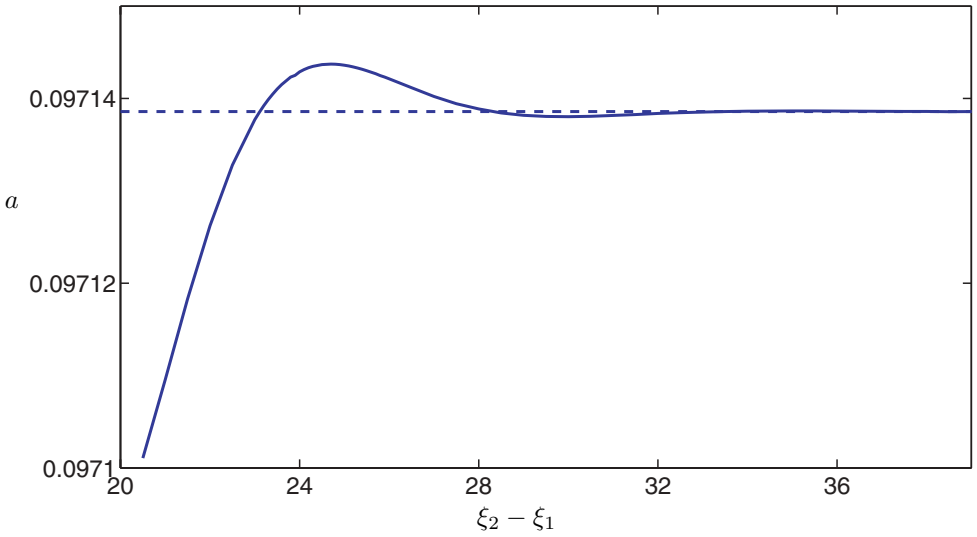

FIG. 7.9. *Plot of computed* a *obtained for* $(d, c, \gamma, b, r) = (1, 1, 0, 1, 0)$ *as a function the distance between the two pulses,* $\xi_2 - \xi_1$*, and compared with the horizontal line, the computed* a *value for the one-pulse solution.*

is a polar plot of a versus θ for the mixed continuous/discrete model and what we observed is that smaller values of a are obtained for $\sigma_1 \approx 1$ and compared with $\sigma_1 \approx 0$. This may be compared with the lack of anisotropy for the continuous model in Figure 7.10(ii) and the four-fold symmetry for the discrete model in Figure 7.10(iii).

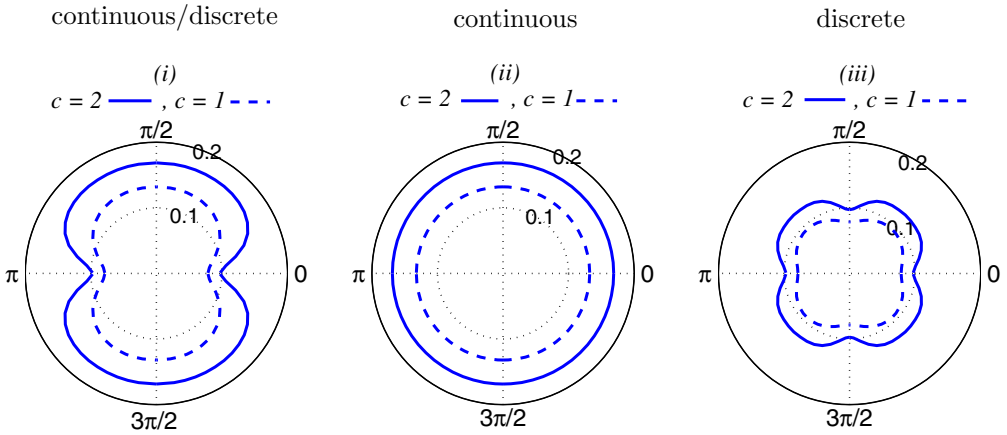

FIG. 7.10. *Polar plot of* $(\theta, a(\theta))$ *for* $(b, r) = (1, 0)$*; see* (7.2). *In plot* (i) $(d, g) = (1, 1)$ *with* $c = 2$ *and* $c = 1$ *for the mixed continuous/discrete version of the equation, in plot* (ii) $(d, g) = (0, 1)$ *with* $c = 2$ *and* $c = 1$ *for the continuous version of the equation, and in plot* (iii) $(d, g) = (1, 0)$ *with* $c = 2$ *and* $c = 1$ *for the discrete version of the equation.*

8. Conclusion. For a particular version of the FitzHugh–Nagumo equation (one which includes both spatially discrete and spatially continuous diffusive operators) with the McKean nonlinearity describing excitability, we have demonstrated how to construct candidate traveling wave solutions and have given tools for verifying if they are indeed solutions. This equation is meant to include models of action potential propagation on several length scales, from the internodal scale to the scale where a pulse becomes a spike. We begin by discussing the infinite number of eigenvalues obtained from linearizing. Leading edge behavior is governed by real eigenvalues, pulse trailing tails by complex ones (with nonzero real parts). Since solutions approach fixed points exponentially as we approach either plus or minus infinity, we can and do use the Fourier transform to derive candidate solutions. The one-front solutions (no recovery) we find have appeared in the Nagumo equation literature and their existence verification is relatively straightforward. The existence of pulse solutions, however, is more difficult. We have related existence to the pulse's relation to the "unstable root" of the reaction term, i.e., $\phi = a$, pointwise. At any point along the solution the solution is either above, below, or crossing a. The series of lemmas and theorems presented supply conditions, based on the derived candidate solutions, for verifying that these conditions are true, i.e., that a one-pulse solution crosses a exactly twice. Among the items that our numerical investigations of the solution behavior illustrate are

- that for single fronts more than one solution can exist;
- that for single pulses there is a range of a values such that there exists at least two distinct pairs of solution pulses;
- that the speed of front solutions can be seen as a bound for the speed of pulse solutions;
- that the distance between multiple pulse shows a dependence on the parameter a;
- that the spatially discrete diffusion operator retards propagation when compared to the spatially continuous diffusion operator.

Acknowledgments. The authors are grateful to Chris Lee and Paul Raff, who helped initiate this investigation as part of the REU site program DMS-9912293 at Colorado School of Mines.

COMBUSTION STABILIZATION BY FORCED OSCILLATIONS IN A DUCT*

ABRAM DORFMAN†

Abstract. The feasibility of stabilizing premixed combustion by forced oscillation is analytically demonstrated through the simulation of an active control input-output mechanism. The developed model is used for analysis of the interactions between an autonomous oscillation in a duct, a loudspeaker's input, and the unsteady heat release. We assume that the autonomous oscillations (at frequency ω_0) exist in a duct containing a flame with a loudspeaker at the input. At $t = 0$, the loudspeaker starts to generate oscillations at a different frequency ω. To find the resulting oscillations (the output), a mathematical technique is needed that takes into account (1) the pressure and velocity fields in the duct when the loudspeaker starts; (2) the variable amplitudes of the resulting oscillations, which depend on time and location; and (3) coupling of the fresh and burnt gas flows at the flame. Such a technique differs significantly from that used by previous authors for studying single oscillation/flame interactions. The mathematical development leads to an exact solution that gives a stability criterion in the form of a system of two integro-differential equations. Analysis shows that the stability domains of the time lag depend mainly on the flame location and the fresh/burnt gases temperature ratio. Numerical results are obtained for a centrally located flame and for the temperature ratio 1500 K/300 K.

Key words. combustion stability, perturbation, Laplace transform, integro-differential equations

1. Introduction.

Since the 1950s, when combustion instabilities caused numerous failures during the development of rocket motors, considerable effort has been spent on the investigation of this phenomenon. Since that time, a number of mathematical models have been developed to identify the mechanism of oscillations and to find ways to reduce their magnitude or suppress them. Crocco and Cheng [1] first studied this problem by using a simple (n-τ) model, where n is an interaction index and τ is a time lag.

The idea behind the time lag τ is that there is always an interval between the time of injection of the propellant and the time at which burning occurs. The interaction index, n, describes the intensity of the coupling between unsteady heat release and velocity fluctuations in the reaction zone. According to the Rayleigh criterion, this coupling process is responsible for combustion instabilities. The interaction index is usually taken as a constant of proportionality between the heat release and the velocity oscillation. The governing equations for this model are obtained from simplified forms of the conservation laws. As a version of the (n-τ) model will be used in this study, more details are given in subsection 3.3.

Crocco and Cheng also provide reviews of other early works [1, 2, 3]. Overviews of later results [4, 5, 6, 7], contemporary reviews [8, 9, 10, 11, 12, 13, 14, 15, 16], surveys of advanced numerical methods [17, 18], and contemporary models of turbulent flame dynamics [17, 19] are also available.

The time lag model was intensively used for both developing physical understanding and correlating experimental data by Crocco and associates in the 1960s [1, 2, 3, 4, 6]. Due to its simplicity, this approach is still of interest [9, 11, 20, 23, 24]. In particular, as described in a recent article [20], this model can be used for detailed analysis of the basic processes responsible for instabilities in premixed combustion. However, we note that this model is restricted to linear processes.

Later, Culick [10, 22] used the Galerkin method and presented the solution of the relevant wave equation as a series of normal modes. This model describes the linear and nonlinear behavior of the oscillations, but the heat release is still considered as a linear process. Culick's model was widely used for solving some basic problems of combustion instabilities [10, 21, 22, 25, 26, 27, 28, 29], and recently it was applied to model a closed-loop active control system with feedback. Two types of controller were considered, with fixed parameters [28] and with variable ones, self-tuned to the operating conditions [29]. The limitations of this model arise from the expansion in normal modes, which is based on the assumption that the studied problems differ only by a small amount from the unperturbed case. A second limitation of this approach results from the necessary truncation of the series expansion.

The kinematic laminar combustion model [30] is constructed using fundamental mechanistic principles. Poiseuille flow in a tube with a thin flame that moves at constant velocity was considered. Analysis of the moving flame front leads to differential equations for the flame surface area and for the unsteady heat release. These results allow for the derivation of a model describing the oscillation/flame interaction in (n-τ) terms. Using this model together with Culick's technique, different applications, including feedback control, have been addressed [31, 32, 33, 34, 35].

A second laminar model was developed by Merk [36]. To study combustion instabilities, he employed transfer functions and an analogy to electrical circuits. The developed theory was used to determine the stability domains for a duct with a thin flame. The stability analysis showed that the value of the time lag is very important because instability was found to occur in a certain interval of the time lag.

The basic ideas of this method have been applied in recent two papers [37, 38]. In the first one, in particular, a review of using transfer function to study premixed flames is given. In the second work, authors employed this method to predict and control instabilities in systems with inclined laminar flames. The studied system is described by a network of transfer functions that simulate acoustic elements in a combustor. To derive analytical expressions for the transfer functions, the transport G-equation is used. Conical and V-flames are considered. It is shown that in both cases, models containing one dimensionless parameter are a good approximation only for low frequencies. The limitations of such a model (considered, for example, in [30]) are discussed in [37, 38]. At higher frequencies, the flame dynamics are controlled by two independent parameters. Additional improvements could be achieved by taking into account convective effects.

Although laminar models are not applicable to devices with turbulent motion, they are important for developing a better understanding of the associated physics. They may also be applied to more complex models by fitting parameters to experimental data [39].

In contrast to Culick, Peracchio and Proscia [39] proposed a model that describes the coupling of a linear oscillation with turbulent nonlinear heat release. They adapted laminar model relations from [30]. By fitting model parameters to experimental data, an expression for the heat release was obtained. The dependence of the heat release

on the fuel/air ratio was also taken into account. The linear acoustics were described by Culick's equation, and the stability analysis was performed using the Laplace transform. On the basis on this model, the technique of identification of limit cycling systems has been developed [40].

Lang et al. [23] proposed a model to study the feedback active control. They used the (n-τ) approach and the solution of the wave equation for a duct with a thin flame. Autonomous oscillations with constant amplitudes were considered. Satisfying the boundary conditions leads to an expression for the stability criterion. Using this criterion and the transfer function, the authors analyzed stability with and without control. The results were compared with the authors' experimental data. Gulati and Mani [24] studied the effect of the equivalence ratio and the flow rate on the control performance using the same approach.

In these two works, specific cases were considered for comparison with experimental data. McManus, Poinsot, and Candel [9] applied the same model for a general analytical investigation of feedback active control in a duct. Ignoring the temperature jump across the flame, the authors analyze stability with and without control. As a result, the stability domains of frequency can be computed for the two first harmonic modes.

Two models with nonlinear heat release effects were proposed by Dowling. In the first [41], the idea of saturated heat release is used. According to that idea, a nonlinearity occurs when the linearly varying heat release becomes constant (i.e., saturates). In the second work [42], the Fliefil et al. [30] approach is extended to turbulent combustion. Unlike the authors of study [39], who fitted the laminar model parameters to the experimental data, Dowling applied the basic idea to a turbulent flame. By using the same assumption of neglecting expansion across the flame front, the relations are derived for the flame surface area and for the unsteady heat release. In both studies, the acoustics are treated as linear and are modeled by the well-known general solution of the wave equation. The solutions for the fresh and burnt gases are conjugated at the flame. To perform this conjugation, the conservation equations, written for the flame zone, and experimental data from [43] are employed. Applications have been subsequently investigated [44, 45, 46].

The brief review presented here considered contemporary analytical methods of modeling combustion instabilities and active control simulation. This part of the extensive literature on combustion instabilities has been reviewed since these studies are closely related to the subject of the current investigation. Experimental and numerical results may be found in the reviews mentioned above.

The literature review has shown that different analytical approaches can be used to study the interaction of oscillations and unsteady heat release, including the mechanism of this phenomenon. At the same time, the analytical models of active control are based on the input-output approach, without considering the processes inside the combustor.

In this article, we develop a model for simulating the active control input-output mechanism. The model describes the interaction of an existing oscillation in the combustor with a control input and with unsteady heat release. This case of the interaction of two oscillations in the combustor, one already existing and the other incoming, with unsteady heat release, is quite different from the well-known single oscillation/heat release coupling problem.

The proposed model for studying this type of interaction is based on the solution of the wave equation which takes into account the following facts: (1) There is a flow

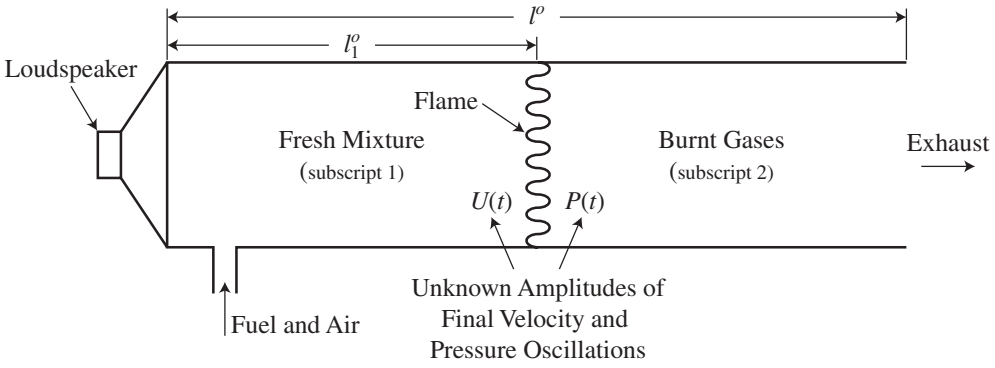

FIG. 1. *Schematic diagram of the modeled combustor as a duct.*

in the combustor when the control input enters. Therefore, the corresponding velocity and pressure fields should be used as initial conditions. (2) The result of interaction of the two different oscillations is complex, with unknown amplitude depending on time and location. (3) The resulting oscillation should be found by the conjugation of two wave equation solutions obtained separately for each part of combustor (i.e., the fresh and burnt gases). (4) While the wave equation is second order, there is only one boundary condition in each part of the combustor divided by the flame. Hence, two other conditions are needed.

For such additional conditions, we use two unknown variables defining, at the flame, the amplitudes of the velocity on the upstream side, and of the pressure on the downstream side. The corresponding mathematical technique leads to a system of two integro-differential equations that determine these unknown functions. A more detailed description of the model and mathematical technique is given in sections 3 and 4.

This system of two integro-differential equations can also be used to develop a stability criterion. Using the stability analysis, the feasibility of stabilizing the premixed combustion by forced oscillation is demonstrated in sections 5 and 6. The ranges of the time lag providing stability are derived and are determined to depend mainly on the flame location and burnt/fresh gases temperature ratio (section 5).

In this study, a combustor in the form of a duct with simple boundary conditions is considered and the (n-τ) approach is used to compute the unsteady heat release. In this case, the exact solution is obtained. The presented model of two oscillations/heat release interaction and mathematical technique may be applied to more complex combustor forms, boundary conditions, and unsteady heat release theories.

2. Problem formulation. The flame is located at $x = l_1$ in a duct of length l (Figure 1) with the loudspeaker at the input ($x = 0$). Assume that in such a duct, when the loudspeaker is off, autonomous oscillations at frequency ω_0 exist. At time $t = 0$, the loudspeaker starts to generate oscillations at frequency $\omega \neq \omega_0$.

Our goals are (1) a stability analysis of the autonomous oscillations when the loudspeaker is off; (2) computing the oscillation that results from the interaction of those existing in the duct autonomously and those from the loudspeaker; and (3) a stability analysis of the final flow and defining the combustion and forced oscillation characteristics that stabilize or suppress initially unstable oscillations.

Although this problem looks close to that of McManus, Poinsot, and Candel [9], they differ in essence. In [9] the active control is considered using the transfer function and the same simple waves with constant amplitudes as in the case without control. In this study, we simulate the mechanism of input–output control considering the interaction of two oscillations at different frequencies with unsteady heat release. The result of this interaction is a complex oscillation with variable amplitudes. We obtain this resulting oscillation by solving the wave equation with initial, boundary, and conjugation conditions.

3. Model. According to our goals, the model is intended to solve the following parts of the whole problem: (1) determining the pressure and velocity fields of the autonomous regime and a stability analysis when the loudspeaker is off; (2) determining the pressure and velocity fields in the two parts of the duct when the loudspeaker is on; (3) obtaining the resulting oscillation by conjugating the flows in the two parts of the duct at the flame; and (4) a stability analysis when the loudspeaker is on.

3.1. Basic assumptions. The proposed model is based on the same assumptions as the Lang, Poinsot, and Candel [23] model and others of this type. They are as follows [9, 23, 24]: (1) Flow in the combustor is a one-dimensional current of inviscid, non-heat-conducting gas with constant properties. (2) The effect of the mean flow and the mean heat transfer on the acoustic waves may be neglected, as well as the effect of pressure drop and heat losses. (3) The acoustic oscillations are plane longitudinal waves. (4) The flame is a thin sheet dividing the duct into two parts with fresh and burnt gases (subscripts 1 and 2, Figure 1).

3.2. Governing equations. According to assumption 1, the flow in the combustor is governed by one-dimensional conservation equations of mass, momentum, and energy:

$$\frac{\partial \rho}{\partial t}+\frac{\partial(\rho u)}{\partial x}=0, \quad \frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+\frac{1}{\rho}\frac{\partial p}{\partial x}=0, \quad \frac{\partial p}{\partial t}+u\frac{\partial p}{\partial x}+p\kappa\frac{\partial u}{\partial x}=(\kappa-1)\quad q_V, \tag{3.1}$$

where ρ, p, u, x, t, q_v, and κ are density, pressure, velocity, distance from loudspeaker, time, heat generation per unit volume, and the ratio of specific heats. The parameters in (3.1) are expanded into mean ($\bar{p}$) and fluctuating (p') components. Assuming that the mean parts are uniform, neglecting density fluctuations, and using $c^2=\kappa\bar{p}/\bar{\rho}$ for the speed of sound, one gets linearized momentum and energy equations,

$$\bar{\rho}\frac{\partial u'}{\partial t}+\frac{\partial p'}{\partial x}=0, \qquad \frac{\partial p'}{\partial t}+\rho c^2\frac{\partial u'}{\partial x}=(\kappa-1)\,q'_V. \tag{3.2}$$

Outside of the flame zone, $q'_V=0$. In such a case, eliminating one of the variables from (3.2) by differentiating leads to the two wave equations

$$\frac{\partial^2 u}{\partial t^2}-c^2\frac{\partial^2 u}{\partial x^2}=0, \qquad \frac{\partial^2 p}{\partial t^2}-c^2\frac{\partial^2 p}{\partial x^2}=0, \tag{3.3}$$

where the sign ($'$) is omitted because, in conformity with assumption 2, only fluctuating components need to be considered.

Using the mean density, $\bar{\rho}$, the length of the duct, l, and the speed of sound, c, as scales, we introduce nondimensional variables

$$x=\frac{x^\circ}{l}, \quad t=\frac{t^\circ c}{l}, \quad u=\frac{u^\circ}{c}, \quad p=\frac{p^\circ}{\bar{\rho}c^2}, \quad q_V=\frac{q_V^\circ l}{\bar{\rho}c^3}, \quad k=\frac{\omega^\circ l}{c}. \tag{3.4}$$

Here ω and k are frequency and wave number, and the superscript $^\circ$ is applied to distinguish dimensional from nondimensional variables. In the following, we use nondimensional quantities, except scales, and in some cases where dimensional variables are marked with sign ($^\circ$).

Since the duct is divided in two parts with fresh and burnt gases, there are two values of the speed of sound and corresponding wave numbers. However, if we neglect the slight temperature dependence of the specific heat ratio, we obtain the relationship $c_2/c_1 = (T_2^\circ/T_1^\circ)^{1/2} = \zeta$, where T_1° and T_2° are the temperatures of the fresh and burnt gases. Then, setting for the burnt gases $k_2 = k$, one gets $k_1 = k\zeta$ for the fresh gases. Since we use the speed of sound c_2 to obtain the dimensionless wave number, the nondimensional time is also determined by this speed of sound. With $c_1/c_2 = (T_1^\circ/T_2^\circ)^{1/2}$, the pressure scales for the fresh and burnt gases are equal ($c_1^2\bar\rho_1 = c_2^2\bar\rho_2$), because $\bar\rho_1/\bar\rho_2 = T_2^\circ/T_1^\circ$.

3.3. Boundary and conjugate conditions. Two boundary and two conjugate conditions are applied. One boundary condition defines the source of the oscillations. We suppose that the autonomous oscillations in the duct are caused by flame fluctuations, while the forced oscillations are produced by the loudspeaker. Assuming that both oscillations are harmonic, we have in the autonomous and forced cases, respectively,

$$u_1(l_1,t) = \alpha_0 \exp(-ik_0 t), \qquad u_1(0,t) = \alpha \exp(-ikt), \tag{3.5}$$

where $l_1 = l_1^\circ/l$ is the flame location, α is amplitude, and subscript 0 denotes the autonomous regime.

The second condition is as in [9, 23]: zero pressure fluctuation at the exhaust

$$p_2(1,t) = 0, \tag{3.6}$$

where the unit 1 indicates the nondimensional length of the duct.

Two conjugation conditions at the flame are adapted from [9, 23]. They are derived on the basis of the (n-τ) model and have the form

$$p_1(l_1,t) = p_2(l_1,t), \tag{3.7}$$

$$\zeta u_2(l_1,t) - u_1(l_1,t) = n u_1(l_1, t-\tau). \tag{3.8}$$

The first expression specifies the continuity of pressure across the flame. The second one defines the velocity jump caused by the high temperature of the burnt gases.

Relation (3.8) is obtained from the energy equation in (3.1) [9, 23]. The derivation starts by letting the flame zone width be Δx°. Then, the average value of the velocity derivative in the flame is $(u_2^\circ - u_1^\circ)/\Delta x^\circ$. The first two terms in the energy equation in (3.1) define the material pressure derivative. Since the pressure does not change across the flame, these two terms become zero in the flame zone. Omitting these terms, using the formula for the speed of sound $c^2 = \kappa p^\circ/\bar\rho$, and then introducing the dimensionless variables defined in (3.4), one gets the average velocity jump in the form $\zeta u_2 - u_1 = (\kappa - 1) q_V \Delta x$. Following Crooco and Cheng [1], the unsteady heat release is expressed using the interaction index, n, and the velocity fluctuation at the flame front, but with regard to time lag: $(\kappa - 1) q_V \Delta x = n u_1(l_1, t-\tau)$. These last two relations yield (3.8).

When the loudspeaker is off, the four boundary conditions (3.5)–(3.8) determine the pressure and velocity amplitudes of autonomous oscillations in the duct. However,

when the loudspeaker is on (i.e., when the interaction of two oscillations with different frequencies occurs), these four conditions are insufficient.

It is known that the result of such interactions is a complex oscillation with time and location dependent velocity and pressure amplitudes. As was mentioned above, we determine this oscillation by solving the wave equation separately for each part of the duct. To have two boundary conditions in each part, we introduce, in addition to (3.5)–(3.8), two unknown functions, $U(t)$ and $P(t)$. They define the velocity and pressure amplitudes on the upstream and downstream sides of the flame, respectively (see Figure 1), such that

$$|u_1(l_1,t)|_{\max} = \alpha U(t), \qquad |p_2(l_1,t)|_{\max} = \alpha P(t). \tag{3.9}$$

Conjugation of the solutions obtained for the two parts of the duct at the flame leads to a system that determines the functions $U(t)$ and $P(t)$.

3.4. Initial conditions. When the loudspeaker starts, autonomous oscillations with frequency ω_0 exist in the combustor. Hence, the pressure and velocity related to these oscillations at $t = 0$ are the initial conditions for solving the wave equation. They are found using conditions (3.5)–(3.8) in the next section.

4. Mathematical development. This section contains three parts. In the first part, the autonomous oscillations that exist when the loudspeaker is off are considered. The two goals of this part are (1) to find the pressure and velocity distributions in the duct when the loudspeaker starts—these are used as the initial conditions in solving the wave equation for the resulting oscillations; and (2) stability analysis of the autonomous regime—this information is needed to answer the main question: Are there conditions under which loudspeaker oscillations stabilize or suppress initially unstable autonomous oscillations?

The second part of this section includes solutions of the wave equations for the two parts of the duct, which give the pressure and velocity fields before and after the flame, in the fresh and burnt gases. The technique of conjugating these fields at the flame is presented in the third part of this section. The conjugation gives the final oscillation, i.e., the output of the interaction between the autonomous and forced oscillations. Subsequently, in section 5, this result is used in a stability analysis to determine if the final oscillations are stable.

4.1. Loudspeaker off. This problem is similar to that in the McManus, Poinsot, and Candel study [9], but in contrast to their solution, we take into account the temperature jump across the flame. We also assume that the flame fluctuations cause a harmonic velocity oscillation, given by (3.5), at the flame instead of imposing the condition $u_1(0,t) = 0$ at the input.

In (3.5), α_0 is an arbitrary complex amplitude. In study [9], the velocity oscillation at the flame front is also harmonic, but with a specific amplitude, which corresponds to the case of zero velocity at the inlet. At the same time, a specific velocity oscillation at the inlet corresponds to (3.5) at the flame in this study. As will be shown in subsection 4.1.1, such corresponding amplitudes at the flame in the first case and the velocity at the inlet in the second one are

$$\alpha_0 = 1-\exp(-2ik_0l_1\zeta), \qquad u(0,t) = \exp[-ik_0(l_1\zeta+t)]-(1-\alpha_0)\exp[ik_0(l_1\zeta-t)]. \tag{4.1}$$

Thus, the boundary conditions in both cases are similar. However, in the case of a closed inlet, it is natural to put zero velocity at $x = 0$, as well as the simple condition (3.5) at the flame instead of condition (4.1) at the inlet in the case with arbitrary amplitude α_0.

4.1.1. Pressure and velocity distributions. The oscillations in the duct are considered as waves with constant amplitudes A_i and B_i, similar to those in [9, 23]:

$$\begin{aligned} &A_1\exp\{ik_0[\zeta(x-l_1)-t]\}\pm B_1\exp\{-ik_0[\zeta(x-l_1)+t]\},\\ &A_2\exp\{ik_0[\zeta(x-l_1)-t]\}\pm B_2\exp\{-ik_0[\zeta(x-l_1)+t]\}. \end{aligned} \tag{4.2}$$

Here sums define the pressure, while differences give the velocity, $k_0=\omega_0^\circ l/c_2$, and $t=t^\circ c_2/l$.

Substituting (4.2) in the boundary and conjugate conditions (3.5)–(3.8) yields

$$\begin{aligned} &A_1-B_1=\alpha_0, \qquad A_2\exp[ik_0(1-l_1)]+B_2\exp[-ik_0(1-l_1)]=0,\\ &A_1+B_1=A_2+B_2, \qquad \zeta(A_2-B_2)-(A_1-B_1)[1+n_0\exp(ik_0\tau_0)]=0, \end{aligned} \tag{4.3}$$

where $1-l_1$ is the duct length behind the flame. The parameters (τ_0,n_0) are different from (τ,n) for the final oscillations since it is known that in general they depend on the oscillation frequency and combustion characteristics.

Because α_0 is arbitrary, it follows from (4.3) that one may set $A_1=1$. Then the first three equations in (4.3) determine the other amplitudes A_i and B_i. Using them together with (4.2), one obtains the desired pressure and velocity distributions:

$$\begin{aligned} p_{10}&=\exp\{ik_0[\zeta(x-l_1)-t]\}+(1-\alpha_0)\exp\{-ik_0[\zeta(x-l_1)+t]\},\\ u_{10}&=\exp\{ik_0[\zeta(x-l_1)-t]\}-(1-\alpha_0)\exp\{-ik_0[\zeta(x-l_1)+t]\},\\ p_{20}&=\frac{2-\alpha_0}{1-\exp[-2ik_0(1-l_1)]}\{\exp[-ik_0(x-l_1+t)]-\exp[ik_0(x+l_1-t-2)]\},\\ u_{20}&=\frac{2-\alpha_0}{1-\exp[-2ik_0(1-l_1)]}\{-\exp[-ik_0(x-l_1+t)]-\exp[ik_0(x+l_1-t-2)]\}. \end{aligned} \tag{4.4}$$

The expressions in (4.1) follow from the second equation of (4.4) if one puts $u_{10}(l_1,t)=0$ (to obtain the first expression) and $x=0$ (to obtain the second one).

4.1.2. Stability analysis. The last equation in (4.3) can be used to determine α_0. After substituting for the amplitudes A_i and B_i, this equation takes the form

$$\zeta(2-\alpha_0)\{1+\exp[-2ik_0(1-l_1)]\}+\alpha_0\{1-\exp[-2ik_0(1-l_1)]\}[1+n_0\exp(i\omega_0\tau_0)]=0. \tag{4.5}$$

This equation gives a generalized stability criterion for loudspeaker oscillations (3.5) with arbitrary amplitude α_0. The criterion obtained in [9, 23] with determinant may also be derived from the last equation of (4.3). This criterion follows also from (4.5) if one sets $\alpha_0=1-\exp(-2ik_0l_1\zeta)$, which corresponds to the case considered in [9].

Setting in (4.5) $\alpha_0=\alpha_{0R}+i\alpha_{0I}$ and $k_0=k_{0R}+ik_{0I}$ and separating the result into real and imaginary parts leads to

$$\begin{aligned} \alpha_{0R}&=\frac{2\zeta\{h_C\{1+\exp[2k_{0I}(1-l_1)\cos\phi]\}+h_S\sin2\phi\exp[2k_{0I}(1-l_1)]\}}{h_C^2+h_S^2},\\ \alpha_{0I}&=\frac{2\zeta\{h_S\{1+\exp[2k_{0I}(1-l_1)\cos\phi]\}-h_C\sin2\phi\exp[2k_{0I}(1-l_1)]\}}{h_C^2+h_S^2},\\ h_C&=f_C^+\exp[2k_{0I}(1-l_1)]+f_C^-, \qquad h_S=f_S^-\exp[2k_{0I}(1-l_1)]+f_S^+,\\ f_S^+&=n_0\sin\vartheta_0, \qquad f_S^-=(\zeta+1)\sin2\phi-n\sin(\vartheta_0-2\phi),\\ f_C^+&=(\zeta+1)\cos2\phi+n\cos(\vartheta_0-2\phi), \qquad f_C^-=(\zeta-1)-n_0\cos\vartheta_0. \end{aligned} \tag{4.6}$$

Here $\phi=k_{0R}(1-l_1)$, $\vartheta_0=2\pi(\tau_0/T_0)$, and T_0 is the autonomous oscillations period.

The neutral curves are obtained from (4.6) by setting $\exp[2k_{0I}(1-l_1)]=1$. To specify the stability domains, derivatives of k_{0I} with respect to α_{0R} and α_{0I} are needed:

$$
\begin{aligned}
2(1-l_1)\frac{\partial k_{0I}}{\partial \alpha_{0R}} &= \frac{(f_C^+ + f_C^-)^2 + (f_S^+ + f_S^-)^2}{g_C(f_C^+ + f_C^-) - g_S(f_S^+ + f_S^-)},\\
2(1-l_1)\frac{\partial k_{0I}}{\partial \alpha_{0I}} &= \frac{(f_C^+ + f_C^-)^2 + (f_S^+ + f_S^-)^2}{g_C(f_S^+ + f_S^-) + g_S(f_C^+ + f_C^-)},\\
g_C = 2\zeta\cos 2\phi - \alpha_{0R}f_C^+ - \alpha_{0I}f_S^-, &\qquad g_S = -2\zeta\sin 2\phi + \alpha_{0R}f_S^- - \alpha_{0I}f_C^+.
\end{aligned}
\tag{4.7}
$$

As an example, in Figure 2 the neutral curves $\alpha_0 = f(\tau_0/T_0)$ and the corresponding derivatives are given for the following data: $n_0 = 0.5, \phi = k_{0R}(1-l_1) = 0.4\pi, \zeta^2 = 5$. The derivative $\partial k_{0I}/\partial\alpha_{0I}$ is negative throughout the curve $\alpha_0 = f(\tau_0/T_0)$, while the other derivative, $\partial k_{0I}/\partial\alpha_{0R}$, is negative only in zone 3 (Figure 2(b)). Since on the neutral curves $k_{0I} = 0$, the sign of the derivative indicates the stability domain location. It lies above the neutral curve for negative derivatives and below the neutral curve for positive ones. Hence, in this case, the stability domains are located: outside of the curves in zones 1 and 4, inside of the curves in zone 2, and above both of the curves in zone 3. These regions are marked with hatching in Figure 2(a).

To determine the real and imaginary parts of α_0 for a given value of τ_0/T_0, one may choose from Figure 2(a) only α_{0R} or α_{0I}. The other should be found from the equality which is derived by solving (4.6) for $\exp[2k_{0I}(1-l_1)]$:

$$
\exp[2k_{0I}(1-l_1)] = \frac{-2\zeta + \alpha_{0R}f_C^- + \alpha_{0I}f_S^+}{2\zeta\cos 2\phi - \alpha_{0R}f_C^+ - \alpha_{0I}f_S^-} = \frac{\alpha_{0R}f_S^+ - \alpha_{0I}f_C^-}{2\zeta\sin 2\phi - \alpha_{0R}f_S^- + \alpha_{0I}f_C^+}.
\tag{4.8}
$$

For example, if for the unstable regime and $\tau_0/T_0 = 0.2$ one takes $\alpha_{0R} = 0.8$ from Figure 2(a), the equality (4.8) gives $\alpha_{0I} = 0.87$ and $\exp[2k_{0I}(1-l_1)] = 1.2$.

Thus, the analysis indicates that there are both stable and unstable autonomous oscillation regimes. We will show that unstable autonomous oscillations can be stabilized by the loudspeaker's input if the time lag and forced oscillation frequency correspond to specific domains. To show this, we start by determining the velocity and pressure fields that arise as an output of the interaction between the autonomous and loudspeaker oscillations.

4.2. Loudspeaker on. In this case the pressure and velocity fields are obtained by solving the wave equations (3.3) for each portion of the duct. The method of solution of such linear homogeneous equations with initial (4.4) and boundary ((3.5), (3.6), and (3.9)) conditions is well known [47]. After converting the inhomogeneous boundary condition (3.5) or (3.9) to a homogeneous one, the desired solution is presented as a sum of two others. One is a solution of the original equation (3.3) with a given initial, but homogeneous boundary condition. The other satisfies the zero initial and boundary conditions and an inhomogeneous equation that arises instead of the inhomogeneous boundary condition. In this case, such inhomogeneous wave equations contain the unknown functions $U(t)$ or $P(t)$ from the boundary conditions (3.9). Finally, this leads to a system of two integro-differential equations that determine these functions.

4.2.1. Velocity and pressure in the front of the flame. To find the velocity in the duct portion upstream of the flame, the first wave equation in (3.3) is solved. Let the required solution have the same form as the loudspeaker oscillation (3.5), such that

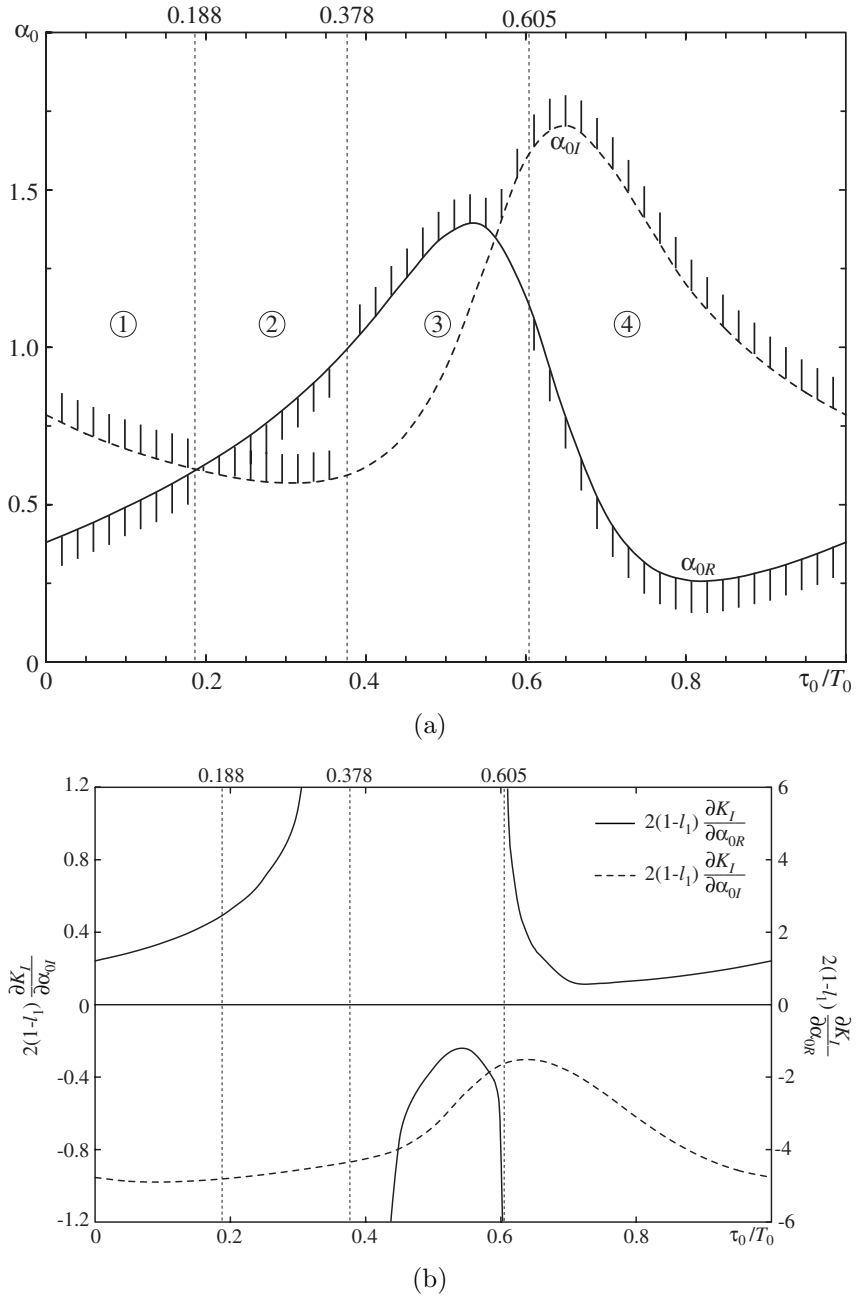

FIG. 2. *Neutral curves and stability domains for autonomous oscillations in a duct.* $n_0 = 0.5, \phi = 0.4\pi, T_2^0/T_1^0 = 5$. (a) *Neutral curves.* (b) *Derivatives of the neutral curves.* (τ_0/T_0): $0.188 =$ *the intersection of curves,* 0.378 *and* $0.605 =$ *changes of sign of the derivative* $\partial k_I/\partial\alpha_{0R}$.

$$u_1(x,t) = \alpha F(x,t)\exp(-ikt), \tag{4.9}$$

with the unknown function $F(x,t)$ defining the amplitude. The boundary condition for this function at the input follows from (3.5), while at the flame it is defined by (3.9):

$$F(0,t) = 1, \qquad F(l_1,t) = U(t). \tag{4.10}$$

Conditions (4.10) are transformed to homogeneous ones by the substitution

$$F(x,t) = \Phi(x,t) - (x/l_1)[1 - U(t)] + 1. \tag{4.11}$$

After using (4.10) and (4.11), the wave equation (3.3) takes an inhomogeneous form with the right-hand side containing the unknown function $U(t)$ and its first two derivatives. Replacing c_1 for c for fresh gases in (3.3), we present this equation in the form

$$\frac{\partial^2\Phi}{\partial t^2} - 2ik\frac{\partial\Phi}{\partial t} - k^2\Phi - \frac{1}{\zeta^2}\frac{\partial^2\Phi}{\partial x^2} = \frac{x}{l_1}Z(t) + k^2\left(1 - \frac{x}{l_1}\right), \tag{4.12}$$

$$Z(t) = -\frac{\partial^2 U}{\partial t^2} + 2ik\frac{\partial U}{\partial t} + k^2 U, \qquad \Phi(0,t) = \Phi(l_1,t) = 0. \tag{4.13}$$

Since $u_{10}(x,0)$, defined by (4.4), describes the velocity field in the combustor when the loudspeaker starts, the initial conditions are found by comparing (4.4), (4.9), and (4.11). Setting $t = 0$ in these expressions, one gets $\Phi(x,0)$ after solving the equation $u_{10}(x,0) = u_1(x,0)$. Similarly, the derivative is found after differentiating (4.4), (4.9), and (4.11):

$$\begin{aligned}\Phi(x,0) = {} & \frac{1}{\alpha}\{\exp[ik_0\zeta(x-l_1)] - \exp[-ik_0\zeta(x-l_1)]\} \\ & + \frac{\alpha_0}{\alpha}\exp[-ik_0\zeta(x-l_1)] + \frac{x}{l_1}\left(1 - \frac{\alpha}{\alpha_0}\right) - 1,\end{aligned} \tag{4.14}$$

$$\left(\frac{\partial\Phi}{\partial t}\right)_{t=0} = i(k-k_0)\left[\Phi(x,0) - \frac{x}{l_1} + 1\right]. \tag{4.15}$$

As indicated, the solution of (4.12) will be represented as a sum $\Phi = \Phi^{(1)} + \Phi^{(2)}$. The solution of the homogeneous part of (4.12), $\Phi^{(1)}$, satisfying the initial conditions (4.14) and (4.15) is obtained by a separation of variables and using a Fourier series:

$$\begin{aligned}\Phi^{(1)} = \sum_{m=1}^{\infty} \frac{l_1\zeta}{2m\pi}\sin\frac{m\pi x}{l_1}\Bigg\{ & -E_{+1}\left[\delta_{m1}(k_0 - \gamma_{m1}) - \frac{2}{m\pi}(k-k_0)\right] \\ & + E_{-1}\left[\delta_{m1}(k_0 + \gamma_{m1}) - \frac{2}{m\pi}(k-k_0)\right]\Bigg\}, \\ & + E_{\pm 1} = \exp[i(k \pm \gamma_{m1})t], \qquad \gamma_{m1} = \frac{m\pi}{l_1\zeta},\end{aligned}$$

$$\begin{aligned}\delta_{m1} = {} & \frac{2m\pi}{\alpha[(m\pi)^2 - (k_0 l_1\zeta)^2]}\{[\exp(-ik_0 l_1\zeta) - \exp(ik_0 l_1\zeta)] + \alpha_0[(-1)^{m+1} + \exp(ik_0 l_1\zeta)]\} \\ & - \frac{2}{m\pi}[(-1)^{m+1}(\alpha_0/\alpha) + 1].\end{aligned} \tag{4.16}$$

To get the solution of the inhomogeneous part of (4.12), $\Phi^{(2)}$, meeting the homogeneous conditions (4.13), Duhamel's principle is used [47]. The impulse function Φ^*

is defined as a solution of the homogeneous equation (4.12) with conditions given at $t = \eta$:

$$\Phi^*|_{t=\eta} = 0, \qquad \frac{\partial \Phi^*}{\partial t}|_{t=\eta} = \frac{x}{l_1} Z(\eta) + k^2 \left(1 - \frac{x}{l_1}\right), \tag{4.17}$$

where the derivative is equal to the right-hand side of (4.12). Then, according to Duhamel's principle, one gets the desired solution by integrating the impulse function

$$\begin{aligned} \Phi^{(2)} &= \int_0^t \Phi^* \left(\frac{x}{l_1}, t, \eta\right) d\eta \\ &= \sum_{m=1}^{\infty} \frac{l_1 \zeta}{(m\pi)^2} \sin \frac{m\pi x}{l_1} \left[(-1)^{m+1} i(E_{-1} J_{-1} + E_{+1} J_{+1}) + k^2 \right. \\ &\qquad \left. - \left(\frac{E_{-1}}{k - \gamma_{m1}} - \frac{E_{+1}}{(k + \gamma_{m1})} - \frac{2\gamma_{m1}}{k^2 - \gamma_{m1}^2}\right)\right], \\ J_{\pm 1} &= \int_0^t \frac{Z(\eta)}{E_{\pm 1}(\eta)}\, d\eta. \end{aligned} \tag{4.18}$$

The sum of (4.16) and (4.18) determines the required solution of (4.12):

$$\begin{aligned} \Phi(x,t) &= \sum_{m=1}^{\infty} \frac{l_1 \zeta}{(m\pi)^2} \sin \frac{m\pi x}{l_1} Y_{m1}, \\ Y_{m1} &= (-1)^{m+1} i(E_{-1} J_{-1} - E_{+1} J_{+1}) \\ &\quad + E_{-1} \left[\tfrac{m\pi\delta_{m1}}{2}(k_0 + \gamma_{m1}) - (k - k_0) + \frac{k^2}{k - \gamma_{m1}}\right] \\ &\quad - E_{+1} \left[\frac{m\pi\delta_{m1}}{2}(k_0 - \gamma_{m1}) - (k - k_0) + \frac{k^2}{k + \gamma_{m1}}\right] - \frac{2k^2\gamma_{m1}}{k^2 - \gamma_{m1}^2}. \end{aligned} \tag{4.19}$$

This expression, together with (4.9) and (4.11), specifies the velocity field $u_1(x,t)$ upstream of the flame. When the velocity is known, the pressure field is obtained by integrating the first equation in (3.2) from 0 to x:

$$\begin{aligned} p_1(x,t) = \alpha l_1 \zeta \exp(-ikt) &\left\{ \sum_{m=1}^{\infty} \frac{l_1 \zeta}{(m\pi)^3} \left[\cos \frac{m\pi x}{l_1} - 1\right] \left(\frac{dY_{m1}}{dt} - ikY_{m1}\right) \right. \\ &- \frac{1}{2} \left(\frac{x}{l_1}\right)^2 \left(\frac{dU}{dt} - ikU\right) \\ &\left. - ik \frac{x}{l_1} \left(\frac{x}{2l_1} - 1\right)\right\} + \exp(-ikt) p_{10}(0,0). \end{aligned} \tag{4.20}$$

It can be shown that when $t = 0$, (4.20) becomes the initial value $p_{10}(x,0)$ defined by (4.4).

4.2.2. Pressure and velocity behind the flame. The procedure of determining the pressure behind the flame is similar to that of the velocity computed in section 4.2.1. The solution is presented in the same form as (4.9) with the unknown function $F_p(x,t)$ as

$$p_2(x,t) = \alpha F_p(x,t) \exp(-ikt). \tag{4.21}$$

To have a homogeneous boundary condition that satisfies (3.6) and (3.9), a transformation, analogous to (4.11), is applied:

$$F_p(x,t) = \frac{1-x}{1-l_1}P(t) + \Phi_p(x,t). \tag{4.22}$$

Then one gets an equation similar to (4.12), but with a different right-hand side:

$$\frac{\partial^2\Phi_p}{\partial t^2} - 2ik\frac{\partial\Phi_p}{\partial t} - k^2\Phi_p - \frac{\partial^2\Phi_p}{\partial x^2} = \frac{1-x}{1-l_1}Z_p(t), \tag{4.23}$$

$$Z_p(t) = -\frac{d^2P}{dt} + 2ik\frac{dP}{dt} + k^2P, \qquad \Phi_p(l_1,t) = \Phi_p(1,t) = 0. \tag{4.24}$$

The initial conditions are found by the same way as conditions (4.14) and (4.15). Comparing (4.21) and (4.22) with $p_{20}(x,0)$, given by (4.4), yields $\Phi_p(x,0)$. The derivative is found after differentiating (4.4), (4.21), and (4.22):

$$\begin{aligned}\Phi_p(x,0) = \frac{2-\alpha_0}{\alpha}\Bigg\{&\frac{1}{1-\exp[-2ik_0(1-l_1)]}\{\exp[-ik_0(x-l_1)]\\ &-\exp[-ik_0(2-x-l_1)]\} - \frac{1-x}{1-l_1}\Bigg\},\end{aligned} \tag{4.25}$$

$$\left(\frac{\partial\Phi_p}{\partial t}\right)_{t=0} = i(k-k_0)\Phi_p(x,0). \tag{4.26}$$

The solution of (4.23) satisfying the boundary condition (4.24) and the initial conditions (4.25) and (4.26) is obtained in the same way as (4.19), giving

$$\begin{aligned}&\Phi_p(x,t) = \sum_{m=1}^{\infty}\frac{1-l_1}{(m\pi)^2}\sin\frac{m\pi(1-x)}{1-l_1}Y_{m2},\\ &Y_{m2} = (-1)^{m+1}i(E_{-2}J_{-2} - E_{+2}J_{+2}) - \frac{m\pi\delta_{m2}}{2}[E_{-2}(k_0+\gamma_{m2}) - E_{+2}(k_0-\gamma_{m2})],\\ &E_{\pm2} = \exp[i(kt\pm\gamma_{m2})t], \quad \gamma_{m2} = \frac{m\pi}{1-l_1}, \quad J_{\pm2} = \int_0^t\frac{Z_p(\eta)}{E_{\pm2}}\,d\eta,\\ &\delta_{m2} = (-1)^{m+1}\left\{\frac{2m\pi(2-\alpha_0)}{\alpha\{(m\pi)^2 - [k_0(1-l_1)]^2\}} - \frac{2\{1-\exp[-2ik_0(1-l_1)]\}}{m\pi}\right\}.\end{aligned} \tag{4.27}$$

Since the pressure is known, the velocity behind the flame is found by integrating the second of equations (3.2) from 1 to x, giving

$$\begin{aligned}u_2(x,t) = \alpha(1-l_1)\exp(-ikt)\Bigg\{&\sum_{m=1}^{\infty}\frac{1-l_1}{(m\pi)^3}\left[1-\cos\frac{m\pi(1-x)}{1-l_1}\right]\left(\frac{dY_{m2}}{dt} - ikY_{m2}\right)\\ &+\frac{1-x}{2(1-l_1)}\left(\frac{dP}{dt} - ikP\right)\Bigg\} + \exp(-ikt)\ u_2(0,0).\end{aligned} \tag{4.28}$$

The unknown functions $U(t)$ and $P(t)$, present in (4.20), (4.28) and in integrals $J_{\pm1}$ (4.19) and $J_{\pm2}$ (4.27), are found using the conjugation procedure described in the next subsection. Then the velocity and pressure fields may be calculated in each portion of the duct. These are determined upstream of the flame by (4.9), (4.11),

(4.19), and (4.20) and downstream by (4.21), (4.22), (4.27), and (4.28). Data related to the duct (l_1), the autonomous (α_0, k_0) and loudspeaker (α, k) oscillations, the fresh and burnt gases temperatures (T_1°, T_2°), and parameters (n, τ) should be known in order to perform the calculations.

In this study, we use the derived relations to estimate the characteristics of the combustion and loudspeaker oscillations that provide stabilization of initially unstable autonomous waves.

4.3. Conjugation of pressure and velocity at the flame. The conjugation conditions (3.7) and (3.8) contain the values of the pressure and velocity at the flame. To get these quantities for each part of the duct, we proceed as follows. Setting $x = l_1$ in (4.9), (4.11), (4.19), (4.20), (4.21), (4.22), (4.27), and (4.28), we substitute the results in (3.7) and (3.8). Then, taking into account that $F(l_1, t) = U(t)$ and that $F_p(l_1, t) = P(t)$, we get a system determining unknown functions $U(t)$ and $P(t)$:

$$\sum_{m=1,3,\dots}^{\infty} \frac{2l_1\zeta}{(m\pi)^3}\left(\frac{dY_{m1}}{dt} - ikY_{m1}\right) + \frac{1}{2}\left[\frac{dU}{dt} - ik(U+1)\right] + \frac{1}{l_1\zeta}\left[P - \frac{p_{10}(0,0)}{\alpha}\right] = 0,$$
$$\sum_{m=1,3,\dots}^{\infty} \frac{2(1-l_1)}{(m\pi)^3}\left(\frac{dY_{m2}}{dt} - ikY_{m2}\right) + \frac{1}{2}\left(\frac{dP}{dt} - ikP\right)$$
$$+ \frac{1}{(1-l_1)}\left[\frac{u_{20}(0,0)}{\alpha} - \frac{U + nU(t-\tau)\exp(ik\tau)}{\zeta}\right] = 0. \tag{4.29}$$

After using (4.19) and (4.27) for Y_{m1} and Y_{m2}, and two relations based on Euler's formula, $E_+ + E_- = 2\exp(ikt)\cos(\gamma_m t)$ and $E_+ - E_- = 2i\exp(ikt)\sin(\gamma_m t)$, the last system takes the form of two integro-differential equations:

$$2\exp(ikt)\int_\vartheta^t \left(\frac{d^2U}{dt^2} - 2ik\frac{dU}{dt} - k^2U\right)\exp(-ik\eta)\sum_{m=1,3,\dots}^{\infty}\frac{2}{(m\pi)^2}\cos[\gamma_{m1}(t-\eta)]\,d\eta$$
$$-\frac{1}{2}\left(\frac{dU}{dt} - ikU\right) - \frac{1}{l_1\zeta}P = G(t),$$
$$G(t) = -\sum_{m=1,3,\dots}^{\infty}\frac{4}{(m\pi)^2}\left\{i\exp(ikt)\cos(\gamma_{m1}t)\left[\frac{m\pi\delta_{m1}}{2}k_0 - (k-k_0) + \frac{k^3}{k^2-\gamma_{m1}^2}\right] - \frac{1}{2}ik\right.$$
$$\left. + \gamma_{m1}\exp(ikt)\sin(\gamma_{m1}t)\left(\frac{m\pi\delta_{m1}}{2} + \frac{k^2}{k^2-\gamma_{m1}^2}\right) - \frac{ik^3}{k^2-\gamma_{m1}^2}\right\} - \frac{1}{l_1\zeta\alpha}p_{10}(0,0), \tag{4.30}$$

$$2\exp(ikt)\int_\vartheta^t \left(\frac{d^2P}{dt^2} - 2ik\frac{dP}{dt} - k^2P\right)\exp(-ik\eta)\sum_{m=1,3,\dots}^{\infty}\frac{2}{(m\pi)^2}\cos[\gamma_{m2}(t-\eta)]\,d\eta$$
$$-\frac{1}{2}\left(\frac{dP}{dt} - ikP\right) + \frac{1}{\zeta(1-l_1)}[U + nU(t-\tau)\exp(ik\tau)] = G_p(t),$$
$$G_p(t) = -\sum_{m=1,3,\dots}^{\infty}\frac{2}{(m\pi)^2}\exp(ikt)m\pi\delta_{m2}[ik_0\cos(\gamma_{m2}t) + \gamma_{m2}\sin(\gamma_{m2}t)] + \frac{u_{20}(0,0)}{\alpha(1-l_1)}. \tag{4.31}$$

Here, the unknown functions $U(t)$ and $P(t)$ are placed on the left-hand sides, while others that are considered as known form $G(t)$ and $G_p(t)$ on the right-hand sides.

The system (4.30), (4.31) has two forms, according to different parts of the combustion process. There is no combustion during the first period, $0 \le t \le \tau$, after

injection but before burning of the propellant. Hence, in this case, the interaction index is zero ($n = 0$), and the lower limit ϑ of the integrals is the time when the injection starts, $\vartheta = 0$. For the second period, $t \geq \tau$, after the combustion starts, $n > 0$, and the lower limit ϑ is equal to the time lag ($\vartheta = \tau$). For our purpose, we use the second form of the system (4.30), (4.31) because our goal is to study the behavior of the final oscillation as $t \to \infty$.

5. Stability analysis. We perform a stability analysis on the system (4.30), (4.31). We need find out whether the functions $U(t)$ and $P(t)$, defining the velocity and pressure amplitudes, are bounded or grow infinitely as $t \to \infty$. The new variables

$$V = U\exp(-ikt), \quad V_p = P\exp(-ikt), \quad H = G\exp(-ikt), \quad H_p = G_p\exp(-ikt) \tag{5.1}$$

reduce the expressions with unknown functions $U(t)$ and $P(t)$ and their two derivatives to second derivatives of V and of V_p. Then the system (4.30), (4.31) simplifies to

$$\int_\tau^t \frac{d^2V}{dt^2} \sum_{m=1,3,\ldots}^{\infty} \frac{4}{(m\pi)^2}\cos[\gamma_{m1}(t-\eta)]\,d\eta - \frac{1}{2}\frac{dV}{dt} - \frac{V_p}{l_1\zeta} = H(t), \tag{5.2}$$

$$-\int_\tau^t \frac{d^2V_p}{dt^2} \sum_{m=1,3,\ldots}^{\infty} \frac{4}{(m\pi)^2}\cos[\gamma_{m2}(t-\eta)]\,d\eta + \frac{1}{2}\frac{dV_p}{dt} - \frac{1}{\zeta(1-l_1)}[V+nV(t-\tau)] = H_p(t). \tag{5.3}$$

5.1. Laplace transform. The Laplace transform of the system (5.2), (5.3) yields

$$[s^2V(s) - sV(\tau) - V'(\tau)] \sum_{m=1,3,\ldots}^{\infty} \frac{4}{(m\pi)^2}\frac{s}{s^2+\gamma_{m1}^2} - \frac{1}{2}[sV(s) - V(\tau)] - \frac{V_p(s)}{l_1\zeta} = H(s), \tag{5.4}$$

$$\begin{aligned} -[s^2V_p(s) - sV_p(\tau) - V_p'(\tau)] &\sum_{m=1,3,\ldots}^{\infty} \frac{4}{(m\pi)^2}\frac{s}{s^2+\gamma_{m2}^2} + \frac{1}{2}[sV_p(s) - V_p(\tau)] \\ &- \frac{1}{\zeta(1-l_1)}[V(s) + nV(s)\exp(-s\tau)] = H_p(s). \end{aligned} \tag{5.5}$$

Solving (5.4) and (5.5) for $V(s)$ and $V_p(s)$, and writing $V(s)$ as a fraction, one obtains

$$V(s) = \frac{M(s)}{N(s)}, \tag{5.6}$$

$$N(s) = \left[\sum_{m=1,3,\ldots}^{\infty} \frac{4s^3}{(m\pi)^2(s^2+\gamma_{m1}^2)} - \frac{s}{2}\right]\left[-\sum_{m=1,3,\ldots}^{\infty} \frac{4s^3}{(m\pi)^2(s^2+\gamma_{m2}^2)} + \frac{s}{2}\right] \tag{5.7}$$

$$\begin{aligned} M(s) = &\left\{\begin{array}{l} -\dfrac{1}{\zeta^2 l_1(1-l_1)}[1+n\exp(-s\tau)], \\ [sV(\tau)+V'(\tau)]\displaystyle\sum_{m=1,3,\ldots}^{\infty} \frac{4s}{(m\pi)^2(s^2+\gamma_{m1}^2)} - \frac{1}{2}V(\tau) + H(s) \end{array}\right\} \\ &\times\left[-\sum_{m=1,3,\ldots}^{\infty} \frac{4s^3}{(m\pi)^2} \times \frac{1}{s^2+\gamma_{m2}^2} + \frac{s}{2}\right] \\ &+ \frac{1}{l_1\zeta}\left\{-[sV_p(\tau) + V_p'(\tau)] \sum_{m=1,3,\ldots}^{\infty} \frac{4s}{(m\pi)^2(s^2+\gamma_{m2}^2)} + \frac{1}{2}V_p(\tau) + H_p(s)\right\}, \end{aligned} \tag{5.8}$$

$$V_p(s) = l_1\zeta\left\{V(s)\left[\sum_{m=1,3,\dots}^{\infty}\frac{4s^3}{(m\pi)^2(s^2+\gamma_{m1}^2)}-\frac{s}{2}\right]-[sV(\tau)+V'(\tau)]\right.$$
$$\left.\times\sum_{m=1,3,\dots}^{\infty}\frac{4s}{(m\pi)^2(s^2+\gamma_{m1}^2)}+\frac{1}{2}V(\tau)-H(s)\right\}. \tag{5.9}$$

It is known [48, 49] that this system is stable if all roots of the equation $N(s)=0$ are to the left of the imaginary axis in the complex s plane and if no roots on the imaginary axis are repeated. Since the last term of $N(s)$ contains the product $s\tau$, we should consider the complex variable $s\tau$ instead of s. Multiplying the equation $N(s)=0$ by τ, setting $s\tau=\sigma+i\psi$, and dividing the resulting expression into real and imaginary parts, we obtain the following two equations:

$$\left(-gX_{1R}-hX_{1I}+\frac{\sigma}{2}\right)\left(-gX_{2R}-hX_{2I}+\frac{\sigma}{2}\right)$$
$$+\left(-gX_{1I}+hX_{1R}-\frac{\psi}{2}\right)\left(gX_{2I}-hX_{2R}+\frac{\psi}{2}\right)$$
$$+\frac{\theta^2 l_1}{(1-l_1)}[1+n\exp(-\sigma)\cos\psi]=0,$$

$$X_{1R}=\sum_{m=1,3,\dots}^{\infty}\frac{4[\sigma^2-\psi^2+(m\pi\theta)^2]}{(m\pi)^2\{4\sigma^2\psi^2+[\sigma^2-\psi^2+(m\pi\theta)^2]^2\}},$$

$$g=\sigma^3-3\sigma\psi^2,\qquad X_{1I}=\sum_{m=1,3,\dots}^{\infty}\frac{8\sigma\psi}{(m\pi)^2\{4\sigma^2\psi^2+[\sigma^2-\psi^2+(m\pi\theta)^2]^2\}}, \tag{5.10}$$

$$\left(-gX_{1R}-hX_{1I}+\frac{\sigma}{2}\right)\left(gX_{2I}-hX_{2R}+\frac{\psi}{2}\right)$$
$$-\left(-gX_{1I}+hX_{1R}-\frac{\psi}{2}\right)\left(-gX_{2R}-hX_{2I}+\frac{\sigma}{2}\right)$$
$$-\frac{\theta^2 l_1}{(1-l_1)}n\exp(-\sigma)\sin\psi=0,$$

$$X_{2R}=\sum_{m=1,3,\dots}^{\infty}\frac{4\{\sigma^2-\psi^2+[m\pi l_1\theta\zeta/(1-l_1)]^2\}}{(m\pi)^2\{4\sigma^2\psi^2+\{\sigma^2-\psi^2+[m\pi l_1\theta\zeta/(1-l_1)]^2\}^2\}},$$

$$h=3\sigma^2\psi-\psi^3,\qquad X_{2I}=\sum_{m=1,3,\dots}^{\infty}\frac{8\sigma\psi}{(m\pi)^2\{4\sigma^2\psi^2+\{\sigma^2-\psi^2+[m\pi l_1\theta\zeta/(1-l_1)]^2\}^2\}}, \tag{5.11}$$

$$\theta=\frac{c_1\tau^\circ}{l_1^\circ}. \tag{5.12}$$

The characteristic system (5.10), (5.11) includes two unknowns, σ and ψ, and four nondimensional parameters. They define the flame location, l_1; the temperature ratio, $\zeta^2=T_2^\circ/T_1^\circ$; the interaction index, n; and the dimensionless time lag, θ. For each preset imaginary part, $\pm\psi$, of the complex root, the characteristic system (5.10), (5.11) allows for calculation of the real part, σ, of this root and one of four parameters if three others are known. This makes it possible to investigate the effect of these four parameters on stability. In this study, we investigate the effect of the nondimensional time lag, θ.

5.2. Stability domains (numerical results). The system (5.10), (5.11) does not have any purely real or imaginary roots. It follows from the fact that in the only meaningful case, $n > 0$, the first equation has no roots when $\psi = 0$, and the second one has no roots when $\sigma = 0$. Hence, the system (5.10), (5.11) may have only complex roots. In such a case, to determine the stability domains, one should estimate the range of parameters that corresponds to complex roots with only negative real parts.

The numerical results were obtained for the case of a centrally located flame, $l_1 = 1/2$, and a temperature ratio $\zeta^2 = 1500$ K/300 K. Since l_1 and ζ are given, the real part of the complex root, σ, and the dimensionless time lag, θ, depend on the interaction index, n, and the imaginary part, $\pm\psi$. However, (5.10) and (5.11) cannot be solved for either σ or θ. Therefore, we solve each equation for the interaction index n and then compute it by both equations. Since l_1 and ζ are given, each equation determines n as a function of the dimensionless time lag θ and of the complex root of the system $\sigma \pm i\psi$. Thus, in such a situation, the goal is to find, for each preset magnitude of $\pm\psi$, such values of θ and σ that provide identical results of n given by (5.10) and (5.11). Estimates were found by trial and error and then refined by iterations. Mathcad 8 Professional was utilized. The results obtained for $(\psi/\pi) = \pm(10/18, 14/18, 17/18)$ are given in Figure 3.

From the analysis of system (5.10), (5.11) and numerical results, we see the following.

(1) In the case of no combustion, when $n = 0$, the dimensionless time lag $\theta = 0$. Starting from this point, the dimensionless time lag increases as n grows until $n = \sim (6 - 10)$. After that point, it changes slowly, approaching an asymptote (Figure 3(a)). The asymptotic property of the function $\theta(n)$ is a result of the condition $T_2^\circ/T_1^\circ =$ constant that we used in the calculation. The data corresponding to the condition $\theta =$ constant and variable ζ (Figure 4), shows that the temperature of the burnt gases increases as the interaction index grows.

(2) As the time lag increases, the corresponding absolute value $|\sigma|$ increases as well (Figure 3(b)). After reaching a maximum over the range of $n = \sim (3 - 4)$, $|\sigma|$ rapidly decreases, approaching zero as $n \to \infty$. In this case, the product of the first two expressions in (5.10) vanishes because $\sigma = g = X_I = 0$. Then (5.10) takes the form

$$\left\{\sum_{m=1,3,\ldots}^{\infty} \frac{4\psi^3}{(m\pi)^2[\psi^2 - (m\pi\theta)^2]} - \frac{\psi}{2}\right\} \times \left\{\sum_{m=1,3,\ldots}^{\infty} \frac{4\psi^3}{(m\pi)^2 - \{\psi^2 - [m\pi l_1\theta\zeta/(1-l_1)]^2\}} - \frac{\psi}{2}\right\} - \frac{\theta^2 l_1}{(1-l_1)} = \theta^2 n\cos\psi. \tag{5.13}$$

Since the right-hand side of this equation goes to infinity as $n \to \infty$, this equation is satisfied when the first sum in the left-hand side also approaches infinity. The first value of (θ/ψ) when this occurs is $0.106103292\ldots$. This value also satisfies (5.11) because this equation contains the same sum. Thus, the asymptotic value of the dimensionless time lag is

$$\theta_a = 0.106103292\ldots\psi. \tag{5.14}$$

(3) The calculation shows that in the domain of dimensionless time lag $0 < \theta < 0.36$ for all $n > 0$, the real parts, σ, of the complex roots are negative. Although

FIG. 3. *Nondimensional time lag* (a) *and real part of the complex roots of the characteristic system* (5.10), (5.11) (b) *for resulting oscillations for the case of centrally located flame* ($l_1 = 1/2$) *and temperature ratio* $T_2^0/T_1^0 = 5$.

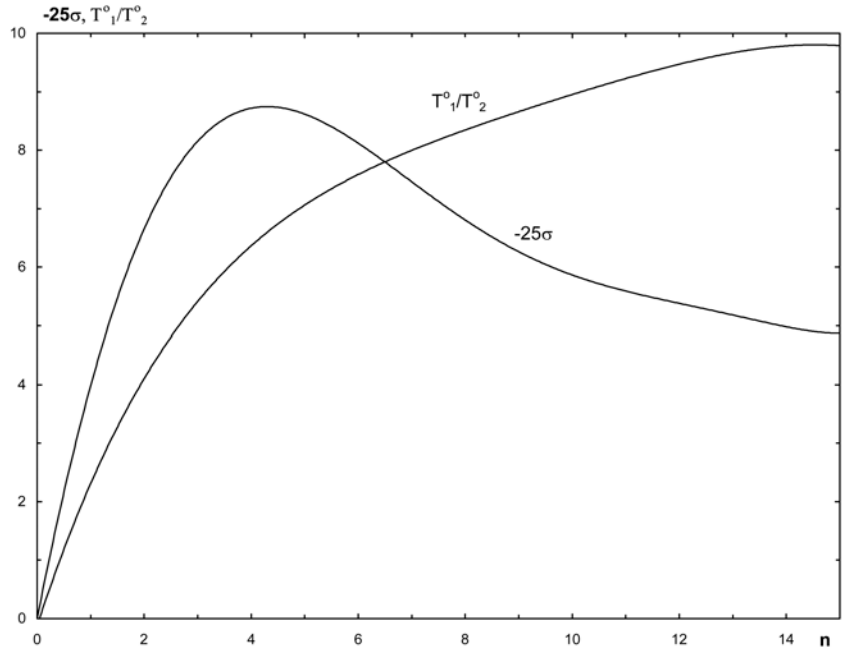

FIG. 4. *Temperature ratio and real part of the complex roots of the characteristic system* (5.10), (5.11) *for resulting oscillations for the case of centrally located flame* $l_1 = 1/2$, $\theta = 0.2$, *and* $\psi = (12/18)\pi$.

these roots correspond to stability conditions, it is not sufficient to say that the final oscillation is stable. Other roots in the obtained domains may not satisfy the stability conditions. Since we know that the system (5.10), (5.11) does not have purely real or imaginary roots, we need to show that this system does not have complex roots with positive real parts, σ, in these domains. To do it, we use two forms of (5.11).

(a) According to Figure 3(a), for small n, the stability dimensionless time lag, θ, is also small. For this case, we use the first nonzero term of the Taylor's series of (5.11),

$$\frac{2\sigma\psi}{4\sigma^2\psi^2 + (\sigma^2+\psi^2)^2} + n\exp(-\sigma)\sin\psi = 0. \tag{5.15}$$

It is clear that in the case of $\sigma > 0$ and $\psi > 0$ this equation does not have roots. Hence, there are no complex roots with positive real parts for small n and θ.

(b) For not small n, the function $\theta(n)$ has an asymptotic character. Here, the stability dimensionless time lag changes slowly so that the ratio θ/ψ remains almost constant, varying from 0.08 to 0.12. Note that, according to (5.14), this ratio is strongly constant as $n \to \infty$.

In view of this fact, we transform the two first terms in (5.11) to variables

$$\mu = \frac{\sigma}{\psi}, \qquad \nu = \frac{\theta}{\psi}. \tag{5.16}$$

After some algebra, $\sigma\psi$ appears as a factor, and (5.11) may be presented in the form

$$\sigma f(\mu,\nu) = \frac{\theta^2 l_1 n \exp(-\sigma)\sin\psi}{(1-l_1)\psi}, \tag{5.17}$$

$$f(\mu,\nu) = \left(-g^* X_{1R}^* - h^* X_{1I}^* + \frac{1}{2}\right)\left(g^* X_{2I}^* - h^* X_{2R}^* + \frac{1}{2}\right) - \left(-g^* X_{1I}^* + h^* X_{1R}^* - \frac{1}{2}\right)\left(-g^* X_{2R}^* - h^* X_{2I}^* + \frac{1}{2}\right).$$

Here, $*$ denotes the terms in (5.11) transformed to the variables defined in (5.16). Since $(\sin\psi)/\psi$ is positive, the right-hand side of (5.17) is always positive. Since the left-hand side of this equation is a product $\sigma f(\mu,\nu)$, the sign of σ coincides with that of function $f(\mu,\nu)$. Computations show that in the domain indicated above, $\nu = 0.08$–0.12, this function is negative for all positive μ. Then there are also no complex roots with positive real parts.

(4) Thus, the system (5.10), (5.11) has only complex roots with negative real parts. Hence, the corresponding values of the dimensionless time lag, $0 < \theta < 0.36$, given in Figure 3(a), determine the stability domain. Each of these θ defines, according to (5.12), a dimensional time lag $\tau^\circ = \theta(l_1^\circ/c_1)$ that theoretically provides the linear stability of the final oscillation in a duct with centrally located flame and temperature ratio 1500 K/300 K. This is true regardless of the stability of autonomous oscillations because no restrictions about this were used in the stability analysis. For other flame locations and temperature ratios, the time lag stability domains may be found by the same technique.

(5) In general, the nondimensional time lag depends on the flame location, the ratio of the burnt/fresh gas temperatures, and the interaction index. However, numerical results show that, except for relatively small n, the time lag depends only slightly on the interaction index (Figure 3(a)). Then the stability domains of the nondimensional time lag depend mainly on the flame location and the burnt/fresh gases temperature ratio if n is not small.

(6) Knowing θ, possible frequencies of forced oscillation may be estimated. Taking into account that the time lag usual is a fraction of the period of oscillation, one obtains

$$0 < \frac{\tau}{T} < 1, \qquad 0 < \omega^\circ < \frac{2\pi c_1}{l_1^\circ \theta}\left(\frac{\tau}{T}\right). \tag{5.18}$$

The performed above analysis shows that the dimensionless time lag from the stability domain $0 < \theta < 0.36$ (Figure 3(a)) and forced oscillation at frequency from the range (5.18) theoretically provide the linear stability of the final oscillation in a duct with centrally located flame and temperature ratio 1500 K/300 K no matter that initial oscillations is not stable. For other flame locations and temperature ratios, analogous stability analysis may be made by the same technique.

6. Asymptotic correlation as $t \to \infty$ for pressure and velocity behind flame. Since the problem is linear, to answer a question of stability means to find out whether the parameters of the final oscillation are bounded or become infinite as $t \to \infty$. To do this, we calculate the pressure and velocity behind the flame as $t \to \infty$. The pressure behind the flame is obtained from (4.21), while the velocity is easier to calculate by (3.8) and (4.9) than using (4.28). Considering relations (3.9) and (5.1), we have $F_p(l_1,t) = P(t) = V_p(t)\exp(ikt)$, $F(l_1,t) = U(t) = V(t)\exp(ikt)$,

and $F(l_1, t-\tau) = U(t-\tau) = V(t-\tau)\exp[ik(t-\tau)]$. Substituting these results into (4.21) and (3.8), one gets, after using (4.8),

$$\lim_{t\to\infty} p_2(l_1,t) = \alpha \lim_{t\to\infty} V_p(t), \tag{6.1}$$

$$\lim_{t\to\infty} u_2(l_1,t) = \frac{\alpha}{\zeta} \lim_{t\to\infty} [V(t) + V(t-\tau)\exp(ik\tau)]. \tag{6.2}$$

Thus, to find the parameters behind the flame as $t \to \infty$, one needs the limits of the functions $V(t)$ and $V_p(t)$. These may be determined by the inverse Laplace transform of expression (5.6) and (5.9). A second way is possible, in particular, when all roots of the denominator in (5.6) are to the left of the imaginary axis, which is simpler because it gives the result without using the inverse transform.

Since it was shown above that these conditions are satisfied, we first find the values of $V(t)$ and $V_p(t)$ as $t \to \infty$ by computing limits of $sV(s)$ and $sV_p(s)$ as $s \to 0$ [49]. The denominator in (5.6) does not become zero as $s \to 0$ because we have seen that $s = 0$ is not a root of the equation $N(s) = 0$. At the same time, it is clear that $sM(s)$, according to (5.8), approaches zero as $s \to 0$. Therefore, we have from (5.8)

$$\begin{aligned}
\lim_{t\to\infty} V(t) &= \lim_{s\to 0} sM(s) \\
&= \lim_{s\to 0} \left\{ \left\{ [sV(\tau) + V'(\tau)] \sum_{m=1,3,\ldots}^{\infty} \frac{4s^2}{(m\pi)^2(s^2+\gamma_{m1}^2)} - \frac{s}{2}V(\tau) + sH(s) \right\} \right. \\
&\times \left[\frac{s}{2} - \sum_{m=1,3,\ldots}^{\infty} \frac{4s^3}{(m\pi^2)(s^2+\gamma_{m1}^2)} \right] \\
&\left. - \frac{1}{l_1\zeta} \left\{ [sV_p(\tau) + V_p'(\tau)] \sum_{m=1,3,\ldots}^{\infty} \frac{4s^2}{(m\pi^2)(s^2+\gamma_{m2}^2)} - \frac{s}{2}V_p(\tau) - sH_p(s) \right\} \right\} \\
&= 0.
\end{aligned} \tag{6.3}$$

It follows from (5.9) that the other limit of interest also equals zero:

$$\begin{aligned}
\lim_{t\to\infty} V_p(t) &= \lim_{s\to 0} sV_p(s) \\
&= \lim_{s\to 0} l_1\zeta \left\{ sV(s) \left[\sum_{m=1,3,\ldots}^{\infty} \frac{4s^3}{(m\pi)^2(s^2+\gamma_{m1}^2)} - \frac{s}{2} \right] - [sV(\tau) + V'(\tau)] \right. \\
&\left. \times \sum_{m=1,3,\ldots} \frac{4s^2}{(m\pi)^2(s^2+\gamma_{m2}^2)} + \frac{s}{2}V(\tau) - sH(s) \right\} \\
&= 0.
\end{aligned} \tag{6.4}$$

In evaluating these limits, two others, $\lim[sH(s)] = 0$ and $\lim[sH_p(s)] = 0$, as $s \to 0$, are taken into account. They follow from (4.30), (4.31), and (5.1).

There are two types of oscillations in the t domain, which correspond to the zero limit in the s domain. They are: a suppressed oscillation and a steady-state one with zero mean value amplitude [49]. To clarify which oscillation is realized, we take the inverse Laplace transform of (5.6). This is a tiresome procedure because decomposition of the function $V(s)$ leads to sum of about 30 fractions of the types

$$\frac{1}{s^2+\gamma^2}, \quad \frac{s}{s^2+\gamma^2}, \quad \frac{1}{s+ik}, \quad \frac{1}{s^2+2\mu s+\mu^2+v^2}, \quad \frac{s}{s^2+2\mu s+\mu^2+v^2}. \tag{6.5}$$

The inverse transformation of these fractions yields the following expressions:

$$(6.6)\quad \frac{\sin\gamma t}{\gamma},\quad \cos\gamma t,\quad \exp(-ikt),\quad \frac{\exp(-\mu t)\sin\nu t}{\nu}\exp(-\mu t)\left(\cos\nu t-\frac{\mu}{\nu}\sin\nu t\right).$$

Since the two last functions become zero as $t\to\infty$, the result contains the three others:

$$(6.7)\quad \lim_{t\to\infty}V(t)=\sum_{m=1,3,\dots}^{\infty}\sum_{j=1,3,\dots}^{\infty}C_{1mj}\cos\gamma_{m1}t+D_{1mj}\sin\gamma_{m1}t+C_{2mj}\cos\gamma_{m2}t + D_{2mj}\sin\gamma_{m2}t+C_{3mj}\exp(-ikt).$$

The coefficients C_{mj} and D_{mj} depend on several others (from 4 to 9), which arise by decomposition of (5.6) into the fractions given in (6.5). These others depend on $\gamma_{m1}=m\pi/l_1\zeta,\gamma_{m2}=m\pi/(1-l_1),\mu=\sigma/\tau,v=\psi/\tau$, and k. Since the coefficients C_{mj} and D_{mj} in the double-sums (6.7) are proportional to $1/m^2$, or to $1/j^2$, or to their product, these sums converge. Hence, the function $V(t)$ is bounded as $t\to\infty$. An analogous expression for $V_p(t)$ is found by applying (5.9).

It is clear from (6.7) that the limit of the function $V(t)$ as well as the limit of the function $V_p(t)$ (as it is analogous) describe steady-state oscillatory motion with finite amplitudes and zero mean value for a period. Expressions (6.1) and (6.2) differ from functions $V(t)$ and $V_p(t)$ only by factors α and (α/ζ), respectively. Hence, the pressure and velocity behind the flame also perform steady-state oscillations with finite amplitudes and zero mean values as $t\to\infty$. Since the stability analysis was performed without any restriction on the initial oscillation stability (see subsection 5.2), this result is true no matter if the initial oscillation is stable or unstable.

Thus, the asymptotic analysis proves that the pressure and velocity behind the flame that form by interaction of initial and forced oscillations are bounded as $t\to\infty$. This issue confirms the stability analysis result: at the specific dimensionless time lags from the stability domains (Figure 3(a)), the forced oscillations at corresponding frequencies from the range (5.18) stabilize unstable initial autonomous oscillations in a duct. Hence, the active control by forced oscillation theoretically provides linear stability of combustion in the duct with initially unstable autonomous oscillations.

7. Conclusion. (1) A model and mathematical technique have been developed to simulate the input-output mechanism in an active control system. In this case, an existing oscillation in the combustor interacts with a control input and with a flame. Such a model and mathematical technique significantly differ from well-known ones for single oscillation/flame interactions.

(2) The model has been used to demonstrate the feasibility of stabilizing premixed combustion by forced oscillation. It is assumed that the oscillations at frequency ω generated by the loudspeaker are imposed on autonomous oscillations at frequency ω_0 in a duct.

(3) The problem of the interaction of two oscillations has been solved by conjugating wave equation solutions obtained separately for each portion of the duct. The whole solution takes into account (a) the initial conditions, i.e., the velocity and pressure fields existing in the combustor when the control input enters; (b) two boundary conditions in the duct; (c) conditions to conjugate the flows of fresh and burnt gases at the flame; (d) the fact that in each part of the duct only one boundary condition is known, and, hence, two others are needed. Because of that, two unknown functions are introduced which define the pressure and velocity amplitudes at the flame. The

stability analysis is reduced to a system of two integro-differential equations determining these functions.

(4) A stability analysis has been performed using the system of characteristic equations (5.10), (5.11). Two general results are derived: (a) The characteristic system does not have any purely real or imaginary roots, and (b) the nondimensional time lag (5.12) depends on the flame location, burnt/fresh gases temperature ratio, and interaction index.

(5) Numerical results and stability domains for the dimensionless time lag have been obtained for a centrally located flame and a burnt/fresh gases temperature ratio 1500 K/300 K. It has been proved that the characteristic system (5.10), (5.11) has only complex roots with negative real parts in the stability domains of the nondimensional time lag $0 < \theta < 0.36$. Knowing the time lag and the limits of the ratio τ/T, the corresponding range (5.18) of possible frequencies of forced oscillation has been estimated.

(6) It has been shown that behind the flame in the duct, the resulting pressure and velocity perform steady-state oscillations with finite amplitudes and zero mean values as $t \to \infty$. Thus, the forced oscillations at specific dimensionless time lags from the stability domains and corresponding frequencies stabilize unstable autonomous oscillations in the duct.

(7) The developed mathematical technique may be applied for different combustion models, configurations, boundary and initial conditions. In the case of the considered problem formulation for combustion in a duct, an exact solution has been obtained.

ω-HARMONIC FUNCTIONS AND INVERSE CONDUCTIVITY PROBLEMS ON NETWORKS*

SOON-YEONG CHUNG† AND CARLOS A. BERENSTEIN‡

Abstract. In this paper, we discuss the inverse problem of identifying the connectivity and the conductivity of the links between adjacent pair of nodes in a network, in terms of an input-output map. To do this we deal with the weighted Laplacian Δ_ω and an ω-harmonic function on the graph, with its physical interpretation as a diffusion equation on the graph, which models an electric network. After deriving the basic properties of ω-harmonic functions, we prove the solvability of (direct) problems such as the Dirichlet and Neumann BVPs. Our main result is the global uniqueness of the inverse conductivity problem for a network under a suitable monotonicity condition.

Key words. discrete Laplacian, inverse conductivity problem, diffusion equation

Introduction. A network represents a way of interconnecting any pair of users or nodes by means of some meaningful links. Thus, it is quite natural that its structure can be represented, at least in a simplified form, by a connected graph whose vertices represent nodes and whose edges represent their links.

The problem of discovering the detailed inner structure of the network from a collection of boundary measurements can be seen as a type of inverse problem, analogous to those arising in tomography. For example, problems of interest include checking connectivity, tracking data traffic, performance of software or hardware, security, reliability, and so on. In particular, when we have some problems on a part of the network or when we are in need of finding such a part having problems, it is almost impossible to investigate the whole network, since the network may be too vast and its structure or connectivity too complicated. For this reason, the study of the inverse problem to recover the whole network with partial data is becoming increasingly important for practical applications.

From the graph theoretical point of view, problems involving graph identification have been among the most important and famous open problems in graph theory [BH]. Most of the work on this subject has concentrated on spectral graph theory, on the realization of graphs with given distances, and on the reconstruction of graphs from vertex deleted subgraphs (see [B2], [B3], [Ch], [CY], [CGGS], [CO], [CL], [CvDGT], [CvDS], and [HY]). Thus far, spectral theory has been one of the most significant tools used in studying graphs, and it has led to noteworthy progress in the study of these questions. But, as is well known, graphs are not in general completely characterized by their spectra (see [CvDGT, p. 66]).

In this paper another method of studying the graph identification problem will be introduced—a discrete version of the inverse conductivity problem.

The original aim of the inverse conductivity problem was to identify the conductivity coefficient in continuous media from boundary measurements, such as Dirichlet data, Neumann data, or their appropriate combinations.

The discrete or finite nature of graphs makes working on graphs basically easier than investigating these problems in the continuous case. On the other hand, their discrete nature also gives rise to several disadvantages. For example, solutions of the Laplace equation (introduced in section 2) do not have the local uniqueness property, nor is their uniqueness guaranteed by the Cauchy data, contrary to the continuous case, where they are the most important mathematical tools used to study the inverse conductivity problem and related problems.

The purpose of this paper is to give a discrete analogue of the inverse conductivity problem as studied in a number of publications, such as [A], [Ca], [I], [IP], [KS], and [SU]. To do this we introduce an elliptic operator on the graph, the ω-Laplacian Δ_ω, and interpret it as a diffusion equation on the graph modeled by the electric network. Since little has been studied so far about partial differential equations on graphs, we will establish several useful properties of Δ_ω, which are essential to solve the inverse problem.

The inverse problem we study is to identify the connectivity of the nodes and the conductivity of the edges between each adjacent pair of nodes. The following global uniqueness result for the inverse conductivity problem in a network is the main result of this paper. We prove it in section 4.

THEOREM. *Let ω_1 and ω_2 be weights with $\omega_1 \le \omega_2$ on $\overline{S} \times \overline{S}$ and $f_1,\ f_2 : \overline{S} \to \mathbb{R}$ be functions satisfying, for $j = 1,\ 2$,*

$$\begin{cases} \Delta_{\omega_j} f_j(x) = 0, \ x \in S, \\ \frac{\partial f}{\partial_{\omega_j} n}(z) = \psi(z), \ z \in \partial S, \\ \int_S f_j \ d_{\omega_j} = K \end{cases}$$

for a given function $\psi : \partial S \to \mathbb{R}$ with $\int_{\partial S} \psi = 0$ and a given constant $K > 0$.

If we assume that

(i) $\omega_1(z, y) = \omega_2(z, y)$ *on* $\partial S \times \overset{\circ}{\partial} S$,

(ii) $f_1|_{\partial S} = f_2|_{\partial S}$,

then we have

$$f_1 = f_2 \text{ on } \quad \overline{S}$$

and

$$\omega_1 = \omega_2 \quad \text{on} \quad \overline{S} \times \overline{S}.$$

The second conclusion $\omega_1 = \omega_2$ above is exactly what we want to have. In fact, it shows not only whether or not each pair of nodes is connected by a link but also how nice the link is.

Both the monotonicity condition $\omega_1 \le \omega_2$ and the normalization condition $\int_S f_j \, d_{\omega_j} = K$ will be shown to be necessary by means of counterexamples. In fact, even in the continuous case, some form of monotonicity has also been considered (see [I], [Ca], and [A]).

To paraphrase the previous discussion in terms of communications networks, there are two clear ways such a network can be disrupted. One occurs when some nodes

fail or "cease to exist," in which case the structure of the network as a graph has changed. The other occurs when traffic among some nodes becomes so large that for practical purposes the network is also disrupted; this corresponds to the problem we consider here. The traffic may become extremely slow, but the structure of the underlying graph has not changed. This closely resembles the problem we consider here. Besides, there are also indications that there are possible applications to fault-testing in VLSI design and random walks with weighted transition probabilities. See also [ClMM], [AJB1], and [AJB2].

We organized this paper as follows: First, we discuss calculus on graphs in section 1, and in section 2 we introduce ω-harmonic functions on graphs and some good properties of them, which are useful later and for further study. In fact, those properties are interesting by themselves in the authors' opinion.

In section 3, we discuss the direct problems such as the Dirichlet BVP (DBVP) and Neumann BVP (NBVP) and give a physical interpretation of Δ_ω. Additional useful properties of ω-harmonic functions will be introduced.

Finally, in section 4, we prove the global uniqueness result for the inverse problem under the monotonicity condition. For its proof, we introduce a discrete version of the Dirichlet principle, which is an essential tool for the proof of the main theorem.

After the authors completed this paper, Professor Gunter Uhlmann informed the authors that Professor Morrow with his collaborators had published a series of papers (see [CM1], [CM2], [MMC], [IM] and [MIC]) on the inverse problem for networks. But their results were concentrated on the networks of special types such as circular networks or integer lattices. Moreover, their approaches do not seem to work for the networks of general type considered in this paper.

1. Calculus on weighted graphs. We shall begin with some definitions of graph theoretic notions frequently used throughout this paper.

By a *graph* $G = G(V, E)$ we mean a finite set V of *vertices* with a set E of two-element subsets of V (whose elements are called *edges*). The set of vertices and edges of a graph G are sometimes denoted by $V(G)$ and $E(G)$, or simply V and E, respectively. As conventionally used, we denote by either $x \in V$ or $x \in G$ the fact that x is a vertex in G.

A graph G is said to be *simple* if it has neither multiple edges nor loops, and G is said to be *connected* if for every pair of vertices x and y there exists a sequence (termed a *path*) of vertices $x = x_0, x_1, x_2, \dots, x_{n-1}, x_n = y$ such that x_{j-1} and x_j are connected by an edge (termed *adjacent*) for $j = 1, 2, \dots, n$.

A graph $S = S(V', E')$ is said to be a *subgraph* of $G(V, E)$ if $V' \subset V$ and $E' \subset E$. Then, we call G a *host graph* of S. If E' consists of all the edges from E which connect the vertices of V' in its host graph G, then S is called an *induced* subgraph. It is noted that an induced subgraph of a connected host graph may not be connected.

A *weighted (undirected) graph* is a graph $G(V, E)$ associated with a *weight* function $\omega : V \times V \to [0, \infty)$ satisfying

(i) $\omega(x, x) = 0, \quad x \in V$,

(ii) $\omega(x, y) = \omega(y, x) \quad$ if $x \sim y$,

(iii) $\omega(x, y) = 0 \quad$ if and only if $\quad \{x, y\} \notin E$.

Here, $x \sim y$ means that two vertices x and y are connected (adjacent) by an edge in E. In this case, $\{x, y\}$ denotes the edge connecting the vertices x and y.

In particular, a weight function ω satisfying

$$\omega(x, y) = 1 \quad \text{if } x \sim y$$

is called the *standard* weight on G. The physical meaning of the weight function will be discussed later in section 3.

The *degree* $d_\omega x$ of a vertex x in a weighted graph $G(V,E)$ with a weight ω is defined to be

$$d_\omega x := \sum_{y\in V} \omega(x,y).$$

Throughout this paper, all the subgraphs in our concern are assumed to be induced, simple, and connected subgraphs of a weighted graph. A function on a graph is understood to be a function defined just on the set of vertices.

The integration of a function $f : G \to \mathbb{R}$ on a graph $G = G(V,E)$ is defined by

$$\int_G f d_\omega \quad \left(\text{or simply } \int_G f\right) := \sum_{x\in V} f(x) d_\omega x.$$

We shall now define the directional derivative of a function $f : G \to \mathbb{R}$. For each x and $y \in V$ we define

$$D_{\omega,y} f(x) := [f(y) - f(x)] \sqrt{\frac{\omega(x,y)}{d_\omega x}}.$$

The gradient ∇_ω of function f is defined to be a vector

$$\nabla_\omega f(x) := \big(D_{\omega,y} f(x)\big)_{y\in V},$$

which is indexed by the vertices $y \in V$. Then it is easy to see that

$$\begin{aligned}\int_G |\nabla_\omega f(x)|^2 &= \sum_{x\in V} |\nabla_\omega f(x)|^2 d_\omega x \\ &= \sum_{x\in V}\sum_{y\in V} |f(y) - f(x)|^2 \omega(x,y) \\ &= 2 \sum_{\{x,y\}\in E} |f(y) - f(x)|^2 \omega(x,y).\end{aligned}$$

This integral is called the energy of f on G.

For a subgraph S of a graph $G = G(V,E)$, the (vertex) *boundary* ∂S of S is the set of all vertices $z \in V$ not in S but adjacent to some vertex in S, i.e.,

$$\partial S := \{z \in V - S | z \sim y \text{ for some } y \in S\},$$

and the *inner boundary* $\mathring{\partial} S$ is defined by

$$\mathring{\partial} S := \{y \in S | y \sim z \text{ for some } z \in \partial S\}.$$

Also, by $\overline{S}$ we denote a graph whose vertices and edges are in S and vertices in ∂S. We note here that by definition the boundary ∂S does not contain edges.

The (outward) *normal derivative* $\frac{\partial f}{\partial_\omega n}(z)$ at $z \in \partial S$ is defined to be

$$\frac{\partial f}{\partial_\omega n}(z) := \sum_{y\in S} [f(z) - f(y)] \cdot \frac{\omega(z,y)}{d'_\omega z},$$

where $d'_\omega z = \sum_{y\in S} \omega(z,y)$.

The ω-*Laplacian* Δ_ω of a function $f : G \to \mathbb{R}$ on a graph G is defined by

$$\Delta_\omega f(x) := \sum_{y \in V} [f(y) - f(x)] \cdot \frac{\omega(x,y)}{d_\omega x}, \quad x \in V. \tag{1.1}$$

For notation, notions, and conventions we refer the reader to [Ch] and [CvDS].

Remark 1.1.

(i) The discrete Laplacian on graphs can be found in several places, such as [Ch], [CvDS], and [B1]. But the ω-Laplacian defined above is not exactly the same as the one considered in those references. In fact, the definition used here will give us an advantage of a more consistent treatment in section 2.

(ii) The first derivatives and gradient in a discrete sense have not been introduced precisely so far in the literature, as far as the authors know. But the first derivative $D_{\omega,y}$ defined above may still be unsatisfactory in the sense that Leibniz's rule does not hold. In spite of this defect, it will be seen later that it has the appropriate physical meaning and works very well with respect to calculus on graphs.

In what follows, a function f defined on $\overline{S}$ may be understood as a function on its host graph G such that $f = 0$ on $G \setminus \overline{S}$ if necessary.

THEOREM 1.2. *Let S be a subgraph of a host graph G. Then for any pair of functions $f : \overline{S} \to \mathbb{R}$ and $h : \overline{S} \to \mathbb{R}$ we have*

$$2 \int_{\overline{S}} h(-\Delta_\omega f) = \int_{\overline{S}} \nabla_\omega h \cdot \nabla_\omega f. \tag{1.2}$$

Proof. A direct use of the definitions mentioned above gives

$$\begin{aligned}
2 \int_{\overline{S}} h(-\Delta_\omega f) &= 2 \sum_{x \in \overline{S}} h(x)[-\Delta_\omega f(x)] d_\omega x \\
&= -2 \sum_{x \in \overline{S}} h(x) \left\{ \sum_{y \in V(G)} [f(y) - f(x)] \omega(x,y) \right\} \\
&= 2 \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} h(x)[f(x) - f(y)] \omega(x,y) \\
&= \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} h(x)[f(x) - f(y)] \omega(x,y) + \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} h(y)[f(y) - f(x)] \omega(x,y) \\
&= \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \left\{ [f(y) - f(x)] \sqrt{\omega(x,y)} \right\} \cdot \left\{ [h(y) - h(x)] \sqrt{\omega(x,y)} \right\} \\
&= \sum_{x \in \overline{S}} \left\{ \nabla_\omega f(x) \cdot \nabla_\omega h(x) \right\} d_\omega x \\
&= \int_{\overline{S}} \nabla_\omega f \cdot \nabla_\omega h. \qquad \square
\end{aligned}$$

The above theorem yields many useful formulas such as the graph version of the Green theorem.

COROLLARY 1.3. *Under the same hypotheses as above we have the following identities:*

(i)

$$2\int_{\overline{S}} f(-\Delta_\omega f) = \int_{\overline{S}} |\nabla_\omega f|^2 .$$

(ii)

$$\int_{\overline{S}} h\Delta_\omega f = \int_{\overline{S}} f\Delta_\omega h.$$

(iii) *(Green's formula)*

$$\int_S (f\Delta_\omega h - h\Delta_\omega f) = \int_{\partial S} \left(f\frac{\partial h}{\partial_\omega n} - h\frac{\partial f}{\partial_\omega n}\right).$$

Proof. (i) is trivial and (ii) can be easily obtained by the symmetry in (1.2). We prove (iii). In view of (ii) we have

$$\begin{aligned} 0 &= \int_{\overline{S}} [f\Delta_\omega h - h\Delta_\omega f] \\ &= \int_S [f\Delta_\omega h - h\Delta_\omega f] + \int_{\partial S} [f\Delta_\omega h - h\Delta_\omega f]. \end{aligned}$$

Then, since S is the induced subgraph, it follows that $\omega(z,y) = 0$ for all z and $y \in \partial S$ and

$$\begin{aligned} \int_S [f\Delta_\omega h - h\Delta_\omega f] &= \int_{\partial S} [h\Delta_\omega f - f\Delta_\omega h] \\ &= \sum_{z\in\partial S} [h(z)\Delta_\omega f(z) - f(z)\Delta_\omega h(z)]d_\omega z \\ &= \sum_{z\in\partial S}\sum_{y\in S} \Big\{ h(z)\big[f(y) - f(z)\big]\omega(z,y) - f(z)\big[h(y) - h(z)\big]\omega(z,y)\Big\} \\ &= \sum_{z\in\partial S} \left[h(z)\left\{ -\frac{\partial f}{\partial_\omega n}\right\} + f(z)\frac{\partial h}{\partial_\omega n}(z)\right] d_\omega z \\ &= \int_{\partial S} \left[f\frac{\partial h}{\partial_\omega n} - h\frac{\partial f}{\partial_\omega n}\right]. \qquad \square \end{aligned}$$

In the continuous case, the following are well-known formulas:

$$\Delta(fg) = f\Delta g + 2\nabla f\cdot\nabla g + g\Delta f,$$

$$\int_\Omega \nabla f\cdot\nabla g + \int_\Omega f\Delta g = \int_{\partial\Omega} f\frac{\partial g}{\partial n}.$$

Here we introduce a discrete analogue of these formulas.

THEOREM 1.4. *Under the same hypotheses as in Theorem* 1.2*, the following identities hold:*

(i)

$$\Delta_\omega(fh) = f\Delta_\omega h + \nabla_\omega f\cdot\nabla_\omega h + h\Delta_\omega f,$$

(ii)

$$\int_S \nabla_\omega f\cdot\nabla_\omega h + \int_S [f\Delta_\omega h + h\Delta_\omega f] = \int_{\partial S} \frac{\partial(fh)}{\partial_\omega n}.$$

Proof. (i) can be obtained by an elementary manipulation. Using now (i) and Theorem 1.2, (iii) with $h \equiv 1$ we obtain (ii). $\square$

2. ω-harmonic functions. In this section we will discuss the functional properties of functions which satisfy the equation

$$\Delta_\omega f(x) := \sum_{y\in\overline{S}} \big[f(y) - f(x)\big] \frac{\omega(x,y)}{d_\omega x} = 0. \tag{2.1}$$

For a subgraph S with boundary $\partial S \neq \phi$ of a host graph G with a weight ω we say that a function $f : \overline{S} \to \mathbb{R}$ is *ω-harmonic* on S if it satisfies (2.1) for all $x \in S$, i.e.,

$$f(x) = \frac{1}{d_\omega x} \sum_{y\in\overline{S}} f(y)\omega(x,y), \quad x \in S.$$

This implies that the value of f at x is given by a weighted average of the values of f at its neighboring vertices. From this point of view, we can clearly expect the following result to be true.

THEOREM 2.1 (minimum and maximum principle). *Let S be a subgraph of a host graph G with a weight ω and $f : \overline{S} \to \mathbb{R}$ be a function.*

(i) *If $\Delta_\omega f(x) \geq 0, x \in S$, and f has a maximum at a vertex in S, then f is constant.*
(ii) *If $\Delta_\omega f(x) \leq 0, x \in S$, and f has a minimum at a vertex in S, then f is constant.*
(iii) *If $\Delta_\omega f(x) = 0, x \in S$, and f has either a minimum or maximum in S, then f is constant.*
(iv) *If $\Delta_\omega f(x) = 0, x \in S$, and f is constant on the boundary ∂S, then f is constant.*

Proof. (ii) can be done in a similar way as in (i). (iii) and (iv) are easily obtained from (i) and (ii).

We prove (i). Assume that f has a maximum at a vertex $x_0 \in S$. Then

$$f(x_0) \geq f(y), \quad y \in \overline{S}, \tag{2.2}$$

and

$$f(x_0) \leq \sum_{y\in\overline{S}} f(y) \frac{\omega(x_0,y)}{d_\omega x_0}. \tag{2.3}$$

Suppose that there exists $y_0 \in \overline{S}$ such that $x_0 \sim y_0$ and $f(x_0) \neq f(y_0)$, i.e., $f(x_0) > f(y_0)$ in view of (2.2). Then it follows from (2.3) that

$$\begin{aligned} f(x_0) &\leq \sum_{\substack{y\in\overline{S}\\ y\neq y_0}} \frac{f(y)\omega(x_0,y)}{d_\omega x_0} + \frac{f(y_0)\omega(x_0,y_0)}{d_\omega x_0} \\ &< \sum_{\substack{y\in\overline{S}\\ y\neq y_0}} \frac{f(x_0)\omega(x_0,y)}{d_\omega x_0} + \frac{f(x_0)\omega(x_0,y_0)}{d_\omega x_0} \\ &= f(x_0), \end{aligned}$$

which implies that $f(x_0) = f(y)$ for all $y \in \overline{S}$ such that $y \sim x_0$. Now, for any $x \in \overline{S}$, there exists a path

$$x_0 \sim x_1 \sim x_2 \sim \cdots \sim x_{n-1} \sim x_n = x,$$

since S is connected. By applying the same argument as above inductively we see that $f(x_0) = f(x)$. □

The following is an easy consequence of the above theorem.

COROLLARY 2.2. *Under the same hypotheses as in Theorem* 2.1, *the following statements are true:*

(i) *If* $\Delta_\omega f \geq 0$ *on* S *and* $f|_{\partial S} \leq 0$ (< 0), *then* $f \leq 0$ (< 0) *on* S.

(ii) *If* $\Delta_\omega f \leq 0$ *on* S *and* $f|_{\partial S} \geq 0$ (> 0), *then* $f \geq 0$ (> 0) *on* S.

COROLLARY 2.3. (1) *If two functions* f *and* g *on* $\overline{S}$ *satisfy*

$$\Delta_\omega f = 0 \text{ and } \Delta_\omega g \geq 0$$

on S, *then* $g|_{\partial S} \leq f|_{\partial S}$ *implies* $g \leq f$ *on* S.

(2) *If a function* $f : \overline{S} \to \mathbb{R}$ *satisfies*

$$\Delta_\omega f(x) = 0, \quad x \in S,$$

and $|f|$ *has a maximum in* S, *then* f *is constant.*

In the continuous case, it is well known that a local maximum principle holds for a harmonic function in an open subset $\Omega \subset \mathbb{R}^n$. But it is not hard to see that the local maximum principle is no longer true in general in our case. Moreover, the local uniqueness principle does not hold in general. As a matter of fact, it is rather natural to expect that such discrepancies are caused by the discrete nature of graphs.

A nonempty subset Γ of vertices of a subgraph $\overline{S}$ is said to be a surface in $\overline{S}$ if $\Gamma = \partial T$ for a subgraph T whose vertices belong to S. In this case, we denote by $\overset{\circ}{\Gamma}$ the inner boundary $\overset{\circ}{\partial} T$. For each vertex $z \in \Gamma$ and $x \in \overset{\circ}{\Gamma}$ we define

$$d'_\omega z := \sum_{y \in \overset{\circ}{\Gamma}} \omega(y, z) \quad \text{(inward degree)}$$

and

$$d''_\omega x := \sum_{z \in \Gamma} \omega(x, z) \quad \text{(outward degree)}.$$

In addition, for a function f on $\overline{S}$ we write

$$\int_\Gamma f(z) d'_\omega z = \sum_{z \in \Gamma} f(z) d'_\omega z \quad \text{(inward integral)}$$

and

$$\int_{\overset{\circ}{\Gamma}} f(x) d''_\omega x = \sum_{x \in \overset{\circ}{\Gamma}} f(x) d''_\omega x \quad \text{(outward integral)}.$$

We use these notions to obtain the following interesting properties of ω-harmonic functions.

THEOREM 2.4. *Let* S *be a subgraph of a host graph with weight* ω *and let* $f : \overline{S} \to \mathbb{R}$. *Then* f *is* ω*-harmonic on* S, *i.e., for all* $x \in S$,

$$\Delta_\omega f(x) = 0, \tag{2.4}$$

if and only if for every surface Γ *in* $\overline{S}$

$$\int_{\Gamma} f(z)d'_{\omega}z = \int_{\overset{\circ}{\Gamma}} f(y)d''_{\omega}y. \tag{2.5}$$

Proof. Let $x \in S$ and $\Gamma_x = \{y \in \overline{S} | x \sim y\}$. Then Γ_x is a surface in $\overline{S}$ and $\overset{\circ}{\Gamma}_x = \{x\}$. Since $d_{\omega}x = d''_{\omega}x$ on $\overset{\circ}{\Gamma}_x$ and $d'_{\omega}z = \omega(x,z)$, (2.5) implies

$$f(x)d_{\omega}x = \sum_{z\in\Gamma_x} f(z)\omega(x,z),$$

which implies (2.4) immediately

Assume now that (2.4) holds and let Γ be a surface in $\overline{S}$ such that $\Gamma = \partial T$ for a subgraph $T \subset S$. We use Green's formula (Corollary 1.3, (iii)) to obtain

$$\begin{aligned} 0 &= \int_T \Delta_{\omega} f \\ &= \int_{\Gamma} \frac{\partial f}{\partial_{\omega} n} \\ &= \sum_{z\in\Gamma} \frac{\partial f}{\partial_{\omega} n}(z) d'_{\omega}z \\ &= \sum_{z\in\Gamma}\sum_{y\in\overset{\circ}{\Gamma}} \big[f(z) - f(y)\big]\omega(z,y). \end{aligned} \tag{2.6}$$

Then it follows that

$$\sum_{z\in\Gamma}\sum_{y\in\overset{\circ}{\Gamma}} f(z)\omega(z,y) = \sum_{z\in\Gamma}\sum_{y\in\overset{\circ}{\Gamma}} f(y)\omega(z,y)$$

or, equivalently,

$$\sum_{z\in\Gamma} f(z)\Big[\sum_{y\in\overset{\circ}{\Gamma}} \omega(z,y)\Big] = \sum_{y\in\overset{\circ}{\Gamma}} f(y)\Big[\sum_{z\in\Gamma} \omega(z,y)\Big],$$

which yields (2.5). □

In view of (2.6) we obtain the edge version of Theorem 2.4, the so-called dual theorem, as follows.

COROLLARY 2.5. *Under the same conditions as in Theorem* 2.4, *the formula* (2.5) *is equivalent to*

$$\sum_{\{z,y\}\in E(\Gamma,\overset{\circ}{\Gamma})} \big[f(z) - f(y)\big]\omega(z,y) = 0,$$

where $E(\Gamma, \overset{\circ}{\Gamma})$ *denotes the set of all edges joining a vertex in* Γ *and a vertex in* $\overset{\circ}{\Gamma}$.

For two vertices x and y in a connected graph, the distance $d(x,y)$ between x and y is the number of edges in a shortest path joining x and y.

For a vertex x_0 in a subgraph S we write

$$\Gamma_j(x_0) := \big\{y \in \overline{S} | \quad d(x_0,y) = j\big\}, \quad j = 0,1,2,\ldots,$$

which is called a neighborhood of x_0 with radius j.

Then the following is a variant of Theorem 2.4.

COROLLARY 2.6. *Let S and f be the same as in Theorem* 2.4. *Then f is ω-harmonic on S if and only if for every $x_0 \in S$*

$$\int_{\Gamma_j(x_0)} f(x) d''_\omega x = \int_{\Gamma_{j+1}(x_0)} f(x) d'_\omega x \tag{2.7}$$

for each j with $\Gamma_j(x_0) \subset S$.

Proof. Letting $j = 0$ in (2.7), we have the sufficiency. To prove the necessity, consider an induced subgraph T whose vertices are exactly those of $\bigcup_{k=0}^{j} \Gamma_k(x_0)$. Then it is easy to see that

$$\partial T = \Gamma_{j+1}(x_0) \text{ and } \overset{\circ}{\partial} T \subset \Gamma_j(x_0).$$

But a vertex x in $\Gamma_j(x_0)$, which does not belong to $\overset{\circ}{\partial} T$, does not make any contribution to the outer integral $\int_{\Gamma_j(x_0)} f(x) d''_\omega x$, since $d''_\omega x = 0$. Hence, condition (2.5) in Theorem 2.4 shows the condition is necessary. □

The following is the dual version of the above corollary.

COROLLARY 2.7. *Under the same conditions as in Corollary* 2.6 *the formula* (2.7) *is equivalent to*

$$\sum_{\{x,y\} \in E(\Gamma_j(x_0), \Gamma_{j+1}(x_0))} \big[f(x) - f(y)\big] \omega(x,y) = 0,$$

where $E(\Gamma_j(x_0), \Gamma_{j+1}(x_0))$ denotes the set of all edges joining a vertex in $\Gamma_j(x_0)$ and a vertex in $\Gamma_{j+1}(x_0)$.

3. The Dirichlet and Neumann BVPs: Direct problems. In this section, we discuss the direct problems such as the Dirichlet BVP (DBVP) and Neumann BVP (NBVP) (cf. [Ch], [CY], [CO], [BCE1], and [BCE2]).

We start this section with a physical interpretation of the ω-Laplace and ω-Poisson equations. Consider a host graph G with a weight ω and an (induced) subgraph S. For a surface Γ in $\overline{S}$ with $\Gamma = \partial T$ for some $T \subset S$ and $z \in \Gamma$, the flux of energy passing through z to its adjacent nodes in T is given by

$$-\sum_{y \sim z} \big[f(z) - f(y)\big] \cdot \frac{\omega(z,y)}{d'z}, \tag{3.1}$$

where $d'z = \sum_{y \sim z, y \in T} \omega(z,y)$ and f is a potential function in a diffusion field on a network (for example, an electrostatic field, a thermal field, or an elastic membrane). Here, the weight $\omega(z,y)$ plays the role of the conductivity of the diffusion along the edge $\{z,y\}$. In fact, (3.1) is exactly $-\frac{\partial f}{\partial_\omega n}(z)$ on Γ by definition (see section 1), and thus, by Green's formula we have

$$\int_T (-\Delta_\omega f) = \int_\Gamma \left(-\frac{\partial f}{\partial_\omega n}\right),$$

which is the flow across Γ.

On the other hand, assume that T gains (or loses) an amount of energy $\int_T g$, where g is the energy density. Then we have

$$\int_T (-\Delta_\omega f) = \int_T g.$$

Therefore, since T is arbitrary, by taking T to be any single vertex $x \in S$ we obtain the vertex equation

$$-\Delta_\omega f(x) = g(x), \quad x \in S. \tag{3.2}$$

Thus, it is reasonable to say that the conductivity equation on a graph can be represented as in (3.2), where $\omega(x, y)$ corresponds to the edge conductivity on the edge x, y.

Following the work of Fan Chung and her collaborators [Ch], [CY], and [CO], we will discuss first (3.2) on a graph $G = G(V, E)$ with a weight ω and no boundary. We consider the matrix

$$\Delta_\omega(x, y) = \begin{cases} -1 & \text{if } x = y, \\ \frac{\omega(x,y)}{d_\omega x} & \text{if } x \sim y, \\ 0 & \text{otherwise.} \end{cases}$$

We can consider the function f as a N-dimensional vector, where $N = |V|$ denotes the number of vertices of the graph G. Thus, (3.2) can be understood as a matrix linear equation. Let D denote the diagonal matrix with the (x, x)th entry having the value $d_\omega x$ for each x and $\mathcal{L}_\omega = D^{1/2}\Delta_\omega D^{-1/2}$. Then $(-\mathcal{L}_\omega)$ is a nonnegative definite symmetric matrix so that it has the eigenvalues

$$\lambda_0 < \lambda_1 \leq \lambda_2 \leq \cdots \leq \lambda_{N-1}$$

and corresponding eigenfunctions

$$\Phi_0, \Phi_1, \Phi_2, \ldots, \Phi_{N-1}, \tag{3.3}$$

which are orthonormal in the sense that for each pair of distinct i and j

$$\sum_{x \in V} \Phi_i(x) \cdot \Phi_j(x) = 0,$$

while, for all j,

$$\sum_{x \in V} |\Phi_j(x)|^2 = 1.$$

It is easy to show that (see [Ch]) $\lambda_0 = 0, \lambda_1 > 0$ and $\Phi_0(x) = \frac{\sqrt{d_\omega x}}{\sqrt{\mathrm{vol}(G)}}$, $x \in V$, and $\mathrm{vol}(G) := \sum_{x \in V} d_\omega x$.

In what follows, we occasionally use the notation $\langle\ ,\ \rangle_X$, defined by $\langle f, g\rangle_X = \sum_{x \in X} f(x)g(x)$ for simplicity. Now we have the following solvability result for the Poisson equation.

THEOREM 3.1. *Let $G = G(V, E)$ be a graph with a weight ω and $f : G \to \mathbb{R}$ be a function. Then the equation*

$$\Delta_\omega f(x) = g(x), \quad x \in V, \tag{3.4}$$

has a solution if and only if $\int_G g = 0$. *In this case, the solution is given by*

$$f(x) = a_0 + \langle \Gamma_\omega(x,\cdot), g\rangle_V, \quad x \in V, \tag{3.5}$$

where a_0 *is an arbitrary constant and*

$$\Gamma_\omega(x,y) = \sum_{j=1}^{N-1} \left(-\frac{1}{\lambda_j}\right) \Phi_j(x)\Phi_j(y)\sqrt{\frac{d_\omega y}{d_\omega x}}, \quad x,y \in V. \tag{3.6}$$

Proof. Assume that $\int_G g = 0$. Then

$$\begin{aligned}\langle D^{1/2}g, \Phi_0\rangle &= \sum \sqrt{d_\omega x}\, g(x) \cdot \frac{\sqrt{d_\omega x}}{\sqrt{\mathrm{vol}G}} \\ &= \frac{1}{\sqrt{\mathrm{vol}G}} \int_G g \\ &= 0,\end{aligned}$$

where D is the diagonal matrix whose xth diagonal entry is $d_\omega x$.

Consider the orthogonal expansion

$$\left(D^{1/2}f\right)(x) = \sum_{j=0}^{N-1} a_j \Phi_j(x), \quad x \in V,$$

where $a_j = \langle D^{1/2}f, \Phi_j\rangle, j = 0,1,2,\ldots,N-1$. Then since $\mathcal{L}_\omega D^{1/2} = D^{1/2}\Delta_\omega$ and

$$\begin{aligned}-\lambda_j a_j &= \langle D^{1/2}f, \mathcal{L}_\omega \Phi_j\rangle \\ &= \langle \mathcal{L}_\omega D^{1/2} f, \Phi_j\rangle \\ &= \langle D^{1/2}g, \Phi_j\rangle,\end{aligned}$$

we have

$$a_j = \left(-\frac{1}{\lambda_j}\right)\langle D^{1/2}g, \Phi_j\rangle, \quad j = 1,2,\ldots,N-1,$$

and a_0 is an arbitrary constant. Hence

$$\sqrt{d_\omega x} f(x) = a_0 \frac{\sqrt{d_\omega x}}{\sqrt{\mathrm{vol}G}} + \sum_{j=1}^{N-1} \left(-\frac{1}{\lambda_j}\right)\left[\sum_{y\in V} g(y)\Phi_j(y)\sqrt{d_\omega y}\right]\Phi_j(x).$$

This is equivalent to

$$f(x) = \frac{a_0}{\sqrt{\mathrm{vol}G}} + \sum_{j=1}^{N-1}\left(-\frac{1}{\lambda_j}\right)\sum_{y\in V} g(y)\Phi_j(y)\frac{\sqrt{d_\omega y}}{\sqrt{d_\omega x}}\Phi_j(x),$$

which gives (3.5) with a different constant a_0. Conversely, a simple computation shows that

$$\Delta_\omega \cdot \Gamma_\omega\, g(x) = g(x) + \frac{1}{\mathrm{vol}G}\int_G g, \quad x \in V,$$

which implies that every function of the form (3.5) gives a solution to the equation (3.4).

The proof of the converse is easy. □

The matrix Γ_ω in (3.6) is called the Green function of Δ_ω. The following corollary is a Liouville-type theorem for ω-harmonic functions.

COROLLARY 3.2. *Under the same conditions as in Theorem* 3.1, *every solution* f *of*

$$\Delta_\omega f(x) = 0, \quad x \in V,$$

is constant.

The following corollary describes all functions which are ω-harmonic except possibly on a given (singularity) set T.

COROLLARY 3.3. *Under the same conditions as in Theorem* 3.1, *let* $T \subset V$. *Then every solution to*

$$\Delta_\omega f(x) = 0, \quad x \in V \setminus T,$$

can be represented as

$$f(x) = a_0 + \sum_{y \in T} \Gamma_\omega(x, y)\alpha(y), \quad x \in V, \tag{3.7}$$

where a_0 *is an arbitrary constant and*

$$\alpha(y) = \Delta_\omega f(y), \quad y \in T.$$

In particular, if $T = \{x_0\},\ x_0 \in V$, then (3.7) can be written as

$$f(x) = a_0 + \alpha_0 \Gamma_\omega(x, x_0), \quad x \in V,$$

where $\alpha_0 = \Delta_\omega f(x_0)$.

Let us now turn to BVPs and their eigenvalues. For a subgraph S of a host graph G with a weight ω, the *Dirichlet eigenvalues* of $-\mathcal{L}_\omega = -D^{1/2}\Delta_\omega D^{-1/2}$ are defined to be the eigenvalues

$$\nu_1 \le \nu_2 \le \cdots \le \nu_n$$

of the matrix $-\mathcal{L}_{\omega,S}$, where $\mathcal{L}_{\omega,S}$ is a submatrix of $\mathcal{L}_\omega$ with rows and columns restricted to those indexed by vertices in S and $n = |S|$. Let $\phi_1, \phi_2, \ldots, \phi_n$ be the linearly independent functions on $\overline{S}$ such that for each $j = 1, 2, \ldots, n$,

$$\mathcal{L}_{\omega,S}\phi_j(x) = (-\nu_j)\phi_j(x), \quad x \in S, \quad \text{and} \quad \phi_j|_{\partial S} = 0.$$

In fact, $\phi_1, \phi_2, \ldots, \phi_n$ are the eigenfunctions corresponding to $\nu_1 \le \nu_2 \le \cdots \le \nu_n$ and can be assumed to be orthonormal in the same sense as above, namely, that for each pair of distinct i and j

$$\sum_{x \in S} \phi_i(x) \cdot \phi_j(x) = 0,$$

while, for all j,

$$\sum_{x \in S} |\phi_j(x)|^2 = 1.$$

As usual, the first eigenvalue $\nu_1 > 0$. (See, for instance, [Ch].)

One can follow now the standard procedure to define Green functions $\gamma_{\omega,S}$ as follows:

$$\gamma_{\omega,S}(x,y)=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\phi_j(x)\phi_j(y)\frac{\sqrt{d_\omega y}}{\sqrt{d_\omega x}},\quad x,y\in S. \tag{3.8}$$

Letting D_S stand for the diagonal matrix whose xth entry is $d_\omega x$ for each $x\in S$ and setting $\Delta_{\omega,S}=D_S^{-1/2}\mathcal{L}_{\omega,S}D_S^{1/2}$, one can easily verify that

$$\gamma_{\omega,S}\Delta_{\omega,S}=\Delta_{\omega,S}\gamma_{\omega,S}=I \tag{3.9}$$

and

$$\Delta_{\omega,S}(x,y)=\sum_{j=1}^{|S|}(-\nu_j)\phi_j(x)\phi_j(y)\frac{\sqrt{d_\omega y}}{\sqrt{d_\omega x}},\quad x,y\in S, \tag{3.10}$$

where I denotes the $|S|$-dimensional identity matrix.

The DBVP was solved by Chung in [CY], when the graph has the standard weight. (For the interested reader, despite some minor errata, the proof given there is correct.) We prove now the solvability of the DBVP for graphs with arbitrary weights using a different method.

THEOREM 3.4. *Let S be a subgraph of a host graph with a weight ω and $\sigma:\partial S\to\mathbb{R}$ be a given function. Then the unique solution f to the Dirichlet boundary value problem (DBVP)*

$$\begin{cases}\Delta_\omega f(x)=0, & x\in S,\\ f|_{\partial S}=\sigma\end{cases}$$

can be represented as

$$f(x)=-\langle\gamma_\omega(x,\cdot),B_\sigma\rangle_{y\in S},\quad x\in S, \tag{3.11}$$

where

$$B_\sigma(y)=\sum_{z\in\partial S}\frac{\sigma(z)\omega(y,z)}{d_\omega y},\quad y\in S. \tag{3.12}$$

Proof. Let f be a solution of the DBVP. Then

$$\begin{aligned}0&=\sum_{y\in S}\gamma_{\omega,S}(x,y)\Delta_\omega f(y)\\ &=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\left[\sum_{y\in S}\phi_j(y)\sqrt{d_\omega y}\Delta_\omega f(y)\right]\\ &=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\left[\int_S\left(D_S^{-1/2}\phi_j\right)\cdot\Delta_\omega f\right]\\ &=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\left[\int_S f\cdot\Delta_\omega\left(D_S^{-1/2}\phi_j\right)\right.\\ &\quad\left.+\int_{\partial S}\left\{\left(D_S^{-1/2}\phi_j\right)\cdot\frac{\partial f}{\partial_\omega n}-f\cdot\frac{\partial}{\partial_\omega n}\left(D_S^{-1/2}\phi_j\right)\right\}\right].\end{aligned} \tag{3.13}$$

Here, we have used Green's formula from Corollary 1.3. On the other hand, one can show that

$$\Delta_\omega\big(D_S^{-1/2}\phi_j\big)(x) = (-\nu_j)\big(D_S^{-1/2}\phi_j\big)(x), \quad x \in S,$$

since $\phi_j = 0$ on ∂S. From this identity and orthonormality of ϕ_j we can conclude that

$$\begin{aligned}
&\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\left[\int_S f\cdot\Delta_\omega\big(D_S^{-1/2}\phi_j\big)\right]\\
&=\sum_{j=1}^{|S|}\frac{\phi_j(x)}{\sqrt{d_\omega x}}\cdot\left[\sum_{y\in S} f(y)\cdot\frac{\phi_j(y)}{\sqrt{d_\omega y}}\cdot d_\omega y\right]\\
&=\sum_{y\in S} f(y)\left[\sum_{j=1}^{|S|}\phi_j(x)\phi_j(y)\sqrt{\frac{d_\omega y}{d_\omega x}}\,\right]\\
&= f(x).
\end{aligned}$$

Hence, from the equality (3.13) and the fact that $\phi_j = 0$ on ∂S, we have

$$\begin{aligned}
f(x) &= \sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\int_{\partial S}\left[f\cdot\frac{\partial}{\partial_\omega n}\big(D_S^{-1/2}\phi_j\big)\right]\\
&=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\left[\sum_{z\in\partial S} f(z)\cdot\frac{\partial}{\partial_\omega n}\big(D_S^{-1/2}\phi_j\big)(z)\cdot dz\right]\\
&=\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\sum_{z\in\partial S}\sigma(z)dz\left[\sum_{y\in S}\left\{\frac{\phi_j(z)}{\sqrt{d_\omega z}}-\frac{\phi_j(y)}{\sqrt{d_\omega y}}\right\}\frac{\omega(z,y)}{d_\omega z}\right]\\
&=-\sum_{j=1}^{|S|}\left(-\frac{1}{\nu_j}\right)\frac{\phi_j(x)}{\sqrt{d_\omega x}}\sum_{y\in S}\phi_j(y)\sqrt{d_\omega y}\left(\sum_{z\in\partial S}\frac{\sigma(z)\omega(z,y)}{d_\omega y}\right)\\
&=-\sum_{y\in S}\gamma_{\omega,S}(x,y)B_\sigma(y)\\
&=-\langle\gamma_{\omega,S}(x,\cdot),B_\sigma\rangle_S
\end{aligned}$$

for each $x \in S$. Moreover, a simple calculation shows that every function of the form (3.11) gives a solution.

The desired uniqueness result now follows easily from Theorem 2.1. □

Remark 3.5.

(i) The identity (3.11) can be rewritten as

$$f(x)=\sum_{j=1}^{|S|}\frac{1}{\nu_j}\sum_{y\in S}\left[\sum_{z\in\partial S}\frac{\sigma(z)\omega(y,z)}{d_\omega y}\right]\phi_j(y)\phi_j(x)\sqrt{\frac{d_\omega y}{d_\omega x}},\quad x\in S.$$

In fact, B_σ is a function on S depending only on the value of σ on ∂S and $B_\sigma(y) = 0$ for $y \in S\setminus \overset{\circ}{\partial} S$. On the other hand, two different boundary conditions σ_1 and σ_2 may give rise to the same solution whenever $B_{\sigma_1} = B_{\sigma_2}$.

(ii) (3.11) can be understood as a matrix multiplication by

$$f = -\gamma_{\omega,S} \cdot B_\sigma \text{ on } S \tag{3.14}$$

or, equivalently,

$$\Delta_{\omega,S} f = -B_\sigma \text{ on } S \tag{3.15}$$

in view of (3.8). The relation (3.15) enables us to identify uniquely the boundary values from an ω-harmonic function f with $\Delta_\omega f = 0$ on S.

Now we characterize the ω-harmonic functions with a set of singularities in a subgraph with nonempty boundary.

THEOREM 3.6. *Let S be a subgraph of a graph with weight ω and $T \subset S$. Then every $f : \overline{S} \to \mathbb{C}$ satisfying*

$$\Delta_\omega f(x) = 0, \quad x \in S \setminus T,$$

can be uniquely represented as

$$f(x) = h(x) + \sum_{y \in T} \gamma_{\omega,S}(x,y)\beta(y), \quad x \in \overline{S}, \tag{3.16}$$

where h is an ω-harmonic function on S satisfying $h|_{\partial S} = f|_{\partial S}$ and $\beta(y) = \Delta_\omega f(y)$, $y \in T$.

Proof. The uniqueness is easy, by Theorem 2.1. Now let $\beta(y) := \Delta_\omega f(y), y \in T$. Then we have

$$\Delta_\omega f(x) = \begin{cases} 0, & x \in S \setminus T, \\ \beta(x), & x \in T. \end{cases}$$

Define, for $x \in \overline{S}$,

$$f_1(x) := \sum_{y \in T} \gamma_{\omega,S}(x,y)\beta(y)$$

and

$$h(x) := f(x) - f_1(x).$$

Then $h|_{\partial S} = f|_{\partial S}$ and, for each $x \in S$,

$$\begin{aligned} \Delta_\omega h(x) &= \Delta_\omega f(x) - \Delta_\omega \left[\sum_{y \in T} \sum_{j=1}^{|S|} \left(-\frac{1}{\nu_j} \frac{\phi_j(x)}{\sqrt{d_\omega x}} \cdot \phi_j(y) \sqrt{d_\omega y} \right) \beta(y) \right] \\ &= \Delta_\omega f(x) - \sum_{y \in T} \sum_{j=1}^{|S|} \frac{\phi_j(x)}{\sqrt{d_\omega x}} \cdot \left[\phi_j(y) \sqrt{d_\omega y} \beta(y) \right] \\ &= \Delta_\omega f(x) - \sum_{y \in T} \delta(x,y)\beta(y) \\ &= 0, \end{aligned}$$

which completes the proof. □

Remark 3.7.

(i) In particular, if $T = \{x_0\}$, $x_0 \in S$, then (3.16) can be written simply as

$$f(x) = h(x) + \gamma_{\omega,S}(x, x_0)\beta(x_0),$$

where $\beta(x_0) = \Delta_\omega f(x_0)$.

(ii) In fact, in view of (3.16) and Theorem 3.4, the solution to the nonhomogeneous DBVP

$$\begin{cases} \Delta_\omega f(x) = g(x), & x \in S, \\ f|_{\partial S} = \sigma \end{cases}$$

can be represented by

$$f(x) = -\langle \gamma_{\omega,S}(x, \cdot), B_\sigma \rangle_S + \langle \gamma_{\omega,S}(x, \cdot), g \rangle_S.$$

Now we will discuss the Neumann boundary value problem (NBVP). The solvability of the NBVP and its proof have not been seen yet in any literature, at least to the best of the authors' knowledge.

First, we recall Green's formula

$$\int_S \Delta_\omega f = \int_{\partial S} \frac{\partial f}{\partial_\omega n}.$$

Hence, if there exists a solution to

$$\begin{cases} \Delta_\omega f = g & \text{on } S, \\ \frac{\partial f}{\partial_\omega n} = \psi & \text{on } \partial S, \end{cases}$$

then by Green's formula it is necessary that $\int_S g = \int_{\partial S} \psi$.

THEOREM 3.8. *Let S be a subgraph of a host graph G with a weight ω and let $f : \overline{S} \to \mathbb{R}$, $g : S \to \mathbb{R}$, and $\psi : \partial S \to \mathbb{R}$ be functions with $\int_{\partial S} \psi = \int_S g$. Then the solution to the NBVP*

$$\begin{cases} \Delta_\omega f(x) = g(x), & x \in S, \\ \frac{\partial f}{\partial_\omega n}(z) = \psi(z), & z \in \partial S, \end{cases}$$

is given by

$$f(x) = a_0 + \langle \Gamma_\omega(x, \cdot), g \rangle_S - \langle \Gamma_\omega(x, \cdot), \psi \rangle_{\partial S},$$

where Γ_ω is the Green function of Δ_ω on the graph $\overline{S}$ as a new host graph of S and a_0 is an arbitrary constant.

Proof. We rewrite the NBVP as

$$\begin{cases} \sum_{y \in \overline{S}} \left[f(y) - f(x) \right] \frac{\omega(x,y)}{d_\omega x} = g(x), & x \in S, \\ \sum_{y \in S} \left[f(y) - f(z) \right] \frac{\omega(y,z)}{d'_\omega z} = -\psi(z), & z \in \partial S. \end{cases} \tag{3.17}$$

To solve the system (3.17), consider $\overline{S}$ as a new host graph with the weight ω and with no boundary. Then S is still a subgraph of $\overline{S}$. (In fact, we should note here that if we regard $\overline{S}$ as a subgraph of G, then its boundary $\partial\overline{S}$ may not be empty.) Then, for each $z \in \partial S$, the inner degree $d'_\omega z$ is equal to $d_\omega z$ in this new graph $\overline{S}$, since

the induced subgraph has no edges between the vertices on ∂S. Hence (3.17) can be written as

$$\begin{cases} \sum_{y\in V_0} \big[f(y)-f(x)\big]\frac{\omega(x,y)}{d_\omega x} = g(x), & x\in S,\\ \sum_{y\in V_0} \big[f(y)-f(z)\big]\frac{\omega(y,z)}{d'_\omega z} = -\psi(z), & z\in \partial S, \end{cases} \tag{3.18}$$

where V_0 is the set of vertices in $\overline{S}$. Hence (3.18) is equivalent to

$$\sum_{y\in V_0} \big[f(y)-f(x)\big]\frac{\omega(x,y)}{d_\omega x} = \Psi(x), \quad x\in \overline{S}, \tag{3.19}$$

where

$$\Psi(x) = \begin{cases} g(x), & x\in S,\\ -\psi(x), & x\in \partial S. \end{cases}$$

Therefore, the NBVP is equivalent to

$$\Delta_\omega f(x) = \Psi(x), \quad x\in \overline{S}.$$

Thus, it follows from Theorem 3.1 that

$$\begin{aligned} f(x) &= a_0 + \langle \Gamma_\omega(x,\cdot), \Psi\rangle \\ &= a_0 + \sum_{y\in V_0} \Gamma_\omega(x,y)\Psi(y) \\ &= a_0 + \sum_{y\in S} \Gamma_\omega(x,y)g(y) - \sum_{z\in \partial S} \Gamma_\omega(x,z)\psi(z) \\ &= a_0 + \langle \Gamma_\omega(x,\cdot), g\rangle_S - \langle \Gamma_\omega(x,\cdot), \psi\rangle_{\partial S}, \end{aligned}$$

where a_0 is an arbitrary constant. This completes the proof. □

Remark 3.9. The solution to the NBVP is uniquely determined by the Neumann data ψ on ∂S up to an additive constant. Thus, we get a unique solution if we prescribe the value of f at some vertex in S or, for example, if we seek the solution f with $\int_S f =$ (a given constant).

4. Inverse problems. In the previous section, we have seen that for a function $\psi : \partial S \to \mathbb{R}$ with $\int_{\partial S} \psi = 0$ the NBVP

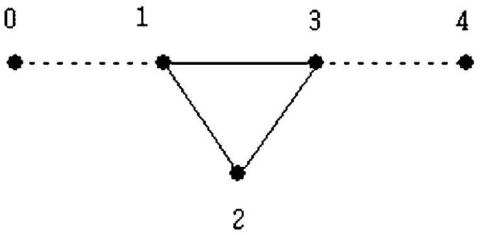
$$(NBVP) \begin{cases} \Delta_\omega f(x) = 0, & x\in S,\\ \frac{\partial f}{\partial_\omega n}(z) = \psi(z), & z\in \partial S, \end{cases}$$

has a unique solution up to an additive constant. Therefore, the Dirichlet data $f|_{\partial S}$ is well defined up to an additive constant.

In this section, we will discuss the inverse conductivity problem on the network (graph) S with nonempty boundary, which consists in recovering the conductivity (connectivity or weight) ω of the graph by using the so-called input-output map, for example, by using the Dirichlet data induced by the Neumann data (Neumann-to-Dirichlet map), with one boundary measurement.

In order to deal with this inverse problem , we need at least to know or be given the boundary data such as $f(z)$, $\frac{\partial f}{\partial_\omega n}(z)$ for $z\in\partial S$ and ω near the boundary. So it

is natural to assume that $f|_{\partial S}$, $\frac{\partial f}{\partial_\omega n}|_{\partial S}$, and $\omega|_{\partial S \times \overset{\circ}{\partial} S}$ are known (given or measured). But even though we are given all these data on the boundary, we are not guaranteed, in general, to be able to identify the conductivity ω uniquely. To illustrate this we consider a graph S whose vertices are $\{1, 2, 3\}$ and $\partial S = \{0, 4\}$ as follows:



with the weight

$$\omega(0,1) = 1,\ \omega(0,k) = 0 \quad (k = 2,\ 3,\ 4),$$

and

$$\omega(3,4) = 1,\ \omega(k,4) = 0 \quad (k = 0,\ 1,\ 2).$$

Let $f : \overline{S} \to \mathbb{R}$ be a function satisfying $\Delta_\omega f(k) = 0,\ k = 1, 2, 3$. Assume that

$$f(0) = 0,\ f(1) = 1,\ f(3) = 3,\ f(4) = 4,\ f(2) = (\text{unknown}).$$

Thus, since $\overset{\circ}{\partial} S = \{1, 3\}$, the boundary data $f|_{\partial S}$, $\frac{\partial f}{\partial_\omega n}|_{\partial S}$ and $\omega|_{\partial S \times \overset{\circ}{\partial} S}$ are known.

In fact,

$$\frac{\partial f}{\partial_\omega n}(0) = f(0) - f(1) = -1,$$
$$\frac{\partial f}{\partial_\omega n}(4) = f(4) - f(3) = 1.$$

The problem is to determine

$$\omega(1,2) = x,\ \ \omega(2,3) = y,\ \ \omega(1,3) = z, \quad \text{and} \quad f(2).$$

From $\Delta_\omega f(k) = 0,\ k = 1, 2, 3$, we have

$$f(1) = \frac{f(0) + xf(2) + zf(3)}{1 + x + z} = 1,$$
$$f(2) = \frac{xf(1) + yf(3)}{x + y},$$
$$f(3) = \frac{zf(1) + yf(2) + f(4)}{z + y + 1} = 3.$$

This system is equivalent to

$$\begin{cases} x(y-1) + y(x-1) + 2z(x+y) = 0, \\ f(2) = \frac{x+3y}{x+y}. \end{cases} \tag{4.1}$$

This system has infinitely many solutions. For instance, assume $z = 0$; that is, the two vertices 1 and 3 are not adjacent. Then (4.1) is reduced to

$$\begin{cases} \frac{1}{x}+\frac{1}{y}=2, \\ f(2)=\frac{x+3y}{x+y}. \end{cases} \tag{4.2}$$

For example, $(x,y,z)=(1,1,0)$ or $(2,2/3,0)$ satisfy the first equation. In fact, it is easy to see that there are infinitely many pairs (x,y) of nonnegative numbers satisfying the first equation in (4.2) so that $f(2)$ is undetermined as a result.

In view of the above example, in order to determine the weight ω uniquely we need some more information other than $f|_{\partial S}$, $\frac{\partial f}{\partial_\omega n}|_{\partial S}$, and $\omega|_{\partial S\times\mathring{\partial}S}$. To motivate the main theorem we impose in this example the additional constraints that

$$x\geq 1,\ y\geq 1,\ \text{and } z\geq 0 \tag{4.3}$$

in (4.1). Then (4.1) yields a unique triple of solution $x=1,\ y=1,\ z=0$, and $f(2)=2$.

As a matter of fact, even the inverse conductivity problem of the diffusion equation

$$P[a;u]:=\begin{cases} \operatorname{div}[a(x)\nabla u(x)]=0, & x\in\Omega, \\ u|_{\partial\Omega}=\sigma \end{cases} \tag{4.4}$$

in a bounded open subset $\Omega\subset\mathbb{R}^n$ has been studied under some additional constraints besides Dirichlet and Neumann data (see [A], [BF], [Ca], [I], [IP], and [SU]). In particular, in [A] and [I] it is shown that there is a global uniqueness result under the condition that

(i) $a_1=a_2$ near $\partial\Omega$, and $a_1\leq a_2$ in Ω,
(ii) $\frac{\partial u_1}{\partial n}=\frac{\partial u_2}{\partial n}$ on $\partial\Omega$,
(iii) $\int_\Omega u_1=\int_\Omega u_2=0$,

where $P[a_j;u_j]=0,\ j=1,2$ in (4.4).

Now we are in a position to state the first main theorem of this paper.

THEOREM 4.1. *Let ω_1 and ω_2 be weights with $\omega_1\leq\omega_2$ on $\overline{S}\times\overline{S}$ and $f_1,\ f_2:\overline{S}\to\mathbb{R}$ be functions satisfying that*

$$\begin{cases} \Delta_{\omega_j} f_j(x)=0, & x\in S, \\ \frac{\partial f}{\partial_{\omega_j} n}(z)=\psi(z), & z\in\partial S, \end{cases}$$

for a given function $\psi:\partial S\to\mathbb{R}$ with $\int_{\partial S}\psi=0$ and $j=1,\ 2$.

If we assume that

(i) $\omega_1(z,y)=\omega_2(z,y)$ *on* $\partial S\times\mathring{\partial}S$,
(ii) $f_1|_{\partial S}=f_2|_{\partial S}$,

then we have

(i) $f_1=f_2$ *on* $\overline{S}$,
(ii) $\omega_1(x,y)=\omega_2(x,y)$ *whenever* $f_1(x)\neq f_1(y)$, *or* $f_2(x)\neq f_2(y)$.

To prove this result we adapt the method of energy functionals, extensively used for theory of nonlinear partial differential equations. For functions $\sigma:\partial S\to\mathbb{R}$ and $g:\overline{S}\to\mathbb{R}$ we define a functional by

$$I_\omega[h]:=\int_{\overline{S}}\left[\frac{1}{4}|\nabla_\omega h|^2-hg\right] \tag{4.5}$$

for every function h in the set

$$A := \{h : \overline{S} \to \mathbb{R} | \quad h|_{\partial S} = \sigma\}, \tag{4.6}$$

which is called the admissible set. In the continuous case, the well-known Dirichlet principle states that the energy minimizer in the admissible set is a solution of the DBVP. We derive here the discrete version of Dirichlet's principle as follows.

THEOREM 4.2 (Dirichlet's principle). *Assume that $f : \overline{S} \to \mathbb{R}$ is a solution to*

$$\begin{cases} -\Delta_\omega f = g & \text{on } S, \\ f|_{\partial S} = \sigma. \end{cases} \tag{4.7}$$

Then

$$I_\omega[f] = \min_{h \in A} I_\omega[h]. \tag{4.8}$$

Conversely, if $f \in A$ satisfies (4.8)*, then f is the solution of* (4.7)*, and the only one.*

Proof. Let h be a function in A. Then, making use of (1.2) in Theorem 1.2, we have

$$\begin{aligned} 0 &= \int_{\overline{S}} (-\Delta_\omega f - g)(f - h) \\ &= \int_{\overline{S}} \big[(-\Delta_\omega f)(f - h) - g(f - h)\big] \\ &= \int_{\overline{S}} \left[\frac{1}{2}\nabla_\omega f \cdot \nabla_\omega (f - h) - g(f - h)\right] \\ &= \frac{1}{2}\int_{\overline{S}} |\nabla_\omega f|^2 - \frac{1}{2}\int_{\overline{S}} \nabla_\omega f \cdot \nabla_\omega h - \int_{\overline{S}} g(f - h). \end{aligned}$$

Hence

$$\begin{aligned} \int_{\overline{S}} \left[\frac{1}{2}|\nabla_\omega f|^2 - gf\right] &= \int_{\overline{S}} \left[\frac{1}{2}\nabla_\omega f \cdot \nabla_\omega h - gh\right] \\ &= \frac{1}{2}\sum_{x \in \overline{S}} \sum_{y \in \overline{S}} |\big[f(y) - f(x)\big] \cdot \big[h(y) - h(x)\big]| \cdot \omega(x, y) - \int_{\overline{S}} gh \\ &\le \frac{1}{2}\sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \frac{\big[f(y) - f(x)\big]^2 + \big[h(y) - h(x)\big]^2}{2} \cdot \omega(x, y) - \int_{\overline{S}} gh \\ &= \frac{1}{4}\int_{\overline{S}} |\nabla_\omega f|^2 + \frac{1}{4}\int_{\overline{S}} |\nabla_\omega h|^2 - \int_{\overline{S}} gh, \end{aligned}$$

where we used the triangular inequality

$$|ab| \le \frac{a^2 + b^2}{2}, \quad a, b \in \mathbb{R}.$$

Thus, it follows that

$$\int_{\overline{S}} \left[\frac{1}{4}|\nabla_\omega f|^2 - gf\right] \le \int_{\overline{S}} \left[\frac{1}{4}|\nabla_\omega h|^2 - gh\right],$$

which implies

$$I_\omega[f] \le I_\omega[h], \quad h \in A.$$

Since $f \in A$, we have

$$\min_{h \in A} I_\omega[h] = I_\omega[f].$$

Now we prove the converse. Let T be a subset of vertices in S and

$$\chi_T(x) = \begin{cases} 1, & x \in T, \\ 0 & \text{otherwise.} \end{cases}$$

Then $f + \tau\chi_T \in A$ for each real number τ, since $\chi_T = 0$ on ∂S. Define

$$i(\tau) := I_\omega[f + \tau\chi_T], \quad \tau \in \mathbb{R}.$$

Then

$$\begin{aligned} i(\tau) &= \int_{\overline{S}} \left[\frac{1}{4} |\nabla_\omega f + \tau \nabla_\omega \chi_T|^2 - (f + \tau\chi_T) g \right] \\ &= \frac{1}{4} \int_{\overline{S}} |\nabla_\omega f|^2 + 2\tau \nabla_\omega f \cdot \nabla_\omega \chi_T + \tau^2 |\nabla_\omega \chi_T|^2 - \int_{\overline{S}} (f + \tau\chi_T) g. \end{aligned}$$

Note that the scalar function $i(\tau)$ has a minimum at $\tau = 0$ and thus $\frac{di}{d\tau}(0) = 0$. That is,

$$\begin{aligned} 0 &= \frac{1}{2} \int_{\overline{S}} \nabla_\omega f \cdot \nabla_\omega \chi_T - \int_{\overline{S}} \chi_T \cdot g \\ &= \int_{\overline{S}} \left[\chi_T (-\Delta_\omega f - g) \right] \\ &= \sum_{x \in T} \left[-\Delta_\omega f(x) - g(x) \right] d_\omega x. \end{aligned}$$

In particular, taking $T = \{x\}, x \in S$, we obtain

$$-\Delta_\omega f(x) - g(x) = 0,$$

which is the required result. The uniqueness follows from Theorem 3.4. □

Now we are ready to prove Theorem 4.1.

Proof of Theorem 4.1.

(i) Let $\sigma : \partial S \to \mathbb{R}$ be the function defined by

$$\sigma(z) = f_1(z) = f_2(z), \quad z \in \partial S,$$

using the hypothesis (ii). Define

$$I_{\omega_1}[h] := \frac{1}{4} \int_{\overline{S}} |\nabla_{\omega_1} h|^2 d_{\omega_1}$$

for every h in the admissible set

$$A = \left\{ h : \overline{S} \to \mathbb{R} | \quad h|_{\partial S} = \sigma \right\}.$$

Then, by virtue of Theorem 1.2 we have

$$\begin{aligned} I_{\omega_1}[h] &= \frac{1}{2} \int_{\overline{S}} h(-\Delta_{\omega_1} h) d_{\omega_1} \\ &= \frac{1}{2} \int_S h(-\Delta_{\omega_1} h) d_{\omega_1} + \frac{1}{2} \int_{\partial S} h(-\Delta_{\omega_1} h) d_{\omega_1}. \end{aligned}$$

Moreover, by the coincidence of the Dirichlet and Neumann data we can see that the boundary ∂S and the inner boundary $\mathring{\partial} S$ are well defined independently of the values of the weights $\omega_1,\ \omega_2$ and, moreover, for $z \in \partial S$,

$$d_{\omega_1} z = \sum_{y \in \mathring{\partial} S} \omega_1(z,y) = \sum_{y \in \mathring{\partial} S} \omega_2(z,y) = d_{\omega_2} z, \tag{4.9}$$

$$\begin{aligned} \Delta_{\omega_1} f_1(z) &= \sum_{y \in \mathring{\partial} S} \big[f_1(y) - f_1(z)\big] \frac{\omega_1(z,y)}{d_{\omega_1} z} \\ &= \sum_{y \in \mathring{\partial} S} \big[f_2(y) - f_2(z)\big] \frac{\omega_2(z,y)}{d_{\omega_2} z} \\ &= \Delta_{\omega_2} f_2(z). \end{aligned} \tag{4.10}$$

Then, it follows from the condition $\omega_1 \le \omega_2$ that

$$\begin{aligned} I_{\omega_1}[f_1] &= \frac{1}{2} \int_{\partial S} f_1(-\Delta_{\omega_1} f_1) d_{\omega_1} \\ &= \frac{1}{2} \int_{\partial S} f_2(-\Delta_{\omega_2} f_2) d_{\omega_1} \\ &= \frac{1}{2} \int_{S} f_2(-\Delta_{\omega_2} f_2) d_{\omega_2} + \frac{1}{2} \int_{\partial S} f_2(-\Delta_{\omega_2} f_2) d_{\omega_2} \\ &= \frac{1}{2} \int_{\overline{S}} f_2(-\Delta_{\omega_2} f_2) d_{\omega_2} \\ &= \frac{1}{4} \int_{\overline{S}} |\nabla_{\omega_2} f_2|^2 d_{\omega_2} \\ &= \frac{1}{4} \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \big[f_2(x) - f_2(y)\big]^2 \omega_2(x,y) \\ &\ge \frac{1}{4} \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \big[f_2(x) - f_2(y)\big]^2 \omega_1(x,y) \\ &= \frac{1}{4} \int_{\overline{S}} |\nabla_{\omega_1} f_2|^2 d_{\omega_1} \\ &= I_{\omega_1}[f_2]. \end{aligned}$$

Using Dirichlet's principle (Theorem 4.2), one sees that $f_1 = f_2$ on $\overline{S}$.

(ii) In the proof of (i) we actually have proved that $I_{\omega_1}[f_1] = I_{\omega_1}[f_2]$. In other words, taking $f := f_1 = f_2$ on $\overline{S}$,

$$\sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \big[f(x) - f(y)\big]^2 \omega_2(x,y) = \sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \big[f(x) - f(y)\big]^2 \omega_1(x,y),$$

or, equivalently,

$$\sum_{x \in \overline{S}} \sum_{y \in \overline{S}} \big[f(x) - f(y)\big]^2 \cdot \big[\omega_2(x,y) - \omega_1(x,y)\big] = 0.$$

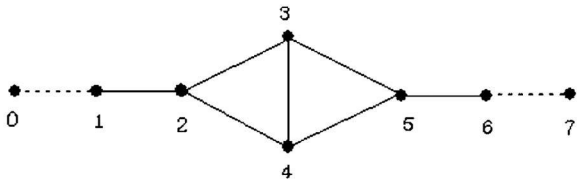
Therefore, we have

$$\big[f(x)-f(y)\big]^2\cdot\big[\omega_2(x,y)-\omega_1(x,y)\big]=0$$

for all $x\in\overline{S}$ and $y\in\overline{S}$. This gives (ii). □

Remark 4.3. In Theorem 4.1 above, if $f:=f_1=f_2$ is injective on S, then we are able to get $\omega_1=\omega_2$ on $\overline{S}\times\overline{S}$. For example, if S is the path P_n on n vertices with arbitrary weight ω, then it is not hard to see that every nonconstant ω-harmonic function f on P_n is strictly monotonic and hence all the weights are identified. But, in general, most graphs, even with the standard weight do not admit an injective solution to the DBVP or NBVP. Therefore, it will be quite interesting to figure out a pair of graphs and weights which admits an injective solution to the DBVP or NBVP.

To develop an idea to improve Theorem 4.1 we consider a graph $S=\{1,\ 2,\ 3,\ 4,\ 5,\ 6\}$ with $\partial S=\{0,\ 7\}$ as follows:



Suppose that ω_1 is the standard weight and ω_2 is the weight given by $\omega_1=\omega_2$ except only $\omega_2(3,\ 4)=k,\ k\geq 1$. Then $\omega_1\leq\omega_2$ throughout the graph $\overline{S}$ and $\omega_1=\omega_2$ except on the edge $\{3,4\}$. Now define a function $f:\overline{S}\to\mathbb{R}$ as

$$f(0)=a,\ f(1)=a-\alpha,\ f(2)=a-2\alpha,\ f(3)=f(4)=\frac{2a-5\alpha}{2},$$

$$f(5)=a-3\alpha,\ f(6)=a-4\alpha,\ f(7)=a-5\alpha,$$

where a and α are arbitrary real numbers. Then it is easy to verify that f satisfies both the equations

$$\Delta_{\omega_1}f(x)=0=\Delta_{\omega_2}f(x),\quad x\in S.$$

Here, we note that f is uniquely determined by the Dirichlet data $f(0)=a,\ f(7)=a-5\alpha$ and the Neumann data

$$\frac{\partial f}{\partial_\omega n}(0)=f(0)-f(1)=\alpha,\quad \frac{\partial f}{\partial_\omega n}(7)=f(7)-f(6)=-\alpha,$$

and each value $f(x)$ is determined regardless of the weight $\omega_2(3,4)=k$. This implies that we cannot identify the weight $\omega_2(3,\ 4)=k$ even with all possible boundary data. To derive a key idea to overcome this difficulty, we take $a>0$ and α so that $f(0)>0$ and $f(7)>0$. By a direct calculation (or using Corollary 2.2) we see that

$$f(m)>0,\ m=0,1,2,\dots,7.$$

Suppose that f satisfies the relation

$$\int_S f d_{\omega_1}=\int_S f d_{\omega_2}. \tag{4.11}$$

Then, since

$$\int_S f d_{\omega_1} = 2f(1) + 3f(2) + 3f(3) + 3f(4) + 3f(5) + 2f(6)$$

and

$$\int_S f d_{\omega_2} = 2f(1) + 3f(2) + (2+k)f(3) + (2+k)f(4) + 3f(5) + 2f(6),$$

it follows that

$$k\big[f(3) + f(4)\big] = f(3) + f(4),$$

which gives $k = 1$. Therefore, in order to identify the weight over all edges we need to impose an additional condition such as (4.11).

Now we return to the general situation. We know that for a function $\psi : \partial S \to \mathbb{R}$ with $\int_{\partial S} \psi = 0$ and $j = 1,\ 2$, the equation

$$\begin{cases} \Delta_{\omega_j} h_j(x) = 0,\ x \in S, \\ \frac{\partial h}{\partial_{\omega_j} n}(z) = \psi(z),\ z \in \partial S, \\ \int_S h_j\ d_{\omega_j} = 0 \end{cases} \tag{4.12}$$

has a unique pair of solutions (h_1, h_2). Let

$$m_j = \min_{z \in \partial S}\ h_j(z), \quad j = 1, 2, \tag{4.13}$$

and

$$m_0 = \max_{j=1,2}\ |m_j| \cdot \mathrm{vol}(S, \omega_j), \tag{4.14}$$

where $\mathrm{vol}(S, \omega_j) = \sum_{x \in S} d_{\omega_j} x$.

Motivated by the above example, we refine Theorem 4.1 as follows.

THEOREM 4.4. *Let ω_1 and ω_2 be weights with $\omega_1 \le \omega_2$ on $\overline{S} \times \overline{S}$ and $f_1,\ f_2 : \overline{S} \to \mathbb{R}$ be functions satisfying that for each $j = 1,\ 2$,*

$$\begin{cases} \Delta_{\omega_j} f_j(x) = 0,\ x \in S, \\ \frac{\partial f}{\partial_{\omega_j} n}(z) = \psi(z),\ z \in \partial S, \\ \int_S f_j\ d_{\omega_j} = K \end{cases} \tag{4.15}$$

for a given function $\psi : \partial S \to \mathbb{R}$ with $\int_{\partial S} \psi = 0$ and a given constant K with $K > m_0$. (Here, m_0 is the constant in (4.14)*.)*

If we assume that

(i) $\omega_1(z, y) = \omega_2(z, y)$ *on* $\partial S \times \overset{\circ}{\partial} S$,

(ii) $f_1|_{\partial S} = f_2|_{\partial S}$,

then we have

$$f_1 \equiv f_2$$

and

$$\omega_1(x, y) = \omega_2(x, y)$$

for all x and y in $\overline{S}$.

Proof. We have already shown in Theorem 4.1 that $f_1 \equiv f_2$. Now, for each $j = 1, 2$, we choose a constant C_j so that $C_j \cdot \mathrm{vol}(S, \omega_j) = K$. Then, it follows that $C_j > |m_j|$ and hence $h_j(x) + C_j > 0,\ x \in S$, by the maximum principle (or Corollary 2.2). Moreover, the function $\tilde{h}(x) := h_j(x) + C_j$ satisfies (4.15). By the uniqueness of the solution we have

$$f_j(x) = \tilde{h}(x) = h_j(x) + C_j > 0,\ x \in S.$$

Let $f := f_1 = f_2$ on $\overline{S}$. Then it follows from the condition $\int_S f_1\ d_{\omega_1} = K = \int_S f_2\ d_{\omega_2}$ that

$$\sum_{x \in S} f(x) d_{\omega_1}(x) = \sum_{x \in S} f(x) d_{\omega_2}(x)$$

or, equivalently,

$$\sum_{x \in S} f(x) \big[d_{\omega_2}(x) - d_{\omega_1}(x) \big] = 0.$$

Since $f(x) > 0$ and $d_{\omega_1}(x) \geq d_{\omega_1}(x)$ for all $x \in S$, we have

$$\begin{aligned} 0 &= d_{\omega_2}(x) - d_{\omega_1}(x) \\ &= \sum_{y \in \overline{S}} \big[\omega_2(x, y) - \omega_2(x, y) \big]. \end{aligned}$$

Since $\omega_1(x, y) \leq \omega_2(x, y)$, we obtain

$$\omega_1(x, y) = \omega_2(x, y)$$

for all x and y in $\overline{S}$, as required. □

Remark 4.5. In the above proof, the condition $K > m_0$ was used only to guarantee that $f_j(x) > 0,\ x \in S$. Hence, if we replace this condition by $f|_{\partial S} > 0,\ j = 1, 2$, in Theorem 4.4, we arrive at the same conclusion. Practically the positive solutions are easily available by adjusting the boundary values.

As seen in the study of the inverse conductivity problem in the continuous case (see, for instance, [A], [Ca], [I], [IP], [SU]), it would be worthwhile to prove the uniqueness under a condition weaker than the monotonicity condition $\omega_1 \leq \omega_2$ imposed above. Moreover, it would also be interesting to consider a stability theorem for the same conductivity equation.

Acknowledgments. We take the opportunity to thank David Walnut and the anonymous referees for their thoughtful comments.

DISTANCE FUNCTIONS AND GEODESICS ON SUBMANIFOLDS OF $\mathbb{R}^d$ AND POINT CLOUDS*

FACUNDO MÉMOLI† AND GUILLERMO SAPIRO†

Abstract. A theoretical and computational framework for computing intrinsic distance functions and geodesics on submanifolds of $\mathbb{R}^d$ given by point clouds is introduced and developed in this paper. The basic idea is that, as shown here, intrinsic distance functions and geodesics on general co-dimension submanifolds of $\mathbb{R}^d$ can be accurately approximated by extrinsic Euclidean ones computed inside a thin offset band surrounding the manifold. This permits the use of computationally optimal algorithms for computing distance functions in Cartesian grids. We use these algorithms, modified to deal with spaces with boundaries, and obtain a computationally optimal approach also for the case of intrinsic distance functions on submanifolds of $\mathbb{R}^d$. For point clouds, the offset band is constructed without the need to explicitly find the underlying manifold, thereby computing intrinsic distance functions and geodesics on point clouds while skipping the manifold reconstruction step. The case of point clouds representing noisy samples of a submanifold of Euclidean space is studied as well. All the underlying theoretical results are presented along with experimental examples for diverse applications and comparisons to graph-based distance algorithms.

Key words. geodesic distance, point clouds, manifolds, high dimensions, eikonal equations, random coverings, fast marching

1. Introduction.

One of the most popular sources of point clouds are three-dimensional (3D) shape acquisition devices, such as laser range scanners, with applications in geoscience, art (e.g., archival study), medicine (e.g., prosthetics), manufacturing (from cars to clothes), and security (e.g., recognition), among other disciplines. These scanners generally provide raw data in the form of (noisy) unorganized point clouds representing surface samples, and often produce very large numbers of points (tens of millions, for example, for the *David* model used in this paper). With the increasing popularity and very broad applications of this source of data, it is natural and important to work directly with such representations, without having to go through the intermediate step of fitting a surface to each (a step that can add computational complexity and introduce errors). See, for example, [11, 18, 20, 29, 33, 45, 46, 56, 58] for a few recent works with this type of data. Note that point clouds can also be used as primitives for visualization (e.g., [12, 33, 59]), as well as for editing [72].

Another important field where point clouds are found is in the representation of high-dimensional manifolds by samples (see, for example, [36, 44, 67]). This type of high-dimensional and general codimensional data appears in almost all disciplines, from computational biology to image analysis and financial data. Due to the extremely high number of dimensions in this case, it is impossible to perform manifold reconstruction, and the work needs to be done directly on the raw data, meaning the

point cloud. Also in this area, large amounts of data are becoming available, from neuroscience experiments with neural recording of millions of points to large image and protein databases.

Note that in general a point cloud representation is codimension free, in contrast with other popular representations such as triangular meshes. Some operations, such as the union of point clouds acquired from multiple views, are much easier when performed directly on the representations than when performed on the triangular meshes obtained from them. This paper addresses one of the most fundamental operations in the study and processing of submanifolds of Euclidean space, the computation of intrinsic distance functions and geodesics. We show that these computations can be made by working directly with the point cloud, without the need for reconstructing the underlying manifold. Even if possible (for example, at low dimensions), the meshing operation is avoided, saving computations and improving accuracy. The distance computation itself is performed in computationally optimal time. We present the corresponding theoretical results, experimental examples, and basic comparisons to mesh-based distance algorithms.[1] The results are valid for general dimensions and codimensions, and for (underlying) manifolds with or without boundary. These results include the analysis of noisy point clouds obtained from sampling the manifold. We provide bounds on the accuracy of the computations that depend on the sampling rate and pattern as well as on the noise, thereby addressing real manifold sampling scenarios.

A number of key building blocks are part of the framework introduced here. The first one is based on the fact that distance functions intrinsic to a given submanifold of $\mathbb{R}^d$ can be accurately approximated by Euclidean distance functions computed in a thin offset band that surrounds this manifold. This concept was first introduced in [49], where convergence results were given for hypersurfaces (codimension one submanifolds of $\mathbb{R}^d$) without boundary. This result is reviewed in section 2. In this paper, we first extend these results to general codimensions and deal with manifolds with or without boundary in section 3. Interestingly, we also show that the approximation is true not only for the intrinsic distance function but also for the intrinsic minimizing geodesic.

The approximation of intrinsic distance functions (and geodesics) by extrinsic Euclidean ones permits us to compute them using computationally optimal algorithms in Cartesian grids (as long as the discretization operation is permitted, memorywise;[2] see sections 7.1 and 8). These algorithms are based on the fact that the distance function satisfies a Hamilton–Jacobi partial differential equation (see section 2), for which consistent and fast algorithms have been developed in Cartesian grids [35, 62, 63, 69].[3] (See [40] for extensions to triangular meshes, and [68] for other Hamilton–Jacobi equations.) That is, due to these results, we can use computationally optimal algorithms in Cartesian grids (with boundaries) also to compute distance functions, and from them geodesics,[4] intrinsic to a given manifold, and in a computationally

[1] Theoretical results on the accuracy of the technique for 3D mesh-based computationally optimal distance computation proposed in [40] have not been reported to the best of our knowledge.

[2] This is of course just a limitation of a straightforward implementation that doesn't avoid allocating memory to empty grids and works in the embedding dimension, and not a limitation of the theoretical and computational frameworks here developed.

[3] Tsitsiklis first described an optimal-control type of approach to solving the Hamilton–Jacobi equation, while independently Sethian and Helmsen both developed techniques based on upwind numerical schemes.

[4] Geodesics are the integral curves corresponding to the gradient directions of the intrinsic distance function, and are obtained by back-propagating in this gradient direction from the target point to the source point.

optimal fashion. Note that, in contrast with the popular Dijkstra algorithm, these numerical techniques are consistent; they converge to the true distance when the grid is refined. Dijkstra's algorithm suffers from digitization bias due to metrication error when implemented on a grid (if no new graph edges are added to account for the new diagonals in each successive level of refinement of the grid); see [52, 53].

Once these basic results are available, we can then move on and deal with point clouds. The basic idea here is to construct the offset band directly from the point cloud, without the intermediate step of manifold reconstruction.[5] This is addressed in section 4 and section 5 for noise-free points and manifold samples, and in section 6 for points considered to be noisy samples of the manifold. In these cases, we explicitly compute the probability that the constructed offset band contains the underlying manifold. As we expect, this probability is a function of the number of point samples, the noise level, the size of the offset, and the basic geometric characteristics of the underlying manifold. This then covers the most realistic scenario, where the manifold is randomly sampled and the samples contain noise, thereby providing bounds that relate the error to the quality of the data. In the experimental section, section 7, we present a number of important applications. These applications are given to show the importance of this novel computational framework, and are by no means exhaustive. The data used in these examples were obtained from real acquisition devices, following laser scanning and photometric stereo. Concluding remarks are presented in section 8, where we also report the directions our research is taking.

To conclude this introduction, we should note that, to the best of our knowledge, the only additional work explicitly addressing the computation of distance functions and geodesics for point clouds is the one reported in [9, 67].[6] The comparison of performance in the presence of noise for our framework and the one proposed in [9, 67] is deferred to Appendix A.[7]

2. Preliminary results and notation. In this section we briefly review the main results in [49], where the idea of approximating intrinsic distances and geodesics by extrinsic ones was first introduced.

2.1. Notation. First, we introduce some basic notation that will be used throughout the article. For a compact and connected set $\Omega \in \mathbb{R}^d$, $d_\Omega(\cdot,\cdot)$ denotes the intrinsic distance between any two points of Ω, measured by paths constrained to be in Ω. We will also assume the convention that if $A \subset \mathbb{R}^d$ is compact, and x, y are not both in A, then $d_A(x,y) = D$ for some constant $D \gg \max_{x,y\in A} d_A(x,y)$. Given a k-dimensional submanifold $\mathcal{M}$ of $\mathbb{R}^d$, $\Omega^h_{\mathcal{M}}$ denotes the set $\{x \in \mathbb{R}^d : \ d(\mathcal{M},x) \le h\}$ (here the distance $d(\cdot,\cdot)$ is the Euclidean one). This is basically an h-offset of $\mathcal{M}$. To state that the sequence of functions $\{f_n(\cdot)\}_{n\in\mathbb{N}}$ uniformly converges to $f(\cdot)$ as $n \uparrow \infty$, we frequently write $f_n \overset{n}{\rightrightarrows} f$. For a given event $\mathcal{E}$, $\mathbb{P}(\mathcal{E})$ stands for its probability of occurring. For a random variable (R.V. from now on) X, its mean value is denoted by $\mathbb{E}(X)$. By

[5] Recent results such as those reported in [57] provide efficient techniques for constructing such bands for point cloud data.

[6] In addition to studying the computation of distance functions on point clouds, [9, 67] address the important combination of this with multidimensional scaling for manifold analysis. Prior work on using geodesics and multidimensional scaling can be found in [61].

[7] While concluding this paper, we learned of a recent extension to Isomap reported in [31]. This paper is also mesh-based, and follows the geodesics approach in Isomap with a novel neighborhood/connectivity approach and a number of interesting theoretical results and novel dimensionality estimation contributions. Further analysis of Isomap, as a dimensionality reduction technique, can be found in [19].

$X \sim \mathbf{U}[A]$ we mean that the R.V. X is *uniformly distributed* in the set A. For a function $f : \Omega \to \mathbb{R}$ and a subset A of Ω, $f|_A : A \to \mathbb{R}$ denotes the restriction of f to A. For a smooth function $f : \Omega \to \mathbb{R}$, Df, $D^2 f$, and $D^3 f$ stand for the first, second (Hessian matrix), and third differential, respectively, of f. Given a point x on the complete manifold $\mathcal{S}$, $B_{\mathcal{S}}(x, r)$ will denote the (intrinsic) open ball of radius $r > 0$ centered at x, and $B(y, r)$ will denote the *Euclidean* ball centered at y of radius r. Finally, $\log x$ will denote the natural logarithm of $x \in \mathbb{R}^+$.

2.2. Prelude. In [49], we presented a new approach for the computation of weighted intrinsic distance functions on hyper-surfaces. We proved convergence theorems and addressed the fast, computationally optimal, computation of such approximations; see comments after Theorem 1 below. The key starting idea is that distance functions satisfy the (intrinsic) Eikonal equation, a particular case of the general class of Hamilton–Jacobi partial differential equations. Given $p \in \mathcal{S}$ (a hypersurface in $\mathbb{R}^d$), we want to compute $d_{\mathcal{S}}(p, \cdot) : \mathcal{S} \to \mathbb{R}^+ \cup \{0\}$, the intrinsic distance function from every point on $\mathcal{S}$ to p. It is well known that the distance function $d_{\mathcal{S}}(p, \cdot)$ satisfies, in the viscosity sense (see [47]), the equation

$$\begin{cases} \|\nabla_{\mathcal{S}} d_{\mathcal{S}}(p, x)\| = 1 & \forall x \in \mathcal{S}, \\ d_{\mathcal{S}}(p, p) = 0, \end{cases}$$

where $\nabla_{\mathcal{S}}$ is the intrinsic differentiation (gradient). Instead of solving this intrinsic Eikonal equation on $\mathcal{S}$, we solve the corresponding extrinsic one in the offset band $\Omega^h_{\mathcal{S}}$:

$$\begin{cases} \|\nabla_x d_{\Omega^h_{\mathcal{S}}}(p, x)\| = 1 & \forall x \in \Omega^h_{\mathcal{S}}; \\ d_{\Omega^h_{\mathcal{S}}}(p, p) = 0, \end{cases}$$

where $d_{\Omega^h_{\mathcal{S}}}(p, \cdot)$ is the Euclidean distance and therefore now the differentiation is the usual one.

THEOREM 1 (see [49]). *Let p and q be any two points on the smooth (orientable, without boundary) hypersurface $\mathcal{S}$; then $\left| d_{\mathcal{S}}(p, q) - d_{\Omega^h_{\mathcal{S}}}(p, q) \right| \leq C_{\mathcal{S}} \sqrt{h}$ for small enough h,*[8] *where $C_{\mathcal{S}}$ is a constant depending on the geometry of $\mathcal{S}$.*

This simplification of the intrinsic problem into an extrinsic one permits the use of the computationally optimal algorithms mentioned in the introduction. This makes computing intrinsic distances, and from them geodesics, as simple and computationally efficient as computing them in Euclidean spaces. Moreover, as detailed in [49], the approximation of the intrinsic distance $d_{\mathcal{S}}$ by the extrinsic Euclidean one $d_{\Omega^h_{\mathcal{S}}}$ is never less accurate than the numerical error of these algorithms.

In [49], the result above was limited to hypersurfaces of $\mathbb{R}^d$ (codimension one submanifolds of $\mathbb{R}^d$) without boundary, and the theory was applied to implicit surfaces, where computing the offset band is straightforward. It is the purpose of the present work to extend Theorem 1 to deal with (1) submanifolds of $\mathbb{R}^d$ of any codimension and possibly with boundary,[9] (2) convergence of geodesic curves in addition to distance functions, (3) submanifolds of $\mathbb{R}^d$ represented as point clouds and (4) random sampling of submanifolds of $\mathbb{R}^d$ in the presence of noise. We should note that Theorem 1 holds even when the metric is not the one inherited from $\mathbb{R}^d$, obtaining weighted distance

[8] "Small enough h" means that $h < 1/\max_i \kappa_i(\mathcal{S})$, where $\kappa_i(\mathcal{S})$ is the ith principal curvature of $\mathcal{S}$. This guarantees having smoothness in $\partial\Omega^h_{\mathcal{S}}$; see [49].

[9] We will later impose some convexity conditions on the boundary in order to get rate of convergence estimates. However, the uniform convergence in itself doesn't require other hypotheses beyond smoothness.

functions; see [49]. Although we will not present these new results in such generality, this is a simple extension that will be reported elsewhere.

3. Submanifolds of $\mathbb{R}^d$ with boundary. We first extend Theorem 1 to more general manifolds, and we deal not only with distance functions but also with geodesics. The first extension is important for the learning of high-dimensional manifolds from samples and for scanned open volumes. The extension to geodesics is important for path planning on surfaces and for finding special curves such as crests and valleys; see [8, 49].

First we need to recall some results that will be key ingredients in our proofs below. All our results rest upon a certain degree of smoothness of geodesics in manifolds with boundary. We use "shortest path" and "minimizing geodesic" interchangeably.

THEOREM 2 (see [1]). *Let $\mathcal{M}$ be a C^3 Riemannian manifold with C^1 boundary $\partial\mathcal{M}$. Then any shortest path of $\partial\mathcal{M}$ is C^1.*

We will eventually need more regularity on the geodesics than simply C^1. This is achieved by requiring more regularity of the boundary.

THEOREM 3 ([48]). *Let $\mathcal{U} : \mathbb{R}^d \to \mathbb{R}$ be a C^3 function such that for some $h \in \mathbb{R}$*

(i) *the interior of $\{x \in \mathbb{R}^d | \, \mathcal{U}(x) = h\}$ is nonempty and there we have $D\mathcal{U}(x) \neq 0$.*

(ii) *the "obstacle" $\{x \in \mathbb{R}^d | \, \mathcal{U}(x) \geq h\}$ is compact.*

Let p and q be any two points in the same connected component of $\{x \in \mathbb{R}^d | \, \mathcal{U}(x) \leq h\}$; then the shortest (constrained) path joining both points is C^1 and has Lipschitz first derivative.

We now present the usual definition of length, as follows.

DEFINITION 1. *Let $\alpha : [a, b] \to \mathbb{R}^d$ be a curve, then we define its length $\mathbf{L}(\alpha)$ as*

$$\mathbf{L}(\alpha) \stackrel{\triangle}{=} \sup_{a=t_0<\cdots<t_N=b} \sum_{k=0}^{N-1} \|\alpha(t_{k+1}) - \alpha(t_k)\|.$$

Remark 1. Note that if α is Lipschitz with constant $\mathcal{L}_\alpha$, then $\mathbf{L}(\alpha) = \int_a^b \|\dot{\alpha}(t)\| dt$ and $\mathbf{L}(\alpha) \leq \mathcal{L}_\alpha (b - a)$.

PROPOSITION 1. *Let $\mathcal{S}$ be a smooth compact submanifold of $\mathbb{R}^d$ with boundary $\partial\mathcal{S}$. Let x, y be any two points in $\mathcal{S}$. Then $d_{\Omega_{\mathcal{S}}^h}(x, y)$ converges pointwise as $h \downarrow 0$.*

Proof. Since $\Omega_{\mathcal{S}}^h \subseteq \Omega_{\mathcal{S}}^{h'}$ if $h' \geq h$, we have that $d_{\Omega_{\mathcal{S}}^h}(x, y) \geq d_{\Omega_{\mathcal{S}}^{h'}}(x, y)$ Also, for any $h > 0$, $d_{\Omega_{\mathcal{S}}^h}(x, y) \leq d_{\mathcal{S}}(x, y) \leq \operatorname{diam}(\mathcal{S}) < +\infty$. Hence, the sequence $\{d_{\Omega_{\mathcal{S}}^h}(x, y)\}_{h>0}$ (for fixed x and y over $\mathcal{S}$) is bounded and nondecreasing, and therefore it converges to the supremum of its range. ∎

THEOREM 4. *Let $\mathcal{S}$ be a compact C^2 submanifold of $\mathbb{R}^d$ with (possibly empty) smooth boundary $\partial\mathcal{S}$. Let x, y be any two points in $\mathcal{S}$. Then we have*

1. *uniform convergence of the distances:*

$$d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}}(\cdot, \cdot) \stackrel{h\downarrow 0}{\rightrightarrows} d_{\mathcal{S}}(\cdot, \cdot);$$

2. *convergence of the geodesics: Let x and y be joined by a unique minimizing geodesic $\gamma_{\mathcal{S}} : [0, 1] \to \mathcal{S}$ over $\mathcal{S}$, and let $\gamma_h : [0, 1] \to \Omega_{\mathcal{S}}^h$ be a $\Omega_{\mathcal{S}}^h$-minimizing geodesic; then*

$$\gamma_h \stackrel{h\downarrow 0}{\rightrightarrows} \gamma_{\mathcal{S}}.$$

Proof. Given our hypothesis on $\mathcal{S}$, and according to [26], there exists $H > 0$ such that $\partial\Omega_{\mathcal{S}}^h$ is $C^{1,1}$ for all $0 < h \leq H$. Then Theorem 2 guarantees that for $0 < h \leq H$, $\gamma_h : [0,1] \to \Omega_{\mathcal{S}}^H$, the $\Omega_{\mathcal{S}}^h$ length-minimizing geodesic joining x and y is of class C^1. Since $d_{\Omega_{\mathcal{S}}^h}(x,y) \leq d_{\mathcal{S}}(x,y) \leq \operatorname{diam}(\mathcal{S}) < +\infty$ for any $h \in (0,H]$, we see that we can admit our $\Omega_{\mathcal{S}}^h$-geodesics to have Lipschitz constant $\mathcal{L} \leq \operatorname{diam}(\mathcal{S})$. Obviously, the set $\Omega_{\mathcal{S}}^H$ is bounded, and then the family $\{\gamma_h\}_{0<h\leq H}$ is bounded and equicontinuous. Hence, by the Ascoli–Arzelá theorem, there exist a subsequence $\{\gamma_{h_k}\}_{k\in\mathbb{N}}$ and a curve $\gamma_0 \in C^0([0,1],\mathcal{S})$ such that $\max_{t\in[0,1]} \|\gamma_{h_k}(t) - \gamma_0(t)\| \overset{h_k\downarrow 0}{\longrightarrow} 0$.

Moreover, by writing $|\gamma_0(t)-\gamma_0(t')| \leq |\gamma_{h_k}(t)-\gamma_0(t)| + |\gamma_{h_k}(t')-\gamma_0(t')| + \mathcal{L}|t-t'|$ and using the (pointwise) convergence of γ_{h_k} towards γ_0, we find that $\mathcal{L}$ is also a Lipschitz constant for γ_0. Then we have $\gamma_0 \in C^{0,1}([0,1],\mathcal{S})$.

Now, since γ_0 lies on $\mathcal{S}$ but may not be a shortest path, we have that its (finite) length is greater than or equal to $d_{\mathcal{S}}(x,y)$. We also have the trivial inequality $d_{\mathcal{S}}(x,y) \geq d_{\Omega_{\mathcal{S}}^h}(x,y)$. Putting this all together, we obtain

$$\mathbf{L}(\gamma_h) = d_{\Omega_{\mathcal{S}}^h}(x,y) \leq d_{\mathcal{S}}(x,y) \leq \mathbf{L}(\gamma_0).$$

Therefore

$$\limsup_{h\downarrow 0} \mathbf{L}(\gamma_h) = \limsup_{h\downarrow 0} d_{\Omega_{\mathcal{S}}^h}(x,y) \leq d_{\mathcal{S}}(x,y) \leq \mathbf{L}(\gamma_0).$$

Note that $\mathbf{L}(\gamma_0) = \mathbf{L}(\lim_{h_k\downarrow 0}\gamma_{h_k}) \leq \liminf_{h_k\downarrow 0} \mathbf{L}(\gamma_{h_k})$. This is the semicontinuity of length, an immediate consequence of its definition; see [41].

Since $\liminf_{h_k\downarrow 0}(\cdot) \leq \limsup_{h_k\downarrow 0}(\cdot) \leq \limsup_{h\downarrow 0}(\cdot)$, we see that $\limsup_{h\downarrow 0} d_{\Omega_{\mathcal{S}}^h}(x,y)$ $= \limsup_{h\downarrow 0} \mathbf{L}(\gamma_h)$ equals $d_{\mathcal{S}}(x,y)$ for all x and y in $\mathcal{S}$. From Proposition 1, we find that in fact $\lim_{h\downarrow 0} d_{\Omega_{\mathcal{S}}^h}(x,y)$ exists and equals $d_{\mathcal{S}}(x,y)$. Then, we have that the function $d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}}(\cdot,\cdot)$ satisfies the following:

(i) $d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}} : \mathcal{S}\times\mathcal{S} \to \mathbb{R}\cup\{0\}$ is continuous for each $H > h > 0$;
(ii) for each $(x,y) \in \mathcal{S}\times\mathcal{S}$, $\{d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}}(x,y)\}_h$ is nondecreasing;
(iii) $d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}}(\cdot,\cdot)$ converges pointwise towards $d_{\mathcal{S}}(\cdot,\cdot)$, which is continuous.

Then by Dini's uniform convergence theorem (see [6]) we can conclude that the convergence is uniform.

We can also see that γ_0 must be a minimizing geodesic of $\mathcal{S}$ since from the above chain of equalities $\mathbf{L}(\gamma_0) = d_{\mathcal{S}}(x,y)$. Then, if there was only one such curve joining x with y, we would have uniform convergence (along any subsequence!) of γ_h towards γ_0.[10] □

Remark 2. In Theorem 4, the convergence (of distances) is uniform, but we will have forfeited rate of convergence estimates unless we impose additional conditions on $\partial\mathcal{S}$, as we do in Corollary 3. Note that the new setting is wider than the one considered in Theorem 1 since the codimension of the underlying manifold is not necessarily 1. This is very important for applications such as dimensionality reduction, where the dimension of the underlying manifold is unknown beforehand.

COROLLARY 1. *Let $\mathcal{S}$ and $\partial\mathcal{S}$ satisfy the hypotheses of Theorem* 4. *Let $\{\Sigma_i\}_{i\in\mathbb{N}}$ be a family of compact of sets in $\mathbb{R}^d$ such that $\mathcal{S} \subseteq \Sigma_i$ for all $i \in \mathbb{N}$ and $d_{\mathcal{H}}(\Sigma_i,\mathcal{S}) \overset{i\uparrow+\infty}{\longrightarrow} 0$.*

[10] This follows from the fact that uniform convergence of γ_h to γ_0 is equivalent to the statement that for any subsequence $\{\gamma_{h_i}\}$ there exists a further subsubsequence $\{\gamma_{h_{i_k}}\}$ uniformly converging to γ_0.

Then,

$$d_{\Sigma_i}(\cdot,\cdot)\,|_{\mathcal{S}\times\mathcal{S}} \overset{i\uparrow+\infty}{\rightrightarrows} d_{\mathcal{S}}(\cdot,\cdot),$$

where $d_{\mathcal{H}}$ stands for the Hausdorff distance between sets.

We now present a uniform rate of convergence result for the distance in the band in the case $\partial\mathcal{S}=\emptyset$, and from this we deduce Corollary 3 below, which deals with the case $\partial\mathcal{S}\neq\emptyset$. This result generalizes the one presented in [49] because it allows for any codimension.

THEOREM 5. *Under the hypotheses of Theorem 4, with $\partial\mathcal{S}=\emptyset$, we have that for small enough $h>0$,*

$$\max_{(x,y)\in\mathcal{S}\times\mathcal{S}} \left| d_{\Omega_{\mathcal{S}}^h}|_{\mathcal{S}\times\mathcal{S}}(x,y) - d_{\mathcal{S}}(x,y)\right| \leq C_{\mathcal{S}}\sqrt{h}, \tag{1}$$

where the constant $C_{\mathcal{S}}$ does not depend on h. Also, we have the "relative" rate of convergence bound

$$1 \leq \sup_{\substack{x,y\in\mathcal{S}\\ x\neq y}} \frac{d_{\mathcal{S}}(x,y)}{d_{\Omega_{\mathcal{S}}^h}(x,y)} \leq 1 + C_{\mathcal{S}}\sqrt{h}. \tag{2}$$

Proof. This is a remake of our proof of the main theorem in [49]; therefore we skip some technical details which can be found there. Throughout the proof we will sometimes write d_h instead of $d_{\Omega_{\mathcal{S}}^h}$ for the sake of notational simplicity. We will denote by k ($\leq n-1$) the dimension of $\mathcal{S}$.

Let γ_0 be the arc length parametrized $\mathcal{S}$-shortest path joining the points $x,\ y\in\mathcal{S}$; clearly, we have $\mathrm{trace}(\gamma_0)\subset\mathcal{S}$. Let γ_h be the $\Omega_{\mathcal{S}}^h$ arc length parametrized shortest path joining x and y, which, as we know from Theorem 4, uniformly converges toward γ_0. For a number H as in the proof of Theorem 4, we have $\gamma_h\in C^{1,1}([0,d_h],\mathcal{S})$, and also $\eta:\Omega_{\mathcal{S}}^H\to\mathbb{R}$ defined by $\eta(x)\overset{\triangle}{=}\frac{1}{2}d^2(x,\mathcal{S})$ is smooth; see Appendix B. We define the projection operator $\Pi_{\mathcal{S}}:\Omega_{\mathcal{S}}^H\to\mathcal{S}$ by $\Pi_{\mathcal{S}}(x)=x-D\eta(x)$. We refer the reader to Appendix B for properties of $\Pi_{\mathcal{S}}$ and η which we use below.

Now, $d_{\Omega_{\mathcal{S}}^h}(x,y)=\mathbf{L}(\gamma_h)\leq d_{\mathcal{S}}(x,y)\leq\mathbf{L}(\Pi_{\mathcal{S}}(\gamma_h))$; then

$$\begin{aligned}
d_{\mathcal{S}}(x,y)-d_{\Omega_{\mathcal{S}}^h}(x,y) &\leq |\mathbf{L}(\Pi_{\mathcal{S}}(\gamma_h))-\mathbf{L}(\gamma_h)|\\
&\leq \int_0^{d_h}\left\|\dot{\overline{\Pi_{\mathcal{S}}(\gamma_h(t))-\gamma_h(t)}}\right\|\,dt\\
&= \int_0^{d_h}\left\|\dot{\overline{D\eta(\gamma_h(t))}}\right\|\,dt\\
&\leq \sqrt{d_h\int_0^{d_h}\dot{V}(t)\cdot\dot{V}(t)\,dt} \qquad \text{(by Cauchy–Schwarz inequality)}\\
&\leq \sqrt{d_h\int_0^{d_h}V(t)\cdot\ddot{V}(t)\,dt} \quad \text{(integrating by parts; see below),}
\end{aligned}$$

where $V(t)\overset{\triangle}{=}D\eta(\gamma_h(t))$ and $V(0)=V(1)=0$; see Appendix B.

Also $\dot{V}(t)=D^2\eta(\gamma_h(t))\dot{\gamma}(t)$, and since $\dot{\gamma_h}$ is Lipschitz and η is smooth, $\ddot{V}(t)$ exists almost everywhere and $\ddot{V}(t)=D^3\eta(\gamma_h(t))[\dot{\gamma}_h(t),\dot{\gamma}_h(t)]+D^2\eta(\gamma_h(t))\ddot{\gamma}(t)$ at points of

existence. Then since $D^3\eta D\eta = D^2\eta(\boldsymbol{I} - D^2\eta)$ and $D^2\eta D\eta = D\eta$ (see Appendix B),

$$\begin{aligned} V \cdot \ddot{V} &= D^3\eta(\gamma_h)[D\eta(\gamma_h), \dot{\gamma_h}, \dot{\gamma_h}] + D^2\eta[\ddot{\gamma_h}, D\eta(\gamma_h)] \\ &= \left(D^2\eta(\gamma_h)\left(\boldsymbol{I} - D^2\eta(\gamma_h)\right)\right)[\dot{\gamma_h}, \dot{\gamma_h}] + \ddot{\gamma_h} \cdot D\eta(\gamma_h). \end{aligned}$$

The matrix $\Lambda(t) \stackrel{\triangle}{=} D^2\eta(\gamma_h(t))(\boldsymbol{I} - D^2\eta(\gamma_h(t)))$ filters out normal components and has eigenvalues associated with the tangential bundle given by

$$\lambda_i(t) = \frac{d(t)\lambda_i(0)}{(1 + d(t)\lambda_i(0))^2} \qquad \text{for } 1 \leq i \leq k,$$

where we let $d(t) = d(\gamma_h(t), \mathcal{S})$. Note that $\max_{1\leq i\leq k}|\lambda_i(t)|$ can be bounded by $d(t)$ times a certain finite constant K' independent of h.

On the other hand, we can bound $|\ddot{\gamma}_h(t)|$ almost anywhere by a finite constant, say K, which takes into account the maximal curvature of all the boundaries $\partial\Omega^h_{\mathcal{S}}$, $0 < h < H$, but does not depend on h.

Putting all this together, we find (recall that $\|D\eta(x)\| = \sqrt{2\eta(x)} = d(x, \mathcal{S})$; see Appendix B)

$$\begin{aligned} \left(d_{\mathcal{S}}(x,y) - d_{\Omega^h_{\mathcal{S}}}(x,y)\right)^2 &\leq d_h \int_0^{d_h} \Lambda(t)[\dot{\gamma}_h, \dot{\gamma}_h]dt \\ &\quad + d_h \int_0^{d_h} \|\ddot{\gamma}_h\| \, \|D\eta(\gamma_h)\|dt \\ &\leq K' \max_{t\in[0,d_h]} d(t)\, d_h^2 + K \max_{t\in[0,d_h]} d(t) d_h^2. \end{aligned}$$

Now, remembering that d_h stands for $d_{\Omega^h_{\mathcal{S}}}(x,y)$, that $\mathrm{trace}(\gamma_h) \subset \Omega^h_{\mathcal{S}}$, and defining $C = K + K'$, we arrive with only a little simple additional work, at the relations (1) or (2). ∎

Remark 3. Note that, as the simple case of a circle in the plane shows, the rate of convergence is at most $C \cdot h$.

We immediately obtain the following corollary, which will be useful ahead.

COROLLARY 2. *Let $p \in \mathcal{S}$ and $r \leq H$; then $B(p,r) \cap \mathcal{S} \subseteq B_{\mathcal{S}}(p, r(1 + C_{\mathcal{S}}\sqrt{r}))$.*

Proof. Let $q \in B(p,r) \cap \mathcal{S}$; then by (2), $d_{\mathcal{S}}(p,q) \leq d_{\Omega^r_{\mathcal{S}}}(p,q)(1 + C_{\mathcal{S}}\sqrt{r})$. However, $q \in B(p,r) \subset \Omega^r_{\mathcal{S}}$, and thus $d_{\Omega^h_{\mathcal{S}}}(p,q) = \|p - q\| \leq r$, which completes the proof. ∎

DEFINITION 2. (see [21]) *We say that the compact manifold $\mathcal{S}$ with boundary $\partial\mathcal{S}$ is* strongly convex *if for every pair of points x and y in $\mathcal{S}$ there exists a unique minimizing geodesic joining them whose interior is contained in the interior of $\mathcal{S}$.*

Using basically the same procedure as in Theorem 5 with the convexity hypotheses above, we can prove the following corollary, whose (sketched) proof is presented in Appendix C.

COROLLARY 3. *Under the hypotheses of Theorem 2, and assuming $\mathcal{S}$ to be strongly convex, we have for small enough $h > 0$ the same conclusions of Theorem 5 (rate of convergence).*

Remark 4. Note that in case $\partial\mathcal{S} \neq \emptyset$ is not strongly convex, then obviously the same statement of Corollary 3 remains valid for any strongly convex subset of $\mathcal{S}$.

To conclude, in this section we extended the results in [49] to geodesics and distance functions in general codimension manifolds with or without (smooth) boundary, thereby covering all possible manifolds in common shape, graphics, visualization, and

learning applications.[11] We are now ready to extend this to manifolds represented as point clouds.

4. Distance functions on point clouds. We are now interested in making computations on manifolds represented as point clouds, i.e., *sampled manifolds*. In the case of this paper we will restrict ourselves to the computation of intrinsic distances.[12] Let $\mathcal{P}_n \stackrel{\triangle}{=} \{p_1, \ldots, p_n\}$ be a set of n different points sampled from the *compact* submanifold $\mathcal{S}$ and define[13]

$$\Omega^h_{\mathcal{P}_n} \stackrel{\triangle}{=} \bigcup_{i=1}^{n} B(p_i, h).$$

Let h and $\mathcal{P}_n$ be such that $\mathcal{S} \subseteq \Omega^h_{\mathcal{P}_n}$. We then have $(\mathcal{S} \subseteq)\Omega^h_{\mathcal{P}_n} \subseteq \Omega^h_{\mathcal{S}}$. We now want to consider $d_{\Omega^h_{\mathcal{P}}}(p, q)$ for any pair of points $p, q \in \mathcal{S}$ and prove some kind of proximity to the real distance $d_{\mathcal{S}}(p, q)$. The argument carries over easily since

$$d_{\Omega^h_{\mathcal{S}}}(p, q) \leq d_{\Omega^h_{\mathcal{P}_n}}(p, q) \leq d_{\mathcal{S}}(p, q),$$

and hence

$$0 \leq d_{\mathcal{S}}(p, q) \; - \; d_{\Omega^h_{\mathcal{P}_n}}(p, q) \leq d_{\mathcal{S}}(p, q) \; - \; d_{\Omega^h_{\mathcal{S}}}(p, q), \tag{3}$$

and the rightmost quantity can be bounded by $C_{\mathcal{S}}\, h^{1/2}$ (see section 3) in the case that $\partial\mathcal{S}$ is either convex or void. In general, without hypotheses on $\partial\mathcal{S}$ other than some degree of smoothness, we can also work out uniform convergence since by virtue of Theorem 4 the upper bound in (3) uniformly converges to 0. The key condition is $\mathcal{S} \subset \Omega_{\mathcal{P}^h_n}$, something that can obviously be coped with using the compactness of $\mathcal{S}$.[14] We can then state the following claim.

THEOREM 6 (uniform convergence for point clouds). *Let $\mathcal{S}$ be a compact smooth submanifold of $\mathbb{R}^d$ possibly with boundary $\partial\mathcal{S}$. Then the following hold:*

1. General case: *Given $\varepsilon > 0$, there exists $h_\varepsilon > 0$ such that for all $0 < h \leq h_\varepsilon$ one can find finite $n(h)$ and a set of points $\mathcal{P}_{n(h)}(h) = \{p_1(h), \ldots, p_{n(h)}(h)\}$ sampled from $\mathcal{S}$ such that*

$$\max_{p,q \in \mathcal{S}} \left(d_{\mathcal{S}}(p, q) - d_{\Omega^h_{\mathcal{P}_{n(h)}(h)}}(p, q) \right) \leq \varepsilon.$$

2. $\partial\mathcal{S}$ is either void or convex: *For every sufficiently small $h > 0$ one can find finite $n(h)$ and a set of points $\mathcal{P}_{n(h)}(h) = \{p_1(h), \ldots, p_{n(h)}(h)\}$ sampled from $\mathcal{S}$ such that*

$$\max_{p,q \in \mathcal{S}} \left(d_{\mathcal{S}}(p, q) - d_{\Omega^h_{\mathcal{P}_{n(h)}(h)}}(p, q) \right) \leq C_{\mathcal{S}} \sqrt{h}.$$

[11] Although in this paper we consider only manifolds with constant codimension, many of the results are extendible to variable codimensions, and this will be reported elsewhere.

[12] Note that having the intrinsic distance allows us to compute basic intrinsic properties of the manifold; see e.g., [13].

[13] The balls now used are defined with respect to the metric of $\mathbb{R}^d$; they are not intrinsic.

[14] By compactness, given $h > 0$, we can find finite $N(h)$ and points $p_1, p_2, \ldots, p_{N(h)} \in \mathcal{S}$ such that $\mathcal{S} = \cup_{i=1}^{N(h)} B_{\mathcal{S}}(p_i, h)$. But since for $p \in \mathcal{S}$, $B_{\mathcal{S}}(p, h) \subset B(p, h) \cap \mathcal{S}$, we also get $\mathcal{S} \subset \cup_{i=1}^{N(h)} B(p_i, h)$.

In practice, one must worry about both the number of points and the radii of the balls. Obviously, there is a tradeoff between both quantities. If we want to use few points, in order to cover $\mathcal{S}$ with the balls we have to increase the value of the radius. Clearly, there exists a value H such that for values of h smaller than H we do not change the topology; see [3, 4, 5]. This implies that the number of points must be larger than a certain lower bound. This result can be generalized to ellipsoids which can be locally adapted to the geometry of the point cloud [15], or from minimal spanning trees. Note that we are interested in the smallest possible offset of the point cloud that covers $\mathcal{S}$. Further comments on this are presented below and are also the subject of current efforts to be reported elsewhere.

The practical significance of the previous Theorem is clear. Part 1 says that in general, given a desired precision for the computation of the distance, we have a maximum *nonzero* value for the radius of all the balls, below which we can always find a *finite* number of points sampled from the manifold for which the "Ω-set" formed by those points achieves the desired accuracy;[15] that is, we can choose the radius at our convenience *within* a certain range which depends on this level of accuracy. Part 2 says more, since it actually links ε to h_ε. It basically says that the radius of the balls must be of the order of the square of the desired error.

5. Extension to random sampling of manifolds. In practice, we really do not have too much control over the way in which points are sampled by the acquisition device (e.g., scanner) or given by the learned sampled data. Therefore it is more realistic to make a probabilistic model of the situation and then try to conveniently estimate the probability of achieving a prescribed level of accuracy as a function of the number of points and the radii of the balls. It will be interesting to see how geometric quantities of $\mathcal{S}$ enter in those bounds we will establish. However, since the bounds are based in local volume computations and all manifolds are locally Euclidean, those curvature dependent quantities will be asymptotically negligible.

We now present a simple model for the current setting, while results for other models can be developed from the derivations below. Here we assume that the points in $\mathcal{P}_n$ are independently and identically sampled on the submanifold $\mathcal{S}$ with the uniform probability law;[16] we will write this as $p_i \sim \mathbf{U}[\mathcal{S}]$. For simplicity of exposition, we will restrict ourselves to the case when $\mathcal{S}$ has no boundary.[17] Also, we deal only with uniform independently and identically distributed (i.i.d.) sampling; results for other sampling models, including those adapted to the manifold geometry, can be easily obtained following the developments below and will be reported elsewhere.

We have to define the way in which we are going to measure accuracy. A possibility for such a measure is (for each $\varepsilon > 0$)

$$\mathbb{P}\left(\max_{p,q\in\mathcal{S}}\left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right) > \varepsilon\right). \tag{4}$$

There is a potential problem with this way of testing accuracy, since we are assuming that when we use the approximate distance, we will be evaluating it on $\mathcal{S}$. This might seem a bit awkward since we don't exactly know all the surface but just

[15] We are considering the case when all the balls have the same radii.

[16] This means that for any subset $A \subseteq \mathcal{S}$ and any $p_i \in \mathcal{P}_n$, $\mathbb{P}(p_i \in A) = \frac{\mu(A)}{\mu(S)}$, where $\mu(\cdot)$ stands for the measure (area/volume) of the set.

[17] In order to extend the results in this section to the case $\partial\mathcal{S} \neq \emptyset$, the same considerations discussed in [9] remain valid in our case.

some points on it. Moreover, a more natural and real-problem-motivated approach would be to measure the discrepancy over $\mathcal{P}_n$ itself (see section 7 ahead), over part of this set, or over another *trial* set of points $\mathcal{Q}_m$.

However, since for any set of points $\mathcal{Q}_m \subset \mathcal{S}$ we have that the following inclusion of events,

$$\left\{ \max_{p,q\in\mathcal{Q}_m} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q) \right) > \varepsilon \right\} \subseteq \left\{ \max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q) \right) > \varepsilon \right\},$$

holds, bounding (4) suffices for dealing with any of the possibilities mentioned above. Note that we are somehow considering $d_{\Omega^h_{\mathcal{P}_n}}$ defined for all pairs of points in $\mathcal{S} \times \mathcal{S}$, even if it might happen that $\mathcal{S} \cap \Omega^h_{\mathcal{P}_n} \neq \mathcal{S}$. In any case we extend $d_{\Omega^h_{\mathcal{P}_n}}$ to all $\Omega^h_{\mathcal{S}} \times \Omega_{\mathcal{S}}$ by a large constant, say $k \operatorname{diam}(\mathcal{S})$, $k \gg 1$.

Let us spell out a few definitions so as to avoid an overload of notation:

$$\mathcal{E}_\varepsilon \triangleq \left\{ \max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q) \right) > \varepsilon \right\}, \tag{5}$$

$$\mathcal{I}_{h,n} \triangleq \left\{ \mathcal{S} \subseteq \Omega^h_{\mathcal{P}_n} \right\}. \tag{6}$$

Now, since $\mathcal{E}_\varepsilon = (\mathcal{E}_\varepsilon \cap \mathcal{I}_{h,n}) \cup (\mathcal{E}_\varepsilon \cap \mathcal{I}^c_{h,n})$, using the union bound and then Bayes rule, we have

$$\begin{aligned} \mathbb{P}(\mathcal{E}_\varepsilon) &\leq \mathbb{P}(\mathcal{E}_\varepsilon \cap \mathcal{I}_{h,n}) + \mathbb{P}\left(\mathcal{E}_\varepsilon \cap \mathcal{I}^c_{h,n}\right) \\ &= \mathbb{P}(\mathcal{E}_\varepsilon \mid \mathcal{I}_{h,n})\, \mathbb{P}(\mathcal{I}_{h,n}) + \mathbb{P}\left(\mathcal{E}_\varepsilon \mid \mathcal{I}^c_{h,n}\right) \mathbb{P}\left(\mathcal{I}^c_{h,n}\right) \end{aligned}$$

$$\Downarrow$$

$$\mathbb{P}(\mathcal{E}_\varepsilon) \leq \mathbb{P}(\mathcal{E}_\varepsilon \mid \mathcal{I}_{h,n}) + \mathbb{P}\left(\mathcal{I}^c_{h,n}\right). \tag{7}$$

It is clear now that we must find a convenient lower bound for the second term in the previous expression, the probability of covering all $\mathcal{S}$ with the union of balls. (The first term will be dealt with using the convergence theorems presented in previous sections.) For this we need a few lemmas.

LEMMA 1. *Let K be an upper bound for the sectional curvatures of $\mathcal{S}$ ($\operatorname{diam}(\mathcal{S}) = k$) and $x \in \mathcal{S}$ be a fixed point. Then, under the hypotheses on $\mathcal{P}_n$ described above, there exist a constant $\omega_k > 0$ and a function $\theta_{\mathcal{S}}(\cdot)$ with $\lim_{h\downarrow 0} \frac{\theta_{\mathcal{S}}(h)}{h^{k+1}} = 0$ such that for small enough $h > 0$*

$$\mathbb{P}\left(\left\{x \notin \Omega^h_{\mathcal{P}_n} \cap \mathcal{S}\right\}\right) \leq \left(1 - \frac{\omega_k\, h^k + \theta_{\mathcal{S}}(h)}{\mu(\mathcal{S})}\right)^n. \tag{8}$$

Moreover, one can further expand the right-hand side of (8) *as*

$$\left(1 - \frac{\omega_k h^k (1 - K c_k h^2) + \phi_{\mathcal{S}}(h)}{\mu(\mathcal{S})}\right)^n$$

for some c_k depending only on the dimension k of $\mathcal{S}$ and a function $\phi_{\mathcal{S}}$ such that $\frac{\phi_{\mathcal{S}}(h)}{h^{k+2}} \to 0$ as $h \downarrow 0$.

Proof.

$$\mathbb{P}\left(\left\{x \notin \Omega^h_{\mathcal{P}_n} \cap \mathcal{S}\right\}\right) = \mathbb{P}\left(\left\{\bigcap_{i=1}^n \{x \notin B(p_i,h) \cap \mathcal{S}\}\right\}\right) \tag{9}$$

$$= \mathbb{P}\left(\left\{\bigcap_{i=1}^n \{p_i \notin B(x,h) \cap \mathcal{S}\}\right\}\right) \tag{10}$$

$$= \prod_{i=1}^n \mathbb{P}\left(\{p_i \notin B(x,h) \cap \mathcal{S}\}\right) \tag{11}$$

$$= \prod_{i=1}^n \left(1 - \mathbb{P}\left(\{p_i \in B(x,h) \cap \mathcal{S}\}\right)\right). \tag{12}$$

Since $B_{\mathcal{S}}(x,h) \subseteq B(x,h) \cap S$,[18] then $\mu\left(\mathcal{S} \cap B(x,h)\right) \geq \mu\left(B_{\mathcal{S}}(x,h)\right)$. On the other hand, note that

$$\begin{aligned}\mathbb{P}\left(\{p_i \in B(x,h) \cap \mathcal{S}\}\right) &= \frac{\mu\left(\mathcal{S} \cap B(x,h)\right)}{\mu\left(\mathcal{S}\right)} \\ &\geq \frac{\mu\left(B_{\mathcal{S}}(x,h)\right)}{\mu\left(\mathcal{S}\right)}.\end{aligned}$$

Finally, as shown in Appendix D, one can lower bound $\mu\left(B_{\mathcal{S}}(x,h)\right)$ using information on the curvatures of $\mathcal{S}$, by means of the Bishop–Günther volume comparison theorem. More precisely, we can write

$$\mu\left(B_{\mathcal{S}}(x,h)\right) \geq \min_{\zeta \in \mathcal{S}} \mu\left(B_{\mathcal{S}}(\zeta,h)\right) \geq \omega_k h^k + \theta_{\mathcal{S}}(h),$$

where $\frac{\theta_{\mathcal{S}}(h)}{h^q} \to 0$ when $h \to 0$ for $q \leq k+1$. Therefore, from (9) we obtain

$$\mathbb{P}\left(\left\{x \notin \Omega^h_{\mathcal{P}_n} \cap \mathcal{S}\right\}\right) \leq \left(1 - \frac{\omega_k\, h^k + \theta_{\mathcal{S}}(h)}{\mu\left(\mathcal{S}\right)}\right)^n.$$

The last assertion follows from Proposition 3. ∎

Remark 5. Note that we cannot, however, from (8), conclude that $\mathbb{P}(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n}) \leq \left(1 - \frac{\omega_k\, h^k + \theta_{\mathcal{S}}(h)}{\mu(\mathcal{S})}\right)^n$. In order to upper bound $\mathbb{P}(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n})$ we will first estimate $\mathbb{P}(B_{\mathcal{S}}(x,\delta) \nsubseteq \Omega^h_{\mathcal{P}_n})$ for any $x \in \mathcal{S}$ and small $\delta > 0$. Then we will use the compactness of $\mathcal{S}$ by covering it with a finite δ-net consisting of $\mathcal{N}(\mathcal{S},\delta)$ points, and conclude by using the union bound. Yet another intermediate step will therefore be to estimate the covering number $\mathcal{N}(\mathcal{S},\delta)$.

LEMMA 2. *Under the hypotheses of the previous lemma, let $\delta \in (0,h)$; then*

$$\mathbb{P}\left(B_{\mathcal{S}}(x,\delta) \nsubseteq \Omega^h_{\mathcal{P}_n}\right) \leq \left(1 - \frac{\omega_k\,(h-\delta)^k + \theta_{\mathcal{S}}(h-\delta)}{\mu\left(\mathcal{S}\right)}\right)^n. \tag{13}$$

Proof. We find α and β such that $\{B_{\mathcal{S}}(q,\delta) \subseteq \Omega^h_{\mathcal{P}_n}\} \supseteq \{q \in \Omega^{\alpha h+\beta\delta}_{\mathcal{P}_n}\}$. Note first that for any $x \in B_{\mathcal{S}}(q,\delta)$, $|x-q| \leq d_{\mathcal{S}}(x,q) \leq \delta$. Assume that the event $\{q \in \Omega^{\alpha h+\beta\delta}_{\mathcal{P}_n}\}$

[18] Consider $z \in B_{\mathcal{S}}(x,h)$; then $d_{\mathcal{S}}(x,z) \leq h$, but always $d(x,z) \leq d_{\mathcal{S}}(x,z)$, and thus $d(x,z) \leq h$, which implies $z \in B(x,h) \cap \mathcal{S}$.

holds. Then for some $p_r \in \mathcal{P}_n$, $q \in B(p_r, \alpha h + \beta\delta)$; that is, $|q - p_r| \leq \alpha h + \beta\delta$. Now, note that

$$|x - p_r| \leq |x - q| + |q - p_r| \leq \alpha h + (\beta + 1)\delta.$$

If we force the rightmost number to be h, we find that we must have $(1+\beta)\delta = (1-\alpha)h$, and then $\alpha h + \beta\delta = h - \delta$. Then we have found $B_{\mathcal{S}}(q, \delta) \subseteq B(p_r, h-\delta) \subset \Omega^h_{\mathcal{P}_n}$. Hence (using (8)), $\mathbb{P}(B_{\mathcal{S}}(q,\delta) \subseteq \Omega^h_{\mathcal{P}_n}) \geq \mathbb{P}(q \in \Omega^{h-\delta}_{\mathcal{P}_n} \geq 1 - (1 - \frac{\omega_k\,(h-\delta)^k + \theta_{\mathcal{S}}\,(h-\delta)}{\mu(\mathcal{S})})^n$. ∎

We also need the next lemma, whose proof is deferred to Appendix C.

LEMMA 3 (bounding the covering number). *Under the hypotheses of Lemma* 2 *and further assuming* $\mathcal{S}$ *to be compact, we have that for any small enough* $\delta > 0$ *there exists a* δ*-covering of* $\mathcal{S}$ *with cardinality*

$$\mathcal{N}(\mathcal{S}, \delta) \leq \frac{\mu\,(\mathcal{S})}{\omega_k(\delta/2)^k + \theta_{\mathcal{S}}(\delta/2)}. \tag{14}$$

PROPOSITION 2. *Let the set of hypotheses sustaining all of the previous lemmas hold. Let also* $([0,1) \ni)\, x_h \triangleq \frac{\omega_k(h/2)^k + \theta_{\mathcal{S}}\,(h/2)}{\mu(\mathcal{S})}$, *where* ω_k *and* $\theta_{\mathcal{S}}$ *are given as in the proof of Lemma* 1. *Then*

$$\mathbb{P}\left(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n}\right) \leq \frac{e^{-nx_h}}{x_h}. \tag{15}$$

Proof. Consider a finite $\frac{h}{2}$-net covering $\mathcal{S}$ given by Lemma 3, that is, $\mathcal{S} = \bigcup_{i=1}^{\mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right)} B_{\mathcal{S}}(q_i, \frac{h}{2})$; then

$$\begin{aligned}
\mathbb{P}\left(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n}\right) &= \mathbb{P}\left(\bigcup_{x \in \mathcal{S}} \{x \notin \Omega^h_{\mathcal{P}_n}\}\right) \\
&= \mathbb{P}\left(\bigcup_{i=1}^{\mathcal{N}(\mathcal{S}, \frac{h}{2})} \bigcup_{x \,\in\, B_{\mathcal{S}}(q_i, \frac{h}{2})} \{x \notin \Omega^h_{\mathcal{P}_n}\}\right) \\
&\leq \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right) \max_{1 \leq i \leq \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right)} \mathbb{P}\left(\bigcup_{x \,\in\, B_{\mathcal{S}}(q_i, \frac{h}{2})} \{x \notin \Omega^h_{\mathcal{P}_n}\}\right) \\
&= \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right) \max_{1 \leq i \leq \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right)} \mathbb{P}\left(B_{\mathcal{S}}\left(q_i, \frac{h}{2}\right) \nsubseteq \Omega^h_{\mathcal{P}_n}\right) \\
&= \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right) \left(1 - \min_{1 \leq i \leq \mathcal{N}\left(\mathcal{S}, \frac{h}{2}\right)} \mathbb{P}\left(B_{\mathcal{S}}\left(q_i, \frac{h}{2}\right) \subseteq \Omega^h_{\mathcal{P}_n}\right)\right).
\end{aligned}$$

Using the lemmas above, we obtain

$$\mathbb{P}\left(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n}\right) \leq \frac{(1 - x_h)^n}{x_h},$$

and we conclude by using the inequality $1 - x \leq e^{-x}$, valid for $x \geq 0$. ∎

It is both interesting and useful to find a relation between n (the number of points in the cloud), h (the radii of the balls), and k (the dimension of the manifold) which guarantees $\lim_{n\uparrow+\infty,\, h\downarrow 0} \mathbb{P}(\mathcal{S} \nsubseteq \Omega^h_{\mathcal{P}_n}) = 0$. For this purpose we will use Proposition 2.

Note that $h > 0$ will be small, and also, if we are attempting to approximate $d_{\mathcal{S}}$, h should tend to 0.[19]

Remark 6. Note that for $\{a_m\}_{m\in\mathbb{N}}$, $a_m \downarrow 0$, $\frac{e^{-ma_m}}{a_m}$ goes to zero as $m \uparrow \infty$ if a_m is asymptotically greater than or equal to $\frac{\log m}{m}$. Then, in order to have the right-hand side of (15) tend to zero, we should have $x_h \gtrsim \frac{\log n}{n}$, and the condition relating h, k, and n should then be[20]

$$h^k \gtrsim \left(\mu(\mathcal{S})\frac{2^k}{\omega_k}\right)\frac{\log n}{n}. \tag{16}$$

Also, under this condition we can estimate the rate at which $\frac{e^{-nx_h}}{x_h}$ approaches zero as $n \uparrow \infty$. For example, with $x_h \simeq \frac{\log n}{n}$, $\frac{e^{-nx_h}}{x_h} \simeq \frac{1}{\log n}$ as $n \uparrow \infty$. Note that, of course, we can speed up the convergence towards zero by choosing slower variations of x_{h_n} with n; for instance, with $x_{h_n} \simeq \frac{\log n^\gamma}{n}$, $\gamma \geq 1$, we have $\frac{e^{-nx_h}}{x_h} \simeq \frac{1}{\gamma(\log n)n^{\gamma-1}}$ as $n \uparrow \infty$. Bounds for $\mathbb{P}(\mathcal{S} \not\subseteq \Omega^h_{\mathcal{P}_n})$ similar to ours can be found in [27]. It can be seen that our bounds are better than the ones reported in [27] for a certain range of k, the dimension of $\mathcal{S}$. We should point out that with our bounds we can obtain rates of convergence comparable to the optimal ones. Let us elaborate on this: In the case of the unit circle S^1 it is known (see [66]) that

$$p_1(n,h) \stackrel{\triangle}{=} 2ne^{-n\frac{h}{\pi}} \simeq \mathbb{P}\left(S^1 \not\subseteq \Omega^h_{\mathcal{P}_n}\right) \tag{17}$$

for n large and $\frac{h}{\pi} \ll 1$, whereas our bound is $p_2(n,h) \stackrel{\triangle}{=} \frac{e^{-n}h/2\pi}{h/2\pi} \gtrsim \mathbb{P}(S^1 \not\subseteq \Omega^h_{\mathcal{P}_n})$. Choose for p_1, $h_n^{(1)} = \gamma_1\pi\frac{\log n}{n}$ and for p_2, $h_n^{(2)} = \gamma_2\pi\frac{\log n}{n}$. Plugging these expressions into the formulas for p_1 and p_2, we find $p_1 = 2n^{1-\gamma_1}$ and $p_2 = \frac{2}{\gamma_2(\log n)}n^{1-\frac{\gamma_2}{2}}$. Hence, by letting $(2 >)\gamma_2 = 2\gamma_1$ (which is equivalent to $\frac{h_n^{(2)}}{h_n^{(1)}} = 2$), we obtain $p_2 \lesssim p_1$. The *optimal* bound (17) for the case of S^1 is derived using direct knowledge of the distribution of the minimal number of random arcs (of a certain fixed size) needed to cover S^1 completely. This distribution is unknown for all nontrivial cases [66, 34]. In the case of the sphere S^2, also in [66], a bound of the type $\mathbb{P}(S^2 \not\subseteq \Omega^h_{\mathcal{P}_n} \leq CN^2e^{-DNh^2})$ is reported (for certain constants C and D); however, the proof seems to use properties of symmetry of the sphere in a fundamental way. Other interesting bounds which could be used in this situation are those in [38].

We should finally point out that the problem of covering a certain domain (usually S^1) with balls centered at random points sampled from this domain has been studied by many authors [66, 27, 28, 37, 65, 39, 34] and even by Shannon in [64].

We have the following interesting corollary, whose proof can be found in Appendix C.

COROLLARY 4. *Let $\mathcal{S}$ be a smooth compact submanifold of $\mathbb{R}^d$ without boundary. We have that if* (16) *holds, then for any $\varepsilon > 0$*

$$\lim_{h,n}\mathbb{P}\left(d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}_n}) > \varepsilon\right) = 0,$$

where $d_{\mathcal{H}}$ is the Hausdorff distance between sets.

[19] For constant $h > 0$, by definition $0 < x_h < 1$, and then obviously $\frac{e^{-nx_h}}{x_h} \to 0$ as $n \uparrow \infty$.

[20] This kind of condition is commonplace in the literature of random coverings; see, e.g., [25, 65, 22].

We are now ready to state and prove the following convergence theorem.

THEOREM 7. *Let $\mathcal{S}$ be a k-dimensional smooth compact submanifold of $\mathbb{R}^d$. Let $\mathcal{P}_n = \{p_1, \dots, p_n\} \subseteq \mathcal{S}$ be such that $p_i \sim \mathbf{U}[\mathcal{S}]$ for $1 \le i \le n$. Then if $h = h_n$ is such that $h_n \downarrow 0$ and (16) holds as $n \uparrow \infty$, we have that for any $\varepsilon > 0$,*

$$\mathbb{P}\left(\max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right) > \varepsilon\right) \overset{n\uparrow\infty}{\longrightarrow} 0.$$

Proof. We base our proof on (7). We first note that $\mathbb{P}(\mathcal{E}_\varepsilon \mid \mathcal{I}_{h,n}) = 0$ for n large enough because, from considerations at the beginning of section 4, $\max_{p,q\in\mathcal{S}}(d_{\mathcal{S}}(p,q) - d_{\Omega^{h_n}_{\mathcal{P}_n}}(p,q)) \le C_{\mathcal{S}}\sqrt{h_n}$ whenever $\mathcal{S} \subseteq \Omega_{\mathcal{P}^{h_n}_n}$ holds. Let $N = N(\varepsilon) \in \mathbb{N}$ be such that $h_n < (\frac{\varepsilon}{C_{\mathcal{S}}})^2$ for all $n \ge N(\varepsilon)$. Then, for $n \ge N(\varepsilon)$, $\mathbb{P}(\mathcal{E}_\varepsilon) = \mathbb{P}\big(\mathcal{I}^c_{h,n} \le \frac{e^{-nx_{h_n}}}{x_{h_n}}\big)$, and since by assumption (16) holds, the right-hand side goes to 0 as $n \uparrow \infty$. ∎

Remark 7.

1. As can be gathered from the preceding proof, for fixed $\varepsilon > 0$ and large $n \in \mathbb{N}$,

$$\mathbb{P}\left(\max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right) > \varepsilon\right)$$

can be upper bounded by $\frac{e^{-nx_{h_n}}}{x_{h_n}}$. For example, setting $x_{h_n} = \gamma\frac{\log n}{n}$ for $\gamma \ge 1$ yields (given n big enough)

$$\mathbb{P}\left(\max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right) > \varepsilon\right) \le \frac{1}{\gamma\, n^{\gamma-1}\log n}.$$

2. Then we see that by requiring $\sum_{n\ge1} \frac{e^{-nx_{h_n}}}{x_{h_n}} < \infty$ and using the Borel–Cantelli lemma, we obtain *almost sure convergence*, namely,

$$\mathbb{P}\left(\lim_{n\uparrow\infty} \max_{p,q\in\mathcal{S}} \left(d_{\mathcal{S}}(p,q) - d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right) = 0\right) = 1.$$

This can be guaranteed (for example) by setting $x_{h_n} = \gamma\frac{\log n}{n}$ for $\gamma > 2$.

This concludes our study of distance functions on (noiseless) point clouds (sampled manifolds). We now turn to the even more realistic scenario where the points are considered to be *noisy* samples.

6. Noisy sampling of manifolds. We assume that we have some uncertainty on the actual position of the surface, and we model this as if each point in the set of sampled points is modified by a (not yet random) perturbation of magnitude smaller than Δ. More explicitly, each p_i is given as $p_i = p + \zeta \times \vec{v}$ for some $\vec{v} \in S^{d-1}$, some p in $\mathcal{S}$, and $\Delta \ge \zeta \ge 0$. Then we can guarantee that the point p from which p_i comes can be found inside $B(p_i, \Delta) \cap \mathcal{S}$. We are again interested in comparing $d_{\Omega^h_{\mathcal{P}_n}} : \Omega^h_{\mathcal{P}_n} \to \mathbb{R}^+ \cup \{0\}$ with $d_{\mathcal{S}} : \mathcal{S} \to \mathbb{R}^+ \cup \{0\}$, but now these functions have different domains; therefore we must be careful in defining a meaningful way of relating them. If we consider

$$\mathcal{F}^\Delta_{\mathcal{S}} \triangleq \{f \mid f : \Omega^\Delta_{\mathcal{S}} \to \mathcal{S},\ f(p) \in B(p,\Delta) \cap \mathcal{S}\},$$

we can compare, for some $f \in \mathcal{F}^\Delta_{\mathcal{S}}$ and $1 \le i, j \le n$, $d_{\Omega^h_{\mathcal{P}_n}}(p_i, p_j)$ with $d_{\mathcal{S}}(f(p_i), f(p_j))$. Note that as the perturbation's magnitude goes to zero, $\mathcal{F}^\Delta_{\mathcal{S}} \ni f(p) \overset{\Delta\downarrow0}{\longrightarrow} p$, for $p \in \Omega^\Delta_{\mathcal{S}}$. The next step is to write $\max_{1\le i,j\le n} \|d^h_{\Omega_{\mathcal{P}_n}}(p_i,p_j) - d_{\mathcal{S}}(f(p_i), f(p_j))\|$, the biggest

error we have for our set of points. And finally, the next logical step is to look at the worst possible choice for f:

$$\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n;\Delta,h) \triangleq \sup_{f\in\mathcal{F}_{\mathbb{S}}^{\Delta}} \max_{1\leq i,j\leq n} \left| d_{\mathbb{S}}(f(p_i),f(p_j)) - d_{\Omega^h_{\mathcal{P}_n}}(p_i,p_j)\right|. \tag{18}$$

We start by presenting deterministic bounds for the expression in (18), and only later will we be more (randomly) greedy and, in the spirit of Theorem 7, prove for $\varepsilon>0$ a result of the form ($\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n;\Delta,h)$ will be a R.V.)

$$\mathbb{P}\left(\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n;\Delta,h)>\varepsilon\right) \xrightarrow{n\uparrow\infty} 0.$$

6.1. Deterministic setting. The idea is to prove that for some convenient function $\widehat{f}\in\mathcal{F}_{\mathbb{S}}^{\Delta}$ we can write

$$\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n;\Delta,h) \leq \max_{1\leq i,j\leq n} \left| d_{\mathbb{S}}(\widehat{f}(p_i),\widehat{f}(p_j)) - d_{\Omega^h_{\mathcal{P}_n}}(p_i,p_j)\right| + \lambda(h,\Delta),$$

where $0\leq\lambda(x,y)\xrightarrow{x,y\downarrow 0}0$. The natural candidate for $\widehat{f}$ is the orthogonal projection onto $\mathbb{S}$, $\Pi_{\mathbb{S}}:\Omega^H_{\mathbb{S}}\to\mathbb{S}$, whose properties are discussed in Appendix B. Then we see that we can reduce everything to bounding $\max_{p,q\in\mathbb{S}}\|d_{\mathbb{S}}(p,q)-d_{\Omega^h_{\mathcal{P}_n}}(p,q)\|$. This is simple since if $\mathcal{P}_n\subset\Omega^{\Delta}_{\mathbb{S}}$, then $\Omega^h_{\mathcal{P}_n}\subset\Omega^{h+\Delta}_{\mathbb{S}}$, and $d_{\mathbb{S}}\geq d_{\Omega^h_{\mathcal{P}_n}|_{\mathbb{S}}}\geq d_{\Omega^{h+\Delta}_{\mathbb{S}}|_{\mathbb{S}}}$, and finally from Theorem 5, $\|d_{\mathbb{S}}-d_{\Omega^h_{\mathcal{P}_n}}\|_{L^\infty(\mathbb{S})}\leq C_{\mathbb{S}}\sqrt{h+\Delta}$.

Let $\mathbb{S}\subset\Omega^h_{\mathcal{P}_n}$, $f\in\mathcal{F}^{\Delta}_{\mathbb{S}}$, and $1\leq i,j\leq n$. Then, after using the triangle inequality a number of times, we can write the bound

$$\begin{aligned}\left| d_{\mathbb{S}}(f(p_i),f(p_j)) - d_{\Omega^h_{\mathcal{P}_n}}(p_i,p_j)\right| \leq\ & 2\sup_{f\in\mathcal{F}^{\Delta}_{\mathbb{S}}}\max_{p\in\mathcal{P}_n} d_{\mathbb{S}}(f(p),\Pi_{\mathbb{S}}(p))\\ &+\max_{p,q\in\mathbb{S}}\left| d_{\mathbb{S}}(p,q)-d_{\Omega^h_{\mathcal{P}_n}}(p,q)\right|\\ &+\max_{p,q\in\mathcal{P}_n}\left| d_{\Omega^h_{\mathcal{P}_n}}(p,q)-d_{\Omega^h_{\mathcal{P}_n}}(\Pi_{\mathbb{S}}(p),\Pi_{\mathbb{S}}(q))\right|.\end{aligned}$$

The last term can be bounded by 2Δ, the one in the middle has already been discussed, and hence we are left with the first one. Using Corollary 2, we find that since $f(p)\in B(\Pi_{\mathbb{S}}(p),2\Delta)\cap\mathbb{S}$, then in fact $f(p)\in B_{\mathbb{S}}(\Pi_{\mathbb{S}}(p),2\Delta(1+C_{\mathbb{S}}\sqrt{\Delta}))$ and $d_{\mathbb{S}}(f(p),\Pi_{\mathbb{S}}(p))\leq 2\Delta(1+C_{\mathbb{S}}\sqrt{2}\sqrt{\Delta})$. Summing up, under the condition $\mathbb{S}\subset\Omega^h_{\mathcal{P}_n}$, we obtain the desired result,

$$\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n;\Delta,h)\leq C_{\mathbb{S}}\sqrt{h+\Delta}+2\Delta(2+\sqrt{2}C_{\mathbb{S}}\sqrt{\Delta}). \tag{19}$$

6.2. Random setting. Assume that $\{p_1,\ldots,p_n\}$ is a set of i.i.d. random points such that each $p_i\sim\mathbf{U}[\Omega^{\Delta}_{\mathbb{S}}]$. At this time, we want to estimate the probability of having $\mathbb{S}\subseteq\Omega^h_{\mathcal{P}_n}$. It is easy to see that as a first "reality compliant" condition one should have that the noise level not be too big with respect to h. We will impose $h\geq\Delta$ for simplicity's sake, as can be understood from the convergence theorem below. Since the techniques are similar to those used in the noise-free case, we will present its proof in Appendix C.

THEOREM 8. *Let $\mathbb{S}$ be a k-dimensional smooth compact submanifold of $\mathbb{R}^d$. Let $\mathcal{P}_n=\{p_1,\ldots,p_n\}$ be such that $p_i\sim\mathbf{U}[\Omega^{\Delta}_{\mathbb{S}}]$ for $1\leq i\leq n$. Then if $h=h_n$, $\Delta=\Delta_n$*

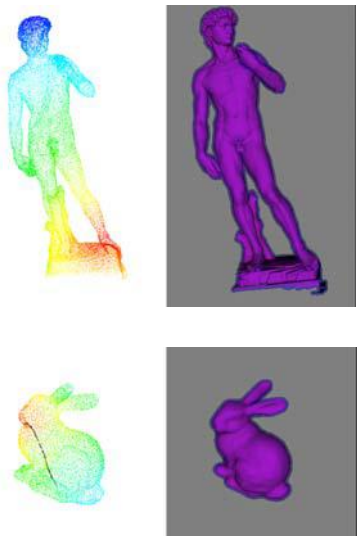

FIG. 1. *Intrinsic distance function for a point cloud. A point is selected in the head of the David, and the intrinsic distance is computed following the framework introduced here. The point cloud is colored according to the intrinsic distance to the selected point, going from bright red (far) to dark blue (close). The offset band, given by the union of balls, is shown next to the distance figure. Bottom: Same as before, with a geodesic curve between two selected points.*

are such that $\Delta_n \leq h_n$ *and* $h_n \downarrow 0$ *and* $\Delta_n^k \gtrsim \frac{\log n}{n}$ *as* $n \uparrow \infty$*, we have that for any* $\varepsilon > 0$*,*

$$\mathbb{P}\left(\mathcal{L}_{\mathbb{S}}(\mathcal{P}_n; \Delta, h) > \varepsilon\right) \xrightarrow{n\uparrow\infty} 0.$$

We have now concluded the analysis of the most general case for noisy sampling of manifolds. Note that, although the results in this and in previous sections were presented for Euclidean balls, they can easily be extended to more general covering shapes (check Corollary 1 above), e.g., following [15, 36], or using minimal spanning trees, or from the local directions of the data [56]. In addition, the recently developed approach reported in [57] can be used for defining the offset band in an adaptive fashion. This will improve the bounds reported here. Similarly, the results can be extended to other sampling or noise models following the same techniques developed here.

7. Implementation details and examples. We now present examples of distance matrices and geodesics for point clouds (Figure 1), use these computations to find intrinsic Voronoi diagrams (Figure 2; see also [42, 43, 71]); and compare the results with those obtained with mesh-based techniques (Figure 3).[21] We also present examples in high dimensions and use, following and extending [24], our results to compare manifolds given by point clouds. All these exercises are to exemplify the importance of computing distance functions and geodesics on point clouds, and are by no means exhaustive. The 3D data sets used come from real point cloud data and have been obtained either from range scanners (*David* model) or via photometric stereo techniques (man and woman).

[21] All the figures in this paper are in color. VRML files corresponding to these examples can be found at http://mountains.ece.umn.edu/∼guille/pc.htm.

FIG. 2. *Voronoi diagram for point clouds. Four points (left) and two points (right) are selected on the cloud, and the point cloud is divided (colored) according to the geodesic distance to these four points. Note that this is a surface Voronoi, based on geodesics computed with our proposed framework, not a Euclidean one.*

The theoretical results presented in the previous sections show that the intrinsic distance and geodesics can be approximated by the Euclidean ones computed in the band defined (for example) by the union of balls centered at the points of the cloud. The problem is then simplified to first computing this band (no need for mesh computation, of course), and then using well-known computationally optimal techniques to compute the distances and geodesics inside this band, exactly as done in [49] for implicit surfaces (where the interested reader can also find explicit computational timings and accuracy comparisons with mesh-based approaches). The band itself can be computed in several ways, and for the examples below we have used constant radii. Locally adaptive radii can be used, based, for example, on diameters obtained from minimal spanning trees or on the recent work reported in [57]. Automatic and local estimation of h defining $\Omega^h_{\mathcal{P}_n}$, which will improve the bounds reported here, was not pursued in this paper and is the subject of current implementation efforts.

The software implementation of the algorithm is based on using the fast Euclidean distance computation algorithms, usually referred to as *fast marching* algorithms [35, 62, 63, 69], twice. We omit the description of this algorithm since it is well known. The starting point is defining a grid over which all the computations are performed. This amounts to choosing Δ_{x_i}, the grid spacing in each direction $i = 1, \ldots, d$, which will determine the accuracy of the numerical implementation (the offset band includes fewer than 10 grid points).[22] In the first round we compute the band $\Omega^h_{\mathcal{P}_n} = \{x \in \mathbb{R}^d : d(\mathcal{P}_n, x) \leq h\}$ by specifying a value of zero for the function $\Psi(x) = d(\mathcal{P}_n, x)$ on the points $x \in \mathcal{P}_n$. Since in general these points will not be on the grid, we use a simple multilinear interpolation procedure to specify the values on neighboring grid points. The second use of the fast distance algorithm is also simply reduced to using Ψ to define $\Omega^h_{\mathcal{P}_n}$ by using the simple modification reported in [49]. The computation of geodesics was done using a simple Runge–Kutta gradient descent procedure, much in the way described in [49], with some obvious modifications.

[22] Adaptive grids inside the fixed or variable width offset band could be used as well; see, for example, [30].

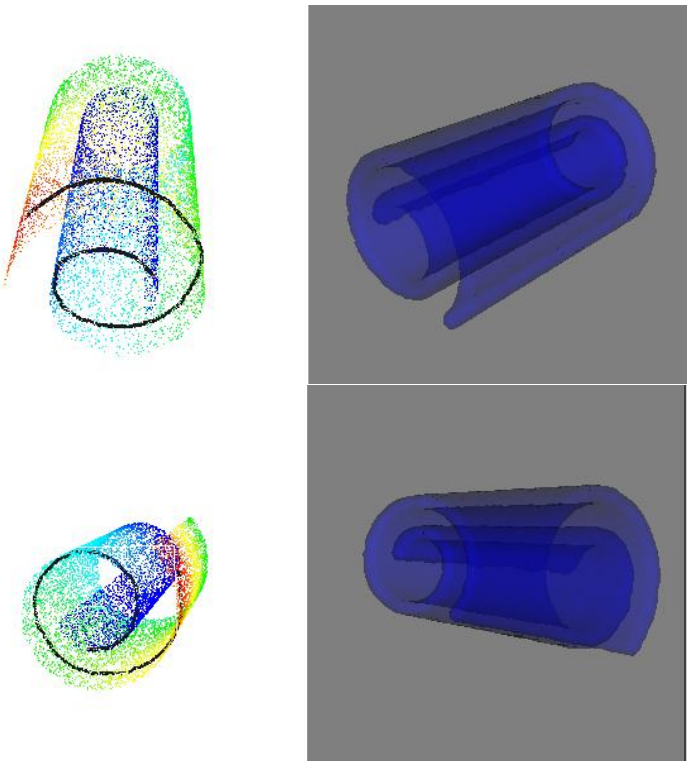

FIG. 3. *Examples of geodesic computations. This data is used to study the algorithm robustness to noise, see Appendix A.*

All the code and 3D visualization was developed in C++ using both Flujos (which is written using Blitz++; see [7]) and VTK (see [70]). For matrix manipulation and visualization of other results we used MATLAB. We are currently working on a more advanced implementation of the proposed framework that permits us to work with high-dimensional data without having the memory allocation problems that result from blind and straightforward allocation of resources to empty and nonused grids.

7.1. High-dimensional data. In this section we present a simple example for high-dimensional data. We embed a circle of radius 15 in $\mathbb{R}^5$, and use a grid of size $34 \times 4 \times 4 \times 4 \times 34$ (with uniform spacing $\Delta x = 1$) such that each of the sample points is of the form $p_i = 15\,(\cos(\frac{2\pi i}{N}), 0, 0, 0, \sin(\frac{2\pi i}{N})) + (17, 2, 2, 2, 17)$, for $1 \leq i \leq N$. We then use our approach to compute the (approximate) distance function d_h in a band in $\mathbb{R}^5$, and then the error $e_{ij} = |d_{\mathcal{S}}(p_i, p_j) - d_h(p_i, p_j)|$ for $i, j \in \{1, \ldots, N\}$. In our experiments we used $h = 2.5 > \Delta x\sqrt{5}$.[23] We randomly sampled 500 points from the $N = 1000$ points used to construct the union of balls to build the 500×500 error matrix $((e_{ij}))$. We found $\max_{ij}\{e_{ij}\} = 2.0275$, that is, a 4.3% L_∞-error. In Figure 4 we show the histogram of all the (500^2) entries of $((e_{ij}))$. We should also note that when following the dimensionality reduction approach in [67], with the geodesic distance computation proposed here, the correct dimensionality of the circle was obtained.

[23] For a discussion on how to make a preliminary estimation of the value of h, see [49].

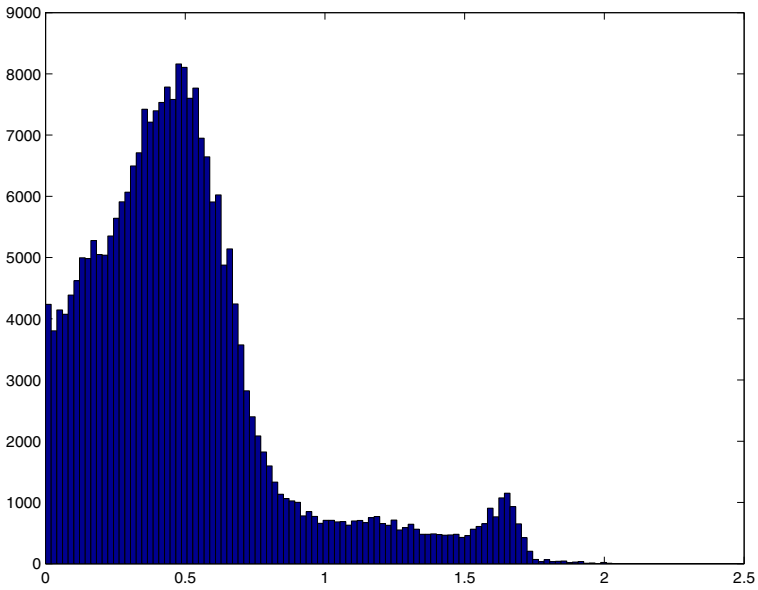

FIG. 4. *Histogram for the error in the case of a circle embedded in* $\mathbb{R}^5$.

In high dimensions, when the grid is too large, our current numerical implementation becomes unusable. The problem stems from the fact that we require too much memory space, most of which is not really used, since the computations are conducted only in a band around $\mathcal{P} \subset \mathbb{R}^d$. To be more precise, the memory requirements of our current direct implementation, which uses a d-dimensional array to make the computations, are $\simeq (\max_i l_i)^d$, whereas we really need a storage capacity of order $\mu_k(\mathcal{S})h^{d-k}$, where l_i is the size of $\mathcal{P}$'s bounding box along the ith direction, $1 \leq i \leq d$, and $\mu_k(\mathcal{S})$ is the measure of the k-dimensional manifold $\mathcal{S}$ (embedded in $\mathbb{R}^d$). This memory problem is to be addressed by a computation that is not based on discretizing the whole band. (Note, of course, that the theoretical foundations presented in this paper are independent of the particular implementation.) We are currently working on addressing this specific issue.

7.2. Object recognition. The goal of this application is to use our framework to compare manifolds given by point clouds. The comparison is done in an intrinsic way, that is, isometrically (bending) invariant. This application is motivated by [24], where they use geodesic distances (computed using a graph-based approach) to compare 3D triangulated surfaces. In contrast with [24], we compare point clouds using our framework (which is not only based in the original raw data, but also, as shown in Appendix A, more robust to noise than mesh approaches such as those of [24] and is valid in any dimensions), and use a different procedure/similarity metric between the manifolds. The authors in [24] basically project into low-dimensional manifolds and use eigenvalues and eigenvectors of a centralized matrix related to the *distance matrices* (matrices which in each entry (i, j) have the value of the intrinsic distance between (projected) points p_i and p_j of the cloud), which are clearly not sufficient to distinguish nonisometric objects. (Nonisometric objects can have distance matrices with the same eigenvalues.) A different study, based on direct comparisons of distance matrices, is used here and detailed in Appendix E.

TABLE 1
Information about the models used in our recognition experiments.

Dataset	Number of points in the cloud (n)	Grid size used
Bunny	15862	$80 \times 80 \times 70$
MAN2	26186	$120 \times 90 \times 200$
MAN3	26186	$120 \times 90 \times 165$
MAN5	26186	$120 \times 85 \times 160$
WOMAN2	29624	$120 \times 105 \times 175$
WOMAN3	29624	$120 \times 100 \times 180$

Our task then is to compare two manifolds in an intrinsic way; i.e., we want to check whether they are isometric or not. We want to check this condition by using point clouds representing each one of the manifolds. Let $\mathcal{S}_1$ and $\mathcal{S}_2$ be two submanifolds of $\mathbb{R}^d$ and sample on each of them the two point clouds $\mathcal{P}_n^{(1)} \subset \mathcal{S}_1$ and $\mathcal{P}_n^{(2)} \subset \mathcal{S}_2$. Then, following our theory, we compute the corresponding distances in the offset bands for these two sets of points, $d_{\Omega^{h_1}_{\mathcal{P}_n^{(1)}}}$ and $d_{\Omega^{h_2}_{\mathcal{P}_n^{(2)}}}$, and for point subsets $\{q_1^{(1)}, \ldots, q_m^{(1)}\} = \mathcal{Q}_m^{(1)} \subseteq \mathcal{P}_n^{(1)}$, $\{q_1^{(2)}, \ldots, q_m^{(2)}\} = \mathcal{Q}_m^{(2)} \subseteq \mathcal{P}_n^{(2)}$ we compute the corresponding $m \times m$ pairwise distance matrices (as defined above)

$$D_1 = \left(\left(d_{\Omega^{h_1}_{\mathcal{P}_n^{(1)}}} (q_i^{(1)}, q_j^{(1)}) \right) \right) \quad \text{and} \quad D_2 = \left(\left(d_{\Omega^{h_2}_{\mathcal{P}_n^{(2)}}} (q_i^{(2)}, q_j^{(2)}) \right) \right).$$

Let $\mathcal{PM}_m$ be the set of $m \times m$ permutation matrices and $\|\cdot\|$ a unitary transformation invariant norm[24] (fix the Frobenius norm: $\|A\| = \sqrt{\sum_i \sum_j a_{ij}^2}$). Then we define the $\mathcal{J}$-distance between (distance) matrices D_1 and D_2 as

$$d_{\mathcal{J}}(D_1, D_2) \stackrel{\triangle}{=} \min_{P \in \mathcal{PM}_m} \|D_1 - P D_2 P^T\|.$$

Clearly, if $d_{\mathcal{J}}(D_1, D_2) = 0$, then we have an isometry between the discrete metric sets $(\mathcal{Q}_n^{(1)}, d_{\Omega^{h_1}_{\mathcal{P}_n^{(1)}}})$ and $(\mathcal{Q}_n^{(2)}, d_{\Omega^{h_2}_{\mathcal{P}_n^{(2)}}})$. This should allow us to establish a *rough isometry* (see [14, section 4.4]) between $\mathcal{S}_1$ and $\mathcal{S}_2$ with interesting constants.

The exact details on how this metric is approximated and how the subsets of points $\mathcal{Q}$ are selected is presented in Appendix E. For the experiments regarding recognition of shapes we used the datasets listed in Table 1.

In Figure 5 we present the histogram of the error $e(100)/100$ for 20 different 100×100 distance matrices corresponding to the full Bunny model, with the 100 points chosen as in the "packing procedure" described in Appendix E, where the exact definition of $e(\cdot)$ is also given (see (28)). We computed the mean of $e(100)/100$ over the $19 \times 18 \times \cdots \times 1 = 190$ comparison experiments to be 0.4774 with standard deviation 0.0189. This can be interpreted as indicating that when one considers a large enough set of points, the information contained in the packing set is representative of the metric information of the manifold, independently of the particular choice of the packing set. This claim needs some further theoretical justification, which could come if a result of the following fashion were proved:[25]

[24] $\|AU\| = \|A\|$ for any matrix A and any *unitary* matrix U.

[25] Note added in proof: After this paper was submitted for publication, we proved that a properly modified version of the above claim holds *in probability*; see [50] for details.

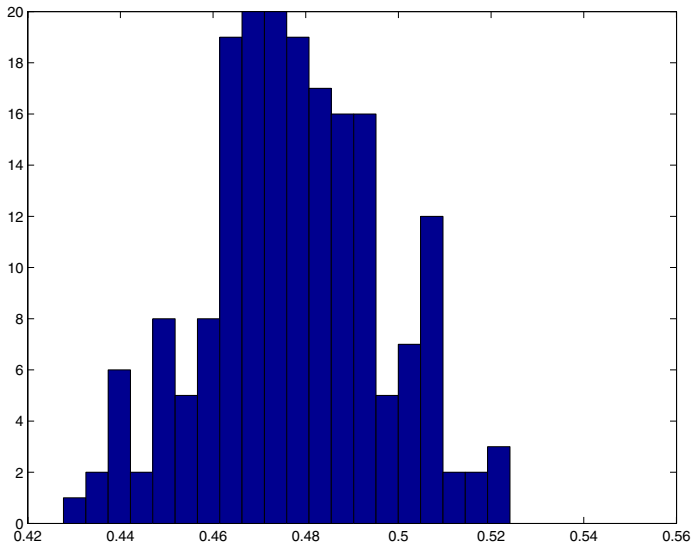

FIG. 5. *Histogram showing the errors for different selections of point clouds on the bunny model.*

Let $\mathcal{S}$ be a smooth compact k-dimensional submanifold of $\mathbb{R}^k$ such that its Ricci curvature is bounded below by $\kappa(n-1)$ with $\kappa \leq 0$. Let $\mathcal{Q}_m^{(r)} \subset \mathcal{S}$, $r = 1, 2$, be such that $d_{\mathcal{S}}(q_i^{(r)}, q_j^{(r)}) \geq \varepsilon$ and $B_{\mathcal{S}}(\mathcal{Q}_m^{(r)}, R)$ covers $\mathcal{S}$ for some $R > \varepsilon > 0$. Then, with D_1 and D_2 defined as before,

$$d_{\mathcal{J}}(D_1, D_2) \leq 2mC_{\mathcal{S}}\sqrt{h} + C(R, \varepsilon, m),$$

where the exact form of $C(R, \varepsilon, m)$ is to be determined, leading to an optimal choice of m (the size of the subset).

Using the same procedure, described in Appendix E, to choose the sets $\mathcal{Q}_m^{(i)}$, we computed the errors (according to $e(D_1, D_2)$) for five artificial human models; three of them are bendings of a man and two are bendings of a woman; see Figures 6 and 7. Details on these models are also given in Table 1. The results of this cross-comparison are presented in Table 2 below.

TABLE 2

Cross-comparisons for the human models using the error measure $e(300)/300$ normalized by the maximum of the errors.

MODEL	Man2	Man3	Man5	Woman2	Woman3
Man2	$*$	0.0514	0.0570	0.4690	0.4853
Man3	$*$	$*$	0.0206	0.4701	0.4859
Man5	$*$	$*$	$*$	0.4702	0.4862
Woman2	$*$	$*$	$*$	$*$	0.2639
Woman3	$*$	$*$	$*$	$*$	$*$

These examples show how our geodesic distance computation technique, when complemented with the matrix metric in Appendix E, can be used to compare manifolds given by point clouds, in a bending-invariant fashion and without explicit manifold reconstruction. More exhaustive experimentation and additional theoretical justification will be reported elsewhere.

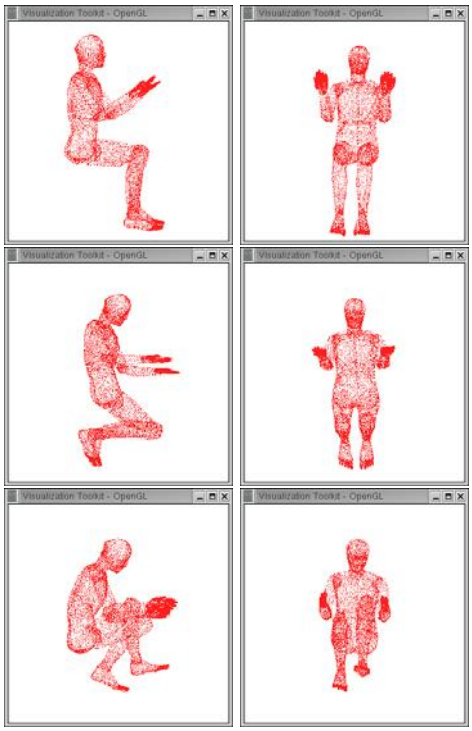

FIG. 6. *MAN models. From top to bottom (two views of each model): MAN*2*, MAN*3*, and MAN*5*.*

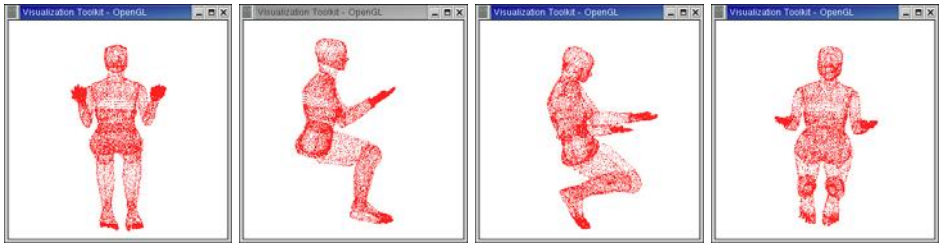

FIG. 7. *WOMAN models. From left to right (two views of each model): WOMAN*2 *and WOMAN*3*.*

Before concluding, we should comment that, as frequently done in the literature, we could normalize the geodesic distances if scale invariance were also required. Moreover, we could also consider in the distance matrix only nonzero entries for local neighborhoods. In addition, the use of techniques for computing eigenvalues and eigenvectors such as those in the work of Coifman and colleagues [17], on high-dimensional geometric multiscale analysis should be explored.

8. Concluding remarks. In this paper, we have extended our previous work [49] to deal with (smooth) submanifolds of $\mathbb{R}^d$ (of any codimension) and possibly with boundary, and using these extensions, we have also shown how to compute intrinsic distance functions on a generic manifold defined by a point cloud, without the intermediate step of manifold reconstruction. The basic idea is to use well-developed computational algorithms for computing Euclidean distances in an offset band sur-

rounding the manifold, to approximate the intrinsic distance. The underlying theoretical results were complemented by experimental illustrations.

As mentioned in the introduction, an alternative technique for computing geodesic distances was introduced in [9, 67] (see also [31]). In contrast with our work, the effects of noise were not addressed in [9, 31]. Moreover, as one can see from considerations in Appendix A, our framework seems to be more robust to noise. We should note that the memory requirements of the current way of implementing our framework are large, and this needs to be addressed for very high dimensions (the framework is, of course, still valid). In particular, we are interested in direct ways of computing distances inside regions defined by union of balls, without the need to use the Hamilton–Jacobi approach. Several classical computer science implementation tricks can be applied to avoid this memory allocation problem, and this is part of our current implementation efforts.

We are currently working on the use of this framework to create multiresolution representations of point clouds (in collaboration with C. Moenning and N. Dyn; see [55] and also [11, 18, 20, 58]), to further perform object recognition for larger libraries, and to compute basic geometric characteristics of the underlying manifold—all this, of course, without reconstructing the manifold. (See [54] for recent results on normal computations for 2D and 3D noisy point clouds.) Some results in these directions are reported in [50, 55]. Further applications of our framework for high-dimensional data are also currently being addressed, beyond the preliminary (toy) results reported in section 7. Of particular interest in this direction is the combination of this work with the one developed by Coifman and colleagues and the recent one in [31].

Appendix A. Comparison with mesh-based strategies for distance calculation in the presence of noise. We now make some very basic comparisons between our approach to geodesic distance computations and those based on graph approximations to the manifold, such as the one in Isomap [67, 31].[26] (Comparisons of the band framework with the one reported in [40] for 3D triangulated surfaces are reported in [49].) The goal is to show that such graph-based techniques are more sensitive to noise in the point cloud sample (and the error can even increase to infinity with the increase in the number of points). This is expected, since the geodesic in such techniques goes through the noisy samples, while in our approach, they just go through the union of balls. We make our argument only for the $1D$ case, while the high-dimensional cases can be similarly studied.

A.1. 1D theoretical case. Let us consider a rectilinear segment of length L and $n+1$ equispaced points $p_1, \ldots, p_{n+1}$ in that segment. Consider the *noisy* points $q_i = p_i + \zeta_i \vec{n}$, where $\vec{n}$ is the normal to the segment and ζ_i $1 \leq i \leq n$ are independent R.V. uniformly distributed in $[-\Delta, \Delta]$. Let $l = L/n$ denote the distance between adjacent p_i's. Let d_g^Δ denote the length of the polygonal path $\overline{q_1 q_2 \ldots q_{n+1}}$ and $d_0 = L$. Then obviously $d_g^\Delta \geq d_0$ for any realization of the R.V.'s ζ_i. Let $d_i = \|p_i - p_{i+1}\|$; then by Pythagoras theorem $d_i = \sqrt{l^2 + z_i^2}$, where $z_i = \zeta_i - \zeta_{i+1}$ are R.V.'s with triangular density in $[-2\Delta, 2\Delta]$.

Next we compute $\mathbb{E}(d_i) = \frac{1}{2\Delta} \int_{-2\Delta}^{2\Delta} \sqrt{l^2 + z^2}(1 - \frac{|z|}{2\Delta})\, dz$. The result is

$$\mathbb{E}(d_i) = \sqrt{l^2 + 4\Delta^2} + \frac{l^2}{2\Delta} \log\left(\frac{2\Delta + \sqrt{l^2 + 4\Delta^2}}{l}\right) - \frac{1}{6\Delta^2}\left((l^2 + 4\Delta^2)^{3/2} - l^3\right).$$

[26] Isomap builds a mesh by locally connecting the (noisy) samples.

TABLE 3
Results of simulations with the Swiss Roll dataset.

Noise power (n_k^2)	$\max_{ij}\lvert D_{ij}^{g,n_k} - D_{ij}^{g,0}\rvert$	k	$\max_{ij}\lvert D_{ij}^{h,n_k} - D_{ij}^{h,0}\rvert$	h
0.0001	2.5222	7	0.5266	1.8
0.01	4.6409	7	0.9430	1.8
0.04	5.1737	7	1.2489	1.8
0.09	5.3292	7	1.4682	1.8
0.16	5.4651	7	1.7965	1.8

Now assuming $\frac{\Delta}{l} \ll 1$, we find that up to first order $\mathbb{E}(d_i) \simeq l + \Delta$ and

$$\mathbb{E}\left(d_g^\Delta - d_0\right) \simeq n\Delta.$$

From this we also get[27]

$$p_g \triangleq \mathbb{P}\left(d_g^\Delta - d_0 > \varepsilon\right) \lesssim \frac{n\Delta}{\varepsilon}.$$

On the other hand, for our approximation d_h^Δ, if the segment is contained in the union of the balls centered at the sampling points, $d_h^\Delta = d_0$. The probability of covering the segment by the band can be made arbitrarily close to 1 by increasing n. More precisely, one can prove that if p stands for the value of the probability of *not covering* the segment, then $p \leq k\frac{L}{\Delta}(1 - k'\frac{\Delta}{L})^n$, for some positive constants k and k'. Then we can write

$$p_h \triangleq \mathbb{P}\left(d_h^\Delta - d_0 > \varepsilon\right) \leq \frac{k''}{\varepsilon}\frac{L}{\Delta}\left(1 - k'\frac{\Delta}{L}\right)^{n+1}.$$

The comparison is now easy. We see that in order to have p_g vanish as $n \uparrow \infty$, Δ must go to zero *faster* than $\frac{1}{n}$. However, we know that by requiring $\Delta \simeq \frac{\log n}{n} \gtrsim \frac{1}{n}$ we have $p_h \downarrow 0$ as $n \uparrow \infty$. This means that the graph approximation of the distance is more sensitive to noise than ours.[28] This gives some evidence about why our approach is more robust than popular mesh-based ones. Next we present results of some simulations carried out in order to further verify our claim.

A.2. Simulations. In Table 3 we present results of simulations carried out for the SwissRoll dataset [67]; see Figure 3. We used 10,000 points to define the manifold. We then generated 10,000 noise vectors, each component being uniform with power one and zero mean. Then we generated noisy datasets from the noiseless SwissRoll dataset by adding the noise vector times a constant n_k to each vector of the noiseless initial dataset. We then chose 1000 corresponding points in each dataset and computed the intrinsic pairwise distance approximation, obtaining the matrices $\{(D_{ij}^{g,n_k})\}$ and $\{(D_{ij}^{h,n_k})\}$ for the graph-based and our approach, respectively, where $k = 1, 2, \ldots, 5$, $i, j \in [1, 1000]$, and n_k denotes the noise level. We then computed the values of $\max_{ij}\lvert D_{ij}^{g,n_k} - D_{ij}^{g,0}\rvert$ and $\max_{ij}\lvert D_{ij}^{h,n_k} - D_{ij}^{h,0}\rvert$ for each k, where $D_{ij}^{g,0}$ and $D_{ij}^{h,0}$ stand for noiseless intrinsic distance approximations. In Table 3, h indicates the radii and k the size of the neighborhood for Isomap. The graph approximation shows

[27] Also, with similar arguments we can prove that $\max_{\zeta_1,\ldots,\zeta_{n+1}}(d_g^\Delta - d_0) \simeq \frac{2n^2\Delta^2}{L}$.

[28] Another way of seeing this is by noting that, for a fixed noise level Δ, by increasing n we actually worsen the graph approximation, whereas we are making our approximation better.

less robustness to noise than our method, as was argued above. This is also true for the sensitivity,[29] where our approach outperforms the graph-based one by at least one order of magnitude. Note that the sensitivity for our approach can be formally studied from Theorem 3.

Appendix B. Properties of Euclidean distance functions. The references for this section are [2, pp. 12–16], and [26].

THEOREM 9 (see [2]). *Let $\Gamma \subset \mathbb{R}^d$ be a compact, smooth manifold without boundary. Then $\eta(x) \stackrel{\triangle}{=} \frac{1}{2}d^2(\Gamma, x)$ is smooth in a tubular neighborhood U of Γ. Also, in U it satisfies $\|D\eta\|^2 = 2\eta$.*

COROLLARY 5. *The projection operator $\Pi : U \to \Gamma$, for a given $x \in U$, can be written as $\Pi(x) = x - D\eta(x)$. Moreover, this operator is smooth.*

Remark 8. Differentiation of the relation $\langle D\eta, D\eta\rangle = 2\eta$ gives us $D^2\eta D\eta = D\eta$. Differentiating once more, we also find $D^3\eta D\eta = D^2\eta$.

THEOREM 10 (see [2]). *Let Γ and U be as in Theorem 9, and let $y \in U$ and $x = y - D\eta(x) \in \Gamma$, $k = \dim(\Gamma)$. Then, denoting by $\lambda_1, \ldots, \lambda_n$ the eigenvalues of $D^2\eta(y)$,*

$$\lambda_i(y) = \begin{cases} \frac{d(\Gamma,y)\kappa_i(x)}{1+d(\Gamma,y)\kappa_i(x)} & \text{if } 1 \le i \le k, \\ 1 & \text{if } k < i \le n, \end{cases}$$

where $\kappa_i(x)$ are the principal curvatures of Γ at x along $Dd(\Gamma, y) \in N_x\Gamma$, where $N_x\Gamma$ is the normal space to Γ at x.

Appendix C. Deferred proofs.

Proof of Corollary 3. We present only a sketch of the proof. Let $\mathcal{M}$ be an extension of $\mathcal{S}$ such that $\mathcal{S}$ is still strongly convex in $\mathcal{M}$, and let $0 < \delta \stackrel{\triangle}{=} \min_{x\in\mathcal{S}} \min_{z\in\mathcal{M}} \|x - z\|$. Then, $\overline{B(x,\alpha)} \cap \overline{B(z,\beta)} = \emptyset$ for all $x \in \mathcal{S}$, $z \in \partial\mathcal{M}$, and $\alpha, \beta < \frac{\delta}{3}$. Hence, $\Omega^\alpha_{\mathcal{S}} \cap \Omega^\beta_{\partial\mathcal{M}} = \emptyset$ for $\alpha, \beta \le \frac{\delta}{3}$.

For any $x, y \in \mathcal{S}$ consider γ_h the $\Omega^h_{\mathcal{M}}$-minimizing geodesic, $\mathbf{L}(\gamma_h) = d_{\Omega^h_{\mathcal{M}}}(x, y)$.

By the convexity of $\mathcal{S}$ there exists a unique $\mathcal{M}$-minimizing geodesic $\gamma_0 \subset \mathcal{S}$ joining x, y, and then, by Theorem 4, γ_h uniformly converges to γ_0. In particular, for any $\epsilon > 0$ there exists $h_\epsilon > 0$ such that $\gamma_h \subset \Omega^\epsilon_{\gamma_0}$ for all $h < h_\epsilon$. Choose $\epsilon \le \frac{\delta}{3}$; then $\gamma_h \subset \Omega^\epsilon_{\gamma_0} \subset \Omega^\epsilon_{\mathcal{S}}$. Furthermore, if $h \le \frac{\delta}{3}$, then $\Omega^\epsilon_{\gamma_0} \cap \Omega^h_{\mathcal{M}} = \emptyset$, and therefore γ_h does not touch $\partial\Omega^h_{\mathcal{M}} \cap \partial\Omega^h_{\partial\mathcal{M}}$. Thus, γ_h is $C^{1,1}$ for $h \le \frac{\delta}{3}$. Note that with this choice of h we have $\Omega^h_{\mathcal{S}} \cap \mathcal{M} \subset \mathrm{int}(\mathcal{M})$, and therefore we also have a smooth orthogonal projection operator $\Pi : \Omega^h_{\mathcal{S}} \to \mathcal{M}$.

Proceeding as in the first steps of the proof of Theorem 5, we have $\mathbf{L}(\gamma_h) = d_{\Omega^h_{\mathcal{M}}}(x, y) \le d_{\mathcal{M}}(x, y) \le \mathbf{L}(\Pi(\gamma_h))$, since $\Pi(\gamma_h) \subset \mathcal{M}$ but may not be a minimizing path. Then, using the convexity of $\mathcal{S}$ in $\mathcal{M}$, $d_{\mathcal{M}}(x, y) = d_{\mathcal{S}}(x, y)$, and therefore $0 \le d_{\mathcal{S}}(x, y) - d_{\Omega^h_{\mathcal{M}}}(x, y) \le |\mathbf{L}(\Pi\gamma_h) - \mathbf{L}(\gamma_h)|$, which can be bounded by a constant times $\sqrt{h}$ just mimicking the proof of Theorem 5. We conclude by noting that $\Omega^h_{\mathcal{S}} \subset \Omega^h_{\mathcal{M}}$, and hence $d_{\mathcal{S}}(x, y) - d_{\Omega^h_{\mathcal{M}}}(x, y) \ge d_{\mathcal{S}}(x, y) - d_{\Omega^h_{\mathcal{S}}}(x, y)$. ∎

Proof of Lemma 3. We now estimate the covering number $\mathcal{N}(\mathcal{S}, \delta)$. The idea is constructive, very simple, and of course standard. We consider the following procedure (adopted from [9]): Let q_1 be any point in $\mathcal{S}$, and choose $q_2 \in \mathcal{S}\backslash B_{\mathcal{S}}(q_1, \delta)$. Then choose $q_3 \in \mathcal{S}\backslash\{B_{\mathcal{S}}(q_1, \delta) \cup B_{\mathcal{S}}(q_2, \delta)\}$. Iterate this procedure until it is no longer possible

[29] Sensitivity is defined as $\left|1 - \frac{\text{distance for noisy points}}{\text{distance for clean points}}\right|$.

to choose any point $q \in \mathcal{S}\backslash\{\cup_{k=1}^{\mathcal{N}(\mathcal{S},\delta)} B_{\mathcal{S}}(q_k,\delta)\}$; in such a case $\mathcal{S} = \cup_{k=1}^{\mathcal{N}(\mathcal{S},\delta)} B_{\mathcal{S}}(q_k,\delta)$. Note that $B_{\mathcal{S}}(q_k,\frac{\delta}{2}) \cap B_{\mathcal{S}}(q_l,\frac{\delta}{2}) = \emptyset$ if $k \neq l$, and therefore we can bound $\mathcal{N}(\mathcal{S},\delta) \leq \frac{\mu(\mathcal{S})}{\min_{x\in\mathcal{S}} \mu(B_{\mathcal{S}}(x,\delta/2))}$. Therefore, using the Bishop–Günther inequalities in the same manner as in Lemma 1, we find (14). ∎

Proof of Corollary 4. Note first that the random variable $d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}_n})$ is bounded by $\max\{\text{diam }(\mathcal{S}) + h, h\}$. By definition of the Haussdorf distance, $d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}_n}) = \max\left(\sup_{x\in\mathcal{S}} d(x,\Omega^h_{\mathcal{P}}), \sup_{y\in\Omega^h_{\mathcal{P}_n}} d(y,\mathcal{S})\right)$. Then, $\sup_{x\in\mathcal{S}} d(x,\Omega^h_{\mathcal{P}_n}) \leq \text{diam }(\mathcal{S}) + h$ by the triangle inequality, and $\sup_{y\in\Omega^h_{\mathcal{P}}} d(y,\mathcal{S}) \leq h$, trivially.

Now, we can write $\mathbb{E}(d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}_n})) = \mathbb{E}(\mathbb{E}(d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}})\|\mathbb{1}_{\left[\mathcal{S}\subseteq\Omega^h_{\mathcal{P}}\right]}))$, but the inner expected value can be bounded by h when $\mathbb{1}_{\left[\mathcal{S}\subseteq\Omega^h_{\mathcal{P}_n}\right]} = 1$, and by $\max\{\text{diam}\,(\mathcal{S})+h, h\}$ when $\mathbb{1}_{\left[\mathcal{S}\subseteq\Omega^h_{\mathcal{P}}\right]} = 0$. Using Chebyshev's inequality, we find

$$\begin{aligned}\mathbb{P}\left(d_{\mathcal{H}}(\mathcal{S},\Omega^h_{\mathcal{P}_n}) > \delta\right) &\leq \frac{h}{\delta}\mathbb{P}\left(\{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}}\}\right) + \frac{\max\{\text{diam}\,(\mathcal{S})+h, h\}}{\delta}\left(1-\mathbb{P}\left(\{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}}\}\right)\right)\\ &\leq \frac{h}{\delta} + \frac{\text{diam}\,(S)+h}{\delta}\left(1-\mathbb{P}\left(\{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}}\}\right)\right),\end{aligned}$$

a quantity that goes to zero for any fixed $\delta > 0$ as $h \downarrow 0$ and $n \uparrow \infty$, provided that (16) holds. ∎

Proof of Theorem 8. Since the proof is almost identical to that of Theorem 7, many steps will be skipped. Note that since $\mathcal{S}$ is compact, there exists an upper bound K for all its sectional curvatures. This will allow us to use the volume comparison theorems as before.

We can start from the adequate version of (7). We must bound both $\mathbb{P}(\{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}_n}\}^c)$ and $\mathbb{P}(\mathcal{L}_{\mathcal{S}}(\mathcal{P}_n;\Delta,h) > \varepsilon \,|\, \{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}_n}\})$. The second term can be bounded in an identical way as its $\Delta = 0$ counterpart was, obtaining

$$\mathbb{P}\left(\mathcal{L}_{\mathcal{S}}(\mathcal{P}_n;\Delta,h) > \varepsilon \,|\, \{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}_n}\}\right) \leq \frac{C_{\mathcal{S}}\sqrt{h+\Delta} + 2\Delta(2+\sqrt{2}C_{\mathcal{S}}\sqrt{\Delta})}{\varepsilon}, \tag{20}$$

which vanishes as $n \uparrow \infty$.

Now we upper bound $\mathbb{P}(\{\mathcal{S}\subseteq\Omega^h_{\mathcal{P}_n}\}^c)$. Everything carries over in the same fashion as in the proof of Lemma 1, except that now we must take into consideration that the p_i's are not necessarily on $\mathcal{S}$ but inside $\Omega^{\Delta}_{\mathcal{S}}$. Following the described steps, we obtain

$$\mathbb{P}\left(\left\{x \notin \Omega^h_{\mathcal{P}_n}\cap\mathcal{S}\right\}\right) \leq \left(1 - \frac{\mu\left(B(x,h)\cap\Omega^{\Delta}_{\mathcal{S}}\right)}{\mu\left(\Omega^{\Delta}_{\mathcal{S}}\right)}\right)^n. \tag{21}$$

Notice that, since we are working with $h \geq \Delta$, we have $B(x,\Delta) \subset B(x,h)\cap\Omega^{\Delta}_{\mathcal{S}}$ (see Figure 8), and we can rewrite the bound in (21) as

$$\mathbb{P}\left(\left\{x \notin \Omega^h_{\mathcal{P}_n}\cap\mathcal{S}\right\}\right) \leq \left(1 - \frac{\mu\left(B(x,\Delta)\right)}{\mu\left(\Omega^{\Delta}_{\mathcal{S}}\right)}\right)^n \tag{22}$$

$$= \left(1 - \frac{\mu\left(B(\cdot,\Delta)\right)}{\mu\left(\Omega^{\Delta}_{\mathcal{S}}\right)}\right)^n. \tag{23}$$

We can bound this quantity using formulas akin to Weyl's tube theorem. More precisely, as explained in Appendix D, we can write

$$\mu\left(\Omega^{\Delta}_{S}\right) = \mu\left(\mathcal{S}\right) v(d-k,\Delta) + \varphi_{\mathcal{S}}(\Delta),$$

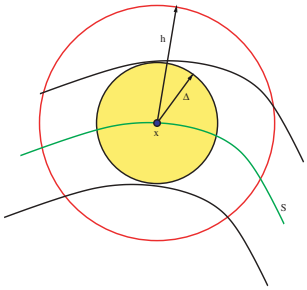

FIG. 8. $B(x,\Delta) \subset B(x,h) \cap \Omega_S^{\Delta}$.

where $\frac{\varphi_{\mathcal{S}}(\Delta)}{\Delta^{d-k+1}} \to 0$ as $\Delta \to 0$ and $v(D,R)$ is the volume of the ball of radius R in D-dimensional Euclidean space.

Now, for $x \in \mathcal{S}$ we must find a bound for $\mathbb{P}(B_{\mathcal{S}}(x,\delta) \not\subseteq \Omega^h_{\mathcal{P}_n})$, but as in the proof of Lemma 2, $\mathbb{P}(B_{\mathcal{S}}(x,\delta) \not\subseteq \Omega^h_{\mathcal{P}_n}) \leq \mathbb{P}(x \notin \Omega^{h-\delta}_{\mathcal{P}_n} \cap \mathcal{S})$, which can be bounded by (22). Also the bound (14) for the covering number still works in this case, and thus we can write $\mathbb{P}(\mathcal{S} \not\subseteq \Omega^h_{\mathcal{P}_n} \cap \mathcal{S}) \leq \frac{(1-y_\Delta)^n}{x_h}$, where $y_\Delta \stackrel{\triangle}{=} \frac{\mu(B(\cdot,\Delta))}{\mu(\Omega_S^{\Delta})}$. Also since $h \geq \Delta$, $x_h \geq x_\Delta$, then

$$\mathbb{P}\left(\mathcal{S} \not\subseteq \Omega^h_{\mathcal{P}_n}\right) \leq \frac{(1-y_\Delta)^n}{x_\Delta}.$$

But with Δ small enough, $y_\Delta \simeq \alpha\Delta^k$ and $x_\Delta \simeq \beta\Delta^k$, and then Lemma 4 and the hypotheses guarantee that $\mathbb{P}(\{\mathcal{S} \subset \Omega^h_{\mathcal{P}_n}\}^c) \to 0$ as $n \uparrow \infty$. □

Appendix D. Basic differential geometry facts. In this section we collect some facts that were used throughout the article, following [32].

D.1. Measure of a *d*-dimensional ball. Recall the definition of the Γ function:

$$\Gamma(\alpha) = \int_0^{+\infty} e^{-t} t^{\alpha-1} dt.$$

THEOREM 11. *The volume of d-dimensional ball of radius r is given by*

$$v(d,r) \stackrel{\triangle}{=} \mu\left(B(\cdot,r)\right) = \omega_d r^d,$$

where $\omega_d = \frac{2\pi^{d/2}}{d\Gamma(d/2)}$.

D.2. Bishop–Günther inequalities for the measure of a geodesic ball.

THEOREM 12. *Let $\mathcal{S}$ be a complete k-dimensional Riemannian manifold, assume r to be smaller than the distance between $m \in \mathcal{S}$ and $Cut(m,\mathcal{S})$ (cut locus of the points m in $\mathcal{S}$). Let $K^{\mathcal{S}}$ be the sectional curvatures of $\mathcal{S}$ and γ a constant. Then if* $\widehat{V}_\gamma(r) \stackrel{\triangle}{=} \frac{2\pi^{k/2}}{\Gamma(k/2)} \int_0^r \left(\frac{\sin(t\sqrt{\gamma})}{\sqrt{\gamma}}\right)^{k-1} dt$, *then*

$$K^{\mathcal{S}} \geq \gamma \ \textit{implies} \ \mu\left(B_{\mathcal{S}}(m,r)\right) \leq \widehat{V}_\gamma(r), \tag{24}$$

$$K^{\mathcal{S}} \leq \gamma \ \textit{implies} \ \mu\left(B_{\mathcal{S}}(m,r)\right) \geq \widehat{V}_\gamma(r). \tag{25}$$

PROPOSITION 3. *We have the following Taylor expansion for $\widehat{V}_\gamma(r)$, the volume of a geodesic ball in a space of constant sectional curvature γ:*

$$\widehat{V}_\gamma(r) = \omega_k r^k \left(1 - r^2 \frac{\gamma}{6} \frac{k(k-1)}{k+2}\right) + \phi(r),$$

where $\frac{\phi(r)}{r^{k+2}} \longrightarrow 0$ as $r \downarrow 0$.

D.3. Weyl's tube theorem.

THEOREM 13. *Let $\mathcal{S}$ be a k-dimensional manifold topologically embedded in $\mathbb{R}^d$. Assume that $\mathcal{S}$ is compact closure, and that every point in the tube $T(\mathcal{S}, r) = \{x \in \mathbb{R}^d$ such that, $d(\mathcal{S}, x) \leq r\}$ has a unique shortest geodesic connecting it with $\mathcal{S}$; then the volume $\mu(T(\mathcal{S}, r))$ of the tube is given by*

$$\mu(T(\mathcal{S}, r)) = r \frac{\sqrt{\pi}}{\Gamma(3/2)} \sum_{i=0}^{\left[\frac{d-1}{2}\right]} \frac{k_{2i}(\mathcal{S}) r^{2i}}{I(i)}, \tag{26}$$

where $I(i) = 1 \cdot 3 \cdot 5 \cdot \cdots \cdot (2i+1)$ and the numbers k_{2i} depend on the curvature structure of $\mathcal{S}$. For our purposes we need know only that $k_0 = \mu(\mathcal{S})$.

COROLLARY 6. *The volume of the tube $T(\mathcal{S}, r)$ can be expanded as*

$$\mu(T(\mathcal{S}, r)) = \mu(\mathcal{S})\ v(d-k; r)\ +\ \phi_{\mathcal{S}}(r),$$

where $\frac{\phi_{\mathcal{S}}(r)}{r^{d-k}} \xrightarrow{r \downarrow 0} 0$

Appendix E. Details on object recognition. The ideal objective is to actually compute the $\mathfrak{I}$-distance between D_1 and D_2 as described in section 7.2; however, this is a very hard problem since there are $m!$ $m \times m$ permutation matrices. The choice of m is subject to compromise: on one hand, we want it to be big enough so as to capture the metric structure of $\mathcal{S}_i$ with the information given by $(\Omega_n^{(i)}, d_{\Omega_{\mathcal{P}_n^{(i)}}^{h_i}})$; on the other hand, we want to be able to actually make the computations involved without too much processing cost. Therefore we should attempt to circumvent this $m!$ search space by exploiting some other information we might have.

One possibility for bypassing this difficulty is to try to upper bound the $\mathfrak{I}$-distance by some difference between eigenvalues of the matrices. However, it turns out that one can easily find two distance matrices which have positive $\mathfrak{I}$-distance (they are not *cogredient*) but have the same spectra. Then an upper bound should take into account also another term that measures our inability to really differentiate distance functions by looking only at their eigenvalues. Of course this information must then be contained in the eigenvectors.[30]

A way of dealing with this particular issue is working with the spectral factorization of each of the matrices. Let $D_1 = QDQ^T$ and $D_2 = \widehat{Q}\widehat{D}\widehat{Q}^T$, where Q and $\widehat{Q}$ are unitary matrices and D and $\widehat{D}$ are diagonal matrices whose entries are the eigenvalues of D_1 and D_2, respectively. Note that we are not saying anything about the order in which those eigenvalues are presented; for convenience, let

[30] Another idea, for example, is the following: We know that the searched-for isometry (if it exists) must be a Lipschitz continuous map, and therefore it makes no sense to consider the huge set of transformations spanned by $\mathcal{PM}_m$. We leave the exploitation of this idea for future work.

$D_{11} = |D_{11}| > |D_{22}| > \cdots > |D_{mm}|$ and $\widehat{D}_{11} = |\widehat{D}_{11}| > |\widehat{D}_{22}| > \cdots > |\widehat{D}_{mm}|$.[31] Then with little effort we can write

$$\min_{P \in \mathcal{PM}_m} \|D_1 - P D_2 P^T\| \leq \|(Q - P\widehat{Q})D\| + \|(Q - P\widehat{Q})\widehat{D}\| + \|D - \widehat{D}\|. \tag{27}$$

Note that if W is any matrix and T is diagonal, then $\|WT\|^2 = \sum_k \|W_{(:,k)} t_{kk}\|^2 = \sum_k \|W_{(:,k)}\|^2 t_{kk}^2$ where $W_{(:,k)}$ is the kth column vector of W. Using this observation, we note that the first two terms in (27) can be bounded as follows (let $Q = (q_1|\ldots|q_m)$, and $\widehat{Q} = (\widehat{q}_1|\ldots|\widehat{q}_m)$):

$$\|(Q - P\widehat{Q})D\| + \|(Q - P\widehat{Q})\widehat{D}\| = \sqrt{\sum_k D_{kk}^2 \|q_k - P\widehat{q}_k\|^2} + \sqrt{\sum_k \widehat{D}_{kk}^2 \|q_k - P\widehat{q}_k\|^2}.$$

Now, using the trivial inequality $\frac{\sqrt{a}+\sqrt{b}}{2} \leq \sqrt{\frac{a+b}{2}}$ for all $a, b \geq 0$, we finally arrive at the expression

$$\min_{P \in \mathcal{PM}_m} \|D_1 - P D_2 P^T\| \leq \sqrt{\sum_{k=1}^m (D_{kk} - \widehat{D}_{kk})^2} + \sqrt{2}\sqrt{\sum_{k=1}^m (D_{kk}^2 + \widehat{D}_{kk}^2)\|q_k - P\widehat{q}_k\|^2}. \tag{28}$$

This inequality holds for any $P \in \mathcal{PM}_m$. It is important to note that in case D_1 and D_2 are cogredient, all their eigenvectors will also be related through that same permutation; therefore this inequality is sharp.[32]

Note that in the second term of (28), the values of $\|q_i - P\widehat{q}_i\|$ are weighted by $(D_{ii}^2 + \widehat{D}_{ii}^2)$, so one can think that since $\|q_i - P\widehat{q}_i\| \leq 2$, the most important terms of the sum will be those for which $(D_{ii}^2 + \widehat{D}_{ii}^2)$ is large. This is not a rigorous consideration, but gives some guidelines on how to compute an approximate bound when the sizes of the distance matrices are prohibitively large.

In some situations, the choice of the subsampled set size m that guarantees a good metric approximation in the sense discussed above might be too large, making the computation of the full bound (28) onerous. But still a measure of similarity must be provided which does not require the computation of all of the eigenvalues and eigenvectors of each distance matrix. Therefore, in order to estimate $d_{\mathcal{J}}(D_1, D_2)$, we use the following idea: Instead of computing all the eigenvalues and eigenvectors of the matrices D_1 and D_2, compute the $N \ll m$ more important ones, where important means, in the light of the expression for the bound, those with the largest moduli, at least for the part of the bound involving eigenvectors. Then, for a (computationally) reasonable N we define the approximate error bound (still letting P be any convenient choice of a permutation matrix)

$$e(N) \triangleq \sqrt{\sum_{k=1}^N (D_{kk} - \widehat{D}_{kk})^2} + \sqrt{2}\sqrt{\sum_{k=1}^N (D_{kk}^2 + \widehat{D}_{kk}^2)\|q_k - P\widehat{q}_k\|^2}. \tag{29}$$

[31] We have used Frobenius theorem [51], which asserts that nonnegative matrices have a positive largest absolute value eigenvalue. Note that we have also assumed that there are no repeated eigenvalues.

[32] Note that from (27) one can obtain $d_{\mathcal{J}}(D_1, D_2) \leq \|D - \widehat{D}\| + (\|D\| + \|\widehat{D}\|)\|Q\widehat{Q}^T - P\|$; then one further idea to be explored is how to best approximate a given unitary matrix by a permutation matrix. This would not only allow us to obtain an explicit bound for the $\mathcal{J}$-distance, but would also provide us with a low metric distortion way of mapping S_1 ($\mathcal{P}_n^{(1)}$) into S_2 ($\mathcal{P}_n^{(2)}$), with applications like texture mapping, brain warping, etc.

Now, we fix the permutation P as follows: Let S be the permutation matrix such that Sq_1 is a column vector whose components are sorted from largest to smallest. Do the same with $\widehat{q}_1$ to obtain $\widehat{S}$; then compare Sq_1 with $\widehat{S}\widehat{q}_1$, which amounts to comparing q_1 with $S^T\widehat{S}$; hence we let $P = S^T\widehat{S}$. We could again use a more sophisticated way of choosing P, but this one suffices for demonstration purposes and, of course, achieves equality in (28) when both matrices are cogredient.

Another possibility is to directly compare the distance matrices according to the expression $\|D_1 - PD_2P^T\|$, using a certain sensible choice for P. We first put both matrices in a "canonical" order. Let (i_1, j_1) be one position on the matrix D_1 with the maximum value. We then order the rest of the points in the set according to their distances to either $q_{i_1}^{(1)}$ or $q_{i_2}^{(1)}$ from smallest to largest.[33] This induces an ordering for the matrix D_1, letting P_1 be the underlying permutation matrix. We do the same with D_2 and obtain P_2. Finally we let

$$e_G(D_1, D_2) \stackrel{\triangle}{=} \|D_1 - P_1^T P_2 D_2 P_2^T P_1\|,$$

and note that obviously $d_{\mathcal{J}}(D_1, D_2) \leq e_G(D_1, D_2)$ and that the inequality is sharp.

E.1. Choice of the point cloud subset $\mathcal{Q}^{(i)}$. In general, the number of points in the cloud is too big. This means that the actual computation of the distance matrices, if done using all the points in the cloud, and subsequent eigenvalue and eigenvector computations (if needed) become onerous. Therefore we need a procedure which allows us to select a small cardinality subset $\mathcal{Q}_m$ of $\mathcal{P}_n$ for which we will actually compute the approximate distance matrix, but still using $\mathcal{P}_n$ to define the offset $\Omega^h_{\mathcal{P}_n}$ inside which the computations are performed. This subset $\mathcal{C}_r \subset \mathcal{P}_n$ must be "representative" of the geometry of the underlying manifold. One way of selecting those points is by not allowing them to cluster inside any region of the manifold. This can be accomplished in practice by using the "packing idea" in [24]: Given $m < n$, choose the first point $c_1 \in \mathcal{C}_m$ randomly, then proceed by always choosing a point as far as possible from the set of points that have already been chosen. End the process when m points have been chosen. This is the procedure used in the experiments.

Acknowledgments. We acknowledge useful conversations on the topic of this paper with L. Aspirot, P. Bermolén, R. Coifman, D. Donoho, N. Dyn, J. Giesen, O. Gil, R. Gulliver, R. Kimmel, A. A MIXTURE THEORY FOR THE GENESIS OF RESIDUAL STRESSES IN GROWING TISSUES I: A GENERAL FORMULATION*

ROBYN P. ARAUJO† AND D. L. SEAN MCELWAIN†

Abstract. In this paper a theoretical framework for the study of residual stresses in growing tissues is presented using the theory of mixtures. Such a formulation must necessarily be a solid-multiphase model, comprising at least one phase with solid characteristics, owing to the fundamental role played by the incompatibility of strains in generating residual stresses. Since biological growth involves mass exchange between cellular and extracellular phases, field equations are presented for individual phases and for the mixture as a whole which incorporate this phenomenon. Appropriate constitutive equations are then deduced from first principles, appealing to the second law of thermodynamics.

The analysis shows that the distinguishing feature of multiphase models involving mass exchange is the necessity to propose an additional constitutive postulate between the variables in the mass-balance equation in order to close the model. In particular, the defining characteristic of a solid-multiphase model which describes biological growth is a constitutive postulate which relates the process of interphase mass exchange (cell proliferation/cell death) with the expansion or contraction of the solid phase. Thus, the framework presented here represents a new class of mathematical models which extends the concepts of poroelasticity to accommodate continuous volumetric growth. A set of modelling equations is then proposed for the simplest case of a solid-multiphase model, being a biphasic mixture of a linear-elastic solid and an inviscid fluid.

Key words. tissue growth, mixture theory, residual stresses, continuum mechanics, constitutive equations, porous media

1. Introduction.

The evolution and spatial distribution of tissue stresses is of fundamental importance in a number of physiological phenomena. The experimentally observed phenomenon of vascular collapse in tumors, for example, which has been attributed to the elevated tissue stresses resulting from confined proliferation of tumor cells [5, 9], represents a significant barrier to the delivery of blood-borne therapeutic drugs. Such stresses are *residual* in nature, arising in the tissue when it is free of external loads, and result from the incompatibility of growth strains [21, 38, 40].

Fung [20] further notes the existence of residual stresses in living organs and highlights the importance of such stresses to physiological functions, asserting that "in a living organism, the function of its organs depends on the levels of their internal stress and strain."

Hence continuum models of growing tissues would provide a theoretical framework for a wide range of studies in biology, ranging from tumor biology and anticancer therapies [23, 38] to studies in embryology [7, 34], developmental biology, and plant physiology [18], in addition to providing tools for prediction and analysis for a wide range of projects in the rapidly growing field of tissue engineering [31].

Nevertheless, the underlying phenomenological determinants of residual stresses, as well as their purpose and implications in both normal tissue development and

†School of Mathematical Sciences, Queensland University of Technology, PO Box 2434 Brisbane, QLD 4001 Australia (s.mcelwain@qut.edu.au).

various pathological conditions, are poorly understood since there is a paucity of mathematical models to elucidate these phenomena.

Gatenby [22] explains that "recent research in tumour biology, particularly that using new techniques from molecular biology, has produced information at an explosive pace. Yet a conceptual framework within which all these new (and old) data can be fitted is lacking." Gatenby and Maini [23] add that "clinical oncologists and tumour biologists possess virtually no comprehensive theoretical model to serve as a framework for understanding, organizing and applying these data," noting the necessity to "(develop) mechanistic models that provide real insights into critical parameters that control system dynamics." Murray [32] concurs, arguing that "the goal is to develop models which capture the essence of various interactions allowing their outcome to be more fully understood."

Indeed, while experimental approaches may attest to the *existence* of residual stresses and provide information about their distribution in tissues, the underlying mechanisms governing their genesis cannot be fully elucidated in the absence of mathematical modeling owing to the fundamental role played by the incompatibility of growth strains in their formation [40]. Mathematical analysis provides the key to identifying incompatible growth and represents a tool for investigating the roles of a variety of phenomenological aspects of growing tissues—distribution of nutrients, growth-related density changes, stress modulated cell-proliferation and apoptosis, geometric effects—in promoting incompatibilities and the associated residual stresses.

An important consideration in the mathematical modelling of tissue growth is the choice between single-phase mechanics and mixture theory [2]. The former, which appeals to an analogy with thermal expansion, incorporates a *source term* in the balance of mass, with the phase or phases responsible for the mass source remaining implicit to the model. While Skalak [39] claims that volumetric growth is analogous to thermal expansion—an analogy which forms the basis of the tissue growth models by Shannon and Rubinsky [38], Jones et al. [26], and Araujo and McElwain [4]—it does not consider all the processes which determine the stresses induced during biological tissue growth. Indeed, Araujo and McElwain [4] note that the single-constituent framework does not take into account the net fluid movement associated with the growth process and the Darcy-like drag terms in the equilibrium of forces—a consideration which may be significant when the elastic (residual) stresses are small.

Multiphase models, on the other hand, which are based on mixture theory, clarify the nature of any mass sources, and consider the role of interstitial fluid in the growth process. While several *fluid* multiphase models of growing tissues have been proposed recently [15, 16, 28], it is essential to recognize that these models provide no basis for examining the genesis of *residual* stresses in tissues, which requires a consideration of the tissue's *solid* characteristics.

Hence, a theoretical framework which enables the growth process and the associated development of tissue stresses to be modeled naturally, without recourse to an analogy with thermal expansion, is lacking.

This paper is the first in a series of papers which elaborate a mixture theory for the genesis of residual stresses in growing soft tissues, based on field equations which incorporate interphase mass exchange. This paper presents a general formulation for deducing thermodynamically appropriate constitutive equations relevant to the study of biological growth. In section 2, the field equations are presented, being adapted from the classical field theories developed by Truesdell and Toupin [42] and the theory of mixtures developed by Bowen [12] and manipulated into the forms most useful to further exploration of the problem at hand. In sections 3 and 4, these classical

theories are used as a guide to developing a particular form of the second axiom of thermodynamics from which the relevant constitutive equations may be deduced most readily, neglecting the influence of possible density changes associated with a change of phase. Constitutive assumptions for a general mixture of n phases are then outlined in section 5, following the pioneering work on constitutive modeling by Coleman and Noll [17], Ehlers [19], and Bowen [12].

In sections 6 through 8, a simple two-phase mixture of an elastic solid and an inviscid fluid is considered in detail. Since this solid-biphasic mixture must be able to exhibit continuous volumetric expansion to model the process of biological growth and an associated evolution of residual stresses, this paper stands alone in the mathematical literature pertaining to solid tumor growth, enucleating the very essence of the closure problem relevant to continuous growth of a tissue with solid characteristics. The solutions to these biphasic equations will be presented in the next paper in the series.

1.1. Differentiation conventions and index of symbols. The following conventions will be adopted throughout this paper.

If $\hat{\alpha_i}$ and $\boldsymbol{\alpha}_i$ are scalar and vector/tensor properties of the ith constituent, respectively, then $\boldsymbol{\nabla}\hat{\alpha_i}$ and $\boldsymbol{\nabla}.\boldsymbol{\alpha}_i$ denote the gradient and the divergence, respectively, with respect to *spatial* coordinates. (Note that in many references and texts in continuum mechanics these symbols are used to denote partial differentiation with respect to the *reference configuration*.) The symbols $\mathbf{Grad}\hat{\alpha_i}$ and $\mathbf{Div}\boldsymbol{\alpha}_i$ will denote the gradient and divergence, respectively, with respect to the *reference configuration*.

In addition, the symbol $\frac{D^i}{Dt}$ denotes the material derivative following the motion defined by $\mathbf{v}_i$, the velocity of the ith constituent. The symbol $\frac{D}{Dt}$, on the other hand, represents the material derivative following the motion defined by $\mathbf{v}_m$, the velocity of the mixture as a whole.

Table 1.1 gives a summary of the nomenclature adopted in this paper, along with the equation in which each symbol first appears. Each quantity is given a more complete description when it is first introduced in the text.

2. Constituent field equations. The balances of mass, linear momentum, angular momentum, and energy for the ith constituent of an n-phase mixture are summarized below. The equations incorporate a mass exchange term, so that the mass of the ith constituent may increase (or decrease) at the expense of other constituents. All constituents are equipresent at each spatial point.

2.1. Balance of mass. The balance of mass for the ith constituent, or *phase*, of an n-phase mixture is given by

$$\frac{D^i(\phi_i\rho_i)}{Dt} + (\phi_i\rho_i)\boldsymbol{\nabla}\cdot\mathbf{v}_i = \Gamma_i, \tag{2.1}$$

or, equivalently,

$$\frac{\partial(\phi_i\rho_i)}{\partial t} + \boldsymbol{\nabla}.(\phi_i\rho_i\mathbf{v}_i) = \Gamma_i, \tag{2.2}$$

where ϕ_i and ρ_i are the volume fraction and density, respectively, of the ith phase and Γ_i is the mass supplied to the ith phase per unit time per unit mixture volume. Truesdell and Toupin's [42] rule for differentiating a determinant gives the identity

$$\frac{D^i}{Dt}(\det\mathbf{F}_i) = (\det\mathbf{F}_i)\boldsymbol{\nabla}\cdot\mathbf{v}_i,$$

TABLE 1.1
Symbols.

Symbol	Description	Equation of first occurrence
ϕ	Volume fraction	(2.1)
ρ	True density	(2.1)
Γ	Mass supply	(2.1)
$\mathbf{F}$	Deformation Gradient	(2.3)
$\mathbf{v}$	Velocity	(2.1)
$\boldsymbol{\sigma}$	Partial Cauchy stress tensor	(2.7)
$\boldsymbol{\sigma}_I$	*Inner* mixture stress tensor	(2.16)
$\mathbf{g}$	Acceleration due to gravity	(2.7)
$\boldsymbol{\pi}$	Phase interaction force	(2.7)
$\mathbf{w}$	Diffusion velocity	(2.11)
$\mathbf{m}$	Angular momentum supply	(2.13)
$\mathbf{L}$	Velocity gradient	(2.18)
u	Internal energy	(2.18)
$\mathbf{q}$	Heat flux	(2.18)
r	Heat production rate	(2.18)
ε	Phase interaction energy supply	(2.18)
η	Entropy	(3.1)
θ	Absolute temperature	(3.1)
ψ	Helmholtz free energy	(3.4)
$\mathbf{K}$	Chemical potential tensor	(3.5)
ζ	Lagrangian multiplier	(4.4)
$\mathbf{X}$	Reference coordinates	(8.2)
$\mathbf{x}$	Spatial coordinates	(8.9)
μ, λ	Lamé constants	(8.22)

which enables (2.1) to be expressed by

$$\frac{D^i}{Dt}\left(\phi_i \rho_i \det\mathbf{F}_i\right) = \Gamma_i \det\mathbf{F}_i, \tag{2.3}$$

where $\mathbf{F}_i$ is the deformation gradient of the ith phase with respect to the reference configuration. The volume fractions, ϕ_i, are subject to the constraint

$$\sum_{i=1}^{n} \phi_i = 1, \tag{2.4}$$

which implies that the mixture is *saturated*.

The balance of mass for the mixture is expressed by

$$\frac{D\rho_m}{Dt} + \rho_m \boldsymbol{\nabla} \cdot \mathbf{v}_m = 0, \tag{2.5}$$

where ρ_m and $\mathbf{v}_m$ are the density and velocity, respectively, of the mixture as a whole. A comparison of (2.5) with the summation of (2.2) over all n phases allows the mixture density, ρ_m, to be defined by

$$\rho_m = \sum_{i=1}^{n} \phi_i \rho_i,$$

and the mixture velocity, $\mathbf{v}_m$, to be defined by

$$\mathbf{v}_m = \frac{1}{\rho_m} \sum_{i=1}^{n} (\phi_i \rho_i \mathbf{v}_i),$$

while yielding the following expression for the conservation of mass:

$$\sum_{i=1}^{n} \Gamma_i = 0. \tag{2.6}$$

2.2. Balance of linear momentum. The balance of linear momentum for the ith phase of an n-phase mixture is given by

$$\phi_i \rho_i \frac{D^i \mathbf{v}_i}{Dt} = \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_i + \phi_i \rho_i \mathbf{g} + \boldsymbol{\pi}_i, \tag{2.7}$$

or, equivalently,

$$\frac{\partial}{\partial t}(\phi_i \rho_i \mathbf{v}_i) + \boldsymbol{\nabla}.(\phi_i \rho_i \mathbf{v}_i \otimes \mathbf{v}_i) = \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_i + \phi_i \rho_i \mathbf{g} + \boldsymbol{\pi}_i + \Gamma_i \mathbf{v}_i, \tag{2.8}$$

where $\boldsymbol{\sigma}_i$ is the partial Cauchy stress tensor for the ith phase, $\mathbf{g}$ is the acceleration due to gravity, and $\boldsymbol{\pi}_i$ is the locally produced force per unit volume on the ith phase due to its interactions with the other phases. The symbol $\otimes$ denotes the dyadic vector product.

The balance of linear momentum for the mixture is expressed by

$$\rho_m \frac{D\mathbf{v}_m}{Dt} = \boldsymbol{\nabla} \cdot \boldsymbol{\sigma}_m + \rho_m \mathbf{g}, \tag{2.9}$$

where $\boldsymbol{\sigma}_m$ is the Cauchy stress tensor of the mixture as a whole. A comparison of (2.9) with the summation of (2.8) enables the mixture stress tensor to be defined by

$$\boldsymbol{\sigma}_m = \sum_i (\boldsymbol{\sigma}_i - \phi_i \rho_i \mathbf{w}_i \otimes \mathbf{w}_i), \tag{2.10}$$

where $\mathbf{w}_i$ denotes the diffusion velocity defined by

$$\mathbf{w}_i = \mathbf{v}_i - \mathbf{v}_m \tag{2.11}$$

and gives rise to the following expression for the conservation of linear momentum:

$$\sum_{i=1}^{n} (\boldsymbol{\pi}_i + \Gamma_i \mathbf{v}_i) = 0. \tag{2.12}$$

2.3. Balance of angular momentum. The balance of angular momentum for the ith phase of an n-phase mixture is given by

$$\frac{\partial}{\partial t}\Big(\phi_i \rho_i \mathbf{x} \times \mathbf{v}_i\Big) + \boldsymbol{\nabla} \cdot \Big(\phi_i \rho_i (\mathbf{x} \times \mathbf{v}_i) \otimes \mathbf{v}_i\Big) = \boldsymbol{\nabla} \cdot (\mathbf{x} \times \boldsymbol{\sigma}_i) + \mathbf{x} \times (\phi_i \rho_i \mathbf{g} + \boldsymbol{\pi}_i + \Gamma_i \mathbf{v}_i) + \mathbf{m}_i, \tag{2.13}$$

where $\mathbf{m}_i$ is a vector representing the supply of angular momentum to the ith phase. The symbol $\times$ denotes a cross product, in which the quantity

$$(\mathbf{x} \times \boldsymbol{\sigma}_i)\mathbf{e} = \mathbf{x} \times (\boldsymbol{\sigma}_i \mathbf{e})$$

for all vectors $\mathbf{e}$ (see Bowen [12]). Appealing to the balance of linear momentum produces

$$\mathbf{M}_i = \boldsymbol{\sigma}_i - \boldsymbol{\sigma}_i^T \tag{2.14}$$

from (2.13), where $\mathbf{M}_i$ is a skew-symmetric tensor arising from the angular momentum supply vector, $\mathbf{m}_i$. Since the sum of the momentum supplies over all phases must vanish, then

$$\sum_{i=1}^{n} \mathbf{M}_i = \mathbf{0}. \tag{2.15}$$

Thus, the summation of (2.14) over all phases implies that the *inner* part of the mixture stress tensor, which is defined by Truesdell and Toupin [42] as

$$\boldsymbol{\sigma}_I = \sum_{i=1}^{n} \boldsymbol{\sigma}_i, \tag{2.16}$$

is symmetric. Noting that the quantity

$$\sum_{i=1}^{n} \phi_i \rho_i \mathbf{w}_i \otimes \mathbf{w}_i$$

must also be symmetric implies that the mixture stress tensor is symmetric. Note, however, that the partial Cauchy stress tensors are symmetric if and only if $\mathbf{m}_i = \mathbf{0}$ (and hence $\mathbf{M}_i = \mathbf{0}$), that is, for nonpolar materials. In this particular study, it is assumed that the components of the growing tissue do behave as nonpolar materials, so that $\mathbf{m}_i = \mathbf{0}$ and that

$$\boldsymbol{\sigma}_i = \boldsymbol{\sigma}_i^T. \tag{2.17}$$

A more general theory would have to be developed to consider tissues comprising micropolar fluids.

2.4. Balance of energy. The energy balance for the ith phase of an n-phase mixture is given by

$$\phi_i \rho_i \frac{D^i u_i}{Dt} = tr(\mathbf{L}_i \boldsymbol{\sigma}_i) - \boldsymbol{\nabla} \cdot \mathbf{q}_i + \phi_i \rho_i r_i + \varepsilon_i, \tag{2.18}$$

or, equivalently,

$$\frac{\partial}{\partial t}(\phi_i \rho_i u_i) + \boldsymbol{\nabla} \cdot (\phi_i \rho_i u_i \mathbf{v}_i) = tr(\mathbf{L}_i \boldsymbol{\sigma}_i) - \boldsymbol{\nabla} \cdot \mathbf{q}_i + \phi_i \rho_i r_i + \varepsilon_i + \Gamma_i u_i, \tag{2.19}$$

where $\mathbf{q}_i$ is a measure of the rate of heat flow across a unit area from the ith constituent, r_i is the rate of heat production per unit mass within the ith constituent, ε_i is the energy supply per unit mass per unit time to the ith constituent due to energy exchange between the constituents, u_i is the internal energy per unit mass of the ith constituent, and $\mathbf{L}_i$ is the velocity gradient of the ith constituent with respect to spatial coordinates.

Truesdell and Toupin [42] argue that for the overall conservation of energy in the mixture, "the energy supplied by an excess internal energy rate, plus the energy supplied by the work of the excess inertial forces against diffusion, plus the energy supplied by the creation of mass, must add up to zero for the mixture." This implies the following expression for the conservation of energy:

$$\sum_{i=1}^{n} \left[\varepsilon_i + \Gamma_i \left(u_i + \frac{1}{2} \mathbf{w}_i \cdot \mathbf{w}_i \right) + \mathbf{w}_i \cdot \pi_i \right] = 0,$$

or, equivalently, by appealing to (2.12),

$$\sum_{i=1}^{n}\left[\varepsilon_i+\Gamma_i\left(u_i+\frac{1}{2}\mathbf{v}_i\cdot\mathbf{v}_i\right)+\mathbf{v}_i\cdot\pi_i\right]=0. \tag{2.20}$$

3. The second law of thermodynamics. The second law of thermodynamics, which may be expressed in the form of the Clausius–Duhem inequality, places limitations on the admissible paths of thermodynamic processes, thereby placing restrictions on constitutive equations. The Clausius–Duhem inequality states that the rate of entropy increase is greater than or equal to the entropy input rate.

Following Rajagopal and Tao [37], it is assumed that the second law of thermodynamics holds for the mixture as a whole. In addition, a single, spatially uniform temperature is assumed for all phases since growth involves exchanges of mass among the phases and because the growth process itself is slow in comparison with the time it would take for any possible temperature gradients to equilibrate. Indeed, it is unlikely that stresses arising from a gradient of thermal expansion would be significant in biological tissues. Therefore if η_i denotes the entropy per unit mass of the ith constituent and θ denotes the absolute temperature of the mixture, then the inequality may be expressed by

$$\sum_i\left[\frac{D^i}{Dt}(\phi_i\rho_i\eta_i)+\phi_i\rho_i\eta_i\boldsymbol{\nabla}.\mathbf{v}_i+\boldsymbol{\nabla}.\left(\frac{\mathbf{q}_i}{\theta}\right)-\frac{\phi_i\rho_i r_i}{\theta}\right]\geq 0. \tag{3.1}$$

The entropy inequality for the mixture is given by

$$\rho_m\frac{D\eta_m}{Dt}+\sum_i\boldsymbol{\nabla}.\left(\frac{\mathbf{h}_i}{\theta}\right)-\sum_i\left(\frac{\phi_i\rho_i r_i}{\theta}\right)\geq 0, \tag{3.2}$$

where $\mathbf{h}_i$ is an influx vector for the ith constituent—as yet unrelated to $\mathbf{q}_i$—and η_m is the entropy density for the mixture defined by

$$\eta_m=\frac{1}{\rho_m}\sum_i\phi_i\rho_i\eta_i.$$

Hence, reconciling (3.1) and (3.2) requires the constitutive postulate,

$$\mathbf{h}_i=\mathbf{q}_i+\phi_i\rho_i\theta\eta_i\mathbf{w}_i. \tag{3.3}$$

The second axiom of thermodynamics, as expressed by (3.1), may now be manipulated further to obtain a form from which constitutive equations may be deduced readily. To this end, the internal energies, u_i, will be eliminated in favor of the Helmholtz free energy densities, ψ_i, where

$$\psi_i=u_i-\theta\eta_i. \tag{3.4}$$

Employing the Helmholtz free energy is particularly expedient when deducing constitutive equations since it is the portion of the internal energy available for doing mechanical work at constant temperature [30]. Further, the process of deducing constitutive equations is facilitated by the introduction of the chemical potential for each phase, which, for *general* mixtures, is given by the linear transformation

$$\mathbf{K}_i=\psi_i\mathbf{I}-\frac{\boldsymbol{\sigma}_i}{\phi_i\rho_i}.$$

The change of variables brought about by this transformation is common in the established literature relating to thermodynamic theories of constitutive equations. (See Bowen [11, 12] and Bowen and Wiese [14] for further details on the use of the chemical potential tensor in the study of general mixtures.)

Now, incorporating the balance of mass (2.1) and the energy equation (2.18) and introducing the variables ψ_i and $\mathbf{K}_i$ enable the second law of thermodynamics to be expressed by the dissipation inequality

$$-tr\sum_{i=1}^{n}\phi_i\rho_i\mathbf{K}_i.\mathbf{L}_i-\rho_m\eta_m\frac{D\theta}{Dt}-\sum_{i=1}^{n}\frac{D^i\Psi_i}{Dt}-\sum_{i=1}^{n}\mathbf{v}_i.\left(\boldsymbol{\pi}_i+\frac{\Gamma_i}{2}\mathbf{v}_i\right)\geq 0, \tag{3.5}$$

where

$$\Psi_i=\phi_i\rho_i\psi_i \tag{3.6}$$

represents the Helmholtz free energy of the ith constituent per unit mixture volume. A full derivation of this inequality is given in the appendix.

4. The assumption of incompressibility. In the present paper it will be assumed that each of the n phases is intrinsically incompressible, thereby placing an added constraint on their motion and giving rise to an indeterminacy in the second law of thermodynamics. The assumption of incompressibility is a common one in mathematical models of biological tissues on account of the high water content of the cells and interstitial fluid and the very low compressibility of other extracellular constituents, such as the large macromolecules comprising the extracellular matrix [1].

The balance of mass for the ith phase may now be expressed by

$$\frac{\partial\phi_i}{\partial t}+\boldsymbol{\nabla}.(\phi_i\mathbf{v}_i)=\frac{\Gamma_i}{\rho_i},$$

the summation of which over the n phases gives

$$\sum_{i=1}^{n}(\boldsymbol{\nabla}\phi_i.\mathbf{v}_i+\phi_i\boldsymbol{\nabla}.\mathbf{v}_i)=\sum_{i=1}^{n}\frac{\Gamma_i}{\rho_i}\triangleq\hat{\gamma}, \tag{4.1}$$

employing the saturation constraint (2.4). At this point, the principle of material frame-indifference (or *objectivity*) is considered, which requires that the response of the material and its individual constituents (and hence its constitutive equations, to be developed later from the present analysis) be independent of the observer [6]. Since relative velocities are objective, while individual velocities are not, (4.1) may be expressed in terms of relative velocities by noting that

$$\sum_{i=1}^{n}\mathbf{v}_i.\boldsymbol{\nabla}\phi_i=\sum_{i=1}^{n}(\mathbf{v}_i-\mathbf{v}_1).\boldsymbol{\nabla}\phi_i,$$

where one phase is nominated as the reference phase with the subscript 1. Assuming that the densities of all phases are equal (so that $\rho_i=\rho_m=\rho$ and $\hat{\gamma}=0$) enables (4.1) to reduce to

$$\sum_{i=1}^{n}\Big[(\mathbf{v}_i-\mathbf{v}_1).\boldsymbol{\nabla}\phi_i+\phi_i tr\mathbf{L}_i\Big]=0. \tag{4.2}$$

From a mathematical standpoint, this assumption of equal phase densities allows the model to isolate the growth-induced stresses arising from spatially nonuniform (incompatible) growth, without the potentially confounding effects of additional stresses associated with density changes. In addition, the assumption of equal densities simplifies the ensuing analysis considerably. Further, the argument may be justified from a phenomenological point of view by noting that in a growing tissue, the growth process itself arises from exchanges of mass among individual tissue constituents. In particular, cells grow and proliferate by taking in interstitial fluid—water and proteins (and other molecules contained in the interstitial fluid)—and relinquish these substances on cell death. Thus, while different phases may exhibit fundamentally different mechanical behavior, they are composed of similar substances.

Now, recognizing that

$$\mathbf{L}_i = \grave{\mathbf{F}}_i \mathbf{F}_i^{-1}$$

by the chain rule, where

$$\grave{\mathbf{F}}_i = \frac{D^i \mathbf{F}_i}{Dt},$$

and that

$$\sum_{i=1}^{n} \mathbf{v}_i . \left(\boldsymbol{\pi}_i + \frac{\Gamma_i}{2} \mathbf{v}_i \right) = \sum_{i=1}^{n} \left[\boldsymbol{\pi}_i + \frac{1}{2} \Gamma_i (\mathbf{v}_i - \mathbf{v}_1) \right] . (\mathbf{v}_i - \mathbf{v}_1) \tag{4.3}$$

now enables the second axiom of thermodynamics to be expressed in the form

$$\begin{aligned} &-tr \sum_{i=1}^{n} \mathbf{F}_i^{-1} (\phi_i \rho \mathbf{K}_i - \phi_i \zeta \mathbf{I}) \grave{\mathbf{F}}_i - \rho \eta_m \frac{D\theta}{Dt} - \sum_{i=1}^{n} \frac{D^i \Psi_i}{Dt} \\ &- \sum_{i=1}^{n} \left[\boldsymbol{\pi}_i + \frac{1}{2} \Gamma_i (\mathbf{v}_i - \mathbf{v}_1) - \zeta \boldsymbol{\nabla} \phi_i \right] . (\mathbf{v}_i - \mathbf{v}_1) \geq 0, \end{aligned} \tag{4.4}$$

where ζ is a Lagrangian multiplier.

5. Constitutive assumptions for a general n-phase mixture. As expressed by Coleman and Noll in [17], "a material is defined by a constitutive assumption, which is a restriction on the processes that are admissible in a body consisting of the material."

In discussing the various principles governing constitutive equations, Passman and Nunziato [33] describe the principle of equipresence as "too general," claiming that it is "difficult to accept as a universal axiom appropriate to all mixture theories." (According to this principle, "all dependent variables depend on all independent variables, unless the entropy inequality requires otherwise" [25, 41].) They proceed to explain that "in multiphase mixtures (where) the individual constituents are clearly separated physically, . . . it is plausible to think of the mixture as being ideal, or phase separated. For such mixtures the Principle of Equipresence can reasonably be replaced by the Principle of Phase Separation." By this principle, the material-specific dependent variables of a given phase (such as the stress and the Helmholtz free energy density) depend only on the independent variables of that phase. The interaction variables (such as the momentum transfer term, $\boldsymbol{\pi}_i$) depend on all the independent variables. (See Passman and Nunziato [33] for a more detailed discussion of these principles.)

Much of the classical work in this field has relied on the former, more general principle. Thus, in predicating the current study on these classical, well-established approaches, this paper appeals to this general principle in deducing thermodynamically appropriate constitutive equations in spite of the fact that the individual phases of biological tissues are clearly separated and distinct. Nevertheless, the simpler principle of phase separation is used to advantage in subsequent analysis, allowing the constitutive equations to be manipulated into useable forms.

Furthermore, Ehlers [19] emphasises the fact that "the general constitutive framework must be based on the assumption of second-grade materials . . . , thus making use of the most natural framework in constitutive modelling for multiphase media, additionally avoiding so-called 'simple' results." Thus, following Bowen [12], Bowen and Weise [14], and Ehlers [19], and noting from (4.2) that the constitutive assumptions for $\mathbf{K}_i$ and $\boldsymbol{\pi}_i$ must reflect an indeterminacy consistent with the entropy inequality, the following general constitutive postulate is proposed:

$$\begin{aligned}\left(\Psi_i, \eta_i, \left(\boldsymbol{\pi}_i + \frac{1}{2}\Gamma_i(\mathbf{v}_i - \mathbf{v}_1) - \zeta\boldsymbol{\nabla}\phi_i\right), (\phi_i\rho\mathbf{K}_i - \phi_i\zeta\mathbf{I}), \mathbf{q}\right)\\ = f(\theta, \mathbf{F}_j, \dot{\mathbf{F}}_j, \mathbf{G}_j, \phi_j, \mathbf{n}_j, (\mathbf{v}_j - \mathbf{v}_1)),\end{aligned} \tag{5.1}$$

where f is a smooth function, with the following quantities being defined for clarity:

$$\mathbf{G}_j = \mathbf{Grad}\mathbf{F}_j$$

and

$$\mathbf{n}_j = \boldsymbol{\nabla}\phi_j.$$

As discussed by Bowen in [10] and [12], (5.1) describes a mixture which allows for the combined effects of elasticity, heat conduction, diffusion, viscosity, buoyancy, immiscibility, and variable volume fractions. As noted by Bowen in [13], "an *immiscible* mixture is one where locally one can distinguish between mixture volumes and constituent volumes (and therefore) a model of an immiscible mixture would necessarily allow the volume fractions to effect the mixture response." Having established a general framework, then, it remains for a *particular* constitutive postulate to be chosen to carry the analysis through to completion, to arrive at a full set of modeling equations.

6. A biphasic mechanical model of tissue growth. In this section, the general constitutive assumption (5.1) is applied to a two-phase model comprising an elastic solid (indicated by the subscript s) and an inviscid fluid (indicated by the subscript f), being the simplest case of a solid-multiphase model. In this case, the constitutive equations reduce to

$$\left(\Psi_i, \eta_i, \left(\boldsymbol{\pi}_f + \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s) - \zeta\boldsymbol{\nabla}\phi_f\right), (\phi_i\rho\mathbf{K}_i - \phi_i\zeta\mathbf{I}), \mathbf{q}\right) = f(\theta, \mathbf{F}_s, \mathbf{G}_s, (\mathbf{v}_f - \mathbf{v}_s)) \tag{6.1}$$

with $i = f, s$. Since the effect of viscosity is not being considered in this simplified model, the derivatives of the deformation gradients do not appear among the independent variables in (6.1). The volume fractions and their gradients are also omitted from the set of independent variables since the *specific* Helmholtz free energy, ψ_i, is to

be considered independent of volume fraction, with the volume-averaged Helmholtz free energy, Ψ_i, being related to volume fraction via (3.6). Note that in a two-phase model, only one of the mass exchange terms, Γ_i, or volume fraction terms, ϕ_i, need be considered since the constraints (2.4) and (2.6) give the corresponding terms for the other phase. Further, since one of the phases is a solid and the other a fluid, the volume fractions ϕ_s and $\phi_f = 1 - \phi_s$ will henceforth be referred to as the *solidity* and the *porosity*, respectively.

Using (6.1) the total derivative of the Helmholtz free energy for the solid is given by

$$\begin{aligned}\frac{D^s\Psi_s}{Dt} &= \left(\frac{\partial\Psi_s}{\partial\theta}\right)\left(\frac{D\theta}{Dt}\right) + tr\left(\frac{\partial\Psi_s}{\partial\mathbf{F}_s}\right)^T \grave{\mathbf{F}}_s + C\left(\frac{\partial\Psi_s}{\partial\mathbf{G}_s}\right)\otimes\grave{\mathbf{G}}_s \\ &\quad + \left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f-\mathbf{v}_s)}\right).\left[\frac{D^f(\mathbf{v}_f-\mathbf{v}_s)}{Dt} + \grave{\mathbf{F}}_f\mathbf{F}_f^{-1}(\mathbf{v}_s-\mathbf{v}_f) - \grave{\mathbf{F}}_s\mathbf{F}_s^{-1}(\mathbf{v}_s-\mathbf{v}_f)\right],\end{aligned}$$

while the total derivative of the Helmholtz free energy for the fluid is given by

$$\begin{aligned}\frac{D^f\Psi_f}{Dt} &= \left(\frac{\partial\Psi_f}{\partial\theta}\right)\left(\frac{D\theta}{Dt}\right) + tr\left(\frac{\partial\Psi_f}{\partial\mathbf{F}_s}\right)^T \left[\grave{\mathbf{F}}_s + \mathbf{G}_s\mathbf{F}_s^{-1}(\mathbf{v}_f-\mathbf{v}_s)\right] \\ &\quad + C\left(\frac{\partial\Psi_f}{\partial\mathbf{G}_s}\right)\otimes\left[\grave{\mathbf{G}}_s + (\mathbf{GradG}_s)\mathbf{F}_s^{-1}(\mathbf{v}_f-\mathbf{v}_s)\right] \\ &\quad + \left(\frac{\partial\Psi_f}{\partial(\mathbf{v}_f-\mathbf{v}_s)}\right).\left[\frac{D^f(\mathbf{v}_f-\mathbf{v}_s)}{Dt}\right].\end{aligned}$$

Therefore the entropy inequality becomes

$$\begin{aligned}&-tr\sum_{i=f,s}\mathbf{F}_i^{-1}\left(\phi_i\rho\mathbf{K}_i - \phi_i\zeta\mathbf{I}\right)\grave{\mathbf{F}}_i - \rho\eta_m\frac{d\theta}{dt} \\ &-\left(\boldsymbol{\pi}_f + \frac{1}{2}\Gamma_f(\mathbf{v}_f-\mathbf{v}_s) - \zeta\boldsymbol{\nabla}\phi_f\right).(\mathbf{v}_f-\mathbf{v}_s) - \left(\frac{\partial\Psi_I}{\partial\theta}\right)\frac{D\theta}{Dt} \\ &-tr\mathbf{F}_s^{-1}\left(\mathbf{F}_s\left(\frac{\partial\Psi_I}{\partial\mathbf{F}_s}\right)^T - (\mathbf{v}_s-\mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f-\mathbf{v}_s)}\right)\right)\grave{\mathbf{F}}_s \\ &-(\mathbf{v}_f-\mathbf{v}_s).\left(\mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{F}_s}[\mathbf{G}_s]\right)\right) \\ &-C\left(\frac{\partial\Psi_I}{\partial\mathbf{G}_s}\right)\otimes\grave{\mathbf{G}}_s - (\mathbf{v}_f-\mathbf{v}_s).\left(\mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{G}_s}[\mathbf{GradG}_s]\right)\right) \\ &-\left(\frac{\partial\Psi_I}{\partial(\mathbf{v}_f-\mathbf{v}_s)}\right).\left[\frac{D^f(\mathbf{v}_f-\mathbf{v}_s)}{Dt}\right] \\ &-tr\mathbf{F}_f^{-1}\left((\mathbf{v}_s-\mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f-\mathbf{v}_s)}\right)\right)\grave{\mathbf{F}}_f \geq 0,\end{aligned}$$

where

$$\Psi_I = \sum_{i=f,s}\Psi_i = \sum_{i=f,s}\phi_i\rho_i\psi_i$$

denotes the inner part of the mixture Helmholtz free energy. Here, the notation $\mathbf{X}[\mathbf{Y}]$, where $\mathbf{X}$ is a tensor of rank p and $\mathbf{Y}$ is a tensor of rank $p+1$, denotes a vector defined

in component form by

$$\mathbf{X}[\mathbf{Y}] = X_{k_1 k_2 \ldots k_p} Y^{k_1 k_2 \ldots k_p q} \mathbf{e}_q.$$

where $\mathbf{e}_q$ are basis vectors. (See, for example, (1.10) in Bowen and Weise [14] or (1.1.58) in Bowen [12].) Now rearranging the inequality produces

$$\begin{aligned}
&-tr\mathbf{F}_s^{-1}\left(\phi\rho_s\mathbf{K}_s - \phi_s\zeta\mathbf{I} + \mathbf{F}_s\left(\frac{\partial\Psi_I}{\partial\mathbf{F}_s}\right)^T - (\mathbf{v}_s - \mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f - \mathbf{v}_s)}\right)\right)\dot{\mathbf{F}}_s \\
&- tr\mathbf{F}_f^{-1}\left(\phi_f\rho\mathbf{K}_f - \phi_f\zeta\mathbf{I} + (\mathbf{v}_s - \mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f - \mathbf{v}_s)}\right)\right)\dot{\mathbf{F}}_f \\
&- \left(\rho\eta_m + \frac{\partial\Psi_I}{\partial\theta}\right)\frac{D\theta}{Dt} - \left(\frac{\partial\Psi_I}{\partial\mathbf{g}}\right).\frac{D\mathbf{g}}{Dt} - C\left(\frac{\partial\Psi_I}{\partial\mathbf{G}_s}\right)\otimes\dot{\mathbf{G}}_s \\
&- (\mathbf{v}_f - \mathbf{v}_s).\left(\mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{G}_s}[\mathbf{GradG}_s]\right)\right) - \left(\frac{\partial\Psi_I}{\partial(\mathbf{v}_f - \mathbf{v}_s)}\right).\left[\frac{D^f(\mathbf{v}_f - \mathbf{v}_s)}{Dt}\right] \\
&- \left[\boldsymbol{\pi}_f + \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s) - \zeta\boldsymbol{\nabla}\phi_f + \mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{F}_s}[\mathbf{G}_s]\right)\right].(\mathbf{v}_f - \mathbf{v}_s) \geq 0.
\end{aligned}$$

Following Coleman and Noll's argument [17],

$$\theta,\ \mathbf{F}_s,\ \mathbf{G}_s \text{ and } (\mathbf{v}_f - \mathbf{v}_s)$$

are held *fixed* while *varying* the quantities

$$\frac{D\theta}{Dt},\ \dot{\mathbf{F}}_s,\ \dot{\mathbf{G}}_s,\ \mathbf{GradG}_s \text{ and } \frac{D^f(\mathbf{v}_f - \mathbf{v}_s)}{Dt}.$$

This yields the following necessary and sufficient conditions:

$$\phi_s\rho\mathbf{K}_s - \phi_s\zeta\mathbf{I} + \mathbf{F}_s\left(\frac{\partial\Psi_I}{\partial\mathbf{F}_s}\right)^T - (\mathbf{v}_s - \mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f - \mathbf{v}_s)}\right) = \mathbf{0}, \tag{6.2}$$

$$\phi_f\rho\mathbf{K}_f - \phi_f\zeta\mathbf{I} + (\mathbf{v}_s - \mathbf{v}_f)\otimes\left(\frac{\partial\Psi_s}{\partial(\mathbf{v}_f - \mathbf{v}_s)}\right) = \mathbf{0}, \tag{6.3}$$

$$\rho\eta_m = -\frac{\partial\Psi_I}{\partial\theta},$$

$$\frac{\partial\Psi_I}{\partial\mathbf{G}_s} = \mathbf{0},$$

$$\sum_{i=f,s}(\mathbf{v}_i - \mathbf{v}_s).\left(\mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{G}_s}[\mathbf{GradG}_s]\right)\right) = \mathbf{0},$$

$$\frac{\partial\Psi_I}{\partial(\mathbf{v}_f - \mathbf{v}_s)} = \mathbf{0},$$

and

$$-\mathbf{f}.(\mathbf{v}_f - \mathbf{v}_s) \geq 0, \tag{6.4}$$

where

$$\mathbf{f} = \boldsymbol{\pi}_f + \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s) - \zeta\boldsymbol{\nabla}\phi_f + \mathbf{F}_s^{-1T}\left(\frac{\partial\Psi_f}{\partial\mathbf{F}_s}[\mathbf{G}_s]\right).$$

7. Development of linearized constitutive equations. In this section, the constitutive equations (6.2), (6.3), and (6.4) deduced in the previous section will be linearized about the thermodynamic equilibrium using the method discussed by Bowen [12], in order to express the equations in useable forms.

Let $\hat{\xi}$ denote the complete set of independent variables

$$\hat{\xi} = (\mathbf{F}_s, \mathbf{G}_s, (\mathbf{v}_f - \mathbf{v}_s)),$$

noting that there is no longer any dependence on temperature or temperature gradients. Let $\hat{\xi}^{0E}$ denote the subset of these variables,

$$\hat{\xi}^{0E} = (\mathbf{F}_s, \mathbf{G}_s, \mathbf{0}).$$

Let $\hat{\xi}^{0R}$ denote the reference state about which the constitutive equations for $\mathbf{f}$ and $\boldsymbol{\sigma}_s$ will be linearized,

$$\hat{\xi}^{0R} = (\mathbf{I}, \mathbf{0}, \mathbf{0}).$$

At the state $\hat{\xi}^{0E}$, where $\mathbf{v}_s = \mathbf{v}_f$, the quantity

$$-\mathbf{f}.(\mathbf{v}_f - \mathbf{v}_s) \geq 0$$

is a minimum, such that $\hat{\xi}^{0E}$ defines the thermodynamic equilibrium. Now in the vicinity of the thermodynamic equilibrium,

$$\phi_s \rho \mathbf{K}_s = \phi_s \zeta \mathbf{I} - \mathbf{F}_s \left(\frac{\partial \Psi_I}{\partial \mathbf{F}_s} \right)^T,$$

$$\phi_f \rho \mathbf{K}_f = \phi_f \zeta \mathbf{I},$$

and

$$\mathbf{f} = -\kappa(\mathbf{v}_s - \mathbf{v}_f),$$

where κ is a constant, sometimes referred to as the diffusive drag coefficient. Therefore,

$$\boldsymbol{\sigma}_s = \phi_s \rho \psi_s \mathbf{I} - \phi_s \zeta \mathbf{I} + \mathbf{F}_s \left(\frac{\partial \Psi_I}{\partial \mathbf{F}_s} \right)^T, \tag{7.1}$$

$$\boldsymbol{\sigma}_f = \phi_f \rho \psi_f \mathbf{I} - \phi_f \zeta \mathbf{I}, \tag{7.2}$$

and

$$\boldsymbol{\pi}_f = -\kappa(\mathbf{v}_s - \mathbf{v}_f) - \frac{1}{2}\Gamma_f(\mathbf{v}_s - \mathbf{v}_f) + \zeta \boldsymbol{\nabla} \phi_f - \mathbf{F}_s^{-1T} \left(\frac{\partial \Psi_f}{\partial \mathbf{F}_s}[\mathbf{G}_s] \right). \tag{7.3}$$

Now, appealing to the principle of phase separation,

$$\begin{aligned} \boldsymbol{\sigma}_s &= (\phi_s \rho \psi_s - \phi_s \zeta)\mathbf{I} + \rho \mathbf{F}_s \left(\frac{\partial (\phi_s \psi_s + \phi_f \psi_f)}{\partial \mathbf{F}_s} \right)^T \\ &= -\phi_s(\zeta - \rho \psi_s)\mathbf{I} + \rho \mathbf{F}_s \left(\frac{\partial \phi_s}{\partial \mathbf{F}_s}\psi_s + \phi_s \frac{\partial \psi_s}{\partial \mathbf{F}_s} - \frac{\partial \phi_s}{\partial \mathbf{F}_s}\psi_f \right)^T. \end{aligned}$$

Hence,

$$\boldsymbol{\sigma}_s = -\phi_s(\zeta - \rho\psi_s)\mathbf{I} + \phi_s\rho\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T + \rho(\psi_s - \psi_f)\mathbf{F}_s\left(\frac{\partial\phi_s}{\partial\mathbf{F}_s}\right)^T. \tag{7.4}$$

Similarly, for the momentum transfer terms, the principle of phase separation gives

$$\boldsymbol{\pi}_f = -\kappa(\mathbf{v}_f - \mathbf{v}_s) - \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s) + \zeta\boldsymbol{\nabla}\phi_f + \mathbf{F}_s^{-1T}\left(\rho\psi_f\left(\frac{\partial\phi_s}{\partial\mathbf{F}_s}\right)[\mathbf{G}_s]\right). \tag{7.5}$$

8. Modeling biological growth: Mass exchanges, solid deformation, and fluid flow. To reduce (7.4) to a usable form, an expression for $\frac{\partial\phi_s}{\partial\mathbf{F}_s}$ must be deduced from the balance of mass for the solid phase, which is given by

$$\frac{D^s}{Dt}(\rho\phi_s\mathrm{det}\mathbf{F}_s) = \Gamma_s\mathrm{det}\mathbf{F}_s. \tag{8.1}$$

Thus, in general

$$\rho\phi_s\mathrm{det}\mathbf{F}_s = \int_0^t \Gamma_s(\mathbf{X}_s,\tau)\mathrm{det}\mathbf{F}_s(\mathbf{X}_s,\tau)d\tau \triangleq \hat{\Theta}_s, \tag{8.2}$$

where

$$\hat{\Theta}_s = \hat{\Theta}_s(\mathbf{X}_s, t),$$

and $\mathbf{X}_s$ denotes the reference coordinates. Hence, using Jacobi's identity [42],

$$\frac{\partial(\mathrm{det}\mathbf{F}_s)}{\partial\mathbf{F}_s} = (\mathrm{det}\mathbf{F}_s)\mathbf{F}_s^{-1T},$$

the derivative of the solidity with respect to the solid deformation gradient is given by

$$\frac{\partial\phi_s}{\partial\mathbf{F}_s} = -\phi_s\mathbf{F}_s^{-1T} + \frac{1}{\rho\mathrm{det}\mathbf{F}_s}\frac{\partial\hat{\Theta}_s}{\partial\mathbf{F}_s}. \tag{8.3}$$

Therefore, (7.4) becomes

$$\boldsymbol{\sigma}_s = -\phi_s(\zeta - \rho\psi_s)\mathbf{I} + \phi_s\rho\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T - \phi_s\rho(\psi_s - \psi_f) + \frac{(\psi_s - \psi_f)}{\mathrm{det}\mathbf{F}_s}\mathbf{F}_s\left(\frac{\partial\hat{\Theta}_s}{\partial\mathbf{F}_s}\right)^T. \tag{8.4}$$

Thus the constitutive equations are

$$\boldsymbol{\sigma}_s = -\phi_s P\mathbf{I} + \phi_s\rho\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T + \frac{(\psi_s - \psi_f)}{\mathrm{det}\mathbf{F}_s}\mathbf{F}_s\left(\frac{\partial\hat{\Theta}_s}{\partial\mathbf{F}_s}\right)^T \tag{8.5}$$

and

$$\boldsymbol{\sigma}_f = -\phi_f P\mathbf{I}, \tag{8.6}$$

where

$$P = \zeta - \rho\psi_f. \tag{8.7}$$

In addition,

$$\frac{\partial\phi_s}{\partial\mathbf{X}_s} = \frac{\partial\phi_s}{\partial\mathbf{F}_s}\left[\frac{\partial\mathbf{F}_s}{\partial\mathbf{X}_s}\right] = \left(-\phi_s\mathbf{F}_s^{-1T} + \frac{1}{\rho\mathrm{det}\mathbf{F}_s}\frac{\partial\hat{\Theta}_s}{\partial\mathbf{F}_s}\right)[\mathbf{G}_s]. \tag{8.8}$$

Now

$$\boldsymbol{\nabla}\phi_s = \frac{\partial \phi_s}{\partial \mathbf{x}_s} = \mathbf{F}_s^{-1T}\frac{\partial \phi_s}{\partial \mathbf{X}_s}, \tag{8.9}$$

where $\mathbf{x}_s$ denotes spatial coordinates. Hence

$$\boldsymbol{\nabla}\phi_s = \mathbf{F}_s^{-1T}\left(\frac{\partial \phi_s}{\partial \mathbf{F}_s}\right)[\mathbf{G}_s] = \mathbf{F}_s^{-1T}\left(-\phi_s\mathbf{F}_s^{-1T} + \frac{1}{\rho \det\mathbf{F}_s}\frac{\partial \hat{\Theta}_s}{\partial \mathbf{F}_s}\right)[\mathbf{G}_s].$$

Thus, (7.5) for the momentum transfer term for the fluid phase, $\boldsymbol{\pi}_f$, now becomes

$$\begin{aligned}\boldsymbol{\pi}_f &= -\kappa(\mathbf{v}_f - \mathbf{v}_s) - \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s) + \zeta\boldsymbol{\nabla}\phi_f + \rho\psi_f\boldsymbol{\nabla}\phi_s \\ &= P\boldsymbol{\nabla}\phi_f - \kappa(\mathbf{v}_f - \mathbf{v}_s) - \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s).\end{aligned} \tag{8.10}$$

Noting the conservation of linear momentum,

$$\boldsymbol{\pi}_f + \Gamma_f\mathbf{v}_f + \boldsymbol{\pi}_s + \Gamma_s\mathbf{v}_s = \mathbf{0}$$

then gives the momentum transfer term for the solid phase, $\boldsymbol{\pi}_s$, being

$$\boldsymbol{\pi}_s = P\boldsymbol{\nabla}\phi_s + \kappa(\mathbf{v}_f - \mathbf{v}_s) - \frac{1}{2}\Gamma_f(\mathbf{v}_f - \mathbf{v}_s). \tag{8.11}$$

In a detailed analysis of Darcy's law for growing porous media, Preziosi and Farina [36] have shown that the process of interphase mass exchange plays a negligible role in momentum transfer. Thus, the final term in each of (8.10) and (8.11) may be neglected in practice.

Returning to the constitutive equation for the stress in the solid (8.5), note that the quantity $\hat{\Theta}_s$ depends on both the mass exchange term, Γ_s, and the solid phase deformation, $\mathbf{F}_s$. Clearly, then, manipulation of this equation into a useable form requires a phenomenological assumption about the functional form of the mass exchange term. Furthermore, the distinguishing feature of a mass-exchange model which describes biological growth, as opposed to, say, models which describe solidification/melting or some other phase change, is the fact that the mass-exchange term, Γ_s, and the expansion/contraction of the solid matrix, $\det\mathbf{F}_s$, *are not independent*. Indeed, such is the very essence of the unique closure problem peculiar to the study of biological growth, and it is a novel feature of the present work that such phenomenological aspects of growing tissues may be incorporated into the modeling framework.

Consider that the balance of mass for the solid phase may also be expressed in the form

$$\rho\frac{D^s\phi_s}{Dt} + \phi_s\rho\frac{1}{\det\mathbf{F}_s}\frac{D^s(\det\mathbf{F}_s)}{Dt} = \Gamma_s. \tag{8.12}$$

Note that

$$\rho\frac{D^s\phi_s}{Dt} = \frac{D^s}{Dt}\left(\frac{m_s}{V_m}\right),$$

where m_s is the mass of the solid phase in V_m, the volume of the mixture. Now

$$\frac{D^s}{Dt}\left(\frac{m_s}{V_m}\right) = \frac{D^s m_s}{Dt}\left(\frac{1}{V_m}\right) - \frac{\phi_s\rho}{V_m}\frac{D^s V_m}{Dt}.$$

Since

$$\frac{D^s m_s}{Dt}\left(\frac{1}{V_m}\right) = \Gamma_s,$$

the quantity

$$-\frac{\phi_s \rho}{V_m}\frac{D^s V_m}{Dt}$$

reflects the time rate of change of the solidity which results from the flow of fluid into, or out of, the deformed solid matrix. Now since

$$\Gamma_s = \underbrace{\frac{D^s}{Dt}\left(\frac{m_s}{V_m}\right)}_{total} - \underbrace{\left(-\frac{\phi_s \rho}{V_m}\frac{D^s V_m}{Dt}\right)}_{flow/deformation},$$

then

$$\underbrace{\frac{D^s(\phi_s \rho)}{Dt}}_{total} + \underbrace{\phi_s \rho \frac{1}{\det \mathbf{F}_s}\frac{D^s(\det \mathbf{F}_s)}{Dt}}_{flow/deformation} = \underbrace{\frac{D^s}{Dt}\left(\frac{m_s}{V_m}\right)}_{total} + \underbrace{\left(\frac{\phi_s \rho}{V_m}\frac{D^s V_m}{Dt}\right)}_{flow/deformation} = \Gamma_s$$

describes the mass balance for the solid phase.

Therefore, since the solidity is regulated by two separate processes—mass exchange and solid matrix deformation/fluid flow—a further constitutive postulate is required to relate any two of the three quantities ϕ_s, Γ_s, and $\det\mathbf{F}_s$ to decompose the balance of mass into two independent equations.

Suppose, for example, that the mass exchange and solid matrix deformation are related in such a way as to keep the volume fractions constant, reflecting a tissue which tends to exhibit a "natural" ratio of cells to extracellular fluid. (Note that this particular choice of constitutive postulate would be insufficient to model a growing tumor tissue which contains regions of coagulative necrosis, since these regions consist predominantly of fluid and cellular debris and are therefore characterized by significantly higher proportions of fluid than the rest of the tissue.) In this case, the balance of mass would be represented by

$$\rho \frac{D^s \phi_s}{Dt} = 0 \tag{8.13}$$

and

$$\rho\phi_s \frac{1}{\det\mathbf{F}_s}\frac{D^s(\det\mathbf{F}_s)}{Dt} = \rho\phi_s \boldsymbol{\nabla}\cdot\mathbf{v}_s = \Gamma_s. \tag{8.14}$$

Now that the constitutive postulate (8.14) has been proposed, the phenomenological assumption for Γ_s is no longer required to be a function of $\det\mathbf{F}_s$.

Assuming, for example, that Γ_s is proportional to the effective cell density, $\rho\phi_s$, and to some regulating factor such as nutrient concentration, c, implies that

$$\Gamma_s = \alpha\rho\phi_s c, \tag{8.15}$$

where α is a constant of proportionality and where the functional form for c will also be determined by a phenomenological assumption (appealing to a diffusion model, say).

Now (8.1) becomes

$$\frac{1}{\rho\phi_s \det\mathbf{F}_s}\frac{D^s}{Dt}(\rho\phi_s \det\mathbf{F}_s) = \alpha c,$$

so that

$$\rho\phi_s \det\mathbf{F}_s = e^{\int_0^t \alpha c(\mathbf{X}_s,\tau)d\tau},$$

which gives

$$\frac{\partial\phi_s}{\partial\mathbf{F}_s} = -\phi_s\mathbf{F}_s^{-1T}. \tag{8.16}$$

Now the constitutive equations reduce to

$$\boldsymbol{\sigma}_s = -\phi_s P\mathbf{I} + \phi_s\rho\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T \tag{8.17}$$

and

$$\boldsymbol{\sigma}_f = -\phi_f P\mathbf{I}, \tag{8.18}$$

with P being given by (8.7). Substitution of the new definition for $\frac{\partial\phi_s}{\partial\mathbf{F}_s}$ into (8.8) and (8.9) then produces (8.10) and (8.11), illustrating that the momentum equations are unaffected by the simplified definition for $\frac{\partial\phi_s}{\partial\mathbf{F}_s}$.

8.1. Linear elasticity. If the solid phase is assumed to be elastically isotropic, the Helmholtz free energy density is a function of the solid deformation gradient, $\mathbf{F}_s$, through the left Cauchy–Green strain tensor defined by $\mathbf{B}_s = \mathbf{F}_s\mathbf{F}_s^T$, so that

$$\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T = 2\mathbf{B}_s\frac{\partial\psi_s}{\partial\mathbf{B}_s}. \tag{8.19}$$

To formulate a linearized constitutive equation, an approximate expression is required for the right-hand side of (8.19) which is valid in the vicinity of the reference state $\hat{\xi}^{0R}$. Departures from $\hat{\xi}^{0R}$ may be measured by the quantity ϵ defined by

$$\epsilon^2 = tr\mathbf{H}_s\mathbf{H}_s^T + C\left(\mathbf{Grad}\mathbf{H_s}\otimes\mathbf{Grad}\mathbf{H_s}\right) + (\mathbf{v}_f - \mathbf{v}_s)\cdot(\mathbf{v}_f - \mathbf{v}_s),$$

where $\mathbf{H}_s = \mathbf{F}_s - \mathbf{I}$ is the displacement gradient of the solid phase. Thus, departure from the reference state, $\hat{\xi}^{0R}$, is *small* when $\epsilon < 1$.

Moreover,

$$\begin{aligned}\mathbf{B}_s &= \mathbf{I} + 2\mathbf{E}_s + \mathbf{H}_s\mathbf{H}_s^T\\ &= \mathbf{I} + 2\mathbf{E}_s + O(\epsilon^2),\end{aligned}$$

where $\mathbf{E}_s$ is the classical infinitesimal strain tensor defined by

$$\mathbf{E}_s = \frac{1}{2}\left(\mathbf{H}_s + \mathbf{H}_s^T\right). \tag{8.20}$$

Thus,

$$\mathbf{F}_s\left(\frac{\partial\psi_s}{\partial\mathbf{F}_s}\right)^T = \frac{\partial\psi_s}{\partial\mathbf{E}_s} + 2\mathbf{E}_s\left(\frac{\partial\psi_s}{\partial\mathbf{E}_s}(\hat{\xi}^{0R})\right) \tag{8.21}$$

in the linear theory. The Helmholtz free energy density for the solid phase, ψ_s, is now to be expanded into a polynomial about $\hat{\xi}^{0R}$, including terms up to second order since ψ_s must be differentiated to obtain the stress. Furthermore, since the Helmholtz free energy is, by definition, the energy available to do mechanical work, it is a function only of the component of the strain tensor associated with a stress response. Indeed, the strain tensor $\mathbf{E}_s$ may be decomposed into the contribution due to growth $\mathbf{E}_s^G$ and the contribution due to stress $\mathbf{E}_s^S$, i.e.,

$$\mathbf{E}_s = \mathbf{E}_s^G + \mathbf{E}_s^S.$$

Now,

$$\psi_s(\mathbf{B}_s) = \psi_s(\mathbf{I}) + \sigma_0\left(tr\mathbf{E}_s^S\right) + \frac{1}{2}\lambda_0\left(tr\mathbf{E}_s^S\right)^2 + \mu_0 tr\left(\mathbf{E}_s^S\mathbf{E}_s^S\right) + O(\epsilon^3). \tag{8.22}$$

Thus, substituting (8.22) into (8.21) yields

$$\boldsymbol{\sigma}_s = -\phi_s P\mathbf{I} + \lambda\left(tr\mathbf{E}_s^S\right)\mathbf{I} + 2\mu\mathbf{E}_s^S,$$

where

$$\lambda = \lambda(\rho_s, \phi_s) = \lambda_0$$

and

$$\mu = \mu(\rho_s, \phi_s) = \mu_0 + \sigma_0,$$

where σ_0, the so-called prestress, will be assumed zero. Now, the portion of the strain tensor due to growth may be expressed by

$$\mathbf{E}_s^G = g\boldsymbol{\Omega},$$

where g is the increase in volume per unit volume of the solid matrix due to growth (as yet unrelated to Γ_s), and

$$\boldsymbol{\Omega} \triangleq \begin{bmatrix} \gamma_1 & 0 & 0 \\ 0 & \gamma_2 & 0 \\ 0 & 0 & \gamma_3 \end{bmatrix} \tag{8.23}$$

defines the anisotropy tensor, where γ_1, γ_2, and γ_3 are the anisotropic growth multipliers defined by Araujo and McElwain [4, 3] with $\gamma_1 + \gamma_2 + \gamma_3 = 1$. Hence, isotropic growth corresponds to $\gamma_1 = \gamma_2 = \gamma_3 = \frac{1}{3}$. By allowing the tissue to grow anisotropically in response to the prevailing stress field, so that the expansion occurs preferentially in directions of least stress, the constitutive law is able to exhibit stress-relaxation in the absence of viscous dissipation. The mathematical theory of anisotropic growth has been developed by Araujo and McElwain [4, 3], while the phenomenon has been demonstrated experimentally by Helmlinger et al. [24]. Thus, in regularizing the elasticity by incorporating stress-relaxation into the growth component of the constitutive equation rather than in the stress-response component, anisotropic growth may be said to impart a *pseudo-viscoelasticity* to growing tissues. Appropriate functional forms for the anisotropic growth multipliers will be considered in the next paper in this series.

Now the constitutive equation for the solid phase becomes

$$\begin{aligned}\boldsymbol{\sigma}_s &= -\phi_s P\mathbf{I} + \lambda\left(tr\mathbf{E}_s - g\right)\mathbf{I} + 2\mu\left(\mathbf{E}_s - g\boldsymbol{\Omega}\right)\\ &= -\phi_s P\mathbf{I} + \lambda tr\mathbf{E}_s\mathbf{I} + 2\mu\mathbf{E}_s - g\left(3\lambda + 2\mu\right)\boldsymbol{\Omega}.\end{aligned} \tag{8.24}$$

Note that (8.24) was derived based on the two key assumptions of the intrinsic incompressibility of the phases and constant volume fractions, which together imply that $\lambda \to \infty$. While this may generally be introduced to the model by initially permitting compressibility and then allowing λ to tend to infinity in the *solution* of the boundary value problem, a more convenient approach in this case is to make the strain tensor the subject of the equation by noting that the trace of (8.24) is

$$tr\mathbf{E}_s = \frac{tr\boldsymbol{\sigma}_s + 3\phi_s P}{3\lambda + 2\mu} + g,$$

which gives

$$\mathbf{E}_s = \frac{1}{2\mu}\boldsymbol{\sigma}_s - \frac{\lambda}{2\mu(3\lambda + 2\mu)}(tr\boldsymbol{\sigma}_s + 3\phi_s P)\mathbf{I} + g\boldsymbol{\Omega}. \tag{8.25}$$

Now, in the limit as $\lambda \to \infty$, (8.25) becomes

$$\mathbf{E}_s = \frac{1}{2\mu}\boldsymbol{\sigma}_s - \left(\frac{tr\boldsymbol{\sigma}_s + 3\phi_s P}{6\mu}\right)\mathbf{I} + g\boldsymbol{\Omega}. \tag{8.26}$$

Note that while (8.26) represents a correct statement of the relationship between stress and strain when growth occurs, it must be able to reflect the fact that growth is a continuous process which creates movement. Thus, to accommodate the continuous expansion of the solid matrix due to the growth process, (8.25) must be differentiated with respect to time using an objective convected tensorial derivative such as the corotational (Jaumann) derivative (see, for example, [8] or [27]). Thus, (8.26) becomes

$$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \frac{1}{2\mu}\frac{\mathcal{D}\boldsymbol{\sigma}_s}{\mathcal{D}t} - \frac{1}{6\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(tr\boldsymbol{\sigma}_s + 3\phi_s P\right)\mathbf{I} + \frac{\mathcal{D}g}{\mathcal{D}t}\boldsymbol{\Omega},$$

where the notation $\frac{\mathcal{D}}{\mathcal{D}t}$ denotes an appropriate convected derivative. Taking the trace of this new equation now gives[1]

$$\frac{\mathcal{D}g}{\mathcal{D}t} = \boldsymbol{\nabla}\cdot\mathbf{v}_s + \frac{3\phi_s}{2\mu}\frac{\mathcal{D}P}{\mathcal{D}t},$$

which identifies the relationship between g and Γ_s via (8.14), being

$$\Gamma_s = \phi_s\rho\frac{\mathcal{D}g}{\mathcal{D}t} - \frac{3\phi_s^2\rho}{2\mu}\frac{\mathcal{D}P}{\mathcal{D}t}. \tag{8.27}$$

This enables the constitutive equation to be expressed in the form

$$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \frac{1}{2\mu}\frac{\mathcal{D}\boldsymbol{\sigma}_s}{\mathcal{D}t} - \frac{1}{6\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(tr\boldsymbol{\sigma}_s + 3\phi_s P\right)\mathbf{I} + \left(\boldsymbol{\nabla}\cdot\mathbf{v}_s + \frac{3\phi_s}{2\mu}\frac{\mathcal{D}P}{\mathcal{D}t}\right)\boldsymbol{\Omega}$$

[1]Strictly, the trace of the convected derivative of the infinitesimal strain tensor should be the divergence of the velocity vector with respect to the *reference* coordinates, i.e., $\mathbf{Div}(\mathbf{v_s})$ rather than $\boldsymbol{\nabla}\cdot\mathbf{v}_s$, based on the definition of the infinitesimal strain tensor given in (8.20). Nevertheless, if the strains required to ensure compatibility are small, as appropriate to the use of linearized constitutive equations, then $\mathbf{Div}(\mathbf{v_s})$ and $\boldsymbol{\nabla}\cdot\mathbf{v}_s$ may be used interchangeably here.

or

$$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \boldsymbol{\nabla}\cdot\mathbf{v}_s\boldsymbol{\Omega} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right) + \frac{\phi_s}{2\mu}\frac{\mathcal{D}P}{\mathcal{D}t}\left(3\boldsymbol{\Omega} - \mathbf{I}\right), \tag{8.28}$$

which reduces to

$$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \frac{1}{3}\boldsymbol{\nabla}\cdot\mathbf{v}_s\mathbf{I} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right) \tag{8.29}$$

in the special case of isotropic growth.

9. Summary of biphasic equations and comparison with single phase equations. Table 9.1 gives a summary of the suite of equations for the biphasic model of a growing tissue developed in this paper. Intriguingly, only the special case of isotropic growth gives rise to a solid phase constitutive equation identical to that used in single phase models, which consider growth as an analogy to thermal expansion. Nevertheless, it is essential to recognize that this combination of elasticity and isotropic growth does not incorporate the crucial aspect of stress-relaxation into the constitutive law. Indeed Lubkin and Jackson [29] explain that "the fatal mathematical combination of multiple phases, elasticity, and contractility renders the contractile-poroelastic model ill-posed.... The elasticity must then be regularized by a viscous term in order for solutions to exist." Araujo and McElwain [4] have shown that the elasticity may be regularized by considering *anisotropic* growth, thereby obviating the necessity to appeal to more complicated viscoelastic principles in many situations.

TABLE 9.1
Comparison of biphasic equations with single phase equivalents.

Equation type	Biphasic equations	Single phase equation
Balance of mass	$\phi_s\rho\boldsymbol{\nabla}\cdot\mathbf{v}_s = \Gamma_s$ $\rho\frac{D^s\phi_s}{Dt} = 0$ $\boldsymbol{\nabla}\cdot(\phi_s\mathbf{v}_s + \phi_f\mathbf{v}_f) = 0$	$\rho\boldsymbol{\nabla}\cdot\mathbf{v} = \Gamma$
Constitutive equations: Isotropic growth	$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \frac{1}{3}\boldsymbol{\nabla}\cdot\mathbf{v}_s\mathbf{I} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right)$ $\boldsymbol{\sigma}_f = -\phi_f P\mathbf{I}$	$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \frac{1}{3}\boldsymbol{\nabla}\cdot\mathbf{v}_s\mathbf{I} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right)$
Anisotropic growth	$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \boldsymbol{\nabla}\cdot\mathbf{v}_s\boldsymbol{\Omega} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right) + \frac{\phi_s}{2\mu}\frac{\mathcal{D}P}{\mathcal{D}t}\left(3\boldsymbol{\Omega} - \mathbf{I}\right)$ $\boldsymbol{\sigma}_f = -\phi_f P\mathbf{I}$	$\frac{\mathcal{D}\mathbf{E}_s}{\mathcal{D}t} = \boldsymbol{\nabla}\cdot\mathbf{v}_s\boldsymbol{\Omega} + \frac{1}{2\mu}\frac{\mathcal{D}}{\mathcal{D}t}\left(\boldsymbol{\sigma}_s + \frac{1}{3}tr\boldsymbol{\sigma}_s\right)$
Momentum equations[2]	$\boldsymbol{\nabla}\cdot\boldsymbol{\sigma}_s + \kappa(\mathbf{v}_f - \mathbf{v}_s) = 0$ $\phi_f\boldsymbol{\nabla}P = -\kappa(\mathbf{v}_f - \mathbf{v}_s)$	$\boldsymbol{\nabla}\cdot\boldsymbol{\sigma} = 0$

[2]Note that, in keeping with other published models of growing tissues [26, 36], inertial and body forces, as well as mass-exchange effects, are neglected in the momentum equations presented here.

10. Concluding remarks. In this paper, a theoretical framework for a solid-multiphase model of a growing tissue has been presented which extends the concepts of poroelasticity to accommodate continuous volumetric growth. Moreover, in incorporating a solid phase, the model provides a basis for the study of residual stresses, which is of fundamental importance in a wide range of studies in biology, physiology, and tissue engineering.

The general equations developed in sections 2 through 6 have been applied to a two-phase model of an elastic solid and an inviscid fluid in sections 7 through 9. The analysis points to a crucial phenomenological aspect of tissue growth, illustrating that such a process must consist of a coordinated combination of the "swelling" of the solid (cellular) phase due to the influx of extracellular fluid—which is, in essence, the inverse of the consolidation concept of poroelasticity—and the exchange of mass whereby extracellular fluid is incorporated into the cellular phase. This combination of processes necessitates the inclusion of an additional constitutive postulate—in which the mass-exchange term is related to the solid phase expansion—among the modeling equations to close the model.

In the present paper, a particular constitutive postulate has been chosen which reflects a tissue whose ratio of cells to extracellular fluid is constant throughout its volume. The assumption of linear-elasticity and *mechanical* isotropy (cf. isotropic *growth*) for the solid phase then enables simple constitutive equations between stress and strain to be specified for both the solid and fluid phases. Solutions to these biphasic equations will be presented in the next paper in this series.

This work may be extended in a number of ways. More complicated relationships between interphase mass exchange and solid phase expansion may be proposed, enabling the model to consider the formation of necrotic regions. Additionally, the equations could be rederived by incorporating a dependence of the Helmholtz free energy of the solid phase, Ψ_s, on both the solid deformation gradient, $\mathbf{F}_s$, and its convected derivative, $\overset{\nabla}{\mathbf{F}}_s$ (see sections 6 and 7 of the present paper) to produce a viscoelastic constitutive law (see, for example, Pioletti et al. [35]). This would enable the elasticity of the solid phase to be regularized in situations where anisotropic growth provides insufficient stress-relaxation [3].

Appendix. Development of the dissipation inequality. In this section, the second axiom of thermodynamics as expressed by (3.1) will be manipulated further to obtain a form from which constitutive equations may be deduced readily. Incorporating the balance of mass as expressed by (2.1) enables (3.1) to be expressed in the form

$$\sum_{i=1}^{n} \frac{1}{\theta}\left[\Gamma_i \eta_i \theta + \phi_i \rho_i \theta \frac{d^i \eta_i}{dt} + \theta \boldsymbol{\nabla}.\left(\frac{\mathbf{q}_i}{\theta}\right) - \phi_i \rho_i r_i\right] \geq 0. \tag{A.1}$$

Further, incorporating the energy equation (2.18) enables (A.1) to be expressed in a form which does not include the rate of heat production per unit mass within the ith constituent, r_i, explicitly, being

$$\sum_{i=1}^{n} \frac{1}{\theta}\left[\Gamma_i \eta_i \theta + \phi_i \rho_i \theta \frac{d^i \eta_i}{dt} + \theta \boldsymbol{\nabla}.\left(\frac{\mathbf{q}_i}{\theta}\right) - \phi_i \rho_i \frac{d^i u_i}{dt} + tr(\mathbf{L}_i \boldsymbol{\sigma}_i) - \boldsymbol{\nabla}.\mathbf{q}_i + \varepsilon_i\right] \geq 0.$$

Introducing the relation

$$\hat{\epsilon_i} \triangleq \varepsilon_i + \Gamma_i \left(u_i + \frac{1}{2}\mathbf{v}_i.\mathbf{v}_i\right) + \mathbf{v}_i.\pi_i$$

now enables the inequality to be expressed in the form

$$\sum_{i=1}^{n}\left[\phi_i\rho_i\left(\theta\frac{d^i\eta_i}{dt}-\frac{d^iu_i}{dt}\right)+tr(\mathbf{L}_i\boldsymbol{\sigma}_i)+\hat{\epsilon_i}-\Gamma_i\left(u_i+\frac{1}{2}\mathbf{v}_i.\mathbf{v}_i-\eta_i\theta\right)-\mathbf{v}_i.\pi_i\right]\geq 0.$$

The internal energies, u_i, will be eliminated at this point in favor of the Helmholtz free energy densities, ψ_i, where

$$\psi_i = u_i - \theta\eta_i. \tag{A.2}$$

Hence, the inequality becomes

$$-\sum_{i=1}^{n}\phi_i\rho_i\frac{d^i\psi_i}{dt}-\rho_m\eta_m\frac{d\theta}{dt}+tr\sum_{i=1}^{n}(\mathbf{L}_i\boldsymbol{\sigma}_i)-\sum_{i=1}^{n}\Gamma_i\left(\psi_i+\frac{1}{2}\mathbf{v}_i.\mathbf{v}_i\right)-\sum_{i=1}^{n}\mathbf{v}_i.\pi_i\geq 0.$$

At this stage, the chemical potential is introduced, being the linear transformation defined by

$$\mathbf{K}_i=\psi_i\mathbf{I}-\frac{\boldsymbol{\sigma}_i}{\phi_i\rho_i};$$

see Bowen and Wiese [14], noting that in the present paper it is assumed that $\boldsymbol{\sigma}_i=\boldsymbol{\sigma}_i^T$ (see section 2.3). Therefore,

$$\begin{aligned}-\sum_{i=1}^{n}\phi_i\rho_i\frac{d^i\psi_i}{dt}-\rho_m\eta_m\frac{d\theta}{dt}-tr\sum_{i=1}^{n}\phi_i\rho_i\mathbf{K}_i.\mathbf{L}_i+tr\sum_{i=1}^{n}\phi_i\rho_i\psi_i\mathbf{L}_i\\ -\sum_{i=1}^{n}\Gamma_i\psi_i-\sum_{i=1}^{n}\mathbf{v}_i.\left(\pi_i+\frac{\Gamma_i}{2}\mathbf{v}_i\right)\geq 0,\end{aligned}$$

which further reduces to

$$-tr\sum_{i=1}^{n}\phi_i\rho_i\mathbf{K}_i.\mathbf{L}_i-\rho_m\eta_m\frac{d\theta}{dt}-\sum_{i=1}^{n}\frac{d^i}{dt}(\phi_i\rho_i\psi_i)-\sum_{i=1}^{n}\mathbf{v}_i.\left(\pi_i+\frac{\Gamma_i}{2}\mathbf{v}_i\right)\geq 0 \tag{A.3}$$

by appealing to the balance of mass. Some authors (see, for example, Bowen [12]) define the quantity

$$\Psi_i=\phi_i\rho_i\psi_i$$

which represents the Helmholtz free energy of the ith constituent per unit mixture volume. Rewriting (A.3) in terms of Ψ_i gives

$$-tr\sum_{i=1}^{n}\phi_i\rho_i\mathbf{K}_i.\mathbf{L}_i-\rho_m\eta_m\frac{d\theta}{dt}-\sum_{i=1}^{n}\frac{d^i\Psi_i}{dt}-\sum_{i=1}^{n}\mathbf{v}_i.\left(\boldsymbol{\pi}_i+\frac{\Gamma_i}{2}\mathbf{v}_i\right)\geq 0. \tag{A.4}$$

Acknowledgments. The authors thank the referees for their helpful comments and constructive criticisms.

MODELING, DESIGN, AND OPTIMIZATION OF A SOLID STATE ELECTRON SPIN QUBIT*

R. E. CAFLISCH†, MARK F. GYURE‡, HANS D. ROBINSON§, AND ELI YABLONOVITCH†

Abstract. This paper describes a solid state system in which a qubit is realized as the spin of a single trapped electron in a quantum dot and read functionality is via an adjacent quantum wire with a single or a small number of conductive states. Because of the limited design window for this system, simulation is an important guide to an experimental search for successful designs. We use a semianalytic approximation that is accurate enough to provide meaningful results and computationally simple enough to allow high throughput, as needed for design and optimization. In particular, we find designs that achieve double pinchoff (i.e., a single trapped electron in the dot and a single conductive state in the wire). After relaxing the design requirements to allow for a small number of conductive states in the wire, we find successful designs that are optimally robust, in the sense that their success is unlikely to be affected by fabrication errors.

1. Introduction.

Quantum logic, based on manipulation and interaction of binary quantum states or "qubits," has great potential for communication and computation. Quantum communication could offer absolute security [14] and transmission rates beyond the Shannon limit [5]. Quantum computation could greatly accelerate the solution of certain important problems, such as prime factorization [15], database searching [6], and simulation of quantum systems [16]. This potential has motivated a large effort to develop and implement quantum logic. Currently, the foremost problem for quantum communication and computation is the implementation of qubits in a robust and scalable system, which will allow for error correction and control of decoherence. Solid state implementations of a qubit, based on an electron or nuclear spin confined to a quantum dot, have been proposed in [1, 8, 9, 10, 11, 12, 17, 18].

This paper is concerned with the design of a single qubit system in a solid state implementation, as proposed in [3, 17], in which a qubit is represented as the spin of a single electron confined in a quantum dot. A quantum wire is placed below the quantum dot, so that the conductivity of the wire will depend sensitively on the charge present in the dot. The wire can then be used to verify the presence of a single electron in the quantum dot and, in the presence of a spin polarized electron reservoir, to read out the spin of that electron. The latter can be accomplished in several ways, for instance, by measuring tunneling times from the reservoir into the qubit. As the spin singlet state has lower energy than the triplet states [4], we can arrange to make tunneling into a triplet state energetically forbidden, and since the singlet state must

be formed using two opposite spins, the tunneling time will then depend strongly on the relative alignment of the qubit spin to the reservoir spin.

In our design, the quantum dot and wire are formed in two vertically stratified, parallel semiconductor quantum wells and are defined electrostatically using lithographically patterned gates on the surface of the semiconductor. Further description of the geometry and electrostatics of this system are provided in section 2. An alternative design using a horizontal placement of quantum dots has been carried out in [18].

A successful qubit design requires a single electron in the quantum dot and a small number of conduction states in the quantum wire. If there is only a single state in the quantum wire, it can be used both as spin reservoir and charge sensor. Moreover, the design should be robust with respect to fluctuations or errors in modeling and fabrication. These are very stringent requirements that are difficult to satisfy, and numerical simulation can serve as an important guide in the experimental search for successful designs.

The principal goal of the present study is development of a semianalytic model and its application to design and optimization for this quantum system. This reduced order model is based on a number of approximations that restrict its validity. Comparison to full scale numerical simulations, however, indicate that its accuracy is sufficient to provide meaningful results. Computational speed is the model's great virtue, enabling the high throughput that is required for design and optimization of the quantum system.

There are three distinct aspects to simulation of this quantum system: construction of a mathematical model embodying the correct physics, development of an effective numerical method for solving the model, and use of the numerical method to search for a successful design. The semianalytic model and its use for design and optimization, as presented in this paper, address only the last of these. Related efforts, which are beyond the scope of this paper, include a full-scale numerical method for the Schrödinger–Poisson model [2] and simulations using nextnano^3 [13] that include more detailed physics.

Furthermore, design of this qubit system is an intermediate, but important step toward the much more challenging goal of constructing a quantum device. A functioning quantum device using this qubit system must satisfy additional requirements, such as preparation of initial data, coupling of qubits, measurement of the qubit state, control of decoherence, and error correction, that are not included in the present design problem.

In section 2 we develop a Schrödinger–Poisson model for simulation of the electrostatic potential and the single electron wavefunction, and we formulate design goals for performance of this system. A reduced order, semianalytic model is derived in section 3 using square well or parabolic approximations for the electrostatic potential. In section 4 the accuracy and validity of this semianalytic model is assessed by comparison to full scale numerical solution of the Schrödinger–Poisson model from [2]. Successful designs with double pinchoff are found in section 5 through a random search in parameter space. A measure of design robustness, in terms of the sensitivity of the design to fabrication errors, is formulated in section 6. In section 7, an analysis is presented that greatly simplifies the computation of design robustness. Using this simplified analysis, a search for designs that are optimally robust is described in section 8. Finally, conclusions are presented in section 9.

2. Qubit design problem. This sections describes the solid state system and the design goals for a qubit. This description includes one-, two-, and three-dimensional versions of the system.

2.1. Qubit system description. The layered semiconductor system consists of a series of material layers, with layer i consisting of material m_i and having thickness dz_i, in which z is a measure of the distance from the top planar surface, increasing in the downward direction. In addition there are δ-doped layers of zero thickness at the boundaries of some of the material layers, with a density σ_k of ions per area in the kth δ-doped layer. Note that the charge density σ is the doping density times an activation factor, so that it is less than the actual doping density. Volumetric doping, including intrinsic doping, is neglected.

As an example that will be used in this study and is pictured in Figure 1, consider a system that consists of the following layers, in order starting at $z = 0$:

- layer of material A of thickness dz_1;
- δ-doped layer with charge density σ_1;
- layer of material A of thickness dz_2;
- layer of material B of thickness dz_3, the layer containing the quantum dot;
- layer of material A of thickness dz_4;
- layer of material B of thickness dz_5, the layer containing the quantum wire;
- layer of material A of thickness dz_6;
- δ-doped layer with charge density σ_2;
- layer of material A of infinite thickness.

The geometry of these layers is one-dimensional; higher dimensionality is determined by the geometry of the gates. At the top of the material system, i.e., $z = 0$, there are a series of gates G_m on which the electron potential energy ϕ_m is specified. Away from the gates, the energy is taken to be equal to a constant free surface potential ϕ_0.

In this study the following gate geometries and potentials are considered:

- gate G_g consisting of a circle $r < R_g/2$ for the three-dimensional geometry or an interval $|x| < R_g/2$ for the two-dimensional geometry, on which the potential energy is ϕ_g;
- two gates $G_{b\pm}$, in which G_{b+} consists of points with $x > R_b/2$ and G_{b-} consists of points with $x < -R_b/2$ in both the two-dimensional and three-dimensional geometries, with potential ϕ_b on both gates;
- no gates for the one-dimensional geometry;
- potential energies $\phi_g = -V_g + \phi_{schottky}$ and $\phi_b = -V_b + \phi_{schottky}$, where $\phi_{schottky}$ is the Schottky barrier, and V_g and V_b are the voltages applied to the gates.

In this description all distances are measured in nm, the doping densities are measured in units of electrons cm^{-2}, and the energy ϕ is in units of eV.

A drawing of the device structure, with parameters from an optimally robust design as in (8.1), is shown in Figure 1. A schematic drawing of the gates, the potentials in the quantum wells, and the electron densities is shown in Figure 2. Positive potential energy (ϕ_b) on the planar side gates raises the potential on the sides of both quantum wells. Negative potential energy (ϕ_g) on the circular, central gates lowers the potential energy, primarily in the upper well. This leads to a localized electron density (i.e., a quantum dot) in the upper well and an electron density along a line (i.e., a quantum wire) in the lower quantum well.

The layer widths dz_i and the charge densities σ_i are determined during the material growth, and the gate sizes R_i are determined during the device fabrication. These parameters cannot be changed after fabrication. Thus the parameters can be divided into two sets: the vector of operation parameters $v_o = (\phi_g, \phi_b)$, which can be varied during operation of the device, and the vector of design parameters

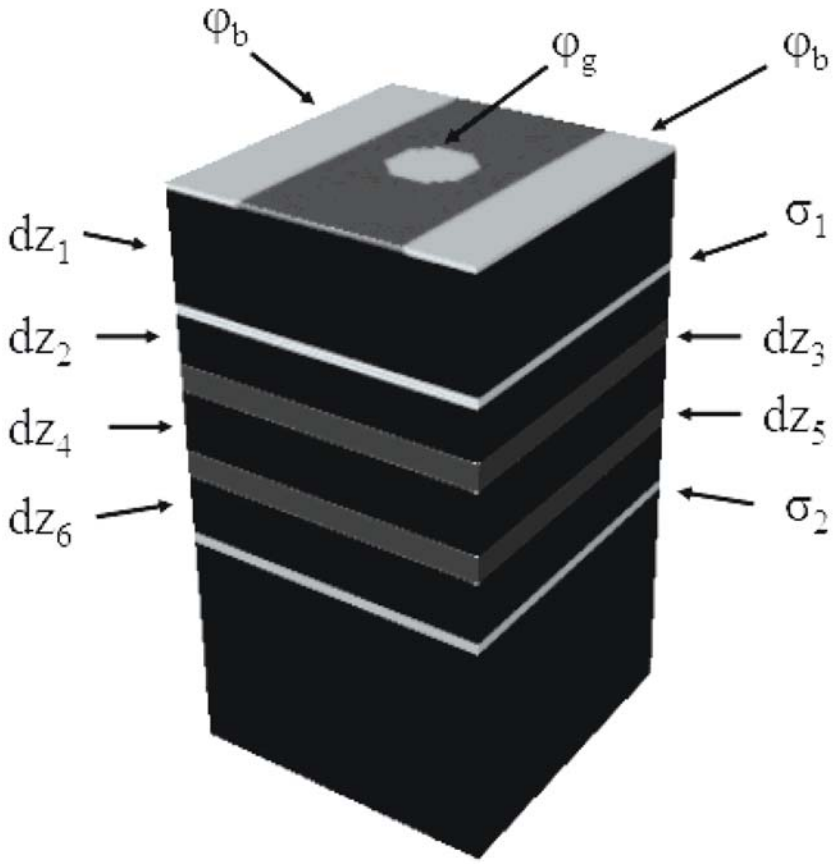

FIG. 1. *Schematic drawing of the device geometry. The depths of the material layers are dz_i, in which dz_3 is the depth of the upper quantum well, which contains the quantum dot, and dz_5 is the depth of the lower quantum well, which contains the quantum wire. The charge densities in the delta-doped layers are σ_i. The electrostatic potential of the central gate (a circle of diameter R_g in a three-dimensional geometry) is ϕ_g, and the electrostatic potential of the two side gates (separated by a distance R_b) is ϕ_b. In a two-dimensional geometry the central gate would be an infinite strip parallel to the side gates.*

$v_d = (dz_1, dz_2, dz_3, dz_4, dz_5, dz_6, R_g, R_b, \sigma_1, \sigma_2)$, which cannot be changed during operation. A device design can be identified with a choice of the design vector v_d. These are chosen from a subset C of R^{10} that has been determined from some external consideration, such as additional constraints or previous experience. These have the form

$$\underline{dz}_i < dz_i < \overline{dz}_i \quad \text{for} \quad 1 \le i \le 6, \tag{2.1}$$

$$\underline{R}_g < R_g < \overline{R}_g, \tag{2.2}$$

$$\underline{R}_b < R_b < \overline{R}_b, \tag{2.3}$$

$$\underline{\sigma}_i < \sigma_i < \overline{\sigma}_i \quad \text{for} \quad 1 \le i \le 2, \tag{2.4}$$

$$\underline{\phi}_g < -\phi_g < \overline{\phi}_g, \tag{2.5}$$

$$\underline{\phi}_b < \phi_b < \overline{\phi}_b. \tag{2.6}$$

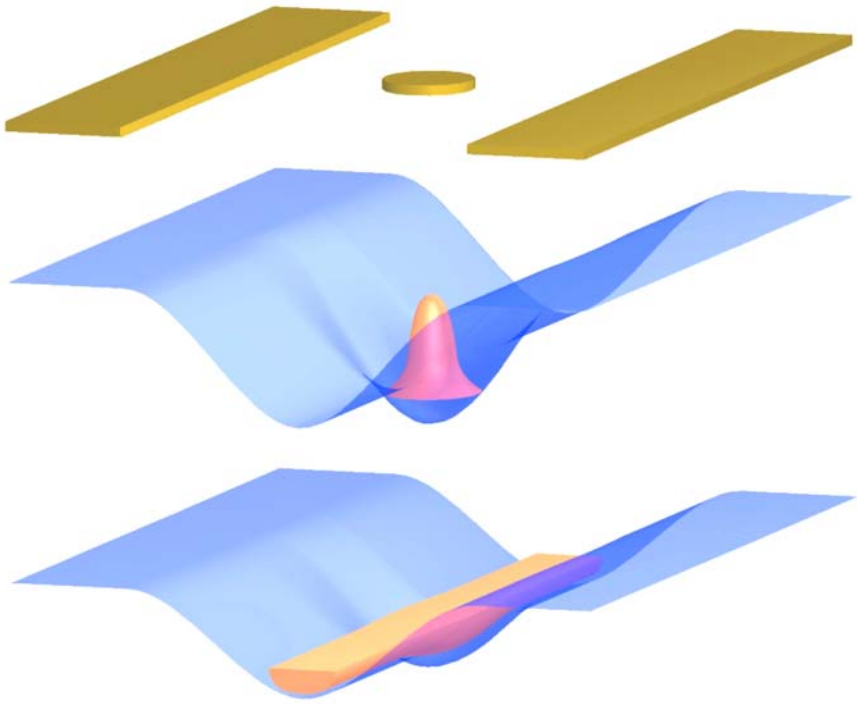

FIG. 2. *Schematic drawing of the gates, the potential energies in the quantum wells, and the electron densities in the dot and the wire.*

In the design searches conducted below, a typical set of constraints was the following:

$$
\begin{aligned}
20 &< dz_1 < 40(nm),\\
20 &< dz_2 < 40(nm),\\
5 &< dz_3 < 10(nm),\\
dz_4 &= 16(nm),\\
5 &< dz_5 < 15(nm),\\
dz_6 &= 50(nm),\\
50 &< R_g < 100(nm),\\
50 &< (R_b - R_g)/2 < 400(nm),\\
0 &< \sigma_1 < 4 \times 10^{11}(cm^{-2}),\\
0 &< \sigma_2 < 4 \times 10^{11}(cm^{-2}),\\
0.1 &< -\phi_g < 0.3(eV),\\
0 &< \phi_b < 2.0(eV).
\end{aligned}
\tag{2.7}
$$

The constraints on dz_4 were chosen to allow electrons to tunnel between dot and wire on a ms time scale; 16 nm is appropriate for the InP/InGaAs system. The lower bounds on R_g and R_b are representative of what can be easily accomplished with e-beam lithography. The upper bounds on σ_i are set to avoid hopping conduction through the doping layers. The upper bound on ϕ_b and the lower bound on ϕ_g are set

to avoid passing any current through the gates into the sample, which would disrupt the qubit. The lower bound on ϕ_g is set to ensure formation of a quantum dot with a bound electron state; at smaller voltages, the electron may not be bound, which the central gate, the parabolic approximation in section 3 may fail to predict. The remaining constraints are reasonable limits that were imposed to speed the design search.

2.2. Schrödinger–Poisson model. The electrostatic potential Φ is assumed to satisfy the Poisson equation

$$\nabla \cdot \epsilon \nabla \Phi = \sigma_1 \delta_1 + \sigma_2 \delta_2 - \rho_\psi \tag{2.8}$$

in which $\epsilon = k\epsilon_0/e^2$ is the scaled dielectric constant, δ_i is a δ-function on ith δ-doped interface, and ρ_ψ is the number density for electrons in the wire, which must be determined self-consistently as described below. The function Φ is the potential energy for an electron, measured in eV. For this equation the boundary conditions are taken to be Dirichlet conditions (i.e., Φ prescribed) at the top, Neumann conditions (i.e., $\partial\Phi/\partial n = 0$) at the bottom, and periodic conditions on the sides.

The electronic wave function for the unbound electron of lowest energy is assumed to satisfy a single particle Schrödinger equation

$$-\nabla \cdot \left(\frac{\hbar^2}{2m} \nabla \Psi \right) = -(\Phi + U)\Psi + \lambda \Psi \tag{2.9}$$

in which e is the electron charge, m is the electron effective mass, U is the conduction band offset relative to material A (InP in the examples below), λ is the energy level (eigenvalue) in units of eV, and Ψ is wave function (eigenfunction).

As an example, for InP, $In_xGa_{1-x}As$, and $Al_yIn_{1-y}As$, with alloy fractions $x = 0.53$ and $y = 0.48$, the material parameters are given in Table 1 and the relevant physical constants are given in Table 2.

TABLE 1
Material parameters.

Parameter	InP	$In_{0.53}Ga_{0.48}As$	$Al_{0.48}In_{0.52}As$	Units
k	12.61	13.9	12.7	1
$\epsilon = k\epsilon_0/e^2$	.697	.769	0.702	1/(eV nm)
m	.079	.041	0.0733	m_0
$\hbar^2/2m$	.484	.94	0.522	eV/nm^2
U	0	.224	0.25	eV

TABLE 2
Physical constants.

Constant	Value	Units
$\hbar^2/2m_0$	.0382	eV/nm^2
ϵ_0	8.854×10^{-12}	$C^2N^{-1}m^{-2}$
ϵ_0/e^2	.0553	1/(eV nm)

For the solutions of interest in this study, the electrons are localized either in a dot in the upper layer or along a wire in the lower layer. This implies that the eigenfunctions for the Schrödinger equation (2.9) are each localized in either the dot or the wire. The eigenvalues and eigenfunctions in the quantum dot are labeled

λ_k^d, Ψ_k^d; those in the wire are labeled λ_k^w, Ψ_k^w. Also denote $d\lambda = \lambda_2 - \lambda_1$ as the difference between the first two eigenvalues. The eigenfunctions are normalized so that $\int |\Psi|^2 dx = 1$. The self-consistent charge density is $\rho_\psi = \sum |\Psi|^2$, summed over all $\lambda < E_F$, in which the Fermi energy E_F is set to 0.

To emphasize the dependence of the eigenvalues λ on the gate voltages ϕ_g and ϕ_b and the design vector v, we shall sometimes write $\lambda = \lambda(\phi_g, \phi_b, v)$.

Note that the eigenfunctions for the quantum dot are quite distinct from those for the quantum wire. So computation of these eigenfunctions is equivalent to a computation using two separate wave functions for the dot and wire, and so it correctly represents the charge density in the wire and its affect on the dot. Interaction terms between the dot and wire are omitted, because they are small. On the other hand, tunneling effects between the dot and wire are important for detection of an electron in the dot using the wire. These tunneling effects are beyond the scope of the current model.

2.3. Design goals. The design goals for the quantum dot are to have a single confined electron under the gate and no confined electron states away from the gate. The design goals for the quantum wire are to have a small number k of conduction states in the wire, with no additional states in the wire under the gate. Denote E_k^d and E_k^w to be the energy for k electrons in the dot and for k conduction states in the wire, respectively. Also denote $E_k^d(0)$ and $E_k^w(0)$ to be the same energies but with no voltage on the central gate; i.e., $\phi_g = 0$. An unbound electron will be localized if its energy is less than the Fermi energy $E_F = 0$. The design goals can thus be stated as

$$E_1^d < 0 < E_2^d, \tag{2.10}$$

$$0 < E_1^d(0), \tag{2.11}$$

$$E_k^w < 0 < E_{k+1}^w, \tag{2.12}$$

$$E_k^w(0) < 0 < E_{k+1}^w(0). \tag{2.13}$$

Since $E_k^w < E_k^w(0)$, (2.12), and (2.13) can be recombined as

$$E_k^w(0) < 0 < E_{k+1}^w. \tag{2.14}$$

As shown below, the energy level E_2^d is smaller than $E_1^d(0)$ in the regime of interest, so that (2.11) is redundant.

In the quantum dot, the energy for a single electron is the lowest eigenvalue, so that $E_1^d = \lambda_1^d$ and $E_1^d(0) = \lambda_1^d(0)$. For the energy of two electrons, there is an interaction (Coulomb) correction $E_2^d = \lambda_2^d + \tilde{E}_2^d$. In the wire, we identify a conduction state, as an eigenfunction for the cross-section of the wire and neglect the interaction among different conduction states. Thus $E_k^w = \lambda_k^{w2D}$ and $E_k^w(0) = \lambda_k^{w2D}(0)$, in which λ_k^{w2D} and $\lambda_k^{w2D}(0)$ are the two-dimensional eigenvalues and $\phi_g = 0$ for $\lambda_k^{w2D}(0)$. Therefore the operation goals can be rewritten as

$$\lambda_1^d < 0 < \lambda_2^d + \tilde{E}_2^d, \tag{2.15}$$

$$\lambda_1^{w2D}(0) < 0 < \lambda_2^{w2D}. \tag{2.16}$$

The design goal is to find a device design v_d, for which there is a choice of operation parameters v_o such that the operation goals (2.15) and (2.16) are satisfied. A second design goal, that the operation goals are still met in the presence of growth and fabrication uncertainties, is formulated in section 6.

3. Semianalytic model. In this section we formulate a simplified semianalytic model that represents an approximate solution of the Schrödinger–Poisson equation. As described below, the potential Φ in each of the upper and lower quantum wells is approximated as a parabola in the lateral directions x and y and a square well in the depth direction z. Because the layered geometry is independent of x and y and the gates have a reflection symmetry with respect to both x and y, the first derivatives Φ_x and Φ_y are 0 on the centerline $x = y = 0$. Thus the lateral variation of the potential near the either quantum dot and quantum wire is approximately given by $\frac{1}{2}(x^2\Phi_{xx} + y^2\Phi_{yy})$.

3.1. Approximations for electrostatics. For the potential $\Phi = \Phi^{1D}$ due to modulationally doped layers but not including the effect of the gates, put the bottom boundary condition at ∞, omit any self-consistent terms, and neglect the variation in dielectric constant by using the value for material A throughout to obtain

$$\Phi^{1D} = \begin{cases} \phi_{top} - \epsilon_A^{-1}(\sigma_1 + \sigma_2)z, & 0 < z < z_1, \\ \phi_{top} - \epsilon_A^{-1}(\sigma_1 z - \sigma_2 z_1), & z_1 < z < z_2, \\ \phi_{top} - \epsilon_A^{-1}(\sigma_1 z_2 - \sigma_2 z_1), & z_2 < z, \end{cases} \tag{3.1}$$

in which $z_1 = dz_1$ and $z_2 = dz_1 + dz_2 + dz_3 + dz_4 + dz_5 + dz_6$ are the positions of the δ-doped layers.

The potential $\Phi = \Phi_L^{2D}$, due to a gate that is a strip (in three dimensions) (i.e., $|x| < L/2, z = 0$) with potential $\Phi = 1$ on the gate and $\Phi = 0$ away from gate, is

$$\Phi_L^{2D}(x,z) = \pi^{-1}\left(\arctan\left(\frac{x + L/2}{z}\right) - \arctan\left(\frac{x - L/2}{z}\right)\right). \tag{3.2}$$

On the central axis $x = 0$, the values of Φ and its second derivative are

$$\Phi_L^{2D}(x = 0, z) = 2\pi^{-1}\arctan(L/2z), \tag{3.3}$$

$$\Phi_{Lxx}^{2D}(x = 0, z) = -\pi^{-1}z^{-2}\frac{2L/z}{(1 + L^2/4z^2)^2}. \tag{3.4}$$

The potential $\Phi = \Phi_d^{3D}$, due to a gate that is a circle (i.e., $r = |(x,y)| < d/2$) with potential $\Phi = 1$ on the gate and $\Phi = 0$ away from gate, is

$$\begin{aligned} \Phi_d^{3D}(\mathbf{x}) &= \Phi(r,z) \\ &= \frac{|z|}{2\pi}\int_0^{2\pi}\int_0^{d/2} |\mathbf{x} - \mathbf{x}'|^{-3} r'\,dr'\,d\theta' \\ &= \frac{|z|}{2\pi}\int_0^{2\pi}\int_0^{d/2} (z^2 + (r - r'\cos\theta')^2 + r'^2\sin^2\theta')^{-3/2} r'\,dr'\,d\theta'. \end{aligned} \tag{3.5}$$

On the central axis $r = 0$, the values of Φ and its second derivative are

$$\Phi_d^{3D}(r = 0, z) = 1 - (1 + (d/2z)^2)^{-1/2}, \tag{3.6}$$

$$\Phi_{drr}^{3D}(r = 0, z) = -\frac{3}{2}|z|(d/2)^2(z^2 + (d/2)^2)^{-5/2}. \tag{3.7}$$

Add these together to obtain the total potential as

$$\Phi = \begin{cases} \Phi^{1D} + \phi_b(1 - \Phi_d^{2D}) + \phi_g\Phi_L^{2D} & \text{in two dimensions,} \\ \Phi^{1D} + \phi_b(1 - \Phi_d^{2D}) + \phi_g\Phi_L^{3D} & \text{in three dimensions.} \end{cases} \tag{3.8}$$

The second derivatives of the total potential on the central axis are

$$\Phi_{xx} = \begin{cases} -\phi_b \Phi^{2D}_{dxx} + \phi_g \Phi^{2D}_{Lxx} & \text{in two dimensions,} \\ -\phi_b \Phi^{2D}_{dxx} + \phi_g \Phi^{3D}_{Lrr} & \text{in three dimensions,} \end{cases} \tag{3.9}$$

$$\Phi_{yy} = \begin{cases} 0 & \text{in two dimensions,} \\ \phi_g \Phi^{3D}_{Lrr} & \text{in three dimensions.} \end{cases} \tag{3.10}$$

All the subsequent computations for the semianalytic model were performed using MATLAB programs.

3.2. Approximations for Schrödinger. The approximation for the Schrödinger eigenfunctions and eigenvalues relies on separation of variables: if m is constant and $\Phi(x, y, z) = \Phi^x(x) + \Phi^y(y) + \Phi^z(z)$, then

$$\lambda = \lambda^x + \lambda^y + \lambda^z, \tag{3.11}$$

$$\Psi(x, y, z) = \Psi^x(x)\Psi^y(y)\Psi^z(z) \tag{3.12}$$

in which

$$-(\hbar^2/2m)\Psi^x_{xx} = -\Phi^x\Psi^x + \lambda^x\Psi^x, \tag{3.13}$$

$$-(\hbar^2/2m)\Psi^y_{yy} = -\Phi^y\Psi^y + \lambda^y\Psi^y, \tag{3.14}$$

$$-(\hbar^2/2m)\Psi^z_{zz} = -\Phi^z\Psi^z + \lambda^z\Psi^z. \tag{3.15}$$

Use separation of variables to find eigenvalues in a channel of width w and center z. Neglect variation of Φ across the well and approximate the x-dependence for Φ^{2D} (i.e., for a gate that is a strip in three dimensions) or the (x, y)-dependence for Φ^{2D} (i.e., for a gate that is a circle in three dimensions) as parabolic with

$$\Phi^{2D} \approx \Phi^x_{2D}(x) \qquad = .5\Phi_{xx}(x = 0, z)\ x^2, \tag{3.16}$$

$$\Phi^{3D} \approx \Phi^x_{3D}(x) + \Phi^y_{3D}(y) = .5\Phi_{rr}(r = 0, z)(x^2 + y^2). \tag{3.17}$$

Both the two-dimensional and three-dimensional problems have been written as a sum of one-dimensional parabolic potentials. The eigenvalue and eigenvalue spacing for a one-dimensional parabolic potential $\Phi(x) = \phi_b x^2$ are

$$\lambda^p_1 = (\Phi_{xx}\hbar^2/4m)^{1/2}, \tag{3.18}$$

$$d\lambda^p = 2\lambda^p_1. \tag{3.19}$$

We denote λ^{px} and λ^{py} for the eigenvalues due to the parabolic potential in the x- and y-directions, respectively, and $d\lambda^{px}$ and $d\lambda^{py}$ for the corresponding eigenvalue spacing.

In the z-direction, the potential is approximately a square well, since

$$\Phi^z(z) = \begin{cases} 0 & |z - z_0| > L/2, \\ -U & |z - z_0| < L/2 \end{cases} \tag{3.20}$$

in which U is the offset in wells, neglecting variation across the well. The eigenvalues for this square well are solutions of

$$\lambda^{sw} = c_1 k_1^2 - U, \tag{3.21}$$

$$k_1^2(1 + (c_1/c_0)\tan^2(k_1 w/2)) = U/c_1 \tag{3.22}$$

in which c_0 and c_1 are the values of $\hbar^2/2m$ outside the well and in the well, respectively; i.e., c_0 is the value for material A (InP) and c_1 is the value for material B (InGaAs).

In summary, the eigenfunctions, lowest eigenvalue and eigenvalue spacing are

$$\Psi = \Psi^{sw}(z)\Psi^{px}(x)\Psi^{py}(y), \tag{3.23}$$

$$\lambda = \lambda^{sw} + \lambda^{px} + \lambda^{py}, \tag{3.24}$$

$$d\lambda = \begin{cases} d\lambda^{px} & \text{in two dimensions,} \\ \min(d\lambda^{px}, d\lambda^{py}) & \text{in three dimensions.} \end{cases} \tag{3.25}$$

In the simplest model, we also take the energy for two electrons to be the same as the second eigenvalue in the quantum dot; i.e., set $\tilde{E}_2^d = 0$ in (2.15).

3.3. Generalizations. Two generalizations of the semianalytic model of the previous section are formulated here to include effects of Coulomb interactions and self-consistent terms.

An approximation to the Coulomb correction $\tilde{E}_2^d$ for two electrons in the quantum dot has been developed by Gyure [7]. He computed the energy for two electrons in a one-dimensional parabolic potential using an iterative projection method, then fit the result to the following simple formula:

$$E_2^d = \lambda_1^d + c r_d \gamma_y^\kappa \tag{3.26}$$

in which $r_d = 0.00289\ eV$ is the Rydberg energy, $\gamma_y = \lambda_1^d$, and the (dimensionless) fitting parameters are $c = 3.5213$ and $\kappa = 0.75654$. The one-dimensional approximation was justified by two-dimensional calculations that showed the anisotropy of the potential is large enough in most cases to ignore the smaller dimension. The error induced is relatively small and decreases rapidly with anisotropy ratio.

The most significant self-consistent terms are the effect of the charge in the wire on the potential in the dot. For a wire defined by a parabolic potential of width a_x and a square well of depth a_z, approximate the charge in the wire as being uniformly distributed over an ellipse with a_x and a_z as the principal axes. Define elliptic coordinates (u, v) in the (x, z) plane as

$$x = b\cosh(u)\cos(v), \tag{3.27}$$

$$z = b\sinh(u)\sin(v) \tag{3.28}$$

in which $b = \sqrt{a_x^2 - a_z^2}$, so that the ellipse corresponds to $u = u_e = \cosh^{-1}(a_x/b)$. As an approximation to the potential for an elliptical charge, use

$$\tilde{\Phi} = \begin{cases} \alpha u - \gamma & \text{for } u > u_e, \\ \beta(a_x x^2 + a_z z^2) - \kappa & \text{for } u < u_e. \end{cases} \tag{3.29}$$

In the limit $u \to \infty$, $u \approx \log(r/c)$, which implies that $\alpha = \bar{\rho}/2\pi$ in which $\bar{\rho}$ is the total charge on the ellipse. At the top of the layered material, the correction $\tilde{\Phi}$ should vanish. Apply this at the value $u_0 = u(z = 0, x = 0)$ to get $\gamma = u_0\bar{\rho}/2\pi$. The total charge in the wire $\bar{\rho}$ is approximately given by

$$\bar{\rho} = \pi^{-1}\sqrt{d\lambda^w/c}((2/3)N^{3/2} + N) \tag{3.30}$$

in which $c = \frac{\hbar^2}{2m}$ and $N = -\lambda_1^w/d\lambda^w$ is the number of transverse eigenvalues that are less than the Fermi energy. Formula (3.30) comes from the number of longitudinal states below the Fermi energy for each transverse state. The potential corrections in (3.29) are used to correct the eigenvalue λ_1^w and eigenvalue spacing $d\lambda^w$, which are then used in (3.30). These two equations are solved iteratively to determine $\bar{\rho}$.

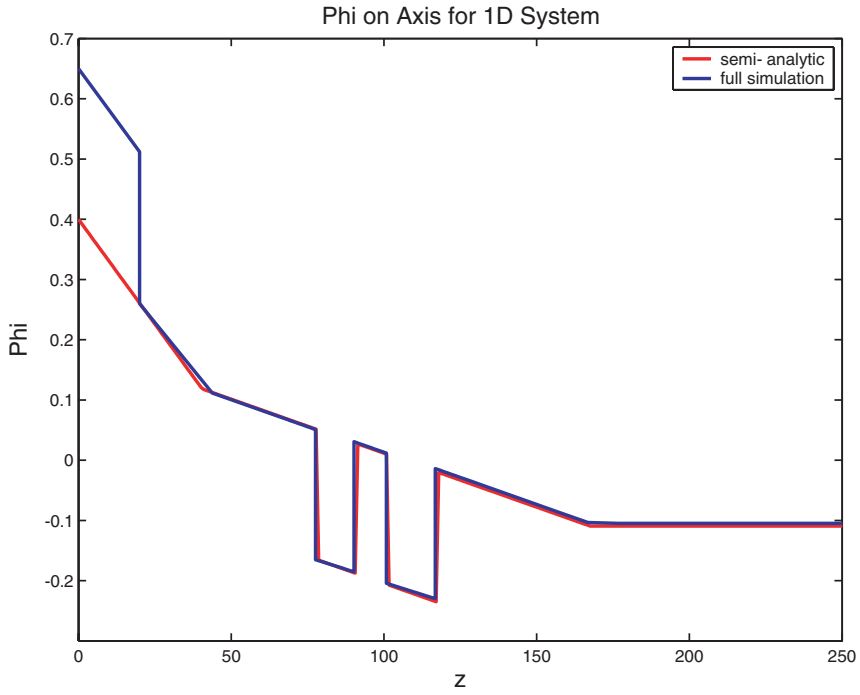

FIG. 3. *Comparison of potential* Φ *for a one-dimensional geometry from the full scale simulation method (blue) and the semianalytic model (red), with no top gates, no Coulomb interactions, self-consistent effects omitted, and no background doping, showing excellent agreement. Disagreement at the top is due to use of a different material layer in the full-scale simulation that does not influence the potential outside that layer and was not included in the semianalytic model.*

4. Validation of semianalytic model. Validation of the semianalytic model is performed by comparison to a full-scale numerical solution of the Schrödinger–Poisson equations by Anderson [2]. Consider a system with design parameters

$$\begin{aligned} v_d &= (dz_1, dz_2, dz_3, dz_4, dz_5, dz_6, R_g, R_b, \sigma_1, \sigma_2) \\ &= (40.5, 37.1, 12.6, 10.6, 16, 50.7, 61, 219.5, 3.6 \times 10^{11}, 1.25 \times 10^{11}) \end{aligned} \tag{4.1}$$

and with operation parameters $v_o = (\phi_g, \phi_b) = (0, 0.53)$. Figures 3, 4, and 5 show the potential on the central line (through the center of the quantum dot) in one, two, and three dimensions, respectively, with no Coulomb interactions, self-consistent effects omitted, and no background doping. In one dimension there are no gates on the top of the system, so that the potential Φ is a function of z only. In two dimensions the central gate is an interval (i.e., a strip in three dimensions); while in three dimensions the central gate is a circular dot. Figure 6 is the same as Figure 4, except that self-consistent effects are included in both the full-scale numerical computation and the semianalytic model. The first eigenvalue is shown for each of these problems in Table 3, in meV.

These results show excellent agreement for the case with no Coulomb interactions and no self-consistent effects. In this case the energy errors in the semianalytic method are all within 6 meV of those for the full simulation. With self-consistent effects, the agreement is still good, with energy errors of size 20 meV.

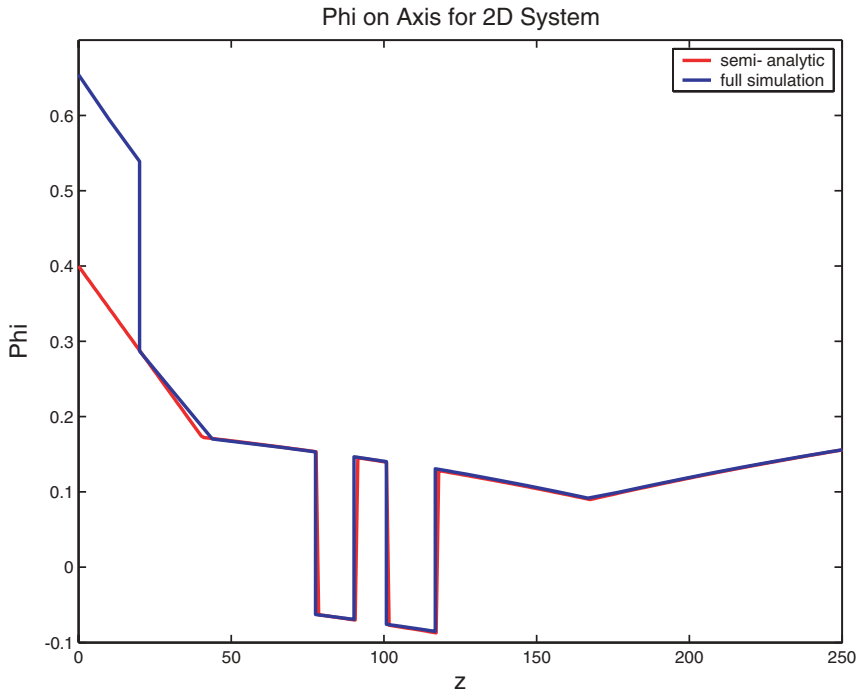

FIG. 4. *Same as Figure* 3 *except that the plot is for the potential* Φ *on the central axis* $x = 0$ *for a two-dimensional geometry.*

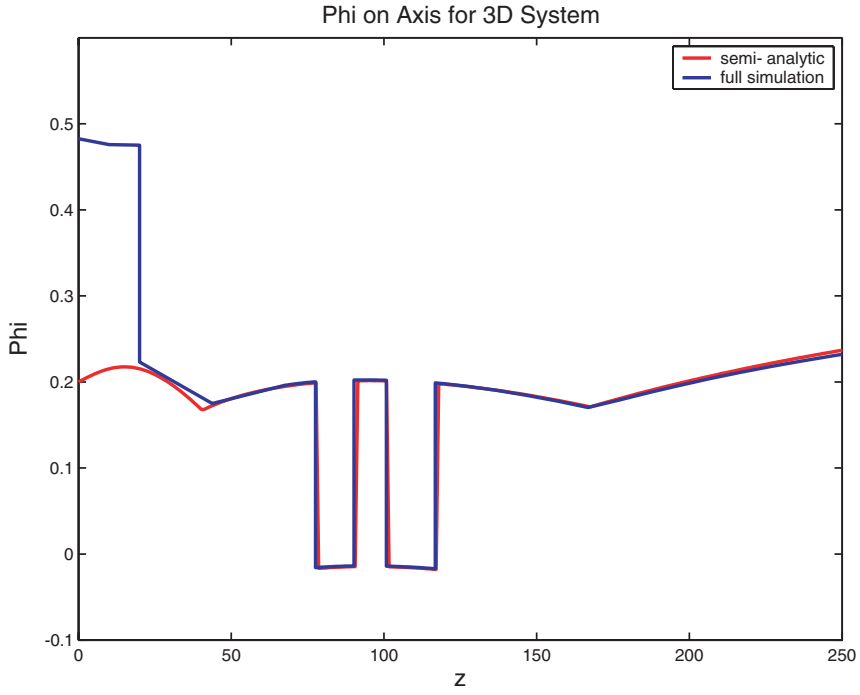

FIG. 5. *Same as Figure* 3 *except that the plot is for the potential* Φ *on the central axis* $r = 0$ *for a three-dimensional geometry.*

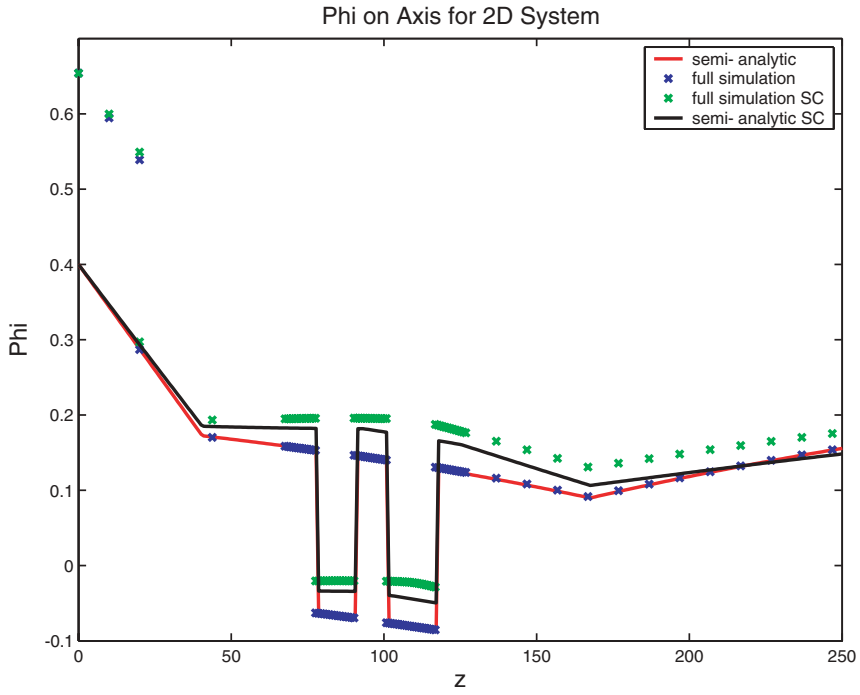

FIG. 6. *Same as Figure 4 but showing the full-scale simulation method with (green) and without (blue) self-consistent terms and the semianalytic model with (black) and without (red) self-consistent terms.*

TABLE 3
Lowest eigenvalues λ_1.

	Dot energies (meV)		Wire energies (meV)	
	simulation	semianalytic	simulation	semianalytic
1D	−144.1	−148.3	−195.9	−201.1
2D	−33.8	−37.3	−58.8	−60.8
3D	22.5	16.6	9.88	7.1
2D SC	11.6	−4.7	−3.7	−23.3

5. Double pinchoff designs. The principal virtue of the semianalytic model is that the eigenvalues in the design criteria (2.15) and (2.16) can be quickly computed, enabling rapid throughput as required for a design study or optimization exercise. In this section we describe a design that achieves the strictest design criterion (2.15) and (2.16) with $k = 1$, i.e., double pinchoff with a single electron in the dot and a single conductive state in the wire.

An example of a system achieving double pinchoff has design parameters

$$v_d = (dz_1, dz_2, dz_3, dz_4, dz_5, dz_6, R_g, R_b, \sigma_1, \sigma_2) \tag{5.1}$$
$$= (40, 94.3, 22.5, 30.3, 17.7, 50, 53.7, 876.7, 3.4 \times 10^{11}, 1.4 \times 10^{11})$$

and operation parameters $v_o = (\phi_g, \phi_b) = (-0.16, 1.47)$. The eigenvalues for this design are $(\lambda_1^d, \lambda_2^d, \lambda_1^w(0), \lambda_2^w) = (-0.67, 2.2, -0.92, 0.27)\ meV$. This system was found by a random search over the full space of possible design parameters and operation

parameters. In a search involving 10 million trial designs, 7 successful designs were found. This establishes existence (within the simulation) of a design meeting the double pinchoff goal. In section 7, however, we show that these double pinchoff designs are not robust with respect to fabrication errors.

6. Design robustness. When a prescribed design is implemented, the outcome will differ from the prescription due to errors and uncertainties in growth and fabrication, including variability in the layer thicknesses and gate sizes and variability in charge density in delta-doped layers due to uncertainties in both the doping level and the ionization fraction. Additional modeling uncertainties, such as uncertainties in the correct boundary conditions at the top of the device and additional physics such as self-consistent terms, are not accounted for in this analysis.

To find a design whose success is insensitive to the growth and fabrication uncertainties, we formulate a measure of design robustness. Assume that the errors in each of the various design parameters are independent and normally distributed and define α_k to be the standard deviation of the kth design parameter. Define a distance function d between two design vectors v and w as

$$d(v,w) = \left(\sum_{k=1}^{K} ((v_k - w_k)/\alpha_k)^2 \right)^{1/2}, \tag{6.1}$$

i.e., $d(v,w)$ is a measure of the distance between v and w in standard deviations. Next fix a design criterion by choosing the number K of allowed conduction states in the wire, and define the robustness R of a successful design v_s as the distance to the nearest unsuccessful design v_u, i.e.,

$$R(v_s) = \min_{v_u} d(v_s, v_u). \tag{6.2}$$

The design robustness optimization problem is to find the most robust design within the constraint set C from (2.1)–(2.6), i.e., v_s is chosen to be the successful design that achieves the following max-min:

$$\max_{v_s \in C} R(v_s) = \max_{v_s \in C} \min_{v_u \in C} d(v_s, v_u). \tag{6.3}$$

As an example for standard deviation of the fabrication, we take standard deviation of the growth processes (layer thicknesses) to be 3% (relative error), the standard deviation of the fabrication (gate sizes) to be 10 nm (absolute error), and the standard deviation of the charge density in the delta-doped layers to be 40% (relative error).

7. Analysis of failure modes. A direct random search for the design v_s that achieves the max-min in (6.3) would involve a double random search over two designs v_s and v_u. This can be considerably improved by analysis of the failure modes, i.e., the closest failed designs v_u for a given successful design v_s. This analysis relies on a linear approximation for the dependence of the eigenvalues λ in the design criteria (2.15) and (2.16), as functions of the gate voltages ϕ_g and ϕ_b.

A successful design v_s is one for which the four design inequalities in (2.15) and (2.16) form a quadrilateral (or triangular) set that has a nonempty intersection with the rectangular constraint set defined by (2.5) and (2.6), in the operation space (ϕ_g, ϕ_b). As the design parameter vector v is (smoothly) varied, the sides of the quadrilateral (or triangle) will (smoothly) vary. The first unsuccessful design v_u

is reached when the intersection becomes just a point. This characterizes the design v_u that occurs in (6.3).

The intersection of the operation window (i.e., the quadrilateral or triangle defined by (2.15) and (2.16)) and the constraint set (defined by (2.5) and (2.6)) can shrink to a point in either of two ways: First, the operation window can shrink to a point in the interior of the constraint set. Second, the operation window can move outside the constraint set with one vertex on the boundary of the constraint set.

We draw the operation window with coordinates $(-\phi_g, \phi_b)$, so that both coordinates are positive. Denote the boundaries of the operation window as follows:

$$a = \{(-\phi_g, \phi_b) : \lambda_1^d(\phi_g, \phi_b) = 0\}, \tag{7.1}$$

$$b = \{(-\phi_g, \phi_b) : \lambda_2^d(\phi_g, \phi_b) = 0\}, \tag{7.2}$$

$$c = \{(0, \phi_b) : \lambda_1^w(0, \phi_b) = 0\}, \tag{7.3}$$

$$d = \{(-\phi_g, \phi_b) : \lambda_2^w(\phi_g, \phi_b) = 0\}. \tag{7.4}$$

Also denote ac to be the point of intersection of the lines a and c if it exists, with coordinates $\phi_g(ac)$ and $\phi_b(ac)$, and similarly for the other intersections. Also denote $0a$ to be the intersection of a with the line $\phi_g = 0$. They have the following properties:

1. c is a horizontal line.
2. a, b, and d are lines with positive slope, with a and b steeper than d.
3. a and b cannot intersect (for $-\phi_g > 0$) and a is to the left of b.
4. $-\phi_g(ac) < -\phi_g(bc)$.
5. The operation window is nonempty if and only if $-\phi_g(ac) < -\phi_g(cd)$.
6. ad is the leftmost and the lowest point of the operation window.

From these properties, it follows that a nonempty operation window can have two possible configurations. If $-\phi_g(bc) < -\phi_g(cd)$, it is a quadrilateral with vertices ad, bd, bc, and ac, which is denoted as Type I. If $-\phi_g(bc) > -\phi_g(cd)$, a nonempty operation window is a triangle with vertices ad, cd, and ac, which is denoted as Type II. These two possibilities are shown in Figure 7.

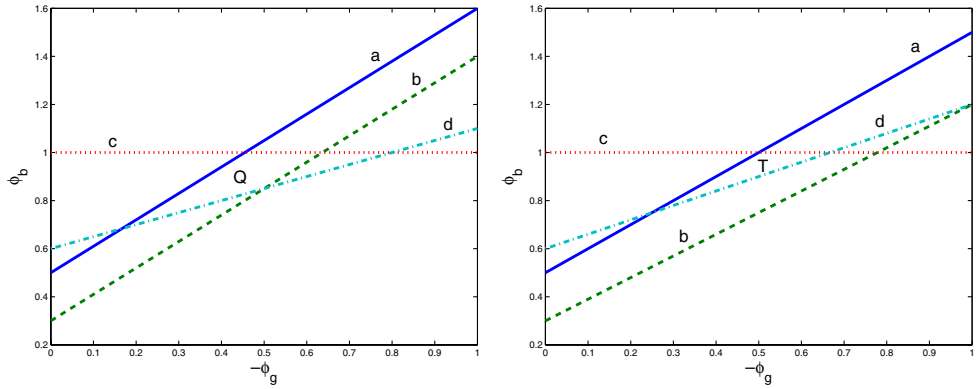

FIG. 7. *A schematic drawing of the operation windows in $(-\phi_g, \phi_b)$. The four lines that define the operation window are a, b, c, and d. The successful operation vectors are those in quadrilateral region labeled Q for the configuration on the left or in the triangular region labeled T for the configuration on the right.*

This information allows characterization of the failure modes:

A Collapse of the operation window can occur only as a transition from Type II, in which the three vertices of the triangle meet as one point acd. Failure mode A is characterized by existence of a triple intersection point acd, which is denoted as point A.

B If the operation window leaves the constraint region through the upper boundary, $\phi_b = \overline{\phi}_b$, then the final point of intersection of the two regions is ad. Failure mode B is characterized by existence of a triple intersection point ad with $\phi_b = \overline{\phi}_b$, which is denoted as point B.

C If the operation window leaves the constraint region through the right boundary, $-\phi_g = \overline{\phi}_g$, then the final point of intersection of the two regions is ad. Failure mode C is characterized by existence of a triple intersection point ad with $-\phi_g = \overline{\phi}_g$, which is denoted as point C.

D If the operation window leaves the constraint region through the lower boundary, denoted as failure mode D, then line c coincides with the lower constraint $\phi_b = \underline{\phi}_b$.

E If the operation window leaves the constraint region through the left boundary, $-\phi_g = \underline{\phi}_g$, then the final point of intersection of the two regions is bc in Type I or cd in Type II. Failure mode E is characterized by existence of a triple intersection point bc or cd with $-\phi_g = \underline{\phi}_g$, which is denoted as point E.

The three failure points A, B, and C, which are the ones that most frequently occur, are illustrated in Figure 8

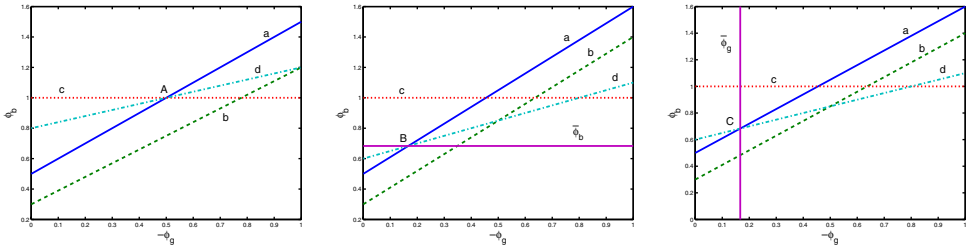

FIG. 8. *A schematic drawing of the failure modes in $(-\phi_g, \phi_b)$, including the four lines a, b, c, and d that define the operation window, and the constraining lines $\phi_b = \bar{\phi}_b$ in the middle and $-\phi_g = \bar{\phi}_g$ in the right. In mode A (left), the operation window has collapsed to a point A in the interior of the constraint set. In mode B (middle), the operation window intersects the constraint set in only a single point B on the upper boundary. In mode C (right), the operation window intersects the constraint set in only a single point C on the right boundary.*

The distance from a successful design v_s to one of the failure points A, B or C can be estimated through a linear approximation. For point A, let $(\Phi_g^A(v), \Phi_b^A(v))$ solve

$$\lambda_1^d(\Phi_g^A(v), \Phi_b^A(v), v) = 0, \tag{7.5}$$

$$\lambda_1^w(0, \Phi_b^A(v), v) = 0. \tag{7.6}$$

Then to leading order, since $\lambda_2^w(\Phi_g^A(A), \Phi_b^A(A), A) = 0$,

$$\begin{aligned} \lambda_2^w(\Phi_g^A(v), \Phi_b^A(v), v) &= \lambda_2^w(\Phi_g^A(v), \Phi_b^A(v), v) - \lambda_2^w(\Phi_g^A(A), \Phi_b^A(A), A) \\ &= (v - A) \cdot \nabla_v \lambda_2^w(\Phi_g^A(v), \Phi_b^A(v), v). \end{aligned} \tag{7.7}$$

At a minimum point, the design difference $v - A$ is parallel to the gradient in (7.7), so that

$$\min |v - A| = |\lambda_2^w(\Phi_g^A(v), \Phi_b^A(v), v)|/|\nabla_v \lambda_2^w(\Phi_g^A(v), \Phi_b^A(v), v)|. \tag{7.8}$$

A similar analysis can be carried out for B and C. For B, $\Phi_b^B(v) = \overline{\phi}_b$ and let $\Phi_g^B(v)$ solve

$$\lambda_1^d(\Phi_g^B(v), \overline{\phi}_b, v) = 0. \tag{7.9}$$

Then to leading order, since $\lambda_2^w(\Phi_g^B(B), \overline{\phi}_b, B) = 0$, it follows that

$$\min |v - B| = |\lambda_2^w(\Phi_g^B(v), \overline{\phi}_b, v)|/|\nabla_v \lambda_2^w(\Phi_g^B(v), \overline{\phi}_b, v)|. \tag{7.10}$$

For C, $\Phi_g^C(v) = \overline{\phi}_g$ and let $\Phi_b^C(v)$ solve

$$\lambda_1^d(\overline{\phi}_g, \Phi_g^C(v), v) = 0. \tag{7.11}$$

Then to leading order, since $\lambda_2^w(\overline{\phi}_g, \Phi_g^C(C), C) = 0$, it follows that

$$\min |v - C| = |\lambda_2^w(\overline{\phi}_g, \Phi_g^C(v), v)|/|\nabla_v \lambda_2^w(\overline{\phi}_g, \Phi_g^C(v), v)|. \tag{7.12}$$

The robustness R and the design robustness optimization problem can now be rephrased as

$$R(v_s) = \min\{|v - A|,\ |v - B|,\ |v - C|\}, \tag{7.13}$$

$$\max_{v_s \in C} R(v_s) = \max_{v_s \in C} \min\{|v - A|,\ |v - B|,\ |v - C|\} \tag{7.14}$$

in which $|v - A|$, $|v - B|$, and $|v - C|$ are defined by (7.8), (7.10), and (7.12). This has the advantage over the formulation (6.3) that it requires only a single random search for successful designs v_s rather than a double random search for v_s and v_d. For each v_s, the min is found by evaluation of the three quantities $|v - A|$, $|v - B|$ and $|v - C|$ from (7.8), (7.10), and (7.12).

For the design v_{dp} that achieved double pinchoff, as described in section 5, the design robustness distance (from (7.13)) is $R(v_{dp}) = 0.3$, which corresponds to probability of about 0.2 of successful design. The search for a more robust design through maximization of $R(v_s)$ as in (7.14) is described in section 8.

8. Design optimization. The search for a maximally robust design v_s in (7.14) can be accelerated by decomposition and some analysis. First select values for the geometrical design parameters $v' = (dz_1, dz_2, dz_3, dz_4, dz_5, dz_6, R_g, R_b)$.

For a given choice of geometrical parameters v', the possible values of the δ-doping densities σ_1 and σ_2 can be determined using the linear dependence of the eigenvalues λ_1^d and λ_1^w on σ_1 and σ_2, as well as on ϕ_g and ϕ_b. The operation window can be characterized as having the point ac inside the constraint set. The two equations (7.1) and (7.3) defining ac can be used to define a mapping between the operation vector $(\phi_g,\ \phi_b)$ and the density vector $(\sigma_1,\ \sigma_2)$. Then the constraint set defined by (2.5) and (2.6) can be mapped to a constraint set in the space of density vectors, which may need to be cut off to accommodate the constraints (2.4). To simplify, we choose a value of $(\phi_g,\ \phi_b)$ that is approximately in the center of the resulting polygon. This is illustrated in Figure 9.

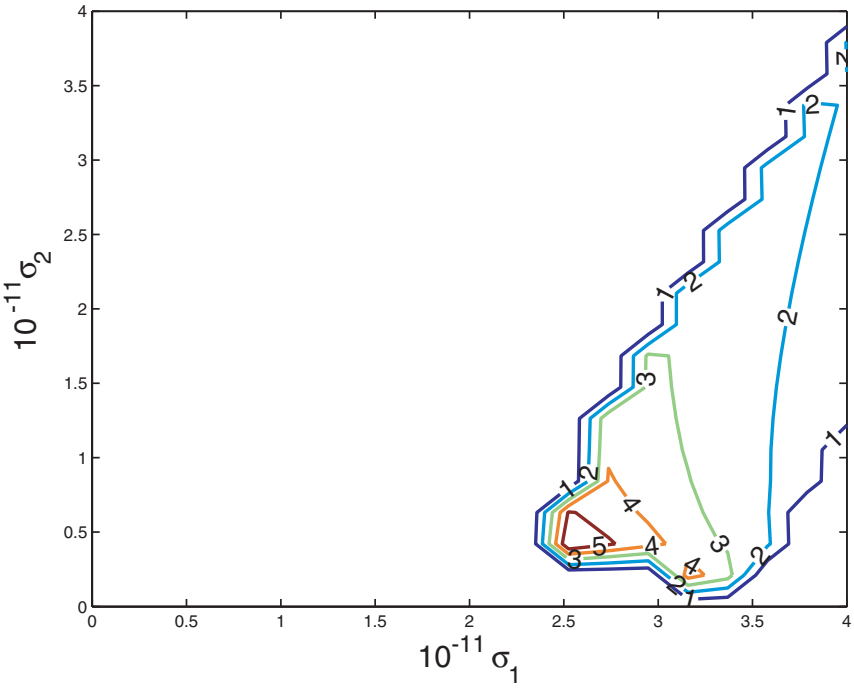

FIG. 9. *Design window in the space of doping densities* (σ_1, σ_2) *for one of the optimally robust designs.*

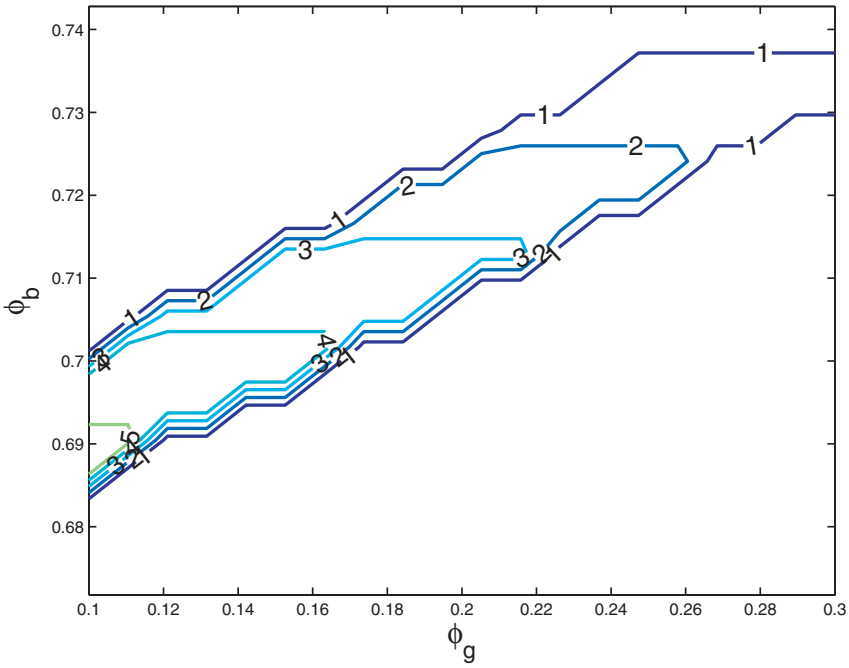

FIG. 10. *Design window in the space of operation vectors* $(-\phi_g, \phi_b)$ *for one of the optimally robust designs.*

Following this procedure for $K = 7$, we have found designs with robustness values of 2.5 or more. A typical result is

$$(8.1)\quad v = (dz_1, dz_2, dz_3, dz_4, dz_5, dz_6, R_g, R_b, \sigma_1, \sigma_2)$$
$$= (47.25, 49.31, 8.24, 16, 23.62, 50, 50.38, 608.28, 3.78 \times 10^{11}, 2.45 \times 10^{11}).$$

The operation vector is $(\phi_g, \phi_b) = (0.24, 1.91)$. The eigenvalues for this design are $(\lambda_1^d, \lambda_2^d, \lambda_1^w(0), d\lambda^w) = (-0.559, 3.60, -33.0, 4.0)$. There are seven transverse states in the wire and the robustness is 2.8, which corresponds to more than 99% probability of a successful design. The resulting operation window is shown in Figure 10.

9. Conclusions. In this work, we have developed a mathematical model for an electron spin qubit system, for the successful design of the system, and for optimization of the design robustness. In addition, we have developed a simple semianalytic model that is both sufficiently accurate to provide relevant results for the system and sufficiently fast to allow for the high throughput required by design and optimization studies. After some analysis to simplify the computation of design robustness, we have performed a random search for designs that satisfy the design criteria and for designs that are maximally robust.

From this search, we have found system designs that achieve double pinchoff, in the sense that they have a single electron in the quantum dot and a single conduction state in the quantum wire. These designs are not sufficiently robust to be practical, having a design robustness of only about 0.3, in terms of standard deviation using a current assessment of design uncertainties. By relaxing the design criterion to allow for a small number (e.g., $K = 7$) of conduction states in the wire, we have found designs that are more than 2.8 standard deviations from an unsuccessful design. Currently these designs are being built and tested for their electronic properties.

Several conclusions can be drawn from the present study. First is the importance of models at different levels of complexity. A full-scale model, as in [2], is needed to give reliable values for the system properties and to provide validation for simpler models. Simpler models that are less computationally intensive are also needed, however, to enable design and optimization studies on a reasonable time scale. In addition, we have been using nextnano^3 [13], a computational physics software package, which includes a much wider set of physics in order to check and validate the results from full-scale numerical solver for the Schrödinger–Poisson equation [2]. Second is the importance of analysis as a method for accelerating the random search that is often required in a design and optimization study. In the present study, the search for an optimally robust design was greatly aided by analysis of the failure modes for a design (i.e., the closest unsuccessful designs to a given successful design) and elimination of the charge variables using their special (linear) occurrence in the model.

THE EFFECT OF DISPERSAL PATTERNS ON STREAM POPULATIONS*

FRITHJOF LUTSCHER†, ELIZAVETA PACHEPSKY‡, AND MARK A. LEWIS§

Abstract. Individuals in streams are constantly subject to predominantly unidirectional flow. The question of how these populations can persist in upper stream reaches is known as the "drift paradox." We employ a general mechanistic movement-model framework and derive dispersal kernels for this situation. We derive thin- as well as fat-tailed kernels. We then introduce population dynamics and analyze the resulting integrodifferential equation. In particular, we study how the critical domain size and the invasion speed depend on the velocity of the stream flow. We give exact conditions under which a population can persist in a finite domain in the presence of stream flow, as well as conditions under which a population can spread against the direction of the flow. We find a critical stream velocity above which a population cannot persist in an arbitrarily large domain. At exactly the same stream velocity, the invasion speed against the flow becomes zero; for larger velocities, the population retreats with the flow.

Key words. nonlocal dispersal, critical domain size, spread speed, drift paradox

1. Introduction.

Many organisms, ranging from river-dwelling flora and fauna to gut-dwelling bacteria, live in environments with predominantly unidirectional flow. As with simple chemostat residents [35], organisms that persist in the presence of such unidirectional flow must resist being washed out by their moving surroundings. The success of many organisms in maintaining a foothold, even at high flow rates, has given rise to the so-called drift paradox of persistence in unidirectional flow [27, 28].

While possible solutions of the drift paradox have been discussed in the ecological literature [27, 28, 41, 22], until recently the discussion has lacked quantitative scrutiny in the form of models that can be used to predict the effect of environmental variables on maintaining the population. Two recent papers have begun to remedy this lack and have analyzed conditions for species persistence and population spread into upstream environments, both analytically and numerically. The models used there are PDE systems, such as a single compartment model with growth, advection, and diffusion [36], or a two-compartment model with separate mobile and stationary states corresponding to aquatic and benthic populations [32].

Flows in river systems are very complex and include, for example, up- and downriver currents as well as turbulent long-distance movement of biota [1]. Although systems of PDEs are the workhorse for spatial ecology models in continuous space [15],

their application is limited as they depict the complex asymmetrical spatial flow in a river through simple advection and diffusion.

Integrodifferential equations [16] are related to PDEs but encompass more general movement patterns than diffusion and advection. In particular, the modeling formalism can allow for a detailed description of the complicated dispersal that arises through river flow. The added realism of integrodifferential models comes at a price: much of the theory for PDEs on problems such as critical domain size for species persistence [34] or population spread [18] has not yet been formulated for their integrodifferential cousins, but see [26] for invasion speeds. We develop some of the theory needed for analysis in this paper.

In this paper we revisit the drift paradox, employing integrodifferential models that allow us to include long-distance dispersal. We show how the long-distance dispersal changes previous washout predictions [32, 36]: populations can always persist under high flow rates providing rare, long-distance dispersal events are sufficient to allow maintenance of a foothold in the river. Our results contrast with those of Lockwood, Hastings, and Botsford [24], where long-distance dispersal is discounted as playing a role in determining population persistence. While our model and application are new, we draw on theoretical ideas that have a distinguished history in the theory of spatial ecology.

The critical domain size is a fundamental ecological quantity that gives the minimal size of a habitable area required for species survival. In turn, it provides an important tool in reserve design and conservation [6, 8]. The first models for the critical domain size using diffusion equations date back to the 1950s [34, 17]. The analysis has since been extended to cover more complex spatial domains [9], the influence of advection [29, 32], and discrete-time integrodifference equations [20, 40, 25].

Another relevant ecological metric is the speed of spread, which is important in a wide range of ecological applications. While some invasions are intended, such as the introduction of biological control agents [4], others can be devastating for native species being out-competed by invaders and for species diversity. The spread of diseases is a worldwide problem and can be treated in the same modeling framework [26].

While the idea of having stationary and mobile compartments has recently been used by numerous authors, for example, to model protein movement in a cell nucleus [10], population dynamics with diffusive movement [23, 13], or wavelike movement [14], the idea of coupling such models to asymmetric spatial flow dynamics via advection and diffusion, as in [32], is a recent one (but see [5]).

We start our investigation by presenting a general framework to derive dispersal kernels from mechanistic movement models, and we apply this framework to derive a thin-tailed and a fat-tailed kernel. In section 3 we present the general integrodifferential model and develop the theoretical results on critical domain size and invasion speeds. The following three sections contain the application of the general theory to persistence and spread in streams. Three cases for dispersal kernels are considered: thin-tailed (section 4), a weighted sum of thin-tailed kernels, accounting for short- and long-distance dispersal (section 5), and, finally, fat-tailed (section 6).

2. Modeling dispersal. In this section, we use a mechanistic approach for individual movement to derive theoretical forms of dispersal kernels. A *dispersal kernel* describes the probability that an individual moves from one location to another in a certain time interval. Such dispersal kernels, also referred to as redistribution kernels or seed shadows, have been measured for many organisms [30]. The mechanistic approach taken here allows for explicit description of the movement process and be-

havior. We assume that population dynamics happen on a much slower time scale than individual movement and hence can be neglected while deriving the kernel. This separation of time scales occurs frequently, and it is certainly true for stream insects, where dispersal can occur over daily time scales, while significant growth typically requires monthly or yearly time scales. The general theory presented here follows, but significantly extends, the results in [30] and is applied to derive a thin-tailed and a fat-tailed dispersal kernel as specific examples for analysis and further development later in the paper.

We denote $\omega(t, x; y)$ as the probability density of the location of a mobile individual with initial location $x = y$. We assume that the individual moves for a random length of time, T, after which it settles, and that the random variable T has a given probability density $p(t)$. The dispersal kernel is now defined as the probability density of stopping points from given initial location, i.e.,

$$\kappa(x, y) = \int_0^\infty p(t)\omega(t, x; y)dt. \tag{2.1}$$

If $\omega(t, x; y)$ depends only on the signed distance from the starting point $\xi = x-y$ rather than the exact location, we simply write $w(t, \xi) = \omega(t, x; y)$ and $k(\xi) = \kappa(x, y)$. Most dispersal kernels in this paper are of this form. For an exception, see Appendix E. When the individual moves by Brownian motion with diffusion coefficient D, the function $w(t, x)$ is the fundamental solution of the heat equation on the real line,

$$w(t, x) = \frac{\exp\left(\frac{-x^2}{4Dt}\right)}{\sqrt{4\pi Dt}}. \tag{2.2}$$

When drift at rate v is included with the Brownian motion, the function $w(x, t)$ is given by (2.2) with x replaced by $x - vt$.

However, if dispersing individuals can jump long distances in short time intervals, the Brownian motion model may not be valid. For example, the Lévy flight model [11] assumes that arbitrarily large jumps can occur over short time scales. The result is a distribution of jump distances which has no variance. In this "anomalous diffusion" case, a typical form for w is the Cauchy distribution

$$w(t, x) = \frac{t}{\rho\pi}\left[\left(\frac{x}{\rho}\right)^2 + t^2\right]^{-1}. \tag{2.3}$$

The parameter ρ has dimension [space/time] and stands for an effective speed. Details of how (2.3) can be derived from a random walk model for individuals are given in Appendix A. As above, we introduce drift at rate v by replacing x with $x - vt$.

We now turn to modeling the stopping time T. The simplest possible assumption is that all individuals disperse for the same, fixed, length of time t_0. In this case

$$p(t) = \delta(t - t_0), \tag{2.4}$$

so that (2.1) yields $k(x) = w(x, t_0)$. Thus, for a fixed dispersal time t_0, the dispersal kernel (2.1) is simply the Gaussian (2.2), possibly shifted if $v \neq 0$, or the Cauchy distribution (2.3), again possibly shifted if $v \neq 0$, evaluated at time t_0. In Figure 2.1, we plot the shapes of these kernels.

A more general form of stopping times comes from defining $\alpha(t)$ as the *settling* or *failure rate* [37], i.e., $\alpha(t)\,dt$ as the probability that the individual ends its movement

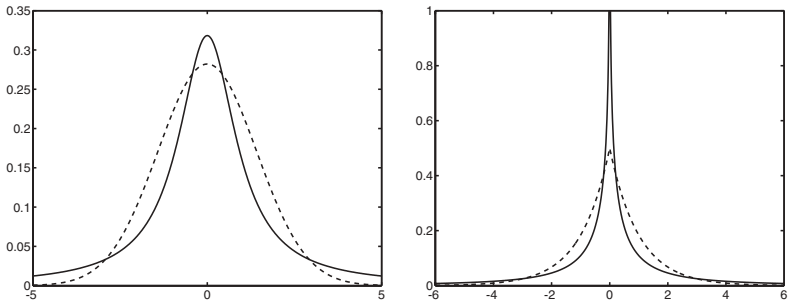

FIG. 2.1. *The plot on the left shows the thin-tailed Gaussian (dashed) and fat-tailed Cauchy (solid) distribution as given in* (2.2) *and* (2.3) *for* $t_0 = 1$ *with parameters* $D = 1$ *and* $\rho = 1$*, respectively. The plot on the right shows the Laplace distribution* (2.6) *(dashed) and the fat-tailed distribution* (2.7) *(solid). Parameters are as above and the settling rate is* $\alpha = 1$*. Note that the fat-tailed distribution has a singularity at the origin.*

during $[t, t + dt)$. The probability density for the stopping times of the individual, also called the lifetime probability density, is then

$$p(t) = \alpha(t) \exp\left(-\int_0^t \alpha(s)\, ds\right). \tag{2.5}$$

The argument of the exponential function is known as the *hazard function* [37].

For constant settling rate α, the dispersal kernel (2.1) is the Laplace transform of the probability density ω with respect to time. In the case of Brownian motion (2.2), the kernel (2.1) becomes the Laplace distribution [7],

$$k(\xi) = \sqrt{\frac{\alpha}{4D}} \exp\left(-\sqrt{\frac{\alpha}{D}}|\xi|\right). \tag{2.6}$$

For constant settling rate α and the Cauchy redistribution function (2.3), the kernel (2.1) becomes the fat-tailed kernel

$$\begin{aligned} k(\xi) &= \theta\, \Re\left\{E_1(i\theta\xi) \exp(i\theta\xi)\right\}/\pi \\ &= -\theta\left(\cos(\theta\xi)\,\mathrm{ci}(\theta\xi) + \sin(\theta\xi)\,\mathrm{si}(\theta\xi)\right)/\pi, \end{aligned} \tag{2.7}$$

where $\theta = \alpha/\rho$. The functions E_1, ci, and si are the exponential, cosine, and sine integrals, respectively,

$$\mathrm{E}_1(x) = \int_1^\infty \frac{\exp(xz)}{z}\, dz,\ \mathrm{ci}(x) = -\int_1^\infty \frac{\cos(xz)}{z}\, dz,\ \mathrm{si}(x) = -\int_1^\infty \frac{\sin(xz)}{z}\, dz. \tag{2.8}$$

The kernels given by (2.6) and (2.7) are plotted in Figure 2.1.

Adding drift into the last two scenarios does *not* simply shift the kernels (2.6) and (2.7) as it did above but instead causes a different kind of asymmetry in dispersal, as we show later. In section 4.1, we employ a somewhat simpler method to derive the kernel for Brownian motion with drift. The case of Lévy flight with drift is done in section 6.

In Appendix B we generalize the simple model of Brownian motion to the case of two (and potentially more) dispersal modes. Individuals switch between these modes. We show that corresponding dispersal kernels can be derived explicitly for constant settling rate.

3. The model equation, critical domain size, and spread speed. In this section, we present the general model for a population subject to population dynamics and spatial movement. It has the form of an integrodifferential equation, for which we give alternative derivations. We then state the main assumptions and prove formulas for the critical domain size and the spread speed of the population.

We consider a single population, which is described by its density $u(t,x)$. Population dynamics such as birth and death of individuals are summarized in the function $f(u)$. Then the dispersal time scale is small compared to the population dynamics time scale; dispersal can be modeled by a position-jump process with jumping rate μ [31]. If an individual jumps, the dispersal kernel $\kappa(x,y)$, as discussed in section 2, describes the probability that the individual moves from some point y to x. Then the evolution of the population density is governed by the following integrodifferential equation:

$$u_t(t,x) = f(u(t,x)) - \mu u(t,x) + \mu \int_\Omega \kappa(x,y)u(t,y)dy. \tag{3.1}$$

The domain of integration Ω will depend on the question we study. In the case of the critical domain size, it will be a bounded interval; in the case of invasion speeds, it will be the real line. Although the model formulation is valid in spatial domains of any dimension, we will restrict ourselves to the one-dimensional case since the applications below will be to systems with unidirectional flow. We assume that the function f is a single-hump function, i.e., $f(0) = f(\bar{u}) = 0$, and $f > 0$ on $(0,\bar{u})$. To prove Theorem 3.2, we will need more assumptions on f and k, which we state then.

There are several ways to derive (3.1). We present a novel approach emphasizing the separation of time scales. Then we present the necessary theoretical results about the critical domain size and invasion speeds.

3.1. Model derivations. Besides the derivation in [31], (3.1) is derived in the ecological literature from a random walk process with variable move length [39]. Reaction and movement are assumed to be on the same time scale [12]. Recently, a very careful derivation of (3.1) has been presented where some scaling issues have been avoided [16].

Here, we present an alternative derivation that respects and even relies on the fact that movement often happens on a much faster time scale than population dynamics. We start by dividing the population into mobile and stationary classes, u and v, respectively, and assume that birth and death processes affect only stationary individuals. Stationary individuals start moving with rate μ, and mobile individuals settle with rate σ. Then we obtain the system

$$u_t = f(u) - \mu u + \sigma v, \qquad v_t = G[v] + \mu u - \sigma v, \tag{3.2}$$

where G is a differential operator describing movement, e.g., $G = D\Delta$ (diffusion) or $G = D\Delta - V\nabla$ (advection and diffusion). Recently, there has been increasing interest in this or similar systems [5, 10, 13, 23, 32]. To apply the quasi steady-state assumption that movement happens on a much faster time scale than population dynamics, we introduce the scaling parameter $\varepsilon = \mu/\sigma$ and rescale v and G in (3.2) to obtain

$$u_t = f(u) - \mu u + \mu\tilde{v}, \qquad \varepsilon\tilde{v}_t = \tilde{G}[\tilde{v}] + \mu u - \mu\tilde{v}, \tag{3.3}$$

where $\tilde{}$ denotes the rescaled quantities. Under the quasi steady-state assumption

$\varepsilon \to 0$, the equation for $\tilde{v}$ gives the linear differential operator

$$\mu u = \left(\mu - \tilde{G}\right) \tilde{v}. \tag{3.4}$$

System (3.2) becomes (3.1), with $\kappa(x, y)$ denoting the Green's function of (3.4), i.e.,

$$\tilde{v}(x) = \int \kappa(x, y) u(y) dy. \tag{3.5}$$

3.2. Critical domain size. As a first step in the analysis of (3.1), we now study the critical domain size problem. We find that parameter space can be divided into two parts, one that allows persistence independently of domain size and dispersal kernel, and one in which persistence depends on these two factors. We assume that there is no immigration into the domain. A population will persist if it grows at low density; therefore, we study conditions such that the zero steady state is unstable. The linearization of (3.1) on the interval $[0, L]$ is given by

$$u_t(t, x) = (r - 1)u(t, x) + \int_0^L \kappa(x, y) u(t, y) dy, \tag{3.6}$$

where we have rescaled time by the rate of movement μ and abbreviated $r = f'(0)/\mu$ as the rescaled growth rate at low density. From (3.6), we immediately see that if $r > 1$, then the zero steady state is unstable *independently* of the domain size and the kind of movement individuals perform. On the other hand, if $r < 1$, then the stability of the zero solution depends on the integral expression in (3.6). We assume that the integral operator

$$I[\phi](x) = \int_0^L \kappa(x, y) \phi(y) dy \tag{3.7}$$

has a unique simple dominant eigenvalue ν for an appropriate choice of function space. In Appendix C, we discuss possible choices and show the following result.

THEOREM 3.1. *Assume that κ is independent of L. The unique simple dominant eigenvalue ν of* (3.7) *is a strictly increasing function of the domain length L. Next, assume $f(0) = 0$ and $f'(0) > 0$. Then the zero steady-state solution of* (3.1) *is unstable provided $\nu(L) > 1 - r$.*

The condition that κ be independent of L means that dispersing individuals do not perceive domain boundaries or at least do not alter their movement behavior there. For example, aquatic individuals in a river stretch without breaks (source, mouth, waterfall), or in a no-fishing zone, or wind-dispersed seeds. In those cases, the dispersal kernel derived on the infinite domain is simply cut off at the domain boundaries [40]. If the movement behavior is altered at the boundary, then the kernel will depend on L (see section E). Then the first statement of the theorem is shown by showing that the smallest eigenvalue of the differential operator (3.4) is a decreasing function of L. In general, this follows from standard arguments; however, in the special case of zero-flux boundary conditions at both ends (i.e., no loss from the domain) this eigenvalue is independent of L.

According to the theorem, the critical domain size is given by $\nu(L) = 1 - r$. In the original nonscaled parameters, the population can persist if

$$f'(0) > \mu(1 - \nu). \tag{3.8}$$

Condition (3.8) is a refinement of the unconditional persistence in case $r > 1$, which we found above. Its interpretation gives a possible explanation of the drift paradox as follows. If the population growth rate at low density, $f'(0)$, exceeds the rate at which individuals move, μ, then the population will always persist, independently of the length of the domain and the kind of movement. In particular, the population can persist in an environment with unidirectional flow. This conclusion was also reached as one possible explanation of the drift paradox in [32]. If $f'(0)$ is smaller than μ, then persistence depends on the term $(1 - \nu)$. As the leading eigenvalue, ν asymptotically gives the fraction of individuals that remains in the domain during dispersal, and consequently, $(1 - \nu)$ is the fraction of individuals leaving the domain due to dispersal. Therefore, if the rate at which individuals move times the probability that they leave the domain during dispersal exceeds the population growth rate, then the population will go extinct. A similar switch from conditional to unconditional persistence in a PDE system was found in [13] (without advection) and [32] (with advection).

3.3. Spread speed. In the previous section, we analyzed population persistence on a bounded domain. Here, we look at population spread into an unbounded, previously uninhabited domain. We first derive the *minimal speed of a traveling wave* of the linearized system (3.6). We follow the usual line of argument, emphasizing the direction in which the wave is moving [26]. In systems with unidirectional flow, the spread in the direction of the drift will be faster than against the drift. This asymmetry requires some modification in the definition of the *asymptotic spreading speed* [3] for the nonlinear model. After we give the modified definition, we show in Theorem 3.2 that the minimal traveling wavespeed and the asymptotic spreading speed coincide.

To determine the wave speed of the linear system, we assume that the kernel is of the form $\kappa(x, y) = k(x - y)$ and change to traveling wave coordinates, $z = x - ct$, where c is the speed of a traveling wave. Then (3.6) gives the following equation for the profile ψ of a traveling wave:

$$-c\psi'(z) = (r - 1)\psi(z) + \int k(z - w)\psi(w)dw. \tag{3.9}$$

In this linear equation, we make the exponential ansatz $\psi(z) = e^{-sz}$, with $s > 0$ ($s < 0$), such that asymptotically, $\psi \to 0$ as $z \to \infty$ ($z \to -\infty$). After canceling equal terms on both sides, we get the characteristic equation

$$sc + 1 - r = \int_{-\infty}^{\infty} k(w)e^{sw}dw =: M(s) \tag{3.10}$$

for $s \neq 0$, where M stands for the moment generating function of k. We will always assume that advection points to the right. Therefore, waves with positive c travel in the direction of advection, and waves with negative c travel against the advection. From (3.10), which will be of use later, the minimal wave speeds are derived as in [26] and given by

$$c^+ = \inf_{s>0} \frac{r - 1 + M(s)}{s}, \quad c^- = \sup_{s<0} \frac{r - 1 + M(s)}{s} \tag{3.11}$$

for waves with decreasing (c^+) and increasing (c^-) profile. Here, we assume that the moment generating function exists at least for some interval containing zero. In

section 6, we discuss the case of a kernel whose moment generating function does not exist except at $s = 0$.

The representation (2.1) of the dispersal kernel for arbitrary settling rate (see (2.5)) is particularly useful in connection with formula (3.11) because the moment generating function of the Gaussian distribution is known. Since the moments of k involve integration in the spatial variable only and since the stopping times are independent of the spatial location, the moment generating function of k is given by

$$M(s) = \int_0^\infty p(t) \exp(Dts^2) dt. \tag{3.12}$$

The concept of the asymptotic spreading speed (henceforth simply referred to as spread speed) for the nonlinear equation was introduced by Aronson and Weinberger [3] and has since been explored in many publications; see [38]. To accommodate for asymmetric spread, we define spread speeds $c_\pm^*$ by the condition

$$\lim_{t\to\infty} u(t, x + ct) = \begin{cases} \bar{u}, & c_-^* < c < c_+^*, \\ 0, & c < c_-^* \text{ or } c > c_+^*, \end{cases} \tag{3.13}$$

where $\bar{u} > 0$ is the positive zero of f, i.e., $f(\bar{u}) = 0$.

THEOREM 3.2. *Assume that f satisfies $f(0) = 0 = f(\bar{u})$ for some $\bar{u} > 0$, $f'(0) > 0$, and the subtangential condition $f(u) \le f'(0)u$. Assume that the kernel satisfies the technical conditions stated in Appendix* D. *Then the spread speeds of the nonlinear equation* (3.1) *are given by* (3.11), *i.e., $c_\pm^* = c^\pm$.*

The proof of this theorem in Appendix D uses the upper bound for the spread speed from [26]. To show that the upper bound equals the lower bound, we construct subsolutions of (3.11) adapting the proof in [2] for a simple epidemic model.

4. A model with unidirectional flow. We now apply the general model (3.1) to study systems with unidirectional flow and the influence of the flow on the critical domain size and the spread speed. The biological system motivating our study is a population of aquatic insects in streams, and our results give possible explanations of the drift paradox. At first, we derive an appropriate dispersal kernel. Then we compute the critical domain size as well as the spread speeds with and against the flow direction. We show that these two important ecological characteristics are related as follows. The spread speed against the flow decreases as the advection increases until, at some critical advection speed, there is no spread against the flow direction. On the other hand, the critical domain size increases with the advection speed until, at some critical advection speed, it becomes infinite, i.e., the population cannot persist in a domain of any size. We show that the two critical advection speeds, indeed, coincide.

4.1. A dispersal kernel with advection. We derive a dispersal kernel that represents the movement of aquatic insects in streams. The larvae of these insects reside on the bottom of the stream, from where they periodically jump into the water column, where they are subject to the flow. Our submodel for individual movement consists of diffusion and advective flow, and we assume constant settling rate. We think of advection as representing the drift velocity experienced by the larvae and of diffusion as a first approximation to the variability in flow speed and direction. Denoting $z(t, x)$ as the density of moving individuals, we obtain the equation

$$z_t = Dz_{xx} - vz_x - \alpha z, \tag{4.1}$$

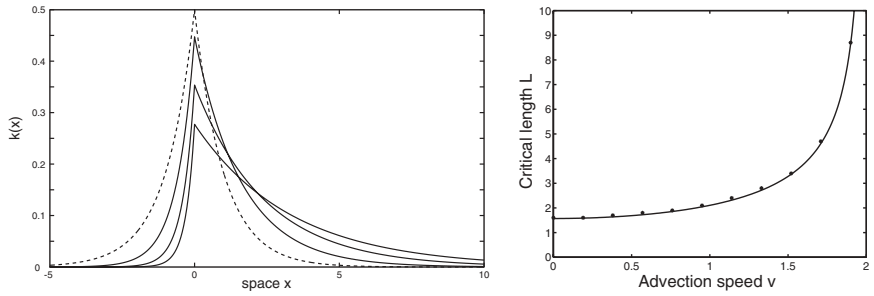

FIG. 4.1. *The picture on the left shows the dispersal kernel* (4.4) *with* $D = 1$, $\alpha = 1$, *and* $v = 1, 2, 3$ *in decreasing height of the peak, solid lines. For comparison, the symmetric kernel for* $v = 0$ *is plotted as the dashed line. The plot on the right gives the critical domain size as a function of the advection as in* (4.6). *The parameters are* $D = 1$, $\alpha = 1$, *and* $r = 0.5$. *The solid line is the analytical expression* (4.6), *stars are numerical results computing the eigenvalue of the integral operator* (C.1), *using Simpson's rule on* 1401 *data points in the interval* $[0, 1]$.

where D is the diffusion constant, v is the advection velocity, and α is the settling rate. Integrating (4.1) over $0 \le t \le \infty$ and applying the initial condition $z(0, x) = \delta(x)$ as well as (B.2), we observe that the dispersal kernel k satisfies

$$\frac{D}{\alpha} k_{xx} - \frac{v}{\alpha} k_x - k = -\delta, \tag{4.2}$$

i.e., k is the Green's function from (3.2). The characteristic equation of (4.2) is $Da^2 - va - \alpha = 0$ with solutions $a_1 > 0$ and $a_2 < 0$, given by

$$a_{1,2} = \frac{v}{2D} \pm \sqrt{\frac{v^2}{4D^2} + \frac{\alpha}{D}}. \tag{4.3}$$

Using the asymptotic boundary conditions for $x \to \pm\infty$ and the matching condition at $x = 0$, we find that k is of the form

$$k(x) = A \exp(a_1 x), \quad x \le 0, \quad \text{and} \quad k(x) = A \exp(a_2 x), \quad x \ge 0. \tag{4.4}$$

The value of the constant A is determined by the condition $\int_{-\infty}^{\infty} k(x)dx = 1$, which leads to

$$A = \frac{a_1 a_2}{a_2 - a_1} = \frac{\alpha}{\sqrt{D(v + 4\alpha)}}. \tag{4.5}$$

Alternatively, this kernel can be expressed by substituting $x \to x - vt$ in (2.2), $\alpha =$ const. in (2.5), and inserting the result in (2.1). In the special case $v = 0$, the Laplace kernel (2.6) results. We plot the shape of k in Figure 4.1 for different values of v while keeping D, α constant. In Appendix E, we contrast the kernel derived here for an infinite domain with a kernel on a finite domain with mixed boundary conditions of the same type as in [32, 36].

4.2. Critical domain size. From the previous section we know that the population persists unconditionally if $r > 1$. For $r < 1$, we have to find L such that $\nu(L) = 1 - r$; see (3.8). This can be calculated analytically. In Appendix F, we convert the integral equation (C.1) into a differential equation, extending earlier work

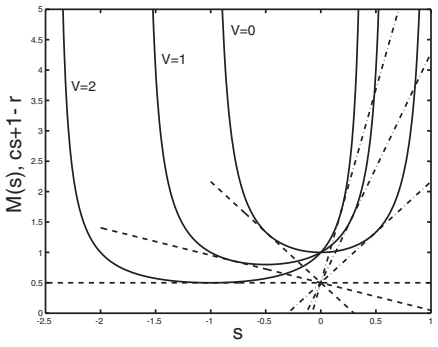

FIG. 4.2. *The hyperbolas are the moment generating function $M(s)$ (4.8) for three different values of v with $D = 1$ and $\alpha = 1$. The straight lines correspond to the left-hand side of (3.10). The slopes of these lines correspond to the spread speeds $c^{\pm}$ according to (3.11). For a more thorough explanation, see corresponding text. For $v = 0$ upstream and downstream spread speed are the same. For $v = 1$ the speed is faster downstream than upstream. For $v = 2$ the upstream spread stops.*

for symmetric kernels [20, 40], and obtain the following expression for L in terms of the eigenvalue ν and the dispersal related constants $a_{1,2}$ from (4.3):

$$L = \frac{4 \arctan\left(\sqrt{\frac{4a_1|a_2|}{\nu(a_1-a_2)^2} - 1}\right)^{-1}}{(a_1 - a_2)\sqrt{\frac{4a_1|a_2|}{\nu(a_1-a_2)^2} - 1}}. \tag{4.6}$$

Setting $\nu = 1 - r$, we can hence determine the critical domain size, which we plot in Figure 4.1 as a function of the advection speed v. As expected, the critical domain size is an increasing function of advection speed. From the plot, it appears that $v = 2$ is the critical advection speed, above which the population cannot persist in a domain of any length. In (4.6), L approaches infinity as the square root in the denominator approaches zero. Hence, the critical advection speed is defined by

$$\nu = 1 - r = \frac{4\frac{\alpha}{D}}{\frac{v^2}{D^2} + 4\frac{\alpha}{D}}. \tag{4.7}$$

For the set of parameters above, $v = 2$ is indeed the critical advection speed.

4.3. Spread speed. We use formulas (3.10) and (3.11) and Theorem 3.2 to determine the speed of spread. The moment generating function for the generalized Laplace kernel (4.4) is given by

$$M(s) = \frac{a_1 a_2}{(a_1 + s)(a_2 + s)}, \qquad -a_1 < s < -a_2. \tag{4.8}$$

In Figure 4.2, we plot the hyperbola $M(s)$ with y-intercept $M(0) = 1$ for three different values of the advection speed v. According to (3.10), we also plot straight lines with slope c, the propagation speed, and y-intercept $1 - r < 1$. As given in (3.11), we plot these straight lines for minimal values of $|c|$, such that the straight line and the hyperbola have a point in common, i.e., we plot the case that the line is tangent to the hyperbola. The resulting slopes give the minimal wave speed.

We find exactly two tangent lines. One of them (dash-dot line) always has positive slope, independent of the advection speed $v \geq 0$. This slope is the spread speed c^+

in the direction of advection. It increases with advection. For the other tangent line, we distinguish two cases. First note that the hyperbola is always positive since we assume k to be nonnegative. If now $r > 1$, then the y-intercept of the straight line is negative, and hence the (dashed) tangent line will always have negative slope. This slope corresponds to c^-, the spread speed against the advection. That means if $r > 1$, then the population can always invade against the advection. If, on the other hand, $r < 1$, then the tangent line has zero slope if the minimum of $M(s)$ equals $1-r$. If the minimum is smaller than $1-r$, then also the dashed tangent line has positive slope. Since the slope corresponds to c^-, and since the minimum of $M(s)$ is decreasing with increasing advection, we find a switch in the population's ability to invade against the advection. For small values of $v > 0$, the population can invade against the advection; for large values of $v > 0$, the population retreats with the advection.

To compute the critical advection velocity at which the switch happens, we compute the minimum of $M(s)$ as

$$M\left(-\frac{a_1+a_2}{2}\right) = -\frac{4a_1a_2}{(a_1-a_2)^2} > 0. \tag{4.9}$$

Therefore, the critical advection speed is given by

$$1-r = -\frac{4a_1a_2}{(a_1-a_2)^2} \qquad \text{or} \qquad v^2 = 4\frac{r}{1-r}\,\alpha D. \tag{4.10}$$

After some rearranging, we find that (4.10) is exactly the same as (4.7). Hence, the advection velocity above which a population cannot persist in a domain of arbitrary length is exactly the same as the advection velocity at which the population stops spreading upstream and starts retreating downstream. This connection between the two ecologically important quantities critical domain size and invasion speed in systems with advection was first hinted at in [36] and then demonstrated in the context of the PDE system (3.2) in [32].

4.4. Upstream settling probability. The probabilities that, after a dispersal event, an individual settles down- or upstream from its initial location are given by

$$P_{\text{down}} = \int_0^\infty k(x)dx = \frac{a_1}{a_1+|a_2|}, \qquad P_{\text{up}} = 1 - P_{\text{down}}. \tag{4.11}$$

For $r < 1$, we compute a critical upstream-settling probability, below which the population cannot persist or spread against the advection. We insert the critical advection velocity (4.10) into (4.3) and find

$$P^*_{\text{down}} = \frac{1+\sqrt{r}}{2}, \qquad P^*_{\text{up}} = \frac{1-\sqrt{r}}{2} \tag{4.12}$$

as the critical downstream and upstream probabilities, respectively. This result is surprising since the two quantities depend only on the population dynamics parameter and *not* on the movement related parameters α and D. Here lies a chance to test the predictions of the model *without* having to estimate α and D, provided we can estimate P_{up}. Later in the paper (Figure 6.2), we plot the critical domain size as a function of the downstream settling probability and compare it to the case of a fat-tailed kernel.

5. Two modes of dispersal. In the case *without advection*, it is known that the shape of the tail of the dispersal kernel has virtually no influence on the critical domain size [24]. On the other hand, the invasion speed for systems without advection crucially depends on the shape of the tail of the dispersal kernel [19]. Even a tiny fraction of long-distance dispersers can have a huge effect on the invasion speed. In the dispersal model of diffusion and settling, longer dispersal distances result from higher diffusion rate or lower settling rate. In the previous section, we showed that in systems *with advection*, there is a close relationship between critical patch size, critical advection velocity, and invasion speed. In this section, we explore how this relationship depends on the shape of the tail of the kernel.

We assume that individuals have two different dispersal modes and choose between those with probabilities p and $1-p$, respectively. We assume that both dispersal modes can be described by the simple advection-diffusion-settling model (4.1), but with possibly different parameters. Hence, the movement model is given by

$$\begin{aligned} z_{1,t} &= D_1 z_{1,xx} - v_1 z_{1,x} - \alpha_1 z_1, \\ z_{2,t} &= D_2 z_{2,xx} - v_2 z_{2,x} - \alpha_2 z_2 \end{aligned} \tag{5.1}$$

with initial conditions $z_1(0,x) = (1-p)\delta(x)$, $z_2(0,x) = p\delta(x)$. Since there is no interaction between the two different dispersal modes, the resulting kernel is simply the weighted sum of the kernels associated with each mode, i.e.,

$$k = (1-p)k_1 + pk_2, \tag{5.2}$$

where $k_{1,2}$ are given in (4.4) with the appropriate parameters. We are thinking of the z_2-compartment as the long-distance dispersers, i.e., we want k_2 to have fatter tails than k_1, and we assume that p is small. All other parameters being equal, k_2 will have fatter tails than k_1 if either $D_2 > D_1$ or $\alpha_2 < \alpha_1$. The effect of varying $v_{1,2}$ depends on whether we are looking at the upstream or the downstream direction. For simplicity and to compare the results of this section with those of the previous section, we restrict ourselves to the case $v_1 = v_2$.

We first explore the case of varying D_2 at equal settling rates $\alpha_1 = \alpha_2$. In Figure 5.1 we plot the critical domain size as a function of the advection speed for three different values of D_2 and for fixed $p = 0.1$ We also plot the critical advection speed at which the upstream spread is zero as a vertical line. We observe the following. At low advection speeds, the critical domain size is indeed insensitive to changes in D_2; i.e., it does not depend strongly on the tail of the dispersal kernel. The critical domain size increases with increasing D_2, reflecting higher loss at higher diffusion rates. At higher advection speeds, the picture is different. The critical domain size does depend crucially on D_2 and it decreases with increasing D_2. Whereas increasing D_2 increases the loss from the domain downstream, it also increases the probability that a few individuals move upstream. Summarizing in biological terms, at small advection speeds it is important to keep many individuals in the domain; at large advection speeds it is more important to have a few individuals dispersing against the advection. The critical advection speed increases with increasing D_2, which was to be expected since the tails of k get fatter. The curves for the critical domain size approach the straight lines for the critical advection speed for upstream spread, and hence the critical advection speed for persistence and invasion agree, as in the previous section.

Next, we vary the settling rate α_2 at equal diffusion coefficients $D_1 = D_2$. The results are plotted in Figure 5.1, which includes the critical domain size and the

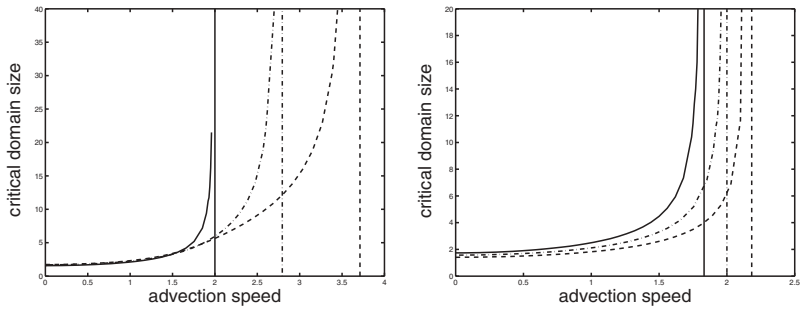

FIG. 5.1. *Left: The critical domain size as a function of the advection speed with dispersal kernel* (5.2). *The parameters are* $D_1 = 1$, $\alpha_1 = \alpha_2 = 1$, $r = 0.5$, $p = 0.1$. *The varying parameter is* $D_2 = 1$ *(solid),* $D_2 = 5$ *(dash-dot), and* $D_2 = 10$ *(dashed). The vertical lines give the critical advection speed for upstream invasion from formula* (3.10). *The values are* $v = 2$, $v = 2.7948$, $v = 3.7114$ *for* $D_2 = 1$, $D_2 = 5$, $D_2 = 10$, *respectively. Right: The critical domain size as a function of the advection speed with dispersal kernel* (5.2). *The parameters are* $D_1 = D_2 = 1$, $\alpha_1 = 1$, $r = 0.5$, $p = 0.1$. *The varying parameter is* $\alpha_2 = 0.1$ *(solid),* $\alpha_2 = 1$ *(dash-dot), and* $\alpha_2 = 10$ *(dashed). The vertical lines give the critical advection speed for upstream invasion from formula* (3.10). *The values are* $v = 1.8321$, $v = 2$, $v = 2.1833$ *for* $\alpha_2 = 0.1$, $\alpha_2 = 1$, $\alpha_2 = 10$, *respectively.*

critical advection speed for upstream spread just as in the previous plot. The two most important observations are that the curves for different α_2 do not intersect and that the curve with the higher α_2 is always the lower one. Hence, independently of the strength of advection, higher settling rate always promotes species persistence and ability to spread upstream. In view of our earlier considerations, this is a surprising result, since decreasing α_2 gives fatter tails of k, yet it reduces the critical advection velocity instead of increasing it as above when we varied D_2.

There are several ways to explain why increasing D_2 and decreasing α_2, which both produce fatter tails of k_2, have opposite effects on the domain length and the invasion speed. Whereas settling rate and diffusion coefficient appear as a quotient in formulas (2.6), (4.3), which determine the tail of the kernel, they appear as a product in formula (4.10) for the critical velocity of upstream propagation. Increasing D_2 in (4.3) decreases both $a_1, |a_2|$ to zero, whereas decreasing α decreases $|a_2|$ to zero and a_1 to v/D. Therefore, increasing D_2 makes the kernel more symmetric, whereas decreasing α_2 makes it less symmetric. This can also be seen by computing the skewness of k from (4.4) as

$$-2\frac{v(v^2+\alpha D)}{(v^2+2\alpha D)\sqrt{v^2+2\alpha D}}, \tag{5.3}$$

which is a decreasing function in the product αD. In more biological terms, in systems with advection, the probability of moving downstream is higher than the probability of moving upstream. Increasing the diffusion rate increases the probability of moving upstream, increasing the settling rate decreases it. Last, dimensional analysis gives the same result. Characteristic length scales are $\sqrt{D/\alpha}$ for a system without advection and v/α for a system without diffusion. The balance between up- and downstream movement is hence given as

$$\sqrt{D/\alpha} \sim v/\alpha \qquad \text{or} \qquad \alpha D \sim v^2. \tag{5.4}$$

6. Dispersal by extremes. In this last section, we explore the ideas from the previous paragraphs in the context of a dispersal kernel whose tails are not expo-

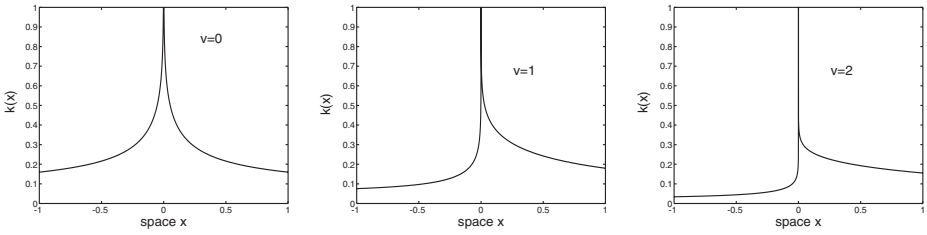

FIG. 6.1. *The fat-tailed kernel from* (6.1) *with parameters* $\mu = 1$, $\alpha = 0.5$ *for different values of advection velocity* v.

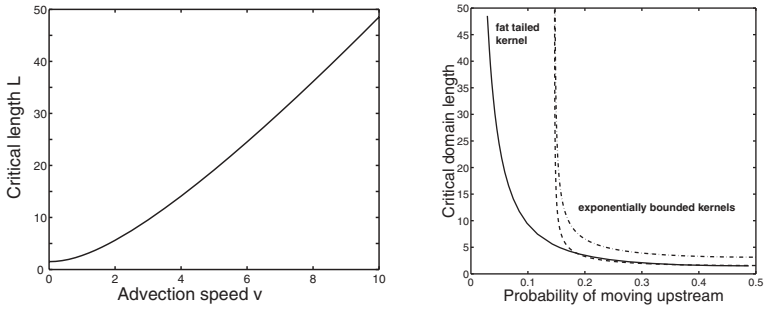

FIG. 6.2. *On the left, the critical domain length for the fat-tailed kernel* (6.1) *is plotted as a function of the advection velocity. The parameters are* $\rho = 1$, $r = 1$, $\alpha = 1$. *On the right, the critical domain length is given as a function of the upstream settling probability. The solid line represents the fat-tailed kernel* (6.1) *with parameters* $\rho = 1$, $r = 1$, $\alpha = 1$. *The dashed and dash-dot line are for the exponential kernel* (4.4) *with parameters are* $\alpha = 1$, $r = 0.5$. *The dashed line corresponds to* $D = 1$, *the dash-dot line to* $D = 4$.

nentially bounded. Such kernels are also known as fat-tailed kernels and describe a situation where long-distance dispersal events are not rare. Different phenomena, such as accelerating invasions, have been shown to occur in that case [19]. We follow the ideas from section 2 to incorporate unidirectional flow in such kernels. Then we numerically investigate how the critical domain size depends on the strength of the flow.

As described in section 2, we compute the appropriate fat-tailed kernel by integrating the Cauchy distribution (2.3) with x replaced by $x - vt$, multiplied with the probability of stopping times (2.5) according to (2.1). This integration yields the asymmetric fat-tailed dispersal kernel

$$k(x) = \frac{\alpha}{(\mu^2 + v^2)\pi} \Re\left((\mu + vi) E_1\left(-\frac{\alpha(v - \mu i)x}{\mu^2 + v^2} \right) \exp\left(-\frac{\alpha(v - \mu i)x}{\mu^2 + v^2} \right) \right). \tag{6.1}$$

In Figure 6.1 we plot this kernel for various values of v. The critical domain length for the fat-tailed kernel (6.1) is plotted as a function of advection speed in Figure 6.2. As expected, it increases with advection speed but it seems to remain finite even for large v. To compare the results for the fat-tailed kernel here with the results from the asymmetric exponential kernel from section 4, we plot the critical domain length in both cases as a function of the probability of settling upstream from the point of release; see section 4.4. If the advection speed is zero, then the probability of settling upstream from the point of release is 0.5. As the advection speed increases, the probability of settling upstream decreases. In the limit as the advection speed approaches

infinity, the upstream probability goes to zero. From the plot in Figure 6.2 we make two observations. The fat-tailed kernel (6.1) produces finite critical domain lengths for smaller upstream probabilities than the exponential kernel; i.e., the population can persist for larger advection speeds. Second, the critical upstream probability for the exponential kernel as computed in (4.12) is independent of the dispersal parameters D and α and depends only on the population growth rate r.

7. Discussion. In this work, we consider integrodifferential models that incorporate population dynamics and individual movement described by dispersal kernels. Extending previous work [30, 32], we consider not only kernels arising from simple random walks but also including (1) unidirectional flow, producing asymmetric kernels, and (2) long-distance jumps (Lévy flight motion), producing fat-tailed kernels. These derivations contribute to the effort to incorporate mechanistic descriptions of individual movement into population models in order to understand the impact of details of individual movement on population dynamics under different conditions.

We obtain general criteria for persistence of a population by deriving the critical domain size for integrodifferential equations. We also extend existing work on the rate of spread [26] and prove that the linear conjecture holds for these systems. Further, we show that in systems with advection there exists a critical advection speed that links population persistence and spread as follows. At a critical advection speed, the population can no longer persist on any finite domain (i.e., the critical domain size is infinite). This critical advection speed is the same as the one that causes upstream propagation to stall (i.e., the upstream propagation speed is 0). We show this result analytically for the modified Laplace kernel and numerically for other kernels; for related results in a PDE model, see [32].

It has been shown that in systems without advection the shape of tails of the dispersal kernel have little effect on persistence [24] but may be a major determinant of the spread rate of a population [19]. Our results show that in systems with advection, the shape of the tails of kernels influences both. With fat-tailed kernels, a population is able to both persist and spread upstream in conditions with higher flow speed.

Whereas the current model gave us valuable insight in dispersal in stream populations and possible explanations for the drift paradox, we plan to continue these investigations using more realistic biological models. The techniques in this paper will be extended to cover, e.g., resource dynamics and predator-prey interaction. Most important, we plan to model a population of larvae and adult stage where adults emerge from the stream and fly upstream to deposit eggs. This mechanism is the most commonly quoted biological hypothesis to solve the drift paradox. Finally, as we are dealing with low population numbers, we intend to compare the results of these deterministic models here to stochastic simulations.

Appendix A. Derivation of the Cauchy distribution for individuals undergoing a random walk. The derivation we use follows [11]. Let Y be a random variable, assuming its values on the integer lattice and describing the number of space steps that an individual jumps each time step. The probability that the individual jumps k steps to the right ($\Pr(Y = k) = p_k$) is defined to be

$$p_k = \begin{cases} 1 - \frac{2m}{\pi} & \text{if} \quad k = 0, \\ \frac{m}{\pi|k|(|k|+1)} & \text{if} \quad k > 0. \end{cases} \tag{A.1}$$

The parameter m, restricted to $0 < m < \pi/2$, describes the likelihood of dispersing. It is straightforward to show that the p_k sum to one. We produce a random walk on

the grid of spacing h with $h > 0$ by letting the walker start at point 0 at instant 0 and defining the location of the individual after n time steps to be

$$X_n = hY_1 + hY_2 + \cdots + hY_n, \tag{A.2}$$

where Y_n are independent, identically distributed random variables, all having the same distribution as Y. We relate space steps h and time steps τ by the speed s, so $h = s\tau$. At time $t = n\tau = nh/s$ we have $h = ts/n$, so that the spreading time associated with distance X_n is to

$$\frac{X_n}{\rho} = \frac{t}{mn}\left(Y_1 + Y_2 + \cdots + Y_n\right), \tag{A.3}$$

where $\rho = ms$ is a speed of spreading. The distribution of the right-hand side of (A.3) converges to the distribution of normalized Cauchy distribution

$$\frac{1}{\pi}\frac{t}{x^2 + t^2} \tag{A.4}$$

in the limit as n approaches infinity [11]. Thus X_n approaches (2.3) in the same limit. For any given fixed time t and speed s the limit n approaches infinity is equivalent to the space step h approaching zero.

Appendix B. Dispersal kernels for multiple dispersal modes. In extending the simple diffusion model for individual movement, we assume that individuals have two different modes of dispersal and that they can switch between these modes. We show how the dispersal kernel can be computed explicitly for constant rates and that the kernel is exponentially bounded. The description for individual movement is given by

$$\begin{aligned} z_{1,t} &= D_1 z_{1,xx} - v_1 z_{1,x} - \mu z_1 + \sigma z_2 - \alpha_1 z_1, \\ z_{2,t} &= D_2 z_{2,xx} - v_2 z_{2,x} - \mu z_2 + \sigma z_1 - \alpha_2 z_2. \end{aligned} \tag{B.1}$$

The parameters D_j, v_j, and α_j are the diffusion rates, the advection speeds, and the settling rates for the different stages. The parameters μ and σ are switching rates between the stages. Initially, there is a certain fraction of the population in each stage, i.e., $z_1(0,x) = p\delta(x)$, and $z_2(0,x) = (1-p)\delta(x)$. The density of stopping points from the respective stages is given by

$$k_j(x) = \int_0^\infty \alpha_j z_j(t,x) \tag{B.2}$$

for $j = 1, 2$, and hence the kernel is given by $k(x) = k_1(x) + k_2(x)$.

The case $\alpha_1 = \sigma = 0$ can be interpreted as two successive modes of dispersal. In the case without advection, this has been treated by [30]. If we consider only movement, not settling ($\alpha_{1,2} = 0$), then we can study the shape of the spatial distribution of z_1 and z_2 as it evolves in time. For systems like (B.1) but without advection, Skalski and Gilliam [33] have constructed an explicit solution and computed asymptotic speeds of spread for a linear model.

From (B.1) we deduce that k_1, k_2 satisfy the system

$$\begin{aligned} -p\alpha_1\delta &= D_1 k_1^{(2)} - v_1 k_1^{(1)} - (\mu + \alpha_1)k_1 + \sigma\frac{\alpha_1}{\alpha_2}k_2, \\ -(1-p)\alpha_2\delta &= D_2 k_2^{(2)} - v_2 k_2^{(1)} - (\sigma + \alpha_2)k_2 + \mu\frac{\alpha_2}{\alpha_1}k_1, \end{aligned} \tag{B.3}$$

where $k_j^{(l)}$ denotes the lth derivative of k_j. Restriction to the interval $(0,\infty)$ and repeated differentiation and substitution of (B.3) yields a fourth-order equation for k_1 as follows:

$$D_1 k_1^{(4)} - \left(v_1 + v_2\frac{D_1}{D_2}\right)k_1^{(3)} - \left(\mu + \alpha_1 - \frac{v_1 v_2 D_1(\sigma+\alpha_2)}{D_2}\right)k_1^{(2)}$$

(B.4)

$$+ \frac{v_1(\sigma+\alpha_2)+v_2(\sigma+\alpha_1)}{D_2}k_1^{(1)} + \frac{(\sigma+\alpha_2)(\mu+\alpha_2)-\mu\sigma}{D_2}k_1 = 0.$$

This is a linear equation with constant coefficients; therefore the solution is readily determined and is exponentially bounded. The coefficients are determined by the usual conditions, i.e., the kernel has to integrate to unity, it has to be continuous at zero, and the jump conditions at zero have to be satisfied.

Appendix C. Proof of Theorem 3.1. The exponential ansatz $u(t,x) = \exp(\lambda t)\phi(x)$ in the linearization (3.6) leads to the eigenvalue problem

$$\nu\phi(x) = I[\phi](x) = \int_0^L k(x,y)\phi(y)dy \tag{C.1}$$

with $\nu = \lambda + 1 - r$. The solution u of (3.6) will grow if $\lambda > 0$ and decay if $\lambda < 0$. Hence, the critical value is given by $\lambda = 0$ or $\nu = 1 - r$.

We now show that the dominant eigenvalue ν^* is a monotone increasing function of domain length. For two domain lengths $L_2 > L_1$, we denote I_j as the linear operator given by (C.1) with L replaced by L_j, $j = 1, 2$. We denote $\nu_{1,2}$ as the corresponding dominant eigenvalues and $\phi_{1,2}$ as corresponding (positive) eigenfunctions. Then $I_2 \geq I_1$ and hence $\nu_2 \geq \nu_1$. We show that the inequality is in fact strict. We write

$$I_2\phi_2 = I_1\phi_2 + \int_{L_1}^{L_2} k(x,y)\phi_2(y)dy.$$

Since $\phi_2 > 0$, the last term is positive and hence there is an $\varepsilon > 0$ such that

$$f\colon = \int_{L_1}^{L_2} k(x,y)\phi_2(y)dy > \varepsilon\phi_1.$$

Then the equation $\nu_2\psi = I_1\psi + f$ has no solution for $\nu_2 \leq \nu_1$ [21]. But ϕ_2 is a solution and hence necessarily $\nu_2 > \nu_1$.

If the dispersal kernel is continuous, then the resulting integral operator on $\mathcal{L}^2[0,L]$ is completely continuous and, for positive kernel, has a unique simple dominant eigenvalue [21]. Therefore, our assumptions are valid for all kernels in sections 4 and 5. In fact, the condition that the kernel be continuous can be weakened by saying that the kernel to the power $1+q$, $q \geq 1$, has to be integrable on $[0,L]^2$ [21]. Numerically, the fat-tailed kernel (2.7) can be bounded by $x^{-0.4}$, which is square integrable, and hence the assumption holds. This is an area of future research.

Appendix D. Proof of Theorem 3.2. By scaling time, we may assume $\mu = 1$ in equation (3.1). It was shown in [26] that $c^- \leq c_-^*$ and $c_+^* \leq c^+$. To show the reversed inequalities, we follow Aronson's proof [2] and show that for all $c \in (c^-, c^+)$ there is a subsolution of (3.1) which expands at speed c. Due to a comparison principle, the true solution has to expand at speed at least c.

We make the following technical requirements on the kernel k [2]. We assume $k \geq 0$ and $\text{supp}(k) = \mathbb{R}$. We assume that the moment generating function $M(s)$ exists for $s \in (\hat{s}^-, \hat{s}^+)$ with $\hat{s}^- < 0$, $\hat{s}^+ > 0$. We assume furthermore that the function

$$A_\lambda(s) = [(M(s) + \lambda)/s], \qquad s \neq 0, \tag{D.1}$$

has exactly one minimum at $\bar{s}^+ \in (0, \hat{s}^+)$ and one maximum at $\bar{s}^- \in (\hat{s}^-, 0)$. In addition, $A_\lambda(s)$ is increasing on $(\hat{s}^-, \bar{s}^-) \cup (\bar{s}^+, \hat{s}^+)$ and decreasing on $(\bar{s}^-, 0) \cup (0, \bar{s}^+)$. Finally, we assume that the function $x \mapsto \exp(sx)k(x)$ is decreasing for large enough x. Note that with this notation, $c^\pm = A_\lambda(\bar{s}^\pm)$ with $\lambda = f'(0) - 1$.

We first switch to a moving coordinate frame and show a comparison principle for the resulting integrodifferential operator. The function $W(t, \xi) = u(t, \xi + ct)$ satisfies

$$W_t = cW_\xi + f(W) - W + \int k(\xi - \eta)W(t, \eta)d\eta =: Q_c[W], \quad W(0, \xi) = u(0, \xi). \tag{D.2}$$

LEMMA D.1 (comparison). *Let V, W be bounded and continuously differentiable functions which satisfy, on $\mathbb{R}^+ \times \mathbb{R}$,*

$$V_t - Q_c[V] \geq W_t - Q_c[W], \tag{D.3}$$

and $V(0, \xi) > W(0, \xi)$ on $\mathbb{R}$. Then $V > W$ on $(0, \infty) \times \mathbb{R}$.

Proof. Let V, W be given. The difference $Z = V - W$ satisfies

$$Z_t - cZ_\xi \geq h(t, \xi)Z + k * Z, \quad Z(0, \cdot) > 0, \tag{D.4}$$

where h is some bounded function, given by the mean value theorem. Suppose there is a first time t_0 such that $Z > 0$ on $[0, t_0) \times \mathbb{R}$, and $Z(t_0, \xi_0) = 0$ for some ξ_0. By assumption, the convolution term in (D.4) is nonnegative on $[0, t_0] \times \mathbb{R}$. Therefore, along the characteristic lines $\xi + ct$, Z is bounded below by the solution of the differential equation $\dot{\zeta} = h\zeta$, $\zeta(0, \xi) = Z(0, \xi) > 0$. Since ζ remains positive, Z has to remain positive. ∎

In the following, we will use Lemma D.1 with nonstrict inequalities, i.e., $V(0, \xi) \geq W(0, \xi)$ implies $V \geq W$ provided V satisfies a well-posed initial value problem, and still refer to that as Lemma D.1. The idea is the same as in [2]. Let V_ϵ, $\epsilon > 0$, be the solution of a well-posed initial value problem with initial value $V_\epsilon(0, \xi) = V(0, \xi) + \epsilon$. Then by the above $V_\epsilon > W$, and in the limit $\epsilon \to 0$, we have $V \geq W$.

LEMMA D.2 (subsolution). *Let $c \in (c^-, c^+)$ be given. Then there exists a function $V_0(\xi)$, which is positive on $(0, \pi/\gamma)$, such that $Q_c[\varepsilon V_0] \geq 0$ and*

$$Q_c[\varepsilon V_0] > 0 \quad \text{on} \quad (0, \pi/\gamma) \tag{D.5}$$

for all sufficiently small $\varepsilon, \gamma > 0$.

Before we prove Lemma D.2, we demonstrate how the subsolution and repeated use of the comparison principle are employed to prove the theorem. Suppose that $W(0, \xi)$ and $c \in (c^-, c^+)$ are given and $W(t, \xi)$ satisfies (D.2). We need to show that $W(t, \xi) \to \bar{u}$ as $t \to \infty$ for all $\xi \in \mathbb{R}$. At first, Lemma D.2 ensures the existence of $V_0(\xi)$, which is positive on $(0, \pi/\gamma)$ for small enough $\gamma > 0$. We apply the comparison principle to εV_0 and V, defined as the solution to

$$V_t = Q_c[V], \qquad V(0, \xi) = \varepsilon V_0(\xi), \tag{D.6}$$

to see that $V(t,\xi) \geq \varepsilon V_0(\xi)$ for all $t > 0$. Next, the comparison principle is applied to $V(t,\xi)$ and $\tilde{V}(t,\xi) = V(t+h,\xi)$ for any fixed $h > 0$. As a result, $\tilde{V} \geq V$ and therefore $V(t,\xi)$ is a nondecreasing function in t for each fixed ξ. On comparing $V(t,\xi)$ with the constant $\bar{u}$, we get that V is bounded by $\bar{u}$, and therefore $V(t,\xi) \to q(\xi)$ for each ξ. Following Aronson [2], one can actually show that $q(\xi) \equiv \bar{u}$.

Finally, for T sufficiently large, there is a bound $m > 0$ such that $W(T,\xi) \geq m > 0$ on $(0,\pi/\gamma)$. We choose $\varepsilon > 0$ such that $\varepsilon V_0 < m$. We now apply the comparison principle to $W(t,\xi)$ and the solution $V(t-T,\xi)$ of $V_t = Q_c[V]$, $V(T,\xi) = \varepsilon V_0(\xi)$, to obtain that $W(t,\xi) \geq V(t-T,\xi)$. This completes the proof.

We now prove Lemma D.2. We first look at the linear equation

$$W_t = L_c[W] \colon = cW_\xi + \lambda W + k * W, \tag{D.7}$$

where $*$ denotes the convolution. For $s \in (\bar{s}^-, \bar{s}^+)\backslash\{0\}$, we define

$$\hat{V}_0(\xi) = e^{-s\xi} \sin \gamma\xi. \tag{D.8}$$

After a little bit of algebra, we find that $L_c[\hat{V}_0](\xi)$ is given by

$$\left[-cs + \lambda + \int e^{s\eta} k(\eta) \cos(\gamma\eta) d\eta\right] \hat{V}_0 + \left[c\gamma - \int e^{s\eta} k(\eta) \sin(\gamma\eta) d\eta\right] e^{-s\xi} \cos \gamma\xi.$$

Therefore, $L_c[\hat{V}_0] > 0$ on $(0,\pi/\gamma)$ if the following two conditions are satisfied:

$$c < \frac{1}{s}\left[\lambda + \int e^{s\eta} k(\eta) \cos(\gamma\eta) d\eta\right] =: \mathcal{A}_\lambda(s,\gamma), \qquad s > 0, \tag{D.9}$$

$$c > \mathcal{A}_\lambda(s,\gamma), \qquad s < 0, \tag{D.10}$$

$$c = \frac{1}{\gamma}\left[\int e^{s\eta} k(\eta) \sin(\gamma\eta) d\eta\right] =: \mathcal{B}(s,\gamma). \tag{D.11}$$

We first establish some properties of the functions $\mathcal{A}_\lambda$ and $\mathcal{B}$. As $\gamma \to 0$, we have uniform convergence on compact subsets of $(\bar{s}^-, \bar{s}^+)\backslash\{0\}$ of

$$\mathcal{A}_\lambda(s,\gamma) \to A_\lambda(s), \quad \mathcal{B}(s,\gamma) \to B(s) \colon = \int \eta e^{s\eta} k(\eta) d\eta.$$

The function $B(s)$ is increasing. Differentiation gives $A'_\lambda(s) = (B(s) - A_\lambda(s))/s$. Hence, due to the assumptions on A_λ, we furthermore see that $B < A_\lambda$ on $(0, \bar{s}^+)$, $B > A_\lambda$ on $(\bar{s}^-, 0)$, and $B(\bar{s}^\pm) = A_\lambda(\bar{s}^\pm)$. Note that $B(0)$ is the average dispersal distance, and since B is an increasing function, $c^- < B(0) < c^+$; i.e., the interval (c^-, c^+) is never empty.

We now return to the construction of $\hat{V}_0$; i.e., we show that conditions (D.9)–(D.11) can be satisfied simultaneously. Without loss of generality, we may assume $c > B(0)$, and hence we restrict ourselves to $s > 0$. First, we can choose $\lambda < f'(0) - 1$ such that $c < A_\lambda(\bar{s}^+)$. Then we can choose $s_0, s_1, \delta, \gamma > 0$, such that

$$B(s_0) + \delta < c < B(s_1) - \delta \quad \text{and} \quad |\mathcal{B}(s,\gamma) - B(s)| < \delta.$$

By continuity, there is a value $s(\gamma)$ such that $\mathcal{B}(s(\gamma),\gamma) = c$ for all sufficiently small γ. Obviously, we can choose γ small enough such that $\mathcal{A}_\lambda(s(\gamma),\gamma) > c$. Hence, the two conditions (D.9), (D.11) can be satisfied simultaneously.

By the same argument as [2], one can show that the modified function

$$V_0(\xi) = \hat{V}_0(\xi), \quad \xi \in [0, \pi/\gamma], \quad V_0(\xi) = 0, \quad \xi > \pi/\gamma, \tag{D.12}$$

also satisfies $L_c[V_0] > 0$ on $(0, \pi/\gamma)$.

As a last step, we have to show that for small enough $\varepsilon > 0$ we have $Q_c[\varepsilon V_0] > 0$ on that same interval. Note that $\lambda < f'(0) - 1$ implies that $\lambda\varepsilon < f(\varepsilon) - \varepsilon$ for small enough $\varepsilon > 0$. Hence, we have $Q_c[\varepsilon V_0] > L_c[\varepsilon V_0] > 0$, on $(0, \pi/\gamma)$, which completes the proof.

Appendix E. The advection diffusion kernel for bounded domains. Movement is modeled by (4.1) on the interval $[-L/2, L/2]$ with initial condition $z(0, x) = \delta(x - y)$. The boundary conditions are

$$\left(z_x - \frac{v}{D} z\right)(t, -L/2) = 0, \qquad z(t, L/2) = 0. \tag{E.1}$$

We interpret these conditions as a stream where individuals cannot enter or leave at the upstream end and are washed out at the downstream end [36]. We nondimensionalize (4.1) by setting $X = x/L$, $T = \alpha t$, $Z = Lz$, which gives

$$Z_T = \frac{1}{\tilde{L}^2} Z_{XX} - \tilde{v} Z - Z, \quad Z(T, 1/2) = 0 = (Z_X - \tilde{L}^2 \tilde{v} Z)(T, -1/2), \tag{E.2}$$

where $\tilde{L}^2 = \alpha L/D$ and $\tilde{v} = v/(\alpha L)$. For convenience, we write the variables t, x in lower case letters again. We want to find the nondimensional kernel given by $\kappa(x, y) = \int_0^\infty \alpha Z(t, x) dt$. The function $W(t, x) = \exp(-L^2 v x/2) Z(t, x)$ satisfies

$$W_t = \frac{1}{L^2} W_{xx} - \beta W, \tag{E.3}$$

where $\beta = 1 + \frac{v^2 L^2}{4}$. Separating variables $W(t, x) = T(t)X(x)$, we get the two independent equations $T' = -(\lambda^2 + \beta)T$ and $X'' = -\lambda^2 L^2 X$ for some $\lambda^2 > 0$. The boundary conditions applied to the equations for X result in the defining condition

$$\lambda = -\frac{vL}{2} \tan(\lambda L). \tag{E.4}$$

We denote its infinitely many (symmetric) nonzero solutions by λ_n, $n = 1, 2, \ldots$. The corresponding family of orthogonal solutions is given by

$$\phi_n(x) = -\tan(\lambda_n L/2) \cos(\lambda_n L x) + \sin(\lambda_n L x) \tag{E.5}$$

with norm

$$\|\phi_n\|_2^2 = \frac{1}{2}(1 + \tan^2(\lambda_n L/2)).$$

The solution of (E.3) can hence be written as an infinite sum where each term is of the form $c_n e^{-(\lambda_n + \beta)t} \phi_n(x)$. To find expressions for the coefficients c_n we approximate the delta distribution by the top hat function,

$$\delta_m(x - y) = \begin{cases} 2m, & |x - y| \le 1/m, \\ 0, & \text{else.} \end{cases}$$

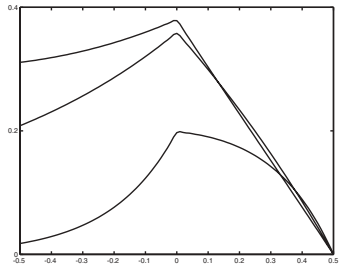

FIG. E.1. *The kernel with advection, no-flux boundary conditions at the left end, zero boundary conditions at the right end, release point in the middle, for* $v = 0.2$ *(top curve),* $v = 1$ *(middle), and* $v = 5$ *(bottom).*

Expanding the approximate initial condition

$$\delta_m(x-y)e^{-\frac{vL^2}{2}x} = \sum c_n\phi_n(x)$$

and using the intermediate value theorem gives

$$c_n = \frac{e^{-\frac{vL^2}{2}y}\phi_n(y)}{\|\phi_n\|_2^2}.$$

Hence, the nondimensionalized kernel is given by

$$k(x,y) = e^{-\frac{vL^2}{2}(y-x)} \sum_n \frac{1}{\lambda_n^2 + 1 + \frac{v^2L^2}{4}} \frac{2}{1+\tan^2(\frac{\lambda_n L}{2})} S(x)S(y), \tag{E.6}$$

where $S(x) = (\sin(\lambda_n Lx) - \tan(\lambda_n L/2)\cos(\lambda_n Lx))$. In Figure E.1 we plot this kernel for three different advection speeds.

Appendix F. Exact derivation of the critical domain length. We determine the critical domain length for the kernel (4.4) by computing the eigenvalue of the corresponding integral operator (C.1), extending earlier work [20, 40]. Scaling the space variable by L gives

$$\nu\phi(x) = \int_0^1 \tilde{\kappa}(x,y)\phi(y)dy, \tag{F.1}$$

where $\tilde{\kappa}$ is defined as κ with a_j, A replaced by $b_j = La_j$, $B = LA$. Differentiating (F.1) gives

$$\nu\phi'(x) = b_2\nu\phi(x) + (b_1 - b_2)\int_x^1 Be^{b_1(x-y)}\phi(y)dy. \tag{F.2}$$

Differentiating again, we obtain

$$\nu\phi''(x) = (b_2 - b_1)B\phi(x) + b_2^2\nu\phi(x) + (b_1^2 - b_2^2)\int_x^1 Be^{b_1(x-y)}\phi(y)dy. \tag{F.3}$$

Substituting (F.2) into (F.3), we get the regular Sturm–Liouville problem

$$\phi''(x) = -b_1|b_2|\left(\frac{1}{\nu} - 1\right)\phi(x) + (b_1 + b_2)\phi'(x), \quad \phi'(0) = b_1\phi(0), \quad \phi'(1) = b_2\phi(1). \tag{F.4}$$

We apply the transformation $\psi(x) = \exp(-\frac{b_1+b_2}{2}x)\phi(x)$ to (F.4) and substitute the original parameters back to obtain

$$\psi'' = -L^2\frac{(a_1-a_2)^2}{4}\left(\frac{4a_1|a_2|}{\nu(a_1-a_2)^2}-1\right)\psi, \tag{F.5}$$

together with the boundary conditions

$$\psi'(0) = L\frac{a_1-a_2}{2}\psi(0) \qquad \text{and} \qquad \psi'(1) = -L\frac{a_1-a_2}{2}\psi(1). \tag{F.6}$$

Equations (F.5) and (F.6) constitute a Sturm–Liouville problem, which one can solve for L as a function of ν [40], and the solution is given by formula (4.6).

Acknowledgment. The authors thank Roger Nisbet for insightful discussions and helpful comments.

A MATHEMATICAL STUDY OF THE HEMATOPOIESIS PROCESS WITH APPLICATIONS TO CHRONIC MYELOGENOUS LEUKEMIA*

MOSTAFA ADIMY†, FABIEN CRAUSTE†, AND SHIGUI RUAN‡

Abstract. This paper is devoted to the analysis of a mathematical model of blood cell production in the bone marrow (hematopoiesis). The model is a system of two age-structured partial differential equations. Integrating these equations over the age, we obtain a system of two nonlinear differential equations with distributed time delay corresponding to the cell cycle duration. This system describes the evolution of the total cell populations. By constructing a Lyapunov functional, it is shown that the trivial equilibrium is globally asymptotically stable if it is the only equilibrium. It is also shown that the nontrivial equilibrium, the most biologically meaningful one, can become unstable via a Hopf bifurcation. Numerical simulations are carried out to illustrate the analytical results. The study may be helpful in understanding the connection between the relatively short cell cycle durations and the relatively long periods of peripheral cell oscillations in some periodic hematological diseases.

Key words. blood cells, hematopoiesis, differential equations, distributed delay, asymptotic stability, Lyapunov functional, Hopf bifurcation

1. Introduction.

Cellular population models have been investigated intensively since the 1960s (see, for example, Trucco [33, 34], Nooney [25], Rubinow [28], and Rubinow and Lebowitz [29]) and still interest a lot of researchers. This interest is greatly motivated, on one hand, by medical applications and, on the other hand, by the biological phenomena (such as oscillations, bifurcations, traveling waves, or chaos) observed in these models and, generally speaking, in the living world (Mackey and Glass [19], Mackey and Milton [20]).

Hematopoiesis is the process by which primitive stem cells proliferate and differentiate to produce mature blood cells. It is driven by highly coordinated patterns of gene expression under the influence of growth factors and hormones. The regulation of hematopoiesis is about the formation of blood cell elements in the body. White and red blood cells and platelets are produced in the bone marrow, from where they enter the blood stream. The principal factor stimulating red blood cell production is a hormone produced in the kidney, called erythropoietin. About 90% of the erythropoietin is secreted by renal tubular epithelial cells when blood is unable to deliver sufficient oxygen. A decrease in the level of oxygen in the blood leads to a release of a substance, which in turn causes an increase in the release of the blood elements from the marrow. There is feedback from the blood to the bone marrow. Abnormalities in the feedback are considered as major suspects in causing periodic hematological diseases, such as autoimmune hemolytic anemia (Bélair, Mackey, and Mahaffy [4] and Mahaffy, Bélair, and Mackey [23]), cyclical neutropenia (Haurie, Dale, and Mackey

[14]), and chronic myelogenous leukemia (Fowler and Mackey [12] and Pujo-Menjouet, Bernard, and Mackey [26]).

Cell biologists classify stem cells as proliferating cells and resting cells (also called G_0-cells) (see Mackey [16, 17]). Proliferating cells are committed to undergo mitosis a certain time after their entrance into the proliferating phase. Mackey supposed that this time of cytokinesis is constant, that is, it is the same for all cells. Most of committed stem cells are in the proliferating phase. The G_0-phase, whose existence is known due to the works of Burns and Tannock [8], is a quiescent stage in the cellular development. However, it is usually believed that 95% of pluripotent stem cells are in the resting phase. Resting cells can exit randomly to either enter into the proliferating phase or be irremediably lost. Proliferating cells can also be lost by apoptosis (programmed cell death).

The model of Mackey [16] has been numerically studied by Mackey and Rey [21] and Crabb, Losson, and Mackey [9]. Computer simulations showed strange behaviors of the stem cell population, such as oscillations and bifurcations. Recently, Pujo-Menjouet and Mackey [27] proved the existence of a Hopf bifurcation which causes periodic chronic myelogenous leukemia and showed the great dependence of the model on the parameters.

In this paper, based on the model of Mackey [16], we propose a more general model of hematopoiesis. We take into account the fact that a cell cycle has two phases, that is, stem cells in process are either in a resting phase or actively proliferating. However, we do not suppose that all cells divide at the same age, because this hypothesis is not biologically reasonable. For example, it is believed that pluripotent stem cells divide faster than committed stem cells, which are more mature cells. There is strong evidence (see Bradford et al. [7]) that indicate that the age of cytokinesis τ is distributed on an interval $[\underline{\tau}, \overline{\tau}]$ with $\underline{\tau} \geq 0$. Hence, we shall assume that τ is distributed with a density f supported on an interval $[\underline{\tau}, \overline{\tau}]$ with $0 \leq \underline{\tau} < \overline{\tau} < +\infty$. The resulting model is a system of two differential equations with distributed delay. A simpler model, dealing with the pluripotent stem cell population behavior, has been studied by Adimy, Crauste, and Ruan [1].

Some results about stability of differential equations with distributed delay can be mentioned. In [6], Boese studied the stability of a differential equation with gamma-distributed delay. Gamma distributions have the property to simplify the nature of the delay and this situation is close to the one with discrete delay. Anderson [2, 3] showed stability results linked to the different moments (especially the expectation and the variance) of the distribution. Kuang [15] also obtained general stability results for systems of delay differential equations. More recently, sufficient conditions for the stability of delay differential equations with distributed delay have been obtained by Bernard, Bélair, and Mackey [5]. They used some properties of the distribution to prove these results. However, in all these works, the authors focused on sufficient conditions for the stability, there is no necessary condition in these studies, and these results are not applicable directly to the model considered in this paper.

This paper is organized as follows. In section 2, we present the model and establish boundedness properties of the solutions. In section 3, we study the asymptotic stability of the equilibria. We give conditions for the trivial equilibrium to be globally asymptotically stable in section 3.1 and investigate the stability of the nontrivial equilibrium in section 3.2. In section 4, we show that a local Hopf bifurcation occurs in our model. In section 5, numerical simulations are performed to demonstrate that our results can be used to explain the long period oscillations observed in chronic

myelogenous leukemia.

2. The hematopoiesis process: Presentation of the model. Denote by $r(t,a)$ and $p(t,a)$ the population densities of resting an proliferating cells, respectively, which have spent a time $a \geq 0$ in their phase at time $t \geq 0$. Resting cells can either be lost randomly at a rate $\delta \geq 0$, which takes into account the cellular differentiation, or enter into the proliferating phase at a rate β. Proliferating cells can be lost by apoptosis (a programmed cell death) at a rate $\gamma \geq 0$ and, at mitosis, cells with age a divide in two daughter cells (which immediately enter the G_0-phase) with a rate $g(a)$.

The function $g : [0, \overline{\tau}) \to \mathbb{R}^+$ satisfies $g(a) = 0$ if $a < \underline{\tau}$ with $0 \leq \underline{\tau} < \overline{\tau} < +\infty$. Moreover, it is assumed to be piecewise continuous such that $\int_{\underline{\tau}}^{\overline{\tau}} g(a)da = +\infty$. The later assumption describes the fact that cells which did not die have to divide before they reach the maximal age $\overline{\tau}$.

The nature of the trigger signal for introduction in the proliferating phase is not clear. However, the work of Sachs [30] shows that we can reasonably think that it strongly depends on the entire resting cell population, that is, $\beta = \beta(x(t))$, with

$$x(t) = \int_0^{+\infty} r(t,a)da, \quad t \geq 0.$$

The function β is supposed to be continuous and positive. Furthermore, from a reasonable biological point of view, we assume that β is decreasing with $\lim_{x\to+\infty} \beta(x) = 0$. This describes the fact that the rate of reentry into the proliferating compartment is a decreasing function of the G_0-phase population.

Usually, it is believed that the function β is a monotone decreasing Hill function (see Mackey [16]), given by

$$\beta(x) = \beta_0 \frac{\theta^n}{\theta^n + x^n}, \quad x \geq 0, \tag{2.1}$$

with $\beta_0 > 0$, $\theta \geq 0$, and $n > 0$. β_0 is the maximal rate of reentry in the proliferating phase, θ is the number of resting cells at which β has its maximum rate of change with respect to the resting phase population, and n describes the sensitivity of the reintroduction rate with changes in the population.

The above parameters values are usually chosen (see Mackey [16]) to be

$$\delta = 0.05 \text{ day}^{-1}, \quad \gamma = 0.2 \text{ day}^{-1}, \quad \beta_0 = 1.77 \text{ day}^{-1}, \quad \text{and} \quad n = 3. \tag{2.2}$$

Although a usual value of θ is $\theta = 1.62 \times 10^8$ cells/kg, it can be normalized without loss of generality when one makes a qualitative analysis of the population.

Then $r(t,a)$ and $p(t,a)$ satisfy the system of partial differential equations

$$\frac{\partial r}{\partial t} + \frac{\partial r}{\partial a} = -\big(\delta + \beta(x(t))\big)r, \quad a > 0,\ t > 0, \tag{2.3}$$

$$\frac{\partial p}{\partial t} + \frac{\partial p}{\partial a} = -\big(\gamma + g(a)\big)p, \qquad 0 < a < \overline{\tau},\ t > 0, \tag{2.4}$$

with

$$r(0,a) = \nu(a),\ a \geq 0, \qquad p(0,a) = \Gamma(a),\ a \in [0, \overline{\tau}].$$

The functions $\nu = \nu(a)$ and $\Gamma = \Gamma(a)$ give the population densities of cells which have spent a time a in the resting and proliferating phase, respectively, at time $t = 0$, that is, the initial populations of cells with age a in each phase.

The boundary conditions of system (2.3)–(2.4), which describe the cellular flux between the two phases, are given by

$$\begin{cases} r(t,0) = 2\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} g(\tau)p(t,\tau)d\tau, \\ \\ p(t,0) = \beta(x(t))x(t). \end{cases}$$

Moreover, we suppose that $\lim_{a\to+\infty} r(t,a) = 0$ and $\lim_{a\to\overline{\tau}} p(t,a) = 0$.

Let $y(t)$ denote the total population density of proliferating cells at time t; then

$$y(t) = \int_0^{\overline{\tau}} p(t,a)da, \qquad t \geq 0.$$

Thus, integrating (2.3) and (2.4) with respect to the age variable, we obtain

$$\frac{dx}{dt} = -\big(\delta + \beta(x(t))\big)x(t) + 2\int_{\underline{\tau}}^{\overline{\tau}} g(\tau)p(t,\tau)d\tau, \tag{2.5}$$

$$\frac{dy}{dt} = -\gamma y(t) + \beta(x(t))x(t) - \int_{\underline{\tau}}^{\overline{\tau}} g(\tau)p(t,\tau)d\tau. \tag{2.6}$$

We define a function G by

$$G(t,a) = \begin{cases} g(a)\exp\left(-\displaystyle\int_{a-t}^{a} g(s)ds\right) & \text{if } t < a, \\ \\ g(a)\exp\left(-\displaystyle\int_{0}^{a} g(s)ds\right) & \text{if } a < t. \end{cases}$$

Set

$$f(\tau) := g(\tau)\exp\left(-\int_0^{\tau} g(s)ds\right), \quad \tau > 0.$$

One can check that f is a density function, supported on $[\underline{\tau}, \overline{\tau}]$, and f represents the density of division of proliferating cells. In particular, $\int_{\underline{\tau}}^{\overline{\tau}} f(\tau)d\tau = 1$.

Using the method of characteristics to determine $p(t,a)$, we deduce, from (2.5)–(2.6), that the process of hematopoiesis is described by the following system:

$$
\left\{
\begin{array}{rcl}
\dfrac{dx}{dt} &=& -\big(\delta+\beta(x(t))\big)x(t) \\
&& + \left\{
\begin{array}{ll}
2e^{-\gamma t}\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} G(t,\tau)\Gamma(\tau-t)d\tau, & 0\le t\le \underline{\tau}, \\
2\displaystyle\int_{\underline{\tau}}^{t} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau & \\
\qquad + 2e^{-\gamma t}\displaystyle\int_{t}^{\overline{\tau}} G(t,\tau)\Gamma(\tau-t)d\tau, & \underline{\tau}\le t\le \overline{\tau}, \\
2\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau, & \overline{\tau}\le t,
\end{array}
\right. \\
\dfrac{dy}{dt} &=& -\gamma y(t)+\beta(x(t))x(t) \\
&& - \left\{
\begin{array}{ll}
e^{-\gamma t}\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} G(t,\tau)\Gamma(\tau-t)d\tau, & 0\le t\le \underline{\tau}, \\
\displaystyle\int_{\underline{\tau}}^{t} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau & \\
\qquad + e^{-\gamma t}\displaystyle\int_{t}^{\overline{\tau}} G(t,\tau)\Gamma(\tau-t)d\tau, & \underline{\tau}\le t\le \overline{\tau}, \\
\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau, & \overline{\tau}\le t.
\end{array}
\right.
\end{array}
\right. \tag{2.7}
$$

One can give a direct biological explanation of system (2.7).

In the equation for the resting cells $x(t)$, the first term in the right-hand side accounts for G_0-cell loss due to either mortality and cellular differentiation (δ) or introduction in the proliferating phase (β). The second term represents a cellular gain due to the movement of proliferating cells one generation earlier. It requires some explanation. First, we recall that all cells divide according to the density f, supported on $[\underline{\tau},\overline{\tau}]$. We shall call, in the following, new proliferating cells, the resting cells introduced in the proliferating phase at the considered time t. When $t\le\underline{\tau}$, no new proliferating cell is mature enough to divide, because cells cannot divide before they have spent time $\underline{\tau}$ in the proliferating phase. Therefore, the cellular gain can proceed only from cells initially in the proliferating phase. When $t\in[\underline{\tau},\overline{\tau}]$, the cellular increase is obtained by division of new proliferating cells and by division of the initial population. Finally, when $t\ge\overline{\tau}$, all initial proliferating cells have divided or died, and the cellular gain is obtained by division of new proliferating cells introduced one generation earlier. The factor 2 always accounts for the division of each cell into two daughter cells at mitosis. The term $e^{-\gamma t}$, with $t\in[0,\overline{\tau}]$, describes the attenuation of the population, in the proliferating phase, due to apoptosis.

In the equation for the proliferating cells $y(t)$, the first term in the right-hand side accounts for cellular loss by apoptosis and the second term is for cellular entry from the G_0-phase. The last term accounts for the flux of proliferating cells to the resting compartment.

We set $\mu:=\int_0^\infty \nu(a)da$. Then, initially, the populations in the two phases are given by

$$x(0)=\mu \qquad \text{and} \qquad y(0)=\int_0^{\overline{\tau}}\Gamma(a)da.$$

At this point, one can make a remark. Since resting cells are introduced in the proliferating phase with a rate β, then $\Gamma(0)$, which represents the population of cells introduced at time $t = 0$ in the cycle, must satisfy

$$\Gamma(0) = \beta(\mu)\mu.$$

Taking into account the inevitable loss of proliferating cells by apoptosis and by division, we suppose that $\Gamma(a)$ is given by

$$\Gamma(a) = \begin{cases} e^{-\gamma a}\beta(\mu)\mu & \text{if } a \in [0, \underline{\tau}), \\ e^{-\gamma a}\exp\left(-\displaystyle\int_{\underline{\tau}}^{a} g(s)ds\right)\beta(\mu)\mu & \text{if } a \in [\underline{\tau}, \overline{\tau}). \end{cases} \tag{2.8}$$

This simply describes that Γ satisfies (2.4) (see Webb [35, p. 8]). With (2.8) and integrating by parts, the initial conditions of system (2.7) become

$$x(0) = \mu, \qquad y(0) = \beta(\mu)\mu \int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\left(\frac{1 - e^{-\gamma\tau}}{\gamma}\right)d\tau. \tag{2.9}$$

When $\gamma = 0$, we have

$$y(0) = \beta(\mu)\mu \int_{\underline{\tau}}^{\overline{\tau}} \tau f(\tau)d\tau.$$

Assume that the function $x \mapsto x\beta(x)$ is Lipschitz continuous. It is immediate to show by steps that, for all $\mu \geq 0$, the system (2.7) under condition (2.9) has a unique nonnegative continuous solution $(x(t), y(t))$ defined on $[0, +\infty)$.

One can notice that problem (2.7) reduces to a system of two delay differential equations, with initial conditions solutions of a system of ordinary differential equations. On $[0, \underline{\tau}]$, the first equation for $x(t)$ in system (2.7) reduces to the ordinary differential equation

$$\begin{cases} \dfrac{d\widetilde{\varphi}}{dt} = -\big(\delta + \beta(\widetilde{\varphi}(t))\big)\widetilde{\varphi}(t) + 2\beta(\mu)\mu \displaystyle\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau, \quad 0 \leq t \leq \underline{\tau}, \\ \widetilde{\varphi}(0) = \mu, \end{cases} \tag{2.10}$$

and, on $[\underline{\tau}, \overline{\tau}]$, the second equation reduces to the nonautonomous delay differential equation

$$\begin{cases} \dfrac{d\varphi}{dt} = -\big(\delta + \beta(\varphi(t))\big)\varphi(t) + 2\beta(\mu)\mu \displaystyle\int_{t}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau \\ \qquad\qquad + 2\displaystyle\int_{\underline{\tau}}^{t} e^{-\gamma\tau} f(\tau)\beta(\varphi(t-\tau))\varphi(t-\tau)d\tau, \qquad t \in [\underline{\tau}, \overline{\tau}], \\ \varphi(t) = \widetilde{\varphi}(t), \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad t \in [0, \underline{\tau}], \end{cases} \tag{2.11}$$

where $\widetilde{\varphi}(t)$ is the unique solution of (2.10) for the initial condition μ.

In the same way, the solution $y(t)$ of the second equation in (2.7), denoted $\psi(t)$, is given in terms of the unique solution $\widetilde{\varphi}(t)$ of (2.10), associated with μ, and the unique solution $\varphi(t)$ of (2.11), for $t \in [0, \overline{\tau}]$.

Then, system (2.7) can be written as an autonomous system of delay differential equations, for $t \geq \overline{\tau}$,

$$\frac{dx}{dt} = -\big(\delta + \beta(x(t))\big)x(t) + 2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau, \tag{2.12a}$$

$$\frac{dy}{dt} = -\gamma y(t) + \beta(x(t))x(t) - \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau, \tag{2.12b}$$

with, for $t \in [0, \overline{\tau}]$,

$$x(t) = \varphi(t), \quad y(t) = \psi(t). \tag{2.13}$$

The solutions of (2.12b) are given explicitly by

$$y(t) = \int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\bigg(\int_{t-\tau}^{t} e^{-\gamma(t-s)}\beta(x(s))x(s)\ ds\bigg)d\tau \qquad \text{for} \quad t \geq \overline{\tau}. \tag{2.14}$$

One can notice that $y(t)$ no longer depends on the initial population $\Gamma(a)$ after one generation, that is, when $t \geq \overline{\tau}$. This can be explained as follows. Cells initially in the proliferating phase have divided or died after one generation; hence, new cells in the proliferating phase can come only from resting cells $x(t)$.

On the other hand, one may have already noticed that the solutions of (2.12a) do not depend on the solutions of (2.12b), whereas the converse is not true. The expression of $y(t)$ in (2.14) gives more precise information on the influence of the behavior of $x(t)$ on the stability of the solutions $y(t)$. These results are proved in the following lemma.

LEMMA 2.1. *Let $(x(t), y(t))$ be a solution of* (2.12). *If $\lim_{t\to+\infty} x(t)$ exists and equals $C \geq 0$, then*

$$\lim_{t\to+\infty} y(t) = \begin{cases} \beta(C)C\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\bigg(\frac{1-e^{-\gamma\tau}}{\gamma}\bigg)d\tau & \text{if } \gamma > 0, \\ \beta(C)C\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} \tau f(\tau)d\tau & \text{if } \gamma = 0. \end{cases} \tag{2.15}$$

If $x(t)$ is P-periodic, then $y(t)$ is also P-periodic.

Proof. By using (2.14), we obtain that

$$y(t) = \int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\bigg(\int_{0}^{\tau} e^{-\gamma s}\beta(x(t-s))x(t-s)\ ds\bigg)d\tau \qquad \text{for} \quad t \geq \overline{\tau}. \tag{2.16}$$

Hence,

$$\lim_{t\to+\infty} y(t) = \beta(C)C\int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\bigg(\int_{0}^{\tau} e^{-\gamma s}\ ds\bigg)d\tau,$$

and (2.15) follows immediately.

When $x(t)$ is P-periodic, then using (2.16) it is obvious to see that $y(t)$ is also periodic with the same period. ∎

Lemma 2.1 shows the influence of (2.12a) on the stability of the entire system, since the stability of solutions of (2.12a) leads to stability of the solutions of (2.12b).

Before studying the stability of (2.12a), we prove a boundedness result for the solutions of this equation. The proof is based on the one given by Mackey and Rudnicki [22] for a differential equation with a discrete delay.

PROPOSITION 2.2. *Assume that* $\delta > 0$. *Then the solutions of* (2.12a) *are bounded.*

Proof. Assume that $\delta > 0$ and $2(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau)\beta(0) \geq \delta$. Since β is decreasing and $\lim_{x\to+\infty} \beta(x) = 0$, there exists a unique $x_0 \geq 0$ such that

$$2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\beta(x_0) = \delta$$

and

$$2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\beta(x) \leq \delta \qquad \text{for} \quad x \geq x_0. \tag{2.17}$$

If $2(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau)\beta(0) < \delta$, then (2.17) holds with $x_0 = 0$. Set

$$x_1 := 2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\frac{\beta(0)x_0}{\delta} \geq 0.$$

One can check that

$$2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\max_{0\leq y\leq x}\Big(\beta(y)y\Big) \leq \delta x \qquad \text{for} \quad x \geq x_1. \tag{2.18}$$

Indeed, let $y \in [0, x)$. If $y \leq x_0$, then

$$2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\beta(y)y \leq 2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\beta(0)x_0 = \delta x_1 \leq \delta x,$$

and, if $y > x_0$, then

$$2\bigg(\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau\bigg)\beta(y)y \leq \delta y \leq \delta x.$$

Hence, (2.18) holds.

Assume, by contradiction, that $\limsup_{t\to+\infty} x(t) = +\infty$, where $x(t)$ is a solution of (2.12a). Then, there exists $t_0 > \overline{\tau}$ such that

$$x(t) \leq x(t_0) \ \text{ for } t \in [t_0 - \overline{\tau}, t_0] \qquad \text{and} \qquad x(t_0) > x_1.$$

With (2.18), we obtain that

$$2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\beta(x(t_0-\tau))x(t_0-\tau)d\tau \leq \delta x(t_0).$$

This yields, with (2.12a), that

$$\frac{dx}{dt}(t_0) \leq -\beta(x(t_0)))x(t_0) < 0,$$

which gives a contradiction. Hence, $\limsup_{t\to+\infty} x(t) < +\infty$. ∎

When $\delta = 0$, the solutions of (2.12a) may not be bounded. We show, in the next proposition, that these solutions may explode under some conditions. However, one can notice, using (2.16), that the solutions of (2.12b) may still be stable in this case.

PROPOSITION 2.3. *Assume that* $\delta = 0$ *and*

$$\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau > \frac{1}{2}. \tag{2.19}$$

In addition, assume that there exists $\overline{x} \geq 0$ *such that the function* $x \mapsto x\beta(x)$ *is decreasing for* $x \geq \overline{x}$. *If* $\mu \geq \overline{x}$, *then the unique solution* $x(t)$ *of* (2.12a) *satisfies*

$$\lim_{t\to+\infty} x(t) = +\infty.$$

Proof. One can notice that, if $\lim_{t\to+\infty} x(t) = C$ exists, then (2.12a) leads to

$$\left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(C)C = 0.$$

It follows that $C = 0$.

Let $\mu \geq \overline{x}$ be given. Consider the equation

$$\widetilde{\varphi}'(t) = 2\beta(\mu)\mu \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - \beta(\widetilde{\varphi}(t))\widetilde{\varphi}(t) \quad \text{for} \quad 0 \leq t \leq \underline{\tau} \tag{2.20}$$

with $\widetilde{\varphi}(0) = \mu$. Since the function $x \mapsto x\beta(x)$ is decreasing for $x \geq \overline{x}$, it is immediate that every solution $\widetilde{\varphi}(t)$ of (2.20) satisfies, for $t \in [0, \underline{\tau}]$,

$$\widetilde{\varphi}'(t) \geq \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(\mu)\mu > 0.$$

Consider now the problem

$$\begin{cases} \varphi'(t) = -\beta(\varphi(t))\varphi(t) + 2\beta(\mu)\mu \displaystyle\int_t^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau \\ \qquad\qquad + 2\displaystyle\int_{\underline{\tau}}^{t} e^{-\gamma\tau} f(\tau)\beta(\varphi(t-\tau))\varphi(t-\tau) d\tau, \quad t \in [\underline{\tau}, \overline{\tau}], \\ \varphi(t) = \widetilde{\varphi}(t), \qquad\qquad t \in [0, \underline{\tau}], \end{cases} \tag{2.21}$$

where $\widetilde{\varphi}(t)$ is the unique solution of (2.20) for the initial condition μ. Then,

$$\varphi'(\underline{\tau}) \geq \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(\mu)\mu > 0.$$

So, there exists $\varepsilon > 0$ such that $\underline{\tau} + \varepsilon \leq \overline{\tau}$ and $\varphi'(t) > 0$ for $t \in [\underline{\tau}, \underline{\tau} + \varepsilon)$. Since $\mu \leq \varphi(\underline{\tau}) \leq \varphi(\tau) \leq \varphi(\underline{\tau} + \varepsilon)$, for $\tau \in [\underline{\tau}, \underline{\tau} + \varepsilon]$, we have

$$\begin{aligned} \varphi'(\underline{\tau} + \varepsilon) &\geq \left(2\int_{\underline{\tau}+\varepsilon}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(\varphi(\underline{\tau} + \varepsilon))\varphi(\underline{\tau} + \varepsilon) \\ &\quad + 2\left(\int_{\underline{\tau}}^{\underline{\tau}+\varepsilon} e^{-\gamma\tau} f(\tau) d\tau\right)\beta(\varphi(\underline{\tau} + \varepsilon))\varphi(\underline{\tau} + \varepsilon) \\ &\geq \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau) d\tau - 1\right)\beta(\varphi(\underline{\tau} + \varepsilon))\varphi(\underline{\tau} + \varepsilon). \end{aligned}$$

Condition (2.19) leads to $\varphi'(\underline{\tau}+\varepsilon)>0$. Using a similar argument, we obtain that

$$\varphi'(t)>0 \qquad \text{for} \quad t\in[\underline{\tau},\overline{\tau}].$$

To conclude, consider the delay differential equation

$$x'(t)=2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau}f(\tau)\beta(x(t-\tau))x(t-\tau)d\tau-\beta(x(t))x(t) \tag{2.22}$$

with an initial condition given on $[\underline{\tau},\overline{\tau}]$ by the solution $\varphi(t)$ of (2.21). Using the same reasoning as in the previous cases, we obtain that

$$x'(\overline{\tau})>0.$$

We thus deduce that

$$x'(t)>0 \qquad \text{for} \quad t\geq 0.$$

This completes the proof. □

The assumption on the function $x\mapsto x\beta(x)$ in Proposition 2.3 is satisfied for example when β is given by (2.1), with $n>1$. In this case, we can take $\overline{x}=\theta/(n-1)^{1/n}$.

We now turn our attention to the stability of (2.12). Problem (2.12) has at most two equilibria. The first, $E_0=(0,0)$, always exists: it corresponds to the extinction of the population. The second describes the expected equilibrium of the population; it is a nontrivial equilibrium $E^*=(x^*,y^*)$, where x^* is the unique solution of

$$\left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau}f(\tau)d\tau-1\right)\beta(x^*)=\delta \tag{2.23}$$

and, from (2.7) and (2.9),

$$y^*=\begin{cases}\beta(x^*)x^*\displaystyle\int_{\underline{\tau}}^{\overline{\tau}} f(\tau)\left(\frac{1-e^{-\gamma\tau}}{\gamma}\right)d\tau & \text{if } \gamma>0,\\[2ex] \delta x^*\displaystyle\int_{\underline{\tau}}^{\overline{\tau}}\tau f(\tau)d\tau, & \text{if } \gamma=0.\end{cases} \tag{2.24}$$

Since β is a positive decreasing function and $\lim_{x\to+\infty}\beta(x)=0$, then the equilibrium E^* exists if and only if

$$0<\delta<\left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau}f(\tau)d\tau-1\right)\beta(0). \tag{2.25}$$

We shall study in section 3 the stability of the two equilibria E_0 and E^*. From Lemma 2.1, we only need to focus on the behavior of the equilibria of (2.12a), that is, $x\equiv 0$ and $x\equiv x^*$, to obtain information on the behavior of the entire population.

3. Asymptotic stability. We first show that E_0 is globally asymptotically stable when it is the only equilibrium and that it becomes unstable when the nontrivial equilibrium E^* appears: a transcritical bifurcation occurs then. In a second part, we determine conditions for the nontrivial equilibrium E^* to be asymptotically stable.

3.1. Stability of the trivial equilibrium. In the next theorem, we give a necessary and sufficient condition for the trivial equilibrium of (2.12a) to be globally asymptotically stable using a Lyapunov functional. For a definition of and information about Lyapunov functionals for delay differential equations, see [13].

THEOREM 3.1. *The trivial equilibrium of the system* (2.12) *is globally asymptotically stable if*

$$\left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau - 1\right)\beta(0) < \delta \tag{3.1}$$

and unstable if

$$\delta < \left(2\int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)d\tau - 1\right)\beta(0). \tag{3.2}$$

Proof. We first assume that (3.1) holds. Denote by C^+ the set of continuous nonnegative functions on $[0,\overline{\tau}]$ and define the mapping $J : C^+ \to [0,+\infty)$ by

$$J(\varphi) = B(\varphi(\overline{\tau})) + \int_{\underline{\tau}}^{\overline{\tau}} e^{-\gamma\tau} f(\tau)\left(\int_{\overline{\tau}-\tau}^{\overline{\tau}} \Big(\beta\big(\varphi(\theta)\big)\varphi(\theta)\Big)^2 d\theta\right)d\tau$$

for all $\varphi \in C^+$, where

$$B(x) = \int_0^x \beta(s)s\ ds \qquad \text{for all } x \geq 0.$$

We set (see [13])

$$\dot{J}(\varphi) = \limsup_{t\to 0^+} \frac{J(x_t^\varphi) - J(\varphi)}{t} \qquad \text{for } \varphi \in C^+,$$

where x^φ is the unique solution of (2.12a) associated with the initial condition $\varphi \in C^+$ and $x_t^\varphi(\theta) = x^\varphi(t+\theta)$ for $\theta \in [0,\overline{\tau}]$. Then,
